The chemical transformations that occur during growth of the shiitake mushroom (*Lentinula edodes*) on oak (*Quercus alba*) were investigated to improve mushroom cultivation and utilization of the spent substrate. Oak logs were decayed by *L. edodes* over 8 years, during which time they were sampled at six intervals (30, 40, 66, 76, 77, and 101 months). Fresh and decayed oak samples were analyzed using solid-state <sup>13</sup>C NMR and pyrolysis–gas chromatography–mass spectrometry as well as off-line thermochemolysis with tetramethylammonium hydroxide. Degraded oak exhibited lower carbon contents and increased oxygen content compared to the control. Solid-state <sup>13</sup>C NMR analysis revealed that polysaccharides were the major component of both fresh and decayed oak but that *L. edodes* mediated the preferential loss of cellulose and xylans as compared to lignin, which remained in an altered form. Several trends point toward the degradation of lignin, including a decrease in the proportion of syringyl units as compared to guaiacyl units and a reduction in side-chain length. An increase in guaiacyl and syringyl acid-to-aldehyde ratios occurred with growth, which suggested that the fungus had caused oxidation of C $\alpha$ –C $\beta$  bonds. The overall effect of *L. edodes* on oak is similar to that of many white-rot fungi, which simultaneously degrade all cell wall components.

KEYWORDS: Lignin; polysaccharide; degradation; shiitake mushroom; *Lentinula edodes*; thermochemolysis, pyrolysis; solid-state <sup>13</sup>C NMR; *Quercus alba*; oak

# INTRODUCTION

The shiitake mushroom, Lentinula edodes, is widely cultivated on oak logs under natural environmental conditions. White-rot, basidomycete fungi degrade lignin, the mainly ether-linked phenylpropanoid biopolymer found in wood cells, either selectively or in parallel with polysaccharides (1). Multiple enzymes are involved in wood decay; these attack wood constituents either directly or indirectly by low-molecular-weight mediators (1). The detection of the enzyme manganese peroxidase, which catalyzes lignin degradation and the protein laccase, which directly oxidizes lignin, confirmed that L. edodes had appreciable lignin-degrading potential (2, 3). The mechanism of lignin decay induced by L. edodes has been investigated using model compounds. Manganese peroxidase, extracted from extracellular fluid of shiitake mycelium, degraded the model compounds vanillyl and veratryl alcohols via side-chain oxidation, aromatic ring cleavage, and methoxyl demethylation (4, 5). It was reported in an additional study that 2,4-dihydroxy-3,3-dimethoxy-5-methyldiphenylmethane was decayed via oxidative cleavage

<sup>†</sup> British Geological Survey.

of the side chain. In contrast, non-phenolic 5,5'-biphenyl and 5,5'-diphenylmethane were found to be unreactive to manganese peroxidase extracted from *L. edodes*, as demonstrated by gas chromatography-mass spectrometry (GC-MS) (6).

Lignin decomposition during solid-state fermentation with L. edodes has been investigated by phosphylitization of fresh and decayed wheat lignin using <sup>31</sup>P NMR spectroscopy (7). The biologically altered lignin was decomposed via stereoselective side-chain oxidation, as suggested by a decrease in the erythro/ threo ratio. The NMR spectra also revealed a greater increase in carboxylic acid groups as compared to aliphatic hydroxyl groups and a decrease in phenolic moieties, which suggested that aromatic ring-cleavage reactions had also occurred during fungal attack. It was also suggested, on the basis of an increase in <sup>1</sup>H NMR resonances at  $\sim 0.8$  and 1.3 ppm, which can be assigned to aliphatic protons, that reductive reactions had occurred upon fungal biodegradation (7). Comparison of the chemical structure of acetylated lignin from Triticum aestivum (wheat) and oak (*Quercus robur*) using <sup>13</sup>C NMR spectroscopy has revealed that the interunit linkages in wheat lignin are significantly different from those in oak (8). Therefore, analysis of hardwood logs is required to elucidate the changes that occur during growth of shiitake mushrooms. We have carried out the

compositional characterization of white oak (*Quercus alba*) logs which are used widely in the United States for shiitake cultivation.

Past evaluation of wood decay during growth of *L. edodes* has been limited; one study investigated the effect of decomposition using infrared spectroscopy and pyrolysis—gas chromatography—mass spectrometry (Py-GC-MS). Both analytical methods revealed a slight preferential removal of lignin as compared to polysaccharides after 98 days of biodegradation. However, no mushrooms were grown in the laboratory-based study (9). Monitoring the chemical composition of oak could aid in the optimization of shiitake production and commercial exploitation of the degraded logs as compost. This investigation used solid-state <sup>13</sup>C NMR, analytical pyrolysis, and thermochemolysis in the presence of tetramethylammonium hydroxide to characterize the molecular changes that occur in white oak as a function of cultivation time during commercial production of *L. edodes*.

#### MATERIALS AND METHODS

**Cultivation of** *L. edodes.* Healthy white oak trees (*Quercus alba*) grown within a 5-mile radius of Shirley, Arkansas, were cut into logs approximately 90 cm long and 10–15 cm in diameter. The moisture content of each log was maintained at  $\sim$ 35% (w/w) by the addition of water. Inoculation was achieved by drilling 30 holes of depth  $\sim$ 2.5 cm in a diamond pattern and packing with fresh spawn of *L. edodes.* After completion of the spawn run (6 months), the colonized logs were placed outside (natural fruiting 2–3 times per year); the temperature range was 7.2–21.1 °C. Samples of oak sapwood ( $\sim$ 5 g dry weight) were removed at 0, 30, 40, 66, 76, 77, and 101 months. Each sample was washed with sterile distilled water to remove surface mycelium and freeze-dried to remove water.

**General.** The authentic standards 4-methoxyacetophenone, 3,4dimethoxybenzaldehyde, 3,4-dimethoxyacetophenone, 1,2,3-trimethoxyphenol, 3,4,5-trimethoxybenzaldehyde, and 3,4,5-trimethoxyacetophenone and the internal standard *n*-eicosane were reagent grade (Sigma-Aldrich Chemical Co., Gillingham, Dorset, U.K). Fresh and fungally decayed oak woods were powdered to pass through a 63- $\mu$ m sieve, extracted in a Soxhlet apparatus with CH<sub>2</sub>Cl<sub>2</sub> for 24 h, and dried under vacuum with P<sub>2</sub>O<sub>5</sub>.

**Elemental Analysis.** The organic carbon, hydrogen, and nitrogen content of oak samples was determined in quadruplicate using a Carlo Erba 1106 elemental analyzer. Ash content was determined gravimetrically following combustion of the dry powdered oak at 650 °C for 18 h (*10*). Blanks and samples were interchanged in order to account for possible instrumental drift.

Bulk Carbon Isotope Analysis. Stable carbon isotopic compositions for dried and powdered oak woods were determined using a Carlo Erba NA1500 elemental analyzer for on-line combustion (oxidation furnace setting 1020 °C; reduction furnace setting 650 °C). CO<sub>2</sub> and N<sub>2</sub> were separated by gas chromatography prior to analysis using a Micromass Optima gas source isotope ratio mass spectrometer. The <sup>13</sup>C/<sup>12</sup>C ratio of the organic carbon in each wood sample is reported relative to PDB carbonate standard using the  $\delta$  <sup>13</sup>C (‰) notation; a second internal cellulose standard (sigmacell, Sigma Chemical Co.) was used to account for instrumental drift. Based upon replicate analyses, the analytical error for the oak woods was ±0.2‰, and that for the authentic cellulose standard was <±0.1‰.

**Pyrolysis–Gas Chromatography–Mass Spectrometry.** Fresh and fungally decayed oak wood samples (0.5–0.7 mg) were placed in borosilicate glass tubes (Clark Electro Chemicals), and both ends of the tubes plugged with pre-extracted silica wool. Pyrolysis–gas chromatography–mass spectrometry (Py-GC-MS) was performed in a flow of helium using a Girdel 75-PY-1 pyrolyzer unit, fitted with a platinum coil connected to a Fisons 8000 series gas chromatograph (GC). The platinum coil was heated for 20 s at 600 °C, as measured by a thermocouple in the sample holder. Volatile products were separated using a 30-m  $\times$  0.25-mm-i.d. Chrompack CP-Sil 8 fused

silica column (film thickness 0.25  $\mu$ m). The GC oven was operated using the following program: isothermal for 5 min at 40 °C, then raised from 40 to 300 °C at 4 °C/min and held isothermally at 300 °C for 10 min with helium as the carrier gas. The GC was directly coupled to a Fisons MD800 mass spectrometer operated at 70 eV with a mass range of m/z 30–550, trap current 140  $\mu$ A, and source temperature 270 °C. Data acquisition and analysis were performed using a Mass Lab data system. Products were tentatively identified by comparison of their mass spectra and relative retention times with those of compounds reported in the literature (11) and the National Institute of Standards library (NIST).

**Pyrolysis Parameters.** The syringyl/guaiacyl ratio (S/G) was calculated by dividing the sum of the peak areas of syringyl units by the sum of the peak areas of guaiacyl units. The guaiacyl phenylpropane/guaiacyl parameters (G:3/G) were measured using peak areas of the cis and trans isomers of 2-methoxy-4-(prop-2-enyl)phenol and 2-methoxy-4-(propan-2-one)phenol as well as 2-methoxy-4-(prop-2-enal)phenol to the sum of guaiacyl units. The syringyl phenylpropane/syringyl ratio (S:3/S) was calculated by dividing the sum of 2,6-dimethoxy-4-(prop-1-enyl)phenol, the two isomers of 2,6-dimethoxy-4-(prop-2-enyl)phenol, 2,6-dimethoxy-4-(prop-1-en-3-one), and 2,6-dimethoxy-4-(prop-2-enal)phenol by the sum of syringyl pyrolysis products.

**Off-Line Thermochemolysis.** For each experiment, borosilicate glass tubing (o.d. 5 mm, i.d. 4 mm), was sealed at one end with a natural gas/oxygen flame to give a vessel of length 13 cm. Each vessel was rinsed with methylene chloride and oven-dried for 12 h at approximately 75 °C. Fresh and fungally decayed spruce wood samples (0.5–1 mg) were placed in individual reaction vessels with 100  $\mu$ L of tetramethylammonium hydroxide (TMAH) solution (25% w/w in methanol). The TMAH preparations were left overnight in a vacuum desiccator in the presence of P<sub>2</sub>O<sub>5</sub> in order to facilitate thorough mixing prior to the removal of methanol under vacuum. The dried mixtures were sealed under vacuum and heated in an oven at 250 °C for 30 min. After cooling, the reaction vessels were opened, and the inner surfaces of the tubes were washed five times with 1 mL of dichloromethane. The combined extracts were dried under a stream of N<sub>2</sub> and dissolved in 100  $\mu$ L of dichloromethane.

**Gas Chromatography–Mass Spectrometry.** GC-MS was performed using a Fisons MD-800 operated at 70 eV with a mass range of m/z 30–600 with helium carrier gas. The GC was fitted with a 30-m × 0.2-mm-i.d. HP-5 fused silica column coated with a 5% phenylmethylsilicone-bonded stationary phase (film thickness 0.25  $\mu$ m). The oven temperature was programmed from 30 to 300 °C at 4 °C/ min and held isothermally at 300 °C for 5 min.

**Thermochemolysis Parameters.** The compound labels (G and S) denote structures shown in **Figure 1**. Acid/aldehyde (Ad/Al)<sub>G</sub> parameters were measured using peak areas of G6 and G4 [(Ad/Al)<sub>G</sub> = G6/G4] as well as methyl 3,4,5-trimethoxybenzoate (S6) and 3,4,5-trimethoxybenzaldehyde (S4) [(Ad/Al)<sub>S</sub> = S6/S4]. The syringyl/guaiacyl ratio (S/G)<sub>TMAH</sub> was calculated by dividing the sum of the peak areas from syringyl derivatives (S4–S16) by the sum of the peak areas from their guaiacyl counterparts (G4-G16). The  $\Gamma$  parameter was determined from the ratio of G6 to the sum of the peak areas of *threo-/erythro*1-(3,4-dimethoxyphenyl)-1,2,3-trimethoxypropane (G14 and G15).

**Solid-State** <sup>13</sup>**C Nuclear Magnetic Resonance.** Solid-state <sup>13</sup>**C** NMR spectra were obtained for fresh and degraded oak samples using a Bruker DSX200 instrument equipped with double-bearing probes for cross polarization (CP) and magic angle spinning (MAS). The resonance frequency for <sup>13</sup>C was 50 MHz, and the sample was spun at the magic angle with a speed of 6.0 kHz. Typically 10 000 scans were accumulated with high-power <sup>1</sup>H decoupling for the CP experiments. For CP, the contact time was 3.0 ms, and the relaxation delay was 1.5 s. Dipolar dephasing experiments were carried out using a dephasing period of 50  $\mu$ s. All spectra were obtained at ambient temperature and processed with a line-broadening factor of 50 Hz. Chemical shifts were calibrated using an external sample of tetrakistrimethylsilane (TKS). Solid-state <sup>13</sup>C NMR determination of the syringyl/guaiacyl ratio (S/G)<sub>NMR</sub> in fresh and decayed oak was made using fresh spruce sapwood (*Picea abies*) to calculate the guaiacyl content (*12*). Briefly, S/G values were measured

from the dipolar dephased spectra with integration of the original spectrum (S + G) and the spruce wood-subtracted spectrum (S-G) between 120 and 160 ppm. The areas of S and G were normalized to an equal number of nonprotonated aromatic carbons by dividing the area of S by 4 and the area of G by 3 to calculate S/G ratios (11).

## RESULTS

The elemental composition and stable carbon isotope values of fresh and decayed oak are presented in **Table 1**. The control oak had a carbon content of 46.6% (w/w), whereas all fungally degraded oak woods had carbon contents of <44.8% (w/w), with the lowest value equal to 39.3% (w/w) after 101 months of decay. In contrast, no significant changes in nitrogen content were observed between the control and inoculation times up to and including 40 months of growth. A decrease in nitrogen content of 0.6% (w/w) was observed for decay times up to and

including 77 months (**Table 1**), and the nitrogen content clearly increased after 101 months of growth. However, overall, the nitrogen content remained lower than the content of all other elements. The hydrogen content of fresh oak was 6.0% (w/w); this generally decreased with growth of *L. edodes* to give a hydrogen content of 4.6% (w/w) after 101 months. The oxygen contents of fresh and decayed oak ranged from a minimum value of 47.1% (w/w) to a maximum value of 54.9% (w/w) (**Table 1**). All decayed oak woods had oxygen contents higher than those of their fresh counterparts.

Changes in the stable carbon isotopic signature from oak occurred with fungal growth (**Table 1**). The  $\delta$  <sup>13</sup>C composition of the control was -27.0%, which is similar to the result of previous measurements made on whole wood from white oak (*13*). Oak woods exhibited an enrichment in  $\delta$  <sup>13</sup>C values upon fungal growth, with the exception of the 66-month time interval, at which it was depleted by 0.9‰ from the control (**Table 1**). A comparison of the  $\delta$  <sup>13</sup>C values determined for fresh oak (-27.0‰) and *L. edodes* fungal mycelium (-23.8‰) shows that the mycelium is enriched by about 3.2‰.

The total ion current GC-MS traces for the flash pyrolysate of oak and oak treated with *L. edodes* are shown in **Figure 2**, and the peak assignments are given in **Table 2**. Chromatograms of fresh and decayed oak were dominated by lignin and polysaccharide pyrolysis products as well as nonspecific compounds such as toluene (1) and styrene (5). The pyrolysate of fresh oak shows several products of polysaccharides, identified as 3-furaldehyde (3), 2,3-dihydro-5-methylfuran-2-one (10), and

Figure 2. Partial chromatogram of the total ion current (TIC) of the pyrolysis products from (A) undegraded control white oak and white oak degraded for (B) 30, (C) 76, and (D) 101 months by *L. edodes*. Labels denote compounds listed in Table 2.

4-hydroxy-5,6-dihydro-(2*H*)-pyran-2-one (**12**), as well as minor amounts of the cellulose product 1,6-anhydro- $\beta$ -D-glucopyranose (levoglucosan) (**36**). The lignin composition of fresh oak is comprised of syringyl (S) and guaiacyl (G) units with minor contributions of *p*-hydroxphenyl (H) moieties (**Figure 2A**). The major lignin pyrolysis products were identified as 2-methoxyphenol (**16**), 2,6-dimethoxyphenol (**25**), 4-methyl-2,6-dimethoxyphenol (28), 4-vinyl-2,6-dimethoxyphenol (37), 4-formyl-2,6dimethoxyphenol (40), 2-methoxy-4-(prop-2-enal)phenol (46), and 2,6-dimethoxy-4-(prop-2-enal)phenol (50) (Figure 2A). The ratios of syringyl to guaiacyl lignin units (S/G) at the different stages of biodegradation are listed in **Table 3**. The (S/G)<sub>pyrolysis</sub> ratio displays an initial decrease from 2.6 in fresh oak to 0.80 after 30 months of decay; with longer decomposition times, this

30	0.80	0.20	0.26
40	0.75	0.19	0.30
66	0.75	0.19	0.30
76	0.73	0.23	0.23
77	0.95	0.13	0.17
101	0.96	0.31	0.22

 $^{a}\,\text{All}$  ratios are calculated using the integration of the relevant peaks in the TICs from Py-GC-MS.

value varied only slightly (**Table 3**). The relative intensity of 2,6-dimethoxy-4-(prop-2-enal)phenol (**50**) decreased relative to that of other products upon 30 months of decay (compare panels A and B of **Figure 2**). Changes in the relative abundance of

lignin units with complete alkyl side chains were also evident from the decrease in G:3/G and S:3/S ratios (**Table 3**). **Figure 3A** shows the major thermochemolysis products from fresh oak, which were identified as 3,4,5-trimethoxybenzaldehyde (**S4**), 3,4,5-trimethoxyacetophenone (**S5**), and 3,4,5-trimethoxybenzoate (**S6**), as well as cis and trans isomers of 1-(3,4,5-trimethoxyphenyl)-2-methoxyethylene (**S7**, **S8**). Other important products included 3,4-dimethoxybenzaldehyde (**G4**) and the enantiomers of 1-(3,4,5-trimethoxyphenyl)-1,2,3-trimethoxypropane (**S14**, **S15**) (**Figure 3A**). The threo/erythro forms of 1-(3,4,5trimethoxyphenyl)-1,2,3-trimethoxypropane (**G14**, **G15**) and **S14**, **S15** are derived from guaiacyl and syringyl moieties, retaining complete propyl ether interunit linkages.

After 30 months of decay by *L. edodes*, the main thermochemolysis products were 3,4-dimethoxybenzoate (**G6**) and **S6** (**Figure 3B–D**), and the amounts of **S5**, **S7**, **S8**, *trans*-1-(3,4,5trimethoxyphenyl)methoxyprop-1-ene (**S11**), **S14**, and **S15** decreased relative to other products. The ratio of dimethoxy-

Figure 3. Partial chromatogram of the total ion current (TIC) of the thermochemolysis products from (A) undegraded control white oak and white oak degraded for (B) 30, (C) 76, and (D) 101 months by *L. edodes.* Labels denote structures shown in Figure 1.

phenol to monomethoxphenol derivatives, determined by the TMAH thermochemolysis method (S/G)<sub>TMAH</sub>, for fresh oak was 2.1, similar to previous measurements made on lignin from oak using alkaline nitrobenzene oxidation (*12*). The S/G values decreased to 1.2 after 30 months of growth of *L. edodes*; for decay times greater than 30 months, the S/G value remained at  $\sim$ 1 (**Figure 4A**). The (Ad/Al)<sub>G</sub>, (Ad/Al)<sub>S</sub>, and  $\Gamma$  values

increased upon fungal decay (**Figure 4A,B**). The (Ad/Al)<sub>G</sub> and  $(Ad/Al)_S$  values of the fresh oak were 0.9 and 1.1, respectively; after 30 months,  $(Ad/Al)_G$  was 3.7 and  $(Ad/Al)_S$  was 2.3 (**Figure 4B**), and after 40 months,  $(Ad/Al)_G$  was 5.9 and  $(Ad/Al)_S$  was 3.4 (**Figure 4B**). With longer decay times (66 months),  $(Ad/Al)_G$  decreased but always remained higher than its undegraded counterparts. Maximum  $(Ad/Al)_G$  values were observed after

Table 4. Distribution of Carbon in Fresh and L. edodes-Degraded Oak Wood as a Percentage of the Total Carbons from <sup>13</sup>C NMR Spectra

	%carbon						
growth time (months)	acetyl 5–30 ppm	methoxyl 50–60 ppm	carbohydrate (C-2, C-3, C-4, C-5, and C-6 of cellulose and xylans) 60–90 ppm	carbohydrate (C-1 of cellulose, xylans, and aliphatic lignin) 95–110 ppm	aromatic lignin 110–160 ppm	carboxyl/carbonyl 160–210 ppm	syringyl/guaiacyl (S/G) <sub>NMR</sub>
0	4.0	11.5	56.0	12.5	10.5	5.5	1.46

101	7.5	16.0	38.5	8.5	20.5	8.5	0.69

40 months of decay; in contrast, the highest (Ad/Al)<sub>s</sub> of 5 was found at 101 months of decomposition (**Figure 4B**). The  $\Gamma$  value for fresh oak was 0.3; after 30 and 40 months, the  $\Gamma$  values were 1.5 and 1.7, respectively (**Figure 4A**). Within experimental error, the  $\Gamma$  values showed little variation for decomposition times greater than 40 months, with the exception of a small increase after 76 months.

Conventional CPMAS <sup>13</sup>C NMR spectra of fresh oak and oak following *L. edodes* growth (40 and 101 months) are presented in **Figure 5**. The control oak is dominated by resonances in the 60–110 ppm region from polysaccharides. The resonance at 72 ppm is from C-2, C-3, and C-5 carbons of cellulose and xylans (*14*). Both crystalline and amorphous cellulose are present in fresh oak, as shown by the peaks at 84 and 89 ppm, respectively (*15*). Additional cellulose resonances are at 66 (C-6) and 106 ppm (C-1) (**Figure 5A**). The distinct single peak at 106 ppm confirmed that the main carbohydrate

Figure 5. Solid-state <sup>13</sup>C CP/MAS NMR spectra for (A) undegraded control white oak and white oak decayed for (B) 40 and (C) 101 months by *L. edodes.* 

in oak was cellulose type I, although there is undoubtedly some overlap with C-1 carbons of xylans at 103 ppm (*16*). There are signals at 60, 72, and 84 ppm in the <sup>13</sup>C NMR spectra of lignin from naturally decayed white oak, assigned to carbon atoms in ether and secondary alcohol functional groups (*14*). However, in unaltered woods, the contribution of carbon from lignin to the 60–110 ppm region is low in comparison to that from the polysaccharides (*17*). Therefore, the areas of the peaks at 66, 72, 84, 89, and 106 ppm provide an estimate of the relative amounts of polysaccharides (**Table 4**). Fresh oak was composed of 69% carbohydrate carbon; at 30 and 40 months, the amounts of polysaccharide carbon were 61% and 64%, respectively. Oak after 66, 76, and 77 months of treatment with *L. edodes* exhibited a decrease in carbohydrate content of only  $\sim 2-3\%$  compared to the undecayed counterpart (**Table 4**). At 101

months of decay, the polysaccharide content was 47%, which is equivalent to an overall decrease of 22% (**Table 4**). The amount of carbohydrate carbon decreased to an average of 62.5% over the entire cropping period (30-101 months).

Fresh and decayed oak samples exhibit resonances between 110 and 160 ppm, attributed to carbon in aromatic rings from lignin (Figure 5). The broad, distinct peak at 136 ppm is from C-1 carbons of aromatic rings, and the peak at 154 ppm is from C-3 and C-5 carbon atoms in syringyl (Figure 5). Other lignin resonances include the shoulder at 148 ppm, assigned to C-3 and C-5 carbons in guaiacyl units, which are O-alkylated. Aromatic carbon in fresh oak was 10.7%; this generally increased with mushroom growth to give an aromatic lignin content of 20.6% after 101 months, which is equivalent to a 10.1% increase from the fresh oak (Table 4). The resonance at 174 ppm is attributed mainly to acetate groups in xylans and carbonyl groups in lignin. The carboxyl/carbonyl content of fresh oak wood was 5.6% (Table 4). Changes in the carboxyl/ carbonyl carbon content (160-200 ppm) were independent of growth time (Table 4). The highest carbonyl/carboxyl contents were observed at 101 months of growth. However, the appearance of a new peak at 33 ppm (101 months), which can be assigned to methylene groups in proteins, suggested that amide carbons could also contribute to the peak at 174 ppm (Figure 5C). The resonance at 56 ppm is from aryl methoxyl carbons of lignin, which comprised 11.4% of the total carbon in fresh oak. The methoxyl content varied in a nonsystematic fashion throughout mushroom cultivation (Table 4). The S/G value of fresh oak, as determined by solid-state <sup>13</sup>C NMR, was 1.46 (Table 4). This decreased to a value of 1.11 after 30 days and continued to slowly decrease to a value of 0.69 after 101 months of biodegradation (Table 4).

### DISCUSSION

The increase in C/N ratio from 160 in fresh oak to 203 after 77 months of mushroom growth is consistent with a decomposition of carbon components by *L. edodes*. Similarly, C/N ratios increased from 14.1 in mushroom compost to 16.3 upon growth of *Agaricus bisporus* (18). The decrease in C/N ratio to 32 after 101 months is explained by the incorporation of nitrogen-rich fungal mycelium and simultaneous carbon loss (**Table 1**) (19). It has been documented that soils amended with wood and bark with high C/N ratios can cause an initial nitrogen starvation of crop plants (20). In this light, it is clear that only oak logs which have been heavily decayed by *L. edodes* (e.g., 101 months) can be considered as a viable compost component for field crop application.

The accumulation of oxygen in woods and wheat straw decayed by white-rot fungi has been previously documented (21-23). The pathway for the oxidative degradation of lignin by isolated extracellular enzymes from *L. edodes* has been proposed (4-7). In these studies, the degradation products of veratryl alcohol, vanillyl alcohol, and phenolic lignin model compounds having carbon-carbon interunit bonds were analyzed using GC-MS and, in some instances, <sup>1</sup>H NMR and IR spectroscopy. Aromatic carboxylic acids were formed by a sequence of autoxidations on alkyl side chains. In the present study, the increase in oxygen content in degraded oak woods is consistent with the oxidation of the lignin observed following incubation of model compounds with enzymes extracted from the extracellular fluid of *L. edodes*.

The overall increase in  ${}^{13}$ C values by an average of 0.8‰ in oak upon mushroom growth was not expected (**Table 1**). It is

well established that microbial degradation of vascular plants causes <sup>13</sup>C depletions due to the preferential degradation of isotopically heavy cellulose and xylans compared to isotopically lighter lignin (24, 25). However, fresh oak gave a  $\delta$  <sup>13</sup>C value of -27%, and *L. edodes* mycelium gave a  $\delta$  <sup>13</sup>C value of -23.8%. Other workers have documented that basidocarps of wood-decomposing fungi are enriched by about 3.5% compared to the wood upon which they grow (26). The <sup>13</sup>C enrichment of oak wood with mushroom growth is therefore consistent with an increase in residual fungal biomass.

Pyrolysis of plant polysaccharides results in major thermal transformations and secondary reactions; thus, the polysaccharides identified in this study cannot be unequivocally related to precursors in the original macromolecule and are of limited diagnostic value. The poorly resolved nature of the cellulose pyrolysis product 1,6-anhydro- $\beta$ -D-glucopyranose (36) in fresh oak also illustrates chromatographic limitations of the technique, and for these reasons an estimate of carbohydrate content was not undertaken (27). Lignin-derived pyrolysis products from the control sample consisted mainly of syringyl and guaiacyl phenols and, to a lesser extent, *p*-hydroxyphenyl moieties, which is consistent with lignin from angiosperm woods including oak species (28). The product 2,6-dimethoxy-4-(prop-2-enal)phenol (50) was identified in large amounts in fresh oak relative to other methoxyphenols (Figure 2A). Other workers have observed the pyrolytic dehydroxylation of sinapyl alcohol to 2,6dimethoxy-4-(prop-2-enal)phenol and dimethoxypropenyl phenols (11, 29). Therefore, 2,6-dimethoxy-4-(prop-2-enal)phenol (50) and the products 38, 39, and 43 may be derived from the thermal alteration of the primary product sinapyl alcohol (2,6dimethoxy-4-(1-hydroxyprop-2-enyl)phenol and do not necessarily reflect primary lignin structure in oak. Similarly, the pyrolysis products 4-vinyl-2-methoxyphenol (24) and 4-vinyl-2,6-dimethoxyphenol (37) are generated from either the pyrolytic decarboxylation of ferulic and sinapic acids, which links xylans to lignin, or the decomposition of related lignin alcohol (30).

The overall chemical composition of oak wood was altered with growth of L. edodes, as revealed by analytical pyrolysis. The decrease in S/G ratio with cultivation time is probably caused by an initial (40 months) preferential decay of S units, after which the S/G ratio stabilizes. The decrease in S/G ratio upon fungal decomposition is explained by syringyl moieties being more susceptible to degradation because they have fewer aryl-aryl bonds and have a lower redox potential than their guaiacyl counterparts (31). The large decrease in S/G values upon decay by L. edodes contrasts with observations from an earlier study, where analytical pyrolysis (Py-GC-MS) of beech wood treated with L. edodes for 98 days revealed a moderate decrease in S/G values from 1.4 to 1.3 upon decay (9). These differences are probably best explained by the longer decay times used in this current study. Further insights into lignin degradation during cultivation of L. edodes are supported by the time-dependent decrease in G:3/G and S:3/S ratios (Table 3). One plausible explanation for this trend is lignin side chains shortening; this is entirely consistent with the known chemical modifications to lignin induced by many white-rot fungi (23, 32, 33). However, the decrease in lignin units with complete  $C_3$  side chains was not accompanied by a concomitant increase in lignin phenols with oxidized side chains, as has been observed during incubation of veratryl alcohol and vanillyl alcohol with L. edodes extracellular enzymes (4). One possible explanation for the trend in this work may be that L. edodes mediated oxidative side-chain cleavage, which at its final stage yields carboxylic acids, which are not readily GC amenable (11).

Thermochemolysis of fresh oak gave an S/G of 2.1, whereas pyrolysis of fresh oak gave an S/G of 2.6. This difference in S/G ratios is probably due to thermolytic as compared to chemolytic mechanisms of macromolecular depolymerization. Lignin pyrolysis produts are derived from the cleavage of both ether and aryl—aryl linkages; in contrast, thermochemolysis acts mainly to break propyl—aryl ether linkages, where there are adjacent hydroxyl groups on the alkyl side chain (34, 35). A comparison of S/G ratios determined from the peak areas of pyrolysis and thermochemolysis products shows similar overall decreases with fungal growth to values of  $\sim 1$  (**Table 3; Figure 4A**).

Application of thermochemolysis in microbial biodegradation studies requires use of both Ad/Al and  $\Gamma$  parameters to infer the extent of oxidative side-chain cracking, since increased Ad/ Al values can potentially result from dehydration of hydroxyl groups on lignin side chains, lowering amounts of aldehyde without an increase in the amount of acid (33). The increases in (Ad/Al)<sub>G</sub> and (Ad/Al)<sub>S</sub> values upon decay suggest that the fungus L. edodes degraded both guaiacyl and syringyl units via oxidative cleavage of the  $C\alpha - C\beta$  at the  $C\alpha$  atom, to yield aldehydes which are further oxidized to carboxylic acid in a manner similar to that in other edible fungi (36). Comparison of the S/G values with  $(Ad/Al)_G$  and  $(Ad/Al)_S$  values reveals that, for decay times up to but not greater than 76 months, the (Ad/Al)<sub>G</sub> values are greater than (Ad/Al)<sub>S</sub> values; this is probably caused by the more rapid decay and complete loss of syringyl units relative to guaiacyl units, as suggested by the decrease of the S/G ratio (Figure 4A,B). The increase in  $\Gamma$ parameters provides additional evidence of oxidative cleavage of propyl ether interunit linkages and associated degradation of guaiacyl moieties within a complete glycerol side chain; however, this process appears to be inhibited for decomposition times greater than 40 months (Figure 4A). The oxidative mechanism of lignin degradation has also been investigated by incubating model guaiacyl lignin dimers with manganese(II) peroxidase isolated from L. edodes. The biphenyl model compound, dihydrocresol, and 3,3-dihydroxy-4,4-dimethoxy-6,6-dimethyldiphenylmethane were decayed via oxidative cleavage of the side chain (6). Therefore, the oxidative side-chain alterations observed in this present work could have also been initiated by Mn peroxidases secreted by L. edodes.

<sup>13</sup>C NMR spectra of fresh and degraded oak show that cellulose and xylans were the major structural constituents of oak wood throughout the entire cultivation period. The polysaccharide content of oak remained remarkably high throughout the early and middle stages of growth and only became heavily decayed after 101 months. In the <sup>13</sup>C NMR spectra of spruce and birch wood, there are resonances at 89 and 84 ppm which can be assigned to C-4 crystalline cellulose and C-4 amorphous cellulose (*37*, *38*). The diminished resolution of both C-4 cellulose peaks with cultivation of *L. edodes* (Figure 5A–C) suggested that there was no preference for removal of the amorphous component of oak. Other workers have also reported that biodegradation of beech wood by *L. edodes* does not effect a preferential decay of amorphous non-cellulosic xylans (*9*).

The occurrence of new resonances at 33 and 170 ppm from lipid and amide carbon in protein after 101 months of decay (**Figure 5C**) suggested a source of fungal biomass. This concept is consistent with previous <sup>13</sup>C NMR spectra of edible mush-rooms, which show resonances from polysaccharides (105, 90 ppm) and protein (170, 33, 55, 20 ppm) components (*39*). Furthermore, the decline in the C/N ratio at the 101-month interval supports the hypothesis that fungal mycelium became

incorporated into the cell wall of oak. In addition, the nonsystematic changes in methoxyl content are not caused by demethylation reactions, such as those observed during brown-rot degradation, but are explained by the incorporation of proteins from fungal mycelium which contribute to the signal at  $\sim$ 56 ppm (*33, 39*).

The S/G values for fresh and decayed oak, as determined by solid-state  ${}^{13}C$  NMR (1.5–0.7), were lower than those calculated from pyrolysis and thermochemolysis data (Tables 3 and 4; Figure 4A). This phenomenon is explained by the higher frequency of guaiacyl units linked by aromatic carbon-carbon bonds (condensed structures) which are not generally cleaved by thermochemolysis and, on the basis of bond energies, are less thermally labile than ether-type linkages (34, 35). The solidstate <sup>13</sup>C NMR S/G values show a gradual decrease from 0 to 101 months, as compared to the more rapid change determined by pyrolysis and thermochemolysis during the first 30 months (Tables 3 and 4; Figure 4A). This suggests that syringyl structures linked via propyl ether interunit bonds are rapidly degraded for the first 30 months of growth. However, with longer decay times, the syringyl moieties linked by carboncarbon bonds are decayed.

The increase in aromatic carbon content after fungal attack (**Table 4**) supports the view that *L. edodes* decayed the polysaccharide components in preference to the lignin. Therefore, the NMR spectra suggest that cellulose, xylans, and lignin were decayed in parallel during cultivation of the edible fungus. Complementary evidence from analytical pyrolysis and thermochemolysis revealed that enzymes secreted by *L. edodes* removed syringyl moieties in preference to guaiacyl units and cleaved the  $C\alpha-C\beta$  bonds in lignin side chains. Future studies in our laboratories will examine the effect of *L. edodes* on the solvent-insoluble constituents of bark from oak using the pyrolytic, thermolytic, and spectroscopic techniques examined in the present study.

#### ACKNOWLEDGMENT

The authors thank Hilary Sloane for bulk C isotope measurements (National Isotope Geosciences Laboratory) and Ian Harrison (British Geological Survey) for helpful comments regarding the manuscript. Samples were collected by Tom Kimmons and co-workers, Ozark Speciality, Arkansas. This paper is published by permission of the Executive Director, British Geological Survey (NERC).
