Abstract: The virtual reflector method simulates new seismic signals by processing traces recorded by a plurality of sources and receivers. The approach is based on the crossconvolution of the recorded signals and makes it possible to obtain the Green's function of virtual reflected signals as if in the position of the receivers (or sources) there were a reflector, even if said reflector is not present. This letter presents the virtual reflector theory based on the Kirchhoff integral representation theorem for wave propagation in an acoustic medium with and without boundary and a generalization to variable reflection coefficients for scattered wavefields.

1. Introduction

In recent years innovative techniques have been introduced in seismics and acoustics to simulate new signals by processing the measurements obtained by a plurality of sources and receivers. These methods are generally classified as "Green's function retrieval" or "seismic interferometry" (SI) and are essentially based on crosscorrelation of traces at different receivers and summation of the crosscorrelated signals over the space of the sources generating the wavefields. In this process, it is not necessary to know the sources and the medium. From a physical point of view, crosscorrelation (or convolution by time reversal) is equivalent to removing the common propagation effects.[1,2] A great advantage of this approach is that also signals from unknown random-phase sources are shaped into interpretable signals because of phase subtraction. In some applications, deconvolution is used instead of correlation to compensate also for source amplitude.[3] Under proper conditions, SI allows one to recover the signal ideally produced by a virtual source located at the position of a receiver.[4] This technique has important applications for ultrasonics,[5] underwater acoustics,[6] seismic exploration, and passive seismics. The method makes it possible to recover the local receiver-to-receiver Earth's response, i.e., the Green's function, and provides virtual sources where it is not possible or difficult to use a real seismic source, such as in borehole and sea-floor marine surveys. Interferometry has been the subject of several theoretical[1–3,5–7] and application studies, and nowadays it is used for seismic exploration purposes.[8,9] With an approach similar to interferometry, Poletto[10] proposed the virtual reflector (VR) method,[11] which also simulates new seismic signals by processing recorded traces from a plurality of sources and receivers, with the following differences with respect to interferometry. The method is based on crossconvolution (different from convolution with time reversal) of source (receiver) signals and subsequent summation in the domain of the receivers (sources). The VR method substantially performs the composition of the filtering effects in the wave propagation. To be effective, the method needs to deal with source signals with transient wavelets. The novel approach makes it possible to obtain virtual reflected signals as if at the

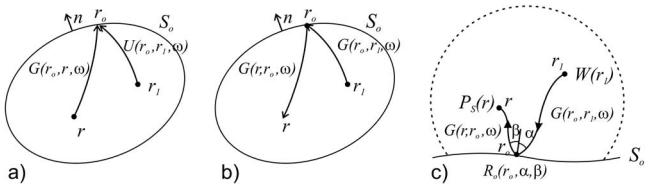

Fig. 1. (a) Acoustic model for VR representation. Two sources are located at r and r_1 encompassed by the surface S_o. (b) Composition of propagation effects and surface integration to obtain the VR signal. (c) The scattered field from reflector S_o is represented by a boundary integral over the reflector. The reflector coefficient $R_o(r_o,\alpha,\beta)$ depends on the reflector geometry and acquisition configuration.

position of receivers (or sources) there were a real reflector even if said reflector is not present there. In this letter we re-formulate the VR theory for an acoustic inhomogeneous medium by using the Kirchhoff–Helmholtz (KH) integral representation theorem.

2. Theory

The scalar fields in an inhomogeneous medium can be expressed by using the Green's integral theorem for scalar functions U and G. Let S be the total surface encompassing a volume of interest V, and n the outward normal direction to the surface. The Green's integral theorem states that

$$\int_V dV[G\nabla^2 U - U\nabla^2 G] = \int_S dS[G\,\nabla\, U - U\,\nabla\, G]\cdot n. \tag{1}$$

The functions U and G are assumed to be the Fourier transforms of causal functions, and in the common use they represent the propagating wavefield and the medium response to an impulse, Green's function, respectively. Let S_o be the outer surface enclosing the volume of interest V. The VR signal is the result of the composition of scalar fields from different sources included in the volume V surrounded by receivers located at outer surface S_o (Ref. 11). Assume that two point sources at internal points r_1 and at r inside S_o [Fig. 1(a)] generate the scalar fields U and G, respectively. They can be expressed as[12–14]

$$U(r,r_1,\omega) - G(r_1,r,\omega) = \frac{1}{4\pi}\int_{S_o} dS_o\left[G(r_o,r,\omega)\frac{\partial U(r_o,r_1,\omega)}{\partial n} - U(r_o,r_1,\omega)\frac{\partial G(r_o,r,\omega)}{\partial n}\right], \tag{2}$$

where $U(r_o,r_1,\omega)$ is the scalar field generated at r_1 and recorded along the surface S_o, r_o is location along the surface, $G(r_o,r,\omega)$ is the Green's function from r to r_o, $\partial/\partial n$ is the normal differentiation operator acting on r_o at surface S_o, and ω is the angular frequency. The advantage of the integral representation is that a suitable propagation Green's function G can be chosen to synthesize a particular U wavefield (and vice versa). Equation (2), with fields U and G satisfying different boundary conditions (BCs), was exploited in developing the reverse-time approach to reflection seismic imaging (e.g., Refs. 15 and 16). When U and G are subject to the same BCs on S_o, the integral vanishes. In this case from Eq. (2), we obtain $G=U$. Conversely, under proper BCs, different for U and G, the integral is in general different from zero. This result corresponds to the fact that, even when the wavefield represented by G from r to r_1 (from r_1 to r if we use reciprocity) is subtracted from U in Eq. (2), part of the synthesized wavefield still remains. If we assume that the medium outside S_o is homogeneous and there are no reflecting objects outside S_o (they may be on S_o), Eq. (2) can be used to represent a perfect VR at S_o. We define a new (VR) wavefield as $V=U-G$. This result comes from the assumption of reflecting BCs on the close surface S_o for G but not for U (or vice versa). In V we subtract direct arrivals and reflections. This reasoning is in agreement with the fact that the VR method provides *only*, however not necessarily *all*, reflected waves from S_o (Ref. 11). The scalar function V,

when derived by Eq. (2), can be used to represent a perfect VR of unit (or constant) reflection coefficient. A generalization can be obtained by including a variable reflection coefficient function, according to a boundary integral representation for the response of a reflector.

Under the assumption that the scalar field $U(r_o,r_1,\omega)$ is produced from a unit source at point r_1 included in the space encompassed by S_o [Fig. 1(a)], said propagation function represents, by definition, the medium response. In this case we can express also the scalar quantity recorded on S_o as $U(r_o,r_1,\omega)=G(r_o,r_1,\omega)$, where $G(r_o,r_1,\omega)$ is the Green's function from r_1 to r_o, and substitute G for U in Eq. (2), by using V, which gives

$$V(r,r_1,\omega)=\frac{1}{4\pi}\int_{S_o} dS_o\left[G(r_o,r,\omega)\frac{\partial G(r_o,r_1,\omega)}{\partial n}-G(r_o,r_1,\omega)\frac{\partial G(r_o,r,\omega)}{\partial n}\right]. \quad (3)$$

In this representation it is intended that the reflecting BC on S_o is applied to only one of the two terms of the sum in the integrand at the right hand side.

3. Synthesis of virtual reflector

Equation (3) allows us to synthesize a VR wavefield with constant reflection coefficient under different BCs. We first analyze the case in which the model contains an equivalent medium with a reflecting interface at the boundary. We consider two cases in which $G(r_o,r,\omega)$ is chosen with a perfect reflecting BC on S_o. The first reflecting BC on S_o for $G(r_o,r,\omega)$ calculated for a given r is $\partial G(r_o,r,\omega)/\partial n=0$ (*Neumann* BC). In this case the contrast medium is perfectly rigid and reflecting (reflection coefficient $R=+1$). Equation (3) becomes

$$V_R(r,r_1,\omega)=\frac{-\imath\omega}{4\pi c}\int_{S_o} dS_o G(r_o,r,\omega)G(r_o,r_1,\omega)\cos(\alpha_o), \quad (4)$$

where we have used the approximation $\partial/\partial n\cong-\imath\omega\cos(\alpha_o)/c$ for the normal derivative, $\imath=\sqrt{-1}$, c is the medium velocity, and α_o is the angle between the ray of $G(r_o,r_1,\omega)$ and the normal at r_o on S_o. The second reflecting BC for $G(r_o,r,\omega)$ on S_o is $G(r_o,r,\omega)=0$ (*Dirichlet* BC). In this case, the contrast medium is vacuum, corresponding to a perfectly-reflecting free surface ($R=-1$). Equation (3) becomes (see Ref. 15)

$$V_F(r,r_1,\omega)=\frac{-1}{4\pi}\int_{S_o} dS_o G(r_o,r_1,\omega)\frac{\partial G(r_o,r,\omega)}{\partial n}. \quad (5)$$

Deriving an equation similar to Eq. (4) from Eq. (5) is strictly not valid for the free surface condition because $G(r_o,r,\omega)$ vanishes on S_o. Conversely, if we substitute the wavefield of the corresponding model without boundary at S_o for the wavefield of the model with boundary, to avoid vanishing of G, and use the same normal-derivative approximation, we obtain as an approximation a virtual relation similar to Eq. (4) with opposite sign.

From Eq. (4) we obtain the VR signal for the acoustic medium *with* reflecting boundary. According to the concept of the VR method,[10] the integral in Eq. (4) is the integral on S_o of the crossconvolution[1] of the non-zero scalar quantities (a factor of 4 is here neglected) measured by receivers located on S_o and produced by unit sources located at r and r_1, respectively [Fig. 1(a)]. Because we consider measured wavefields in an unknown medium configuration, we ignore the factor $\cos(\alpha_o)$. Moreover, to interpret Eq. (4) in terms of propagating wavefields, we use reciprocity and exchange source (ideal image of a reflected source) and receiver at r and r_o (or equivalently at r_1 and r_o). Using the reciprocity condition $G(r,r_o,\omega)=G(r_o,r,\omega)$, the VR representation equation for the equivalent medium with reflecting boundary becomes

$$V_{RF}(r,r_1,\omega) = \frac{\mp \imath\omega}{4\pi c}\int_{S_o} dS_o G(r,r_o,\omega)G(r_o,r_1,\omega), \tag{6}$$

which means that the VR signal is obtained by composing the propagated signals from a unit source at point r_1 to receiver in r_o and from r_o to r (or vice versa) and by integrating over the receiver surface the convolution results [Fig. 1(b)]. Consider now the case in which a reflector is *not* present at S_o boundary (transparent surface). The function $\hat{G}$ *without* reflecting boundary at S_o is related to the function G of the model with boundary by $G(r_o,r_j,\omega)=\hat{G}(r_o,r_j,\omega)+\Delta G(r_o,r_j,\omega)$, where ΔG represents the additional effects due to the presence of the reflecting boundary. In other words, $\hat{G}$ is an approximation of the Green's function G with reflecting boundary, in the sense that $\hat{G}$ does not contain reflections from S_o. The virtual reflections $\hat{V}(r,r_1,\omega)$ from S_o without reflecting boundary are synthesized by substituting the signal $\hat{G}$ for G in Eq. (6). Result (4) [or (6)] and its unbounded approximations are equivalent to the summation of crossconvolutions of the measured signals over the receiver (or source) space as proposed by Ref. 10. For selected events it holds $\hat{V}(r,r_1,\omega)\propto V(r,r_1,\omega)$ since the VR method synthesizes only but not all the reflections from S_o (Ref. 11), without the effects of the additional term ΔG.

The derivation of a generalization of Eq. (6) for the scattered wavefield is based on work of Refs. 17, 12, and 18. For the configuration in Fig. 1(c), the scattered wavefield at an observation point r above the reflector is given by

$$P_S(r,r_1,\omega) = \int_{S_o} dS_o G(r,r_o,\omega)R_o(r_o,\alpha,\beta)G(r_o,r_1,\omega)W(r_1,\omega), \tag{7}$$

where $R_o(r_o,\alpha,\beta)$ is the angle-dependent reflection operator and $W(r_1,\omega)$ is the source signal injected at r_1. In the most general case the reflection operator is a pseudodifferential operator (Ref. 17), but for the VR method we approximate it by a high-frequency angle-dependent reflection coefficient (Refs. 12 and 18). Here $P_S(r,r_1,\omega)$ is the scattered wavefield of the true medium, including the reflector, whereas $G(r,r_o,\omega)$ and $G(r_o,r_1,\omega)$ are Green's functions in one-and-the-same reference medium, which is identical to the true medium above the reflector but continues without a jump in the medium parameters below the reflector. The step to the VR principle is again easily made: assume that in the true medium, S_o is not a reflector but a surface with receivers (or sources), whereas r and r_1 both denote sources (or receivers), then the Green's functions with interchanged coordinates in one of them are obtained by measurements as proposed in the previous sections. Substituting these measurements in Eq. (7), inserting a user defined reflection coefficient, and evaluating the integral gives the VR response P_S. In its simplest form $R_o(r_o,\alpha,\beta)$ can be taken equal to $2i\omega R(r_o)/[c(r_o)\rho(r_o)]$, where ρ is the density of the medium. In particular, by using $R=\mp 1$ with normal incidence approximation and unit source signal $W(r_1,\omega)=1$, from Eq. (7) we obtain again Eq. (6), apart from a scaling factor.

All the reasoning made for the VR representation by sources surrounded by receivers holds, using reciprocity, also for the representation with receivers surrounded by sources.

4. Examples, summary, and conclusions

Figure 2 shows the model used for a two dimensional acoustic simulation by a finite-differences code, where a background homogeneous medium with compressional velocity 2 km/s includes a diffraction body at point D. Synthetic signals are calculated with and without the presence of a reflecting boundary at the circumference (surface S_o) of a circle of radius of 1.8 km. The outer hard-contrast medium velocity is 20 km/s. The signals of two sources, S_1 and S_2, are recorded by 360 receivers located on S_o. Figure 2(c) compares the simulated signals from source S_1 to a control receiver at the position of the source S_2 in the model (1) without and (2) with circular

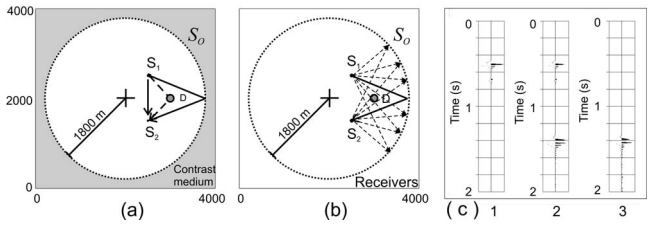

Fig. 2. Synthetic model: (a) With contrast medium at circular boundary S_o. The arrows indicate the direct boundary reflection and diffraction (dashed line) arrivals from the source S_1 to a control receiver at S_2. (b) Representation of the VR arrival (solid line) from the source S_1 to the source S_2. The VR signal is reflected by a VR at S_o and is obtained by processing the signals (dashed arrows) recorded by the receivers on the circle without the contrast medium. (c) Synthetic traces. reflecting boundary and (3) the VR signal calculated by performing the crossconvolution of the signals from the two sources and by integrating the crossconvolutions over the receiver space S_o in the model without reflection boundary.

To summarize, we calculated the KH integral representation of the virtual signal produced by a reflecting surface surrounding two points where sources are located. We showed that the reflection representation is equivalent to composing the wavefields of the two sources recorded on the surface. The analysis demonstrated that halfside of the KH integral represents the crossconvolution term of the VR signal. We generalized the representation for the scattered wavefield from a VR with variable reflection coefficients. Note that the VR method is complementary to SI. The main feature of SI is that the response of a virtual source can be generated without knowing the medium; all that is required is a receiver illuminated from many directions, at the location where one wants to create the virtual source. The VR method enables the generation of the reflection response of a VR without knowing the medium, as long as there are receivers (or sources) distributed along the surface at which one wants to create the VR.

The VR signal synthesis with an ideal reflector has several applications with exploration data.[11] Reference 19 shows examples of identification of and removal of surface reflection events in synthetic marine data and performs the analysis of virtual signals with real borehole data. Other potential applications are signal phase analysis and recovery of the source delay. In these applications the VR signal is used in combination with the interferometry one, provided that the VR and the SI results be obtained by using data with similar source-receiver geometry. For these methods a sufficient spatial sampling of receivers (sources) is required. From a practical point of view, this condition can be reasonably achieved in exploration seismics.

Abstract: Energy streamlines provide insights into mechanisms of wave propagation and scattering and are often utilized to visualize wave fields. In contrast to rays, which are essentially an asymptotic, short-wave concept, energy streamlines adequately represent arbitrary wave fields. However, the usefulness of energy streamlines in studies of wave fields is limited by the fact that, unlike rays, no general laws governing energy streamline refraction are known. Here, a simple refraction law is derived for energy streamlines of acoustic and linearly polarized electromagnetic waves. It is shown that analysis of energy streamlines provides a helpful supplementary perspective on wave transmission through interfaces.

1. Introduction

The energy streamline is defined as a line tangent to which at every point is parallel to the vector of power-flux density at that point. This definition is analogous to the definition of streamline in fluid mechanics as the curve everywhere tangent to the instantaneous direction of the local fluid velocity. Energy streamlines describe energy flow much like conventional streamlines describe mass flow in fluid mechanics.[1] The concept of wave energy streamlines and streamline tubes was introduced by Umov in 1873 and employed in his studies of energy fluxes in fluids and solids (Ref. 2, pp. 201–226 and 535–539). He made use of energy conservation to relate wave intensity to variations in the cross-sectional area of the streamline tube (Ref. 2, pp. 203–204). Umov referred to energy streamlines as "dynamic lines." The modern term was coined by Waterhouse *et al.*[3] Energy streamlines can be defined for instantaneous power flux and for power flux averaged over a wave cycle. For continuous waves in a stationary medium, streamlines of cycle-averaged power flux are independent of time and therefore are the paths along which cycle-averaged wave energy is transmitted from a wave source. A detailed comparison of transmission paths for instantaneous and time-averaged wave energies is presented in Ref. 4.

Energy streamlines reveal intricate details of energy flow in wave fields. A surge in interest to acoustic energy streamlines began in the 1980s (Refs. 3 and 5–7) with the wide availability and application of sound-intensity meters, which measure the vector of power-flux density.[7] As discussed by Fahy (Ref. 7, p. 3), the vector nature of acoustic intensity measurements, as opposed to measurements of scalar acoustic pressure, revolutionized the practice of noise control. Modern applications of wave energy streamlines include studies of wave front dislocations,[8,9] source localization,[7,10] energy vortices in compressible fluids[3,6] and elastic waveguides,[11,12] nanoscale thermal radiation,[13,14] photon tunneling,[13] and bounded beam diffraction, including the Goos–Hänchen shift.[13] Examples of energy streamlines for various wave fields can be found in Refs. 5, 10–14, and 19–22.

Wave energy streamlines are often viewed as an enhancement of rays or as "exact rays"[15] that extend intuitive, graphic portrayal of the wave field inherent to ray theory to evanescent waves and diffracted wave fields, for which the ray theory does not offer an adequate representation. Application of energy streamlines to analyses of specific problems has been impeded by the fact that, unlike rays, no simple laws that govern refraction of streamlines in

volume and at interfaces were known. Abrupt change in energy streamline direction at an interface was observed[10] in results of numerical simulations of acoustic energy streamlines in the problem of spherical wave refraction at a fluid-fluid interface. A remarkably simple refraction law for the acoustic energy streamlines was derived by Chapman[10] from consideration of plane wave transmission through a plane interface of homogeneous fluids. While refraction of rays at an interface, according to Snell's law, is controlled by refraction index, refraction of acoustic energy streamlines, according to Chapman's law, is controlled by the ratio of mass densities of the two fluids in contact.

In this paper, we show that Chapman's law of acoustic energy streamline refraction remains valid at an arbitrary interface in a three-dimensionally inhomogeneous fluid. We also derive similar refraction laws for energy streamlines of linearly polarized electromagnetic waves. The latter refraction laws are valid at interfaces in layered media and in other problems where electromagnetic waves with two orthogonal linear polarizations propagate without coupling.

2. Refraction law for acoustic energy streamlines

Consider linear acoustic waves in a three-dimensionally inhomogeneous, quiescent, inviscid fluid with piecewise continuous sound speed $c(\mathbf{r})$ and mass density $\rho(\mathbf{r})$. Here $\mathbf{r}$ is the position vector. Any surface Γ, at which at least one of the environmental parameters c and ρ is discontinuous, forms a fluid-fluid interface. To describe refraction of acoustic energy streamlines at an interface, it is sufficient to study transformation at the interface of the acoustic power-flux density $\mathbf{I}$, which determines the tangent to the energy streamlines. Acoustic power-flux density is given by the Umov vector[16,17]

$$\mathbf{I} = p\mathbf{v}, \tag{1}$$

where p and $\mathbf{v}$ are the acoustic pressure and fluid velocity in a sound wave.

Boundary conditions on a fluid-fluid interface[16,17] consist in continuity of the acoustic pressure and normal component of the oscillatory velocity:

$$p^{(+)} = p^{(-)}, \quad \mathbf{N}\cdot\mathbf{v}^{(+)} = \mathbf{N}\cdot\mathbf{v}^{(-)}, \quad \mathbf{r}\in\Gamma. \tag{2}$$

Here $\mathbf{N}$ is a unit normal to the interface, and superscripts "(+)" and "(−)" designate the limiting values a physical quantity takes when an observation point approaches a point on Γ from opposite sides of the interface. Since Eq. (2) holds at every point on Γ, derivatives of the acoustic pressure in the directions tangential to Γ are also continuous at the interface. Acoustic pressure gradient and fluid velocity in a linear sound wave are related by the linearized (with respect to the wave amplitude) Euler equation[17] $\partial\mathbf{v}/\partial t = -\nabla p/\rho$. From the Euler equation and continuity of the tangential to Γ components of ∇p, it follows that

$$\rho^{(+)}\,\partial\,\mathbf{v}_\tau^{(+)}/\partial t = \rho^{(-)}\,\partial\,\mathbf{v}_\tau^{(-)}/\partial t, \quad \mathbf{r}\in\Gamma, \tag{3}$$

where the vector $\mathbf{v}_\tau = \mathbf{v} - (\mathbf{v}\cdot\mathbf{N})\mathbf{N}$ has the meaning of the component of the fluid velocity in the directions tangential to the interface. For continuous waves and also for a rather broad class of transient waves, for which $\mathbf{v}\to 0$ at $t\to-\infty$ and/or $t\to+\infty$, from Eq. (3), we obtain

$$\rho^{(+)}\mathbf{v}_\tau^{(+)} = \rho^{(-)}\mathbf{v}_\tau^{(-)}, \quad \mathbf{r}\in\Gamma. \tag{4}$$

For the normal $I_n = \mathbf{N}\cdot\mathbf{I}$ and tangential $\mathbf{I}_\tau = \mathbf{I} - I_n\mathbf{N}$ components of the power-flux density at the interface, from the boundary conditions (2) and (4), we find that

$$I_n^{(+)} = I_n^{(-)}, \quad \rho^{(+)}\mathbf{I}_\tau^{(+)} = \rho^{(-)}\mathbf{I}_\tau^{(-)}, \quad \mathbf{r}\in\Gamma. \tag{5}$$

While it is well known that the normal component of acoustic power-flux density is continuous at interfaces and the tangential component is generally discontinuous,[16,17] the second equation in Eq. (5), which establishes the proportionality of tangential components of the power-flux density on opposite sides of the fluid-fluid interface, appears to be new.

For any point $\mathbf{r}_0$ on Γ, define the plane of incidence as the plane containing $\mathbf{r}_0$ and parallel to vectors $\mathbf{N}(\mathbf{r}_0)$ and $\mathbf{I}^{(+)}(\mathbf{r}_0)$. Equation (5) shows that the vector $\mathbf{I}^{(-)}(\mathbf{r}_0)$ is in the plane of incidence. Let ψ be the acute angle between vectors $\mathbf{I}$ and $\mathbf{N}$ at the interface, so that $\tan\psi = I_\tau/I_n$. From Eq. (5) we find the refraction law for acoustic energy streamlines:

$$\rho^{(+)}\tan\psi^{(+)} = \rho^{(-)}\tan\psi^{(-)}, \quad \mathbf{r}\in\Gamma. \tag{6}$$

This is Chapman's refraction law, which was originally derived in Ref. 10 from other considerations under restrictive assumptions of a plane interface of homogeneous fluids.

The above derivation of Eq. (6) applies to instantaneous values of power-flux density $\mathbf{I}$ and corresponding streamlines in acoustic fields with arbitrary time dependence. If complex notation is used for continuous waves, and P and $\mathbf{V}$ designate complex amplitudes of acoustic pressure $P(\mathbf{r})\exp(-i\omega t)$ and fluid velocity $\mathbf{V}(\mathbf{r})\exp(-i\omega t)$ in a wave of frequency ω, Eqs. (2) and (4) remain valid when P and $\mathbf{V}$ are substituted for p and $\mathbf{v}$. Hence, Eq. (5) holds also for the power-flux density[17] $\bar{\mathbf{I}}=0.5\,\mathrm{Re}(P*\mathbf{V})$ averaged over the wave period. Here "$*$" designates complex conjugation. Therefore, Chapman's refraction law (6) applies to both instantaneous and cycle-averaged power fluxes and corresponding energy streamlines.

At a perfectly reflecting boundary, the normal component I_n of vector $\mathbf{I}$ is zero due to energy conservation. From $\tan\psi=I_\tau/I_n$, one might surmise that energy streamlines are tangent to perfectly reflecting boundaries. However, this is not always the case. For a wave incident from the (+) side of a surface Γ, pressure-release and rigid boundaries Γ can be considered as limiting cases of a fluid-fluid interface of the same geometry, when $m\equiv\rho^{(-)}/\rho^{(+)}$ tends to zero and infinity, respectively. In the limit $m\to\infty$, it follows from Chapman's law (6) that $\psi^{(+)}=\pi/2$, and acoustic energy streamlines are indeed tangent to rigid boundaries, except in the case of normal incidence, where $\psi^{(+)}=\psi^{(-)}=0$. [Angle $\psi^{(+)}$ on a boundary is understood to be the limit of $\psi^{(+)}$ at a point in fluid away from the boundary when the distance from the point to the boundary tends to zero.] In the other case, when $m\to 0$, Chapman's law (6) gives $\psi^{(+)}=0$. Hence, energy streamlines are orthogonal to pressure-release boundaries. This behavior results from the tangential component I_τ of the power-flux density vanishing faster than its normal component I_n when the observation point approaches a pressure-release boundary. The above conclusions can be verified using explicit field expressions in the case of plane wave reflection from a plane boundary.

3. Refraction law for energy streamlines of electromagnetic waves

Consider electromagnetic waves in an inhomogeneous dielectric with piecewise continuous dielectric permittivity $\varepsilon(\mathbf{r})$ and magnetic permeability $\mu(\mathbf{r})$. We assume that the medium is invariant with respect to translations in a certain direction. Then interfaces, i.e., surfaces at which ε and/or μ are discontinuous, are cylindrical surfaces. Introduce orthogonal Cartesian coordinates x, y, and z with the y coordinate axis along the direction of translation invariance. Then ε and μ are independent of y, and any interface Γ can be specified by the equation $f(x,z)=0, -\infty<y<\infty$. The function f is assumed to be sufficiently smooth so that unit normal $\mathbf{N}$ to Γ exists at every point $\mathbf{r}\in\Gamma$. In particular, the medium can be a stratified medium, where $\varepsilon=\varepsilon(z)$ and $\mu=\mu(z)$. In this special case, the interfaces are planes $z=$const. It can be demonstrated that linearly polarized transverse electric (TE) and transverse magnetic (TM) waves propagate in such an environment without coupling.[16] In TE waves, also known as horizontally polarized waves, electric field vector $\mathbf{E}$ is orthogonal to the xz plane. In TM waves, also known as vertically polarized waves, magnetic field vector $\mathbf{H}$ is orthogonal to the xz plane. At an interface, electromagnetic fields satisfy the following boundary conditions:[18]

$$\mathbf{N}\times(\mathbf{E}^{(+)}-\mathbf{E}^{(-)})=0, \quad \mathbf{N}\times(\mathbf{H}^{(+)}-\mathbf{H}^{(-)})=0, \quad \mathbf{r}\in\Gamma, \tag{7}$$

$$\varepsilon^{(+)}\mathbf{N}\cdot\mathbf{E}^{(+)}=\varepsilon^{(-)}\mathbf{N}\cdot\mathbf{E}^{(-)}, \quad \mu^{(+)}\mathbf{N}\cdot\mathbf{H}^{(+)}=\mu^{(-)}\mathbf{N}\cdot\mathbf{H}^{(-)}, \quad \mathbf{r}\in\Gamma. \tag{8}$$

The power-flux density in the electromagnetic field is given by the Poynting vector[18]

$$\mathbf{S} = c(\mathbf{E} \times \mathbf{H})/4\pi, \tag{9}$$

where c is the speed of light in a vacuum. In terms of normal and tangential to the interface components of the Poynting and field vectors, Eq. (9) becomes

$$S_n = c\mathbf{N} \cdot (\mathbf{E}_\tau \times \mathbf{H}_\tau)/4\pi, \quad \mathbf{S}_\tau = (c/4\pi)[E_n(\mathbf{N} \times \mathbf{H}_\tau) - H_n(\mathbf{N} \times \mathbf{E}_\tau)], \quad \mathbf{r} \in \Gamma. \tag{10}$$

According to Eq. (7), vectors $\mathbf{E}_\tau$ and $\mathbf{H}_\tau$ are continuous at the interface. Hence, the normal component of the Poynting vector is also continuous at the interface. (Continuity of S_n is well known and can be viewed as a corollary of the energy conservation law.) The tangential component of the Poynting vector is generally discontinuous at the interface.

In the special case of TE waves in a translationally invariant medium, $E_n=0$. It then follows from Eq. (10) and the boundary condition (8) that

$$\mu^{(+)}\mathbf{S}_\tau^{(+)} = \mu^{(-)}\mathbf{S}_\tau^{(-)}, \quad \mathbf{r} \in \Gamma. \tag{11}$$

Similarly, taking into account that $H_n=0$, for TM waves one finds from Eq. (10) and the boundary condition (8) that

$$\varepsilon^{(+)}\mathbf{S}_\tau^{(+)} = \varepsilon^{(-)}\mathbf{S}_\tau^{(-)}, \quad \mathbf{r} \in \Gamma. \tag{12}$$

Thus, the products $\mu\mathbf{S}_\tau$ and $\varepsilon\mathbf{S}_\tau$ are continuous at the interface in TE and TM waves, respectively.

The Poynting vector has zero y component in TE and TM waves, and the xz plane serves as the plane of incidence. Let ψ be an acute angle between $\mathbf{S}$ and the normal $\mathbf{N}$ to the interface. Then $\tan\psi = S_\tau/S_n$. From Eqs. (11) and (12) and continuity of S_n, we find the refraction law for energy streamlines

$$\mu^{(+)} \tan\psi_{\mathrm{TE}}^{(+)} = \mu^{(-)} \tan\psi_{\mathrm{TE}}^{(-)}, \quad \varepsilon^{(+)} \tan\psi_{\mathrm{TM}}^{(+)} = \varepsilon^{(-)} \tan\psi_{\mathrm{TM}}^{(-)}, \quad \mathbf{r} \in \Gamma \tag{13}$$

of TE and TM waves, respectively. It should be emphasized that refraction laws are distinct for TE and TM waves (except at normal incidence, where TE and TM waves become indistinguishable). Therefore, no universal refraction law, which is independent of the wave polarization, can possibly exist for energy streamlines in a generic electromagnetic field.

The above considerations apply to fields with arbitrary time dependence in media without dispersion. For continuous waves, ε and μ can depend on wave frequency ω in addition to spatial coordinates but are still assumed to be real-valued. Refraction laws (13) remain valid for instantaneous power fluxes and for energy streamlines defined in terms of cycle-averaged power fluxes. Validity of the refraction laws in the latter case can be established by either noting that Eqs. (11) and (12) and $S_n^{(+)} = S_n^{(-)}$ hold at each moment of time or repeating the above analysis for the cycle-averaged power-flux density. For streamlines of the cycle-averaged energy, Eq. (13) was obtained earlier[13] in the special case of plane TM wave refraction in a system consisting of a homogeneous layer between homogeneous half-spaces. Refraction laws (13) for electromagnetic waves also could have been derived, at least in the case of a plane boundary of homogeneous media, from Chapman's refraction law (6) for sound by employing the analogy between electromagnetic and acoustic wave refraction. Brekhovskikh[16] demonstrated that results obtained for sound describe reflection and refraction of linearly polarized electromagnetic waves, if the mass density ratio $\rho^{(+)}/\rho^{(-)}$ is replaced by $\mu^{(+)}/\mu^{(-)}$ for TE waves and $\varepsilon^{(+)}/\varepsilon^{(-)}$ for TM waves.

4. Discussion

Chapman's refraction law (6) is apparently different from Snell's refraction law,[17,18] which describes refraction of plane waves at a plane interface of homogeneous media as well as refraction of rays at an interface in homogeneous or inhomogeneous media. Let $\mathbf{a}_i$, $\mathbf{a}_r$, and $\mathbf{a}_t$ designate vectors which are tangential, respectively, to incident, reflected, and refracted rays (or parallel to wave vectors of incident, reflected, and transmitted plane waves). Snell's law states that normal $\mathbf{N}$ to the interface and vectors $\mathbf{a}_i$, $\mathbf{a}_r$, and $\mathbf{a}_t$ at the point of reflection lie in the same

plane (plane of incidence) and that $\theta_i=\theta_r$, $n^{(+)}\sin\theta_i=n^{(-)}\sin\theta_t$, where θ_i, θ_r, and θ_t are acute angles between $\mathbf{N}$ and $\mathbf{a}_i$, $\mathbf{a}_r$, and $\mathbf{a}_t$. Here $n^{(+)}$ and $n^{(-)}$ are the values the refraction index $n(\mathbf{r})$ takes on the sides of the interface where incident and transmitted waves exist, respectively. Refraction index can be defined as $n(\mathbf{r})=\sqrt{\varepsilon(\mathbf{r})\mu(\mathbf{r})}$ for electromagnetic waves; for acoustic waves $n(\mathbf{r})=s_0/s(\mathbf{r})$, where s is sound speed and s_0 is the value of s at an arbitrary chosen fixed point. Snell's law expresses the equality of tangential to the interface components of wave vectors of incident, reflected, and transmitted waves or, equivalently, equality of phase speeds of traces of these three waves on the interface.[17,18]

It is easy to see that the incidence planes implied in Snell's and Chapman's laws coincide. However, the two laws describe wave refraction in terms of distinct material parameters and predict rather different dependences between incidence and refraction angles. In particular, for electromagnetic waves, Snell's law, unlike Chapman's law (13), is independent of wave polarization. In acoustics, the difference between Snell's and Chapman's laws becomes particularly stark when one considers interfaces with either $\rho^{(+)}=\rho^{(-)}$, $n^{(+)}\neq n^{(-)}$ or $\rho^{(+)}\neq\rho^{(-)}$, $n^{(+)}=n^{(-)}$. One may wonder how two refraction laws can possibly describe the same process.

To understand why Snell's and Chapman's laws are different, it is important to realize that incidence angles as defined from wave power-flux density are generally different from incidence angles defined in terms of wave vector or ray direction. Indeed, power-flux density is uniquely defined at any point in space and moment in time. On the other hand, several rays can pass through a given point simultaneously. The direction of the power flux and tangent to energy streamline are associated with the total wave field and do not necessarily coincide with directions of any of the rays. When a wave is reflected from an interface, wave power flux is a result of the interference of incident and reflected waves and, except for the cases of normal incidence or reflection coefficient being zero, is not parallel to the wave vector of the incident wave. While Snell's law describes the kinematics of wave reflection and refraction, direction of energy streamlines depends on amplitude of reflected wave. For electromagnetic waves, reflection coefficients are polarization-dependent.[16,18] That is why Chapman's law (13) takes different forms for TE and TM waves.

Another important distinction between Chapman's and Snell's laws lies in the difference between their applicability domains. The concept of energy streamlines applies to arbitrary wave fields, while Snell's law refers to wave fields of special, albeit extremely important, types, namely, to plane waves and to short-wave fields, which can be described in ray terms.

Refraction angles $\psi^{(-)}$ and θ_t coincide if the transmitted plane wave or refracted ray never returns to the interface as a result of reflection at other interfaces and boundaries or continuous refraction in the medium. Incidence angles $\psi^{(+)}$ and θ_i will also coincide when the reflection coefficient equals zero. Then angles θ_t and θ_i satisfy both Snell's and Chapman's laws. For the angle of intromission of a plane acoustic wave, i.e., the incidence angle at which there is no reflection from a fluid-fluid interface, from Eqs. (6) and Snell's law, we find that

$$\tan^2\theta_i=(n^2-m^2)/(1-n^2), \tag{14}$$

where $n\equiv n^{(-)}/n^{(+)}=s^{(+)}/s^{(-)}$ and $m=\rho^{(-)}/\rho^{(+)}$. The angle of intromission exists when either $1<n<m$ or $m<n<1$. Equation (14) agrees with results[17] obtained from an explicit expression for the plane wave reflection coefficient. From Snell's and Chapman's (13) laws for electromagnetic waves it follows that Eq. (14) gives the incidence angle at which the reflection coefficient is zero for TM or TE waves, when $n\equiv n^{(-)}/n^{(+)}=[\varepsilon^{(-)}\mu^{(-)}/\varepsilon^{(+)}\mu^{(+)}]^{1/2}$ and $m=\varepsilon^{(-)}/\varepsilon^{(+)}$ or $m=\mu^{(-)}/\mu^{(+)}$, respectively. In the case where $\mu^{(-)}=\mu^{(+)}$, Eq. (14) reduces to the known expression $\tan\theta_i=n$ for Brewster angle[16,18] at which there is no reflection of TM waves.

In conclusion we note that Chapman's law can be extended to other wave types. For instance, consider an isotropic elastic solid with piecewise continuous parameters, which are independent of Cartesian coordinate y. It can be demonstrated that in such a system horizontally polarized shear waves, in which particle displacement is parallel to the y coordinate axis and the field is independent of y, propagate without coupling to compressional waves and vertically polarized shear waves.[17] The refraction law for energy streamlines of horizontally polarized

shear waves is derived quite similarly to the acoustic refraction law (6) and differs from it only by replacing mass density ρ by the reciprocal value $1/\mu$ of the shear modulus $\mu(\mathbf{r})$ of the solid. It is not known whether simple refraction laws exist for energy streamlines of elastic wave fields of other polarizations in solids.

Abstract: Permeability of a porous material with a fluid interface is shown to be related to the propagation of the slow longitudinal wave. The propagation threshold of the slow longitudinal wave occurs when the wave number is higher than the critical wave number, k_{cr}. Measuring k_{cr} can provide the intrinsic permeability of a porous interface. The ability to detect a change in k_{cr} due to differences in pore size and fluid viscosity is demonstrated. This measurement is demonstrated in a model material with two pore sizes and two fluid viscosities. The results suggest opportunities to extend the method to a range of materials of scientific and technical importance.

1. Introduction

In 1956 Biot[1] predicted that fluid-saturated porous materials are able to support the propagation of two longitudinal waves, the fast and slow waves. The slow wave's velocity is always lower than both the compressional wave velocity in the fluid and the longitudinal velocity in the solid frame. The slow longitudinal wave, which does not exist in dense solids, represents an out-of-phase movement of the pore fluid relative to the matrix. This motion is very sensitive to the viscosity of the fluid and the permeability of the porous formation.[2] This slow wave is important since porous materials are ubiquitous in nature and technology in the form of fibrous and granular materials, sediments, bones, and oil-bearing rocks. The slow wave can thus serve an important function as a tool for investigating the ability of fluids to penetrate into these materials.

Experimental observation of Biot's slow wave did not occur for nearly 30 years after Biot's work until Plona[3] observed the slow wave in a specimen made from sintered glass beads. Following Plona's work, extensive consideration was given to the slow wave in different porous media, especially geophysical materials[4,5] and human bones.[6–8] However, most studies of the slow wave were limited to considering the wave as a complication of elastic wave theory when investigating porous materials. Only recently has the possibility been raised that a useful relationship exists between the slow wave and material permeability.[9]

A significant difficulty in studying or utilizing slow waves is that the slow wave is not readily detectable. A particularly important description of the interaction of the slow wave with a porous interface is contained in the critical wave number, k_{cr}. Below the critical wave number the slow wave is highly attenuated since the skin-depth of the fluid in the pores is large relative to the pore size. Ideally, k_{cr} represents a bifurcation below which the slow wave does not propagate.[10] Because of the dependence of the slow wave on the motion of the fluid, the detection of the critical wave number provides a basis for measuring the dynamic interaction between the matrix and the pore fluid.

In scientific and technical applications of porous materials, permeability often represents the reason the porous structure is of interest. For example, when a filtration membrane is used for water treatment or chemical separations, the properties of the porous structure such as pore size, porosity, and tortuosity are constant. However, the permeability typically will change during membrane operation.[11] Permeability is normally determined by measuring the fluid pressure difference across a porous specimen, and the resulting flow rate through the material. There are various existing techniques that utilized this basic scheme.[12] However, many of these methods are invasive and some use potentially dangerous materials. In general, permeability cannot be directly measured.[13] The measurement reported in this paper is the first example of using the slow wave transition to quantify permeability at an interface in real time.

2. Exact solution of critical wave number

The problem of waves in porous materials has been considered by a number of authors.[14,15] Following the notation of Edelman,[10] the bulk wave propagated in an infinite fluid-saturated porous medium with a porosity of n_0 has an exact solution for the critical wave number, k_{cr}, of

$$k_{\mathrm{cr}} = y\frac{\pi}{{\rho_0}^S {U_{II}}^S}, \tag{1}$$

where

$$y = y({\rho_0}^S, {\rho_0}^F, {U_{II}}^S, U^F). \tag{2}$$

${\rho_0}^S$ and ${\rho_0}^F$ represent the partial mass densities of the solid and fluid, respectively. ${U_{II}}^S$ is the velocity of the longitudinal wave in the skeleton, and U^F is the velocity of the fluid. In addition, π is related to the porosity n_0, viscosity of the fluid μ^F, and permeability of the porous medium κ by $\pi = n_0\mu^F/\kappa$. If $r = {\rho_0}^F/{\rho_0}^S$ and $c_f = U^F/{U_{II}}^S$, then y can be described as

$$y^2 = \sqrt[3]{-\frac{b}{2} + \sqrt{\frac{b^2}{4} + \frac{a^3}{27}}} + \sqrt[3]{-\frac{b}{2} - \sqrt{\frac{b^2}{4} + \frac{a^3}{27}}} - \frac{B}{3A}, \tag{3}$$

where

$$a = \frac{1}{3}\left(3\left(\frac{C}{A}\right) - \left(\frac{B}{A}\right)^2\right), \tag{4}$$

$$b = \frac{1}{27}\left(2\left(\frac{B}{A}\right)^3 - 9\left(\frac{B}{A}\right)\left(\frac{C}{A}\right) + 27\left(\frac{D}{A}\right)\right), \tag{5}$$

$$A = 4c_f^2(c_f - 1)^4(c_f + 1)^4, \tag{6}$$

$$B = -(c_f - 1)^2(c_f + 1)^2\left[\left(c_f^2 + \frac{1}{r^2}\right)(c_f^4 - 10c_f^2 + 1) + 24c_f^2\frac{c_f^2 + 1}{r}\right], \tag{7}$$

$$C = -2\left(c_f^4 + \frac{1}{r^4}\right)(c_f^4 - 4c_f^2 + 1) + \left(\frac{c_f^2}{r} + \frac{1}{r^3}\right)(5c_f^6 + 3c_f^4 + 3c_f^2 + 5) + \frac{1}{4}\left(\frac{c_f^8 + 108c_f^6 - 122c_f^4 + 108c_f^2 + 1}{r^2}\right), \tag{8}$$

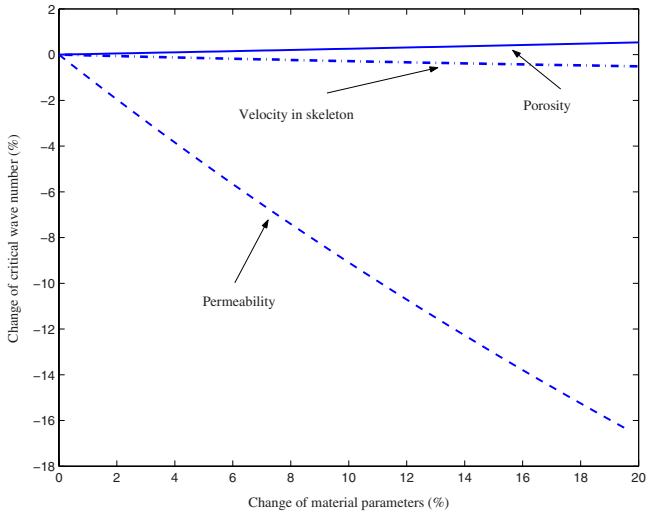

Fig. 1. (Color online) The critical wave number is sensitive to changes in material properties. The solid line shows the increase in the critical wave number when the total porosity is increased. The dash-dotted line shows the effect of changes in the longitudinal velocity of the skeleton. These changes are modest in comparison to those due to a change in the permeability (dashed line).

$$D = -(r+1)^3 \frac{(c_f^2 r + 1)^3}{r^6}. \tag{9}$$

This exact solution of the critical wave number provides a convenient form to directly relate the critical wave number measurement to permeability. If the goal is to configure experiments, this simple solution can be used to identify the range of frequencies for detecting the critical wave number in porous materials.

The critical wave number has been determined for a wide range of porous materials and is, for example, on the order of 70 m^{-1} for sandstone and 0.02 m^{-1} for human cancellous bone. The sensitivity of k_{cr} to material parameters can be determined by varying a single parameter with other properties held constant, as shown in Fig. 1. In many porous materials such as bone, the total porosity will have a large spatial variation. However, when the porosity increases by 20%, the value of k_{cr} increases by only 0.53%. The velocity of the longitudinal wave in the skeleton may also be uncertain for some materials such as partially cross linked polymers used in membranes for separations. Similarly, a 20% increase in the longitudinal wave velocity in the skeleton results in a 0.51% decrease in k_{cr}. In contrast, k_{cr} decreases by approximately 16.7% when the permeability increases by 20%. Thus, while the critical wave number is relatively insensitive to the parameters for which significant uncertainty exists, k_{cr} is highly sensitive to permeability in a porous material. Consequently, a technique that enables k_{cr} to be accurately measured makes possible the determination of the interface permeability, even when many other characteristics of the permeable interface may be uncertain or variable.

3. Method

The slow wave is not readily detectable since the wave is evanescent when a viscous fluid fills the pores.[2] In a through transmission configuration, either the sample must be thick enough for the waves to be separated in time or the existence of the slow wave must be determined from an interference pattern. The ability to access both sides of a sample is also not possible in many applications. However, in a reflection from an interface, energy is transferred into the slow wave that should be detectable as a decrease in the reflection coefficient. Wu *et al.*[16] developed a theoretical analysis to study the reflection and transmission of elastic waves at the interface

Table 1. Material properties of experimental samples.

	Alumina sample 1	Alumina sample 2
Porosity	66%	57%
Particle size (μm)	0.3	1
Density of alumina powder (kg/m^3)	3960	3960
Bulk modulus of solid (N/m^2)	228×10^9	228×10^9
Bulk modulus of frame (N/m^2)	26×10^9	42×10^9
Shear modulus of the frame (N/m^2)	17×10^9	28×10^9
Tortuosity	1.4	1.8
Permeability (m^2)	1.6×10^{15}	7.3×10^{15}

between a fluid and a porous solid. At wave numbers above the critical wave number the reflection coefficient should decrease significantly. This model system builds a bridge between the exact solution of the critical wave number and the experimental permeability measurement. Previous experimental results have not considered the change in reflection in spite of its potential importance as a measurement method.

To provide an appropriate permeability as an input for the modeling, a falling head permeability measurement was used on the samples.[17] The permeability, κ, can be determined based on Darcy's law of fluid flow through porous media according to the following formula:

$$\kappa = \frac{aL}{At}\ln\left(\frac{H_0}{H_1}\right)\frac{\mu}{\rho g}, \tag{10}$$

where a and A are cross-sections of the measuring tube and sample, L denotes the sample thickness, t is the time for the water head to fall from H_0 to H_1, μ is the viscosity of the fluid, ρ is the density of the fluid, and g is the acceleration due to gravity.

4. Acoustic experiment

To experimentally test this hypothesis using two different specimens, alumina porous samples were prepared using 1 and 0.3 μm alumina powders. The powder was placed in a graphite die and hot-pressing at 1375 °C for 48 min in an inert argon atmosphere. The material properties of the two samples are shown in Table 1. Using Eq. (1), the cut-off frequencies corresponding to the calculated critical wave number k_{cr} for the two samples are 10 MHz (0.3 μm; 66% total porosity) and 1 MHz (1 μm; 57% total porosity), respectively.

The test procedure was based on a narrow-band ultrasonic methodology. The equipment includes a function/arbitrary waveform generator (Agilent 33250A, Santa Clara, CA), a digital oscilloscope (Tektronix TDS 520A, Wilsonville, OR), and a gated rf amplifier (Ritec model GA-2500A, Warwick, RI). The samples were vacuum impregnated with fluid. Six broadband ultrasonic transducers (0.5, 1, 2.25, 5, 7.5, and 10 MHz) were excited with a narrow-band gated sine wave to produce measurements at frequencies from 400 kHz to 10 MHz. The angle of the sample was adjusted to provide maximum reflection in order to ensure a normally incident ultrasonic wave insonified the sample. The reflected signal was acquired using the same ultrasonic transducer used to insonify the sample. Three data points were taken at different locations for each sample at each frequency. Because of the homogeneous nature of the sample, no significant difference in the values was measured. For calibration of the apparatus a polished stainless steel reference was used. Figure 2 shows experimental data with the exact solution plotted against a calculated reflection curve for two different samples using water as the pore fluid. The two reflection coefficient curves are clearly separated in frequency domain. The critical wave number is also sensitive to fluid density, wave speed, and viscosity. In some practical applications the viscosity will change significantly during operation and thus impact permeability. Figure 3 compares the effect of using a lower viscosity fluid, acetone (viscosity 0.3 cP) with the

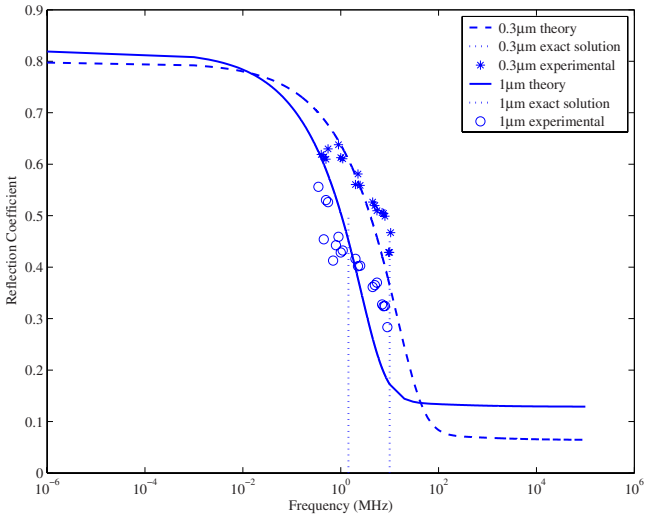

Fig. 2. (Color online) Reflection coefficient vs frequency in water for samples fabricated from two different alumina particle sizes. The dashed line and data point (∗) indicate the calculated and experimental reflection coefficients, respectively, for the 0.3 μm particle-size sample. The solid line and open data points (○) indicate the calculated and experimental reflection coefficients, respectively, for the 1 μm particle-size sample. The vertical dashed lines represent an exact solution for the critical frequencies for each sample.

same test using water (viscosity 1 cP). These data suggest that lower viscosity causes the reflection coefficient transition curve to shift to a lower frequency, which is consistent with the theory.

5. Conclusion

It is evident that this technique is able to sense a permeability change caused by either the difference in the pore structure or a change in the viscosity of the pore fluid. The trends in the

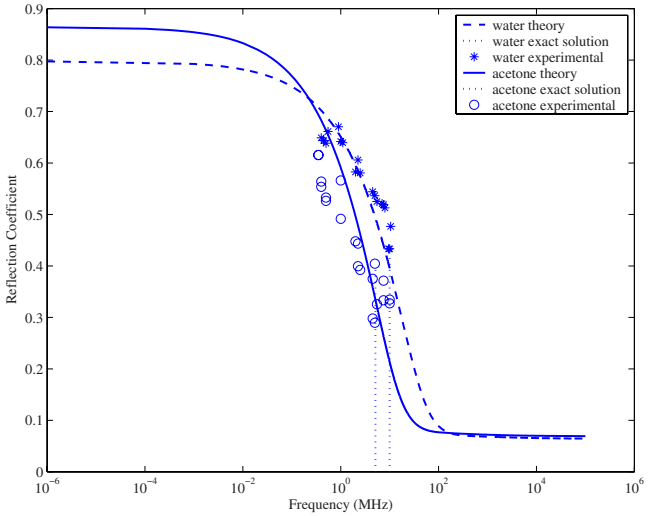

Fig. 3. (Color online) Reflection coefficients for the 0.3 μm sample in water and acetone. The dashed line and data points (*) indicate the calculated and experimental reflection coefficients, respectively, in water. The solid line and open data points (○) indicate the calculated and experimental reflection coefficients, respectively, in acetone. The vertical dashed lines represent an exact solution for the critical frequencies and indicate that a change in fluid viscosity of approximately three times produces a corresponding change in the critical frequency of approximately two times.

experiment are consistent with theory. Therefore, a technique based on the critical wave number measurement may be appropriate for estimating the permeability of a porous material. An appropriate inversion technique for measuring *in situ* permeability will open up a wide range of applications. One application example is the relationship between bone remodeling and interstitial fluid flow that can be probed using slow waves.[6] Many other examples exist for which the permeability controls dynamic processes in technological and natural systems.

Abstract: The dispersion curves of four lowest plate acoustic waves (PAWs) in the *ZX* cut of a periodically poled lithium niobate (PPLN) wafer are computed numerically and investigated experimentally. Experiment is in agreement with simulated dispersion curves. Calculations and measurements reveal the stop-bands in the dispersion curves of the PAW modes in PPLN despite a wafer that has uniform mechanical properties. At a specific wave number, within the frequencies of the stop-bands, the acoustic modes do not propagate.

1. Introduction

Interest in the propagation of acoustic waves in two-dimensional and periodic structures has grown in recent years because of the intriguing properties of acoustic superlattices.[1,2] Existence of acoustic stop-bands or forbidden bands has been shown for a number of periodic media in different solid-based composite structures including one-dimensional ferroelectrics and periodically microtapered optical fibers.[1–6] At a certain wave number, within the frequencies of an acoustic stop-band, a specific acoustic mode cannot propagate. In the case of band gap that is sometimes refered to as a full or complete band gap, no acoustic phonon can be transmitted over a range of wave numbers.[6] The acoustic stop-bands for bulk and surface waves were discovered in two-dimensional composites based on $LiNbO_3$ with air holes,[6] piezoelectric $Bi_{12}GeO_{20}$ filler in a silica substrate,[7] and piezocomposites consisting of the layers of ZnO, PZT4, PZT5, CdS, and ZnO.[8] The main property of the superlattices is a periodicity in material physical of the composite structures including elastic, dielectric and piezoelectric constants and density. As a rule, the speed of an acoustic wave is different in the individual structure components. Despite extensive efforts in this field, the dispersion of plate acoustic waves (PAWs) in periodically poled lithium niobate (PPLN) wafers has not yet been investigated, in spite of contemporary interest in the phenomenology and applications of PPLN crystals.

In this work, we investigate the spectrum of PAWs propagating along *X* axis in the *Z*-cut of a PPLN wafer. PPLN is known to be photonic crystal, and our aim in this study is to search for acoustic stop-bands, thus establishing it as both a photonic and a phononic solid. The hypothesis that PPLN may have an acoustic stop-band is based on the effect of domain resonance observed in periodically polled lithium tantalite.[9]

2. Methods

A model of a PPLN wafer is shown in the inset of Fig. 1(a). The inversely directed arrows represent a periodic polarization in a multidomain array. For theoretical calculations, the inversely poled domains are introduced by periodically changing the sign of a piezoelectric constant in the equations of motion (1) and electrodynamics (2), $(-1)^{n-1}\cdot e_{m,ij}$,

$$\rho\frac{\partial^2 u_i}{\partial t^2}=\frac{\partial T_{ij}}{\partial x_j}=\frac{\partial}{\partial x_j}\left[c^E_{ijkl}\frac{\partial u_k}{\partial x_l}+(-1)^{n-1}\cdot e_{m,ij}\frac{\partial \varphi}{\partial x_m}\right], \quad (1)$$

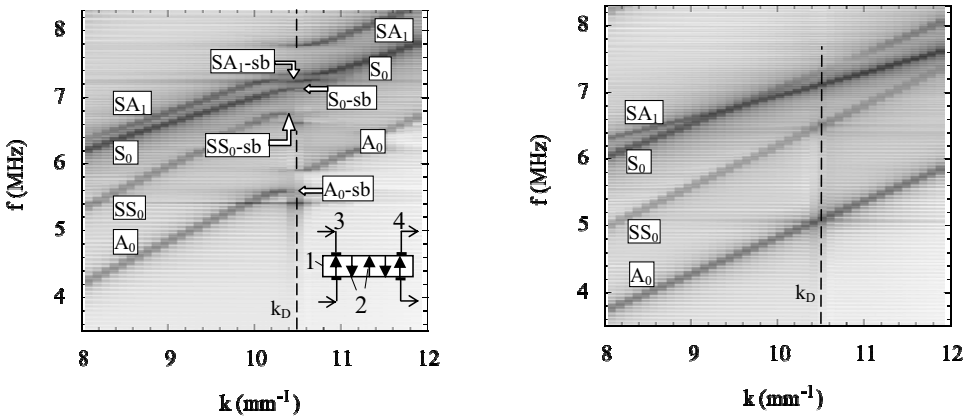

Fig. 1. Numerical dispersion curves for X-propagating PAW in the 0.5-mm-thick Z-cut PPLN with $N=216$ domains of 300-μm-width each: (a) FEM computation with regular piezoelectric constants of $LiNbO_3$. inset in panel (a): 1, PPLN wafer; 2, inversely poled domains; 3, input transducer; 4, output pickup. (b) FEM computation with ten-time-reduced piezoelectric constants. Vertical dashed lines show $k=k_D=(\pi/d)=10.47$ mm^{-1}. The same plate modes are observed in both panels (a) and (b), but the stop-bands appear only in panel (a).

$$\frac{\partial D_m}{\partial x_m}=\frac{\partial}{\partial x_m}\left[(-1)^{n-1}\cdot e_{m,ij}\frac{\partial u_i}{\partial x_j}+\varepsilon^S_{mj}\frac{\partial \varphi}{\partial x_j}\right]=0, \tag{2}$$

where $n=1,2,\ldots,N$ is the domain's number and N is the total number of the domains in the array; indices i, j, k, l, and m change from 1 to 3 representing the X, Y, and Z crystallographic directions; ρ is crystal density; u_i is the acoustic displacement in PAW; T_{ij} is the stress tensor; c^E_{ijkl} is the tensor of elastic moduli at constant electric field; ε^S_{ij} is the dielectric permittivity at constant strain; D_i is the electric displacement in PPLN; and φ is the electric potential. A superscript n standing for the domain number can change from $n=1$ for the first domain at $X=0$ to $n=N$ for the last domain at right end of the sample [see Fig. 1(a)]. In addition to Eqs. (1) and (2), the boundary conditions of zero acoustic stress and electric charge at the plate surfaces are applied. To solve Eqs. (1) and (2) along with the appropriate boundary conditions, one can use Hamilton's variation principle extended to a piezoelectric crystal, where the functional of the total work-energy is minimized to zero,[10]

$$\delta\int (E_{\rm kin}-E_{st}+E_d+W)dt=0. \tag{3}$$

For a wafer of unit width along the Y- axis, the term $E_{\rm kin}=\frac{1}{2}\int \dot{u}^2 dx_1 dx_3$ is the PAW's kinetic energy, the term $E_{st}=\frac{1}{2}\int \mathbf{S}^t\cdot\mathbf{T}dx_1dx_3$ is the PAW's elastic energy due to deformation $\mathbf{S}^t$, and the term $E_d=-\frac{1}{2}\int D_m\cdot(\partial\varphi/\partial x_m)dx_1dx_3$ is the contribution to the total energy due to dielectric displacement D_m that is defined in the parentheses in Eq. (2). The term W is the work done by an excitation force to generate the PAW. Furthermore, we have used the well-known finite element method (FEM) technique to compute the spectrum of PAWs in PPLN. In Fig. 1(a), a fragment of this spectrum near the stop-bands is shown for the four lowest modes. For lower frequencies ($f<3.5$ MHz) and wave vectors ($k<8$ mm^{-1}), the PAW dispersion curves are smooth lines like for regular modes in an acoustic waveguide. In Fig. 1(b), the same dispersion curves are calculated with ten times smaller piezoelectric coefficients, i.e., with $0.1\cdot(-1)^{n-1}\cdot e_{m,ij}$ instead of $(-1)^{n-1}\cdot e_{m,ij}$ in Eqs. (1) and (2).

3. Results and discussion

The dispersion curves of Fig. 1(a) are calculated for a PPLN sample with $N=216$ domains of width $d=300$ μm each. Four computed plate waves are the zero asymmetrical quasi-Lamb mode A_0, the zero shear symmetrical mode SS_0, the zero symmetrical quasi-Lamb wave S_0, and the first shear asymmetrical mode SA_1. The dispersion curves of all four modes (A_0, SS_0, S_0, and SA_1) are discontinued at wave number $k=10.47$ mm^{-1}, which is denoted in the figure by a vertical dashed line. This magnitude of k exactly corresponds to the domain resonance,[9] which takes place at $k_D=(\pi/d)$, where d is the domain width. Four stop-bands for the modes A_0, SS_0, S_0, and SA_1 are shown in Fig. 1(a) by arrows with the corresponding mode indicated. The stop-bands occur when the PAW wavelength $\lambda=2d$ and, consequently, $k=k_D=(\pi/d)$. The PAW modes cannot propagate within their stop-bands because there are no solutions for the acoustic displacements. To find out the physical origin of the stop-bands in Fig. 1(a), we performed a FEM-simulation with ten-times-smaller piezoelectric coefficients, the results of which are shown in Fig. 1(b). A comparison of Figs. 1(a) and 1(b) leads one to conclude that the existence of the stop-bands is a result of the piezoelectric interaction between PAW modes and periodically poled domains. To check this conclusion, we made the additional simulations with different domain widths. Calculations yielded a low frequency shift in stop-band position if the domain width d increased and a high frequency shift when the width decreased. This conclusion is also consistent with the piezoelectric coupling of the waves. Our estimates yield different magnitudes for the effective piezoelectric coupling coefficients K^2 characterizing PAW modes. For instance, at $k=k_D$ for observed plate waves, we have $K^2(SA_1)>K^2(A_0)>K^2(S_0)$. In Fig. 1(a), the widths of the stop-band, Δf, have the same inequality, that is, $\Delta f(SA_1)>\Delta f(A_0)>\Delta f(S_0)$, all at $k=10.47$ mm^{-1}. The mode SS_0 is not reliably computed nor measured at $k>10.47$ mm^{-1}, which means it is not transmitted through the multi-domain array. These acoustic stop-bands are quite unusual because they appear in a mechanically uniform medium having the same density and elastic moduli in all the domains. The only difference is the inverse polarization of neighboring domains. The physics behind these uncommon stop-bands may be attributed to a strong altering of the energies $\boldsymbol{E}_{st}$ and $\boldsymbol{E}_d$ at the acousto-domain resonance condition of $\lambda=2d$, which makes it impossible to satisfy Eq. (3).

The experimental setup for the excitation and detection of PAWs in PPLN is a standard computer controlled system with a rf generator to excite PAWs, small ultrasonic receiver that is connected to a digital oscilloscope, and a computer controlled stage that moves the receiver over PPLN sample surface. A sample [see Fig. 1(a) inset] is fabricated by applying a 22 kV/mm electric field along the Z axis to a 0.5-mm-thick optical grade LN wafer. The inverted ferroelectric domains are 300 μm in width, and thus their spatial period is twice of the domain width. The PAW is excited by applying rf voltage to the 0.9-mm-wide input electrodes that are deposited on the top and bottom surfaces of the PPLN wafer. The sample is placed on a support, which is attached to a computer controlled motorized stage. In a typical run, the stage makes 800 steps to cover the distance of 40.64 mm. Detector 4 is a small piezoelectric transducer brought into contact with the sample in a narrow spot of $\sim 0.15\times 0.2$ mm^2, which is smaller than domain width. Frequency performance of the receiver in the frequency range of the stop-bands, 5.4–7.7 MHz, is a monotonically increasing line without any local extrema. A signal from detector 4 [item 4 in Fig. 1(a)] goes to a digital oscilloscope that records a waveform $u_z(t_j)$ taken at the positions x_i after each single step. When the experimental run is completed, the data are stored in a two-dimensional array, $u_z(t_j,x_i)$. To obtain experimental dispersion curves, the double discrete Fourier transform converts the $u_z(t_j,x_i)$ matrix into its Fourier image $u_z(f_j,k_i)$. A gray-scale plot of the $u_z(f_j,k_i)$ matrix is the experimental spectrum presented in Fig. 2(a). The dispersion curves of Fig. 2(a) are consistent with the FEM computation of Fig. 1(a) for all modes. However, the amplitudes "indicated by the blacker colors in the figures" are different for the various modes. In particular, the modes A_0, S_0, and SA_1 are reliably detected. In contrary, the

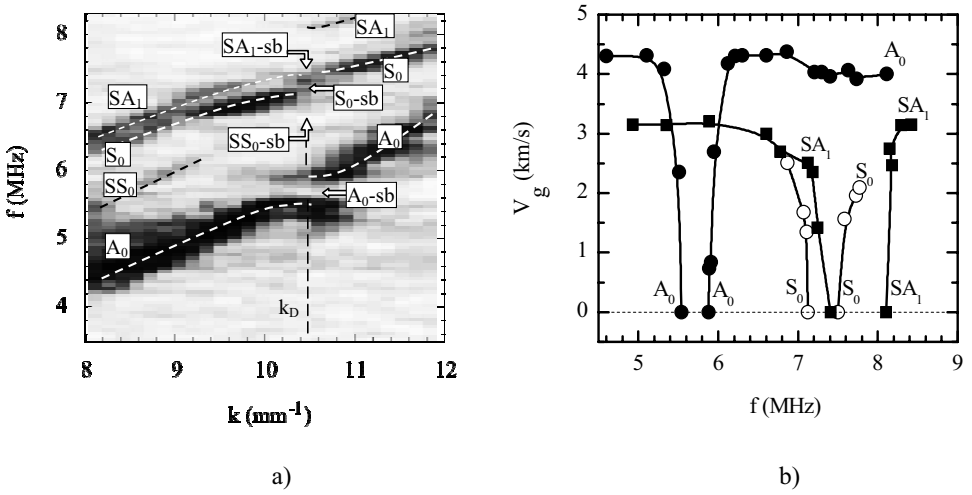

Fig. 2. (a) Experimental dispersion curves and (b) dispersion of the group velocities for *X*-propagating PAW in the 0.5-mm-thick *Z*-cut PPLN with $N=216$ domains of 300-μm-width each. The stop-bands in (a) panel appear at $k=k_D=(\pi/d)=10.47$ mm^{-1}. Arrows with sb-mark show the low frequency edges of the stop-bands. The dashed lines above the original computer generated graphs are plotted over the peak values of the experimental Fourier image $u_z(f_j,k_i)$. In panel (b), the zero group velocity points $V_g=0$ are consistent with the stop-band limits in corresponding modes.

mode SS_0, having mainly a shear displacement u_y, is weakly detected by the receiving transducer, probably because it mainly reads the vertical component of the total acoustical displacement.

As a final test, we analyze the group speeds V_g of three reliably detected modes, A_0, S_0, and SA_1. The magnitudes of V_g are calculated as $2\pi(df/dk)$ taken from the set of experimental data, which are graphically presented in Fig. 2(a). The results are given in Fig. 2(b). A horizontal dashed line represents the zero-speed limit $V_g=0$, where the mode is stopped. In Figs. 2(a) and 2(b), the stop-bands are detected in the frequency ranges of 5.60–5.90 MHz for A_0 mode, 7.10–7.45 MHz for S_0 mode, and 7.35–8.05 MHz for SA_1 mode. The low limits of the stop-bands are shown in Fig. 2(a) by the arrows corresponding to each mode, where the letters "sb" stand for "experimental stop-band." The SS_0 mode has mainly shear displacements along the *y* axis, and so it is not reliably detected. Nevertheless, a low limit of its stop-band may be read on a sufficiently resolved graph as 6.7 MHz, which is shown by dashed arrow in Fig. 2. The experimental stop-bands, positions, and widths are in agreement with the theoretical predictions of Fig. 1(a). The calculated stop-bands run from 5.60 to 5.90 MHz for A_0, 7.15 to 7.35 MHz for S_0, and 7.25 to 7.80 MHz for the SA_1 mode. The calculated stop-band of SS_0 mode starts at 6.75 MHz, as shown in Fig. 1(a).

4. Conclusions

In both the experiment and theory, all stop-bands appear at $k=10.47$ mm^{-1}, which unequivocally supports the hypothesis that the acousto-domain interaction is the origin of the stop-band effect. This conclusion is strongly supported by the additional simulations with different domain widths. In all cases, the stop-band effect takes place under the acousto-domain resonance condition of $\lambda=2d$, when the wavelength of any PAW is equal to two domain widths. The frequency width Δf of the stop-band depends on the piezoelectric coupling of an acoustic mode; for higher coupling coefficients, the stop-band width is larger. A piezoelectric field due to acoustic deformation is mainly responsible for the acousto-domain coupling, as it is clear from the comparison of Figs. 1(a) and 1(b). The results presented in this paper may stimulate research

toward new acousto-optic phenomena in phononic-photonic materials and lead to new applications in acousto-optics, acousto-electronics, ferroelectrics, and ultrasonics such as the construction of efficient microtransducers.

Abstract: Echo threshold variability has previously been examined using stimuli that are carefully controlled and artificial (e.g., clicks and noise bursts), while studies using speech stimuli have only reported average thresholds. To begin to understand how echo thresholds might vary among speech sounds, four syllables were selected in pairs that contrasted abruptness vs gradualness of onset envelopes. *Fusion* and *discrimination suppression thresholds*, two echo thresholds commonly used to study the *precedence effect*, differed among syllables. Results were used to evaluate two predictive heuristics adapted from *perceptual center (p-center)* models.

1. Introduction

Everyday listening conditions are characterized by multiple sound sources and numerous reflections. As a first step toward understanding auditory perception in reverberant conditions, studies have employed a simple experimental paradigm with only a single first-arriving or *lead* sound and a single later-arriving or *lag* sound. The lag is usually an exact replica of the lead, simulating the first reflection to reach the ear in a reverberant environment. At short lead-lag delays, the lead dominates or suppresses perception of lag information along a number of dimensions. This is known as the *precedence effect*. Examples of dimensions over which it operates include perception of the lag as a discrete event (usually assessed subjectively via a *fusion* task) and extraction of lag directional cues (assessed objectively via tasks such as *discrimination suppression*). One common goal has been to quantify echo thresholds, i.e., the lead-lag delay at which the lead ceases to dominate the lag.[1]

While some of the very first work in this area used continuous speech as one kind of stimulus,[2–4] most progress since then has been made using artificial stimuli, which allow greater experimental control but lack acoustic characteristics intrinsic to speech and other naturally produced sounds. The majority of precedence effect studies to date have used clicks or noise bursts that are only a few milliseconds in duration. Such stimuli do not result in temporal overlap between the lead and lag at inter-stimulus delays corresponding to psychophysical echo thresholds.[1] In contrast, a single syllable in speech is usually 150 ms or longer, much longer than echo thresholds reported in a small number of studies for complex sounds such as continuous speech and music.[3,5] Clicks and noise bursts have been generated in laboratories to eliminate periodicities and recognizable transients,[1] while pure tones have been used to eliminate spectral complexity.[6] Stimulus onset characteristics, which play a critical role in the precedence

effect,[6–8] are often held constant and have only been manipulated in a simplified linear fashion.[6] Information in speech is carried by just the kinds of spectral and temporal characteristics that are eliminated from most artificial stimuli.

Systematic variability among echo thresholds for various speech sounds has not previously been reported, and it is not clear how current auditory models might be best adapted to make accurate predictions about such differences. Precedence effect studies that have used speech stimuli[2,3,5] have done so with the implicit simplifying assumption of equivalent thresholds across various speech sounds, reporting only the average results across all speech stimuli used. This assumption has been explicitly built into the few precedence effect models that have attempted to account for experimental results with speech stimuli.[9,10] The current literature does not provide any greater precision in the characterization of speech echo thresholds than the following general observation from the first precedence effect report,[4] p. 335: "The interval over which fusion takes place is not the same for all kinds of sounds. The upper limit of the interval was found to be about 5 ms for single clicks and is apparently much longer, perhaps as much as 40 ms, for sounds of a complex character."

Existing literature points to some acoustic characteristics likely to be most relevant to variability among speech echo thresholds, should there prove to be any. In particular, binaural detection and localization results with non-speech stimuli have demonstrated the distinct importance of onset characteristics for both periodic (i.e., pure tone[6]) and aperiodic (i.e., noise[7,8]) stimuli. The other consistent finding has been the dominance of low-frequency information ($<$1.5 kHz) over high-frequency information in precedence effect phenomena.[11,12]

One can also look to the speech perception literature, where waveform onsets and low-frequency information have emerged as critical predictors of so-called *perceptual centers* or *p-centers*.[13] The p-center is the beat or perceived moment of occurrence of a sound event as distinguished from the absolute acoustic onset.[14] From the p-center literature, we adopted Scott's[13] *frequency-dependent amplitude increase model* (FAIM) for the prediction of speech echo thresholds. Specifically, we replicated Scott's[13] procedure for the calculation of *rise time* values, the metric determined to most accurately predict p-centers. The extension of rise times to the prediction of echo thresholds was consistent with Rakerd and Hartmann's[6] identification of *onset rate* (increase in sound pressure per unit time) as the best predictor of binaural localization ability, but a frequency weighted application of this principle seemed more promising for use with naturally produced sounds. In addition, FAIM rise times have the advantages of being clearly specified and relatively easy to implement with speech stimuli.

The current study addressed two separate but related questions: (1) do echo thresholds for speech sounds vary systematically, and (2) can we predict these thresholds from acoustic characteristics? The first was addressed by applying a repeated-measures analysis of variance (ANOVA) to echo thresholds for different speech sounds; the second required a predictive heuristic, in this case FAIM rise times, and was addressed via correlational analysis.

2. Method

2.1 Participants

Nine young adults, six females and three males, initially volunteered to participate. To continue in the study, participants were required to pass a 20 dB hearing screening at 500, 1000, 2000, 4000, and 8000 Hz for each ear and have a symmetrical hearing profile, defined as no more than a 10 dB discrepancy between right and left ear thresholds at a particular frequency. None had any history of hearing difficulties, but one male was deemed ineligible for participation due to an asymmetrical hearing profile. One female did not return for testing after the initial practice session, leaving a final group of seven participants. All participants spoke English as their first and primary language.

2.2 Stimuli

Four syllables were recorded from an adult female: [bʌ], [dʌ], [wʌ], and [yʌ] (transliterated: "buh," "duh," "wuh," and "yuh"). These stimuli were selected as pairs, [bʌ] vs [wʌ] and [dʌ] vs

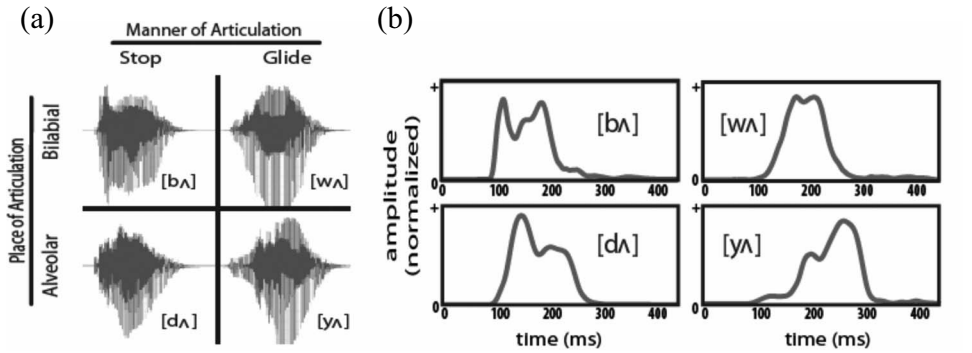

Fig. 1. (a) Raw waveforms of four syllables used as stimuli. Stimuli were digitally sampled at 44.1 kHz, and amplitude levels were root-mean-square equalized (see Multimedia link in text). (b) Outputs from filtering procedure used to calculate onset rise times for each stimulus.

[yʌ], which would differ significantly in terms of rise times but would otherwise have similar spectral and temporal characteristics. The voiced stop consonants in [bʌ] and [dʌ] have abrupt waveform onsets compared to the glides in [wʌ] and [yʌ], which have gradual onsets [see Fig. 1(a)].

[Mm. 1. [bʌ], [wʌ], [dʌ], and [yʌ] stimulus files concatenated in wav format (134 KB).]

Rise times were calculated following the procedure of Scott.[13] Each syllable was passed through a gammatone filter[15] with a center frequency of 578 Hz and an equivalent rectangular bandwidth of 4.0. These outputs, which contained significant information several hundred hertz above and below the center frequency, were full-wave rectified and smoothed with a 25 Hz Butterworth filter [see Fig. 1(b) for results]. The onset time (in milliseconds) between 10% and 90% of the maximum amplitude of each smoothed waveform was calculated, producing a frequency-dependent rise time for each recorded syllable. Rise times (in parentheses following each syllable) predicted that echo thresholds would be ordered as follows, from lowest to highest: [bʌ] (14.83), [dʌ] (33.22), [wʌ] (43.65), and [yʌ] (91.54).

2.3 Equipment

A customized MATLAB program was developed for randomization and presentation of stimuli, which was accomplished via a Tucker-Davis Technologies System 3 multiple input-output processor. Testing took place in a standard IAC sound booth (reverberation time, T_{60}=250 ms), where an array of loudspeakers (Cambridge SoundWorks Henry Kloss Center/Surround IV) was positioned in the horizontal plane. Each speaker in the semi-circular array was at ear level, 1.4 m from the approximate center of the seated participant's head. A computer monitor was placed under the front loudspeaker, and participants entered responses via a mouse by clicking on appropriate icons as instructed.

2.4 Design and procedure

Two tasks were used to measure echo thresholds: fusion and discrimination suppression. All seven participants completed both tasks. Before data collection began, each participant completed a 2-h practice session to establish a consistent response criterion on each task. The procedure for each task and thresholds (50% two sounds perceived on the fusion task, and 70.9% correct, i.e., $d'=1.0$, on the discrimination task) was similar to those described by Freyman *et al.*[16] The following delays, which always produced temporal overlap between lead and lag, were used for both tasks: 1, 5, 10, 15, 20, 25, 30, 35, 40, and 45 ms. For both tasks the following conditions applied: (a) The same stimulus was always presented as both lead and lag at 60 dBA, (b) participants were instructed to face the computer monitor in front (0° azimuth), (c) the lead was always from −45° azimuth, and (d) participants initiated each trial at their own pace using

Table 1. Both raw and centered group-mean thresholds are reported for each syllable on each task. Centered values are relative to the task mean, facilitating cross-task comparisons. Syllable error terms are *within subjects standard deviations* (relative to centered thresholds), consistent with the design of the study. Task mean error terms are *between subjects standard deviations* (relative to raw thresholds).

	Task									
	Fusion					Discrimination				
Group mean	[bʌ]	[dʌ]	[wʌ]	[yʌ]	Task mean	[bʌ]	[dʌ]	[wʌ]	[yʌ]	Task mean
Raw	17.00	14.79	19.23	21.73	18.19	10.91	6.85	13.26	13.83	11.14
Centered	−1.19	−3.40	1.04	3.54	18.19	−0.23	−4.29	2.12	2.69	11.14
Std. dev.	2.36	3.30	2.35	2.15	6.79	3.14	3.33	4.53	2.53	5.72

onscreen controls. During the fusion task, the lag was always presented from +45° azimuth. Participants, who were informed that the task involved an auditory "illusion" and that two sounds were always presented, made a subjective decision as to whether they perceived there to be one or two sounds. No feedback could be given, but participants were instructed to only select two if they were certain they had heard a second sound coming from a location to the right of center. During the discrimination task, the lag was presented from either +35° or +55°. Participants were instructed to decide whether the lag originated from the left or right of a visual reference point at +45° (a two-alternative forced choice), and feedback was given after each response.

The method of constant stimuli was used, and blocks alternated between tasks in a counterbalanced manner. Within each block, all stimuli and delays were used an equal number of times, and the presentation order was completely randomized across stimuli and delays; lag locations were included in this block randomization on the discrimination task. Across all blocks of the fusion task, 20 repetitions were completed for each stimulus at each delay, resulting in 800 total trials. For the discrimination task, 40 repetitions (20 from each lag location) resulted in a total of 1600 trials. Participants were allowed to take breaks as often and for as long as they wanted during testing. They were encouraged to take a minimum of one break every 200 trials. Trials were typically completed across three 2-h testing sessions spaced over several days.

3. Results and discussion

3.1 Echo thresholds

Group mean thresholds are reported in Table 1. Task means, 18.19 ms for fusion and 11.14 ms for discrimination suppression, were slightly higher than those reported in the literature for click stimuli (e.g., 5–9 ms for thresholds on both tasks[16] using identical threshold criteria and free field procedures) but slightly lower than fusion thresholds typically reported for connected speech (e.g., 30–50 ms[3]). Litovsky *et al.*[1] provided a review of thresholds found on both tasks with different types of stimuli. In the present study, the use of single syllables as stimuli, rather than sentences or concatenated word lists, probably explains why thresholds fell somewhere midway between previous results with artificial stimuli, on the one hand, and continuous speech, on the other.

3.2 Analysis of variance

For all statistical tests, a level of $p < 0.05$ was used to determine significance. When task (fusion vs discrimination), manner of articulation (stop vs glide), and place of articulation (bilabial vs alveolar) were entered as factors in a three-way repeated-measures ANOVA, there was a significant main effect of manner, $F(1,6) = 11.45$, $p = 0.02$, and a significant manner by place interac-

tion, $F(1,6)=15.67$, $p=0.01$. No other main effects or interactions were significant. This supported our primary hypothesis that echo thresholds for speech sounds would differ across syllables.

The main effect of manner was in the predicted direction, with stops as a class having lower group mean thresholds than glides, while the interaction of place with manner affected the strength but not the direction of this effect. Therefore, this analysis of onset effects, at the admittedly gross level of syllable category, also provided support for our second hypothesis that the abrupt onsets of stops would tend to result in lower thresholds. Paired-sample *t*-tests reached significance for [dʌ] vs [yʌ], [bʌ] vs [yʌ], and [wʌ] vs [yʌ] on the fusion task and [dʌ] vs [bʌ] and [dʌ] vs [yʌ] on the discrimination task.

3.3 Correlational analyses

Correlations between rise times and group mean echo thresholds were in the predicted direction, but neither slope was statistically significant: $r=0.82$, $r^2=0.67$, and $p=0.18$ for the fusion task, and $r=0.58$, $r^2=0.33$, and $p=0.42$ for the discrimination task. Although the small number of data points meant statistical power was low for this analysis, rise times have two characteristics that may account for their failure to predict observed differences among echo thresholds more accurately. They falsely assume linearity in waveform onsets, and they do not relate onset characteristics to the waveform as a whole.[17] An alternative p-center metric, Howell's[18] *center of gravity* can be adapted to address both of these potential shortcomings. It had never been applied in a frequency-specific manner, but the limited success of frequency-dependent rise times in the current study seemed to warrant the test of a hybrid *frequency-dependent center of gravity* (FCoG) model. In deriving FCoGs, Scott's[13] filtering procedure was again used—and consistent with this procedure, the syllable was defined as beginning and ending at the points where the waveform amplitude was equal to 10% of the maximum amplitude—but the remaining steps were suggested by Howell.[19] The duration from the beginning of the syllable to the point at which the integral (area under the curve) equaled one-half of the integral for the entire syllable was expressed as a ratio over the duration of the entire syllable, i.e., as a unitless proportion. From a signal detection theoretical perspective, this would seem to capture the detectability of the lag onset as well as the masking potential of the continuous and offset portions of the lead in a single metric.

The FCoGs (in parentheses following each syllable) predicted that echo thresholds would be ordered as follows, from lowest to highest: [dʌ] (0.22), [bʌ] (0.41), [wʌ] (0.49), and [yʌ] (0.59). Correlations for the fusion task, $r=0.976$, $r^2=0.952$, and $p=0.02$, and the discrimination task, $r=0.982$, $r^2=0.970$, and $p=0.02$, indicated that FCoGs accounted for almost all of the variance in echo thresholds. Both slopes were significant even after a conservative Bonferroni correction was applied to this *post hoc* analysis.

4. Conclusions

In this investigation, echo thresholds differed as a function of syllable-initial phonetic features and correlated significantly with FCoGs, shedding light on properties of speech stimuli worth exploring further in relation to the precedence effect and speech perception in reverberant situations. Predictive heuristics tested in this study fit most naturally with other signal detection theoretical approaches in the binaural literature (see Saberi and Petrosyan[20] for review) and in the broader perceptual sciences in that they focus on the information-bearing properties of the stimulus. This approach is less popular than physiologically oriented modeling in the binaural literature (see Stern and Trahiotis[21] for review), which focuses on the transformational processes accomplished by the auditory system, but it has shown merit here as an entrée into the characterization of variability among echo thresholds for speech stimuli. In the long run, this complementary approach should facilitate improvements in physiological models as well.

Without experimental data from a much wider variety of stimuli (e.g., different phoneme combinations and talkers), it is difficult to know whether FCoGs or FAIM rise times can be used to predict all speech echo thresholds. Perhaps the most critical test for any predictor will come with initial voiceless consonants, in particular voiceless fricatives. These onsets present a

challenge because they lack both the low-frequency spectral peaks and periodicities characteristic of voiced consonant and vowel sounds. There are no explicit models for how high-frequency-aperiodic and low-frequency-periodic cues are combined to produce precedence effect phenomena when both are sequentially present in a single stimulus, as they are, for example, in syllables that begin with voiceless fricatives. These challenges may require a more complex model, such as the p-center model of Pampino–Marschall,[22] which determines *partial onset events* as well as *syllabic centers of gravity* from frequency-specific loudness dynamics within multiple critical bands. If multivariate predictors prove to be necessary, their application to continuous stimuli may benefit from a learning algorithm and training procedure (e.g., the neural network model of Wilson and Darrell[23]).

Vocal tract modes based on multiple area function sets from one speaker

Brad H. Story
Speech Acoustics Laboratory, Department of Speech, Language, and Hearing Sciences, University of Arizona, Tucson, Arizona 85721
bstory@u.arizona.edu

Abstract: The purpose of this study was to derive vocal tract modes from a wider range of vowel area functions for a specific speaker than has been previously reported. Area functions from Story *et al.* [(1996). J. Acoust. Soc. Am. **100**, 537–554] and Story [(2008). J. Acoust. Soc. Am. **123**, 327–335] were combined in a composite set from which modes were derived with principal component analysis. Along with scaling coefficients, these modes were used to generate a [F1, F2] formant space. In comparison to formant spaces similarly generated based on the two area function sets alone, the combined version provides a wider range of both F1 and F2 values. This new set of modes may be useful for inverse mapping of formant frequencies to area functions or for modeling of vocal tract shape changes.

1. Introduction

For production of vowels, the vocal tract area function has been shown to be fairly well represented by two canonical deformation patterns, or "modes," (e.g., Story and Titze, 1998; Story, 2005b; Mokhtari *et al.*, 2007) derived from principal component analysis (PCA). Such modes have been derived from speaker-specific area function sets, but are similarly shaped (in terms of their variation along the length of the vocal tract) across speakers, and are related to specific patterns of formant frequencies when appropriately scaled and superimposed on a mean area function.

The modal representation of the vocal tract shape allows for an essentially one-to-one mapping between the scaling coefficients of the modes and the first two formant frequencies and has led to a method for mapping time-varying formant frequencies extracted from recorded speech to a time-varying sequence of area functions (Story and Titze, 1998; Story and Titze, 2002; Mokhtari *et al.*, 2007). Development of a kinematic model of the vocal tract area function that can be used to simulate speech is also based on this same modal representation (Story, 2005a). Although both the inverse mapping technique and kinematic model have been shown to be reasonably successful at bridging the area function-to-acoustic relation, the ability of the modal representation to produce a wide range of vocal tract shapes is limited by the original set of area functions on which it is based. For example, the modal representation derived in Story and Titze (1998) and subsequently utilized in Story and Titze (2002) and Story (2004, 2005b) was based on the ten vowel area functions reported for an adult male (Story *et al.*, 1996). Hence, the boundaries of the potential [F1, F2] vowel space afforded by the modal representation are essentially defined by the formant frequencies of those original area functions. Although additional sets of speaker-specific area functions reported by Story (2005b) and Mokhtari *et al.* (2007) have been used to derive modal representations of individual speakers, they are also limited by the range of formant frequencies produced by the original area functions obtained from each speaker. This is not necessarily a severe limitation assuming that each speaker produced hyperarticulated vowels (thus, producing extreme [F1, F2] formant values). If the vowels tend toward being centralized, however, the working space of a modal-based vocal tract model will be constrained.

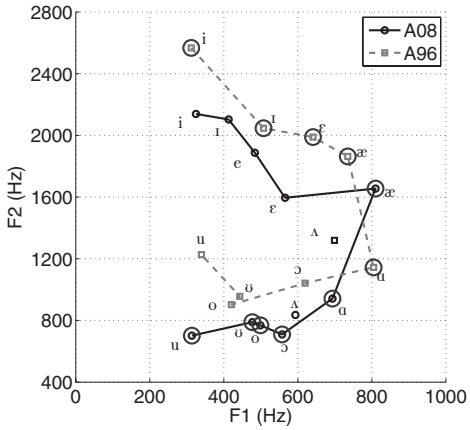

Fig. 1. Vowel space plot of F1 and F2 frequencies calculated from the A96 and A08 versions of each vowel (see text). The data points are connected by solid or dashed lines to clarify the set to which they belong and to provide a rough outline of the possible vowel space. Because of their positions in the F2 vs F1 plane, the two [ʌ] vowels are not connected to the other vowels within their respective sets. The large open circles denote those vowels chosen from each set that were combined in a composite set.

Recently, Story (2008) reported an additional set of 11 vowel area functions for the same speaker who produced the 10 vowels originally reported in Story *et al.* (1996). F1 and F2 formant values were determined from the frequency response function calculated for each area function in the two sets. It was noted that, in general, the F2 values calculated for the new area function set were shifted downward in frequency relative to those calculated for the area functions of,[1] Story *et al.* (1996) as shown in Fig. 1. It was suggested that this difference originated from a tendency, in the new area functions, to slightly constrict the pharyngeal portion of the vocal tract while expanding the oral cavity. Since the new area functions are configured somewhat differently than the 1996 versions and produce different [F1, F2] values, they provide additional samples of the same speaker's vocal tract that might be *combined* with the original set in a PCA. The resulting vocal tract modes and mean area function would then be representative of a wider range of vowel configurations than either area function set alone.

The purpose of this letter is to demonstrate that a modal representation derived from a particular combination of area functions selected from the data of Story *et al.* (1996) and Story (2008) produces an [F1, F2] vowel space that is larger than that produced by modes derived from either area function set alone.

2. Principal component analysis

Area function sets from both Story *et al.* (1996) and Story (2008) were used in the analysis. The area functions of Story *et al.* (1996) included the vowels [i ɪ ɛ æ ʌ ɑ ɔ o ʊ u] and will henceforth be referred to as "A96." In addition to these same ten vowels, the Story (2008) data include the vowel [e]; this set of 11 area functions will be referred to as "A08."

Any given area *function* can be represented by two components, an area vector and a length increment. The area *vector* $A(i)$ contains 44 cross-sectional areas,[2] assumed to represent a concatenation of tubelets ordered consecutively from glottis to lips. The index i denotes this ordering and extends from 1 to 44. The length increment Δ is the distance between consecutive cross-sectional areas and can be considered to be the tubelet length. The 44-section area vectors and length increments, as used in the present study, were reported in Story and Titze (1998) for A96[3] and in Story (2008) for A08. The A96 set, however, was smoothed for this study in the same manner as the A08 set (see Story, 2008, p. 328).

As mentioned in the Introduction, the calculated [F1, F2] formant frequencies for each of the two area function sets are shown in Fig. 1. The open circles indicate the vowels in the plot

that are representative of the boundaries of the displayed vowel space, regardless of set membership, and their corresponding area functions served as the combined data set on which a new PCA was performed. This combined set is referred to as "A9608x" and specifically includes [i ɪ ɛ æ ɑ] from A96 and [æ ɑ ɔ o ʊ u] from A08, where the "x" denotes that the combined set excludes some of the vowels in A96 and A08. Note that the target vowels [æ] and [ɑ] from both A96 and A08 are included in the combined set because they represent part of the overall boundary of the vowel space.

The collection of area vectors for a given set (i.e., A96, A08, or A9608x) can be represented in matrix form as $A(i,j)$, where i is the area index and j denotes the particular vowel in the clockwise order indicated by the points along the dashed or solid lines for A96 and A08, respectively, or by the large circles in Fig. 1 for A9608x (i.e., $j=1$ for [i], $j=2$ for [ɪ],…, $j=11$ for [u]). Following Story (2005b), the PCA was performed on the equivalent diameters of the cross-sectional areas rather than on the areas themselves. In addition, the *length* of each area function was included in the same manner as Yehia *et al.* (1996) and Mokhtari *et al.* (2007) where the variance of the length increment Δ_j is first normalized by the largest variance of the equivalent diameters, and then becomes the 45th element. Thus, a matrix $D(i,j)$, containing diameter and length information, is constructed as

$$D(i,j)=\begin{cases}\sqrt{\dfrac{4}{\pi}A(i,j)} & \text{for } i=1,\ldots,44\\[2ex] \dfrac{(\Delta_j-\bar{\Delta})\sigma_D}{\sigma_\Delta}+\bar{\Delta} & \text{for } i=45,\end{cases} \tag{1}$$

where Δ_j is the length increment of area vector j, $\bar{\Delta}$ is the mean length increment, σ_Δ is the standard deviation of the length increments, and σ_D is the largest standard deviation within any section i of the equivalent diameters.

Matrix $D(i,j)$ can be represented by a mean and variable part,

$$D(i,j)=\Omega(i)+\alpha(i,j), \tag{2}$$

where $\Omega(i)$ is the mean vector across $D(i,j)$, and $\alpha(i,j)$ is the variation superimposed on $\Omega(i)$ to produce a specific vector. The PCA was then carried out by calculating the eigenvectors of a covariance matrix formed with $\alpha(i,j)$. The specific implementation was essentially the same method as reported in Story and Titze (1998), and results in the following parametric representation of the original $D(i,j)$ matrix:

$$\hat{D}(i,j)=\left[\Omega(i)+\sum_{i=1}^{N}q_i(j)\phi_i(i)\right],\quad i=[1,N]\quad (N=45),\quad j=[1,11], \tag{3}$$

where the $\phi_i(i)$'s are 45-element eigenvectors (modes) that, when multiplied by the appropriate scaling coefficients $q_i(j)$, will reconstruct each area vector in $A(i,j)$ for $i=[1,44]$ and each length increment for $i=45$ by the following:

$$\hat{A}(i,j)=\frac{\pi}{4}\hat{D}(i,j)^2,\quad i=[1,44],\quad j=[1,11], \tag{4a}$$

$$\hat{\Delta}(j)=\frac{(\hat{D}(45,j)-\bar{\Delta})\sigma_\Delta}{\sigma_D}+\bar{\Delta},\quad j=[1,11]. \tag{4b}$$

Area functions generated from the mean diameter function $\Omega(i)$ [i.e., $q_i(j)=0$] of each set A96, A08, and A9608x are plotted against the normalized distance[4] from the glottis in Fig. 2(a). It is noted that the area function based on the combined set (thick line) is more constricted in the

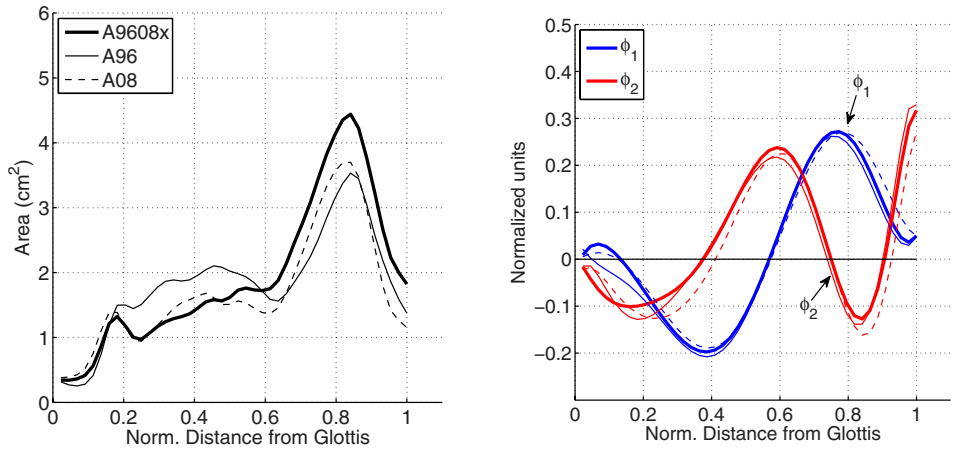

Fig. 2. (Color online) Mean area functions and modes derived for each of the three area function sets A96, A08, and A9608x: (a) mean area functions and (b) ϕ_1 and ϕ_2 modes where the thick line corresponds to set A9608x, the thin line to A96, and the dashed line to A08.

pharyngeal portion (from approximately 0.2 to 0.6 along the length) and more expanded in the oral portion (from 0.6 to 1) than either of the other two.

The two modes that accounted for most of the variance in the analysis of the three area function sets [referred to as $\phi_1(i)$ and $\phi_2(i)$] are shown in Fig. 2(b), again plotted against the normalized distance from the glottis. Note that the modes have been smoothed by fitting them with eighth-order polynomials. This simplifies the visual comparison of the modes but maintains their gross characteristics. As in Fig. 2(a), the thick, thin, and dashed lines represent the A9608x, A96, and A08 sets, respectively. The variances accounted for by each mode in each of the three sets are given in Table 1. The first mode ϕ_1 accounts for greater than 64% of the variance, whereas ϕ_2 accounts for about 20%. The total amount of the variance accounted for by these two modes was greatest for the A9608x set with 89.6%. Qualitatively there are some minor differences in the amplitude of the modes across the three sets, but the overall shape is essentially the same. That is, with a positive scaling coefficient, ϕ_1 will expand the front half of the vocal tract and constrict the back half, and vice-versa with a negative scaling coefficient. When positively scaled, the second mode imposes an expansion near the lips, followed by a constriction, an expansion, and another constriction above the glottis; the opposite effect occurs with a negative scaling coefficient.

3. Vowel space calculations

A mapping was generated for each area function set that relates the two scaling coefficients q_1 and q_2 to the first two formant frequencies (F1 and F2). Based on the PCA performed on each

Table 1. Percentage of the total variance in the matrix $D(i,j)$ accounted for by the two most significant modes (in their smoothed form) calculated for each of the sets A96, A08, and A9608x.

Mode	A96	A08	A9608x
Φ_1	64.8	69.8	65.9
Φ_2	21.3	18.5	23.7
Total	86.1	88.3	89.6

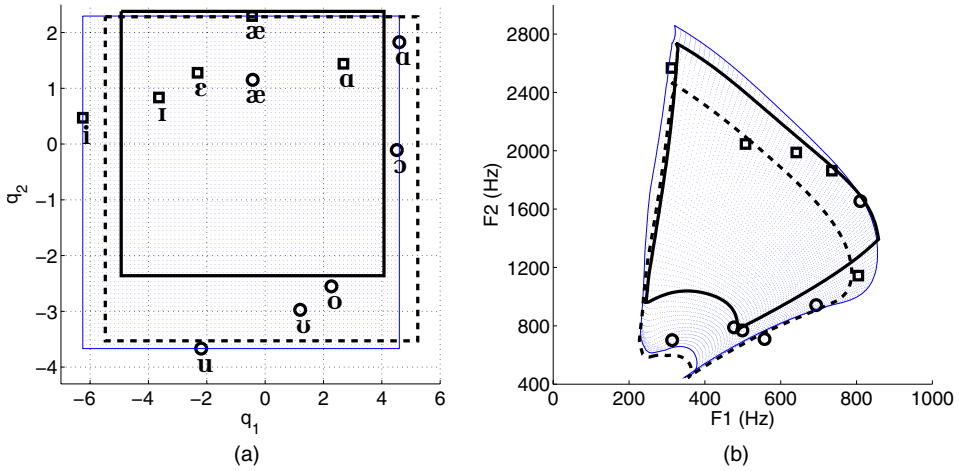

Fig. 3. (Color online) Coefficient and [F1, F2] grids. (a) The grid in the background, bounded by the thin line, represents the coefficient pairs generated for the A9608x set. The squares denote the coefficient pairs corresponding to the vowels chosen from the A96 set whereas the circles are those chosen from the A08 set. The thick solid and dashed lines indicate the outlines of the coefficient grids generated separately for the A96 (solid) and A08 (dashed) sets, respectively. (b) The deformed grid in the background, bounded by the thin line, represents the [F1, F2] space generated from the coefficient grid in (a). The squares and circles denote the calculated [F1, F2] values for the A96 and A08 vowels, respectively. The thick solid and dashed lines represent the outlines of the [F1, F2] spaces generated from coefficient grids for the A96 and A08 sets, respectively.

set, an equal increment continuum was generated for each mode coefficient that ranged from their respective minimum to maximum values. The increments were specified as

$$\Delta q_1 = \frac{q_1^{\max} - q_1^{\min}}{M-1}, \tag{5a}$$

$$\Delta q_2 = \frac{q_2^{\max} - q_2^{\min}}{N-1}, \tag{5b}$$

where M and N are the numbers of increments along each coefficient dimension. For this study $M=N=80$. The coefficient continua were then generated by

$$q_{1m} = q_1^{\min} + m\Delta q_1, \quad m = 0, \ldots, M-1, \tag{6a}$$

$$q_{2n} = q_2^{\min} + n\Delta q_2, \quad n = 0, \ldots, N-1. \tag{6b}$$

with m and n serving as indices along each continuum. By modifying Eq. (3) to contain only two modes and eliminating the dependence on a specific vowel (i.e., jth vowel), an area vector and length increment can be directly generated with

$$A_{mn}(i) = \frac{\pi}{4}[\Omega(i) + q_{1m}\phi_1(i) + q_{2n}\phi_2(i)]^2, \quad i = [1,44], \tag{7a}$$

$$\Delta_{mn} = \frac{(\Omega(i) + q_{1m}\phi_1(i) + q_{2n}\phi_2(i) - \bar{\Delta})\sigma_\Delta}{\sigma_D} + \bar{\Delta}, \quad i = 45. \tag{7b}$$

Shown in Fig. 3(a) is the 80×80 coefficient grid for the A9608x set along with the coefficient pairs that reconstruct the original 11 vowels used in the PCA for this set. The squares and circles represent those vowels extracted from the A96 and A08 sets, respectively, to make up the combined set. Also shown in this figure are the *outlines* of coefficient grids based on the separate

PCAs of the A96 (solid line) and A08 (dashed line) sets. The coefficient ranges are similar for the A9608x and A08 sets, but the range for the A96 set is contracted relative to the other two. It is noted that all three sets have nearly the same upper limit of the q_2 coefficient.

For each of the 6400 coefficient pairs in the grid (i.e., every intersection point), an area vector and length increment were generated. A frequency response function of each resulting area function was then calculated with a frequency-domain technique based on cascaded "ABCD" matrices (Sondhi and Schroeter, 1987; Story *et al.*, 2000). This calculation included energy losses due to yielding walls, viscosity, heat conduction, and acoustic radiation at the lips; side branches such as the piriform sinuses were not considered. Formant frequencies (F1 and F2) were determined by finding the peaks in the frequency response functions with an automated peak-picking algorithm (Titze *et al.*, 1987). These operations were carried out separately for the coefficient grids corresponding to all three area function sets (A96, A08, and A9608x).

The resulting formant space for A9608x is shown in Fig. 3(b). With the exception of a small amount of overlap along the upper edge, this represents a one-to-one mapping between $[q_1, q_2]$ coefficient pairs and [F1, F2] formant pairs, similar to those demonstrated in previous publications (e.g., Story and Titze, 1998; Story, 2005b). The formant pairs corresponding to the 11 vowel area functions in the A9608x set are shown as squares and circles. The formant grid outlines for the A96 and A08 sets are also shown in this figure as solid and dashed lines, respectively. Note that the A08 outline is shifted downward relative to that for A96, as would be expected based on the data shown previously in Fig. 1. More importantly, the formant grid based on A9608x encompasses nearly all of the space outlined by both the A96 and A08 sets.

4. Discussion

Finding the formant grid for the A9608x to be larger than that calculated for either the A96 or A08 sets suggests that the modes based on this combined set may be more useful for purposes of inverse mapping and vocal tract modeling. In the case of inverse mapping, a wider variation in [F1, F2] formant frequencies can be accommodated within the formant space and thus related to a wider range of vocal tract area function shapes. For modeling vocal tract shape change as a component of synthesizing speech (cf. Story, 2005a), the modes from the combined set allow for production of a wider range of formant frequencies than those from the other two sets, and could potentially facilitate more natural sounding synthesis.

The similarity of the mode shapes across each of the three area function sets (A96, A08, and A9608x) does, however, raise the question of whether it would be possible to produce an expanded formant space for either the A96 or A08 sets simply by allowing the mode coefficient values to exceed their ranges produced by the PCA? For example, could the A96 modes and mean diameter function produce a formant space similar to the grid shown in Fig. 3 if the A9608x coefficient space was used instead of the more limited set of A96 coefficients? It is almost certain that expanding the coefficient ranges will have the effect of enlarging the formant space. In fact, Story (2004) used this approach to model a compensation for a lip-tube constraint imposed on the vocal tract shape. But expanding the coefficient range will always be limited by the degree of constriction produced within the vocal tract. That is, increasing the magnitude of either the q_1 or q_2 coefficients will ultimately result in occlusion of the vocal tract, and possibly generating unrealistically short or long tract lengths.

References and links

[1]F1 and F2 formant frequencies measured from audio recordings also indicated the same downward shift of F2 for the Story (2008) study relative to Story *et al.* (1996). The magnitude of the shift, however, was less than that observed in the calculated formants.

[2]The use of 44 elements to represent an area function has been adopted by the author in previous publications, but is not a requirement. The number derives from the approximate spatial resolution obtained in MRI-based recon-

structions of vocal tract shape (e.g., Story *et al.*, 1996). It is also convenient to use 44 elements for simulating speech with acoustic waveguide models because it allows for a sampling frequency of 44.1 kHz when the tract length is approximately 17.5 cm (typical adult male).

[3]The area functions in the A96 set were indeed originally reported in Story *et al.* (1996) but were provided in a form with a variable number of sections (tubelets) where the length increment was constant across all vowels. Story and Titze (1998) resampled the area functions so that each area vector consisted of 44 sections, but the length increment was vowel dependent.

[4]Normalized distance is used for displaying the reconstructed area functions and modes because the actual vocal tract length is variable and depends on a given combination of mode scaling coefficients [see Eq. (7)].

A portable infrasound generator

Joseph Park and James Robertson
Infrasound Laboratory, University of Hawaii, 73-4460 Queen Kaahumanu Highway No. 119, Kailua-Kona, Hawaii 96740
jpark@isla.hawaii.edu, james@isla.hawaii.edu

Abstract: The rotary subwoofer is a novel low frequency transducer capable of efficiently generating infrasound from a compact source. A field-deployable version of this device may find application as a calibration source for infrasound arrays of the International Monitoring System (IMS) [(2001). *The Global Verification Regime and the International Monitoring System* (CTBTO Preparatory Commission Vienna International Centre, Vienna, Austria)]. A prototype tested at the IMS infrasound array I59US demonstrated the ability to insonify all elements of the array from a standoff distance of 3.8 km. Signal-to-noise ratios of continuous wave signals ranged from 5 to 15 dB, indicating the utility of this source to transmit controllable infrasound signals over distances of 5 km.

1. Introduction

The ability to generate controllable infrasound has presented a technical challenge (Bedard and Georges, 2000); one reason is the mass-dominated radiation impedance found in conventional transduction technologies at very low frequencies. For example, the University of Mississippi designed and built a large horncoupled electropneumatic loudspeaker for the U.S. Army Research Laboratory known as the mobile acoustic source (Neill, 1993). The MOAS is frequently referred to as the "mother of all speakers" and was capable of projecting high intensity sound to frequencies as low as 10 Hz, though it was a large, complex system. Use of conventional loudspeaker technology in an array has demonstrated the ability to project acoustic signals down to frequencies of 8 Hz (Walker *et al.*, 2008), though likely not with sufficient sound pressure levels to be detected over ranges on the order of several kilometers.

Availability of a portable device that could project controllable infrasound detectable at ranges of several or tens of kilometers could find immediate use within the infrasound community. For example, the International Monitoring System (IMS) of the Comprehensive Test Ban Treaty Organization (CTBTO) (2001) operates a world-wide network of infrasound monitoring arrays. A portable, controllable source could enable field calibration and verification of operational arrays. Another important issue to the infrasound community is the evaluation of new sensors and the characterization of noise reduction systems, both of which could benefit from a controllable source. Other potential uses might include a surrogate for explosives that are currently employed to generate signals for testing of tactical explosion localization systems, or as a probe for atmospheric propagation studies.

The Thigpen rotary woofer (TRW) (Eminent Technologies, 2008) is a novel low frequency acoustic transducer capable of projecting controllable infrasound from a compact, energy efficient source (Garcés and Park, 2007). The TRW is essentially a baffled fan with blades that have dynamically controlled pitch. An electric motor rotates the hub at constant frequency while blade pitch is dynamically modulated by a control signal. The pitch control mechanism uses a conventional electromagnetic voice coil assembly driven by an audio amplifier to actuate the blades in response to the applied signal. The voice coil longitudinal oscillations are converted to blade axis rotary motion within the hub. Rotation of the blades about their axis changes the angle of attack of the blades as they move through the air creating uneven pressure distributions. It is believed that the TRW changes the radiation impedance from mass-

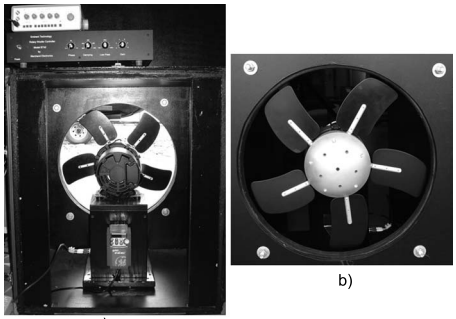

Fig. 1. Photograph of the TRW in a fixed installation. (a) View from inside the building showing the function generator, amplifier, motor controller, and motor, (b) view from the exterior showing the main rotor hub and blades.

dominated to fluid-displacement controlled by creating relatively high particle velocities at the blades of the projector thereby overcoming the canonical difficulty of mass-dominated radiation impedance at low frequencies.

The tested configuration consisted of five equally spaced blades, each approximately B_w=10.2 cm (4 in.) in width by B_L=15.3 cm (6 in.) in length. The outer diameter of the hub is approximately 20.4 cm (8 in.) so that the annular region of radiation has inner and outer radii of R_i=10.16 cm (4 in.) and R_o=25.40 cm (10 in.). Figure 1 shows a photograph of the TRW installed in a fixed laboratory.

Sections 2 and 3 outline portable deployment of the TRW, and demonstrate capability to transmit coherent infrasound signals detectable at ranges of 5 km.

2. Field deployment

To provide a field-deployable mobile prototype, the TRW was installed in a standard 17 ft U-Haul moving van. The installation was achieved by fashioning a baffle for the fan from 1.91 cm (3/4 in.) thick plywood. The fan housing is bolted to the baffle, and the baffle is clamped to the frame of the truck body. A portable generator and power-line filter were used to provide electric power.

On September 26, 2008 this portable system was deployed approximately 3.8 km from the central element ($H1$) of IMS array I59US on the western flank of Hualalai volcano, HI. A photograph of the portable system at the deployment site (19°34′38.32″N, 155°55′35.33″W) is shown in Fig. 2. An aerial view of the deployment layout is shown in Fig. 3. Table 1 lists the approximate distance from the source to each element of the I59US array. The array sensors are

Chaparral Physics (2008) Model 2.2A infrasound microphones. The data are digitized at a sample frequency of 20 Hz and recorded with GPS timestamps.

3. Results

A series of continuous wave (cw), constant frequency, and amplitude sine waves were broadcast according to the schedule listed in Table 2. The fan hub rotational speed for all transmissions was 12 Hz (720 rpm). Figure 4 plots the pressure power spectral density (PSD) recorded at the array sensors for broadcast numbers 2, 3, 8, and 9 of Table 2. These transmissions correspond to frequencies of 8, 6, 5, and 7 Hz, respectively. The three sensors, which are closer than 4.2 km (*H*1, *H*2, and *H*4), exhibit signal-to-noise ratios (SNRs) on the order of 15 dB at all transmission frequencies. Sensor *H*3 has noticeably reduced signal power at the range of 4.9 km. Even with the reduced SNR of approximately 5 dB at 4.9 km, the signal energy is clearly distinct from the noise.

Table 1. Approximate distance from the infrasound source to each of the array elements of I59US.

Array element	Distance (km)
*H*1	3.77
*H*2	4.16
*H*3	4.90
*H*4	3.02

Table 2. Schedule of signals broadcast during the test. All signals were constant amplitude and frequency sine waves. V_{in} is the rms voltage of the blade modulation signal.

No.	Broadcast time (UTC)	Frequency (Hz)	V_{in} (V_{rms})
1	9/29/08 23:53–23:56	8	6.8
2	9/29/08 23:56–23:58	8	10.5
3	9/29/08 23:59–24:03	6	13.1
4	9/30/08 00:03–00:07	4	11.9
5	9/30/08 00:10–00:15	3	18.0
6	9/30/08 00:15–00:20	1	25.6
7	9/30/08 00:20–00:24	3	13.2
8	9/30/08 00:24–00:29	5	16.4
9	9/30/08 00:29–00:34	7	16.0
10	9/30/08 00:34–00:39	8	17.6

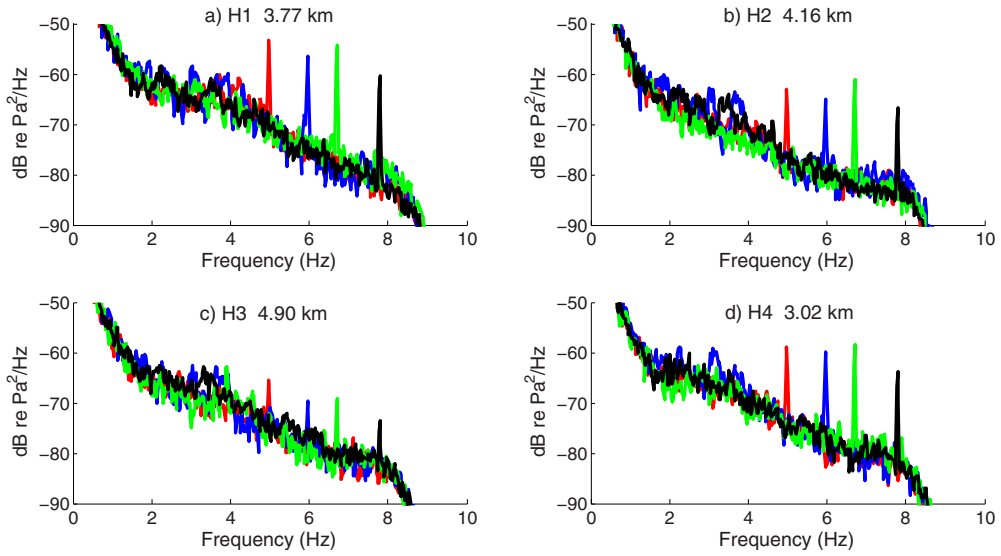

Fig. 4. (Color online) PSD of the recorded pressure at the four sensors from signal transmissions of 5, 6, 7, and 8 Hz. (a) Sensor *H*1, range 3.77 km; (b) sensor *H*2, range 4.16 km; (c) sensor *H*3, range 4.90 km; and (d) sensor *H*4, range 3.02 km.

The broadcast frequencies of 1, 3, and 4 Hz did not exhibit noticeable spectral peaks in the PSD. There are several possible reasons for this. One is the increase in noise levels below 5 Hz that could serve to mask the signals; another is that the output power of the source may attenuate at low frequencies due to the limited backvolume.

4. Conclusion

A prototype of the TRW modified for field deployment has demonstrated the ability to insonify an operational IMS infrasound array with cw signals from a stand-off distance of approximately 3.8 km. This may be the first controlled insonification of an operational IMS infrasound array from a portable device. SNRs in the range 5–15 dB indicate that this technology has merit as a field-deployable infrasound generator.

The development of a controllable infrasound generator will likely find utility in several acoustic applications. For example, the field calibration of infrasound arrays operated by the IMS of the CTBTO (2001), or as a tool for assessing atmospheric propagation studies. Other applications might include the field simulation of geophysical or anthropogenic infrasound sources to assist in the development of infrasound sensors and detection algorithms.

Abstract: When a brass instrument is played loudly, the energy level of the higher harmonics increases dramatically. The generally accepted explanation for this is non-linear steepening of the wavefront and generation of shock waves within the instrument bore. However, it has also been suggested that changes in the player's lip vibration could play a role in generating this "brassy" sound. To test this hypothesis, the dependence of lip opening-area on time has been measured for different dynamic levels in trombones and horns. Results suggest that the behavior of the open area does not change dramatically when the instrument enters the brassy regime.

1. Introduction

One striking feature of orchestral brass instruments is that the timbre is strongly dependent on dynamic level. At the loudest levels, the sound becomes distinctly "brassy" or "cuivré." This dramatic effect occurs due to a marked increase in the energy levels of the higher harmonics,[1,2] and brass musicians commonly use this timbral change as a form of musical expression. It is interesting to note that the effect is more dominant in some instruments than others; for instance, the trombone is generally considered to be "brassier" than the euphonium.

Musical tones are generated in brass instruments as a result of the self-sustained oscillation of the lips of the player.[3] Air flows from the lungs of the player into the mouthpiece of the instrument via the lips, which act as a valve modulating the airflow. This paper describes an experimental study of brass instrument playing at high dynamic levels, and examines the relationship between changes in the nature of the lip motion and the development of brassy timbre.

It is now generally acknowledged that the onset of the brassy regime is primarily a result of the non-linear propagation of the acoustic wavefront along the bore of the instrument, as clearly demonstrated by Hirschberg *et al.*[2] When high amplitude pressure oscillations are generated by the lips, the leading edge of the pressure wave steepens as it progresses through the bore of the instrument. If the air column of the instrument is sufficiently long—and the amplitude of the oscillations high enough—then the pressure rise becomes nearly instantaneous. This "shock-wave" formation gives rise to an increase in the higher frequency components in the tone which is produced.[4]

It has also been suggested by some researchers that the degree to which the lips can open becomes "saturated" or "clipped" during extremely loud playing as the movement of the lips becomes constrained by the rim and cup walls of the mouthpiece.[5–7] This effect, if present, would contribute significantly to the production of a brassy sound. Martin[8] performed some

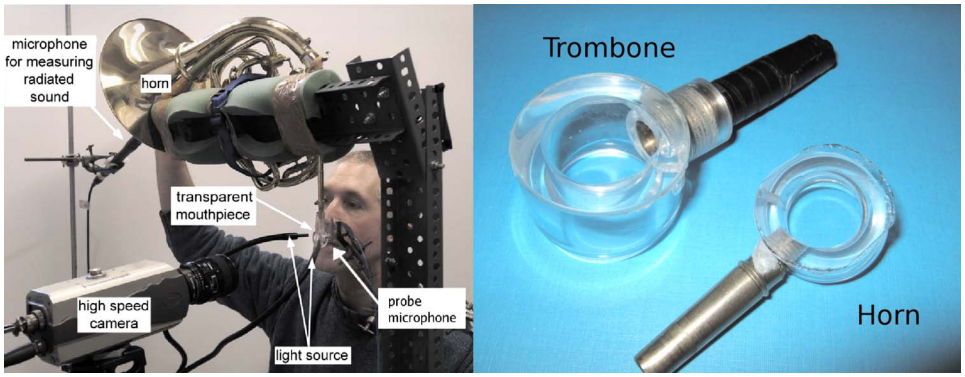

Fig. 1. (Color online) An overview of the complete experimental setup (left) for the horn showing the placement of the microphones, camera, and lightsource. The transparent mouthpieces (right) for both trombone and horn.

early measurements in which he showed that during mezzo forte playing on the cornet the variation of lip open area with time was almost sinusoidal. Other studies, using trombones, showed that the open area between the lips did not behave purely sinusoidally.[9,10] In fact, the "closing" phase of the lip motion took longer than the "opening" phase. This effect was more pronounced in large amplitude playing.

2. Experimental method

Three musicians—skilled amateurs with many years playing experience—were asked to sound pairs of notes at the same pitch but differing dynamic levels. One clearly brassy to the ear of the player (although not at the upper limit of loudness) and the other "non-brassy." The sound radiated from the bell of the instrument was captured using a Brüel and Kjær 4192 microphone at a distance of one bell radius. A PCB 106B pressure transducer was inserted flush with the inner surface of the trombone mouthpiece cup to capture the pressure waveform at the input to the instrument. For measurements of the input pressure in the (much smaller) horn mouthpiece, a short probe attachment was used with the PCB microphone.

The setup for the horn can be seen in Fig. 1 (left). During recordings on the horn, players placed their hand in the bell of the instrument as is normal for orchestral playing. Players were asked to keep their hand in the same position for both brassy and non-brassy playing. A previous study suggests that players are very consistent in where they place their hand.[11]

In order to allow optical access to the lips, transparent mouthpieces, as developed by Bromage,[12] were used [Fig. 1 (right)]. The key acoustic properties of the mouthpieces (throat, shank, cup volume, and rim dimensions) were based on current production designs in order to ensure that the mouthpieces are both realistic and comfortable for the player.

The motion of the lips was captured by a Phantom v.4 high speed digital camera recording at 6000 (trombone) or 8000 (horn) frames per second. At this speed, a strong light source is required and so a Schott model KL1500 cold light source was used to illuminate the lips. The captured footage was then split into a series of numbered grayscale bitmaps, one for each frame.

A threshold gray level was set. All pixels with a grayscale value above the threshold were set to white and all below the threshold (corresponding to the open area of the lips) set to black. This "binary" process can be seen in Fig. 2. For each image, the number of black pixels was counted and the lip open area as a function of time was deduced.

3. Results

Figure 3 shows examples of the radiated and mouthpiece pressure waveforms, recorded on a tenor trombone playing the notes F_3 and $B\flat_3$, for both brassy and non-brassy playing. Inspection of the mouthpiece pressure signals [Fig. 3 (left)] shows that the amplitude of the signal

Fig. 2. A sample lip image, including an example of the isolated open area.

increases as expected from non-brassy to brassy playing, but the waveforms are broadly similar. In contrast, comparison of the radiated sound pressures [Fig. 3 (right)] shows that there is a dramatic change in the form of the pressure signal between non-brassy and brassy playing. Non-linear propagation implies distortion of the pressure wave, which in turn can lead to the formation of a shock-wave. Here, there is clear evidence of shock-wave formation within the bore of the instrument, in agreement with the results of Hirschberg *et al.*[2] and also of Thompson and Strong.[13]

Analysis of the pressure signals recorded on the horn show similar behavior to that of the trombone, as can be seen from the online multimedia files Mm. 1 and Mm. 2. These are stereo recordings of the pressure signal in the mouthpiece (left channel) and the radiated sound (right channel) during brassy (Mm. 1) and non-brassy (Mm. 2) playing.

Mm. 1. A stereo recording of the pressure signal in the mouthpiece (left channel) and radiated sound (right channel) of a horn during brassy playing. Note C4. The starting transient has been removed. This is a file of type "wav." Size 258 kbytes.

Mm. 2. A stereo recording of the pressure signal in the mouthpiece (left channel) and radiated sound (right channel) of a horn during non-brassy playing. Note C4. The starting transient has been removed. This is a file of type wav. Size 258 kbytes.

The spectral centroid represents the distribution of power over frequency and provides a quantitative measurement of the increase in energy of the higher harmonics. It is defined as

$$F_{\mathrm{SC}} = \frac{\sum_{i=1}^{n} F_i A_i}{\sum_{i=1}^{n} A_i}, \tag{1}$$

where F_i is the frequency of the ith harmonic and A_i represents the amplitude of that harmonic.

The spectral centroids for both the mouthpiece pressure and the radiated sound during both brassy and non-brassy playing are shown in Table 1 for two notes recorded on the tenor trombone. For the note $\mathrm{B}\flat_3$ on the trombone, in the case of non-brassy playing, the spectral

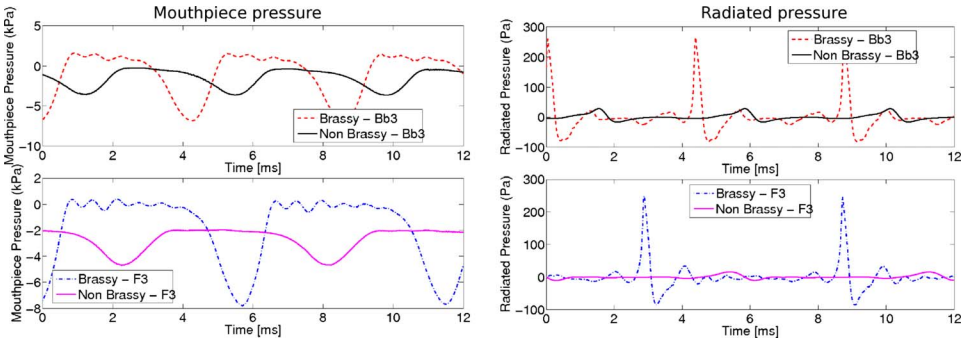

Fig. 3. (Color online) Mouthpiece (left) and radiated (right) waveforms for brassy and non-brassy playing. Notes $\mathrm{B}\flat_3$ (upper) and F_3 (lower) on the tenor trombone. Note that there is a dc offset of approximately 2 kPa in the mouthpiece pressure values.

Table 1. Spectral centroids (SCs) for both non-brassy (nb) and brassy (b) notes, calculated for both the mouthpiece pressure and the radiated sound.

		Mouthpiece pressure			Radiated pressure		
Instrument	Note	SC (nb) (Hz)	SC (b) (Hz)	SC(b)/SC(nb)	SC (nb) (Hz)	SC (b) (Hz)	SC(b)/SC(nb)
Trombone	$B\flat_3$	304	369	1.2	716	1816	2.5
	F_3	251	392	1.6	562	2462	4.4

centroid increases from 304 Hz in the mouthpiece to 716 Hz in the radiated sound—an increase by factor of 2.3. In the case of brassy playing, the centroid increases from 369 to 1816 Hz, an increase by factor of 4.9.

Part of the increase in spectral richness in loud playing is due to the high pass filtering effect of the bell. The effect of the linear filter of the bell at low amplitudes was estimated by comparing bell and mouthpiece frequency spectra. This filter was then applied to the measured mouthpiece spectrum for brassy playing to predict the bell spectrum if only linear propagation were significant. For the note F_3 on the trombone, we found that this calculated spectral centroid was 870 Hz, in comparison with the measured value of 2462 Hz. We conclude that the majority of spectral enrichment corresponds to non-linear propagation.

The spectral centroid of the sound recorded in the mouthpiece increased by a factor of 1.2 in the transition from non-brassy to brassy playing. In contrast, the ratio between the radiated spectral centroids is much larger—a factor of 2.5. The note F_3 as played on the trombone shows a similar trend. This suggests that the main source of the brassy sound does not come from within the mouthpiece of the instrument, but instead comes further downstream before the sound is radiated to the air. This quantitative analysis of the spectral centroid agrees with our qualitative visual analysis of the pressure waveforms shown in Fig. 3.

Comparison of mouthpiece and bell waveforms for the horn showed similar behavior as can be seen in online multimedia Mm. 1 and Mm. 2. However, a quantitative comparison of mouthpiece and bell spectra was not possible because of the difficulty of measuring the pressure in the small horn mouthpiece.

Figure 4 shows the lip open areas for both brassy and non-brassy playing for two notes on two different instruments—tenor trombone ($B\flat_3$ and F_3) (left) and horn (C_4 and F_3) (right). The brassy/non-brassy "pairs" are displayed with a common time-axis, but each lip open area

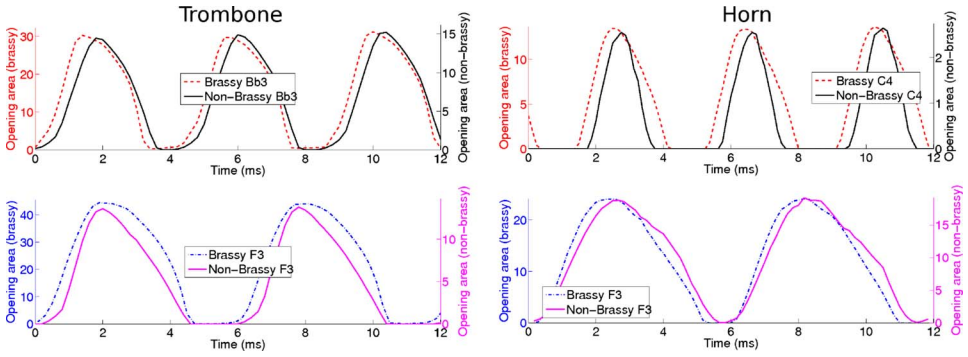

Fig. 4. (Color online) Lip open areas for brassy and non-brassy playing for two notes on the trombone (left) and two on the horn (right). All areas are given in mm^2. The data pairs share a common time-axis but each data set has its own *y*-axis, effectively normalizing the data for ease of comparison.

curve has its amplitude data displayed on a separate *y*-axis (brassy on the left, non-brassy on the right). Videos of both brassy and non-brassy playing corresponding to the note C4 on the horn are supplied as online multimedia in Mm. 3 and Mm. 4, respectively.

Mm. 3. A sample video of the lips of a horn player during brassy playing. Note C4. Framerate of 5 frames per second. This is a video of type "avi." Size 363 kbytes.

Mm. 4. A sample video of the lips of a horn player during non-brassy playing. Note C4. Framerate of 5 frames per second. This is a video of type avi. Size 363 kbytes.

A previous study, by Bromage,[12] found that the width of the lip opening increased quickly in the early part of the vibration cycle, and then remained at a constant value for much of the rest of the cycle. However, during this motion, the lip opening height varied continually and, accordingly, so did the lip open area. For louder notes, the width was constant for a greater proportion of the cycle than for quieter playing. We note, however, that it is the lip open *area* which is the primary variable by which the airflow into the instrument is controlled. From Fig. 4, it is immediately clear that the brassy/non-brassy pairs behave very similarly with respect to the lip open area. The only obvious difference between brassy and non-brassy playing is that, as expected, the brassy lip open areas have a larger amplitude than their non-brassy counterparts. For each brassy/non-brassy pair of measurements, the waveforms of the lip open area as a function of time are very similar, and do not show evidence of clipping in the brassy regime.

4. Conclusions

Spectral centroid data for the pressure signals in the mouthpiece and outside the bell of horns, and trombones support the hypothesis that the primary source of the increase in energy of the higher harmonics in very loud playing is to be found within the bore of the instrument. Studies of the lip motion of brass instrument players using transparent mouthpieces and a high speed digital camera show that the behavior of the lip open area does not vary significantly between brassy and non-brassy playing, providing confirmation that variations of the lip open area with amplitude are not the main source of the distinctive brassy timbre of brass instruments at the dynamic levels used by players in this study.

Abstract: This paper presents a method of determining the compressional wave attenuation in marine sediment from a short range measurement. The data were collected on a vertical line array at a range of 230 m during the Shallow Water 2006 experiments. The sediment attenuation is extracted from the signal strength ratio of the sea bottom reflection to a sub-bottom reflection at different frequencies from 1.75 to 3.15 kHz. Linear frequency dependence of the attenuation is found from the estimation. The sediment attenuation estimate is lower than the values estimated from the inversions of acoustic field data previously done in the vicinity.

1. Introduction

Acoustic attenuation in marine sediment is an important parameter in understanding sound propagation in shallow water. Two approaches are generally used to estimate the sound attenuation in the sediment. One is based on *in-situ* measurements[1] and the other one is based on inferences from different kinds of inversions. *In-situ* measurements are usually done at very small ranges by measuring the signal levels between two embedded probes. The working frequencies are usually high, from several kilohertz to hundreds of kilohertz. Since the propagation distances are so small, this approach provides estimates of the intrinsic attenuation in marine sediments. In the second approach, the inversions that are used to infer sediment attenuation are usually applied to data collected at longer ranges. The frequencies are low, from tens to a few hundred hertz. Attenuation estimates from long range data inversions represent estimates of an overall loss parameter, which accounts for energy loss factors in addition to the intrinsic attenuation of the sediment material, such as sound scattering due to the roughness of the sea bottom and conversion to shear waves.

During the Shallow Water 2006 experiments (SW06),[2] short range experiments were carried out using a vertical line array (VLA) to estimate geoacoustic model parameters. This paper reports estimates of sediment attenuation from this data set. The method is based on measuring the differences of the signal levels from the bottom and sub-bottom reflections at different frequencies. The sediment layer thickness and *p*-wave sound speed are used to determine the values of sediment *p*-wave attenuation in dB/m and dB/λ.

2. Experiment and data

The experiment was carried out on 31 August 2006 on the New Jersey Shelf. The source was deployed from the research vessel Knorr to depths from 15 to 65 m in 10 m intervals. The data were collected on the Marine Physical Laboratory vertical line array (MPL-VLA1) located at (39°1.4771′N, 73°2.259′W). The range between the source and the receiver was approximately 230 m. The VLA consisted of 16 hydrophones equally spaced on the array with a sepa-

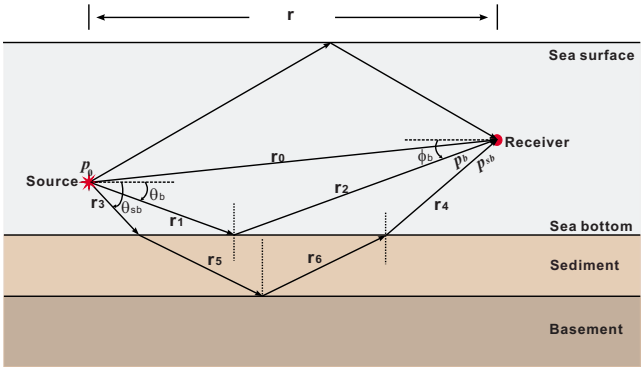

Fig. 1. (Color online) Geoacoustic model and the schematic of direct, surface reflected, bottom reflected, and sub-bottom reflected rays between the source and the receiver.

ration of 3.75 m, and the bottom most hydrophone (No. 1) was 8.2 m above the sea floor. The bathymetry between the source and MPL-VLA1 was almost flat with 79.6 m at the source and 79.0 at MPL-VLA1. The sound speed profiles (SSPs) in the water were recorded at the source position. A thermocline with a strong negative gradient was evident from 12 to 50 m of the SSP. The sediments in the vicinity of the site are clay-rich outer shelf materials.[3]

The signal transmitted was a 1-s linear frequency modulated pulse with a repetition period of 1 s. The signal frequency band was from 1500 to 4500 Hz. The direct, bottom reflected (BR), and surface reflected arrivals are clearly seen in the matched filtered signals for all of the source depths. Strong sub-bottom reflections from the ubiquitous "R-reflector"[3,4] are evident in the signals for most of the source-receiver pairs. The bottom reflected and sub-bottom reflected signals are relatively stable both in amplitude and arrival time. However, due to the oceanographic variation between the source and the VLA, strong fluctuations both in the amplitudes and in the arrival times of the direct and surface reflected arrivals are observed in the matched filtered signals. The complicated micro-structures in the thermocline are the main reason for multiple direct arrivals and consequently the fluctuation of the direct arrivals. As a result, the attempt of generating a measurement of bottom loss versus grazing angle described for an equivalent short range experimental geometry[5] was unsuccessful.

3. The sediment attenuation estimation method

Figure 1 is a schematic of the primary rays between the source and the receiver for the geometry in this study. Let p_0 be the pressure at the source, ξ the vertical directional response of the source, and ζ the vertical directional response of the hydrophone. ξ and ζ are usually functions of the frequency f, as well as θ, the sound launching angle from the source, and ϕ, the sound arrival angle at the receiver. The bottom reflected pressure at the receiver p_b, and the sub-bottom reflected pressure at the receiver p_{sb} are written as

$$p_b = \frac{p_0 V_{\mathrm{bott}} \xi_b(f,\theta_b)\zeta_b(f,\phi_b)}{r_1 + r_2} e^{-\alpha_w(r_1+r_2)}, \tag{1}$$

$$p_{\mathrm{sb}} = \frac{p_0 T_{ws} T_{sw} V_s \xi_{\mathrm{sb}}(f,\theta_{\mathrm{sb}})\zeta_{\mathrm{sb}}(f,\phi_{\mathrm{sb}})}{r_3 + r_4 + r_5 + r_6} e^{-\alpha_w(r_3+r_4)} e^{-\alpha_s^{(\mathrm{neper})}(f)(r_5+r_6)}, \tag{2}$$

where V_{bott} is the reflection coefficient at the sea bottom, V_s is the reflection coefficient at the sub-bottom interface, T_{ws} is the transmission coefficient of sound from the water into the sediment, T_{sw} is the transmission coefficient of sound from the sediment back to the water, r_1+r_2 is the sound path length for the bottom reflected arrival, r_3+r_4 is the sound path length for the

sub-bottom reflected arrival in the water, r_5+r_6 is the sound path length for the sub-bottom reflected arrival in the sediment, α_w is the attenuation in the water, and $\alpha_s^{(\text{neper})}(f)$ is the attenuation in the sediment in Np/m. Since the hydrophones are omni-directional, and the vertical dimension of the source is comparable to the wavelength within the frequency band we are interested in, the ratio of p_b to p_{sb} can be written as

$$\frac{p_b}{p_{\text{sb}}} = \left(\frac{V_{\text{bott}}}{T_{ws}T_{sw}V_s}\right)\left(\frac{r_3+r_4+r_5+r_6}{r_1+r_2}\right)e^{\alpha_w[(r_3+r_4)-(r_1+r_2)]}e^{\alpha_s^{(\text{neper})}(f)(r_5+r_6)}. \quad (3)$$

Equation (3) can further be expressed in logarithmic form as

$$20\log_{10}p_b - 20\log_{10}p_{\text{sb}} = 20\log_{10}B + \alpha_s^{(\text{neper})}(f)(r_5+r_6)(20\log_{10}e), \quad (4)$$

where $B=(V_{\text{bott}}/T_{ws}T_{sw}V_s)[(r_3+r_4+r_5+r_6)/(r_1+r_2)]e^{\alpha_w[(r_3+r_4)-(r_1+r_2)]}$. If we use $\alpha_s(f)$, which is in dB/m to replace $\alpha_s^{(\text{neper})}(f)(20\log_{10}e)$, then Eq. (4) becomes

$$20\log_{10}p_b - 20\log_{10}p_{\text{sb}} = 20\log_{10}B + \alpha_s(f)(r_5+r_6). \quad (5)$$

Several assumptions are made in this analysis. First of all, the value of α_w is very small, so its frequency dependence can be neglected in the analysis. Further, the frequency dependences of V_{bott}, V_s, T_{ws}, and T_{sw} are assumed to be negligible within the bandwidth and at the grazing angles at the bottom and the sub-bottom interfaces in this experiment. Consequently, the sediment p-wave attenuation in dB/m kHz, $\alpha_s^{(f)}$, can be obtained from the relationship of $20\log_{10}p_b - 20\log_{10}p_{\text{sb}}$ versus frequency. Further, the sediment attenuation in dB/λ is obtained using the sediment sound speed c_s in the formula $\alpha_s^{(\lambda)}=\alpha_s^{(f)}c_s/1000$.

4. Data processing procedure

For each source-receiver pair, the received signals were first matched filtered (i.e., compressed), and then the envelopes of the compressed pulses were extracted and aligned with respect to the sea bottom arrivals. Next, the aligned envelopes were averaged over 1 min to increase the signal to noise ratio. The means and the standard deviations of the amplitudes of the sea bottom reflection and sub-bottom reflection are used to control the data quality in order to carry out further analysis. Only the signals in which the sub-bottom and BR paths were clearly separated in time from other water column arrivals such as the surface reflection were used in the analysis.

To obtain the amplitude of the sea bottom and sub-bottom reflections at different frequencies, the compressed pulses were filtered by a series of band pass filters. The center frequencies and the bandwidths of those filters were designed to have (1) enough bandwidth to ensure adequate time resolution in the filtered band to distinguish the two arrivals, (2) reasonable frequency coverage to ensure the filtered signals in adjacent bands contain independent information, and (3) sufficient number of $(20\log_{10}p_b - 20\log_{10}p_{\text{sb}})$ versus frequency samples for the next step of the analysis. The center frequencies of the band pass filters used in this study were 1750–4150 Hz, in 200 Hz separations. The bandwidth of the filters was 500 Hz. Similarly, the envelopes of the band pass filtered signals were summed over 1 min to average out the signal fluctuations. Figure 2 is an example of the aligned compressed pulses and the averaged band pass filtered signal.

The amplitude differences of the sea bottom and sub-bottom reflections obtained at the frequencies up to 3150 Hz were included in the data analysis. For higher frequencies, the signal to noise ratio of the sub-bottom reflection was too low (lower than 2 dB). Both a linear and a power law frequency dependence of the sediment attenuation were investigated in the study. A least-squares method was used as the criterion of the goodness of fit of the observed data to each of the proposed dependences. The data indicated a linear frequency dependence of the attenuation. Figure 3 shows the values of $20\log_{10}p_b - 20\log_{10}p_{\text{sb}}$ obtained at each frequency band, for the source/receiver pair at 45/26 m. It is clear from Eq. (5) that the estimated slope of the line in Fig. 3 is the product of $\alpha_s^{(f)}$ and the sound travel path in the sediment r_5+r_6.

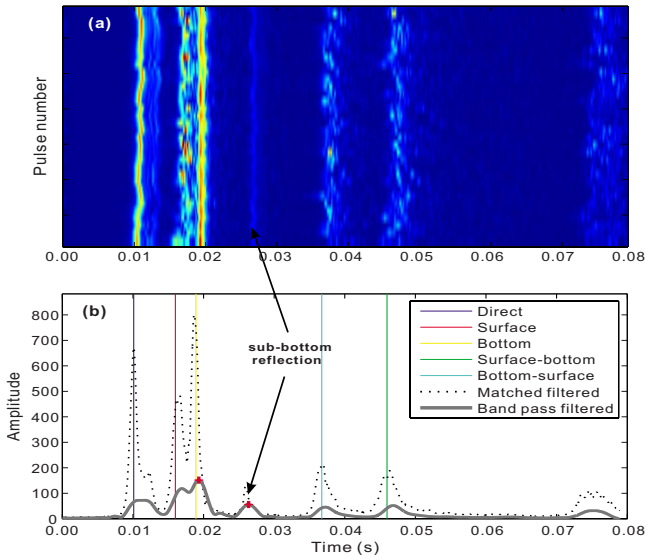

Fig. 2. (Color online) Pre-processed signals for source depth at 45 m and receiver depth at 26 m data. (a) Matched filtered signals for 1 min, plotted for a linear scale. Since only the relative values are used in the calculation, the absolute amplitude value is not specified; and (b) comparison of broadband matched filtered signal and filtered signal by a band pass filter centered at 1750 Hz.

The value of the sound path length in the sediments r_5+r_6 is derived from the sediment layer thickness and the incident angle at the sea bottom interface. The sediment sound speed and the sediment layer thickness were obtained from a multi-stage travel time inversion that has been reported previously.[6] First the water column SSP was inverted to account for the time varying water column environment, so that the effects of the water column variation are mitigated in the further analysis. The inverted profile was then used as an input in the inversion of the sediment sound speed and the layer thickness. Multiple hydrophone signals were used to constrain the inversion. The source launching angle, hydrophone receiving angle, and the incident angle at the sea bottom and sub-bottom interfaces were also obtained in the inversion.

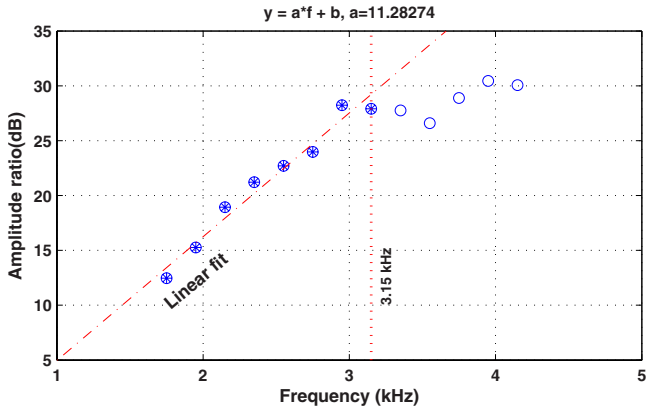

Fig. 3. (Color online) Data fitting of the sediment attenuation versus frequency. The circles are the differences of the amplitude of sea bottom and sub-bottom reflections obtained at different frequency bands. The stars are the actual data points used in the data fitting.

Table 1. Summary of marine sediment attenuation estimates.

Source depth (m)	35		45	
Receiver depth (m)	26.0	29.75	26.0	33.5
Sediment sound speed (m/s)[a]	1597		1600	
Sediment layer thickness (m)[a]	20.6		22.3	
Attenuation (dB/m kHz)	0.092	0.085	0.101	0.088
Attenuation (dB/λ)	0.15	0.14	0.16	0.14

[a]Reference 6.

5. Results and discussion

Table 1 lists the attenuation estimates from the data for four source-receiver pairs. For the four pairs of data, the sum of the standard deviations of the amplitudes of the sea bottom and the sub-bottom reflections is significantly smaller than the variations of $20 \log_{10} p_b - 20 \log_{10} p_{sb}$ from frequency to frequency. The grazing angles are greater than the critical angle at the sea floor and at the R-reflector.

The sediment attenuations are found to have linear frequency dependence in the frequency band of 1.75–3.15 kHz. The estimated sediment attenuations are from 0.085 to 0.101 in dB/m kHz, or from 0.14 to 0.16 in dB/λ. These estimates represent the average values in the layers. The uncertainties of the estimates are mainly from the signal fluctuations both in the amplitude and the travel time that are introduced by the variation of the source and receiver positions, the time varying ocean environment, and the inversion method.

The estimates reported here can be compared with other estimates from the vicinity. Choi *et al.*[7] analyzed close range high frequency (1–20 kHz) bottom loss data from the same site, and inferred the attenuation from a very thin surficial sediment layer from inversions of the measured loss. They found that a frequency dependence of $0.2(f/f_{ref})^{1.6}$ provided the best fit of the measured data at six grazing angles, where f_{ref} is 1 kHz. Turgut and Yamamoto[8] performed *in-situ* sound speed and attenuation measurements at the same site using a wideband acoustic probe, and found a linear frequency dependence of the attenuation for the band 10–80 kHz. Jiang and Chapman[9] inverted long range, multi-tonal low frequency (53–753 Hz) data from an experiment along the same radial path from MPL-VLA1, assuming a non-linear frequency dependence of the attenuation in the sediment layer down to the R-reflector. Their results indicated no sensitivity to attenuation in matched-field inversion for ranges of 1 and 3 km. However, at 5 km, sensitivity to attenuation increased due to the long range propagation distance, and they reported estimates of $0.6(f/f_{ref})^{1.4}$, where the reference frequency f_{ref} is 1 kHz. This result produces greater values for the range 2–3 kHz than the measurements reported here. Other estimates inferred from inversions have been reported by Carey and co-workers[10,11] from sites in the vicinity. Their values are also higher than the measurements reported here.

The estimates of attenuation from inversions of acoustic field data are affected by several different loss mechanisms, in addition to intrinsic attenuation in the sediment. The higher attenuations reported from the acoustic field inversions may simply reflect the effects of other attenuation mechanisms on the results of the experiments. Although the effects of other attenuation mechanisms cannot be ruled out in our experiment, the short range single bottom interaction geometry provides a closer approximation to the simple experimental geometries that are used successfully for measuring attenuation at high frequencies.

6. Conclusion

Marine sediment attenuation for a site on the New Jersey continental shelf was estimated from broadband acoustic data measured by a VLA. The short range–varying source depth–VLA geometry provided a practical way of estimating sediment attenuation at low frequencies. The estimated values are lower than the estimates of attenuation based on inversions of acoustic data.

Sand acoustics: The effective density fluid model, Pierce/Carey expressions, and inferences for porous media modeling

Kevin L. Williams
Applied Physics Laboratory, College of Ocean and Fishery Sciences, University of Washington, Seattle, Washington 98105
williams@apl.washington.edu

Abstract: Recently, Pierce and Carey [J. Acoust. Soc. Am. **124**, EL308–EL312 (2008)] presented a low frequency analysis of sound propagation in sand/silty sediments. Here, equivalent expressions are presented using a low frequency expansion of an unconsolidated version of Biot porous medium theory. The resulting expression for attenuation allows identification of the non-dimensional parameter β in the Pierce/Carey result in terms of physical parameters. The agreement of these two derivations motivates further analyses. The results imply that porous media propagation models that treat the medium's inertia via a single component approximation disregard a fundamental physical effect resulting from the relative inertia of the grains and fluid and are thus incomplete.

1. Introduction

Studies of the constitutive equations for sound propagation in sand sediments are ongoing. Within this topic, the low frequency behavior of sound recently received focused attention by Pierce and Carey.[1] By examining locally averaged stresses and taking into account "the bowing of the fluid velocity profile in the interstices when the overall local region is being accelerated"[1] and the counteraction of this bowing via viscosity, they derived low frequency expressions for sound speed and attenuation. The attenuation they derived includes an explicit dependence on the difference between the density of solid grains and the fluid within the interstices of those grains. A key point is that this result is derived within the context of an unconsolidated sediment, i.e., within the Biot theory nomenclature, no frame rigidity.

In Sec. 2, results equivalent to those of Pierce and Carey are presented, derived from an unconsolidated version of Biot theory known as the effective density fluid model (EDFM).[2] Comparison of expressions allows identification of the non-dimensional parameter β in the Pierce/Carey result in terms of physical parameters from which a numerical range for β can be established. Within Sec. 2, high frequency expressions for attenuation and sound speed are also given.

In Sec. 3, the full EDFM as well as the high and low frequency expressions are examined as functions of frequency and relative grain/fluid density via plots of attenuation and sound speed. The physical interpretation of the plotted results is given and the inferences to porous media acoustics propagation modeling are discussed. Summary is presented in Sec. 4.

2. Pierce/Carey and EDFM expressions

The Pierce/Carey expression for low frequency sound attenuation in sand (with slightly different nomenclature) is

$$\alpha = \omega^2(\beta d^2/\eta)(1/2\rho c_{1f})(\chi_s^2\chi_f(\rho_s - \rho_f)^2). \quad (1)$$

Within Eq. (1), ω is the angular frequency, χ_f is the porosity (the fraction of the sand volume occupied by fluid), χ_s is the fraction of the sand volume occupied by solid (equal to $1-\chi_f$), ρ_f is the fluid density, ρ_s is the grain density, d is the mean grain diameter, and η is the fluid viscosity. Also within the expression, the following definitions apply:

$$\rho = \chi_s \rho_s + \chi_f \rho_f \tag{2}$$

and

$$c_{\mathrm{lf}} = \sqrt{\frac{B_{\mathrm{eff}}}{\rho}}, \tag{3}$$

where c_{lf} is the low frequency sound speed, ρ is the mass density, and B_{eff} is the effective bulk modulus of the sand given by

$$B_{\mathrm{eff}} = (\chi_s / B_s + \chi_f / B_f)^{-1}. \tag{4}$$

B_s is the bulk modulus of the grains and B_f is the bulk modulus of the fluid.

With the same definitions, the EDFM predicts that the (complex) sound speed is

$$c = \sqrt{\frac{B_{\mathrm{eff}}}{\rho_{\mathrm{eff}}}}, \tag{5}$$

where

$$\rho_{\mathrm{eff}} = \rho_f \frac{\alpha_t \chi_s \rho_s + \chi_f (\alpha_t - 1)\rho_f + i\chi_f \rho \eta F / \rho_f \omega \kappa}{\chi_f \chi_s \rho_s + (\alpha_t - 2\chi_f + \chi_f^2)\rho_f + i\chi_f \eta F / \omega \kappa}. \tag{6}$$

In addition to the previous definitions, α_t is the tortuosity, κ is the permeability, and F is a function given in Eq. (5) of the EDFM (Ref. 2) paper. The low frequency asymptotic value of F is unity and its high frequency expression is

$$F_{\mathrm{hf}} = (a_p \sqrt{\omega \rho_f / \eta})((1+i)/4\sqrt{2}), \tag{7}$$

where a_p is the "pore-size parameter,"[2] defined as $a_p = \sqrt{8\alpha_t \kappa / \chi_f}$.

A low frequency expansion of Eq. (5) (and using $k = \omega / c$ within the plane wave expression e^{ikr}) gives

$$\alpha_{lf} = \omega^2 (\kappa / \chi_f \eta)(1/2\rho c_{lf})(\chi_s^2 \chi_f (\rho_s - \rho_f)^2). \tag{8}$$

Comparison of Eqs. (1) and (8) shows that $\beta = \kappa / (\chi_f d^2)$. Note also that the low frequency limit of the EDFM real sound speed is that of Pierce/Carey, Eq. (3) (that equation is also known as Wood's equation). Typical parameter ranges for κ are 10^{-11}–10^{-10} m^2, sand grain diameters are roughly in the range of 0.1–1 mm, and porosities are in the neighborhood of 0.4. For those parameter ranges, β would have values from 2.5×10^{-5} to 2.5×10^{-2}. (The estimate for β in Pierce/Carey[1] was 1.3×10^{-3}.) Plots of Eq. (8) are included in Sec. 3.

It is also useful, for what follows, to give the high frequency sound speed and attenuation expressions derivable from the EDFM [and using Eq. (7)]. Sound speed becomes

$$c_{\mathrm{hf}} = \sqrt{\frac{B_{\mathrm{eff}}}{\rho_{\mathrm{hf}}}}, \tag{9}$$

where

$$\rho_{\mathrm{hf}} = \rho_f \frac{\alpha_t \chi_s \rho_s + \chi_f (\alpha_t - 1)\rho_f}{\chi_f \chi_s \rho_s + (\alpha_t - 2\chi_f + \chi_f^2)\rho_f}. \tag{10}$$

The attenuation is

Table 1. Parameter definitions and values used for the EDFM model.

Parameter	Value
Porosity (χ_f)	0.40
Mass density of sand grains (ρ_s)	2650 kg/m^3
Mass density of water (ρ_f)	1000 kg/m^3
Bulk modulus of sand grains (B_s)	3.6×10^{10} Pa
Bulk modulus of water (B_f)	2.25×10^{9} Pa
Viscosity (η)	0.001 kg/m s
Permeability (κ)	1.0×10^{-10} m^2
Tortuosity (α_t)	1.25

$$\alpha_{\mathrm{hf}}=\left(\sqrt{\frac{\omega\eta}{2\rho_f}}\right)\left(\frac{\chi_f a_p}{8c_{hf}\kappa}\right)\times\chi_s^2\chi_f(\rho_s-\rho_f)^2\times(\alpha_t\chi_s\rho_s+\chi_f(\alpha_t-1)\rho_f)^{-1}$$
$$\times(\chi_f\chi_s\rho_s+(\alpha_t-2\chi_f+\chi_f^2)\rho_f)^{-1}. \tag{11}$$

The implications of Eqs. (1)–(11) are examined as a function of frequency and grain density in Sec. 3 using the parameter values shown in Table 1 which are the same as given in Ref. 2.

3. Attenuation and sound speed results

Physical insight can be gained by examining the results above as the density of the grains goes to infinity. In particular, one sees the following:

$$\lim_{\rho_s\to\infty}\alpha_{\mathrm{lf}}\to\infty, \tag{12}$$

$$\lim_{\rho_s\to\infty}c_{\mathrm{lf}}\to 0, \tag{13}$$

$$\lim_{\rho_s\to\infty}\alpha_{\mathrm{hf}}=\left(\sqrt{\frac{\omega\eta}{2\rho_f}}\right)\left(\frac{\chi_f a_p}{8c_{\mathrm{hf}}\kappa\alpha_t}\right), \tag{14}$$

$$\lim_{\rho_s\to\infty}\rho_{\mathrm{hf}}=\rho_f\frac{\alpha_t}{\chi_f}, \tag{15}$$

$$\lim_{\rho_s\to\infty}c_{\mathrm{hf}}=\sqrt{\frac{\chi_f B_{\mathrm{eff}}}{\alpha_t\rho_f}}. \tag{16}$$

These asymptotic results indicate the following: (1) if, as grain density goes to infinity, there are frequencies low enough that the low frequency expansion applies, then no sound propagates within the medium since the attenuation is infinite and the sound speed zero; (2) if, as grain density goes to infinity, there are frequencies high enough that the high frequency expansion applies, then the attenuation and sound speed become insensitive to the grain density.

Before examining further the question of how the frequency range of validity of the low and high frequency approximations change as grain density increases, some further points can be made using the above results. Any model that uses the mass density in the equation for sound speed (e.g., Wood's equation) will predict that the sound speed goes to zero as grain density goes to infinity. Thus no sound would propagate across a layer of such a medium. This derives from ignoring the fundamental physical effect of inertia that causes the fluid to move relative to the grains (the first ramification of which shows up clearly in Eq. (1) via the dependence on the relative solid and fluid densities). This inertial effect in combination with the finite

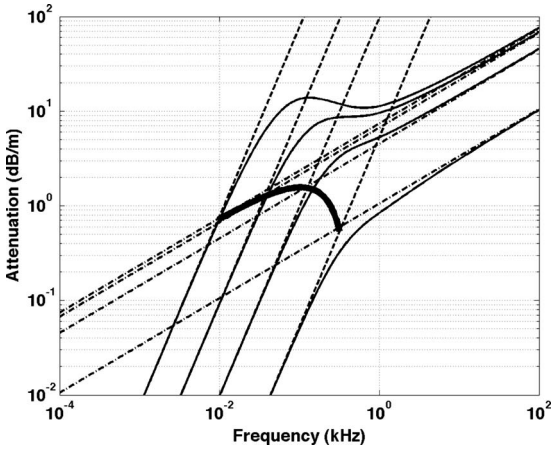

Fig. 1. The frequency dependence of the attenuation in a sand-like sediment. Results for the EDFM (solid lines), the low frequency expansion of the EDFM (dashed lines), and the high frequency expansion of the EDFM (dash-dot line). The parameter values used are given in Table I except that value of the grain density was varied by multiplication by 1, 4, 16, and 64 in going from the lowest to highest curves shown. The thick line segment indicates the value of attenuation at the frequency given by Eq. (17) as the grain density goes from that of sand to 64 times sand. That equation is an estimate of the high frequency limit of the low frequency expressions for attenuation and sound speed.

viscosity eventually results in the fluid breaking free of the solid as frequency is increased and thus causing attenuation and sound speed to become insensitive to grain density [i.e., Eqs. (14) and (16)]. That is, a model that includes this inertial effect (e.g., the Biot model) will predict that, regardless of the grain density of a porous medium, sound will propagate across a layer of that medium (at least at high frequency). Furthermore, it predicts that, as the grain density becomes large, the speed of this propagation is given by Eq. (16).

Now, the question remains as to the frequencies for which Eqs. (12)–(16) apply. Here, this question is examined graphically by using the full EDFM expression for sound speed and attenuation [derived from Eq. (5)] as well as the low and high frequency expressions [Eq. (8) or equivalently 1 and Eqs. (9) and (11)].

Figure 1 shows the attenuation of a porous medium as a function of frequency for the parameters given in Table 1 as well as for cases where the grain density is assumed to be 4, 16, and 64 times the density of sand. The figure shows the full model result and results for the low and high frequency expressions. This progression allows one to see how the frequency range of validity changes for the approximations. In particular, the high frequency approximation remains accurate above about 1 kHz for all grain densities and becomes insensitive to grain density for values above 16 times the density of sand. In contrast, the upper frequency limit of the low frequency approximation is reduced as the grain density increases. The implication is that the frequency range of accuracy for the low frequency approximation tends to zero as grain density goes to infinity. That is, though the asymptotic values given in Eqs. (12) and (13) are correct, the approximations leading to them are not.

Figure 2 shows the sound speed derived from the EDFM for the same parameter values used in Fig. 1. The low and high frequency approximations for each grain density are shown as squares near the ends of the frequency range. The high frequency, infinite density result [Eq. (16)] is shown as a line of diamonds. Again, one notes that as the grain density increases, the frequency range of validity for the low frequency approximation [Eq. (3), which is just Wood's equation] is reduced. This behavior implies that the frequency range of accuracy for the low frequency approximation for sound speed tends to zero as grain density goes to infinity.

From the expansions leading to the low frequency approximations for attenuation and sound speed, one can derive an estimate of the highest frequency (f_h) where the low frequency approximations may be accurate:

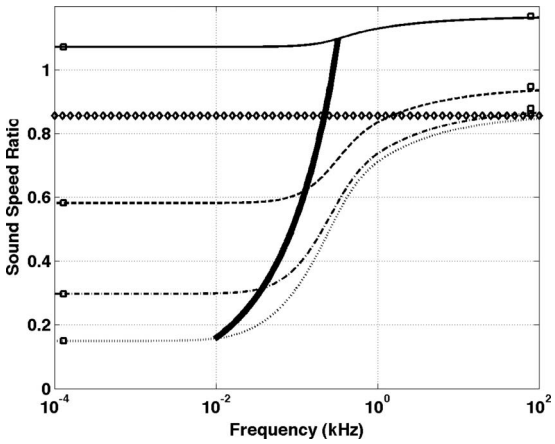

Fig. 2. The frequency dependence of the sound speed in a sand-like sediment (normalized by the sound speed in water as determined using the parameters for water given in Table I). Results for the EDFM are shown. The parameters values used are given in Table I except that value of the grain density was varied by multiplication by 1, 4, 16, and 64 for the solid, dashed, dash-dot, and dotted lines, respectively. The low and high frequency approximations for each grain density are shown as squares near the ends of the frequency range. The high frequency, infinite density result [Eq. (16)] is shown as a line of diamonds; comparison with the other curves indicates that at 100 kHz this limit has effectively been reached for grain densities of 16 times that of sand. The thick line segment indicates the value of sound speed ratio at the frequency given by Eq. (17) as the grain density goes from that of sand to 64 times sand. That equation is an estimate of the high frequency limit of the low frequency expressions for attenuation and sound speed.

$$f_h = \frac{0.1\chi_f \eta}{\kappa(\chi_f \chi_s \rho_s + (\alpha_t - 2\chi_f + \chi_f^2)\rho_f)}. \tag{17}$$

The values for attenuation and sound speed at f_h as the grain density is varied are shown as line segments in the figures. They indicate the f_h is a useful estimate. Examining f_h as the sediment density goes to infinity indeed shows that the useful range of the low frequency approximation goes to zero as grain density goes to infinity.

4. Summary

The low frequency expression for sound attenuation in a sand sediment derived by Pierce and Carey was compared to the low frequency limit of the Biot model in the limit that the medium is unconsolidated (i.e., the EDFM). This comparison allows one to identify the non-dimensional constant in the Pierce/Carey result in terms of physical parameters [i.e., $\beta = \kappa/(\chi_f d^2)$].

One of the important aspects of the Pierce/Carey derivation is that they show how to account for both the inertial effects due to the relative grain/fluid density and the effect of fluid viscosity in a relatively simple manner. The resulting expression for attenuation depends explicitly on the difference in grain and fluid densities. The agreement between the Pierce/Carey and EDFM low frequency attenuation expressions motivated the further analysis examining the high and low frequency limits of both attenuation and sound speed.

The general inference of the examination of attenuation and sound speed as a function of frequency and grain density is that any model that ignores this fundamental inertial effect is missing a key piece of physics that makes it incomplete. Wood's equation is one such model and since the Buckingham[3] model uses Wood's equation it is another example. The point being that, as shown in the analysis of Pierce and Carey and above, the use of the mass density to handle inertia in a porous medium is a low frequency approximation. Thus Wood's equation and Buckingham's model are low frequency approximations. However, even at low frequencies, incorrect treatment of inertia can manifest itself due to an incorrect dependence of attenuation on the relative densities of the grains and fluid. It will certainly manifest itself at high frequencies

because the density being used (mass density) is incorrect [i.e., Eq. (6) should be used]. One can formulate an incomplete model via introduction of hypothesized effects that influence the effective moduli. The moduli can thus be altered to accurately predict sound speed and attenuation as a function of frequency. However, this also masks the problem of incorrectly handling the inertial effect of relative grain/fluid motion. In essence, the problem lies in trying to correct an error in the resistance of the overall medium to motion [the inertia—the denominator in Eq. (5)] by adjusting its resistance to compression [the moduli—the numerator in Eq. (5)]. Though, perhaps mathematically possible, it is physically incorrect. One result of this error is that any prediction that requires acoustic impedance (e.g., the reflection coefficient[4–6]) will also be incorrect.

It is relatively easy to add the inertial effect to a model such as Buckingham's. An attempt to do so was carried out as part of the work by Hefner.[7] However, in doing so the conclusion was reached that one could match both attenuation and sound speed data without hypothesizing the strain-hardening effect put forth by Buckingham. Instead one could rely on a suggestion originally made by Biot to incorporate a complex, frequency dependent modulus. (It is notable that the lowest frequency sound speed data acquired during a recent ocean experiment were actually below Wood's equation prediction—Chotiros *et al.*[8] recently proposed an additional mechanism that could result in speeds below Wood's equation at low frequencies.)

It seems possible to experimentally test the predictions on the effect of relative grain/fluid density. A porous medium constructed using lead grains (whose density is over four times that of sand) represents one easily realizable upper limit while polystyrene grains (density slightly above water) represent another interesting limit.

From a general physics perspective, the results and discussion in Ref. 1 and the preceding sections show that Wood's equation is a low frequency approximation. The approximation essentially comes in treating the porous medium as a single component (from the inertial standpoint the fluid is always assumed to be "locked" to the grains, i.e., no relative motion) through the use of mass density. To correctly treat the inertia of the porous medium, the two components need to be addressed separately. Doing so leads to the prediction that attenuation depends on the relative densities of the two components. It also leads to different predictions for any quantity that requires the use of acoustic impedance since the effective density of this two component medium is not the mass density. One way to understand this one vs two component issue is to imagine a thought experiment where the grain density is taken to infinity. In the one component approximation, the sound speed goes to zero as grain density goes to infinity. On the other hand, if the grains and fluid are treated separately, the prediction is that there will always be a frequency range where sound will travel through the medium at a finite speed and with finite attenuation regardless of grain density. This result is counter to the prediction of any model that uses mass density to describe the inertia of the porous medium at all frequencies. More importantly, it is indicative of a fundamentally different treatment of the medium. In the end, inertial effects due to the two component nature of the medium need to be included before addressing additional physics that may also influence the frequency dependence of propagation within the medium.

Abstract: A statistical estimation of source location incorporating uncertainty in ocean environmental model parameters is derived using a Bayesian approach. From a previous geoacoustic inversion, a posterior probability distribution of the environmental parameters that reflects uncertainty in the ocean environment is obtained. This geoacoustic uncertainty then is mapped into uncertainty in the acoustic pressure field and is propagated through the Bartlett matched-field processor for source localization. Using data from the ASIAEX 2001 East China Sea experiment, the estimated source location and variability over time are compared with the known source positions.

1. Introduction

This paper presents a statistical estimation of source location in the presence of ocean acoustic parameter environmental uncertainty. Many Bayesian approaches for increasing robustness to ocean environmental uncertainty have been developed.[1–7] Averaging over a uniform prior distribution of environmental parameters was proposed earlier in Refs. 1 and 2 as a method of improving robustness of source localization. Dosso and Wilmut[5,6] proposed a Bayesian focalization to quantify source localization with environmental uncertainty. In their Bayesian focalization approach all source positions and environmental parameters are inverted at once. For practical problems involving thousands of source positions, tracking is an efficient alternative. Kalman and particle filtering[4,7] can be used efficiently to track the source and geoacoustic parameters.

Estimation of uncertainty in environmental parameters for a single source-receiver range is well developed using Markov chain Monte Carlo (MCMC) Metropolis–Hasting sampling.[8–10] The processor derived in this paper translates the uncertainty in environmental parameters, which, for example, can be from a previous geoacoustic inversion, to the uncertainty in replica fields for matched-field source localization. The resulting processor is a weighted sum of Bartlett processors over the posterior probability distribution (PPD) of the environmental parameters. We demonstrate the approach using source tow data from the ASIAEX 2001 experiment.[8,11] Using the geoacoustic inversion results for source localization is well known;[12] the focus here is on the accompanying source position uncertainty.

2. Theory

Figure 1 summarizes the statistical estimation of source position using environmental information obtained from a previous geoacoustic inversion.

The classical matched-field processor consists of systematically placing a single frequency test point source at each point of a search grid, computing the acoustic field (replica) at all the elements of the array and then correlating this modeled field with the observed data from

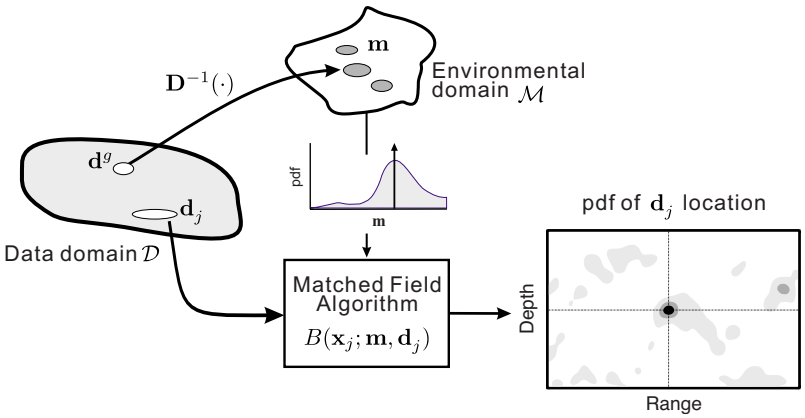

Fig. 1. (Color online) Measured data for source localization $\mathbf{d}_j$ ($\in\mathcal{D}$) is received at time j. From previous measured data $\mathbf{d}^g$ ($\in\mathcal{D}$) environmental parameters $\mathbf{m}$ ($\in\mathcal{M}$) are estimated via geoacoustic inversion along with a PPD of $\mathbf{m}$ that reflects its uncertainty. These environmental parameters then are mapped through a matched-field processor for statistically estimating the source location from $\mathbf{d}_j$.

an unknown source. In absence of data error and error in estimating the environmental parameter vector $\mathbf{m}$, the correlation is maximum when the test source location $\mathbf{x}$ is collocated with the true source

$$B(\mathbf{x}_j;\hat{\mathbf{m}},\mathbf{d}_j)=|\mathbf{w}(\mathbf{x}_j;\hat{\mathbf{m}})^H\mathbf{d}_j|^2=\mathbf{w}(\mathbf{x}_j;\hat{\mathbf{m}})^H\mathbf{R}_j\mathbf{w}(\mathbf{x}_j;\hat{\mathbf{m}}), \tag{1}$$

where $\mathbf{d}_j$ denotes the observed data at time index j, $\hat{\mathbf{m}}$ is an estimate of the parameter vector, and $\mathbf{w}(\mathbf{x};\hat{\mathbf{m}})=\mathbf{d}(\mathbf{x};\hat{\mathbf{m}})/|\mathbf{d}(\mathbf{x};\hat{\mathbf{m}})|$ is the normalized replica vector with the field solution $\mathbf{d}(\mathbf{x};\mathbf{m})$ computed from a acoustic model using the environmental parameter vector $\mathbf{m}$. When multiple snapshots are available, we assume that the signal source term can vary across snapshots, whereas the error power is the same for all snapshots. Then the observed data are efficiently expressed as a data covariance matrix $\mathbf{R}_j=\langle\mathbf{d}_j\mathbf{d}_j^H\rangle$.[13]

2.1 Posterior probability distribution of source position

The uncertainty in environmental parameters is translated to the uncertainty in replica fields for matched-field source localization.[8] The PPD of the source position at time j given the observation $\mathbf{d}_j$ is found via Bayes' rule

$$p(\mathbf{x}_j|\mathbf{d}_j)=\frac{p(\mathbf{d}_j|\mathbf{x}_j)p(\mathbf{x}_j)}{p(\mathbf{d}_j)}, \tag{2}$$

where $p(\mathbf{x}_j)$ is the probability density function (PDF) of $\mathbf{x}_j$ before observing the data. $p(\mathbf{d}_j|\mathbf{x}_j)$ is the likelihood function of the source position $\mathbf{x}_j$ at time step j given the data $\mathbf{d}_j$. This likelihood function can be derived from the PPD of $p(\mathbf{d}_j,\mathbf{m}|\mathbf{x}_j)$, by averaging over the environmental parameter vector $\mathbf{m}$ as follows:

$$p(\mathbf{d}_j|\mathbf{x}_j)=\int p(\mathbf{d}_j,\mathbf{m}|\mathbf{x}_j)\mathrm{d}\mathbf{m}=\int p(\mathbf{d}_j|\mathbf{m},\mathbf{x}_j)p(\mathbf{m}|\mathbf{x}_j)\mathrm{d}\mathbf{m}, \tag{3}$$

where $\mathbf{m}$ is independent of the source position $\mathbf{x}_j$ and the information about $\mathbf{m}$ was obtained from a previous geoacoustic inversion process using data $\mathbf{d}^g$. Therefore,

$$p(\mathbf{m}|\mathbf{x}_j)=p(\mathbf{m})=p(\mathbf{m}|\mathbf{d}^g). \tag{4}$$

The likelihood of the environmental parameters $\mathbf{m}$ and the source position $\mathbf{x}_j$ given $\mathbf{d}_j$ is determined from the assumption of data error statistics. The data error consists of both am-

bient noise as well as error in modeling the environment.[8] For simplicity, the error terms are assumed independent and identically distributed complex Gaussian random variables with variance ν as follows:

$$p(\mathbf{d}_j|\mathbf{m},\mathbf{x}_j,\nu)=\frac{1}{\pi^N\nu^N}\exp\left(-\frac{\phi(\mathbf{x}_j;\mathbf{m},\mathbf{d}_j)}{\nu}\right), \tag{5}$$

where $\phi(\mathbf{x}_j;\mathbf{m},\mathbf{d}_j)=\|\mathbf{d}_j\|^2-B(\mathbf{x}_j;\mathbf{m},\mathbf{d}_j)$ is the Bartlett objective function for the environmental parameter vector $\mathbf{m}$. Note that in Eq. (5) the complex source term has been estimated by a maximum likelihood approach[13] as opposed to integrating it out.[1] The uncertainty in the error variance ν is accounted for by integrating the complex Gaussian PDF over the nuisance parameter ν assuming a non-informative prior for ν (proportional to $1/\nu$) giving the likelihood function[11]

$$p(\mathbf{d}_j|\mathbf{m},\mathbf{x}_j)\propto\frac{1}{\phi(\mathbf{x}_j;\mathbf{m},\mathbf{d}_j)^N}, \tag{6}$$

where N is number of the hydrophones. Substituting Eqs. (6), (4), and (3) into Eq. (2) yields the PPD of $\mathbf{x}_j$ as

$$\begin{aligned}p(\mathbf{x}_j|\mathbf{d}_j)&=\frac{p(\mathbf{x}_j)}{p(\mathbf{d}_j)}\int p(\mathbf{d}_j|\mathbf{m},\mathbf{x}_j)p(\mathbf{m}|\mathbf{d}^g)\mathrm{d}\mathbf{m}\propto p(\mathbf{x}_j)\int\frac{1}{\phi(\mathbf{x}_j;\mathbf{m},\mathbf{d}_j)^N}p(\mathbf{m}|\mathbf{d}^g)\mathrm{d}\mathbf{m}\\&\propto p(\mathbf{x}_j)\sum_{k=1}^{K}\frac{1}{\phi(\mathbf{x}_j;\mathbf{m}_k,\mathbf{d}_j)^N},\end{aligned} \tag{7}$$

where $\phi(\mathbf{x}_j;\mathbf{m}_k,\mathbf{d}_j)$ is the Bartlett objective function for an environmental parameter vector $\mathbf{m}_k$ sampled by a MCMC algorithm. The statistical estimation of source position is based on Eq. (7).

3. Results

Data on a vertical line array from the ASIAEX 2001 East China Sea experiment in 106.5-m water depth are used to illustrate the approach.[8] First, an inversion was carried out at source-receiver range of 1.7 km, indicated by a circle in Fig. 2(a). An environment with 13 unknown parameters with their search bounds indicated in Fig. 2(b) was estimated, including geometrical, geoacoustic, and ocean sound speed empirical orthogonal function coefficients.[8] The inversion was based on a MCMC sampling giving samples $\mathbf{m}_k$ from which the PPD $p(\mathbf{m}|\mathbf{d}^g)$ could be estimated and subsequently used as prior information for source localization with new data $\mathbf{d}_j$. Based on Eq. (7), the samples $\mathbf{m}_k$ corresponding to a particular environment then are combined with the source position data $\mathbf{d}_j$ via the objective function $\phi(\mathbf{x}_j;\mathbf{m}_k,\mathbf{d}_j)$ for each possible location $\mathbf{x}_j$. The prior distribution $p(\mathbf{x}_j)$ was assumed uniform with the depth-range search interval. Summing over all samples gives the PPD of source location $p(\mathbf{x}_j|\mathbf{d}_j)$.

To estimate statistically the source position given the environmental information obtained from the inversion, a measured data vector $\mathbf{d}_j$ is used where the source range was 2.5 km. The source signal was a cw tone at 195 Hz. The signal-to-noise ratio (SNR) was estimated to be 16.3 dB using the ratio of the mean power received in the signal frequency fast Fourier transform bin and the (assumed to be noise) power received outside this bin. The observed data cross spectral density matrix $\mathbf{R}$ is normalized by the largest eigenvalue of the matrix, so that the maximum signal power is 1. For simulation purposes, the desired SNR is generated by varying the noise variance ν_n according to the array SNR definition[8]

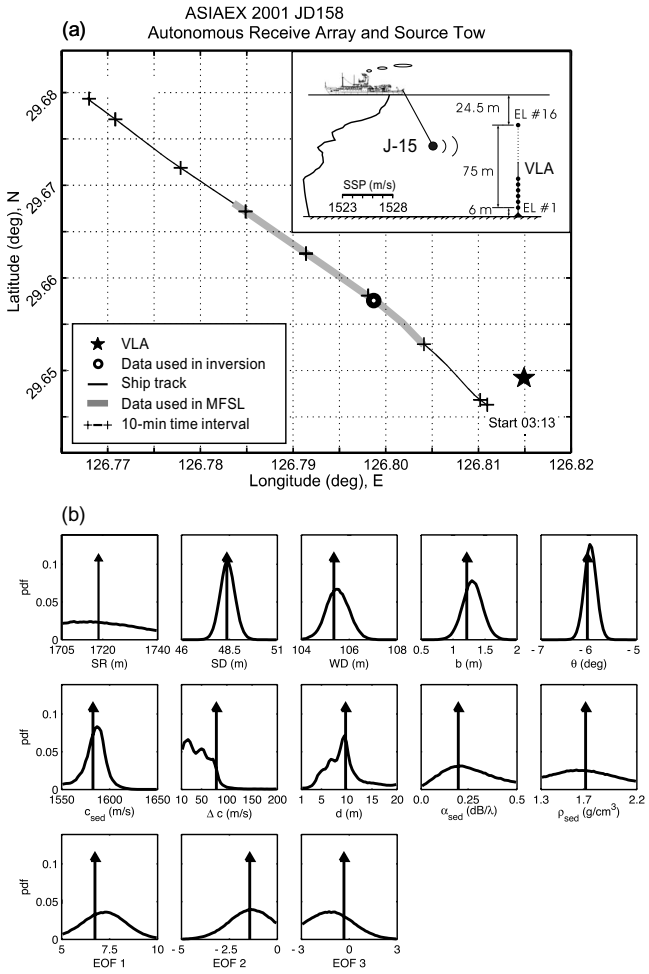

Fig. 2. (a) Track of R/V *Melville* during the ASIAEX 2001 East China Sea experiment. The experimental geometry is shown in the upper right-hand corner of the figure. (b) 1D marginal posterior probability densities and MAP (indicated by arrows) of the model parameters using the measured data obtained at approximately 1.7 km from the source.

$$\mathrm{SNR} = 10 \log \frac{1}{\nu_n} \quad \text{where } \nu_n = \frac{E[\|\mathbf{n}\|^2]}{N} \tag{8}$$

and $\mathbf{n}$ is the noise in the data (the array SNR should not be confused with the element SNR used in, e.g., Ref. 5). Since noise only can be added to the data, we only can lower the SNR from the maximum of 16.3 dB.

The parameter uncertainties are mapped through to the statistical estimation of source localization using Eq. (7). The replica vector for a hypothesized source position $\mathbf{x}$ and for each environmental parameter vector $\mathbf{m}_k$, $\mathbf{w}(\mathbf{x};\mathbf{m}_k)$, is computed using the normal mode propagation model SNAP.[14] Monte Carlo subsampling[8] of the geoacoustic inversion samples is used to evaluate Eq. (7) with $K=900$. The range-depth search grid spacing is 8 m in range from 1500 to 3500 m and 1.4 m in depth from 1 to 99 m.

Figure 3(a) shows the effect of the array SNR on the PPD of source range and depth at a source frequency of 195 Hz and range 2.5 km. The intersection of the lines indicates the peak of the PPD, and the darkest region indicates the 50% highest posterior density (HPD) in which

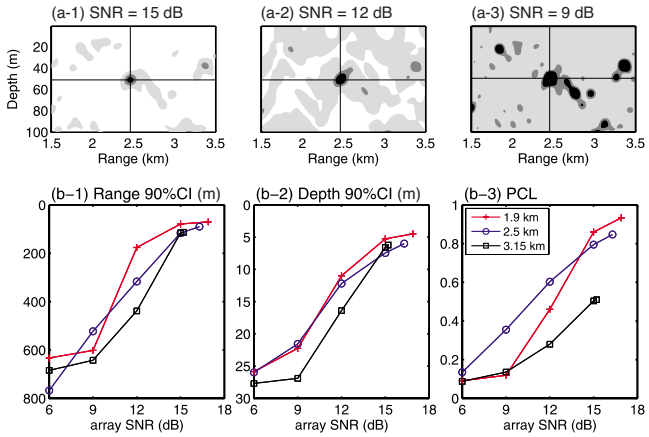

Fig. 3. (Color online) (a) Realizations of PPD of source range and depth for 195 Hz at 2.5 km range for three SNRs. Each panel shows the MAP source position (intersection of thin lines) and the HPD of source position [with 50% (dark), and 75% and 99% (light)]. (b) Source position uncertainty versus SNR for ranges 1.9 (+), 2.5 (○), and 3.15 km (□): (1) and (2) 90% CI, and (3) PCL in a region around the assumed source position.

the source falls given the observed data $\mathbf{d}_j$ and the environmental uncertainty. The range-depth PPD for the various SNRs [Figs. 3(a)(1)–3(a)(3)] shows that the number of competing peaks increases as SNR decreases. Note that the range-depth PPD for low SNR depends on the noise realization. The benefit here is not only we have the maximum *a posteriori* (MAP) estimate of source position but also the level of uncertainty.

The effect of SNR on the source position uncertainties is displayed for three source ranges in Fig. 3(b). The estimated SNRs in the observed data for ranges of 1.9, 2.5, and 3.15 km are 16.9, 16.3, and 15.2 dB, respectively (estimated using adjacent bins, see above). In Figs. 3(b)(1) and 3(b)(2) the 90% credibility interval (CI) extracted from the one-dimensional (1D) marginal distribution is shown. At lower SNR, the noise dominates the uncertainty of source position. For high SNR, the source position uncertainty will not approach zero since uncertainty in the environmental parameters will dominate. From the PPD surfaces in Fig. 3(a) we can

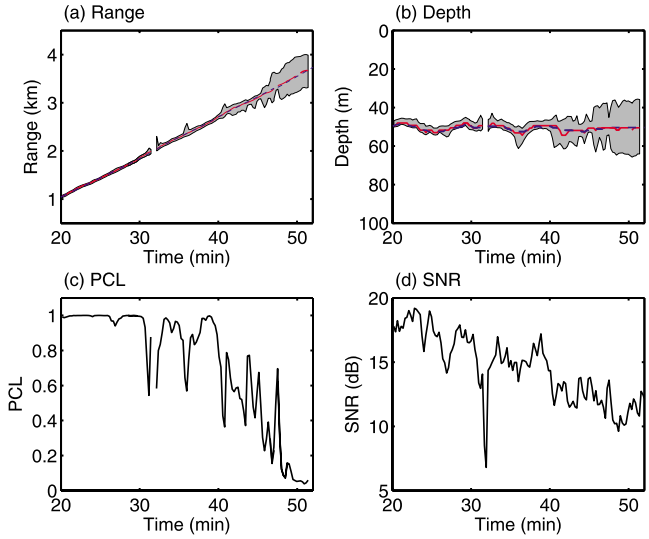

Fig. 4. (Color online) MAP estimate of source range (a) and depth (b) (solid) and their 90% CI (gray area) from time 20 to 52 min. The dashed line indicates the range measured by differential global positioning system (a) and the depth by a depth sensor (b). (c) PCL and (d) SNR estimated from the data.

integrate a region around the source position (an acceptable region of 20 m in depth and 200 m in range) obtaining the probability of correct localization (PCL) (Ref. 2) (this also has been termed integrated probability).[5] The PCL increases with SNR and tends to decrease with range.

As part of the experiment, a source tow from 1 to 3.7 km was performed. Using the estimated geoacoustic parameters and their uncertainty as well as the methodology above the MAP estimate of source position and the 90% CI is presented in Figs. 4(a) and 4(b). Furthermore, Figs. 4(c) and 4(d) show that as the SNR decreases so does the PCL.

4. Summary

Source position estimation in the presence of ocean environment uncertainty is investigated using the ASIAEX 2001 source tow data. A simulation shows that the noise deteriorates the localization performance at lower SNR, while the uncertainty in the ocean environment dominates at higher SNR. Continuous localization using the source tow data indicates that the localization uncertainty increases with range and 1/SNR.

LETTERS TO THE EDITOR

This Letters section is for publishing (a) brief acoustical research or applied acoustical reports, (b) comments on articles or letters previously published in this Journal, and (c) a reply by the article author to criticism by the Letter author in (b). Extensive reports should be submitted as articles, not in a letter series. Letters are peer-reviewed on the same basis as articles, but usually require less review time before acceptance. Letters cannot exceed four printed pages (approximately 3000–4000 words) including figures, tables, references, and a required abstract of about 100 words.

Monitoring stress related velocity variation in concrete with a 2×10^{-5} relative resolution using diffuse ultrasound (L)

(Received 19 June 2008; revised 12 January 2009; accepted 12 January 2009)

Ultrasonic waves propagating in solids have stress-dependent velocities. The relation between stress (or strain) and velocity forms the basis of non-linear acoustics. In homogeneous solids, conventional time-of-flight techniques have measured this dependence with spectacular precision. In heterogeneous media such as concrete, the direct (ballistic) wave around 500 kHz is strongly attenuated and conventional techniques are less efficient. In this manuscript, the effect of weak stress changes on the late arrivals constituting the acoustic diffuse coda is tracked. A resolution of 2×10^{-5} in relative velocity change is attained which corresponds to a sensitivity to stress change of better than 50 kPa. Therefore, the technique described here provides an original way to measure the non-linear parameter with stress variations on the order of tens of kPa.

Concrete is a complex heterogeneous mix of various ingredients of different sizes ranging from centimetric to millimetric gravel and sand to the micrometric porosity of the cement paste. Over the past 30 years or so, various sonic and ultrasonic techniques have been developed to image, characterize, or control the material.[1–4] Applications mostly work in the low frequency regime (a few Hz up to 50 kHz), where the wavelength is greater than the sizes of heterogeneities. In this regime, direct waves do not suffer too much from scattering by the heterogeneities and wave arrivals can be simply related to ballistic (direct or simply reflected) propagation paths. Nevertheless, because the wavelengths are much greater than the microstructure of the concrete, the fine details such as micro-damage or millimetric cracks are hardly visible. In the high frequency regime (above 50 kHz), the elastic wavefield is sensitive to these small details, but the ultrasonic wavelength is also of the order of the aggregates' size. This results in a strong attenuation of the direct (ballistic) wave,[5,6] and the appearance of a long lasting coda made of waves that have been multiply scattered by the internal microstructure.[7,8] The multiple scattering regime is often associated with a catastrophic loss of information, such that most conventional imaging or monitoring techniques fail. Nevertheless, as diffuse waves travel much longer paths than direct or simply reflected ones, they are much more sensitive to weak perturbation of the medium. This idea has been exploited in geophysics to quantify weak changes in the velocity of the earth crust:[9] by comparing two seismic coda obtained from fixed source and receiver at two different times, it is possible to monitor weak velocity variations in the medium. This technique is known as the *seismic doublet* technique or (more recently) *coda wave interferometry*.[10]

Various phenomena can cause acoustic velocity variations in concrete, including chemical reactions, and changes in water content, temperature, or stress. In this work, we focus on the latter effect, i.e., the relation between stress/strain and acoustic velocity, which is known as the acoustoelastic effect.[11–13] Under vertical uniaxial stress $\Delta\sigma$, the ultrasonic velocities in a sample will evolve as (to first order)

$$V_{ij} = V_{ij}^0 + \frac{\partial V_{ij}}{\partial \sigma}\Delta\sigma + o(\epsilon), \tag{1}$$

where ij stands for the wave velocity in direction i for a particle motion in j. The dimensionless non-linear parameter β is defined as

[a)]Electronic mail: eric.larose@ujf-grenoble.fr

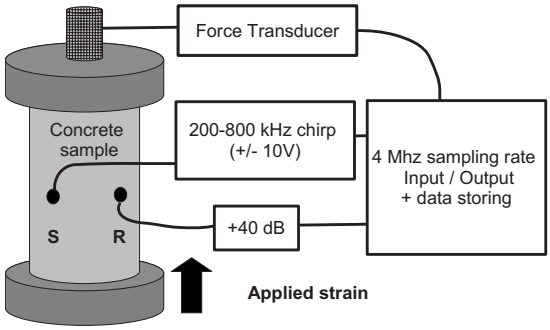

FIG. 1. Schematic view of the experimental setup.

$$\beta_{ij} = -\frac{E}{V_{ij}^0}\frac{\partial V_{ij}}{\partial \sigma} \tag{2}$$

and depends on the second (Lamé) and third (Murnaghan) order elastic constants. $E \approx 3.9 \times 10^{10}$ Pa is Young's modulus. There has been much less attention on the σ-dependence of V in heterogeneous media, such as concrete,[14] than in homogeneous media, and most results have considered variations under significant applied stress. To our knowledge, the use of diffuse ultrasound to evaluate the effect of stress loading on velocity variations has only been reported by Grêt *et al.*[15] and Payan.[16] In these works, the multiple time-window *doublet* technique was used to infer relative velocity variation with a relative resolution of $10^{-3}-10^{-4}$ for stress variation on the order of 1 MPa. Here, we propose to monitor weaker relative velocity variations in concrete down to 2×10^{-5} under weaker load variations (50 kPa). Such precision requires high frequency data (here 500 kHz diffuse ultrasonic data) and a more sensitive data processing technique than the *doublet* technique.

The experimental data presented here were acquired on a concrete sample of 16 cm in diameter and 28.5 cm in height. The concrete was prepared with 17% (in weight) of cement, 31% of fine sand, 43% of gravel (size ranging from 2 to 10 mm), and 9% of water. Two ultrasonic transducers are used in the experiment, one as a source and one as a receiver (labeled S and R, respectively, in Fig. 1). The lateral size of the active part of the transducers (0.7 mm) is much smaller than the wavelength, which makes them very sensitive to multiply scattered waves. The transducers are glued onto the sample using a hot chemical glue (phenyl-salicylic acid) that solidifies with cooling (below 43 °C). The ultrasonic experiment was performed several months after casting the sample.

During the ultrasonic measurements, the concrete specimen was subjected to uniaxial loading. A preliminary load was applied (5 MPa) at which point the reference ultrasonic data $r_0(t)$ were acquired. The applied uniaxial load was then increased to 5.5 MPa in ten steps of 50 kPa with ultrasonic acquisition at each stress increments, k, to provide $r_k(t)$. Each ultrasonic acquisition involved a source excited with a 10 V chirp $s(t)$ of frequencies ranging linearly from 200 to 800 kHz and of duration 10 s. The received signal $r_k(t)$ was amplified by 40 dB and stored in the computer. The recorded waveforms were subsequently cross-correlated with $s(t)$ (time-compression) to provide an estimate of the impulse response of the sample $h_k(t) = r_k(t)s(t)$, for each increment k.

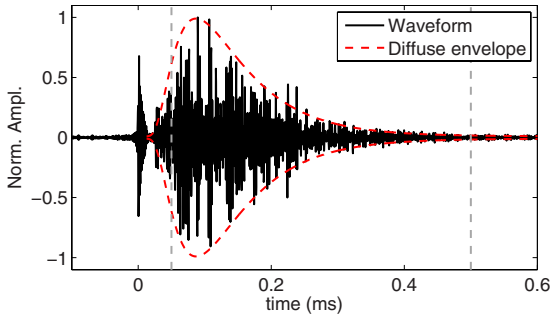

FIG. 2. (Color online) Typical waveform $h[t]$ collected through the concrete sample. The processed time-window marked by two vertical dashed lines extends from 50 to 500 μs.

The effective duration of the time-compressed signal $h_k(t)$ is about 0.6 ms. $h_0(t)$ is the reference waveform corresponding to $r_0(t)$ correlated with $s(t)$. It is noted that the source and receiver positions were kept fixed for all acquisitions and the excitation waveform $s(t)$ was not changed. Note also that the velocity change due to strain is one order of magnitude smaller than the one due to stress change, and is neglected here. The time separating two consecutive measurements is 5 min, over which no stress change was recorded and the ultrasonic records were reproducible. Creep was observed over much longer time scales (several hours) and was negligible in the present experiment.

A typical ultrasonic record is plotted in Fig. 2. This record is composed of (1) the impulse response of the concrete sample, (2) a peak at $t=0$ marking the initial excitation and due to the electronic cross-talk between S and R, and (3) background electronic noise (about 1% relative amplitude). The impulse response consists of a direct wave arriving at 0.023 ms, which is barely visible, and a following coda due to strong multiply scattered waves. The average intensity of the coda, $I(r,t)$, can be described by a diffusion envelope:

$$I(r,t) = \frac{I_0}{8(\pi D t)^{3/2}} e^{-r^2/4Dt - \gamma t}, \tag{3}$$

where I_0 is the energy released by the source, D is the diffusion constant, r is the source-receiver distance, and γ is the dissipation rate. In this experiment around 500 kHz, we find that $\sqrt{I}$ best fits the data for $D=5$ mm$^2/\mu$s and $\gamma=25$ ms^{-1}. This will represent a slight underestimate for D because Eq. (3) only holds for unbounded media. Nevertheless, D and σ values are in agreement with the literature,[7,8] and our rough estimation of D confirms that we are in the strong multiple scattering regime.

For each load k, the record $h_k(t)$ is compared to the reference waveform $h_0(t)$ to evaluate the relative velocity change in the concrete sample. Because of strong multiple scattering, the P- and S-wave arrivals mix together and rapidly attain the equipartition regime.[17] Let a_{ij} be the relative fraction of time that the wave spends in the state ij (polarization in the direction i while propagating in the direction j), then the velocity variation is $dV = \langle a_{ij}(\partial V_{ij}/\partial\sigma)\rangle \Delta\sigma$. Note that we have $\Sigma a_{ij}=1$ and that $\langle . \rangle$ denotes ensemble averaging. If the waves are statistically equipartitioned in all directions, we have $\Sigma a_{i=j}=9\%$ and $\Sigma a_{i\neq j}=91\%$.[17] In general, a_{ij} has a

more complex distribution, but in this work we focus on the average quantity $\langle a_{ij}\beta_{ij}\rangle$. For simplicity, we also assume that the waveforms are just stretched in time. This is again a first order approximation that applies to experimental data in the considered time-window. Nevertheless, velocity variations will progressively decorrelate the waveform.[18] This weak decorrelation, also called distortion, is not studied here although it contains precious information on the medium and its evolution. In particular, we stress that strong distortion and weak stretching might indicate a change in structure rather than a global velocity change. However, here we do not see significant distortion. To summarize, the velocity change dV for load k results in

$$h_k[t] = h_0[t(1+\nu_k)] + n(t), \tag{4}$$

with $\nu_k = dV/V$ and $n(t)$ accounting for additional fluctuations, including electronic noise and the small distortion mentioned earlier. Two processing techniques have been proposed in the literature to estimate dV/V. The first one, called the seismic *doublet* technique, was developed for geophysical purposes about 20 years ago.[9] The idea is to measure a time-shift between two different records in a limited time-window centered at time t. By measuring such time-shifts (or delay) δt at different times t in the coda, it is possible to evaluate the velocity variation, which is simply the average slope of $\delta t(t)$: $dV/V = -\delta t/t$. Such an approach implicitly assumes that the time-shift is constant within the considered time-window, which is generally not the case. Another idea[18,19] is to interpolate h_k at times $t(1-\nu)$ with various relative velocity changes ν.[20] Therefore, ν_k is the ν that maximizes the cross-correlation coefficient:

$$\mathrm{CC}_k(\nu) = \frac{\int_0^T h_k[t(1-\nu)]h_0[t]dt}{\sqrt{\int_0^T h_k^2[t(1-\nu)]dt \int_0^T h_0^2[t]dt}}. \tag{5}$$

Contrary to the *doublet* technique, we do not assume a constant time-shift in the considered time-window [0 T]. The comparison between the two waveforms can therefore be performed over the entire record at once, which results in a more stable, and thus more precise, estimation of dV/V. The comparison between the doublet and the stretching technique will be subject to further investigation.[21] Assuming that h_0 and h_i are stationary waveforms and are well described by Eq. (4), we have a theoretical estimation of CC:

$$\mathrm{CC}_k(\nu) = A\frac{\int_{\Delta f}\rho(f)\mathrm{sinc}(2\pi f(\nu-\nu_k)T)df}{\int_{\Delta f}\rho(f)df} + B(\nu), \tag{6}$$

with f the frequency, Δf the bandwidth, and $\rho(f)$ the spectral density. The constant A depends on the variance of h, noted $\langle h^2\rangle$ and the variance of the additional fluctuations, noted $\langle n^2\rangle$,

$$A = \frac{\langle h^2\rangle}{\langle h^2\rangle + \langle n^2\rangle}. \tag{7}$$

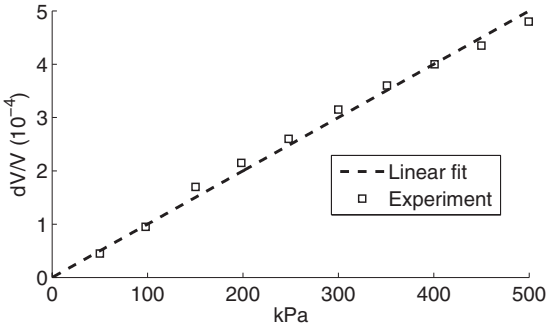

FIG. 3. Relative velocity variations dV/V versus stress variation $\Delta\sigma$.

$B(\nu)$ is a random process of zero mean and standard deviation:

$$\sqrt{\langle B^2\rangle} = \frac{1}{\sqrt{T\Delta f}}\frac{\langle n^2\rangle + 2\sqrt{\langle n^2\rangle\langle h^2\rangle}}{\langle h^2\rangle + \langle n^2\rangle}. \tag{8}$$

If the amplitude of the signal A is much greater than the fluctuations $\sqrt{\langle B^2\rangle}$ of the cross-correlation coefficient CC_k, the maximum of CC_k is obtained for the stretching $\nu = \nu_k$. It is interesting to note that the peak of the sinc function is visible even if the fluctuations (or noise) $n(t)$ are strong. In such a case, increasing the integration time T or the frequency bandwidth Δf can compensate for this strong noise. This is a crucial advantage of the present technique compared to the doublet technique. The dV/V resulting from our measurements are plotted in Fig. 3 versus $\Delta\sigma$. A linear regression of the data yields $\langle (1/V)(\partial V/\partial\sigma)\rangle = 10^{-6}$ kPa^{-1}, which gives an estimate of the non-linear parameter of our sample: $\beta = \langle a_{ij}\beta_{ij}\rangle \approx -40$. The standard deviation from the linear regression for the relative velocity change dV/V is 2×10^{-5}, which indicates that the precision on the evaluation of β is 5%. Note that during the whole experiment, the surrounding air temperature fluctuated within less than 0.8 °C. Temperature variations are too weak and thermal diffusion too slow in the sample (compared to the duration of the experiment) to induce noticeable dV.[10,18,22,23] This assertion is confirmed by the fact that the velocity variations dV are totally decorrelated from the air temperature variations. We therefore propose that the variations are due primarily to stress effects.

A potential application of this technique is on-site assessment of the non-linear constant β of a concrete structure. Our technique is sensitive enough to provide reliable measurements with additional stress $\Delta\sigma$ of the order of 100 kPa. As the non-linear parameter strongly depends on the micro-damage of the concrete, our technique would form an efficient and non-destructive way to probe the integrity of civil engineering structures. Another application is to evaluate the state of stress of a given structure with a predetermined β parameter and can be extended to geophysical media.[24–26]

[20]The interpolation of the data at times $t\,(1-\nu)$ uses a spline interpolation algorithm. It should be noted that this procedure performs well even with our 4 MHz sampling rate. In fact, through numerical tests, we have found that the numerical precision of our processing procedure depends mainly on the signal-to-noise of the data and only feebly on the sampling rate. However, even the effect of signal-to-noise is small; in the case of 1% of electronic noise the error of the estimated relative velocity change ν_k is found to be much smaller than 10^{-6}.

Comment on "Measurement of the frequency dependence of the ultrasonic parametric threshold amplitude for a fluid-filled cavity" (L)

M. Strasberg[a)]
David Taylor Model Basin, NSWCCD, 9500 McArthur Boulevard, Bethesda, Maryland 20817-5700

(Received 23 January 2008; revised 31 October 2008; accepted 5 February 2009)

Measurements of the threshold amplitude of the pump signal for parametric excitation of ultrasonic standing waves in a water-filled container are described in the paper of Teklu *et al.* [(2006). J. Acoust. Soc. Am. **120**, 657–660]. The threshold is reported to *increase* with increasing pump frequency from 2 to 7 MHz, in apparent disagreement with earlier measurements made in 1970 over the same frequency range in similar apparatus showing a *decrease* in parametric threshold with increasing frequency. It is shown that the very theory presented in both papers may explain the frequency dependence observed with the new 2006 data rather than the old 1970 data if proper account is taken of the variation in the acoustic absorption coefficient of water with frequency. However, other questions raised by data in both papers indicate the possibility that the phenomenon they describe was *not* parametric excitation.

I. INTRODUCTION

A paper published in 2006 (Ref. 1) describes new measurements, which apparently were intended to confirm and extend earlier measurements reported in 1970 (Ref. 2) made in similar apparatus and frequency range, both said to indicate parametric excitation of standing ultrasonic waves at megahertz frequencies in a small volume of liquid. Instead, however, the authors find the new measurements to be "in apparent discrepancy" with the measurements reported in the earlier paper.

Parametrically excited oscillations are oscillations that are not excited by a force or pressure applied directly to the excited modes but rather by a sinusoidal variation in the magnitude of a physical quantity (or "parameter"), which influences the natural frequency of the excited mode, the frequency of the parametrically excited oscillation differing from the frequency of the oscillating parameter. Parametric excitation requires the magnitude of the sinusoidal variation to exceed a value called the "threshold" value, and the oscillating parameter is conventionally called the "pump signal." The most easily excited mode, i.e., the mode with the lowest threshold, is usually a mode whose natural (or resonance) frequency is half the frequency of the pump signal.[3]

The main concern of the 2006 paper is the value of the threshold amplitude of the pump signal and its dependence on the pump frequency. For the measurements, standing ultrasonic waves are set up in a small container of water or other liquid between a rigid back plate and an X-cut piezoelectric quartz-crystal disk 1-in. in diameter. The pump signal is a sinusoidal voltage applied to the piezoelectric disk, which results in a small sinusoidal variation in its thickness and corresponding small oscillation in the separation distance between the disk and back plate. Since the natural frequency of a standing wave is inversely proportional to this distance, standing waves between the disk and back plate can be excited parametrically, in principle, if the voltage and corresponding oscillation in separation distance is large enough.

The main concern of the 2006 paper is the observed dependence of the threshold voltage for parametric excitation of standing waves on the frequency of the pump signal, which ranges from 2 to 7 MHz. The reported new 2006 data and the apparent discrepancy with the older 1970 data bring to mind several questions worthy of discussion, among them the following:

(1) The 2006 measurements indicate an increase in threshold amplitude with increasing pump frequency, whereas the 1970 measurements showed a *decrease* in threshold with increasing frequency although performed in similar apparatus and frequency range.
(2) Neither the 2006 nor the 1970 measurements show parametric excitation of a standing wave mode whose natural (or resonance) frequency is one-half the pump frequency, although this mode is usually the most easily excited.
(3) The measured threshold amplitudes are orders of magnitude smaller than the value predicted by the theory described in both papers.

II. THRESHOLD VARIATION WITH FREQUENCY

Figure 3 in the 2006 paper is a plot of the 1970 data (Fig. 5 in the 1970 paper) showing the measured threshold amplitude inversely proportional to frequency. Both papers contend that these data agree with a theoretical calculation of the threshold given by Eq. (12) in the 2006 paper, which, in the notation common to both papers but slightly modified in form, is

[a)]Electronic mail: murray.strasberg@navy.mil

$$A = l_0 \sqrt{\left[\frac{f_n - f_0}{f}\right]^2 + \left[\frac{a\alpha c}{2\pi f}\right]^2}, \quad (1)$$

where A is the threshold oscillatory variation in the distance between the face of the piezoelectric disk and back plate at the onset of parametric oscillations, l_0 is the mean distance between the disk and back plate, $2f$ is the pump *cyclic* frequency, f is half that frequency, f_n is the natural frequency of the parametrically excited oscillation, $a=(f_n/f)^2$, the Greek α is the sound absorption coefficient of the liquid at the excited frequency f_n in nepers per unit distance (1 Np equals 8.7 dB), and c is the ultrasound propagation velocity in the liquid.

For the old 1970 data, both papers assume that $f_0=f \approx f_n$, so the left term under the radical is zero or negligible compared with the right term and $a=(f_n/f)^2=1$. With these assumptions, the equation reduces to

$$A = \alpha c l_0 / 2\pi f, \quad (2)$$

which is Eq. (21) and Eq. (13), respectively, in the 1970 and 2006 papers. The authors of both papers interpret the presence of the frequency f in the denominator of Eq. (2) to indicate that the theoretical threshold is inversely proportional to frequency, therefore agreeing with the old 1970 data. But this conclusion is erroneous because it fails to account for the variation in the absorption coefficient with frequency. The absorption coefficients of water and most common liquids tend to increase with the square of frequency over the range of 1–10 MHz. Because of this variation, values of absorption coefficients at these frequencies are conventionally given in tables by the expression[4]

$$\alpha = K f_n{}^2, \quad (3)$$

where K is a constant whose value depends on the liquid (for water, $K=2.4\times10^{-16}$ s^2/cm) and f is cyclic frequency in hertz, with the subscript n added here to indicate that it is the frequency of the excited mode. Inserting α from Eq. (3) into Eq. (2), the latter becomes

$$A = c l_0 K f_n^2 / 2\pi f = c l_0 K f / 2\pi, \quad (4)$$

indicating that the theoretical threshold amplitude of the pump signal should *increase* proportionally with frequency—not decrease. Accordingly, this may explain the data shown in Fig. 4 of the 2006 paper rather than the 1970 data in Fig. 3.

An attempt to obtain a valid theoretical explanation of the 1970 measurements showing the threshold decreasing with increasing frequency requires re-examining the more general Eq. (1), which may now be written as

$$A = l_0 \sqrt{\left[\frac{f_n - f_0}{f}\right]^2 + \left[\frac{acKf}{2\pi}\right]^2}. \quad (5)$$

Only the left term under the radical can result in a threshold decreasing with frequency—and only if it is larger than the right term and its numerator does not increase with frequency faster than its denominator.

III. THE MISSING MODE

As stated in both papers, theory indicates that the mode with the lowest threshold is a mode whose natural frequency is one-half the pump frequency. However, the spectrum of the excited modes shown in Fig. 3 of the 1970 paper does not contain a line at half the 4 MHz pump frequency.

IV. ABSOLUTE VALUES OF THE THRESHOLD

Neither paper gives measured threshold values of the quantity A that can be compared directly with the theoretical values given by the above equations. Figure 4 of the 2006 paper plots threshold values for the new data in "arbitrary units," and Fig. 3 plots the old 1970 data as the "threshold drive voltage" applied to the piezoelectric disk. A threshold of about 300 V is shown for a pump frequency of 4 MHz. This voltage can be converted into an oscillating path length using the transduction conversion factor $(A/V)=3.2\times10^{-10}$ cm/V listed in Table 1 of the 1970 paper (a value in order-of-magnitude agreement with the X-cut quartz thickness-expander d constant of 2.3×10^{-10} cm/V).[5] Using the larger transducer conversion factor, the estimated measured threshold oscillation is $A=9.6\times10^{-8}$ cm.

Calculating the theoretical threshold based on Eq. (1) for comparison with the above measurement estimate results in a surprise. For the conditions applicable to the old 1970 data, the left term under the radical is neglected, and the right term is evaluated with $l_0=10$ cm, $a=1$, $c=1.45\times10^5$ cm/s, $f_n=f=2\times10^6$ Hz, and $\alpha=2.4\times10^{-16}f^2=9.6\times10^{-4}$ Np/cm $(8.4\times10^{-3}$ dB/cm) in accordance with Eq. (2). The surprising result for the theoretical threshold is $A=1.1\times10^{-4}$ cm—some three orders of magnitude larger than the estimated measured value. If the neglected left term in Eq. (1) were included, the theoretical value would be even larger.

The theoretical threshold should be four times larger for the new 2006 data at the same pump frequency because the factor a in Eq. (1) is stated to equal 4 for the data shown in Fig. 4. Although there is insufficient information to permit estimating the transducer oscillatory displacement for these data, it cannot be significantly larger than the estimated value for the 1970 data because of practical imitations in the voltage that can be applied to the quartz disk.

V. CONCLUSION

Assuming that the theoretical threshold value given by Eq. (1) and (4) and the estimated measured value are both valid, one is forced to speculate that the large disagreement between them may indicate that the observed phenomenon was not parametric excitation of standing waves—a speculation reinforced by the absence of the expected excited standing wave whose natural frequency is one-half the frequency of the pump signal.

The observed phenomenon may be associated with subharmonic generation due to nonlinear ultrasound propagation in the water as discussed, e.g., by Yen,[6] rather than with

parametric excitation. To indicate the possibility of nonlinearity, it would be useful to determine the sound pressure of the pump-frequency standing wave during future measurements.

Time domain formulation of the equivalent fluid model for rigid porous media (L)

Olga Umnova[a] and Diego Turo[b]
Acoustics Research Centre, University of Salford, Salford M5 4WT, England

(Received 14 October 2008; revised 15 January 2009; accepted 26 January 2009)

A set of equations has been derived which corresponds to the time domain formulation of the equivalent fluid model. It models the propagation of an acoustic pulse in rigid frame porous material accounting for both viscous and thermal effects. It has been shown analytically and confirmed numerically that the equations can be reduced to those published previously in the limit of long and short duration pulses. Numerical solutions have been found for different pulse durations and the results have been compared with other time domain models.

PACS number(s): 43.55.Ev, 43.20.Bi, 43.20.Jr [RMW] Pages: 1860–1863

I. INTRODUCTION

The equivalent fluid model originally formulated in 1987[1] is based on a set of independently measurable material parameters and satisfies physically correct behavior in both high and low frequency ranges. The model was later extended[2,3] to include thermal losses in a porous material. In its most general formulation it relies on the knowledge of six parameters, i.e., material porosity ϕ, its tortuosity α_∞, steady state flow resistivity σ_0, thermal permeability k', and finally viscous and thermal characteristic lengths Λ and Λ'. Even if it does not provide the highest level of accuracy for all materials and in all frequency ranges,[4] it still remains widely accepted as one of the most successful semiempirical models in acoustics of porous materials.

Both low and high frequency approximations of the equivalent fluid model can be analytically formulated in the time domain[5,6] and can be used to model propagation of long and short acoustic pulses, respectively. Recently it has been shown that the relaxational model[7] also allows analytical time domain representation.[8–10] Although quite accurate for many materials, this model requires different values of viscous and thermal relaxation times to be used in low and high frequency ranges to satisfy physically correct limits of complex density and complex compressibility functions.[1–3]

In this work, we provide a time domain formulation of the full equivalent fluid model without any restrictions on the frequency bands.

II. TIME DOMAIN MOMENTUM CONSERVATION AND CONTINUITY EQUATIONS

We start with the following frequency domain equations for pressure p and particle velocity v of the plane sound wave:

$$-i\omega\rho_0\alpha(\omega)v = -\partial_x p, \tag{1}$$

$$-i\omega C(\omega)p = -\rho_0 c^2 \partial_x v, \tag{2}$$

here ω is angular frequency, ρ_0 is the equilibrium density of air and c is the sound speed. In the framework of the equivalent fluid model the complex density $\alpha(\omega)$ and complex compressibility $C(\omega)$ can be formulated as

$$\alpha(\omega) = \alpha_\infty\left(1 + \frac{\sqrt{1 - i\omega\tau_2}}{-i\omega\tau_1}\right), \tag{3}$$

$$C(\omega) = \gamma - \frac{\gamma - 1}{1 + \frac{\sqrt{1 - i\omega T_2}}{-i\omega T_1}}, \tag{4}$$

where

$$\tau_1 = \frac{\alpha_\infty\rho_0}{\phi\sigma_0}, \quad \tau_2 = \tau_1\frac{M}{2}, \tag{5}$$

and

$$T_1 = \frac{N_{\mathrm{Pr}}\rho_0 k'}{\phi\eta}, \quad T_2 = T_1\frac{M'}{2}, \tag{6}$$

which can be interpreted as two pairs of viscous and thermal relaxation times, γ is adiabatic constant, η is the dynamic viscosity of air, N_{Pr} is Prandtl number, and

$$M = \frac{8\eta\alpha_\infty}{\phi\sigma_0\Lambda^2} \quad M' = \frac{8k'}{\phi\Lambda'^2} \tag{7}$$

are viscous and thermal shape factors.

The complex tortuosity function (3) can be rearranged in the following way:

$$\alpha(\omega) = \alpha_\infty\left(1 + \frac{1}{-i\omega\tau_1\sqrt{1 - i\omega\tau_2}} + \frac{\tau_2}{\tau_1}\frac{1}{\sqrt{1 - i\omega\tau_2}}\right).$$

Now applying the inverse Fourier transformation to Eq. (1), the following time domain momentum conservation equation can be easily derived:

$$\rho_0\alpha_\infty\partial_t V + I_0(t) = -\partial_x P, \tag{8}$$

where

[a]Author to whom correspondence should be addressed. Electronic mail: o.umnova@salford.ac.uk
[b]Electronic mail: d.turo@pgr.salford.ac.uk

$$I_0(t) = \frac{\rho_0 \alpha_\infty}{\tau_1}\sqrt{\frac{\tau_2}{\pi}}\int_{-\infty}^{t} \frac{\exp\left(-\frac{t-t'}{\tau_2}\right)}{\sqrt{t-t'}} \times\left(\partial_{t'}V(t') + \frac{V(t')}{\tau_2}\right)dt',$$

V and P are particle velocity and acoustic pressure in the time domain. In the derivation, Eq. (8) from Ref. 8 has been used. Expression (4) for the complex compressibility can be rearranged as

$$C(\omega) = 1 + (\gamma - 1)\frac{\sqrt{1 - i\omega T_2}}{\frac{T_1}{T_2}(\sqrt{1 - i\omega T_2})^2 + \sqrt{1 - i\omega T_2} - \frac{T_1}{T_2}}.$$

In the fraction above, the denominator can be factorized as $T_1/T_2(\sqrt{1-i\omega T_2}-x_1)(\sqrt{1-i\omega T_2}+x_2)$, where $x_{1,2} = \sqrt{(T_2/2T_1)^2+1} \mp (T_2/2T_1)$. Further algebra leads to the final expression for $C(\omega)$,

$$C(\omega) = 1 + \frac{(\gamma-1)T_2}{T_1(x_1+x_2)}\left(\frac{x_1}{\sqrt{1 - i\omega T_2} - x_1} + \frac{x_2}{\sqrt{1 - i\omega T_2} + x_2}\right).$$

Now using slightly modified version of Eq. A.2 from Ref. 10, inverse Fourier transformation of Eq. (2) can be performed which results in the following:

$$\partial_t P + I_1(t) + I_2(t) + I_3(t) = -\rho_0 c^2 \partial_x V, \tag{9}$$

where

$$I_1(t) = \frac{\gamma-1}{T_1}\int_{-\infty}^{t} \partial_{t'}P(t')\frac{\exp\left(-\frac{t-t'}{T_2}\right)}{\sqrt{t-t'}}dt',$$

$$I_2(t) = \frac{2(\gamma-1)x_1^2}{T_1(x_1+x_2)}\int_{-\infty}^{t} \partial_{t'}P(t')\exp\left((x_1^2-1)\frac{t-t'}{T_2}\right)dt'.$$

$$I_3(t) = -\frac{\gamma-1}{T_1(x_1+x_2)}\int_{-\infty}^{t} \partial_{t'}P(t')\sum_{m=1}^{2} x_m^2 \times\exp\left((x_m^2-1)\frac{t-t'}{T_2}\right)\operatorname{erfc}\left(x_m\sqrt{\frac{t-t'}{T_2}}\right)dt'.$$

Equations (8) and (9) constitute time domain formulation of the equivalent fluid model.

Now we shall demonstrate that Eqs. (8) and (9) can be reduced to those published previously in the limit of long and short duration pulses. The low frequency approximation of the equivalent fluid model[5] should be applicable to pulses with duration much longer than both τ_2 and T_2. This implies that their central frequencies are much lower than $1/2\pi\tau_2$ and $1/2\pi T_2$. The low frequency approximations of complex density and complex compressibility functions[5] are

TABLE I. Pulse parameters.

Regime	ω_0 (rad/s)	t_0 (s)	f_0 (Hz)
Long pulse (spheres)	50	0.1	11.25
Medium pulse (gravel)	100	0.04	22.50
Medium pulse (spheres)	7 000	0.000 65	1575.60
Short pulse (spheres)	20 000	0.000 3	4501.60

$$\alpha(\omega) \approx \alpha_\infty\left(1 + \frac{1}{-i\omega\tau_1}\right), \quad C(\omega) \approx \gamma. \tag{10}$$

The first equation can be obtained assuming $\omega\tau_2 \to 0$, the second requires $\omega T_2 \to 0$.

In the limit considered, $\partial_t V \ll V/\tau_2$ and V varies much slower with time than $\exp(-(t-t')/\tau_2)$. Consequently, the convolution integral $I_0(t)$ in Eq. (8) can be approximated as

$$I_0(t) \approx \frac{\rho_0\alpha_\infty}{\tau_1}\frac{V}{\sqrt{\pi\tau_2}}\int_{-\infty}^{t}\frac{\exp\left(\frac{t-t'}{\tau_2}\right)}{\sqrt{t-t'}}dt' = \frac{\rho_0\alpha_\infty}{\tau_2}V.$$

This results in the following low frequency/long pulse limit of the momentum conservation equation:

$$\rho_0\alpha_\infty\partial_t V + \frac{\rho_0\alpha_\infty}{\tau_1}V = -\partial_x P, \tag{11}$$

which agrees with Eq. (15) from Ref. 5.

The integrals $I_{1,2}(t)$ in the continuity equation (9) can be represented as

$$I_{1,2}(t) \approx a_{1,2}\partial_t P, \tag{12}$$

where $a_1 = (\gamma-1)T_1/T_1$ and $a_2 = 2(\gamma-1)x_1/(x_1+x_2)$. In the derivation, one of the identities $x_{1,2}^2 - 1 = \mp(T_2/T_1)x_{1,2}$ was used.

To estimate $I_3(t)$ in Eq. (9), the integral identity $\int_0^\infty e^{\beta x}\operatorname{erfc}(\sqrt{\alpha x})dx = 1/\beta(\sqrt{[\alpha/(\alpha-\beta)]}-1)$, which is equivalent to Eq. (6.283) from Ref. 11, has been used, assuming $\alpha = x_m^2/T_2$, $\beta = (x_m^2-1)/T_2$, and $x = t-t'$ which leads to the following:

$$I_3(t) \approx \frac{(\gamma-1)}{(x_1+x_2)}(x_1(x_1-1) + x_2(x_2-1))\partial_t P. \tag{13}$$

Summing Eqs. (12) and (13), the low frequency/long pulse approximation of Eq. (11) is derived:

$$\gamma\partial_t P = -\rho_0 c^2 \partial_x V. \tag{14}$$

This equation is equivalent to the second of Eq. (15) in Ref. 5.

The high frequency approximation of the dynamic density and compressibility functions can be obtained from Eqs. (3) and (4) assuming $\omega\tau_2 \gg 1$ and $\omega T_1 \gg 1$, $\omega T_2 \gg 1$:

$$\alpha(\omega) \approx \alpha_\infty\left(1 + \frac{\sqrt{\tau_2}}{\sqrt{-i\omega\tau_1}}\right), \quad C(\omega) \approx 1 + \frac{(\gamma-1)\sqrt{T_2}}{\sqrt{-i\omega T_1}}.$$

In this regime pulse duration is assumed to be much shorter than τ_2, T_1, and T_2. The convolution integral $I_0(t)$ in Eq. (8) can be simplified assuming that $V/\tau_2 \ll \partial_t V$ and that

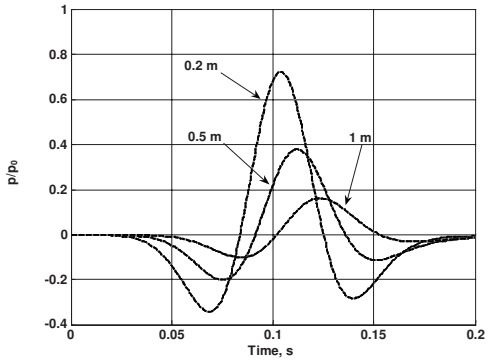

FIG. 1. Long pulse propagation in the packing of spheres. Solid line—equivalent fluid model (8) and (9), dotted line—low frequency approximation (11) and (14), and dashed line—relaxation model (Ref. 8) with relaxation times defined by Eq. (17).

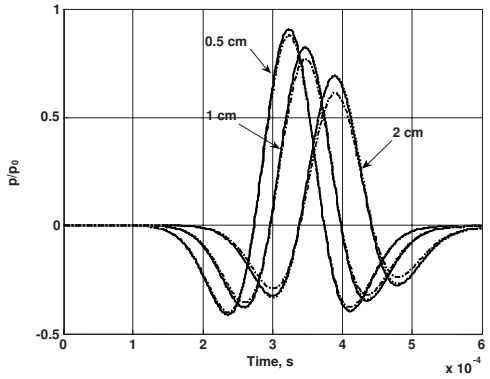

FIG. 2. Propagation of the short pulse in the packing of spheres. Solid line — equivalent fluid model (8) and (9), doted line—high frequency approximation (15) and (16), dash-dotted line—relaxational model (Ref. 8) with relaxation times defined by Eq. (18).

$\exp(-(t-t')/\tau_2)$ varies much slower than $\partial_{t'}V(t')/\sqrt{t-t'}$. Consequently, in the transient regime, the momentum conservation equation takes the following form:

$$\rho_0\alpha_\infty\partial_t V + \frac{\rho_0\alpha_\infty}{\tau_1}\sqrt{\frac{\tau_2}{\pi}}\int_{-\infty}^{t}\frac{\partial_{t'}V(t')}{\sqrt{t-t'}}dt' = -\partial_x P. \tag{15}$$

The first integral $I_1(t)$ of the continuity equation (9) can be simplified as

$$I_1(t) \approx \frac{\gamma-1}{T_1}\sqrt{\frac{T_2}{\pi}}\int_{-\infty}^{t}\frac{\partial_{t'}P(t')}{\sqrt{t-t'}}dt'.$$

The sum of other two integrals is approximated as:

$$I_2(t) + I_3(t) \approx -\frac{(\gamma-1)T_2}{T_1^2}\int_{-\infty}^{t}\partial_{t'}P(t')dt'.$$

In the transient regime it is much smaller than integral $I_1(t)$ and the continuity equation is reduced to the following:

$$\partial_t P + \frac{\gamma-1}{T_1}\sqrt{\frac{T_2}{\pi}}\int_{-\infty}^{t}\frac{\partial_{t'}P(t')}{\sqrt{t-t'}}dt' = -\rho_0 c^2\partial_x V. \tag{16}$$

It can easily be seen now that Eqs. (15) and (16) are exactly the same as Eqs. (25) and (26) of Ref. 5 formulated for the transient regime.

III. NUMERICAL RESULTS

Numerical simulations were performed in order to compare predictions given by different models. The numerical scheme adopted was the forward time centered space scheme.

The convolution integrals present in the equations were computed applying the procedure proposed elsewhere.[9] It is based on the assumption that if equations are discretized using a very short time step, then the functions of pressure and velocity in the convolution integrals can be considered constant during each step. This procedure considerably reduces the computational cost of the simulations.

It is assumed that the acoustic source produces a pulse defined by the following function:

$$f(t) = (1-\omega_0^2(t-t_0)^2)\exp\left(-\frac{\omega_0^2(t-t_0)^2}{2}\right).$$

known as a "Mexican hat."

The pulse is considered as "short" if its central frequency f_0 is at least five times higher than the critical frequency of the material $f_c = 1/2\pi\tau_2$ and "long" if its central frequency is at least one-fifth of the critical frequency. Between these limits the pulse is defined as being of "medium duration." Pulse parameters and are given in Table I.

The simulations have been performed for the packing of identical spherical particles with radius 0.5 mm and packing porosity equal to 0.36 (f_c=868.3 Hz); and gravel with maximum particle dimension 9.02 mm (f_c=10.6 Hz). Viscous parameters of the spherical packing (σ_0=27888 Pa s/m^2, α_∞=1.89, Λ=0.134 mm) have been obtained using the cell model,[12] while those of the gravel have been found in literature.[13] Thermal parameters were obtained using relationship valid for spherical packings.[14] In computations the samples have always been considered infinitely long. Pulses at different locations inside the material have been computed using time domain equivalent fluid model defined by Eqs. (8) and (9), low frequency/long pulse approximations (11) and

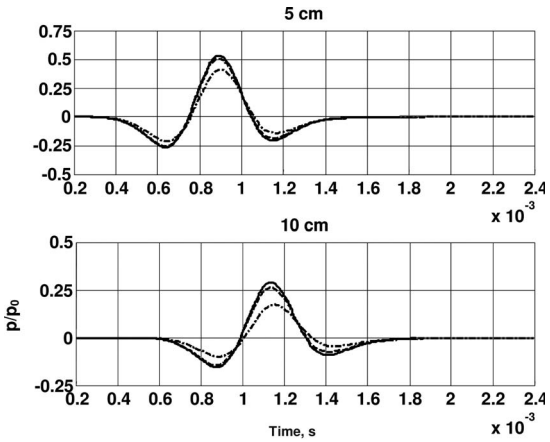

FIG. 3. Propagation of the medium duration pulse in the packing of spheres. Solid line—equivalent fluid model (8) and (9), dashed line—relaxational model (Ref. 8) with relaxation times given by Eq. (17), and dash-dotted line—relaxational model with relaxation times given by Eq. (18).

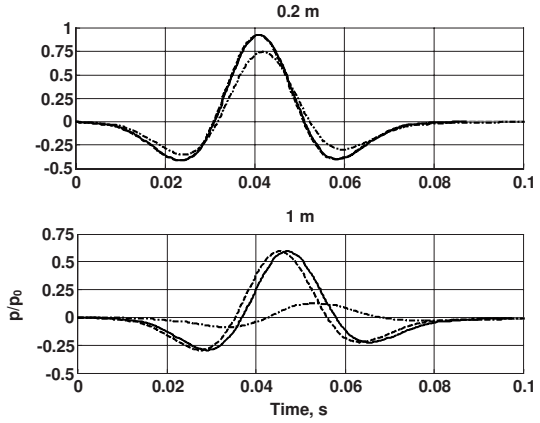

FIG. 4. Propagation of the medium duration pulse in gravel. Legend as in Fig. 3.

(14), high frequency/short pulse approximations (15) and (16), and relaxational model.[8] In the latter two sets of relaxation times have been used:

$$\tau_\nu = \frac{2\rho_0\alpha_\infty}{\phi\sigma_0} \text{ and } \tau_e = \frac{2N_{\mathrm{Pr}}k'\rho_0}{\phi\eta}, \tag{17}$$

which satisfy physically correct low frequency limits of complex density and complex compressibility functions,[1–3] and

$$\tau_\nu = \frac{\Lambda^2\rho_0}{4\eta} \text{ and } \tau_e = \frac{N_{\mathrm{Pr}}\Lambda'^2\rho_0}{4\eta}, \tag{18}$$

which satisfy those limits formulated for high frequencies.

The propagation of the long pulse in the packing of spheres is illustrated in Fig. 1 where its shape at three different distances from the source is shown. The equivalent fluid model predictions are very close to those of its low frequency limit and the relaxational model at all locations.

As shown in Fig. 2, the equivalent fluid model is close to its high frequency limit, whereas the relaxational model diverges slightly as the distance from the source increases.

For the medium duration pulse the comparisons between equivalent fluid model and the relaxational model predictions have been performed. In this range the values of the relaxation times have to be considered as adjustable parameters.[7] However, here we use two pairs defined by Eqs. (17) and (18) instead. It can be noted from Fig. 3, that in the packing of spheres the relaxational model with relaxation times defined by Eq. (17) remains close to the equivalent fluid model even when pulse central frequency is close to f_c. A higher discrepancy was found between the models for a pulse propagating in gravel (Fig. 4). This is due to the fact that the shape factor values for this material, $M=10.03$ and $M'=6.03$, are high and consequently pairs of the relaxation times (17) and (18) are more sharply tuned to satisfy low and high frequency limits. In spherical packing the shape factor values, $M=1.57$ and $M'=1.12$, are both close to unity.

The equations for the low frequency limit of the equivalent fluid model are obviously the fastest to solve, as they do not involve any convolutions. The amount of computational time required for the equivalent fluid model is comparable to other models.

IV. CONCLUSIONS

It has been shown that the equivalent fluid, model allows analytical formulation in the time domain. The derived set of equations can be applied to acoustical pulses without any limitations on their duration provided that wavelength exceeds pore/inclusion size. For the pulses with medium duration numerical solutions are relatively close to those of the time domain relaxational model for the materials with viscous and thermal shape factors close to unity. For materials with larger shape factor values, the two models give considerably different results.

Prediction of the acoustic field due to a point source over a porous layer (L)

Jean F. Allard
Laboratoire d'Acoustique de l'Université du Maine, Avenue Olivier Messiaen, 72000 Le Mans, France

(Received 28 September 2008; revised 19 January 2009; accepted 22 January 2009)

Comparisons are performed between the results of a simple classic formulation for the acoustic field created by a point source above a porous layer and an exact description. A semi-infinite layer and layers of finite thickness are considered. It is shown that for layers of finite thickness and small flow resistivity the use of the classic formulation can lead to large errors close to grazing incidence.

I. INTRODUCTION

A description of sound propagation from a point source over an impedance plane with a specific impedance Z_s was obtained by Chien and Soroka.[1] Let R_1 be the distance from the image S′ of the source S to the microphone M, R_2 the distance from the source to the microphone, z_1 and z_2 the heights of the source and the microphone, r the radial distance from the source to the microphone, and θ_0 the angle of specular reflection. Like in Ref. 1 the angle of specular reflection is the angle between the normal to the plane and S′M. It cannot be initially defined as an angle of incidence because an angle of incidence is related to a plane wave and a point source can be considered as a superposition of plane waves in different directions. The total pressure p_z is the sum of the direct pressure and the reflected pressure p_r,

$$p_z = \frac{\exp(ik_0R_2)}{R_2} + p_r,$$

$$p_r = [V(\theta_0) + (1 - V(\theta_0))F(w)]\frac{\exp(ik_0R_1)}{R_1}, \tag{1}$$

$$F(w) = 1 + i\sqrt{\pi}w\exp(w^2)\mathrm{erfc}(-w), \tag{2}$$

$$w = i\left(\tfrac{1}{2}ik_0R_1\right)^{1/2}[\cos\theta_0 + Z_0/Z_s]. \tag{3}$$

In these equations k_0 is the wave number in the free air and V is the reflection coefficient given by

$$V(\theta) = \frac{Z_s - Z_0/\cos\theta}{Z_s + Z_0/\cos\theta}, \tag{4}$$

where Z_0 is the characteristic impedance of the free air and θ is the classical angle of incidence for a plane wave which is equal to θ_0 in Eqs. (1) and (3). This description is an approximation valid under several conditions,

$$k_0R_1 \gg 1, \tag{5}$$

$$\cos\theta_0 \ll 1,$$

$$Z_0/|Z_s| \ll 1. \tag{6}$$

A description similar to the one of Chien and Soroka[1] was obtained under the same conditions with the pole subtraction method by Brekhovskikh and Godin[2] [see Eq. (1.4.10) of Ref. 2]. Like in Ref. 1, the description of the reflected field is based on the presence of a pole of the reflection coefficient at an angle of incidence θ_p given by

$$\cos\theta_p = -Z_0/Z_s. \tag{7}$$

In the square brackets of Eq. (3) $\cos\theta_0 + Z_0/Z_s$ can be replaced by $\cos\theta_0 - \cos\theta_p$. In Refs. 1 and 2 an important parameter that characterizes the reflection of the spherical field close to grazing incidence is the numerical distance w that depends on the distance from θ_p to θ_0 via $\cos\theta_0 - \cos\theta_p$.

The impedance Z_s does not depend on the angle of incidence, whereas the surface impedance of a porous layer of small flow resistivity can noticeably depend on the angle of incidence. The formulation by Chien and Soroka[1] was modified to account for the extended reaction of porous layers by Nicolas *et al.*[3] and Li *et al.*[4] In the modified formulation the constant impedance Z_s is replaced in Eqs. (3) and (4) by the impedance $Z_s(\theta_0)$ of the layer at an angle of incidence equal to θ_0. The surface impedance at an angle of incidence θ for a porous layer of finite thickness having a motionless frame is given by

$$Z_s(\theta) = \frac{iZ_1}{\phi\cos\theta_1}\cot(k_1l\cos\theta_1), \tag{8}$$

which becomes for a semi-infinite layer $Z_s(\theta) = Z_1/(\phi\cos\theta_1)$. In these expressions ϕ is the porosity, k_1 is the wave number, Z_1 is the characteristic impedance for the waves which propagate in the saturating air in the porous medium, and θ_1 is the complex refraction angle given by

$$\sin\theta_1 = \frac{k_0}{k_1}\sin\theta. \tag{9}$$

There is no rigorous theoretical justification of the modified formulation. Moreover the initial formulation is valid under many restrictive conditions. An exact integral expression of the reflected spherical field which is always valid when the source and the microphone are located above the porous layer can be obtained with the Sommerfeld representation[2] of the sound field. The exact reflected field can be written as

TABLE I. Parameters for the porous media.

Medium	1	2	3
Porosity ϕ	0.98	0.98	0.3
Flow resistivity σ (N m^{-4} s)	10 000	30 000	2000
Thermal permeability k_0' (m^2)	1.84×10^{-19}	6.1×10^{-10}	9.2×10^{-9}
Viscous dimension Λ (μm)	120	70	700
Thermal dimension Λ' (μm)	360	210	2100
Tortuosity α_∞	1.1	1.1	2

$$p_r = i\int_0^\infty \xi d\xi \frac{V(\varphi)}{\mu} J_0(r\xi)\exp[i\mu(z_1+z_2)], \tag{10}$$

where $\mu=\sqrt{k_0^2-\xi^2}$, $\mathrm{Im}\,\mu\geqslant 0$, and φ is defined by $\cos\varphi=\mu/k_0$. The exact pressure field p_e is obtained by adding $\exp(ik_0R_2)/R_2$ to the exact reflected field. The singularity at $\mu=0$ can be removed by using μ instead of ξ as a variable of integration. For $\xi\gg 1$, $i\mu(z_1+z_2)$ is large and negative and beyond a finite value of ξ the contribution to the integral in Eq. (10) is negligible. The evaluation of the integral is easier for small r because the variations in $J_0(r\xi)$ as a function of ξ are slower, and for large z_1+z_2, because $\exp[i\mu(z_1+z_2)]$ decreases faster when μ is imaginary. The precision in the calculation of the integral can be evaluated for a given geometry by setting $V=1$ and comparing the result to $\exp(ik_0R_1)/R_1$. For instance, for a radial distances smaller than 10 m and z_1+z_2 larger than 4 cm, the trapezoidal method can be used to evaluate the integral, and for $r<0.5$ m the trapezoidal method can be used for $z_1+z_2\lessapprox 1$ cm. The modified formulation with p_r obtained by Eqs. (1)–(4) where Z_s is replaced by $Z_s(\theta_0)$ is currently used in long range sound propagation and to evaluate surface impedance and acoustical parameters of porous layers but as far as we know, there is no detailed evaluation of its reliability for thin layers with a small flow resistivity. Comparisons between predictions obtained with the exact integral expression for p_r and the modified formulation are performed for several media, foams with different low resistivities, and a porous pavement. A limitation concerning the use of the modified formulation is shown in the medium frequency range. Previous works are used to explain the good agreement between the modified formulation and the exact integral expression in the low and the high frequency range.

II. PRESSURE PREDICTIONS FOR NON-LOCALLY REACTING MEDIA

Three non-locally reacting media are considered, two materials with a porosity and a tortuosity close to 1, one similar to a foam with a low flow resistivity (medium 1) and the other similar to a foam with a larger flow resistivity (medium 2), and a material with a large tortuosity and a small porosity similar to a porous pavement (medium 3). The acoustical parameters of the media are given in Table I. The models used for the effective density and the bulk modulus of the air in the porous media are described in Ref. 5. The use of different models would lead to similar conclusions. The ratio p_z/p_e of the total pressure p_z predicted with the modified formulation [Eqs. (1)–(4)] with the constant impedance Z_s replaced by $Z_s(\theta_0)$ and the exact pressure p_e predicted with Eq. (10) is represented in Fig. 1 for medium 1 and medium 2. The thickness of the layer is $l=4$ cm. The geometry is defined by $z_1=z_2=0.025$ m and $r=1$ m. The angle of specular reflection $\theta_0=1.52$ rad is close to $\pi/2$. For both media, a good precision is obtained in the low and the high frequency range with the modified formulation. The precision is very poor in the medium frequency range for medium 1, but noticeably increases for medium 2 which has a higher flow resistivity because the dependence of the surface impedance on the angle of incidence decreases when the flow resistivity increases. The good precision in the low frequency range is due to the fact that when the thickness of the layer is small compared to the wavelength in the medium, $|k_1|l\ll 1$, a pole exists at θ_p close to $\pi/2$, the other poles are located far from the real sin θ axis and do not contribute to the reflected field. This pole is called the main pole.[6,7] The poles correspond to a 0 of the denominator of the reflection coefficient and $\cos\theta_p=-Z_0/Z_s(\theta_p)$. It has been shown[6,7] that the modified Chien and Soroka[1] formulation can be used to predict the reflected field with one change in the modified equation (3) where $Z_0/Z_s(\theta_0)$ must be replaced by $-\cos\theta_p=Z_0/Z_s(\theta_p)$. Then the change consists in replacing in the modified formulation $Z_0/Z_s(\theta_0)$ by $Z_0/Z_s(\theta_p)$ in the square brackets. In Fig. 2, $-Z_0/Z_s(\theta_0)$ and $-Z_0/Z_s(\theta_p)$ are represented as a function of frequency for the same layer of medium 1 and the same geometry. Both quantities are close to each other at low frequencies and the modification does not lead to noticeable variations in the predicted pressure. At high frequencies when $|k_1l|\geqslant 1$, the pole subtraction method cannot be used because there is no dominant pole close to $\pi/2$ but the passage path method can be used. The good agreement between p_z and p_e can be explained by using the evaluation of the reflected pressure with the passage path method. It has been shown by Brekhovskikh and Godin[2] that the reflected pressure p_r predicted with this method can be written under the condition of arbitrary dependence of the reflection coefficient on θ and for a product radial distance $\times$ wave number in air $k_0r\gg 1$ [see Eq. (1.2.9) of Ref. 2],

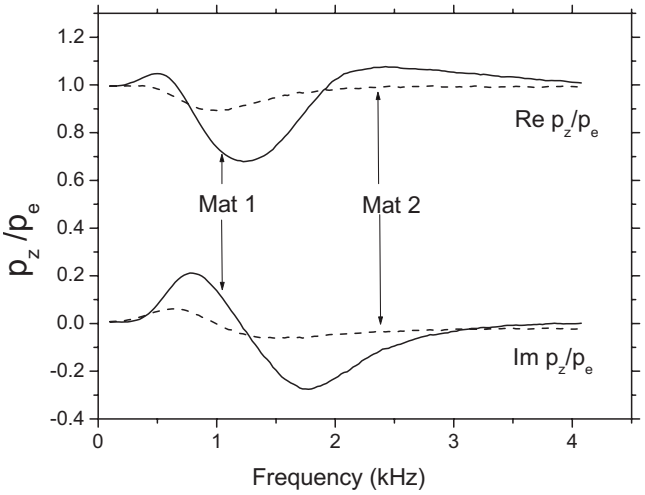

FIG. 1. Ratio p_z/p_e for layers of thickness $l=4$ cm of medium 1 — and medium 2 - - -, p_z pressure predicted with the modified formulation, p_e exact pressure. Geometry: $z_1=z_2=0.025$ m and $r=1$ m.

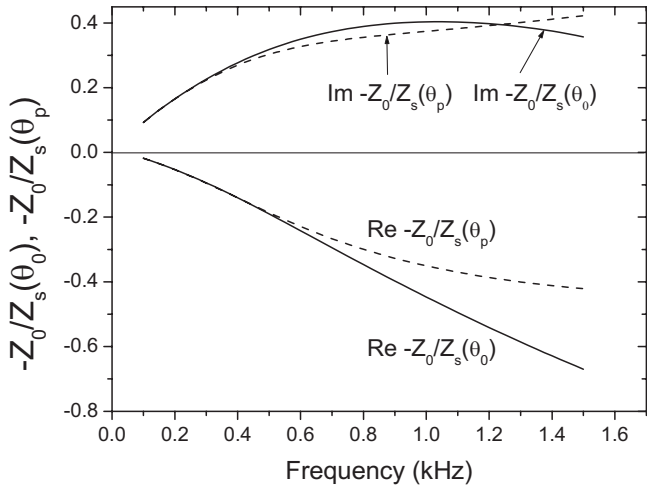

FIG. 2. Comparison between $\cos\theta_p = -Z_s(\theta_p)/Z_0$ for the main pole and $-Z_s(\theta_p)/Z_0$ for the same geometry and the same layer of medium 1 as in Fig. 1.

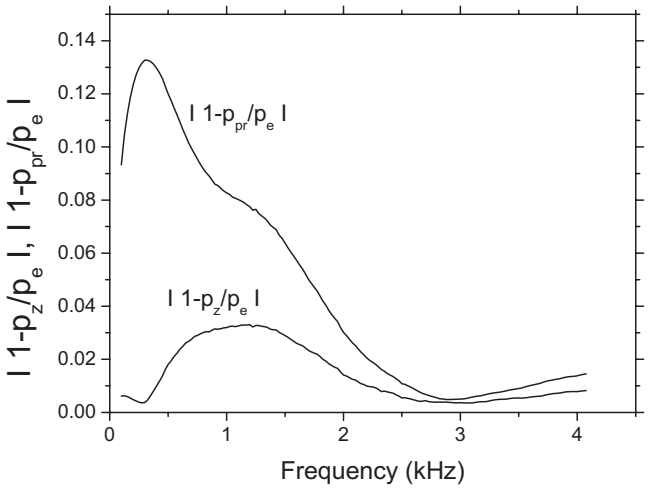

FIG. 3. $|1-p_z/p_e|$ compared to $|1-p_{pr}/p_e|$, p_{pr} pressure predicted with Eq. (14), p_z pressure predicted with the modified formulation, p_e exact pressure. Geometry: $z_1=0.025$ m, $z_2=0.6$ m, and $r=1$ m. Layer of thickness $l=4$ cm of medium 1.

$$p_r = \frac{\exp(ik_0,R_1)}{R_1}\left[V(\theta_0) - \frac{iN}{k_0R_1}\right],$$

$$N = \frac{1}{2}\left[(1-\sin^2\theta)\frac{\partial^2 V}{\partial(\sin\theta)^2} + \frac{1-2\sin^2\theta}{2\sin\theta}\frac{\partial V}{\partial\sin\theta}\right]_{\theta\to\theta_0}. \quad (11)$$

The coefficient N has been calculated by Allard *et al.*[8] for a porous layer of finite thickness [see Eqs. (A.10) and (A.11) of Ref. 8]. At the zero order approximation in θ_0, N is given by

$$N = -2\left(\frac{Z_s(\theta_0)}{Z_0}\right)^2. \quad (12)$$

Using in Eq. (1) of the modified formulation the asymptotic value $1/(2w^2)$ for $F(w)$ and replacing close to grazing incidence $(1-V)$ by -2, Eq. (1) gives the same expression for p_r as Eqs. (11) and (12),

$$p_r = \frac{\exp(ik_0R_1)}{R_1}\left[V(\theta_0) + \frac{2i(Z_s(\theta_0)/Z_0)^2}{k_0R_1}\right]. \quad (13)$$

For a smaller angle of incidence $|1-p_z/p_e|$ is presented in Fig. 3 as a function of frequency for a layer of thickness $l=4$ cm. The new geometry is defined by a radial distance $r=1$ m, $z_1=0.025$ m, and $z_2=0.6$ m. The contribution of the added term $(1-V(\theta_0))F(w)$ to the plane wave reflection coefficient $V(\theta_0)$ is now less important. Let p_{pr} be the predicted pressure obtained by removing the added term

$$p_{pr} = \frac{\exp(ik_0R_2)}{R_2} + V(\theta_0)\frac{\exp(ik_0R_1)}{R_1}. \quad (14)$$

The quantity $|1-p_{pr}/p_e|$ is also presented in Fig. 3. A good approximation for the exact pressure is obtained with p_{pr} but in the low frequency range p_z is much closer to p_e. One reason is the fact that at sufficiently low frequencies the porous medium tends to become locally reacting because $|k_1/k_0|$ increases when frequency decreases. Then the replacement of $Z_0/Z_s(\theta_0)$ by $Z_0/Z_s(\theta_p)$ in the square brackets of Eq. (3) has a negligible effect because $Z_s(\theta_0)$ and $Z_s(\theta_p)$ are close to each other even if $\cos\theta_p$ and $\cos\theta_0$ are noticeably different. For instance, $\cos\theta_0=0.614$ and at 0.5 kHz $\cos\theta_p=-Z_0/Z_s(\theta_p)=-0.186+i0.303$, and $-Z_0/Z_s(\theta_0)=-0.157+i0.350$. The second reason is that the condition $\cos\theta_0 \ll 1$ in Eq. (6) is not drastic.

Pressure variation for two heights of the receiver as a function of frequency above a porous layer is used to evaluate the surface impedance or the acoustic parameters of the medium. For a layer of thickness $l=4$ cm of medium 3 the ratio of the pressure p' for $z_1=0.025$ m, $z_2=0.6$ m, and $r=1$ m over p for $z_1=z_2=0.025$ m and $r=1$ m is presented in Fig. 4. The true ratio p'_e/p_e is compared with the predicted ratio p'_z/p_z obtained with the modified formulation. Large differences between both ratios appear in the medium frequency range, which can lead to noticeable errors in the evaluation of the acoustical parameters for this medium of low flow resistivity.

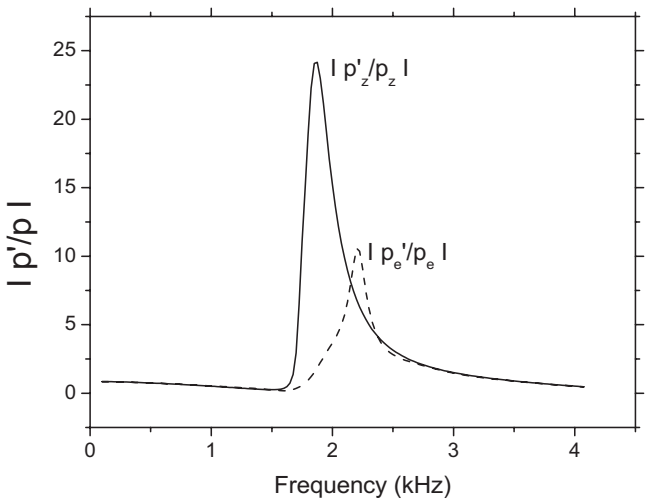

FIG. 4. Modulus of the exact ratio of pressures p'_e at $z_2=0.6$ m and p_e at $z_2=0.025$ m - - -, modulus of the ratio of the predicted pressures with the modified formulation p'_z and p_z —. For both heights of the receiver, $z_1=0.025$ m and $r=1$ m. Layer of thickness $l=4$ cm of medium 3.

TABLE II. Max $|1-p_z/p_e|$ as function of thickness for a layer of medium 1, $z_1=z_2=0.025$ m and $r=1$ m.

Thickness (cm)	2	4	8	∞
Max $\|1-p_z/p_e\|$	0.43	0.33	0.22	0.11
Frequency (kHz)	3.1	1.35	0.65	0.75

A first conclusion after these modelizations is that for thin sound absorbing porous materials having a flow resistivity smaller than 30 000 N m^{-4} s the modified formulation can lead to significant errors in the prediction of the pressure close to grazing incidence. In a second step the dependence on the thickness of the reliability of the modified formulation has been precised in the following way. For medium 1 the maximum of $|1-p_z/p_e|$ as a function of frequency is given in Table II for different thicknesses from 2 cm to infinity for $z_1=z_2=0.025$ m and $r=1$ m. The maximum error increases when the thickness decreases and the maximum reaches the high frequency range. The modified formulation is more reliable for semi-infinite layers. This is due to the fact that like for the case of a plane impedance there is only one pole of the reflection coefficient located at θ_p given by

$$\cos\theta_p=\left(\frac{n^2-1}{(\rho_1/\rho_0\phi)^2-1}\right)^{1/2},$$

$$\mathrm{Re}\cos\theta_p<0, \tag{15}$$

where ρ_0 is the density of air, ρ_1 is the effective density in the porous medium, and $n=k_1/k_0$. Moreover the variations in the surface impedance as a function of the angle of incidence are smaller for a semi-infinite layer than for a layer of finite thickness made of the same porous medium. As indicated previously, the accuracy of the modified formulation increases when the dependence decreases. The expression of the reflected spherical field obtained by Brekhovskikh and Godin[2] at the interface between two semi-infinite fluids [Eq. (1-4-4)] can be used for a semi-infinite porous layer, the density ratio m being replaced by $\rho_1/(\rho_0\phi)$. It can be shown that if the conditions (6) are fulfilled, Eq. (1-4-4) of Ref. 2 leads to the same system of equations as for a thin porous layer, the surface impedance being now given by $Z_s(\theta)=Z_1/(\phi\cos\theta_1)$ and the pole location by Eq. (15).

III. CONCLUSION

Predictions of the reflected spherical point source field obtained from the description by Chien and Soroka[1] modified to account for the non-locally reacting behavior of porous layers, and obtained from an exact model, have been compared. The modified formulation can provide reliable predictions for media with a sufficiently large flow resistivity, but the predictions can present large errors in the medium frequency range for thin layers made of media with a small flow resistivity. For these materials, for small radial distances from the source to the receiver, the modified description should be replaced by the exact description obtained from the Sommerfeld representation.

The full-wave computation of transient acoustic fields with sizes in the order of $100\times100\times100$ wavelengths by 100 periods requires a numerical method that is extremely efficient in terms of storage and computation. Iterative integral equation methods offer a good performance on these points, provided that the recurring spatiotemporal convolutions are computed with a coarse sampling and relatively few computational operations. This paper describes a method for the numerical evaluation of very large-scale, four-dimensional convolutions that employs a fast Fourier transformation and that uses a sampling rate close to or at the limit of two points per wavelength and per period. To achieve this, the functions involved are systematically filtered, windowed, and zero-padded with respect to all relevant coordinates prior to sampling. The method is developed in the context of the Neumann iterative solution of the acoustic contrast source problem for an inhomogeneous medium. The implementation of the method on a parallel computer is discussed. The obtained numerical results have a relative root mean square error of a few percent when sampling at two points per wavelength and per period. Further, the results prove that the method enables the computation of transient fields in the order of the indicated size.

I. INTRODUCTION

The computation of transient acoustic wave fields over very large spatiotemporal domains with inhomogeneous, dispersive, and nonlinear media plays an increasingly important role in the development and operation of novel acoustical applications and devices. For instance, consider the realization of an inverse scattering method for the accurate characterization of biomedical tissue using pulsed ultrasound data. The basis of this inverse method will be a full-wave, forward method that is repeatedly invoked for the computation of a transient acoustic pressure field in the inhomogeneous medium under reconstruction. In case of human organs and ultrasound frequencies, the forward computations may easily involve a domain that measures 100 wavelengths in three spatial directions by 100 periods in time. These forward computations provide a typical example of the kind and size of problems that have motivated the research reported in this paper.

Even with today's parallel computers, the numerical solution of full-wave, forward problems of the abovementioned size is only practically feasible if the applied numerical method is extremely efficient in terms of storage and computation. The largest classes of methods for the numerical solution of forward wave problems are finite difference methods, finite element methods, and integral equation methods. As is motivated below, in this paper iterative integral equation methods are selected for dealing with very large-scale, full-wave, forward problems. A variety of iterative methods exist for solving integral equations,[1–4] e.g., the Neumann iterative solution, over-relaxation methods, and conjugate gradient methods. All these methods aim to provide a sequence of increasingly accurate, global approximations to the wave field, and use convolutions over three-dimensional space and time to obtain these. In practice, the convolutions must be performed numerically, which requires the discretization of the computational domain with respect to its space and time coordinates. This paper describes a method for the numerical evaluation of convolutions over very large spatiotemporal domains. The discussion is limited to equidistant sampling and rectangular grids, and the symbol D_φ is used to indicate the number of grid points per wavelength and per period of a particular field component with temporal (angular) frequency φ. In this respect, the most relevant quantity is D_Φ, where Φ is the chosen maximum temporal angular frequency of interest.

With regard to storage, iterative integral equation methods require that one or more scalar field quantities should be available over the full spatiotemporal grid for further iteration. Since the total amount of grid points in the computational domain is proportional to D_Φ^4, it is paramount to make D_Φ as small as possible to avoid excessive memory requirements. However, the minimum value of D_Φ is dictated by the desired accuracy of the computations. The most memory-demanding operations in an iterative integral equation method are recurring convolutions of functions that depend on the stored iterates and kernel functions that are known in advance, e.g., the Green's function of a background medium. These convolutions involve the entire computational domain. As a consequence of the Nyquist–Shannon sampling theorem,[5] the sampling may in principle be as coarse as $D_\Phi=2$ to yield exact convolutional results at the grid points,

[a]Electronic mail: m.d.verweij@tudelft.nl

 0001-4966/2009/125(4)/1868/11/$25.00

provided that components with an angular frequency above Φ are absent. For the typical example presented above, sampling at the limit $D_\Phi=2$ results in a grid of 1.6×10^9 points, and a parallel implementation of the chosen method demands a memory size in the order of 100 Gbytes. With modern, high-performance computing facilities, this is very well feasible.

From a computational point of view, the numerical convolutions may benefit from using the Fast Fourier Transformation (FFT).[6] For a convolution involving N sample points, this requires only order $N\log(N)$ operations instead of order N^2 operations for a straightforward quadrature rule. In view of this and the fact that N can be kept low by sampling close to or at the limit $D_\Phi=2$, it may be concluded that iterative integral equation methods combine a minimal storage requirement with a strongly reduced computational effort.

For comparison it is noted that standard finite difference or finite element methods use relatively simple, local functions to approximate the wave field and need at least a grid with $D_\Phi=10$ to yield accurate results.[7,8] As a consequence, for the same computational domain these methods need much more storage than an iterative integral equation method. This becomes evident when realizing that the typical example mentioned above now requires 10^{12} grid points.

Although many authors[9–12] employ FFT's for the numerical evaluation of convolutions, this is rarely accompanied by a minimization of the number of grid points. Presumably, this has to do with the fact that a coarse sampling requires special preparations, and for most applications storage is not so much of a bottleneck as computation. Since this paper deals with very large-scale wave problems, the sampling issue is at least as relevant as the application of FFT's. Therefore, this paper focuses on the development of a method for the numerical evaluation of very large-scale, four-dimensional convolutions that is based on FFT's and that uses a sampling rate close to or at the limit $D_\Phi=2$. Since filtering forms the basis of achieving the coarse sampling, this method is referred to as the filtered convolution method. The filtered convolution method is generic because it is applicable in all numerical methods that employ convolutions.

The approach to obtain a coarse sampling is to select a temporal angular cutoff frequency $\Omega\geq\Phi$ and a corresponding spatial angular cutoff frequency K, and to apply ideal filters to remove all higher temporal and spatial frequencies from the quantities to be sampled. This enables temporal and spatial samplings with $D_\Omega=2$, without the occurrence of aliasing. In addition, ideal windows are used to truncate the domain of the quantities, and zero-padding is employed. These steps are necessary to avoid wraparound due to the circular nature of the FFT-based numerical convolution.[6] The use of FFT's implies that the sampling occurs in both the original $\boldsymbol{x},t$ domain and in the transformed $\boldsymbol{k},\omega$ domain, and therefore the filtering and the windowing must in principle be performed in both domains. However, ideal filtering and ideal windowing are dual operations under the Fourier transformation, so a particular operation in one domain is automatically performed when its counterpart is performed in the other domain.

Central in this paper is a systematic explanation of the method that leads to a memory efficient and computationally fast numerical convolution. To describe this in a context, the contrast source formulation of the forward acoustic wave problem is introduced, and the Neumann iterative solution is employed to solve it. The authors are aware that other iterative integral equation methods may be more suitable for solving the problem at hand. However, selection of the best iterative method is not the issue of this paper, and the Neumann iterative solution has been chosen because it provides the most straightforward application of the filtered convolution method.

II. PROBLEM FORMULATION

A. Contrast source problem

The filtered convolution method is developed in the context of solving the system of first-order acoustic equations:

$$\boldsymbol{\nabla}p+\rho_0\partial_t\boldsymbol{v}=\boldsymbol{f}_p+\boldsymbol{f}_c(p,\boldsymbol{v}), \tag{1}$$

$$\boldsymbol{\nabla}\cdot\boldsymbol{v}+\kappa_0\partial_t p=q_p+q_c(p,\boldsymbol{v}), \tag{2}$$

in which p is the acoustic pressure and $\boldsymbol{v}$ is the particle velocity. This so-called contrast source formulation[13,14] is particularly useful for problems involving a medium with a localized inhomogeneous, anisotropic, dispersive, or nonlinear behavior. Outside the localized region, the medium behaves like a homogeneous, isotropic, dispersionless, and linear background medium with a mass density ρ_0 and a compressibility κ_0. The difference between the mass density of the actual medium and the background medium is accounted for by the contrast source density of force $\boldsymbol{f}_c(p,\boldsymbol{v})$, and the difference between the actual compressibility and the background compressibility is covered by the contrast source density of injection rate $q_c(p,\boldsymbol{v})$. The primary source that generates the acoustic wave field is represented by the volume density of force $\boldsymbol{f}_p$ and the volume density of injection rate q_p.

In many cases, combination of Eqs. (1) and (2) leads to a complete elimination of $\boldsymbol{v}$ and results in an acoustic wave equation

$$c_0^{-2}\partial_t^2 p-\boldsymbol{\nabla}^2 p=S_p+S_c(p). \tag{3}$$

Here, $c_0=(\rho_0\kappa_0)^{-1/2}$ is the wave speed of the background medium, and $S_p=\rho_0\partial_t q_p-\boldsymbol{\nabla}\cdot\boldsymbol{f}_p$ represents the primary source. The contrast source $S_c(p)$ now accounts for all differences between the actual medium and the background medium. Examples of contrast sources are

$$S_{c,\mathrm{inh}}(p)=[c_0^{-2}-c^{-2}(\boldsymbol{x})]\partial_t^2 p-\boldsymbol{\nabla}\ln[\rho(\boldsymbol{x})]\cdot\boldsymbol{\nabla}p, \tag{4}$$

$$S_{c,\mathrm{dis}}(p)=[c_0^{-2}\delta(t)-\rho(t)*_t\kappa(t)]*_t\partial_t^2 p, \tag{5}$$

$$S_{c,\mathrm{nl}}(p)=\frac{\beta}{\rho_0 c_0^4}\partial_t^2 p^2, \tag{6}$$

which, respectively, apply to an inhomogeneous medium with spatially varying $c(\boldsymbol{x})$ and $\rho(\boldsymbol{x})$, an attenuative and dispersive medium with relaxation functions $\rho(t)$ and $\kappa(t)$, and a

nonlinear medium with a coefficient of nonlinearity β. The symbol $*_t$ denotes a temporal convolution.

For the background medium, the Green's functions of the first-order acoustic equations and the acoustic wave equation are available in closed form.[15] This enables a solution of the corresponding contrast source problems by an iterative integral equation method, as shown next.

B. Neumann iterative solution

Knowing the Green's function G of the wave equation for the background medium, Eq. (3) may be recast into the integral equation[16,17]

$$p = G*_{\boldsymbol{x},t}[S_p + S_c(p)] = \mathcal{L}[S_p + S_c(p)]. \tag{7}$$

Here, the symbol $*_{\boldsymbol{x},t}$ denotes a convolution over the entire spatiotemporal computational domain, and it is assumed that the support of the primary and contrast source is located entirely within this domain. The convolution with the Green's function forms an integral operator, which is indicated by the symbol $\mathcal{L}$. Now it is supposed that the influence of the contrast source on the total field is relatively weak, i.e., that $\delta p = \mathcal{L}[S_c(p)]$ is small in comparison to $p^{(0)} = \mathcal{L}[S_p]$. Then successive approximations $p^{(j)}$ $(j=0,1,2,\ldots)$ to p may be generated by the Neumann iterative solution[3,4,18]

$$p^{(0)} = \mathcal{L}[S^{(0)}], \quad S^{(0)} = S_p, \tag{8}$$

$$p^{(j)} = p^{(0)} + \mathcal{L}[S^{(j)}], \quad S^{(j)} = S_c(p^{(j-1)}), \quad j \geq 1. \tag{9}$$

To get $\mathcal{L}[S^{(j)}] = \mathcal{L}[S^{(j)}](\boldsymbol{x},t) = \delta p^{(j)}(\boldsymbol{x},t)$, it is necessary to evaluate the four-dimensional convolution integral

$$\mathcal{L}[S^{(j)}](\boldsymbol{x},t) = \int_{\mathcal{D}_T^{(j)}} \int_{\mathcal{D}_X^{(j)}} G(\boldsymbol{x}-\boldsymbol{x}', t-t') S^{(j)}(\boldsymbol{x}',t') d\boldsymbol{x}' dt'. \tag{10}$$

For $j=0$ the integration is over the four-dimensional support $\mathcal{D}_T^{(0)} \times \mathcal{D}_X^{(0)}$ of the primary source $S^{(0)}$, and for $j \geq 1$ the integration is over the four-dimensional support $\mathcal{D}_T^{(j)} \times \mathcal{D}_X^{(j)}$ of the approximate contrast source $S^{(j)}$.

Even in the simplest cases, the convolution integral in Eq. (10) needs to be discretized and numerically evaluated. As has been discussed in Sec. I, for very large-scale problems it is vital to use a sampling that is as coarse as possible, preferably down to the limit $D_\Phi = 2$. In Secs. III and IV, it will be explained how this limit may be reached in case of a one-dimensional (temporal) convolution integral and in case of the four-dimensional (spatiotemporal) convolution integral in Eq. (10).

III. ACHIEVING $D_\Phi = 2$ IN CASE OF A ONE-DIMENSIONAL CONVOLUTION INTEGRAL

A. Basic Fourier theorems

First, it is convenient to recall two basic properties of an arbitrary function $f(t)$ and its Fourier transform

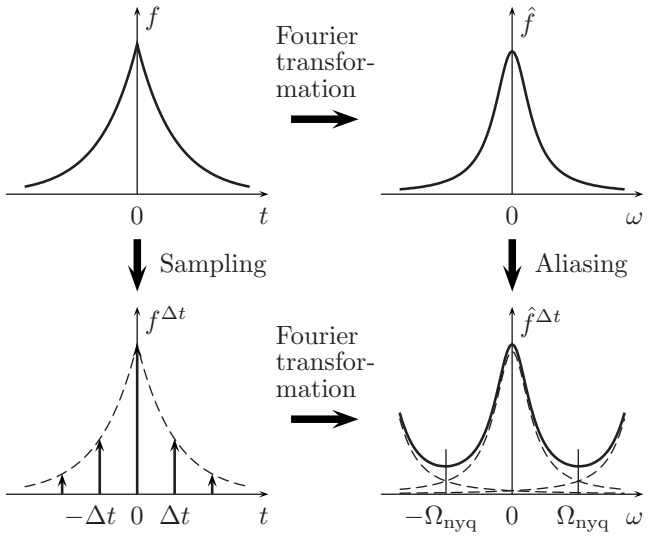

FIG. 1. Illustration of aliasing in the Fourier domain due to the sampling of a function in the original domain.

$$\hat{f}(\omega) = \int_{-\infty}^{\infty} f(t) \exp(-j\omega t) dt. \tag{11}$$

The first property involves the process of equidistant sampling of $f(t)$. If a sampled version of $f(t)$ is represented by

$$f^{\Delta t}(t) = \sum_{n=-\infty}^{\infty} f(n\Delta t)\, \delta\left(\frac{t-n\Delta t}{\Delta t}\right), \tag{12}$$

where Δt is the sampling interval, then the Fourier transform of this function is

$$\hat{f}^{\Delta t}(\omega) = \sum_{m=-\infty}^{\infty} \hat{f}(\omega + m\Omega_{\mathrm{per}}), \tag{13}$$

which is periodic with $\Omega_{\mathrm{per}} = 2\pi/\Delta t$. In the dual case, sampling of $\hat{f}(\omega)$ with a sampling interval $\Delta\omega$ results in a function $f^{\Delta\omega}(t)$ that is periodic with $T_{\mathrm{per}} = 2\pi/\Delta\omega$. If $\hat{f}(\omega)$ is nonzero for $|\omega| > \Omega_{\mathrm{per}}/2$, the terms in Eq. (13) overlap and $\hat{f}^{\Delta t}(\omega) \neq \hat{f}(\omega)$ for $|\omega| < \Omega_{\mathrm{per}}/2$. This is the cause of aliasing and is illustrated in Fig. 1. The quantity $\Omega_{\mathrm{per}}/2 = \pi/\Delta t = \Omega_{\mathrm{nyq}}$ is the angular Nyquist frequency.

The second property involves the restriction of the support of $f(t)$ to an interval $[-T,T]$ according to

$$f^T(t) = f(t)[H(t+T) - H(t-T)], \tag{14}$$

where $H(t)$ is the Heaviside step function and $2T$ is the size of the applied rectangular window. The Fourier transform of this function is

$$\hat{f}^T(\omega) = \frac{T}{\pi} \hat{f}(\omega) *_\omega \mathrm{sinc}(T\omega), \tag{15}$$

in which $\mathrm{sinc}(x) = \sin(x)/x$ is the unnormalized sinc function. In the dual case, restriction of the support of $\hat{f}(\omega)$ to an interval $[-\Omega,\Omega]$ results in a function $f^\Omega(t)$ that is given by

$$f^{\Omega}(t) = \frac{\Omega}{\pi} f(t) *_t \mathrm{sinc}(\Omega t). \tag{16}$$

A finite support in the original domain always leads to an infinite support in the Fourier domain, and vice versa. In this paper, the operations to get $f^T(t)$ or $\hat{f}^T(\omega)$ are referred to as *windowing* and the operations to obtain $f^{\Omega}(t)$ or $\hat{f}^{\Omega}(\omega)$ are referred to as *filtering*.

B. Straightforward discretization of a convolution integral

Second, it is relevant to consider the numerical evaluation of a one-dimensional convolution integral

$$F(t) = G(t) *_t S(t) = \int_{-\infty}^{\infty} G(t-t')S(t')dt'. \tag{17}$$

A straightforward approach is to use the left Riemann sum with a sampling interval Δt and to approximate the convolution integral by the convolution sum[19]

$$F_n = G_n *_n S_n = \Delta t \sum_m G_{n-m} S_m. \tag{18}$$

Here, $G_n = G(n\Delta t)$ and $S_n = S(n\Delta t)$ exactly, but F_n is only an approximation of $F(t)$ at the collocation points $n\Delta t$. The exclusive use of the function values at the collocation points implies that the functions have been sampled. To keep the number of samples finite, both $n-m$ and m must be limited to a finite number, which means the windowing of $G(t)$, $S(t)$, and, consequently, $F(t)$. When the given support of S_n is $[0, N-1]$ and the desired interval of interest of F_n is also $[0, N-1]$, then the support of G_n may be restricted to $[-N+1, N-1]$ without consequences for F_n on the desired interval. For efficiency, the convolution sum is usually evaluated by applying FFT's.[20] Since this implies a circular convolution, wraparound must be avoided *a priori* by supplementing S_n with zero-valued samples S_{-N+1} to S_{-1} (zero-padding).[6] The computational effort of the FFT's thus employed is of order $2N \log(2N)$.[6,19] The remaining approximation error $F_n - F(n\Delta t)$ is due to the sampling and windowing operations. For a typical pulse $S(t)$ with a central angular frequency Ω_0, an accurate evaluation of the components of $F(t)$ up until an angular frequency of interest $\Phi = 2\Omega_0$ may easily require a sampling with $D_\Phi = 10$ or more when no prior measures are taken. This may result in a prohibitively large amount of grid points, especially for convolutions in more dimensions.

C. Coarse discretization of a convolution integral

Now the stage has been set for a discussion of the proposed method for reducing D_Φ while keeping the approximation error under control. The underlying assumption is that a maximum angular frequency of interest Φ can be chosen in such a way that all components of interest in $F(t)$ have an angular frequency $|\omega| \leq \Phi$. This implies that limitation of the spectra of $G(t)$ and $S(t)$ by filtering these functions according to Eq. (16) with an angular cutoff frequency $\Omega \geq \Phi$ only removes insignificant components of $F(t)$. By subsequently taking a sampling interval $\Delta t = \pi/\Omega$, which implies $D_\Phi = 2\pi/\Phi\Delta t = 2\Omega/\Phi$, the situation $\Omega = \Omega_{\mathrm{nyq}}$ is enforced and aliasing is avoided. This means that F_n is obtained as the exact value of $F^{\Omega}(n\Delta t)$, and the approximation error is entirely due to the difference between $F(n\Delta t)$ and $F^{\Omega}(n\Delta t)$, which manifests itself only in the part of the spectrum that is of no interest as long as $D_\Phi \geq 2$. With the proposed method, preference is thus given to discarding the contributions from the frequencies $|\omega| > \Omega$ over making an aliasing error in the frequency range $|\omega| \leq \Omega$.

So far, the approach seems ideal. However, computational reality demands a finite number of samples, and this enforces the windowing of the functions involved. Assuming that the domain of interest ranges from $t=0$ to T, a window with a size $2T$ as given in Eq. (14) is applied to both $G^{\Omega}(t)$ and $S^{\Omega}(t)$. This requires the prior formal extension of the support of $S(t)$ by defining $S(t)=0$ for $-T \leq t < 0$. The given extension corresponds to the zero-padding that is required later on. The application of the window to $G^{\Omega}(t)$ and $S^{\Omega}(t)$, in fact, re-introduces an infinite support of $\hat{G}^{\Omega,T}(\omega)$ and $\hat{S}^{\Omega,T}(\omega)$—the order of the superscripts indicating the order of corresponding operations—that will lead to aliasing. In practice, the associated error is only a fraction of the aliasing error that would occur with a direct sampling of $G(t)$ and $S(t)$.

To summarize, the filtered convolution method for the coarse discretization of a one-dimensional convolution integral involves the following:

(1) Subjecting $G(t)$ and $S(t)$ to an ideal low-pass filter with an angular cutoff frequency $\Omega \geq \Phi$, and to a time window with a size $2T = (2N-1)\pi/\Omega$.
(2) Sampling $G^{\Omega,T}(t)$ and $S^{\Omega,T}(t)$ at $2N$ points with a sampling interval $\Delta t = \pi/\Omega$.
(3) Obtaining the Fourier transforms of G_n and the zero-padded S_n using a $2N$-point FFT.
(4) Multiplying the Fourier transforms and return to the original domain using a $2N$-point inverse FFT.

This yields $F^{\Omega,T}(n\Delta t)$ as an approximation for $F(n\Delta t)$.

Alternatively, if both $\hat{G}(\omega)$ and $\hat{S}(\omega)$ are known, the dual operations may be performed in the transform domain. In this case it is convenient to first perform the windowing. Now the application of the filter to $\hat{G}^T(\omega)$ and $\hat{S}^T(\omega)$ re-introduces an infinite support of $G^{T,\Omega}(t)$ and $S^{T,\Omega}(t)$ that will give rise to time-domain aliasing. Usually, the corresponding error is only a fraction of the time-domain aliasing error that would occur with a direct sampling of $\hat{G}(\omega)$ and $\hat{S}(\omega)$.

IV. ACHIEVING $D_\Phi = 2$ IN CASE OF A FOUR-DIMENSIONAL CONVOLUTION INTEGRAL

A. Extension of the one-dimensional method

For the numerical evaluation of the four-dimensional convolution integral in Eq. (10), the method from Sec. III is applied to all four coordinates of both $G(\boldsymbol{x},t)$ and $S^{(j)}(\boldsymbol{x},t)$. The filtering and windowing operations for the spatial dimensions are denoted by the subscripts K and X, respectively.

The temporal angular cutoff frequency Ω is taken as the prime parameter for both the temporal and the spatial discretizations. As explained in Sec. III C, this quantity directly determines the temporal sampling interval $\Delta t=\pi/\Omega$. The key to the spatial sampling is the decomposition of a wave in three-dimensional space into planar wave components with real angular wavevectors $\boldsymbol{k}$, as provided by the spatial Fourier representation. For a given Ω it is now assumed sufficient to only retain wave components with $|\boldsymbol{k}|=(k_x^2+k_y^2+k_z^2)^{1/2}\leq K=\Omega/c_0$. This choice for the spatial angular cutoff frequency K is justified if the smallest details in the configuration measure at least several wavelengths at Ω. In that case the width of the spatial spectrum of the contrast source mainly depends on that of the field, and since all solutions of the source-free wave equation for the background medium have $|\boldsymbol{k}|=\omega/c_0$, the choice $K=\Omega/c_0$ seems appropriate. The intended use of FFT's implies that k_x, k_y, and k_z stay real. Consequently, in each spatial dimension the maximum possible wavenumber is K and the resulting spatial sampling interval is $\Delta x=\pi/K=\pi c_0/\Omega$. To prevent spatial aliasing with the given spatial sampling, it is *necessary* to ensure that $|k_x|\leq K$, $|k_y|\leq K$, and $|k_z|\leq K$, i.e., to apply an ideal cube-shaped filter in the spatial Fourier domain. However, as stated above, it is assumed *sufficient* to ensure that $|\boldsymbol{k}|\leq K$, i.e., to apply an ideal spherical filter in the spatial Fourier domain.

B. Spatiotemporal filtering and windowing of the four-dimensional Green's function

The four-dimensional, background Green's function occurring in Eq. (10) is[15–17]

$$G(\boldsymbol{x},t)=\frac{\delta(t-|\boldsymbol{x}|/c_0)}{4\pi|\boldsymbol{x}|}. \tag{19}$$

Its temporal Fourier domain equivalent is

$$\hat{G}(\boldsymbol{x},\omega)=\frac{\exp(-jk|\boldsymbol{x}|)}{4\pi|\boldsymbol{x}|}, \tag{20}$$

with $k=\omega/c_0$, and its spatiotemporal Fourier domain counterpart is

$$\tilde{G}(\boldsymbol{k},\omega)=\frac{1}{|\boldsymbol{k}|^2-k^2}. \tag{21}$$

It is convenient to first perform the spatial filtering in the spatiotemporal Fourier domain. Here, the spherical symmetry of $\tilde{G}(\boldsymbol{k},\omega)$ in $\boldsymbol{k}=0$ is used by applying a spherical filter with an angular cutoff frequency K in the spatial Fourier domain, giving

$$\tilde{G}_K(\boldsymbol{k},\omega)=\tilde{G}(\boldsymbol{k},\omega)H(K-|\boldsymbol{k}|). \tag{22}$$

The temporal Fourier domain equivalent of this equation has been derived by Van der Veeken and Blok[21] as

$$\begin{aligned}\hat{G}_K(\boldsymbol{x},\omega)=\hat{G}(\boldsymbol{x},\omega)&+\frac{\cos(k|\boldsymbol{x}|)}{4\pi^2|\boldsymbol{x}|}\{\mathrm{Si}[(K-k)|\boldsymbol{x}|]+\mathrm{Si}[(K+k)|\boldsymbol{x}|]\\&-\pi\}\\&+\frac{\sin(k|\boldsymbol{x}|)}{4\pi^2|\boldsymbol{x}|}\{\mathrm{Ci}[(K-k)|\boldsymbol{x}|]-\mathrm{Ci}[(K+k)|\boldsymbol{x}|]\}\end{aligned} \tag{23}$$

for $|\boldsymbol{x}|>0$, and

$$\hat{G}_K(\boldsymbol{x},\omega)=\frac{K}{2\pi^2}+\frac{k}{4\pi^2}\left[\ln\left(\frac{K-k}{K+k}\right)-j\pi\right] \tag{24}$$

for $|\boldsymbol{x}|=0$. In Eq. (23), $\mathrm{Si}(x)$ and $\mathrm{Ci}(x)$ are the sine and cosine integrals.[22]

Next, the temporal windowing is performed in the temporal Fourier domain. For the *unfiltered* Green's function, this yields

$$\begin{aligned}G^T(\boldsymbol{x},t)&=\frac{\delta(t-|\boldsymbol{x}|/c_0)}{4\pi|\boldsymbol{x}|}[H(t+T)-H(t-T)]\\&=\frac{\delta(t-|\boldsymbol{x}|/c_0)}{4\pi|\boldsymbol{x}|}H(T-|\boldsymbol{x}|/c_0),\end{aligned} \tag{25}$$

and therefore

$$\hat{G}^T(\boldsymbol{x},\omega)=\frac{\exp(-jk|\boldsymbol{x}|)}{4\pi|\boldsymbol{x}|}H(T-|\boldsymbol{x}|/c_0). \tag{26}$$

This result can be applied directly to the first term of Eq. (23), i.e., the unfiltered Green's function. The time windowing of the other terms in Eq. (23), which represent the spatial filtering operation, is more involving. When the time windowing of these terms is simply omitted, a small time-domain aliasing error is made during the evaluation of the temporal convolution sum. As explained at the end of Sec. III C, the temporal filtering of the term $G^T(\boldsymbol{x},\omega)$ that must still take place is going to yield a comparable time-domain aliasing error, so it is decided to restrict the time windowing to the first term of Eq. (23) and to leave the other terms in this equation unaffected. The remaining temporal filtering and spatial windowing operations are performed in the temporal Fourier domain as well by multiplying $\hat{G}_K^T$ with the appropriate rectangular windows. This results in $\hat{G}_{K,X}^{T,\Omega}(\boldsymbol{x},\omega)$.

C. Spatiotemporal filtering of the primary sources

In all practical cases, the spatial support of the primary source $S^{(0)}(\boldsymbol{x},t)$ is limited and the spatial windowing is unnecessary. Likewise, pulsed sources usually have a limited temporal support that makes the temporal windowing superfluous.

When the source signature has a temporal spectrum that is insignificant beyond Ω, the temporal filtering may be skipped as well without the danger of introducing noticeable aliasing. In many other situations, the Fourier transform of the signature is known in analytical form, so the temporal filtering may conveniently be performed in the temporal Fourier domain. The spatial filtering may be applied in a

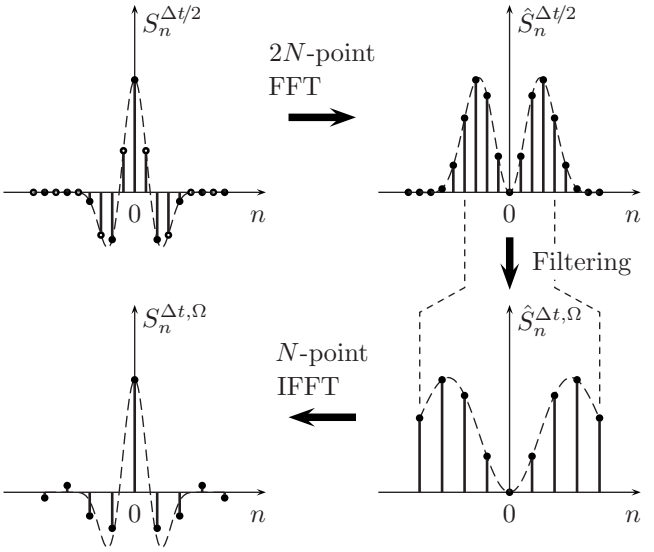

FIG. 2. Numerical procedure for filtering. In this example, the intended number of gridpoints is $N=9$ and the oversampling factor is $a=2$. In the upper left graph, the intermediate samples are indicated by open circles. The dashed curves apply to the unfiltered continuous function.

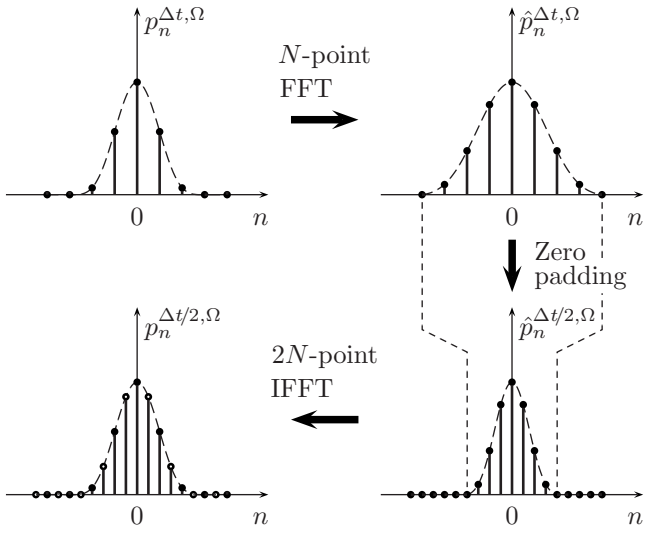

FIG. 3. Numerical procedure for interpolation. In this example, the available number of gridpoints is $N=9$ and the oversampling factor is $a=2$. In the lower left graph, the intermediate samples are indicated by open circles. The dashed curves apply to the continuous function.

similar way whenever the Fourier transform of the source geometry is available in analytical form, e.g., for rectangular or cylindrical piston sources, or for phased array transducers.[23] In such cases, the sampling is directly applied in the Fourier domain. Analytical spatial filtering avoids problems such as staircase effects or the missing out of small sources that are located in between the gridpoints.

When for some coordinate the filtering of the source cannot be employed before the sampling, e.g., when for the relevant coordinate the source can only be characterized through discrete measurements, aliasing must be avoided in a numerical way. For this purpose, the procedure as exemplified in Fig. 2 is proposed. The procedure starts with oversampling the relevant source window at aN points instead of the intended N points. Subjecting the samples to an aN-point FFT yields a discrete version of the Fourier domain function over an interval that is a times as long as intended but, for a properly chosen oversampling factor a, with negligible aliasing at the N points around the origin. Next, all points except those N points around the origin are discarded, thus giving the Fourier domain function over an interval of the intended length. This restriction is the actual filtering step since the remaining discrete interval corresponds with the continuous angular frequency interval $[-\Omega,\Omega]$. Finally, an N-point inverse FFT is performed. This yields N samples in the original domain, at the intended sampling interval and without aliasing. The proposed approach is suitable for the numerical filtering with respect to the spatial coordinates as well.

D. Spatiotemporal filtering of the contrast source

The specific behavior of the contrast source $S^{(j)}(\boldsymbol{x},t)$ depends on the type of contrast present in the medium, as shown at the end of Sec. II A. In any case, $S^{(j)}$ depends on the estimate $p^{(j-1)}$. To discuss the filtering of the contrast source, it is assumed that $p^{(j-1)}$ is bandlimited in all dimensions, with a temporal angular cutoff frequency Ω and a spatial angular cutoff frequency K. Differentiation or convolution of a bandlimited signal yields a result with a bandwidth not exceeding that of the original signal. However, multiplication of a bandlimited signal with another bandlimited signal or with itself causes a result with a bandwidth that is equal to the sum of the bandwidths of both signals involved. Thus, in case of dispersion [Eq. (5)], the contrast source does not require additional filtering. But in case of inhomogeneity [Eq. (4)], the contrast source must be filtered in the spatial dimensions, and in case of nonlinearity [Eq. (6)], the source must be filtered in both the spatial and the temporal dimensions. Detailed analysis shows that for nonlinearity the temporal filtering usually suffices and the spatial filtering may be skipped, but this issue is beyond the scope of this paper.

The abovementioned facts are true for continuous functions as well as their sampled counterparts. Usually, only the sampled version of $p^{(j-1)}$ is available and $S^{(j)}$ must be determined numerically. When this requires the sampled version of a contrast function, e.g., $[c_0^{-2}-c^{-2}(\boldsymbol{x})]$, this must be filtered either analytically (before the sampling) or numerically (after the sampling) to avoid aliasing. When the sampled function $p^{(j-1)}$ is multiplied with a sampled contrast function or with itself, the original sampling intervals $\Delta t=\pi/\Omega$ and $\Delta x=\pi/K$ are no longer sufficient to deal with the increased bandwidth of the result. To avoid aliasing, the relevant sampling intervals must be reduced by some factor a before the multiplication or the squaring takes place. This requires the interpolation of the available samples of $p^{(j-1)}$ without the distortion of the corresponding spectral values. To achieve this, the procedure as depicted in Fig. 3 is suggested. First, an N-point FFT is applied to the available N sample points. The discrete Fourier domain is then extended from N to aN points by zero-padding. Finally, an aN-point inverse FFT is performed. This yields aN samples in the original domain, without distorting the relevant spectral values.

Using the interpolated samples of $p^{(j-1)}$, the relevant

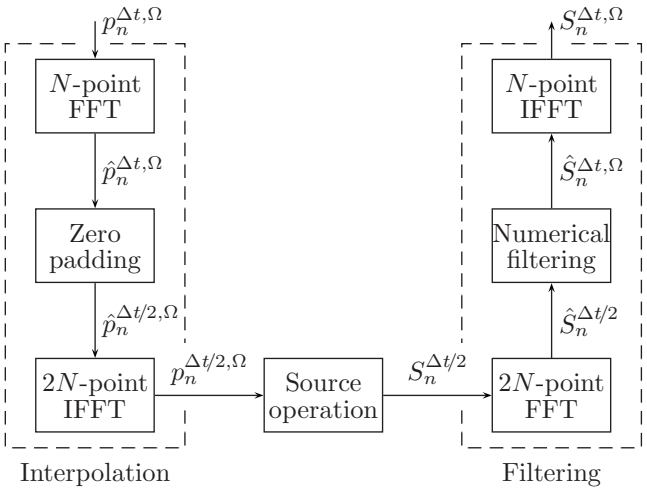

FIG. 4. The entire numerical procedure for the evaluation of the contrast source.

source operation yields aN samples of $S^{(j)}$. This oversampled $S^{(j)}$ is directly amenable for a subsequent numerical filtering according to Fig. 2. The entire numerical procedure for the evaluation of the contrast source is summarized in Fig. 4. At this point, the evaluation of the filtered contrast source may seem computationally involving. However, the contrast source very seldom requires filtering in all four dimensions. When filtering is only required for a subset of the dimensions, the number of operations required for the filtering is at least one order less than for the four-dimensional convolution, and it always pays to reduce the number of grid points by using a proper filtering.

E. Discretization and evaluation of the convolution sum

The filtered and windowed Green's function from Sec. IV B allows for a straightforward sampling. In Secs. IV C and IV D, it has been explained how sampled versions of the filtered and windowed primary source and contrast source are obtained. Apart from the small error introduced by combining filtering and windowing, all aliasing errors have been removed and therefore the sampling may be taken as coarse as $D_\Phi=2$ in all dimensions. The resulting convolution sum can be evaluated efficiently by using a four-dimensional FFT method. To avoid wraparound, all source intervals must be doubled in length by zero-padding, as explained in Sec. III B. As a result, the number of operations required for the convolution is of order $16N^4 \log(16N^4)$.

V. PARALLEL IMPLEMENTATION

The filtered convolution method has been implemented on a single processor system as well as on a multiprocessor parallel system with distributed memory. In both cases, the code has been written in FORTRAN. This section focuses on the parallel implementation[24] of the method as it occurs in the context of the Neumann iterative solution. To ease the notation, the filtering and the windowing of the acoustic quantities are understood without specific indication.

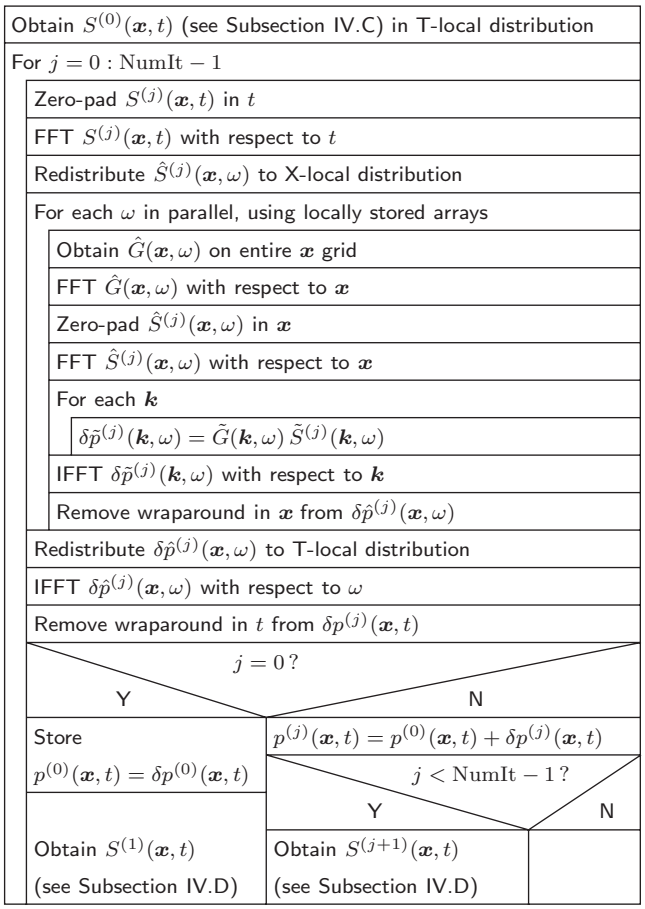

FIG. 5. Structure diagram of the parallel program. All symbols indicating acoustic quantities refer to the filtered and windowed quantities. Note that $\delta p^{(j)}=\mathcal{L}[S^{(j)}]$.

The structure diagram of the parallel program is shown in Fig. 5, in which the evaluation of the convolution plays a central role. To minimize communication, depending on the operation to be applied, either a T-local distribution is used, where each processor is allocated a complete time trace for a limited number of spatial grid points, or an X-local distribution is used, where each processor is allocated the entire spatial domain for a number of time instances or angular frequencies. Inside the outer loop over j, the source function $S^{(j)}(\boldsymbol{x},t)$ is zero-padded in time, transformed in the temporal dimension, and redistributed to X-local. This way, inside the nested loop over ω, the local temporary arrays that hold the spatial data including the zero-padding regions need only be three-dimensional. Another advantage of this approach is that the redistribution steps occur outside the loop over ω. Inside this loop, $\hat{G}(\boldsymbol{x},\omega)$ is evaluated for each spatial point. Either a high-order finite difference scheme or a spectral derivative[25] is used for the evaluation of the temporal derivatives that occur in the primary source function $S^{(0)}(\boldsymbol{x},t)$ and in the contrast source function $S^{(j)}(\boldsymbol{x},t)$ (see Sec. II A). Especially when the numerical interpolation of Fig. 3 is invoked, the route via the transform domain yields the spectral derivative at negligible extra cost. When this option is chosen, care is taken to avoid Gibb's phenomenon[20] that might arise from a jump between the data at the beginning and at the end of the interval that will be transformed by the FFT.

As the filtered convolution method relies heavily on the use of multi-dimensional FFT's, a fast and flexible implementation of the FFT is essential. This is achieved by using the FFTW library.[26]

VI. NUMERICAL RESULTS

The results in this section have been obtained by running the parallel program on an SGI Altix 3700 clustered multiprocessor system of Itanium 2 processors running at 1.3 GHz and with 2 Gbyte memory per processor.

A. The primary source

In the examples that follow, the primary source is flat and located in the plane $z=0$. The source function either follows from a volume density of injection rate $q=Q(x,y,t)\delta(z)$, giving $S=\rho_0\partial_t Q(x,y,t)\delta(z)$, or from a volume density of force $f_z=F_z(x,y,t)\delta(z)$, giving $S=-\partial_z[F_z(x,y,t)\delta(z)]$. The action of these respective sources will be represented by a jump Δv_z in the z component of the particle velocity or a jump Δp in the acoustic pressure. These jumps are only nonzero at the location of the source aperture. For the emitted wave field, symmetry properties make that for $z>0$ these source/saltus descriptions relate to the boundary value descriptions of a source in a perfectly rigid baffle and in a perfectly compliant baffle, respectively, by taking $Q(x,y,t)=2v_{z0}(x,y,t)$ or $F_z(x,y,t)=2p_0(x,y,t)$, where v_{z0} and p_0 are the normal velocity and the pressure prescribed on the boundary. The source functions $Q(x,y,t)$ and $F_z(x,y,t)$ are separated into a time signature and a geometry factor $0\leq A(x,y)\leq 1$. For the time signature, a harmonic wave modulated by a Gaussian envelope is taken. These choices give

$$\begin{pmatrix} Q(x,y,t) \\ F_z(x,y,t) \end{pmatrix} = \begin{pmatrix} Q_0 \\ F_0 \end{pmatrix} A(x,y)\exp[-(2t/t_w)^2]\sin(\omega_0 t), \quad (27)$$

where Q_0 and F_0 are the peak source values, t_w is the pulse width, and ω_0 is the angular center frequency. If there are any position-dependent delays of the time signature, as with focused sources, these may be accounted for in the temporal Fourier domain by using a complex geometry factor

$$\hat{A}(x,y,\omega) = A(x,y)\exp[-j\omega t_d(x,y)], \quad (28)$$

where $t_d(x,y)$ is the delay time. With regard to the temporal filtering of S, the pulse width t_w is taken such that the significant part of the spectrum always occurs below the cutoff frequency, and the filtering operation is omitted. Spatial filtering in the x and y dimensions is performed with the numerical method of Fig. 2. In the z dimension, filtering of the delta function with an ideal filter gives

$$\frac{K}{\pi}\delta(z) *_z \operatorname{sinc}(Kz) = \frac{1}{\Delta x}\operatorname{sinc}(\pi z/\Delta x), \quad (29)$$

which for $z=n\Delta x$ is $1/\Delta x$ for $n=0$ and 0 for $n\neq 0$. In case of a force source, the spatial derivative with respect to z is not directly applied to the delta function but to the result of the convolution, according to the property $G*_z(\partial_z f_z)=\partial_z(G*_z f_z)$.

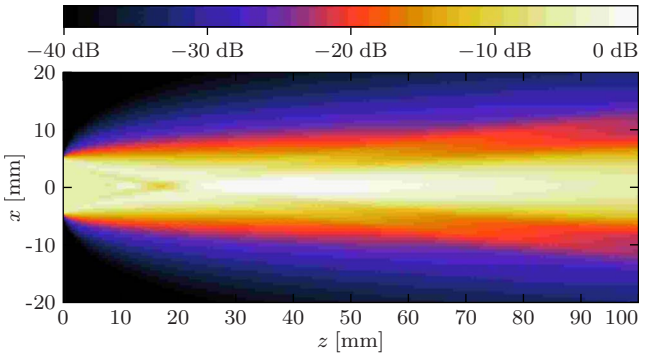

FIG. 6. (Color online) Pressure profile in the plane $y=0$ mm for the cylindrical piston transducer in water. The 0 dB level corresponds to 19.4 kPa. The sampling is $D_F=2.33$.

B. Cylindrical piston transducer in a homogeneous medium

The first example involves a cylindrical piston transducer with a radius of 5 mm, exciting a pulse with a center frequency $f_0=2$ MHz, a pulse width $t_w=3/f_0$, and a maximum surface pressure $p_0=10$ kPa. The action of the transducer is represented by a pressure jump condition. The transducer is spatially filtered by oversampling with a factor $a=8$ followed by numerical filtering, and the derivative in the source function is evaluated with a 30th-order finite difference scheme. The acoustic medium is water with $\rho_0=998$ kg m^{-3} and $c_0=1480$ m s^{-1}. For the applied pressures and frequencies, this medium may be considered linear and lossless. The homogeneous field solution $p^{(0)}(\boldsymbol{x},t)$ has been determined in a computational domain with an approximate spatial size of $40\times 2\times 100$ mm^3 and a co-moving time frame of duration $20/f_0$. The discretization of this domain is given by $D_F=1/F\Delta t$, where the maximum frequency of interest $F=\Phi/2\pi$ is taken 3 MHz. At this frequency, the spectrum of the excitation pulse is 50 dB below the level of the center frequency. Figure 6 shows the computed pressure profile, i.e., the maximum temporal acoustic pressure, in the plane $y=0$ mm for $D_F=2.33$.

To assess the accuracy of the results, in the plane $y=0$ mm the relative root mean square (RRMS) error with respect to a reference solution p_{ref} is considered. This reference follows from a Lobatto integration of an exact expression for the field of the pressure jump source, as derived with the coordinate transformation method described by Harris.[27] The RRMS error is given by

$$\text{Err} = \left(\int_{\mathcal{V}} (p^{(0)} - p_{\text{ref}})^2 dxdzdt \Big/ \int_{\mathcal{V}} (p^{(0)})^2 dxdzdt \right)^{1/2}, \quad (30)$$

where $\mathcal{V}$ is the total xzt-domain. The integrals are evaluated using the left Riemann sum. Table I presents the RRMS error and some other information for different values of D_F. These numerical experiments show that the results for $D_F=2.33$ compare quantitatively very well with the reference solution. The arrival times of the body and edge waves are reproduced correctly. This is also the case for $D_F=2.00$, although for this discretization the error is 4%. The primary cause for this

TABLE I. Data for several computations involving the cylindrical piston transducer in water. The computations are performed for different values of D_F.

D_F	Err (%)	4D grid size ($\times 10^6$ points)	Wall clock time (s)	Number of processors
2.00	4.0	25.72	143	4
2.33	1.0	39.26	230	4
2.67	0.8	60.24	393	4
3.33	0.5	155.7	873	4
4.00	0.5	345.6	686	8
5.33	0.4	1150	1203	48

error is the high-order finite difference scheme that is used for the spatial derivative in the source function. For higher values of D_F, the error decreases quickly to 0.4% at $D_F=5.33$. The main contribution to the latter error comes from the spatial filtering, which is most prominent at the first plane beyond the source. If the results for this plane are left out, the errors for D_F being equal to 3.33, 4.00, and 5.33 decrease to 0.2%, 0.1%, and 0.1%, respectively.

The example proves that domains up to approximately 500×10^6 grid points can be handled successfully and with a limited number of processors. This number of grid points corresponds to a four-dimensional computational domain of 75 wavelengths/periods in each dimension. The latter observation clearly indicates the applicability of the filtered convolution method to very large-scale problems.

As can be seen from the last line of Table I, the problem size and computation time grow massively for increasing values of D_F. This illustrates once more the necessity of using a coarse discretization.

C. Phased array transducer in a homogeneous medium

The second example concerns a 64 element phased array transducer with elements measuring 0.25 mm (width in the x direction) by 12 mm (height in the y direction), and a pitch of 0.3 mm. The elements excite the same surface pressure as the cylindrical transducer mentioned above, and the array is focused at $z=60$ mm, including elevation focusing. The results of the current method are compared with the results from the FIELDII program.[28] Since this program solves the Rayleigh integral,[27] the action of the transducer is now represented by a velocity jump. The phased array source is spatially filtered in the x dimension by analytically filtering one element and subsequently stacking the results, and in the y dimension by numerically filtering a single element by the method of Fig. 2. The temporal derivative in the source function is performed analytically. Again, the medium is water. The homogeneous field solution $p^{(0)}(\boldsymbol{x},t)$ has been determined in a computational domain with an approximate spatial size of $80\times 1\times 100$ mm^3 and a co-moving time frame of duration $40/f_0$. Figure 7 shows the computed pressure profile in the plane $y=0$ mm for $D_F=2.00$ with $F=3$ MHz.

Table II presents the RRMS error in the plane $y=0$ mm, together with other data relating to several discretizations. The listed error has been determined relative to the solution of FIELDII, which was run with a sampling frequency of 400 MHz and 20×40 mathematical elements per physical element. Table II shows that already for $D_F=2.00$ the results from both programs compare very well. This clearly proves that the filtered convolution method is capable of accurately computing the space-time domain acoustic field of complex plane sources, even when sampled at the limit $D_F=2$.

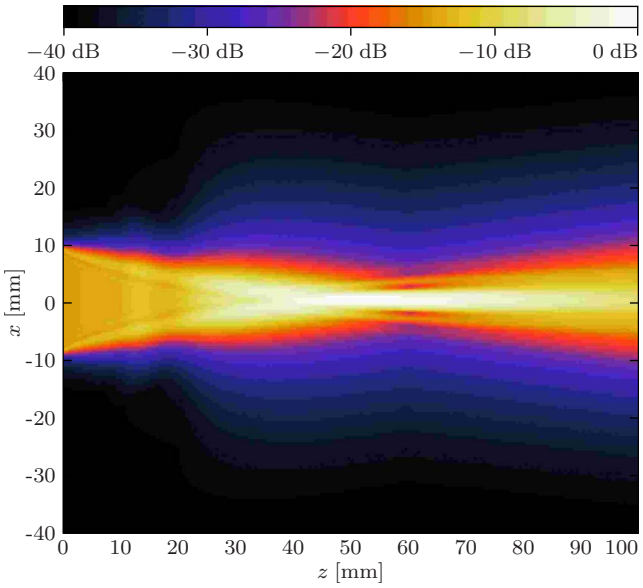

FIG. 7. (Color online) Pressure profile in the plane $y=0$ mm for the phased array transducer in water. The 0 dB level corresponds to 47 kPa. The sampling is $D_F=2.00$.

D. Phased array transducer in an inhomogeneous medium

The third example concerns a phased array transducer with the same geometry and surface pressure as in Sec. VI C. This transducer, however, excites an acoustic field in a medium with an inhomogeneous wave speed and a constant mass density. The distribution of the wave speed in the medium is displayed in Fig. 8(a). The homogeneous embedding is water. This surrounds a homogeneous phase screen ($c=0.95c_0$) with an undulation in the x direction, a water-filled cylinder ($c=0.95c_0$) with a homogeneous wall, and a prolate ellipsoid with an aspect ratio of 2 and a continuously changing wave speed ($\max[c]=1.10c_0$). The inhomogeneous wave speed leads to the contrast source of Eq. (4). The contrast function $[c_0^{-2}-c^{-2}(\boldsymbol{x})]$ is filtered by using the method of Fig. 2 with an oversampling factor $a=2$. Successive approximations $p^{(j)}$ up to $j=9$ have been determined in a computational domain with a spatial size of $42\times 16\times 60$ mm^3 and a

TABLE II. Data for several computations involving the phased array transducer in water. The computations are performed for different values of D_F.

D_F	Err (%)	4D grid size ($\times 10^6$ points)	Wall clock time (s)	Number of processors
2.00	1.6	67.0	352	4
2.67	1.0	161.6	510	8
3.33	0.7	318.1	1380	8

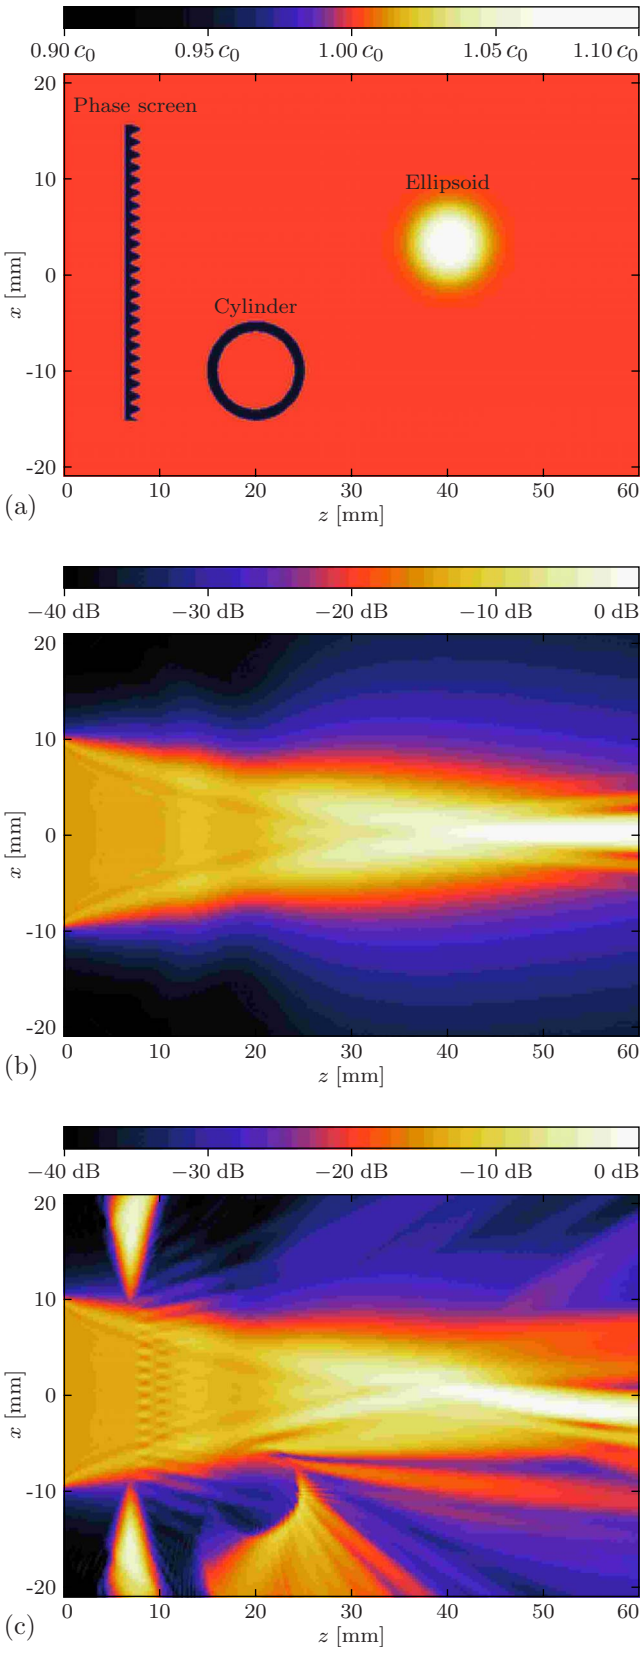

FIG. 8. (Color online) The relative wave speed (a), the pressure profile of $p^{(0)}$ (b), and the pressure profile of $p^{(9)}$ (c) in the inhomogeneous medium, for the plane y=0 mm. In panels (b) and (c), the 0 dB level corresponds to 47 kPa and the sampling is D_F=2.66.

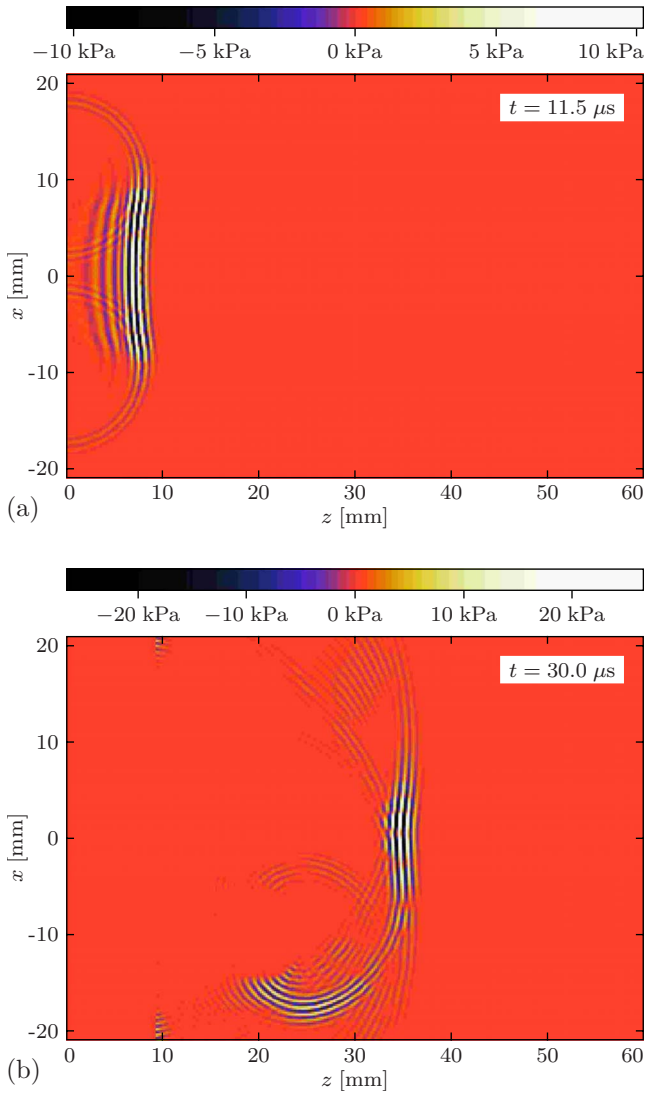

FIG. 9. (Color online) Snapshots of $p^{(9)}$ in the inhomogeneous medium, for the plane y=0 mm. The sampling is D_F=2.66.

co-moving time frame of duration $48/f_0$. Figures 8(b) and 8(c) show the profiles of $p^{(0)}$, i.e., the incident field, and $p^{(9)}$, i.e., an approximation of the total field, in the plane y=0 mm.

The results in Fig. 8(c) clearly reveal the effect of the objects on the beam shape. The phase screen affects the beam shape by generating an interference pattern just beyond the screen and by forming two side-lobes. The wall of the cylinder acts as a curved waveguide, which captures a part of the beam and radiates it off in the negative x direction. The main effect of the ellipsoid, which acts as a diverging acoustic lens, is the diffraction of the beam in the negative x direction. In Fig. 9, which shows snapshots of $p^{(9)}$, the reflections and interferences due to the inhomogeneities are also clearly visible.

In the current case, the successive results are almost identical from j=5 to j=9. However, due to the lack of benchmarking results, it has neither been investigated whether in the given situation the Neumann iterative solution is convergent, nor whether a possible convergence is toward the correct result.[29] In any case, the filtered convolution

method may be combined with more sophisticated iterative schemes[3] with improved convergence properties, such as the successive over-relaxation method or the conjugate gradient method.

The results above have been obtained for $D_F=2.66$ with $F=3$ MHz. For the computation of the successive approximations, the entire spatial domain of $85\times32\times121$ wavelengths and a co-moving time interval of 72 periods, all relating to F, acted as the support of the contrast source. The spatiotemporal grid consisted of 1.16×10^9 points, and it took 4.3 wall clock hours with 48 processors to obtain the iterations up to $j=9$. This proves that very large-scale, complex acoustic wave fields can efficiently be computed with the filtered convolution method.

VII. CONCLUSIONS

A method has been developed for the numerical evaluation of convolutions over very large, four-dimensional domains. The method is quite general and may, for instance, be combined with various iterative integral equation methods for the solution of numerous contrast source problems. In this role, the presented method enables the computation of very large spatiotemporal wave fields by minimizing the storage requirement and strongly reducing the computational effort.

As commonly encountered, the numerical convolutions are performed with the aid of FFT's. The distinguishing feature of the method is that before sampling, the relevant functions are systematically filtered, windowed, and zero-padded with respect to all relevant coordinates. Both analytical and numerical filtering procedures have been presented. Due to these preparatory steps, it is possible to perform numerical convolutions with a sampling that approaches the limit $D_\Phi=2$, i.e., two points per wavelength and per period of the highest angular frequency of interest Φ.

The method has been combined with the Neumann iterative solution of the acoustic contrast source problem for an inhomogeneous medium. Within this context, the method has been implemented on a parallel computer, and numerical results have been obtained for several configurations. Comparison with two separate reference solutions for a homogeneous medium shows that the RRMS error of our results is a few percent for $D_\Phi=2$, and decreases rapidly for finer sampling. The major part of this error is due to the filtering operation, and is thus made consciously. Computation of the transient acoustic wave field in an inhomogeneous medium proves that with the presented method, computational domains in the order of 100 wavelengths in three spatial directions by 100 periods in time can conveniently be dealt with.

[29]The behavior of the Neumann iterative solution in combination with the filtered convolution method has been further investigated for a configuration consisting of an acoustically penetrable, homogeneous sphere in a homogeneous background medium (see Ref. 11). For this case analytical results exist. Successive approximations $\delta p^{(j)}=p^{(j)}-p^{(0)}$ of the scattered field have been determined for several radii of the sphere, several values of the wave speed inside the sphere, and several values of the sampling parameter D_F. For those situations in which the successive approximations clearly tend to a limiting result, the RRMS error of this limiting result with respect to the exact solution has been evaluated. From these comparisons, it may be concluded that the limiting results are indeed an approximation of the exact solution, and become better for higher values of D_F. The latter is explained by the fact that the observed error is almost entirely caused by the spatial filtering of the contrast function of the relatively small sphere.

A micro-machined source transducer for a parametric array in air[a)]

Haksue Lee, Daesil Kang, and Wonkyu Moon
Department of Mechanical Engineering, Pohang University of Science and Technology (POSTECH), San 31, Hyojadong Namgu, Pohang, Kyungbuk 790-784, South Korea

(Received 15 March 2008; revised 15 January 2009; accepted 16 January 2009)

Parametric array applications in air, such as highly directional parametric loudspeaker systems, usually rely on large radiators to generate the high-intensity primary beams required for nonlinear interactions. However, a conventional transducer, as a primary wave projector, requires a great deal of electrical power because its electroacoustic efficiency is very low due to the large characteristic mechanical impedance in air. The feasibility of a micro-machined ultrasonic transducer as an efficient finite-amplitude wave projector was studied. A piezoelectric micro-machined ultrasonic transducer array consisting of lead zirconate titanate uni-morph elements was designed and fabricated for this purpose. Theoretical and experimental evaluations showed that a micro-machined ultrasonic transducer array can be used as an efficient source transducer for a parametric array in air. The beam patterns and propagation curves of the difference frequency wave and the primary wave generated by the micro-machined ultrasonic transducer array were measured. Although the theoretical results were based on ideal parametric array models, the theoretical data explained the experimental results reasonably well. These experiments demonstrated the potential of micro-machined primary wave projector.

I. INTRODUCTION

Parametric arrays (PAs) have been the subject of theoretical[1,2] and experimental[3] studies since the 1960s and are used in active underwater SONAR systems such as sub-bottom profilers[4] or communication transmitters.[5] Their principal advantage is that the highly directional low-frequency sound beam required can be indirectly generated with a relatively small transducer. After an experimental study in air,[6] many researchers and engineers turned their attention to the potential of PA applications in this medium, especially for highly directional parametric loudspeaker systems.[7,8]

Unlike in water, it is difficult to produce the high-intensity acoustic beams required for nonlinear interaction in air with an ultrasonic/acoustic transducer (i.e., source transducer) because the acoustic impedance (415 Pa s/m) is much smaller (1.54 MPa s/m).[9] To achieve the required high-intensity beams with the same transducer in air, the output velocity amplitude should be much higher than in water. Furthermore, the weak nonlinearity and strong attenuation effects in air also reduce the parametric conversion.[6,10] To compensate for the weak radiation characteristics, PA applications in air, especially parametric loudspeakers, have used huge array-type radiators consisting of conventional ultrasonic transducers that require a lot of electrical power.[7] Recently, transducers using active polymers (e.g., piezoelectric or electrostrictive polymers, etc.) have been proposed as high-power radiators in air to improve practical applicability by reducing the volume and simplifying construction.[8,11] One transducer has been applied as a parametric radiator to improve the power efficiency in air, although it still requires a large amount of electrical power.[8] New and useful PA applications, such as small loudspeakers or sensors for mobile systems,[12–14] may be possible if high-intensity source transducers with thinner (or smaller) dimensions and higher efficiency can be developed. Here, the potential for piezoelectric micro-machined ultrasonic transducer (pMUT) arrays to be used as thin, highly efficient, high-intensity primary wave projectors for PAs is examined.

pMUTs and capacitive MUTs have been the objects of numerous studies, mainly for short-range imaging applications such as phased array transducers operating between several and several hundred megahertz in water or air.[15–18] One important feature of thin-film transducers such as MUTs is that their mechanoacoustic efficiency[19] can be improved significantly if the internal mechanical impedance is reduced with thin-film membranes or plates.[20,21] With careful design, this can potentially allow for improvements in the overall electroacoustic efficiency[19] of the transducers because of the improved mechanoacoustic efficiency and low motional loading in air.[16] This feature is important in an air-based acoustic radiator design because the electroacoustic efficiency of bulk piezoelectric lead zirconate titanate (PZT) ceramics is extremely low in air.[22] The main reason for this is due to the mechanoacoustic efficiency and not the electromechanical efficiency.

[a)]Some of these results were presented at the following international conferences: The 151st meeting of the Acoustical Society of America, Providence, Rhode Island (June 5–9, 2006), The SICE-ICASE International Joint Conference 2006, Busan, Korea (October 18–21, 2006), and Transducers and Euroscensors '07, Lyon, France (June 10–14, 2007).

Even though generating high-intensity acoustic wave is generally not too important for micro-machined phased arrays in water, it is possible with micro-machined transducers and should be considered for PAs. There have been reports of pMUT arrays (operating up to hundreds of kilohertz) for generating high-intensity waves in air,[23] but more work on the transducer and array design is still required, especially for PAs in air. The velocity of a micro-machined thin-film radiator should be large enough to generate high-intensity waves. This is expected to be achieved with a proper transduction mechanism design by considering deformation and coupling effects in air. In addition, transducer arrays consisting of small micro-machined transducer units should be designed to generate the required high-intensity sound beams.

It is also important in micro-machined source transducer design to select appropriate operating conditions. These conditions should be based on the physical phenomena involved in the specific application, as well as electroacoustic efficiency and power issues. Although conceptual patents covering micro-machined source transducers and applications in air have recently been filed,[12,13] experimental results have rarely been reported. Although we reported preliminary data[24] and discussed some applications,[24–26] it took us a long time to analyze the experimental results and find the causes of some practical issues[26] encountered. As a fundamental demonstration of capability, a two-channel-type source transducer was designed to generate a difference frequency wave (DFW) with narrow beamwidth to show the feasibility and potential of a micro-machined primary wave projector, and it was evaluated experimentally. The experimental data were compared to theoretical data.

II. SOURCE TRANSDUCER DESIGN

A specific design goal provides coherence to the overall design and experimental procedure. An ultrasonic ranging transducer with a narrow beamwidth in air was selected as a design goal to provide some useful application for PAs in air. The half-power beamwidth (HPBW) of general ultrasonic ranging sensors is too large (18°–50°) (Refs. 27 and 28) to detect the exact location of a small obstacle, and the wide beamwidth often creates low spatial resolution problems in ultrasonic ranging applications such as small mobile robots. Therefore, the source transducer was designed to generate indirectly an ultrasonic pulse with a narrow beamwidth of approximately 5°, chosen to be about the same size as that of conventional ultrasonic ranging sensors.

The source transducer has two major functional requirements. One is to create the proper interaction region to ensure a narrow beamwidth with high sound pressure for the DFW. The other is to generate primary waves of sufficiently high intensity for nonlinear interactions. Therefore, the design procedure consisted in determining the optimal design parameters based on PA theory and constructing the individual pMUTs and transducer array based on those parameters while taking the electroacoustic efficiency into account.

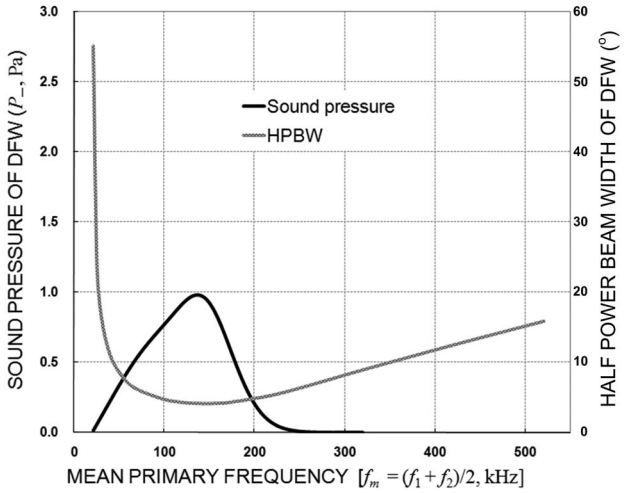

FIG. 1. HPBW and sound pressure of the DFW at 5 m according to the mean frequency of primary waves with selected design parameters (Ref. 30): $2a=32$ mm and $f_d=40$ kHz, assuming an ideal Gaussian source distribution ($P_1=P_2=100$ Pa) with no saturation effects.

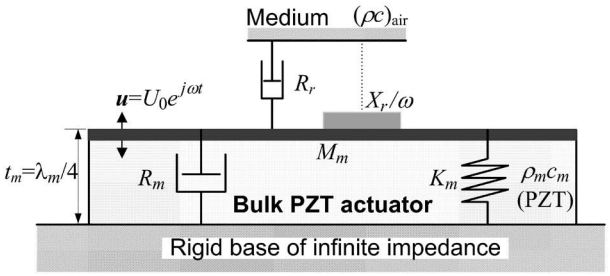
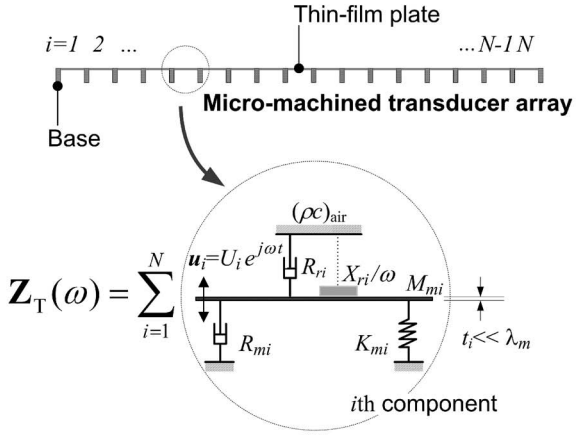
A. Design parameters based on operating conditions

The spatial distribution of the interaction region related to the HPBW and sound pressure level (SPL) of the DFW can be determined by the beam patterns of the primary waves considering diffraction, absorption, and saturation effects.[29,30] Even though these radiation characteristics themselves are complex, previous research[30] has shown that the beamwidth and sound pressure of the DFW can be easily estimated for a given source pressure level of primary waves using the main design parameters: the primary frequencies (f_1 and f_2), the difference frequency (f_d), and the radiation area of the transducer (πa^2, where a is the effective radius of a source transducer).

For this research, a diameter $2a=32$ mm and a difference frequency $f_d=40$ kHz were selected based on the specifications of a conventional ultrasonic ranging sensor. This meant that the primary frequency was the main parameter that determined the beam characteristics of the DFW. Figure 1 shows the HPBW and sound pressure (on the axis of transducer) of the DFW as functions of the mean primary frequency, $f_m=(f_1+f_2)/2$, based on a PA theoretical model.[30] In the calculation,[30] the source transducer was assumed to be a circular radiator with an axisymmetric Gaussian pressure distribution. It should be noted that the model assumed that the f_d/f_m is small, and this means that the graph may not be exactly correct as f_d/f_m becomes larger. The maximum sound pressure and minimum beamwidth could be achieved at an f_m of approximately 140 kHz. Given the selected design values, the expected value of the HPBW was nearly 4°. For this study, the value $f_m=120$ kHz (i.e., $f_1=100$ kHz and $f_2=140$ kHz) was selected instead of the optimal frequency of $f_m=140$ kHz due to the high cutoff frequency (140 kHz) of the microphone used in the experiments. This resulted in a slight increase in the beamwidth and decrease in the sound pressure. The nonlinear interaction length (near-field of the PA) was approximately 2.53 m ($\approx 1/2\alpha_0$, where α_0 is the absorption coefficient at f_m).[6]



(a)



(b)

FIG. 2. Comparison of the equivalent mechanical impedance model. (a) Bulk PZT actuator with quarter-wave resonance (radiation impedance $\mathbf{Z}_r=R_r+jX_r$, internal mechanical impedance $\mathbf{Z}_m=R_m+j(\omega M_m-K_m/\omega)$, and output velocity $\boldsymbol{u}$). (b) Micro-machined transducer array consisting of N identical transducer components (for ith component, radiation impedance $\mathbf{Z}_{ri}=R_{ri}+jX_{ri}$, internal mechanical impedance $\mathbf{Z}_{mi}=R_{mi}+j(\omega M_{mi}-K_{mi}/\omega)$, total mechanical impedance $\mathbf{Z}_T$, and output velocity u_i).

B. Approach to a micro-machined source transducer

Before designing the micro-machined source transducer with the obtained design parameters, the conceptual method for thin-plate flexural transducers to enhance mechanoacoustic efficiency needs to be discussed clearly. Consider the lumped parameter models for a conventional bulk actuator[31] and the micro-machined transducer array, as shown in Fig. 2.[19] For convenience, a matching layer[32] in the bulk actuator is omitted, and the model of the micro-machined clamped circular plate[19] is considered. Before considering the efficiency of the micro-machined transducer array, the mechanoacoustic efficiency of a single driver in the array may be calculated because the efficiency of the array can be estimated by combining the efficiencies of the unit drivers.

For the ith unit driver in Fig. 2(b), the output vibration velocity is $\boldsymbol{u}_i=\mathbf{f}_i/(\mathbf{Z}_{ri}+\mathbf{Z}_{mi})=U_ie^{j\omega t}$ when the harmonic driving force $\mathbf{f}_i=F_ie^{j\omega t}$ excites the driver. Because two energy-consuming components (the internal mechanical damping R_{mi} and acoustical loading R_{ri}) are connected parallel to the mass (i.e., they have the same velocity), the mechanoacoustic efficiency (η_{MA}) of the ith component can be expressed as[19]

$$\eta_{MA,i}=\frac{\text{Radiated power}}{\text{Total dissipated power}}=\Pi_{r,i}/(\Pi_{m,i}+\Pi_{r,i})$$
$$=R_{ri}/(R_{mi}+R_{ri}), \quad (1)$$

where $\Pi_{r,i}$ is the radiated power such that $\Pi_{r,i}=(1/T)\int_0^T\mathrm{Re}[\mathbf{Z}_{ri}\boldsymbol{u}_i]\mathrm{Re}[\boldsymbol{u}_i]dt=\frac{1}{2}R_{ri}U_i^2$ and $\Pi_{m,i}$ is the internal energy loss where $\Pi_{m,i}=(1/T)\int_0^T\mathrm{Re}[\mathbf{Z}_{mi}\boldsymbol{u}_i]\mathrm{Re}[\boldsymbol{u}_i]dt=\frac{1}{2}R_{mi}U_i^2$.

Let a_i and t_i be the radius and thickness of the ith driver, respectively. Because the radiation resistance is at most $1.2(\rho c)_{air}\pi a_i^2$, the mechanical impedance of the driver determines the mechanoacoustic efficiency of the driver, $\eta_{MA,i}$. Because the driver is designed to operate at its first resonance frequency, the lumped parameters for the driver (plate only) can be obtained easily, such that the resonance frequency can be matched as follows:[19,33]

$$K_{mi}=\frac{16\pi}{a_i^2}\cdot\frac{Et_i^3}{(1-\nu^2)}, \quad (2)$$

$$M_{mi}=\frac{192}{\Lambda_0{}^2}\cdot\rho\cdot(\pi a_i^2t_i), \quad (3)$$

where E, υ, ρ, and Λ_0 are the elastic modulus, Poisson's ratio, mass density of the plate, and frequency constant, respectively. The first mode resonance frequency of the circular plate is given as[19]

$$\omega_0=\Lambda_0\frac{t_i}{a_i^2}\left[\frac{E}{12\rho(1-\nu^2)}\right]^{1/2}=\left[\frac{K_{mi}}{M_{mi}}\right]^{1/2}, \quad (4)$$

where $\Lambda_0=10.22$. It is useful to introduce the concept of the characteristic mechanical impedance[34] of a thin-plate driver as follows:

$$Z_{ci}=(M_{mi}K_{mi})^{1/2}=\frac{32\pi}{\Lambda_0}\left[\frac{\rho E}{(1-\nu^2)}\right]^{1/2}t_i^2. \quad (5)$$

In addition, from the definition of the mechanical quality factor, that of the unit driver may be expressed as follows:[31]

$$Q_{mi}=2\pi\times\frac{\text{Energy stored in the vibrator}}{\text{Energy dissipated internally per cycle}}$$
$$=\frac{Z_{ci}}{R_{mi}}=\frac{(M_{mi}K_{mi})^{1/2}}{R_{mi}}. \quad (6)$$

In general, the mechanical Q-factor of an unloaded simple vibration system such as a PZT disk equals that of its material, PZT, and the Q_m of PZT is usually given as a material property.[34]

Now consider the internal mechanical resistance, R_{mi}, in Eq. (6). Because the unit driver is composed of two materials, silicon and PZT, and because there is no joint throughout its structure, its quality factor, Q_{mi}, may be close to those of its component materials, which have values more than 1000 for silicon and about 500 for PZT. In other words, it may be taken as a given value for the unit driver considered here. Hence, the mechanical resistance of the unit driver can be estimated using Eq. (6) as follows:

TABLE I. Material properties.

[a]Assume homogeneous, 100 wafer and out-of-plane motion, Ref. 50.
[b]Using anisotropic matrix, Ref. 34.
[c]Data from manufacturer, Ref. 40.

$$R_{mi} = \frac{1}{Q_{mi}} \cdot (M_{mi}K_{mi})^{1/2} = \frac{1}{Q_{mi}} \frac{32\pi}{\Lambda_0} \left[\frac{\rho E}{1-\upsilon^2} \right]^{1/2} \cdot t_i^2. \quad (7)$$

Equation (7) clearly shows that the mechanical resistance of the unit driver decreases with its thickness t_i. In other words, for any given operating frequency, a smaller value of t_i guarantees a smaller value of R_{mi}, whereas the choice of t_i automatically determines the radius of the unit driver a_i. This suggests that the mechanoacoustic efficiency, $\eta_{MA,i}$, increases as the thickness of the unit driver, t_i, decreases according to Eq. (1). Most acoustic drivers in air have R_m and Z_c considerably larger than the radiation resistance, R_r, and R_m is determined by the characteristic mechanical impedance Z_c of the driver because Q_m is a constant that is usually much larger than 1 for a vibrator structure made of the given materials. This implies that Z_c needs to be reduced. However, it is difficult to make a driver of the conventional size and shape in air such that its Z_c is sufficiently small that R_m is close to R_r. However, as Eq. (7) shows, the micro-machined ultrasonic driver may have a sufficiently small Z_{ci} that its R_{mi} is even smaller than the maximum R_{ri} if the plate is sufficiently thin.

Now consider in detail the method used to improve mechanoacoustic efficiency. In the case of the driver considered above, a very high $\eta_{MA,i}$ in air can be achieved with a unit driver of realizable size and materials. Let us choose $\eta_{MA,i}$ to be 80% in air and assume that the driver will be made of silicon (using the properties in Table I) with $Q_{mi}=500$ for the overall structure of the unit driver. The radiation resistance of the driver may be set as $R_{ri} \approx \pi a_i^2 (\rho c)_{\text{air}}$. From Eqs. (1) and (7), it is easily seen that the ratio R_{mi}/R_{ri} determines $\eta_{MA,i}$. Hence, for a given $\eta_{MA,i}=0.8$, the following is easily obtained:

$$\frac{R_{mi}}{R_{ri}} \approx \frac{1}{Q_{mi}} \cdot \frac{32}{\Lambda_0} \left[\frac{\rho E}{1-\upsilon^2} \right]^{1/2} \cdot \frac{1}{(\rho c)_{\text{air}}} \cdot \left(\frac{t_i}{a_i} \right)^2 \approx \frac{1-\eta_{MA,i}}{\eta_{MA,i}} = 0.25. \quad (8)$$

The aspect ratio (t_i/a_i) is determined automatically as $t_i/a_i \approx 0.03$, and it yields $\omega_0 t_i \approx 21.25$ using Eq. (4). Subsequently, the thickness of the unit driver is also determined as $t_i \approx 28$ μm because ω_0 is given by the operating frequency $f_0=120$ kHz $(=f_m)$. This implies that a_i should be $a_i \approx 933$ μm because the aspect ratio (t_i/a_i) is already given. The resulting values for a_i and t_i are typical sizes of a structure that can be fabricated easily using micro-machining technology.

To increase the efficiency of the source transducer, one must apply the previous results to calculate the efficiency of the array of unit drivers. When the transducer array is driven at the resonance frequency of its unit driver, the total mechanoacoustic efficiency $(\eta_{MA,T})$ of the array can be written as

$$\eta_{MA,T} = \sum_{i=1}^{N} \Pi_{r,i} \Big/ \sum_{i=1}^{N} (\Pi_{m,i} + \Pi_{r,i}) = \sum_{i=1}^{N} \frac{1}{2} R_{ri} U_i^2 \Big/ \left(\sum_{i=1}^{N} \frac{1}{2} R_{mi} U_i^2 + \sum_{i=1}^{N} \frac{1}{2} R_{ri} U_i^2 \right). \quad (9)$$

When generating a plane wave, by assuming equal amplitudes with in-phase driving $(\mathbf{f}_i = F_i e^{j\omega t} = F e^{j\omega t}$, $i=1,2,3,\ldots,N)$ of each component and the same acoustical load on each component (ignoring mutual acoustic impedance[35]), one ensures that the output vibration velocity of each component is the same (i.e., $\boldsymbol{u}_i = U_i e^{j\omega t} = U e^{j\omega t}$, $i=1,2,3,\ldots,N$). Thus Eq. (9) can be rewritten as

$$\eta_{MA,T} = \sum_{i=1}^{N} R_{ri} \Big/ \left(\sum_{i=1}^{N} R_{mi} + \sum_{i=1}^{N} R_{ri} \right) = N \cdot R_{ri} / (N \cdot R_{mi} + N \cdot R_{ri}). \quad (10)$$

If t_i is chosen to be as small as possible, as explained above, the total internal mechanical damping $(N \cdot R_{mi})$ of the silicon-based microstructure becomes much lower than that of a conventional thickness mode transducer, which is determined by a given operating resonance frequency. The mechanical resistance of a conventional thickness mode transducer can be expressed as $R_m \approx 1/Q_m \cdot \omega_0 \cdot M_m = 1/Q_m \cdot \omega_0 \cdot \rho_m A t_m$ and t_m is determined as $\lambda_m/4 (=1/4 \cdot c_m/f_0)$ by the given operating resonance frequency. However, the acoustical loading of the transducer array $(N \cdot R_{ri})$ is approximately equal to that of a conventional transducer (R_r) if the whole shape and radiation area are designed to be similar $(N \cdot \pi a_i^2 \approx A)$. This implies that a micro-machined transducer array can achieve a much larger value of $\eta_{MA,T}$ than a conventional thickness mode

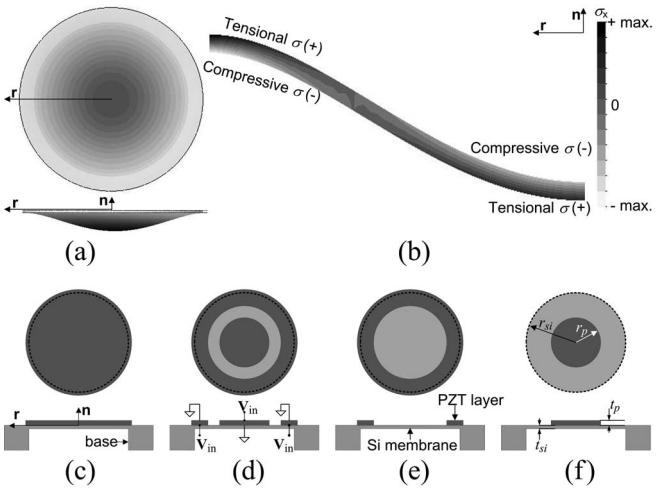

FIG. 3. Schematic design of the unit pMUT structure according to the deformation characteristics: (a) deflection of the circular plate; (b) stress σ_r in the cross section ($0 \leq r \leq r_{si}$); (c) general pMUT structure; (d) driven out of phase; (e) edge-driven; (f) centrally driven.

transducer for a given operating frequency. This improvement in mechanoacoustic efficiency means that the electroacoustic efficiency (η_{EA}) (Ref. 19) can also be enhanced.

Although the mechanical Q-factor for many materials is known, it is difficult to calculate the precise value of Q_m of a unit driver because the exact boundary conditions of the structures are difficult to determine. Therefore, Q_m of a vibration system is frequently estimated by measuring its mechanical responses at the resonance frequency in vacuum. Because Eq. (10) ultimately takes the same form as Eq. (1), $\eta_{MA,T}$ can be evaluated practically by measuring the efficiency of one component, $\eta_{MA,i}$. A detailed evaluation of this is to be continued in Sec. IV A.

Although the high mechanical resistance broadens the resonance peak band, the given difference frequency is too big for the primary frequencies to lie in a single resonance peak band. The unit driver must be driven at its resonance frequency to generate sounds with sufficiently large amplitudes. Hence, two unit drivers with two different resonance frequencies,[36] f_1 (100 kHz) and f_2 (140 kHz), are used as array components. The pMUT unit design was completed before the rest of the array was designed.

C. Unit actuator design

A PZT uni-morph was selected as the transduction mechanism because it is suitable as a resonant radiator and representative of micro-machined acoustic transducers.[15,16,20,23] The unit actuator consisted of a thin silicon plate with a PZT layer on its top surface. The radius and thickness of the circular silicon plate were selected to achieve a resonance frequency slightly above the desired primary frequency. It was important to choose the shape and the dimensions of the PZT layers to increase the diaphragm velocity for a given electrical energy and achieve a high electromechanical coupling coefficient.[15,16,37,38]

Before observing the effect of the PZT dimensions on the electromechanical coupling coefficient, the stress distribution in the cross-section [along the r-direction in Fig. 3(a)] of the silicon plate was calculated without the PZT layer using a finite element method program when the plate was deflected, as shown in Fig. 3(b). On the top surface, compressive stress occurred in the central region, but tensional stress occurred at the edge. This meant that the deposition of the PZT layer on the whole silicon plate, as shown in Fig. 3(c), may have decreased the electromechanical coupling coefficient.[37,38] Similar conclusions using top-electrode dimensions have also been reported,[39] but most research into pMUTs has not considered the effects of the PZT radius on the coupling effects in addition to its thickness. Because the PZT radius is more important in resonance-type microsystems in air (because the PZT provides relatively high damping compared to the silicon substrate), any unnecessary PZT regions had to be etched out.

Two methods to shape and drive the PZT layers for highly efficient actuation based on this physical phenomenon were devised. One method used out-of-phase voltages to drive each side of the PZT layer [Fig. 3(d)]. Although this enhances both compressive and tensional motion and seems to be the most powerful driving method, it is not compatible with large array structures because it requires complex metal line patterns. This causes practical problems such as difficulties in the PZT poling procedure or parasitic impedance[15] reduction due to the complex metal lines. Therefore, partially driving one of the two PZT regions was considered [see Figs. 3(e) and 3(f)]. The central driving method was selected for this research.

Figure 3(f) shows the basic structure of the unit radiator, which is a thin-film plate with a piezoelectric layer attached to its top surface. The ratios of the thickness and radius of the silicon plate and the PZT layer should be selected to have high coupling effects. Analytically well-derived optimal dimensional ratios using the coupling concept have been reported[38] but these ratios could not be applied in the present study because of thickness limitations in PZT fabrication and different substrate material and boundary conditions. Therefore, a finite element method was used to estimate the (k_c) effective coupling coefficient[31]

$$k_c^2 = 1 - \omega_0^2/\omega_a^2, \tag{11}$$

where ω_o and ω_a are the resonance and antiresonance frequencies, respectively. The effective coupling coefficient was estimated by obtaining the resonance and antiresonance frequencies through electrical admittance calculations using a multi-domain finite element method program. Internal damping and acoustic loading were ignored in the calculation. The radius and thickness of the silicon plate were selected to be 600 and 15 μm, respectively, for the f_2 unit driver. Few material properties of the thin-film PZT are currently known. The calculation was therefore based on the properties of bulk PZT 5H,[34] which has the same composition as the thin film (Zr/Ti=52/48) (Ref. 40) used here. Some measured properties by the manufacturer are until now listed to compare them with the bulk values in Table I.

In Fig. 4(a), the curve represents the change in the effective coupling coefficient in the f_2 unit drive with respect to the radius of the PZT layer with a constant thickness of 2.5 μm, which was the maximum consistent thickness of

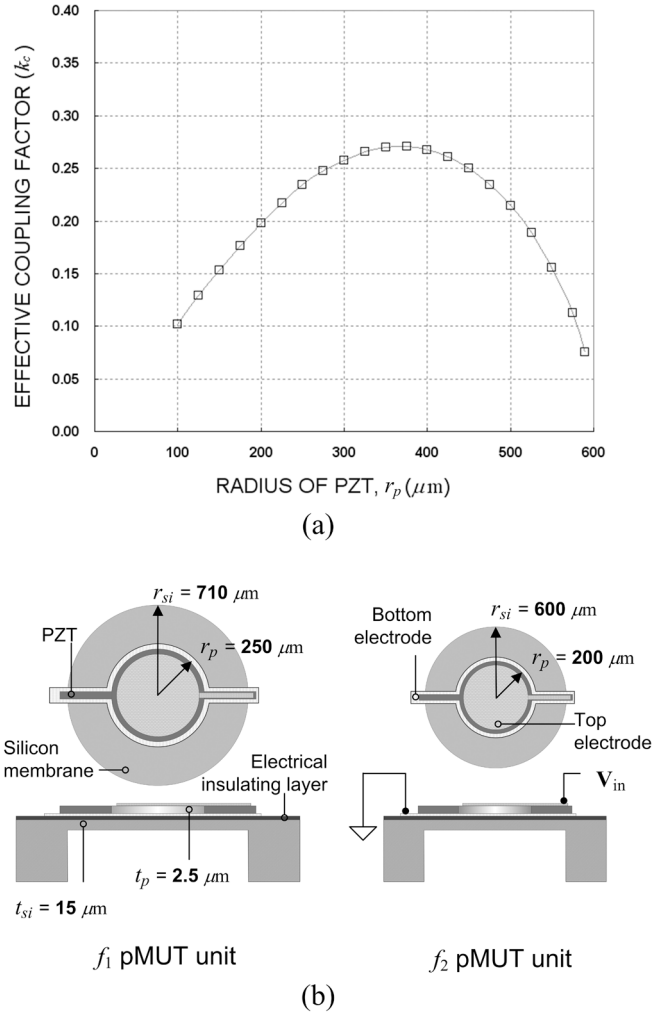

FIG. 4. (Color online) Unit actuators design: (a) effect of the PZT radius on the effective coupling factor for the f_2 pMUT unit and (b) two different resonance frequency-type pMUT units and their schematics.

PZT possible with the wafer-level sol-gel coating and etching process. The coupling coefficient increased as the radius of the PZT increased but decreased for a value of r_p greater than 350 μm. This can be explained by the stress distribution illustrated in Fig. 3(b). However, the maximum value was not used directly in the real actuator design for the input electrical impedance of the whole transducer array. Because all the pMUT units were connected in parallel to ensure in-phase operation, the total electrical capacitance, which was proportional to the top-electrode area of the whole array transducer, was too large when the optimized PZT radius was used. To work around this, the PZT radius was changed to 200 μm. Even with this design value, the effective coupling coefficient of 0.198 was larger than the whole PZT deposition on the thin-film plate [i.e., r_p=600 μm in Fig. 4(a)].

The f_1 pMUT unit was also designed using this process. The resulting two resonance frequency-type pMUT units are shown at the bottom of Fig. 4(b). The outside PZT layer ($r > r_p$) was etched out to reduce internal mechanical damping in the PZT, and only narrow PZT lines were used to connect the top and bottom electrodes to the metal lines of the array outside of the membrane [top of Fig. 4(b)].

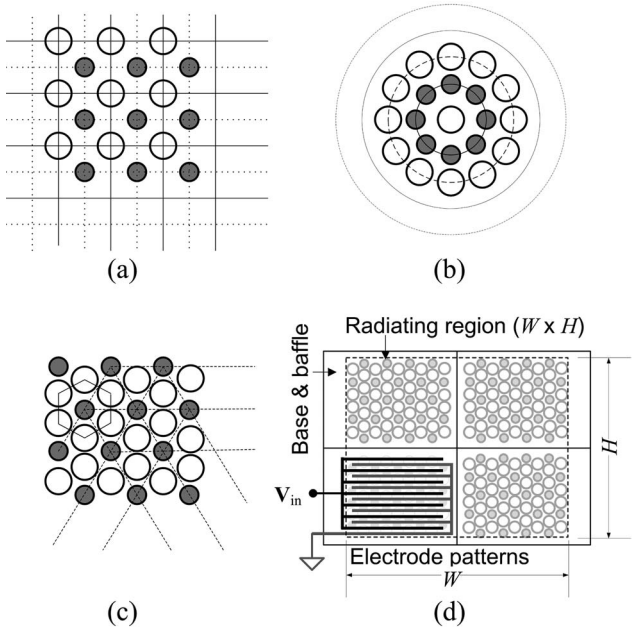

FIG. 5. Several arrangements for mixing the two types of unit radiators (white and gray circles denote unit radiators and f_1 and f_2 indicate resonance frequencies, respectively): (a) square arrangement, (b) ring-type arrangement, (c) hexagonal arrangement, and (d) design using four hexagonal sub-arrays.

D. Transducer array design

Because each primary beam was assumed to be a collimated plane wave in the PA, a basic plane array shape was suitable. There were two design goals in creating the array. One was a good mix of the two different types of unit radiators to ensure the proper interaction between the two primary waves. This meant that the two types of unit radiators had to be repeated on the planar base.[30,36] The other requirement was to improve the radiation output power by increasing the radiation area. The efficient unit radiator did not produce enough power on its own because its active radiating area was too small. Therefore, the output power was increased by the use of an array of many small units. Several arrangement methods[30,35,36] of satisfying these requirements were possible, as shown in Fig. 5. The hexagonal arrangement shown in Fig. 5(c) was chosen for the design because the acoustic loading was expected to be more uniformly distributed by the mutual acoustic impedance.[35,41]

The resulting pMUT array was different from the assumed circular transducer with a Gaussian pressure source distribution. A bulk micro-machined array should have a passive region with zero velocity like a baffle between active units, and a square array with a similar radiation area [$W \times H = 29 \times 26$ mm$^2 \approx \pi(32/2$ mm$)^2$] was selected to increase the fabrication yield instead of using a circular shape. To overcome practical difficulties with uniformity and yield in the fabrication of a large array, the complete transducer consisted of four sub-arrays. Each sub-array had 36 f_1 units and 22 f_2 units, and the units were electrically connected in parallel to generate plane waves. Two symmetrical comb-shaped electrical metal lines were used to achieve a similar electrical metal line resistance for connecting the units in parallel. The final transducer array is shown in Fig. 5(d). The total capaci-

tance of the PZT in the designed array was 173.2 nF.

III. FABRICATION

Figure 6(a)shows the basic fabrication process. A silicon on insulator wafer was used to form the uniform thin film for the array transducer. The device layer, the insulating SiO_2 layer, and the handling layer of the silicon on insulator wafer were 15, 1, and 500 μm thick, respectively. Initial thermal oxidation was applied to the electrical insulating layer between the device silicon layer and the bottom electrode, and the thickness of the SiO_2 was 6000 Å (step I). Pt and Ti were deposited using sputtering on the top of the device layer with thicknesses of 2500 and 330 Å, respectively, to form the bottom electrode. The 2.5-μm-thick PZT layer was coated in the sol-gel process using PZT solution (Zr/Ti=52/48, morphotropic composition; its properties have been described previously[40]). A 2500-Å-thick Pt layer was deposited by sputtering on the PZT layer for the top electrode. After depositing those materials, the electrodes and the PZT layer were patterned by dry etching (step II). A short period of rapid thermal annealing at 650 °C ensured that the PZT layer recovered from the etching damage (step III). The air-gapped pad connection method was used to connect the electrical wire to the top electrode after isolating the top and bottom electrodes.[42] The air-gapped pad connection required three main procedures. First, the sacrificial photoresist (PR) layer was added and patterned onto the space between the top and bottom electrodes (step IV). On the patterned PR, a 3300-Å-thick layer of gold was deposited and patterned by dry etching for the connection (step V); the PR layer was removed in step VII. The backside was etched with an induced coupled-plasma reactive ion etcher using aluminum window patterns to create a thin-film structure (step VI). The complete array transducer was fabricated after releasing the SiO_2 layer between the device and the handing layers (step VII). The air-gapped connection was built after removing the PR. As shown in Fig. 6(b), the fabricated micro-machined transducer arrays were installed on the base, which consisted of a baffle and absorptive backing material. The whole micro-machined structure size was about 35×33 mm^2, including the edge handling portion. Two sets of micro-machined source transducers were constructed and designated as source transducers I and II.

IV. EXPERIMENTAL RESULTS AND DISCUSSION

Before the experiments to generate the DFW with the PA were performed, the dynamic characteristics related to primary wave generation with the pMUT unit samples and the pMUT array were evaluated. The pMUT unit samples were fabricated simultaneously during the pMUT array fabrication. Radiation characteristics of the difference wave were observed to confirm the PA in air. Figure 7 shows the experimental setups for evaluating the vibration and acoustic radiation characteristics. Acoustic measurements were performed in a semi-anechoic chamber 3 m wide, 3 m long, and 2 m high. The ambient acoustic noise in the chamber was below 15 dB re 20 μPa above 150 Hz, and the ambient temperature was assumed to be 20 °C. The transducer and microphone were installed at a height of 1.2 m to reduce the effects of floor reflection during the experiments.

A. Evaluations of unit pMUT performance

The mechanoacoustic efficiency [$\eta_{MA,i}$ in Eq. (1)] of the pMUT unit sample was estimated first. The internal damping of underwater transducers is often measured in air because the acoustic loading in air is negligible compared to that in water.[31] However, the acoustic loading in a micro-machined ultrasonic/acoustic transducer in air is expected to be relatively large compared to the internal damping because of the thin-film plate. To estimate R_{mi} and R_{ri}, a vacuum chamber with a minimum pressure of approximately 0.5 kPa was designed for the velocity response test [Fig. 7(b)]. The vibration velocity amplitude, according to the sweep sinusoidal signal, was measured at the center of the sample, as shown in Fig. 8(a), using a laser Doppler vibrometer [input line **A** and output line **C** in Fig. 7(a)].

The mechanical Q-factor of the f_1 unit sample (f_2 unit sample) was 27 (65) and 275 (378) in air and in vacuum, respectively. Assuming no viscous damping and ignoring the radiation mass [i.e., $X_{ri}/\omega\approx0$ in Fig. 2(b)], these large differences in the Q-factor simply mean that symmetrical acoustical loading at both membrane sides (i.e., top and bottom), $R_{\text{acoustical}}=2R_{ri}\approx\omega_0 m_c(1/Q_{\text{air}}-1/Q_{\text{vac}})$, was very large compared to the internal damping, $R_{mi}\approx\omega_0 m_e(1/Q_{\text{vac}})$,[31,43] where m_e and ω_0 are the equivalent mass of the plate including the PZT layer and the resonance frequency, respectively. In other words, almost all of the mechanical energy was consumed by the acoustical loading. Considering only top

side radiation [i.e., $R_{ri} \approx 0.5 \times \omega_0 m_e (1/Q_{air} - 1/Q_{vac})$], the mechanoacoustic efficiency was estimated using Eq. (1) to be about 82.1% and 70.7% at the resonance frequency in air for the f_1 and f_2 unit samples, respectively. This efficiency is very high compared to conventional transducers and indicates the micro-machined source transducer's potential for efficient radiation in air.[9,19]

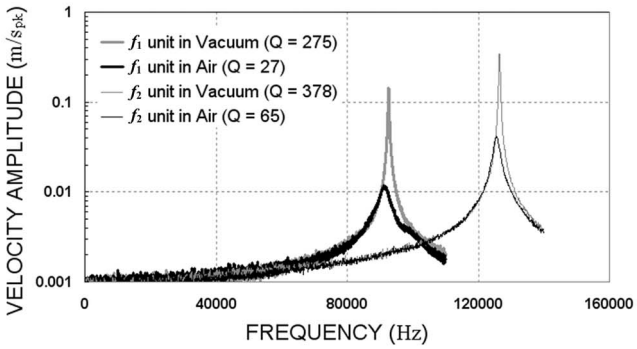
The velocity amplitude of the f_1 unit sample (f_2 unit sample) at resonance in air increased in linear proportion to the input voltage level before 5 V_{pk} (6.5 V_{pk}) and saturated around 10 V_{pk}, as shown in Fig. 8(b). The velocity amplitude response of the f_1 unit sample (f_2 unit sample) up to 5 V_{pk} (6.5 V_{pk}) was approximately 0.42 m/s_{pk} per 1 V_{pk} (0.48 m/s_{pk} per 1 V_{pk}), which is a fairly good dynamic response;[23] a maximum velocity of 1.88 m/s_{pk} (3.12 m/s_{pk}) was achieved. The corresponding sound pressure at the center of the thin-film plate for the maximum velocity of f_2 was calculated by Rayleigh integration[19] with the edge-clamped boundary condition[44] as 915.2 Pa_{pk}. This indicates the potential to use the designed micro-machined transducer as a high-intensity source transducer. However, the pressure distribution of the plate and the baffle region of the array were also taken into account in evaluating its performance.

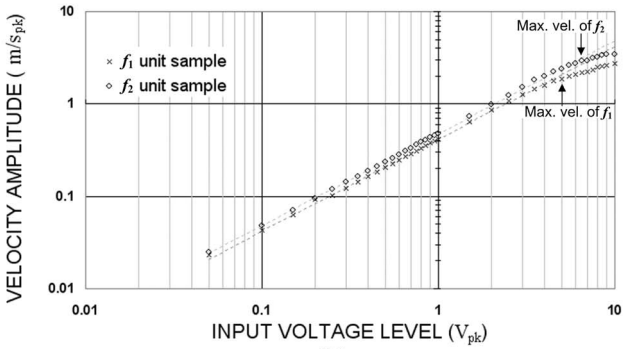
The input electrical admittance[19] of the f_2 unit sample was measured, and the result is shown in Fig. 8(c). Simulated ideal admittance curves are also plotted in this figure, and some parasitic impedance components such as metal line resistance and parasitic impedance through the semiconducting substrate,[13] which are by-products of micro-machining, were detected. This decreased the ideal electroacoustic efficiency, which was around 68% (f_2 unit sample) at resonance, ignoring the parasitic components.

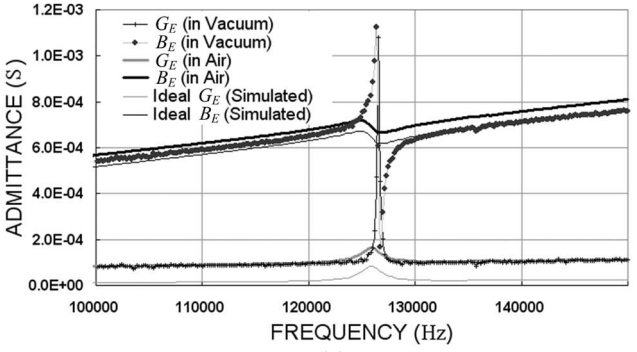
B. Evaluation of the fabricated transducer array

To test the frequency response of the whole pMUT array, the output SPL at a distance of 1 m from the transducer was measured for an input of 3 V_{pk} and a dc bias of −20 V using the test setup illustrated in Fig. 7(a) (input line **A** and output line **D**). The applied dc bias voltage prevented depolarization of the PZT layers, and therefore similar transducer conditions were maintained during the experiments. To use the high-frequency pressure field microphone (B&K 4138 with a high-frequency conditioning amplifier) in a free-field measurement, the microphone was installed perpendicular to the central axis of the transducer [Fig. 7(c)].[45] Additional post-processing was needed in this configuration to acquire an actual response because high-frequency sensitivity was largely reduced. In addition to the direct microphone output signal (measured response), the post-processed data (corrected response) considering free-field correction[19,45] for the 90° incident angle and actuator response of the microphone itself are plotted in Fig. 9. The following analysis and experiments regarding PA were based on the measured response data because the post-processing procedure had uncertainty issues caused by the manual correction process that depended on microphone calibration charts. However, the correction values as a function of the frequency used in this work are also supplied at the bottom of Fig. 9.

Two major peak regions appeared around the designed resonance frequencies, but the peaks were not as clear as those of the velocity responses of unit samples shown in Fig. 8(a). The difference in peak levels was mainly due to the difference in the overall radiation areas of the f_1 units and f_2 units. In case of source transducer I (source transducer II), two major peaks occurred at 94.6 kHz(103 kHz) and 131 kHz(136.5 kHz). Some minor peaks at 101.5 kHz (95.8 kHz) and 134.5 kHz were caused by the nonuniformity of the resonance frequencies in each unit radiator. The lack of clarity in the output SPL response was due to the footing effect,[46] an over-etching phenomenon that occurs in deep-reactive ion etcher processes during the backside bulk etching (depth=500 μm) for thin-film formation. It increases







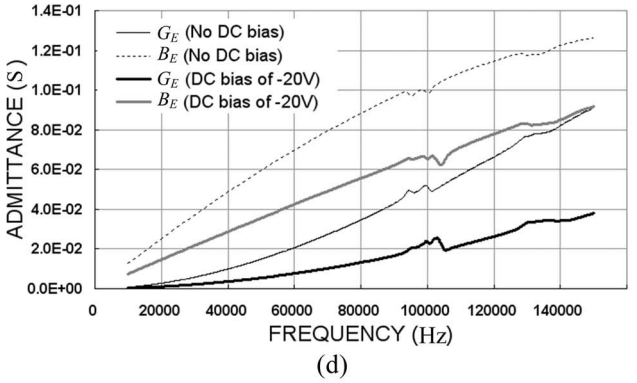


FIG. 8. Dynamic characteristics of unit actuator samples: (a) velocity response in air and in a vacuum, (b) velocity amplitude in the membrane center according to the input voltage level (f_1 pMUT unit sample), (c) the input electrical admittance (f_2 pMUT unit sample), and (d) the input electrical admittance (source transducer II).

the plate radius of some units at the edge of the wafer, causing an irregular decrease in resonance frequency. The resonance frequencies of the test samples in Figs. 8(a)–8(c) also decreased for the same reason. Methods to reduce this effect are under investigation. This non-uniformity in resonance

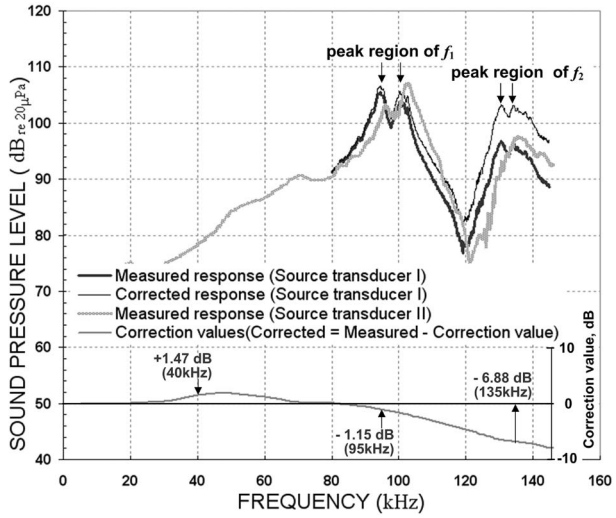

FIG. 9. Output SPL of the transducer as a function of frequency ($z=1$ m in front of transducer, $V_{in}=3$ V_{pk}, and -20 V_{dc} bias) and microphone correction value.

frequencies directly decreased the SPL of the primary waves. The input electrical admittance of source transducer II was measured as shown in Fig. 8(d). However, the curves were strongly distorted by complex parasitic impedance components and the non-uniformity of the resonance frequencies. This was also related to the dc bias voltage. Further analysis of the transducer array gave meaningless results because a solid understanding of all the relations was not obtained.

C. DFW generation

The experiments on DFW generation were conducted with continuous input signals. The experimental setup is shown in Fig. 7(a) (input line **B** and output line **D**). Two dc-biased sinusoidal signals with primary frequencies were generated by two function generators in additive modulation and applied to the micro-machined source transducer after they passed through a power amplifier. Considering the output pressure responses, f_1 and f_2 in the PA experiment were changed to maintain $f_d \cong 40$ kHz. The pressure amplitude of each primary wave was controlled by adjusting the input signal gains. The final input driving signal was

$$\mathbf{V}_{\text{in}}(t) = \mathbf{V}_M(t) + V_{\text{dc}}, \tag{12}$$

where $\mathbf{V}_M(t) = V_1 \cdot \sin(2\pi f_1 t) + V_2 \cdot \sin(2\pi f_2 t + \varphi)$, $V_2/V_1 = \chi$ considering the measured response in Fig. 9) is the modulated driving signal and V_{dc} is the dc bias voltage to polarize the PZT layer. Detailed operating conditions of each source transducer are listed in Table II. For the directional pattern measurements, the high-frequency microphone was installed 0.8 m from source transducer I on the turntable, and the SPL was measured by rotating the transducer. The propagation curves were measured by moving the microphone on a linear rail with source transducer II. Data from one primary wave of f_1 were also plotted on the related graphs. The f_2 data were omitted because of limitations in the fast Fourier transform equipment, but the SPL of f_2 at $z=1$ m was checked with an oscilloscope at the beginning of the experiments.

Difficulties have been often reported in estimating the actual DFW signal of a PA through eliminating various spurious difference signal sources caused by the receiving and transmitting systems.[6,30,36] However, the reduced sensitivity in high-frequency ranges using the perpendicular microphone configuration gave an opportunity to reduce the sources in the receiving system.[47] Compared to a normal incident microphone configuration (+7-dB increment in sensitivity of the microphone used), about −14 dB of the f_2 (135 kHz) primary wave signal could be compressed by this perpendicular installation. Therefore, it worked as a low-pass filter to compress one (f_2) of the primary components. Furthermore, the small downshift ratio between primary and secondary waves $(f_m/f_d \approx 2.9)$ was also expected to reduce the difficulties with spurious signals in this work.[6] Parasitic radiation[6] caused by the transmitting system was expected to be negligible because the two different resonance-type pMUT units were operated nearly independently with a small input voltage level.

1. Models for theoretical references

Appropriate theoretical reference data are required for comparison. However, the exact predictions of the DFW for the fabricated transducer are difficult to discern because of the complex source configurations and the short measurement range (remaining in the near-field of the PA). Therefore, simple ideal cases were selected for prediction, and analytic calculations were performed to generate trends of the DFW for the given primary fields, as follows:

- *Model I*. Rectangular array consisting of ideal circular piston elements to predict primary beam patterns by summing the far-field wave of each element assuming in-phase motion,[19] where each element location and size is matched with the actual transducer; element velocity is a normal value.
- *Model II*. PA model with an axisymmetric Gaussian source,[30] which was used previously in the transducer design to predict the DFW field in the far-field of the source transducer.
- *Model III*. Fenlon solution for collimated infinite plane waves[48] to predict the DFW field near the source transducer.

It is necessary to compare the differences between the actual micro-machined transducer and these theoretical models before addressing the PA experimental results. The main difference in the source pressure distribution between model I and the actual micro-machined transducer is in each element. The actual element is the edge-clamped circular disk, which is slightly deflected to the rear due to the residual stress. In fact, the phases are not identical due to nonuniformity in the resonance frequencies. As discussed in the section dealing with array design, the source distribution on the fabricated transducer array also differs from the axisymmetric Gaussian source of model II and is closer to a rectangular uniform source. The source distributions of these models are plotted using Cartesian coordinates in Fig. 10(a).

2. Beam patterns

The beam pattern of the f_1 primary wave was measured [on the z-x plane in Fig. 10(a)] during the PA experiment. Figure 11(a) shows the measured and calculated beam patterns (ideal transducer array (i.e., model I with f_1 elements and ideal Gaussian source, i.e., model II). The measured beam pattern was similar to that of the estimated ideal transducer array without level differences (less than 5 dB) in some side lobes. Slight unsymmetrical patterns in the measured data were caused by a tilting error in the installation of the transducer. Beam patterns of f_2 were also estimated by the same methods, as shown in Fig. 11(b). Except for the complex side lobes, the major lobe pattern of the transducer array was quite similar to that of the ideal Gaussian source, meaning that a difference frequency beam pattern compari-

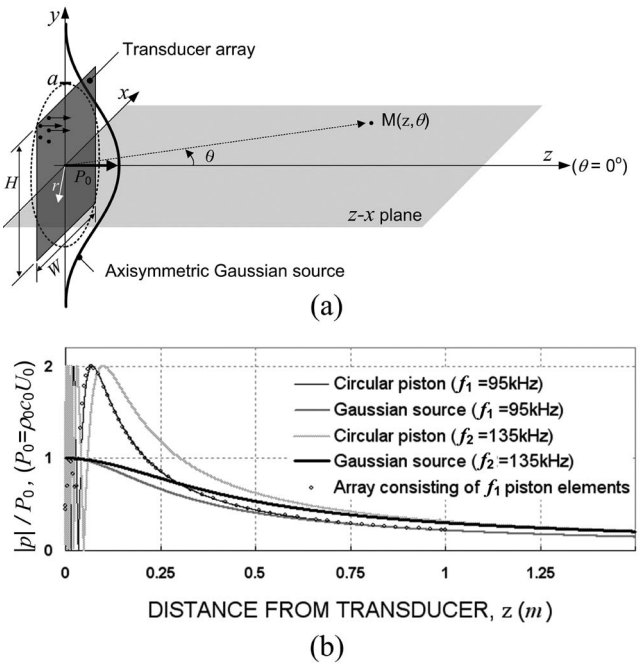

FIG. 10. Source distributions on radiators and calculated pressure amplitude on the z-axis (Refs. 19 and 20): (a) source distributions of the Gaussian and the transducer array; (b) axial pressure amplitudes of the circular piston, the Gaussian source, and the transducer array.

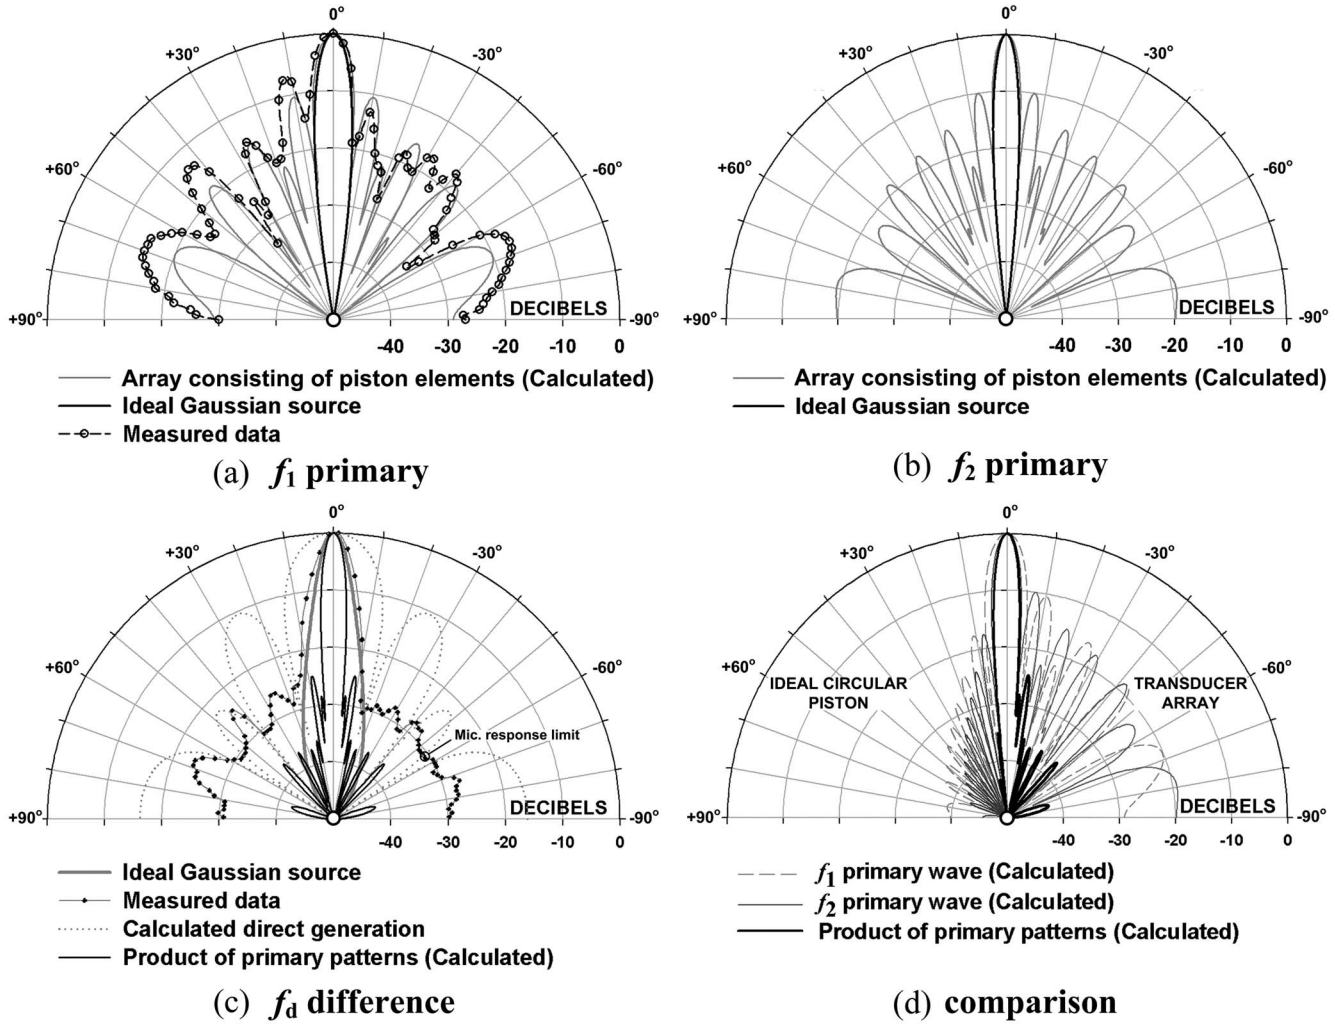

FIG. 11. Beam patterns of the primary and DFWs (z=0.8 m in front of transducer); (a) primary wave, f_1=95 kHz, (b) primary wave, f_2=134.5 kHz, (c) difference wave, f_d=39.5 kHz and product of calculated primary patterns, and (d) calculated primary waves and product pattern of two different sources.

son between the two cases was possible in the discussion of PA generation based on the micro-machined source transducer.

The measured difference frequency beam pattern (solid gray line with black dots) is compared to the theoretical result (solid gray line, model II, using Eq. 6.20 from Ref. 30) in Fig. 11(c). The beam patterns of the major lobes were quite similar. The measured HPBW of the DFW was around 5°, as expected from the design. Even the levels were very small compared to the major lobe (at least −23.8 dB difference), and some minor lobes were observed. To identify the main source of those minor lobes, the product of the simulated primary beam patterns is also plotted in Fig. 11(c). Close correspondence was observed between the angle of the minor lobes and that of the partially collimated primary beams. However, whether the minor lobes of the DFW were caused by the PA or by spurious signals as discussed in Ref. 6 was unclear. Therefore, we measured propagation curves before concluding whether the measured beam pattern was really that of the DFW generated by the PA.[6]

3. Propagation curves

Figure 12 shows the measured propagation curves of the DFW (square dots) and the primary wave (plus dots) for a modulated driving voltage level, $|\mathbf{V}_M(t)|$, of 3 V_{pk}. The measurement for distances greater than 1 m to observe the far-field characteristics of DFW could not be performed due to the limitations of the anechoic chamber. The simulated results for the ideal Gaussian source (model II, using Eq. 6.18 in Ref. 30) are also plotted in this figure for comparison.

Some near-field differences in primary waves occurred because the pressure distribution in the real transducer array (plus dots) was closer to being a uniform source (black dotted line, labeling **c**, $2a$=32 mm) rather than the assumed Gaussian source (heavy black line, $2a$=32 mm). The circular piston was introduced to represent the axial pattern of a uniform source, such as a local maximum, but more realistic behavior near the transducer was that of the ideal transducer array (thin black line, model I). To compare trends in PA generation, the source pressure amplitude (P_1 and P_2=P_0) of two primary waves in the calculation was set to half the local maximum pressure amplitude ($P_{max} \cong 2P_{1\ piston}$=$2P_0$) of the measured primary wave data for convenience.

DFW generation trends of the measurement data (plus dots for f_1 and square dots for f_d) were basically similar to the theoretical results (heavy black line for f_1 and heavy gray line for f_d). However, DFW generation near the transducer of

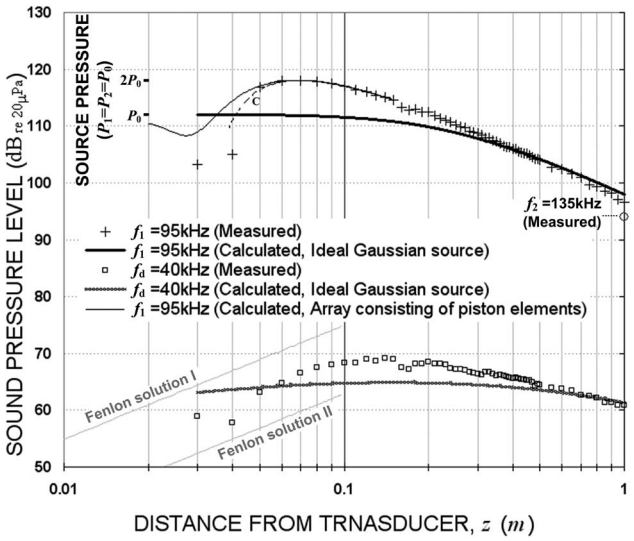

FIG. 12. Propagation curves.

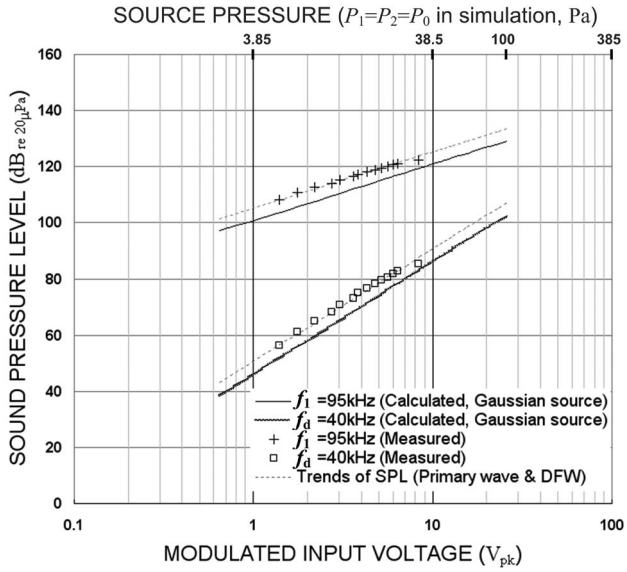

FIG. 13. SPL of primary and secondary waves as a function of input modulated voltage level at z=0.15 m from the transducer.

a Gaussian source is known to be different from a uniform source[49] like the fabricated transducer. Therefore, Fenlon solutions[48] (model III), which describe DFW generation of collimated plane waves, were calculated and are illustrated in the propagation curve to compare the characteristics near the transducer ($z \leqslant 0.1$ m; P_1 and $P_2=2P_0$ for Fenlon solution I and P_1 and $P_2=P_0$ for Fenlon solution II). Unlike the basic assumption in Fenlon solution, the measured pressure amplitude of the primary wave near the transducer was not constant. Therefore, the two solutions were used as maximum and minimum limits. Even though a slight oscillation (at z =0.03 and 0.04 m) in the measured propagation curve of DFW was detected, the increased pattern near the transducer agreed with the theoretical trend. If the spurious microphone signal had a dominant effect on the measured data of the DFW, then a rapid pressure drop (close to −12 dB per doubling distance; see Refs. 6 and 30) would be expected where spherical spreading of primary waves takes place. Therefore, based on the results in Figs. 11 and 12, it appears that the DFW of the PA was successfully generated using the micromachined source transducer.

Unexpected measured data of the primary wave at z =0.03 and 0.04 m should be noted. Their SPLs were much lower (<10 dB) than that of the ideal transducer array (thin black line, model I). The main reason for this is not yet clear due to experimental considerations, such as phase differences in array elements or short measurement distance near the transducer.

With regard to the minor lobes of the DFW in Fig. 11(c), the beam patterns in Fig. 11(d) were calculated assuming a general circular piston transducer to compare them to those of the transducer array. The minor lobes are generally treated as indicators of spurious signals in a measurement or direct sound generation, but in this case the product of the simulated primary beam patterns showed that those minor lobes could also be DFWs generated by the PA. That is, partially collimated side lobes with significant SPL may generate those minor lobes of the DFW. However, to improve the practicality of the source transducer, those minor lobes should be compressed through other considerations in the array design.

4. Maximum performance

To evaluate the maximum performance of the micromachined source transducer, the SPLs of the DFW and primary wave were measured at 0.15 m, where the SPL of the DFW peaks was in Fig. 12, by increasing the modulated input voltage level. Theoretically, the output sound pressure of the DFW is proportional to the value of the two pressure amplitudes of the primary waves multiplied together, assuming no saturation effects,[1] and thus the difference between the SPL of the DFW and primary waves should decrease as the input voltage level increases. Figure 13 shows that each pair of measured and calculated data agreed. The measured maximum SPLs of the difference frequency and primary waves were about 85.4 and 122.5 dB, respectively, for an applied modulated driving voltage level of 8.3 V_{pk} ($V_1 \cong 3.69$ V_{pk} and $V_2 \cong 4.62$ V_{pk}). Based on the trends in Fig. 13, a higher SPL for the DFW would be expected if a higher input voltage could be applied. A higher input voltage could not be used because of thermal problems in the pMUT array; this heat was likely caused by parasitic impedance in the micro-system. Related issues are often reported,[15] but unfortunately, this problem is more common in high-frequency and high-powered micro-systems like the device developed here. A more detailed analysis to resolve this problem is currently in progress.

5. Equivalent source pressure in calculation

The source pressure amplitudes (P_1 and P_2, denoted together as $P_{1,2}$) of the Gaussian source for the PA calculations were defined simply in Sec. IV C 3. Before discussing the method used to define them and its validity, it is necessary to introduce the analytical solutions of Novikov *et al.*[30] that

were used in the DFW field calculations (Ref. 30 is not generally available). The axisymmetric Gaussian source distribution is

$$q_{1,2}(r,z=0) = P_{1,2}\exp(-r^2/a^2), \tag{13}$$

where a and $P_{1,2}$ are the effective radius and the peak source pressure, respectively. Before addressing the solutions, the reduced coordinates (z_a, θ_W) and the reduced amplitude (P_n) transformed from the physical coordinates (z, θ) and sound pressure amplitude of the DFW $(P\_)$ are defined as[30]

$$z_a = z/l_a, \tag{14}$$

$$(\theta_W)^2 = \theta^2 K l_a/2, \tag{15}$$

$$P_n = P\_8c_0^4\rho_0 \exp(z/L_a)/\beta(2\pi f_d)^2 P_1 P_2 a^2, \tag{16}$$

where $l_a = 2/(\alpha_1+\alpha_2-\alpha\_)$, $\alpha_{1,2}$ is the absorption coefficient at the primary frequency, $\alpha\_$ is the absorption coefficient at the difference frequency, $L_a = 1/\alpha\_$, K is the wave number of the difference frequency, and the physical properties ρ_0, c_0, and β are the ambient density ($\rho_0 = 1.21$ kg/m^3 at 20 °C in air), the small signal sound speed ($c_0 = 343$ m/s), and the coefficient of nonlinearity ($\beta = 1.2$), respectively.

Assuming that the ratio f_d/f_m is small, the axial pressure amplitude and the beam pattern of the DFW can be calculated numerically by the following equations:[30]

$$P_n(z_a,0) = i(i+Bz_a)^{-1}\exp\frac{d-iz_a}{i+Bz_a} \times\left[Ei\left(\frac{Bz_a+d}{i+Bz_a}\right) - Ei\left(\frac{d-iz_a}{i+Bz_a}\right)\right], \tag{17}$$

$$P_n(z_a,\theta_W) = i\int_0^{z_a}\exp\left(-y-\frac{(\theta_W)^2 z_a^2(1+iBy)}{i(y-z_a)+yz_aB}\right) \times[i(y-z_a)+yz_aB]^{-1}dy, \tag{18}$$

where $Ei(x) = \int_{-\infty}^{x}(e^y/x)dy$ is the exponential integral, and the parameters B and d are defined as follows:[30]

$$B = L_d l_a/l_{d1}l_{d2}, \tag{19}$$

$$d = L_d/l_a, \tag{20}$$

where L_d is the Rayleigh distance of the difference wave. Equation (18) is valid only at $z \gg l_{d1,d2}$, where $l_{d1,d2}$ is the Rayleigh distance of the primary wave.

The main issue in the axial pressure amplitude calculation with Eqs. (16) and (17) is how to properly define the source pressure $P_{1,2}$ of the Gaussian source from the measured primary fields. It is difficult to define the value directly with the transducer array because the Gaussian source is an axisymmetric source with an ideally infinite radial distribution. The source distributions on the fabricated transducer are closer to the finitely distributed uniform source (especially a rectangular piston with $W \times H \approx \pi a^2$, where $H/W \approx 0.9$) rather than the Gaussian source. A circular piston, the radius of which is the same as the effective radius a, is considered for convenience. Its source distribution is axisymmetric like the Gaussian source, as well as uniform like the actual transducer array. Therefore, it seems to be a link between the two different sources.

If the velocity amplitude of the circular piston (let U_p) is the same as the peak velocity of the Gaussian source (let U_0), their volume velocities are identical to each other. Moreover, in the case of $z \gg a$, they show practically identical axial pressure behaviors.[30] Figure 10(b) shows their axial pressure amplitudes, calculated for the two primary frequencies (f_1 and f_2), when the two velocity amplitudes are the same (i.e., $U_p = U_0$). The source pressure amplitude P_0 of the Gaussian source is half of the local maximum value (let $P_{\max}$; i.e., $P_{\max} = 2P_0$) of the circular piston. The axial pressure pattern (circular dots) of the ideal array (model I) was also calculated only with f_1 elements of unknown velocity amplitude (chosen arbitrarily, and assuming f_2 elements had no significant effect on it). Its level was adjusted by dividing by a constant factor to make the local maximum value of 2. The axial behavior of the ideal array model showed characteristics that were quite similar to those of the uniform piston source, except for the axial patterns near the transducer. In addition, the collimated beam region (i.e., the interaction region distributed along the z-axis) was also approximately similar to that of the uniform source. Therefore, the equivalent source pressure of the ideal transducer array could also be defined in practice considering the relation between the circular piston and the Gaussian source. That is, the existing local maximum value (in the axial pattern of the transducer array, model I) was twice the source pressure.

The measured axial patterns of the f_1 primary wave were also similar to those of the circular piston, including the local maximum point ($z = 0.07$ m in Fig. 12), as for the ideal transducer array. Therefore, the equivalent source pressure $P_{1,2}$ in the calculation model could be defined. Half the local maximum pressure value ($P_{\max}$) of the measured f_1 primary wave was selected as the source pressure in the calculation of the solution (i.e., $P_1 = P_{\max}/2$). This source pressure was used in the calculation of the DFW to predict the far-field of the transducer. In the calculations to determine the DFW fields in Fig. 13, a similar method was used to define the source pressure of the primary wave. That is, the measured primary wave data were assumed to be the pressure amplitude of the ideal circular piston at the same position.

V. CONCLUSION

A MUT and array were designed as a new source transducer in air based on the proper operating condition of the PA. The experiments with the unit samples showed the potential for developing a highly efficient, thin, small primary wave projector. The mechanoacoustic efficiencies of the f_1 and f_2 units were 82.1% and 70.7%, respectively, and the ideal electroacoustic efficiency ignoring parasitic impedance was more than 68%. The MUT also had a noticeable vibration velocity response, which indicated its potential for use as a micro-machined source transducer.

A DFW was generated by the MUT array designed here. The measured beam patterns and the SPL of the DFW were quantitatively similar to the theoretical results obtained from

the ideal models, indicating that the DFW was successfully generated by the PA. The beamwidth was 5°, and the maximum output SPLs of the primary and secondary waves were 122.5 and 85.4 dB, respectively. Even better performance is expected after certain practical problems are addressed.

Two practical issues, those of fabrication uniformity and parasitic impedance, are often considerable in a large array transducer with a high resonance frequency. Detailed analysis and adjustments to the fabrication conditions to reduce these problems are in progress, and results are expected soon.

The transducer can be used as a highly directional ultrasonic transducer for enhancing the spatial resolution in ranging measurements in air, just as in water, because it has a very narrow beamwidth that cannot be achieved using a conventional direct radiation method with the same transducer dimension and operating frequency.

With more theoretical and experimental research, devices for other practical applications will be possible. These could include highly efficient transducers for small or thin directional loudspeakers in mobile appliances. The basis for some of this development has been provided in this paper, and the additional work required to improve the potential of the transducer is already in progress.

On the Larsen effect to monitor small fast changes in materials

Oleg I. Lobkis and Richard L. Weaver[a)]
Department of Physics, University of Illinois at Urbana-Champaign, 1110 West Green, Urbana, Illinois 61801

(Received 22 May 2008; revised 16 January 2009; accepted 22 January 2009)

At sufficient gain an ultrasonic feedback circuit rings with a "Larsen" tone that depends on the acoustic properties of the solid body to which it is attached. Because the frequency of this tone may be measured virtually continuously and with high precision, it is potentially capable of responding to fast small changes in materials. Here a tentative theory for Larsen dynamics is introduced and compared with laboratory measurements. Larsen monitoring is then applied to observation of the curing process of a cement paste sample and to studies of "slow dynamics" in which mesoscale nonlinear materials subjected to modest loads experience a drop in modulus but then recover in a characteristic manner like $\log(t)$. The present technique, using as it does higher frequencies and the Larsen effect and brief transient loads, extends investigations of slow dynamics to earlier times. For the materials and loads investigated, it is found that $\log(t)$ behavior fails at the shortest times, recovery being faster over the first several milliseconds. © *2009 Acoustical Society of America.*

I. INTRODUCTION

It has recently been suggested that measurement of the frequency of direct ultrasonic feedback in an irregular reverberant body could permit monitoring of materials or structures. The Larsen effect[1] in which such feedback results in a single tone is familiar to all. Weaver and Lobkis[2] showed that the width of the steady tone arising from such a nonlinear system can be extremely small and that the frequency of that tone is sensitive to tiny changes in a structure. Detection of changes of a part in 10^8 was shown to be not difficult, and detection of smaller changes is possible in principle. As change in electronics and temperature can also contribute, the technique is best applied to the detection of sudden changes that such drifts are unlikely to generate.

The usual audiofrequency experience is of a single tone, which appears when gain is above a critical level. The tone waxes as amplifier gain is adjusted above that threshold and wanes or disappears when the gain is decreased. It was argued by Weaver and Lobkis[2] that the intrinsic width of the tone was due to background noise and was, in their measurements, too small to measure unless that noise was artificially augmented. It was also shown that the tone was highly stable, varying only due to imperfectly controlled environmental conditions such as temperature. The same considerations apply to the stability of the ultrasonic oscillators used for clocks, and so one imagines that achieving stability greater than that demonstrated in Ref. 2 is technically straightforward.

The frequency of such a tone is easy to measure with high precision and is sensitive to tiny changes in materials. This suggests new methods for nondestructive evaluation structural health monitoring and materials characterization. Here we discuss theory for unstable linear feedback in reverberant acoustic bodies and theory for the resulting limit cycle. We introduce an application to characterization of a material cure and to the phenomenon known as slow dynamics.

The past decade has seen several reports[3–10] of a provocative behavior in materials with mesoscale nonlinearity. These include sandstones and limestones and cements that have complex microstructures composed of imperfectly sintered grains. The nonlinearities observed in these materials are stronger than in classically nonlinear materials. They are generally not quadratic, and they show a memory effect in which loads applied and then removed at one time affect tangent moduli at later times. A typical test from this group will apply a continuous harmonic load to a sample at frequencies of a few kilohertz and will do so with modest strains of the order of 10^{-6}. The load is then released, and the stiffness of the sample is measured and found to be diminished relative to its original stiffness by a fraction proportional to the applied strain. The modulus is then observed to recover slowly, over minutes, and to do so in a manner proportional to the logarithm of time since the load was removed. This is technically a nonlinearity, as modulus depends on load, but it is a nonlinearity of non-classical form, with a slow history dependence. The $\log t$ behavior appears to be universal; it is seen in a variety of materials. It is not understood.

This literature has observed the effect in many materials and at various loads. When temperature is well controlled, the stiffness at late times is identical to the stiffness before the load was applied; the material recovers completely. That it recovers is perhaps unsurprising, as the strains were modest. That its recovery is proportional to $\log t$ over a substantial range in time from 1 to 1000 s or more is intriguing.

The slow-dynamics literature has developed various clever methods for high-precision measurements of the ma-

 0001-4966/2009/125(4)/1894/12/$25.00

terial changes. One way is to monitor the change in resonant frequency. Another is to monitor response to a weak harmonic excitation at a frequency near a resonance. If that frequency is on the shoulder of a vibration resonance, then a change in material properties manifests as a change in amplitude. Both these methods enhance measurement sensitivity by factors of order Q, the quality factor of the resonance. These techniques have so far required a second or more to complete, thus precluding study of slow dynamics immediately after the load is removed. The methods are furthermore poor at short times in that the continuous loading makes problematic the identification of the zero of time needed for an unambiguous identification of log t. For these reasons we conjecture and demonstrate in Sec. IV that Larsen monitoring may complement these methods.

Larsen monitoring is similar to more complex feedback techniques that have existed in the acoustics literature for some time.[11] Ultrasonic sing-around, in which a specified zero crossing in a received transient signal is used to trigger the next transient source, can be used to measure changes in propagation time with exceptional precision. Phase-locked resonance tracking uses a voltage controlled oscillator and a lock-in amplifier, essentially a phase-locked loop, to measure natural frequencies of samples with exceptional precision. In both cases the frequency that the analog nonlinear feedback system chooses is interpretable in terms of a physical quantity, a propagation time, or a natural frequency.

A Larsen circuit uses a simpler, nominally linear, direct feedback for which the source is an algebraic function of the instantaneous input. Because the Larsen field is reverberant, with wavelengths short compared to system size and absorption times long compared to transit times and with multiple complex acoustic paths between source and receiver, the frequency that the Larsen circuit chooses is not readily interpreted as a physical quantity of interest. Only its changes are noteworthy. These changes correspond to changes in material properties at any or all locations within the sample to which the reverberant field penetrates.

In Sec. II a theory for a single Larsen line is formulated. This includes predictions for the linear stability of a quiescent circuit, the resulting steady state screech and its fluctuations, and its sensitivity to changes in material or circuit parameters. Laboratory experiments, both supportive of the theory and not so, are presented in Sec. III. Then in Sec. IV we apply Larsen monitoring to the characterization of a cure evolution and to the slow dynamics of a material sample with mesoscale nonlinear elasticity as it recovers from transient damage,

II. LARSEN CIRCUIT: THEORY

Consider the electro-mechanical circuit illustrated in Fig. 1 in which a waveform $A(t)$ enters a source transducer ("actuator") and is propagated through the sample by an electro-mechanical Greens' function G to a receiver, producing a signal $S(t)$, which is then filtered, amplified [and potentially augmented by amplifier noise $n(t)$], and fed to the actuator. A voltage divider is illustrated that permits control

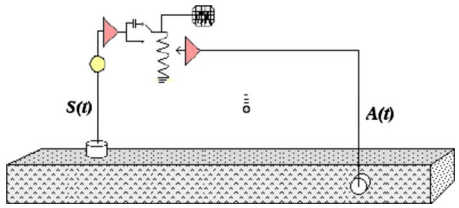

FIG. 1. (Color online) Sketch of test configurations. An electronic feedback circuit filters the signal S with high-pass and band-pass filters (we use passive four-pole filters from TTE) and amplifies it. On occasion it passes then through a switch that inserts extra capacitance. The signal is then passed through an adjustable voltage divider and amplified further before being passed to a piezoelectric actuator at A that provides the ultrasonic source. In some cases the second amplifier is replaced with a comparator, and the system maintained in a regime in which the first amplifier is strictly linear. The circuit typically used two Panametrics model 56000 preamplifiers, each switchable between 40 and 60 dB. Occasionally a third transducer (not shown) monitors the acoustic state of the body. The sample pictured is composed of cured cement paste and has dimensions of $2.5\times2.5\times28$ cm^3. Transducers, typically Physical Acoustics's WD 492 and SNAA04 Acoustic emission sensors, with diameters of 15 and 17 mm and useful frequency ranges from 200 to 700 kHz corresponding to wavelengths of several mm, were placed on different sides of the sample so that their direct fields did not overlap. Typical amplitudes at A are a few volts. Typical signal strengths at S are millivolts or less. Signals were captured and digitized by a LeCroy digital oscilloscope for visual monitoring and by a National Instruments PC-based digitizer with deep (2^{19} words) memory for analysis. Circuit design details are generally unimportant. As described following Eq. (1), a Larsen signal is observed if feedback gain g is sufficient to overcome the electro-mechanical insertion loss between the transducers.

of gain. This simple circuit differs from complex self-oscillating feedback circuits used elsewhere in acoustics[11] and which in principle could be used here as well; it is not *a priori* clear what the relative advantages and disadvantages would be. In the present application, the linear acoustic response G is dominated by a diffuse reverberant field rather than direct propagation. Its Fourier transform, defined by $G(\omega)=\int G(t)\exp\{-i\omega t\}dt$, is an irregular random-looking function of ω with correlations over the range of the inverse of an absorption time. The envelope of $G(\omega)$ is defined by the filters, transducers, and amplifiers. As described below, G's uncontrolled irregular details determine the self-oscillation frequency of the circuit; they are unrelated to any gross material properties.

A. Linear regime

Governing equations for the linear regime, i.e., at signal amplitudes below amplifier saturation, are

$$A(t) = g \otimes S(t),$$

$$S = G \otimes A = G \otimes g \otimes S. \tag{1}$$

The symbol $\otimes$ represents a temporal convolution. Equation (1) predicts unstable growth $S\sim\exp(i\gamma t)$ at (complex) frequency $\gamma=\omega+i\nu$ such that $G(\omega+i\nu)g(\omega+i\nu)=1$. This regime was discussed in Ref. 2, with special attention to the effects of noise. The conclusion suggests, but not compellingly, that the frequency of the ultimate steady state screech is the real part of γ, at least if gain is just sufficient for linear instability such that ν is small and negative.

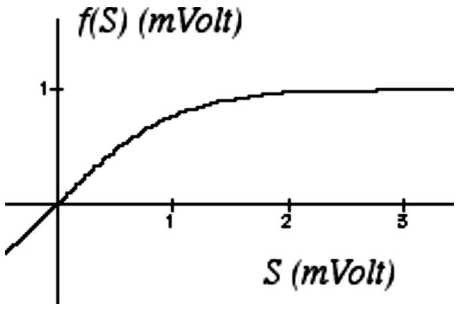

FIG. 2. The nonlinear behavior of the amplifiers is presumed to be smooth, with saturation at an input of several millivolts.

B. Nonlinear circuit

In the nonlinear regime, with saturation, we replace the first of the above equations with

$$A(t) = g \otimes [f(S)], \tag{2}$$

where f is a (odd in S is plausible) function of the signal level S. We also assume that f is instantaneous; there are no nonlinear time delays. Full saturation occurs where $f'(S)=0$. To ensure consistency with the above presumed form in the linear regime, we take $f'(0)=1$. Typically we might expect f to take a form like that illustrated in Fig. 2 with unit slope at small input signal and saturation for input signals greater than a few millivolts. A good choice of f might be

$$f = (F_o/|g|)\tanh(|g|S/F_o), \tag{3}$$

with amplitude of $F_o \sim 5$ V, a typical maximum output of our preamplifiers, and $|g|$, an experimentally adjustable parameter that varies with gain, between 100 (40 db) and 1 000 000 (120 dB). G varies with frequency and sample volume and attenuation. It is independent of gain. Here it is typically of order 10^{-3}, so that about 60 dB is required for the fixed point at $S=0$ to go unstable. The large g limit is simple; for this case $f=(F_o/|g|)\mathrm{sgn}(S)$. This corresponds to the use of a *comparator*[12] rather than a conventional amplifier.

Then, with H defined by

$$H \otimes G \otimes g = \delta(t), \quad \tilde{H}(\omega) = 1/\tilde{G}(\omega)\tilde{g}(\omega), \tag{4}$$

we find that the circuit is governed by the nonlinear time-domain convolution equation

$$H \otimes S = f(S(t)). \tag{5}$$

C. Steady state screech

We seek steady solutions to the above and are particularly interested in the frequencies of such steady solutions. We further seek to understand how sensitive such a solution is to perturbations in material properties, as this is the basis for the imagined applications. It is also desirable to understand the stability of the steady solutions, i.e., the circuit's behavior when it is suddenly perturbed; how quickly does it relax back to the steady solution?

We take S in the form of an oscillation with slowly varying complex amplitude $V(t)$,

$$S(t) = V(t)\exp(i\Omega t) + \text{c.c.} = 2|V(t)|\cos(\Omega t - \phi(t)), \tag{6}$$

where the slowly varying $|V(t)|$ is (half) the instantaneous amplitude of the oscillation, ϕ is $\arg(V)$, and Ω is the nominal frequency of $S(t)$.

If $V(t)$ varies slowly compared to the time delays in H (often equal to acoustic dwell times in the body, i.e., to absorption times), it is helpful to write Eq. (5) as (see the Appendix for a derivation)

$$\exp(i\Omega t)[\tilde{H}(\Omega - id/dt)]V(t) = V\exp(i\Omega t)q(|V|) + hft's. \tag{7}$$

We shall neglect the high frequencies ($hft's$) as multiples of Ω and therefore outside the pass band of Gg. $q(|V(t)|)$ is a function formed from f by extracting the term that is linear in V. q is given in terms of a Fourier integral:

$$q(V_o) = \frac{1}{2\pi V_o}\int_0^{2\pi} \exp(-i\tau)f(2V_o\cos\tau)d\tau$$

$$= \frac{i}{2\pi V_o}\int_0^{2\pi} \exp(-i\tau)f(2V_o\sin\tau)d\tau. \tag{8}$$

If $f(S)$ is an odd function, then q is real. For the special case $f=F_o\,\mathrm{sgn}(S)/|g|$, we find $q(V)=2F_o/\pi|g|V$.

Equation (7) has a steady solution $V(t)=V_o$ given implicitly by

$$q(|V_o|) = \tilde{H}(\Omega), \tag{9}$$

thus implying that the frequency Ω of auto-oscillation must be such that $H(\Omega)$ is real and positive. This is a familiar condition, that the phase gain on any one full pass through the circuit is a multiple of 2π. The conclusion $\mathrm{Im}\,H(\Omega)=0$ is testable in the laboratory; it is confirmed below.

D. Time-dependent perturbations

Now consider a time-dependent V near the above limit cycle, with $V=V_o+u(t)$ and small complex $u(t)$. Equation (7) becomes

$$[\tilde{H}(\Omega - id/dt)][V_o + u(t)] = q(|V_o + u(t)|)[V_o + u(t)]. \tag{10}$$

At leading order in u, this is

$$[\tilde{H}(\Omega - id/dt)]u(t) = q(V_o)u + V_o q'(V_o)\mathrm{Re}\,u. \tag{11}$$

We seek solutions of the form $u=|U|\exp(i\alpha+\lambda t)$. Thus

$$[\tilde{H}(\Omega - i\lambda)] = q(V_o) + V_o q'(V_o)\mathrm{Re}(e^{i\alpha+\lambda t})e^{-i\alpha-\lambda t}. \tag{12}$$

The time dependence drops out only if λ is real. We then deduce

$$[\tilde{H}(\Omega - i\lambda) - \tilde{H}(\Omega)] = V_o q'(V_o)e^{-i\alpha}\cos\alpha, \tag{13}$$

which may be considered an equation for the real quantities λ and α. The equation may be rewritten by eliminating α:

$$|[\tilde{H}(\Omega - i\lambda) - \tilde{H}(\Omega)]|^2$$

$$- V_o q'(V_o)\mathrm{Re}[\tilde{H}(\Omega - i\lambda) - \tilde{H}(\Omega)] = 0. \quad (14)$$

This is an implicit equation for the (real) λ. If λ is small compared to the scale over which H varies (i.e., $\lambda \ll 1/$absorption time), then the difference $H(\Omega - i\lambda) - H(\Omega)$ may be written as $-i\lambda H'(\Omega)$ and an explicit expression derived for λ

$$\lambda = V_o q' \ \mathrm{Im}\ H'/|H'|^2 = (V_o q'/q) H \ \mathrm{Im}\ H'/|H'|^2$$

$$= (V_o q'/q) XY'/(X^2 + Y^2), \quad (15)$$

where $H = 1/Gg = (X + iY)$. The first factor in parentheses in the last term of Eq. (15) is real and dimensionless and of order −1, so we conclude that the Larsen state is stable ($\lambda < 0$) if and only if $\mathrm{Im}\ H' > 0$. We also conclude that

$$\alpha = \arg H'(\Omega) \quad (16)$$

plus any integer multiple of π.

Equation (16), together with the conditions $\mathrm{Im}\ H' > 0$, implies that this perturbation of the Larsen state has an amplitude $V_o + \mathrm{Re}\ u = V_o + |U|\cos\alpha \exp(\lambda t)$. Similarly the perturbed state has a frequency $\Omega + \lambda(|U|/V_o)\sin\alpha \exp(\lambda t)$. The ratio of frequency perturbation to fractional amplitude perturbation is $\lambda \tan\alpha$.

The value of λ predicted by Eq. (15) is of the order of scale of the frequency variations in H. So we expect the assumption $\lambda \ll 1/\tau_{\mathrm{absortption}}$ made following Eq. (14) to be invalid and corresponding predictions to be non-rigorous. Nevertheless, the above gives estimates for λ and α. More precise values must be found by numerical analysis of Eq. (14) based on analytic continuations of H.

E. Time-independent perturbations

We wish also to estimate the effect of a change in material properties on Larsen frequency. If the material perturbation is large, it may well be that the system will jump to an entirely different Larsen state about which little can be said. If the material perturbation is small enough, we expect a comparably small change in Ω for which theoretical insight may be possible. It is helpful to distinguish two parameter regimes, of high and low modal overlaps.

At low overlap, where G is a superposition of contributions from distinct normal modes, the Larsen state will be dominated by a single normal mode r of the sample. In this regime, we may write gG in the form

$$gG \sim B(\omega)/[(\omega - \omega_r) + i\varepsilon_r],$$

where the factor B has a magnitude and phase inherited from the amplifiers and filters, $B = |B|\exp\{i\phi\}$. These vary only slowly with ω. The mode has natural frequency ω_r and a quality factor $Q = \omega_r/2\varepsilon_r$. The Larsen frequency (the solution of $\mathrm{Im}\ gG = 0$) is then

$$\Omega = \varepsilon_r/\tan\phi + \omega_r.$$

Small variations in elastic or inertial properties generate comparable changes in ω_r and relatively negligible changes in Q. Thus the Larsen frequency will track changes in the sample's natural frequencies. Appealing to standard first-order time-independent perturbation theory for normal modes,[13] it may be concluded that increased mass leads to negative semi-definite changes in Larsen frequency. Similarly, decreases in stiffness will lead to negative semi-definite changes in Larsen frequency.

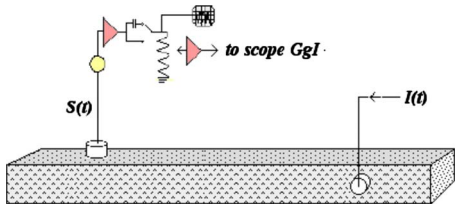

FIG. 3. (Color online) The passive linear response Gg corresponding to Fig. 1 is measured by applying an impulse $I(t)$ to the actuator and measuring the response GgI of the linear circuit.

At high overlap but still in a reverberant regime, gG is the Fourier transform of a causal decaying (but otherwise stationary) Gaussian random process. The resulting statistics on $|gG(\omega)|^2$ are termed Ericson fluctuations.[14] gG is a complex Gaussian random process with correlation range equal to the inverse of an absorption time. Its phase generally increases with frequency, but not strictly so. How its phase depends on changes in material properties is not at all clear. Addition of mass surely must, in some average sense, delay the responses (it lowers wave speeds) and thus augment phase and diminish Larsen frequency. But that is an argument that pertains to an average. We have been unable to reliably conclude that Larsen frequency has the same kind of monotonicity at high overlap that it ought to have at low overlap.

III. MEASUREMENTS OF THE LARSEN SIGNAL: FUNDAMENTALS

Figure 1 illustrates the experimental configuration. A piezoelectric sensor is placed at an arbitrary position $\boldsymbol{S}$ on an irregular elastic body. The signal from the sensor at S is filtered to control the frequency range available to the feedback circuit, amplified, sampled by a digitizer, passed through an adjustable voltage divider, and amplified further before being passed to a piezoelectric actuator at A that provides the ultrasonic source. Sometimes the filter is placed *after* the amplifiers. For reasons described below, sometimes the second amplifier is replaced with a comparator. Turning on the amplifiers leads to a time-domain signal in which a nominally single-frequency signal grows until the amplifiers saturate.

A switch is sometimes inserted, as illustrated, in order to impose a controlled sudden electronic perturbation by adding or deleting a small capacitance. Figure 1 also illustrates the dropping of a small ball to induce a perturbation to the mechanical system in order to investigate slow dynamics (Sec. IV). Figure 3 illustrates the measurement of the linear part of the transfer function, $Gg = 1/H$, needed in Eqs. (9)–(16).

A. Steady state screech

Section II presented some testable theoretical predictions and speculations. In particular it predicted that the

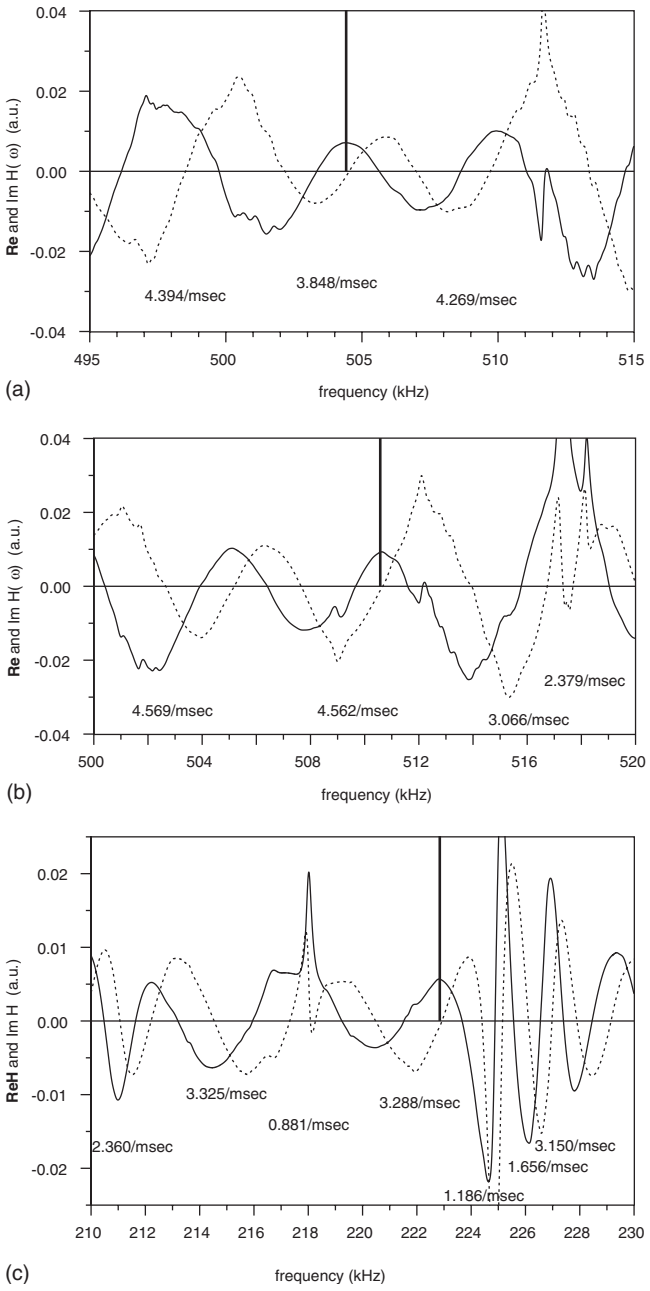

FIG. 4. (a) A span of the spectrum near 500 kHz in a cement paste sample. The bold vertical line indicates the position of the Larsen line. (b) The spectrum H and Larsen frequency of a different configuration. (c) A low-pass filter brings the Larsen state to a frequency of 222.8 kHz.

Larsen frequency Ω is such that Im $H(\Omega)=0$ and Re $H>0$. It also predicted that the Larsen signal, when perturbed, relaxes to its steady state like $\exp(-|\lambda|t)$ with a specified ratio of perturbed frequency and amplitude. Both λ and α are given theoretically in terms of the Greens' function in the vicinity of Ω.

Figure 4 gives some sample spectra $H(\omega)$ as obtained conventionally in the configuration illustrated in Fig. 3 by applying an input pulse $I(t)$ at A and measuring the response $v(t)$ equal to the convolution of Gg and I in a low amplitude regime in which there is no saturation. H was defined as the ratio of their Fourier transforms. $\tilde{H}(\omega)=\tilde{I}(\omega)/\tilde{v}(\omega)$. Superposed on these spectra are vertical lines indicating the frequency of the Larsen screech.

Three cases are shown, corresponding to different transducer positions or different filters. In all cases Im H (the dashed line) vanishes at the Larsen frequency, in accord with Eq. (9). Similarly Re H (solid line) is in all cases positive. Figure 4(a) shows a span of the spectrum near 500 kHz in a cement paste sample. The bold vertical line indicates the position of the Larsen line. Apart from a slight frequency shift that is attributable to temperature drift and/or trigger jitter, the Larsen state has a frequency at which Im $H=0$ and Re $H>0$, as required by theory. There are three other points in this span for which Im $H=0$ and Re $H>0$ also. Each is labeled by its value of $-\lambda$ according to Eq. (15). All are positive, indicating that each is stable (i.e., $\lambda<0$). The labels also show that this Larsen state occurs at the least stable of these points, although the differences are slight. One conjectures that the smaller value for H in the vicinity of 504 kHz, corresponding to a larger value of Gg, may generate stronger linear instability of the quiescent state and may thus be responsible for the system choosing this state rather than one of the others. Alternatively, it may be that the simple theory [Eqs. (6)–(16)] is inadequate for a good estimate of λ. A value of λ of order 4/ms corresponds to an (imaginary) frequency difference of 0.65 kHz, a range over which H is imperfectly approximated as linear.

Figure 4(b) shows the spectrum and the Larsen frequency for different circuit impedances and transducer positions but the same sample and filters. The Larsen state is similar to that of Fig. 4(a). This time the Larsen state chooses the most stable of the candidate frequencies and also the one with the greatest Gg.

Figure 4(c) shows the spectrum and Larsen frequency after the high-pass filter is removed, thus bringing the Larsen state to a frequency of 222.8 kHz. Again one notes a slight shift between the Larsen frequency and the position of the corresponding zero in Im H, again ascribable to temperature drift and/or trigger jitter. In this range of frequencies, there are seven candidate points at which the criteria Im $H=0$ and Re $H>0$ are met. The Larsen dynamics has chosen that frequency, which is among the most stable, and has the greatest value of $gG=1/H$.

B. Time-dependent perturbations

On switching in or out a minor perturbation to the electronics, as illustrated in Fig. 1, we can measure circuit dynamics in the vicinity of the limit cycle. The switching is effected electronically using transistors and takes place in microseconds. Figure 5(a) shows the rms Larsen amplitude in the cement paste sample after this is done. The Larsen signal is seen to evolve after the perturbation with a time scale that is of the order of the absorption, here about 200 μs.

An estimated instantaneous frequency of the signal whose amplitude is given in Fig. 5(a) was determined by a running average of its zero spacings and is shown in Fig. 5(b). The relaxation to the new frequency is, as is the amplitude in Fig. 5(a), accomplished on the scale of the absorption time in the sample. These dynamics are believed to be linear [as assumed in the derivations of Eqs. (10)–(16)] because a

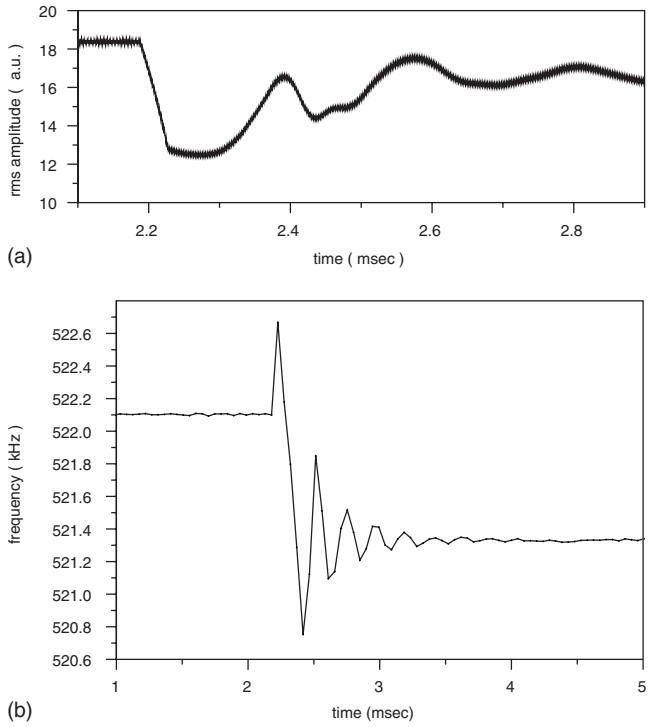

FIG. 5. (a) The Larsen signal's root mean square amplitude (smoothed over a time period of 0.5 ms) relaxes back to a new steady state after a change in impedance is applied at time of 2.2 ms. (b) The instantaneous frequency of the Larsen signal of (a).

repeat test with a greater impedance change merely rescales figures like Fig. 5(b) without affecting their shapes. One can also evaluate the phase accumulation during the transition, $\int[\omega(t)-\omega(\infty)]dt$. It is less than unity, so again linearity is plausible. The decaying oscillations are intriguing, especially as that behavior is not consistent with the theory [Eqs. (10)–(16)], which predicted real λ. The theory appears to be incorrect or inapplicable. The time scale for the relaxation is, however, of the same order as that predicted by theory. One may speculate, inasmuch as the many solutions of Eq. (9) are separated by frequency differences comparable to the beat frequency above, that the oscillations in Fig. 5(b) are such beats.

The above behavior was obtained with the use of a comparator in place of the second amplifier. The use of a pair of conventional ultrasonic preamplifiers (Panasonic 5660B) sometimes allowed perturbations that relaxed hundreds of times more slowly. This is not understood, but these preamplifiers are not well characterized in their saturation regime, nor are they guaranteed to have no nonlinear delay. The advantage of a comparator, which puts out a signal $f(S)$ essentially equal to $F_o\,\mathrm{sgn}(S)$, is that the nonlinearity and saturation behavior are understood and well controlled. Our comparator puts out a signal F_o with a fixed amplitude of about 5 V; it switches at a threshold of ±20 mV, with a switching time of several nanoseconds.

Signal dynamics were also studied in an aluminum bar of dimensions $35\times2.5\times2.5$ cm^3. Absorption in the aluminum was about three times slower than in cement (and dominated by losses into the transducers, not intrinsic mechanisms.) Figure 6 shows the transfer function for this system

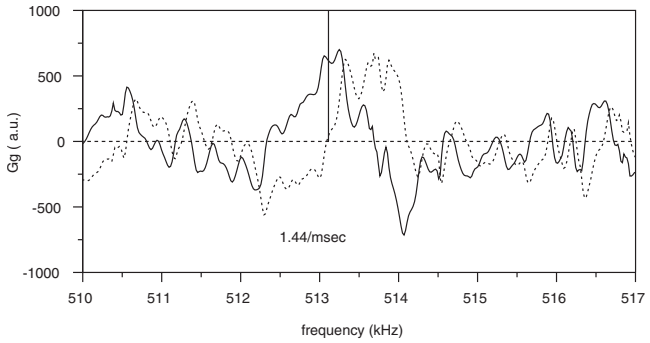

FIG. 6. A Green's function for an aluminum bar in the vicinity of its Larsen frequency.

in the vicinity of the Larsen line at 513.112 kHz. Again the Larsen state has chosen a frequency at which Im Gg vanishes and Re Gg is positive. The line has been labeled with the theoretical stability parameter $\lambda=1.44/\mathrm{ms}$ calculated for this point. Figure 7 shows the instantaneous frequency after a perturbation corresponding to several hertz. Phase perturbation $\int[\omega(t)-\omega(\infty)]dt$ is still small, and acoustic parameters such as modal density and absorption time are similar, yet the behavior is very different. We see that the perturbed signal relaxes to the new equilibrium in an irregular (yet reproducible) manner, but with a time constant of 10 ms or more, much greater than the predicted $\lambda\sim0.69$ ms. The signal dynamics is qualitatively different. Neither system has a behavior that comports with theory. The enormous phase space available in such structures appears to lead to some nonobvious behaviors that, so far, resist theoretical understanding.

C. Time-independent perturbations

The sign of the change in Larsen frequency upon adding mass was also investigated. As in Ref. 2 drops of water, from 1 to 10 mg, were added to the surface of aluminum and cement paste samples (the latter to an applied hydrophobic surface). All tests were conducted in the high modal overlap regime in which a large number of natural modes contribute at any given frequency. These tests were done on a variety of Larsen states at various different frequencies and different transducer positions. In all cases it was found that the origi-

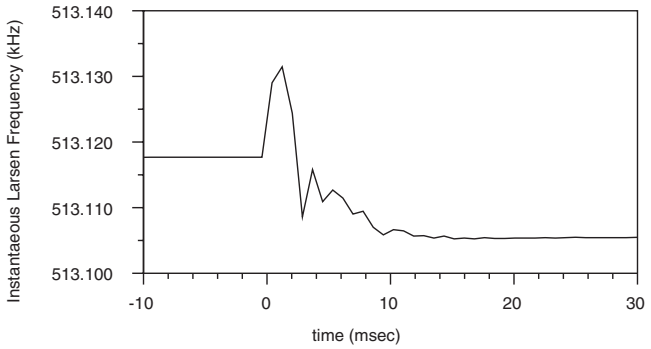

FIG. 7. Larsen dynamics in the aluminum bar. Instantaneous frequency was determined by a chi-square fit to time-windows of length of 0.8192 ms. Amplitude shows similar although somewhat less erratic behavior, varying by about 10%.

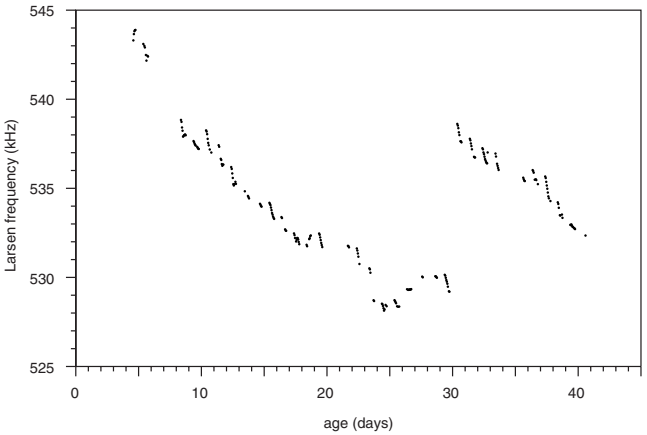

FIG. 8. The Larsen frequency of a sample of cement paste in the weeks following its creation shows a steady slight decrease at about 3% per month. Larsen frequency was assessed several times on each of many days. Within each day we observe a downward drift as sunlight heated the room. The large jump at day 30 is due to a loss of Larsen limit cycle stability and a jump to a new limit cycle; it is not indicative of a correspondingly large (2%!) change in the structure.

nal Larsen state was recovered when the water drop was removed. In no case was the sign of the change in Larsen frequency consistent. Increases were as common as decreases. This is in accord with the theoretical expectations (Sec. II C) that there should be no such monotonicity unless the modes are distinct. The magnitudes of the fractional changes were, as might have been anticipated, comparable to the ratio of added mass to the sample mass.

The change in Larsen signal with ambient temperature or degree-of-material cure was also studied. As seen previously, increased temperature, corresponding as it does in these materials to nearly uniformly decreased wave speed, induced greater delay and lower frequency. Thus Larsen frequency was typically found to evolve slowly and continuously as ambient temperature evolved, by parts in 10^5/min corresponding to small fractions of a degree per minute.

IV. APPLICATIONS

As an illustration of the potential utility of Larsen monitoring, we have used it to study the cure of a cement paste sample and to study the slow dynamics discussed in Sec. I.

A. Cure monitoring

Larsen frequency was monitored in a sample of cement paste in the weeks following its manufacture. At each of several times in the course of each weekday for a month, Larsen frequency was measured at 2 s intervals for 100 s at a time. As seen in Fig. 8 Larsen frequency showed a steady decrease from day to day. This change is attributable to curing; it tracks changes in resonance frequency near 5000 Hz of a sister sample. The steady decrease is modulated by a daily fluctuation attributable to variation in laboratory temperature. At day 30 it jumped autonomously by a large amount [comparable to the spacing between zeros of the imaginary part of the Green's function (see Fig. 4)]. This is presumably due to the Larsen state that it had enjoyed for 4 weeks, losing its stability (due to slow changes in material properties reaching a critical point) and the sample promptly re-settling in a new Larsen state.

Figures 9 show closeups of the Larsen frequency on 2 s intervals in one of the tests on day 15 and one of the tests on day 17. By chance, these exhibit sudden jumps. It is tempting to attribute the jump to a sudden change in material properties. The magnitude of the jump is tiny compared to the frequency scale of Gg; so the jump is unlikely to be like that seen between days 30 and 31. Interestingly, the jump of day 15 is followed by a slow recovery; the jump on day 17 is preceded by a similar trend. Few such changes were seen, but they are probably not rare, as the sample was monitored less than 1% of the time. It would be interesting to observe such changes while simultaneously listening for acoustic emissions.

B. Slow dynamics

Loading the sample by the transient impact of a wooden ball leads to a sudden shift in Larsen frequency that can be controlled. As with the autonomous shifts in Fig. 9, this shift then relaxes over a period of minutes. As described in the slow-dynamics literature,[3–10] application of moderate strains to materials with nonlinear mesoscale elasticity leads to an apparent damage in which the modulus diminishes but then recovers slowly, in a manner similar to that of Fig. 9. In an illustration of the potential usefulness of Larsen monitoring, we apply it here to the detection of such changes following the impact of small wooden balls dropped from a height of 20 cm on a cement paste sample. Concurrently with the ball

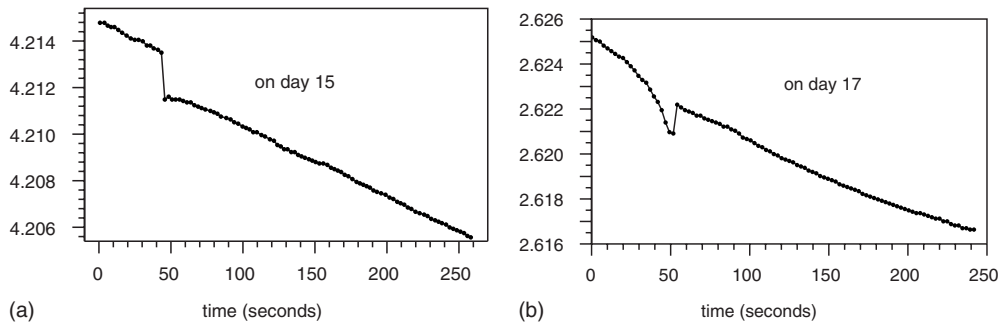

FIG. 9. On days 15 and 17 the cement paste sample exhibited sudden (within the 2 s resolution) changes in Larsen frequency (here plotted less 530 kHz) and slow recoveries. These changes are tiny compared to a shift associated with a change in Larsen state (e.g., Fig. 8 at day 30).

impact, we monitor a ~500 kHz Larsen frequency and find that it diminishes after the impact and then recovers slowly. Acoustic emission from the impact is largely confined to frequencies below 100 kHz and thus has little direct influence on the Larsen circuit, which incorporates a passive four-pole high-pass filter with a 3 dB point at 350 kHz. Our Larsen signals are typically captured at a sample rate of 2.5 MSa/s with 2^{19} 16-bit samples for a signal length of $T=210$ ms. To provide a baseline and a record of temperature drifts, Larsen signals are captured at regular time intervals for several minutes before the impact. The acoustic emission from the impact is then detected by a separate ultrasonic receiver and used as the zero of time and to trigger immediate Larsen monitoring for a period of $T=210$ ms after the impact. At later times the Larsen signals are again captured at non-coterminous finite intervals.

Each 2^{19} word sample is broken into 32 consecutive sub-samples and analyzed for its frequency. This is done in three different ways. One technique is to pad each sub-sample of length $T/32$ with a large number of zeros and then do a discrete Fourier transform. The result has a clear peak that can typically be resolved to a degree far finer than $32/T$. Alternatively, the record is fit by nonlinear least-squares to a sine wave of constant amplitude and phase. In some circumstances, a simple measurement of zero spacing suffices. The three methods were found to yield the same Larsen frequency.

Estimates of maximum loads and contact times may be made based on the familiar quasi-static Hertzian contact theory for elastic spheres.[15,16] We consider a ball of radius R, uniform mass density ρ, mass $m=(4\pi\rho/3)R^3$, Young's modulus E_1, and Poisson ratio ν_1. It impacts at speed $V_{\text{impact}}=\sqrt{2gH}$, where H is the height from which the ball is dropped. Johnson[15] tells us that the contact time T^*, the maximum penetration δ^*, the maximum pressure p^*, and the radius a^* of the contact region are given by (where $1/E=(1-\nu_1^2)/E_1+(1-\nu_2^2)/E_2$ and E_2 and ν_2 pertain to the half space)

$$\delta^* = (15\ \text{V}^2\ \text{m}/16\sqrt{RE})^{2/5}$$

(proportional to R and $H^{2/5}$, at constant ρ, E),

$$a^* = \sqrt{(\delta R)}$$

(proportional to R and $H^{1/5}$, at constant ρ, E)

$$p^* = 2E\delta^*/\pi a^*$$

(independent of R, and scaling with $H^{1/5}$ at constant ρ, E)

$$T^* = 2.87(\text{m}^2/RE^2\ \text{V})^{1/5}.$$

(proportional to R and to $H^{-1/10}$ at constant ρ, E).

Consider a representative case of a 5 mm radius wooden ball (with density of 0.8 g/cc) impacting on a cement half space at 2 m/s, for which $T^*=36\ \mu$s, $m=0.4$ g, $\delta^*=25\ \mu$m, $a^*=0.351$ mm, and $p^*=320$ MPa, for a maximum strain in the cement of 1.3%. The maximum stress is directly under the center of the contact and is compressive. For damage in materials such as cement and stone, the tensile stresses are probably the more important. It is the radial stress that is tensile; its maximum occurs at the edge of the contact zone and is $(1-2\nu)/3$ times the maximum compressive stress and thus considerably less than $|p^*|$. Radial stress then diminishes algebraically with further distance from the center of contact, like r^{-2}, and with depth on a scale of a. The volume that sees comparable tensile stresses thus scales like a^3, i.e., like R^3. It is plausible therefore to suppose that total damage scales with the cube of the radius of the ball.

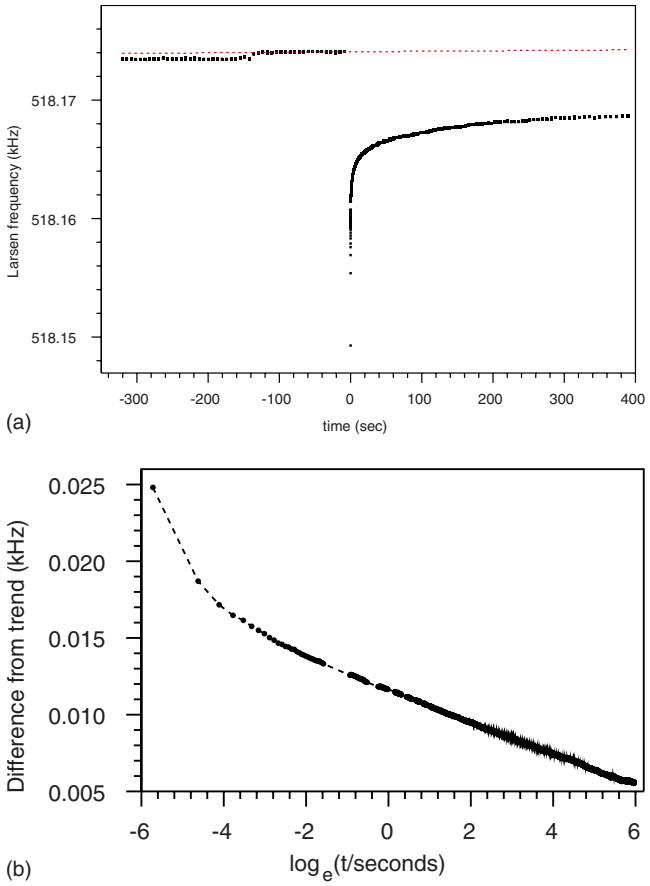

FIG. 10. (Color online) (a) The Larsen frequency of a cement sample is monitored for about 10 min, with continuous sampling at the most critical times. At time "0" a wooden ball impacts upon the sample. The Larsen frequency then drops by about 25 Hz and then recovers. The dotted line is a linear fit to the early time trend. The apparent jump at time −140 s is real, perhaps a small version of those seen in Fig. 9. (b) The difference between the Larsen frequency and the dotted line in (a) is plotted versus the log of the time after the impact.

Heat generated in the sample is bounded by the impact kinetic energy. The above wooden ball carries 0.0008 J for a specimen averaged temperature increase (we assume a 250 g specimen) of order of 10^{-6}°. The fractional modulus change associated with this temperature change is even smaller and negligible compared to the measured fractional frequency change. Thermal diffusivities in cements are of the order of 1 mm^2/s, so the temperature rise immediately under and after the ball impact is greater than this; at 1 s after impact it is about 1°.

A typical result is shown in Fig. 10. The Larsen frequency is seen to be stable for some minutes before impact, with a slow drift that can be ascribed to temperature changes. The observed variation of less than 1 Hz (out of 518.174 kHz) over 300 s corresponds to a temperature variation of 0.04°. The moment of impact is very clear in the plot, where

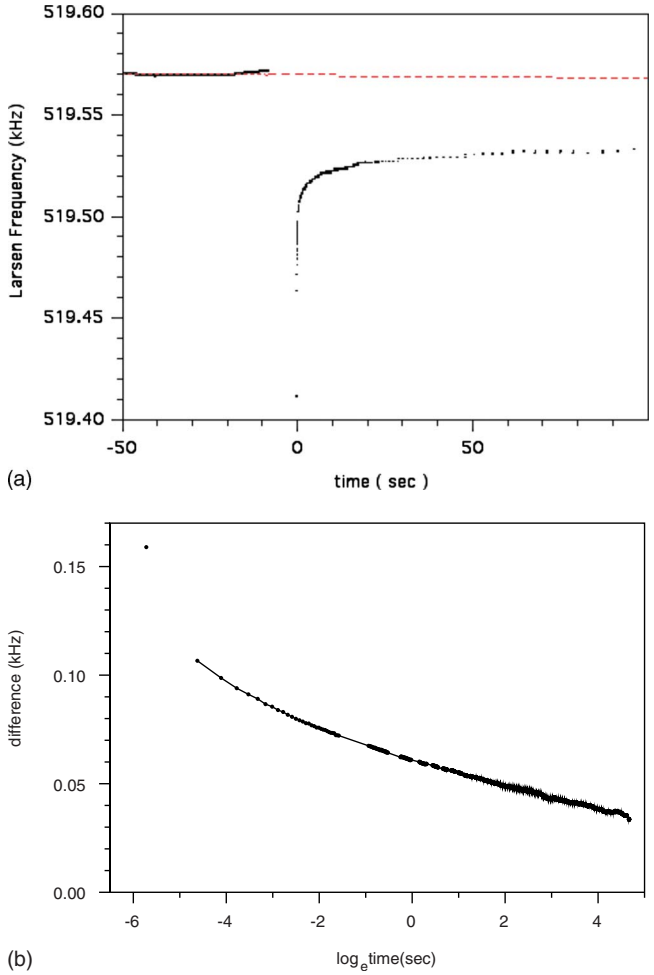

FIG. 11. (Color online) (a) Example of the response to a wooden ball impact on a sandstone sample. (b) $\log t$ relaxation, with accelerated recovery at early times, is also seen in the sandstone sample.

the frequency drops by about 25 Hz. The frequency then tends to recover. At first the recovery is fast; it then slows. It is not obvious whether recovery continues beyond the 400 s of study.

The recovery may be isolated by taking the difference between the instantaneous Larsen frequency and an extrapolation of the Larsen frequency from early times before the impact, thus removing the effects of temperature drift (based on a presumption that the temperature drift proceeds at a constant rate). The difference is plotted in Fig. 10(b) versus the log of time since the impact. As observed in other studies,[3–10] the change is linear in $\log t$. Previous work has been confined to times between 1 and 1000 s after the load is removed. Here the time dependence is extended back to milliseconds. It is seen that the $\log t$ behavior continues, at least in this sample, back to 22 ms. For earlier times yet (the first few data points pertain respectively to $t=3.3$ ms, 9.8 ms, and 16.4 ms), the relaxation is faster than $\log t$. Similar behaviors are observed in sandstone (Fig. 11).

It could be speculated that the accelerated relaxation at short times is an artifact of the signal processing or of the dynamics of the Larsen signal itself. It has not been observed in prior work.[3–10] Our studies (Figs. 5 and 7) of the dynamics of the Larsen frequency subsequent to a sudden change in circuit impedance show, however, that the Larsen dynamics itself has no time scales slower than an absorption time, here of the order of hundreds of microseconds. The accelerated relaxation is therefore attributed to the mechanics of the damaged cement or sandstone.

After 400 s, Fig. 10 shows a recovery of 80%. Extrapolation suggests that complete recovery, if it were to be achieved, would require another 6 h. A reliable study over such long times would require precise control of temperature over that period and has not been attempted here.

The above tests were repeated for three different ball sizes (diameter=3.2, 4.75, and 6.35 mm) and a variety of positions on the cement sample. In every case, the Larsen frequency was found to suddenly diminish at the time of impact and then recover slowly. Curves such as those in Figs. 10 and 11 are typical, but the magnitude of the drop was a random function of position. Figure 12 shows the slopes $\beta = df/d \ln t$, the Δf's at 3.27 ms (the soonest after the impact that we measure), and the Δf's at 1 s (in all cases well into the $\log t$ regime). Each data point is based on impacts at $N=10-20$ different positions. One sigma error bars are plotted; they were constructed by dividing observed standard deviations by $[N-1]^{1/2}$.

It is remarkable how well the data fit simple power law dependence on ball size. The rate of recovery $\beta=df/d \ln t$ scales very closely with the second power of ball radius. The value of Δf at (an arbitrarily chosen) time $t=1$ s within the linear regime scales roughly as the $3d$ power of ball radius. These two powers taken together indicate that the frequency shift at any fixed time is not going to be a simple power of ball radius, so this latter observation cannot be considered robust.

Figure 13 shows a time, $T_{\text{recovery}}=\exp(\Delta f(1.0\ \text{s})/\beta)$, at which recovery would be complete if the linear in $\log t$ behavior were to continue. In accord with the exponents seen for Δf at 1 s and β, one would expect T_{recovery} to be exponential in r. Such an r-dependence is not ruled out by the data which fit tolerably to 2 s times $\exp(1.1r/\text{mm})$, but $T_{\text{recovery}} \sim r^5$ is better supported. The smallness of the error bars shows that there is a positive, but not perfect, correlation between Δf and β across the several ball drops at fixed ball size. Otherwise the fractional error in T_{recovery} would be larger than that of both Δf and β.

The data also permit a calculation (not shown) of what Δf would be if we extrapolated the linear regime to time $t=3.27$ ms. The ratio of that Δf to the actual Δf at that time is very nearly independent of ball size and of ball impact position. In this sense the curvature seen in Fig. 10 is independent of these parameters. The average ratio $\Delta f(3.27\ \text{ms})/(\Delta f(1.0\ \text{s})+5.72\beta)$ was 1.51, 1.43, and 1.43 for the large, medium, and small balls, respectively. This measure of curvature thus appears to be not a function of the damaged volume. This ratio fluctuated randomly with impact position but only slightly; standard deviations were only 0.12, 0.14, and 0.175, respectively. Thus the curvature is also not a function of the position-dependent sensitivity of the Larsen frequency to damage.

It is tempting to conjecture as to the mechanics behind these exponents. That the frequency shifts at times of order of 1 s are proportional to r^3 suggests that it is a measure of

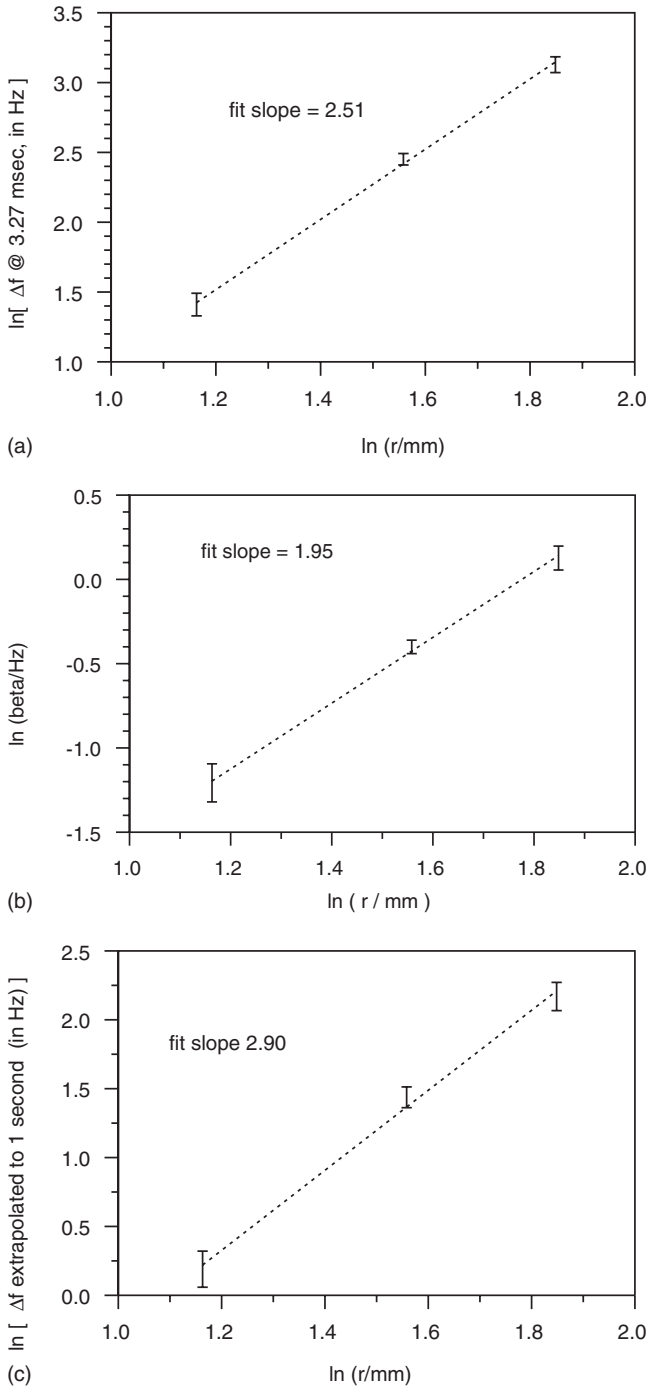

FIG. 12. (a) The shift in Larsen frequency from a base of about 500 kHz, as measured at the first accessible time of 3.27 ms, varies with the size of the wooden ball like $r^{2.5}$. (b) The slope $\beta = df/d \ln t$ varies with ball size like r^{-2}. (c) The frequency shift at a moderate time of 1 s varies like r^3.

the volume of damaged material. That the dependence is not stronger is consistent with the Hertzian elastic contact theory estimate that maximum stress is independent of ball size. That recovery rates scale with r^2 suggests maybe that recovery depends on the surface area of the damaged region. It would be interesting to repeat measurements like these with balls of different materials and/or different impact velocities. Inasmuch as the aim of this report is to illustrate the potential applications of Larsen monitoring, rather than to do materials testing, such is relegated to another occasion.

It is also tempting to compare the slow dynamics seen here with that reported extensively by the group at LANL. Their measurements are very different, using lower strains for the damage, but doing so over larger volumes. Their samples are loaded globally by low strain (of order 10^{-6}) continuous harmonic vibrations at ~3000 Hz. They observe $\Delta f/f$ values at time 1 s that are comparable to those observed here and that scale with strain. They observe a strain-independent time to recovery. Our (compressive) strains are nearly 10^4 times greater, but the volume we damage is only a part in 10^6 of the total volume. In spite of this enormous difference in the parameters of the nonlinear loading, the resulting $\Delta f/f$ and total time to recovery are similar. Precise comparisons would not be meaningful, as different materials can have much stronger or weaker slow dynamics; detailed comparison would require use of matched samples.

That the Larsen frequency always diminishes at impact is noteworthy. Similar behavior is seen in the LANL work.[3–10] There it is perhaps unsurprising, as a diminishment in modulus due to damage will—based on first-order perturbation theory—correspondingly diminish each of the isolated eigenfrequencies of vibration. Theory does not permit us to make a similar inference here. One imagines that diminishment of local modulus at the point of impact ought to lead to randomly signed changes in Larsen frequency, as does an addition of mass (Sec. III C). We are perplexed, but the measurements are unequivocal. Indeed, the frequency shifts associated with the different impact sites were well clustered around their mean, with standard deviations of only 30%.

V. CONCLUSION

Larsen monitoring may be useful for materials characterization or structural health monitoring. For this latter application, it may be compared to that of Lu and Michaels.[17] Its ability to detect small fast mechanical changes lends itself to the monitoring of cure evolution or damage accumulation, especially if these proceed discontinuously. This ability also lends itself to studies of mesoscale nonlinear elastic slow dynamics that would be complementary to those in the literature.

Before any significant application, however, there remain fundamental questions about Larsen signals in reverberant structures. Notable among these is our lack of understanding of the stability of a Larsen state against small perturbations and the rate and manner in which it relaxes; theory developed here does not fully agree with measurements. Nevertheless, some theoretical ideas are confirmed. The Larsen circuit tends to pick the most stable of candidate frequencies at which Im Gg is zero and/or the frequency with the largest Green's function. It may be that these matters can be better understood with numerical simulations and further experiments informed by numerical simulations and theory. Nonlinear dynamical systems composed of reverberant linear waves with electronic gain limited by simple saturation offer a rich topic for investigation.

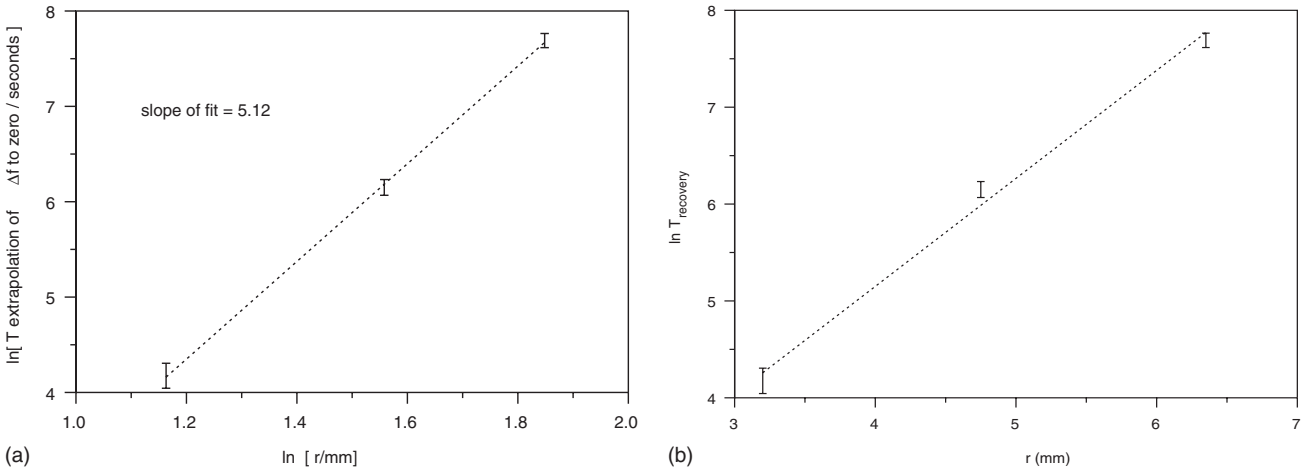

FIG. 13. The extrapolated time at which recovery would be complete were it to continue varies like r^5. An exponential dependence fits the data less well.

fruitful discussions on electronics. We thank John Popovics for the cement paste samples, and advice.

APPENDIX: DERIVATION OF EQUATION (7)

The left and right sides of Eq. (7) are obtained from Eq. (5) by distinct arguments. We start with the definition, Eq. (6),

$$S(t) = V(t)\exp(i\Omega t) + \text{c.c.} = 2|V(t)|\cos(\Omega t - \phi(t)), \quad \text{(A1)}$$

where we have written $V(t)=|V|\exp(-i\phi)$, $|V|$ and ϕ being real and slowly varying with time.

As S is periodic, with period $2\pi/\Omega$, with slowly varying amplitude and phase, so is the right side of Eq. (5), $f(S(t))$. Any periodic function $B(t)$ can be written as a complex Fourier series:

$$B(t) = \sum_{n=-\infty}^{+\infty} b_n \exp(in\Omega t), \quad \text{(A2)}$$

where the complex coefficients are given by an integral over any contiguous period $2\pi/\Omega$ in time,

$$b_n = (\Omega/2\pi)\int B(t)\exp(-in\Omega t)dt. \quad \text{(A3)}$$

We are presuming that S is essentially harmonic, with a single frequency Ω. $f(S(t))$ is not harmonic, but it is periodic. We confine attention to the primary components, $n=\pm 1$, of $f(S(t))$ by arguing that the transfer function gG is weak at the high frequency overtones. Thus

$$f(S(t)) = b_1 \exp(i\Omega t) + \text{c.c.}, \quad \text{(A4)}$$

where

$$b_1 = (\Omega/2\pi)\int f(2|V|\cos(\Omega t - \phi))\exp(-i\Omega t)dt. \quad \text{(A5)}$$

By defining $\Omega t=\zeta$ and $\tau=\zeta-\phi$, this becomes

$$b_1 = (1/2\pi)\int f(2|V|\cos(\zeta - \phi))\exp(-i\zeta)d\zeta$$

$$= (\exp(-i\phi)/2\pi)\int f(2|V|\cos(\tau))\exp(-i\tau)d\tau. \quad \text{(A6)}$$

We recall $V(t)=|V|\exp(-i\phi)$ and see that b_1 is $q(V_o)V(t)$, where q was defined in Eq. (8). Thus we establish the right side of Eq. (7) as equivalent to $f(S(t))$.

For the left side of Eq. (5), which is a linear temporal convolution, we write

$$H \otimes S = \int H(t-\tau)(V(\tau)\exp(i\Omega\tau) + \text{c.c.})d\tau. \quad \text{(A7)}$$

The integral is over all τ. Let $\zeta=t-\tau$ and write

$$H \otimes S = \int H(\zeta)(V(t-\zeta)\exp(i\Omega t - i\Omega\zeta) + \text{c.c.})d\tau$$

$$= \exp(i\Omega t)\int H(\zeta)(V(t-\zeta)\ \exp(-i\Omega\zeta)d\tau + \text{c.c.} \quad \text{(A8)}$$

The slowly varying function $V(t-\zeta)$ is now expanded in a Taylor series around t:

$$H \otimes S = \exp(i\Omega t)$$

$$\times \int H(\zeta)(V(t) - \zeta V'(t) + \cdots)\exp(-i\Omega\zeta)d\zeta + \text{c.c.}$$

$$= \exp(i\Omega t)\left[V(t)\int H(\zeta)\exp(-i\Omega\zeta)d\zeta\right.$$

$$\left. - V'(t)\int H(\zeta)\zeta\exp(-i\Omega\zeta)d\zeta + \cdots\right] + \text{c.c.}$$

$$= \exp(i\Omega t)[V(t)\tilde{H}(\Omega) - iV'(t)\tilde{H}'(\Omega) + \cdots] + \text{c.c.}$$

$$= \exp(i\Omega t)[\tilde{H}(\Omega - id/dt)V(t)] + \text{c.c.} \quad \text{(A9)}$$

This is the left side of Eq. (7).

(Received 10 June 2007; revised 31 December 2008; accepted 26 January 2009)

Acoustic and seismic waves provide a method to localize compliant mines by vibrating the top plate and a thin soil layer above the mine. This vibration is mostly linear, but also includes a small nonlinear deviation. The main goal of this paper is to introduce a method of processing that uses phase-inversion to observe nonlinear effects in a wide frequency band. The method extracts a nonlinear part of surface velocity from two similar broadcast signals of opposite sign by summing and canceling the linear components and leaving the nonlinear components. This phase-inversion method is combined with time reversal focusing to provide increased seismic vibration and enhance the nonlinear effect. The experiments used six loudspeakers in a wood box placed over sand in which inert landmines were buried. The nonlinear surface velocity of the sand with a mine compared to the sand without a mine was greater as compared to a linear technique.

I. INTRODUCTION

The Army seeks methods of detecting landmines using acoustic and seismic wave energy. Most landmines are compliant objects that vibrate readily when subjected to a fluctuating pressure or stress field produced by an external source and this motion induces surface vibrations above a mine that are larger than in the surrounding soil.[1–4] The spatial extent of high vibration above the mine is generally less than a wavelength in soil in a detection band of 50–500 Hz. At higher frequencies, surface waves backscattered off the buried mine have been observed.[5–7] In earlier acoustic detection methods, the surface vibration was assumed to be proportional to the excitation force and nonlinear effects connected with soil and mine vibrations were not taken into account.

Nonlinear acoustic effects can be significant for seismic waves[8,9] and for waves in granular media.[10,11] Previous experiments suggest that nonlinear effects are pronounced in the presence of mines.[12–17] The most investigated nonlinear effect is generation of combination frequency vibrations under simultaneous excitation with two frequency waves.[12–15] This method works effectively for excitation frequencies close to the mine resonance, but is less effective at other frequencies because the nonlinear mine response strongly depends on the linear vibration amplitude, which is low at frequencies away from resonances. Consequently, tests with stepped excitation frequencies are required for detection to guarantee that the optimal frequency is excited since a mine's resonances depend on the type of mine, soil, and burial depth.[1,2,18] An alternate approach is to first find the resonant frequency using linear techniques.[1–4] Both of these methods require significant time for measurements, which makes them less practical for field application than wide band methods.

Time-reversed acoustic methods are used in this work because they provide larger amplitude soil vibrations than unfocused acoustic excitation[19–24] and facilitate measurements of nonlinear responses in the mine and soil. This method leads to large vibrations by generating signals with appropriate temporal delays, ensuring that the seismic and airborne arrivals are in phase in a specific soil region. The resulting pulse vibrates a mine over a wide frequency band.

The time reversal method reduces undesired nonlinear components associated with loudspeakers and propagation, while maintaining high amplitudes at the region of interest. Because the time reversal method focuses the energy spatially, lower source drive levels are required to generate ground vibration of the same amplitude as unfocused excitation systems; this decreases the nonlinear components generated by the speaker system. The spatial focusing maintains the high amplitude of seismic vibration and associated nonlinear effects in the focal area while reducing nonlinearities associated with the soil propagation path.

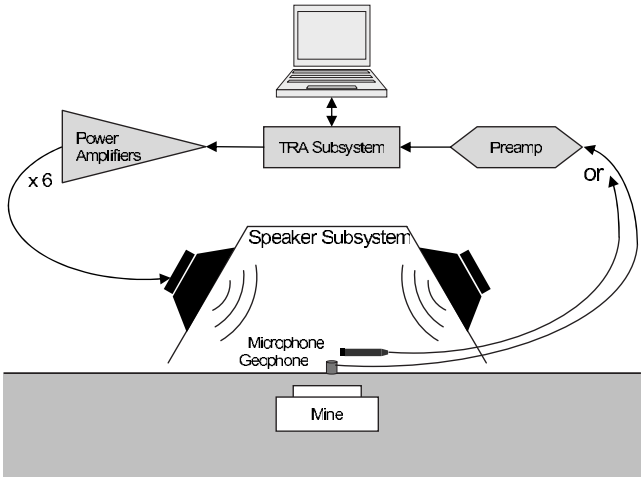

FIG. 1. The schema of the experimental setup for nonlinear time reversal landmine detection. Six simultaneous loudspeaker channels are synchronized with one acquisition channel.

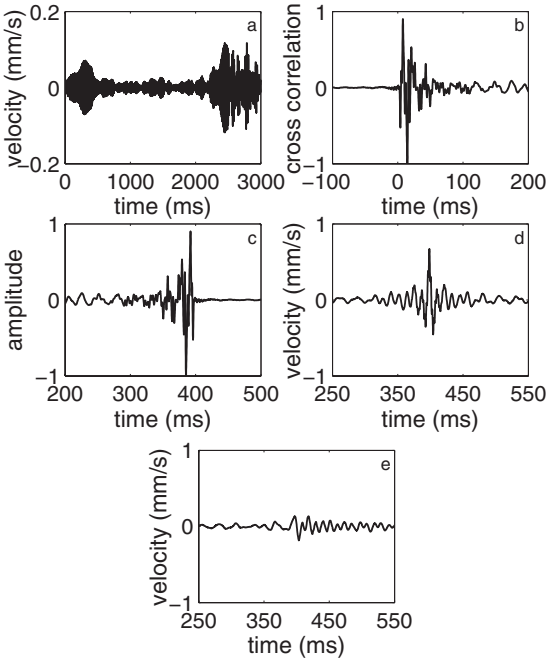

FIG. 2. Examples of signals used during the experiments: (a) surface vibration recorded by a geophone and corresponding to the first loudspeaker, (b) system impulse response estimate based on the cross-correlation of sweep signal and recorded vibration, (c) the time-reversed signal prepared for subsequent broadcasts, (d) focused vibration measurement resulting from the simultaneous time-reversed radiation from all loudspeakers and measured at the focus point, and (e) similar to (d) except measured at 0.6 m from the focus.

This paper investigates the phase-inversion method to measure nonlinear mine vibrations over a broad frequency range. Two similar broadband signal sets with opposite signs are broadcast sequentially and the two recorded responses are summed in postprocessing to cancel the linear component, leaving the nonlinear component. The phase-inversion method was first proposed for ultrasonic imaging of microbubble contrast agents in medical ultrasound. Bubbles have nonlinear responses several orders of magnitude greater than that of tissue and are detectable by considering the response at harmonics or combination frequencies,[25,26] similar to mines. Phase-inversion shows more contrast for bubble detection than the harmonic or combination frequency method and it is widely used in cardiac ultrasonic diagnostics.[25–28]

II. EXPERIMENTAL METHOD

The key components of the experimental setup are the electronic signal control subsystem developed at Artann Laboratories and a speaker subsystem developed at Stevens Institute of Technology[15] (Fig. 1). The electronic subsystem synchronizes six output channels that drive the six speakers and one input channel used for acquisition. A computer controls this subsystem by using custom software to generate, record, process, and store the signals. The speaker subsystem provides an enclosed acoustic space where multiple reflections lead to better focusing of the acoustic signals. The system consists of six speakers, Sony XS-L1265G, with a diameter of 30 cm mounted on the walls of a box in the shape of a hexagonal prism. The vertex of each speaker cone was 0.3 m above the soil surface. The box had a closed top and open base, 1 m across, such that the acoustic field within the enclosure excites the sand surface. The box was hung from a wheeled cart so the lowest edge was 3 cm above the soil.

The test was conducted at an Army test facility in a sand box 1.2 m deep, 3.0 m wide, and 32.7 m long. The *P*-wave and *S*-wave speeds were previously measured and found to be 151 and 118 m/s, respectively. The white beach sand's mineralogy was 98% quartz, 1.5% illite and mica, 0.4% kaolinite, and 0.1% chlorite, with a combined specific gravity of 2.65. The median grain size by mass is 0.3 mm, and the distribution of particle sizes shows 95% of the mass having a grain size between 0.1 and 0.6 mm and 80% having a grain size between 0.2 and 0.5 mm. The current data were collected with soil temperatures of 24–28 °C.

The surface vibrations were measured using an array of geophones without coupling spikes placed on the soil surface. Fifteen geophones, IO SM-11, were available for spatial sampling at 3 in. increments. The mass of a geophone is much less than the mass of soil above the mine, but can lead to a small variation in the resonant frequency.[16,29] A $\frac{1}{2}$ in. microphone, BK 11.5 mV/Pa, was positioned near the focus point 2 cm above the surface in order to compare system nonlinearities to those generated in the sand.

The time reversal focusing was conducted to provide a large amplitude seismic displacement over a large bandwidth. Details of the time reversal multistep process have been previously described[22] and will be briefly recounted here. In the first step, a sweep frequency signal, with frequency from 500 to 50 Hz, was broadcast from one loudspeaker. The resulting seismic vibration was recorded from one geophone at the focal point near the center of the loudspeaker box [Fig. 2(a)]. Next, the cross-correlation was calculated between the recorded vibration and the initial sweep frequency signal. This cross-correlation is proportional to the system impulse response measured in the frequency band 50–500 Hz. The calculated impulse response was normalized by setting the maximum amplitude to 1 [Fig. 2(b)]. Finally, the time reversal occurred by flipping the normalized

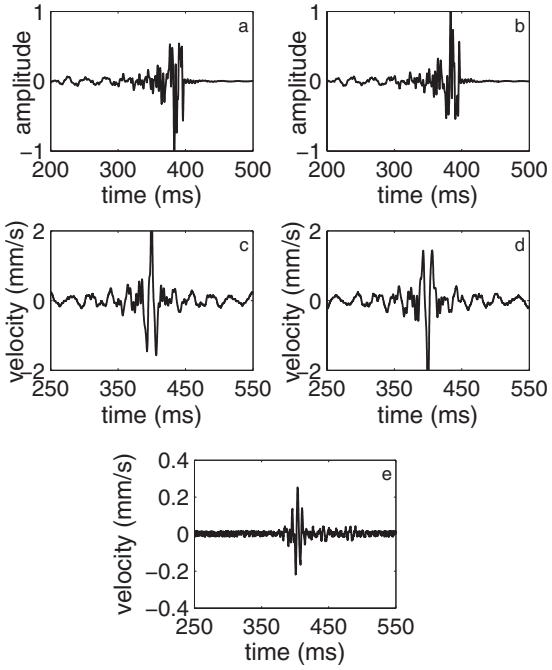

FIG. 3. Representative signals used in the phase-inversion method and measured above a VS-1.6 landmine buried at 5 cm: (a) one channel of the time-reversed impulse response set, (b) similar to (a) except with opposite sign, (c) and (d) reversed and focused signals as measured by the geophone for the standard and phase inverted sets, and (e) the nonlinear response, a sum of the two phase inverted signals divided by 2.

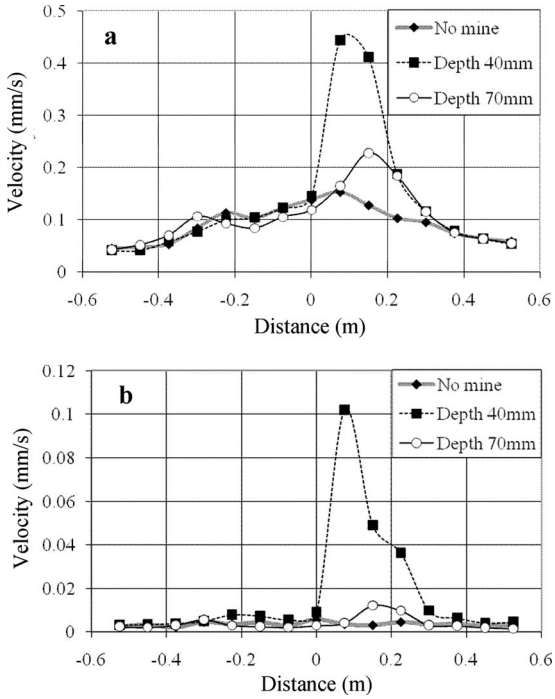

FIG. 4. The peak velocity of the sand surface measured at points on a line passing through the time-reversed focus location. (a) The linear response where the presence of a VS-1.6 antitank landmine increases the local amplitude. (b) The nonlinear response shows a greater mine/no-mine contrast than the linear response.

impulse response [Fig. 2(c)]. This sequence of steps was repeated for all six channels creating a set of six time-reversed impulse responses.

This set was broadcast simultaneously from the loudspeakers. The result was a physical match filter for each channel in the environment that focuses the seismic energy near the selected geophone when broadcast [Fig. 2(d)]. The amplitude of surface vibration decreased with the distance from the focus point when the simultaneous broadcast was measured at different locations [Fig. 2(e)]. The benefit of time reversal processing as used here is its ability to produce large amplitude seismic disturbances that increase the nonlinear response.

III. NONLINEAR TIME REVERSAL TEST WITH A LANDMINE

Time reversal focusing creates a short vibration pulse in the sand that is ideal for the nonlinear phase-inversion method. The radiated signals described above are broadcast twice but with opposite signs, one followed by the other [Figs. 3(a) and 3(b)]. The received signals consist of linear and nonlinear components [Figs. 3(c) and 3(d)]. The linear components have opposite signs, as is apparent in the figure. However, even ordered nonlinear components of these two signals have the same sign, and when the two signals are added together the linear components cancel each other and the even ordered nonlinear components add constructively. The summations are twice the nonlinear amplitude generated in a single pulse so the responses of the summed signals are divided by 2 [Fig. 3(e)]. This summation procedure also eliminates odd ordered nonlinearities, which played a lesser role in earlier experiments.[12,15,16]

Preliminary data from the microphone and geophone were compared in sand without a mine using the phase-inversion process to be sure that nonlinearities are generated in the sand as opposed to the loudspeakers. The pressure ratio of the peak amplitude of the nonlinear component to the peak amplitude of the combined linear and nonlinear measured signals is 7.5×10^{-3} as measured on the microphones and the same ratio for soil velocities is 86×10^{-3} as measured on the geophone. This indicates that the majority of the nonlinear component is being generated in the soil and relatively little is generated by the equipment or in the air.

The principle testing was conducted over sand with and without landmine using the geophone array. Three mines were tested individually: an Italian VS-1.6 antitank with a diameter of 22 cm, a Russian PMN antipersonnel with a diameter of 11 cm, and an Italian VS-50 antipersonnel with a diameter of 9 cm. Surface velocity time traces were measured at locations on a line using the techniques described above. The peak linear velocity of these traces illustrates that the response is greater above the VS-1.6 and PMN mines than in the sand without a mine, but not so with the VS-50 mine, Figs. 4(a) and 5(a). However, the peak nonlinear velocity is greater than the sand without a mine for all of the mines tested. The mine/no-mine contrast ratio is an important detection parameter and is computed as a ratio of the maximum peak velocity over the mine to the peak velocity without the mine at the same point. This ratio is greater for the nonlinear responses than the linear, Table I.

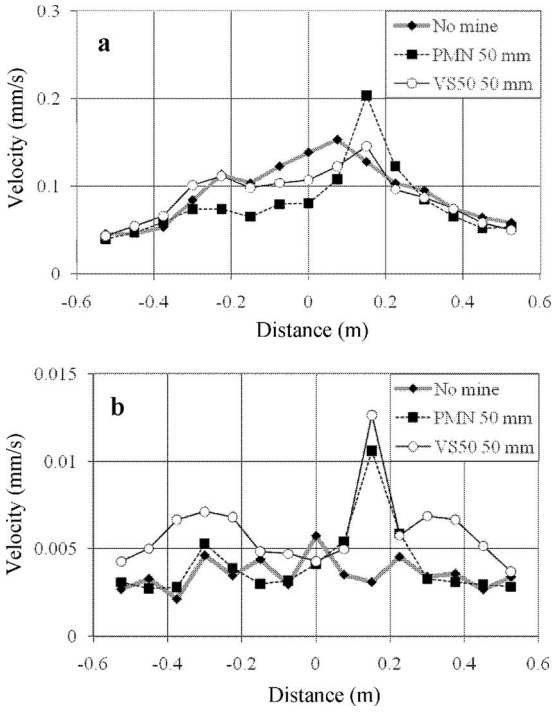

FIG. 5. The peak velocity of the sand surface measured at points on a line passing through the time-reversed focus location. (a) The linear response where the presence of antipersonnel landmines increases the local amplitude. (b) The nonlinear response shows a greater mine/no-mine contrast than the linear response.

IV. CONCLUSION

The nonlinear effects connected with mine vibration in sand were investigated over a wide frequency band using the phase-inversion method. Time reversal acoustic focusing excited the soil/mine vibration by increasing seismic energy in the region being interrogated. A mine/no-mine contrast was observed for linear and nonlinear responses. The contrast for the nonlinear response was higher than for linear response.

This paper demonstrates that phase-inversion processing of a pair of wide band pulses, computed using time reversal techniques, is an effective tool for measuring mine nonlinearities. The technique could be implemented on many sensor systems being developed for landmine detection. These systems often combine spatial sampling of surface vibration using laser vibrometers or contact sensors with acoustic or vibration excitation.[1–4] The implementation of the nonlinear time reversal technique to these systems was demonstrated in a recent test where time reversal focusing was used with the landmine detection system that includes four shakers and a 16-beam laser Doppler vibrometer for fast scanning of a soil region.[4] Tests of this system in the time reversal regime demonstrated good spatial and temporal focusing in soil without a mine. This suggests that broadband nonlinear data could be obtained using existing linear mine detection systems, ultimately improving landmine detection.

TABLE I. Surface velocity contrast ratios.

Mine type	Depth (mm)	Contrast ratio	
		Linear	Nonlinear
VS-1.6 antitank	40	2.9	28.9
VS-1.6 antitank	70	1.8	3.9
PMN antipersonnel	50	1.6	3.4
VS-50 antipersonnel	50	1.1	4.0

Finite difference time domain electroacoustic model for synthetic jet actuators including nonlinear flow resistance

Gerben Kooijman[a] and Okke Ouweltjes
Philips Research Laboratories, High Tech Campus 36, 5656AE Eindhoven, The Netherlands

(Received 11 July 2008; revised 16 January 2009; accepted 22 January 2009)

A lumped element electroacoustic model for a synthetic jet actuator is presented. The model includes the nonlinear flow resistance associated with flow separation and employs a finite difference scheme in the time domain. As opposed to more common analytical frequency domain electroacoustic models, in which the nonlinear resistance can only be considered as a constant, it allows the calculation of higher harmonics, i.e., distortion components, generated as a result of this nonlinear resistance. Model calculations for the time-averaged momentum flux of the synthetic jet as well as the radiated sound power spectrum are compared to experimental results for various configurations. It is shown that a significantly improved prediction of the momentum flux—and thus flow velocity—of the jet is obtained when including the nonlinear resistance. Here, the current model performs slightly better than an analytical model. For the power spectrum of radiated sound, a reasonable agreement is obtained when assuming a plausible slight asymmetry in the nonlinear resistance. However, results suggest that loudspeaker nonlinearities play a significant role as well in the generation of the first few higher harmonics.

I. INTRODUCTION

Synthetic jets are used in various application fields such as aerodynamic flow control, propulsion, micro-pumps, surface cleaning, and heat transfer enhancement, see e.g., Refs. 1–5. For the purpose of cooling of electronic products by means of forced convection, synthetic jets are believed to be promising due to a number of advantages over fan-based technology:

- lower noise level;
- better efficiency: less power needed for same cooling performance;
- higher reliability, longer lifetime;
- lower cost;
- beneficial form factor allows for high degree of freedom in design and ease of installation in devices, also miniaturization is possible;
- ideal for spot-cooling: cooling of small components that generate a lot of heat, which are found ever more in electronic devices.

Note that some other techniques for localized cooling of electronics are discussed in, e.g., Ref. 6.

Research on efficient sound reproduction at low frequencies by a small form-factor device has recently led to the development of a special resonant loudspeaker system.[7] This system basically consists of a loudspeaker connected to a tube, see Fig. 1(a). It was found that this system could also be used as a synthetic jet actuator. The acoustic motion of the fluid results in the formation of a pulsating jet at the outlet of the tube: as air is pushed out of the tube during one-half of a cycle, flow separation at the edges of the outlet occurs (provided that the Strouhal number is low enough, see, e.g., Ref. 8), and a jet is formed. During the intake part of a cycle, air is sucked into the tube from all directions. Averaged over a complete cycle no mass is injected into the fluid domain. However, due to the described difference between the inward motion of air at intake and the outward motion in the form of a jet, a net momentum is injected into the fluid domain. Therefore, synthetic jet actuators are also known as zero-net mass flux, nonzero momentum flux devices.

To diminish the radiated sound, a dipole actuator, as shown in Fig. 1(b), has been proposed.[9] Here, basically, two tubes are placed on either side of a loudspeaker. In this way the acoustic motions at the outlets of the tubes are in antiphase, minimizing the generated sound. Similarly, a quadrupole synthetic jet cooler, comprising two loudspeakers and four tubes, has been presented.[9] As an alternative, in order to reduce the radiated sound, the enclosed backing volume of the original resonant loudspeaker system can be omitted,[10] see Fig. 1(c). This yields, due to the resulting acoustic shortcut between the back of the loudspeaker and the tube outlet, a geometrically asymmetric dipole actuator: the acoustic volume velocity at the back of the loudspeaker and at the tube outlet are (more or less) equal in magnitude but opposite in phase.

In this paper, a lumped element electroacoustic model of such an asymmetric dipole actuator is presented. The model includes the nonlinear resistance associated with the flow separation at the tube ends. Furthermore, the model employs a finite difference scheme in the time domain. This allows the calculation of the higher harmonics of the fundamental signal with which the actuator is driven, which are generated due to the nonlinear resistance. This is opposed to more common analytical frequency domain electroacoustic models in-

[a]Electronic mail: gerben.kooijman@philips.com

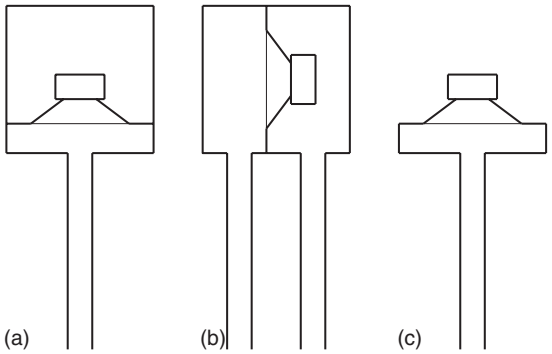

FIG. 1. Schematic drawing of (a) resonant loudspeaker system (Ref. 7), (b) dipole cooler (Ref. 9), and (c) asymmetric dipole cooler (Ref. 10).

cluding nonlinear flow resistance, see, e.g., Ref. 11. There, the variation in the nonlinear resistance with time (as it is proportional to the acoustic velocity) cannot be accounted for, and consequently no higher harmonics can be calculated.

Model predictions for the momentum flux of the synthetic jet will be compared to experimental results. Also, a measured power spectrum including generated higher harmonics of the driving signal will be compared to a model calculation. The latter is particularly of interest in the application of cooling as for these actuators acoustic annoyance is, besides tube resonances, mainly caused by higher harmonics, rather than by the low fundamental driving frequency.

II. MODEL

Lumped element modeling (see, e.g., Ref. 12) is employed for the asymmetric dipole synthetic jet actuator shown in Fig. 1(c). The equivalent circuit including the electrical and mechanical domain of the loudspeaker and the acoustical domain is depicted in Fig. 2. In the respective domains the voltage e, force F, and pressure p are the effort variables, and the current I, velocity v, and volumetric flow rate U (often called volume velocity in acoustics) are the flow variables. Coupling between the electrical and the mechanical domain is by a gyrator according to $F=BlI$ and $e_{\mathrm{emf}}=Blv$, with Bl the force factor and e_{emf} the counter-electromotive force. Coupling between the mechanical and the acoustical domains is by a transformer according to $p=F/S_d$ and $U=vS_d$, with S_d the loudspeaker's membrane area. The considered lumped elements are the electrical resistance R_e and inductance L_e of the loudspeaker's voice coil, and the mechanical resistance R_m, mechanical compliance C_m, and moving mass M_m of the loudspeaker's cone. Furthermore, in the acoustical domain we have the acoustical compliance C_{ac}:

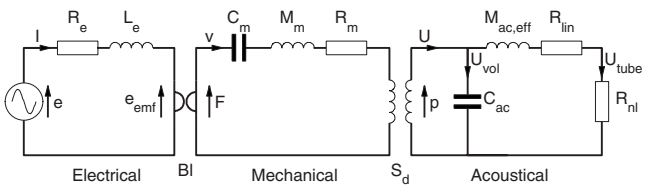

FIG. 2. Lumped element circuit representation of the asymmetric dipole synthetic jet actuator.

$$C_{\mathrm{ac}}=\frac{V}{\rho c^2}, \tag{1}$$

of the volume V between the loudspeaker and tube, with ρ and c the mass density, respectively, speed of sound. The tube can be considered as a lumped acoustical mass M_{ac}:

$$M_{\mathrm{ac}}=\frac{\rho L}{S}, \tag{2}$$

with L and S its length (including end correction) and cross sectional area, respectively. However, damping in wave propagation, which can be accounted for if the tube were modeled as a transmission line, is then not considered in first instance. Nevertheless, when approximating the transfer of acoustic pressure and volume velocity over a transmission line for low frequency: $(\omega L/c)^2 \ll 1$, it is found that the tube can be considered as an "effective" acoustical mass:

$$M_{\mathrm{ac,eff}}=\frac{\mathrm{Re}(k)}{k_0}M_{\mathrm{ac}}, \tag{3}$$

in series with a linear resistance:

$$R_{\mathrm{lin}}=-cM_{\mathrm{ac}}\,\mathrm{Im}(k). \tag{4}$$

The linear resistance accounts for the wave damping (for the fundamental frequency). Here k is the wavenumber, and $k_0=\omega/c$. Note that in the above the acoustic radiation impedance at the loudspeaker back and at the tube outlet is neglected. Accounting for visco-thermal losses at the tube walls, the wavenumber is given by[13]

$$k=-i\frac{\omega}{c}\sqrt{\gamma\frac{J_0(\sigma)}{J_2(\sigma)}+\gamma-1},$$

$$\sigma=0.72i^{3/2}\sqrt{Pr}Sh, \tag{5}$$

where J_0 and J_2 are Bessel functions of the first kind of zeroth and second order, respectively. Sh is the shear number: $Sh=(d/2)\sqrt{\omega/\nu}$, with d the diameter of the tube and ν the kinematic viscosity. Pr is the Prandtl number, and γ is the ratio of specific heats. Alternatively, for low Helmholtz numbers: $He=\omega d/(2c)\ll 1$, and high shear numbers: $Sh\gg 1$, the following expression can be used:[13,14]

$$k=\frac{\omega}{c}\left(1+\frac{1-i}{\sqrt{2}}\frac{1}{Sh}\left(1+\frac{\gamma-1}{\sqrt{Pr}}\right)-\frac{i}{Sh^2}\left(1+\frac{\gamma-1}{\sqrt{Pr}}-\frac{1}{2}\gamma\frac{\gamma-1}{Pr}\right)\right). \tag{6}$$

In the remainder Eq. (5) will be employed, unless stated otherwise.

The nonlinear resistance R_{nl} considered here is associated with the flow separation from the tube's ends, both inside the actuator and at the actuator's outlet. The nonlinear acoustic impedance of orifices has been studied by, among others, Ingard and Labate,[15] Ingard and Ising,[16] and Thurston *et al.*[17] More recently Petculescu and Wilen[18] studied the nonlinear impedance for constrictions in a pipe. Thurston *et al.*[17] and Iguchi *et al.*[19] found that in many cases a quasi-steady approach for the nonlinear acoustic impedance can be

used. The instantaneous behavior of the nonlinear impedance for oscillatory flow is in that case equivalent to the minor loss for steady flow, which has an associated pressure drop related to the Bernoulli effect. In general, we can then write for the nonlinear resistance as function of time t (the impedance is now purely real):

$$R_{\mathrm{nl}}(t) = \frac{\rho K |U_{\mathrm{tube}}(t)|}{2S^2}, \quad K = K_{\mathrm{out}}, \quad U_{\mathrm{tube}}(t) > 0,$$

$$K = K_{\mathrm{in}}, \quad U_{\mathrm{tube}}(t) < 0, \tag{7}$$

with $U_{\mathrm{tube}}(t)$ the acoustic volume velocity in the tube, and K a constant called the loss parameter. The asymmetry of the geometry is accounted for by considering separate K_{in} and K_{out}. In Fig. 10 of Petculescu and Wilen[18] values for K_{in}, K_{out} of about 1 for short tubes, $L/d \approx 1$, to about 1.4 for long tubes, $L/d \approx 20$, are reported. Note here that these results apply for tube exits with a radius of curvature of 1.85 mm. Flow separation and hence the nonlinear loss parameter nevertheless depend somewhat on the radius of curvature, see also, e.g., Refs. 20 and 21. Especially when the radius of curvature becomes very small (less than a few tens of a millimeter), the nonlinear loss parameter can differ from the above mentioned values.

From analyzing the circuit of Fig. 2, the following two equations can be derived in the time-domain:

$$\frac{de(t)}{dt} = c_1 \frac{d^3U(t)}{dt^3} + c_2 \frac{d^2U(t)}{dt^2} + c_3 \frac{dU(t)}{dt} + c_4 U(t) - c_5 \frac{dU_{\mathrm{tube}}(t)}{dt} - c_6 U_{\mathrm{tube}}(t),$$

$$c_1 = \frac{L_e M_m}{S_d Bl},$$

$$c_2 = \frac{R_e M_m + L_e R_m}{S_d Bl},$$

$$c_3 = \frac{R_e R_m}{S_d Bl} + \frac{L_e S_d}{Bl C_{\mathrm{ac}}} + \frac{L_e}{S_d Bl C_m} + \frac{Bl}{S_d},$$

$$c_4 = \frac{R_e S_d}{Bl C_{\mathrm{ac}}} + \frac{R_e}{S_d Bl C_m},$$

$$c_5 = \frac{L_e S_d}{Bl C_{\mathrm{ac}}},$$

$$c_6 = \frac{R_e S_d}{Bl C_{\mathrm{ac}}}, \tag{8}$$

and

$$U(t) = C_{\mathrm{ac}} M_{\mathrm{ac,eff}} \frac{d^2U_{\mathrm{tube}}(t)}{dt^2} - cC_{\mathrm{ac}} M_{\mathrm{ac}} \,\mathrm{Im}(k) \frac{dU_{\mathrm{tube}}(t)}{dt} + \frac{\rho K C_{\mathrm{ac}}}{2S^2} |U_{\mathrm{tube}}(t)| \frac{dU_{\mathrm{tube}}(t)}{dt} + \left(\frac{\rho K C_{\mathrm{ac}}}{2S^2} \frac{d|U_{\mathrm{tube}}(t)|}{dt} + 1 \right) U_{\mathrm{tube}}(t). \tag{9}$$

In the latter equation, Eqs. (4) and (7) are used for substituting for the linear and nonlinear acoustic resistances.

Subsequently, the quantities $e(t)$, $U(t)$, and $U_{\mathrm{tube}}(t)$ are discretized to a number of N points. The system of equations (8) and (9) can now be solved numerically by a finite difference scheme, resulting in the following matrix equation:

$$\begin{bmatrix} \mathbf{U} \\ \mathbf{U}_{\mathrm{tube}} \end{bmatrix} = \mathbf{M}^{-1} \begin{bmatrix} \mathbf{D}_1 \mathbf{e} \\ \mathbf{0} \end{bmatrix},$$

$$\mathbf{M} = \begin{bmatrix} \mathbf{m}_1 & \mathbf{m}_2 \\ \mathbf{m}_3 & \mathbf{m}_4 \end{bmatrix},$$

$$\mathbf{m}_1 = c_1 \mathbf{D}_3 + c_2 \mathbf{D}_2 + c_3 \mathbf{D}_1 + c_4 \mathbf{I}_{\mathbf{d}},$$

$$\mathbf{m}_2 = -c_5 \mathbf{D}_1 - c_6 \mathbf{I}_{\mathbf{d}},$$

$$\mathbf{m}_3 = -\mathbf{I}_{\mathbf{d}},$$

$$\mathbf{m}_4 = C_{\mathrm{ac}} M_{\mathrm{ac,eff}} \mathbf{D}_2 - cC_{\mathrm{ac}} M_{\mathrm{ac}} \,\mathrm{Im}(k) \mathbf{D}_1 + \frac{\rho C_{\mathrm{ac}}}{2S^2} [(K|\mathbf{U}_{\mathrm{tube}}|)_{\mathbf{d}} \mathbf{D}_1 + (\mathbf{D}_1 (K|\mathbf{U}_{\mathrm{tube}}|))_{\mathbf{d}}] + \mathbf{I}_{\mathbf{d}}. \tag{10}$$

Here, $\mathbf{e}$, $\mathbf{U}$, $\mathbf{U}_{\mathrm{tube}}$, and $|\mathbf{U}_{\mathrm{tube}}|$ are column vectors of length N representing the discretized version of the corresponding quantities. $\mathbf{D}_{1,2,3}$ are $N \times N$ matrices giving the first, second, and third order differential operators, respectively. Since an exact single period of a periodic (harmonic) voltage signal $e(t)$ will be considered as input, these operators satisfy a periodic condition. The differential operators employed in the present work are accurate to $O((\Delta t)^6)$, with Δt the discretization step in t. Furthermore, $\mathbf{I}_{\mathbf{d}}$ is the $N \times N$ identity matrix, and subscript $\mathbf{d}$ with a vector indicates an $N \times N$ matrix containing that vector on its diagonal. The term $K|\mathbf{U}_{\mathrm{tube}}|$ is evaluated at each discrete point as an asymmetrical K can be considered: $K_{\mathrm{in}} \neq K_{\mathrm{out}}$. Note that, in considering the linear resistance associated with wave damping, the wavenumber k corresponding to the imposed fundamental frequency is taken. This is a justifiable approximation, as it is found that the velocity amplitude at the higher harmonics is small compared to that at the fundamental frequency. The model, Eq. (10), is solved iteratively in a MATLAB implementation.

III. COMPARISON WITH EXPERIMENTAL RESULTS

In this section, model results for the momentum flux of the jet and, subsequently, the radiated sound are compared to experimental results. The asymmetric dipole synthetic jet actuator used consists of a custom loudspeaker (PSS 41 03978) connected to a square 6×6 cm^2 aluminum plate with a

TABLE I. Common parameters of the employed synthetic jet actuators.

Electrical resistance	R_e	5.70 Ω
Inductance	L_e	9.46×10^{-4} H
Force factor	Bl	5.36 N/A
Mechanical resistance	R_m	0.543 kg s^{-1}
Moving mass	M_m	4.70×10^{-3} kg
Compliance	C_m	5.42×10^{-4} m/N
Cone area	S_d	1.30×10^{-3} m^2
Front volume	V	1.20×10^{-5} m^3

thickness of 8 mm. A cavity is milled in the plate at the loudspeaker's side to accommodate the motion of the cone. At the other side a tube can be placed in a hole drilled in the middle of the plate. Different actuators are obtained by using tubes with different length and/or diameter. The common parameters of the actuators, i.e., that of the loudspeaker and the front volume V between speaker and tube are given in Table I.

A. Momentum flux

Neglecting viscous effects in the jet, the momentum flux I_{flow} through the plane perpendicular to the jet can be considered to be constant with distance from the outlet of the actuator. Since only the outward directed part of the fluid's acoustic motion at the tube exit contributes to the jet, the time-averaged momentum flux is

$$\overline{I_{\text{flow}}} = \frac{\rho}{S}\frac{1}{T}\int_{\substack{0,\\ U_{\text{tube}}(t)>0}}^{T} (U_{\text{tube}}(t))^2 dt. \tag{11}$$

For the numerical electroacoustic model, the time-averaged momentum flux is

$$\overline{I_{\text{flow}}} = \frac{\rho}{S}\frac{1}{N}\sum_{\substack{n=1,\\ \mathbf{U}_{\text{tube}}(n)>0}}^{N} (\mathbf{U}_{\text{tube}}(n))^2. \tag{12}$$

Experimentally, the time-averaged momentum flux can be found by letting the synthetic jet actuator blow on a balance, see Fig. 3. As the surface of the balance deflects the jet in the radial direction perpendicular to the original direction of the jet, the force exerted on the balance equals the momentum flux, provided that the jet is completely covered by the surface of the balance. Measurements and calculations of the momentum flux have been done for several configurations and different applied voltages. Moderate length brass tubes with diameter between 3 and 6 mm and length 30 and 60 mm as well as very long flexible plastic tubes with diameter 6 mm and length 1000 and 2030 mm have been used. The configurations are indicated by the diameter d and length L of the tube in millimeters as well as the rms value of the applied voltage. So, e.g., the configuration with $d=3$ mm, $L=60$ mm and rms voltage 3 V is denoted d3L60 3 V.

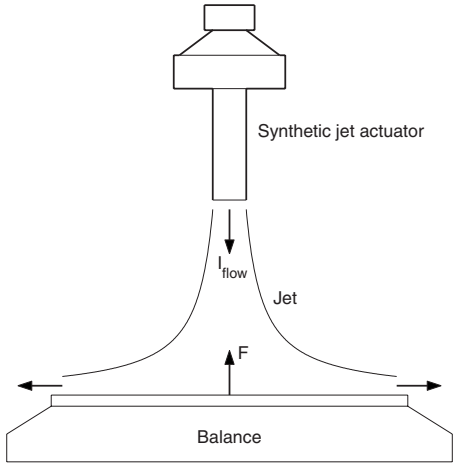

FIG. 3. Schematic drawing of set-up for measuring the momentum flux of the synthetic jet.

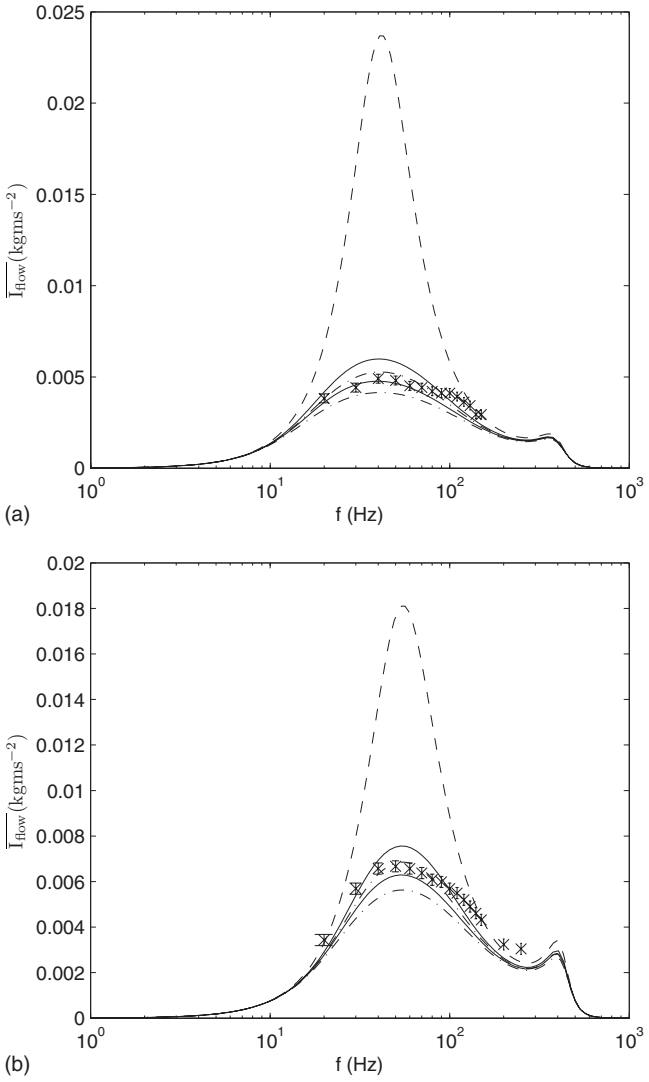

FIG. 4. Momentum flux for configurations: (a) d3L60 3 V and (b) d4L60 3 V. × markers: measurements; dashed lines: analytical model linear; dashed-dotted lines: analytical model nonlinear; solid lines: numerical model nonlinear. Higher and lower values are for $K_{\text{in}}=K_{\text{out}}=1$ and $K_{\text{in}}=K_{\text{out}}=1.4$, respectively.

1. Moderate length tubes

Results for the configurations with moderate length brass tubes, namely, d3L60 and d4L60 at 3 V, and d6L30 and d6L60 at 2 V, are shown in Figs. 4 and 5.

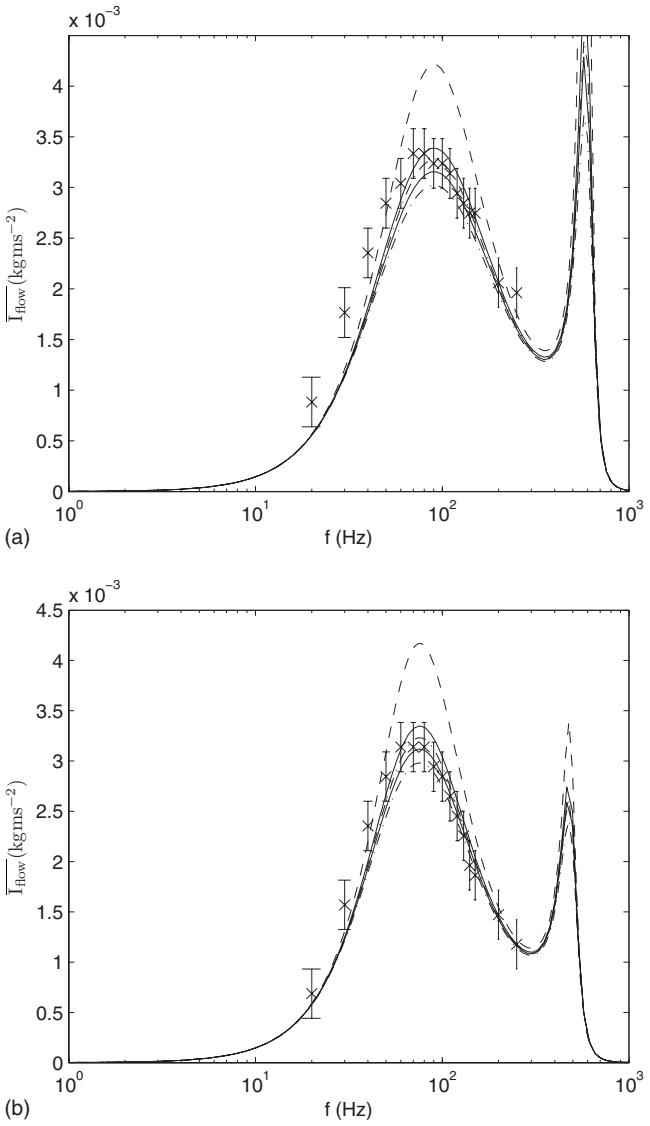

FIG. 5. As in Fig. 4 for configurations: (a) d6L30 2 V and (b) d6L60 2 V.

Both calculations with the current numerical model of Sec. II, including nonlinear losses, and an analytical lumped element electroacoustic model (in frequency domain) without and with nonlinear losses are done. In the latter case the nonlinear flow resistance is set constant to $R_{nl}=\rho K|\hat{U}_{tube}|/(2S^2)$, with $\hat{U}_{tube}$ the complex amplitude of the volume velocity in the tube (see also Ref. 11). The number of points used for the numerical calculations is $N=100$, using more points gave no significant difference in results. It was verified that without accounting for nonlinear losses the results obtained from the numerical model are identical to those obtained by the analytical model. In all cases wave damping is accounted for by means of Eq. (5). Results from both the analytical and the numerical model are obtained with the nonlinear loss parameter $K_{in}=K_{out}=1$ (giving the corresponding higher values for the momentum flux) and $K_{in}=K_{out}=1.4$ (giving the lower values for the momentum flux). These values for K_{in}, K_{out} correspond to, respectively, short tubes, $L/d\approx 1$, and long tubes, $L/d\approx 20$, see Ref. 18. The iteration process in the analytical model was stopped once the absolute value of the difference in $\hat{U}_{tube}$ between two successive iterations divided by the absolute value of $\hat{U}_{tube}$ was less than 10^{-6}. For the numerical model iteration was stopped once at each discrete point, the absolute value of the difference in $\mathbf{U}_{tube}$ between two successive iterations divided by the maximum absolute value of $\mathbf{U}_{tube}$ was less than 10^{-6}. For both models the number of iterations needed for the present calculations was about 30 at maximum.

Generally, a good prediction of the momentum flux is obtained when including the nonlinear resistance. The smaller the diameter of the tube, the higher the flow velocity, and the higher the (effect of) nonlinear resistance. This is especially apparent for the d3L60 configuration, where the momentum flux differs by about a factor 5, and the velocity thus by a factor ~2.2, between the calculations with and without nonlinear losses. Furthermore, it was found that the effect of damping in wave propagation is much smaller than that of the nonlinear losses. In the analytical model, the nonlinear resistance is considered as constant, and the amplitude of the velocity is used to calculate it. So, in fact, the maximum value of the nonlinear resistance is used over a complete cycle, yielding an overestimation. This results in the lower value of the momentum flux calculated by the analytical model compared to that calculated by the numerical method, and consequently less good agreement with experimental results. Note here that of course the nonlinear resistance for the analytical model could also be calculated from the rms value of the velocity. However, it was found that this, in fact, in turn gives an underestimation of the nonlinear loss (the results for $K_{in}=K_{out}=1.4$ would in that case be about equal to the results for $K_{in}=K_{out}=1$ as displayed in Figs. 4 and 5). Furthermore, when considering the relative length L/d of the tubes, there is a good correspondence between the measured momentum flux and the one calculated with the numerical method using either $K_{in}=K_{out}=1$ for the shorter tubes or $K_{in}=K_{out}=1.4$ for the longer tubes. Wave damping is included by means of Eq. (5). As the effect is relatively small for these short tubes using Eq. (6) instead gave no significant difference.

2. Very long tubes

For the configurations with a very long tube, caution has to be taken in using the low-frequency approximation, as $(\omega L/c)^2 \ll 1$ is actually not valid everywhere: for the 1000 and 2030 mm tubes $\omega L/c=1$ at a frequency of $f=55$ Hz and $f=27$ Hz, respectively. Two different linear calculations with the analytical model have been carried out. In the first the tube is considered as a transmission line; in the second it is considered as an acoustical mass, i.e., low-frequency approximation. Calculations including nonlinear losses are carried out with the analytical as well as the numerical model, and are both in low-frequency approximation. The nonlinear loss parameter is taken $K_{in}=K_{out}=1.4$. Since the tubes are very long, wave damping will be much more important. The model calculations and the experimental results are given in Fig. 6. Comparing results from the linear model with and without low-frequency approximation, it is observed that with the low-frequency approximation still the first resonance is predicted quite well. When accounting for the non-

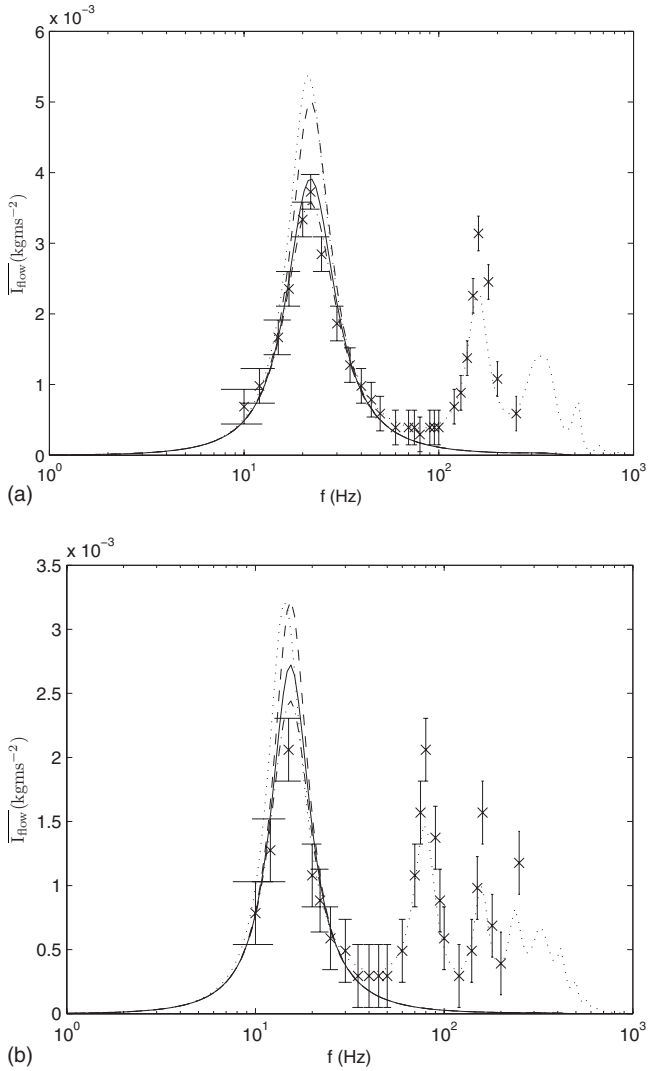

FIG. 6. Momentum flux for configurations: (a) d6L1000 3 V and (b) d6L2030 3 V. × markers: measurements; dotted lines: analytical model, linear; dashed lines: analytical model, linear, low frequency approximation; dashed-dotted lines: analytical model, nonlinear, low frequency; solid lines: numerical model, nonlinear, low frequency. Nonlinear loss parameter of $K_{in}=K_{out}=1.4$ is used.

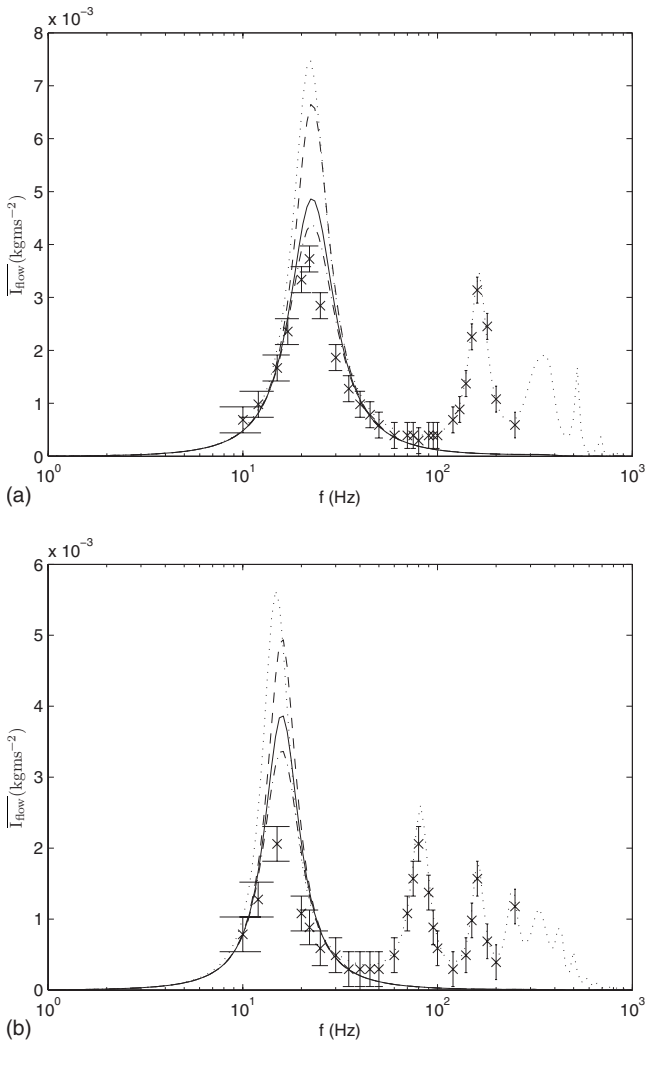

FIG. 7. Momentum flux for configurations: (a) d6L1000 3 V and (b) d6L2030 3 V. As in Fig. 6, but with wave damping according to Eq. (6) instead of Eq. (5).

linear losses, an improved prediction of the measured momentum flux at the first resonance is obtained. However, for the resonances at higher frequencies it is seen that the momentum flux is already underestimated by the linear model when using Eq. (5). It was found that using the wave damping model according to Eq. (6), valid for high shear numbers, yields better results for the higher frequencies, but worse results at the first resonance. This is depicted in Fig. 7. The shear number ranges here from ~6 for $f=10$ Hz to ~30 for $f=250$ Hz.

B. Radiated sound

The nonlinear flow resistance results in the generation of higher harmonics of the fundamental frequency with which the loudspeaker is driven, i.e., distortion occurs. In this section, model results for the sound power radiated by the asymmetric dipole cooler will be compared to experimental results.

With the current model, the volume velocity at the loudspeaker, $U(t)$, and at the tube outlet, $U_{tube}(t)$, are calculated in the time domain. These volume velocities can be considered in the frequency domain using a Fourier transform. The complex amplitudes–as function of angular frequency ω—of the volume velocity at the back of the loudspeaker and at the tube outlet are $-\hat{U}(\omega)$ and $\hat{U}_{tube}(\omega)$, respectively.

Considering the tube outlet and loudspeaker back as monopole radiators, it can be derived that the time-averaged total radiated acoustic power as function of frequency equals

$$\bar{P}(\omega)=\frac{k_0^2\rho c|\hat{U}_m(\omega)|^2}{8\pi}+\frac{k_0^4\rho c|p_d(\omega)|^2}{24\pi}, \tag{13}$$

see, e.g., Ref. 22. This corresponds to the radiated power of a monopole with strength (i.e., volume velocity):

$$\hat{U}_m(\omega)=\hat{U}_{tube}(\omega)-\hat{U}(\omega), \tag{14}$$

plus that of a dipole, with dipole strength:

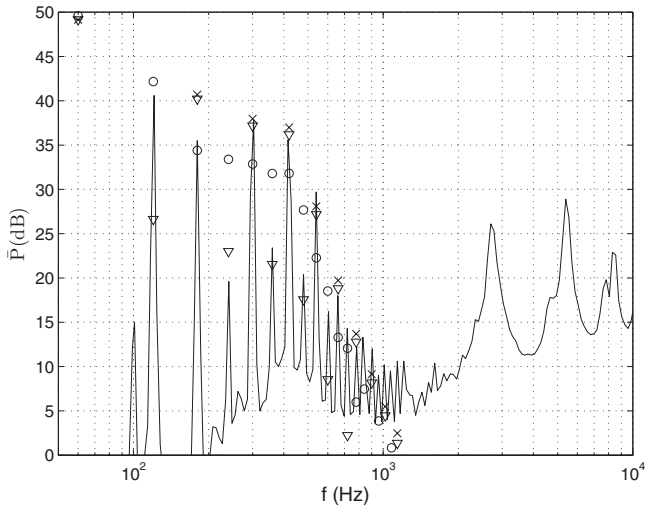

FIG. 8. Power spectrum of radiated sound for the d4L60 driven at 60 Hz and 3 V rms voltage. Solid line: experimental result. Model results are for × markers: symmetric nonlinear resistance with $K_{in}=K_{out}=1.2$. ○ markers: fully asymmetric nonlinear resistance with $K_{in}=0$, $K_{out}=1.2$. ▽ markers: asymmetric nonlinear resistance with $K_{in}=0.9$, $K_{out}=1.2$.

$$p_d(\omega) = (\hat{U}(\omega) + \hat{U}_{\text{tube}}(\omega))\frac{a}{2}. \tag{15}$$

Here, a is the distance between the loudspeaker back and the tube outlet. The above holds in the far-field approximation, i.e., $k_0 r$ large, with r the distance to the actuator, and for $k_0 a$ small.

Power spectra of the radiated sound for various configurations have been measured in a 227 m^3 reverberant room. Frequencies below 100 Hz are filtered out, as below this frequency the sound field is not diffuse enough to give accurate results. The spectrum for the configuration d4L60 driven at 60 Hz and 3 V rms voltage is shown in Fig. 8. The acoustic power is expressed in decibels relative to a reference of 10^{-12} W. The higher harmonics at 120 Hz, 180 Hz,…, etc., can be clearly discerned. Also the tube resonances, giving the broad peaks at ~2800 Hz, ~5500 Hz,…, etc., are observed. Additionally, the figure depicts some results obtained from the numerical model. Here, calculations have been done for a symmetric nonlinear resistance with nonlinear loss parameters $K_{in}=K_{out}=1.2$, as well as for two cases with asymmetric nonlinear resistance. For the symmetric nonlinear resistance, only odd harmonics are generated. However, from the experimental results it can be clearly seen that, although the odd harmonics are dominant in level, even harmonics occur as well. This suggests that there is some asymmetry in the nonlinear resistance. The effect of this asymmetry is investigated in Fig. 8 by considering a "full" asymmetrical configuration with nonlinear loss parameters $K_{in}=0$, $K_{out}=1.2$ (thus only nonlinearity at outflow), and an intermediate configuration with $K_{in}=0.9$, $K_{out}=1.2$. For both cases even as well as odd harmonics are indeed observed. Comparison with the experimental results shows here that the full asymmetrical case gives a clear overestimate of the even harmonics, whereas the intermediate case gives a better prediction for the higher harmonics (except for the first higher harmonic, which is now underestimated). Note here that the full asymmetrical case also gives a deviant prediction of the momentum flux: $\overline{I_{\text{flow}}}=9.3\times10^{-3}$ kg m s^{-2}, whereas experimentally $\overline{I_{\text{flow}}}=6.6\times10^{-3}$ kg m s^{-2}, and for the intermediate asymmetrical case: $\overline{I_{\text{flow}}}=7.2\times10^{-3}$ kg m s^{-2}. So, a (very plausible) slight asymmetry in the nonlinear resistance yields the generation of both even and odd harmonics, and gives a reasonable quantitative agreement with experimental results. This also means that in principle the values of the nonlinear loss parameters K_{in}, K_{out} would have to be known quite accurately to obtain an accurate quantitative prediction of the complete (power) spectrum of the radiated sound. Furthermore, regarding the volume velocity, the higher harmonics are very small compared to the fundamental frequency (at least one order in magnitude smaller). Therefore, other nonlinearities in the system, e.g., nonlinearities in the suspension of the loudspeaker, that have a negligible effect on the total volume velocity—and thus on the blowing velocity of the actuator—may still be important as well for the radiation of higher harmonics. In principal, these loudspeaker nonlinearities cannot be isolated in the measurements on the synthetic jet actuator. Also, the enclosure, i.e., the volume and tube of the actuator, has influence on the nonlinearities of the loudspeaker. Nevertheless, in order to obtain some indication, distortion spectra of the loudspeaker without any enclosure (dipole configuration) as well as the loudspeaker in a closed box of 0.9 l (monopole configuration) have been measured at a driving frequency of 60 Hz. As loudspeaker nonlinearities are greatly dependent on the cone excursion, the applied voltage for both cases was chosen such that the excursion is the same as for the synthetic jet actuator configuration. Determined from lumped element modeling, this yielded rms voltages of 2.0 and 1.9 V, respectively, to have a loudspeaker cone excursion amplitude of 1.03 mm. For the first three higher harmonics, thus up to 240 Hz, the observed level, relative to the fundamental, in these spectra was roughly of the same order as in the spectrum of the synthetic jet actuator, see Fig. 8. For the other higher harmonics, the level was generally at least 10 dB lower than in the case of the synthetic jet actuator. From this it can tentatively be concluded that in the spectrum of Fig. 8 the distortion components above the third higher harmonic at 240 Hz are mainly generated by the nonlinear flow resistance, whereas for the first three higher harmonics loudspeaker nonlinearities play a significant role as well.

Finally, since both in the experiment and in the model the odd harmonics are dominant in level, and globally a reasonable agreement is obtained for these harmonics, it is found that a fair estimate for the total power of the radiated higher harmonics can be obtained for most cases. This is shown in Table II. Here, in determining the total measured sound power, the contribution of the tube resonances is omitted. For the calculated sound power nonlinear loss parameter $K_{in}=K_{out}=1.2$ is taken for all cases. In Table II the measured total radiated power by the harmonics is usually larger than the calculated one. This is partly due to the fact that the first higher harmonic is underestimated by the model (for a symmetrical nonlinear flow resistance, it is absent in model results).

TABLE II. Total power radiated by high harmonics for various configurations, measured in a reverberant room and calculated from the numerical model with $K_{in}=K_{out}=1.2$.

Configuration	Total power measurement (dB)	Total power model (dB)
d4L30 60 Hz 3 V	50.4	48.2
d4L60 60 Hz 3 V	44.6	43.8
d6L30 60 Hz 3 V	45.7	42.6
d6L30 70 Hz 3 V	48.9	46.0
d6L30 80 Hz 3 V	46.9	49.4
d6L60 60 Hz 3 V	47.7	40.8
d6L60 70 Hz 3 V	49.2	44.3
d6L60 80 Hz 3 V	47.3	46.3

IV. CONCLUSIONS

An electroacoustic model, in which nonlinear flow resistance associated with flow separation can be included, is presented for an asymmetric dipole synthetic jet actuator. The numerical model employs a finite difference scheme in the time domain, allowing for a full inclusion of the nonlinear resistance.

Model calculations for the time-averaged momentum flux of the jet are compared to experimental results for various synthetic jet actuator configurations. It is shown that a significantly improved prediction of the momentum flux—and thus flow velocity—of the jet is obtained when including the nonlinear resistance. Here, the current model performs slightly better than a more common analytical frequency domain electroacoustic model, in which the nonlinear resistance can only be considered as a constant.

As opposed to such an analytical model, with the numerical model also higher harmonics, i.e., distortion components, generated as a result of the nonlinear resistance, can be calculated. For a single configuration the power spectrum of radiated sound, measured in a reverberant room, is compared to the calculated one. A reasonable agreement is obtained when assuming a plausible slight asymmetry in the nonlinear resistance (i.e., a difference between inflow and outflow). It was also found that probably distortion above the third higher harmonic is mainly caused by the nonlinear flow resistance, whereas for the first three higher harmonics loudspeaker nonlinearities play a significant role as well. Furthermore, in principle, for an accurate prediction of the distortion the exact nonlinear resistance at in- and outflow would have to be known. Nevertheless, a fair prediction of the total radiated power of higher harmonics is obtained, which is less sensitive to the exact value of the nonlinear resistance.

The presented method can also in general be used for loudspeaker systems containing a bass port.

(Received 12 June 2008; revised 22 January 2009; accepted 23 January 2009)

Propagation of energy along the sound channel axis cannot be formally described in terms of geometrical acoustics due to repeated cusped caustics along the axis. In neighborhoods of these cusped caustics, a very complicated interference pattern is observed. Neighborhoods of interference grow with range and overlap at long ranges. This results in the formation of a complex interference wave—the axial wave—that propagates along the sound channel axis like a wave belonging to a crescendo of near-axial arrivals. The principal properties of this wave are calculated for the actual space-time configuration realized during a 2004 long-range propagation experiment conducted in the North Pacific. The experiment used *M*-sequences at 68.2 and 75 Hz, transmitter depths from 350 to 800 m, and ranges from 50 to 3200 km. Calculations show that the axial wave would be detectable for an optimal geometry—both transmitter and receiver at the sound channel axis—for a "smooth" range-dependent sound speed field. The addition of sound speed perturbations—induced here by simulated internal waves—randomizes the acoustic field to the extent that the axial wave becomes undetectable. These results should be typical for mid-latitude oceans with similar curvatures about the sound speed minimum.

I. INTRODUCTION

The world's mid-latitude oceans possess a well-known deep sound channel where decreasing sound speed—due to decreasing temperature—with increasing depth gives way to increasing sound speed—due to increasing hydrostatic pressure—with increasing depth. This sound channel has long been exploited in studies of long-range sound ocean acoustic propagation. Often, the most prominent characteristics of sound propagation in this channel are early arrivals well described by geometrical acoustic theory, followed by a crescendo of energy that propagates along the center, or axis, of the channel. It is impossible to explain this late-arriving energy using geometrical acoustics because of the presence of repeated cusped caustics along the axis. Figure 1 illustrates a typical representation of caustics for these kinds of oceans.

In the neighborhood of an isolated cusp, the acoustic field is described by the Pearcey integral.[1] The extent of the cusp neighborhood where the geometrical acoustic formulas are not applicable increases with range,[2] and at a certain propagation range, the neighborhoods of adjacent cusps overlap. This results in a more complicated diffractive pattern that cannot be described by the Pearcey integral. The interference of the wave fields that correspond to near-axial rays leads to formation of a coherent structure that propagates along the axis like a wave. This component of the acoustic field is called the "axial wave." The range at which the cusp neighborhoods begin to overlap depends on frequency and sound speed profile properties, such as the curvature of the profile at the axis depth. When the distance between the transmitter and receiver increases, the number of caustic cusps participating in the axial wave formation increases as well.

The term axial wave appeared in the early 1970s in papers by Buldyrev[3] and Buldyrev *et al.*[4] Those studies were done for the simplest medium model with the purpose of obtaining a global description of propagation in the presence of cusped caustics.

For a range-independent ocean model where the variables are separable, the formula for the axial wave is derived by transforming the contour integral that gives the exact solution of the point transmitter problem.[5] Analysis of the resulting integral representation of the axial wave shows that it includes the solutions of the Helmholtz equation localized near the sound channel axis and a weight function that does not depend on medium properties. The main advantage of the

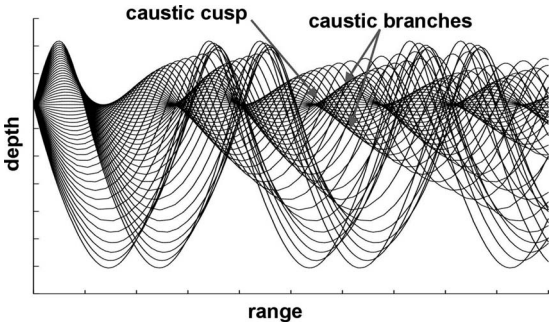

FIG. 1. Caustic features at relatively short ranges $0 \leqslant x \leqslant 150$ km, as illustrated by ray tracing. The sound speed profile (assumed in this example to be independent of range) is typical for the deep ocean at mid-latitudes; the transmitter (at zero range) is located at the sound channel axis (1 km), where the sound speed reaches its minimum.

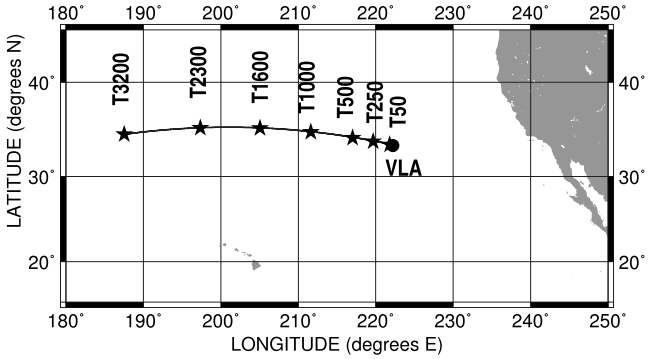

FIG. 2. LOAPEX geometry. The solid line (a geodesic arc on an oblate spheroidal model earth) shows the main LOAPEX path where stars indicate the seven stations: T50, T250, T500, T1000, T1600, T2300, and T3200. The VLA is marked by a circle.

derived formula for the axial wave is the possibility to generalize it to a range-dependent ocean, as was done by Grigorieva and Fridman.[6]

In the time-of-arrival pattern (the acoustic field as a function of depth and time, at a given range), the axial wave formed by rays with small launch angles is a component of the late-arriving energy. In long-range ocean acoustic propagation, the axial crescendo accounts for a significant portion of the radiated energy but is not currently utilized in acoustical oceanography problems. It is therefore important and useful to have a mathematical model for this component of the near-axial finale.

In this paper, the principal features of the axial wave are calculated for several increasingly realistic ocean medium models. These ocean models are derived from actual conditions encountered during the Long-Range Ocean Acoustic Propagation Experiment (LOAPEX), conducted in the North Pacific from 10 September to 10 October 2004. The goal of this paper is to demonstrate these calculations and to determine whether or not the axial wave could have been detected given optimal transmitter/receiver geometries and actual LOAPEX transmitter/receiver geometries. The general outline of this paper is as follows. In Sec. II we describe the LOAPEX sound speed data as well as the calculation of a smooth two-dimensional sound speed field approximation. In Sec. III we discuss the dependence of the main properties of the axial wave on propagation range, depth of the transmitter relative to the depth of the sound channel axis, and frequency for two ocean models: first, a smooth sound speed approximation and, second, the smooth approximation with additive perturbations representative of internal-wave induced variability. In Sec. IV we summarize the principal results. Appendix A includes the integral representations of the axial wave for range-independent and range-dependent ocean models. In Appendix B we give a short description of the acoustic fluctuations due to internal waves that are used for simulations in this paper.

II. SMOOTH TWO-DIMENSIONAL MODEL OF LOAPEX SOUND SPEED FIELD

A detailed summary of LOAPEX is given by Mercer *et al.*[7] The experiment geometry is shown in Fig. 2. Seven transmit stations, T50, T250, T500, T1000, T1600, T2300, and T3200, were located at ranges of 50, 250, 490, 990, 1600, 2300, and 3200 km, respectively, from a vertical line array (VLA). At each of these seven stations, the LOAPEX acoustic transmitter was suspended from the ship to conduct periodic transmissions for several hours. Multiple transmitter depths were used at each of these seven stations, involving 350, 500, and/or 800 m. At the transmitter depth of 800 m, the transmitted signal had a carrier frequency of 75 Hz, and at transmitter depths of 350 and 500 m, it had a carrier frequency of 68.2 Hz. The interelement spacing on the 20-element VLA was 35 m throughout the central region of the sound channel axis.

Figure 3 shows the upper ocean sound speed profiles obtained from the conductivity-temperature-depth (CTD) measurements at six stations (T250, T500, T1000, T1600, T2300, and T3200). The formula for the axial wave (see Appendix A) requires derivatives to fourth order of the sound speed $c(x,z)$ with respect to both range and depth. These were obtained by modeling the actual measurement profiles with a smooth representation, constructed as follows.

A 14th-order polynomial was fit in the least squares sense to each sound speed profile over the depth interval $[350,1500]$ m. This order was chosen because it gave reasonable fidelity to the actual measurements without excessive complexity. Figure 4 shows both the sound speed profile at station T50 and the corresponding polynomial approximation. The sound speed profile at the VLA was represented by that at station T50.

Using the polynomial sound speed profiles from these seven stations, the "smooth" two-dimensional sound speed field was calculated by generating additional sound speed profiles every 50 km in range using linear interpolation and then by interpolating the total sound speed profile data set (polynomials plus interpolated) using two-dimensional fifth-order splines. The calculated sound channel axis depth is shown in Fig. 5, where dots correspond to the depth of the transmitter at its closest to the channel axis. At stations T3200 and T2300, this depth was 500 m, at station T1600 this depth was 350 m, and at stations T1000, T500, T250, and T50 this depth was 800 m.

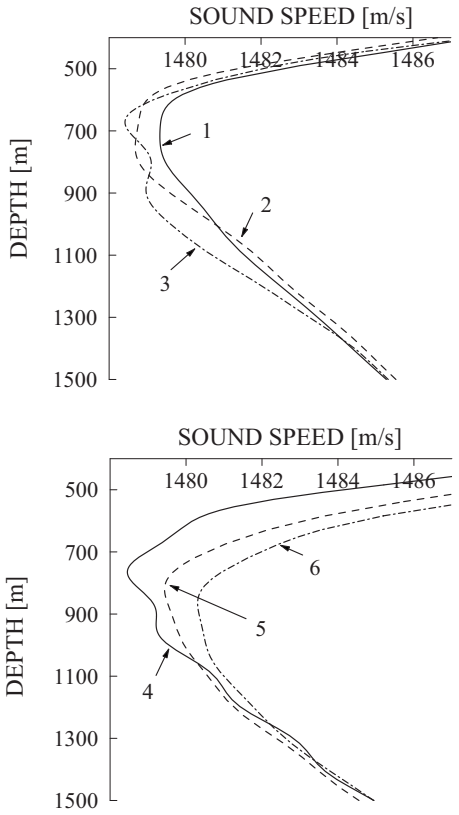

FIG. 3. Upper ocean sound speed profiles obtained from CTD data at six stations. The upper panel contains the sound speed profiles for stations T250 (1), T500 (2), and T1000 (3), and the lower panel contains the sound speed profiles for stations T1600 (4), T2300 (5), and T3200 (6).

The VLA hydrophone nearest the sound speed minimum (635.678 m) had a median depth over the entire deployment of 621.72 m, a location roughly 14 m from the channel axis.

III. MAIN PROPERTIES OF THE AXIAL WAVE

The integral representations of the axial wave for range-independent and range-dependent ocean models are written out in Appendix A.

A. Dependence on propagation range

Range dependence for a range-independent ocean has previously been examined[8] for the Munk canonical sound

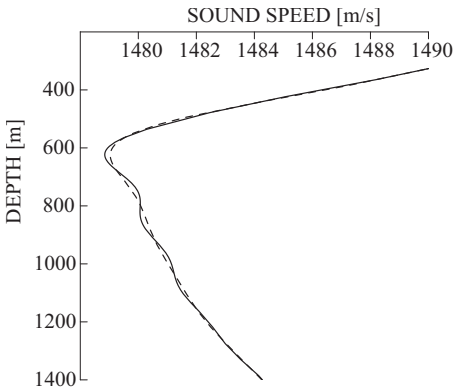

FIG. 4. Sound-speed profile obtained from CTD measurement at station T50 (solid) and its 14th degree polynomial approximation (dashed).

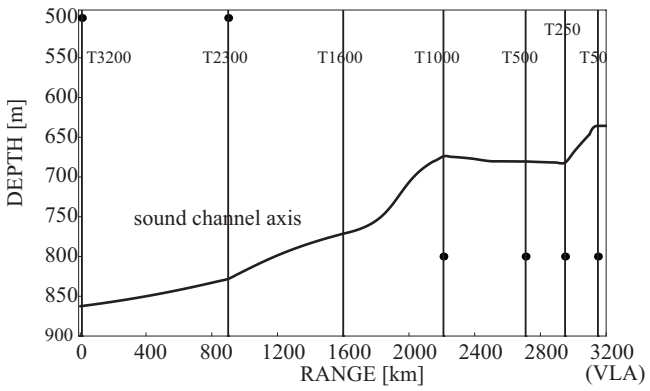

FIG. 5. The sound channel axis for the smooth two-dimensional sound speed field approximation. Dots show the depth of the transmitter when closest to the channel axis. No reference marks are shown for station T1600 because the only transmitter deployment depth, 350 m, was too far from the channel axis to generate a significant axial wave (see Sec. III B).

speed profile[9] and the average sound speed profile from the Acoustic Engineering Test (AET). The effect of the range-dependent LOAPEX sound speed profile is characterized by the transmission loss (TL) in Fig. 6. For this calculation, the transmitter is placed at the station T3200 sound channel axis depth, and the frequency is 68.2 Hz. The receiver is assumed to be located at the sound channel axis in the 50 km range interval adjoining the VLA. The TL varies from 117 to 120 dB. The dashed line in Fig. 6 indicates a range dependence of $x^{-3/4}$ for the wave amplitude. Thus, the axial wave decreases with range faster than the low-order modes. Discontinuities in the TL take place at distances $x=3154.58$, 3163.74, 3172.92, 3182.26, and 3191.31 km, where the number of waves corresponding to rays with small launch angles participating in the axial wave formation changes by 1. The transmitter level in LOAPEX (Ref. 7) was about 194 dB, and the ambient noise level throughout the sound channel at the VLA was roughly 70–80 dB re 1 μPa^2/Hz at 75 Hz. Based on this calculation (which neglects internal waves, see below) the axial wave would have been detectable if the transmitter and receiver had been located at the sound channel

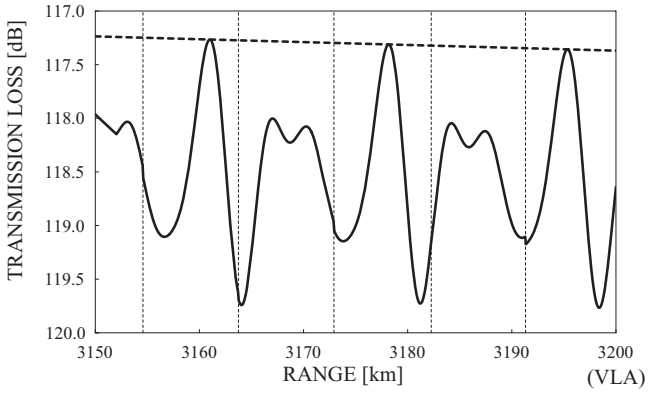

FIG. 6. Axial wave TL at the channel axis over the final 50 km of the LOAPEX path for a signal launched from a transmitter located at the station T3200 channel axis (862.535 m). The range-dependent sound speed is represented by a smoothed approximation of actual sound speed measurements. The frequency is 68.2 Hz. The heavy dash line represents an $x^{-3/4}$ dependence in amplitude. The vertical dashed lines indicate the locations of discontinuities in the TL (see text).

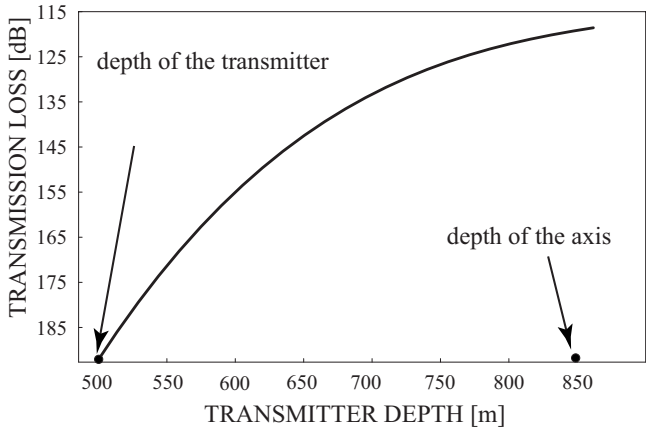

FIG. 7. Dependence of the axial wave TL on the depth of the transmitter placed at 3200 km from the receiver. (The sound speed minimum is at 862.535 m at station T3200.) The frequency is 68.2 Hz. The receiver is at the depth of the sound speed minimum (635.678 m) at the location of the VLA.

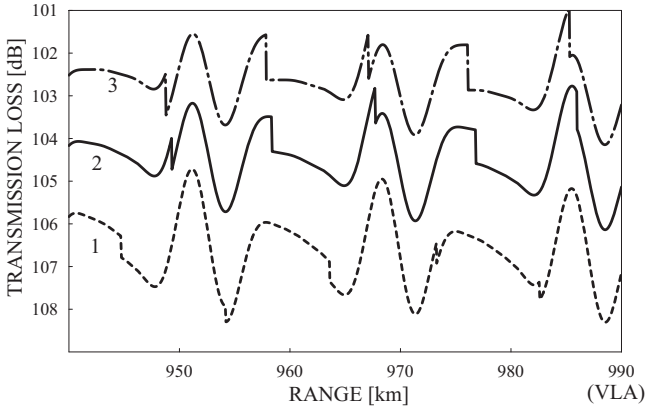

FIG. 8. TL for an axial wave launched from a transmitter at the sound channel axis (674.026 m) at station T1000. TL is predicted at the channel axis over the final 50 km. Curve (1) corresponds to 56.25 Hz, (2) to 75 Hz, and (3) to 93.75 Hz.

axis, even at a range of 3200 km. (This assumes some form of pulse compression post-processing gain, as is commonly used in long-range propagation experiments.[9])

B. Dependence on transmitter depth

Depth dependence at different propagation ranges for a range-independent ocean has previously been examined[8] for the Munk canonical sound speed profile[9] and the average sound speed profile from AET. The effect of depth dependence for the range-dependent LOAPEX sound speed profile is characterized by the TL in Fig. 7. For this calculation, the transmitter is at station T3200 and the depth is varied from the sound channel axis (862.535 m) up to 500 m, the depth of the actual transmitter deployment. The frequency is 68.2 Hz. The receiver is located on the sound channel axis. The TL increases rapidly when the distance between the transmitter and the channel axis increases. At the actual deployment depth of the transmitter, the TL is 192.683 dB. As was noted above, the transmitter level in LOAPEX (Ref. 7) was about 194 dB. Thus, the axial wave could not have been detected for this configuration (range of 3 200 km and transmitter depth of 500 m).

The distances between the sound channel axis depth and the actual transmitter deployment depths were similar at stations T2300 and T1600 (328.1 and 421.4 m for transmitter depths of 500 and 350 m, respectively); hence, calculations similar to that shown in Fig. 7 indicate that the axial waves radiated by the transmitter deployed at stations T2300 and T1600 could also not have been detected.

C. Dependence on frequency

One transmitted M-sequence is well approximated by a signal with center frequency of 75 Hz and bandwidth of 37.5 Hz. (This is the full width between half-amplitude points in the transform envelope.) Figure 8 shows the dependence of axial wave TL (at a single frequency) when the transmitter is at the sound channel axis at station T1000 (i.e., at range 990 km.) The receiver depth is the channel axis depth at the VLA. The frequencies are taken to be 56.25, 75, and 93.75 Hz. Axial wave TL is seen to increase with decreasing frequency (i.e., the amplitude decreases with decreasing frequency.) This result depends on the number of overlapping cusped caustic neighborhoods. At lower frequency, these neighborhoods are spatially larger, and more such neighborhoods overlap, and hence more waves interfere with the wave propagating along the axis. For this example (at 990 km), 16 waves interfere at 56.25 Hz, 14 at 75 Hz, and 12 at 93.75 Hz.

To investigate variation in the time domain, it is natural to define the axial wave propagation time, T, as

$$T = \frac{\partial}{\partial \omega}\tilde{\varphi}, \tag{1}$$

where ω is a cyclic frequency and $\tilde{\varphi}$ is a phase function of the axial wave $\tilde{H}$ given by Eqs. (A14) and (A15),

$$\tilde{H} = \exp(i\tilde{\varphi})|\tilde{H}|. \tag{2}$$

Table I shows the arrival time of the axial wave and the arrival time of the lowest mode in the adiabatic approximation. The difference in arrival times decreases as the frequency increases. At 75 Hz, the difference is 36.8 ms. By comparison, the arrival time of a fictitious wave traveling along the axis—the reference arrival time—is 669.483 s and does not depend on frequency.

When at fixed frequency the propagation range decreases, the difference in arrival time between the axial wave and the lowest mode in the adiabatic approximation de-

TABLE I. Arrival times of the axial wave, t_{aw} and the lowest mode in the adiabatic approximation t_{lm} at frequency f with the transmitter at the sound channel axis. The receiver is at range 990 km and the depth of the sound channel axis (635.678 m) at the location of the VLA.

f (Hz)	t_{aw} (s)	t_{lm} (s)	$t_{aw}-t_{lm}$ (ms)
56.25	669.4511	669.4134	37.7
75.00	669.4620	669.4252	36.8
93.75	669.4657	669.4438	21.9

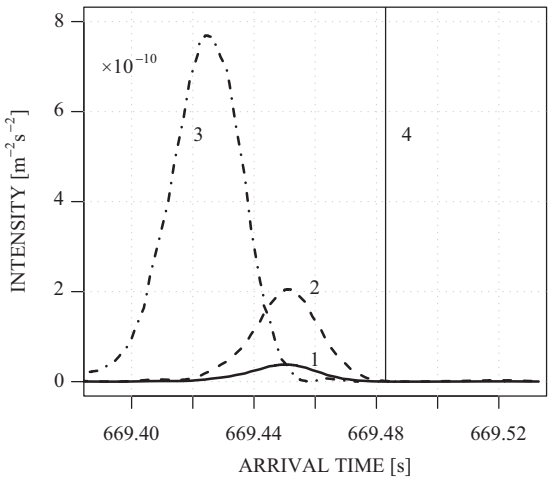

FIG. 9. Predicted intensity envelopes of the axial wave at 990 km for the smooth range-dependent ocean. The receiver is at the channel axis, and the transmitter is at station T1000. Curve (1) corresponds to a transmitter depth of 800 m and (2) the transmitter depth at the channel axis. Curve (3) is the intensity of the lowest mode in the adiabatic approximation when the depth of the transmitter is 800 m. Vertical line (4) indicates the reference arrival time for the wave traveling along the axis.

creases as well. Hence, all of the following calculations will be made for station T1000, where this difference is largest.

To calculate numerically the time domain representation of the axial wave, one considers the Fourier transform over the truncated domain $[\omega_{\rm lo}, \omega_{\rm hi}]$ of the function $\tilde{H}(\omega)$ [see Eqs. (A14) and (A15)] weighted by an appropriate spectral weighting function $\tilde{F}(\omega)$:

$$H(t) = \frac{1}{2\pi}\int_{\omega_{\rm lo}}^{\omega_{\rm hi}} \tilde{F}(\omega)\tilde{H}(\omega)e^{i\omega t}d\omega. \tag{3}$$

As noted above, an M-sequence is well approximated (after pulse compression) by a pulsed sinusoid with a center frequency of 75 Hz modulated by a Gaussian envelope with bandwidth of 37.5 Hz. In this case

$$\tilde{F}(\omega) = \exp\left(-\tfrac{1}{2}\sigma_t^2(\omega-\omega_0)^2\right), \tag{4}$$

where

$$\omega_0 = 150\pi\ \text{s}^{-1}, \quad \sigma_t = \frac{\sqrt{2\log 2}}{37.5\pi}, \quad s = 0.009\,994\ \text{s}. \tag{5}$$

The choice of integration interval $[\omega_{\rm lo}, \omega_{\rm hi}]=[\omega_0-\Delta_\omega, \omega_0+\Delta_\omega]$, with $\Delta_\omega=75\pi\ \text{s}^{-1}$, gives

$$\int_{\omega_0-\Delta_\omega}^{\omega_0+\Delta_\omega} \tilde{F}^2(\omega)d\omega \Big/ \int_{-\infty}^{+\infty} \tilde{F}^2(\omega)d\omega = 0.999\,132. \tag{6}$$

This integration interval is twice the bandwidth. Thus, the use of this interval $2\pi[37.5, 112.5]$ rad/s ([37.5, 112.5] Hz) provides adequate accuracy for pulse propagation modeling.

Figure 9 shows the time domain intensity envelopes of the axial wave for a receiver on the sound channel axis. The propagation range is 990 km. The maximal values of these envelopes are −120.273 and −112.941 dB for transmitter depths of 800 m and the channel axis, respectively. The maximal value of the intensity envelope of the lowest mode in the adiabatic approximation, $|H_{\rm lm}(t)|^2$, for a transmitter depth of 800 m is −107.200 dB. For comparison, the arrival time, or reference time, of the intensity peak of a wave traveling along the axis is shown: if this wave could be described by geometrical acoustics formulas (valid except at some ranges where its maximum value tends to infinity), the intensity envelope would have a shape similar to that of the axial wave. The reference time is 669.483 s. At the ranges under consideration, however, the wave traveling along the axis would interfere with other waves corresponding to rays with small launch angles and therefore cannot be described by simple geometrical acoustics formulas.

Figure 9 shows a 27 ms delay between the axial wave arrival and the lowest mode arrival. In this case (the delay is of the same order as the pulse width), the delay would be marginally adequate to resolve the axial wave were the two pulses of equal size, but the much larger modal signal will dominate and mask the axial wave signal for even the most favorable transmitter location (i.e., at the channel axis).

D. Effect of ocean internal waves on the axial wave

To study the effect of the environmental variability on the axial wave, a simple (but realistic) model for sound speed perturbations due to internal waves (see Appendix B) is used. Simulations were based on the buoyancy frequency profile based on LOAPEX CTD measurements made at station T50. To simplify the description of the sound speed perturbations, a single frequency corresponding to the semi-diurnal tide was chosen, and only the first ten modes were utilized. These modes introduce ocean structure with horizontal wavelengths ranging from 150 km down to 15 km. The complete environment is then formed by adding the smooth approximation—which now assumes the role of the "background"—and the (zero-mean) perturbations.

Simulations of the axial wave with this ocean model indicate that the maximal value of the intensity envelope is essentially zero for "full strength" perturbations. To understand the nature of this result, calculations were made for a set of ocean models in which the sound speed perturbations due to internal waves are scaled by an arbitrary small coefficient ε. This coefficient ε is taken to be 0.075, 0.09, and 0.15. (Results in the previous sections correspond to $\varepsilon=0.0$.)

Figure 10 shows the time domain intensity envelope of the axial wave, $|H(t)|^2$, at the range of 990 km, when the transmitter and receiver are placed at the channel axis of the unperturbed ocean for different values of ε. For $\varepsilon=0.075$, the maximal intensity is −124.200 dB; for $\varepsilon=0.09$, it is −126.559 dB; and for $\varepsilon=0.15$, it is −136.001 dB. For comparison, the maximal intensity in an ocean without internal waves is −112.941 dB (see Fig. 9). For a more realistic full strength value of ε of 1, the internal waves essentially randomize the depth of the sound channel axis to such an extent that they completely destroy the coherent structure of the axial wave, rendering it undetectable.

IV. SUMMARY

A ray diagram for a transmitter located at the sound channel axis in an ocean with a typical mid-latitude sound

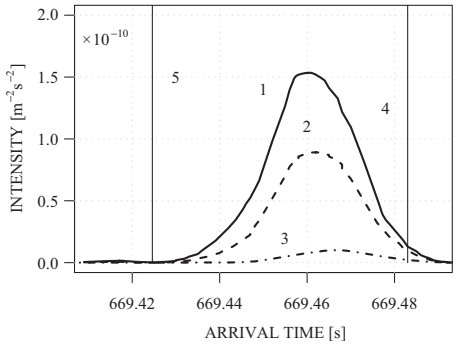

FIG. 10. Predicted axial wave time domain intensity at 990 km range. Transmitter and receiver are at the sound channel axis of the unperturbed ocean. The strength of the sound speed fluctuations is parametrized by a multiplicative coefficient ε: (1) corresponds to $\varepsilon=0.075$, (2) to $\varepsilon=0.09$, and (3) to $\varepsilon=0.15$. Vertical line (4) indicates the reference arrival time of the wave traveling directly along the sound channel axis, and vertical line (5) shows the arrival time of the lowest mode in the adiabatic approximation, both for an unperturbed ocean.

speed profile is characterized by the formation of numerous repeated cusped caustics along the axis. In neighborhoods of these cusped caustics, geometrical acoustics approximations are not valid because their application presupposes that the waves associated with individual ray paths do not interfere with one another. Neighborhoods of interference grow with range, and at a certain propagation range they overlap. This results in the formation of a diffractive (as opposed to ray, i.e., geometrical acoustics) component of the field—the axial wave—that propagates along the axis.

Axial wave propagation modeling has been carried out here for the environment realized during the 2004 LOAPEX experiment, which involved late-summer conditions in the North Pacific.

The two-dimensional range-dependent sound speed field was modeled to a first approximation by smooth polynomial and spline interpolation of the actual sound speed profiles derived from CTD measurements obtained along the 3200 km propagation path. A second, more complex, approximation was constructed by adding to the first approximation a zero-mean sound speed fluctuation field representing sound speed perturbations due to a (simplified) Garrett–Munk internal-wave field.

With respect to range, the TL of the axial wave was seen to be worse than cylindrical spreading. As an example, for 68.2 Hz (one of the LOAPEX frequencies), the smooth sound speed field and an optimal geometry (transmitter and receiver on the channel axis), the axial wave loses 117–120 dB over 3200 km. Given that the LOAPEX transmitter level was about 194 dB, the axial wave might have been detectable over ambient noise assuming some form of period averaging or other post-processing gain.

Actual LOAPEX transmitter deployment depths were not on the channel axis. With respect to transmitter depth, the axial wave strength was shown to decrease with increasing distance from the channel axis. At stations T3200, T2300, and T1600, these distances were at least 362.5, 328.1, and 421.4 m, respectively. In all these cases, the transmitter was too far off-axis to launch a detectable axial wave. Configurations were more favorable at stations T1000, T500, and T250, where separations were 125.9, 119.5, and 117.9 m, respectively.

With respect to frequency, the axial wave strength was seen to increase with frequency. This is related to the number of interfering cusped caustic regions, which decrease as frequency increases, i.e., as wavelengths get shorter. The corresponding propagation time was examined for station T1000, where the range was 990 km. At this station, the transmitter carrier frequency was 75 Hz. The axial wave was shown to arrive later than the lowest mode in the adiabatic approximation by more than a carrier period and hence might be separately resolvable.

To formally determine resolvability, it is necessary to incorporate bandwidth information. The axial wave time domain signature was synthesized by inverse Fourier transforming the axial wave function weighted by a Gaussian with bandwidth of 37.5 Hz centered at 75 Hz. (These values approximate the spectral shape of a LOAPEX 75 Hz M-sequence.) At 990 km, the axial wave pulse was shown (for a transmitter depth of 800 m or at the axis, and the smooth sound speed field) to be dominated by the nearby (earlier) pulse from the lowest mode in the adiabatic approximation to the extent that even with a delay of 27 ms, the axial wave pulse would not be separately resolvable. Resolution capacity degrades further for shorter ranges because the difference in arrival times between the two pulses decreases.

Predictions for the more complex—and hence more realistic—ocean model indicated that randomization of the sound speed seriously degrades the coherent structure of the axial wave. These predictions imply that it would not be possible to detect the axial wave for any transmitter/receiver configuration for the environmental settings corresponding to those encountered during LOAPEX.

As is well known, the effect of internal waves is negligible in the Arctic Ocean. This region is characterized by the formation of a near-surface waveguide where the axial wave exists. This situation coupled with the weakness of the internal-wave field might possibly create favorable conditions for axial wave detection.

APPENDIX A: INTEGRAL REPRESENTATION OF THE AXIAL WAVE

In the frequency domain in a range-independent ocean where the variables are separable, the formula for the axial wave is obtained by transforming the contour integral that gives the exact solution of the point transmitter problem. The integral representation of the axial wave is of a different form for a normal waveguide[9] where the wave traveling along the sound channel axis is the last to arrive and for the abnormal waveguide where the situation is opposite. In most

long-range propagation experiments (in particular, in LOAPEX), deep-water waveguides are normal. Therefore, only normal waveguides will be considered below.

The formula for the axial wave may be written in terms that can be obtained for a range-dependent ocean as well.[5] This formula includes the solutions to the Helmholtz equation

$$\frac{\partial^2 u^0}{\partial x^2} + \frac{\partial^2 u^0}{\partial z^2} + \frac{\omega^2}{\bar{c}^2(z)} u^0 = 0, \tag{A1}$$

where ω is a cyclic frequency and $c(z)$ is the sound speed that can be expanded in the case of small $|z-z_0|$ in the form

$$\bar{c}(z) = \bar{c}_0 + \frac{\bar{c}_2}{2!}(z-z_0)^2 + \frac{\bar{c}_3}{3!}(z-z_0)^3 + \cdots, \quad \bar{c}_2 > 0. \tag{A2}$$

These solutions are concentrated near the sound channel axis $z=z_0$ and decay exponentially outside a narrow strip containing the axis as ω tends to infinity. They are derived in the form of a product of the exponential function and the parabolic cylinder function[10,11] $D_q(\Psi)$, $q=0,1,\ldots$,

$$u^0(x,z) = u_q^0(x,z) = \exp\left\{ i\omega \sum_{m=0}^{M+1} \alpha_m^0(x,\xi)\omega^{-m/2} + O(\omega^{-M/2}) \right\} D_q\left(\sum_{m=0}^{M-1} \beta_m^0(x,\xi)\omega^{-m/2} + O(\omega^{-M/2}) \right). \tag{A3}$$

The coefficients $\alpha_m^0(x,\xi)$ and $\beta_m^0(x,\xi)$, which are polynomials in $\xi=\sqrt{\omega}\,(z-z_0)$, are found from a recursive system of partial differential equations resulting from the substitution of Eq. (A3) into Eq. (A1). M is taken equal to 3, which gives a residual [the difference between the left-hand side of Eq. (A1) and zero] of order $O(\omega^{1/2})$. As a result, one gets[5]

$$u_q^0(x,z) = \exp\left\{ i\left(\frac{\omega}{\bar{c}_0}x - \left(q+\frac{1}{2}\right)\frac{x}{a} + \frac{i}{4\sqrt{3}}\chi\frac{\xi}{a}\frac{1}{\sqrt{\omega}} + \left[\frac{i}{8}\left(b-1+\frac{5}{6}\chi^2\right)\frac{\xi^2}{a^2} - \frac{1}{2}\frac{\bar{c}_0}{a^2}\left(b\left(q+\frac{1}{2}\right)^2 + \frac{1}{4}\left(b-1+\frac{3}{4}\chi^2\right)\right)x \right]\frac{1}{\omega} + O\left(\frac{1}{\omega^{3/2}}\right)\right)\right\} D_q\left(\sqrt{2}\left(\frac{\xi}{\sqrt{a\bar{c}_0}} + \frac{1}{\sqrt{3}}\frac{\sqrt{\bar{c}_0}}{\sqrt{a}}\chi\left[\frac{1}{4a\bar{c}_0}\xi^2 + \left(q+\frac{1}{2}\right)\right]\frac{1}{\sqrt{\omega}} + \frac{1}{12}\left[\frac{1}{a^{5/2}\sqrt{\bar{c}_0}}(b-1+\chi^2)\xi^3 + 3\frac{\sqrt{\bar{c}_0}}{a^{3/2}}\left(q+\frac{1}{2}\right)\left(b-1+\frac{1}{3}\chi^2\right)\xi\right]\frac{1}{\omega} + O\left(\frac{1}{\omega^{3/2}}\right)\right)\right), \tag{A4}$$

where $\bar{c}_0$ is the axial sound speed, $a=\sqrt{\bar{c}_0/\bar{c}_2}$ is the characteristic dimension of the waveguide, the value

$$\chi = \frac{2}{3^{3/2}}\frac{\bar{c}_3\sqrt{\bar{c}_0}}{\bar{c}_0^{3/2}} \tag{A5}$$

characterizes the difference of the actual waveguide from the appropriate symmetric waveguide, where $\chi=0$, and

$$b = \frac{1}{8}\left(\frac{\bar{c}_4\bar{c}_0}{\bar{c}_2^2} - 1 - \frac{5}{3}\frac{\bar{c}_3^2\bar{c}_0}{\bar{c}_2^3}\right) \tag{A6}$$

defines the type of a waveguide. If $b<0$ the waveguide is normal, and if $b>0$ it is abnormal.

Saying that ω tends to infinity means that the dimensionless frequency $\kappa=(\omega/\bar{c}_0)\,a$ is large. In LOAPEX, for the sound speed profile shown in Fig. 4 at the frequency of 75 Hz one obtains $\kappa=845.87$.

In a normal range-independent waveguide, the integral representation of the axial wave, $\tilde{H}^0(\omega)=\tilde{H}^0(x_r,z_r,z_s;\omega)$ has the following form:

$$\tilde{H}^0(\omega) \sim \frac{1}{\sqrt{ax_r}} \int_{\infty\exp(-3i\pi/4)}^{\infty\exp(i\pi/4)} p^0(\tau) u^0_{\tau-1/2}(0,z_s) \times u^0_{\tau-1/2}(x_r,z_r)\,d\tau. \tag{A7}$$

Here $(0,0,z_s)$ and $(x_r,0,z_r)$ are the coordinates of the transmitter and receiver, respectively, $z_s \leqslant z_r$; $u^0_{\tau-1/2}(x,z)$ is obtained from $u^0_{\tau-1/2}(x,z)$ by replacing $D_{\tau-1/2}(\Psi)$ with $D_{\tau-1/2}(-\Psi)$. The weight function

$$p^0(\tau) = \frac{e^{-i\pi/4}}{4\pi}\exp\left(-i\frac{\pi}{2}(K^0-1)\right)2^{-\tau} \times \frac{\Gamma(\tau+1/2)}{\Gamma^2(\tau/2+3/4)}\frac{e^{i\pi K^0\tau}}{1+ie^{i\pi\tau}}[D_{\tau-1/2}(0)]^{-2} \tag{A8}$$

includes the integer K^0 that satisfies the inequalities

$$\frac{x_r}{\pi a}\left(1-|b|^{1/2}\left(\frac{\omega}{\bar{c}_0}x_r\right)^{-0.5+\delta}\right) \leqslant K^0 < \frac{x_r}{\pi a}\left(1-|b|^{1/2}\left(\frac{\omega}{\bar{c}_0}x_r\right)^{-0.5+\delta}\right)+1, \tag{A9}$$

where $0<\delta<1/2$. With such a choice of the number K^0, the wave corresponding to a ray that crosses the waveguide axis K^0-1 times will be the last wave that does not interfere with

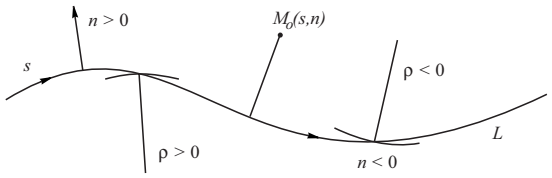

FIG. 11. The (s,n)-coordinates near the waveguide axis L in the (x,z)-plane.

the wave propagating directly along the waveguide axis and can be observed independently of the latter.[5] The selection of a constant δ is discussed in Ref. 5. For most medium models, δ can be taken to be 0.1. In all our simulations of the axial wave, we put δ equal to 0.1 as well.

If $z_r < z_s$, the integral representation of the axial wave takes on the form

$$\tilde{H}^0(\omega) \sim \frac{1}{\sqrt{ax_r}} \int_{\infty \exp(-3i\pi/4)}^{\infty \exp(i\pi/4)} p^0(\tau) u^0_{\tau-1/2}(0,z_s) \times \underline{u}^0_{\tau-1/2}(x_r,z_r) d\tau. \quad \text{(A10)}$$

The integration contour in Eqs. (A7) and (A10) begins at infinity in the complex τ-plane and goes to $\tau=0$ along the straight line arg $\tau=-3\pi/4$. From $\tau=0$ it goes out to infinity along the straight line arg $\tau=\pi/4$.

In a range-dependent ocean it is assumed that the ocean sound speed, c, depends on depth coordinate z and coordinate x measured along the transmitter-receiver direction. In this case the sound channel axis is some curve L. Assume that the curve L can be represented parametrically as $x=x(s)$, $z=z(s)$, where the parameter s is taken to be the arc length along L measured in a given direction from some initial point. Introduce a new system of coordinates (s,n) in the vicinity of L. The coordinates (s,n) of an arbitrary point M_0 will be defined as follows: $|n|$ is the length of the normal dropped from M_0 to L, and s is the arc length along L from the initial point to the base of the normal (Fig. 11). In addition, assume that n is positive if M_0 is to the left of L as one moves along L in the direction of increasing values of s. The Lamé coefficients h_1 and h_2 of the coordinate system (s,n) are

$$h_1 = 1 + \frac{n}{\rho(s)}, \quad h_2 = 1. \quad \text{(A11)}$$

Here $\rho(s)$ is the radius of curvature of L. It is assumed to be positive if the center of curvature lies to the right of L, i.e., among negative values of n, and the radius of curvature is negative otherwise (see Fig. 11).

The sound speed $c(x,z)$ in (s,n)-coordinates is denoted by $c(s,n)$ as before. It is assumed that the sound speed $c(s,n)$ is differentiable a sufficient number of times with respect to both variables s and n and therefore can be expanded in the case of small $|n|$ in the form

$$c(s,n) = c_0(s) + c_1(s)n + \frac{1}{2!}c_2(s)n^2 + \cdots. \quad \text{(A12)}$$

In a range-dependent ocean, the integral representation of the axial wave is constructed from the solutions to the Helmholtz equation written in (s,n)-coordinates. These solutions $u_q(s,n)$, $q=0,1,\ldots$, have the nature of waves propagating along the range-variable sound channel axis L and tending rapidly to zero outside a boundary layer surrounding the axis. They appear in a form similar to Eq. (A3),

$$u_q(s,n) = \exp\left\{ i\omega \sum_{m=0}^{M+1} \alpha_m(s,\nu)\omega^{-m/2} + O(\omega^{-M/2}) \right\} \times D_q\left(\sum_{m=0}^{M-1} \beta_m(s,\nu)\omega^{-m/2} + O(\omega^{-M/2}) \right). \quad \text{(A13)}$$

The coefficients $\alpha_m(s,\nu)$ and $\beta_m(s,\nu)$, which are polynomials in $\nu=\sqrt{\omega}n$, are obtained from a recursive system of partial differential equations resulting from the substitution of Eq. (A13) into the Helmholtz equation.[6] Introduction of the variable $\nu=\sqrt{\omega}n$ and representation of the desired solution in the form of a product of the rapidly varying (for large ω) exponential function and the parabolic cylinder function, which varies more slowly, means that in finding of the solution (A13), one uses the parabolic equation method (or the boundary layer method) pioneered by Tappert.[12]

As opposed to the adiabatic approximation of low-order modes that depend only on medium properties along the vertical line parallel to the z-axis, the newly obtained solutions to the Helmholtz equation accumulate the information about medium properties near the range-variable sound channel axis along the whole propagation range. The coefficients $\alpha_m(s,\nu)$ and $\beta_m(s,\nu)$ are found[6] up to M equal to 3. In this case, substituting the newly obtained solutions into the Helmholtz equation yields residuals of order $O(\omega^{-1/2})$.

Let us assume that in the coordinate system (s,n) introduced in the vicinity of the sound channel axis L on the (x,z)-plane, the transmitter is at $s=0$, $n=n_s$, and the receiver is at $s=s_r$, $n=n_r$. By analogy with Eq. (A7) for the axial wave in a range-independent medium, if $n_s \leqslant n_r$ the integral representation of the axial wave, $\tilde{H}(\omega)=\tilde{H}(s_r,n_r,n_s;\omega)$, in a range-dependent ocean will have the form

$$\tilde{H}(\omega) \sim \frac{1}{\sqrt{as_r}} \int_{\infty \exp(-3i\pi/4)}^{\infty \exp(i\pi/4)} p(\tau) \underline{u}_{\tau-1/2}(0,n_s) u_{\tau-1/2}(s_r,n_r) d\tau. \quad \text{(A14)}$$

where $p(\tau)$ is the weight function, $\underline{u}_{\tau-1/2}(s,n)$ is obtained from $u_{\tau-1/2}(s,n)$ by replacing $D_{\tau-1/2}(\Psi)$ with $D_{\tau-1/2}(-\Psi)$, and $a=\sqrt{c_0/c_2}$ is the characteristic dimension of the range-independent waveguide with the sound speed $\bar{c}(z)$ along the vertical line passing through the transmitter $c(0,z)=\bar{c}(z)$ [see also Eq. (A2)].

If $n_r < n_s$ the integral representation of the axial wave has the form

$$\tilde{H}(\omega) \sim \frac{1}{\sqrt{as_r}} \int_{\infty \exp(-3i\pi/4)}^{\infty \exp(i\pi/4)} p(\tau) u^0_{\tau-1/2}(0,n_s) \underline{u}^0_{\tau-1/2}(s_r,n_r) d\tau. \quad \text{(A15)}$$

In the case of a range-independent medium, the integrals (A14) and (A15) must reduce to the integrals (A7) and (A10), respectively. On the other hand, the weight function

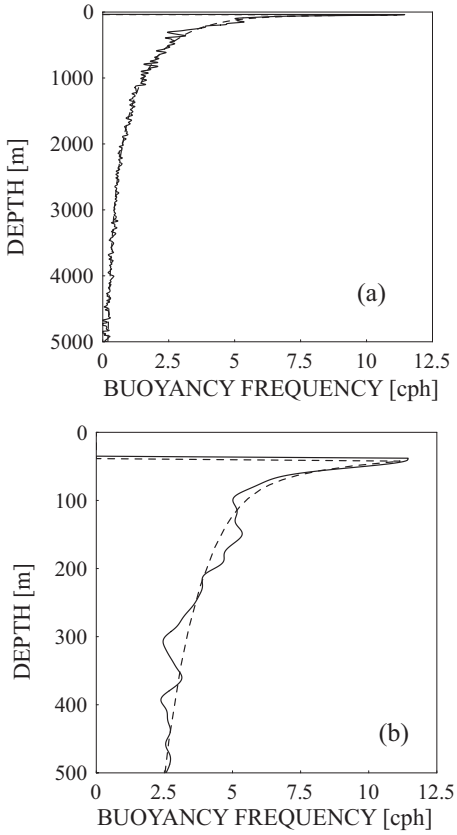

FIG. 12. Buoyancy frequency profile obtained from a CTD cast at station T50 (solid) and its smooth approximation (dashed). Panel (a) corresponds to the depth interval (0,5 000) m and panel (b) to the depth interval (0,500) m.

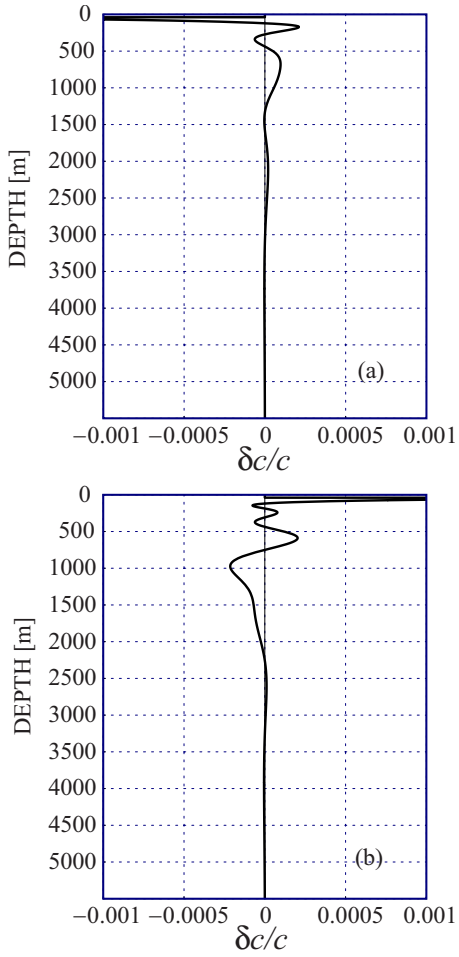

FIG. 13. (Color online) Sound-speed perturbations versus depth for one realization of a ten-mode internal-wave field. Panel (a) shows the perturbation at the VLA, and panel (b) shows the perturbation at 990 km from the VLA (station T1000).

$p(\tau)$ must be independent of medium properties. It can be shown that this requirement is equivalent to the localization principle,[13] which asserts that the high-frequency asymptotic behavior of a wave field depends only on properties of the medium in the vicinity of the ray. Thus, the weight function $p(\tau)$ in Eqs. (A14) and (A15) is given by the same expression (A8) as in the case of a range-independent ocean. The integer K contained in $p(\tau)$ satisfies the inequalities that are the generalization of Eq. (A9) to the case of a range-dependent medium.[6]

APPENDIX B: SOUND-SPEED PERTURBATIONS DUE TO INTERNAL WAVES

We shall assume that the ocean sound speed along the transmitter-receiver direction $\hat{c}(x,z,t)$, consists of the unperturbed sound speed profile $c(x,z)$ and a small perturbation, $\delta c(x,z,t)$, dependent on range x, depth coordinate z, and time l,

$$\hat{c}(x,z,t) = c(x,z) + \delta c(x,z,t). \tag{B1}$$

The vertical position z varies from $z=0$ at the ocean surface to $z=-D$ $(D>0)$ at the ocean bottom. The second horizontal spatial coordinate has been omitted since for the choice of δc below, the cross-range gradients of the sound speed are typically two orders of magnitude smaller than the vertical gradients, and therefore the sound propagation is believed to be sufficiently well described as two dimensional (i.e., having no out-of-plane scattering).

The quantity δc will represent the sound speed perturbations due to a field of internal waves. For these numerical experiments, δc is constructed from a superposition of linear internal waves, constrained by the following assumptions: the ocean depth $D=6$ km is range independent and the buoyancy profile $N(z)$ is obtained as a smooth approximation of measured data. Figure 12 shows the buoyancy frequency profile from the LOAPEX CTD cast at station T50 and a smooth approximation used for simulations.

Neglecting the small effects due to internal-wave currents, the sound speed perturbations due to internal waves are given by[14,15]

$$\delta c/c \approx GN^2(z)\zeta(x,z,t), \tag{B2}$$

where ζ is the vertical water displacement due to the internal waves, and G, assumed constant here,[15] has the value of 3.0 s^2/m.

The displacement ζ is constructed from the superposition of a subset field of linear internal waves traveling along the transmitter-receiver direction. For linear waves in a flat bottom ocean, the displacement ζ is given by

$$\zeta(x,z,t) = \mathrm{Re}(W(z)e^{i(kx-\Omega t)}), \tag{B3}$$

where $W(z)$ satisfies

$$(\Omega^2 - f_i^2)\frac{d^2W}{dz^2} + (N^2(z) - \Omega^2)k^2W = 0 \tag{B4}$$

subject to the boundary conditions $W(0)=W(-D)=0$. Here the inertial frequency f_i is taken to be 1 cycle/day $=(\pi/4.32)\times 10^{-4}$ s^{-1}, corresponding to a latitude of 30°. Given the wave frequency Ω there can be found a sequence of modes $W_j(z)$ and corresponding wave numbers k_j, $j=1,2,\ldots$, that solve Eq. (B4). These modes form an orthogonal set so that

$$\int_{-D}^{0} (N^2(z) - f_i^2)W_m(z)W_n(z)dz = \gamma\delta_{mn}, \tag{B5}$$

where γ is any arbitrary normalization constant independent of m and n; for later convenience[15] γ is taken to be $2/(BN_0^2)$. Here $B=1$ km and N_0 is found from the condition[16]

$$N_0B = \int_{-D}^{0} N(z)dz. \tag{B6}$$

To simplify the description of the sound speed perturbations, a single frequency Ω is chosen, $\Omega=2\pi/12.5$ rad h^{-1} $=(\pi/2.25)\times 10^{-4}$ s^{-1}, corresponding to the semi-diurnal tide. Summing over the first ten modes associated with that tidal frequency produces the model internal-wave field or, more specifically, an internal-tide field.

After summing, the internal-wave displacement is given by

$$\zeta(x,z,t) = \mathrm{Re}\left(\sum_{j=1}^{10} A_jW_j(z)e^{i(k_jx-\Omega t+\lambda_j)}\right), \tag{B7}$$

where λ_j are random phases. $A_je^{i\lambda_j}$ is a complex random variable with A_j weighted according to

$$\langle A_j^2\rangle = q(j^2 + j_*^2)^{-1}, \tag{B8}$$

where $j_*=3$. If the Garrett–Munk[17] spectral density, a function of mode number and wave number, is integrated over wave number k, then the remaining dependence of mode number j is as above.[15] Following Ref. 14, let

$$q = \frac{E_0 j_*}{\pi}\frac{BN_0^2}{2\hat{\rho}}, \tag{B9}$$

where $E_0=0.4$ J/cm$^2=4\times 10^3$ kg/s^2 is the mean energy and $\hat{\rho}=1$ g/cm$^3=10^3$ kg/m^3 is the density of water.

Construction of the internal-wave modes $W_j(z)$ follows the method proposed by Colosi and Brown,[16] where Wentzel–Kramers–Brillouin scaling of both the modal amplitude and the depth coordinate is used,

$$V(z) = (N(z)/N_0)^{1/2}W(z) \tag{B10}$$

and

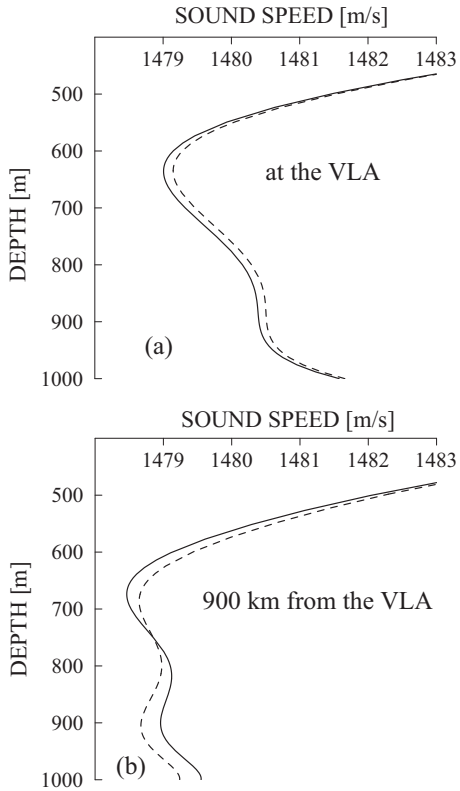

FIG. 14. Sound-speed profiles without internal waves (solid) and for one realization of a ten-mode internal-wave field (dashed). Panel (a) shows these profiles at the VLA and panel (b) shows these at 990 km from the VLA.

$$\hat{\xi}(z) = \frac{1}{N_0B}\int_{-D}^{z} N(z')dz'. \tag{B11}$$

As a result,[16] the approximate solution of Eq. (B4) satisfying the boundary conditions $W(0)=W(-D)=0$ and the normalizing condition (B5) will be of the form

$$W_j(z) = \frac{\sqrt{2}\sqrt{N(z)}}{N_0^{3/2}\sqrt{B}}\sin\left(\frac{k_jBN_0}{\sqrt{\Omega^2 - f_i^2}}\hat{\xi}(z)\right), \tag{B12}$$

with

$$\frac{k_jBN_0}{\sqrt{\Omega^2 - f_i^2}} = j\pi, \quad j = 1,2,\ldots. \tag{B13}$$

For the buoyancy frequency profile shown in Fig. 12, $B_0=0.008\,97$ s$^{-1}\approx 5.16$ cycles/h. Figure 13 shows the sound speed fluctuations induced by the first ten modes of the internal-wave field. Figure 14 demonstrates the perturbed and unperturbed sound speed profiles at two propagation ranges: at the VLA and at station T1000. Modes 1–10 introduce the ocean structure with horizontal wavelengths ranging from 150 down to 15 km.

Effects of incident field refraction on scattered field from vertically extended cylindrical targets in range-dependent ocean waveguides

Elizabeth T. Küsel and Purnima Ratilal
Department of Electrical and Computer Engineering, Northeastern University, Boston, Massachusetts 02115

(Received 9 September 2008; revised 26 January 2009; accepted 27 January 2009)

The effect of incident field refraction on the scattered field from vertically extended cylindrical targets is investigated. A theoretical model for the total scattered field from a cylindrical target in a range-dependent ocean waveguide is developed from Green's theorem. The locally scattered field on the target surface is estimated as a function of the incident field by applying the appropriate boundary conditions on continuity of acoustic pressure and normal velocity, making the model applicable to general penetrable cylinders. The model can account for depth dependence in medium sound speed and hence refraction in the incident field along the target depth. Numerical implementation is done for a passive acoustic reflector, a long cylindrical air-filled rubber hose, often deployed vertically in experiments to provide calibration and charting consistency for wide-area active sonar systems. Analysis with the model indicates that refraction in the incident field along the target depth must be taken into account to accurately estimate the scattered field level from vertically extended cylindrical targets. It is demonstrated that the standard Ingenito waveguide target scattering model, which assumes that the incident field is planar along the target extent, can lead to significant errors of 10 dB or more in estimating the scattered field level.

I. INTRODUCTION

In real ocean waveguides, the water column sound speed profile can vary significantly as a function of depth leading to acoustic field propagation that is highly refractive. Here, we investigate the effect of non-planar incident field on the scattered field from finite vertically extended cylindrical targets in range-dependent ocean waveguides. To better quantify the effect, we develop a theoretical model for the scattered field from a vertically extended cylindrical target that accounts for non-planar incident field over the target depth by direct application of Green's theorem.[1,2] The locally scattered field on the target surface at each depth is estimated as a function of the incident field by applying the boundary conditions on continuity of acoustic pressure and normal velocity, making the model applicable to general penetrable cylinders. Since the scattering contributions are calculated at each depth of the target, the object does not need to be located in an iso-speed layer. Furthermore, the scattering model for vertically extended cylindrical targets developed here can be implemented using both normal modes and the parabolic equation (PE) acoustic propagation models making the approach applicable to general range-dependent environments.[3,4]

The formulation is applied to calculate the scattered field from a cylindrical target[5] manufactured by BBN Systems and Technologies (Cambridge, MA) in several shallow water environments with different sound speed profile and bathymetry. The BBN target is often deployed during acoustic experiments[6,7] serving as a passive acoustic reflector for its known high target strength. Experiments that have deployed the BBN target include the ONR-sponsored 2006 Ocean Acoustic Waveguide Remote Sensing (OAWRS) Experiment at Georges Bank in the Gulf of Maine, and the 2001[8,9] and 2003 (Ref. 10) Acoustic Clutter Imaging Experiments in the New Jersey Strataform under the ONR Geoclutter Program. The BBN target is essentially a 30 m long and 7 cm diameter air-filled cylindrical hose made of gum rubber, suspended vertically off the seafloor at specified depths using a combination of anchors and floats. It provides a means to validate full-field waveguide scattering models and to minimize charting errors in range and bearing for active sonar systems. The scattered field from the BBN targets can also be compared to that from other targets of interest, such as fish schools, underwater vehicles, and the sea bottom, in order to determine their relative target or scattering strengths.

The scattering of sound by an object in an ocean waveguide is complicated due to multi-modal propagation and dispersion. The ocean-acoustic standard, Ingenito[11] waveguide target scattering model, is a widely used method[12–15] to calculate the single scattering from arbitrary sized objects in a horizontally stratified ocean waveguide. This approach is based on normal mode theory and it decomposes the incident field at the target center into modal plane waves. The object's plane wave scatter function is used to couple the incident and scattered modes which are then propagated to the receiver. The Ingenito model is therefore valid for large scatterers, large compared to the acoustic wavelength, in an ocean waveguide. However, it only applies to objects contained within an iso-speed layer because of modal plane wave decomposition at the target center. The Ingenito model cannot account for changes in medium sound speed along the target depth and assumes that the incident field is planar over the

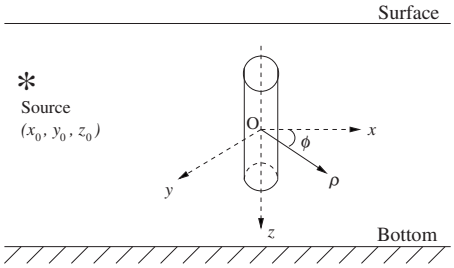

FIG. 1. Geometry of the scattering problem from a vertically extended cylindrical target of radius a and length L. The origin of the coordinate system is at the center of the cylinder.

target extent. Other approaches[16–22] for modeling object scattering in a waveguide are similarly limited, applicable to or implemented only for objects contained in an iso-speed layer. Some models[16,17,23–26] are only valid for horizontally stratified range-independent environments while others, such as the sonar equation,[27] are only valid for compact scatterers,[28] small compared to the acoustic wavelength, in a waveguide.

The theoretical vertically extended cylindrical target waveguide scattering (VETWS) model developed here is first calibrated against the Ingenito[11] model for the BBN target in a Pekeris waveguide where the target is contained within the iso-speed water column layer. The two models lead to scattered field levels as a function of range that match perfectly in this environment. The VETWS model is then implemented in a waveguide with the highly refractive water-column sound speed profile from the Gulf of Maine. In this environment, the BBN target extends over a depth where the water-column sound speed cannot be approximated as a constant and the field incident on the target is highly nonplanar. We show that when the Ingenito model is applied in this environment, it leads to significant errors of 10 dB or more in estimating the scattered field level for the BBN target.

Section II presents the theoretical approach and analytical formulation used to model the scattered field from a finite vertically extended cylindrical target in a general ocean waveguide. In Sec. III we describe the numerical implementation for the BBN target, and present results of calculations in both range-independent and range-dependent shallow water environments with different sound speed profiles. We compare the scattered field level using our model with that from the Ingenito model for each case.

II. THEORETICAL FORMULATION

In this section we develop the analytic formulation for the scattered field from a vertically extended cylindrical target in a range-dependent ocean waveguide. The origin of the coordinate system is placed at the target center with the z-axis pointing vertically downward and aligned with the axis of the cylinder, as shown in Fig. 1. The coordinates for points on the target are denoted by $\vec{r}_t=(x_t,y_t,z_t)=(\rho_t\cos\phi_t,\rho_t\sin\phi_t,z_t)$. Given a time harmonic source at location $\vec{r}_0$ and receiver at location $\vec{r}$, the total scattered field from the target is obtained by application of Green's theorem

$$P_{\text{scat}}(\vec{r})=-\oint_S [P(\vec{r}_t)\nabla_t G(\vec{r}|\vec{r}_t)-\nabla_t P(\vec{r}_t)G(\vec{r}|\vec{r}_t)]\cdot\vec{n}_t dA_t. \tag{1}$$

In Eq. (1), integration is performed over the surface S of the scatterer, $P(\vec{r}_t)$ is the total acoustic pressure on the target surface, $G(\vec{r}|\vec{r}_t)$ is the waveguide Green's function, and $\vec{n}_t$ is the unit vector normal to the surface of the object pointing away from the medium. Equation (1) is applicable to general targets with arbitrary boundary conditions.

The total pressure field on the surface of the target can be written as the sum of incident and scattered components

$$P(\vec{r}_t)=P_{\text{inc}}(\vec{r}_t)+P_{\text{scat}}(\vec{r}_t). \tag{2}$$

For a cylindrical target of radius $\rho_t=a$ and length L in an ocean waveguide, the local incident field on the surface of the target can be calculated numerically from an acoustic propagation model. The local scattered field on the surface of the cylindrical scatterer, on the other hand, is approximated in terms of Hankel functions as follows:

$$P_{\text{scat}}(\vec{r}_t)\approx\sum_{n=0}^{\infty}A_n(z_t)H_n^{(1)}(k(\vec{r}_t)\rho_t)\cos(n\phi_t). \tag{3}$$

At each depth point along the length of the target, this decomposition of the locally scattered field into cylindrical harmonics is valid since the acoustic mode cycle distances are typically much larger than the radius of the cylinder. In the above approximation, $H_n^{(1)}$ is the Hankel function of first kind and order n, and $k(\vec{r}_t)=\omega/c(\vec{r}_t)$ is the medium wavenumber, where ω is the circular frequency and $c(\vec{r}_t)$ is the range and depth-dependent medium sound speed. The depth-dependent coefficients $A_n(z_t)$ are optimally obtained by a least squares inversion applying the appropriate boundary condition at the surface of the target.

We assume that the radius of the cylinder is small compared to its length so that scattering is dominated by contributions from the curved surface of the cylinder and the contribution from the end caps is negligible. This also ensures that single scattering dominates for the vertically extended cylinder and multiple scattering with the waveguide boundaries is negligible.[29]

Next we examine three different boundary conditions for the finite vertically extended cylinder, the pressure-release, rigid, and penetrable surfaces.

A. Pressure-release target

The pressure-release condition states that the total pressure field at the target surface given by Eq. (2) must vanish. Substituting $P(\vec{r}_t)=0$ into Eq. (1) we observe that the first term under the integral sign goes to zero, and we obtain a simplified form for the total scattered field

$$P_{\text{scat}}(\vec{r})=\oint_S [\nabla_t P(\vec{r}_t)G(\vec{r}|\vec{r}_t)]\cdot\vec{n}_t dA_t. \tag{4}$$

In order to solve Eq. (4), we need to define the gradient of the local incident and local scattered pressure fields at the target surface. Over the curved surface of the circular cylinder,

$$\nabla_t P(\vec{r_t}) \cdot \vec{n_t} = -\frac{\partial P(\vec{r_t})}{\partial \rho_t}, \tag{5}$$

i.e., the gradient of the field dotted with the normal vector to the surface is just the derivative in the radial direction. The gradient of the incident field on the surface of the target can be calculated numerically from an acoustic propagation model. In order to calculate the gradient of the locally scattered field on the surface of the target, however, we first make use of Eq. (3) and the boundary condition to find the coefficients $A_n(z_t)$ and hence the local scattered field.

By substituting Eq. (3) and the pressure-release boundary condition into Eq. (2), we can write the resulting equation as a system of linear equations of the form

$$B\vec{q} = \vec{p} \tag{6}$$

at each depth point of the cylinder, where B is an $M \times N$ matrix of coefficients $H_n^{(1)}(k(\vec{r_t})\rho_t)\cos(n\phi_t)$, where M is the number of discrete points in azimuth around the cylinder and N is the number of terms of the Hankel function, $\vec{q}$ is the vector of coefficients $A_n(z_t)$ of length N we are interested in finding, and $\vec{p}$ is of size M and corresponds to $-P_{\text{inc}}(\vec{r_t})$, the negative incident pressure field at discrete azimuthal points around the cylinder. At each depth z_t of the target, we calculate the least-squares solution for $A_n(z_t)$ that minimizes $(\vec{p} - B\vec{q})$.

Once the coefficients $A_n(z_t)$ are determined and hence an approximation for the local scattered field, we use Eqs. (3) and (5) to calculate the gradient of the field as follows:

$$\frac{\partial P_{\text{scat}}(\vec{r_t})}{\partial \rho_t} = \sum_{n=0}^{\infty} A_n(z_t) H_n^{(1)'}(k(\vec{r_t})\rho_t)\cos(n\phi_t), \tag{7}$$

where $H_n^{(1)'}$ is the derivative of the Hankel function with respect to ρ_t expressed as[30]

$$\frac{\partial H_n^{(1)}(k(\vec{r_t})\rho_t)}{\partial \rho_t} = -k(\vec{r_t})H_{n+1}^{(1)}(k(\vec{r_t})\rho_t) + \frac{n}{\rho_t}H_n^{(1)}(k(\vec{r_t})\rho_t). \tag{8}$$

Substituting Eqs. (7) and (8), along with the gradient of the incident field and the waveguide Green's function into Eq. (4), we can calculate the scattered field from the pressure-release cylindrical target at any location in the waveguide. The summation in Eqs. (3) and (7) is truncated at N which is the maximum number of terms sufficient for accurately satisfying the boundary condition. However, since we are also calculating the gradient of the local scattered pressure analytically by Eq. (7), more terms may be needed in order to obtain a stable solution. For targets with small radius such that $ka \ll 1$, we expect only a few terms to be necessary in the approximations.

B. Rigid target

For a target with a rigid boundary, the radial component of the particle velocity must vanish at the surface

$$u(\vec{r_t}) = u_{\text{inc}}(\vec{r_t}) + u_{\text{scat}}(\vec{r_t}) = 0. \tag{9}$$

Note that on the surface of the circular cylinder, the radial component of the particle velocity and the total pressure are related by

$$u(\vec{r_t}) = -\frac{i}{\omega d(\vec{r_t})}\frac{\partial P(\vec{r_t})}{\partial \rho_t}, \tag{10}$$

where d is the medium density. Applying Eqs. (9) and (10) to Green's theorem in Eq. (1), the second term goes to zero and the total scattered field can be calculated from the simplified form below,

$$P_{\text{scat}}(\vec{r}) = -\oint_S [P(\vec{r_t})\nabla_t G(\vec{r}|\vec{r_t})] \cdot \vec{n_t} dA_t. \tag{11}$$

Equations (9) and (10) are used along with Eqs. (7) and (8) to find a least-squares solution for the depth-dependent coefficients $A_n(z_t)$ and the local scattered field. Once these quantities are computed, Eq. (11) is used to calculate the total scattered field at the receiver location.

C. Penetrable target

Let the region outside a homogeneous penetrable cylindrical target be called medium 1 and the region inside the target be called medium 2. The total pressure field in medium 1 is

$$P_1(\vec{r}) = P_{\text{inc}}(\vec{r}) + P_{\text{scat}}(\vec{r}), \tag{12}$$

where $P_{\text{inc}}(\vec{r})$ is calculated using a waveguide acoustic propagation model, as before, and $P_{\text{scat}}(\vec{r})$ is defined in Eq. (3). The pressure field inside the cylindrical target can be expressed as

$$P_2(\vec{r}) \approx \sum_{n=0}^{\infty} B_n(z_t) H_n^{(1)}(k(\vec{r_t})\rho_t)\cos(n\phi_t), \tag{13}$$

where the coefficients $B_n(z_t)$ are determined by application of the boundary conditions.

For this specific case, the two boundary conditions to be satisfied on the surface of the homogeneous penetrable cylindrical target are continuity of acoustic pressure, $P_1(\vec{r_t}) = P_2(\vec{r_t})$, and continuity of the radial component of particle velocity, $u_1(\vec{r_t}) = u_2(\vec{r_t})$. Applying these conditions to Eqs. (3) and (13), we obtain a system of equations that are optimally inverted to find the coefficients $A_n(z_t)$ of Eq. (3) and $B_n(z_t)$ of Eq. (13). Once these coefficients are determined, the total pressure field on the surface of the target can be calculated with Eq. (12) and its gradient with Eqs. (5), (7), and (8). Finally, Green's theorem, Eq. (1), is used to compute the total scattered field level at any location in the waveguide.

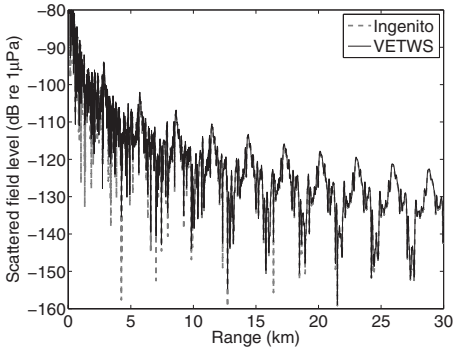

FIG. 2. Scattered field level from the BBN target in a 100 m deep Pekeris waveguide over sandy bottom of Example 1 calculated with the VETWS model and Ingenito model. Source of frequency 415 Hz is co-located with receiver at $z=50$ m; target is centered at $z=50$ m.

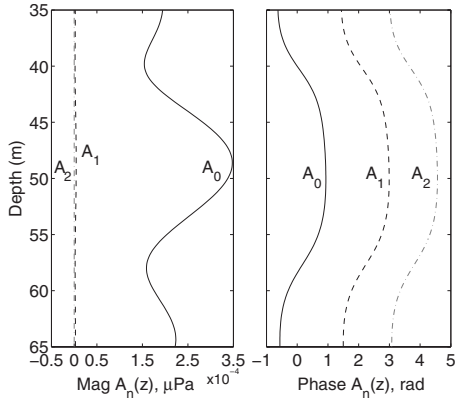

FIG. 3. Plot of magnitude and phase of coefficients $A_n(z_t)$ of Example 1 for target located at 20 km from 415 Hz source.

III. ILLUSTRATIVE EXAMPLES

We implement the scattering model derived in Sec. II for a $L=30$ m long BBN cylindrical target of radius $a=3.5$ cm. The air-filled BBN target satisfies a pressure-release boundary condition so that the equations in Sec. II A are used to compute the scattered field level. A normal mode model[31] is used to calculate the waveguide Green's function for the range-independent cases while the PE model[4] is used for the range-dependent environment. For all calculations, a monostatic configuration is used with a harmonic source of frequency either 415 or 950 Hz co-located with a receiver that measures backscattered fields from the cylindrical target. The acoustic wavelength is much larger than the target's radius, but smaller than its length. The geometry of the problem is shown in Fig. 1. In order to validate our model, we first compare the VETWS model results with Ingenito's scattering solution for the Pekeris waveguide. In addition, we also demonstrate the VETWS result in a layered waveguide with significant sound speed change as a function of target depth and in a range-dependent environment with downslope wedging bottom.

A. Range-independent cases

In order to implement the Ingenito[11,14] scattering model, the following scatter function for a pressure-release cylinder is used:[32,33]

$$S(\alpha,\beta;\alpha_i,\beta_i) = -\frac{kL}{\pi}\mathrm{sinc}\left[\frac{kL}{2}(\cos\alpha_i - \cos\alpha)\right] \times \sum_{m=0}^{\infty} B_m(-j)^m \cos(m[\beta-\beta_i]). \quad (14)$$

The above formula expresses the fact that the cylinder scatters in the vertical like a finite length array through the sinc function[32] and in azimuth through the cylindrical harmonics, where the amplitude of each harmonic for the pressure-release cylinder is given by

$$B_m = -\varepsilon_m j^m \frac{J_m(ka)}{H_m(ka)}. \quad (15)$$

In the above two equations, α and β correspond to the elevation and azimuth angles of the scattered plane waves, α_i and β_i correspond to the elevation and azimuth angles of the incident plane waves, ε_m is the Neumann number defined as $\varepsilon_0=1$, and $\varepsilon_m=2$ for $m\neq 0$, and J_m is the Bessel function of the first kind and order m.

We first compare the VETWS model with the Ingenito model for the BBN target in a 100 m deep Pekeris waveguide over a sandy bottom. The source, receiver, and target centroid are placed at $z=50$ m. The environmental parameters used in this example are water sound speed $c_w=1500$ m/s, bottom sound speed $c_b=1700$ m/s, bottom density $\rho_b=1.9$ g/cm^3, and bottom attenuation $\alpha_b=0.8$ dB/λ.

The total backscattered field level from the target as a function of source-target separation up to 30 km range for a source of frequency 415 Hz is shown in Fig. 2. As expected for this case where the object is contained in the iso-speed water column layer, the scattered levels calculated using the two methods are in very good agreement. Figure 3 shows the depth-dependent coefficients $A_n(z_t)$ of Eqs. (3) and (7) for the Pekeris waveguide problem when the target is located at r

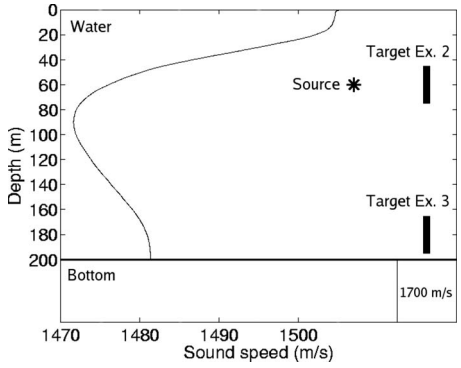

FIG. 4. Mean sound speed profile for Gulf of Maine, during September and October 2006, used in the calculations of the total scattered field for Examples 2 and 3. Source and target locations in depth for both examples are also shown for reference.

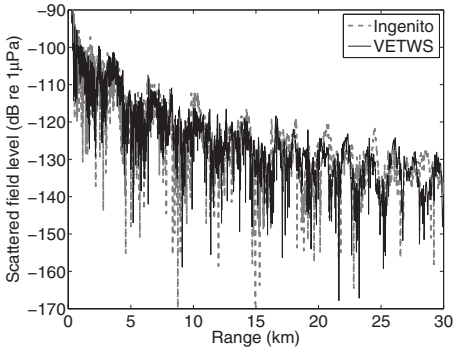

FIG. 5. Scattered field level from the BBN target in the depth-dependent waveguide scenario of Example 2 calculated with the VETWS model and Ingenito model. Source of frequency 415 Hz is co-located with receiver at $z=60$ m; target is centered at $z=60$ m.

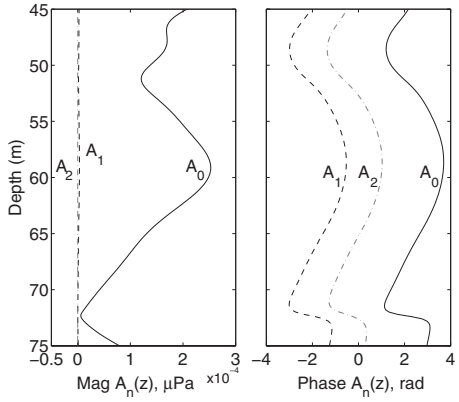

FIG. 6. Plot of magnitude and phase of coefficients $A_n(z_t)$ of Example 2 for target located at 20 km from 415 Hz source.

$=20$ km from the source. Note that only the first three terms in the sum of Eq. (7) are necessary to obtain a stable solution since $ka<0.1$.

Next, we examine the scattering from the BBN target in a 200 m deep waveguide with a depth-dependent sound speed profile over a flat sandy bottom. The sound speed profile used in the calculations, shown in Fig. 4, is the mean sound speed profile derived from 185 expendable bathythermograph measurements acquired during the OAWRS experiment in the Gulf of Maine between September and October 2006. For this environment, we consider two different source-receiver-target configurations illustrated in Fig. 4. In Example 2, the source and receiver are placed at $z=60$ m, and the target is centered at the same depth. In Example 3, the source and receiver are located at $z=60$ m, and the target is centered at $z=180$ m and is suspended 5 m off the bottom. For both examples, calculations are performed for two different frequencies.

In the geometry of Example 2, the target is contained within a layer where the medium sound speed change over the target depth is substantial, about 15 m/s. Figure 5 shows the level of the scattered field calculated using the VETWS model and Ingenito's model for Example 2 for a source of 415 Hz. In this case, the Ingenito model overestimates the scattered field level by roughly 3–5 dB. The modal interference structure of the scattered fields from the two models differ for this case. For the Ingenito model, the interference pattern for the scattered field level depends on the Green's function modal interaction with range at the target center. For the VETWS model, the interference pattern depends on the modal interaction integrated over the depth of the target. Furthermore, the Ingenito model does not account for changes in sound speed along the depth extent of the target. Instead, it uses the sound speed information at the center of the object and assumes that it is contained in an otherwise homogeneous layer. Our VETWS model, on the other hand, takes into account changes in medium sound speed and hence the incident acoustic field refraction along the depth extent of the target. The magnitude and phase of the coefficients $A_n(z_t)$ for Example 2 are shown in Fig. 6 for a target located at $r=20$ km from the 415 Hz source. Because of non-planar, refractive incident field over the target depth, the magnitude and phase of $A_n(z_t)$ in Fig. 6 vary much more drastically compared to Fig. 3 for the iso-speed Pekeris waveguide where these quantities vary smoothly over the target depth. The results for Example 2 using a source of frequency 950 Hz are similar to the lower frequency result, where the Ingenito model overestimates the scattered field level by roughly 3–5 dB.

The results for Example 3, in which the target is centered at $z=180$ m, are shown in Figs. 7(a) and 7(b) for the 415 and 950 Hz sources, respectively. Note that in this ex-

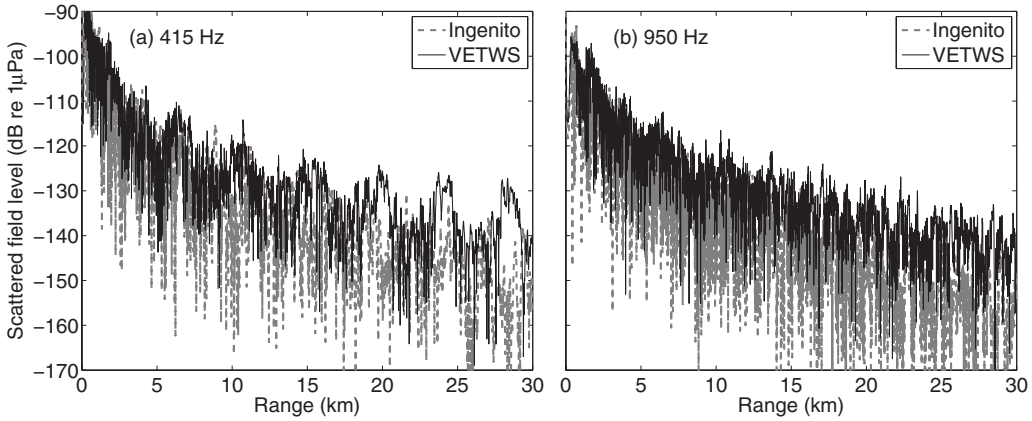

FIG. 7. Scattered field level from the BBN target in the depth-dependent waveguide scenario of Example 3 calculated with the VETWS model and Ingenito model. Source of frequency in (a) 415 Hz and in (b) 950 Hz is co-located with receiver at $z=60$ m; target is centered at $z=180$ m.

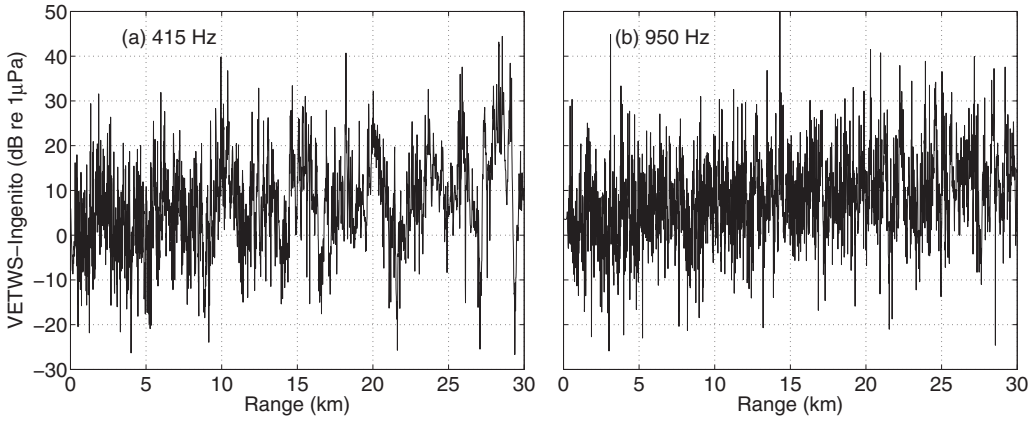

FIG. 8. Difference in scattered field level between the VETWS model and Ingenito model for Example 3 with target centered at $z=180$ m and sources of (a) 415 Hz and (b) 950 Hz.

ample, the target is contained within a layer where the medium sound speed changes by roughly 2 m/s over the target depth. For both frequencies the Ingenito model underestimates the scattered field level by more than 10 dB on average, beyond roughly 20 km source-target separation. The difference in the scattered field level from the VETWS and Ingenito models is shown in Figs. 8(a) and 8(b) for source frequencies of 415 and 950 Hz, respectively. We can observe from these plots that the difference between the two models increases on average with range for this source-receiver-target configuration.

B. Example in a range-dependent environment

In this section, the VETWS model is implemented with the PE to determine the total scattered field from the BBN target in a range-dependent environment. We consider the case of an iso-speed water layer with sound speed $c_w=1500$ m/s, over a downsloping wedge sandy bottom with sound speed $c_b=1700$ m/s. The bathymetry and sound speed used in this example are shown in Fig. 9. The source and receiver are placed at $z=50$ m, and the target is centered at the same depth. Figure 10 shows the total scattered field level for a source of frequency 415 Hz.

For comparison, we also apply the Ingenito model to calculate the total scattered field from the BBN target. Since Ingenito's model is implemented here using a range-independent normal mode model, we approximate the range-dependent waveguide as range-independent using the mean water depth, which in this case is 150 m. Other environmental parameters and the source-receiver-target configuration remain the same. The result is shown in Fig. 10 where we observe that the differences in the total scattered field between the correct range-dependent treatment of the waveguide and its approximation as range-independent are significant. Errors of over 10 dB for ranges greater than 10 km suggest the importance of our approach when calculating the scattered field from vertically cylindrical targets at long ranges from the receiver in real ocean environments.

In the future, the VETWS model developed here will be applied to examine the scattered field data from BBN targets deployed in the Gulf of Maine during the OAWRS experiment with a wide-area sonar in September to October 2006. The current model will be readily applicable to the highly range-dependent environment near Georges Bank where the targets were deployed. A stochastic propagation model will be used in conjunction with the VETWS model to take into account fluctuations in the medium and hence the observed scattered returns from the BBN target.

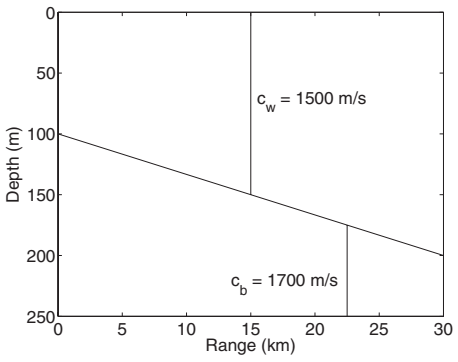

FIG. 9. Bathymetry and sound speed profile used in the calculations of the total scattered field for the range-dependent example.

IV. CONCLUSION

A theoretical model for the scattered field from a penetrable vertically extended cylindrical target in a range-

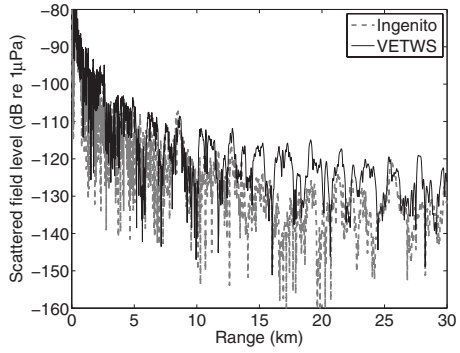

FIG. 10. Scattered field level from the BBN target in the range-dependent environment of Example 4 calculated with the VETWS model. Ingenito model is plotted as reference for a 150 m deep water column. Source of frequency 415 Hz is co-located with receiver at $z=50$ m; target is centered at $z=50$ m.

dependent ocean waveguide is developed from Green's theorem. The model takes into account changes in medium sound speed along the depth extent of the object and hence accounts for non-planar incident field on the target surface. The model is numerically implemented for the BBN target in several different shallow water waveguides. The BBN target is a thin and long air-filled rubber hose often deployed vertically during active acoustic imaging experiments at sea for accurate charting and sonar calibration. The model is validated against the Ingenito waveguide scattering model in an iso-speed Pekeris waveguide where both models lead to identical scattered field levels for the BBN target. In a realistic ocean waveguide, however, with significant change in medium sound speed over the target depth, our analysis shows that the Ingenito model can lead to errors of 10 dB or more in estimating the scattered field level. This is because the Ingenito model assumes that the incident wave over the extent of the target is planar. Our analysis indicates that changes in medium sound speed and hence refraction of the incident acoustic field along the depth extent of a vertically long target must be taken into account in order to accurately estimate its scattered field level in a general ocean waveguide.

A simplified approach to solving finite rough surface scattering problems

J. A. Fawcett
DRDC Atlantic, P.O. Box 1012, Dartmouth, Nova Scotia, B2Y 3Z7, Canada

(Received 5 June 2008; revised 28 January 2009; accepted 28 January 2009)

In this paper a simplified approach is described for the computation of scattering from finite length rough surfaces. In an earlier paper [Fawcett, J. Acoust. Soc. **118**, 1348–1357 (2005)], it was described how to solve such problems by considering a scattering chamber and using the method of wavefield superposition to satisfy the various boundary and continuity conditions. In this paper, a form of the field in the interior of the scattering chamber is assumed and the solution to the scattering problem is reduced to solving a system of equations just along the rough surface. The solution to this system of equations can then be used to compute the scattered or total fields anywhere in the half-space. The results of this approach are compared to those obtained by other methods. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3085645]

I. INTRODUCTION

In order to compute the field scattered from a rough surface, various authors[1–5] have utilized boundary integral equation methods (BIEMs). In Refs. 1 and 2, exact integral equation solutions to an infinite surface scattering problem are derived with the assumption that the surface is periodic in nature. In Refs. 3 and 4, the integral equations for the unknown fields on an infinite scattering surface are truncated at finite integral limits. These limits can be varied until a stable solution is obtained. In addition, the incident field is tapered in order to minimize the effects of the truncation. In the case that the deformations to the half-space are only inward, one can use the half-space Green's function appropriate to the flat portion of the surface and obtain an integral equation only on the deformed surface.[5] However, this approach is not valid if the deformation contains outward sections. In Ref. 6, an exact spectral formulation is described for the solution of scattering from a finite periodic surface. There are many other numerical approaches (see, for example, Refs. 7 and 8) which can be used to model the scattering from a rough surface.

Wavefield superposition methods have been used by several authors[9–13] in target scattering and range-dependent propagation problems. In Ref. 9 wavefield superposition is used to represent the scattered field external to a target and the computational results are compared to those obtained using a Helmholtz integral representation. In Refs. 10 and 11, wavefield superposition is again used to model target scattering but in the presence of waveguide or half-space boundaries. In Refs. 12 and 13 the method is applied to compute the scattering from range-dependent seabed interfaces. In these cases, the wavefield superposition method involves utilizing multiple sets of point sources to model the fields (possibly elastic) in the seabed and in the water column. In the present paper and in Ref. 14, a novel application of the wavefield superposition method is used to reduce infinite surface (but finite roughness) scattering problems to finite computational domains. In Ref. 14 we described some of the problems associated with modeling scattering from a general finite roughness section, particularly in the case of a distant point source and possibly distant receivers. Truncated integral equation methods, including the extrapolation of the solution using the half-space Green's function in the Helmholtz integral, were discussed. In that reference, the concept of a surrounding scattering chamber (including the rough surface as one of the boundaries) was introduced and wavefield superposition was used to represent the interior and exterior pressure fields. In this approach, there is a set of point sources just exterior to the rough surface, a set of sources just exterior to a bounding arc in the water column, and a set of sources just interior to this same arc. The first two sets of sources are free space sources and represent the interior field in the scattering chamber. The last set of point sources are the appropriate half-space sources which represent the exterior field and ensure that this field satisfies the exterior boundary conditions. The continuity conditions across the arc and the boundary condition along the rough surface allow for the solution of the coefficients of all these sources. In the case that M coefficients are used for each set of sources, then the solution of a system of $3M \times 3M$ equations is required.

In this paper, we start from the same approach as Ref. 14. However, by assuming a representation of the field in the interior, we can reduce the scattering problem to solving a simple $M \times M$ system along the rough boundary. In Sec. II, we describe this new approach and in the numerical examples we examine its accuracy for some rough surface scattering problems using both integral equation approaches and the full method of Ref. 14 for comparison.

II. THEORY

In Fig. 1 a schematic of a pressure-release surface rough surface bounding a constant velocity half-space is shown. The curves C_1 and C_2 comprise the boundary and define the curves for the placement of point sources in the computational method of Ref. 14. The curve C_1 includes the rough surface and small flat sections of $z=0$, the curve C_2 is a

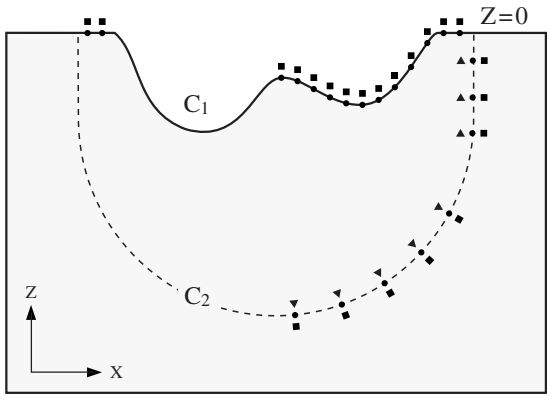

FIG. 1. A schematic diagram showing the bounding curves and point sources which are used in the field representations of Ref. 14 and this paper.

semi-circle in the water half-space. The sources exterior to the scattering chamber (indicated by squares in Fig. 1) represent the field in the interior of the chamber. The sources interior to C_2 (triangles) express the exterior, scattered field and will not be considered in this paper. The positions of the displaced point sources, exterior to C_1 will be denoted as $\boldsymbol{S}_j$, $j=1,\ldots,N$ and those exterior to C_2 as $\boldsymbol{S}_j$, $j=N+1,\ldots,2N$. These sources will have complex amplitudes defined as $\{\hat{a}_j\}$ and $\{b_j\}$, respectively. Thus, we can write for the field interior of $\Omega \equiv C_1 \cup C_2$,

$$p^I(\boldsymbol{R}) = \sum_{C_1} \hat{a}_j G_f(\boldsymbol{R};\boldsymbol{S}_j) + \sum_{C_2} b_j G_f(\boldsymbol{R};\boldsymbol{S}_j), \tag{1}$$

where G_f denotes the free space Green's function,

$$G_f(\boldsymbol{R};\boldsymbol{S}_j) = -i/4H_0^1(k|\boldsymbol{R}-\boldsymbol{S}_j|), \tag{2}$$

$\boldsymbol{R}$ denotes the Cartesian coordinate (x,z) and k denotes the wavenumber in the half-space.

In this paper, instead of using Eq. (1) we will assume a representation of the pressure field in the interior of Ω in the form

$$p^I(\boldsymbol{R}) = \sum_{j=1}^{N} a_j G_f(\boldsymbol{R};\boldsymbol{S}_j) + p_h^{\text{inc}}(\boldsymbol{R}), \tag{3}$$

where p_h^{inc} is the half-space incident field for a pressure-release surface,

$$p_h^{\text{inc}} = -i/4[H_0^1(k\sqrt{(x-x_s)^2+(z-z_s)^2}) - H_0^1(k\sqrt{(x-x_s)^2+(z+z_s)^2})] \tag{4}$$

for a point source at (x_s,z_s). In Eq. (1) there is no explicit representation of the incident field; however, in Ref. 14 it is explicit in the representation of the external field and it implicitly enters into the interior field through the continuity conditions satisfied by the interior and exterior fields along C_2. In Eq. (3) we have reduced the number of point sources to be just those lying to the exterior of C_1 but we have explicitly introduced the half-space incident field. Intuitively, it seems reasonable to consider the pressure field in Ω as composed of the incident field, corresponding to the infinite undeformed surface, and a scattered field represented by point sources along the rough section of the pressure-release surface. The coefficients a_j in Eq. (3) are determined by satisfying the pressure-release boundary condition at the discrete points $\boldsymbol{R}_i$ along C_1,

$$\sum_{j=1}^{N} a_j G_f(\boldsymbol{R}_i;\boldsymbol{S}_j) = -p_h^{\text{inc}}(\boldsymbol{R}_i), \quad i=1,\ldots,N. \tag{5}$$

The expression, Eq. (3), represents not only the interior pressure field but can be used to define its spatial derivatives. Thus, once we have found a_j we can generate the normal derivative of the pressure field along C_1 using the formula

$$\frac{\partial p(\boldsymbol{R}_i)}{\partial n} = \sum_{j=1}^{N} a_j \frac{\partial G_f(\boldsymbol{R}_i;\boldsymbol{S}_j)}{\partial n} + \frac{\partial p_h^{\text{inc}}(\boldsymbol{R}_i)}{\partial n}. \tag{6}$$

Let us consider a spatial point $\boldsymbol{R}=(x,z)$ that lies outside the bounding curve C_2. From Ref. 14, we can compute the pressure field at this point from an integral over just the rough section C_1

$$p(\boldsymbol{R}) = -\int_{C_1} G_h(\boldsymbol{R},\boldsymbol{R}(s')) \frac{\partial p(\boldsymbol{R}(s'))}{\partial n'} ds' + p_h^{\text{inc}}(\boldsymbol{R}). \tag{7}$$

Here $G_h(\boldsymbol{R},\boldsymbol{R}(s'))$ is the half-space Green's function

$$G_h(\boldsymbol{R},\boldsymbol{R}(s')) = -i/4[H_0^1(k\sqrt{(x-x(s'))^2+(z-z(s'))^2}) - H_0^1(k\sqrt{(x-x(s'))^2+(z+z(s'))^2})]. \tag{8}$$

For points $\boldsymbol{R}$ within Ω, the expression of Eq. (3) is used to compute the field. The accuracy of Eq. (7) in computing the pressure field in the domain exterior to Ω is dependent on the accuracy of $\partial p(\boldsymbol{R})/\partial n$ computed using Eq. (6). This, in turn, depends on the accuracy of the representation of the wavefield, Eq. (3) (and its spatial derivatives), near the rough surface C_1.

The method of this paper will also apply for the case of a rigid surface with the appropriate change of boundary conditions and Green's Function. In this case, Eq. (5) becomes

$$\sum_{j=1}^{N} a_j \frac{\partial G_f(\boldsymbol{R}_i;\boldsymbol{S}_j)}{\partial n} = -\frac{\partial p_h^{\text{inc}}(\boldsymbol{R}_i)}{\partial n}, \quad i=1,\ldots,N, \tag{9}$$

where now p_h^{inc} denotes the half-space incident field for a rigid boundary condition along $z=0$. The external field relation, Eq. (7), becomes

$$p(\boldsymbol{R}) = \int_{C_1} \frac{\partial G_h}{\partial n'}(\boldsymbol{R},\boldsymbol{R}(s')) p(s') ds' + p_h^{\text{inc}}(\boldsymbol{R}). \tag{10}$$

In Ref. 14 we used the method of wavefield superposition to solve the continuity and boundary conditions along the boundaries of the numerical scattering chamber. In this paper we have reduced the scattering problem to simply satisfy a boundary condition along C_1. If we allow the superposition point source positions $\boldsymbol{S}_j$ in Eqs. (3) and (9) to approach the boundary, we obtain a boundary integral equation for the unknown source distributions $\alpha(s)$ for these two cases, pressure-release and rigid boundary conditions, respectively,

$$\int_{C_1} G(\boldsymbol{R}(s);\boldsymbol{R}(s'))\alpha(s')ds' = -p_1^{\text{inc}}(\boldsymbol{R}(s)), \tag{11}$$

$$-\alpha(s)/2+\int_{C_1}\frac{\partial G(\boldsymbol{R}(s);\boldsymbol{R}(s'))}{\partial n}\alpha(s')ds'=-\frac{\partial p_2^{\mathrm{inc}}(\boldsymbol{R}(s))}{\partial n}. \tag{12}$$

Here we have used subscripts with the incident fields to emphasize that they are different in the two cases and are the half-space incident fields appropriate to the boundary condition along $z=0$. The advantage of using the boundary integral formulation is that it avoids any questions related to the optimal positioning of the superposition point sources relative to the surface. The disadvantage is that one must account for singularities in the Green's function and its normal derivative as a source point approaches the boundary. In Eq. (12) this results in the term $-\alpha(s)/2$. In Eq. (11) the singularity is logarithmic and is not explicitly shown but can be analytically integrated over a discrete panel. Once the distributions $\alpha(s)$ have been found, then the integral form of Eq. (3) can be used for both the pressure-release and rigid boundary conditions to compute the pressure field within Ω,

$$p^I(\boldsymbol{R})=\int_{c_1}\alpha(s')G_f(\boldsymbol{R};\boldsymbol{R}(s'))ds'+p_h^{\mathrm{inc}}(\boldsymbol{R}). \tag{13}$$

Also once $\alpha(s)$ has been determined, then either Eq. (7) (pressure-release boundary condition) or Eq. (10) (rigid boundary condition) can be used to compute the field exterior to Ω. In order to use Eq. (7), we compute (in a discretized form) the normal derivative of the field along C_1 from

$$\frac{\partial p(\boldsymbol{R}(s))}{\partial n}=\int_{C_1}\frac{\partial G_f(\boldsymbol{R}(s);\boldsymbol{R}(s'))}{\partial n'}\alpha(s')ds'+\frac{\partial p_{\mathrm{inc}}(\boldsymbol{R}(s))}{\partial n} \tag{14}$$

and in order to use Eq. (10) for the rigid boundary condition, we compute the pressure field along C_1 using

$$p(\boldsymbol{R}(s))=\int_{C_1}G_f(\boldsymbol{R}(s);\boldsymbol{R}(s'))\alpha(s')ds'+p^{\mathrm{inc}}(\boldsymbol{R}(s)). \tag{15}$$

In both these cases, since we are computing the field or its normal derivative upon the surface itself, we must use the appropriate analytic evaluation of the singular behavior when the evaluation point $\boldsymbol{R}(s)$ is coincident with one of the discrete points $\boldsymbol{R}(s')$.

In the numerical examples, we will require a method to benchmark the proposed method of this paper. One possible method would be to use the wavefield superposition method of Ref. 14 using all the unknown sources. However, as an independent approach we will implement a standard, truncated BIEM. For the pressure-release and rigid conditions, we will use the following integral formulations:

$$\frac{1}{2}\frac{\partial p(\boldsymbol{R}(s))}{\partial n}+\int_C\frac{\partial G(\boldsymbol{R}(s);\boldsymbol{R}(s'))}{\partial n}\frac{\partial p(s')}{\partial n'}ds'=\frac{\partial p^{\mathrm{inc}}(\boldsymbol{R}(s))}{\partial n}, \tag{16}$$

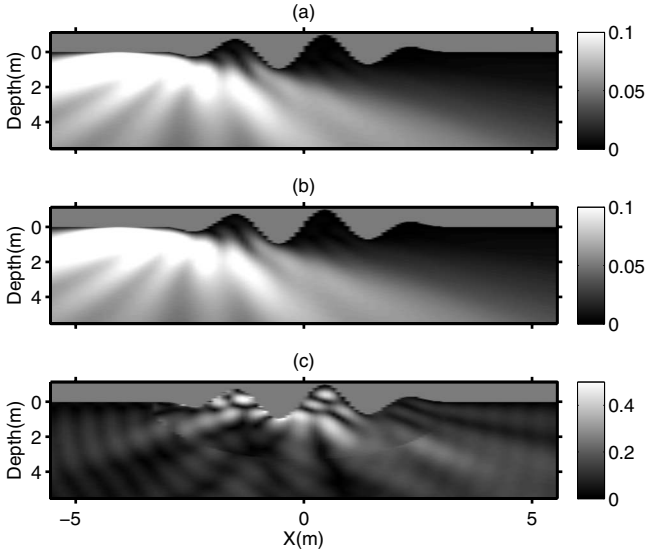

FIG. 2. The total pressure fields (amplitude) for the pressure-release boundary condition: (a) the result from a standard truncated BIEM, (b) the result using the SISC method, and (c) the amplitude of the difference between the two computed fields. The image values in this panel have been scaled so that the maximum value of the grayscale corresponds to 0.5% of the maximum value of the colorbar used in the upper two plots.

$$\frac{p(\boldsymbol{R}(s))}{2}-\int_C\frac{\partial G(\boldsymbol{R}(s);\boldsymbol{R}(s'))}{\partial n'}p(s')ds'=p^{\mathrm{inc}}(\boldsymbol{R}(s)). \tag{17}$$

In this case, the incident field and the Green's function are those for free space, in contrast, to Eqs. (11) and (12) where the half-space Green's functions are used. The integral equations of Eqs. (16) and (17) should be over the entire half-space boundary, but, numerically we will truncate them after a sufficient length (i.e., the curve C will, in general, be longer than C_1) to have achieved a convergent solution.

III. NUMERICAL EXAMPLES

For the numerical examples, we consider a flat surface with a tapered sinusoidal deformation given by

$$z(x)=\sin(\pi x)\cos((x/3)\pi/2),\quad -3<x<3, \tag{18}$$

$$z(x)=0,\quad |x|>3, \tag{19}$$

where increasing depth corresponds to increasingly negative values of z. A 1500-Hz point source is located at a range of 4 m [with respect to (0,0)] and angle of 5° off the x-axis. For the truncated integral equation approach, we consider the computational domain $-15\ \mathrm{m}\leqslant x\leqslant 15\ \mathrm{m}$ with 1500 discrete points used. For the superposition method, we consider the interval $-3.3\ \mathrm{m}\leqslant x\leqslant 3.3\ \mathrm{m}$ to define C_1 of Fig. 1 and the unknown point source distribution using 600 discrete points. The bounding curve C_2 is the semicircle $|\boldsymbol{R}|=3.3$ m. One can certainly obtain accurate solutions using fewer than 600 points but for the error comparisons shown in Figs. 2 and 3 these values were used. Once the point sources have been determined for the interval [−3.3 m 3.3 m], the pressure field can be computed for a much larger numerical grid. Equation (7) [after using Eq. (14) to compute the normal derivative on

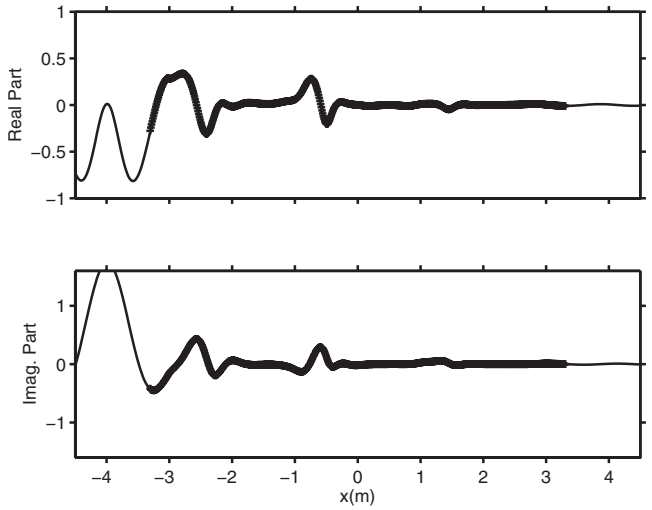

FIG. 3. The solid line shows the real and imaginary parts of the normal derivative of the pressure field along the surface as directly computed by the truncated BIEM. The + signs show the computed values, SISC method, along C_1.

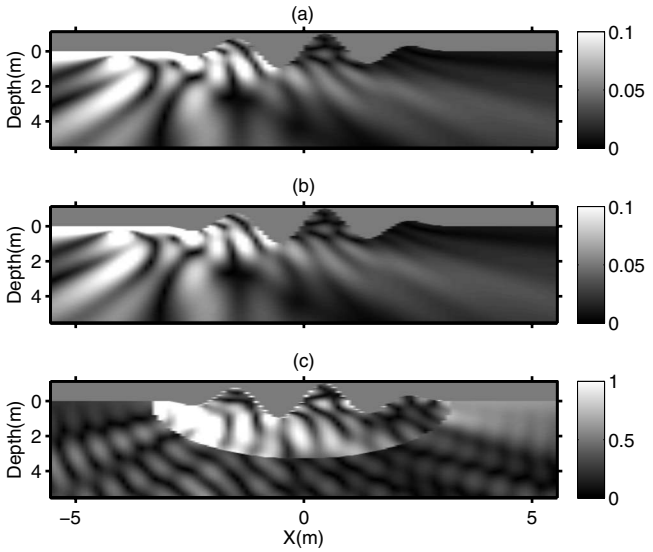

FIG. 4. The total pressure fields (amplitude) for the rigid boundary condition: (a) the result from a standard truncated BIEM, (b) the result using the SISC method, and (c) the amplitude of the difference between the two computed fields. The image values in this panel have been scaled so that the maximum value of the grayscale corresponds to 1% of the maximum value of the colorbar used in the upper two plots.

C_1] is used to compute the pressure field for $|\boldsymbol{R}|>3.3$ m and Eq. (13) is used to compute the pressure field in the interior of Ω. We will refer to the approach of this paper as the surface integral scattering chamber (SISC) method. In Fig. 2 we show the computed total pressure field in the box $[-5.5\ \text{m}\ 5.5\ \text{m}]\times[1.1\ \text{m}\ -5.5\ \text{m}]$ as computed using the standard truncated integral equation approach and the SISC method. In addition, Fig. 2(c) shows the amplitude of the difference between the two solutions scaled by a factor of 1000 so that the maximum amplitude of the colorbar in this plot corresponds to 0.5% the maximum value of the colorbar used in the upper plots. There is a small amount of difference between the BIEM and SISC methods. The differences are largest near the rough scattering surface. There is a slight discontinuity at $|\boldsymbol{R}|=3.3$ m. This is the boundary between the regions where the two different integral representations are used to compute the pressure field using the SISC method. The difference between the two methods is a result of any discretization errors in each of the two methods, BIEM and SISC, but is also a result of any errors in the assumption of Eq. (3). In Fig. 3, we show a comparison of the real and imaginary parts of the normal derivative of the total field as computed by the SISC method using Eq. (14) (+) with those computed using the BIEM method (solid). For the standard BIEM, the normal derivative is solved directly in the interval $[-15\ \text{m}\ 15\ \text{m}]$ using Eq. (16) and the resulting values are shown for a larger interval than is used by the SISC method. As can be seen, the computed values from the two methods show excellent agreement. It is the normal derivative values along C_1 which are used by the SISC method [Eq. (7)] in the computation of the pressure field in the exterior of Ω.

The previous computations are now repeated for a rigid boundary condition using the same numerical parameters as for the pressure-release computations. In Fig. 4 we show the resulting pressure field grids as computed using the BIEM and SISC methods and the difference field, Fig. 4(c). Once again, the differences are small but the error is larger than for the pressure-release boundary condition of Fig. 2 and the discontinuity at the SISC computational boundary $|\boldsymbol{R}|=3.3$ m is evident. In Fig. 5 the computed pressure field upon the scattering surface is shown as computed directly using the standard BIEM and as computed using the solution $\alpha(s)$ from the SISC method [Eq. (15)]. As can be seen, the agreement is excellent.

Finally, we use the SISC method to compute the field scattered by the rigid rough surface for a source 1° off the horizontal at a range of 1000 m. In this case, the truncated BIEM approach cannot be used without using a very large number of points. In order to provide a benchmark for the method of this paper, we use the scattering-chamber/wavefield superposition approach of Ref. 14 (modified for rigid boundary conditions) with 601 free space point source exterior to C_1 $[-3.3\ \text{m}\ 3.3\ \text{m}]$, 601 free space point sources exterior to C_2, and 601 rigid-half-space point sources interior

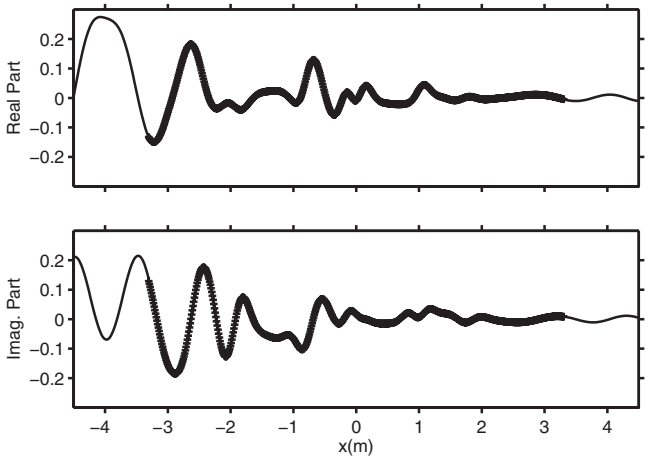

FIG. 5. The solid line shows the real and imaginary parts of the pressure field along the surface as directly computed by the truncated BIEM. The + signs show the computed values, SISC method, along C_1.

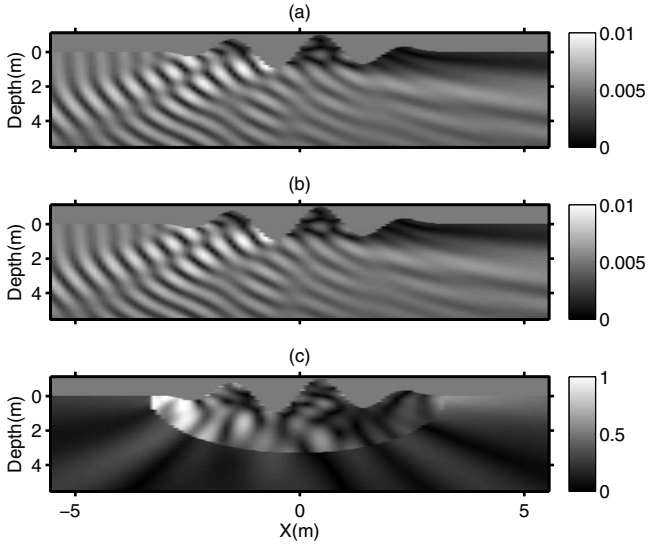

FIG. 6. The total pressure fields for the rigid boundary condition: (a) the result from using the full scattering-chamber approach of Ref. 14, (b) the result using the SISC method, and (c) the amplitude of the difference between the two computed fields. The image values in this panel have been scaled so that the maximum value of the colorbar corresponds to 1% of the maximum value of the grayscale used in the upper two plots. The source is located 1000 m to the left at an angle of 1° with respect to the horizontal.

to C_2. The sources were displaced a distance of 0.04 m from the curves along the normal directions. The resulting total fields are shown for the two methods in Fig. 6. The agreement is excellent. However, the bottom difference plot in Fig. 6 (it is scaled so that the maximum amplitude of the colorbar corresponds to 1% of the maximum amplitude of the colorbar in the upper plots) shows the main differences to be within the SISC interior domain Ω and there are once again discontinuities at the SISC computational boundary $|\boldsymbol{R}|=3.3$ m. The differences in the exterior domain $|\boldsymbol{R}|>3.3$ m are small.

IV. SUMMARY

We have shown in this paper that an infinite surface scattering problem, but with a general finite roughness section, can be accurately solved using a finite interval integral equation. The integral equation was derived by considering a numerical scattering chamber in conjunction with the method of wavefield superposition. Using an assumed representation for the pressure field in the interior of the scattering chamber, the solution to the scattering problem was reduced to solving a single set of equations along the finite rough surface. In the limit of the point sources approaching the scattering surface, integral equations were obtained. For the particular numerical examples considered, the method yielded very accurate results for both pressure-release and rigid boundary conditions.

(Received 22 April 2008; revised 19 January 2009; accepted 22 January 2009)

Monopole acoustic logs in a homogeneous fluid-saturated porous formation can be simulated by the real-axis integration (RAI) method to analytically solve Biot's equations [(1956a) J. Acoust. Soc. Am. **28**, 168–178; (1956b) J. Acoust. Soc. Am. **28**, 179–191; (1962) J. Appl. Phys. **33**, 1482–1498], which govern the wave propagation in poro-elastic media. Such analytical solution generally is impossible for horizontally stratified formations which are common in reality. In this paper, a velocity-stress finite-difference time-domain (FDTD) algorithm is proposed to solve the problem. This algorithm considers both the low-frequency viscous force and the high-frequency inertial force in poro-elastic media, extending its application to a wider frequency range compared to existing algorithms which are only valid in the low-frequency limit. The perfectly matched layer (PML) is applied as an absorbing boundary condition to truncate the computational region. A PML technique without splitting the fields is extended to the poro-elastic wave problem. The FDTD algorithm is validated by comparisons against the RAI method in a variety of formations with different velocities and permeabilities. The acoustic logs in a horizontally stratified porous formation are simulated with the proposed FDTD algorithm.

I. INTRODUCTION

Acoustic logging is a useful technique to explore formation properties in geophysics and oil engineering. Important applications of acoustic logging include evaluation of porous formation parameters such as porosity and permeability (Williams *et al.*, 1984; Tang and Cheng, 1996), detection of fractures and measurement of fracture permeability (Hardin *et al.*, 1987; Hornby *et al.*, 1989), and imaging structural characteristics of formation away from the borehole (Hornby, 1989; Tang *et al.*, 2007).

In order to study the relations between acoustic logging responses and properties of porous formations, Rosenbaum (1974) first simulated the axisymmetric responses of the monopole acoustic logs in a homogeneous fluid-saturated porous formation using the real-axis integration (RAI) method to solve Biot's equations (Biot, 1956a, 1956b, 1962), which governs the acoustic wave propagation in poro-elastic media. Then Schmitt *et al.* (1988) analyzed the effects of the permeability, the pore geometry, the properties of the pore fluid, and the borehole radius on the acoustic logs. With the RAI method, Schmitt (1988) simulated the monopole acoustic logs in radially layered fluid-saturated porous formations. Unfortunately, this RAI approach, being analytical, does not work for the common case where the porous formation is horizontally stratified. To solve this, one seeks instead a numerical approach, such as finite-difference, finite-element, or boundary-element method. In this work, a finite-difference time-domain (FDTD) scheme is developed.

There have been several FDTD algorithms presented in the literature for the modeling of acoustic wave propagation in porous media (e.g., Zhu and McMechan, 1991; Dai *et al.*, 1995; Dong *et al.*, 2000; Zeng *et al.*, 2001; Zeng and Liu, 2001). These algorithms are valid and correct only in the low-frequency limit, where the fluid flow in pore space is practically a Poiseuille flow (Biot, 1956a) and the viscous force term in Biot's equations can be treated as independent of frequency. This is so since at low-frequency, the inertial force is much less than the viscous force and hence can be safely ignored. Recently, improved algorithms considering the inertial effect in the viscous fluid flow in poro-elastic media are proposed by Masson *et al.* (2006) and Guan and Hu (2008), but still not working very well for inertial flow in the high-frequency range, where the inertial force dominates. Both works use Taylor expansion to approximate the frequency correction function for the viscous force in the time domain. This idea is extended in the current work to model the acoustic logs in a horizontally stratified fluid-saturated porous formation.

In numerical simulations of wave propagation in an unbounded medium, some absorbing boundary condition needs to be employed to eliminate the spurious reflections from the artificial boundaries of the computational region. In the past 30 years, a great many absorbing boundary conditions have been developed: for example, one-wave equations (Clayton and Engquist, 1977; Reynolds, 1978; Liao *et al.*, 1984; Higdon, 1991), damping layers or sponge zones (Cerjan *et al.*, 1985; Kosloff and Kosloff, 1986; Sochacki *et al.*,1987), and optimal boundary conditions (Peng and Toksöz, 1995). These absorbing boundary conditions, although successful in many applications, are only effective for waves within a specific

[a]Electronic mail: gwllzh@tom.com

range of incidence angles and frequencies. Berenger (1994) proposed a highly effective perfectly matched layer (PML) as an absorbing boundary condition for electromagnetic waves. The PML has the remarkable property of having a zero reflection coefficient for all incidence angles and frequencies before discretization. Chew and Liu (1996) and Hastings *et al.* (1996) independently demonstrated that the PML can also be applied for acoustic waves. These early schemes require field-splitting in the PML to avoid convolutional operations in the time domain, which means the equations in the PML are different from those in the computational region and computational complexity is increased. Roden and Gedney (2000) proposed a nonsplitting PML technique for finite-difference modeling of electromagnetic wave problems, featuring a recursive convolution evaluation and identical equation form in both PML and the computational region. A similar scheme was used by Wang and Tang (2003) for finite-difference modeling of elastic wave propagation. In this paper, the nonsplitting PML schemes is extended to solve the poro-elastic wave problems.

In Secs. II and III, after a review of Biot's theory of wave propagation in poro-elastic media, we adopt the method of complex stretched coordinates (Chew and Weedon, 1994; Liu and Tao, 1997; Wang and Tang, 2003) to formulate the FDTD discretization of Biot's equations. Then we show the comparisons between the FDTD and the RAI methods of the simulated waveforms in variety of formations with different velocities and permeabilities to validate the FDTD algorithm. Finally, we give numerical simulation examples of the acoustic logs in a horizontally stratified porous formation.

II. FORMULATION

A. Biot's equations

According to Biot (1956a, 1956b, 1962), assuming an $e^{-i\omega t}$ time dependence of all field quantities, the equations that describe the acoustic field in an isotropic, homogeneous fluid-saturated porous medium can be expressed as follows:

$$-i\omega\mathbf{w} = (-\nabla p + \omega^2\rho_f\mathbf{u})\kappa/\eta, \tag{1}$$

$$\nabla\cdot\boldsymbol{\tau} = -\omega^2(\rho\mathbf{u} + \rho_f\mathbf{w}), \tag{2}$$

$$\boldsymbol{\tau} = (H-2G)(\nabla\cdot\mathbf{u})\mathbf{I} + C(\nabla\cdot\mathbf{w})\mathbf{I} + G(\nabla\mathbf{u} + \nabla\mathbf{u}^{\mathbf{T}}), \tag{3}$$

$$-p = C\nabla\cdot\mathbf{u} + M\nabla\cdot\mathbf{w}, \tag{4}$$

where $\mathbf{u}$ is the displacement of the solid phase, $\mathbf{w}$ is the relative flow between the fluid and the solid phase, $\boldsymbol{\tau}$ is the bulk stress tensor, $\mathbf{I}$ is the identity tensor, p is the pore fluid pressure, ρ_f and η are the density and viscosity of the pore fluid, respectively, ρ is the density of the formation, G is the shear modulus of the formation, H, C, and M are porous medium moduli as defined by Biot (1962). Note that κ is the dynamic permeability defined by Johnson *et al.* (1987) with the following form:

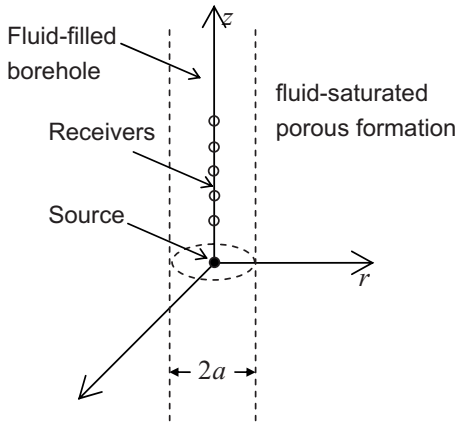

FIG. 1. Schematic of the acoustic logging model. The fluid-filled borehole of radius a is embedded in a horizontally stratified fluid-saturated porous formation. The excited source and the receivers are along the borehole axis, and the source is located at the origin.

$$\kappa(\omega) = \kappa_0\left[\left(1-\frac{4i\omega}{m\omega_c}\right)^{1/2} - i\frac{\omega}{\omega_c}\right]^{-1}, \tag{5}$$

where κ_0 is the Darcy permeability. Note the term $(1-4i\omega/m\omega_c)^{1/2}$ denotes the frequency correction function for the viscous force term in Biot's equations. Here $\omega_c = \phi\eta/\alpha_\infty\rho_f\kappa_0$ is a critical frequency, where α_∞ is the tortuosity. And m is a dimensionless parameter given by $m = \phi\Lambda^2/\alpha_\infty\kappa_0$, where Λ is the weighted volume-to-surface radio. For typical sandstones, $m \approx 8$.

In the low-frequency limit ($\omega \ll \omega_c$), the viscous force dominates and the fluid flow in pore space controlled by viscous shearing is practically a Poiseuille flow. The inertial force increases gradually with frequency and matches the viscous force at $\omega = \omega_c$. Beyond that, the inertial force starts to dominate and the viscous boundary layers first develop. These viscous boundary layers shrink with increasing frequency and at $\omega \gg \omega_c$, the fluid flow in pore space switches to a high-frequency inertial flow. The algorithm to be developed in this work does not drop the inertial term in the viscous fluid flow, thus can be applied at higher frequencies. Recall that FDTD algorithms for the acoustic logs simulation in literature are valid only in the low-frequency limit ($\omega \ll \omega_c$).

B. Finite-difference implementation

A schematic of the acoustic logging model is shown in Fig. 1, where a fluid-filled borehole is embedded in an unbounded fluid-saturated porous formation. With a cylindrical coordinate system (r, z, θ), the borehole axis lies along the central axis z of the cylinder, and the monopole point acoustic source is located at the origin. All field quantities are independent of θ due to axisymmetry.

For the FDTD discretization of Biot's equations governing the acoustic field in the porous formation, we need to rewrite Eqs. (1)–(4) in terms of velocities and stresses in the cylindrical coordinates. Substituting Eq. (5) into Eq. (1), and setting $D_1 = 4/m\omega_c$ and $D_2 = 1/\omega_c$, we get

$$\frac{\eta}{\kappa_0}(\sqrt{1-i\omega D_1}-i\omega D_2)\begin{bmatrix} v_{wr} \\ v_{wz} \end{bmatrix} = -\begin{bmatrix} \frac{\partial p}{\partial r} \\ \frac{\partial p}{\partial z} \end{bmatrix} + i\omega\rho_f \begin{bmatrix} v_{ur} \\ v_{uz} \end{bmatrix}, \tag{6}$$

where $v_{wq}=-i\omega w_q$ and $v_{uq}=-i\omega u_q$ $(q=r,z)$ are the velocity components of the relative flow and the solid phase motion in the i-direction, respectively. Equation (2) can be written as

$$-i\omega\rho\begin{bmatrix} v_{ur} \\ v_{uz} \end{bmatrix} - i\omega\rho_f\begin{bmatrix} v_{wr} \\ v_{wz} \end{bmatrix} = \begin{bmatrix} \frac{\partial}{\partial r}+\frac{1}{r} & -\frac{1}{r} & 0 & \frac{\partial}{\partial z} \\ 0 & 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial r}+\frac{1}{r} \end{bmatrix}\begin{bmatrix} \tau_{rr} \\ \tau_{\theta\theta} \\ \tau_{zz} \\ \tau_{rz} \end{bmatrix}, \tag{7}$$

where τ_{rr}, $\tau_{\theta\theta}$, τ_{zz}, and τ_{rz} are the components of the bulk stress tensor $\boldsymbol{\tau}$. Similarly, the rest Biot's equations can be expressed in terms of velocities and stresses in the cylindrical coordinates.

In this work, the PML is used as the absorbing boundary condition. To introduce the PML, we will modify the equations in the complex stretched coordinates. In the frequency domain, the complex coordinate-stretching variable is chosen as $s_q=1+\Omega_q/i\omega$ $(q=r,z)$, where Ω_q is the stretching function with respect to q. In the PML, the regular coordinate variable q is replaced by the complex coordinate variable $\tilde{q}$, and the spatial derivative $\partial/\partial\tilde{q}$ is expressed in terms of the complex coordinate-stretching variable as $\partial/\partial\tilde{q}=(1/s_q)\partial/\partial q$. Thus, the r components of Eqs. (6) and (7), for example, are changed to

$$\frac{\eta}{\kappa_0}(\sqrt{1-i\omega D_1}-i\omega D_2)v_{wr}-i\omega\rho_f v_{ur} = -\frac{1}{s_r}\frac{\partial p}{\partial r}, \tag{8}$$

$$-i\omega(\rho v_{ur}+\rho_f v_{wr}) = \left(\frac{1}{s_r}\frac{\partial}{\partial r}+\frac{1}{\tilde{r}}\right)\tau_{rr}-\frac{\tau_{\theta\theta}}{\tilde{r}}+\frac{1}{s_z}\frac{\partial\tau_{rz}}{\partial z}, \tag{9}$$

where $\tilde{r}=\int_0^r s_r(r')dr'=r(1+\bar{\Omega}_r/i\omega)$ and $\bar{\Omega}_r=1/r\int_0^r\Omega_r(r')dr'$.

Before discretization, we transform the equations from the frequency domain to the time domain in a way similar to Wang and Tang (2003). For example, in the time domain, Eqs. (8) and (9) become

$$\frac{\eta}{\kappa_0}\left(\sqrt{1+D_1\frac{\partial}{\partial t}}+D_2\frac{\partial}{\partial t}\right)v_{wr}+\rho_f\frac{\partial v_{ur}}{\partial t} = -(1+\phi_r)\frac{\partial p}{\partial r}, \tag{10}$$

$$\rho\frac{\partial v_{ur}}{\partial t}+\rho_f\frac{\partial v_{wr}}{\partial t} = \left[(1+\phi_r)\frac{\partial}{\partial r}+\left(\frac{1+\bar{\phi}_r}{r}\right)\right]\tau_{rr} - \left(\frac{1+\bar{\phi}_r}{r}\right)\tau_{\theta\theta}+(1+\phi_z)\frac{\partial\tau_{rz}}{\partial z}, \tag{11}$$

where $\phi_q=-\Omega_q e^{-\Omega_q t}*$, $(q=r,z)$, and $\bar{\phi}_r=-\bar{\Omega}_r e^{-\bar{\Omega}_r t}*$ are convolution operators introduced by Wang and Tang (2003). Equations (10) and (11) are modified Biot's equations in the PML region. These equations automatically reduce to Biot's equations in the computational region, where Ω_q and $\bar{\Omega}_r$ become zero.

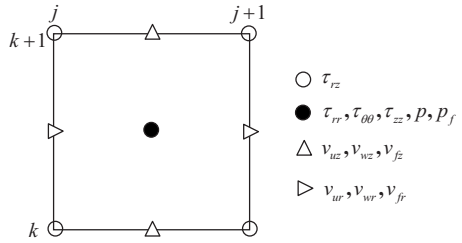

FIG. 2. The velocity-stress FDTD staggered grid in the cylindrical coordinates.

Now we discretize the velocities and stresses by using a staggered finite-difference grid (e.g., Virieux, 1986), as shown in Fig. 2. The grid sizes Δr and Δz in the r- and z-directions, respectively, are constant. To discretize $\sqrt{1+D_1\partial/\partial t}$ $(D_1=4/m\omega_c)$ in Eq. (10), a Taylor expansion in the frequency domain under the condition that $|4\omega/m\omega_c|<1$ gives

$$\sqrt{1-\frac{4i\omega}{m\omega_c}} = 1-\frac{2i\omega}{m\omega_c}+\frac{2}{m^2}\left(\frac{\omega}{\omega_c}\right)^2+o\left(\frac{\omega^3}{\omega_c^3}\right). \tag{12}$$

For a typical sandstone (where $m\approx 8$) and $\omega<\omega_c$, the third term in the right hand side of Eq. (12) is higher order and can be ignored. Hence in the time domain the term $\sqrt{1+D_1\partial/\partial t}$ can be approximated as $1+(D_1/2)\partial/\partial t$.

Then, applying the second-order central difference approximations, one obtains

$$\frac{\eta}{\kappa_0}\left[\frac{1}{2}+\left(\frac{D_1}{2}+D_2\right)\frac{1}{\Delta t}\right]v^{n+1/2}_{wr(j,k+1/2)}+\frac{\rho_f}{\Delta t}v^{n+1/2}_{ur(j,k+1/2)} = \frac{\eta}{\kappa_0}\left[-\frac{1}{2}+\left(\frac{D_1}{2}+D_2\right)\frac{1}{\Delta t}\right]v^{n-1/2}_{wr(j,k+1/2)}+\frac{\rho_f}{\Delta t}v^{n-1/2}_{ur(j,k+1/2)} - \left(\frac{\partial p^n}{\partial r}+P^n_{pr}\right)_{(j,k+1/2)}, \tag{13}$$

where n and $(j,k+1/2)$ are the indices of time and space steps, respectively, Δt is the time step, and P^n_{pr} denotes convolution integral,

$$P^n_{pr} = -\Omega_r\int_0^{n\Delta t} e^{-\Omega_r(n\Delta t-t)}\frac{\partial p(r,t)}{\partial r}dt. \tag{14}$$

The above integral can be further approximated with the trapezoidal rule, where

$$P^n_{pr} = e^{-\Omega_r\Delta t}P^{n-1}_{pr}-\frac{1}{2}\Omega_r\Delta t\left(e^{-\Omega_r\Delta t}\frac{\partial p^{n-1}}{\partial r}+\frac{\partial p^n}{\partial r}\right). \tag{15}$$

Similar to the discretization of Eq. (10), Eq. (11) can be discretized as

$$\rho v_{ur(j,k+1/2)}^{n+1/2} + \rho_f v_{wr(j,k+1/2)}^{n+1/2}$$
$$= \rho v_{ur(j,k+1/2)}^{n-1/2} + \rho_f v_{wr(j,k+1/2)}^{n-1/2} + \Delta t\left[\left(\frac{\partial \tau_{rr}^n}{\partial r} + P_{rrr}^n\right) + \left(\frac{\tau_{rr}^n - \tau_{\theta\theta}^n + Q_{r\_\theta r}^n}{r}\right) + \left(\frac{\partial \tau_{rz}^n}{\partial z} + P_{rzz}^n\right)\right]_{(j,k+1/2)}, \quad (16)$$

where

$$P_{rrr}^n = e^{-\Omega_r \Delta t} P_{rrr}^{n-1} - \frac{1}{2}\Omega_r \Delta t\left(e^{-\Omega_r \Delta t}\frac{\partial \tau_{rr}^{n-1}}{\partial r} + \frac{\partial \tau_{rr}^n}{\partial r}\right), \quad (17)$$

$$Q_{r\_\theta r}^n = e^{-\bar{\Omega}_r \Delta t} Q_{r\_\theta r}^{n-1} - \frac{1}{2}\bar{\Omega}_r \Delta t[e^{-\bar{\Omega}_r \Delta t}(\tau_{rr}^{n-1} - \tau_{\theta\theta}^{n-1}) + \tau_{rr}^n - \tau_{\theta\theta}^n], \quad (18)$$

$$P_{rzz}^n = e^{-\Omega_z \Delta t} P_{rzz}^{n-1} - \frac{1}{2}\Omega_z \Delta t\left(e^{-\Omega_z \Delta t}\frac{\partial \tau_{rz}^{n-1}}{\partial z} + \frac{\partial \tau_{rz}^n}{\partial z}\right). \quad (19)$$

With Eqs. (13) and (16), $v_{ur(j,k+1/2)}^{n+1/2}$ and $v_{wr(j,k+1/2)}^{n+1/2}$ can be solved. The other velocity and stress field quantities in the porous formation can also be obtained from Biot's equations with a similar discretization.

The acoustic field in the fluid-filled borehole is governed by the velocity-pressure fluid equations. The discretization of the field quantities in the borehole and the treatment of the point source on the borehole axis have been given by Guan and Hu (2008) and are incorporated in Appendix A.

It is worth noting that the field quantities at medium interfaces require special treatment. Two kinds of interfaces are involved in this work. One is the interface between two layers in the porous formation, and the other is the borehole wall between the borehole fluid and the porous formation. All the interfaces are considered as open pore interface, which permits relative fluid flow across it. The discretization of the field quantities at the interface between two layers has an identical form with those in homogeneous porous medium, with the only difference that the effective medium parameter (average of the two, see e.g., Taflove and Hagness, 2005) should be used. Note, however, that effective medium parameter cannot be applied in the case of borehole wall, since the governing equations in the borehole are different from those in the formation. A solution to this issue using the boundary conditions of the open pore interface is given in Appendix B.

III. NUMERICAL SIMULATIONS

For all simulations of acoustic logs in the following work, the borehole radius is set to 0.10 m and the borehole fluid velocity and density are assumed to be 1500 m/s and 1000 kg/m^3, respectively. A stretching function of $\Omega_q(q) = -V_{\max}(a\gamma + b\gamma^2)\ln \alpha / T$, $(q = r, z)$ is taken, as given in Wang and Tang (2003), where $V_{\max}$ is the maximum wave velocity, $\gamma = q/T$, T is the width of the PML, $a = 0.25$, $b = 0.75$, and $\alpha = 10^{-6}$ denotes a predefined level of wave absorption.

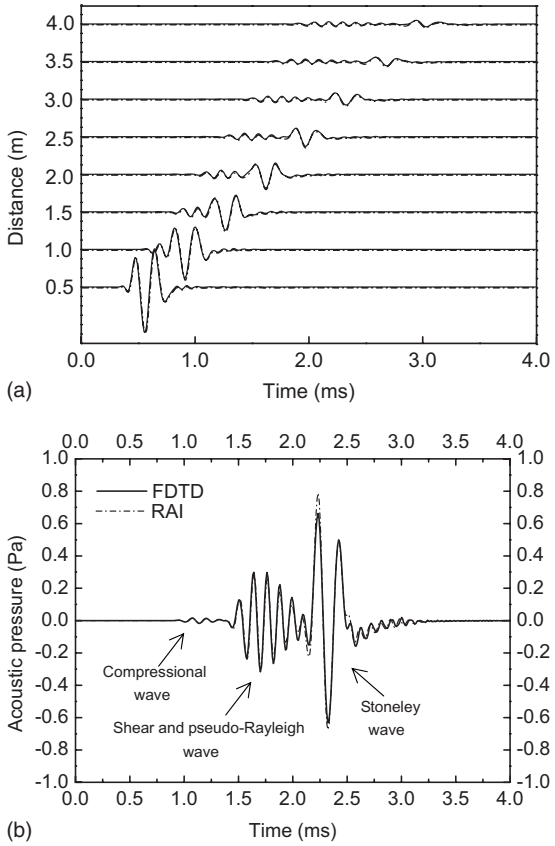

FIG. 3. Comparisons between the FDTD and the RAI methods of the simulated waveforms of the acoustic logs in a homogeneous porous formation (Formation I). The center frequency of the source is $f_0 = 6$ kHz. (a) Pressure waveforms at different locations along the borehole axis. (b) The waveforms of (a) at the location $z = 3.0$ m.

A. Homogeneous porous formations

To check the FDTD algorithm, comparisons of the FDTD against the RAI methods of the simulated acoustic logs for the case with the homogeneous porous formations around the borehole are performed.

In Fig. 3(a) the simulated pressure waveforms at different locations along the borehole axis obtained from the FDTD algorithm are compared with those from the RAI method. The waveforms are normalized with respect to the peak value of the response at a location of receiver-to-source distance $z = 0.5$ m. The formation parameters are listed in the first column (Formation I) of Table I. The formation has a compressional velocity of 3975 m/s and a shear velocity of 2455 m/s. The source has a center frequency and a pulse width of $f_0 = 6$ kHz and $T_c = 0.5$ ms, respectively. The finite-difference grid sizes are set to $\Delta r = \Delta z = 0.0125$ m according to the formula $\Delta r = V_{\min}/10 f_{\max}$ in Alford *et al.* (1974), where $V_{\min}$ is the minimum wave velocity, and $f_{\max}$ is the maximum source frequency where $f_{\max} = 2f_0$. The time step is chosen as $\Delta t = 2 \times 10^{-3}$ ms, following the Courant stability condition $\Delta t < \Delta r / \sqrt{2} V_{\max}$. This condition, which was proposed for FDTD modeling of electromagnetic waves, has been demonstrated by Masson *et al.* (2006) to be valid for poro-elastic waves. There are 160 and 320 cells in the r- and z-directions of the computational region, respectively. The PML contains 40 cells in all directions outside the computa-

TABLE I. Parameters of the porous formations. The relationships between ϕ and K_b and G_b are assumed to obey the experimental results of Vernik (1994).

Parameter	Property	Formation I	Formation II	Formation III
ϕ	Porosity (%)	20	10	40
κ_0	Darcy permeability (Darcy)	1	0.01	10
K_b	Frame bulk modulus (GPa)	14.39	22.63	10.93
G_b	Frame shear modulus (GPa)	13.99	22.23	3.01
K_s	Solid bulk modulus (GPa)	35.70	35.70	33.17
K_f	Pore fluid bulk modulus (GPa)	2.25	2.25	2.0

ρ_f	Pore fluid density (kg/m^3)	1000	1000	1290
η	Pore fluid viscosity (Pa s)	10^{-3}	10^{-3}	10^{-4}
α_∞	Tortuosity	3	3	3
m	Dimensionless parameter	8	8	8

tional region. The waveforms at different locations from $z=0.5$ m to $z=4.0$ m with the two methods show excellent agreement, as depicted in Fig. 3(a). More details at $z=3$ m are given in Fig. 3(b). It is clear that the waveforms consist of three different wave groups: a compressional, a shear, and pseudo-Rayleigh, and a Stoneley wave group. For the two methods, Fig. 3(b) shows that the phase and the amplitude of the three wave groups agree well, with only a small deviation on the Stoneley wave amplitude.

Analysis shows that the above deviation is caused by the discrete Fourier transforms (DFTs) in the RAI method and the finite-difference discretization in the FDTD method. Two DFTs are required in RAI to transform the field quantities from frequency-wavenumber domain to time-space domain. But the choice of DFT parameters turns out to have an influence on the accuracy of the RAI simulated waveforms. This also explains the obvious deviations of the simulated waveforms between the FDTD and the RAI methods in Guan and Hu (2008). In Fig. 3, the sampling intervals and the sampling numbers of the two DFTs in the RAI method are set to $D_z=4\times10^{-3}$ m, $N_{kz}=10240$, $D_f\approx10$ Hz, and $N_{ft}=10240$. Note that compared to those in Guan and Hu (2008), here D_z and D_f are reduced by ten times and N_{kz} and N_{ft} are increased by ten times, resulting more accurate results. Recall that D_z and D_f are the sampling intervals in the space and the frequency domains, respectively, N_{kz} and N_{ft} are the sampling numbers from the wavenumber domain to the space domain and that from the frequency domain to the time domain, respectively.

We point out two important observations in the RAI calculation. First, a smaller interval in the frequency domain gives more accurate result on the frequency domain integral, especially when the integrand contains rapid oscillation or singularities, as the acoustic logging response function in this work. Second, a smaller interval in the space domain guarantees a closer location to the point of interest for each waveform. The finite-difference grid size can affect the accuracy of the FDTD simulated waveforms. We found that the deviation becomes smaller than that in Fig. 3, when we reduce Δr and Δz by ten times, but this is costly.

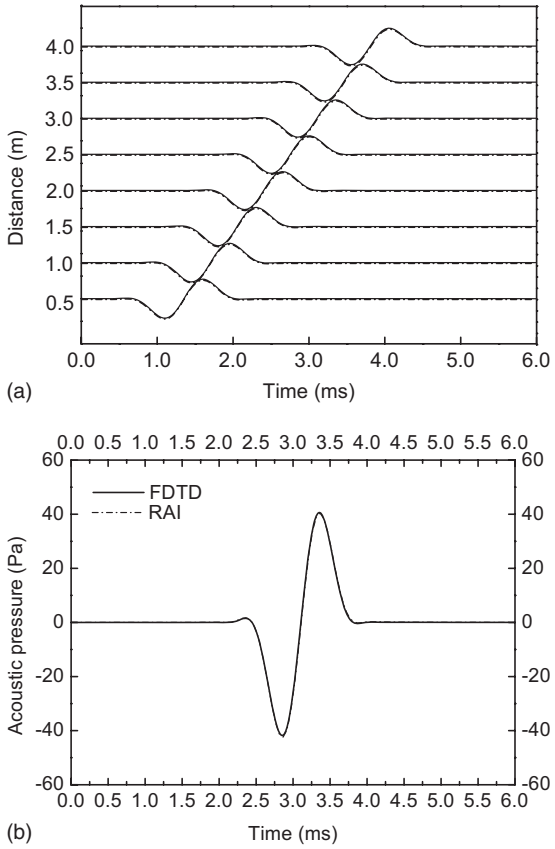

FIG. 4. Same as Fig. 3 except that the porous formation around the borehole is the Formation III and a center source frequency $f_0=1$ kHz is employed. (a) Pressure waveforms at different locations along the borehole axis. (b) The waveforms of (a) at the location $z=3.0$ m.

Figure 4 gives a comparison between the FDTD and the RAI methods of the simulated waveforms in a porous formation with a low permeability and a low porosity. The input parameters of the formation are listed in the second column (Formation II) of Table I. The formation has a compressional velocity of 4700 m/s and a shear velocity of 2990 m/s. The center frequency and the pulse width of the source are $f_0=1$ KHz and $T_c=2.0$ ms, respectively. At these frequencies, the compressional and shear waves are not very well excited, while the Stoneley wave dominates the waveforms. The finite-difference grid sizes are set to $\Delta r=\Delta z=0.01$ m and the time step is chosen as $\Delta t=1.5\times10^{-3}$ ms. Figure 4(a) shows excellent agreement between the two methods of the simulated waveforms at different locations along the borehole axis from $z=0.5$ m to $z=4.0$ m. Figure 4(b) shows more details at $z=3.0$ m.

In Figs. 3 and 4, the porous media surrounding the borehole are fast formations, where the shear velocity is faster than the borehole fluid velocity. The comparison for a slow porous formation is given in Fig. 5. The input parameters of the formation are listed in the third column (Formation III) of Table I. The formation has a compressional velocity of 2840 m/s and a shear velocity of 1190 m/s which is slower than the borehole fluid velocity. The critical frequency of this formation is $\omega_c=\phi\eta/\alpha_\infty\rho_f\kappa_0\approx1$ kHz. To check the validity of the FDTD algorithm for modeling poro-elastic wave problems with frequencies higher than the critical frequency, a

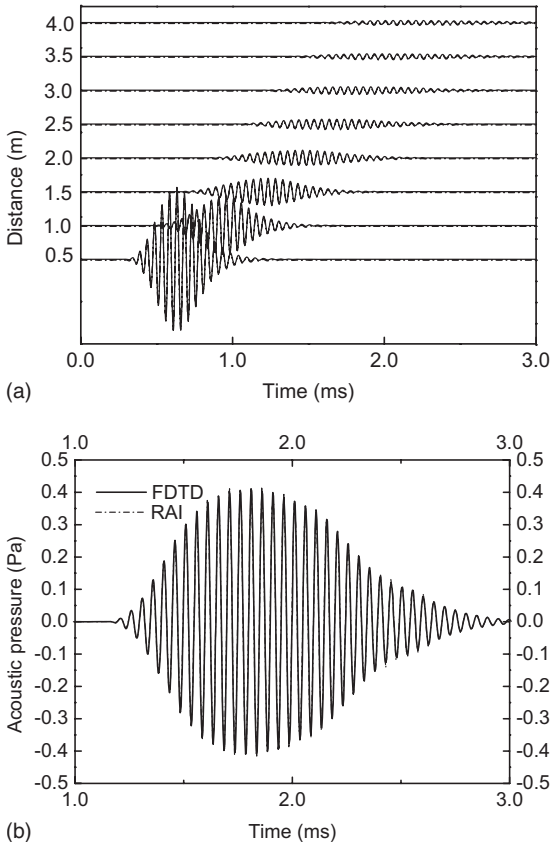

FIG. 5. Same as Fig. 3 except that the porous formation around the borehole is the Formation III and a higher source frequency $f_0=20$ kHz is employed. (a) Pressure waveforms at different locations along the borehole axis. (b) The waveforms of (a) at the location $z=3.0$ m.

source with a center frequency of $f_0=20$ kHz is employed. The finite-difference grid sizes are set to $\Delta r=\Delta z=0.0025$ m and the time step is chosen as $\Delta t=0.5\times10^{-3}$ ms. Figure 5(a) shows the comparison of the simulated pressure waveforms at different locations along the borehole axis. The compressional wave dominates the waveforms of the acoustic logging, because the shear and pseudo-Rayleigh wave cannot be received in soft formations and the Stoneley wave is not effectively excited at around 20 kHz. More details at $z=3$ m is given in Fig. 5(b). Note that the time axis of Fig. 5(b) is set from 1.0 to 3.0 ms, to show the phase of the waveforms clearly. Similar to the comparisons in Figs. 3 and 4, excellent agreement between the two methods is also observed in Fig. 5.

We have compared the FDTD modeled acoustic logs with the RAI method, with different source center frequencies from 1 to 20 kHz and in variety of formations with different velocities and permeabilities. The excellent agreement between the two methods of the waveforms in Figs. 3–5 confirms that the FDTD algorithm is valid and correct, and can be applied at frequencies higher than the critical frequency.

B. Horizontally stratified formation

Now we use the FDTD algorithm to simulate the acoustic logs in a horizontally stratified formation. The formation around the borehole has three layers, and the medium parameters of the layers are listed in Table I. The layer, which lies between 1.5 and 2.5 m above the source, is of Formation III (with high porosity and permeability). The other two layers are of Formation I.

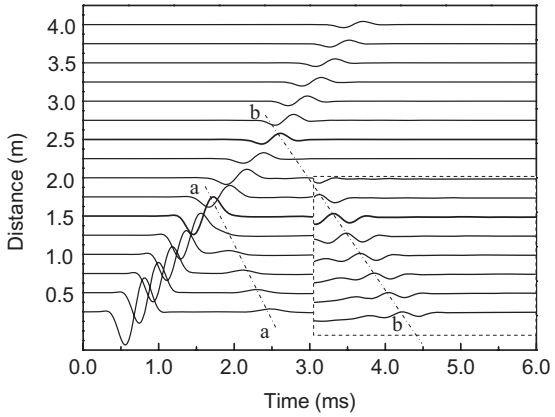

FIG. 6. FDTD modeled waveforms of the pressure at different locations along the borehole axis of the acoustic logs in a horizontally stratified porous formation. The layer, between 1.5 and 2.5 m, is the Formation III. The other two layers are the Formation I. The source center frequency is $f_0=2$ kHz.

Shown in Fig. 6 are the FDTD modeled pressure waveforms at different locations along the borehole axis. In order to show clearly the reflections of the Stoneley wave at the interfaces between two layers, the source center frequency $f_0=2$ kHz and the pulse width $T_c=2.0$ ms are employed. In Fig. 6, the line a-a marks the Stoneley wave reflected from the interface at $z=1.5$ m, which is similar to that in Kostek *et al.* (1998). In their work, the acoustic logs in elastic media with horizontal fluid-filled fractures was simulated. The reflected Stoneley wave from the second interface at $z=2.5$ m is very small. When we magnify by ten times the waveforms received from 3.0 to 6.0 ms, it is seen and is

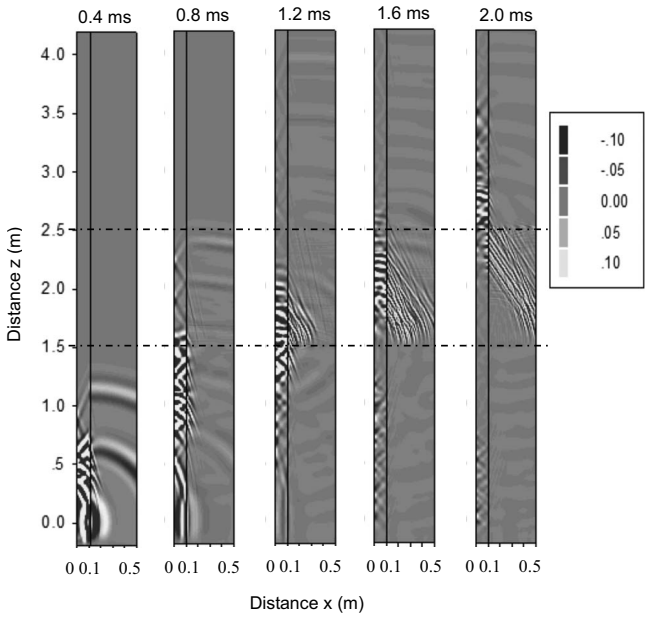

FIG. 7. Simulation of the wave-field distribution at five instants of 0.4, 0.8, 1.2, 1.6, and 2.0 ms of the acoustic logs in the horizontally stratified porous formation. The source center frequency is $f_0=20$ kHz.

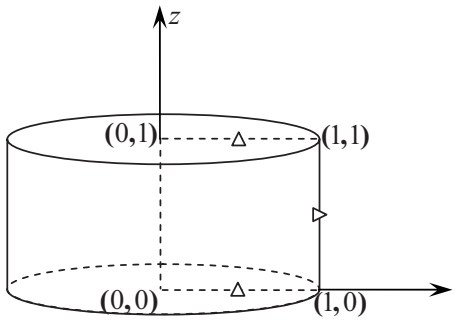

FIG. 8. Schematic of the volume integral region of the source-grid.

marked by the line *b*-*b* in Fig. 6. The reason is that most of the wave energy is attenuated in the interlayer and transmitted from the interface.

In Fig. 7, we show the wave-field distribution at instants of 0.4, 0.8, 1.2, 1.6, and 2.0 ms. In order to identify different wave groups in the wave-field, a higher center frequency $f_0=20$ kHz and a shorter pulse width $T_c=0.08$ ms are used in this simulation. In the slides of Fig. 7, no obvious wave reflection is observed from the outer boundaries, indicating that the wave-field is well absorbed in the PML. Shown in the first slide at 0.4 ms, the fastest pulse in the formation is the transmitted compressional wave from the borehole and then is the transmitted shear wave. The compressional head wave in the borehole also can be seen. In the slide at 0.8 ms, the large-amplitude arrival propagates to the interface at $z=1.5$ m, which is the pseudo-Rayleigh wave in the borehole. For the frequency range in this simulation, the Stoneley wave is too weak to be identified within the pseudo-Rayleigh wave packet. In the three later slides at 1.2, 1.6, and 2.0 ms, it is seen that part of the pseudo-Rayleigh wave energy in the borehole is reflected back at the interface, and part of the wave energy is leaked into the porous formation by the Biot slow wave (Biot 1956a, 1956b) and is rapidly dissipated. The Biot slow wave is related to the fluid motion in the porous formation, whose velocity is around 650 m/s in the interlayer. It moves much deeper into the formation at the location from $z=1.5$ m to $z=2.5$ m, because the attenuation coefficient in the interlayer is eight times lower than that in the other two layers.

IV. CONCLUSIONS

We have proposed a velocity-stress FDTD algorithm with nonsplitting PML to model the monopole acoustic logs in horizontally stratified fluid-saturated porous formations. By considering the inertial force on the viscous fluid flow in pore space, the algorithm can be applied in cases with frequencies higher than the critical frequency. In acoustic logging, the discretization of the field quantities on the borehole wall is difficult than that in seismic exploration, because the governing equations in the borehole are different from those in the formation. We have discretized the field quantities on the borehole wall in Appendix B.

The proposed FDTD algorithm is used to simulate axisymmetric acoustic logging responses excited by sources with center frequencies from 1 to 20 kHz and in homogeneous formations with different velocities and permeabilities. The FDTD simulated waveforms are compared with those by the RAI methods. The excellent agreement in every comparison confirms the validity and correctness of the FDTD algorithm.

In an example for the horizontally stratified formation, the reflected Stoneley waves from the upper and lower interfaces of the interlayer are observed in the waveforms, while the transmission wave becomes small in amplitude. An interesting phenomenon is the appearance of Biot slow wave in the soft interlayer, which originates on the borehole wall and propagates into the formation.

APPENDIX A: TREATMENT OF THE POINT SOURCE AND DISCRETIZATION OF THE EQUATIONS IN THE BOREHOLE

The velocity-stress equations of the acoustic wave in the fluid-filled borehole can be expressed as (Liu and Tao, 1997)

$$\rho_b \frac{\partial \mathbf{v}_f}{\partial t} = -\nabla p_f, \tag{A1}$$

$$\frac{\partial p_f}{\partial t} = -\rho_b c_{bm}^2 \nabla \cdot \mathbf{v}_f + F(r,z,t), \tag{A2}$$

where p_f is the borehole fluid pressure, $\mathbf{v}_f$ and ρ_b are the velocity vector and the density of the borehole fluid, respectively, c_{bm} is the sound speed in the borehole fluid, and $F(r,z,t)$ is the function determined by the source, which becomes zero for source-free grids.

In terms of the staggered grid shown in Fig. 2 and noting that Ω_r and $\bar{\Omega}_r$ become zero due to the absence of the r-direction PML in the borehole, the acoustic wave equations for source-free grids are discretized as

$$v_{fr(j,k+1/2)}^{n+1/2} = v_{fr(j,k+1/2)}^{n-1/2} - \frac{\Delta t}{\rho_b} \frac{\partial p_{f(j,k+1/2)}^n}{\partial r}, \tag{A3}$$

$$v_{fz(j+1/2,k)}^{n+1/2} = v_{fz(j+1/2,k)}^{n-1/2} - \frac{\Delta t}{\rho_b} \left(\frac{\partial p_f^n}{\partial z} + P_{pfz}^n \right)_{(j+1/2,k)}, \tag{A4}$$

$$p_{f(j+1/2,k+1/2)}^{n+1} = p_{f(j+1/2,k+1/2)}^n - \rho_b c_{bm}^2 \Delta t \left[\frac{\partial v_{fr}^{n+1/2}}{\partial r} + \frac{v_{fr}^{n+1/2}}{r} + \left(\frac{\partial v_{fz}^{n+1/2}}{\partial z} + P_{vfz}^{n+1/2} \right) \right]_{(j+1/2,k+1/2)}, \tag{A5}$$

where v_{fr} and v_{fz} are the components of the velocity vector $\mathbf{v}_f$, and

$$P_{pfz}^n = e^{-\Omega_z \Delta t} P_{vfz}^{n-1} - \frac{1}{2} \Omega_z \Delta t \left(e^{-\Omega_z \Delta t} \frac{\partial p_f^{n-1}}{\partial z} + \frac{\partial p_f^n}{\partial z} \right), \tag{A6}$$

$$P_{vfz}^{n+1/2} = e^{-\Omega_z \Delta t} P_{vfz}^{n-1/2} - \frac{1}{2}\Omega_z \Delta t \left(e^{-\Omega_z \Delta t} \frac{\partial v_{fz}^{n-1/2}}{\partial z} + \frac{\partial v_{fz}^{n+1/2}}{\partial z} \right). \tag{A7}$$

The point source employed is the same as described by Tsang and Rader (1979), with the peak pressure being 100 Pa at a location of 0.01 m away from the source. This source is introduced by letting $F(r,z,t)=4\pi c_{bm}^2 \delta(r,z)S(t)$ in Eq. (A2), where $\delta(r,z)$ is the delta function, $S(t)=\int_0^t s(t')dt'$, and the source pulse function $s(t)$ used in this paper is

$$s(t) = \begin{cases} \frac{1}{2}\left[1+\cos\frac{2\pi}{T_c}\left(t-\frac{T_c}{2}\right)\right]\cos 2\pi f_0\left(t-\frac{T_c}{2}\right), & 0 \le t \le T_c \\ 0, & t<0 \text{ or } t>T_c, \end{cases} \tag{A8}$$

where f_0 and T_c denote the center frequency and the pulse width of the source, respectively. Equation (A2) for the source-grid can be discretized by the volume integral method. Using the generalized Gauss formula, the volume integral of Eq. (A2) is expressed as (see Fig. 8)

$$\int\int\int_\Omega \frac{\partial p_f}{\partial t} dV = -\rho_b c_{bm}^2 \oiint_\Sigma \mathbf{v}_f \cdot d\mathbf{s} + 4\pi c_{bm}^2 S(t) \int\int\int_\Omega \delta(r,z) dV, \tag{A9}$$

where Ω and Σ denote the volume and the surface area of the cylindrical body shown in Fig. 8. Applying the integral mean value theorem to Eq. (A9) yields

$$p_{f(1/2,1/2)}^{n+1} = p_{f(1/2,1/2)}^{n} + \frac{c_{bm}^2 \Delta t}{\Delta z}\left[-\rho_b \left(v_{fz(1/2,1)}^{n+1/2} - v_{fz(1/2,0)}^{n+1/2} + 2\frac{\Delta z}{\Delta r} v_{fr(1,1/2)}^{n+1/2} \right) + \frac{4}{(\Delta r)^2} F^{n+1/2} \right]. \tag{A10}$$

APPENDIX B: TREATMENT OF THE FIELD QUANTITIES AT THE INTERFACE

On the borehole wall ($j=r_a$), the quantity $v_{fr(r_a,k+1/2)}^{n+1/2}$ cannot be discretized directly according to Eq. (A3), because the space derivative $\partial/\partial r$ in Eq. (A3) breaks at the medium interface. Using the approximation $\partial p_{f(r_a,k+1/2)}^n/\partial r \approx \partial p_{f(r_a-1/4,k+1/2)}^n/\partial r$ in Eq. (A3) yields

$$v_{fr(r_a,k+1/2)}^{n+1/2} = v_{fr(r_a,k+1/2)}^{n-1/2} - \frac{\Delta t}{\rho_b} \frac{\partial p_{f(r_a-1/4,k+1/2)}^n}{\partial r}. \tag{B1}$$

Similarly, the quantities $v_{ur(r_a,k+1/2)}^{n+1/2}$ and $v_{wr(r_a,k+1/2)}^{n+1/2}$ on the borehole wall cannot be obtained from Eqs. (12) and (15). Introducing the approximation $\partial p_{(r_a,k+1/2)}^n/\partial r \approx \partial p_{(r_a+1/4,k+1/2)}^n/\partial r$ to Eq. (12) and the approximations $\partial \tau_{rr(r_a,k+1/2)}^n/\partial r \approx \partial \tau_{rr(r_a+1/4,k+1/2)}^n/\partial r$ and $\tau_{\theta\theta(r_a,k+1/2)}^n \approx (3\tau_{\theta\theta(r_a+1/2,k+1/2)}^n - \tau_{\theta\theta(r_a+3/2,k+1/2)}^n)/2$ to Eq. (15), and using the fact that the variables P_{pr}^n in Eq. (12) and P_{rrr}^n and $Q_{r\_\theta r}^n$ in Eq. (15) are zero on the borehole wall, we obtain

$$\frac{\eta}{\kappa_0}\left[\frac{1}{2}+\left(\frac{D_1}{2}+D_2\right)\frac{1}{\Delta t}\right] v_{wr(r_a,k+1/2)}^{n+1/2} + \frac{\rho_f}{\Delta t} v_{ur(r_a,k+1/2)}^{n+1/2} = \frac{\eta}{\kappa_0}\left[-\frac{1}{2}+\left(\frac{D_1}{2}+D_2\right)\frac{1}{\Delta t}\right] v_{wr(r_a,k+1/2)}^{n-1/2} + \frac{\rho_f}{\Delta t} v_{ur(r_a,k+1/2)}^{n-1/2} - \frac{\partial p_{(r_a+1/4,k+1/2)}^n}{\partial r}, \tag{B2}$$

$$\rho v_{ur(r_a,k+1/2)}^{n+1/2} + \rho_f v_{wr(r_a,k+1/2)}^{n+1/2} = \rho v_{ur(r_a,k+1/2)}^{n-1/2} + \rho_f v_{wr(r_a,k+1/2)}^{n-1/2} + \Delta t \left[\frac{\partial \tau_{rr(r_a+1/4,k+1/2)}^n}{\partial r} - \frac{1}{r}\left(\frac{3}{2}\tau_{\theta\theta(r_a+1/2,k+1/2)}^n - \frac{1}{2}\tau_{\theta\theta(r_a+3/2,k+1/2)}^n \right) + \left(\frac{\tau_{rr}^n}{r} + \frac{\partial \tau_{rz}^n}{\partial z} + P_{rzz}^n \right)_{(r_a,k+1/2)} \right]. \tag{B3}$$

The acoustic fields on the borehole wall obey the boundary conditions of the open pore interface (Hu *et al.* 2007):

$$v_{fr(r_a,k+1/2)}^{n+1/2} = v_{ur(r_a,k+1/2)}^{n+1/2} + v_{wr(r_a,k+1/2)}^{n+1/2}, \tag{B4}$$

$$p_{f(r_a,k+1/2)}^n = p_{(r_a,k+1/2)}^n, \tag{B5}$$

$$-p_{f(r_a,k+1/2)}^n = \tau_{rr(r_a,k+1/2)}^n, \tag{B6}$$

$$0 = \tau_{rz(r_a,k)}^n. \tag{B7}$$

From Eq. (B7), we derive that the term $(\partial \tau_{rz}^n/\partial z + P_{rzz}^n)_{(r_a,k+1/2)}$ in Eq. (B3) is zero. When substituting Eqs. (B5) and (B6) into Eqs. (B2) and (B3), respectively, there remain four unknown field quantities in Eqs. (B1)–(B4). By solving these equations, we can derive the field quantities on the borehole wall, i.e., $v_{fr(r_a,k+1/2)}^{n+1/2}$, $v_{ur(r_a,k+1/2)}^{n+1/2}$, and $v_{wr(r_a,k+1/2)}^{n+1/2}$.

(Received 2 October 2007; revised 29 January 2009; accepted 30 January 2009)

Previous *in situ* investigations of seagrass have revealed acoustic phenomena that depend on plant density, tissue gas content, and free bubbles produced by photosynthetic activity, but corresponding predictive models that could be used to optimize acoustic remote sensing, shallow water sonar, and mine hunting applications have not appeared. To begin to address this deficiency, low frequency (0.5–2.5 kHz) acoustic laboratory experiments were conducted on three freshly collected Texas Gulf Coast seagrass species. A one-dimensional acoustic resonator technique was used to assess the biomass and effective acoustic properties of the leaves and rhizomes of *Thalassia testudinum* (turtle grass), *Syringodium filiforme* (manatee grass), and *Halodule wrightii* (shoal grass). Independent biomass and gas content estimates were obtained via microscopic cross-section imagery. The acoustic results were compared to model predictions based on Wood's equation for a two-phase medium. The effective sound speed in the plant-filled resonator was strongly dependent on plant biomass, but the Wood's equation model (based on tissue gas content alone) could not predict the effective sound speed for the low irradiance conditions of the experiment, in which no free bubbles were generated by photosynthesis. The results corroborate previously published results obtained *in situ* for another seagrass species, *Posidonia oceanica*. © *2009 Acoustical Society of America.*

I. INTRODUCTION

The acoustical characteristics of seagrass beds are important in a number of naval, commercial, and ecological applications. Gas-filled channels (aerenchyma) within the seagrass plants and gas bubbles generated by the plants during photosynthesis dominate their acoustic behavior and numerous studies have demonstrated and analyzed significant acoustic effects due to this acoustic contrast with the water and ocean bottom. For example, mine hunting performance is severely reduced in seagrass meadows. McCarthy and Sabol[1] attempted to locate a Manta target simulator (an inert version of a Manta naval mine) that was deployed in a meadow of *Zostera marina* using two commercial side scan sonars operating at both 100 and 500 kHz. Neither sonar was able to detect the target in numerous attempts. Similarly, a hand-held mine hunting sonar deployed by divers and operating in the 115–140 kHz frequency range was unable to detect the target.[1] Backscatter from the seagrass was sufficiently strong to completely obscure reflections from the Manta target simulator.

Since shallow water sonar performance can be severely limited by reverberation, Lyons and Abraham[2] studied the variation in seafloor reverberation level at 80 kHz in the presence of *Posidonia oceanica* near Sardinia and Sicily. They found that the mean seafloor backscatter strength in the presence of seagrass was about 10 dB higher across a range of grazing angles than compared to a sand-covered bottom and varied between 0 and 8 dB higher than a mud bottom, depending on grazing angle. While the mean backscatter strength was not uniquely related to the bottom characteristics, they found that a combination of mean backscatter strength and a statistical description of the variability of the backscatter could potentially characterize the bottom. The variability was attributed to the inhomogeneous distribution of *Posidonia* density and the motion of leaves due to swell or currents.

Seagrass meadows serve as habitat for many economically important estuarine organisms. The same acoustic characteristics that obscure mines and hinder sonar performance can potentially be used to assess the ecological condition and the extent of this valuable littoral ecosystem. Consequently, acoustic remote sensing methods are under development to exploit these characteristics.[3] Side scan sonar has been used extensively for imaging seagrass beds and as a possible management tool for littoral ecosystems.[4] An extensive comparison between seagrass mapping by side scan sonar and by aerial photography was conducted by Mulhearn.[5] Komatsu *et al.*[6] showed that plant-occupied volume can be extracted from the three-dimensional images produced by multi-beam side scan sonar. Finally, Hermand[3] conducted extensive studies over the past decade on the acoustic remote sensing of seagrass photosynthesis using frequencies ranging from 0.1 to 16 kHz. One study[7] on *Posidonia oceanica* was conducted

[a)]Electronic mail: pswilson@mail.utexas.edu

in the frequency range 0.1–1.6 kHz, which overlaps the frequency range used in this work. Photosynthetic activity produces free gas bubbles on the plants and in the water column which affects the local sound speed and hence the waveguide impulse response. Hermand's technique relies on monitoring the acoustic impulse response between two locations in a shallow water waveguide and inverting for a measurement of oxygen productivity.

In all the applications described above, accurate predictive models that relate the physical characteristics of plant anatomy, density, and photosynthetic activity to the acoustic scattering and propagation response could potentially be used to (1) infer target and ecological parameters from acoustic sonar and remote sensing signals and (2) improve and optimize acoustic image formation for mapping and target identification. As a first step toward the development of such models, the hypothesis that the acoustic behavior of immersed plant leaves or rhizomes can be considered an effective medium dominated by internal plant gas content was investigated. Photosynthetically produced gas bubbles attached to tissue surfaces or in the water surrounding the plants were excluded. Low frequency (0.5–2.5 kHz) laboratory experiments were conducted on three freshly collected species: *Thalassia testudinum* (turtle grass), *Syringodium filiforme* (manatee grass), and *Halodule wrightii* (shoal grass). This frequency range is directly applicable to the remote sensing application of Hermand[3] and Hermand *et al.*[7] but is significantly lower than the frequencies used in side scan sonar studies and object detection applications. Despite this discrepancy, the frequency range used in the present study is an appropriate starting point for the investigation of the fundamental physics of a fluid-loaded gas-bearing structure such as seagrass tissue because at sufficiently low frequencies, below the resonance frequency of any individual gas-filled cavity, the relative acoustic importance of the gas content compared to the tissue can be assessed through the use of an effective medium model, such as Wood's equation.[8] This study is not intended to lead directly to a model of propagation and scattering in the presence of seagrass in the frequency range of side scan and mine hunting sonar systems, but is instead intended to yield basic insight into the acoustic behavior of seagrass tissue.

A one-dimensional acoustic resonator technique was used to assess the biomass and effective acoustic properties of individual leaves and rhizomes. Independent biomass and gas content estimates were gathered using macro- and microscopic tissue imagery. The acoustic results were compared to model predictions based on Wood's equation[8] for a two-phase medium. The effective sound speed in the plant-filled resonator was strongly dependent on plant biomass, but the Wood's equation model (based on gas content alone) was unable to describe the effective sound speed for the low irradiance conditions of the experiment, in which no free bubbles were generated by photosynthesis. These laboratory results corroborated findings obtained *in situ* for another seagrass species, *Posidonia oceanica*.[3]

II. LOW FREQUENCY ACOUSTIC RESPONSE AND PLANT BIOMASS

Seagrass leaves and rhizomes contain internal gas-filled channels (aerenchyma)[9] and during photosynthesis, gas bubbles produced by the plant are found attached to external surfaces. This study was focused on the effects of the aerenchyma on the acoustic response characteristics; hence the experiments were done in sufficiently low light conditions to prevent external bubble formation. The following hypotheses were investigated: (1) the acoustic response is dominated by the gas within the aerenchyma and (2) seagrass tissues, when gas-free, possess acoustic properties close to those of water. Under these assumptions, the contents of the acoustic resonator (seawater and plants) were considered to be an effective acoustic medium composed of a liquid seawater phase and a gas phase, as is done for air bubbles in water.

The speed of sound in this medium is a strong function of the gas content, or void fraction, which is defined as $\chi = V_{\mathrm{gas}}/V_{\mathrm{tot}}$. The volume of gas in the aerenchyma is V_{gas} and the total volume of the resonator is V_{tot}. If the frequency of the acoustic excitation is well below the resonance frequency of the largest gas cavity, then the effective medium sound speed c_{eff} is given by Wood's equation[8]

$$\frac{1}{c_{\mathrm{eff}}^2} = \frac{(1-\chi)^2}{c_\ell^2} + \frac{\chi^2}{c_g^2} + \chi(1-\chi)\frac{\rho_g^2 c_g^2 + \rho_\ell^2 c_\ell^2}{\rho_\ell \rho_g c_\ell^2 c_g^2}, \tag{1}$$

where the subscripts ℓ and g refer to the liquid and gas phases, respectively, c_i is the intrinsic sound speed of phase i, and ρ_i is the density of phase i. If hypotheses (1) and (2) are true, then the sound speed observed inside the resonator should be directly related to the aerenchyma gas volume via Eq. (1) and also related to the plant biomass. In this study, leaf and rhizome volume was used to represent the biomass. The exact composition of the gas inside the aerenchyma is not known. Since it must contain oxygen and potentially nitrogen, the gas was considered to be air. The density difference between oxygen and nitrogen leads to a sound speed difference between the pure gases of about 7%, but this was found to be negligible in comparison to other sound speed effects observed in this study. The sound speed for air (315 m/s) originally cited by Wood was used,[8] which is appropriate for air bubbles in water at the surface.[10]

III. EXPERIMENT

Acoustical response trials were conducted *in vitro* using a one-dimensional acoustic resonator (Fig. 1) constructed from transparent polyvinyl chloride (PVC) schedule 40 pipe of circular cross-section (60 ± 0.5 mm outer diameter and 4.2 ± 0.2 mm wall thickness) and with length $L = 401 \pm 1$ mm. The cylinder was filled with fresh seawater from the Gulf of Mexico that had spent several hours in an outdoor settling tank to minimize interference from suspended particulates. Seagrass leaves or rhizomes were placed in the resonator (additional details about the plant tissue preparation are provided below). The air-water interface at the top and a Styrofoam block at the bottom of the cylinder provided pressure release acoustic boundary conditions to a high degree of approximation, as described in Ref. 11.

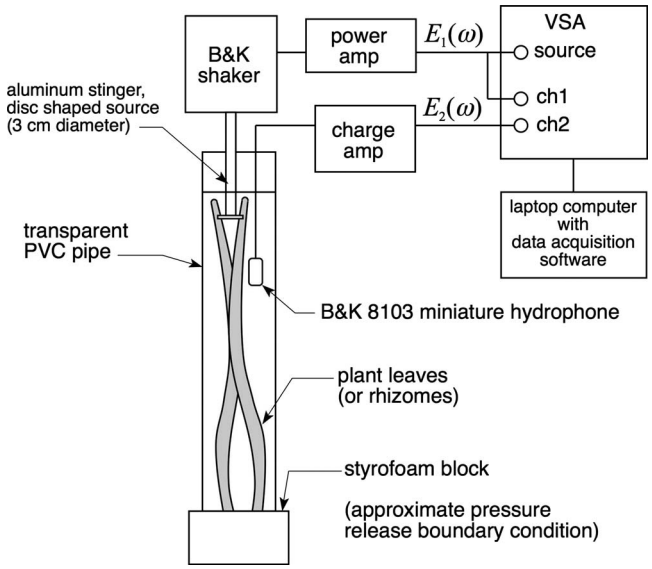

FIG. 1. The acoustic resonator and the measurement instrumentation are shown.

Acoustic standing waves were generated with a 3-cm-diameter aluminum piston that was attached to an electromechanical shaker via an aluminum stinger. Band-limited periodic chirps were produced by a vector signal analyzer (VSA) and directed to the shaker through a power amplifier. The source signal was also digitized by the VSA. The piston was positioned a few centimeters below the air-water interface. The acoustic pressure inside the resonator was received with a miniature hydrophone, positioned a few centimeters below the source. The received signals were amplified with a charge amplifier, band-pass filtered (10 Hz–10 kHz), and digitized by the VSA. According to manufacturer specifications, the source velocity response was flat to within less than ± 1 dB in the experimental frequency range.

Relative acoustic pressure spectra y were then calculated onboard the VSA by way of a transfer function $y = P(\omega)/E_1(\omega) = [E_2(\omega)/M]/E_1(\omega)$, which yields the acoustic pressure $P(\omega)$ per unit voltage input $E_1(\omega)$ (see Fig. 1). The hydrophone system sensitivity M was used to convert the voltage $E_2(\omega)$ measured at the output of the charge amplifier into an acoustic pressure $P(\omega)$. According to the manufacturer's calibration, M varied less than ± 1 dB within the experimental frequency range and it was taken to be a constant. The spectra were calculated using 1601 frequency bins, 1.5 Hz resolution bandwidth, and 20 spectral averages, as defined by Eqs. (24)–(27) of Ref. 12. The use of a transfer function measurement preserved the phase of the acoustic pressure relative to the excitation signal and yielded the coherence function. The number of averages and the amplitude of the excitation were chosen to achieve a near-unity coherence function at all frequencies of interest, which guaranteed a high signal-to-noise ratio and ensured linear behavior.[13] Peak pressures inside the resonator were typically less than 170 dB re 1 μPa.

Live plants were collected intact with sediment cores from the Gulf of Mexico near the Marine Science Institute (MSI) in Port Aransas, TX and transported in seawater to MSI. *Thalassia* plants were collected on 9 November 2005, and *Halodule* and *Syringodium* plants were collected on 14 August 2007. The living plant cores were stored in transparent cylindrical chambers filled with seawater for 12–24 h between collection and the acoustic measurements. Previous work has shown that this artificial environment causes no detrimental effects on the plants within 5 days of collection.[14] The experimental protocol described below refers specifically to the preparation of leaves, but the same procedures were followed for rhizomes. The desired number of leaves was first removed from a plant by hand, rinsed of sediment in a seawater bath, and then transferred to the acoustic resonator, all without exposing the leaves to the air. No direct lighting was used. Only the diffuse fluorescent lighting present in the laboratory was incident upon the plants and no photosynthetic gas production expressed through external bubble formation was observed during the experiments. Hence these experiments represent a baseline case, corresponding to a minimum level of photosynthetic activity. It is known that the plant gas content and external bubble formation are a function of photosynthetic activity,[3] but variation in the illumination level was not included in this study.

The acoustic pressure spectra were then obtained as described above. The temperature of the water within the resonator was measured with a thermocouple gauge and ranged from 20.5 to 25.6 °C, depending on the time of day at which the seawater was drawn from the outdoor settling tank. The salinity was measured with a refractometer and remained constant throughout the experiments at 30 ppt. Temperature and salinity measurements were used to calculate the density and sound speed of the water using the UNESCO International Equation of State.[15] The mean water temperature near Port Aransas, TX, where these plants were collected, ranges from 13 to 30 °C over the course of the year;[16] hence the laboratory temperatures are within the range encountered in nature.

The leaves were removed from the resonator, laid flat on a table, and photographed alongside a machinist's scale. The surface area S of each leaf was measured using image analysis software. The thickness t was measured by imaging approximately five excised cross-sections from each leaf with a video microscope. The volume V_{leaf} of each leaf was then obtained from $V_{\text{leaf}} = S \times \bar{t}$, where $\bar{t}$ is the mean thickness of each leaf. Since the rhizomes of all three species and the leaves of *Syringodium* are circular in cross-section, their volumes were calculated from length (l) and the projected area (S_p) measurements using image analysis software; rhizome or leaf volume was calculated from $V = \pi S_p^2/4l$.

The leaf void fraction was obtained from image analysis that was performed on microscopic leaf cross-sections from the literature,[17] but no such cross-section images were found in the literature for the rhizomes. Digital cross sectional images of rhizomes were obtained using a microscope with backlighting. In both cases, image analysis was used to obtain the total area of the cross-section A_{tot} and the combined area of all the pores A_p within the cross-section (which are distinct in the images). Since the cross-sections are nearly uniform in the direction normal to the plane of the cross-

TABLE I. A different resonator tube was used for each seagrass species. The physical properties used in the evaluation of the elastic waveguide model for each resonator are shown. For all three, the resonator tube material was schedule 40 PVC pipe. When two entries appear within a cell, they are for the rhizomes and leaves, respectively.

	Thallasia	*Syringodium*	*Halodule*
Seawater sound speed, c_0 (m/s)	1517	1521	1517, 1519

section images, the leaf void fractions were obtained with $\chi_{\text{leaf}}=V_{\text{air}}/V_{\text{leaf}}=A_p l/A_{\text{tot}} l=A_p/A_{\text{tot}}$. The same was done for the rhizomes. The existence of the leaf cross-sections in the literature was fortunate because sectioning the leaf tissue without causing visible damage to the leaf structure was difficult. The structures inside the leaves are generally smaller than the structures inside the rhizomes, and the leaf tissue is also softer than the corresponding rhizome tissue and tears more easily. Variation in leaf and rhizome internal void fraction within the species is possible, but to the author's knowledge, this has not been quantified in the literature.

IV. ELASTIC WAVEGUIDE EFFECT

In a gas-filled acoustic resonator, the walls are effectively rigid. In a liquid-filled resonator, there is significant coupling between the fill-liquid and the resonator walls. The result is a reduced sound speed relative to that observed in an unconfined environment. This effect is hereafter referred to as the elastic waveguide effect. An exact analytic model[18] for sound propagation in a finite-thickness elastic-walled, fluid-filled cylindrical tube was used to relate the speeds observed in the resonator to the intrinsic sound speed the material would exhibit in an unconfined environment. This procedure (and its validity) is discussed in Ref. 11 and summarized here. Equation (A1) of Ref. 11 is the dispersion relation for the resonator waveguide. The intrinsic (free-field) sound speed c_0 of the material that fills the resonator is an input parameter to Eq. (A1). The phase speed c_{ph} of the resonator's plane wave mode is an output. The resonator measurements described here yield the effective phase speed c_{eff} observed inside the resonator. The intrinsic sound speed c_0 is then varied in Eq. (A1) until the model output c_{ph} matches the measured value c_{eff}. The value of c_0 that achieves the match is reported as the effective sound speed that the material inside the resonator (seawater and plants) would exhibit in the ocean.

Three replicate resonator tubes were used in this work. The physical parameters needed for the elastic waveguide model [Eq. (A1), Ref. 11] are given in Table I. The sound speeds for the tube walls were initially calculated from the PVC manufacturer's specifications, but the values that were ultimately used (and reported in Table I) were obtained via a calibration procedure that utilized distilled degassed fresh water. With the internal liquid properties and the wall density known, the longitudinal sound speed in the wall was varied in the elastic waveguide model until the predicted phase speeds matched the speed measured during the calibration. There was about a 0.5% difference in phase speeds exhibited by the three resonator tubes when filled with distilled degassed water.

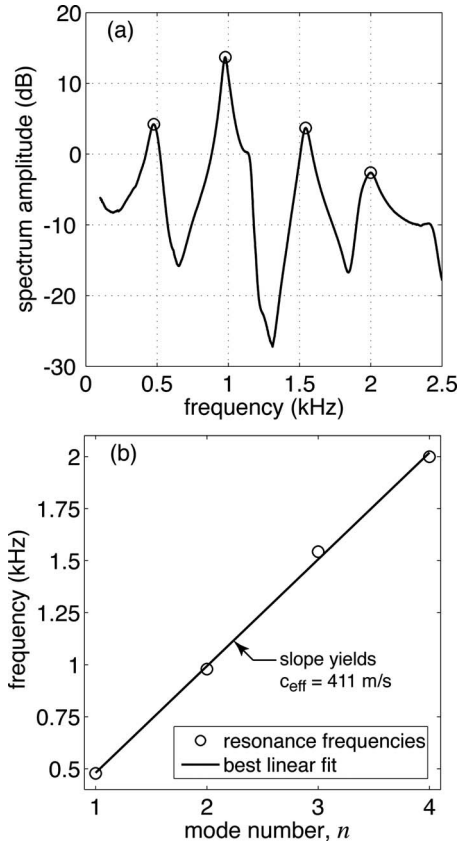

FIG. 2. A typical resonator spectrum (a) for three *Thalassia* leaves. Four resonance peaks are identified. The resulting best-fit sound speed is shown in (b).

V. RESULTS AND DISCUSSION

A typical spectrum from the resonator, obtained with three *Thalassia* leaves, is shown in Fig. 2(a). Four resonance frequencies were identified. The effective sound speed c_{eff} inside the water-and-leaf-filled resonator is inferred from the slope of the curve [Fig. 2(b)], which is the least-squares linear fit to the measured resonance frequencies. The nth resonance frequency is given by $f_n=(c_{\text{eff}}/2L)n$, where L is the length of the water column inside the resonator. Increased leaf biomass inside the resonator (adding additional leaves) shifts the spectrum toward lower resonance frequencies, which indicates a lower effective sound speed and clearly demonstrates that seagrass abundance is directly correlated with an acoustic parameter suitable for remote sensing.

Sound speeds c_{eff} (inferred from the resonance frequencies), free-field sound speeds c_0 (after correction for the elastic waveguide effect), and the apparent void fraction inside the resonator [see Eq. (1)] are reported in Table II. Biomass

TABLE II. Measured resonator sound speeds, associated free-field sound speeds, and apparent resonator void fractions are presented for *Thalassia testudinum*, *Syringodium filiforme*, and *Halodule wrightii*. Also shown are the acoustic- and image-based leaf and rhizome void fractions. The acronym VF is used for "void fraction."

as represented by plant tissue volume fraction was also positively correlated with leaf and rhizome number [Figs. 3(a) and 3(b)] in *Thalassia* for both acoustic and image-based measurements. The image-based leaf (χ_{leaf}) and rhizome (χ_{rhiz}) void fractions were determined with the image analysis shown in Figs. 4 and 5. The image-based biomass was compared to the acoustic-based biomass measurement with the following relationship:

$$\left.\frac{V_{\text{leaves}}(m)}{V_{\text{tot}}}\right|_{\text{acoustic}} = \frac{V_{\text{air}}(m)}{V_{\text{tot}}}\frac{1}{\chi_{\text{leaf},a}} = \frac{\chi(m)}{\chi_{\text{leaf},a}}, \tag{2}$$

where $\chi_{\text{leaf},a}$ is the apparent leaf void fraction observed acoustically based on our previous hypotheses and m is the number of leaves. The same approach was applied to rhizome tissue. These calculations reveal a major difference between image- and acoustic-based biomass measurements, es-

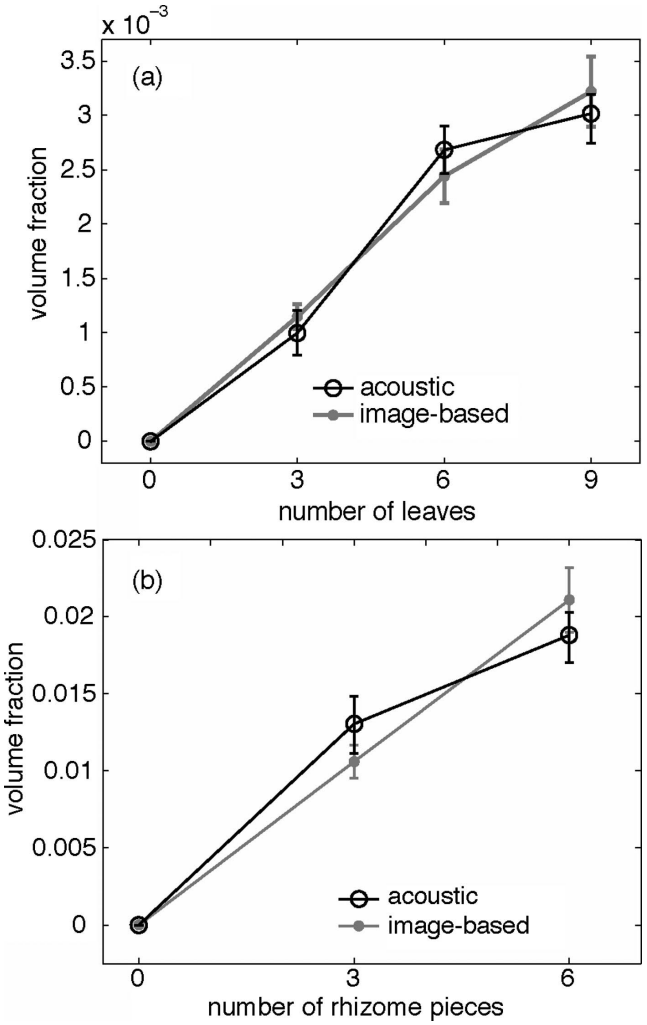

FIG. 3. *Thalassia testudinum.* Comparison of image- and acoustic-based biomass measurements as a function of the number of leaves (a) and rhizomes (b) in the resonator. The vertical axis is total volume fraction V_i/V_{tot} (i=leaves or rhizomes). The error bars are described in the text.

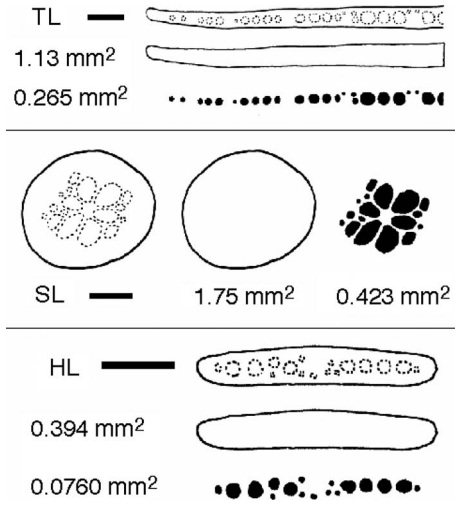

FIG. 4. Microscopic cross-sections of seagrass leaves (L) for *Thalassia* (T; top panel), *Syringodium* (S; middle panel), and *Halodule* (H; bottom panel). Since the cross-sections are nearly uniform perpendicular to the plane of the image, the void fraction is pore area/total area. Leaf sections adapted from Ref. 17. Only half the width of the leaf section is shown for TL. The aerenchyma are the circular features outlined with dashed lines or with black fill. Horizontal black scale bars are 0.5 mm in length. In each panel, the total leaf and pore area are shown adjacent to their corresponding images.

pecially in rhizomes (Fig. 3 and Table II). The best-fit values of $\chi_{\text{leaf},a}$ and $\chi_{\text{rhiz},a}$ (Table II) are means determined from the minimum and maximum values that allowed overlap of the error bars for all the points on both curves (Fig. 3). Such a fitting procedure was used because the curves go through the origin, and hence a linear least-squares approach (fitting only the slope) gave preferential consideration to the final point.

The error bars on the acoustic data represent the effects of uncertainty in the resonator length L and the finite resolution bandwidth of the spectrum measurement. The error bars on the image-based data are due to the finite resolution of the digital images. The leaves and rhizomes of *Thalassia* have extended shapes, where the length is much greater than the thickness. The primary uncertainty is in the accuracy of the thickness measurement, which was limited to about 2 pixels out of 20 in *Thalassi*a. The image-based leaf and rhizome void fractions are 6.8 and 28 times larger than the acoustically-determined void fractions (Table II).

The same procedure was repeated to obtain the physical properties, sound speeds, and void fractions of leaves and rhizomes for *Syringodium filiforme* and *Halodule wrightii* (Tables I and II). The cross-section imagery that yielded tissue void fraction appears in Figs. 4 and 5. The positive relationship between tissue (leaf or rhizome) abundance and volume fraction, as noted in *Thalassia* (Fig. 3), is also readily visible in *Syringodium* (Fig. 6) and *Halodule* (Fig. 7). As in *Thalassia*, however, comparison between the acoustic- and image-based biomass assessments in *Syringodium* and *Halodule* shows significant differences. For all three species, it is clear that biomass is directly proportional to the effective acoustic sound speed of the plant-filled water, but for *Syringodium*, the image-based leaf and rhizome void fractions are 63 and 72 times larger than the acoustically-determined void

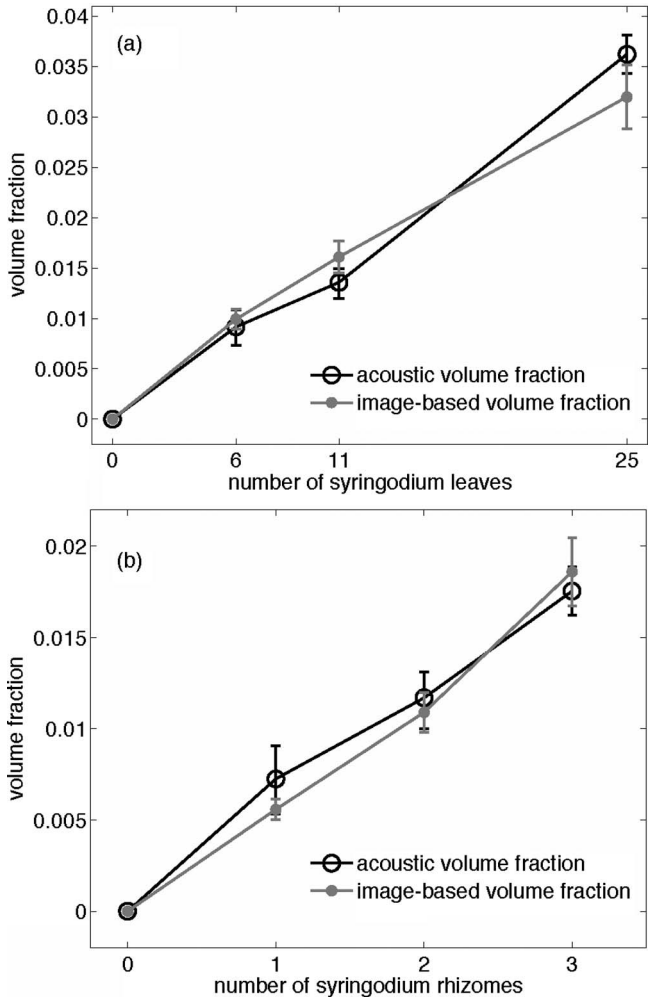

FIG. 6. *Syringodium filiforme*. Comparison of image- and acoustic-based biomass measurements as a function of the number of leaves and rhizomes in the resonator. The vertical axis is total volume fraction V_i/V_{tot} (i =leaves or rhizomes). The error bars are described in the text.

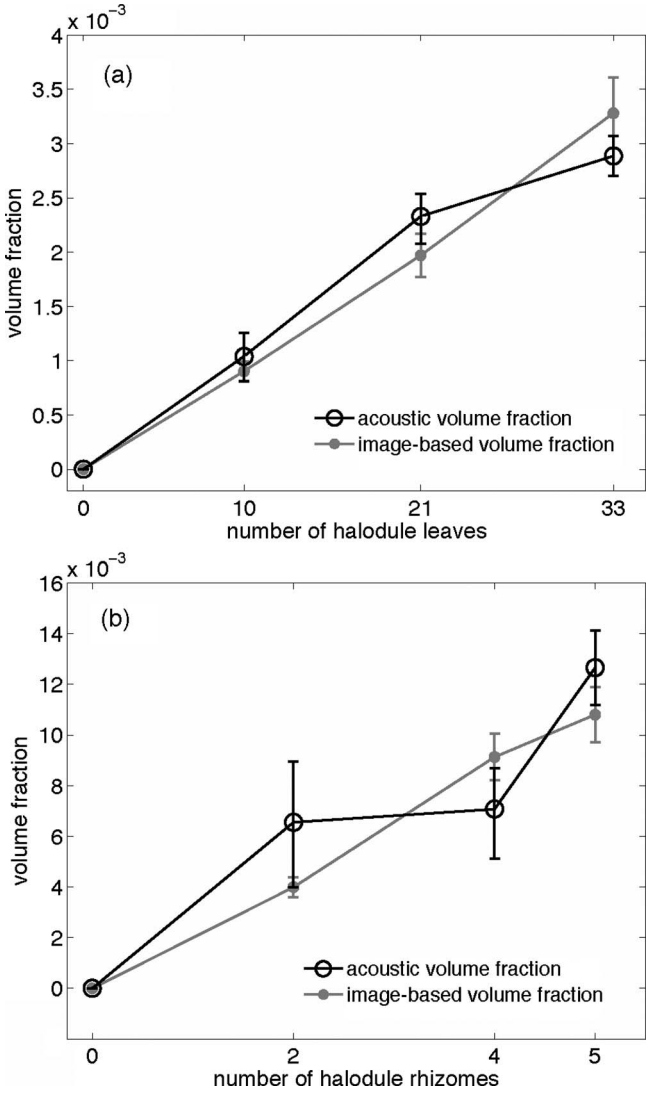

FIG. 7. *Halodule wrightii*. Comparison of image- and acoustic-based biomass measurements as a function of the number of leaves and rhizomes in the resonator. The vertical axis is total volume fraction V_i/V_{tot} (i=leaves or rhizomes). The error bars are described in the text.

fractions (Table II). In *Halodule*, the image-based leaf and rhizome void fractions are 6.8 and 62 times larger than the acoustically-determined void fractions (Table II).

A comparison of the ratio of the image-based to acoustically-determined void fractions for both leaves and rhizomes of all three species reveals some interesting differences (Fig. 8) that reflect the acoustic importance of the tissue. A ratio of unity indicates plants that behave acoustically like air bubbles in water. An increasing ratio indicates increasing tissue stiffness, which effectively reduces the acoustic contrast of the internal gas and thereby reduces the acoustic contrast of the plant. For all three species, the rhizome tissue is stiffer than the leaf tissue, and there is a large difference between the two tissues for both *Thalassia* and *Halodule*. *Syringodium* exhibits the highest tissue stiffness of the three species, and the leaf and tissue stiffness is of similar magnitude. The high stiffness of *Syringodium* leaves may be explained by the cylindrical shape of its above-ground photosynthetic tissues. Volumetric excitation of the pore space places the circumferential tissue in tension, with hoop-like structures resisting expansion. For all three species, the rhizomes are circular in cross-section with internal gas-filled pores, similar to *Syringodium* leaves. In contrast, the leaves of *Thalassia* and *Halodule* are flat and there is little tissue to resist the expansion.

The three species examined here exhibit significantly different acoustic-based and image-based void fractions. Since the image-based void fractions are from direct observations of the plant structure, they were considered to be the best estimate of the actual plant void fraction. One must therefore conclude that hypotheses (1) and (2) are incorrect. Wood's equation is insufficient and the acoustic response of all three species (*Thalassia testudinum*, *Syringodium filiforme*, and *Halodule wrightii*) is dependent on both gas content and the tissue acoustic properties. This corroborates a similar result Hermand[3] found *in situ* for *Posidonia oceanicus.*

There are a number of potential differences between the *in vitro* response observed in the present work and the *in situ* response. First, these experiments were conducted under sufficiently low light conditions to prevent the appearance of bubbles on the leaf surfaces, which indicates that photosyn-

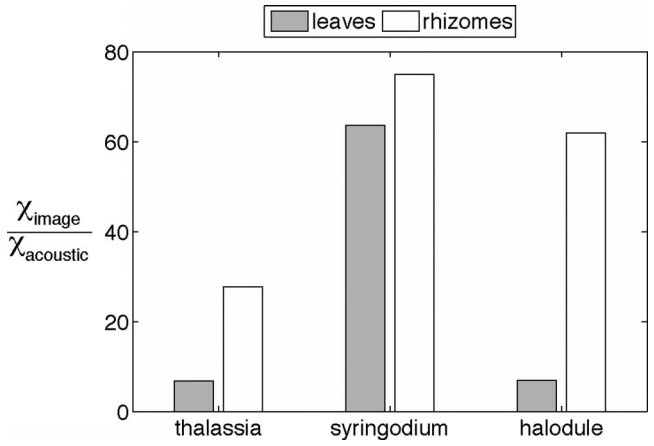

FIG. 8. The ratio of the image-based to acoustically-determined void fractions for both leaves and rhizomes of each species. This ratio is a measure of the importance of the tissue acoustic parameters. A ratio of unity indicates plants that behave acoustically like air bubbles in water. An increasing ratio indicates increasing tissue stiffness, which effectively reduces the acoustic contrast of the internal gas and also reduces the acoustic contrast of the plant.

thetic respiration was not underway during the experiments. *In situ*, under different light conditions and hence, different photosynthetic respiration conditions, the acoustic response of all three species will likely be different because the gas content and internal pressure of the plant will be different. A limited number of measurements under light saturation conditions were conducted and significant bubble production on the leaves of *Thalassia* was observed, which in turn further reduced the effective resonator sound speed, as expected. This was accompanied by a significant temperature increase in the resonator to unnaturally high levels. Resonator temperature control will have to be implemented in the present apparatus to accurately investigate the effect of illumination level. Second, the results reported here are for near-surface conditions. Because the sound speed in a gas is dependent on the ambient pressure, the acoustic response of seagrass will also be a function of depth. Third, during the present experiments, the acoustic axis was oriented along the length of the leaves whereas *in situ*, the acoustic axis could be oriented perpendicular to the leaves. Since some seagrass species have long, thin, relatively flat leaves, there is likely an excitation frequency above which the effective acoustic properties for cross-leaf propagation may be a function of leaf orientation. Despite these complexities, this work shows that seagrass biomass is directly related to the low frequency effective sound speed in a body of water containing seagrass plants. Further, the ability to remotely detect gas content in both above- and below-ground tissues may provide a reliable technique to rapidly assess photosynthetic production in seagrass beds that are chronically exposed to limiting light conditions in estuarine environments.[3,7,14]

VI. CONCLUSIONS

The low frequency acoustic properties of seagrass leaves and rhizomes were investigated *in vitro* using an acoustic resonator technique and image-based biomass measurements. The effective sound speed inside a plant-and-water-filled resonator was found to be proportional to overall tissue biomass contained in the resonator. The effective sound speed decreased as the number of leaves (or rhizome pieces) increased. The change in sound speed was reduced for physically smaller leaf species (*Halodule* < *Syringodium* < *Thalassia*). Gas content is clearly important, but since gas content (via Wood's equation) by itself did not describe the observed sound speeds, the acoustic response of the tissue must also be considered in the development of future acoustic models of sound propagation in seagrass beds. Finally, we found that flat leaves exhibited more acoustic contrast than did circular cross-section leaves or rhizomes, potentially due to hoop stress in the outer layers of the circular cross-section tissues characteristic of *Syringodium*.

The present work is a first step toward modeling sound propagation in seagrass beds. Additional work is needed to fully understand even the simplified laboratory experiments reported here. Significant additional work is needed to understand the complexities mentioned above and additional complexity found *in situ*, such as diurnal and seasonal variations.

Retrieval of Green's functions of elastic waves from thermal fluctuations of fluid-solid systems

(Received 21 October 2008; accepted 22 January 2009)

Fluctuation-dissipation and flow reversal theorems are used to study long-range correlation of thermal phonons in a stationary heterogeneous mechanical system comprised of arbitrary inhomogeneous fluid flow and anisotropic solid. At thermal equilibrium, with an appropriate choice of physical observables to characterize thermal fluctuations within the fluid and within the solid, the general integral expression for the two-point correlation function of the fluctuations reduces to a linear combination of deterministic Green's functions, which describe wave propagation in opposite directions between the two points. It is demonstrated that the cross-correlation of thermal noise contains as much information about the environment as can be obtained in active reciprocal transmission experiments with transceivers placed at the two points. These findings suggest a possible application of ambient noise cross-correlation to passive acoustic characterization of inhomogeneous flows in fluid-solid systems in laboratory and geophysical settings.

I. INTRODUCTION

Rather counterintuitively, linear wave fields possess significant correlations at ranges that are large compared to the wavelength, even when the waves are generated by random delta-correlated sources. Two-point correlation function of diffuse wave fields is closely related to the Green's function describing wave propagation between the two points. Apparently, Rytov was the first to derive a simple algebraic relation[1,2] between the spatial cross-correlation function of diffuse noise and the deterministic Green's function. Rytov considered electromagnetic fields of thermal origin in motionless dielectrics and applied his theory of fluctuational electrodynamics to extend Kirchhoff's law of thermal radiation, calculate thermal noise in extended receiving arrays, and develop a theory of macroscopic cohesion forces.[2,3] Much later, Rytov's relation was rediscovered in the seismology community.[4–6] A broad interest in the relation between long-range noise correlation and characteristics of deterministic wave propagation was generated by seminal experiments of Weaver and Lobkis.[7–9] They demonstrated that cross-correlation of thermal phonons[7,8] and other diffuse fields of elastic waves[9] in solids received at two points gives the time-domain Green's function between the points, i.e., the wave field that would be observed at one point if an impulsive point source were placed at the other. Green's function contains as complete environmental information as can be obtained from wave transmission between the two points. Thus, probing of an environment by emitting and receiving waves can be replaced, in principle, by cross-correlation of ambient noise.

Ambient noise tomography has rapidly become an extremely valuable technique in seismology[10–20] and helioseismology.[21–23] Promising applications of ambient noise cross-correlation to passive remote sensing have been proposed in underwater acoustics,[24–29] mechanical and civil engineering,[30–33] and medical acoustics.[34,35]

Theoretically, the relation between cross-correlation of random fields in a stationary medium and the deterministic acoustic Green's function has been established using normal modes of a closed system,[7–9] time-reversal arguments,[36,37] stationary phase analysis,[26,38–40] or reciprocity considerations;[6,40–43] for recent reviews see Weaver and Lobkis[44] and Gouédard *et al.*[16] Extension of this work to arbitrary inhomogeneous moving fluids showed that the cross-correlation of an acoustic field due to random sources distributed on a surface gives a combination of acoustic Green's functions, which describe sound propagation in opposite directions between the two points, and contains information necessary to characterize both sound speed and flow velocity.[40] Similar results, but for a fluid with slow and weakly varying currents, were independently obtained in Refs. 42 and 45. Recently, it was shown that cross-correlation of thermal phonons in an arbitrary inhomogeneous fluid flow in thermal equilibrium also gives a combination of Green's functions corresponding to sound propagation in opposite directions.[43] These results suggest the possibility of passive remote sensing of inhomogeneous flows, including precise measurements of flow velocities that are small compared to sound speed, which is highly relevant to environmental monitoring and medical diagnostics.

In the laboratory as well as in geophysical settings, elastic waves are normally encountered in environments comprising both fluid and solid components, although the effect of the fluid on waves within a solid and vice versa is sometimes negligible. In other problems, such as wave propagation in porous media and passive acoustic monitoring of either ocean dynamics with sensors placed on the ocean

[a)]Electronic mail: oleg.godin@noaa.gov

bottom or a fluid motion within a vessel with sensors located on its external wall, an account of coupling between waves in the fluid and the solid is paramount.[46] Acoustic noise in fluid-solid environments with flow can have diverse origins, including cavitation noise, aerodynamic noise, or biological and shipping noise in the ocean. Here we consider thermal noise, i.e., waves representing chaotic thermal motion of molecules, atoms, ions, and electrons in a coupled fluid-solid system. Unlike other types of acoustic noise, thermal phonons are inevitably present in fluids and solids. Thermal noise often dominates the noise field at sufficiently high frequencies.[7,8,34,47–52] Measurements of intensity and correlation properties of thermal radiation underlie acoustic brightness thermometry and thermoacoustic tomography, which have important biomedical applications.[48,51,53,54]

In this paper, we apply the fluctuation-dissipation[3,55] and flow reversal[56–58] theorems (FRTs) to calculate statistical moments of thermal fluctuations in rather general fluid-solid systems, which comprise arbitrary inhomogeneous fluid flow and an anisotropic solid. We show that time-domain Green's functions corresponding to wave propagation in both directions between any two points can be found as time derivatives of the cross-correlation function of thermal noise measured at the two points.

The plan of the paper is as follows. Equations governing wave fields in moving fluids and anisotropic solids as well as boundary conditions at boundaries and interfaces are formulated in Sec. II. The FRT, which expresses reciprocity of wave fields in fluid-solid systems, is discussed in Sec. III. In Sec. IV, the theorem is applied (i) to derive general expressions for wave fields generated by extraneous forces and strains and (ii) to establish certain integral identities for the Green's functions. Effective macroscopic sources of thermal noise are found in Sec. V using a spectral formulation[3] of the fluctuation-dissipation theorem (FDT). Results of Secs. IV and V are combined in Sec. VI to calculate the cross-correlation function of thermal fluctuations in terms of deterministic Green's functions of elastic waves, which correspond to various types of system excitation. Implications for passive remote sensing and relation to earlier work are addressed in Sec. VII.

II. GOVERNING EQUATIONS AND BOUNDARY CONDITIONS

Consider elastic waves in a stationary (i.e., independent of time t) heterogeneous environment consisting of a compressible fluid moving past a deformable solid structure (Fig. 1). Linear acoustic fields in an inhomogeneous moving fluid with sound speed $c(\mathbf{x})$, mass density $\rho(\mathbf{x})$, and flow velocity $\mathbf{U}(\mathbf{x})$ are governed by the equations[56,57]

$$\rho\frac{d^2\mathbf{w}}{dt^2}+\nabla p+(\mathbf{w}\cdot\nabla)\,\nabla\, p_0-\frac{\nabla p_0}{\rho c^2}(p+\mathbf{w}\cdot\nabla p_0)=\mathbf{F}, \quad (1)$$

$$\nabla\cdot\mathbf{w}+(p+\mathbf{w}\cdot\nabla p_0)/\rho c^2=B, \quad d/dt\equiv\partial/\partial t+\mathbf{U}\cdot\nabla, \quad (2)$$

where p, p_0, and $\mathbf{w}$ are acoustic pressure, background pressure (i.e., the pressure in the absence of acoustic waves), and oscillatory displacement of fluid particles due to an acoustic wave. The acoustic wave is generated by sources with volume densities $\mathbf{F}$ of force and dB/dt of volume velocity. The gradient of the background pressure is given by the Euler equation as $\nabla p_0=-\rho(\mathbf{U}\cdot\nabla)\mathbf{U}$. The oscillatory displacement $\mathbf{w}$ is related to the oscillatory velocity of fluid particles, i.e., the linear perturbation of fluid velocity due to acoustic wave, by the equation[56,57] $\mathbf{v}=d\mathbf{w}/dt-(\mathbf{w}\cdot\nabla)\mathbf{U}$. For continuous waves (CWs) we will assume and suppress the time dependence $\exp(-i\omega t)$.

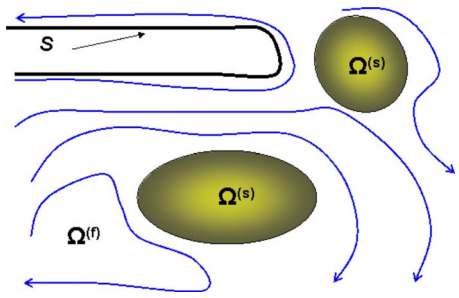

FIG. 1. (Color online) Geometry of the problem. A heterogeneous mechanical system is comprised of moving fluid, which occupies domain $\Omega^{(f)}$, and anisotropic solid, which occupies domain $\Omega^{(s)}$. Aside from fluid-solid interfaces, the boundary $\partial\Omega^{(f)}$ of the fluid may contain pressure-release, rigid, or impedance surfaces S.

Equations (1) and (2) have been derived[56,57] neglecting irreversible thermodynamic processes. It is common to model sound propagation in a medium with dissipation by formally attributing frequency-dependent complex values to sound speed and mass density.[59] With complex $c(\mathbf{x},\omega)$ and $\rho(\mathbf{x},\omega)$, Eqs. (1) and (2) become model governing equations for CW acoustic fields in a moving fluid with dissipation. Note that assigning complex values to sound speed and mass density results in only an approximate description of the physical processes in the fluid with dissipation. In particular, the model does not account for viscous and thermal waves (see Brekhovskikh and Godin[59]). These rapidly attenuating waves are not important for long-range field correlations, which are the subject of this paper.

The linearized boundary conditions[56,57] for the CW acoustic field at an impedance (i.e., locally reacting) surface S within a moving fluid are

$$p+(\mathbf{N}\cdot\nabla p_0-i\omega\zeta)\mathbf{w}\cdot\mathbf{N}=0, \quad \mathbf{x}\in S, \quad (3)$$

where $\mathbf{N}$ is a unit normal to S and $\zeta=\zeta(\mathbf{x},\omega)$ is the impedance of the surface. The impedance is a property of the surface and is supposed to be independent of the background flow velocity. Free and rigid boundaries can be viewed as special cases of the impedance surface corresponding to zero or infinite impedance, respectively. In addition, the normal component of the background flow velocity is zero[57] on S and any boundary impenetrable to fluid:

$$\mathbf{U}\cdot\mathbf{N}=0. \quad (4)$$

In a quiescent fluid ($\mathbf{U}\equiv 0$), Eqs. (1) and (2) reduce to standard equations,[57,59]

$$\rho\frac{\partial \mathbf{v}}{\partial t}+\nabla p=\mathbf{F},\quad \nabla\cdot\mathbf{v}+\frac{1}{\rho c^2}\frac{\partial p}{\partial t}=\frac{\partial B}{\partial t},\tag{5}$$

of linear acoustics of motionless media. Some authors[60] do not appreciate the well-known fact that, unless $\mathbf{U}=\text{const}$, replacing partial time derivatives[42,45,60] $\partial/\partial t$ with material time derivatives d/dt in Eq. (5) does not lead to the correct governing equations for sound in an inhomogeneous flow. Strictly speaking, use of such model equations instead of the correct governing equations for sound in moving fluid in Refs. 42, 45, and 60 limits the validity domain of their conclusions to the trivial case of uniform flow.

Linear waves in an arbitrary inhomogeneous and anisotropic solid are governed by the equations[59,61]

$$\rho\partial^2 w_j/\partial t^2=\partial\sigma_{jk}/\partial x_k+F_j,\tag{6}$$

$$\sigma_{jk}=C_{jkmn}(u_{mn}+e_{mn}),\quad u_{mn}=\frac{1}{2}\left(\frac{\partial w_m}{\partial x_n}+\frac{\partial w_n}{\partial x_m}\right),\tag{7}$$

where $\mathbf{w}$, u_{jk}, and σ_{jk} are, respectively, displacement of particles and strain and stress tensors in the wave generated by an external force with volume density $\mathbf{F}$ and an external strain e_{mn}; C_{jkmn} is the elastic modulus tensor. Here and below summation over repeated Latin subscripts j, k, m, n, l, $s=1,2,3$ is implied. In terms of the compliance tensor α_{jkmn}, the stress-strain relationship (7) can be alternatively written as

$$\alpha_{mnjk}\sigma_{jk}=u_{mn}+e_{mn}.\tag{8}$$

The tensors u_{jk}, e_{mn}, and σ_{jk} are symmetric: $u_{jk}=u_{kj}$, $e_{mn}=e_{nm}$, $\sigma_{jk}=\sigma_{kj}$, while the tensors C_{jkmn} and α_{jkmn} are invariant with respect to interchange of the indices within the first or second pair and of the pairs. These symmetry properties are systematically utilized in the transformations in Secs. III–VI. As long as σ_{jk} and $u_{nm}+e_{mn}$ can be arbitrary symmetric tensors, the compliance and elastic modulus tensors are related by the equation

$$\alpha_{mnjk}C_{jkrs}=\tfrac{1}{2}(\delta_{mr}\delta_{ns}+\delta_{nr}\delta_{ms}),\tag{9}$$

where δ_{mn} is the Kronecker delta symbol. Dissipation of CW elastic waves in a solid is modeled[59,61] by attributing complex values to density and material tensors C_{jkmn} and α_{jkmn}. As in the case of fluid, we disregard rapidly attenuating thermal waves in a solid. Below we will need the following relation between imaginary parts of the compliance and elastic modulus tensors:

$$C_{jkrs}C^{*}_{mnlq}\,\mathrm{Im}\,\alpha_{mnjk}=-\,\mathrm{Im}\,C_{lqrs},\tag{10}$$

which is a corollary of the identity (9). Here and below, the asterisk denotes complex conjugation.

Equations (6) and (7) for elastic waves in solids contain a description of acoustic waves in a motionless fluid (i.e., in the absence of a background flow). When $C_{jkmn}=\rho c^2\delta_{jk}\delta_{mn}$ and $\sigma_{jk}=-p\delta_{jk}$ Eqs. (6) and (7) reduce to Eqs. (1) and (2) with $\mathbf{U}=0$ and become equivalent to Eq. (5). Note that sound in fluid is generated by a source of external strain only when resulting volume change is nonzero: $e_{nn}\neq 0$. Then the source of external strain is equivalent to a source of volume velocity with $B=-e_{nn}/3$. These relations are utilized below to verify results obtained for waves in fluid-solid systems against known results for acoustic fields in fluids.

Boundary conditions on rigid and free boundaries of a solid are[59] $\mathbf{w}=0$ and $\sigma_{jk}N_k=0$, respectively. Linearized kinematic boundary condition[57,58] on a fluid-solid interface Γ consists in continuity of the normal displacement $\mathbf{w}\cdot\mathbf{N}$. Generally, a solid in contact with inhomogeneous fluid flow is deformed even in the background state, i.e., in the absence of waves. Assuming that the background stress tensor $\sigma^{(0)}_{jk}$ and its normal derivative are diagonal on the interface, the linearized dynamic boundary condition[58] can be written as

$$\sigma_{jk}N_j+[p+(\mathbf{w}\cdot\mathbf{N})H_0]N_k=0,\quad \mathbf{x}\in\Gamma,\tag{11}$$

where

$$H_0=\mathbf{N}\cdot\nabla p_0+\tfrac{1}{3}(\mathbf{N}\cdot\nabla)\sigma^{(0)}_{nn}.\tag{12}$$

III. RECIPROCITY RELATIONS IN FLUID-SOLID SYSTEMS

The FRT[56–58] relates the wave field $p^{(1)},\mathbf{w}^{(1)},\sigma^{(1)}_{jk}$ generated by a set $B^{(1)},\mathbf{F}^{(1)},e^{(1)}_{jk}$ of sources in a medium with flow velocity $\mathbf{U}(\mathbf{x})$, with an acoustic field $p^{(2)},\mathbf{w}^{(2)},\sigma^{(2)}_{jk}$ generated by another set $B^{(2)},\mathbf{F}^{(2)},e^{(2)}_{jk}$ of sources in a medium with the same geometry of the interfaces and boundaries, the same sound speed, elastic modulus tensor and density, and *reversed* flow with velocity $-\mathbf{U}(\mathbf{x})$. Note that the flow reversal does not change the background pressure field $p_0(\mathbf{x})$. Using Eqs. (1) and (2) to calculate the quantity

$$a^{(f)}=\mathbf{F}^{(2)}\mathbf{w}^{(1)}-\mathbf{F}^{(1)}\mathbf{w}^{(2)}+B^{(1)}p^{(2)}-B^{(2)}p^{(1)}\tag{13}$$

and Eqs. (6) and (7) to calculate the quantity

$$a^{(s)}=\mathbf{F}^{(2)}\mathbf{w}^{(1)}-\mathbf{F}^{(1)}\mathbf{w}^{(2)}+e^{(1)}_{mn}\sigma^{(2)}_{mn}-e^{(2)}_{mn}\sigma^{(1)}_{mn},\tag{14}$$

and applying the Gauss divergence theorem, we obtain

$$\int_{\Omega^{(f)}}a^{(f)}d^3\mathbf{x}+\int_{\Omega^{(s)}}a^{(s)}d^3\mathbf{x}=\int_{\partial\Omega^{(f)}}\mathbf{N}\cdot\mathbf{j}^{(f)}ds+\int_{\partial\Omega^{(s)}}\mathbf{N}\cdot\mathbf{j}^{(s)}ds.\tag{15}$$

Here $\Omega^{(f)}$ and $\Omega^{(s)}$ are arbitrary domains occupied by fluid and solid, respectively, with the boundaries $\partial\Omega^{(f)}$ and $\partial\Omega^{(s)}$, $\mathbf{N}$ is an external unit normal to the boundaries, and

$$\mathbf{j}^{(f)}=p^{(2)}\mathbf{w}^{(1)}-p^{(1)}\mathbf{w}^{(2)}-\rho\mathbf{U}(\mathbf{w}^{(1)}\cdot\tilde{d}\mathbf{w}^{(2)}/dt+\mathbf{w}^{(2)}\cdot d\mathbf{w}^{(1)}/dt),\tag{16}$$

$$j^{(s)}_k=\sigma^{(1)}_{jk}w^{(2)}_j-\sigma^{(2)}_{jk}w^{(1)}_j.\tag{17}$$

The tilde denotes quantities referring to a medium with reversed flow. In particular, $\tilde{d}/dt=\partial/\partial t-\mathbf{U}\cdot\nabla$. The boundaries $\partial\Omega^{(f)}$ and $\partial\Omega^{(s)}$ are not required to be simply connected. Parts of $\partial\Omega^{(f)}$ and $\partial\Omega^{(s)}$ may be located at infinity. Derivation of the FRT (13)–(17) parallels that presented in Ref. 58 and differs only by inclusion of the external strain as additional type of wave sources in the solid.

Below we assume that, aside from fluid-solid interfaces, the fluid is either unbounded or has ideal (i.e., free or rigid) or impedance boundaries, while the solid is either unbounded or has ideal boundaries. According to Eqs. (3), (4), (16), and (17), normal components of the vectors $\mathbf{j}^{(f)}$ and $\mathbf{j}^{(s)}$ vanish on such boundaries. According to Eqs. (4), (11), (16), and (17), $(\mathbf{j}^{(f)}-\mathbf{j}^{(s)})\cdot\mathbf{N}=0$ at the fluid-solid interface. As external normals to the surfaces $\partial\Omega^{(f)}$ and $\partial\Omega^{(s)}$ have opposite directions on the fluid-solid interface, contributions of such interfaces into integrals over $\partial\Omega^{(f)}$ and over $\partial\Omega^{(s)}$ in Eq. (15) cancel each other. Parts of $\partial\Omega^{(f)}$ and $\partial\Omega^{(s)}$ that are located at infinity do not contribute to the surface integrals in Eq. (15).[56–58] Thus, when the domain $\Omega\equiv\Omega^{(f)}\cup\Omega^{(s)}$ is chosen to be the entire volume occupied by the fluid and the solid, the right side of Eq. (15) vanishes.

In the absence of a background flow ($\mathbf{U}\equiv 0$), FRT (13)–(17) relates wave fields created by two different sets of sources in the same environment and extends the acoustic reciprocity principle[57] and the Betti reciprocal relation of dynamic elasticity[61] to fluid-solid systems.

The FRT relates wave fields in the original medium and in the medium with reversed flow. A similar relation can be derived for a wave field due to a set of sources and a complex conjugate of a wave field due to another set of sources in the same medium. Using Eqs. (1) and (2) to calculate the quantity

$$A^{(f)}=\mathbf{F}^{(2)*}\mathbf{w}^{(1)}-\mathbf{F}^{(1)}\mathbf{w}^{(2)*}+B^{(1)}p^{(2)*}-B^{(2)*}p^{(1)} \tag{18}$$

and Eqs. (6) and (7) to calculate the quantity

$$A^{(s)}=\mathbf{F}^{(2)*}\mathbf{w}^{(1)}-\mathbf{F}^{(1)}\mathbf{w}^{(2)*}+e^{(1)}_{mn}C_{jkmn}\,\partial\, w^{(2)*}_{j}/\partial x_k - e^{(2)*}_{mn}C^{*}_{jkmn}\,\partial\, w^{(1)}_{j}/\partial x_k, \tag{19}$$

after application of the Gauss divergence theorem we obtain

$$\begin{aligned}\int_{\Omega^{(f)}}A^{(f)}d^3\mathbf{x}+\int_{\Omega^{(s)}}A^{(s)}d^3\mathbf{x}&=\int_{\partial\Omega^{(f)}}\mathbf{N}\cdot\mathbf{J}^{(f)}ds+\int_{\partial\Omega^{(s)}}\mathbf{N}\cdot\mathbf{J}^{(s)}ds+2i\int_{\Omega^{(f)}}\left(\mathrm{Im}\frac{1}{\rho c^2}\right)\\&\times(p^{(1)}+\mathbf{w}^{(1)}\cdot\nabla p_0)(p^{(2)}+\mathbf{w}^{(2)}\cdot\nabla p_0)^{*}d^3\mathbf{x}\\&+2i\int_{\Omega^{(s)}}\left[\omega^2\mathbf{w}^{(1)}\cdot\mathbf{w}^{(2)*}\,\mathrm{Im}\,\rho-\frac{\partial w^{(1)}_m}{\partial x_n}\frac{\partial w^{(2)*}_j}{\partial x_k}\mathrm{Im}\,C_{jkmn}\right]d^3\mathbf{x}.\end{aligned} \tag{20}$$

Here

$$\mathbf{J}^{(f)}=p^{(2)*}\mathbf{w}^{(1)}-p^{(1)}\mathbf{w}^{(2)*}+\rho\mathbf{U}[\mathbf{w}^{(1)}(\mathbf{U}\cdot\nabla)\mathbf{w}^{(2)*}-\mathbf{w}^{(2)*}(\mathbf{U}\cdot\nabla)\mathbf{w}^{(1)}+2i\omega\mathbf{w}^{(1)}\cdot\mathbf{w}^{(2)*}], \tag{21}$$

$$J^{(s)}_k=\sigma^{(1)}_{jk}w^{(2)*}_j-\sigma^{(2)*}_{jk}w^{(1)}_j, \tag{22}$$

and $\Omega^{(f)}$, $\Omega^{(s)}$, $\partial\Omega^{(f)}$, and $\partial\Omega^{(s)}$ have the same meaning as in Eq. (15). In derivation of Eq. (20), it has been assumed that acoustic field dissipation in fluid is described by an imaginary part of the fluid compressibility $1/\rho c^2$, while the other fluid parameters are real-valued. Note that, according to Eqs. (21) and (22), those parts of the surfaces $\partial\Omega^{(f)}$ and $\partial\Omega^{(s)}$, which are located at infinity or coincide with ideal boundaries, do not contribute to surface integrals in the right-hand side of Eq. (20), as in the FRT (15). According to the boundary condition (3), the normal component of the vector $\mathbf{J}^{(f)}$ [Eq. (21)] is also zero on an impedance boundary provided that the impedance is purely reactive ($\mathrm{Re}\,\zeta=0$). From the boundary conditions (4) and (11) and continuity of $\mathbf{w}\cdot\mathbf{N}$, it follows that fluxes of vectors $\mathbf{J}^{(f)}$ [Eq. (21)] and $\mathbf{J}^{(s)}$ [Eq. (22)] through a fluid-solid interface cancel each other. Thus, when the domain $\Omega\equiv\Omega^{(f)}\cup\Omega^{(s)}$ is chosen to be the entire volume occupied by the fluid and the solid and the medium is either unbounded or has only ideal boundaries or purely reactive impedance boundaries, the surface integrals can be omitted in the right-hand side of Eq. (20).

The identity (20) extends to flow-structure problems the "correlation-type" reciprocity relations, which have been previously derived for waves in inhomogeneous solids[42] and moving fluids[43] with dissipation as well as in flow-structure problems without dissipation.[58] In the particular case[57,58] where the wave field with the superscript (2) is chosen to be the same as the wave field with the superscript (1), Eq. (20) expresses conservation of wave energy, with the imaginary part of the surface integrals in the right-hand side giving time-averaged energy flux through the boundaries of the fluid and solid domains $\Omega^{(f)}$ and $\Omega^{(s)}$, volume integrals giving wave energy dissipation in the fluid and the solid, and the imaginary part of the left-hand side describing time-averaged power output of the wave sources.

IV. GREEN'S FUNCTIONS

As in Refs. 40 and 43, we define the Green's function $G(\mathbf{x},\mathbf{x}_1,t)$ as the acoustic pressure at point $\mathbf{x}$ in fluid due to a point source of volume velocity with $B=\delta(\mathbf{x}-\mathbf{x}_1)\delta'(t)$ and $\mathbf{F}=0$. The stress tensor σ_{jk} in the solid and oscillatory displacement $\mathbf{w}$ generated by such an acoustic source will be denoted as $s_{jk}(\mathbf{x},\mathbf{x}_1,t)$ and $\mathbf{g}(\mathbf{x},\mathbf{x}_1,t)$, respectively. In the case of a motionless fluid, the Green's function so defined corresponds to the field of a monopole sound source. The frequency spectrum $G(\mathbf{x},\mathbf{x}_1,\omega)$ of the time-domain Green's function $G(\mathbf{x},\mathbf{x}_1,t)$ has the meaning of the CW Green's function. In a motionless fluid, $\mathbf{g}(\mathbf{x},\mathbf{x}_1,\omega)=(\rho\omega^2)^{-1}\nabla G(\mathbf{x},\mathbf{x}_1,\omega)$. For the Green's functions G and $\tilde{G}$ in the original medium and in a medium with reversed flow, a simple symmetry relation follows from Eq. (15):

$$G(\mathbf{x},\mathbf{x}_1,\omega)=\tilde{G}(\mathbf{x}_1,\mathbf{x},\omega). \tag{23}$$

From the Green's function definition and FRT (15), we obtain

$$p(\mathbf{x},\omega)=\frac{i}{\omega}\int d^3\mathbf{y}[B(\mathbf{y})\tilde{G}(\mathbf{y},\mathbf{x},\omega)-\mathbf{F}(\mathbf{y})\cdot\tilde{\mathbf{g}}(\mathbf{y},\mathbf{x},\omega)+e_{mn}(\mathbf{y})\tilde{s}_{mn}(\mathbf{y},\mathbf{x},\omega)] \tag{24}$$

for the acoustic field in the fluid, which is jointly generated by the distributed CW sources of an external force with an arbitrary density $\mathbf{F}$, of volume velocity with a density B within the fluid, and of an external strain with a density e_{mn}

in the solid. The integral in Eq. (24) is taken over the entire domain occupied by the sources.

To derive another important identity for the Green's function $G(\mathbf{x},\mathbf{x}_1,\omega)$, we apply the reciprocity relation (20) to wave fields generated by sources with the frequency spectra $B^{(r)}=-i\omega\delta(\mathbf{x}-\mathbf{x}_r)$, $\mathbf{F}^{(r)}=0$, and $e_{mn}^{(r)}=0$, where $r=1,2$. With $\Omega\equiv\Omega^{(f)}\cup\Omega^{(s)}$ representing the whole domain occupied by the fluid and the solid and assuming that medium boundaries, if any, are free, rigid, or locally reacting surfaces with purely reactive impedance, we obtain

$$
\begin{aligned}
&-0.5\omega[G(\mathbf{x}_2,\mathbf{x}_1,\omega)+G^*(\mathbf{x}_1,\mathbf{x}_2,\omega)]\\
&=\int_{\Omega^{(f)}}\left(\mathrm{Im}\frac{1}{\rho c^2}\right)[G(\mathbf{x},\mathbf{x}_1,\omega)+\mathbf{g}(\mathbf{x},\mathbf{x}_1,\omega)\cdot\nabla p_0]\\
&\quad\times[G(\mathbf{x},\mathbf{x}_2,\omega)+\mathbf{g}(\mathbf{x},\mathbf{x}_2,\omega)\cdot\nabla p_0]^* d^3\mathbf{x}\\
&\quad+\int_{\Omega^{(s)}}\left[\omega^2\mathbf{g}(\mathbf{x},\mathbf{x}_1,\omega)\cdot\mathbf{g}^*(\mathbf{x},\mathbf{x}_2,\omega)\mathrm{Im}\,\rho\right.\\
&\quad\left.-\frac{\partial g_m(\mathbf{x},\mathbf{x}_1,\omega)}{\partial x_n}\frac{\partial g_j^*(\mathbf{x},\mathbf{x}_2,\omega)}{\partial x_k}\mathrm{Im}\,C_{jkmn}\right]d^3\mathbf{x}. \qquad (25)
\end{aligned}
$$

Identities of this kind, which relate a Green's function to an integral of a product of two Green's functions, are sometimes termed Ward identities.[60]

Now we introduce Green's functions for wave sources located within the solid. Let a source of external strain with $e_{mn}=\delta(\mathbf{x}-\mathbf{x}_1)\delta'(t)E_{mn}$ and $\mathbf{F}=0$ in the solid generate stresses and displacements with frequency spectra $\sigma_{jk}(\mathbf{x})=E_{mn}S_{mn,jk}(\mathbf{x},\mathbf{x}_1,\omega)$ and $\mathbf{w}(\mathbf{x})=E_{mn}\mathbf{T}_{mn}(\mathbf{x},\mathbf{x}_1,\omega)$ in the medium. Here E_{mn} is an arbitrary symmetric tensor. In particular, the frequency spectrum of the pressure generated by the external strain source at a point $\mathbf{x}$ in fluid is $p(\mathbf{x})=-S_{mn,jj}(\mathbf{x},\mathbf{x}_1,\omega)E_{mn}/3$. The tensor $S_{mn,jk}(\mathbf{x},\mathbf{x}_1,\omega)$ has the meaning of Green's tensor for stresses due to a CW source of external strain. It is invariant with respect to permutation of indices in the first or second pairs.

By applying the FRT (15) to wave fields generated by different sources of external strain in the original medium and in the medium with reversed flow, we obtain a reciprocity-type symmetry relation for the Green's tensor $S_{mn,jk}$ [compare with Eq. (23)]:

$$
S_{jk,mn}(\mathbf{x},\mathbf{x}_1,\omega)=\tilde{S}_{mn,jk}(\mathbf{x}_1,\mathbf{x},\omega). \qquad (26)
$$

Another important identity is obtained by applying the reciprocity relation (20) to wave fields generated in the original medium by two distinct sources of external strain with the frequency spectra $e_{mn}^{(r)}=-i\omega\delta(\mathbf{x}-\mathbf{x}_r)E_{mn}^{(r)}$, $\mathbf{F}^{(r)}=0$, $B^{(r)}=0$, and $r=1,2$. Again assuming, as in the derivation of Eq. (25), that $\Omega\equiv\Omega^{(f)}\cup\Omega^{(s)}$ represents the whole domain occupied by the fluid and the solid and that medium boundaries, if any, are free, rigid, or locally reacting surfaces with purely reactive impedance, from Eq. (20) we obtain

$$
\begin{aligned}
&-\frac{\omega}{2}\left[C_{jkmn}(\mathbf{x})\frac{\partial T_{ls,j}^*}{\partial x_k}(\mathbf{x},\mathbf{x}_2,\omega)\big|_{\mathbf{x}=\mathbf{x}_1}+C_{jkls}^*(\mathbf{x}_2)\frac{\partial T_{mn,j}}{\partial x_k}(\mathbf{x},\mathbf{x}_1,\omega)\big|_{\mathbf{x}=\mathbf{x}_2}\right]\\
&=\int_{\Omega^{(f)}}\left(\mathrm{Im}\frac{1}{\rho c^2}\right)\left[\frac{1}{3}S_{mn,jj}(\mathbf{x},\mathbf{x}_1,\omega)+\mathbf{T}_{mn}(\mathbf{x},\mathbf{x}_1,\omega)\cdot\nabla p_0\right]\left[\frac{1}{3}S_{ls,jj}(\mathbf{x},\mathbf{x}_2,\omega)+\mathbf{T}_{ls}(\mathbf{x},\mathbf{x}_2,\omega)\cdot\nabla p_0\right]^* d^3\mathbf{x}\\
&\quad+\int_{\Omega^{(s)}}\left[\omega^2\mathbf{T}_{mn}(\mathbf{x},\mathbf{x}_1,\omega)\cdot\mathbf{T}_{ls}^*(\mathbf{x},\mathbf{x}_2,\omega)\mathrm{Im}\,\rho-\frac{\partial T_{mn,j}(\mathbf{x},\mathbf{x}_1,\omega)}{\partial x_k}\frac{\partial T_{ls,j'}^*(\mathbf{x},\mathbf{x}_2,\omega)}{\partial x_{k'}}\mathrm{Im}\,C_{jkj'k'}(\mathbf{x})\right]d^3\mathbf{x}. \qquad (27)
\end{aligned}
$$

In the derivation of Eq. (27), we made use of arbitrariness of the symmetric tensors $E_{mn}^{(1)}$ and $E_{mn}^{(2)}$.

For a wave field generated by arbitrary distributed sources of external strain in the solid, volume velocity in the fluid, and external force, from the FRT (15) we find

$$
\begin{aligned}
\sigma_{mn}(\mathbf{x},\omega)=\frac{i}{\omega}\int d^3\mathbf{y}\left[\left(e_{jk}(\mathbf{y})-\frac{B(\mathbf{y})}{3}\delta_{jk}\right)\tilde{S}_{mn,jk}(\mathbf{y},\mathbf{x},\omega)\right.\\
\left.-\mathbf{F}(\mathbf{y})\cdot\tilde{\mathbf{T}}_{mn}(\mathbf{y},\mathbf{x},\omega)\right], \qquad (28)
\end{aligned}
$$

where the integral is taken over the entire volume occupied by the sources.

Let elastic waves be generated by random sources that are located in a fluid-solid domain Ω, have zero statistical mean, and are δ-correlated in space:

$$
\begin{aligned}
&\langle B(\mathbf{x})\rangle=0,\quad\langle\mathbf{F}(\mathbf{x})\rangle=0,\quad\langle e_{mn}(\mathbf{x})\rangle=0,\\
&\langle B(\mathbf{x})B^*(\mathbf{y})\rangle=Q^{(1)}(\mathbf{x})\delta(\mathbf{x}-\mathbf{y}),\\
&\langle B(\mathbf{x})F_j^*(\mathbf{y})\rangle=Q_j^{(2)}(\mathbf{x})\delta(\mathbf{x}-\mathbf{y}),\\
&\langle F_m(\mathbf{x})F_j^*(\mathbf{y})\rangle=Q_{mj}^{(3)}(\mathbf{x})\delta(\mathbf{x}-\mathbf{y}),\\
&\langle e_{mn}(\mathbf{x})F_j^*(\mathbf{y})\rangle=Q_{mnj}^{(4)}(\mathbf{x})\delta(\mathbf{x}-\mathbf{y}), \qquad (29)\\
&\langle e_{mn}(\mathbf{x})e_{jk}^*(\mathbf{y})\rangle=Q_{mnjk}^{(5)}(\mathbf{x})\delta(\mathbf{x}-\mathbf{y}).
\end{aligned}
$$

Here and below, angular brackets $\langle\cdot\rangle$ denote ensemble average. With B and e_{mn} being identically zero, respectively, within the solid and the fluid, the random source densities B

and e_{mn} are assumed to be uncorrelated. Due to the linearity of the problem, the oscillatory displacement, acoustic pressure in the fluid, and stresses in the solid in the resulting random wave field are zero on average. For a two-point correlation function of acoustic pressure in a moving fluid, from Eqs. (24) and (29) we find

$$\langle p(\mathbf{x}_1)p^*(\mathbf{x}_2)\rangle = \omega^{-2}\int_\Omega d^3\mathbf{y}[Q^{(1)}(\mathbf{y})\tilde{G}(\mathbf{y},\mathbf{x}_1)\tilde{G}^*(\mathbf{y},\mathbf{x}_2) - Q_j^{(2)}(\mathbf{y})\tilde{G}(\mathbf{y},\mathbf{x}_1)\tilde{g}_j^*(\mathbf{y},\mathbf{x}_2) - Q_j^{(2)*}(\mathbf{y})\tilde{G}^*(\mathbf{y},\mathbf{x}_2)\tilde{g}_j(\mathbf{y},\mathbf{x}_1)$$
$$+ Q_{mj}^{(3)}(\mathbf{y})\tilde{g}_m(\mathbf{y},\mathbf{x}_1)\tilde{g}_j^*(\mathbf{y},\mathbf{x}_2) - Q_{mnl}^{(4)}(\mathbf{y})\tilde{s}_{mn}(\mathbf{y},\mathbf{x}_1)\tilde{g}_l^*(\mathbf{y},\mathbf{x}_2) - Q_{mnl}^{(4)*}(\mathbf{y})\tilde{s}_{mn}^*(\mathbf{y},\mathbf{x}_1)\tilde{g}_l(\mathbf{y},\mathbf{x}_2)$$
$$+ Q_{mnjk}^{(5)}(\mathbf{y})\tilde{s}_{mn}(\mathbf{y},\mathbf{x}_1)\tilde{s}_{jk}^*(\mathbf{y},\mathbf{x}_2)]. \tag{30}$$

Here and below, where it cannot lead to confusion, the argument ω is suppressed for brevity. Similar expressions can be obtained for correlation of other observables in the fluid and the solid. In particular, when external forces are uncorrelated with sources of the external strain in the solid (and, hence, $Q_{mnj}^{(4)} \equiv 0$) for the cross-correlation of stresses within the solid, from Eqs. (28) and (29) we find

$$\langle \sigma_{mn}(\mathbf{x}_1)\sigma_{jk}^*(\mathbf{x}_2)\rangle = \omega^{-2}\int_\Omega \{[Q_{lqrs}^{(5)}(\mathbf{y})$$
$$+ Q^{(1)}\delta_{lq}\delta_{rs}/9]\tilde{S}_{mn,lq}(\mathbf{y},\mathbf{x}_1)\tilde{S}_{jk,rs}^*(\mathbf{y},\mathbf{x}_2)$$
$$- Q_s^{(2)}(\mathbf{y})\tilde{S}_{mn,qq}(\mathbf{y},\mathbf{x}_1)\tilde{T}_{jk,s}^*(\mathbf{y},\mathbf{x}_2)/3$$
$$- Q_s^{(2)*}(\mathbf{y})\tilde{S}_{jk,qq}^*(\mathbf{y},\mathbf{x}_2)\tilde{T}_{mn,s}(\mathbf{y},\mathbf{x}_1)/3$$
$$+ Q_{ls}^{(3)}(\mathbf{y})\tilde{T}_{mn,l}(\mathbf{y},\mathbf{x}_1)\tilde{T}_{jk,s}^*(\mathbf{y},\mathbf{x}_2)\}d^3\mathbf{y}. \tag{31}$$

Note that the Green's functions and tensors in the integrands in Eqs. (24) and (28) [and, consequently, in Eqs. (30) and (31)] correspond to wave fields in the medium with reversed flow. Integration in Eqs. (24), (28), (30), and (31) is over the receiver, rather than the source, position. The latter property of Eqs. (30) and (31) greatly simplifies derivation of local relationships between noise cross-correlation and deterministic Green's functions and tensors, which is outlined below in Sec. VI.

V. THERMAL NOISE AND THE FLUCTUATION-DISSIPATION THEOREM

A thermal acoustic field in fluids and solids is produced by the chaotic thermal motion of microscopic particles such as atoms, ions, and electrons. The FDT allows one to represent acoustic noise at a state close to thermal equilibrium as a field due to effective, random, macroscopic wave sources. Let small perturbations of a continuous system be described by a set $\{\xi_\beta(\mathbf{x},t)\}, \beta=1,2,3,\ldots,N$ of generalized coordinates, and macroscopic equations of motion can be written in terms of spectral components of the generalized coordinates as follows:

$$\sum_{\gamma=1}^{N}\hat{K}_{\beta\gamma}(\mathbf{x},\omega)\xi_\gamma(\mathbf{x},\omega) = f_\beta(\mathbf{x},\omega), \quad \beta=1,2,\ldots,N. \tag{32}$$

Here $\hat{K}_{\beta\gamma}(\mathbf{x},\omega)$ is a linear operator, and $f_\beta(\mathbf{x},\omega)$ are spectral components of generalized forces. The generalized forces and generalized coordinates are also related by the requirement that the statistical average of volume density of the power created by a force $f_\beta(\mathbf{x},t)$ is $\langle f_\beta(\mathbf{x},t)\,\partial\xi_\beta(\mathbf{x},t)/\partial t\rangle$. According to the FDT, thermal fluctuations of the system can be viewed as generated by random generalized forces with zero mean and the following correlation functions (Ref. 2, p. 119; Ref. 3, p. 273; Ref. 55, p. 389):

$$\langle f_\beta(\mathbf{x})f_\gamma^*(\mathbf{y})\rangle = -\frac{i\Theta}{2\pi\omega}[\hat{K}_{\gamma\beta}^*(\mathbf{x},\omega) - \hat{K}_{\beta\gamma}(\mathbf{y},\omega)]\delta(\mathbf{x}-\mathbf{y}),$$
$$\Theta = \frac{\hbar\omega}{2}\coth\frac{\hbar\omega}{2\kappa T}, \tag{33}$$

where T is temperature, Θ is the mean energy of a quantum oscillator, and $\hbar$ and κ are Planck's and Boltzmann's constants. In the classical (or high-temperature) limit, where $\hbar\omega \ll \kappa T$, $\Theta(T,\omega) \approx \kappa T$.

To characterize the thermal noise sources located within a moving dissipative fluid, we choose[43] $\xi_j = w_j$, $j=1,2,3$; $\xi_4 = p$. From the expression[57] $\int d^3\mathbf{x}[\mathbf{F}(\mathbf{x},t)\cdot\partial\mathbf{w}(\mathbf{x},t)/\partial t + p(\mathbf{x},t)\,\partial B(\mathbf{x},t)/\partial t]$ for acoustic energy production by sound sources, it follows that the generalized forces corresponding to the chosen generalized coordinates are $f_j = F_j$, $j=1,2,3$; $f_4 = -B$. Statistical properties of these sources[43] follow Eq. (29) with

$$Q^{(1)} = \frac{\Theta}{\pi\omega}\mathrm{Im}\frac{1}{\rho c^2}, \quad Q_m^{(2)} = -\frac{\Theta}{\pi\omega}\frac{\partial p_0}{\partial x_m}\mathrm{Im}\frac{1}{\rho c^2}, \tag{34}$$
$$Q_{mn}^{(3)} = \frac{\Theta}{\pi\omega}\frac{\partial p_0}{\partial x_m}\frac{\partial p_0}{\partial x_n}\mathrm{Im}\frac{1}{\rho c^2}, \quad \mathbf{x}\in\Omega^{(f)},$$

when wave dissipation in the fluid is described by its complex compressibility. Note that in a generic inhomogeneous flow, the sources of extraneous force and volume velocity prove to be correlated. This is in contrast to the *ad hoc* source model assumed in Ref. 42.

To characterize the thermal noise sources located in a solid, we choose $\xi_j = w_j$, $j=1,2,3$; $\xi_4 = -\sigma_{11}$, $\xi_5 = -(\sigma_{12}+\sigma_{21})$, $\xi_6 = -(\sigma_{13}+\sigma_{31})$, $\xi_7 = -\sigma_{22}$, $\xi_8 = -(\sigma_{23}+\sigma_{32})$, and $\xi_9 = -\sigma_{33}$ as generalized coordinates. Following Ref. 58, it is easy to show that the rate of wave energy production by sources of external force and strain in a solid is given by the expression $\int d^3\mathbf{x}[\mathbf{F}(\mathbf{x},t)\cdot\partial\mathbf{w}(\mathbf{x},t)/\partial t + e_{mn}(\mathbf{x},t)\,\partial\sigma_{mn}(\mathbf{x},t)/\partial t]$. Hence, the generalized forces corresponding to the chosen generalized coordinates are $f_j = F_j$, $j=1,2,3$; $f_4 = e_{11}$, $f_5 = e_{12}+e_{21}$, $f_6 = e_{13}+e_{31}$, $f_7 = e_{22}$, $f_8 = e_{23}+e_{32}$, and $f_9 = e_{33}$. The operators $\hat{K}_{\beta\gamma}$, $\beta,\gamma = 1,2,\ldots,9$ introduced in Eq. (32) are found from Eqs. (6) and (8): $\hat{K}_{jk} = -\rho\omega^2\delta_{jk}$, $\hat{K}_{j4} = \delta_{j1}\partial/\partial x_1$, $\hat{K}_{j5} = \delta_{j1}\partial/\partial x_2 + \delta_{j2}\partial/\partial x_1$, $j,k = 1,2,3,\ldots,\hat{K}_{56} = -4\alpha_{1213},\ldots,\hat{K}_{98} = -2\alpha_{2333},\hat{K}_{99} = -\alpha_{3333}$. Using Eq. (33) to calculate correlation functions of the volume densities of the effective sources $\mathbf{F}$ and e_{mn} of thermal fluctuations in the solid, we arrive at Eq. (29) with

$$Q^{(3)}_{mn} = \frac{\Theta\omega}{\pi}\delta_{mn}\,\mathrm{Im}\,\rho, \quad Q^{(4)}_{mnj} = 0, \tag{35}$$

$$Q^{(5)}_{mnjk} = \frac{\Theta}{\pi\omega}\mathrm{Im}\,\alpha_{mnjk}, \quad \mathbf{x}\in\Omega^{(s)}.$$

An inspection shows that Eq. (35) reduces to known results in the two particular cases previously considered in the literature, namely, for waves in a motionless fluid,[43] where $\alpha_{mmnn} = (\rho c^2)^{-1}$, and for waves in a homogeneous isotropic solid with $\mathrm{Im}\,\rho = 0$.[62] Note that even in the fluid case, where wave dissipation is described by two scalar quantities $\mathrm{Im}\,\rho$ and $\mathrm{Im}(\rho c^2)^{-1}$, the volume density of the noise sources is generally not proportional to the local value of the plane-wave attenuation coefficient, unlike in the simple phenomenological model of Ref. 39.

Although Eq. (33) strictly applies only at thermal equilibrium, resulting expressions for effective sources of thermal noise hold also when the temperature T varies as long as temperature gradients are sufficiently small so that the contribution of non-equilibrium processes remains negligible (Ref. 3, p. 128). Then Eqs. (34) and (35) allow one to calculate two-point statistical moments of thermal wave fields in the fluid and in the solid in rather general systems, for instance, in the inhomogeneous flow of a cold gas past heated solid bodies. Similar calculations for a number of simple geometries, e.g., waves due to delta-correlated random sources in a sphere or in a half-space with a plane boundary, have been carried out[2,3] in studies of thermal electromagnetic fields. The necessary calculations and especially their results simplify greatly when temperature is constant throughout the domain occupied by the effective sources of thermal noise. This important special case is considered in the next section.

VI. GREEN'S FUNCTION RETRIEVAL FROM NOISE CROSS-CORRELATION

Consider the two-point correlation of the spectral densities of pressure fluctuations within the fluid in a fluid-solid system in thermal equilibrium. We have shown in Sec. V that the thermal fluctuations can be viewed as generated by delta-correlated random sources of volume velocity and external force located within the fluid and by sources of external force and strain located within the solid. Taking into account that the mean energy Θ [Eq. (33)] of a quantum oscillator does not depend on position, from Eqs. (30), (34), and (35) we find

$$\begin{aligned}\langle p(\mathbf{x}_1,\omega)p^*(\mathbf{x}_2,\omega)\rangle &= \frac{\Theta}{\pi\omega^3}\left\{\int_{\Omega^{(f)}}\left(\mathrm{Im}\frac{1}{\rho c^2}\right)[G(\mathbf{y},\mathbf{x}_1,\omega)+\mathbf{g}(\mathbf{y},\mathbf{x}_1,\omega)\cdot\nabla p_0]\right.\\ &\times[G(\mathbf{y},\mathbf{x}_2,\omega)+\mathbf{g}(\mathbf{y},\mathbf{x}_2,\omega)\cdot\nabla p_0]^* d^3\mathbf{y}\\ &+\int_{\Omega^{(s)}}[\omega^2\mathbf{g}(\mathbf{y},\mathbf{x}_1,\omega)\cdot\mathbf{g}^*(\mathbf{y},\mathbf{x}_2,\omega)\mathrm{Im}\,\rho\\ &\left.+\tilde{s}_{mn}(\mathbf{y},\mathbf{x}_1,\omega)\tilde{s}^*_{jk}(\mathbf{y},\mathbf{x}_2,\omega)\mathrm{Im}\,\alpha_{jkmn}]d^3\mathbf{y}\right\}.\end{aligned} \tag{36}$$

This result extends earlier calculations of the thermal noise cross-correlation in homogeneous or weakly inhomogeneous quiescent fluid[50,62] and in an arbitrary inhomogeneous moving fluid[43] to flow-structure problems. As long as thermal fluctuations have Gaussian statistics, knowledge of the correlation function (36) provides a full description of the random field $p(\mathbf{x},\omega)$ and enables one to calculate any statistical moment of the pressure fluctuations.[3]

From the property (10) of the elastic modulus and compliance tensors and Eq. (7), which relate displacements $\mathbf{g}$ and stresses s_{mn} due to the same source within the fluid, it follows that $s_{mn}(\mathbf{y},\mathbf{x}_1)s^*_{jk}(\mathbf{y},\mathbf{x}_2)\mathrm{Im}\,\alpha_{jkmn} = -(\partial g_m/\partial y_n)(\mathbf{y},\mathbf{x}_1)\times(\partial g^*_j/\partial y_k)(\mathbf{y},\mathbf{x}_2)\mathrm{Im}\,C_{jkmn}$. Then, using the integral identity (25) and the symmetry property (23) of the Green's functions, from Eq. (36) we obtain

$$\begin{aligned}\langle p(\mathbf{x}_1,\omega)p^*(\mathbf{x}_2,\omega)\rangle = &-(2\pi\omega^2)^{-1}\Theta[G(\mathbf{x}_1,\mathbf{x}_2,\omega)\\ &+G^*(\mathbf{x}_2,\mathbf{x}_1,\omega)].\end{aligned} \tag{37}$$

Thus, in the frequency domain, the cross-correlation of thermal noise equals the product of a temperature-dependent function, which does not depend on coordinates, and a sum of the CW Green's functions, which describe sound propagation in opposite directions between the two points. In the particular case of motionless media, the Green's function G is reciprocal according to Eq. (23), and the sum reduces to twice the real part of the Green's function. The simple and general relation (37) between the two-point correlation of thermal pressure fluctuations and the deterministic Green's function, i.e., the pressure field due to a point source of volume velocity, in fluid-solid systems with flow does not differ from the result[43] derived previously in the fluid case.

The two-point correlation of the spectral densities of stress fluctuations within the solid in a fluid-solid system in thermal equilibrium can be calculated using Eqs. (31), (34), and (35). With Θ [Eq. (33)] being independent of position,

we find

$$\langle \sigma_{mn}(\mathbf{x}_1,\omega)\sigma^*_{jk}(\mathbf{x}_2,\omega)\rangle = \frac{\Theta}{\pi\omega^3}\left\{\int_{\Omega^{(f)}} \mathrm{Im}\frac{1}{\rho c^2}\left[\frac{1}{3}\tilde{S}_{mn,ll}(\mathbf{y},\mathbf{x}_1,\omega) + \tilde{\mathbf{T}}_{mn}(\mathbf{y},\mathbf{x}_1,\omega)\cdot\nabla p_0\right]\times\left[\frac{1}{3}\tilde{S}_{jk,rr}(\mathbf{y},\mathbf{x}_2,\omega) + \tilde{\mathbf{T}}_{jk}(\mathbf{y},\mathbf{x}_2,\omega)\cdot\nabla p_0\right]^* d^3\mathbf{y} + \int_{\Omega^{(s)}} [\omega^2\tilde{\mathbf{T}}_{mn}(\mathbf{y},\mathbf{x}_1,\omega)\cdot\tilde{\mathbf{T}}^*_{jk}(\mathbf{y},\mathbf{x}_2,\omega)\mathrm{Im}\ \rho + \tilde{S}_{mn,lq}(\mathbf{y},\mathbf{x}_1,\omega)\tilde{S}^*_{jk,rs}(\mathbf{y},\mathbf{x}_2,\omega)\mathrm{Im}\ \alpha_{lqrs}(\mathbf{y})]d^3\mathbf{y}\right\}. \quad (38)$$

In order to simplify this result, we multiply Eq. (38) by arbitrary symmetric tensors E_{mn} and E^*_{jk}, use Eq. (7) to express $\tilde{S}_{mn,lq}$ and $\tilde{S}^*_{jk,rs}$ in the integral over $\Omega^{(s)}$ in terms of $\tilde{\mathbf{T}}_{mn}$ and $\tilde{\mathbf{T}}^*_{jk}$:

$$E_{mn}\tilde{S}_{mn,lq}(\mathbf{y},\mathbf{x}_1,\omega) = C_{lqrs}(\mathbf{y})[E_{mn}\,\partial T_{mn,m'}(\mathbf{y},\mathbf{x}_1,\omega)/\partial y_{n'} - i\omega E_{m'n'}\delta(\mathbf{y}-\mathbf{x}_1)],$$

$$E^*_{jk}\tilde{S}^*_{jk,rs}(\mathbf{y},\mathbf{x}_2,\omega) = C_{rsj'k'}(\mathbf{y})[E^*_{jk}\,\partial T^*_{jk,j'}(\mathbf{y},\mathbf{x}_2,\omega)/\partial y_{k'} - i\omega E_{j'k'}\delta(\mathbf{y}-\mathbf{x}_2)],$$

and apply Eq. (10) to relate imaginary parts of the material tensors $\alpha_{lqr\,s}$ and C_{lqrs}. After some algebra, involving the symmetry property (26) and the integral identity (27) for the Green's tensors $S_{mn,lq}$ and $\mathbf{T}_{mn}$, from Eq. (38) we obtain the simple relation

$$\langle \sigma_{mn}(\mathbf{x}_1,\omega)\sigma^*_{jk}(\mathbf{x}_2,\omega)\rangle = -(2\pi\omega^2)^{-1}\Theta[S_{jk,mn}(\mathbf{x}_1,\mathbf{x}_2,\omega) + S^*_{mn,jk}(\mathbf{x}_2,\mathbf{x}_1,\omega)] \quad (39)$$

between the cross-correlation function of thermal fluctuations of stresses within the solid and the deterministic Green's tensor corresponding to sources of the external strain. Equation (39) extends to flow-structure problems the Rytov's calculation[62] of the thermal noise cross-correlation in an isotropic homogeneous solid. Note that as in Eq. (37), the right-hand side of Eq. (39) contains Green's tensors describing wave propagation in opposite directions between the points $\mathbf{x}_1$ and $\mathbf{x}_2$.

Remarkably, the parameters specifying dissipative properties of the medium drop out from the final results, Eqs. (37) and (39). These equations express the elastic wave counterpart of the result established much earlier for equilibrium thermal electromagnetic fields (Ref. 2, Sec. 3.9; Ref. 3, Sec. 15) in motionless dielectrics.

In the high-temperature limit, Θ becomes independent of frequency: $\Theta(T,\omega)\approx\kappa T$, and, as pointed out in Ref. 43, Eq. (37) can be concisely written in the time domain. If one defines the cross-correlation function $C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,\tau)$ of statistically stationary pressure fluctuations within the fluid and the power spectrum $C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,\omega)$ of the fluctuations in a standard way as

$$C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,\tau) \equiv \langle p(\mathbf{x}_1,t-\tau)p(\mathbf{x}_2,t)\rangle = \int_{-\infty}^{+\infty} C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,\omega)e^{-i\omega\tau}d\omega, \quad (40)$$

then $C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,\omega)=\langle p^*(\mathbf{x}_1,\omega)p(x_2,\omega)\rangle$, and from Eq. (37) we find

$$(\partial^2/\partial\tau^2)C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,\tau) = (2\pi)^{-1}\Theta[G(\mathbf{x}_1,\mathbf{x}_2,-\tau) + G(\mathbf{x}_2,\mathbf{x}_1,\tau)]. \quad (41)$$

Because of causality, $G(\mathbf{x},\mathbf{y},t)=0$ at $t<0$. Hence,

$$G(\mathbf{x}_2,\mathbf{x}_1,\tau) = \frac{2\pi}{\kappa T}\frac{\partial^2}{\partial\tau^2}C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,\tau), \quad (42)$$

$$G(\mathbf{x}_1,\mathbf{x}_2,\tau) = \frac{2\pi}{\kappa T}\frac{\partial^2}{\partial\tau^2}C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,-\tau), \quad \tau>0.$$

In motionless media, cross-correlation function $C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,\tau)$ is an even function of time delay τ; in moving fluid, according to Eq. (42), the difference $C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,\tau) - C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,-\tau)$ provides a measure of acoustic nonreciprocity.

Quite similarly, the Green's tensors $S_{mn,jk}(\mathbf{x}_1,\mathbf{x}_2,t)$ in the time domain can be retrieved from measurements of the cross-correlation function

$$C^{(\sigma)}_{mnjk}(\mathbf{x}_1,\mathbf{x}_2,\tau) \equiv \langle \sigma_{mn}(\mathbf{x}_1,t-\tau)\sigma_{jk}(\mathbf{x}_2,t)\rangle = \int_{-\infty}^{+\infty} C^{(\sigma)}_{mnjk}(\mathbf{x}_1,\mathbf{x}_2,\omega)e^{-i\omega\tau}d\omega \quad (43)$$

of fluctuations of the stress tensor components within the solid. Because of causality, $S_{mn,jk}(\mathbf{x}_1,\mathbf{x}_2,t)=0$ at $t<0$. Then, from Eqs. (39) and (43) it follows that

$$S_{jk,mn}(\mathbf{x}_2,\mathbf{x}_1,\tau) = \frac{2\pi}{\kappa T}\frac{\partial^2}{\partial\tau^2}C^{(\sigma)}_{mn,jk}(\mathbf{x}_1,\mathbf{x}_2,\tau),$$

$$S_{jk,mn}(\mathbf{x}_1,\mathbf{x}_2,\tau) = \frac{2\pi}{\kappa T}\frac{\partial^2}{\partial\tau^2}C^{(\sigma)}_{mn,jk}(\mathbf{x}_1,\mathbf{x}_2,-\tau), \quad \tau>0. \quad (44)$$

Note that in a solid in a mechanical contact with a fluid flow, generally $C^{(\sigma)}_{mn,jk}(\mathbf{x}_1,\mathbf{x}_2,\tau)\neq C^{(\sigma)}_{mn,jk}(\mathbf{x}_1,\mathbf{x}_2,-\tau)$ and elastic wave propagation is nonreciprocal, although the solid itself is macroscopically motionless. Like Eq. (38) used in the derivation of Eq. (44), the latter applies also in the case where one of the points $\mathbf{x}_1$ and $\mathbf{x}_2$ is located within the fluid while the other is within the solid.

The results (42) and (44) will hold at an arbitrary temperature T if one replaces the noise correlation functions by their appropriately filtered versions, the filter shape being uniquely determined by the frequency dependence $\Theta(T,\omega)$ [Eq. (33)] of the mean energy of a quantum oscillator.

VII. DISCUSSION

In view of the extensive earlier work reviewed in Sec. I, it is now widely expected that a two-point correlation function of ambient noise provides an estimate of or is "essentially equal"[60] to a deterministic Green's function. The actual questions, then, are: under what conditions does the relation between the cross-correlation and Green's functions take place, whether it is exact or approximate, and what is the nature of the approximation. Answers to these questions are system-specific. In Secs. II–VI, we considered thermal fluctuations in rather general fluid-solid systems with stationary inhomogeneous flow. Such mechanical systems, while encountered in a wide range of applications, apparently do not belong to the class of systems covered by recent "unified" derivations[42,60,63] of the relation between the noise cross-correlation and Green's function. Moreover, our approach differs from some earlier work[6,39,42,64,65] in that, instead of *assuming* noise source properties, which simplify derivations and/or lead to a compact relation between noise cross-correlations and deterministic Green's functions, we *derive* effective macroscopic sources of thermal noise from the first principles.

In the analysis of thermal fluctuations in Secs. V and VI, we have purposefully avoided energy equipartitioning arguments.[8,9,41,44,63] Instead, the FDT is used in the spectral form proposed by Rytov[1–3,56] to determine local densities of equivalent macroscopic sources of thermal noise. This leads to Eqs. (36) and (38), which describe statistics of thermal fluctuations in heterogeneous systems with *variable* temperature. In the special case of position-independent temperature, integral expressions (36) and (38) for the thermal noise cross-correlation simplify greatly and allow for exact local relations (37), (42), and (44) with deterministic Green's functions (tensors).

Weaver and Lobkis[7,8] presented an elegant proof of equivalence between pulse echo response, defined as voltage in a receiver circuit of an acoustic transducer after emission of a short pulse by the same transducer, and cross-correlation of thermal noise in the receiver circuit of the transducer. The derivation assumes thermal equilibrium, relies on the Callen–Welton formulation[66] of the FDT, and is valid in the limit of vanishing resistive part of electro-mechanical impedance of the transducer. The derivation[7,8] is remarkably simple and does not require an actual analysis of fields of elastic waves. A difficulty of extending the derivation to noise cross-correlation was pointed out.[7,8] In contrast to this approach, the results obtained in Secs. V and VI are formulated in terms of acoustic observables and apply to both cross-correlation and autocorrelation functions of noise.

This paper extends earlier analyses of thermal noise in inhomogeneous moving fluids[43] and motionless fluids[50] and solids[7,8,62] to bounded or unbounded coupled fluid–anisotropic solid systems with arbitrary inhomogeneous fluid flow; the fluid and the solid can be arbitrarily inhomogeneous, and neither fluid nor solid domains are required to be simply connected or finite. Remarkably, at thermal equilibrium (but not in the general case of spatially varying temperature), the relation between the cross-correlation of thermal pressure fluctuations and the deterministic Green's function is unaffected by the presence of the solid. Unlike an earlier theory[7,8] of thermal noise correlation in motionless media, our results apply equally to open systems, waveguides, and resonators.

It should be emphasized that the appearance of the relation between the noise correlation function and the Green's function depends on the definition of the latter and on the choice of a physical observable used to represent the noise. For instance, if the Green's function were defined as the pressure field due to a source of volume velocity with $B=\delta(\mathbf{x}-\mathbf{x}_1)\delta(t)$ instead of $B=\delta(\mathbf{x}-\mathbf{x}_1)\delta'(t)$, first-order derivatives with respect to τ would appear in Eq. (42) instead of the second-order derivatives. If the Green's function were defined as the acoustic pressure due to a source with $B=\delta(\mathbf{x}-\mathbf{x}_1)H(t)$, where $H(t)$ denotes the step function, the Green's function $G(\mathbf{x}_2,\mathbf{x}_1,t)$ would be proportional to the correlation function $C^{(p)}(\mathbf{x}_1,\mathbf{x}_2,t)$ of thermal pressure fluctuations at high temperatures. Furthermore, if the Green's function were defined as the acoustic pressure within the fluid due to a source of an external force, rather than a source of volume velocity, no relation as simple as Eq. (42) would hold in the general case of inhomogeneous fluid flow with or without solid inclusions. For the simple relations (44) between cross-correlation of noise within the solid and the deterministic Green's tensor $S_{jk,mn}$ to be valid, the noise has to be characterized in terms of the stress tensor fluctuations.

The practical significance of our theoretical findings lies in their possible application to passive acoustic characterization of fluid-solid systems, including monitoring of the physical parameters of inhomogeneous flows. In many geophysical, engineering, and biomedical applications, the flow velocity is small compared to the phase speed of elastic waves. For instance, the ratio of velocity of ocean currents and winds in the troposphere to sound speed typically does not exceed 3×10^{-4} and 5×10^{-2}, respectively. Admissible absolute errors in flow velocity measurements are often much smaller than uncertainty in knowledge of the sound speed. The difficulties of remote sensing of slow flows in uncertain environments are overcome by measurements of acoustic nonreciprocity in reciprocal transmission experiments, where time-synchronized acoustic transceivers, i.e., a combination of a sound source and receiver(s), are employed to generate and receive signals propagating in opposite directions.[67,68] Non-reciprocity of acoustic observables, such as the difference in travel times or phases of waves propagating between two points in opposite directions, is induced by fluid flow, vanishes in quiescent media, and is insensitive to uncertainties in sound speed and system geometry. Reciprocal transmission experiments enable active acoustic tomography of slow flows.[67,68] Equations (37), (39), (42), and (44) demonstrate that all the information normally obtained via active reciprocal transmissions is retrievable from cross-correlation of thermal noise. Note that one can make noise measurements in a motionless part of the fluid or within the solid (e.g., within or on the external wall of a pipe carrying a fluid flow). Thus, ambient noise cross-correlation can be employed for passive acoustic characterization of inhomogeneous flows in fluid-solid environments.

Passive acoustic techniques offer important advantages over remote sensing of ocean and atmosphere with active techniques: low cost (a receiver substitutes a technologically much more complicated transceiver) and possibility of noninvasive (in particular, avoiding any harm to marine life potentially associated with powerful underwater sound sources and likely annoyance to local populations associated with active acoustic tomography of the atmosphere) and clandestine measurements in denied areas. Furthermore, the passive systems allow for exploitation of extremely broad bandwidth of ambient noise, which exceeds by far the bandwidth of available non-explosive manmade sound sources used in remote sensing; much longer periods of autonomous operation due to drastic reduction in power consumption; and increased spatial resolution of measurements due to the greater number of paths along which the Green's function is evaluated, compared to an active system with the same number of sensors. The chief potential benefit for biomedical applications lies in the noninvasive nature of passive *in vivo* measurements.[35,49,53] The key practical limitation of the approach is the requirement of a sufficiently long averaging time necessary to evaluate the correlation function of noise, during which the system needs to remain time-invariant.

The theoretical results presented above can be extended to ambient noise of non-thermal origin, which is due to random sources distributed on boundaries and interfaces or within the solid and the fluid. When the density of the random sources is not necessarily connected to the local dissipative properties of the medium, no exact local relation between the noise cross-correlation and deterministic Green's functions generally holds. However, an asymptotic estimate of the Green's functions can be obtained from the noise cross-correlation of high-frequency waves when the wavelength is small compared to spatial scales of variability of the parameters of the medium and statistical moments of densities of the random sources. This extension of the theory will be presented in a separate paper.

Revisiting experimental methods for studies of acidity-dependent ocean sound absorption

Timothy F. Duda[a)]
AOPE Department, MS 11, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

(Received 28 October 2008; revised 5 February 2009; accepted 6 February 2009)

The practical usefulness of long-range acoustic measurements of ocean acidity-linked sound absorption is analyzed. There are two applications: Determining spatially-averaged *p*H via absorption measurement and verifying absorption effects in an area of known *p*H. The method is a differential-attenuation technique, with the difference taken across frequency. Measurement performance versus mean frequency and range is examined. It is found that frequencies below 500 Hz are optimal. These are lower than the frequency where the measurement would be most sensitive in the absence of noise and signal fluctuation (scintillation). However, attenuation serves to reduce signal-to-noise ratio with increasing distance and frequency, improving performance potential at lower frequencies. Use of low frequency allows longer paths to be used, with potentially better spatial averaging. Averaging intervals required for detection of fluctuations or trends with the required precision are computed. © *2009 Acoustical Society of America.*

I. INTRODUCTION

Here, a multiple-frequency acoustic method to measure ocean *p*H-dependent sound absorption is reinvestigated. The method was first investigated by Jin and Worcester (1989). Using knowledge of how *p*H and absorption are related (Mellen and Browning, 1977; Brewer *et al.*, 1995), the method can be used either to determine spatially-averaged *p*H or to investigate details of absorption behavior if *p*H is known. Details regarding the first of these uses are the main focus of this paper, although the expressions can be modified for the reverse investigation. Applying the method as an acidity measure, ocean *p*H and temporal *p*H variations are estimated from the difference of sound attenuation at two (or more) frequencies. Being more specific, the technique would provide a nearly instantaneous remote measurement of sound absorption along an acoustic path, inferred mean *p*H along the path, and possibly a mean *p*H depth-profile in a slice filled by a set of acoustic paths oscillating vertically in the ocean acoustic waveguide. For studies of the temporal behavior of biogeochemical conditions over large physical scales, such an averaged *p*H measurement may (or may not) have sampling advantages over accumulated point measurements of *p*H in the situation of evolving ocean acidity having high-frequency or small-scale variability.

Global-mean ocean acidity must reflect future changes in atmospheric carbon dioxide concentration, which is rising, via flux of carbon dioxide into the ocean (see Doney *et al.*, 2009a). An estimate of the average surface ocean water *p*H reduction from preindustrial times to 1996 is 0.1 unit (Brewer, 1997; Orr *et al.*, 2005). This trend is predicted to continue, with further reduction by 0.3–0.5 units possible in the next 100 years (Caldeira and Wickett, 2005; Orr *et al.*, 2005) with consequences to biogeochemical systems (see Sec. II). Because sound absorption is inversely related to *p*H, it is possible that the ocean may become sonically noisier, all else constant (Hester *et al.*, 2008). Measurements of global *p*H conditions are thus desirable. If trends are spatially broad and temporally smooth, infrequent and sparse localized *p*H measurements would adequately detect the conditions. If there are significant small-scale variations as suggested by Doney *et al.* (2009b), then more frequent and comprehensive measurements would be required to detect trends amidst the fluctuations.

Measurements of average large-scale *p*H conditions are typically made by accumulating point measurements along transects (Fig. 1) via programs such as the World Ocean Circulation Experiment (WOCE), the Joint Global Ocean Flux Study, and follow-up studies, or with time series (Fig. 2). More frequent or spatially-averaged measurements could be made with the acoustic method, if required. An acoustic measure of *p*H would have less accuracy and precision than individual point measurements but may provide equally valid mean estimates in the case of considerable variability of the individual measurements.

The acoustic measurement methodology for *p*H-dependent absorption has been established by prior research (Jin and Worcester, 1989; Brewer *et al.*, 1995). However, thorough analysis and implementation have lagged theoretical and technical readiness. Recent advances in ocean acoustic systems and in observations of long-range signal fluctuations (which add uncertainty to the measurement) make this a good time to revisit this technology. Inexpensive and reliable sound projectors are available at frequencies of 200–600 Hz. These are suitable for long-term use at ocean observatories that are coming online, along with highly capable receiver systems assembled from off-the-shelf components. In light of this new technology and new interest in possible trends in ocean acidity, this paper builds on the

ence of two (or more) frequencies must be determined after propagation over fairly long distances of a few hundred kilometers, but such propagation degrades signal-to-noise ratio and introduces variability via scattering from mesoscale, internal wave, and surface wave phenomena. In this paper, signal averaging requirements necessary to achieve useful results are analyzed.

The methodology can be described very simply. Research has established the relationship between aqueous boric acid-borate equilibrium and energy absorption of sound below 1 kHz (Fisher and Simmons, 1977), although some anomalous behavior has been identified which suggests some interaction between borate and other ions occurs in the ocean (Mellen *et al.*, 1981, 1983). Pressure-sensitive reactions of the relevant ions modify the phase lag between pressure and velocity in sound waves, leading to energy loss. This is linked to *p*H because the concentration of hydroxide OH^- (Mellen and Browning, 1977) and/or carbonate CO_3^{2-} (Mellen *et al.*, 1983) plays a role. The kinetic behavior of the slowest reaction introduces a time scale of about a 100 ms, giving the 1 kHz transition frequency (Zeebe *et al.*, 2001). At high frequencies sound absorption is dominated by other processes and is not strongly dependent on *p*H, whereas below 10 kHz it is strongly *p*H dependent. This makes the shape of the absorption curve in the transition region, centered at about 600 Hz, *p*H-dependent in a manner that allows *p*H to be estimated from the shape of the curve. The absolute absorption at low frequency is also *p*H dependent, but can be difficult to measure because of uncertain net scattering loss. The shape of the absorption curve, determined by comparing signal level at two or more frequencies, is more sensible to study experimentally than absolute absorption because many propagation and scattering processes also affecting signal level are weak functions of frequency. That is, differencing over frequency minimizes detrimental scattering effects if they are weak functions of frequency (Jin and Worcester, 1989).

The differential technique can reduce or eliminate interference from mesoscale and weak internal-wave scattering, as long as such scattering does not cause wavefronts to break up into discernable micro-multi-path arrivals. However, some internal-wave induced fluctuations will exist, caused by interfering micro-fronts, and must be averaged over. Jin and Worcester (1989) recognized this as a major concern. They estimated the number of independent samples needed to provide useful measurements of *p*H (better than 0.05 accuracy) to lie in the range of 44–100 for the case of 450–650 Hz signals propagated 750 km, with sample independence attained when sample spacing exceeds the acoustic fluctuation time scale of tens of minutes. Results from internal-wave induced fluctuation research over the past two decades are incorporated here into a new analysis to re-determine the best frequencies to use and the number of samples needed. It is found that slightly lower frequencies are better, and that many more than the previous estimate of 100 samples may be needed.

The methodology is reviewed here from beginning to end, and the sampling requirements re-examined. First, motivation for ocean acidity and sound absorption studies is

discussed (Sec. II). Next, the physical chemistry of the problem is reviewed (Sec. III). In Sec. IV, the sensing method using long-range propagation is outlined [Jin and Worcester (1989) redux]. Section V examines the effectiveness of various frequency bands and path lengths in an idealized situation with steady acoustic propagation conditions and additive noise. Section VI shows how the probable presence of signal fluctuations dramatically increases the number of required samples that would need to be averaged together to obtain good results. Section VII summarizes the work.

II. MOTIVATION

Global ocean *p*H is likely to decrease because of ocean uptake of carbon dioxide deposited by society into the atmosphere. It is accepted that global surface *p*H has been reduced from 8.2 to 8.1 in the past 200 years (Brewer, 1997). Models predict that the surface *p*H will continue to drop as the atmospheric carbon dioxide concentration increases (Caldeira and Wickett, 2005). Local conditions such as vertical *p*H profiles throughout the world may be less amenable to prediction. A notable implication is that probable future inorganic carbon uptake by the ocean and oceanic *p*H reductions have the potential to profoundly affect calcium carbonate shelled or skeleton-producing animals, including (but not limited to) small pteropods, coral, clams, and lobsters (e.g., Feely *et al.*, 2004; Orr *et al.*, 2005, and references cited therein).

Changes in ocean *p*H whether from anthropogenic CO_2 or from other causes are equally important acoustically. The acid level responds to other factors besides uptake of carbon dioxide, such as decreased ventilation from changes in physical climate, many of which are also likely to reduce *p*H (Hester *et al.*, 2008). A simplified view of the carbon uptake effect is given: Aqueous carbon dioxide combines with water to form carbonic acid, which can dissociate into bicarbonate and hydrogen ions, or carbonate and two hydrogen ions. Because bicarbonate is very soluble, hydrogen ions and available carbonate ions will tend to form bicarbonate, which buffers the system against *p*H drop. However, this reduces carbonate concentration, which has the detrimental effect on calcium carbonate mineral structures. Even in water remaining supersaturated with respect to calcium carbonate, decreased calcification rates are expected (Orr *et al.*, 2005).

Such *p*H and carbonate changes would affect localized ecosystems at coastal margins (Feely *et al.*, 2008; Wootton *et al.*, 2008) as well as pelagic ecosystems and their fisheries such as tuna. Coastal ecosystem alteration would have significant natural and economic impact, and may indeed be closely tied to what is happening offshore. Therefore, both coastal and pelagic situations are of interest. The deep-sea ocean volume in some sense sets the boundary condition for regional acidity, and may serve as a reservoir or be a driver of change. Orr *et al.* (2005) and Feely *et al.* (2004) showed that subpolar regions are likely to be the first to reach undersaturation of calcium carbonate minerals calcite and aragonite, with probable pronounced biological impacts in those important areas.

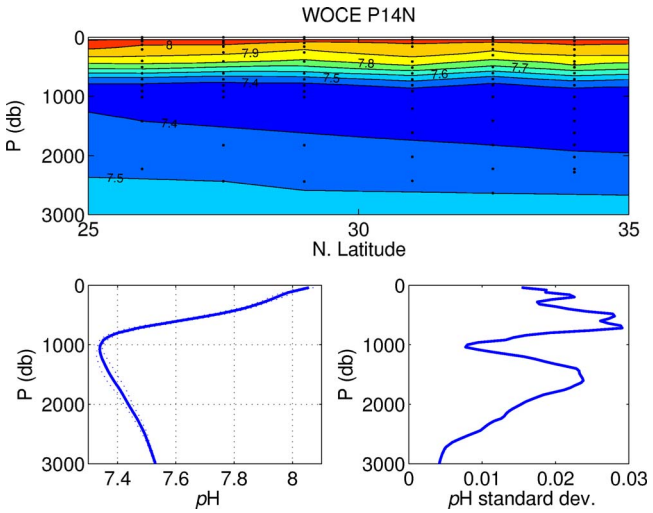

FIG. 3. (Color online) A portion of WOCE transect P14N from 1993 (Fig. 1) is shown in the top panel. The longitude is approximately 180°. The mean profile is shown at lower left, and the standard deviation profile at lower right. The dots in the upper panel show the locations of the data points. Data are from the Carbon Dioxide Information Analysis Center (CDIAC, 2009a).

Tracking *p*H in certain areas over time with effective averaging of short-term and small-scale variability may be desirable to assess the progress of these changes. However, representative measures of average deep-sea *p*H using ships are expensive. Sections of oceanic *p*H show mesoscale spatial and temporal variations (Fig. 1), which must be averaged over time and space in order to determine mean values and trends. At least two papers show scatter plots of oceanic *p*H from hydrographic cruises with fluctuations of ± 0.05 about a mean profile (Brewer *et al.*, 1995; Ternon *et al.*, 2001) illustrating the natural variability and possible sampling problem. Hawaii Ocean Timeseries (HOT) measurements show similar variability (Fig. 2), as do transects of *p*H (Fig. 3).

There are many features of the global carbonate system that may or not be stable. An example is the subsurface tongue of low *p*H seen in Figs. 1 and 3. This is associated with low surface *p*H in the subpolar region associated with carbon dioxide flux into the ocean at those higher latitudes due in part to thermodynamic effects (Takahashi *et al.*, 2006). The feature is consistent with low alkalinity tongues descending from the subpolar North Pacific in hydrography sections (CDIAC, 2009b). Similar features occur in the South Atlantic and South Pacific but not in the North Atlantic.

A full examination of *p*H variability in the Atlantic Ocean is available (Ternon *et al.*, 2001). The work shows that *p*H can be predicted from various local parameters (temperature, salinity, oxygen concentration, nitrate concentration, etc., not including carbon dioxide and carbonate) but only to within roughly 0.02.

Note that reduced ocean *p*H would mean reduced absorption of sound below a few kilohertz, possibly causing the ocean to become noisier at those frequencies, all else equal (Hester *et al.*, 2008).

One approach toward quantifying trends in oceanic *p*H, and associated sound absorption, and testing our ability to predict them would be implementation of a frequency-

dependent acoustic absorption system in the deep sea [Jin and Worcester (1989) type]. An acoustic system could automatically and make repeated instantaneous spatially-averaged measurements and may be able to make the absorption and *p*H measurements with useful precision and accuracy. This technique could prove cost effective with respect to ship-survey *p*H methods, particularly if implemented south of 40° S, one of the subpolar areas at risk of profound carbonate biogeochemistry change. Other reasons for measuring the *p*H of the pelagic ocean are that pelagic *p*H modeling may be more robust than in coastal regions and may be at the point of testability, and that spatial averaging over the known scales of natural variability with long-range acoustics is straightforward. The acoustic measurement resolution limit for *p*H will be shown to be about 0.05, larger than the variations shown in Figs. 2 and 3 for the central North Pacific, and thus would be unable to improve upon transect-mean estimates from areas having comparable variability. The acoustic technique would be most useful in areas with higher spatial variability or strong temporal variability.

III. *p*H -DEPENDENT SOUND ABSORPTION FROM BORATE RELAXATION

A solution containing the borate ion ($B(OH)_4^-$) and boric acid ($B(OH)_3$), present in small quantities in ocean water, changes volume when the dissolved boric acid/borate changes between three states, the end members being boric acid and borate. The volume change causes absorption as described below. Many coupled reactions may occur in concert with the borate reactions. A concise recent summary of uncertainties regarding the chemistry appears in Hester *et al.*, 2008. The simplest candidate reaction that may result in sound absorption is

$$B(OH)_3 + OH^- \leftrightarrow B(OH)_3 \cdot OH^- \leftrightarrow B(OH)_4^- \quad (1)$$

(Mellen and Browning, 1977; Mellen *et al.*, 1980), which does not involve other coupled reactions. This describes absorption data qualitatively but not quantitatively. Boric acid concentration exceeds borate at oceanic *p*H. This process roughly explains the frequency dependence of absorption because the right-hand step has the slower time constant than the other (somewhere around a millisecond) and yields a reduction in volume. The equilibrium state of Eq. (1) is pressure-dependent, explaining why acoustic waves trigger the transient volume changes. The system thus has what might be loosely described as a dynamic compressibility, which gives sound-speed an imaginary component (Liebermann, 1949). The borate acoustic absorption with relaxation frequency in the 1 kHz range was identified in the laboratory (Yeager *et al.*, 1973). That work followed earlier work involving salts with higher relaxation frequencies, primarily magnesium sulfate. Another system of reactions with similar absorption behavior is

$$\begin{array}{ccc} H_2O + B(OH)_3 + OH^- + CO_3^{2-} & \leftrightarrow & B(OH)_4^- + HCO_3^- + OH^- \\ \updownarrow & & \updownarrow \\ H_2O + B(OH)_3 \cdot OH^- + CO_3^{2-} & \leftrightarrow & B(OH)_4^- + H_2O + CO_3^{2-} \end{array} \quad (2)$$

(Mellen *et al.*, 1983). This is a reduced notation for a few possible systems that include pairing of some of the ions with metallic ions. The horizontal steps are the slow ones associated with low-frequency absorption. This system was proposed to account for absorption differences between solutions of borate alone and artificial seawater solutions containing dissolved inorganic carbon. Both Eqs. (1) and (2) involve *p*H via the role of the OH^- concentration.

The dissolution of CO_2 in the ocean and the subsequent formation of carbonic acid (H_2CO_3) change the concentration of hydroxide (OH^-) by releasing protons and forming three ions: bicarbonate (HCO_3^-), carbonate (CO_3^{2-}), and hydronium (H_3O^+, equivalent for our purposes to protons, H^+). (This changes the *p*H, the negative of the base-10 logarithm of hydronium concentration.) The hydronium ions react with the OH^- ions in the alkaline ocean to form water, changing the OH^- concentration, and thus also changing the relative concentrations of boric acid and borate, which alters the absorption because the transient reactions of Eq. (1) and/or Eq. (2) proceed at levels determined by the concentrations. In the weakly alkaline ocean, the reagent in Eq. (1) or Eq. (2) with least concentration is the hydroxide ion, so the reaction is closely coupled to its concentration. As a result, absorption is an increasing function of *p*H (decreasing function of acidity). This *p*H dependency is independent of the sum concentration of borate and boric acid, which is essentially proportional to salinity.

Two additional chemical species cause absorption, magnesium sulfate and magnesium carbonate, but they have higher relaxation frequencies. Their absorptions are weak with respect to that of borate and are essentially constant with respect to frequency and *p*H at the low frequencies of interest here.

IV. DIFFERENTIAL-ATTENUATION MEASUREMENTS OF ABSORPTION

Using notation in Brewer *et al.* (1995), the coefficient of sound absorption (units dB/km) can be written as

$$\alpha(f) = \alpha_b(f) + \alpha_m(f) + \alpha_c(f). \quad (3)$$

Below 1 kHz the *p*H-sensitive borate term α_b dominates. Below 700 Hz the other terms (magnesium sulfate α_m and magnesium carbonate α_c) can be neglected (Fisher and Simmons, 1977). Signal power in decibels is defined as a ratio $P = 10\log_{10}(I/I_0)$, where I is intensity (peak amplitude squared for a sine wave) and I_0 is a reference value. The borate term can be written as

$$\alpha_b = (S/35)A_b(f^2 f_b/(f^2 + f_b^2)), \quad (4)$$

where $A_b = 0.1$ K, $f_b = 0.9 \times 10^{T/70}$ kHz, S is salinity (psu), and T is temperature (°C). The *p*H-dependence (NBS *p*H scale) is contained in $K = 10^{(p\mathrm{H}-8)}$. Figure 4 shows borate absorption versus frequency for various *p*H values at fixed salinity and temperature. The measurement of absorption (and thus of *p*H if the other parameters are sufficiently well known) cannot be reliably made by measuring signal strength at one frequency in the ocean because acoustic forward scattering processes from mesoscale eddies, surface en-

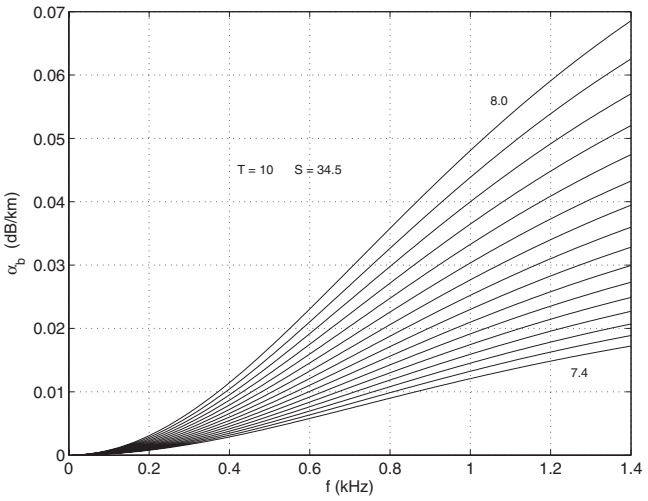

FIG. 4. Borate absorption α_b as a function of frequency is plotted for temperature 10° and salinity 34.5 for *p*H from 7.4 to 8.0 by 0.04 increments. Total absorption values at 1 kHz are 18% higher (*p*H 8.1) to 65% higher (*p*H 7.4) than the borate absorption.

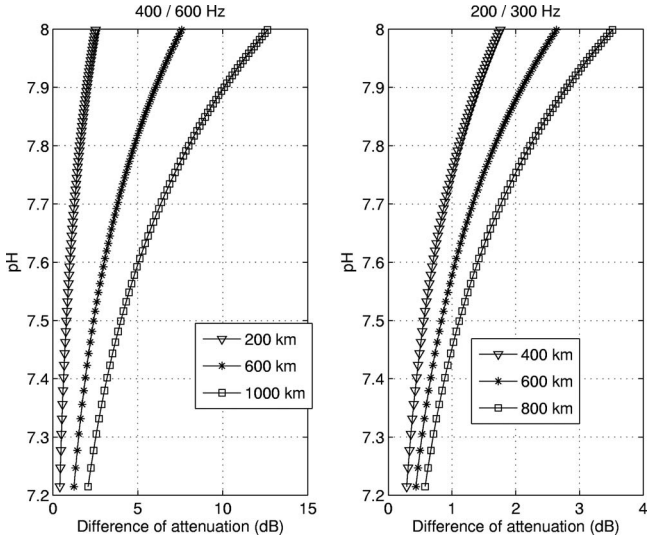

FIG. 5. D_A versus *p*H computed using expression (10) is plotted for two different frequency pairs and a few propagation distances.

counter, and seabottom encounter cause large fluctuations in energy. However, *p*H-dependent sound absorption due to borate is a function of frequency, so that the fingerprint of this process can be obtained using energy measurement at two or more frequencies, enabling recovery of *p*H. This assumes that scattering loss differences between the frequencies are small. For the frequencies investigated here, this is most questionable for surface reflecting rays in high sea states (Erbe and Farmer, 2000; Brekhovskikh and Lysanov, 1982). Such rays may be the only type available for long-range paths in polar regions; in other areas fully refracted rays should be available.

Loosely following Jin and Worcester (1989) but altering the equations to include updated information in Brewer *et al.* (1995), the differential attenuation along a single propagation path Γ with arc increment ds is given by

$$D_A(f_1,f_2) = \int_\Gamma \alpha(f_2)ds - \int_\Gamma \alpha(f_1)ds = \int_\Gamma \int (\partial\alpha(s)/\partial f)dfds, \quad (5)$$

where f is frequency in kilohertz. The paths are the same, so after retaining only the dominant term α_b,

$$D_A = \int_\Gamma (S(s)/35)A_b(s)f_b(s)\left(\frac{f_2^2}{f_2^2+f_b^2(s)} - \frac{f_1^2}{f_1^2+f_b^2(s)}\right)ds. \quad (6)$$

The position-dependent terms (those dependent on s) are functions of either T or *p*H. If *p*H is known then measurement of D_A would test the veracity of the expressions for K, A_b, and f_b. Alternatively, comprehensive inversion of a group of ray-integrals (6) using methods in Munk *et al.*, 1995 would provide S, K (thus *p*H), and f_b (thus T) as functions of position in a source-receiver vertical slice. However, acoustic data alone would probably be insufficient for a complete two-dimensional inversion. A reasonable approach more likely to yield reliable inversion would be to divide the integrals into a few parts each corresponding to depth increments, such as 0–100 m, 100–200 m, etc., and to incorporate auxiliary information to refine the solution (such as limiting *p*H fluctuations to the upper kilometer, for instance). Temperature structure (affecting f_b) is sufficiently well-known to allow inversion for *p*H. A test-case published by Jin and Worcester (1989) derived a solution for a path that could be approximated with a constant T equal to 4°. This is the temperature near the sound channel axis at lower latitude sites (such as HOT, Fig. 2). A constant low temperature assumption is also suitable for polar regions. At this temperature, the frequency f_b=1 kHz (note that f_b increases to 2 kHz at 24°), and integration gives the approximate solution

$$D_A = A_bLC \quad (7)$$

for S equal to 35, where L is source-receiver distance in kilometers, and where

$$C = \frac{f_2^2}{f_2^2+1} - \frac{f_1^2}{f_1^2+1}. \quad (8)$$

From this, using the definition $A_b = 0.0237\times 10^{(0.83p\mathrm{H}-6)}$, they obtain

$$p\mathrm{H} = 0.83^{-1}\left[6 + \log_{10}\left(\frac{D_A}{0.0237LC}\right)\right]. \quad (9)$$

Using our definition of A_b and letting S vary gives the slightly different expression

$$p\mathrm{H} = 8 + \log_{10}\left(\frac{350D_A}{SLC}\right). \quad (10)$$

Figure 5 shows the differential absorption that must be measured at various frequencies and ranges to determine *p*H using this constant temperature approximation [i.e., using Eq. (10)]. Salinity of 35 psu is assumed. The measurement sensitivity is given by $d(pH)/dD_A = (\ln(10)D_A)^{-1} = 0.4343/D_A$. From Fig. 5, at 600 km range, bandwidth of 200 Hz (400, 600 Hz), a ΔpH of 0.05 at *p*H 7.6 yields ΔD_A of 0.58 dB.

Source and receiver depth placement can contribute to how Eq. (6) is utilized to investigate differential attenuation and/or *p*H. Use of near-axial acoustic rays to determine *p*H, which travel through water where *p*H and T are relatively constant, as opposed to vertically cycling rays which integrate over vertically varying T, *p*H, and thus α_b, is the scenario leading to Eqs. (7) and (10), but those paths undergo much scattering and may have amplitude fluctuations that make them unusable (Duda *et al.*, 1992; Colosi *et al.*, 1994) (effects of scattering are discussed in Sec. VI). Polar regions also have near-constant temperature (a few °C variations), although the rays cycle vertically and reflect from the surface, which may add frequency-dependent surface loss. A full vertically-dependent inverse determination would be straightforward to implement and would show a slightly different relationship between distance, D_A, and mean *p*H than Eq. (10), but Eq. (10) is used as a guideline for measurement sensitivity in Sec. V, as done by Jin and Worcester (1989). Note that receivers at multiple depths in the oceanic sound channel on a single mooring would receive eigenray signals that may be spaced such that their internal-wave fluctuation effects are independent, adding reliability to the measurement. Section VI addresses how independent measurements must be used to build statistical reliability of the method.

In a full inversion, a depth profile of *p*H is a likely result. This procedure is analogous to temperature inversion, and would require differential attenuation to be measured along more than one acoustic eigenray. Simplification (i.e., depth function parametrization) may be helpful if the approximate depth profile of *p*H is known and has its shape constrained by known processes, or if the depth profile of rms *p*H fluctuations is known (i.e., fluctuations limited to the near-surface region).

The crucial quantity α_b is T- and S-dependent at fixed *p*H, as shown. In situations where this constant T approximation is usable, neglect of expected natural T and S variations along the acoustic path would lead to errors of not more than 4% in forward modeling of D_A. This would give errors smaller than 0.03 in *p*H computation from observed D_A.

V. MEASUREMENT EFFECTIVENESS VERSUS FREQUENCY AND RANGE

To satisfy the goal of making meaningful continuous spatially-averaged measurements, long measurement ranges are desired to average over mesoscale features. The primary acoustic data, D_A, grow with range and become more easily measurable. Thus, there are two reasons why long propagation paths are desirable. This would imply that low frequencies are necessary because of the prototypical frequency dependence of absorption, which is empirically in the Pacific, for example (disregarding details appearing in Sec. IV) (Munk *et al.*, 1995)

$$\alpha(f) = 0.79A\frac{f^2}{0.8^2+f^2} + \frac{36f^2}{5000+f^2} \quad \text{dB/km}, \tag{11}$$

where f again has units of kilohertz and the geographically variable quantity A is 0.055 for the North Pacific. On the other hand, the measurement sensitivity to frequency, $|\partial\alpha/\partial f|$, related to D_A, has a peak near 0.6 kHz (Fig. 6), apparently diminishing the effectiveness of lower frequencies, as reasoned by Jin and Worcester (1989). This is shown here to not be the entire story, with a balance occurring between low differential attenuation at low frequency and short range, and low signal strength at high frequency and long range.

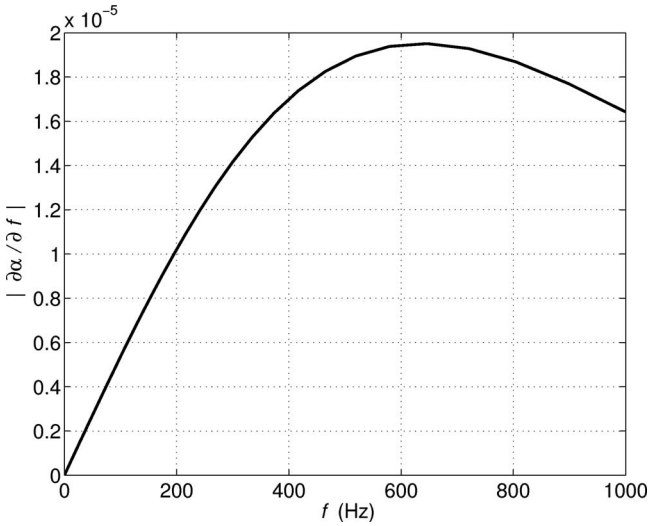

FIG. 6. The derivative of the absorption curve is shown.

A. Signal method

The system design assumed in this performance analysis section is one capable of making acoustic measurements of discrete eigenray arrivals (wavefront segments, equivalently) that are common to two (or more) frequency bands. This can involve looking at the band-edges of a wideband signal (as with Jin and Worcester, 1989), which would have lower signal to noise than the band center, or it can involve looking at two independent bands from either one source or two sources. The amplitude difference is taken to obtain D_A. In addition to occupying two or more bands, the signals in each band must have enough bandwidth to provide good coherent processing gain via pulse-compression techniques (Munk *et al.*, 1995). This is required to improve signal-to-noise ratio and to identify acoustic ray geometry if full inversion of Eq. (6) is desired. Signal strength measurements (i.e., attenuation) would be made using peak amplitudes of pulse-compression output for isolated identified eigenrays. Alternatively, spectral level of the pulse-compression output for the isolated arrivals could be used, which would correspond to a base-band version of the received signal spectrum with significant signal power gain, with gain given by the ratio of the total signal duration divided by the inverse signal bandwidth (or code digit length). Ideally, signals in each band would be transmitted at the same time from very closely spaced sources. The best situation would be to use one source with a very broad bandwidth, more than 300 Hz.

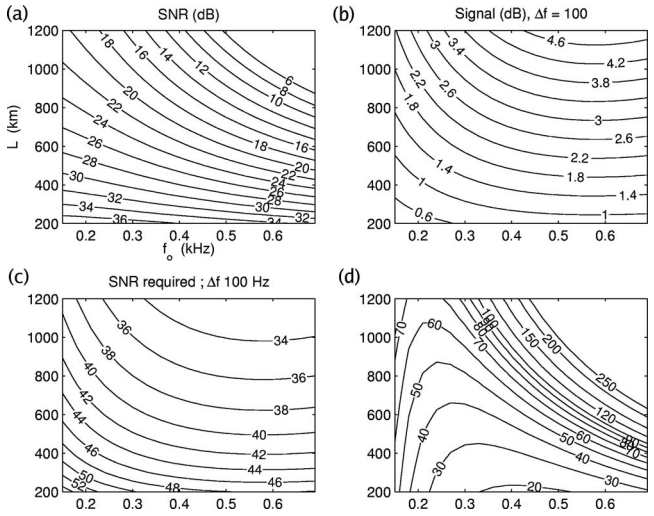

FIG. 7. Four plots display contours of four different quantities versus center frequency and path length L of a dual-frequency differential-attenuation system. (a) SNR from formula (12) is shown. PG=24 dB, SL=185 dB. (b) Signal level D_A for 100 Hz frequency difference, pH=7.8 is shown. (c) SNRR to achieve the D_A-scaled ε requirement [from (b)] for detection of a pH difference of 0.05. This is computed from Eq. (13) after determining the ε requirements from the D_A curves in (b). (d) The number of samples needed to achieve the required ε (or SNRR) computed from information in panels (a) and (c) using Eq. (14b).

B. Dependency of signal-to-noise ratio

To determine the best frequency (without building an expression for optimum frequency at this time), begin with the sonar equation

$$\mathrm{SNR}(f,L) = \mathrm{SL} - \mathrm{TLa}(f,L) - \mathrm{TLg}(L) - (\mathrm{NL}(f) - \mathrm{PG}). \tag{12}$$

The terms are signal-to-noise ratio (SNR), source level (SL), absorption transmission loss (TLa), geometrical spreading transmission loss (TLg), noise level (NL), and processing gain (PG) [PG is substituted for the conventional array gain (AG)]. Here, set source level=185 dB, noise level=65 dB (moderate sea state), and PG=24 dB for a coded pulse. TLg is conservatively expressed as spherical spreading, which approximately accounts for the division of energy into multiple arrivals by having excess loss beyond that of cylindrical spreading that might better describe pure tone transmission. Figure 7(a) shows SNR for these parameters as a function of frequency and range. SNR decreases with frequency and range.

C. Dependency of differential attenuation

Figure 7(b) shows $D_A(f,L)$ from Eq. (7) modeled for 100 Hz separation. The signal D_A increases with range and center frequency, except above 600 Hz. Note the SNR and the signal (D_A) have opposed trends in terms of suitability with respect to frequency and range.

An important aspect of the inversion problem is the accuracy of D_A measurement. For oceanic transmission measurements, there are two effects which cause difficulty in measuring this difference of two mean signal levels. One is the fact that the measurement is composed of signal plus noise, not just signal. The other is the frequency-dependence of natural signal fluctuations caused by interfering microfronts.

In the presence of Gaussian noise, Jin and Worcester (1989) showed that upper-bound of measurement error for signal strength, in decibels, is given by

$$\varepsilon = 20\log_{10}(1 + \sqrt{2} \times 10^{-\mathrm{SNRR}/20}), \tag{13}$$

where SNRR is the realized signal-to-noise ratio after pulse compression and averaging, also in decibels. The raw SNR can be improved using short-term signal averaging. Averaging N measurements gives realized signal-to-noise ratio of $\mathrm{SNRR}=\mathrm{SNR}+10\log_{10} N$. For a desired ε of 0.1 dB and a reasonable estimated SNR of 26 dB, for example, close to 40 measurements would be needed to achieve the required SNRR of 42 dB.

In the inverse sense of the problem, the required ε for an effective measurement of pH from D_A can be computed as a function of frequency and range. Expression (13) can be used to obtain SNRR, and SNR and SNRR can be used to obtain N. A starting point is the derivative of Eq. (10) given earlier. From the 200–300 Hz D_A curve in Fig. 5 for L=600 km and pH=7.8, mean D_A is about 1.7 dB and $\Delta D_A = \Delta p\mathrm{H} D_A/0.4343$ is equal to 0.20 dB for ΔpH=0.05. To measure this, assume that signal level at each frequency must be determined to an accuracy of $\Delta D_A/4$ (i.e., ε is required to be less than 0.05 dB in each band for center frequency 250 Hz, L=600 km). (These requirements are rough, and can be improved during design of an actual system using statistical methods. They serve the purpose here, yielding approximate measurement requirements versus frequency and range. Absolute numbers of required measurements may vary slightly.) Because D_A is a function of range and frequency, the required $\varepsilon(f,L)/\varepsilon(0.25,600) = DA(f,L)/DA(0.25,600)$. Figure 7(c) contours $\mathrm{SNRR}(f,L)$ computed directly from these $\varepsilon(f,L)$ using Eq. (13) and the scaling requirements obtained from data of Fig. 5.

Figure 7(d) shows the required number of samples $N(f,L)$ needed for a successful detection of delta-pH of 0.05, computed from SNRR (Fig. 7(c)) and SNR (Fig. 7(a)). Two formulas for this are

$$\sqrt{N} = (\sqrt{2} \times 10^{-\mathrm{SNR}/20})/(10^{\varepsilon/20} - 1), \tag{14a}$$

$$N = 10^{(\mathrm{SNRR-SNR})/10}. \tag{14b}$$

There is a "trough" in the plot showing a low N requirement extending from [400 Hz, 200 km] to [250 Hz, 800 km] (lower center to upper left). The measurement is possible at any of the ranges and frequencies covered in the figure, but the fewest samples are needed at the shortest ranges where SNR is high. If chemical measurement issues demand that longer ranges be used, frequencies of 250–400 Hz would be best, as indicated by the trough.

To summarize this section, for the inverse problem (pH determination), the balance between the undesirable decrease in SNR with frequency and range, and the desirable DA improvement with increasing range and frequency has been quantified. This is independent of the desirability to propagate long distances to achieve good spatial averaging.

VI. INTERNAL-WAVE EFFECTS

Next, frequency-dependent fluctuations of the arrivals that are caused by internal waves are considered. The differencing would reject fluctuations common across the measurement band, but that is a best-case scenario. The worst case is treated here. Many of the fluctuation effects caused by internal waves are somewhat coherent across frequency, but they are treated here as independent at the two frequencies. For fluctuations with normal statistics, the mean-squared error of the mean estimate is equal to the variance divided by the number of samples, MSME$=\mu_2/N$. This allows fluctuation parameter statistics to be converted to estimates of the quality of sampled means. The presence of internal-wave induced intensity fluctuations is commonly known, and numerous theoretical and computational studies exist. However, the intensity fluctuation variance at 500 km range is poorly delineated in the literature. This is because difficulties such as inadequate SNR have left comparisons of data with scattering theory unable to fully test the theories.

It is known that an impulsive sound wavefront in the temperate ocean sound channel deforms into an accordion shape (in space at fixed time, and in time at a fixed distance from the source) (Munk *et al.*, 1995). Each leg of the accordion corresponds to a single member of the multi-path arrival structure and to a specific number of upper turning points of the looping sound rays plus an initial direction index (two choices, up or down). Each arrival at a point receiver corresponds to sound that is concentrated along eigenrays connecting source to receiver. The intensity and phase fluctuations of each arrival can be estimated using integrals of ocean properties such as sound-speed anomaly along each ray (Flatté *et al.*, 1979; Flatté and Rovner, 2000). Many of the effects causing intensity (I) fluctuation, such as fluctuating focus effects along the rays due to internal waves, are weakly dependent on frequency. Thus, D_A would be only weakly sensitive to them. In the ideal case of infinite SNR and frequency independence of internal-wave effects, a borate absorption measurement could be made with a single measurement of intensity difference at two frequencies, taking only an instant.

However, intensity fluctuations exist which vary across a frequency band on an instantaneous basis. Experiment and computer simulations have shown that internal waves can cause each of the arrivals to be composed of many micro-multi-path arrivals (Colosi *et al.*, 1994; Simmen *et al.*, 1997). Interference between these arrivals can cause intensity fluctuations that are stronger functions of frequency than the intensity fluctuations of intact wavefronts because interference is a function of phase, and phase in each band of broadband sound propagated over a fixed path is a function of frequency. The result is that intensity can fluctuate rapidly and independently at two measurement frequencies. Thus, a scintillation in the intensity difference over the two frequencies (which is related to our desired parameter D_A via $D_A = 10\log_{10}(I_2/I_1)$) will result.

Jin and Worcester (1989), using a spectral formalism, computed that about 100 intensity-difference measurements would be needed to suitably average the intensity fluctuations in order to achieve a measurement error of 0.3 dB for 550 Hz, range 750 km in the North Pacific. The expression is $\varepsilon = 10\log_{10}(1+((M-1)/2NM)^{1/2})$, where M is the number of interfering micro-rays and N is the number of averaged receptions. More averaging would be required to achieve 0.1 dB (see Sec. V C).

There are a few published numbers for the total intensity fluctuation. The scintillation index is defined to be the intensity variance divided by the square of the mean intensity, $SI=\mu_2/\mu_1^2$. This has been observed to be between 0.2 and 2.0 for various resolved early arrivals in a 1000 km experiment, with an average value of 0.9 (Duda and Bowlin, 1994). These numbers include macro effects of internal waves that are weak functions of frequency, and thus overestimate the fluctuations that should remain after frequency differencing. Values far above 1.0 correspond to strong interference of a few signals, those at 1.0 correspond to saturation (interference of many arrivals), and values less than 0.3 correspond to weak scattering (Born or Rytov) (Flatté *et al.*, 1979). Note that intensity statistics are not normal, but can be approximated as such for the smaller observed values of SI. This is not a severe problem because this is a study of confidence intervals and error bars, and the improvements gained via averaging will be realized nonetheless, although improvement is more difficult to quantify than in the case of normally distributed fluctuations.

It is convenient to obtain a unified expression for the number of measurements needed to obtain the required precision in the presence of the two noise processes: internal-wave induced intensity fluctuation and additive Gaussian noise. Define signal waveform as $S(t)=S_0(t)+S_{IW}(t)+n(t)$, where S_0 is mean signal, S_{IW} is additive zero-mean internal-wave fluctuation, and n is noise. Using methods in Jin and Worcester (1989) and expressions from Sec. V, one can write for the typical measurement error at each frequency

$$\varepsilon = 20\log_{10}\left(1+\frac{\langle|S_{IW}|^2\rangle^{1/2}}{\langle|S_0|^2\rangle^{1/2}}+\sqrt{2}\times 10^{-(\mathrm{SNR}+10\log N)/20}\right). \tag{15}$$

The triangle inequality has been used, so this is an upper bound on the deviation between the mean of measured energy S^2 and the desired energy S_0^2 [i.e., on $10\log_{10}(\langle S^2\rangle/\langle S_0^2\rangle)$]. Now assume that the second term in brackets, the fluctuation amplitude contribution, is reduced with averaging. With normal statistics, the second term becomes $SA/\sqrt{N}$. Our newly defined scintillation amplitude statistic $SA=\langle|S_{IW}^2|\rangle^{1/2}/\langle|S^2|\rangle^{1/2}$ is (oddly) similar in shape to SI for many reasonable pdf's of S_{IW}, but there is no simple analytic relationship. For fluctuations with a normal distribution, SA/SI exceeds 1 for low SI but tends to have a value near 0.62 for SI greater than 0.7. SA is about $SI/2$ for exponentially distributed populations with SI near 1.4. Rearrangement of Eq. (15) yields

$$\sqrt{N}=(SA+\sqrt{2}\times 10^{-\mathrm{SNR}/20})/(10^{\varepsilon/20}-1). \tag{16}$$

In the limit of SA going to zero, this expression properly reverts to Eq. (14a) which applies to the case of steady signal with noise.

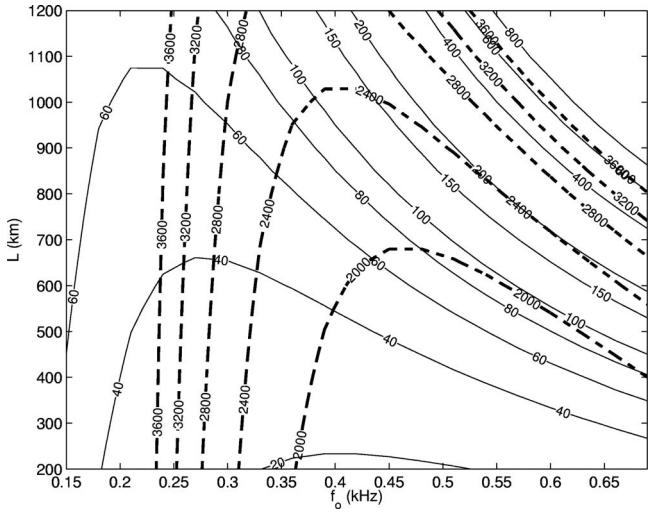

FIG. 8. The required number of samples for *p*H measurement with 0.05 precision for the situation of fluctuating signal and noise, and 100 Hz frequency difference, is contoured over center frequency and range (bold dashed lines). The same quantity for the steady signal and noise situation is also shown (solid lines, repeated from Fig. 5(d)).

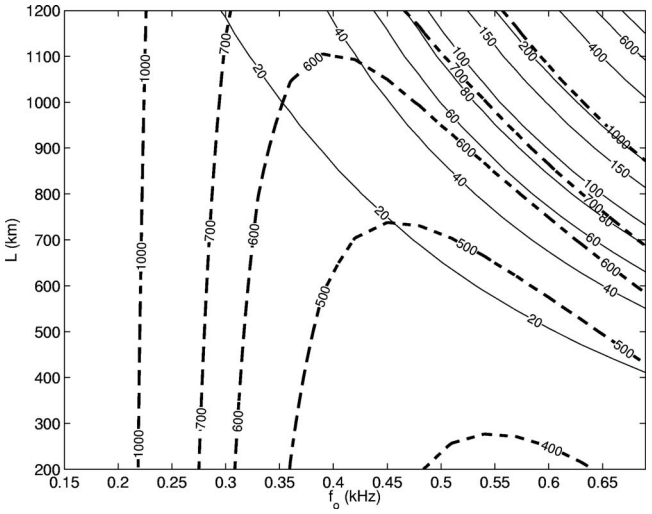

FIG. 9. The number of samples needed to measure *p*H to an accuracy of 0.05 units using a 200 Hz bandwidth measurement is contoured. Dashed contours are for the case that includes signal fluctuations and noise, and the solid contours are for the case of noise only.

The second term of the numerator is typically about 0.11 (22 dB SNR), whereas the scintillation term [for individual wavefront (ray) arrivals] is likely to always exceed this. This means that the signal fluctuations will compromise the measurement ability much more than noise. This agrees with the comparison of the two effects made by Jin and Worcester (1989). The most stringent scenario that they calculate is that 225 measurements would be needed to average over signal fluctuations to reduce error to 0.2 dB. Figure 8 contours the number of samples needed for realistic values of *SA* and shows that many more than their estimates may be needed. Modeling *SA* to be linear with range, starting at $SA=0$ at zero range and growing to $SA=1.0$ at 1000 km range, the plot shows contours of *N* needed to reduce ε to the value needed to effectively sample the expected *DA* to a *p*H precision of 0.05 (analogous to procedures of the prior section). These are calculated from Eq. (16). Some of the *N* contours for the noise-only result of Fig. 7(d) are replotted. The two sets of contours have different shapes, and the fluctuating signal result shows that far more measurements must be averaged than in the noise-only case. There is an order of magnitude difference at range of 800 km with 600 Hz. For the case that includes fluctuations, there is a "trough" of greatest effectiveness (minimum number of points) passing through 400 Hz, 1000 km. If *SA* is reduced by 50% (i.e., weaker internal-wave scattering is assumed), the *N* values fall to about one-third of the values indicated in the contour plot over the area of the trough, which retains its shape. Figure 9 shows results computed in a similar fashion to those of Fig. 8 except a band separation of 200 Hz is used. The time required to obtain the required order-500 samples can be estimated. For a fluctuation coherence time of 5 min, the time would be about 2 days. As with the 100 Hz separation situation shown in Fig. 8, reducing SA by 50% decreases *N* by about 70% with little change in the shape of the contours.

There is a possibility that internal-wave induced amplitude fluctuations of distinct arrivals are correlated over frequency. In this case it would be advantageous to difference the peak amplitudes of the pulses before averaging (predifferencing). Noise would remain, but fluctuation effects might be reduced or eliminated. An expression for difference ε can be developed. With noise treated as independent over frequency, the expression will look like Eq. (15) except a difference amplitude statistic can be substituted for *SA*. Because the differencing is done first, the tolerance for ε for a given delta-*p*H is eased with respect to that used earlier by a factor of 2 (i.e., the value is 0.12 dB for delta-*p*H of 0.05 at 600 km, 250 Hz). The amplitude statistic [second term in Eq. (15)] can take the form $A=\langle|S_{IW1}|-|S_{IW2}|\rangle/\langle|S_{01}|-|S_{02}|\rangle$, where subscripts indicate frequency band one or two. Averaging then yields $SA\sqrt{2/N}$ for the case of uncorrelated fluctuations. This method produces curves similar to those of Fig. 8, but approximately double the numbers of samples indicated in that figure are needed. Thus, adding uncorrelated fluctuations before the averaging process increases their detrimental effect. However, if internal-wave fluctuations are correlated in the two bands, then very improved performance would result. For perfect correlation of internal-wave fluctuations across the band, the noise-only results would hold for the pre-difference technique.

VII. SUMMARY

The technique of using differential acoustic attenuation measurements at frequencies below 600 Hz to determine the precise nature of absorption effects (direct measurement) and by extension average *p*H (inverse measurement) has been examined. The basic processes are reviewed and the equations are derived. The capabilities of many frequency difference pairs and various acoustic path lengths at providing attenuation measurements of the required accuracy in a noisy environment are examined.

Differential attenuation (energy difference between two frequency bands) might be measurable with equipment of existing types, either using a broad sweep system (Morozov

and Webb, 2003) or two systems, each with bandwidth of 50 Hz or more, operating in bands separated by 100 or 200 Hz (or more). Using established formulas, estimates are made of the required measurement accuracy, in decibels, to make meaningful *p*H measurement (inverse problem) for various propagation distances, various center frequencies, and two-frequency band separations. The results are in the form of contours of the quantity of independent samples required to be averaged together to measure effects consistent with *p*H fluctuations of 0.05.

Two scenarios are examined: steady signal (idealized) and fluctuating signal (more realistic). Separated multi-path signal peaks used to estimate energy received after propagating distances of a few hundred kilometers are not steady, but fluctuate, largely due to internal-wave effects. The fluctuations of energy in the field have not been well characterized in the literature. These fluctuations are of order 1 in comparison with the mean energy, so in the high SNR case they dominate the error of the measurement. Conservative estimates of the number of samples required are made assuming the fluctuations are independent in the two frequency bands whose energy is differenced to obtain the measurement. The values are a few thousand for 100 Hz separation, and order 500 for 200 Hz separation.

The results reflect a competition between two effects. Attenuation difference grows with range and has a maximum at about 600 Hz. Signal-to-noise ratio shrinks with range and frequency. The result is that paths of 600–1000 km and frequencies of 375–450 Hz may be most practical for large-scale sensing. These frequencies are below the frequency of maximum sensitivity (600 Hz), and their effectiveness stems from having better SNR than 600 Hz. Using three rather than two frequencies would provide a slightly better measure of the attenuation curve than would a simple two-frequency difference by adding information.

To confront small open questions regarding the chemistry (Mellen *et al.*, 1983; Zeebe *et al.*, 2001) and the dependencies in Eq. (4), differential-attenuation measurements of absorption can be combined with ship surveys to verify absorption behavior. Regarding the inverse problem (*p*H measurement), the method would provide a spatially-averaged measure that is less precise than individual *in situ* *p*H measurements. It would be most useful in two applications. One is in regions of high spatial variability, where unrealistically large numbers of *p*H measurement profiles would be required to obtain a good mean estimate. The other application is a time series measurement of *p*H variability. This may be most cost-effective in remote regions where a time series involving *in situ* samples would be difficult. A few hundred transmissions through independent internal-wave fields (a source of noise in the attenuation measurement), possible in a period of a few days, would provide a mean *p*H value. Repeat transmission cycles provide the time series. Time series could also be provided by moored autonomous *p*H sensors, but fixed-site point sensors may be at risk of not representing large-scale mean *p*H conditions very well because of local bias effects. Clearly there are advantages and disadvantages of each measurement technology. Perhaps the strongest potential for the acoustic measure is in remote polar areas, where undersaturation of calcium carbonate minerals may occur first, with strong biological consequences.

(Received 2 December 2008; revised 3 February 2009; accepted 5 February 2009)

Methods are developed for estimating the size/density of cetacean populations using data from a set of fixed passive acoustic sensors. The methods convert the number of detected acoustic cues into animal density by accounting for (i) the probability of detecting cues, (ii) the rate at which animals produce cues, and (iii) the proportion of false positive detections. Additional information is often required for estimation of these quantities, for example, from an acoustic tag applied to a sample of animals. Methods are illustrated with a case study: estimation of Blainville's beaked whale density over a 6 day period in spring 2005, using an 82 hydrophone wide-baseline array located in the Tongue of the Ocean, Bahamas. To estimate the required quantities, additional data are used from digital acoustic tags, attached to five whales over 21 deep dives, where cues recorded on some of the dives are associated with those received on the fixed hydrophones. Estimated density was 25.3 or 22.5 animals/1000 km^2, depending on assumptions about false positive detections, with 95% confidence intervals 17.3–36.9 and 15.4–32.9. These methods are potentially applicable to a wide variety of marine and terrestrial species that are hard to survey using conventional visual methods. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3089590]

I. INTRODUCTION

Cetaceans (whales and dolphins) form a key part of marine ecosystems, and yet many species are potentially threatened with extinction by human activities. One essential element of an effective conservation or management strategy is a reliable estimate of population size ("abundance") or, equivalently, number per unit area ("density"). However, most cetacean species are hard to survey, since they live at low density over large areas of ocean and spend almost all of their time underwater. The object of this paper is to increase the repertoire of tools available for making species assessments, by developing and demonstrating methods for estimating cetacean density from surveys of their vocalizations collected from fixed passive acoustic sensors.

Currently, the main method for obtaining estimates of density is through visual line transect surveys. A set of randomly placed lines is traversed by an observation platform (e.g., ship, airplane, or helicopter) and all sighted animals of the target species are recorded, together with their perpendicular distance from the line. In the standard method, it is assumed that all animals on the transect line (i.e., at zero distance) are seen with certainty, but that probability of detection declines with increasing distance from the line. The distribution of observed detection distances is then used to estimate the average probability of detection, and this in turn allows estimation of population abundance or density. Line transects are a special case of distance sampling methods, which are described in detail in the two standard texts by Buckland *et al.* (2001, 2004).

Visual line transect methods have a number of disadvantages for surveying cetaceans: they can only be performed during daylight hours and are strongly dependent on good weather conditions; they do not work well for species that spend long periods of time underwater; they are expensive to do well and have restricted temporal coverage. On the other hand, some cetacean species make frequent and characteristic vocalizations, and this has led to increasing recent interest in the use of passive acoustic methods for monitoring cetacean populations (see review by Mellinger *et al.*, 2007b). One solution is to replace or supplement the visual observers on a shipboard line transect survey with a towed passive acoustic platform, since even a simple two-element hydrophone array can be used to obtain locations of repeatedly vocalizing animals, and hence the required perpendicular distances. This has proved particularly effective for sperm whales (*Physeter macrocephalus*), which are long, deep divers and hence hard to detect visually, but produce loud

echolocation clicks (Hastie *et al.*, 2003; Barlow and Taylor, 2005; Lewis *et al.*, 2007).

Acoustic line transect methods still require an expensive survey platform and have restricted temporal coverage. By contrast, technology exists where fixed acoustic sensors (either anchored or buoyed) can be deployed to record data over long periods or transmit it to shore via cables. Mellinger *et al.* (2007b) provide a review of the potential modalities. Such sensors have the potential to provide relatively inexpensive long-term monitoring and, if deployed in a wide-baseline array, could also cover large spatial areas.

There are several examples of the use of fixed acoustic sensors to provide an index of abundance, or at least to detect the presence of a species over time (e.g., Au *et al.*, 2000; Charif *et al.*, 2001; Moore *et al.*, 2006; Mellinger *et al.*, 2007a; Stafford *et al.*, 2007). However estimating absolute density or abundance from such data is considerably more difficult, although considerably more useful too. Broadly, the key problems are as follows: (i) to convert the number of vocalizations detected to the number produced within a defined area, by accounting for false positive and false negative detections, and (ii) to convert this estimate of vocalizations produced to the average number of animals present. To date, no method has been proposed that might be used in general to estimate cetacean density from fixed passive acoustic devices (Mellinger *et al.*, 2007b), although several papers have addressed elements of the problem (e.g., Aubauer *et al.*, 2000; McDonald and Fox, 1999; Wiggins *et al.*, 2004; Stafford *et al.*, 2007; Zimmer *et al.*, 2008).

This paper presents a framework for estimating cetacean density from an array of fixed passive acoustic detectors. The framework lays its foundation in a type of distance sampling survey methodology called cue counting (Buckland *et al.*, 2001) and is general enough that it might be used under considerably different scenarios, with appropriate modifications that are also discussed. The proposed approach is illustrated by a case study: estimating the density of Blainville's beaked whale, *Mesoplodon densirostris* (Md), at the Atlantic Undersea Test and Evaluation Center (AUTEC) range, an instrumented US Navy testing range in the Bahamas. Part of the data used here were also used in a previous attempt to estimate Md density at AUTEC by Moretti *et al.* (2006), which provides a useful comparison for the results obtained.

II. STATISTICAL FRAMEWORK FOR ESTIMATING DENSITY

Density D is defined as a number of animals per unit area, and hence density can be expressed as

$$D = N/a, \tag{1}$$

where N is the number of animals present in a region of area a. It is therefore straightforward to convert any density estimate into an abundance estimate, as long as the area it applies to is known, as $N=Da$. Given the number of animals n detected in survey area a, an intuitive estimator of abundance is given by

$$\hat{D} = \frac{n}{a\hat{P}}, \tag{2}$$

where $\hat{P}$ represents the estimated probability of detecting an animal. P can be estimated by a number of methods, of which distance sampling (Buckland *et al.*, 2001) is arguably the most commonly used.

A. Proposed estimator and variance

Here it is assumed that a set of replicate fixed passive acoustic sensors has been deployed using a random design (e.g., systematic random) within the survey region of interest (see, for example, Buckland *et al.*, 2001, Chap. 7 and Buckland *et al.*, 2004, Chap. 7, for discussions of appropriate sampling designs). The goal is to estimate average density and/or abundance of a cetacean species over the time period that the sensors were deployed. The methods generalize easily to multiple species, spatial and temporal stratification, etc. They are also applicable to single sensor situations and nonrandom sensor placement, although in these cases caveats must be introduced.

The methods proposed here involve counting (for a known period of time) the number of detected acoustic cues produced by the animals of interest, and appropriately scaling up this number of detected cues to estimate animal density. The appropriate definition of a cue is study-specific, but it will usually be a distinct animal vocalization such as a song unit, echolocation click, etc. Considering Eq. (2), an estimate of density $\hat{D}$ from the n_c detected cues over a time period T (and additional information detailed below) can be obtained by

$$\hat{D} = \frac{n_c(1-\hat{c})}{K\pi w^2 \hat{P} T \hat{r}}, \tag{3}$$

where w is the distance away from the hydrophones beyond which cues are assumed to not be detected, $\hat{P}$ is the estimated average probability of detecting a cue made within distance w, $\hat{r}$ is the estimated cue production rate, $\hat{c}$ is the estimated proportion of false positive detections, and K is the number of replicate sensors used.

Note that Eq. (3) can be seen as a special case of Eq. (2). $n_c(1-\hat{c})$ corresponds to the number of detected cues that were actually from the target species. $T\hat{r}$ corresponds to the number of cues produced by an average animal during the recording time T. Hence $n_c(1-\hat{c})/T\hat{r}$ corresponds to n in Eq. (2), while $K\pi w^2$ corresponds to a in Eq. (2).

Strictly speaking, the hydrophones should be independent sampling units, but in practice some clicks are detected at more than one hydrophone. However, Buckland (2006) showed by simulation that these methods are insensitive to this sort of nonindependence.

Assuming independence of the various random components, the variance for the density estimator can be approximated via the delta method (Seber, 1982) (see also Powell, 2007, for an applied review of the method) as

$$\mathrm{var}(\hat{D}) \approx D^2\{CV(n_c)^2 + CV(\hat{r})^2 + CV(\hat{c})^2 + CV(\hat{P})^2\}, \quad (4)$$

where CV denotes the coefficient of variation of the estimate, i.e., the standard error of the estimate divided by the estimate.

The variance in n_c can be estimated from the empirical variance of the cue counts n_{cj} $(j=1,2,\ldots,K)$ over K hydrophones, as is usually done for conventional distance sampling methods (Buckland *et al.*, 2001, p. 78) as

$$\mathrm{var}(n_c) = K\sum_{j=1}^{K} \frac{[n_{cj} - n_c/K]^2}{K-1}.$$

For the other three components, obtaining the appropriate variance will depend on how these are estimated. Examples are given in the case study.

Confidence intervals on density can be obtained by assuming that the density estimate follows a log-normal distribution (Buckland *et al.*, 2001, p. 77). An alternative approach for obtaining both variance and confidence intervals is the nonparametric bootstrap [Buckland *et al.*, 2001; see section 3.6 for details in this context, and Efron and Tibshirani, 1993 for an overview]. Both the analytic and bootstrap methods are commonly employed in conventional distance sampling.

Sections II B–II D consider methods for obtaining estimates of the three components P (probability of detection), r (cue production rate), and c (false positive proportion).

B. Probability of detection

To understand the potential methods for estimating P, it is convenient to start by describing the estimation of the detection function, $g(y)$, that is the probability of detecting a cue given it is produced at horizontal distance y. Here y refers to horizontal distance (i.e., projected onto the sea surface); the use of direct (i.e., slant) distances is discussed later.

In conventional distance sampling methods, including cue counting, $g(y)$ is estimated using the horizontal distances of detected objects from the line or point (usually referred to as "transect," with the equivalent here being a point with the acoustic sensor at the center, from which acoustic cues are detected). This is feasible because, with random transect placement, the *true* distribution of object distances is known; hence any departure in the distribution of *detected* distances from this known distribution can be attributed to the detection process. Specifically, in variants of distance sampling where the transect is a point, as in the current case, the true distribution of horizontal object distances, $h(y)$, is given by $2y/w^2$, where w is some distance beyond which detections are not recorded (and can be infinity). Thus, the probability density function (pdf) of observed distances, $f(y)$, is given by

$$f(y) = \frac{h(y)g(y)}{\int_0^w h(y)g(y)dy} = \frac{2yg(y)}{w^2 P}, \quad (5)$$

where $P = \int_0^w h(y)g(y)dy$ acts as a normalizing constant that ensures $f(y)$ is a pdf (i.e., that integrates to 1). Note that $g(y)$ can be multiplied by any constant without changing $f(y)$; in other words, the observed distances give information about the shape of $g(y)$ (i.e., the change in detectability with distance) but not the absolute level of $g(y)$. Therefore, an additional assumption must be made before $g(y)$ can be estimated, and the conventional assumption is that all objects at zero distance are detected, i.e., that $g(0)=1$. Then, given a parametric model for $g(y)$, the parameters of the model can be estimated from a sample of distances using, for example, maximum likelihood estimation.

Once an estimate of the detection function parameters is obtained, it is straightforward to estimate the average probability of detecting an object within w, as the average of the estimated detection probability at each distance multiplied by the density of objects at that distance:

$$\hat{P} = \int_0^w \hat{g}(y)h(y)dy. \quad (6)$$

Specialized software, DISTANCE (Thomas *et al.*, 2006), is freely available for the analysis of such data, and variance estimates and confidence limits are readily available from the output.

The conventional approach is sometimes possible using data from fixed acoustic sensors, so long as (i) horizontal distances to detected cues can be obtained, and (ii) the basic assumptions are met: that the true distribution of horizontal object distances, $h(y)$, is known and that $g(0)=1$. Calculation of horizontal distances using a single bottom-mounted sensor was demonstrated by McDonald and Fox (1999), using transmission loss and multi-path methods to estimate distance to calling fin whales near a Hawaiian seamount, and by Wiggins *et al.* (2004), using waveguide propagation to estimate distances to North Pacific right whales in the Bering Sea. However, the assumption of known $h(y)$ is often questionable with a single sensor. If cues are received on multiple sensors and can be associated, then time differences of arrival can potentially be used to localize the source, thereby providing a distance (e.g., Freitag and Tyack, 1993). However, the conventional methods would then need to be extended to allow the input data to be a set of detections of the same cue from multiple sensors at different distances.

An alternative way to obtain the detection function is to derive it from assumed models for sound production, propagation, and detection. This approach was demonstrated (using different modeling approaches and on different species) by Zimmer *et al.* (2008) and Stafford *et al.* (2007). Such approaches are naturally heavily dependent on the accuracy of the models and input parameters.

A third approach is to estimate the detection function empirically, using a set of experimental "trials" where vocalizations are produced at known times and distances from sensors, and the outcome is whether they are detected or not. One way to achieve this is to play recorded vocalizations, but a more realistic method involves placing acoustic recording tags on a sample of animals that are within the vicinity of the sensors, and using the tag data to determine where and when vocalizations were produced. Ideally, this additional experiment should be undertaken concurrently with the primary survey and on a representative sample of animals and sensors; otherwise differences in conditions between the tagging experiment and the primary survey will need to be accounted

for, by modeling covariates thought to influence detectability and then predicting detectability at the time of the trials. This is the approach taken in the case study, and the analysis options are described more fully later.

C. Cue production rate

The cue production rate r can be estimated using acoustic tag data, as described at the end of the Sec. II B, and this is the approach taken in the case study. Again, ideally, this would be collected concurrently with the primary survey and on a representative sample of animals. Otherwise, factors that potentially affect cue rate such as season, time of day, sex, etc., will need to be accounted for.

A second approach, if additional experimental tagging data are unavailable, is to use a cue rate estimate published elsewhere. For some species, which have very predictable vocalization patterns, this may produce a reliable estimate; for others it will not.

A third alternative, if it is possible to associate successive vocalizations from individual animals within the sensor array (such as when calls are uniquely identifiable or density is very low), and if it can be determined when animals are so close to a sensor that no calls will be missed, is to use the cue rate from vocalizations produced by these animals. However, for species that can pass by a sensor without producing any cues, this will inevitably lead to an overestimate of cue rate.

D. False positive proportion

To be recorded as a cue, a sound must go through a two-stage process: it must be (i) detected as being potentially relevant and (ii) classified as the correct type of sound. Because of the volume of data involved, both stages are typically performed by computer algorithms.

If a sound of interest, i.e., a vocalization by an animal from the target species within distance w of a sensor, is not detected, or is detected but incorrectly classified, it is referred to as a "false negative." (In statistics, this is also known as a type II error, considering the combined detection and classification process to be a statistical test.) The detection function, via the estimated detection probability, corrects for this type of error.

On the other hand, it is possible for a sound that is not a vocalization from the target species to be detected and classified as a cue, creating a "false positive" (or a type I error). The proportion of sounds classified as cues that do not come from the target species is the false positive proportion, and this must be estimated. As with the previous components, there are multiple ways to achieve this.

The most direct approach is to take a sample of the sounds classified as cues and manually check what proportion are false positives. This is the approach taken in the case study, and relies on the human operator to make correct classifications. If a human operator cannot be considered reliable, an alternative is to use some performance statistics of the detector/classifier, for example, on data where animals were known to be vocalizing because they were tagged or being observed from a nearby boat, and predict the average false positive proportion under the conditions of the survey being analyzed. This requires knowledge of all the variables that affect the false positive proportion, and their distribution both for the dataset where the performance characteristics were tested and for the dataset for which density is being estimated. This seems hard to implement as it implicitly requires one to know the total number of positive and negative sounds (i.e., whale clicks versus sounds from other sources). Hence the first approach is to be preferred wherever it is feasible.

Note in general, one cannot generalize to other scenarios the proportion of false positives in a given place and time. In particular, if the relative abundance of species contributing to false positives changes, the false positive proportion will change accordingly.

III. CASE STUDY: BLAINVILLE'S BEAKED WHALES AT AUTEC

The proposed methods are illustrated here with a detailed case study: the estimation of average density of Blainville's beaked whales, Md, at the AUTEC underwater tracking range during a 6 day period in spring 2005. The inference made is restricted to the time periods, during these 6 days, for which recordings were available (see below for details).

Beaked whales are considered difficult to survey using visual methods, since they make long, deep dives and are relatively difficult to sight even for the short periods of time they are at the surface (Barlow *et al.*, 2006; Barlow and Gisiner, 2006). However, they make regular high-frequency echolocation clicks during the deeper part of their dives (Johnson *et al.*, 2004) which, although highly directional (Zimmer *et al.*, 2005), can be detected by both surface-and bottom-mounted hydrophones, with the latter likely to have better detection ranges (Zimmer *et al.*, 2008). Md have previously been detected up to 6500 m slant range from the AUTEC hydrophones (Ward *et al.*, 2008).

AUTEC is an instrumented US Navy testing range located in the Tongue of the Ocean, Bahamas. It contains a wide-baseline array of 93 cabled hydrophones, mounted 4–5 m off the sea floor at depths between 1.3 and 2 km, and with an upward, roughly hemispherical beam pattern. For the data presented in this study, 82 hydrophones were digitally recorded at 96 kHz (Fig. 1): 68 wideband hydrophones spaced 4 km apart with a usable bandwidth from 50 Hz to 45 kHz, and 14 hydrophones spaced 1.8 km apart with a bandwidth from 8 to 50 kHz (bandwidth and spacing values are approximate). Previous research utilizing this hardware has demonstrated the presence of Md at AUTEC, developed suitable automated detectors and estimated approximate animal density (Moretti *et al.*, 2006; DiMarzio *et al.*, 2008; Ward *et al.*, 2008).

The processed data and metadata used in this paper were submitted to the Ocean Biogeographic Information System and are accessible via http://seamap.env.duke.edu/.

A. Case study data and data processing

Two sets of data were used in the case study. The first (the "primary dataset") was a set of recordings taken on 82

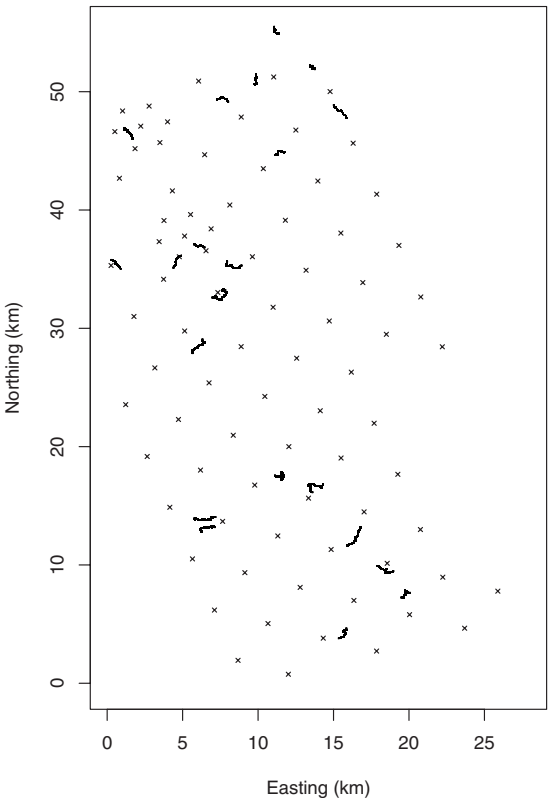

FIG. 1. The spatial layout of the AUTEC hydrophones that were recording during the collection of the primary survey data, represented by small crosses. Also shown as dots (perceived as solid lines) are the locations of the tagged Blainville's beaked whales when each click recorded on the DTag was produced.

hydrophones during 6 days in spring 2005 (between 17:03 GMT, 26 April and 08:32 GMT, 2 May 2005). These were processed to extract detections of Md foraging clicks (the cues), and the number of detections was used as the basis for estimating average density of Md over the 6 day period. For operational reasons the data were divided into 12 sets, and entire sets (2, 5, 7, and 11), as well as some scattered minutes, were not used. These periods were removed from the analysis for various reasons (e.g., problems with acoustic recordings, system tests being conducted over the range, etc.).

Traditional hyperbolic localization techniques used to obtain the position of sound sources such as whales require a click to be detected on at least four hydrophones. However, previous studies have observed that the combination of Md narrow beam width and AUTEC's wide hydrophone baselines result in clicks often not being detected on more than one or two hydrophones simultaneously (Ward *et al.* 2008); hence detection function and cue rate estimation methods based on localizing Md at AUTEC were considered infeasible. Therefore, a second dataset was required to obtain these quantities. This (the "auxiliary dataset") comes from acoustic tagging studies carried out in October 2006 and August–September 2007 in which five whales were fitted with digital acoustic tag (DTag) acoustic recording tags (Johnson and Tyack, 2003) which remained attached for a total of 21 deep dives (Table I). The tag data were used to estimate the cue rate. A subset of the data was further processed to estimate the location of the whales at each click event, and these clicks were matched with clicks received on surrounding AUTEC hydrophones to enable estimation of the detection function.

TABLE I. Details about the tagged whales used in case study analysis: Tag ID, date the animal was tagged, number of dives while animal was tagged, and number of dives with data available for estimating the detection function $g(y)$.

A brief description follows of the processing required to extract detections from the main dataset, and to extract click rates, locations, and associations with AUTEC hydrophones from the auxiliary dataset.

1. Processing of primary dataset

Clicks were detected using a multi-stage fast Fourier transform (FFT)-based energy detector (Morrissey *et al.*, 2006), using data digitally recorded from the range hydrophones at a 96 kHz sampling rate. A 2048-point FFT with 50% overlap was used. This provides a 46.875 Hz frequency resolution and a 10.67 ms time resolution. During the first stage, an adaptive threshold was run in each bin of the FFT. If energy above threshold was detected, the bin was set to a "1" and a detection report was generated. During the second stage, detections are classified based on the frequency distribution of the detected signal. Detections are classified as beaked whale clicks by evaluating the ratio of bins above threshold to the total number of bins within the frequency band of 24–48 kHz (Morrissey *et al.*, 2006; Ward *et al.*, 2008). Additionally, a second check is performed by examining the number of bins set outside the 24–48 kHz "beaked whale band." If this exceeds 10%, then the detection is reclassified as a dolphin as they are more likely to have significant spectral energy below 24 kHz.

The detection reports classified as beaked whales were then summed into a final output consisting of the number of beaked whale clicks per minute for each hydrophone over the recording period.

2. Processing of auxiliary dataset

Additionally, DTag (Johnson and Tyack, 2003) data, both positional and acoustic, were available for five whales, in a total of 21 (Table I) deep dives. The tag records continuously from a built-in hydrophone and suite of sensors that convey information on positional data: animal depth, heading, pitch, and roll. The sensors sample the orientation of the animal in three dimensions with sufficient resolution to capture individual fluke strokes (Johnson and Tyack, 2003). The speed from the pressure sensor, heading, and pitch angle were used to reconstruct a three-dimensional "pseudotrack"

for each animal during the period the tag was attached (Johnson and Tyack, 2003). These data were used for the estimation of click rates, and also for simulation of click characteristics involved in the estimation of the mean detection probability (see below).

For the estimation of the detection function, further data processing was required. For four whales and a total of 13 of the deep dives, these DTag data were associated with matched filter detections from the surrounding hydrophones, localized, and the pseudotrack georeferenced (i.e., absolute rather than relative coordinates obtained; see Ward *et al.*, 2008 for further details). Once georeferenced, the DTag accelerometer and magnetometer data for each click within the georeferenced portion of the dive were used to calculate the spatial relationship between the whale and each hydrophone in the whale orientation frame (see Johnson and Tyack, 2003; Ward *et al.*, 2008, for further details). An indicator of detection (1—detected; 0—not detected) could then be generated for each click produced at each surrounding hydrophone (using the same FFT-based detector as in the primary survey click count data), as well as a set of corresponding click characteristics in the frame of the whale (namely, slant distance, vertical, and horizontal off-axis angles with respect to the whale's orientation).

B. Case study density estimation methods

1. Estimating probability of detection

As stated earlier, the conventional distance sampling approach of estimating average detection probability using detection distances could not be used due to the difficulty in easily localizing Md clicks using the wide-baseline hydrophone array at AUTEC. Hence auxiliary data from the tagging study were used, where for each click produced by a tagged whale, it was known which of the surrounding hydrophones detected the click.

If tags had been applied to a large random sample of animals from the population present at AUTEC during the 6 day period of interest, then the average proportion of clicks that were detected would be an unbiased estimator of the average detection probability required. However, the tags were applied in a different time period, and the sample size of tags was not large. For both of these reasons, a more complex approach was required, where the probability of detection was modeled as a function of covariates thought to influence detectability, and the fitted relationship then used to estimate average detection probability during the 6 day period.

The modeling approach used was a generalized additive model (GAM, Wood, 2006), with a binomial response and logistic link function, to model the probability of detecting a Md click as a function of available covariates. The dependent variable used was the outcome of the detection and classification process (i.e., detected and classified as a cue/not detected or not classified as a cue) for each click produced by the tagged whale at each hydrophone within 8 km of the location of the whale (at the moment of the first click in the corresponding dive). The explanatory variables considered were the slant whale-hydrophone distance and the horizontal (*hoa*) and vertical (*voa*) off-axis angles, measured on the frame of the whale, with respect to the hydrophone (e.g., a 0,0 angle pair corresponds to a whale pointing straight at the hydrophone). For slant distance, a cubic regression spline basis was used, while for the off-axis angles a two-dimensional tensor product based smooth was used, to incorporate interactions between the horizontal and vertical angles. The largest detection distance for a click was at around 6.5 km, and the model was fitted truncating all data for which distance was larger than 8 km. The maximum degrees of freedom for the smooth of slant distance were set to 4 as, *a priori*, a relatively smooth decreasing function of distance was expected. The models were implemented using the library mgcv in R version 2.8.0 (R Development Core Team, 2008).

Given the fitted detection function model, there are, in general, two approaches for using this model to predict average probability of detection for the primary dataset. If the values of the covariates used in the model are also known for each detection in the primary dataset, then detection probability can be predicted conditional on these values and an average taken. However, if the covariate values for each detected click in the primary dataset are not known, but the *distribution* of the covariate values is known, then its effect can be integrated out of the model, giving the correct average detection probability. This is the approach taken in conventional distance sampling with the distance covariate [Eq. (6)].

In the current study, the values of slant distance and orientation were not known for any of the clicks in the primary dataset. Hence, a simulation approach was used to approximate the distribution of these covariates, based on the motion data from the DTags in the auxiliary dataset. The underlying assumptions were as follows: (i) the paths recorded in the 21 DTag dives from the auxiliary dataset are representative of the paths during the primary survey period, and (ii) the initial position of dives is random with respect to hydrophone position during the primary survey period. To implement the simulation, the following procedure was repeated many times:

(1) Generate the hypothetical location of the first click in a deep dive (x_i, y_i); locations were generated randomly in a buffer area of 8 km around AUTEC.
(2) Sample a dive from the 21 DTag dives available and select the data corresponding to the position of the whale in space (x, y, z location, pitch, heading and roll) at each click event.
(3) Relocate that dive such that the first click is at (x_i, y_i).
(4) For each click event, obtain the slant distance, *hoa* and *voa* with respect to all hydrophones closer than a distance of 8 km to the whale position.

In practice, instead of sampling each click event, only every 100th click was sampled as this was found to increase the speed of convergence of the algorithm to the true distribution of the covariate values. With this refinement, the distributions stabilized after 1000 simulated dives.

Given the above samples from the distribution of cova-

riates, the detection function model fitted earlier was used to estimate detection probability for each click, and the mean of this was taken as an estimate of average detection probability, $\hat{P}$.

To estimate the variance in $\hat{P}$ a nonparametric bootstrap procedure was implemented (e.g., Efron and Tibshirani, 1993). In each of 250 bootstrap replicates, a sample of dives was taken with replacement from the set of 13 dives from which the original detection function had been estimated, the GAM was refitted to this bootstrap resample, and the new fitted model used to produce a new estimate of $\hat{P}$. The empirical variance obtained over these bootstrap estimates is an estimate of the original variance of $\hat{P}$ (see pp. 82–83 of Buckland *et al.*, 2001, for further details in a similar context). This approach assumes that the dives are statistically independent.

2. Estimating cue production rate

The cue production rate (mean number of clicks per whale per second) was estimated using the DTag data. To avoid bias, the periods used for estimating the cue rate were restricted to complete deep-dive cycles (from the start of a deep dive to the start of the next), for which both sound and positional data were available, in a total of 21 deep dives from five whales.

The mean click rate was estimated as a weighted mean of click rate per deep-dive cycle, weighted by deep-dive cycle time length. The variance of this weighted mean was estimated using Cochran's approximation as recommended by Gatz and Smith (1995).

3. Estimating false positive proportion

To estimate the proportion of false positives in the main dataset, a sample of 30 systematically spaced 10 min periods was selected for analysis. For each of the 10 min sample periods, all hydrophones with detections were manually examined using a binary spectrogram display program (Moretti *et al.*, 2006). One of the sample periods was corrupted due to a system test being conducted by range technicians, and was removed from further analysis.

Experienced analysts classified the clicks and assigned click counts into one of the following seven categories: Md, delphinid, sperm whale, boat, pinger, other (which could include other beaked whale species), or "mixed" (i.e., when, in a given minute, Md clicks and other sound sources were not unambiguously distinguishable). Hence the false positive proportion might be between two extreme values, depending on whether all or none of the mixed detections is considered Md clicks. For the density estimates presented here both are used, leading to upper and lower bounds for density, with the best estimate of density likely lying somewhere in between these. The false positive proportion was estimated as the weighted mean of the proportion of false positives by sample period, with total number of clicks detected by sample period as weights. The variance of this weighted mean was estimated using the same procedure as described for the mean click rate variance.

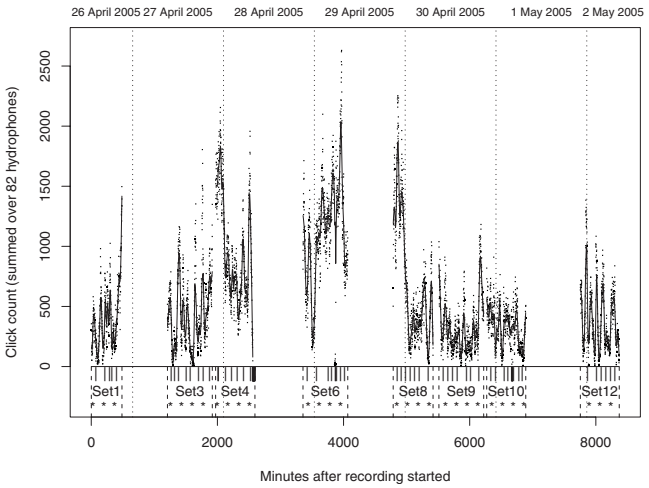

FIG. 2. Click counts per minute, summed over the 82 recording hydrophones, for the 6 day period of the primary dataset. Time is indexed as minutes since recording started. For operational reasons the data were divided into sets, and some sets (2, 5, 7 and 11) were not used. A standard lowess smooth of click counts over time is shown for the sets used. The small black vertical dashes ("|") are scattered minutes within the 8 sets used which were faulty and hence removed from the data. The sample periods used for the estimation of the false positive proportion are represented by " *". The limits of each day and set are represented by dotted and dashed lines, respectively.

C. Case study results

After removing minutes with problems, click counts were available for 4961 min in the primary dataset (Fig. 2).

Pooled over the 82 recording hydrophones, a total of 2 940 521 sounds classified as being beaked whale clicks were detected. Considering hydrophones as independent spatial replicates, the standard deviation of the total number of sounds was 161 373, resulting in a *CV* of 5.5%.

The estimated click rate was 0.407 (clicks/second), with a standard error of 0.040, resulting in a *CV* of 9.8%.

Overall, of the 160 302 sounds detected and considered to be beaked whale clicks during the sample periods used for the false positive proportion estimation, only 78 450 (corresponding to slightly under 50%) were unambiguously identified as Md clicks. The complement of the proportion of false positives, $1-\hat{c}$, was estimated to be 0.549 ($se=0.011$, $CV=1.99\%$) or 0.489 ($se=0.011$, $CV=2.29\%$), depending on whether the mixed clicks are considered to be all or none from Md.

The estimated detection function is shown in Fig. 3. The maximum distance at which a click was detected was 6504 m. The estimated mean detection probability for clicks produced within 8 km of the hydrophones (clicks outside this buffer are assumed to have 0 detection probability) was 0.032, with an associated *CV* of 15.9%.

Using Eq. (3) the estimated Md density at AUTEC over the recording period was 25.3 or 22.5 animals per 1000 km^2 (with respectively 19.5% and 19.6% *CV*'s), depending on the $\hat{c}$ used. Assuming a log-normal distribution for the density estimate, the respective 95% confidence intervals for density are 17.3–36.9 and 15.4–32.9. Note that the contribution of n, $1-\hat{c}$, $\hat{P}$, and $\hat{r}$ to the overall variance estimate on density is

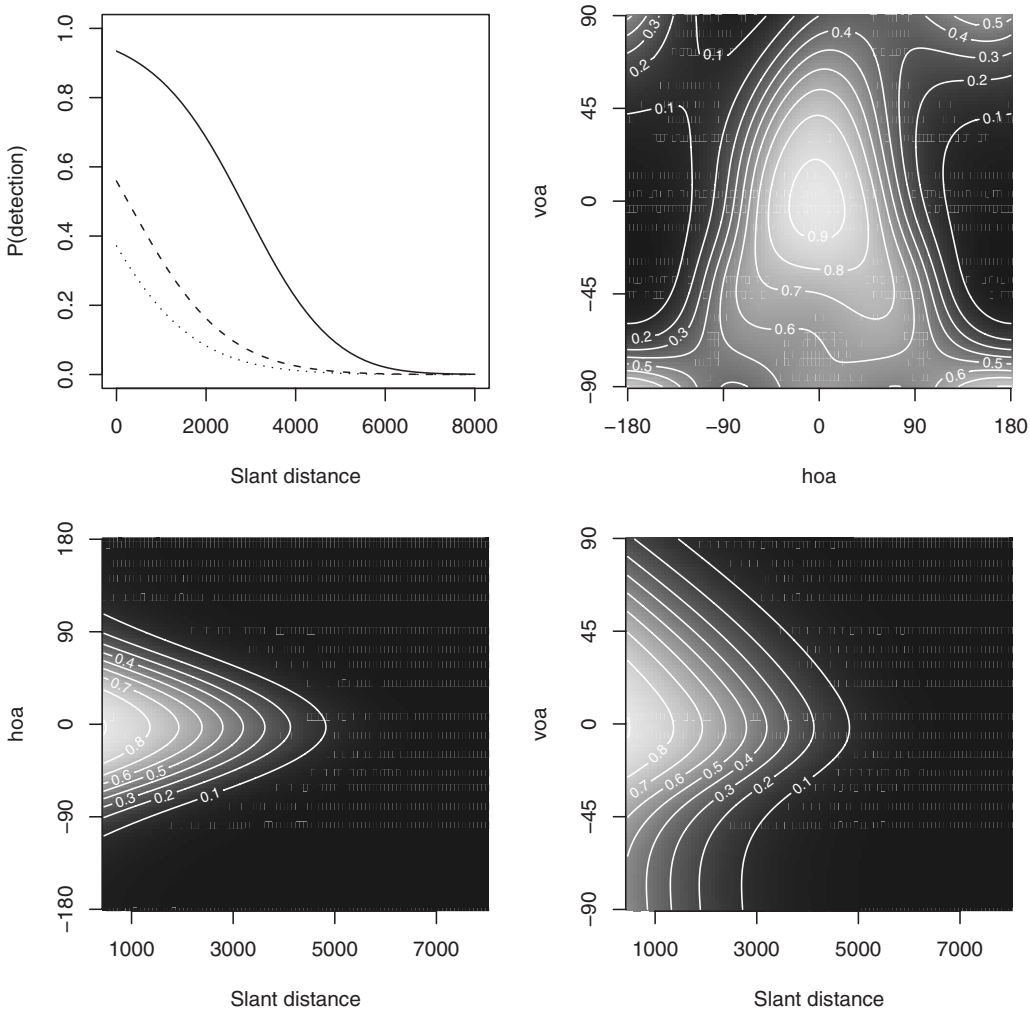

FIG. 3. The estimated detection function. Partial plots (on the response scale) of the fitted smooths for a binomial GAM model with slant distance and a 2D smooth of *hoa* and *voa*. For the top left plot, the off-axis angles are fixed at 0, 45, and 90° (respectively the solid, dashed, and dotted lines). Remaining plots are two-dimensional representations of the smooths, where black and white represent respectively an estimated probability of detection of 0 and 1. Distance (top right panel) and angle not shown (bottom panels) are fixed respectively at 0 m and 0 °.

respectively, 8, 1, 66, and 25%.

IV. DISCUSSION

A. Assessment of case study

1. Comparison with previous work on beaked whales

The case study provided estimates of Md density at AUTEC over a short time period of 6 days. Although true density is not known with certainty, the estimates obtained are consistent with other sources. The vast majority of confirmed beaked whale sightings in the Northern Bahamas are for Md (Claridge, 2006), but the presence of Cuvier's beaked whale (*Ziphius cavirostris*) and Gervais's Beaked Whale (*Mesoplodon europaeus*) have recently been noted at the range.[1] Clicks potentially from other species were treated as false positives, and hence the density estimate presented is valid for Md only.

Using a method based on isolating and counting groups of diving whales over a fixed time period, Moretti *et al.* (2006) obtained estimates of beaked whales at AUTEC using the same primary dataset as analyzed in this paper. Despite their method having some *ad hoc* components, requiring strong assumptions about animal movement and an independent estimate of mean group size, the reported density estimates of 22.0 or 30.0 (depending on the estimate for mean group size used) Md per 1000 km^2 are consistent with the estimates obtained here. (Following a more recent, unpublished, revision of the their estimation process, the area covered by the survey was revised, leading to point estimates of 25.4 or 34.7 Md per 1000 km^2.)

The estimated detection function model (Fig. 3) was consistent with what was expected *a priori*: a decreasing function of distance and a decreasing function of the off-axis angles. This reflects the intuitive notions that the further away and off-axis a Md click is, the harder it is to detect. This also represents further evidence for the high directionality of beaked whale clicks, as has been demonstrated for Cuvier's beaked whale (Zimmer *et al.*, 2005).

The detection of a click seems to be slightly more likely if "below" the whale (negative *voa*) than "above" the whale (positive *voa*): an observation that deserves further investigation in characterizing the Md beam pattern.

At first sight, our results could seem to contradict those from Zimmer *et al.* (2008), which used the passive sonar

equation to model the maximum detection range of Cuvier's beaked whale clicks using a shallow hydrophone in the Mediterranean sea, and predicted a maximum detection range of 4 km. The pertinent parameters utilized were source level of 200 dB re 1 μPa at 1 m, 40 kHz center frequency and processing bandwidth, depth of 0 m, spectral noise level of 30 dB re 1 μPa^2 Hz^{-1}, absorption coefficient of 9.5 dB km^{-1}, and receiver threshold of 14 dB. The deeper hydrophones at AUTEC reduce transmission loss and masking noise, and the processing bandwidth at AUTEC was smaller. In addition, there is justification for assuming a higher maximum source level, since the measurements on which the 200 dB level is based is thought to be an underestimation (Zimmer *et al.*, 2005), and since source levels are known to vary considerably within and between individuals (Zimmer *et al.*, 2008). Johnson *et al.* (2006) reported center and −10 dB frequencies for Md measured at close range using acoustic tags of 38.3 and 26.6 kHz, and hence source levels of 210 and 200 dB re 1 μPa at 1 m at these two frequencies are plausible. Other pertinent parameters are 24 kHz processing bandwidth, depth of 1300 m (approximately mid-way between whale and hydrophone), spectral noise level of 26 dB re 1 μPa^2 Hz^{-1}, absorption coefficients of 8.9 and 5.1 dB km^{-1} at the two frequencies, and receiver threshold of 14 dB. These parameters provide maximum detection ranges of 5.7 km at 38.3 kHz and 7.6 km at 26.6 kHz. The largest observed detection range of a tagged animal in the case study was 6504 m; the above simplistic modeling exercise (e.g., assuming only spherical spreading) suggests that while the high frequency components of the click will be lost at such ranges, sufficient energy remains at lower frequencies to trigger the detector used. Supporting this, the mean received center frequency for clicks detected at 6.5 km range or greater was 29.7 kHz.

2. Assessment of detection probability estimation

Average detection probability was estimated in the case study using a sample of tagged whales for which it could be determined whether cues produced by the whale were detected on surrounding AUTEC hydrophones. However, the simple proportion of these cues detected could not be used directly to estimate average detection probability during the primary survey period for two reasons. First, the sample size was small (four whales over 13 dives), so it is unlikely that the distribution of potentially important covariates in the sample, such as distance from hydrophone, was representative of that over the 6 days of the primary survey. Second, the auxiliary (tag) data were collected at a different time period, when detection conditions were likely different.

The general solution to this problem is to construct a model that includes all the variables that affect detectability and for which the distribution of that variable differs between the auxiliary and the primary datasets. Model selection techniques could be used to select among a suite of candidate variables. Average detectability is then estimated for the correct values of these variables at the time of the primary survey. This approach requires that data are available on the variables affecting detectability both at the time of the auxiliary and primary surveys.

In the case study, because of the small sample size of tags, it was felt that variables indexing the whale's orientation and position relative to the hydrophones may differ between auxiliary and primary data. Both orientation and position were thought *a priori* to have an important influence on detectability. Since orientation and position were not known for cues received in the primary survey, a simulation approach was used to estimate the distribution of these variables during the primary survey. The simulation assumed that a whale's initial position was random with respect to hydrophone horizontal distance (because in the simulation whales were initially located at random within the AUTEC range), and that the dive behavior of the 21 dives from five whales for which data were available in the auxiliary dataset reflected the behavior of whales during the primary survey. The assumption that whale location is random relative to hydrophone seems largely reasonable, given that there were a large number of hydrophones throughout the study area. However, one may expect slightly fewer whales than predicted at larger horizontal distances, because some of the edge hydrophones cover areas that are too shallow for Md to dive in. Nevertheless, the overall influence of these "edge effects" is likely small.

There is no evidence against the assumption that the diving behavior recorded on the 21 dives is representative of that for whales in the primary survey, although this is currently untestable. Baird *et al.* (2008) reported no evidence of a tag-on effect, very similar dive times, and absence of diurnal patterns in dive cycles for Md (with tag durations of up to 72 h).

There are three possibly important variables affecting the detection function that were not considered in the case study. The first is potential differences between hydrophones, since it is possible (but not likely) that the distribution of sensitivities of hydrophones used in the auxiliary dataset is not representative of the 82 recording during the primary survey. The second relates to vertical directivity in the hydrophones, as raised by a reviewer. However, a preliminary analysis of the data revealed that including the vertical angle in the model produced inconsistent results. This is likely because most of the clicks within detection range are made within a narrow band of possible vertical angles with respect to the hydrophones, so any effect of vertical directivity was too negligible to estimate. Even if a strong effect existed, the results of the model reported here would have integrated it implicitly, provided the distribution of vertical angles in the DTag data was representative of the distribution in the 6 day dataset. The third, and potentially more important, is differences in ambient noise conditions, since tags can only be applied during calm weather. For example, mean wind speed, recorded at a location close to the AUTEC range, was 6.1 kn (range 1.1–13.8) during the 13 deep dives used for estimating the detection function, but 12.4 kn (range 2.5–20.8) during the primary survey period. Higher wind speed could reduce detectability, and hence the current estimate of average detection probability could be an overestimate. However the extent of the effect given the depth of the hydrophones remains to be determined. One potential approach would be to include variables such as wind speed, or ambient noise mea-

sured at the hydrophone, in the empirical detection function modeling. However, predicting detection probability for the primary survey period would then mean extrapolating significantly outside the range of the data since maximum wind speed was significantly higher in the primary survey period. An alternative would be to analytically model the effect of increased noise on the detection algorithm, but this is unlikely to be as robust as an empirical approach. A more attractive alternative is to take sound samples from the hydrophones during the primary survey period when no clicks were present and under a range of known wind speeds, use these to contaminate the hydrophone sound files used in the auxiliary study, and thereby empirically study the effect of increased noise on detectability. These approaches will be the subject of a future study.

The detection function was estimated considering only direct path detections. If multi-path detections were included in the click counts in the primary data set, then detection probability could have been underestimated and density correspondingly overestimated. While this is unlikely to have occurred, it might be worth to be investigated further.

It would have been better to have the primary dataset and the auxiliary dataset from the same time period. However, this was not possible because there were not readily available sound recordings for the entire range for the days in which there were DTags. Additionally, placement of DTags corresponded to events considerably spread in time and therefore the mean density estimated over these time periods would be less meaningful.

The method used to estimate probability of detection in the auxiliary dataset assumes that there are no false associations between clicks produced by the whale carrying the tag and clicks detected at the hydrophones. Conceivably, especially if there were other animals around the tagged whale, it is possible that some clicks produced by other animals were wrongly associated with detected clicks on the hydrophone. If this happened, one would overestimate the probability of detecting a click, leading to an underestimation of density. However, this false association seems unlikely: of all clicks detected at more than 4 km, 94.8% were at both *hoa* and *voa* of less than 30°; if these were false associations, one would expect that these correspond to a random sample of off-axis angles, rather than to mostly on-axis clicks. Another check would be to compare the received sound intensity at different frequencies within the 24–48 kHz range for the long-range detections to those predicted from a model of sound production and propagation.

3. Assessment of cue production rate estimation

The auxiliary dataset was also used in estimating click production rate, and hence the assumption is required that average click production rate during the time of the auxiliary survey is equal to that in the primary survey. Information reported in Baird *et al.* (2008) and Tyack *et al.* (2006) about the constancy of deep-dive cycles was fundamental to be confident that a single dive rate was adequate for both day and night periods.

Whenever the cue-count approach proposed here is used, there will be the requirement for an unbiased estimate of average cue production rate to convert cue density into animal density. The application of these methods therefore requires further fundamental research in this area, such as evaluation of cue rates and changes in cue rate as a function of time of day (e.g., Baumgartner and Fratantoni, 2008), year (e.g., Whitehead and Weilgart, 1990), or any other covariates (e.g., group size, season, bottom depth, geographic location, etc). Douglas *et al.* (2005) report that differences in worldwide vocal production (for sperm whales) means that estimates of abundance that are based on cue rates need to be based on data from the population of interest, rather than from another population or some global average.

Note that it is not sufficient to have estimates of the click rate (or inter-click interval) of diving whales from only during vocal parts of their dives—a quantity that is relatively easily obtained from hydrophone data. This will grossly overestimate the required cue production rate, since it ignores the silent time spent between dives. For animals that can spend long periods of time silent, long-term tags or (if feasible) focal follows from the surface are the only options, unless individuals can be tracked through individually recognizable vocalizations.

If cue rate is density dependent, these methods become harder to implement, and it becomes more important to estimate cue rate during the primary survey. If cue rate depends on local group size, then it is important to also estimate cue rate during the primary survey. Failing that, it is still possible to estimate mean cue rate provided one has estimates of the relationship between cue rate and group size, and also the distribution of group sizes during the primary survey.

4. Assessment of false positive proportion estimation

In studies where a manual analysis of the data provides a reliable "gold standard," false positive proportion is the easiest component to estimate. The variance of this component is also easily controllable by taking additional random samples for manual analysis until it is down to an acceptable level. In the case study, the contribution to the overall variance (around 1%) from this component was very small. This does not account for variance due to the specific human operator, and if this is believed to be a considerable source of variation one might consider having different operators repeating the task to quantify it. Here such a procedure was not deemed necessary.

Despite the method being general, it must be noted that values estimated under a given scenario are valid only under that scenario: the number of false positives is dependent on the number of sound sources producing false positives. As an example, everything else being the same, in an area where dolphins (a major source of false positives for the FFT detector used) were much more abundant than at AUTEC, one would expect a much larger proportion of false positives than what was found here.

About half of the sounds recorded as beaked whale clicks were estimated to be false positives in the case study. Such a high proportion was unexpected, although a fair proportion of false positives was expected *a priori*. This emphasizes the importance of accounting for false positives as part of density estimation. A second important lesson is that a

high false positive proportion is not necessarily a barrier to reliable density estimation: it is less important what the characteristics of the detector/classifier are than being able to accurately determine them. This is in contrast to other applications of cetacean detectors—for example, as part of a harm mitigation system—where a large number of false positives would lead to mitigation measures being triggered far more often than required.

The inability to unambiguously classify a proportion of the detected clicks led to increased uncertainty in the reported density estimates, with estimates changing by about 10% depending on how mixed clicks are accounted for.

B. Alternative approaches

1. Alternative methods for estimating P in a cue-counting framework

In the case study, the detection function was estimated based on the auxiliary tagging data. However, sound propagation modeling approaches like those used by Zimmer *et al.* (2008) or Stafford *et al.* (2007) might be alternatively used to obtain the detection function. Alternatively, one could implement broadcasting trials, by mimicking the animal's sound, to empirically estimate the detection function. This would naturally require a comprehensive understanding of the sound production and sound characteristics for the species under study. Ideally, multiple approaches would be used as a way to test the robustness of the results. In all of these cases, the detection function will have to be assumed to be representative of the detection function during the sampling period.

The advantages of using conventional distance sampling methods as described in Buckland *et al.* (2001) are as follows: (i) that the detection function is based on the distances to the detected cues, hence there is no need for additional data from tagging studies, and (ii) the detection function is necessarily valid for the conditions under which the data were collected.

For beaked whales at AUTEC such an approach would be hard to implement, because a given click is often not detected on more than one or two hydrophones, but in a setting where acoustic localization of cues is more feasible such an approach is recommended. Alternative methods of obtaining distances, such as using received sound levels or multi-path detections, may prove useful. Nonetheless, under such a setting there are two fundamental assumptions to estimate the detection function which were not required for the case study: (i) the probability of detecting a cue at distance zero must be 1 (or at least known) and (ii) the distribution of distances of all cues, detected or not, pooled across hydrophones, must be triangular (see Buckland *et al.*, 2001). There is an additional shortcoming for the use of conventional distance sampling methods: the distances required are those to the actual cues (i.e., excluding false positives); alternatively the detection function must be the same for true and false positives. The former seems hard to achieve, and the latter might be unreasonable under some scenarios.

As was described previously, had tags been applied to a large random sample of animals, then P could simply be estimated from the proportion of detected clicks, therefore avoiding the complex modeling exercise presented here. For the data at hand, such an estimate would be 0.036 (CV of 0.155), which is similar to the results from the GAM approach. Nevertheless, the simpler approach cannot be recommended in general for such a small number of dives because the assumptions underlying it are much more restrictive. Rather than having to be representative of the spread of the covariates included in a detection function model, the proportion of clicks detected by dive would have to be representative of the average P.

2. Alternative frameworks for estimating density from fixed passive acoustics

The framework presented here focused on estimating density from an analysis of cues, but other approaches can be envisaged based on detecting animals or groups of animals, and the potential for further research in this area is enormous. If animals can be located based on their vocalizations then the use of an approach similar to the "snapshot" point transect method (Buckland, 2006) could be envisaged. The method could be applied directly if animals could be located using single hydrophone data (e.g., Tiemann *et al.*, 2004); if multiple hydrophones were required for localization then additional development would be needed to account for the dependencies between hydrophones necessary to generate a distance. A major advantage of such an approach would be that it does not require an estimate of cue rate, and so is potentially feasible without any auxiliary data. Similar approaches could be used if groups could be isolated and localized, but additional information on mean group size would be required.

A disadvantage of snapshot type methods is that they require the counts to be discretized into intervals separated in time, so as to introduce statistical independence between samples. Alternative methods that explicitly account for the continuous nature of data acquisition but require information about animal movement exist in the historical literature (e.g., Skellam, 1958); however these need further development to account for issues such as imperfect detection.

In situations, such as for Md at AUTEC, where groups of diving animals can be isolated acoustically, even if not accurately localized, then there is the potential to use a cue counting approach based on counting group dive starts rather than individual clicks. At AUTEC, the probability of detecting a group dive start is 1, so there is no need to estimate the component P in Eq. (3). Similarly, false positives are relatively simple to identify. The cue rate required is the rate of dive initiations, and this could be obtained from time-depth-recording tags, or by tracking focal groups. Hence, such an approach seems potentially feasible and is the subject of ongoing research.

If detections of cues, animals, or groups on multiple hydrophones can be associated, then alternative density estimation methods may be possible that are based on mark-recapture, rather than distance sampling methods. Especially noteworthy are spatially explicit mark-recapture methods (Efford *et al.*, 2008). Mark-recapture methods have the advantage, over conventional distance sampling methods, of

not having to assume that the true distribution of animals with respect to samplers is known (Sec. II B), which is unrealistic if a small number of hydrophones is used. However, mark-recapture methods have their own assumptions, and it is not easy *a priori* to decide which will be more adequate in general.

V. CONCLUSIONS

The framework that has been laid out here is applicable to any study where the key components can be estimated: average detection probability, cue rate, and false positive proportion. Although the case study involved an array of 82 hydrophones over a relatively restricted area and time period, the same methods can be used on a far smaller number of hydrophones (with some loss of precision, obviously), or hydrophones distributed over a much larger area and sampling a longer time period.

Passive acoustic methods are potentially most useful for species that are poorly covered by visual methods but that produce loud, distinctive, predictable vocalizations. Towed acoustic (and visual) methods tend to be better where the goal is wide spatial coverage but narrow temporal coverage; fixed acoustic methods tend to be better where density estimates over long time periods are required. However, the optimal modality depends on many factors, including the study goals, target species, and current technology (the last of which is evolving rapidly). Optimal survey design is an important future research field, in terms of (i) optimal modality for a given situation, (ii) the trade-off between efforts on primary and auxiliary surveys (if required), and (iii) the number and placement of sensors.

Although the focus of this paper has been on estimating cetacean abundance using underwater acoustic data, there is no conceptual extra step required for implementing it with sound recording devices in terrestrial environments. Potential examples include forest surveys of songbirds, territorial monkey species such as gibbons, and elephants (e.g., Payne *et al.*, 2003). Fixed passive acoustics methods are potentially invaluable for monitoring density over time at multiple sites without requiring a large amount of human resources, and for this reason will probably become common practice in the future.

Regarding monitoring of cetaceans, to date most studies have used acoustic data as an index of abundance over time or space (e.g., Stafford *et al.*, 2007). This requires strong (and largely untestable) assumptions that the factors relating number of calls detected to density remain constant (see Anderson, 2001, 2003, for a discussion of these issues). Here, such approaches are improved upon by allowing estimation of these factors, leading to inferences about density.

Mellinger *et al.* (2007b) urged the need for the development of statistical methods for estimating cetacean populations acoustically. This paper shows that the foundations for such methods are laid, and hopes to contribute to their widespread use.

ACKNOWLEDGMENTS

Steve Martin and Dave Moretti provided extensive comments which greatly improved the paper. The authors would like to thank other members of the DECAF project for comment and discussions which are reflected throughout the manuscript: Ron Morrissey, Dave Mellinger, David Borchers, and Catriona Harris. Mark Johnson provided help in processing the DTag data. Danielle Harris, Steve Buckland, Walter Zimmer, Jay Barlow and an anonymous reviewer provided useful comments that improved the clarity and readability of the manuscript. Tagging was performed under US National Marine Fisheries Service research Permit Nos. 981-1578-02 and 981-1707-00 to P.L.T. and with the approval of the Woods Hole Oceanographic Institution Animal Care and Use Committee. This work was funded by two partners under the National Oceanographic Partnership Program: the Ocean Acoustics Program of the US National Marine Fisheries Service, Office of Protected Resources, and the International Association of Oil and Gas Producers Joint Industry Programme on Exploration and Production Sound and Marine Life.

(Received 21 July 2008; revised 2 December 2008; accepted 22 January 2009)

Recent fundamental results concerning the ultimate performance of electromagnetic absorbers were adapted and extrapolated to the field of sound waves. It was possible to deduce some appropriate figures of merit indicating whether a particular structure was close to the best possible matching properties. These figures of merit had simple expressions and were easy to compute in practical cases. Numerical examples illustrated that conventional state-of-the-art matching structures had an overall efficiency of approximately 50% of the fundamental limit. However, if the bandwidth at −6 dB was retained as a benchmark, the achieved bandwidth would be, at most, 12% of the fundamental limit associated with the same mass for the matching structure. Consequently, both encouragement for future improvements and accurate estimates of the surface mass required to obtain certain desired broadband properties could be provided. The results presented here can be used to investigate the broadband sound absorption and to benchmark passive and active noise control systems. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3081529]

I. INTRODUCTION

Ultrasound techniques are widely employed for medical or non-destructive testing applications, and their use frequently requires layers or multilayers with specific characteristics. It is often desirable to optimize the transmission coefficient between the transducer and the propagation medium. For this, quarter-wavelength matching layers constituted of stacked materials are to a large extent used to improve the coupling between piezoelectric transducers and the propagation medium.[1] While it is relatively simple to fabricate a narrowband adapter, the achievement of a broadband coupling efficiency is often preferred. Efficient absorbers are also required in ultrasonic systems in order to suppress unwanted reflection from the walls of a water tank. The optimization of matching structures and absorbers is related to the physics of waves in layered media, which is a very general problem. The concepts of reflection and transmission, impedance, and wave velocity are common for electromagnetic, acoustic, and electronic applications. Electromagnetic waves as well as sound waves can be described using a common matrix formalism.[1–3] All these fields have experienced a beneficial cross-fertilization over the years. For instance, the perfectly matched layer (PML) approach developed by Bérenger[4] for electromagnetic waves is now used in acoustics.[5,6] As another example, the concept of active absorbers has been proposed in the acoustic community[7] as well as in the field of electromagnetics.[8] Metamaterials and cloaking devices are other examples of recent concepts that present shared interests in these communities.[9–12]

Recently, Rozanov[13] authored a major advance concerning the understanding of the ultimate performance of multilayered electromagnetic absorbers. He proved that the broadband performance of an absorber could be no better than a quantity related to its overall thickness. This property is connected with the causality principle, and is consequently very general. The obtained result was comparable to those established by Bayard–Bode and extended by Fano[14] with regard to broadband-matching of electronic networks.

The purpose of the present paper was to investigate the transposition of this result to acoustics, particularly to the case of ultrasonic matching structures and absorbers. The study was developed on the basis of one-dimensional models at normal incidence. Typical examples of matching layers for piezoelectric transducers and ultrasonic absorbing walls are presented in Sec. II, for which the broadband reflection and

transmission coefficients were obtained through numerical approaches. Section III describes the derivation of general theoretical results concerning the reflection and transmission coefficients of multilayered ultrasonic structures. It is shown that these results become simplified in the cases of a matching structure, as well as for an absorbing structure. The theoretical predictions have been compared to numerical results, and this comparison is discussed in Sec. IV.

II. DESIGN OF MATCHING LAYERS AND ABSORBERS

In the following, numerical examples are used to introduce the general problems treated in the theoretical part. Moreover, they also provide benchmarks in order to confront the theoretical results.

A. Matching structure

In view of being used for ultrasonic transducer applications, piezoelectric materials such as PZT are widely employed. Let us consider a semi-infinite PZT material separated by a plane from a semi-infinite water tank, with a sound wave arising from the PZT side under normal incidence on the interface. Because of the large acoustic impedance mismatch between the two materials (Table I), there was a significant reflection at the interface, and the transmission was limited. In this paper, the complex reflection coefficient associated with the amplitude of the reflected pressure wave is denoted r and the complex transmission coefficient (associated with the amplitude of the transmitted pressure wave) is denoted t (see the Appendix). Moreover, the intensity reflection coefficient R is employed. It can be expressed in decibels and is related to r (see the Appendix) according to

$$R = 10\log_{10}|r|^2 = \frac{10}{\log(10)}\ln|r|^2. \tag{1a}$$

A similar relation is used to define the coefficient T from t by

$$T = 10\log_{10}|t|^2. \tag{1b}$$

A very general case consists in a matching stack inserted between an ambient medium, indexed a, and a final medium, indexed b, with a sound wave originating from medium a under normal incidence [Fig. 1(a)]. In order to improve the energy transfer, a common approach is to insert a quarter-wavelength matching layer with an acoustic impedance ranging between the two materials or a multilayer [Figs. 1(a) and 1(b)] with appropriate thicknesses. For transducer applications, this gives rise to an increase in their sensitivity.

In the so-called "harmonic adaptation" approach, the acoustic impedance Z of a quarter-wavelength matching layer is indexed H and given by

$$Z_{H(N,n)} = (Z_a)^P (Z_b)^{1-P} \quad \text{with} \quad P = \frac{N+1-n}{N+1}, \tag{2}$$

where N is the total number of quarter-wavelength matching layers, and n is the considered number of these layers, with $1 \le n \le N$. Moreover, Z_a is the impedance of the PZT layer

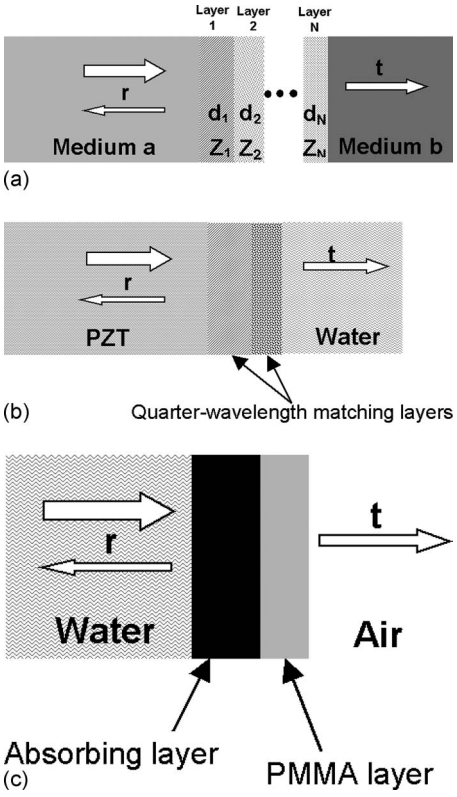

FIG. 1. (a) A sketch of a multilayered (N) structure between incident (a) and propagation (b) media; (b) a sketch of a PZT/water structure with an adaptation layers; (c) a sketch of a water tank coated with an absorbing layer.

(ambient), and Z_b that of the water (final medium), according to the notations in Fig. 1(a).

More particularly, in the case of a single quarter-wavelength matching layer, the acoustic impedance becomes

$$Z_{H(1,1)} = (Z_a Z_b)^{1/2}. \tag{3a}$$

A thicker structure with two-quarter-wavelength matching layers is expected to provide a better bandwidth. In this approach, the impedance of the two layers should be

$$Z_{H(2,1)} = Z_a^{2/3} Z_b^{1/3} \quad \text{and} \quad Z_{H(2,2)} = Z_a^{1/3} Z_b^{2/3}. \tag{3b}$$

In the so-called "impulse regime" approach, a broadband condition is formalized through the binomial transformer formula.[15] The acoustic impedance of the considered quarter-wavelength matching layer is indexed I. One can demonstrate that it can be written as follows:

$$Z_{I(N,n)} = (Z_a)^P (Z_b)^{1-P} \quad \text{with} \quad P = \frac{2^{N+1-n} - 1}{2^{N+1} - 1}. \tag{4}$$

More particularly, a single quarter-wavelength matching layer should verify

$$Z_{I(1,1)} = Z_a^{1/3} Z_b^{2/3}. \tag{5a}$$

A two-quarter-wavelength matching layer structure in this approach corresponds to

$$Z_{I(2,1)} = Z_a^{3/7} Z_b^{4/7} \quad \text{with} \quad Z_{H(2,2)} = Z_a^{1/7} Z_b^{6/7}. \tag{5b}$$

These acoustic impedance values can be obtained in composite materials where a tungsten powder is dispersed in an epoxy resin.[16] The ultrasonic characteristics of the various materials are summarized in Table I.

The modeling of the studied structure was developed on the basis of a one-dimensional assumption and took into account multiple reflections between the interfaces. Thus, a Debye series expansion based on the Fresnel reflection and transmission coefficients led to unconditionally stable formulas. By using the notation proposed by Conoir,[17] a recursive approach could be implemented.[18] The R and T coefficients of these structures are shown in Fig. 2. A significant reduction in the unwanted reflection coefficient at the central frequency 1 MHz was observed in all cases, along with an improvement of the transmission coefficient. It was clearly observed that two-quarter-wavelength matching layers—as opposed to a single quarter-wavelength matching layer—increased the bandwidth, but also rendered the matching structure thicker and heavier.

B. Absorber

Let us consider a semi-infinite water tank separated from the air by a 1-cm thick PMMA planar wall (polymethyl methacrylate polymer or its corresponding commercial Plexiglas™), with an ultrasonic wave arising under normal incidence. Because of the large impedance mismatch between the water and the air, a very large reflection occurred unless an ultrasonic absorber was placed against the PMMA wall [Fig. 1(c)]. Figure 3 presents the intensity reflection coefficient R for an elastomeric absorber that was either 30 or 60 mm thick, with properties reported in Ref. 19. In this example, increasing the absorber thickness improved the low-frequency operation and increased the overall efficiency. The different material characteristics are reported in Table II.

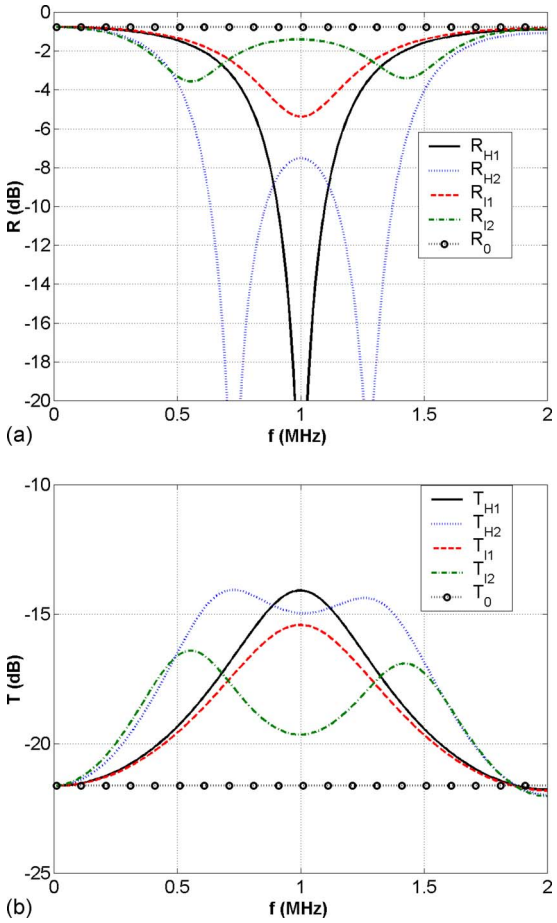

FIG. 2. (Color online) The reflection R and transmission T coefficients associated with the PZT-water interface (circles: R_0 and T_0) and with various matching structures tuned at 1 MHz (solid lines: $H1$; dotted lines: $H2$; dashed lines: $I1$; dashed-dot lines $I2$; see Table I for further details).

III. THEORETICAL APPROACH

The main focus was placed on the very general problem of broadband adaptation. It became clear that perfect match-

TABLE II. Physical parameters used to calculate the reflection and transmission properties of a water/absorber/tank/air structure. (Z: acoustical impedance; ρ: density; v: longitudinal wave velocity; α: attenuation coefficient; d: thickness).

Medium	Composition	Z (MRa)	ρ (kg m^{-3})	v (m s^{-1})	α (dB mm^{-1} MHz^{-1})	d (mm)
Ambient	Water	1.5	1000	1480	0	∞
Final medium	Air	4×10^{-4}	1.2	330	0	∞
Tank wall	PMMA	3.5	1270	2750 @ 2 MHz	$0.13+0.94\times(\mathrm{F/MHz})$	10
Absorber	Loaded elastomer	1.8	1150	1670 @ 2 MHz	$0.74\times(\mathrm{F/MHz})^{1.38}$	30 60

ing in order for no reflection to occur was possible at a single frequency, as evidenced in Fig. 2 for the case $H1$. However, would it be possible to design a sandwich of adaptation layers operating over a significant bandwidth, so that no reflection would take place over the entire frequency operating range? If not, are there design rules that indicate how thick, or how heavy, the adaptation sandwich should be in order to attain some given figure of merit in terms of adaptation? Similar questions can be raised, concerning the transmission coefficient. A simple mathematical solution to a perfect broadband-matching layer would be to take an adaptation structure that works at a single frequency, such as $H1$, with the requirement that the index varies as $1/f$, for which the impedance is constant with the frequency f. However, such a material would be impossible to manufacture since it does not respect causality.

In the following, the general problem of broadband adaptation is treated with the constraint that the materials in the matching layers respect the causality principle, which limits the variation of their properties with the frequency. This problem of broadband adaptation has been solved for electromagnetic waves in 1998.[13,20,21] The seminal work of Rozanov[13] established the relation between the broadband efficiency of microwave absorbers and the minimum thickness that was necessary in order to obtain this efficiency. It has provided a sound figure of merit for the absorbers and an accurate basis for comparing various absorber types. This approach was successfully extended to broadband antenna substrates, as well as to high impedance planes.[22] It has further been very useful for anticipating the best way to use new material concepts, such as metamaterials.[10] Moreover, it can provide benchmarks for comparing passive and active impedance-matching solutions. These relations belong to a large class of results derived from the causality principle, such as Kramers–Kronig, and they can be viewed as the counterparts of Bayard–Bode and Fano results[14] related to impedance-matching in electronics. However, the derivation provided by Rozanov[13], employed in the present study, differs from the Fano approach.

In accordance with previous work,[13] the aim of the present study was to investigate the integral of the intensity reflection coefficient R over the wavelength spectrum. As an illustration, Fig. 4(a) depicts the reflection coefficient associated with the case $H1$ reported in Table I. It shows not only the dip of the reflection coefficient at the central operation frequencies but also the behavior of this quantity over an extremely broad bandwidth. For very large wavelengths, the reflection coefficients tend toward that at a PZT/water interface, denominated $R_0=10\log_{10}|r_0|^2$ (see the Appendix). Contrarily, at small wavelengths, interference effects lead to numerous peaks. The aim of the derivation presented below was to determine the integral of the hatched area. In the case presented here, the integral was clearly negative. Due to the fact that it is much more common to describe the reflection coefficient as a function of the frequency, rather than as a function of the wavelength, the derivation was carried out

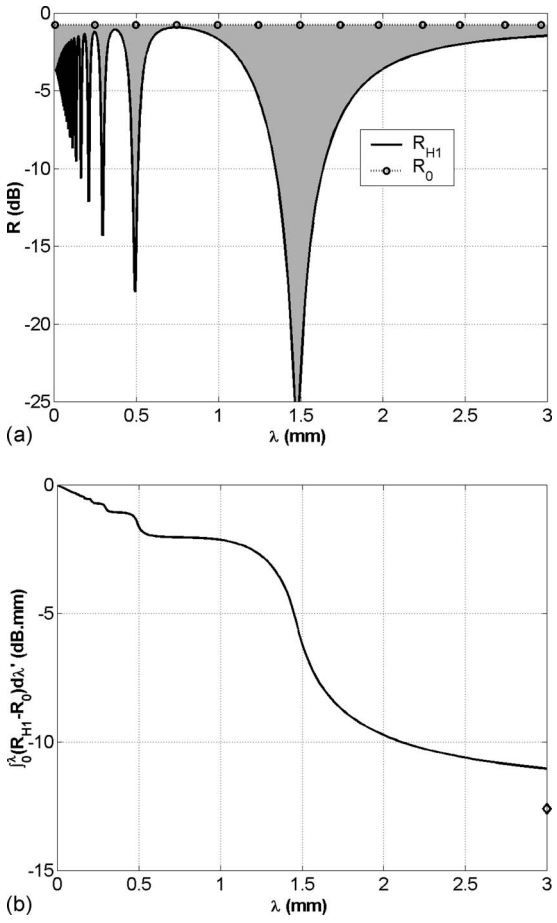

FIG. 4. (a) The reflection coefficient in PZT in the presence of an adaptation layer $H1$ between PZT and water (solid line R_{H1}); the wavelength is calculated in the water; the straight dashed line with circles represents the asymptotic value R_0 of the reflection coefficient. (b) The integral of the reflection coefficient over the wavelength in water, corresponding to the gray area in Fig. 4(a). The symbol (diamond) on the right axis represents the asymptotic value of the integral.

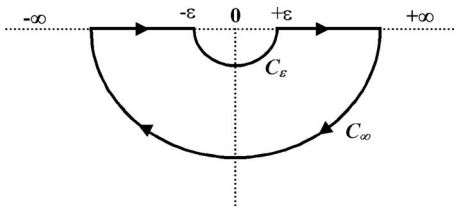

FIG. 5. A sketch of the integration contour in the complex plane.

with all literal expressions as a function of the frequency. Moreover, with the exception of Fig. 4, all results are displayed as functions of the frequency.

A. General case

The pressure reflection coefficient $r(f)$ as a function of the complex frequency f is analytic over the lower half plane,[5] and this property is due to causality.[13,14] Our main interest was directed toward the properties of $\log(r(f))$; however, this function was not analytic due to the possible presence of zeros of the pressure reflection coefficients. The zeros of r in the lower half plane should be denominated f_q, where $1 \leq q \leq Q$, and Q is the number of poles. Rozanov[13] introduced an ancillary function $r'(f)$ with two attractive properties: for real frequencies $|r(f)|=|r'(f)|$ and $\log(r'(f))$ is analytical over the lower half plane. $r'(f)$ is defined by

$$r'(f) = r(f)\prod_{q=1}^{q=N}\frac{f-f_q^*}{f-f_q} = r(f)\frac{(f-f_1^*)}{(f-f_1)}\frac{(f-f_2^*)}{(f-f_2)}\cdots\frac{(f-f_Q^*)}{(f-f_Q)}, \tag{6}$$

where the asterisk stands for the complex conjugation.

At zero frequency, the pressure reflection coefficient tends toward a real limit r_0. The quantity of interest is the integral of $\log(r(f)/r_0)$ over the wavelength range λ. Since $\lambda=c/f$, where c is the celerity of the waves, it corresponds to the integral over f of $\log(r(f)/r_0)/f^2$, within a proportionality factor. Using the aforementioned properties of $r'(f)$, and taking into account that $r'(-f^*)=r'(f^*)$, the quantity of interest is

$$\int_0^\infty \log\left|\frac{r(f)}{r_0}\right|^2\frac{df}{f^2} = \int_{-\infty}^\infty \log\left(\frac{r'(f)}{r_0}\right)\frac{df}{f^2}. \tag{7}$$

The right-hand part of Eq. (7) is the integral of a function that is analytical in the lower half of the complex plane, except in zero. As a consequence, the integral of this quantity over a closed contour sketched in Fig. 5 is zero. The integral over the real axis corresponds to the right member of Eq. (7), which is the quantity to be calculated. The integral over the circle C_∞ tends toward zero when the radius of this circle increases, because of the $1/f^2$ factor in the function to be integrated. The integral over the circle C_ε can be expressed as a function of the derivative of the pressure reflection coefficient at null frequency. It follows that

$$\int_0^\infty \log\left|\frac{r(f)}{r_0}\right|^2\frac{df}{f^2} = \pi\,\mathrm{Im}\left(\frac{d(r(f))}{r_0 df}\right)_{F=0} + 2\pi\,\mathrm{Im}\left(\sum_q \frac{1}{f_q}\right). \tag{8}$$

Since the f_q are in the lower half plane,

$$\mathrm{Im}\left(\sum_q \frac{1}{f_q}\right) \geq 0. \tag{9}$$

This gives

$$\int_0^\infty (R-R_0)\frac{df}{f^2} \geq \frac{10\pi}{\log(10)}\mathrm{Im}\left(\frac{d(r(f))}{r_0 df}\right)_{f=0}. \tag{10}$$

The derivation of the first order development of $r/r_0(f)$ in f around $f=0$ for a multilayer is given in the Appendix. It is expressed as a function of the acoustic impedances Z_a and Z_b of the ambient and final media, of the thicknesses d_n of the various layers, of their acoustic characteristics in the low-frequency limit, the impedance Z_n, and the speed of sound c_n. Alternatively, Z_n can be expressed as a function of the density ρ_n, through $Z_n=\rho_n.c_n$. Consequently,

$$\int_0^\infty (R-R_0)\frac{df}{f^2} \geq -\frac{40\pi^2}{\log(10)}\frac{Z_a}{Z_a^2-Z_b^2}(m-Z_b^2h) = -K_{RR}, \tag{11}$$

where

$$m = \sum_n d_n\frac{Z_n}{c_n} = \sum_n d_n\rho_n, \tag{12}$$

$$h = \sum_n \frac{d_n}{Z_n c_n} = \sum_n \frac{d_n}{\rho_n c_n^2}, \tag{13}$$

and $40\pi^2/\log(10)\approx 171$.

Here, m is the mass per unit of surface of the matching layers.

It should be noted that the left-hand side of Eq. (11) is generally negative, where an increasing negativity corresponds to an enhanced antireflection efficiency. The right-hand side of Eq. (11) is also a negative number, which is indeed a prediction of the performance bounds of the multilayer structure in terms of antireflection efficiency.

A similar approach can be worked out for the transmission coefficient T

$$\int_0^\infty (T-T_0)\frac{df}{f^2} \geq -\frac{20\pi^2}{\log(10)}\frac{(m+Z_aZ_bh)}{Z_a+Z_b}. \tag{14}$$

B. Case of a transducer matching structure

In the case of a matching structure attached to a transducer, a number of simplifications can be made. In particular, $Z_a \gg Z_b$ and $Z_b^2h \ll m$ as calculated in Table III for harmonic adaptation [in other cases Eq. (11) must be used]. As a consequence, Eq. (11) becomes

TABLE III. Calculated parameters (h, Z_b^2h, m, and Z_aZ_bh) for various adaptation layers and absorbing structures.

Configuration	h ($m^2\ s^2\ kg^{-1}$)	Z_b^2h ($kg\ m^{-2}$)	m ($kg\ m^{-2}$)	Z_aZ_bh ($kg\ m^{-2}$)
		Adaptation structure		
$H1$	3.5×10^{-14}	0.08	1.8	
$H2$	8.3×10^{-14}	0.18	3.9	
$I1$	6.2×10^{-14}	0.14	1.0	
$I2$	15.6×10^{-14}	0.35	1.6	
		Absorber structure		
30-mm	1×10^{-11}	1.9×10^{-6}	47	0.0065
60-mm	2×10^{-11}	3.7×10^{-6}	82	0.013

$$\int_0^\infty (R-R_0)\frac{df}{f^2} \geq -\frac{40\pi^2}{\ln(10)}\frac{m}{Z_a}. \tag{15}$$

Equation (15) is a remarkably simple expression. It proves that whatever the arrangement of layers in a matching structure, a certain minimum weight is required in order to obtain the desired antireflection properties. However, it should be kept in mind that this is a bound, and that it, naturally, does not prevent the building of very inefficient absorbers from high mass walls. In the case where the material parameters m and Z_a are not precisely known, it is useful to notice that the relative uncertainty of the limit is simply the sum of the relative uncertainties on m and Z_a. The relation associated with the transmission is not relevant in this case, since the integral quantity related to the transmission in Eq. (14) is not an adequate figure of merit for high transmission structures.

C. Case of an absorber at a water/air interface

In the case of an absorber at a water/air interface, $Z_a \gg Z_b$ and $Z_aZ_bh \ll 1$ as calculated in Table III for our studied cases. It follows that

$$\int_0^\infty (T-T_0)\frac{df}{f^2} \geq -\frac{20\pi^2}{\ln(10)}\frac{m}{Z_a} = -K_{RT}. \tag{16}$$

It simply reads that the integrated efficiency of an absorber at the water/air interface, in order to absorb waves propagating in the water, is bounded by the mass of the absorber. Rozanov's bound for the transmission coefficient T is half of that for the reflection coefficient R, i.e., $K_{RT}=K_{RR}/2$. Efficiency to minimize the transmitted waves from water to air is described by the left-hand side of Eq. (16).

IV. DISCUSSION

It is useful to compare the theoretical predictions with the various numerical examples that were investigated in the first part of this study. Such a comparison should provide a check of the general predictions on particular examples and introduce a more general discussion.

A. Matching structure

Figure 6(a) illustrates the reflection coefficient R associated with the $H1$ structure at the PZT-water interface (Table I), and Fig. 6(b) displays that the argument of the integral in Eq. (11) rapidly tended toward zero as f increased. As a consequence, it can be seen in Fig. 6(c) that the integral was very close to its asymptotic value when the upper integration frequency was above the third resonance. This statement was consistent with what can be observed in Fig. 4(b), where the partial integral was represented as a function of the wavelength in water: the contribution of wavelengths shorter than the third resonance was found to be negligible. Rozanov's

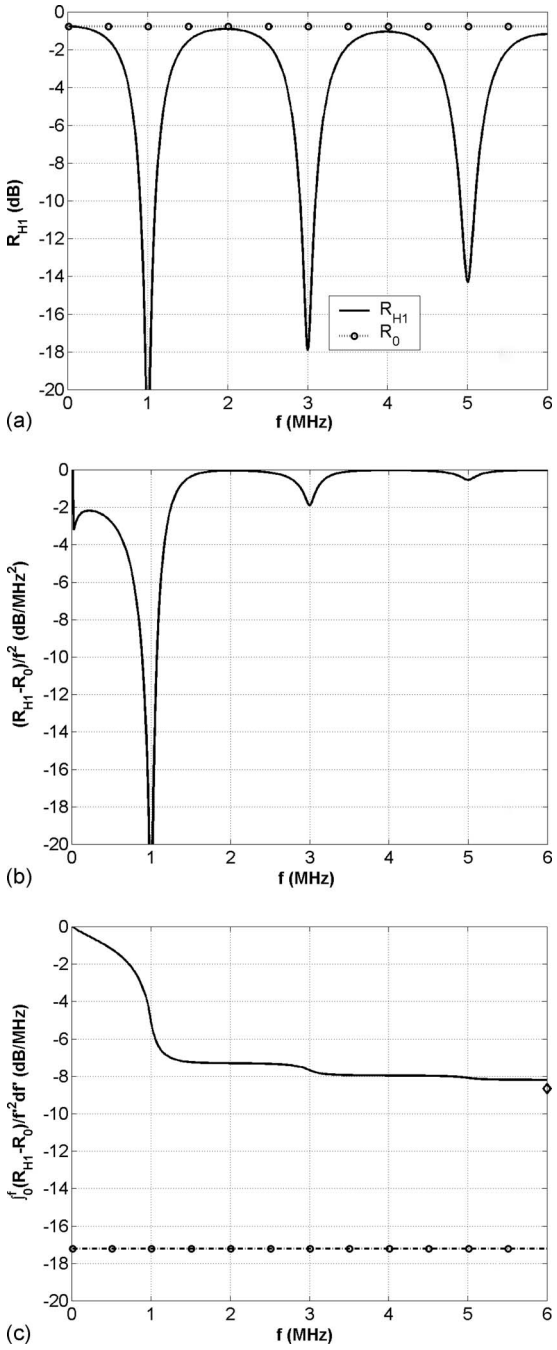

FIG. 6. (a) A reflection coefficient through PZT in the presence of an adaptation layer $H1$ between PZT and water, as a function of the frequency (solid line R_{H1}). The limit R_0 at zero frequency is indicated by the dashed line with circles. (b) The reflection coefficient R_{H1} weighted by $1/f^2$. (c) The corresponding partial integral (solid line) and comparison with the Rozanov limit (dashed line with circles). The symbol (diamond) on the right axis correspond to the summation up to 250 MHz.

TABLE IV. Values of Rozanov bounds K_{RR}, figures of merit η and η', and bandwidth $\Delta f/f$ for the matching structures.

Adaptation structure	K_{RR} (dB MHz^{-1})	$\left\lvert \int_0^\infty (R-R_0)\frac{df}{f^2} \right\rvert$ (dB MHz^{-1})	η (%)	$\Delta f/f$ at -6 dB (%)	η' (%)
$H1$	17	8.65	50	34	10
$H2$	39	19.4	50	87	12
$I1$	9	4.3	49	0	0
$I2$	13	6.3	48	0	0

bound K_{RR} associated with the integral of the reflection coefficient R was calculated using Eq. (15), and is presented in Table IV. It is also displayed in Fig. 6(c), and the prediction of Eq. (15) was clearly fulfilled.

The three other impedance-matching structures described in Table I were also investigated. Their reflection coefficients R are presented in Fig. 7(a), and the integrals as well as Rozanov's bounds are pictured in Fig. 7(b). It can be seen that the integral quantity is in module about a factor 0.5 from Rozanov's bound. Table IV summarizes Rozanov's bounds for the various structures. It is quite straightforward to understand that the increased broadband efficiency of the $H2$ structure was strongly connected with its considerably heavier surface weight of 3.9 kg m^{-2} (Table III), as compared to the much less efficient $I1$ structure with a weight of only 1 kg m^{-2}. These results also suggested that certain possibilities remained in order to increase the antireflection efficiency with the same mass, through a more clever arrangement of materials, and possibly the use of dispersive matter.

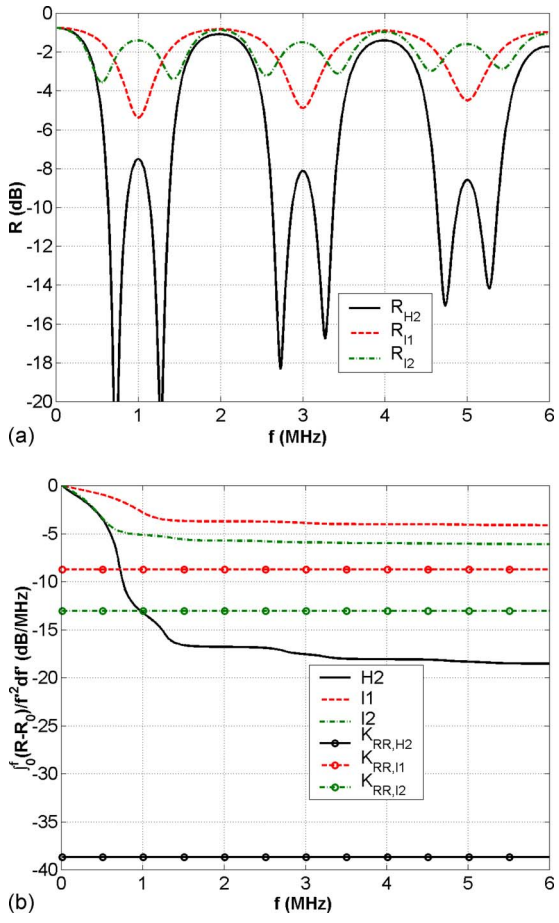

FIG. 7. (Color online) (a) The reflection coefficients through PZT in the presence of various adaptation layers between PZT and water, as functions of the frequency ($H2$: solid line; $I1$: dashed line; $I2$: dashed-dot line). (b) The corresponding partial integrals and a comparison with their respective Rozanov limits K_{RR} (horizontal lines with circles).

B. Absorber

Let us consider the absorbing structure described in Fig. 1(c) and Table II, for which the reflection coefficient R is given in Fig. 3. The integral associated with the reflection coefficient R is presented in Fig. 8, and Table V provides the calculated value of Rozanov's bounds. It was expectedly found that, for each absorber thickness, the integral did not go as far in the negative values as the ultimate bounds according to Eq. (15). Significant room for optimization was expected in the present case, since the integral was in module about 20 times less than Rozanov's bound. The transmission coefficients T for the two absorber thicknesses are given in Fig. 9(a), and their associated integrals can be seen in Fig. 9(b). Each integral was approximately five times less in module than its associated value of K_{RT}.

C. Fundamental and practical uses of Rozanov's relations

It has been established that the wideband efficiency of antireflection layers, either in the matching layer configura-

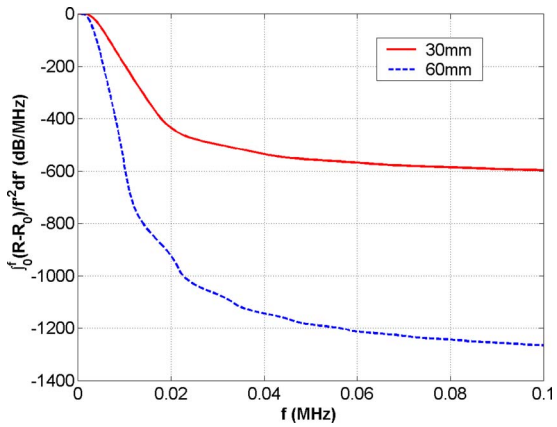

FIG. 8. (Color online) The partial integral associated with the reflection coefficient at a water/absorber/PMMA/air interface, for an absorber thickness of 30-mm (solid line) or 60-mm (dashed line). The reflection coefficient R is displayed in Fig. 3.

TABLE V. Values of Rozanov bounds K_{RR} and K_{RT} for the absorber structures.

Absorber thickness (mm)	K_{RR} (dB MHz^{-1})	K_{RT} (dB MHz^{-1})
30	11 500	5 800
60	20 000	10 000

tion or in the absorbing layer configuration, was bounded by a simple expression K_{RR}. In practical cases, the bound is proportional to the surface mass of the structure, divided by the impedance of the ambient media. This provides straightforward hints for the engineering of ultrasonic matching and absorbing layers. The main point is that it affords a clear figure for the minimum budget required to build the necessary reflection properties. This budget is not calculated in money, but in kg m^{-2}. The second point is that it provides an indicator for the efficiency of the designed structure. The following ratio η is a good candidate for this

$$\eta = \frac{-1}{K_{RR}} \int_0^\infty (R - R_0) \frac{df}{f^2}. \tag{17}$$

η cannot exceed unity as a consequence of Eq. (11). The closer the ratio is to 100%, the closer the solution is to the ultimate limits. Examples have been presented above, where this ratio could range from nearly 50% (the matching structures) down to 5% (with the elastomeric absorber).

In a number of practical cases, the benefits brought by a matching or an absorbing multilayer are summarized as a certain frequency band $[f_1, f_2]$ where the intensity reflection coefficient R has been reduced below a certain level $R_{\min}$ expressed in decibels. Since $R \leq R_{\min}$ in the interval $[f_1, f_2]$, it follows, according to Eq. (11), that

$$0 \geq (R_{\min} - R_0) \frac{f_2 - f_1}{f_1 f_2} \geq \int_0^\infty (R - R_0) \frac{df}{f^2} \geq -K_{RR}. \tag{18}$$

It is then possible to establish

$$(f_2 - f_1)(R_0 - R_{\min}) \leq K_{RR} f_1 f_2. \tag{19}$$

In the case where the bandwidth $\Delta f = f_2 - f_1$ is relatively small compared to the center resonance frequency $f_r = (f_1 + f_2)/2$, it is possible to obtain a simple expression of the maximum bandwidth that can be brought by a certain mass of the matching or absorbing multilayer. Subsequently, Eq. (19) reduces to

$$\Delta f (R_0 - R_{\min}) \leq K_{RR} f_r^2. \tag{20}$$

It is sometime preferred to use the relative bandwidth $\Delta f / f_r$, and the bound for this quantity also has a simple expression

$$\frac{\Delta f}{f_r} \leq K_{RR} \frac{f_r}{R_0 - R_{\min}}. \tag{21}$$

In the same way as for Eq. (17), it is possible to obtain a simple figure of merit associated with a matching or an absorbing multilayer

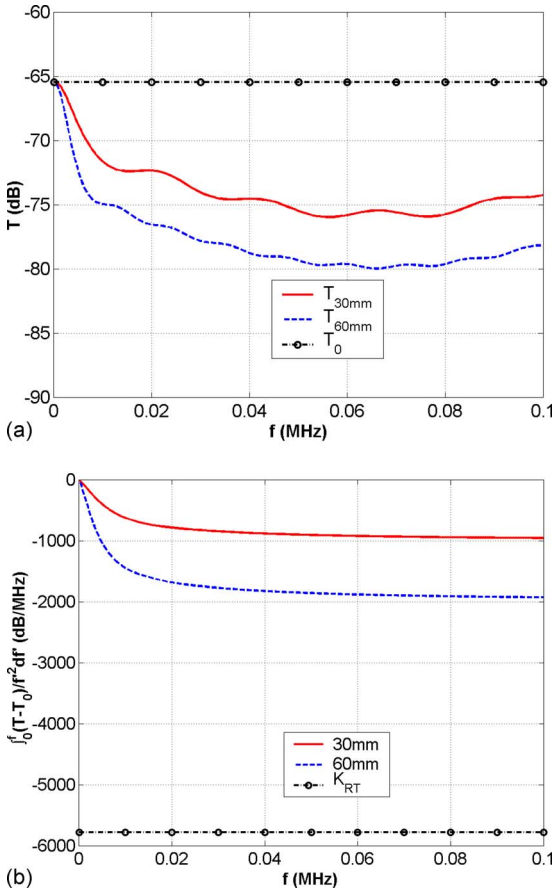

FIG. 9. (Color online) (a) The transmission coefficient at a water/absorber/PMMA/air interface, for an absorber thickness of 30-mm (solid line) or 60-mm (dashed line). (b) The corresponding partial integral associated with the transmission coefficient (30-mm: solid line; 60-mm: dashed line) and the Rozanov limit K_{RT} for the 30-mm case (horizontal dashed line with circles).

$$\eta' = \frac{\Delta f (R_0 - R_{\min})}{K_{RR} f_r^2}. \tag{22}$$

η' is always lower than unity as a consequence of Eq. (21). It is enough to know the bandwidth Δf at $R_{\min}$ (decibels), the center frequency f_r, the mass m of a multilayer, and the characteristics of the initial and final medium to compute the figure of merit η'.

An illustration related to the practical use of Rozanov's bounds in association with bandwidth consideration is provided in Fig. 10. This illustration is associated with the quarter-wavelength matching structure $H2$ (already presented in Figs. 2 and 7, as well as in Tables I, III, and IV). Figure 10 displays the reflection coefficient R close to the matching frequency $f_r = 1$ MHz. It can be seen that the bandwidth at -6 dB of the structure $H2$ is [0.57 MHz, 1.44 MHz]. The gray area is the quantity $\Delta f (R_0 - R_{\min})$, corresponding to the left-hand side of Eqs. (19) and (20). This quantity is bounded by Rozanov's constant times the square of the central frequency, according to Eq. (20). In this example, $\Delta f (R_0 - R_{\min}) = 4.6$ MHz dB, while the bound is 39 MHz dB: the prediction of Eq. (20) is thus fully verified. The gray area is $\eta' = 12\%$ of the ultimate limit, given the mass that has been involved in building the $H2$ structure.

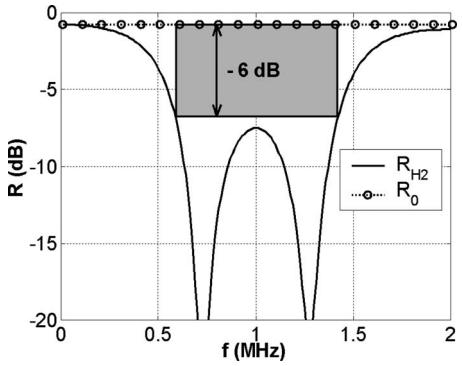

FIG. 10. The reflection coefficient associated with the matching structure $H2$ at the PZT-water interface; the bandwidth at $R_{min}=-6$ dB is also sketched, along with the reflection coefficient R_0 in the absence of a matching layer. The gray area is bounded, according to Eq. (20).

The adimensional figures of merit η and η' are useful clues in order to detect which cases can be significantly improved by further design efforts, and which ones cannot. They may also be useful for comparing passive structures and active sound absorbers,[23] as well as for guiding the optimization process of broadband sound absorbers.[24] In the case of very miniature systems, such as silicon-based microelectromechanical system, the requirements of a significant surface mass may be a limitation in order to obtain good matching properties. In this case, the theoretical results presented here suggest various paths to cope with this limitation. For instance, a very abrupt reflection curve should be synthesized, with very little remaining attenuation outside the working bandwidth, especially at lower frequencies. The high frequency tail gives negligible contribution to the integral, whereas the low-frequency tail, corresponding to large wavelengths, may significantly contribute to the integral, and therefore lead to larger masses, as can be seen in Fig. 6. Table IV indicates that the integral on the left-hand side of Eq. (15) reaches about $\eta=50\%$ of its maximal allowed value for a given mass, whereas the bandwidth at -6 dB is, at most, $\eta'=12\%$ of its maximal allowed value for the same given mass.

From a more fundamental point of view, Rozanov's bound provides a good benchmark for comparing very different approaches for impedance-matching, including passive and active methods. Further, it raises fundamental questions that are not answered by the present work. Is it possible to attain these bounds? If so, what are the material properties required for this task? Is the influence of the frequency dispersion of the material properties important? Is it possible to derive global optimization criteria that include the piezoacoustic transducer and its driving electronics? The existence of a matrix formalism describing the entire system,[25] as well as the existence of similar relations both in electronics[14] and for ultrasounds, suggests that such unified figures of merit may exist. It is believed that the acoustic community can further adapt these results to its specific theoretical and applied problems, including broadband sound absorption and active noise control.[23,24]

D. Common points and differences with the electromagnetic case

Although the formal description is the same, significant differences exist between Rozanov's relations for the electromagnetic and ultrasonic cases. The existence of a reference medium (vacuum) for the celerity of the electromagnetic waves renders it more customary to describe electromagnetic waves through their wavelength. As a consequence, the expression of Rozanov's relations in terms of an integral over the wavelength is probably more suitable in the electromagnetic domain than in the ultrasonic field.

While the expressions of Rozanov's bound are the same when written as a function of the impedances, indices, and thicknesses of the various layers, they become very different when expressed as functions of other physical parameters. In Eqs. (11), (15), and (16), m is the surface mass in the case of acoustics, while it corresponds to the sum of the permeability by thickness product of the different layers for electromagnetic materials. A sum rule related to the surface mass of electromagnetic absorbing materials was derived, but associated with the integral over f, rather than over λ.[26]

It seems much more common to use materials with a strong frequency dispersion of the electromagnetic properties[21] as opposed to materials with a strong frequency dispersion of the acoustic properties. However, the advent of metamaterials in the sonic range may provide new and attractive techniques to carve sharp ultrasonic resonance features that could prove appealing.[10]

The canonical cases are also quite different in the various domains. In electromagnetics, one always considers $Z_b=0$, which is a fully adequate description of conductors, and therefore one obtains $|r_0|=1$, and $R_0=10\log_{10}|r_0|^2=0$ dB. The acoustic impedance-matching structure for an ultrasonic transducer departs from that configuration, and it is consequently necessary to establish the integral relations taking into account a nonzero R_0. In the case of the absorbing wall between water and air, R_0 is close to 0 as in the electromagnetic case. However, the transmission into air may be a concern since air does not dampen the acoustic waves. As a consequence, the relation associated with the transmission coefficient, Eq. (16), makes sense.

V. CONCLUSION

The ultimate performance of matching and absorbing structures used in ultrasonic applications is bounded by the surface mass. This result is very general, since it was derived from the causality principle. The bounds provided practical indications that could be applied to the conception of multilayer structures, and the relations gave rise to certain figures of merit that could come in useful for comparing passive and active absorbers or matching structures. These figures of merits are simple to compute in practical cases, requiring only the knowledge of the bandwidth and of the mass of the matching structure. Nevertheless, certain questions remain unanswered; for instance, whether it is possible

to attain these bounds, and, if so, with which structure. In addition, further adaptations to the case of broadband sound absorption and noise control are expected to lead to fruitful developments.

APPENDIX

Let us consider a plane wave incoming under normal incidence on a multilayer structure as sketched in Fig. 1(a). The pressure P and local displacement speed v between two faces of layer 1 are related by

$$\begin{pmatrix} P(d_1) \\ v(d_1) \end{pmatrix} = \overline{\overline{M}}_1 \begin{pmatrix} P(0) \\ v(0) \end{pmatrix}, \tag{A1}$$

with

$$\overline{\overline{M}}_1(f) = \begin{pmatrix} \cos\left(\frac{2\pi f d_1}{c_1}\right) & -jZ_1 \sin\left(\frac{2\pi f d_1}{c_1}\right) \\ -j/Z_1 \sin\left(\frac{2\pi f d_1}{c_1}\right) & \cos\left(\frac{2\pi f d_1}{c_1}\right) \end{pmatrix}, \tag{A2}$$

where Z_1 and c_1 are the acoustic impedance and sound celerity for the medium 1 at the frequency f, and d_1 is its thickness. Since only the first order development in f is required in Eq. (10), it is convenient to express the first order development of the above matrix as

$$\overline{\overline{M}}_1(f) = \overline{\overline{I}} - j2\pi f \begin{pmatrix} 0 & \frac{Z_1 d_1}{c_1} \\ \frac{d_1}{Z_1 . c_1} & 0 \end{pmatrix} + \overline{\overline{O}}(f^2). \tag{A3}$$

Here, $\overline{\overline{I}}$ is the identity matrix and $\overline{\overline{O}}(f^2)$ designates terms that are in f^2 and higher orders. Z_1 and c_1 are the low-frequency limits of the acoustic impedance and sound celerity. For the whole multilayer, the pressure and velocity fields at the output interface of the multilayer, denoted with the index n, are related to the fields at the first interface, denoted with the index 0, through

$$\begin{pmatrix} P_n \\ v_n \end{pmatrix} = \overline{\overline{M}} \begin{pmatrix} P_0 \\ v_0 \end{pmatrix} \quad \text{with} \quad \overline{\overline{M}} = \prod_{i=1}^{n} \overline{\overline{M_{n-i+1}}} = \overline{\overline{M}}_n \ldots \overline{\overline{M}}_1, \tag{A4}$$

resulting in

$$\overline{\overline{M}}(f) = \overline{\overline{I}} - j2\pi f \begin{pmatrix} 0 & m \\ h & 0 \end{pmatrix} + \overline{\overline{O}}(f^2), \tag{A5}$$

where m is the surface mass defined by

$$m = \sum_{i=1}^{n} \frac{Z_i d_i}{c_i} = \sum_{i=1}^{n} d_i \rho_i \tag{A6}$$

and

$$h = \sum_{i=1}^{n} \frac{d_i}{Z_i c_i}. \tag{A7}$$

The fields at interfaces 0 and n can be expressed as functions of the pressure field P_i associated with the incoming sound wave

$$\begin{pmatrix} P_0 \\ v_0 \end{pmatrix} = \begin{pmatrix} 1-r \\ \frac{1+r}{Z_a} \end{pmatrix} P_i \quad \text{and} \quad \begin{pmatrix} P_n \\ v_n \end{pmatrix} = \begin{pmatrix} t \\ \frac{t}{Z_b} \end{pmatrix} P_i. \tag{A8}$$

Therefore,

$$\begin{pmatrix} t \\ \frac{t}{Z_b} \end{pmatrix} = \overline{\overline{M}} \begin{pmatrix} 1-r \\ \frac{1+r}{Z_a} \end{pmatrix} \tag{A9}$$

and it follows that

$$\frac{r}{r_0} = 1 - j2\pi f \frac{2Z_a}{Z_a^2 - Z_m^2}(m - Z_b^2 h) + O(f^2), \tag{A10}$$

$$\frac{t}{t_0} = 1 - j2\pi f \frac{(m + Z_a Z_b h)}{Z_a + Z_b} + O(f^2), \tag{A11}$$

where

$$r_0 = \frac{Z_a - Z_b}{Z_a + Z_b} \quad \text{and} \quad t_0 = \frac{2Z_b}{Z_a + Z_b} \tag{A12}$$

are, respectively, the reflection and transmission coefficients in the absence of the multilayer.

(Received 14 June 2008; revised 23 January 2009; accepted 24 January 2009)

The rotary subwoofer is a novel acoustic transducer capable of projecting infrasonic signals at high sound pressure levels. The projector produces higher acoustic particle velocities than conventional transducers which translate into higher radiated sound pressure levels. This paper characterizes measured performance of a rotary subwoofer and presents a model to predict sound pressure levels. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3082115]

I. INTRODUCTION

While considerable technological progress has focused on infrasound sensors, signal processing, and propagation effects, fundamental physical barriers have hindered the development of a controllable infrasound source.[1] Classic audio transduction technology such as voice-coil activated diaphragms, piezoelectric resonators, and magneto-resistive sheets lack either the large spatial dimensions or vibratory displacements required to effectively radiate high-intensity infrasound.

A massive horncoupled electropneumatic loudspeaker was developed for the U.S. Army Research Laboratory: the mobile acoustic source (MOAS).[2] The MOAS is frequently referred to as the "mother of all speakers" and was capable of projecting high-intensity sound to frequencies as low as 10 Hz, though it was a large, power intensive, complex system. Use of conventional loudspeaker technology in an array has demonstrated the ability to project acoustic signals down to frequencies of 8 Hz;[3] however, the source levels were modest. Inventors have explored more exotic loudspeaker technology, for example, the "hydrosonic subwoofer" used fluid coupling to impedance match infrasound to enclosure vibrations,[4] while optimization of a driven Helmholtz resonator also demonstrated infrasound generation.[5] However, these devices have peculiar needs such as fluid bladders or require physical changes to tune alternate frequencies. Explosive sources (including air guns) can generate sufficient acoustic pressures; however, they are relatively uncontrollable in amplitude and duration, and are not amenable to continuous-wave sound projection. Explosives also entail a host of environmental and safety issues.

An alternative technology has been recently developed consisting of a baffled fan with dynamically controlled blade pitch[6,7] and is referred to as the rotary speaker. An electric motor rotates the fan hub at a constant frequency Ω while the blade pitch is dynamically controlled by a signal $s(t)$ at frequency ω_s (Fig. 1). In the non-radiating state, blade pitch is zero with minimal air displacement. In the radiating mode the blade pitch is actively modulated according to the input signal and the resultant pulses of air create high amplitude coherent oscillations in a controlled manner.

Classic transduction techniques are limited by poor radiation resistance at small values of ka, where k is the wavenumber and a the characteristic dimension of the radiator. For example, a uniformly oscillating piston in a rigid semi-infinite baffle operating at $ka \ll 1$ has a radiation resistance R_r that is close to zero. Efficient radiation does not occur until higher frequencies are reached $(ka > 4)$ where $R_r \approx 1$. This paper demonstrates that the rotary speaker overcomes this limitation by efficiently projecting relatively high sound pressure levels (SPLs) even though the source is compact $(ka \ll 1)$. We speculate that the rotary woofer creates an effective R_r even though $ka \ll 1$ because it changes the radiation impedance from reactance (mass-loading) dominated to resistance (fluid displacement) dominated by virtue of increased particle velocities.

This paper has three main goals: to introduce the rotary subwoofer as a controllable infrasound generator to the acoustics community, to present measurements and performance characterization of the device, and to present a simple theoretical model for the source. This paper is organized as follows. Section II provides a physical description of the source and its installation; Sec. III details the measurements and their results. Characterization of the speaker enclosure is explored in this section to explain increased amplitudes of farfield radiation. Section IV presents an acoustic model of the source based on an effective particle velocity distribution. Results of the model are compared with measurements in Sec. V, and discussion of the results are provided.

II. SPEAKER DESCRIPTION AND INSTALLATION

The rotary speaker pitch mechanism uses a conventional electromagnetic voice-coil assembly driven by an audio amplifier to pitch the blades in response to the applied signal $s(t)$. The voice-coil longitudinal oscillations are converted to blade axis rotary motion within the hub. The tested configuration consisted of five equally spaced blades, each approxi-

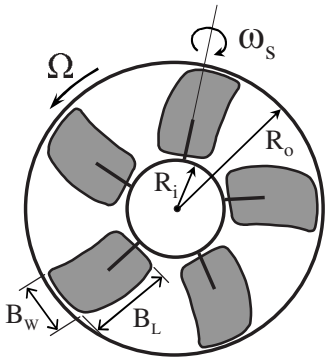

FIG. 1. The rotary subwoofer consists of a hub of radius R_i rotating at a fixed rate of Ω with blades of length B_L and width B_W modulated in pitch by signal $s(t)$ with frequency ω_s.

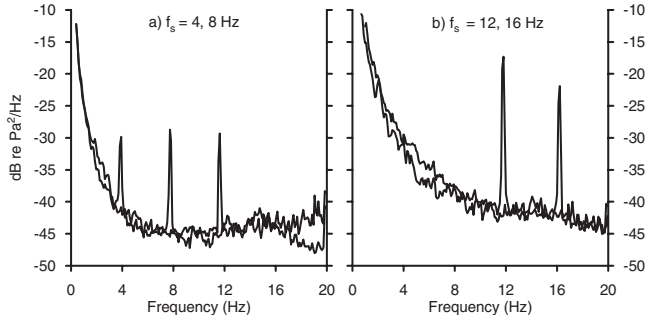

FIG. 3. Acoustic power spectra measured at range of 1820 m with fan rotation frequency of $F=17$ Hz. (a) shows signal frequencies of $f_s=4$ and 8 Hz and (b) $f_s=12$ and 16 Hz.

mately $B_W=10.2$ cm (4 in.) in width by $B_L=15.3$ cm (6 in.) in length. The outer diameter of the hub is approximately 20.4 cm (8 in.) so that the annular region of radiation has inner and outer radii of $R_i=10.16$ cm (4 in.) and $R_o=25.40$ cm (10 in.). The axis of the rotor is approximately 61 cm (24 in.) above the ground.

The speaker is installed at the Infrasound Laboratory with the rotor hub and blades flush with a heavy sound board baffle that is clamped inside an exterior door opening with dimensions 91.4 cm (3 ft) × 213.4 cm (7 ft). The projector radiates into free space outside the building, while the building interior forms the back volume. Figure 2 shows a photograph of the installed source.

The building dimensions are approximately 9.14 m (30 ft) × 18.3 m (60 ft) × 4.3 m (14.2 ft). There are no structural partitions within the building. Construction consists of a bolted steel frame, with W- and S-shape I-beams used as columns and beams. Corrugated steel panels are screwed to the frame to form exterior walls and roof. The result is a building with considerable structural compliance compared to a concrete block design. When the rotary woofer is in operation the exterior wall panels are easily observed to oscillate.

III. MEASUREMENTS

Measurements were conducted with calibrated Chaparral Physics model 2.2A infrasound microphones.[8] Data were recorded and digitized on a RefTek model 130-01 at a sample frequency of 100 Hz. Input signals were generated by an EZ Digital FG-8002 function generator. The blade actuation signal $s(t)$ was a sine wave with constant amplitude and frequency ω_s for any given measurement. Minimum record lengths for each measurement were 120 s. Spectral processing used a 50% data overlap with 1024 point Welch's averaged modified periodogram method and a minimum of 25 averages.

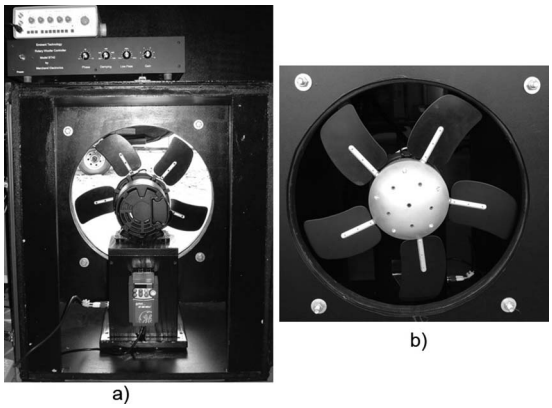

FIG. 2. Photograph of the installed source. (a) view inside the building showing the function generator, amplifier, motor controller, and motor and (b) view from the exterior showing the main rotor hub and blades.

Owing to the small atmospheric absorption of infrasound (less than 0.005 dB/km for frequencies below 16 Hz),[9] we were able to easily detect the source at considerable distance. Figure 3 shows on-axis spectra recorded at a range of 1820 m for signal frequencies of $f_s=4$, 8, 12, 16 Hz with a constant fan rotation of $F=17$ Hz. Figure 3(a) shows the $f_s=4$ and 8 Hz results recorded in the morning with light winds and lower noise levels. The $f_s=4$ Hz signal produced the harmonic at 12 Hz. Figure 3(b) plots the results at $f_s=12$ and 16 Hz during a period of higher winds and higher background noise. During the noisier measurement period the 4 Hz signal would not have been detectable without filtering. Even at a range of 1.8 km, there is impressive signal-to-noise ratio exceeding 20 dB for the 12 and 16 Hz projections.

The acoustic model presented in Sec. IV decomposes the particle velocities at the face of the blades into two components. The first is produced by the rotational velocity of the fan about the main hub at frequency F, the other from the rotational velocity of the blade about its actuation axis at frequency f_s. The velocity component produced from main hub rotation will change in proportion to the frequency F, the radius of the hub, and the outer radius of the blades. The component related to f_s is controlled by the amplitude of the signal $s(t)$ and the rate of blade actuation f_s. As the amplitude of $s(t)$ increases the blade pitch actuation increases driving the blade through larger displacements and higher velocities.

Figures 4 and 5 quantify changes in SPL as a function of the three parameters F, f_s, and $|s(t)|_{\text{rms}}$. To estimate the SPL at a particular signal frequency, a time-series analysis was used. A bandpass filter of 1 Hz was centered on the signal frequency; the computed variance provides an estimate of the signal power and is converted into decibels.

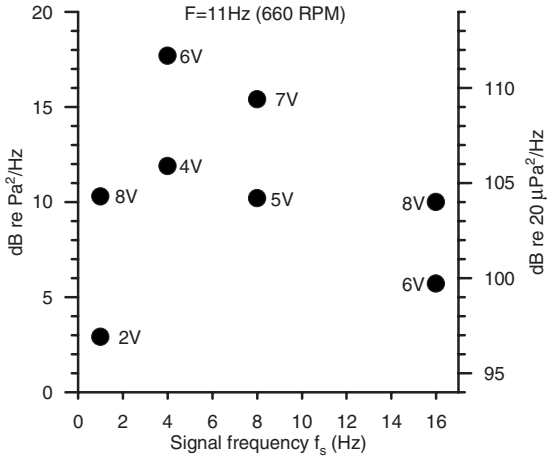

FIG. 4. SPL from measurements at 1 m with $F=11$ Hz versus signal frequency f_s. rms voltage amplitude of the drive signal is denoted next to each measurement.

Figure 4 presents projector SPL measured at 1 m with a constant hub frequency of $F=11$ Hz (660 rpm). Values of root mean square (rms) input signal voltage amplitude ($V_{\text{in}}=|s(t)|_{\text{rms}}$) are denoted next to each estimate. It is clear that at this fan rotation frequency the signal frequencies of $f_s=4$, 8 Hz produce a more efficient response than the lower or higher signal frequencies. It can also be observed that for a specific signal frequency that an increase in signal amplitude (blade pitch actuation) produces an increase in projected SPL, for example, at $f_s=4$ Hz an increase in input signal power from 4 to 6 V_{rms} results in a measured SPL increase of about 5 dB.

Measurements of SPL at 1 m with a hub rotational frequency of $F=17$ Hz (1020 rpm) are shown in Fig. 5. Compared to the $F=11$ Hz results, we find significant increases in SPL. Data represented by solid symbols were recorded at a range of 1 m, while the open symbols were recorded at a range of 1820 m and corrected to 1 m based on spherical spreading loss. Peak levels measured at 1 m were 28.1 dB re Pa^2/Hz (122.2 dB re 20 $\mu\text{Pa}^2/\text{Hz}$).

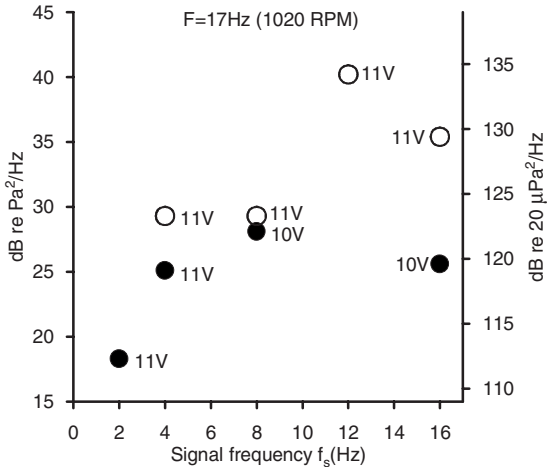

FIG. 5. SPL from measurements at 1 and 1820 m with $F=17$ Hz versus signal frequency f_s. Solid symbols were recorded at a range of 1 m; open symbols were recorded at a range of 1820 m and corrected to 1 m. rms voltage amplitude of the drive signal is denoted next to each measurement.

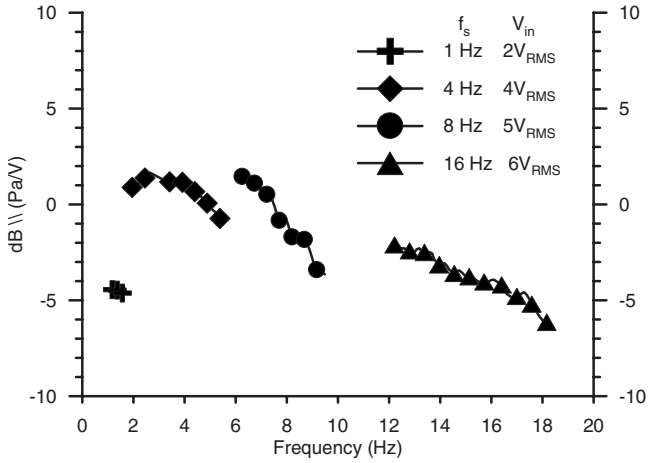

FIG. 6. Composite signal transfer function with values of coherence >0.98.

SPL estimates at 12 and 16 Hz from the range corrected 1820 m measurements are unexpectedly high. Two possible mechanisms for this could be changes in the propagation channel and resonant coupling from the baffle/back volume. It is known that changes in temperature profile and wind conditions can produce a profound impact on the local (<50 km) propagation of infrasound.[10] The measurements at $f_s=12$ and 16 Hz were performed with a southwest (040°) wind of approximately 4 m/s aligned with the direction of the projector axis (032°), while the $f_s=4$ and 8 Hz measurements were collected earlier in the day with little or no wind.

Resonant coupling could arise from forced oscillation of the building close to its natural modes. For a rectangular enclosure of dimensions l_x, l_y, lowest axial mode eigenfrequencies in hertz are $\omega_n=c/\pi l_x$ and $\omega_m=c/\pi l_y$, which evaluate to $f_n=9.4$ Hz ($l_x=18.3$ m) and $f_m=18.8$ Hz ($l_y=9.14$ m). When the enclosure is driven at frequency ω, the axial modes can be described by

$$P_{nm}=\frac{A_{nm}\cos k_n x\cos k_m y}{\sqrt{(1/Q_{nm})^2+(\omega/\omega_{nm}-\omega_{nm}/\omega)^2}}, \tag{1}$$

where A_{nm} is determined by the source and Q_{nm} the quality factor governed by boundary losses.[11] It is assumed that change in eigenfrequency as a result of the building panel oscillation is small since the oscillations are much smaller than the characteristic building dimensions.

The second term in the denominator describes an amplification (α) factor that maximizes P_{nm} when $\omega=\omega_n$. At a signal frequency of $f_s=12$ Hz and building eigenfrequency of $f_n=9.4$ Hz, the value of $\alpha_n=2.03$. With $f_s=16$ Hz, $f_m=18.8$ Hz and $\alpha_m=3.19$. This suggests that signal frequencies of 12 and 16 Hz are close enough to modal frequencies of the building that there is potential for amplification of building panel oscillation at the drive frequencies. It is therefore possible that the building itself is acting as an extended radiator when driven at signal frequencies of 12 and 16 Hz.

Figure 6 plots a composite transfer function of the output acoustic power at a range of 1 m to the input voltage signal power V_{in}. There are four distinct transfer function spectra plotted in Fig. 6, a separate measurement at each of the four drive frequencies $f_s=1$, 4, 8, and 16 Hz, with a

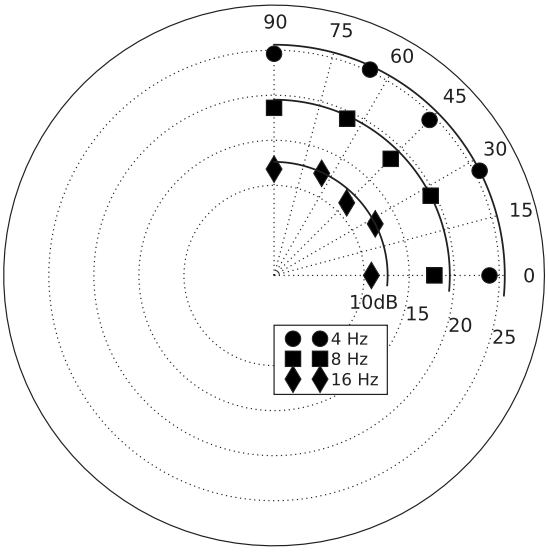

FIG. 7. Angular response measured at a range of 1 m for the drive frequencies f_s=4, 8, 16 Hz. Data are SPL in units of Pa^2/Hz. The axis of the fan is aligned at 0°.

constant fan rotation frequency of $F=11$ Hz. Portions of each spectrum were plotted only if the input/output coherence was greater than 0.98. Interpreting the coherence as a metric of input/output linearity, we can see that as the drive frequency increases the spectral band over which the assumed linear response is valid increases, though in none of the measurements does it cover the entire spectrum. A possible reason is that as the drive frequency decreases the increasing compliance of the diaphragm may decouple the input/output.

Turning attention to the amplitude of the transfer functions, the speaker exhibits maximal power conversion over the 3–8 Hz band at this F. This is consistent with the measurements presented in Fig. 4. A notable result of Fig. 6 are the relatively large amplitudes (>-4 dB), which indicate a high transduction efficiency despite the low value of kR_o.

A five-point angular response of the projector at a range of 1 m is shown in Fig. 7. At the low wavenumbers and small radiator dimensions ($kR_o<0.15$) of the rotary speaker, the radiation field of a baffled simple source should be monopole. The data show a persistent reduction of approximately 2 dB on-axis for all measurements, with similar results at a range of 10 m. Reasons for this departure from the expected omnidirectional radiation are not clear. Evaluation with the source model discussed below indicates that radiation from the wall/baffle is capable of reducing the on-axis pressure.

IV. ACOUSTIC MODEL

The rotary speaker relies on the motion of the hub and blades to generate significant particle velocities, while the dynamically controlled blade pitch creates the fluctuating signal pressure pulses. These two components are similar to those found in cooling/turbo-machinery fans and helicopter rotor blades, both of which have been extensively studied. There are, however, some differences. Fan studies are typically assessed with inclusion of duct or strut interactions; the

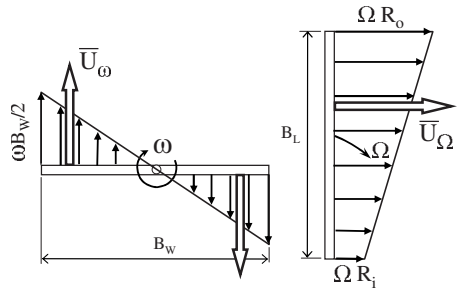

FIG. 8. Blade velocity distributions from the blade pitch modulation frequency ω and the fan rotation Ω.

authors are not aware of cases where the blade pitch is dynamically modulated to produce a desired output signal. Fans have been shown to generate discrete tones as the blades encounter ingested turbulence leading to uneven pressure distributions across the blade,[12–15] which is analogous to the controlled fluctuations of the rotary speaker. Helicopter rotors conspicuously generate discrete sound from turbulence or vortex interactions,[13,16] though the main rotors are not baffled and the blade pitch is not modulated at a signal frequency.

An in-depth analysis of the radiation might employ the Ffowcs Williams–Hawkings extension of Lighthill's acoustic analogy applied to sources in motion,[16,17] or, evaluation of Kirchhoff's integral for moving surfaces.[18,19] In the case that the blades can be considered point sources in the low-frequency limit, the method of Morfey and Tanna could be applied.[20] All of these methods require significant resource investments for successful application. Instead, we will use Rayleigh's integral based on an effective particle velocity to estimate pressure distributions of the projector.

Considering the baffled fan as a planar radiator producing an effective annular surface normal velocity $U_n(S)$, a Green's function form of the Rayleigh integral may be used to represent the pressure at the field point $\mathbf{x}$ produced by the velocity distribution over the surface S.

$$p(\mathbf{x}) = \frac{i\omega\rho}{2\pi}\int U_n(S)\frac{e^{jkr}}{r}dS, \tag{2}$$

where ρ is the atmospheric density and r the magnitude of the position vector from the center of the fan to the field point.

With the fan rotational frequency Ω greater than the blade modulation frequency ω_s, we assume that the net result of forcing on the surrounding air is production of coherent annular rings of pressure pulses. Since the values of ka are small, the source is acoustically compact and an effective particle velocity representation is justified. The effective particle velocity of the ring is modeled by assuming superposition of the blade rotational velocity, U_Ω, with the particle velocity U_ω induced by the dynamically adjusted blade pitch.

Figure 8 depicts velocity distributions of the blade along the transverse and longitudinal directions. The velocity along the length of the blade (dimension B_L in Figs. 1 and 8) is $U_\Omega(R)=\Omega(R_i+R)$, where R is the radial distance from the hub center and takes values in the range $[R_i,R_o]$. An effective velocity evaluated at the centroid of the distribution

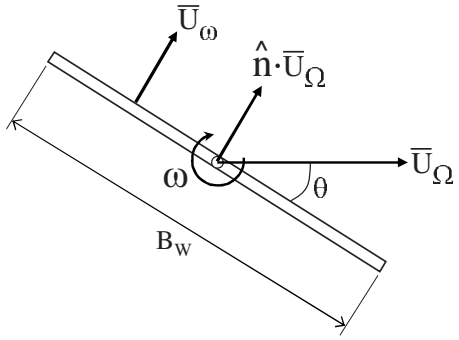

FIG. 9. Effective particle velocity normal to the blade is modeled as the sum of the normal component of fan rotational velocity $\hat{n}\bar{U}_\Omega$ with the effective velocity from the blade pitch modulation $\bar{U}_\omega$.

gives $\bar{U}_\Omega = \Omega[R_i + 2(R_o - R_i)/3]$. Across the width of the blade (dimension B_W) the velocity is ωR_w, with $R_w \in [0, \pm B_W/2]$, and an effective value can be specified as $\bar{U}_\omega = \pm \omega 2B_W/3$.

As the blade varies its angle of attack (θ) according to the signal $s(t)$, the normal component of U_Ω will vary as $\hat{n}\bar{U}_\Omega = \sin(\theta)\bar{U}_\Omega$, as shown in Fig. 9. The composite particle velocity normal to the blade is then

$$\bar{U}_n = \bar{U}_\omega + \hat{n}\bar{U}_\Omega. \tag{3}$$

The maximal value of $\hat{n}\bar{U}_\Omega$ will correspond to the largest excursion of blade pitch $\theta = \theta_{\max}$ during application of the signal $s(t)$. Since we are interested in pressure amplitude we will evaluate $\hat{n}\bar{U}_\Omega$ at $\theta_{\max}$ with the assumption that the maximal particle velocity is the primary contributor to the pressure maxima.

Equation (3) is used in Eq. (2) to compute the radiated pressure of the fan. Equation (2) is numerically evaluated over a grid covering the annular area between the fan hub and baffle. The grid consists of 732 elements of area 2.32 cm^2 each.

The only variable of the model that is not precisely determined is $\theta_{\max}$. This value is directly dependent on the amplitude of the input signal V_{in}. While we were able to measure V_{in}, we did not have access to instrumentation that could quantify θ under operating conditions. Observation of the blades indicated that typical values of $\theta_{\max}$ varied between 25° and 60° with V_{in} in the range of 2–11 V_{rms}. Based on this observation we assume a linear relation between V_{in} and $\theta_{\max}$ with values listed in Table I.

V. RESULTS AND DISCUSSION

A. Model results

Results of Eq. (2) compared to measured data at a fan rotational frequency of $F = 17$ Hz are shown in Table II. Model results are within 2 dB of measured data at drive frequencies of $f_s = 2$, 4, and 8 Hz. However, at 16 Hz the pressure is overestimated by 11 dB. The measured data follow the trend of the transfer function such that the output at $f_s = 16$ Hz is about 3 dB down from the output at $f_s = 8$ Hz, while the model predicts a 6 dB increase. This could indicate that the blade actuation component of the particle velocity $\bar{U}_\omega$ is higher in the model than in the physical system or that the linear combination of the blade rotation and actuation velocities is no longer a valid representation of the particle velocities.

TABLE II. Model results for a fan speed of 17 Hz (1020 rpm) compared to measured values (SPL shown in Fig. 5) at a range of 1 m. Data and model SPL are decibels re Pa^2/Hz.

f_s (Hz)	V_{in}	$\theta_{\max}$ (deg)	Ω/ω_s	$\bar{U}_\Omega/\bar{U}_\omega$	SPL	Model
2	11	58.8	8.5	57.5	18.3	17.7
4	11	58.8	4.3	28.7	25.1	23.8
8	10	55.0	2.1	13.7	28.1	29.8
16	10	55.0	1.1	6.9	25.6	36.4

Examination of the ratio of fan rotation frequency to blade actuation frequency, Ω/ω_s, and of $\bar{U}_\Omega/\bar{U}_{\omega_s}$, reveals that the model breaks down when $\Omega/\omega_s < 2$ or $\bar{U}_\Omega/\bar{U}_\omega < 10$. This indicates that our assumption for model validity that the fan rotational frequency Ω should be greater than the blade modulation frequency ω_s to produce coherent pressure pulses that can be modeled with an effective velocity distribution was off by a factor of 2.

Model results compared to measured data with $F = 11$ Hz are presented in Table III. At signal frequencies of $f_s = 1$ and 4 Hz the predicted and measured values are within 5 dB; however, at the higher frequencies the pressures are severely overpredicted. These results follow the conditions observed above where the model breaks down for $\Omega/\omega_s < 2$ or $\bar{U}_\Omega/\bar{U}_\omega < 10$.

B. Discussion

We have decomposed the effective particle velocity of the rotary speaker into two components, the blade rotational velocity, U_Ω, and the signal modulated blade pitch velocity U_ω. Comparison of the magnitude of these components reveals that the electric motor that drives the hub and blades at frequency Ω is the primary accelerator of the particle velocity. For example, at $F = 17$ Hz and $f_s = 8$ Hz the normal component of effective particle velocity from the hub rotation is $\bar{U}_\Omega = 12.3$ m/s while the blade actuation velocity is $\bar{U}_\omega = 1.3$ m/s. The majority of the consumed power is used to drive the motor and rotate the hub, on the order of 100 W, while the power consumed by the signal actuating the blades is roughly 10 W. This relatively small value of signal power

producing high levels of acoustic power results in large transfer function amplitudes and good transduction efficiency.

Measurements of radiated sound power found SPLs at a range of 1 m of 28 dB re Pa^2/Hz (122 dB re 20 $\mu Pa^2/Hz$). It was clearly demonstrated that increasing the value of rotor velocity or blade pitch actuation produced increases in SPL. This is consistent with the expectation that increased particle velocities are a contributing factor to radiation performance. Measured values of SPL at a range of 1820 m found significant signal-to-noise ratios, indicating that detection ranges of the projected infrasound could exceed 2 km. Unexpectedly high values of SPL were recorded at 12 and 16 Hz at a range of 1820 m. It is suggested that the building which forms the back volume of the speaker is resonating at these drive frequencies, which may increase the farfield SPL. Another candidate mechanism for the increased levels are changes in atmospheric propagation conditions. Further study is warranted to research this discrepancy.

A coarse measurement of angular response found reasonable agreement with monopole radiation as expected for a baffled source with $kR_o \ll 1$. However, a roughly 2 dB reduction in the on-axis response was observed at all frequencies. Use of the Rayleigh integral model indicates that radiation from the building wall may be contributing to this, though reduction in SPL of 2 dB could not be reproduced. This represents another area where additional research is needed.

A simple model based on effective particle velocities applied to Rayleigh's integral was developed to predict radiated pressures. The model assumes that the velocity distribution can be considered a linear superposition of effective blade velocities from the fan rotation and the blade pitch actuation. Model results at $F=17$ Hz were within 2 dB of measured values at signal frequencies of $f_s=2,4,8$ Hz, but overpredicted pressure by 11 dB at $f_s=16$ Hz. Model values at $F=11$ Hz were within 5 dB at $f_s=1$ and 4 Hz, but were too large by more than 10 dB for $f_s=8$ and 16 Hz. It was observed that when $\Omega/\omega_s<2$ the model results are poor. This may be an indication that the effective particle velocity representation is no longer valid. A detailed model with improved particle velocity distributions and analysis methods are suggested to address this problem.

VI. CONCLUSION

The rotary subwoofer is a novel acoustic transducer capable of efficiently generating controllable infrasound signals at high SPLs. It is suggested that the speaker overcomes the canonical difficulty of conventional transducers operating in the infrasound band, that the radiation resistance is near zero with radiation impedance dominated by mass-loading, by changing the impedance to fluid displacement dominated by virtue of increased particle velocities. Another unique aspect of the rotary subwoofer is the high transduction efficiency in terms of input signal power to radiated sound power.

The development of a controllable infrasound generator will likely find utility in several acoustic applications. For example, the field calibration of infrasound arrays is operated by the International Monitoring System of the Comprehensive Test Ban Treaty Organization, and as a tool for assessing atmospheric propagation studies. Other applications might include the field simulation of geophysical or anthropogenic infrasound sources to assist in the development of infrasound sensors and detection algorithms.

(Received 22 May 2008; revised 4 November 2008; accepted 25 January 2009)

A miniature differential microphone is described having a low-noise floor. The sensitivity of a differential microphone suffers as the distance between the two pressure sensing locations decreases, resulting in an increase in the input sound pressure-referred noise floor. In the microphone described here, both the diaphragm thermal noise and the electronic noise are minimized by a combination of novel diaphragm design and the use of low-noise optical sensing that has been integrated into the microphone package. The differential microphone diaphragm measures 1×2 mm^2 and is fabricated out of polycrystalline silicon. The diaphragm design is based on the coupled directionally sensitive ears of the fly *Ormia ochracea*. The sound pressure input-referred noise floor of this miniature differential microphone has been measured to be less than 36 dBA. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3082118]

I. INTRODUCTION

Any pressure-sensitive microphone that has an output that depends on the direction of a propagating sound wave must detect the difference in acoustic pressure at a minimum of two points in space. While directional microphones have been used in audio applications for many decades, they can be very challenging to design for applications that have substantial size constraints. One important application for miniature directional microphones is in hearing aids. It is well-known that the use of directional acoustic sensing in hearing aids can be a very effective means of reducing the influence of unwanted background acoustic noise and as a result can significantly improve the understanding of speech in noisy environments (Amlani *et al.*, 2006; Blamey *et al.*, 2006; Hornsby and Ricketts, 2007; Ricketts *et al.*, 2003; Walden *et al.*, 2004). In hearing aids, it is highly desirable that the distance between the points at which the pressure is sensed be kept to a bare minimum, on the order of a few millimeters in order for the size of the device to be cosmetically acceptable. Unfortunately, as this separation distance is reduced, the difference in the sensed pressures is also reduced proportionally. In miniature directional microphones, the desired pressure difference signal can be similar in level to the internal noise and can be very difficult to accurately extract from the average, or common-mode pressure. The main purpose of the present study is to describe a miniature differential microphone that is able to accurately detect pressure differences with minimal influence of microphone noise.

A. Biological inspiration

The approach to the design of the differential microphone described here is based on the mechanical principles employed in the ears of the fly *Ormia ochracea* (Miles *et al.*, 1995). This fly detects spatial gradients in the sound pressure because it has a mechanical connection between the tympana, resulting in the two ears moving in opposite directions in response to pressure differences on their outer surfaces. This differs from the detection of pressure differences by simply allowing the incident sound to drive either side of a single membrane or by subtracting the outputs of two nondirectional microphones. It is well-known that by combining the detection of the pressure gradient along with the pressure, it is straightforward to construct an output that has any of a number of first-order directivity patterns (Olson, 1947; Beranek, 1954). The essence of the mechanical response of *Ormia*'s ears has been shown to be a mechanical realization of a simple sum and difference circuit invented by Blumlein in the earliest days of stereo audio (Blumlein, 1931; Gerzon, 1994; Miles *et al.*, 1997). A simple system to mimic this is described in Miles *et al.* (1997). The mechanical connection between the *Ormia*'s ears has been shown to dramatically

improve the accuracy of estimates of sound source orientation by an analysis of the Cramer–Rao bound (Akcakaya and Nehorai, 2008).

While there are a number of remarkable characteristics of *Ormia*'s auditory system, the feature that the present study focuses on is the fly's unusual apparatus for detecting sound pressure gradients. This is driven by the fact that accurately detecting pressure gradients is the greatest challenge in creating miniature directional microphones. *Ormia*'s ears respond to a combination of the pressure gradient and the pressure to produce directionally sensitive tympanal response (Miles *et al.*, 1995). Achieving the proper combination of the responses due to pressure and pressure gradient is remarkable in a biological system but in a man-made device, it is a simple matter to combine these signals by either an analog circuit or digital processor.

In *Ormia ochracea*'s auditory system, it has been shown that the mechanical structure of the ears allows the response to pressure gradient and pressure to combine in such a way that the tympanum that is closest to a sound source responds with 10–20 dB greater amplitude than the opposite tympanum. This enhanced response amplitude causes the neural sensory cells in the ear closest to the sound source to fire with dramatically less latency than those of the opposite ear (Oshinsky, 1998; Mason *et al.*, 2001). The reduced latency of the neural response provides the central nervous system with the essential information on the orientation of the sound source.

The auditory system of *Ormia ochracea* thus amounts to a multi-stage processor to indicate the direction of a sound source. Because the two tympana are so close together that temporal cues in the incident sound wave are not usable by the nervous system, the mechanical structure of the ears acts to convert these miniscule time of arrival differences into significant differences in tympanal displacements. These differences in displacement are then converted by the sensory nervous system into significantly enhanced temporal differences in neural response, which are then much more readily processed by the central nervous system. The end result for the central nervous system is essentially the expansion or amplification of temporal cues in the incident sound.

Again, the focus of the present effort is to borrow ideas from the fly to help solve the challenging problem in creating miniature directional microphones: the detection of sound pressure gradients.

B. Detection of pressure gradients

The typical method of creating a directional sound sensor is to use a pair of closely spaced nondirectional microphones, as is commonly employed in directional hearing aids. In the absence of microphone noise and mismatches in phase or amplitude sensitivity of the two microphones, it is possible to determine the direction of arrival of a sound relative to the line connecting the microphones with arbitrary accuracy with this first-order small aperture array. Unfortunately, for microphone spacings that are very small relative to the sound wavelength, microphone noise and mismatches in sensitivity or phase can adversely affect the directional response. The primary difficulty is that for small microphone spacings it is difficult to accurately detect differences in the pressures incident on the two microphones. The focus of the present effort is to create a small sensor that provides an accurate measure of the pressure gradient without suffering from these problems.

Any pressure-sensitive diaphragm is a differential sensor because it responds to the difference in pressure on its two sides. Great care is typically taken to convert it to a nondirectional microphone by designing an enclosure to prevent sound from driving one of the two sides of the diaphragm. While a pressure difference sensor is simple to create, the challenge is to obtain adequate response when the size of the device is reduced. Low sensitivity to the desired signal results in a greater influence of electronic and mechanical/thermal noise. In a system that is intended to localize sound, the Cramer–Rao bound on the accuracy of the localization is strongly determined by the system noise floor (see, for example, Friedlander, 1984). In a first-order sound localization system that relies on processing of a combination of the first-order pressure gradient and the pressure [as is done in *Ormia*'s ears (Miles *et al.*, 1997)], the challenge then is to obtain an accurate, low-noise measurement of the pressure gradient; the pressure itself can be measured with much less difficulty because it is much higher in level than the pressure gradient.

The system used for detection of pressure gradients in *Ormia's* ears suggests an alternative method of constructing a differential microphone than the use of a simple single diaphragm. A primary aim of the present study is to examine whether or not this approach can result in a differential microphone having better noise performance than can be achieved with existing approaches. The noise performance of a microphone is strongly dependent on its size. In the case of a differential microphone, the noise performance also strongly depends on the effective distance between the points of pressure measurement. In the following, we have attempted to take these two critical features into account.

C. Other studies of *Ormia*-inspired microphones

A number of researchers have reported the construction of microphones based on the ears of *O. ochracea*. A system is described in Miles *et al.* (1997) that combines the outputs of two nondirectional microphones in a manner that is analogous to the in-phase and out-of-phase vibrational modes of *Ormia's* coupled ears, which provide measures of the pressure and pressure gradient, respectively. This use of the combination of the average and differential pressures to achieve a directionally-sensitive output, as mentioned above, is described in Blumlein (1931). Microphone diaphragms having a directional response based on *Ormia's* ears, using the combination of these two modes of vibration, are described in Yoo *et al.* (2002). The diaphragms were fabricated out of either polycrystalline silicon or Parylene. The diaphragms had dimensions of 1×2 mm^2 and had thicknesses of 1.2 and 2.4 μm for the polysilicon and Parylene diaphragms, respectively. The design and analysis of the acoustic response of these microphones is described in Gibbons and Miles (2000).

Ormia-inspired differential microphone diaphragms are described in Miles *et al.* (2002) having improved sensitivity over those of the earlier design of Gibbons and Miles (2000) and Yoo *et al.* (2002). Measured frequency responses are shown to be in excellent agreement with predictions of the response to incident sound. The microphone diaphragms again had dimensions of 1×2 mm^2 and were fabricated out of polycrystalline silicon. These diaphragms have also been described in Miles *et al.* (2004) and Miles and Hoy (2006) and are predecessors of the design described in the present study. Saito *et al.* (2002) reported a microphone diaphragm inspired by *Ormia's* ears that is supported on a gimbal. This circular diaphragm is made of bronze and has a radius of 10.8 mm and a thickness of 30 μm. A signal processing scheme, intended to be used with a miniature, silicon version of this diaphragm to achieve two-dimensional sound source separation is described in Ono *et al.* (2005).

An *Ormia*-inspired differential microphone having dimensions of 1×2 mm^2, fabricated out of polysilicon and that incorporates optical sensing to obtain an electronic output, was reported by Cui *et al.* (2006). The electronic output of the microphone is shown to have a directivity pattern similar to the figure-eight pattern expected for a first-order differential microphone. A CMOS-compatible directional microphone inspired by *Ormia's* ears is presented in Sung *et al.* (2007). The diaphragm dimensions are 840×410 μm^2. The acoustic response of the diaphragm was detected using a laser vibrometer and was shown to have a directivity pattern similar to the expected figure eight. A pair of mylar diaphragms having radii of 3.5 mm and 22 μm thickness that are glued to a 2.54 cm $\times$ 1.2 mm $\times$ 100 μm rod made of either steel or brass to mimic *Ormia's* ears has been reported by Chen and Yu (2008). It is shown that the incorporation of the connecting rod increased the time delay of the acoustic response of the two diaphragms.

It should also be pointed out that *Ormia's* ability to localize sound has inspired a number of researchers to develop signal processing algorithms for sound source localization that utilize the detection of sound pressure gradients in air (see, for example, Ando, 1995; Stanacevic and Cauwenberghs, 2005; Lockwood and Jones, 2006; Ando *et al.*, 2007; and Mohan *et al.*, 2008).

The differential microphone diaphragm described here is designed to behave like a rigid plate that is supported on carefully-designed flexible pivots (Miles *et al.*, 2004). Pressure gradients acting on the exposed surface of the diaphragm produce a net moment and hence cause it to rotate about its central hinge supports. By taking advantage of microfabrication technology, the diaphragm can be designed to be very lightweight and have very high compliance, enabling it to respond well to minute sound pressure gradients even though the largest dimension of the differential diaphragm is only 2 mm.

D. Optical sensing

In order to transduce the motion of the diaphragm into an electronic signal, we have incorporated a high-sensitivity, low-noise optical sensing scheme providing minimum detectable displacement on the order of 10 fm/$\sqrt{\text{Hz}}$, using approximately 61 μW of laser power (Hall and Degertekin, 2002; Lee *et al.*, 2004; Cui *et al.*, 2006; Miles and Degertekin, 2007). The majority of successful miniature microphone designs employ capacitive sensing, which suffers from instability when used on highly compliant diaphragms because the required bias voltage causes a significant force that attracts the diaphragm toward the biasing electrode. The use of low-noise optical sensing allows our differential microphone diaphragm to have very high compliance, which is important in achieving good sensitivity to pressure gradients.

The use of optical sensing and a highly compliant and responsive diaphragm has resulted in the achievement of very low electronic noise from the microphone. As a result, the noise floor of the microphone is primarily influenced by its thermal noise, resulting from random impacts between the diaphragm and the surrounding air. It is well-known that the equivalent input sound pressure associated with this thermal noise is proportional to the amount of passive energy dissipation in the system (Gabrielson, 1993; Thompson *et al.*, 2002; Hall *et al.*, 2007). The design developed here does not require the use of a backplate electrode, which is typically the dominant cause of viscous damping in capacitive microphones (Thompson *et al.*, 2002; Homentcovschi and Miles, 2004; Homentcovschi and Miles, 2005; Hall *et al.*, 2007). In addition, because the dominant motion of the diaphragm consists of rotation about its flexible supports, acoustic radiation damping and other sources of viscous damping can be kept to a minimum. As a result, the overall design approach leads to a system having low noise relative to the desired pressure gradient being sensed.

In the following, the designs of the microphone diaphragm and the optical sensing scheme are described along with an analysis of the noise performance. The microphone's response and noise outputs are shown to agree very well with predictions. Finally, the noise floor of the differential microphone is compared with what can be achieved with current, commercially available hearing aid microphones.

II. DIFFERENTIAL MICROPHONE DIAPHRAGM AND OPTICAL SENSOR

Figure 1 shows a design model of the microphone diaphragm. It consists of a stiffened plate supported by flexible pivots. The overall dimensions of the diaphragm are 1×2 mm^2. The diaphragm is fabricated out of polycrystalline silicon having a thickness of approximately 1 μm. Stiffeners, indicated in Fig. 1, are incorporated to cause the diaphragm to respond as a rigid plate that is supported on flexible pivots. The stiffeners are approximately 20 μm tall and 2 μm thick. The finite element design model has been used in a numerical optimization procedure to optimize the dimensions of the diaphragm and the stiffeners to achieve low noise and high acoustic sensitivity. Approximate expressions are used for the noise performance and the sensitivity (as derived below), which are used to construct an objective function in the iterative design. The ANSYS finite element model accounts for all of the resonant vibrational modes that can have an influence on the acoustic response. The struc-

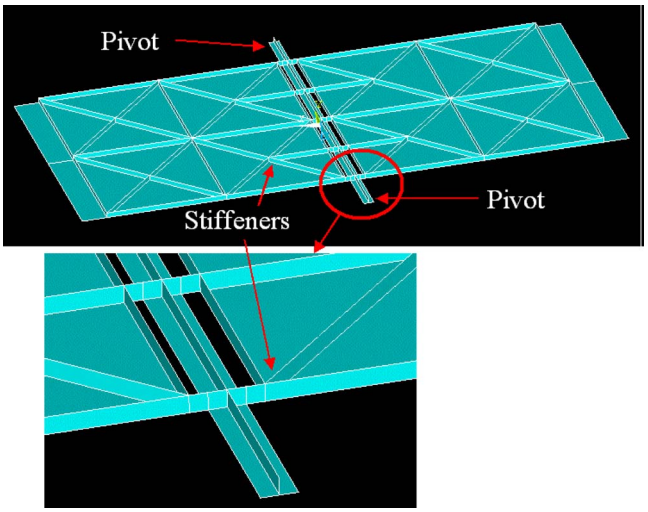

FIG. 1. (Color online) Design model of the microphone diaphragm. The diaphragm consists of a stiffened plate that is supported by flexible pivots. The stiffeners are also indicated in Fig. 4.

tural optimization has been carried out to ensure that the response is dominated by the mode in which the diaphragm rotates about its supports as a rigid plate. The dimensions of the stiffeners have been optimized to attenuate the influence of these undesirable modes. The mode shapes predicted by the design model are shown in Fig. 2. The first mode, consisting of out-of-phase motion of the two ends of the diaphragm, has a predicted resonant frequency of 821.7 Hz while the second mode, having both ends move in-phase, has a predicted resonant frequency of 15 002.7 Hz. The stiffening effect of the air volume within the package behind the microphone diaphragm has been taken into account in the

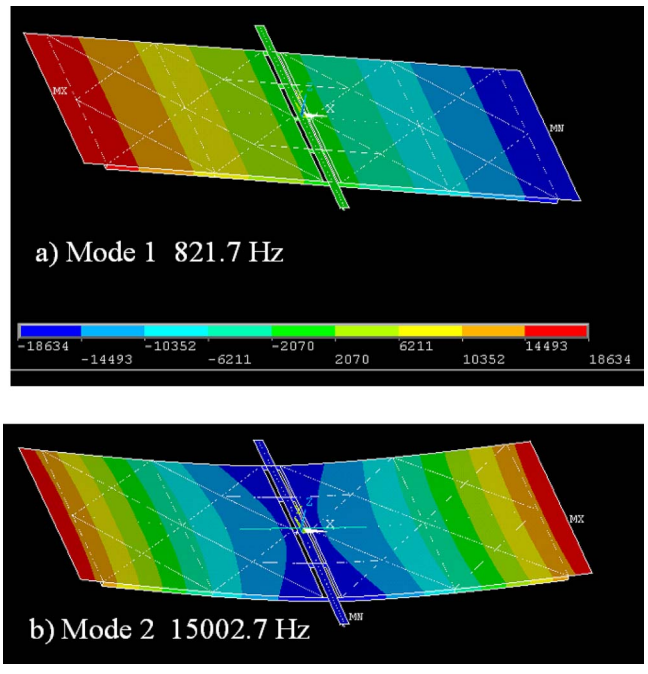

FIG. 2. (Color online) The mode shapes of the first two resonant modes of the diaphragm as predicted by the finite element (ANSYS) design model. The first mode shown in panel (a) consists of the diaphragm rotating as a rigid plate about its supporting pivots. The second mode shown in panel (b) consists of both ends of the diaphragm moving in-phase.

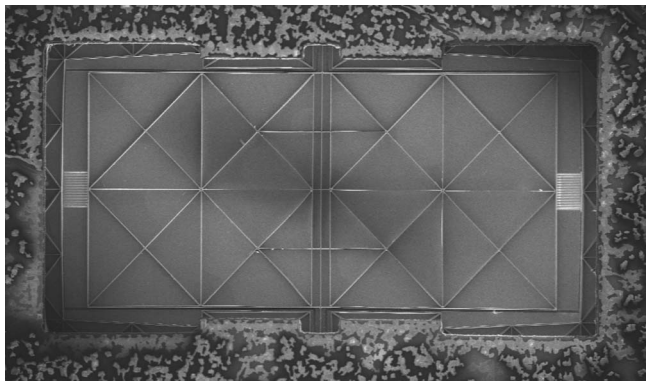

FIG. 3. Scanning electron micrograph of the microphone diaphragm. This image shows the back side of the diaphragm through the hole etched through the back of the wafer.

finite element model. Figure 3 shows a scanning electron micrograph showing the stiffeners as seen through a hole that has been etched through the thickness of the silicon wafer, as described below. Figures 4(a) and 4(b) show a photograph and the mask design of the top surface of the microphone diaphragm. The figure shows gold mirrors at each end of the diaphragm used in the optical sensing system described below.

Figure 5 shows the fabrication process flow for the microphone diaphragm. The fabrication starts with a deep reactive ion trench etch into the 4 in. test grade silicon wafer that acts as the mold for the polysilicon stiffeners. This is followed by a wet oxidation at 1100 °C to grow a 1 μm thick thermal oxide layer on the wafer surface and in the trenches [Fig. 5(a)]. This oxide is used as an etch stop for a subsequent backside cavity etch. The next step is to deposit and planarize polycrystalline silicon to form a 1 μm thick diaphragm having stiffeners. The phosphorus-doped polysilicon is deposited at 580 °C and subsequently annealed at 1100 °C in argon gas for 60 min in order to reduce intrinsic stress in the film. The polysilicon is then etched to define the optical grating and the slits that separate the diaphragm from

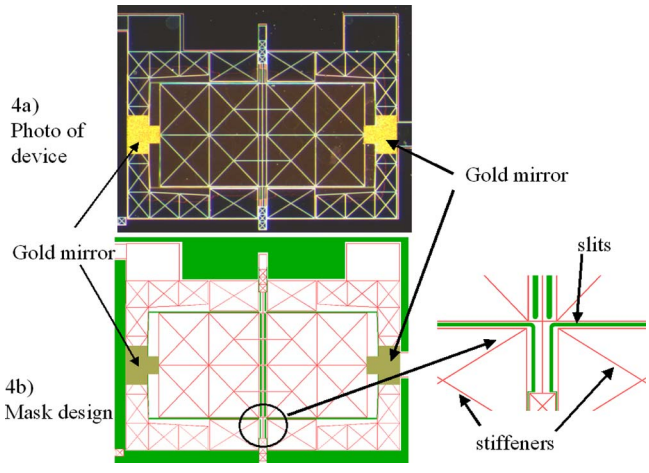

FIG. 4. (Color online) Photograph (a) and the mask design (b) of the top surface of the microphone diaphragm. The figure shows gold mirrors at each end of the diaphragm used in the optical sensing system. A close-up of the mask design is shown to indicate the stiffeners and the slit that is cut to form the perimeter of the diaphragm.

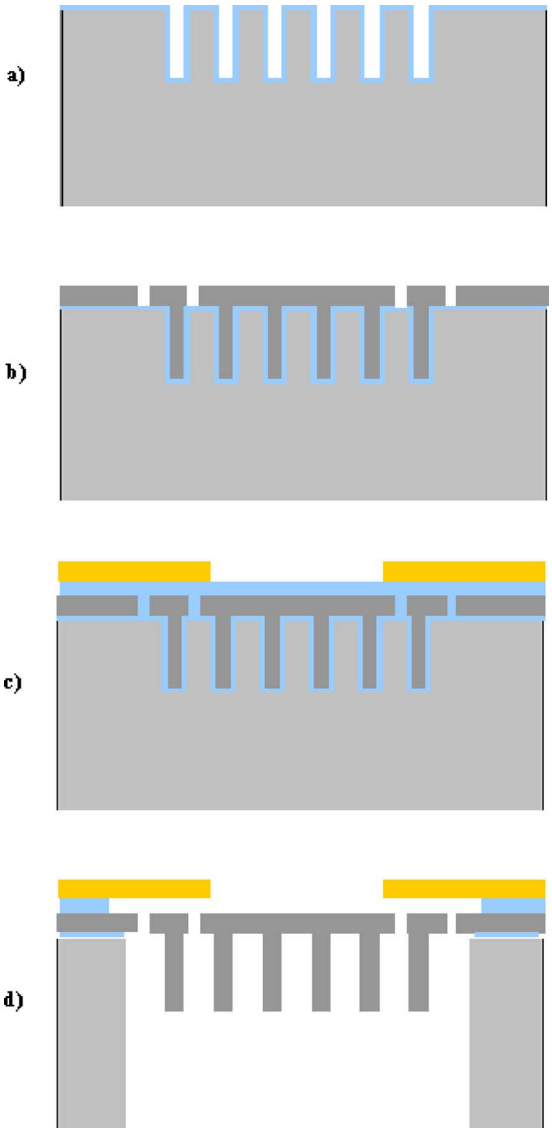

FIG. 5. (Color online) Fabrication process flow for the microphone diaphragm. The fabrication starts with a deep reactive ion trench etch into the 4-in. test grade silicon wafer. This is followed by a wet oxidation to grow a 1 μm thick thermal oxide layer on the wafer surface and in the trenches [Fig. 5(a)]. The next step is to deposit and planarize polycrystalline silicon to form a 1 μm thick diaphragm having stiffeners. The polysilicon is then etched to define the optical grating and the slits that separate the diaphragm from the substrate [Fig. 5(b) and in the inset of Fig. 4(b)]. This is followed by PECVD oxide deposition, chrome and gold seed layer evaporation, and gold plating to form the gold mirrors [Fig. 5(c)]. The back cavity is then etched using a deep reactive ion etch and the thermal and PECVD oxide layers are removed in buffered oxide etchant to release the structures [Fig. 5(d)].

the substrate [Fig. 5(b)]. This is followed by plasma enhanced chemical vapor deposition (PECVD) oxide deposition, chrome and gold seed layer evaporation, and gold plating to form the gold mirrors. Both the oxide layer and the gold mirrors are 5 μm in thickness [Fig. 5(c)]. The back cavity is then etched using a deep reactive ion etch and the thermal and PECVD oxide layers are removed in buffered oxide etchant to release the structures [Fig. 5(d)].

A schematic of the optical sensing scheme is shown in Fig. 6 (Cui *et al.*, 2006; Miles and Degertekin, 2007). This consists of an optical grating (an array of slits), a mirror

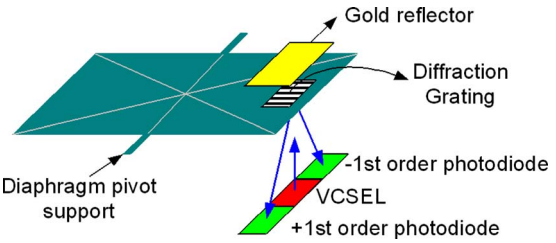

FIG. 6. (Color online) Schematic of the differential microphone diaphragm and the optical components. This consists of an optical grating (an array of slits), a mirror placed above the diaphragm, a light source (in this case a VCSEL), and photodetectors. The light that is reflected back to the photodetectors is modulated by the relative motion between the grating on the diaphragm and the mirror. The electrical output of the photodetectors is thus proportional to the diaphragm motion, providing the sensitivity of an interferometer.

placed above the diaphragm, a light source [in this case a vertical cavity surface emitting laser (VCSEL)], and photodetectors. The light that is reflected back to the photodetectors is modulated by the relative motion between the grating on the diaphragm and the mirror. The electrical output of the photodetectors is thus proportional to the diaphragm motion, providing the sensitivity of an interferometer. Similar optical detection structures have already been used to implement low-noise micromachined omnidirectional microphones (Hall *et al.*, 2005; 2007). Figure 7 shows an end-view of the diaphragm and optical components. The optical components and the silicon chip containing the microphone diaphragm have been assembled in a package depicted in Figs. 8 and 9. The silicon chip containing the directional microphone diaphragm shown in Figs. 8 and 9 contains an array of three microphone diaphragms, two differential diaphragms, and one nondirectional microphone diaphragm. This microphone array on the chip has been fabricated in order to explore the use of co-located directional microphones in a signal processing scheme as part of this effort described in Mohan *et al.* (2008).

In Sec. III, we examine the physical principles that determine the noise performance of the microphone. Experimental results will then be described and compared with predictions.

III. ANALYTICAL MODEL FOR MICROPHONE RESPONSE AND NOISE FLOOR

In order to construct a simplified model that can predict the microphone's noise performance, it is necessary to write down expressions for the response to sound. Because the

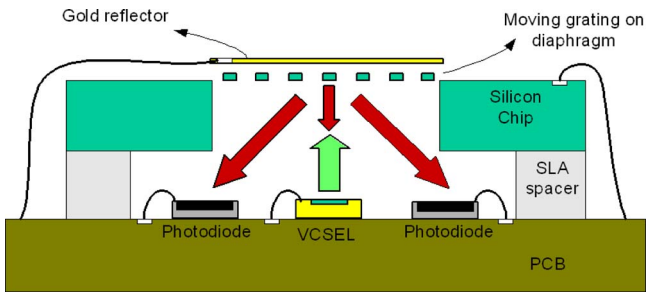

FIG. 7. (Color online) End-view of the diaphragm and optical components.

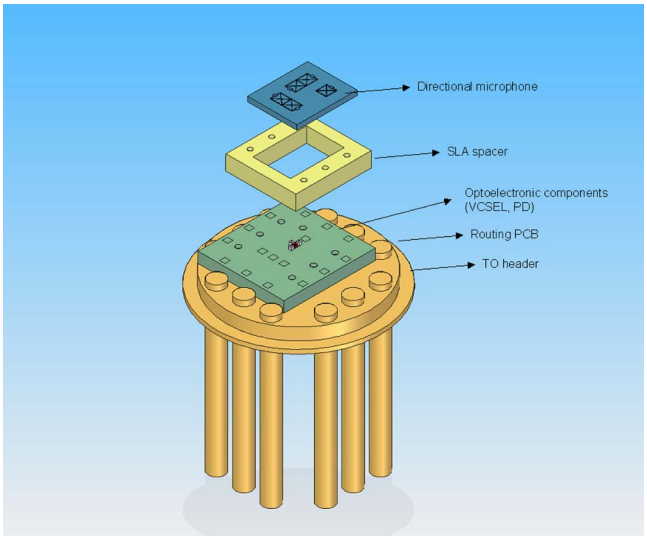

FIG. 8. (Color online) Package assembly design for the optical components and the silicon chip containing the microphone diaphragm.

diaphragm is intended to rotate about its hinge axis due to the sound pressure gradient, we first write the relation between the pressure gradient and the applied moment about the axis of rotation. A simple lumped-parameter model for the diaphragm's rotation can then be written in terms of the equivalent mass moment of inertia, I, about the axis of rotation, the equivalent torsional stiffness, k_t, and the equivalent viscous damping constant, c_t. The equivalent driving moment due to thermal excitation is then determined along with the equivalent pressure of an incident plane sound wave that would cause the same response as the thermal excitation. While the microphone diaphragm has been designed to respond primarily in its first resonant mode, the second mode of vibration, in which the two ends translate in-phase, can influence the response. The effects of the response of this translational mode along with the noise due to electronic circuits are included in an expression for the equivalent sound pressure noise.

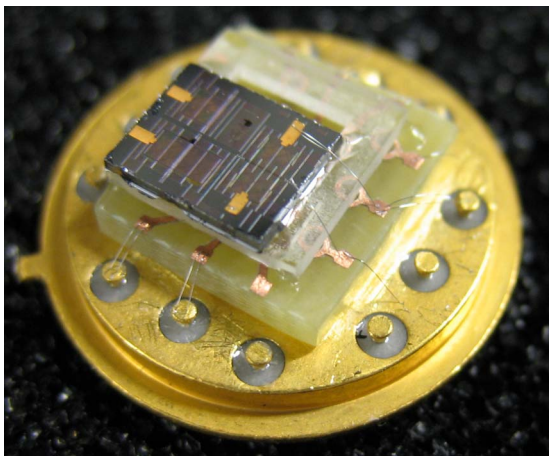

FIG. 9. (Color online) Photograph of the assembled microphone. The optical components are below the microphone diaphragm chip and are not visible.

A. Relation between sound pressure gradient and driving moment

We will assume that the microphone diaphragm is small relative to the wavelength of sound so that the spatial variation in pressure is small over its surface. Taking the origin of our coordinate system to be at the center of the diaphragm with the rotation oriented in the y direction and the length L measured in the x direction, the sound pressure as a function of x and t can be expanded in a two-term Taylor's series,

$$p(x,t) \approx p(0,t) + x \left.\frac{\partial p}{\partial x}\right|_{x=0}. \tag{1}$$

The moment applied by the sound field about the diaphragm's axis of rotation is then given by

$$M(t) = \int_{-L/2}^{L/2} bxp(x,t)dx \approx \int_{-L/2}^{L/2} bxp(0,t)dx + \int_{-L/2}^{L/2} bx^2 \left.\frac{\partial p}{\partial x}\right|_{x=0} dx, \tag{2}$$

where we have used the expansion in Eq. (1). b is the width of the diaphragm. Carrying out the integrations on the right in Eq. (2) gives

$$M(t) \approx \left.\frac{\partial p}{\partial x}\right|_{x=0} I_A, \tag{3}$$

where, for this simple rectangular diaphragm, the area moment of inertia about the axis of rotation is $I_A = bL^3/12$.

Equation (3) shows that the moment applied to the diaphragm is the product of the pressure gradient in the x direction and the area moment of inertia.

As mentioned above, the diaphragm has been designed so that the only vibrational modes that influence its motion in the audible frequency range have one of the two mode shapes shown in Fig. 2. While additional, ultrasonic modes could easily be included in our noise analysis, our present aim is to construct a model containing only the essential features that guide design.

B. Lumped-parameter model for diaphragm rotation

We first consider the motion due to the mode which is dominated by rotation about the pivot axis. Then, the contribution to the noise due to the second mode of vibration will be accounted for. Since the diaphragm has been designed so that its dominant vibrational mode consists of pure rotation as a rigid body, the equation of motion of the diaphragm in terms of its rotation, θ, may be taken to be

$$I\ddot{\theta} + k_t\theta + c_t\dot{\theta} = M(t), \tag{4}$$

where I is the mass moment of inertia, k_t is the equivalent torsional stiffness, and c_t is the effective dashpot constant for rotation. Equation (4) can also be expressed in the more convenient form

$$\ddot{\theta} + \omega_0^2\theta + 2\omega_0\zeta\dot{\theta} = \frac{M(t)}{I}, \tag{5}$$

where $\omega_0^2 = k_t/I$, and ζ is the damping ratio, $\zeta = c_t/2\sqrt{k_t I}$.

Because our aim is to examine the response of the diaphragm due to random thermal excitation from the surrounding medium, and compare that to the response due to sound, the incident sound field will be taken to be a weakly stationary random signal. This enables us to examine the effects of both the acoustic and thermal excitations using power spectral densities. By using Eq. (5), the power spectral density of the rotation of the diaphragm can be shown to be

$$S_{\theta\theta}(\omega) = \frac{S_{MM}(\omega)/I^2}{(\omega_0^2 - \omega^2)^2 + (2\omega_0\zeta\omega)^2}, \tag{6}$$

where $S_{MM}(\omega)$ is the power spectral density of the applied moment, $M(t)$.

C. Response due to thermal excitation

We would like to compare the response of the microphone due to acoustic excitation with that due to random thermal excitation from the surrounding gas. The equipartition theorem and the Nyquist relation can be used to calculate the response due to thermal excitation. Assuming, for now, that the response is dominated by a single rotational mode of vibration as assumed above, then

$$\tfrac{1}{2}K_B T = \tfrac{1}{2}k_t E[\theta^2]_n, \tag{7}$$

where $K_B = 1.38 \times 10^{-23}$ J/K is Boltzmann's constant, and T is the absolute temperature. $E[\theta^2]_n$ is the mean square response due to the thermal excitation. If the power spectral density of the moment due to thermal excitation, S_{MM}^N, is independent of frequency, ω, then for a system governed by Eq. (5), the mean square response of the rotation is obtained by integrating the power spectral density of Eq. (6) over all frequencies (Lin, 1967),

$$E[\theta^2]_n = \frac{\pi S_{MM}^N}{2\zeta\omega_0^3 I^2} = \frac{\pi S_{MM}^N}{k_t c_t} = \frac{K_B T}{k_t}, \tag{8}$$

where we have also used Eq. (7). Equation (8) then gives the two-sided power spectral density of the applied moment due to the thermal excitation (with units of $(\mathrm{N\,m})^2/\mathrm{rad/s}$),

$$S_{MM}^N = \frac{K_B T c_t}{\pi}. \tag{9}$$

D. Equivalent input pressure due to a plane sound wave

Since directional microphones are typically characterized in terms of their response to incident plane waves, it is convenient to re-cast Eq. (9) to determine the equivalent sound pressure of an incident wave that would correspond to the response due to thermal excitation. If the sound pressure is due to a plane wave incident with a speed c_0 at an angle ϕ relative to the direction that is tangent to the plane of the diaphragm, then the pressure on the diaphragm can be expressed as

$$p(x,t) = p\left(t - \frac{x}{c_0}\cos(\phi)\right). \tag{10}$$

In the case where the sound pressure is a weakly stationary random signal, the power spectral density of the sound pressure at $x=0$ may be obtained from the Fourier transform of the autocorrelation function of the pressure, $R_{pp}(\tau) = E[p(t)p(t-\tau)]$, where E denotes the expected value,

$$S_{pp}(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-j\omega\tau} R_{pp}(\tau)\, d\tau. \tag{11}$$

Since the moment, $M(t)$, in Eq. (3) depends on the pressure gradient, we need the power spectral density of the gradient to determine the power spectral density of the response. From Eq. (10), the gradient of the pressure, $dp/dx = p_x(x,t)$ at $x=0$ is

$$p_x(t) = \dot{p}(t)\frac{-\cos(\phi)}{c_0}. \tag{12}$$

The autocorrelation function of the gradient, $\partial p/\partial x$ at $x=0$, may then be written as

$$R_{p_x p_x}(\tau) = E[p_x(t)p_x(t-\tau)] = \left(\frac{\cos(\phi)}{c_0}\right)^2 E[\dot{p}(t)\dot{p}(t-\tau)]. \tag{13}$$

Taking the transform of Eq. (13) as in Eq. (11) enables us to obtain the power spectral density of the pressure gradient as

$$S_{p_x p_x}(\omega) = \left(\frac{\omega\cos(\phi)}{c_0}\right)^2 S_{pp}(\omega). \tag{14}$$

By using Eqs. (3) and (14), we can obtain the relation between the power spectral density of the applied moment and that of the pressure for this plane wave,

$$S_{MM}(\omega) = I_A^2\left(\frac{\omega\cos(\phi)}{c_0}\right)^2 S_{pp}(\omega). \tag{15}$$

Equations (6) and (15) give the power spectrum of the response as

$$S_{\theta\theta}(\omega) = \frac{(\omega\cos(\phi)/c_0)^2 (I_A/I)^2 S_{pp}(\omega)}{(\omega_0^2 - \omega^2)^2 + (2\omega_0\omega\zeta)^2}. \tag{16}$$

The relation between the spectral densities in Eq. (15) along with Eq. (9) can allow us to write the power spectral density of the pressure due to a plane wave, $S_{pp}(\omega)$, that would cause the same response as the thermal excitation,

$$S_{pp}^N(\omega) = \frac{S_{MM}^N}{I_A^2(\omega\cos(\phi)/c_0)^2} = \frac{K_B T c_t}{\pi I_A^2(\omega\cos(\phi)/c_0)^2}. \tag{17}$$

This result is normally evaluated for sound that is incident at $\phi=0$, the most sensitive direction. The power spectrum of the response due to thermal excitation may be written by replacing $S_{pp}(\omega)$ with $S_{pp}^N(\omega)$ in Eq. (16),

$$S^N_{\theta\theta}(\omega) = \frac{(\omega\cos(\phi)/c_0)^2(I_A/I)^2 S^N_{pp}(\omega)}{(\omega_0^2-\omega^2)^2+(2\omega_0\omega\zeta)^2} = \frac{K_B T c_t/(\pi I^2)}{(\omega_0^2-\omega^2)^2+(2\omega_0\omega\zeta)^2}. \quad (18)$$

E. Influence of the translational mode on noise performance

While the motion of the diaphragm is typically dominated by rotation, θ, at most frequencies of interest in audio applications, it is also important to account for the second mode shown in Fig. 2(b) in which the ends of the diaphragm move in the direction normal to the plane. This translational mode will be described by the coordinate $X(t)$. Assuming that the properties of the diaphragm are symmetric about its axis of rotation, the coordinates $X(t)$ and $\theta(t)$ will be uncoupled. The equation governing $X(t)$ is

$$m\ddot{X} + kX + c\dot{X} = p(0,t)A,$$

$$\ddot{X} + \omega_X^2 X + 2\omega_X\zeta_X\dot{X} = p(0,t)A/m, \quad (19)$$

where m is the effective mass, k is the equivalent stiffness, c is the equivalent dashpot constant, ω_X is the natural frequency, and ζ_X is the damping ratio. A is the equivalent area of the diaphragm and $p(0,t)$ is the surface average of the sound pressure acting on the diaphragm [which is also equal to $p(x,t)$ at $x=0$].

As in Eq. (6), the power spectral density of the translational mode is related to that of the acoustic pressure by

$$S_{XX}(\omega) = \frac{S_{pp}(\omega)(A/m)^2}{(\omega_X^2-\omega^2)^2+(2\omega_X\zeta_X\omega)^2}. \quad (20)$$

If both the rotational and translational modes are accounted for, the equipartition theorem states that each uncoupled mode receives the same thermal energy, $K_BT/2$, so that the thermal energy imparted to the translational mode is

$$\tfrac{1}{2}K_BT = \tfrac{1}{2}kE[X^2]_N, \quad (21)$$

where $E[X^2]_N$ is the mean square of the response of the mode due to thermal excitation. Proceeding as in Eqs. (5), (6), and (18), the power spectral density of the translational mode due to thermal excitation is

$$S^N_{XX}(\omega) = \frac{K_BTc/(\pi m^2)}{(\omega_X^2-\omega^2)^2+(2\omega_X\omega\zeta_X)^2}. \quad (22)$$

Because the response is detected at the end of the diaphragm at a distance d from the pivot, the detected displacement, $W(t)$, is related to the translation and rotation by

$$W(t) = X(t) + d\theta(t). \quad (23)$$

F. Equivalent input pressure noise including effects of electronic circuit noise

Since the output of the microphone must be detected using non-ideal electronic circuits, there will be some contribution to the noise due to noise generated in the circuits. This electronic noise can be represented by an equivalent displacement noise of the diaphragm $W^e(t)$, having a power spectral density given by $S^{Ne}_{WW}(\omega)$. The noise due to the electronics is not examined in detail here; the relative contribution due to laser intensity noise, shot noise in the photodetectors, and noise from other electronic components will be examined in other studies.

Since the thermal excitation is comprised of spatially random impacts of gas molecules with the diaphragm, the electronic noise and the thermal responses of the two modes are uncorrelated. Equations (18), (22), and (23) allow us to write the power spectral density of the thermal response of $W(t)$ as

$$S^N_{WW}(\omega) = \frac{K_BTc_td^2/(\pi I^2)}{(\omega_0^2-\omega^2)^2+(2\omega_0\omega\zeta)^2} + \frac{K_BTc/(\pi m^2)}{(\omega_X^2-\omega^2)^2+(2\omega_X\omega\zeta_X)^2} + S^{Ne}_{WW}(\omega). \quad (24)$$

Having the power spectral density of the equivalent displacement noise in Eq. (24), it is possible to estimate the power spectral density of the sound pressure that would produce this level of noise. To compute this input pressure-referred spectral density, note that the power spectral density of the displacement response due to sound pressure is

$$S_{WW}(\omega) = |H_{PW}(\omega)|^2 S_{pp}(\omega), \quad (25)$$

where

$$H_{PW}(\omega) = \frac{A/m}{\omega_X^2-\omega^2+2\omega_X\omega\zeta_X\hat{J}} + \frac{\hat{J}\omega\cos(\phi)dI_A/(c_0I)}{\omega_0^2-\omega^2+2\omega_0\omega\zeta\hat{J}}. \quad (26)$$

Equations (24) and (25) may be used to obtain an equivalent sound pressure power spectral density that would cause the predicted noise response power spectrum, $S^N_{WW}(\omega)$,

$$S^{Nt}_{pp}(\omega) = \left(\frac{K_BTc_td^2/(\pi I^2)}{(\omega_0^2-\omega^2)^2+(2\omega_0\omega\zeta)^2} + \frac{K_BTc/(\pi m^2)}{(\omega_X^2-\omega^2)^2+(2\omega_X\omega\zeta_X)^2} + S^{Ne}_{WW}(\omega)\right)\frac{1}{|H_{PW}(\omega)|^2}. \quad (27)$$

In order to allow direct comparisons with measured results, the predicted spectral density of the displacement noise in Eq. (24) can be modified to predict the output voltage noise, $S^N_{VV}(\omega)$, by

$$S^N_{VV}(\omega) = |H_{WV}(\omega)|^2 \times S^N_{WW}(\omega), \quad (28)$$

where $H_{WV}(\omega)$ is the transfer function between the diaphragm displacement and the output voltage in V/m, given in Table I.

Knowing the displacement relative to the pressure, $H_{PW}(\omega)$, in Eq. (26) and the output voltage for a given displacement, $H_{WV}(\omega)$, the output voltage relative to the input sound pressure is

TABLE I. Parameters used in predictions.

Estimated diaphragm mechanical parameters
Mass moment of inertia, $I=5\times10^{-15}$ kg m^2
Rotation mode natural frequency, $f_r=735$ Hz
Rotational mode damping ratio, $\xi_r=0.16$
Rotational dashpot constant$=c_t=7.389\times10^{-12}$ N m s/rad
Translational mode effective mass, $m=4\times10^{-8}$ kg
Translational mode natural frequency, $f_t=15220$ Hz
Translational mode damping ratio, $\xi_t=0.25$
Translational mode dashpot constant$=c=0.001\,912\,6$ N s/m
Diaphragm dimensions
Length, $1=2.2\times10^{-3}$ m
Width, $b=10^{-3}$ m
Area moment of inertia, $I_A=bl^3/12=8.87\times10^{-13}$ m^4
Electrical parameters
Electrical/mechanical sensitivity: $H_{WV}(f)=0.0056$ V/nm
Parameters for noise prediction
Boltzmann's constant$=K_B=1.38\times10^{-23}$ J/K
Absolute temperature$=T=293$ K
Diaphragm parameters from ANSYS finite element design model
$I=3.49\times10^{-15}$ kg m^2

Translational mode natural frequency, $f_t=15\,002.7$ Hz

$$H_{PV}(\omega)=H_{PW}(\omega)\times H_{WV}(\omega). \tag{29}$$

IV. COMPARISONS WITH EXISTING TECHNOLOGY

A straightforward and common way to create a directional acoustic sensor is through the use of a pair of omnidirectional microphones. The equivalent input-referred noise of this directional system can be estimated knowing the noise floors of the two-omnidirectional microphones, $S_{oo}^N(\omega)$, and by accounting for the loss of sensitivity to sound when the outputs of the microphones are subtracted to achieve a directional response. This loss of sensitivity can be accounted for by multiplying the output sensitivity of the omnidirectional microphones by $\omega d_o/c$, where ω is the frequency in rad/s d_o is the distance between the microphones, and c is the sound speed. In addition, because the power of the uncorrelated noise of the microphones is added when the output signals are subtracted, the resultant noise power spectrum is effectively increased by a factor of 2. By taking the difference of the two signals to achieve a directional output, the equivalent sound input-referred noise is then

$$S_{dd}^N(\omega)=2\left(\frac{c}{\omega d_o}\right)^2 S_{oo}^N(\omega). \tag{30}$$

To compare the equivalent input pressure noise levels of a two-omnidirectional microphone system with that of the present study, it can be more convenient to express the equivalent input noise levels in decibels. If $\mathrm{SPL}_{oo}(\omega)$ is the equivalent input sound pressure level of the two-omnidirectional microphones, then the input-referred noise level of the directional system may be estimated from

$$\mathrm{SPL}_{dd}(\omega)=10\log_{10}S_{dd}^N(\omega)=\mathrm{SPL}_{oo}(\omega)+3-20\log_{10}\left(\frac{\omega d_o}{c}\right). \tag{31}$$

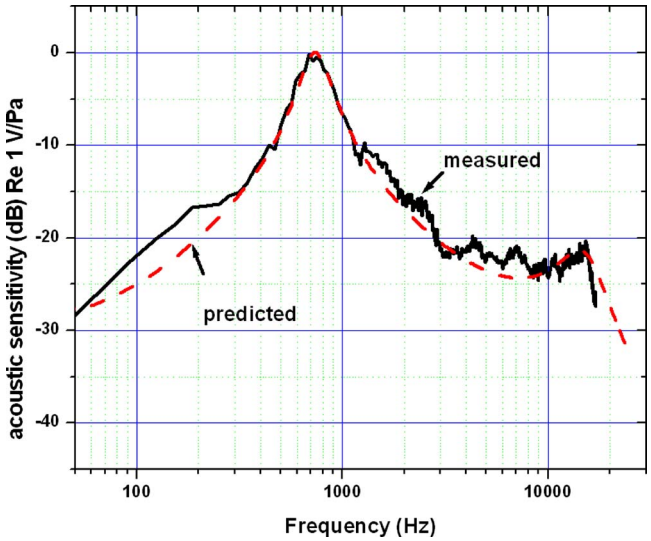

FIG. 10. (Color online) Comparison of predicted and measured electrical output in response to sound. The results are normalized relative to the sound pressure that is incident on the diaphragm. The data shown in this and the following figures were obtained by averaging auto- and/or cross power spectral density estimates from 20 records of the measured signals. The spectra were computed using the fast Fourier transform algorithm applied to the discrete time domain data. A coherence squared function was also calculated between the measured input signal and the response. Data were rejected when the coherence was less than 0.85. The coherence was typically greater than 0.95.

V. MEASURED RESULTS

The electrical output of the microphone shown in Fig. 9 has been measured relative to the incident sound pressure as measured by a calibrated reference microphone. The results are shown as a function of frequency in hertz in Fig. 10 along with those predicted by Eq. (29). The sound source was oriented in the most sensitive direction for the microphone. The measured and predicted results are in very close agreement. Figure 10 shows that the frequency dependence of the sensitivity is that of a bandpass filter as expected from the form of Eq. (16) for the power spectral density of the diaphragm rotation.

Since a flat frequency response is sought in most microphone applications, it may be desirable to incorporate a compensation filter that will result in a flat frequency response over most of the audible range. This frequency compensation can be accomplished without influencing the sound input-referred noise because, as will be discussed below, the noise is dominated by the diaphragm thermal noise (and not the noise from the electronics). The diaphragm thermal noise is superimposed on the detected sound pressure so its relation to the sound pressure is not affected by subsequent process-

ing of the signal. In addition, an active electronic feedback system is being developed that provides the beneficial effects of damping for both the transient response and frequency response of the diaphragm without adversely affecting the noise performance (Miles, 2008).

The physical parameters used in evaluating Eq. (29) to obtain the predicted results shown in Fig. 10 are given in Table I. The mass moment of inertia, I, the natural frequencies, equivalent mass, m, and the damping constants have been identified empirically through a least squares curve fit of the measured displacement of the diaphragm due to sound using the method outlined in the Appendix. Table I also lists the mass moment of inertia and the first two natural frequencies predicted by our finite element design model. The predicted and measured frequencies of the rotational mode are 821.7 and 735 Hz, respectively (12% error). The predicted and measured in-phase mode frequencies are 15002.7 and 15220 Hz, respectively (1.4% error). The resonant frequencies of the fabricated device were thus very close to those of our finite element design model.

The agreement between measured and predicted results indicates that the measured characteristics of the diaphragm are consistent with those expected from an analytical model based only on the physical dimensions and known material properties. It is also important to note that the frequencies of the first two modes are separated by roughly a factor of 20, which results in the rotational mode dominating the response over a wide range of frequencies.

The relation between the output voltage and the diaphragm displacement, $H_{WV}(\omega)$ in Eqs. (28) and (29), has been obtained by measuring the electrical output and the diaphragm displacement (measured using a Veeco optical profilometer) due to a voltage applied between the mirror shown in Figs. 4, 6, and 7 and the diaphragm.

The measured directivity pattern of the diaphragm is shown in Fig. 11 along with the figure-eight pattern expected for an ideal differential microphone. The measured results are shown to be in reasonable agreement with the ideal dipole pattern.

The output noise of the microphone as predicted by Eq. (28), in terms of the single-sided power spectral density (with units of $\mathrm{V}/\sqrt{\mathrm{Hz}}$), is compared to the measured output noise in Fig. 12. The measurements were performed while the microphone was placed in an anechoic chamber at the Georgia Institute of Technology to minimize sources of acoustic noise. The noise floor of the anechoic chamber was measured using a 1/2 in. Larson Davis model 2541 microphone and is significantly below the measured noise shown here; external acoustic noise does not influence these results except at very low frequencies. For frequencies below about 3 kHz, the output noise is strongly influenced by the thermal noise of the rotational mode of the diaphragm as predicted by the first term in Eq. (24). As shown in Fig. 12, the total microphone noise is dominated by the thermal noise for frequencies below about 3 kHz. The discrepancy between the predicted and measured noise below 100 Hz is likely due to acoustic noise in the anechoic chamber. The discrepancy at frequencies above 3 kHz is probably due to electronic noise in the optical system.

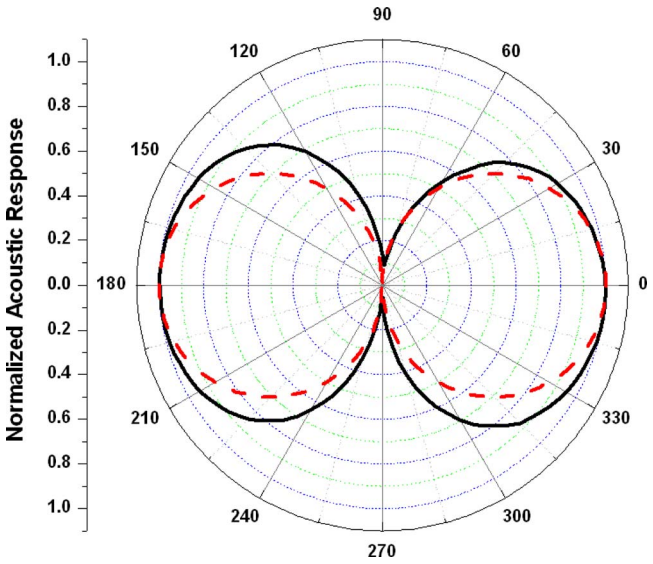

FIG. 11. (Color online) The measured directivity pattern of the diaphragm along with the figure eight pattern expected for an ideal differential microphone. The directivity measurements are performed in an anechoic chamber. The directional microphone is mounted on a rotation stage which can be controlled with a motion controller. The sound source is at a fixed location and driven by a pure tone sine wave at a frequency of approximately 800 Hz.

The equivalent sound input pressure-referred noise as predicted by Eq. (27) is compared to the measured input pressure-referred noise in Fig. 13. The measured results are obtained by dividing those of Fig. 12 by those given in Fig. 10.

The one-third octave band levels of the narrowband input pressure-referred noise of Fig. 13 are shown in Fig. 14. The corresponding dBA levels of the measured and predicted data are 35.6 and 34 dBA, respectively. The difference between the predicted and measured results is most likely due to electronic noise $S_{WW}^{Ne}(\omega)$, which has been neglected in the predictions and has not been measured independently.

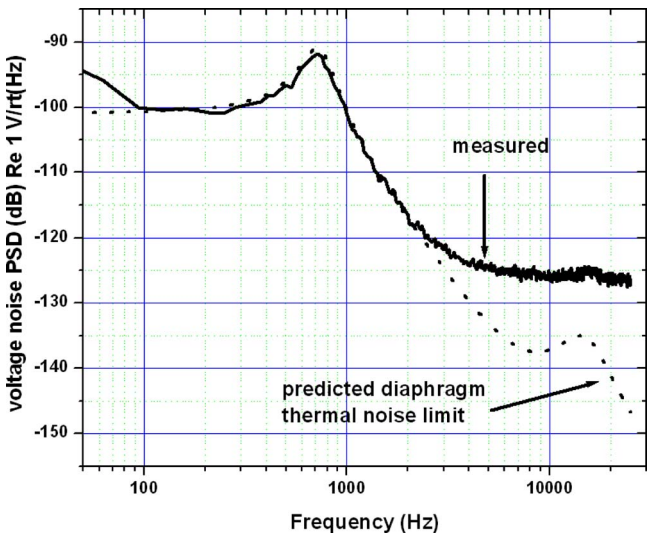

FIG. 12. (Color online) The output noise of the microphone as predicted by Eq. (28) compared to the measured output noise. The predicted results were obtained while neglecting the contribution due to the electronic noise, $S_{WW}^{Ne}(\omega)$, in Eq. (24).

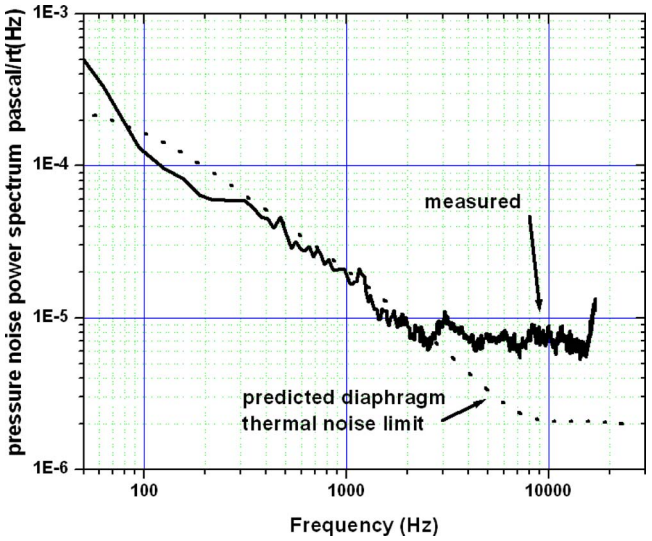

FIG. 13. (Color online) The equivalent sound input pressure-referred noise as predicted by Eq. (27) compared to the measured input pressure-referred noise. The measured results are obtained by dividing those of Fig. 12 by those given in Fig. 10. As in Fig. 12, the thermal noise limit was estimated by neglecting the contribution of electronic noise.

To compare the results obtained in the present study with those of commercially available hearing aid microphones, Eq. (31) has been evaluated to estimate the equivalent input noise of a differential sound sensor composed of two Knowles low-noise EM omnidirectional microphones. The noise floor of these omnidirectional microphones, $\mathrm{SPL}_{oo}(\omega)$, obtained from Knowles.com, is shown in the figure along with the results of Eq. (31). It is assumed that the spacing between the microphones is $d_o=10$ mm. The estimated noise of the differential sound sensor constructed by subtracting the output of the Knowles EM microphones is substantially higher than that of the differential microphone described here. In the microphone developed here, one can roughly estimate the effective separation distance between the pressure sensors to be the distance between the centers of each side, separated by the axis of symmetry, which is half the diaphragm length, or 1 mm. It is important to note that the effective separation distance, d_o, of the omnidirectional microphones is ten times that of the microphone developed in the present study. As can be seen in Eq. (31), this factor of 10 gives the two microphone system a noise floor advantage of approximately 20 dB, yet its noise is substantially higher over much of the audible frequency range and its A-weighted noise floor of 47.9 dBA is more than 10 dB higher.

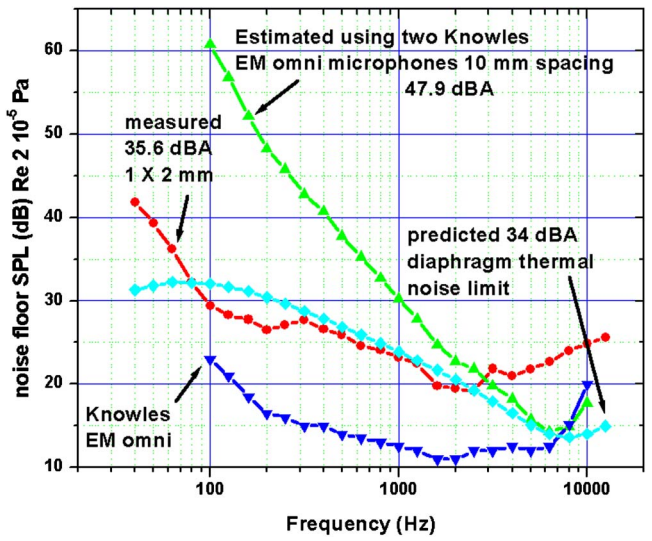

FIG. 14. (Color online) The one-third octave band levels of the narrowband input pressure-referred noise of Fig. 13. Equation (31) has been evaluated to estimate the equivalent input noise of a differential sound sensor composed of two Knowles low-noise EM omnidirectional microphones. The noise floor of these omnidirectional microphones, $\mathrm{SPL}_{oo}(\omega)$, obtained from Knowles.com is shown in the figure along with the results of Eq. (31). It is assumed that the spacing between the microphones is $d_o=10$ mm. The estimated noise of the differential sound sensor constructed by subtracting the output of the Knowles EM microphones is substantially higher than that of the differential microphone described here.

VI. CONCLUSIONS

The miniature differential microphone described in this paper is able to detect pressure gradients with minimal influence of microphone noise. This is accomplished through the use of a microphone diaphragm that rotates about a highly compliant central hinge due to an applied moment resulting from an incident sound wave. By minimizing the mass, stiffness, and passive damping in the diaphragm design, it is possible to achieve adequate sensitivity to sound and low thermal/mechanical noise. The use of a low-noise optical detection scheme has resulted in a design in which the total microphone noise is dominated by the diaphragm thermal/mechanical noise rather than noise in the electronic components over much of the audible frequency range.

APPENDIX: EMPIRICAL ESTIMATION OF DIFFERENTIAL MICROPHONE MECHANICAL PARAMETERS

The predictions of the response and noise performance through the analysis described in Sec. III above rely on knowledge of the effective mass, stiffness, and damping of the microphone diaphragm. For the rotational mode, these are I, k_t, and c_t in Eq. (4). These have been obtained by processing the measured response power spectra for the diaphragms due to a weakly stationary random acoustic excitation. The parameters are identified through a least squares approach where the mean square error in the model equation

[Eq. (4)] is minimized (Su, 2005). The approach leads to a linear system of three normal equations for the three unknown parameters, I, k_t, and c_t. Power spectral density functions estimated from the measured random response are used to obtain the statistical information for construction of the normal equations. The empirical estimation process is outlined in this Appendix. It is shown that this procedure is essentially similar to the frequency domain method that is derived for deterministic signals presented in Raol *et al.* (2004), Napolitano *et al.* (2001), and Morelli (1999).

As discussed in Sec. III above, the mechanical system is modeled as a linear second order resonator, as described in Eq. (4). If the actual measured rotation of the diaphragm, $\theta(t)$, is entered into the equation, errors in the model will introduce an error in the net moment, $\epsilon(t)$, so that Eq. (4) becomes

$$\tilde{I}\ddot{\theta}(t) + \tilde{c}_t\dot{\theta}(t) = \tilde{k}_t\theta(t) = M(t) + \epsilon(t). \tag{A1}$$

The mean squared error, $E[\epsilon^2(t)]$, where $E[\ ]$ is the expected value, is minimized by differentiating with respect to each unknown parameter,

$$\frac{\partial E[\epsilon^2(t)]}{\partial \tilde{I}} = 0,$$

$$\frac{\partial E[\epsilon^2(t)]}{\partial \tilde{c}_t} = 0,$$

$$\frac{\partial E[\epsilon^2(t)]}{\partial \tilde{k}_t} = 0. \tag{A2}$$

Equations (A1) and (A2) lead to a system of equations for the unknown parameters that may be written in matrix form as

$$\begin{bmatrix} E[\ddot{\theta}^2] & E[\dot{\theta}\ddot{\theta}] & E[\theta\ddot{\theta}] \\ E[\ddot{\theta}\dot{\theta}] & E[\dot{\theta}^2] & E[\theta\dot{\theta}] \\ E[\ddot{\theta}\theta] & E[\dot{\theta}\theta] & E[\theta^2] \end{bmatrix} \begin{pmatrix} \tilde{I} \\ \tilde{c}_t \\ \tilde{k}_t \end{pmatrix} = \begin{pmatrix} E[M\ddot{\theta}] \\ E[M\dot{\theta}] \\ E[M\theta] \end{pmatrix}. \tag{A3}$$

The expected values in Eq. (A3) may be expressed in terms of correlation functions $R_{\dot{\theta}\dot{\theta}}(\tau)$ and $R_{M\dot{\theta}}(\tau)$ when $\tau=0$. For weakly stationary signals, the correlation functions may be determined from the inverse Fourier transforms of the auto- and cross spectral density functions, $S_{\dot{\theta}\dot{\theta}}(\omega)$ and $S_{M\dot{\theta}}(\omega)$, by the *Weiner–Khinchine relations*.

$$E[\dot{\theta}(t)\dot{\theta}(t-\tau)] = R_{\dot{\theta}\dot{\theta}}(\tau) = \int_{-\infty}^{\infty} e^{\hat{J}\omega\tau} S_{\dot{\theta}\dot{\theta}}(\omega)d\omega,$$

$$E[M(t)\dot{\theta}(t-\tau)] = R_{M\dot{\theta}}(\tau) = \int_{-\infty}^{\infty} e^{\hat{J}\omega\tau} S_{M\dot{\theta}}(\omega)d\omega. \tag{A4}$$

The two-sided autospectral density function is real valued and an even function of frequency, and the two-sided cross spectral density function is complex with the real part an even function of frequency and the imaginary part an odd function of frequency (Bendat and Piersol, 1986; Lin, 1967). Therefore $S_{\dot{\theta}\dot{\theta}}(\omega)=S_{\dot{\theta}\dot{\theta}}(-\omega)$ and $S_{M\dot{\theta}}(-\omega)=S^*_{M\dot{\theta}}(\omega)$, where * is the complex conjugate, and the expected values in Eq. (A3) are

$$E[\ddot{\theta}^2] = \int_{-\infty}^{\infty} \omega^2 S_{\dot{\theta}\dot{\theta}}(\omega)d\omega = 2\int_0^{\infty} \omega^2 S_{\dot{\theta}\dot{\theta}}(\omega)d\omega,$$

$$E[\dot{\theta}^2] = \int_{-\infty}^{\infty} S_{\dot{\theta}\dot{\theta}}(\omega)d\omega = 2\int_0^{\infty} S_{\dot{\theta}\dot{\theta}}(\omega)d\omega,$$

$$E[\theta^2] = \int_{-\infty}^{\infty} \frac{1}{\omega^2} S_{\dot{\theta}\dot{\theta}}(\omega)d\omega = 2\int_0^{\infty} \frac{1}{\omega^2} S_{\dot{\theta}\dot{\theta}}(\omega)d\omega,$$

$$E[\ddot{\theta}\theta] = E[\theta\ddot{\theta}] = -\int_{-\infty}^{\infty} S_{\dot{\theta}\dot{\theta}}(\omega)d\omega = -2\int_0^{\infty} S_{\dot{\theta}\dot{\theta}}(\omega)d\omega,$$

$$E[\ddot{\theta}\dot{\theta}] = E[\dot{\theta}\ddot{\theta}] = \int_{-\infty}^{\infty} \hat{J}\omega S_{\dot{\theta}\dot{\theta}}(\omega)d\omega = 0,$$

$$E[\dot{\theta}\theta] = E[\theta\dot{\theta}] = -\int_{-\infty}^{\infty} \frac{\hat{J}}{\omega} S_{\dot{\theta}\dot{\theta}}(\omega)d\omega = 0, \tag{A5}$$

and

$$E[M\ddot{\theta}] = \int_{-\infty}^{\infty} \hat{J}\omega S_{M\dot{\theta}}(\omega)d\omega = 2\int_0^{\infty} \Re[\hat{J}\omega S_{M\dot{\theta}}(\omega)]d\omega,$$

$$E[M\dot{\theta}] = \int_{-\infty}^{\infty} S_{M\dot{\theta}}(\omega)d\omega = 2\int_0^{\infty} \Re[S_{M\dot{\theta}}(\omega)]d\omega,$$

$$E[M\theta] = -\int_{-\infty}^{\infty} \frac{\hat{J}}{\omega} S_{M\dot{\theta}}(\omega)d\omega = -2\int_0^{\infty} \Re\left[\frac{\hat{J}}{\omega} S_{M\dot{\theta}}(\omega)\right]d\omega, \tag{A6}$$

where $\Re$ denotes the real part. Solving Eq. (A3) for the mechanical parameters gives

$$\tilde{I} = \frac{E[\theta^2]E[M\ddot{\theta}] - E[\theta\ddot{\theta}]E[M\theta]}{E[\ddot{\theta}^2]E[\theta^2] - E[\theta\ddot{\theta}]^2},$$

$$\tilde{c}_t = \frac{E[M\dot{\theta}]}{E[\dot{\theta}^2]},$$

$$\tilde{k}_t = \frac{E[\ddot{\theta}^2]E[M\theta] - E[\ddot{\theta}\theta]E[M\ddot{\theta}]}{E[\ddot{\theta}^2]E[\theta^2] - E[\theta\ddot{\theta}]^2}. \tag{A7}$$

The finite Fourier transforms of the signals are

$$\dot{\Theta}(\omega,T) = \frac{1}{2\pi}\int_{-T}^{T} e^{-\hat{J}\omega t}\dot{\theta}(t)dt,$$

$$\mathcal{M}(\omega,T) = \frac{1}{2\pi}\int_{-T}^{T} e^{-\hat{J}\omega t} M(t)dt, \tag{A8}$$

which enables the calculation of the auto- and cross spectral densities,

$$S_{\dot{\theta}\dot{\theta}}(\omega) = \lim_{T\to\infty} \frac{\pi}{T} E[|\dot{\Theta}(\omega,T)|^2],$$

$$S_{M\dot{\theta}}(\omega) = \lim_{T\to\infty} \frac{\pi}{T} E[\mathcal{M}^*(\omega,T)\dot{\Theta}(\omega,T)]. \tag{A9}$$

When the signals are deterministic and their Fourier transforms exist, the identification procedure is the same as that described by Raol *et al.* (2004), Napolitano *et al.* (2001), and Morelli (1999). The Fourier transform can be applied to the governing equation and arranged as $\underline{Z}=[Y]\underline{\beta}+\underline{\varepsilon}$ for discrete data:

$$\begin{pmatrix} \mathcal{M}(\omega_1) \\ \mathcal{M}(\omega_2) \\ \vdots \\ \mathcal{M}(\omega_n) \end{pmatrix} = \begin{bmatrix} \ddot{\Theta}(\omega_1) & \dot{\Theta}(\omega_1) & \Theta(\omega_1) \\ \ddot{\Theta}(\omega_2) & \dot{\Theta}(\omega_2) & \Theta(\omega_2) \\ \vdots & \vdots & \vdots \\ \ddot{\Theta}(\omega_n) & \dot{\Theta}(\omega_n) & \Theta(\omega_n) \end{bmatrix} \begin{pmatrix} \tilde{I} \\ \tilde{c}_t \\ \tilde{k}_t \end{pmatrix} + \underline{\varepsilon}. \tag{A10}$$

The least squares solution for complex data is

$$\underline{\beta} = (\Re([Y]^{*T}[Y]))^{-1}\Re([Y]^{*T}\underline{Z}) \tag{A11}$$

and is the same solution as described in terms of the spectral densities when the signals are deterministic with $\ddot{\Theta}(\omega) = \hat{j}\omega\dot{\Theta}(\omega)$ and $\Theta(\omega) = -(\hat{j}/\omega)\dot{\Theta}(\omega)$.

1. Parameter estimation for the differential microphone diaphragm

The power spectra required in the above procedure were estimated from measured acoustic response of the microphones. Using a random excitation signal to drive a loudspeaker, a Doppler laser vibrometer (Polytec PSV-300H) was used to measure the out-of-plane velocity of the diaphragm and a probe microphone (Bruel and Kjaer Type 4182) measured the sound pressure at the diaphragm. Transfer functions of the velocity with respect to the sound pressure were estimated with a spectrum analyzer from averaged estimates of the auto- and cross power spectral densities. Two transfer functions for the diaphragm response were used for the mechanical parameter identification, $H_{p\dot{w}_1}(\omega)$ and $H_{p\dot{w}_2}(\omega)$, where $\dot{w}_1(t)$ and $\dot{w}_2(t)$ are the velocities at two points on opposite halves of the differential diaphragm separated by the pivot, and $p(t)$ is the sound pressure at the pivot. The spectral density functions in Eq. (A6) were estimated from $H_{p\dot{w}_1}(\omega)$, $H_{p\dot{w}_2}(\omega)$, and the sound pressure autospectral density $S_{pp}(\omega)$.

Assuming that the diaphragm is symmetric about the pivot axis, the rotation is approximated as $\theta=(w_1-w_2)/(2d)$, and the driving moment is estimated from the sound pressure using the plane wave model, $M=-\dot{p}(t)\cos(\phi)I_a/c_0$. The auto- and cross spectral density functions that are needed in the identification procedure are related to the measured transfer functions by $S_{\dot{\theta}\dot{\theta}}(\omega) = |H_{p\dot{\theta}}(\omega)|^2 S_{pp}(\omega)$ and $S_{M\dot{\theta}}(\omega) = H^*_{pM}(\omega)H_{p\dot{\theta}}(\omega)S_{pp}(\omega)$, where $H_{p\dot{\theta}}(\omega) = (H_{p\dot{w}_1}(\omega) - H_{p\dot{w}_2}(\omega))/(2d)$, and $H^*_{pM}(\omega) = \hat{j}\omega\cos\phi I_A/c_0$. This gives

$$S_{\dot{\theta}\dot{\theta}}(\omega) = \left|\frac{H_{p\dot{w}_1}(\omega) - H_{p\dot{w}_2}(\omega)}{2d}\right|^2 S_{pp}(\omega),$$

$$S_{M\dot{\theta}}(\omega) = \frac{\hat{J}\omega\cos\phi I_A}{c_0}\left(\frac{H_{p\dot{w}_1}(\omega) - H_{p\dot{w}_2}(\omega)}{2d}\right)S_{pp}(\omega). \tag{A12}$$

The same procedure is used to estimate the parameters of the translational mode, governed by Eq. (19). The average diaphragm displacement is $X=(w_1+w_2)/2$ and the average normal force due to the sound pressure is $F=pA$. The spectral density functions for the identification algorithm in this case are

$$S_{\dot{X}\dot{X}}(\omega) = \left|\frac{H_{p\dot{w}_1}(\omega) + H_{p\dot{w}_2}(\omega)}{2}\right|^2 S_{pp}(\omega),$$

$$S_{F\dot{X}}(\omega) = \frac{A(H_{p\dot{w}_1}(\omega) + H_{p\dot{w}_2}(\omega))}{2} S_{pp}(\omega). \tag{A13}$$

The integrals of the spectral density functions for the expected values are approximated by summation over a user selected frequency range, where the mode in question is dominant, and where data quality is good, as verified by coherence squared functions.

The aim of this paper is to introduce a simplified model for an uncertain solid layer sandwiched between two acoustic fluid layers and using the ultrasonic characterization with an acoustic source placed in one fluid layer. Uncertainties are taken into account with a probabilistic model of the elasticity tensor. Its parameters are the mean value of the random tensor and a dispersion parameter that controls the statistical fluctuation level. The characterization of the solid layer given a database of actual measurements consists in the determination of the (i) elastic parameters of the mean elasticity model, (ii) the dispersion parameter, and (iii) mass density of the solid. This is performed with a numerical solver of wave propagation and for *in vivo* data collected previously. The model is representative of measurements of human bone properties with the so-called axial transmission technique. The capability of the model to predict the velocity of the first experimental arriving signal in the statistical sense is proved. The identified anisotropic elasticity tensor of cortical bone from actual data based on the simplified model is given.

I. INTRODUCTION

Elastic wave propagation can be used to characterize the anisotropic elasticity tensor of solids. For highly heterogeneous materials (e.g., concrete, wood, soft tissue, bone, etc.) not only the values of the stiffness constants may vary within the tested structure but also the material symmetry. For biological materials this is basically a consequence of their multiscale organization and of significant variations in the constitution at the nanoscopic scales. When the length scale of the heterogeneities is larger or of the order of magnitude of the wavelength, the determination of the elastic properties with acoustic waves is a challenge. If the acoustic signals used for material characterization have a large amount of scatter, the elastic tensor may be considered as not unique: the probed elastic properties depend on the actual wave path inside the material. In this context, the problem of elasticity identification may advantageously be formulated as the determination of a mean elasticity tensor and of the fluctuations of the elasticity around the mean tensor. In other words, since any model useful for the elasticity identification is always a rough approximation of the reality, the modeling of uncertainties may be considered in order to extend the domain of validity of the model.

The aim of this paper is to introduce a simplified elastoacoustic model useful for the ultrasonic characterization of a solid layer with uncertain elastic behavior. The determination of an uncertain elastic layer that represents a human compact bone is considered. However, the method developed is of a wider interest as it may be applied straightforward to the characterization of other materials. The complexity level of such a biomechanical system is such that a multiscale approach should be developed to represent all the mechanical behavior and would allow (among others) the ultrasonic characterization of a human compact bone to be simulated. Nevertheless, such a multiscale model would be very expensive and in this paper, we are only interested by the ultrasonic characterization of a human compact bone. So, such a multiscale model seems to be too "complete" for the present objectives. This is why a simplified model is introduced and is representative of *in vivo* measurements of bone properties with the so-called axial transmission technique (it should be noted that the other mechanical behaviors of the biomechanical system are not explored). Nevertheless, a question still remains. *In vivo* measurements exhibit a random fluctuation of the ultrasonic characterization which is not related to the

[a]Electronic mail: christophe.desceliers@univ-paris-est.fr

measurement errors related to the probe used. So it is investigated whether the proposed wave propagation model including a stochastic model of bone anisotropic elastic properties is able to account for *in vivo* measurements in a statistical sense. Thus, if such a stochastic simplified model has the same statistical properties as the *in vivo* measurements database, then it may be a good candidate for the detection of disease bone.

The axial transmission technique provides the velocity of ultrasonic waves axially transmitted along compact (cortical) bone through a linear arrangement of transmitters and receivers placed on the same side of the skeletal site. This technique has been extensively used to probe bone quality at the radius [see Bossy *et al.* (2004a) and Camus *et al.* (2000)]. In particular, the bidirectional axial transmission technique associated with a measurement of the velocity of the first arriving contribution of the signal (FAS) is a technique sensitive to the elasticity of radius cortical bone. Bossy *et al.* (2004b, 2004c), Grimal *et al.* (2007), and Raum *et al.* (2005) also suggested that bone mass density and bone thickness are other less important determinants of the FAS. Accordingly, as a matter of simplification, thickness will be considered as fixed in this work and density will be taken as a deterministic varying parameter of a probabilistic model to be identified as well as the mean elastic properties. For the purposes of the present work, experimental data previously collected with a bidirectional axial transmission device could be used to investigate the possible determination of compact bone stiffness tensor. In addition, a procedure to compensate the observed variations in soft tissue thickness under the probe is implemented in the probe. Accordingly, the possible variations in soft tissue thickness can be disregarded in the model.

The simplified elasto-acoustic model is a three-layer system: a solid layer sandwiched between two inviscid acoustic fluid layers. The elastic layer (cortical bone) is a homogeneous anisotropic elastic material while the fluid (acoustic) layers represent soft tissues. The uncertainties on the elasticity of bone are introduced via a probabilistic approach developed in Soize (2001, 2005). It should be noted that a first application of the parametric probabilistic approach to the axial transmission technique can be found in Macocco *et al.* (2006). The parameters of the probabilistic model are the mean value of the random elasticity tensor and an additional parameter that controls the statistical fluctuation level. The mean model for bone is transversely isotropic and the uncertain fluctuations are anisotropic.

The determination of the parameters of the model, including the parameters of the probabilistic model, is formulated as an optimization problem. Thus, the solution of this optimization problem yields an optimal probabilistic model for taking into account the uncertainties related to the elasticity tensor of the cortical layer. A family of probabilistic models for the cortical layer is introduced using information theory. Then, among all the probabilistic model of this family, the optimal one is identified. Hence, it should be noted that the mean values of the elasticity tensor are not expected to be accurately equal to those of the cortical bone of a given patient. Anyway, the experimental measurements used in this paper are not related to only one patient but to a set of several patients. So, pretending to identify the values of the actual elastic tensor for a given patient would be meaningless with the experimental database used. The algorithm used to calculate the values of the cost function for several test values of the parameters of the stochastic model is performed by means of a stochastic solver based on the Monte Carlo method associated with a hybrid numerical solver of wave propagation presented in Desceliers *et al.* (2008): for each independent realization of the random effective elasticity tensor, the transient elasto-acoustic response is calculated by the wave propagation solver.

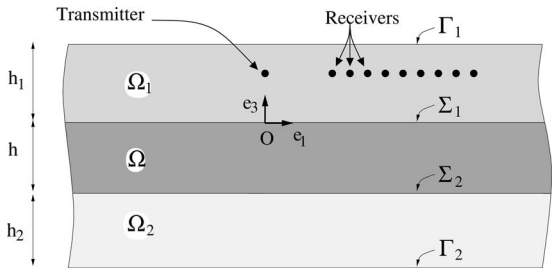

FIG. 1. Geometry of the multilayer system.

The capability of the stochastic model to represent the elasto-acoustic response of the uncertain system is demonstrated by a comparison of the model output to a database of *in vivo* measurements. In order to obtain a rich database from the statistical point of view, measurements from 168 patients were pooled; then the database takes into account a large variability of the properties of the elasto-acoustic system under consideration. Finally, the validation of the model consists in the comparison of the statistical properties of the model response to those of the *in vivo* measurements. Once validated, the model can be used to analyze the cortical bone stiffness tensor.

II. SIMPLIFIED MODEL OF THE MULTILAYER SYSTEM

The model consists of an anisotropic elastic homogeneous layer of thickness h sandwiched between two homogeneous inviscid acoustic fluids. The two fluids have identical density ρ_f and celerity c_f. The elastic layer is characterized by its mass density ρ and a stiffness tensor. In this work, the multilayer system is used to simulate experimental *in vivo* signals obtained with the so-called axial transmission technique.

The model geometry and the location of the acoustic source and receivers are shown in Fig. 1. The acoustic source is defined as a line source, placed inside Ω_1, and parallel to $\mathbf{e}_2$ where $(\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3)$ is an orthonormal basis for the space, $\mathbf{e}_3$ being normal to the fluid-solid interfaces. The wave field will be computed at each point $\mathbf{x}$ of the multilayer system with coordinate denoted (x_1,x_2,x_3) in the reference Cartesian frame $\mathbf{R}(O,\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3)$, where O is the origin placed on interface Σ_1.

The upper fluid layer (domain Ω_1) represents skin, muscle, and echographic gel used in the experiment to ensure a good contact between the ultrasonic probe and the skin. The elastic layer (domain Ω) represents the cortical bone while the lower fluid layer (Ω_2) models the marrow.

The thicknesses of the fluid layers Ω_1 and Ω_2 and of the elastic layer Ω are denoted h_1, h_2, and h, respectively. Free boundary conditions are applied on top of the upper fluid layer (surface Γ_1) and bottom of the lower fluid layer (surface Γ_2). In this paper, attention is focused on the biomechanical variability of bone elasticity. Accordingly, the density and the stiffness tensor of the elastic layer are considered as varying parameters of a probabilistic model to be identified while all the other parameters have fixed values. The varying parameters are identified following the procedure described in Sec. V.

III. PROBABILISTIC MODEL OF UNCERTAINTIES FOR THE ELASTICITY MATRIX OF THE SOLID LAYER

This section is devoted to the construction of a probabilistic model of the elastic material constituting the solid layer. The model accounts for uncertainties of the elastic constants in the bone material. That is, the bone elasticity is described by a mean stiffness tensor (with a prescribed symmetry: transverse isotropy in the paper) to which a random fluctuation is superimposed. Let c_{ijkh} be the components of the mean elasticity tensor on basis $(\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3)$. Then, mean elasticity matrix is defined as

$$[C] = \begin{pmatrix} [\tilde{C}_1] & [\tilde{C}_2] \\ [\tilde{C}_3] & [\tilde{C}_4] \end{pmatrix},$$

in which

$$[\tilde{C}_1] = \begin{pmatrix} c_{1111} & c_{1122} & c_{1133} \\ c_{2211} & c_{2222} & c_{2233} \\ c_{3311} & c_{3322} & c_{3333} \end{pmatrix},$$

$$[\tilde{C}_2] = \begin{pmatrix} \sqrt{2}c_{1123} & \sqrt{2}c_{1131} & \sqrt{2}c_{1112} \\ \sqrt{2}c_{2223} & \sqrt{2}c_{2231} & \sqrt{2}c_{2213} \\ \sqrt{2}c_{3323} & \sqrt{2}c_{3331} & \sqrt{2}c_{3312} \end{pmatrix},$$

$$[\tilde{C}_3] = \begin{pmatrix} \sqrt{2}c_{2311} & \sqrt{2}c_{2322} & \sqrt{2}c_{2333} \\ \sqrt{2}c_{3111} & \sqrt{2}c_{3122} & \sqrt{2}c_{3133} \\ \sqrt{2}c_{1211} & \sqrt{2}c_{1222} & \sqrt{2}c_{1233} \end{pmatrix},$$

$$[\tilde{C}_4] = \begin{pmatrix} 2c_{2323} & 2c_{2331} & 2c_{2312} \\ 2c_{3123} & 2c_{3131} & 2c_{3112} \\ 2c_{1223} & 2c_{1231} & 2c_{1212} \end{pmatrix}.$$

It should be noted that $[C_3]=[C_2]^T$. The construction of the probabilistic model consists in substituting $[C]$ by a random matrix $[\mathbf{C}]$ for which the probability density function is constructed using the information theory [see Shannon (1948, 1997)] with the available information defined as follows: (1) the random matrix $[\mathbf{C}]$ is a second-order random variable with values in the set $\mathbb{M}^+(\mathbb{R})$ of all the (6×6) real symmetric positive-definite matrices, (2) the mean value of random matrix $[\mathbf{C}]$ is the mean elasticity matrix $[C]$, and (3) the norm of the inverse matrix of $[\mathbf{C}]$ is a second-order random variable. It has been shown in Soize (2001, 2005) that the random matrix $[\mathbf{C}]$ can then be written as

$$[\mathbf{C}] = [L]^T[\mathbf{G}][L], \tag{1}$$

in which the (6×6) upper triangular matrix $[L]$ corresponds to the Cholesky factorization $[C]=[L]^T[L]$ and where the probability density function $p_{[\mathbf{G}]}$ of random matrix $[\mathbf{G}]$ is written as

$$p_{[\mathbf{G}]}([G]) = \mathbb{1}_{\mathbb{M}^+(\mathbb{R})}([G])c(\det[G])^b \exp\{-a\ \mathrm{tr}[G]\}, \tag{2}$$

where $a=7/(2\delta^2)$, $b=a(1-\delta^2)$, $\mathbb{1}_{\mathbb{M}^+(\mathbb{R})}([G])$ is equal to 1 if $[G]$ belongs to $\mathbb{M}^+(\mathbb{R})$ and is equal to zero if $[G]$ does not belong to $\mathbb{M}^+(\mathbb{R})$, $\mathrm{tr}[G]$ is the trace of matrix $[G]$ and where positive constant c is such that

$$c = \frac{(2\pi)^{-15/2}a^{6a}}{\prod_{j=1}^{6}\Gamma(\alpha_j)},$$

in which $\alpha_j=7/(2\delta^2)+(1-j)/2$ and where Γ is the gamma function. The parameter δ allows the dispersion of the random matrix $[\mathbf{C}]$ to be controlled. Thus, the parameters of the probabilistic model of uncertainties for the elasticity matrix are the components of $[C]$ and the coefficient δ. For such a probabilistic model, the random matrix $[\mathbf{G}]$ manifests the same statistical fluctuation in all its diagonal components and the same statistical fluctuation in all its extradiagonal components. It should be noted that the statistical fluctuations of the random matrix $[\mathbf{C}]$ are scaled with respect to the coefficients of the mean matrix $[C]$ [see Eq. (1)]. One of the important aspects of the probabilistic model is that it takes into account any anisotropic fluctuation of the elasticity tensor. However, the components of random matrix $[\mathbf{C}]$ are statistically dependent real-valued random variables. The generator of the independent realizations of random matrix $[\mathbf{G}]$ according to its probability density function [Eq. (2)] is given in the Appendix.

IV. COMPUTATION OF THE RANDOM TRANSIENT WAVE RESPONSE

A. Solving the equations

The transient elasto-acoustic response of the multilayer fluid-solid system is computed in the time-domain with a fast and efficient hybrid solver [see Desceliers *et al.* (2008)]. The symmetry of the problem allowed the previous problem to be reformulated in terms of the spatial coordinates x_1 and x_3 yielding a two-dimensional-space boundary value problem. The solver is based on a time-domain formulation associated with a one-dimensional-space Fourier transform for the infinite layer dimension (along the x_1 direction) and uses a finite element approximation in the direction perpendicular to the layers (along the x_3 direction). For a given mean elasticity matrix $[C]$, this solver allows the displacement field $\mathbf{u}$ in Ω and the pressure fields p_1 and p_2 in Ω_1 and Ω_2, respectively, to be calculated. Consequently, there exist three mappings g_{p_1}, $g_{\mathbf{u}}$ and g_{p_2} such that

$$p_1(\mathbf{x},t) = g_{p_1}(\mathbf{x},t;[C]), \tag{3}$$

$$\mathbf{u}(\mathbf{x},t) = g_{\mathbf{u}}(\mathbf{x},t;[C]), \tag{4}$$

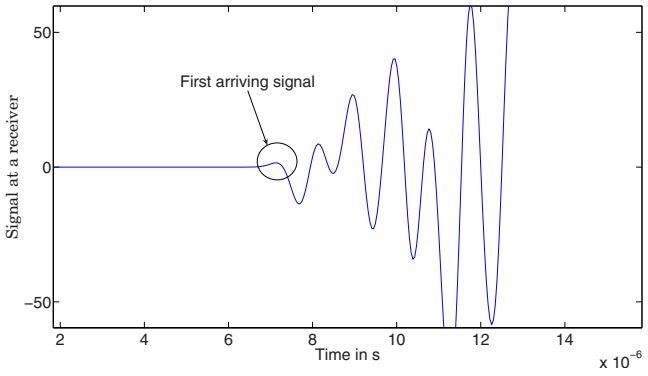

FIG. 2. (Color online) Example of a signal at receivers calculated by the model.

$$p_2(\mathbf{x},t) = g_{p_2}(\mathbf{x},t;[C]). \tag{5}$$

In addition, we introduce the von Mises stress at point $\mathbf{x} \in \Omega$ and at time t which is denoted by $\sigma^{\mathrm{vm}}(\mathbf{x},t)$. There also exists a mapping g_{vm} such that

$$\sigma^{\mathrm{vm}}(\mathbf{x},t) = g_{\mathrm{vm}}(\mathbf{x},t;[C]). \tag{6}$$

B. Velocity of the FAS and the axial transmission technique

The simulation of the actual measurements performed with the axial transmission technique consists in recording the signals $t \mapsto p_1(\mathbf{x},t)$ at several receivers located in Ω_1. The first arriving contribution of the signal is considered. Following the signal processing method used with the experimental device the velocity of FAS is determined from the time of flight of the first extremum of the contribution. Figure 2 shows a part of a simulated signal and the FAS. The simulated velocity v^{mod} of the FAS is estimated based on the different time arrivals at the consecutive receivers. Consequently, there exists a mapping g_{velo} such that

$$v^{\mathrm{mod}} = g_{\mathrm{velo}}(p_1). \tag{7}$$

C. Random transient wave response and random velocity of the FAS

The transient elasto-acoustic response of the stochastic multilayer fluid-solid system is random. Accordingly, the pressure and displacement fields are modeled by three random fields P_1, $\mathbf{U}$, and P_2 indexed by $\Omega_1 \times [0,T_{\max}]$, $\Omega \times [0,T_{\max}]$, and $\Omega_2 \times [0,T_{\max}]$ and with values in $\mathbb{R}$, $\mathbb{R}^3$, and $\mathbb{R}$, respectively. Substituting the mean elasticity matrix $[C]$ by the random matrix $[\mathbf{C}]$ in Eqs. (3)–(5) yields

$$P_1(\mathbf{x},t) = g_{p_1}(\mathbf{x},t;[\mathbf{C}]),$$

$$\mathbf{U}(\mathbf{x},t) = g_{\mathbf{u}}(\mathbf{x},t;[\mathbf{C}]),$$

$$P_2(\mathbf{x},t) = g_{p_2}(\mathbf{x},t;[\mathbf{C}]).$$

In addition, the velocity of the FAS and the von Mises stress are random variables denoted by V^{mod} and $\Sigma^{\mathrm{vm}}(\mathbf{x},t)$, respectively, such that [see Eqs. (6) and (7)]

$$\Sigma^{\mathrm{vm}}(\mathbf{x},t) = g_{\mathrm{vm}}(\mathbf{x},t;[\mathbf{C}]),$$

$$V^{\mathrm{mod}} = g_{\mathrm{velo}}(P_1). \tag{8}$$

V. IDENTIFICATION PROCEDURE OF THE STOCHASTIC MODEL

The objective of this section is to present a method to identify all the parameters of the stochastic model from a database of *in vivo* signals obtained previously. The parameters to identify are the components $[C]_{ij}$ of the mean elasticity matrix $[C]$, the coefficient δ that controls the statistical fluctuations of random elasticity tensor, and the mass density ρ.

A. Experimental database and random experimental velocity of the FAS

The signal used as input data for the determination of the parameters of the probabilistic model is associated with the wave propagation in the solid layer. This signal is referred to as FAS because, in practice, it always reaches the receivers first. This means that the other waves (direct wave from transmitter to receivers, waves guided by the fluid layer, etc.) arrive much later than the used signal. The physical reason for this is that the propagation path associated with the FAS includes a part in the solid for which the velocity is much higher than the fluid velocity. Accordingly, the FAS is not affected by the propagation in the top fluid layer and is representative of the solid plate acoustical properties. The latter was evidenced in simulations [see Bossy *et al.* (2004b), Camus *et al.* (2000), and Grimal and Naili (2006)] and experiments [see Bossy *et al.* (2004a)] which yield a FAS velocity of about 4000 m/s, which is the actual documented mean longitudinal wave velocity in compact bone.

In addition, the relative precision error on velocity measurements of the probe assessed on plates of academic materials such as Perspex or aluminum is lower than 0.2–0.3 [see, for instance, Bossy *et al.* (2004a)] which means that measurement errors can be neglected in the determination procedure.

The *in vivo* measurements were previously performed on a population of 168 subjects examined at the third distal radius. This group is a subset of a larger group of patients who participated to a clinical evaluation of the bidirectional axial transmission device. The multi-element probe operating at a center frequency of 1 MHz recorded 20 series of axially transmitted signals without particular angular scanning protocol except natural micro-movements of the operator. The experimental database finally consisted of 2018 measurements of FAS velocity. Each velocity measurement is considered as a realization of a random variable V^{exp} corresponding to the random variable V^{mod} obtained with the stochastic simplified model. The mean value of V^{exp} is $v^{\mathrm{exp}} = E\{V^{\mathrm{exp}}\}$ and its coefficient of variation Δ^{exp} is defined by $(\Delta^{\mathrm{exp}})^2 = E\{(V^{\mathrm{exp}})^2\}/(v^{\mathrm{exp}})^2 - 1$ in which $E\{\cdot\}$ is the mathematical expectation. Accordingly, the database consists of $N = 2018$ statistically independent realizations $V^{\mathrm{exp}}(\hat{\theta}_1), \ldots, V^{\mathrm{exp}}(\hat{\theta}_N)$ of random variable V^{exp}. Using the usual statistical

estimators and since N is sufficiently large, $v^{\exp}$ and $\Delta^{\exp}$ can reasonably be estimated by

$$v^{\exp} = \frac{1}{N}\sum_{k=1}^{N} V^{\exp}(\hat{\theta}_k),$$

$$\Delta^{\exp} = \frac{1}{v^{\exp}}\sqrt{\frac{1}{N}\sum_{k=1}^{N} V^{\exp}(\hat{\theta}_k)^2 - (v^{\exp})^2}.$$

B. Optimization problem for the identification procedure

For the identification procedure, it is assumed that the mean elasticity matrix represents a transverse isotropic homogeneous medium for which the plane (x_2,x_3) is the plane of isotropy. Then, all the components $[C]_{ij}$ are zeros except the following:

$$[C]_{11} = \frac{e_L^2(1-\nu_T)}{(e_L - e_L\nu_T - 2e_T\nu_L^2)},$$

$$[C]_{22} = \frac{e_T(e_L - e_T\nu_L^2)}{(1+\nu_T)(e_L - e_L\nu_T - 2e_T\nu_L^2)},$$

$$[C]_{12} = \frac{e_T e_L \nu_L}{(e_L - e_L\nu_T - 2e_T\nu_L^2)},$$

$$[C]_{23} = \frac{e_T(e_L\nu_T + e_T\nu_L^2)}{(1+\nu_T)(e_L - e_L\nu_T - 2e_T\nu_L^2)},$$

$$[C]_{44} = g_T,$$

$$[C]_{55} = g_L,$$

with $[C]_{22}=[C]_{33}$, $[C]_{12}=[C]_{13}=[C]_{21}=[C]_{31}$, $[C]_{23}=[C]_{32}$, and $[C]_{55}=[C]_{66}$ and where (1) e_L and e_T are the longitudinal and transverse Young moduli, (2) g_L and g_T are the longitudinal and transversal shear moduli, and (3) ν_L and ν_T are the longitudinal and transversal Poisson coefficients such that $g_T=e_T/2(1+\nu_T)$. Consequently, for this case, the matrix $[C]$ is written as $[C]=[\chi(e_L,\nu_L,g_L,e_T,\nu_T)]$ in which the function $[\chi]$ is completely defined. This equation shows that $[C]$ does not depend on 21 independent coefficients but only on 5 independent coefficients. Then, the unknown parameters of the stochastic model would be the coefficients e_L,ν_L,g_L,e_T,ν_T, the mass density ρ, and the coefficient δ. Let $\mathbf{a}$ be the vector such that $\mathbf{a}=(\rho,e_L,\nu_L,g_L,e_T,\nu_T)$. The problem consists in finding vector $\mathbf{a}$ and coefficient δ such that the stochastic model can represent the experimental database in a statistical sense. The optimal values $(\mathbf{a}^{\text{opt}},\delta^{\text{opt}})$ for $(\mathbf{a},\delta)$ are given by solving the following optimization problem:

$$(\mathbf{a}^{\text{opt}},\delta^{\text{opt}}) = \arg\min_{(\mathbf{a},\delta)} F^{\text{cost}}(\mathbf{a},\delta), \tag{9}$$

in which $F^{\text{cost}}(\mathbf{a},\delta)$ is a cost function which has to be defined. The optimization problem defined by Eq. (9) is solved by the simplex algorithm [see Nelder and Mead (1965)]. For each iteration of the simplex algorithm, the cost function has to be calculated which requires to solve the stochastic equations with Monte Carlo simulations (see Appendix).

1. Cost function associated with the usual least-square approach

The cost function $F^{\text{cost}}(\mathbf{a},\delta)$ associated with the usual least-square approach is defined as

$$F^{\text{cost}}(\mathbf{a},\delta) = E\{(V^{\exp} - V^{\text{mod}}(\mathbf{a},\delta))^2\},$$

in which $V^{\text{mod}}(\mathbf{a},\delta)$ is defined by Eq. (8) and where the dependence in $\mathbf{a}$ and δ is written. It should be noted that $V^{\exp}$ and $V^{\text{mod}}(\mathbf{a},\delta)$ are two independent random variables. Consequently, $F^{\text{cost}}(\mathbf{a},\delta)$ can be rewritten as

$$F^{\text{cost}}(\mathbf{a},\delta) = E\{(V^{\exp} - v^{\exp})^2\} + (v^{\exp} - v^{\text{mod}}(\mathbf{a},\delta))^2 + E\{(V^{\text{mod}}(\mathbf{a},\delta) - v^{\text{mod}}(\mathbf{a},\delta))^2\}, \tag{10}$$

in which $v^{\text{mod}}(\mathbf{a},\delta)=E\{V^{\text{mod}}(\mathbf{a},\delta)\}$. The first term in the right-hand side of Eq. (10) represents the variance of the random experimental velocity $V^{\exp}$ of the first arriving signal (which is independent of $\mathbf{a}$ and δ). The second term in the right-hand side of Eq. (10) corresponds to the bias between the stochastic simplified model and the experimental system. The last term in the right-hand side of Eq. (10) is variance of the random velocity V^{mod} of the first arriving signal calculated with the stochastic simplified model. It should be noted that this variance is equal to zero if $\delta=0$. Nevertheless, numerical experiments show that, for $\delta=0$, it is always possible to find a value $\mathbf{a}_0^{\text{opt}}$ of parameter $\mathbf{a}$ such that $v^{\exp} - v^{\text{mod}}(\mathbf{a},\delta)=0$. Consequently, the usual least-square approach yields $\mathbf{a}^{\text{opt}}=\mathbf{a}_0^{\text{opt}}$ and $\delta^{\text{opt}}=0$. Such a solution does not allow the statistical fluctuations due to uncertainties to be taken into account (because $\delta^{\text{opt}}=0$) which proves that the cost function defined by Eq. (10) is not adapted. This is the reason why a nonusual cost function is introduced below.

2. Cost function adapted to the problem

We introduce a cost function F^{cost} which is more sensitive to the statistical fluctuations of the model, i.e., to the values of δ. Such a cost function is written as

$$F^{\text{cost}}(\mathbf{a},\delta) = \frac{(v^{\exp} - v^{\text{mod}}(\mathbf{a},\delta))^2}{(v^{\exp})^2} + \frac{(\Delta^{\exp} - \Delta^{\text{mod}}(\mathbf{a},\delta))^2}{(\Delta^{\exp})^2},$$

in which

$$\Delta^{\text{mod}} = \sqrt{\frac{E\{V^{\text{mod}}(\mathbf{a},\delta)^2\}}{v^{\text{mod}}(\mathbf{a},\delta)^2} - 1}.$$

This cost function is used for the optimization problem defined by Eq. (9) in order to identify the parameters $\mathbf{a}$ and δ.

VI. RESULTS

A. Numerical data

The mean elasticity matrix of the cortical bone (layer Ω) is completely defined by the vector $\mathbf{a}=(\rho,e_L,\nu_L,g_L,e_T,\nu_T)$. The following numerical values for the components of $\mathbf{a}$ are used (1) for the direct simulations presented in Sec. VI B and (2) as initial parameters for the optimization presented in

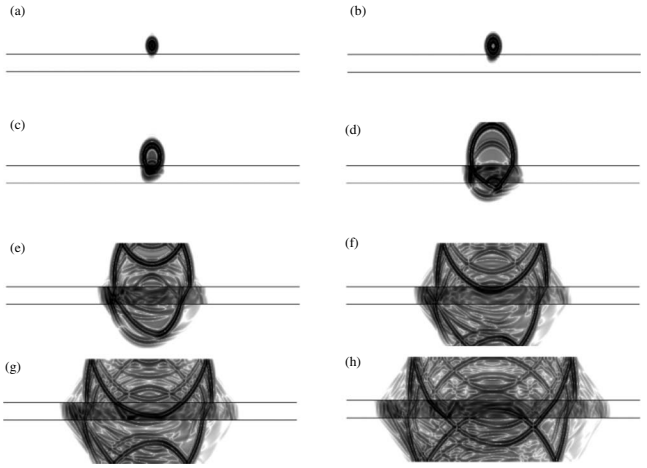

FIG. 3. Wave propagation in the three layers for a given realization of the random elasticity matrix at $t=1.56$ μs (a), $t=2.06$ μs (b), $t=2.94$ μs (c), $t=5.89$ μs (d), $t=9.72$ μs (e), $t=13.55$ μs (f), $t=15.31$ μs (g), and $t=119.88$ μs (h).

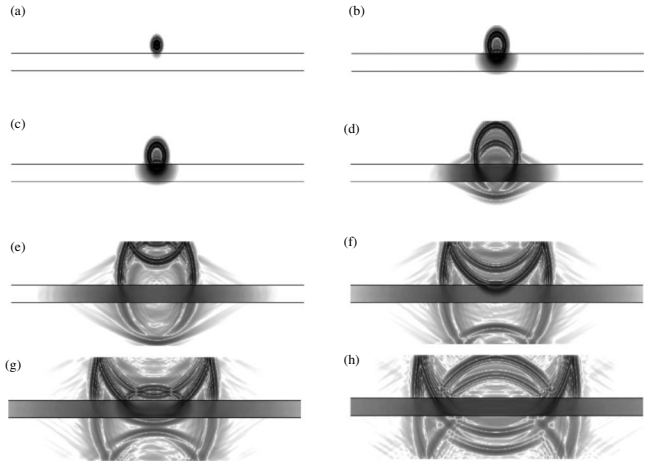

FIG. 4. Propagation of the mean waves in the three layers at $t=1.56$ μs (a), $t=2.06$ μs (b), $t=2.94$ μs (c), $t=5.89$ μs (d), $t=9.72$ μs (e), $t=13.55$ μs (f), $t=15.31$ μs (g), and $t=119.88$ μs (h).

Sec. VI C: $\rho=1722$ kg m^{-3}, $e_L=16.6$ GPa, $\nu_L=0.38$, $g_L=4.7$ GPa, $e_T=9.5$ GPa, $\nu_T=0.44$, $g_T=3.3$ GPa, $\rho_f=1000$ kg m^{-3}, and $c_f=1500$ m s^{-1}. The acoustic line source is located at $x_1^S=0$ and $x_3^S=2\times10^{-3}$ m and the time-history of the acoustic pulse is $F(t)=F_1\sin(2\pi f_c t)e^{-4(tf_c-1)^2}$, where $f_c=1$ MHz is the center frequency and $F_1=100$ N.

B. Analysis of the propagation of the uncertainties

In this section, we present an analysis of the propagation of the uncertainties in the multilayer system with $h_1=10^{-2}$ m, $h=4\times10^{-3}$ m, and $h_2=10^{-2}$ m. First, the wave propagation of one realization of the system is analyzed and clearly shows the effect of the anisotropy. Second, we analyze the mean value and the variance of the random wave propagation. This information allows the propagation of uncertainties to be quantified.

Let $[\mathbf{C}(\theta)]$ be one realization of the random elasticity matrix $[\mathbf{C}]$. For an elasticity matrix $[\mathbf{C}(\theta)]$, the realizations of the pressure fields in the two fluid media and the realization of the von Mises field in the solid medium are $P_1(\theta)$, $P_2(\theta)$, and $\Sigma^{\mathrm{vm}}(\theta)$ and such that

$$P_1(\mathbf{x},t;\theta)=g_{p_1}(\mathbf{x},t;[\mathbf{C}(\theta)]),$$

$$P_2(\mathbf{x},t;\theta)=g_{p_2}(\mathbf{x},t;[\mathbf{C}(\theta)]),$$

$$\Sigma^{\mathrm{vm}}(\mathbf{x},t;\theta)=g_{\mathrm{vm}}(\mathbf{x},t;[\mathbf{C}(\theta)]).$$

Figures 3(a)–3(h) show the graphs of the functions $(x_1,x_3)\mapsto P_1(x_1,x_3,t;\theta)$, $(x_1,x_3)\mapsto\Sigma^{\mathrm{vm}}(x_1,x_3,t;\theta)$, and $(x_1,x_3)\mapsto P_2(x_1,x_3,t;\theta)$ at different value of time t. Let $\underline{P}_1$, $\underline{\Sigma}^{\mathrm{vm}}$, and $\underline{P}_2$ be the mean values of the stochastic fields P_1, Σ^{vm}, and P_2. Figures 4(a)–4(h) show the graphs of functions $(x_1,x_3)\mapsto\underline{P}_1(x_1,x_3,t)$, $(x_1,x_3)\mapsto\underline{\Sigma}^{\mathrm{vm}}(x_1,x_3,t)$, and $(x_1,x_3)\mapsto\underline{P}_2(x_1,x_3,t)$ at different time t. Let var_{P_1}, $\mathrm{var}_{\Sigma^{\mathrm{vm}}}$, and var_{P_2} be the variances of the stochastic fields P_1, Σ^{vm}, and P_2. Figures 5(a)–5(h) show the graphs of the functions $(x_1,x_3)\mapsto\mathrm{var}_{P_1}(x_1,x_3,t)$, $(x_1,x_3)\mapsto\mathrm{var}_{\Sigma^{\mathrm{vm}}}(x_1,x_3,t)$, and $(x_1,x_3)\mapsto\mathrm{var}_{P_2}(x_1,x_3,t)$ at different time t.

Figures 3–5 taken together illustrate the stochastic wave propagation phenomenon. It can be seen in Fig. 3 that for one given realization, the wave field is particularly complex due to the anisotropy: in Fig. 3 (which corresponds to a realization $[\mathbf{C}(\theta)]$ of the stiffness matrix with a relative strong deviation from transverse anisotropy) the complex anisotropy is, in particular, evidenced by the asymmetry with respect to $(O,\mathbf{e}_3)$ of the wave field in the solid and in the bottom fluid layer. Such an asymmetry can be understood making use of slowness curves for anisotropic media [see, for instance, Royer and Dieulesaint (1999)]: if the slowness curves happen to be asymmetric with respect to $\mathbf{e}_3$, the waves at the right and left of $(O,\mathbf{e}_3)$ will travel at different velocities. In contrast, the mean and variance wave fields shown in Figs. 4 and 5 are quasisymmetric with respect to $(O,\mathbf{e}_3)$. This illustrates the fact that the anisotropic fluctuations of the stochastic elasticity matrix driven by δ do not have, on average, any preferential direction. Of course this can only be observed for the mean value and the variance. It should also be

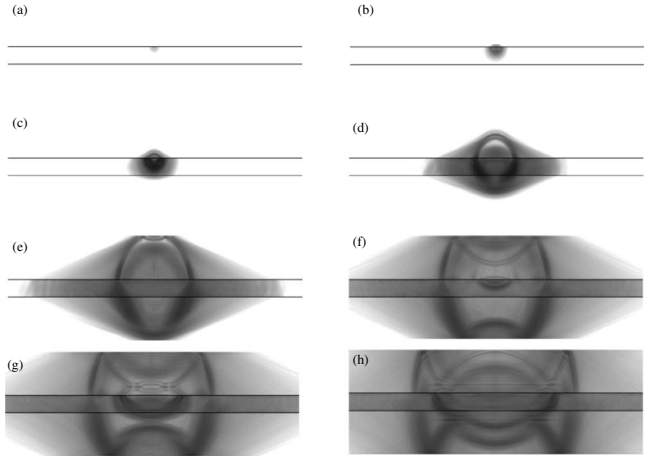

FIG. 5. Propagation of the uncertainties in the three layers at $t=1.56$ μs (a), $t=2.06$ μs (b), $t=2.94$ μs (c), $t=5.89$ μs (d), $t=9.72$ μs (e), $t=13.55$ μs (f), $t=15.31$ μs (g), and $t=119.88$ μs (h).

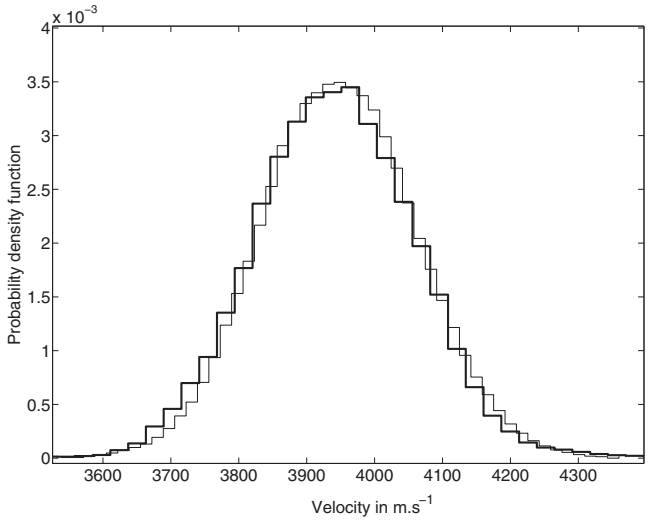

FIG. 6. Graph of the probability density function $v \mapsto p_{V^{\exp}}(v)$ (thick solid lines) and graph of the density probability density functions $v \mapsto p_{V^{\mathrm{mod}}}(v;\mathbf{a}^{\mathrm{opt}},\delta^{\mathrm{opt}})$ with $\mathbf{a}=\mathbf{a}^{\mathrm{opt}}$ and $\delta=\delta^{\mathrm{opt}}$ (thin solid lines).

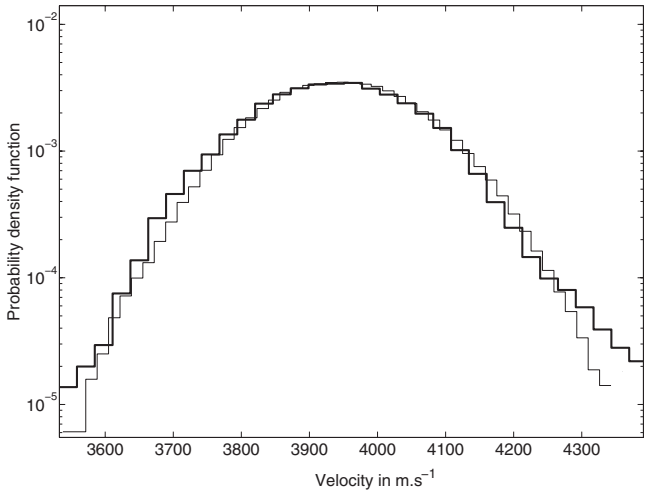

FIG. 7. Graphs of $v \mapsto \log(p_{V^{\exp}}(v))$ (thick solid lines) and $v \mapsto \log(p_{V^{\mathrm{mod}}}(v;\mathbf{a}^{\mathrm{opt}},\delta^{\mathrm{opt}}))$ (thin solid lines).

noted that the mean value of the different wave field realizations is not identical to the wave field obtained with the mean model unless $\delta=0$ (i.e., no statistical fluctuation of the elasticity tensor). Figure 5 shows that there is a significant propagation of the uncertainties whose intensity is relative to the variances. Note that the upper wavefront in Figs. 3 and 4 corresponding to the direct cylindrical wave from the source is missing in Fig. 5 while the other waves which have interacted with the solid layer are observed. This is an illustration of the fact that the uncertainties in the wave propagation problem are associated with an interaction with the random elastic layer. Furthermore the intensity of the uncertainties is higher where the amplitude of the wave (close to the wave front) is higher. In addition, it can be deduced from the comparison of Figs. 4 and 5 that the dispersion coefficient of the wave propagation is not the same everywhere in the multilayer system.

C. Experimental validation of the stochastic model and identification of the model parameters

The determination of the vector $\mathbf{a}=(\rho,e_L,\nu_L,g_L,e_T,\nu_T)$ and the coefficient δ was carried out using the method presented in Sec. V with $h_1=2\times10^{-3}$ m, $h=4\times10^{-3}$ m, and $h_2=10^{-2}$ m. The solutions $\mathbf{a}^{\mathrm{opt}}=(\rho^{\mathrm{opt}},e_L^{\mathrm{opt}},\nu_L^{\mathrm{opt}},g_L^{\mathrm{opt}},e_T^{\mathrm{opt}},\nu_T^{\mathrm{opt}})$ and δ^{opt} are such that $\rho^{\mathrm{opt}}=1598.8$ kg m^{-3}, $e_L^{\mathrm{opt}}=17.717$ GPa, $\nu_L^{\mathrm{opt}}=0.3816$, $g_L^{\mathrm{opt}}=4.7950$ GPa, $e_T^{\mathrm{opt}}=9.8254$ GPa, $\nu_T^{\mathrm{opt}}=0.4495$, and $\delta^{\mathrm{opt}}=0.1029$. For $\mathbf{a}=\mathbf{a}^{\mathrm{opt}}$ and $\delta=\delta^{\mathrm{opt}}$, the realizations $V^{\mathrm{mod}}(\mathbf{a},\delta;\theta_1),\ldots,V^{\mathrm{mod}}(\mathbf{a},\delta;\theta_N)$ of random velocity $V^{\mathrm{mod}}(\mathbf{a},\delta)$ are constructed with the stochastic simplified model and then, the probability density function $v \mapsto p_{V^{\mathrm{mod}}}(v;\mathbf{a},\delta)$ of $V^{\mathrm{mod}}(\mathbf{a},\delta)$ is estimated. Figure 6 shows in linear scale (1) the probability density function $v \mapsto p_{V^{\exp}}(v)$ of the random variable $V^{\exp}$ estimated with $N=2018$ experimental realizations $V^{\exp}(\hat{\theta}_1),\ldots,V^{\exp}(\hat{\theta}_N)$ and (2) the probability density function $v \mapsto p_{V^{\mathrm{mod}}}(v;\mathbf{a}^{\mathrm{opt}},\delta^{\mathrm{opt}})$. The same data are plotted in Fig. 7 in logarithmic scale in order to analyze the small levels of probabilities. These figures validate the stochastic simplified model in the statistical sense for the prediction of the velocity of the FAS.

VII. DISCUSSION AND CONCLUSIONS

A simplified elasto-acoustic multilayer model has been developed to simulate the ultrasonic wave propagation in a complex biomechanical system. In order to improve the simplified model, the uncertainties related to elastic behavior of the solid layer have been taken into account using a probabilistic approach. The determination of the stochastic model parameters was conducted for *in vivo* data collected previously with an ultrasonic axial transmission device.

Because the plots of the experimental and modeled probability density functions in Figs. 6 and 7 are so close, the stochastic simplified elasto-acoustic model is validated in the statistical sense regarding the prediction of the velocity of the FAS. Not only the mean value and the variance of the velocity are accurately predicted but also the experimental probability distribution is very well predicted; this remarkable result is not usual for such a complex system as that under consideration.

Furthermore, some values of the mean elastic constants of cortical bone and their fluctuations corresponding to the *in vivo* measurement database have been identified. As far as we know, the present work is the first attempt to identify the random anisotropic elasticity tensor of cortical bone from actual measurement data. Note that the elastic parameter of the mean model which, after the optimization, is the most changed compared to the provided nominal elasticity values is the Young modulus e_L in the axial direction. This is consistent with the physics of the wave propagation associated with the FAS when the thickness is large compared to the wavelength: basically the velocity of the observed FAS tends to the velocity of a head wave initiated on the flat fluid-solid interface [see Bossy *et al.* (2002)] and which is associated with bulk longitudinal wave propagation in the solid.

However, the identified elasticity values may not be compared straightforward to the actual bone elasticity values since they depend on the model configuration and on the fact that only the FAS contribution was considered. In the calcu-

lations, the thickness of the bone layer has been fixed among the largest physiological values; in these conditions, the FAS is known to be almost insensitive to the radius thickness [see Bossy *et al.* (2002)].

APPENDIX: STOCHASTIC SOLVER

In this appendix, we present the stochastic solver that we have used to calculate the cost function F^{cost}. This stochastic solver is based on the Monte Carlo numerical method. First, the generator of independent realizations of the random matrix $[\mathbf{G}]$ presented in Soize (2001, 2005) is used. Random matrix $[\mathbf{G}]$ is written as $[\mathbf{G}]=[\mathbf{L}_G]^T[\mathbf{L}_G]$ in which $[\mathbf{L}_G]$ is a random upper triangular (6×6) real matrix whose random elements are independent variables defined as follows.

(1) For $j<j'$, the real-valued random variable $[\mathbf{L}_G]_{jj'}$ is written as $[\mathbf{L}_G]_{jj'}=\sigma U_{jj'}$ in which $\sigma=\delta/\sqrt{7}$ and where $U_{jj'}$ is a real-valued Gaussian random variable with zero mean and variance equal to 1.

(2) For $j=j'$, the positive-valued random variable $[\mathbf{L}_G]_{jj'}$ is written as $[\mathbf{L}_G]_{jj'}=\sigma\sqrt{2V_j}$ in which σ is defined above and where V_j is a positive-valued gamma random variable whose probability density function p_{V_j} with respect to dv is written as

$$p_{V_j}(v)=\mathbb{1}_{\mathbb{R}^+}(v)\frac{v^{(7/(2\delta^2)+(1-j)/2)}e^{-v}}{\Gamma(7/(2\delta^2)+(1-j)/2)}.$$

Then, n_s statistical independent realizations of random elasticity matrix $[\mathbf{C}]$ are constructed and are such that $[\mathbf{C}(\theta_1)]=[L]^T[\mathbf{G}(\theta_1)][L],\ldots,[\mathbf{C}(\theta_{n_s})]=[L]^T[\mathbf{G}(\theta_{n_s})][L]$. Let $P_1(\theta_1),\ldots,P_1(\theta_{n_s})$ be n_s statistical independent realizations of random field P_1 which are such that, for all $\mathbf{x}\in\Omega_1$ and $t\geq 0$, $P_1(\mathbf{x},t;\theta_1)=g_{p_1}(\mathbf{x},t;[\mathbf{C}(\theta_1)]),\ldots,P_1(\mathbf{x},t;\theta_{n_s})=g_{p_1}(\mathbf{x},t;[\mathbf{C}(\theta_{n_s})])$. As soon as the realizations of the random field P_1 are obtained, the realizations of the random velocity V^{mod} are deduced by $V^{\text{mod}}(\theta_1)=g_{\text{velo}}(P_1(\theta_1)),\ldots,V^{\text{mod}}(\theta_{n_s})=g_{\text{velo}}(P_1(\theta_{n_s}))$. For each value of $\mathbf{a}$ and δ, the value of the cost function $F^{\text{cost}}(\mathbf{a},\delta)$ is calculated by $F^{\text{cost}}_{n_s}$ (for sufficiently large values of n_s) such that

$$F^{\text{cost}}_{n_s}=\frac{(v^{\text{exp}}-v^{\text{mod}}_{n_s})^2}{(v^{\text{exp}})^2}+\frac{(\Delta^{\text{exp}}-\Delta^{\text{mod}}_{n_s})^2}{(\Delta^{\text{exp}}_N)^2},$$

in which $v^{\text{mod}}_{n_s}$ and $\Delta^{\text{mod}}_{n_s}$ are the estimations of v^{mod} and Δ^{mod} defined as

$$v^{\text{mod}}_{n_s}=\frac{1}{n_s}\sum_{k=1}^{n_s}V^{\text{mod}}(\theta_k),$$

$$\Delta^{\text{mod}}_{n_s}=\frac{1}{v^{\text{mod}}_{n_s}}\sqrt{\frac{1}{n_s}\sum_{k=1}^{n_s}V^{\text{mod}}(\hat{\theta}_k)^2-(v^{\text{mod}}_{n_s})^2}.$$

(Received 5 August 2008; revised 4 December 2008; accepted 13 January 2009)

A nonlinear model equation in Rayleigh–Plesset form is developed for volume oscillations of a compliant object buried close to the surface in soil. The equation takes into account the stress-free boundary condition on the surface of the ground. The model is fully nonlinear given exact relations for the elastic potential energy stored in deformation of the object and the soil. Expansions of the potential energies for weak nonlinearity are provided in terms of elastic constants that can be determined experimentally. When the shear modulus is allowed to increase with depth below the surface, the natural frequency predicted by the model first decreases and thereafter increases with burial depth, in agreement with reported observations. Perturbation solutions are derived for the displacements on the surface of the ground at the second harmonic and difference frequency due to the nonlinear response of the object to acoustic excitation.

I. INTRODUCTION

Recent investigations[1–3] have revealed promising developments in the use of nonlinear acoustics for detection of land mines. Techniques based on the nonlinear response of a buried object to acoustic excitation can sometimes provide better discrimination between mines and other buried objects, and higher probability of detection, than obtained using linear methods.[3] It is thus desirable to have an appropriate model for the nonlinear response of a buried object to acoustical or seismic excitation. The model should account for the elastic properties of both the object and the surrounding soil.

The first such model was developed by Donskoy *et al.*[1] In this model the buried object and soil are characterized by lumped elements that obey nonlinear constitutive relations. The model predicts a continual decrease in the natural frequency with increasing burial depth. However, experiments have shown that the natural frequency ultimately increases with burial depth after passing through a minimum value.[2,4] The model was subsequently modified by Zagrai *et al.*[5] to account for soil stiffness that increases with burial depth in order to describe the eventual increase in natural frequency.

In a model developed by Sabatier and co-workers,[6,7] the soil is considered to be a continuous medium rather than a system of lumped elements. The continuous medium was modeled as an effective fluid, and thus elasticity of the soil is not taken into account. The natural frequency predicted by this model therefore decreases with depth until asymptotically approaching a limiting value. Nonlinear effects are also not taken into account. However, since the medium surrounding the object is continuous, compressible, and includes an interface corresponding to the surface of the ground, the model may be appropriate for scattering problems that cannot be investigated using a lumped-element model of the soil. The governing equations in the model must be solved numerically.

In the present paper, a nonlinear model equation is derived for the vibrational response of a compliant object buried in soil close to the surface and subjected to an applied acoustic pressure. Elasticity and nonlinearity of both the object and the soil are taken into account. The object is considered to be acoustically compact, and its dynamics are modeled as the radial pulsation of an elastic sphere. Since the frequencies of interest for mine detection are very low, typically several hundred hertz, and the objects are buried close to the surface of the ground, the region including the object and neighboring surface is in the reactive near field of the compressional waves radiated by or scattered from the object. The soil is therefore modeled as an incompressible elastic medium.

The equation of motion for such an object buried near the surface of an incompressible elastic half-space is derived using Lagrangian mechanics. Kinetic and potential energies of both the object and soil are taken into account. The result is an equation for the radial oscillation of the object that is expressed in Rayleigh–Plesset form. Correction terms that account for compressibility of the soil are shown to be very small. An expression is derived for the natural frequency in the linear approximation that accounts for both its initial decrease with depth due to increased inertia of the soil, and its eventual increase with depth due to increased rigidity of the soil. Perturbation solutions are derived for the displacement on the surface of the soil at the second harmonic and difference frequency resulting from a bifrequency acoustic pressure imposed on the object. Numerical calculations presented are based on material, soil, and acoustic source parameters reported in the literature.

II. THEORETICAL MODEL

We consider an acoustically compact object whose dynamical response to a disturbance may be characterized by its change in volume. The volume is in turn represented by

the instantaneous radius $R(t)$ of a sphere that occupies the same volume. The physical attributes of the object are characterized by a lumped inertia and stiffness. As justified at the end of this section, the continuous medium surrounding the object is presumed to be incompressible, with elasticity associated only with shear deformation. Lagrange's equation is used to derive the dynamical equation for the radial motion of the object:

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{R}}\right) - \frac{\partial L}{\partial R} = 0 \tag{1}$$

where $L=T-U$ is the Lagrangian, T is the kinetic energy, and U is the potential energy of the system. Overdots on R and other quantities signify time derivatives.

Kinetic energy is stored in the motion of both the object and the surrounding soil:

$$T = \tfrac{1}{2}M\dot{R}^2 + 2\pi\rho R^3\dot{R}^2, \tag{2}$$

where M is the effective moving mass of the object, and ρ is the (constant) density of the soil. For example, M is the actual mass of a thin spherical shell, and it would be 0.6 times the mass of a solid elastic sphere. The second term in Eq. (2) is the kinetic energy in the soil.[8]

Potential energy in the system may be stored in deformation of both the object and the surrounding soil, and it may be altered due to work done by external forces. The expression for the potential energy is separated accordingly:

$$U = U_{\text{obj}} + U_{\text{soil}} + U_{\text{ext}}. \tag{3}$$

The potential energy stored in the object is expressed as a function of change in effective radius relative to the equilibrium value R_0:

$$U_{\text{obj}} = \frac{K_1}{2!}\left(\frac{R-R_0}{R_0}\right)^2 + \frac{K_2}{3!}\left(\frac{R-R_0}{R_0}\right)^3 + \cdots, \tag{4}$$

where the stiffness constants K_i have units of energy. The derivative required in Eq. (1) is

$$\frac{dU_{\text{obj}}}{dR} = \frac{1}{R_0}\left[K_1\left(\frac{R-R_0}{R_0}\right) + \frac{K_2}{2!}\left(\frac{R-R_0}{R_0}\right)^2 + \cdots\right], \tag{5}$$

which is the force required to displace the surface of the object from R_0 to R.

For comparison with experiment, the stiffness constants associated with the surface of the object may be more conveniently expressed as coefficients k_i having units of pressure per unit distance.[1] In this case, and in the linear approximation, Eq. (5) reduces to $dU_{\text{obj}}/dR = K_1R'/R_0^2$, where $R' = R-R_0$. Equating this force to $4\pi R_0^2 k_1 R'$ yields

$$K_1 = 4\pi R_0^4 k_1. \tag{6}$$

Similar relations are easily developed for higher-order coefficients. Frequently when considering nonlinearity in a spring, one ignores the quadratic (K_2) term in Eq. (5) and includes only the cubic (K_3) term (not shown). This practice is associated with the notion of a spring stiffness that increases as deviation from the equilibrium length increases, both in compression and tension. However, quadratic nonlinearity will be present in objects with complex geometries, and for sufficiently small deformations quadratic nonlinearity always dominates cubic nonlinearity.

The elastic energy stored by radial deformation in an incompressible medium may be expressed in terms of the expansion[8]

$$U_{\text{soil}} = 8\pi R_0^3\left[\mu\left(\frac{R-R_0}{R_0}\right)^2 - \frac{1}{2}\left(\mu+\frac{A}{3}\right)\left(\frac{R-R_0}{R_0}\right)^3 + \cdots\right], \tag{7}$$

where μ is the shear modulus and A is the third-order elastic constant in the notation of Landau and Lifshitz.[9] The required derivative is

$$\frac{dU_{\text{soil}}}{dR} = 16\pi R_0^2\left[\mu\left(\frac{R-R_0}{R_0}\right) - \frac{3}{4}\left(\mu+\frac{A}{3}\right)\left(\frac{R-R_0}{R_0}\right)^2 + \cdots\right], \tag{8}$$

which is the force required to displace the surface of the soil in contact with the object from R_0 to R.

Two external forces on the system are taken into account, and those are due to gravity and incident acoustic waves. Work done by these external forces changes the potential energy stored in the object (which is compressible) but not in the soil (which is incompressible), such that

$$U_{\text{ext}} = (\rho g d + p_{\text{ac}})(V - V_0), \tag{9}$$

where $\rho g d$ is the static pressure due to burial at depth d, g is the acceleration due to gravity, $p_{\text{ac}}(t)$ is the pressure perturbation due to an incident acoustic wave, $V=\frac{4}{3}\pi R^3$ is the volume of the object, and V_0 is its equilibrium value in the absence of static load. The required derivative is thus

$$\frac{dU_{\text{ext}}}{dR} = 4\pi R^2(\rho g d + p_{\text{ac}}). \tag{10}$$

Substitution of the expressions for T and U in Eq. (1) yields

$$\left(1+\frac{M}{4\pi\rho R^3}\right)R\ddot{R} + \frac{3}{2}\dot{R}^2 = -\frac{1}{4\pi\rho R^2}\left(\frac{dU_{\text{obj}}}{dR} + \frac{dU_{\text{soil}}}{dR}\right) - gd - \frac{p_{\text{ac}}(t)}{\rho}, \tag{11}$$

which is a modified form of the Rayleigh–Plesset equation for a bubble in an infinite liquid.

To complete the model we must satisfy the stress-free boundary condition on the surface of the ground. This condition can be satisfied by extending the medium throughout the half-space above the ground and introducing an image of the object that pulsates in opposite phase at height d above the plane where the surface had been located. At distance r from the object, the pressure variations in the free field due to volume oscillations of the object are described by $p = \rho\ddot{V}/4\pi r$. While this is the familiar expression for radiation from a monopole, it is not a linear approximation.[10] The pressure exerted on the object due to its image at distance $r=2d$ and with opposite phase will thus be $p_{\text{im}} = -\rho\ddot{V}/8\pi d$. Adding the term $-p_{\text{im}}/\rho = \ddot{V}/8\pi d$ to the right-hand side of Eq. (11) and using the relation $\ddot{V} = 4\pi R(R\ddot{R} + 2\dot{R}^2)$ yield

$$\left(1+\frac{M}{4\pi\rho R^3}-\frac{R}{2d}\right)R\ddot{R}+\left(\frac{3}{2}-\frac{R}{d}\right)\dot{R}^2 = -\frac{1}{4\pi\rho R^2}\left(\frac{dU_{\rm obj}}{dR}+\frac{dU_{\rm soil}}{dR}\right)-gd-\frac{p_{\rm ac}(t)}{\rho}. \quad (12)$$

The stress-free boundary condition is automatically taken into account by the dynamical equation for the radial oscillation of the object.

Equation (12) is the main result of this investigation. If the potential energies $U_{\rm obj}$ and $U_{\rm soil}$ are known, it is a fully nonlinear model for the forced pulsation of an elastic object buried near the surface of an elastic half-space. The remainder of the paper is devoted to approximate analytical solutions derived by perturbation under the condition of weak nonlinearity. Nonlinearity is included through quadratic order in the radial displacement, and therefore Eqs. (5) and (8) define all elastic constants required for calculations.

We conclude this section by assessing the effect of compressibility of the elastic medium. To do so, we return to Eq. (11) for an object in an infinite elastic medium. As shown elsewhere,[11] the effect of weak compressibility on a pulsating sphere in an infinite elastic medium is to impose a pressure (negative normal stress) $p_{\rm rad}=-\rho\ddot{V}/4\pi c_l$ on the sphere that is associated with radiation of the compressional wave at speed c_l. This pressure is taken into account by adding the term $-p_{\rm rad}/\rho=\ddot{V}/4\pi c_l$ to the right-hand side of Eq. (11). The stress-free boundary condition for an elastic half-space is then taken into account as above by adding the image term $\ddot{V}/8\pi d$ to the right-hand side. Compressibility introduces a finite time delay $2d/c_l$ for propagation of the compressional wave from the image to the object, such that the image term becomes $\ddot{V}(t-2d/c_l)/8\pi d$. Expansion of the image term in powers of $1/c_l$ yields $\ddot{V}(t)/8\pi d-\dddot{V}(t)/4\pi c_l$ to first order in $1/c_l$. The second term in the expansion thus cancels $-p_{\rm rad}/\rho$, indicating that for pulsation near a stress-free surface the correction for compressibility is of second order in $1/c_l$. The effect of compressibility in the context of the problem at hand is therefore very small. This conclusion is not surprising, because at low frequencies the pulsating object and its antiphase image form a dipole, the radiation efficiency of which is very poor at low frequencies.

III. LINEAR APPROXIMATION

Equation (12) is linearized with respect to the dimensionless radial displacement

$$\xi=(R-R_0)/R_0 \quad (13)$$

to obtain, taking Eqs. (5) and (8) into account,

$$\left(1+\frac{M}{4\pi\rho R_0^3}-\frac{R_0}{2d}\right)\ddot{\xi}+\left(\frac{K_1}{4\pi\rho R_0^5}+\frac{4\mu}{\rho R_0^2}\right)\xi = -\frac{gd}{R_0^2}-\frac{p_{\rm ac}(t)}{\rho R_0^2}. \quad (14)$$

In terms of the quantities

$$m=\frac{3M}{4\pi\rho R_0^3}, \quad \omega_{\rm obj}^2=\frac{K_1}{4\pi\rho R_0^5}, \quad \omega_{\rm soil}^2=\frac{4c_t^2}{R_0^2}, \quad (15)$$

where $c_t=(\mu/\rho)^{1/2}$ is the shear wave speed in the soil, Eq. (14) becomes

$$\left(1+\frac{m}{3}-\frac{R_0}{2d}\right)\ddot{\xi}+(\omega_{\rm obj}^2+\omega_{\rm soil}^2)\xi=-\frac{gd}{R_0^2}-\frac{p_{\rm ac}(t)}{\rho R_0^2}. \quad (16)$$

Alternatively, Eq. (16) may be expressed in the form

$$\ddot{\xi}+\omega_0^2\xi=-\frac{\omega_0^2}{\omega_{\rm obj}^2+\omega_{\rm soil}^2}\left(\frac{gd}{R_0^2}+\frac{p_{\rm ac}(t)}{\rho R_0^2}\right), \quad (17)$$

where the natural angular frequency ω_0 is defined by

$$\omega_0^2=\frac{\omega_{\rm obj}^2+\omega_{\rm soil}^2}{1+m/3-R_0/2d}, \quad (18)$$

$\omega_{\rm obj}$ is the natural frequency of an object with negligible mass in an infinite incompressible liquid, and $\omega_{\rm soil}$ is the natural frequency of a spherical cavity in an infinite incompressible elastic medium. The parameter m is the ratio of the effective moving mass of the object to the mass of the soil displaced by the presence of the object.

Due to the static load taken into account by the term $-gd/R_0^2$ in Eq. (16), free oscillations occur not about radius R_0 but instead about a local equilibrium radius $R_1<R_0$ determined by setting $\ddot{\xi}=0$ and $p_{\rm ac}=0$. The corresponding dimensionless displacement is

$$\xi_0=\frac{R_1-R_0}{R_0}=-\frac{gd}{R_0^2(\omega_{\rm obj}^2+\omega_{\rm soil}^2)}. \quad (19)$$

The magnitude of this static displacement may be estimated by considering a soft object ($\omega_{\rm obj}^2\ll\omega_{\rm soil}^2$), for which the expression reduces to $\xi_0=-gd/4c_t^2$. Taking $c_t=100$ m/s for soil and $d=1$ m for the burial depth one obtains $\xi_0=-2.5\times10^{-4}$. In the quadratic approximation, even for this excessively large burial depth, the static displacement is found to introduce a negligible change in the natural frequency, and it has no effect on generation of the second harmonic and difference frequency. The term $-gd$ in Eq. (12) is therefore ignored from this point forward.

As burial depth is increased, Eq. (18) assumes the limiting form

$$\omega_0^2=\frac{\omega_{\rm obj}^2+\omega_{\rm soil}^2}{1+m/3}, \quad d\gg R_0. \quad (20)$$

If the soil is homogeneous and therefore $\omega_{\rm soil}$ is a constant, then ω_0 is a monotonically decreasing function of depth, asymptotically approaching the lower bound determined by Eq. (20). This saturation effect was observed in experiments reported by Alberts *et al.*[7] on land mines immersed in water and buried in sand.

For numerical calculations we use equilibrium radius $R_0=0.1$ m and object stiffness $K_1=5\times10^5$ N m. The latter corresponds to the value $k_1=5\times10^8$ Pa/m from the table provided by Donskoy *et al.*,[1] and which is related to K_1 by Eq. (6). The density of the soil is taken to be $\rho=2000$ kg/m^3 and the damping coefficient to be $\delta=0.1$.

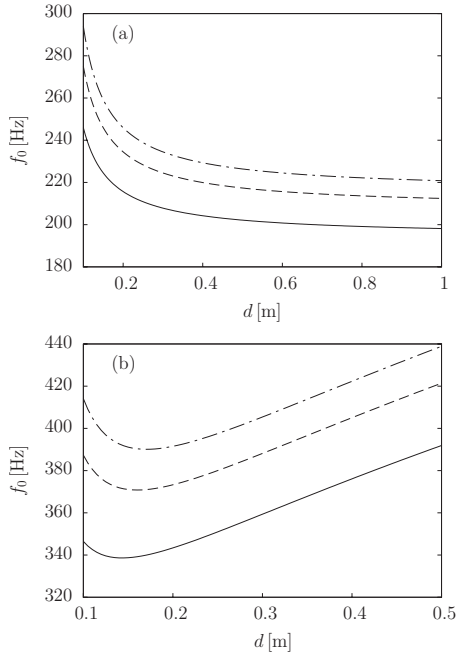

FIG. 1. Natural frequency as a function of burial depth for $R_0=0.1$ m, $\rho=2000$ kg/m^3, $K_1=5\times10^5$ N m, $\delta=0.1$, (a) $c_t=0$, and (b) $c_t=146d^{0.32}$ m/s, where d has units of meters, for $m=1$ (solid lines), $m=0.5$ (dashed lines), and $m=0.25$ (dot-dash lines).

Shown in Fig. 1(a) is the natural frequency $f_0=\omega_0/2\pi$ as a function of depth d for several values of the moving mass parameter m when the elasticity of the soil is ignored and therefore $\omega_{\text{soil}}=0$. It is observed that f_0 decreases as m increases, and that the asymptotic behavior described by Eq. (20) is reached at $d\sim1$ m. The frequency decreases because the pulsating object must move more soil when it is farther from the surface, which increases the effective mass loading on the object. As discussed above, the decrease in frequency associated with the increase in static load due to gravity is negligible.

Elasticity of the soil is now taken into account, and in particular its observed dependence on depth. Empirical relations developed by Nottis[12] for shear wave speeds as functions of depth, based on measurements made in various surficial materials along the lower Hudson Valley, permit calculation of natural frequency as a function of depth in inhomogeneous media. While evaluation of the integral resulting in Eq. (7) is based on the assumption that the coefficients μ, A, etc., are constant throughout the medium surrounding the object,[8] the effect of shear elasticity is in fact confined to a very small region in the neighborhood of the object. It is therefore reasonable to permit μ and thus c_t to vary locally with d in order to estimate the effect of inhomogeneity. On the basis of the relation obtained by Nottis[12] for glacial outwash sand and gravel, we let

$$c_t=100(d/0.305)^{0.32}=146d^{0.32}\ \text{m/s}, \tag{21}$$

where d in this equation possesses units of meters.

Taking all other parameters to be the same as in Fig. 1(a), one obtains the results in Fig. 1(b). Inhomogeneity characterized by a shear modulus that increases with depth thus eliminates saturation. Instead, after passing through a minimum value the natural frequency eventually increases with distance from the surface. Measurements of resonance frequency as a function of depth by Korman and Sabatier[2] and by Kang *et al.*[4] exhibit similar behavior.

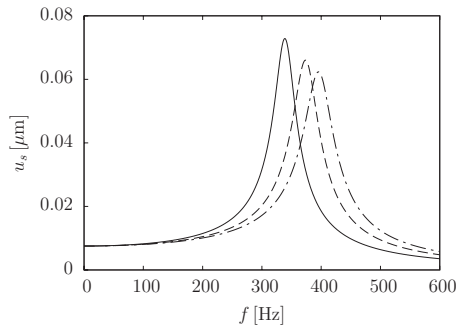

FIG. 2. Ground surface displacement at the drive frequency, as a function of drive frequency, for the same parameters as in Fig. 1(b) but with fixed depth $d=0.125$ m and acoustic pressure amplitude $p_0=5$ Pa, and again for $m=1$ (solid lines), $m=0.5$ (dashed lines), and $m=0.25$ (dot-dash lines).

Damping must be taken into account to model forced oscillations, and it is introduced *ad hoc* in Eq. (16) as follows:

$$\left(1+\frac{m}{3}-\frac{R_0}{2d}\right)(\ddot{\xi}+\delta\omega_0\dot{\xi})+(\omega_{\text{obj}}^2+\omega_{\text{soil}}^2)\xi=-\frac{p_{\text{ac}}(t)}{\rho R_0^2}. \tag{22}$$

The dimensionless damping coefficient δ is related to the quality factor Q by $\delta=1/Q$. It must be recognized that δ will inevitably vary with both depth and frequency due to the boundary condition imposed by the free surface and the composition of the object.

Forced excitation of the object is considered by representing the applied acoustic pressure as

$$p_{\text{ac}}=p_0\cos\omega t=\text{Re}[p_0e^{i\omega t}]. \tag{23}$$

The corresponding solution of Eq. (22) is expressed as

$$\xi(t)=\text{Re}[\Xi(\omega)e^{i\omega t}], \tag{24}$$

where the complex amplitude is

$$\Xi(\omega)=-\frac{p_0}{\rho R_0^2(\omega_{\text{obj}}^2+\omega_{\text{soil}}^2)(1-\omega^2/\omega_0^2+i\delta\omega/\omega_0)}. \tag{25}$$

Of particular interest is the displacement of the ground surface directly above the object. For a pulsating spherical source in an incompressible medium, the radial displacement u in the medium is inversely proportional to the square of the distance r from the center of the source, and thus $u=(R_0/r)^2\xi$. Directly above the object there will be doubling of the particle displacement at the free surface. For the magnitude of the ground surface displacement we thus write

$$u_s(\omega)=2(R_0/d)^2R_0|\Xi(\omega)|. \tag{26}$$

The surface displacement as a function of drive frequency $f=\omega/2\pi$ is plotted in Fig. 2 for the conditions in Fig. 1(b) but with fixed depth $d=0.125$ m and acoustic pressure amplitude $p_0=5$ Pa. The latter corresponds to a sound pressure level of approximately 105 dB (re 20 μPa) on the surface of the ground and is comparable to that used by Korman and

Sabatier,[2] as are the resulting surface displacements predicted in Fig. 2.

IV. QUADRATIC APPROXIMATION

In the quadratic approximation one obtains in place of Eq. (22)

$$\left(1+\frac{m}{3}-\frac{R_0}{2d}\right)(\ddot{\xi}+\delta\omega_0\dot{\xi})+(\omega_{\text{obj}}^2+\omega_{\text{soil}}^2)\xi = \Omega^2\xi^2-\left(1-\frac{2m}{3}-\frac{R_0}{d}\right)\xi\ddot{\xi}-\left(\frac{3}{2}-\frac{R_0}{d}\right)\dot{\xi}^2-\frac{p_{\text{ac}}(t)}{\rho R_0^2}, \tag{27}$$

where the quantity

$$\Omega^2=\left(2-\frac{K_2}{2K_1}\right)\omega_{\text{obj}}^2+\frac{1}{4}\left(11+\frac{A}{\mu}\right)\omega_{\text{soil}}^2 \tag{28}$$

contains the nonlinearity coefficients K_2 and A for the object and soil, respectively. The notation Ω^2 is employed to serve as a reminder in subsequent equations that the quantity has units of frequency squared.

A. Second harmonic

The acoustic excitation is given again by Eq. (23), for which the solution is now expressed as

$$\xi(t)=\text{Re}[\Xi_1(\omega)e^{i\omega t}+\Xi_2(\omega)e^{i2\omega t}]. \tag{29}$$

With $\Xi_1(\omega)$ and $\Xi_2(\omega)$ taken to be first- and second-order quantities, respectively, substitution of Eq. (29) in Eq. (27) yields

$$\Xi_2(\omega)=\frac{N_2(\omega)}{D_2(\omega)}\Xi_1^2(\omega) \tag{30}$$

at second order, where $\Xi_1(\omega)$ is given by Eq. (25), and with

$$N_2(\omega)=\Omega^2+\left(\frac{5}{2}-\frac{2m}{3}-\frac{2R_0}{d}\right)\omega^2, \tag{31}$$

$$D_2(\omega)=2(\omega_{\text{obj}}^2+\omega_{\text{soil}}^2)\left(1-\frac{4\omega^2}{\omega_0^2}+i\delta\frac{2\omega}{\omega_0}\right). \tag{32}$$

Figure 3(a) shows the surface displacement u_{2s} at the second harmonic as a function of source frequency for the same parameters as in Fig. 2. In addition, the values $K_2/K_1=10^5$ and $A/\mu=0$ were chosen for the nonlinearity parameters of the object and the soil, respectively. The motivation for choosing $A/\mu=0$ is that for soft elastic media such as loose soil $A/\mu=O(1)$,[13] in which case its contribution in Eq. (28) is negligible. We chose $K_2/K_1=10^5$ by determining the value required to predict surface displacements comparable to those measured at the second harmonic by Korman and Sabatier.[2] The frequency response observed in Fig. 3(a) is characteristic of nonlinear bubble oscillations, whereby the peak on the right results from driving the object at its natural frequency, and the peak on the left occurs when the second harmonic coincides with the natural frequency. In Fig. 3(b) the drive frequency is fixed at $f=340$ Hz while the depth is varied. The surface displacement drops rapidly as the burial depth is increased.

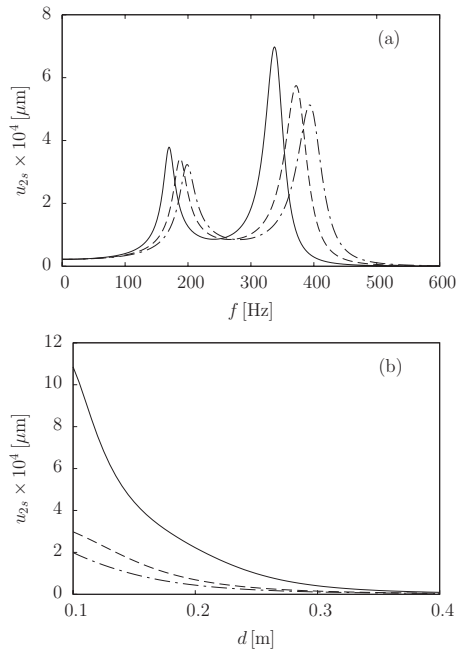

FIG. 3. Ground surface displacement at the second harmonic (a) as a function of drive frequency for fixed burial depth $d=0.125$ m, and (b) as a function of burial depth for fixed drive frequency $f=340$ Hz. The parameters are the same as in Fig. 2, but with $K_2/K_1=10^5$, $A/\mu=0$, and again for $m=1$ (solid lines), $m=0.5$ (dashed lines), and $m=0.25$ (dot-dash lines).

B. Difference frequency

We now let

$$p_{\text{ac}}=p_a\cos\omega_a t+p_b\cos\omega_b t=\text{Re}[p_a e^{i\omega_a t}+p_b e^{i\omega_b t}]. \tag{33}$$

The first-order response is expressed as

$$\xi_1(t)=\text{Re}[\Xi_{1a}(\omega_a)e^{i\omega_a t}+\Xi_{1b}(\omega_b)e^{i\omega_b t}], \tag{34}$$

where the complex amplitudes $\Xi_{1a}(\omega_a)$ and $\Xi_{1b}(\omega_b)$ are given by Eq. (25) with ω set equal to ω_a and ω_b, and p_0 set equal to p_a and p_b, respectively. The desired second-order response is now at the difference frequency $\omega_d=\omega_b-\omega_a$, with

$$\xi_d(t)=\text{Re}[\Xi_d(\omega_a,\omega_b)e^{i\omega_d t}]. \tag{35}$$

Equation (27) thus yields at second order

$$\Xi_d(\omega_a,\omega_b)=\frac{N_d(\omega_a,\omega_b)}{D_d(\omega_a,\omega_b)}\Xi_{1a}^*(\omega_a)\Xi_{1b}(\omega_b), \tag{36}$$

where the asterisk signifies complex conjugate, and

$$N_d(\omega_a,\omega_b)=2\Omega^2-\left(3-\frac{2R_0}{d}\right)\omega_a\omega_b+\left(1-\frac{2m}{3}-\frac{R_0}{d}\right)(\omega_a^2+\omega_b^2), \tag{37}$$

$$D_d(\omega_a,\omega_b)=2(\omega_{\text{obj}}^2+\omega_{\text{soil}}^2)\left(1-\frac{\omega_d^2}{\omega_0^2}+i\delta\frac{\omega_d}{\omega_0}\right). \tag{38}$$

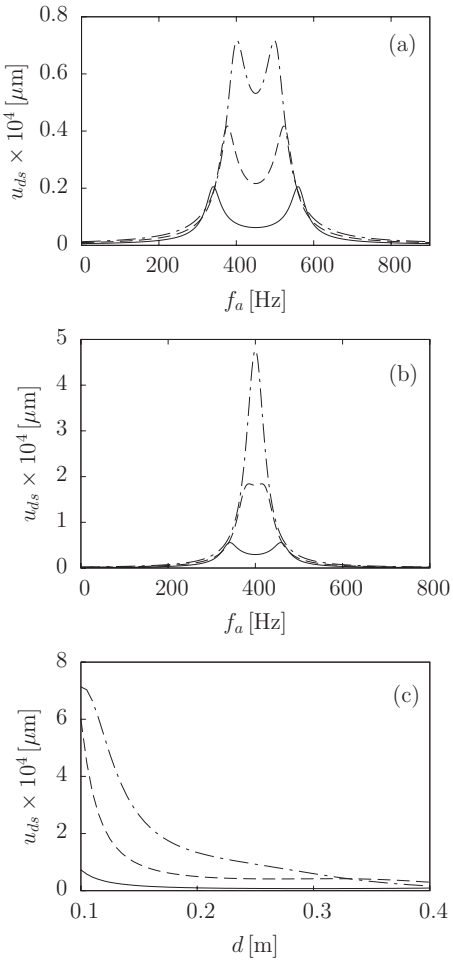

FIG. 4. Ground surface displacement at the difference frequency for the same material and geometric parameters as in Fig. 2(a), with $p_a=p_b=5$ Pa, and again for $m=1$ (solid lines), $m=0.5$ (dashed lines), and $m=0.25$ (dot-dash lines). (a) As a function of f_a for $f_b=900$ Hz. (b) As a function of f_a for $f_b=800$ Hz. (c) As a function of d for $f_a=400$ Hz and $f_b=800$ Hz.

Figure 4(a) shows the surface displacement u_{ds} at the difference frequency f_d as a function of the lower primary frequency f_a for fixed $f_b=900$ Hz. The parameters are otherwise the same as in Fig. 3(a), with $p_a=p_b=5$ Pa. The two maxima in each frequency response occur at the values of f_a for which $f_a=f_0$ and $f_b-f_a=f_0$, the center frequency of which is $f_a=f_b/2$. Figure 4(b) is based on the same parameters as in Fig. 4(a) except for $f_b=800$ Hz. Lowering the upper primary frequency f_b is seen to move the peaks closer together, and for $m=0.25$ only a single peak is observed. Figure 4(c) shows the dependence on burial depth for $f_a=400$ Hz and $f_b=800$ Hz.

V. CONCLUSION

The fully nonlinear model equation developed for the pulsation of a compliant object buried close to the surface in soil is expressed in Rayleigh–Plesset form. The stress-free condition on the surface of the ground is included in the model equation. The main restriction on the model is that the object size and burial depth are on the order of, or smaller than, the compressional wavelength in the medium. This condition permits the system dynamics to be determined completely by the volume oscillations of the object, and it allows the soil to be modeled as an incompressible elastic solid. In the linear approximation, the model predicts the natural frequency to first decrease and thereafter increase as burial depth is increased, in agreement with observations. The model yields simple analytical expressions for the response of the object and the displacement of the ground at the second harmonic and difference frequency of an acoustic excitation. The aforementioned features may make the model useful for investigating more complicated problems involving nonlinearity associated with scattering of elastic waves from a buried object.

(Received 26 September 2008; revised 23 January 2009; accepted 30 January 2009)

The present paper deals with the multiple scattering by randomly distributed elastodynamic systems at the surface of a horizontally layered elastic halfspace due to an incident plane wave. Instead of solving this problem for a particular configuration of the system, multiple scattering theory is used to compute the ensemble response statistics. The Dyson equation is used to calculate the mean field, while the nonstationary second order statistics are obtained by means of the Bethe–Salpeter equation. This allows for the determination of the mean square response of the system in the time and frequency domains. This model is used to study multiple scattering between buildings under seismic excitation. The influence of multiple scattering on the seismic site response is verified. Furthermore, the influence of the footprint and the damping of the buildings are investigated. The results are compared to results of a coupled finite element/boundary element solution for a group of buildings. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3086290]

I. INTRODUCTION

The dynamic behavior of a master structure coupled to complex substructures has received considerable attention in the past.[1–7] For vibroacoustic simulations of complex structures in the medium frequency range, Soize[1] introduced the concept of structural fuzzy. In this theory, the master structure is the main part of the system that is well represented by a deterministic mechanical model. The fuzzy substructure consists of a large number of secondary subsystems and is modeled by a probabilistic boundary impedance. Pierce *et al.*[3] and Strasberg and Feit[4] showed that for a large number of small substructures with closely spaced resonance frequencies, a damping of the master structure is obtained. This damping is due to a transfer of energy[2,5] from the primary structure to the secondary subsystems and therefore referred to as "apparent damping." Energy initially transferred to the subsystems can be returned to the master structure at later times. In the absence of true losses, the coupled system tends to an equipartition of energy.[2,5] Weaver[8,9] studied the energy flow for a plate in flexure interacting with randomly distributed sprung masses. The mean[8] and mean square response[9] are calculated based on multiple scattering theory.[10–13]

The problem of randomly distributed sprung mass systems interacting with an infinite plate in flexure is very similar to the one of the seismic response of urban sites. The buildings act as elastodynamic scatterers and can be considered as the locally reacting fuzzy substructure on top of the soil that plays the role of the wave-bearing master structure. Moreover, the interaction between the buildings is determined by resonant multiple scattering,[14] as the natural frequencies of high-rise buildings are in the frequency range of seismic excitation. This problem has been studied by several authors to more satisfactorily explain features of seismic records from urban arrays.[15] Wirgin and Bard[16] used a two-dimensional model of regularly spaced cylindrical blocks on top of a horizontally layered halfspace. Clouteau and Aubry[17] analyzed the response of a three-dimensional periodic city model, using a coupled finite element/boundary element method. Guéguen *et al.*[18] used an independent scattering approximation for a group of 180 buildings of the Roma Norte quarter of Mexico City. Mezher *et al.*[19] and Mezher[20] performed calculations for a group of 77 buildings of the same quarter, fully accounting for multiple wave scattering. Boutin and Roussillon[21] proposed a simplified analytical procedure, where the city is modeled as an equivalent layer at the soil's surface. Fernández-Ares and Bielak[22] used the domain reduction method[23] to study the seismic response of 88 sprung mass systems with a three-dimensional model taking into account the simulation of the earthquake source and propagation path effects, as well as the presence of the shallow basin underneath Mexico City. Kham *et al.*[24] studied periodically and nonperiodically spaced cities using two-dimensional boundary element models.

In the present paper, the model of randomly distributed elastodynamic systems at the surface of an elastic halfspace is used to study the seismic site response. The Dyson equation is used to calculate the mean response due to an incident plane wave, while the non-stationary second order statistics are obtained from the Bethe–Salpeter equation. Based on earlier developments,[25] a methodology is presented that takes into account the finite size of the interface between the scatterer and the halfspace. The results are complementary to those of Weaver[6,8] as the wave-bearing master structure is a

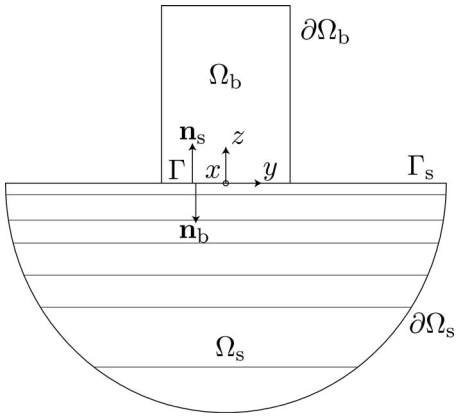

FIG. 1. The single scatterer problem.

horizontally layered elastic halfspace instead of a plate in flexure. Furthermore, the model is of large value for the interpretation of the results of the previously cited studies that consider the detailed response for a single city configuration with a limited number of buildings.

The outline of this paper is as follows. First, the equations of motion governing the single scatterer problem are formulated. An approximate expression is derived for the scattering operator in terms of the dynamic stiffness of the scatterer, the dynamic stiffness of the layered halfspace supporting a single scatterer, and the Green's functions of the halfspace. Next, the Foldy mean field approximation is considered. The mean Green's tensor of the coupled system and the mean response due to a vertically incident plane wave are calculated using Fourier transform techniques. The field correlation is obtained from the Foldy approximation of the Bethe–Salpeter equation. The configurationally averaged field quantities are used to study the seismic response of an urban site. The results are compared to a coupled finite element/boundary element solution for a group of 77 buildings.

II. THE SINGLE SCATTERER PROBLEM

A. Governing equations

In the following, the dynamic response of a single scatterer due to an incident wavefield is considered. The halfspace is assumed to be horizontally layered, and consists of a number of (homogeneous) layers with different Lamé coefficients λ and μ, and density ρ, on top of a homogeneous halfspace. The bounded elastic domain occupied by the scatterer is denoted as Ω_b, while Ω_s represents the unbounded elastic halfspace (Fig. 1). $\partial\Omega_b$ and $\partial\Omega_s$ are the boundaries of Ω_b and Ω_s, respectively. Γ_s is the part of $\partial\Omega_s$ corresponding to the free surface of the halfspace without the scatterer, while Γ is the common interface $\partial\Omega_b \cap \partial\Omega_s$. A right-handed Cartesian frame of reference $\mathbf{x}=(x,y,z)$ is used with its origin at the center of gravity of the interface Γ. For both subdomains, a linear elastic behavior is assumed, so that the displacement field $\mathbf{u}(\mathbf{x})$ satisfies the Navier equation in the frequency domain:

$$-\operatorname{div}\sigma(\mathbf{u})(\mathbf{x}) - \rho\omega^2\mathbf{u}(\mathbf{x}) = 0, \quad \mathbf{x} \in \Omega_b, \Omega_s, \tag{1}$$

where $\sigma(\mathbf{u})(\mathbf{x})$ denotes the elastic stress tensor at the point $\mathbf{x}$ for the displacement field $\mathbf{u}(\mathbf{x})$, ρ denotes the mass density, and ω denotes the circular frequency. It is assumed that no body forces are present, so that the right hand side of Eq. (1) is zero. The continuity of displacements and equilibrium of stresses at the common interface Γ are

$$\mathbf{u}_s(\mathbf{x}) = \mathbf{u}_b(\mathbf{x}), \quad \mathbf{x} \in \Gamma, \tag{2}$$

$$\sigma_s(\mathbf{u}_s)(\mathbf{x}) \cdot \mathbf{n}_s(\mathbf{x}) + \sigma_b(\mathbf{u}_b)(\mathbf{x}) \cdot \mathbf{n}_b(\mathbf{x}) = 0, \quad \mathbf{x} \in \Gamma, \tag{3}$$

where the subscript s refers to the elastic halfspace and the subscript b refers to the scatterer. For both subdomains, $\mathbf{n}(\mathbf{x})$ represents the outward unit normal vector to the boundary at point $\mathbf{x}$. At the common interface Γ, $\mathbf{n}_s(\mathbf{x}) = -\mathbf{n}_b(\mathbf{x})$. In the following, the tractions $\sigma_s(\mathbf{u}_s)(\mathbf{x}) \cdot \mathbf{n}_s(\mathbf{x})$ are denoted as $\mathbf{t}_s(\mathbf{u}_s)(\mathbf{x})$. An approximate solution of the problem is obtained, decomposing the displacements $\mathbf{u}_b(\mathbf{x})$ into the six rigid body modes $\boldsymbol{\psi}_m(\mathbf{x})$ and N structural modes $\boldsymbol{\varphi}_m(\mathbf{x})$ of the scatterer fixed on Γ:

$$\begin{aligned}\mathbf{u}_b(\mathbf{x}) &= \sum_{m=1}^{6} \boldsymbol{\psi}_m(\mathbf{x}) c_m + \sum_{m=1}^{N} \boldsymbol{\varphi}_m(\mathbf{x}) q_m \\ &= \Psi(\mathbf{x})\mathbf{c} + \Phi(\mathbf{x})\mathbf{q}, \quad \mathbf{x} \in \Omega_b,\end{aligned} \tag{4}$$

where c_m and q_m are the generalized coordinates. The rigid body modes are collected in the matrix $\Psi(\mathbf{x}) = [\boldsymbol{\psi}_1(\mathbf{x}) \ldots \boldsymbol{\psi}_6(\mathbf{x})]$, and the matrix $\Phi(\mathbf{x}) = [\boldsymbol{\varphi}_1(\mathbf{x}) \ldots \boldsymbol{\varphi}_N(\mathbf{x})]$ contains the structural modes. The generalized coordinates are collected in the vectors $\mathbf{c}$ and $\mathbf{q}$. In a cylindrical frame of reference (r,θ,z), the matrix $\Psi(\mathbf{x})$ is written as follows:

$$\Psi(r,\theta,z) = \begin{bmatrix} 1 & -z & 0 & 0 & 0 & -r\sin\theta \\ 0 & 1 & 0 & 0 & z & r\sin\theta \\ 0 & 0 & 1 & -r\sin\theta & r\cos\theta & 0 \end{bmatrix}, \tag{5}$$

where the center of gravity of Γ is the rotational center of the rotational rigid body modes.

In the halfspace, the displacement field $\mathbf{u}_s(\mathbf{x})$ is decomposed into the free field motion $\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$, defined as the wavefield in the homogeneous layered halfspace Ω_s without the scatterer, and the diffracted wavefield $\mathbf{u}_d(\mathbf{x})$. The wavefield $\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$ contains the incoming wave that propagates toward the free boundary $\partial\Omega_s$ as well as the waves that are reflected at the interfaces between layers. The diffracted wavefield $\mathbf{u}_d(\mathbf{x})$ represents the modification of the wavefield due to the scatterer and is decomposed into the locally diffracted wavefield $\mathbf{u}_{d0}(\mathbf{x})$ that cancels the free field motion $\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$ at the interface Γ by definition, and the wavefields $\mathbf{u}_{dm}(\mathbf{x})$ radiated by the displacement modes $\psi_m(\mathbf{x})$:

$$\begin{aligned}\mathbf{u}_s(\mathbf{x}) &= \mathbf{u}_{\mathrm{ff}}(\mathbf{x}) + \mathbf{u}_{d0}(\mathbf{x}) + \sum_{m=1}^{6} \mathbf{u}_{dm}(\mathbf{x}) c_m \\ &= \mathbf{u}_{\mathrm{ff}}(\mathbf{x}) + \mathbf{u}_{d0}(\mathbf{x}) + \mathbf{U}_d(\mathbf{x})\mathbf{c}, \quad \mathbf{x} \in \Omega_s,\end{aligned} \tag{6}$$

where the matrix $\mathbf{U}_d(\mathbf{x}) = [\mathbf{u}_{d1}(\mathbf{x}) \cdots \mathbf{u}_{d6}(\mathbf{x})]$. At the interface Γ, $\mathbf{u}_{d0}(\mathbf{x}) = -\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$ and $\mathbf{u}_{dm}(\mathbf{x}) = \boldsymbol{\psi}_m(\mathbf{x})$, so that the continuity

of displacements in Eq. (2) is satisfied. The equilibrium of stresses at the interface Γ in Eq. (3) is now elaborated as follows:

$$\mathbf{t}_s(\mathbf{u}_{\mathrm{ff}})(\mathbf{x}) + \mathbf{t}_s(\mathbf{u}_{d0})(\mathbf{x}) + \sum_{m=1}^{6} \mathbf{t}_s(\mathbf{u}_{dm})(\mathbf{x}) c_m + \sum_{m=1}^{6} \mathbf{t}_b(\boldsymbol{\psi}_m)(\mathbf{x}) c_m + \sum_{m=1}^{N} \mathbf{t}_b(\boldsymbol{\varphi}_m)(\mathbf{x}) q_m = 0. \tag{7}$$

A weak variational formulation of the equilibrium leads to the following system of equations:

$$\begin{bmatrix} \mathbf{K}^b_{qq} & \mathbf{K}^b_{qc} \\ \mathbf{K}^{bT}_{qc} & \mathbf{K}^b_{cc} + \mathbf{K}^s \end{bmatrix} \begin{pmatrix} \mathbf{q} \\ \mathbf{c} \end{pmatrix} = \begin{pmatrix} 0 \\ \mathbf{F}^s \end{pmatrix}, \tag{8}$$

where superscript T denotes the matrix transpose. The matrices $\mathbf{K}^b_{qq}$, $\mathbf{K}^b_{qc}$, and $\mathbf{K}^b_{cc}$ are calculated from the rigid body modes $\boldsymbol{\psi}_m(\mathbf{x})$ and the structural modes $\boldsymbol{\varphi}_m(\mathbf{x})$ of the scatterer fixed at Γ:

$$\mathbf{K}^b_{qq} = \mathrm{diag}(-\omega^2 + 2i\zeta_m\omega_m\omega + \omega_m^2), \tag{9}$$

$$\mathbf{K}^b_{qc} = -\rho_b\omega^2 \int_{\Omega_b} \Phi^T(\mathbf{x})\Psi(\mathbf{x})d\mathbf{x}, \tag{10}$$

$$\mathbf{K}^b_{cc} = -\rho_b\omega^2 \int_{\Omega_b} \Psi^T(\mathbf{x})\Psi(\mathbf{x})d\mathbf{x}, \tag{11}$$

where ω_m and ζ_m are the natural frequencies and damping ratios, respectively, corresponding to the structural mode $\boldsymbol{\varphi}_m$ and ρ_b is the mass density of the scatterer. In Eq. (8), $\mathbf{K}^s$ is the dynamic stiffness matrix of the halfspace. The elements $[\mathbf{K}^s]_{lm}$ of the matrix $\mathbf{K}^s$ are

$$[\mathbf{K}^s]_{lm} = \int_\Gamma \mathbf{t}_s(\mathbf{u}_{dm})(\mathbf{x}) \cdot \boldsymbol{\psi}_l(\mathbf{x})dS. \tag{12}$$

When the tractions $\mathbf{t}_s(\mathbf{u}_{dm})$ are collected in the matrix $\mathbf{T}_d = [\mathbf{t}_s(\mathbf{u}_{d1}) \cdots \mathbf{t}_s(\mathbf{u}_{d6})]$, Eq. (12) can be written as

$$\mathbf{K}^s = \int_\Gamma \mathbf{T}^T_d(\mathbf{x})\Psi(\mathbf{x})dS. \tag{13}$$

The force vector $\mathbf{F}^s$ in Eq. (8) represents the equivalent load due to the wavefield $\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$. The elements $[\mathbf{F}^s]_l$ of the force vector are calculated from the tractions $\mathbf{t}_s(\mathbf{u}_{\mathrm{ff}})(\mathbf{x})$ of the wavefield $\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$ and the tractions $\mathbf{t}_s(\mathbf{u}_{d0})(\mathbf{x})$ of the locally diffracted wavefield $\mathbf{u}_{d0}(\mathbf{x})$:

$$[\mathbf{F}^s]_l = -\int_\Gamma [\mathbf{t}_s(\mathbf{u}_{\mathrm{ff}})(\mathbf{x}) + \mathbf{t}_s(\mathbf{u}_{d0})(\mathbf{x})] \cdot \boldsymbol{\psi}_l(\mathbf{x})dS = -\int_\Gamma \mathbf{t}_s(\mathbf{u}_{\mathrm{ff}})(\mathbf{x}) \cdot \boldsymbol{\psi}_l(\mathbf{x})dS + \int_\Gamma \mathbf{t}_s(\mathbf{u}_{dl})(\mathbf{x}) \cdot \mathbf{u}_{\mathrm{ff}}(\mathbf{x})dS. \tag{14}$$

The second term has been elaborated, replacing $\boldsymbol{\psi}_l(\mathbf{x})$ by its equivalent $\mathbf{u}_{dl}(\mathbf{x})$ for $\mathbf{x} \in \Gamma$, using reciprocity, and making use of the fact that $\mathbf{u}_{d0}(\mathbf{x})$ is by definition equal to $-\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$ for $\mathbf{x} \in \Gamma$. For a scatterer at the free surface of the halfspace, $\mathbf{t}_s(\mathbf{u}_{\mathrm{ff}})(\mathbf{x})$ vanishes for $\mathbf{x} \in \Gamma$:

$$\mathbf{F}^s = \int_\Gamma \mathbf{T}^T_d(\mathbf{x})\mathbf{u}_{\mathrm{ff}}(\mathbf{x})dS. \tag{15}$$

The calculation of the dynamic stiffness matrix $\mathbf{K}_s$ of the layered halfspace in Eq. (13) and the load $\mathbf{F}^s$ in Eq. (15) requires the solution of a boundary value problem where displacements $\mathbf{u}_{dm} = \boldsymbol{\psi}_m$ are prescribed at Γ and the corresponding tractions $\mathbf{t}_s(\mathbf{u}_{dm})$ are unknown. This problem is solved numerically by a boundary element method[26,27] based on regularized boundary integral equations.[28] For a scatterer at the free surface of a horizontally layered halfspace, the following boundary integral is derived for the tractions $\mathbf{t}_s(\mathbf{u}_{dm})$:

$$\psi_m(\mathbf{x}) = \int_\Gamma \mathbf{U}^G(\mathbf{x},\mathbf{x}')\mathbf{t}_s(\mathbf{u}_{dm})(\mathbf{x}')dS_{\mathbf{x}'} \quad \mathbf{x} \in \Gamma, \tag{16}$$

where $dS_{\mathbf{x}'}$ indicates that the surface integral is performed with respect to $\mathbf{x}'$, and $\mathbf{U}^G(\mathbf{x},\mathbf{x}')$ is the Green's tensor of the halfspace Ω_s. Each element $[\mathbf{U}^G]_{ij}(\mathbf{x},\mathbf{x}')$ represents the displacement at the position $\mathbf{x}'$ in the direction $\mathbf{e}_j$ due to a unit impulse load at the position $\mathbf{x}$ in the direction $\mathbf{e}_i$.[29,30] The Green's tensor $\mathbf{U}^G(\mathbf{x},\mathbf{x}')$ of a layered elastic halfspace[29,30] is obtained by means of the direct stiffness[31,32] or the reflection-transmission method.[33] In a boundary element method, Eq. (16) is solved by discretization of the interface Γ. Compared to other domain discretization techniques such as the finite element method, the advantage is that only Γ needs to be discretized and that energy radiation into the halfspace is modeled correctly through the use of Green's functions that satisfy Sommerfeld's radiation conditions.

The generalized coordinates $\mathbf{q}$ are now eliminated from Eq. (8):

$$(\mathbf{K}^b + \mathbf{K}^s)\mathbf{c} = \mathbf{F}^s, \tag{17}$$

where $\mathbf{K}^b$ is the dynamic stiffness matrix of the scatterer:

$$\mathbf{K}^b = \mathbf{K}^b_{cc} - \mathbf{K}^{bT}_{qc}(\mathbf{K}^b_{qq})^{-1}\mathbf{K}^b_{qc}. \tag{18}$$

For a scatterer at the free surface of a halfspace, the generalized coordinates $\mathbf{c}$ are found solving Eq. (17) with the generalized force (15) on the right hand side:

$$\mathbf{c} = (\mathbf{K}^b + \mathbf{K}^s)^{-1}\left[\int_\Gamma \mathbf{T}^T_d(\mathbf{x})\mathbf{u}_{\mathrm{ff}}(\mathbf{x})dS\right]. \tag{19}$$

B. The scattering operator for a single scatterer

The total wavefield $\mathbf{u}_s(\mathbf{x})$ in the layered halfspace is obtained by introducing solution (19) in Eq. (6). The diffracted wavefield $\mathbf{u}_d(\mathbf{x})$ now becomes

$$\mathbf{u}_d(\mathbf{x}) = \mathbf{u}_{d0}(\mathbf{x}) + \mathbf{U}_d(\mathbf{x})(\mathbf{K}^b + \mathbf{K}^s)^{-1}\left[\int_\Gamma \mathbf{T}_d^T(\mathbf{x})\mathbf{u}_{\mathrm{ff}}(\mathbf{x})dS\right]. \tag{20}$$

The wavefields $\mathbf{u}_{d0}$ and $\mathbf{u}_{dm}$ are computed from the corresponding stresses at Γ:

$$\begin{aligned}\mathbf{u}_d(\mathbf{x}) = &\int_\Gamma \mathbf{U}^G(\mathbf{x},\mathbf{x}')\mathbf{t}_s(\mathbf{u}_{d0})(\mathbf{x}')dS_{\mathbf{x}'} \\ &+ \left[\int_\Gamma \mathbf{U}^G(\mathbf{x},\mathbf{x}')\mathbf{T}_d(\mathbf{x}')dS_{\mathbf{x}'}\right] \\ &\times(\mathbf{K}^b + \mathbf{K}^s)^{-1}\left[\int_\Gamma \mathbf{T}_d^T(\mathbf{x}')\mathbf{u}_{\mathrm{ff}}(\mathbf{x}')dS_{\mathbf{x}'}\right].\end{aligned} \tag{21}$$

To further simplify this expression, $\mathbf{U}^G(\mathbf{x},\mathbf{x}')$ and the free field motion $\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$ are approximated in terms of the modes $\Psi(\mathbf{x})$ for $\mathbf{x}\in\Gamma$:

$$\begin{aligned}\mathbf{u}_{\mathrm{ff}}(\mathbf{x}) &\approx \Psi(\mathbf{x})\left[\int_\Gamma \Psi^T(\mathbf{x})\Psi(\mathbf{x})dS\right]^{-1}\int_\Gamma \Psi^{\mathrm{T}}(\mathbf{x})\mathbf{u}_{\mathrm{ff}}(\mathbf{x})dS \\ &= \Psi(\mathbf{x})\left[\int_\Gamma \Pi^T(\mathbf{x})\mathbf{u}_{\mathrm{ff}}(\mathbf{x})dS\right], \quad \mathbf{x}\in\Gamma,\end{aligned} \tag{22}$$

$$\begin{aligned}\mathbf{U}^G(\mathbf{x},\mathbf{x}') &\approx \int_\Gamma \mathbf{U}^G(\mathbf{x},\mathbf{x}')\Psi(\mathbf{x}')dS_{\mathbf{x}'} \\ &\quad\times\left[\int_\Gamma \Psi^T(\mathbf{x})\Psi(\mathbf{x})dS\right]^{-1}\Psi^T(\mathbf{x}') \\ &= \left[\int_\Gamma \mathbf{U}^G(\mathbf{x},\mathbf{x}')\Pi(\mathbf{x}')dS_{\mathbf{x}'}\right]\Psi^{\mathrm{T}}(\mathbf{x}'), \quad \mathbf{x}'\in\Gamma,\end{aligned} \tag{23}$$

where the second equality in Eqs. (22) and (23) defines the matrix $\Pi(\mathbf{x})=\Psi(\mathbf{x})[\int_\Gamma \Psi^T(\mathbf{x})\Psi(\mathbf{x})dS]^{-1}$ that collects the scaled rigid body modes for any $\mathbf{x}\in\Gamma$. For scatterers that have a circular footprint with a radius R, Eq. (5) leads to the following expression for the matrix $\Pi(\mathbf{x})$ in a cylindrical frame of reference (r,θ,z):

$$\Pi(r,\theta) = \begin{bmatrix} \frac{1}{\pi R^2} & 0 & 0 & 0 & 0 & -\frac{2r\sin\theta}{\pi R^4} \\ 0 & \frac{1}{\pi R^2} & 0 & 0 & 0 & \frac{2r\sin\theta}{\pi R^4} \\ 0 & 0 & \frac{1}{\pi R^2} & -\frac{4r\sin\theta}{\pi R^4} & \frac{4r\cos\theta}{\pi R^4} & 0 \end{bmatrix}. \tag{24}$$

Introducing Eqs. (22) and (23) in Eq. (21) gives

$$\begin{aligned}\mathbf{u}_d(\mathbf{x}) = &-\left[\int_\Gamma \mathbf{U}^G(\mathbf{x},\mathbf{x}')\Pi(\mathbf{x}')dS_{\mathbf{x}'}\right] \\ &\times\int_\Gamma \mathbf{T}_d^T(\mathbf{x}')\mathbf{u}_{\mathrm{ff}}(\mathbf{x}')dS_{\mathbf{x}'} \\ &+\left[\int_\Gamma \mathbf{U}^G(\mathbf{x},\mathbf{x}')\Pi(\mathbf{x}')dS_{\mathbf{x}'}\right] \\ &\times\mathbf{K}^s(\mathbf{K}^b + \mathbf{K}^s)^{-1}\mathbf{K}^s \\ &\times\left[\int_\Gamma \Pi^T(\mathbf{x})\mathbf{u}_{\mathrm{ff}}(\mathbf{x})dS\right],\end{aligned} \tag{25}$$

where the first term is elaborated in a similar way as the force vector in Eq. (14) and Eq. (13) is used to rewrite the second term. Using approximation (22) for the wavefield $\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$ in the first term allows combining both terms on the right hand side:

$$\begin{aligned}\mathbf{u}_d(\mathbf{x}) = &-\left[\int_\Gamma \mathbf{U}^G(\mathbf{x},\mathbf{x}')\Pi(\mathbf{x}')dS_{\mathbf{x}'}\right]\underbrace{[\mathbf{K}^s(\mathbf{K}^b + \mathbf{K}^s)^{-1}\mathbf{K}^b]}_{\mathbf{K}^{b'}} \\ &\times\left[\int_\Gamma \Pi^T(\mathbf{x}')\mathbf{u}_{\mathrm{ff}}(\mathbf{x}')dS_{\mathbf{x}'}\right]\end{aligned} \tag{26}$$

The scattered wavefield is obtained as the product of three terms. The first, rightmost term, is the excitation by the wavefield $\mathbf{u}_{\mathrm{ff}}$, obtained as its projection on the scaled rigid body modes $\Pi(\mathbf{x})$. The multiplication of the first and second terms gives the forces at the interface Γ. The second term is therefore defined as the modified dynamic stiffness $\mathbf{K}^{b'}$ of the scatterer. The third term redistributes the total forces at Γ and calculates the displacements in the halfspace Ω_s using the Green's tensor $\mathbf{U}^G(\mathbf{x}',\mathbf{x})$. The entire sequence of operations is the scattering operator. The dependence of $\mathbf{u}_d(\mathbf{x})$ on $\mathbf{x}$ is now rewritten as $\mathbf{u}_d(\mathbf{x},z)$, where $\mathbf{x}=(x,y)$. For a horizontally layered halfspace, the Green's tensor only depends on the relative horizontal position $\mathbf{x}'-\mathbf{x}$, and is written as $\mathbf{U}^G(\mathbf{x}'-\mathbf{x},z',z)$. For a scatterer at an arbitrary fixed position $(\mathbf{x}_b,z=0)$, Eq. (26) becomes

$$\begin{aligned}\mathbf{u}_d(\mathbf{x},z) = &-\left[\int_{\Gamma_s} \mathbf{U}^G(\mathbf{x}'-\mathbf{x},0,z)\Pi(\mathbf{x}'-\mathbf{x}_b)d\mathbf{x}'\right] \\ &\times\mathbf{K}^{b'}\left[\int_{\Gamma_s} \Pi^T(\mathbf{x}''-\mathbf{x}_b)\mathbf{u}_{\mathrm{ff}}(\mathbf{x}'',0)d\mathbf{x}''\right],\end{aligned} \tag{27}$$

where $\Pi^T(\mathbf{x}-\mathbf{x}_b)$ is zero for any point $\mathbf{x}\notin\Gamma$, so that the integrations over Γ can be replaced by integrations over the entire free surface $\Gamma_s=\mathbb{R}^2$ of the halfspace.

III. THE FOLDY MEAN FIELD APPROXIMATION

A. General formulation

In the following, the case is considered where a large number of scatterers are randomly distributed at the surface of the halfspace with an areal density ρ_{sc} and known scattering characteristics. The response of the coupled system due

to a vertically incident plane wave is studied. In order to solve this problem, a similar strategy as in the single scatterer case can be followed,[19,20] as will be discussed in Sec. VI. Instead, however, the configurationally averaged field quantities are calculated in an approximate way using multiple scattering theory. The approximation is based on truncated series expansions and only valid if the areal density of the scatterers is sufficiently small. Weaver used a similar methodology to calculate the mean response[8] and mean square response[9] for a plate interacting with randomly distributed sprung masses. More details regarding the derivation of the mean field approximations are found in Refs. 12 and 13 and more recent work by Weaver[8,9] and Photiades.[34]

Based on the solution (27) in the single scatterer case, the Foldy approximation[10,12,13,8] of the mean field $\underline{\mathbf{u}}(\mathbf{x})$ is formulated as follows:

$$\underline{\mathbf{u}}(\mathbf{x},z) = \mathbf{u}_{\mathrm{ff}}(\mathbf{x},z) - \rho_{sc}\int_{\Gamma_s} \mathbf{U}^G(\mathbf{x}'-\mathbf{x},0,z) \times \left\langle \int_{\Gamma_s} \Pi(\mathbf{x}'-\mathbf{x}_b)\mathbf{K}^{b'} \int_{\Gamma_s} \Pi^{\mathrm{T}}(\mathbf{x}''-\mathbf{x}_b) \right\rangle \times \underline{\mathbf{u}}(\mathbf{x}'',0)d\mathbf{x}''d\mathbf{x}_b d\mathbf{x}', \tag{28}$$

where the angular brackets denote the averaging with respect to the scatterer characteristics. A double Fourier transformation with respect to the horizontal coordinates $\mathbf{x}$ transforms the triple convolution into consecutive products in the wavenumber domain:

$$\tilde{\underline{\mathbf{u}}}(\mathbf{k},z) = \tilde{\mathbf{u}}_{\mathrm{ff}}(\mathbf{k},z) - \rho_{sc}\tilde{\mathbf{U}}^G(-\mathbf{k},0,z)\langle\tilde{\Pi}(\mathbf{k})\mathbf{K}^{b'}\tilde{\Pi}^T(-\mathbf{k})\rangle\tilde{\underline{\mathbf{u}}}(\mathbf{k},0), \tag{29}$$

where $\mathbf{k}$ collects k_x and k_y and the tilde denotes the representation of the variable in the wavenumber domain. An evaluation of this equation at $z=0$ allows for the calculation of the mean field $\tilde{\underline{\mathbf{u}}}(\mathbf{k},0)$ at the surface of the halfspace. The mean field $\tilde{\underline{\mathbf{u}}}(\mathbf{k},z)$ for any other z follows from a subsequent evaluation of the right hand side of Eq. (29).

When the scatterers have a circular footprint with a radius R, Eq. (24) can be used to compute the Hankel transform $\tilde{\Pi}(\mathbf{k})$ in the cylindrical wavenumber domain (k_r,ψ):

$$\tilde{\Pi}(\mathbf{k}) = \begin{bmatrix} \frac{2J_1(k_rR)}{k_rR} & 0 & 0 & 0 & 0 & -4i\sin\psi\frac{J_2(k_rR)}{k_rR^2} \\ 0 & \frac{2J_1(k_rR)}{k_rR} & 0 & 0 & 0 & 4i\cos\psi\frac{J_2(k_rR)}{k_rR^2} \\ 0 & 0 & \frac{2J_1(k_rR)}{k_rR} & -8i\sin\psi\frac{J_2(k_rR)}{k_rR^2} & 8i\cos\psi\frac{J_2(k_rR)}{k_rR^2} & 0 \end{bmatrix}, \tag{30}$$

where $J_1(x)$ and $J_2(x)$ are Bessel functions of the first kind, of orders 1 and 2, respectively. The relation between the Hankel transform in a cylindrical frame of reference and a double Fourier transform in a Cartesian frame[35] can be used to obtain the matrix $\tilde{\Pi}(\mathbf{k})$ in the wavenumber domain (k_x,k_y). In a similar way, an expression for the Green's tensor $\tilde{\mathbf{U}}^G(\mathbf{k},z',z)$ in the Cartesian wavenumber domain is obtained from its Hankel transform.[31]

The formulation of the ladder approximation of the Bethe–Salpeter equation in Sec. IV requires the mean Green's tensor $\tilde{\underline{\mathbf{U}}}^G(\mathbf{k},z,z')$ in the Foldy approximation:[9]

$$\tilde{\underline{\mathbf{U}}}^{GT}(\mathbf{k},z,z') = \tilde{\mathbf{U}}^{GT}(\mathbf{k},z,z') - \rho_{sc}\tilde{\mathbf{U}}^G(-\mathbf{k},0,z) \times\langle\tilde{\Pi}(\mathbf{k})\mathbf{K}^{b'}\tilde{\Pi}^T(-\mathbf{k})\rangle\tilde{\underline{\mathbf{U}}}^{GT}(\mathbf{k},0,z'). \tag{31}$$

For $z=0$, an equation in terms of $\tilde{\underline{\mathbf{U}}}^G(\mathbf{k},0,z')$ is obtained. The Green's tensor $\tilde{\underline{\mathbf{U}}}^G(\mathbf{k},z,z')$ for any other z is found from a subsequent evaluation of Eq. (31).

B. Foldy mean field for a vertically incident plane wave

When the response $\mathbf{u}_{\mathrm{ff}}(\mathbf{x},z)$ of the homogeneous layered halfspace Ω_s is generated by an incoming plane wave propagating through the underlying halfspace, the wavefield $\mathbf{u}_{\mathrm{ff}}(\mathbf{x},z)$ can be written in the frequency domain as

$$\mathbf{u}_{\mathrm{ff}}(\mathbf{x},z) = \mathbf{u}_{\mathrm{ff}}(z)\exp(-ik_y^s y)\pi\delta(\omega-\omega^s) + \mathbf{u}_{\mathrm{ff}}^*(z)\exp(ik_y^s y)\pi\delta(\omega+\omega^s), \tag{32}$$

where the superscript "*" denotes the complex conjugate, $\mathbf{u}_{\mathrm{ff}}(z)$ is the complex amplitude of the wavefield at depth z, and ω_s the circular frequency of the wave. The wavenumber k_y^s is found from the wavenumbers k_p and k_s for P- and S-waves in the underlying halfspace as $k_p\cos\alpha$ and $k_s\cos\alpha$, respectively, where α is the angle of incidence. The amplitude $\mathbf{u}_{\mathrm{ff}}(z)$ is computed from the amplitude of the incoming wave in the underlying halfspace by the direct stiffness method[31,32] or the reflection-transmission method.[33] The wavenumber domain representation $\tilde{\mathbf{u}}_{\mathrm{ff}}(\mathbf{k},z)$ is found by a double forward Fourier transform:

$$\tilde{\mathbf{u}}_{\mathrm{ff}}(\mathbf{k},z) = 4\pi^3 \mathbf{u}_{\mathrm{ff}}(z)\,\delta(k_x)\,\delta(k_y - k_y^s)\,\delta(\omega - \omega^s) + 4\pi^3 \mathbf{u}_{\mathrm{ff}}^*(z)\,\delta(k_x)\,\delta(k_y + k_y^s)\,\delta(\omega + \omega^s). \quad (33)$$

In the following, only the first term on the right hand side of this equation is considered. The contribution of the second term is found as the complex conjugate of the mean field due to the first term, with a frequency dependence $\delta(\omega+\omega^s)$ instead of $\delta(\omega-\omega^s)$. For an *SH*-wave with a polarization according to $\mathbf{e}_x$, the amplitude $\mathbf{u}_{\mathrm{ff}}(z)$ can be rewritten as $u_{\mathrm{ff}x}(z)\mathbf{e}_x$. Furthermore, the wave is assumed to be vertically incident, so that $\alpha=\pi/2$, $k_y^s=0$ and the delta function $\delta(k_y - k_y^s)$ reduces to $\delta(k_y)$. Based on Eq. (29), the Foldy approximation $\underline{\tilde{\mathbf{u}}}(\mathbf{k},z)$ of the mean field is obtained from the wavefield $\tilde{\mathbf{u}}_{\mathrm{ff}}(\mathbf{k},z)$ at the free surface $\Gamma_s(z=0)$ of the homogeneous layered halfspace Ω_s. Without loss of generality, it is assumed that the amplitude $\mathbf{u}_{\mathrm{ff}}(z)$ has a unit value at $z=0$. This leads to the following expression for $\underline{\tilde{\mathbf{u}}}(\mathbf{k},0)$:

$$\underline{\tilde{\mathbf{u}}}(\mathbf{k},0) = 4\pi^3 \delta(\mathbf{k})\,\delta(\omega - \omega^s)\mathbf{e}_x - \rho_{sc}\tilde{\mathbf{U}}^G(-\mathbf{k},0,0)\langle \tilde{\mathbf{\Pi}}(\mathbf{k})\mathbf{K}^{b\prime}\tilde{\mathbf{\Pi}}^T(-\mathbf{k})\rangle \underline{\tilde{\mathbf{u}}}(\mathbf{k},0), \quad (34)$$

where the product $\delta(k_x)\delta(k_y)$ is rewritten as $\delta(\mathbf{k})$. The mean field $\underline{\tilde{\mathbf{u}}}(\mathbf{k},0)$ can therefore be expressed as $4\pi^3\delta(\mathbf{k})\delta(\omega - \omega^s)\underline{\mathbf{u}}(0)$ with $\underline{\mathbf{u}}(0)$ the amplitude at $z=0$. Introducing this expression in Eq. (34) and performing an inverse Fourier transform from $\mathbf{k}$ to $\mathbf{x}$ give

$$\underline{\mathbf{u}}(\mathbf{x},0) = \mathbf{e}_x - \rho_{sc}\tilde{\mathbf{U}}^G(-\mathbf{k}=0,0,0) \times \langle \tilde{\mathbf{\Pi}}(\mathbf{k}=0)\mathbf{K}^{b\prime}\tilde{\mathbf{\Pi}}^T(-\mathbf{k}=0)\rangle \underline{\mathbf{u}}(\mathbf{x},0), \quad (35)$$

where the common factor $\pi\delta(\omega-\omega^s)$ has been dropped. For a limiting small wavenumber $\mathbf{k}\to 0$, the matrix $\tilde{\mathbf{\Pi}}(\mathbf{k})$ tends to

$$\lim_{\mathbf{k}\to 0} \tilde{\mathbf{\Pi}}(\mathbf{k}) = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \end{bmatrix}. \quad (36)$$

As $\tilde{\mathbf{U}}^G(-\mathbf{k}=0,0,0)$ is diagonal as well, the equations for different mean field components uncouple, and only the component $\underline{u}_x(0)$ corresponding to the polarization $\mathbf{e}_x$ of the incident wave is nonzero. For a given layered halfspace, the mean response $\underline{u}_x(0)$ only depends on the density ρ_{sc} and the first diagonal element $\langle[\mathbf{K}^{b\prime}]_{11}\rangle$ of the modified dynamic stiffness.

In the following, it is investigated how the distribution of scatterers at the surface of the halfspace affects the response of a single scatterer. The average response $\underline{\mathbf{u}}_b(\mathbf{x},0)$ at $z=0$ is calculated from the Foldy mean field $\underline{\mathbf{u}}(\mathbf{x},0)$:

$$\underline{\mathbf{u}}_b(\mathbf{x},0) = \left[\frac{1}{S_b}\int_\Gamma \Psi(\mathbf{x})dS\right]\langle(\mathbf{K}^b + \mathbf{K}^s)^{-1}\mathbf{K}^s\rangle \times \left[\int_\Gamma \Pi^T(\mathbf{x})\underline{\mathbf{u}}(\mathbf{x},0)dS\right], \quad (37)$$

where S_b is the area of the interface Γ and the first term between brackets is a matrix that contains the average displacement vector at Γ for each of the rigid body modes $\psi_m(\mathbf{x})$.

IV. THE BETHE–SALPETER EQUATION

A. General formulation of the ladder approximation

The Bethe–Salpeter equation[12] is an equation in terms of the correlation function $\mathbf{R}(\mathbf{x}',z',\mathbf{x}'',z'',t',t'')$ or, equivalently, $\langle \mathbf{u}(\mathbf{x}',z',t')\otimes\mathbf{u}(\mathbf{x}'',z'',t'')\rangle$, with $\otimes$ denoting the outer product. A representation in the frequency domain $\mathbf{S}(\mathbf{x}',z',\mathbf{x}'',z'',\omega',\omega'')$ is obtained by a double Fourier transform with respect to t' and t''. In the present case, the nonstationary Bethe–Salpeter equation in terms of $\mathbf{S}(\mathbf{x}',z',\mathbf{x}'',z'',\omega',\omega'')$ is formulated as follows:[12,36]

$$\begin{aligned}\mathbf{S}(\mathbf{x}',z',\mathbf{x}'',z'',\omega',\omega'') &= \underline{\mathbf{u}}(\mathbf{x}',z',\omega')\otimes\underline{\mathbf{u}}^*(\mathbf{x}'',z'',\omega'') \\ &+ \int_{\Gamma_s}\int_{\Gamma_s}\int_{\Gamma_s}\int_{\Gamma_s}[\underline{\mathbf{U}}^G(\mathbf{y}_1'-\mathbf{x}',0,z',\omega') \\ &\otimes \underline{\mathbf{U}}^{G*}(\mathbf{y}_1''-\mathbf{x}'',0,z'',\omega'')]:\mathbb{K}(\mathbf{y}_1',\mathbf{y}_1'',\mathbf{x}_1',\mathbf{x}_1'',\omega',\omega'') \\ &:\mathbf{S}(\mathbf{x}_1',0,\mathbf{x}_1'',0,\omega',\omega'')d\mathbf{y}_1'd\mathbf{y}_1''d\mathbf{x}_1'd\mathbf{x}_1'', \end{aligned} \quad (38)$$

where the fourth order tensor $\mathbb{K}(\mathbf{y}_1',\mathbf{y}_1'',\mathbf{x}_1',\mathbf{x}_1'',\omega',\omega'')$ is the kernel of the intensity operator, which is expressed as an infinite sum of operators using a diagram approach.[12,36] The operator ":" defines the double contraction of two tensors. For two fourth order tensors $\mathbb{A}$ and $\mathbb{B}$, the double contraction $\mathbb{A}:\mathbb{B}$ is a fourth order tensor $\mathbb{C}$ with $[\mathbb{C}]_{ijkl} = \Sigma_{m,n}[\mathbb{A}]_{ijmn}[\mathbb{B}]_{mnkl}$. The double contraction of the fourth order tensor $\mathbb{A}$ with the matrix $\mathbf{B}$ is the matrix $\mathbf{C}$, with $[\mathbf{C}]_{ij} = \Sigma_{k,l}[\mathbb{A}]_{ijkl}[\mathbf{B}]_{kl}$ when $\mathbf{C}=\mathbb{A}:\mathbf{B}$, and $[\mathbf{C}]_{kl}=\Sigma_{i,j}[\mathbf{B}]_{ij}[\mathbb{A}]_{ijkl}$ when $\mathbf{C}=\mathbf{B}:\mathbb{A}$. In the Foldy approach, the ladder approximation of the kernel of the intensity operator is[9]

$$\begin{aligned}\mathbb{K}(\mathbf{y}_1',\mathbf{y}_1'',\mathbf{x}_1',\mathbf{x}_1'',\omega',\omega'') &= \rho_{sc}\int_{\Gamma_s}\langle[\Pi(\mathbf{y}_1'-\mathbf{x}_b)\mathbf{K}^{b\prime}\Pi^T(\mathbf{x}_1'-\mathbf{x}_b)] \\ &\otimes[\Pi^*(\mathbf{y}_1''-\mathbf{x}_b)\mathbf{K}^{b\prime *}\Pi^\dagger(\mathbf{x}_1''-\mathbf{x}_b)]\rangle \\ &= \rho_{sc}\int_{\Gamma_s}[\Pi(\mathbf{y}_1'-\mathbf{x}_b)\otimes\Pi^*(\mathbf{y}_1''-\mathbf{x}_b)] \\ &:\langle\mathbf{K}^{b\prime}\otimes\mathbf{K}^{b\prime *}\rangle:[\Pi^{\mathrm{T}}(\mathbf{x}_1'-\mathbf{x}_b)\otimes\Pi^\dagger(\mathbf{x}_1''-\mathbf{x}_b)]d\mathbf{x}_b, \end{aligned} \quad (39)$$

where the superscript "†" denotes the Hermitian conjugate. In the derivation, the footprint of the scatterers and the matrix $\Pi(\mathbf{x})$ is assumed to be the same for all scatterers. As $\Pi(\mathbf{x})$ is real, $\Pi^*(\mathbf{y}_1''-\mathbf{x}_b)=\Pi(\mathbf{y}_1''-\mathbf{x}_b)$ and $\Pi^\dagger(\mathbf{x}_1''-\mathbf{x}_b)=\Pi^{\mathrm{T}}(\mathbf{x}_1''-\mathbf{x}_b)$ in Eq. (39).

B. Foldy field correlation approximation for a vertically incident plane wave

For a vertically incident plane wave, the correlation $\mathbf{S}(\mathbf{x}',z',\mathbf{x}'',z'')$ only depends on the relative horizontal position $\mathbf{x}''-\mathbf{x}'$ and is written as $\mathbf{S}(\mathbf{x}''-\mathbf{x}',z'',z')$. In a similar way as for the mean field, the solution $\mathbf{S}(\mathbf{x}''-\mathbf{x}',0,0)$ for $z''=z'=0$ allows for the evaluation of $\mathbf{S}(\mathbf{x}''-\mathbf{x}',z'',z')$ for any

(z'', z'). The vertical coordinates are therefore omitted, assuming an implicit evaluation at $z''=0$ and $z'=0$. This leads to the following expression:

$$\mathbf{S}(\mathbf{x}''-\mathbf{x}') = \underline{\mathbf{u}}(\mathbf{x}') \otimes \underline{\mathbf{u}}^*(\mathbf{x}'') + \rho_{sc}\int_{\Gamma_s}\int_{\Gamma_s}\int_{\Gamma_s} [\underline{\mathbf{U}}^G(\mathbf{y}_1'-\mathbf{x}') \times \Pi(\mathbf{y}_1'-\mathbf{x}_b) \otimes \underline{\mathbf{U}}^{G*}(\mathbf{y}_1'-\mathbf{x}'')\Pi(\mathbf{y}_1'-\mathbf{x}_b)] :\langle \mathbf{K}^{b'} \otimes \mathbf{K}^{b'*}\rangle : \left[\int_{\Gamma_s}\int_{\Gamma_s} \Pi^T(\mathbf{x}_1'-\mathbf{x}_b) \otimes \Pi^T(\mathbf{x}_1'' - \mathbf{x}_b) : \mathbf{S}(\mathbf{x}_1''-\mathbf{x}_1')d\mathbf{x}_1' d\mathbf{x}_1''\right] d\mathbf{x}_b d\mathbf{x}_1' d\mathbf{x}_1'', \quad (40)$$

where the dependence on ω' and ω'' is understood implicitly as well. The final bracketed term is defined as the matrix $\mathbf{S}_\Pi(\mathbf{x}''-\mathbf{x}')$, evaluated at $\mathbf{x}''=\mathbf{x}'=\mathbf{x}_b$:

$$\mathbf{S}_\Pi(\mathbf{x}''-\mathbf{x}') = \int_{\Gamma_s}\int_{\Gamma_s} [\Pi^{\mathrm{T}}(\mathbf{x}_1'-\mathbf{x}') \otimes \Pi^{\mathrm{T}}(\mathbf{x}_1''-\mathbf{x}'')] : \mathbf{S}(\mathbf{x}_1''-\mathbf{x}_1')d\mathbf{x}_1' d\mathbf{x}_1''. \quad (41)$$

Equation (40) is formulated in the wavenumber domain by a Fourier transform with respect to $\mathbf{x}''-\mathbf{x}'$:

$$\tilde{\mathbf{S}}(\mathbf{k}) = \tilde{\underline{\mathbf{S}}}(\mathbf{k}) + \rho_{sc}[\tilde{\underline{\mathbf{U}}}^G(\mathbf{k})\tilde{\Pi}(-\mathbf{k}) \otimes \tilde{\underline{\mathbf{U}}}^{G*}(\mathbf{k})\tilde{\Pi}(\mathbf{k})] :\langle \mathbf{K}^{b'} \otimes \mathbf{K}^{b'*}\rangle : \mathbf{S}_\Pi(0), \quad (42)$$

where $\tilde{\underline{\mathbf{S}}}(\mathbf{k})$ is the Fourier transform of $\underline{\mathbf{u}}(\mathbf{x}') \otimes \underline{\mathbf{u}}^*(\mathbf{x}'')$. Equation (42) is transformed into an equation in terms of $\mathbf{S}_\Pi(0)$, applying the operator $[\tilde{\Pi}^T(\mathbf{k}) \otimes \tilde{\Pi}^T(-\mathbf{k})]$: on both the left and right hand sides, integrating over all wavenumbers and multiplying by $1/4\pi^2$:

$$\mathbf{S}_\Pi(0) = \underline{\mathbf{S}}_\Pi(0) + \rho_{sc}\left[\frac{1}{4\pi^2}\int_{\mathbb{R}^2} \tilde{\Pi}^T(\mathbf{k})\tilde{\underline{\mathbf{U}}}^G(\mathbf{k})\tilde{\Pi}(-\mathbf{k}) \otimes \tilde{\Pi}^T(-\mathbf{k})\tilde{\underline{\mathbf{U}}}^{G*}(\mathbf{k})\tilde{\Pi}(\mathbf{k})d\mathbf{k}\right] :\langle \mathbf{K}^{b'} \otimes \mathbf{K}^{b'*}\rangle : \mathbf{S}_\Pi(0). \quad (43)$$

For a vertically incident plane *SH*-wave with a unit displacement in a direction $\mathbf{e}_x$ at the surface of the halfspace, $\underline{\mathbf{S}}_\Pi(0)$ is equal to $[\tilde{\Pi}^T(0) \otimes \tilde{\Pi}^T(0)] : \mathbf{e}_x \otimes \mathbf{e}_x$. The solution $\mathbf{S}_\Pi(0)$ of Eq. (43) allows to obtain the correlation $\tilde{\mathbf{S}}(\mathbf{k})$ in the wavenumber domain from Eq. (42). Integrating both the left and right hand sides of this equation over all wavenumbers and multiplying by $1/4\pi^2$ give the correlation $\mathbf{S}(\mathbf{x}''-\mathbf{x}')$ at $\mathbf{x}''=\mathbf{x}'$:

$$\mathbf{S}(0) = \underline{\mathbf{S}}(0) + \rho_{sc}\left[\frac{1}{4\pi^2}\int_{\mathbb{R}^2} \tilde{\underline{\mathbf{U}}}^G(\mathbf{k})\tilde{\Pi}(-\mathbf{k}) \otimes \tilde{\underline{\mathbf{U}}}^{G*}(\mathbf{k})\tilde{\Pi}(\mathbf{k})d\mathbf{k}\right] :\langle \mathbf{K}^{b'} \otimes \mathbf{K}^{b'*}\rangle : \mathbf{S}_\Pi(0). \quad (44)$$

The solution $\mathbf{S}_\Pi(0)$ is also used to calculate the correlation $\langle \mathbf{u}_b(\mathbf{x},0) \otimes \mathbf{u}_b^*(\mathbf{x},0)\rangle$ of the displacements at the interface Γ between a scatterer and the halfspace:

$$\langle \mathbf{u}_b(\mathbf{x},0) \otimes \mathbf{u}_b^*(\mathbf{x},0)\rangle = \left[\frac{1}{S_b}\int_\Gamma \Psi(\mathbf{x}) \otimes \Psi(\mathbf{x})dS\right] :\langle (\mathbf{K}^b + \mathbf{K}^s)^{-1}\mathbf{K}^s \otimes [(\mathbf{K}^b + \mathbf{K}^s)^{-1}\mathbf{K}^s]^*\rangle : \mathbf{S}_\Pi(0). \quad (45)$$

In the following, the correlation length is assumed to be large compared to the footprint of the scatterers, so that $\mathbf{S}(\mathbf{x}''-\mathbf{x}')$ approaches a constant value for $\mathbf{x}''$ and $\mathbf{x}'$ on Γ. As a result, only a 3×3 submatrix of $\mathbf{S}_\Pi(0)$ remains and needs to be calculated from Eq. (43) and accounted for in Eqs. (44) and (45).

V. SEISMIC RESPONSE OF A CITY

A. The dynamic characteristics of the layered halfspace

In the following, the multiple scattering between buildings is studied for the case of a plane, vertically incident *SH*-wave, with dynamic soil and building characteristics corresponding to the case of Mexico City. The soil is modeled as a horizontally layered halfspace. Table I summarizes the layer thickness t, the shear wave velocity C_s, the longitudinal wave velocity C_p, the density ρ, and the material damping ratio β of the soil model. Material damping is modeled in the frequency domain by complex Lamé coefficients $\lambda(1+2\beta i)$ and $\mu(1+2\beta i)$, where β is the hysteretic material damping ratio. In order to assess the effect of multiple reflections at the interfaces between layers in the halfspace, the site transfer function is calculated for a vertically incident *SH*-wave. The site transfer function is the ratio between the response at the free surface of the layered halfspace in Table I and the response at the free surface of a homogeneous halfspace with the dynamic soil characteristics of the underlying halfspace (layer 15 in Table I). Figure 2 shows the site transfer function as a function of the circular frequency ω of the incoming wave. The presence of the upper, softer layers results in a

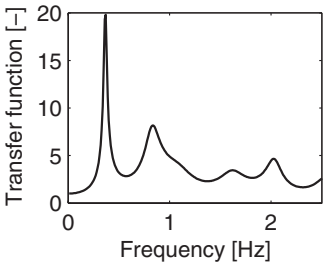

FIG. 2. Site transfer function.

first site resonance frequency with an amplification factor of 20 near 0.4 Hz. Higher site resonance frequencies are observed at 0.8, 1.6, and 2.0 Hz.

B. The dynamic characteristics of the scatterers

The buildings are modeled as elastodynamic cylinders uniformly distributed at the soil's surface. All buildings have a footprint $S_b=625\ m^2$, with a radius $R=14.1$ m. The areal density ρ_{sc} of the buildings is η/S_b, where η is the ratio of the built and total surface. A value of $\eta=0.06$ is considered, corresponding to a density $\rho_{sc}=1.02\times10^{-4}\ \mathrm{m}^{-2}$. The number of floors of the buildings follows the distribution in Fig. 3(a) for the Roma Norte district in Mexico City.[18] The height of the buildings equals $h=2.90n$. The mass m_b of the buildings is estimated as $0.36n\rho_bS_b$, with $\rho_b=2500\ \mathrm{kg}/m^3$ and 0.36 m an equivalent floor slab thickness. The mass is uniformly distributed over the cylinder.

The natural frequency of the first horizontal mode of a building fixed at its base is estimated from the number of floors n as $10/n$ using a common rule of thumb. In order to account for deviations between buildings with the same number n of floors, the natural frequencies are equally distributed over $\{10/n+1, 10/n+0.5, 10/n, 10/n-0.5, 10/n-1\}$. Since the city quarter consists of buildings with 6–16 floors, the fundamental resonance frequencies are between 0.6 and 2.0 Hz [Fig. 3(b)]. Resonance frequencies ω_m of higher modes are obtained applying a factor $2m-1$ on the fundamental resonance frequency. The corresponding mode shapes $\varphi_m(\mathbf{x})$ are the horizontal modes of a shear building. A uniform shear-beam continuum provides a good approximation of the horizontal response when the building has many identical stories.[37] The equation that governs shear wave propagation through the structure is similar to the one for axial wave propagation in a bar. The mode shapes $\varphi_m(\mathbf{x})$ for the horizontal motion in the direction $\mathbf{e}_x$ are therefore[37]

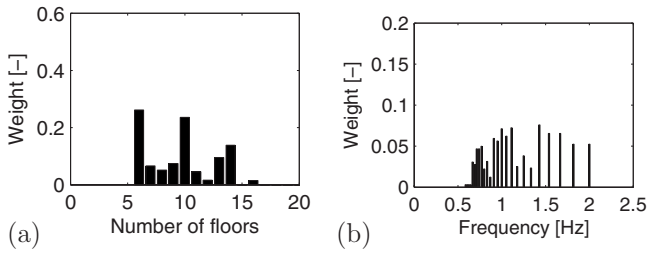

FIG. 3. Distribution of (a) the number of floors of the buildings and (b) the fundamental resonance frequencies.

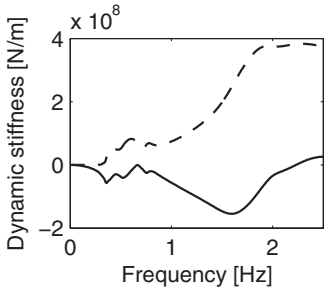

FIG. 4. Real (solid line) and imaginary parts (dashed line) of the first diagonal element $\langle[\mathbf{K}^{b'}]_{11}\rangle$ of the mean modified dynamic stiffness matrix.

$$\varphi_m(z)=\left\{\sqrt{\frac{2}{m_b}}\sin\left((2m-1)\frac{\pi z}{2h}\right),0,0\right\}^T. \tag{46}$$

The horizontal motion in the direction $\mathbf{e}_y$ is represented by similar mode shapes. The damping ratio ζ_m has a value of 0.05 for all buildings. These dynamic characteristics are used to calculate the dynamic stiffness $\mathbf{K}^b$ of the building using Eqs. (9)–(11) and (18). The dynamic stiffness $\mathbf{K}^s$ of the halfspace for a single scatterer is computed according to Eq. (13) using a boundary element method[26,27] based on the Green's functions of a layered elastic halfspace. The Green's functions are calculated by a reflection-transmission method.[33] The modified dynamic stiffness $\mathbf{K}^{b'}$ is computed from the dynamic stiffness $\mathbf{K}^b$ of the building and the dynamic stiffness $\mathbf{K}^s$ of the halfspace according to Eq. (26).

For a vertically incident *SH*-wave with a polarization according to $\mathbf{e}_x$, the mean response $\underline{u}_x(0)$ only depends on the first diagonal element $\langle[\mathbf{K}^{b'}]_{11}\rangle$ of the modified dynamic stiffness. Figure 4 shows the element $\langle[\mathbf{K}^{b'}]_{11}\rangle$ as a function of the circular frequency ω. At low frequencies, the dynamic stiffness is primarily real and scales as $-\omega^2$. In this frequency range, the buildings act as an additional mass at the soil's surface. At higher frequencies, the imaginary part becomes larger with local maxima at the natural frequencies of the buildings, coupled to the soil. The natural frequencies are slightly lower than those of a building fixed at its base [Fig. 3(b)], due to the additional flexibility provided by the soil.

C. Modification of the site response due to a plane *SH*-wave

The amplitude $u_{\mathrm{ffx}}(z)$ of the *SH*-wave at the free surface Γ_s of the homogeneous layered halfspace Ω_s is obtained as the product of the site transfer function (Fig. 2) and the frequency domain representation of a Ricker pulse centered at 0.75 Hz. The Ricker pulse therefore corresponds to the response at the free surface of a homogeneous halfspace with the properties of the underlying halfspace for the same incoming wave. Figure 5(a) compares the amplitude $u_{\mathrm{ffx}}(0)$ of the free field motion and the mean site response $\underline{u}_x(0)$ at the soil's surface. The maxima near 0.4 and 0.8 Hz of the response of the homogeneous layered halfspace correspond to the first and second site resonance frequencies. The higher resonance frequencies in the site transfer function (Fig. 2) are suppressed by the multiplication with the Ricker pulse and not observed in the response of the homogeneous layered

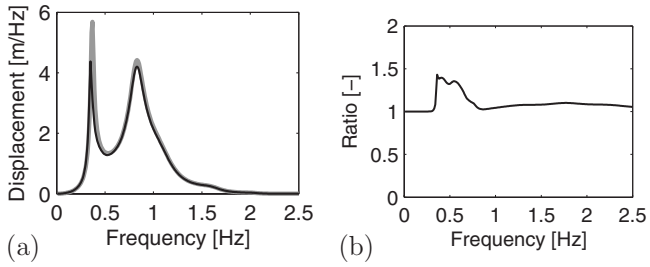

FIG. 5. (a) Comparison of the modulus of the mean (black line) response and the modulus of the response of the homogeneous layered halfspace (gray line). (b) Ratio of the mean square modulus of the response and the square modulus of the mean site response in the direction $\mathbf{e}_x$.

halfspace [Fig. 5(a)]. Comparing the mean response to the response of the homogeneous halfspace shows that the first site resonance frequency has shifted to a lower value due to the additional mass of the buildings. At higher frequencies, the mean site response is slightly smaller.

Figure 5(b) shows the ratio of the mean square modulus and the square modulus of the response in the direction $\mathbf{e}_x$. The mean square modulus is obtained from Eq. (43) for the filtered correlation $\mathbf{S}_{\Pi}(0)$ and a subsequent evaluation of the correlation $\mathbf{S}(0)$ according to Eq. (44). At low frequencies, the ratio is close to unity and the total site response is equal to the mean site response. In this frequency range, the wavelength in the soil is large compared to the building dimensions and the presence of the buildings results in a uniform modification of the site response. At higher frequencies, the ratio is larger due to the contribution of waves scattered by the buildings. The scattered waves are not accounted for in the mean response due to phase incoherence across the ensemble. The reduction in the mean site response (Fig. 5(a)) therefore corresponds to an apparent loss of energy. The observed loss of coherency shows that the buildings induce a spatial variation in the site response in this frequency range.

D. Influence of the scatterers

Figures 6(a)–6(c) compare the root mean square modulus of the displacements in the directions $\mathbf{e}_x$, $\mathbf{e}_y$, and $\mathbf{e}_z$ to the modulus of the wavefield $\mathbf{u}_{\mathrm{ff}}(\mathbf{x},0)$ at the free surface Γ_s of the homogeneous layered halfspace Ω_s. The response is similar in the direction $\mathbf{e}_x$ [Fig. 6(a)], apart from the small shift of the first site resonance frequency that was also observed for the mean response [Fig. 5(a)]. In the directions $\mathbf{e}_y$ and $\mathbf{e}_z$, however, the wavefield at the free surface Γ_s of the homogeneous layered halfspace Ω_s is zero, whereas the waves scattered by the buildings contribute to these components of the wavefield. These transverse components are slightly smaller than the incident wavefield but have a similar order of magnitude.

Figure 7 compares the root mean square value of the time history of the displacements in the directions $\mathbf{e}_x$, $\mathbf{e}_y$, and $\mathbf{e}_z$ which are obtained by a double inverse Fourier transform of the correlation in the frequency domain. Without buildings, the response in the direction $\mathbf{e}_x$ [Fig. 7(a)] shows an undulated behavior, corresponding to an exponentially decaying harmonic signal at the site resonance frequency. In the presence of buildings, a slightly smaller response is observed at early times and a higher response at later times. At early times, energy is transferred to the buildings, which is returned to the soil at later times. The undulated behavior is no longer observed at later times as the response mainly consists of scattered waves, with phase incoherence across the ensemble. These scattered waves are the only source of the response in the directions $\mathbf{e}_y$ and $\mathbf{e}_z$. Compared to the response in $\mathbf{e}_x$ [Fig. 7(a)], a slight time delay is observed corresponding to the time required for a building to retransmit energy into the soil after excitation by a seismic wave. The time scale is given by the dwell time t_{dwell}, estimated as $1/\omega_{\mathrm{ssi}}\zeta_{\mathrm{ssi}}$ (Ref. 25) from the natural frequency ω_{ssi} of the building coupled to the soil and the damping ratio ζ_{ssi} corresponding to radiation damping.

E. Influence of the scatterer footprint

In the following, the influence of the footprint S_b is investigated for a constant ratio $\eta=0.06$ of the built and total surface. Figure 8 shows the root mean square value of the frequency content for buildings with a footprint $S_b=312.5\ \mathrm{m}^2$ and $2500\ \mathrm{m}^2$, respectively. Apart from a smaller peak at the site resonance frequency for the smaller footprint, the response in $\mathbf{e}_x$ (Fig. 8) is relatively little affected by the difference in S_b. The shift of the first site resonance frequency is the same in both cases, as the ratio of the built and total surface and, therefore, the additional mass at the soil's surface is the same. The response in the directions $\mathbf{e}_y$ and $\mathbf{e}_z$ is much more affected by the change in the footprint S_b. The smaller footprint generally results in a smaller contribution of scattered waves to the response.

F. Influence of the scatterer internal damping

Figure 9 shows the root mean square value of the frequency content for buildings with a damping ratio $\xi=0.01$ and $\xi=0.20$, respectively. The value of 0.20 is unrealistically high for a building, but has been chosen to illuminate the role of energy dissipation in the buildings. When energy is

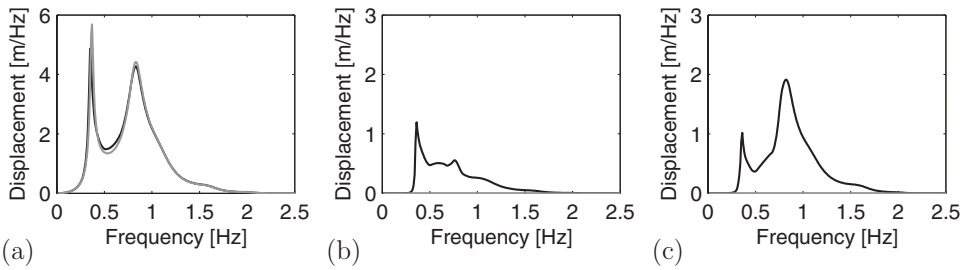

FIG. 6. Comparison of the root mean square modulus of the frequency contents (a) $\sqrt{\langle |u_x(\omega)|^2 \rangle}$, (b) $\sqrt{\langle |u_y(\omega)|^2 \rangle}$, and (c) $\sqrt{\langle |u_z(\omega)|^2 \rangle}$ for an areal density $\rho_{sc}=1.02\times10^{-4}\ \mathrm{m}^{-2}$ (black line) and the modulus of the wavefield at the free surface of the homogeneous layered halfspace (gray line).

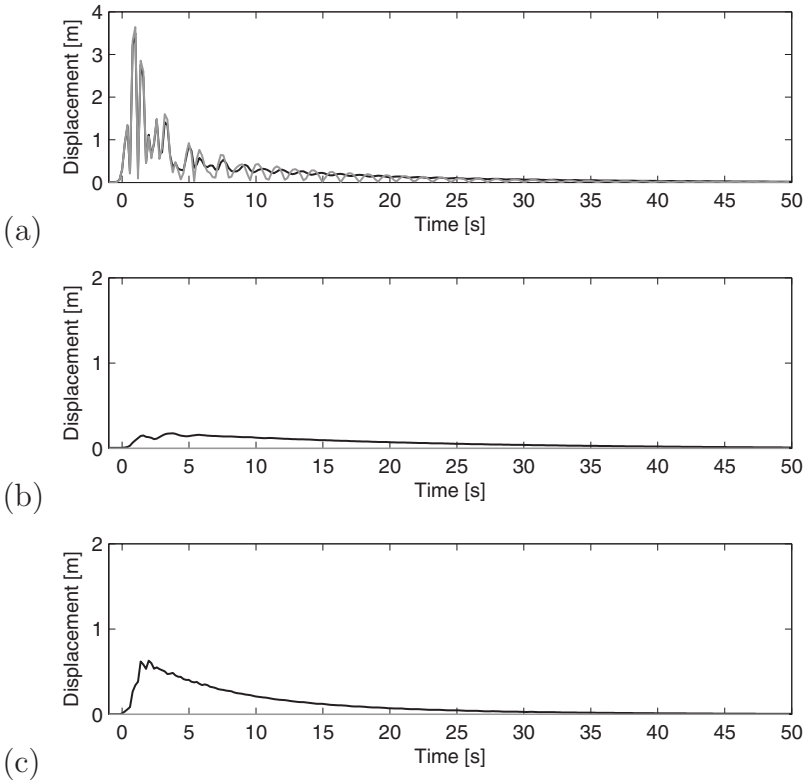

FIG. 7. Comparison of the root mean square time histories (a) $\sqrt{\langle|u_x(t)|^2\rangle}$, (b) $\sqrt{\langle|u_y(t)|^2\rangle}$, and (c) $\sqrt{\langle|u_z(t)|^2\rangle}$ for an areal density $\rho_{sc}=1.02\times10^{-4}$ m^{-2} (black line) and the absolute value of the wavefield at the free surface of the homogeneous layered halfspace (gray line).

transferred to the buildings, less energy is absorbed for the lower damping value, while more energy is radiated back into the soil. The response is only slightly affected, however, by the change in the damping ratio. This is due to the fact that energy is mainly absorbed by radiation and material damping in the soil.

VI. COMPARISON TO RESULTS FOR A CITY SAMPLE

A. Coupled FE/BE solution for a collection of buildings

The configurationally averaged field quantities are now compared to the results of a coupled finite element/boundary element method, where the buildings are modeled with finite elements and coupled to the layered halfspace model for the soil in Table I using the boundary element method. In order to determine the seismic response of the coupled system, a similar strategy is followed as in the single scatterer case (Sec. II). The displacements of each building k are decomposed according to Eq. (4) into the rigid body modes $\Psi^k(\mathbf{x})$ and the structural modes $\Phi^k(\mathbf{x})$ of the building fixed at the interface Γ_k between building k and the halfspace. The corresponding generalized coordinates are $\mathbf{c}^k$ and $\mathbf{q}^k$. The displacement field $\mathbf{u}_s(\mathbf{x})$ in the layered halfspace is decomposed into the wavefield $\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$ in the homogeneous layered halfspace Ω_s without scatterers, the locally diffracted wavefield

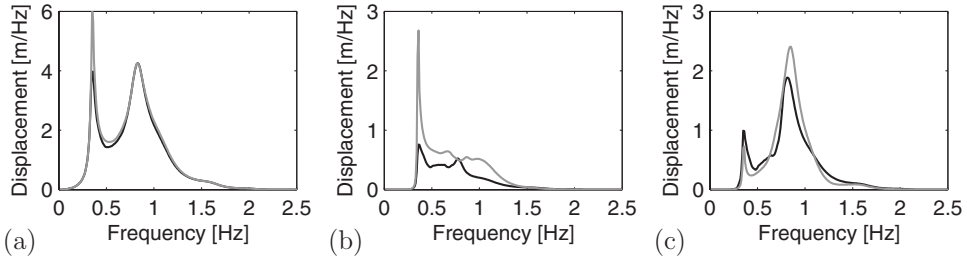

FIG. 8. Comparison of the root mean square modulus of the frequency contents (a) $\sqrt{\langle|u_x(\omega)|^2\rangle}$, (b) $\sqrt{\langle|u_y(\omega)|^2\rangle}$, and (c) $\sqrt{\langle|u_z(\omega)|^2\rangle}$ for the case of a city composed of buildings with a footprint $S_b=312.5$ m^2 (black line) and $S_b=2500$ m^2 (gray line).

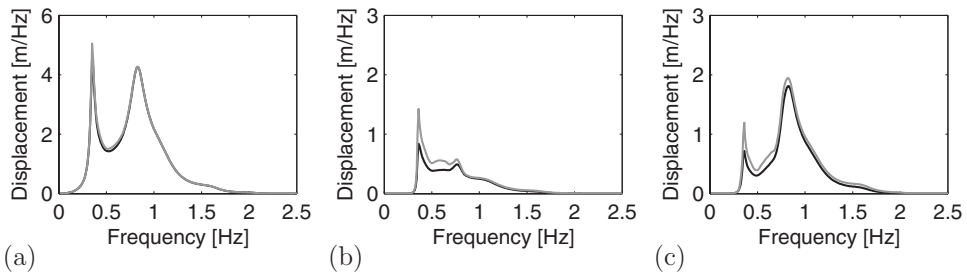

FIG. 9. Comparison of the root mean square modulus of the frequency contents (a) $\sqrt{\langle|u_x(\omega)|^2\rangle}$, (b) $\sqrt{\langle|u_y(\omega)|^2\rangle}$, and (c) $\sqrt{\langle|u_z(\omega)|^2\rangle}$ for the case of a city composed of buildings with an internal damping $\xi=0.01$ (black line) and $\xi=0.20$ (gray line).

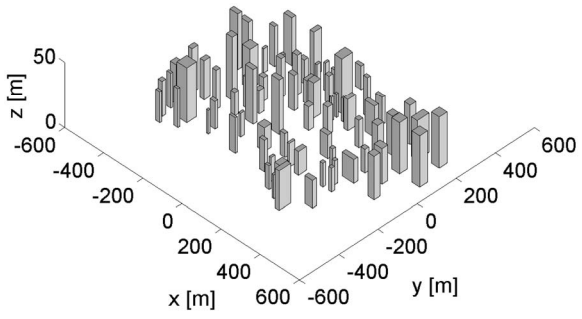

FIG. 10. The city configuration.

$\mathbf{u}_{d0}(\mathbf{x})$, that cancels the wavefield $\mathbf{u}_{\mathrm{ff}}(\mathbf{x})$ at every interface Γ_k, and the wavefields $\mathbf{u}_{dm}^k(\mathbf{x})$ scattered by the rigid body modes $\boldsymbol{\psi}_m^k(\mathbf{x})$ of the scatterers:[19,20]

$$\mathbf{u}_s(\mathbf{x}) = \mathbf{u}_{\mathrm{ff}}(\mathbf{x}) + \mathbf{u}_{d0}(\mathbf{x}) + \sum_{k=1}^{N_b} \sum_{m=1}^{6} \mathbf{u}_{dm}^k(\mathbf{x}) c_m^k, \tag{47}$$

where N_b is the number of buildings considered. The scattered wavefields $\mathbf{u}_{dm}^k(\mathbf{x})$ are by definition equal to $\boldsymbol{\psi}_m^k(\mathbf{x})$ for $\mathbf{x} \in \Gamma_k$ and zero for $\mathbf{x} \in \Gamma_l (l \neq k)$. A weak variational formulation of the equilibrium at $\cup \Gamma_k$ leads to

$$[\mathbf{K}^s + \mathbf{K}^b]\mathbf{c} = \mathbf{F}^s, \tag{48}$$

where $\mathbf{c}$ collects the generalized coordinates $\mathbf{c}^k$, and $\mathbf{K}^b$ is a block diagonal matrix with the dynamic stiffness matrices $\mathbf{K}^{bk}$ in Eq. (18) on its diagonal. The dynamic stiffness matrix $\mathbf{K}^s$ of the soil is a fully populated matrix composed of the following block matrices:

$$[\mathbf{K}^s]_{lk} = \int_{\Gamma_l} [\mathbf{T}_d^k(\mathbf{x})]^T \boldsymbol{\Psi}^l(\mathbf{x}) dS, \tag{49}$$

where $\mathbf{T}_d^k(\mathbf{x})$ collects the tractions $\mathbf{t}_s(\mathbf{u}_{dm}^k)(\mathbf{x})$. The vector $\mathbf{F}^s$ on the right hand side of Eq. (48) contains the seismic loading $\mathbf{F}^{sk}$ in Eq. (15) for each building. Solving Eq. (48) gives the generalized coordinates $\mathbf{c}^k$ of the modes $\boldsymbol{\psi}_m^k(\mathbf{x})$. The displacement field $\mathbf{u}_s(\mathbf{x})$ in the soil is obtained subsequently from Eq. (47).

B. Results

This methodology has been used to calculate the response of 77 buildings positioned on an area of 783 $\times$1006 m^2, as shown in Fig. 10. The ratio η of the built and total surface and the statistics of the number of building floors are the same as in Sec. V. In this model, however, the footprint of the buildings varies between 100 m^2 for four buildings with 6 floors and 2500 m^2 for a building with 14 floors. The previously considered value S_b=625 m^2 is the mean footprint. The dynamic stiffness matrix $\mathbf{K}^{bk}$ of the buildings is computed by means of the finite element method (FEM), using the MATLAB Structural Dynamics Toolbox.[38] The columns and beams of the buildings are modeled by beam elements, while plate elements are used for the floors of the buildings. All structural modes $\varphi_m(\mathbf{x})$ with a natural frequency below 30 Hz are accounted for. Both the dynamic stiffness matrix $\mathbf{K}_s$ of the soil in Eq. (49) and the seismic loading $\mathbf{F}^s$ in Eq. (15) are computed by a boundary element method[26] (BEM) with the computer program MISS.[27] The boundary element program uses the Green's functions of a horizontally layered halfspace, so that the radiation of waves into the layered halfspace and multiple wave scattering between the buildings are properly accounted for. The maximum element size in the discretization of the interfaces Γ_k is chosen as 5 m based on the results of a convergence study.[20]

Figure 11 compares the root mean square modulus of the frequency content as obtained by the Foldy–Ladder approximation and the result of the coupled FEM/BEM. Whereas all previous results concern the exciting field as obtained by the Foldy approach,[10,11] the response at the interface between the buildings and the soil is now considered. These results are calculated from the solution of Eq. (43) and a subsequent evaluation of Eq. (45). Assuming ergodicity, the spatially averaged field quantities for this city configuration can be compared to the ensemble averages from the present analysis. As the size of the city is of the same order of magnitude as the wavelength in the soil at low frequencies, it can be anticipated that its finite size will affect the results. The results of a second calculation by means of the Foldy–Ladder approximation with a smaller areal density $\rho_{sc}/16$ are therefore shown as well. The shaded area on the figures corresponds to the results for all buildings of the city quarter and illustrates the scatter of the response. Generally speaking, the response in the direction $\mathbf{e}_x$ is relatively well predicted, while in the directions $\mathbf{e}_y$ and $\mathbf{e}_z$, it is overestimated, particularly near the site resonance frequency and in the low frequency range. The overestimation of the contribution of scattered waves may be due to the finite size of the city that affects all buildings at low frequencies, and buildings at the city limits

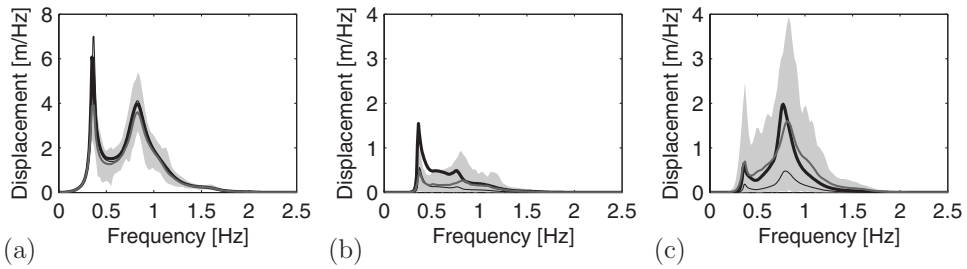

FIG. 11. Comparison of the root mean square modulus of the frequency contents (a) $\sqrt{\langle |u_x(\omega)|^2 \rangle}$, (b) $\sqrt{\langle |u_y(\omega)|^2 \rangle}$, and (c) $\sqrt{\langle |u_z(\omega)|^2 \rangle}$ of the response at the building-soil interface as obtained with the Foldy–Ladder approximation for an areal density $\rho_{sc}=1.02\times10^{-4}$ m^{-2} (thick black line) and $\rho_{sc}=6.39\times10^{-6}$ m^{-2} (thin black line) with the spatially averaged values for a particular city configuration (dark gray line). The envelope of all results for the particular city configuration is superimposed (light gray area).

at higher frequencies. Furthermore, the results in Fig. 8 show that the site response and, therefore, the response of the buildings are sensitive to the footprint of the buildings. Taking into account the difference between the building models, foundation areas, and the finite size of the city in the coupled FEM/BEM calculation, the agreement is reasonable.

VII. CONCLUSION

Within the frame of the present paper, the Foldy equation for the mean field and the Foldy–Ladder approximation of the Bethe–Salpeter equation are used to study the multiple scattering by randomly distributed finite-sized resonant scatterers at the surface of a horizontally layered elastic halfspace. Based on the solution in the single scatterer case, the configurationally averaged response and correlation are calculated for a vertically incident plane *SH*-wave. This solution is used to analyze the seismic response of an urban site, where each building acts as a scatterer at the soil's surface. In the low frequency range, where the wavelength in the soil is large with respect to the dimensions of the buildings, the presence of the buildings results in a uniform modification of the site response. The site response is therefore accurately characterized by the mean field, as there is no loss of coherency in this frequency range. At higher frequencies, the mean square response becomes substantially larger than the mean response, due to the fact that waves scattered by the buildings contribute to the seismic response of the site. The solution is compared to results for a city quarter, where multiple scattering between the buildings is fully accounted for.

A wave-based finite element analysis for acoustic transmission in fluid-filled elastic waveguides

Andrew T. Peplow
Hoare Lea Acoustics, 140 Aztec West Business Park, Bristol BS32 4TX, United Kingdom

(Received 2 February 2008; revised 26 January 2009; accepted 3 February 2009)

This paper describes an original numerical prediction technique developed for the analysis of coupled vibro-acoustic problems in fluid waveguides. Specifically it is a wave-based method that adopts a spectral element approach. Unlike the conventional element-based methods, this technique uses wave functions that satisfy the governing equations to describe the dynamic variables exactly. One advantage is that fine domain discretizations, used by element-based methods near the fluid-structure interface typically, are no longer required. Hence the resulting model sizes are much smaller than element-based methods yielding a more time-efficient prediction technique that may allow handling of mid-frequency applications. Another advantage is that dispersion relations between propagating and excitation wavenumbers are easily obtained, and an example to show this, as well as a discussion on how the wave-based prediction technique can be used for two coupled vibro-acoustic problems: a cavity with a non-reflecting boundary and a silencer duct problem, is presented. Its beneficial characteristics compared to element-based methods are demonstrated through the validation study and transmission loss examples.

I. INTRODUCTION

In this work a development of an acoustic wave-based technique for waveguides is presented. This technique now provides solutions to sound transmission through coupled structural-acoustic systems. The method used is a development to the acoustic spectral finite-element method (SFEM) by Peplow and Finnveden.[1] Essentially the wave-based method makes use of the exact acoustic solutions in one direction and an expansion in the cross-section consistent with that used for finite elements. The exact solutions are plane-wave-like functions. For problems such as acoustic radiation in a half-space, the exact solutions will be Bessel functions and spherical Bessel functions for two and three dimensions, respectively. Applying this strategy to a half-space leads to the known scaled boundary FEM that has been summarized for unbounded Helmholtz problems by Song.[2] Nevertheless, for waveguide problems, the approximation scheme used here is more or less similar to the partition of unity method (PUM) proposed by Babuška and Melenk[3] and developed by Laghrouche and Bettess.[4] The idea proposed is to employ a combination of polynomial functions and analytic functions for approximation without imposing any mesh-dependent conditions on the analytic functions. The benefit of the SFEM implemented here though over the PUM is only for geometries such as waveguides. That is, the analytic functions are chosen automatically through solving a system of homogeneous second order differential equations. However, extending the SFEM to radiation problems, mentioned above, will lead to difficulties described by Song[2] but will not be encountered by PUM. To be consistent and save confusion with earlier work[1] the wave-based method will be referred in the text henceforth as the SFEM.

Many noise control engineering designs encounter vibro-acoustic transmission problems. These problems involve the interaction between the vibrations of a mechanical structure and the sound field in its surroundings. At present, the most commonly used prediction techniques for solving complex duct problems numerically are finite-element-based methods. In the traditional FEMs, the problem domain is discretized into a finite number of small elements. All other standard element-based methods including boundary element methods also express the dynamic response variables in terms of simple but approximating shape functions. Because of this approximation, a sufficient number of elements per wavelength are required to obtain reasonable accuracy. With increasing frequency, wavelengths shorten, so that the number of elements must increase accordingly to maintain the same level of accuracy. Therefore, computational resources restrict the practical use of these element-based methods to low-frequency applications. However, in the past decade or so, a spectral wave-based prediction technique has been developed and has proven to be a successful tool for analyzing arbitrary sized vibro-acoustic problems in the low- and mid-frequency ranges.[5] The technique is based on an indirect semi-analytic approach where the dynamic response variables are described by a set of wave functions, which exactly satisfy the governing differential equations. These functions take the form $\exp(i\lambda x)$ and are thus dependent on the wavenumber λ. If the imaginary part of the wavenumber is zero the wave functions are propagating waves and these carry energy. Otherwise when the imaginary part of λ is non-zero the functions are evanescent waves and these do not transmit energy. The strategy for obtaining all wave functions, including exponentially increasing and decaying waves, is described in the work by Peplow and Finnveden.[1]

Previously the SFEM has been applied to a number of acoustic and structural waveguide problems. In particular, the method developed by Finnveden[5,6] can be viewed as a merger of the dynamic stiffness method and the FEM. The principle of the method is based on a variational formulation for non-conservative motion in the frequency domain. Use of a variational formulation for the spectral method provides a natural basis for approximations and a straightforward method for combination with standard finite elements. Indeed, the motivation behind this approach is to permit direct coupling with standard finite-element software. The end product allows non-standard problems in computational wave propagation to be resolved.

In the super-SFEM pursued here, the region of interest is decomposed into rectangular elements. A variational formulation for the underlying equations of motion is then approximated using trial functions that are conforming across element boundaries. The pressure field in each element is expressed as a combination of polynomials in the transversal z-direction with wave influence functions in the longitudinal x-direction. From the variational formulation eigenfunctions of a derived differential operator are chosen as the wave influence trial functions in the description of the acoustic pressure and displacement fields for the local *spectral element*. Local dynamic stiffness matrices for all the elements are then combined to form the global stiffness matrix for the complete problem and hence given a particular source the pressure and displacement fields may be found at any point within the fluid and structural regions. Since the element does not rely on any wavelength-dependent discretization in the longitudinal direction the SFEM can be applied to fairly short as well as very long wave transmission problems. In this way, only partial discretization is needed, and since these are smaller and more computationally efficient models, this technique allows also handling of mid-frequency applications.

Previously the SFEM technique has been used to study vibrations in beam frameworks[5,7] and for fluid-filled pipes.[6] Here the important problem for calculating propagating waves, as these are the only waves which transmit energy, is developed in Sec. V, which is identical to that analyzed by Fahy.[8] Coupled dispersion characteristics for fluid-filled cylindrical pipes have also been presented by Fuller and Fahy.[9] The authors used a numerical solution methodology in solving the coupled dispersion equation by performing studies for different values of shell thickness to radius ratio and also different material combinations. The behavior of various branches of the dispersion curve under the influence of these parameters was also discussed in the article by Pavic.[10] In his study of vibrational energy flow in a cylindrical shell the author also obtained the dispersion curves of a fluid-filled cylindrical shell. Similarly Finnveden[5] studied the effect of a flange on wave propagation down a fluid-filled elastic cylinder. This also included finding dispersion curves for the fluid-filled pipe through a finite-element discretization in the radial direction. Here we use a similar methodology to devise finite-element basis functions to generation wave influence functions for fluid structural elements. We study a simple validation case and a reactive flexible duct assemblage example. Dissipative devices such as acoustic linings or silencers are often used to reduce the noise levels. These work well in the mid- and high-frequency ranges but are less effective for low-frequency acoustics. In many applications the silencer device comprises a two-dimensional reactive silencer in which a flexible structure is attached to the external wall of the expansion chamber parallel to the axis of the inlet/outlet ducts. Controlling radiated noise by a membrane or plate at the interface between a silencer and the duct has been studied extensively by Huang and co-workers[11–15] where the stiffness of the air-back cavity has been employed as a controlling parameter. If, however the height of the membrane above the level of the inlet/outlet ducts can be varied, the device may be tuned by selecting the membrane height that gives the widest stop-band for a specified frequency.[11] In this paper there is no air-backed cavity; the radiation impedance of the plate is due to the interaction of the air duct mode and the *in vacuo* mode of the plate.

The basic concepts of the computational technique are briefly discussed for a vibro-acoustic problem defined in a bounded cavity domain. The performance of the new technique in terms of computational load is compared with existing FEMs through this validation example.

The purpose of the present study is to evaluate a new computational method for predicting sound transmission through flexible ducts with non-uniform but regular waveguides. The paper is organized as follows: In Sec. II the variational principle for non-conservative acoustic motion is stated. In Secs. III and IV a description of the trial functions is given and associated dynamic stiffness matrices are presented. Acoustic responses and displacements for the structure for various geometries are shown in Sec. V and some conclusions are given in Sec. VI.

II. ANALYSIS

The acoustical pressure and structural flexural displacement will be denoted by $p^*(\underline{x},t)$ and $w^*(\underline{x},t)$, respectively. The linearized acoustical wave equation, without sources, for the steady-state pressure assuming harmonic motion, $e^{-i\omega t}$, on suppressing the asterisks, then becomes

$$\nabla^2 p(\underline{x}) + k^2 p(\underline{x}) = 0, \quad \underline{x} \in \Omega_P, \tag{1}$$

where $k=\omega/c_0$ is the acoustic wavenumber, c_0 is the sound speed, i is the imaginary unit $i=\sqrt{-1}$, ∇^2 is the two-dimensional Laplacian operator, and coordinate vector $\underline{x}=(x,z)$. The physical system may be excited at a frequency $\omega=2\pi f$, through acceleration $\nabla_p=\rho_0\dot{\mathbf{u}}$ where ρ_0 is density of fluid and $\mathbf{u}$ represents the particle velocity. A typical fluid-filled rectangular region, Ω_F in the x-z plane, and a fluid-filled cavity backed by a thin, flexible plate Ω_P, on the right hand side, are both shown in Fig. 1(b). The origin is indicated and the plate, denoted by Γ_P, lies on the x-axis.

The steady-state normal displacement $w(\underline{x}_s)$ of the plate is governed by the dynamic equation

$$(D_s\nabla^4 - \rho_s t\omega^2)w(\underline{x}_s) = p(\underline{x}_s), \quad \underline{x}_s \in \Gamma_P, \tag{2}$$

where D_s denotes flexural rigidity, ρ_s is the mass per unit volume, t is plate thickness, and $(x,0)=\underline{x}_s \in \Gamma_P$. To uniquely

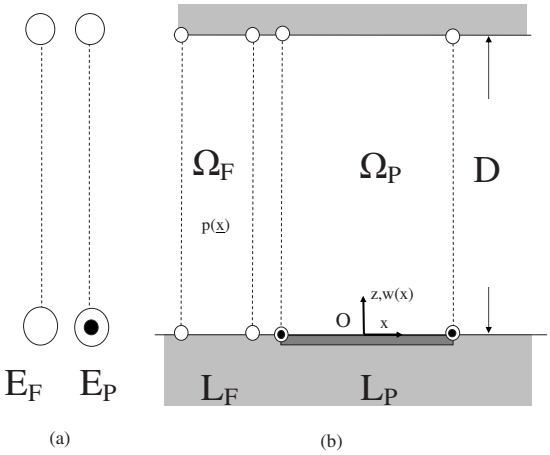

FIG. 1. Illustration of the two types of elements: (a) cross-sectional WFEs, acoustic (E_F) and coupled acoustic-structure elements (E_P), and elements defined over regions Ω_F and Ω_P of height D; (b) acoustic spectral finite element of width L_F (left) and coupled fluid-structure spectral finite element of width L_P (right).

define the displacement, four boundary conditions must be specified, that is, conditions are required at the two plate ends. These can model clamped, simply supported, or free plate ends. All combinations of the boundary conditions may be included in this analysis; however, for the model examples here, only clamped and simply supported ends are examined. Hence for the plate defined over length L_P: $\underline{x}_s \rightarrow x \in [-L_P/2, +L_P/2]$, two sets of boundary conditions at end-points $x_1 = -L_P/2$ and $x_2 = L_P/2$ are required, either simply supported (SS) or clamped (CC) at both ends, respectively,

$$w(x_1) = w(x_2) = 0, \quad \frac{d^2w}{dx^2}(x_1) = \frac{d^2w}{dx^2}(x_2) = 0 \tag{3}$$

or

$$w(x_1) = w(x_2) = 0, \quad \frac{dw}{dx}(x_1) = \frac{dw}{dx}(x_2) = 0. \tag{4}$$

If Γ_F denotes the boundary for the fluid-filled region, the acoustic boundary condition for absorbing locally reacting walls is given by

$$\frac{i}{\rho_0 \omega}\frac{\partial p}{\partial n}(\underline{x}) = \frac{p(\underline{x})}{\zeta}, \quad \underline{x} \in \Gamma_F, \tag{5}$$

where n denotes the normal outgoing direction and ζ is the surface impedance. To define an interface condition between the fluid and the structure, continuity of fluid particle velocity and structure velocity is specified as

$$\frac{i}{\rho \omega}\frac{\partial p}{\partial n}(\underline{x}_s) = -i\omega w(\underline{x}_s), \quad \underline{x}_s \in \Gamma_P. \tag{6}$$

Figure 1(b) shows a typical geometry of a plate enclosed by fluid-filled cavity used in the analysis.

The devised FEM here derives solutions to coupled problems defined through Eqs. (1)–(6). Briefly, the implementation of the numerical method is split into two stages: development of *waveguide finite elements* (WFEs) defined over cross-sections [Fig. 1(a)], and then construction of *super-spectral finite elements* defined over combinations of arbitrary length regions [Fig. 1(b)], which provide the dynamic stiffness matrices.

A. Variational statement

In what follows the displacement-pressure variables are converted to a displacement-velocity potential (w, ϕ) formulation for purposes of symmetry and likely non-dimensional convenience, $p(\underline{x}) = -i\rho_0 \omega \phi(\underline{x})$. A typical waveguide airway section is shown in Fig. 1(b). We assume that the waveguide is formed by a uniform constant-depth rectangular region of acoustic fluid surrounded by a sound absorbing lining or backed by a vibrating plate. The finite element formulation allows geometrical rectangular discontinuities such as stairsteps or silencers; however, for the WFE construction in this section, we assume that the waveguide is divided equally in the vertical direction throughout.

Equations within Ω_P and the continuity conditions at all interfaces may be expressed in a single weak variational statement. That is, the full problem may be reformulated in a convenient form as a stationary solution of the functional[6]

$$\begin{aligned} L_{\Omega_P} = \rho_0 \int_{\Omega_P} -k^2 \phi^a \phi + \nabla \phi^a \cdot \nabla \phi d\Omega_P - \rho_0 \int_{\Gamma_F} \phi^a \frac{\partial \phi}{\partial n} \\ + \phi \frac{\partial \phi^a}{\partial n} d\Gamma_F - \rho_0 \omega \int_{\Gamma_P} \phi^a w + w^a \phi d\Gamma_P \\ + \int_{\Gamma_P} \left(D_S \frac{d^2 w^a}{dx^2}\frac{d^2 w}{dx^2} - m_s \omega^2 w^a w \right) d\Gamma_P, \end{aligned} \tag{7}$$

where $\Omega_P = \Omega_F \cup \Gamma_P \cup \Gamma_F$. The superscripted symbol ϕ^a denotes the complex conjugate of the sound pressure in the adjoint system, similar to the original system with negative damping.[5] For ease of exposition the losses have been omitted in the finite element formulations in Secs. III and IV but are included in the numerical examples in Sec. V through complex valued acoustic wavenumber and flexural rigidity. For brevity fluid boundaries, Γ_F are assumed rigid so that integrals over these boundaries are also omitted. Modifications of the finite element matrices to include losses and boundary impedance are straightforward.[1] As shown in Ref. 5 and discussed in Refs. 1 and 6, the losses may be accounted by employing a variational principle similar to Hamilton's principle whereby, in the functionals describing kinetic and potential energies, the quadratic forms are replaced with symmetric bilinear forms and complex conjugates in the adjoint negatively damped system. With this approach the mechanisms of variational methods are retained for non-conservative systems. The ansatz above, Eq. (7), may now be used as a variational form for the acoustical and structural response solutions. The procedure for a finite-element idealization for the waveguide, and generation of suitable basis functions, is detailed in Sec. III.

III. FINITE ELEMENT MODELING

In fluid-filled flexible waveguides with constant geometrical cross-section, the solutions of the governing equations of motion are a combination of exponential terms and

cross-sectional modes that describe the propagation and transmission of energy. Thus, the axial x-dependence is separable from the cross-sectional z-dependencies. For the displacement and fluid motion a combination of polynomials is assumed. In the finite-element discretization a cross-section is divided so that material parameters are constant within each interval. Within one WFE, the acoustic and displacement fields may be represented in the coordinate system. A dimensionless $(1\times m)$ real-valued matrix of polynomials $[\hat{\mathbf{N}}(z)]=[N_1(z),N_2(z),\ldots,N_m(z)]$ is defined with the given coordinate functions as elements. A column vector $\mathbf{S}(x)$ of unknowns is defined as

$$S(x,z)=(w(x),\phi(x,z))^T=[\mathbf{N}(z)]\mathbf{S}(x), \tag{8}$$

where the matrix

$$[\mathbf{N}(s)]=\begin{bmatrix}1 & \mathbf{0}\\ 0 & \tilde{\mathbf{N}}(z)\end{bmatrix}, \tag{9}$$

$[\mathbf{N}(z)]$ is a $2\times(m+1)$ matrix, and $\mathbf{0}$ denotes a zero $(1\times m)$ row vector. Section III A describes a development of the variational approach for determining the WFEs $\mathbf{S}(x)$ by construction of a polynomial eigenvalue problem.

A. The coupled vibro-acoustic model

First the variational statement, Eq. (7), in Sec. II A is developed further to obtain *wave influence* basis functions $\mathbf{S}(x)$.

Consider the functional L_{Ω_P}, Eq. (7), for a single arbitrary region $\Omega_P=c\times d$. Substitution of expression (9) into the resulting form, where subscript $_x$ denotes x-derivative, yields the approximation

$$\begin{aligned}L_{\Omega_P}=&-k^2\int_d \mathbf{S}^a(x)[\mathbf{M}]\mathbf{S}(x)dx+\int_d \mathbf{S}^a(x)[\mathbf{K}_0]\mathbf{S}(x)dx\\&+\int_d \mathbf{S}^a(x)[\mathbf{K}_1]\mathbf{S}(x)dx+\int_d \mathbf{S}_x^a(x)[\mathbf{K}_2]\mathbf{S}_x(x)dx\\&+\int_d \mathbf{S}_{xx}^a(x)[\mathbf{K}_4]\mathbf{S}_{xx}(x)dx.\end{aligned} \tag{10}$$

Square $(m+1)\times(m+1)$ matrices are given by

$$[\mathbf{M}]=\begin{pmatrix}m_s c_0^2 & \mathbf{0}\\ \mathbf{0}^T & [\hat{\mathbf{M}}]\end{pmatrix},\quad [\mathbf{K}_0]=\begin{pmatrix}0 & \mathbf{0}\\ \mathbf{0}^T & [\hat{\mathbf{K}}_0]\end{pmatrix}, \tag{11}$$

$$[\mathbf{K}_1]=-\rho_0 c_0\omega\begin{pmatrix}0 & \mathbf{1}\\ \mathbf{1}^T & [\hat{\mathbf{0}}]\end{pmatrix},\quad [\mathbf{K}_2]=\begin{pmatrix}0 & \mathbf{0}\\ \mathbf{0}^T & [\hat{\mathbf{K}}_2]\end{pmatrix}, \tag{12}$$

$$[\mathbf{K}_4]=\begin{pmatrix}D_S & \mathbf{0}\\ \mathbf{0}^T & [\hat{\mathbf{0}}]\end{pmatrix}. \tag{13}$$

Note that all the matrices are real, square, and symmetric $(m+1)\times(m+1)$ matrices. In particular, $[\mathbf{M}]$ is regular positive definite and $[\mathbf{K}_4]$ is a real, rank-deficient symmetric $[\mathrm{rank}([\mathbf{K}_4])=1]$ matrix. Matrices $[\mathbf{K}_2]$, $[\mathbf{K}_1]$, $[\mathbf{K}_0]$, and $[\mathbf{M}]$ are given by

$$[\hat{\mathbf{K}}_2]=\rho_0\int_c [\mathbf{N}]^T[\mathbf{N}]\mathrm{d}z, \tag{14}$$

$$[\hat{\mathbf{K}}_0]=\rho_0\int_c [\nabla_z\mathbf{N}]^T[\nabla_z\mathbf{N}]\mathrm{d}z, \tag{15}$$

$$[\hat{\mathbf{M}}]=\rho_0\int_c [\mathbf{N}]^T[\mathbf{N}]\mathrm{d}z. \tag{16}$$

Note that $[\hat{\mathbf{K}}_1]$ is the coupling matrix and matrices $[\hat{\mathbf{M}}]$ and $[\hat{\mathbf{K}}_2]$ are identical.

B. Waveguide finite element modeling

A resulting set of ordinary differential equations to the Euler–Lagrange equations, which correspond to Eq. (10), may be found by taking an appropriate first variation

$$\left([\mathbf{K}_4]\frac{d^4}{dx^4}-[\mathbf{K}_4]\frac{d^2}{dx^2}+k[\mathbf{K}_1]+[\mathbf{K}_0]-k^2[\mathbf{M}]\right)\mathbf{S}(x)=0. \tag{17}$$

The system of equations, Eq. (17), has constant coefficients in the form of the real, symmetric $(m+1)\times(m+1)$ matrices. Hence, the solutions of the linear homogeneous system may be written as

$$\mathbf{S}(x)=\mathbf{\Phi}e^{i\lambda x}, \tag{18}$$

where $\mathbf{\Phi}$ is the column vector representing the nodal structural amplitudes, Φ_1, and $\Phi_2,\ldots,\Phi_{m+1}$ representing the velocity potential amplitudes. Under this assumption Eq. (17) reduces to a fourth order polynomial eigenvalue problem

$$(\lambda^4[\mathbf{K}_4]+\lambda^2[\mathbf{K}_2]+k[\mathbf{K}_1]+[\mathbf{K}_0]-k^2[\mathbf{M}])\mathbf{\Phi}=0. \tag{19}$$

Given a frequency ω or acoustic wavenumber k and collecting terms this expression may be abbreviated as

$$(\lambda^4[\mathbf{K}_4]+\lambda^2[\mathbf{K}_2]+[\bar{\mathbf{K}}_0])\mathbf{\Phi}=0, \tag{20}$$

where $[\bar{\mathbf{K}}_0]=-k^2[\mathbf{M}]+k[\mathbf{K}_1]+[\mathbf{K}_0]$. We seek all the eigenvalues or wavenumbers, λ; the leading matrix in the polynomial expansion, Eq. (20), is a "rank 1" singular matrix and hence the procedure for reducing the polynomial eigenvalue problem to a simple eigenvalue problem is not straightforward.[16] We shall see that a solution procedure is possible for Eq. (20) that yields eigenvalues in pairs, $\lambda^{\pm}=\pm\lambda$, indicating that pairs of eigenmodes result to Eq. (18) with the same phase speed propagating in the positive and negative axial directions. To resolve the quadratic eigenvalue problem (20) a dummy variable $\lambda^2\mathbf{\Phi}$ is introduced as discussed in Ref. 16. This extends the dimension of the eigenvalue problem to $2(m+1)\times 2(m+1)$ as

$$\left\{\begin{bmatrix}\bar{\mathbf{K}}_0 & 0\\ \mathbf{K}_2 & -\bar{\mathbf{K}}_0\end{bmatrix}-\lambda^2\begin{bmatrix}0 & \bar{\mathbf{K}}_0\\ -\mathbf{K}_4 & 0\end{bmatrix}\right\}\begin{Bmatrix}\lambda^2\mathbf{\Phi}\\ \mathbf{\Phi}\end{Bmatrix}=0. \tag{21}$$

The left hand matrix is invertible and the right hand matrix is rank-deficient equal to $(m+2)$. The generalized matrix eigenvalue problem above may be rewritten as standard

eigenvalue problem, in $1/\lambda^2$, by multiplying the full expression by the invertible matrix. It is clear then that the resulting eigenvalue problem has at most $(m+2)$ distinct, non-zero finite eigenvalues. That is, there are at least $(m+2)$ infinite eigenvalues, λ^2, to be discarded as non-physical. Since the standard eigenvalue problem is equivalent to the original matrix problem (21) the eigenspace is spanned by $(m+2)$ eigenvectors each of dimension $2(m+1)$. On inspection of Eq. (21) this matrix problem provides $2(m+2)$ positive and negative propagating wavenumbers $\lambda^{\pm}$ with corresponding eigenvectors $\Phi^{\pm}$ of length $(m+1)$. Note that the eigenvalue problem is not solved numerically as a simple eigenvalue problem described here. The resolution of the matrix eigenvalue problem, Eq. (21), itself may be achieved by a number of standard computational routines. In the present analysis a *QZ* algorithm was used as implemented in MATLAB 7.0.2. This allows a "rank deficient" generalized eigenvalue problem to be solved and produces a set of finite number of complex-valued eigenvalues λ_j^2, $j=1,\ldots,(m+2)$ with corresponding cross-sectional *mode shapes*.

IV. SUPER-SPECTRAL FINITE-ELEMENT MODELING

An approximate solution to the original problem is determined by selecting a solution $[w(x),\phi(x,z)]$ from a discrete set of basis functions determined by a finite-element discretization of a region Ω_P, Fig. 1(b). Construction of the set of basis functions, Eq. (8), and local dynamic stiffness matrix, defined over the region Ω_P as in Fig. 1(b), $x \in d$, where $-D \leqslant x \leqslant +D$ is described in Ref. 1 with minor amendments to take into account the structural displacement. By consideration of the solutions in Eq. (18) it is clear that each wave influence function may be written as a linear combination of the following functions:

$$S_{jk}(x) = \sum_{l=1}^{2(m+2)} \bar{\Phi}_{jl} E_l(x) A_{lk} s_k, \quad j = 1, \ldots, (m+1), \quad k = 1, \ldots, 2(m+2), \tag{22}$$

where entries $\bar{\Phi}_{jl}$ and $E_l(x)$ take the values of eigenvectors and exponential functions, respectively. Coefficients A_{lk} are determined by scaling the set of wave influence functions to unity as described by Peplow and Finnveden.[1] For the variational parameters, there corresponds m acoustic degrees of freedom leaving two degrees of freedom for the structure. For example, if the unknowns are denoted by the vectors $(W_{xx}, W, \phi_1, \ldots, \phi_m)$ then simply supported conditions (3) may be represented through the combination

$$S_{jk}(x) = \begin{cases} \displaystyle\sum_{l=1}^{2(m+2)} \bar{\Phi}_{jl} \Lambda_l^2 E_l(x) A_{lk} s_k \\ k = 1, \ldots, 2(m+2), \quad j = 1 \\ \displaystyle\sum_{l=1}^{2(m+2)} \bar{\Phi}_{jl} E_l(x) A_{lk} s_k \\ k = 1, \ldots, 2(m+2), \quad 2 \leqslant j \leqslant (m+1) \end{cases} \tag{23}$$

or through the unknowns $(W_x, W, \phi_1, \ldots, \phi_m)$ clamped conditions (4) may be represented using the combination

$$S_{jk}(x) = \begin{cases} \displaystyle\sum_{l=1}^{2(m+2)} \bar{\Phi}_{jl} \Lambda_l E_l(x) A_{lk} s_k \\ k = 1, \ldots, 2(m+2), \quad j = 1 \\ \displaystyle\sum_{l=1}^{2(m+2)} \bar{\Phi}_{jl} E_l(x) A_{lk} s_k \\ k = 1, \ldots, 2(m+2), \quad 2 \leqslant j \leqslant (m+1). \end{cases} \tag{24}$$

Hence, the Lagrangian and the local dynamic stiffness matrix, $[L]_{\log}$, for a certain super-spectral element may be written as

$$L_\Omega = \mathbf{s}^T [L]_\infty \mathbf{s}, \tag{25}$$

where

$$[L]_{\text{loc}} = [A]^T ([\bar{\Phi}]^T (-k^2[\mathbf{M}] + [\mathbf{K_0}] + k[\mathbf{K_1}])[\bar{\Phi}] + \langle \mathbf{\Lambda} \rangle [\bar{\Phi}]^T [\mathbf{K_2}] [\bar{\Phi}] \langle \mathbf{\Lambda} \rangle + \langle \mathbf{\Lambda^2} \rangle [\bar{\Phi}]^T [\mathbf{K_4}] [\bar{\Phi}] \langle \mathbf{\Lambda^2} \rangle) * [E_l]][A]. \tag{26}$$

where $*$ denotes the Schur product. The global dynamic stiffness matrix is assembled by calculated local dynamic stiffness matrices for each region, such as Ω_P in Fig. 1(b). For example, consider a uniform waveguide geometry consisting of three super-spectral elements, with $(m+2)$ degrees of freedom across each element cross-section. A $2(m+1) \times 2(m+1)$ generalized matrix eigenvalue problem is solved for the WFE and a $2(m+2) \times 2(m+2)$ local dynamic stiffness matrix (26) is generated for each super-spectral element. Enforcing continuity of velocity potential, displacement, and slope across neighbors and combining local dynamic stiffness matrices result in a $4(m+2) \times 4(m+2)$ frequency-dependent global dynamic stiffness matrix. Acoustic sources are modeled as either volume point sources or given mechanical sources such as normal velocities or accelerations defined on boundaries. These are introduced into the governing equations of motion via the variational formulation (7).

Evaluation of the dynamic stiffness matrix above applies to a simple super-spectral finite element for a given frequency, $\omega = 2\pi f$. The frequency-dependent matrix is banded, complex, and symmetric. For a combination of super-spectral finite elements, describing a general fluid domain, the corresponding dynamic stiffness matrix has a block diagonal structure; each block derived from the expression in Eq. (26).

The complete element formulation, for a single arbitrary length super-spectral element, costs little in terms of computational expenditure. Including assembling local element matrices, solving eigenvalue problems, and evaluating the global dynamic stiffness matrix, Eq. (26), this required approximately 0.04 s on a 1.3 GHz Pentium Centrino PC for a 13, $(m=11)$, degree-of-freedom super-spectral element. Accuracy of the method is similar to a one-dimensional standard FEM and is described in Ref. 1.

V. NUMERICAL EXAMPLES

In the following we illustrate the efficacy of the present approach through accurate solutions to simple canonical

propagation and transmission problems in water-filled waveguides. If not specified the wavespeed of the fluid was taken to be $c_0=1500$ ms^{-1} with density $\rho_0=1000$ kg m^{-3}. Zero damping is assumed for evaluation of dispersion relations but typical values used in the validation sections, Secs. V B and V C, are 0.001% and 1.0% for the fluid and structure, respectively. Dispersion relations for coupled systems with given propagating wave mode shapes are shown first followed by examples for forced responses where frequency values for excitation were not only chosen arbitrarily but to best illustrate each case. The form of the flexural rigidity of the steel plate D_s is given by EI where E is the modulus of elasticity $E=2\times10^{11}$ N/m^2 of and I is the moment of inertia $I=t^3/12(1-\nu^2)$ where t is the thickness of the plate, $\nu=0.3$ is Poisson's ratio, ρ_s is the mass per unit volume 7850 kg/m^3, and hence $m_s=\rho_s t$ is the mass per unit length of the beam. Note that the SFEM solutions found have been converted and presented as acoustic pressure values.

A. Dispersion relations

Dispersion relations between propagating wavenumbers and frequency provide important information about vibration and acoustical energy that may transmit through a coupled system. Useful by-products, then, of the SFEM are the calculation propagating wavenumbers, or the eigenvalues, λ (with zero imaginary part) also referred to as the propagating wavenumbers, and may be obtained from the matrix eigenvalue problem (19). For a given frequency the element matrices are assembled, Eqs. (11)–(13), yielding solutions of the quadratic eigenvalue problem through Eq. (19). Three cases are considered, a fluid-only case, a fluid coupled to a "heavy" steel structure, and a fluid coupled to a "light" steel structure. The parameters were chosen to highlight dominant features of the dispersion curves in the full coupled system. First the fluid-only problem, depicted by the left-hand plot in Fig. 1(a) and approximated using quartic polynomial shape functions, Eq. (9), defined over three elements in the z-direction resulted in 13×13 element matrices, Eqs. (11)–(13). For this case the uncoupled fluid-only eigenvalue problem, not shown here, was adopted; see Ref. 1 for details. Figure 2 shows the dispersion relations found from the numerical scheme against exact values shown by dashed lines. The right hand plots in Fig. 2 show the eigenvectors associated with the propagating modes at two frequencies, 2000 and 3500 Hz. The zero order (plane-wave) mode, depicted by the dashed line, and the first and second order modes, depicted by dashed-dotted and dotted lines, are clearly evident.

Now consider the situation including a structure depicted in right-hand plot of Fig. 1(a). Using the same element shape functions for the fluid domain the fully coupled eigenvalue problem (21) increases to a 28×28 generalized eigenvalue problem. Given two thickness of plates, $t=22.0$ mm and $t=4.0$ mm, the dispersion relations up to frequency 5.0 kHz are shown in Figs. 3 and 4.

In the coupled fluid-structure systems the appearance of dispersion curves, along the frequency axis, now shifts to the right in frequency as the plate thickness decreases. Notably

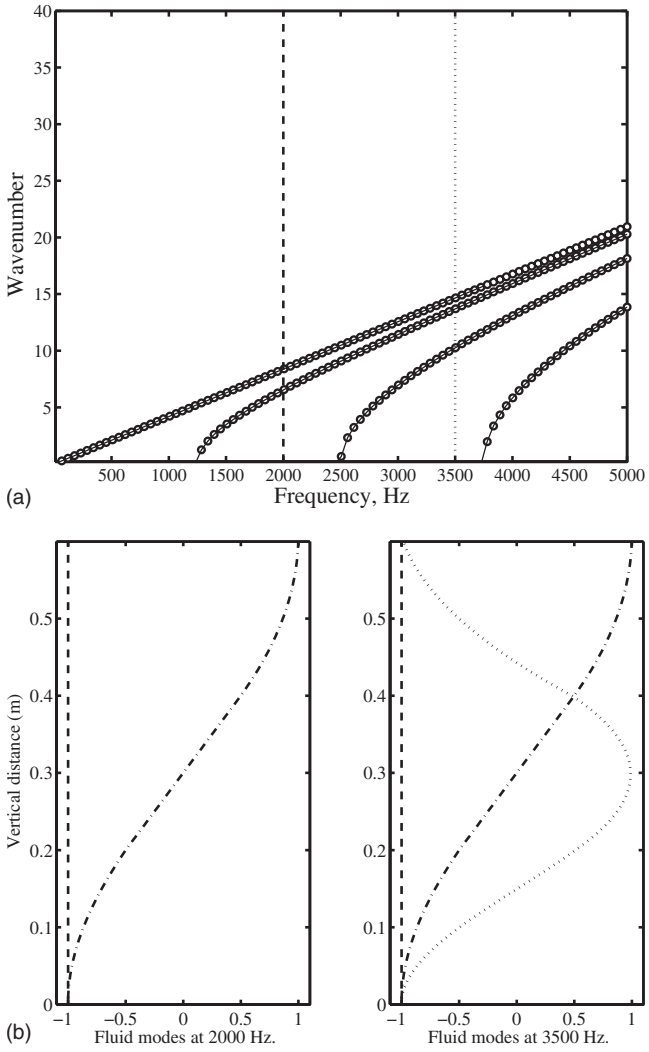

FIG. 2. Dispersion relations depicting real propagating wavenumbers, λ, versus frequency, f, for water-filled rigid duct of height $D=0.6$ m. (a) Circles (○) denote WFE solution curves from Ref. 1 and dashed lines depict exact dispersion curves for fluid. (b) Non-dimensionalized cross-sectional fluid modes Φ, $\|\Phi\|_\infty=1$, at frequencies 2000 and 3500 Hz indicated by vertical lines in (a).

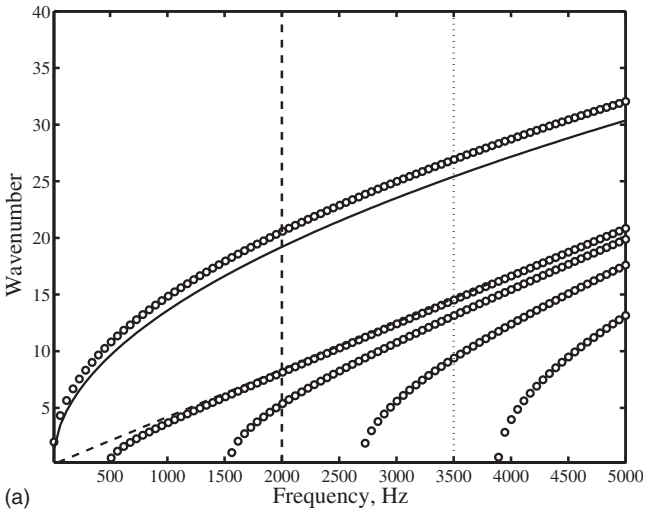
the appearance of propagating waves (cut-on) undergoes a shift to the right eventually reaching the rigid boundary to sound-soft duct cut-on eigenvalues. Specifically as the plate thickness decreases Figs. 3(a) and 4(a) show the propagating plane-wave mode curve tending toward the zero pressure value cut-on eigenvalue, corresponding to 625 Hz. The mode shape is shown by dashed line in Figs. 3(a) and 4(a). Similarly the first and second order modal curves also shift to the right along the frequency axis.

On comparing Figs. 3(a) and 4(a) to Fig. 2(a) an upper branch showing the advent of a structural-like wave is evident. The solid lines in Figs. 3(a) and 4(a) show the uncoupled structural curve in the vicinity of this coupled dispersion curve. The corresponding modeshapes for these curves are given by solid lines in Figs. 3(b) and 4(b). Generally the coupled dispersion curves remain close to the uncoupled curves and undergo transitions between the *in vacuo* structural and the uncoupled acoustic solutions. The mode shape, given by a solid line, clearly has a *near-field*-like



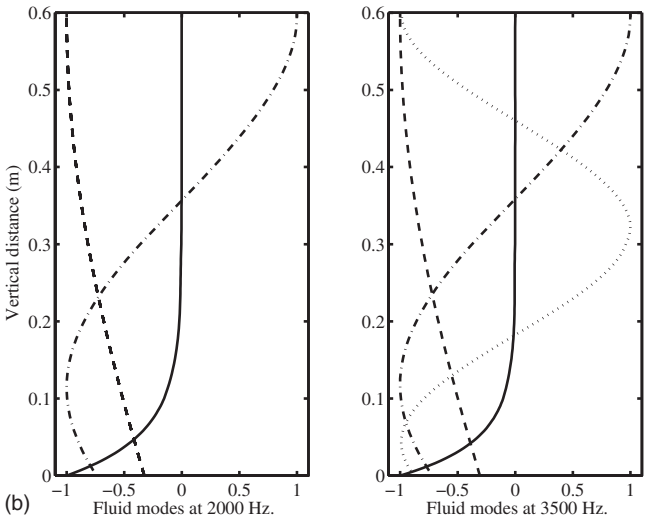


FIG. 3. Dispersion relations, similar to Fig. 2, showing real propagating wavenumbers versus frequency for water-filled steel-backed duct of height $D=0.6$ m with thickness of steel plate, $t=0.022$ m. (a) Circles (○) denote WFE solution curves from Eq. (19). Solid lines correspond to *in vacuo* dispersion relations. (b) Non-dimensionalized cross-sectional fluid modes Φ, $\|\Phi\|_\infty=1$, at frequencies 2000 and 3500 Hz indicated by vertical lines in (a).

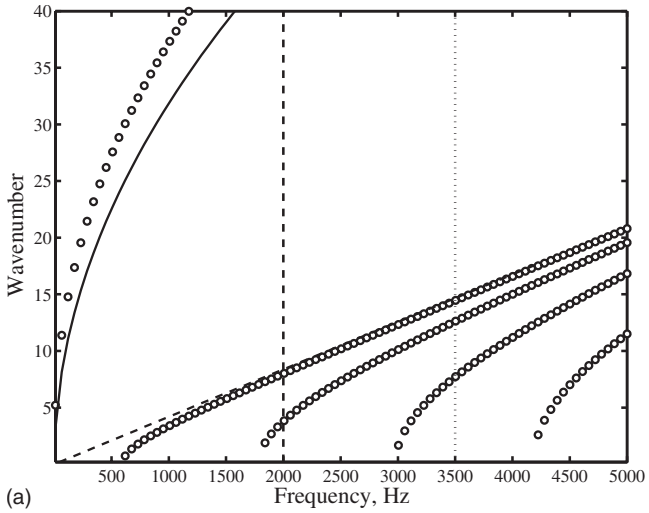

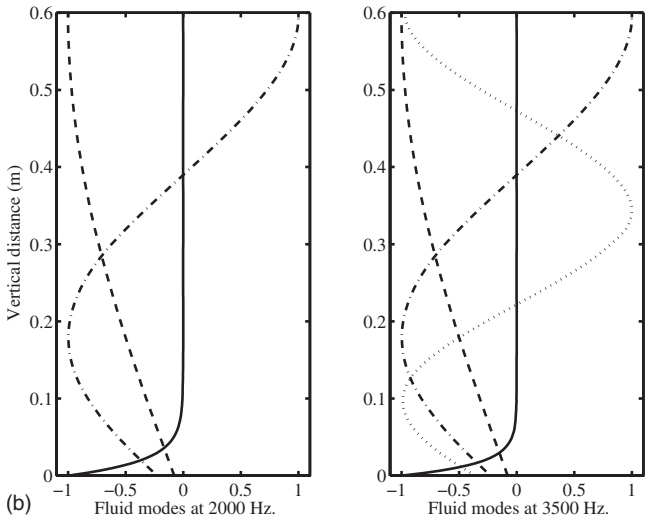

FIG. 4. Dispersion relations showing real propagating wavenumber λ versus frequency for water-filled steel-backed duct of height $D=0.6$ m with thickness of steel plate, $t=0.004$ m. (a) Circles (○) denote WFE solution curves from Eq. (19). Lines correspond to *in vacuo* dispersion relations. (b) Non-dimensionalized cross-sectional fluid modes Φ, $\|\Phi\|_\infty=1$, at frequencies 2000 and 3500 Hz indicated by vertical lines in (a).

characteristic. As the plate thickness decreases it is shown in Figs. 3(b) and 4(b) that this near-field feature is more prominent. It is also evident that the corresponding fluid modes, from a cross-section with rigid sides, Fig. 2 case, also undergo significant variations as the plate thickness decreases, Figs. 3 and 4.

An important observation here is that the SFEM should be able to capture all the propagating waves in the vibro-acoustic system. Otherwise the physics of the original system and the SFEM semi-analytical model will not be compatible. Hence the number of degrees of freedom, and hence the size of the model, should be sufficiently large so that all the cross-section propagating mode shapes are sufficiently approximated. Although this approximation is essentially one-dimensional the size of the model is clearly frequency dependent and warrants a two-dimensional error analysis. Numerical errors for simple two-dimensional acoustic problems have been discussed in Ref. 1.

B. Validation example for open-ended box

Section V A considers the free propagating modes, as a subset of the WFE derivation. However, we are primarily concerned with fluid-structure interaction, and therefore we now proceed to apply SFEM to the case of a fluid volume bounded by a plate that is excited by mechanical forces. In order to illustrate the high accuracy that can be obtained with the SFEM, the case is considered of a steel plate of length $L_P=0.5$ and thickness $t=0.001$ m backed by a water-filled cavity of depth $D=0.6$ m, see Fig. 5, where the right-hand panel undergoes anechoic termination. Simulations are compared against FEMLAB multiphysics calculations.[17] The triangular mesh for cubic shape functions for the FEMLAB calculations is shown in Fig. 5. To compare the performances of the SFEM with the existing element-based techniques, coupled finite-element multiphysics models of the considered problem have been solved with FEMLAB 3.1.[17] The structural FEM meshes consist of triangular isotropic plane strain two-dimensional elements; similarly the acoustic FEM mesh

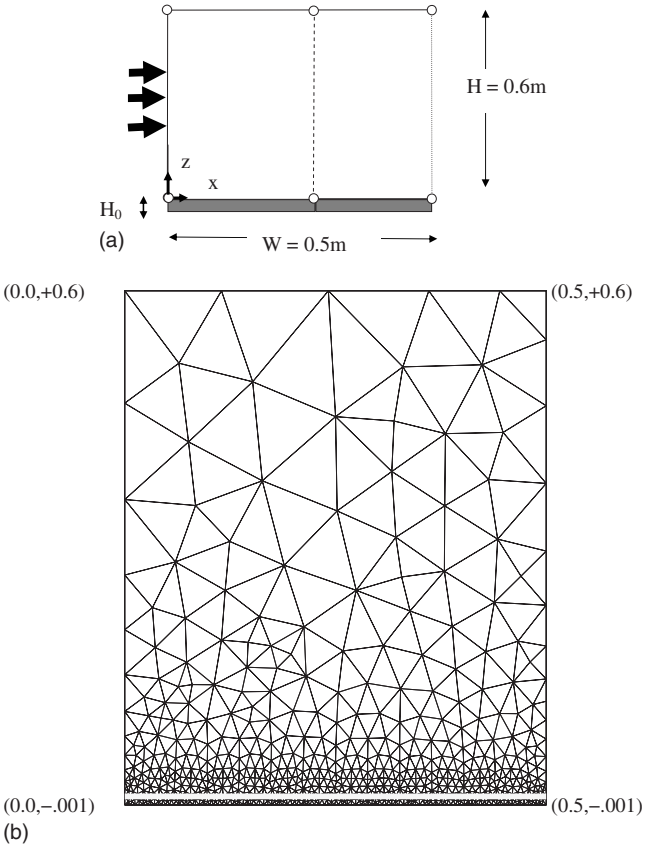

FIG. 5. Geometries for SFEM and FEMLAB methods. Excitation is a unit normal acceleration denoted by arrows with an anechoic termination boundary on the right-hand wall: (a) spectral finite-element "mesh" for the coupled vibro-acoustic problem; (b) illustration of a standard triangulated mesh for coupled problem showing a 1312 triangular graded mesh close to the fluid-structure interface where structure plate thickness equals $t=0.001$ m.

consists of triangular fluid elements. Cubic interlopatory shape functions are used throughout. The steps toward generating a suitable mesh are not described here but the mesh for the thin elastic solid region is quite fine due to the geometry. The white line in Fig. 5(b) shows the interface between solid and fluid regions, and normal acceleration is assumed continuous between the fluid and structural regions. To compare with FEMLAB simulations the plate edges are chosen simply supported equation (3) in the examples shown here and the dynamic stiffness matrix is derived using wave functions given in Eq. (23).

Figure 6 shows the normal plate displacement predictions and the normal fluid pressure predictions along the fluid-plate structure interface at 830 Hz. Solutions obtained with the SFEM wave model consist of 57 degrees of freedom with two SFEM elements each derived by local dynamic 19×19 stiffness matrix. Calculations were performed against a FEMLAB multiphysics simulation using 1312 cubic shape functions defined over triangular elements for the structural and acoustic shape functions totaling 1808 degrees of freedom. For computational expenditure for single frequency calculations, FEMLAB totaled 4.5 s in FEMLAB to complete pre- and post-processing simulations to illustrate solutions, Fig. 6. CPU expenditure time for wave-based SFEM simulation was 0.18 s for solving and post-processing the solution. Assuming the exact solution is attained by FEMLAB software relative errors for the SFEM technique were less than 2.0% on average as shown in Fig. 6.

C. Transmission loss for flexible muffler

To predict the acoustic performance of a complex pipe system a plane wave acoustic source is assumed. This is achieved through a given uniform mechanical velocity source and is included in the calculation of the transmission loss (TL) of the system.[18] The derivation of TL, as well as their use with the numerical methods, is based on plane wave propagation sound sources (i.e., the entire face of the inlet section moving in unison) and an anechoic termination, i.e., $\zeta=\rho_0 c_0$ at the left- and right-hand end sections of the silencer region, see Fig. 7. This models completely anechoic source and termination conditions at inlet and outlet and is easily implemented in the geometrical definitions for SFEM and FEMLAB models. The dimension of the regions used in the FEMLAB and SFEM calculations are illustrated in Fig. 7. The geometry of each model is identical with the velocity source assumed to be situated at the inlet pipe, $x=-0.5$ m at the left-hand side. Note that the length of the outlet pipe for the SFEM may have had arbitrary axial length but was fixed to the FEMLAB geometry for comparison purposes. The lengths of the inlet and outlet pipes were 0.5 m in both simulation models. Nonetheless TL results shown in Fig. 9 were found to be identical for all arbitrary length outlet pipes considered in the SFEM model.

Firstly, for validation, Fig. 8 shows a comparison between FEMLAB and SFEM calculations for the geometry and graded mesh close to plate of thickness $t=H_0=0.001$ m shown in Fig. 7 for a given uniform unit velocity at the left-hand panel. The computational expenditure for this single frequency calculation is similar to the example in Sec. V B. The FEMLAB simulation consisted of 2732 DOFs against 58 DOFs for the SFEM for the complete assembly. The depth of the chamber was fixed at $D=0.05$ m and height of the inlet and outlet pipes $H=0.13$ m. Assuming accuracy of the FEMLAB solution the averaged relative errors for plate displacement and acoustic pressure at the interface, shown in Figs. 8(b) and 8(c), were 2.70% and 3.43%, respectively.

Following this validation the TL of the complex silencer system is now shown. The definition of TL is the ratio of the incident sound power to the transmitted sound power. As long as the inlet and outlet regions of the muffler are of the same cross-section, and the properties of the fluid density do not change, then the TL can be expressed as

$$\mathrm{TL}=20\log 10\left|\frac{P_i}{P_t}\right|, \tag{27}$$

where P_i is the root mean square (rms) pressure of the incident wave, and P_t is the rms pressure of the transmitted wave with chamber in place. Assuming a plane wave propagating source P_i and P_t are easily calculated; see Ref. 18. This can be simplified to the following equation: $\mathrm{TL}=\mathrm{SPL}_i-\mathrm{SPL}_t$ where it is understood that SPL_i is obtained without the silencer in place, and SPL_t is obtained with the silencer in place. Hence TL shows loss of energy expected through the waveguide system show in Fig. 7. The solutions presented in

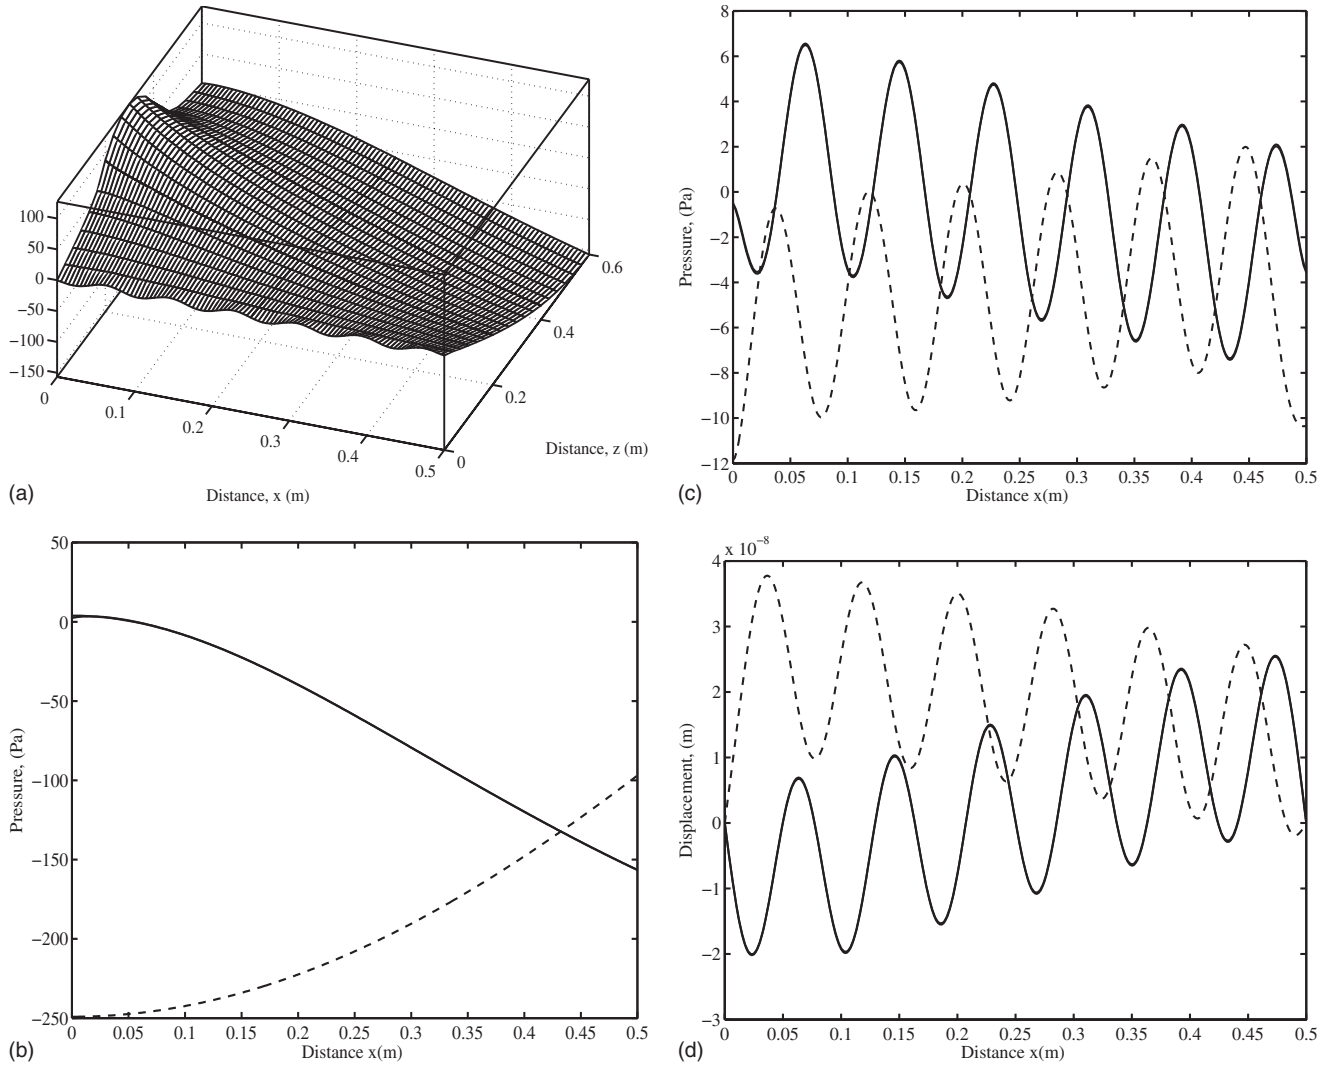

FIG. 6. Solutions for coupled vibro-acoustic problem, water-filled rigid box enclosed by steel plate, thickness $t=0.001$ m at frequency 830 Hz. Comparisons with FEMLAB [1808 degrees of freedom (DOFs)] and SFEM (57 DOFs): (a) a mesh plot for real part of pressure and remaining plots; solid line: real; dashed line: imaginary; (b) acoustic pressure at $z=0.6$, relative error 0.40%; (c) acoustic pressure at $z=0.0$, relative error 2.66%; and (d) displacement of plate at $z=0.0$, relative error 1.91%.

Fig. 9 are attainable in FEMLAB taking 10 CPU minutes and SFEM less than 1 CPU minute for 290 calculations. Note that no significant post-processing expenditure was used here. Figure 9 shows results from SFEM and FEMLAB simulations in a logarithmic frequency range from 10.0 to 3000.0 Hz in 290 steps. The TL for a fluid-only silencer combination is seen in Fig. 9(a) where the depth of the chamber is increased from $D=0.01$, 0.05, 0.09 m to its maximum value $D=0.13$ m. The relative change in TL is about 1.0 dB between each case, the maximum TL attained for the $D=0.13$ m case. Note that plane wave transmission is no longer possible beyond 2900 Hz, evident by the presence of the peak in the solid line in Fig. 9(a).

Next follows the introduction of the plate structure as shown in Fig. 7(b). The system is the same as illustrated in Fig. 9(a) and curves denoted equivalently, except that in this case the chamber is backed by a fixed given plate with thickness $t=0.004$ m. A striking difference in the TL of the system is clearly observable in Fig. 9(b) due to the introduction of a coupled element in the water-filled chamber. Evidence of the complex energy exchange between the fluid and the structure is shown even in the shallowest silencer chamber $D=0.01$ m given by dotted curve in Fig. 9(b). This plot shows significant TL up to 200 Hz with a slight pass-band between 200 and 550 Hz.

Figure 9(c) demonstrates the influence of the mass and bending stiffness of the plate for fixed chamber depth $D=0.01$ m. Again the objective of a muffler is that TL should be small for low frequencies, so that steady flow is not inhibited and TL is higher at high frequencies to inhibit vibro-acoustic noise. We see from this plot that where the "mass" of the plate is lower the silencer behaves like a high-pass filter. However, the silencer should act as a low-pass filter not inhibiting low-frequency wave propagation. The system acts as a quarter-wavelength muffler since the fluid modes cut on at finite non-zero frequencies; see Figs. 3 and 4. A trapped-mode arises causing the system to inhibit energy transmission. However, this phenomenon is particular to the plane case of two-dimensional rectangular waveguides. In Ref. 19 this stop-band phenomenon has been studied for

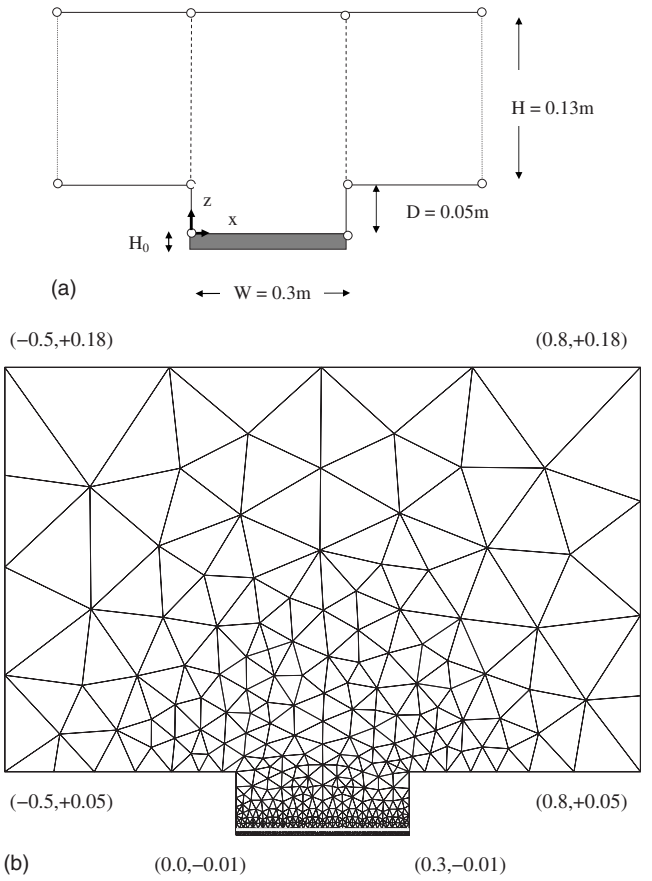

FIG. 7. Geometries for SFEM and FEMLAB methods for flexible muffler example. Excitation is unit normal acceleration at left-hand boundary and anechoic termination boundary on right-hand wall: (a) spectral finite element mesh for coupled vibro-acoustic problem; (b) illustration of standard triangulated mesh for coupled problem showing 1872 triangular elements and graded mesh close to plate of thickness $t=H_0=0.001$ m.

elastic inclusions in fluid-filled cylinders recently. Here, though, a fluid mode exists at arbitrary small frequencies. Thus the trapped-mode phenomena cannot occur at very low frequencies.

VI. CONCLUSIONS

A spectral method in the form of a finite-element scheme has been used to treat the problem of sound transmission in uniform and non-uniform waveguides carrying an acoustic fluid backed by a structural element. A unique feature of the spectral finite-element approach is the use of basis functions generated from linear generalized eigenvalue calculations. The basis functions themselves, which are solutions to the homogeneous reduced wave equations, may be defined over regions of arbitrary length backed by structural elements. Direct wavenumber comparison with a standard FEM solver has been shown to yield satisfactory results for fluid-structure interaction examples. In particular, it has been shown that the TL and hence the energy exchange of a simple silencer assembly, with a heavy fluid, are sensitive to the structural interact ion with the fluid for deep as well as very shallow chambers.

The waveguide geometries that have been given the most attention in the present study are that of a rectangular duct lined by a structure on the side of a geometrical non-

A correction of random incidence absorption coefficients for the angular distribution of acoustic energy under measurement conditions

Cheol-Ho Jeong[a)]
Department of Electrical Engineering, Acoustic Technology, Technical University of Denmark (DTU), DK-2800 Kgs. Lyngby, Denmark

(Received 18 June 2008; revised 24 November 2008; accepted 19 January 2009)

Most acoustic measurements are based on an assumption of ideal conditions. One such ideal condition is a diffuse and reverberant field. In practice, a perfectly diffuse sound field cannot be achieved in a reverberation chamber. Uneven incident energy density under measurement conditions can cause discrepancies between the measured value and the theoretical random incidence absorption coefficient. Therefore the angular distribution of the incident acoustic energy onto an absorber sample should be taken into account. The angular distribution of the incident energy density was simulated using the beam tracing method for various room shapes and source positions. The averaged angular distribution is found to be similar to a Gaussian distribution. As a result, an angle-weighted absorption coefficient was proposed by considering the angular energy distribution to improve the agreement between the theoretical absorption coefficient and the reverberation room measurement. The angle-weighted absorption coefficient, together with the size correction, agrees satisfactorily with the measured absorption data by the reverberation chamber method. At high frequencies and for large samples, the averaged weighting corresponds well with the measurement, whereas at low frequencies and for small panels, the relatively flat distribution agrees better.

I. INTRODUCTION

A diffuse field is an idealized concept, and it is the basis of several standardized measurements, e.g., the absorption of materials, the sound power of noise sources, and the transmission loss of walls. For a perfectly diffuse field, two assumptions must be satisfied (for example, see Ref. 1).

(1) The local energy density in a room is uniform (the spatial diffusion).
(2) The energy is uniformly incident onto a surface from all directions (the directional diffusion).

In a reverberation room except regions near boundaries, the first condition may be satisfied. At locations about one wavelength apart from boundaries, the deviation of sound pressure is bounded within 1 dB in a large reverberation chamber (0.7λ from corners and edges and 0.25λ from surfaces).[2] Despite attempts to obtain a diffuse sound field in a reverberation room, the second assumption of the random incidence is very hard to fulfill. In particular, when a test specimen covers one surface as in the absorption and sound transmission loss measurement, an ideal diffusivity is rarely obtained. As a compensation, truncation of the angle of incidence was introduced in the calculation of transmission loss, and typical values of the limiting angle vary from 70° to 85° based on empirical data.[3,4] This implies that acoustic energies are not uniformly incident on a sample surface. From this observation, one may deduce that grazingly incident energies are negligible.

The random incidence absorption coefficient is based on the assumption that the intensities of the incident sound are uniformly distributed over all possible directions. In addition, a random distribution of phase of the wave incident on the wall is also assumed. These assumptions result in Paris formula associated with $\sin(2\theta)$.[5] However, the measured absorption coefficient by Sabine's formula (sometimes referred to as the Sabine absorption coefficient) shows a significant discrepancy compared with the random incident coefficient from measured impedance data.[6] It is known that measured absorption coefficients are overestimated for small absorber samples and sometimes exceed unity, even for a nearly locally reacting surface. Theoretically, the random incidence absorption coefficient cannot exceed 0.951 for the specific surface impedance of 1.567. Reasons for the overestimation have been widely accepted to be the finite size of samples and the edge diffraction.[7–12]

To match the theoretical values with measured data, several works have been studied. Concerning the sound transmission loss, de Bruijn[13] addressed the influence of the degree of diffusivity in measurement conditions. Kang *et al.*[14] employed several Gaussian weighting functions for the calculation of sound transmission loss to achieve better agreements with the measurement. Kang *et al.*[15] also measured the incident energy density onto a sample in a reverberation chamber using sound intensimetry. The measured incident intensity decreases with increasing incidence angle; however,

 0001-4966/2009/125(4)/2064/8/$25.00

it becomes rather uniform at low frequencies. For the absorption measurement, Makita and Fujiwara[16] investigated possible maximum and minimum values of absorption coefficients assuming non-uniform incident energy, although they had no idea of the angular distribution of the incident energy distribution. They tested unrealistic weighting functions, but this research revealed that the absorption coefficient can exceed unity depending on the directional energy distribution. Makita and Hidaka[17] suggested a revised cosine law of oblique incident energy considering the effective mean free paths of sound rays and reverberation time. However, this modified function is not experimentally validated. Thomasson[18,19] concentrated mainly on the size effect of an absorbing sample, by introducing the concept of averaged radiation impedance. The averaged radiation impedance varies with panel size and aspect ratio under the assumption that the radiation impedance depends weakly on the azimuth angle. However, an ideal diffuse field was assumed in his study. Several semi-empirical corrections have also been suggested. London[20] defined a quantity called the equivalent real impedance and used this quantity for computing the reverberation absorption coefficient. Atal[21] suggested an empirical correction by multiplying a frequency-dependent complex quantity in the form of $(a+bj)$. Dämmig[22] examined the effect of sample locations and room shapes on the sound absorption using the ray tracing method. This work is based on statistical analyses of incidence angles, not the incident energies, to explain the variation of measured absorption coefficients in several source locations and rooms.

In the present study, angular distributions of energy density incident onto an absorbing sample have been investigated using the beam tracing method. The final objective of this study is to improve the agreement by weighting the calculated absorption coefficient according to the actual incident energy density instead of assuming an ideally diffuse incident field.

II. ANGULAR DISTRIBUTION OF ENERGY DENSITY AS A WEIGHTING FUNCTION

First of all, the angular distribution of the reverberant energy density must be calculated. In this study, the beam tracing method[23–25] is employed to simulate the sound propagation in a reverberation chamber. Triangular beams, which are emitted from a source, are followed by their central axes (hereafter rays) without splitting algorithm.[26,27] Instead of splitting beams when beams intersect more than one surface at edges or corners, a large number of beams having a sufficiently small solid angle emanate and illuminate a reverberant field. Only specular reflection is adopted during the tracing, and a negligible absorption coefficient of 0.01 is assigned for all surfaces of a reverberation chamber irrespective of the frequency. The incidence angles and energies coming from these angles, which are computed by the geometrical acoustics technique, will eventually construct an angular distribution of incident energy density as a function of the incidence angle.

Two chambers were chosen as test examples: one is a rectangular parallelepiped chamber and the other is a room

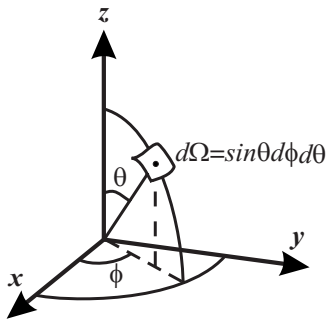

FIG. 1. Spherical polar coordinate representing solid angle element.

with non-parallel surfaces. In accordance with ISO 354 (Ref. 28) and ASTM C 423–02,[29] the sources are located at trihedral corners of the rooms. The assumption that an absorber sample covers one whole surface of the room facilitates the simulation in a way that one can collect all the information of beams incident onto the specific surface. This surface, on which an absorber is installed, is called a target surface.

During the beam tracing, the information on the directional energies and angles of incidence is saved. Acoustic energy decays inversely proportional to r^2 and it is reduced by $(1-\alpha_i)$ whenever beam hits surfaces. Here, r denotes the traveling distance and α_i denotes the absorption coefficient of the ith surface. For a steady-state condition, a total directional energy from θ_i is calculated by summing all components over an interval, $[\theta_{i,l}\ \theta_{i,u}]$. Here, $\theta_{i,l}$ and $\theta_{i,u}$ are the lower and upper limits of the interval, respectively, and θ_i is the arithmetic mean of two limiting values. The directional energy density is the ratio between the total incident sound energy, E_θ, and the corresponding solid angle, Ω_θ. Using a generalized concept of solid angle in terms of spherical polar coordinates, θ and ϕ, respectively (see Fig. 1), the solid angle element is expressed as $d\Omega=\sin\theta d\phi d\theta$. By integrating the azimuth angle, ϕ, from 0 to 2π and the polar angle, θ, over the corresponding interval of $[\theta_{i,l}\ \theta_{i,u}]$, one can find the solid angle at θ_i, as follows:

$$\Omega_{\theta_i}=\int_0^{2\pi}\int_{\theta_{i,l}}^{\theta_{i,u}} d\Omega=\int_0^{2\pi}\int_{\theta_{i,l}}^{\theta_{i,u}} \sin\theta d\theta d\phi$$
$$=2\pi\int_{\theta_{i,l}}^{\theta_{i,u}} \sin\theta d\theta. \quad (1)$$

The solid angle in Eq. (1) increases with the angle of incidence. The directional energy density is defined as the total directional energy incident over the interval of $[\theta_{i,l}\ \theta_{i,u}]$ divided by the corresponding solid angle as follows:

$$D(\theta_i)=\frac{E_{\theta_i}}{\Omega_{\theta_i}}. \quad (2)$$

When the reverberant energy density is computed, the result will be utilized as a weighting function in the calculation of absorption coefficient. In Sec. V, the effect of weighting functions will be discussed by comparing the angle-weighted absorption coefficients with the measured absorption data in a reverberation chamber.

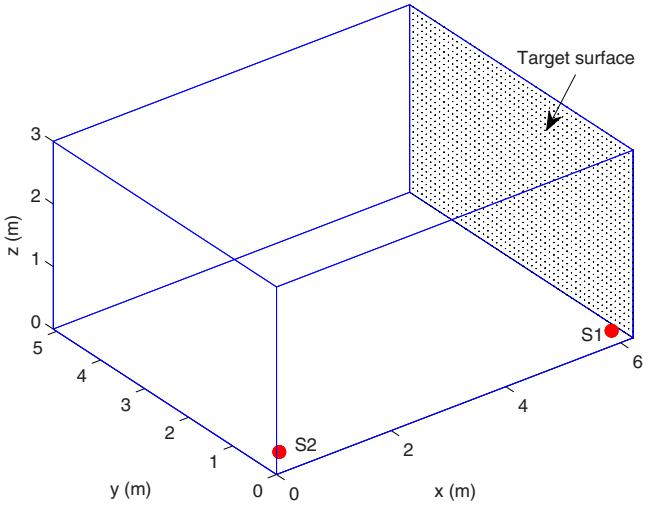

FIG. 2. (Color online) A rectangular room. Target surface is (6.2 m, y, z) plane and two corner sources are located at (6 m, 0.2 m, 0.1 m) and (0.2 m, 0.2 m, 0.2 m), respectively.

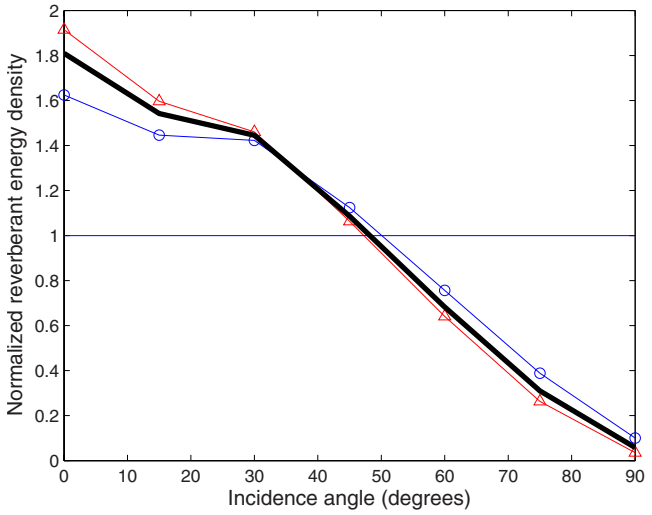

FIG. 3. (Color online) A comparison of reverberant energy density for two corner sources. (—○—) S1 at (6 m, 0.2 m, 0.1 m), (—△—) S2 at (0.2 m, 0.2 m, 0.2 m), and (thick solid line) averaged distribution over 90 source locations.

III. A RECTANGULAR ROOM

In general, lecture rooms and some reverberation chambers are rectangular. This kind of room usually has the problem that the interference is strong due to pairs of parallel surfaces. In this study, all surfaces are assumed smooth, and scattering is not taken into account.

A test rectangular room model is shown in Fig. 2. The edge lengths are 6.2 m, 5.1 m, 3.0 m, and the volume is 94.8 m^3. The target surface of interest is parallel to the y-z plane and located at (6.2 m, y, z). In order to examine the effect of source locations, two possible source locations are chosen in accordance with ISO 354[28] and ASTM C 423–02:[29] According to the standards, a loudspeaker should face into the trihedral corners of a room. The first source, S1, is located at (6 m, 0.2 m, 0.1 m) and S2 is located at (0.2 m, 0.2 m, 0.2 m). In the simulation, 8000 beams were used to scan the space. The number of reflections per beam is limited to 50. It goes without saying that directly transmitted energies from the sources to the target surface contribute the most owing to the shortest distance of propagation. (It is not allowed to place a source near a specimen in measuring the sound transmission loss because the direct radiation is too dominant.)

Incident energy densities for two sources are shown in Fig. 3, which are similar to the energy distributions of direct rays, because the directly transmitted energy overwhelms the total acoustic energy. This normalized energy density shows a similarity with the results by Kang and co-workers.[14,15] Because the source S2 is far from the target surface, only a few direct rays (172 out of 8000) strike the surface. It was found that there is an upper limiting angle of direct incidence, 42° for S2 case. That means there is no directly incident intensity above 42°. Accordingly the normally incident energy is higher than the obliquely incident energy. The acoustic energy density from the normal direction (0°) for S2 is 18% higher than that for S1, due to the lack of obliquely incident direct rays. It can be summarized that when a source is located far from the surface, the normally incident energy is more highlighted, whereas more energies from oblique directions are incident onto the surface for source locations close to the surface.

For 90 equally spaced ($6\times5\times3$) source locations, the average angular distribution of reverberant energy density was simulated and displayed in Fig. 3 (thick line). Sources are distributed by combining x values of (1, 2, 3, 4, 5, 6 m) and y values of (1, 2, 3, 4, 5 m) and z values of (0.2, 1.1, 2 m). The averaged reverberant energy density clearly shows that the acoustic energy density above 80° is lower than 0.2, which will be considered negligible.

IV. A ROOM WITH NON-PARALLEL SURFACES

In Fig. 4, a reverberation room with non-parallel surfaces is shown. The volume of the space is 179 m^3 and the

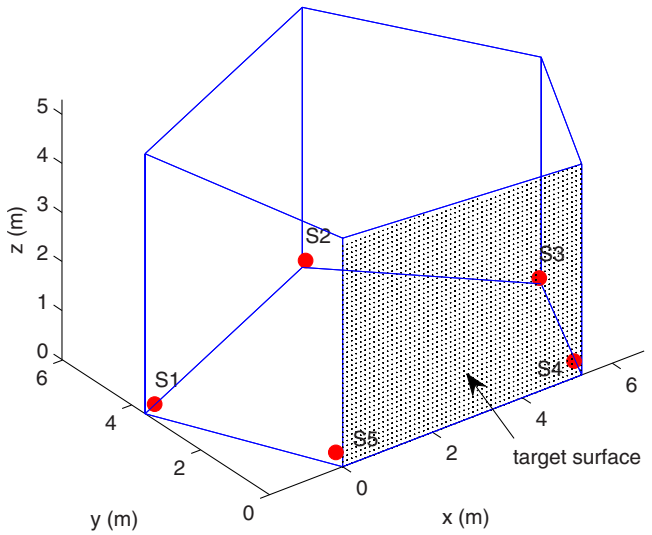

FIG. 4. (Color online) An irregularly shaped room. Target surface is (x, 0, z) plane and five corner sources are located at (−1.5 m, 3.5 m, 0.2 m), (3.7 m, 5.9 m, 0.2 m), (6.6 m, 2.9 m, 0.2 m), (5.3 m, 0.2 m, 0.2 m), and (0 m, 0.2 m, 0.2 m), respectively.

TABLE I. Geometrical nodal data of a reverberation chamber in Fig. 4.

Node numbering	Coordinate		
	x (m)	y (m)	z (m)
1	0	0	0
2	5.32	0	0
3	6.71	2.99	0
4	3.72	6.02	0
5	−1.63	3.61	0
6	0	0	4.66
7	5.32	0	4.30
8	6.71	2.99	4.62
9	3.72	6.02	5.30
10	−1.63	3.61	5.30

absorption coefficient is also 0.01, irrespective of surface and frequency. Geometrical nodal points of the model are listed in Table I. The target surface is x-z plane. Simulations were carried out for five trihedral corner sources shown in Fig. 4.

Figure 5 shows the normalized energy density for five corner sources. For source S1, direct rays from the normal direction cannot reach the target surface. The lowest direct angle of incidence is 23°. By only considering direct sound, the energy density shows a single peak at 45° due to the non-existence of the normal components. However, the reverberant energy density has two peaks at 0° and 45°. This result is apparently different from the rectangular room result, which shows a decreasing tendency with the angle of incidence. The energy is re-distributed due to the lack of direct normal incident rays.

The source S2 is located at the farthest distance of all sources. A high energy density value was found for the normally incident direct ray, as expected. As discussed in Sec. III, a long distance between a source and a target surface emphasizes the importance of the normal direction. An abrupt decrease was found above 45° and the contribution becomes less than 0.5.

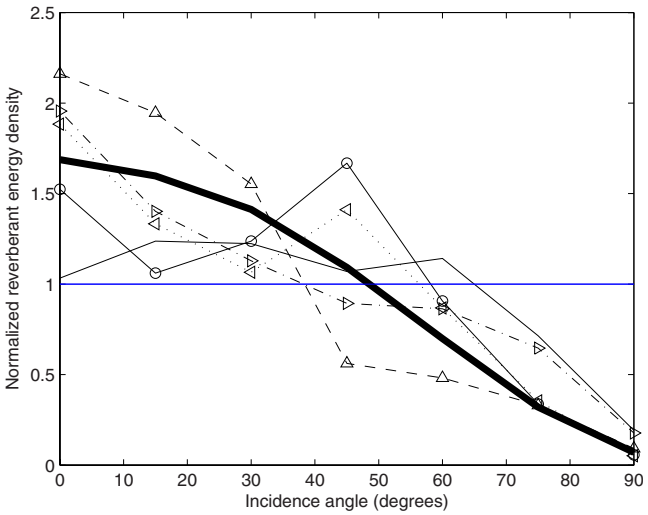

FIG. 5. (Color online) A comparison of angular reverberant energy densities for five corner sources. (—○—) S1, (--△--) S2, (···◁···) S3, (·–▷·–) S4, (—) S5, and (thick solid line) averaged distribution over 96 source locations.

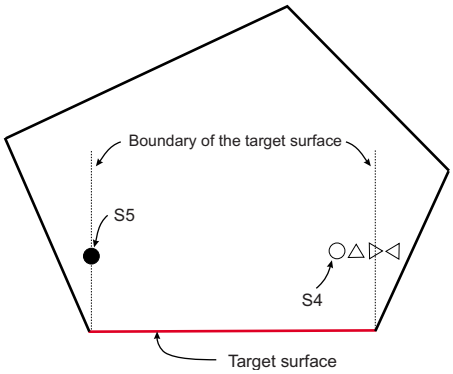

FIG. 6. (Color online) Source locations of S4 and S5 in plane view.

For source S3, the incident energy density shows a strong similarity with that of S1. As the sound source is invisible from the normal direction of the target surface, the incidence angle of 45° becomes pronounced. Therefore a double peak shaped distribution was found for the reverberant acoustic energy density.

The remaining two source locations, S4 and S5, at (5.3 m, 0.2 m, 0.2 m) and (0 m, 0.2 m, 0.2 m), respectively, are situated closer to the target surface. The reverberant acoustic energy densities of two cases show a large difference: The energy continuously decreases for S4, while it is relatively uniform until 60° for S5. In Fig. 6, source locations are illustrated. While the shaded source is located perpendicularly from the boundary of the target surface, two unshaded sources (circle and triangle) are located within the boundary of the target surface. If the source is located within the boundary, the normally incident energy is too pronounced.

Figure 7, which shows the effects of source locations, supports the above statement. By changing x-coordinate of a sound source position from 5.3 to 5.33 m with a step of 0.01 m, one can clearly see that the normal energy density loses its importance, when the source moves away from the surface boundary (refer to the symbols in Fig. 6). When a

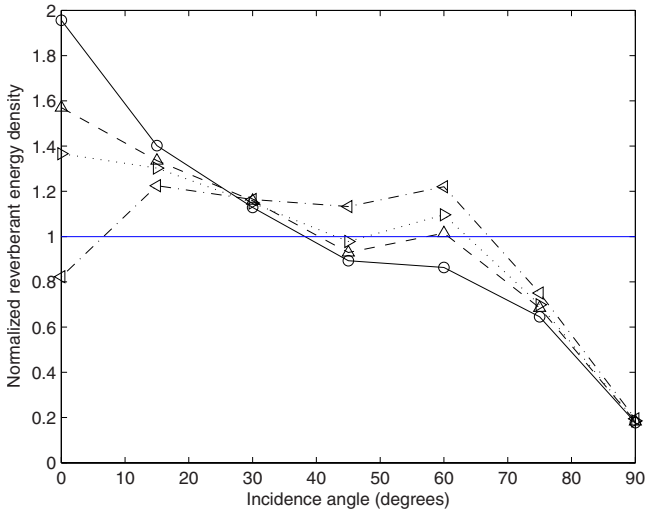

FIG. 7. (Color online) A comparison of reverberant energy densities. x-coordinate of sources varies from 5.30 to 5.33 m with a step of 0.01 m. (—○—) x=5.30 m, (--△--) x=5.31 m, (···▷···) x=5.32 m, and (·–◁·–) x=5.33 m (see Fig. 6).

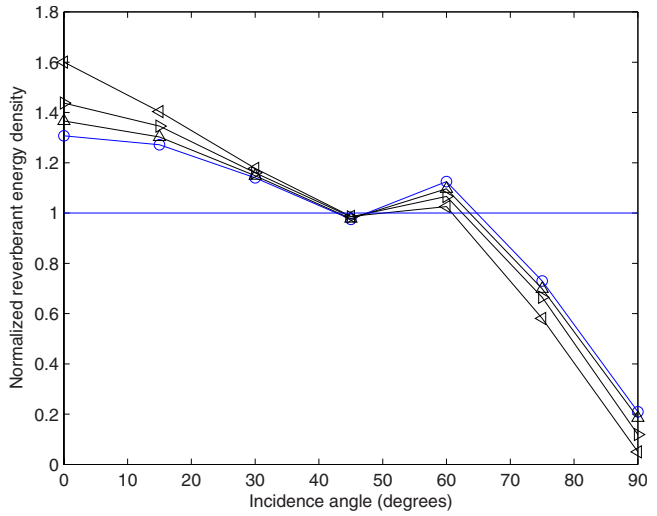

FIG. 8. (Color online) Effects of distance on the reverberant energy densities. (—○—) d=0.01 m, (—△—) d=0.20 m, (—▷—) d=0.50 m, and (—◁—) d=1.00 m. x-coordinate of sources is set to 5.32 m.

source is located outside the boundary, absence of direct normal components decreases overall reverberant energy density for the normal incidence. In order to have a relatively uniform energy distribution, it is desirable to locate the acoustic center of sound source perpendicularly from the surface boundary.

In Fig. 8, effects of a distance between the source and the target surface are shown. Provided that the x-coordinate of source locations is fixed to 5.32 m (perpendicularly from the boundary), distances from the surface to the source were changed to 0.01, 0.2, 0.5, and 1 m. The shorter the distance, the more uniform the reverberant acoustic energy is. It can be concluded that the preferable source location for the uniform reverberant energy is the closest possible and perpendicularly from the boundary of the target surface. For a rectangular room, the ideal position does not exist, because all possible locations are found within the boundary of the target surface.

The thick line in Fig. 5 shows the averaged result over 96 equi-spaced source locations in the irregularly shaped room. The averaged result corresponds well with the rectangular room result, shown in Fig. 3. The calculated reverberant energy densities will be used as a weighting factor in computing absorption coefficients from surface impedances.

V. COMPARISONS WITH THE MEASUREMENT

In Fig. 9, an absorption chart in terms of the real and imaginary parts of the impedance is shown when adopting the averaged energy density for the rectangular room. The solid line and the broken line represent the random incidence absorption coefficient and the angle-weighted absorption coefficient, respectively, calculated as follows:

$$\alpha_{\text{infinite,random}} = \int_0^{\pi/2} \alpha_\theta \sin(2\theta) d\theta, \tag{3a}$$

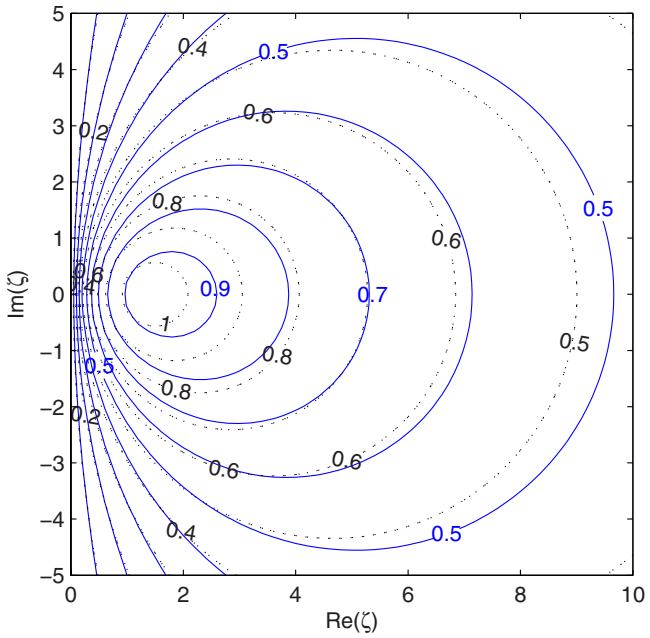

FIG. 9. (Color online) An absorption chart in terms of real and imaginary parts of specific impedance. (——) uniform incidence; (----) angle-weighted.

$$\alpha_{\text{infinite,weighted}} = \int_0^{\pi/2} \alpha_\theta w(\theta) \sin(2\theta) d\theta. \tag{3b}$$

Here, α_θ means the angle dependent absorption coefficient and $w(\theta)$ is the weighting function. According to this chart, if the absorption coefficient is between 0.7 and 0.8, the angle-weighted absorption coefficients are similar to the random incidence absorption coefficients. It is apparent that the maximum random incidence absorption coefficient is less than unity, while the angle-weighted absorption can exceed unity, as in actual reverberation chamber measurements, inside the smallest circle. It should be noted that the result in Fig. 9 cannot be generalized, because the specific weighting function was employed. Moreover, the panel is assumed to be infinitely extended.

It is always necessary to consider the size effect in calculating absorption coefficients. In this study, Thomasson's size correction[18,19] for a finite rectangular panel was adopted. The absorption coefficient for a finite panel is computed using the concept of averaged field impedance as follows:

$$\alpha_{\text{fin}}(\theta) = \frac{4\ \text{Re}(Z_w)}{|Z_w + \bar{Z}_f|^2}. \tag{4}$$

Here, θ is the incidence angle, Z_w is the wall impedance, and $\bar{Z}_f$ is the averaged field impedance over azimuth angle from 0 to 2π expressed as $\bar{Z}_f = 1/2\pi \int_0^{2\pi} Z_f d\phi$. Z_f is the field impedance (sometimes called the radiation impedance) of the wall, which means the impedance of the vibrating surface that radiates sound in the surrounding medium. The field impedance is known as $1/\cos\theta$ for an infinitely large plate; however, the field impedance for a finite sample differs from $1/\cos\theta$, in particular, near grazing incidence.[18,19,30] The field impedance for a finite panel is expressed as follows [see Ref. 18, Eq. (18) and Ref. 19, Eq. (A1)]:

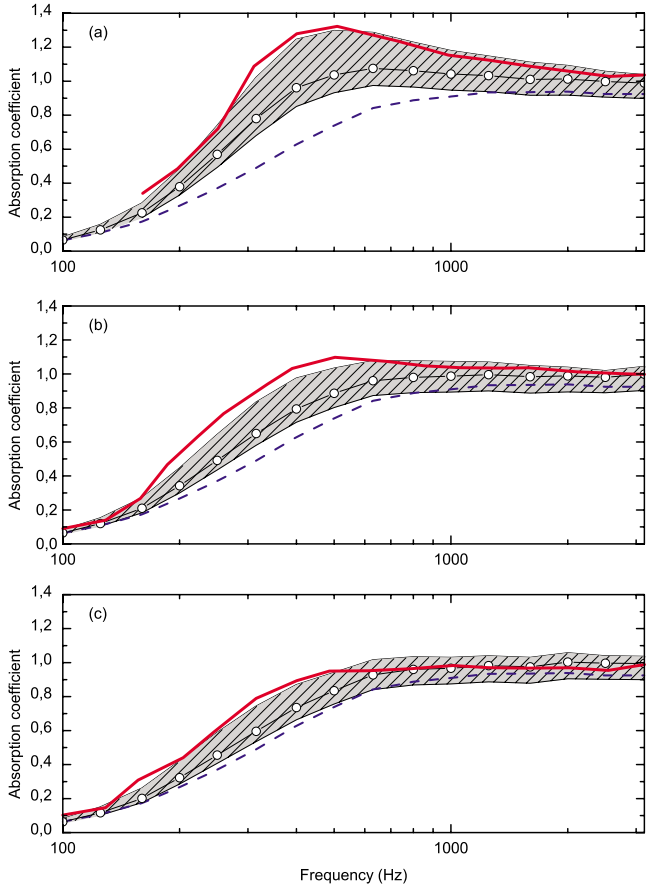

FIG. 10. (Color online) A comparison of absorption coefficient between the reverberation chamber measurement and the angle-weighted value calculated from Z_w. (——) measurement and (—○—) absorption adopting the averaged weighting function. (gray hatched area) Possible range of the angle-weighted absorption coefficient and (– –) random incidence absorption. (a) $e=1.2$ m, (b) $e=2.4$ m, and (c) $e=3.6$ m.

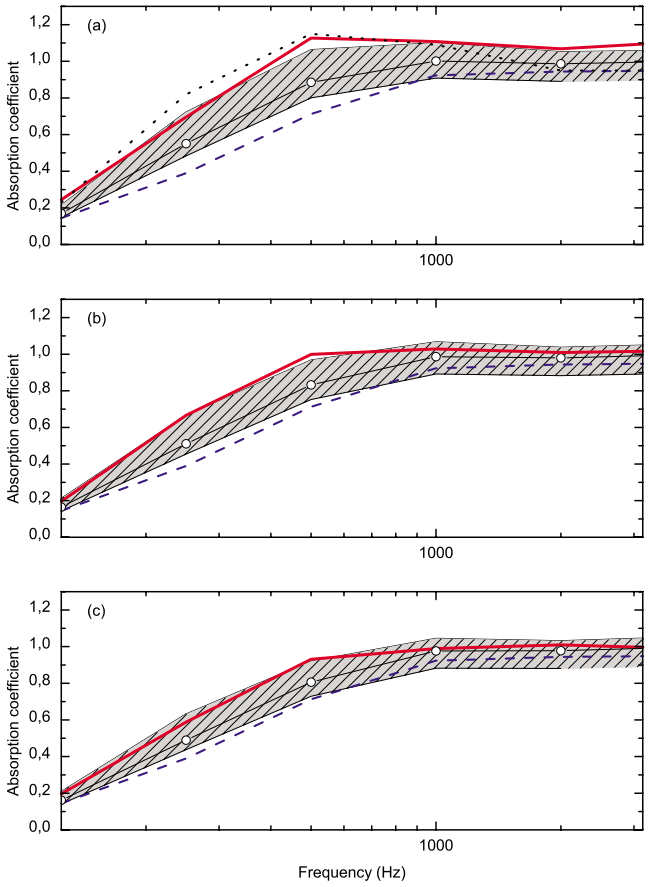

FIG. 11. (Color online) A comparison of absorption coefficient between the reverberation chamber measurement and the angle-weighted value calculated from Z_w. (——) Measurement and (—○—) absorption adopting the averaged weighting function. (gray hatched area) Possible range of the angle-weighted absorption coefficient, (– –) random incidence absorption, and (···) Thomasson's model (Ref. 19). (a) $S=4$ m^2, (b) $S=8$ m^2, and (c) $S=12$ m^2.

$$Z_f = \frac{ik}{S}\int_{S_a}\int\int_{S_a}\int Ge^{ik[\mu_x(x_o-x)+\mu_y(y_o-y)]}dxdydx_ody_o, \quad (5)$$

where k is the wavenumber, $S=\int_{S_a}\int dxdy$, $\mu_x=\sin\theta\cos\phi$, $\mu_y=\sin\theta\sin\phi$, $G=-(2\pi R)^{-1}\exp(ikR)$, and $R=\sqrt{(x-x_o)^2+(y-y_o)^2}$. Consequently the angle-weighted and size-corrected absorption coefficient is calculated as follows:

$$\alpha_{\text{weighted}} = 2\int_0^{\pi/2} w(\theta)\alpha_{\text{fin}}(\theta)\sin(\theta)d\theta$$

$$= 2\int_0^{\pi/2} w(\theta)\frac{4\ \text{Re}(Z_w)}{|Z_w+\bar{Z}_f|^2}\sin(\theta)d\theta, \quad (6)$$

where $w(\theta)$ is the weighting function, which is the angular distribution of energy density by the beam tracing method. The calculated angle-weighted absorption coefficient has been compared with previously published measurements in Figs. 10 and 11. The first absorber consists of 0.05 m thick mineral wool in Thomasson's work.[19] The specific flow resistance and the density of this material were 30 kN s/m^4 and 50 kg/m^3, respectively, and the surface impedance is also taken from Ref. 19. Three kinds of samples were chosen as follows: 1.2×1.2, 2.4×2.4, and 3.6×3.6 m^2. The measured absorption coefficient is the average value from two reverberation chambers with volumes of 190 and 200 m^3, with sufficient diffusion.

The calculated absorption coefficients are shown in Fig. 10 for three different sample sizes. The shaded region denotes a possible range of the angle-weighted absorption coefficient by adopting two limiting angular distributions. The upper curve is obtained by adopting the relatively uniform weighting (for S5 in Fig. 5) and the lower curve is found by adopting the most non-uniform pattern (for S2 in Fig. 5). The hollow circle denotes the angle-weighted absorption coefficient by the averaged weighting function, shown in Fig. 5. Two thick average weighting lines in Figs. 3 and 5 are both similar to a Gaussian distribution. The maximum difference between them is found to be 5% at the normal direction. Because two weighting functions yield nearly the same angle-weighted absorption coefficient, the averaged weighting function in Fig. 5 will be used hereafter. The averaged weighting case can be regarded as a sort of mean value between two limiting absorption coefficients (hereafter, three curves will be named the upper curve, the lower curve, and the averaged weighting, respectively). Large variations in measured data were found depending on sample sizes. In Fig. 10(a), for the smallest sample of edge length (e) of 1.2 m, the maximum value of measured absorption becomes

nearly 1.4. It is apparently due to the size effect, because this kind of overestimation does not occur for the larger two surfaces. One can clearly see that the random incidence absorption from the surface impedance data is far below the measured data. For the smallest sample (a), the measured data correspond well with the upper curve. However, the shaded region becomes narrower, as the frequency increases. When the sample size is four times larger (b), then the measured curve converges to the averaged weighting at high frequencies in Fig. 10(b). Beyond 1 kHz, errors are bounded to 4%. For the largest sample (only this sample is large enough in accordance with ISO 354 specification), the measured curve agrees well with the averaged weighting at frequencies over 800 Hz. One can observe that the measured curve corresponds well with the upper limit value at low frequencies, but the high frequency absorption approaches the averaged weighting case. The three comparisons revealed that the upper curve can be a reasonable guideline at low frequencies.

The second example is the measured data from the second round robin test by Kosten.[11] The material was a rockwool, 5 cm thick, and the density being 100 kg/m^3 (see Ref. 31 for more information, e.g., surface impedance data). Three different surface areas of 4, 8, and 12 m^2 were tested. It should be noted that the measured data are the averaged value over 19 different reverberation chambers all over the world. The degree of diffusion is different from laboratory to laboratory. Dimensions and aspect ratios of samples are not provided. Only the information on sample sizes is given. Samples had different aspect ratios and sometimes different sizes. For example, the surface area varies from 7.5 to 8.25 m^2 for the 8 m^2 sample. Because the author does not have any detailed information on samples, they are regarded as square samples, the edge length e being calculated as $\sqrt{S}$.

Figure 11 shows a comparison between the reverberation chamber measurement and the theoretical angle-weighted absorption coefficient. For the smallest sample in Fig. 11(a), the measured data correspond well with the upper curve, similarly with Fig. 10(a). In this case, Thomasson's model was also compared with the measured data. Thomasson's model[19] seems to agree acceptably below 1 kHz, but it starts to underestimate beyond 1 kHz. In his paper, Thomasson admitted that the deviation at highest frequencies could not be explained. On the other hand, when the proper weighting function is incorporated, the result is improved. It is also observed that the upper curve shows a reasonable guideline at low frequencies and for small size, whereas the averaged weighting agrees well with the measurement for high frequencies and larger samples.

Therefore, a non-dimensionalized parameter, ke, which is multiplication of the wavenumber and the characteristic length of a sample, is introduced to effectively indicate the general trend of the relative errors. A high value of ke means a high frequency and/or a large sample. For small ke, one can see that the upper curves agree well with the measurement. As ke increases, the averaged weighting curve becomes closer to the measurement. The lower curves seem meaningless for all cases, because most of measured absorptions are higher than the angle-weighted absorption coefficient by the averaged weighting function.

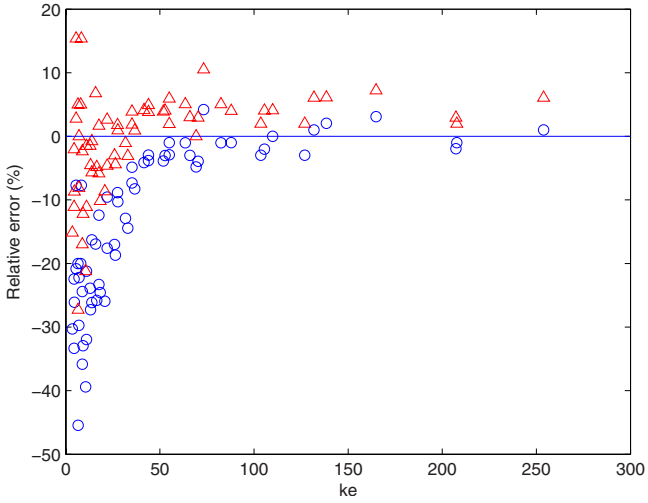

FIG. 12. (Color online) A relative error of the weighted absorption coefficient as a function of ke. (○) Averaged weighting and (△) upper curve.

The relative error of the angle-weighted absorption coefficient is illustrated in Fig. 12. The measured value is used as a reference in defining the relative error. One can see the clear tendency that the error of the averaged weighting function (hollow circle) decreases with increasing ke. The error of upper curve is smaller for low ke, but the error converges to 7% biased from the measurement, as ke becomes higher. One can also observe that the error of the averaged weighting seldom is positive (except five cases), which means the measured value is generally higher than the angle-weighted absorption by the averaged weighting. If ke is higher than 50, the results by the averaged weighting will be acceptable. The upper curve shows smaller errors for low ke, but the error is still too large to be acceptable (the maximum error is 23%). Larger errors at low ke may originate from neglecting diffraction phenomenon in the calculation. It should be mentioned here that the distribution of measured intensity at lower frequency in a reverberant condition is flatter than the intensity distribution at high frequencies in Ref. 15. This fact also supports the better agreement employing the more uniform energy distribution at low frequencies.

It can be summarized that non-uniform energy density can reduce discrepancies between the measured absorption coefficient and the theoretical value when it is taken into account with the size correction. A high value of ke guarantees an acceptable precision by using the averaged weighting, which is similar to a Gaussian distribution.

VI. CONCLUSIONS

The angular distribution of energy density incident on a sample has been simulated for a rectangular room and a reverberation chamber with non-parallel surfaces by using the beam tracing method. A large variation in incident energy density was found depending on the source position. To achieve a uniform distribution, the source should be located perpendicularly from the boundary of the target surface, as close as possible to the target surface. Therefore a room with non-parallel walls is advantageous for obtaining a uniform distribution. A long distance from a source to a target surface

results in a concentration of acoustic energy near the normal direction. The simulated reverberant energy distribution plays the role of a weighting factor in calculating the angle-weighted absorption coefficient. The importance of non-uniform incident energy becomes significant for high ke values. For smaller values of ke, the calculated absorption coefficient adopting fairly uniform distribution agrees well with the measurement, while the averaged Gaussian-like weighting function agrees better with the measurement for high ke.

(Received 11 March 2008; revised 20 January 2009; accepted 20 January 2009)

Teachers often suffer from health problems related to their voice. These problems are related to their working environment, including the acoustics of the lecture rooms. However, there is a lack of studies linking the room acoustic parameters to the voice produced by the speaker. In this pilot study, the main goals are to investigate whether objectively measurable parameters of the rooms can be related to an increase in the voice sound power produced by speakers and to the speakers' subjective judgments about the rooms. In six different rooms with different sizes, reverberation times, and other physical attributes, the sound power level produced by six speakers was measured. Objective room acoustic parameters were measured in the same rooms, including reverberation time and room gain, and questionnaires were handed out to people who had experience talking in the rooms. It is found that in different rooms significant changes in the sound power produced by the speaker can be found. It is also found that these changes mainly have to do with the size of the room and to the gain produced by the room. To describe this quality, a new room acoustic quantity called "room gain" is proposed. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3081396]

I. INTRODUCTION

The primary means of communication in most educational settings are speech and listening. The acoustics of the lecture room can restrict or support the speaker and improve the sound of the voice and the intelligibility of speech. The room acoustics in lecture rooms is therefore an important issue when considering the productivity and working environment in schools and other teaching situations. Thus, a large amount of work has been carried out within this field. However, the large body of published articles focuses on the point of view of the listener. It is therefore easy to find works on speech intelligibility in the room and advisable reverberation times (RTs) and background noise levels (BNLs) in order to achieve good learning conditions, etc., (see, e.g., Bistafa and Bradley[1]). There are also standards and recomendations,[2–4] indicating how well established this field is.

However, it is known that teachers often suffer from health problems or tension related to their voice. Recent works made it evident that the teacher's labor is one of the professions with high vocal demands.[5] Examples of other professions with high vocal demands are actors, singers, journalists, telephone operators, and military personnel. Studies show that a majority of teachers have experienced vocal problems, about one-tenth have severe problems, and 5% have experienced such severe, numerous, and frequent voice problems that their working ability is challenged.[5] For the teacher, in the long run, this voice load due to speaking in the classroom can result in voice disorders such as hoarseness and voice fatigue and can even force teachers to retire early from their profession. Lubman and Sutherland[6] disclosed that this is an important economic problem for governments and private schools.

Most teachers have probably experienced that different rooms vary in comfort when one speaks in them. However, even though the vocal problem is so important, just a few studies about the speaker and his behavior in and impression of the lecture room have been accomplished. One example is Kleiner and Berntson,[7] where the early reflections of the sound produced by the speaker were studied in a synthetic experimental setup. A system of loudspeakers in an anechoic chamber was used to simulate different rooms. All settings simulated rooms with different shapes but the same volume. The interest was in the effect of lateral and vertical early reflections on the speakers' comfort. Different combinations of delayed simulated reflections were tested. A paired-comparison test was used in order to find the setting preferred by the speakers. It was concluded that symmetrical settings were preferred over asymmetrical ones. There was however no significant difference between the different symmetrical settings, and perfectly symmetrical settings are not realistic in real rooms with a movable speaker. It can be noted that this was an entirely subjective study—no objective values were calculated from the simulated impulse responses. Kob *et al.*[8] presented results from a study where the voice status of 25 teachers were investigated using standard methods as applied by audimetrisists, phoniatricians, and speech therapists, in addition to an acoustic analysis of speech and voice samples. The acoustics of some rooms was

[a]Electronic mail: jbr@elektro.dtu.dk

 0001-4966/2009/125(4)/2072/11/$25.00

also investigated, and the result of speaking in different rooms was analyzed dependent on the voice status. The results indicate an influence of both the room acoustics and the voice status on the voice quality of the teachers. But the study used RT and speech transmission index as the parameters describing the room acoustic environment. Thus, no clear distinction was made between the problem perceived by the listener and the speaker.

Several studies in which different voice parameters were measured in real classrooms have been reported, e.g., Rantala *et al.*[9,10] or Jonsdottir *et al.*[11] However, in these studies the influence of the room was not included. Instead, the focus here was to study different subgroups of speakers, e.g., with and without voice problems. The voice parameters were primarly the voice level [defined as the sound pressure level a distance of 1 m from the speaker] and pitch (more specifically the fundamental frequency F_0 of the voice signal) and fluctuations in these parameters.

Thus, the literature relating the room to the speaker and the voice signal produced is rather thin; not much information is available on how to design or improve the room in order to make a better environment for the speaker. However, such information is available in the field of acoustics of rooms for music performance. Also here, the majority of works deal with the conditions for the audience, but there have also been studies concerning how musicians experience and react to the room acoustics. An important example is Gade,[12] who, in a laboratory experiment in an anechoic chamber equipped with a loudspeaker system similar to that of Kleiner and Berntson,[7] let musicians play in and react to simulated sound fields. Gade[13] also carried out corresponding subjective and objective studies in real concert halls. In both cases the subjective response answered by the musicians were correlated with different objective measures. Gade found that the "support" provided by the room—the sensation that the room responds to his instrumental effort—is important for the musicians. Gade defines an objective measure, called *ST*, that correlates well with the sensation of support. *ST* is determined as

$$ST = 10 \log \frac{E_{20-x}}{E_{\text{dir}}}, \tag{1}$$

where E_{20-x} is the energy in the impulse response from 20 ms to x ms (x being either 100 or 200 ms, or even infinity) [see Eq. (2)] and E_{dir} is the energy in the direct path, defined as $E_{\text{dir}}=E_{0-10}$, which is the energy within the first 10 ms. The impulse response is to be measured with a source-receiver distance of 1 m. Obviously, 1 m distance is larger than the typical distance between the musician's ear and his instrument, but this distance was still chosen to obtain a measure with sensible variation and dynamic range. *ST* is thus the fraction of energy coming later than 20 ms relative to the direct sound. In the absence of reflected sound *ST* equals $-\infty$ dB, and a zero support, $ST=0$ dB, means that the total contribution from the reflections equals the direct sound. This definition works well in large rooms where the direct part of the impulse response is clearly separated from the reflections, but measurements of ST is problematic for smaller rooms. Another problem with the definition in Eq. (1) is that it does not clearly reflect what happens close to the source, which at the same time is the position to be studied. In the real situation, e.g., in case of singing or speaking, the source is the mouth and the receiver position is the ear, just a few centimeters away. The direct path is thus described by the transfer function (or impulse response) from the mouth, around the head, to the ear in absence of reflections. How to deal with this is not obvious in case of the definition in Eq. (1). A third problem is that an anechoic chamber is included in the present study, and *ST* is undefined in such a room. Thus, in the present study we have made use of another definition using the measured impulse response of a setup with an artificial dummy head torso and taking as reference the measured value in an anechoic room. The new quantity is called room gain, with abbreviation RG and variable G_{RG} (see Sec. II C).

It seems likely that the vocal problems of teachers are due to the voice level being increased in different situations when teachers feel uncomfortable with the environment. The environment here not only includes the physical environment of the lecture room, but also the students and the overall working conditions. There are two hypotheses here, one being that vocal health problems are related to an environment where the speaker feels that he must increase his voice, the other being that the physical environment itself can cause the speaker to increase his voice. Only the latter will be tested in the present paper. The aim of this project was thus to find some of the parameters that cause the speaker to force their voice and situations when it is uncomfortable to speak.

Aspects not taken into account in this study are the influence of the audience, including the background noise (BN) produced by them, the change in voice during the day, the influence of voice problems of the subjects and other aspects related to the subjects (e.g., mood or attitude toward teaching), and the speech intelligibility in the rooms, subjectively or objectively. Moreover, the study only deals with nonamplified voices.

One question is then which objectively measurable parameters to include in the study. Real rooms are to be used, and the focus is on the speaker, not the listener. Thus, the parameters should be related to what the speaker experiences at the position where he speaks. Parameters related to speech recognition and intelligibility are therefore left out. The impulse response contains all information of the transfer path from source to receiver, and most measures can be calculated from it. It is however important that the source and receiver positions are as correct as possible. Parameters that are extracted from the impulse response are the RT and the RG. Parameters not included in the impulse response are those not directly related to the acoustic transfer path—that is, BN and the size of the room. Thus, four basic parameters are chosen to characterize each room—RT, RG, BNL and *volume*. However, different variants of these parameters were tested as well.

In the subjective study, most of the questions were related to the objective parameters. Thus, the subjects were asked about the impression of reverberation and support, as well as background level in the rooms studied. They were also asked about the general impression of speaking in the

room and if they raised their voice when speaking. A question about echo phenomena was also included in order to be able to say if this parameter influences the general impression of the room.

The main findings in this paper is that the different rooms significantly change the sound power produced by the speaker. It is found that these changes mainly have to do with the size and the RG of the room.

II. METHOD

A. Method overview

Both subjective responses and objective measures of the room and of the voice level are collected. A selection of different natural acoustic environments are used—opposite of using a synthetic sound field. In simulated sound fields the variables can be changed rapidly and with precision in wide ranges. However, the sound quality is still limited due to the need for real time processing of the signals produced by the speaker. Moreover, the visual impression of the room cannot easily be included—this might be a positive aspect in many cases, but here it is important to get the visual size of the room and the distance to the audience right. Therefore, real rooms were chosen to be used—six in total. The range in the physical parameters of the rooms used was wide, including small meeting and listening rooms, a medium size lecture room, two larger auditoria, one with high RT and one with low RT, and a large anechoic room.

In the six rooms the sound power level produced by six speakers was measured. Each of the speakers held a short lecture (about 5 min). Objective room acoustic parameters were measured in the rooms as well, and a subjective questionnaire was handed out to about 20 persons who had experience in speaking in the rooms. A statistical analysis was then used to find relationships between the subjective responses and the objective measures.

B. The subjects

In the objective study six speakers were used. Three of these were teachers at Acoustic Technology, Ørsted*DTU; the other three were students in acoustics. In one of the rooms (meeting room 112, building 352), only five speakers were present. The speakers had no known voice pathology. Each speaker was instructed to give the same lecture in all rooms. However, as the speakers did not have a written text to read, the lectures were not identical. Most speakers used a laptop computer with a Powerpoint presentation as the basis of the speech. In order to get the background level identical, a laptop and a video projector (if available in the room) were present also for those not using it. All speakers were male, age about 20–55. There is a possibility that the speakers do not fully represent all relevant speakers, as it consisted of those finding it interesting to participate. Actually, the teachers participating were known to have weak voices (low voice power). However, most of the analysis are made on a relative voice power level (VPL) (see Sec. II C), which decreases the variance in the data. Another subset problem might be that all subjects were acousticians, a fact that might influence the result—we choose to believe that this has a minor influence only.

In the subjective study 21 subjects participated (between 14 and 21 responses were collected for each room, see Table I). The subjects were teachers and students in acoustics—the participants in the objective part were also present in the subjective part. Both male and female subjects aged between about 20 and 60 participated.

C. Objective measurements and equipment

1. Impulse response measurements

The impulse response $h(t)$ of the rooms is measured to calculate RT and RG. The equipment used for the measurements were power amplifier LAB 300 from LAB Gruppen, microphone unit type 4192-L-001 Brüel & Kjær (B&K), conditioning preamplifier Nexus type 2690 B&K, and sound level calibrator type 4231 B&K. In case of the reverberation measurements, an omnidirectional dodecahedron loudspeaker was used, and in case of the RG measurements a dummy head torso was used, as described below. The DIRAC software[14] was used with e-sweep excitation signal. The sweep length was 21.8 s.

2. Reverberation time

Generally, the most important room acoustic parameter is the RT (variable T_{30}) (see ISO 3382).[15] The *early decay time* (EDT) (variable T_{EDT}), is the RT determined from the first 10 dB range of the decay curve. The EDT is known to be more closely related to the subjective impression of reverberation than RT. In the analysis EDT was mainly used. (A reference of these basic room acoustic parameters is Kuttruff.[16])

The RT is calculated from the impulse response using the Schroeder method.[16] The RTs were calculated in octave

bands. In order to describe the RT as a single number, the arithmetic mean of the RT in the octave bands centered in 500 and 1000 Hz is used.

3. Room gain

The transmission path from the mouth to the ear has three parts: bone conduction, a direct airborne part, and a room reflection part; it is the latter path that is of interest here. The perceived beneficial increase in the loudness caused by the room is assumed to be due to the early reflections as compared to the direct response without reflections, perceived as one's ability to hear oneself properly in the room. This is here denoted as a gain, or support, caused by the room. The parameter used in the present study is called RG (variable G_{RG}). It is defined as the energy (in decibels) of the impulse response measured between the mouth and the ear of a dummy head torso, taking as reference the corresponding measurement in the anechoic chamber where only the direct sound is present. As explained earlier, the reason for not using the support measure *ST* is that small rooms are also to be included in the present study, and then the definition of the *ST* is not appropriate, as the direct part of the impulse cannot be separated from the rest of the impulse response. Moreover, an anechoic chamber is included in the study, and here $ST=-\infty$.

The energy of an impulse response in a time interval t_1 to t_2 can be calculated as

$$E_{t_1-t_2}=\int_{t_1}^{t_2} h^2(t)dt, \tag{2}$$

where $h(t)$ is the impulse response. The energy in the entire impulse response is in the same way,

$$E=\int_0^{\infty} h^2(t)dt. \tag{3}$$

The corresponding impulse energy level is $L_E=10\log E/E_{\mathrm{ref}}$, where E_{ref} is the reference value. The RG is then defined as the energy in decibel in the signal relative to the direct energy as measured in the anechoic chamber,

$$G_{\mathrm{RG}}=L_E-L_{E,\mathrm{ach}}=10\log E/E_{\mathrm{ach}}, \tag{4}$$

where $L_{E,\mathrm{ach}}$ and E_{ach} are the impulse energy level and energy in the anechoic chamber, respectively.

The RG is related to the support *ST*, as defined in Eq. (1). If it is assumed that $E_{\mathrm{dir}}\approx E_{0-20}\approx E_{\mathrm{ach}}$ and $E_{20-x}\approx E_{20-\infty}$, then

$$ST\approx 10\log\frac{E-E_{0-20}}{E_{\mathrm{ach}}}\approx 10\log(10^{G_{\mathrm{RG}}/10}-1). \tag{5}$$

A support value of $ST=0$ thus corresponds to $G_{\mathrm{RG}}=3$ dB, meaning that the reflections contribute with the same energy as the direct sound. It should, however, be noticed that the source/receiver distance is different in the definition of *ST* as compared to G_{RG}.

The equipment used was the same as described under the impulse response above, with the following changes: dummy head, head and torso simulator type 4128 with right ear simulator type 4158 and left ear simulator type 4159 B&K, and power amplifier for the sound source (the dummy mouth).

The dummy head was placed in the area where the speaker normally stands during the lecture (next to the blackboard or similar). The average of six different positions of the dummy head was used. Moreover, the average RG of the left and right channels was calculated and used in the data analysis.

The RG was calculated from the impulse response by means of postprocessing in MATLAB. All signals have been normalized with a maximum amplitude of the signal to 1 (amplitude of the first peak of the impulse response). Some problems with the signals were found during the analysis. Noise was found in all the signals. In order to reduce the effect of this problem, all the impulse response signals were truncated (cutted) so as to avoid the last part of the signal, which mainly contained noise. Thus, the noise effect was minimized, and it is judged that its influence can be disregarded.

The RG was calculated per octave band. In order to define the RG of the room with one characteristic value, the arithmetic mean of the RG in the octave bands between 125 Hz and 4 kHz is used.

4. Background noise level

In a speech situation the BNL (variable $L_{BN,A}$) is important. BNL can be defined as the sound pressure level of the noise measured in the absence of the sound under investigation—in this case the speech. The BN can originate from the ventilation systems, the outdoor environment and traffic, equipment such as computers and projectors, and the students/audience. As the BNL increases, the speaker may increase his voice to compensate and overcome the noise in order to be heard. The voice will be affected by the mental pressure due to the failure of being heard. The frequency content in the voice signal will then be changed—there will be more high frequency content due to an increased fundamental frequency. These changes are known as the Lombard effect; an early reference is Lane and Tranel.[17] The effect is included in ANSI-S3.5.[2] (Sometimes, the term "Lombard effect" is restricted to just the increase.) This is also closely related to the fact that in a situation with several people talking to each other, they increase their voice to overcome the BNL that is produced by all the persons speaking, producing a nonlinear feedback loop, see, e.g., Hodgson *et al.*[18] Naturally, the number of students and their behavior during the lecture also may play an important role here—the students will contribute to the background level and probably react in relation to the Lombard effect. However, this aspect is not part of the present work (due to schedule reasons and time limits); the present project is focused on the characteristics of the room only, leaving this important aspect to further research. The number of listeners present in the room was just a few (3–5) and adult, so there contribution to the BNL is assumed to be low. The BNL naturally present in the rooms (from the ventilation system, video projector, computers, etc.) was, however, registered.

The equipment used to measure L_{BN} is the same as for the impulse response measurements for the reverbation. The measurement duration is 21.8 s. The mean value of six microphone positions have been used in all rooms. The positions were in the area the teacher was using. To get a single value, the A-weighted level $L_{BN,A}$ is used. The equipment used by the speakers (laptop computer and projector) was present in the room during the measurement.

5. Room volume

Of the objective parameters describing the rooms, finally the size or *volume* (variable V) has also been used. The hypothesis here is that the speakers unconsciously adjusts the level of the voice depending on the room size and the distance to the audience, so that everyone is likely to hear. However, it is not clear if it is the volume by itself or a typical length scale in the room that is the primary variable here. Thus, V, $\log V$, and $\sqrt[3]{V}$ were all tested.

6. Voice power level

With the rooms defined, the last step is to define the behavior of the speaker in the room. In this project, this is described by the strength of the speaker's voice. The quantity used here is the *voice power level* (VPL) (variable L_W) that is the source power in decibel. Thus, the sound power level produced during speech by the different test speakers was measured in the different rooms.

The measurement of the VPL is a central issue of this paper. The measurements are made with a computer phone conversation headset, placed on the speaking subjects. The experimenter made sure that the position of the headset was fixed to the same position in all measurements, about 3 cm from the mouth. The equipment consisted of Headset Creative HS-390 and sound analyzer DIRAC. The signals were measured while the speaker was lecturing for about 5 min. An average of 15 signal segments of 21.8 s were used for each subject.

A calibration procedure was needed to transfer the measured signals to sound power level L_W. The dummy head torso equipped with a loudspeaker in the mouth was placed in a reverberation chamber with the headset attached in the same position as described above. A broad band noise signal was fed to the loudspeaker and measured simultaneously by the headset and with microphones in the reverberant field of the room according to sound power level standard measurements (ISO 3743-2). The measurements and calibrations were performed in octave bands. The relation between the sound power of a source and the sound pressure level in one position determined by a microphone can generally be expressed as $L_W=L_p+G$, where G is a gain constant for the setup (depending on the source-receiver distance and source directivity) and L_p is the sound pressure level as measured by the headset. It is now assumed that the microphone is so close to the source that only the direct field is present (i.e., the signal to noise ratio is assumed to be so good that the room response can be neglected). Moreover, it is also assumed that all speakers had the same directivity, equal to that of the dummy head. It is thus assumed that G is constant during all measurements in all rooms. (Note that this quantity obviously is different from G_{RG}.) Finally, having determined both L_W and L_p at the same time in the reverberation chamber, the gain constant G is determined.

The VPL is determined in octave bands from 125 Hz to 4 kHz. In order to have a single value, three different methods are tested: linear ($L_{W,l}$) and A-weighted ($L_{W,A}$) absolute VPL and linear VPL relative to the VPL in the anechoic chamber (ACH), ΔL_W. Note that the subtraction is made for each speaker, so that ΔL_W is made relative to the VPL for that speaker in the ACH. In this way the variance is reduced. The ACH room was chosen as it was the room with the highest average VPL. (The room with the lowest VPL, the meeting room (MR), was also considered to be used as a reference, but this idea was dropped as not all speakers spoke in this room.)

D. The rooms

To get good statistic results, it is important to apply a wide range and even distribution of the different physical variables defining the room. The rooms and the values of the objective measures are given in Table I. The rooms were a small MR and an IEC listening room (IEC), a medium size lecture room (LR), two larger auditoria, one with high RT (A21) and one with low (A81), and a large anechoic room (ACH). Including the anechoic room means that the subjects have a very clear reference for RT and RG—which both are zero in this room. Besides, ACH is relevant as it represents out door surroundings. The range covered by the volume, the RT and the RG can be considered large in comparison to what can be found in real life situations. For the BN, only the naturally present BN was included. Thus, this variation is small as compared to what can be found in real life situations.

E. Questionnaire and subjective response

In an attempt to relate the objective parameters of the room and the VPL to the subjective experience of the rooms, a questionnaire was designed. The questions were formulated after a first interview with a few teachers. The parameters considered are described below.

The questions were answered for each of the rooms in which the subject had experience talking. Thus, the subjects were not necessarily in the room when the questions were answered—in an attempt to increase the number of answered questionnaires. 21 subjects answered the questions; the number of answers for each room varied between 14 and 21 (see Table I). The questions were answered on a scale from 1 to 7. Only the natural numbers were used. Taking the arithmetic average of these answers, a subjective response variable S_i was formed, where the index i is the abbreviation of the question (see below).

The questions are the following (the questions are given in italic fonts)—it should, however, be noted that the these are not exactly the questions used (due to poor English).

Do you consider this room to be good to speak in? This question is referred to the degree of comfort and how easy it is to speak in the room. The rank is between low if the room

TABLE II. Significance test of the subjective response parameters and VPL parameters (different versions) using ANOVA. The following symbols are used: * means significant at the 5% level, *** means significant at the 0.1% level, and — means no significance at the standard levels.

Question	GSI	TR	ECHO	BN	IV	ES	$L_{W,I}$	$L_{W,A}$	ΔL_W
p-value	$<10^{-6}$	$<10^{-6}$	0.046	0.16	$<10^{-6}$	$<10^{-6}$	0.13	0.11	0.036
Significance	***	***	*	—	***	***	—	—	*

is not good to speak in and high if it is good to speak in. This parameter is labeled GSI, variable S_{GSI}.

Do you think the RT is too long in the room? This question clearly refers to the objective parameter of RT. The rank in this case goes from "no" if the reverberation is not too long or "yes" if it is too long. This parameter is labeled TR, variable S_{TR}.

Have you noticed echo phenomena in the room? The sensation of echo might influence the general impression of the room, so this response is introduced even though it is not represented in the objective parameters. The answers should be covered between low if no echo is noticed and high if there is too much echo. This parameter is labeled ECHO, with variable S_{ECHO}. A low score is considered good.

Is the BN too high in the room? The subjects' response might be from "yes" if they think there is a lot of BN in the studied room to "no" if they think that there is no noise in the room. This parameter is labeled BN, variable S_{BN}. A low score is considered good.

Do you have to increase your voice in this room to be heard? This question is interrelated to the sound power level. The answer is between "no" if the subjects think they did not increase the voice, to "yes" if they did have to increase the voice. This parameter is labeled IV, variable S_{IV}. A low score is considered good.

Is there enough support in this room? This has to do with whether the room helps the speaker to hear himself. The rank is between bad support if they believe that the room does not yield support at all and good support if the support is sufficient. This parameter is labeled ES, variable S_{ES}. A high score is considered good.

F. Data analysis

The statistical analysis of the data was carried out in MATLAB. This analysis incorporates analysis of variance (ANOVA), correlation coefficients, and linear regressions.

In order to find relationships between the subjective responses and the objective parameters—a psychometric function—some postprocessing has been done. The psychometric function, relating a subjective parameter S with upper limit $S_{\max}$ and lower limit $S_{\min}$, and an objective parameter d (or a linear combination between such parameters) should be an S-shaped function. The reason for this is that the objective parameter is not bounded, $d \in [-\infty\infty]$, but the subjective parameter is bounded, $S \in [S_{\min}S_{\max}]$. One choice of such a function is

$$S = \frac{S_{\max} - S_{\min}}{1 + e^{-d}} + S_{\min} \tag{6}$$

(this choice of psychometric function is taken from paired-comparison theory[19,20]). The point of using such a relation is that S has a finite domain $S \in [S_{\min} \cdots S_{\max}]$, whereas d might have an infinite domain $d \in [-\infty \cdots \infty]$. In the present case $S_{\max}=7$ and $S_{\min}=1$. Solving for d in Eq. (6), a suitable transformation from the finite S-domain to the infinite d-domain of the objective measures is found,

$$d_S \equiv -\ln \frac{S_{\max} - S}{S - S_{\min}}. \tag{7}$$

The parameter d_S can be used as the dependent variable in regressions connecting objective measures to subjective response.

However, in some cases the objective parameter is nonnegative, $d>0$. That is the case for the RT and the RG. Moreover, in the present study the extreme situation of zero RT and RG is included in the study due to the use of the anechoic chamber. In these cases Eqs. (6) and (7) have to be modified. The following equations then applies:

$$S = \frac{2(S_{\max} - S_{\min})}{1 + e^{-d}} + 2S_{\min} - S_{\max} \tag{8}$$

and

$$d_S \equiv -\ln \frac{S_{\max} - S}{S - 2S_{\min} + S_{\max}}. \tag{9}$$

However, in many cases the range of the objective parameter is so small that the error of using a linear regression directly between d and S is small. That is actually the case in the present study, and in the result section below, the regressions are often performed both using the psychometric function and directly between S and d.

III. RESULTS

A. Validity and quality of the data

An ANOVA is used to examine if the variations in the data are sigificant. The left part of Table II presents these results concerning the subjective parameters. The variations are significant except for BN, where no significant variations are found at the 5% level or better (p-value of 0.16), and for detection of echo ECHO, where the variations are significant at the lower level of 5% (p-value of 0.046), but not higher. It should here be noted that the variation in the background level of the rooms was small and that there are no known problems with echo or flutter echo in the rooms used. In the

TABLE III. The rooms used in the experiments and their objective values.

Abbrev.	$L_{W,l}$ (dB)	$L_{W,A}$ (dB)	ΔL_W (dB)
A81	62.9	60.0	−1.30
A21	63.9	60.9	−0.08
LR	62.9	60.1	−1.93
MR	58.7	55.2	−4.33
ACH	65.0	62.1	0
IEC	59.8	57.0	−4.32

same way, the right part of Table II presents the significance test of different versions of the VPL. Here the significance of the variations in the data is less, probably due to the lower number of subjects participating. However, taking VPL relative to the result in the anechoic chamber, ΔL_W, yields significant variations at the 5% level (p-value of 0.036).

In the further analysis, only $L_{W,l}$ and ΔL_W will be used describing the VPL. $L_{W,A}$ is disregarded as it does not increase the significance much and is not as straightforward as $L_{W,l}$. Moreover, results depending on the subjective responses BN and absolute VPL, $L_{W,l}$, should be considered only as trends.

B. Relationships among objective parameters

The objective parameters used to describe the rooms were presented in Table I. The objective changes in the VPL are presented in Table III. The correlation matrix between these parameters is given in Table IV. It should be noted that the VPL measures correlate well with the volume, especially log V, and the RG G_{RG}. There is no significant correlation between the VPL measures and RT and BN. It should also be noted that the RT measures and the BN measure do not correlate significantly with any other measure.

Note that the correlation between support ST as calculated in Eq. (1) and the other parameters is not included here as the support is undefined in the anechoic chamber due to the lack of reflections (the value would be $-\infty$).

The results of single variable linear regression are found in Table V. Only results with $p<0.1$ are shown. It is shown once again that log V and G_{RG} correlate well with VPL. A multiple linear regression model using these two variables is

TABLE V. Single variable linear regression. Only regressions with $p<0.1$ are shown. Left: between VPL ΔL_W and the objective parameters. Right: between S_{GSI} and the subjective parameters. The variables b_0 and b_1 are the regression constants, the constant term and the linear term, respectively.

Dependent variable	ΔL_W		S_{GSI}	
Independent variables	log V	G_{RG}	S_{IV}	S_{ES}
R^2	0.78	0.74	0.73	0.61
p	0.02	0.03	0.03	0.07
b_1	2.94	−4.40	−0.90	0.72
b_0	−9.64	−0.021	8.30	1.91

$$\Delta L_W = -5.68 + 1.81 \log V - 2.28 G_{\mathrm{RG}}, \tag{10}$$

with $R^2=0.86$ and $p=0.05$. The improvement of using two parameters is described by the fact that R^2 increases from 0.78 to 0.86 and at the same time the model is at the limit of significance. The model is shown in Fig. 1.

C. Relationships among subjective parameters

The subjective response parameters are presented in Table VI. The correlation matrix for these parameters is given in Table VII. Using the objective domain transformation according to Eqs. (7) and (9) yielded similar results.

The results of single variable linear regressions are found in the right part of Table V. Only results with $p<0.1$ are shown. It can be seen that S_{IV} and S_{ES} correlate well with S_{GSI}; these regressions are also shown in Figs. 2 and 3. A multiple linear regression model using these two variables is

$$S_{GSI} = 6.82 - 0.715 S_{IV} - 0.189 S_{ES}, \tag{11}$$

with $R^2=0.74$ and $p=0.13$. Thus, the improvement of the two parameter model was not large, and the model is not significant. This is probably due to a high linear dependency between S_{IV} and S_{ES}.

D. Relationships between subjective and objective parameters

Table VIII shows the correlation between the objective parameters and the subjective responses (the number of objective parameters has been reduced as T_{30} and $\sqrt[3]{V}$ have been

TABLE IV. Correlation matrix for the objective measures, including the VPL. Only correlations with p-values lower than 0.2 are shown. In parentheses: $0.2>p>0.1$; roman upright: $0.1>p>0.05$; italic: $0.05>p>0.01$; boldface: $p<0.01$.

ignored). Using the objective domain transformation according to Eq. (7) and (9) again yields similar results (a slightly better correlation on average).

The results from single variable linear regressions are found in Table IX. Only the regressions with $p<0.1$ are shown. The regression between IV and ΔL_W is shown in Fig. 4, and that between TR and T_{EDT} is shown in Fig. 5. A multiple linear regression model for IV using two variables is

$$S_{IV} = -0.198 + 1.73 \log V - 1.11 G_{\mathrm{RG}}, \tag{12}$$

with $R^2=0.90$ and $p=0.03$. The improvement of using two parameters is described by the fact that R^2 increases from 0.86 to 0.90 while the model is still significant.

IV. ANALYSIS AND DISCUSSION

The ANOVA test in Table II indicates that in general the statistical quality of the subjective data is better than in the VPL data. One reason for this is probably the higher number of participants in the subjective questionnaire (about 20) as compared to the VPL measurements (about 6). However, it is known that it is difficult to get statistically consistent data for the voice strength (see, e.g., Rantala *et al.*[9]). Anyway, in the present study significant variations in the VPL data are found in case of the relative VPL, ΔL_W, using just six subjects. One reason for this is the normalization procedure of the data by taking the value relative to the anechoic chamber. In this way the natural variation in VPL among the subjects is reduced, and only the increments for different rooms are studied. Moreover, using a wide range of different rooms—including the anechoic chamber, large auditoriums, and small meeting rooms—is likely to increase the variation in VPL.

Considering Table IV, room volume and RG show high correlation with the VPL. An increase in volume increases the VPL, and an increase in RG decreases the VPL. These results are significant if considering ΔL_W related to $\log V$ and G_{RG}. Of the size measures, the logarithm of the volume, $\log V$, has the highest correlation. One can regard $V^{1/3}$ to be a typical length scale of the room and $\log V$ to be related to the average sound pressure level in the room for a given source power level. Thus, the fact that the increase in VPL is better correlated to $\log V$ than $V^{1/3}$ suggests that the aural cues might be more important than the visual cues. The VPL relative to the value in the anechoic chamber, ΔL_W, correlates in general better than the absolute linear VPL, $L_{W,l}$. This is probably linked to the fact that ΔL_W has higher significance than $L_{W,l}$ in the ANOVA test in Table II. Equation (10) expresses the relationship between ΔL_W, $\log V$, and G_{RG}, also shown in Fig. 1. In Table VIII there is a trend that ΔL_W is correlated with ES, the question related to support in the room. Moreover, $\log V$ and G_{RG} are correlated to IV, the

TABLE VI. The rooms used in the experiments and their subjective response values. The scale is between 1 and 7. The notation is $\bar{S}/s$, where $\bar{S}$ is the average value and s is the standard deviation. In the further analysis the average value is used then denoted as S.

question if the subject had to increase the voice to be heard. There is also a trend that log *V* and G_{RG} are correlated to ES. These results confirm the results above.

Considering again Table IV, RT and BNL did not show any correlation with the VPL. Both of these results can seem surprising; RT is the generally most frequently used room acoustic measure, and BN is known to increase the speech level in other circumstances, e.g., in connection with the Lombard effect.[18] However, there is an important difference between these parameters in the present study. The variation in the RT data is rather large, T_{EDT} from 0.01 s in the anechoic room to 1.53 s in auditorium 21, but the variation in background level is small, from 41.8 dB (A) in auditorium 21 to 53.5 dB (A) in auditorium 21 (see Table I). "Large" and "small" should be understood as relative to what is normally found in lecture rooms. Moreover, the BNL in the room used was too low to influence speech. It is thus quite likely that a dependency in BN could be found if more extreme values had been included. The same conclusion does not apply for the RT. Moreover, in Table VIII it can be noted that ΔL_W is not correlated with the corresponding subjective responses TR or BN, which confirms the discussion above.

Considering the correlation among the subjective responses (Table VII), it can be noted that the question of whether the room is good to speak in, GSI, is correlated with the question about increase in voice level to be heard, IV. Thus, the ability to make oneself heard is judged to be important in the general judgment of the room. This is confirmed in Table VIII where GSI is correlated with ΔL_W. There is also a trend that GSI is correlated to ES, the question of whether there is enough support in the room. The other questions (TR, ECHO, and BN) do not show any correlation. It can thus be concluded that a room is good to speak in if it has support, and it is not necessary to increase the voice too much.

In Table VII it can also be seen that the question of whether the RT is too long, TR, is correlated to the question of whether there is too much BN (with negative sign due to the orientations of the subjective scales). Moreover, in Table VIII it is found that also T_{EDT} is correlated to BN but L_{BN} is not. This might seem strange. However, it should be remembered here that the questionnaire was not answered at the same time as the measurements, and that the subjects had the option to answer it while being elsewhere. Thus, BN is rather the experience of the BN as they could remember it. The most severe source of BN is probably the students present during the lecture. In the light of the Lombard effect, it is likely that this noise increases with increasing RT. It is thus not so surprising that T_{EDT} turns out to correlate well with BN. Thus, the subjective response BN does not refer to and is not related to the measured BN.

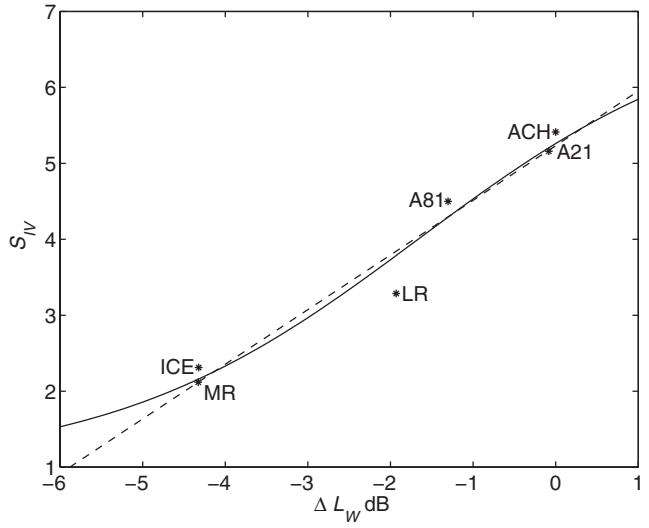

FIG. 4. Regression model between subjective variable S_{IV} (increase voice) against increase in VPL ΔL_W according to Table IX. Room abbreviation according to Table I. Solid line: Using objective domain transformation equation (7). Dashed line: Linear regression.

TABLE VIII. Correlation matrix for the objective and the subjective measures using the subjective scale S. Only correlations with p-values lower than 0.2 are shown. In parentheses: $0.2>p>0.1$; roman upright: $0.1>p>0.05$; italic: $0.05>p>0.01$; boldface: $p<0.01$.

Obj. and subj.	S_{GSI}	S_{TR}	S_{ECHO}	S_{BN}	S_{IV}	S_{ES}
$L_{W,l}$	−0.80	—	—	—	**0.94**	−0.80
ΔL_W	*−0.82*	—	—	—	**0.98**	−0.79
T_{EDT}	—	**0.96**	—	*−0.90*	—	—
V	—	—	—	—	0.79	(−0.65)
$\log V$	(−0.63)	—	—	—	**0.93**	−0.77
L_{BN}	—	(0.65)	0.78	—	—	—
G_{RG}	0.68	—	—	—	*−0.83*	0.80

In Table VII it is also found that there is a trend that the question of whether echo is noticed, ECHO, is correlated to the question of whether there is enough support in the room, ES. This can be interpreted as follows: the reflections that contribute to the RG and support also might be imagined to cause echo phenomena, e.g., flutter echo. However, ECHO does not show big influence on any other parameter and is not correlated with GSI or IV, so it is judged that echo phenomena have not influenced the results. None of the rooms are known to have problems with flutter echo.

In Table VII the question of whether there is enough support in the room, ES, is correlated to the question of whether the subject had to increase the voice to be heard, IV. This seems natural, and it is also reflected in the correlation between ΔL_W and G_{RG} among the objective measurements (Table IV).

The strong correlation between the subjective response of increasing the voice, S_{IV}, and the objectively measured VPL should be noticed in Table VIII. This can be interpreted as the subjects being aware that they have to increase the voice in the room.

In Table VIII T_{EDT} is strongly correlated to TR. Thus, the subjects are aware of the RT. It should then be remembered that all subjects were teachers or students in acoustics and therefore familiar with the concept of RT.

Concerning the frequency rang of RT and RG: the frequency rang used (the octave bands from 125 Hz to 4 kHz for the RG and 500 Hz and 1 kHz octave bands for the RT) has in this study been assumed to be most responsible for the impression of the two measures. Different versions of the parameters have been tested, but not reported, and the chosen definitions and frequency range give good correlation. However, there probably is a need for more research in order to finetune the measures.

Using the regression between ΔL_W and IV (Table IX and Fig. 4), some preliminary design guidelines can be proposed. If a subjective response of $S_{IV} \leqslant 3$ is regarded as a good room, the model yields that this corresponds to $\Delta L_W \leqslant -3.1$ dB. Now, using the model in Eq. (10) (see Fig. 1), this corresponds to $G_{RG} \geqslant 0.80 \log V - 1.1$ dB. Thus, for a room with volume 100 m^3 the RG should be $G_{RG} \geqslant 0.5$ dB, and for a room with volume 1000 m^3 the RG should be $G_{RG} \geqslant 1.3$ dB. It should however be noted that such guidelines are preliminary, and should not be used before further evidence has been obtaind. Also note that the recommended values might be difficult to realize in reality for large auditoriums. Thus, these guidelines are limited to smaller rooms and rooms without voice amplification systems.

V. CONCLUSIONS

The voice power relative to the value in the anechoic chamber varies significantly between room.

The increase in the voice power produced by a speaker lecturing in a room is correlated with the size of the room (especially $\log V$) and the gain produced by the reflections in the room, G_{RG}. These relations are significant.

No significant correlation is found between the increase in the voice power and the RT or background level of the

room in this study. The latter is probably due to the too small variations in the background levels in the rooms studied.

The general impression of whether a room is good to speak in is linked to the impression of whether it is necessary to increase the voice in the room and if the room provides support to the speaker. The former relation is significant, and the latter is only a trend.

There is a significant correlation between the question of whether the subject had to increase the voice and the actual increase in voice power. There is also a significant correlation between the question about the reverberation in the room and the measured RT. This means that the subjects participating were aware of these parameters.

ACKNOWLEDGMENTS

The authors are grateful to the colleagues and students at DTU participating in the study. Most of the practical work presented in this paper were carried out by two students at DTU during their MSc projects, Gaspar Payá Bellester and Lilian Reig Calbo.

A general wave decomposition formula for the measurement of normal incidence sound transmission loss in impedance tube

Yacoubou Salissou[a] and Raymond Panneton
GAUS, Department of Mechanical Engineering, Université de Sherbrooke, Sherbrooke, Quebec J1K 2R1, Canada

(Received 14 October 2008; revised 16 January 2009; accepted 22 January 2009)

Two types of general methods can be found in the literature for the determination of the normal incidence sound transmission loss (nSTL) of acoustical elements. The first one is based on the transfer matrix (TM) approach, and the second one is based on the wavefield decomposition (WD) theory. From all the techniques proposed in the literature, the general TM methods (two-load or two-source location) are the only methods yielding the exact nSTL of an acoustical element without any assumptions on its symmetry and on the termination (i.e., the load). Except for the case of an anechoic termination, there is no method based on the WD theory which yields exact nSTL. This paper presents a general WD method to measure the exact nSTL of an acoustical element without any assumptions on its symmetry and on the termination. Similar to general TM methods for non-symmetrical elements, four microphones and two loads will be required. As a first validation of the method, symmetrical and non-symmetrical porous materials are investigated. Results are discussed and compared with some existing methods and with the classical two-load method. A perfect agreement is found with the classical two-load method.

I. INTRODUCTION

In the past, numbers of methods have been published to measure the normal incidence plane wave sound transmission loss (nSTL) of acoustical elements (i.e. materials, mufflers, expansion chambers, etc.). Some are limited to symmetrical elements, and some are not. Since reciprocity of sound transmission has been proven[1] (at least for linear elements separating identical fluid media), the only assumption that remains is on the symmetry of the element. Since symmetrical elements rarely show a perfect symmetry in terms of its acoustical surface properties[2] (i.e., absorption, reflection or impedance), one would prefer to use a general method which does not assume symmetry.

Two types of general methods can be found in the literature. The first one is based on the transfer matrix (TM) approach, and the second one is based on the wavefield decomposition (WD) theory. A review of some of these methods is given by Tao and Seybert.[3] Following the TM approach, the acoustical element is modeled as a TM. Then, the objective of the approach is to propose an experimental procedure to determine the coefficients of the matrix from which the nSTL will be deduced. On the other hand, the WD theory deals with the complex wavefields upstream and downstream the element. The objective is to conveniently decompose these wavefields in terms of forward and backward propagating waves. From this decomposition, the nSTL can be directly deduced.

The most referred general TM methods are the two-load method proposed by Lung and Doige[4] in 1983, and the two-source location method proposed by Munjal and Doige[5] in 1990. These methods are also referred as four-microphone methods since two microphones are flush mounted on the upstream tube, and two microphones are flush mounted on the downstream tube—the acoustical element being placed between the two tubes. With the two-load method, a loudspeaker is placed at one end (upstream) to generate noise, while sound pressures are measured at the four microphones for two different downstream tube terminations (for example, anechoic, rigid, or open end). With the two-source location method, a unique arbitrary termination is used; however, this time the sound pressure measurements are performed with the loudspeaker mounted at one end, and repeated when the loudspeaker is mounted at the other end. Both methods theoretically give identical results and yield the exact nSTL of the acoustical element. An application of the TM method for the characterization of porous materials using a modified impedance tube was presented by Song and Bolton[6] for symmetrical materials in 2000, and was extended to the evaluation of the nSTL of non-symmetrical materials by Olivieri *et al.* in 2006.[7] However, it is worth mentioning that the latter method is not different to the original two-load method. In fact, Eq. (7) in the paper by Olivieri *et al.*[7] is identical (however, written differently) to Eq. (2) in the original paper by Lung and Doige.[4]

For the WD theory, the most known method was used by Seybert and Ross.[8] This method requires two flush mounted microphones on the upstream tube, and one on the downstream tube. A loudspeaker is placed at the upstream end, and an anechoic termination is assumed at the downstream end. With the two upstream microphones, one can decompose the wavefield upstream the element in terms of an incident wave (A) and a reflected wave (B). With the anechoic termination assumption, the downstream microphone di-

[a]Electronic mail: yacoubou.salissou@usherbrooke.ca

rectly measures the sound pressure of the transmitted wave (C). From the ratio (C/A) between the transmitted and incident pressures, the nSTL can be deduced. The main limitation of the method is due to the anechoic termination. In fact, constructing a fully anechoic termination is difficult. Consequently, a part of the transmitted wave is reflected by the termination, and multiple forward and backward reflections occur in the downstream tube. To attempt eliminating this problem, Chung and Blaser[9,10] also used a decomposition in the downstream tube using two flush mounted microphones. The decomposition yields one wave (C) propagating toward the termination and one wave (D) propagating back to the element to test. Again, from ratio C/A, they deduced the nSTL. This approach is not exact since wave C is not equal to the first transmitted wave. In fact, C is equal to the sum of the first transmitted wave (the only one existing in the case of an anechoic termination) and all the multiple back reflected waves propagating in the direction of the termination. In this case, the only situation where ratio C/A yields the exact nSTL is again when the termination is fully anechoic. If the termination is not fully anechoic and the back surface of the element to test is relatively absorbing (i.e., the dominating waves in the downstream tube are only the first transmitted wave and its first reflection on the termination), the Chung and Blaser four-microphone method gives a better estimation than the Ross and Seybert three-microphone method which assumes a fully anechoic termination. A downstream description similar to the one used by Chung and Blaser was also applied to the TM approach by Bonfiglio and Pompoli.[11] In their hybrid WD-TM method, only a single four-microphone measurement is required (i.e., the method only requires one load). Even if the symmetry assumption is used, their method compares well with the original two-load method for non-symmetrical elements. As previously mentioned, the method should work until the back surface of the element to test is relatively absorbing (this point will be shown in this paper). Finally, it is worth mentioning that some previous studies in the literature also showed that only the two-load methods can provide reliable value of nSTL.[12]

From this brief literature review, if the termination is not fully anechoic and the acoustical element is not symmetrical, or not fully symmetrical, the general four-microphone TM methods (two-load or two-source location) are the only methods yielding the exact nSTL. For this general situation, there exists no equivalent WD method yielding the exact nSTL. It is worth mentioning that recent attempts to generalize the WD method were published;[13,14] however, at the theoretical level, some discussions remain (they will be underlined later on in this paper).

The objective of this paper is to develop a general WD method to measure the exact nSTL of an acoustical element without any assumptions on its symmetry and on the termination. Similar to the general TM methods for non-symmetrical elements, four microphones and two loads will be required. The challenge is to use a proper theoretical description to finally retrieve the exact nSTL.

This paper is structured as follows. Section II presents the theoretical developments behind the proposed wave decomposition method. Section III tests the method using a transmission tube on symmetrical and non-symmetrical materials, and studies the effects of the terminations. Also, it compares the proposed method to other existing methods. Finally, Sec. IV draws conclusions on this work.

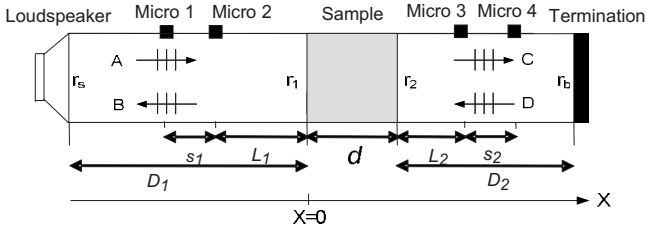

FIG. 1. Schematic view of the experimental setup.

II. THEORY

A schematic view of the impedance tube used to measure the nSTL is shown in Fig. 1. This apparatus consists of a finite-length rigid walled impedance tube with circularly shaped and uniform inner cross-section. At one end, the tube features a loudspeaker, and at the other end, the tube can be fitted with an arbitrary termination condition. The loudspeaker is used to generate a plane wave field in the impedance tube. There are two microphones flush mounted upstream the sample and two microphones flush mounted downstream the sample.

For this setup, Ho *et al.*[13] proposed an improved WD method which takes explicitly into account the multiple wave reflections in the upstream and downstream tubes. The method was limited to symmetrical acoustic systems. Using the symmetry property, Ho *et al.* assumed that the reflection coefficient (r_1) of the front surface of the sample is equal to the one of its back surface (r_2). This assumption is too restrictive since the reflection coefficient is a global surface indicator which also depends on the condition behind the sample. For instance, on the upstream side there is an air cavity with a loudspeaker, and on the downstream side there is an air cavity with an arbitrary termination. Therefore, even though the material is symmetrical, the reflection coefficient of an incident plane wave impinging its front face is different from the one of an incident plane wave impinging its back face (i.e., $r_1 \neq r_2$). A similar restrictive assumption seems to be used also by Dong-Li *et al.*[14] [for example, see Eqs. (5) and (10) in Ref. 14].

Based on the work by Ho *et al.*,[13] under steady state harmonic condition, and eventually making no assumption on the reflection coefficients, the total wave propagating toward the sample in the upstream tube can be explicitly written as

$$p_u^a(x) = ae^{-jk_0x}(1 + r_1r_se^{2jk_0D_1} + (r_1r_s)^2e^{4jk_0D_1} + \cdots)$$
$$= \frac{ae^{-jk_0x}}{1 - r_1r_se^{2jk_0D_1}}. \quad (1)$$

The first term in Eq. (1) is the wave just emitted by the loudspeaker, the second term is the wave reflected by the sample and the loudspeaker while traveling the entire length of the front tube twice, the third term is the second wave

reflected by the sample and the loudspeaker while traveling the entire length of the front tube four times, and so on. The final result is the sum of an infinite number of these multiple reflections

Similarly, the total wave traveling away from the sample in the upstream tube can be explicitly written as

$$p_u^b(x) = ar_1 e^{jk_0 x}(1 + r_1 r_s e^{2jk_0 D_1} + (r_1 r_s)^2 e^{4jk_0 D_1} + \cdots) = \frac{ar_1 e^{jk_0 x}}{1 - r_1 r_s e^{2jk_0 D_1}}. \quad (2)$$

Here, it is worth commenting on the nature of the steady state harmonic condition. Under this steady state condition, if one tries interpreting the first term in Eq. (2), it has to be seen as the first incident wave reflected by the sample which is backed by the downstream tube and its termination. With two microphones flush mounted on the upstream tube, this reflection coefficient r_1 is readily obtained using the transfer function method [ASTM E1050-98 (Ref. 15) or ISO 10534-2:1998 (Ref. 16)]. Consequently, this first reflected term implicitly takes into account all the multiple reflections of the first incident wave taking place in the sample and in the downstream tube. This would not be true, if the observations were done in the time domain. The aforementioned comment is also valid for all the terms in Eqs. (1) and (2), and for all the equations below.

Adding up Eqs. (1) and (2), the total sound pressure field in the upstream tube is given by

$$p_u(x) = \frac{a}{1 - r_1 r_s e^{2jk_0 D_1}}(e^{-jk_0 x} + r_1 e^{jk_0 x}). \quad (3)$$

With the origin fixed at the front surface of the sample, one easily finds that the total incident sound pressure at $x=0$ is $a/(1-r_1 r_s \exp(2jk_0 D_1))$. This incident wave is attenuated as it goes through the sample by the complex sound transmission coefficient t. On the rear face, the incident pressure is now $[a/(1-r_s r_1 \exp(2jk_0 D_1))]t$. Treating this term as the sound source in the downstream tube, and following the same approach as in the upstream tube, the total pressure field in the downstream tube is

$$p_d(x) = \frac{a}{(1 - r_1 r_s e^{2jk_0 D_1})(1 - r_2 r_b e^{2jk_0 D_2})}(e^{-jk_0 x} + r_b e^{jk_0 x})t. \quad (4)$$

Contrary to Ho *et al.*,[13] the reflection coefficient r_2 in Eq. (4) is not assumed equal to r_1. In fact, r_2 is the reflection coefficient seen by x-negative propagating waves in the downstream tube, and r_1 is the reflection coefficient seen by x-positive propagating waves in the upstream tube. Since D_1 is not necessarily equal to D_2, and the reflection coefficient of the loudspeaker (r_s) is not equal to the one of the termination (r_b), it is clear that r_1 and r_2 will never be equal, even though the sample is symmetrical.

Equations (3) and (4) are now used to evaluate the sound pressures at microphones 1–4. They are, respectively, given by

$$p_1 = \frac{a}{1 - r_1 r_s e^{2jk_0 D_1}}(e^{jk_0(L_1+s_1)} + r_1 e^{-jk_0(L_1+s_1)}), \quad (5)$$

$$p_2 = \frac{a}{1 - r_1 r_s e^{2jk_0 D_1}}(e^{jk_0 L_1} + r_1 e^{-jk_0 L_1}), \quad (6)$$

$$p_3 = \frac{a}{(1 - r_1 r_s e^{2jk_0 D_1})(1 - r_2 r_b e^{2jk_0 D_2})}(e^{-jk_0 L_2} + r_b e^{jk_0 L_2})t, \quad (7)$$

$$p_4 = \frac{a}{(1 - r_1 r_s e^{2jk_0 D_1})(1 - r_2 r_b e^{2jk_0 D_2})} \times (e^{-jk_0(L_2+s_2)} + r_b e^{jk_0(L_2+s_2)})t. \quad (8)$$

Defining the transfer function between microphones 1 and 2 by $H_{12}=p_1/p_2$, and substituting p_1 and p_2 with Eqs. (5) and (6), respectively, the reflection coefficient of the sample on the loudspeaker side can be expressed in terms of the transfer function as

$$r_1 = \frac{H_{12} - e^{jk_0 s_1}}{e^{-jk_0 s_1} - H_{12}} e^{2jk_0 L_1}. \quad (9)$$

Similarly, defining the transfer function $H_{43}=p_4/p_3$ and using Eqs. (7) and (8), the reflection coefficient of the termination can be expressed as

$$r_b = \frac{H_{43} - e^{-jk_0 s_2}}{e^{jk_0 s_2} - H_{43}} e^{-2jk_0 L_1}. \quad (10)$$

Finally, from Eqs. (6) and (7), the transfer function between microphones 3 and 2 is given by

$$H_{32} = \frac{p_3}{p_2} = \frac{1}{1 - r_2 r_b e^{2jk_0 D_2}} \frac{e^{-jk_0 L_2} + r_b e^{jk_0 L_2}}{e^{jk_0 L_1} + r_1 e^{-jk_0 L_1}} t. \quad (11)$$

In this equation, one can note that the transmission coefficient t and reflection coefficient r_2 are the only remaining two unknowns. If one needs to determine the transmission coefficient, the reflection coefficient needs first to be found. The reflection coefficient r_2 can be obtained by changing the termination of the tube (second load). Indeed, using a termination with a different reflection coefficient r_b' will change the reflection coefficient of the sample on the loudspeaker side to r_1'. However, since the upstream tube remains unaffected by this operation, the reflection coefficient r_2 remains unchanged. For the second load, the modified reflection coefficients are

$$r_1' = \frac{H_{12}' - e^{jk_0 s_1}}{e^{-jk_0 s_1} - H_{12}'} e^{2jk_0 L_1}, \quad (12)$$

and

$$r_b' = \frac{H_{43}' - e^{-jk_0 s_2}}{e^{jk_0 s_2} - H_{43}'} e^{-2jk_0 L_2}, \quad (13)$$

where H_{12}' and H_{43}' are, respectively, the new transfer functions between microphones 1 and 2 ($H_{12}'=p_1'/p_2'$), and microphones 4 and 3 ($H_{43}'=p_4'/p_3'$) under the second load condition. For this second load, the new transfer function between microphones 3 and 2 is given by

$$H'_{32} = \frac{p'_3}{p'_2} = \frac{1}{1 - r_2 r'_b e^{2jk_0 D_2}} \frac{e^{-jk_0 L_2} + r'_b e^{jk_0 L_2}}{e^{jk_0 L_1} + r'_1 e^{-jk_0 L_1}} t. \quad (14)$$

Introducing the parameters

$$h = H_{32}/H'_{32}, \quad (15)$$

and

$$r = \frac{e^{-jk_0 L_2} + r_b e^{jk_0 L_2}}{e^{-jk_0 L_2} + r'_b e^{jk_0 L_2}} \frac{e^{jk_0 L_1} + r'_1 e^{-jk_0 L_1}}{e^{jk_0 L_1} + r_1 e^{-jk_0 L_1}}, \quad (16)$$

one can deduce from Eqs. (11) and (14) the reflection coefficient of the sample on the downstream side

$$r_2 = \frac{r - h}{r r'_b - h r_b} e^{-2jk_0 D_2}. \quad (17)$$

Finally, using Eqs. (17) and (11), the transmission coefficient and the nSTL of the sample can be expressed, respectively, as

$$t = H_{32}(1 - r_2 r_b e^{2jk_0 D_2}) \frac{e^{jk_0 L_1} + r_1 e^{-jk_0 L_1}}{e^{-jk_0 L_2} + r_b e^{jk_0 L_2}}. \quad (18)$$

and

$$\text{nSTL} = -20 \log(t). \quad (19)$$

III. EXPERIMENTAL TESTS

The six transfer functions (H_{12}, H_{43}, H_{32}, H'_{12}, H'_{43}, and H'_{32}) are measured similarly to the standard transfer function method[15] using a homemade impedance tube. The diameter of the tube is 44.5 mm and its validity range is from 300 to 4200 Hz. The other parameters of the setup shown in Fig. 1 are $D_1 = 190$ mm, $D_2 + d = 362$ mm, $s_1 = 25$ mm, $s_2 = 25$ mm, $L_1 = 45$ mm, and $L_2 + d = 271$ mm. A dual-channel fast Fourier transform analyzer and two 1/4 in. microphones are used to conduct measurements successively in pairs (1-2, 3-2, 4-3) at the four locations. Implementation of a four-microphone measurement is also possible to reduce measurement time. Random noise using a Hanning window and an averaging over 100 measurements are used. The standard sensor switching technique was used to compensate the microphone phase and amplitude mismatch.

Two symmetrical and two non-symmetrical materials are used for these experimental tests. For each sample, four different termination combinations are tested to determine the nSTL: rigid-anechoic, rigid-absorbent, absorbent-absorbent, and anechoic-absorbent. Three different absorbents are used. Absorbent 1 is a 22-mm-thick floor material made of porous recycled foams backed by a rigid end cap. Absorbent 2 is a 15-mm-thick car headliner foam backed by a rigid end cap. Absorbent 3 is a 25-mm-thick melamine foam backed by a rigid end cap. The rigid termination is the rigid end cap alone. The anechoic termination is a 200-mm conical block of melamine foam backed by the rigid end cap. The measured reflection coefficient amplitudes of the five possible terminations are shown in Fig. 2. The reflection coefficient of the rigid termination is 97%–99% instead of its ideal value of 100%. This deviation may be attributed to some energy dissipation in the viscous and thermal skin layers of the tube, and to uncertainties on the exact location of the acoustic centers of the microphones. The reflection of the absorbing ("anechoic") termination ranges from 70% at low frequencies to 5% at high frequencies. This represents a significant deviation from its ideal value of 0%. Finally, one can note that the reflection coefficients of the two Absorbents 1 and 2 are close for frequencies lower than 2000 Hz.

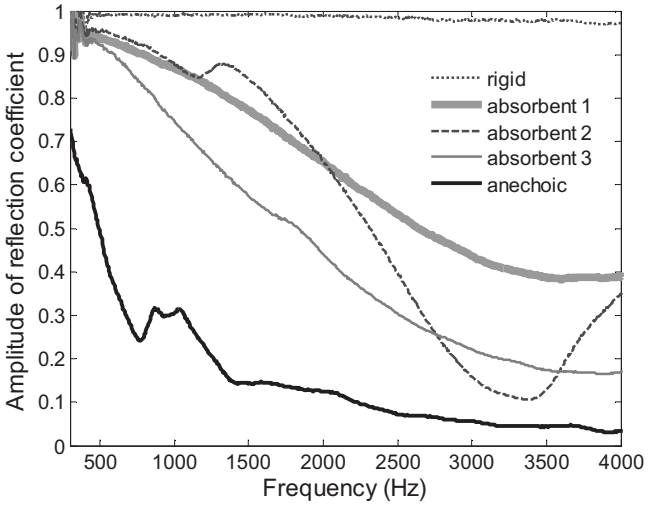

FIG. 2. Amplitudes of the reflection coefficient of the five termination loads which can be used in the measurements of the normal incidence sound transmission.

A. Symmetrical materials

The first tested symmetrical material is a 25-mm-thick melamine foam. The second symmetrical material is a 15-mm-thick car headliner. The relative difference curves on the amplitude of the surface impedance of each of those materials are plotted in Fig. 3. From these curves and according to the symmetry criterion presented elsewhere by the authors,[2] both materials can be considered symmetrical in terms of their acoustical properties.

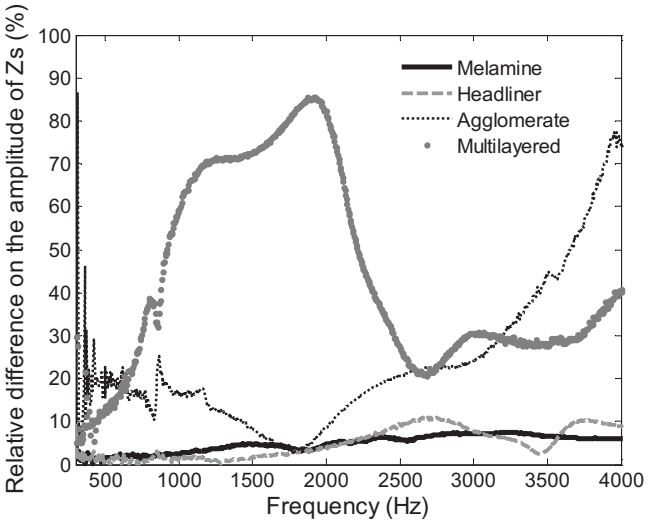

FIG. 3. Relative difference on the amplitude of the surface impedance (Z_s) of the tested samples.

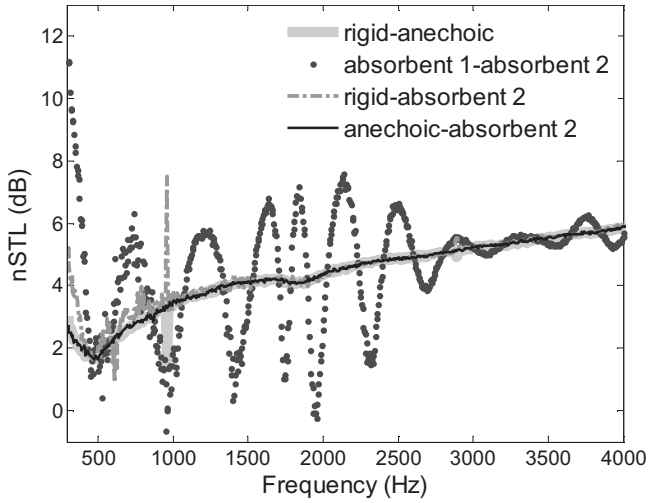

FIG. 4. nSTL of a 25-mm-thick melamine foam measured using the proposed WD method with four different load combinations.

1. Melamine foam

Using the developed method, the measured nSTLs of the melamine foam for four combinations of two loads are shown in Fig. 4. Note that the absorbing loads used in this characterization are absorbents 1 and 2. As one can note, all combinations of two loads provide similar results, except for the combination of the two absorbents. Indeed, in order to have a better result, one needs to choose a combination of two loads with very different reflection properties. This condition is only achieved with the three other load combinations. Also, for the combinations using the rigid end, one can note a singularity around 1000 Hz corresponding to the resonance frequency. To avoid this resonance, a termination combination made of anechoic-absorbent or two absorbents with different reflection coefficients should be chosen.

Next, the results obtained from the proposed method and those obtained from several existing four-microphone methods (see Ref. 17) are compared in Fig. 5. For the methods using two loads, the load combination absorbent 1-anechoic was used. For the methods using one load, the anechoic load was used. Since all the tested methods use the same four microphones, the same set of pressure measurements were used to feed these methods. Consequently, equivalent methods should yield identical results.

In Fig. 5(a), one can note that the proposed two-load WD method and the classical two-load TM method by Lung and Doige[4] yield the same (identical) results. This proves that the aforementioned theoretical development seems general as expected. In contrast, the one-load WD method by Ho *et al.*[13] appears to be inaccurate [see Fig. 5(b)]. Indeed, the result from this method exhibits a periodic fluctuation. The fluctuation is due to the fact that Ho *et al.* assumed that $r_1 = r_2$ for a symmetrical material. As pointed out previously, even though the material is acoustically symmetrical, r_1 is not necessarily equal to r_2 since the conditions upstream and downstream the sample are different. Note that this error will increase as the amount of incident power backward the sample increases. This justifies the need of an anechoic end in order to apply this approximated method. At high frequencies (>3000 Hz), the partially anechoic end used in this work almost behaves as a fully anechoic termination, with a reflection coefficient amplitude less than 0.1 (see Fig. 2). As a result, the fluctuation almost disappears in this frequency range and the approximated nSTL overlaps with the one obtained from the proposed general WD method.

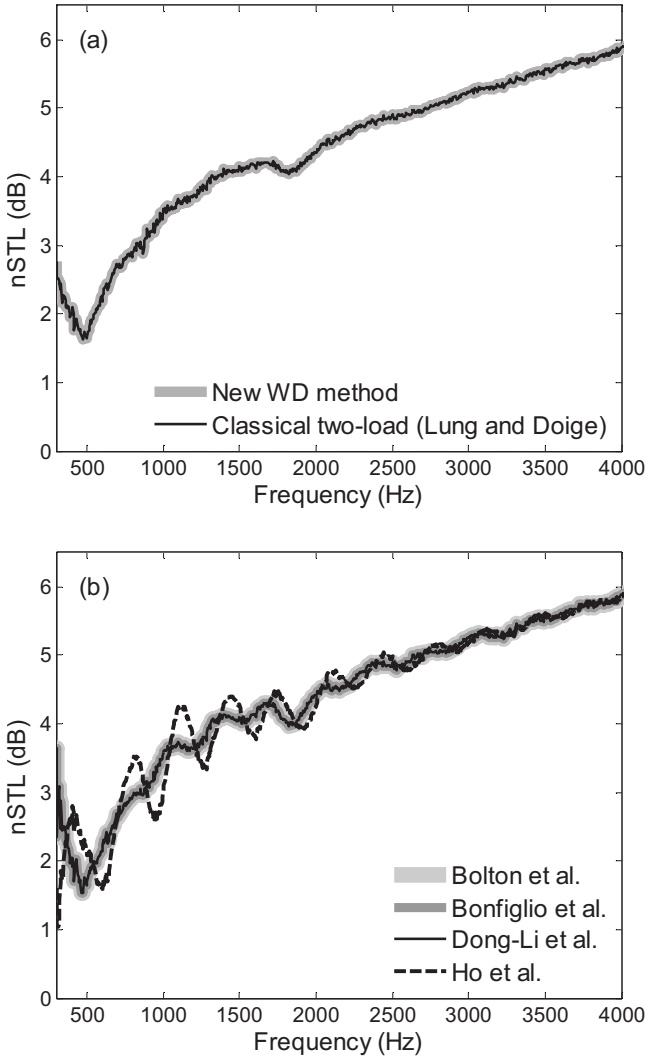

FIG. 5. Measured nSTL of a 25-mm-thick melamine foam. Comparison between the different four-microphone methods. (a) Two-load methods. (b) One-load methods. The two-load methods use the absorbent 1-anechoic load combination. The one-load methods use the relatively anechoic load.

The TM method by Song and Bolton,[6] the hybrid WD-TM method by Bonfiglio and Pompoli,[11] and the WD method by Dong-Li *et al.*[14] are compared in Fig. 5(b). All three methods are one-load methods and yield similar (identical) results. This is logical since the material is absorbing and symmetrical, and all three methods take into account (but differently) the transmitted and transmitted-reflected waves in the downstream segment. However, compared to the results obtained with the proposed method and the classical two-load method in Fig. 5(a), the one-load methods show slight fluctuations. These fluctuations are mainly due to the fact that higher order reflected waves in the downstream tube are not considered by these one-load methods, and/or

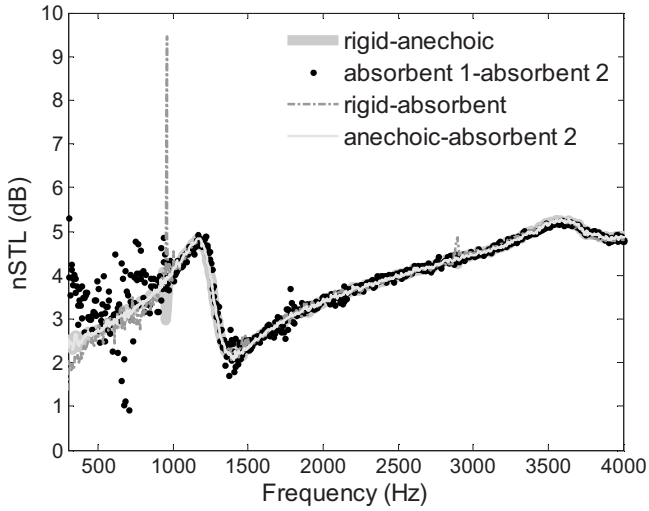

FIG. 6. nSTL of a 15-mm-thick car headliner foam measured using the proposed WD method with four different load combinations.

the material is not fully symmetrical (see Fig. 3). However, those fluctuations are minor compared to those obtained with the WD method by Ho *et al.*[13]

2. Headliner foam

For this sample, the absorbing loads used in the nSTL characterizations are absorbents 1 and 3. The measured nSTLs for the headliner are shown in Fig. 6. The same comments on the effects of the termination combination can be done. Again, the results are in good agreement. For the load combinations using the rigid end, the singularity around 1000 Hz is still observed. Because of the more significant difference between the reflection coefficients of the two absorbents used in combination, the corresponding result is more accurate. However, one can note a relative dispersion at low frequencies. This corresponds to the range in which the reflection coefficients of the two absorbents are close. In Fig. 7, the result from the proposed method is compared to those obtain from the other two-load and one-load methods. Analyzing those results yield exactly the same conclusions previously obtained.

B. Nonsymmetrical materials

The first tested non-symmetrical sample, referenced as multilayer 1, is a 20-mm-thick multilayer made of a thick layer of rigid closed-cell polyurethane foam in sandwich between two thin impervious paper films. The second non-symmetrical sample, referenced as multilayer 2, is a 20-mm-thick multilayer made of a thick layer of rigid closed-cell polyurethane foam in sandwich between one thin paper film and one thin impervious aluminum film. The relative difference curves on the amplitude of the surface impedance of each of these multilayered panels are also plotted in Fig. 3. As expected, according to the symmetry criterion presented elsewhere by the authors,[2] these multilayered samples are clearly non-symmetrical in terms of their acoustical properties, mostly the second multilayer. Their nSTLs are measured using the termination combination made of absorbent 1 and the partially anechoic end. The results are plotted in Fig.

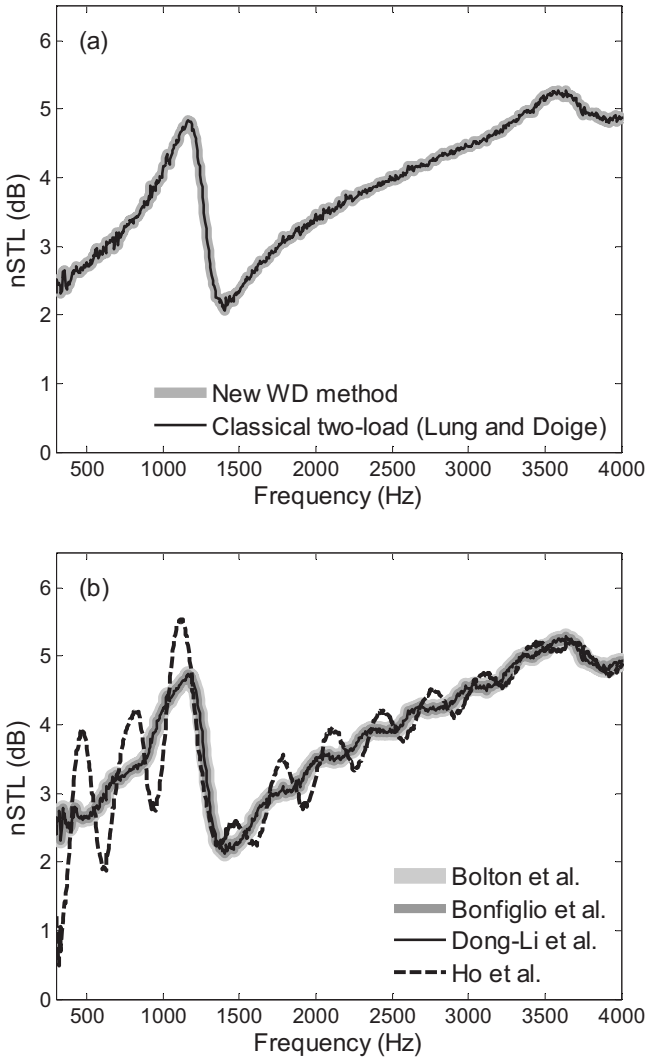

FIG. 7. Measured nSTL of a 15-mm-thick car headliner foam. Comparison between the different four-microphone methods. (a) Two-load methods. (b) One-load methods. The two-load methods use the absorbent 1-anechoic load combination. The one-load methods use the relatively anechoic load.

8. Again, both the proposed method and the classical two-load method[4] yield similar results for both asymmetrical multilayers [see Figs. 8(a) and 8(c)]. However, for all the one-load methods, the fluctuations are more important than those observed in Fig. 5 for the symmetrical materials. The fluctuations are of similar magnitudes for both multilayers, even if multilayer 2 is much more asymmetrical than multilayer 1. This proves the fluctuations are mostly attributed to the higher order reflections in the downstream tube which are not correctly modeled with the one-load methods. These higher order reflections are more important since the back surfaces of the multilayers are reflective and not absorbing as for the melamine and headliner foams.

IV. CONCLUSION

In this paper, based on the work by Ho *et al.*,[13] a general two-load WD method to measure the nSTL of an acoustical element without any assumptions on its symmetry and on the termination has been presented and discussed. Comparisons with the classical two-load TM method by Lung and Doige[4]

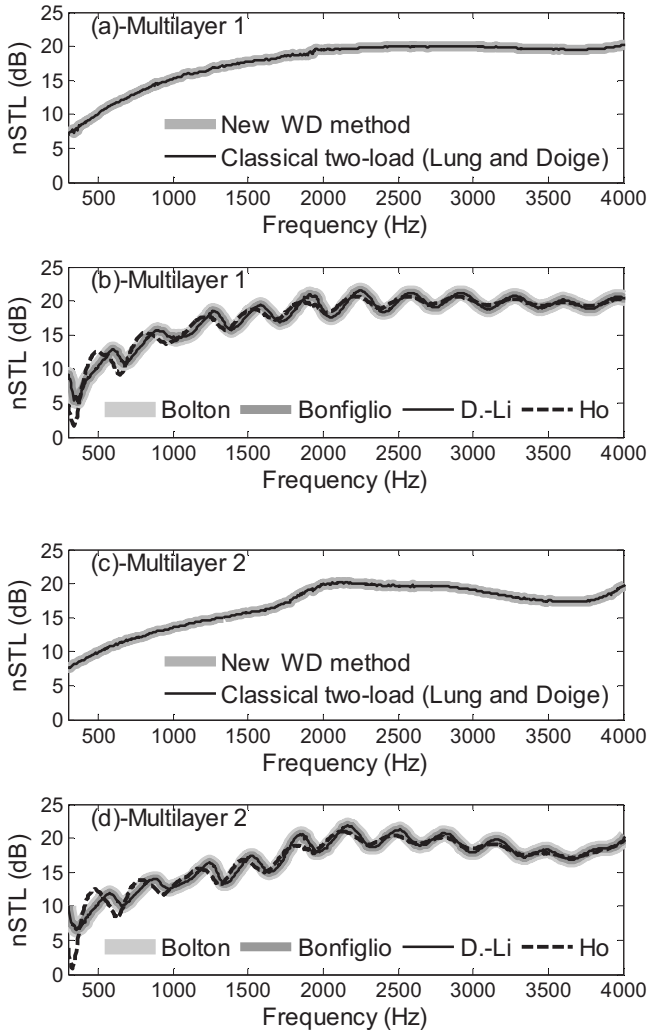

FIG. 8. Measured nSTL of the two asymmetrical multilayers. Comparison between the developed new WD method and the classical two-load method for (a) multilayer 1 and (c) multilayer 2. Comparison between the one-load methods for (b) multilayer 1 and (d) multilayer 2.

showed that the proposed method yields identical results. With a view to obtain accurate results, it was shown that one needs to use two loads of relatively different reflection coefficients. The ideal load combination can be made from a partially anechoic termination and an absorbing material, or from two absorbing materials with different reflective properties.

Also, it was shown that the recent one-load methods yield similar results, and may yield to fluctuating transmission loss curves when applied to asymmetrical acoustical elements having a reflective back surface. The fluctuation is less important if the back surface of the elements is absorbing in view to minimize the effects of the higher order reflections in the downstream tube.

Finally, it is worth emphasizing that the determination of the nSTL of an arbitrary acoustical element requires necessarily (at least at this time and until evidence of the contrary) four microphones and two loads (or two-source locations). The one-load methods remain approximated methods which can work well in many cases; however, since all cases are not tested yet, these methods must be used with cautions. Their main advantage is that they only use one set of measurements, making their implementation twice less time consuming than the general four-microphone methods.

A realization of sound focused personal audio system using acoustic contrast control

Ji-Ho Chang,[a] Chan-Hui Lee,[b] Jin-Young Park,[c] and Yang-Hann Kim[d]
Department of Mechanical Engineering, Center for Noise and Vibration Control, Korea Advanced Institute of Science and Technology, Science Town, Daejeon 305-701, Korea

(Received 6 May 2008; revised 21 January 2009; accepted 24 January 2009)

A personal audio system that does not use earphone or any wire would have great interest and potential impact on the audio industries. In this study, a line array speaker system is used to localize sound in the listening zone. The contrast control [Choi, J.-W. and Kim, Y.-H. (2002). J. Acoust. Soc. Am. **111**, 1695–1700] is applied, which is a method to make acoustically bright zone around the user and acoustically dark zone in other regions by maximizing the ratio of acoustic potential energy density between the bright and the dark zone. This ratio is regarded as acoustic contrast, analogous with what is used for optical devices. For the evaluation of the performance of acoustic contrast control, experiments are performed and the results are compared with those of uncontrolled case and time reversal array. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3082114]

I. INTRODUCTION

Recently personal devices such as desktops, laptop computers, portable multimedia player, and cellular phones are widely used. The users listen to sound from the devices by earphones or loudspeakers, but it induces some troubles; earphones are not only burdensome to wear but also uncomfortable to use for a long time, and loudspeakers make sound that others do not want to hear.

A personal audio system that uses loudspeakers but focuses sound only around the user can solve these problems of earphones and loudspeakers. In this study, we propose a system to localize sound only around the user by using a line array of control sources. That is, the objective of this study is to increase acoustic potential energy only in a zone including the user but to reduce in the other zone by controlling the input signals, which are fed into control sources. In order to realize it, we apply the previous research on acoustic contrast control.[1]

There are other sound focusing methods such as parametric array, time reversal array, beamforming, and inverse filtering (for example, see Refs. 2–5). They can be good candidates to tackle this problem, but they have limitations; for example, parametric array consumes too much power to be applied to portable devices and occupies too large area.

In Sec. II, the acoustic contrast control is briefly explained. In Secs. III and IV, the process that the acoustic contrast control is applied to the system is described regardless of the size of the array. Then in Sec. V, a specific example of the system that can be attached on 17 in. monitor display is represented. In order to verify the system, we have experiments and compare the results with those of uncontrolled case and time reversal array to evaluate the performance of acoustic contrast control.

II. THEORETICAL BACKGROUND: ACOUSTIC CONTRAST CONTROL

"Acoustic contrast control" has been proposed by Choi and Kim.[1] "Acoustic contrast" means the ratio of acoustic potential energy density between acoustically bright zone and dark zone that we selected (Fig. 1). Acoustic contrast control provides us the optimal solution set that maximizes acoustic contrast. By applying the method, we can increase or reduce acoustic potential energy density as we want.

Let us consider L control sources located at the positions $\boldsymbol{r}_s=[\boldsymbol{r}_s^{(1)}\boldsymbol{r}_s^{(2)}\cdots\boldsymbol{r}_s^{(L)}]$ and denote source inputs as $\mathbf{q}(\omega)=[q^{(1)}(\omega)q^{(2)}(\omega)\cdots q^{(L)}(\omega)]^T$ where ω indicates radial frequency. The transfer functions between source inputs and pressure at a position $\boldsymbol{r}$ can be expressed by $\mathbf{h}(\boldsymbol{r}|\boldsymbol{r}_s,\omega)=[h(\boldsymbol{r}|\boldsymbol{r}_s^{(1)},\omega)h(\boldsymbol{r}|\boldsymbol{r}_s^{(2)},\omega)\cdots h(\boldsymbol{r}|\boldsymbol{r}_s^{(L)},\omega)]$. A sound field generated by the control sources can be expressed as

$$p(\boldsymbol{r},\omega)=\mathbf{h}(\boldsymbol{r}|\boldsymbol{r}_s,\omega)\mathbf{q}(\omega). \tag{1}$$

Because the acoustic potential energy density $e(\omega)$ in zone V is proportional to square of pressure, we can write it as

$$\begin{aligned} e(\omega)&=\frac{1}{V}\int_V p(\boldsymbol{r},\omega)^H p(\boldsymbol{r},\omega)dV \\ &=\mathbf{q}(\omega)^H\left(\frac{1}{V}\int_V \mathbf{h}(\boldsymbol{r}|\mathbf{r}_s,\omega)^H\mathbf{h}(\boldsymbol{r}|\boldsymbol{r}_s,\omega)dV\right)\mathbf{q}(\omega) \\ &=\mathbf{q}(\omega)^H\mathbf{R}(\omega)\mathbf{q}(\omega), \end{aligned} \tag{2}$$

where V means the volume of control zone and $\mathbf{R}(\omega)$ is the spatial correlation matrix. If we select acoustically bright zone V_b and dark zone V_d, then the acoustic potential energy density in the bright zone $e_b(\omega)$ and that in the dark zone $e_d(\omega)$ are, respectively, expressed by

$$e_b(\omega)=\mathbf{q}(\omega)^H\mathbf{R}_b(\omega)\mathbf{q}(\omega) \tag{3}$$

and

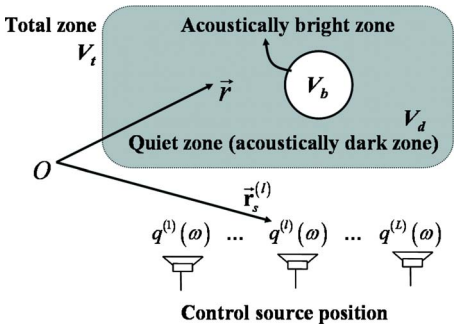

FIG. 1. (Color online) Definition of acoustic variables and control zone: V_t, total control zone ($V_t = V_b \cup V_d$); V_b, acoustically bright zone; V_d, acoustically dark zone; $\mathbf{r}_s^{(l)}$, position of the lth control source; and $q^{(l)}(\omega)$, the lth control source input.

$$e_d(\omega) = \mathbf{q}(\omega)^H \mathbf{R}_d(\omega)\mathbf{q}(\omega), \tag{4}$$

where $\mathbf{R}_b(\omega)$ and $\mathbf{R}_d(\omega)$ are the spatial correlation matrices of the bright zone and the dark zone, respectively.

Acoustic contrast $\beta(\omega)$ is defined by the ratio of the potential energy density between the bright and the dark zone as follows:

$$\beta(\omega) = \frac{e_b(\omega)}{e_d(\omega)} = \frac{\mathbf{q}(\omega)^H \mathbf{R}_b(\omega)\mathbf{q}(\omega)}{\mathbf{q}(\omega)^H \mathbf{R}_d(\omega)\mathbf{q}(\omega)}. \tag{5}$$

It is proved that the contrast control solution $\mathbf{q}_c(\omega)$ that maximizes $\beta(\omega)$ is determined to be the eigenvector which is correspondent to the maximum eigenvalue of the matrix $\mathbf{R}_d(\omega)^{-1}\mathbf{R}_b(\omega)$.[1]

III. PROBLEM DEFINITION

Before we apply the acoustic contrast control, it is noteworthy that the positions of control sources, the bright zone, and the dark zone have to be determined.

For simplicity, let us assume that sources radiate sound in free field. This is practically acceptable because the user uses the device within a short distance and direct sound is dominant compared to reverberant sound.

A. The positions of control sources

Because we have interest in a personal device that can be easily moved, the array of control sources is assumed to be attached on the device [Fig. 2 (left)]. The control sources are to be placed outside the display so that it does not obstruct the vision. The display has usually rectangular shape; therefore a line array can be regarded to be attached on the upper part or lower part of the display [Fig. 2 (left)]. Let us

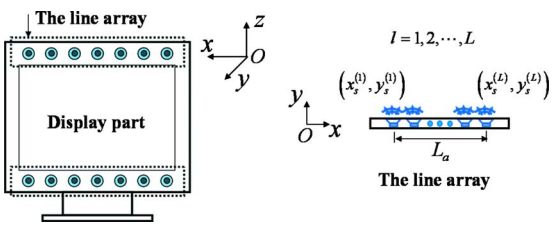

FIG. 2. (Color online) The line array of control sources that can be attached on the upper or lower side of display part (left) and the position of control sources (right).

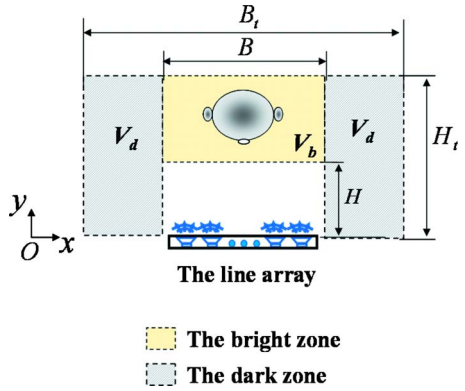

FIG. 3. (Color online) The bright zone and the dark zone: The bright zone is the region that includes the user's head in front of the array and defined as $\{(x,y)|H \le y \le H_t, -B/2 \le x \le B/2\}$, and the dark zone is the region near the bright zone defined as $\{(x,y)|-B_t/2 \le x \le -B/2$ or $B/2 \le x \le B_t/2, 0 \le y \le H_t\}$.

also assume the line array has L control sources on x axis and aperture size of the line array is L_a [Fig. 2 (right)]. Then the position of the lth control source can be expressed by

$$(x_s^{(l)}, y_s^{(l)}) = \left(-\frac{L_a}{2} + (l-1)\frac{L_a}{L-1}, 0\right), \tag{6}$$

where $l = 1,2,\ldots,L$ as illustrated in Fig. 2 (right).

B. The bright zone

The sound field generated by the line array that we assumed has dependency around the axis of the array (x axis) so that we cannot control sound field around the axis independently. Therefore we control the sound in two-dimensional plane as defined in Fig. 3. The bright zone V_b has to include the user's head. The width of the bright zone is denoted as B, and it has to be larger than the width of the user's head. This allows the head movement without inducing abrupt change in sound pressure that is designed to be generated in the bright zone.

The distance between the array and the end of the zone is denoted as H_t, as shown in Fig. 3. The distance between the array and the front of the zone is denoted as H. They determine the position and size of the user's head. It is noteworthy that H has to be big enough to avoid the effect of evanescent wave that is possible in the vicinity of the array. In other words, kH must be bigger than 1 ($kH > 1$) where k indicates the wave number.

Therefore acoustic bright zone V_b is defined as the rectangular shape region, $\{(x,y)|H \le y \le H_t, -B/2 \le x \le B/2\}$ (Fig. 3).

C. The dark zone

The other entire region except the bright zone can be regarded as dark zone V_d. However, the front region of the array, $\{(x,y)|-B/2 < x < B/2, 0 < y < H\}$, does not have to be dark zone because no one will be between the device and the user (Fig. 3). The region away from the bright zone in y direction, $H_t < y$, is not needed to be bright zone nor dark

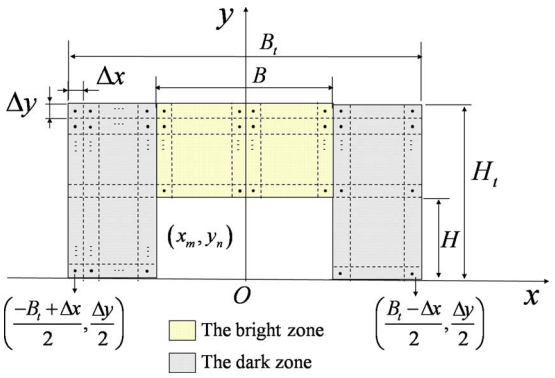

FIG. 4. (Color online) The measurement points: $(x_m, y_n)=((-B_t+\Delta x)/2+(m-1)\Delta x, \Delta y/2+(n-1)\Delta y)$, where $m=1,2,\ldots,B_t/\Delta x$ and $n=1,2,\ldots,H_t/\Delta y$.

zone because the region is out of our interest. The rear region of the array, $y<0$, is excluded because the region is out of interest as well.

The width of total zone that includes both the bright zone and the dark zone is denoted by B_t. To include the other entire zone, B_t can be regarded as infinity. However, even if B_t is a finite value, the contrast control makes the other entire region dark because pressure in the outer region of the dark zone is as low as pressure in the dark zone. Therefore, B_t can be a finite value and the dark zone can be a region that includes only those who are right beside the user.

Therefore, dark zone V_d is defined as the rectangular shaped region of $\{(x,y)|-B_t/2\leq x\leq -B/2$ or $B/2\leq x\leq B_t/2, 0\leq y\leq H_t\}$, as shown in Fig. 3.

IV. SOLUTION METHOD

In practice, the sound field of interest is discretized by measurement points, and then the acoustic contrast control is applied. The solution that maximizes the acoustic contrast is obtained at each frequency, and then the solutions at the frequencies construct a multi-channel filter to filter a monosignal.

A. Applying the acoustic contrast control at each frequency

Let us denote the measurement spacing with respect to x and y as Δx and Δy (see Fig. 4). It is noteworthy that the spacings, Δx and Δy, have to be smaller than at least half of the minimum wavelength for all frequency range to avoid spatial aliasing problem. Then the positions can be written as

$$(x_m, y_n) = \left(\frac{-B_t+\Delta x}{2} + (m-1)\Delta x, \frac{\Delta y}{2} + (n-1)\Delta y\right), \quad (7)$$

where $m=1,2,\ldots,B_t/\Delta x$ and $n=1,2,\ldots,H_t/\Delta y$. B_t and B are multiples of $2\Delta x$, and H_t and H are multiples of Δy, then m and n are integers.

The transfer functions between source inputs and pressure at the position (x_m, y_n) by the L control sources with source strength of unity can be expressed by

$$\mathbf{h}(x_m, y_n|\mathbf{x}_s, \mathbf{y}_s, \omega) = [h(x_m, y_n|x_s^{(1)}, y_s^{(1)}, \omega) \; h(x_m, y_n|x_s^{(2)}, y_s^{(2)}, \omega) \cdots h(x_m, y_n|x_s^{(L)}, y_s^{(L)}, \omega)], \quad (8)$$

where $\mathbf{x}_s=[x_s^{(1)}x_s^{(2)}\cdots x_s^{(L)}]$ and $\mathbf{y}_s=[y_s^{(1)}y_s^{(2)}\cdots y_s^{(L)}]$. If we denote the input signals into the control sources as $\mathbf{q}(\omega)=[q^{(1)}(\omega)q^{(2)}(\omega)\cdots q^{(L)}(\omega)]^T$, the pressure at the position (x_m, y_n) is

$$p(x_m, y_n, \omega) = \mathbf{h}(x_m, y_n|\mathbf{x}_s, \mathbf{y}_s, \omega)\mathbf{q}(\omega). \quad (9)$$

The spatial correlation matrix (which is explained in Sec. II) of the bright zone is expressed in discrete form

$$\mathbf{R}_b(\omega) = \frac{1}{B(H_t-H)} \times \sum_{m=(B_t-B)/2\Delta x+1}^{(B_t+B)/2\Delta x} \sum_{n=H/\Delta y+1}^{H_t/\Delta y} \mathbf{h}(x_m, y_n|\mathbf{x}_s, \mathbf{y}_s, \omega)^H \times \mathbf{h}(x_m, y_n|\mathbf{x}_s, \mathbf{y}_s, \omega)\Delta x\Delta y. \quad (10)$$

The spatial correlation matrix of the dark zone is

$$\mathbf{R}_d(\omega) = \frac{1}{(B_t-B)Ht} \times \sum_{m=1}^{(B_t-B)/2\Delta x} \sum_{n=1}^{H_t/\Delta y} \mathbf{h}(x_m, y_n|\mathbf{x}_s, \mathbf{y}_s, \omega)^H \times \mathbf{h}(x_m, y_n|\mathbf{x}_s, \mathbf{y}_s, \omega)\Delta x\Delta y + \frac{1}{(B_t-B)H_t} \sum_{m=(B_t+B)/2\Delta x+1}^{(B_t/\Delta x)+1} \times \sum_{n=1}^{H_t/\Delta y} \mathbf{h}(x_m, y_n|\mathbf{x}_s, \mathbf{y}_s, \omega)^H \mathbf{h}(x_m, y_n|\mathbf{x}_s, \mathbf{y}_s, \omega)\Delta x\Delta y. \quad (11)$$

As shown in Sec. II, the problem to maximize the acoustic contrast is reduced to an eigenvalue problem as

$$\mathbf{R}_d(\omega)^{-1}\mathbf{R}_b(\omega)\mathbf{q}(\omega) = \beta(\omega)\mathbf{q}(\omega). \quad (12)$$

The contrast control solution $\mathbf{q}_c(\omega)$ is obtained as the eigenvector that corresponds to the maximum eigenvalue.

B. Constructing a multi-channel filter

The solution set which is obtained at each frequency is composed of complex numbers correspondent to channels. The solution sets at all frequencies of interest construct a multi-channel filter. A monosignal is filtered by the multi-channel filter and then the resultant signals are fed into the channels, respectively. The filtering process can be taken in time domain or frequency domain.

It is noteworthy that the frequency range has to be determined by the linear region of loudspeakers and the frequency interval has to be determined by considering required length of the impulse response of the solutions. In other words, in order to treat reverberations, time length is re-

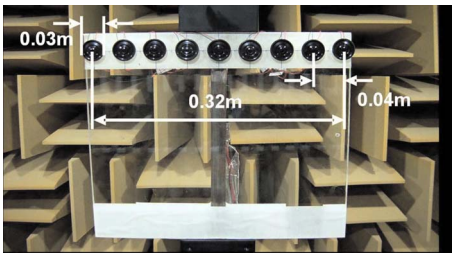

FIG. 5. (Color online) The loudspeaker array; the diameter of a loudspeaker is 0.03 m, the spacing between loudspeakers is 0.04 m, the number of loudspeakers is 9, and the aperture size is 0.32 m.

quired to be long, and then the frequency interval, which is the inverse of time length of the impulse response, has to be short.

V. THE REALIZATION OF A SYSTEM FOR 17 in. DISPLAY

In order to make sure that the method can be practically realizable, we need a well designed experiment. As a specific example of the personal audio system, we considered the 17 in. monitor display which is used in a laptop computer, desktop computer, or TV. We used loudspeakers whose diameter is 0.03 m as control sources. The experiment was done in an anechoic chamber $[(3.6^W \times 3.6^L \times 2.4^H \text{ m}^3)$; cut-off frequency: 100 Hz] to satisfy free-field assumption.

A. Experimental setup

Figure 5 shows the loudspeaker array that is used in the experiment. Considering the scale of 17 in. monitor display (the width is 0.32 m and height is 0.27 m), we regarded the aperture of control source array L_a to be 0.32 m. We used nine control sources ($L=9$) with equal spacing, 0.04 m, then the aperture size will be L_a, 0.32 m. Then the positions of control sources are

$$(x_s^{(l)}, y_s^{(l)}) = (-0.16 + 0.04(l-1), 0) \quad \text{(m)}, \tag{13}$$

$$l = 1, 2, \ldots, 9.$$

Figure 6 shows frequency response function $[\mathbf{h}(x_m, y_n | \mathbf{x}_s, \mathbf{y}_s, \omega)$ of Eq. (8)] and coherence between the input voltage signal into a loudspeaker unit and the output pressure (Pa) signal which is measured at a point 1 m ahead. Based on the figure, we selected the available frequency range to be 800 Hz–5 kHz because the coherence function is unity in the range; it means that the loudspeaker has linear response with respect to the input signal. The frequency range is discretized by $\Delta f = 10$ Hz because we determine the time length of impulse response to be 0.1 s. The time length is enough because we assume the free-field condition and we do not consider reflections. The number of the discretized frequencies N is 521.

We also assumed that B is 0.4 m. The H_t and H can be 0.6 and 0.2 m, respectively, to include the user's head, which is fairly large to allow the head movement. It is noteworthy that H has to be bigger than 0.07 m to satisfy $kH > 1$ for all frequency range that we have an interest in, 800 Hz–5 kHz. The width of total control zone B_t is decided to be 0.8 m.

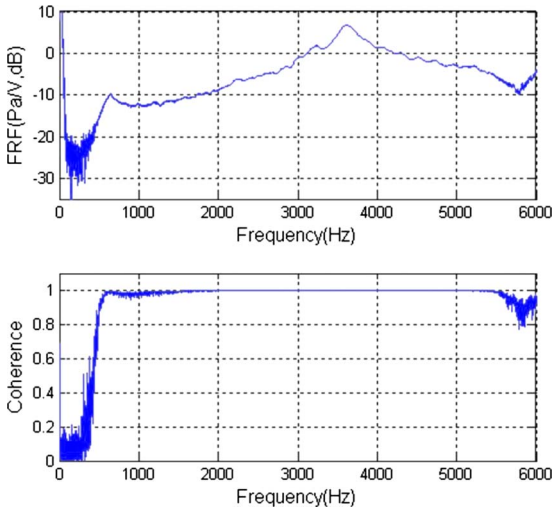

FIG. 6. (Color online) Frequency response function and coherence of a loudspeaker unit; the available frequency range is about 800 Hz–5 kHz.

Then the width of each dark zone (on the left and the right side of the bright zone) is 0.2 m, which includes the head of each person who can be right beside the user. The widths of the dark zones do not have to be big to include the head movement because the sound pressure in the outer region of the dark zone is as low as in the dark zone.

B. Measuring transfer functions and obtaining solutions

The measurement spacings Δx and Δy are decided to be 0.02 m, which is about 1/3 of wavelength of the highest frequency of interest, 5 kHz. Then the measurement position is

$$(x_m, y_n) = (-0.39 + 0.02(m-1), 0.01 + 0.02(n-1)) \quad \text{(m)}, \tag{14}$$

where $m = 1, 2, \ldots, 40$ and $n = 1, 2, \ldots, 30$.

We used 20 array microphones, which are spaced by 0.04 m to avoid scattering effect that is possible when the microphones are too close. Signal generating part is composed of PC, multi-channel sound card, multi-channel audio amp, and the loudspeaker array. Measuring part is composed of array microphones, analog-to-digital converter, and PC. In total, 60 steps (2 steps in x-axis and 30 steps in y-axis) of measurements were performed.

At each frequency, we have the transfer function $\mathbf{h}(x_m, y_n | \mathbf{x}_s, \mathbf{y}_s, \omega)$ [Eq. (8), the size 1×9] at all measurement points [Eq. (7), 40×30 points]. For example, Fig. 7 represents absolute value of transfer function by the first loudspeaker. From this transfer function, we can obtain the solution as explained in Sec. II. We obtain the spatial correlation matrices $\mathbf{R}_b(\omega)$ and $\mathbf{R}_d(\omega)$ [Eqs. (10) and (11); their size is 9×9] and the contrast control solution $\mathbf{q}_c(\omega)$ by solving the eigenvalue problem.

C. Experimental results

Then the resultant pressure at each point $p(x_m, y_n, \omega)$ is obtained by multiplication of the transfer function

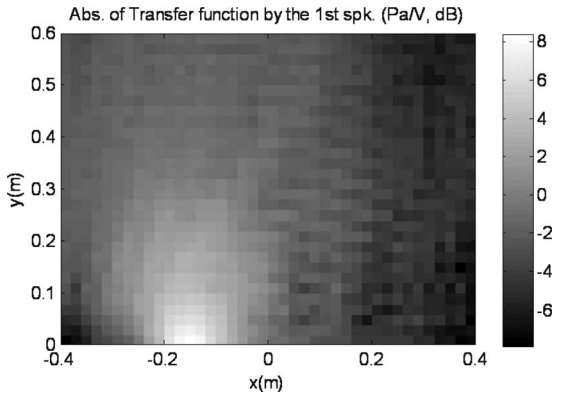

FIG. 7. Absolute values of transfer function between input voltage (V) and sound pressure (Pa) on the sound field of interest by the first loudspeaker, which is located at (−0.16 m, 0 m).

$\mathbf{h}(x_m, y_n | \mathbf{x}_s, \mathbf{y}_s, \omega)$ and the solution $\mathbf{q}_c(\omega)$ [Eq. (9)]. It is assumed to be same as actual pressure because this system is linear.

In order to evaluate this solution, we compare it with two other cases: Uncontrolled case and time reversal array case. The solution in the uncontrolled case $\mathbf{q}_{EI}(\omega)$ is determined by

$$\mathbf{q}_{EI}(\omega) = \sqrt{\frac{\sum_{l=1}^{L} |q_c^{(l)}(\omega)|^2}{L}} [1 \quad 1 \cdots 1]^T, \tag{15}$$

which is normalized for its power to be that of $\mathbf{q}_c(\omega)$. The solution has equal inputs into all channels. On the other hand, the solution in the time reversal array case $\mathbf{q}_{\mathrm{TRA}}(\omega)$ is determined by

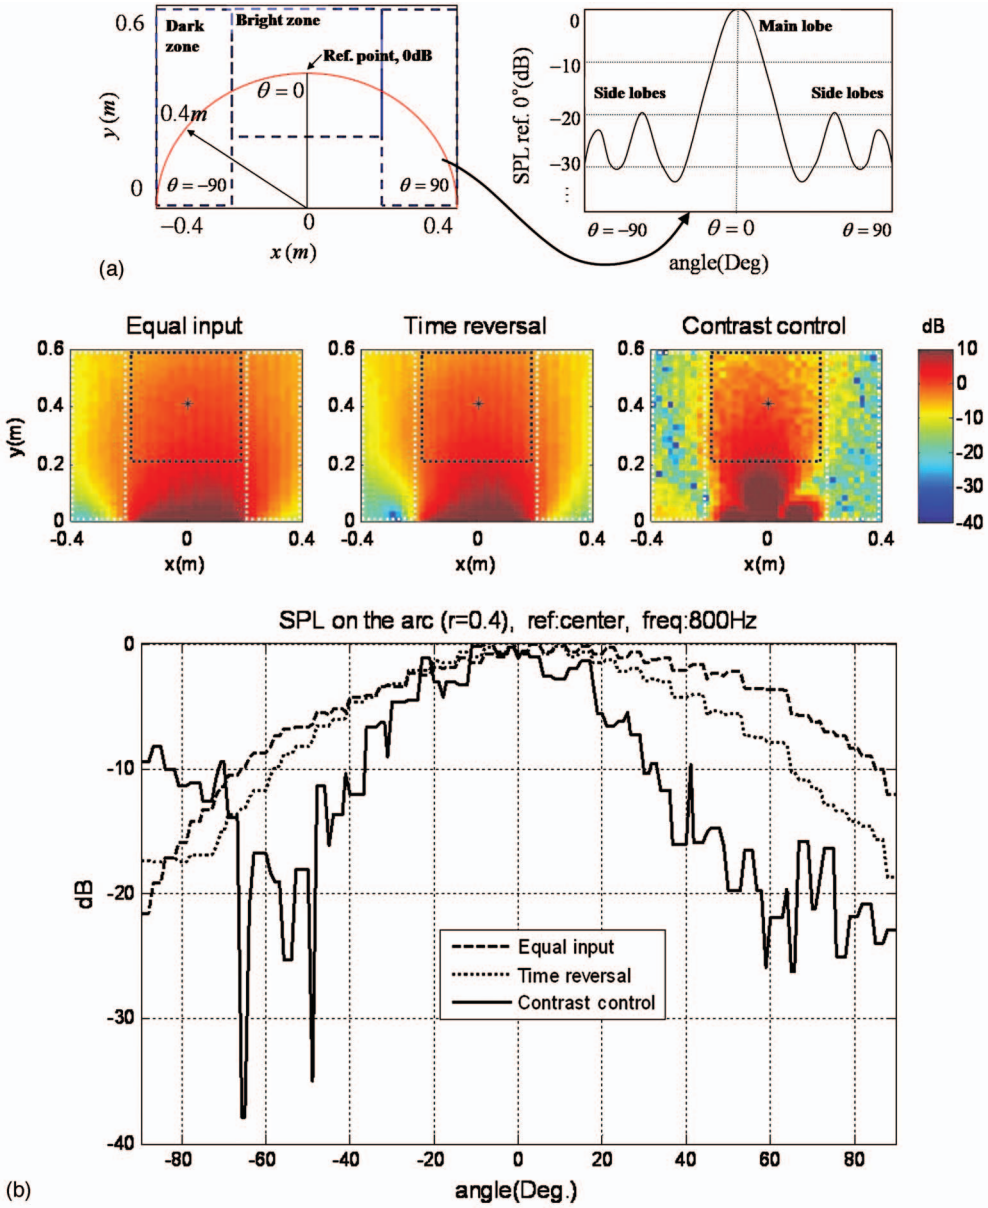

FIG. 8. The experiment results at the selected frequencies: 800 Hz and 5 kHz. (a) Sound field and its angular characteristics on the arc (0.4 m radius): The magnitude of sound pressure is expressed in decibel scale when the reference value is the pressure at the center (0.0 1 m, 0.4 m). The angle is 90° on the $+x$ axis and −90° on the $-x$ axis. The angle increases clockwise. (b) The results at 800 Hz; the top three figures show sound fields by equal input, time reversal, and contrast control, respectively. The mark " *" on the figures represents the position of the reference point. The center rectangle indicates the bright zone and the other rectangles at the sides indicate the dark zone. The bottom figure shows the angular characteristics in the three cases.

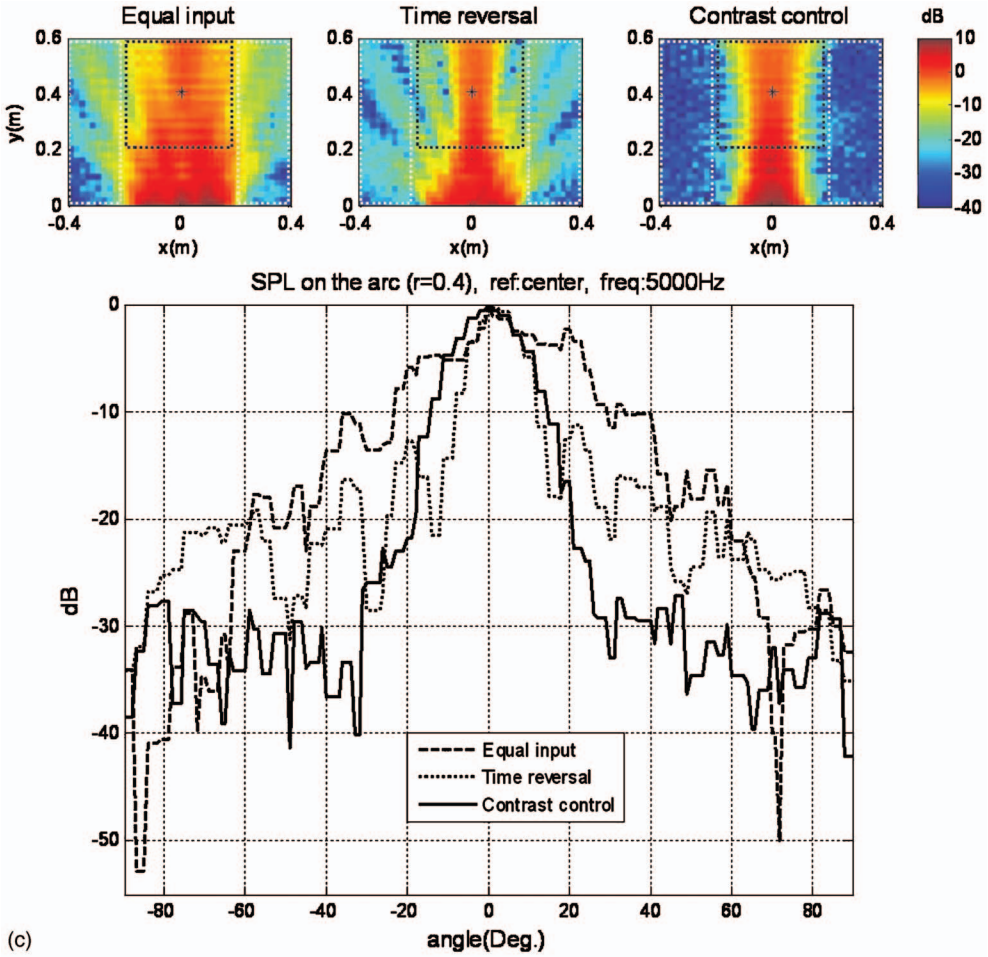

FIG. 8. (c) The results at 5 kHz; the structures of the figures are the same as what is described in the above Fig. 8(b).

$$\mathbf{q}_{TRA}(\omega) = \sqrt{\frac{\sum_{l=1}^{L} |q_c^{(l)}(\omega)|^2}{\sum_{l=1}^{L} |h(x_0, y_0 | x_s^{(l)}, y_s^{(l)}, \omega)|^2}} \times \mathbf{h}(x_0, y_0 | \mathbf{x}_s, \mathbf{y}_s, \omega)^H, \quad (16)$$

which is normalized so that its power is equal to that of $\mathbf{q}_c(\omega)$ and (x_0, y_0) is the location of the center of the user, (0.01 m, 0.4 m). [In fact, (0.01 m, 0.4 m) is considered as the center point because the center (0 m, 0.4 m) does not belong to the measurement points.]

Figure 8 shows the results of the experiments at the two selected frequencies: 800 Hz and 5 kHz. As illustrated in the left figure of Fig. 8(a), the top three figures of Figs. 8(b) and (c) show sound fields by equal input (uncontrolled case), time reversal, and contrast control, respectively. The sound pressure level is expressed by color. The center rectangle indicates the bright zone and the other rectangles at the sides indicate the dark zone. The magnitude of sound pressure is expressed in decibel scale when the reference value is the pressure at the center. The bottom figure shows the angular characteristics in the three cases. As shown in the right figure of Fig. 8(a), the sound pressure on the arc whose radius is 0.4 m is plotted with respect to the angle. (In fact, measurement points that are the closest ones to the arc are chosen.) The angle is 90° on the $+x$ axis and $-90°$ on the $-x$ axis, and increases clockwise. Sound pressure levels in the three cases are represented, respectively.

At all frequencies, the upper figures of Figs. 8(b) and (c) show that the sound pressure levels of the dark zones in the contrast control are lower than those in the equal input cases (uncontrolled cases) and time reversal array cases. The lower figures of Figs. 8(b) and (c) show that most levels of side lobes in contrast control are lower than those in the equal input cases and time reversal array cases. In the contrast control, except 800 Hz, the levels of most side lobes are lower than -20 dB.

Figure 9 shows the acoustic contrast in the three cases in the entire frequency region of interest, 800 Hz–5 kHz. In the contrast control case, the contrasts are more than 19 dB and higher than those in the other cases. Especially as frequency increases, the contrast in the contrast control case increases gradually while the contrasts in the other cases do not; as frequency goes high, the difference of the contrasts in the contrast control and the others has tendency to increase.

Due to the limited frequency range, sound quality for this system is inadequate to play music sounds, but speech sounds can be recognized. The frequency range of this system depends on that of loudspeakers, which has to do with the size of loudspeaker units. In other words, the size of

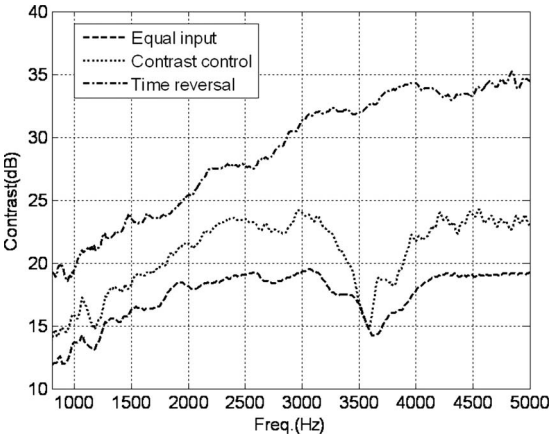

FIG. 9. The contrast in the three cases: Equal input (uncontrolled case), acoustic contrast control, and time reversal array.

loudspeakers, which are used in this system, is too small to generate the low frequency sound below 800 Hz. Therefore, in order to improve the sound quality, larger loudspeakers have to be used, and then the size of this system will also be larger.

VI. CONCLUSION

Acoustic contrast control was applied to develop a sound focused personal audio system. A line array of control sources was considered. As a specific example of the system, we considered a line array that can be attached on 17 in. monitor display. The interest frequency range was from 800 Hz to 5 kHz. Experimental results show that the cases of acoustic contrast control provide lower levels of side lobes and higher contrasts than the equal input case and time reversal array at all frequencies. In the contrast control, the levels of most side lobes are lower than −20 dB at the selected frequencies and the contrasts are more than 19 dB at all frequencies. In addition, as frequency goes high, the difference of the contrasts in the contrast control and the others has tendency to increase.

(Received 4 September 2008; revised 29 January 2009; accepted 4 February 2009)

Beamforming is done with an array of sensors to achieve a directional or spatially-specific response by using a model of the arriving wavefront. Real acoustic sources may deviate from the conventional plane wave or monopole model, causing decreased array gain or a total breakdown of beamforming. An alternative to beamforming with the conventional source model is presented which avoids this by using a more general source model. The proposed method defines a set of "sub-beamformers," each designed to respond to a different spatial mode of the source. The outputs of the individual sub-beamformers are combined in a weighted sum to give an overall output of better quality than that of a conventional (monopole) beamformer. It is shown that with appropriate weighting, the optimum array gain can be achieved. A simple method is demonstrated to estimate the weighted sum, based on the observed data. The variance and bias of the estimate in the presence of noise are evaluated. Simulation and experimentally measured results are shown for a simple directive source. In the experiment, the proposed method provides an array gain of about 11 dB while beamforming using a point source model achieves only −4 dB.

I. INTRODUCTION

Beamforming is done with an array of sensors to achieve a directional or spatially-specific response. It relies on a model of the wavefront (source model) arriving at the array to calculate the time delay, or frequency domain phase shift, that must be applied to the signal of each sensor so that they may be summed coherently. In what is often called near-field beamforming,[1] a point source (monopole) model is typically used. If the source is distant from the array, wavefront curvature is neglected (far-field assumption).

We are concerned here with sources that do not radiate as point sources and for which a different source model must be used to compute the beamforming weights.[2,3] The source may have an elaborate directivity pattern caused by a complex sound production mechanism, as for a musical instrument,[4,5] or it may consist of spatially distributed radiating elements with arbitrary but fixed phase relationships. These deviations from the point source model are most noticeable when the source subtends a large angle about the array. They may result in a decrease in array gain or a total breakdown of beamforming. To avoid this, a more realistic source model is required than is typically seen in the literature or done in practice.

Beamforming based directly on a specific source model is referred to here as *conventional beamforming*. With this method, the proper source model would have the same directivity and orientation as the actual source; however, source directivity and orientation are unknown in most cases. This paper introduces an alternative approach to conventional beamforming. The general principle is to define a set of "sub-beamformers," each beamforming on a different spatial mode of the source. The outputs of the individual sub-beamformers are combined in a weighted sum to give an overall output of better quality than that of a conventional beamformer using the monopole model. This paper shows that, with the appropriate weighting, the sum of the sub-beamformers gives the same optimum array gain as conventional beamforming with the exact source model. A method to estimate the sub-beamformer weights based on the observed data is demonstrated. The bias and variance of the estimate in the presence of noise are evaluated.

The proposed method has the following benefits when compared with beamforming using a point source model:

- it can overcome deteriorated beamformer response that occurs when a null of the source directivity falls on the receiving array,[3]
- in a stationary environment, once the sub-beamformer weights are evaluated, the computational complexity can be made the same by combining the sub-beamformers,

[a)]Electronic mail: christian.bouchard@nrc-cnrc.gc.ca

- it has similar performance when beamforming on point sources, and
- it works with the same array geometry and hardware.

Beamforming can be used for spatial differentiation, tracking, or high quality sound pickup at a distance from the source. The proposed beamforming method is developed to address the latter objective. Unlike near-field acoustical holography[6] (NAH) or other techniques,[7,8] the method does not address reconstruction of the acoustic pressure field near the source or evaluation of the surface velocity of the source. Furthermore, unlike NAH, the near-field criterion for beamforming is wavefront curvature rather than the presence of evanescent components.

Here, we introduce the method and demonstrate through simulation and experiment its advantages over conventional beamforming with a point source. Detailed quantification of performance is beyond the scope of this paper and so this important analysis is left to future work. In general, however, the performance of the proposed method depends on the source directivity and position, on the array geometry, and the environment in which the array is operating. Reverberation and interfering sources can also be expected to have a strong impact on performance, particularly in regard to estimation of the sub-beamformer weights.

The principles of beamforming and array noise gain optimization are reviewed in Sec. II, and the proposed method is introduced in Sec. III. Section IV presents an estimator of the weight to give each sub-beamformer in the linear sum of the proposed method and provides the bias and variance of this estimator for a known noise field. In Sec. V it is shown that if the source directivity pattern and source location with respect to the array do not change with time then it is possible to obtain the overall beamformer output without computing the output of each sub-beamformer. In this case, the method is computationally equivalent to beamforming directly with a source model. Section VI compares simulations and measurements for a simple directive source when beamforming with both the proposed method and using the point source model. Section VII compares the proposed method with the phase-mode spherical array[9–11] and shows that the methods are quite different even though they both use spherical harmonic expansions. Concluding remarks are in Sec. VIII.

II. ARRAY BEAMFORMING AND OPTIMIZATION

The complex exponential $e^{i2\pi ft}$ is used here for the time dependence. Where no ambiguity exists, the continuous and discrete cases are distinguished by the use of t or n as the time parameter and the use of f or k as the frequency parameter, respectively.

The forward Fourier transform is applied to the time-domain signal $p_l(t)$ at the lth microphone to obtain $p_l(f)$ in the frequency domain. In the discrete (time sampled) case the normalized discrete Fourier transform is used to obtain $p_l(k)$ (normalization by $\sqrt{N}$, where N is the number of time samples used in the transform).

In the frequency domain, the beamformed output of an array of L microphones is

$$y(f) = \sum_{l=1}^{L} w_l^*(f) p_l(f), \tag{1}$$

where $w_l(f)$ is the complex valued beamforming weight for the lth microphone. The asterisk denotes complex conjugation.

The output of microphone l, located at the point (r_l, θ_l, ϕ_l), is composed of the signal of interest, s, and additive noise e_l,

$$p_l(f) = s(f, r_l, \theta_l, \phi_l) + e_l(f). \tag{2}$$

The noise is assumed to be uncorrelated with the signal. Using vector notation, the beamforming weights are assembled in a vector $\mathbf{w}(f)$ and the microphone outputs in a vector $\mathbf{p}(f) = \mathbf{s}(f) + \mathbf{e}(f)$. The vector $\mathbf{s}(f)$ is called the *signal model*. The array output is

$$y(f) = \mathbf{w}^H(f)\mathbf{p}(f). \tag{3}$$

The superscript H indicates the Hermitian conjugate transpose. The beamforming weight vector may be optimized in regard to some criteria, such as the signal-to-noise ratio (SNR) or directional response pattern.

The *gain* of the microphone array is defined as the ratio of the SNR at the output of the beamforming array to the SNR of a single reference microphone. For development of the theory, the reference SNR is defined here, as it is in Ref. 12, to be the ratio of the average signal power spectral density over the L microphones of the array, $\sigma_{\mathbf{s}}^2(f) = \mathbf{s}^H(f)\mathbf{s}(f)/L$, to the average noise power spectral density over the array, $\sigma_{\mathbf{e}}^2(f) = E\{\mathbf{e}^H(f)\mathbf{e}(f)\}/L$. The resulting expression for the gain of the array at a specific frequency is

$$G(f) = \frac{\mathbf{w}^H(f)\mathbf{R}_{\mathbf{ss}}(f)\mathbf{w}(f)}{\mathbf{w}^H(f)\mathbf{R}_{\mathbf{ee}}(f)\mathbf{w}(f)}, \tag{4}$$

where $\mathbf{R}_{\mathbf{ss}}(f) = \mathbf{s}(f)\mathbf{s}^H(f)/\sigma_{\mathbf{s}}^2(f)$ is called the normalized signal cross-power spectral density matrix, and $\mathbf{R}_{\mathbf{ee}}(f) = E\{\mathbf{e}(f)\mathbf{e}^H(f)\}/\sigma_{\mathbf{e}}^2(f)$ is the normalized noise cross-power spectral density matrix. Provided $\mathbf{R}_{\mathbf{ee}}(f)$ is not singular, the array gain is maximized with respect to SNR with the weight vector[12]

$$\mathbf{w}_{\text{opt}}(f) = \alpha(f)\mathbf{R}_{\mathbf{ee}}^{-1}(f)\mathbf{s}(f). \tag{5}$$

The scaling factor $\alpha(f)$ is an arbitrary complex constant and it is set to unity in the remainder of this paper. When the noise at the microphone outputs is additive white-noise uncorrelated from sensor to sensor, such as in spatially uncorrelated white-noise, $\mathbf{R}_{\mathbf{ee}}(f)$ is equal to the identity matrix $\mathbf{I}_L$ and the optimum weight vector becomes equal to the signal model itself

$$\mathbf{w}_{\text{opt}}(f) = \mathbf{s}(f) \quad \text{when} \quad \mathbf{R}_{\mathbf{ee}} = \mathbf{I}_L. \tag{6}$$

In this case, the array gain is called *white-noise gain*.

For the point source model, the optimum weight at the lth microphone to maximize the white-noise gain is

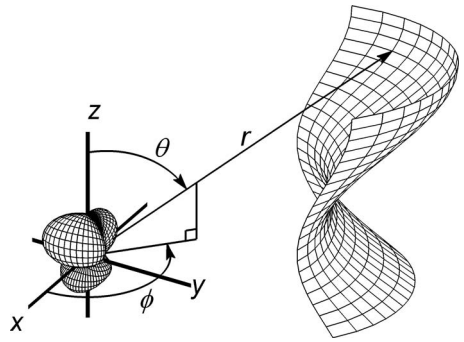

FIG. 1. Arbitrary discrete array and source with an arbitrary directivity (magnitude shown, phase not shown).

$$w_{\mathrm{opt},l}(f) = \frac{1}{r_l} e^{-i2\pi f r_l/c}, \tag{7}$$

where r_l is the distance from microphone l to the source and c is the speed of sound. In the time domain, this is a delay-and-sum beamformer

$$y(t) = \sum_{l=1}^{L} \frac{1}{r_l} p_l(t + t_l), \tag{8}$$

where $t_l = r_l/c$ is the propagation time to reach the lth microphone.

III. DEVELOPMENT OF THE PROPOSED METHOD

Figure 1 illustrates schematically the directivity magnitude of an arbitrary source, at some frequency f, and a discrete sensor array with some arbitrary geometry. (The phase of the directivity is not shown.) For notational convenience, and without loss of generality, the source is located at the center of the spherical coordinate system.

Using a decomposition[6] into spherical harmonic modes (n,m) at frequency f, the outgoing wave from a source generates a signal at a point (r,θ,ϕ),

$$s(f,r,\theta,\phi) = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} s_{nm}(f) h_n^{(2)}(\kappa r) Y_n^m(\theta,\phi), \tag{9}$$

where $h_n^{(2)}(\kappa r)$ is the Hankel function of the second kind of order n, $\kappa = 2\pi f/c$ is the wave number, and $Y_n^m(\theta,\phi)$ is the spherical harmonic function of order n and degree m. The factor $s_{nm}(f)$ in the summation is a complex number equal to the contribution of the spherical harmonic mode (n,m) from the source at frequency f; it is referred to here simply as the *mode strength*.

The directivity of the source, and so the mode strengths s_{nm}, is often unknown. This section demonstrates that if these mode strengths can be determined then a properly weighted linear sum of specially defined beamformers (called *sub-beamformers*) provides a response equivalent to that of conventional beamforming with the exact source model. In this case, the optimum array gain is achieved.

For a discrete and time sampled array, the signal in the kth frequency bin of the lth sensor is

$$s_l(k) = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} s_{nm}(k) h_n^{(2)}(\kappa_k r_l) Y_n^m(\theta_l,\phi_l), \tag{10}$$

where κ_k is the wave number at the center of frequency bin k. A *signal model vector* $\mathbf{s}(k)$ is formed from the signal component of all microphones,

$$\mathbf{s}(k) = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} s_{nm}(k) \mathbf{Y}_n^m(k), \tag{11}$$

where, for notational convenience, we also define the *mode vector*

$$\mathbf{Y}_n^m(k) = [h_n^{(2)}(\kappa_k r_1) Y_n^m(\theta_1,\phi_1) \cdots h_n^{(2)}(\kappa_k r_L) Y_n^m(\theta_L,\phi_L)]^T. \tag{12}$$

The reader is cautioned that the letter Y is used both for the mode vector and for the spherical harmonic function, albeit in different font properties, and that the mode vector $\mathbf{Y}_n^m(k)$ contains both the spherical harmonic and the Hankel function of the second kind.

The weight vector to maximize the array gain given by Eq. (5) is

$$\mathbf{w}(k) = \mathbf{R}_{\mathbf{ee}}^{-1}(k) \sum_{n=0}^{\infty} \sum_{m=-n}^{n} s_{nm}(k) \mathbf{Y}_n^m(k), \tag{13}$$

or, rearranging,

$$\mathbf{w}(k) = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} s_{nm}(k) \mathbf{R}_{\mathbf{ee}}^{-1}(k) \mathbf{Y}_n^m(k). \tag{14}$$

Inserting this weight vector into Eq. (3), the optimized array beamformer output is

$$y(k) = \left\{ \sum_{n=0}^{\infty} \sum_{m=-n}^{n} s_{nm}(k) \mathbf{R}_{\mathbf{ee}}^{-1}(k) \mathbf{Y}_n^m(k) \right\}^H \mathbf{p}(k) \tag{15a}$$

$$= \sum_{n=0}^{\infty} \sum_{m=-n}^{n} \underbrace{s_{nm}^*(k)} \underbrace{\{\mathbf{Y}_n^{mH}(k) \mathbf{R}_{\mathbf{ee}}^{-1}(k) \mathbf{p}(k)\}} \tag{15b}$$

$$= \sum_{n=0}^{\infty} \sum_{m=-n}^{n} \{s_{nm}(k)\}^* \{y_{nm}(k)\}. \tag{15c}$$

Each factor $y_{nm}(k)$ in the curly bracket in Eq. (15c) has the form of a beamformer [viz., Eq. (3)] with beamforming weight vector $\mathbf{w}_{nm}(k) = \mathbf{R}_{\mathbf{ee}}^{-1}(k) \mathbf{Y}_n^m(k)$. Considering the form of the gain-optimized array weight vector given in Eq. (5), the beamformer $y_{nm}(k)$ is called a *gain-optimized sub-beamformer* of order n and degree m.

Since the gain-optimized sub-beamformers are readily computed from the signals at the microphone array, then the linear sum of sub-beamformers in Eq. (15c) can be used to perform beamforming with optimal gain if the weights $s_{nm}(k)$ can be found somehow. Figure 2 shows a schematic of the proposed method with the array data processed in parallel through a set of sub-beamformers and the outputs $y_{nm}(k)$ multiplied by $s_{nm}^*(k)$ and summed.

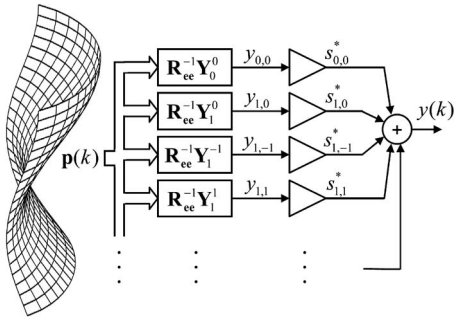

FIG. 2. Proposed method schematic.

It is noteworthy that if the source can be decomposed using some other set of modes $\mathbf{M}_m(k)$ as

$$\mathbf{s}(k) = \sum_{m=0}^{M} s_m(k)\mathbf{M}_m(k), \tag{16}$$

then the method can be applied using

$$y_m(k) = \mathbf{M}_m^H(k)\mathbf{R}_{\mathbf{ee}}^{-1}(k)\mathbf{p}(k). \tag{17}$$

IV. ESTIMATING THE MODE STRENGTHS

Since the strength of each mode of the source is generally unknown, it is necessary to estimate $s_{nm}(k)$ in Eq. (15c). If the source has only a single mode, (n,m), with strength $s_{nm}(k)$, then the sub-beamformer output for that mode would be

$$y_{nm}(k) = \mathbf{Y}_n^{mH}(k)\mathbf{R}_{\mathbf{ee}}^{-1}(k)\{s_{nm}(k)\mathbf{Y}_n^m(k) + \mathbf{e}(k)\} \tag{18}$$

Based on this observation, and defining the coefficient

$$C_{n'm'}^{nm}(k) = \mathbf{Y}_n^{mH}(k)\mathbf{R}_{\mathbf{ee}}^{-1}(k)\mathbf{Y}_{n'}^{m'}(k), \tag{19}$$

we define a possible estimator for the mode strength as

$$d_{nm}(k) = \frac{1}{C_{nm}^{nm}(k)} y_{nm}(k). \tag{20}$$

If the source has other modes, then this estimator of the (n,m) mode strength will be biased. The bias is a weighted sum of the other mode strengths

$$E\{d_{nm}(k)\} - s_{nm}(k) = \frac{1}{C_{nm}^{nm}(k)} \sum_{\substack{n'=0 \\ (n',m')\neq(n,m)}}^{\infty} \sum_{m'=-n'}^{n'} C_{n'm'}^{nm}(k) s_{n'm'}(k). \tag{21}$$

Notice that the bias is independent of the average noise power over the array.

The variance of the estimator is proportional to the average noise power over the array

$$\mathrm{Var}\{d_{nm}(k)\} = \frac{\sigma_{\mathbf{e}}^2(k)}{\mathbf{Y}_n^{mH}(k)\mathbf{R}_{\mathbf{ee}}^{-1}(k)\mathbf{Y}_n^m(k)} = \frac{\sigma_{\mathbf{e}}^2(k)}{C_{nm}^{nm}(k)}. \tag{22}$$

We have assumed that the noise field, and hence $\mathbf{R}_{\mathbf{ee}}(k)$, is known; in practice, however, $\mathbf{R}_{\mathbf{ee}}(k)$ would have to be estimated. In this case, the bias and variance would need to take into account the characteristics of the estimator of $\mathbf{R}_{\mathbf{ee}}(k)$.

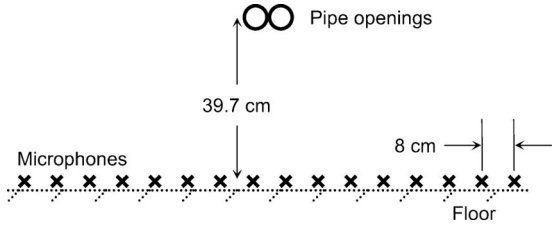

FIG. 3. Experiment setup.

Reverberation can be expected to degrade the mode strength estimation but this is not addressed here.

V. COMPUTATIONAL COMPLEXITY

The beamforming weight vector $\mathbf{w}_{nm}(k)$ and the source mode strength estimate $d_{nm}(k)$ must be estimated for each sub-beamformer. The number of such parameters to be estimated increases with the number N_{order} of spherical harmonic mode orders being considered. In practice, N_{order} should be determined by the expected complexity of the source. If the source directivity pattern and source location with respect to the array do not change with time, once the source mode strengths are estimated it is possible to reduce the amount of computation necessary to obtain the overall beamformer. This is done by computing an overall beamforming weight vector using Eq. (14) with the estimate $d_{nm}(k)$ replacing $s_{nm}(k)$ which is then used to beamform, without requiring the computation of the individual sub-beamformer outputs. The resultant beamformer output is

$$y(k) = \underbrace{\left\{\sum_{n=0}^{N_{\mathrm{order}}} \sum_{m=-n}^{n} d_{nm}(k)\mathbf{R}_{\mathbf{ee}}^{-1}(k)\mathbf{Y}_n^m(k)\right\}^H}_{=\ \mathbf{w}^H(k)} \underbrace{\mathbf{p}(k)}_{\mathbf{p}(k)}. \tag{23}$$

VI. SIMULATION AND MEASUREMENT RESULTS

This section describes the simulation and experimental demonstration of the proposed method using a directional source and a microphone array. The setup of the demonstration is shown schematically in Fig. 3.

The linear array has 16 uniformly spaced 0.25-in. (6 mm) electret microphones with 8-cm spacing. The array is positioned on the floor with the microphone centers approximately 9 mm above the floor. The source is constructed with two 1-in. (26 mm) PVC (polyvinyl chloride) pipes, approximately 3 m long, each connected to a compression driver. The pipes are approximately parallel with their open ends in contact. The centers of the opening are $h=39.7$ cm directly above the microphone array and in line with the axis of the array.

A 1-kHz test signal is sent to each compression driver. The input signals to the drivers are always 180 deg out of phase with respect to each other and their amplitudes are independently adjustable. The acoustic signal measured at the microphone array includes the 1-kHz test tone, room re-

verberation, noise, and distortion. Identical drivers, pipes, and couplers were used to minimize differences between the two source channels so that a dipole source is approximated when the drive voltages are equal. Since reverberation (image sources) is inevitable in a non-anechoic environment, the microphones are positioned as close as possible to the floor (which is vinyl over wood frame) so that the dominant (nearest) image source is symmetrically positioned about the array axis and will not affect the apparent source directivity. To reduce the effects of other source images, various absorbing panels and plush furniture are positioned about the room, as distant as possible from the source and array. Due to the hard floor and ceiling, the reverberation time in the vicinity of the array is about 700 ms.

For analysis and simulation, a coordinate system is defined with the origin between the centers of the pipe openings, the xy-plane parallel to the floor, the x-axis parallel to the microphone array, and the z-axis passing through the array center, so that the array center is located at $(0,0,-h)$. The center of the pipe openings is located at $(\pm dx/2,0,0)$, where dx is the pipe diameter. The source due to each of the pipes is modeled as a point source at the effective position $(\pm dx/2,-dl,0)$, which is a small distance dl in front of the pipe end.[13] In the simulation computations, this small displacement of the source is modeled but reverberation and noise are ignored.

Digital signals are acquired from the microphone array using a 16-channel anolog-to-digital converter with 16-bit resolution and a sampling rate of 48 kHz. Processing is done offline using a 4096-point fast Fourier transform (FFT) with hamming windowing on each microphone signal to obtain the Fourier coefficient for the single FFT bin containing the 1-kHz test tone. The Fourier coefficients from the 16 microphones are assembled into the microphone signal vector $\mathbf{p}(k)$.

As an indication of the SNR, the FFT bin containing the 1-kHz tone for each of the 16 channels was observed to have a power spectral density at least 40 dB higher when the signal was present than when no signal was present.

In this demonstration of the proposed method, only sub-beamformers of order $N_{\text{order}}=4$ or less are considered. This number was chosen because it is more than adequate for a dipole and provides low computational complexity. Typically, some knowledge of the source characteristics would be used to guide the selection of a value for N_{order}. The contribution to each mode $d_{nm}(k)$ is estimated using Eq. (20), and the overall beamforming weight vector is then obtained as

$$\mathbf{w}(k)=\sum_{n=0}^{4}\sum_{m=-n}^{n} d_{nm}(k)\mathbf{Y}_n^m(k). \tag{24}$$

The optimized white-noise gain for the beamformer is computed as

$$G_{\text{out,dB}}(k)=10\log\left(\frac{\mathbf{w}^H(k)\hat{\mathbf{R}}_{\mathbf{ss}}(k)\mathbf{w}(k)}{\mathbf{w}^H(k)\mathbf{w}(k)}\right). \tag{25}$$

This differs slightly from the white-noise gain in Eq. (4) [with $\mathbf{R}_{\mathbf{ee}}(k)$ equal to the identity matrix] because in our measurements the matrix $\mathbf{R}_{\mathbf{ss}}(k)$ is unknown and is estimated from a single microphone signal vector $\mathbf{p}(k)$, which includes some noise. It is estimated as

$$\hat{\mathbf{R}}_{\mathbf{ss}}(k)=\frac{L}{\mathbf{p}^H(k)\mathbf{p}(k)}\cdot\mathbf{p}(k)\mathbf{p}^H(k). \tag{26}$$

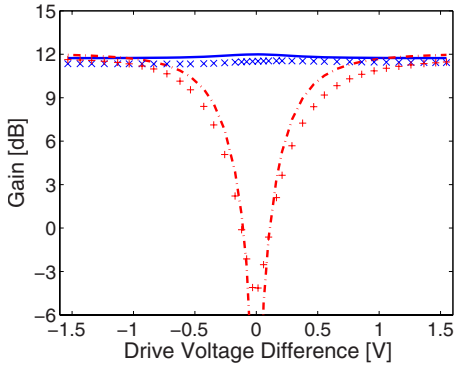

FIG. 4. (Color online) Array gain for varying drive voltage difference $V_{\text{driver\#2}}-V_{\text{driver\#1}}$. Driver No. 1 voltage is held at a fixed value of 1.534 V while driver No. 2 voltage is varied from 0 to 1.548 V, then driver No. 2 voltage is held at a fixed value of 1.548 V while driver No. 1 voltage is reduced to 0. Simulated (—) and measured (×) results for the proposed method, and simulated (·–) and measured (+) results for beamforming with a point source model.

If the drive voltage to either one of the drivers is reduced to zero, the overall source will change from a dipole to a monopole. Figure 4 shows the white-noise gain according to Eq. (25) for the measurement and simulation data, for the proposed method and beamforming with a point source model, when the drive voltages are changed. The pressure magnitude and phase at the end of each tube are not available so white-noise gain is plotted as a function of drive voltage difference. Note that for the proposed method, Eq. (24) is evaluated at each drive voltage whereas the point source model for conventional beamforming is kept constant for all drive voltages.

The optimum white-noise gain is constant; it depends only on the number of sensors and is independent of the source. From Eqs. (4) and (6), the optimum white-noise gain is $10\log(L)$, which is equal to 12.04 dB for an array of 16 sensors. As expected,[3,14] beamforming with a point source model deteriorates and does not perform properly when the drive voltages are equal and the source is a dipole. In which case, Fig. 4 shows a gain slightly below −4 dB for the measurement. On the other hand, for both the measurement and simulation, the proposed method maintains a gain of more than 11 dB.

At the source, only modes $(n,m)=(1,-1)$ and $(n,m)=(1,1)$ are necessary to generate a dipole with the orientation described for the setup. Table I presents the white-noise gain of each sub-beamformer in response to the dipole in the simulated case, computed using $\mathbf{w}(k)=\mathbf{Y}_n^m(k)$ in Eq. (25). It shows that numerous sub-beamformers have similar (but slightly lower) white-noise gain than the two required modes. This is because the linear array has a limited view of the dipole and so the source looks somewhat similar to other modes. (This would not be the case for a dense array completely surrounding the source.)

TABLE I. White-noise gain (in decibels) for each sub-beamformer $y_{nm}(k)$ in response to the dipole in the simulated case.

n	0	1	2	3	4
m	White-noise gain (dB)				
−4					−13.34
−3				11.37	11.61
−2			−20.59	−19.57	−18.35
−1		12.04	11.90	10.83	6.73
0	−17.78	−17.90	−19.04	−22.46	−26.33
1		12.02	11.88	10.80	6.67
2			−10.72	−10.05	−9.38
3				11.34	11.57
4					−8.43

As the overall source approaches a monopole (extreme left or right of the figure), conventional point source beamforming achieves slightly more gain than the proposed method.

A beampattern plot is often used to illustrate the spatial selectivity of a beamforming array using the conventional point source model. For conventional far-field beamforming (plane wave source model) the beampattern is simply a function of arrival direction while for near-field beamforming (point source model) it also depends on the distance from the source to the receiving array. These beampatterns can be easily displayed as one- or two-dimensional plots but spatial selectivity is much more difficult to depict for the proposed method because it is also dependent on the source directivity.

To provide some indication of spatial selectivity for the proposed method, Fig. 5 illustrates how the response varies with the source position when the overall source approximates a dipole. It presents results for source locations at fixed height above the array and along the length of the array. (This is actually done by shifting the array.) The beamforming weight vector for the proposed method is computed using Eqs. (20) and (24), with the source over the center of the array. The beamforming weight vector is then held constant for all other positions. Similarly, the beamforming weight vector for the conventional beamformer is based on a point source over the array center and is held fixed.

There is a good match between measurements and simulation results in Fig. 5. The side lobe levels obtained with the proposed method and with the conventional beamformer using the point source model are not greatly different but the proposed method overcomes the failure to sense the dipole source at the proper position.

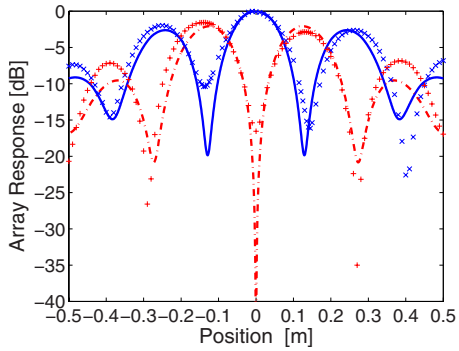

FIG. 5. (Color online) Array response along the x-axis for a dipole source. Simulated (—) and measured (×) results for the proposed method, and simulated (·–) and measured (+) results for beamforming with a point source model.

VII. COMPARISON OF THE PROPOSED METHOD WITH THE PHASE-MODE SPHERICAL ARRAY

The phase-mode spherical array[9–11] has some similarities in form to the proposed method. Both methods use spherical harmonic decomposition and perform a linear combination of eigenbeamformers or sub-beamformers (respectively). Beyond this, the two methods are very different.

The eigenbeamformers mathematically decompose the signal received at the array using spherical harmonics, whereas the proposed method decomposes the source itself. The eigenbeamformers use a spherical array to make the decomposition straightforward, whereas the proposed method applies to any array geometry. The phase-mode spherical array applies to known source models such as plane-waves or point sources whereas the proposed method addresses more general and unknown sources.

The number of modes used by the phase-mode spherical array is determined by the desired accuracy of approximation to beamforming directly with a point source model, and the optimization criterion, whereas the number of modes used with the proposed method is determined by the source complexity. For example, with a monopole source, the phase-mode spherical array requires an infinite number of modes to obtain the optimum white-noise gain, whereas the proposed method with one mode reduces identically to the conventional beamformer using the point source model.

The beamforming weights of each eigenbeamformer are fixed whereas the weight vector of each sub-beamformer depends on the source position and orientation with respect to the array, the array geometry, and the frequency. The weight vector also depends on the normalized noise cross-power spectral density matrix $\mathbf{R}_{\mathbf{ee}}(k)$ when maximizing the array gain.

The weights used in the output stage of the phase-mode spherical array depend on the source position, the array radius, the frequency, and the optimization criterion whereas

the weights to obtain the overall output of the proposed method depend only on the source mode strengths and optimization criterion.

The proposed method addresses a problem with significantly more degrees of freedom (source directivity and orientation) than beamforming with the conventional point source model and this is reflected in the need to estimate more parameters for the same order of harmonic decomposition.

VIII. CONCLUDING REMARKS

Simulation and experimentally measured results were shown for a simple directive source. In the experiment, when the source approached a dipole, the proposed method provided an array gain of about 11 dB while beamforming using a point source model achieved only -4 dB.

Optimization has been considered with respect to the noise field and is based on knowledge of the normalized noise cross-power spectral density matrix $\mathbf{R}_{\mathbf{ee}}(k)$. For clarity and simplicity, the proposed method has been introduced without considering possible techniques for estimating this matrix.

The mode vectors $\mathbf{Y}_n^m(k)$ are determined by the beamforming position; hence these vectors must be updated as the beamformer is steered to different positions. It has been assumed that the source position is known and position estimation is not addressed here.

A simple, intuitive estimator of the source mode strengths is proposed in Sec. IV, and the bias and variance of this estimate are analyzed. It may be possible to devise alternative estimators to reduce the bias or variance; however, the proposed estimator is computationally simple.

The proposed method is inherently adaptive in that an estimate of the unknown source mode strengths is obtained from the observed data. Reflections (reverberation) may affect these estimates and generally degrade beamforming performance. If the source directivity (and position) is known *a priori*, so that estimation is not required, then reflections behave as additional virtual sources that are reduced by the directivity of the proposed beamformer, just as for beamforming with the conventional source model.

The spherical harmonic orders included in the overall beamformer must be limited to a finite number N_{order}. This value should be estimated from the general complexity of the source. For the dipole example considered here, $N_{\text{order}}=4$ was found to be adequate.

The proposed method can be applied easily to situations of well known source directivity and noise. It constitutes a step toward beamforming in more general applications on unknown directional sources. Further work should address obtaining improved estimates of the mode strength, the number of modes required, and $\mathbf{R}_{\mathbf{ee}}(k)$.

Basic theory and properties of statistically optimized near-field acoustical holography

Jørgen Hald[a)]
Brüel & Kjær Sound & Vibration Measurement A/S, Skodsborgvej 307, DK-2850 Nærum, Denmark

(Received 14 August 2008; revised 19 December 2008; accepted 12 January 2009)

To avoid the requirement set by standard near-field acoustical holography (NAH) to measure an area that fully covers the source, a set of so-called patch NAH methods has been introduced. One such method is the statistically optimized NAH (SONAH). In this method, the acoustic quantities on a mapping surface near the measurement surface are calculated by using a transfer matrix defined in such a way that all propagating waves and a weighted set of evanescent waves are projected with optimal average accuracy. The present paper gives an overview of the basic theory of SONAH, including a description of phenomena such as spatial aliasing and wave-number domain leakage. A revised and generalized mathematical formulation is given, covering the calculation of all three components of particle velocity and the use of up to six virtual source planes. A set of formulas for the inherent estimation error level of the method is derived and used to visualize the regions of validity of the SONAH predictions for some typical microphone array geometries. The sensitivity of the inherent error level distribution to changes in the parameters of the SONAH algorithm is also investigated. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3079773]

I. INTRODUCTION

Near-field acoustical holography (NAH) is a very useful tool for three-dimensional (3D) visualization of sound radiation and for precise noise source localization based on measurements over a surface near the sound source. Its ability to reconstruct also the evanescent wave components ensures a very high spatial resolution. The oldest form of NAH (Refs. 1–3) is based on regular-grid measurements across a level surface in a separable coordinate system, allowing the NAH calculation to be performed by spatial discrete Fourier transform (DFT). As a consequence, the processing is very fast, but a side effect of using the DFT is severe spatial windowing effects unless the measurement area fully covers the areas with high sound pressure. In some cases this requirement on the measurement area cannot be fulfilled, and in many cases the necessary size becomes prohibitively large.

A set of techniques has therefore been developed to reduce the spatial windowing effects, still maintaining the DFT spatial processing.[4–9] The cost is increased complexity and computational demands. Typically an iterative procedure is first used to extrapolate the measured sound pressure outside the measured area, followed by application of the standard DFT based holography method on the extended data window.

Another set of methods avoiding the use of spatial DFT has also been developed. The decreased computational efficiency can then more or less be compensated by a reduction in the required measurement area. One such method is Helmholtz' equation least-squares (HELS),[10,11] and another similar method is the statistically optimized NAH (SONAH).[12–19] Both use a local model of the sound field in terms of elementary wave functions—typically spherical wave functions for the case of HELS and typically plane wave functions for the case of SONAH—and both perform a (least-squares or least norm) fit of the elementary wave model (EWM) to the measured sound field data. HELS performs the fit of model to data explicitly, while SONAH does it implicitly, as will be detailed in Sec. II A of the present paper. A third much related technique is the equivalent source method.[20–22] Here, the local sound field is represented by a distribution of monopole point sources outside the model region, typically inside the volume of the real source, and a least-squares fit of the monopole excitations to the measured data is performed. The fourth and final technique that shall be mentioned is patch inverse Boundary Element Method (BEM).[22–24]

The SONAH method has been described mostly in conference proceedings[13,15–17] plus three journal papers[12,14,18] that introduce the basic method and a couple of special implementations. A comprehensive description of the basic theory and properties of the method is missing. The aim of the present paper is to give such a description. Some of the ideas from the three conference papers[13,15,17] are used here, but in a common framework that includes a more compact and general mathematical formulation plus a treatment of wave-number leakage. The more general formulation covers, for example, calculation of all three components of particle velocity. Beyond that, the previously described formulations with a single virtual source plane[13] (free-field conditions) and two virtual source planes[15] are extended to the case of six virtual source planes, which allows general sound fields in a box shaped homogeneous regions to be handled. Another new contribution is a description of the inherent error level of the SONAH method and its use to visualize the regions of validity of the sound field predictions.

Results from actual measurements have not been included since that would make the paper too long, but such

a)Electronic mail: jhald@bksv.com

results can be found in Refs. 13–16, 18, and 19. Likewise, no direct comparison of reconstruction accuracies between SONAH and other NAH techniques is given. Such comparisons based on simulated and actual measurements can be found in Refs. 12, 13, 16, and 17.

In Sec. II the basic general theory of the SONAH method is outlined. Two alternative derivations are given in Sec. II A to support the explanation of some important properties of the method. Section II B outlines the planar free-field case of SONAH, and Sec. II C describes the non-free-field cases with two and six virtual source planes. The inherent relative error descriptor of SONAH is then derived in Sec. II D, and Sec. II E introduces the concept of wave-number leakage in relation to SONAH. Section III presents a set of computer simulations to show the accuracy of the method in some typical cases. The focus is on visualizing the regions of validity of the method and on explaining the limitations and the observed errors.

II. THEORY OF SONAH

A. General underlying formulation

Assume that the complex time-harmonic sound pressure $p(\mathbf{r}_i)$ has been measured at a set of positions $\mathbf{r}_i$, $i=1,2,\ldots,I$, in a source-free region Ω occupied by a homogeneous fluid. We consider the problem of reconstructing the sound field in Ω based on the measured pressures. To do that we use a set of elementary wave functions, Ψ_n, $n=1,\ldots,N$, fulfilling the homogeneous wave equation in Ω and capable of representing with a sufficiently high accuracy all sound pressure fields that can exist in Ω. Typically, these elementary wave functions can be plane, cylindrical, or spherical waves, or they can be sound fields from elementary sources such as monopole, dipole, and/or multipole point sources distributed outside Ω. The first step in a typical reconstruction process, as published, for example, in the HELS method,[10,11] is to determine the amplitude and phase of each elementary wave function in the representation of the sound field. This is done by requiring that the EWM represent as accurately as possible the measured pressures:

$$p(\mathbf{r}_i)=\sum_{n=1}^{N} a_n\Psi_n(\mathbf{r}_i), \quad i=1,\ldots,I, \tag{1}$$

a_n being the complex expansion coefficients. If $I\geq N$ and if the measurement points have been suitably chosen, then the expansion coefficients can be found by least-squares solution of Eq. (1). Otherwise the problem is under-determined, and among the infinity of solutions to Eq. (1) the one with the smallest 2-norm will be adopted. The least norm solution will be subsequently referred to as a least norm EWM (LN-EWM), while the least-squares solution shall be called a least-squares EWM (LS-EWM).

To obtain a matrix formulation, we define the matrix $\mathbf{B}$ of wave function values at the measurement positions:

$$\mathbf{B}\equiv\{\Psi_n(\mathbf{r}_i)\}\equiv\begin{Bmatrix}\Psi_1(\mathbf{r}_1) & \Psi_2(\mathbf{r}_1) & \cdots & \Psi_N(\mathbf{r}_1)\\ \Psi_1(\mathbf{r}_2) & \Psi_2(\mathbf{r}_2) & & \Psi_N(\mathbf{r}_2)\\ \vdots & & \ddots & \vdots\\ \Psi_1(\mathbf{r}_I) & \Psi_2(\mathbf{r}_I) & \cdots & \Psi_N(\mathbf{r}_I)\end{Bmatrix} \tag{2}$$

and the vectors $\mathbf{p}$ and $\mathbf{a}$ with measured pressures and with expansion coefficients, respectively:

$$\mathbf{p}\equiv\{p(\mathbf{r}_i)\}\equiv\begin{Bmatrix}p(\mathbf{r}_1)\\ p(\mathbf{r}_2)\\ \vdots\\ p(\mathbf{r}_I)\end{Bmatrix}, \quad \mathbf{a}\equiv\{a_n\}\equiv\begin{Bmatrix}a_1\\ a_2\\ \vdots\\ a_N\end{Bmatrix}. \tag{3}$$

Using these definitions Eq. (1) can be rewritten in the following form:

$$\mathbf{Ba}=\mathbf{p}. \tag{4}$$

With $I\geq N$ the least-squares (LS-EWM) solution is $\mathbf{a}=(\mathbf{B}^H\mathbf{B})^{-1}\mathbf{B}^H\mathbf{p}$, and with $I<N$ the least norm (LN-EWM) solution is[25] $\mathbf{a}=\mathbf{B}^H(\mathbf{BB}^H)^{-1}\mathbf{p}$, the symbol H representing Hermitian transpose. In practice, regularization has to be applied in these solutions. We shall consider only Tikhonov regularization, and in that case the LS-EWM and LN-EWM formulas become

$$\tilde{\mathbf{a}}=(\mathbf{B}^H\mathbf{B}+\varepsilon\mathbf{I})^{-1}\mathbf{B}^H\mathbf{p} \tag{5}$$

and

$$\tilde{\mathbf{a}}=\mathbf{B}^H(\mathbf{BB}^H+\varepsilon\mathbf{I})^{-1}\mathbf{p}, \tag{6}$$

respectively, ε being a positive regularization parameter and $\mathbf{I}$ a unit diagonal quadratic matrix of appropriate dimensions. It is shown in Appendix A that actually the two regularized formulas (5) and (6) provide exactly the same solution independent of the values of I and N. But for $I<N$ it is still a computational advantage to use the LN-EWM formula (6) because the matrix $\mathbf{BB}^H$ has smaller dimension than $\mathbf{B}^H\mathbf{B}$.

The combined least-squares and least norm properties of, for example, the regularized least-squares formula (5) are evident from the following statement given by Hansen:[26] The solution $\tilde{\mathbf{a}}$ provided by Eq. (5) with any positive regularization parameter ε has the smallest norm $\|\mathbf{a}\|_2$ among all those coefficient vectors $\mathbf{a}$ that provide residual norms not exceeding $\|\mathbf{B}\tilde{\mathbf{a}}-\mathbf{p}\|_2$, and it has the smallest residual norm $\|\mathbf{Ba}-\mathbf{p}\|_2$ among all vectors $\mathbf{a}$ with a norm that does not exceed $\|\tilde{\mathbf{a}}\|_2$.

Assuming from now on that the elementary wave functions Ψ_n constitute a complete basis in Ω, all sound pressure fields can be represented by these functions, so we can use the vector $\mathbf{a}$ of expansion coefficients to represent the true pressure in Ω. Plane wave spectra and spherical wave functions constitute complete basis function sets in suitably defined domains. The vector $\tilde{\mathbf{a}}$ then represents the corresponding coefficient vector estimated from the array measurements. Using that vector $\tilde{\mathbf{a}}$, the reconstructed sound pressure $\tilde{p}(\mathbf{r})$ at an arbitrary point $\mathbf{r}$ in Ω can be calculated by summation of the wave function contributions:

$$\tilde{p}(\mathbf{r}) \equiv \sum_{n=1}^{N} \tilde{a}_n \Psi_n(\mathbf{r}) = \tilde{\mathbf{a}}^T \boldsymbol{\alpha}(\mathbf{r}), \quad \boldsymbol{\alpha}(\mathbf{r}) \equiv \begin{Bmatrix} \Psi_1(\mathbf{r}) \\ \Psi_2(\mathbf{r}) \\ \vdots \\ \Psi_N(\mathbf{r}) \end{Bmatrix}, \tag{7}$$

T representing the transpose of a matrix or vector. This reconstructed pressure field fulfils the homogeneous wave equation in Ω because all expansion functions do. The particle velocity in a direction χ can then be estimated from the reconstructed sound pressure by application of Euler's equation:

$$\tilde{u}_\chi(\mathbf{r}) = \frac{-1}{j\omega\rho_0} \frac{\partial \tilde{p}(\mathbf{r})}{\partial \chi}. \tag{8}$$

Here, ω is the angular frequency, ρ_0 is the density of the medium, and the implicit time variation is $e^{j\omega t}$. Other symbols to be used subsequently are the propagation speed of sound, c, and the wave-number, $k \equiv \omega/c$.

The LS-EWM method described above applied to a single-origin spherical wave representation of the sound field is a basic version of the HELS method. The region of validity, Ω, of the field model is in that case a finite or infinite homogeneous spherical shell centered at the origin of the spherical wave functions. Spherical wave functions are efficient for representing the sound field in such regions because they are discretely indexed and because a finite subset can provide an accurate representation in a finite spherical shell. Cylindrical and plane waves by nature constitute continuous spectra in a wave-number domain, so use of these in the above formulation must involve a subset of the wave functions obtained by sampling in the wave-number domain. The SONAH method to be introduced now overcomes this sampling problem by solving the field estimation problem in a dual way.

Following the earlier derivations by Hald[13,15] of SONAH based on plane wave functions, we require the reconstructed sound pressure $\tilde{p}(\mathbf{r})$ at a point $\mathbf{r}$ in Ω to be obtained as a linear combination of the known sound pressure values:

$$\tilde{p}(\mathbf{r}) = \mathbf{p}^T \mathbf{c}(\mathbf{r}), \tag{9}$$

where the vector $\mathbf{c}(\mathbf{r})$ contains the complex estimation weights. The vector $\mathbf{c}$ is then obtained by requiring that the prediction formula (9) provides in a least-squares sense the best average prediction for all expansion functions Ψ_n. With reference to Eqs. (2) and (7), this means that $\mathbf{c}(\mathbf{r})$ should be found as the least-squares solution to the following set of linear equations:

$$\mathbf{B}^T \mathbf{c}(\mathbf{r}) = \boldsymbol{\alpha}(\mathbf{r}). \tag{10}$$

Clearly, this equation is under-determined whenever the EWM Eq. (4) is over-determined and vice versa. Only the Tikhonov regularized solution shall be considered, meaning that the least-squares and least norm solutions to Eq. (10) can be both expressed in terms of the least-squares formula:

$$\mathbf{c}(\mathbf{r}) = (\mathbf{A}^H \mathbf{A} + \varepsilon \mathbf{I})^{-1} \mathbf{A}^H \boldsymbol{\alpha}(\mathbf{r}), \tag{11}$$

where the matrix $\mathbf{A}$ is the transpose of $\mathbf{B}$:

$$\mathbf{A} \equiv \mathbf{B}^T. \tag{12}$$

From the definitions (7) and (12), it follows that the elements of $\mathbf{A}^H\mathbf{A}$ and $\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})$ are given by formulas (13) and (14) below, respectively, * representing complex conjugate:

$$[\mathbf{A}^H \mathbf{A}]_{ij} = \sum_n \Psi_n^*(\mathbf{r}_i) \Psi_n(\mathbf{r}_j), \tag{13}$$

$$[\mathbf{A}^H \boldsymbol{\alpha}(\mathbf{r})]_i = \sum_n \Psi_n^*(\mathbf{r}_i) \Psi_n(\mathbf{r}). \tag{14}$$

The matrix $\mathbf{A}^H\mathbf{A}$ can be seen as a matrix of cross correlations between the measurement points in the domain of the elementary wave functions (expansion functions), and the vector $\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})$ then contains the cross correlations between the measurement points and the estimation position $\mathbf{r}$ (see Steiner and Hald[12]). Notice that $\mathbf{A}^H\mathbf{A}$ is a Hermitian symmetric matrix with non-negative eigenvalues, and that its dimensions equal the number I of measurement points, independent of the number of expansion functions. This will be very effectively exploited in connection with continuous spectra of wave functions.

The SONAH prediction formulation just derived can be shown to provide the same solution as the LS-EWM and LN-EWM formulas. Actually, the LN-EWM Eqs. (7) and (6) easily lead to the SONAH formulation:

$$\begin{aligned} \tilde{p}(\mathbf{r}) = \tilde{\mathbf{a}}^T \boldsymbol{\alpha}(\mathbf{r}) &= \mathbf{p}^T [(\mathbf{B}\mathbf{B}^H + \varepsilon \mathbf{I})^{-1}]^T \mathbf{B}^* \boldsymbol{\alpha}(\mathbf{r}) \\ &= \mathbf{p}^T [(\mathbf{B}\mathbf{B}^H + \varepsilon \mathbf{I})^T]^{-1} \mathbf{B}^* \boldsymbol{\alpha}(\mathbf{r}) \\ &= \mathbf{p}^T [\mathbf{A}^H \mathbf{A} + \varepsilon \mathbf{I}]^{-1} \mathbf{A}^H \boldsymbol{\alpha}(\mathbf{r}) = \mathbf{p}^T \mathbf{c}(\mathbf{r}). \end{aligned} \tag{15}$$

Here we have used the fact that for any non-singular quadratic matrix the transpose of the inverse equals the inverse of the transpose, and we have used Eqs. (12) and (11).

In EWM methods, where a vector $\tilde{\mathbf{a}}$ of expansion coefficients is explicitly calculated, spatial filtering/smoothing can be done both in the regularized solution for $\tilde{\mathbf{a}}$ and by attenuating the components of $\tilde{\mathbf{a}}$ representing high spatial frequencies before $\tilde{\mathbf{a}}$ is used for sound field reconstructions. Since SONAH does not calculate $\tilde{\mathbf{a}}$, spatial filtering/smoothing can be done only in the regularization. Making this role of the regularization work properly, however, requires a suitable scaling of the elementary wave functions, as will be explained in Sec. II B focusing on plane wave representations.

An interesting difference between the presented EWM and SONAH derivations is that the SONAH derivation considers from the beginning with Eqs. (9) and (10) the prediction problem, whereas the EWM derivation just fits a set of basis functions at the measurement positions.

B. SONAH plane wave formulation for free-field conditions

We consider now the special case where the elementary waves are plane propagating and evanescent waves, and we start with free-field conditions, as illustrated in Fig. 1, where sources behind a source plane, $z=z_0^+$, $z_0^+<0$, radiate into the

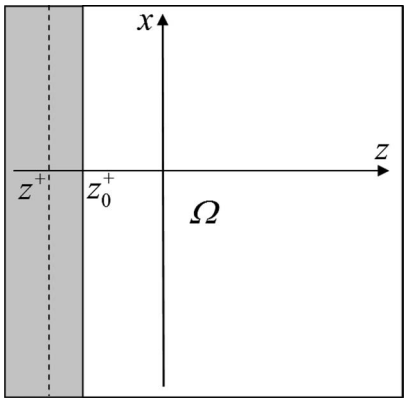

FIG. 1. Free-field measurement geometry with only one source plane (vertical line) and one virtual source plane (dashed vertical line). The domain Ω of the sound field representation is white.

source free, homogeneous half space Ω with $z \geq z_0^+$. In this half space, the radiated sound field can be represented by plane wave functions of the form

$$\Phi_{\mathbf{k}}(\mathbf{r}) \equiv F(k_z) e^{-j(k_x x + k_y y + k_z (z - z^+))}, \tag{16}$$

where F is an amplitude weighting function, $z=z^+$ is the so-called virtual source plane where the wave functions are scaled, $\mathbf{r} \equiv (x,y,z)$ is a position vector, and $\mathbf{k} \equiv (k_x, k_y, k_z)$ is a wave-number vector with

$$k_z \equiv \begin{cases} \sqrt{k^2 - (k_x^2 + k_y^2)} & (k_x^2 + k_y^2) \leq k^2 \\ -j\sqrt{(k_x^2 + k_y^2) - k^2} & (k_x^2 + k_y^2) > k^2 \end{cases}. \tag{17}$$

Thus, the complete set of expansion functions constitutes a continuous spectrum in the two wave-number variables k_x and k_y. The virtual source plane $z=z^+$ could be coincident with the real source plane, $z=z_0^+$, but typically it should be chosen behind that plane, i.e., $z^+ < z_0^+$. The superscript + on the coordinates of the real and virtual source planes indicates that waves propagating in the positive z-axis direction are represented.

To use the EWM or SONAH formulations given in the previous section, we select first a discrete subset by regular sampling with intervals $(\Delta k_x, \Delta k_y)$ in the two-dimensional (2D) wave-number domain (k_x, k_y):

$$\Psi_n(\mathbf{r}) \equiv \kappa \Phi_{\mathbf{k}_n}(\mathbf{r}), \quad \kappa \equiv \sqrt{\frac{\Delta k_x \Delta k_y}{2\pi k^2}}. \tag{18}$$

Here, $\mathbf{k}_n$ are the wave-number domain sampling points, and the scaling factor κ has been introduced to support a smooth transition to the use of continuous wave-number spectra. When choosing the sampling spacing, one should be aware that a regular discrete representation in the wave-number domain will represent a field that is spatially periodic,[3] leading to wrap-around errors just like in traditional NAH based on spatial DFT processing. The wave-number domain sampling spacing should therefore be smaller than 2π divided by the smallest acceptable distance between the periodic replica in the represented sound field. At the same time, the sampling area should cover all propagating waves and all those evanescent waves that have significant amplitude in the measurement region. This almost inevitably leads to a number N of expansion functions Ψ_n larger than the number I of measurement positions. The equivalent EWM problem will therefore be under-determined, and the solution (6) will be dominantly a least norm solution.

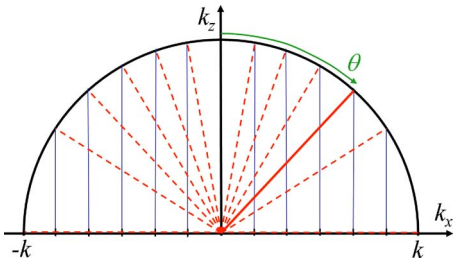

FIG. 2. (Color online) Equidistant samples along the k_x-axis and their mapping on corresponding directions of plane wave propagation.

We consider first a unit weighting, $F(k_z)=1$, of the wave functions, as used in previous publications on SONAH. Then according to Eq. (16) all plane wave functions $\Phi_{\mathbf{k}}(\mathbf{r})$ have amplitude equal to 1 on the virtual source plane, $z=z^+$, and all elements in the sampled and scaled discrete subset $\Psi_n(\mathbf{r})$ have amplitude equal to κ on that plane. The EWM expansion coefficient vector, $\tilde{\mathbf{a}}$, is therefore a scaled discrete wave-number spectrum of the reconstructed sound pressure on the virtual source plane, and the matrix $\mathbf{B}$ can be seen as a matrix of transfer functions from that scaled plane wave spectrum to the sound pressure values at the microphone positions. According to the definition in Eq. (2), the elements of $\mathbf{B}$ are given by Eq. (18) with the microphone coordinates inserted. Clearly, through the transfer matrix $\mathbf{B}$, evanescent wave components ($\Phi_{\mathbf{k}}$ with $k_x^2 + k_y^2 > k^2$) will get an attenuation that increases exponentially with wave-number. The overall trend must therefore be that the higher wave-number components will be represented in the smaller singular values of the matrix $\mathbf{B}$. This property ensures that appropriate filtering of the evanescent wave components can be performed by Tikhonov regularization in the inverse solution for the scaled wave-number spectrum, $\tilde{\mathbf{a}}$. Some combinations of propagating waves will also be represented by small singular values, for example, combinations that represent sound radiation from areas in the virtual source plane far from the measurement positions.

Because of the above mentioned under-determined nature of the EWM problem, the solution will dominantly be a minimum norm solution. A further reduction in the norm of the solution vector, $\tilde{\mathbf{a}}$, will be introduced by the regularization. The solution process will therefore minimize the energy in the wave-number spectrum and consequently also, according to Parseval's theorem,[27] the energy in the pressure distribution on the virtual source plane (and on parallel planes) under the constraint that the pressure at the microphones is well represented. As a result, a good sound field representation is achieved within a volume around the array, while an increasing underestimation will be seen away from the array. Since SONAH and EWM provide the same reconstruction [see Eq. (15)], the consequences will be the same for SONAH. The simulated measurements to be presented in Sec. III confirm this hypothesis.

Figure 2 illustrates the regular sampling of Eq. (18)

along the k_x wave-number axis at $k_y=0$. Inside the radiation circle, i.e., for $k_x^2+k_y^2 \le k^2$, a specific sample at (k_x,k_y) corresponds to a plane wave propagating in the direction of the vector (k_x,k_y,k_z), with k_z given by Eq. (17).[3] In Fig. 2, this direction can be found by projecting the sample position k_x up on the shown half circle with radius k. Clearly, with a constant density of the sample points in the (k_x,k_y)-plane, the angular density of the plane waves will be highest close to the z-direction and will decrease when the off-axis angle θ increases toward 90°. Thus, if we use a constant weighting function F, then plane waves propagating near the axial direction will get a higher weight than the far off-axis waves in the least-squares solution (11) for the prediction weights of SONAH. This can be compensated by applying a higher weight F to the off-axis waves. Considering an infinitely small area segment on the (k_x,k_y)-plane, it will represent an area on the directional hemisphere $k_x^2+k_y^2+k_z^2=k^2$, which is larger by a factor of $1/\cos(\theta)=k/|k_z|$. A constant directional power density of the weighting function can therefore be obtained by choosing F such that $|F(k_z)|^2 k/|k_z|$ is constant, for example,

$$F(k_z) = F_0 \sqrt{\frac{k}{|k_z|}}, \tag{19}$$

where F_0 is a constant. Equations (13), (14), (16), and (18) show that the contributions to the elements of the matrices $\mathbf{A}^H\mathbf{A}$ and $\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})$ are obtained by summation over wave-number contributions, which are scaled by $|F|^2$. This is the reason for choosing the equalization to be on the directional power density and not on the directional amplitude density. The "omni-directional weighting" of Eq. (19), applied also outside the radiation circle, has been found to provide on the average slightly better accuracy than the constant weighting $F(k_z)=1$, and it will be used subsequently as the default weighting.

To remove completely the wrap-around problem caused by the discrete representation in the wave-number domain, we now let the sampling spacing in the (k_x,k_y)-plane go to zero, meaning that the summations in Eqs. (13) and (14) become integrals over the (k_x,k_y)-plane. From Eqs. (18), (13), and (14) we obtain

$$[\mathbf{A}^H\mathbf{A}]_{ij} = \sum_n \Phi_{\mathbf{k}_n}^*(\mathbf{r}_i)\Phi_{\mathbf{k}_n}(\mathbf{r}_j)\frac{\Delta k_x \Delta k_y}{2\pi k^2} \underset{\substack{\Delta k_x\to 0\\ \Delta k_y\to 0}}{\to} \frac{1}{2\pi k^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\Phi_{\mathbf{k}}^*(\mathbf{r}_i)\Phi_{\mathbf{k}}(\mathbf{r}_j)dk_x dk_y, \tag{20}$$

$$[\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})]_i = \sum_n \Phi_{\mathbf{k}_n}^*(\mathbf{r}_i)\Phi_{\mathbf{k}_n}(\mathbf{r})\frac{\Delta k_x \Delta k_y}{2\pi k^2} \underset{\substack{\Delta k_x\to 0\\ \Delta k_y\to 0}}{\to} \frac{1}{2\pi k^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\Phi_{\mathbf{k}}^*(\mathbf{r}_i)\Phi_{\mathbf{k}}(\mathbf{r})dk_x dk_y. \tag{21}$$

The $1/2\pi k^2$ scaling factor has been chosen with the aim of obtaining nice dimensionless expression for the matrix elements. Letting the sampling spacing go to zero will tend to strengthen the under-determined nature of the problem, motivating further the numerical investigations of the estimation errors in Sec. III. These investigations show that very good accuracy is, in general, achieved within a volume around the measurement positions, and this conclusion agrees with results from both simulated and actual measurements.[12–19] In particular, numerous published[12,13] and un-published applications to small measurement grids (patch calculations) show a significant gain in reconstruction accuracy by replacing the wrap-around errors of DFT based NAH with the least norm errors of plane wave SONAH.

An interesting observation in relation to Eqs. (20) and (21) above is that the discrete wave model can be seen as a way of performing numerical computation of the integrals, with the same function evaluation points (Gauss points) used in all integrals.

Use of the limiting values (20) and (21) of the matrix elements implies that the matrix $\mathbf{A}$ and the vector $\boldsymbol{\alpha}(\mathbf{r})$ have a dimension that is infinite. $\mathbf{A}$ and $\boldsymbol{\alpha}(\mathbf{r})$ will be used anyway in a couple of subsequent derivations, where they should be thought of as limiting cases for $N\to\infty$, corresponding to the sampling intervals $(\Delta k_x,\Delta k_y)$ approaching zero. The vector $\tilde{\mathbf{a}}$ of expansion coefficients of the equivalent EWM should in the same way be considered as a limiting case.

As shown in Appendix B, the 2D integrals in Eqs. (20) and (21) can be reduced to one-dimensional integrals through application of Eqs. (16), (17), and (19): The integrals can be expressed in terms of the following two functions of two variables:

$$I_p(\rho,\zeta) \equiv \int_0^{\pi/2} J_0(\rho\sin(\theta))e^{j\zeta\cos(\theta)}\sin(\theta)d\theta, \tag{22}$$

$$II_p(\rho,\zeta) \equiv \int_0^{\infty} J_0(\rho\sqrt{1+v^2})e^{-\zeta v}dv, \tag{23}$$

where J_0 is the Bessel function of order zero. The function I_p represents contributions from inside the radiation circle in the wave-number domain, and the function II_p represents contributions from outside the radiation circle. The contributions I_p and II_p can be combined into a single function III_p defined as

$$III_p(\rho,\zeta_1,\zeta_2) \equiv I_p(\rho,\zeta_1) + II_p(\rho,\zeta_2). \tag{24}$$

Using this function, formulas (20) and (21) for the matrix elements can be reformulated as follows (see Appendix B):

$$[\mathbf{A}^H\mathbf{A}]_{ij} = F_0^2 III_p(kR_{ij}^{xy}, k(z_i-z_j), k(z_i+z_j-2z^+)), \tag{25}$$

$$[\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})]_i = F_0^2 III_p(kR_i^{xy}, k(z_i-z), k(z_i+z-2z^+)). \tag{26}$$

Here, $\mathbf{r}_i \equiv (x_i,y_i,z_i)$ and $\mathbf{r}_j \equiv (x_j,y_j,z_j)$ are two microphone positions, the pressure estimation position is $\mathbf{r}\equiv(x,y,z)$, R_{ij}^{xy} is the distance between the projections of microphone positions i and j on the xy-plane (or, more generally, on the virtual source plane), and R_i^{xy} is the distance between the projections of microphone position i and the pressure calculation position on the xy-plane.

Different methods for determination of the regularization parameter ε of Eq. (11) have been investigated by Go-

mes and Hansen,[16] and the *L*-curve method was found to provide the overall most stable result in connection with SONAH. Earlier studies with uncorrelated measurement errors had pointed at generalized cross validation (GCV). The second important parameter in SONAH is the position $z=z^+$ of the virtual source plane. Results published by Hald and Gomes[17] show that optimal accuracy is obtained by positioning the virtual source plane one to one and a half measurement grid spacing behind the physical source plane, i.e., further away from the measurement grid than the physical source surface. Slightly larger distances were often better at low frequencies. In case of an irregular measurement grid, the criterion should use the average grid spacing.

To obtain particle velocity estimates, we apply Euler's Eq. (8) to the SONAH pressure estimate given by Eqs. (9) and (11). As a result we obtain

$$\tilde{u}_\chi(\mathbf{r}) = \frac{-1}{j\omega\rho_0}\frac{\partial\tilde{p}(\mathbf{r})}{\partial\chi} = \frac{1}{\rho_0 c}\mathbf{p}^T(\mathbf{A}^H\mathbf{A}+\varepsilon\mathbf{I})^{-1}\mathbf{A}^H\boldsymbol{\beta}_\chi(\mathbf{r}), \quad (27)$$

where

$$\mathbf{A}^H\boldsymbol{\beta}_\chi(\mathbf{r}) \equiv \frac{-1}{jk}\frac{\partial\{\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})\}}{\partial\chi}. \quad (28)$$

Explicit formulas for $\mathbf{A}^H\boldsymbol{\beta}_\chi(\mathbf{r})$ can be obtained by inserting Eq. (26) in Eq. (28), followed by application of expressions (22) and (23) for the functions I_p and II_p. For the z-component we obtain

$$[\mathbf{A}^H\boldsymbol{\beta}_z(\mathbf{r})]_i = F_0^2 III_z(kR_i^{xy}, k(z_i-z), k(z_i+z-2z^+)), \quad (29)$$

and for the x- and y-components we obtain

$$\frac{[\mathbf{A}^H\boldsymbol{\beta}_x(\mathbf{r})]_i}{jk(x_i-x)} = \frac{[\mathbf{A}^H\boldsymbol{\beta}_y(\mathbf{r})]_i}{jk(y_i-y)} = F_0^2 III_{xy}(kR_i^{xy}, k(z_i-z), k(z_i+z-2z^+)). \quad (30)$$

The new functions III_z and III_{xy} are listed in Appendix C together with III_p. Appendix C also gives the form these functions would have with a constant weighting ($F(k_z)=1$) of the elementary waves, and some considerations are given to the calculation of the functions.

Typically in the present free-field case a planar array will be used, but SONAH supports in any case arbitrary 3D measurement grids.

C. SONAH plane wave formulation for non-free-field conditions

When sources and reflecting objects are not restricted to a half space, then the plane wave functions defined in Eq. (16) no longer constitute a complete basis for sound fields in the measurement region.

We consider first the case illustrated in Fig. 3, where measurements are taken in a homogeneous and source-free slab/slice between two parallel source planes, $z_0^+ \le z \le z_0^-$. The part of the sound field with sources for $z<z_0^+$ can be represented by the basis functions of Eq. (16), to be written in the following as $\Phi_{\mathbf{k}}^{z+}$. To represent also the sound field components with sources for $z>z_0^-$, we have to add a corresponding set of plane wave functions $\Phi_{\mathbf{k}}^{z-}$ with virtual source plane at $z=z^-$, $z^- \ge z_0^-$, resulting in the combined set

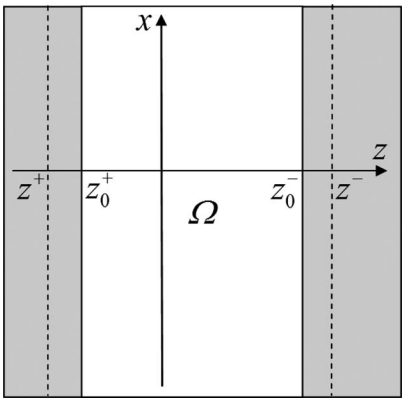

FIG. 3. Two parallel source planes limiting a homogeneous and source-free region. The two corresponding virtual source planes are shown as dashed lines.

$$\Phi_{\mathbf{k}}^{z+}(\mathbf{r}) \equiv F_{z+}(k_z)e^{-j(k_x x+k_y y+k_z(z-z^+))}, \quad (31)$$

$$\Phi_{\mathbf{k}}^{z-}(\mathbf{r}) \equiv F_{z-}(k_z)e^{-j(k_x x+k_y y-k_z(z-z^-))}, \quad (32)$$

where the definition of k_z in Eq. (17) is still used, and omnidirectional weighting is applied for both sets:

$$F_{z+}(k_z) = F_{0,z+}\sqrt{\frac{k}{|k_z|}}, \quad F_{z-}(k_z) = F_{0,z-}\sqrt{\frac{k}{|k_z|}}. \quad (33)$$

A set of plane wave functions as given in Eq. (31) or Eq. (32) is often referred to just as a "virtual source plane" in the present paper. So adding a virtual source plane means adding a set of plane wave functions in the SONAH (or EWM) method. Equations (13), (14), (20), and (21) show that a SONAH estimation procedure taking into account the combined set of basis functions, Eqs. (31) and (32), can be obtained by adding the contributions from the two sets in the elements of the matrices $\mathbf{A}^H\mathbf{A}$ and $\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})$. The result of doing this is

$$[\mathbf{A}^H\mathbf{A}]_{ij} = F_{0,z+}^2 III_p(kR_{ij}^{xy}, k(z_i-z_j), k(z_i+z_j-2z^+)) + F_{0,z-}^2 III_p(kR_{ij}^{xy}, k(z_j-z_i), k(2z^- - z_i - z_j)), \quad (34)$$

$$[\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})]_i = F_{0,z+}^2 III_p(kR_i^{xy}, k(z_i-z), k(z_i+z-2z^+)) + F_{0,z-}^2 III_p(kR_i^{xy}, k(z-z_i), k(2z^- - z_i - z)). \quad (35)$$

The vectors $\mathbf{A}^H\boldsymbol{\beta}_\chi(\mathbf{r})$ needed for estimation of particle velocity can be derived just like for the free-field case with the following result:

$$[\mathbf{A}^H\boldsymbol{\beta}_z(\mathbf{r})]_i = F_{0,z+}^2 III_z(kR_i^{xy}, k(z_i-z), k(z_i+z-2z^+)) - F_{0,z-}^2 III_z(kR_i^{xy}, k(z-z_i), k(2z^- - z_i - z)), \quad (36)$$

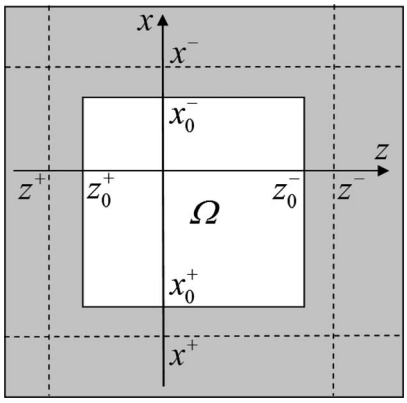

FIG. 4. Source planes on all sides of a box shaped homogeneous and source-free region. The corresponding virtual source planes are shown as dashed lines.

$$\frac{[\mathbf{A}^H\boldsymbol{\beta}_x(\mathbf{r})]_i}{jk(x_i-x)}=\frac{[\mathbf{A}^H\boldsymbol{\beta}_y(\mathbf{r})]_i}{jk(y_i-y)}$$
$$=F_{0,z+}^2 III_{xy}(kR_i^{xy},k(z_i-z),k(z_i+z-2z^+))$$
$$+F_{0,z-}^2 III_{xy}(kR_i^{xy},k(z-z_i),k(2z^--z_i-z)). \quad (37)$$

The above formulation puts no restriction on the selection of the measurement positions, but a planar array will not be sufficient to get accurate predictions. This can be illustrated by the fact that sources which are image symmetric in the measurement plane cannot then be distinguished because at every microphone they produce the same pressure. Typically, a dual layer array consisting of two identical planar rectangular arrays will be used as described by Hald.[15] The weight on the waves with sources on either side of the array can be adjusted through the coefficients $F_{0,z+}$ and $F_{0,z-}$. Typically, both parameters will be chosen equal to 1, but if no significant sources are present on one side of the array, better estimates can be achieved by setting one of them equal to zero, providing thereby the information of the single-sided source distribution to the formulation. In the applications of the present paper, the coefficient are set to 1.

The extension of the case with sources on both sides of an infinite planar slab/slice to the case illustrated in Fig. 4 with sources on all six sides of a box shaped volume is straightforward: We just add contributions to the matrix elements from six sets of plane wave functions belonging to the respective six sides of the box. Actually, with omnidirectional weighting of the plane wave functions, the formulas for sources on only two opposite sides take into account plane propagating waves from all directions because each side includes all plane waves from a hemisphere with equal weights. But the two sides do not include all types of evanescent waves: Waves decaying in the x-and y-directions are missing.

D. Generic inherent estimation errors

According to the derivation in Sec. II A, SONAH performs a linear prediction of a sound field parameter at a calculation point based on a set of measured quantities, the prediction coefficients being characterized as providing in a least-squares sense the best estimate for all plane propagating waves and a weighted set of the evanescent waves. It is then interesting to see how well on an average the values of these wave functions are predicted at the calculation point.

Considering first free-field conditions, the set of plane propagating and evanescent wave functions is given by Eq. (18) with the number of functions approaching infinity as described in Eqs. (20) and (21). The vector $\boldsymbol{\alpha}(\mathbf{r})$ contains according to the definition in Eq. (7) the true values of all these elementary waves at the calculation point $\mathbf{r}$. Equations (18), (12), and (2) show that one row of the matrix $\mathbf{A}$ contains the values of one of the wave functions across the measurement positions. In the process of calculating the prediction error, we need a possibility of using a spectrum of test wave functions different from the spectrum used in the calculation of the prediction weight vector $\mathbf{c}(\mathbf{r})$ in Eq. (11). Here, we will consider only the case where the test wave function spectrum has also the form given in Eq. (16) but is scaled in the plane $z=z_s^+$ instead of the virtual source plane $z=z^+$ used in the SONAH prediction. This new virtual source plane, $z=z_s^+$, can be used to set up the matrix $\mathbf{A}_s$ and the vector $\boldsymbol{\alpha}_s(\mathbf{r})$. Since one row of $\mathbf{A}_s$ contains the values of one of the test wave functions across all measurement positions, it follows from Eq. (9) that the vector $\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})$ defined as

$$\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})\equiv\mathbf{A}_s\mathbf{c}(\mathbf{r}) \quad (38)$$

contains the SONAH estimates of the test wave functions at the calculation point. The 2-norm of this vector is a measure of the average amplitude of the predictions:

$$\|\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})\|_2^2=\tilde{\boldsymbol{\alpha}}_s^H\tilde{\boldsymbol{\alpha}}_s=\mathbf{c}^H(\mathbf{r})[\mathbf{A}_s^H\mathbf{A}_s]\mathbf{c}(\mathbf{r}). \quad (39)$$

Here, the matrix $\mathbf{A}_s^H\mathbf{A}_s$ can be calculated in the same way as the matrix $\mathbf{A}^H\mathbf{A}$, just using the virtual source plane $z=z_s^+$. An average underestimation will be characterized by the prediction norm $\|\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})\|_2$ being smaller than the true norm $\|\boldsymbol{\alpha}_s(\mathbf{r})\|_2$. To find the true norm $\|\boldsymbol{\alpha}_s(\mathbf{r})\|_2$, we notice from Eqs. (18), (12), and (2) that one column of the matrix $\mathbf{A}_s$ contains the exact values of all test wave functions at a microphone position, just like $\boldsymbol{\alpha}_s(\mathbf{r})$ contains all function values at the calculation point. The value of $\boldsymbol{\alpha}_s^H\boldsymbol{\alpha}_s$ can therefore be calculated using expression (25) for a diagonal element $[\mathbf{A}_s^H\mathbf{A}_s]_{ii}$ of the matrix $\mathbf{A}_s^H\mathbf{A}_s$, just by replacing the microphone position $\mathbf{r}_i$ by the calculation position $\mathbf{r}$:

$$\|\boldsymbol{\alpha}_s(\mathbf{r})\|_2^2=\boldsymbol{\alpha}_s^H\boldsymbol{\alpha}_s=F_0^2 I_p(0,0)+F_0^2 II_p(0,k(2z-2z_s^+))$$
$$=F_0^2\left[1+\frac{1}{2k(z-z_s^+)}\right]. \quad (40)$$

Here, the analytic expressions for the two integrals can be easily verified using the definitions (22) and (23). The inherent average amplitude gain $A(\mathbf{r})$ is then defined as

$$A(\mathbf{r})\equiv\frac{\|\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})\|_2}{\|\boldsymbol{\alpha}_s(\mathbf{r})\|_2}. \quad (41)$$

The 2-norm of the estimation error vector $\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})-\boldsymbol{\alpha}_s(\mathbf{r})$ can be calculated by application of Eq. (38):

$$\|\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})-\boldsymbol{\alpha}_s(\mathbf{r})\|_2^2=(\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})-\boldsymbol{\alpha}_s(\mathbf{r}))^H(\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})-\boldsymbol{\alpha}_s(\mathbf{r}))$$
$$=\|\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})\|_2^2+\|\boldsymbol{\alpha}_s(\mathbf{r})\|_2^2$$
$$-2\,\mathrm{Re}\{\boldsymbol{\alpha}_s^H(\mathbf{r})\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})\}=\|\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})\|_2^2$$
$$+\|\boldsymbol{\alpha}_s(\mathbf{r})\|_2^2-2\,\mathrm{Re}\{[\mathbf{A}_s^H\boldsymbol{\alpha}_s(\mathbf{r})]^H\mathbf{c}(\mathbf{r})\}, \tag{42}$$

and finally the generic inherent average estimation error level $E(\mathbf{r})$ is defined as

$$E(\mathbf{r})\equiv 10\log\left(\frac{\|\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})-\boldsymbol{\alpha}_s(\mathbf{r})\|_2^2}{\|\boldsymbol{\alpha}_s(\mathbf{r})\|_2^2}\right). \tag{43}$$

When the wave-number spectrum of the test field equals the spectrum used in the SONAH derivation, i.e., $\boldsymbol{\alpha}_s(\mathbf{r})=\boldsymbol{\alpha}(\mathbf{r})$, then because of Eqs. (10) and (38) the numerator in Eq. (43) is just the residual in the solution of Eq. (10) for the SONAH prediction weight vector.

The above description can be extended to non-free-field conditions simply by application of the extended formulas for the elements of the matrices $\mathbf{A}_s^H\mathbf{A}_s$ and $\mathbf{A}_s^H\boldsymbol{\alpha}_s(\mathbf{r})$, for example, Eqs. (34) and (35) for the case of sources on two sides. In that case, expression (40) for $\boldsymbol{\alpha}_s^H\boldsymbol{\alpha}_s$ has to be extended just like Eq. (25) was extended to Eq. (34):

$$\boldsymbol{\alpha}_s^H\boldsymbol{\alpha}_s=F_{0,z+}^2 I_p(0,0)+F_{0,z+}^2 II_p(0,k(2z-2z_s^+))$$
$$+F_{0,z-}^2 I_p(0,0)+F_{0,z-}^2 II_p(0,k(2z_s^--2z))$$
$$=F_{0,z+}^2\left[1+\frac{1}{2k(z-z_s^+)}\right]+F_{0,z-}^2\left[1+\frac{1}{2k(z_s^--z)}\right]. \tag{44}$$

The question to be considered next is how the generic inherent error level relates to the sound pressure prediction error for a particular sound field. To do this we consider a test sound field specified by its true plane wave expansion coefficient vector $\mathbf{a}$, and we allow for different virtual source planes for the test waves and for the SONAH/EWM predictions. In analogy with Eq. (7), the sound pressure at the calculation position is then $p(\mathbf{r})=\mathbf{a}^T\boldsymbol{\alpha}_s(\mathbf{r})$, and similarly from Eqs. (4) and (12) the vector of sound pressure values at the microphones is $\mathbf{p}=\mathbf{A}_s^T\mathbf{a}$. Use of this second relation in combination with Eq. (15) leads to the following expression for the EWM expansion coefficient vector estimate:

$$\tilde{\mathbf{a}}^T=\mathbf{p}^T[\mathbf{A}^H\mathbf{A}+\varepsilon\mathbf{I}]^{-1}\mathbf{A}^H=\mathbf{a}^T\mathbf{A}_s[\mathbf{A}^H\mathbf{A}+\varepsilon\mathbf{I}]^{-1}\mathbf{A}^H, \tag{45}$$

and the estimated sound pressure is therefore $\tilde{p}(\mathbf{r})=\tilde{\mathbf{a}}^T\boldsymbol{\alpha}(\mathbf{r})$. To rewrite that in terms of the estimates $\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})$ of the test plane wave functions (based on their values at the microphones), we use the following expression obtained from Eqs. (38) and (11):

$$\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})=\mathbf{A}_s[\mathbf{A}^H\mathbf{A}+\varepsilon\mathbf{I}]^{-1}\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r}). \tag{46}$$

Combining this relation with Eq. (45) leads to

$$\tilde{p}(\mathbf{r})=\tilde{\mathbf{a}}^T\boldsymbol{\alpha}(\mathbf{r})=\mathbf{a}^T\mathbf{A}_s[\mathbf{A}^H\mathbf{A}+\varepsilon\mathbf{I}]^{-1}\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})=\mathbf{a}^T\tilde{\boldsymbol{\alpha}}_s(\mathbf{r}), \tag{47}$$

meaning that we get the following expression for the relative error level in the sound pressure calculation:

$$E_p(\mathbf{r})\equiv 10\log\left(\frac{|\tilde{p}(\mathbf{r})-p(\mathbf{r})|^2}{|\mathbf{p}(\mathbf{r})|^2}\right)$$
$$=10\log\left(\frac{|\mathbf{a}^T[\tilde{\boldsymbol{\alpha}}_s(\mathbf{r})-\boldsymbol{\alpha}_s(\mathbf{r})]|^2}{|\mathbf{a}^T\boldsymbol{\alpha}_s(\mathbf{r})|^2}\right). \tag{48}$$

If in Eq. (48) we consider $\mathbf{a}$ as a vector of incoherent stochastic variables with equal rms values, and if we average the numerator and the dominator separately, then from Eq. (48) we obtain actually Eq. (43). For particular sound fields, however, $E_p(\mathbf{r})$ will differ from $E(\mathbf{r})$. In particular, $E_p(\mathbf{r})$ may be small because contributions from different wave-number components can cancel each other, which cannot happen for $E(\mathbf{r})$. $E(\mathbf{r})$ is therefore considered to be a better general measure of the error level, provided all components of the plane wave expansion coefficient vector $\mathbf{a}$ have almost equal amplitudes. This happens when the wave-number amplitude spectrum on the virtual source plane has a form close to a scaled version of $F(k_z)$ [see Eq. (16)].

E. Wave-number spectra of the reconstructed field

Wrap-around errors were entirely eliminated in plane wave SONAH by the use of continuous plane wave spectra, but spatial aliasing and wave-number domain leakage caused by the spatial sampling (discrete measurement points) and a finite measurement area cannot be avoided. For planar regular-grid arrays the spatial sampling introduces periodic replica in the wave-number domain, denoted as spatial aliasing, and the spatial window associated with the finite array size introduces leakage. This is basic Fourier acoustics theory.[3] But for irregular arrays, Fourier acoustic principles do not directly apply. In the description to be given here, the aliasing and leakage phenomena will be both covered by the term leakage.

To study wave-number leakage we need to calculate wave-number spectra associated with the sound field reconstructed by SONAH. Only free-field conditions and a planar measurement grid in the plane $z=0$ will be considered. The wave-number spectrum $\tilde{P}(k_x,k_y,z)$ of the reconstructed pressure in any plane parallel with the measurement plane is defined through the 2D Fourier transform:[3]

$$\tilde{P}(k_x,k_y,z)\equiv\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\tilde{p}(x,y,z)e^{j(k_x x+k_y y)}dxdy. \tag{49}$$

From Eqs. (49) and (15) we get

$$\tilde{P}(k_x,k_y,z)=\mathbf{q}^T\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\mathbf{A}^H\boldsymbol{\alpha}(x,y,z)e^{j(k_x x+k_y y)}dxdy, \tag{50}$$

where the vector $\mathbf{q}$ is obtained from the vector $\mathbf{p}$ of measured pressure in the following way:

$$\mathbf{q}^T\equiv\mathbf{p}^T[\mathbf{A}^H\mathbf{A}+\varepsilon\mathbf{I}]^{-1}. \tag{51}$$

The integration in Eq. (50) can be worked out analytically using expression (21) for the elements of the vector $\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})$. If unit wave-number weighting is considered, $F(k_z)=1$, then the result is

$$\tilde{P}(k_x,k_y,z) = \frac{2\pi}{k^2} e^{-jk_z z} e^{j(k_z - k_z^*)z^+} \sum_i q_i e^{j(k_x x_i + k_y y_i)}, \quad (52)$$

q_i being the elements of $\mathbf{q}$ and $(x_i, y_i, 0)$ the coordinates of the measurement positions. Clearly, the plane wave spectrum depends on the z-coordinate only through the factor $e^{-jk_z z}$:

$$\tilde{P}(k_x,k_y,z) = \tilde{P}(k_x,k_y,0) e^{-jk_z z}, \quad (53)$$

which should be expected[3] since the reconstructed field satisfies the homogeneous wave equation in a homogeneous source-free half space.

An expression similar to Eq. (52) with $z=z^+$ can be derived by considering elements of the expansion coefficient vector $\tilde{\mathbf{a}}$ obtained from the equivalent EWM problem in Eq. (6). This agrees with the previously given statement that the vector $\tilde{\mathbf{a}}$ is a scaled wave-number spectrum in the virtual source plane. Use of Eqs. (6), (12), and (51) leads to the expression $\tilde{\mathbf{a}}^T = \mathbf{q}^T \mathbf{A}^H$, which agrees with Eq. (52) except for a constant scaling factor.

For leakage investigations we need to calculate the wave-number spectrum $\tilde{P}(k_x,k_y,z)$ resulting from a simulated measurement on an incident plane propagating or evanescent wave.

III. NUMERICAL INVESTIGATIONS OF RECONSTRUCTION ERRORS

A primary focus of the investigation in this section will be that of getting basic information about the regions of validity of the SONAH reconstructions for a couple of typical array geometries and as a function of frequency. Measurement errors will not be considered, and methods for automatic determination of the regularization parameter (GCV, L-curve, etc.) will not be investigated either. Instead the reader is referred to Gomes and Hansen.[16] The regularization parameter ε needed in Eqs. (11) and (27) will be determined from a specified dynamic range D (signal-to-noise-ratio) using the following formula from Steiner and Hald:[12]

$$\varepsilon = [\mathbf{A}^H \mathbf{A}]_{ii} 10^{-D/10}, \quad (54)$$

where $[\mathbf{A}^H \mathbf{A}]_{ii}$ is a diagonal element of the matrix $\mathbf{A}^H \mathbf{A}$. This relation was derived for a planar array and free-field conditions, in which case all diagonal elements are equal. Here we use, in general, the average value of the diagonal elements. Typical values of D lie in the range between 15 and 30 dB. Unless something else is specified, the following parameter choices have been used subsequently:

- dynamic range: $D=30$ dB
- identical virtual source planes for the test wave spectrum and for the wave spectrum used in SONAH prediction: $z_s^+ = z^+, z_s^- = z^-, \ldots$
- omni-directional weighting of the plane wave functions [see Eq. (19)]

A. Region of accurate pressure reconstruction in the measurement plane

We start with an investigation of the generic inherent error distributions in the array plane $z=0$ of two different irregular planar array designs. Both have a diameter equal to 0.75 m, and both are optimized for beamforming application up to at least 20 kHz. One is a spoke wheel array consisting of 13 identical six-element line arrays arranged as spokes in a wheel (see Fig. 5). The other is a sector wheel array[28] consisting of seven identical angular sectors with 12 microphones irregularly but uniformly distributed in each sector. The uniform distribution of the sector wheel array was maintained during the array geometry optimization in order to obtain good performance in connection with SONAH applications. Since the arrays are planar, we have to assume free-field conditions and use only a single virtual source plane in SONAH. An average element spacing is defined by calculating the average array area per element, and for both array geometries it is close to 7 cm. For a regular rectangular array, this spacing would support a frequency range up to around 2 kHz, and to avoid spatial aliasing up to that frequency, a standoff distance not smaller than the array grid spacing should be chosen. Since the virtual source plane should be positioned approximately one microphone spacing behind a real source surface at $z_0^+ = -7$ cm, we choose a virtual source plane 14 cm from the array plane, i.e., at $z^+ = -14$ cm.

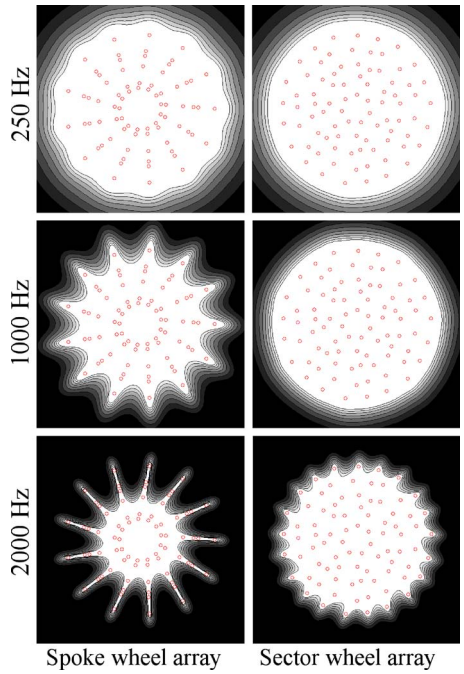

FIG. 5. (Color online) Inherent relative error level E of sound pressure reconstruction in the measurement plane for two irregular planar microphone arrays. Circles: measurement positions. White areas: $E<-20$ dB. Black areas: $E>-6$ dB. Gray-scale contour interval: 2 dB.

The contour plots in Fig. 5 show the inherent relative error level $E(\mathbf{r})$ of the sound pressure prediction in the array plane with the microphone positions indicated by circles. White areas represent inherent error levels $E(\mathbf{r})$ below -20 dB, and the gray contours show the degradation of the accuracy in steps of 2 dB to error levels larger than -6 dB represented by black. At low frequencies, both arrays can provide a good sound pressure representation across the entire array area, but already at 1 kHz the gaps in the microphone distribution of the spoke wheel array become too big to provide good representation in the gaps. The sector wheel array

provides acceptable pressure representation over the full array area all the way up to 2 kHz, which is clearly not the case for the spoke wheel array geometry. The spoke wheel array is very good for beamforming applications, though, and its support structure is easier to build in large sizes.

B. Region of accurate pressure reconstruction outside the measurement plane

We now turn to an investigation of the region of accurate sound pressure prediction in a plane normal to the array plane. Instead of the irregular arrays designed for beamforming, we consider regular 8×8 element single layer ($8\times8\times1$) and dual layer ($8\times8\times2$) arrays with 3 cm element spacing in the x- and y-directions, covering the area $0\leq x\leq21$ cm, $0\leq y\leq21$ cm. Both array types have a microphone layer in the xy-plane $z=0$, and the dual layer array has an additional identical layer at $z=3$ cm. We look at the relative sound pressure prediction error in the xz-plane $y=10.5$ cm, which is a symmetry plane of the arrays. Just like for the irregular planar arrays, we choose for the single layer regular array a virtual source plane at a distance from the array equal to two times the array element spacing, i.e., $z^+=-6$ cm. For the dual layer array we choose the same distance to the front virtual source plane and a distance to the rear virtual source plane equal to 19 times the element spacing, i.e., $z^+=-6$ cm, $z^-=60$ cm.

Figure 6 shows in the left column the inherent error level $E(\mathbf{r})$ of the single layer array (with a single virtual source plane) and in the right column the inherent error level $E(\mathbf{r})$ of the dual layer array (with two virtual source planes). The middle column shows the relative error $E_p(\mathbf{r})$ of the sound pressure prediction by the single layer array for a specific sound field: the field of a monopole point source at $(x,y,z)=(7.5,7.5,-6.0)$ cm. The mapping area extends 6 cm beyond the array area in both directions along the x-axis, and in the z-direction from $z=-3$ cm to a distance equal to four times the array element spacing in the positive z-direction. Clearly, the error distribution $E_p(\mathbf{r})$ of the particular sound field prediction is more irregular and, in general, lower than the inherent error. Significantly smaller errors are achieved in certain areas than predicted by the inherent error level. As explained in Sec. II D, this can be because error contributions from different plane wave components cancel each other in $E_p(\mathbf{r})$. The inherent error level avoids such cancellation effects and provides a much more general picture of the estimation accuracy of the method, although it does not give an upper bound on the error. For example, larger relative errors can occur in connection with very reactive sound fields, i.e., fields with a very high relative content of evanescent waves. The dual layer array is seen to extend significantly the region of accurate representation as compared to the single layer array, although the degrees of freedom in the sound field have also been increased by adding an extra virtual source plane.

The reason for the rather limited extent in the z-direction of the region with low prediction errors is that SONAH assumes nothing about the extent of the source distribution in the xy-directions. The field beyond some distance in front of the array cannot be accurately predicted because there can be contributions from source areas far from the array, for which the array measurement does not provide sufficient information. The minimum norm solution process then uses this lack of information about all the degrees of freedom in the field model to minimize the "energy" in the reconstructed field, resulting in the observed underestimation. One can think of the reconstructed field as being "focused" within the measurement region, representing well the measured sound pressure values. Before and after the measurement region, the field gradually defocuses. In order to provide, e.g., good far-field estimates, some assumption about the size of the source area would have to be integrated in the method. This could, for example, be done by the use of a SONAH formulation based on a limited distribution of monopole sources instead of plane propagating and evanescent waves. Brüel & Kjær SVM A/S has a patent pending, covering SONAH implementations based on distributions of monopoles, dipoles, and/or multipoles.

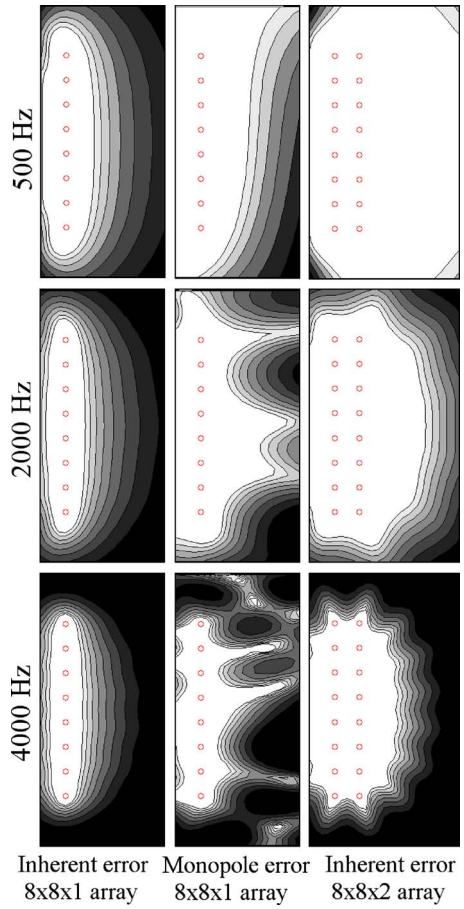

FIG. 6. (Color online) Relative error levels in the xz symmetry plane of single and dual layer 8×8 element microphone arrays. Left column: inherent error level E of the single layer array. Middle column: relative error of monopole pressure estimated using the single layer array. Right column: inherent error level E of the dual layer array.

C. Wave-number leakage

To illustrate some typical leakage behavior, which will be used to explain some observations in Sec. III D, we consider measurement with the single layer $8\times8\times1$ element

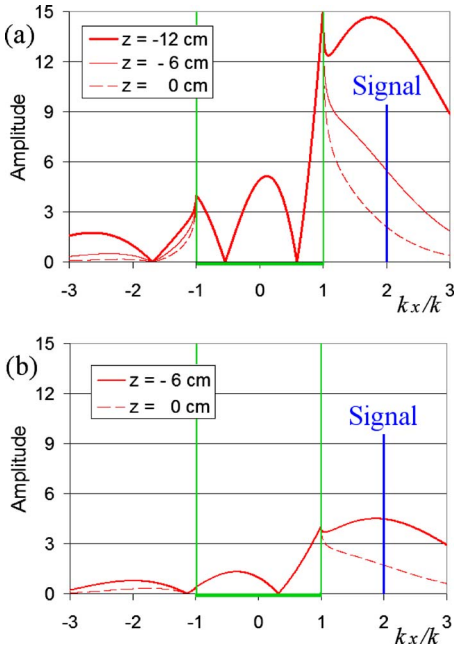

FIG. 7. (Color online) Wave-number (leakage) spectra at different z-coordinates for the same simulated measurement on a single evanescent wave with $k_x/k=2$, $k_y/k=0$. The two figures represent different virtual source plane distances: (a) $d=12$ cm and (b) $d=6$ cm. The frequency is 500 Hz, and the measurement plane is at $z=0$ cm.

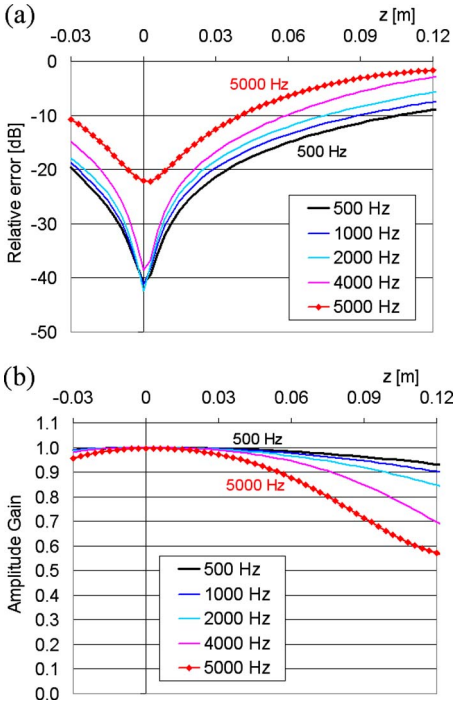

FIG. 8. (Color online) (a) Inherent relative error level E and (b) amplitude gain A on the symmetry axis normal to the measurement plane for an 8 $\times$8 element planar microphone array.

array of Sec. III B, and for simplicity a unit weighting ($F(k_z)=1$) of the plane wave functions is used. We consider a single 500 Hz evanescent wave propagating along the x-axis. The true wave-number spectrum has a single component at $(k_x,k_y)=(2k,0)$. Figure 7(a) shows slices along the k_x-axis of the wave-number spectra of Eq. (52) for a SONAH sound field reconstruction with virtual source plane distance $d=12$ cm. Three curves are shown, representing three different z-coordinates: $z=-d=-12$ cm, $z=-6$ cm, and $z=0$ cm. The horizontal axis shows normalized wave-numbers, k_x/k, so the points $k_x/k=\pm 1$ represent intersections with the radiation circle and the intervals $|k_x/k|>1$ represent evanescent waves. In the virtual source plane, $z=-d$, the wave-number spectrum has its maximum near the wave-number $k_x/k=2$ of the true wave field, and the leakage components decrease fairly smoothly away from that maximum. Figure 7(b) shows comparable SONAH wave-number spectra from the same simulated measurement, just with the virtual source plane at a shorter distance $d=6$ cm. Again, in the virtual source plane the maximum occurs near $k_x/k=2$, and the leakage spectrum decreases fairly smoothly away from that maximum. Thus, the leakage seems to be introduced in the virtual source plane, and the forward propagation from the virtual source plane to the measurement plane then strongly attenuates the evanescent wave components, while the plane wave components retain their amplitude. So in the measurement plane actually the plane wave leakage components are stronger than the component at the true wave-number of the original signal. If a larger value is chosen for the virtual source plane distance, then the reconstruction on the virtual source plane of a measured evanescent wave component requires a stronger amplification, leading to stronger leakage components that retain their amplitude inside the radiation circle at all z-coordinates. As mentioned previously, the EWM and SONAH reconstructions will always be very accurate at and near the measurement positions. The effect of the leakage described above is that a small portion of the evanescent waves is "converted" into propagating waves, which will erroneously contribute to the sound intensity and to the far field.

D. Sensitivity of reconstruction accuracy to changing parameters of SONAH

To limit the amount of data in the investigation of sensitivity to parameter changes, we look at the prediction errors only along the center axis normal to the array. Again, only the single layer $8\times8\times1$ array of Sec. III B will be considered. Figure 8(a) shows the inherent error level for the same condition as that represented in the left column of Fig. 6, so what we see is just a set of horizontal slices through the middle of the contour plots in the left column of Fig. 6. Two additional frequencies have been included in Fig. 8(a): 1 kHz and the higher limiting frequency 5 kHz of the 3 cm spaced regular array grid. Clearly, at 5 kHz the inherent error level has started a quick increase, even in the measurement plane, but an acceptable reconstruction can still be achieved. Figure 8(b) shows the corresponding curves of amplitude gain $A(\mathbf{r})$. Even at 5 kHz the amplitude is still accurately predicted within one array grid spacing from the array plane, but outside that interval an increasing underestimation is observed. As mentioned previously, this can be seen as a consequence of the fact that the equivalent EWM problem will perform a least norm estimation of the plane wave spectrum, thus minimizing the energy in the reconstructed sound field.

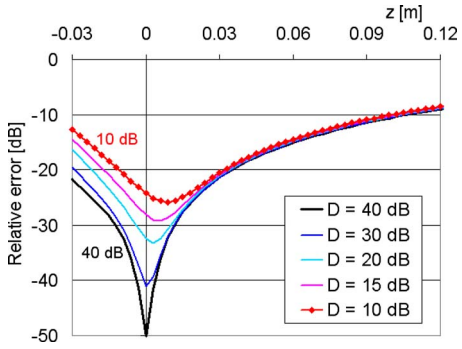

FIG. 9. (Color online) Inherent relative error level E on the symmetry axis normal to the array plane for an 8×8 element planar microphone array at 500 Hz. The curves represent different dynamic ranges, D, used in the SONAH processing.

In Fig. 8 the regularization parameter was determined from Eq. (54) with a fixed dynamic range D equal to 30 dB. The next step is to see how the reconstruction error changes when the dynamic range D is changed. Figure 9 presents the sensitivity of the inherent error level E to changes in D at a low frequency, 500 Hz. A set of curves is labeled with the corresponding values of D, which range from 10 to 40 dB. The prediction of pressure further away from the source region than the measurement plane is insensitive, while the prediction closer to the source region improves with increasing values of D. This should be expected at low frequencies since a smaller value of D will limit the reconstruction of the evanescent waves and since the evanescent waves constitute a bigger part of the sound field at low frequencies and close to the source region. Figure 10 presents corresponding curves for the inherent amplitude gain A in the SONAH estimation at a high frequency, 4000 Hz. Here, an increasing underestimation is observed at all positions (even further away from the source region) when the value of D becomes smaller than around 20 dB. The explanation must be that at high frequencies the propagating plane waves constitute a bigger part of the plane wave spectrum and thus of the singular value spectrum of the SONAH auto-correlation matrix $\mathbf{A}^H\mathbf{A}$. When D is reduced beyond some point, then even parts of the propagating wave components will be significantly attenuated by the regularization.

The question to be investigated now is how the error

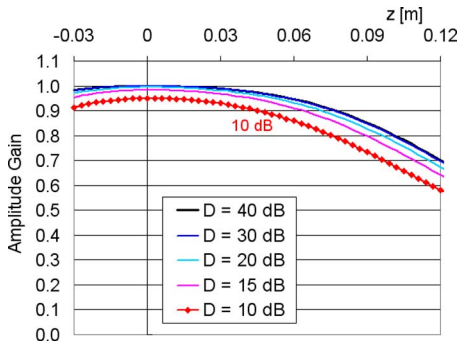

FIG. 10. (Color online) Amplitude gain A on the symmetry axis normal to the array plane for an 8×8 element planar microphone array at 4000 Hz. The curves represent different dynamic ranges, D, used in the SONAH processing.

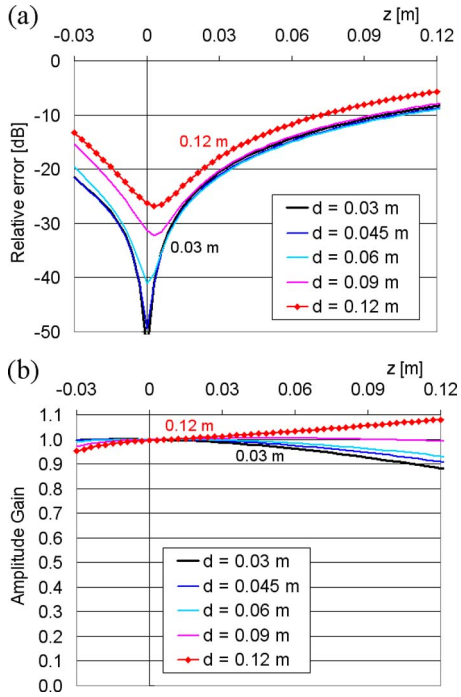

FIG. 11. (Color online) (a) Inherent relative error level E and (b) amplitude gain A on the symmetry axis normal to the array plane for an 8×8 element planar microphone array at 500 Hz. The curves represent different virtual source plane distances, d, used in the SONAH processing, while the virtual source distance defining the actual content of evanescent waves is kept constant at 6 cm.

level changes when the virtual source planes ($z=z_s^+,\ldots$) used for the test wave spectra differ from the virtual source planes ($z=z^+,\ldots$) used in the SONAH algorithm. This can, to some extent, show the sensitivity of SONAH to the wave-number amplitude spectrum of a real sound field having a different shape from the one for which the SONAH prediction weight vector $\mathbf{c}$ was calculated [see Eqs. (18), (16), and (10)]. Only free-field conditions and the use of a single virtual source plane shall be considered. For the results presented in Figs. 11 and 12, we have retained the previously used virtual source plane $z=z_s^+=-6$ cm for the test wave spectrum, i.e., in the calculation of $\mathbf{A}_s^H\mathbf{A}_s$, $\mathbf{A}_s^H\boldsymbol{\alpha}_s$, and $\boldsymbol{\alpha}_s^H\boldsymbol{\alpha}_s$ used in Eqs. (39), (40), and (42), while a varying virtual source plane $z=z^+=-d$ at distance d from the array has been used for the SONAH predictions. A large value of d will put a low weight on the evanescent waves in the SONAH estimation. Without regularization the smallest generic inherent error should be achieved with $z^+=z_s^+$ i.e., $d=6$ cm: The SONAH prediction weight vector $\mathbf{c}$ minimizes the residual in Eq. (10), and with $z^+=z_s^+$ that will automatically minimize the generic inherent error for the test field. But because of the regularization ($D=30$ dB), the inherent error may be slightly smaller with $z^+\neq z_s^+$. Figure 11 presents the sensitivity of the inherent error level E and the amplitude gain A to changes in d at a low frequency, 500 Hz, and Fig. 12 shows the corresponding results for a high frequency, 4000 Hz. Each plot contains a set of curves labeled with the corresponding values of d, which range from 3 to 12 cm.

At 500 Hz the error level is rather insensitive to a too small virtual source distance, d, i.e., a too high weight on the

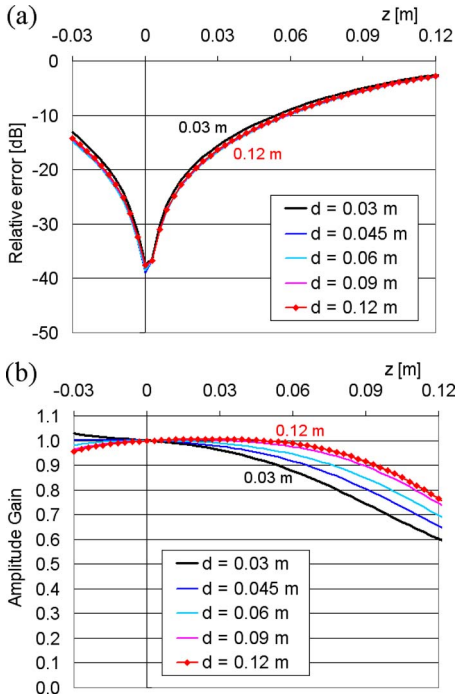

FIG. 12. (Color online) (a) Inherent relative error level E and (b) amplitude gain A on the symmetry axis normal to the array plane for an 8×8 element planar microphone array at 4000 Hz. The curves represent different virtual source plane distances, d, used in the SONAH processing, while the virtual source distance defining the actual content of evanescent waves is kept constant at 6 cm.

evanescent waves in the reconstruction, but a too large distance eventually results in a slight overestimation ($A>1$) of the level further away from the source region than the measurement plane. The explanation is the one outlined in Sec. III C above: Evanescent wave components leak into propagating components, leading to overestimation of the sound pressure further away from the source region and underestimation closer to the source region. As explained in Sec. III C, this leakage increases with increasing virtual source plane distance, d. Looking at the more general increase in the inherent error level for $z<0$, occurring also when d is large, there is an additional source of error: Because too low weight is put on the evanescent waves in the SONAH calculation matrices (due to the large virtual source distance), the chosen regularization parameter will prevent some of these wave components from being sufficiently reconstructed.

At 4 kHz the evanescent waves constitute, in general, a much smaller part of the sound field, so the sensitivity to putting more or less weight on them in the SONAH calculation is smaller. The biggest effect is on the amplitude gain when a too small virtual source distance, d, is used, putting a higher weight on the evanescent waves in the reconstruction than suggested by the actual wave-number spectrum. Close to the source region an overestimation is observed, while further away a heavier underestimation than normal is seen. The explanation is probably leakage, just the other way than described in Sec. III C: Some small propagating wave components will leak into evanescent waves, which will be attenuated away from the source area and amplified toward the source area.

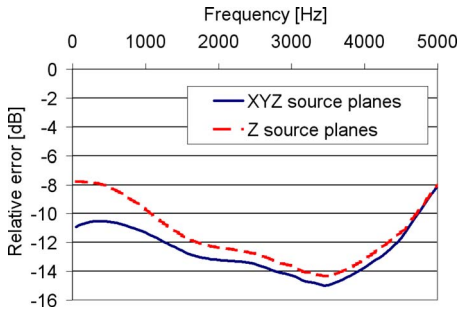

FIG. 13. (Color online) Accuracy improvement gained by adding plane wave functions from all six sides instead of from just two sides in a SONAH calculation of 3D vector intensity from a single monopole point source in the center plane of a dual layer 8×8 element microphone array. The point source is 6 cm outside of the array area.

E. Sources in the array plane: Need for six virtual source planes

Figure 13 shows an example of the accuracy improvement gained by adding plane wave functions from all six sides instead of from just two sides, allowing a correct modeling of evanescent wave components that decay along directions in the xy-plane. A simulated measurement is performed with the same $8\times8\times2$ dual layer array geometry as the one described in Sec. III B. A single monopole point source is placed at $(x,y,z)=(-6.0,7.5,1.5)$ cm, i.e., in the center plane between the two array layers and 6 cm outside the array area. Clearly, this monopole will create evanescent wave types that decay along directions in the xy-plane. SONAH is used to predict the intensity vectors at the measurement positions in the front array plane $z=0$ cm, based on the 128 measured pressure values. The relative average error level is then calculated using the formula

$$L_{\mathrm{err}}=10\log_{10}\left(\frac{\sum|\mathbf{I}_i-\tilde{\mathbf{I}}_i|}{\sum|\mathbf{I}_i|}\right), \tag{55}$$

where $\mathbf{I}_i$ is the true intensity vector at calculation point number i, $\tilde{\mathbf{I}}_i$ is the SONAH estimate of the same vector, and the summations are over i. The SONAH calculation is performed using a 30 dB dynamic range, $D=30$ dB, and the virtual source planes are chosen to be 6 cm away from the array in all directions: $z^-=9$ cm, $z^+=-6$ cm, $x^-=27$ cm, $x^+=-6$ cm, $y^-=27$ cm, and $y^+=-6$ cm. Thus, the monopole is located on the boundary of the box defined by the six virtual source planes. Looking at Fig. 13, the low-frequency intensity estimation is seen to be significantly more accurate when all six source planes are present than when only those parallel with the xy-plane are present. The improvement vanishes, however, with increasing frequency because the evanescent waves constitute a smaller part of the sound field at higher frequencies.

IV. CONCLUSIONS

The basic theory and a revised mathematical formulation of SONAH have been given, first in a general form allowing arbitrary expansion functions and then for the special cases of one, two, or six sets of plane wave functions representing

different virtual source planes. The relation to the EWM method was outlined and used in the explanation of some important properties of the SONAH method, in particular the underestimation beyond some distance from the measurement region. To obtain a general measure of the prediction accuracy of SONAH, a set of formulas for the inherent error level was derived. These have proven to be very useful to visualize and determine the regions of validity of the SONAH predictions with given array geometries. Two typical types of array geometry were treated in the paper: first, planar irregular arrays optimized for broadband beamforming application and second, small single and dual layer regular array grids. The sensitivity of the inherent error level to changes in parameters of the SONAH algorithm was then investigated and shown to be fairly small for parameter values within realistic intervals. This investigation covered the choice of regularization parameter and the setting of the virtual source plane distance, which controls the weight applied to the evanescent waves in the SONAH estimation. Finally, a simulated measurement with a monopole sound source in the array plane was used to check the benefit of adding six virtual source planes instead of just two: Some improvement was achieved (up to 3 dB at low frequencies) due to the added ability to correctly model evanescent waves that decay along directions in the array plane.

APPENDIX A: REGULARIZED LEAST-SQUARES AND LEAST NORM SOLUTIONS

The regularized, generalized inverses $\mathbf{A}^{+}_{LS,\varepsilon}$ and $\mathbf{A}^{+}_{LN,\varepsilon}$ of an arbitrary matrix $\mathbf{A}$ associated with the least-squares (5) and least norm (6) solution formulas, respectively, are

$$\mathbf{A}^{+}_{LS,\varepsilon} \equiv (\mathbf{A}^H\mathbf{A} + \varepsilon\mathbf{I})^{-1}\mathbf{A}^H, \tag{A1}$$

$$\mathbf{A}^{+}_{LN,\varepsilon} \equiv \mathbf{A}^H(\mathbf{A}\mathbf{A}^H + \varepsilon\mathbf{I})^{-1}, \tag{A2}$$

where the regularization parameter ε is positive real. Premultiplication with the non-singular square matrix $(\mathbf{A}^H\mathbf{A}+\varepsilon\mathbf{I})$ and post-multiplication with the non-singular square matrix $(\mathbf{A}\mathbf{A}^H+\varepsilon\mathbf{I})$ on both $\mathbf{A}^{+}_{LS,\varepsilon}$ and $\mathbf{A}^{+}_{LN,\varepsilon}$ show that $\mathbf{A}^{+}_{LS,\varepsilon}=\mathbf{A}^{+}_{LN,\varepsilon}$:

$$\begin{aligned}(\mathbf{A}^H\mathbf{A} + \varepsilon\mathbf{I})\mathbf{A}^{+}_{LS,\varepsilon}(\mathbf{A}\mathbf{A}^H + \varepsilon\mathbf{I}) &= \mathbf{A}^H(\mathbf{A}\mathbf{A}^H + \varepsilon\mathbf{I}) \\ &= \mathbf{A}^H\mathbf{A}\mathbf{A}^H + \varepsilon\mathbf{A}^H, \\ (\mathbf{A}^H\mathbf{A} + \varepsilon\mathbf{I})\mathbf{A}^{+}_{LN,\varepsilon}(\mathbf{A}\mathbf{A}^H + \varepsilon\mathbf{I}) &= (\mathbf{A}^H\mathbf{A} + \varepsilon\mathbf{I})\mathbf{A}^H \\ &= \mathbf{A}^H\mathbf{A}\mathbf{A}^H + \varepsilon\mathbf{A}^H. \end{aligned} \tag{A3}$$

APPENDIX B: REDUCTION IN SONAH CORRELATION INTEGRALS

We consider the integral expressions for the correlation functions $[\mathbf{A}^H\mathbf{A}]_{ij}$ and $[\mathbf{A}^H\boldsymbol{\alpha}(\mathbf{r})]_i$ in Eqs. (20) and (21). Since they have exactly the same form, we consider only the first of them:

$$[\mathbf{A}^H\mathbf{A}]_{ij} = \frac{1}{2\pi k^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\Phi^*_{\mathbf{k}}(\mathbf{r}_i)\Phi_{\mathbf{k}}(\mathbf{r}_j)dk_xdk_y, \tag{B1}$$

which through application of Eqs. (16) and (19) becomes

$$\begin{aligned}[\mathbf{A}^H\mathbf{A}]_{ij} = \frac{F_0^2}{2\pi k^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{k}{|k_z|} \\ \times e^{j[k_x(x_i-x_j)+k_y(y_i-y_j)]}e^{j[k_z^*z_i-k_zz_j+(k_z-k_z^*)z^+]}dk_xdk_y.\end{aligned} \tag{B2}$$

To reduce the integral we transform to polar coordinates in two dimensions in both the wave-number domain and in the spatial domain:

$$\begin{pmatrix}k_x\\k_y\end{pmatrix} = K\begin{pmatrix}\cos(\psi)\\\sin(\psi)\end{pmatrix}, \quad \begin{pmatrix}x_i-x_j\\y_i-y_j\end{pmatrix} = R_{ij}\begin{pmatrix}\cos(\varphi_{ij})\\\sin(\varphi_{ij})\end{pmatrix}. \tag{B3}$$

With these definitions, the argument of the first exponential function in Eq. (B2) can be rewritten as

$$k_x(x_i-x_j) + k_y(y_i-y_j) = KR_{ij}\cos(\psi-\varphi_{ij}), \tag{B4}$$

and since k_z does not depend on the polar angle ψ, the polar angle integration can be performed analytically with the following result:[29]

$$\begin{aligned}[\mathbf{A}^H\mathbf{A}]_{ij} &= \frac{F_0^2}{2\pi k^2}\int_0^{\infty}\int_0^{2\pi}\frac{k}{|k_z|} \\ &\quad\times e^{jKR_{ij}\cos(\psi-\varphi_{ij})}e^{j[k_z^*z_i-k_zz_j+(k_z-k_z^*)z^+]}Kd\psi dK \\ &= \frac{F_0^2}{k^2}\int_0^{\infty}\frac{k}{|k_z|}J_0(KR_{ij})e^{j[k_z^*z_i-k_zz_j+(k_z-k_z^*)z^+]}KdK,\end{aligned} \tag{B5}$$

where J_0 is the Bessel function of order zero. Equations (17) and (B3) show that k_z can be expressed as

$$k_z = \begin{cases}\sqrt{k^2-K^2}, & K\le k\\ -j\sqrt{K^2-k^2}, & K>k,\end{cases} \tag{B6}$$

which implies that $k_z^*=k_z$ for $K\le k$ and $k_z^*=-k_z$ for $K>k$. Use of this in Eq. (B5) leads to

$$\begin{aligned}[\mathbf{A}^H\mathbf{A}]_{ij} &= \frac{F_0^2}{k^2}\int_0^{k}\frac{k}{|k_z|}J_0(KR_{ij})e^{jk_z(z_i-z_j)}KdK \\ &\quad+\frac{F_0^2}{k^2}\int_k^{\infty}\frac{k}{|k_z|}J_0(KR_{ij})e^{-jk_z(z_i+z_j-2z^+)}KdK,\end{aligned} \tag{B7}$$

where we can insert Eq. (B6) to obtain

$$\begin{aligned}[\mathbf{A}^H\mathbf{A}]_{ij} &= \frac{F_0^2}{k^2}\int_0^{k}\frac{k}{\sqrt{k^2-K^2}}J_0(KR_{ij})e^{j\sqrt{k^2-K^2}(z_i-z_j)}KdK \\ &\quad+\frac{F_0^2}{k^2}\int_k^{\infty}\frac{k}{\sqrt{K^2-k^2}}J_0(KR_{ij})e^{-\sqrt{K^2-k^2}(z_i+z_j-2z^+)}KdK.\end{aligned} \tag{B8}$$

Here, the square roots are a problem in connection with numerical integration. To get rid of them, we introduce the following variable substitutions for K:

TABLE I. Integral expressions for the functions used to set up the SONAH correlation matrices. Both unit weighting $[F(k_z)=1]$ and omni-directional weighting $[F(k_z)=\sqrt{k/|k_z|}]$ of the plane wave functions are covered.

	$F(k_z)$	
	1	$\sqrt{k/\lvert k_z\rvert}$
$I_p(\rho,\zeta)$	$\int_0^{\pi/2} J_0(\rho\sin(\theta))e^{j\zeta\cos(\theta)}\sin(\theta)\cos(\theta)d\theta$	$\int_0^{\pi/2} J_0(\rho\sin(\theta))e^{j\zeta\cos(\theta)}\sin(\theta)d\theta$
$II_p(\rho,\zeta)$	$\int_0^{\infty} J_0(\rho\sqrt{1+v^2})e^{-\zeta v}v\,dv$	$\int_0^{\infty} J_0(\rho\sqrt{1+v^2})e^{-\zeta v}dv$
$I_z(\rho,\zeta)$	$\int_0^{\pi/2} J_0(\rho\sin(\theta))e^{j\zeta\cos(\theta)}\sin(\theta)\cos^2(\theta)d\theta$	$\int_0^{\pi/2} J_0(\rho\sin(\theta))e^{j\zeta\cos(\theta)}\sin(\theta)\cos(\theta)d\theta$
$II_z(\rho,\zeta)$	$\int_0^{\infty} J_0(\rho\sqrt{1+v^2})e^{-\zeta v}v^2dv$	$\int_0^{\infty} J_0(\rho\sqrt{1+v^2})e^{-\zeta v}v\,dv$
$I_{xy}(\rho,\zeta)$	$\int_0^{\pi/2} \frac{J_1(\rho\sin(\theta))}{\rho\sin(\theta)} e^{j\zeta\cos(\theta)}\sin^3(\theta)\cos(\theta)d\theta$	$\int_0^{\pi/2} \frac{J_1(\rho\sin(\theta))}{\rho\sin(\theta)} e^{j\zeta\cos(\theta)}\sin^3(\theta)d\theta$
$II_{xy}(\rho,\zeta)$	$\int_0^{\infty} \frac{J_1(\rho\sqrt{1+v^2})}{\rho\sqrt{1+v^2}} e^{-\zeta v}(1+v^2)v\,dv$	$\int_0^{\infty} \frac{J_1(\rho\sqrt{1+v^2})}{\rho\sqrt{1+v^2}} e^{-\zeta v}(1+v^2)dv$

$$K=\begin{cases} k\sin(\theta), & K\le k \\ k\sqrt{1+v^2}, & K>k, \end{cases} \tag{B9}$$

with new variables θ and v, and as a result Eq. (B8) becomes

$$[\mathbf{A}^H\mathbf{A}]_{ij}=F_0^2\int_0^{\pi/2} J_0(kR_{ij}\sin(\theta))e^{jk(z_i-z_j)\cos(\theta)}\sin(\theta)d\theta + F_0^2\int_0^{\infty} J_0(kR_{ij}\sqrt{1+v^2})e^{-k(z_i+z_j-2z^+)v}dv, \tag{B10}$$

where the functions to be integrated are smooth and well suited for numerical integration.

APPENDIX C: 2D FUNCTIONS USED TO SET UP SONAH CORRELATION MATRICES

In Table I, J_0 and J_1 are the Bessel functions of order 0 and 1, respectively. The author has been able to find partial analytic expressions only for a couple of the integrals in the table and for some special parameter values, so the integrals in general have to be calculated by numerical integration. The number of integrations can be reduced very much by generating (by numerical integration) and storing 2D tables for discrete values of the variables ρ and ζ. To calculate the integrals for specific values of ρ and ζ, interpolations have to be performed between the values in the tables. Alternatively, 2D approximation functions covering different domains can be constructed. Brüel & Kjaer SVM A/S has a patent pending, covering the use of tables and approximation functions to speed up the execution of SONAH implementations.

The 2D functions of Table I are, in practice, used only through the following combination functions:

$$III_p(\rho,\zeta_1,\zeta_2)\equiv I_p(\rho,\zeta_1)+II_p(\rho,\zeta_2), \tag{C1}$$

$$III_z(\rho,\zeta_1,\zeta_2)\equiv I_z(\rho,\zeta_1)-jII_z(\rho,\zeta_2), \tag{C2}$$

$$III_{xy}(\rho,\zeta_1,\zeta_2)\equiv I_{xy}(\rho,\zeta_1)+II_{xy}(\rho,\zeta_2). \tag{C3}$$

Multiple-point statistical room correction for audio reproduction: Minimum mean squared error correction filtering

Fredrik Lingvall[a] and Lars-Johan Brännmark[b]
Signals and Systems Group, Department of Engineering Sciences, Uppsala University, P.O. Box 528, SE-751 20 Uppsala, Sweden

(Received 17 October 2008; accepted 30 December 2008)

This paper treats the problem of correction of loudspeaker and room responses using a single source. The objective is to obtain a linear correction filter, which is robust with respect to listener movement within a predefined region-of-interest. The correction filter is based on estimated impulse responses, obtained at several positions, and a linear minimum mean squared error criteria. The impulse responses are estimated using a Bayesian approach that takes both model errors and measurement noise into account, which results in reliable impulse response estimates and a measure of the estimation errors. The correction filter is then constructed by using information from both the estimated impulse response coefficients and their associated estimation errors. Furthermore, in the optimization criteria a time-dependent reflection filter is introduced, which attenuates the high frequency parts of the reflected responses, that is, the parts of the responses that cannot be compensated with a single source system. The resulting correction filter is shown to significantly improve both the temporal and spectral properties of the responses compared to the uncorrected system, and, furthermore, the obtained correction filter has a low level of pre-ringing.

I. INTRODUCTION

The aim of digital room correction is, in general, to improve audio reproduction in, for example, domestic or automotive sound systems. Improve means here to compensate, or at least reduce, the distortions of the signal due to both a non-perfect source and acoustic diffraction and room effects. In digital room correction this is normally accomplished by first acquiring data to estimate the room impulse responses and then construct a correction filter based on the estimated impulse responses.[1]

It is known that direct inversion of acoustic impulse responses acquired at a single listening point results in excessive boost at some frequencies due to interference induced deep spectral notches in the impulse responses, which results in high noise amplification,[2,3] and, furthermore, the correction performance quickly deteriorates when the listener moves away from the reference correction point.[4,5] In this area of application, spatial robustness is essential since the position of the listener cannot be expected to be fixed. In the literature, several approaches to robust design of correction filters have been studied. Examples of such approaches include complex smoothing,[6] multiple-point equalization of common poles,[7] derivative constrained equalization,[8] spatial averaging with fuzzy clustering of room responses,[9] time-domain inversion with frequency-dependent regularization,[2] and robust multiple-point designs.[4,10,11]

Another important issue in correction filter design is to try to avoid non-causal preresponses of the correction filter; non-causal means here the filter effects that occur before the main correction filter delay. Allowing a delay in the system normally improves the correction performance,[12] but it also implies a mixed phase character of the correction filters. It is known that mixed phase designs generate a pre-response in the filter, which may generate an audible pre-ringing in the corrected system.[3,13]

This paper is concerned with compensation of loudspeaker and room effects, using a single source, by means of deconvolution of acoustic impulse responses based on data measured at more than one listening point. The objective is to obtain correction filters, with a low amount of pre-ringing, that are robust in the sense that the position of the listener is allowed to vary within a predefined region-of-interest while still obtaining a good, or at least reasonable, compensation for room and loudspeaker characteristics. The reason for choosing such an objective is that we must realize that the one cannot perfectly reproduce the input signal at every point in a region-of-interest. This is mainly for two reasons: (i) we are using a single source so we cannot control (beamform) the sound field spatially and (ii) we do not know the impulse responses at every point in advance and we must, therefore, estimate them based on data acquired at a finite set of observation points. Hence, we only have knowledge of the characteristics of the sound reproduction system at some points, and, furthermore, the estimated impulse responses have a finite length and are based on noisy measurements resulting in limited accuracy of the impulse response estimates.

In this paper we will discuss a statistical inferential[14] method for estimating acoustic impulse responses as well as a method to design robust compensation filters based on (i)

[a]Electronic mail: fredrik.lingvall@gmail.com

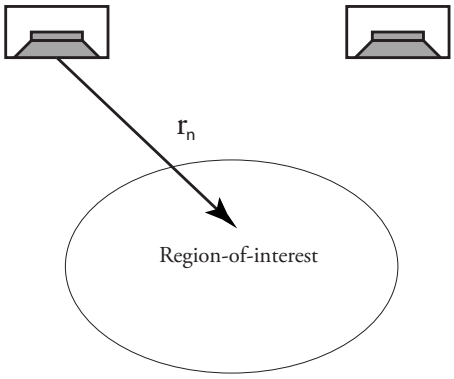

FIG. 1. Typical measurement setup.

impulse responses estimated from data acquired at several observation points and (ii) a linear minimum mean squared criteria. Note that we are seeking a linear finite impulse response filter that can be used for real time compensation.

This paper is organized as follows: in Sec. II a linear matrix-based impulse response model is introduced, which then is used in the estimation of the acoustic impulse responses, which is discussed in Sec. III. Furthermore, In Sec. IV the robust multiple-point design method for correction filters are described as well as how room reflections can be treated by means of a non-stationary filtering approach. In Sec. V the experiments are discussed, and, finally, in Sec. VI a discussion and the conclusions are given.

II. A LINEAR IMPULSE RESPONSE MODEL

Consider the loudspeaker setup shown in Fig. 1. We measure the acoustic pressure wave form at an observation point $\mathbf{r}_n=(x_n,y_n,z_n)$ using a microphone. If we let the loudspeaker be located at origo, $\mathbf{r}=(0,0,0)$, then we can express the received signal at the nth position as

$$y(\mathbf{r}_n,t)=h(\mathbf{r}_n,t)*u(t)+e(t), \tag{1}$$

where $*$ denotes temporal convolution. Note that the impulse response $h(\mathbf{r}_n,t)$ is a function of position due to diffraction effects of the loudspeaker and room effects, such as reflections and room modes; the impulse response, $h(\mathbf{r}_n,t)$, is comprised of several parts, such as the amplifier response, the electro-acoustical response of the loudspeaker, the acoustic (diffraction) response of the loudspeaker, the room impulse response, and the response of the microphone.

Here we are concerned with digital processing of the acoustic data; hence we need a discrete model of the system. This can readily be obtained by sampling the impulse responses, input signals, and the acquired data; here we represent, by convention, the data $\mathbf{y}_n$, the input signal $\mathbf{u}$, and the impulse responses $\mathbf{h}_n$ by column vectors. The discrete form of Eq. (1) can then be expressed as

$$\mathbf{y}_n=\mathbf{h}_n*\mathbf{u}+\mathbf{e}, \tag{2}$$

where $*$ now denotes discrete temporal convolution. Furthermore, a discrete-time convolution of two vectors $\mathbf{u}$ and $\mathbf{h}$ can be expressed as a matrix-vector multiplication of the form

$$\mathbf{h}*\mathbf{u}=\mathbf{H}\mathbf{u}=\mathbf{u}*\mathbf{h}=\mathbf{U}\mathbf{h}, \tag{3}$$

where the matrices $\mathbf{H}$ and $\mathbf{U}$ have a Toeplitz form consisting of delayed versions of $\mathbf{h}_n$ and $\mathbf{u}$, respectively.[12,15] If $\mathbf{h}_n$ is of length L_h and $\mathbf{u}$ is of length L_u, then the length of the discrete-time convolution, $\mathbf{h}_n*\mathbf{u}$, will be L_h+L_u-1. We will assume, for the remaining part of the paper, that when a matrix convolution, of the form (3), is used then the Toeplitz matrices involved have a dimension such that the length of the resulting vector is the same as for the normal form of the discrete-time convolution. Now, by using the matrix-vector notation in Eq. (3), the model (2) becomes

$$\mathbf{y}_n=\mathbf{H}_n\mathbf{u}+\mathbf{e}=\mathbf{U}\mathbf{h}_n+\mathbf{e}. \tag{4}$$

III. ESTIMATING ACOUSTIC IMPULSE RESPONSES

Before we can design the correction filter, we need to obtain the impulse responses, $\mathbf{h}_n$, for each observation point $\mathbf{r}_n$. To do this we play a suitable identification signal to the system and measure the acoustic waveform using a microphone at $\mathbf{r}_n$, as discussed in Sec. II. We must, however, acknowledge that the measurements are never error free; we will always have quantization errors, thermal noise, acoustic disturbances, etc. Also, we are using a discrete model of finite length, which never can describe the system perfectly. We have, therefore, chosen a Bayesian approach to estimate the impulse responses, which takes these uncertainties into account. More precisely, we have used the optimal linear estimator—also known as the linear minimum mean squared error (LMMSE) estimator or the maximum *a posteriori* estimator under Gaussian assumptions.

A. Prior information

A powerful feature in Bayesian analysis is that prior information is naturally incorporated, which significantly can improve our estimates. In this case we are interested in estimating acoustic impulse responses, and we know, for example, *a priori* that it takes a certain amount of time for the sound to travel from the active area of the loudspeaker to the observation point. The impulse response must consequently have a zero amplitude for that time interval, and data for this time interval can, therefore, be removed since it carries no information relevant to the design of the correction filter. For the response corresponding to the remaining time interval, which consists of a direct response and room responses (reflections and room modes), the direct response is often the strongest. However, if we have no knowledge from, for example, previous measurements, then it is difficult to say how much stronger the direct response is compared to the responses due to the room. Furthermore, we normally do not know if the impulse response amplitudes are more likely to be positive or negative. We can, however, say something regarding the mean signal variation since, in a typical measurement situation, the output power and the microphone gain is adjusted so that a sufficient acquired signal variation is obtained. This mean signal variation will correspond to a mean variation in the impulse responses, which we denote as

σ_h. Based on probability theory,[16,17] we can then assign a zero-mean Gaussian (prior) probability density function (pdf) to the impulse responses

$$p(\mathbf{h}_n|I) = \frac{1}{(2\pi)^{L_h/2}|\mathbf{C}_h|^{1/2}} e^{-(1/2)\mathbf{h}_n^T \mathbf{C}_h^{-1} \mathbf{h}_n}, \tag{5}$$

where $\mathbf{C}_h = \sigma_h^2 \mathbf{I} \, \forall \, n$.

B. The optimal linear estimator for acoustic impulse responses

To estimate the impulse responses $\mathbf{h}_n$, we first perform N experiments, one for each observation point, where we obtain the data $\mathbf{y}_n$, $n=1,2,\ldots,N$. Using the linear model (4), for the nth measurement point, the optimal linear estimate of $\mathbf{h}_n$ can be found by minimizing the mean squared error (MSE) criteria,

$$J(\mathbf{K}) = \arg\min_{\mathbf{K}} E\{\|\mathbf{h}_n - \hat{\mathbf{h}}_n\|^2\} = \arg\min_{\mathbf{K}} E\{\|\mathbf{h}_n - \mathbf{K}\mathbf{y}_n\|^2\}, \tag{6}$$

which has the closed form solution given by[18]

$$\hat{\mathbf{h}}_n = \mathbf{K}\mathbf{y}_n = \mathbf{C}_h \mathbf{U}^T (\mathbf{U}\mathbf{C}_h\mathbf{U}^T + \mathbf{C}_e)^{-1} \mathbf{y}_n, \tag{7a}$$

where $E\{\cdot\}$ is the expectation operator, $\mathbf{C}_e$ is the noise covariance matrix, $\mathbf{C}_h$ is the impulse response covariance matrix given by Eq. (5), and T is the transpose operator.

The covariance matrix $\mathbf{C}_h$ allows us to incorporate *a priori* knowledge regarding the impulse responses. A conservative setting is, as discussed in Sec. III A, to let $\mathbf{C}_h = \sigma_h^2 \mathbf{I}$; that is, we have no *a priori* knowledge of correlations and time varying amplitude variations of the individual magnitudes of the impulse response coefficients—if such correlations and amplitude variations do exist, then they must solely be given by the data.

The noise term, $\mathbf{e}$, in the model (4) above accounts for all uncertainties that we may have. As previously discussed we typically have model errors due to the finite length of the impulse responses, as well as the electronic measurement and the acoustic interference that cannot be avoided. Here we have also used a conservative model of the noise and let the covariance matrix have the form $\mathbf{C}_e = \sigma_e^2 \mathbf{I}$. The value of σ_e is, however, in practice seldom known beforehand. By using probability theory we could assign a prior for σ_e and integrate (marginalize) it out.[16,17] This would, however, lead to a more complicated non-Gaussian posterior. An often good approximation is to estimate σ_e from data and then use the estimated value in Eq. (7a), which is the method chosen in this paper (the procedure for estimating the noise variance is described in Appendix A). The estimator (7a) can be rewritten in the equivalent form

$$\hat{\mathbf{h}}_n = (\mathbf{U}^T \mathbf{C}_e^{-1} \mathbf{U} + \mathbf{C}_h^{-1})^{-1} \mathbf{U}^T \mathbf{C}_e^{-1} \mathbf{y}_n, \tag{7b}$$

which can be practically useful since the size of the matrix inverse may then be smaller. The latter form (7b) can also be obtained by assuming a Gaussian distributed $\mathbf{h}_n$ and $\mathbf{e}$ and then choosing the estimate $\hat{\mathbf{h}}_n$ where the *a posteriori* pdf has its maximum.

In summary, we have assumed that $\mathbf{h}$ and $\mathbf{e}$ are zero mean and mutually independent with covariance matrices $\mathbf{C}_h = E\{\mathbf{h}_n \mathbf{h}_n^T\} = \sigma_h^2 \mathbf{I}$ and $\mathbf{C}_e = E\{\mathbf{e}\mathbf{e}^T\} = \sigma_e^2 \mathbf{I}$, respectively.

C. The impulse response error

An important feature of Bayesian analysis is that we obtain a measure of the accuracy of our estimates. This is given by the posterior distribution, which for the estimator in Eq. (7a) and (7b) is Gaussian. The estimation error, $\boldsymbol{\epsilon} = \hat{\mathbf{h}} - \mathbf{h}$, is then also (zero-mean) Gaussian where the covariance matrix for $\boldsymbol{\epsilon}$ is given by[18]

$$\begin{aligned} \mathbf{C}_\epsilon &= \mathbf{C}_h - \mathbf{C}_h \mathbf{U}^T (\mathbf{U}\mathbf{C}_h\mathbf{U}^T + \mathbf{C}_e)^{-1} \mathbf{U}\mathbf{C}_h \\ &= (\mathbf{C}_h^{-1} + \mathbf{U}^T \mathbf{C}_e^{-1} \mathbf{U})^{-1}, \end{aligned} \tag{8}$$

where we have dropped $\mathbf{C}_e$'s dependence on $\mathbf{r}_n$ to simplify the notation.

IV. THE CORRECTION FILTER

The objective with the design of the correction filter is that the filter, as mentioned in Sec. I, should be robust in the sense that the listener should be able to move within a predefined region while still obtaining a reasonable correction. Since we are using a single source we cannot compensate for all (position-dependent) loudspeaker and room effects. That is, in particular, the reflected responses vary significantly over the region-of-interest,[5] and such effects, therefore, cannot be compensated—at least not without using a multiple-channel system. However, at lower frequencies the sound pressure varies more slowly with respect to listener movement, and if the position change is within a half wavelength then the sound wave will have a similar phase for the corresponding frequency. Thus, the correction filter can therefore compensate for the lower frequency room effects, and the cut-off frequency, where compensation is possible, is directly related to the size of our chosen correction region.[19] This information can be included in the design criteria, which will be further discussed below.

A. The linear minimum mean squared error correction filter

The objective is now to reproduce the input signal, $\mathbf{u}$, using linear pre-filtering according to

$$\hat{\mathbf{u}}_n * \boldsymbol{\delta}_{k-d_n} = \mathbf{h}_n * \mathbf{u} * \mathbf{f} + \mathbf{e} = \mathbf{H}_n \mathbf{U}\mathbf{f} + \mathbf{e}, \tag{9}$$

where $\mathbf{f}$ denotes the correction filter and where $\boldsymbol{\delta}_{k-d_n} = 1$ for $k = d_n$ and otherwise zero. Note that $\hat{\mathbf{u}}_n$ will be delayed relative to $\mathbf{u}$ due to the filtering delays associated with $\mathbf{h}_n$ and the filter delay due to the compensation filter $\mathbf{f}$ (i.e., it takes some time for the signal to pass through the system and the correction filter). We must, therefore, introduce a delay, d_n, in Eq. (9) in order to obtain a realistic estimator.

To find the linear filter we choose the filter, $\mathbf{f}$, that minimizes the mean squared sound reproduction error at a set of N observation points according to

$$\mathbf{f}_{\mathrm{OPT}} = \sum_{n=1}^{N} \arg\min_{\mathbf{f}} E\{\|\mathbf{u} * \boldsymbol{\delta}_{k-d_n} - \hat{\mathbf{u}}_n\|^2\}$$

$$= \sum_{n=1}^{N} \arg\min_{\mathbf{f}} E\{\|\boldsymbol{\Lambda}_{k-d_n}\mathbf{u} - \hat{\mathbf{u}}_n\|^2\}, \quad (10)$$

where $\boldsymbol{\Lambda}_{k-d_n}$ is the Toeplitz convolution matrix that corresponds to $\boldsymbol{\delta}_{k-d_n}$. We have again used a conservative approach and assumed that $E\{\mathbf{u}\mathbf{u}^T\} = \mathbf{C}_u = \sigma_u^2\mathbf{I}$.

Now, by using the estimated impulse responses in Eqs. (9) and (10) and equating the derivative with respect to $\mathbf{f}$ to zero, the correction filter which minimizes Eq. (10) becomes

$$\mathbf{f}_{\mathrm{LMMSE}} = \left(\sum_n \hat{\mathbf{H}}_n\hat{\mathbf{H}}_n^T\right)^{-1}\sum_n \hat{\mathbf{H}}_n^T\boldsymbol{\delta}_{k-d_n}, \quad (11)$$

where the dependence of the prior for $\mathbf{u}$ disappears since σ_u cancels out.

B. The LMMSE correction filter for room impulse responses with errors

Since we must estimate the room impulse responses from data, there will be deviations in our estimates from the true impulse responses, and, as discussed in Sec. III C, these deviations can be treated as Gaussian. A model that takes these uncertainties into account can then be expressed as

$$\mathbf{y}_n = (\hat{\mathbf{h}}_n + \Delta\mathbf{h}_n) * \mathbf{u} + \mathbf{e} = (\hat{\mathbf{H}}_n + \Delta\mathbf{H}_n)\mathbf{u} + \mathbf{e}, \quad (12)$$

where $\Delta\mathbf{h}_n \sim N(\mathbf{0}, \mathbf{C}_\epsilon^{(n)})$. Following the procedure used in Sec. IV A and using Eq. (12) in Eq. (10) results in

$$\mathbf{f}_{\mathrm{LMMSE}} = \left(\sum_n \hat{\mathbf{H}}_n^T\hat{\mathbf{H}}_n + \tilde{\mathbf{C}}_\epsilon^{(n)}\right)^{-1}\sum_n \hat{\mathbf{H}}_n^T\boldsymbol{\delta}_{k-d_n}, \quad (13)$$

where $\tilde{\mathbf{C}}_\epsilon^{(n)} = E\{\Delta\mathbf{H}_n^T\Delta\mathbf{H}_n\}$, which approximately is given by $\tilde{\mathbf{C}}_\epsilon^{(n)} \approx \text{Ł}_h\tilde{\sigma}_\epsilon^2\mathbf{I}$ (see Appendix B).

C. Reflection response filtering

Recall from the discussion in Sec. IV that we cannot compensate for reflections and high frequency room modes using a single source. Note, however, that since the reflection responses always arrive after the direct response, we can apply a suitable time varying filter to the impulse responses to attenuate the reflection effects in the impulse responses while keeping the low frequency room modes. Thus, by this procedure we can reduce the influence of the reflections in the design of the reconstruction filter.

The non-stationary filtering can be obtained by using a filter matrix where the columns are not delayed versions of the same filter, as for a normal Toeplitz convolution matrix, but now the filters are changing with time. This can be expressed in matrix form by multiplying the impulse response matrices $\mathbf{H}_n$ with a reflection filter matrix $\mathbf{F}_R$, that is, we replace $\mathbf{H}_n$ in the criteria (10) with $\mathbf{F}_R\mathbf{H}_n$, which results in the new criteria,

$$\mathbf{f}_{\mathrm{OPT}} = \arg\min_{\mathbf{f}} \sum_n E\{\|\mathbf{u} * \boldsymbol{\delta}_{k-d_n} - \mathbf{U}\mathbf{F}_R\mathbf{H}_n\mathbf{f}\|^2\}. \quad (14)$$

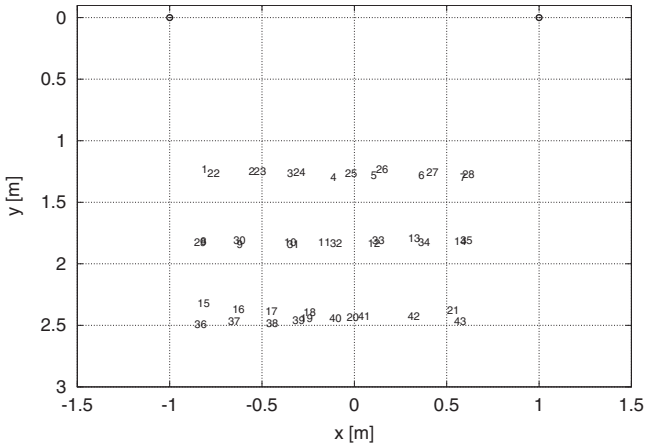

FIG. 2. The measurement setup. The circles indicate the loudspeaker positions and the numbers, 1–43, indicate the microphone measurement positions.

V. EXPERIMENTS

To verify the presented theoretical results above, experiments have been performed in a 5.8 m long, 4.5 m wide, and 2.6 m high room, which is designed after the live-end/dead-end principle; the wall behind the loudspeakers has sound absorbing draperies, and the wall at the opposite side to the loudspeakers has a sound diffuser. The data have been acquired using a DPA 4004 Reference microphone and an RME Multiface 24-bit sound card. The acoustic data were acquired at 43 measurement points, where measurements 1–21 were acquired at a height of 1.09 m and measurements 22–43 were acquired at 1.32 m, respectively. Two Genelec 8040A loudspeakers were used, and the layout of the experiments is shown in Fig. 2. In the results for the left loudspeaker presented here, the data from the 10th observation point, at $(-0.38, 1.83, 1.09)$ m, was used for evaluation, and the correction filter is based on data from the remaining 42 measurements. Furthermore, an impulse response (and correction filter) vector length of 16 384 elements was used here, which corresponds to a time duration of 371 ms. We have used white input signals of a duration of 3 s, sampled at a sampling frequency of 44.1 kHz, in the experiments, and the acoustic impulse responses were estimated using Eq. (7a) and (7b). We have given all estimated impulse responses an equal weight in the construction of the correction filter, and the data have, therefore, been normalized. We have also used a lower limit of 20 Hz and an upper limit 20 kHz for the working range of the correction filter.

In Fig. 3(a) the first part of the estimated impulse response for measurement point $(-0.38, 1.83, 1.09)$ m is shown. The response seen just before 2 ms is the direct path response, and the first (floor) reflection is the response seen at approximately 5 ms. One can also see that the frequency response, shown in Fig. 3(b), has many dips, which is known to cause problems in direct inversion approaches since then a division by zero nearly occurs.

Note that the arrival times of the same reflections but at different measurement points will not be the same since the propagation distances to the objects that reflect the sound will be different at different points. This is shown in Fig. 4(a)

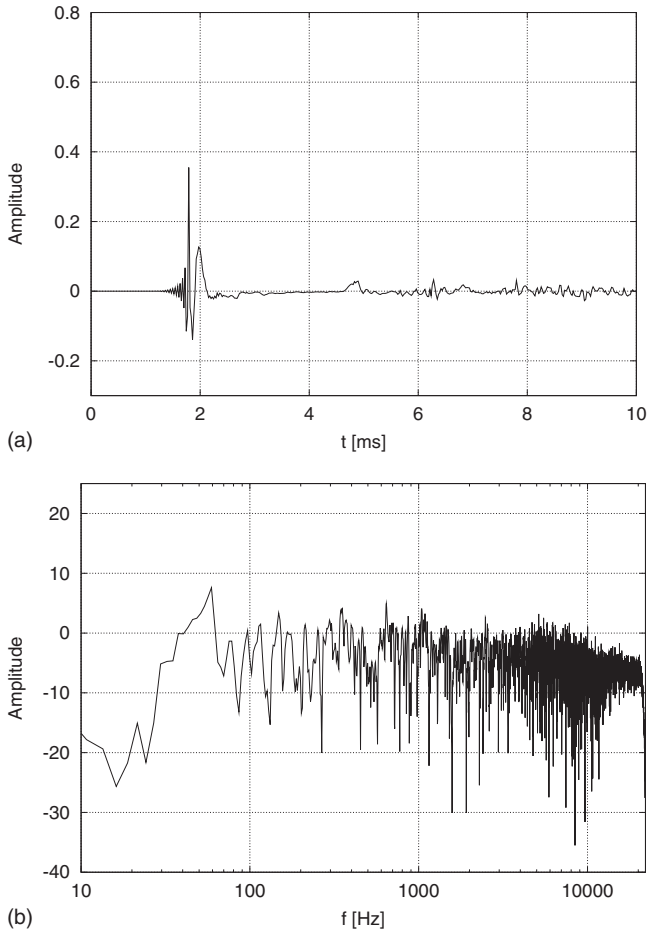

FIG. 3. The estimated acoustic impulse response for position (−0.38, 1.83, 1.09) (m).

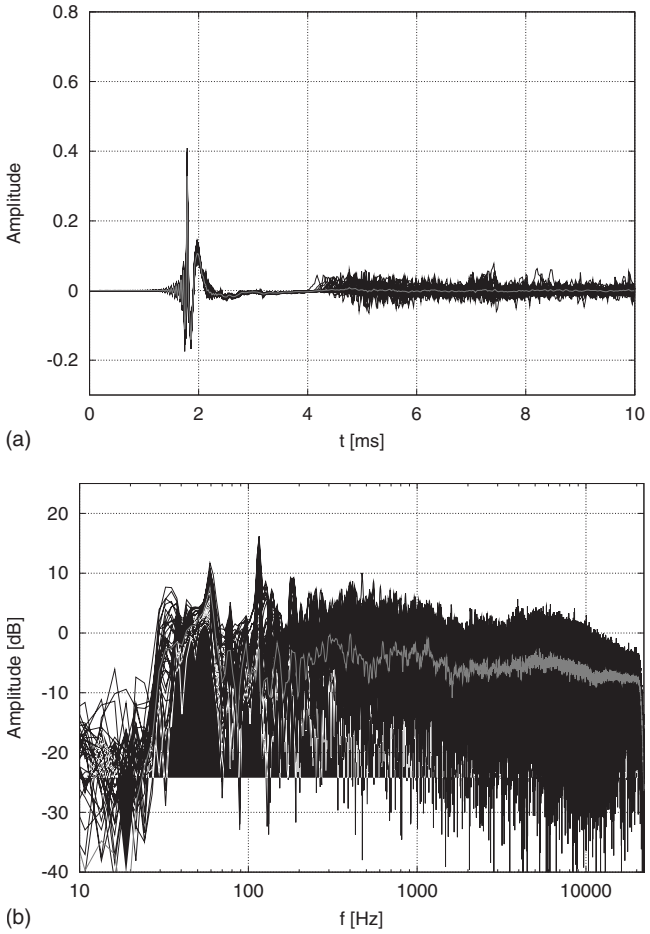

FIG. 4. The estimated acoustic impulse responses.

where all estimated impulse responses have been plotted in the same graph. As can be seen in the figure, the direct path impulse responses have similar, but not identical, shapes for all measurement points, but the reflections, which all arrive after 4 ms, vary significantly between different measurement points. This can also be seen by observing the average of the estimated impulse responses, shown as the gray solid line in Fig. 4(b); here it can be observed that the reflection part of the average impulse is close to zero since negative and positive responses does not arrive coherently for different points, and these parts will, therefore, almost cancel out in the average.

To further study the variability between estimated impulse responses, the spectra at each point have been plotted in the same graph in Fig. 4(b). Here we can see that the spectra have peaks and dips at roughly the same frequencies up to approximately 100–200 Hz, but above 200 Hz the peaks and dips occur at different frequencies for different points. This can also be seen in the average frequency response, shown as the gray solid line, which is relatively flat (with a falling trend) above 200 Hz with no strong isolated peaks or dips.

The LMMSE correction filter, based on the 42 "training" measurements, was then computed using Eq. (13), and the resulting filter is shown in Fig. 5. As seen in the frequency response in Fig. 5(b), the correction filter does not have excessive filter gain at any frequency. There is a peak at approximately 25 Hz since the loudspeakers do not transmit much energy below 30 Hz (see Fig. 4). One can also observe that there is three, or four, relatively well separated common resonance peaks in the spectra shown in Fig. 4(b) between 50 and 200 Hz. These peaks have corresponding dips in the correction filter's spectrum. One can also note that the correction filter compensates for the falling trend above 2–3 kHz seen in the average impulse response spectra in Fig. 4(b). The falling trend of the frequency responses can partly be explained by the diffraction effects of the acoustic source, which depend on the size of the source and the position of the measurement point; the fall-off trend for high frequencies increases when the distance from center-axis of the source increases (see, for example, Ref. 20).

To further show the properties of the LMMSE correction filter, the estimated impulse response for measurement point (−0.38, 1.83, 1.09) was filtered using the correction filter (shown in Fig. 5), which is displayed in Fig. 6. First one can observe, in Fig. 6(a), that the corrected system has a significantly shorter direct response compared to the uncorrected system. Second, the pre-ringings are roughly 50 dB lower than the maximum direct response [see Fig. 6(b)]. Third, the frequency response of the corrected system, shown in Fig. 6(c), is significantly closer to a flat response compared to uncorrected system. The correction is, as expected, not perfect since there are, in particular, still some dips in the spec-

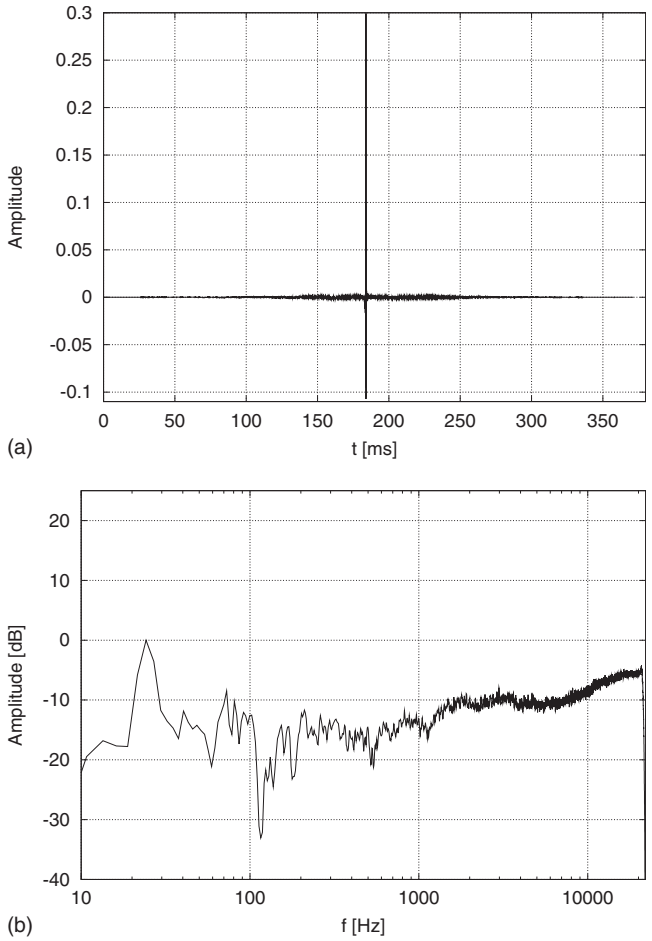

FIG. 5. The LMMSE correction filter.

tra for the corrected system. The high frequency part of the correction filter is also somewhat "noisy" [see Fig. 5(b)].

To see if the robustness of the correction can be improved by incorporating more prior information, we have also performed experiments using the (slightly heuristic) reflection filter approach described in Sec. IV C. Figure 7 shows the results where a non-stationary reflection filter with a cut-off frequency of 90 Hz was used when designing the correction filter. The start time for the non-stationary reflection filter was 3.6 ms, and the filter length was gradually increased until 5.6 ms where the full length (of four periods at the cut-off frequency) was reached. By comparing the results in Figs. 6(a) and 7(a), one can see that the correction of the direct response is similar both with and without reflection filtering, which was expected since the direct response was not affected by the filter. However, if we compare the results presented in logarithmic scale in Figs. 6(b) and 7(b), we can see that the reflection filter approach significantly has reduced the amplitudes of the pre-ringings. Furthermore, the high frequency parts of the correction filter is significantly smoother when reflection filtering is used, which can be seen by comparing Figs. 5(b) and 7(c).

VI. SUMMARY AND CONCLUSIONS

This paper treats the particular problem of the design of robust correction filters based on several impulse response

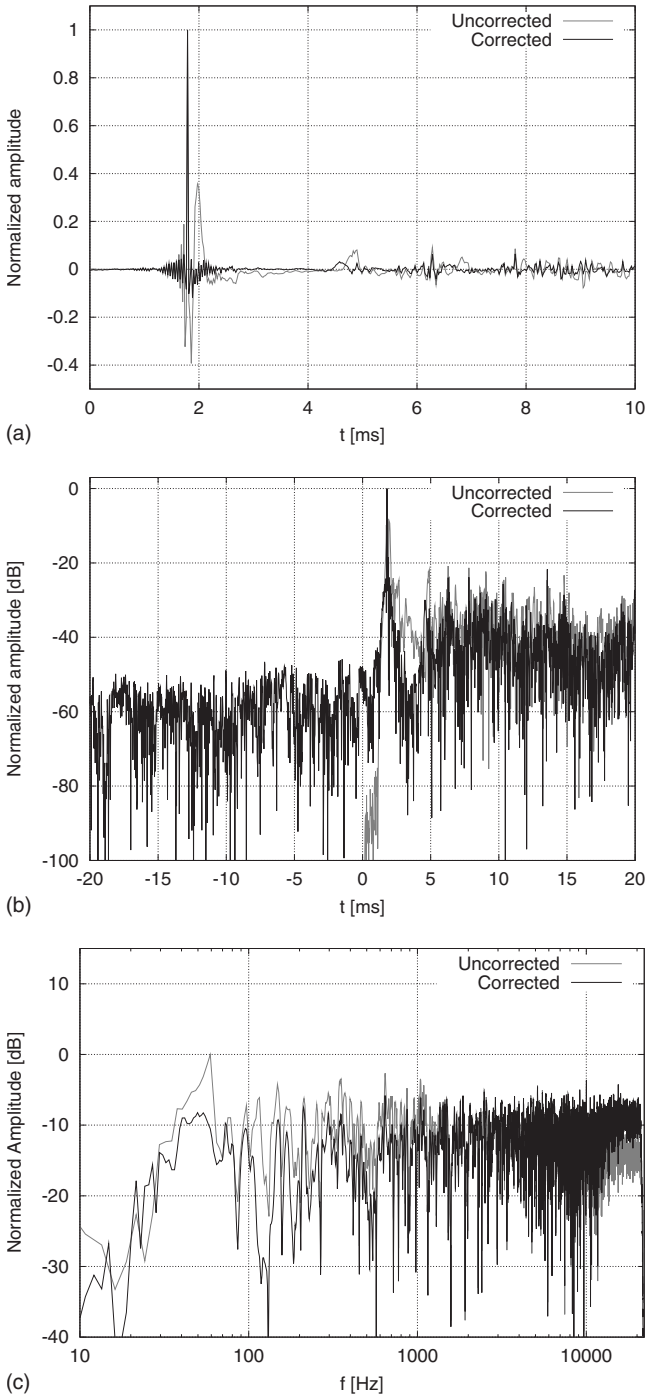

FIG. 6. The uncorrected and corrected impulse responses for measurement position $(-0.38, 1.83, 1.09)$ (m).

measurements. Clearly, the objective is to obtain the best correction possible, but we must first acknowledge the limitations of the experimental conditions and specify a realistic goal for our filter design. Here we are considering correction using a single source, and we are using a finite impulse response model where we must estimate the coefficients in the model from a limited number of noisy data. Due to the uncertainties, we have used a statistical approach in the design of the correction filter. The approach consists of two steps where we first estimate the impulse responses at a finite number of observation points in our region-of-interest, and then we construct a correction filter based on the estimated

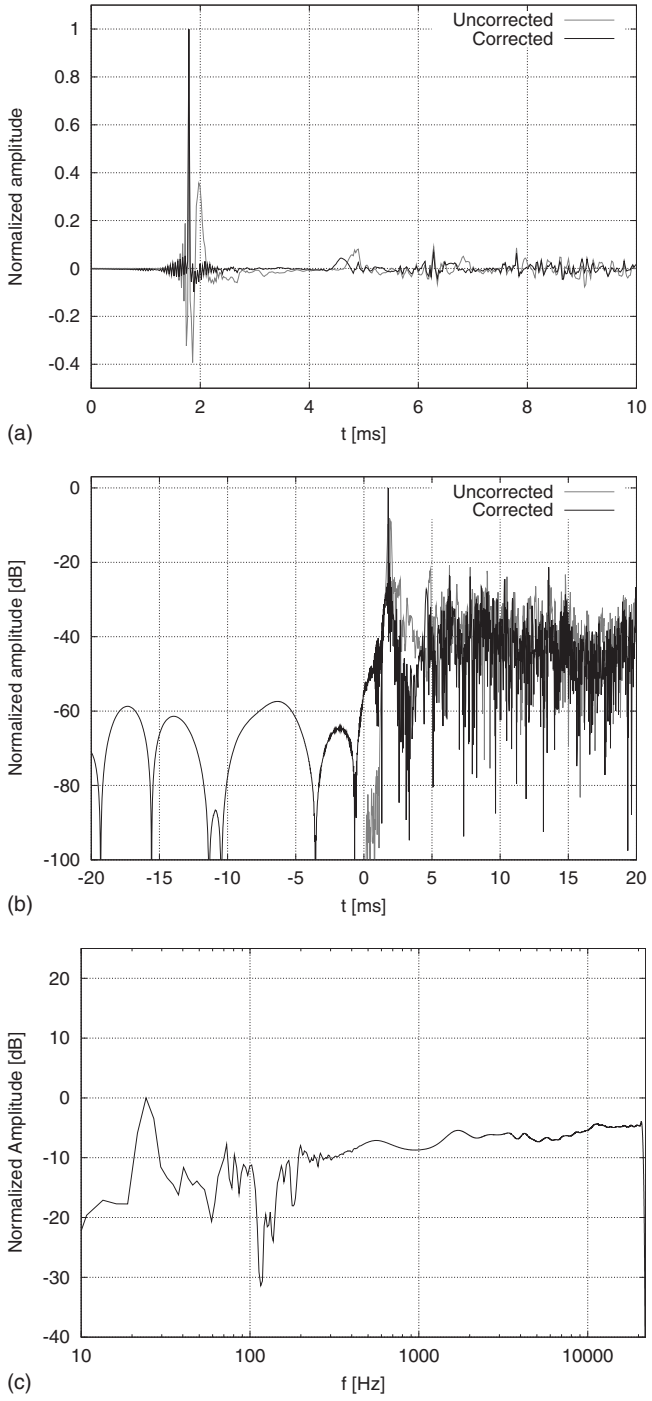

FIG. 7. The uncorrected and corrected impulse responses for measurement position (−0.38, 1.83, 1.09) (m) using a correction filter based on reflection filtered impulse responses.

impulse responses. By taking the uncertainties (i.e., the model error and measurement noise) into account, we have obtained reliable estimates of the impulse responses, which is vital for the design of the correction filter. The correction filter is then constructed by using a linear minimum mean squared criteria. We have, furthermore, introduced a time-dependent reflection filter in criteria, which attenuates the high frequency parts of the reflected responses, that is, the parts of the responses that we cannot compensate with a single source system.

As can be seen in the results from the experiments presented in this paper, the statistical multiple-point correction method introduced here is capable of significantly improving both the temporal and spectral responses compared to the uncorrected system. Furthermore, the obtained correction filter has a low level of pre-ringing, which was in the order of 60 dB lower than the direct response for the data used in this paper.

APPENDIX A: ESTIMATING THE NOISE VARIANCE

Here we are interested to estimate the noise variance σ_e^2 only and we, therefore, marginalize over the impulse response coefficients according to

$$p(\sigma_e|\mathbf{y}_n) \propto p(\sigma_e|I)\int_{\mathbf{h}_n} p(\mathbf{h}_n|I)p(\mathbf{y}_n|\mathbf{h}_n,\sigma_e,I)d\mathbf{h}_n = p(\sigma_e|I)\mathcal{L}(\sigma_e). \tag{A1}$$

If we, for convenience, use a uniform prior for $\mathbf{h}_n$, then the integral in Eq. (A1) becomes

$$\mathcal{L}(\sigma_e) = \int_{\mathbf{h}_n} \frac{1}{R_h}\frac{1}{(2\pi)^{L/2}\sqrt{|\sigma_e^2\mathbf{I}|}} \times \exp\left\{-\frac{1}{2\sigma_e^2}(\mathbf{y}_n-\mathbf{U}\mathbf{h}_n)^T(\mathbf{y}_n-\mathbf{U}\mathbf{h}_n)\right\}d\mathbf{h}_n, \tag{A2}$$

where $R_h=\mathbf{h}_{\max}-\mathbf{h}_{\min}$ is large enough so that the integral, in practice, can be evaluated from $-\infty$ to ∞. Then, after evaluating the Gaussian integral, Eq. (A2) becomes,

$$\mathcal{L}(\sigma_e) = \frac{1}{R_h}\frac{1}{(2\pi)^{L/2}\sqrt{|\sigma_e^2\mathbf{I}|}}\sqrt{\left(\frac{(\sigma_e^2 2\pi)^{L_h}}{|\mathbf{U}^T\mathbf{U}|}\right)} \times \exp\left\{-\frac{1}{2\sigma_e^2}\mathbf{y}_n^T(\mathbf{I}-\mathbf{U}(\mathbf{U}^T\mathbf{U})^{-1}\mathbf{U}^T)\mathbf{y}_n\right\}. \tag{A3}$$

Furthermore, since the noise variance is a scale parameter, we use a (normalized) Jeffreys prior for σ_e,[17]

$$p(\sigma_e|I) = \frac{1}{\log(\sigma_{\max}/\sigma_{\min})}\frac{1}{\sigma_e}, \tag{A4}$$

where $\sigma_{\min}$ is a small value but larger than zero (typically determined by the bit resolution of the analog-to-digital converter) and $\sigma_{\max}$ is a large but finite value. Using Eqs. (A4) and (A3) in Eq. (A1), and equating the derivative of the log of the posterior (with respect to σ_e) to zero, then results in

$$\hat{\sigma}_e = \sqrt{\frac{\mathbf{y}_n^T(\mathbf{I}-\mathbf{U}(\mathbf{U}^T\mathbf{U})^{-1}\mathbf{U}^T)\mathbf{y}_n}{L-L_h+1}}; \tag{A5}$$

that is, Eq. (A5) is the maximum *a posteriori* estimate of σ_e for a uniform prior of $\mathbf{h}_n$.

Recall from Sec. II that here the noise describes the model misfit, and different impulse response lengths will, therefore, result in different values of the estimated noise variance. As an example, the estimated σ_e for six impulse response lengths are given in Table I for the observation point at (−0.38, 1.83, 1.09). One can note that estimated σ_e becomes smaller when the impulse response length in-

TABLE I. Estimated σ_c for six different impulse response lengths, L_h, for the observation point (−0.38, 1.83, 1.09) (m).

L_h	512	1024	2048	4096	8192	16 384
σ_c	0.1644	0.1241	0.0585	0.0226	0.0126	0.0119

creases. This trend can also be seen in Fig. 8 where the normalized log likelihood for σ_e has been plotted for three different impulse response lengths. Here, one can also observe that the value of the most likely σ_e decreases when the impulse response length increases since a longer impulse response can describe the data better, and, furthermore, the posteriors are so narrow that they are essentially delta functions; hence, the actual limits of the prior for σ_e have negligible influence of the posterior.

APPENDIX B: AN APPROXIMATE EXPRESSION FOR THE ERROR COVARIANCE MATRIX

The error covariance matrix $\mathbf{C}_e$ was given in Eq. (8). This expression can be simplified by noting that since we are using a white excitation signal the matrix $\mathbf{U}^T\mathbf{U}$ will be nearly diagonal and can, therefore, be approximated with $\mathbf{u}^T\mathbf{u}\mathbf{I}$. By making this approximation, Eq. (8) reduces to

$$\mathbf{C}_\epsilon \approx \left(\frac{1}{\sigma_h^2}\mathbf{I} + \frac{\mathbf{u}^T\mathbf{u}}{\sigma_e^2}\mathbf{I}\right)^{-1} = \frac{\sigma_h^2\sigma_e^2}{\sigma_e^2 + \sigma_h^2\mathbf{u}^T\mathbf{u}}\mathbf{I}. \tag{B1}$$

If we use this approximation in the correction filter discussed in Sec. IV B, then the matrix $\tilde{\mathbf{C}}_e^{(n)} = E\{\Delta\mathbf{H}_n^T\Delta\mathbf{H}_n\}$ reduces to

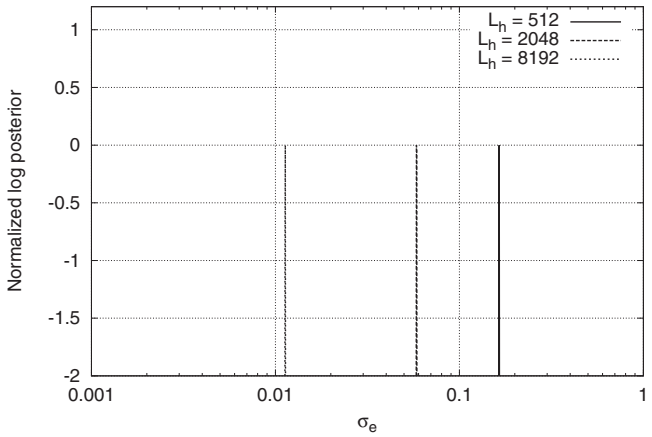

FIG. 8. The normalized log posterior for σ_e for three different impulse response lengths at observation point (−0.38, 1.83, 1.09) (m). The solid line corresponds to an impulse response length of 512 (right curve), the dashed line to 2048 (middle curve), and the dotted line to 8192 (left curve), respectively.

$$\tilde{\mathbf{C}}_\epsilon^{(n)} \approx \mathrm{L}_h\frac{\sigma_h^2\sigma_e^2}{\sigma_e^2 + \sigma_h^2\mathbf{u}^T\mathbf{u}}\mathbf{I} = \mathrm{L}_h\tilde{\sigma}_\epsilon^2\mathbf{I}, \tag{B2}$$

where we have dropped the dependence of n for σ_e^2 to simplify the notation.

Estimating the operating point of the cochlear transducer using low-frequency biased distortion products

Daniel J. Brown,[a] Jared J. Hartsock, Ruth M. Gill, Hillary E. Fitzgerald, and Alec N. Salt
Department of Otolaryngology, School of Medicine, Washington University in St. Louis, St. Louis, Missouri 63110

(Received 7 November 2008; revised 26 January 2009; accepted 26 January 2009)

Distortion products in the cochlear microphonic (CM) and in the ear canal in the form of distortion product otoacoustic emissions (DPOAEs) are generated by nonlinear transduction in the cochlea and are related to the resting position of the organ of Corti (OC). A 4.8 Hz acoustic bias tone was used to displace the OC, while the relative amplitude and phase of distortion products evoked by a single tone [most often 500 Hz, 90 dB SPL (sound pressure level)] or two simultaneously presented tones (most often 4 kHz and 4.8 kHz, 80 dB SPL) were monitored. Electrical responses recorded from the round window, scala tympani and scala media of the basal turn, and acoustic emissions in the ear canal were simultaneously measured and compared during the bias. Bias-induced changes in the distortion products were similar to those predicted from computer models of a saturating transducer with a first-order Boltzmann distribution. Our results suggest that biased DPOAEs can be used to non-invasively estimate the OC displacement, producing a measurement equivalent to the transducer operating point obtained via Boltzmann analysis of the basal turn CM. Low-frequency biased DPOAEs might provide a diagnostic tool to objectively diagnose abnormal displacements of the OC, as might occur with endolymphatic hydrops.

I. INTRODUCTION

There is a general consensus in the literature that tight regulation of the organ of Corti (OC) position and the related operating point (OP) of the cochlear transducer is necessary for the maintenance of hearing sensitivity, and modulation of the OP has been directly linked to auditory threshold fluctuations (Hirsh and Ward, 1952; Davis, 1983; Patuzzi *et al.*, 1984a, 1984b; Kim, 1986; Kemp, 1986; Dallos, 1992). Furthermore, it has been suggested that the hearing dysfunction in patients with Meniere's disease may be related to endolymphatic hydrops, which may involve an abnormal displacement of the OC (Valk *et al.*, 2004; Xenellis *et al.*, 2004). Presently there is no accurate, non-invasive objective measure of the OC position or OP. The main aim of the present study was to develop methods to estimate the OC position non-invasively using low-frequency biased distortion product otoacoustic emissions (DPOAEs). We also aimed to compare this estimate to measurements of the OP obtained through Boltzmann analysis of the cochlear microphonic (CM).

Researchers have previously estimated the OP using low-frequency tones to bias the OC position while measuring even-order distortion products in both the CM and DPOAEs (Frank and Kössl, 1996; Kirk *et al.*, 1997; Kirk and Patuzzi, 1997; Bian *et al.*, 2002; Bian, 2004; Sirjani *et al.*, 2004; Bian, 2006). When the OP of a nonlinear transducer with a first-order Boltzmann distribution is near zero (the symmetric point on the transfer curve), sinusoidal inputs produce relatively symmetric distorted outputs, and the amplitude of the even-order distortions in the output signal are relatively small compared to situations when the OP is displaced from zero and the output is asymmetric. Conversely, the amplitudes of odd-order distortions are largest when the OP is near zero and decrease as the OP is displaced from zero (Weiss and Leong, 1985; Frank and Kössl, 1996).

Despite recent research into the use of DPOAEs for the estimation of the cochlear transducer OP, there are many potential sources of nonlinearity in the cochlea that may contribute to DPOAE generation. One possibility is that they are generated by distortion of the mechanical-to-electrical transduction in the cochlea via the mechanoelectrical transduction (MET) channels on the hair bundles (Corey and Hudspeth, 1979), which is then reverse-transduced into mechanical vibration (Kim, 1986; Kirk and Yates, 1998; Yates and Kirk, 1998)), producing distortion products in the ear canal (Lukashkin and Russell, 1997, 1998; Liberman *et al.*, 2004). Another possibility is that DPOAEs are predominantly generated by distortion in the electrical-to-mechanical process that underlies the active amplification of OC vibration (Santos-Sacchi, 1991) or nonlinear compliance of the MET channels (Howard and Hudspeth, 1988; Jaramillo *et al.*, 1993). Whatever the mechanism underlying distortion in the cochlea, if the sources of distortion products in both the ear canal and the electrical response in the cochlea were the same, both sets of distortion products would have similar characteristics and might be used to determine the properties of transduction in the cochlea.

Forward-transduction in the cochlea follows a Boltzmann distribution due to the distribution of MET channel conductance (Holton and Hudspeth, 1986; Kros, 1996). Re-

[a]Author to whom correspondence should be addressed. Electronic mail: danielbrown@med.usyd.edu.au

searchers have used the CM as an approximation of the local MET channel conductance and have fitted a first-order Boltzmann function to the relationship between the CM and the acoustic stimulus (Corey and Hudspeth, 1983; Crawford *et al.*, 1989; Patuzzi and Rajan, 1990, Patuzzi and Moleirinho, 1998; Sirjani *et al.*, 2004), assuming that the CM is dominated by local hair cells (Dallos *et al.*, 1972; Patuzzi *et al.*, 1989) and that the MET channels are the dominant nonlinearity in the forward-transduction (Holton and Hudspeth, 1986; Kros, 1996). The three main parameters used to fit the Boltzmann function

$$y = V_{\text{off}} + \left(- P_{\text{sat}} + \frac{2 \cdot P_{\text{sat}}}{1 + \exp(2 \cdot S \cdot P_{\text{sat}}(\text{input} + \text{OP}))} \right)$$

are the OP, which is related to the asymmetry of transduction, the saturating voltage (P_{sat}), which is related to the potential between the open and closed states of the MET channels, and a sensitivity parameter (S), which represents the slope of the curve at the mid-point of the Boltzmann curve (Sirjani *et al.*, 2004). The OP is of particular interest because it is most likely a reasonable estimate of the resting conductance of the MET channels, which can be affected by a number of mechanical changes in the cochlea such as (1) displacements of the OC toward either scala vestibuli (SV) or scala tympani (ST), possibly due to a pressure differential across the partition (Nieder and Nieder, 1968a, 1968b; Patuzzi and Sellick, 1983; Russell and Kossl, 1992; Cheatham and Dallos, 1994), (2) hair cell length changes, which are a property of the outer hair cells (OHCs) (Brownell *et al.*, 1985; Zenner, 1986; Evans and Dallos, 1993), and (3) changes in the MET channel compliance (Howard and Hudspeth, 1988; Jaramillo *et al.*, 1993). Normally, the cochlea is relatively insensitive to dc pressures in the ear canal due to the acoustic high-pass filtering properties of the middle ear and helicotrema (Dallos, 1970; Ruggero *et al.*, 1986), and therefore the OP is most likely determined by cochlear factors, as mentioned above.

Despite the cochlear's insensitivity to dc pressures in the ear canal, we expected that low-frequency tones could be used to displace the OC position and transducer OP, thereby altering the phase and amplitudes of the distortion products in the CM and DPOAE evoked by a probe stimulus. We also predicted that properties of the transducer, such as its OP, could be indirectly determined from the amplitude and phase of the distortion products measured during low-frequency biasing. Presumably, the instantaneous pressure of a bias tone that causes even-order distortion products to be reduced to a minimum would represent the point where the transducer OP was displaced back to the mid-point of the Boltzmann transducer curve, which is what we define as zero OP. In this case, the applied bias pressure would be equal, but oppositely directed to the unbiased, innate OP of the transducer. This technique allows us to non-invasively probe the OP and monitor it during experimental manipulations.

II. METHODS

A. Animal preparation

Cochlear potentials and otoacoustic acoustic emissions (OAEs) were recorded in acute experiments in 19 NIH strain pigmented guinea pigs of either sex. Animals were anesthetized with an initial dose of 100 mg/kg sodium thiobutabarbital (Inactin, Sigma, St. Louis) and maintained in a state of deep anesthesia by periodic supplements via a cannula in the external jugular vein. Pancuronium bromide (2 mg/ml) was given intravenously as a muscle relaxant to reduce myogenic artifacts and to eliminate middle ear muscle contractions. Animals were artificially ventilated through a tracheal cannula, with end-tidal CO_2 maintained near 38 mm Hg (5%). Heart rate and vascular pO_2 were monitored with a pulse-oximeter (Surgivet, Waukesha, WI). Rectal temperature was maintained at 38 °C with a dc-powered, thermistor-controlled heating blanket. Animals were mounted in a head-holder, and the auditory bulla was exposed by a ventral approach, allowing access to the cochlea. The external ear canal was transected to allow placement of a hollow ear bar, through which acoustic signals were delivered.

The experimental protocols for this study were approved by the Animal Studies Committee of Washington University (Approval Nos. 20040209 and 20070147).

B. Acoustic stimulus generation, calibration, and acoustic emission recording

Tucker-Davis (TD) system-3 hardware was used to generate acoustic stimuli under the control of a custom-written Visual Basic (Microsoft) program. Three channels of sinusoidal stimuli were generated by two TD-RP2 modules, with each channel passed through a TD-PA5 attenuator to control level before being amplified by a headphone amplifier (TD-HB7). Two channels of probe stimuli (f1 and f2) were delivered to the ear canal by a modified Etymotic ER10C system coupled to the hollow ear bar. The third sound channel was used to generate and deliver 4.8 Hz bias tones. Bias tones were generated by a Sennheiser HD 580 or HD 265 driver, sealed into an acrylic coupler and connected to the ear bar with a short length of polyethylene tubing. All sound stimuli were delivered, and acoustic emissions were recorded within this closed sound system. The microphone within the ER10C system was used both for recording acoustic emissions and for the calibration of stimuli. In each animal, calibration curves were determined for all three transducers by tracking the attenuation required to generate a stimulus level of 70 dB SPL (sound pressure level) in the external canal as frequency was varied in $\frac{1}{4}$ octave steps. Calibration tables were generated, taking into account sensitivity changes of the microphone as a function of frequency. These calibration data were used by the software to deliver all subsequent stimuli calibrated on a dB SPL basis. Stimulus levels presented in this study were measured close to the tympanic membrane so they exclude the normal gain of 5–10 dB (from 2 to 10 kHz) provided by the ear canal (Sinyor and Laszlo, 1973). Calibrating at the tympanic membrane therefore means that the cochlea was exposed to stimulation levels of 5–10 dB lower than those experienced when stimuli are calibrated and pre-

TABLE I. Distortion levels measured in the ear bar, with and without an animal present. All levels are dB SPL, with standard deviation (±) and number of animals used (n) shown.

Stimulus	500 Hz, 90 dB SPL	500 Hz, 90 dB SPL	4 and 4.8 kHz, 80 dB SPL	4 and 4.8 kHz, 80 dB SPL
DPOAE:	2f1	3f1	f2-f1	2f1-f2
No animal (dB SPL)	35	18	−22	−4
Noise floor (dB SPL)	−15	−18	−27	−11
Animal average (dB SPL)	44 (±10, n=15)	42 (±7, n=15)	26 (±5, n=7)	29 (±10, n=7)
Noise floor (dB SPL)	−7 (±8)	−14 (±6)	−3 (±8)	−13 (±8)

sented free field. In order to calibrate the 4.8 Hz bias tones with the Etymotic ER10C microphone, it was necessary to extend the microphone response curve to lower frequencies, which was performed by comparing coupler responses from the ER10C with those of a Brüel & Kjær 4135 $\frac{1}{4}$ in. microphone as frequency was varied.

1. Transient hypoxia

Transient hypoxia was induced by coupling the ventilator output to the input through a container of CO_2 absorber (Sodalime, W.A. Grace, S.A.), so that the animal was rebreathing the same air, thereby slowly reducing the O_2 level, while the CO_2 was maintained at a constant low level to minimize vascular changes. The container incorporated a narrow vent line to maintain constant atmospheric pressure in the system. Gas sampling for CO_2 analysis was disabled during the procedure. Hypoxia was allowed to develop until endocochlear potential (EP) fell below approximately 50 mV, after which room-air ventilation was restored.

C. Cochlear potential recording (non-biased)

Cochlear potentials were recorded from a Ag/AgCl ball electrode placed on the bone at the margin of the round window (RW) membrane or from electrolyte-filled glass pipettes inserted into ST or scala media (SM). Signals from the RW electrode were recorded differentially with respect to a platinum needle electrode at the vertex using a TD HB4 optically coupled amplifier with a gain of 1000× and high-pass filtered at 5 Hz. Glass pipettes with a 5 μm tip diameter were filled with 500 mM NaCl for ST recordings or with 500 mM KCl for SM recordings. Responses from the glass pipettes were recorded through dc-coupled electrometer amplifiers with a gain of 10, referenced to the animal's earth electrode, which consisted of a salt-bridge AgCl electrode placed on the exposed muscles of the neck. EP was also recorded from pipettes inserted into SM, with the voltage measured prior to inserting the pipette into SM defining the zero level.

Cochlear potentials and acoustic emissions were collected simultaneously using the input channels of the TD-RP2 modules, sampling at 24 or 48 kHz. The software permitted data from four input channels to be collected and averaged simultaneously. In addition, two channels of data were also sampled at 44.1 kHz and streamed to disk using a PC equipped with an internal sound card. Time-averaged waveforms from the TD system were subjected to a number of analyses, including the following.

(i) Fast Fourier transform (FFT) spectral analysis using National Instruments Component Works routines called by the Visual Basic software. For responses collected without low-frequency biasing, FFT spectra were typically obtained from non-windowed time waveforms collected as the average of ten phase-locked 8192-point, 168 ms duration epochs. Three FFT spectra, each derived from independent data collections, were then averaged to form a final spectrum from which measurements were made. Spectral phase data were not averaged but were measured from the last block of data collected. The frequencies of probe stimuli were adjusted to ensure that the collected waveform contained an integer number of complete cycles, allowing sharp spectra to be obtained without windowing the time waveforms. The level of distortion generated by the sound delivery system, in response to one or two probe tones, was measured with the speakers and microphone placed in the ear bar, identical to experimental testing, but with the ear bar sealed into a 0.3 ml cavity, partly filled with wire wool to diffuse standing waves. A summary of the distortion product levels with and without an animal present is presented below in Table I. It should be noted that DPOAE levels in the animal depend greatly on the position of the OP in the cochlea where they are generated, which can vary between normally hearing animals, so there is an inherent complexity of averaging DPOAEs across animals. Nonetheless, we have provided average distortion levels for the purposes of indicating that they were well above that generated by the sound delivery system and well above the noise floor measured 10 Hz on either side of the distortion product.

(ii) A Boltzmann analysis of the CM waveform was performed using a 21 ms segment of the averaged time waveform described above. The waveform was transferred online to an Excel spreadsheet and fitted with a waveform synthesized from a Boltzmann curve relating voltage output to applied pressure input (Kirk *et al.*, 1997; Sirjani *et al.*, 2004). The parameters derived from this analysis were the following: P_{sat}: the saturation voltage of the curve, slope: the maximum steepness of the transducer function at zero input pressure, and OP_{Boltz}: the OP, which represents the position on the transducer curve at the zero crossings of the probe stimulus. Because the Boltzmann equation used in the present study multiplied the OP by the

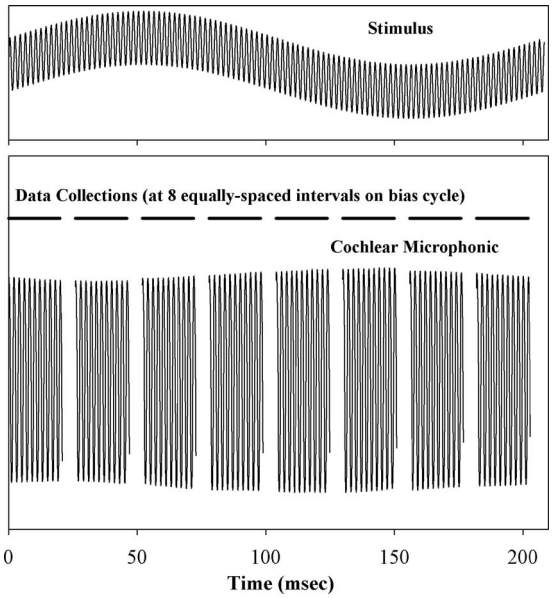

FIG. 1. Schematic of the experimental protocol in which a 4.8 Hz biasing tone is utilized to modulate OP of the cochlea during the simultaneous presentation of a probe tone. During each 208 ms cycle of the bias tone, eight independent collections were performed, and results were averaged over multiple bias cycles. Each of the eight data blocks was subsequently analyzed separately.

sensitivity to the probe stimulus [i.e., $2^{*}S/P_{\mathrm{sat}}{}^{*}$(input +OP)], the $\mathrm{OP}_{\mathrm{Boltz}}$ estimate obtained from CM measurements was effectively scaled in terms of probe tone pressure. Those parameters providing the best fit to a specific CM waveform were transferred back to the control program for plotting and storage. Online analysis of CM waveforms was only performed for responses to single-tone stimuli. Acoustic stimuli were turned on 5–6 s before data collection commenced to avoid onset phenomena, which might be related to efferent effects (Lukashkin and Russell, 2002; Halsey *et al.*, 2005).

(iii) The level of a tone-burst required to evoke a 10 μV compound action potential (CAP) waveform, averaged from ten consecutive responses evoked at a rate of 10.9/s, was measured for a range of tone-burst frequencies from 1 to 22 kHz. This allowed verification that the animal had normal sensitivity at the start of the experiment and that experimental protocols were not causing sensitivity changes.

D. Responses collected during low-frequency biasing

It has previously been shown that the guinea pig cochlea generates CM to stimuli with frequencies as low as 0.1 Hz (Salt and Demott, 1999), demonstrating that their OHCs are capable of transducing extremely low frequencies. The biasing protocol in the present study utilized a 4.8 Hz tone with a period of 208 ms, which allowed eight independent, equally-spaced, 21 ms data collections to be performed during each cycle of the bias (Fig. 1). The data buffers (1024 points with 48 kHz sampling or 512 points with 24 kHz sampling) were too short to obtain sharp spectra, so four independent data collections were made (32 buffers total), and the four waveforms collected at the same point on the bias were concatenated, producing 2048 points at 24 kHz or 4096 points at 48 kHz (84 ms of data in both cases), which was subjected to spectral and Boltzmann analysis. Stimulus frequencies were optimized to ensure an integer number of cycles in the original buffers so that concatenation did not contribute noise to the spectra. In addition, signals from the microphone were digitally high-pass filtered below 100 Hz to minimize transitions at the concatenation points. The eight independent time waveforms collected during the bias cycle were subjected to spectral and Boltzmann analysis as described above.

E. Modeled distortion generation

Interpretation of changes in DPOAE levels due to displacements of the OP was simplified by considering what was theoretically expected. The cochlear transducer was represented by a first-order Boltzmann transducer driven by one or two probe sinusoids, with OP varied to represent displacements by the bias tone. The generation of distortion products by a nonlinear transducer and their amplitude and phase relationship to the transducer's OP have been previously described using slightly different transducer properties as those used in the present study (Weiss and Leong in 1985; Frank and Kössl, 1996; Kirk *et al.*, 1997; Sirjani *et al.*, 2004). The specific parameters of the Boltzmann function used to model distortion generation were $y=1-2/[1+\exp(-4\cdot(x+\mathrm{OP}))]$, which were chosen so that the output waveform represented a typical CM recorded from the basal turn [Fig. 2(A), middle row]. The transfer function of the input sinusoid to the output waveform, with the OP at −1.2, zero, and +1.2, is shown in Fig. 2(B), where the input sinusoid plus the OP are plotted on the *x*-axis, and the output waveforms from Fig. 2(A) are plotted on the *y*-axis. The amplitude and phase of the distortion products measured from FFTs of the output waveform were then compared as OP was varied from one extreme (+1.2) to the other (−1.2) [Figs. 2(C)–2(J)].

Similar to the changes observed in previous studies, the amplitude of the 2f1 and f2-f1 distortion products (referenced to the amplitude of f1) was lowest when the OP was near zero [Figs. 2(C) and 2(G)], while the amplitude of the 3f1 and 2f1-f2 distortions was greatest when the OP was at zero [Figs. 2(E) and 2(I)]. The phase of the 2f1 and f2-f1 distortions flipped between 90° and 270° (relative to f1) as the OP changed from positive to negative values [Figs. 2(D) and 2(H)], while the phase of the 3f1 and 2f1-f2 distortion products was 0° or 180° depending on the OP value, flipping phase when the amplitude of these distortions was close to zero [Figs. 2(F) and 2(J)].

We also determined that when the transducer was driven by a probe sinusoid that produced substantial saturation of the transducer (i.e., when the amplitude of the output waveform was within 5% of maximum transducer output with the OP at zero), the 3f1 and 2f1-f2 distortions passed through a minimum as the OP was displaced. For one-tone probes, these minima occurred when the OP was near $\frac{1}{4}$ the peak-to-peak amplitude of the input sinusoid [Fig. 2(E)], while for two probe inputs these minima occurred near $\frac{1}{5}$ the peak-to-

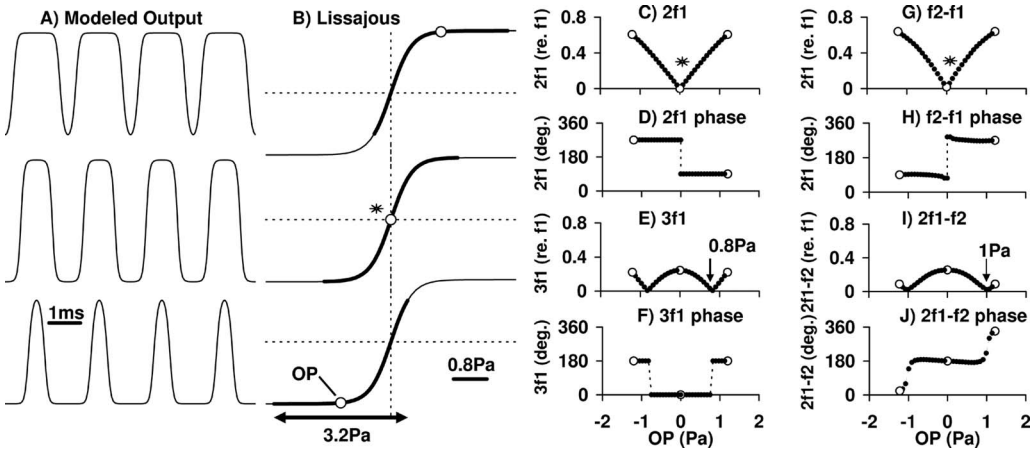

FIG. 2. Modeled changes in the distortion products generated by a pressure transducer with a first-order Boltzmann distribution driven by one or two sinusoids, as the transducer OP was varied. (A) The modeled transducer output when the OP was −1.2 Pa (top), 0 Pa (middle), and 1.2 Pa (bottom waveform), and the transducer was driven with a single 3.2 Pa peak-to-peak sinusoid. (B) The Lissajous curves of the modeled outputs from (A) (thick black line) plotted as a function of the sinusoidal input displaced by the OP (open circle) and approximated with a Boltzmann curve (thin black line). [(C)–(F)] The amplitude and phase of 2f1 and 3f1 distortion products (relative to f1) versus the OP, as the OP was biased from −1.2 to 1.2 Pa in 0.075 Pa steps. [(G)–(J)] The amplitude and phase of the f2-f1 and 2f1-f2 distortion products produced when the same transducer was driven with two sinusoids with a peak-to-peak amplitude of 5 Pa and the OP was varied from −1.2 to 1.2 Pa.

peak amplitude of probe sinusoids [Fig. 2(I)]. We found this relationship to be to be important because it allowed our OP_{Bias} measurement, derived from DPOAE biasing, to be referenced to the transducer displacement produced by the probe tone. This meant we could describe our OP_{Bias} measurement as a pressure relative to the probe tone (in pascal), by scaling our OP_{Bias} values so that these notches occurred at the appropriate pressures (presented in more detail in Sec. II F).

F. OP_{Bias} derived from the amplitude of the biased distortion products

With a clear understanding of the relationship between the OP and the amplitude distortion products, we could then begin to derive an estimate of the OP from the modulation of the DPOAEs throughout a bias tone. That is, in addition to estimating the Boltzmann OP (OP_{Boltz}) derived by fitting a synthesized probe stimulus to the CM waveforms, we could also derive an OP estimate from the bias-induced modulation of the distortion products measured from either the ear canal or CM, which we termed "OP_{Bias}." The OP_{Bias} estimate was derived by fitting a synthesized bias-induced modulation of distortion products generated by a first-order Boltzmann transducer (where the bias directly modulated OP of the transducer) to the measured distortion products in the ear canal or CM throughout the acoustic bias tone. While both the OP_{Boltz} and the OP_{Bias} are both estimates of the transducer OP and both are presented relative to the level of the probe tone(s), we have used different subscripts to clarify that the two measures come from completely different analytic techniques.

Figure 3 demonstrates how OP_{Bias} was derived from the eight measurements of f2-f1 and 2f1-f2 DPOAE amplitude throughout the 4.8 Hz bias. In cases where only one probe

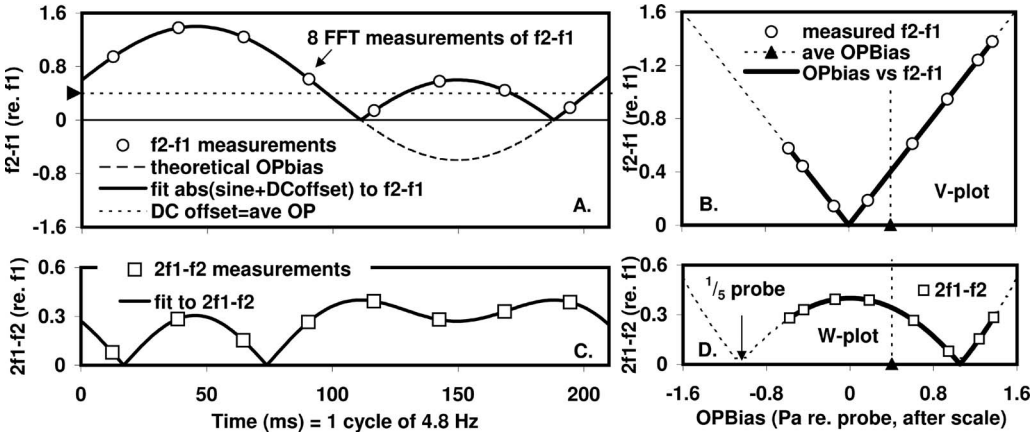

FIG. 3. (A) The eight FFT measures of f2-f1 throughout the bias (white circles), fitted with the absolute amplitude of a sinusoid plus a dc offset (thick black line). The dc offset was assumed to be proportional to the transducer OP without any bias (dashed line with arrowhead), and the sinusoid with the dc offset was assumed to be proportional to the modulation of the OP (dashed sinusoid). (B) The f2-f1 measurements and fit plotted against the sinusoid plus dc offset. (C) The eight FFT measurements of 2f1-f2 during the bias (white squares), overlaying the f2-f1 modulation. (D) The 2f1-f2 measurements plotted against the sinusoid plus dc offset fitted to the f2-f1 measurements, scaled so that the notches in the modulation (which was fitted with the absolute amplitude of an inverted parabola) occurred at $\frac{1}{5}$ of the peak-to-peak amplitude of the probe input (i.e., 5 Pa in this case).

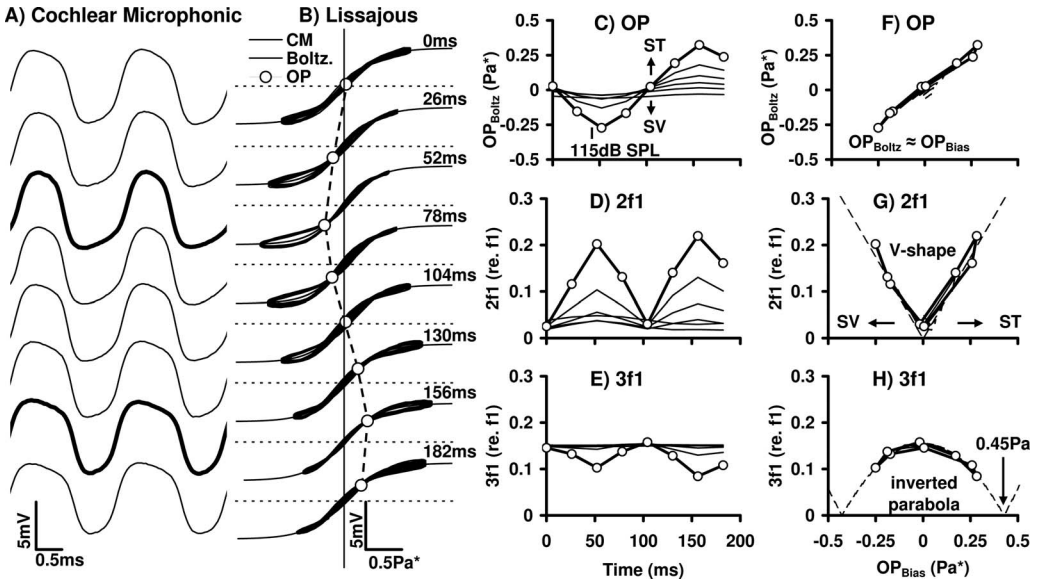

FIG. 4. Effects of a 4.8 Hz bias tone on the CM recorded from SM in the basal turn of animal PH05. (A) CM waveforms plotted for the eight points in the bias cycle as described in the methods. (B) CM data from (A) (black, coursing lines) versus the sinusoidal input displaced by the fitted OP_{Boltz} (white circles), shown with the fitted Boltzmann transducer curve (extended black line). [(C)–(E)] The OP_{Boltz} and the amplitudes of 2f1 and 3f1 respectively plotted as a function of time during one bias cycle. The amplitudes of the distortion products (2f1 and 3f1) are presented as a ratio relative to f1. [(F)–(H)] OP, 2f1, and 3f1 respectively plotted as a function of OP_{Bias}. The near-linear relationship between the OP_{Boltz} and OP_{Bias} values throughout the bias suggests that OP_{Bias} was as accurate an estimate of the transducer OP as the OP_{Boltz} measure. Furthermore, there was a V-shaped relationship between 2f1 and the OP, and a W-shaped relationship between 3f1 and the OP [dashed lines in (G) and (H)], with 3f1 nearing zero as the OP neared $\frac{1}{4}$ the pressure of the probe tone (equal to 0.45 Pa for the 500 Hz, 90 dB SPL tone).

tone was used, the OP_{Bias} was derived from the modulation of 2f1 and 3f1 using the same method. The same technique was also used to derive OP_{Bias} from the bias-induced modulation distortion products in CM waveforms. In the figure, the absolute amplitude of a 4.8 Hz sinusoid with an added dc offset was fitted to the spectral amplitude of eight f2-f1 distortion product measurements (relative to the spectral amplitude of f1), which were modulated by the low-frequency bias [Fig. 3(A)]. The dc offset, amplitude, and phase of the sinusoid were adjusted to best fit the modulated amplitude of the f2-f1 distortion product. The instantaneous "sinusoid +dc offset" at each point on the bias waveform was theoretically proportional to the transducer OP throughout the bias, and the amplitude of f2-f1 could be plotted against it to produce a *V*-plot [Fig. 3(B)]. In order to directly compare the OP_{Bias} and OP_{Boltz} estimates, we transformed OP_{Bias} onto a scale related to the pressure of the probe tone. To scale OP_{Bias}, the amplitude of the biased 2f1-f2 (relative to f1) was plotted against the bias sinusoid+dc offset pressures, as was done for f2-f1 [Fig. 3(D)]. This resulted in a "W-shaped" curve, similar to an inverted parabola, with minima in the amplitude of the distortion products that occurred at specific bias values. From our model of distortion generated by a first-order Boltzmann function (Sec. II E), we determined that these minima theoretically occurred at $\frac{1}{4}$ of the peak-to-peak amplitude of the probe for single-tone inputs or $\frac{1}{5}$ peak-to-peak amplitude for two-tone inputs [Figs. 2(E) and 2(I)]. We could therefore scale our OP_{Bias} values so that notches in the modulated 2f1-f2 distortion product occurred at values which were equivalent to $\frac{1}{5}$ the peak-to-peak pressure of the probe. If there was insufficient modulation to produce a minimum in 2f1-f2, we extrapolated the modulation using an inverted parabola fitted to the modulation pattern. The scaled dc offset [Fig. 3(A)] or the average of all OP_{Bias} points fitted throughout the bias cycle [Figs. 3(B) and 3(D), vertical dashed line] represented the transducer OP at the zero crossings of the bias, i.e., comparable to measurements without a bias present.

III. RESULTS

A. Low-frequency biasing of the cochlear microphonic

An example of the effect of a 4.8 Hz 115 dB SPL bias tone on the CM evoked by a 500 Hz 90 dB SPL tone, recorded from the SM in the basal turn, is shown in Fig. 4(A). The two heavy traces show the responses nearest the maximum and minimum bias pressures, in which considerable differences in CM waveshape are apparent. The thick coursing lines on the Lissajous plots [Fig. 4(B)] show the same CM waveforms (*Y*-axis) plotted relative to the 500 Hz sinusoidal input (*X*-axis) with the bias-induced OP changes added to it. The extended thin lines are the fitted Boltzmann functions, and the white circles indicate the OP_{Boltz}, which is the location on the Boltzmann curve at the zero crossings of the 500 Hz input sinusoid. The changes in the OP_{Boltz} produced by the bias tone almost entirely account for the bias-induced shape changes of the CM. The bias-induced changes in OP_{Boltz}, 2f1, and 3f1 for the eight time points during the bias are shown in Figs. 3(C), 3(E), and 3(D), respectively. Curves with symbols show changes during the 115 dB SPL bias tone, while thinner lines show the similar but progressively smaller modulations as the bias tone was reduced in 5 dB steps.

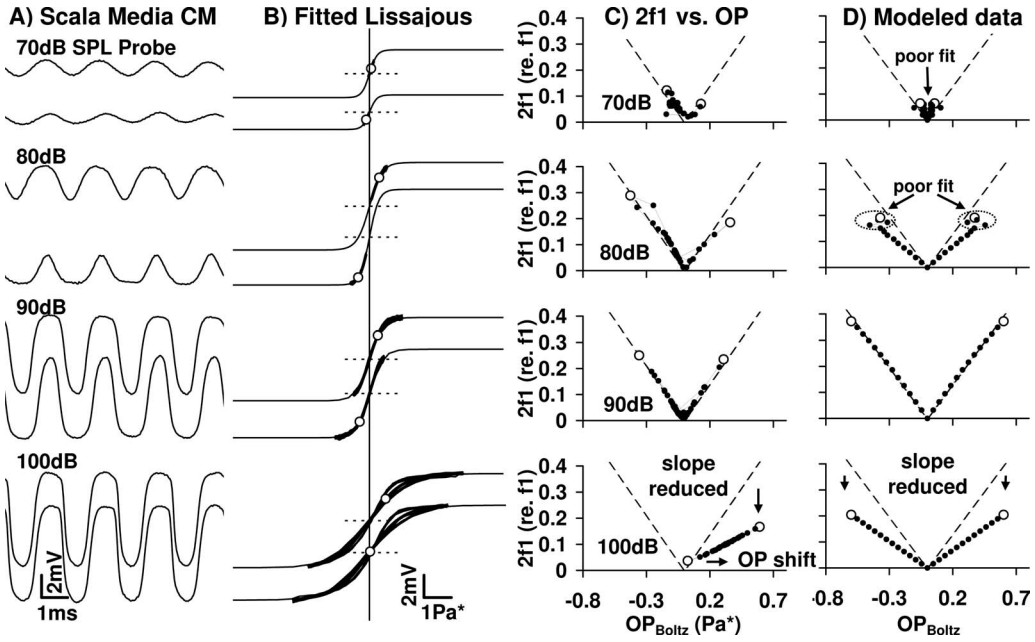

FIG. 5. (A) The CM waveforms from animal PH09, evoked by 70, 80, 90, and 100 dB SPL, 500 Hz tones, at the extremes of the 115 dB SPL, 4.8 Hz bias, with the level of the 500 Hz probe shown above each set of two CM waveforms. (B) The Lissajous curves of the CM waveforms from (A) (coursing black line) plotted as a function of the probe displaced by the fitted OP_{Boltz} (open circles) and approximated with a Boltzmann curve (extended black line). (C) The amplitude of the 2f1 distortion products (relative to f1) versus the OP_{Boltz} derived from the CM evoked by different level 500 Hz probes, recorded throughout 4.8 Hz bias tones at 100, 105, 110, and 115 dB SPL. The dashed lines in (C) is the V-shaped relationship between 2f1 and the OP_{Boltz} when the stimulus was 90 dB SPL. (D) The modeled 2f1 versus OP_{Boltz} plots when a modeled first-order Boltzmann transducer was driven with different level sinusoids, and the OP was varied from −0.6 to +0.6. The outputs of the modeled transducer were ac coupled before being re-fitted with a Boltzmann function to mimic the ac coupling of the CM responses. The extreme OP displacements are shown as white circles.

Changes in OP_{Boltz} approximately followed a sinusoidal modulation during the 4.8 Hz sinusoidal bias tone, demonstrating that OP_{Boltz} was a reliable indicator of the transducer input. The relative amplitude of the second harmonic (2f1, relative to the amplitude of f1) showed a bimodal modulation, with distortion minima occurring when OP_{Boltz} was near zero and maxima when OP_{Boltz} was furthest from zero. Conversely, the relative amplitude of the third harmonic (3f1, relative to f1) was minimal when OP_{Boltz} was biased from zero and maximal when OP_{Boltz} was at zero. The three measures plotted against OP_{Bias} are shown in Figs. 4(F)–4(H). OP_{Boltz} followed a near-linear relationship with OP_{Bias} [Fig. 4(F)], suggesting that both methods estimated the transducer OP similarly. The second harmonic showed substantial changes in amplitude as the OP was displaced (93% modulation), producing a V-shaped relationship when plotted against OP_{Bias} [Fig. 4(G)]. Changes in the 3f1 amplitude throughout the bias were far smaller (35% modulation), with the amplitude of 3f1 largest when OP_{Bias} was closest to zero and reaching a minimum as OP_{Bias} neared $\frac{1}{4}$ the peak-to-peak pressure of the probe (0.45 Pa).

B. Single-tone probe level and modulation of the OP

The probes used to evoke CM or DPOAEs in this study were high-level, sufficient to produce saturated CM waveforms without being traumatic. CAP thresholds and the EP, measured before and immediately after the presentation of our DPOAE probes, were unaltered by the presentation of probes at levels lower than 100 dB SPL for 500 Hz tones and lower than 85 dB SPL for 4 and 4.8 kHz frequencies (Salt *et al.*, 2009).

Examples of biased CM waveforms produced by 500 Hz probe tones at 70, 80, 90, and 100 dB SPL, at the extreme bias points during a 115 dB SPL 4.8 Hz tone, are shown in Fig. 5(A). At each level of probe stimulus, CM waveforms for the positive and negative limits of the bias are plotted against time [Fig. 5(A)] or against the input stimulus [Fig. 5(B)]. On the Lissajous curves in Fig. 5(B), the output waveforms are indicated by thick dark lines and the OP is indicated by open circles. At each probe level, the difference between the two paired curves demonstrates the OP changes induced by the bias.

The amplitude of 2f1 from the CM evoked at each probe level used was measured during a range of 4.8 Hz bias tones at levels of 100, 105, 110, and 115 dB SPL and is plotted versus the OP_{Boltz} in Fig. 5(C) [i.e., each plot in Fig. 5(C) consists of a group of 2f1 versus OP_{Boltz} measurements, with the probe level indicated on the left, but with all bias tone levels]. Calculated changes in 2f1 and OP_{Boltz} fitted to the ac-coupled output of a first-order Boltzmann equation (using the same equation described in Sec. II E), driven by different level probes and with various OP displacements, are also shown in Fig. 5(D). Initially, it appeared that there was less modulation of the OP by the bias tone when the 500 Hz probe level was 70 dB SPL. However, we found the same result in both the CM and model-derived waveforms and demonstrated that it was due to errors in fitting a Boltzmann curve to a relatively undistorted waveform evoked by a low-

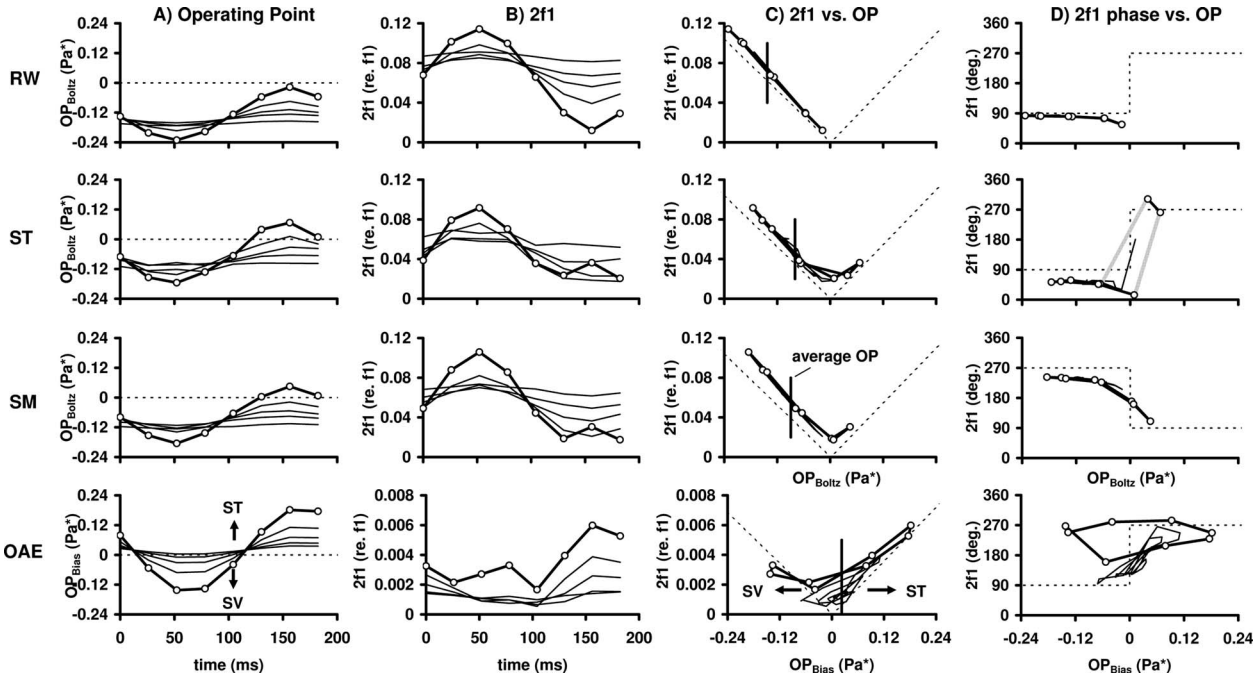

FIG. 6. [(A) and (B)] The OP_{Boltz} and 2f1 (white circles) simultaneously measured in animal PH10 from the RW CM (top row), ST CM of the basal turn (second row), SM CM of the basal turn (third row), and the OP_{Bias} and 2f1 from the ear canal OAE (bottom row) during simultaneous presentation of both 500 Hz, 90 dB SPL and 4.8 Hz, 115 dB SPL tone. The OP_{Boltz} from the CMs were derived from Boltzmann fits to the CM waveforms, while the OP_{Bias} was derived from the relative displacement of the DPOAEs throughout the 4.8 Hz bias tone, as described in Sec. II F. Thin black lines are similar modulations using lower sound-level bias tones from 95 to 110 dB SPL in 5 dB steps. [(C) and (D)] The amplitude and phase of 2f1 versus the OP_{Boltz} or OP_{Bias} for each recording location. The dashed lines in each plot are the modeled changes in the amplitude and phase of 2f1 for similar OP modulations.

level stimulus. To avoid inaccurate Boltzmann fits to the CM, we generally used probe levels that produced sufficiently saturated CM waveforms, without producing any temporary or permanent changes in cochlear function, which in the case of 500 Hz tones was around 90 dB SPL.

Apart from an underestimation of the OP with low-level tones, the slope of the V-shaped relationship between 2f1 and the OP_{Boltz} [Fig. 5(D), dashed lines] varied for different input levels, particularly for 100 dB SPL. We attributed this to a variation in the relative amplitude of 2f1 to f1 over the range of input levels that was also present in the modeled data. One main difference between the real [Fig. 5(C)] and modeled [Fig. 5(D)] changes in the relationship between 2f1 and the OP_{Boltz} was a substantial positive shift in the average OP_{Boltz} in the real data when the probe level was 100 dB SPL, representing a physiological adaptation of the OP toward ST during the high-level probe tone. This OP displacement with high-level probes has been reported in previous studies (Patuzzi and Moleirinho, 1998).

C. Simultaneous modulation of distortion products from different locations

In a number of experiments, we simultaneously estimated the OP from different recording locations during 4.8 Hz biasing. The estimated OP_{Boltz} derived from the CM recorded from the RW, ST of the basal turn, and SM of the basal turn and the estimated OP_{Bias} derived from the modulated DPOAE are shown throughout the low-frequency bias in Fig. 6(A). Symbols show the influence of the bias tone at 115 dB SPL with thin lines representing similar modulations at lower bias levels from 110 to 95 dB SPL in 5 dB steps. All OP measures were modulated in-phase and by a similar amount, except for OP_{Bias} from the DPOAEs, which was modulated 40% more than any of the OP_{Boltz} measures. The average OP throughout the bias differed between recording locations [Fig. 6(C), vertical lines], although the average OP from ST and SM measurements, which were at the same region along the length of the cochlea, was similar. This resulted in different modulations of the second harmonic, e.g., 2f1 from the RW was modulated sinusoidally, while 2f1 from ST, SM, and the ear canal measurements was modulated bimodally. This was best explained when the amplitude of 2f1 was plotted against the modulated OP from each recording location [Fig. 6(C)]. In these plots there was a V-shaped relationship indicated by the dashed line in each plot. As the OP from the ST, SM CM, and the OAE recordings passed through zero during the bias, the 2f1 was bimodally modulated. In contrast, the mean OP estimated from the RW CM was at a more negative value and the displacement by the bias did not cause it to cross zero, so the 2f1 exhibited a simpler sinusoidal modulation. The phase of 2f1 from each location is plotted against the OP for each set of data in Fig. 6(D). As predicted from the model (see Fig. 2), 2f1 phase changed by $180° \pm 40°$ when the OP crossed zero for the ST and SM recordings. However, the same phase relationship was not observed in the 2f1 versus OP_{Bias} plot from DPOAE [Fig. 6(D), bottom plot] because the phase of f1 in the ear canal was dominated by the stimulus and therefore was unrelated to the phase of the distortion products generated within the cochlea.

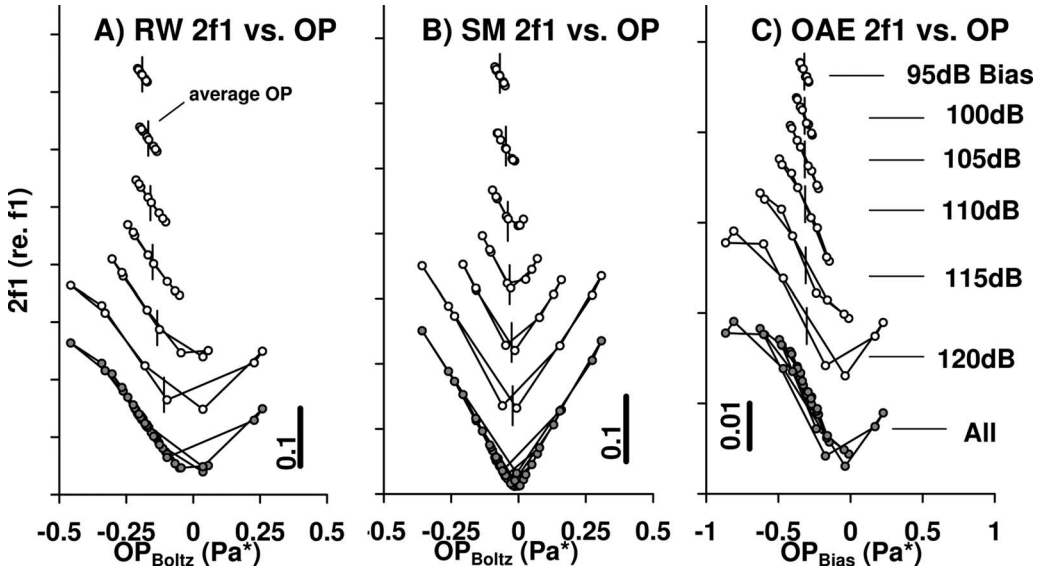

FIG. 7. Animal PH13. Modulations of the OP_{Boltz}, OP_{Bias}, and 2f1 with different levels of the 4.8 Hz tones ranging from 95 to 120 dB SPL (shown at the right of the figure). In each plot, 2f1 (relative to f1) has been plotted versus the estimated OP for each of the bias tone levels (open circles), with each bias level then shifted vertically from the next. In each plot, all biases within that plot have been overlaid at the bottom (gray circles). [(A) and (B)] 2f1 versus the OP_{Boltz} derived from the RW CM and SM CM evoked by a 500 Hz, 90 dB SPL tone during the 4.8 Hz bias. (C) 2f1 DPOAE evoked by a 500 Hz, 90 dB SPL tone versus OP_{Bias} derived from the modulation of the DPOAEs throughout the 4.8 Hz bias.

D. Bias level with a single-tone probe

We intended to use the average OP_{Bias} value as an estimate of the resting OC displacement and transducer OP. Therefore, we investigated if the bias tone altered the *average* OP by measuring the OP_{Boltz} and OP_{Bias} during the bias tone at a range of bias levels from 95 to 115 dB SPL. The average OP throughout the bias only underwent minor changes as the level of the bias tone increased [e.g., 0.08 Pa, Fig. 7(A), dashed vertical lines]. Higher-level bias tones typically produced larger modulations of the OP and 2f1, maintaining the V-shaped relationship, with minimal changes in the average OP values. In each plot of Fig. 7 the amplitude of 2f1 versus the OP at each bias level has been shifted vertically for clearer visualization of the overall OP bias (Fig. 7, white circles), with all bias levels then overlaid at the bottom of each plot (gray circles). The level of bias for each plot is provided at the right of the figure. The plots of 2f1 versus OP_{Boltz} derived from the RW and SM CM evoked by a 500 Hz, 90 dB SPL probe tone are shown in Figs. 7(A) and 7(B), while 2f1 versus the OP_{Bias} from the simultaneously recorded DPOAE is shown in Fig. 7(C). In all three cases the average OP was negative, equivalent to a displacement of the OC toward SV. At lower bias levels the 2f1 was modulated sinusoidally, while at higher bias levels (at 115 dB for the RW, 105 dB for SM, and 115 dB for the OAE), the 2f1 was modulated bimodally.

As in Fig. 7, higher-level biases produced proportionally more modulation of the OP up to 120 dB SPL, which was the highest bias level used in this study. The average modulation of the OP_{Boltz} derived from the CM evoked by a 500 Hz, 90 dB SPL tone, for different bias levels, recorded from both the RW and SM is shown in Fig. 8. For bias levels above 80 dB SPL, modulation of OP_{Boltz} (on a logarithmic scale) increased in a linear fashion with increasing bias level, demonstrating that the displacements produced by the bias tones were not saturating over this range for levels up to 120 dB SPL. Typically, levels of the 4.8 Hz bias lower than 80 dB SPL produced modulations of the OP that were below the normal variation in the OP_{Boltz} throughout the bias, i.e., representing the noise floor (Fig. 8, white circles).

E. Bias level with a two-tone probe

Figure 9 shows changes in f2-f1 distortion (upper row) and 2f1-f2 distortion (lower row) measured at different sites,

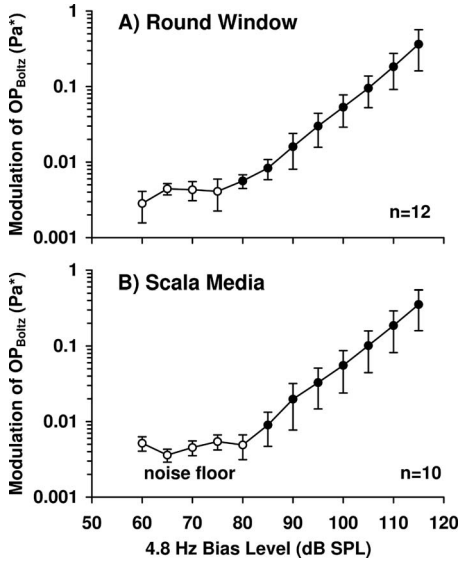

FIG. 8. The average modulation of the OP_{Boltz} (peak-to-peak OP change) derived from the 500 Hz, 90 dB SPL evoked CM recorded from (A) the RW and (B) SM of the basal cochlear turn, with the level of the 4.8 Hz bias varied from 60 to 115 dB SPL. The number of animals used to obtain the average modulation is shown in each figure. White circles represent modulations that were below the average variation in the OP_{Boltz} throughout the bias (the noise floor).

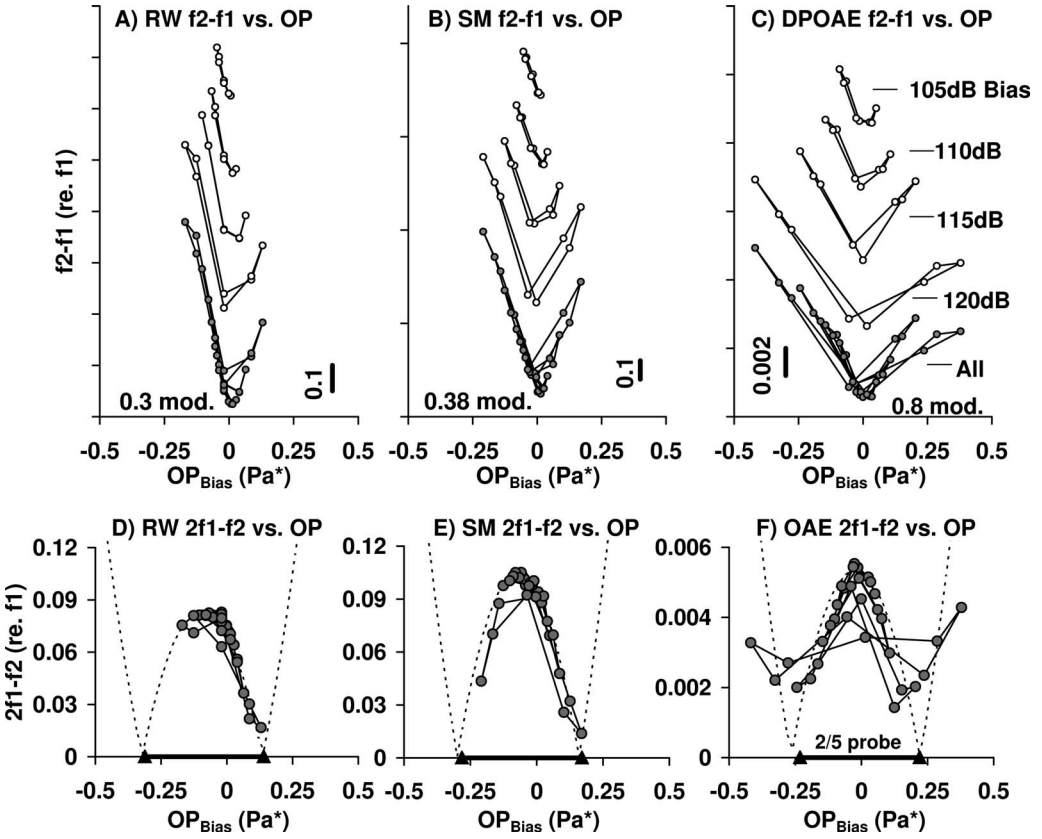

FIG. 9. Animal PH13. Modulations of the OP_{Bias} and f2-f1 derived from the modulated RW CM, SM CM, and DPOAE responses evoked by 4 and 4.8kHz, 80 dB SPL tones during different levels of a 4.8 Hz tone, ranging from 105 to 120 dB SPL (shown at the right of the figure). [(A)–(C)] f2-f1 (relative to f1) versus the OP_{Bias} for each of the bias tone levels (open circles), with each bias level shifted vertically from the next, and all biases within that plot overlaid at the bottom (gray circles). [(D)–(F)] 2f1-f2 versus the OP_{Bias} derived from each recording, demonstrating that the amplitude of 2f1-f2 neared zero when the OP_{Bias} was displaced to $\frac{1}{5}$ of the peak-to-peak pressure of the probe or that the difference between the OP_{Bias} values at which the notches occurred was $\frac{2}{5}$ the pressure of the probe.

as bias level was varied from 105 to 120 dB SPL. The probe stimuli in this case were tones at 4 and 4.8 kHz presented at 80 dB SPL. With the high-frequency probe stimuli, a reliable Boltzmann analysis of the CM was not possible [due to factors such as electrical low-pass filtering of the CM by the cochlear scalae; see Strelioff (1973) and Patuzzi *et al.* (1989)], and therefore OP_{Boltz} could not be obtained. In contrast, our estimate of OP_{Bias} is unaltered by changes in the overall amplitude of the distortion products (as might occur with electrical or acoustical filtering) but depends upon their modulation and the appearance of notches or minima throughout the bias. This allowed us to estimate OP_{Bias} even though Boltzmann analysis of the CM was not possible. We have therefore plotted the distortion products from each of the RW, SM, and OAE recordings against OP_{Bias} for each location. The f2-f1 distortion product from each recording was modulated bimodally [Figs. 9(A)–9(C)], particularly at higher levels of bias pressure in a similar manner to the modulation of 2f1 evoked by single tones (Fig. 7). The magnitude of OP_{Bias} derived from the ear canal was over twice that derived from the basal turn CM recordings evoked by the two-tone stimulus, suggesting that the bias produced more displacement of the OC at the region where the DPOAEs were generated in the cochlea than at the base of the cochlea where the local CM was recorded.

The amplitudes of the 2f1-f2 distortion products are shown in Figs. 9(D)–9(F), further illustrating the technique used to relate OP_{Bias} values to the probe. The OP_{Bias} values were scaled so that minima in the modulated 2f1-f2 occurred 0.45 Pa apart (which was 2/5 the peak-to-peak pressure of the probe stimulus in the ear canal). It was necessary to extrapolate the minima in the case of the RW and SM recordings [Figs. 10(D) and 10(E)], while the DPOAE 2f1-f2 was modulated sufficiently to produce notches [Fig. 10(F)]. While our modeled data suggested that the amplitude of 2f1-f2 should have been maximal when the amplitude of f2-f1 was close to zero, there was a slight difference between the OP_{Bias} values at the maximal 2f1-f2 position and the minimal f2-f1 position, particularly for the RW recording. These responses are analogous to the bias-induced modulation of 3f1 to a single tone [Fig. 4(H)] and confirm that the OP can be derived from ear canal DPOAE measurements.

F. Using distortion measures to track OP during hypoxia

One way of comparing OP_{Boltz} from CM and OP_{Bias} from DPOAEs is to compare the two measures during manipulations that are known to change OP. Figure 10 shows the results from an experiment in which OP_{Boltz} and OP_{Bias} measures from the CM and DPOAE were compared during hypoxic episodes. Hypoxia has been shown to produce

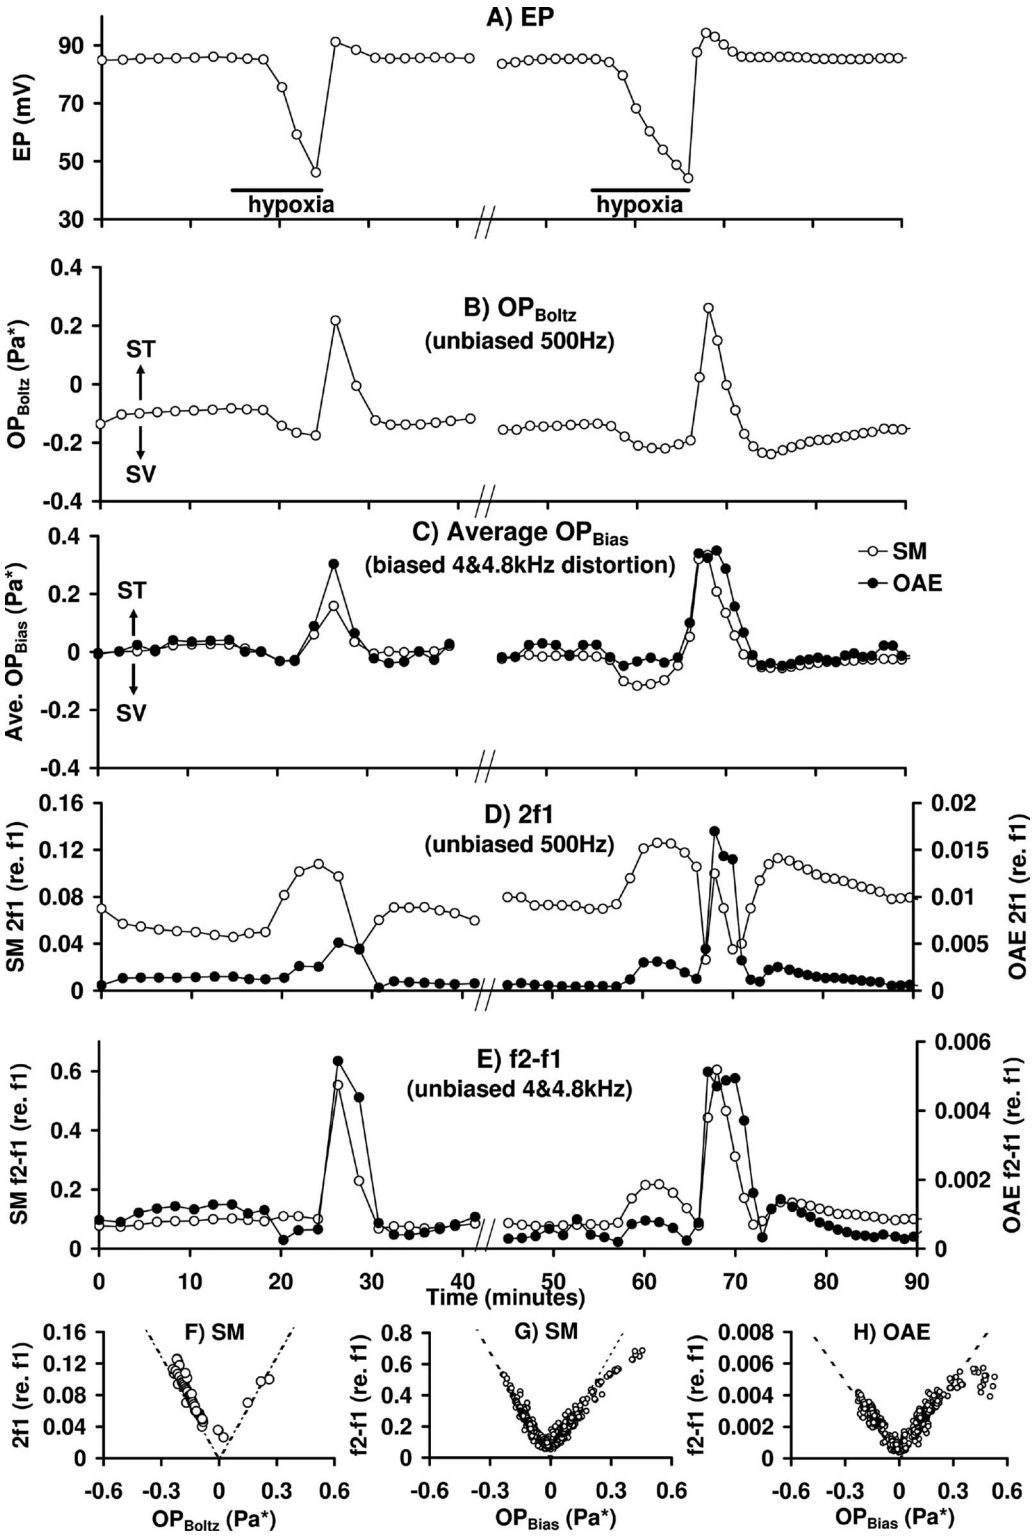

FIG. 10. [(A)–(E)] Repeated measurements in animal PH14 during two hypoxic events [rebreathing times indicated by dark bars in (A)], with a 20 min break between recordings (indicated as line-breaks). (A) EP. (B) OP_{Boltz} obtained from 500 Hz, 90 dB SPL evoked CM. (C) The average OP_{Bias} obtained from biased CM and DPOAE responses evoked by 4 and 4.8 kHz 80 dB SPL tones during a 4.8 Hz, 115 dB SPL tone. (D) The relative amplitude of 2f1 from the CM and DPOAE evoked by a 500 Hz, 90 dB SPL tone. (E) The relative amplitude of f2-f1 from the CM and DPOAE evoked by 4 and 4.8 kHz, 80 dB SPL tones with no bias. Black circles represent measures from the CM, and white circles those from the ear canal. (F) A *V*-plot of the data in (B) versus the data in (D). [(G) and (H)] *V*-plots of the data from (E) versus the data in (C). Note that there are eight times more points in (G) and (H) than in (F) because there were eight measures of the distortion products and OP_{Bias} during the low-frequency bias.

changes in the EP, DPOAEs, and Boltzmann parameters (Rebillard and Lavigne-Rebillard 1992; Patuzzi and Moleirinho, 1998; Olzowy *et al.*, 2008). Responses were repeatedly evoked by successive probes consisting of a 500 Hz, 90 dB SPL tone, simultaneously presented at 4 and 4.8 kHz, 80 dB SPL tones with a 115 dB SPL, 4.8 Hz bias tone and at 4 and

4.8 kHz, 80 dB SPL tones without a bias tone, with approximately 10 s of silence separating each probe set. Biased responses were used to derive the average OP_{Bias} from both the ear canal and the CM, while responses without the bias provided the unbiased two-tone distortion products.

Around 3–5 min after hypoxia was initiated, the EP began to decline gradually [Fig. 10(A)]. Concurrently, the OP_{Boltz} and OP_{Bias} values shifted toward SV [Figs. 10(B) and 10(C)]. When EP reached 48 mV normal ventilation was restored and the EP rapidly increased with an over-shoot before recovering to around 85 mV. As the EP recovered, OP_{Boltz} and OP_{Bias} shifted to around +0.2 Pa, equivalent to a shift toward ST, before decreasing with a slight over-shoot toward negative values. After a 20 min break in recordings, a second hypoxia was induced, producing similar but slightly larger changes in each measurement. During this second hypoxia CM, EP, and distortion products were monitored more frequently.

Prior to the hypoxic events, the OP_{Bias} was closer to zero than OP_{Boltz}. This difference was most likely due to differences in probe stimuli rather than being a difference in the method of estimating the OP *per se*. Regardless of this initial difference, the induced changes in OP_{Bias} and OP_{Boltz} were similar throughout both hypoxic events.

The amplitudes of the unbiased 2f1 and f2-f1 distortion products from the 500 Hz, 4 kHz, and 4.8 kHz probes throughout the recordings are presented in Figs. 10(D) and 10(E). While there were differences in the amplitudes of the unbiased 2f1 distortion product between CM and OAE recordings, this can be explained on the basis of a different initial OP of the transducer responses dominating the CM and the DPOAEs. The amplitudes of the unbiased f2-f1 distortion product from the CM and DPOAE were similar throughout the experiment, suggesting that the transducer generating f2-f1 in the CM and DPOAE had similar initial OPs. Induced distortion changes are more easily explained using plots of 2f1 or f2-f1 versus the OP_{Boltz} or OP_{Bias}, as shown in Figs. 10(F)–10(H). In all cases, distortion was reduced as the OP measure moved closer to zero.

IV. DISCUSSION

The present study outlined the dependence of DPOAE amplitude on the OP of the transducer and demonstrated that with a clear understanding of this relationship, DPOAE measurements can be used to non-invasively monitor cochlear function. In particular, low-frequency biasing of DPOAEs could be used to non-invasively estimate the resting position of the OC, which might provide a clinical tool for diagnosing disorders that perturb the normal transducer position, such as endolymphatic hydrops. Previous studies have attempted to use the amplitude of the DPOAEs as indicators of cochlear function (Rebillard and Lavigne-Rebillard 1992; Kossowski *et al.*, 2001; Kujawa and Liberman, 2001; Garner *et al.*, 2008; Olzowy *et al.*, 2008), reporting complex changes in the DPOAEs that were difficult to interpret, particularly as changes in the OP were not taken into consideration. Furthermore, other studies have taken similar approaches to investigate hearing function in humans (Mrowinski *et al.*, 1996; Hensel *et al.*, 2007; Bian and Scherrer, 2007) and animals (Frank and Kössl, 1996; Kirk *et al.*, 1997; Lukashkin and Russell, 2002; Bian, 2004; Sirjani *et al.*, 2004; Salt *et al.*, 2005) and have reported similar relationships between pressure in the ear canal, the OP, and the amplitude of the DPOAEs as those reported here. However, this study is the first to directly relate the OP obtained from CM recordings to the OP derived solely from simultaneously recorded DPOAEs.

A. Differences between the OP_{Boltz} derived from CM and the OP_{Bias} derived from DPOAEs

While both OP_{Boltz} derived from the CM and OP_{Bias} derived from the DPOAEs were modulated sinusoidally during the low-frequency bias and both changed in a similar manner during the hypoxia experiments in the present study, often there were differences between the average OP_{Boltz} and average OP_{Bias}. As discussed by Kirk *et al.* (1997), who directly compared the Boltzmann OP from basal CM recordings to the biased DPOAEs, there are several possible reasons why there might be differences between the OP_{Boltz} and the minimal point of the f2-f1 DPOAE throughout the bias (equivalent to the average OP_{Bias} value in our study). To briefly summarize the points made by Kirk *et al.* (1997); first, the nonlinear transducer generating the DPOAEs might be better described by a *second-order* Boltzmann distribution, resulting in differences between the OP_{Boltz} (which was estimated using a *first-order* Boltzmann function) and our measurement of the OP_{Bias}. Second, there might be differences in adaptation to the probe tone between sources underlying the generation of OP_{Boltz} and OP_{Bias}. We present another explanation here, that the OP_{Boltz} derived from the basal turn CM is an estimate of the OC position at the base of the cochlea, while the OP_{Bias} derived from the DPOAEs is an estimate of the OC position at the overlapping region stimulated by the probe tone(s), more apical in the cochlea, and that there were differences between the resting OC position at either location. Therefore, it would be unreasonable to directly relate the amplitude of the DPOAEs to the OP_{Boltz} or distortion products from basal turn CM recordings, and it is essential to apply an individual OP estimate to the transducer generating the DPOAE.

The portion of the cochlea the OP_{Boltz} and OP_{Bias} measurements represent is most likely a weighted sum of the regions stimulated by the probe tones contributing to the CM and DPOAE measurements and most likely increases with the level of the stimulus as broader regions of the cochlea are recruited. That the OP_{Boltz} derived from the RW CM was often different from the OP_{Boltz} derived from ST or SM recordings in the present study (Fig. 6), which were as little as 4 mm apical from the RW, further suggests that the OC position can differ throughout the cochlea and that the OP_{Boltz} estimate is a relatively local measure of OC position. Furthermore, that the estimates of OP derived from ST and SM measurements made at the same region along the length of the cochlea were similar, even though their CM amplitudes differed almost tenfold, and their polarities were opposite,

indicates that the OP differences between locations throughout the cochlea were not due to the analysis technique.

Previous studies of DPOAEs suggest they are generated at both the "overlapping" region of the cochlea stimulated by the two probe tones (near the characteristic region of the probes) *and* at the characteristic region of the DPOAE itself (Talmadge *et al.*, 1999; Shera and Guinan, 1999). However it has been suggested that the presence of a low-frequency bias tone can suppress the component generated at the characteristic region of the DPOAE (Talmadge *et al.*, 1999; Bian and Scherrer, 2007), simplifying the regions of the cochlea contributing to the DPOAEs. Presumably, the OP_{Bias} derived from DPOAEs is primarily a measure of the OC position at the overlapping region and would be dependent on the probe frequency, which could be varied to investigate the resting position of the OC at different regions throughout the cochlea.

B. The OP_{Boltz} is a measure of local transduction

One motive for simultaneously measuring the OP_{Boltz} derived from ST and SM at the same region along the length of the cochlea in the present study was to demonstrate that Boltzmann analysis of CM is an accurate measure of local transduction. It had recently been suggested that distortion products in the CM were generated at distal regions within the cochlea, particularly for low-level stimuli (Zheng *et al.*, 2008). For stimulus levels that permitted reliable Boltzmann fits (above 80 dB SPL, Fig. 5), our OP_{Boltz} measurements derived from ST and SM CM were modulated in-phase and by a similar amount by the low-frequency bias, even though the ST and SM CM amplitudes differed by a factor of around 10, and the CM waveforms were of opposite polarity. If electrical distortion components from CM generated at more apical regions in the cochlea summated with CM generated in the basal turn where our measurements of ST and SM CM were made, our ST and SM OP_{Boltz} measurements would have been modulated 180 degrees out-of-phase during low-frequency biasing because remote potentials spread electrotonically to the basal turn would not invert polarity across the cochlear partition, and our analysis incorporated the inversion of the locally generated CM. Our data suggest that distortion in the CM is generated at the cochlear partition and that Boltzmann analysis of this CM is an accurate measure of local transduction, at least for 500 Hz stimulus levels above 80 dB SPL.

Similar changes in the amplitude and phase of the distortion products have been observed using the whole-cell voltage clamp technique to monitor the receptor current of OHCs (Takahashi and Santos-Sacchi, 1999), and Olson (2004) demonstrated that distortion products in fluid pressure measurements made close to the basilar membrane were generated locally, rather than at regions distal to the recording location. These studies provide further evidence that the dominant nonlinearity underlying distortion generation in the CM is produced by *local* OHC electromotility and that the distortion products in the CM can be used to estimate the OP of local OHC transduction.

C. Cochlear distortion products behave as predicted from a first-order Boltzmann function

Similar to results from previous studies (Kirk *et al.*, 1997; Sirjani *et al.*, 2004), the present study found that the amplitudes of the even-order distortion products from the CM and ear canal were minimal when the OP measure (OP_{Boltz} or OP_{Bias}) was near zero and maximal when the OP measure was displaced from zero. Conversely, the odd-order distortion products were maximal when the OP was near zero and minimal when the OP was displaced by $\frac{1}{4}$ to $\frac{1}{5}$ the peak-to-peak pressure of the probe. These changes suggest that the transducer generating distortion in the cochlea can be modeled with a first-order Boltzmann distribution function. However, there were several differences between the modeled and measured distortion products that suggest that slightly more accurate assessment of cochlear transduction might be achieved with more complex analysis methods, as discussed previously in detail by Patuzzi and Moleirinho (1998) with regard to Boltzmann analysis of the CM.

With the OP of a first-order transducer at zero, there should have been no even-order distortion products generated; however, often the even-order distortion products in the CM and DPOAE were not reduced to zero when the OP measure was near zero [Fig. 6(C)]. Furthermore, the relative phase of the even-order distortion products generated by such a transducer should have been either 90° or 270° (depending on the polarity of the OP and with the phase of f1 at zero), although often their phases were as much as 15° different from this when the OP was maximally displaced by the bias tone and as much as 90° different when the OP was near zero [Fig. 6(D)]. One likely explanation for the differences between the modeled and the measured distortion products is that there were additional non-dominant sources of distortion. Another possible explanation is that the CM and DPOAE distortion products are generated by a region of the cochlea along which the transducer properties change slightly, and therefore the distortion products are a slightly complex weighted sum of the contributing region, producing differences between our measured data and our estimates based on a single transducer.

In the case of the CM recorded from the base of the cochlea, which is predominantly generated by local hair cells (Dallos *et al.*, 1972; Patuzzi *et al.*, 1989), the other sources might have been either (1) other sources of nonlinearity in the local transduction, which also produced distortion of the receptor current but only dominated when the OP of the foremost nonlinearity was near zero, (2) distortion products generated by OHC at other regions of the cochlea, which spread electrotonically to the recording location and had different characteristics (phase and amplitude) than those generated by basal hair cells, (3) distorted OC vibration generated at other regions in the cochlea, which then produced additional vibration at the base of the cochlea, or (4) low-level distortion of the acoustic stimulus resulting in a non-sinusoidal stimulus. Whatever the other source(s) of distortion in the CM were, it resulted in only minor deviations from the values predicted by a first-order Boltzmann equation.

In the case of the DPOAEs, many previous studies have

researched the sources of DPOAEs in the cochlea, with the general consensus that there are two main contributors, a linear reflection component and a nonlinear distortion component (Talmadge *et al.*, 1999; Shera and Guinan, 1999). Multiple contributions to the DPOAEs might result in complex modulations of the DPOAE amplitudes throughout the bias that could not be modeled as a single transducer with a Boltzmann distribution. However, in the present study the DPOAEs often followed a bimodal modulation, suggesting either that one of the components typically dominated the DPOAE generation or that both components contributed equally, producing similar DPOAE modulations. We did not attempt to investigate the contribution from either component, and most likely there was some complex summation of the two sources, which decreased the accuracy of our OP_{Bias} measure slightly. Given the similarity between the OP_{Boltz} measure from basal turn CM, which is a more local measure and the OP_{Bias} from the DPOAEs measured in the present study, this inaccuracy is most likely small.

It is worth noting here that in the present study our Boltzmann function expressed OP_{Boltz} in terms of a static pressure in the ear canal [using $S^*P^*_{sat}(\text{input}+\text{OP})$ in the equation], rather than as a measure unrelated to ear canal pressure but still proportional to the asymmetry of transduction [using $(S^*P_{sat})+\text{OP}$ in the equation]. Patuzzi and Moleirinho (1998) used the latter method as they assumed that some OP changes might have been due to slight micromechanical changes in the position of the OC, unrelated to the ear canal pressure. While there are several situations that might lead to a difference between the OP estimated using these different methods, such as changes in middle ear conductance or a change in the OC compliance during a low-frequency bias, we routinely compared our OP measure to that obtained using the method employed by Patuzzi and Moleirinho (1998) and found the differences to be minimal, only differing substantially for changes in probe level, for which it was not possible to determine the preferable method as OP changes with stimulus level might have been produced by OC compliance changes *or* micromechanical changes in the OC position.

D. Probe and bias level effects on OP estimate

Ideally, we would want to use probe levels that generate distortion products in the ear canal or CM that are well above the noise floor of the recording and that generate CM waveforms that are sufficiently saturated to allow accurate Boltzmann analysis. However, relatively high probe levels (e.g., above 100 dB SPL for 500 Hz tones) often caused unwanted adaptation of the OP measure [Fig. 5(C)] and might lead to temporary threshold shifts particularly in the case of high-frequency probe tones (at levels above approximately 85 dB SPL for continuous stimulation; Chang and Norton, 1996). Therefore, the ideal range of probe levels used for the present techniques is most likely limited to around 65–80 dB SPL for high-frequency probe tones (i.e., around 4 kHz) and around 80–95 dB SPL for low-frequency tones (i.e., around 500 Hz). These probe levels did not alter the CAP thresholds or EP measurements before or after presentation of the probes, suggesting that they did not cause any temporary or permanent changes in cochlear function the guinea pigs used in this study, other than a rapid slight adaptation which occurred at the immediate onset of the probe with a time constant of around 1 s (which was not included in our analysis of the responses), similar to that observed by Kujawa and Liberman (2001), and which was most likely related to efferent activity. As stimulus levels were measured close to the tympanic membrane, they were effectively 5–10 dB lower than if they had been presented and calibrated free field since no ear canal gain is available in this preparation.

Such levels are on the upper limit of what would be acceptable for human DPOAE testing (although levels as high as 85 dB SPL at 4 kHz have been used; Lonsbury-Martin *et al.*, 1990). We are currently evaluating whether OP_{Bias} can be determined from DPOAEs that does not require the transducer to be saturated.

While the slope of the relationship between the amplitude of the even-order distortion products and the OP changed over a range of sound levels (Fig. 5), this did not affect our estimation of the OP_{Bias} because it was not based solely on the amplitude of the distortion products. Rather, it was based on notches in the amplitude of the modulated distortion products during the bias, as outlined in Sec. II F, and the overall ratio of the distortion product to f1 (i.e., the *y*-axis of our *V*-plots) was not a key factor in our analysis.

Generally, different bias tone levels (from 95 to 115 dB SPL) simply produced different levels of OP modulation (Fig. 8), producing only a slight change in the average OP measure [Fig. 7(A)], which most likely reflects a small amount of OP adaptation to the bias tone. It was often necessary to use bias levels of 110 dB SPL in order to produce bimodal modulation of the even-order distortion products and a modulation of the odd-order distortion products that allowed estimation of notches in its amplitude, which was a limitation of the technique used to estimate OP_{Bias}. However, it is important to note that the cochlea is generally insensitive to such low-frequency stimuli due to the high-pass filtering characteristics of the helicotrema, as described below, and following exposure to the highest level bias tones used in the present study, cochlea sensitivity was unchanged. While the presence of the bias might have been responsible for the slight changes in the OP measure over the range of bias levels, these changes were negligible in comparison to the experimentally induced changes in OP such as that produced by hypoxia.

E. Referencing OP_{Bias} to the probe level

In order to compare the OP_{Boltz} and OP_{Bias} measures, it was necessary to reference the OP_{Bias} values to the level of the probe stimulus in the ear canal using characteristic changes in the distortion products as outlined in Sec. II F of the present study. This allowed estimation of the relative displacement of the OP at the region where the DPOAEs were generated in the cochlea, and it overcame the problem that the level of the distortion products in the ear canal could

change due to factors unrelated to the OP, such as conductive losses as the DPOAEs were transmitted from the cochlea to the ear canal.

Similar to results published in previous studies (Takahashi and Santos-Sacchi, 1999; Bian and Scherrer, 2007), we found amplitude minima or "notches" in the odd-order distortion products in the CM and DPOAEs during modulations of the OP. From our model of distortion generated by a first-order Boltzmann function, we found that for inputs which sufficiently saturated the transducer, these notches occurred at certain OP values that were related to the probe level. With the assumption that the modulated odd-order distortion products adhered to the relationship between the OP and notches in the modulated odd-order distortion products, we were able to relate the OP_{Bias} values to the probe based on the notches in the modulated odd-order distortion products. The values of the OP_{Boltz} and the corrected OP_{Bias} derived from the CM were similar [Fig. 4(F)], as was the magnitude of the overall changes in the OP_{Bias} and OP_{Boltz} during induced hypoxias, suggesting that the method for relating the OP_{Bias} to the probe level in the ear canal was viable.

The finding that the OP_{Bias} derived from the DPOAEs was modulated two to three times more than the OP_{Bias} derived from the basal turn CM during the low-frequency bias (Fig. 9) suggested that the bias produced a larger displacement of the OC near the 4–4.8 kHz characteristic frequency region than at the base of the cochlea. Presumably, this reflects the mechanical impedance change to low frequencies along the length of the cochlea (von Békésy, 1960; Patuzzi, 1996). Previous studies have used low-frequency modulation of odd-order DPOAEs to non-invasively estimate the sensitivity of the OC displacement to a low-frequency bias tone in humans (Bian and Scherrer, 2007; Marquardt *et al.*, 2007), changing the bias tone frequency between 15 and 480 Hz and examining the differences in the notches of the odd-order distortion products.

It is worth noting here that the same technique might be used to examine sensitivity of the OC displacement to the high-frequency probe tone(s) because the notches in the odd-order DPOAEs are a function of the sensitivity to both the bias tone *and* the probe tone(s) (i.e., notches in the biased odd-order distortions occur at $\frac{1}{4}$ or $\frac{1}{5}$ the pressure of the probe tone, which depends on the sensitivity to the probe tone). Interestingly, this might provide a non-invasive objective measure of the OC displacement and sensitivity throughout the entire cochlea (i.e., if the bias frequency is held constant while the probe frequencies are swept).

F. Estimating the transducer OP

This study did not attempt to determine the dominant nonlinearity underlying distortion in the ear canal and cochlea, be it nonlinearity of MET channel compliance (Howard and Hudspeth, 1988; Jaramillo *et al.*, 1993), nonlinearity of MET channel conductance (Corey and Hudspeth, 1979) that produces mechanical distortion via reverse-transduction (Kirk and Yates, 1998), or nonlinearity in the active process itself, whatever that process may be (see Hudspeth, 2008 for recent review). Rather, we suggest that the dominant nonlinearity underlying distortion in both the ear canal and the CM is similar and that this distortion is related to the displacement of the OC.

Because we did not have a direct measure of the OC displacement, we estimated the OP as a measure that was *equivalent* to displacements of the OC produced by an acoustic stimulus in the ear canal. Measuring the OP relative to the probe stimulus allowed us to compare the OC displacement produced by the high-frequency probe tones (500 Hz or 4 and 4.8 kHz) to that produced by the low-frequency bias tone (4.8 Hz).

The 115 dB SPL, 4.8 Hz tone was equivalent to 32 Pa peak-to-peak pressure in the ear canal but, relative to the 500 Hz, 90 dB SPL probe tone (which was 1.79 Pa peak-to-peak), only produced a 0.19 Pa modulation of the OP_{Boltz} (Figs. 7 and 8). This suggests that the 4.8 Hz tone was 45 dB less effective in displacing the OC than the 500 Hz tone. This difference is most likely due to the acoustic high-pass filtering of the helicotrema, which attenuates frequencies lower than 100 Hz (Dallos, 1970; Ruggero *et al.*, 1986; Marquardt *et al.*, 2007). Presumably, higher-frequency bias tones would have produced a relatively larger displacement of the OC and greater modulation of the OP and would explain the more sensitive modulation of the DPOAEs reported by Bian and Scherrer (2007) who used 25–100 Hz bias tones.

We have recent evidence that suggests that the sensitivity differences between the high-frequency and bias tones are abnormal with auditory disorders such as endolymphatic hydrops (Marquardt *et al.*, 2007; Hensel *et al.*, 2007). If the helicotrema were partially or fully blocked off due to distension of Reissner's membrane with endolymphatic hydrops, we might expect to see a larger sensitivity to the low-frequency bias tone due to the reduced effectiveness of the helicotrema as a low-frequency shunt. This has been confirmed experimentally in recent experiments where gel was injected into the cochlear apex (Salt *et al.*, 2009).

Finally, low-frequency biasing of DPOAEs might provide a twofold indication of hydrops. First, if endolymphatic hydrops generates an over-pressure in SM, displacing the OC toward ST, the OP_{Bias} estimate obtained using low-frequency DPOAE biasing would be abnormally positive. Second, if endolymphatic hydrops resulted in distension of Reissner's membrane and blockage of the helicotrema, we might expect to find an abnormally high sensitivity to the low-frequency bias tone, as evident in the level of the bias required to produce notches in the odd-order distortion product.

(Received 29 October 2008; revised 27 January 2009; accepted 28 January 2009)

Measurements of distortion-product (DP) waves inside the cochlea have led to a conception of wave propagation that is at variance with the "classical" attitude. Of the several alternatives that have been proposed to remedy this situation, the feed-forward model could be a promising one. This paper describes a method to apply the inverse solution with the aim to attain a feed-forward model that accurately reproduces a measured response. It is demonstrated that the computation method is highly successful. Subsequently, it is shown that in a feed-forward model a DP wave generated by a two-tone stimulus is almost exclusively a forward-traveling wave which property agrees with the nature of the experimental findings. However, the amplitude of the computed DP wave is only substantial in the region where the stimulation patterns of the two primary tones overlap. In addition, the model developed cannot explain coherent reflection for single tones. It has been suggested that a forward transversal DP wave induced by a (retrograde) compression wave could be involved in DP wave generation. This topic is critically evaluated.

I. INTRODUCTION

Models of cochlear mechanics usually consist of a dual fluid-filled channel of which the parts are separated by a flexible partition. The solution of the model equation then represents the equilibrium between the hydrodynamics of the fluid and the dynamics of the partition—which is dominated by the basilar membrane (BM) and the cells of the organ of Corti. In a "classical" model, the mechanical properties of the cochlear partition depend only on the *local* longitudinal coordinate. Classical models have abundantly been used for a great variety of purposes. "Non-classical" models contain mechanical properties that depend on variables at more than one location. Such models have been used to explain properties that could not be explained by a classical model. In the field of non-classical models, feed-forward models have been considered in more detail (a few examples: Steele *et al.*, 1993; Geisler and Sang, 1995; Wen and Boahen, 2003). In a feed-forward model, the pressure at location x depends on the velocity at the same location (the "passive" or classical component of the dynamics) as well as on the velocity at location $x-\Delta x$ (the non-classical component) where Δx is a positive constant—generally taken to be equal to several times the diameter of an outer hair cell (OHC). This type of model has unique properties in its modes of wave propagation (de Boer, 2007) which makes it suitable to explain wave-propagation properties of observed distortion products (DPs) (for specific references, see further on). To clarify why this would be important, a few descriptive steps have to be taken.

Step 1: A classical model. The response of the viable, living cochlea is quite different from that of the *postmortem* cochlea. This implies that the dynamics of the cochlear partition is quite different in these two cases. In the *postmortem* cochlea, the BM has passive properties; its dynamics can be described by an impedance which has stiffness and mass, and a positive resistance. In the living cochlea, an additional mechanism causes the response to show a pronounced peak, and when we assume linearity, this effect can be described by an additional component, the "active" component, of the BM impedance. It is generally agreed that the effects of this additional impedance are caused by OHCs; the precise manner in which these cells perform their task is greatly unknown at present. One factor involved may be the mechanical action of the Internal Spiral Sulcus, as described in the literature, see de Boer (1993) and Steele and Lim (1999). A possible mechanism taking care of the necessary frequency selectivity may reside in resonance of the tectorial membrane, see, e.g., Neely and Kim (1986) for a model based on ideas by Allen (1980) and Zwislocki and Kletsky (1979). de Boer (1996), Patuzzi (1996), and Robles and Ruggero (2001) have written reviews. It is repeated that in this context the cochlear model, including the action of the OHCs, is assumed linear.

Step 2. When the cochlea is stimulated by two primary

a)Author to whom correspondence should be addressed. Electronic mail: nuttall@ohsu.edu

tones, with frequencies f_1 and f_1, the OHCs, being intrinsically nonlinear physiological transducers, will generate harmonic components with the same frequencies and their multiples, but also intermodulation components, which we will term DPs. These DPs are mainly generated in the *overlap region* which is the region where the excitation patterns of the two primary tones overlap. One of the most important of those DPs has the frequency $2f_1-f_2$. From the overlap region, two waves with the DP frequency are assumed to originate. One travels toward the helicotrema, and the other one toward the stapes. Physically, these two waves should have the same or closely related propagation properties. However, in experiments, they manifest themselves quite differently. The apical DP wave is easily observable but the reverse DP wave is not. In fact, where one would expect that reverse wave to exist, between the overlap region and the stapes, it is impossible or hard to find. In that region a forward wave dominates (Ren, 2004; He *et al.*, 2007, 2008; de Boer *et al.*, 2008; Dong and Olson, 2008). This curious phenomenon forms a challenge to theorists.

Step 3. One of the theories advanced to explain this property involves feed-forward. As has been observed (Steele *et al.*, 1993) and proven rigorously (de Boer, 2007), the mechanism of feed-forward, when adjusted to show wave amplification for forward-traveling waves, demonstrates wave attenuation for reverse waves. That is, the propagation of a reverse wave differs from that of a forward wave. Finding out the main characteristics of cochlear models with feed-forward (and feed-backward) with respect to measured data forms the main topic of the present paper.

Step 4. Another explanation of the anomalous direction of wave propagation of DP waves has been brought forward; it involves compression waves (Ren, 2004). Briefly, the proposed mechanism is as follows. In the region of overlap, the OHCs form a large number of tiny sound sources oscillating with the DP frequency. Together all these sources give rise to a compression wave in the fluid. Ideally, that wave has an infinite velocity of propagation, and it invades all tissues and spaces of the inner ear instantly. The mechanism by which a compression wave turns into a transversal wave is the same as that by which we hear bone-conducted sound. The compression wave reaches the region of the oval and round windows. Because the mechanical impedances of the two membranes are quite different, the two membranes will start to oscillate with different velocities. As a result, a "normal" propagating wave starts at the windows, having the DP frequency as its frequency. A short discussion of compression waves is included in this paper.

In earlier work of the present authors, the *inverse-solution method* (de Boer, 1995a, 1995b; de Boer and Nuttall, 1999) has been used for several purposes (e.g., to explain intensity effects: de Boer and Nuttall, 2000; to assess tones versus noise stimuli: de Boer and Nuttall, 2002; to analyze spontaneous oscillations of the BM: de Boer and Nuttall, 2006b; to analyze general wave-propagation properties: de Boer *et al.* 2007). In the inverse solution, the mechanical impedance of the BM is derived from a given BM response curve. That work was always centered at a classical cochlear model.

In the present study, it is shown how the inverse method can be extended to a feed-forward model. This application will result in a non-classical model, a feed-forward model, which is shown to provide an accurate reproduction of the response actually measured in a physiological experiment. An application in a different sense is illustrated for the case of a DP wave generated by nonlinear distortion of OHCs. This extension forms the main theme of the present work. Discussion of feed-backward and combination of feed-forward with feed-backward is beyond the scope of this paper.

II. DERIVATION: THE INVERSE SOLUTION

We will first consider the case of the classical, linear model, with two fluid-filled channels. In such a model, the local velocity of the BM only depends on the local pressure difference across it, and not on influences from elsewhere, from other locations. In that case the mechanics of the organ of Corti is lumped into the concept of a mechanical impedance (a point-impedance), called the BM impedance Z_{BM}. This impedance relates (in a way to be detailed further on) the pressure across the BM at a point x along the length of the BM to the velocity of the BM at the *same* location x. That impedance, obviously a function of location x, is converted into a diagonal matrix $\mathbf{Z}_{\mathrm{BM}}$. In this step we have tacitly replaced the continuous variable x by a finite sequence of N samples. The model equation then reads (de Boer *et al.*, 2007):

$$\left(i\omega\rho\mathbf{G}+\tfrac{1}{2}\mathbf{Z}_{\mathrm{BM}}\right)\mathbf{v}=-i\omega\rho\mathbf{S}v_{\mathrm{st}}. \tag{1}$$

The matrix $\mathbf{G}$ of size $N\times N$ (which constitutes the Green's function) represents the hydrodynamics of the fluid inside the model. The vector $\mathbf{S}$ (a column vector) is the stapes propagator (see Mammano and Nobili, 1993) and v_{st} is the stapes velocity. The "stylized" model of the cochlea has the form of a rectangular block in which the BM occupies a fraction (in our case 0.2) of the width, as in earlier work (de Boer, 1995a, 1995b). From Eq. (1) the BM velocity $\mathbf{v}$ (again a column vector) can be solved for a given form of $\mathbf{Z}_{\mathrm{BM}}$—this constitutes the *forward* solution.

The normal procedure of the *inverse* solution consists of two parts. First, from the given BM velocity $\mathbf{v}$ the pressure $\mathbf{p}$ that is solely due to hydrodynamics is determined. Normally, this is formed from the combination of the first term and the right-hand member of Eq. (1):

$$\mathbf{p}=i\omega\rho\mathbf{G}\mathbf{v}+i\omega\rho\mathbf{S}v_{\mathrm{st}}. \tag{2}$$

It is important to notice that the pressure $\mathbf{p}$ is solely determined by the hydrodynamics of the fluid because the matrix $\mathbf{G}$ and the vector $\mathbf{S}$ solely depend on the geometry of the bony shell of the cochlea. In the second step the effective BM impedance Z_{eff} is determined from the so-computed pressure $\mathbf{p}$ and the (given) BM velocity $\mathbf{v}$ (all variables are tacitly considered to be functions of location x):[1]

$$Z_{\text{eff}} = -2p/v. \tag{3}$$

In fact, Z_{eff} is a function of location x, but for reasons of clarity and simplicity we will omit the dependence on x from our equations wherever that is feasible.

To verify the accuracy of the procedure, the *resynthesized response* of the model is computed by substituting the derived impedance Z_{eff}, converted into a diagonal matrix $\mathbf{Z}_{\text{eff}}$, into the model Eq. (1) and solving that equation for $\mathbf{v}$. Because an inverse solution is known to be like an "ill-posed problem," this step is not superfluous (for more details on resynthesis see de Boer and Nuttall, 1999).

It should now be recognized that the so-derived BM impedance Z_{eff} is composed of a passive part that represents the impedance of the BM in the *postmortem* cochlea and an active part that induces the response of the viable cochlea to deviate so drastically from the *postmortem* response. This distinction is of prime importance.

In a *feed-forward* model, the OHC contribution from the BM velocity at location x results in an added pressure at location $(x+\Delta x)$, where Δx is positive. Assume, for a moment, that this is the only effect of the dynamics of the BM; this means that we temporarily omit the mechanical dynamics of the (passive) BM. Introduce X_{ffw} (tacitly assumed to be a function of x) to express the coefficient with which the local velocity has to be multiplied to find the associated (shifted) pressure, in an analogous way as Eq. (3). The function X_{ffw} is recognized to be a transfer impedance. In essence, it is a continuous function of x but as before we will consider it as a finite sequence of N samples. In matrix language X_{ffw} is to be converted into an *off-diagonal* matrix $\mathbf{X}_{\text{ffw}}$; the diagonal is distant from the main diagonal by a number of steps that corresponds to Δx. When $\mathbf{X}_{\text{ffw}}$ contains elements below the main diagonal, we have feed-forward, when it contains elements above the main diagonal, we have feed-backward. If Eq. (3) is rewritten as $p=-\frac{1}{2}Z_{\text{eff}}v$, it is easy to see that the product $\frac{1}{2}\mathbf{X}_{\text{ffw}}\mathbf{v}$ relates the (shifted) OHC-generated pressure to the velocity $\mathbf{v}$. The model equation then becomes

$$\left(i\omega\rho\mathbf{G} + \tfrac{1}{2}\mathbf{X}_{\text{ffw}}\right)\mathbf{v} = -i\omega\rho\mathbf{S}v_{\text{st}}, \tag{4}$$

in complete analogy to Eq. (1).[2] In the forward solution, it is this equation that has to be solved for $\mathbf{v}$.

In the feed-forward case, the first step of the inverse solution is identical to that in a classical model: the pressure $\mathbf{p}$ is computed from the hydrodynamic equation (2). Note again that this step only involves hydrodynamical concepts, the matrix $\mathbf{G}$ and the vector $\mathbf{S}$. The second step of the inverse solution is different because the vectors $\mathbf{v}$ and $\mathbf{p}$ do not refer to the same points on the x-axis. Dividing the *shifted* pressure p by the unmodified velocity v produces the function X_{ffw}, in an analogous fashion as Z_{eff} in Eq. (3). This is the feed-forward impedance function which, transformed into an off-diagonal matrix $\mathbf{X}_{\text{ffw}}$ and used in the model Eq. (4), should produce an accurate replica of the original given BM velocity $\mathbf{v}$. This elaboration forms the core of the feed-forward inverse solution and the associated resynthesis.

Actually, the situation is somewhat more complicated. We must take into account that the BM in the model has an inherent passive mechanical component that is not influenced by actions of OHCs. For reasons of simplicity, we will assume that this component is not involved in any form of feed-forward and that it can be represented by a classical impedance, called the passive BM impedance. This impedance has to be included in our inverse procedure but it has to remain outside the feed-forward process. Call that impedance function Z^{pass} and its associated diagonal matrix $\mathbf{Z}^{\text{pass}}$. Redefine the pressure $\mathbf{p}$ as follows:

$$\mathbf{p} = \left(i\omega\rho\mathbf{G} + \tfrac{1}{2}\mathbf{Z}^{\text{pass}}\right)\mathbf{v} + i\omega\rho\mathbf{S}v_{\text{st}}. \tag{5}$$

It is this pressure that has to be produced by the feed-forward impedance X_{ffw}. Equation (5) is the analog of Eq. (2) for the case where the classical passive BM impedance is explicitly included. The pressure $\mathbf{p}$ according to Eq. (5) is, in shifted form, divided by $\mathbf{v}$ to yield the transfer impedance X_{ffw}. Convert this impedance to an off-diagonal matrix $\mathbf{X}_{\text{ffw}}$ and substitute it into the "complete" model equation:

$$\left(i\omega\rho\mathbf{G} + \tfrac{1}{2}(\mathbf{Z}^{\text{pass}} + \mathbf{X}_{\text{ffw}})\right)\mathbf{v} = -i\omega\rho\mathbf{S}v_{\text{st}}. \tag{6}$$

This equation can be solved for $\mathbf{v}$. Note that $\mathbf{Z}^{\text{pass}}$ is a diagonal and $\mathbf{X}_{\text{ffw}}$ an off-diagonal matrix. The so-obtained resynthesized response should be a good approximation of the given BM velocity with which the inverse procedure was started. It has been our experience that in the feed-forward case the inverse method is more prone to errors than in the classical case. Therefore, the resynthesis step is really essential.

From the above derivation, it should be clear that $\mathbf{Z}^{\text{pass}}$ does not necessarily have to be the passive BM impedance, measured *postmortem*. It can be any impedance that behaves as a point-impedance, i.e., any impedance that relates pressure to velocity at the same location. In fact, it can be a combination of the actual passive BM impedance and a fraction of the (classical) active component of the effective BM impedance. In that way any "degree" of feed-forward can be built in (from 0 to 100%), and in that respect, the inverse-solution method outlined above is quite universal. In the present paper, we will leave that extension unexplored, to preserve space, and we will consider only the passive component of the BM impedance to be separated out in the classical sense as in Eqs. (5) and (6).

III. EXAMPLE I: FEED-FORWARD—SINGLE TONES

Responses were measured at the BM of the guinea pig, with the beam of a laser interferometer directed at a location on the BM that has a best frequency (BF) in the range from 16 to 20 kHz. The measurement method has been described before (de Boer and Nuttall, 2000). The protocols of the experiments, which were performed on deeply anesthetized animals, were approved by the Oregon Health & Science Committee on the Use and Care of Animals and consistent with NIH guidelines for humane treatment of animals. For the single-tone stimulus case, we utilized responses measured at low levels, of the order of 20–40 dB sound pressure level (SPL), and responses of the same cochlea measured *postmortem*. Responses are measured as functions of frequency and have been converted into "cochlear patterns,"

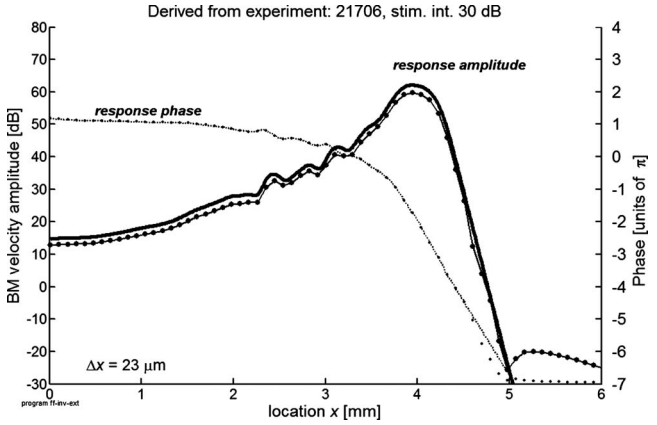

FIG. 1. Result of resynthesis in the single-tone case. Length of the model: 12 mm, divided into 1024 segments. Parameters of model are derived from an experiment. Frequency: 17 kHz. The passive component of the BM impedance has been determined from the *postmortem* response of the same animal, and the remainder of BM dynamics is interpreted in terms of feed-forward (see Eqs. (5) and (6)). Full-drawn and finely dotted curves: original response, amplitude (scale on the left), and phase (scale on the right). Coarsely dotted curves: resynthesized response, amplitude, and phase. For clarity, the amplitude of the resynthesized response has been plotted 2 dB lower than the original amplitude. This figure illustrates the fidelity of the sequence inverse-solution-resynthesis in the feed-forward model.

i.e., response functions as functions of the location variable x, valid for one frequency (usually chosen to be equal to the BF corresponding to a low-level response). A standard frequency-location map has been used in the conversion, refinements of the mapping procedure are described in de Boer and Nuttall (1999). For the two-tone computations (Sec. IV), we assume that the model is stimulated by two fairly strong tones of which we know the excitation patterns. In that case, we estimate the distribution of DP sources for third-order distortion occurring in the OHCs—in the same way as we have done before (de Boer *et al.*, 2007).

By way of Fig. 1, we illustrate the fidelity of the inverse solution in the case where one component of BM dynamics is contained in the *postmortem* impedance Z^{pass} and the other part involved in the feed-forward process. That is, we have used Eq. (5) as the basis of the inverse solution and Eq. (6) for resynthesis. The model has a length of 12 mm (of which only a part is shown), divided into 1024 sections. The feed-forward distance Δx has been given the value 23 μm. For clarity the resynthesized amplitude is drawn 2 dB below the original amplitude curve; the two phase curves coincide over most of their ranges, and are seen to depart from one another where the amplitude has dropped more than 50 dB from its peak.

The example of Fig. 1 has been selected because of its almost ideal resynthesis. More realistic cases are presented by Fig. 2 which shows results of four experiments, in four different animals. Again it is evident that the resynthesized response curves are good imitations of the original responses. However, there is more variability in and between the data sets, but that is mainly outside the main response region. We conclude that the inverse solution is sufficiently accurate for our further needs. We will now use this method to predict the behavior of DP waves in a feed-forward setting.

IV. EXAMPLE II: FEED-FORWARD—TWO STIMULUS TONES AND DPS

Let us consider the case where the model is stimulated by two tones, with frequencies f_1 and f_2. These tones are presented with an intermediate intensity; we will call the appropriate response functions $v^{(1)}$ and $v^{(2)}$. Again we have

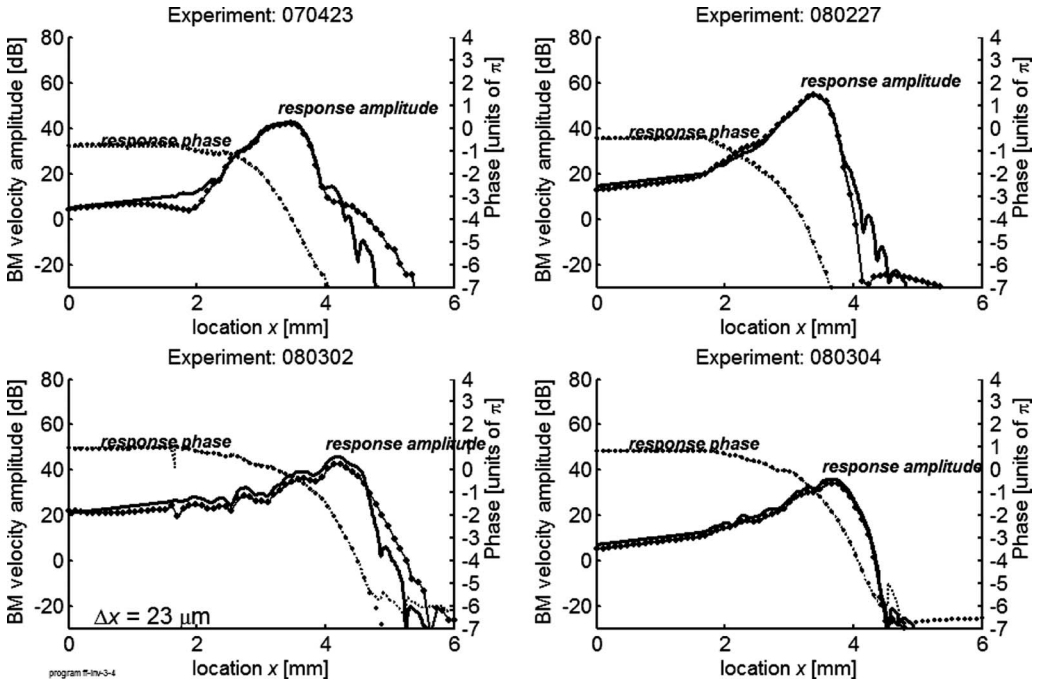

FIG. 2. Results of inverse solution followed by resynthesis in four different experiments. Parameters of the model are derived from these experiments. Tone frequency: 17 kHz. The amplitude of the resynthesized wave is drawn 2 dB lower than the original amplitude.

omitted the dependence on location x. For each of the two tones, the corresponding transfer impedance X_{ffw} can be determined; call these two functions $X_{\mathrm{ffw}}^{(1)}$ and $X_{\mathrm{ffw}}^{(2)}$. It is repeated that both functions only represent the OHC-controlled components of the BM dynamics; the passive component Z^{pass} has been separated out. The transfer impedances $X_{\mathrm{ffw}}^{(1)}$ and $X_{\mathrm{ffw}}^{(2)}$ as well as the passive components Z^{pass} refer to the two different frequencies, f_1 and f_2, respectively. A product $p_{\mathrm{act}}^{(1)}$ like

$$p_{\mathrm{act}}^{(1)} = -\tfrac{1}{2}\mathrm{v}^{(1)}X_{\mathrm{ffw}}^{(1)} \tag{7}$$

will now represent the active pressure developed by the hair cells due to tone 1 for the frequency f_1. Similarly, $p_{\mathrm{act}}^{(2)}$ defined by

$$p_{\mathrm{act}}^{(2)} = -\tfrac{1}{2}\mathrm{v}^{(2)}X_{\mathrm{ffw}}^{(2)} \tag{8}$$

will represent the OHC pressure corresponding to tone 2 for the frequency f_2. In both products, the displacement Δx has to be taken into account, of course.[3] In the limit of small nonlinear distortion, the DP with frequency $2f_1-f_2$ will appear in the output of the OHCs with an amplitude $A_{\mathrm{DP}}(x)$ given by (for more details, see de Boer *et al.*, 2007)

$$A_{\mathrm{DP}}(x) = A(p_{\mathrm{act}}^{(1)}(x))^2 \,.\, (p_{\mathrm{act}}^{(2)}(x))^*, \tag{9}$$

where we have deliberately reintroduced the independent variable x. It is recalled that $p_{\mathrm{act}}^{(1)}(x)$ and $p_{\mathrm{act}}^{(2)}(x)$ refer to the same x-axis but intrinsically contain information about two different frequencies, f_1 and f_2. In contrast, the resulting coefficient $A_{\mathrm{DP}}(x)$ describes the complex amplitude for a wave with the DP frequency f_{DP} equal to $2f_1-f_2$. The square in Eq. (9) arises because the expression for f_{DP} contains the term $2f_1$, the superscript asterisk (*) denotes the complex conjugate and is needed because the DP frequency contains the term $-f_2$. The multiplier A will be specified further on. It is stressed that Eq. (9) implies that the drive behind the DP wave, as it is expressed by the pressure $A_{\mathrm{DP}}(x)$, is solely due to physiological effects produced by viable OHCs (as in our earlier work on DP waves, de Boer *et al.*, 2007). That we are again using the case of small nonlinear distortion is based on the fact that experiments on DP waves have yielded consistent results for stimulus signals as weak as 40 and 50 dB SPL (He *et al.*, 2007).

The pressure distribution $A_{\mathrm{DP}}(x)$ acts as a source distribution for the resulting DP wave, with the DP frequency equal to $2f_1-f_2$. That DP wave can now be computed from a small variation in the model equation, Eq. (6), where the stapes excitation term $-i\omega\rho\mathbf{S}v_{\mathrm{st}}$ is replaced by the column vector $\mathbf{A}_{\mathrm{DP}}$ which represents $A_{\mathrm{DP}}(x)$. The resulting equation reads

$$\left(i\omega\rho\mathbf{G} + \tfrac{1}{2}(\mathbf{Z}^{\mathrm{pass}} + \mathbf{X}_{\mathrm{ffw}})\right)\mathbf{v} = +\mathbf{A}_{\mathrm{DP}}. \tag{10}$$

All terms are to be evaluated at the DP frequency f_{DP}. The transfer impedance X_{ffw} is determined from a measured tone response of the animal, at the lowest feasible level (usually 20 dB SPL). The passive impedance Z^{pass} is determined from the *postmortem* response, at the highest level (100 dB). Both of these parameters are evaluated for the DP frequency and are functions of location x. For the computation of $A_{\mathrm{DP}}(x)$ (see Eq. (9)), responses and impedances are used for higher levels, adapted to the appropriate frequencies, f_1 and f_2. For the method to reduce reflection of the DP wave at the stapes end, we refer to de Boer *et al.* (2007).

Figure 3 shows four representative theoretical results computed from results of four experiments. Two tones of 40 dB SPL with frequencies f_1 and f_2, with the frequency ratio equal to 1.08, were used as stimuli. The amplitudes of the excitation patterns produced by these tones are shown by dashed curves (labeled: f_1 and f_2) and suggested by shading. The levels at which these patterns are plotted are arbitrary; they are selected for visual clarity. The resulting DP waves are computed as described above. In each panel, the solid thick curve shows the amplitude of the computed DP wave and the coarsely dashed curve shows the phase; the scale for the amplitude appears on the left, that for the phase on the right. The amplitude factor A in Eq. (9) has been selected so that in the region of maximum response to the DP frequency, the amplitude is around 50 dB.

Figure 3 shows results for the same experiments as used for the publication at the Keele Symposium (de Boer and Nuttall, 2008), produced with a small variation in the original program. Figure 4 shows results, plotted in the same layout, for a further set of four animals. In this case the results show somewhat more variability. It should be remembered that the "best" results of computations are usually obtained from experiments that yield "smooth" impedance curves; in the present cases more realistic results are shown. It should be clear that a considerable part of the DP wave propagates in the forward direction. In addition, this property is evident also outside the region where the amplitude of the DP wave is substantial, and that is the main result of the present study. There are irregularities in the phase curves but in no case is a clear reverse wave present near or not far from the stapes. As an afterthought, it is quite surprising that a feed-forward effect, active over a distance of just a few hair-cell diameters, and only present in the active region of the cochlea, can have such a profound effect, even on small-amplitude waves at a considerable distance.

V. ABOUT THE DP COMPRESSION WAVE

We were inspired to study feed-forward (and its variations) by the results from measurements on the DP wave, both inside the cochlea (see the references mentioned in Sec. I) and outside it, in the form of otoacoustic emissions (Ruggero, 2004; see also Siegel *et al.*, 2005). As stated in Sec. I, it has been attempted by some authors to explain these findings by a mechanism that invokes a compression wave. That explanation has been criticized on several grounds, notably on its inability to explain frequency-and-location-selective "activity" (de Boer and Nuttall, 2006a) and its failure to explain the Allen–Fahey effect (Shera *et al.*, 2007; Shera and Guinan, 2007). In other words, it cannot be the compression wave that induces propagation of DP waves in the cochlea. (To quote Shakespeare's Hamlet: "There are more things in heaven and earth, Horatio, than are dreamt of in your philosophy.") In all that work, the background of the elabora-

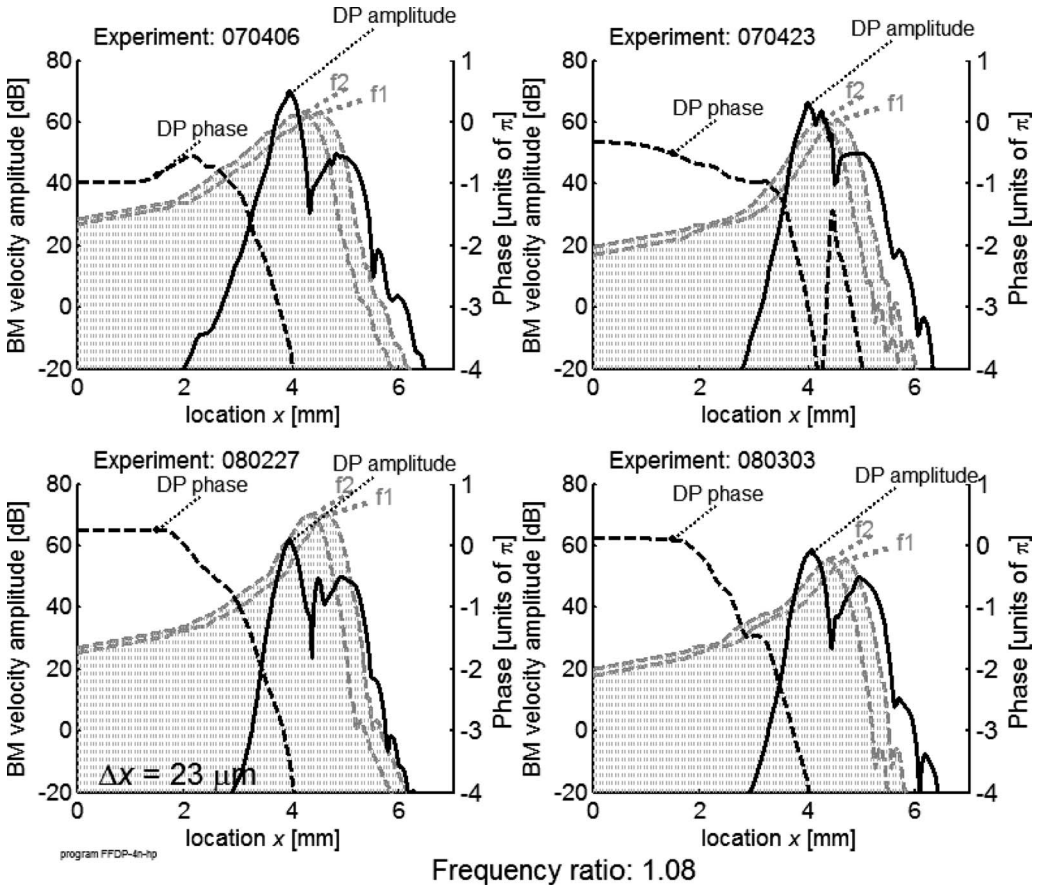

FIG. 3. DP waves generated in a stylized three-dimensional model with feed-forward. Two tones of 40 dB SPL with frequencies f_1 (14.57 kHz) and f_2 (15.74 kHz) are used as stimuli. The amplitudes of the excitation patterns produced by these tones are shown by dashed curves (labeled f_1 and f_2) and suggested by shading. Generation of the DP wave with frequency $2f_1-f_2$ (13.41 kHz) computed as described in de Boer *et al.* (2007), and further described in the text. Reflection of the DP wave at the stapes has been suppressed. Solid thick curve: amplitude of the resulting DP wave. Ordinate scale on the left. Coarsely dashed curve: the associated DP phase response, scale on the right. The thick and the thin dotted curves show amplitude and phase, respectively, of the response to a single low-level tone with the DP frequency started at the stapes. These curves serve as landmarks.

tions has been a classical model of the cochlea. We presently want to discuss the effect of a compression wave in a feed-forward model, but we should keep in mind the reservations expressed in the cited papers.

The main point is this: In the cases we have shown in Figs. 3 and 4 the computed DP wave generated by the feed-forward mechanism is extremely small in the region between the stapes and the primary-tone response patterns. It is so small that whatever is the amplitude of the *compression-induced wave* (in the sequel to be called CI-W), the latter will be dominant in most of that region. This type of DP wave would then be the only source of otoacoustic emissions and also control what we observe inside the cochlea. For this reason (and for this reason only, see the above-mentioned counter-arguments and restrictions), we will present an estimate of the CI-W in our model.

The compression-induced DP wave has been analyzed in Shera *et al.* (2007), and we accept the main idea. We will assume that $A_{\mathrm{DP}}(x)$ given by our Eq. (9) is also the source distribution of the compression wave. In this way, we will be able to compare the CI-W directly with the DP wave considered in Sec. IV.

Two compression waves arise from the overlap region, one toward the helicotrema and one toward the stapes. In theoretical exercises, the fluid is usually considered incompressible. In a more practical situation, the fluid is compressible and the speed of sound in it finite. In fact, for frequencies around 17 kHz, the length of the guinea-pig cochlea is of the order of a quarter wavelength. This means that for a high frequency the basally generated compression wave encounters an obstacle. The essentially very large impedance of the top of the cochlea (it is all bone) is transformed into a small impedance in the region where the compression wave is generated. Therefore, we must expect that the apical part of the compression wave "shunts" the basal part so that the latter arises from a smaller pressure than $A_{\mathrm{DP}}(x)$. If we take $A_{\mathrm{DP}}(x)$ as the source and compute a compression-induced DP wave from it, we are decidedly *over-estimating* the basal compression wave. Here we end our short excursion into the domain of finite compressibility of the fluid. In the sequel, we consider only an ideal fluid.

Integration over space yields the pressure p_{evo} that drives the compression wave:

$$p_{\mathrm{evo}} = \int_0^L A_{\mathrm{DP}}(x)dx, \tag{11}$$

where L denotes the length of the model.[4] As said, from here

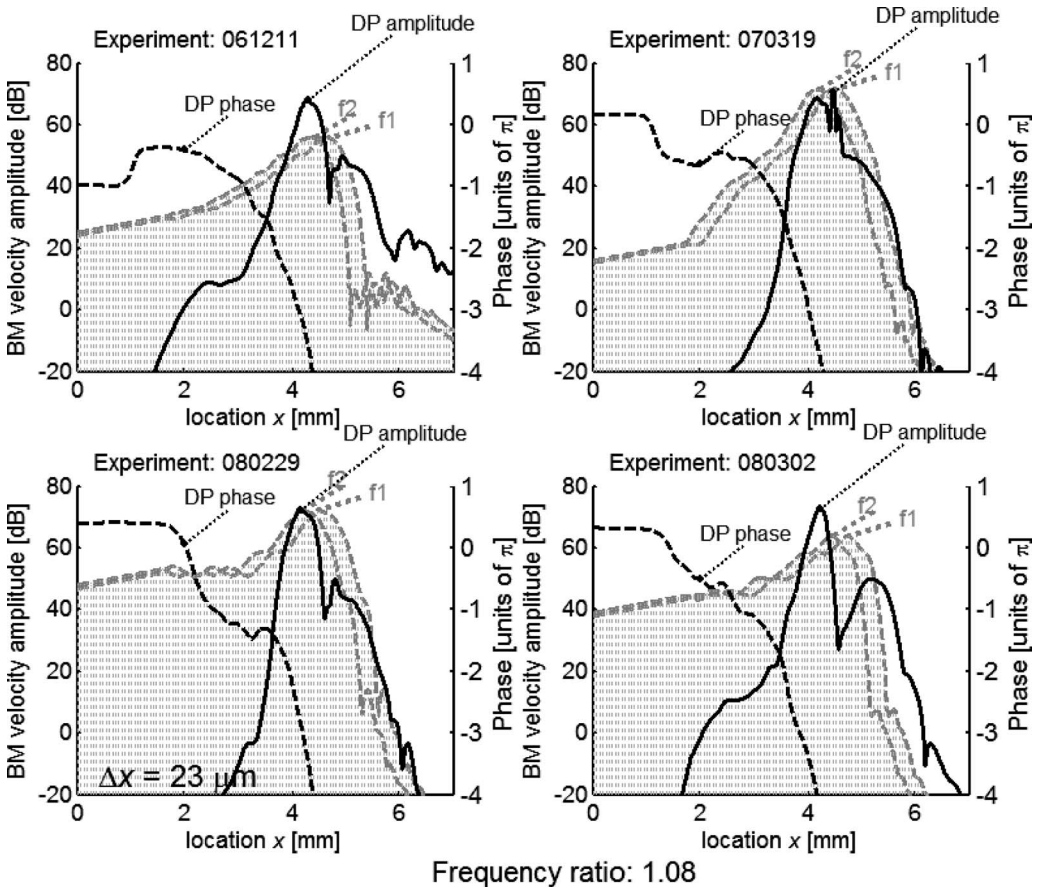

FIG. 4. Same as Fig. 3, with a different selection of animals. In these cases, the results display more variability.

on we again assume the compression wave to have an infinite velocity of propagation; hence p_{evo} is the same everywhere. At the location of the stapes, the compression wave is equal to p_{evo}. If we divide the pressure p_{evo} by the effective input impedance of the cochlea (the impedance loading the oval window), we obtain the equivalent stapes velocity (at least, if we ignore the impedance of the round window, see Shera *et al.*, 2007). The input impedance of the model can easily be found from our computations. To this impedance, another impedance must be added: the radiation impedance representing the sound that is going to the outer world, via the middle ear. For simplicity, we assume this impedance to be equal to the aforementioned input impedance—implying an ideal impedance match between cochlea and middle ear. This reduces the amplitude of the CI-W by 6 dB. It should finally be recalled that all variables involved must be computed for the DP frequency.

Figure 5 shows four representative results. The figure shows the amplitudes of the computed CI-Ws. These amplitudes are normalized in exactly the same way as the DP waves. As a result, the panels display the relation between the CI-W and the "regular" feed-forward DP wave. It is clear that there is considerable variation between the panels; we have selected experiments from the sets shown in earlier figures to demonstrate the extremes of the CI-W. It is also clear that in the region where the DP frequency shows its own maximum, the DP wave and the CI-W are of comparable magnitude. The figure confirms what has been said above: outside the main region of the DP wave it is the CI-W that dominates. With respect to direction of propagation, there is no difference. However, because the CI-W does not have the required properties (see above), we should see these results only as indicative, not as final outcomes. At any rate, the figures show the relation between the amplitudes of the computed CI-W and the regular feed-forward DP wave correctly, because they have been derived from the same DP source function $A_{DP}(x)$ and plotted with the same normalization factor. We should recall that the compression wave can directly be identified in experiments on intra-cochlear pressure (Dong and Olson, 2008 and earlier work). It was found that the Distribution Product Oto-Acoustical-Emission (DPOAE) related to the compression wave is "Much lower than the actual DPOAE we have measured in the ear canal" (citation from *loc. cit.*).

VI. EXPLANATIONS, CONCLUSIONS, LIMITATIONS

The main property that emerges from Figs. 3 and 4 is that the computed DP wave is almost exclusively a forward wave, over most of its range. The theory described in de Boer (2007) yields that forward and reverse waves have quite different amplification properties, but that theory is only valid in a structure exclusively governed by feed-forward. Apparently, it is also valid in the case where the passive component of the BM impedance is included.

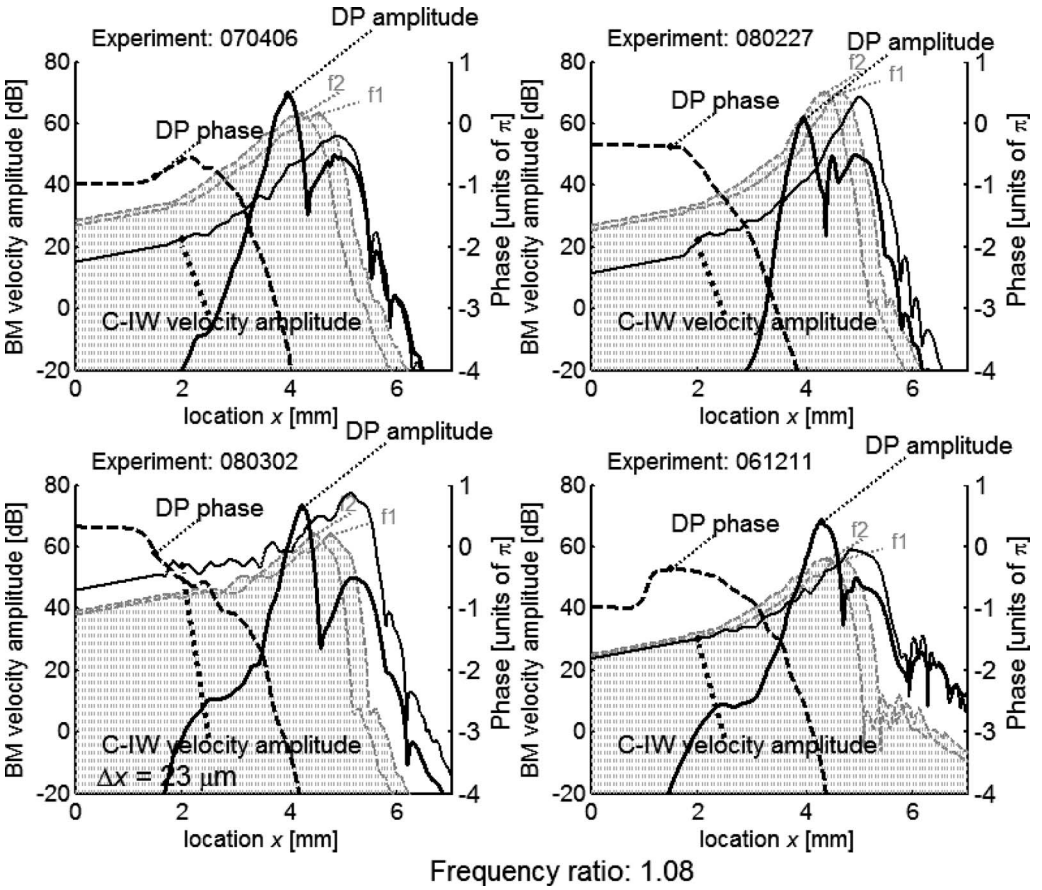

FIG. 5. In addition to the DP wave, the CI-W is shown. Only the amplitude of that wave is shown (the phase follows that of a simple tone at the same frequency injected at the stapes). Experiments have been selected to show "normal" as well as "large" amplitudes of that wave. It has been assumed that the middle ear is loaded by the same impedance as the input impedance of the cochlea. The short-circuit effect of the apical part of the CI-W (see text) has been neglected.

Where the DP wave originates, in the region of overlap, both forward and reverse waves are initiated. Going to the left, toward the stapes, the reverse wave starts to be progressively attenuated in a feed-forward model. And still more to the left even the forward wave dwindles to a very small amplitude. One may ask the following questions: Why is not there a substantial forward wave in this region? Does not there exist some kind of effective stimulus here that would generate it? The answer is no. In this region, the DP drive pressure $A_{DP}(x)$ is too small to have an effect by itself. Secondary effects (due to hydrodynamics and the passive BM impedance) of that drive pressure have been found to remain restricted to the region where $A_{DP}(x)$ is maximal.

In effect, the theoretical prediction of a small forward-going DP wave in this region is contrary to experiment. In de Boer *et al.* (2008), it is shown that the forward-propagating character of the DP wave is present in almost all of the region between overlap region and stapes. A similar conclusion can be drawn from the other papers on this subject mentioned in Sec. I. Apparently, if feed-forward is a concept to be included in the explanation of the data, it has to be extended or modified. We recall what has been said about a possible combination of a classical and a feed-forward model at the end of Sec. II.

There is a further problem with the feed-forward concept. As demonstrated here, the principle of feed-forward does not allow a sizable reverse DP wave to occur. The same would be true for any other (non-classical) type of reverse wave. As a consequence, the principle of coherent reflection cannot work in such a model. We further refer to the discussion of this topic in the Keele paper (de Boer and Nuttall, 2008), and await further theoretical developments. At this point, we can only add that a mechanism including a CI-W does not alleviate that problem. Only the extension of the feed-forward concept alluded to in the ending part of Sec. II can do that.

For the sake of completeness, we computed the CI-W, and found it to have all the properties we could have predicted. We did not pursue this topic any further because, from various sides, it can be argued that the CI-W cannot be the DP wave observed inside the cochlea and cannot be the source of DP otoacoustic emissions.

ACKNOWLEDGMENTS

From the many data sets collected in close collaboration with Jiefu Zheng, a number of the smoothest responses were selected for the illustrations in this paper. Dr. Zheng is gratefully acknowledged for his important contributions. Interactions with Christopher Shera have considerably improved the authors' thinking. The authors are also grateful to Renato

Nobili and Fabio Mammano who kindly put their Green's function program code at their disposal. This study received support from NIH NIDCD Contract No. R01 DC 00141.

[1]The minus sign and the factor 2 are due to sign conventions. Upward movement of the BM is counted positive, p is the pressure in the upper channel, and $-p$ in the lower channel.

[2]Actually, in the resynthesis procedure, the stapes velocity should be replaced by the virtual stapes velocity (de Boer and Nuttall, 1999).

[3]It should be noted that the expression $\frac{1}{2}v^{(1)}X^{(1)}_{\mathrm{ffw}}$ with shifted x-scales in the two factors is identical to the corresponding classical expression $\frac{1}{2}v^{(1)}Z^{(1)}_{\mathrm{BMact}}$ with equal x-scales, where $Z^{(1)}_{\mathrm{BMact}}$ is the "active" component of the classical BM impedance for tone 1. This can be seen by comparing Eq. (6) with its classical counterpart, Eq. (1). The same is valid for tone 2.

[4]At first sight, it may be confusing to observe that $A_{\mathrm{DP}}(x)$ and p_{evo} have different dimensions. In fact, $A_{\mathrm{DP}}(x)$ has the meaning of being a pressure *density*, the pressure produced by OHCs per unit of length.

Judging the similarity of soundscapes does not require categorization: Evidence from spliced stimuli

(Received 27 February 2008; revised 20 January 2009; accepted 26 January 2009)

This study uses an audio signal transformation, *splicing*, to create an experimental situation where human listeners judge the similarity of audio signals, which they cannot easily categorize. Splicing works by segmenting audio signals into 50-ms frames, then shuffling and concatenating these frames back in random order. Splicing a signal masks the identification of the categories that it normally elicits: For instance, human participants cannot easily identify the sound of cars in a spliced recording of a city street. This study compares human performance on both normal and spliced recordings of soundscapes and music. Splicing is found to degrade human similarity performance significantly less for soundscapes than for music: When two spliced soundscapes are judged similar to one another, the original recordings also tend to sound similar. This establishes that humans are capable of reconstructing consistent similarity relations between soundscapes without relying much on the identification of the natural categories associated with such signals, such as their constituent sound sources. This finding contradicts previous literature and points to new ways to conceptualize the different ways in which humans perceive soundscapes and music.

I. INTRODUCTION

Categorizing and comparing percepts are central abilities for human cognition. They do not operate in isolation, but rather depend greatly on one another. When we lack specific knowledge, we often rely on domain-general similarity to guide categorization.[1] Reciprocally, we often judge the similarity of objects by comparing their features, i.e., based on their prior categorization.[2] However, the exact nature of the relation between similarity and categorization still eludes modern cognitive science.[3] There have been empirical demonstrations of categorization processes conducted in apparent independence from similarity, but rather based on semantic representations looking like rules or theories.[4] Further, features used for similarity depend on context, culture, and experience, and different strategies often operate at the same time to reinforce each other and eliminate context-driven noise.

This complex interdependence also holds in the specific case of auditory perception. The vast psychology literature studying similarity judgments for musical signals has made constant efforts to control for unwanted high-level recognition effects, by using short or synthesized stimuli.[5,6] Research on the perception of environmental audio scenes (or *soundscapes*) also suggests that similarity and categorization are deeply entangled. The perceived similarity of soundscapes is believed to be based on the prior identification of their constituent sources:[7,8] "If there are cars in both signals, then these are similar." Similarly, psycholinguistic studies[9] have concluded that the subjective "unpleasantness" of an urban soundscape increases when more mechanical sound sources (e.g., vehicles) are identified than natural sources (e.g., voices or birds).

In the case of soundscapes, however, recent computational studies seem to contradict that similarity should rely on categorization. A common algorithmic paradigm to simulate human judgments of audio similarity is to model audio signals as global statistical distributions of local features computed on very short (cf. 50-ms) frames. This technique, called bag-of-frames (BOF), uses only low-level and short-term spectral information, and does not rely on any prior categorization of, e.g., sound sources. In a recent study,[10] we established that BOF, simple as it is, was computationally sufficient to simulate similarity with near-perfect precision for soundscapes. Therefore, from the sole point of view of information processing, categorization does not seem to be necessary to compare soundscape signals. However, we found significantly lower performance when applied to polyphonic music signals.

The present paper aims to clarify this situation. While our previous study[10] was a machine experiment, this one is a human psychological experiment. We create an experimental situation where human listeners produce judgments of similarity for audio signals, which they cannot easily categorize, by manipulating the signals with an algorithmic transformation called *splicing*. Splicing alters an audio signal by segmenting it into 50-ms frames, then shuffling and concatenat-

a)Electronic mail: aucouturier@gmail.com
b)Electronic mail: boris.defreville@orelia.fr

ing these frames back in random order. Spliced signals by construction have the same frames than the original signals, hence the same local features, as well as the same statistics of features; only the time ordering of the frames is modified.

Splicing is a known technique in language science: It is typically used to process spoken sentences for listening experiments so that their lexical content is lost but their vocal content (prosody, timbre, etc.) preserved to some extent.[11] Similar effects are known for music signals: It is difficult to identify instruments or even produce any qualitative description of shuffled or reversed music.[12] This is hardly surprising: Psychophysical experiments[5] have long established the importance of dynamics, notably the attack time and fluctuations of the spectral envelope, in the perception of individual instrument notes.

In this study, we confirm that splicing acts as a categorization mask for both music and soundscape, and use this property to study the influence of categorization on the processing of similarity for both music and soundscapes.

II. METHODS

A. Data

Each subject was presented (in tasks described below) a set of 12 audio stimuli in either of 4 conditions: normal music (NM), spliced music (SM), normal soundscape (NS), spliced soundscape (SS). Each stimulus is a 20-s stereo sound file sampled at 44.1 kHz, normalized at zero dc, and has maximum amplitude of −3 dB. The 12 stimuli in the NM condition are excerpts of western popular music of various genres from the period 1950–2000. The 12 stimuli in the NS condition are excerpts of urban soundscapes used in our previous study.[10] Stimuli in the two spliced conditions (SM and SS) were obtained from the stimuli in the associated normal condition (NM and NS, respectively) by the following algorithmic transform:

(1) A "normal" signal is truncated into successive, nonoverlapping 2048-point time frames (46.4 ms at 44.1 kHz).
(2) Frames are shuffled in random order (using a pseudorandom generator initialized with a common seed for all files).
(3) Frames are concatenated back to an audio signal of same length as original.

B. Participants

55 subjects participated, all relatively young ($M=20.70$, $SD=3.56$) Japanese undergraduate students. There were 45 male participants, and 10 female participants, with no significant age difference between sexes [$F(1,55)=1.15$, $p=0.288$]. All participants distributed in roughly equal proportion over all four conditions (NM:15, SM:15, NS:13, and SS:12), with no gender bias. We kept data from all participants for the analysis presented below.

C. Tasks

Each subject was presented stimuli from only one of the four tested conditions (randomized). The test consisted of a categorization task (used to validate the effect of splicing) and a similarity task. To prevent priming effects, every subject performed the similarity task before the categorization task.

1. Similarity task

In the similarity task, participants were asked to judge similarity relations in a set of triads presented one after the other. We presented 44 triads per condition, arranged in a $\lambda=2$ balanced incomplete block design (all possible pairs of stimuli appear twice). Although the set of triads is incomplete, it was designed so that all triads in a given spliced condition have a corresponding normal triad in the normal condition composed of the three same stimuli in their original version.

For each presented triad, participants were asked to select the pair of stimuli they deemed were most similar to one another. Participants were given no other information than the sole audio presentation of the stimuli (no file name, no editorial information on the recording, etc.). Prior to the test, participants received the following instructions:

> When judging the "similarity" of such sounds, please try to listen to the immediate, global impression of the sound, and not to finer, analytical details.[13] For instance, you may want to say that a Bob Dylan song "sounds like" another piece (e.g., a Bossa Nova piece by Joao Gilberto), because they both have a soft acoustic guitar and a gentle male voice. In a noisy background, e.g., a crowded cafe, one could be mistaken for the other. Judging that the same Bob Dylan guitar song is similar to, say, a Joni Mitchell piano song (because both artists have the same influences, and performed at similar periods), or that the Bossa Nova piece is similar to a recent Brazilian electronic piece (because they are both from Brazil) would be irrelevant for this test.

Additionally, when tested in one of the spliced conditions (SM and SS), participants were instructed to do the following:

> [...] please try to listen to these sound extracts as if they were natural ones, i.e., focus on your immediate, holistic sensation of how much these sounds sound like one another (and try to refrain from analytical thinking).

Stimuli could be listened to as many times as needed; answers could be given before listening to a stimuli in full; in case they could recognize the original recording from which a given extract was taken (which is mostly relevant for the music conditions), participants were instructed to judge similarities based on the sole extract, and not on the unpresented original material.

2. Categorization task

In the second task, each of the 12 stimuli of the tested condition is presented again one after the other. For instance, after judging similarities in a set of 44 triads of SM, a participant is asked to categorize each of the individual SM

TABLE I. Influence of splicing manipulation on inter-subject agreement on most-agreed value for categorization task.

		Normal condition	Spliced condition	Significance
Music	Source	$\beta_{NM}=0.79$	$\beta^*_{SM}=0.59$	$F(1,80)=18.23,\ p<0.001$
	Mood	$\beta_{NM}=0.67$	$\beta^*_{SM}=0.37$	$F(1,62)=73.05,\ p<0.001$
	Type	$\beta_{NM}=0.64$	$\beta^*_{SM}=0.36$	$F(1,8)=10.56,\ p=0.012$
Soundscapes	Source	$\beta_{NS}=0.89$	$\beta^*_{SS}=0.52$	$F(1,56)=30.19,\ p<0.001$
	Mood	$\beta_{NS}=0.68$	$\beta^*_{SS}=0.38$	$F(1,32)=28.70,\ p<0.001$
	Type	$\beta_{NS}=0.75$	$\beta^*_{SS}=0.46$	$F(1,20)=6.75,\ p=0.017$

recordings that composed the triads. For each stimulus, users were instructed to check through a list of descriptions that they think could apply (forced choice). As before, participants were given no other information than the sole audio presentation of the stimuli. The presented descriptions were organized in three broad categories (sources, moods, and types), which content varied depending on the tested condition (full list given in the Appendix).

Each category was designed to contain descriptions that apply naturally for all items (e.g., "car" sounds for a "boulevard" soundscape) as well as distractors, which do not apply[14] for any of the presented data (e.g., "violin" source for music and "boat" sounds for soundscapes). In each category, a wildcard description ("I don't know") was also included. Apart from the wildcard choice, none of the descriptions were enforced to be mutually exclusive, i.e., participants were left free to check as many as they thought could apply. Prior to the test, participants received the following instructions:

> This time, the task may require you to think analytically about the signals: Which instruments/sound sources you perceive, how you judge the sound emotionally, how you would describe the genre of the music, or to which type of environment the recording corresponds?

Additionally, when tested in one of the spliced conditions (SM and SS), participants were instructed to do the following:

> [...] please try to describe what you think the signal was *before* scrambling. For instance, all scrambled signals tend to sound rhythmically complex and maybe evoke tensed emotions associated with randomness. Please try to refrain from judging such properties, but rather focus on what you can perceive of the original signal. Imagine you are listening to the sound over a very strangely distorted telephone: We want you to describe the sound played at the other end, not to describe the telephone.

As before, each successive stimulus could be listened to as many times as needed; answers could be given before listening to a stimulus in full; participants were instructed to categorize the content of the sole extracts, rather than any unpresented context they might recognize.

D. Apparatus

Data were gathered in four sessions held on 4 days of December 2007, with randomized conditions. All participants were tested in the same room, in a calm environment, with the same apparatus: Audio was presented with closed-type headphones (always the same model), and the test application (a set of php scripts running on a local server) ran on G4 Apple computers. All instructions and tests were conducted in Japanese. Participants were instructed to set the audio volume to a comfortable level before the test. Three experimenters were present at any time to give instructions and answer queries. Participants were rewarded 1000 JPY (cf. 10 USD) for their participation, which took between 30 and 60 min.

III. RESULTS

A. Influence of splicing on categorization

In this section, we measure how much the descriptions (sources, moods, and types) that apply consensually to the normal stimuli can still be judged consistently in the corresponding spliced stimuli.

For a given stimulus s in a given condition c, we define the "agreement on best value" for a given description d $\beta_c(s;d)$ as the proportion of participants who agree on the most-agreed value (i.e., true or false) of description d for s. For example, when an extract of a *Beethoven* piano sonata is presented, most participants agree that the value for the description *piano* (a member of the *source* category) is "true." For stimuli s in a *spliced* condition c (i.e., one of SM and SS), we then compute the "agreement on best normal value" $\beta^*_c(s;d)$ as the proportion of participants (among all participants tested in condition c) who agree on the most-agreed value (i.e., true or false) of description d judged for the corresponding normal stimuli. We then average over all stimuli s in condition c, then all descriptions d in a given category (i.e., one of "source," "mood," and "type"). With the same example as above, $\beta^*_{SM}(s;d)$ measures the proportion of participants judging description *piano* to be true for the spliced variant of the sonata.

We observe the following:

- There is a severe and significant degradation of the agreement measured in spliced conditions over the most-agreed values judged in the corresponding normal conditions, when considering only *true* values in normal condition,

i.e., increased number of false negatives (see Table I).
- No significant degradation of agreement due to splicing when considering only *false* values in normal condition, i.e., no increase in false positives.
- Splicing reduces the number of hits per (stimulus and description) pair (participants check less descriptions for spliced signals than for the corresponding signals in normal condition), for all category groups and for both music and soundscape, but only significantly so for soundscape sources [number of checks: $M=2.75<M=1.89$, $F(1,19)=7.93$, $p=0.011$].
- The degradation of β_c^* due to splicing on the categorization tasks is of similar degree for music and soundscapes, for the mood category [$\Delta=-0.3$, but $F(1,47)=0.02$, $p=0.891$] and the type category [$\Delta=-0.28$, but $F(1,14)=0.01$, $p=0.944$]. The degradation of the agreement on source values is more severe for soundscapes than music: The agreement difference from NM to SM $\beta^*_{SM}(s;d\in\text{source})-\beta_{NM}(s;d\in\text{source})$ ($M=-0.20$) is smaller than from NS to SS $\beta^*_{SS}(s;d\in\text{source})-\beta_{NS}(s;d\in\text{source})$ ($M=-0.37$), with statistical significance [$F(1,68)=7.48$, $p=0.008$].

These results show that splicing significantly hinders the recognition of sources, moods, and types associated with stimuli in their normal conditions. This masking effect is not significantly different for music and soundscapes for both mood and type descriptions, but more important for soundscape sources than for music sources.

B. Influence of splicing on similarity performance

In this section, we measure how much of the similarity relations established by participants listening to normal stimuli ("ground truth") can still be identified by the participants listening to their spliced variants.

For a given triad t in a condition c, we define the "agreement on best pair" $\alpha_c(t)$ as the proportion of participants who agree on the most-agreed pair of "most" similar stimuli. For example, when presented a triad composed of two Beethoven piano sonatas and a *Coltrane* jazz piece, most participants judge that the pair of most similar stimuli is the one composed of the two sonatas. For triads t in the spliced conditions c, we then compute the "agreement on best *normal* pair" $\alpha_c^*(t)$ as the proportion of participants who agree over the most consensual pair judged by the participants tested on the same triad, but in the normal condition. We then average over all triads in the condition. With the same example as above, $\alpha^*_{SM}(t)$ is the proportion of participants who, when presented the triad composed of the spliced variants of the two sonatas and the jazz piece, judge that the pair of most similar stimuli is the one composed of the two spliced sonatas.

We observe the following:

- There is a significant degradation of agreement in the spliced conditions over the pairs most agreed on in the normal conditions, i.e., if two stimuli are consensually judged similar to one another in their normal condition, their spliced variants are not necessarily judged similar. This is true[15] for music ($[\alpha_{NM}]=0.86>\alpha^*_{SM}=0.53$, $F(1,48)=6.78$, $p=0.012$] as well as soundscapes [$\alpha_{NS}=0.91>[\alpha^*_{SS}]=0.77$, $F(1,48)=6.28$, $p=0.016$].
- However, the degradation due to splicing is 2.5 times more severe for music than for soundscapes: The agreement difference $\alpha_{NM}(t)-\alpha^*_{SM}(t)$ ($M=0.33$, SD=0.27) is larger than $\alpha_{NS}(t)-\alpha^*_{SS}(t)$, ($M=0.13$, SD=0.25) with statistical significance [$F(1,44)=6.38$, $p=0.015$].

SSs have only slightly different similarity relations to one another than in the normal condition, whereas the relations consensually judged in NM are lost when it is spliced. This opposes all effects found on categorization, which is equally hindered for music and soundscapes (and even more for soundscapes in the case of "source" categories).

IV. DISCUSSION

We find that splicing significantly impedes the recognition of source, mood, and type descriptions that can be consensually made (by our tested participants) for stimuli in their normal condition. We also find that splicing has a significant, but small influence on similarity performance for soundscape signals; for music, however, the similarity relations that are consensually established for normal signals are completely lost by splicing.

The difference observed between music and soundscape signals when spliced may result from several undesired effects. First, similarity judgments could be more difficult (i.e., less consensual) for music than for soundscapes even in the normal condition. However, we found that similarity judgments for NM signals are as consistent across participants as judgments for NS signals [$\alpha_{NM}=0.70<\alpha_{NS}=0.77$, but $F(1,86)=3.34$, $p=0.071$], so this effect is ruled out.

Second, judging the similarity of SM may be a more disorienting task than for SSs. But again, we found that similarity judgments for spliced signals are as consistent as judgments for normal signals ($\alpha_{NM}=0.70>\alpha_{SM}=0.66$ [$F(1,86)=1.27$, $p=0.262$]; $\alpha_{NS}=0.77>\alpha_{SS}=0.76$ [$F(1,86)=0.13$, $p=0.719$]). Poor similarity precision on SM is *consistently* observed for all participants.

Third, our results may be explained by the participants' lack of training for the task of listening to spliced signals. While a positive effect of training cannot be ruled out, it is interesting to note that judgments made on spliced signals reach the same degree of consensus than judgments made on ecologically valid, normal signals. For instance, the categories judged for spliced stimuli are as consistent as the categories for normal signals, e.g., for music moods [$\beta_{NM}(\text{mood})=0.90<\beta_{SM}(\text{mood})=0.90$, $F(1,26)=0.03$, $p=0.873$], types [$\beta_{NM}(\text{type})=0.85<\beta_{SM}(\text{type})=0.85$, $F(1,22)=0.00$, $p=0.998$], or sources [$\beta_{NM}(\text{source})=0.86<\beta_{SM}(\text{source})=0.83$, $F(1,29)=0.35$, $p=0.561$].

Finally, the difference observed between music and soundscapes may result from uncontrolled recognition effects of familiar music. If participants recognize the music stimuli used in the experiment, they may judge music similarity in the normal condition based on extra-acoustical information such as the artists' country. Since this recognition

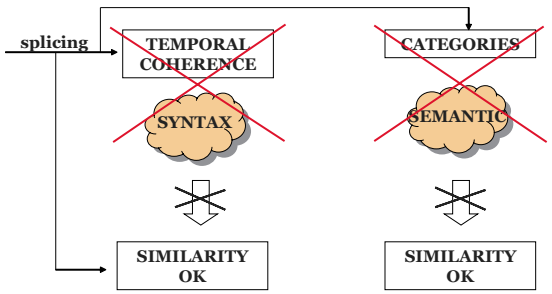

FIG. 1. (Color online) A schematic representation of the links found here between similarity, syntax, and semantics for soundscape perception. Splicing affects the temporal coherence of the audio signals, which was found to hinder activation in brain centers responsible for the processing of linguistic syntax. Since splicing preserves soundscape similarity to a large extent, we find here that soundscape similarity does not logically require syntactic processing of the type involved by speech and music (left). Moreover, splicing is found to hinder categorization. Therefore, soundscape similarity does not require the identification of the categories usually elicited by normal stimuli, most notably sound sources (right). See main text for details.

is likely lost when spliced, this information cannot be recruited to compare SM, and performance is degraded. For soundscapes, however, this recognition effect is negligible, which could explain the lesser difference from normal to spliced. This explanation can probably be ruled out, too. First, we found in debriefing the experiments that the participants did not recognize the stimuli in the NM condition (pieces that are relatively well known in the western world are not necessarily well known in Japan). Second, it was recently reported that listeners can make a distinction between familiar and unfamiliar music even in spliced stimuli with frame size between 50 and 100 ms.[16]

A. Splicing and syntax

Spliced signals sound distinctively unnatural. Physically, splicing preserves long-term statistical distributions of frames as well as local spectral content (since each individual frame is left untouched), but loses short-term dynamical relationships between frames. In particular, the frame rate adopted here is typically faster than the note rate in music, so even intra-note consistency (transient, sustain, and decay) is not preserved. Brain imaging studies show that spliced musical signals (for frame size around 500 ms) engender decreased activation in the left inferior frontal cortex,[17,18] a region closely associated with the processing of linguistic structure, or *syntax*, in spoken and signed languages.

We found here that humans are capable of comparing soundscapes in a way which resists splicing: Two soundscapes deemed similar to one another in normal condition are likely to be also found similar when listened in spliced condition. This suggests that judging the similarity of soundscapes does not require syntactic processing of the type involved by speech and music (Fig. 1, left). Whether syntactic processing is activated by the perception of non-SSs but contributes little, or whether it is simply not recruited even in normal situations, is left open for further investigation.

B. Splicing and semantics

Our results confirm that splicing is a categorization mask for non-speech audio signals. Degraded agreements for "true" categorical values, but not for "false" values, show that splicing masks the recognition of normally perceived categories (increased number of false negatives), but does not introduce any confabulated categories (no significant increase in false positives): One may not hear guitar in a spliced guitar signal, but one is unlikely to hear piano instead. This effect is the same for music and soundscapes.

These results are consistent with the use of splicing for speech signals,[11] and can be easily explained by the well-documented importance of the temporal envelopes for, say, musical instrument recognition.[5] However, they appear to contradict studies focusing on the perception of very short sounds. In a 1999 study (published only recently), Gjerdingen and Perrott[19] observed that, given as little as 250 ms of audio, human listeners were able to recognize the genre of a musical extract correctly more than 70% of the times. Similar effects were reproduced for further categories (including moods) for extracts as small as 50 ms,[20] which is the size of the frames we use here. That this ability should not hold for *sequences* of frames is intriguing and could point to an important role of short-term memory and attentional processes.

From our data, it is difficult to clarify the causal relation between loss of temporal coherence (by construction) and distorted ability to categorize. Friend and Farrar[21] studied the effect of splicing speech on judgments of the speaker's affective state, and found that it increased ratings of anger and excitement. They suggested that this depends on the speech-mimetic features of the resulting time series. Spliced signals contain regular artificial transients (due to the arbitrary concatenation of non-adjacent frames) and give an impression of high tempo and limited pausing regardless of the original signal. These features are often correlates of anger in normal speech. For music and soundscapes, we observed here that splicing typically did not introduce confabulated categories, and we could not find any systematic effect of splicing on the categorization of mood descriptions. However, similar effects cannot be ruled out and should be further investigated.

C. Soundscape similarity does not require categorization

The better similarity results obtained in spliced condition for soundscapes than for music could be explained by a possible recognition effect, which would be retained in the case of soundscapes. If more analytical details (i.e., descriptions) were preserved in SSs than in SM, then their comparably better similarity could be based on a comparison of high-level features in the way proposed by Tversky.[2] However, we found that splicing degrades categorization to a similar degree for both music and soundscape, and even to a greater degree for soundscapes when considering sound sources, so this effect can be ruled out. The fact that splicing preserves more of the music sources (instruments) than of the soundscape sources would in effect predict better similarity performance for music than for soundscapes, if based on analytical features. Moreover, we find here that relatively

good soundscape similarity does not require source, mood, or type categorization (we have the former without the latter in the spliced condition) (Fig. 1, right).

First, this suggests that a significant part of the process of comparing two soundscapes does not require high-level semantic features, but rather relatively raw representations, arguably generic. Second, this result indicates, in particular, that humans are able to give accurate and consensual judgments of the similarity of soundscapes with no prior recognition of their constituent sound sources. This is a surprising result, in apparent contrast with previous studies, which usually conclude that perceptive judgments of categorization and similarity on soundscapes are based on the identification, and then connotation, of sources. Psycholinguistic studies[9] only report on correlations. There are well-studied effects of "*a posteriori* rationalization" in such methodologies,[22] in which participants produce a lexical explanation ("because there are cars") for a cognitive process (here, "these two soundscapes are similar"), which may be independent from these causes.

We should be careful in concluding too strongly on "similarity without categorization." It is probably impossible to prevent categorization in normally cognitive participants, even for highly distorted stimuli such as the ones used here. What we are losing here by splicing is referential categorization in the conceptual system associated with normal stimuli: Participants find it impossible to map a spliced stimulus to categories that apply for normal stimuli, such as "piano" or "dog bark." However, when presented a spliced stimulus, participants likely build categories in a *ad hoc* semantic system adapted to spliced sounds (e.g., "sounds that go *flpflpflp*"). What we find here is that these *ad hoc* categories bear no relation with the "natural" categories: This spontaneous categorization of spliced signals does not help the participants retrieve the categories used for normal conditions. It is possible yet, if properly trained with pairs of normal and spliced stimuli, that participants can learn a mapping between both semantic systems, e.g., learn that "sounds that go *flpflpflp*" are usually spliced variants of songs containing *guitar*.

D. Does music similarity require categorization?

We found here that severely degraded music similarity (−33% agreement) is correlated with severely degraded categorization (cf. −30% agreement). From these data, we cannot conclude on the causality between these two processes. First, maybe similarity requires categorization, i.e., two music stimuli that are said to "sound the same" can only be said so because they are first categorized with a variety of descriptors (e.g., musical instruments, moods, etc.) and then found to share a significant number of such descriptors. If this is so, then splicing acts as a content mask on categorization and impedes similarity by hurting its prerequisite. Conversely, maybe categorization requires similarity, i.e., music classification operates as an exemplar matching process[23] based on a partly generic assessment of similarity (e.g., if it sounds like a rock song, then it is rock). The content-masking property of splicing could then be the consequence, rather than the cause, of this degraded similarity. Finally, maybe music categorization and similarity operate in conditional independence given a common cause, such as syntactic processing, which is degraded by splicing. This should be submitted to further investigation, e.g., with the help of brain imaging techniques, which are increasingly used to characterize semantic processing both for music[24] and natural sounds.[25]

ACKNOWLEDGMENTS

The authors would like to thank Brian Gygi, Geraint Wiggins, and anonymous reviewers for their useful comments. This research was partially funded by a JSPS Postdoctoral Fellowship for Foreign Researcher. Yusuke Kanayama helped with the logistics of the experimentation and Masumi Nasukawa with the Japanese translation of our instructions.

APPENDIX: DESCRIPTIONS USED IN CATEGORIZATION TASK

The following are descriptions for NM and SM:

- Sources: acoustic guitar, bass, brass (trumpet, etc.), drums, electric guitar (saturated), electric guitar (clear), harmonica, piano, strings (violin, etc.), synthesizer, vocals (male), vocals (female), and wind (flute, etc.).
- Moods: aggressive, calm, carefree, cerebral, cold, energetic, fun, happy, intimate, party/celebratory, passionate, plaintive, sad, and tense/anxious.
- Types: blues, club/dance, classic rock and roll, contemporary rock, country, electronic, experimental, folk, hard rock, heavy metal, jazz, pop, punk, and psychedelic.

The following are descriptions for NS and SS:

- Sources: car, truck, bus, bird, voice (male), voice (female), voice (children), boat, motorbike, footsteps, plane, train, industrial machinery, building site equipment, dog bark, water noise (rain, sea), collision noise, and car horns/siren.
- Moods: calm, disturbing, familiar, noisy, pleasant, restful, stimulating, stressful, unbearable, and unpleasant.
- Types: airport, avenue, calm street, construction site, factory, highway/motorway, intercity road, outway for emergency vehicles, park, railway, school yard, shopping/pedestrian street, street market, and technical equipment.

The masking of interaural delays

Andrew J. Kolarik and John F. Culling[a)]
School of Psychology, Cardiff University, Tower Building, Park Place, Cardiff CF10 3AT, United Kingdom

(Received 5 December 2006; revised 26 January 2009; accepted 28 January 2009)

Four experiments measured discrimination of interaural time delay (ITD) thresholds for broadband noise in the presence of masking noise of the same bandwidth as the target (0.1–3 kHz for experiments 1–3 and 0–10 kHz for experiment 4). In experiments 1–3, listeners performed interaural two–interval two–alternative forced–choice (2I-2AFC) delay discrimination tasks with stimuli composed of delayed and masking noises mixed in proportions of delayed noise ranging between 1 and 0.05. Experiments 1–3 employed interaurally correlated, anticorrelated, and uncorrelated maskers, respectively. Experiment 4 measured centering accuracy for continuous noise with a range of interaural coherences (equivalent to proportion of delayed noise) obtained by mixing delayed and interaurally uncorrelated noises. Results indicate that in the presence of an interaurally correlated masker ITD thresholds doubled for every halving of the proportion of delayed noise power in the stimulus. This function became steeper as the masking noise changed from interaurally correlated, to uncorrelated, to anticorrelated. The results were compared to thresholds predicted by a model based on variations in the distribution of interaural phase differences of the stimulus components.

I. INTRODUCTION

Listeners can use three primary acoustic cues for sound localization: interaural time differences (ITDs), interaural level differences (ILDs), and spectral cues introduced by the head, torso, and pinnae. At low frequencies, listeners tend to rely on the ITD cue for sound lateralization (Wightman and Kistler, 1992). At higher frequencies, listeners tend to rely on ILDs to lateralize sounds (Kuhn, 1977). Elevation and disambiguation between the frontal and rear hemifields are provided by monaural spectral changes in the sound caused by reflections among the corrugations of the pinna (Lopez-Poveda and Meddis, 1996), head movements that change the binaural cues (Perret and Noble, 1997), and movements of the sound source that the listener controls (Wightman and Kistler, 1999). In spite of these cues, the presence of masking noise has a debilitating effect on listeners' abilities to localize sounds. In order to quantify these effects, a range of studies has investigated localization (Jeffress *et al.*, 1962; Good and Gilkey, 1996) and lateralization (Egan and Benson, 1966; Cohen, 1981; Ito *et al.*, 1982) in the context of masking noise. The effect of masking noise in the presence of delayed noise is also important when modeling binaural temporal windows using a lateralization paradigm (Wagner, 1991; Bernstein *et al.*, 2001).

Previous research has demonstrated the adverse effects of masking noise on ITD discrimination, and that different types of masking noise vary in their impact on listeners' abilities to lateralize narrow-band signals. Specifically, lateralization of a signal embedded in masking noise is least disrupted by the presence of interaurally correlated noise and most disrupted by anticorrelated noise, with disruption from uncorrelated noise falling between the two.

Egan and Benson (1966) investigated listener's abilities to lateralize a monaural tone with a duration of 250 ms at frequencies of 500 and 390 Hz embedded in binaural noise (either interaurally correlated or uncorrelated). Lateralization thresholds were obtained by varying the signal-to-noise ratio (SNR) adaptively using a 2I-2AFC task. In the presence of interaurally correlated noise, lateralization thresholds were found to be 4–5 dB lower than when an uncorrelated masker was present.

Cohen (1981) measured ITD just-noticeable-differences (jnds) around zero ITD for a 250 Hz sinusoid presented against broadband masking noise which was interaurally correlated, uncorrelated, or anticorrelated. The ITD jnd was measured as a function of SNR. For a constant SNR, jnds were highest for the anticorrelated masking condition and lowest when the masker was interaurally correlated. jnds were intermediate when the masker was uncorrelated. The slope of the thresholds versus SNR was steeper when the masker was uncorrelated than when the masker was interaurally correlated, and the two slopes converged at approximately 19 dB above N0S0 detection threshold (denoted MoSo in Fig. 2 of Cohen, 1981). Thus, at high SNRs, ITD jnds were at their lowest and equal for both interaurally correlated and uncorrelated masking noises. At lower SNRs, jnds were larger when the masker was interaurally uncorrelated. When the masker was interaurally anticorrelated, ITD jnds were larger than jnds for interaurally correlated and uncorrelated masking noises, and increased as SNR was reduced.

Finally, Ito *et al.* (1982) measured interaural time jnds for narrow-band noise (1/3 octave wide) in the presence of a broadband masker. jnds were measured at a fixed SNR for a range of interaural configurations of the masker: interaurally correlated, anticorrelated, and uncorrelated, plus quiet (no masker), and six conditions that manipulated the perceived

lateral position of the masker. Similar to Cohen's (1981) study using tonal stimuli, jnds were smallest for the interaurally correlated masking condition, larger for the uncorrelated masker, and largest for the anticorrelated masking condition. No consistent relation was observed between the perceived lateral position of the masker and the magnitude of the jnd. Ito *et al.* (1982) were able to successfully model the hierarchy of ITD jnds for each interaural configuration of the masker using a model based on variations in the distribution of interaural phase differences of the stimulus components.

This effect of masking noise on ITD processing has been used in studies that have investigated the temporal resolution of the binaural system. Temporal resolution can be modeled using a temporal window that is described by one or more time constants, the duration of which describes the resolution of the system. In the studies of Wagner (1991) and Bernstein *et al.* (2001), temporal windows were measured for barn owls and human participants, respectively, by presenting a burst of interaurally delayed noise (the probe) temporally contiguous with masking noise. It was assumed that the listener detects the ITD imposed on the probe by centering a temporal window at the midpoint of the probe in order for the maximum amount of interaurally delayed noise to fall within the window. The window integrates together the instantaneous interaural delays of the probe with the interaural delays of the masking noise that also falls within the window. In order to model a temporal window, it is assumed that the integration results in an internal, effective ITD that is lower than the external ITD imposed on the probe (Bernstein *et al.*, 2001). Given that the probe and surrounding noise have equal power, the integration should yield the same internal ITD value as direct mixing at the same energy ratio. As a result, the external ITD must be increased to a magnitude that will bring the internal ITD up to threshold. When the probe duration is long, ITD thresholds will be low as very little masking noise enters the window, reducing the internal effective ITD. As the probe duration decreases, more masking noise enters the window and is integrated with the probe ITD, increasing ITD threshold.

It is important to quantify the effect of the masking noise on ITD threshold, as this is explicitly modeled during the window fitting procedure. Best-fit ITD thresholds are calculated by using a coefficient that relates threshold to proportion of delayed noise present. Bernstein *et al.* (2001) effectively assumed that when a broadband interaurally delayed noise target (N_τ) is heard in the presence of masking interaurally correlated or uncorrelated noise (N_0 or N_u), the effective internal ITD is doubled for each halving of the proportion of delayed noise present within the window; that is, that the masking noise dilutes the interaurally delayed noise. Having fit windows using the dilution assumption in the case of interaurally correlated masking noise, Bernstein *et al.* (2001) assessed how well the same windows fitted data in the case when the masking noise was interaurally uncorrelated. They were modeled using the same assumption, but with an adjustment to account for a change in sensitivity, as thresholds in the presence of interaurally uncorrelated masking noise were higher than corresponding thresholds when the masker was interaurally correlated. Experiments 1 and 3 investigate whether the dilution assumption is valid for interaurally correlated and uncorrelated masking noises, respectively.

In the latter case, the dilution assumption appears to run contrary to the findings of Jeffress *et al.* (1962), who measured participants' centering judgments at a range of interaural correlations by mixing interaurally correlated and uncorrelated noises. The data of Jeffress *et al.* (1962) show that for each halving of the coherence (which is equivalent to the proportion of delayed noise present), thresholds are substantially *less than* doubled (see Figs. 4 and 5, bottom right panel).

The following experiments investigate the effects of masking interaurally correlated (experiment 1), anticorrelated (experiment 2), and uncorrelated (experiments 3 and 4) noises on participants' ability to lateralize broadband noise using the localization cue provided by ITD, by directly mixing the target and masking noise in various proportions.[1] The aims of these experiments were fourfold.

The first aim was to test the dilution assumption in the case of interaurally correlated, anticorrelated, and uncorrelated maskers; when a broadband interaurally delayed noise target (N_τ) is heard in the presence of masking noise, does the detectable ITD double for each halving of the proportion of delayed noise present?

The second aim was to compare listeners' abilities to lateralize a signal embedded in noise to previous studies. The results of Cohen (1981) and Ito *et al.* (1982) found the smallest ITD jnds for interaurally correlated masking conditions, larger jnds for uncorrelated maskers, and the largest jnds for anticorrelated masking conditions. If the results of the current experiments follow this ordinal relationship among masking noises, then ITD threshold slope as a function of proportion of delayed noise present for interaurally uncorrelated masking noise will fall between the anticorrelated and the correlated masking noise slopes. Results with an interaurally uncorrelated masker can be directly compared to those of Jeffress *et al.* (1962), but comparisons with Egan and Benson (1966), Cohen (1981), and Ito *et al.* (1982) are complicated by the difference in bandwidth of the delayed signal.

The third aim was to quantify the effects of masking noise in order to apply the findings to the modeling techniques employed when measuring the binaural temporal window using a lateralization paradigm. This was achieved by measuring masking coefficients (the slope describing ITD threshold versus proportion of delayed masking noise) for interaurally correlated, anticorrelated, and uncorrelated masking noises.

The fourth aim was to compare the results of the experiments to thresholds predicted by the model of Ito *et al.* (1982), which is based on interaural phase difference.

II. METHODS COMMON TO EXPERIMENTS 1–3

The stimuli were generated digitally with a sampling rate of 44.1 kHz and 16-bit sample depth using MATLAB, band-limited between 100 and 3000 Hz prior to presentation, and gated with 10-ms raised-cosine onset and offset ramps. Listeners were presented with the stimuli over Sennheiser

HD590 headphones at an overall sound level of 75 dB (A), played through a 24-bit Edirol UA-20 sound card and passed through an MTR HPA-2 headphone amplifier in a single-walled Industrial Acoustics Company (IAC) sound-attenuating booth within a sound-deadened room. Trial-by-trial feedback was provided. Interaural time delays were imposed on the stimuli by adding a ramp function to the phase spectrum at one ear, resulting in an ongoing ITD (i.e., no onset-time difference).

III. EXPERIMENT 1: INTERAURALLY CORRELATED MASKING NOISE

In the first experiment, participants were given a 2I-2AFC discrimination task, where noise with an interaural correlation of 1 was mixed with interaurally delayed noise so that each interval was composed of delayed noise and correlated noise mixed at a predetermined proportion. Half the delay was imposed on interval 1, and half the delay, in the opposite direction, was imposed on interval 2. Consistent with the model of Bernstein *et al.* (2001), it was hypothesized that for each halving of the proportion of delayed noise present, the threshold ITD would double. Thus, on a log-log plot, according to the dilution assumption, as the proportion of delayed noise decreased and more interaurally correlated noise was mixed into the stimuli, thresholds would increase in a linear manner on a 1:1 slope. The slope describing ITD threshold versus proportion of delayed interaurally correlated noise was defined here as the correlated masking coefficient (CMC).

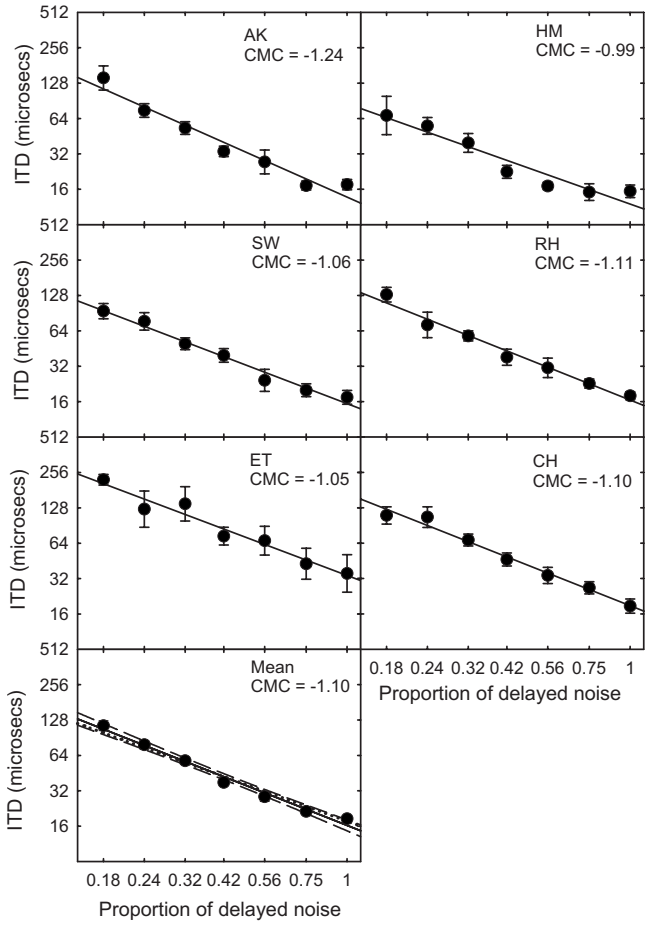

FIG. 1. Results for experiment 1 (correlated masker). Solid regression lines are plotted for individual listeners and the mean. The dotted line represents a slope of −1. Dashed lines represent 95% confidence intervals. Both axes are plotted logarithmically.

A. Stimuli and procedure

Six participants (including one of the authors) took part in the experiment. One was male and five were female, aged between 18 and 25. All participants except for ET and RH had previous experience with psychophysical experiments. Untrained participants received at least 5 h of training before data collection. Excluding the author, they were paid upon completion.

Listeners' performed a two-interval discrimination task. Three independent Gaussian noises were generated (N_1 and N_3), and a delayed copy of $N_1(N_2)$. The magnitude of the delay imposed on N_1 was half that of the delay difference between the two intervals. To keep the power constant, the noises were scaled in amplitude in the following manner, such that p is the proportion of the total power of the stimulus that is made up of delayed noise.

$$\text{Left channel: } \sqrt{p}N_1 + \sqrt{1-p}N_3. \quad (1)$$

$$\text{Right channel: } \sqrt{p}N_2 + \sqrt{1-p}N_3. \quad (2)$$

The second interval was created using the same procedure, except that the delayed noise was presented to the opposite ear. The adapted variable was the difference in ITD between the two intervals. The inter-stimulus interval was 500 ms, and each interval had a duration of 100 ms. ITD thresholds were obtained for $p=1$, 0.75, 0.56, 0.42, 0.32, 0.24, and 0.18.

The listener's task was to identify in which direction the sound image moved from interval to interval (left to right or right to left), corresponding to the ITDs embedded within each interval. Participants pressed "1" if the noise moved from right to left, and "2" if it moved left to right. The sign of the interaural delay was randomized and trial-by-trial feedback was provided. The ITD was varied adaptively in order to obtain a 70.7% correct estimate (Levitt, 1971). Each adaptive track started with the ITD set to 500 μs. Initially, the step size of the adaptive track corresponded to a factor of 0.2 and was reduced to a factor of 0.05 following two reversals. Threshold was obtained after a further ten reversals. The last ten reversals composed a measurement phase, and the average of the reversals within the measurement phase was taken as threshold.

Each listener performed nine experimental runs. Measurement began after performance had stabilized; experimental thresholds were taken by averaging the remaining runs after the listener achieved thresholds below 500 μs at each proportion of delayed noise (nine runs for AK, CH, RH, and SW, eight runs for HM, and four runs for ET).

B. Results

Figure 1 shows threshold ITDs measured at different proportions of delayed noise mixed with interaurally correlated noise. When $p=1$, all the noise within each interval was delayed, producing the lowest thresholds for the six listeners (an average of 18.5 μs). Threshold ITD was found to approximately double for each halving of delayed noise present. The slope of the regression line of the mean observed data was -1.10 and accounted for 98% of the variance. The dotted line represents predicted values based on a CMC of -1 and falls within the 95% confidence intervals of the mean data, showing that the data do not deviate significantly from this trend.

C. Discussion

As the proportion of delayed noise decreased and more interaurally correlated masking noise was mixed into the intervals, thresholds increased in a log-linear manner on an approximately 1:1 slope so that for each halving of the delayed noise present, the threshold ITD doubled, supporting the dilution assumption of Bernstein *et al.* (2001).

The following two experiments characterized the effect of interaurally anticorrelated (experiment 2) and uncorrelated (experiment 3) masking noises on ITD threshold and examined whether thresholds change in the same manner as they do in the presence of interaurally correlated masking noise. However, we modified the method for these experiments compared to experiment 1 because we anticipated a potential problem. If one considers cross-correlation as a mathematical approximation to human ITD processing, the effect of increasing ITD will be to move a peak in the cross-correlation function further and further from zero. As ITD increases, the contrast between the cross-correlation functions for a positive and a negative ITD increases monotonically as the peaks separate. However, as there must be some limit to the range of delays over which cross-correlation is performed by the auditory system, this contrast eventually saturates and begins to decline, suggesting that discrimination performance will decline once again. Perceptually, the laterality reaches an extreme at somewhere around the ecological limit of naturally occurring ITDs, and then images start to become diffuse (Blodgett *et al.*, 1956). Adding interaurally uncorrelated noise can only be expected to make the task harder, as the noise will reduce the size of the cross-correlation peaks without altering their locations. Cohen (1981) and Ito *et al.* (1982) found that both interaurally uncorrelated and anticorrelated masking noises produced higher ITD jnds than correlated masking noise, raising the danger that, for a low proportion of delayed noise, threshold might be close to a nonmonotonic section of the underlying psychometric function. With these facts in mind, we decided to obtain psychometric functions in experiments 2 and 3, rather than the adaptive track paradigm in order to avoid potential violation of assumption 1 of Levitt (1971) (p. 468): "The expected proportion of positive responses is a monotonic function of stimulus level (at least over the region in which observations are made)."

To obtain a psychometric function, stimuli were produced with a range of fixed ITDs, and the percentage of correct responses at each ITD was recorded. From these data, the 71% correct point of the psychometric function can be interpolated from a fitted function to obtain threshold values that can be directly compared to those obtained using the adaptive track method.

IV. EXPERIMENT 2: INTERAURALLY ANTICORRELATED MASKING NOISE

The log-linear slope describing ITD threshold versus the proportion of interaurally anticorrelated noise was defined here as the anticorrelated masking coefficient (AMC). This was measured in experiment 2.

A. Stimuli and procedure

Three participants (including one of the authors) took part in the experiment. One was male and two were female, aged between 18 and 28. All participants had previous experience with psychophysical experiments. Excluding the author, they were paid upon completion.

Listeners' performed a 2I-2AFC discrimination task. Stimuli were generated in the same way as in experiment 1, but with interaurally anticorrelated (correlation$=-1$) rather than correlated masking noise. That is to say, using Eqs. (1) and (2) except that N_3 was inverted in one channel. Intervals were presented so that the delayed noise in the first interval was presented to the ear favored by the interaural delay embedded in the interval, and the delayed noise in the second interval presented to the opposing ear. The inter-stimulus interval was 500 ms.

The listener's task was to identify in which direction the sound image moved between the two intervals (left to right or right to left), corresponding to the ITDs embedded within each interval. The direction of ITD change was randomized and trial-by-trial feedback was provided. The participants were tested at a stimulus duration of 100 ms with ITDs of 1024, 512, 256, 128, 64, 32, 16, and 8 μs. Initially, a block of trials was presented with proportions of 1, 0.5, 0.2, and 0.1, the order in which the eight ITDs were presented within the block was randomized, and 20 trials were repeated for each ITD. A second block of trials with proportions of 0.75, 0.25, 0.15, and 0.05 followed. Each block consisted of 8 ITDs$\times$4 proportions$\times$20 repetitions$=$640 trials in all. Following two training runs, participants performed three experimental runs at each proportion. The average of the three runs was taken as threshold. Two-parameter (slope and threshold) logistic functions were fitted to the data, and the 71% points of the functions were taken as thresholds in order to compare the thresholds with those taken in experiment 1 using the adaptive track procedure.

B. Results

Figure 2 shows threshold ITDs measured at different proportions of delayed noise mixed with interaurally anticorrelated noise. When $p=1$, all the noise within each interval was delayed, producing the lowest thresholds for the three listeners. Although listener EO's thresholds were substan-

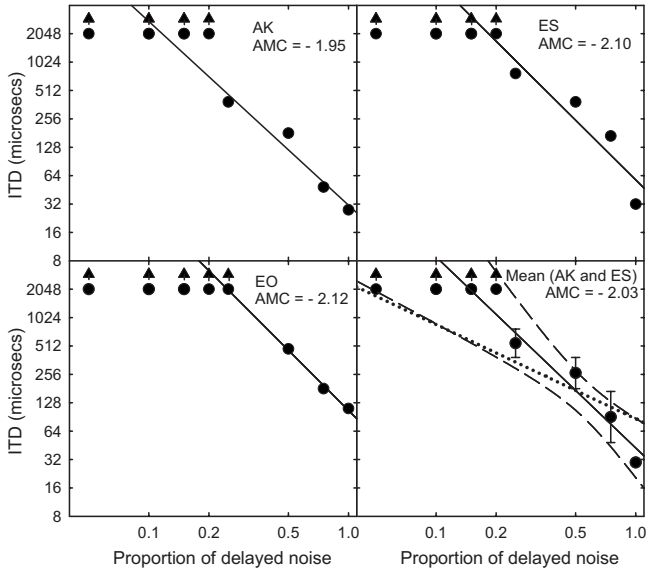

FIG. 2. Results for the experiment 2 (interaurally anticorrelated masker). Solid regression lines are plotted for individual listeners and the mean. Mean thresholds are plotted as an average across data for listeners AK and ES only, as listener EO displayed lower sensitivity than these listeners. Upward pointing arrows indicate that a measure of threshold could not be obtained for those coherences as the 71% point of the psychometric function fell outside the measured range. The dotted line represents a slope of −1. Dashed lines represent 95% confidence intervals. Both axes are plotted logarithmically.

tially higher than those of other listeners, the slope relating threshold to proportion of delayed noise present was approximately equal to that of other listeners, indicating that the sensitivity of this listener was lower than that of the others.[2] Consequently, mean thresholds in the bottom right panel of Fig. 2 are plotted as an average of listeners AK and ES only. Threshold ITD was found to more than double for each halving of delayed noise present. The slope of the regression line of the mean observed data was −2.03 and accounted for 92% of the variance. The dotted line represents predicted values based on a slope of −1 and falls outside the 95% confidence intervals of the mean data (represented by dashed lines in Fig. 2), showing that the slope of the data is significantly steeper than −1.

C. Discussion

As the proportion of delayed noise decreased and more interaurally anticorrelated noise was mixed into the intervals, thresholds increased in a log-linear manner on a slope of −2.03 so that for each halving of the delayed noise present, the threshold ITD more than doubled. As the slope of ITD thresholds was steeper than that observed when an interaurally correlated masker was employed (i.e., −1, see Fig. 1), the presence of interaurally anticorrelated noise was more disruptive to listener's abilities to lateralize a signal embedded in noise than interaurally correlated masking noise. These results follow the same hierarchy as those of Cohen (1981) and Ito *et al.* (1982), who found that ITD jnds were larger for interaurally anticorrelated than correlated masking conditions.

V. EXPERIMENT 3: INTERAURALLY UNCORRELATED MASKING NOISE

In experiment 3, the effect of interaurally uncorrelated masking noise on ITD threshold was assessed using stimuli comparable to experiments 1 and 2. The interaural coherence of each interval was manipulated by mixing interaurally delayed and uncorrelated noises. Note that when interaurally delayed and uncorrelated noises are added, the interaural coherence is equal to the proportion of delayed noise power in the stimulus, so the proportion of delayed noise is numerically equivalent to the coherence and to the interaural correlation when the noise delay is zero. The slope describing ITD threshold versus the proportion of interaurally uncorrelated noise was defined here as the uncorrelated masking coefficient (UMC).

Results obtained using an interaurally uncorrelated masker can be directly compared with those of Jeffress *et al.* (1962), who investigated the effect of interaural correlation on the ability of participants to center a noise. In that study, interaurally correlated and uncorrelated noises were mixed in each ear to obtain interaural correlations of 1, 0.75, 0.5, 0.25, 0.2, 0.15, 0.1, and 0. Participants adjusted a delay line in the presence of continuous noise in order to center the noise in their heads. The standard deviation of each participant's centering judgment was measured as a function of interaural correlation. This standard deviation should, in principle, be equivalent to an ITD threshold. The slope relating such a threshold ITD to correlation/coherence/proportion of delayed noise was −0.48 (see Fig. 4, bottom right panel). This slope is considerably shallower than the CMC values observed in experiment 1 with interaurally correlated masking noise that ranged from −0.99 to −1.24 (see Fig. 1).

To examine any effects of stimulus duration in experiment 3, participants were tested at three stimulus durations (100 ms, 500 ms, and 1 s). The long-duration stimulus conditions were included in order to be more comparable with the experiment of Jeffress *et al.* (1962) in which continuous noise was used.

A. Stimuli and procedure

Three listeners took part in experiment 3. One (the first author) was male and two were female, aged between 18 and 25. All listeners had participated in experiment 1. Excluding the author, they were paid upon completion.

Listeners' performed a 2I-2AFC discrimination task. To manipulate coherence, two independent Gaussian noises (N_1 and N_2) were generated and mixed: the left channel was presented containing noise N_1, and the right channel contained a mixture of two noises N_1 (delayed) and N_2 mixed in the proportion (p).

$$\text{Left channel:} N_1. \tag{3}$$

$$\text{Right channel:} pN_1 + \sqrt{1-p^2}N_2. \tag{4}$$

An interaural delay was added to one channel after noise mixing. Participants were tested at stimulus durations of 100 ms, 500 ms, and 1 s. Following two training runs, participants performed three experimental runs for each coherence

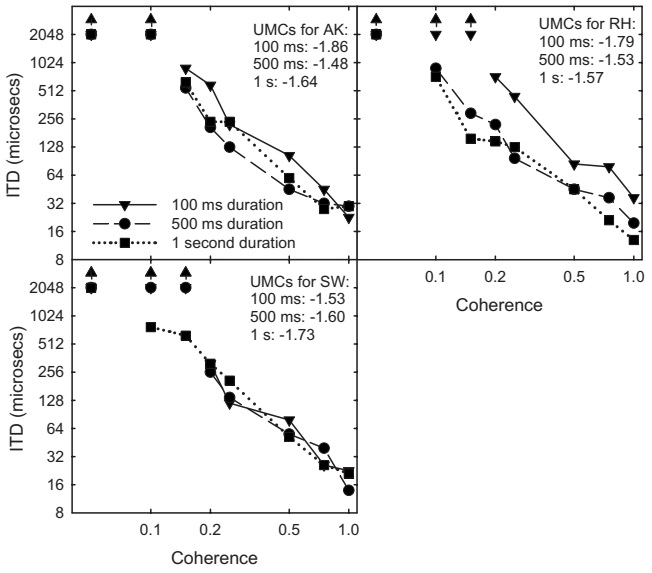

FIG. 3. Individual data for experiment 3 (interaurally uncorrelated masker) for stimulus durations of 100 ms (downward pointing filled triangles joined by solid lines), 500 ms (filled circles joined by dashed lines), and 1 s (filled squares joined by dotted lines). Thresholds represent 71% discriminability. Upward pointing arrows indicate that a measure of threshold could not be obtained for those coherences as the 71% point of the psychometric function fell outside the measured range. Both axes are plotted logarithmically.

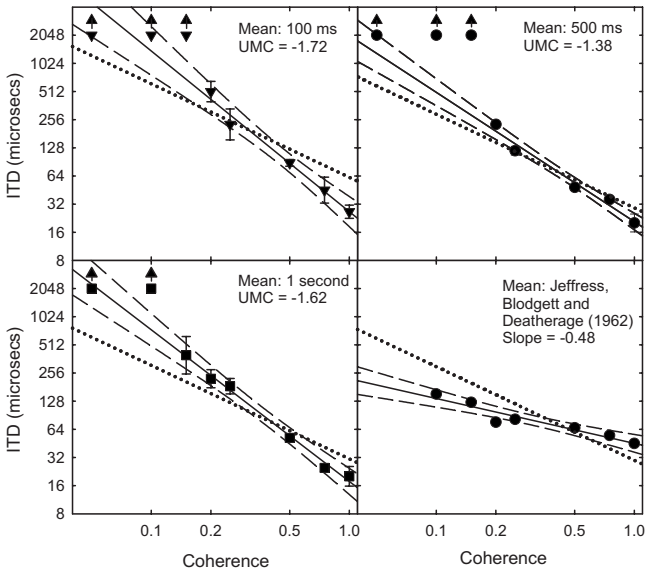

FIG. 4. Mean results for experiment 3 (interaurally uncorrelated masker). Each panel shows results at each of the three stimuli durations, and the bottom right panel shows mean data replotted from Jeffress *et al.* (1962), who used continuous stimuli. Solid regression lines are plotted for each duration. The plotted thresholds are 71% points averaged from the last three experimental runs. The dotted line represents thresholds with a slope of −1. Dashed lines represent 95% confidence intervals. Both axes are plotted logarithmically.

at each stimulus duration. Participants were tested in blocks of coherences of 1, 0.5, 0.2, 0.1, 0.75, 0.25, 0.15, and 0.05 by measuring psychometric functions using the procedure described in experiment 2.

B. Results

Figure 3 shows individual data for the three stimulus durations. UMCs ranged from −1.48 to −1.86 (for clarity, regression lines representing the UMC for each participant and duration are not plotted). The mean of the UMCs measured for individual participants across all listeners and stimulus durations was −1.64. When the coherence was unity, all the noise within each interval was delayed, producing the lowest thresholds for the three listeners. Threshold ITD was found to more than double for each halving of coherence. Thresholds at the lowest coherences could not be measured as the 71% point of the psychometric function fell outside the measurable range.

Figure 4 shows the mean of the data across listeners for the three stimulus durations. The dotted lines represent predicted values based on a UMC of −1. At all three stimulus durations the dotted lines fall outside of the 95% confidence intervals of the regression (represented by dashed lines in Fig. 4), in each case indicating that the slope of the data was significantly steeper than −1. The mean UMCs for each duration ranged from −1.38 to −1.72, which were substantially higher than the slope of −0.48 obtained by Jeffress *et al.* (1962). No consistent effect of stimulus duration was observed, and the range of UMCs obtained across stimulus duration and listener was wide (−1.48 to −1.86).

C. Discussion

As coherence decreased, thresholds rose so that each time the coherence was halved, thresholds more than doubled (see Figs. 3 and 4). Once again, this finding contrasts with the effect on ITD of interaurally correlated masking noise observed in experiment 1, where thresholds were observed to double, and indicates that the dilution hypothesis does not hold for the case where an interaurally uncorrelated masker is present.

An explanation of the differing influences of interaurally correlated, anticorrelated, and uncorrelated masking noises was put forward by Ito *et al.* (1982) based on their model. They measured interaural time jnds for narrow-band noise in the presence of a broadband masker. They were able to model the hierarchy of ITD jnds at a fixed SNR of approximately +10 dB for various interaural configurations of the masker (smallest for the interaurally correlated masker, larger for the uncorrelated masker, and largest for the anticorrelated masker). Their model was based on variations in the distribution of interaural phase differences of the stimulus components and similar to the models proposed by Webster (1951) and Jeffress *et al.* (1956).

The explanation of Ito *et al.* (1982) essentially encompassed signal detection notions of how changing the ratio between the mean (μ) and the standard deviation (σ) is predicted to affect sensitivity, that discriminability depends on the differences in the means relative to the standard deviation of the two ITD distributions. When no masking noise was present, thresholds were approximately equal for all types of masking noise (see Figs. 1–4), but when masking noise was added the distribution of ITDs became wider and the standard deviation increased, requiring an increase in the magni-

tude of ITD to support discrimination. According to this model, the slopes of the CMC, UMC, and AMC differ because, as Ito *et al.* (1982) showed, the variability of short-term estimates of ITD about their mean of zero was comparably small in the presence of an interaurally correlated masker, larger when an uncorrelated masker was present, and largest when an anticorrelated masker was present. The predictions of the model of Ito *et al.* (1982) are evaluated more fully in Sec. VI.

Steeper UMCs at all three stimulus durations were observed in the current experiment compared to the slope observed by Jeffress *et al.* (1962) (see Fig. 4). These results suggest that the shallow slope obtained in their experiment was probably not due to their use of continuous stimuli, as the UMC obtained with each stimulus duration was considerably steeper than the slope obtained by Jeffress *et al.* (1962). The following experiment was carried out in order to replicate the experiment of Jeffress *et al.* (1962), and explored the possibility that the shallow slope of their results stemmed from the narrow range of ITDs that were employed in their study.

VI. EXPERIMENT 4: REPLICATION OF Jeffress *et al.* (1962)

As described in the introduction to experiment 3, Jeffress *et al.* (1962) asked listeners to center a noise in their heads by means of adjusting a delay line with an ITD range of ± 450 μs. It is not clear whether an adjustment beyond the ITD limit resulted in the ITD reaching a hard limit where the delay line reached its maximum and the knob consequently stopped moving, or whether the sign of the interaural delay was reversed at this point, flipping the lateralization of the stimulus from one side of the head to the other. It seems reasonable to assume that the latter was the case[3] as the former would give the listener a rather obvious cue. Even so, it is possible that an unintended cue was still present. The distance from the control knob's "flipping point" when the ITD limit was reached could have been used by the listener as a method of producing relatively accurate centering. Increasing the range of the ITDs available would reduce the usefulness of this cue because the laterality produced by ITD decreases above about 1 ms (Blodgett *et al.*, 1956) which would prevent the stimulus "flipping" in perceived laterality. This possibility was addressed in the following replication of the experiment of Jeffress *et al.* (1962), where participants performed the task with ITDs ranging from ± 450 μs, 1 ms, and 2 ms. An increase in threshold slope with increasing ITD range would support the hypothesis that a restricted range provided a cue based on the stimulus flipping in laterality when the ITD limit was reached.

A. Stimuli and procedure

Three listeners took part in experiment 4. One (the first author) was male and two were female, aged between 18 and 25. The author had participated in experiments 1–3, and the others were naïve participants. Excluding the author, they were paid upon completion.

The stimuli consisted of continuous broadband (0–10 kHz) noise generated by concatenating 102.4-ms segments of noise drawn at random from a 5-s buffer. The coherence of the stimuli was manipulated using the same mixing method implemented in experiments 1 and 2, but with N_3 replaced by an independent noise at one ear. All noises were obtained from the 5-s buffer. The participants' task was to center the noise in their heads by using keyboard controls. Pressing '1' resulted in a decrement in stimulus ITD of 36 μs, '2' a decrement of 9 μs, "3" an increment of 9 μs, and "4" an increment of 36 μs. Pressing "x" terminated the program. If the ITD limit was reached, the sign of the interaural delay was reversed. Each stimulus trial was initially presented with a random ITD within the specified range. Initially, participants were presented with a block of trials with coherences of 1, 0.75, 0.5, 0.25, 0.2, 0.15, 0.1, and 0 with an ITD range of ± 450 μs in order to familiarize them with the experimental setup. Following this training, participants were given another block of trials with the ITD ranging from ± 450 μs, and blocks of ± 1 and ± 2 ms followed. This procedure was repeated three times, and the standard deviation of the three runs at each ITD range was taken as threshold.

All stimuli were generated on-line at a sampling frequency of 20 kHz using a TDT AP2 array-processor card and presented via a TDT System-2 psychoacoustic rig (DD1, PA4, FT5-9, and HB6) and presented over Sennheiser HD650 headphones at an overall sound level of 70 dB (A) in a single-walled IAC sound-attenuating booth within a sound-deadened room. Filtering was performed using an FT6 reconstruction filter with a low pass cut-off frequency of 10 kHz. No feedback was given.

B. Results

Figure 5 shows results from the replication of Jeffress *et al.* (1962) at ITD ranges of ± 0.45, ± 1, and ± 2 ms. The dotted lines represent predicted values based on a UMC of -1. The slope of the data at an ITD range of ± 0.45 ms (-0.54) was comparable to the slope obtained by Jeffress *et al.* (1962), which was -0.48. As the range increased, the slope of the data became steeper. At a range of ± 2 ms, the slope of the data (-1.67) was comparable to the UMCs observed in experiment 3.

C. Discussion

The data from experiment 4 show that the shallow slope of ITD thresholds obtained by Jeffress *et al.* (1962) was probably due to the limited range of ITDs (± 0.45 ms) that were employed in that study. The increase in threshold slope with increasing ITD range supports the hypothesis that a restricted ITD range provides a cue based on the stimulus flipping in laterality when the ITD limit was reached. Increasing the range progressively reduced the usefulness of this cue because the laterality produced by ITD decreases above about 1 ms (Blodgett *et al.*, 1956).

VII. PREDICTIONS OF THE MODEL OF Ito *et al.* (1982)

The model developed by Ito *et al.* (1982) was implemented computationally in order to compare the experimen-

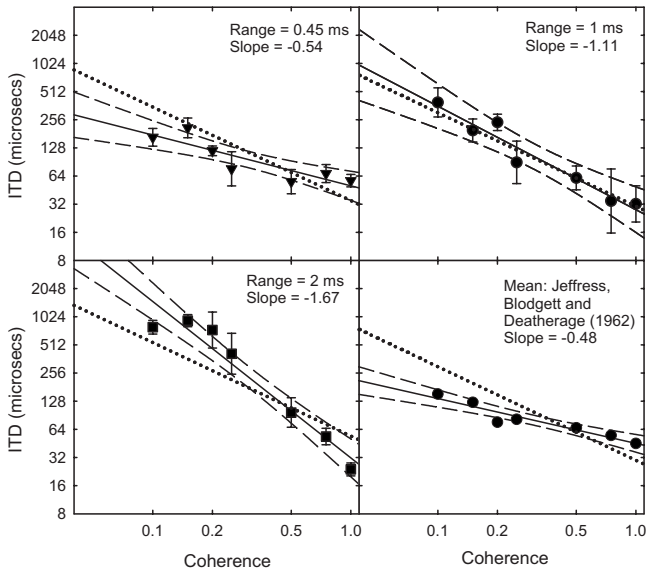

FIG. 5. Mean results for experiment 4. Each panel shows results with continuous stimuli at ITD ranges of ±0.45 μs [the range employed by Jeffress *et al.* (1962)], ±1 ms, and ±2 ms. Solid regression lines are plotted for each range of ITD. The plotted thresholds are averaged standard deviations for the three participants. The dotted line represents thresholds with a slope of −1. Dashed lines represent 95% confidence intervals. Both axes are plotted logarithmically.

tal results with thresholds produced by the model (see Appendix). Figure 6 (right panel) shows the effect of p on the predicted thresholds produced by our implementation of the model (each data point is the mean of four simulations) and compares it to the mean coefficients observed for experiments 1–3 (left panel). Interestingly, the ordinal relationship among the three types of masking noise changes as a function of p. For p below about 0.5 (corresponding to 0-dB SNR), interaurally uncorrelated noise was predicted to be the most effective masker. The fitted slope to the thresholds simulated for an interaurally correlated masker (−1.07) was very similar to the CMC obtained in experiment 1 (−1.10).

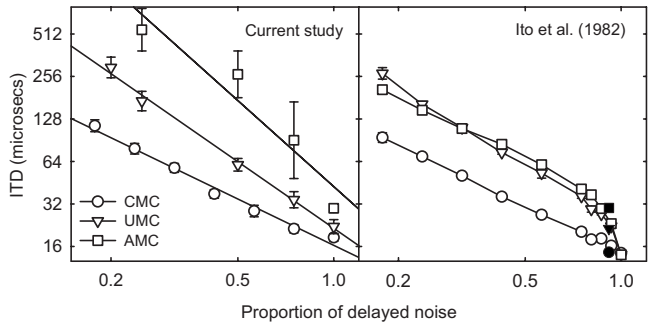

FIG. 6. Mean masking thresholds from the current study (left panel) and predicted thresholds produced by implementation of the model developed by Ito *et al.* (1982) (right panel). Circles indicate an interaurally correlated masker, triangles indicate an uncorrelated masker, and squares an anticorrelated masker. Solid regression lines are plotted for coefficients produced in the current study. The plotted CMC thresholds are averaged across all listeners, and the AMC thresholds are averaged over listeners AK and ES. Plotted UMC thresholds are averaged across all listeners and all stimuli durations. Thresholds plotted from the model of Ito *et al.* (1982) are averaged across four simulations. Filled symbols are the plotted means of thresholds taken from Fig. 1 of Ito *et al.* (1982). Both axes are plotted logarithmically.

The fitted slope for an interaurally uncorrelated masker (−1.52) was very similar to the mean UMC observed in the current study (−1.57), but the fitted slope for an anticorrelated masker (−1.35) was considerably shallower than the mean AMC observed in experiment 2 (−2.03). Thresholds simulated for masking interaurally uncorrelated and anticorrelated noises were observed to be curvilinear in the region of high correlation (see right panel of Fig. 6). Filled symbols indicate thresholds taken from Fig. 1 of Ito *et al.* (1982) for the first set of four listeners in interaurally correlated, uncorrelated, and anticorrelated conditions at a single SNR of +10.3 dB, equivalent to a proportion of delayed noise (p) of 0.915. Despite differences in the stimuli employed [the stimuli of Ito *et al.* (1982) were band-limited to 1/3 octave around 500 Hz (445–561 Hz) with a duration of 350 ms, whereas stimuli in the current experiment were broadband (0–3 kHz) with durations ranging between 100 ms and 1 s], the ordinal relation between thresholds obtained with interaurally correlated, uncorrelated, and anticorrelated masking noises and the magnitude of the ITD thresholds is similar across the two studies.

In summary, implementation of the model of Ito *et al.* (1982) produced a slope of thresholds for interaurally correlated masking noise that closely matched the CMC observed in experiment 1, and produced the ordinal relationship among the three types of masking noises for p values above approximately 0.5. However, the functions relating proportion of delayed noise to ITD threshold for interaurally uncorrelated and anticorrelated noises were incorrectly predicted to be curvilinear, and below $p=0.5$ the ordinal relationship changed, with uncorrelated noise predicted to produce more effective masking than anticorrelated noise.

VIII. GENERAL DISCUSSION

The results of the experiments described in this study indicated that the presence of masking noise resulted in an increase in the ITD threshold of delayed noise. In the case of an interaurally correlated masker, for each halving of the proportion of delayed noise present, threshold ITD doubled (i.e., ITD threshold slope=−1). ITD threshold slope was steeper than −1 in the case of an interaurally uncorrelated masker (−1.64), and steeper still in the case of an interaurally anticorrelated masker (−2.03). Thus, the experiments described in this paper indicate that masking noise with an interaural correlation of 1, anticorrelated noise, and uncorrelated noise would be integrated within a binaural temporal window in different ways. Modeling the temporal window should thus depend on the type of masker incorporated in the design of the experiment.

For example, Bernstein *et al.* (2001) measured temporal windows by presenting the listener with a burst of interaurally delayed noise (the probe) temporally fringed with masking noise. Best-fit thresholds were calculated in the following manner. First, the integral of the area occupied by the probe was computed and divided by the total integral of the window. This value represented the proportion of delayed noise within the window and is affected by the duration and the assumed shape of the window. Best-fit ITD thresholds

were then calculated by using a coefficient that related threshold to proportion of delayed noise present. By using the assumption that masking noise diluted the delayed noise, Bernstein *et al.* (2001) effectively determined predicted threshold ITDs using a coefficient of −1. The experiments described in this paper have allowed temporal windows to be measured using stimuli of a similar design to Bernstein *et al.* (2001) employing uncorrelated masking noise and determining predicted threshold ITDs using the UMC (Kolarik and Culling, 2009). When interaurally correlated masking noise is present, then the CMC (−1) should be modeled to predict thresholds, for uncorrelated masking noise the UMC (−1.64) should be modeled, and for anticorrelated masking noise the AMC (−2.03) should be modeled.

IX. CONCLUSIONS

The data described within this paper demonstrate the following conclusions.

(1) When interaurally correlated masking noise is mixed with delayed noise, ITD threshold doubles for each halving of delayed noise present.
(2) When interaurally anticorrelated or uncorrelated masking noise is mixed with delayed noise, ITD threshold more than doubles for each halving of delayed noise present. The presence of interaurally anticorrelated noise is more debilitating to the listener than the presence of uncorrelated noise.

ACKNOWLEDGMENTS

The work was supported by the EPSRC. Thanks are due to Steve Colburn and an anonymous reviewer for their helpful comments relating to earlier drafts of the manuscript. We would also like to thank Mike Akeroyd for his discerning advice and to Torsten Marquardt for his thoughtful comments. Summaries of these findings were presented at the September 2005 BSA and May 2006 ASA meetings.

APPENDIX

The model of Ito *et al.* (1982) of sensitivity to interaural delay under masking was implemented computationally using MATLAB. Stimuli similar to those used by Ito *et al.* (1982) in their experiments were generated and band-limited to 1/3 octave around 500 Hz (445–561 Hz) with a duration of 350 ms. To create the stimulus, delayed and masking noises were added together in the appropriate ratio. Ito *et al.* (1982) employed a single SNR of +10.3 dB equivalent to a proportion of delayed noise (p) of 0.915. The mean interaural phase difference was derived by calculating the analytic signal and thus the instantaneous phase for each channel, subtracting the instantaneous phase of the left channel from the right, wrapping values outside the range $\pm\pi$ back into that range, and then taking the average across the entire 350-ms stimulus. We found that implementing internal noise as additive interaural phase noise with a standard deviation of 1.5 rad as independent samples yielded good predictions of the data of Ito *et al.* (1982). If the resulting mean instantaneous interaural phase was positive, the model reported the stimulus on the right, and otherwise on the left. Predictions of percent correct were produced by repeating these operations for 200 such stimuli. Predicted thresholds were derived by generating psychometric functions for seven noise delays logarithmically spaced between 10 and 316 μs and taking the 75% point from a fitted logistic function.

[1]It is assumed that the binaural system does not distinguish between the temporal differences between sequential presentation of noises (as per the stimuli presented by Bernstein *et al.* (2001) and simultaneously presented delayed target and masking noise (as in the current experiments). For example, the temporal sequence of ITDs in the experiment of Bernstein *et al.* (2001) with interaurally correlated masking noise is described by a series of zero values during presentation of the interaurally correlated noise preceding the probe, followed by a series of values at the test ITD, followed by a series of zero values during the interaurally correlated noise lagging the probe. In the current experiments where delayed and masking noises are directly mixed, the sequence of ITD values is always random due to the combination of the delayed and masking noises. When delayed noise is mixed with interaurally correlated masking noise, the interaction of the two statistically independent noises results in a random distribution of noises with a mean determined by the relative power of the noise components, where the mean is between zero and the ITD of the delayed noise. When the delayed target noise and the masking noise are mixed within a hypothetical temporal window, it is assumed that it is still the proportion of delayed noise within a window that dictates threshold ITD, regardless of how it is temporally distributed.

[2]Participant EO received an additional 4 h of data collection in order to establish whether further training would result in lower thresholds. As no further improvement was observed, and as this listener was already previously experienced in psychophysical experiments, it was concluded that she was less sensitive than the others.

[3]Jeffress *et al.* (1962) were able to accurately predict listeners' chance performance at a correlation of zero by assuming a rectangular chance distribution among the points of the switch that listeners used to respond in a condition that was included as check on the experimental method. Had the end-points of the delay line been marked by a fixed limit to the knob movement, listeners would have been able to at least avoid setting the knob close to this limit.

The experiments presented in this paper explore the hypothesis that cochlear gain is reduced, in a frequency-specific manner, over the course of a sound (called a "precursor") which was designed to activate the medial olivo-cochlear reflex (MOCR). Psychophysical tuning curves (PTCs) and off-frequency growth of masking (GOM) functions were measured with two precursors. The on-frequency precursor condition, which was hypothesized to activate the MOCR at the signal frequency, produced a PTC with a lower best frequency in all subjects consistent with less gain. This same condition produced a GOM function with less gain and an elevated compression breakpoint. The data were analyzed with two models. The gain-reduction model, which assumed a change in the basilar membrane input-output function, was superior at predicting the data relative to a model of additivity of masking. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3081383]

I. INTRODUCTION

The auditory system, like other sensory systems, adjusts to stimuli in the environment. Some adjustments may protect the ear from harm (such as the stapedial reflex), while others may facilitate perception of a signal of interest. For example, Dean *et al.* (2005) showed that rate-level functions in the inferior colliculus adjust to the statistical characteristics of the input waveform intensity. Such an adjustment may facilitate perception by optimizing auditory dynamic range and avoiding the deleterious effects of saturation. In humans, it may be possible to study how the auditory system adjusts to sound through perceptual experiments involving auditory masking. For example, under certain conditions the detection of a short signal, presented simultaneously with a masker, improves when preceded by a sound (often called a "precursor") rather than silence. This improvement in detection threshold has been referred to as "overshoot" (Zwicker, 1965) or the "temporal effect" (Hicks and Bacon, 1992) and has been a source of study for over 40 years. For generality, the term precursor may be regarded as a separate sound or an extension of the masker's duration.

Overshoot may occur as a result of an adjustment in the auditory system over the course of the precursor. Although the hypothesized mechanisms of this adjustment are still a matter of debate, recent psychophysical experiments suggest that it may be related to a decrease in cochlear gain (von Klitzing and Kohlrausch, 1994; Strickland, 2001, 2004; Strickland and Krishnan, 2005; Strickland, 2008). Such a decrease in gain may be mediated by the medial olivo-cochlear reflex (MOCR) (Schmidt and Zwicker, 1991). Efferent fibers from the MOCR connect directly to the outer hair cells in the cochlea. These hair cells, which are associated with the cochlear amplifier, amplify soft sounds (i.e., provide "gain") and sharpen tuning (or "frequency selectivity") by feeding energy into the cochlea's basilar membrane (BM). In addition, they help determine the BM's input/output (I/O) function, which describes how much gain is applied to a stimulus of a given intensity. Animal studies report a frequency-specific reduction in BM gain and frequency selectivity when the MOCR is elicited (Guinan and Gifford, 1988; Cooper and Guinan, 2006). The current study explored whether similar reductions in frequency selectivity and gain could be observed in humans through perceptual experiments involving precursors in forward masking.

The hypothesis that gain reduction explains overshoot seems counterintuitive because for some overshoot conditions, frequency selectivity increases when a precursor is present (Bacon and Viemeister, 1985; Bacon and Moore, 1986; Kimberley *et al.*, 1989; Bacon *et al.*, 2002; Strickland, 2004). Although a broadband precursor has been shown to decrease frequency selectivity (Strickland, 2001), a notched precursor, having the same spectrum as the masker, increases frequency selectivity. Strickland (2004) hypothesized that suppression may account for this dichotomy. This hypothesis was supported by showing that the data were consistent with a BM I/O model which assumed gain decreased in cochlear regions overlapping with the frequency spectrum of the precursor. The author argued that at wide notch widths, suppressive masking largely determined thresholds and reasoned that suppression may decrease over the course of the precursor. If this were the case, masking due to suppression would also decrease. Such an effect would require higher masker levels at wide masker notch widths and produce higher estimates of frequency selectivity.

If the opposing findings regarding frequency selectivity in overshoot are related to a reduction in suppression, it may be possible to control for suppression by using a forward masking technique. Although precursor studies related to forward masking and frequency selectivity are limited, insight may be garnered from studies on forward masker duration. Unfortunately, these studies are inconclusive. For example,

Kidd *et al.* (1984) reported a slight broadening of tuning as masker duration increased while Bacon and Jesteadt (1987) reported a slight sharpening of tuning when measuring psychophysical tuning curves (PTCs) and masking patterns (MPs), respectively. This failure to show a consistent effect may be understood by considering a conceptual model of forward masking that assumes two underlying masking mechanisms which differ in their time-course of influence. The first mechanism has a short time-course and masks the signal by virtue of a continuation of masker-related neural activity (Oxenham, 2001). This mechanism is theoretically similar to the temporal window model (Moore *et al.*, 1988) and is assumed to be effective for short maskers (or parts of longer maskers) existing 20–30 ms prior to the signal's onset (i.e., neural activity "persists" for at least 20–30 ms). The second mechanism, which has a longer time-course, produces masking by reducing the gain of the cochlear amplifier. This mechanism is assumed to be effective for maskers existing at least 40–70 ms prior to the signal's onset. Specifically, the masking effect of this second mechanism is assumed to follow the time-course of the MOCR as described by Backus and Guinan (2006). Under the assumption that forward masking is a mix of neural persistence and gain reduction, the PTC and MP data discussed above become difficult to interpret because neither masking mechanism is under experimental control. In other words, for a given masker frequency and duration, the relative contribution of each mechanism is unknown.

Krull and Strickland (2008) described a precursor-based technique that may control or isolate the masking effects of the gain-reduction mechanism. This technique took advantage of the "sluggishness" of the MOCR by restricting the masker duration and the masker-signal interval such that gain-reduction effects from the masker should be minimal (i.e., gain-reduction effects were primarily from the precursor). The study by Krull and Strickland (2008) was limited to estimating cochlear gain via growth of off-frequency masking; however, if the MOCR were involved, frequency selectivity may also change in a manner consistent with less cochlear-amplifier gain. The current set of experiments adopts the technique described by Krull and Strickland (2008) to test this hypothesis. Behavioral estimates of frequency selectivity and gain were measured using PTCs and off-frequency growth of masking (GOM) functions, respectively. Within each experiment, data were measured for two conditions which differed by the frequency of the precursor. In the on-frequency precursor condition, the precursor was the same frequency as the signal and was assumed to elicit the MOCR at the signal place. Conversely in the off-frequency precursor condition, the precursor's frequency was fixed well below the signal frequency and was assumed to have little to no effect on the cochlear amplifier at the signal place. Under the assumption of MOCR-induced gain reduction, the on-frequency precursor condition may result in a broader PTC and a GOM function consistent with less gain. In the general discussion, a model is described that tests the assumption of MOCR-induced gain reduction. An additional model based on additivity of masking is also tested.

II. METHODS

A. Subjects and procedures

Four normal-hearing subjects were recruited for the experiment. All were clinically normal on measures of acoustic immittance, distortion-product otoacoustic emissions, and pure-tone audiometry (thresholds were below 15 dB HL at audiometric frequencies between 250 and 4000 Hz). Subjects were between 24 and 27 years of age and were recruited among the students and staff at Purdue University and citizens of the Greater Lafayette community. All were inexperienced with psychoacoustic tasks and paid for their time except subject 3, who is the first author. Prior to data collection, the subjects were given 2–3 h of practice on each experiment to minimize learning effects.

In both of the experiments, masker level at threshold was measured using a three-interval forced-choice task. Subjects listened to the stimuli in a double-walled sound-attenuating booth. For a given trial, the listener pressed a button to indicate the interval in which the signal was perceived. Visual stimuli marked the observation intervals and feedback was provided to indicate a correct or an incorrect response. If the response was incorrect, the masker level decreased. If the response was correct over two successive trials, the masker level increased. This stepping rule converged on the level where the subject achieved 70.7% correct (Levitt, 1971). A run consisted of 50 trials. An even number of reversals, excluding the first two, were averaged to estimate the threshold for a run. The step size was 5 dB until the second reversal, after which it decreased to 2 dB. At least two and often three runs were averaged for the final threshold estimate of each condition. Runs with a standard deviation greater than 5 dB were excluded. If performance improved appreciably over successive runs, measurement continued until performance stabilized, after which only the last two or three measurements were averaged. Each experimental session was limited to 1–1.5 h in length.

B. Stimuli

The digitally-generated stimuli were presented through four separate D/A channels (TDT DA 3-4), low-pass filtered at 10 kHz (TDT FT5 and TDT FT6-2), and adjusted by programmable attenuators (TDT PA4). The stimuli were then mixed (TDT SM3), passed through a headphone buffer (TDT HB6), and presented to the listener's left ear via an ER-2 insert earphone.

The stimulus paradigm used for the GOM and PTC experiments is depicted in Fig. 1. This paradigm contains the following three components: (1) a fixed-level tonal precursor, (2) a variable-level tonal masker, and (3) a fixed-level 4 kHz signal. In all conditions, the total durations (including onset/offset ramps) of the precursor, masker, and signal were 160, 20, and 6 ms, respectively. Each had 5 ms $\cos^2$ onset and offset ramps except the signal, where this value was 3 ms. There was no delay between the offset of one component (i.e., precursor, masker, or signal) and the onset of the next. High-pass noise (cutoff frequency $= 1.2 \times$ signal frequency) was gated 50 ms before precursor onset and 50 ms after signal offset at a spectrum level 40 dB below the signal level

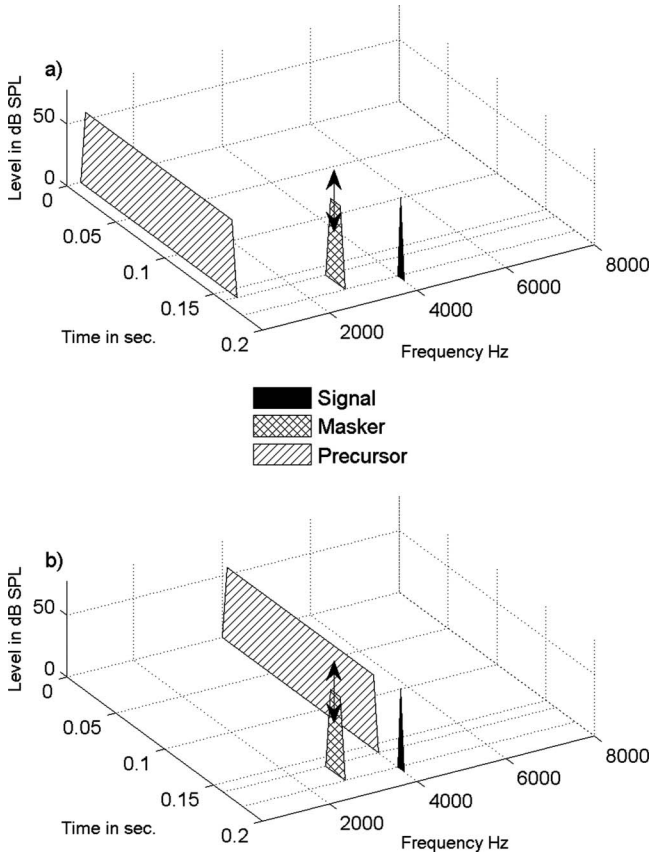

FIG. 1. Three dimensional representation of the stimuli used in the experiments. Temporal and spectral parameters of the signal and precursor are shown for the off-frequency (a) and on-frequency precursor (b) conditions. Masker level at threshold was the dependent variable in all conditions. In experiment 1, thresholds were measured for a series of masker frequencies (Note: only one frequency is displayed in the figure) to construct two PTCs, one for each precursor frequency. In experiment 2, thresholds for an off-frequency masker were measured for a series of signal levels to construct two GOM functions, one for each precursor frequency.

to restrict off-frequency listening. Within each experiment, data were collected for two precursor frequencies. The 4 kHz precursor ("on-frequency precursor") was designed to elicit the MOCR at the signal place, while the 0.8 kHz precursor ("off-frequency precursor") functioned as a control. This stimulus paradigm attempted to restrict MOCR-induced gain reduction to cochlear regions at and near the signal by (1) fixing the level, frequency, and duration of the on-frequency precursor across all conditions and (2) minimizing masker duration and masker-signal delay such that MOCR-induced gain reduction from the masker was minimal during the presentation of the signal.

In addition to attempting to control for the MOCR, this stimulus paradigm minimized any attention-related effects by including a precursor in all conditions rather than comparing measurements with and without a precursor. Data from a pilot experiment (Fig. 2) found that thresholds for the 0.8 kHz precursor condition were nearly identical to thresholds without a precursor. These pilot data are from S3 and involve a slightly longer masker (40 ms) than the experiments described below.

Thresholds for the signal were measured in quiet for all subjects and are displayed in Table I. Also displayed is the

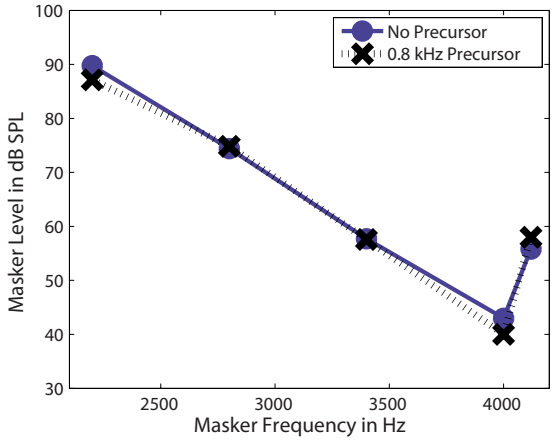

FIG. 2. (Color online) Data comparing PTCs measured without a precursor and with the 0.8 kHz control precursor. Note that these conditions produce similar thresholds and suggest the 0.8 kHz control precursor is an appropriate approximation of thresholds without a precursor.

level of the signal in the PTC experiment, the level of the precursor (L_{PE}), and the level of the precursor needed to just mask the signal in the absence of the masker (L_{PA}).

C. Experiment 1: Psychophysical tuning curves

Experiment 1 estimated frequency selectivity at the signal place. The signal level was fixed at 17–23 dB SL (i.e., approximately 20 dB SL). The masker level was adjusted to find threshold for a series of masker frequencies ranging from approximately 2000 to 5000 Hz. Data were collected in steps of approximately 400 and 80 Hz for masker frequencies below and above the signal frequency, respectively. The precursor level was fixed at 60 dB SPL for all subjects except subject 4, who was unable to perform the task at this level. For this subject, the precursor level was lowered to 50 dB SPL.

D. Experiment 2: Growth of masking functions

Experiment 2 estimated the I/O function at the signal frequency using the GOM technique first described by Oxenham and Plack (1997). This technique often involves comparing on and off-frequency GOM data to account for any non-linearities in forward masking (Oxenham and Plack, 2000; Oxenham and Bacon, 2004); however, for short masker-stimulus intervals (0–10 ms) the on-frequency GOM function is linear with a slope of 1. This suggests that the off-frequency GOM function can be directly interpreted as an estimate of the I/O function without measuring on-frequency GOM. The masker frequency was fixed at 2.8 kHz. A similar experiment (Oxenham and Plack, 1997) reported using a masker frequency one octave below the signal frequency. Initial data collection revealed that it was not possible to measure threshold for such a low masker frequency without exceeding the limits of the equipment (95 dB SPL). Therefore, the masker's frequency was raised sufficiently to measure threshold and maintain a reasonable assumption of linear growth at the signal place. Thresholds were obtained for a series of fixed signal levels from near threshold to 40–60 dB SL in 3 or 5 dB steps.

III. RESULTS AND DISCUSSION

Figure 3 displays the individual data for the PTC and GOM experiments in the top and bottom rows, respectively. Squares and asterisks are data for the off-frequency and on-frequency precursors. Dashed and solid lines are model fits to the data and are discussed below.

A. PTC data

Masker level is plotted as a function of masker frequency for the PTC data. Error bars were omitted for clarity [the average standard deviations by subject number for the off- and on-frequency data were 2.38, 3.82 (S1), 3.00, 2.60 (S2), 1.34, 2.51 (S3), 3.18, 2.11 (S4)]. Roex (p,w,t) filter shapes were fitted to the data as described by Yasin and Plack (2003) and represent the data reasonably well (see Table I for rms error values). The filter parameters were allowed to vary independently for the upper and lower skirts of the filter. In order to fit the roex functions, two additional free parameters were added ("BF" and L_{BF}). Parameter estimates were obtained using a least-squares minimization procedure using the MATLAB function "fminsearch." The equations which described the output of the roex filter for the lower and upper skirts were

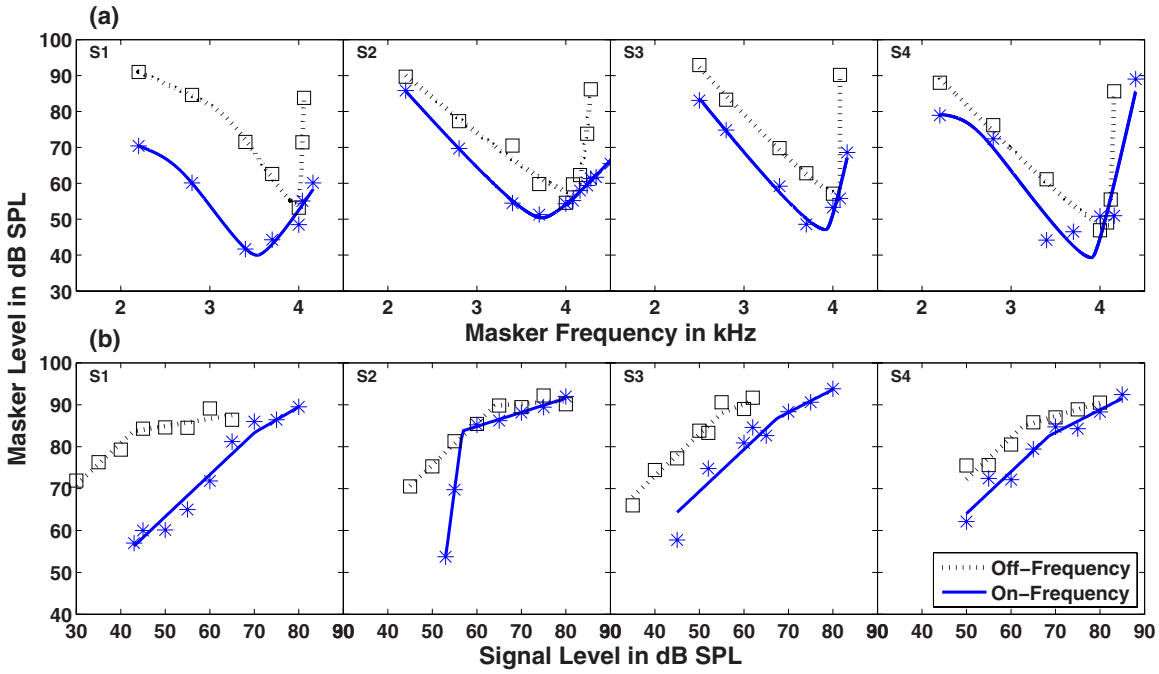

FIG. 3. (Color online) PTC (a) and GOM (b) results. The data are presented for each subject individually (S1–S4). Squares and asterisks represent the off-frequency and on-frequency precursor data, respectively. Dotted and solid lines are model fits to the data (see text).

$$W(f) = L_{\mathrm{BF}} - 10\log\left[(1-\mathrm{wl})\left(1+\mathrm{pl}\left|\frac{f-\mathrm{BF}}{\mathrm{BF}}\right|\right)e^{-\mathrm{pl}|f-\mathrm{BF}/\mathrm{BF}|} + \mathrm{wl}\left(1+\mathrm{tl}\left|\frac{f-\mathrm{BF}}{\mathrm{BF}}\right|\right)e^{-\mathrm{tl}|f-\mathrm{BF}/\mathrm{BF}|}\right], \quad (1)$$

$$W(f) = L_{\mathrm{BF}} - 10\log\left(1+\mathrm{pu}\left|\frac{f-\mathrm{BF}}{\mathrm{BF}}\right|\right), \quad (2)$$

where BF is the filter's best frequency, L_{BF} is the estimated output at BF, p ("pl" or "pu") and tl determine the filter slopes for the tip and tail, respectively, and wl delineates the intersection of pl and tl.

Table I presents the parameter estimates of the fitting procedure. The cells marked "NA" denote when a parameter did not appreciably improve the fit. Filter sharpness (Q_{10}) was estimated by dividing BF by the filter bandwidth at 10 dB above L_{BF}.

Three general patterns emerged from the PTC data. First, masker levels at threshold were lower in the on-frequency precursor condition at all masker frequencies (except for S4 at 4 kHz). Second, the estimated Q_{10} was reduced in all subjects in the on-frequency precursor condition; however, this effect was not significant ($t[3]=1.57$, p(one-tailed)$=0.106$). Finally, the estimated BF was consistently lower in the on-frequency precursor condition ($t[3]=4.32$, p(one-tailed)$=0.011$).

B. GOM data

The GOM results are plotted on the bottom row of Fig. 3. Masker level is plotted as a function of signal level. Error bars were omitted for clarity [the average standard deviations for the off and on-frequency data were 0.98, 2.57 (S1), 2.27, 3.13 (S2), 1.11, 0.81 (S3), 0.65, 1.64 (S4)]. Two lines were simultaneously fitted to the GOM data for each condition using a minimization procedure with three free parameters (G, c, and "BP1"). This procedure was modified from Yasin and Plack (2003). The first line was fitted to the lower leg of the data and was constrained to have a slope of 1. The y-intercept of this line was a free parameter (G) and can be interpreted as an estimate of gain. The second line was fitted to the upper leg of the data and its slope (c) can be interpreted as an estimate of compression. The lower breakpoint (BP1) delineated the end of the first line and the beginning of the second line. An additional breakpoint ("BP2") was initially a free parameter; however, it did not improve the fitting procedure so its value was fixed at 100 dB. The two-line model fits were given by

$$\mathrm{BM}(L_{\mathrm{in}}) = L_{\mathrm{in}} + G, \quad L_{\mathrm{in}} \le \mathrm{BP1}, \quad (3)$$

$$\mathrm{BM}(L_{\mathrm{in}}) = \mathrm{IBP1} + c(L_{\mathrm{in}} - \mathrm{BP1}), \quad \mathrm{BP1} < L_{\mathrm{in}} \le \mathrm{BP2}, \quad (4)$$

$$\mathrm{BM}(L_{\mathrm{in}}) = \mathrm{IBP2} + (L_{\mathrm{in}} - \mathrm{BP2}), \quad L_{\mathrm{in}} > \mathrm{BP2}, \quad (5)$$

where L_{in} is the input signal level, $\mathrm{BM}(L_{\mathrm{in}})$ is the estimated masker level at threshold, and the "internal breakpoints" are IBP1$=G+$BP1 and IBP2$=$IBP1$+c$(BP2$-$BP1). For one subject (S2), the lowest data point resulted in a poor model fit and an incorrect characterization of the breakpoint. The poor fit was largely due to the steep slope of the lower leg of the data. A similar steep slope was also observed in some subjects by Strickland (2008) and Krull and Strickland (2008) and may be related to the absolute threshold effects discussed by Plack and Skeels (2007). For this subject, the slope of the line fit to the lower leg of the data was allowed to vary. As a result of this minor change in the model, S2's data were not included in the statistical tests for gain.

The parameter estimates of the GOM fitting procedure are displayed in Table I. The on-frequency precursor condition produced lower estimates of gain ($t[2]=2.95$, p(one-tailed)$=0.049$) and higher estimates of the compression slope ($t[3]=-3.97$, p(one-tailed)$=0.028$) compared to the off-frequency precursor condition. There was no significant effect with respect to the breakpoint ($t[3]=-2.74$, p(one-tailed)$=0.138$). This was unexpected considering a previous study by Krull and Strickland (2008) that reported an increase in breakpoint under similar conditions. Three of the four subjects in the current study exhibited a fairly large increase in breakpoint, while the other (S2) showed a decrease. This reversal in the direction of the breakpoint for S2 may explain why this effect was not significant.

The estimates of compression slope are similar to previous studies with respect to the off-frequency precursor data. For example, Rosengard *et al.* (2005) reported values between 0.20 and 0.37 compared to a range of 0.07–0.46 in the current study. The slightly elevated values of compression slope in subjects 3 and 4 are likely a result of insufficient data above BP1 to obtain an accurate estimate. This is also true for the compression estimates in the on-frequency precursor condition for subjects 1 and 3.

Oxenham and Plack (1997) reported that the off-frequency GOM function became "more linear" between 40–50 dB, which can be interpreted as an estimate of BP1. The present study's estimates are somewhat higher than this range for three out of four of the subjects; however, similar high breakpoints have been observed in individual subjects in previous studies. For example, two subjects in Moore *et al.* (1999) (i.e., subjects JP and AG in Fig. 4) appear to have breakpoints between 55 and 60 dB SPL. Similarly, subject 2 in Oxenham and Plack (2000) showed no definable breakpoint up to the maximum signal threshold obtained (approximately 55 dB SPL). Finally, consistent with the current study, Krull and Strickland (2008) reported breakpoints above 60 dB SPL for two of their three subjects.[1]

Comparing the current data across experiments reveals a pattern that is consistent with a decrease in cochlear-amplifier gain in the on-frequency precursor condition. This pattern is characterized by lower estimates of gain, frequency selectivity, and BF. A similar pattern was noted by Strickland (2001), who measured frequency selectivity in simultaneous masking with and without a broadband precursor. The author interpreted these data as a reduction in cochlear gain and supported this interpretation using a simple BM I/O function model. Although frequency selectivity was measured, Strickland (2001) would not have been able to observe a decrease in BF due to the measurement method (i.e., notched-noise

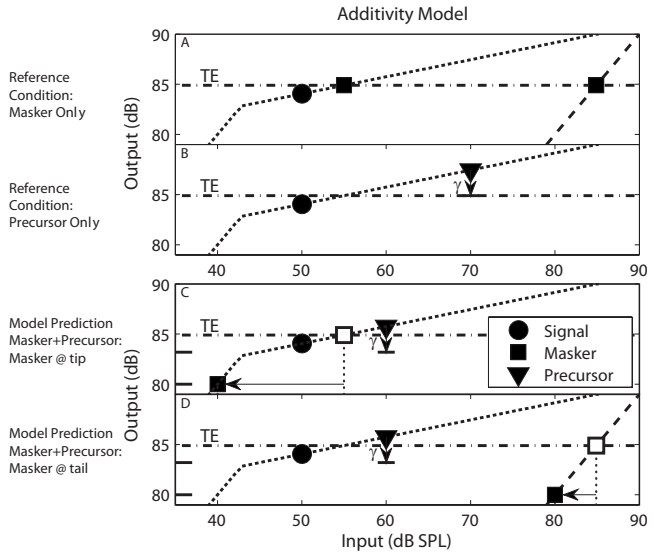

FIG. 4. Schematic representation of the additivity model using estimated BM I/O functions. The dotted line represents the I/O function fit to the GOM data in the off-frequency precursor condition [$BM_{unadapted}$(in)], while dashed lines represent a linear I/O function for the off-frequency masker. Panel (a) displays threshold for the signal (circle) in the presence of the masker (squares) alone. The data from this condition determined the signal-to-masker ratio at threshold. Panel (b) displays the threshold for the signal in the presence of the precursor (triangle) alone at L_{PA}. The constant γ represents the decay of the precursor energy during the silent interval between the signal and precursor. The value of γ was determined in panel (b) and assumed to be the same in panels (c) and (d). Panels (c) and (d) display how the precursor (at L_{PE}) and masker outputs (solid dashes on the y-axis) might add to produce an additivity-of-masking effect for the tip and tail frequencies. The horizontal line labeled "TE" represents the total energy needed to mask the signal (i.e., the addition of the masker and precursor outputs equal TE). The leftward pointing arrows represent the decrease in masker input needed to maintain a constant signal-to-masker+precursor ratio at the output of the BM I/O function. The open squares [and filled triangles in (c) and (d)] are the input(s) to the model and the closed squares are the predicted output.

method). In a recent forward masking study, Krull and Strickland (2008) estimated the BM I/O function using the off-frequency GOM technique. They reported a 5–20 dB reduction in gain across subjects when a 60 dB SPL precursor was present. This range is similar to Strickland (2008) and the current study, where a similar precursor produced 9–27 dB of gain reduction. It is noteworthy that physiological studies on the MOCR have observed reductions in BM gain of the same magnitude (Murugasu and Russell, 1996).

IV. GENERAL DISCUSSION AND MODELING

Although the pattern of results discussed above is consistent with a decrease in gain in the on-frequency precursor condition, there are other potential interpretations, the most prominent of which involves the additivity of masking (Oxenham and Moore, 1994; Plack and O'Hanlon, 2003; Plack *et al.*, 2006, 2007). Under this interpretation, the precursor and masker are viewed as two maskers whose intensities add after being processed by the auditory periphery. A typical additivity-of-masking experiment consists of two phases. During the first phase, the signal level is fixed and thresholds are measured for each masker individually. In the second phase, the maskers are presented together at the levels measured in the first phase, and the signal level at threshold is then measured. In a linear system, this approach should lead to a 3 dB increase in signal level relative to the first phase; however, threshold shifts are often much larger. This phenomenon is referred to as "excess masking" and has been interpreted as evidence of compression (Penner *et al.*, 1980). Under the additivity-of-masking assumption, the magnitude of excess masking is related to the amount of compression and the relative input levels of the two maskers for a given signal level. In experiment 2, the precursor level was fixed; therefore, as the signal level increases, any partial (or additive) masking from the precursor decreases. This argument suggests that excess masking should be largest at low signal levels where the partial masking from the precursor is highest. Qualitatively, this appears to be the case in all four subjects.

A modeling approach was used to evaluate the additivity-of-masking hypothesis. The experimental design in the current study differs from typical additivity-of-masking experiments; therefore, the model (hereafter referred to as the "additivity model") also differs and involves a few more assumptions. To compare the hypotheses of additivity and gain reduction, a "gain-reduction" model was tested as well. This model was also evaluated by predicting data from a previous study that was interpreted in terms of additivity of masking (Plack *et al.*, 2006).

For the current data set, the purpose of modeling was to predict the on-frequency precursor data (solid lines Fig. 3) by using the off-frequency precursor data (dotted lines Fig. 3) as a reference. For the PTC predictions, two masker frequencies were modeled, one at the signal frequency (4000 Hz) and the other well below the signal frequency (≈2200 Hz). These frequencies will be referred to as the "tip" and "tail" frequencies, respectively. They were chosen because their BM I/O functions were either measured in experiment 2 (tip frequency) or reasonably assumed to be linear with a slope of 1 (tail frequency). For the GOM predictions, only the additivity model was evaluated. Both additivity and gain-reduction models assumed no effect from the *off-frequency* precursor; therefore, in subsequent sections the term precursor will be reserved for the *on-frequency* precursor, unless otherwise stated.

A. Additivity model

Under the additivity-of-masking assumption, the effective intensities of the masker and precursor add internally at the output of the auditory periphery. Two thresholds were used as reference conditions and are shown schematically in Figs. 4(a) and 4(b).[2] These thresholds describe the individual internal representations of the precursor and masker when presented individually with the signal. Specifically, the precursor reference condition [Fig. 4(b)] was the threshold for the signal in the presence of the precursor at a 20 ms precursor-signal interval and is represented by the column L_{PA} in Table I. The masker reference condition [Fig. 4(a)] was the threshold measured for the off-frequency PTC at the tip and tail frequencies. All reference thresholds were assumed to be a function of the BM I/O function and a constant signal-to-masker ratio (or signal-to-precursor ratio for

the case of the precursor alone) at the output of the auditory periphery. An estimate of this ratio was obtained from the reference threshold for the masker alone and can be interpreted graphically as the vertical distance between the filled circle and filled squares in Fig. 4(a). For each listener, the fitted GOM function in experiment 2 (off-frequency precursor condition) served as the estimate of the BM I/O function [$BM_{unadapted}$(in)]. The internal representation of the precursor when presented alone with the signal ($IRP_{reference}$) was estimated by

$$IRP_{reference} = BM_{unadapted}(L_{PA}) + \gamma \quad (6)$$

in decibels, where L_{PA} is level of the precursor needed to mask the signal in the absence of the masker and γ is a constant representing the decrease in precursor output during the 20 ms silent interval between the precursor and signal. For the combined masker-precursor case, it was assumed that the signal was detected at a constant signal-to-masker +precursor ratio after peripheral processing; therefore, the total energy (TE) needed to mask the signal at threshold was described by

$$TE = 10\log(10^{IRP_{model}/10} + 10^{IRM_{model}/10}), \quad (7)$$

where IRP_{model} is Eq. (6) evaluated at L_{PE} and IRM_{model} is the predicted internal representation of the masker in the on-frequency precursor condition. IRM_{model} was solved from Eq. (7):

$$IRM_{model} = 10\log(10^{TE/10} - 10^{IRP_{model}/10}) \quad (8)$$

and then passed into the inverse of the BM I/O function to predict the masker threshold for the on-frequency precursor condition.

B. Gain-reduction model

In contrast to the additivity model, the gain-reduction model (Fig. 5) did not assume energetic masking from the precursor. Rather, it assumed that the precursor reduced the gain of the BM I/O function, after which the signal was detected at a constant signal-to-masker ratio. For each listener, the fitted GOM function in experiment 2 (on-frequency precursor condition) served as an estimate of the BM I/O function [$BM_{adapted}$(in)]. Note that for this model, the signal-to-masker ratio was determined solely by the masker (i.e., the precursor intensity did not add to the masker intensity before detection).

C. Model predictions and discussion

The predictions of the additivity and gain-reduction models are presented in Fig. 6. The PTC (top row) and GOM (bottom row) data were replotted. Dashed and solid lines represent the reference data (i.e., the input to the models) and the data to be predicted, respectively. Accurate model predictions lie near the solid line for a given listener. First consider the PTC predictions. The triangles and circles represent the additivity and gain-reduction model predictions, respectively (rms error: additivity model=8.17 dB; gain-reduction model=3.40 dB). As expected both models predicted a reduction in masker level at threshold relative to the reference

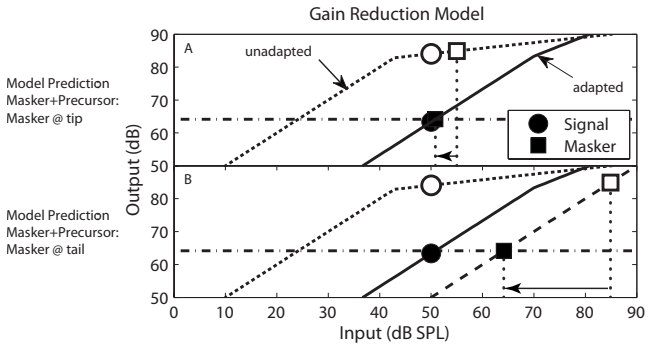

FIG. 5. Schematic representation of the gain-reduction model. This model assumed the on-frequency precursor reduced BM gain (or equivalently "adapted" the on-frequency I/O function). Two masker frequencies are schematized, one at the same frequency as the signal (a) and the other far below the signal frequency (b). Within each panel, the masker (squares) and signal (circles) are plotted for the masker alone condition (open symbols), or for the masker+precursor condition (closed symbols). Notice that the masker alone condition assumes that the signal and on-frequency masker operate on the unadapted I/O function [$BM_{unadapted}$(in), dotted lines], while the masker+precursor condition assumes that the signal and on-frequency masker operate on the adapted I/O function [$BM_{adapted}$(in), solid lines]. The dashed line in (b) represents the linear I/O function for the off-frequency masker. The horizontal line represents the masker output needed to maintain a constant signal-to-masker ratio at the output of the adapted I/O function.

data. At the tip frequency, the models are nearly equally accurate (except for S1, where the additivity model is poor). In contrast, a deviation between models is observed at the tail frequency, where the gain-reduction model is more accurate.[3] Krull and Strickland (2008) reported a similar finding when attempting to model precursor effects on off-frequency GOM under the additivity assumption. Their additivity model underestimated the effect of the precursor in all three of their subjects. Consistent with their findings, the current additivity simulations involving off-frequency masking (i.e., the tail frequency condition of the PTC experiment and the entire GOM experiment) underestimated the effect of the precursor. These results suggest that although additivity of masking explains data for two consecutive forward maskers with energy at the signal frequency, it may not explain data for two consecutive forward maskers having energy at and well below the signal frequency [however, see Arifianto and Plack (2008)].

It is important to note that the gain-reduction model does not to attempt to predict the shift in BF observed in the data. In order to predict this shift, the model would need an estimate of the BM I/O function at each masker frequency. Given the current data, such estimates are not available; however, a decrease in BF is often associated with an excitation pattern dominated by the passive mechanics of the BM (Ruggero *et al.*, 1997). This domination may occur as a result of high input levels (Moore *et al.*, 2002) or due to a decrease in the active process. For example, Yasin and Plack (2003) observed a decrease in BF in their PTC data when a suppressor was present, which is consistent with suppression functioning as an instantaneous decrease in the active process. The decrease in BF observed in the current experiment may also reflect a decrease in the active process given the low signal level used to measure the PTCs.

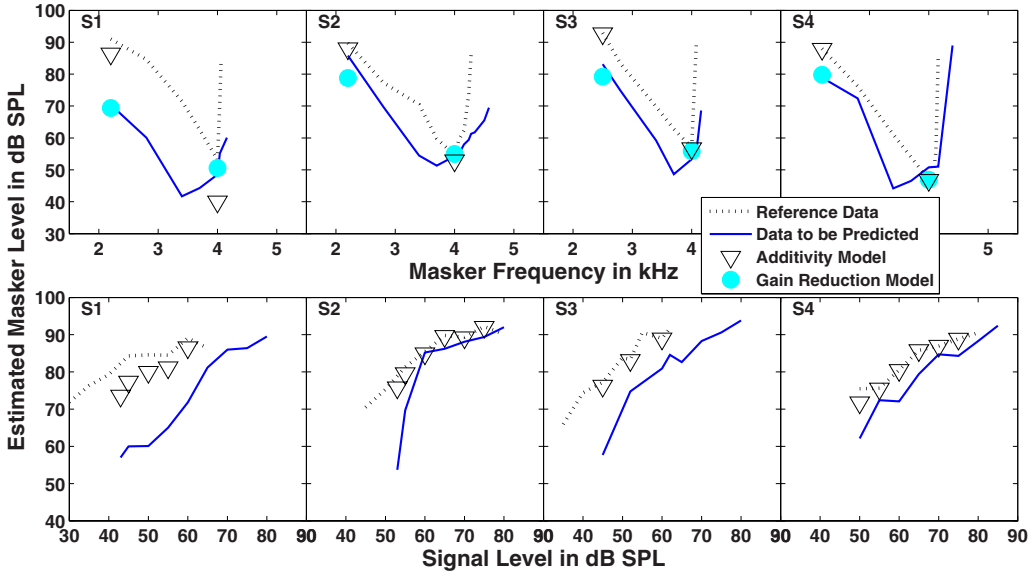

FIG. 6. (Color online) Model prediction for the PTC (top row) and GOM (bottom row) experiments. The predictions of the additivity (PTC and GOM data) and the gain-reduction (PTC data only) models are displayed as open triangles and filled circles, respectively. The models were intended to predict the on-frequency precursor data (asterisks in Fig. 3), which are replotted as a solid line. The dashed lines are the off-frequency data replotted and serve as a reference.

D. Modeling previous data

To further test the gain-reduction model, predictions were obtained for the mean data in Plack *et al.* (2006). This study involved measuring signal threshold in the presence of one or two temporally non-overlapping on-frequency forward maskers (M1 and M2). Using an additivity-of-masking model, Plack *et al.* (2006) were able to predict signal thresholds for the combined masker condition (M1+M2), by referencing signal thresholds from the separate masker conditions (M1 or M2 alone) and assuming a constant signal-to-masker ratio. A similar approach was taken in the current study; however, it was assumed that M1 reduced the gain of the I/O function rather than adding with M2 at the output of the BM. Figure 7 displays the predictions of the gain-reduction model and the I/O function which minimized the error of these predictions. The equation for this I/O function was similar to that used in Plack *et al.* (2006), except in units of decibels and with the additional constant d:

$$f(x) = ax^3 + bx^2 + cx + d, \tag{9}$$

where x is the input signal level (dB SPL) and a, b, and c are coefficients. The assumptions of the model were as follows: (1) The signal was detected at a constant signal-to-masker ratio at the output of the auditory periphery, (2) signal thresholds for M2 alone were a result of an I/O function with high gain (dotted line in Fig. 7), and (3) signal thresholds for M1+M2 were a result of an I/O function with relatively lower gain (solid line in Fig. 7). The coefficients for the "high-gain" I/O function were fixed at the values measured for the mean data in Plack *et al.* (2006) ($a=4.3\times10^{-5}$, $b=-9.9\times10^{-3}$, $c=0.913$, and $d=0$). Gain reduction was simulated by allowing the parameter d to vary, while constraining

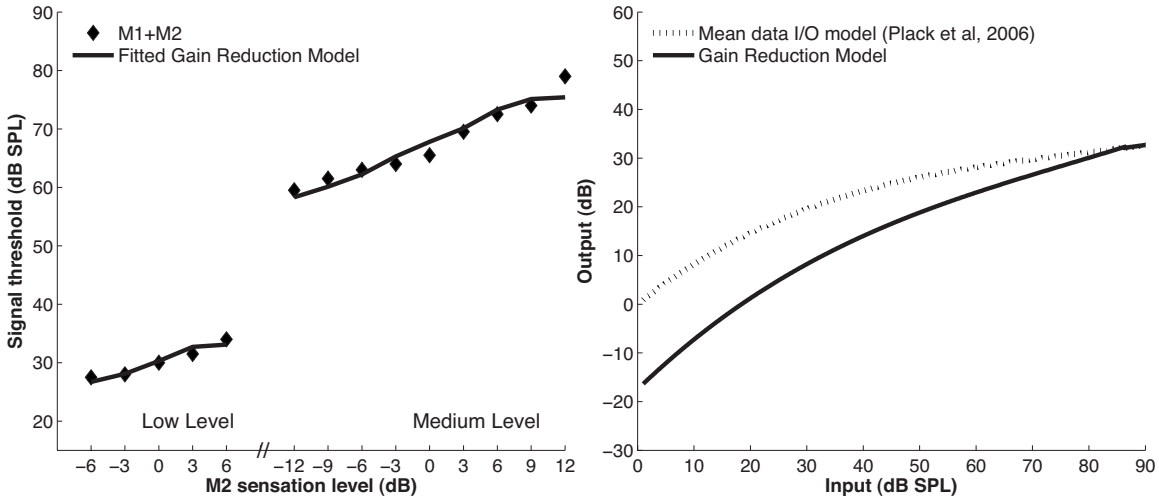

FIG. 7. Gain-reduction model predictions of Plack *et al.* (2006) (mean data) and the I/O function which minimized the error of the predictions. Parameter estimates of the gain-reduction model were $d=-17.48$, $x_{eq}=85.47$, and $k=-9.81$

the output to be equal to the high-gain model above a certain input level (x_{eq}). This constraint produced the following relationship for the coefficient c:

$$c = [f(x_{eq}) - ax_{eq}^3 - bx_{eq}^2 - d]/x_{eq}, \quad (10)$$

where $f(x_{eq})$ is the output of the high-gain polynomial model at x_{eq}. The values of a and b were constrained to be equal to those of the high-gain model; therefore, the three free parameters in the gain-reduction model were d, x_{eq}, and the threshold signal-to-masker ratio (k). As shown in Fig. 7, the gain-reduction model captures the data reasonably well. These results support the previous observation that additivity and gain-reduction models are equally accurate when the maskers (or the masker and precursor) have the same frequency.[4]

V. SUMMARY AND CONCLUSIONS

The experiments and model simulations presented in this study support the hypothesis that a reduction in gain can account for the effects of a precursor (or second masker) in the current study and at least one previous study. This conclusion is consistent with previous studies in forward and simultaneous masking which have also modeled masking data as a reduction in gain (Strickland, 2001; Oxenham, 2001; Strickland, 2004; Strickland and Krishnan, 2005; Strickland, 2008; Krull and Strickland, 2008). This study also showed that additivity of masking can account for some of the data in the experiments; however, for much of the data the size of the precursor effect was larger than predicted by additivity.

An interesting dichotomy emerges when comparing simultaneous and forward masking in terms of precursor effects. In simultaneous masking, a precursor usually improves detectability relative to thresholds without a precursor, while the opposite is true in forward masking. This dichotomy suggests that the human auditory system is designed for optimal performance in simultaneous masking tasks. Such a design seems appropriate given that most "everyday" listening tasks involve detecting and understanding signals embedded in background noise. In such environments, the MOCR may adjust gain to reduce the influence of competing signals and their effects on neural adaptation and transmitter depletion (Guinan, 2006). Similarly, such an adjustment may help to shift the rate-level functions of auditory neurons to optimize encoding of the signal of interest (Dean *et al.*, 2005).

ACKNOWLEDGMENTS

We would like to thank the associate editor Magdalena Wojtczak and reviewers Chris Plack and Andrew Oxenham for their helpful comments and suggestions on previous versions of this manuscript. Similarly, we would like to thank Vidya Ganesh for her comments on the revised manuscript. This work was funded in part by NIH (NIDCD) Grant Nos. RO1-DC008327 and T32-DC00030.

[1]The frequency response of the ER-2 headphones used in the current study may contribute to the high breakpoints. These headphones produce a flat frequency response at the level of the eardrum. Many of the previous studies have used circumaural headphones such as the Sennheiser HD580 (Rosengard *et al.*, 2005), which may produce a slightly higher output in the 2–6 kHz region (the frequency region of our signal) when calibrated in a similar manner.

[2]This schematic is based on the data from S1 with a slight modification to add visual clarity. This modification involved slightly increasing the masker level at threshold, as well as slightly decreasing the value of L_{PA}.

[3]It is not surprising that the gain-reduction model predicts the data at the tail frequency since the estimated I/O functions used in the model were derived under similar stimuli conditions as the data being predicted. These data could have been equally well predicted by a BM model where gain varied as a parameter; however, to limit the number of the parameters to the model, the GOM functions were used instead.

[4]The model simulations were limited to the M1+M2 data. Although the model could be revised to include M1 predictions, such a revision would require adding additional assumptions and parameters. In an effort to reduce the model's parameters and assumptions, we limited our predictions to the M1+M2 data.

Many sounds in the environment have temporal envelope fluctuations that are correlated in different frequency regions. Comodulation masking release (CMR) illustrates how such coherent fluctuations can improve signal detection. This study assesses how perceptual grouping mechanisms affect CMR. Detection thresholds for a 1-kHz sinusoidal signal were measured in the presence of a narrowband (20-Hz-wide) on-frequency masker with or without four comodulated or independent flanking bands that were spaced apart by either 1/6 (narrow spacing) or 1 octave (wide spacing). As expected, CMR was observed for the narrow and wide comodulated flankers. However, in the wide (but not narrow) condition, this CMR was eliminated by adding a series of gated flanking bands after the signal. Control experiments showed that this effect was not due to long-term adaptation or general distraction. The results are interpreted in terms of the sequence of "postcursor" flanking bands forming a perceptual stream with the original flanking bands, resulting in perceptual segregation of the flanking bands from the masker. The results are consistent with the idea that modulation analysis occurs within, not across, auditory objects, and that across-frequency CMR only occurs if the on-frequency and flanking bands fall within the same auditory object or stream.

I. INTRODUCTION

The audibility of a target sound embedded in another masking sound can be improved by adding sound energy that is remote in frequency from both the masker and the target (Hall *et al.*, 1984). This effect is known as comodulation masking release (CMR) and is observed when the remote sound and the masker share coherent patterns of amplitude modulation. Most ecologically relevant sounds, such as speech and animal vocalizations, have coherent amplitude modulation patterns across different frequency regions, suggesting that the detection and recognition advantages conveyed by such coherent modulations may play an important role in our ability to deal with natural complex acoustic environments (e.g., Klump, 1996; Nelken *et al.*, 1999).

CMR has been measured in two ways. The first, often referred to as the "band-widening experiment," is to use a single band of noise, centered around the signal frequency, as a masker and to compare thresholds for modulated and unmodulated noise maskers as a function of the masker bandwidth (e.g., Hall *et al.*, 1984; Carlyon *et al.*, 1989). For the random noise, with irregular fluctuations in amplitude that are independent of different frequency regions, the signal threshold increases as the masker bandwidth increases up to about the critical bandwidth at that frequency and then remains constant, in broad agreement with the classical power spectrum model of masking (Fletcher, 1940; Patterson and Moore, 1986). For the modulated noise, a random noise that is amplitude modulated using a lowpass filtered noise as a modulator, the pattern of results is quite different. Here, signal thresholds typically decrease as the bandwidth increases beyond about 100 Hz (for a signal frequency of 2 kHz); thus, increasing the masker energy and bandwidth makes the signal easier to detect. These findings suggest that listeners may compare the outputs of different auditory filters to enhance signal detection. The fact that the decrease in threshold with increasing bandwidth only occurs with the modulated noise indicates that fluctuations in the masker are critical and that the fluctuations need to be correlated across frequency bands.

The second method is to use a masker consisting of several narrow masker bands of noise, typically with bandwidths between 20 and 50 Hz, which have relatively slow inherent amplitude fluctuations. One band is centered at the signal frequency (on-frequency band) and one or more other bands (flanking bands) are spectrally separated from the on-frequency band (e.g., Hall *et al.* 1984; Schooneveldt and Moore, 1987). When the flanking bands are uncorrelated with the on-frequency band, there is sometimes a slight el-

[a)]Portions of these data were presented at the 2003 International Symposium on Hearing in Paris, France, the proceedings of which are published as Dau *et al.*, 2005.
[b)]Electronic mail: tda@elektro.dtu.dk

evation but typically no effect on signal threshold, so long as the flanking bands are not so close in frequency as to produce direct masking. However, when the amplitude fluctuations of the flanking bands are correlated with those of the on-frequency band, the addition of the flanking bands can produce a release from masking (Hall *et al.*, 1984; Schooneveldt and Moore, 1987; Cohen and Schubert, 1987). CMR has been found even if the signal and on-frequency band are presented to one ear and the flanking bands to the other ear (Schooneveldt and Moore, 1987; Cohen and Schubert, 1987; Buss and Hall, 2008).

Even though CMR has been investigated in many studies, the underlying mechanisms are still not clear. It was originally assumed that CMR results from across-channel comparisons of temporal envelopes (e.g., Buus, 1985). However, there is evidence that within-channel cues, i.e., information from only the one peripheral channel tuned to the signal frequency, can account for a considerable part of the effect in some conditions, suggesting that within-channel processing can lead to an overestimation of "true" across-channel CMR (Schooneveldt and Moore, 1987). This conclusion was supported by simulations of data from a bandwidening experiment, using a modulation filterbank analysis of the stimuli at the output of the auditory filter tuned to the signal frequency (Verhey *et al.*, 1999; Piechowiak *et al.*, 2007). Additionally, for the CMR experiments using flanking bands, McFadden (1986) pointed out that it is imprecise to assume that one channel is receiving only the on-frequency band plus signal and another channel is receiving only the flanking band. Often, the two bands will be incompletely resolved. When this happens, the resulting waveform may contain envelope fluctuations resulting from beats between the carrier frequencies of the on-frequency and the flanker bands. These beats can facilitate signal detection without across-channel comparisons being involved (Schooneveldt and Moore, 1987). Thus, at least part of the CMR in many situations can be explained in terms of the use of within-channel rather than across-channel cues.

The authors of several studies have suggested that higher-level processes, such as object formation, may be involved in CMR, because certain stimulus manipulations designed to perceptually segregate the masker from the flanking bands have resulted in a reduction or elimination of CMR (McFadden and Wright, 1992; Grose and Hall, 1993). However, when manipulating perceptual grouping, it is often difficult to rule out mechanisms such as neural inhibition, forward suppression, or adaptation (Calford and Semple, 1995; Ulanovsky *et al.*, 2004; Wehr and Zador, 2005) that might at least partly be based on more peripheral processing. For example, neuronal adaptation, the decline over time of neural responses during sensory stimulation, might have affected the neural representation of the flanking masker bands in the experimental conditions of Grose and Hall (1993). In their study, CMR was reduced or eliminated either by gating the flanking bands on earlier and gating off later than the on-frequency masker band, or by presenting a series of precursor bands at the same frequencies as the flanking masker bands to perceptually segregate the on-frequency from the flanking masker bands. In both cases, it is at least conceivable that the main effect of the precursors or leading onset asynchronies was to reduce the neural response to the flanking masker bands.

To exclude adaptation as a possible basis for the reduction or elimination of CMR, the present study focused on sounds that occurred *after* the target in time. Sounds occurring after a target and masker interval could in principle affect their perception by, for instance, binding with the flanking bands to form a separate perceptual stream (Dannenbring and Bregman, 1978; Bregman, 1990). Our hypothesis was that if across-frequency modulation analysis (and hence CMR) occurs primarily within auditory objects, then CMR could be eliminated by sounds that occur after the target, so long as these sounds are successfully segregating the on-frequency masker and the flanking masker bands into different auditory objects, thereby disrupting the across-frequency (but within-object) modulation processing. On the other hand, if across-frequency modulation processing is a lower-level or "automatic" process that is not governed by auditory grouping mechanisms, then sounds occurring after the target in time should not affect CMR.

II. RETROACTIVE STIMULUS EFFECTS ON CMR

A. Method

1. Listeners

Six normal-hearing listeners ranging in age from 25 to 39 years participated in the experiments. Two of the listeners were the first and second authors. All listeners received several hours of listening experience prior to the final data collection.

2. Apparatus and stimuli

Listeners were seated in a double-walled sound attenuating booth in front of a computer keyboard and monitor. The stimuli were presented diotically via Sennheiser HD580 headphones. Signal generation and presentation during the experiments were controlled by computer using the AFC software package for MATLAB, developed at the University of Oldenburg and the Technical University of Denmark. The stimuli were digitally generated at a sampling rate of 32 kHz and converted to analog signals by a high-quality 24-bit sound card (RME DIGI96/8 PAD).

Figure 1 shows schematic spectra of the stimuli: The target (a 1-kHz tone) was masked by a narrow (20-Hz wide) band of noise centered at 1 kHz. Four flanking bands of noise (each 20-Hz wide) were presented with temporal envelopes that were either random (condition R) and thus uncorrelated with that of the on-frequency masker, or coherent (condition C) with the masker envelope. The envelope fluctuations, or modulations, of the bands are indicated by the different shades of gray. The coherent across-frequency modulation of condition C was expected to enhance the audibility of the target, and hence reduce its detection threshold, relative to its threshold in condition R. The novel conditions investigated the retroactive influence of stimulus presentation on CMR. Several additional bursts of noise, termed postcursors, were presented at the frequencies of the original flanking bands (conditions PR and PC). The enve-

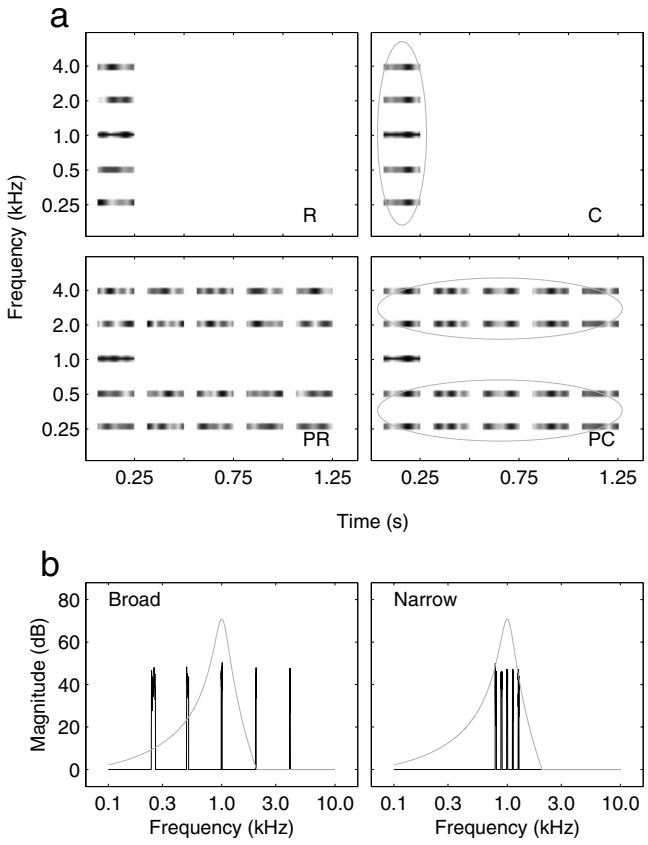

FIG. 1. Schematic representation of the experimental conditions. (a) Four conditions with a 1-kHz target tone (black horizontal line) masked by a noise band centered at 1-kHz with random flankers (R), comodulated flankers (C), random flankers followed by four postcursors (PR), and comodulated flankers followed by four comodulated postcursors (PC). The shades of gray indicate the distribution of envelope fluctuations in the masker and flanker bands. (b) Power spectra for the broadband configuration (with one-octave spacing between the noise bands) and narrowband configuration (with one-sixth octave spacing). The gray curves represent the magnitude response of the auditory filter centered at the target frequency.

lope coherence of the postcursors was the same as that for the original flanking masker bands. The postcursors were designed to "capture," and to form a single auditory stream with, the original flanking bands and thus to perceptually segregate them from the masker (Bregman and Pinker, 1978), as shown schematically in Fig. 1(a) (gray ellipses).

The experiment was performed using two spectral configurations [Fig. 1(b)]. In the broadband configuration, the noise bands were centered at 250, 500, 1000, 2000, and 4000 Hz, i.e., with one-octave spacing between the bands such that they primarily stimulated separate auditory filters along the tonotopic axis. The gray curve in Fig. 1(b) indicates the magnitude transfer function of a gammatone bandpass filter (e.g., Patterson *et al.*, 1995) tuned to the signal frequency (1 kHz). In the narrowband configuration, the noise bands were centered at 794, 891, 1000, 1123, and 1260 Hz, representing a sixth-octave spacing centered around the target frequency. In this case, within-channel processes were likely to play a strong role (Schooneveldt and Moore, 1987; Verhey *et al.*, 1999), because all the components fell within the same frequency region. To the extent that the effect of the postcursors is limited to across-frequency processing, they should not affect CMR for the narrowband configuration. Hence, the narrowband configuration acted as a control condition for any potential non-specific distraction or interference effects produced by the postcursors.

In both cases, the noise bands were generated in the time domain as independent Gaussian noise tokens for each of the presentation intervals. The noise tokens were restricted to the appropriate bandwidth in the spectral domain via a Fourier transform. Comodulated noises were frequency-shifted versions of the masker band at 1000 Hz. The level of each of the noise bands was 60 dB sound pressure level (SPL). The four postcursors at the flanking-band frequencies all had the same duration and level as the masker bands (187.5 ms, including 20-ms raised-cosine ramps) and were separated by gaps of 62.5 ms, giving an overall repetition period of 250 ms.

3. Procedure

An adaptive, three-interval, three-alternative forced-choice procedure was used in conjunction with a 1-up, 2-down tracking rule to estimate the 70.7% correct point on the psychometric function (Levitt, 1971). The intervals were marked on a computer monitor and feedback was provided after each trial. Listeners responded via the computer keyboard or mouse. The initial step size of the target level was 8 dB, which was reduced to 4 and 2 dB after the second and fourth reversals, respectively. The adaptive run then continued for a further six reversals at the final step size, and threshold was defined as the mean of the levels at those last six reversals. Four threshold estimates were obtained and averaged from each listener in each condition. The intra-individual standard deviations were typically around 1–2 dB and rarely exceeded 4 dB. Final thresholds reported here are the mean across listeners, who all showed comparable patterns of results across conditions. Typical individual differences were around 2–3 dB and maximally reached 5–6 dB.

B. Results and discussion

The experimental data are shown in Fig. 2. In the broadband configuration (circles and filled bars), the results for conditions R and C were as expected from previous studies (Schooneveldt and Moore, 1987): The target threshold in the presence of the masker was significantly lower for the coherently modulated flanking bands than for the randomly modulated flanking bands [paired t-test; $t(5)=7.21$, $p<0.001$]. This difference in threshold, reflecting the amount of CMR, was 6.1 dB. However, this CMR was eliminated when the postcursors were added: Thresholds in condition PC were not significantly different from those in condition R [paired t-test; $t(5)=0.73$, $p=0.50$]. Similarly, there was no significant difference between thresholds in conditions PR and PC [paired t-test; $t(5)=0.59$, $p=0.58$], confirming the lack of effect of coherent amplitude modulations when the postcursors were present. The elimination of the CMR by sounds occurring after the target suggests that the postcursors led to perceptual segregation of the flanking bands from the masker, so that the coherent modulations in the flanking bands were no longer processed with those of the masker.

The results from the narrowband configuration (Fig. 2, squares and open bars) show that the effect of the postcursors

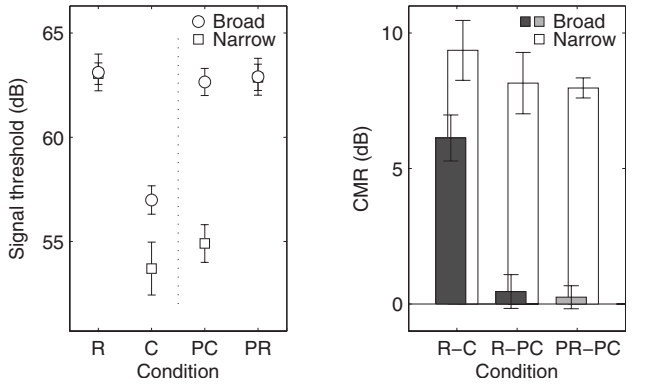

FIG. 2. Mean masked thresholds for the target tone (left) and amount of CMR (right) for the broadband (circles and filled bars) and the narrowband configurations (squares and open bars). Error bars denote one standard error across subjects. Conditions are indicated on the abscissa (R=random modulations of the flanking bands, C=comodulated flanking bands, PC =postcursors with comodulated flanking bands, and PR=postcursors with randomly modulated flanking bands). The amount of CMR, defined as the difference between thresholds in the random and the comodulated conditions, is indicated for the standard condition without postcursors, R-C, and for the conditions with postcursors (R-PC and PR–PC).

is unlikely to be a non-specific distraction effect: Here, the average target threshold in the presence of the masker (R) was 9.4 dB lower for the coherently modulated than for the randomly modulated flanking bands [paired t-test; $t(5)=8.46$, $p<0.001$], as expected (Schooneveldt and Moore, 1987). However, in contrast to the broadband configuration, no significant reduction in CMR was produced when the postcursors were added [C-PC, $t(5)=-1.06$, $p=0.34$]. When compared to the random condition with postcursors, PR-PC (right open bar), the amount of CMR was 8.0 dB, in contrast to a non-significant 0.25 dB in the broadband configuration (right light-gray bar). Thus, postcursors eliminated CMR in the broadband configuration where CMR is likely to be based on across-frequency processing, but did not significantly affect target detection in the narrowband configuration, where CMR is more likely to be based on within-channel cues. In other words, the postcursors were successful at eliminating CMR only when CMR was likely to be based on a true across-frequency analysis of coherent modulations occurring in remote frequency bands.

Overall, the results are difficult to account for in terms of traditional neuronal adaptation or inhibition mechanisms because the critical sound components (the postcursors) occurred after the presentation of both the masker and target. However, it is possible in principle that the postcursors in a given trial affected the representation of the flankers in the following trial, via some form of long-term adaptation. In other words, despite the temporal gaps between successive trials, the postcursors may have influenced the response to the flanking bands in the next trial, which in turn may have reduced CMR. Long-term adaptation effects have been observed in the auditory pathways, particularly at higher levels, such as cortex (e.g., Ulanovsky *et al.*, 2004; Altmann *et al.*, 2007). Another possibility is that the postcursors induced some distraction effect that selectively impaired performance in the wideband, but not the narrowband conditions. For instance, if attention were exogenously diverted toward the frequency regions of the flanking bands by the postcursors, and if this shift in attention affected signal detection, then this would be expected to selectively affect results for the wideband condition. Such an attentional effect would be less likely to affect results for the narrowband condition, because the frequency region of the flankers was close to that of the target. Both these possibilities were addressed in the following control conditions.

III. CONTROL CONDITIONS: MISSING AND OFF-FREQUENCY POSTCURSORS

A. Rationale

To address the possibility that the effect of the postcursors was due to longer-term effects on flankers in following trials, the first burst of postcursors following the flankers was replaced with a silent gap. The gap was expected to reduce or eliminate the perceptual grouping of the flankers with the postcursors, but would not be expected to eliminate any longer-term adaptation effects. To address the possibility that the effect of the postcursors was due to an attentional shift away from the target frequency, a second control condition was run in which the postcursors were shifted by a half-octave away from the frequencies of the flankers. In this case, attention would still be expected to shift from the target frequency, but the postcursors would no longer be expected to form a perceptual stream with the flanking masker bands. Thus, if the effect of the postcursors in experiment 1 was primarily due to an exogenous attentional shift, then CMR should be reduced even when the center frequencies of the postcursors are shifted; however, if the effect was due to perceptual grouping of the flanking maskers and postcursors into a single stream, then CMR should remain when the center frequencies are shifted, because the postcursors should no longer form a stream with the flanking masker bands.

B. Methods

The target and the flankers were the same as for the broadband configuration in the main experiment. The same listeners took part, and the apparatus and procedures for estimating thresholds were also the same. The left panel of Fig. 3(a) shows schematic spectrograms of the stimuli for the first control condition, where the first of the four postcursors was removed (gap-postcursor condition, GP); the right panel of Fig. 3(a) shows schematic spectrograms of the stimuli for the second control condition, where the center frequencies of the postcursors were shifted relative to the flanker center frequencies. The off-frequency postcursors were positioned with half-octave separation from the respective flanking bands, i.e., at 354, 707, 1414, and 2828 Hz.

C. Results and discussion

The data in Fig. 3(b) show that CMR is not affected by the postcursors, if the first postcursor is omitted. The threshold obtained in the comodulated condition with gap-postcursor (GPC) was not significantly different from the threshold obtained in the original condition C [from Fig. 2; $t(5)=-0.76$, $p=0.483$]. CMR was 5.5 dB when defined as

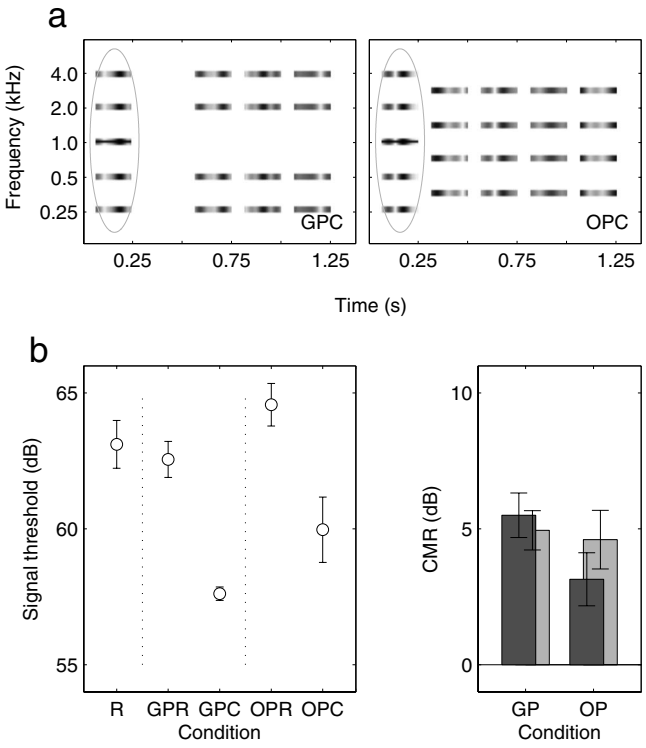

FIG. 3. Control stimulus conditions to further test the hypothesis that CMR is associated with auditory grouping. (a) Conditions with gap and postcursors (GPC, left) where the first postcursor was eliminated, and with off-frequency postcursors (OPC, right) where the postcursors were presented at intermediate frequencies. The last letter C in the abbreviations indicates that the comodulated condition is shown. (b) Mean masked thresholds and standard errors (left panel) are shown for the different stimulus conditions. The corresponding amounts of CMR for the conditions GP and OP are shown in the right panel. Dark-gray bars indicate the conditions R-GPC and R-OPC and light-gray bars indicate the conditions GPR-GPC and OPR-OPC.

R-GPC (dark-gray bar), and 4.9 dB when defined as GPR-GPC (light-gray bar). Both CMR effects were highly significant [$t(5)=6.73$, $p=0.001$ and $t(5)=6.85$, $p=0.001$, respectively] and were not significantly different from one another [$t(5)=0.81$, $p=0.456$]. The results from the second control experiment, where the postcursors were presented at intermediate frequencies (off-frequency postcursors-OP) show slightly elevated thresholds both for the random (OPR) and the comodulated (OPC) conditions compared to the standard thresholds, R and C. However, the amount of CMR, as measured by the difference between OPR and OPC conditions [right-hand light-gray bar; 4.6 dB, $t(5)=4.26$, $p<0.01$], was highly significant and was close (within 1.5 dB) to that found in the standard condition without postcursors, R-C.

In summary, the results from the two additional control conditions indicate that the effects of the postcursors cannot be ascribed to either long-term, across-trial adaptation or to a general distraction or attentional effect produced by the presence of the postcursors. The findings support the idea that retroactive effects of perceptual segregation can lead to a deterioration in target detection.

IV. DISCUSSION

The results show that across-frequency modulation processing may interact with the processes that give rise to auditory object and stream formation. The effects of poststimulus manipulations make an interpretation based solely on neural inhibition or forward suppression (Las *et al.*, 2005) unlikely. Instead, the current results suggest the influence of higher-level processes, whereby modulations can be processed efficiently across different frequency regions only if they form part of the same auditory object. Stated another way, the modulation analysis observed in the tasks of the present study seems to be performed on objects, rather than frequency channels.

Retroactive effects in hearing, although rare, have been reported before. For instance, in speech perception, segments of a sound occurring after the offset of a vowel can affect the perceived identity of the vowel (Darwin, 1984; Darwin *et al.*, 1989; Roberts and Moore, 1990); noise bursts can be perceived differently depending on the following vowel (Liberman *et al.*, 1952); and certain features of sounds are perceived or remembered less well when followed by a masking sound (Massaro, 1975). Warren (1970) found strong retroactive effects of context on the recognition of "missing" speech sounds, when parts of a speech sound in recorded sentences were replaced with an extraneous sound (such as a tone or a gap). Retroactive effects on the simple detection of an auditory target are less commonly observed. One example is backward masking, which occurs when a brief target, e.g., a tone pulse, is presented just before a masker (e.g., Elliott, 1962; Oxenham and Moore, 1995). Another example is related to the detection of a brief target that is gated on synchronously with a masker, similar to the well-known "overshoot" effect (e.g., Zwicker, 1965). When the masker is gated on and off with the target, thresholds are often higher than when the masker continues beyond the offset of the target (Kidd and Wright, 1994). In this case, the additional masker energy *improves* performance, possibly by eliminating the potential masking produced by the masker offset transient. Such effects are typically observed only for very short target durations and for maskers that follow immediately (within 10 ms) of the end of the masker. The targets used in the present study were much longer (187.5 ms), as were the gaps between the flankers and the postcursors (62.5 ms), suggesting that the effects observed here are probably not related to those of backward masking or overshoot.

The results place strong constraints on the search for neural correlates of across-frequency modulation processing. The current findings seem incompatible with recent physiological studies suggesting that neural correlates of CMR may be found at the brainstem level, i.e., at an early stage of auditory processing (Pressnitzer *et al.*, 2001; Verhey *et al.*, 2003; Neuert *et al.*, 2004). In Pressnitzer *et al.* (2001), some of the recorded units in the cochlear nucleus (CN) of guinea pigs showed responses consistent with perceptual CMR. The addition of a comodulated flanking band in a CMR paradigm produced a strong reduction in the response to the masker band modulation, making the signal more salient in the corresponding poststimulus time histograms. A decision statistic based on d' showed that threshold was reached at lower signal levels for the comodulated condition than for the reference condition. Using a computational model, Pressnitzer *et al.* (2001) and Meddis *et al.* (2002) demonstrated that a

simple neural circuit consisting of the inhibition of a narrowband unit by a wideband inhibitor is able to replicate many of the physiological findings. These results thus provided evidence for an enhanced representation of the signal in the brainstem when presented in comodulated backgrounds. It is also possible that certain neurons in the brainstem that respond after a signal has ended show an altered representation when a subsequent masker is presented. However, the data shown in the present study lead us to question to what extent such across-channel processing actually reflects a direct physiological correlate of the perceptual across-channel CMR.

Several studies have investigated neural correlates of CMR at higher stages in the auditory pathways. In the primary auditory cortex of the cat, Nelken *et al.* (1999) considered the disruption of a neuron's envelope-following response as a correlate for CMR. Using a flanking-band experiment conceptually similar to the one considered in the present study, Nelken *et al.* (1999) showed that single units in the auditory cortex can demonstrate a response consistent with CMR. These units tended to lock to the envelope of the slowly fluctuating noise, whereas the addition of a low-level tone suppressed the envelope locking, a phenomenon that was referred to as "locking suppression." Such disruption of the envelope-following response to the masker at a cortical level was considered as a complementary strategy of achieving an enhanced signal representation in a modulated noise background (Nelken *et al.*, 1999; Langemann and Klump, 2001; Verhey *et al.*, 2003).

In a later study, the evolution of locking suppression along the auditory pathway was investigated (Las *et al.*, 2005). Recordings were made in the primary auditory cortex (A1) and in two preceding subcortical nuclei, the inferior colliculus (IC) and the medial geniculate body (MGB). Las *et al.* (2005) showed that, whereas responses in IC resembled in many aspects those in CN, a new response pattern appeared in MGB and became dominant in A1, whereby the representation of the tone was more explicit in the higher stages than in the brainstem. Specifically, Las *et al.* (2005) proposed that the enhancement of the representation of the low-level tone in slowly fluctuating noise-by suppression of envelope locking in the ascending auditory system-could be a correlate of the formation of an auditory object (the tone) as a separate entity from the background noise.

Nelken (2004) and Las *et al.* (2005) proposed that, while most of the physical attributes of the sound and many interesting auditory features might already be extracted in the brainstem (e.g., the IC), the *organization* of these features into auditory objects takes place in the auditory cortex using temporal and spectral contexts at several time scales. The nonlinear interaction between stimulus components in the primary auditory cortex thus results in a more abstract representation of sounds in terms of auditory objects. The perceptual data from the present study seem to be consistent with this interpretation. However, it remains unclear to what extent such a process may account for the grouping effects observed here. The decision mechanisms that can relate neural activity and percepts in scene analysis experiments need to be specified. Such mechanisms will need to operate over more than the duration of the stimulus, to account for the retroactive effects shown here. The stimulus configurations tested in the present study might provide a basis for explicitly testing the existing hypotheses regarding the neural representation of across-channel CMR.

Finally, the results of this study also provide challenges for future models of modulation processing and perception. While the recent model of Piechowiak *et al.* (2007), which reflects an across-channel extension of the modulation filterbank model of Dau *et al.* (1997), can account for a variety of detection and masking data, including across-channel CMR, it is not able to simulate the elimination of CMR as a result of perceptual segregation of the masker band from the flanker bands. Likewise, recent models of spectro-temporal processing in the auditory system proposed by Chi *et al.* (2005) cannot account for this finding. In both modeling approaches, the signal energy across time and frequency is essentially integrated linearly. This might be successful in relatively simple sound conditions but fails in more complex sound situations where perception depends on the acoustical context. However, the output of the processing models might provide some of the important auditory features as input to the "central processor." The models have been shown to be valuable as pre-processors in, for example, automatic speech recognition and objective assessment of speech quality (Hansen and Kollmeier, 1999; Tchorz and Kollmeier, 1999; Chi *et al.*, 2005). It remains to be seen how best such representations can be manipulated to predict the effects described in this study.

Can temporal fine structure represent the fundamental frequency of unresolved harmonics?

Andrew J. Oxenham,[a] Christophe Micheyl, and Michael V. Keebler
Department of Psychology, University of Minnesota, 75 East River Road, Minneapolis, Minnesota 55455

(Received 21 March 2008; revised 4 February 2009; accepted 4 February 2009)

At least two modes of pitch perception exist: in one, the fundamental frequency (F0) of harmonic complex tones is estimated using the temporal fine structure (TFS) of individual low-order resolved harmonics; in the other, F0 is derived from the temporal envelope of high-order unresolved harmonics that interact in the auditory periphery. Pitch is typically more accurate in the former than in the latter mode. Another possibility is that pitch can sometimes be coded via the TFS from *unresolved* harmonics. A recent study supporting this third possibility [Moore *et al.* (2006a). J. Acoust. Soc. Am. **119**, 480–490] based its conclusion on a condition where phase interaction effects (implying unresolved harmonics) accompanied accurate F0 discrimination (implying TFS processing). The present study tests whether these results were influenced by audible distortion products. Experiment 1 replicated the original results, obtained using a low-level background noise. However, experiments 2–4 found no evidence for the use of TFS cues with unresolved harmonics when the background noise level was raised, or the stimulus level was lowered, to render distortion inaudible. Experiment 5 measured the presence and phase dependence of audible distortion products. The results provide no evidence that TFS cues are used to code the F0 of unresolved harmonics. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3089220]

I. INTRODUCTION

Many sounds in our environment, such as voiced speech, musical tones, and some animal vocalizations, are harmonic, comprising frequencies that are all at, or close to, integer multiples of a fundamental frequency (F0). We tend to hear a pitch corresponding to the F0, even when there is no energy at the F0 itself. This phenomenon has various terms, including the "pitch of the missing fundamental," periodicity pitch, and residue pitch (e.g., Schouten, 1940; Licklider, 1954).

The mechanisms of pitch perception have been the subject of numerous studies over the past century and are still being debated today (Plack *et al.*, 2005). There is broad consensus on certain aspects of pitch perception. For instance, low-numbered harmonics (<10) typically produce a more salient pitch and more accurate F0 discrimination than do high-numbered harmonics. The transition from strong to weak pitch with increasing lowest harmonic number (N) within a complex corresponds reasonably well with the transition from resolved to unresolved harmonics, as estimated by the dependence of F0 difference limens (F0DLs) on the phase relationships between components (Houtsma and Smurzynski, 1990; Shackleton and Carlyon, 1994; Bernstein and Oxenham, 2006a, 2006b), although it does not appear to be peripheral resolvability per se that determines the changes in percept with increasing N (Houtsma and Goldstein, 1972; Bernstein and Oxenham, 2003, 2008).

Resolved harmonics (such as isolated pure tones) may be coded by their tonotopic (place) representation (e.g., Wightman, 1973), by phase-locking to the temporal fine structure (TFS) in the auditory nerve (e.g., Meddis and O'Mard, 1997), or by a combination of both (Shamma and Klein, 2000; Oxenham *et al.*, 2004). In so-called "pattern recognition" models of pitch, the estimates of the individual frequencies are combined to derive the overall F0 (Goldstein, 1973; Terhardt, 1974).

For unresolved harmonics, which interact within the passband of single peripheral auditory filters, the F0 may be extracted via phase-locking to the temporal envelope of the complex waveform after peripheral filtering, by phase-locking to TFS peaks located near envelope peaks, or both. Early evidence in favor of the use of TFS to derive the F0 from unresolved harmonics came from experiments using sinusoidally amplitude-modulated (SAM) tones (e.g., de Boer, 1956; Schouten *et al.*, 1962). A SAM tone has three tonal components, the carrier frequency (f_c) and two side bands, one above and one below the carrier, with the frequency spacing between the components corresponding to the modulation frequency (f_m). When f_c is an integer multiple of f_m, the waveform is periodic and consists of three consecutive harmonics with an F0 equal to f_m. When f_c is not an integer multiple of f_m, the temporal envelope is still periodic, with a frequency f_m; however the TFS no longer shares the same F0. The fact that listeners heard a shift in pitch when the f_c was shifted, even when f_m remained the same, was taken as evidence that listeners were sensitive to the TFS of complex waveforms (de Boer, 1956; Schouten *et al.*, 1962). One potential confound in these early experiments was that the spectral centroid of the complex shifted with the f_c, leaving open the possibility that listeners were responding to a change in the spectrum of the three-tone complex rather than to a change in the TFS. Moore and Moore (2003) ad-

[a]Author to whom correspondence should be addressed. Electronic mail: oxenham@umn.edu

dressed this issue by using stimuli with more components, which were either harmonically related or were all shifted upward by the same amount in Hertz, and filtering them such that the spectral envelope of the stimuli remained constant. When the lowest harmonic number (N) present was about 14 or higher, no pitch shifts were heard when the frequencies of the components were shifted, suggesting that listeners were only sensitive to the temporal envelope and not to the TFS. At low values of N a pitch shift was heard, but this may have been due to the frequency shifts of the individual resolved harmonics. At intermediate N values of around 9, significant pitch shifts were found. Moore and Moore (2003) concluded that the results at intermediate values of N could be interpreted in two ways: First, if the harmonics were partially resolved, listeners may have been able to extract the individual frequencies of some of the harmonics and thus perceived a pitch shift by way of a shift in the individual harmonic frequencies; second, if the harmonics were unresolved, listeners may have been sensitive to the TFS of the complex waveform, in line with the theories of de Boer (1956) and Schouten *et al.* (1962). In a follow-up study, Moore *et al.* (2006a) attempted to distinguish between these two possibilities.

Moore *et al.* (2006a) measured F0DLs for three-component harmonic complexes centered at 2000 Hz as a function of F0 or, equivalently, the lowest harmonic number present. Either the three components were all in cosine phase (COS) or the middle component was shifted by 90° to produce what is often referred to as alternating phase (ALT). It was assumed that accurate F0 discrimination, as reflected by low F0DLs, implied that listeners were able *either* to access resolved harmonics *or* to process the TFS information from unresolved harmonics. Moore *et al.* (2006a) proposed to distinguish between these two possibilities by assessing whether or not F0DLs were dependent on the component phase relationships: if the components were resolved, then F0DLs should be independent of phase, whereas if they were unresolved, the components would interact within the auditory periphery and F0DLs might be phase-dependent. When N was 6 or 7, Moore *et al.* (2006a) found that F0DLs were low, and there was no effect of component phase, consistent with the harmonics being resolved. When N was 8, mean F0DLs in the COS condition were still as low as those when N was 6 or 7, but now mean F0DLs in the ALT condition were about a factor of 2 higher. The combination of low F0DLs and a phase effect led Moore *et al.* (2006a) to conclude that listeners were indeed using TFS to code the F0 from unresolved harmonics for values of N between about 8 and 10.

The conclusions of Moore *et al.* (2006a) have important theoretical implications. They suggest that listeners are able to use TFS for extracting not only information about the frequencies of individual resolved harmonics or the center frequency of a narrowband sound but also information about the F0 of a complex tone. Although the idea stems from early pitch research (e.g., Schouten, 1940; de Boer, 1956), more recent approaches have tended to consider pitch perception as originating from two cues [or possibly two mechanisms—see Carlyon and Shackleton (1994)], one that involves the individual frequencies of resolved harmonics (coded via place and/or TFS) and one that involves the F0 of the unresolved harmonics (coded via temporal envelope cues) (e.g., Shamma and Klein, 2000). The suggestion that TFS may play another role for unresolved harmonics in the "intermediate" range of harmonic numbers (for N between 8 and 11) can be interpreted as adding a third pitch mechanism, which has implications for models of pitch processing. Another important implication of the results of Moore *et al.* (2006a) relates to the current debate regarding the role of TFS encoding in relation to the listening difficulties experienced by hearing-impaired individuals. Recent studies have extended the work of Moore *et al.* (2006a) to hearing-impaired listeners (Moore *et al.*, 2006b; Hopkins and Moore, 2007) and have shown that in most of these listeners, there was no evidence for this intermediate region, where phase effects are found despite good (low) F0DLs. This has been interpreted as evidence that hearing-impaired listeners have reduced access to TFS cues (Moore *et al.*, 2006b; Hopkins and Moore, 2007). The idea that hearing-impaired listeners have difficulties extracting TFS information in a way that cannot be simply explained by poorer frequency selectivity (and fewer resolved harmonics) has also been extended to studies of speech reception (e.g., Lorenzi *et al.*, 2006; Hopkins *et al.*, 2008). Because of their theoretical importance and their influence on subsequent research on TFS coding, the results of Moore *et al.* (2006a) deserve closer consideration.

One puzzling aspect of the results of Moore *et al.* (2006a) is that they found a strong phase effect even when there was no increase in the F0DLs for the COS complex. Although this is crucial to their interpretation that TFS coding is involved, it does not seem consistent with earlier studies. For instance, Houtsma and Smurzynski (1990) used complexes that were either in sine phase, which is thought to produce a highly modulated temporal envelope after auditory filtering, or in negative Schroeder phase (Schroeder, 1970), which is thought to produce a much less modulated temporal envelope (e.g., Kohlrausch and Sander, 1995; Oxenham and Dau, 2001). Houtsma and Smurzynski (1990) found that phase affected performance only once F0DLs in the sine-phase complex were elevated. Similar results were obtained in studies by Bernstein and Oxenham (2005, 2006b) when comparing sine-phase and random-phase complexes. Moore *et al.* (2006a) suggested that the difference might be due to the possibility that random and Schroeder phases do not produce the "optimally" flat temporal envelope produced by ALT-phase complexes and that the earlier studies had used complexes with more components.

Another difference between the study of Moore *et al.* (2006a) and the previous ones is the level of background noise used to mask distortion products. Houtsma and Smurzynski (1990) used a pink noise and presented their tones 20 dB above masked threshold; Bernstein and Oxenham (2003, 2005, 2006b) used a noise that produced roughly equal pure-tone detection thresholds at all frequencies (e.g., Moore *et al.*, 2000), and presented their tones on average between 10 and 15 dB above masked threshold. In contrast, Moore *et al.* (2006a) used threshold equalizing noise at a level of 30 dB/ERB_N, where ERB_N refers to the average value of the equivalent rectangular bandwidth of the auditory

filter for young normal-hearing listeners at moderate levels (Glasberg and Moore, 1990). Because their complexes were presented at a level of 60.2 dB SPL (sound pressure level) per component, the tones were likely to have been 30–35 dB above their masked threshold.

The level of distortion products induced by two-, three-, and multitone complexes has been the subject of much research (e.g., Goldstein, 1967; Smoorenburg, 1972a, 1972b; Buunen *et al.*, 1974; Pressnitzer and Patterson, 2001). The effective level of the distortion products is influenced by a number of variables, but it is not unusual to find distortion products at levels as high as 20 dB below the level of the primary components. The level and phase of distortion products have been shown to vary with the phase relations of the (three or more) primary components (Buunen *et al.*, 1974; Pressnitzer and Patterson, 2001), and a number of researchers have proposed that some phase effects found in pitch perception can be ascribed to changes in the levels of distortion products (Goldstein, 1973; Buunen *et al.*, 1974; Fleischer, 1976; for an early review, see Moore, 1977). Thus, it appears that the noise level used by Moore *et al.* (2006a) may not have been sufficient to mask distortion products. This in turn implies that changes in the relative levels of the distortion products with changes in phase may have influenced their results. The present study was designed to repeat the study of Moore *et al.* (2006a) with the same level of noise used in the original study and with a higher level of background noise to assess the extent to which their results and conclusions were affected by the audibility of distortion products.

II. EXPERIMENT 1: REPLICATION WITH LOW BACKGROUND NOISE LEVEL

A. Methods

1. Subjects

Four listeners (aged 18–22 yr) took part. All four had normal hearing, defined as having audiometric thresholds of 20 dB HL (hearing level) or less at octave frequencies between 250 and 8000 Hz. Following pure-tone audiometry, the listeners were given the opportunity to familiarize themselves with the stimuli and task. In all experiments in this study, all listeners had some musical education and had played a musical instrument at some point in their life. In addition, most of them had already participated in pitch discrimination experiments prior to this study. Therefore, they had no difficulty understanding the instructions, and by the end of the first 2-h session, their thresholds already fell within the same range as those obtained by one of the authors, who had extensive experience in pitch discrimination tasks, and they showed no clear signs of further improvement. In this and all subsequent experiments, elevated thresholds, obtained at first in a few of the listeners (mostly those with the least amount of musical training or prior experience in pitch discrimination tasks), were discarded before actual data collection began.

2. Procedure

This experiment measured F0DLs using a two-interval two-alternative forced-choice method with a 3-down 1-up adaptive procedure that tracks the 79% correct point on the psychometric function (Levitt, 1971). The two intervals contained complex tones with F0s that differed by an amount of ΔF0, expressed as a percentage of the F0 around which the two interval F0s were geometrically centered ($F0_c$). The initial value of ΔF0 was 20%, which was initially varied (increased or decreased, according to the adaptive procedure) by a factor of 1.414 for the first four reversals in the adaptive rule. The factor was reduced to 1.189 for the final four reversals. Threshold was defined as the geometric mean value of ΔF0 at the last four reversals. At least four threshold estimates were obtained for each subject in each condition. The reported threshold was taken as the geometric mean of all estimates.

3. Stimuli

The stimuli were the same as those used by Moore *et al.* (2006a). Each complex tone consisted of three consecutive harmonics, each with a level of 60.2 dB SPL (65 dB SPL overall). The nominal number of the lowest harmonic, N, ranged from 4 to 14. The nominal frequency of the center component was 2000 Hz, which was roved by $\pm 10\%$ on each trial to encourage listeners to base their judgments on comparisons within each trial, rather than on any long-term memory representations. To reduce the effectiveness of spectral cues (as opposed to F0 cues), the value of N was roved across intervals, such that the actual lowest harmonic for each stimulus could be $N-1$, N, or $N+1$. The roved value was selected independently (with replacement) in each interval. The three components were added either in cosine phase (COS condition) or in alternating phase (ALT condition), where the phase of the center component lagged by 90° (sine phase). Each complex tone had a total duration of 480 ms, gated on and off with 20-ms raised-cosine ramps. The two complex tones within each trial were separated by an interstimulus interval of 300 ms.

A background threshold equalizing noise (Moore *et al.*, 2000) was added, which was gated on 400 ms before the first interval and gated off 400 ms after the second interval. The noise was generated in the spectral domain and contained energy between 50 and 3000 Hz. The level of the noise was set to 30 dB SPL/ERB_N, so that the individual tones were about 30–35 dB above their masked thresholds in the noise.

B. Results and discussion

The mean results across the four listeners are shown in Fig. 1, where F0DLs are plotted as a function of the lowest harmonic number (N) of the three-tone complex for COS (open symbols) and ALT (filled symbols) complexes. Despite inter-individual variability, as also found by Moore *et al.* (2006a), the mean data obtained in this experiment replicated the main findings from the experiment of Moore *et al.* (2006a): for low values of N, F0DLs were low and similar in COS and ALT phases; at high values of N, F0DLs were higher and were generally higher in ALT than in COS phase.

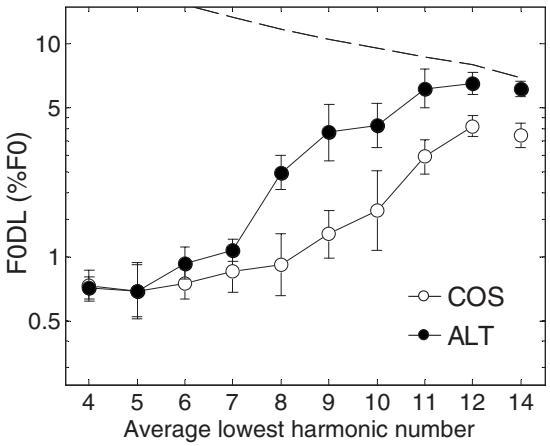

FIG. 1. Mean F0DLs for three-component complexes as a function of the lowest harmonic number present (N). Filled symbols represent results for stimuli in ALT phase; open symbols represent results for stimuli in COS phase. Error bars represent ±1 standard error of the mean. The level of the threshold equalizing noise was set at 30 dB/ERB$_N$, meaning that the components were about 30–35 dB above their masked thresholds in noise. The dashed line shows the predicted thresholds based solely on spectral, rather than F0, information.

According to the reasoning of Moore *et al.* (2006a), if TFS can be used to code the F0 of unresolved harmonics, then some conditions should exist where (a) F0DLs are small, implying accurate coding using TFS, and (b) a phase effect is found, implying that the harmonics are unresolved. Such conditions can be seen in Fig. 1 for values of N between 8 and 10, where F0DLs are still relatively small in the COS condition but not in the ALT condition. To test this more formally, we established a "cutoff" F0DL, at the midpoint between the "asymptotic" low and high F0DLs, estimated using the geometric mean of the F0DLs in the COS condition at the lowest and highest value of N tested. We then took the highest value of N at which the F0DL in the COS condition fell below the cutoff value for the F0DL; this represented the condition for which the harmonics were most likely to be unresolved and still produce low F0DLs. Finally, we performed a paired t-test comparing the (log-transformed) F0DLs in the COS and ALT conditions for the selected value of N.

For the data in Fig. 1, the cutoff F0DL value was 1.64%. The highest N value for which the mean COS F0DLs fell below the cutoff was 10. A paired t-test at this value of N produced a significant effect of phase [paired $t(3)=2.93$, one-tailed $p=0.031$]. This finding of significant phase interactions for conditions in which the F0DLs are low is consistent with the results and conclusions of Moore *et al.* (2006a). In other words, these data show that a phase effect can occur, even when F0DLs are low, in line with the idea that TFS can be used to code the F0 of unresolved harmonics.

As the value of ΔF0 increases, the roving of lowest harmonic number by ±1 ceases to rule out the use of spectral (as opposed to F0) cues. The dashed curve in Fig. 1 shows the prediction of performance based solely on the (perfect or noiseless) frequency discrimination of the lowest component in each complex, as described in detail by Moore *et al.* (2006a). It can be seen that the mean F0DLs at the highest values of N approached this limit in the ALT, but not the COS, condition.

C. Experiment 1a: Using a different roving technique

As discussed by Moore *et al.* (2006a), their roving technique (also used here in experiment 1) leads to a listener obtaining 67% correct responses at small values of ΔF0, even if all responses are based solely on the increase in the frequency of the lower spectral edge of the stimulus and not on the change in F0. This is because with the three possible values of the lowest harmonic number in each interval (N_{INT}), the probability that the N of the interval with the higher F0 will be the same as or greater than the N of the interval with the lower F0 is 67% (or 6 out of 9). Although 67% is lower than the tracking percent correct of 79%, it is still considerably higher than the 50% value of chance in a more typical two-alternative forced-choice experiment. Also, for two out of the nine possible combinations of N, the difference in N between the intervals was 2, producing a very large change in timbre, which listeners may have found distracting. Both these factors may have led subjects to lend more weight to the spectral pitch of the stimuli, rather than the desired periodicity pitch. Experiment 1a was designed to avoid these potential confounds by restricting the difference in N_{INT} between the two intervals within a trial to 1 and by ensuring that at small values of ΔF0, listeners would only achieve 50% correct by using spectral edge cues. We achieved this goal by ensuring that the lowest harmonic number in the two intervals was always different and always differed by only 1. In other words, the possible combinations of the lowest harmonic number in the two intervals were $(N-1,N)$, $(N,N-1)$, $(N,N+1)$, and $(N+1,N)$. All other details in the experiment were the same as in the main experiment, except that the background noise was now broadband (extending from 50 Hz to 19.2 kHz) instead of being lowpass filtered at 3 kHz. Seven normal-hearing subjects took part in this experiment. Two of these listeners also took part in experiment 1. The ages of the subjects ranged from 19 to 33. The different roving paradigm led to some different predictions for thresholds based only on the frequency of the lowest harmonic. Briefly, the frequency of the lowest harmonic is a consistently reliable cue when $(N-1)\mathrm{F0}_H > N\mathrm{F0}_L$, where $\mathrm{F0}_H$ and $\mathrm{F0}_L$ are the F0s of the higher- and lower-F0 interval within a trial, respectively. Given that $\mathrm{F0}_H=\mathrm{F0}_L(1+\Delta\mathrm{F0}/100)$, where ΔF0 is the difference between $\mathrm{F0}_H$ and $\mathrm{F0}_L$ in percent, the inequality can be solved for ΔF0, such that spectral cues are reliable under the following condition:

$$\Delta\mathrm{F0} > 100[N/(N-1)-1]. \quad (1)$$

This prediction is shown as a dashed curve in Fig. 2, along with the mean results from experiment 1a. It can be seen that F0DLs were somewhat higher overall than in experiment 1. This is consistent with the prediction that a higher sensitivity (d') is required to achieve 79% correct when performance based on spectral cues is 50%, as opposed to 67%, although part of the difference may simply be due to inter-subject

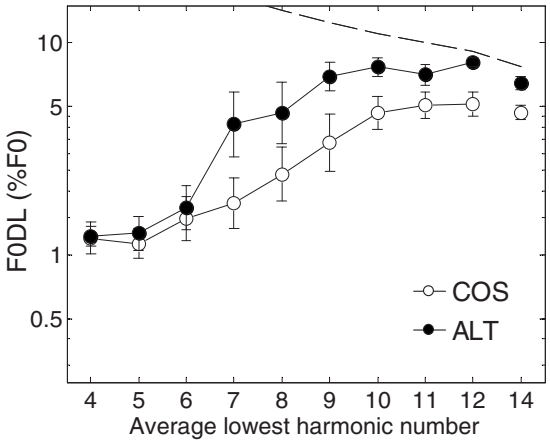

FIG. 2. As in Fig. 1, except that the noise was broadband, instead of low-pass filtered at 3 kHz, and that the roving of the N followed a different procedure (see text for details). As in Fig. 1, error bars in this and following figures represent ± 1 standard error of the mean. In this and all following figures, the dashed line shows predicted thresholds based on spectral rather than F0 information. These predictions differ slightly from those shown in Fig. 1 due to the use of a different lower-harmonic-number randomization rule.

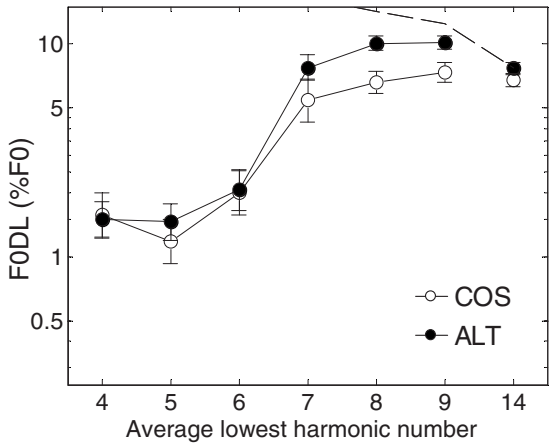

FIG. 3. As in Fig. 2, except that the level of the background noise was 20 dB higher, which should have been sufficient to mask distortion products.

variability. Other than that, the pattern of results was similar to that found in the main experiment.

Using the same analysis that was used for experiment 1, the cutoff F0DL (i.e., the geometric mean of the lowest and highest group F0DLs) was 2.37%, and the highest value of N with an F0DL below that cutoff in the COS condition was 7. For this value of N, a paired t-test revealed a significant effect of phase [paired $t(6)=2.92$, one-tailed $p=0.014$]. Thus, consistent with the results from experiment 1, conditions existed in which F0DLs were low but a phase effect was observed. The similarity in the pattern of results between experiments 1 and 1a was supported by a mixed-model analysis of variance (ANOVA), with experiment as a between-subjects variable and N and phase as within-subject variables.[1] The ANOVA revealed a significant main effect of experiment [$F(1,9)=8.44$, $p=0.017$], in line with F0DLs being somewhat higher in experiment 1a, but no interactions of the other variables (N and phase) with experiment ($p>0.1$ in all cases).

III. EXPERIMENT 2: REDUCING THE AUDIBILITY OF DISTORTION PRODUCTS WITH BROADBAND NOISE

A. Rationale

Both experiments 1 and 1a were successful in replicating the basic results of Moore *et al.* (2006a), in particular the finding that low F0DLs, implying TFS processing, were found in conjunction with phase dependencies, implying unresolved harmonics, at intermediate values of N. However, as discussed in Sec. I, the background noise level was not sufficient to rule out the audibility of distortion products, the amplitudes of which may have varied with the phase relationships and may have influenced the results. This possibility was tested here by raising the level of the background noise to 50 dB SPL/ERB$_N$, which led to the individual components of the complex being between 10 and 15 dB above their masked thresholds.

B. Methods

The stimuli and procedure were the same as in experiment 1a, with the exception that the level of the background noise was increased by 20 dB. The roving paradigm was the same as that used in experiment 1a, so that at small values of ΔF0 listeners would obtain only 50% correct by basing their judgments on the frequency of the lowest harmonic present, rather than on the F0. Nine normal-hearing listeners (aged 18–33) took part in this experiment. Seven of them also participated in either experiment 1 or experiment 1a, or both. The experiments were not run systematically in the order in which they are described in this article. In fact, those listeners who took part in both experiment 2 and experiment 1 or 1a had completed experiment 2 first.

C. Results and discussion

The mean F0DLs across the nine listeners are plotted in Fig. 3. Again, filled symbols represent thresholds for ALT phase, and open symbols represent thresholds for COS phase. The dashed line represents predictions based solely on the frequency of the lowest harmonic, as described in experiment 1a. Many trends in the data are similar to those observed in experiments 1 and 1a. In particular, F0DLs are low at low values of N and increase at higher values of N, and differences between COS and ALT conditions only emerge at higher values of N. However, some differences between these and the earlier results are also apparent. Most importantly, for our purposes, is the apparent lack of a phase effect at values of N for which F0DLs were low. Using the same analysis that was used for experiment 1, the cutoff F0DL (i.e., the geometric mean of the lowest and highest group F0DLs) was 3.40%, and the highest value of N with an F0DL below that cutoff in the COS condition was 6. In contrast to experiments 1 and 1a, no significant phase effect was found for this value of N [paired $t(8)=0.219$, one-tailed $p=0.416$].

This pattern is not consistent with the results of Moore *et al.* (2006a), as replicated in experiments 1 and 1a, but it is
