sented in Table I. Known amounts also were added as single tests to kidney, bile, intestinal contents, and two samples of commercial feed stuffs. In each case, the recovery of the individual compound was within the ranges reported for that compound in Table I, column 5.

The quantitative determination of phenothiazine and phenothiazone was based on their conversion to the ambercolored *N*-nitroso derivatives. This was carried out by treating the phenothiazine eluate directly with nitrous acid and in the case of phenothiazone, by first reducing the eluate and then treating it with nitrous acid. In both instances the colors were stable for at least 1 hour. In the case of thionol, advantage was taken of its intense blue color in alkaline solution which had a strong absorption band at 590 m μ , possibly the spectrum of the phenolate ion (3). The color was not stable at high concentrations and so was read as soon as possible after addition of the alkaline buffer.

Phenothiazine-5-oxide is converted to the sulfonium salt (1, 2, 5) when it is dissolved in strong acid. The resulting orange-pink solution had an absorption band at 445 m μ and was unstable; however, addition of one drop of ferric chloride solution produced a stable color with a maximum absorption at 520 m μ .

PESTICIDES AND FOOD FLAVOR

Effect of Insecticides and Fungicides on the Flavor Quality of Fruits and Vegetables

A NORTHEAST REGIONAL PROJECT (NE-15) was activated in July 1954 to determine the effects of pesticides on the quality of fruits and vegetables by means of organoleptic tests. Its primary concern was to uncover any association of poor flavor quality or off-flavor with pesticidal treatments.

The first task of the committee was to determine the extent of agreement on sample ratings among panels in different laboratories through exchange of samples. A second objective was the development of a scoring technique which would quickly, economically, and precisely evaluate the off-flavor hazard in the use of pesticides.

Preliminary Procedure

In 1954, a lack of uniform test material hampered the work of the committee because the project was activated too late to plant and treat crops specifically for the study. The use of crops designed for other purposes forcefully pointed to the necessity of an adequate supply of samples as uniform as is possible with biological material and controlled in every respect except for the variable under study.

Some of the first year's experiments were confounded by extraneous influences whereby significantly different results could erroneously be attributed ELIZABETH F. MURPHY

to pesticides. Three examples illustrate this confounding.

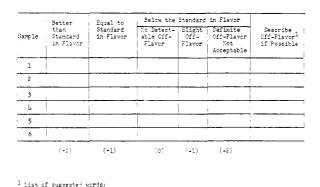

Incomplete sealing of a few cans of snap beans resulted in flat-sour development, thereby nullifying an experiment.

The inclusion of some immature squash (to obtain sufficient control sample) resulted in overprocessing at the same time-temperatures that were optimum for mature squash. The resulting scorched flavor confounded the results of the study.

Apple juices from methoxychlortreated trees were significantly lowerscored and in some cases rated as offflavor by nearly all of the participating laboratories. It was known that the methoxychlor-treated trees were heavily During 6 years, seven experiment stations and the Bureau of Human Nutrition, U. S. Department of Agriculture, tested by organoleptic methods the effects of pesticides on the flavor of 20 vegetables and three fruits. Common samples were exchanged and evaluated by the cooperating agencies, using a method developed by the group. Some pesticides were tested enough times (11 to 68 tests) to derive a picture of the distribution of flavor effects in terms of a control sample—i.e., better, equal, poorer, slight, and definite offflavor. Five single insecticides and one fungicide were associated with a notable degree of poor flavor quality. Six combinations of pesticides had adverse effects on flavor. Some of these seemed to be related to specific components of the multiple treatments, while others were ascribed to interaction. No ill effect on flavor quality was noted in association with ten insecticides, three fungicides on potatoes, and three fungicides on apples.

Instructions: Check the column where you think each sample belongs.

Bister Burnt	Fragrant Medicinal	Cily Putrid	Salty Sour	
Earthy	Metallic	Fuckery	Spicy	
Flat	Musty	Rancid	Sweet	
			Woody	

Figure 1. NE-15 score sheet for flavor evaluation

Values assigned to each category are given in parentheses below columns. The values are used for mean score calculations.

damaged by mites and the apples, therefore, less ripe. Thus a maturity difference was associated with the pesticide treatment. In consequence, the results from that treatment had to be omitted.

These experiences emphasize the need for the quality investigator to have a completely detailed history of the samples from planting through all stages of growth, harvest, storage, and processing in order to evaluate cause with effect intelligently.

A four-point scale was used in 1954. This was built around a conception of average flavor: 4, better than average; 3, average; 2 and 1, slight and definite degrees of off-flavor. The method was considered by the judges to be wanting in two respects: a need for a labeled standard sample (untreated or previously shown to be of good quality) to give them a common reference point and a fifth scale point to indicate poorer than standard but not necessarily off-flavor.

Accepted Procedure

In 1955, a five-point scale with a labeled standard was adopted (Figure 1). The samples were judged in relation to a coded or "blind" reference sample, which was always included as an unknown. Scores of +2 to -2 were assigned for variance analysis, so that a final minus score indicated off-flavor, with its magnitude showing the degree of off-flavor (2, 3). With this method, excellent agreement was obtained among several laboratories with panels differing in size and composition (3).

A list of suggested words was appended to the score sheet for the judges to use in identifying the off-flavor (if any), but the result was meaningless because of disagreement on the connotation of descriptive terms. Good correlations were obtained only in a general breakdown between words conveying "pleasant" vs. "unpleasant" taste sensations. Semantic agreement would undoubtedly be possible with intensive panel training on the the identification of individual flavors. This would presuppose the knowledge by the investigator of the specific off-flavor developed in the final product form (which could be a metabolite of entirely different flavor than the original additive) and be extremely timeconsuming with panels having as many as 40 judges.

In a few instances, other organoleptic techniques were used: Ranking and paired comparisons were used for a number of tests. These methods do not lend themselves to an interpretation of off-flavor and must result only in "significantly better or poorer" than the standard. A five-point scoring technique was used in some tests by the Human Nutrition Research Division, in which 5 indicated no off-flavor and 4 to 1 were degrees of off-flavor.

The panels varied in number from five trained people to 40 or more. All laboratories selected judges who had demonstrated taste acuity in previous studies. In general, each unit in the tables represents a mean value from a minimum of 40 judgments (judge \times replication). In relatively few instances the value was derived from 20 judgments (5 judges \times 4 replications).

Most of the results from 1955 through 1960 are based on the 1955 NE-15 method (Figure 1) wherein two criteria had to be satisfied in order to label a sample "off-flavor": (A) It must be significantly (P = 0.05) lower-scored than the coded standard and (B) it must be associated with a minus score.

Results

In 1960, the project was terminated and a list of all of the tested pesticides was prepared.

The resulting data are shown in the tables. Table I demonstrates the effects of insecticides on the flavor of fruits and vegetables when a single insecticide was the only variable. Table II lists the observed influences of single fungicides on flavor. Table III shows the effects of multiple pesticides on flavor—

i.e., application to the crop of two or more insecticides, fungicides, or a combination of the two. Pesticides in Table III are cross-indexed to make the information useful to both pathologists and entomologists, even though this involves repetition of the data.

On some pesticides, relatively few observations were made. A few of these involved new and/or experimental materials. Others were discarded after brief testing because of discontinuance of the use of the pesticide, the introduction of new and more effective materials to supersede the old, or limited applica-It was decided to release all bility. of the findings for the benefit of the users and manufacturers of the materials as well as to stimulate other investigators to fill the gaps where more data are needed. The data reported here were combined from all cooperating laboratories. They were verified independently by each investigator, who interpreted his own results.

The tables include some information on the actual amounts of pesticidal materials applied. For sprays, this is presented as pounds or quarts per 100 gallons

per application as necessary in area of production. The pesticides in dust form are recorded as total pounds of actual ingredient per acre for soil or foliar applications or a combination of the two. An insecticide applied at 1 pound per acre nine times is recorded as 9 pounds. In a few experiments, excessive dosages were applied to simulate careless use of pesticides or to telescope the effect of long-term applications-e.g., 20 pounds per acre of chlordan or 15 pounds per acre of toxaphene per year for several years. Possible relevant details as to dates of application, nearness to harvest, depth and distribution of soil-applied chemicals, soil type, etc., are omitted. The locations of the field trials are labeled, and the reader may obtain the treatment schedules in greater detail from these sources.

Fifteen of the 36 single insecticides were represented by 14 to 68 evaluations and seven of the 17 combined insecticides by 14 to 45 tests. Fungicides were not so widely tested. Three of the 11 single fungicides were tested 13 times and three of 11 combinations were evaluated 16 to 43 times. Many of the data have been or will be published in greater detail as separate studies.

Average scores of treated samples showing "slight off-flavor" were infrequent and "definite off-flavor" average scores were rare enough to be ignored. Both off-flavor categories are tabulated and discussed together.

Discussion is generally limited to those pesticides or combinations of pesticides on which a sufficient number of evaluations were made to give some conception of distribution.

Discussion

About 21, 10, and 20% of the samples treated with BHC, lindane, and toxaphene, respectively, were judged to be off-flavor. The multiple pesticide treatments including toxaphene were judged off-flavor in 14% of the samples.

Five single insecticides indicated a noteworthy degree of adverse effect on flavor quality (significantly "poorer than standard" plus off-flavor). BHC, lindane, and toxaphene treatments induced poor flavor quality in 57, 55, and 48% of 14, 20, and 25 samples, respectively. The high level of ill effects from toxaphene was mainly for potato samples grown on soil treated with 15 pounds per acre applied in alternate years for 9 to 11 years as well as in the test year, a relatively high dosage (probably three to five times the amount necessary for insect control). Twenty-five per cent of the 24 samples treated with endrin and 16% of the 68 samples treated with malathion were judged to be in the poorer flavor category.

Single insecticides which in general did not induce poor flavor quality as based on 14 or more evaluations were: chlordan, DDT, Dibrom, Dilan, dimethoate, heptachlor, phosphamidon, Sevin, Thiodan, and Trithion.

Improved flavor quality was observed in 10 to 13% of the samples treated with chlordan, heptachlor, lindane, and endrin. Two of these—lindane and endrin—also showed an appreciable degree of poorer flavor.

Samples treated with toxaphene in combination with other insecticides had poor flavor quality in 50% of 14 tests, reflecting the results with potatoes (three of seven poor samples). About 28% of 18 samples treated with Sevin in combination with other pesticides were evaluated as poorer than standard, seemingly because of the interaction of pesticides. Samples treated with the combination of DDT with other pesticides showed quality loss in 24% of 38 samples, demonstrating the influence of toxaphene (five of nine poor samples). The single effect of Sevin and DDT was negative. Malathion in combination induced adverse flavor effects in 27% of 45 samples as compared with its single influence on 16% of 68 samples.

Three of the 11 single fungicides— Bordeaux, tribasic copper, and zineb, with 13 tests each on potatoes only showed no ill effects on flavor and induced better flavor quality in approximately one third of the 13 tests. Although the PCNB treatments involved potatoes only in one crop year, in 11 tests (by two laboratories on two varieties from North Dakota and one from Maine) five of the samples were judged off-flavor and the other six poorer than standard.

None of the fungicides in combination resulted in mean scores showing slight or definite off-flavor. Poorer samples were evident, however, in nine of 43 (21%) captan-treated, and five of 18 (28%) thiram-treated samples. Of these 14 poorer samples, six were in combination with malathion and five others involved Sevin. With multiple pesticides, it is difficult to ascribe poor flavor quality to a single component of the treatment, and the possibility of interaction should not be ignored.

There was no evidence of improved flavor quality associated with multiple treatments.

In the data shown some contradictory results are noted, in that the use of certain pesticides resulted in better as well as poorer flavor. These aberrant situations may be related to specific crop response, to soil type, to crop years with their varying macro- or micro-climate, to pesticidal carriers, to method, time, and distribution of the pesticides, or to unknown factors. The data presented from the NE-15 long-term study admirably demonstrate the need for continued and multiple observations before dogmatic interpretations may be made.

New Jersey was a member of the NE-15 project for three years with emphasis on instrumentation. The New Jersey Food Technology Department pursued taste panel evaluations on samples grown, treated, and tested in New Jersey. More ill effects were evident in the New Jersey tests than among all of the others-e.g., aldrin, chlordan, and dieldrin were classified as poorer than standard (1). The New Jersey results were omitted from the tables and the general discussion because they did not represent the group findings and because no samples were exchanged with other members. The validity of the New Jersey tests is recognized, and it is deemed that neither methodology nor panel acuity is responsible for the lack of agreement. Possible factors which may be related to the discrepancy between the New Jersey and the other samples are soil type, product form, formualtion of the pesticides, and other extraneous influences as discussed above. The NE-15 study was not designed to examine these possible interacting agents and any a posteriori conclusions would be of dubious validity.

Conclusions

Coordinated through the NE-15 regional project, seven state experiment Stations and the U. S. Department of Agriculture examined by organoleptic methods crops treated with pesticides to determine their influence on flavor quality.

During six years, 528 evaluations on 36 single insecticides, 152 on 18 combinations of insecticides, 66 on 11 single fungicides, and 118 on 11 fungicide combinations were made. Each average score represented the opinion of a trained or experienced panel ranging from five to 40 members and was based on a minimum of 20 judgments.

Insecticide evaluations involved 23 crops (20 vegetables and three fruits). Fungicide treatments were used on six crops (five vegetables and one fruit).

Five of the single insecticides and one of the single fungicides were associated with a notable degree of poor flavor quality. Six combinations of pesticides had adverse effects on flavor. Some of these seemed to be related to specific components of the multiple treatments while others were ascribed to interaction.

The committee does not condemn nor endorse any particular pesticide or combination of pesticides. Both known and unknown influences may alter the picture and vitiate any blanket conclusions. We suggest rather that these data be considered a reference summary for the reader to consult according to his own interest as to crop, amount of pesticide, number of crop years tested, and degree of accord among analysts.

Acknowledgment

Persons responsible for furnishing uniform samples to the laboratories were: entomologists: L. P. Ditman, University of Maryland; Phillip Garman, Connecticut Experiment Station; C. H. Hoffman, Entomology Research Division, U. S. Department of Agriculture; G. W. Simpson, University of Maine; and W. D. Whitcomb, Massachusetts Agricultural Experiment Station. Pathologists: Reiner Bonde, University of Maine; F. L. Howard, University of Rhode Island; and D. H. Palmiter, New York Experiment Station. Horticulturist: V. R. Boswell, Crops Research Division, U. S. Department of Agriculture.

Gratitude is accorded to the many conscientious panel members and laboratory assistants and to the several entomologists and pathologists who are not specifically credited.
