Conjugate pads are used to accept recognition labels and keep these labels stable during their entire shelf life period. Recognition labels are added to a treated conjugate pad by impregnating them in a conjugate suspension or dispensing them with quantitative noncontact dispensers.

After a sample is added to a strip, this sample migrates through a sample pad to a conjugate pad, where recognition labels are immobilized. Analytes in a given sample then interact with recognition labels when they migrate to an analytical region. Specific biological components are then bound at a test line and a control line via quantitative dispensers.

The absorbent pad resembles the engine of a LFI device; the absorbent pad pulls fluid and retains this fluid during the whole assay.

LFI Principle To Detect Foodborne Pathogens. Competitive assay and sandwich assay are the two kinds of formats commonly used in LFI. Competitive assay is preferred when target analytes exhibit low molecular weight or present a single specific antigen. Sandwich assay is performed when target analytes present several epitopes, such as pathogens. In a sandwich assay, the first analyte ligand (monoclonal antibodies are commonly used) is used to label markers. The second ligand (polyclonal antibodies are widely used) is placed on the test zone of a nitrocellulose membrane and assigned as the test line. The specific antibodies coating the control line capture excess labeled antibodies and conjugates. As sample extract is applied to the LFI device, the labeled first ligand initially binds to the target analyte to form an analyte−ligand complex; this complex then migrates forward by capillary force to the test zone. The second ligand in the test zone subsequently binds to the target analyte. Detectable signal enhancement in the test zone directly corresponds to the amount of a target analyte in a sample. In sandwich assay, detectable signal enhancement is observed as target analyte concentration increases.

CONVENTIONAL LFI TO DETECT FOODBORNE PATHOGENS

Colloidal gold lateral flow strip is considered as one of the most widely used tools to detect foodborne pathogens. Colloidal gold is essentially inert and forms spherical particles. Antibodies bind to the surfaces of these gold particles with enormous strength when correctly coupled, thus providing a high degree of long-term stability.[41,42] Hence, ligands exhibit good compatibility with biomolecules and can retain biochemical activities of tagged biomolecules. Colloidal gold-based LFI has been applied to detect foodborne pathogens.[43−50] Furthermore, a LFI device has been used to determine the analytical sensitivity of *E. coli* O157 of approximately 10^5 CFU/mL.[51,52] Preechakasedkit et al.[53] also used colloidal gold-based LFI strip to detect *S. typhimurium*, and the limit of detection was 1.14×10^5 CFU/mL. Ueda et al.[54] applied the colloidal gold LFI strip to detect *L. monocytogenes*, and the detection limit of this assay was 10^6 CFU/mL. The detection limit of *Vibrio harveyi* was 10^6 CFU/mL when a colloidal gold LFI was used.[55] Wiriyachaiporn et al.[56] further developed a LFI device to detect *Staphylococcus aureus*, and the result showed a detection limit of 10^6 CFU/mL. Colloidal gold-based LFI has also been widely applied in commercial detection. Table 1 summarizes the information regarding conventional colloidal gold LFI applied to detect foodborne pathogens in industries from some manufacturers. Although this summary includes only several commercial products, the main trends of colloidal gold LFI in the detection of foodborne pathogens are shown.

RECENT ADVANCEMENTS IN LFI TO DETECT FOODBORNE PATHOGENS

Researchers have devoted efforts to develop a rapid and sensitive lateral flow assay platform to screen foodborne pathogens (Table 2). New advancements in lateral flow assay have also been developed to detect foodborne pathogens; these advancements include innovating novel labels, designing new formats of LFI, combining with other methods, and developing signal amplification systems.

Innovation of Novel Label Application. An ideal label should be stable, have low nonspecific binding, be cost-effective,

and be easily conjugated; an ideal label could also be used for multianalyte detection. Many efforts have also been devoted to discover novel labels to enhance detection sensitivity. In this paper, the types of the new labels successfully applied to enhance the sensitivity of LFI to detect foodborne pathogens are described; these new labels include colored labels, luminescent nanoparticles (NPs), and labels based on other properties.

Colored Labels. Colored labels are visible to the naked eye. They have been widely used in many fields owing to their convenience; colloidal gold and colored latexes are the most common labels in LFI. Carbon nanoparticles have also been applied as labels owing to their low price, nontoxicity, and high signal intensity; they can easily bind ligands to their large surface area, and they are suitable for LFI detection because of their "black-on-white" test results.[57,58]

Blažková[59] used carbon as a label to develop a nucleic acid test strip to detect *Cronobacter* spp. The PCR products of the analytes were conjugated with biotin on one side and digoxigenin on the other side. Carbon NPs were labeled with neutravidin as capture conjugate. Anti-digoxigenin antibodies and biotin−protein conjugates were sprayed on NC membrane as test line and control line, respectively. The detection limit of PCR product was 8 ng.

Luminescent NPs. Luminescent NPs have been extensively investigated because these NPs exhibit high sensitivity and spectral characteristics. Fluorescent dyes,[60] quantum dots,[61] and up-converting emitters[62] have been applied as labels to detect *Campylobacter jejuni*, *E. coli* O157:H7, and *Vibrio* in a LFI system.

Fluorescent dyes display low photostability and are highly quenched by the environment and concentration.[63] To overcome these drawbacks, researchers should couple multiple fluorescent dyes to a carrier or produce particles loaded with fluorescent dyes. Xie et al.[64] applied LFI based on fluorescent microspheres as labels to detect *E. coli* O157:H7 with the reader, which was from Shanghai Huguo Science Instrument Co. Ltd. (excitation wavelength = 470 nm; emission wavelength = 520 nm). The results showed that the sensitivity of this LFI system was 10^4 CFU/mL, whereas the sensitivity of LFI based on colloidal gold was 10^5 CFU/mL.

Quantum dots have been applied to bioassays and biosensors due to excellent signal brightness, size-tunable light emission, broad excitation spectrum, narrow emission spectrum, and excellent stability resisting photobleaching.[65−67] Bruno[68] compared colloidal gold with quantum dot versions in lateral flow test strips to detect *E. coli* O157:H7. A hand-held long-wave UV light (365 nm) and an orange Schott glass filter were used for illumination and enhancing visual detection of quantum dot particles. The limits of detection of *E. coli* O157:H7 were 6000 and 600 cells per test in a buffer by using colloidal gold lateral flow assay system and quantum dot lateral flow assay system, respectively.

Up-converting emitters are reportedly more sensitive than conventional labels such as colloidal gold or colored latex beads.[69] Up-converting emitters exhibit several advantages, including long lifetime and sequential two-photon absorption possible in a microsecond time scale. With these emitters, background absorption can be minimized because of anti-Stokes luminescence, and biomolecular photodegradation does not occur because of excitation occurring in the infrared area and the ease of production.[70] An ultrasensitive up-conversion fluorescent lateral flow strip based on NaYF4:Yb,Er NPs was applied to detect *Vibrio anguillarum*.[62] Carboxyl-modified β-NaYF4:Yb,Er NPs were synthesized by a facile one-pot solvothermal approach and then coupled with mAb as a conjugate probe in lateral flow assay. Continuous wave near-infrared spectrum laser at λ = 980 nm was used to excite the up-conversion nanoparticles on the strip by the up-converting nanoparticles−LFI biosensor. The sensitivity of the up-converting fluorescent strip was 10^2 CFU/mL and 100 times higher than that in enzyme-linked immunosorbent assays and exhibited good specificity attributed to no cross reaction with eight other pathogens.

Other Labels. In addition to colored and luminescent particles, new labels, including magnetic beads, enzymes, and liposomes, are also applied in LFI.

Magnetic beads have been widely used to separate target analytes; these magnetic beads have also been used as carriers and labels to detect pathogens.[71−74] Wang et al.[75] developed a superparamagnetic lateral flow assay to detect *Bacillus anthracis* spores. Anti-*B. anthracis* mAbs were conjugated to 300 nm superparamagnetic beads to capture bacterial spores. Different anti-*B. anthracis* mAbs were sprayed onto a nitrocellulose membrane as a test line, and goat anti-mouse IgG was used as a control line. The detection system yielded a linear range from 4×10^3 CFU/mL to 4×10^6 CFU/mL, and reproducible

DOI: 10.1021/jf5046415
J. Agric. Food Chem. 2015, 63, 745−753

detection limits were 200 spores mg^{-1} in milk powder. These superparamagnetic beads were larger and reaction time was longer than other types of strip tests because spores were larger (approximately 1 μm in diameter) than other analytes (such as proteins). The conjugates that run through a membrane required a long reaction time when the conjugates of magnetic beads and antibodies captured the spores. Small-diameter particles were also used as labels. With these particles, the flow rate was higher and reaction time was shorter; however, the use of these materials reduced detection sensitivity. Yan et al.[76] discussed the effect of the characteristics of Fe_3O_4 NPs (including particle size, size distribution, surface biomodification, magnetic property, and colloidal stability) on LFI when these Fe_3O_4 NPs were used as labels to detect *V. parahemolyticus*. To increase sensitivity and decrease false-positive reaction, they chose Fe_3O_4 NPs, which had small size and good colloidal stability as the labels. The 200 nm Fe_3O_4 nanoparticles were selected for the detection system.

In another approach, enzymes as labels were introduced to lateral flow assay to decrease the limit of detection. Enzymes can be linked to biomolecules to form complexes and exhibit enzymatic and immunological activities. The reaction between enzymes and substrates amplifies optical signals. Enzyme-linked immunosorbent assay (ELISA) based on the reaction between enzymes and substrates is considered to be one of the most outstanding assays. Hence, ELISA combined with lateral flow assay to detect analytes could be an excellent strategy to amplify signals.[77] Park et al.[78] fabricated a LFI based on sandwich ELISA to detect *E. coli* O157:H7. Optical signals were generated by the reaction between horseradish peroxidase (HRP) and its substrate, which could be read directly by the naked eye. The lower limit of detection was 10^3 CFU/mL.[78] A similar method was applied to detect *S. typhimurium*. An immunostrip was used to quantitatively determine *S. typhimurium* in the range from 9.2×10^3 CFU/mL to 9.2×10^6 CFU/mL based on chemiluminescent signals.[79]

Liposomes are formed from amphiphilic molecules and can encapsulate and immobilize molecular markers, such as dyes, via covalent or hydrophobic interactions. Khreich et al.[80] encapsulated sulfordamine B in liposomes as labels to detect fluorescent signals and obtained a 15-fold increase in sensitivity compared with the optical detection sensitivity of colored labels. Immunoliposome-encapsulated sulforhodamine B has also been applied as a capture label to detect *S. typhimurium* and compared with traditional colloidal gold lateral flow strip.[81−83] The result showed that the sensitivity of the immunoliposome immunoassay strip was higher than that of the traditional colloidal gold immunoassay strip; this high sensitivity was appropriate to detect food matrix.

New Formats of LFI. The application of antibodies in a LFI system exhibits several weaknesses, including difficult preparation and poor stability. A new ligand should be discovered to replace antibody. With advances in nucleic acid- and genomic sequence-based techniques, various detection methods have been developed using nucleic acid rather than antibodies. A rapid and sensitive detection system, which is called nucleic acid LFI,[84−86] has been developed. In the detection of *S. aureus* by nucleic acid LFI, quantum dot−streptavidin conjugate was used as a capture probe. Anti-digoxigenin antibody and BSA−biotin conjugate were sprayed on a membrane as a control line and a test line, respectively.[87] This detection system was based on two reaction systems, including digoxigenin and anti-digoxigenin, streptavidin, and biotin. DNA extracted from the analytes in a sample was labeled with digoxigenin on one side and with biotin on the other side. The schematic of detection principles is shown in Figure 1B. The limits of detection of *S. aureus* were 3 CFU/mL and 30 CFU/g in spiked milk powder and meat samples, respectively. Extracted DNA from analytes in a sample is usually amplified by PCR. LAMP was applied to perform rapid and sensitive nucleic acid amplification combined with lateral flow assay.[88−90] A shorter time is needed to amplify target DNA by LAMP than by PCR because a set of four primers that recognize a total of six distinct sequences on the target DNA is used in LAMP; LAMP also relies on the autocycling strand displacement of DNA synthesis performed by the large DNA polymerase under isothermal conditions.

Aptamers are another choice to replace antibodies as recognition molecules used for bacterial detection methods to bind specific analytes.[91−94] Yonekita et al.[95] used antimicrobial peptides (AMPs) as recognition probes for bacteria in a LFI. Streptavidin−colloidal gold was conjugated with biotinylated AMP, which was used as a capture probe. Anti-analyte antibodies were then sprayed on a test line, whereas anti-streptavidin antibodies were sprayed on a control line. Moreover, LFI was applied to simultaneously detect and identify Shiga toxin-producing *E. coli* O157, O26, and O111 (Figure 2). Studies have focused on the simultaneous detection

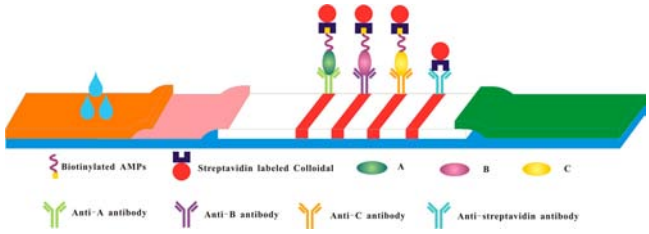

Figure 2. Schematic of the multiplex LFI strip. Antianalyte antibodies were sprayed on test lines to capture *E. coli* O157 (A), *E. coli* O26 (B), and *E. coli* O111 (C). Analytes were mixed with streptavidin-colloidal gold conjugate solution, and the mixtures were added to the sample pad of the LFI strip. After 15 min, positive or negative results could be determined. (Adapted from Yonekita et al.[95])

by LFI.[96,97] A simultaneous detection system exhibits several advantages, such as simplicity, rapidity, and sample-saving, compared with single detection. Yu et al.[98] developed a colloidal gold LFI to simultaneously detect *V. cholerae* serogroups O1 and O139, which could cause epidemic and pandemic cholera. The result showed that 100% sensitivity and 100% specificity were obtained for O1 and O139 in all of the tested strains. The loss of intensity in the test line after 21 weeks was not significant compared with that after 4 weeks; LFI remained stable for at least 3 months when stored dry at room temperature.

Combination with Other Methods. The sensitivity and specificity of methods used to detect foodborne pathogens should be improved. Immunomagnetic separation (IMS) performs an increasingly important function in the isolation and concentration of foodborne pathogens in food samples.[99−101] A detection method of combined IMS and LFI can significantly improve sensitivity, decrease detection time, and eliminate interference from food matrices.[102−104] Cui et al.[105] used IMS and traditional colloidal gold LFI to detect *E. coli* O157:H7. The results showed that the detection limit was 7.6×10^3 CFU/mL; thus, the result was 10 times higher than that of colloidal gold lateral flow assay. The schematic is shown in Figure 3. Chen et al.[106] developed a LFI test to detect *Cronobacter* and used silica-coated magnetic NPs to separate nucleic acid from

DOI: 10.1021/jf5046415
J. Agric. Food Chem. 2015, 63, 745−753

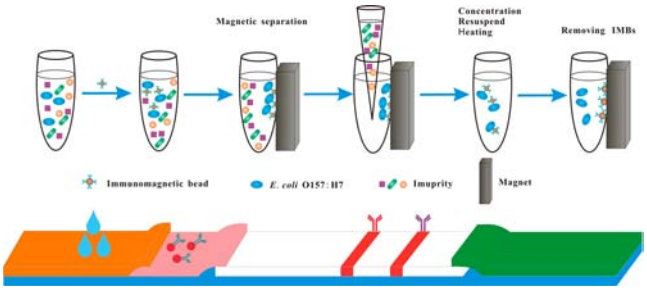

Figure 3. Schematic of immunomagnetic separation combined with colloidal gold LFI. (Adapted from Cui et al.[105])

Cronobacter lysate. The detection limit of this technique was 10^7 CFU/mL in pure culture, and 1 mL of 10^5 CFU *Cronobacter* was detected as positive in pure culture after silica-coated magnetic NP treatment was administered.

In a food matrix, some nontarget analytes may cause false-positive results. In the primary enrichment phase, the growth of closely related nontarget bacteria should be suppressed to improve detection sensitivity. Muldoon and co-workers[107] applied specific bacteriophages, which could suppress non-*Salmonella* bacterial growth for the control of cross-reactive non-*Salmonella* bacteria during primary sample enrichment. The bacteriophage cocktail that was added into primary enrichment significantly reduced the false positives of the immunochromatographic test strip. False positives were reduced from 32 of 115 samples tested to 0 in naturally contaminated beef samples.

Development of the Signal Amplification System. *Application of a Biotin−Streptavidin System.* Several approaches have been used to amplify signals of traditional gold colloidal LFI. These approaches aim to improve LFI sensitivity. To increase sensitivity effectively, a biotin−streptavidin system has been applied in lateral flow assay. The biotin−streptavidin system exhibits good reaction specificity and high affinity; hence, this system has been widely applied in many field detections.[108,109] Furthermore, this system can greatly contribute to signal amplification and background activity reduction.[110] Zhao et al.[111] prepared colloidal gold immunochromatographic strip based on a biotin−streptavidin system to detect *E. coli* O157:H7. Colloidal gold labeled anti-*E. coli* O157 monoclonal antibodies and biotinylated anti-*E. coli* O157 polyclonal antibodies were impregnated in a conjugated pad and a sample pad, respectively. Streptavidin and goat anti-mouse antibodies were immobilized in a test line and a control line of nitrocellulose membrane, respectively. *E. coli* O157 bound to biotinylated antibody and colloidal gold-labeled antibody to form a biotinylated antibody−analyte−colloidal gold-labeled antibody complex. This complex migrated to the detection zone by capillary action. The test line became red when the complex was captured by streptavidin via high-affinity biotin−streptavidin interaction (Figure 4). Streptavidin coated in the test line could reduce the background signal and amplify the detection signal owing to the high affinity between biotin and streptavidin. This method could detect *E. coli* O157 at a minimum of 2.3×10^3 CFU/mL without enrichment. Sensitivity was nearly 100 times higher than that of traditional lateral flow assay.[52]

Enzyme Amplification. In another approach involving signal amplification, enzymes are introduced to a lateral flow assay. Cho et al.[112] prepared an antibody−enzyme−magnetic NP complex as a label to detect *L. monocytogenes* by employing a lateral flow assay. In this strategy, magnetic properties and enzyme catalytic

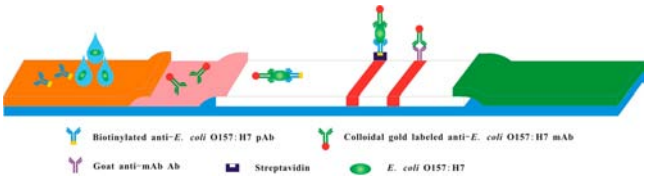

Figure 4. Schematic of the colloidal gold LFI based on biotin−streptavidin system to detect *E. coli* O157:H7.

amplifications were combined, thereby generating a darker signal on magnetic beads because of enzyme−substrate reaction (Figure 5). The study included three steps as follows: (1)

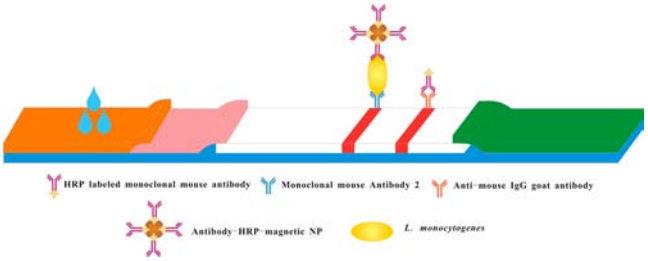

Figure 5. Schematic of LFI based on enzyme combined with magnetic separation step to detect *L. monocytogenes*. (Adapted from Cho et al.[112])

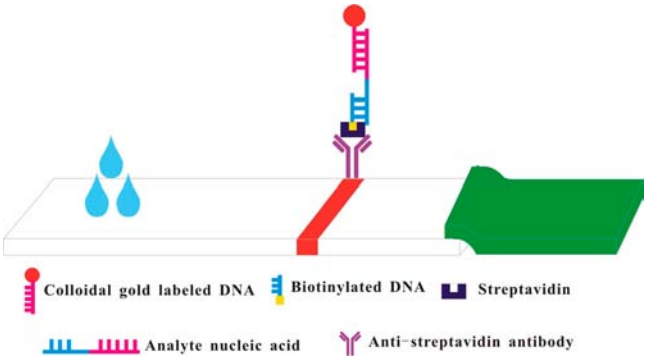

Figure 6. Schematic of LFI. As immunoreaction was completed, test strip was soaked in silver enhancer reagent to intensify the signal of gold nanoparticles. (Adapted from Liu et al.[118])

magnetic separation and concentration; (2) lateral flow immunochromatography; and (3) signal generation by placing HRP substrates on the absorption pad on the lateral side of a nitrocellulose membrane pad (Figure 5). Signals were captured as images using a scanner. The optical densities of the images were digitized by using image analysis program (Multianalyst version 1.1, Bio-Rad Laboratories, Hercules, CA, USA) to obtain the signal value. After the signal was amplified, the limit of detection of 95 CFU/mL was obtained in buffer solution.

Silver Enhancement. Silver nucleation on gold has been applied to perform sensitive biosensing and achieve signal amplification.[113−116] Silver precipitates on gold and can enhance electrochemical and colorimetric signals; silver can also vary the resistance or conductance of a substrate.[117] Color is greatly enhanced on the basis of the reaction between silver salt and reducing agent when silver is deposited on gold. Liu et al.[118] utilized a 16S rDNA/rRNA probe-conjugated AuNPs and silver enhancement method based on sandwich LFI to detect *Salmonella*. In this assay, anti-avidin antibody was sprayed onto a nitrocellulose membrane to capture avidin. A biotinylated

DOI: 10.1021/jf5046415
J. Agric. Food Chem. 2015, 63, 745−753

capture probe was conjugated with avidin and 16S rDNA/rRNA probe-conjugated AuNPs as a capture probe to capture *Salmonella*-targeted nucleic acid. Both biotinylated probe and probe-conjugated AuNPs could capture *Salmonella*-targeted nucleic acid; these probes then constituted sandwich LFI. To improve detection sensitivity and intensify AuNP signal, researchers soaked test strips in silver enhancer reagents. Nucleic acids were detected from 10^7 bacterial cells. The detection limit was as low as 10^4 cells after silver enhancement was performed (Figure 6).

CONCLUSIONS

Traditional lateral flow assay has been widely applied to detect foodborne pathogens. However, detection sensitivity is limited. As such, future studies should focus on enhancing detection sensitivity and decreasing detection time of LFI to detect foodborne pathogens. Scientists have devoted efforts to attain these goals. This review described recent LFI advancements, including using new labels, applying new formats, combining other methods, and utilizing signal amplification systems, in foodborne pathogen detection. With these advancements, detection sensitivity and detection time can be greatly improved. In the future, hard work should be done to further improve the stability and convenience of these sensitive lateral flow immunoassays.

ABSTRACT: Metabolite identification and quantitation impose great challenges on risk assessment of agrochemicals, as many metabolite standards are generally unavailable. In this study, metalaxyl metabolites were identified by time-of-flight mass spectrometry and semiquantified by triple quadrupole tandem mass spectrometry with self-prepared ^{13}C-labeled metalaxyl metabolites as internal standards. Such methodology was employed to characterize the stereoselective metabolism of metalaxyl in rat hepatic microsomes successfully. Metabolites derived from hydroxylation, demethylation, and didemethylation were identified and semiquantified. The results indicated that (+)-*S*-metalaxyl eliminated preferentially as the enantiomer fraction was 0.32 after 60 min incubation. The amounts of hydroxymetalaxyl and demethylmetalaxyl derived from (−)-*R*-metalaxyl were 1.76 and 1.82 times higher than that of (+)-*S*-metalaxyl, whereas didemethylmetalaxyl derived from (+)-*S*-metalaxyl was 1.44 times larger than that from (−)-*R*-metalaxyl. This study highlights a new quantitation approach for stereoselective metabolism of chiral agrochemicals and provides more knowledge on metalaxyl risk assessment.

KEYWORDS: *metabolic profile, LC-MS, rat hepatic microsome, stereoselective metabolism, metabolite identification*

INTRODUCTION

To facilitate the elimination and/or utilization of exogenous chemicals, all living creatures perform a certain level of metabolism, which might result in the activation of drugs or even the production of new toxic species.[1,2] In some cases, metabolites show better bioactivities than the parent compound, such as acetaminophen from acetanilide.[3] In some other cases, metabolites exhibit more toxicities than the parent compound.[4−6] For example, Mitchell proposed that a toxic metabolite of acetaminophen is the main cause of acetaminophen-induced hepatic necrosis.[7] Also, metabolites are always important indicators of biological processes. Therefore, identification and quantitation of metabolites are very important in metabolism research as well as risk assessments of xenobiotics.[8] As for chiral drugs, it is well-known that stereochemistry has a marked impact on biological activity as well as biological processes such as absorption, degradation, metabolism, and excretion behavior in organisms. Enantiomers of a chiral compound can interact with biomacromolecules stereoselectively, leading to entirely different and even contradictory biological effects.[9] Consequently, stereoselective metabolic investigation is important for ecotoxicological and environmental risk assessment of current chiral pesticides. The main purpose of this study is to introduce a new way to facilitate the accurate comparison of the stereoselective metabolism of a chiral xenobiotic.

Nowadays, regarding the analytical tools used for qualitative and quantitative analysis of metabolites, mass spectrometry (MS) coupled with liquid chromatography (LC) is considered to be the most preeminent and widely used tool,[10−12] due primarily to its superior sensitivity, selectivity, speed of analysis, cost effectiveness, and ability to separate, detect, and identify metabolites even in the presence of many endogenous interferences.[13] Since molecular weight determination is always the first and basic step for qualitative analysis of metabolites, MS instruments with high-resolution mass measurement, such as time-of-flight (TOF) or Fourier transform (FT) mass spectrometers, are always preferred in this step. Then, for further structural confirmation, tandem mass spectrometry (MS/MS) is often used mainly because it covers a variety of scanning techniques including product ion, precursor ion, and neutral loss scanning. The results provide information on a series of characteristic fragment ion masses, all of which correspond to part of the unknown molecule. For metabolite quantitation, triple quadrupole MS coupled with LC operated in the multiple reaction monitoring (MRM) mode is considered as the gold standard.[14]

Traditionally, discovery of new metabolites from a single parent molecule is performed by tracking radioactive tracers that are catabolized from a radioactive parent compound.[15,16] Another widely used approach is stable isotope labeling.[17] For instance, Chowdhury et al. utilized stable isotope-labeled drugs to aid the detection and identification of ribavirin metabolites in rats.[18] The advantage of stable isotope labeling is that the metabolites are labeled in complex biological matrixes, which

can be distinguished from various interferences and possible laboratory contaminants.[19]

For the quantitative analysis of metabolites, the lack of metabolite standards always imposes a significant limitation. This is also the bottleneck for comprehensive metabolism research for chiral pesticides. Although synthesis of some potential metabolites can be achieved in theory, it would be a quite expensive and complex endeavor. Another possible approach to get metabolites might be incubation of substrates with in vivo methods[20] or some in vitro systems.[21,22] For example, in vivo methods often include administering fluorescent, isotopic, or radioactive labeled substrates to the living biological model, while potential in vitro systems often include cell cultures, enzyme mixtures, and liver microsomes. Simplicity and availability are the most obvious advantages of in vitro technologies. The relatively high concentration of substrate as well as metabolites in an in vitro system makes the metabolic study much easier than that with in vivo systems.[23] Microsomal incubation is a valuable and the most widely used tool for metabolism research on xenobiotics,[24] as it contains a significant amount of metabolic enzymes. Clements et al. developed a strategy of using liver microsomal incubation with drug candidates for the preparation of phase I drug metabolites, which could then be used as standards for in vivo experiments.[25] This approach inspired us that the microsomal incubation could be a possible and convenient way to produce metabolite "standards" of a pesticide.

Metalaxyl [*N*-(2,6-dimethylphenyl)-*N*-(methoxyacetyl)-D,L-alanine methyl ester, MX, Figure 1] is a systemic fungicide

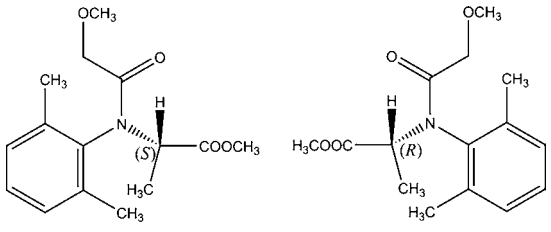

Figure 1. Chemical structure of metalaxyl enantiomers.

with protective and curative actions against oomycetes. Since introduction in 1977, it has been widely used in agriculture and horticulture.[26] It has also been reported that metalaxyl has many hazardous effects on humans and other nontarget organisms.[27,28] Recently, metalaxyl and its metabolites were detected in groundwater.[29,30] For a comprehensive risk assessment of metalaxyl, data on the stereoselective metabolism are indispensable. Therefore, the present work involved the following four aspects: (1) TOF-MS was employed to acquire the accurate molecular mass information and preliminary structural presumption of MX metabolites; (2) ^{13}C-labeled MX incubation and MS/MS detection were carried out for further structure identification; (3) ^{13}C-labeled metabolites were prepared and used as internal standards for quantitation; (4) stereoselective metabolism of MX enantiomers were quantitively investigated in rat hepatic microsomes.

MATERIALS AND METHODS

Chemicals. Racemic MX (*rac*-MX) standard (>99% purity) was provided by Institute for Control of Agrochemicals, China Ministry of Agriculture. (+)-*S*-MX and (−)-*R*-MX were prepared on an Agilent high-performance liquid chromatography (HPLC) with a preparative chiral column containing cellulose-tris(3,5-methylphenylcarbamate)-based chiral stationary phase (CDMPC−CSP, provided by the Department of Applied Chemistry, China Agricultural University, Beijing). $^{13}C_6$-MX and β-nicotinamide adenine dinucleotide phosphate (NADPH) were purchased from Sigma-Aldrich (St Louis, MO). $^{13}C_6$-MX acid [*N*-(2, 6-dimethylphenyl)-*N*-(methoxyacetyl)-alanine] was synthesized in our own laboratory. HPLC grade solvents were purchased from Beijing Chemicals (Beijing, China). All other chemicals and solvents were analytical grade and purchased from standard commercial sources. Water was purified with a Milli-Q system.

Stock solutions of *rac*-, (+)-*S*-, and (−)-*R*-MX were prepared in 2-propanol and were stored at −20 °C. Working standard solutions were obtained by dilutions of the stock solution in 2-propanol.

Animals. Adult male Sprague−Dawley rats (200−250 g, 5−6 weeks old) were purchased from the Vital River Laboratory Animal Company (Beijing, China) and were fed with a standard diet before use. All rats were handled in accordance with the standard guidelines for care and use of laboratory animals as laid down in the EU directive 2010/63/EU. Rat hepatic microsomes were prepared with a procedure as described by Zhu[31] and were stored at −80 °C.

Incubation of MX with Microsomes for Metabolite Identification. For the detection and identification of MX metabolites, rat hepatic microsomal incubations with MX of various time periods were carried out with a series of samples and controls in parallel. In particular, *rac*-MX (100 μM) was prepared in ethanol and added into the microsomal incubation system, which was made up of 1 mg of microsomal protein and 50 mM Tris-HCl buffer (pH7.4) with 5.0 mM $MgCl_2$. The ethanol added to each incubate was less than 1.0% v/v. After preincubation in a water bath at 37 °C for 5 min, NADPH at a final reaction concentration of 1.0 mM was added to the mixtures to initiate the reaction, resulting in a final total reaction volume of 1.0 mL. By adding 1 mL of acetonitrile containing 0.1% formic acid(v/v), the reactions were terminated after incubation in the water bath (37 °C) for 5, 10, 20, 30, and 60 min. The samples were vortexed for 3 min. To obtain a clear extract for analysis, samples were frozen at −20 °C for 1 h for protein precipitation and then centrifuged at 12 000*g* at 4 °C for 4 min, and the supernatant was transferred to a new tube for one more centrifugation. Eventually the clear extract was collected for analysis.

Qualitative Analysis of MX and Its Metabolites in Microsomes. Samples were first analyzed by Agilent 1290 UPLC/microTOF Q II system (Bruker Co., DE); thus, the accurate molecular weights of the metabolites were acquired. A reversed-phase Agilent UPLC C18 analytical column (50 × 2.1 mm i.d., 1.8 μm) was used. The electrospray ionization (ESI) source was operated at 4 kV and a desolvation temperature of 200 °C. The mobile phase was water/acetonitrile (90/10), and the flow rate was 0.1 mL/min. All MS spectra were obtained in the positive mode, and argon was used as collision gas for the MS/MS measurements. The instrument was calibrated in the *m*/*z* range 50−600. MS data were processed via Bruker Data Analysis software 4.1.

The metabolites were further identified by an API 2000 LC-MS/MS System (AB Sciex Instruments) equipped with a turbo electrospray ionization probe in the MRM scan mode. Liquid chromatography was carried out using an Agilent 1200 (Santa Clara, CA) series HPLC equipped with a G1322 degasser, G1311A quatpump, G1316B column compartment, and G1329A autosampler (Wilmington, DE). A Waters Atlantis T3 column (150 × 2.1 mm i.d., 3 μm) (Eschborn, Germany) was used. The mobile phase system was 0.1% formic acid in water (v/v):0.1% formic acid in acetonitrile (v/v) 50:50. A flow rate of 0.3 mL/min and an injection volume of 40 μL were adopted in all steps. Positive ionization mode was used for detection of all analytes. The ion spray voltage was 4000 V, and the ion source temperature was 450 °C. The curtain gas was set at 10 psig, while ion source gas 1 and 2 were set at 45 and 50 psig, respectively. For data acquisition and analysis, Analyst v.1.4.2 (Applied Biosystems/MDS SCIEX) was used.

Finally, rat hepatic microsomal incubation with ^{13}C-labeled MX was performed to reconfirm metabolites as well as to produce the ^{13}C-

DOI: 10.1021/jf5025104
J. Agric. Food Chem. 2015, 63, 754−760

labeled metabolites, which along with the synthesized ^{13}C-labeled MX acid were used as internal standard in the subsequent stereoselective metabolism research of MX enantiomers.

Quantitative Analysis for Stereoselective Metabolism of MX Enantiomers. (+)-*S*- and (−)-*R*-MX were incubated in the microsomal system described above, respectively. After 0, 5, 10, 20, 30, and 60 min, 10 μL of internal standard and 140 μL of acetonitrile containing 0.1% formic acid (v/v) were added to 50 μL of the incubation mixture to terminate the reaction. Then the samples were vortexed and centrifuged, and the supernatant was collected and stored at −20 °C until analysis. Triple quadrupole MS coupled with LC was used for quantitation. The LC solvents, column, and MS parameters used for the sample analysis were identical to those of the qualitative analysis described above.

RESULTS AND DISCUSSION

Identification of the Possible MX Metabolites by Rat Hepatic Microsomes. Data from LC-TOF-MS indicated that possible metabolites of hydroxylation, probably at two sites (M1 and M2), demethylation (M3), and didemethylation (M4) were detected after the microsomal incubation with 100 μM MX. Figure 2 shows the full-scan chromatogram and the extracted mass chromatograms of the metabolites formed by 60 min incubation. Table 1 lists the exact masses and fragmentation of MX and the detected metabolites. The fragment ions of these potential metabolites corresponded to the proposed structures.

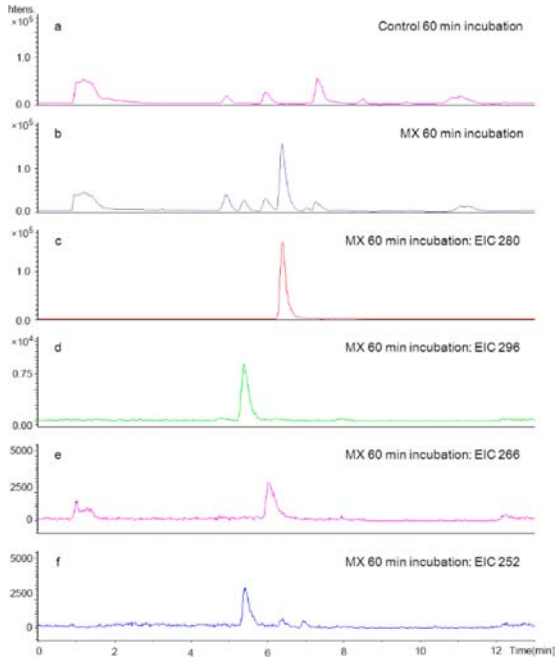

Figure 2. Total ion current chromatograms of UPLC-TOF-MS from the 60 min microsome incubations of (a) the control and (b) metalaxyl. Extracted ion chromatograms of (c) *m*/*z* 280, (d) *m*/*z* 296, (e) *m*/*z* 266, and (f) *m*/*z* 252.

In the present study, the structure of the potential metabolites was presumed based on the LC-TOF-MS data and previously reported in vivo metabolic data.[32] In general, the demethylation metabolite (*m*/*z* 266) should be *N*-(2,6-dimethylphenyl)-*N*-(methoxyacetyl)alanine (M3), the MX acid. The didemethylation metabolite (*m*/*z* 252) should be *N*-(2,6-dimethylphenyl)-*N*-(hydroxyacetyl)alanine (M4). For the hydroxylation metabolite (*m*/*z* 296), the two possible positions of hydroxylation resulted in two possible structures: *N*-(2,6-dimethyl-5-hydroxyphenyl)-*N*-(methoxyacetyl)alanine methyl ester (M1) and *N*-(2-hydroxymethyl-6-methylphenyl)-*N*-(methoxyacetyl)alanine methyl ester (M2). M1 and M2 are two isomers of hydroxymetalaxyl. Figure 3 summarizes the proposed biotransformation pathways of MX in rat hepatic microsomes.

Much research has focused on the metabolism of MX in matrixes such as soil,[33,34] plants,[26] fungus[35] and microsomes.[36,37] In general, MX acid was the main metabolite in most soil matrixes.[38,39] In human liver microsomes, as reported by Abass, hydroxylation, didemethylation, and lactone formation were the main biotransformation reactions.[37] Since the metabolic profile of a compound always varies with the species used, the difference in metabolic behavior between human and rat liver microsomes may be partly attributed to different CYPs participating in MX metabolism.

Quantitation Method for Metabolite Analysis. After preliminary confirmation of MX metabolites, ^{13}C-labeled MX was incubated with rat hepatic microsomes (1) for further confirmation of the formation of the metabolites and (2) to obtain ^{13}C-labeled metabolites, which were then used as the "internal standards" for identification and quantitative analysis of metabolites in the subsequent stereoselective metabolism study of MX. As a result, hydroxymetalaxyl (*m*/*z* 296), demethylmetalaxyl (*m*/*z* 266), and didemethylmetalaxyl (*m*/*z* 252) were all reconfirmed in this step. A 60 min incubation time was considered as optimal, giving the highest yield of ^{13}C-labeled metabolites. Thus, besides a minor level of $^{13}C_6$-MX acid, the demethylation metabolite (*m*/*z* 266), which was synthesized through a hydrolysis method, other labeled metabolites were successfully achieved with the incubation of $^{13}C_6$-MX for 60 min.

Quantitative analysis of MX metabolites was carried out by LC-MS/MS. All analytes showed a strong signal of the quasimolecular ion $[M + H]^+$ under positive electrospray ionization mode. The parameters of MRM mode for all analytes were optimized by selecting the most abundant product ion. Table 2 listed the MRM parameters for all analytes. Figure 4 illustrated a set of MRM chromatograms for the 60 min

microsomal incubation of MX. Hydroxymetalaxyl (m/z 296), didemethylmetalaxyl (m/z 252), and demethylmetalaxyl (m/z 266) were detected. None of them were detected in the absence of rat hepatic microsomes.

Stereoselective Metabolism of (+)-*S*- and (−)-*R*-MX. (+)-*S*- and (−)-*R*-MX at a concentration of 100 μM were incubated with rat hepatic microsomes, respectively. The degradation curves for MX enantiomers are shown in Figure 5a. (+)-*S*-MX degraded faster than its antipode through the incubation period with a $t_{1/2}$ of 21.00 and 36.47 min for (+)-*S*- and (−)-*R*-MX, respectively. In addition, the enantiomer fraction (EF) was used to measure the stereoselective metabolism of MX (Figure 6). EF was calculated from the peak areas of (+)-*S*- and (−)-*R*-MX following the equation:

$$\text{EF} = (+)\text{-}S\text{-MX}/[(+)\text{-}S\text{-MX} + (-)\text{-}R\text{-MX}] \quad (1)$$

The EF was 0.32 after 60 min incubation, also indicating that degradation of MX in rat hepatic microsomes was stereoselective. This was consistent with the degradation aspect of *rac*-MX in rat hepatic microsomes in a previous study.[36]

In the present study, the peak area ratio of each metabolite and its corresponding ^{13}C-labeled internal standard was used to

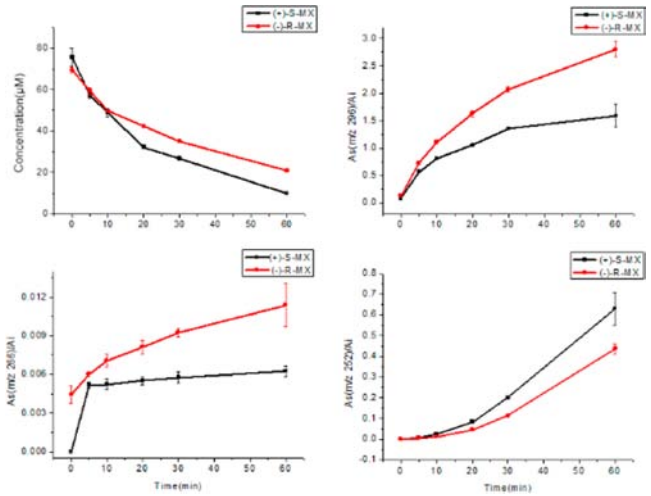

Figure 5. Concentration−time curves of (a) metalaxyl, (b) the hydroxymetalaxyl metabolites (m/z 296), (c) the demethylmetalaxyl metabolite (m/z 266), and (d) the didemethylmetalaxyl metabolite (m/z 252) after incubation of 100 μM (+)-*S*- and (−)-*R*-metalaxyl with rat hepatic microsomes, respectively.

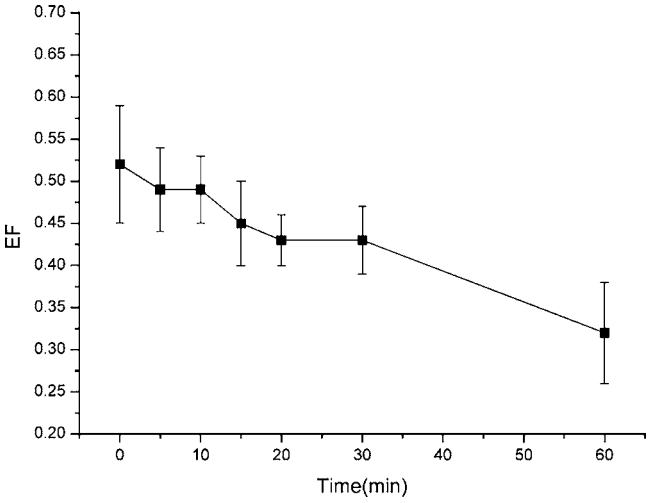

Figure 6. Temporal variations of EFs of metalaxyl in the rat hepatic microsome in the 60 min time course after exposure to 100 μM metalaxyl enantiomers.

compare the differences of metabolic profile between the two enantiomers of MX. Therefore, with the ratio values at different incubation times figured out, metabolite formation from (+)-*S*- and (−)-*R*-MX by rat hepatic microsomes during the incubation is shown in Figure 5b−d.

The amount of all metabolites increased over incubation time. For both enantiomers of MX, the hydroxymetalaxyl metabolites (m/z 296) were the major metabolites. The didemethylmetalaxyl metabolite (m/z 252) was at a moderate level, and demethylmetalaxyl metabolite (m/z 266) was found as the minor metabolite, probably because it could undergo further demethylation. A previous in vivo study indicated that metabolites resulted from didemethylation, hydroxylation of the aromatic methyl group, and demethylation of the ester group were major metabolites, while phenyl ring hydroxyl, ether group demethylated, and lactone metabolites were minor metabolites.[40] Compared with in vitro systems, more complex metabolic pathways exist in vivo, and conditions such as cofactors and concentration of NADPH are also different. These might explain the difference in metabolite formation between the in vitro and in vivo systems.

Except for a small quantity of demethylmetalaxyl metabolite (m/z 266), other metabolites were not detected in the control group. It seemed that MX underwent a slight hydrolysis in the absence of NADPH system.

It is obvious that rat hepatic microsome exhibited significant stereoselectivity in the formation of all detected metabolites. (+)-*S*- and (−)-*R*-MX demonstrated quantitatively different metabolite patterns. Transformation of (−)-*R*-MX to its hydroxymetalaxyl (m/z 296) and demethylmetalaxyl metabolite (m/z 266) was markedly preponderant over its (+)-*S*-isomer, while the case of didemethylmetalaxyl metabolite (m/z 252), a secondary dimethyl metabolite of demethylmetalaxyl metabolite (m/z 266), was just the opposite. Specifically, after 60 min incubation, the amounts of hydroxymetalaxyl and demethylmetalaxyl derived from (−)-*R*-MX were 1.76 and 1.82 times higher than that of (+)-*S*-MX, whereas the production of didemethylmetalaxyl from (+)-*S*-MX was 1.44 times more than that from (−)-*R*-MX. Therefore, the minor amount of demethylmetalaxyl metabolite (m/z 266) from (+)-*S*-MX might well be attributed to the preferential transformation to its secondary dimethyl metabolite (m/z 252). As the fungicidal activity of metalaxyl was mainly attributed to the (−)-*R*-MX, it is interesting that the more active isomer (for target organism) also showed a higher metabolic activity in the in vitro system of the nontarget organism.

Abundant reports suggested that two enantiomers of a chiral compound could always show differences in pharmacokinetic processes (absorption, distribution, metabolism, protein binding, and excretion).[41] Optically active biological macromolecules might behave stereoselectivity when interacting with a chiral drug. In the present study, our results demonstrated that degradation of the parent MX as well as formation of the metabolites in rat hepatic microsomes were observably stereoselective, which should be highly attributed to the existence of several microsomal mono-oxygenases differing in their stereoselectivities and inducibilities for the enantiomers.

In summary, we proposed a new approach using the peak area ratio of each metabolite and its corresponding stable isotope-labeled internal standard to quantitatively compare the stereoselective metabolic behavior of two enantiomers of a chiral compound. According to P. Schieberle,[42] the quantitation method proposed in the present study should be categorized into the "Stable Isotope Dilution Assays (SIDA)". As commercially unavailability of many labeled analytes was claimed as the main drawback of SIDA, our present study proposed a method using real biological samples to obtain the labeled standards. But the absolute quantities of the labeled metabolites were unclear, and it is difficult to establish the MRM method for some minor metabolites at very low concentrations. This should be regarded as the main limitation of our microsomal incubation method. With most of the main metabolites having been quantified, this approach could be of great value for its extensive application in the field of stereoselective metabolism research of a chiral compound, which is important for its comprehensive ecotoxicological and environmental risk assessment.

ABSTRACT: To better understand the tolerance of strawberries (*Fragaria vesca* L.) to high CO_2 in storage atmospheres, fermentation and cellular damage were investigated. Fruits were stored for 3 and 6 days at 0 °C in the presence of different CO_2 levels (0, 20, or 40%) with 20% O_2. Changes in pyruvate decarboxylase (PDC) and alcohol dehydrogenase (ADH) gene expression and in fermentative metabolites, as well as in bound water and malondialdehyde (MDA) concentrations, were analyzed. In strawberries stored without added CO_2, up-regulation of *PDC* and *ADH* was not associated with an increase in fermentative metabolites. By contrast, moderate ethanol fermentation in fruits exposed to 20% CO_2 seems to be essential to maintain fruit metabolism, reducing both lipid peroxidation and cellular water stress. However, if the CO_2 concentration increases (40%), the excess acetaldehyde and ethanol produced were closely correlated with a decrease in bound water and production of MDA.

KEYWORDS: *high CO_2 levels, fermentative genes, acetaldehyde, ethanol, MDA, bound water*

INTRODUCTION

Low temperature is used to prolong the storage life of strawberries and to slow fungal decay, mainly caused by gray mold (*Botrytis cinerea*) that grows at temperatures as low as 0 °C. Thus, relying on low-temperature storage to efficiently control gray mold must involve coadjuvant treatment to preserve the quality of the fruit while enhancing disease resistance. High CO_2 levels (15−20%) are used commercially as an effective means of limiting fungal decay.[1] Strawberries are tolerant to elevated high CO_2 concentrations, although distinct cultivars exhibit different degrees of high CO_2 tolerance, and they accumulated different levels of fermentative metabolites, such as acetaldehyde and ethanol.[2] These fermentative products influence fruit quality and may also act as natural fungicides or insecticides.[3]

Strawberries are highly appreciated for their tasty flavor and nutritional value, and in particular they are a particularly good source of polyphenols, of which proanthocyanidins, produced from the condensation of flavan-3-ol units, are the main phenolics.[4] Genetic and growth conditions affect the content and composition of proanthocyanidins,[5] although quantitative differences are often driven by environmental storage conditions. Flavan-3-ols have positive effects on human health,[6] as well as contributing to defense and stress resistance toward different fungi.[7] Interestingly, short-term high-CO_2 treatment (20% CO_2 for 3 days) is an effective treatment for the accumulation of (+)-catechin and procyanidins B1 and B3.[8] In some astringent-type fruits such as persimmon, the effectiveness of high-CO_2 treatment (95−100% CO_2) to promote deastringency is based on the decrease of soluble tannins concentrations through their polymerization by acetaldehyde.[9,10] This role of acetaldehyde as the main polymerizing agent was demonstrated in model solution systems with (+)-catechin or (−)-epicatechin.[11]

In addition to the above, high CO_2 levels also modified the water status of several high-CO_2-tolerant fruits, such as table grapes and strawberries, affecting the unfreezable (bound) water fraction as detected by differential scanning calorimetry (DSC).[12,13] Although ethanol is a small, polar molecule able to enter the hydration layer of membranes and weaken interlipid hydrogen bonding,[14,15] its influence on fruit cellular water has scarcely been investigated. Water molecules have a primary structural role in the maintenance of cell membrane, participating in the hydrogen-bonded network or hydration layer. In yeast, ethanol concentrations as low as 5% (w/v) reduce water availability sufficiently to have metabolic consequences.[16] Thus, we hypothesize that perturbations in bound water, which are essential to maintain cell membrane structure, may be associated with changes in the accumulation of fermentative metabolites. Moreover, and consistent with the above, it is likely that some of the reported effects of high CO_2 treatment occur through the accumulation of fermentative metabolites.

Nevertheless, excessively high-CO_2 treatments may also have an adverse effect on strawberry quality associated with oxidative stress. Enhanced rate of active oxygen species (ROS), often leading to oxidative damage, is an integral part of many stressful

environmental conditions.[17] ROS have been recognized as contributing to injury via direct lipid peroxidation that may disrupt membrane integrity.[18,19] Peroxidation of lipids may lead to a radical chain reaction that is usually accompanied by the formation of a wide variety of products, including alkanes and carbonyl compounds. The most widely used index of lipid peroxidation is malondialdehyde (MDA) formation, often assayed through thiobarbituric acid (TBA). However, several other compounds are also reactive toward TBA, leading to an overestimation of MDA content. The quantitative determination of MDA by HPLC with UV detection after its derivatization with dinitrophenylhydrazone (DNPH) greatly improves the selectivity and the analytical detection limit of the MDA assay.[20] Thus, using this technique, in the present work we have tried to see if the damage produced by excessively high-CO_2 treatment (40%) or severely low-temperature (0 °C) storage could be also attributed to oxidative stress.

Fermentative metabolism is closely linked to the availability of respiratory substrates, including malic acid, the oxidative decarboxylation of which results in the formation of pyruvic acid that may eventually be converted to fermentative compounds. The activation of ethanolic fermentative metabolism should allow NAD^+ regeneration so that a net ATP production can be generated. In the first step of the ethanol fermentation pathway, pyruvate is the substrate of pyruvate decarboxylase (PDC), yielding CO_2 and acetaldehyde. Subsequently, acetaldehyde is reduced to ethanol with the concomitant oxidation of NADH to NAD^+ by alcohol dehydrogenase (ADH). Changes in the activities and gene expression of *PDC* and *ADH* under high-CO_2/low-O_2 conditions have been reported in *Fragaria* × *ananassa*,[21−23] yet there is little information about the specific effect of high-CO_2 levels under unlimited O_2 conditions in *Fragaria vesca*.

The aim of this study was to first determine the effect of low-temperature and high-CO_2 levels on *ADH* and *PDC* expression as well as on levels of fermentative metabolites, ethanol and acetaldehyde. Accordingly, the transcript abundance of these genes and fermentative metabolites were analyzed in Mara des Bois strawberries exposed for 3 and 6 days to different CO_2 concentrations (0, 20, and 40%) during storage at 0 °C. In addition, we set out to stablish the CO_2 doses and exposure times capable of activating fermentative metabolism. To achieve this, the availability of respiratory substrates was determined, as was the potential damage of the accumulated ethanol and acetaldehyde on lipid peroxidation and cellular water stress. This was done by analyzing bound water content and MDA.

MATERIALS AND METHODS

Plant Material. The organic strawberries used in this study (*F. vesca* L. Mara des Bois) were grown in an orchard in San Sebastian de los Reyes (Madrid, Spain). Strawberries belonging to the first and second inflorescences were harvested, immediately transported to the Institute of Food Science Technology and Nutrition, and selected for uniform size and color. The strawberries with 1 mg flavonoids/g FW and a harvest maturity index of 12 (total soluble solids/titratable acidity ratio) were stored at 0 °C (±0.5) and >95% relative humidity in three sealed containers with a capacity of 1 m^3. Fifteen plastic boxes, each containing approximately 0.5 kg of fruit, were stored in each container and exposed to different CO_2 concentrations (0, 20, or 40%) with 20% O_2 under a continuous flow. Strawberries were analyzed after 3 and 6 days of treatment using fruit analyzed at harvest as a control. The CO_2 and O_2 concentrations were measured using a gas analyzer (PBI Dansensor mod, Checkmate 9900). At harvest and from each treatment group (0, 20, and 40% CO_2-treated fruit), 45 strawberries were selected for quality analysis (pH, soluble solids content, titratable acidity) and fermentative metabolites quantification. Another 45 fruits were removed at random from each of group, divided into three batches of 15 strawberries, frozen in liquid nitrogen, and stored at −80 °C for further analysis. The 15 strawberries from each batch served as a biological replicate, and two different measurements were taken from each of the three biological replicates.

Relative Gene Expression Assessed by Quantitative RT-PCR. RNA extraction was conducted according to the protocol of Yu et al.,[24] with modifications from samples of strawberry treated with 0, 20, and 40% CO_2 stored for 0 or 3 days. Total RNA was extracted three times from 0.4 g of each sample with CTBA-based extraction buffer. The quality and purity of the total RNA were evaluated by agarose gel electrophoresis and spectrometry (NanoDrop 2000, Thermo Scientific), and it was then treated with DNase (DNase I, RNase-free, Thermo) to remove any genomic DNA before synthesizing cDNAs from 1 μg of each sample using the iScript TM Reverse Transcription Supermix for RT-qPCR (Bio-Rad). RT-PCR amplification was carried out in a 96-well plate iCycler iQ thermal cycler (Bio-Rad) and quantified using iCycler iQTM-associated software (Real Time Detection System Software, version 2.0), evaluating each gene in at least two independent runs. Sequences from the NCBI database and from the available literature (in particular, refs 21 and 25) were used to design the following gene specific primers using Primer3 software. The primer pairs used in the RT-qPCR for pyruvate decarboxylase (XM_004302484) were FvPDC_F, GTTGCTTGAGTGGGGGTC-TA, and FvPDC_R, ATCTGTGAATGCGAATGAAGG; and those for alcohol dehydrogenase (XM_004290520) were FvADH_QFw2, GCCCTTCTATACTGTGTCCTC, and FvADH_QRv2, ACTGTT-CTGGCTGACTGGTT.

The relative expression of all the genes studied was assayed using quantitative RT-PCR (RT-qPCR). To calculate the efficiency of the reaction (optimal range 90−110%) and to establish the most suitable template concentration, the cDNAs synthesized from serial dilutions of total RNA were amplified (between 40 and 2.5 ng). Standard curves and linear equations were determined by plotting cycle threshold (Ct) values (*y*-axis) against the logs of the total RNA (*x*-axis). The efficiency of each individual run was calculated on the basis of the raw fluorescence data (ΔRn) exported as output file and subsequently imported into the LinReg PCR program. The specificity of the products was validated by analyzing the dissociation curves, evaluating in agarose gels, and sequencing (Genomic Department of the CIB-CSIC). The *actin-97-like* housekeeping gene from *F. vesca* (XM_004307470) was not regulated by low-temperature or high-CO_2 levels (data not shown) and, thus, it was used as the internal reference gene to normalize the transcript profiles according to the $2^{-\Delta\Delta Ct}$ method and relative to the calibrator sample (fruit at harvest). The *actin-97-like* was amplified with the primers FvActin_Fw, GGGTTTGCTGGAGATGATG, and FvActin_Rv, CACGATTGG-CCTTGGGATTC. Similarly, the specificity of the products was validated by analyzing the dissociation curve in agarose gels and by sequencing. Three biological replicates were assessed for each treatment and sample, each with three technical replicates.

Ethanol and Acetaldehyde Content. Ethanol and acetaldehyde were analyzed from the headspace of juice of three replicates of 15 strawberries without calyx, immediately after harvest and for each storage period. An aliquot (5 mL) of juice was transferred to 10 mL vials, closed tightly with crimp-top caps and TFE/silicone septum seals, and frozen at −80 °C. Gas chromatography (Thermo Trace, Thermo Fisher Scientific) was used to measure the ethanol and acetaldehyde according to the procedure of Valencia-Chamorro et al.[26] The setup included an autosampler (model HS 2000), a flame ionization detector (FID), and a 1.2 m × 0.32 cm (i.d.) Poropack QS 80/100 column, with the injector set at 175 °C, the column at 150 °C, the detector at 200 °C, and the carrier gas at 28 mL/min. A 1 mL sample of the headspace was withdrawn from vials previously equilibrated in a water bath at 20 °C for 1 h and for 15 min at 40 °C, and it was then injected onto the GC. Ethanol and acetaldehyde were identified by comparison of the retention times with standards, and the results were expressed as milligrams per 100 mL of juice.

Figure 1. Two histograms (A) represent the relative expression of fermentative genes and the two tables (B) show the levels of fermentative metabolites. The histograms reflect the relative expressions of the *PDC* gene XM_004302484 and the *ADH* gene M_004290520 in Mara des Bois strawberries *Fragaria vesca*, immediately after harvesting (day 0) and after 3 and 6 days of storage at 0 °C in different concentrations of CO_2 (0, 20, or 40%), maintaining a constant concentration of O_2 (20%). Transcripts were measured by quantitative RT-PCR and normalized against those *actin-97-like* used as a reference gene. The results were calculated relative to a calibrator sample (day 0) using the formula $2^{-\Delta\Delta Ct}$ and the values representing the means ± SE of three replicates (n = 6). The tables show changes in acetaldehyde and ethanol (mg/100 mL) under the same conditions described above. Each letter indicates significant differences between the means determined by Tukey's test (P < 0.05).

Determination of Water Fractions Content. The water fractions content were determined on a differential scanning calorimeter (DSC822e, Mettler-Toledo Inc., Columbus, OH, USA) equipped with a liquid nitrogen cooling accessory, according to the procedure of Goñi et al.[27] The method based on the heat of fusion was used to calculate the unfreezable water (bound) content, whereas the total water content was determined after a stable weight had been obtained following drying at 105 °C.

Chromatographic Determination of MDA. MDA was determined as its hydrazone by high-performance liquid chromatography using 2,4-dinitrophenylhydrazine (DNPH) for derivatization and following the method previously described by Mateos et al.,[28] with slight modifications in the chromatographic conditions. Frozen fruit samples of approximately 1 g were homogenized in 10 mL of ultrapure water and centrifuged at 30000*g* for 20 min; after filtering through a 0.45 μm pore size membrane, the supernatants were collected to quantify MDA.

An aliquot (250 μL) of the sample was placed in a 1.5 mL Eppendorf, and 50 μL of 6 M NaOH was added to achieve alkaline to hydrolyze protein-bound MDA by incubating this mixture in a 60 °C water bath for 30 min. The protein was then precipitated with 125 μL of 35% (v/v) perchloric acid, and the mixture was centrifuged at 2800*g* for 10 min. A 250 μL aliquot of the supernatant was transferred to another Eppendorf vial and mixed with 25 μL of DNPH prepared as a 5 mM solution in 2 M hydrochloric acid. Finally, this reaction mixture was incubated for 20 min at room temperature, protected from light. An aliquot of 50 μL of this reaction mixture was injected onto an Agilent 1100 HPLC-DAD with a Nucleosil 100 RP-18 column (4.0 mm × 125 mm, 5 μm particle size, Agilent) preceded by a Lichrospher guard column (4.0 mm × 4.0 mm). Samples were isocratically eluted with a mixture of 0.2% (v/v) acetic acid in deionized water and acetonitrile (75:25 v/v), applied at a flow rate of 0.7 mL/min at room temperature for 40 min. Chromatograms were acquired at 310 nm. Standard MDA was prepared by acidic hydrolysis of 1,1,3,3-tetraethoxypropane in 1% sulfuric acid. Like the experimental samples, the standards were treated with 6 M NaOH for 30 min at 60 °C, followed by protein precipitation with 35% perchloric acid and derivatization with DNPH. Concentrations were expressed as nanomoles of MDA per gram of FW.

Determination of Sucrose and Malic Acid Contents. Sucrose and malic acid were measured according to the method of Blanch et al.[15] using a Metrohm Advanced compac ion chromatography apparatus (867 IC Metrohm). Sucrose was determined by HPAEC-PAD with a Metrosep Carb 1-250 IC column (4.6 mm × 250 mm) and malic acid by HPAEC with an IC-819 conductivity detector equipped with a Metrosep Organic Acids column (7.8 mm × 100 mm). Sucrose and malic acid were identified by their retention times and quantified on the basis of calibration curves derived from standards; their contents were expressed as milligrams per gram of FW of the sample. The data represent the means of the three replicates on which two different measurements were taken.

Determination of Total Soluble Solids and Titratable Acidity. The total soluble solids were determined using a digital refractometer (Atago PR-101, Atago, Japan), expressed as a percentage. The titratable acidity was analyzed by titration with 0.1 N NaOH to pH 8.1 (Mettler DL-70, Mettler-Toledo, Spain).

Statistical Analysis. The analysis of variance (ANOVA) was performed using SPSS v. 19.0. Multicomparison of the means was performed using Tukey's test, with the level of significance set at P < 0.05. The main effects of CO_2 treatment and storage time and the treatment × time interaction were analyzed.

RESULTS AND DISCUSSION

Effect of CO_2 on *PDC* and *ADH* transcripts and on fermentative metabolites. To better understand the effect of low-temperature and high-CO_2 levels on fermentative metabolism, we analyzed the expression of genes encoding for PDC and ADH by RT-qPCR in strawberries stored for 3 and 6 days with 0, 20, or 40% CO_2 in 20% O_2 (Figure 1). We analyzed the expression of the gene codifying for the Fvpdc isoform 2-like (XP_004302532), which is the PDC isoform in *F. vesca* with the highest homology to the Fapdc1 (AF333772) from *Fragaria* × *ananassa* that has been shown to be induced by

DOI: 10.1021/jf505715s
J. Agric. Food Chem. 2015, 63, 761−768

stress conditions.[23] Likewise, we studied the expression of genes codifying for the predicted *F. vesca* ADH isoform XP_004290568, which was the sequence with the highest homology to the ADH from *Fragaria* × *ananassa* (P17648) involved in cold tolerance.[25] The expression of *PDC* was already high at harvest, but storage at 0 °C without added CO_2 induced a progressive accumulation of its transcripts. After 3 days, *PDC* expression had increased 40%, and this increase reached 77% after 6 days. However, in fruit exposed to 20 and 40% CO_2 *PDC* expression was similar to that found in fruit at harvest, suggesting that application of high-CO_2 levels prevented the increase in *PDC* transcription induced by low temperature. These results agree with those of Ponze-Valadez et al.,[21] who found that CO_2 inhibited *PDC* expression in Jewel strawberries during the first days of storage at 2 °C. Even with an atmosphere of 60% CO_2 for 7 days,[23] no effect in PDC mRNA levels in Chandler strawberries was detected. Low temperature induced its transcription even more drastically. After 3 and 6 days without added CO_2, *ADH* expression was 8.5- and 23-fold higher than that of fruit at harvest, respectively. This increase was more moderate in the fruit exposed to 20% CO_2, and it was even less pronounced when fruits were exposed to 40% CO_2. *ADH* mRNA accumulation by low temperature has been reported in several plant species.[29,30] Also in Jewel strawberries, the *ADH* expression, which was low at harvest, increased after the second day of storage at low temperature,[21] although accumulation of ethanol was not shown. Considering that in the present work all samples exhibited the same O_2 (20%), our results indicate that factors other than O_2 are influencing the expression of *PDC* and *ADH* genes. The observed marked accumulation of *PDC* and *ADH* transcripts in strawberries stored without added CO_2 seems to indicate that low temperature is involved in the induction of both genes.

The lowest ethanol values were found in strawberries stored without added CO_2 (Figure 1B), and ethanol was not even detected after 6 days. By contrast, a marked increase in ethanol content was detected following exposure to CO_2, and whereas a 4-fold increase was measured after 3 days in 20% CO_2, the increase was 41-fold in 40% CO_2. When fruits were exposed to CO_2 for 6 days, the increase in ethanol was more pronounced, whereas no such increase was found in fruit that was not exposed to CO_2. In the case of acetaldehyde, again the highest levels were found in fruit treated with 40% CO_2. Furthermore, after a 3 day exposure to 40% CO_2, the increase in acetaldehyde in fruit was higher than that observed for ethanol. Also in Chandler strawberries treated with 50% CO_2 and with oxygen kept at 21%, acetaldehyde markedly increased with respect to untreated fruit, and its levels were higher compared with those under hypoxia conditions.[31] A progressive increase in acetaldehyde and ethanol concentrations has also been reported in other fruits during ripening at 20 °C and under elevated CO_2 and normal atmospheric oxygen concentration.[32] Moreover, Zhang and Watkins[22] showed that accumulation of fermentative metabolites and *ADH* transcripts in CO_2-treated strawberries was temperature dependent, being higher at 20 °C than at 2 °C. Our results indicate that the highest ethanol values were obtained in fruit exposed to 40% CO_2 for 6 days (67.7 ± 2.8 mg/100 mL). Despite its accumulation, there was significantly less ethanol than in the juice of other fruits such as oranges[26,33] and less than the level indicated by Ben-Aire et al.[34] as an off-flavor developed in persimmons (75 mg/100 mL). Also in 40% CO_2-treated fruit the highest levels of acetaldehyde were quantified, reaching values of 10 mg/100 mL. In 20% CO_2-treated fruit the maximum ethanol and acetaldehyde levels were 4- and 10-fold lower than those found in 40% CO_2-treated ones. Furthermore, the accumulation of such fermentative metabolites was not correlated with the strongest expression of *PDC* and *ADH*. Our results show that *PDC* and *ADH* expression was up-regulated by low temperature and it was unmodified (*PDC*) or weakly induced (*ADH*) by high levels of CO_2. The sharp induction of *PDC* and *ADH* driven by low temperature was not accompanied by a shift toward ethanolic fermentation, such that the levels of acetaldehyde and ethanol did not increase concomitantly. Although high CO_2 appears to exert a clear influence in avoiding the specific induction of *PDC* and *ADH* genes analyzed in this work, fruit is able to maintain an active fermentative metabolism based on the accumulation of ethanol and acetaldehyde. In light of the discrepancies between *ADH* transcripts and ethanol content described elsewhere[21,22] and the data shown here, the correlation between fermentative metabolites and *PDC* and *ADH* gene expression still requires further study. Accordingly, other experiments should be performed to determine if there is a *PDC* or *ADH* isoform specifically induced by high concentrations of CO_2.

Cellular Water Stress in Response to Various CO_2 Levels. The determination of bound water content by DSC showed a clear difference between CO_2 doses and duration of exposure (Figure 2). In freshly harvested strawberries, the bound water (2.5 g/g DW) was slightly lower than in fruit exposed to 20% CO_2, which exhibited the highest values. By contrast, the bound water content decreased in fruit stored at low temperature in air, although less so than in fruit maintained in 40% CO_2 in which a marked depletion was quantified after 3 days. The low bound water content then remained constant for a further 3 days, reaching values of 0.71 g/g DW. Modifications

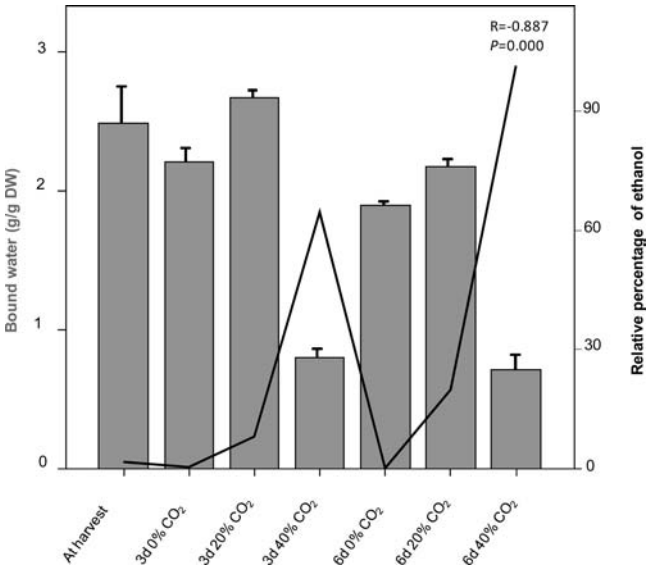

Figure 2. Correlation between ethanol and bound water in Mara des Bois strawberries *Fragaria vesca* immediately after harvesting (day 0) and after 3 days of storage at 0 °C in different CO_2 concentrations (0, 20, or 40%), maintaining a constant concentration of O_2 (20%). The bound water content is represented by the shaded bars, whereas the line shows the relative percent of ethanol over maximum level. The *R* value and significance level are indicated in the top right-hand corner of the figure. An inverse correlation was also found between bound water and acetaldehyde ($R = -0.836$; $P = 0.000$) (data not shown).

J. Agric. Food Chem. 2015, 63, 761−768

of water fractions have already been detected in several fruits during ripening and storage.[12,27] Our present results indicate that excessively high CO_2 leads to a significant conversion of bound water to free water content, with the consequent implications on the availability of water in the cell. Interestingly, the decrease in the content of bound water was inversely correlated with the increase in the levels of ethanol (R = −0.887) (Figure 2) and acetaldehyde (R = −0.836, data not shown). Strawberries treated with 40% CO_2 showed the highest fermentative volatile values and the lowest values for bound water. This good correlation seems to indicate that there is competition between acetaldehyde and/or ethanol and bound water, and excessive fermentative metabolites can disrupt membrane structures. Klemm[35] reported that alcohol and water compete with each other on target membrane molecules, specifically, lipids and proteins near the membrane surface. Ethanol could bind certain targets preferentially and displace water, leading to conformational consequences. Using model membrane systems, FTIR spectroscopic evidence revealed that alcohol has a nonstereospecific binding capacity for membrane surface molecules and that such binding occurs at sites that would otherwise be occupied by hydrogen-bonded water.[36] Our results suggest that fermentative metabolites can modulate the displacement of water from the hydrogen-bonded network in the hydration layer, resulting in a reduction of bound water. Ethanol also perturbed cell membranes by weakening interlipid hydrogen bonding, involving water.[14] Furthermore, as we previously reported that 40% CO_2 treatment affected cellular structure and water potential in strawberries,[13] our results suggest that excess alcohol might trigger cellular water stress. Alternatively, the lack of ethanol in fruit stored without added CO_2 may restrain the flexibility of the membrane, in part, through the changes in membrane rigidity associated with storage at low temperature.[37] Consequently, the beneficial effect of 20% CO_2 treatment may be attributed to the stabilization of membrane component interactions, involving water. Indeed, keeping the water fractions within normal parameters seems to be important to maintain a relatively constant distance between membrane components and to stabilize lipid−lipid interactions that strongly influence the structure of biological membranes.

Oxidative Damage in Response to Various CO_2 Levels. Oxidative damage was quantified by measuring MDA using HPLC-UV detection as the DNPH derivative. Figure 3 shows the HPLC chromatogram at 310 nm of strawberry homogenates after treatment for MDA determination, indicating the hydrazone derivative of MDA, which was confirmed by spiking samples with standard MDA before the treatment. A good chromatographic peak resolution was obtained, with no interfering peaks, which allowed a straightforward determination of the MDA derivative. Using this precise and sensitive method, the effect of low temperature and high CO_2 concentrations on lipid peroxidation was evident (Figure 3). After 3 days, MDA levels increased in fruit stored without added CO_2 with respect to freshly harvested fruit and then declined, indicating that radical-induced damage is involved in the initial stage of storage at low temperature. When strawberries were treated with 20% CO_2 for 3 days, the MDA levels increased, but to lower levels than for strawberries stored without added CO_2, and then remained constant for a further 3 days. In fruits treated with 40% CO_2, higher levels of MDA were detected than for strawberries stored without added CO_2, mainly after 6 days of treatment.

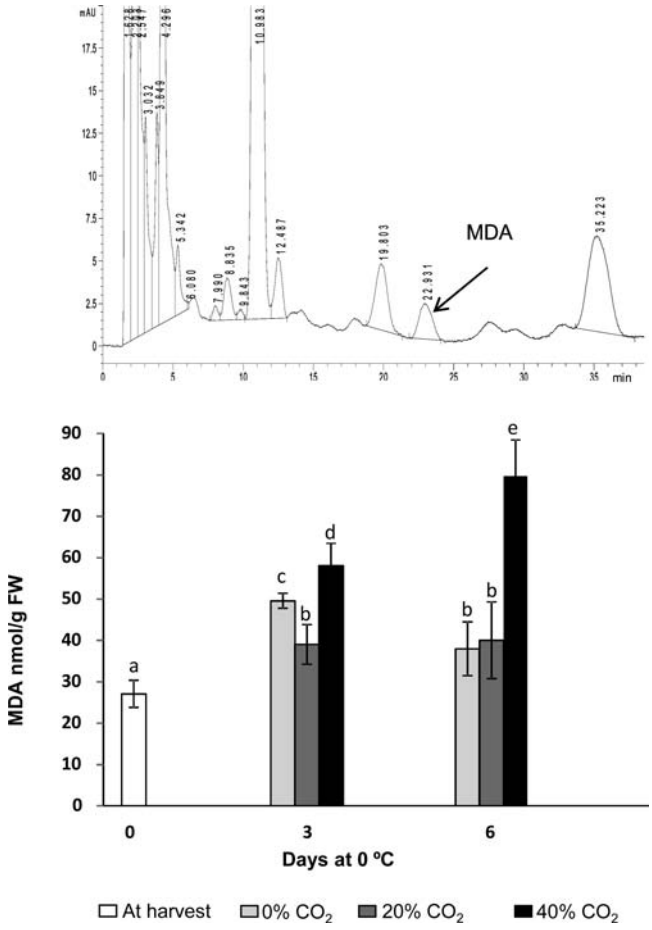

Figure 3. Chromatogram showing the MDA peak and a graph indicating the changes in the levels of MDA in Mara des Bois strawberries *Fragaria vesca* immediately after harvesting (day 0) and after 3 days of storage at 0 °C in different CO_2 concentrations (0, 20, or 40%), maintaining a constant concentration of O_2 (20%). Each letter indicates significant differences between the means determined by Tukey's test (P < 0.05).

Membrane phospholipids, and especially the group of polyunsaturated fatty acids, are susceptible to reactions with free radicals. The significant increase in MDA in fruit tissues indicates enhanced lipid peroxidation. Lipid peroxidation may be the result of more than one environmental factor, including chilling temperature.[38] Our data indicate that 20% CO_2 reduces the oxidative stress caused by severely low temperature, supporting the significant increase previously observed in several tissues of table grape bunches as a response to low-temperature storage.[39,40] Given the high MDA levels in 40% CO_2-treated fruit, we suggest that the decomposition of lipid hydroperoxide is possibly enhanced by the accumulation of potentially toxic levels of acetaldehyde and/or ethanol that disproportionally affect the displacement of water molecules in this hydrogen-bonded water network, thereby disrupting membrane structure. The above changes in membrane stability associated with excessive fermentative metabolites might also accelerate the oxidative damage determined by an increase in MDA levels.

Changes in Sucrose, Malic Acid, Total Soluble Solids, pH, and Titratable Acidity in Response to Various CO_2 Levels. At harvest, a steady-state level of sucrose was maintained in CO_2-treated fruit, this being the main constituent

of carbohydrate reserve (Table 1). By contrast, a decrease in sucrose was observed in fruit stored without additional CO_2 (0%) after both 3 and 6 days in storage at 0 °C. These results reveal that without added CO_2, fruits deplete their energy reserves, leading to a decrease in sucrose and lower levels of total soluble solids after 6 days in storage. Conversely, fruits saved energy reserves when exposed to CO_2 and had more abundant sucrose than fruits stored at low temperature without added CO_2. Ethanol synthesis has generally been regarded as the means to regenerate NAD^+ required to sustain glycolytic energy production. Furthermore, and consistent with the pH-stat mechanism for H^+ consumption, the activation of ethanol synthesis in CO_2-treated fruit could be an important role given that ethanol synthesis is not accompanied by H^+ production and, so, it could be a way to limit cytoplasmic acidification. Although cytoplasmic pH determination has not been performed in this study, the fruit extract pH indicated that fruit with excessive CO_2 levels (40%) exhibited the highest pH levels and the lowest titratable acidity (Table 1). Increasing pH and decreasing titratable acidity in strawberry tissues was more marked in fruit stored in high CO_2 atmospheres.[41] Malic acid content is involved in regulating cytoplasmic pH, and changes in endogenous malate levels in response to experimental treatment are expected to cause cytoplasmic pH shifts.[42] The lowest values of malic acid were found in fruit exposed to 20% CO_2 for 3 days (Table 1). The decrease in malic acid in fruit treated with 20% CO_2 for 3 days might prevent a drop in the cytoplasmic pH and, consequently, a high degree of fermentation might not be required in accordance with the aforementioned hypothesis. A significant role for malate in the regulation of cytoplasmic pH in hypoxic plant tissue has been proposed.[43] However, when the exposure to CO_2 treatment was stronger and persisted longer, this pattern changed. In the case of fruit stored at 0 °C without added CO_2, the up-regulation of fermentative genes while ethanol formation was restricted implies that the potential capacity for ethanolic fermentation was insufficient. Ethanolic fermentation not only is considered to be the main factor in providing energy under low oxygen concentrations but also has additional important functions in the presence of atmospheric oxygen.[44]

Our results show that following exposure to high CO_2 under unlimited oxygen conditions, the activation of fermentative metabolism in fruit with the associated production of ethanol and acetaldehyde may represent an essential supplementary metabolic pathway for energy production. Favorable fermentative metabolism in strawberries exposed to 20% CO_2, with a marked increase in the levels of fermentative metabolites, should promote the consumption of reducing power and H^+. Moreover, the reoxidation of NADH in 20% CO_2-treated fruit seems to be potentiated by the activation of malic acid decarboxylation in accordance with the decrease in malic acid quantified in these treated fruit. Stimulation of NADP-ME activity in 20% CO_2-treated fruit has already been reported.[45] Thus, the activation of fermentative metabolism has been described as an adaptive response of fruit to stressful conditions.[21] Therefore, the controlled modulation of ethanol and acetaldehyde levels that are allowed to accumulate in strawberry tissues in fruit seems to be an extremely important protective mechanism for conferring tolerance to high-CO_2 levels, thus reducing damage to severely low temperature.

Our data indicate that the expression of *PDC* and *ADH* genes in *Fragaria vesca* Mara des Bois strawberries stored at low temperature without added CO_2 is greatly in excess of the rate of fermentation metabolites. Moreover, the progressive decrease in the transcript levels of *PDC* and *ADH* as CO_2 increases suggests that the induction of fermentative genes is correlated with low-temperature storage. Our results demonstrate that treating strawberries with 20% CO_2 activates fermentative metabolism by means of a marked increase in the levels of fermentative metabolites. Moreover, favorable fermentative metabolism combined with the activation of malic acid decarboxylation may represent a protective mechanism. On exposure to 40% CO_2, the exclusive disposition of fermentative metabolism caused damage due to the excessive accumulation of fermentative metabolites in the fruit, leading to elevated oxidative stress as witnessed by acute MDA production. Moreover, excess ethanol and acetaldehyde accumulation could potentially accelerate the loss of membrane integrity, provoking the loss of bound water fraction that resembles cellular water stress. Therefore, the controlled modulation of ethanol and acetaldehyde levels in fruit concomitant with an activation of malic decarboxylation may in part explain complex processes such as cross tolerance between low temperature and beneficial high-CO_2 concentrations.

This study demonstrates the up-regulation of ADC and PDC in strawberries at 0 °C in conditions of unlimited O_2 while nonaccumulation of fermentative products occurred. Moreover, storage at low temperature was coupled to oxidative stress, exacerbated by excessive high CO_2 (40%) and controlled by beneficially high-CO_2 (20%) levels. Furthermore, the accumulation of fermentative products was correlated with marked changes in fruit water status, without the influence of extra surrounding water.

ABSTRACT: The aroma-active compounds in typical cola-flavored carbonated beverages were characterized using gas chromatography−olfactometry and gas chromatography−mass spectrometry. The potent odorants in the top three U.S. brands of regular colas were identified by aroma extract dilution analysis (AEDA). Among the numerous odorants identified, eugenol (spicy, clovelike, sweet) and coumarin (sweet, herbaceous) were predominant in all colas. Other predominant odorants in at least one brand included guaiacol (smoky) and linalool (floral, sweet), while 1,8-cineole (minty, eucalyptus-like) was a moderately potent odorant in all colas. Determination of the enantiomeric compositions indicated that (*R*)-(−)-linalool (34.5%) was a more potent odorant than the (*S*)-(+)-enantiomer (65.6%) due to its much lower odor detection threshold. In addition, lemon-lime and cooling attributes determined by sensory descriptive analysis had the highest odor intensities among the eight sensory descriptors. The aroma profiles of the three colas were in good agreement with the potent odorants identified by AEDA.

KEYWORDS: *cola-flavored carbonated beverage, potent odorant, aroma extract dilution analysis, enantiomer, sensory descriptive analysis*

INTRODUCTION

Carbonated beverages are the largest segment of the soft drink industry, and cola is the predominant flavor accounting for 54.0% of the global revenues generated by the soft drink and bottled water industry.[1] The sales of cola-flavored carbonated beverages in 2010 were about $14 billion of the soft drink market in the United States.[2,3] According to product labels and published literature, the uniqueness and complexity of cola is a result of the mixture of natural flavors derived from vanilla extract and essential oils of citrus, cassia or cinnamon, coriander, nutmeg, and neroli.[4,5]

Despite its popularity, there are only a few studies on the flavor chemistry of cola. Cola aroma has been studied by both sensory[6] and instrumental[7−9] techniques. Headspace volatiles of decarbonated colas were evaluated by solid-phase microextraction (SPME) and dynamic headspace analysis.[8] These researchers reported that terpenes and aldehydes were the major volatiles, and those in highest abundance were limonene and a mixture of α- and γ-terpineol. Limonene along with γ-terpinene and *p*-cymene were identified as the three most abundant headspace volatiles in off-flavored cola.[7] Another study asserted that (*Z*)-terpin hydrate could be used as a volatile marker to differentiate cola stains from the dark color stains caused by other beverages, including beer, coffee, black tea, Oolong tea, and green tea.[9]

However, the potent odorants of cola have not been reported. Gas chromatography−olfactometry (GCO), which uses the human nose as a detector of GC, was developed and applied to indicate the odorants from the complex mixture of both aroma volatiles and odorless volatiles. Aroma extract dilution analysis (AEDA), which is frequently used, is a screening method used to rank the relative potency of aroma-active compounds found in foods.[10,11] It has been used to identify the potent odorants in foods, beverages, and nonfoods, including pomegranate juice[12] and scented candles.[13]

In the present study we aimed to determine the potent odorants in the top three U.S. brands of regular cola-flavored carbonated beverages on the basis of AEDA. The aroma-active compounds in typical cola were characterized using GCO and GC−mass spectrometry (GC−MS). The aroma-active compounds with the most impact were then identified by AEDA. The results of this study can provide a foundation for further studies leading to the identification of key aroma components and improvements in the flavor and shelf life stability of cola-flavored carbonated beverages.

MATERIALS AND METHODS

Materials. The top three U.S. brands of regular cola-flavored carbonated beverages (Coca-Cola, Pepsi, and RC, designated as cola A, cola B, and cola C, respectively) and the references used in sensory evaluation (Table 1) were purchased from local markets (Urbana, IL) during 2010−2011. Odor-free water used in this experiment was prepared by boiling deionized−distilled water to two-thirds of its initial volume.

Chemicals. General-reagent- or HPLC-grade chemicals, such as anhydrous diethyl ether, anhydrous sodium sulfate, dichloromethane, hydrochloric acid, sodium bicarbonate, and sodium chloride, were obtained from Fisher Scientific (Fair Lawn, NJ). Ultra-high-purity (UHP) nitrogen and UHP helium were purchased from S.J. Smith (Davenport, IA).

Table 1. Attributes, Definitions, and References Used for Sensory Descriptive Analysis of Cola-Flavored Carbonated Beverages

attribute	definition	reference		
		product (manufacturer)	preparation[a]	intensity[b]
lemon-lime	aromatic reminiscent of lemon or lime	Sprite (lemon-lime soda) (Coca-Cola Co., Atlanta, GA)	50 mL	7
orange	aromatic reminiscent of orange	Sunkist (orange soda) (Sunkist Growers, Inc., Sherman Oaks, CA)	50 mL	9
brown spice	aromatic associated with allspice, cinnamon, clove, mace, nutmeg (spicy)	whole cloves (McCormick & Co., Inc., Hunt Valley, MD)	0.2 g	10
herbal	aromatic associated with dried herbs, hay, or grass	dried long grass (cut into 2 cm pieces)	3 g	9
vanilla	vanilla-like aroma	vanillin (compound **58**; Fluka, Buchs, Switzerland)	10 mL (50 ppm in water)	8
caramel	sweet aromatic	Werther's Original (chewy caramels) (made in Germany for Storck USA L.P., Chicago, IL)	one piece (~6 g)	6
cooling	cooling aroma, but not identical to mint	Halls (Mentho-Lyptus) (made in Canada, distributed by Cadbury Adams USA LLC, Parsippany, NJ)	10 mL (3.5 mg/mL of water)	7
pine	aromatic reminiscent of pine needles	Pine-Sol (original) (Fabricado Para the Clorox Co., Oakland, CA)	10 mL (100 ppm in water)	7

Reference Standard Compounds. The standard compounds used to confirm the structures of the aroma compounds listed in Table 2 were supplied by the companies given in parentheses: compounds **1**−**6**, **8b**, **9**−**11**, **13**, **14**, **16**, **19**−**22** (**22a** and **22b**), **24**, **25** (**25a** and **25b**), **26**−**29**, mixture of **30** and **34**, **31** (**31a** and **31b**), **32**, **37**, **38**, **41**, **43**, **45**−**49**, **51**, **52**, **56**, and **57** (Sigma-Aldrich, St. Louis, MO); **12** (TCI, Portland, OR); **33**, **36**, and **39** (Bedoukian, Danbury, CT); **40** (Firmenich, Princeton, NJ); mixture of **53** and **54** (Alfa Aesar, Lancashire, U.K.); **8a**, **22a**, **58** (Fluka, Buchs, Switzerland). 2,3-Dehydro-1,8-cineole (compound **7**) was synthesized according to the published literature.[14]

Isolation of Volatile Compounds. Odor-free deionized−distilled water (200 mL) and diethyl ether (150 mL) were added to the extraction chamber of a continuous liquid−liquid extraction (CLLE) apparatus (part no. Z562440, Sigma-Aldrich) equipped with a 5 °C condenser, 48 °C water bath (250 mL distillation flask), and magnetic stirrer. One can of cola sample (355 mL) was poured through the cooled condenser to avoid loss of aroma compounds and rinsed with 50 mL of water. After extraction for 18 h at a condensation rate of 2 drops/s, the solvent layer was concentrated to 50 mL by Vigreux column distillation at 43 °C. The volatile compounds were isolated from any nonvolatile compounds by solvent-assisted flavor evaporation (SAFE) according to the litelature.[13,15] The aroma extract was fractionated with aqueous 0.5 M $NaHCO_3$ (3 × 20 mL) into acidic (aqueous phase) and neutral-basic (organic phase) fractions. The aqueous layer was acidified to pH 2 with aqueous 4 N HCl and extracted with diethyl ether (3 × 20 mL). Each fraction was washed with saturated aqueous NaCl (2 × 15 mL), concentrated to 10 mL by Vigreux column distillation, and dried over 2 g of anhydrous Na_2SO_4. The ether extract was further concentrated by Vigreux column distillation to 350 μL and kept at −70 °C until analysis.

Identification of Aroma-Active Compounds. The aroma extracts were analyzed by GCO and GC−MS.

GCO. GCO was conducted using a 6890 gas chromatograph (Agilent Technologies, Inc., Santa Clara, CA) equipped with a flame ionization detector (FID) and olfactory detection port (DATU Technology Transfer, Geneva, NY). The aroma extract (2 μL) was injected in the cool on-column mode (+3 °C oven tracking mode) to avoid injection bias and reduce the chance for thermal degradation of any labile compounds. Separations were performed on RTX-Wax and RTX-5 SILMS capillary columns (both 15 m × 0.32 mm i.d. × 0.5 μm df; Restek, Bellefonte, PA). The column effluent was split 1:5 between the FID (250 °C) and olfactory detection port, respectively. The oven temperature was programed from 40 to 225 °C at a ramp rate of 10 °C/min for the RTX-Wax column or a ramp rate of 6 °C/min for the RTX-5 SILMS column, with initial and final hold times of 5 and 20 min, respectively. The flow rate of the helium carrier gas was 2 mL/min.

GC−MS. The GC−MS system consisted of a 6890 GC/5973 mass selective detector (Agilent Technologies, Inc.). A 1 μL volume of extract was injected into either the Stabilwax (30 m × 0.25 mm i.d. × 0.25 μm df; Restek) or SAC-5 (30 m × 0.25 mm i.d. × 0.25 μm df; Supelco, Bellefonte, PA) capillary columns in the cool on-column mode (+3 °C oven tracking mode). The initial oven temperature was 35 °C. After 5 min, the oven temperature was increased at 4 °C/min to the final temperature (225 °C for Stabilwax or 240 °C for SAC-5) and held for 20 min. The flow rate of helium carrier gas was 1 mL/min. The mass spectra were recorded in full scan mode (35−300 amu, scan rate 5.27 scans/s, interface temperature 280 °C, and ionization energy 70 eV).

The retention index (RI) of each compound was calculated using the retention time (RT) of that compound compared against the RTs of a series of standard *n*-alkanes.[16] The aroma-active compounds were positively identified on the basis of comparison of their RI values (on two different polarity stationary phases), odor properties, and mass spectra against those of authentic standard compounds to avoid erroneous identifications. A compound was considered to be tentatively identified if no authentic standard was available for comparison. In this case mass spectra were compared against those in the NIST2008 mass spectral database, and retention indices were compared to literature values.

Aroma Extract Dilution Analysis. The aroma extract was diluted stepwise (1:3, v/v) using diethyl ether as described previously.[13,17] Each dilution was performed by GCO on an RTX-Wax column. The sniffing time for each panelist was about 30 min per run. The flavor dilution (FD) factor for a specific odorant, which is the highest dilution at which panelists can smell that compound, was reported on the basis of averaging the $\log_3$ FD factors of three panelists (one female and two males, 20−47 years old) after rounding off to the nearest whole number.

Determination of Enantiomer Composition. The enantiomeric compositions of selected aroma-active compounds were investigated by GC-FID using an InertCap CHIRAMIX column (30 m × 0.32 mm i.d. × 0.25 μm df; GL Sciences Inc., Tokyo, Japan). A 2 μL volume of the aroma extract or standard solution (~1 ppm in dichloromethane) was injected in the hot split (5:1) mode at 250 °C. The oven temperature program started from 100 °C for 1 min, then was ramped at 1 °C/min to 180 °C, and was held for 10 min. Helium was used as a carrier gas at a flow rate of 2.5 mL/min. The configuration of each chiral compound was determined on the basis of comparison of its retention time against that of an authentic standard compound. The relative composition of each enantiomer pair in cola A was based on the average from four aroma extracts.

Sensory Descriptive Analysis. The human subject protocol number 11249 was approved by The University of Illinois at Urbana-Champaign Institutional Review Board (IRB). Ten panelists (students

[a]Numbers correspond to those in Table 3. [b]Retention indices determined by GCO on two different stationary phases (RTX-Wax and RTX-5 SILMS). [c]Fraction: acidic (A); neutral-basic (NB). [d]Odor quality determined by GCO. [e]Flavor dilution factors were determined on an RTX-Wax column and were derived from average $\log_3$ FD factors [n = 3 (1 female and 2 males, 20−47 years old)] after rounding off to the nearest whole number. [f]Identification criteria: retention index (RI); odor quality (O); mass spectra (MS); reference standard compound (S). [g]RI determined by GC−MS.

and staff, seven females and three males, 22−38 years old) were selected on the basis of the participants' abilities to detect and describe differences in aroma characteristics. They were trained for approximately 15 h to evaluate the aroma (by nose) of authentic cola samples consisting of different brands, lots, packages, and colas stored under various conditions. Terminologies with definitions and commercially available references were developed and are listed in Table 1. Cola-flavored carbonated beverage (50 mL) was prepared in a 125 mL Teflon sniff bottle (Nalgene PTFE wash bottle without a siphon tube; Nalge Nunc International, Rochester, NY). The bottles were covered with aluminum foil and labeled with randomly generated three-digit codes. To minimize nasal irritation caused by high levels of carbon dioxide, the sample bottles were kept open at room temperature for 30 min before evaluation, which allowed most the of carbon dioxide to passively escape. The serving orders of test samples were randomized, and the colas were presented one at a time to the panelist. In individual booths, the panelists evaluated the samples by gently squeezing the bottle and sniffing the expressed air. They were asked to rate the intensity of each attribute on a 15 cm line scale with two end anchors from none to strong.

Statistical analysis. The mean score of each attribute/term was calculated and then plotted to establish the aroma profile as spider web plots. Analysis of variance (ANOVA) was performed with the SAS program (SAS Institute Inc., Cary, NC) to detect significant differences among cola samples. If there was a significant difference (p-value < 0.05), the least significant difference (LSD) was used to check which samples differed.

RESULTS AND DISCUSSION

The top three U.S. brands of regular cola-flavored carbonated beverages were chosen for comprehensive aroma analysis. The CLLE method was used to isolate the aroma compounds from colas because decarbonation and extraction could be performed at the same time. The odor representativeness of the extract was checked by using strip paper, and the aroma extract obtained from each cola by CLLE had a characteristic colalike odor. This confirmed that the extract contained the typical aroma-active compounds of the colas.

Volatile Components. Total ion chromatograms were similar for all three cola-flavored carbonated beverages. Monoterpenes and sesquiterpenes were the major compounds in all colas. Among these, the most abundant were limonene (**8**), α-terpineol (**31**), and γ-terpinene (**10**). However, not all volatile compounds found in foods significantly contribute to food aroma. In the past, flavor scientists have not been successful in creating aroma models from the most abundant volatiles. For this reason, GCO has been applied to help identify trace-level potent odorants and to distinguish aroma-active compounds (odorants) from volatiles that contribute essentially no odor.

Aroma-Active Components. A combined total of 58 odorants were detected in the colas (Table 2), of which 2 were unidentified. Most of the odorants found in colas originate from the flavoring ingredients, including vanilla extract and essential oils of citrus, cassia or cinnamon, coriander, nutmeg, and neroli.[4,5] However, some may have been derived from nonvolatile components, for example, furfural (**20**), which was reported as an acid hydrolysis product of *d*-fructose.[18] Moreover, some of these compounds can be derived from other odorants, such as formation of α-terpineol (**31**) from limonene (**8**) due to acid-catalyzed reaction.[19]

It should also be noted that the highly volatile aroma compounds with RI values on a polar column (RTX-Wax) of less than 1000 were not identified in the present study. They might be lost during extraction and concentration of the extract or might not be present in the colas considering the list of ingredients used in cola flavorings. Essential oils are generally obtained by distillation methods which cause loss of highly volatile compounds.

The odor activity value (OAV) concept has been used to estimate the degree to which a particular volatile contributes to the overall aroma of food. It is defined as the ratio of the concentration of an aroma compound in the food to its odor detection threshold in the food matrix. The accuracy of an OAV depends on accurate quantification and determination of the odor threshold. However, the odor detection thresholds of some compounds, especially unknowns, cannot be measured. For this reason, AEDA was used to indicate the impact of an aroma compound in colas in the present study. This technique can rank the odorants by their relative potency on the basis of OAVs in air.

Potent Odorants. The FD factors of all odorants found in the colas are shown in Table 2. Eugenol (**51**) (spicy, clovelike, sweet) and coumarin (**56**) (sweet, herbaceous) were predominant odorants in all colas. These odorants have been reported in cinnamon and cassia (Chinese cinnamon) oils.[20,21] Eugenol is also a common volatile compound of nutmeg oil.[22]

Guaiacol (**41**) (smoky note) was a potent odorant in colas A and B, while linalool (**22**) (floral, sweet) had high odor potency in cola C. Linalool also had relatively high potency in cola A. This odorant is reported as one of the most aroma-active compounds contributing to the overall flavor of lemon oil[23] and orange peel oil.[24] It is also a major component of the essential oils of coriander[25] and neroli.[26] In addition, linalool is reported as a dominant alcohol in orange oil,[27] and it was perceived in highest aroma intensity after octanal and wine lactone.[28]

The compound 1,8-cineole (**9**) (minty, eucalyptus-like) was a moderately potent odorant in all colas. It was reported as one of the aroma compounds with the most impact in orange peel oil.[24] This compound was also the second most abundant volatile found in cinnamon oil distillated from root bark.[20] 1,8-Cineole not only is present naturally in essential oils, but also is reported as a secondary degradation product of limonene and α-terpineol by acid-catalyzed reactions.[19]

DOI: 10.1021/jf504953s
J. Agric. Food Chem. 2015, 63, 769−775

However, the most abundant volatiles, including limonene, α-terpineol, and γ-terpinene, had low odor potencies in the colas. The FD factors of highly potent odorants found in citrus oil, such as neral (**30**) and geranial (**34**), were also low in all colas because of their possible degradation by acid-catalyzed reactions. It is well-known that citral (a mixture of neral and geranial) is extremely unstable under acidic conditions, resulting in the formation of various products.[29] The half-life of citral in carbonated soft drinks is about 6 days.[30] Oxidation of citral can occur under certain conditions,[31] but this is unlikely to occur in carbonated beverages due to the very low level of oxygen. The degradation mechanism for citral has already been proposed.[30−33] Neral (*cis*-isomer) and geranial (*trans*-isomer) can rearrange by isomerization reactions. Then, *p*-menthadien-8-ols can be converted directly from neral by the series of acid-catalyzed reactions starting from cyclization. These intermediates are further degraded by disproportionation, redox, and dehydration reactions to form α,*p*-dimethylstyrene (**17**) and *p*-cymene (**11**), which are more stable. The compound 2,3-dehydro-1,8-cineole (**7**) is also formed as a result of the deterioration of citral by acid-catalyzed reactions. It is very unstable in acid conditions, but it is found at low levels in colas due to the steady state reached among various precursor compounds via reversible acid-catalyzed reactions.[33] It should also be noted that this compound was a predominant odorant in lemon-lime carbonated beverages.[14]

Among the three brands, the aroma profile of cola A was the most complex. Additional moderately potent odorants in cola A included methyleugenol (**46**) (haylike, dried grass), 4-terpineol (**25**) (earthy, soapy, woody), (*E*)-cinnamaldehyde (**48**) (cinnamon-like, sweet), (*Z*)- and (*E*)-isoeugenols (**53** and **54**) (clovelike, sweet), and an unknown with an RI of 2399 on the RTX-Wax column (**55**) (clovelike, sweet). It is interesting to note that 4-terpineol, which is a major volatile in nutmeg oil,[34] may be a degradation product of some terpenes via acid-catalyzed reactions.[19] It was also reported to be a potent odorant in a stored emulsion of lemon oil in an aqueous citric acid solution.[23]

β-Damascenone (**40**) (apple sauce, sweet) was another moderately potent odorant in cola C. Vanillin (**58**), however, was not detected by GCO in this beverage. This finding suggests that vanilla extract may be used at only a low concentration in cola C. The low level of vanillin is also supported by low potency of guaiacol (**41**) in the cola since both compounds are important aroma components of vanilla extract.[35] Furthermore, it was indicated that the main component influencing the sweet note of cola C was coumarin, not vanillin. Coumarin mixed with vanillin is reportedly used in cream soda because it is not highly volatile and its aroma intensity is 3 times higher than that of vanillin.[36] Tonga bean extract which contains coumarin has also been used as a vanilla substitute.[36] However, coumarin, tonga bean, and tonga extract are not permitted for use in human foods in the United States[37] because of toxicity concerns.[38] Although coumarin is prohibited for use as a flavoring compound, it occurs naturally in cinnamon oil[20] and vanilla extract,[39] which are natural flavors used in cola-flavored carbonated beverages.

While AEDA is the useful screening technique to rank the aroma compounds in order of potency, the method is, however, based on the odor activity of the aroma compound in air. The effect of the food matrix on cola odor was not taken into account in the present study. The potent odorants identified in colas should be further analyzed by OAVs to correct for the limitations of AEDA. Additional sensory studies on aroma reconstitution and omission models should also be conducted to verify the OAV calculation.

Enantiomeric Composition. Cola A was chosen to investigate the enantiomeric composition of selected aroma-active compounds since some of them had high FD factors. Furthermore, different enantiomers may have different odor detection thresholds and odor characteristics. The chemical structures and enantiomeric distributions of chiral compounds identified in cola A are shown in Table 3. *d*-Limonene or the (*R*)-(+)-isomer (**8b**) was present in greatest abundance (97.2%). This is to be expected because it is well-known that *d*-limonene is commonly present in citrus oils. The majority of *d*-limonene results in more fresh citruslike odor characteristics in the essential oils, while *l*-limonene has a harsh, turpentine note.[40]

Table 3. Enantiomeric Distribution of Aroma Compounds Identified in Cola A

compd no.[a]	compd name	distribution ratio[b]
8a:8b	(*S*)-(−)-limonene:(*R*)-(+)-limonene	2.8:97.2
22a:22b	(*R*)-(−)-linalool:(*S*)-(+)-linalool	34.5:65.5
25a:25b	(*S*)-(+)-4-terpineol:(*R*)-(−)-4-terpineol	51.0:49.0
31a:31b	(*S*)-(−)-α-terpineol:(*R*)-(+)-α-terpineol	55.1:44.9

[a]Numbers correspond to those in Table 2, and the letters following the numbers indicate the elution order of enantiomers from an InertCap CHIRAMIX column. [b]Enantiomeric excess expressed as a percentage (n = 4).

Linalool found in natural flavor is usually present as a mixture of the (*R*)-(−)-isomer (**22a**) and (*S*)-(+)-isomer (**22b**) at different ratios. The odor description of **22a** is floral, with a woody lavender note, while **22b** is perceived as sweet and floral.[40] The enantiomeric composition of linalool in cola A was 34.5% (*R*)-(−)-enantiomer and 65.5% (*S*)-(+)-enantiomer. (*R*)-(−)-Linalool is predominant in neroli oil, while (*S*)-(+)-linalool comprises 60−70% of coriander oil.[41] Although the amount of (*S*)-(+)-linalool in cola was almost 2-fold higher than that of (*R*)-(−)-linalool, the odor threshold in water of the latter enantiomer is about 9 times lower than that of the former stereoisomer (0.8 and 7.4 ppb, respectively[42]). Thus, at similar concentrations (*R*)-(−)-linalool should make a greater aroma contribution than (*S*)-(+)-linalool in cola-flavored carbonated beverage.

In addition, the enantiomeric compositions of the 4-terpineols (51.0% (*S*)-(+)-enantiomer (**25a**) and 49.0% (*R*)-(−)-enantiomer (**25b**)) and α-terpineols (55.1% (*S*)-(−)-enantiomer (**31a**) and 44.9% (*R*)-(+)-enantiomer (**31b**)) in cola occurred as approximately racemic mixtures. The enantiomeric pairs of 2,3-dehydro-1,8-cineole (**7**), isoborneol (**29**), and borneol (**32**) were, however, not determined on the chiral GC capillary column because of their low concentrations in cola extracts.

Sensory Analysis. Aroma (by nose) of decarbonated colas was described by eight attributes, including lemon-lime, orange, brown spice, herbal, vanilla, caramel, cooling, and pine (Table 1). Citrus, caramel, and vanilla have been reported as aromas and aromatics (aroma-by-mouth) of regular and diet colas by descriptive analysis.[6] In the present study, all colas (A, B, and C) had similar aroma profiles, except the lemon-lime intensity in cola B was significantly lower than in colas A and C (*p*-value

J. Agric. Food Chem. 2015, 63, 769−775

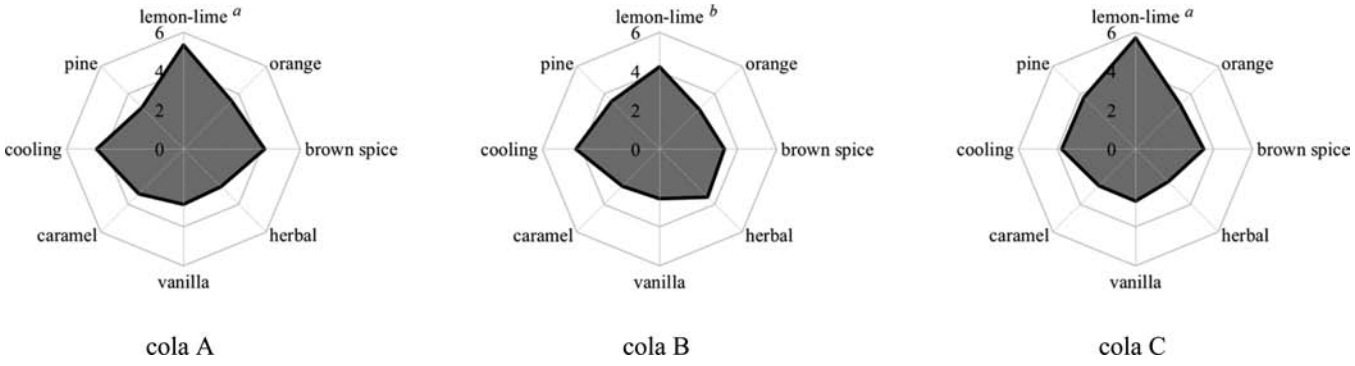

Figure 1. Aroma (by nose) profiles of cola-flavored carbonated beverages from sensory descriptive analysis. Attributes followed by different italic superscript letters are significantly different (p-value < 0.05) [n = 10 (7 females and 3 males, 22−38 years old)]. Odor intensity was rated on a 15 cm line scale.

< 0.05) (Figure 1). Lemon-lime and cooling attributes were dominant attributes in all colas. Brown spice, herbal, and pine attributes were moderate intensities in all colas. The results of sensory analysis agreed well with potent odorants identified by AEDA (Table 2) when the odor characteristic of high FD factor compounds was considered. The low intensity of the lemon-lime note in cola B was probably due to the low potency of linalool (**22**) in that product. This finding was supported by the previous research which revealed that linalool has the highest FD factor in lemon-lime carbonated beverages.[14] Furthermore, the cooling note of cola could be associated with a higher level of 1,8-cineole (**9**). The high-potency aroma compounds were also responsible for the other aroma attributes, such as brown spice aroma from eugenol (**51**) or vanilla note from coumarin (**56**). Additionally, the moderately spicy note of cola A compared to the other colas was possibly the result of the impact of methyleugenol (**46**) and the isoeugenols (**53** and **54**).

Supporting Information

ABSTRACT: Thirty aroma-active components of a cola-flavored carbonated beverage were quantitated by stable isotope dilution assays, and their odor activity values (OAVs) were calculated. The OAV results revealed that 1,8-cineole, (*R*)-(−)-linalool, and octanal made the greatest contribution to the overall aroma of the cola. A cola aroma reconstitution model was constructed by adding 20 high-purity standards to an aqueous sucrose−phosphoric acid solution. The results of headspace solid-phase microextraction and sensory analyses were used to adjust the model to better match authentic cola. The rebalanced model was used as a complete model for the omission study. Sensory results indicated that omission of a group consisting of methyleugenol, (*E*)-cinnamaldehyde, eugenol, and (*Z*)- and (*E*)-isoeugenols differed from the complete model, while omission of the individual components of this group did not differ from the complete model. These results indicate that a balance of numerous odorants is responsible for the characteristic aroma of cola-flavored carbonated beverages.

KEYWORDS: *cola-flavored carbonated beverage, odor activity value, stable isotope dilution assay, aroma reconstitution model, omission study*

INTRODUCTION

Cola is the predominant flavor among the various types of carbonated beverages. The uniqueness and complexity of cola flavor is due to a mixture of various natural flavor ingredients, including vanilla extract and essential oils of citrus, cassia or cinnamon, coriander, nutmeg, and neroli.[1,2] Despite its popularity, there is limited information about the flavor chemistry of cola. In our previous study, 58 odorants from the top three U.S. brands of regular cola were identified by gas chromatography−olfactometry (GCO) and aroma extract dilution analysis (AEDA).[3] On the basis of those findings, the most potent odorants in all colas were eugenol and coumarin. Guaiacol and linalool were predominant odorants in at least one brand, while 1,8-cineole was a moderately potent odorant in all colas. Among enantiomeric aroma compounds, (*R*)-(−)-linalool, despite being the less abundant enantiomer in cola, was regarded as a more potent odorant than the (*S*)-(+)-enantiomer because of its much lower odor detection threshold. GCO and AEDA were also found to be in good agreement with aroma profiles generated by sensory descriptive analysis.

The application of AEDA is a useful method for ranking the relative potency of odorants, but the interactions between the odorants and food matrix is not taken into account. Calculation of odor activity values (OAVs) is the next step of flavor analysis, and it is necessary to verify the analytical data by aroma recombination studies.[4] Omission tests which compare the complete model with models in which one or more odorants have been omitted may also be conducted to identify the character-impact odorants.[5] Furthermore, suppression and synergistic effects of aroma compounds can be identified by omission studies as well.[6]

The objectives of the present study were to (1) quantitate the potent odorants by stable isotope dilution assays (SIDAs), (2) identify key potent odorants by calculation of OAVs, and (3) investigate character-impact odorants by sensory evaluation of aroma reconstitution and omission models. Knowledge of key odorants which contribute to the typical flavor of cola could be used as quality indicator compounds to develop products with superior flavors and to investigate the flavor changes which occur during storage.

MATERIALS AND METHODS

Materials. Regular Coca-Cola and the references for sensory descriptive analysis were purchased from local markets (Urbana, IL) in 2011−2012.

Chemicals. General-reagent- or HPLC-grade chemicals were purchased from Fisher Scientific (Fair Lawn, NJ). Sucrose was supplied by Sigma-Aldrich (St. Louis, MO).

Standard Compounds. The standard compounds listed in Tables 1−4 were supplied by the companies given in parentheses: **8b**, **9**, **13**, **16**, **19**, **21**, **22** (**22a** and **22b**), **25** (**25a** and **25b**), **26**, **28**, **29** (**29a** and **29b**), mixture of **30** and **34**, **31** (**31a** and **31b**), **32a**, **32b**, **37**, **41**, **43**, **46**, **48**, **49**, **51**, **56**, and **57** (Sigma-Aldrich); **36** and **39** (Bedoukian, Danbury, CT);

40 (Firmenich, Princeton, NJ); mixture of **53** and **54** (Alfa Aesar, Lancashire, U.K.); **58** (Fluka, Buchs, Switzerland).

All aroma compounds used for odor threshold determination and reconstitution study were purified by vacuum distillation and/or flash chromatography before use. Chemical purities were determined by neat injection (hot split) GC-FID analysis. Each compound was determined to be free of any odor impurities by analysis of a 100 mg/L solution by the GCO technique previously described.[3]

All the enantiomeric distributions were determined using the method previously described.[3]

Isotope Standard Compounds. The following isotopically labeled standards were obtained from the commercial sources listed in parentheses: [$^2H_3$]acetic acid (**I-19**), [$^2H_7$]butanoic acid (**I-26**), 2-methoxy-[$^2H_3$]phenol ([$^2H_3$]guaiacol) (**I-41**), and [$^2H_3$]-*p*-cresol (**I-49**) (CDN, Quebec, Canada); [$^{13}C_2$]phenylacetic acid (**I-57**) (Isotec, Miamisburg, OH).

Syntheses. The following compounds were synthesized according to the procedures reported in the literature: [$^2H_2$]limonene (**I-8**);[7] [$^2H_3$]-1,8-cineole (**I-9**), [$^2H_4$]octanal (**I-13**), [$^2H_4$]nonanal (**I-16**), [$^2H_4$]decanal (**I-21**), [$^2H_7$]-4-terpineol (**I-25**), [$^2H_3$]isoborneol (**I-29**), [$^2H_6$]neral (**I-30**), [$^2H_3$]-*α*-terpineol (**I-31**), [$^2H_3$]borneol (**I-32**), [$^2H_6$]geranial (**I-34**), [$^2H_6$]nerol (**I-36**), and [$^2H_6$]geraniol (**I-39**);[8] [$^2H_2$]linalool (**I-22**);[9] [$^2H_2$]-3-methylbutanoic acid (**I-28**);[10] [$^2H_4$]-*β*-damascenone (**I-40**);[11] [$^{13}C_2$]-2-phenylethanol (**I-43**);[12] [$^2H_3$]vanillin (**I-58**).[13] The synthetic procedures used to prepare the following compounds are provided in the Supporting Information: [$^{13}C_2$]-2-phenethyl acetate (**I-37**), [$^2H_3$]eugenol (**I-51**), [$^2H_6$]methyleugenol (**I-46**), [$^2H_3$]-(*Z*)- and [$^2H_3$]-(*E*)-isoeugenols (**I-53** and **I-54**), (*Z*)- and (*E*)-isoeugenols (**53** and **54**), [$^2H_5$]cinnamaldehyde (**I-48**), and [$^2H_6$]coumarin (**I-56**).

Stable Isotope Dilution Assay. The isotopically labeled standards of selected aroma-active compounds were prepared individually in dichloromethane (∼1 mg/mL) instead of methanol to avoid decomposition. The chemical and isotopic stabilities were confirmed using an aqueous citrate buffer (pH 2.3, 0.12% (w/v) citric acid) for 18 h. The appropriate amounts of all isotope standards, determined by preliminary experiments, were added into cola as internal standards before extraction.

Isolation of Limonene and α-Terpineol. About 5 mL of cola from the original can were poured into a 20 mL scintillation vial containing 5 mL of diethyl ether to prevent loss of volatiles. The exact weight of cola was recorded as the weight difference. The isotope standards were added into the cola layer before extraction. The sample was decarbonated by sonication (model 2200; Branson Ultrasonics, Co., Danbury, CT) using an ice−water bath at 10 °C for 5 min and then shaken (DS-500 orbital shaker; VWR Scientific, Batavia, IL) at 200 rpm for 10 min. The separated aroma extract was dried over 1 g of anhydrous Na_2SO_4 and concentrated to 0.5 mL by Vigreux column distillation at 43 °C before analysis by gas chromatography−mass spectrometry (GC−MS).

Isolation of Other Aroma Compounds. The volatile compounds were extracted from one can of cola (335 mL) in the same manner as previously described.[3] The aroma components were isolated by continuous liquid−liquid extraction (CLLE), and any nonvolatiles were removed by solvent-assisted flavor evaporation (SAFE) before fractionation into acidic and neutral-basic fractions as previously described.[3]

A 1 μL volume of the aroma extract was injected into a GC−MS system in the cold splitless mode (−50 °C held for 0.1 min and then raised at 12 °C/s to 250 °C). Volatile compounds were separated on either a Stabilwax (polar phase) or an SAC-5 (nonpolar phase) capillary column. For quantitation, the mass ions for isotopes and unlabeled target compounds were chosen on the basis of uniqueness and relative intensity. The peak areas for selected ions were integrated using MSD ChemStation software (Agilent Technologies, Inc.). The concentration of each target compound was calculated from the area ratio and GC−MS response factor (R_f) using eq 1. R_f was calculated as the inverse of the slope of the calibration plot of the area ratio versus mass ratio (eq 2), determined by analysis of five levels of a standard compound (unlabeled) against the isotope (labeled) compound. The reported average concentration value was determined from four cans of cola from the same code date.

$$\text{concentration}_t = (\text{concentration}_i)R_f\left[\frac{\text{area of ion}_t}{\text{area of ion}_i}\right] \quad (1)$$

$$R_f = \frac{\Delta[\text{mass}_t/\text{mass}_i]}{\Delta[\text{area of ion}_t/\text{area of ion}_i]} \quad (2)$$

Here i = labeled internal standard and t = target compound.

Odor Activity Values. The OAV of a compound was calculated as the ratio of its concentration in cola to its odor threshold in water. The odor detection thresholds in water of the aroma-active compounds were obtained from the literature or determined in our laboratory.

Determination of Odor Thresholds in Water. The odor detection threshold of high-purity (*E*)-cinnamaldehyde (**48**) (99.9+%) was determined orthonasally following a published procedure[6] by 11 panelists (7 females and 4 males, 22−47 years old).

Determination of Odor Thresholds in Air. The relative odor thresholds of (*Z*)- and (*E*)-isoeugenols (**53** and **54**) in air were evaluated by GCO according to a method reported in the literature[14] using eugenol (**51**) as the internal standard. The high-purity standards of isoeugenols and eugenol were prepared in CH_2Cl_2 and diluted stepwise (1:3, v/v). The panelists evaluated each dilution by GCO (following the same procedure in the previous study[3]) until they were not able to smell any odor. The highest dilution of each aroma compound was recorded, and the relative odor thresholds of (*Z*)- and (*E*)-isoeugenols were calculated on the basis of that of eugenol (0.2−0.3 ng/L of air[15]). The group threshold was calculated as the geometric mean of individual thresholds of seven panelists (three females and four males, 21−38 years old).

Aroma Reconstitution Model. The cola composition, including pH, soluble solids, and titratable acidity, was determined for a decarbonated (by sonication) cola on the basis of three samples with different code dates. The model matrix was prepared on the basis of the information in Table 5 using a sucrose−phosphoric acid solution. The cola base was adjusted to pH 2.31 using aqueous 1 M NaOH or HCl.

Table 5. pH and Chemical Composition of Decarbonated Cola

	mean ± SD[a]
pH (at 25 °C)	2.31 ± 0.03
soluble solids (°Brix, corrected to 20 °C)	10.73 ± 0.06
titratable acidity (g of citric acid/100 mL)	0.1226 ± 0.0011
titratable acidity (g of phosphoric acid/100 mL)	0.0625 ± 0.0006

[a]Mean and standard deviation of products having three different code dates.

The model was constructed on the basis of quantitation data from SIDA. The high-purity standards (Table 4) were prepared individually in methanol, except octanal, nonanal, and decanal (**13**, **16**, **21**). High-purity standards of these aldehydes were dissolved in pentane to avoid degradation reactions and diluted in methanol just before preparation of the model. The solutions of aroma compounds were spiked into the cola matrix. To determine if the model was similar to the actual product, the model was compared to decarbonated cola (authentic cola) by sensory descriptive aroma profiling following the procedure from our previous study.[3] The approval protocol number from the University of Illinois at Urbana-Champaign Institutional Review Board (IRB) for conducting all sensory analyses in this experiment was 11249. The aroma profile provided information about the major aroma attributes (terms) of cola and the cola model and how they were similar or how they differed, thus allowing for the possibility of adjusting the model to better match the authentic cola. The model was deemed appropriate for omission studies on the basis of the similarity (or "matching") of its aroma profile to that of the authentic cola. Ten trained panelists (seven females and three males, 23−45 years old) participated in this descriptive analysis in individual sensory booths.

Solid-Phase Microextraction. Headspace solid-phase microextraction (HS-SPME) was also used to compare the HS volatiles of authentic cola and those of cola models for the purpose of adjusting the model to better match the authentic cola. Commercial cola or cola models (5 mL) and 1 g of NaCl were prepared in 20 mL screw top headspace vials equipped with a Teflon-coated stir bar and a Teflon-lined silicon closure. The sample vial was incubated at 40 °C for 10 min at an agitator speed of 250 rpm. The SPME fiber (50/30 μm DVB/Carboxen/PDMS StableFlex; Supelco, Bellefonte, PA) was exposed into the HS of the sample vial, and the HS volatiles were extracted for 20 min at the same temperature. Then the aroma volatiles in SPME fiber were desorbed in the hot splitless injection port of the GC−MS or GCO system at 260 °C for 14 min with a 4 min GC valve delay. The volatiles were separated on a polar capillary column (RTX-Wax or Stabilwax), and the GC parameters were the same as previously described.[3] The semi-quantitation of HS volatiles was determined by use of 2-methyl-3-heptanone as the internal standard.

Omission Studies of Aroma Reconstitution Models. Omission studies were performed by comparing the complete model against the omission models using the *R*-index ranking test following the procedure in the literature.[6] Potent odorants were grouped on the basis of their similar odor characteristics, properties, or origins of the compounds (Table 6). The complete model of cola was constructed as described above, and the omission models were prepared by omitting a group of odorants (methanol was spiked instead). All samples (50 mL) were prepared in sniff bottles (Nalgene PTFE wash bottle without a siphon tube; Nalge Nunc International, Rochester, NY) covered with aluminum foil. The complete model was labeled as the control, and the omission models and another set of complete model were labeled with random three-digit codes.

Table 6. *R*-Index Values for the Omission Test of Groups of Compounds

group[a]	odorants omitted[b]	*R*-index, JB[c]
1, citrus/floral	(*R*)-(+)-limonene (**8b**), linalool (**22**), nerol (**36**), geraniol (**39**)	53.57
2, herbal/cooling	1,8-cineole (**9**), 4-terpineol (**25**), isoborneol (**29**), α-terpineol (**31**), borneol (**32a** and **32b**)	32.14
3, aldehyde	octanal (**13**), nonanal (**16**), decanal (**21**)	53.57
4, vanilla	guaiacol (**41**), coumarin (**56**), vanillin (**58**)	53.57
5, brown spice	methyleugenol (**46**), (*E*)-cinnamaldehyde (**48**), eugenol (**51**), (*Z*)-isoeugenol (**53**), (*E*)-isoeugenol (**54**)	67.86*

[a]Description of each group. [b]Compound numbers correspond to those in Tables 1−4 and 7 and Figure 2. [c]Calculated by using John Brown computation against the complete model and expressed as a percentage. *Significantly different from the complete model at α = 0.05 (the critical value for the two-tailed test, α = 0.05 and n = 28 (19 females and 9 males, 20−48 years old), is 17.65).

The test samples (omission models and complete model) were presented to the panelists [n = 28 (19 females and 9 males, 20−48 years old)] using randomized and balance serving orders. After the panelists evaluated the samples, they were asked to rank the test samples on how similar they were to the control (complete model). The *R*-index values were calculated as the percentage of times the sample was ranked less similar to the complete model using the John Brown computation.[16] These values were compared to the critical value of *R*-index 50% for the two-tailed test at α = 0.05. For example, the sample is significantly different from the control if its *R*-index is more than 67.65 (50 + 7.65, which is the critical value for n = 28).

Additional omission studies were conducted for individual components of a group whenever a group omission model was determined to be significantly different from the complete model. Twenty-six panelists (eighteen females and eight males, 20−48 years old) evaluated the test samples against the control sample in the same manner as recently described. In addition, the omission model which significantly differed from the complete model was subjected to sensory descriptive (aroma profile) analysis by an eight-member trained panel (five females and three males; 26−45 years old). A paired t test performed with the SAS program (SAS Institute Inc., Cary, NC) was used to compare the attribute means of the complete model and those of the omission model.

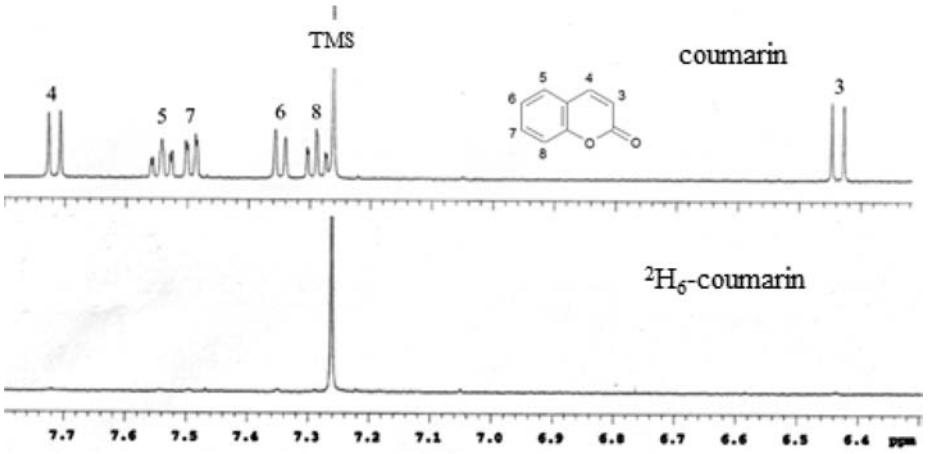

Figure 1. ^{1}H NMR spectra of coumarin and [$^2H_6$]coumarin in $CDCl_3$ (contains TMS as the internal standard).

RESULTS AND DISCUSSION

On the basis of results from our previous study,[3] Coca-Cola, which contained most of the potent odorants found in other cola-flavored carbonated beverages, was chosen as the representative sample for the present study. The odor-active compounds from AEDA were selected for calculation of OAVs based on their high potency (high flavor dilution (FD) factor). Some less potent odorants were also quantitated. In particular, limonene (**8**) and α-terpineol (**31**), which had low FD factors, were included in this experiment since these two odorants were present at the highest abundance in all colas,[3] so they might exert some influence on the perception of cola aroma.

Quantitation by Stable Isotope Dilution Assay. In the present study, SIDA was used for accurate quantitation. The SIDA method is highly accurate since isotopically labeled compounds are used as internal standards. However, the perfect integration of isotope standard solution into the original food matrix has to be taken into account. If the isotope is prepared in an organic solvent, the recovery experiment should be conducted. In addition, it is preferable that the isotope standard should be more than 3 mass units higher than the analyte to ensure a linear calibration curve.[17]

All isotopes used in this study (Figure 2) were labeled with deuterium, except for phenylacetic acid (**I-57**) and its derivatives (**I-37** and **I-43**), which were labeled with ^{13}C. Among synthesized isotopes, [$^2H_6$]coumarin (**I-56**) was prepared by exchanging the hydrogen atoms with deuterium atoms. The electron-impact (EI) mass spectrum of **I-56** indicated that six atoms of hydrogen were substituted, but it was important to confirm the chemical structure of this isotope by nuclear magnetic resonance (NMR). The ^{1}H NMR spectra of **I-56** showed no signal (Figure 1), except for internal standard (TMS) and solvent ($CDCl_3$) peaks. This confirmed that all hydrogen atoms were nearly completely replaced by deuterium atoms.

The concentrations of selected odorants identified in the cola are shown in Table 1. Among 30 aroma compounds, limonene (**8**) was in highest abundance, followed by α-terpineol (**31**) and acetic acid (**19**). Neral (**30**), geranial (**34**), and β-damascenone (**40**) were present at levels below their limits of detection by either full scan or SIM modes of GC−(EI)MS.

Odor Detection Thresholds. The odor thresholds determined in different matrixes will not be the same because of interaction with other components.[18] Odor thresholds in water were used to calculate OAVs of potent odorants in cola since the solubilities, which affect the volatilities, in cola should be very close to those in water. A previous study of flavor release from sucrose solution indicated that flavor release of the 13 aroma compounds studied, including compounds such as linalool and β-damascenone in water and those in aqueous 20% (w/v) sucrose solution, were not significantly different.[19]

Most odor thresholds in water of potent odorants were obtained from the literature (Tables 1 and 2). It is also important to note that the odor threshold of isoborneol (**29**) is for a racemic mixture (49.1:50.9) of the two enantiomers. Enantiomers can have different odor thresholds; therefore, the configuration of chiral compounds should be considered. Among chiral aroma compounds in cola, linalool (**22**) showed the greatest difference (more than 9-fold) with respect to the odor detection thresholds of the two enantiomers.

The aroma compound used to determine the odor threshold must be highly pure before testing. Sometimes this is difficult or nearly impossible, such as in the case of the two isomers of isoeugenol, which could not be separated by using flash chromatography or high-pressure flash chromatography, so determination of their odor thresholds in water was not possible. Their odor thresholds in air should, however, give some indication of how much they influence cola aroma. Unfortunately, these values are not available in the literature. For this reason, the relative odor thresholds in air of the (*Z*)- and (*E*)-isoeugenols (**53** and **54**) were determined by GCO in the present study.

Eugenol (**51**), which has an odor threshold in air of 0.2−0.3 ng/L of air,[15] was used as the internal standard. The relative odor threshold in air of (*Z*)-isoeugenol (0.4−0.6 ng/L of air) was about 2-fold higher than that of eugenol, while the value of (*E*)-isoeugenol (0.1−0.2 ng/L of air) was slightly lower (Table 3).

Odor Activity Values. OAVs of specific aroma-active compounds in cola were calculated as the ratio of the concentrations of the aroma compounds in cola to their odor detection thresholds in water (Tables 1 and 2). In cola-flavored carbonated beverages, limonene (**8**) had the highest OAV followed by 1,8-cineole (**9**), octanal (**13**), and linalool (**22**). OAVs for some potent odorants from our previous study[3] could not be calculated due to a lack of concentration data (e.g., neral (**30**), geranial (**34**), and β-damascenone (**40**)), or their odor detection thresholds in water were unavailable (e.g., (*Z*)-isoeugenol (**53**) and (*E*)-isoeugenol (**54**)). Additionally, the OAVs of borneol (**32**) were reported as the values of the (+)- and

Figure 2. Chemical structures of isotope standards. Note a: The letter "I" means isotopically labeled compound followed by the numbers which correspond to those in Tables 1 and 2.

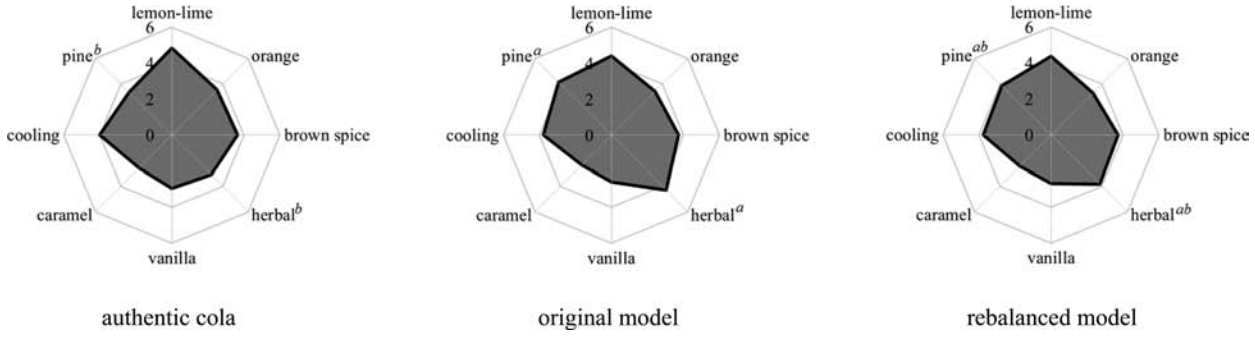

Figure 3. Aroma (by nose) profiles by means of sensory descriptive analysis of cola models compared to authentic cola. Attributes followed by different italic superscript letters are significantly different (p-value < 0.05) [n = 10 (7 females and 3 males, 23−45 years old)]. Odor intensity was rated on a 15 cm line scale.

(−)-isomers because the enantiomeric excess of borneol in cola could not be determined.[3]

When the enantiomeric composition was taken into account, the OAVs of (*S*)-(−)-limonene (**8a**; *l*-isomer) and (*R*)-(+)-limonene (**8b**; *d*-isomer) decreased to 0.3 and 8, respectively, while the OAV of (*R*)-(−)-linalool (**22a**) increased to 60. The other enantiomer pairs ((*S*)-(+)- and (*R*)-(−)-4-terpineols (**25a** and **25b**); (*S*)-(−)- and (*R*)-(+)-α-terpineols (**31a** and **31b**)) showed lower OAVs than the racemic mixtures (**25** and **31**). Furthermore, their values decreased to below 1 (were not considered as aroma-active compounds).

By means of OAV calculations, 1,8-cineole (**9**), (*R*)-(−)-linalool (**22a**), and octanal (**13**) were the most potent odorants which contribute to the overall aroma of cola. Compounds of moderate potency included nonanal (**16**), (*S*)-(+)-linalool (**22b**), decanal (**21**), and (*R*)-(+)-limonene (**8b**).

1,8-Cineole (**9**) is one of the most odor-active compounds in orange peel oil,[18] and it is reported as a secondary degradation product of limonene and α-terpineol by acid-catalyzed reactions.[20] Additionally, it is the second most abundant volatile compound found in cinnamon oil distilled from root bark.[21]

The higher potency of octanal (**13**) by means of OAV calculation compared to AEDA results[3] was due to its low odor detection threshold in water. AEDA is proportional to OAV in air. The nonpolar aroma is volatilized easier from the aqueous phase, resulting in a higher OAV when compared to a polar compound with a similar FD. Octanal is the highest intensity aroma compound in orange oil,[22] and this aldehyde was reported as a moderately potent odorant in orange oil[23] and fresh lemon oil.[24]

As mentioned in our previous study,[3] linalool (**22**) is an important potent odorant of lemon oil[24] and orange peel oil.[23] This compound is highly abundant in coriander oil,[25] neroli oil,[26] and orange oil.[27] (*S*)-(+)-Linalool (**22b**) comprises 60−70% of coriander oil, while the (*R*)-(−)-enantiomer (**22a**) is predominant in neroli oil.[28] The higher potency on the basis of the OAV of (*R*)-(−)-linalool over (*S*)-(+)-linalool in cola flavor was due to the lower odor detection threshold of the (*R*)-(−)-enantiomer.

Limonene (**8**) is the major volatile component of lemon oil,[29] lime peel oil,[30] and orange oil.[22] It was also present at the highest concentration in cola. The major enantiomer of limonene in cola was the (*R*)-(+)-isomer (**8b**), accounting for 97%.[3] Its odor threshold is very high compared to those of the other aroma-active compounds found in cola, so it is important to note that the high potency of this enantiomer was due to its high concentration, not its low odor detection threshold.

The other important potent odorants were vanillin (**58**), borneol (**32**), coumarin (**56**), and eugenol (**51**). The lower potencies, by means of OAV calculation, of coumarin and eugenol as compared to their high FD factors from AEDA[3] are due to the low volatilities of these compounds. For example, the odor threshold in air of eugenol is 0.2−0.3 ng/L of air,[15] while its threshold in water is considerably higher at 6 ng/g.[31] Since the concentrations and in-air thresholds (Table 3) of the (*Z*)- and (*E*)-isoeugenols (**53** and **54**) are similar to those of eugenol, their odor potencies in cola may be equally low. In addition, the OAV of coumarin was less than that of vanillin, but the intensity of coumarin is considered to be about 3 times higher than that of vanillin.[32]

Aroma Reconstitution Models. All aroma compounds which had OAVs higher than 1 in Table 1 (**8**, **9**, **13**, **16**, **21**, **22**, **25**, **31**, **32**, **51**, **56**, and **58**) were used to construct the cola aroma reconstitution model. Some odorants which had OAVs lower than 1 were included in the model reconstitution since they could impact the cola flavor or flavor release/partitioning. In this case, isoborneol (**29**), nerol (**36**), geraniol (**39**), guaiacol (**41**), methyleugenol (**46**), (*E*)-cinnamaldehyde (**48**), (*Z*)-isoeugenol (**53**), and (*E*)-isoeugenol (**54**), which had medium or high FD factors in colas,[3] were used to prepare the cola aroma model.

The high-purity aroma compounds listed in Table 4 were used to prepare the model. The purities of the aroma compounds were more than 99%, except for isoborneol (**29**; 98.7%; plus 1.3% borneol) and (+)-borneol (**32b**, 96.5%; plus 3.5% isoborneol).

DOI: 10.1021/jf504954p
J. Agric. Food Chem. 2015, 63, 776−786

Isoeugenol was present as a mixture of (*Z*)- and (*E*)-isomers (**53** and **54**). (*R*)-(+)-Limonene (**8b**) was used to prepare the cola model because it is present at 97% enantiomer excess in cola,[3] while isoborneol (**29**) and borneol (**32**) were added as racemic mixtures since their enantiomeric distributions could not be evaluated in commercial cola.[3] It is, however, important to note that linalool (**22**), 4-terpineol (**25**), and α-terpineol (**31**) used in this experiment had enantiomeric ratios different from those reported in our previous study.[3] These standard compounds were used to construct the cola model on the basis of quantitation data determined by SIDA.

The chemical composition and pH of commercial cola were examined after decarbonation by sonication. The mean values were a pH of 2.31, soluble solids content of 10.73 °Brix, and titratable acid content of 0.1226 g of citric acid/100 mL or 0.0625 g of phosphoric acid/100 mL (Table 5). The variation was slight among three different code dates of cola, and the above values are close to the values published by Coca-Cola's scientists for acidity of 0.1246% (w/v) and a pH value of 2.4.[33] Soluble solids contents were 11.1 °Brix for original Coca-Cola and 11.5 °Brix for Pepsi.[34] The composition in this table was used to make the matrix of cola model (sucrose−phosphoric acid solution). This cola base was odorless, and it did not differ from odor-free water.

The actual concentration of each aroma compound used to construct the cola aroma reconstitution model is shown in Table 4. The "original" model prepared from a cola matrix and high-purity standards on the basis of quantitation data had a characteristic cola aroma, but could be distinguished from the authentic sample in terms of the intensity of some aroma descriptors. In particular, the herbal and pine attributes of the original cola model were significantly higher than those of commercial cola (Figure 3). The differences between the two aroma profiles may be caused by (1) the matrix or (2) aroma volatiles and/or the balance of odorants above the headspace. To confirm that the synthetic cola base was comparable to the odorless authentic cola base, an odorless matrix was prepared from commercial cola. The aroma volatiles of decarbonated authentic cola were removed by diethyl ether extraction (three times, 1 h each) followed by SAFE for 8 h. The nonvolatile residue was then reconstituted with odor-free water to its original composition. The procedure was repeated to obtain the odorless authentic matrix. By comparison of the overall aroma, the odor characteristic of the cola model obtained from this matrix was similar to that of the cola model prepared from a synthetic base. It was thus concluded that the synthetic matrix was identical to the commercial cola base.

Another possible reason was verified by using SPME. The HS aromas of authentic cola and the model determined by GCO had similar profiles, except for β-damascenone (**40**), which was not detected in the model. The results from GC−MS also indicated that the relative HS concentrations of some aroma-active compounds in the model were different from those in commercial cola (data not shown). For example, the HS concentration of linalool (**22**) in the model was higher than that in authentic cola. Moreover, the high-purity standard of linalool contained a higher percentage of the (*R*)-(−)-enantiomer (**22a**), which has a lower odor threshold than the (*S*)-(+)-enantiomer (**22b**),[35] than the original cola reported in the previous study.[3] Thus, the concentrations of nonanal (**16**), linalool (**22**), and nerol (**36**) above the HS were adjusted one by one to better match (within 0.5-fold of the HS concentration of commercial cola), and this model was designated as "rebalanced". On the basis of HS data, (*R*)-(+)-limonene (**8b**) and (*E*)-cinnamaldehyde (**48**) had to be increased by about 3- and 5-fold, respectively. Unfortunately, the adjusted models seemed obviously different from the authentic cola and were noticeably higher in piney or cinnamon odors. The appropriate amounts of these two aroma components were further adjusted by sensory analysis. Furthermore, the concentration of vanillin, which could not be detected by SPME on GC−MS, was increased. Compounds not quantitated but which had high FD factors[3] included β-damascenone (**40**), 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (**47**), and sotolon (**52**). These were also evaluated by addition to the model in an attempt to improve the overall aroma. Each of them was added at the odor threshold level or increased by up to 10 times their threshold, but they were not included in the rebalanced model since they caused no improvement or had a negative effect. The actual concentration of each aroma compound in the rebalanced model is reported in Table 4. On the basis of sensory descriptive analysis, the aroma profile of the model did not differ from that of the authentic cola (Figure 3). Therefore, this model was used as the complete model for the omission study.

Omission Studies. Omission studies of the cola aroma reconstitution models involved the omission of various groups of compounds instead of single odorants. The 20 high-purity standard compounds used to construct the cola aroma reconstitution model were categorized into five groups (Table 6). (*R*)-(+)-Limonene (**8b**), linalool (**22**), nerol (**36**), and geraniol (**39**), which had odor characteristic of citrus/floral perceived by GCO,[1] comprised group 1. The aroma compounds in group 2, including 1,8-cineole (**9**), 4-terpineol (**25**), isoborneol (**29**), α-terpineol (**31**), and borneol (**32a** and **32b**), had similar herbal/cooling notes as determined by GCO.[1] Meanwhile, group 5 consisted of methyleugenol (**46**), (*E*)-cinnamaldehyde (**48**), eugenol (**51**), and (*Z*)- and (*E*)-isoeugenols (**53** and **54**) and was designated as the brown spice group according to the aroma characters identified during descriptive analysis in the previous study.[3] Furthermore, not only is eugenol present in nutmeg oil, but it is also a major volatile in cinnamon oil distillated from leaf.[21,36] Guaiacol (**41**) was classified in group 4 along with coumarin (**56**) and vanillin (**58**) because of the origin of these compounds in vanilla bean.[37] Octanal (**13**), nonanal (**16**), and decanal (**21**) were categorized in group 3 as the aldehyde group due to their similar properties. These three aliphatic straight-chain aldehydes are known to cross-adapt because of their similar odor qualities,[38] and they also share the same I7 mammalian odorant receptors.[39]

Omission models were compared against the complete model by sensory evaluation. There are several sensory techniques used to discriminate the omission models from the complete model. The *R*-index ranking test is superior to different general tests because this method can provide the degree of difference among samples in a single experiment.[16] In addition, the *R*-index ranking test can reduce the error of numerical estimates of rating scale testing, and John Brown's *R*-index computation is not difficult to perform.[16] The ranking test is also appropriate for untrained panelists.[40]

The *R*-index results revealed that only the group 5 omission model was statistically different from the complete model (Table 6). Nineteen of the total twenty-eight panelists (67.86%) ranked this omission model as less similar to the complete model. This indicated that methyleugenol (**46**), (*E*)-cinnamaldehyde (**48**), eugenol (**51**), and (*Z*)- and (*E*)-isoeugenols (**53** and **54**) were the most important aroma compounds which contribute to the cola flavor. However, the impact of the "brown spice" group on

J. Agric. Food Chem. 2015, 63, 776−786

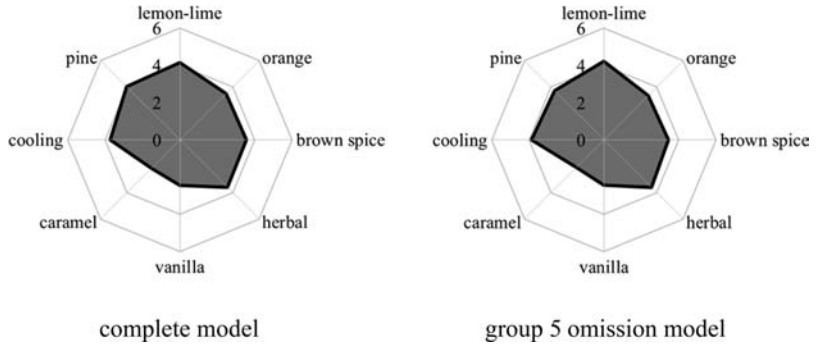

Figure 4. Aroma (by nose) profiles of the group 5 omission model compared to the complete model [n = 8 (5 females and 3 males, 26−45 years old)]. Odor intensity was rated on a 15 cm line scale.

the overall aroma was not in agreement with the main contributors as indicated by the OAVs. This may be because odor thresholds in the cola matrix may differ from those in water. Odor thresholds of some odorants are also affected by the pH of the matrix, for example, 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone.[41] In addition, the mixture suppression or synergy of aroma compounds was not taken into account for OAV calculations.

The descriptive analysis of aroma (by nose) was also performed to compare between the group 5 omission model (brown spice) and the complete model. The two models could not be differentiated by the sensory descriptive analysis results (Figure 4). The complexity of the cola flavor and cross-adaptation might be the reasons to explain this result. The omission model contained guaiacol (**41**) and coumarin (**56**), which were described as having a spicy note. Not only similar odor quality,[42] but also similar chemical structure[43] can result in cross-adaptation. The chemical structure of guaiacol consists of −OH and $-OCH_3$ functional groups on the six-membered ring, which is similar to the structure of eugenol (**51**). Additionally, it could be concluded that the *R*-index ranking test is more powerful than descriptive analysis to discriminate the omission models from the complete model.

The additional omission test was conducted on the basis of omission of each of the aroma compounds in group 5 singularly. However, all omission models did not differ from the complete model (Table 7). This means that the omission of the individual odorants could not be recognized. Food flavor is a result of several odorants, and a change in odor quality or intensity caused by omission of a single or sometimes even several odorants is usually hard to detect.[4]

Table 7. *R*-Index Values for Omission Studies of Single Compounds

odorants omitted[a]	*R*-index, JB[b]
methyleugenol (**46**)	34.62
(*E*)-cinnamaldehyde (**48**)	53.85
eugenol (**51**)	50.00
(*Z*)- and (*E*)-isoeugenols (**53** and **54**)	42.31

[a]Compound numbers correspond to those in Tables 1−4 and 6 and Figure 2. [b]Calculated by using John Brown computation against the complete model and expressed as a percentage (the critical value for the two-tailed test, α = 0.05 and n = 26 (18 females and 8 males, 20−48 years), is 18.25).

Supporting Information

ABSTRACT: Garlic (*Allium sativum* L.), which is a widely distributed plant, is globally used as both spice and food. This study identified five novel phenolic compounds, namely, 8-(3-methyl-(*E*)-1-butenyl)diosmetin, 8-(3-methyl-(*E*)-1-butenyl)chrysin, 6-(3-methyl-(*E*)-1-butenyl)chrysin, and Alliumones A and B, along with nine known compounds **6**−**14** from the ethanol extract of garlic. The structures of these five novel phenolic compounds were established via extensive 1D- and 2D-nuclear magnetic resonance spectroscopy experiments. The effects of the phenolic compounds isolated from garlic on the enzymatical or nonenzymatical formation of sulfur-containing compounds produced during garlic processing were examined. Compound **12** significantly reduced the thermal decomposition of alliin, whereas compound **4** exhibited the highest percentage of alliinase inhibition activity (36.6%).

KEYWORDS: *Allium sativum, phenolic compounds, alliin, alliinase*

INTRODUCTION

Garlic (*Allium sativum* L.), which is a widely distributed plant, has been used as spice, food, and folk medicine worldwide for hundreds of years.[1,2] Garlic is a leading herbal remedy used by alternative medical practitioners. Garlic exhibits a wide range of therapeutic effects, such as hypolipidaemic,[3] antiatherosclerotic,[4] antidiabetic,[5] antimicrobial,[6] anticarcinogen,[7] and immunomodulatory[8] activities.

The characteristic smell and health activities of garlic result from sulfur-containing volatiles;[9] these substances are formed when fresh, raw garlic is chopped or crushed, thereby rupturing the intracellular compartments that contain the nonprotein amino acid alliin (*S*-allyl-L-cysteine sulfoxide), pyridoxal-5-phosphate-dependent enzyme alliinase (L-(+)-*S*-alk(en)-ylcysteine sulfoxide lyase, EC 4.4.1.4), and α, β-eliminating endogenous lyase from *Allium* spp.[10,11] or from alliin, which is also a product nonenzymatically formed when garlic or alliin is thermally processed at temperatures >100 °C.[9,12−14]

Aside from S-containing volatiles, garlic also contains phenolic compounds, including the flavonoids[15−17] myricetin, quercetin, and apigenin, as well as phenolic acids,[18] such as gallic, chlorogenic, ferulic, *o*-coumaric, and cinnamic acids, the contents of which were affected by the genotype and location of garlic and the processing condition of "seed" cloves. For instance, the white and Chinese garlic cultivars contained higher contents of total phenolics and ferulic acid than those of the purple garlic cultivars;[18] phenolic compounds were more abundant in the leaves than in the bulbs;[19] and low-temperature conditioning of garlic seed cloves increased the synthesis of phenolic compounds, resulting in a threefold content increase compared with those conditioned at room temperature.[20] Most phenolic compounds exhibit interesting biochemical properties, such as anti-HIV property,[21] capability to protect low-density lipoprotein cholesterol from oxidation,[22] antioxidative characteristics,[23−26] inhibition of ACE activity.[27] and binding affinity toward P-glycoprotein.[28]

Besides having various biological activities, phenolic compounds usually play important roles in food processing.[29] They easily form complexes with other food component such as protein and lipid via hydrogen bonding interactions, leading to changes in physicochemical properties of the latter such as solubility, thermal stability, and digestibility.[30−34] Therefore, phenolic compounds, as the major metabolites of garlic, could interact with alliin or alliinase during garlic processing. These phenolic compounds affect the formation of S-containing compounds, thereby altering the flavor and health benefits of garlic. However, little information is available on the systematic isolation of the phenolic compounds from garlic and the effect of such compounds on alliin or alliinase.

This research aimed to characterize phenolic compounds from garlic and study the effects of them on the enzymatical or nonenzymatical formation of S-containing compounds. Fourteen phenolic compounds that were isolated from garlic, including five novel flavones, were investigated to determine the inhibitory activities of the compounds on the enzymatical or nonenzymatical formation of S-containing compounds. To our knowledge, this study provided the first evidence of the functions of phenolic compounds in garlic during alliinase catalyst reaction and thermal decomposition of alliin.

MATERIALS AND METHODS

General Experimental Procedures. All chemicals, including alliin (98.5%) and alliinase (EC 4.4.1.4, 1000 U/mg), were purchased

from Aladdin Industrial Corporation (China). Distilled water was used throughout the experiments. All the experiments were performed at room temperature unless stated otherwise. UV/vis spectra were obtained using a Spectrumlab 53 UV−visible spectrophotometer (Shanghai Lengguang Technology Co., Ltd., Shanghai, China). Nuclear magnetic resonance (NMR) spectra were acquired using a 400 MHz NMR machine (Bruker), and IR spectra were obtained using a Fourier transform-infrared spectrophotometer (Nicolet Avatar). All the experiments were performed in triplicate.

Plant Material. In January 2014, garlic (*Allium sativum* L.) was collected from Guangzhou, which is located in the Guangdong province of China. Voucher specimens (Accession No. 201410005) were deposited at the herbarium of the Jinan University.

Extraction and Isolation. Around 25 kg of air-dried garlic was peeled and extracted thrice with 95% ethanol (3 × 30 L) at 80 °C. The extract was evaporated to dryness in a vacuum at 60 °C, and 1500.5 g of the crude extract was obtained. The crude extract was purified using an Amberlite A21 column (dimension of column: 10 cm, flow rate: 20 mL/min, eluted with 0%, 25%, 50%, 75%, 90%, and 100% ethanol, volume of solvent: 6 × 40 L) to afford six fractions, namely, fractions 1−6. Fraction 1 contained high amounts of sugar and amino acids, which were not further separated. Fraction 2 (10.1 g, 25% ethanol fraction) was further separated by passing the compounds to a Sephadex LH-20 column (dimension of column: 4 cm, flow rate: 2 mL/min, solvent: MeOH, volume of solvent: 2000 mL) to afford two fractions, namely, fractions 2A and 2B. After evaporation of the solvent at a reduced pressure, fraction 2A (4.2 g) was passed through a 100 g silica gel column by using MeOH/CH_2Cl_2 (2:10) as the eluting solvent to afford compound **12** (300 mg). Fraction 2B (2.4 g) was also passed through a 50 g silica gel column, developed with PE/EtOAc (5:0.5, 5:1, and 5:2), and monitored via thin-layer chromatography by using PE/EtOAc (5:1) to afford compounds **8** (20 mg, R_f = 0.35) and **9** (10 mg, R_f = 0.40). Fraction 3 (14.0 g, 50% ethanol fraction) was separated using a silica gel column (200 g) and eluted by PE/EtOAc (5:1). Subsequently, the fraction was separated by a Sephadex LH-20 column (dimension of columns: 1 cm, flow rate: 0.2 mL/min, solvent: MeOH, volume of solvent: 200 mL) to afford compound **10** (8.8 mg) and another fraction (subfraction A). Subfraction A was further purified by HPLC [250 mm × 10 mm YMC-Pack-C_{18} column, mobile phase: MeOH/H_2O (30:70), detection wavelength: 254 nm, flow rate: 1.0 mL/min] to obtain compound **7** (8.3 mg, Rt = 10.5 min). Fraction 4 (12.1 g, 75% ethanol fraction) was subjected to RP_{18} gel (200 g) column by using MeOH−H_2O (from 8:2 to 9:1) as the eluting solvent to obtain two fractions, namely, 4A and 4B. Fraction 4A was separated using a silica gel column and EtOAc/PE (1:5) as the eluting solvent. Fraction 4A was then purified via preparative TLC CH_2Cl_2/PE(1:1) to afford compound **1** (11 mg, R_f = 0.5). Fraction 4B was subjected to a Sephadex LH-20 column (dimension of column: 1 cm, flow rate: 0.1 mL/min, solvent: MeOH, volume of solvent: 180 mL) and then purified via preparative HPLC [250 mm × 10 mm YMC-Pack-C_{18} column, mobile phase: MeOH/H_2O (20:80), detection wavelength: 254 nm, flow rate: 1.0 mL/min] to obtain compounds **4** (10 mg, Rt = 13.5 min) and **5** (11 mg, Rt = 14.8 min). Fraction 5 (25.8 g, 90% ethanol fraction) was separated using a silica gel column and EtOAc/PE (1:5) to afford three fractions, including 5A−5C. Fraction 5A was separated by a Sephadex LH-20 column (dimension of column: 1 cm, flow rate: 0.2 mL/min, solvent: CH_3COCH_3, volume of solvent: 170 mL) to obtain compound **14** (14.6 mg), and fraction 5B was chromatographed using a silica gel column (400 g) with CH_2Cl_2/MeOH mixtures of increasing polarity to afford compound **11** (10.4 mg). Fraction 5C was separated using a Sephadex LH-20 column (dimension of column: 1 cm, flow rate: 0.2 mL/min, solvent: MeOH/H_2O (1:1), volume of solvent: 240 mL) to yield compound **6** (18.8 mg). Meanwhile, fraction 6 (10.2 g, 100% ethanol fraction) was separated by silica and developed with CH_2Cl_2/MeOH (100:1, 100:5, 10:1) to obtain two fractions, namely, fractions 6A and 6B. Fraction 6A was purified using a silica gel column [30g, CH_2Cl_2/CH_3COCH_3 (100:1)] and further prepared via preparative TLC (EtOAc/PE (5:1) to obtain compounds **2** (8.1 mg, R_f = 0.4) and **3** (8.4 mg, R_f = 0.34). Fraction 6B was separated using a silica gel column (30 g, CH_2Cl_2/MeOH [50:1]) to obtain compound **13** (10.9 mg).

Alliin and Allicin Analysis. Quantitative analyses of alliin and allicin were performed using an Agilent 1260 infinity quaternary liquid chromatography (Hewlett-Packard, Wilmington, NC) equipped with a 250 cm × 4.6 mm ODS-A-C_{18} (5 nm particle size) column. The HPLC conditions were as follows: alliin and allicin, as mobile phase of MeOH/H_2O (20:80) and (15:85), detection wavelength of 220 and 254 nm, and flow rate of 0.8 and 1.0 mL/min, respectively.

Allicin Synthesis. Alliin was synthesized as previously described with slight modifications.[35] Diallyl disulfide was placed under vacuum at 0 °C to remove traces of allyl disulfide. A solution of diallyl disulfide (1.00 g, 7.0 mmol) in chloroform (30 mL) and *m*-chloroperbenzoic acid (77%, 1.79 g, 8.0 mmol) in chloroform (5 mL) was added dropwise at 0 °C. The reaction mixture was stirred at 0 °C for 1 h. Anhydrous sodium carbonate (8 g) was added in small portions with vigorous stirring. The reaction mixture was stirred for an additional 0.5 h at 0 °C and then filtered through a pad of Celite and magnesium sulfate. The filtrate was concentrated under reduced pressure to yield 0.90 g (85% yields) of crude allicin, which was purified by column chromatography (PE: EtOAc, 80:20). ^{1}HNMR (400 MHz,

DOI: 10.1021/jf505982f
J. Agric. Food Chem. 2015, 63, 787−794

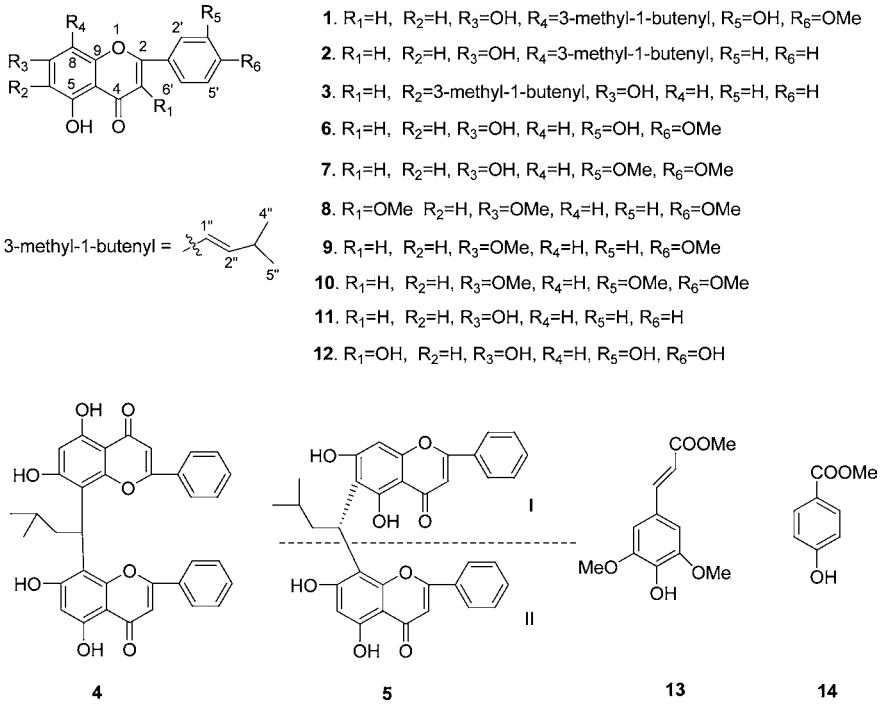

Figure 1. Structures of compounds **1**−**14**.

CD_3CO_2D): δ 3.72−3.92 (m, 4H), 5.20−5.56 (m, 4H), 5.88−5.99 (m, 2H); ^{13}CNMR (100 MHz, CD_3CO_2D): δ 35.0, 59.9, 119.1, 124.0, 125.8, 132.9 ppm.

Thermal Decomposition of Alliin. The thermal decomposition of alliin was estimated by determining its content in the samples according to a previously described method.[12,36] Exactly 5 mg of alliin, 1.0 mg of phenolic compounds isolated from garlic (control: no phenolic compound added), and water were placed in a 5 mL glass tube. The tube was then sealed and equilibrated for 24 h. After equilibration, the tube was heated in an oven at 120 °C for 2 h, cooled in a freezer to −18 °C, and crushed into water to a total volume of 5 mL. The resulting solution was immediately analyzed for alliin content.[10,21] The inhibition percentage was calculated as follows: inhibition percent = [(content of alliin − content of control)/content of control] × 100%. Triplicate measurements were performed.

Assay of Alliinase Activity. Alliinase activity was assayed by determining the production of pyruvate from alliin according to a previously described method with slight modifications.[10] Briefly, the alliinase activity was assayed by determining the production of allicin from alliin. Around 0.5 mL of a 890 U mL^{-1} alliinase sample was added to 1 mL of the standard reaction mixture containing 60 mmol L^{-1} sodium phosphate buffer (pH = 6.5), 25 μmol L^{-1} pyridoxal phosphate, 1 mmol L^{-1} phenolic compounds isolated from garlic (control: no addition of phenolic compound), and 20 mmol L^{-1} pure alliin as substrate. The enzymatic reaction was incubated at 25 °C for 5 min, and the reaction was terminated by adding 2 mL of 0.1 g L^{-1} trichloroacetic acid. The solution was centrifuged to remove the precipitated protein, and the supernatant was assayed for pyruvate concentration via colorimetric analysis. Around 0.5 mL of 1.0 g kg^{-1} 2,4-dinitrophenylhydrazine was added to the supernatant and incubated at 25 °C for 5 min. Exactly 5 mL of 0.5 mol L^{-1} NaOH was then added to the solution and incubated at 25 °C for 10 min. The absorbance at 520 nm was determined using a Spectrumlab 53 UV−visible spectrophotometer (Shanghai Lengguang Technology Co., Ltd., Shanghai, China). The pyruvate concentration was calculated according to the pyruvate standard curve, and the inhibition percentage was calculated as follows: alliinase inhibition (%) = [(content of control − content of pyruvate)/content of control] × 100%. Triplicate measurements were performed.

Procedure for Allicin Decomposition. Allicin decomposition was estimated by determining the content of allicin in the samples according to a previously described method.[35] Exactly 0.5 mg of phenolic compound (control: no phenolic compound added) was added into 0.5 mL of 10 mmol L^{-1} allicin aqueous solution at room temperature. The aliquots were withdrawn from the reaction mixture at a regular time interval (24 h). The resulting solution was immediately analyzed for allicin content, after which the decomposition percentage of allicin was calculated. Each value is the average obtained from three runs of chromatography performed on the sample. Allicin decomposition (%) = [(initial content of allicin − content of allicin)/initial content of allicin] × 100%.

RESULTS AND DISCUSSION

Identification of Compounds 1−14. Exactly 95% aqueous ethanol extract of garlic was separated successively by partitioning the extract using Amberlite A21 column (eluted with 0%, 25%, 50%, 75%, 90%, and 100% ethanol) and repeated Sephadex LH-20 columns. Gel column chromatography afforded five new phenolic compounds **1**−**5** (Figure 1). Nine known compounds, namely, diosmetin (**6**),[37] 2-(3,4-dimethoxyphenyl)-5,7-dihydroxy-4*H*-chromen-4-one (**7**),[38] 5-hydroxy-3,7-dimethoxy-2-(4-methoxyphenyl)-4*H*-chromen-4-one (**8**),[39] 5-hydroxy-7-methoxy-2-(4-methoxyphenyl)-4*H*-chromen-4-one (**9**),[40] 2-(3,4-dimethoxyphenyl)-5-hydroxy-7-methoxy-4*H*-chromen-4-one (**10**),[41] chrysin (**11**),[42] quercetin (**12**),[4,43] (*E*)-methyl 3-(4-hydroxy-3,5-dimethoxyphenyl)-acrylate (**13**),[44] and methyl-4-hydroxybenzoate (**14**),[45] were also obtained and identified based on their spectral data and comparison with literature reports.

Compound **1** exhibited the molecular structure $C_{21}H_{20}O_6$. This result was inferred from the HR-EIMS, ^{13}C NMR, and DEPT data, which indicated 12 degrees of unsaturation. The IR spectrum indicated the presence of hydroxyl groups (3377 cm^{-1}) and a carbonyl group (1643 cm^{-1}), which was conjugated with an aromatic ring. The ^{1}H NMR spectrum provided signals of most functional groups, including five

aromatic protons [δH 6.58 (1H, s), 6.24 (1H, s), 7.39 (1H, d, *J* = 2.0) 7.04 (1H, d, *J* = 8.4 Hz), and 7.48 (1H, dd, *J* = 8.4 and 2.0 Hz)] and a 3-methyl-1-butenyl group [6.54 (1H, d, *J* = 16.4 Hz, H-1″), 6.48 (1H, dd, *J* = 16.4 and 6.8 Hz, H-2″), 2.53 (1H, m, H-3″), and 1.18 (6H, d, *J* = 6.8 Hz, H-4″ and H-5″)]. The ^{13}C NMR spectrum (Table 1) also exhibited signals for one carbonyl group, seven aromatic methane groups, and seven aromatic quaternary C, including at least four oxygenated C signals at δC 155.9, 161.1, 164.1, and 166.1. This result revealed that compound **1** contained a flavone skeleton. Compound **1** was deduced as 3-methyl-1-butenyl group-substituted diosmetin[22] based on 2D NMR spectrum. In the HMBC spectrum, the following long-range cross peaks (^2J and ^3J) were observed in a ring: singlet at δH 6.24 (H-6) with C-5 (δC 161.1), C-7 (δC 164.1), C-8 (δC 106.6), and C-10 (δC 105.3); as well as methane doublet at δH 6.54 (H-1″) correlated with C-7 (δC 164.1), C-8 (δC 106.6), and C-9 (δC 155.9), which indicated that the 3-methyl-1-butenyl group was attached at C-8. An aromatic methoxy group at δH 3.94 correlated with C-4′ (δC 152.6), and another proton at δH 6.48 (H-2′) showed cross peaks with C-6′ (δC 120.1), C-3′ (δC 148.3), and C-4′ (δC 152.6). These results indicated the presence of a 3′-hydroxyl-4′-methoxybenzoyl moiety. The stereochemistry at C-2″ was *E* because the coupling constant between H-1″ and H-2″ was 16.4 Hz.[46] Thus, the structure of compound **1** was (*E*)-5,7-dihydroxy-2-(3-hydroxy-4-methoxyphenyl)-8-(3-methylbut-1-enyl)-4*H*-chromen-4-one, which was named as 8-(3-methyl-(*E*)-1-butenyl) diosmetin.

MeO	56.4					

Compound **2** was obtained as a yellow amorphous powder. The EIMS exhibited a molecular ion peak at *m*/*z* 323 [M + 1]. The elemental formula of the compound was $C_{20}H_{18}O_4$, as confirmed by the results of HR−ESI−MS ([M + H] 323.1279; calcd for $C_{20}H_{19}O_4$, 323.1278). The IR and UV data of compound **2** were compared with those of compound **1**, and the same basic skeleton as compound **1** was observed in compound **2**. The ^{13}C NMR spectra of **2** displayed signals for one carbonyl group, seven aromatic methane groups, including two symmetrical aromatic methane groups, as well as seven aromatic quaternary C, including three oxygenated C signals at δC 165.3, 161.1, and 165.5. Analysis of the ^{13}C NMR of compound **2** showed that an aromatic methoxy and two oxygenated aromatic quaternary C signals were eliminated, and two aromatic methane signals were added compared with those of compound **1**, which indicated that the C-3′ and C-4′ positions cannot be substituted by the methoxy and hydroxyl groups. The results revealed that compound **2** contained a chrysin skeleton.[42] Compound **2** was deduced as an isomer of 8-prenychrysin.[47] By contrast, the ^{13}C NMR and DEPT data of **2** are similar to those of 8-prenylchrysin, except that a downfield quaternary carbon signal and a methylene signal in 8-prenylchrysin were replaced by two methane signals in **2**, which indicated that **2** contained 3-methyl-1-butenyl group instead of prenyl group in 8-prenylchrysin.[44] In the HMBC NMR experiments, proton δH 6.46 (H-1″) showed correlations with C-7 (δC 165.5), C-8 (δC 106.8), and C-9 (δC 155.9), thereby confirming that the 3-methyl-1-butenyl group was attached at C-8. Accordingly, compound **2** was identified as (*E*)-5,7-dihydroxy-8-(3-methylbut-1-enyl)-2-phenyl-4*H*-chromen-4-one, which was named as 8-(3-methyl-(*E*)-1-butenyl)-chrysin.

Compound **3** exhibited the same molecular formula ($C_{20}H_{18}O_4$) according to the HR−ESI−MS ([M + H] 323.1271; calcd for $C_{20}H_{19}O_4$, 323.1278). The IR bands showed the presence of OH groups (3363 cm^{-1}). A comparison of the NMR spectra of compounds **2** and **3** (Table 1) showed the similarity of the two compounds. The major difference indicated that one aromatic methane signal at δC 100.5 and an aromatic quaternary C signal at δC 106.8 in compound **2** were replaced by that at δC 95.7 and δC 111.5 in compound **3**. This finding implied that the 3-methyl-1-butenyl group, which substituted the position in compound **3**, was different from that in compound **2**. The correlations between a methane doublet at δH 6.63 (H-1″) and C-7 (δC 168.6), C-8 (δC 95.7), and C-9 (δC 157.7) in the HMBC spectrum suggested that the 3-methyl-1-butenyl group was linked to a C-6 carbon. Thus, the structure was characterized as (*E*)-5,7-dihydroxy-6-(3-methylbut-1-enyl)-2-phenyl-4*H*-chromen-4-one, which was named as 6-(3-methyl-(*E*)-1-butenyl)chrysin.

Compound **4** was isolated as a yellow powder. The molecular formula of compound **4** was $C_{35}H_{28}O_8$ according to the results of ^{13}C (DEPT), NMR spectra, and HR−ESI−MS ([M + H] 577.1840; calcd for $C_{35}H_{29}O_8$, 577.1857). The ^{1}H and ^{13}C NMR spectral data of compound **4** were analogous to those of compound **2**. The ^{13}C NMR spectrum showed that two signals, which were ascribed to methane C atoms (δC = 30.1 ppm) at C-1″ and C-2″ (δC = 42.0 ppm) in compound **4**, were observed in place of the two olefinic C atoms (δC = 117.3 and 142.3 ppm, respectively) in compound **2**. The characteristic proton signal at δH = 5.54 ppm, which was attributed to C-1″ (δC = 30.1 ppm), suggested that C-1″ was linked with two symmetric flavone moieties that combined the molecular formula with ^{13}C NMR spectral data and was confirmed by the significant HMBC cross peaks from the methane proton at δH 5.54 to C-8 (δC = 110.4 ppm) and C-7 (δC = 172.1 ppm). Thus, compound **4** was determined as 8,8′-(3-methylbutane-1,1-diyl)bis(5,7-dihydroxy-2-phenyl-4*H*-chromen-4-one), which is a novel natural compound named *Alliumone A*.

J. Agric. Food Chem. 2015, 63, 787−794

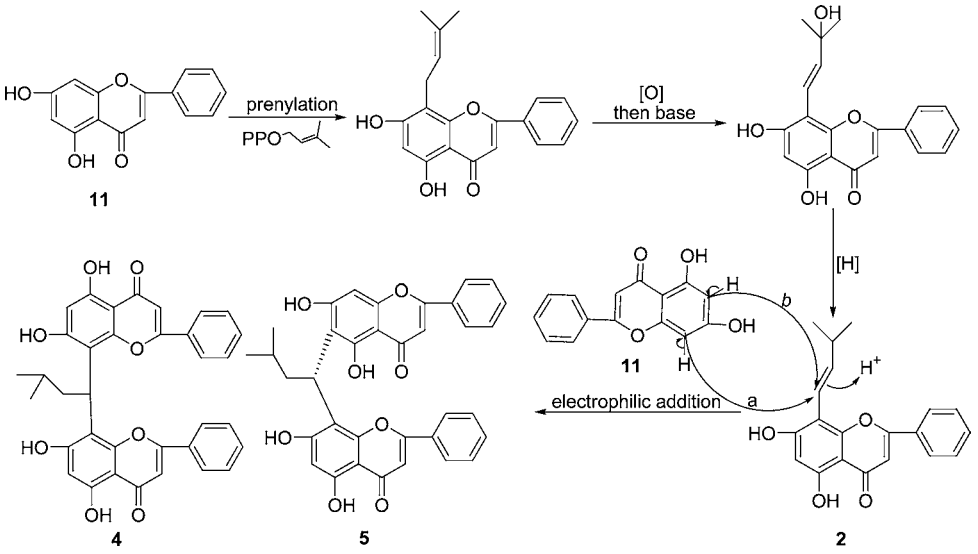

Figure 2. Proposed biosynthesis of **4** and **5**.

Compound **5** was obtained as a yellow amorphous powder. The molecular formula of compound **5** was $C_{35}H_{28}O_8$ according to the ^{13}C (DEPT), NMR spectra, and HR−ESI−MS ([M + H] 577.1857; calcd for $C_{35}H_{28}O_8$, 577.1857). These results were the same as those for compound **4**. The NMR signals of compound **5** appeared in pairs at the same region as those of compound **4**, which suggested that compound **5** was the nonsymmetrical isomer of compound **4**. The presence of a correlation peak from the characteristic proton signal at δH = 5.74 ppm, which was ascribed to C-1″, C-8, and C-6, in the HMBC experiment (δC = 28.0 ppm), demonstrated that C-1″ was attached to the C-8 of unit I and C-6 of unit II. A detailed analysis of the HMBC, H-2″(I) to C-4″(I) and C-1″(I), H-8(I) to C-10(I) and C-7(I), H-6(II) to C-10(II) and C-8(II), H-3(I II) to C-4(I II), C-10(I II), and C-1′(I II), as well as H-4′(I II) to C-3′/5′(I II) and C-2′/6′(I II), facilitated the assignment of all the protons and Cs. An *S* configuration of a chiral center was tentatively assigned according to the optical rotation [$(\alpha)_{20}^{D}$ +10.04 (c 0.001, methanol)] of compound **5** with that of (*S*)-1-ferrocenyl-4-(1-cyclopentylethyl)benzene.[48] In conclusion, the structure of compound **5** was determined as (*S*)-8-(1-(5,7-dihydroxy-4-oxo-2-phenyl-4*H*- chromen-6-yl)-3-methylbutyl)-5,7-dihydroxy-2-phenyl-4*H*-chromen-4-one, which is a novel natural compound named *Alliumone B*.

A plausible biogenetic pathway to **4** and **5** was proposed (Figure 2). Compound **11** generated 8-prenylchrysin though prenylation reaction. The prenyl group of the latter was oxidized and then basified, leading to form 8-(3-hydroxy-3-methyl-but-1-enyl)chrysin, which was similar to the last step of the formation of hyperualones B.[49] The resulting compound was reduced to generate **2**, which further produced the electrophilic addition reaction at the C(1″)= C(2″) bond with C-8 of **11** via a or C-6 of **11** via b (Figure 2), thereby forming **4** and **5**, respectively.

Effect of Phenolic Compounds on Thermal Degradation of Alliin. Previous research reported that alliin is self-degraded or thermally decomposed to generate volatile S-containing compounds.[12−14] These compounds are generated from alliin via hydrolysis or free-radical rearrangement.[14] Most phenolic compounds are strong radical scavengers; thus, we investigated the effects of phenolic compounds isolated from garlic on the thermal decomposition of alliin (Figure 3). The phenolic

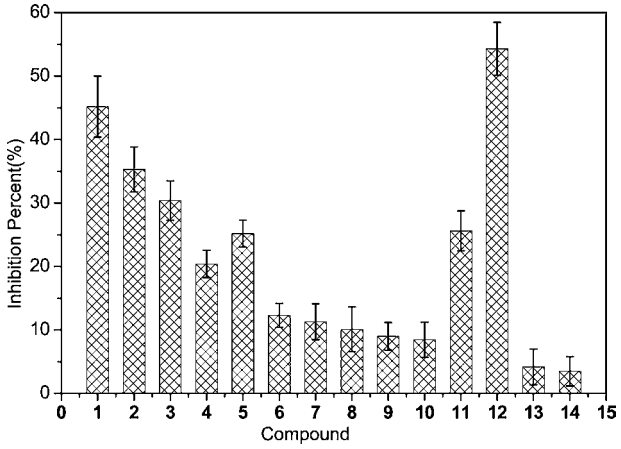

Figure 3. Effect of phenolic compounds from garlic on thermal degradation of alliin.

compounds positively affected the inhibition of the thermal degradation of alliin, in which addition of flavones, such as compounds **11** and **12,** led to stronger inhibition than that of other phenolic compounds, including **13** and **14**. Compound **12** exhibited a maximum inhibition of about 51% compared with compound **14,** which exhibited 5.2% inhibition.

The hydroxyl group in the flavones affected the inhibition ability of the compounds. Compound **11** exhibited more potential inhibition ability than those of compounds **9** and **10** because the latter compounds lacked a hydroxyl substituent at the 7-position of the A ring. This result suggested that the hydroxyl group substituent at the 7-position of the A ring can increase the inhibition ability of the compound. The 3-methyl-1-butenyl group substituent on the flavone skeleton also increased the inhibition capability of the flavone, particularly when the substituent was located at the 8-position of the A ring. This result was exhibited by compounds **2**, **3**, and **11**. Compounds **2** and **3** exhibited one 3-methyl-1-butenyl group substituent at the 8- and 6-positions, respectively, whereas compound **11** lacked a 3-methyl-1-butenyl group substituent in the skeleton. Thermal degradation assay results showed that compounds **2** and **3** exhibited stronger inhibition ability than that of compound **11**. Compound **2** also exhibited better

DOI: 10.1021/jf505982f
J. Agric. Food Chem. 2015, 63, 787−794

inhibition activity than compound **3**, which suggested that the presence of a 3-methyl-1-butenyl group at the 8-position in the skeleton caused stronger inhibition ability relative to that with a 3-methyl-1-butenyl group at the 6-position.

The above results indicated that most flavones clearly exhibited strong inhibition during the alliin degradation. This finding was expected because the flavones behaved as strong radical scavengers, which prevented free radical reaction during the thermal process. The 3-methyl-1-butenyl group substituent, which behaved as an electron-donating substituent at the ring, also decreased the vertical ionization potentials, thereby resulting in better antioxidant activity.[50] This behavior can strongly inhibit the thermal degradation of alliin.

Effect of Phenolic Compounds on Alliinase Activity. The alliinase catalyst reaction was affected by the temperature, pH, concentration, solvent, and presence of additives.[8,9,51,52] However, the functions of the phenolic compounds, which are major secondary metabolites of garlic in the alliinase activity, remain unknown. Figure 4 shows the effects of 14

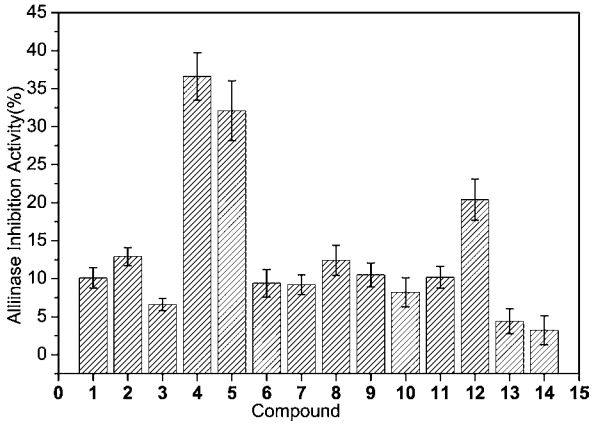

Figure 4. Alliinase inhibition activity of phenolic compounds isolated from garlic.

phenolic compounds isolated from garlic on the alliinase activity. The results indicated that flavones with more hydroxyls (e.g., compound **12**) exhibited higher inhibitory activity than that with more methoxyls (e.g., compounds **8** and **9**). Biflavone **4** also showed the highest percentage of alliinase inhibition activity at 36.6%. Moreover, compound **5** exhibited 32.7% alliinase inhibition activity. The alliinase inhibition activities of compounds **4** and **5** were correspondingly 3.6 and 3.2 times more potent than that of compound **11**. These results implied that the efficiency of flavones as inhibitors of alliinase depended largely on their chemical structures, relative orientation, and number of hydroxyl groups attached to the aromatic ring.

In addition to interactions with alliinase and alliin, phenolics may also interact with allicin as the reactive species formed upon the alliinase cleavage of alliin. Allicin is very unstable and thus easily decomposes into S-containing volatiles. Phenolics could affect allicin stability. Therefore, two phenolics **4** and **12**, which respectively showed strong interaction with alliinase and alliin, were selected to evaluate their effects on allicin stability (Figure 5). After 144 h of the test, the addition of phenolics **4** and **12** caused the decomposition percentage of allicin to reach 47% and 48%, respectively, compared with the control at 52%. This finding is consistent with that obtained by Fujisawa.[53] This result implies that the addition of phenolics slightly promoted allicin stability at room temperature.

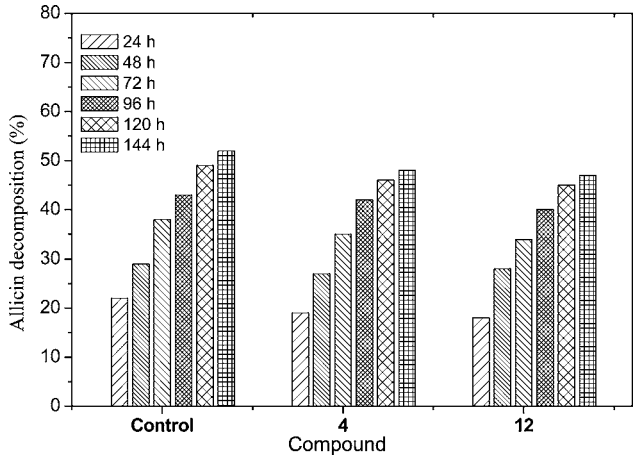

Figure 5. Decomposition percentage of allicin with phenolic compounds **4** and **12**. Each value is the average obtained from three runs of chromatography performed on the sample.

In the present study, five novel flavones, namely, 8-(3-methyl-(*E*)-1-butenyl)diosmetin, 8-(3-methyl-(*E*)-1-butenyl)-chrysin, 6-(3-methyl-(*E*)-1-butenyl)chrysin, and Alliumones A and B, together with nine known compounds **6**−**14**, were identified from the ethanol extract of garlic. To our knowledge, this research is the first systematic report on phenolic compounds from garlic and thus provides the first evidence of the effects of phenolic compounds in garlic on the enzymatical or nonenzymatical formation of S-containing compounds. This study demonstrated that compounds **12** exhibited the strongest inhibition ability for the thermal degradation of alliin (51%), and biflavone **4** showed the highest percentage of alliinase inhibition activity (36.6%). The results may serve as important references for garlic processing.

ABSTRACT: Tasty components in *Lentinula edodes* pileus and stipe at different growth stages were studied. Mannitol, trehalose, arabitol, and glucose were the main soluble polyols and sugars, whereas succinic acid, malic acid, and citric acid were the main organic acids. Mannitol contents were the highest in the pileus and increased at mature growth stages, although arabitol contents were the highest in the stipe and peaked at stage 5. Succinic acid contents peaked at stage 5 in the pileus and stipe during mature growth stages. Threonine (sweet taste) values were the highest among all the detected amino acids, followed by glutamic acid (MSG-like taste). MSG-like 5′-nucleotide contents could account for nearly 50% of the total 5′-nucleotides. Equivalent umami concentration (EUC) values of stage 5 exhibited higher levels during mature growth stages. Tasty components in the stipe were rich and EUC values were high, which might be useful for further processing and byproduct development of *L. edodes*.

KEYWORDS: *Lentinula edodes, tasty components, equivalent umami concentration, growth stages*

INTRODUCTION

Lentinula edodes (Berk.), usually called Xianggu in China, shiitake in Japan, is one of the most important traditional edible and medicinal fungus in China and other East Asian countries for its desirable tasty flavor and great medicinal properties.[1−6] The tasty components in edible mushrooms are primarily several water-soluble substances, including soluble sugars, free amino acids, 5′-nucleotides, and organic acids, which present a variety of taste, such as sweet, umami, sour, and so on. Soluble sugars and polyols, contained in mushrooms, contribute to a sweet taste but not to the typical mushroom taste.[7] Organic acids, related to the metabolic processes of synthetic phenols, amino acids, esters, and aromatic substances,[8] contribute an important part of edible mushroom flavor. Umami taste is recognized as a basic taste, typified by glutamic acid and its salt monosodium glutamate (MSG), which give a savory meat soup or rich meaty taste sensation.[9] Aspartic acid, glutamic acid, and some 5′-nucleotides were also considered as MSG-like components, and values of equivalent umami concentration (EUC) were used to evaluate umami of mushrooms.[10]

Currently, both the pileus and stipe of *L. edodes* were available for food flavor components in China. Recent literatures were just aimed at the tasty components in fruiting bodies of *L. edodes*.[11−13] However, there were few reports about the profiles of tasty components of *L. edodes* in different parts (pileus and stipe) or at different growth stages. Therefore, the aims of our study were to systematically evaluate the main tasty components in *L. edodes* pileus and stipe at different growth stages, in order to further elucidate the synergistic effect of umami tasty components and mechanism of flavor producing in the pileus and stipe during growth stages. The results would be beneficial for further processing in the flavors and fragrances industry.

MATERIALS AND METHODS

Mushroom Materials. *L. edodes* used in this study were cultivated in Xiufeng Edible Fungi Cooperative, Jinshan district, Shanghai, China. The strain, Shenxiang 16 ((2009) No. 002, was recognized by Edible Fungus of Shanghai Agricultural Commodities) and bred by the Improved and Standardized Spawn Breeding Center (ISSBC), Shanghai Academy of Agricultural Sciences, China. Fresh *L. edodes* were harvested at six different stages (Figure 1) according to their growth characteristics (Table 1). The stipe of *L. edodes* formed at stage 1 and was fully extended at stage 6. After stage 4, its inner membrane would crack naturally. Samples were dried by hot air (DHG-9145A, Hengke Technology Ltd., Shanghai, China) at 50 ± 2 °C with maximum air speed, and samples were ground using an ultracentrifugal mill and sieving machine to obtain powder (80 mesh).

Analysis of Soluble Sugars by HPAEC-PAD. Soluble sugars and polyols were extracted and analyzed according to Ajlouni et al.[14] Suspensions of powdered mushroom (0.5 g) in 50 mL of 80% ethanol were shaken at 150 rpm for 45 min at room temperature (26 °C). After filtration through Whatman No. 3 filter paper, the residue was washed five times with additional 25 mL volumes of 80% ethanol. The combined filtrate and rinsed water were evaporated to dryness at 50 °C on

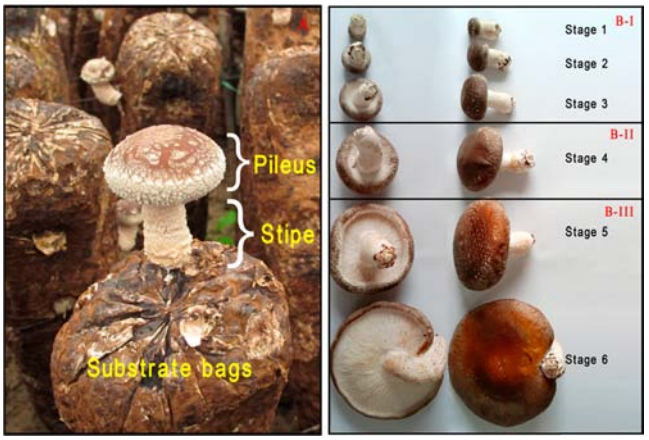

Figure 1. Photograph of *L. edodes* at different growth stages. **A** The fruit body consists of pileus (cap) and stipe (stalk) growing on substrate bags. Developmental processes were divided into three phases: **B−I**, primary developing stages; **B−II**, middle stage; and **B−III**, mature stages.

a rotary evaporator. Extracted solids were redissolved in deionized water to a final volume of 10 mL, and the solution was filtered (0.22 μm cellulose filter, Millipore) prior to analysis. Components were identified by high performance anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD) using the Dionex ICS2500 HPAEC-PAD system (Thermo Fisher China Ltd., Shanghai). Corresponding condition of test method referenced the report by Li et al.[15] Each sugar or polyol was identified and quantified using authentic sugar or polyol standards (Sigma-Aldrich, St. Louis, United States).

Analysis of Organic Acids by HPLC. The extraction of organic acids was modified from a method described by Li et al.[16] Mushroom powder (1.0 g) diluted with 50 mL of 0.1 N HCl (analytical reagent, Sinopharm) was shaken for 60 min at 60 °C for analysis of organic acids. The suspension was centrifuged at 10 000 rpm (15 000*g*) for 20 min after cooling. Then the extraction was filtered through 0.22 μm mixed cellulose esters filter (Welch) to inject into HPLC. The HPLC conditions were carried by Li et al.[16] Each organic acid was identified and quantified using authentic standards (Sinopharm Chemical Reagent Co. Ltd., Shanghai, China) based on their retention time; samples were further quantified by comparing their peak area with the relevant calibration curves of the standard compounds.

Analysis of Free Amino Acids by Amino Acid Analyzer. Free amino acids were extracted and analyzed according to Li et al.[16] Dried *L. edodes* powder sample (0.5 g) was mixed with 30 mL of 0.1 mol/L HCl (GR) solution and then placed into an ultrasonic bath for 30 min at 40 °C. The sample was left to stand for 30 min and then centrifuged at 6000 rpm (4000*g*) for 3 min. The supernatant and 10% sulfosalicylic acid solution were mixed according to the proportion of 1:1 (v/v). The mixture was left at 4 °C for 1 h and then centrifuged at 12 000 rpm (18 000*g*) for 30 min at 4 °C, immediately transferred the supernatant to the tube, and adjusted pH value to 2.0 with 10 mol/L NaOH/HCl. The final supernatant liquid was filtered with Millipore 0.45 μm PES filters (Milford, U.S.A.). The filtrate was loaded onto L-8800 high-speed amino acid analyzer (Hitachi, Japan). The standard amino acid solutions, type ANII and type B, were obtained from Wako (Wako-shi, Japan).

Analysis of 5′-Nucleotides by HPLC. 5′-Nucleotides were extracted and analyzed as described by Taylor et al.[17] A suspension of *L. edodes* powder (1.0 g) in 25 mL of deionized water was boiled for 1 min, cooled, and then centrifuged at 12 000 rpm (18 000*g*) for 15 min. The sediment was repeated with 20 mL of deionized water, and the combined extraction was filtered through a 0.22 μm cellulose membrane (Millipore) prior to analysis by high-performance liquid chromatography (HPLC). The HPLC conditions were carried by Li et al.[15] Each 5′-nucleotide was identified and quantified using 5′-nucleotide standards (Sigma-Aldrich, St. Louis, United States).

Formula of Equivalent Umami Concentration (EUC). The equivalent umami concentration [EUC, g monosodium glutamate (MSG) per 100 g dry raw material weight] is the concentration of MSG equivalent to the umami intensity of that given by the mixture of MSG and a 5′-nucleotide and is represented by the following addition equation:[18]

$$Y = \sum a_i b_i + 1218\left(\sum a_i b_i\right)\left(\sum a_j b_j\right)$$

where Y is the EUC of the mixture in terms of g MSG per 100 g dry raw material weight; a_i is the concentration (g per 100 g dry raw material weight) of each umami amino acid [aspartic acid (Asp) or glutamic acid (Glu)]; a_j is the concentration (g per 100 g dry raw material weight) of each umami 5′-nucleotide [5′-inosine monophosphate (5′-IMP), 5′-guanosine monophosphate (5′-GMP), 5′-xanthosine monophosphate (5′-XMP) or 5′-adenosine monophosphate (5′-AMP)]; b_i is the relative umami concentration (RUC) for each umami amino acid to MSG (Glu, 1 and Asp, 0.077); b_j is the RUC for each umami 5′-nucleotide to 5′-IMP (5′-IMP, 1; 5′-GMP, 2.3; 5′-XMP, 0.61 and 5′-AMP, 0.18); and 1218 is a synergistic constant based on the concentration of g per 100 g dry raw material weight used.

Statistical Analysis. All experiments were performed three times. Tukey's Honestly Significant Difference (Tukey HSD) test was conducted when the samples exhibited a significance

difference between samples, with the level of significance set at P < 0.05. Both ANOVA and Tukey HSD were performed with IBM SPSS Statistics 20.

RESULTS AND DISCUSSION

Analysis of Tasty Components in *Lentinula edodes* at Different Stages and Parts. The tasty components of fruit body (pileus and stipe) and different developmental stages of *L. edodes* were investigated. Results were compared with other findings in the literature.

Soluble Sugars and Polyols. Mannitol, trehalose, arabitol, and glucose, considered as the main mushroom polyols or soluble sugars in former reports,[11,12,15,19] were found in the pileus and stipe of *L. edodes* at different growth stages in this research (Table 2). The contents of mannitol were the highest in the pileus, whereas arabitol values were highest in the stipe. In the pileus, the contents of mannitol appeared as an "N" shape developing curve during all the growth stages. It had increased profiles at primary developing stages (stages 1−3) and stages 4−6, whereas it decreased from stage 3 to stage 4. Both mannitol and trehalose increased profiles in the pileus and stipe during mature growth stages. Arabitol showed a high peak at stage 5 in the stipe and had different profiles compared with the results reported by Yang et al.[11] Fucose, arabinose, and frutocose were detected both in the pileus and stipe, but rhamnose was just detected in the stipes. Kim et al.[12] found that freeze-dried *L. edodes* (Strain No. KKU-05, Hwago) fruiting body contained ribose, xylcose, manose, and sucrose (2.40, 7.98, 23.12, and 2.33 mg/g, respectively). Yang et al.[11] found that *L. edodes* (271) and *L. edodes* (Tainung 1) contained manninol, glucose, and trehalose (83.8 and 134 mg/g, 28.6 and 14.2 mg/g, 29.2 and 3.74 mg/g, respectively). The discrepancy in varieties and contents of main soluble sugars and polyols might be due to the difference in strains and cultivation media of fungus, and fucose, rhamnose, and fructose in *L. edodes* have not been reported or detected in the previous studies.

Organic Acids. As main organic acids, succinic acid, citric acid, and malic acid were detected both in the pileus and stipes of *L. edodes*, with descending order of succinic acid > citric acid > malic acid at each growth stage (Table 3). Hiroshi[20] reported that malic acid, fumaric acid, and citric acid were the main organic acids in shiitake (*L. edodes*), whereas in this research,

[a]Each value is expressed as mean ± standard deviation ($n = 3$). Means with different letters within a row are significantly different ($P < 0.05$). [b]MSG-like (monosodium glutamate-like): Asp + Glu; Sweet: Ala + Gly + Ser + Thr; Bitter: Arg + His + Ile + Leu + Met + Phe + Try + Val; Tasteless: Lys + Tyr + GABA. [c]5′-CMP: 5′-sytosine monophosphate; 5′-UMP: 5′-uridine monophosphate; 5;-GMP: 5′-guanosine monophosphate; 5′-AMP: 5′-adenosine monophosphate. [d]MSG-like 5′-nucleotides: 5′-AMP + 5′-GMP + 5′-IMP + 5′-XMP, while 5′-IMP and 5′-XMP was not detected in this study. [e]Flavor 5′-nucleotides defined by Chen (1986): 5′-GMP + 5′-IMP + 5′-XMP, while only 5′-GMP was detected in this study.

the contents of succinic acid were significantly higher than those of other detected organic acids, peaked at stage 2 in the pileus and stage 3 in the stipe, respectively, during primary developing stages, and came to a relatively stable levels at mature growth stages. Succinic acid and its sodium salt were the characteristic umami components, rich in marine shellfishes, such as scallop (370 mg/g) and oyster (50 mg/g).[21] Those results would be benefit to a further research of the umami formation mechanism in *L. edodes*. The contents of succinic acid were from 122.9 mg/g to 197.1 mg/g in the pileus and 43.5 mg/g to70.5 mg/g in the stipe during the growth of *L. edodes* fruiting body, higher than the contents of succinic acid in several cultivated mushrooms reported by Li et al.[15] Citric acid, had a mild and refreshing acidity,[22] as the second highest organic acid in pileus and stipe ranged from 53.22 mg/g to 77.60 mg/g and 19.8 mg/g to 40.6 mg/g, respectively, and reached certain steady values at mature growth stages. It also got a top value at stage 2 in the pileus and stage 1 in the stipe, respectively. Malic acid, with a refreshing acidity and a slightly bitter taste,[23] ranked at the third level at mature growth stages in pileus and stipe. At mature stages, the contents of succinic acid in pelius were approximately 3-fold higher than those in stipe, whereas values of citric acid in pelius were 2-fold compared with those in stipe.

Free Amino Acids and 5′-Nucleotides. In this study, 21 amino acids were identified in the pileus and stipe of the growth stages of *L. edodes* (Table 4 and Table 5). The results showed that the contents of threonine were the highest among all amino acids, accounting for 90% of sweet amino acids, with higher values in pileus compared with those of stipe, and achieved relatively steady level at mature growth stages. Glutamic acid as the second highest free amino acid, also accounting for 90% of MSG-like amino acids, were higher in pileus than those of stipe and peaked at stage 5 during the

[a]Each value is expressed as mean ± standard deviation ($n = 3$). Means with different letters within a row are significantly different ($P < 0.05$). [b]MSG-like (monosodium glutamate-like): Asp + Glu; Sweet: Ala + Gly + Ser + Thr; Bitter: Arg + His + Ile + Leu + Met + Phe + Try + Val; Tasteless: Lys + Tyr + GABA. [c]5′-CMP: 5′-sytosine monophosphate; 5′-UMP: 5′-uridine monophosphate; 5;-GMP: 5′-guanosine monophosphate; 5′-AMP: 5′-adenosine monophosphate. [d]MSG-like 5′-nucleotides: 5′-AMP + 5′-GMP + 5′-IMP + 5′-XMP, while 5′-IMP and 5′-XMP was not detected in this study. [e]Flavor 5′-nucleotides defined by Chen (1986): 5′-GMP + 5′-IMP + 5′-XMP, while only 5′-GMP was detected in this study.

mature growth stages. The contents of total free amino acids were in the range of 22.0−27.7 mg/g in the pileus and 11.8−19.8 mg/g in the stipe, which peaked at stage 2 in the former and stage 1 in the latter during the primary developing stages, and both reached steady levels at mature stages. Komata grouped the free amino acids into several classes on the basis of their taste characteristics (Table 4).[24] Asp and Glu acids were MSG-like components, which gave the most mushroom taste (the umami taste or palatable taste).[25] The contents of MSG-like amino acids were in the range of 2.34−4.65 mg/g in the pileus and 1.56−3.56 mg/g in the stipe. The values of sweet amino acids in the pileus (11.0−14.1 mg/g) were higher than those in the stipe (5.59−10.7 mg/g). The MSG-like amino acids and sweet amino acids were considered as the main amino acids in *L. edodes* fruiting body. γ−Aminobutyric acid (GABA) is a biologically active compound, and the presence of GABA in *L. edodes* would be beneficial to humans in addition to their palatable taste and other therapeutic effects.[26,27]

Yang et al. reported that contents of MSG-like taste active amino acids could be divided into three ranges: low (<5 mg/g), middle (5−20 mg/g), and high ranges (>20 mg/g).[11] Our study found that the contents of MSG-like taste active amino acids in the growth of *L. edodes* (1.56−4.65 mg/g) were in the low range, but they were higher than some medicinal mushrooms (0.17−0.50 mg/g) reported by Mau et al.[28] and most commercial mushrooms reported by Yang et al.[11]

Yamaguchi et al. reported that 5′-nucleotides, detected in mushrooms, could contribute to MSG-like taste.[10] Our study identified four 5′-nucleotides (5′-CMP, 5′-AMP, 5′-GMP and 5′-UMP) in the pileus and stipe of *L. edodes* fruiting body (Table 4 and Table 5). As for the MSG-like taste active 5′-nucleotides, their contents were 2.45−5.28 mg/g in the pileus and 1.73−2.90 mg/g in the stipe, and they accounted for nearly

DOI: 10.1021/jf505410a
J. Agric. Food Chem. 2015, 63, 795−801

50% of total 5′-nucleotides contents at each growth stage of pileus and stipe. The contents of 5′-AMP (0.87−2.47 mg/g) and 5′-GMP (0.86−2.81 mg/g) were similar during the whole stages in the pileus and stipe, and their contents were mostly higher in the pileus than those of stipe.

5′-GMP gave the meaty favor, and is also a flavor enhancer, which could induce much umami taste production, and these umami tastes were stronger than MSG.[7] The contents of flavor 5′-nucleotides were 1.34−2.81 mg/g in the pileus and 0.86−1.41 mg/g in the stipe during the growth of *L. edodes* fruiting body in this research (Table 4 and Table 5). It demonstrated a peak at stage 1 in the pileus and stage 2 in the stipe during the primary developing stages, with slightly increasing profiles in the pileus and stable levels in the stipe, respectively, at mature growth stages. Yang[11] reported that contents of flavor 5′-nucleotides could be divided into three ranges: low (<1 mg/g), middle (1−5 mg/g), and high (>5 mg/g), and found the contents of flavor 5′-nucleotides in *L. edodes* (271) and *L. edodes* (Tainung 1) were, respectively, in high range and middle range, whereas the contents of flavor 5′-nucleotides in the pileus of *L. edodes* during whole growth stages in this research were all in the middle range.

Evaluation of *Lentinula edodes* at Different Stages and Parts Using Equivalent Umami Concentration (EUC). Yamaguchi et al. reported that the combination of umami amino acids and umami 5′-nucleotides would synergistically increase the umami taste of mushrooms. Using the equation derived from sensory evaluation,[18] the EUC value of stage 1 in the pileus was the highest among all the *L. edodes* growth stages (Figure 2). However, *L. edodes* fruit bodies were

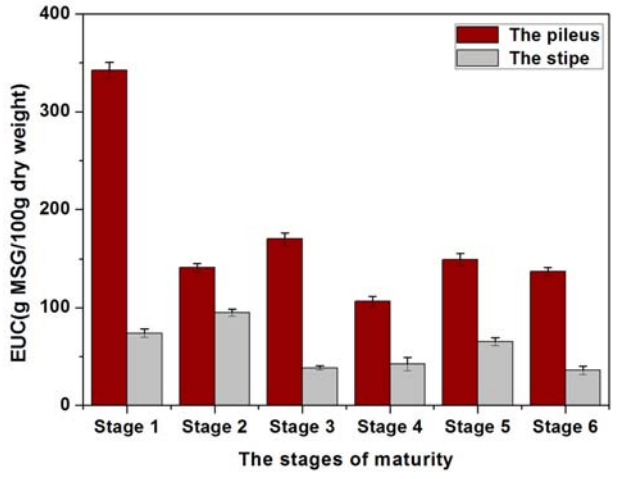

Figure 2. Changes in the equivalent uamami concentration (EUC) of *L. edodes* at different stages of maturity in the pileus and stipe. Each value was expressed as mean ± standard deviation (n = 3).

usually picked at stage 5, which exhibited higher EUC values at mature stage. At stage 6, when *L. edodes* fruit bodies pileus are exposed completely, the fruit bodies became overmatured, and their EUC values decreased. These results were different from those reported by Tsai et al.[29]

Mau reported that the EUC values of flavor components in mushroom were usually classified into four levels: first level of >1000 g MSG/100 g dry weight, second level of 100−1000 g MSG/100 g dry weight, third level of 10−100 g MSG/100 g dry weight, and fourth level of <10 g MSG/100 g dry weight.[30] EUC values of several cultivated mushrooms were at third level (11.19−88.37 g MSG/100g dry weight),[19] and those of several medicinal mushrooms were at the fourth level (0.66−7.92 g MSG/100g dry weight).[30] In this study, EUC values of the pileus (106.8−342.7 g MSG/100 g dry weight) were at the second level, and those of the stipe (35.93−95.11 g MSG/100g dry weight) were at the third level. The EUC values of the pileus were mostly higher than those of *L. edodes* (271), and significantly higher than those of *L. edodes* (Tainung 1).[11] Furthermore, tasty components in the stipe of *L. edodes* were rich and EUC values were higher than other several cultivated mushrooms[15] and medical mushrooms,[30] which might be useful for further processing and byproduct development of *L. edodes*.

ABSTRACT: The number of fishery products with a quite detailed description of the origin is increasing. This trend is driven by the interest of consumers and the fight against illegal unregulated and unreported fisheries. Unfortunately, there is a lack of methods to prove this information experimentally besides the document-based traceability assessments. For marine fish population genetics is a promising strategy, but research is concentrated only on a few species. Saithe is a commercially important fish species, despite the fact that genetic knowledge is scarce regarding the specification of populations. For a comparative study cost- and time-effective strategies were tested: We found RAPD-PCR to be a useful method for low-budget research or prestudies. Adoption of microsatellites from closely related species turned out to be possible with limited success quota. Our results suggest a clustered structure of populations within the Northeast Atlantic, probably overlapping in the northern North Sea.

KEYWORDS: *RAPD, microsatellites, saithe, populations*

INTRODUCTION

On the fish and seafood market an increasing number of products are labeled regarding to the origin in much detail. Market analyses throughout the EU showed that consumers are highly interested in the origin of their seafood.[1] Labeling ranges from local-marketing strategies ("Fish from our own coast") or ways of direct marketing from fisheries[2] to the labeling of origin because of environmental concerns of consumers. From December 2014 EU regulation No. 1379/2013 will apply for all fishery products.[3] Article 38 of this regulation prescribes obligatory information about the subcatch area or subdivision for all unprocessed and smoked fishery products being sold to the consumer. Notably, this rule is valid only when the fish originates from the oceans surrounding the EU: Northeast Atlantic (FAO 27) or Mediterranean and Black Sea (FAO 37).

If scientific data should be used to uncover fraud regarding the origin and fight against illegal, unreported, and unregulated (IUU) fishing activities, it is inevitable to connect the area of origin to specific data, which are also available in a fillet.[4]

The actual tracing system for fishery products is very detailed and employs high bureaucratic effort.[3,5] It sets high standards for fresh and frozen unprocessed fishery products. Processed products are covered by the general traceability requirement of food law.[6] During processing the composition may change, due to heading, gutting, adding of ingredients, or water loss by salting or smoking. This makes tracing along the food chain very complex in real life, especially because production chains are often split into single operations taking place in several different countries or even continents.

Most of the fishery products are placed on the market as a fillet or as part of a processed food. DNA is still available in highly processed products even when damaged due to low pH values or enzymatic ripening processes, but population genetic-based methods are still on the level of scientific investigation and not suitable for routine analysis. Mass spectrometry-based strategies have been shown to work well for coastal organisms[7] but are not suitable for pelagic fish because these methods are based on the climate and composition of plankton in the area of production which is much more leveled in the open water.

While identification of species is already common practice in food control laboratories,[8,9] validation of the authentication of origin is possible only in a few cases, like, for example, herring, Atlantic cod, and Pacific salmon species.[10]

Currently, data derived from population genetic investigations of marine fishes had mostly been used to answer biological questions or optimize management areas.[11,12] Furthermore, to date population genetic research of North Atlantic fish species used for human consumption has been performed only for a limited number of species. Reiss et al.[12] and Olsson (p 121f)[13] provided an overview on the number and quality of genetic population studies of managed species in the Northeast Atlantic. It can be seen that herring (*Clupea harengus*), cod (*Gadus morhua*), and salmon (*Salmo salar*) have been studied in detail. On the other hand, there is almost no population genetic knowledge of commercially important species like sprat (*Sprattus sprattus*), Norway pout (*Trisopterus esmarkii*), and saithe (*Pollachius virens*), all of these species providing a TAC quota (total annual catch) of more than 100 kt each.[14]

Before population genetics can be applied for authentication purposes, the population genetic structure of the respective

species and migratory processes have to be understood. Furthermore, a lot of data and samples have to be collected, but the question is how to design a study for a species where genetic knowledge is very low. For the development of specific markers and their validation a large number of sequences and samples are required. Each project has to be planed as detailed as possible, which appears to be difficult if there is no knowledge available regarding the number of populations present. We have chosen RAPD-PCR as examples for easy-access methods. An attempt to employ Exon primed Intron crossing PCR had to be abandoned because the number of variable markers was too small.[15] Our other approach was the adoption of microsatellite primers from closely related species, in our case from the family of *Gadidae*.

Biology of Saithe. The literature about saithe populations is dominated by data from tagging studies. The deficiency is that tagging can only be carried out on juvenile fish, not on larvae. This does not take into account the larval drift by the subtropical gyre, and most of the large-scale tagging studies were carried out before the 1990s.[16,17]

There are historical reports about unusual larval drifts of saithe into the Spitzbergen fjords (1967), the southern North Sea (1967), or the Limfjord (1932/33).[18] Furthermore, there are indications that migration routes of saithe are being affected in recent years by salmon farming.[17]

It is known that juvenile saithe remain in the area they have been drifted to for some years. For fisheries the year classes 4 and 5 are most important, because they migrate out of the fjords and live in the open water forming schools. The assumption that saithe return to their spawning grounds has never been convincingly proved, but there are indications that larger fully mature saithe (older than 6 years or larger than 60 cm) enter the spawning areas at spawning times.[19,20] Larger saithe, which are more than 60 cm long, seem to wander through the whole Northeast Atlantic.[16]

Actually the ICES expect four independent stocks of saithe within the Northeast Atlantic (FAO 27): (i) Northeast Arctic (Norwegian) saithe, (ii) saithe from North Sea/Western Scotland, (iii) Icelandic saithe, and (iv) Faroese saithe.[14]

To date, papers dealing with population genetics of saithe are rare.[12,22] After early publications of Child[21] and Denovan and Wright,[22] saithe was no longer the focus of population genetic researchers. In recent years, Eiriksson and Arnason sequenced fragments of the mitochondrial cytochrome oxidase 1 (MT-CO1) gene of 1160 individuals from Canada, Norway, Iceland, and Faroer.[23] This fragment of mitochondrial DNA did not show a significant differentiation between sampling areas but found connections between sex and migratory behavior. In another project 270 fish were genotyped from Canada, Norway, Faroer, and Barents Sea using a set of 115 SNPs, but detailed data have not been published, yet.[24]

Population Genetic. Population genetic tools can be divided into two main groups: easy-access methods and species-specific methods.

Easy-access methods are transferable between species, require relatively low cost and development times, and are useful tools in small-scale research and prestudies. Examples are fingerprinting methods, like RAPD (random amplified polymorphic DNA) and AFLP (amplified fragment-length polymorphism). Also easy access are methods using defined loci being still interspecific like EPIC-PCR (exon primed intron crossing) and assays based on mitochondrial DNA.

Species-specific methods like MSats (Microsatellites) and SNPs (single-nucleotide polymorphism) are generally suitable for automation, making them candidate systems for routine analysis, but their development is time consuming and normally requires more or less high-throughput sequencing.[4,25]

Random Amplified Polymorphic DNA (RAPD)-PCR. The idea of RAPD-PCR is that only one single short primer (10−15 bp long) is used for PCR. Because these primers are that short, they statistically will find some sites to anneal on opposite strands of a given template DNA.[26] The resulting band pattern (fingerprint) is individual and will therefore contain DNA bands which are characteristic for individuals.

RAPD-PCR is a DNA fingerprinting technique that has often been used in species identification and population genetic research for species, whose genome has not been sequenced very extensive as being the case for most of the fish used for human consumption. RAPD-PCR was widely applied in the past for population genetics.[27,28] On the other hand, it was not used very often in recent years due to development of next-generation sequencing (NGS) technologies and more sophisticated methods with higher resolution and reproducibility.

The problem is that very short primers require a relatively low annealing temperature (often 36 °C is used) giving rise to unspecific bands which are not reproducible.[29] Despite these drawbacks RAPD-PCR became a popular tool in population genetics because of its simplicity, low cost, and low requirements regarding laboratory equipment.

Microsatellite (MSat)-PCR. Microsatellites do frequently occur in the noncoding region of the genome. They consist of repeats of 2−5 base pairs. Copy mistakes are likely to occur in these regions, adding or removing one repeat motive. This leads to length polymorphisms providing a lot of markers because after many generations each population develops its characteristic profile of MSat frequencies. If enough data (from many individuals and more than 5 loci) are available it is possible to make meta-analysis giving information about timelines when populations did depart. Furthermore, the method can be automated easily, if fully developed.

This makes microsatellites one of the working horses, being widely used in population genetics.[11,12] Their potential for use even in processed fishery products is high, because the respective amplicons are quite short (100−300 bp). The major drawback is that markers have to be developed for every species anew, requiring a lot of time and resources.[30]

O'Reilly showed that many primers he developed for Alaska Pollack (*Theragra chalcogramma*) could be used for other gadoid species, too.[31] Charrier found 7 MSat primers for whiting (*Merlangius merlangus*) by testing 37 primers developed for other fish of the same family (*Gadidae*).[32]

The current study is aimed to give insights into the toolbox of population genetics. We developed a modus operandi how to design a pilot study providing a first glimpse of the population structure enabling the scientist to plan a detailed study on the species of interest. As a model we used saithe.

MATERIALS AND METHODS

Samples. The origin of samples is shown in Figure 1. Most samples were taken by the German research vessel Walther Herwig III. The commercial sample "CS" was bought from German North Sea Saithe trawl fisheries, catch position defined by tracking code (vessel Susanne, NC 120). Fish were kept under melting ice until filleted. A piece of the fillet was frozen and used for later DNA extraction. Samples "IS" were taken by Icelandic scientists (vessel Ottó N. Porláksson, ID 1578) and

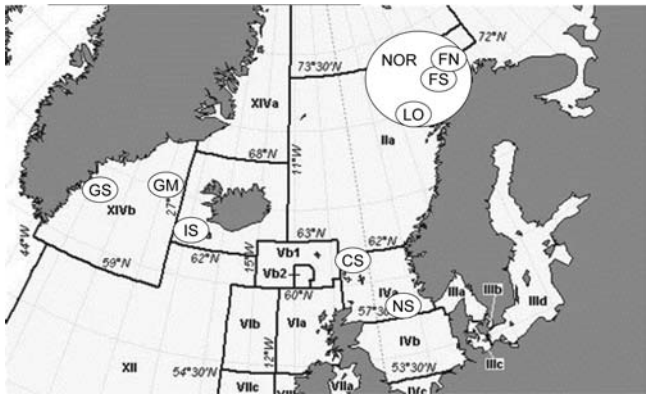

Figure 1. Sampling areas of *P. virens*. Year of sampling 2009 (NS), 2010 (GM, GS), 2011 (IS), and 2012 (NOR, CS).

reached our lab preserved in ethanol. A geographic overview is given in Figure 1. More details are given in Table 3.

The three Norwegian samples (LO, FS, FN) only consisted of 10 individuals, each of which is a very small number for population genetic analyses. Because they came from a similar sampling area and had been collected within 2 days they were combined to one "Norway" sample (NOR, 30 individuals).

DNA Extraction and General PCR Conditions. DNA was extracted using the CTAB (cetyltrimethylammonium bromide) DNA extraction protocol.[33] The DNA concentration was adjusted to 10 ng/μL after fluorimetric quantification using Hoechst 33258.[34]

HOT FIREPol DNA Polymerase kits from Solis Biodyne (Cat. Nos. 01-02 and 02-31, Tartu, Estonia) and HotStarTaq Master Mix from QIAGEN (Cat. No. 203443, Hilden, Germany) were used for PCR. The reaction mixtures both contained Tris-HCl, $(NH_4)_2SO_4$ and detergents, 2.5 mM $MgCl_2$, 0.1 μM of primers (each), 200 μM dNTP mix, and 2 ng DNA/μL PCR assay; assay volume was 12 or 16 μL (depending on cycler requirements).

In RAPD-PCR, 0.16 μM primer (just one per reaction) was used. Reproducibility of DNA patterns was tested by repeating the PCR assays for three times with a set of 15 samples.

Gel Electrophoresis. Electrophoresis was carried out under different conditions: agarose gels and large homemade polyacrylamide gels.

Agarose gel electrophoresis was done using gels containing 2% (w/v) agarose; PCR products were visualized by staining with ethidium bromide (0.1 μg/mL final concentration).

Native PAGE for Msat Analysis. Large polyacrylamide gels (16 × 18 cm) were prepared according to Wang et al.[35] Total acrylamide concentration and duration of an electrophoretic run varied depending on allele sizes from 2.5 h, 8% to 4 h, 6.6%.

Gels were stained with silver and afterward scanned using a desktop scanner.[36] The sizes of the alleles were calculated semiautomatically by the software package QUANTITY ONE (version 4.6.8, BioRad laboratories, Inc.).

RAPD-PCR Analysis. The Random Primer Kit A (Art. No. HP22.1; Roth, Karlsruhe, Germany) was chosen for RAPD-PCR. The kit contains 20 different primers having a length of 10 nucleotides. All of the 20 primers of the Roth Random Primer Kit A were used for screening.

The PCR conditions were optimized according to Welsh and McClelland for better reproducibility:[37] preheating 95 °C/15 min, then 10 cycles of 95 °C/20 s, annealing temperature 1 (AT1)/40 s, 72 °C/90 s, followed by 30 cycles of 95 °C/20 s, AT2/40 s, 72 °C/90 s, and a final heating at 72 °C for 10 min; then the temperature was held at 10 °C. AT1 was 2−4 °C lower than AT2 (compare Table 1).

Reproducibility was checked by repeated analyses of a set of 14 samples for three times.

MSat-Analysis. All microsatellite markers, chosen from the literature, contained repeats of 4 base pairs. Furthermore, they were described to work with more than one gadoid species or successfully used in a study on Pollock (*Pollachius pollachius*).[38] Accordingly, 10 primers were selected originally described for *Gadus morhua* and 8 primers developed for *Theragra chalcogramma*.[31,39−41] The scientific name of Alaska Pollock recently changed from *Theragra chalcogramma* to *Gadus chalcogrammus* by taxonomical considerations.[42] Furthermore, two *Merlangius merlangus* primers were tested as well as single primers for *Macruronus magellanicus* and *Micromesistius poutassou*.[32,43,44]

PCR conditions were standardized using the following protocol: Initial denaturation (15 min 95 °C), followed by 35 cycles (20 s 95 °C, 40 s AT, 90 s 70 °C), and a final annealing (10 min 72 °C). Annealing temperature was taken from literature and varied within the test for every primer set.

Amplification was possible with 10 primer pairs (Tch18-F/R,[31] Tch20-F/R,[31] Gmo1-F/R,[39] Gmo24-F/R,[40] Gmo37-F/R,[48] Gmo46-F/R,[40] Gmo132-F/R,[39] Pop14c-F/R,[32] Pop18a-F/R,[32] Tch12-F/R[31]). Only Gmo24-F/R (AT = 52 °C), Gmo46-F/R (AT = 55 °C), and Pop18a-F/R (AT = 56 °C) showed variability typical for microsatellites.

These three primers were used for further analyses using large polyacrylamide gels as described above.

Data Processing: Statistical Analyses. For binary markers (RAPD, RFLP, SNP) the presence or absence of the chosen bands was determined by visual inspection and brought into a matrix. Thus, a binary pattern was evaluated for every individual. This matrix was used for analysis using GenAlEx.[45,46]

Expected and observed heterozygosity (H_e) was calculated per sample, per loci, and for all loci and all samples.

The population genetic structure between the samples was analyzed using two independent methods. Nei's genetic distance and F, R, and Φ statistics were computed using GenAlEx. The larger the value of Nei's D is, the larger is the difference between two samples. The resulting values are not to be seen on an absolute scale but should rather be compared within one study. Genetic differentiation analysis

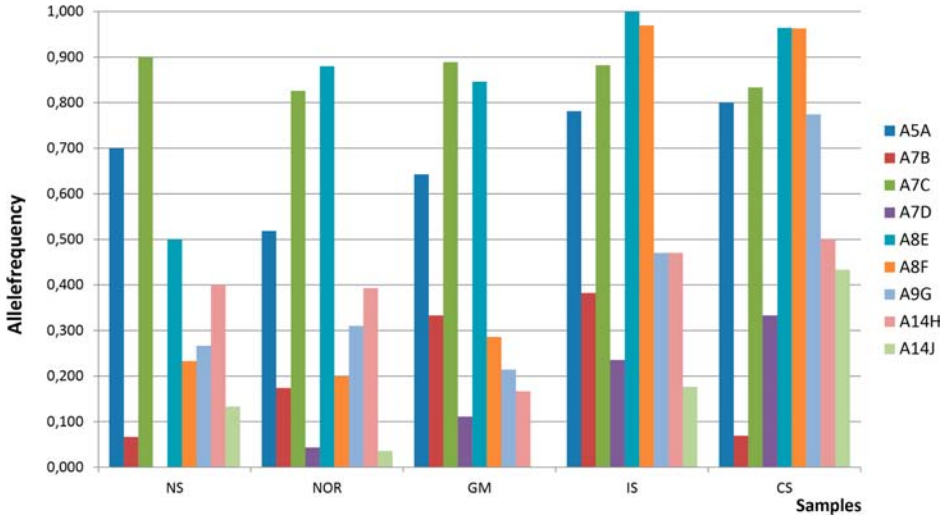

Figure 2. Differences in allele frequency among samples from different origin using RAPD-PCR. Detailed description of markers is shown in Table 1.

using Nei's D is based on similarities but does not differentiate between similarity by chance and statistically significant similarities. Values range from zero to infinity.

AMOVA is a distance-based analysis that allows the hierarchical partitioning of genetic variation among populations.[47]

Calculation of Φ_{PT} is similar to F statistics but a special adoption for binary and diploid data, while R statistics take into account the stepwise mutation model, which can be assumed for microsatellites.[45,46] Populations were tested for significant differentiation based on 999 permutations. Similar to Nei's D statistics a high similarity between samples leads to small values, while the p value gives the probability that two samples do not differ. Accordingly, $p < 0.05$ indicates significant differentiation and $p < 0.01$ can be interpreted as highly significant.

The matrices of Nei's D were used for construction of an UPGMA (unweighted pair-group method with arithmetic mean) dendrogram using the online tool of Edwards.[48]

RESULTS

RAPDs. Five primers were elected, providing nine variable alleles that matched our requirement regarding reproducibility (Table 1). The sample from location GS did not amplify with all primers and was withdrawn from analysis. The loci-specific data are shown in Table 1, pointing out that six out of nine alleles showed significant variation among samples, marked by an asterisk in column Φ_{PT}.

The differences in allele frequency among samples is outlined in Figure 2. The illustration was chosen to point out the fingerprinting character of this approach. A similar pattern also led to similarity detected by Nei's D (see Figure 4A) and Φ_{PT} statistics (see Table 4). The molecular variance among samples was 16% (Φ_{PT} = 0.159, p = 0.001).

MSats. Analyses of MSats were performed using large self-made polyacrylamide gels being suitable for MSat analyses.[35] Exemplary, a gel can be seen in Figure 3. A 25 bp ladder was used as a ruler for the sizing of the alleles. According to our experience a resolution of less than ±1% is not achievable using large self-cast gels. Therefore, it was necessary to choose 4 bp repeats in the project. The general problem was that locus Gmo24 provided alleles from 300 bp to 400 bp, so an error of 1% is the same size as one repeat. Furthermore, the long run times of 4 h, necessary to separate these larger alleles sufficiently, led to increased influence of laminary effects on the gel.

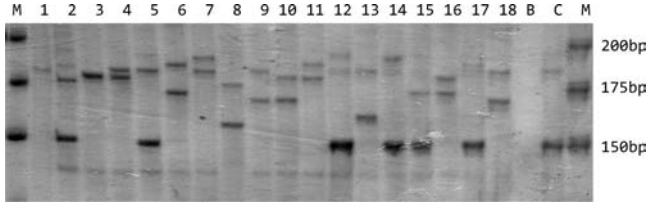

Figure 3. *P. virens* from the North Sea. Primer: Pop18a on a large self-cast polyacrylamide gel. M: DNA ladder 25bp, 1−18. Samples: B blind and C control sample.

The statistical data from the MSat analyses are shown in Table 2. Microsatellite analyses provide much higher statistical power than binary dominant markers.[27] Data analyses can treat every allele independently (F statistics) or take into account the stepwise mutation model (R statistics).[46]

The F_{st} values indicate very low but highly significant molecular variation among samples (2% among samples, 10% among individuals, and 88% within population), while the R_{st} values show higher differentiation (24% among samples, 7% among individuals, and 69% within samples). However, this differentiation is mostly caused by the primer Gmo24-F/R. Taking into account that the sizing at this locus provided the lowest reliability and R_{st} statistics are even more vulnerable to sizing errors than others, we concentrate on the F statistics for further interpretation.

Comparison of Population Genetic Data. Statistical data of all samples are shown in Table 3.

We are aware of the logical gap for applying the H_e value to dominant markers like RAPDs and RFLP patterns,[28] because differentiation between homozygotes and heterozygotes is not possible. Homozygous organisms carrying two identical copies of the same (dominant) allele provide the same pattern as if only one haplotype contains the dominant allele. Despite the fact that we show this value for comparison of our results with other publications, but we do not make any conclusions from this value.

The genetic distance was analyzed using Nei's D statistics. The results were transferred into an UPGMA dendrogram for visualization purposes and can be seen in Figure 4.

Results of AMOVA-based analyses of RAPD (pairwise Φ statistics) and MSat (pairwise Fst statistics) are shown in Table 4.

DISCUSSION

Data Assessment from a Population Genetic View. Because of the small number of samples the final number of populations stays unclear, but we observed two main clusters that were detected independently by RAPD and by MSat analyses: (i) One continental cluster containing samples NS and NOR and (ii) a second cluster containing samples IS and CS. However, Φ_{PT} and F_{st} statistics also detected significant differentiation within these clusters.

Despite samples NS and CS being both caught in waters belonging to the northern North Sea area (ICES Region IVa), both statistics indicate a definite differentiation between these samples. This is an indication that in the northern part of the North Sea probably more than one population is present.

The small numbers of individuals in the samples from Greenland does not allow an interpretation of this data.

Tagging studies revealed a close relationship between Norwegian and North Sea Saithe on one hand and between Faroese and Icelandic Saithe on the other.[16,17]

Eiriksson and Arnasson found only limited transatlantic genetic structure by sequencing a 460 bp fragment of the mitochondrial cytochrome *c* oxidase subunit I (MT-CO1) gene of 1162 individuals.[23] No differentiation between Canadian, Icelandic, Faroese, and Norwegian samples was found (F_{CT} = −0.0037, p = 0.93). A small but significant differentiation was found if female and male individuals were separated. Ogden described mitochondrial markers to be suitable for differentiation of species with a very limited gene flow for many generations, and the MT-CO1 gene especially is used as a barcoding gene due to its very low intraspecific variation.[11] Neutral nuclear loci like microsatellites provide higher potential of detecting regional genetic differentiation, which could explain the differences between these results.

A recent change in the migratory behavior of saithe as a consequence of large-scale salmon farming is indicated by a comparison of migratory behavior before 1990, when salmon farming started its exponential growth, and recent studies. There are indications that outward migration of young saithe from the Norwegian fjords is delayed or that the fish do not migrate offshore at all.[17]

Population Genetics as a Tool for Authentication Purposes. Population genetic research is always based on statistical analysis. It has to be kept in mind that genetic variation within a population is subject to constant change by genetic drift, despite this influence being very small in large populations.[49]

The application of population genetic methods for authentication purposes is actually only possible for a very limited number of species which have been studied in recent years as case studies like herring (*Clupea harengus*) and cod (*Gadus morhua*).[25] However, for many other species population genetic knowledge is very low.[12] Undoubtedly the goal is to develop methods suitable for routine analysis and validation between laboratories, because they are intended to be a tool for forensic argumentation. To gain this sufficient biological data are required regarding stock structure, habitats, and migration routes before development of markers suitable for routine analysis will start.

Thus, normally a biological study is the starting point, based on scientific samples with known origin, size, weight, and sex. Depending on the knowledge of a species, the first problem often is the tailoring of the study. We chose saithe as an example of a well-known fish, whose population structure is still not fully understood, despite a lot of tagging studies being made in recent decades.[16,17]

The methods available in population genetics can be divided into two groups: easy-access markers, which do not need species-specific development, and markers suitable for robotic testing.

Examples for easy-access markers are fingerprinting methods, like RAPD or AFLP, or locus-specific but not species-specific markers (like EPIC). Such markers are not suitable for routine analysis but can shed a first light on a genetic structure within a species, and they may provide a starting point for further marker development. Methods based on mitochondrial genes like MT-CO1 or cytochrome *b* are easy to access as well, but long evolutionary time is necessary before populations do differ.[4,11]

RAPD-PCR is still a powerful tool for low-cost population genetic studies.[27,28] Primer sets are commercially available, 10 bp long primers are cheap, and only simple agarose gels are necessary for detection. The major drawback is that this method is known for its reproducibility problems,[29] but these problems should be solvable within a single laboratory. PCR conditions, reagents (kits), and thermocyclers have to be kept constant for the whole study. We strongly recommend choosing the allele carefully and confirming their reproducibility. In conclusion, RAPD-PCR gives a chance for laboratories to provide a fast and cost-efficient impression of an underexplored species within a few months without employing large-scale sequencing technology. Thus, RAPD-PCR is a useful tool for prestudies that can help to plan a detailed working program. Detected variable loci can be sequenced and might provide an alternative source for development of species-specific markers.

We expected EPIC-PCR to be a very easy to access method as well. However, a large number of loci have to be checked to find suitable markers. The occurrence of pseudo genes bears problems. Cloning is an option for few samples but not for a large numbers of samples as required in population genetics. The resulting laborious optimization of markers stays in contrast to our idea of easy-access markers. If a group is working on many species in parallel EPIC might be a useful start. In our opinion EPIC is a powerful tool for development of species-specific markers, because SNPs and MSats are very likely to occur at introns, but they are not as easy to access as RAPD markers and being binary dominant markers too do not provide a higher statistical power.

For authentication purposes "markers suitable for robotic testing" are required, providing the chance for validated methods answering the question of origin within a few days.[4] Their development is very laborious and costly and requires a large number of sequences to be analyzed.[25,30] For a sufficient database a set of at least 5 microsatellites is required,[12] which we did not achieve in our study. For studies based on SNPs a much higher number of loci is necessary; because they provide only binary data, studies are often based on more than 50 single-nucleotide polymorphisms.[4]

The adoption of MSat loci from closely related species might provide a shortcut, but a lot of loci have to be checked. We tried 25 MSats loci described for fishes of the same family (*Gadidae*) finding that only three of them flanked a region containing Msats. Charrier made similar experience in a study regarding Pollock (*Pollachius pollachius*) detecting 6 MSat loci from testing 37 primers.[32]

Prestudies using easy-access markers are a tool on the way of marker development. They give an imprint of the genetic diversity of a species. This can help to tailor large-scale studies regarding the amount of markers and samples needed. Easy-access markers are also a suitable starting point for further marker development. If population genetics should be applied for authentication purposes development of species-specific markers is inevitable as well as validation of data in large-scale studies that also take into account long-term stability of markers and migration routes.

ACKNOWLEDGMENTS

We thank Heiða Pálmadóttir (MATIS, Reykjavík, Iceland) for organizing samples of Icelandic saithe for our study and Malte Damerau (Thünen Institut, Hamburg, Germany) for his guidance to population genetics.

ABBREVIATIONS USED

Sample Abbreviations

CS, commercial sample (Northern North Sea)
IS, Icelandic
NOR, Norwegian (LO, Lofoten; FS, Fugloybanken South, FN, Fugloybanken North)

DOI: 10.1021/jf506201m
J. Agric. Food Chem. 2015, 63, 802−809

NS, North Sea
GM, Greenland (middle)
GS, Greenland (south)

Other Abbreviations

AFLP, amplified fragment-length polymorphism
AT, annealing temperature
EPIC, exon primed intron crossing
MSat, microsatellites
MT-CO1, mitochondrial cytochrome oxidase 1
PAGE, polyacryl gel electrophoresis
RAPD, random amplified polymorphic DNA
SNP, single nucleotide polymorphism
FAO, Food and Agriculture Organization of the United Nations
ICES, International Council for the Exploration of the Sea
TAC, total annual catch

Rapid Discrimination and Feature Extraction of Three *Chamaecyparis* Species by Static-HS/GC−MS

Ying-Ju Chen,[†,‡] Chun-Ya Lin,[†] Sen-Sung Cheng,[§] and Shang-Tzen Chang*[,†]

[†]School of Forest and Resource Conservation, National Taiwan University, Taipei 10617, Taiwan

[‡]Division of Forest Chemistry, Taiwan Forestry Research Institute, Taipei 10070, Taiwan

[§]Experimental Forest, National Taiwan University, Nan-Tou 55750, Taiwan

ABSTRACT: This study aimed to develop a rapid and accurate analytical method for discriminating three *Chamaecyparis* species (*C. formosensis*, *C. obtusa*, and *C. obtusa* var. *formosana*) that could not be easily distinguished by volatile compounds. A total of 23 leaf samples from three species were analyzed by static-headspace (static-HS) coupled with gas chromatography−mass spectrometry (GC−MS). The static-HS procedure, whose experimental parameters were properly optimized, yielded a high Pearson correlation-based similarity between essential oil and VOC composition (r = 0.555−0.999). Thirty-six major constituents were identified; along with the results of cluster analysis (CA), a large variation in contents among the three different species was observed. Principal component analysis (PCA) methods illustrated graphically the relationships between characteristic components and tree species. It was clearly demonstrated that the static-HS-based procedure enhanced greatly the speed of precise analysis of chemical fingerprint in small sample amounts, thus providing a fast and reliable tool for the prediction of constituent characteristics in essential oil, and also offering good opportunities for studying the role of these feature compounds in chemotaxonomy or ecophysiology.

KEYWORDS: *VOCs, Chamaecyparis species, cluster analysis, principal component analysis, static-HS/GC−MS*

INTRODUCTION

The wood of *Chamaecyparis* is strong and fragrant, even-grained, and highly valued, with high-quality termite and decay resistance.[1,2] *Chamaecyparis formosensis* (Cf) and *Chamaecyparis obtusa* var. *formosana* (Cof) are two species belonging to the *Chamaecyparis* genus in Taiwan. They are the premier coniferous timber trees of the island. However, a critical habitat designation (along with cool temperatures and high moisture content) and shade intolerance led to minimal regeneration in established stand and decline of both species.[1] On a restricted habitat, these two species usually grow together, but with distinct overlapping elevation bands, Cf at lower elevations (850−2600 m) and Cof above it (1200−2800 m). *Chamaecyparis obtusa* (Co), another species belonging to *Chamaecyparis*, is also found in Taiwan. It has been highly valued and heavily exploited in Japan for centuries.[2−4] It is a tough task to differentiate the subtle characteristics among these three species, in contrast to strong chemical differentiation which was consistent also in specimens collected from sympatric populations.[5] Terpene composition of conifers is usually strongly inherited and has been widely used as a biochemical marker in chemotaxonomic studies to characterize plant species and their geographical or botanical origins.[6−8] In a previous study, the phylogenetic relationships of the *Chamaecyparis* were established, according to their chemical compositions of leaf essential oils, to account for the characteristic compounds of Cf, Cof, and Co, respectively.[7] Lin et al. (2011) subsequently demonstrated that solid-phase microextraction (SPME) could be a rapid technique for differentiating these three species.[9] However, the major feature compounds were not in good agreement with those of essential oils.

Static headspace (static-HS) is an ideal technique that has been proven to be an efficient and convenient sampling method.[10,11] It was in particular advantageous for the analysis of volatile compounds in intricate and heterogeneous matrices.[12] In the past decade, this technique has been employed to investigate various differences in aromatic profile, and to characterize components within different provenances, structures, or vegetative stages.[10,13−15]

The purpose of this study was to develop an accurate and stalwart technique, static-HS coupled with gas chromatography−mass spectrometry (GC−MS), and chemometrics to discriminate three *Chamaecyparis* species according to their feature volatile compounds. The experimental conditions are optimized, and comparative studies are conducted on the typical static-HS and conventional hydrodistillation profiles of leaf samples collected from different regions in the hope of confirming the applicability of the method developed for the chemical characterization of their volatile compounds and for the prediction of main compositions of essential oils in plants.

MATERIALS AND METHODS

Plant Materials. In the present study, fresh mature leaves of three species of *Chamaecyparis* (*C. formosensis* (Cf), *C. obtusa* var. *formosana* (Cof), and *C. obtusa* (Co)) were obtained from different locations in Taiwan. Depending on the availability and accessibility of trees, leaves of Cf were collected from trees growing in Huisun Experimental Forestry (2 trees), Dueigaoyue Tract (2 trees), Chiayi (2 trees),

Taichung (2 trees), and Chutung (single tree); Cof leaves were collected from trees growing in Mt. Chilan (single tree), Neimaopu Tract (single tree), Taichung (2 trees), and Chutung (3 trees); and Co leaves were collected from trees growing in Sitou (4 trees), Huisun Experimental Forestry (2 trees), and Hoshe (single tree). Samples were obtained by clipping the foliage from healthy noninfected trees of each species. Table 1 lists the coniferous leaf specimens studied. There are 23 trees sampled in current study, and each tree sample was extracted in triplicate. The composition data of all tree samples from the same location were averaged and given a sample ID, and therefore, a total of 12 samples are presented in the following results. Voucher specimens were deposited with the Laboratory of Wood Chemistry (School of Forestry and Resource Conservation, National Taiwan University), and the leaves studied were kept frozen at −80 °C until analysis.

Headspace Analysis Conditions. A PerkinElmer Headspace Turbomatrix 40 (PerkinElmer, USA) was used for headspace analysis. Fresh leaves were clipped into small pieces, and 20 mg samples were placed in 22 mL vials sealed with headspace PTFE-coated silicone rubber septa and caps (PerkinElmer, USA). To develop an optimal headspace procedure for the determination of volatile organic compounds (VOCs) from three *Chamaecyparis* species, key parameters such as equilibration time and temperature were adjusted. The headspace parameters are listed in Table 2.

Volatile Compound Analyses. Volatile compounds were analyzed using a Turbomatrix 40 headspace autosampler, connected to a Clarus 600 gas chromatograph mass spectrometer (PerkinElmer Inc.), equipped with a DB-5ms column (J&W Scientific, Folsom, CA). A chromatographic temperature program was run as follows: from 50 to 200 °C at 3 °C/min, then heating at 5 °C/min to 250 °C, and held for 5 min. Helium was used as the carrier gas at a flow rate of 1 mL/min. The temperatures of the injection port and transfer line were both 250 °C. The MS parameters were ionization voltage (EI), 70 eV; mass range, 45−400 amu; and ion source temperature, 230 °C. The Kovats indices (KI)[16] were calculated for all compounds using a homologous series of *n*-alkanes (C_9−C_{22}) on the DB-5ms column. Identification of individual components was performed using the Wiley/NBS Registry of Mass Spectral Database (version 7) and NIST MS Search (version 2), published literature, and several authentic reference compounds. Quantitative analysis was carried out using a Trace GC Ultra (Thermo Scientific, Waltham, MA) with an FID (Thermo Scientific). The temperatures of the injection port and the detector were 250 and 270 °C, respectively. The parameters of the column, split ratio, oven temperature program, carrier gas, and flow rate of GC-FID were identical to those of GC/MS. The quantity of compounds was obtained by integrating the peak area of the chromatograms, and quantification was performed using percentage peak area calculations using the GC-FID.

Table 2. Headspace Parameter Studied

thermostating temp	50 °C, 100 °C, 150 °C
thermostating time	30 min, 50 min
needle temp	more than 10 deg above thermo temp
transfer line temp	more than 10 deg above needle temp
pressurization time	0.3 min
injection time	0.02 min
carrier gas pressure	103.4 kPa

Statistical Analyses. Statistical analyses were performed using the SPSS program package (SPSS 17.0). Pearson correlation was performed to evaluate the significance and direction of an obtainable correlation between equilibrium time, temperature, and measurable variables (VOCs), and to determine the headspace parameters that achieve maximum correlation with compounds of essential oils. Data collected were subjected to analysis of variance (ANOVA), and the means were separated by the Scheffé test at $P \leq 0.05$. In addition, the method of Chen et al. was employed to evaluate the similarity of volatile compounds extracted from fresh leaves.[7]

The results were further processed with a discriminative study by cluster analysis (CA) and principal component analysis (PCA) to detect clustering formation and to establish the relationships between species and their volatile components. PCA biplot was utilized to highlight the interaction between samples and variables.[17] CA and PCA were performed using the MVSP software (Multivariate

RESULTS AND DISCUSSION

Optimization of HS Parameters. Series of preliminary tests had been made for optimizing the experimental conditions of sample preparation and instrumental analysis. To elaborate on mutual relationships between the quantities of compounds or classes of components in the essential oils and VOCs extracted by HS technique, the static-HS analysis was optimized by studying the effects of the relevant experimental parameters (equilibration time and temperature) on the volatile composition profile. Furthermore, to screen for optimal parameters under which the volatile composition profiles correspond well with essential oils, the two databases were integrated and correlation analysis between the essential oils and the volatile composition database was performed. As shown in Table 3, at HS equilibrium time of both 30 min and 50 min and oven temperature of 50 °C, a highly significant positive correlation (Pearson's $r = 0.961-1.000$, $P < 0.001$) occurred

DOI: 10.1021/jf505587w
J. Agric. Food Chem. 2015, 63, 810−820

between the leaf volatile composition and essential oil component of Cf. As for Cof, leaves from Chutung showed good statistical significance (Pearson's $r = 0.863$, $P < 0.001$) between volatile components and essential oil composition at HS equilibrium time of 50 min and oven temperature of 150 °C, while volatiles extracted from leaves collected at the other three locations also showed a statistically significant positive correlation (Pearson's $r = 0.759-0.849$, $P < 0.001$) with their essential oils. Regarding Co, leaves from Sitou equilibrated at oven temperature of 150 °C for 50 min showed a highly significant positive correlation (Pearson's $r = 0.906$, $P < 0.001$) between the volatiles and essential oils, while volatiles extracted from leaves collected at Huisun and Hoshe exhibited significant correlations (Pearson's $r = 0.817-0.866$, $P < 0.001$) with essential oil on HS at oven temperature of 100 °C for equilibrium time of 50 min.

According to previous research, the leaf essential oils of Cf contained a predominance of monoterpene hydrocarbons. As for the essential oils of Cof, sesquiterpene hydrocarbons and oxygenated sesquiterpenes constituted the major fractions; while monoterpene hydrocarbons and oxygenated monoterpenes accounted for the largest fractions in the oils of Co.[7] Taken as a whole, the essential oil components found in Cof and Co had higher proportion of polar compounds, and their molecular weights were higher than those of compounds found in Cf. The reason that Cof and Co have higher boiling points than Cf might be the additional energy required to break the hydrogen bonds for vaporization of the molecules. Alternatively, the association of molecules through hydrogen bonding increases the molecular weight, thereby reducing volatility.[18]

In addition, as seen in Table 3, the equilibrium temperature seems to be a much more important factor than equilibrium time on volatile composition profiles. All samples treated at equilibrium time of 50 min and oven temperature of 150 °C showed good correlation (Pearson's $r > 0.555$) between VOCs and essential oils. Terpenes are the main volatile components of plant essential oils. Several studies have been conducted on the bioactivities of essential oils and some of their major constituents.[19,20] The bioactivities of essential oils are attributable to monoterpenes, sesquiterpenes, and other hydrocarbons.[21] For "biomining", the experimental parameters obtained in this study could be employed to screen for unraveled species, which might have economic or potential bioactive compounds. According to an overview published by Goren et al.,[22] the higher the equilibrium temperature, the greater the number of compounds were detected in the chromatogram. The optimum sample temperature (200 °C) for analyzing *Satureja trhymbra* was determined by the maximum number of compounds detected.[22] However, the correlations between essential oils and volatile profiles were not examined by statistical tests.

Volatile Organic Compound Analyses. To investigate the VOCs extracted from three *Chamaecyparis* species (Cf, Cof, and Co), a static-HS was employed to extract the volatile compounds from fresh leaves and the composition of VOCs was then analyzed using GC-FID and GC/MS. From the static-HS/GC–MS chromatogram (Figure 1), 24 apparent peaks were detected and there were significant differences among the volatile components patterns of these three *Chamaecyparis*. The volatile components identified were separated into five categories, i.e., monoterpene hydrocarbons, oxygenated monoterpenes, sesquiterpene hydrocarbons, oxygenated sesquiterpenes, and others. Integrating the GC-FID peak areas of individual constituents showed that the leaf VOCs of Cf contained a predominance of monoterpene hydrocarbons (98.23–99.82%), among which α-pinene (89.30–96.90%) was the main constituent, followed by β-myrcene (0.82–4.70%) and β-pinene (1.94–3.44%) (Table 4). For Cof, sesquiterpene hydrocarbons (52.29%, 44.46%) and oxygenated sesquiterpenes (30.95%, 42.20%) constituted the two major fractions in the VOCs of leaves collected from Taichung and Chutung, respectively. These were in agreement with the constituents in leaf essential oils.[7] As for the VOCs of leaves collected from Mt. Chilan, sesquiterpene hydrocarbons (74.96%) constituted the major fraction, while sesquiterpene hydrocarbons (57.03%) and monoterpenoids hydrocarbons (32.04%) accounted for the largest fraction in the VOCs of leaves collected from Neimaopu. Variations in VOC composition of Cof leaves collected from four locations were observed; since leaves were collected from Taichung and Chutung in the same season and with similar environmental factors—high altitude (2037–2205 m) and low temperature (6.5–8 °C)—they had relatively higher contents of sesquiterpenes compared to the other two locations. A similar variation in VOC composition was also observed for Co leaves collected from different locations. Even though three Co samples have similar altitude distribution, leaves collected from Huisun and Hoseh, with higher temperature (22.7–23.5 °C), were characterized by higher contents of monoterpenes. Chemical compositions of secondary metabolites typically affected by different factors, such as temperature, precipitation, light, and growing site, might alter the qualitative/quantitative amount of the volatile composition. Season is related to a combination of these environmentally regulated factors.[23] In the present study, most of the samples were collected in winter and summer, and such environmental information (Table 1) is insufficient to provide an adequate basis for analyzing the environmental influence on the chemical variations. A further investigation concerning correlation between chemical composition and seasonal variation is warranted.

The VOCs extracted from Cof leaves contained primarily thujopsene (30.35–49.77%), β-elemol (0.87–28.60%), sabinene (1.03–14.97%), *cis*-thujopsenal (0.00–14.72%), and β-himachalene (0.61–9.43%). In addition, *cis*-thujopsenal was found mainly in VOCs extracted from leaves collected at Mt. Chilan, β-elemol was found primarily in VOCs extracted from leaves collected at Taichung and Chutung, and thujopsene was the dominant compound in VOCs from leaves collected at all locations. These results are similar to previous findings, in which the major/characteristic compounds of leaf essential oils from Cof are thujopsene (Taichung), β-elemol (Chutung), and *cis*-thujopsenal (Mt. Chilan). As for Co, the leaf VOCs comprise mainly sabinene (8.55–24.58%), α-terpinyl acetate (16.98–23.50%), L-bornyl acetate (6.48–11.38%), β-elemol (0.51–11.95%), and thujopsene (2.81–9.78%). These data are also in agreement with previous findings;[7] the leaf essential oil of Co was characterized by α-terpinyl acetate and L-bornyl acetate. To sum up, the leaf compositions of these three *Chamaecyparis* species extracted using the static-HS technique correspond well to those from hydrodistillation (i.e., essential oils).[7]

Multivariate Data Analyses. To investigate the variation in compositions of VOCs among three *Chamaecyparis* species, the data in Table 4 were examined using CA. The resulting dendrogram shows the existence of three major clusters (Figure

[d]Identification according to comparison of mass spectrum (MS), Kovats index (KI), and coinjection with standard compounds (STD). [e]Species sharing the same letter are not significantly different in relative content (Scheffé, $P = 0.05$).

2). The first group, Cof, comprised Neimaopu, Chutung, Taichung, and Chilan areas, and the similarity between these samples was 48.17%. The second group (Co) was composed of Hoshe, Huisun, and Sitou areas, and the similarity within this group was 59.01%. The third group (Cf) included Chutung, Taichung, Chiayi, Dueigaoyue, and Huisun areas, and the similarity within this group was 94.97%. There was only a 25.12% similarity between Co and Cof, revealing that these two species were considerably different. Furthermore, the similarity between Cf and these two species was significantly low, only 4.01%. These results are not only in good agreement with our previous findings but also in accordance with morphological and genetic classifications.[24,25] In addition, PCA was also performed to differentiate the data listed in Table 4. The results of the PCA score plot (Figure 3) indicated that PC1 and PC2 explained 84.77% and 10.52%, respectively, of the total variance. PCA can be quite useful in visualizing the relationships between responses of characteristic components in different species. As reported in the "Biplot Analysis" (Figure 3), the distribution of the groups indicated significant statistical differences among the different species. The PCA mapping clearly distinguished the samples according to their dominant volatile compounds, and they were clustered into three groups. The species Cf belongs to the group with a high content of α-pinene, while the other two species Cof and Co cluster in the opposite part of the graph since they contain only small amounts of this component. By contrast, the second group, Cof, contains high levels of thujopsene and β-elemol. The last group includes the species Co that contains higher contents of α-terpinyl acetate, L-bornyl acetate, sabinene, and limonene. These results showed that the above-mentioned compounds could be useful indicators for distinguishing Cf, Cof, and Co. Although it has been demonstrated that essential oil or SPME technique could be employed to discriminate these species, static-HS, compared with a conventional technique, hydrodistillation, involves shorter extraction time (50 min against 6 h for hydrodistillation) and lower energy cost. Furthermore, static-HS can accurately perform the essential oil/VOC compositions for different species, while the SPME technique shows highly selective adsorption toward chemicals, with the results slightly different from the real chemical profiles, even though it is a feasible and rapid technique for differentiating *Chamaecyparis* species.

It is notable that the major limitation of static-HS is that the concentrations of volatiles in the vapor phase were dependent on the partition coefficients. The sensitivity of headspace analysis is directly affected by the vapor pressure and boiling point of analyzed compounds. High and medium volatile compounds, such as monoterpene and sesquiterpene, usually have a reliable reproducibility; high-molecular-weight compounds, as well as tightly bound and encapsulated volatiles, are usually not suitably analyzed by headspace system.[26,27] The utility of headspace technique depends on whether the target analytes have enough concentration in a small amount of gas sample to be detected reliably by GC, due to limited capacity of gas chromatograph injection port (0.1−2.0 mL). One part per million (ppm) may be assayed in a reproducible way in general analytes (in some practical terms will reach ppb level) using this technique, but the technique is still less sensitive when compared to the purge and trap method (ppt level).[28] Equilibrium of volatile compounds in the headspace is highly temperature dependent. Elevating the temperature of the sample can assist in achieving equilibrium more quickly by

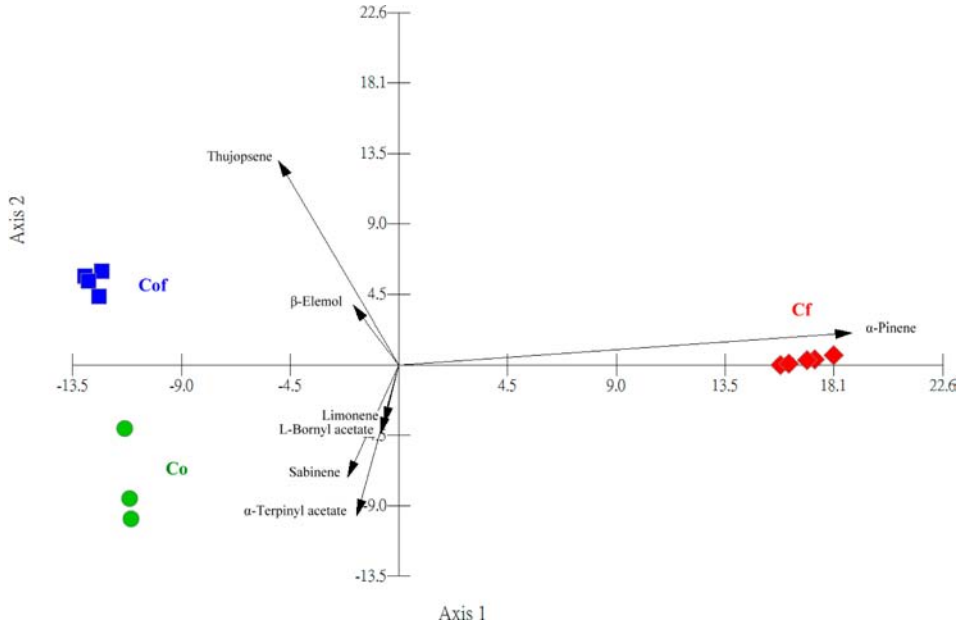

Figure 3. Biplot for PCA (principal component analysis) carried out on volatile compound contents of three *Chamaecyparis* species.

increasing the volatility of the analytes. Some sample matrices, such as oil samples, require higher temperature (160−200 °C) and longer equilibration times due to the slower diffusion rate in viscous or fusible crystalline systems.[26] However, in this experiment, 100−150 °C equilibrium temperature has shown a good correlation and identical chromatogram between VOCs and essential oils for most samples. It demonstrated that selectivity and loss of heavy compounds were not diminished with static-HS sampling in this study. In particular, static-HS has also been shown to be a good technique for agricultural quality management, such as bioactive components of medical plants and aroma quality control of grapes, by discriminating the characteristic compounds being used as indicators of different harvesting times/maturation stages.[11,29] These applications demonstrated that static-HS is a reproducible and reliable technique used in biochemical research and quality management.

Secondary metabolites (e.g., terpenoids and alkaloids) play important ecological roles in the relation of plants to their environment adaptation. Some kinds of phytochemical data are likely to be meaningful in determining phylogeny.[30] Terpenoids constitute an important class of secondary plant compounds that are further classified into various groups such as monoterpenoids (C_{10}), sesquiterpenoids (C_{15}), diterpenoids (C_{20}), triterpenoids (C_{30}), tetraterpenoids (C_{40}) and poly-C polyterpenoids. These compounds have been used in plant taxonomic studies, such as specific and subspecific distinction, geographic races, and hybrid detection.[31,32] Volatile monoterpenoids and sesquiterpenoids, the major components of essential oils, are the compounds most commonly used in taxonomy. For *Juniperus* (Cupressaceae), many studies have been conducted to determine the intraindividual, ontogenetic, seasonal, and population variations in these compounds.[32] Therefore, biochemical characteristics of plants have been employed taxonomically for a long time, and chemical compounds can be analyzed quantitatively using gas chromatography by integrating areas under the peaks for each compound, and qualitatively, which has been used extensively

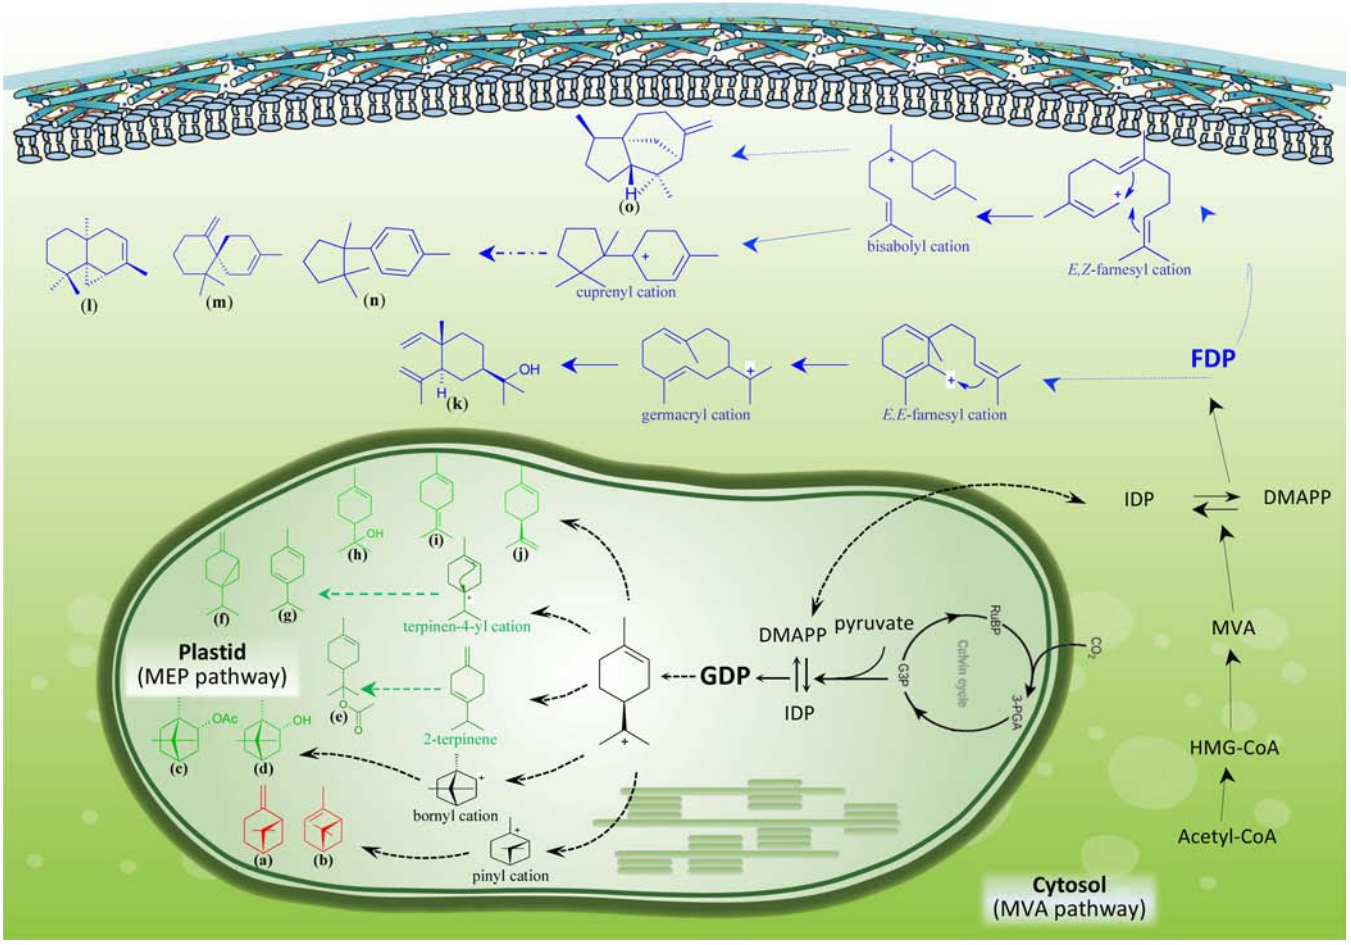

Figure 4. Biosynthetic pathway of the minor characteristic compounds from three *Chamaecyparis* species: (a) β-pinene; (b) α-pinene; (c) bornyl acetate; (d) L-borneol; (e) α-terpinyl acetate; (f) sabinene; (g) γ-terpinene; (h) α-terpineol; (i) terpinolene; (j) limonene; (k) β-elemol; (l) thujopsene; (m) (−)-β-chamigrene; (n) (+)-cuparene; (o) (+)-β-cedrene.

in plant systematics, using analyses of infraspecific variations to determine phylogenetic relationship of families and other high-level taxonomic groups.[31−33]

Characteristic Compounds. In addition to the aforementioned results, α-pinene, (−)-thujopsene, and α-terpinyl acetate play important roles as leading discriminators for distinguishing Cf, Cof, and Co. A few minor compounds also showed significant differences ($p < 0.05$) of relative abundance between these species. As can be seen from Table 4, sabinene, β-pinene, limonene, γ-terpinene, terpinolene, L-borneol, α-terpineol, L-bornyl acetate, α-terpinyl acetate, (+)-β-cedrene, thujopsene, (−)-β-chamigrene, and (+)-cuparene showed statistically significant difference between the three species, among which, for β-pinene, Cf had the highest content (1.94−3.44%), while the other two species had only rare contents. As for sabinene (8.55−24.58%), limonene (4.10−10.39%), γ-terpinene (2.09−3.57%), terpinolene (0.50−1.01%), L-borneol (0.08−0.20%), α-terpineol (0.15−0.27%), and L-bornyl acetate (6.48−11.38%), the species with a relatively high content of these compounds is Co. In the same way, for (+)-β-cedrene, (−)-β-chamigrene, and (+)-cuparene, Cof had the highest content among these three species. All characteristic compounds are widely occurring in coniferous trees as a constituent of essential oils. Various bioactivities have been demonstrated, such as inhibiting root growth of weed species,[34] antimicrobial and antioxidant properties,[35] and usage as an anticancer agent.[36] Some trends in distribution of terpenoids in distinct conifer families may already be observed and can be taken as valuable chemical characteristics, i.e., cedrene, chamigrene, and cuparene were usually associated with Cupressaceae.[37] Furthermore, β-pinene and γ-terpinene were assumed to be responsible for water stress in various studies.[20,38−40]

Interestingly, in terms of the biosynthesis pathway, these characteristic compounds associated with Cof were essentially derived from the mevalonate (MVA) pathway, while the compounds belonging to both Cf and Co were derived from the methylerythritol phosphate (MEP) pathway (Figure 4). MVA and MEP were two independent pathways for the biosynthesis of isoprenoid (also referred to as terpenoids) precursors coexisting within the plant cells.[41] The MVA pathway supplies acetyl CoA-derived precursors for the production of sesquiterpenes and triterpenes in cytosol, whereas the MEP pathway provides pyruvate-derived IPP and DMAPP for the biosynthesis of monoterpenes, diterpenes, and tetraterpenes in plastid.[42] Terpenoids characterize the greatest variety of metabolites with great diversities in structures and functions.[43] Monoterpenes and sesquiterpenes act as natural defense agents and are involved in communications between plants and their environments.[44] In many plant species, diterpenes and sesquiterpenes also act as phytoalexins.[45] They fulfill the same role but have some functional differences.[46] Terpenoids have a myriad of functions in ecological

DOI: 10.1021/jf505587w
J. Agric. Food Chem. 2015, 63, 810−820

interactions of living organisms. It is generally recognized that the most abundant compounds associate with activity toward pollinators, herbivores, or herbivore enemies. According to recent research perspectives, compounds present in minor amounts rather than major members of volatile blends are responsible for their biological activity.[47]

Furthermore, some terpenoids and primary metabolites function as antioxidants and play important roles in photosynthesis, with regulation of growth and development[48] attributed to the MEP pathway.[44,49] Many studies have confirmed that photosynthesis is the major source for the synthesis of IPP for MEP-derived terpenoids. Compared with the MVA pathway, the MEP pathway was closely connected with sugar metabolism.[50] On the other hand, plants treated with MEP or MVA pathway-specific inhibitors confirmed that the MVA pathway functions for plant development, and the MEP pathway functions for pigment formation in young tissues.[50] It was suggested that allocation of resources varies by species, and depends especially on the specific chemical defensive compounds produced.[51] Depending on species, phenological stages, ages, and genetics, plants might increase growth, secondary metabolite production, or combination of both in response to varied nutrients.[52] Terpenoids constitute the most diverse group of natural products, and have been used as models for the study of the evolution of chemical functions and of the ecological impacts of evolutionary change.[53] According to the distribution of habitat type and our preliminary experiment, Cof and Cf exhibit different characteristics of water use. It is worth further investigation to examine whether the characteristic compounds' coming from the MEP or MVA pathway would influence the plants' habitat adaptation.

In spite of inconsistent findings on a possible relationship between abiotic stress and essential oil quality,[40] the significant changes in relative contents could be a defense mechanism and a biochemical adaptation to environment constraints.[20] The potential relationship between these characteristic compounds and the regional distribution or evolution in these three *Chamaecyparis* species warrants more in-depth study.

In conclusion, the present study provides a novel strategy for objective discrimination of three *Chamaecyparis* species, according to the potential volatile compounds analyzed by static-HS/GC−MS. The parameters affecting the extraction efficiency were optimized. Besides being useful in chemotaxomical studies, this method opens new opportunities for estimating or determining the leaf essential oils of uninvestigated species. Additionally, chemometric methods, like one-way ANOVA, CA, and PCA, can highlight significant differences between the indiscernible species. For complete functional characteristics of feature compounds, further research is required to ascertain the possible correlation between chemical markers, environmental factors, and the evolution of the genus *Chamaecyparis*.

Supporting Information

ABSTRACT: Precise and accurate quantitation of maize grain allergens is important for seed and food industries. The major allergen in maize grain is Zea m 14, a lipid transfer protein (LTP). The B73 maize genome encodes for at least six LTPs sharing 15%−87% sequence identity to Zea m 14. Phylogenetic analysis of the maize LTP family revealed one gene that corresponds to Zea m 14 (denoted as LTPa) and two other genes sharing 43% (LTPc) and 74% (LTPb) identity with Zea m 14 that are putative homologues. Using stable isotope peptide mimics as internal standards for LTPs, we present a multiple reaction monitoring mass spectrometry approach for multiplexed, absolute quantitation of all three LTP proteins and alternative transcript models therein. To validate quantitative accuracy, a redundant peptide, simultaneously representing the two most abundant LTPs, was included. Analysis of 21 maize varieties revealed LTPa was most prominently expressed in maize grain, ranging from 9 to 32 μg LTP/mg protein. Proteins belonging to the LTPb and LTPc gene models were also expressed but at approximately 10- and 100-fold lower levels than LTPa, respectively. The quantitative results provided by the redundant peptide show around 95% agreement with the sum of the two unique peptides, thus providing support for the LTP gene models and validating the accuracy of this method. Though not all Zea m 14-related LTPs are abundant in grain, their high sequence homology and detectable expression in maize grain signify that LTPb and LTPc are putative allergens and should be accounted for in any quantitation strategy for maize LTP allergens.

INTRODUCTION

Reports on the food allergenicity of maize grain are few despite significant maize consumption on a global basis.[1,2] Some cases of allergenicity to maize have been reported;[3−8] though not all cases can be confirmed as representing true food allergenicity. For example, research by Jones et al.[7] and, separately, Pasini et al.[9] have found that less than half of subjects with positive skin prick tests (SPT) or CAP-FEIA (fluorescence enzyme immunoassay) to maize reacted clinically to an oral challenge. In 2000, Pastorello et al. discovered a salt-soluble IgE-binding component of maize flour, a 9 kDa protein, Zea m 14, and suggested it represents the major allergen of maize responsible for food induced allergic reactions.[3] Zea m 14 was identified as lipid transfer protein (LTP), a ubiquitous protein belonging to the pathogen resistant group of plant proteins. Sera from 86% of patients with systemic symptoms after maize grain ingestion and positive SPT exhibited immunoreactivity to this 9 kDa protein.[3,10] LTP is now acknowledged to be the major allergen in maize grain.

At the cellular level, LTPs are generally located in the apoplast, and most of these proteins contain eight conserved cysteines forming four disulfide bridges, which make them highly resistant to loss of transfer function at high temperature or pH changes.[11] As a group, plant LTPs display a high degree of structural homology, as revealed by sequence alignment and hydrophobic cluster analysis.[12,13] In 1994, a unifying nomenclature for pathogenesis-related proteins (PRs) was proposed on the basis of their sequence, enzymatic, or biological activity.[14] Recently this list has been extended to contain 14 families, including the PR-14-type proteins referred to as LTPs.

Expression analysis by immunoblotting of Zea m 14, based on IgG polyclonal antibody detection specific for an LTP peptide, indicated that its abundance varies in mature grain from various maize hybrids grown under different conditions. Significant differences in relative LTP abundance (up to 10-fold differences) between maize hybrids were demonstrated and occurred across a greater range (up to 20-fold) in nonirrigated plots, indicating differences in allergenic potential.[15,16] The natural variation in protein allergen expression in food crops is in part due to differences in the genetic backgrounds of commercial nongenetically modified (GM) varieties, and interactions with the environment such as nutrient and water availability, differences in moisture, temperature, plant pathogens, harvest timing, and storage conditions.[17] Recent work in soybean shows that both genetics and environmental differences contribute to allergen expression levels, with environment playing the larger role among related breeding lines.[18] Although LTPs from botanically related plants share IgE-binding epitopes,[19] it has been shown that patients allergic to LTPs show a high variability in the IgE reactivity to vegetable

foods, including maize.[15] However, at present it remains unclear how patient allergy to maize LTP may vary in response to the actual exposure levels in various maize-derived foods.

The technical objectives for developing a LTP detection method were focused on verifying the number of related LTP isoforms and whether these can be quantified individually with precision, reliability, and accuracy. Currently there is no rapid quantitative method for analyzing multiple isoforms of LTP in a multiplexed manner. Western blot analysis represents a well-established, robust, and reliable method to accurately detect specific proteins within a multitude of matrix compounds, such as those found in seeds, including endogenous allergens in their host plant matrices.[20,21] LTP was first characterized by IgE-binding studies using the Western blot format.[22] Typically, LTP has been studied with human serum and detecting IgE antibody binding, as is the case with most allergens for the purpose of characterizing patient responses, as well as identifying newly discovered protein allergens. However, for the purpose of characterizing LTP content (and isoforms therein) in maize, a more selective and accurate analytical approach is desirable and may be preferred for supporting further study of all related LTP isoforms and their content in foods, allergen preparations (used for clinical allergy studies), and GMO plants (as a means to identify allergen risk).

MATERIALS AND METHODS

Reagents. All reagents were purchased from Research Products International Corp. (Mount Prospect, IL, USA) unless stated otherwise. Organic solvents were purchased from Sigma-Aldrich (St. Louis, MO, USA) unless stated otherwise. AQUA peptide standards, containing either a C-terminal heavy lysine or arginine, were custom synthesized by Sigma Life Science Custom Products (The Woodlands, TX, USA).

LTP Homology Assessment. Phylogenetic analysis was performed using the "One-click" Phylogeny.fr.[23] Pairwise alignments were performed using ClustalO on UniProtKB (http://www.uniprot.org/uniprot/), and percent identity values were recorded.

Maize Grain Samples. The goal was to develop LTP analytical capability using a broad sampling of maize across various breeding backgrounds and production locations under varying environmental conditions. Samples of grain (approximately 50 g of whole grain) were taken as subsamples from bags of mature and harvested maize. The maize varietal characteristics and breeding histories were not taken into account in the LTP analysis in this work in terms of data interpretation. Supporting Information (SI) Table 1 is provided to show the variety of production years, hybrid varieties, and production locations.

Protein Extraction. Total protein was extracted from a sample subset of five maize kernels from each maize variety. Five replicates were prepared for each variety. Each sample was homogenized and total protein was extracted using a phenol partition protocol[24] modified for smaller volumes. Briefly, five maize kernels from each replicate in each variety were weighed and pulverized for 30 s using a 50 mL Waring blender. One hundred milligrams (±5 mg) were portioned for each sample, which represents a single biological replicate. Extraction buffer (1:1 mix of sucrose buffer (0.9 M sucrose, 100 mM Tris-HCl pH 8.0, 10 mM EDTA, 0.4% ß-mercaptoethanol) and Tris buffered phenol (pH 8.0) were added to each sample in a 1:60 ratio (mL buffer: mg sample). Samples were shaken for 1 h at 4 °C using a Bead Ruptor 24 (Omni International, Kennesaw, GA, USA) on speed 1. Sample tubes were centrifuged at 17000*g* at 4 °C for 5 min in a benchtop centrifuge. The upper phenol phase was transferred to a new tube and was back extracted with 1 volume of fresh sucrose buffer by vortexing lightly at room temperature for 5 min and repeating the centrifugation step above. The phenol phase was removed and protein precipitated with five volumes of ice-cold precipitation solution (0.1 M ammonium acetate in 100% methanol). The samples were vortexed and incubated for 16 h at −20 °C to precipitate the protein. Protein was pelleted by centrifugation at 4000*g* for 10 min at 4 °C and then washed twice with 1 mL of 0.1 M ammonium acetate in methanol, twice with 1 mL of ice-cold 80% (v/v) acetone in water, and once in 1 mL of 70% (v/v) ethanol in water. Protein pellets were stored in 0.5 mL of 70% (v/v) ethanol at −20 °C. Each of the five replicates was analyzed separately using mass spectrometry.

Preparation of Samples for AQUA-MRM. Protein was dissolved in a chaotrope-containing buffer (8 M urea, 50 mM Tris-HCl, pH 8.0) followed by quantification using the Bradford assay (Bio-Rad Laboratories Inc., Hercules, CA, USA) with bovine gamma globulin standard (2 mg/mL, Bio-Rad). Maize protein was portioned (20 μg/sample) and spiked with AQUA peptides (dissolved in 50% (v/v) acetonitrile (ACN), 1% (v/v) formic acid) at 50 fmol/μg, prior to chemical treatment. Protein was reduced by adding dithiothreitol (DTT) to 10 mM and incubated for 1 h at RT. Alkylation was performed by adding iodoacetamide (IAA) to 50 mM and incubated at RT in the dark for 1 h. Urea was diluted and IAA neutralized by adding 3 volumes of a solution containing 10 mM ammonium bicarbonate and 10 mM DTT. Trypsin (Promega, Madison, WI, USA) was added to sample protein at a 1:49 ratio and digestion proceeded for 18 h at 37 °C. After digestion, samples were frozen at −80 °C and evaporated to dryness using a Centrivap (ThermoFisher Scientific, Waltham, MA, USA). Dried protein digests were dissolved immediately prior to mass spectrometry analysis to a concentration of 0.40 μg/μL with 5% (v/v) ACN, 0.1% formic acid (v/v) in water.

Verification of Complete Protein Digestion. Trypsin digests of proteins were qualitatively assessed by SDS-PAGE and staining with colloidal Coomassie Brilliant Blue dye (CBB). Briefly, digested protein remaining from the samples used for the AQUA-MRM analysis was combined from the five sample replicates and lyophilized to dryness. Remaining undigested protein from samples prepared for AQUA-MRM analysis was also pooled from the five sample replicates. Both undigested and digested samples were diluted or dissolved, respectively, with SDS-PAGE sample buffer to 1 μg/μL, based upon calculations prior to digestion. Twenty-five microliters (25 μg) was loaded into wells of Any kD Mini-PROTEAN TGX PAGE gels (Bio-Rad Laboratories Inc., Hercules, CA, USA). PageRuler Plus (Thermo Scientific, Carlesbad, CA, USA) was used as protein standard. Gels were resolved as recommended by the manufacturer, until the dye front was ∼1.0 cm from the bottom of the gel. Gels were stained overnight with CBB and destained in water for 6 h before imaging.

Sample Preparation for Discovery Analysis. To assess the LTP component in maize kernels, four representative kernel varieties were assayed using two complementary untargeted "discovery" proteomics workflows: GeLC and in-solution digestion. Protein for these experiments was extracted, dissolved, and assayed for concentration as described in *Protein extraction* and *Verification of complete protein digestion*. Fifty micrograms of protein from each variety was either digested in-solution (without AQUA addition) or resolved by SDS-PAGE. SDS-PAGE and in-solution digestion were performed as described in *Verification of complete protein digestion* and *Preparation of samples for AQUA-MRM*, but using Precision Plus protein standard for SDS-PAGE (Bio-Rad Laboratories Inc., Hercules, CA, USA). For in-gel digestion, the stained region between 20 kDa and 10 kDa was excised and processed as in ref 24.

Discovery Mass Spectrometry. Discovery LC-MS/MS was performed with an Orbitrap mass spectrometer (Thermo Fisher Scientific, Bremen, DE). Resolution settings were 30,000 for MS1 (m/z range of 300−2000) and unit resolution for MS2 acquisitions. Data-dependent acquisition was employed using one MS scan followed by nine MS2 scans for the nine most abundant ions, with dynamic exclusion enabled. Peptides were concentrated and desalted in-line using a C_8 CapTrap, peptide trapping cartridge (Michrom Bioresources, Auburn, CA USA) prior to MS analysis. HPLC separations were performed using in-house fused silica nanospray needles, 10.5 cm length, (360 μm outer diameter, 150 μm inner diameter; Polymicro Technologies, Phoenix, AZ USA), that were packed with "Magic C18AQ" (200 Å, 5 μm particles; Michrom

Figure 1. Sequence homology of LTPs found by LC-MS/MS showing relatedness to Zea m 14 (sp|P19656). (A) Phylogram of the top maize proteins (translated gene sequences) identified during the discovery experiment. Zea_m14_sp_P19656_1 and 2 represent the two isoforms of UniProt entry P19656, both of which are recognized as LTP allergen Zea m 14. Other entries containing T01 and T02 indicate putative, annotated splice variants. Numbers at branch points are branch support values. (B) Pairwise Clustal Omega percent identity scores from alignments performed between Zea m 14 isovariant 2 and the other listed accessions. LTPs in gray have greater than 42% sequence identity with Zea m 14−2 and were given an abbreviation (Abbv column) to simplify nomenclature. These same LTPs were also clustered together phylogenetically (shown in A).

Bioresources) with an ACN gradient from 2 to 45% ACN over 80 min, followed by 17 min for column washing and equilibration. RAW files were searched using SEQUEST (v 1.20) via Proteome Discoverer (v 1.3.0.339) with three databases: UniProt/SwissProt (November, 2012), B73 genome (5b.60, maizesequence.org), and Zea maize UniGene translated transcriptome (Zm166, via NCBI) with carbamidomethylation as a fixed modification for cysteines, methionine oxidation as a variable modification, a parent ion mass tolerance of 20 ppm, and a fragment ion mass tolerance of 0.80 Da. Results were filtered using mass accuracy and confidence filters of 10 ppm and high, respectively.

Targeted AQUA-MRM Mass Spectrometry. Targeted mass spectrometric analysis was performed on a column with 2 μg of protein digestion and a 5 μL loading volume. The linear range of the endogenous analyte was assessed from the maximum possible loading amount, 2.4 μg/injection to 0.0038 μg/injection by 5-fold serial dilutions (SI Figure 1). Autosampling, chromatography, and mass spectrometry were performed as described in ref 18 while using the application-specific transition ions for the LTP AQUA-MRM (SI Table 2). Analysis was conducted within the predetermined linear range of quantification for the AQUA peptides, which was determined for individual transition ions (four most intense). Each LTP AQUA peptide was used as an internal control at 200 fmol/injection, which is within the linear quantitative range.

Determination of LTP Concentration in Biological Samples. The concentration of each native LTP isoform and variants therein was calculated using the response ratio (native/AQUA peptide) for a single transition ion, multiplied by the concentration of the AQUA internal standard. The concentration was expressed as μg LTP/mg of total protein extracted from maize kernel for each LTP in each maize extract and was calculated as follows:

Calculation 1: [Response ratio from mass spectrometer × fmol of AQUA peptide/1 μg of protein sample = fmol of native peptide/μg of protein sample]; Calculation 2: [moles of native LTP × FW (g/mol) of LTP = g LTP/μg of protein sample]; Calculation 3: [g LTP × (1 × 10^6 μg LTP/g LTP) × (1000 μg protein sample/1 mg protein sample) = μg LTP/mg protein sample].

RESULTS

LTP Discovery Proteomics. Although the Zea m 14 allergen has been described as the major maize grain allergen, the recognition that LTP proteins would likely be expressed as a family of isoforms provided the impetus to survey and characterize the "total LTP load" that a maize variety may express. An initial discovery experiment was conducted to assess the diversity of LTPs in representative samples. Orbitrap mass spectrometry was used to accurately identify measurable peptides for the targeted and expressed LTPs in four representative varieties of maize. Two complementary peptide preparation methodologies were used: one method utilized fractionation by SDS-PAGE while the other used unfractionated "total" protein. Both peptide preparations were subjected to LC-MS/MS and protein identification workflows searching three databases: UniProt/Swiss-Prot, *Zea mays* B73 inbred translated genome, and the *Zea mays* UniGene transcriptome. Putative LTPs were extracted from the list of discovered

DOI: 10.1021/jf504708u
J. Agric. Food Chem. 2015, 63, 821−828

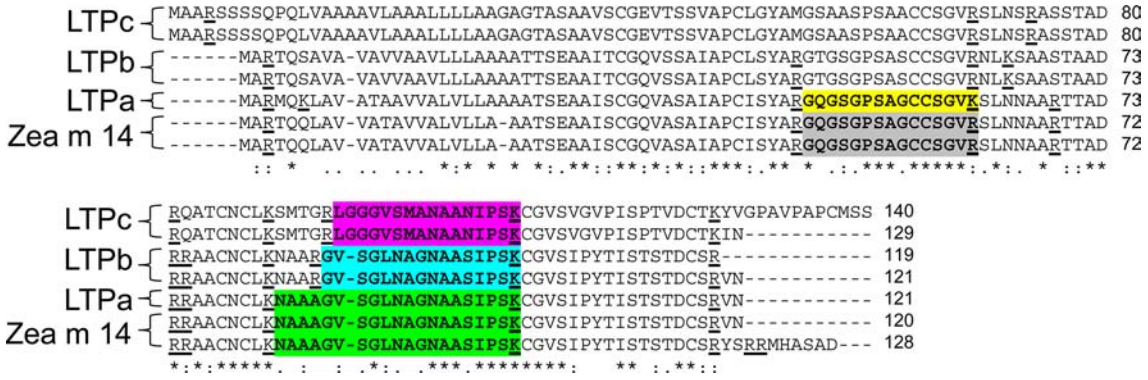

Figure 2. LTP protein alignment showing peptides for AQUA analysis. Ideal, quantitative tryptic peptides are highlighted. Specificity is indicated by color. Putative splice variants are paired by brackets. Each LTP has at least one peptide that distinguishes it, and two of them share one peptide (green). Trypsin cleavage sites are heavy underscored. Amino acid positions are indicated at the ends of each line.

proteins using molecular weight filters (20 kDa) and local BLAST analysis via BioEdit software using Zea m 14 as a query sequence; 20 kDa was the upper limit as a rational filter considering the LTP proteins are not likely to exceed ~13−15 kDa. In total, 13 LTP sequence listings (accessions) were identified from the four biological samples with high confidence, including Zea m 14 (P19656 in UniProt, Table 1). Two of the 13 accessions, GRMZM2G010868 and GRMZM5G898755, each had two splice variants annotated in the maize genome database (www.maizesequence.org). One of them, P19656, had an isoform annotated in UniProt, P19656-2 (http://www.uniprot.org/uniprot/). Three others, Q2QYL2, Q7XJ39, and Q43194, were from nonmaize sources, and were excluded.

LTP Homology Assessment. To create an AQUA-MRM assay that quantified all selected LTP paralogs to allergen Zea m 14, the ten maize LTPs discovered during our proteomic screen of various maize proteomes were grouped by their phylogenetic relationships (Figure 1A). A clear relationship was apparent between Zea m 14 and maize gene loci GRMZM2G10 1958, GRMZM2G010868, and GRMZM5G898755, including both presumptive splice variants for the two latter loci. In addition, sequence identity was assessed by pairwise sequence alignments between each LTP and Zea m 14 (Figure 1B). The percent identity scores for the seven proteins that grouped closest to Zea m 14 in the phylogram also shared the highest sequence identity with greater than 42% identity. It should be noted that none of the maize B73 loci were 100% identical to Zea m 14, although GRMZM2G101958 was closest at 87%. Taken together, these results show that, of the maize LTP candidate proteins, GRMZM2G101958, GRMZM2G010868, and GRMZM5G898755 are most similar to Zea m 14 and reasonably could contribute to food allergenicity based on a level of shared identity and function homology that may lead to cross-reactivity/cross-sensitization; for well described allergens such as those from pollen, this would generally be 50% shared identify or more.[25] To simplify nomenclature, the isoforms and splice variants for LTPs with greater than 42% identity to Zea m 14 were grouped and named LTPa, b and c (Figure 1B).

Sequence Assessment of LTPs. The feasibility of using AQUA-MRM as a quantitation method for these small and highly similar proteins was assessed using sequence alignment and manual sequence inspection. All isoforms and splice variants of Zea m 14, LTPa, LTPb, and LTPc were aligned using Clustal Omega (Figure 2). Possible tryptic peptides were critiqued for their selectivity and appropriateness for use as AQUA-MRM standards (i.e., labeled peptides to be included in each sample analysis[26]). The N-terminus of all LTPs had very few tryptic cleavage sites. LTPa has a peptide that starts at residue 48, and an analogous peptide in Zea m 14 starts at residue 47. These peptides differ in the C-terminal cleavage site, with LTPa having a Lys and Zea m 14 having an Arg (GQGSGPSAGCCSGVK and GQGSGPSAGCCSGVR). Neither peptide has neighboring downstream cleavage sites or double cleavage sites that could lead to "ragged ends", as was the case for the analogous peptide in LTPb, which has a C-terminal arginine with a lysine two residues away (GTGSGP SASCCSGV**R**NL**K**). LTPb also has only one available peptide at residue 87 (GVSGLNAGNAASIPSK). LTPc has only one available peptide which starts at residue 88 (LGGGVSMANAA NIPSK). LTPa and Zea m 14 both have a second available peptide which is shared between them, which starts at residue 84 in LTPb and 83 in Zea m 14 (NAAAGVSGLNAGNA ASIPSK). This second peptide is an improvement on the first peptide, as it is free from modifiable amino acids which negatively affect protein quantitation by AQUA-MRM. In addition, this second peptide can be used in parallel to measure both of these proteins (Zea m 14s and LTPa) together, while their first peptide can provide the quantities of each separately. Because AQUA-MRM quantitation yields molar quantities for target analytes, the quantities of Zea m 14 and LTPa as measured by their independent peptides can be directly compared to the signal of the second, conserved peptide (NAAAGVSGLNAGNAASIPSK; Figure 2, green). Theoretically, the quantity of the second peptide, which is shared between them, should equal the sum of the concentration of the two isoform-specific peptides (Figure 2, gray and yellow peptides). This assay design was pursued to reveal whether Zea m 14 (P19656-1) and its isovariant (P19656-2) were *bona fide* proteins, as neither is a perfect match to B73 gene locus GRMZ M2G101958 (LTPa). A matrix presentation of the LTP sequences and their representative peptides is shown in Table 2. To ensure that each of these peptides is protein specific, BLAST analysis of the translated B73 genome and the *Zea mays* (Zm166) UniGene transcriptome was performed. None of the peptides had an exact match to any protein other than the expected LTPs. Finally, none of these peptides discriminate between the putative splice variants observed for each of the three gene loci, which differ at the C-terminus (Figure 2). However, resolving these variants was not necessary to devise a comprehensive, absolute quantitative assay for each of the classes of endogenous LTP allergens in maize.

[a]Tryptic peptides are in columns, and the LTP accessions in rows. Asterisks are placed at the intersections of peptides and LTP accessions to which they belong. The peptide highlighted in gray is shared by two LTPs (the same as the green peptide in Figure 2). All other peptides are unique to the respective LTP isoform.

Bioanalytical Method Validation for Native and AQUA Peptides. Bioanalytical method validation requires the determination of many parameters, including specificity, precision, linear quantitative range, and carryover. Carryover between analytical runs was assessed during the AQUA peptide dilution series experiments, which used a fixed amount of maize grain protein as matrix and the cognate endogenous peptide therein as the control to calculate a response ratio. A blank run between each dilution in the series was assessed for residual native peptide signal and compared to that of the previous analytical runs. Each analytical run contained 2 μg of native peptides. Background was subtracted for both analytical runs and blank runs. The resulting signals for the blank runs were divided by the sum of the blank signal and the average area from the analytical runs, and multiplied by 100 to find the percent of total signal present in the blank run. Each peptide was assessed individually. On average, all were below 0.9% except the LTPc peptide, which was at 1.30%.

The linear range of native (endogenous) peptides used in these assays was determined by a six point, 5-fold dilution series from 2.4 μg to 0.0038 μg/injection (including a zero control), with duplicate injections. AQUA peptides were spiked at 40 fmol/μL. When the log5 values of the response ratios (RRs, endogenous/AQUA) were plotted against the log5 values of the matrix amounts, R^2 values for all transition ions were between 0.9842 and 1.000, and slope values were between 1.05 and 0.885 when the zero control was excluded. The experimentally verified linear dynamic range was nearly 4 orders of magnitude for each peptide, although the current instrument and column capabilities likely offer a broader range. Duplicate injections provided percent relative standard deviation (%RSD) values that averaged less than 11% across all dilutions and all peptides except LTPc, which was 36% (SI Figure 1).

The linear range of AQUA peptides was assessed by a seven-point, 5-fold dilution series from 0.5 pmol to 0.16 fmol/injection including a zero control with duplicate injections (SI Figure 2). For all peptides and transition ions therein, except LTPc, this six point dilution series was linear with R^2 values ranging from 0.996 to 0.9999, when excluding the zero control. For most of these assays, the LLOD and ULOQ exceeded the six point dilution series. However, for the LTPc peptide the LLOD was 0.16 fmol and the ULOQ was 100 fmol. The LLOQ of 0.8 fmol and linear range from 0.8 to 100 fmol offered R^2 values ranging between 0.991 and 0.9996 when excluding the zero control. Considering the linear range for all AQUA peptide dilution series, the slopes ranged from 0.8873 to 1.0038, with the majority being less than 5% under 1.00 (without zero control). Duplicate injections yielded response ratio %RSDs that averaged less than 8% across all dilutions. AQUA-MRM assay parameters for all peptides are listed in SI Table 2. The lower and upper limits of quantification (LLOQ/ULOQ) were assessed in terms of their surrogate proteins, by converting the molar quantity for each peptide into the gram quantity for the respective protein (Table 3). For LTPa, the LLOQ was 9.39 pg/injection (0.8 fmol). For LTPb, the LLOQ was 1.88 pg/injection (0.16 fmol). The LLOQ for LTPc was 10.66 pg/injection (0.8 fmol). For Zea m 14 and LTPa/Zea m 14, the LLOQ was 2.03 pg/injection (0.16 fmol) for both.

LTP AQUA-MRM Analysis. Absolute measures of the concentration in maize grain extracts for all LTPs in each variety are graphed in Figure 3. Figure 3 (top panel) shows the higher abundance LTPa and Zea m 14, while Figure 3 (bottom) contains the quantities of the lower abundance LTPb and LTPc isoforms. In most samples, both LTPa and Zea m 14 were present at similar concentrations. However, in four of the samples (variety 1, 2, 14, and 15), one of those LTPs is below either detection or quantification limits. The third series in Figure 3 (top), labeled "LTPa/Zea m 14", shows the result which simultaneously quantifies both LTPa and Zea m 14 together via a shared peptide. In all cases where either LTPa or Zea m 14 proteins are low or undetected, the quantity of the single, representative LTP is similar to the concentration of the peptide that is common to both LTPa and Zea m 14 (i.e., LTPa/Zea m 14). In addition, for the samples where both Zea m 14 and LTPa are present in similar concentrations, the additive value of the two independent assays (each protein represented by its unique peptide) is similar to the LTPa/Zea m 14 value. When the sums of the independent LTPa and Zea

Table 3. Summary Table for Proteins and Peptides[a]

Prot Abbv	IUIS allergen nomenclature	MM (g/mol)	AQUA peptide sequence	AQUA assay LLOQ (pg/injection)	AQUA assay ULOQ (ng/injection)
LTPa	none	11742.84	GQGSGPSAGCCSGVK	9.39	5.87
LTPb	none	11718.82	GVSGLNAGNAASIPSK	1.88	5.86
LTPc	none	13319.46	LGGGVSMANAANIPSK	10.66	6.66
Zea m 14	Zea m 14	12659.23	GQGSGPSAGCCSGVR	2.03	6.33
LTPa/Zea m 14	Zea m 14	12659.23	NAAAGVSGLNAGNAASIPSK	2.03	6.33

[a]LLOQ is the lower limit of quantitation and represents the lowest point at which we demonstrated quantitative accuracy during our assay development. ULOQ is the highest amount tested with AQUA peptides, though assays with native peptides showed linearity of response beyond this value.

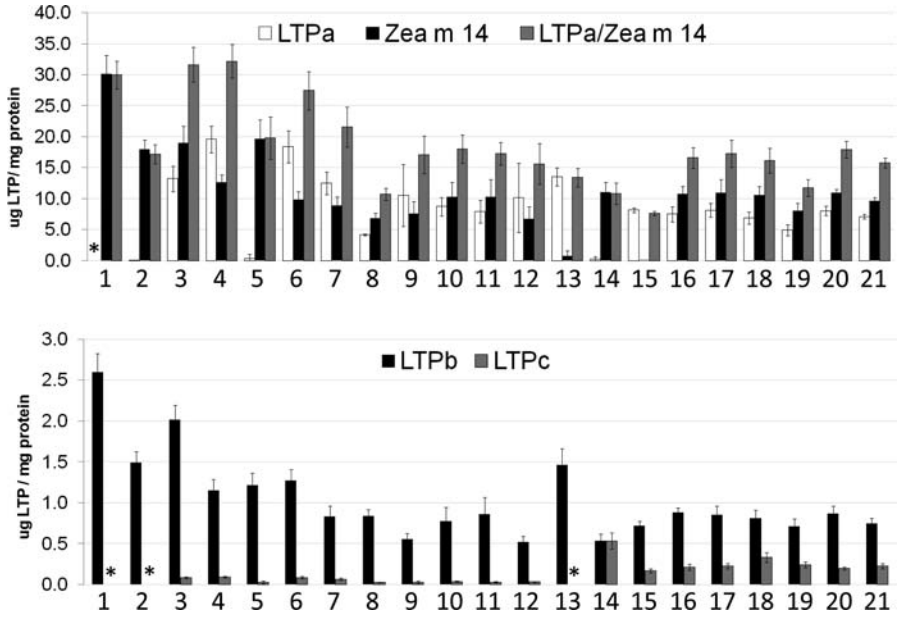

Figure 3. Absolute quantities of LTPs in each variety. LTPa/Zea m 14 represents the quantity provided by the peptide assay which monitors both LTPa and Zea m 14 simultaneously using a peptide that is shared by both proteins. Error bars represent standard deviation for five biological replicates. Numbers below the *x*-axis are variety identifiers. Asterisks indicate samples below detection limits.

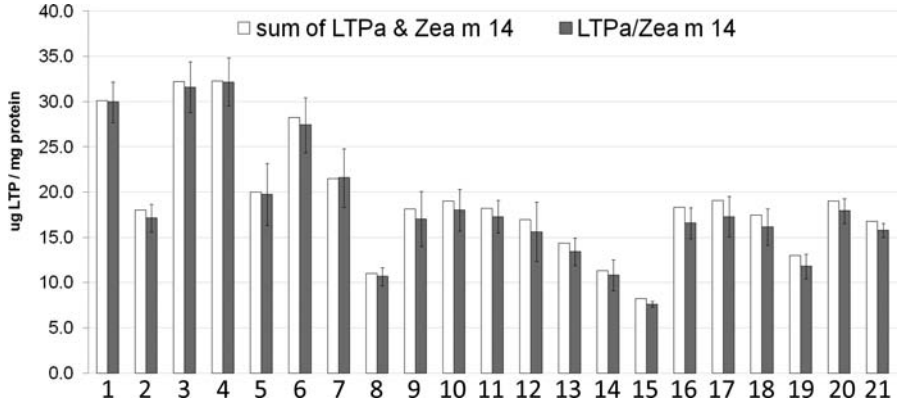

Figure 4. Stoichiometric agreement between three separate LTP AQUA-MRM assays. Error bars represent standard deviation for five biological replicates. Numbers below the *x*-axis are variety identifiers.

m 14 are plotted with the shared peptide LTPa/Zea m 14 values, it is evident that the shared peptide represents the sum of the individual peptides (Figure 4). The average percent error for the sum of LTPa and Zea m 14 versus the value measured by the LTPa/Zea m 14 is only 5.3%. LTPb and LTPc isoforms are less abundant, with LTPb being the more abundant species (Figure 3, bottom panel). LTPc was below detection or quantification limits in five varieties, numbers 1, 2, 5, 11, and 13.

DISCUSSION

The premise behind developing analytical approaches for measuring food allergens is to gain a better understanding of their precise expression levels (referred to as absolute) in various plant organs and to extend this technology toward their identification in processed foods and the environment. Traditionally, allergen detection and quantification methods have relied primarily on antibody-based approaches, employing either IgE antibodies derived from allergic patient sera or IgG antibodies raised in animals against individual allergens. However, it is generally understood that most antibody-based methods provide semiquantitative, relative estimates of content and that specificity and reproducibility can be affected by matrix components in the grain and foods in which allergens are usually monitored. Using a comparative approach to determine feasible assays for soybean allergens, Pedersen et al.[27] found that matrix component interference could be minimized. By using a general ranking of abundance of the targeted soy within a given food type, calculated soy levels were consistent across assays (higher abundance equaled a higher level of measured soy); however, "...the measured soy levels given by each of these assays were not in correlation with each other, allowing only semi-quantitative estimations of the soy content". In contrast, absolute measures of protein allergens, such as has been developed for LTP by mass spectrometry, when paired with an understanding of genetic/bioinformatic background, can provide reliable concentration values for the total abundance of related isoforms *in planta*.

The sequence of the B73 maize genome, coupled with in-depth transcriptomics, provided predictive gene models for the

J. Agric. Food Chem. 2015, 63, 821−828

LTP family of proteins. Amino acid sequence alignment revealed three genes sharing between 43% and 87% amino acid identity with Zea m 14. Three additional genes shared between 15% and 29% sequence identity and clustered phylogenetically apart from the others, and were therefore not considered close homologues to Zea m 14. The most closely related gene to Zea m 14 was GRMZM2G101958 (LTPa), which due to a presumptive alternative translation termination site shared 87% identity. Therefore, it is likely that the Zea m 14 allergen arose from this gene. This is supported by the observation that one of the two reported Zea m 14 transcript variants is identical to the LTPa gene at the variable C-terminus. Three of the peptides for this multiplexed maize LTP assay were developed to verify the existence of both the reported sequence for Zea m 14 as well as the LTPa transcript. The two discriminating peptides GQGSGPSAGCCSGV(R/K) differed only in the terminating residue. A third peptide was developed to a conserved sequence for LTPa and the two variants for Zea m 14 (NAAAGVSGLNAGNAASIPSK). Quantitative analysis of 21 maize varieties revealed the existence of both the LTPa and Zea m 14 proteins, albeit with varying abundance among them (Figure 3). The levels of LTPa varied from undetectable to almost 20 μg LTPa/mg maize grain protein among the 21 varieties studied. Zea m 14 ranged from undetectable to 30 μg LTP/mg maize grain protein. To confirm the accuracy of these results, the third peptide was designed against a domain conserved in all three transcripts and was included in the multiplexed assay performed for each sample. This peptide overlapped with the multiple gene variants documented for LTPa and was included in each analysis. The results confirmed the values for the two independent peptides, with an average percent error of 5.3%. The results from this peptide demonstrate signals from the two specific peptides were authentic and accurate, as the sum was equivalent to the conserved peptide representing all three gene products in all varieties (Figure 4). These proteins are considered to represent the bulk of LTP expression in maize grain.

LTP homologues encoded by genes GRMZM2G010868 (LTPb) and GRMZM5G898755 (LTPc) were 74% and 43% identical to Zea m 14, respectively, at the amino acid level. Each of these two gene assemblies were represented by two transcript variants exclusively variable at the C-terminus (Figure 2). Two peptides were designed to discern these two genes but not the transcript variants that arose from them (Figure 2). Analysis of the 21 maize varieties revealed both proteins are present within maize grain at variable levels. Expression of LTPb ranged from 0.5 to 2.5 μg LTPb/mg maize grain protein. LTPc exhibited a low level of expression, varying from undetectable to 0.5 μg LTPc/mg maize grain protein. Although the levels of LTPb and LTPc gene products were lower than LTPa, this is dependent upon the specific maize variety being analyzed (Figure 3). Therefore, to accurately assess the total LTP allergen "load" in maize grain, it is essential to monitor all three LTP isoforms related to Zea m 14.

To our knowledge, only one other nonantibody-based method for quantifying maize LTPs has been described, which uses LC-UV/MS.[28] In this method, LTPs were selectively extracted and analyzed intact utilizing liquid chromatography coupled to UV absorbance for quantitation. Quantitation was performed using external calibration curves with a prepared mix of LTPs standardized by amino acid analysis. Analysis of maize grain revealed an LTP concentration ranging from 58 to 678 μg/g grain fresh weight from 14 maize varieties. Using the AQUA-MRM approach, we determined total LTPa (Zea m 14) concentration to be 9 to 32 μg LTP/mg protein among 21 maize varieties. Assuming maize grain is 10% protein by weight, the values from Kuppannan et al.[28] convert to 0.58−6.78 μg LTP/mg protein. Two LTP variants were observed in 2010 by Kuppannan et al.,[28] and it is likely variant A is the Lys-containing version of Zea m 14 (GQGSGPSAGCC SGVK/R) denoted as LTPa in Figure 2, as determined by MS analysis of this tryptic peptide. Thus, for direct comparison to the values reported here for Zea m 14 (LTPa), it is necessary to sum the values for "LTP" and "LTP variant A" in ref 28. This produced a range of 2.23−8.14 μg LTP/mg protein, which is close to values reported here using AQUA-MRM. The slightly lower estimate of maize grain LTP concentration by Kuppannan et al. could be due to varietal or methodological differences between these two approaches. Variant B observed by Kuppannan et al.[28] was up to 20-fold less abundant than the other LTP variants; therefore, it would be reasonable to conclude this represented one of the related LTP genes (i.e., LTPb or LTPc in our study) based upon values reported here.The method presented here has the advantage of added selectivity by utilizing signal derived from individual peptide ions present in each chromatographic peak, so that even coeluting species are distinguished during quantitative analysis. In addition, each assay utilizes internal reference standards that are isotope-labeled and analyzed simultaneously, which increases quantitative accuracy and reproducibility.

In summary, the maize allergen Zea m 14 is part of a family of LTPs with related gene isoforms and putative splice or translation variants. Additionally, LTPs are small, 7−10 kDa proteins and therefore contain few proteotypic peptides for quantitation in a typical bottom-up AQUA-MRM workflow. Despite these limitations, we demonstrated a robust, multiplexed assay for three LTP genes and the 2−3 variants of each of these genes, which varied by as little as a single amino acid. We rigorously validated this multiplexed assay for absolute quantitation from extracts of maize grain in order to provide reliable and repeatable concentration measurements in a complex seed matrix. As a control, a redundant peptide that represents the theoretical sum of two specific peptides was employed as part of the methodology. The quantitative results from this redundant peptide support the theoretical sum and thus verify the accuracy of these predictive gene models as well as the AQUA-MRM method (Figure 4). In total, this quantitative study design accounted for all LTPs related to Zea m 14. It provided the specificity, accuracy, reproducibility, sensitivity, and linear quantitative range to be employed for comprehensive Zea m 14 allergen assessment in maize with the possibility of validation with other food matrices. In the future, experimental field designs that help elucidate the natural variability in LTP expression may be useful in providing a baseline. It is becoming well established that environmental factors and the genetic background of various crop varieties are the basis for largest percentage of variability. This variability will need to be better studied in order to work toward an understanding of exposure risk for the LTP allergen.

ABSTRACT: Selected ion flow tube−mass spectrometry (SIFT-MS) has recently gained interest as an alternative method to traditional GC-MS for the detection of targeted volatile sample compounds, due to its ease of use, its speed and sensitivity, and its potential for real-time quantification. The feasibility of this technique was demonstrated using the case of the production of ethanol during sourdough fermentation. The potential of SIFT-MS as an online monitoring device for food fermentations was further demonstrated by the detection of acetoin in certain sourdough fermentations. This allowed discrimination between sourdough fermentation processes and illustrated the importance of real-time monitoring of food fermentations.

KEYWORDS: *SIFT-MS, GC-MS, fermentation, online monitoring, sourdough, Lactobacillus, volatile organic compounds*

INTRODUCTION

Food fermentation processes have been performed since ancient times, in the first place as a way to preserve food products and in the second place to increase their nutritional value and organoleptic properties.[1] In contrast to the action of desirable microorganisms (bacteria, yeasts, and to a lesser extent, filamentous fungi), the outgrowth or action of undesirable microorganisms can lead to spoilage of the end-products. Therefore, considerable research efforts have been made to the control and monitoring of food fermentation processes. One such way is the application of (functional) starter cultures, i.e., the inoculation of a large number of cultivated dedicated microbial cells.[2] An example of a fermented food that has benefited from this development is sourdough. Sourdough is a fermented cereal-based product initially made through spontaneous fermentation of a cereal flour−water mixture or continuous reinoculation of fresh flour by the addition of a part of a previous fermentation batch.[3] A more industrial approach to the production of sourdough involves the addition of selected starter cultures, which can be lactic acid bacteria (LAB) and/or yeasts.[2,3] However, even modern sourdough production is subjected to considerable batch-to-batch variations. One way to minimize end-product variations is to improve the control of the fermentation processes, preferably through online monitoring of microbial growth, substrate consumption, and/or metabolite production.[4] However, online monitoring through chromatography and/or mass spectrometry of food fermentation processes, whether spontaneous or starter culture-initiated, is challenging, in particular with respect to the analysis of volatile organic compounds in real-time. To the authors' knowledge, only online gas chromatography for the quantitative analysis of off-gases has been implemented.[5] Semiquantitative analysis of volatile organic compounds has been made possible by means of membrane inlet mass spectrometry and direct-injection mass spectrometric techniques.[6,7]

Selected ion flow tube−mass spectrometry (SIFT-MS) is a relatively new mass spectrometric technique that finds its origin in the study of gas-phase ion−molecule reactions.[8,9] It applies soft chemical ionization of volatile compounds with selected reagent ions, i.e., H_3O^+, NO^+, and O_2^+, which are generated in situ. As a result of the reaction of these reagent ions with the volatile organic compounds produced from the fermentation process, product ions of the volatile organic compounds are formed. Because of the soft ionization employed, little fragmentation of these product ions occurs. A quantitative measurement of the volatile compounds at ultratrace levels can be achieved without external calibration providing the fundamental kinetic parameters for the reagent ion-volatile organic compound reactions are known. The signal amplitudes of the selected product ions are used to calculate the concentrations of the targeted volatile compounds present in the sample. The use of three selected reagent ions and the ability to directly analyze the headspace above samples increase the identification power of the technique, rendering a priori separation and tedious or discriminating sample preparation obsolete, hence allowing real-time measurements.

Since it was first described by Španěl and Smith in 1996, the SIFT-MS technique has advanced tremendously.[10] Its selectivity, sensitivity, and ease and speed of measurement have boosted its applications. So far, SIFT-MS has gained attention in the areas of environmental monitoring,[11,12] (petro)chemical applications,[13,14] and clinical analysis.[15−17]

Because of the complexity of targeted chemicals and their concomitant matrices, applications of SIFT-MS in the field of food and flavor analysis present promising results.[18−21] Indeed, the use of SIFT-MS for the identification and quantification of volatile organic compounds, suitable as biomarkers and often emitted by microbial cultures or related to (fermented) foods, has been described.[22−24] However, the potential of SIFT-MS for the analysis of volatile organic compounds, indicating spoilage or contributing to the aroma of (fermented) foods, has not yet been realized fully.[25−34] Moreover, no reports exist on the use of SIFT-MS as an online measurement technique for the monitoring of (food) fermentation processes.

The aim of the present study was to develop and validate a SIFT-MS setup that is useful for the online monitoring of volatile metabolites during sourdough fermentations in parallel with quantitative online gas analysis.

MATERIALS AND METHODS

Design of an Online Monitoring SIFT-MS Setup. A unique SIFT-MS setup for the online monitoring of the headspace of fermentation vessels was designed (Figure 1). Sourdough fermentations involving heterofermentative LAB and generating typical volatile compounds, such as ethanol and acetic acid, were performed as a case study. To sweep volatiles toward the SIFT instrument (Syft Voice 200; Syft Technologies Ltd., Christchurch, New Zealand), nitrogen gas was added to the fermentation vessels (Biostat B-DCU fermentors; Sartorius AG, Melsungen, Germany) at 0.35 bar. In addition, this created a small overpressure (0.2 bar) area at the inlet of the autosampler (CGM2000; Umwelttechnik MCZ, Bad Nauheim, Germany), needed for its proper operation. Condensation pots (100 mL glass bottles) were connected directly with the headspace of the fermentors, bypassing the condensors and filters present at their standard gas outlets and operating as a physical water trap for water condensation at room temperature. Heated (105 °C) 1/4′′ polytetrafluoroethylene (PTFE) transfer lines connected these glass bottles with the entrance of the autosampler to avoid condensation of water and volatile compounds. The autosampler was equipped with four digital mass flow controllers and a mixing chamber. Three mass flow controllers were connected to the fermentation vessels and one to the dilution gas. The mass flow controllers were operated by the autosampler software, allowing the selection of gas inflow from a fermentation vessel and an appropriate amount of dilution gas (high-grade nitrogen gas), hence enabling the autosampler to act both as a selection and a dilution device. Dilution and sample gases were mixed in the mixing chamber and an amount of 25 mL min^{-1} of the gas blend was transferred to the SIFT-MS by means of the MS vacuum. This way, the evolution of volatile compound signals were followed as a function of time for multiple fermentation vessels and the SIFT-MS, controlled by LabSyft software (Syft Technologies Ltd.), could be operated under the analytical conditions required. Additionally, the autosampler device was equipped with a permeation oven, through which internal standards were added to the gas blend. Two internal standards were applied by means of permeation tubes, i.e., toluene (Metronics Inc. Poulsbo, WA, USA) with a diffusion rate of 75 ng min^{-1} at 50 °C and fluorobenzene (KIN-TEK Laboratories, La Marque, TX, USA) with a diffusion rate of 8.511 ng min^{-1} at 60 °C. This adaptation allowed the continuous monitoring of the performance of the SIFT-MS, correcting for incidental instrumental variations. The standards were applied separately. The permeation oven was set at 50 or 60 °C, depending on the permeation tubes used. A constant flow of permeation gas (nitrogen gas) at 200 mL min^{-1} was applied, which was mixed with the gas blend in the mixing chamber. To evaluate this setup, the breakthrough time, which was defined as the time needed to get 10% of the equilibrium response, and the mixing time, which was defined as the time needed to obtain a response in the SIFT-MS corresponding to 95% of the final equilibrium response, were determined by the addition of ethanol as a tracer compound, in a concentration of 34 mM, to a 2-L Biostat B-DCU fermentor (Sartorius AG, Melsungen, Germany) filled with 1.5 L of ultrapure water. Three aeration methods were compared, namely, headspace aeration and aeration through a ring sparger or a microsparger (Figure 2).

Applications. *Strains and Media.* *Lactobacillus fermentum* IMDO 130101, a strain previously isolated from a spontaneous laboratory rye sourdough, was used for the fermentations in wheat sourdough simulation medium (W-SSM).[35,36] *Lactobacillus sanfranciscensis* IMDO 150101, a strain isolated from a spontaneous laboratory teff sourdough (unpublished results), was used for the starter culture-initiated sourdough fermentations based on teff flour. The strains were stored at −80 °C in modified de Man-Rogosa-Sharpe-5 (mMRS-5) medium,[37] supplemented with 25% (vol vol^{-1}) glycerol as cryoprotectant. Solid media of W-SSM and mMRS-5 were prepared by adding 1.5% (wt vol^{-1}) agar (Oxoid Ltd., Basingstoke, Hampshire, UK) to the broth.

Fermentations in Wheat Sourdough Simulation Medium. W-SSM was composed of (per liter) wheat peptone, 12.0 g; granulated yeast extract, 12.0 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; $MnSO_4 \cdot H_2O$, 0.05 g; KH_2PO_4, 4.0 g; K_2HPO_4, 4.0 g; Tween 80, 1.0 mL; and vitamin solution, 1.0 mL. The latter had the following composition (per liter): cobalamine, 0.2 g; folic acid, 0.2 g; nicotinamide, 0.2 g; pantothenic acid, 0.2 g; pyridoxal-phosphate, 0.2 g; and thiamine, 0.2 g.[36] All chemicals were obtained from VWR International (Darmstadt, Germany). Three W-SSM fermentations were carried out in parallel in 2-L Biostat B-DCU fermentors (Sartorius AG, Melsungen,

DOI: 10.1021/jf505111m
J. Agric. Food Chem. 2015, 63, 829−835

Germany). To estimate the variability of the methodology developed, each of these three parallel fermentations were carried out in triplicate. All medium components, except for carbohydrates and the vitamin solution, were dissolved in 1.25 L of distilled water, and the pH of the medium was adjusted to 5.5 by adding HCl and/or NaOH, prior to sterilization (121 °C, 2.1 bar, 20 min) of the fermentors. The carbohydrate mixture (250 mL), consisting of maltose, sucrose, glucose, and fructose in a final concentration of 10 g L^{-1}, 2 g L^{-1}, 0.5 g L^{-1}, and 0.5 g L^{-1}, respectively, was sterilized (121 °C, 2.1 bar, 20 min) separately, and the vitamin solution was filter-sterilized (0.2-μm Minisart PES filters; Sartorius AG, Goettingen, Germany); both were added aseptically to the sterile fermentors, prior to inoculation. The fermentation temperature was kept at 30 °C. The pH of the medium was kept constant at 5.5 through automatic addition of a 1.5 M NaOH solution to the fermentation broth. The stirring speed was fixed at 300 rpm. Temperature, pH, and agitation were controlled online (MicroMFCS for Windows NT software, Sartorius AG, Melsungen, Germany). Sterile nitrogen gas was continuously blown through the fermentation medium at a rate of 200 mL min^{-1}. The inoculum was prepared through three subcultures of 12 h in W-SSM. The first two subcultures were carried out in 10 mL of medium; the third subculture in 100 mL. The transfer volume was always 1.0% (vol vol^{-1}).

Starter Culture-Initiated Teff Sourdough Fermentations. Starter culture-initiated sourdough fermentations (8 kg) were carried out in duplicate in 15-L Biostat C fermentors (Sartorius AG, Melsungen, Germany) filled with 6 L of sterile water and 2 kg of teff flour.[38] An inoculum of 1.0% (vol vol^{-1}) of the starter culture, subcultured twice in mMRS-5 overnight, was used. This dough was incubated at 30 °C for 72 h, while the mixture was kept homogeneous through stirring (300 rpm). The headspace of the fermentors was flushed with sterile air at a flow rate of 1 L min^{-1}.

Off-Line Sample Analyses. During fermentation, samples were regularly withdrawn from the fermentors for the determination of bacterial counts, residual carbohydrates, and metabolites produced, as described previously.[36] Briefly, bacterial counts were determined by plating 10-fold dilutions of W-SSM fermentation samples or samples of fresh mixtures of 10 g of teff sourdough sample with 90 mL of sterile saline (0.85%, wt vol^{-1}, NaCl) on W-SSM agar (W-SSM fermentations) or mMRS-5 agar (starter culture-initiated teff sourdough fermentations), followed by incubation at 30 °C for 48 h.

For metabolite target analysis, a given amount of W-SSM (50 mL) or sourdough sample (approximately 100 g) was centrifuged (8,041*g* for 20 min at 4 °C) to remove solids, and the supernatant was stored at −20 °C until further analysis. Concentrations of residual carbohydrates (maltose, sucrose, fructose, and glucose) and mannitol produced were determined through high-performance anion exchange chromatography with pulsed amperometric detection, applying a standard addition protocol.[39] Concentrations of lactic acid were determined using high-performance liquid chromatography with refractive index detection (HPLC-RI), through external standards.[39] Concentrations of acetic acid, ethanol, and acetoin were determined through HPLC-RI and gas chromatography (GC) with flame ionization detection, using external standards.[40] Concentrations of volatile compounds were determined through static headspace-GC-MS (SH-GC-MS).[41] Peak identification was achieved by comparison with pure standard compounds and library confirmation (NIST 08, National Institute of Standards and Technology, Gaithersburg, MD, USA).

Online Analysis of Gases and Volatile Compounds. The headspace of the fermentation vessels was analyzed for carbon dioxide and targeted volatile compounds during the sourdough fermentation processes for either 48 or 72 h. Carbon dioxide was quantified through online gas chromatography by means of a Compact-GC (Interscience, Louvain-la-Neuve, Belgium).[5] Briefly, a headspace sample was pumped through an analytical cell, containing a PoraBOND Q column (Varian, Palo Alto, CA, USA) coupled to a thermal conductivity detector. Helium was used as carrier gas. The following conditions were applied: valve temperature, 60 °C; injection volume, 20 μL; carrier gas module mode, constant pressure (70 kPa); split flow, 5 mL min^{-1}; reference flow, 1 mL min^{-1}; column temperature, 60 °C; and detector temperature, 110 °C. A four-position selection valve allowed automated sequential sampling of the three fermentation vessels and injection of calibration gas mixtures (Saphir calibration gases; Air Liquide, Paris, France). Each fermentor was sampled twice every hour. The carbon dioxide concentration was summarized over the entire fermentation period and expressed in millimolars.

Volatile sample compounds were monitored through SIFT-MS. All fermentors were sampled consecutively during 20 min so that each fermentor was sampled once per hour. During the sampling time, a full scan (m/z^{-1} 10 to 250 for H_3O^+, 15−250 for NO^+, and 15−250 for O_2^+) and a selected ion mode (SIM) scan (settle time, 80 s; measurement time, 100 s) were run.[42] A list of the ions measured is presented in Supporting Information, Table S1.

To verify the results obtained by SIFT-MS, an online dynamic headspace-GC-MS analysis (Agilent 6890 gas chromatograph coupled to an Agilent 5973N mass spectrometer; Agilent Technologies, Santa Clara, CA, USA), was performed. Every hour, a gas sample of 1 mL was withdrawn from a Pall flow cell (CTC Analytics AG, Zwingen, Switzerland), which was connected to the gas outflow of one fermentation vessel by means of a 1/4″ PTFE transfer line, and injected into a capillary column (DB-WAXetr, Agilent Technologies) at a rate of 500 μL s^{-1}.

The carbon recovery was calculated by dividing the total amount of carbon present in the metabolites by the total amount of carbon added as carbohydrates.

RESULTS AND DISCUSSION

Optimization of the Online Monitoring SIFT-MS Setup. The Syft Voice200 instrument is a very sensitive device since its linear range is a magnitude lower than the anticipated concentrations of volatile compounds emitted by a microbial culture.[42,43] Consequently, it was necessary to dilute the headspace samples with dilution gas (nitrogen gas) prior to introduction into the instrument in a dilution chamber (part of the autosampler) to obtain more appropriate concentrations (Figure 1).

The mass flow controllers of the autosampler required an input pressure of 0.2 bar, hence making it necessary to put the fermentation vessels under overpressure. It was found that the required pressure of the inflowing gas had to be 0.35 bar to compensate for the pressure drop between the gas inlet of the fermentors and the mass flow controllers of the autosampler. However, this altered the measurement of the carbon dioxide concentration with the Compact-GC. Indeed, when the gas outflow was restricted, the concentration of carbon dioxide quickly increased to values out of the linear range of the apparatus. Therefore, a sufficiently high gas flow rate of 200 mL min^{-1} was applied. A valve, regulating the outflow of gas and a union tee were installed, making continuous gas flow and decompression to atmospheric pressure possible. This way, the disturbance of the system, for instance by pressure swings influencing biological and physicochemical parameters of the fermentation processes, was minimized, and simultaneous measurements by Compact-GC and SIFT-MS were feasible.

Addition of the condensation pots substantially increased the system's mixing time to around 60 min, as measured with a sample gas flow rate of 10 mL min^{-1}. This made it the limiting step of the measurements and hence determined the overall reaction time of the setup (Figure 2). To compensate for this, the sample gas flow rate was increased to 40 mL min^{-1}. This in turn lowered the breakthrough time from around 9−11 to 6 min. With respect to the time frame of sourdough fermentation (48 h), both the mixing time and breakthrough time were considered acceptable. Unfortunately, an increase of the sample gas flow rate required a proportional increase of the dilution gas

DOI: 10.1021/jf505111m
J. Agric. Food Chem. 2015, 63, 829−835

flow rate, to maintain a linear system response. To limit dilution gas usage, however, this load was allowed to be below 10 ppmv. Also, it is noteworthy that the aeration method did not determine the breakthrough time due to the installment of a condensation pot.

A method for the determination of the concentrations of metabolites of heterofermentative LAB metabolism was developed. Additionally, common organic contaminants were included in the method to control the risk of misinterpretation due to pollution by laboratory air. The internal standards were added and measured to monitor the system performance of the SIFT-MS setup. Toluene exhibited interference with one or more volatile sample compounds, while the measured signal of fluorobenzene did not alter during the course of a W-SSM fermentation. Therefore, fluorobenzene was preferred as the internal standard and was used during subsequent experiments. Product ions that, according to the LabSyft software library, could cause interference were removed from the method in several optimization rounds. An initial screening, using online GC-MS and SH-GC-MS, showed that ethanol was the main volatile present. It was preferably detected by SIFT-MS. As a result, ethanol impeded the determination of other volatile sample compounds. No additional compounds were found upon dilution of the sample gas. The response of these compounds could have disappeared in the elevated noise due to their low expected level.

Application of SIFT-MS during W-SSM Fermentation. The unique technical setup for the online monitoring of carbon dioxide and microbial volatiles and the method developed for the quantitative determination of these microbial volatiles were applied to follow up a fermentation with *Lb. fermentum* IMDO 130101 in W-SSM. Online SIFT-MS measurements of volatile compounds present in the headspace of the fermentors were compared with HPLC-RI measurements of the concentrations of these volatiles in the fermentation broth. A typical fermentation pattern, represented in Figure 3, shows the simultaneous production of lactic acid, ethanol, acetic acid, and carbon dioxide, along with the consumption of the carbohydrates. As described previously, maltose and glucose were the preferred energy sources, while sucrose was consumed once these carbohydrates were exhausted.[36] Fructose was used mainly as an alternative external electron acceptor and converted into mannitol, allowing concomitant production of acetate instead of ethanol.[36] However, the limited concentration of fructose (5 mM) present in W-SSM limited acetate formation to 5 mM.

Only 80−85% of the carbon supplied under the form of carbohydrates could be accounted for in the metabolites measured. Following the heterofermentative metabolism of *Lb. fermentum*, 65 mM of carbon dioxide was produced, as measured by online gas chromatography. This was stoichiometrically correct, indicating a successful coupling of the Compact-GC with the fermentors as part of the whole configuration for online measurements of fermentation gases and microbial volatiles. Although lactic acid (60 mM) was produced equimolar to the sum of the ethanol and acetic acid concentrations, its concentration in the headspace of the fermentors was too low for detection by SIFT-MS. This might be due to several factors. First, the Henry coefficient, describing the division of volatile organic compounds between the gaseous and liquid phases, is much higher for ethanol than that for lactic acid.[44,45] Second, as for all organic acids, the pH of the medium, which was automatically adjusted to 5.5, influenced the equilibrium.[46] The latter effect also influenced the concentration of acetic acid in the headspace of the fermentors. Third, charged compounds could have been adsorbed on parts of the setup, removing them from the headspace.[47] Therefore, neither lactic acid nor acetic acid could be found in the headspace of the fermentors by means of the current online SIFT-MS setup. In addition, ethanol evaporation, due to the high gas flow rates through the system, was not taken into account.[48] Finally, a comparison of the current setup with a closed model system showed a pressure loss of around 10%.

Nevertheless, a comparison between the concentrations of ethanol in the medium, as measured by off-line SH-GC-MS, and the concentrations of ethanol in the dynamic headspace, as measured by online SIFT-MS, showed their parallel evolution (Figure 4). Additionally, the online GC-MS measurements showed the same parallel evolution as the online SIFT-MS measurements. This indicates that online measurement of ethanol concentrations in the dynamic headspace of a fermentor by SIFT-MS can be used as a tool to monitor the production of ethanol in the fermentation broth. As ethanol is a key metabolite of the heterofermentative metabolism of LAB, it

J. Agric. Food Chem. 2015, 63, 829−835

can be used as biomarker for the online monitoring of food fermentations involving heterofermentative LAB.

To correct for biological variation, the ratio between the ethanol concentrations in the headspace, as measured by online SIFT-MS, and the ethanol concentrations in the fermentation broths, as measured by HPLC-RI, was calculated and averaged, based on three series of fermentations carried out in triplicate, and was $(1.1 \pm 0.1)\ 10^{-4}$ (mol per liter in the gas phase) (mol per liter in the liquid phase)$^{-1}$. Hence, analysis of the dynamic headspace by online SIFT-MS according to the setup of the present study could be used as a tool to monitor fermentations with a variability of only 13%. However, this variability may still be lowered, as the present study included changes in methodology or setup, for example, by the introduction of a SIM method. The advantage of a SIM method over a full mass scan is that only those volatile organic compounds of interest are monitored, and in the SIM mode of operation, ion products from these volatile organic compounds are averaged over longer periods, thus improving the accuracy of the measurements.[42,49]

Application of Online SIFT-MS during Starter Culture-Initiated Teff Sourdough Fermentation. Heterofermentative metabolism of *Lb. sanfranciscensis* IMDO 150101 resulted in the production of lactic acid, ethanol, acetic acid, and mannitol out of maltose, glucose, fructose, and sucrose during teff sourdough fermentation (data not shown). Besides ethanol and acetic acid, the application of online SIFT-MS during a *Lb. sanfranciscensis*-initiated teff sourdough fermentation showed the production of another volatile sample compound, namely, acetoin (Figure 5), known to be produced by cocultures of *Lb.*

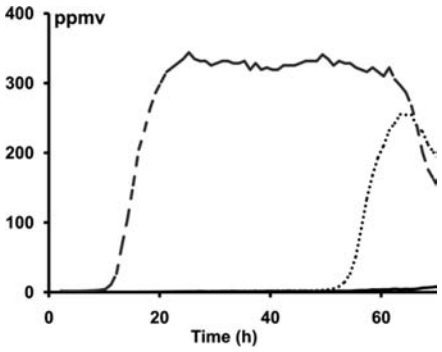

Figure 5. Profile of targeted sample compounds measured by online SIFT-MS, namely, ethanol (– – –), acetoin (···), and acetic acid (–).

sanfranciscensis and *Saccharomyces cerevisiae* under (acid) stress conditions.[50] The low concentrations present in this sourdough (5 mM) corresponded with a large response (255 ppmv) in the SIFT-MS, which was in contrast with the low response for acetic acid (12 ppmv), despite the high concentrations of the latter in this sourdough (70 mM). Several factors could be accountable for the discrepancy. However, all this seems to limit the use of SIFT-MS to the monitoring of noncharged, volatile compounds, unless precautions are taken to trap these compounds. Nevertheless, the detection of acetoin and ethanol demonstrated the feasibility of SIFT-MS as a real-time monitoring unit for sourdough fermentation processes. Interestingly, extensive microbiological analysis of these fermentation processes showed that the *Lb. sanfranciscensis* IMDO 150101 starter culture added did not dominate all of the fermentations performed (data not shown), allowing other microbiota to grow out, which was confirmed by differences in the volatile sample compounds found through SIFT-MS, i.e., a lowered production of ethanol and acetoin.

In conclusion, the feasibility of SIFT-MS to monitor fermentations through gas sampling in the headspace of fermentation vessels was illustrated, using the case of the production of ethanol during sourdough fermentation. The setup and methodology presented could be used not only to monitor a fermentation process online but also to (semi)-quantify volatiles in real-time without the need for additional samplings. The potential of SIFT-MS as an online monitoring device for food fermentations was further demonstrated by the detection of acetoin in certain sourdough fermentations. This allowed discrimination between sourdough fermentation processes and illustrated the importance of real-time monitoring of food fermentations. However, the performance of the SIFT-MS technique in complex matrices needs further examination, as the current device is restricted to the monitoring of sufficiently volatile compounds.

ABSTRACT: This work evaluated the effects of extra virgin olive oil (EVOO) phenols, hydroxytyrosyl acetate (**2**) and 3,4-dihydroxyphenylglycol (**3**), as well as two new acyl derivatives of **3**, 4-(1,2-di(butanoyloxy)ethyl)benzene-1,2-diol (**7**) and 4-(1,2-di(lauroyloxy)ethyl)benzene-1,2-diol (**8**), on LPS-stimulated murine peritoneal macrophages in comparison with hydroxytyrosol (HTy, **1**). Compounds **2**, **3**, **7**, and **8** showed a strong reactive oxygen species (ROS)-scavenging activity, reducing significantly nitrite levels with a significant decrease on iNOS expression [**2** (50 μM, 0.44 ± 0.03; 100 μM, 0.44 ± 0.01; $p < 0.01$); **3** (50 μM, 0.37 ± 0.03; 100 μM, 0.37 ± 0.01; $p < 0.001$); **7** (50 μM, 0.45 ± 0.06; $p < 0.01$)] . However, only **2** and **3** down-regulated COX-2 expression [**2** (50 μM, 0.72 ± 0.04, $p < 0.05$; 100 μM, 0.54 ± 0.06, $p < 0.01$); **3** (50 μM, 0.56 ± 0.05, $p < 0.05$; 100 μM, 0.37 ± 0.04; $p < 0.001$)] and prevented IKBα degradation [**2** (100 μM, 1.63 ± 0.14, $p < 0.01$); **3** (100 μM, 1.82 ± 0.09; $p < 0.01$)] ; the diacylated compounds **7** and **8** showed worse anti-inflammatory activity than the parent **3**. In conclusion, **2** and **3** phenolic derivatives could play an important role in the anti-inflammatory effect of EVOO. The implication of this study for the nutrition and general health of the population rests in the possible use of natural HTy derivatives with better hydrophilic/lipophilic balance, thus improving its pharmacodynamic and pharmacokinetic profiles, as new dietary supplements in foods.

KEYWORDS: *EVOO, phenols, inflammation, macrophages, NF-κB*

INTRODUCTION

Macrophages are major components of the innate immune system and play a critical role in the inflammation process. Resident macrophages produce pro-inflammatory cytokines and chemokines that attract other cells, including neutrophils and additional macrophages. These cells are activated by exposure to bacterial lipopolysaccharide (LPS) among others. LPS-stimulated macrophages disrupt the balance of the intracellular reduction−oxidation state, which leads to oxidative stress characterized by a major shift in the cellular redox balance and usually accompanied by reactive oxygen species (ROS)-mediated damage.[1] Macrophages express enzymes such as inducible nitric oxide synthase (iNOS) and cylcooxygenase-2 (COX-2) that regulate inflammatory processes.[2] Actually, both proteins are responsible for the overproduction of NO and prostaglandin E_2 (PGE_2), respectively, in inflammation. The process of gene expression of these pro-inflammatory mediators involves multiple signal transduction pathways such as mitogen-activated protein kinases (MAPKs) and nuclear transcription factor κB (NF-κB) pathways. These pro-inflammatory mediators and pathways are regarded as essential anti-inflammatory targets.[3] For this reason, the stimulation of macrophages with LPS constitutes an excellent model for the screening and subsequent evaluation of the effects of candidate drugs on the inflammatory pathway.[4]

Extra virgin olive oil (EVOO), the characteristic fatty component of the Mediterranean diet, is rich in a variety of phenolic compounds, mainly constituted by secoiridoid derivatives of 2-(3,4-dihydroxyphenyl)ethanol (hydroxytyrosol, HTy) (**1**) and 2-(4-hydroxyphenyl)ethanol (tyrosol) along with minor amounts of free HTy and hydroxytyrosyl acetate (HTy-Ac) (**2**).[5]

Evidence has accumulated on the favorable properties of these EVOO phenolic compounds, which have shown a broad spectrum of beneficial activities such as antioxidant, free radical scavenging, anti-inflammatory, or anticancer,[6−8] as well as very good available safety/toxicity.[9] HTy is one of the most studied phenols, which has demonstrated important biological properties acting as a powerful antioxidant scavenger of free radicals[10−13] and modulating signaling pathways involved in antioxidant/detoxifying enzyme regulation, contributing to prevent oxidative stress associated cell damage.[14] In addition, HTy reduces DNA, lipid, and protein damages and strengthens the intracellular antioxidant enzyme mechanisms, protecting the peripheral blood mononuclear cells against oxidative stress.[15] Moreover, antiplatelet aggregation, antiatherogenic,

cardioprotective, antimicrobial, antiviral, anticancer, and anti-inflammatory activities have been reported.[11] Recently, we have demonstrated that supplementation of the diet with HTy may improve chronic colitis through inducible nitric oxide synthase (iNOS) down-regulation plus its antioxidant capacity.[16] Nevertheless, the low lipophilicity of this compound has encouraged us to study two HTy derivatives also present in EVOO: one more lipophilic, hydroxytyrosyl acetate (**2**), and another more hydrophilic, 3,4-dihydroxyphenylglycol (**3**), than HTy (**1**)[17,18] to improve the pharmacokinetic profile and increase bioavailability. The concentration of **2** is approximately equal to that of HTy in some olive oil varieties such as Arbequina, but is twice as high as that of HTy in the Picual variety and 3−4 times as high in the Manzanilla and Hojiblanca varieties.[5] Previous studies have shown that **2** exerts an in vitro neuroprotective effect and an antiplatelet effect in vivo[19] acting as a potential alternative to HTy (**1**) as platelet antiaggregant in prophylaxis for vascular disease. Moreover, another study has demonstrated its ability to increase glucose consumption in 3T3-L1 adipocytes and C2C12 myotubes through the down-regulation of PPARγ, C/EBPα, and SREBP-1c and their downstream target genes (GLUT4, CD36, and FAS).[20] On the other hand, dihydroxyphenylglycol (**3**) is an important phenolic compound that appears in higher concentration than HTy in certain table olive preparations (naturally processed olives)[21] and also importantly presents in the solid olive waste of olive oil extraction.[22] This phenol has shown higher antioxidant and antiradical capacities than HTy and a lipid peroxidation prevention comparable with that of vitamin E.[23] In addition, its bioavailability and antioxidant properties have been demonstrated in vitamin E-deficient rats,[24] and it may also protect against platelet activation and adhesion.[25] However, the anti-inflammatory properties of **2** and **3** and the molecular mechanisms involved remain unexplored.

Furthermore, different studies on phenolic compounds have shown the importance of acyl derivatives of natural phenols because their lipophilic nature allows them to cross the cytoplasmic cell membranes and their uptake by cells, providing a potential protection of membrane constituents.[26,27] Besides, the native phenols that contain several hydroxyl groups often undergo conjugation reactions such as the formation of β-glucuronides catalyzed by a family of enzymes known as the uridine diphosphoglucuronosyl transferases (UGTs). Conjugation with a sulfate moiety or with glutathione also occurs, catalyzed by various sulfotransferases and glutathione-*S*-transferases, respectively. These conjugated products are ideal substrates for various excretory transmembrane transport processes in the liver and kidneys.[26] A deacylation step by lipases of the human digestive system prior to glucuronidation or sulfation may delay the excretion process. In this context, two new derivatives from 3,4-dihydroxyphenylglycol (**3**), 4-(1,2-bis(butanoyloxy)ethyl)benzene-1,2-diol (**7**), and 4-(1,2-bis(lauroyloxy)ethyl)benzene-1,2-diol (**8**) have been synthesized and tested in peritonea macrophages.

Taking this background into account, the aim of the present work was to investigate the potential effects of compounds **2**, **3**, **7**, and **8** in murine macrophage inflammatory response induced by LPS in comparison with hydroxytyrosol (**1**). In this sense, antioxidant activity and protein expression of pro-inflammatory (iNOS and COX-2) enzymes as well as the role of mitogen-activated protein kinases (MAPKs) and nuclear transcription factor-kappa B (NF-κB) signaling pathways involved in the anti-inflammatory effects were determined.

MATERIALS AND METHODS

Chemicals. *General Chemical Procedures.* ^{1}H (300.1 MHz) and ^{13}C (75.5 MHz) NMR spectra were recorded on a Bruker Avance-300 spectrometer. Mass spectra (LSI-MS) were recorded on a Micromass AutoSpec-Q mass spectrometer. IR spectra were recorded on a Jasco FT-IR 4100 spectrophotometer. TLC was performed on silica-coated aluminum sheets from Merck (silica gel 60 F_{254}); spots were visualized by UV light and by staining with vanillin/H_2SO_4 in EtOH (1.5 g of vanillin in 100 mL of 95% EtOH/concentrated H_2SO_4 100:1). Column chromatography was performed using silica gel 60 (particle size 63−200 μm, Merck). All reactions were carried out under a nitrogen or argon atmosphere with dry solvents. Hydroxytyrosol (**1**), obtained from olive mill wastewaters,[28] was used after purification by column chromatography (EtOAc/hexane 1:5 → 1:2).

*3,4-Bis(benzyloxy)phenylglycol (**4**).* To a solution of **3** (200 mg, 0.57 mmol) in dry acetone (20 mL) were added K_2CO_3 (640 mg, 4.63 mmol) and BrBn (320 μL, 2.72 mmol). The mixture was refluxed in the dark for 12 h, filtered, and concentrated to dryness. Column chromatography (EtOAc/hexane 1:5 → 1:1) gave **4** as a white solid (162 mg, 81%): ^{1}H NMR (300 MHz, CD_3OD) δ 7.50−7.29 (m, 10H, Ph), 7.11 (d, 1H, $J_{2,6}$ = 1.9 Hz, Ar-2), 7.02 (d, 1H, $J_{5,6}$ = 8.3 Hz, Ar-5), 6.93 (dd, 1H, $J_{6,5}$ = 8.3 Hz, $J_{6,2}$= 1.9 Hz, Ar-6), 5.15 and 5.13 (2 s, 2H each, 2 OCH_2Ph), 4.62 (t, 1H, J = 6.0 Hz, CH), 3.58 (d, 2H, J = 6.0 Hz, CH_2); ^{13}C NMR (75.5 MHz, CD_3OD) δ 151.1, 150.5 (Ar-3, Ar-4), 139.7, 139.7 (2 Ph-*ipso*), 137.9 (Ar-1), 130.3 (4 Ph-*m*), 129.7 (2 Ph-*p*), 129.6, 129.5 (4 Ph-*o*), 121.6 (Ar-6), 117.2 (Ar-5), 115.6 (Ar-2), 76.4 (CH), 73.4 and 73.3 (2 OCH_2Ph), 69.5 (CH_2); IR (cm^{-1}) 3382, 1515, 1258, 1226, 1135, 1012, 737, 694; HR-LSI-MS m/z calcd for $C_{22}H_{22}NaO_4$ ([M + Na]$^+$) 373.1410, found 373.1429.

*1,2-Bis(benzyloxy)-4-(1,2-bis(butanoyloxy)ethyl)benzene (**5**).* To a solution of **4** (553 mg, 1.58 mmol) in pyridine (3 mL) at 0 °C was added butanoyl chloride (500 μL, 4.81 mmol), and the mixture was stirred for 15 min. The solution was kept at 0 °C overnight. Some drops of water were added, and the solution was diluted with CH_2Cl_2 (90 mL). The solution was washed with 1 M HCl (30 mL) until the pH value reached 1; then it was washed with 1 M $NaHCO_3$ (30 mL) and finally with water. The organic phase was dried ($MgSO_4$), filtered, and concentrated to dryness. The residue was purified by column chromatography (EtOAc/hexane 1:5 → 1:1) to give the product as a colorless syrup (775 mg, quant): ^{1}H NMR (300 MHz, CD_3OD) δ 7.48−7.29 (m, 10H, Ph), 7.06 (d, 1H, $J_{3,5}$ = 1.9 Hz, Ar-3), 7.04 (d, 1H, $J_{6,5}$ = 8.3 Hz, Ar-6), 6.94 (dd, 1H, $J_{5,6}$ = 8.3 Hz, $J_{5,3}$ = 1.9 Hz, Ar-5), 5.95 (dd, 1H, J = 7.0 Hz, J = 5.0 Hz, CH), 5.16 and 5.15 (2s, 2H each, 2 OCH_2Ph), 4.33−4.24 (m, 2H, CH_2O), 2.33 (m, 2H, αCH_2), 2.27 (t, 2H, J = 7.3 Hz, $\alpha'CH_2$), 1.65 and 1.62 (2 sext, 2H each, J = 7.4 Hz, 2 βCH_2), 0.95 and 0.94 (2 t, 3H each, J = 7.4 Hz, 2 CH_3); ^{13}C NMR (75.5 MHz, CD_3OD) δ 175.6, 175.1 (2 CO), 151.4, 151.1 (Ar-1, Ar-2), 139.5 (2 Ph-*ipso*), 132.3 (Ar-4), 130.3 (4 Ph-*m*), 129.8 (2 Ph-*p*), 129.6, 129.5 (4 Ph-*o*), 122.2 (Ar-5), 117.1 (Ar-6), 116.1 (Ar-3), 75.1 (CH), 73.4 and 73.3 (2 OCH_2Ph), 67.8 (CH_2), 37.9, 37.7 (αCH_2), 20.3, 20.2 (βCH_2), 14.7 (2 CH_3); IR (cm^{-1}) 2967, 1736, 1514, 1248, 1166, 1137, 1007, 735, 696; HR-LSI-MS m/z calcd for $C_{30}H_{34}O_6$ ([M]$^+$) 490.2355, found 490.2341.

*1,2-Bis(benzyloxy)-4-(1,2-bis(lauroyloxy)ethyl)benzene (**6**).* To a solution of **4** (400 mg, 1.12 mmol) in pyridine (2.5 mL) at 0 °C was added lauroyl chloride (780 μL, 3.37 mmol), and the mixture was stirred for 15 min. The solution was kept at room temperature for 72 h. Some drops of water were added, and the solution was diluted with CH_2Cl_2 (150 mL). The solution was washed with 1 M HCl (30 mL) until the pH value reached 1; then it was washed with 1 M $NaHCO_3$ (30 mL) and finally with water. The organic phase was dried ($MgSO_4$), filtered, and concentrated to dryness. The residue was purified by column chromatography (EtOAc/hexane 1:5 → 1:1) to give the product as a colorless syrup (0.76 g, 95%): ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ 7.57−7.32 (m, 10H, Ph), 6.93 (d, 1H, $J_{3,5}$ = 1.9 Hz, Ar-3), 6.86 (d, 1H, $J_{6,5}$ = 8.1 Hz, Ar-6), 6.79 (dd, 1H, $J_{5,6}$ = 8.1 Hz, $J_{5,3}$ = 1.9 Hz, Ar-5), 5.94 (dd, 1H, J = 7.5 Hz, J = 4.8 Hz, CH), 5.23 and 5.20 (2s, 2H each, 2 OCH_2Ph), 4.33−4.24 (m, 2H, CH_2O), 2.38 (m, 2H, αCH_2), 2.32 (m, 2H, $\alpha'CH_2$), 1.67−1.58 (m, 4H, βCH_2

The mixture was filtered through a Celite pad and concentrated to dryness. The residue was purified by column chromatography (EtOAc/hexane 1:3) to give a product as a white solid (199 mg, 79%): ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ 6.93 (d, 1H, $J_{3,5}$ = 1.9 Hz, Ar-3), 6.86 (d, 1H, *J* = 8.1 Hz, Ar-6), 6.79 (dd, 1H, *J* = 1.9 Hz, *J* = 8.1 Hz, Ar-5), 5.94 (dd, 1H, *J* = 7.5 Hz, *J* = 4.8 Hz, CH), 4.33−4.24 (m, 2H, CH_2O), 2.34−2.29 (m, 4H, 2 αCH_2 ester), 1.67−1.58 (m, 4H, 2 βCH_2 ester), 1.33 (m, 32H, 16 CH_2 ester), 0.94−0.90 (m, 6H, 2 CH_3); ^{13}C NMR (75.5 MHz, $(CD_3)_2CO$) δ 173.1, 172.6 (2 CO), 145.8, 145.6 (Ar-1, Ar-2), 129.3 (Ar-4), 119.0 (Ar-5), 115.7 (Ar-6), 114.5 (Ar-3), 73.2 (CH), 66.2 (CH_2), 34.5, 34.3, 33.9, 32.4, 29.3, 25.3, 25.2, 22.9 (CH_2 ester), 14.4 (2 CH_3); IR (cm^{-1}) 2917, 2849, 1734, 1699, 1169; HR-LSI-MS *m*/*z* calcd for $C_{32}H_{54}NaO_6$ ($[M + Na]^+$) 557.3813, found 557.3797.

DPPH Radical Scavenging Activity. The free radical scavenging activities of **1**−**3**, **7**, and **8** were measured by decrease in the absorbance of methanolic solution of 1,1-diphenyl-2-picrylhydrazyl radical (DPPH) and was used for the determination of the antioxidant capacity of the compounds in the study.[28,29] Increasing concentrations of each product (1.56−100 μM, in methanol) were added at an equal volume (10 mL) to methanol solution of DPPH (400 μg mL^{-1}). Different concentrations of L-ascorbic acid (1.25−100 mg mL^{-1}) were used as the standard antioxidant. This acid has been widely used as a reference standard in the DPPH assay of polyphenols.[30−32] After 30 min at room temperature, the absorbance values were measured at 517 nm on a spectrophotometer and converted into the percentage antioxidant activity using the following equation: DPPH antiradical scavenging capacity (%) = (absorbance of sample − absorbance of blank) × 100/absorbance of blank. Methanol plus different concentrations of product solution was used as a blank, whereas DPPH solution plus methanol was used as a control. Dose−response curves (1.25−100 μg mL^{-1}) were performed for each product to obtain the respective half-maximum inhibitory concentration (IC_{50}), a value that denotes the concentration of sample required to scavenge 50% of DPPH radicals.

Animals. Fifteen 8−10-week-old male Swiss mice provided by Harlan Interfauna Ibérica (Barcelona, Spain), weighing 20−30 g, were randomly placed in cages (5 mice/cage) and maintained under constant conditions of temperature (20−25 °C) and humidity (40−60%) with a 12 h light/dark cycle and fed standard rodent chow (Panlab A04, Seville, Spain) and water ad libitum throughout the experiment in our Animal Laboratory Center (Faculty of Pharmacy, University of Seville, Spain). All animal care and experimental procedures complied with the Guidelines of the European Union regarding animal experimentation (Directive of the European Counsel 2010/63/EU) and followed a protocol observed by the Animal Ethics Committee of the University of Seville. All studies involving animals are reported in accordance with the ARRIVE guidelines for reporting experiments involving animals.

Isolation and Culture of Murine Peritoneal Macrophages. After 1 week of acclimation, peritoneal macrophages from five mice were elicited by intraperitoneal injection of 1 mL of sterile thioglycollate medium (10% w/v) (Scharlau, Barcelona, Spain), and behavioral observation, water and food consumptions, loss of body weight, and survival were daily monitored until sacrifice. After 3 days, mice were euthanized in the laboratory surgical area by CO_2 exposure and peritoneal exudate cells were obtained by lavage with ice-cold PBS. After centrifugation, cells were suspended in RPMI 1640 medium (PAA, Pasching, Austria) supplemented with 10% heat-inactivated fetal calf serum (FCS) (PAA), L-glutamine (2 mM), glucose (4.5 g l^{-1}), and HEPES buffer (10 mM), in the presence of 100 mg mL^{-1} streptomycin and 100 U mL^{-1} penicillin (PAA) and then seeded in culture plates (1 × 10^6 cells mL^{-1}) for 2 h at 37 °C in a 5% CO_2 humidified atmosphere. After 2 h, nonadherent cells were removed by washing with PBS and fresh RPMI 1640 medium supplemented with 5% FCS containing **1**−**3**, **7**, and **8**, respectively, was added. After 30 min, murine peritoneal macrophages (1 × 10^6 cells mL^{-1}) were treated with 5 μg mL^{-1} of LPS from *Escherichia coli* (Sigma-Aldrich, St. Louis, MO, USA) in the absence or presence of each compound in the study for 18 h. In each experiment, viability was always ≥95%. Stock solutions of **1**−**3**, **7**, and **8** at a concentration of 100 mg mL^{-1} were always freshly prepared in dimethyl sulfoxide (DMSO) (Panreac, Barcelona, Spain) and diluted to the desired concentration in the culture medium. The final concentration of DMSO in the culture medium was ≤1% in all experiments, and it had no significant influence on cell response.

Cell Viability Assay. Cells seeded in 96-well plates (1 × 10^5 cells $well^{-1}$) were incubated in the presence or absence of **1**−**3**, **7**, and **8** for 18 h. At the end of the exposure time, the effect of these compounds on cell growth/viability was analyzed by sulforhodamine B (SRB) assay.[33] After incubation time, adherent cell cultures were fixed in situ by adding 50 μL of 50% (w/v) cold of trichloroacetic acid (Sigma-Aldrich) and incubated for 60 min at 4 °C. The supernatant was discarded, and plates were washed five times with deionized water and dried. Fifty microliters of SRB (Sigma-Aldrich) solution (0.4% w/v) in 1% acetic acid (Panreac) was added to each well and incubated for 30 min at room temperature. Plates containing SRB solution were washed five times with 1% acetic acid. Then, plates were air-dried, and 100 μL per well of 10 mmol L^{-1} Tris base, pH 10.5 (Sigma-Aldrich), was added, and the absorbance of each well was read on an enzyme-linked immunosorbent assay reader at 510 nm (BioTek, Bad Friedrichshall, Germany). Finally, cell survival was measured as the percentage of absorbance compared with that obtained in control cells (nontreated cells).

Measurement of Nitrite Production. Cells in a 24-well plate were untreated or treated with different concentrations of **1**−**3**, **7**, and **8** and 30 min later stimulated with LPS for 18 h. The culture supernatants (100 μL) were transferred to a 96-well assay plate mixed with Griess reagent (Sigma, St. Louis, MO, USA) and incubated for 15 min at room temperature. The amount of nitrite, as an index of NO generation, was determined by a spectrophotometric method using the Griess reaction[34] and obtained by extrapolation from a standard curve with sodium nitrite. The absorbance at 540 nm was measured by an enzyme-linked immunosorbent assay reader (BioTek). Results were expressed as the nitrite production percentage compared with LPS control cells (stimulated untreated cells). One micromolar dexamethasone (Sigma) was used as positive control (data not shown).

Immunoblotting Detection. Cells (1 × 10^6 cells mL^{-1}) were untreated or treated with **1**−**3**, **7**, and **8** and stimulated with LPS for 18 h. After incubation, cells were rinsed, scraped off, and collected in ice-cold PBS containing a cocktail of protease and phosphatase inhibitors and processed as described by Sánchez-Hidalgo et al.[35] to isolate

J. Agric. Food Chem. 2015, 63, 836−846

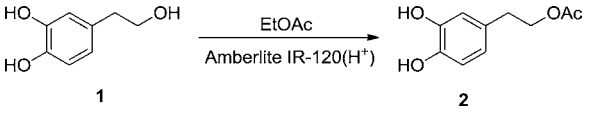
proteins. Protein concentration was measured for each sample using a protein assay reagent (Bio-Rad, Hercules, CA, USA) according to the Bradford method and using γ-globulin as a standard.[36] Aliquots of supernatant containing equal amounts of protein (20 μg) were separated on 10% acrylamide gel by sodium dodecyl sulfate–polyacryamide gel electrophoresis. In the next step, the proteins were electrophoretically transferred into a nitrocellulose membrane and incubated with specific primary antibodies: rabbit anti-COX-2 and rabbit anti-iNOS (Cayman Chemical, Ann Arbor, MI, USA) (1:2500 and 1:1000, respectively); rabbit anti-IκBα, (Cell Signaling, Danvers, MA, USA) (1:1000); mouse anti-pJNK, rabbit anti-JNK, mouse anti-pp38, and rabbit anti-p38 (Santa Cruz Biotechnology, Santa Cruz, CA, USA) (1:1000) overnight at 4 °C. After rinsing, the membranes were incubated with a horseradish peroxidase-labeled (HRP) secondary antibody antirabbit (Cayman Chemical) (1:50000) or anti-mouse (Dako, Atlanta, GA, USA) (1:2000) containing blocking solution for 1–2 h at room temperature. To prove equal loading, the blots were analyzed for β-actin expression using an anti-β-actin antibody (Sigma-Aldrich). Immunodetection was performed using enhanced chemiluminescence light-detecting kit (Pierce, Rockford, IL, USA). The immunosignals were captured using an LAS-3000 Imaging System from Fujifilm Image Reader (Stamford, CT, USA), and densitometric data were studied following normalization to the housekeeping loading control. The signals were analyzed and quantified by an Image Processing and Analysis in Java (ImageJ, Softonic) and expressed in relation to the DMSO–LPS-treated cells.

Statistical Evaluation. All values in the figures and text are expressed as arithmetic means ± standard error (SEM). Experiments were carried out in triplicate. Data were evaluated with Graph Pad Prism version 5.01 software (San Diego, CA, USA). The statistical significance of any difference in each parameter among the groups was evaluated by one-way analysis of variance (ANOVA), using Tukey's multiple-comparisons test as post hoc test. P values of <0.05 were considered statistically significant. In the experiments involving densitometry, the figures shown are representative of at least three different experiments performed on different days.

RESULTS

Chemistry. The synthesis of HTy-Ac (**2**) was carried out from hydroxytyrosol (**1**) by a chemoselective acid-catalyzed transacetylation reaction (74%) by refluxing in EtOAc in the presence of a strong acidic resin (Scheme 1), following a proprietary procedure.[37] The naturally occurring 3,4-dihydroxyphenylglycol (**3**) was prepared from 3,4-dihydroxyphenacyl chloride following a procedure reported elsewhere (Sánchez-Fidalgo et al. 2014, submitted for publication).

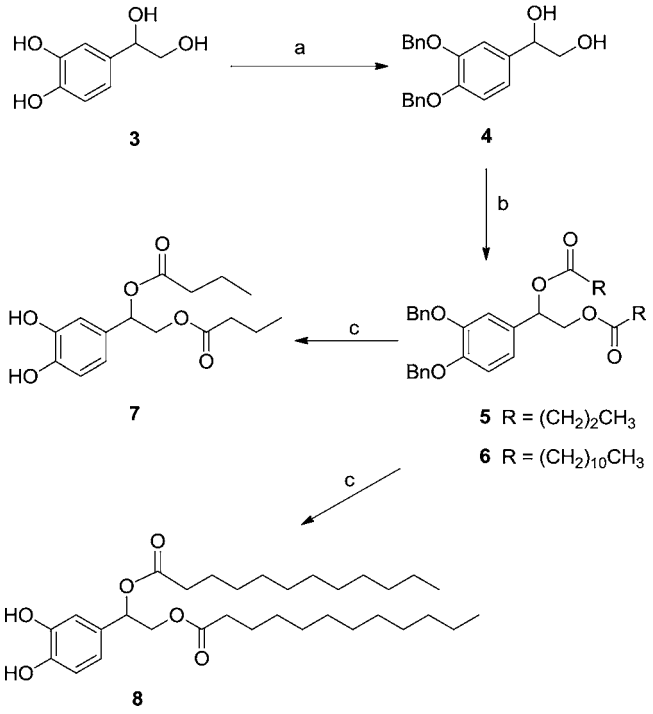
Scheme 1. Synthesis of Hydroxytyrosyl Acetate (2) by Chemoselective Transesterification Reaction of 1



Although hydroxytyrosol and its lipophilic derivatives have been widely studied, there are many fewer reports on the biological properties and the chemical transformations of compound **3**. Herein we describe for the first time the synthesis of diacyl derivatives of **3** in order of increasing its reduced lipophilia.

Chemoselective protection of catechol fragment of **3** was performed in good yield (81%) by treatment with benzyl bromide in acetone under reflux the presence of potassium carbonate (Scheme 2). The higher acidity of the phenolic hydroxyl groups compared to the aliphatic alcohol explains the observed selectivity. The exhaustive acylation of the glycol moiety with butanoyl and lauroyl chlorides (3 equiv) in pyridine gave **5** and **6** in excellent yield (quant and 95%, respectively). Finally, deprotection of the catechol moiety of **5** and **6** by hydrogenolysis afforded **7** and **8** in a good yield (90 and 79%, respectively).

Scheme 2. Synthesis of Diacylated 3,4-Dihydroxyphenylglycols, 7 and 8, from 3[a]



[a]Conditions: (a) BnBr, K_2CO_3, acetone, reflux, 12 h; (b) acyl chloride, pyridine, room temperature, 72 h; (c) H_2, 10% Pd/C, EtOH, or THF, room temperature, 24 h.

DPPH Radical Scavenging Activity of 1–3, 7, and 8. DPPH scavenging activity assay is a useful method for determination free radical scavenging activities of antioxidant compounds. As shown in Figure 1, the DPPH radical scavenging rates of the compounds were found to be higher than those of the standard ascorbic acid. However, compounds **1–3** have shown the best antioxidant activities. The IC_{50} values, defined as the effective concentration at which the antioxidant activity was 50% of **1–3**, **7**, and **8** and ascorbic acid, were 1.60 ± 0.21, 1.73 ± 0.26, 1.55 ± 0.11, 7.49 ± 0.26, 5.04 ± 0.215, and 14.30 ± 0.60 μM, respectively.

Effects of 1–3, 7, and 8 on Cell Viability. To evaluate the anti-inflammatory effect of these compounds, we determinate their effect on the viability of mouse peritoneal macrophages by SRB assay. After 18 h, our data demonstrated that the viability of cells treated with **1**, **2** and **3** separately was not significantly reduced at concentrations of 25–100 μM (data not shown). However, **7** and **8** at 100 μM had cell viability <90%; therefore, these compounds were assayed at 25 and 50 μM in the next studies.

Effects of 1–3, 7, and 8 on Nitrite Production. LPS induces the synthesis and release of NO into murine macrophage cell medium by iNOS protein expression.[38] As shown in Figure 2, co-incubation with **2**, **3**, and **7**, separately, significantly reduced nitrite production at similar levels of **1** (***, p < 0.001 vs DMSO–LPS control).

Figure 1. DPPH scavenging effect of hydroxytyrosol (**1**), hydroxytyrosyl acetate (**2**), 3,4-dihydroxyphenylglycol (**3**), 4-(1,2-bis(butanoyloxy)-ethyl)benzene-1,2-diol (**7**), and 4-(1,2-bis(lauroyloxy)ethyl)benzene-1,2-diol (**8**). Values are expressed as the mean ± SEM. Values are the mean of three experiments. IC_{50} values represent the means ± SEM of three measurements.

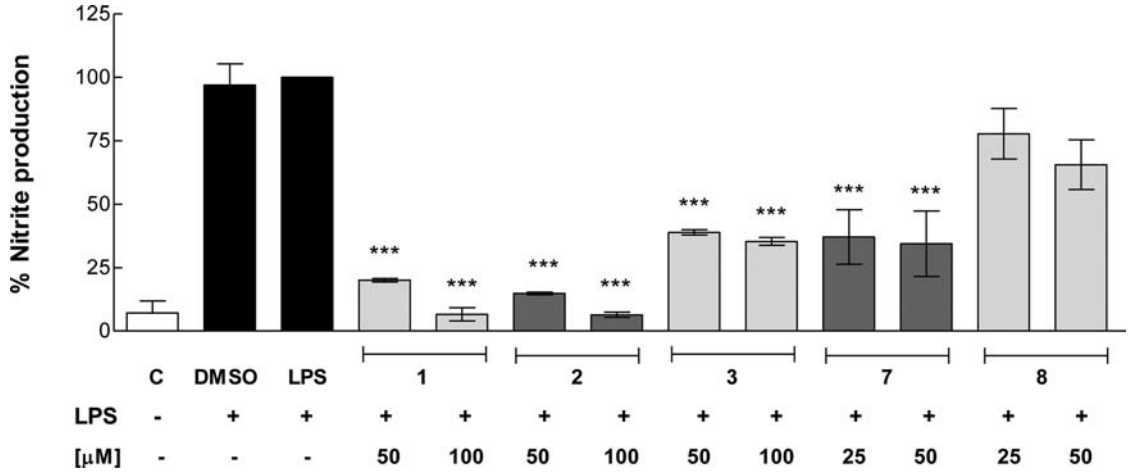

Figure 2. Effect of hydroxytyrosol (**1**), hydroxytyrosyl acetate (**2**), 3,4-dihydroxyphenylglycol (**3**), 4-(1,2-bis(butanoyloxy)ethyl)benzene-1,2-diol (**7**), and 4-(1,2-bis(lauroyloxy)ethyl)benzene-1,2-diol (**8**) on LPS-induced NO production. Each value represents the mean ± SEM for three independent experiments. (***) $p < 0.001$ versus DMSO-treated control cells.

Effects 1−3, 7, and 8 on iNOS Expression. The above data suggest that these compounds could down-regulate iNOS enzyme activity. This hypothesis was assessed by measuring of iNOS protein levels by Western blotting. Immunoblotting analysis demonstrated that **1**−**3** caused a significant inhibition of LPS-induced iNOS expression at 50 and 100 μM (** $p <$ 0.01, and ***, $p < 0.001$ vs DMSO−LPS control, respectively) (Figure 3). However, a significant iNOS reduction was observed only with the highest concentration (50 μM) of **7**

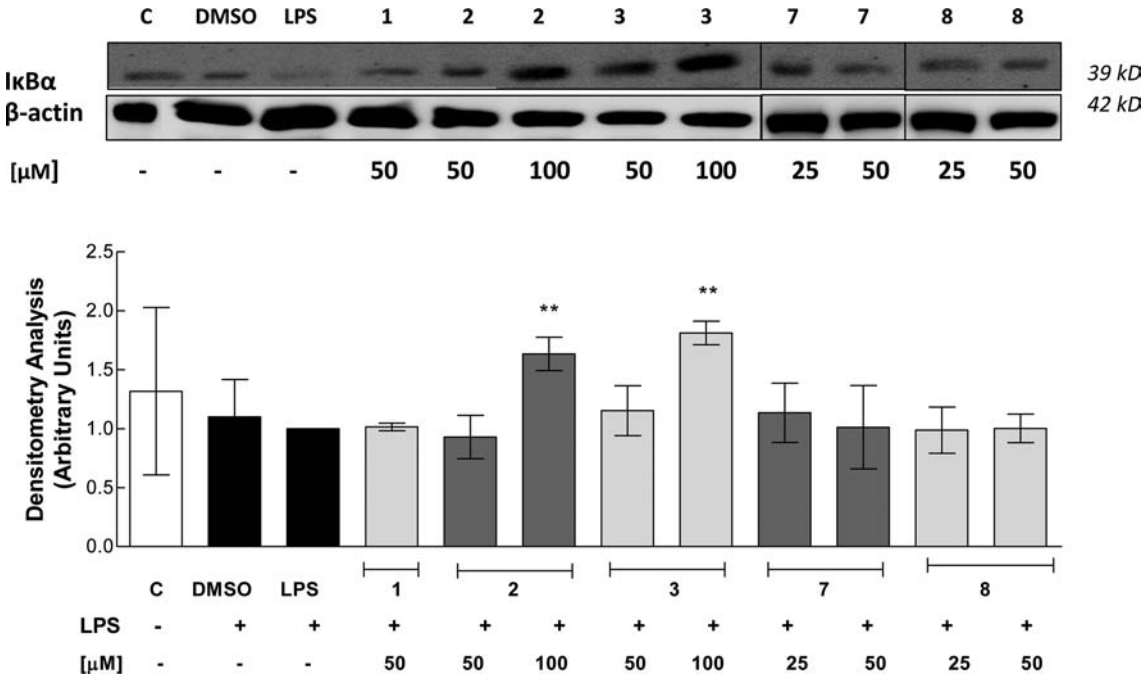

Figure 5. Effect of hydroxytyrosol (**1**), hydroxytyrosyl acetate (**2**), 3,4-dihydroxyphenylglycol (**3**), 4-(1,2-bis(butanoyloxy)ethyl)benzene-1,2-diol (**7**), and 4-(1,2-bis(lauroyloxy)ethyl)benzene-1,2-diol (**8**) on IKBα degradation in murine peritoneal isolated macrophages. Cells were untreated or treated with **1**−**3**, **7**, and **8** for 18 h in the presence of LPS. As controls, cells were also treated with DMSO (solvent control) and LPS or untreated in the absence of LPS. The results are representative of three independent experiments. Densitometry was performed following normalization to the control (β-actin housekeeping gene). Data are expressed as the mean ± SEM. (**) $p < 0.01$ versus DMSO-treated control cells.

effects of **1**−**3**, **7**, and **8** on COX-2 inflammation-related enzyme. COX-2 protein expression was remarkably increased after LPS stimulation, whereas a significant down-regulation on this pro-inflammatory protein expression was seen in macrophages treated with 50 μM **1** and 50 and 100 μM **2** and **3**: (**1**) *, $p < 0.05$; (**2**) *, $p < 0.05$, and **, $p < 0.01$, respectively; and (**3**) *, $p < 0.05$, and ***, $p < 0.001$, respectively, vs DMSO−LPS control) (Figure 4). However, no COX-2 expression changes were observed after treatment with **7** and **8**.

Effects of 1−3, 7, and 8 on LPS-Induced IKBα Degradation in LPS-Murine Peritoneal Macrophages. NF-κB is a pleiotropic mediator in the control of several inducible and tissue-specific genes and is one of the key regulators of the cellular responses to oxidative stress in mammalian cells.[39] NF-κB activation is initiated by the LPS-activated IκBα kinase signal followed by phosphorylation and degradation of IκBα. After IκBα is degraded, NF-κB in the NF-κB−IκBα complex is free to be translocated into the nucleus, where it can induce the expression of pro-inflammatory genes contributing to the damage. To determine whether pro-inflammatory protein down-regulation is regulated by the IκBα pathway, we measured the expression levels of IκBα in cytosolic fractions of mouse peritoneal macrophages treated with 5 μg mL^{-1} LPS and incubated in the presence or absence of the compounds individually for 18 h. As shown in Figure 5, pretreatment with **2** and **3** at 100 μM significantly prevented IκBα translocation (**, $p < 0.01$ vs DMSO control). Nevertheless, no changes were observed after **1**, **7**, and **8** treatments.

Effects of 2 and 3 on LPS-Induced MAPKs Activation in Murine Peritoneal Macrophages. To explore the possible molecular mechanisms of compounds **2** and **3** underlying the anti-inflammatory effects, we determined their potential effects on the MAPKs signaling pathway. We evaluated whether both concentrations (50 and 100 μM) were able to modulate JNK and p38 MAPKs activation after 18 h of LPS stimulation by Western blotting. Our findings demonstrated no significant changes in p38 and JNK protein phosphorylation after both treatments, suggesting that the MAPKs signaling pathway does not make a consistent contribution in the anti-inflammatory activities of **2** and **3** HTy derivatives on mouse peritoneal macrophages (Figure 6).

DISCUSSION

Our findings have shown for the first time that these phenol compounds, mainly compounds **2** and **3**, showed significant antiradical and antioxidant activities and thus prevented the progression of cellular damage induced by LPS acting as effective antioxidants. Balance disruption of the intracellular reduction−oxidation state has been observed in activated macrophages, which leads to oxidative stress characterized by a major shift in the cellular redox balance and usually accompanied by ROS-mediated damage.[1] Therefore, modulators of ROS production and ROS-induced signaling pathways, especially in macrophages, could represent potential targets for anti-inflammatory intervention.[40] Our findings are in agreement with other in vitro studies in which EVOO-isolated phenols, that is, **1** or oleuropein showed strong antioxidant effects acting as powerful scavenger of free radicals in a similar range and higher than those tested in our study (50−100 μM).[41,42] In addition, **2** has shown protective effects against oxidative DNA damage in blood cells[43] and against iron-induced oxidative stress in human cervical cells (HeLa)[44] as well as a neuroprotective effect in a model of hypoxia−reoxygenation in rat brain slices, both in vitro and after oral administration.[12] On the other hand, **3** presented higher antioxidant and antiradical capacities and reducing power than **1** and prevented lipid peroxidation to a degree that was comparable with that of

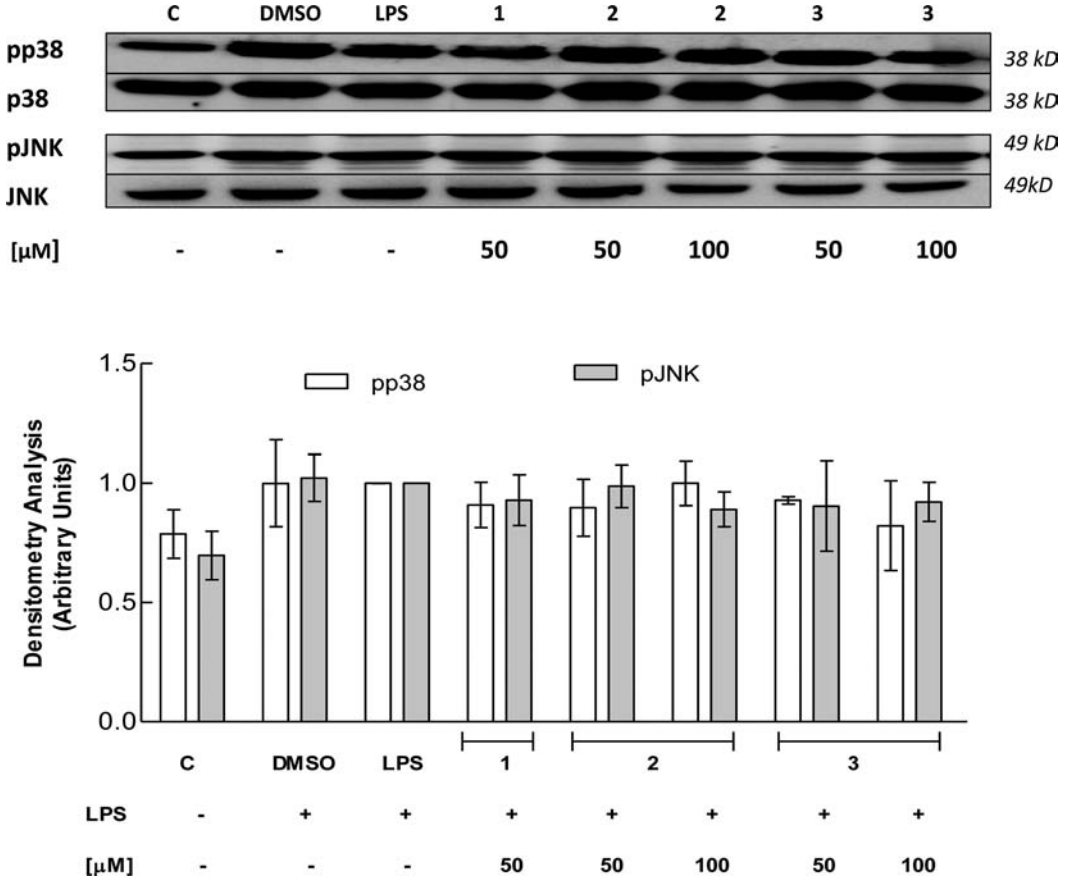

Figure 6. Effect of hydroxytyrosol (**1**), hydroxytyrosyl acetate (**2**), and 3,4-dihydroxyphenylglycol (**3**) on p38 and JNK MAPKs activation in murine peritoneal macrophages. Cells were untreated or treated with **1**−**3** (50 and 100 μM) for 18 h in the presence of LPS. As controls, cells were also treated with DMSO (solvent control) and LPS or left untreated in the absence of LPS. The results are representative of three independent experiments. Densitometry was performed following normalization to the control (JNK and p38 housekeeping genes, respectively).

vitamin E.[21] Furthermore, **1** and **3** have shown free radical scavenging properties after measuring plasma levels of thiobarbituric acid reactive substances by HPLC in a vitamin E-deficient rats in vivo model, which may represent relevant antioxidant activities by which these olive phenolics could have beneficial impact on health.[24]

Stimulation of macrophages by LPS induces transcription of the iNOS gene and generation of large amounts of NO. NO acts as an intracellular messenger, which modulates the formation of endogenous ROS including hydrogen peroxide, peroxynitrite, and other potential oxidants that orchestrate the inflammatory response.[40] In the present study we found that exposure of peritoneal macrophages to LPS resulted in a significant increase of nitrite/nitrate levels as a NO production indicator and an up-regulation of iNOS protein expression. However, **1**−**3** and **7** reduced significantly both nitrite production and iNOS expression, in contrast to **8**, which showed a lower reduction of NO production at 50 μM but no changes in LPS-induced iNOS expression.

COX-2, the inducible isoform of COX, is the key enzyme that catalyzes the two sequential steps in the biosynthesis of prostaglandins (PGs) from arachidonic acid and plays a critical role in inflammatory response. Our data showed that COX-2 protein expression was significantly induced by LPS stimulation, but treatments of LPS-stimulated murine macrophages with **1**−**3** produced a remarkable down-regulation of COX-2 expression. Nevertheless, no changes were observed after treatment with **7** and **8**. These results are in accordance with a previous study by Richard et al. in which **1** prevented the up-regulation of iNOS and COX-2 and inhibited the production of PGE_2 in RAW murine macrophages.[45] Similar data were obtained in THP-1 cells and in cultured endothelial cells.[46,47]

Toll-like receptors (TLRs) are located as well as macrophages on other immune cells such as dendritic cells and T and B cells, where they play an important role in the detection of pathogens and enable their elimination from the body.[48,49] LPS can trigger groups of different TLR especially TLR4, starting downstream signaling cascades, including mitogen-activated protein kinases (MAPKs) and the nuclear transcription factor kappa-B (NF-κB) pathways. NF-κB, as a dimeric transcription factor, exists in the cytoplasm as an inactive complex with the inhibitory protein IκBα. When cells are challenged with pro-inflammatory stimuli, for example, LPS, IκBα undergoes phosphorylation and subsequently ubiquitination, allowing NF-κB to translocate to the nucleus. As a result, NF-κB binds to κB enhancer elements present in the promoter region of many pro-inflammatory genes, for instance, iNOS and COX-2.[50] Our results show that pretreatment with **2** and **3** significantly prevented IκBα degradation after LPS stimulus. However, no significant changes were observed in IκBα expression after **1**, **7**, and **8** treatments. Other researchers have shown that anti-inflammatory activity by EVOO isolated phenols is mediated, at least in part, by NF-κB signaling. For instance, **1** at 25−100 μM has been demonstrated to block NF-κB intracellular oxidative stress attenuating iNOS and COX-2 expressions in human monocytes.[46] This capacity to regulate

DOI: 10.1021/jf503357s
J. Agric. Food Chem. 2015, 63, 836−846

NF-κB genes was also described in J774 murine macrophages and in N2a cells against amyloid-β-induced toxicity.[51,52] Nevertheless, our data are in agreement with another previous paper in which no significant changes after co-incubation with **1** in HT-29 human cells were observed.[53] Moreover, a recent paper has showed that HTy suppressed NO production by decreasing iNOS gene expression through a mechanism independent of the NF-κB signaling pathway.[54] Maybe these discrepancies could be explained in terms of different phenol concentrations and changes on cell experimental conditions.

As above-mentioned, LPS can induce MAPK activation. MAPKs are a family of serine−threonine kinase enzymes that orchestrate the recruitment of gene transcription, protein biosynthesis, cell cycle control, apoptosis, and differentiation and allow cells to respond to oxidative stress and inflammatory stimuli from their extracellular environment.[55] MAPKs include extracellular signal-regulated kinases (ERKs-1 and -2), c-Jun N-terminal kinases (JNKs), and p38 MAPKs. In fact, MAPKs have been shown to play important roles in iNOS and COX-2 up-regulation induced by various stimuli in mammalian cells. Nevertheless, our findings demonstrated no significant changes in p38 and JNK protein phosphorylation after treatments, suggesting that MAPKs signaling pathway does not make a consistent contribution in the anti-inflammatory effects of **2** and **3** in mouse peritoneal macrophages. In conclusion, this study establishes for the first time that the natural HTy derivatives **2** and **3** present in EVOO inhibit LPS-induced oxidative stress and inflammatory response via direct down-regulation of NO generation. These protective effects seem to be due to a down-regulation of iNOS and COX-2 protein expression via inhibition of the NF-κB signaling pathway. Acylation of the side chain of 3,4-hydroxyphenylglycol **3** by catechol protection, acylation of aliphatic hydroxyl groups, and deprotection afforded diacylated **7** and **8**. which show worse anti-inflammatory activity than the parent **3**. Furthermore, **8**, with the longer acyl chains, showed the worst behavior on the stimulated macrophages. The implication of this study for nutrition and general health of the population rests in the possible use of natural HTy derivatives with better hydrophilic/lipophilic balance, thus improving their pharmacodynamic and pharmacokinetic profiles, as new dietary supplements in foods; however, further in vivo studies are in progress to fully understand the role of EVOO phenols in the management of inflammation-related diseases.

Demethoxycurcumin Modulates Human P-Glycoprotein Function via Uncompetitive Inhibition of ATPase Hydrolysis Activity

Yu-Ning Teng,[†] Yow-Wen Hsieh,[†,‡] Chin-Chuan Hung,*[,†,‡,∥] and Hui-Yi Lin*[,†,‡,∥]

[†]Department of Pharmacy, College of Pharmacy, China Medical University, Taichung, Taiwan

ABSTRACT: Curcuminoids are major components of *Curcuma longa* L., which is widely used as spice in food. This study aimed at identifying whether curcumin, demethoxycurcumin, and bisdemethoxycurcumin could modulate efflux function of human P-glycoprotein and be used as chemosensitizers in cancer treatments. Without altering P-glycoprotein expression levels and conformation, the purified curcuminoids significantly inhibited P-glycoprotein efflux function. In rhodamine 123 efflux and calcein-AM accumulation assays, demethoxycurcumin demonstrated the highest inhibition potency (inhibitory IC_{50} = 1.56 ± 0.13 μM) among the purified curcuminoids, as well as in the fold of reversal assays. Demethoxycurcumin inhibited P-glycoprotein-mediated ATP hydrolysis under concentrations of <1 μM and efficiently inhibited 200 μM verapamil-stimulated ATPase activity, indicating a high affinity of demethoxycurcumin for P-glycoprotein. These results suggested that demethoxycurcumin may be a potential additive natural product in combination with chemotherapeutic agents in drug-resistant cancers.

KEYWORDS: *curcuminoids, demethoxycurcumin, P-glycoprotein, multidrug resistance, kinetic mechanism*

INTRODUCTION

Human P-glycoprotein (P-gp), encoded by the *ABCB1* gene, is an efflux transporter that belongs to the ATP-binding cassette (ABC) transporter superfamily.[1] It is a 170 kDa transmembrane protein and expresses abundantly in the apical membranes of major excretory organs, such as the kidney, liver, and intestines, as well as the luminal surface of blood−tissue interfaces, such as the blood−brain, blood−testis, and blood−ovarian barriers.[2] A wide range of therapeutics drugs are substrates of P-gp, including anticancer agents (e.g., vinca alkaloids, anthracyclines, and taxanes), HIV protease inhibitors, immunosuppressive drugs, antidepressants, and steroids.[3] It affects the absorption, distribution, and elimination of these substrates and contributes a major role in multidrug resistance (MDR) in cancer treatment.[4] The overexpressed P-gp has been found in several human tumors and confers resistance to chemotherapeutic agents.[5] Therefore, identifying molecules that interfere with human P-gp function or expression may be a potential target for reversing MDR in cancers.

To date, three generations of P-gp inhibitors have been developed.[6] However, none of these compounds could achieve beneficial clinical outcomes.[7] The most considerable reasons for the failure of these synthetic compounds were the toxicities and pharmacokinetic interactions.[4] These clinical reports led to the search for P-gp inhibitors from natural products, which are generally considered to be safer and nontoxic at usual doses. Curcuminoids are natural phenolic compounds extracted from the rhizome of *Curcuma longa* Linn. and are commonly used as spices in food and health products. The three major isolated curcuminoids are curcumin, demethoxycurcumin, and bisdemethoxycurcumin.[8] Previous studies have shown that natural curcuminoids possess many pharmacological activities, such as anti-inflammation, antioxidant, and anticancer effects.[9−13] Besides these effects, several studies have shown that the commercial grade mixture of curcuminoids, composed of approximately 77% curcumin, 17% demethoxycurcumin, and 3% bisdemethoxycurcumin, were able to modulate P-gp expression and function in hepatocytes and cancer cells.[14,15] Most of the previous studies utilized the commercial grade curcuminoids and were unable to identify the individual effect of the three major curcuminoids on P-gp. Recently, limited studies reported that the isolated curcumin, demethoxycurcumin, and bisdemethoxycurcumin may diversely contribute to the influence of P-gp expression and function.[16,17] However, inconsistent results have been obtained among different studies, and kinetic mechanisms of interactions between P-gp and the three major curcuminoids were not investigated.

The present study aimed to evaluate the effect of individual curcuminoids, including curcumin, demethoxycurcumin, and bisdemethoxycurcumin, on human P-gp expression and function. Further in-depth biochemical and kinetic mechanism investigation was performed to elucidate the differential P-gp inhibition potency of these major curcuminoids. The effect of the most potent curcuminoid on the sensitivity of the chemotherapeutic agent in the P-gp overexpression cells was also examined to evaluate the potential of curcuminoids to overcome P-gp-mediated MDR in cancer chemotherapy.

MATERIALS AND METHODS

Chemicals. *R*-(+)-Verapamil, doxorubicin, MTT reagent, DMSO, rhodamine 123, and calcein-AM were purchased from Sigma Chemical Co (St. Louis, MO, USA). The Flp-In system and all cell culture medium were obtained from Invitrogen (Carlsbad, CA, USA). The full-length human *ABCB1* cDNA in pMDRA1 was supplied by the Riken BRC DNA bank (RDB No. 1372) (Ibaraki, Japan). Curcumin (C), demethoxycurcumin (DMC), and bisdemethoxycurcumin

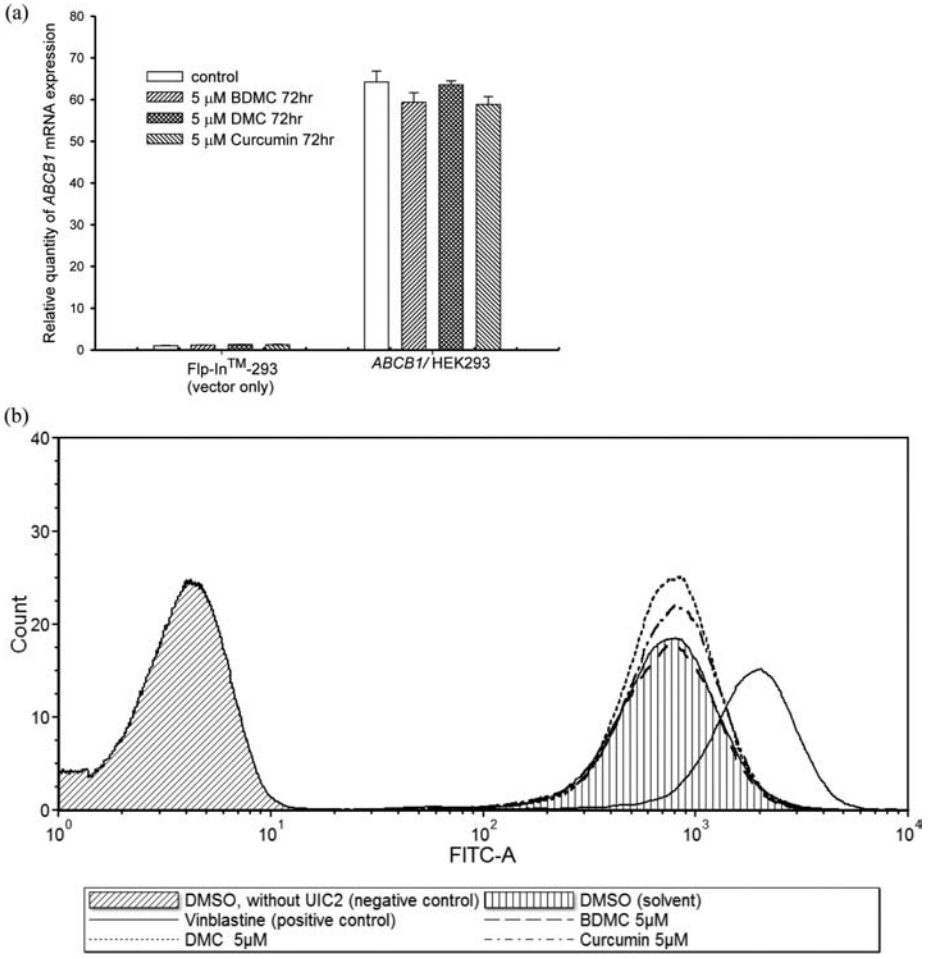

Figure 1. Effect of purified curcuminoids on P-gp mRNA expression and conformational changes. (a) Human P-gp mRNA levels were detected by real-time quantitative RT-PCR. There were no significant differences between no treatment and 72 h of treatment of 5 μM purified curcuminoids. Data are presented as the mean ± SE of at least three experiments, each in triplicate. (b) MDR1 shift assay was applied to examine the effect of 5 μM purified curcuminoids on P-gp conformational changes. Vinblastine, a P-gp substrate, was used as a positive control. The peaks of purified curcuminoids did not shift, as compared to the solvent, indicating that the purified curcuminoids did not change the conformation of P-gp to the open form.

(BDMC) were extracted and isolated from roots of *Curcuma longa* as in our previous study;[18] the isolated three pigments were identified to be >98% pure.

Cell Culture. The human P-gp overexpression cells were established and verified in our previous studies.[19,20] To be brief, the host Flp-In-293 cells were cultured in DMEM containing 10% fetal bovine serum and 100 μg/mL zeocin at 37 °C, 95% humidity, and 5% CO_2. The constructed pcDNA5/*ABCB1* plasmid and pOG44 plasmid were cotransfected into the Flp-In-293 cells. The human P-gp stable transfected cells (*ABCB1*/HEK293) were selected on the basis of hygromycin B resistance.

Cytotoxicity Assay. Cytotoxicities of curcuminoids toward Flp-In-293 and *ABCB1*/HEK293 cells were determined by MTT assay. The cells were seeded into 24-well plates overnight, and series concentrations of curcuminoids (from 1 to 500 μM) were added. After 72 h of incubation, the medium was removed, and 200 μL of fresh culture medium containing 0.5 mg/mL MTT was added. The medium was removed after incubation at 37 °C for 4 h, and 200 μL of DMSO was added. After incubation at room temperature for 30 min, 100 μL of solution was transferred to a 96-well plate, and absorbance was measured using an ELISA plate reader (Molecular Devices, Sunnyvale, CA, USA) at 570 nm with a reference wavelength of 650 nm. The sensitivities of Flp-In-293 and *ABCB1*/HEK293 cells to doxorubicin were also evaluated by the MTT assay. The concentration reaching 50% cell growth inhibition (IC_{50}) was calculated, and the fold reversal factor was further determined according to the previous study.[21]

Real-Time Quantitative RT-PCR and MDR1 Shift Assay. *ABCB1* mRNA expression levels were evaluated by real-time quantitative RT-PCR. The Qiagen RNeasy kit (Valencia, CA, USA) was used to extract total RNA from the transfected cells. The primers and probes for human *ABCB1* and *GAPDH* genes were Taqman Assay on Demand reagents (Applied Biosystem, Foster City, CA, USA). The relative expression of *ABCB1* mRNA was analyzed using an ABI Prism 7900 Sequence Detection System and normalized to the amount of *GAPDH* in the same cDNA by using the standard curve method described by the manufacturer.

The conformation change of P-gp after the addition of test compound was examined by using a MDR1 Shift Assay kit (EMD Millipore Corp., Billerica, MA, USA) according to the manufacturer's protocol. UIC2 shift was shown in the presence of a P-gp substrate such as vinblastine. A total of 5×10^5–1×10^6 cells were prepared per reaction and resuspended with warm UIC2 binding buffer. Cells were incubated at 37 °C for 10 min and then treated with DMSO or vinblastine or test compounds. Cells were incubated at 37 °C for 30 min and then treated with IgG2a (negative control antibody) or UIC2 working solution (P-gp conformational sensitive antibody). Cells were incubated at 37 °C for 15 min and then washed with iced UIC2 binding buffer twice. A secondary antibody, goat anti-mouse IgG ALEXA 488, was added at 4 °C for 15 min, and then iced UIC2 binding buffer was added. The fluorescence was measured by FACS analysis (BD FACSCanto System).

P-gp ATPase Activity Assays. The Pgp-GIO assay system (Promega, Madison, WI, USA) was used to evaluate the effect of curcuminoids on P-gp ATPase activity according to the manufacturer's protocol. In a 96-well untreated white plate, curcuminoids (from 1 to 100 μM) were incubated with 25 μg of recombinant human Pgp membrane. The P-gp-GIO assay buffer was used as the untreated control, 200 μM verapamil was used as the positive control of drug-induced P-gp ATPase activity, and 100 μM sodium orthovanadate was used as the selective inhibitor of P-gp ATPase activity. The ATPase activity was initiated by the addition of 5 mM MgATP and incubated at 37 °C for 60 min. Further luminescence was initiated by adding 50 μL of ATP detection reagent; after 20 min of incubation at room temperature, the plate was read on the SpectraMax Gemini XS microplate spectrofluorometer (Molecular Devices Co.).

Rhodamine 123 Efflux Assay. For the rhodamine 123 efflux assays, 1×10^5 cells/well were seeded on 96-well plates and cultured for 24 h. The cells were washed and preincubated with Hanks' balanced salt solution (HBSS) for 30 min, and subsequently incubated in 1 μM rhodamine 123 for 30 min with or without curcuminoids in triplicate. After a washing with warm PBS, cells were allowed to efflux rhodamine 123 for 10 min at 37 °C in the incubator. Samples (100 μL) were collected and transferred to 96-well black plates. The fluorescence was measured by the SpectraMax Gemini XS microplate spectrofluorometer (Molecular Devices Co.) with the excitation set at 485 nm and the emission set at 535 nm. The rhodamine 123 concentration was obtained by comparison to the standard curve. Each experiment was performed at least three times, each in triplicate on different days.

Calcein-AM Uptake Assay. For the calcein-AM uptake study, 1×10^5 cells/well were placed on 96-well black plates and cultured overnight. Before the uptake assay, cells were washed and preincubated with HBSS for 30 min and subsequently with curcuminoids for 30 min. After preincubation, calcein-AM was added and incubated at 37 °C in the incubator for 30 min. After a washing with ice-cold HBSS, cells were lysed with 1% Triton X-100, and intracellular calcein fluorescence was analyzed by the SpectraMax Gemini XS microplate spectrofluorometer (Molecular Devices Co.) with the excitation at 485 nm and the emission at 535 nm. Each experiment was performed at least three times, each in triplicate on different days.

Fluorescent Doxorubicin Efflux Assay. For doxorubicin efflux assays, 1×10^5 cells/well were seeded on 96-well plates. After overnight incubation, cells were washed and incubated with HBSS for 30 min. Then, the cells were subsequently incubated in 10, 20, or 30 μM fluorescent doxorubicin for 3 h with or without curcuminoids in triplicate. After being washed with warm PBS, cells were allowed to efflux fluorescent doxorubicin for 2 h at 37 °C in the incubator. Samples (100 μL) were collected and transferred to 96-well black plates. The fluorescence of doxorubicin was measured by the SpectraMax Gemini XS microplate spectrofluorometer (Molecular Devices Co.) with the excitation set at 485 nm and the emission set at 590 nm. The doxorubicin concentration was obtained by comparison to the standard curve. Each experiment was performed at least three times, each in triplicate on different days.

Data and Statistical Analysis. For evaluation of inhibitor potency, IC_{50} values were calculated by using the equation

$$E = E_0\left(\frac{IC_{50}^s}{IC_{50}^s + I^s}\right)$$

where E is the observed efflux in the presence of inhibitor; E_0, the efflux in the absence of inhibitor; I, the inhibitor concentration; IC_{50}, the concentration that caused 50% inhibition of the maximal drug effect; and s, the slope factor.

For kinetic studies, kinetic parameters were estimated by nonlinear regression using Scientist v2.01 (MicroMath Scientific Software, Salt Lake City, UT, USA) according to the equation

$$V = \frac{V_{max} \times C}{K_m + C}$$

where V denotes the efflux rate; V_{max}, the maximal efflux rate; K_m, the Michaelis–Menten constant; and C, the substrate concentration.

Statistical differences were evaluated by ANOVA followed by post hoc analysis (Tukey's test) or Student's t test. The statistical significance was set at p value <0.05.

RESULTS

Expression and Basic Function Evaluation of Human P-gp in Established Cell Line. The *ABCB1* mRNA expression was significantly higher in stable transfected HEK293 cells (*ABCB1*/HEK293) than in the Flp-In-293 cells (vector only; host cells) ($p < 0.001$; Figure 1a). After 72 h of treatment with 5 μM curcumin (C), demethoxycurcumin (DMC), or bisdemethoxycurcumin (BDMC), the *ABCB1* mRNA expression remained unchanged (Figure 1a). The cytotoxicity assays indicated that curcuminoids at concentrations ranging from 1 to 5 μM did not affect *ABCB1*/HEK293 cell viability. The cytotoxicities IC_{50} of curcumin, demethoxycurcumin, and bisdemethoxycurcumin for *ABCB1*/HEK293 cells were 7.29 ± 0.51, 8.31 ± 0.71, and 10.72 ± 1.42 μM, respectively.

The basic P-gp function of *ABCB1*/HEK293 cells was confirmed by MDR1-shift assay utilizing UIC2 antibody. The conformation-specific antibody, UIC2, recognizes the extracellular epitopes of P-gp after conformation change induced by substrates or inhibitors.[22,23] The addition of the positive control drug vinblastine to *ABCB1*/HEK293 cells resulted in increased UIC2 binding to P-gp, whereas none of the curcuminoids induced P-gp conformation change (Figure 1b).

Effects of Curcuminoids on P-gp Efflux Function. The P-gp fluorescence substrate, rhodamine123, was used as a model compound to investigate the effects of curcuminoids on P-gp function. The efflux of rhodamine 123 was significantly inhibited by curcuminoids in *ABCB1*/HEK293 cells (Figure 2a). As compared to the no-treatment control, the addition of C, DMC, or BDMC, as well as the well-known P-gp inhibitor verapamil, to *ABCB1*/HEK293 cells reduced rhodamine 123 efflux significantly ($p < 0.01$; Figure 2a).

The effects of curcuminoids on P-gp efflux function were further confirmed by the calcein-AM uptake assay. Calcein-AM is a nonfluorescent lipophilic P-gp substrate. After entering living cells, it would be hydrolyzed by esterase and become fluorescent calcein. Therefore, the intracellular calcein fluorescence was inversely correlated to P-gp function. The addition of C, DMC, or BDMC significantly increased the intracellular accumulation of calcein as compared to the no-treatment control ($p < 0.01$; Figure 2c).

Molecular and Kinetic Mechanisms of Interactions between Curcuminoids and P-gp. To detect the influence of curcuminoids on the P-gp ATPase activity, series concentrations of curcuminoids (from 1 to 10 μM) were incubated with recombinant human P-gp membranes. DMC and BDMC were demonstrated to inhibit both P-gp basal ATPase activity and 200 μM verapamil-stimulated P-gp ATPase activity, whereas C was demonstrated to inhibit P-gp basal ATPase activity but was unable to inhibit 200 μM verapamil-stimulated P-gp ATPase activity (Figure 3).

The rhodamine 123 efflux inhibition kinetics of curcuminoids was further investigated by Lineweaver–Burk plot (Figure 4). In *ABCB1*/HEK293 cells, when the concentration of C, DMC, or BDMC increased, both the maximum rate (V_{max}) and the affinity (K_m) of rhodamine 123 efflux decreased (Figure 4; Table 1). These results suggested that curcuminoids may inhibit human P-gp via uncompetitive inhibition. The P-gp inhibition

J. Agric. Food Chem. 2015, 63, 847–855

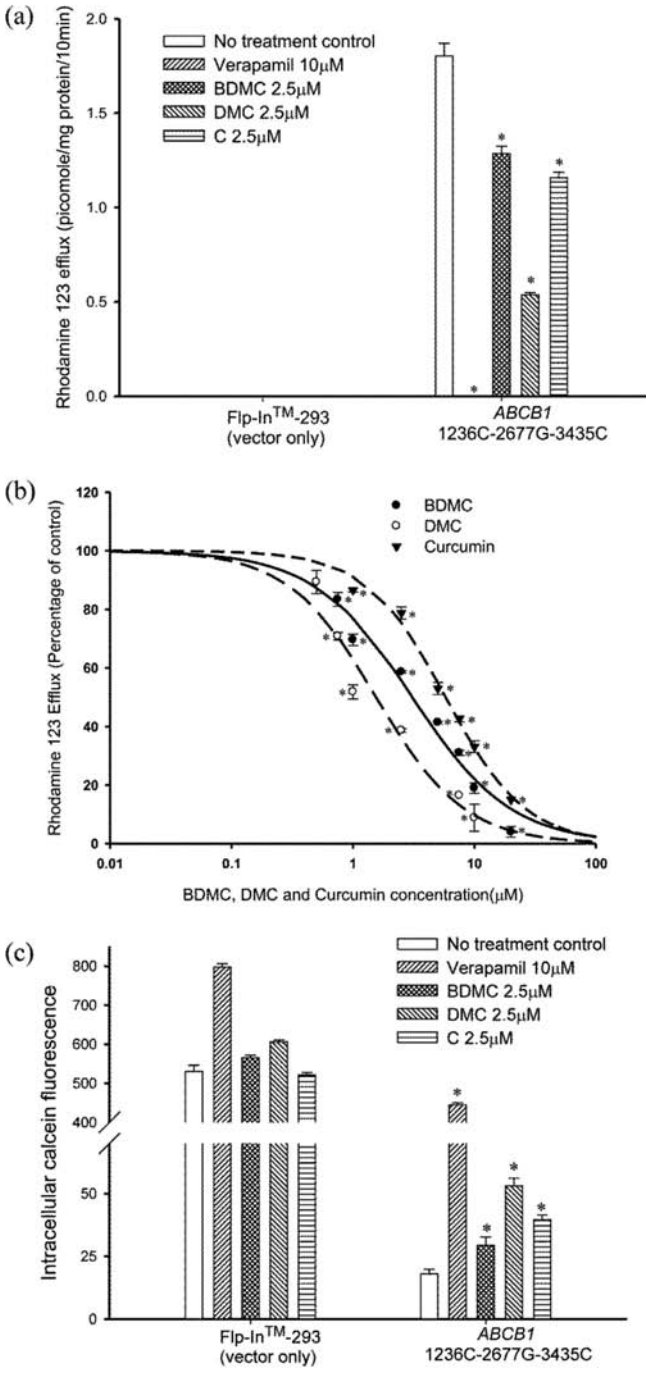

Figure 2. Evaluation of influences of purified curcuminoids on P-glycoprotein efflux function. (a) In the rhodamine 123 efflux assay, purified curcuminoids significantly inhibited P-gp mediated efflux of rhodamine 123 under nontoxic concentrations. Verapamil 10 μM was used as a positive control. (*) $p < 0.05$ as compared to rhodamine 123 efflux without purified curcuminoids (no treatment control). (b) The IC_{50} values of the inhibitory effect of C, DMC, and BDMC on rhodamine 123 efflux by P-gp were 5.8 ± 0.32, 1.56 ± 0.13, and 3.08 ± 0.19 μM, respectively, indicating that DMC possessed the most potent effect on rhodamine 123 efflux by P-gp. (c) In the calcein-AM uptake assay, purified curcuminoids increased intracellular accumulation of calcein under nontoxic concentrations in P-gp. Verapamil 10 μM was used as a positive control. (*) $p < 0.05$ as compared to calcein-AM uptake without purified curcuminoids (no treatment control). The above data are presented as the mean ± SE of at least three experiments, each in triplicate.

potency of curcuminoids was demonstrated by dose response study, and DMC was the most potent P-gp inhibitor among the curcuminoids (Figure 2b; Table 1).

Effects of Curcuminoids on the Sensitivity of Doxorubicin in P-gp Overexpressed ABCB1/HEK293 Cells. The multidrug resistant reversal abilities of curcuminoids were evaluated by co-administered P-gp overexpressed cells with curcuminoids and doxorubicin. The IC_{50} of doxorubicin with or without curcumunoids was calculated, and the fold of reversal was further determined (Table 2). The combinations of purified curcuminoids significantly lower the IC_{50} of doxorubicin in human P-glycoprotein expressed cells. The fold of reversal of DMC was the highest among the tested curcuminoids.

The effect of DMC on P-gp-mediated doxorubicin efflux and the kinetic mechanism were further investigated. DMC significantly inhibited doxorubicin efflux in a dose-dependent manner (Figure 5a,b). As for the kinetic mechanism of P-gp-mediated doxorubicin efflux, when the concentration of DMC increased, the V_{max} decreased with the K_m of doxorubicin remaining unchanged (Figure 5c; Table 3). These results suggested that DMC may inhibit doxorubicin efflux by P-gp via noncompetitive inhibition.

DISCUSSION

Multidrug resistance remains one of the major problems to be resolved in cancer chemotherapy. Although quantities of human P-gp inhibitors have been developed, none of them can provide clinical benefits without toxic side effects. Therefore, efforts have turned to identifying natural products with P-gp inhibitory effects and without systemic toxicities. In the present study, curcuminoids were demonstrated to possess P-gp inhibitory effects under nontoxic concentrations. Among the major curcuminoids, DMC exhibited the strongest P-gp inhibition potency with the highest multidrug resistance reversal ability. The kinetic studies revealed that DMC may interact with P-gp transport of rhodamine 123 via uncompetitive inhibition and doxorubicin through noncompetitive inhibition. Furthermore, ATPase assay demonstrated that DMC was capable of inhibition of both P-gp basal ATPase activity and verapamil-stimulated P-gp ATPase activity. These results indicated that DMC was a potential candidate to be developed as a multidrug resistance reversal agent.

Previous studies have reported the anticancer effects of curcuminoids.[24] It has been suggested that the cancer preventive activities of commercial curcuminoids may be related to the suppression of NF-κB, the regulation of Wnt signaling pathway, and also the inhibition of mTOR signaling.[25−29] In terms of the reversal of multidrug resistance, commercial curcuminoids were reported to be able to increase the accumulation of daunorubicin in P-gp overexpressing human carcinoma KB-C2 cells in a concentration-dependent manner.[30] The efflux of the P-gp fluorescence substrate, rhodamine 123, by KB-C2 cells was also reduced by commercial curcuminoids.[30] Furthermore, the expression of P-gp in multidrug-resistant human cervical carcinoma cells was reported to be down-regulated by commercial curcuminoids in another study.[14] The individual effects of C, DMC, and BDMC on P-gp expression and function were tested in limited studies.[16,17] One study focused on the characterization of C, DMC, and BDMC effects on P-gp function using KB-V1 and KB-3-1 cells, which were multidrug resistance and drug sensitive cervical carcinoma cells, respectively.[17] Their results demonstrated that

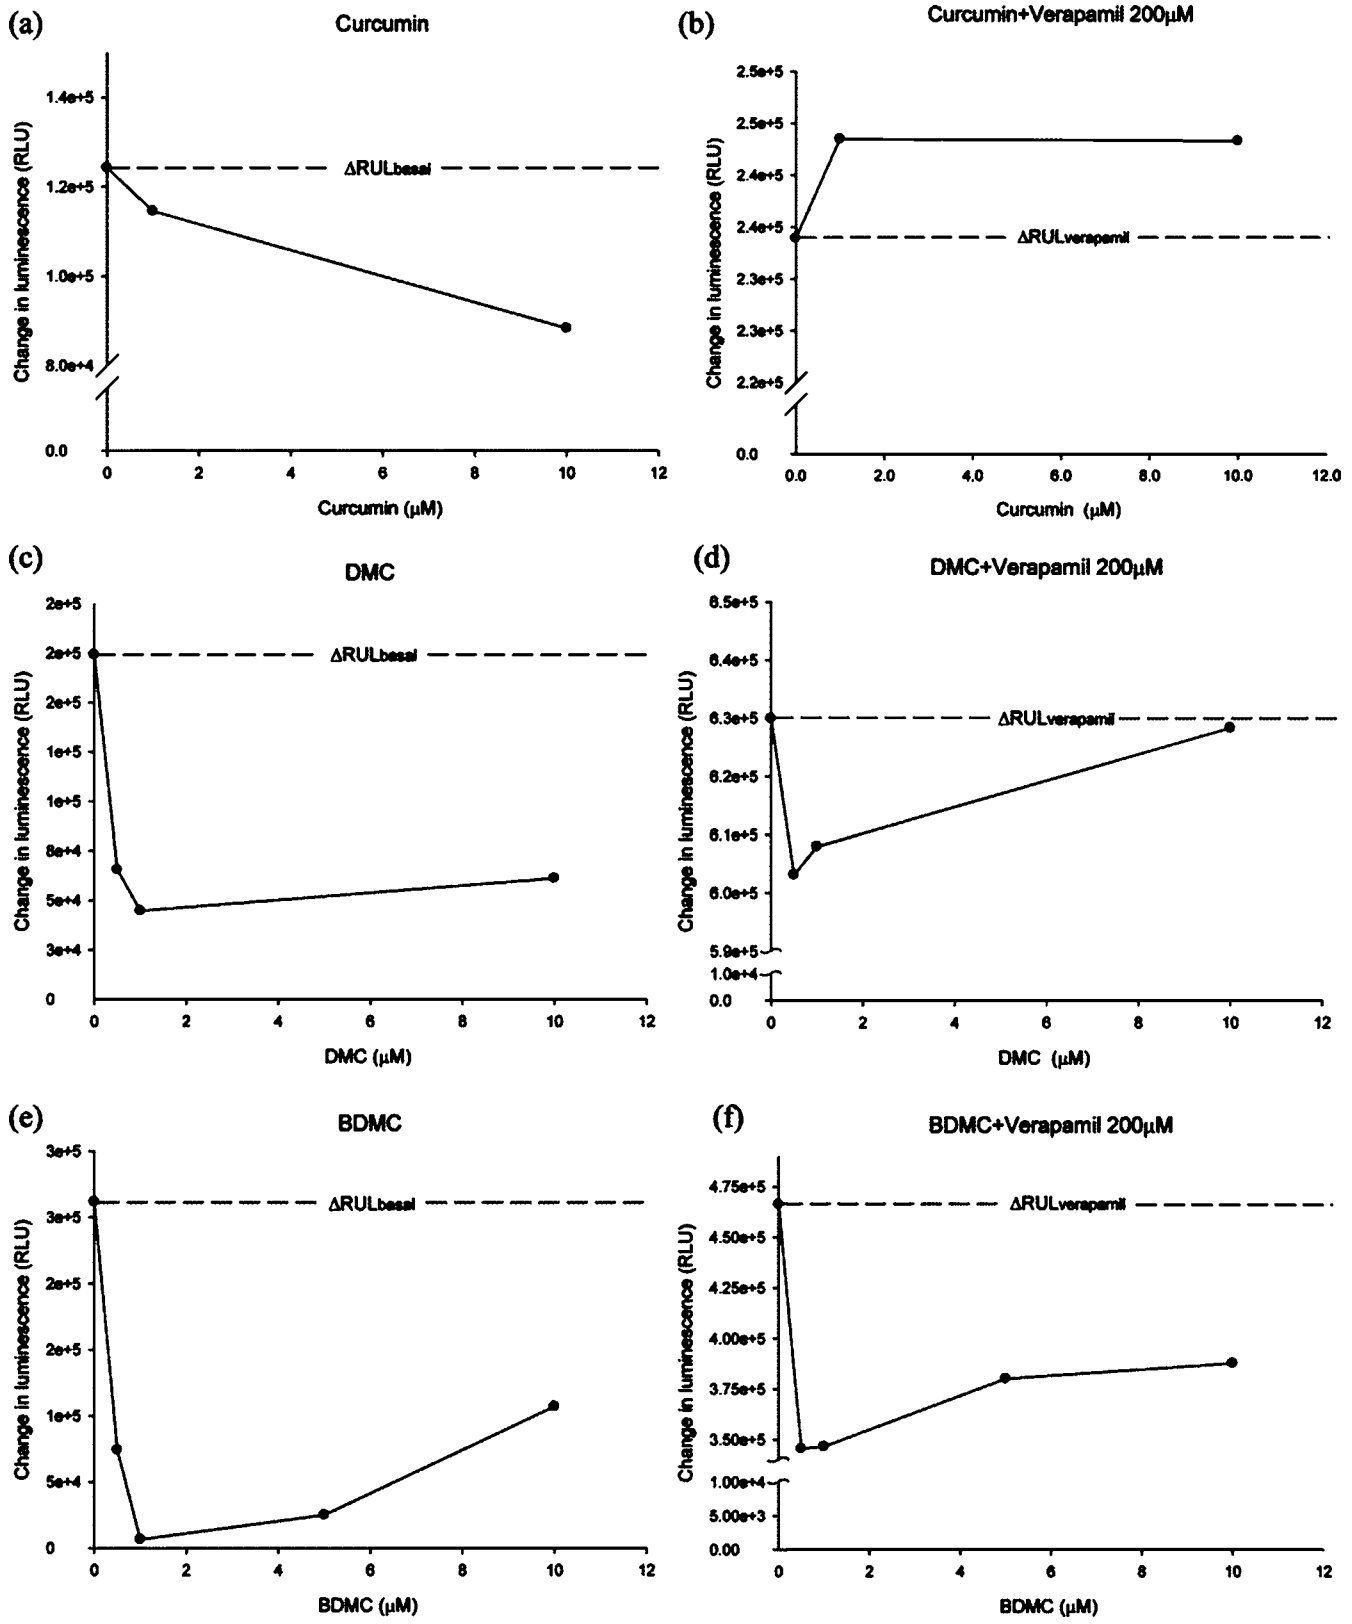

Figure 3. Effect of purified curcuminoids on P-glycoprotein ATPase activity. Data were analyzed in terms of RLUs. (a, c, e) Incubation with C, DMC, or BDMC (0.5−10 μM) inhibited the P-gp ATPase activity. (b, d, f) C, DMC, or BDMC (0.5−10 μM) was tested for its capacity to inhibit 200 μM verapamil-stimulated P-gp ATPase activity. C showed stimulatory effect on 200 μM verapamil-stimulated P-gp ATPase activity at a concentration of 5 μM, whereas DMC or BDMC inhibited 200 μM verapamil-stimulated P-gp ATPase activity at a concentration of 5 μM.

C, DMC, and BDMC all can inhibit P-gp function, and C was shown to be the most active form among the major curcuminoids.[17] In another study, the effects of C, DMC, and BDMC on P-gp transport function were examined by using

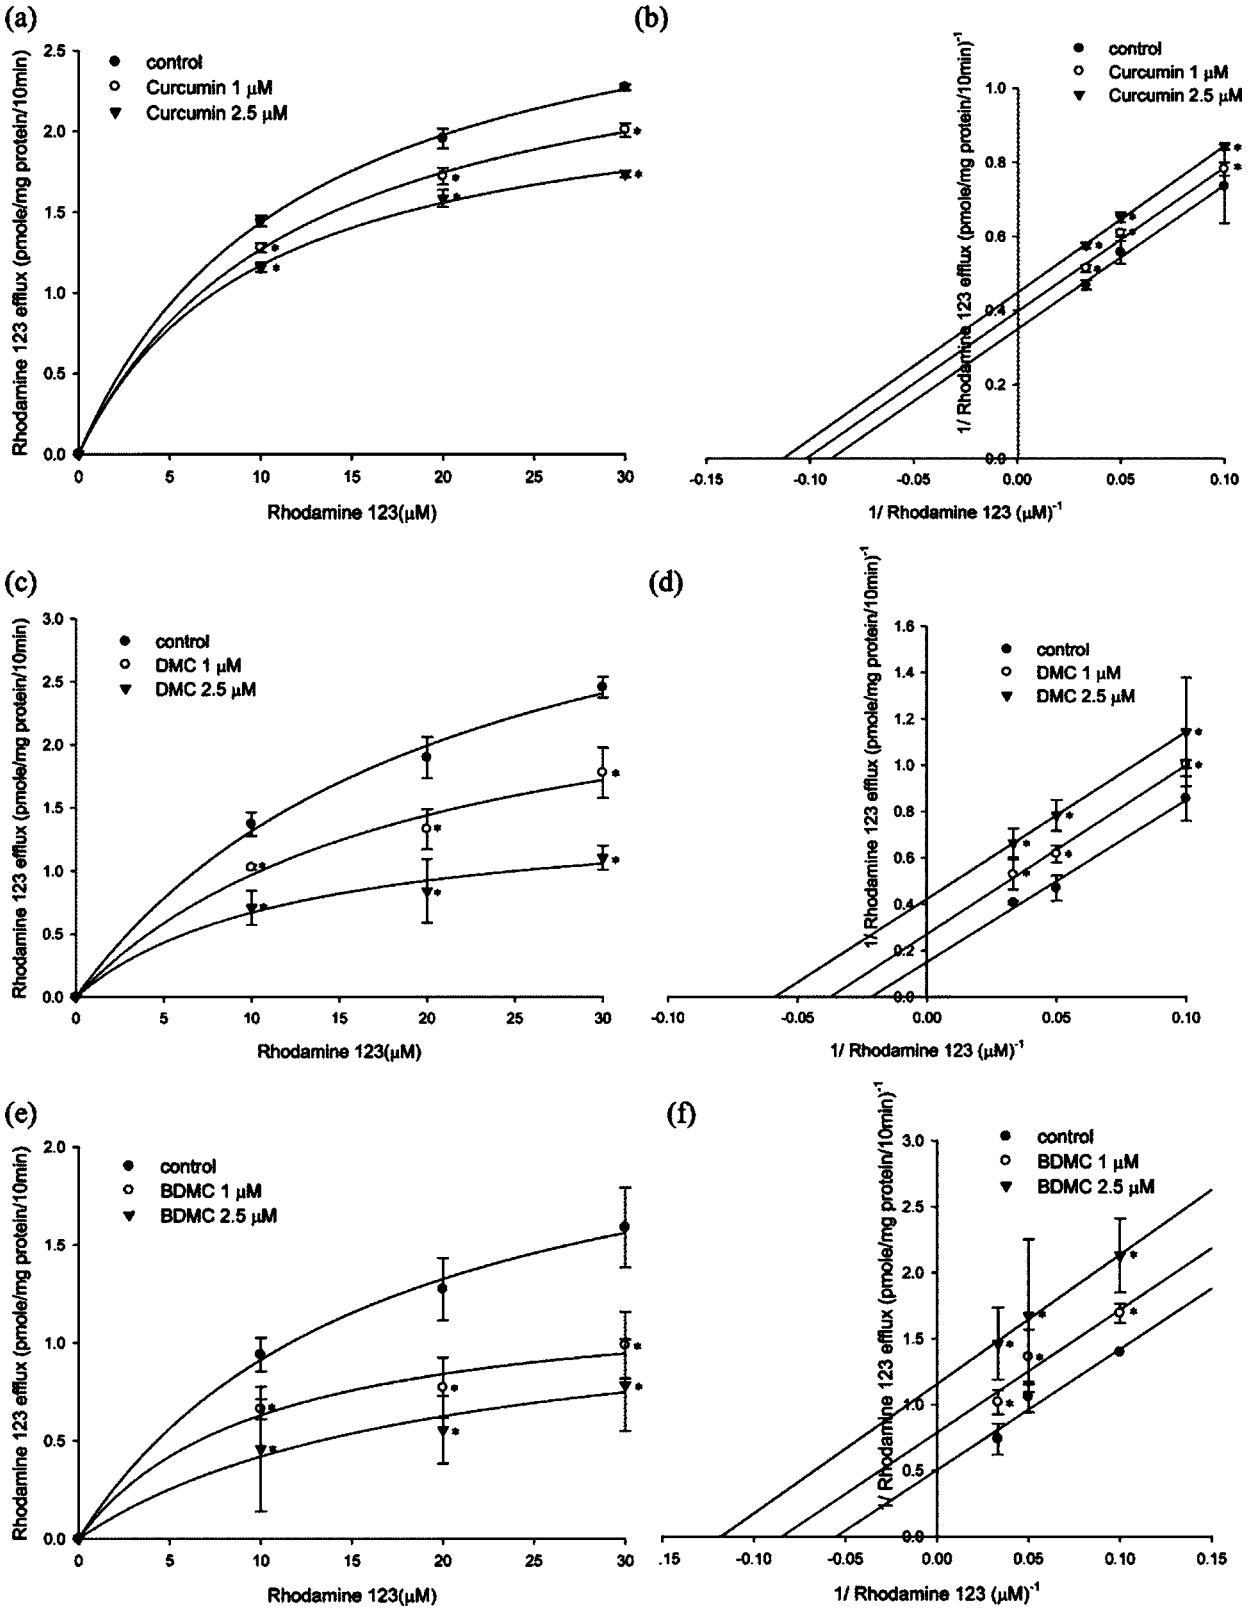

Figure 4. Concentration-dependent rhodamine 123 efflux (10−30 μM) in the presence or absence of purified curcuminoids: (a, b) curcumin; (c, d) DMC; (e, f) BDMC. The left panels show the nonlinear regression analysis of rhodamine 123 efflux, and the right panels demonstrate the Lineweaver−Burk plot analysis of rhodamine 123 efflux. Data are presented as the mean ± SE of at least three experiments, each in triplicate. (∗) $p < 0.05$ as compared to rhodamine 123 efflux without purified curcuminoids (control).

Caco-2 and vinblastine-selected Caco-2 cells.[16] It showed that C and DMC could inhibit P-gp function; however, BDMC showed no effect on P-gp function.[16] These discrepancies may result from the use of different cell lines and drugs to induce resistance. To clarify whether curcuminoids have the potential to be used as multidrug resistance reversal agents, we performed

the analyses in HEK293 cells, which were stably transfected with human P-gp to avoid the disturbance of baseline expression of transporters and the different drug-induced transporter expression levels.

In the present study, DMC was demonstrated to be the most potent P-gp inhibitor among the major curcuminoids. Several studies also showed that DMC possessed the most efficient cytotoxic effects toward breast cancer and prostate cancer cells.[18,31,32] It was reported that DMC may activate AMPK and thus inhibit energy metabolic and oncogenic signaling pathways in triple-negative breast cancer cells.[31] It was also shown in another study that DMC may down-regulate HSP70 and EGFR and further influence the proliferation of prostate cancer cells.[18] DMC was also shown to induce human glioma cells arrested at G2/M phase and apoptosis.[33] Although C is the most abundant form of natural curcuminoids, it can be degraded easily both in vivo and in vitro.[34] The instability of C limited its biological activity, and thus the efficacy of anticancer and P-gp inhibition was reduced; on the other hand, compared to C, DMC lacks the methoxy group, which links directly to the benzene ring, and this slight difference led to the more stable chemical character of DMC.[35] In the present study, DMC was demonstrated to be a 3.5-fold more potent P-gp inhibitor than C. The kinetic mechanisms of C, DMC, and BDMC were similar. These curcuminoids acted as uncompetitive inhibitors of human P-gp and inhibited ATPase activity of P-gp. These results indicated that the structural stability plays a critical role for the potency of curcuminoids. The difference among C, DMC, and BDMC was the ability to inhibit verapamil-induced ATPase activity. Only C was unable to inhibit verapamil-induced ATPase activity; both DMC and BDMC inhibited verapamil-induced ATPase activity under low concentration. These results suggested that DMC and BDMC may compete for the ATPase binding sites of verapamil, whereas C might act on the other binding pockets.

Table 3. Effect of Demethoxycurcumin on Doxorubicin Transport by Human P-Glycoprotein

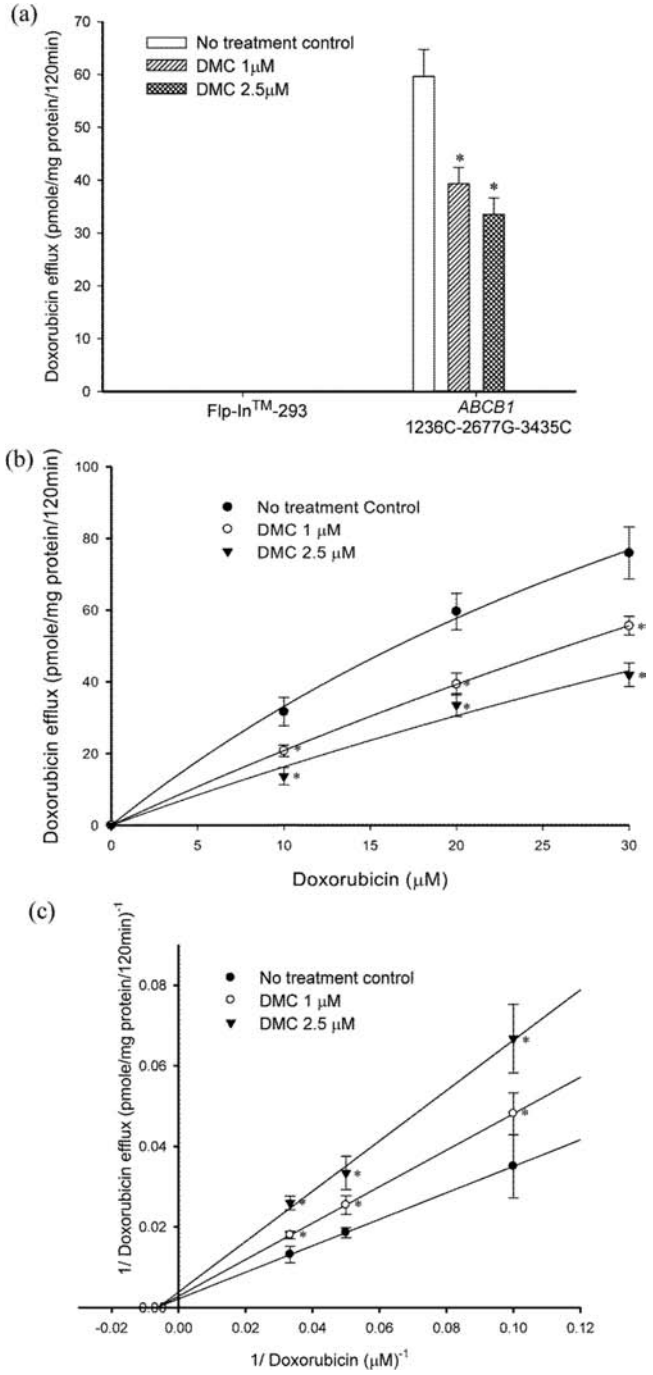

Figure 5. Concentration-dependent doxorubicin efflux (10−30 μM) in the presence or absence of DMC: (a) dose-dependent effect of DMC on doxorubicin efflux by P-gp; (b) nonlinear regression analysis of the inhibition effect of DMC on doxorubicin efflux; (c) Lineweaver−Burk plot analysis of the inhibition effect of DMC on doxorubicin efflux. Data are presented as the mean ± SE of at least three experiments, each in triplicate. (*) $p < 0.05$ as compared to doxorubicin efflux without DMC (control).

The strength of this study was the use of stable cloned human P-gp expression cells. With the stable and identical P-gp expression level, the kinetic mechanisms and potency of C, DMC, and BDMC were clarified. The fold of reversal factor of doxorubicin further demonstrated the reversal of drug sensitivity by treatment of individual major curcuminoids. However, there were still weakness in this study. The effects of multidrug-resistant reversal curcuminoids still need to be verified in animal models. The other important issue is the low bioavailability of curcuminoids irrespective of the route of administration. There are several strategies to improve the bioavailability of curcuminoids, including utilization of nanoparticle preparations, concomitant administration with metabolic pathway blocking agents, or modification of the structures of curcuminoids.

In conclusion, the results of this study demonstrated that DMC treatment inhibited human P-gp function through ATPase inhibition via uncompetitive inhibition. It also reversed the doxorubicin-resistant cells to doxorubicin-sensitive cells. Further in vivo studies about the P-gp inhibition effect of DMC may provide evidence to support DMC used as an add-on natural product in chemotherapy patients.

Supporting Information

ABSTRACT: Fructo-oligosaccharides (FOS) are usually regarded as a type of prebiotic, favorably stimulating the growth of bifidobacteria and lactobacilli. However, they are not the specific substrates for these target species, and other bacteria, such as *Streptococcus*, *Escherichia*, and *Clostridium*, have been shown to be able to utilize FOS. Previous studies have mainly investigated only a few bacteria groups, and few reports analyzed the global effects of FOS on intestinal microbial communities. In this study the effects of FOS on gut bacteria in mice were investigated through a 16S rRNA metagenomic analysis. In the FOS-low group, the abundance of *Actinobacteria* significantly increased and that of *Bacteroidetes* decreased after FOS diet (5%) for 3 weeks. In the FOS-high group, *Enterococcus* was promoted and levels of *Bifidobacterium* and *Olsenella* both notably increased after FOS diet (25%) and the microbiota tended to revert to initial structure 2 weeks after FOS treatment ceased. The most striking observation was that *Olsenella* became a dominant genus comparable with *Bifidobacterium* after FOS treatment, and one strain of *Olsenella*, isolated from mice feces, was confirmed, for the first time, to be capable of using FOS. The results indicated that metagenomic analysis was helpful to reveal the FOS effects on the global composition of gut communities and new target for future studies.

KEYWORDS: *fructo-oligosaccharides, prebiotic, intestinal microbiota, 16S rRNA metagenomic, Olsenella*

INTRODUCTION

The human gastrointestinal tract is home to >10^{12} organisms.[1] Maintaining the balance of the microbial communities is crucial for host health, and perturbation of their composition may induce a range of diseases including obesity, diabetes, and inflammatory bowel disease.[2−4] It is well recognized that the composition of gut microbiota is dependent on individual genotype[5] and environmental factors,[6−8] among which diet is of particular importance.

Nondigestible oligosaccharides are able to reach the large intestine and modify the microbial community. Fructo-oligosaccharides (FOS) are regarded as a prebiotic and have well documented beneficial health effects,[9,10] which are achieved by restructuring of the gut microbiota. Although FOS are usually considered to favorably stimulate the growth of bifidobacteria and lactobacilli, there is increasing evidence that FOS are not entirely specific for these bacteria and can also be used by non-bifidobacteria, such as *Streptococcus*,[11] *Escherichia*,[12] and *Clostridium*.[13] Valcheva et al. found that FOS treatment increased the abundance of *Clostridium leptum* in rats[14] and stimulated the growth of *Faecalibacterium prausnitzii* in humans.[15] Shen et al. assessed the effects of FOS on *Bifidobacterium*, the *Clostridium leptum* subgroup, and *Bacteriodes* in human flora-associated piglets and found that the effects varied at different developmental stages.[16] In contrast to most expectations, Licht et al. and Bovee-Oudehoven et al. found that dietary FOS increased colonic permeability in rats[17,18] and dose-dependently increased the translocation of *Salmonella* in mice and rats,[19−21] indicating the adverse effects of FOS consumption. Moreover, an overdose of prebiotics can lead to the development of intestinal discomfort,[9,22−24] including borborygmi and tympanites, which might be caused by the increase in gas production and osmotic pressure.[22−24] Thus, the effects of FOS on gut bacteria are far more complex than the bifidogenic effects. Being limited to the analytical technologies, previous studies mainly focused on the changes of given groups of bacteria during FOS consumption, and there were few reports on the global effects of FOS use on the gut communities.[25] Therefore, more detailed and extensive studies are required to investigate the effects of FOS on the composition of gut microbiota using the available advanced analytical technologies.

In this study, mice were fed FOS at low and high doses, and the composition of the fecal microbiota was determined using a high-throughput MiSeq sequencing technique to assess the effects of the FOS treatment. 16S rRNA metagenomic analysis was performed on both bifidobacteria and non-bifidobacteria to reveal the relationship between FOS and gut bacteria.

MATERIALS AND METHODS

Chemicals and Reagents. Fructo-oligosaccharides (Meioligo P, Meiji Seika Kaisha, Ltd., Japan) comprised 6.5% fructosylfructosyl nystose (GF5), 43.4% 1F-β-fructofuranosyl nystose (GF4), 40.9% nystose (GF3), 7.1% 1-kestose (GF2), and 2.1% glucose and fructose.

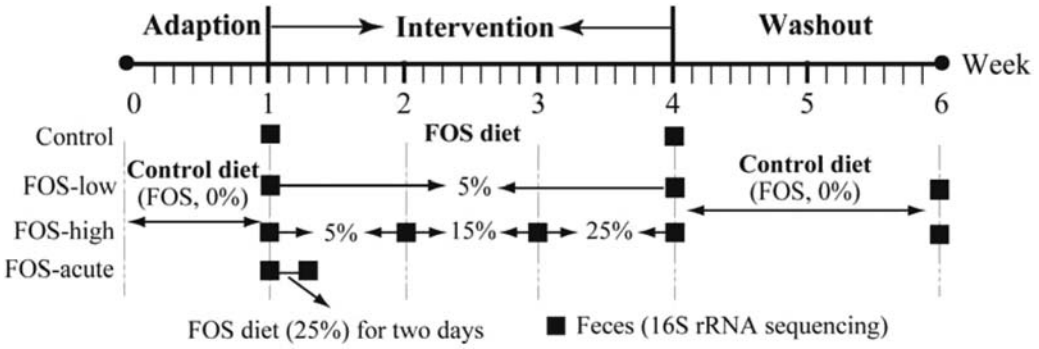

Figure 1. Experimental design. Thirty-two mice were randomly and equally divided into four groups (control, FOS-low, FOS-high, and FOS-acute). In the control group, mice were fed the control diet (FOS, 0%), and feces were collected at the 1st and 4th weeks. In the FOS-low group, mice were fed diet supplemented with FOS (5%) for 3 weeks, and feces were collected at the 1st, 4th, and 6th weeks. In the FOS-high group, mice were fed diet with FOS at increasing proportions, 5% for the 2nd week, 15% for the 3rd week, and 25% for the 4th week. Feces were collected at the 1st, 2nd, 3rd, 4th, and 6th weeks. In the FOS-acute group, mice were fed diet with FOS (25%) for 2 days and feces were collected before and after the FOS treatment.

Animals and Sample Collection. Six-week-old male C57BL/6J mice were obtained from the Shanghai Laboratory Animal Center (Shanghai, China) and maintained in an IVC rodent caging system. The mice were housed in a temperature- and humidity-controlled room under a strict 12 h light cycle and fed a commercial mouse diet; water was given ad libitum. All of the protocols used in this study were approved by the Ethics Committee of Jiangnan University, China (JN No. 20140306-0910-7), and the procedures were carried out in accordance with the European Community guidelines (Directive 2010/63/EU) for the care and use of experimental animals.

The mice were randomly divided into four groups (n = 8 for each group), as shown in Figure 1. The average body weight was 19.6 ± 0.8 g. The mice were adapted to the new environment for 1 week, followed by a 3 week intervention period and a 2 week washout period. The commercial diet was smashed and amended with FOS at different proportions, and pellets were formed. In this study, the dose of FOS was determined according to a pre-experiment. Twenty-four 6-week old male C57BL/6J mice were randomly and equally divided into six groups, which were given diets supplemented with FOS at proportions of 2, 5, 10, 20, 25, and 30%. The diet was weighed daily to calculate the FOS intake, and the FOS proportions corresponded to doses of 0.1, 0.2, 0.4, 0.6, 0.8, and 1.0 g of FOS per mouse per day (PMPD), respectively. Feces were daily collected for observation. Diarrhea was diagnosed as poorly formed, looser, and more watery feces than normal. Slight diarrhea was found in the 25 and 30% groups after 1 week. Therefore, the FOS proportion was set at 5% for the FOS-low group and 25% for the FOS-high group. The dose was based on a body weight of 20 g. As shown in Figure 1, the control group was fed the control diet (FOS, 0%) throughout the experiment, and the other three groups were fed the diets supplemented with FOS at different proportions (5, 15, and 25%) during the intervention period. Diet was weighed daily and recorded for calculating the actual FOS intake (Supporting Information, Figure S1), and body weight was recorded every week. At the times indicated in Figure 1, mice were transferred to separate sterilized cages, and feces were collected in individual sterile EP tubes on ice, which were taken to the laboratory within 2 h of collection for further study. After the experiment, the mice were euthanized by intraperitoneal injection of 200 mg/kg sodium pentobarbital euthanasia solution.

DNA Extraction, PCR Amplification, Quantification, and Sequencing. Microbial genome DNA was extracted from fecal samples using FastDNA Spin Kit for Soil (MP Biomedicals, catalog no. 6560-200) following the manufacturer's instructions. The V4 region of the 16S rRNA was PCR amplified from microbial genome DNA using the primers (forward primer, 5′-AYTGGGYDTAAAGNG-3′; reverse primer, 5′-TACNVGGGTATCTAATCC-3′) as described previously.[26] The PCR procedures were 95 °C for 5 min; 95 °C for 30 s, 50 °C for 30 s, and 72 °C for 30 s, repeat for 30 cycles; and 72 °C for 10 min. The PCR products were excised from a 1.5% agarose gel, purified by GeneClean Turbo (MP Biomedicals, catalog no. 111102400) and quantified by Quant-iT PicoGreen dsDNA Assay Kit (Life Technologies, catalog no. P7589) according to the instructions. Libraries were prepared using TruSeq DNA LT Sample Preparation Kit (Illumina, catalog no. FC-121-2001) and sequenced for 500+7 cycles on Illumina Miseq using the MiSeq Reagent Kit (500 cycles-PE, catalog no. MS-102-2003).

Bioinformatic Analysis. Sequences with an average quality score <30, containing ambiguous bases, homopolymer run exceeds 6, having mismatches in primers, or sequence length <200 bp were removed. Pair-end reads that overlapped longer than 10 bp and without any mismatch were assembled according to their overlap sequence. Reads that could not be assembled were discarded. Barcode and sequencing primers were trimmed from the sequences.

Sets of trimmed sequences with >97% identity were defined as an operational taxonomic unit (OTU). The OTUs were assigned to a taxonomy using the Ribosomal Database Project (RDP) Naive Bayes classifier.[27] Representative sequences from each cluster were aligned with the PyNAST aligner[28] to the greengenes core set in QIIME.[29] A phylogeny was constructed within QIIME using FastTree.[30] Rarefaction curves, alpha diversity, and beta diversity calculations were also performed using QIIME. The Chao1 estimator and Shannon diversity index were estimated to evaluate the ecological diversity of the microbiota in each sample. The similarity among the microbial communities was determined using UniFrac analysis[31] with weighted and unweighted principal coordinate analysis (PCoA).

Statistical Analysis. The differences among groups were analyzed using ANOVA with Tukey's honestly significant difference post hoc test, and Student's t test was used to identify the differences between two groups. The analyses were performed using SPSS software (version 16.0; SPSS Inc., Chicago, IL, USA). Significance was accepted at $P < 0.05$.

Nucleotide Sequence Accession Numbers. The sequences reported in this paper have been deposited in the Rapid Annotation using Subsystems Technology for Metagenomes database (MG-RAST) under the accession no. 4578758.3−4578850.3.

Isolation and Identification of *Olsenella* from Mice Feces. To isolate *Olsenella* from mice feces, three mice were fed a diet supplemented with FOS at a dose of 0.8 g PMPD for 1 week. On day 7, the mice were transferred to sterilized individual cages. Fresh feces were collected in 5 mL sterile EP tubes and immediately dispersed in 0.9% salt solution. Fecal samples were diluted 10^{-5}, 10^{-6}, and 10^{-7}, plated on brain−heart infusion (BHI, Oxoid) agar, and incubated anaerobically at 37 °C for 48 h. Colonies were selected, Gram-strained, and identified using 16S rRNA gene sequencing.

Growth of *Olsenella* on FOS. Strains of *Olsenella* were cultured anaerobically in BHI media with and without FOS (8 g/L) at 37 °C for 24 h. The absorbance at 600 nm (OD_{600}) was recorded every 2 h, and the amount of FOS in the culture supernatant was determined on a Waters 600 high-performance liquid chromatography system (Waters Corp., Milford, MA, USA), equipped with a 600 pump, an autosampler, and a refractive index detector. Separations were carried out using a

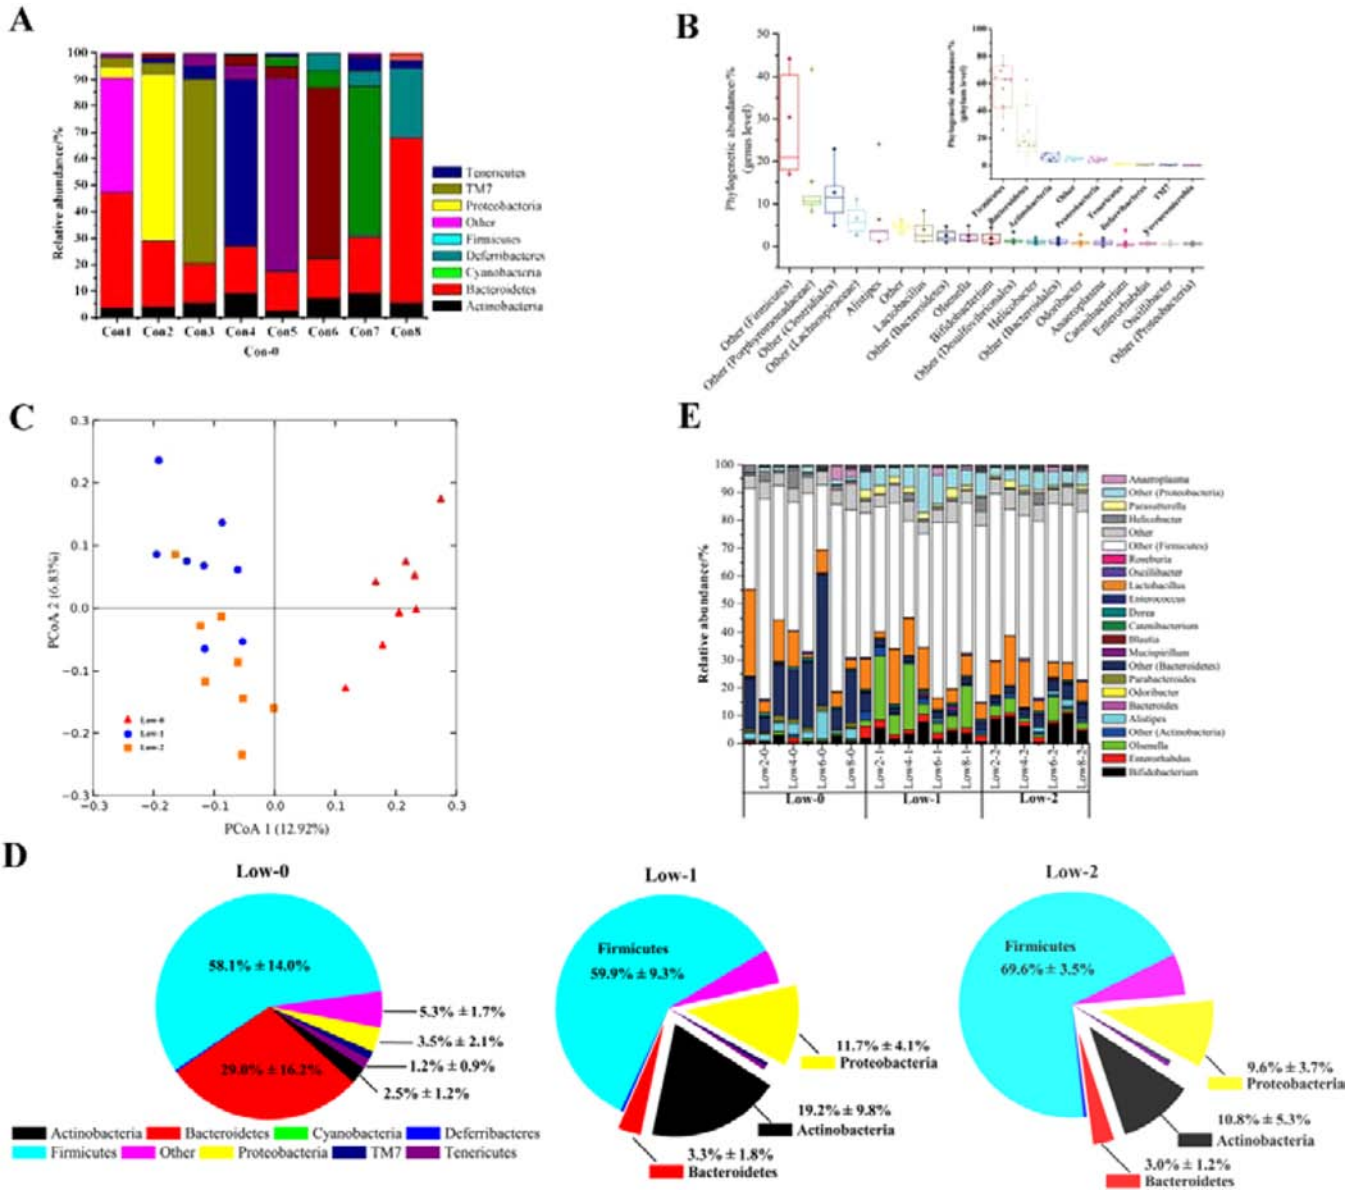

Figure 2. Effect of FOS at a low dose on the fecal microbiota: (A) interindividual variation in the proportion of major phyla for the control group; (B) bacterial diversity at the phylum and genus levels (>0.5%) for the control group; (C) principal coordinate (PCoA) score plots based on unweighted UniFrac metrics at the different periods (each point represents the composition of fecal microbiota of one mouse); relative abundance of main phyla (D) and genera >0.1% (E) at different periods. Sequences that could not be classified into any known group were assigned as "other". Con, control group; Low, FOS-low group. The number following the abbreviations stands for the mouse number. For example, Con1 and Con2 stand for the first and second mice in the control group. Con-0 stands for the 1st week. The number following "Low-" stands for the period: "0", before FOS treatment; "1", intervention period; "2", washout period. The abundance of main phyla is expressed as the mean ± SEM.

Waters SugarPak1 column (6.5 × 300 mm, i.d. = 3.5 μm), and the column temperature was set at 85 °C. The mobile phase was water with the flow rate of 0.4 mL/min, and the injection volume was 10 μL.

RESULTS

A data set consisting of 1,265,448 high-quality, classifiable 16S rRNA gene sequences was generated from 93 fecal samples through MiSeq sequencing analysis. The average sequence read was 13607 per sample (Supporting Information, Table S1). All of the sequences were clustered with representative sequences, and a 97% sequence identity cutoff was used. The number of OTUs per sample ranged between 334 and 2936 (Table S1).

Effect of FOS at Low Dose on the Composition of Fecal Microbiota. At the phylum level (Figure 2A,B), the gut bacteria community was mostly dominated by *Firmicutes* and *Bacteroidetes*, and the average ratio between *Firmicutes* and *Bacteroidetes* was 3.04 (ranging from 0.42 to 5.04). At the genus level (Figure 2B), unknown genera belonging to *Firmicutes*, *Porphyromonadaceae*, *Clostridiales*, *Lachnospiraceae*, *Bacteroidetes*, *Desulfovibrionales*, *Bacteroidales*, and *Proteobacteria* and *Alistipes*, *Lactobacillus*, *Olsenella*, *Bifidobacterium*, *Helicobacter*, *Odoribacter*, *Anaeroplasma*, *Catenibacterium*, *Enterorhabdus*, and *Oscillibacter* all comprised >0.5% of the microbiota.

The fecal microbiota was profoundly affected after FOS treatment (0.2 g PMPD) for 3 weeks (Figure 2C). The abundance of *Firmicutes* was maintained at about 60%, whereas that of *Bacteroidetes* dropped markedly from 29.0 to 3.3% (Figure 2D). Accordingly, the average ratio of *Firmicutes* and *Bacteroidetes*

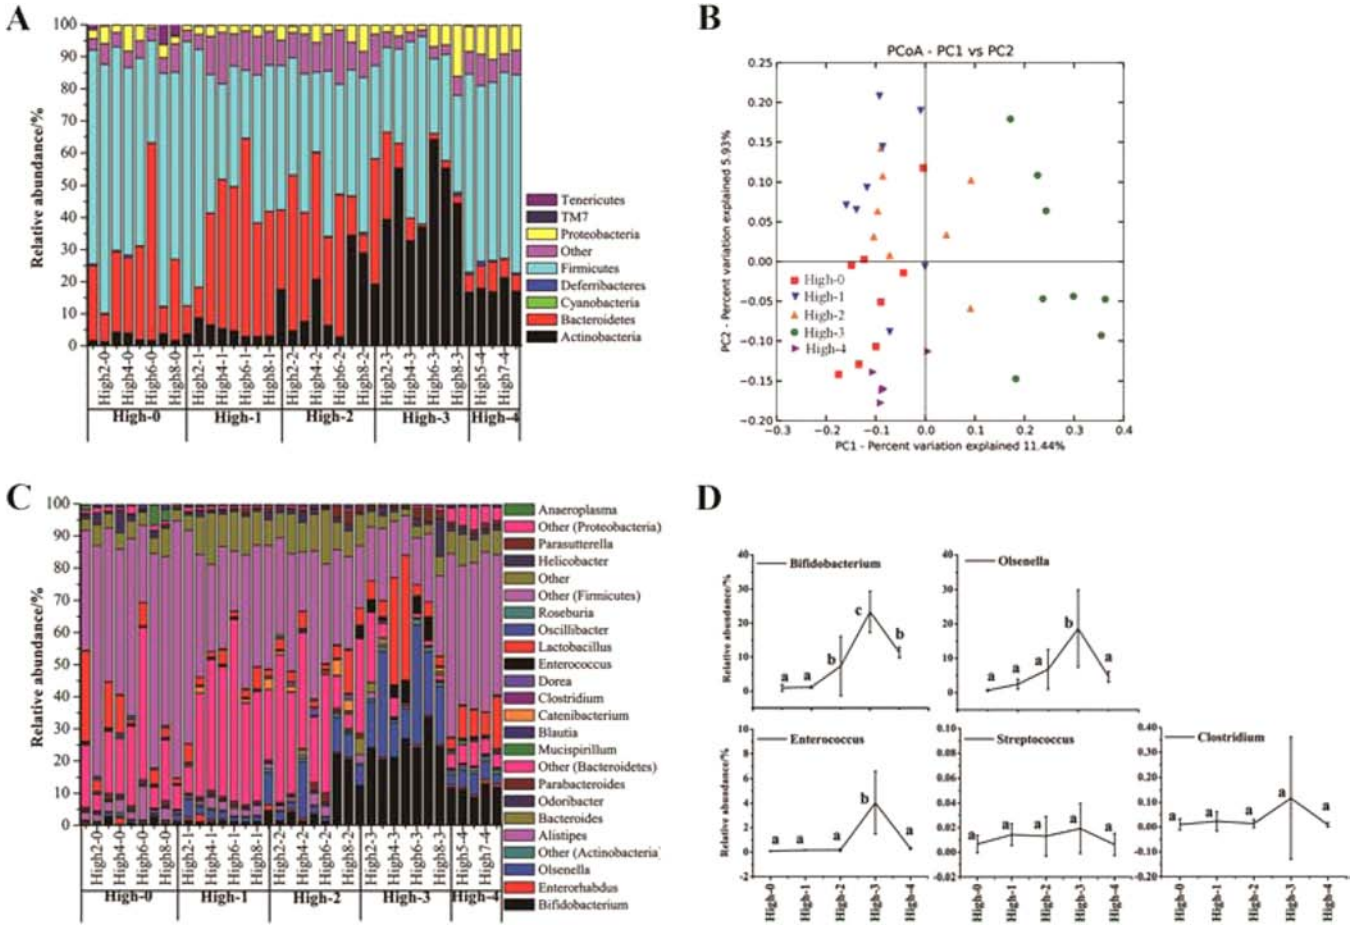

Figure 3. Effect of FOS with increasing doses on the fecal microbiota. (A) Relative abundance of main phyla at different periods. Sequences that could not be classified into any known group were assigned as "other". High, FOS-high group. High1, High2, High3, High4, High5, High6, High7, and High8 stand for the first, second, third, fourth, fifth, sixth, seventh, and eighth mice in the FOS-high group. The number following "High-" stands for the period. "0", before FOS treatment; "1", intervention period (FOS, 5%); "2", intervention period (FOS, 15%); "3", intervention period (FOS, 25%); "4", washout period. (B) Principal coordinate (PCoA) score plots were based on unweighted UniFrac metrics at the different periods. Each point represents the composition of fecal microbiota of one mouse. (C) Relative abundance of main genera >0.1% at different periods. (D) Changes of the abundance of selected genera at different periods. Mean values ± SEM are plotted. Significant differences ($P < 0.05$) are indicated with different letters (a, b, c).

increased to 34.97 (ranging from 9.97 to 79.89). Moreover, significant increases in *Actinobacteria* ($P < 0.01$, Student's *t* test) were observed.

As expected, the abundance of *Bifidobacterium* was significantly increased (Figure 2E, $P < 0.05$), confirming the bifidogenic property of FOS. However, the level of *Lactobacillus* remained stable during the FOS treatment. In addition, the levels of many non-bifidobacteria increased after the FOS treatment. Interestingly, the level of *Olsenella* belonging to *Actinobacteria* increased significantly from 0.7 to 10.7% ($P < 0.01$, Student's *t* test), which was even higher than that of *Bifidobacterium*.

During the washout period, the diet was reverted to the control diet. Slight decreases in *Actinobacteria* and *Proteobacteria* were observed (Figure 2D). The abundance of *Olsenella* was also reduced (Figure 2E). It seems that the effect of FOS on the fecal microbiota did not last long, although the original composition had not fully recovered after 2 weeks.

Effects of FOS at High Dose on the Composition of Fecal Microbiota. During the intervention period, the proportion of *Actinobacteria* continued to increase and reached 44.8% ($P < 0.01$, Student's *t* test), whereas that of *Firmicutes* declined from 57.1 to 34.2% (Figure 3A, $P < 0.01$, Student's *t* test). As shown in Figure 3A, a significant increase in *Actinobacteria* ($P < 0.01$, Student's *t* test) and a decrease in *Bacteroidetes* were observed at the fourth week (High-3). The data points shift from the left of the score plot (High-2) to the right side of the graph (High-3) at the fourth week, indicating significant changes in the fecal microbiota (Figure 3B).

Among the *Actinobacteria*, *Bifidobacterium* and *Olsenella* were the two most abundant genera. During the first 3 weeks, the levels of these genera remained lower. However, they both increased significantly (Figure 3C, $P < 0.05$, Student's *t* test) at the fourth week when the dose reached 0.8 g PMPD. For *Lactobacillus*, no significant changes were observed during the FOS treatment except for significant increases in two mice at the fourth week. Two weeks after the FOS treatment stopped, the fecal microbiota changed and tended to revert to the original levels before the FOS treatment as indicated by the cluster results between the data points of High-4 and High-0 (Figure 3B).

During the first 3 weeks, the level of *Enterococcus* remained low at 0.1%. However, it significantly increased to 4.0% at the fourth week (Figure 3D). The levels of *Streptococcus* and *Clostridium* were also increased at the fourth week, although the increases were not significant and their abundance remained low (Figure 3D). Similarly to *Bifidobacterium*, the abundance of *Olsenella* significantly increased, and it was even higher than that of

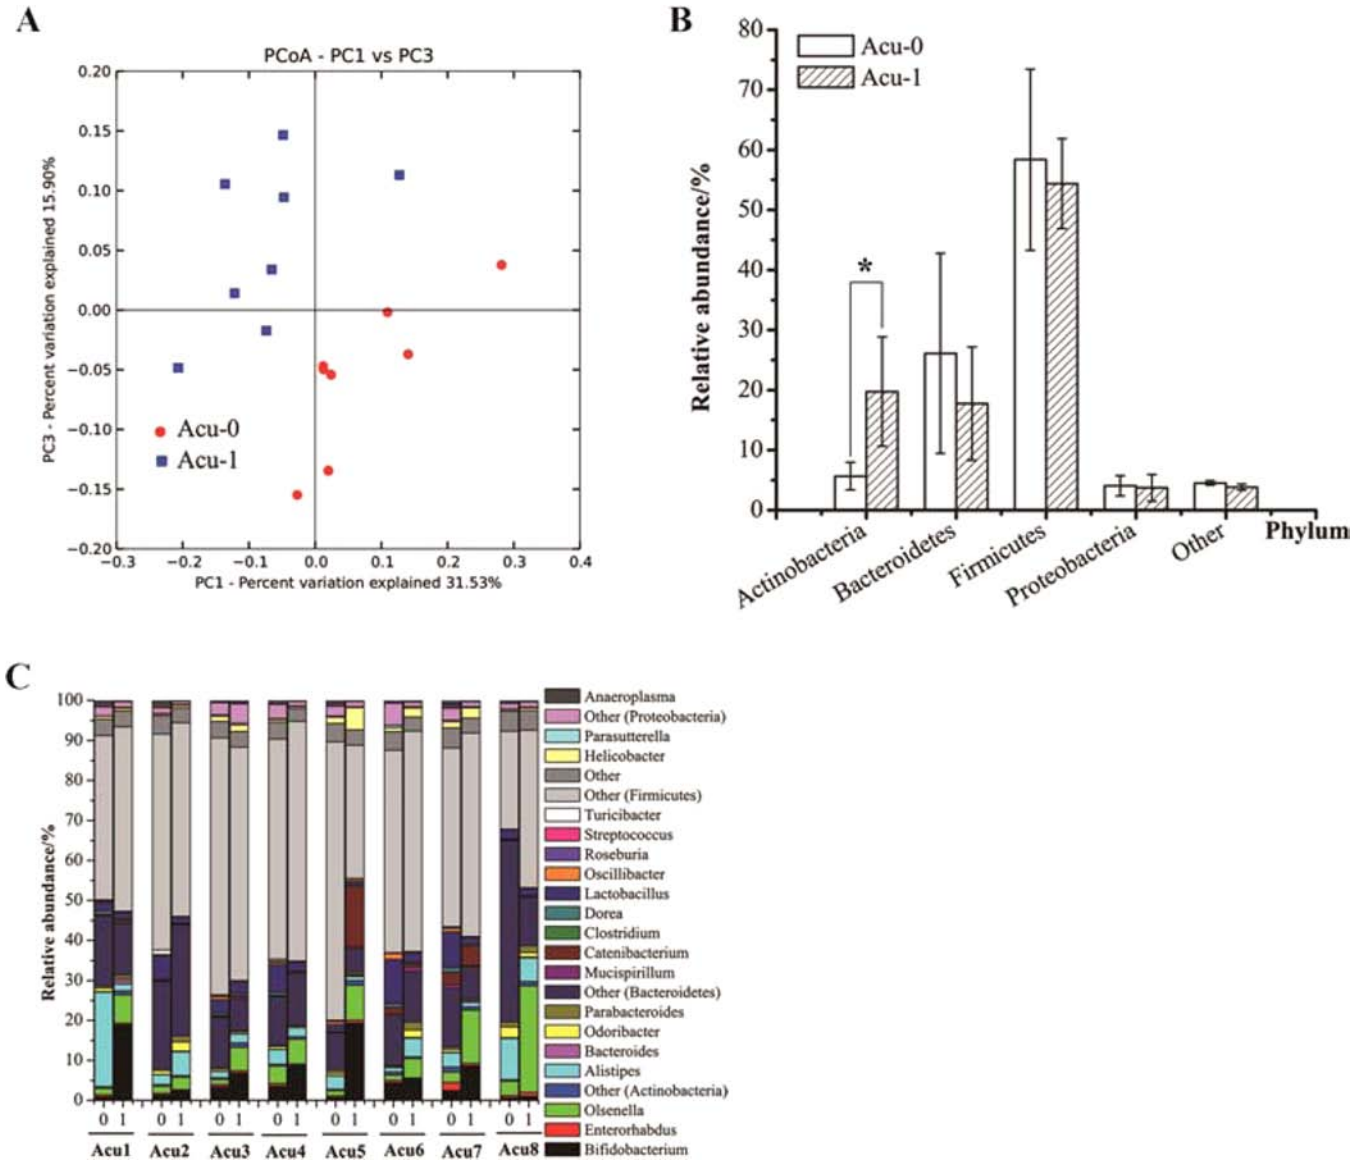

Figure 4. Effect of one-time consumption of FOS on the fecal microbiota. (A) Principal coordinate (PCoA) score plots based on weighted UniFrac metrics. Each point represents the composition of fecal microbiota of one mouse. Relative abundance of five phyla >1% (B) and main genera of different mice before and after FOS treatment (C). Sequences that could not be classified into any known group were assigned as "other". Acu, FOS-acute group; Acu-0, before FOS treatment; Acu-1, after FOS treatment. Acu1, Acu2, Acu3, Acu4, Acu5, Acu6, Acu7, and Acu8 stand for the first, second, third, fourth, fifth, sixth, seventh, and eighth mice in the FOS-acute group. The abundance of main phyla is expressed as the mean ± SEM (∗, $P < 0.05$, Student's t test).

Table 1. Ratio of *Bifidobacterium* and *Olsenella* before and after FOS Treatment

mice		Acu1	Acu2	Acu3	Acu4	Acu5	Acu6	Acu7	Acu8
Bifidobacterium/ *Olsenella* (B/O)	Acu-0	0.53	0.77	2.61	0.79	0.53	3.30	0.92	0.16
	Acu-1	2.65	0.76	1.15	1.42	2.21	1.09	0.64	0.04

Bifidobacterium in several mice at the fourth week. Therefore, more attention needs to be paid to the non-bifidobacteria, especially *Olsenella* and *Enterococcus*, during FOS treatment at high doses.

Effects of FOS on the Fecal Microbiota in an Acute Model. An acute model was established to study the effect of one-time consumption of FOS on fecal microbiota. After 2 days of FOS treatment (FOS, 25%), feces were collected and sequenced. A PCoA based on unweighted Unifrac distances was performed using the obtained sequence data (Figure 4A). Points representing the fecal microbiota of mice before (Acu-0) and after treatment (Acu-1) clustered at the bottom right and top left, respectively. There were significant increases in *Actinobacteria* ($P < 0.001$, Student's t test) and slight decreases in *Bacteroidetes* and *Firmicutes* (Figure 4B). The dramatic increase of *Actinobacteria* was mainly attributable to the significant increases in *Bifidobacterium* and *Olsenella* (Figure 4C, $P < 0.05$, Student's t test). However, the level of *Bifidobacterium* was not significantly different from that of *Olsenella*. Therefore, the FOS were able to selectively stimulate the rapid growth of both *Bifidobacterium* and *Olsenella* in the gut. To make clear the effects of initial abundance of bacteria on the final abundance,

DOI: 10.1021/jf505156h
J. Agric. Food Chem. 2015, 63, 856−863

correlation between the initial and final ratios of *Bifidobacterium* and *Olsenella* (B/O) was investigated (Table 1). The Pearson correlation coefficient was −0.07, which suggests that the final B/O was not correlated with the initial B/O.

Isolation and Identification of *Olsenella* from Mouse Feces and Characterization of Its Growth on FOS. After 7 days of enrichment, seven purified isolates from fecal samples were identified by 16S rRNA sequencing, one of which was confirmed as the genus *Olsenella* (Table 2). The most positive match was *Olsenella* sp. F0004 (accession no. EU592964.1). However, the "Ident" was only 93%, indicating that this strain may belong to unknown species of the genus *Olsenella*. In addition, the sequence of the V4 region of 16S rRNA for *Olsenella* (206 bp) was obtained from the established MiSeq library, which could be found in the sequences of 16S rRNA for mou02 (1373 bp).

Table 2. Identified Strains Isolated from Mouse Feces

no.	strain	most positive match	Ident (%)	GenBank
1	Mou01	*Lactobacillus animalis* JCM 8697 (AB911535.1)	99	KM405313
2	Mou02	*Olsenella* sp. F0004 (EU592964.1)	93	KM405314
3	Mou03	*Lactobacillus animalis* JCM 8697 (AB911535.1)	99	KM405315
4	Mou04	*Lactobacillus* sp. sy4 (KJ801851.1)	99	KM405316
5	Mou09	*Lactobacillus johnsonii* strain LB-19 (HM772969.1)	99	KM405318
6	Mou12	*Lactobacillus taiwanensis* JCM 8687 (AB911525.1)	99	KM405319
7	Mou19	*Lactobacillus taiwanensis* JCM 8687 (AB911525.1)	99	KM405320

The strain mou02 grew faster in BHI medium with the addition of FOS (Figure 5A), indicating that FOS could be used by the *Olsenella* strain mou02, which was confirmed by HPLC analysis (Figure 5B).

DISCUSSION

FOS have long been known to act as a prebiotic that can improve human health by selectively stimulating the growth of beneficial bacteria and reducing the levels of putrefactive bacteria. However, previous studies have mainly focused on specific organisms, such as bifidobacteria, lactobacilli, clostridia, and bacteriodes.[16,32−34] In this study, the effects of FOS on intestinal bacterial populations were investigated using 16S rRNA metagenomic analysis, which can cover the genera existing in the gut.

The FOS were found to alter the intestinal microbiota. Significant increases in the abundance of *Actinobacteria* and decreases in *Bacteroidetes* were observed after FOS treatment (Figures 2D and 3A, High-3), consistent with the results of Rycroft et al.,[33] who evaluated the in vitro fermentation properties of prebiotics on fecal slurry. However, no effect or higher *Bacteroidetes* were observed in mice fed FOS,[34,35] which was consistent with the results at lower doses (Figure 3A, High-1, High-2), indicating that the effect of FOS on *Bacteroidetes* was dependent on dose and time. After 3 weeks, the abundance of *Firmicutes* remained at 60% for the FOS-low group (Figure 2D), but dropped to 35% for the FOS-high group (Figure 3A), indicating that the effect of FOS on the composition of the intestinal microbiota was dependent on the dose. Moreover, the microbial diversity within each group was quantified at given time points (α diversity) (Figure 6). The Shannon index (SI) was estimated to evaluate the ecological diversity of the microbiota in each fecal sample, with a higher SI indicating greater diversity. Significant decreases in α diversity were detected for High-3 and Acu-1 ($P < 0.05$). The decrease for Acu-0 occurred after only 2 days on the FOS diet (FOS, 25%), demonstrating that diet rapidly altered the gut bacteria.[36] Therefore, FOS treatment at a dose of 0.8 g PMPD had a profound effect on the composition and diversity of the intestinal microbiota. Furthermore, the microbiota reverted to their original structure during the washout period (Figure 6), suggesting that the bacterial populations gradually reverted to their prefeeding structures once the FOS treatment ceased.[34,37]

During the FOS treatment, the most striking change in the fecal microbiota was the increase in *Actinobacteria*, of which *Bifidobacterium* and *Olsenella* were the two most dominant genera. It is not surprising that the FOS stimulated the growth of *Bifidobacterium*. However, the abundance of *Olsenella* was also significantly increased and was even higher than *Bifidobacterium* in certain mice (Figures 3B and 4C). *Olsenella* has been described as a member of the oral microbiota[38,39] and is considered an

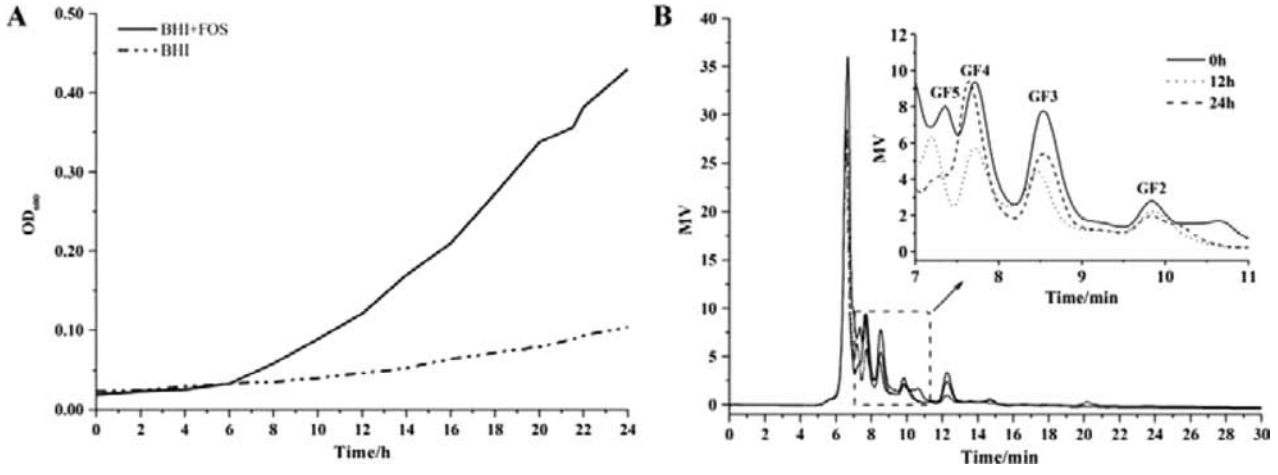

Figure 5. (A) Growth of the *Olsenella* strain mou02 in BHI and BHI-FOS media. The concentration of FOS was 8 g/L. (B) HPLC analysis of the supernatant for the *Olsenella* strain mou02 in BHI-FOS medium at different times: ——, 0 h; ···, 12 h; - - -, 24 h. Peaks at 7.3, 7.7, 8.5, and 9.9 min were assigned as GF5, GF4, GF3, and GF2, respectively.

opportunistic pathogen according to Technische Regeln für Biologische Arbeitstoffe (TRBA 466) and the Human Opportunistic Pathogen (HOP) Library (Gifu University, Genetic information Genetic Resource Center of Human Pathogens) that is closely related to endodontic disease.[38,39] *Olsenella* is also part of the normal bacterial flora in the human gut (http://www.hmpdacc.org/resources/data_browser.php).[40] However, little is known about the role that *Olsenella* plays in the gut, and the genus is seldom mentioned in previous studies on the effects of FOS on intestinal microbiota. Owing to the high-throughput MiSeq sequencing technique used in this study, *Olsenella* was found to be greatly stimulated by FOS and became the dominant genus comparable with *Bifidobacterium* after the FOS treatment. Moreover, we extensively explored the changes of all genera in the gut, rather than focusing on only limited and specific bacteria. Therefore, we suspect that the FOS preferentially stimulated the growth of beneficial bacteria such as *Bifidobacterium* at a low dose but that they also promoted the non-bifidobacteria such as *Olsenella* and *Enterococcus* when the dose was sufficiently high.

One strain of *Olsenella* was isolated from the mouse feces and was confirmed to be capable of utilizing FOS (Table 2; Figure 5). This may be the first reported finding on the utilization of FOS by *Olsenella*. Although not examined in this study, some bacteria in the *Enterococcus*, *Streptococcus*, and *Clostridium* genera may also have the ability to use FOS.

In conclusion, 16S rRNA metagenomic analysis was helpful in investigating the global effects of FOS on the composition of intestinal microbiota. The FOS were found to alter the microbiota, stimulating the growth of *Bifidobacterium* and *Olsenella* at low doses and promoting the growth of non-bifidobacteria such as *Enterococcus* at high doses. However, the FOS effects were not permanent and the microbiota gradually reverted to their initial structure after the FOS treatment ceased. Owing to the high-throughput MiSeq sequencing technique, we found that *Olsenella* became a dominant genus comparable with *Bifidobacterium* after FOS treatment, especially at high doses, and we proved for the first time that one strain of *Olsenella* was able to grow on FOS. More attention should be paid to the non-bifidobacteria, such as *Olsenella* and *Enterococcus*, in future studies to reveal the interactions between FOS and human gut bacteria.

Antioxidant Potential of Date (*Phoenix dactylifera* L.) Seed Protein Hydrolysates and Carnosine in Food and Biological Systems

Priyatharini Ambigaipalan and Fereidoon Shahidi*

Department of Biochemistry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X9

ABSTRACT: Date seed protein hydrolysates were evaluated for antioxidant activity as well as solubility and water-holding capacity in food and biological model systems. Date seed protein hydrolysates as well as carnosine exhibited >80% of solubility over a pH range of 2−12. The hydrolysates and carnosine at 0.5% (w/w) were also found to be effective in enhancing water-holding capacity and cooking yield in a fish model system, which was nearly similar to sodium tripolyphosphate (STPP; 0.3%, w/w). Incorporation of hydrolysates (200 ppm) in fish model systems resulted in the highest inhibition (30%) of oxidation in comparison to butylated hydroxytoluene (BHT; 9%). In addition, hydrolysates and carnosine inhibited β-carotene oxidation by 75%. The hydrolysates (0.1 mg/mL) inhibited LDL cholesterol oxidation by 60%, whereas carnosine inhibited oxidation by 80% after 12 h of incubation. Additionally, hydrolysates and carnosine effectively inhibited hydroxyl (6 mg/mL) and peroxyl (0.1 mg/mL) radical-induced DNA scission. Therefore, date seed protein hydrolysates could be used as a potential functional food ingredient for health promotion.

KEYWORDS: *date seed, protein hydrolysate, solubility, water-holding capacity, carnosine, LDL cholesterol, DNA scission*

INTRODUCTION

Hydrolysates are defined as proteins that are chemically or biologically broken down to peptides of various sizes. Enzymatic hydrolysis of food proteins is an efficient way to recover potent bioactive peptides.[1] Hydrolysis of proteins using various enzymes could improve the functional properties by influencing the molecular size, hydrophobicity, and polar groups of peptides.[2] Functional properties of protein hydrolysates such as solubility, water-holding capacity, and emulsifying and foaming properties are substantially useful characteristics for many food applications.[1] Apart from functionalities, several studies have shown the potential application of protein hydrolysates for the nutritional or pharmaceutical industry due to their antioxidant activity.[3−6]

Bioactive peptides generally contain 3−20 amino acid units,[7] but in some cases this range may be extended. Lunasin, for example, is a food-derived peptide with anticancer activity, composed of 43 amino acids with a molecular weight of 5400 Da.[8] Depending on the amino acid sequence, these peptides may be involved in various biological functions such as antihypertension, opioid agonists or antagonists, immunomodulatory, antithrombotic, antioxidant, anticancer, and antimicrobial activities, in addition to nutrient utilization.[9,10]

The reactivity of free radicals on biological molecules (lipids, proteins, and DNA) may be considered as the initiating stage for several chronic diseases. For example, oxidation of low-density lipoprotein (LDL) cholesterol by free radicals or metal ions is an important cause for developing atherosclerotic lesions that lead to coronary heart disease.[11] Furthermore, Wettasinghe and Shahidi[12] reported that oxidation of DNA and strand scission play an important role in carcinogenesis. Thus, researchers have a greater interest in developing novel antioxidative compounds from various plant and animal sources. Carnosine is a β-alanylhistidine dipeptide, present at millimolar concentrations in skeletal muscle and absorbed into plasma, that has been shown to have antioxidative property.[13−15] Thus, a well-known bioactive peptide, carnosine, was used in this study to compare the functional and antioxidative properties of date seed protein hydrolysates. In this study, date seed protein hydrolysates hydrolyzed using various enzymes (Alcalase, Flavourzyme, and Thermolysin) were compared to carnosine, an antioxidative peptide, with respect to functional (solubility and water-holding capacity) and antioxidative properties in various food (cooked comminuted fish model and β-carotene−linoleate model) and biological (human LDL and DNA) model systems.

MATERIALS AND METHODS

Materials. Ground date (*Phoenix dactylifera* L.) seed sample was provided by Dr. A. S. Al-Khalifa of King Saud University, Riyadh, Saudi Arabia. Alcalase (2.4 AU/g) and Flavourzyme (1000 LAPU/g) were procured from Novozymes, Bagsvaerd, Denmark. Thermolysin (50−100 units/mg protein) was purchased from Sigma-Aldrich Canada Ltd. (Oakville, ON, Canada). All chemicals used were obtained from Fisher Scientific Ltd. (Ottawa, ON, Canada) or Sigma-Aldrich Canada Ltd. The solvents used were of ACS grade, pesticide grade, or HPLC grade and were used without any further purification.

Preparation of Protein Hydrolysate. Ground date seed sample was defatted with hexane (1:5, w/v) for 5 min. The crude protein content was determined by using micro-Kjeldhal analysis.[16] The date seed protein hydrolysates were prepared using Alcalase (AL), Flavourzyme (FL), and Thermolysin (TH) by individual or sequential treatment as described in Table 1. Twenty grams of defatted date seed sample was suspended in 100 mL of water and hydrolyzed batchwise in a reaction vessel, equipped with a stirrer, thermometer, and pH electrode according to the conditions presented in Table 1. The pH (changes as a result of hydrolysis) was kept constant by the addition of

a known amount of 4 M NaOH. The degree of hydrolysis (%) was then determined by the trinitrobenzenesulfonic acid (TNBS) method described by Alder-Nissen (1979). The date seed protein hydrolysates obtained were freeze-dried and stored at −20 °C for subsequent analyses.

Solubility of Protein Hydrolysates. The solubility of date seed protein hydrolysate was determined according to the method described by Shahidi, Han, and Synoweicki[17] with modifications. Freeze-dried date seed protein hydrolysate (10 mg/mL, w/v) was dispersed in distilled water, and its pH was adjusted to 2, 5, 8, and 12 by the addition of a 1 N or 6 N HCl or 1 N or 6 N NaOH solution. The contents were mixed, and the mixture was centrifuged at 7500*g* for 15 min. The protein contents in the supernatant were determined using the Biuret method, and the total protein content in the sample was determined by solubilizing the sample in 0.5 N NaoH. The solubility of date seed protein hydrolysates was determined using the following equation:

$$\text{solubility (\%)} = \frac{\text{protein content in supernatant}}{\text{total protein content in sample}} \times 100$$

Determination of Water-Holding Capacity. The water-holding capacity of date seed protein hydrolysates was determined according to the method described by Shahidi and Synowiecki.[18] A fish model system was prepared using 8.5 g of ground salmon and 1.5 g of distilled water in a preweighed 50 mL centrifuge tube. Date seed protein hydrolysates (0.5%, w/w) were added and mixed thoroughly. A control without any protein hydrolysate and positive controls sodium tripolyphosphate (0.3%, w/w) and carnosine were also prepared. The mixture was allowed to stand in a cold room for 1 h and subsequently cooked at 95 °C in a water bath for 1 h. The cooked samples were cooled under a stream of cold tap water, and the drip water was determined using a filter paper. The final weight of the cooked fish was recorded. The drip volume was calculated as the difference between the initial weight and final weight. The water-holding capacity for different date seed protein hydrolysates was expressed as decrease of drip volume against the control.

Antioxidant Activity in Cooked Comminuted Fish Model System. The antioxidant activity of date seed protein hydrolysates in the cooked comminuted fish model system was determined as described by Wettasinghe and Shahidi.[19] Ground salmon (40 g) was mixed with 10 g of deionized water in Mason jars. Date seed protein hydrolysate (200 ppm) was added directly to the mixture. A control without protein hydrolysate and a positive control using butylated hydroxytoluene (BHT; 200 ppm) were also prepared. Samples were cooked in a thermostated water bath at 80 °C for 40 min while stirring every 5 min with a glass rod. After cooling to room temperature, the fish samples were transferred into plastic bags and stored in a refrigerator at 4 °C for 14 days. Thiobarbituric acid reactive substances (TBARS) were analyzed on days 0, 7, and 14 using a modified version of the method described by Wijeratne, Abou-Zaid, and Shahidi.[20] Fish samples (1 g) in centrifuge tubes were mixed with trichloroacetic acid (10%, 2.5 mL) and vortexed for 2 min at high speed. TBA reagent (0.02 M, 2.5 mL) was then added to the tube, followed by further vortexing for 30 s. Samples were centrifuged at 3000*g* for 10 min and the supernatants filtered through Whatman no. 3 filter paper. The tubes were covered with aluminum foil, placed in a boiling water bath for 45 min, and subsequently cooled to room temperature under running cold tap water. The absorbance of the resultant pink TBA−MDA (malondialdehyde) adduct was read at 532 nm. A standard curve was prepared using 1,1,3,3-tetramethoxypropane, a precursor of MDA (0−6 ppm). TBARS values, calculated using the standard curve, were expressed as milligrams of MDA equivalent per kilogram of sample.

Antioxidant Activity in Oil-in-Water Emulsions. A β-carotene−linoleate model system was used to evaluate the antioxidant activity of date seed protein hydrolysates in an oil-in-water emulsion.[1] β-Carotene (10 mg) was dissolved in chloroform (10 mL), and an aliquot (1.2 mL) of it was transferred into a flask containing linoleic acid (40 mg) and Tween 40 (400 mg). A blank without β-carotene was also prepared (40 mg of linoleic acid + 400 mg of Tween 40). Chloroform was removed under a nitrogen stream; 100 mL of oxygenated distilled water was added to the flask, and the mixture was stirred vigorously for 30 min. Date seed protein hydrolysates (0.5 mg/mL; 0.5 mL) dissolved in deionized water were mixed with 4.5 mL of the above emulsion. A control without protein hydrolysate and a mixture of blank (without β-carotene) was prepared for each sample. The absorbance at 470 nm was read immediately after the addition of the emulsion. The tubes were incubated in a shaking water bath at 50 °C, and the absorbance was read over a 105 min period at 15 min intervals. A kinetic curve was plotted against blank-corrected absorbance and time. One hundred parts per million of Trolox and carnosine were used as a positive control. Antioxidant activity of date seed protein hydrolysates in protecting β-carotene/linoleic acid oxidation was calculated using the equation

$$\text{antioxidant activity (\%)} = [(A_0 - A_t)/(A^\circ_0 - A^\circ_t)] \times 100$$

where A_0 and A_t are corrected absorbance values for test samples measured at zero time and after incubation, respectively, whereas A°_0 and A°_t are corrected absorbance values for control at time zero and at time t after incubation, respectively.

Cupric Ion-Induced Human Low-Density Lipoprotein (LDL) Peroxidation. The inhibitiory effect of cupric ion-induced human LDL peroxidation was determined according to the method described by Liyana-Pathirana and Shahidi.[21] LDL (5 mg/mL) was dialyzed against 100 volumes of 10 mM phosphate buffer (pH 7.4, 0.15 M NaCl) using a dialysis tube with a molecular weight cutoff of 12−14 kDa (Fisher Scientific, Nepean, ON, Canada) at 4 °C under a nitrogen blanket in the dark for 12 h. Diluted LDL cholesterol (0.04 mg LDL/mL) was mixed with the date seed protein hydrolysate solutions (0.1 mg/mL). Carnosine was used as a positive control. The samples were preincubated at 37 °C for 15 min. The reaction was initiated by adding a solution of cupric sulfate (50 μM), and the samples were then incubated at 37 °C for 22 h. The formation of conjugated dienes (CD) was recorded at 234 nm using a diode array spectrophotometer (Agilent, Palo Alto, CA, USA). The appropriate blanks were run for each sample by replacing LDL cholesterol and $CuSO_4$ with distilled water for background correction. The inhibitory effect of tested samples on the formation of conjugated dienes (% inhibition CD) was then calculated using the equation

$$\text{\% inhibition CD} = [(\text{Abs}_{\text{control}} - \text{Abs}_{\text{sample}})/(\text{Abs}_{\text{control}} - \text{Abs}_{\text{native}})] \times 100$$

$$\text{Abs}_{\text{control}} = (A^\circ_0 - A^\circ_t)$$

$$\text{Abs}_{\text{sample}} = (A_0 - A_t)$$

DOI: 10.1021/jf505327b
J. Agric. Food Chem. 2015, 63, 864−871

where $Abs_{control}$ is the absorbance of LDL + $CuSO_4$ + PBS, Abs_{sample} is the absorbance of LDL + $CuSO_4$ + sample/standard, and Abs_{native} is the absorbance of LDL + PBS. A_0 and A_t are absorbance values for test samples measured at zero time and at time t after incubation, respectively, whereas $A°_0$ and $A°_t$ are corrected absorbance values for control at time zero and at time t after incubation, respectively.

Inhibition of Peroxyl and Hydroxyl Radical-Induced Supercoiled DNA Strand Scission. Peroxyl and hydroxyl radical-induced supercoiled plasmid DNA strand scission inhibitory activity of date seed protein hydrolysate was determined according to the method described by Chandrasekara and Shahidi.[22] Supercoiled plasmid DNA (pBR 322) (50 μg/mL) was dissolved in 10 mM phosphate buffer (PBS, pH 7.4), and date seed protein hydrolysates were dissolved in distilled water. In a 0.5 mL eppendorf tube date seed protein hydrolysate (0.1 mg/mL, 2 μL), PBS (2 μL), pBR 322 (50 μg/mL, 2 μL), and 4 μL of 7 mM 2,2′-azobis(2-methylpropanimidamide dihydrochloride (AAPH) were added to generate peroxyl radicals, whereas date seed protein hydrolysate (6 mg/mL, 2 μL), PBS (2 μL), pBR 322 (50 μg/mL, 2 μL), $FeSO_4$ (0.5 mM, 2 μL), and H_2O_2 (0.5 mM, 2 μL) were added to produce hydroxyl radicals. The mixture was incubated at 37 °C for 1 h in the dark. A control with DNA alone, a positive control with carnosine (0.1 mg/mL), and a blank devoid of protein hydrolysates were also prepared. After incubation, 1 μL of the loading dye (0.25% bromophenol blue, 0.25% xylene cyanol, and 50% glycerol) were added to the reaction mixture. The mixture (10 μL) was loaded onto 0.7% agarose gel prepared in Tris−acetic acid−EDTA (TAE) buffer (40 mM Tri−-acetate containing 1 mM EDTA, pH 8.5). SYBR safe (5 μL) was added into agarose gel solution (50 mL) as a gel stain. Electrophoresis was conducted at 80 V for 90 min using a model B1A horizontal mini gel electrophoresis system (Owl Separation Systems Inc., Portsmonth, NH, USA) and a model 300 V power supply (VWR International Inc., West Chester, PA, USA) in TAE buffer. The DNA bands were visualized under trans-illumination of UV light using the Alpha-Imager gel documentation system (Cell Biosciences, Santa Clara, CA, USA). The intensity (area %) of bands was quantified with the Chemi-Imager 4400 software (Cell Biosciences). The retention of supercoiled DNA strand (%) was calculated using the following equation:

$$\text{DNA retention (\%)} = (\text{area of supercoiled DNA with oxidative radical and protein hydrolysate/area of supercoiled DNA in control})$$

Statistical Analysis. All determinations were replicated three times and mean values and standard deviations reported. One-way ANOVA was performed, and the mean separations were performed by Tukey's HSD test ($p < 0.05$) using SPSS 16.0 for Windows (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Solubility of Protein Hydrolysates. The protein content of defatted date seed sample was 6.7%, on a dry weight basis, and the degree of hydrolysis ranged between 11 and 13%. Molecular weights of peptides, determined using a quadrupole orthogonal time-of-flight hybrid tandem mass spectrometer, ranged from 2062.9 ± 0.0 to 116803.8 ± 0.4 Da (unpublished data). Solubility is one of the most important properties of protein hydrolysates, which is required in many functional applications such as emulsions, foams, and gels.[2,3] The solubility of date seed protein hydrolysate in the pH range of 2−12 is shown in Figure 1. All date seed protein hydrolysates as well as carnosine exhibited >80% of solubility at range of pH 2−12. Solubility of date seed hydrolysates increased to 97% with increasing pH. Hydrolysis of proteins by enzymes potentially affects the molecular size and hydrophobicity, as well as polar and ionizable groups of protein hydrolysates.[23] Dong, Zeng, Wang, Liu, Zhao, and Yang[4] showed that the solubility of silver carp hydrolysates increases with lower molecular mass protein fraction at high degrees of hydrolysis. Gbogouri, Linder, Fanni, and Parmentier[24] suggested that the smaller peptides from proteins have proportionally more polar residues, which could form hydrogen bonds with water and thus increase solubility. The high solubility of date seed protein hydrolysate reveals its potential applications in formulated food systems.

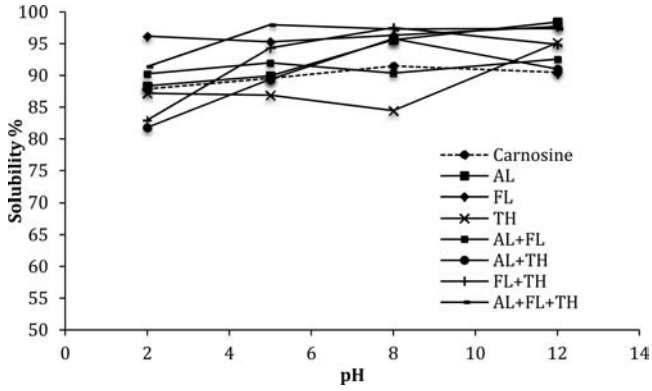

Figure 1. Solubility of date seed protein hydrolysates and carnosine at various pH values.

Water-Holding Capacity. All date seed protein hydrolysates enhanced the water-holding capacity of salmon fish and thus improved cooking yield (Figure 2). There was no siginificant difference among protein hydrolysates (0.5%) and sodium tripolyphosphate (STTP; 0.3%) with respect to decrease in drip volume. However, date seed flour exhibited a low water-holding capacity (1.8%) in comparison to protein hydrolysates. Cumby, Zhong, Naczk, and Shahidi[25] observed an increase water-holding capacity of ground pork meat model system for rapeseed proteins hydrolyzed using Alcalase and Flavourzyme. The authors suggested that that lower molecular weight peptides could be more effective in holding water than are larger-sized peptides due to its greater hydrophilicity. However, the type of amino acid present in the peptides could also play an important role. Decrease in drip volume percentage of carnosine (4.3%) was also lower than date seed protein hydrolysates. Das, Anjaneyulu, and Biswas[26] showed that ground buffalo meat containing 1.0 and 1.5% carnosine significantly improved water-holding capacity and lowered cooking loss. Thomsen and Zeuthen[27] showed that the water-holding capacity increases with increasing meat pH. Thus, the

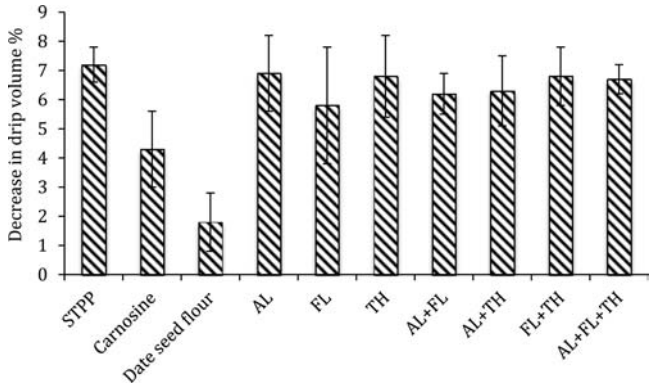

Figure 2. Decrease in drip volume (%) of date seed protein hydrolysates, date seed flour, carnosine, and STPP.

DOI: 10.1021/jf505327b
J. Agric. Food Chem. 2015, 63, 864−871

authors[26] concluded that the increase in meat pH by carnosine probably accounts for the decrease in cooking loss. Our study shows that 0.5% of date seed protein hydrolysates could be used as an alternative to STPP to increase cooking yield of fish meat.

Antioxidant Activity of Date Seed Protein Hydrolysates in Cooked Comminuted Fish Meat Model System. The antioxidant activity of date seed protein hydrolysates in cooked salmon was measured by the thiobarbituric acid (TBA) assay. TBA assay is a spectrophotometric detection of TBARS, namely, MDA, one of the secondary lipid peroxidation products used to measure the extent of lipid degradation. Ground salmon was treated with BHT (200 ppm) or carnosine (200 ppm) or date seed protein hydrolysates (200 ppm) before cooking. Table 2 shows the

Table 2. TBARS Values of Fish Model System Containing Date Seed Protein Hydrolysates, BHT, and Carnosine Stored for 14 Days

	TBARS[a] (mg/kg)		
	0 days	7 days	14 days
control	4.6 ± 0.1e	5.6 ± 0.2e	5.9 ± 0.0
BHT	3.8 ± 0.0cd	5.2 ± 0.0de	5.6 ± 0.1
carnosine	4.0 ± 0.0d	4.9 ± 0.0cd	5.0 ± 0.1
AL	4.1 ± 0.2d	5.4 ± 0.1e	5.7 ± 0.0
FL	4.7 ± 0.1e	5.5 ± 0.1e	5.9 ± 0.0
TH	3.4 ± 0.2bc	5.0 ± 0.1cd	5.5 ± 0.0
AL + FL	3.6 ± 0.0c	3.8 ± 0.0a	5.5 ± 0.1
AL + TH	3.0 ± 0.1b	4.6 ± 0.0b	5.0 ± 0.0
FL + TH	2.5 ± 0.2a	3.9 ± 0.1a	4.8 ± 0.3
AL + FL + TH	4.6 ± 0.1e	4.8 ± 0.0bc	5.5 ± 0.0

[a]All data represent the mean of triplicates. Values followed by the same letter are not significantly different ($P > 0.05$) by Tukey's HSD test.

TBARS values of samples throughout the storage period. The initial TBARS value of salmon (4.6 mg MDA equiv/kg) were found to be higher than that of pork model system (~1.0 mg MDA equiv/kg) studied elsewhere.[6] This could be due to the presence of polyunsaturated fatty acids in fish that could increase TBARS during cooking. The fish system containing FL + TH hydrolysate displayed significantly ($p < 0.05$) lower TBARS value compared to BHT upon cooking. Generally, the TBARS of cooked salmon increased as the storage time increased up to 14 days of storage ($p < 0.05$). Inhibition percentage of TBARS production in fish model system containing date seed protein hydrolysates or carnosine or BHT is shown in Figure 3. After 7 days of storage, fish systems with AL + FL (32%) and FL + TH (30%) hydrolysate showed the highest percentages of TBARS inhibition in comparison to BHT (7%). Carnosine exhibited a higher percentage of inhibition (12%) compared to BHT (6.6%) after 7 days of storage. Decker and Crum[28] showed that the antioxidant activity of carnosine (0.5−1.5%) in cooked salted and unsalted ground pork is greater than those of the lipid-soluble free radical scavengers BHT and α-tocopherol but less than that of STPP. In another study on ground buffalo meat, carnosine at 1.0 and 1.5% significantly lowered the TBARS values as compared to control sample. The inhibition of TBARS production in the fish system containing date seed protein hydrolysate could be most likely due to its radical-scavenging activity as well as chelating activity toward Fe^{2+}. In comparison

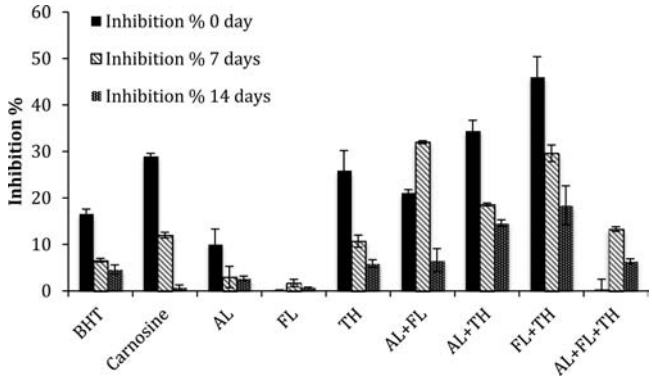

Figure 3. Inhibition of TBARS production in fish model system containing date seed protein hydrolysates, carnosine, and BHT.

to fish system containing AL + FL, AL + TH, and FL + TH hydrolysates (200 ppm), BHT (200 ppm) showed a lower inhibition after 7 days of storage. Thus, date seed protein hydrolysates prepared using combinations of AL + FL, AL + TH, and FL + TH could be used to control oxidation in a fish model system.

Antioxidant Activity of Date Seed Protein Hydrolysates in Oil-in-Water Emulsion. A β-carotene−linoleate model system was used to evaluate the antioxidant activity of date seed protein hydrolysates in an oil-in-water emulsion. Oxidation of linoleic acid in the emulsion system gives rise to the formation of free radicals and hydroperoxides. The free radicals so formed attack the β-carotene molecule, causing it to lose its conjugation and eventually decolorize. This loss of color could be monitored spectrophotometrically at 470 nm. The presence of antioxidants can counteract the bleaching of β-carotene during the coupled oxidation of linoleic acid and β-carotene in the emulsified aqueous system. Figure 4 shows the effect of date seed protein hydrolysates, at a concentration of 0.1 mg/mL, on β-carotene bleaching in the aforementioned system. β-Carotene content in the control samples decreased to a greater extent compared to those containing date seed protein hydrolysates or trolox or carnosine, which retained high amounts of β-carotene after 105 min. Positive controls trolox (~54−63%) and carnosine (~58−75%) showed significantly ($p < 0.05$) higher inhibitory effect against β-carotene bleaching than date seed protein hydrolysates up to 60 min. The percent inhibition of β-carotene oxidation inhibition by date seed protein hydrolysates ranged between 66.9 and 73.7%. Hydrolysates prepared using a combination of FL and TH showed the highest inhibition (73.7%) followed by AL + TH ~ FL ~ AL > AL + FL+TH ~ TH ~ AL + FL. Several studies have shown that amino acids possess strong antioxidant activity in linoleic acid and methyl linoleate model systems,[29] for example, tryptophan and lysine in butter fat,[30] proline in sardine oil,[31] methionine in vegetable oils,[32] and histidine, threonine, lysine, and methionine in a sunflower oil emulsion.[33] Furthermore, Aruoma, Laughton, and Halliwell[34] showed the antioxidative effect for taurine, hypotaurine, carnosine, and anserine using in vivo models. However, Pratt and Hudson[35] reported that some amino acids such as cysteine, histidine, and tryptophan at higher concentration may act as prooxidants. Copper bound to amino acids or peptides has been shown to have a strong catalyzing effect on the oxidation of linoleic acid.[1] Amarowicz and Shahidi[1] suggested that differences in the antioxidant properties of peptides might originate from their synergistic

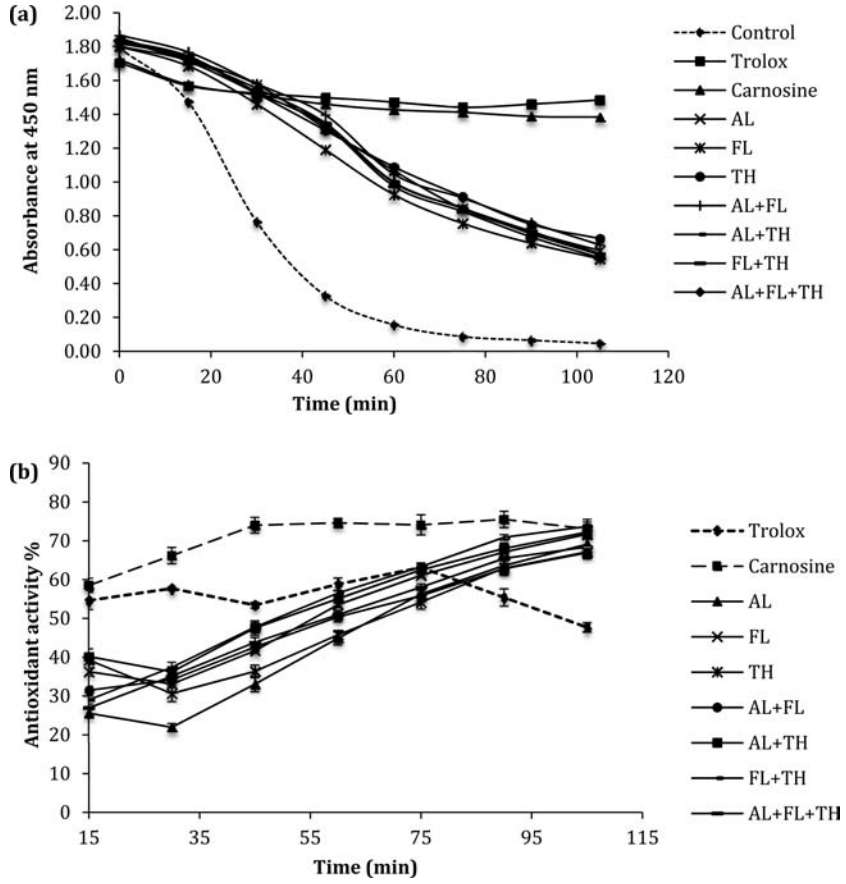

Figure 4. (a) β-Carotene bleaching as affected by date seed protein hydrolysates, trolox, and carnosine as measured by changes in absorbance value at 450 nm; (b) antioxidant activity of date seed protein hydrolysates, trolox, and carnosine against β-carotene bleaching.

action with the emulsifier (Tween 40) used in the analysis. Furthermore, Wijeratne, Abou-Zaid, and Shahidi[20] reported that hydrophobic antioxidants have higher efficiency than hydrophilic ones in preventing oxidation in oil-in-water emulsion systems by preferentially orienting themselves at the oil−water interface. Emulsifiers decrease the particle size of peptides and increase the contact surface of the phases.[29] This lends support to findings of this study that could be attributable to the presence of hydrophobic amino acids in date seed protein hydrolysates.

Cupric Ion-Induced Human Low-Density Lipoprotein Peroxidation. Cupric ion has been shown to be effective in initiating the oxidation of EDTA-free human LDL, as measured by the formation of conjugated dienes. The presence of both cholesteryl linoleate and cholesteryl arachidonate within the LDL core provides a rich source of lipid peroxidation substrate.[36] Therefore, the greater the lipophilic property of the antioxidant, the more effective it will be to extend the LDL oxidation lag phase once induced by[37] Cu^{2+}. LDL oxidation plays a major role in atherogenesis and coronary heart disease. Date seed protein hydrolysates and carnosine at a concentration of 0.1 mg/mL rendered a protective effect against human LDL oxidation (Figure 5), and this was higher. Date seed protein hydrolysates and carnosine exhibited higher after 12 h of incubation, being 50−60 and 80.9%, respectively. There was no significant difference ($p > 0.05$) among date seed protein hydrolysates after 12 h of incubation. Hydrolyates prepared using AL and TH showed the highest percentage of inhibition among all enzymatic treatments. Hydrolysate

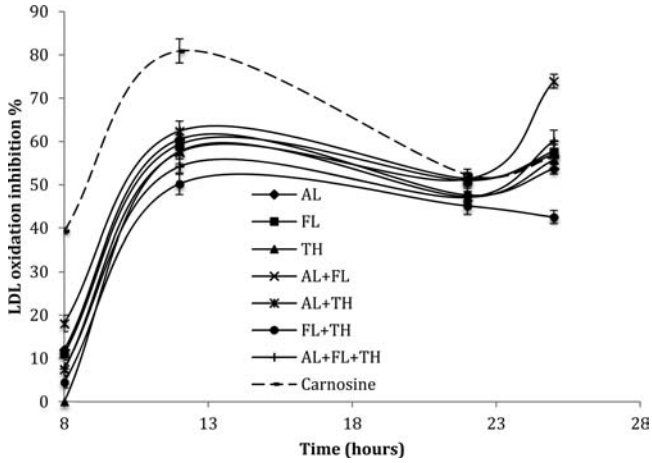

Figure 5. Inhibition against human LDL cholesterol oxidation by date seed protein hydrolysates and carnosine incubated at 37 °C for 25 h.

prepared using only TH had no inhibition at 8 h, but it increased to ∼57% after 12 h. However, percent inhibition decreased after 22 h of incubation in all date seed hydrolydates as well as in carnosine. Decker, Ivanov, Zhu, and Frei[16] investigated the ability of carnosine to inhibit the oxidation of LDL in comparison to its constituent amino acid, histidine. They showed that carnosine is capable of inhibiting copper-promoted oxidation reactions by chelating copper ions. However, carnosine's inhibitory activity against copper is shown to be less than that of histidine in LDL model, due to

DOI: 10.1021/jf505327b
J. Agric. Food Chem. 2015, 63, 864−871

its lower ability to remove copper from the surface of the macromolecules.[16] Alvarez-Parrilla, de la Rosa, Amarowicz, and Shahidi[5] reported that the inhibition of LDL oxidation by polyphenols could be attributed to different mechanisms, including hydrogen donation, lipid radical scavenging, metal chelation,[38] and protein binding.[21] Chen and Frei[39] reported that direct binding of cupric ions to LDL is important for copper reactivity because modification of histidine decreased the binding of copper to LDL and decreased copper-promoted oxidation rates. In this study, the inhibitiory effect of date seed protein hydrolysates on human LDL cholesterol oxidation could be attributed to the chelating power of protein hydrolysates for copper ions as well as scavenging of free radicals in LDL. In a previous study, Kittiphattanabawon, Benjakul, Visessanguan, and Shahidi[6] showed that gelatin hydrolysate from blacktip shark at various degrees of hydrolysis showed promising inhibitiory effect on LDL cholesterol oxidation. Several studies have shown that the presence of certain amino acids in protein hydrolysates, such as histidine, tryptophan, tyrosine, phenylalanine, methionine, leucine, glycine, or proline enhances the scavenging and chelating activities of peptides.[40−42] Thus, date seed protein hydrolyzed using Alcalase, Flavourzyme, and Thermolysin alone or in combination could protect human LDL cholesterol from oxidation and reduce oxidative stress in the body.

Inhibition of Peroxyl and Hydroxyl Radical-Induced Supercoiled DNA Strand Scission. Free radicals generated in living cells have been shown to induce base modification and DNA strand breakage, which may subsequently lead to mutation and carcinogenesis.[43] The most common radical in biological systems is the superoxide radical anion, which is produced mostly within the mitochondria of a cell.[44] Superoxide alone or combination with other free radicals could damage the DNA at both the phosphate backbone and the nucleotide bases. Davies[45] reported that this could lead to strand scission, sister chromatid exchange, and DNA−DNA and DNA−protein cross-links. Supercoiled DNA (form I) may be converted to a nicked open circular form (form II) and a linear form (form III) when its single strands are cleaved by free radicals.[43] To assess the protective effect of date seed protein hydrolysates on hydroxyl and peroxyl radical-induced DNA scission, agarose gel electrophoresis was used, which could be used to detect the forms of DNA separately. Percentage inhibition of DNA strand scission induced by peroxyl and hydroxyl radicals is presented in Table 3. Date seed protein hydrolysates exhibited inhibitory effects against peroxyl and hydroxyl radical-induced DNA scission in a concentration-dependent manner (Figure 6). Although date seed protein hydrolysates exhibited a protective effect against peroxyl radical-induced DNA scission at a concentration of 0.1 mg/mL, they were effective only at 6 mg/mL against hydroxyl radical-induced DNA scission, ranging from 13.8 to 33.0%. The positive control, carnosine, exhibited an inhibition of 30.6%. AL hydrolysate exhibited the highest inhibition of 33.0% against hydroxyl radical, which is slightly higher than that rendered by carnosine, whereas the mixture of three enzymes (AL + FL + TH) showed the lowest inhibition of 13.8%. All other enzymatic treatments exhibited no significant difference ($p > 0.05$) in inhibition of hydroxyl radicals (19.5−24.2%). For peroxyl radical-induced DNA scission, inhibition by the date seed protein hydrolysates ranged from 22.1 to 83.2% at a concentration of 0.1 mg/mL. All enzymatic treatments of date seed proteins exhibited significantly ($p < 0.05$) higher percentage of inhibition against peroxyl radical compared to that of carnosine (22.1%). Decker, Livisay, and Zhou[46] observed the changes in carnosine concentrations in oxidizing skeletal muscle and suggested that carnosine may not be as effective a free radical scavenger in vivo as other antioxidants such as α-tocopherol. This seems plausible, because carnosine exhibited a lower percentage of inhibition against peroxyl radical-induced DNA scission compared to date seed protein hydrolysates. AL hydrolysate showed significantly ($p < 0.05$) higher inhibition percentage of both peroxyl and hydroxyl radical-induced DNA scission, whereas the mixture of three enzymes (AL + FL + TH) showed the lowest percentage of inhibition. The inhibitory effect of date seed protein hydrolysates may be due to their ability to scavenge hydroxyl and peroxyl radicals and via their chelating activity. In this experiment, it was evident that the level of inhibition against hydroxyl radical was substantially lower compared to that against peroxyl radical even at a higher concentration. A similar observation was reported by Madhujith and Shahidi[47] for barley extracts. Hydroxyl radicals are short-lived and extremely reactive among all reactive oxygen species.[22] In contrast, peroxyl radicals exhibit a long half-life and have a greater affinity to diffuse into cells.[6] Thus, Hunag, Ou, and Prior[48] suggested that the direct scavenging of the hydroxyl radical by dietary antioxidants in a biological system is unrealistic as the cellular concentration of dietary antioxidants is negligible compared with DNA and other biological molecules. Therefore, the protective effect of date seed protein hydrolysates toward hydroxyl radical could be mainly due to the chetaltion of Fe(II), whereas that of peroxyl radicals may be due to a scavenging effect. This may explain the large variations observed in inhibition efficacies observed for hydroxyl and peroxyl radical-induced DNA scission. Regardless, this study demonstrated that date seed protein hydrolysates could serve as potential antimutagenic agents in food and biological systems.

Table 3. Inhibition of Peroxyl Radical-Induced DNA Scission by Date Seed Protein Hydrolystes and Carnosine[a]

	DNA scission inhibition (%)	
protein hydrolysate	hydroxyl radical	peroxyl radical
carnosine	30.6 ± 2.1c	22.1 ± 0.4a
AL	33.0 ± 1.4c	83.2 ± 1.5e
FL	20.5 ± 1.6b	47.8 ± 1.0b
TH	24.2 ± 1.6b	78.5 ± 2.4de
AL + FL	23.9 ± 1.4b	76.8 ± 1.3d
AL + TH	19.5 ± 1.9ab	75.2 ± 2.2d
FL + TH	21.4 ± 1.3b	77.4 ± 1.0d
AL + FL + TH	13.8 ± 2.2a	55.2 ± 0.4c

[a]All data represent the mean of triplicates. Values followed by the same letter are not significantly different ($P > 0.05$) by Tukey's HSD test.

This study revealed that date seed protein hydrolysates have a good solubility over a wide range of pH (pH 2−12) and improved water-holding capacity of fish products. In addition, date seed protein hydrolysates exhibited different antioxidant activities depending on the test model systems. Thus, date seed protein hydrolysates could be used as a natural additive possessing functionalities and antioxidative properties in food systems. Furthermore, date seed protein hydrolysates inhibited human LDL cholesterol oxidation and peroxyl and hydroxyl radical-induced supercoiled plasmid DNA strand scission.

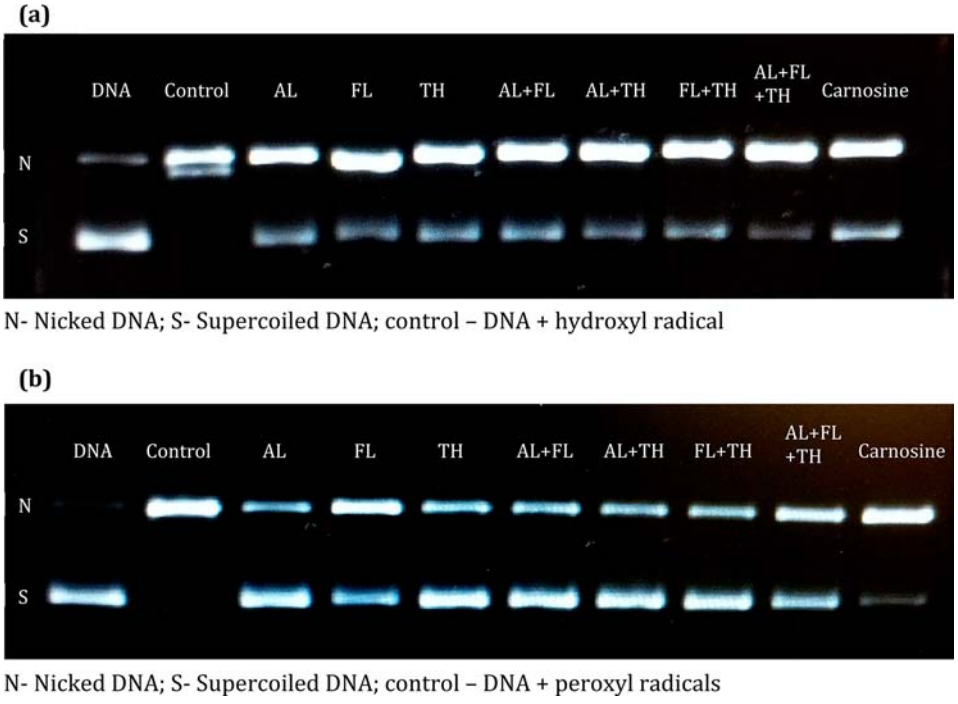

Figure 6. (a) Agarose gel electrophoresis of inhibition of hydroxyl radical-induced DNA scission by date seed protein hydrolystes and carnosine (6 mg/mL); (b) peroxyl radical-induced DNA scission by date seed protein hydrolystes and carnosine (0.1 mg/mL).

Therefore, it could be a potential functional food ingredient for health promotion. However, the antioxidant effect of date seed protein hydrolysate could also be influenced by the presence of other biomolecules, including minute amounts of water-soluble phenolics in the crude material, but this effect is considered to be minimal. Therefore, purification of date seed proteins, fractionation of the resultant peptides, and their sequencing may provide further clarity.

putative toxins (i.e., tremetone, **1**, dehydrotremetone, **2**, etc.) in any of the other *Isocoma* spp. Review literature[4,21] has suggested that *Isocoma hartwegii*, *I. coronopifolia*, and *I. tenuisecta* may be toxic and cause the same disease syndrome as *I. pluriflora*. In the past year we investigated a case of poisoning in cattle near Mesa, AZ, where *Isocoma acradenia* was the suspected causative agent. Using previously described analytical methods for *I. pluriflora*,[19] relatively high concentrations of tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, were detected in the *I. acradenia* as well as two unidentified compounds not detected in *I. pluriflora*.

The discovery of tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, in *I. acradenia*, in addition to the overall absence of reported livestock poisonings and lack of chemical analyses of the *Isocoma* spp. native to the southwestern United States, prompted us to undertake a systematic study to analyze the different *Isocoma* spp. for the suspected *I. pluriflora* toxins, tremetone, **1**, dehydrotremetone, **2**, and other structurally related compounds using both field collections and herbarium specimens.

MATERIALS AND METHODS

Plant Material. Five different *Isocoma* spp. were collected from 12 different locations (Table 1) and dried at ambient temperature. Composite collections of the above ground parts (the top 15 cm of green stems with leaves) of at least nine plants were collected randomly at each site. The plants collected were in early to full flower. *Isocoma* plants were identified by Robert Johnson, Plant Collection Manager, Stanley L. Welsh Herbarium at Brigham Young University, Provo, UT. Voucher specimens for the different *Isocoma* spp. collections were deposited at the Poisonous Plant Research Laboratory Herbarium, Logan, UT, and accession numbers are listed in Table 1. Leaf tissue from the *Isocoma* spp. specimens at the Poisonous Plant Research Laboratory, Intermountain Herbarium at Utah State University, S. L. Welsh Herbarium at Brigham Young University, University of Texas Herbarium, S. M. Tracy Herbarium at Texas A & M University, Arizona State University Herbarium, University of New Mexico Herbarium, University of Arizona Herbarium, and the University of California at Riverside Herbarium was sampled for analysis of tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, and other structurally related compounds. All plant specimens were ground to pass through a 1 mm screen.

Extraction and Isolation of Compounds. Dry, ground plant material (150 g) was Soxhlet-extracted for 72 h with hexane (700 mL). The hexane extract was rotary-evaporated to 200 mL and extracted with an equal volume of MeOH:H_2O (90:10) three times. MeOH:H_2O (90:10) was rotary-evaporated to a viscous dark green residue. Residue was dissolved in MeOH:H_2O (90:10) to result in a concentration of 50 mg/mL, filtered through a 30 mm Nylon 0.45 μm syringe filter (National Scientific Co., Rockwood, TN) and a 1.5 mL sample injected onto a Waters Prep LC2000 preparative chromatography system equipped with a UV/vis detector (Millipore Co., Millford, MA) monitoring at λ 280 nm. The HPLC column (150 mm × 21.20 mm i.d., 10 μm, Luna C18(2) with a 50 mm × 21.20 mm guard column of the same material (Phenomenex Inc., Torrance, CA). The mobile phase flow rate was 25 mL/min. The mobile phase program was water−acetonitrile, (65:35, v:v) for 5 min followed by a linear gradient to a composition of 65% acetonitrile at 20 min; the mobile phase composition was then held at 65% acetonitrile for an additional 5 min for total run time of 25 min. The major peaks were

[a] n = 10 for all sites except Pecos, Carlsbad, and Marble Canyon where n = 9. [b] The concentrations in italics are expressed in tremetone equivalents.

collected separately from multiple injections. The combined fractions, corresponding to each of the major peaks, were each evaporated to <30% of the original volume and extracted three times with equal volumes of $CHCl_3$. These three $CHCl_3$ extracts were combined, dried over anhydrous Na_2SO_4, filtered, and rotary-evaporated to dryness. Using this method, 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, and 7-isopentenyloxycoumarin, **5**, were isolated from *I. acradenia* collected at the Mesa, AZ, site.

NMR Analysis. NMR spectra of compounds in $CDCl_3$ were recorded using a JEOL ECX-300 300 MHz NMR spectrometer (JEOL Ltd., Peabody, MA). ^{1}H NMR and ^{13}C NMR assignments were determined using HSQC and HMBC experiments.

Gas Chromatography–Mass Spectrometry. GC/MS data were acquired using a Trace GC Ultra and Polaris Q mass spectrometer (Thermo Fisher Scientific, Waltham, MA) equipped with a split/splitless injector and a 30 m × 0.25 mm, 0.25 μm film thickness DB-5MS (Agilent Technologies Inc., Santa Clara, CA) column. The injection volume was 1.5 μL, the injection port temperature was 250 °C, and the injector was operated in the splitless mode. Split vent flow rate was 50 mL/min and purged after 0.80 min. Oven temperature was 80 °C for 1 min, increased 80–300 °C at 30 °C/min, and held at 300 °C for 3.0 min. Electron impact ionization (EI) at 70 eV was used with an ion source temperature of 200 °C. The detector scanned the mass range from m/z 50 to m/z 650.

*4-Hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**.* ^{1}H NMR, ^{13}C NMR, EIMS, and UV were in agreement with previously reported literature.[22,23]

*7-Isopentenyloxycoumarin, **5**.* ^{1}H NMR, ^{13}C NMR, EIMS, and UV were in agreement with previously reported literature.[24−26]

Analytical Scale Extraction and HPLC Analysis. Using a HPLC method developed for the quantitation of tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, in white snakeroot and rayless goldenrod,[19] the concentrations of **1**−**5** were determined in the different *Isocoma* spp. collections. Dry, ground aerial plant material was weighed (100 mg) into a screw top glass test tube (16 mL). The plant material was extracted (16 h) by mechanical rotation with hexane:ethyl acetate (70:30, v:v) (8 mL) at ambient temperature. HPLC was performed using an LC-20AT (Shimadzu Co., Kyoto, Japan) equipped with an autosampler and PDA detector from the same vendor and a 100 mm × 2.1 mm i.d., 5 μm, Betasil C_{18}, with a 10 mm × 2.1 mm i.d. guard column of the same material (Thermo Hypersil-Keystone, Bellefonte, PA). Samples (10 μL) in hexane:ethyl acetate (70:30, v:v) were injected on to the column and eluted with a 20 mM ammonium acetate–acetonitrile mobile phase at a flow rate of 0.4 mL/min. The mobile phase program was 20 mM ammonium acetate–acetonitrile (65:35, v:v) for 4 min followed by a linear gradient to a composition of 65% acetonitrile at 20 min. At 21 min the composition was increased to 100% acetonitrile for 5 min. The eluant was monitored at 280 nm. Under these conditions tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, 4-hydroxy-3-(3-methyl-2-butenyl)-acetophenone, **4**, and 7-isopentenyloxycoumarin, **5**, eluted at 10, 14.4, 17.8, 7.7, and 12.7 min, respectively. The concentrations of tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, in plant field collections were quantitated against seven point tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, calibration curves using previously isolated tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**.[19] 4-Hydroxy-3-(3-methyl-2-butenyl)-acetophenone, **4**, and 7-isopentenyloxycoumarin, **5**, were quantitated against the tremetone, **1**, standard curve and are thus expressed in tremetone equivalents. The standard solutions were prepared by serial dilution with hexane:ethyl acetate (70:30, v:v) over the range of 0.78 μg/mL to 200.0 μg/mL. The calibration curve had R^2 of 0.9999. Plant material (25 mg) from herbarium specimens was extracted in 2 mL of hexane/ethyl acetate (70:30, v:v). Qualitative analysis for the compounds of interest was performed as described above.

Maps. Distribution maps of *Isocoma* spp. were created using ArcGIS software by ESRI. State boundary data was downloaded from the U.S. Census Bureau TIGER/Line shapefiles.[27]

RESULTS AND DISCUSSION

Isolation and Identification of Compounds. Tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, were previously isolated from *I. pluriflora*.[19] In this study, 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, and 7-isopentenyloxycoumarin, **5**, were isolated from *I. acradenia* plant material collected from the Mesa, AZ (Figure 1), site by Soxhlet extraction with hexane and reversed phase HPLC. The identification of 4-hydroxy-3-(3-methyl-2-butenyl)-acetophenone, **4**, and 7-isopentenyloxycoumarin, **5**, was confirmed based on comparison of spectroscopic data with those previously reported.

Isocoma pluriflora. *I. pluriflora* is native to Arizona, New Mexico, West Texas, and Northern Mexico (Figure 1).[1] Tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltreme-

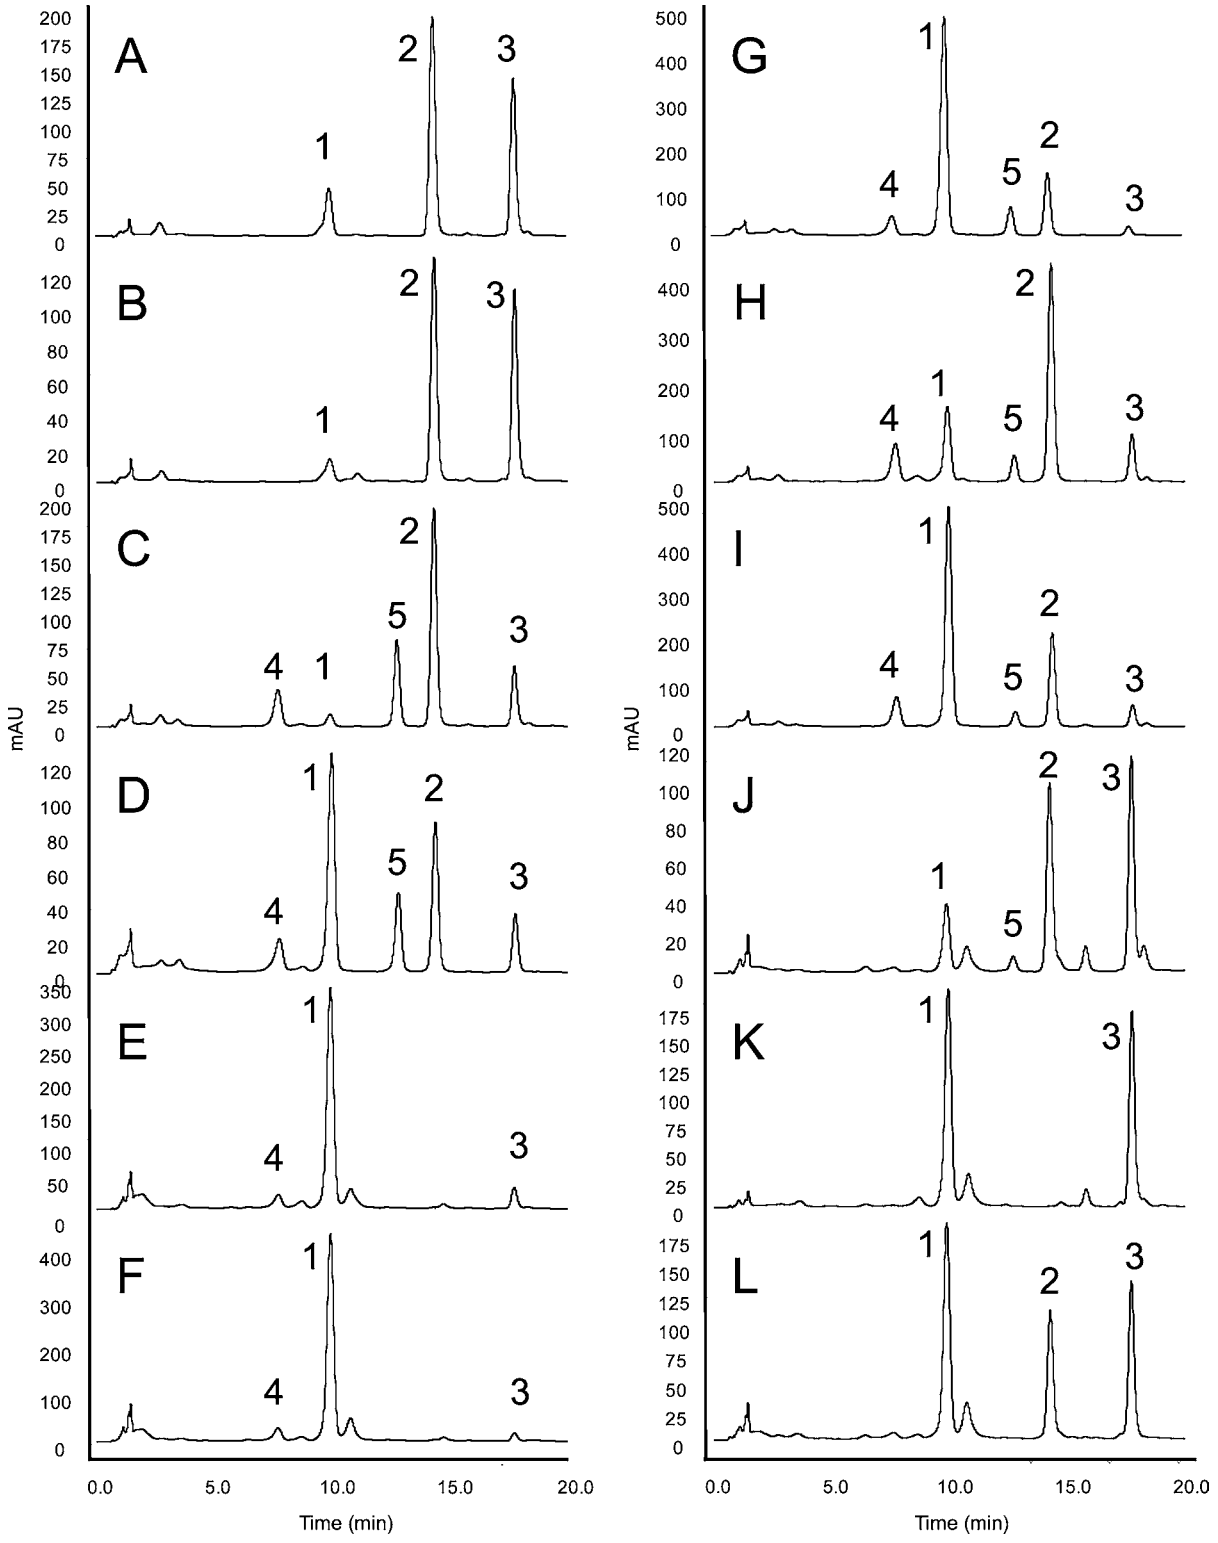

Figure 3. HPLC chromatograms of extracts from *Isocoma* spp. collected from (A) *I. pluriflora*, Pecos; (B) *I. pluriflora*, Carlsbad; (C) *I. tenuisecta*, Tucson; (D) *I. tenuisecta*, Red Rock; (E) *I. azteca*, Newcomb; (F) *I. azteca*, Tsaya; (G) *I. acradenia*, Mesa; (H) *I. acradenia*, Kingman; (I) *I. acradenia*, Wickenburg; (J) *I. rusbyi*, Marble Canyon; (K) *I. rusbyi*, Tuba City; (L) *I. rusbyi*, Holbrook. Peak numbers refer to compound structures in Figure 2.

tone, **3**, were present in all the field collected plants at Pecos, TX, and Carlsbad, NM (Table 2, Figure 3). Compounds **4** and **5** were not present in any of the field collected plants (Table 2, Figure 3). The presence of these three benzofurans and the concentrations of these compounds are consistent with previously analyzed plant material from the same Pecos site collected in 2008 and 2009 and from a site in Palo Duro Canyon also in Reeves County, TX, collected in 2009.[19,28] The mean concentrations of the three benzofuran ketones in the *I. pluriflora* plants from the Pecos site were approximately double the concentration from the Carlsbad site. *I. pluriflora* collected at the Pecos site in 2008 was poisonous and produced trembles

DOI: 10.1021/jf505423h
J. Agric. Food Chem. 2015, 63, 872−879

in both goats and horses under controlled dosing conditions.[5−8] Tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, and 7-isopentenyloxycoumarin, **5**, were present in *I. pluriflora* sampled from herbarium specimens (n = 33) representing locations from 21 different counties in Texas and New Mexico as well as Mexico at a frequency of 82, 12, 45, and 36%, respectively (Table 3). The herbarium data and field collection data differed in the frequency of detection of dehydrotremetone and 3-oxyangeloyltremetone. Additionally, 7-isopentenyloxycoumarin, **5**, was detected in herbarium specimens but not field collections. This is the first report of this compound in *I. pluriflora*. Consistent between the field collections and herbarium collection was the high frequency of tremetone and the absence of 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**.

Table 3. Frequency of Tremetone, 1, Dehydrotremetone, 2, 3-Oxyangeloyltremetone, 3, 4-Hydroxy-3-(3-methyl-2-butenyl)acetophenone, 4, and 7-Isopentenyloxycoumarin, 5, Observed in *Isocoma* spp. Herbarium Survey

Isocoma tenuisecta. *I. tenuisecta* is native to southern Arizona and southwestern New Mexico (Figure 1).[1] Tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, and 7-isopentenyloxycoumarin, **5**, were present in 95% or greater of all the field collected plants at Tucson, AZ, and Red Rock, AZ (Table 2, Figure 3). This is the first report of these compounds in *I. tenuisecta*. The mean concentrations of these compounds at the Tucson site were approximately double the mean concentration from the Red Rock site. Tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, 4-hydroxy-3-(3-methyl-2-butenyl)-acetophenone, **4**, and 7-isopentenyloxycoumarin, **5**, were present in *I. tenuisecta* sampled from herbarium specimens (n = 22) representing locations from 8 counties in Arizona and New Mexico at a frequency of 50, 27, 82, 23 and 100%, respectively (Table 3). The herbarium data and field collection data differed in the frequency of detection of tremetone, **1**, dehydrotremetone, **2**, and 4-hydroxy-3-(3-methyl-2-butenyl)-acetophenone, **4**. Consistent between the field collections and herbarium collection was the high frequency of 3-oxyangeloyltremetone, **3**, and 7-isopentenyloxycoumarin, **5**.

Isocoma azteca. *I. azteca* is native primarily to northwest New Mexico and northeast Arizona (Figure 1).[1] Tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, and 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, were present in 90% or greater of all the field collected plants at Newcomb, NM, and Tsaya, NM, with the exception of dehydrotremetone, **2**, which was detected in only 20% of the plants collected at Tsaya, NM (Table 2, Figure 3). This is the first report of these compounds in *I. azteca*. The mean concentrations of tremetone, **1**, 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, and 3-oxyangeloyltremetone, **3**, were similar between the two collections, however, the mean concentration of dehydrotremetone, **2**, was very low at the Tsaya site as only two of the plants contained dehydrotremetone, **2**, and they both had relatively low concentrations (<0.005 μg/mg). Plants from the *I. azteca* collection sites had the highest concentration of tremetone, **1**, of any of the other major compounds observed in any of the field collections of *Isocoma* spp. with the average concentration of tremetone, **1**, in plants at the Tsaya site approaching 1% of the dry plant material. *I. azteca* samples from herbarium specimens (n = 18) representing locations from 3 counties in Arizona and New Mexico were qualitatively analyzed (Table 3). Tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, were present in sampled herbarium specimens (n = 18) representing locations from 3 counties in Arizona and New Mexico at a frequency of 100, 56 and 61%, respectively. Consistent between the field and herbarium collections was the high frequency of tremetone, **1** (100%), and the absence of 7-isopentenyloxycoumarin, **5**. Somewhat similar between the field and herbarium collections was the frequency of occurrence of dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**. Most inconsistent between the field and herbarium collections was the absence of 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, in the herbarium specimens.

Isocoma acradenia. *I. acradenia* is native to southern California, southern Nevada, the western half of Arizona, and northwest Mexico (Figure 1).[1] Tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, and 7-isopentenyloxycoumarin, **5**, were present in all the field collected plants at Mesa, AZ, Kingman, AZ, and Wickenburg, AZ (Table 2, Figure 3). This is the first report of these compounds in *I. acradenia*. The mean concentrations of the 5 major compounds in plants from the Mesa site and Wickenburg site were similar but differed from the Kingman site. Plants collected from the Kingman site had approximately double the concentration of 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, and 4 times the concentrations of dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, but half the mean concentration of tremetone, **1**, compared to the Mesa and Wickenburg sites. Tremetone, **1**, dehydrotremetone **2**, 3-oxyangeloyltremetone, **3**, 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, and 7-isopentenyloxycoumarin, **5**, were present in *I. acradenia* sampled herbarium specimens (n = 46) representing 23 different counties in California, Arizona, and Nevada as well as Mexico at a frequency of 89, 26, 67, 48, and 90%, respectively. Consistent between the field and herbarium collections was the frequency of occurrence of tremetone, **1**, and 7-isopentenyloxycoumarin, **5**, while 3-oxyangeloyltremetone, **3**, was somewhat similar between the two different collections. Dehydrotremetone, **2**, and 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, occurred at a lower frequency in herbarium specimens compared to the field samples.

Isocoma rusbyi. *I. rusbyi* is primarily native to central southeastern Utah, and central northeastern Arizona (Figure 1).[1] Tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, and

DOI: 10.1021/jf505423h
J. Agric. Food Chem. 2015, 63, 872−879

7-isopentenyloxycoumarin, **5**, were present in all the field collected plants from Marble Canyon, AZ. Plants collected from Holbrook, AZ, and Tuba City, AZ were qualitatively similar to those from Marble Canyon, AZ, other than that 7-isopentenyloxycoumarin, **5**, was not detected in the plants from Holbrook and dehydrotremetone, **2**, was not present in the plants from Tuba City. Quantitatively, plants from Holbrook, AZ, had approximately double the mean concentration or more of dehydrotremetone, **2**, 3-oxyangeloyl-tremetone, **3**, and 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, compared to the other two sites. This is the first report of these compounds in *I. rusbyi*. Tremetone, **1**, 3-oxyangeloyltremetone, **3**, and 7-isopentenyloxycoumarin, **5**, were present in *I. rusbyi* sampled herbarium specimens (n = 25) representing 9 different counties in Arizona, Colorado, New Mexico, and Utah at a frequency of 88, 88, and 40%, respectively. Consistent between field and herbarium collections was the occurrence of tremetone, **1**, 3-oxyangeloyltremetone, **3**, and 7-isopentenyloxycoumarin, **5**. Inconsistent between field and herbarium collections was the presence of 4-hydroxy-3-(3-methyl-2-butenyl)acetophenone, **4**, and dehydrotremetone, **2**, although compound **4** was detected at low concentrations in field collections, which may partially explain it being not present in the herbarium specimens.

Other *Isocoma* Species. In addition to the five species above for which field and herbarium collections were analyzed, we also analyzed herbarium specimens from 8 other species, *I. menziesii*, *I. coronopilofolia*, *I. drummondi*, *I. veneta*, *I. hartwegii*, *I. gypsophila*, *I. tomentosa*, and *I. arguta*. The distribution of these species is shown in Figure 4.[1] The number of herbarium

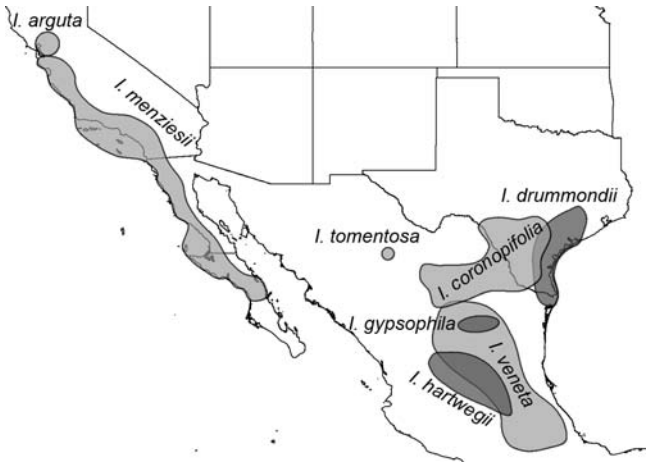

Figure 4. Map of the distribution of *Isocoma menziesii*, *I. coronopilofolia*, *I. drummondi*, *I. veneta*, *I. hartwegii*, *I. gypsophila*, *I. tomentosa*, and *I. arguta*.

specimens analyzed for each of these species ranged from 1 to 36 (Table 3). The number analyzed was limited by the available specimens from cooperating herbaria. 3-Oxyangeloyltremetone, **3**, was present in each of these species generally at frequencies ranging from 70 to 100% (Table 3). Other benzofuran ketones including tremetone, **1**, and structurally similar compounds (**4** and **5**) were also detected in select species. This is the first report of these compounds in *Isocoma menziesii*, *I. coronopilofolia*, *I. drummondi*, *I. veneta*, *I. hartwegii*, *I. gypsophila*, *I. tomentosa*, and *I. arguta*. In conclusion, one or more of the benzofuran ketones and similar compounds were found in all the *Isocoma* species analyzed to date.

In this study we analyzed both field collections and herbarium samples for tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, and structurally related compounds from the 5 major *Isocoma* spp. native to the southwestern United States. Both collections demonstrated that all three of the benzofuran ketones and at least one of the structurally related compounds were present in all 5 of the major *Isocoma* spp. native to the southwestern United States. This is the first report of these compounds in *I. tenuisecta*, *I. azteca*, *I. acradenia*, and *I. rusbyi*. The herbarium samples were of interest because we could sample a large number of plants from a large geographical area in a relatively short amount of time, however, since we were sampling limited leaf material from the specimens, the specimens were collected at different times of the year, and the specimens were collected over many different years, these samples were analyzed qualitatively but not quantitatively. In contrast, with the field collections we were able to sample representative samples from each species, collect replicate samples, and make collections at the same time of the year and during the same phenological stage. We were able to perform both qualitative and quantitative analysis with the field samples, however, we were limited to two or three locations for each of the 5 *Isocoma* spp. Due to the differences in the field and herbarium collections we were only able to make some broad qualitative comparisons between the two types of collections. Overall, the most consistent observations between the two types of collections were that tremetone, **1**, and 3-oxyangeloylytremetone, **3**, were the most observed benzofuran ketones. Inconsistent between the two types of collections was that dehydrotremetone, **2**, was present in the majority of the field collections, but was conspicuously absent in many of the herbarium specimens. To investigate the low frequency of dehydrotremetone, **2**, in the herbarium specimens, we sampled a herbarium specimen of *I. pluriflora* from the Pecos site held at the Intermountain Herbarium at Utah State University that we collected on May 8, 2008, and analyzed this herbarium specimen by HPLC.[19] We initially analyzed plant material collected at the Pecos site collected on May 8, 2008, by HPLC on February 18, 2009. The concentrations of tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, were all lower in the herbarium specimen than in plant material from the same collection analyzed over 5 years earlier (Figure 5). All three benzofuran ketones appeared to decrease at herbarium storage conditions over the 5+ year time period; however, dehydrotremetone, **2**, appeared to decrease the most under these conditions. Although this data is limited, this comparison offers a possible explanation to the low frequency of dehydrotremetone, **2**, observed in the herbarium samples compared to the recently collected field samples. This comparison is also a caution that herbarium specimens may not accurately reflect the composition of secondary compounds in the field and should be evaluated in conjunction with samples analyzed shortly after collection. This comparison with *I. pluriflora* also suggests that tremetone, **1**, and dehydrotremetone, **2**, may be present in the *Isocoma* spp. *I. menziesii*, *I. coronopilofolia*, *I. drummondi*, *I. veneta*, *I. hartwegii*, *I. gypsophila*, *I. tomentosa*, and *I. arguta*, but no conclusions can be made as we only sampled herbarium specimens. As tremetone, **1**, and dehydrotremetone, **2**, have been suggested as the toxins in *I. pluriflora*,[13−15] and in light of the apparent loss of these compounds in *Isocoma* spp. over time at room temperature, a study documenting this phenomenon is warranted.

J. Agric. Food Chem. 2015, 63, 872−879

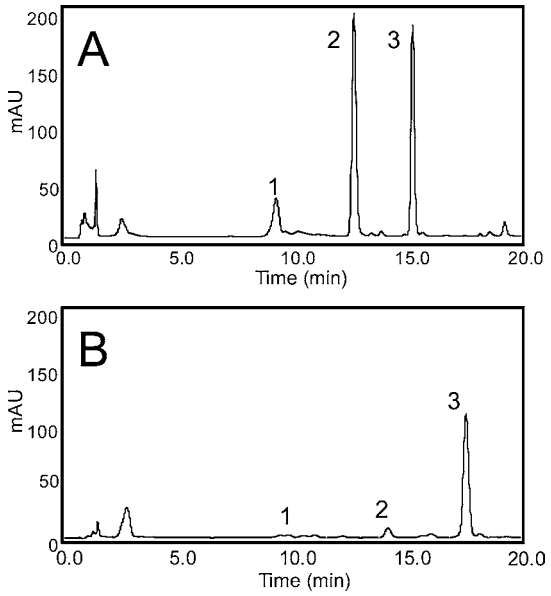

Figure 5. HPLC chromatograms of extracts from *I. pluriflora*, Pecos, collected on May 8, 2008: (A) analyzed February 18, 2009, (B) leaf tissue from voucher specimen #250012 held at the Intermountain Herbarium at Utah State University and analyzed November 4, 2014. Peak retention times are different due to a different Betasil C_{18} column used in the analysis. Peak numbers refer to compound structures in Figure 2.

It has been well established that *I. pluriflora* is poisonous, causing a disease called trembles and milksickness in livestock.[2−4] Tremetone, **1**, and dehydrotremetone, **2**, have been suggested as the toxins in *I. pluriflora* responsible for the disease[13−15] and have also been suggested as the toxins responsible for the same disease caused by white snakeroot, native to the eastern and midwestern United States.[4,14,15] Four other *Isocoma* spp., *I. tenuisecta*, *I. azteca*, *I. acradenia*, and *I. rusbyi*, are native to southwestern United States on land used extensively for livestock production. These plants were analyzed and found to contain tremetone, **1**, dehydrotremetone, **2**, and other compounds of similar structure at concentrations comparable to *I. pluriflora*.[5−8] These results raise the question: Why is there an absence of reports in the literature of livestock poisoning due to *I. tenuisecta*, *I. azteca*, *I. acradenia*, and *I. rusbyi*? One answer may be that tremetone, **1**, dehydrotremetone, **2**, and other compounds of similar structure are not the compounds responsible for toxicity in *I. pluriflora* or in white snakeroot even though they are common to both plants. Tremetone, **1**, and dehydrotremetone, **2**, as isolated compounds have not been documented to cause toxicity in a mammalian or livestock model. This may suggest that *I. pluriflora* and/or white snakeroot may share another unique compound(s) responsible for causing the same disease. However, in order to determine if *I. tenuisecta*, *I. azteca*, *I. acradenia*, and *I. rusbyi* are or are not toxic, well designed, controlled dosing studies in livestock using the toxic *I. plurifora* as a control must be conducted. Dosing studies in livestock using these different *Isocoma* spp. can result in valuable information into the toxic compound. For example if *I. azteca* from the Tsaya site, which contains approximately 1% of tremetone, **1**, and relatively low concentrations of dehydrotremetone, **2**, and other compounds, is dosed to livestock under the same regimen as toxic *I. pluriflora* and is found not to be toxic, serious doubt must be given into the role of tremetone, **1**, as the singular toxin.

In conclusion, this is the first report of tremetone, **1**, dehydrotremetone, **2**, 3-oxyangeloyltremetone, **3**, and similar compounds in *I. tenuisecta*, *I. azteca*, *I. acradenia*, and *I. rusbyi*. Tremetone, **1**, and dehydrotremetone, **2**, have been suggested as the toxins in *I. pluriflora*. The concentrations of tremetone, **1**, dehydrotremetone, **2**, and 3-oxyangeloyltremetone, **3**, in *I. tenuisecta*, *I. azteca*, *I. acradenia*, and *I. rusbyi* are similar to those in toxic *I. pluriflora*. In addition, tremetone, **1**, 3-oxyangeloyltremetone, **3**, and stucturally related compounds were reported for the first time in 8 other species, *Isocoma menziesii*, *I. coronoplofolia*, *I. drummondi*, *I. veneta*, *I. hartwegii*, *I. gypsophila*, *I. tometosa*, and *I. arguta*.

Jackson (Muskegon, MI). HPLC-grade chloroform, methyl pentadecanoate, and methanolic hydrochloride were purchased from Sigma-Aldrich (St. Louis, MO).

Strains and Culture Conditions. The *D. tertiolecta* strain UTEX LB999 (henceforth referred to simply as "LB999") acclimated to an optimal temperature of 21 °C was obtained from the culture collection of algae at the University of Texas at Austin, and another strain, SCCAP K-0591 (henceforth referred to simply as "K-0591"), acclimated to an optimal temperature of 15 °C was obtained from the Scandinavian Culture Collection in Copenhagen, Denmark. To enable direct comparison, both strains were grown photoautotrophically under the same conditions—except for temperature—under illumination from fluorescent lamps at 50 μE/(m^2 s) in 3-fold f/2 medium[19] without vitamins. The culture medium consisted of 225 mg/L $NaNO_3$, 15 mg/L $NaH_2PO_4{\cdot}7H_2O$, and 1 mL of trace-elements stock solution (4.16 g/L Na_2EDTA, 3.15 g/L $FeCl_3{\cdot}6H_2O$, 0.01 g/L $CuSO_4{\cdot}5H_2O$, 0.022 g/L $ZnSO_4{\cdot}7H_2O$, 0.01 g/L $CoCl_2{\cdot}6H_2O$, 0.18 g/L $MnCl_2{\cdot}4H_2O$, and 0.006 g/L $Na_2MoO_4{\cdot}2H_2O$) in artificial seawater (24.7 g/L NaCl, 0.66 g/L KCl, 8.48/L $MgCl_2{\cdot}6H_2O$, 1.9 g/L $CaCl_2{\cdot}2H_2O$, 3.07 g/L $MgSO_4{\cdot}7H_2O$, and 0.18 g/L $NaHCO_3$). The concentration of nitrate was kept at 2.68 mM throughout the culture period by measuring it every 24 h and adding nitrate stock solution as required.

Algal cultures were set up in 400 mL bubble-column photobioreactors at a fresh cell weight (FCW) inoculation concentration of 0.1 g/L and with 0.1 vvm aeration using 2% CO_2-enriched air to provide a carbon source for the culture. The microalgal concentration (cells/mL) and FCW (g/L) were determined daily using a Multisizer 3 Coulter counter (Beckman Coulter, Miami, FL).

Culture shifting was performed when the FCWs (cell concentrations) of LB999 and K-0591 were 1.76 g/L (7.7×10^6 cells/L) and 1.12 g/L (4.3×10^6 cells/L), respectively (Figure S1 in the Supporting Information). The time point at which ND was triggered—when the FCW reached half that measured at the beginning of the stationary phase for each strain—was determined on the basis of a preliminary study that the most-significant changes in FA profiles were observed in that time point.[20] The cells were harvested at that point and washed three times with centrifugation at 1500 rpm for 5 min (UNION 32R PLUS, Hanil Science Industrial, Incheon, Korea) to remove the nutrients. The cells were then transferred to either nitrate-sufficient (NS) or ND medium and cultured for 12 h. The algal cells were harvested by transferring 400 mL of the cell suspensions to 50 mL tubes, and then they were precipitated by centrifugation at 1500 rpm for 5 min. The transparent supernatant was discarded, and the cell pellets were completely washed four times with distilled water by centrifugation and resuspension. The collected algal cells were freeze-dried and kept in labeled tubes at −80 °C before extraction.

Extraction of Total Lipids. Glycerolipids and glycerophospholipids were extracted from 1 mg of dried biomass from each sample extracted using a modified Folch procedure, as described previously.[9] The extracts were dried with nitrogen gas, capped, and stored at −20 °C for chip-based nanoelectrospray ionization (nano-ESI) direct infusion.

Methylation of FAs. FAs were extracted by adding 200 μL of chloroform/methanol (2:1, v/v) to 5 mg of dried cells. The FAs were then converted into fatty acid methyl esters (FAMEs) by incubating the samples in 300 μL of 1.25 M methanolic hydrochloride for 1 h at 85 °C[21] and then adding 1 mL of hexane and incubating for 1 h at room temperature. A 90 μL aliquot of the upper layer was transferred to a vial, 10 μL of methyl pentadecanoate was added, and the mixture was vortexed.

Analysis of Glycerolipids and Glycerophospholipids. Glycerolipids and glycerophospholipids were analyzed in positive and negative ion modes on a linear ion-trap mass spectrometer (LTQ-XL, ThermoFisher Scientific, San Jose, CA) equipped with an automated nanoinfusion/nanospray source (Triversa NanoMate System, Advion Biosciences, Ithaca, NY). The ionization voltage and gas pressure were set to 1.4 kV and 0.4 psi, respectively, and the ion source was controlled using Chipsoft 8.3.1 software (Advion Biosciences). All lipid samples were dissolved in 500 μL of methanol/chloroform (9:1, v/v) containing 7.5 mM ammonium acetate; 15 μL of each sample was loaded into a 96-well plate (Eppendorf, Hamburg, Germany), which was then sealed with aluminum film (ThermoFisher Scientific) using a heat sealer. The 96-well plate was placed onto a NanoMate cooling plate set at a temperature of 5 °C. A 5 μL volume of each of the samples was aspirated and infused into a mass spectrometer via an Advion ESI chip with 5.5 μm [inner diameter (i.d.)] emitter nozzles. Biological triplicates of the LB999 samples were each analyzed in triplicate by nano-ESI mass spectrometry (MS), while biological duplicates of the K-5091 samples were each analyzed in triplicate.

Full-scan spectra were collected in mass-to-charge ratio (m/z) ranges of 400−1200 and 500−1300 in positive and negative ion modes, respectively. The mass spectra of each sample were acquired in profile mode over a 2 min period. The capillary temperature was set to 200 °C; the capillary voltage and tube lens were set to 47 and 145 V, respectively, in positive mode, and to −44 and −132 V in negative mode. The target automatic gain control values for full MS and multistage MS were 30000 and 10000, respectively. MS/MS was applied to pooled samples for identification of lipid species. The normalized collision energy was set to 35% with an isolated width of 3 m/z units and a charge state of 1. The dynamic exclusion parameters were a repeat duration of 60 s, an exclusion duration of 60 s, and an exclusion list size of 50.

Analysis of FAMEs. The samples were analyzed using a gas chromatograph (model 7890A, Agilent Technologies, Santa Clara, CA) equipped with a mass-selective detector (model 5975C, Agilent Technologies), an autosampler (7683B series, Agilent Technologies), a split/splitless injector, an injection module, and ChemStation software. The GC inlet temperature was set to 250 °C, and 1.0 μL of sample was injected in duplicate. Helium was used as the carrier gas in constant-flow mode at 1.0 mL/min. A fused silica capillary column of 5% phenyl methylpolysiloxane phase (DB-5, Agilent Technologies) with film dimensions of 30 m × 0.25 mm (i.d.) × 0.25 μm was used for analysis. The detector voltage was set to 1812 V, and the auxiliary, MS source, and MS quadrupole temperatures were set to 280, 230, and 150 °C, respectively.

The split ratio and mass range for the FAME analysis were 5:1 and 40−400 Da, respectively, and data were obtained in full-scan mode. The initial oven temperature of 70 °C was held for 3 min before being ramped first to 130 °C at a rate of 20 °C/min, to 178 °C at 4 °C/min, to 200 °C at 1 °C/min, and finally to 290 °C at 10 °C/min. The total run time was 40 min.

Data Acquisition and Processing. The full-scan data were acquired using a nano-ESI-MS system and processed with Expressionist MSX v2013.0.39 software (Genedata, Basel, Switzerland). The spectral scans obtained between 0.5 and 1.5 min were averaged, then spectrum smoothing, m/z alignment, and baseline subtraction were performed, and the obtained data were prepared for multivariate analysis. One-way analysis of variance was performed using Expressionist MSX software. The data matrices exported from Expressionist MSX were imported to SIMCA-P software (version 13.0, Umetrics, Umeå, Sweden) for principal component analysis (PCA), for which Pareto scaling and mean centering were applied.

For the GC−MS-based FAME analysis, mass spectral data were processed using the AMDIS (Automated Mass Spectral Deconvolution and Identification System) and SpectConnect (http://spectconnect.mit.edu/). The AMDIS was initially used for mass spectrum deconvolution, which isolates the target peaks from the noise and overlapping peaks.[22] The following settings were used: a component width of 12, adjacent peaks subtraction of 1, medium resolution, low sensitivity, and medium shape requirement. The resulting *.elu files were subsequently analyzed using an online peak-filtering algorithm. The FAs were identified using the National Institute of Standards and Technology mass spectral search program, with a match quality greater than 70% set as the criterion for peak assignment. Normalization was then performed by dividing the base peak intensity of each compound by that of methyl pentadecanoate (the internal standard) to obtain the relative intensities of the FAs in each sample. The composition of each FA in *D. tertiolecta* samples is presented as a percentage, which was

[a]Abbreviations: RT, retention time; SFA, saturated FA; MUFA, monounsaturated FA; PUFA, polyunsaturated FA; MS, mass spectrometry; m/z, mass-to-charge ratio. [b]Data are the mean ± SD values for biological and experimental repetitions at $n = 6$ for LB999 and $n = 4$ for K-0591. [c]A t test was conducted for the NS and ND conditions. Key: ns, no significant difference ($p < 0.05$); ↑, significantly high percentage composition compared with that of the NS condition; ↓, significantly low percentage composition compared with that of the NS condition. [d]Cx:y, FA annotation, where x is the number of carbon atoms and y is the number of double bonds.

obtained by dividing the relative intensity of the FA by the sum of the total FA relative intensity. Significant differences were detected by a t test using the PASW Statistics 19 software (IBM, Somers, NY). The cutoff for statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

FA Profiles. Table 1 presents the FA composition of algal oil extracted from the two *D. tertiolecta* strains (K-0591 and LB999) with different optimal growth temperatures (15 and 21 °C, respectively). The dominant FAs were C18:3, C16:0, and C18:2, results which are similar to those of previous studies finding the main components of *D. tertiolecta* to be C18:3 and C16:0.[16,23] Linolenic acid (C18:3) was the most abundant FA in both strains, but was the predominant FA in K-0591. It is known that microalgae change their FA composition at low temperature as a method of maintaining their membrane fluidity.[24] It has been reported that the level of unsaturated lipids in *Dunaliella salina* increases when the temperature is reduced from 30 to 12 °C.[25] In this context, the main alteration implemented to prevent membrane rigidification is an increase in polyunsaturated FAs (PUFAs), including C18:3. Preserving the fluidity of the chloroplast membrane is essential for effective photosynthetic function at low temperature. For example, membrane fluidity is crucial for electron transport among the photosynthetic complexes, as well as for gas exchange.[26] In addition, PUFAs have a protective effect against the damage caused by high light intensity and UV radiation.[27]

When nitrate was deficient, the percentage compositions of C16:1 and C20:0 were significantly increased in both strains, whereas that of C18:3 was decreased in both. Nitrogen deficiency generally takes place toward the end of cell growth, when cell division is attenuated following an energy-storing process. Palmitoleic acid (C16:1) is associated with energy storage.[28] Conversely, the biosynthesis of PUFAs usually occurs during the growth phase.[29] Therefore, ND conditions seem to transfer the cell status from a growth stage to an energy-storage stage in both the low- and higher-temperature-acclimated *D. tertiolecta* strains.

Meanwhile, the FAs extracted from K-0591 and LB999 that had changed most significantly (in terms of the percentage composition) were linolenic acid (C18:3) and palmitic acid (C16:0), respectively. Interestingly, it appears that the reduction in C18:3 in K-0591 might have been affected by the decline of two lipid species: digalactosyldiacylglycerol (DGDG) 18:3/16:4 and *lyso*-diacylglyceryl-*N*,*N*,*N*-trimethylhomoserine (DGTS; *lyso*-DGTS) 18:3 (Table 2). In addition, the increase in C16:0 in LB999 under ND conditions was consistent with the elevation of lipid species containing C16:0 (Table 2). Together these results show that the characteristic changes in FA profiles in both strains were caused by changes in their lipid profiles.

PCA Using the Nano-ESI-MS Data Set. *D. tertiolecta* samples were characterized according to their lipid profiles, which were detected by nano-ESI-MS in both the positive and negative ion modes. The processed mass spectral data were then subjected to PCA. The PCA score plot revealed a clear separation between LB999 and K-0591 when using the detected ions in the two ion modes (Figure 1). The algal

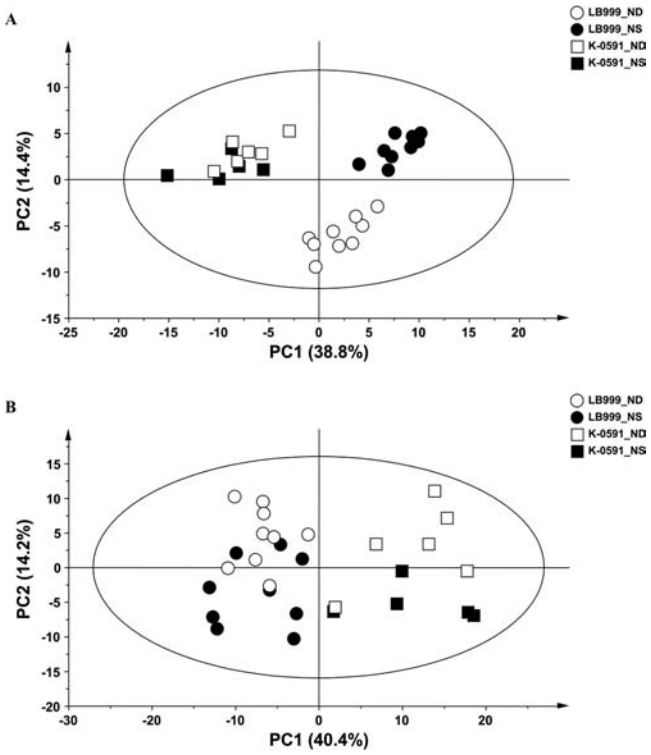

Figure 1. Principal component analysis score plot derived from the nanoelectrospray ionization mass spectrometry (nano-ESI-MS) data of two *D. tertiolecta* samples, a 21 °C-optimized strain (LB999; circles) and a 15 °C-optimized strain (K-0591; squares), under nitrate-sufficient (NS; filled symbols) and nitrate-deficient (ND; open symbols) conditions in (A) positive ion mode and (B) negative ion mode. Abbreviations: PC1, principal component 1; PC2, principal component 2.

strains exhibited different trends according to their response to the nitrate condition. Interestingly, the lipid profile of LB999 exhibited a clearer separation between the NS and ND conditions than did K-0591 in the positive ion mode. This implies that nitrate deficiency markedly alters the lipid profile in LB999 but not in K-0591.

Lipid Profile. Figure 2 shows representative spectra of lipids from a pooled lipid extract sample of the two *D. tertiolecta* strains in positive and negative ion modes. In total, 16 DGTS species, 7 DGDG species, 3 *lyso*-DGTS species, and 2 monogalactosyldiacylglycerol (MGDG) species were detected in positive ion mode, and 3 sulfoquinovosyldiacylglycerol (SQDG) species, 3 phosphatidylglycerol (PG) species, and 1 phosphatidylinositol (PI) species were detected in negative ion mode. MGDG 34:7 was detected in both ion modes (Table 2).

Comparison of K-0591 and LB999 under the normal, NS conditions revealed significantly higher levels of DGTS in K-0591. DGTS is known to be a substrate for the further desaturation of FAs. For example, DGTS appears to act as a major substrate for the sequential desaturation of C18:1 to C18:3. Moreover, DGTS is regarded as a donor of eicosapentaenoic acid (C20:5) for chloroplast lipids.[30] Therefore, it can be hypothesized that the high levels of DGTS species with unsaturated fatty acyl chains in K-0591 could aid the maintenance of a highly unsaturated, adequately fluid chloroplast membrane at low temperatures.

To investigate the association of DGTS with low-temperature adaptation, lipid profiles were compared using the LB999 cultures cultivated at different temperatures (15 and 21 °C). Each cell was harvested at mid exponential phase on the basis of the growth curve under each temperature condition. The growth of LB999 cells was significantly retarded in the 15 °C culture, and they entered the stationary phase earlier than those cultivated at 21 °C (data not shown). These results imply that cultivation at a temperature (15 °C) that is lower than the normal cultivation temperature (21 °C) caused cold stress and physiological changes in LB999 cells.

Interestingly, the levels of DGTS species were lower in LB999 cells cultivated at 15 °C than those cultivated at 21 °C (Table S1 in the Supporting Information). DGTS was previously shown to be involved in desaturation of FAs, and the biosynthesis of PUFA was found to be generally enhanced during the dramatic exponential growth of microalgae.[28,31] The higher levels of DGTS species in the K-0591 strain seemed to be positively associated with robust growth even at low temperature, which is a consequence of long-term cold adaptation of that strain over many years. However, the lower levels of DGTS species in LB999 cells cultivated at 15 °C might be caused by short-term exposure stress to a low-temperature condition rather than to long-term cold adaptation. It is assumed that the contribution of DGTS species to low- temperature conditions is feasible only in long-term adaptation and evolution, as in the case of the K-0591 strain.

DGTS species with odd-numbered fatty acyl chains, such as C17 and C19, were also detected. The role of odd-numbered FAs in algae remains unclear; however, it has been reported that odd-numbered, branched-chain FAs such as C15:0 and C17:0 have a relatively low melting point and thus contribute to cold adaptation in the bacterium *Listeria monocytogenes*.[32]

The levels of DGDG 18:3/16:0 and MGDG 18:3/16:4 were higher in K-0591 than in LB999, while those of two DGDG species (DGDG 18:3/16:2 and DGDG 18:3/16:1) were lower. Johnson et al revealed that MGDG 16:0/18:1 is the preferred precursor moiety of DGDG biosynthesis.[33] Moreover, it was observed that DGDG 16:0/18:2 (rather than DGDG 16:0/18:1) was found in *Brassica napus* leaves grown at low temperature.[32] It can therefore be assumed that the higher level of DGDG 18:3/16:0 may be the result of sequential desaturation of MGDG 16:0/18:1 as a base form under low-temperature conditions. In addition, it was reported that rapid desaturation of the MGDG fatty acyl groups occurred in both the C16 and C18 species at low temperature, resulting in highly desaturated fatty acyl chains in MGDG from *B. napus* leaves.[34] This is supported by the present finding that the level of the highly unsaturated formed MGDG 18:3/16:4 was higher in the low-temperature K-0591 strain than in LB999. Therefore, these unique DGDG and MGDG patterns of fatty acyl chains were presumably caused by cold adaptation of *D. tertiolecta*.

The lipid compositions of organisms grown with and without nitrate (i.e., NS and ND conditions) were compared to determine which lipid species affect the metabolism of *D. tertiolecta* under ND conditions. Most of the DGTS species were increased in LB999 after 12 h of ND conditions. It is known that oil globules accumulate under nutrient-limited conditions. DGTS appears to play a role as a polar lipid monolayer that aids the formation of oil globules in green algae.[35] However, the levels of most lipids, including the DGTS species, were not changed in K-0591 under the same conditions. K-0591 was initially collected from the North Sea close to Denmark, where concentrations of dissolved nitrogen

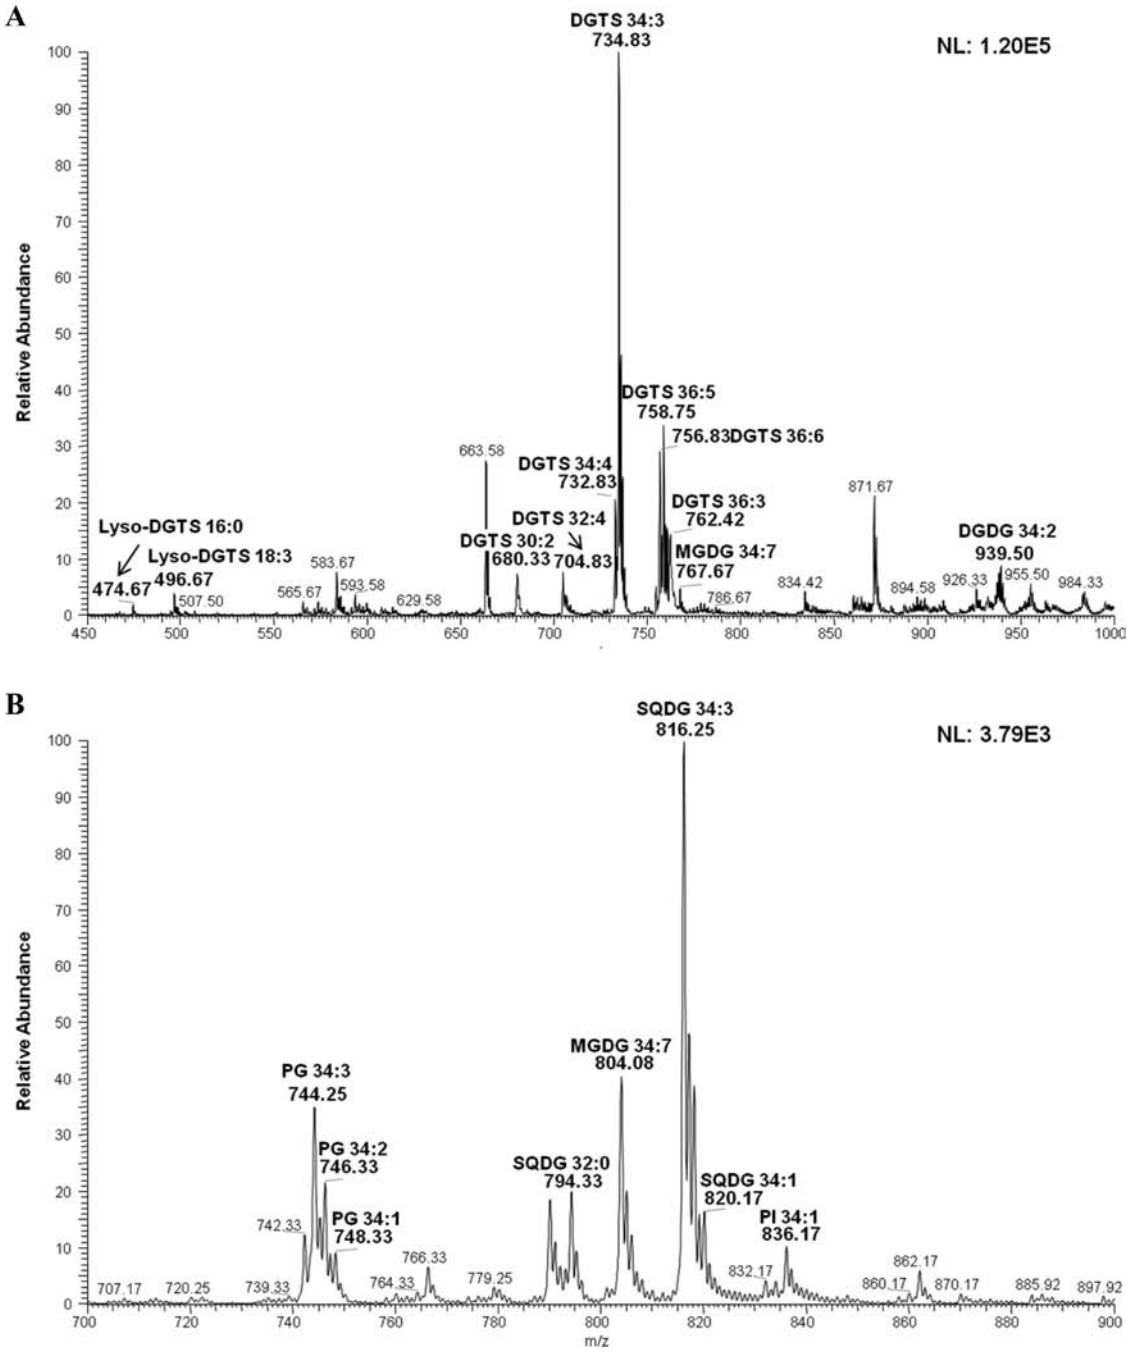

Figure 2. Representative spectra of lipid profiles from *D. tertiolecta* derived from nano-ESI-MS in (A) positive ion mode and (B) negative ion mode. Abbreviations: DGTS, diacylglyceryl-*N*,*N*,*N*-trimethylhomoserine; MGDG, monogalactosyldiacylglycerol; DGDG, digalactosyldiacylglycerol; SQDG, sulfoquinovosyldiacylglycerol; PG, phosphatidylglycerol; PI, phosphatidylinositol; *m*/*z*, mass-to-charge ratio; NL, normalized intensity level.

are very low.[36] It was therefore speculated that K-0591 has already acclimated to extreme conditions in which nitrogen is deficient. Meanwhile, the level of lyso-DGTS 18:3 was decreased in both strains.

There were no changes in the levels of MGDG and SQDG species in LB999, but there were significant increases in those of DGDG 18:3/16:2, PI 18:1/16:0, and PG 18:1/16:0. Mock and Kroon[37] demonstrated that the levels of DGDG, PG, and PI increase under nitrogen-deficient conditions in Antarctic sea-ice diatoms. They showed that photosynthesis was reduced under these conditions, resulting in the loss of proteins that regulate photosynthesis in the thylakoid membrane. Consequently, the level of DGDG and phospholipids—which are bilayer-forming lipids—seemed to be increased to stabilize the membrane structures.[37] Meanwhile, exposing K-0591 to nitrate deficiency produced no significant changes in lipid species except for reductions in the levels of *lyso*-DGTS 18:3 and DGDG 18:3/16:4.

In this study we conducted a comprehensive lipid analysis based on GC−MS and nano-ESI-MS of *D. tertiolecta*. The lipid profiles of two *D. tertiolecta* strains with different optimal growth temperatures were compared to determine the lipid species affecting the acclimation to low-temperature and ND conditions. The significant feature of the low-temperature (15

°C) strain K-0591 was that its levels of C18:3, DGTS species, MGDG 18:3/16:4, and DGDG 18:3/16:0 were higher than those of the LB999 strain grown at 21 °C. It appears that these lipid species contribute to desaturation of the cell membrane to maintain its fluidity under low-temperature conditions. K-0591 changed little under ND conditions, whereas large amounts of DGTS, DGDG, PI, and PG species had accumulated in LB999. These changes in the lipid profiles of LB999 could be the result of an increased number of oil globules and a compensation response to the reduced level of photosynthetic proteins observed under ND conditions. Notably, the levels of DGTS species in *D. tertiolecta* were higher under low-temperature and ND conditions. This implies that DGTS species could be candidate compounds related to acclimation to low temperature and nitrate deficiency. However, further experiments should be conducted to observe the changes in DGTS species at various time points and temperatures in each of these strains to verify this hypothesis.

The development of microalgal strains with tolerance of low temperature appears to be important from an economic viewpoint, because this would make the large-scale, open-pond cultivation of these microalgae possible even at relatively low temperatures. Such development could improve one of the current drawbacks of open-pond systems: diurnal and seasonal temperature fluctuations. In addition, prolonged cultivation while retaining a consistent FA composition under ND conditions would be feasible if microalgal strains with tolerance of such conditions can be developed. Although different nitrogen levels could induce changes in lipid and FA profiles in microalge,[38,39] it is not easy to control the nitrogen concentration in an open-pond system in a natural environment subject to events such as rain or evaporative water loss. Therefore, maintaining a constant lipid profile is necessary for the quality-controlled production of microalgal biofuel.

The findings of this study provide a deeper understanding of the differential lipid metabolism in two *D. tertiolecta* strains with different optimized growth temperatures when they are subjected to nitrate deficiency. This lipidomics tool could be a useful technique for elucidating certain lipid species potentially related to adaptation under various environmental conditions. Furthermore, this study provides new insight into the development of new strains that can survive under low-temperature and low-nutrient conditions using metabolic engineering targeting certain lipid species such as DGTS.

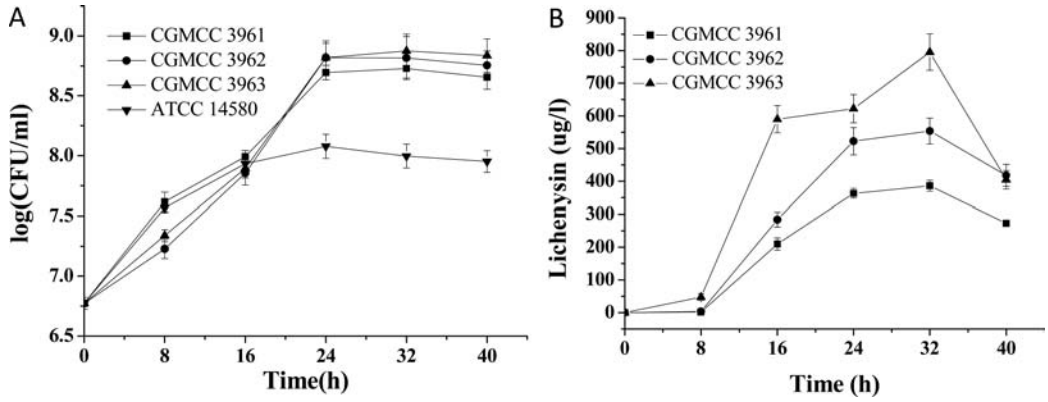

Figure 1. Time profile of lichenysin produced by different strains of *B. licheniformis* cultured in sorghum extract. (A) Biomass; (B) lichenysin concentration.

liquor is a symbolic drink of China, just as whisky is for Scotland and brandy for France. It is produced by a unique spontaneous and solid-state fermentation process with sorghum as the main material.[19] This process is rich in nutrition and accumulates a complex microbial community, including bacteria, yeast, and fungi. In this process, fungi produce amylase and glucoamylase to hydrolyze starch in cereal to oligosaccharide and also produce protease and peptidase to hydrolyze protein to oligopeptides and amino acids. These small molecular compounds are then consumed and transformed to ethanol and flavor compounds by yeast and bacteria.[20] *B. licheniformis* is a dominant species in this process. Its biosynthetic activity of lichenysin might be important for its survival and predominance in this community, because the produced lichenysin might show inhibition of other strains. Since there are rich nutritional and complex microbial communities in the liquor-making process, it is important to reveal the mechanism of lichenysin biosynthesis by producers in the Maotai-flavor liquor-making process. Therefore, the comparative transcriptome of these producers and a non-producer, *B. licheniformis*strain ATCC 14580, was carried out in a simulated liquor-making process. It is important to reveal the mechanism of the lichenysin biosynthetic process, including the substance supply and transformation by these strains in this complex process. This work would supplement the knowledge of lichensysin biosynthesis and promote the lichenysin production industry.

MATERIALS AND METHODS

Strains. Lichenysin producers were isolated from Chinese Maotai-flavor liquor-making process, on the basis of hemolysis zone on blood agar.[21] Then the obtained strains were cultured in sorghum extract, and their lichenysin productivity was determined by ultra-performance liquid chromatography (UPLC). Strains *B. licheniformis* CGMCC 3961, 3962,[22] and 3963[23] showed the highest lichenysin productivity. *B. licheniformis* ATCC 14580, obtaining from Shanghai Institute of Industrial Microbiology, did not originate from Maotai-liquor fermentation process.

Culture Conditions. In order to simulate the fermentation process of liquor making, the fermentation medium was prepared with sorghum. Sorghum extract was prepared as previously reported.[19] Strains were inoculated in 50 mL of sorghum extract medium and incubated at 37 °C for 40 h with an agitation speed of 150 rpm. To investigate the effect of different substrates on lichenysin production, strains were inoculated in synthetic medium with different substrates: 20 g/L glucose, amino acids, casein hydrolysate, respectively. The amino acids contained 5 g/L each L-leucine, L-aspartate, L-isoleucine, L-valine, and L-glutamine (the component unit of lichenysin). The synthetic medium was prepared according to a previous report[24] with minor modifications. It included 20 g/L glucose, 24 g/L $(NH_4)_2HPO_4$, 14.2 g/L $Na_2HPO_4{\cdot}12H_2O$, 3.0 g/L KH_2PO_4, 0.5 g/L NaCl, 0.24 g/L $MgSO_4{\cdot}7H_2O$, and 0.014 g/L $CaCl_2$, with the addition of 10 mL of metal ions mixture. Metal ions mixture contained 1.6 g/L $FeSO_4{\cdot}7H_2O$, 0.1 g/L $MnCl_2{\cdot}H_2O$, 0.17 g/L $ZnCl_2$, 0.043 g/L $CuCl_2{\cdot}H_2O$, 0.06 g/L $CoCl_2{\cdot}H_2O$, and 0.06 g/L $Na_2MoO_4{\cdot}2H_2O$. Strains were inoculated in 50 mL of the synthetic medium and incubated at 37 °C with an agitation speed of 150 rpm. The strain was incubated for 32 h to determine lichenysin yield and incubated for 24 h to determine the gene expression levels by quantitative real-time polymerase chain reaction (qRT-PCR).

RNA Extraction and cDNA Preparation. Total RNA was extracted from *B. licheniformis* CGMCC 3961, 3962, and 3963 and *B. licheniformis* ATCC 14580 cells cultured in sorghum extract and synthetic medium by use of RNeasy micro kits (Qiagen). DNase I was used to remove DNA contamination. The obtained RNA was determined by a nanobiosizing assay (Agilent) and then amplified and labeled by use of a one-color DNA labeling kit (NimbleGen) to obtain the cDNA sample.

Gene Expression Arrays. The obtained cDNA samples from strains cultured in sorghum extract were used for gene expression array processing. The expression array chip used contained 385 000 probes representing 4196 genes (NimbleGen). Target cDNA was hybridized to microarrays, and the processed slides after hybridization were scanned as reported.[22] The raw data of fluorescent intensity were extracted, normalized, background-corrected, and statistically analyzed as reported.[22] Genes with an absolute change >2.0-fold were identified as significantly differentially expressed genes.

Quantitative Real-Time Polymerase Chain Reaction. To verify the microarray results, two differentially expressed genes (*dppA* and *dppC*) were further analyzed by qRT-PCR. To investigate the effect of substrate on lichenysin production, strains were inoculated in synthetic medium with different substrates for 24 h. The obtained cDNA samples were also used for qRT-PCR. Relative transcript abundance was detected by SYBRGreen (Invitrogen) on the ABI 7900HT thermal cycler by use of gene-specific primers. The primer pairs were as follows: *dppA* (BLi01392), 5′-GGCTTATTTCGGGAGATGT-3′ (forward) and 5′-TTTCTTTGACGGCTGCTG-3′ (reverse); *dppB* (BLi01393), 5′-CACGACATTGACCTTTGTGA-3′ (forward) and 5′-ACGAAACGGGAAATCCTC-3′ (reverse); *dppC* (BLi01394), 5′-ATCGTCCAGATGACCTTG-3′ (forward) and 5′-CAGTCCGTCTCCAACAAC-3′ (reverse); *dppD* (BLi01395), 5′-TTGAGGCAGTATCCGCAC-3′ (forward) and 5′-TCACGGCGATTCTGTCTG-3′ (reverse); *dppE* (BLi01396), 5′-CGAAAGAAACGGCTGGAG-3′ (forward) and 5′-CATTTGGCATCATCACGG-3′ (reverse); 16S rDNA (reference gene), 5′-GTAACCTGCCTGTAAGACTG-3′ (forward) and 5′-TGTCTCAGTCCCAGTGTG-3′ (reverse); *ypqE* (BLi02359), 5′-TGATGGGTGACGGAATG-3′ (forward) and 5′-

Quantification of Lichenysin in Fermentation Broth. *B. licheniformis* was inoculated into 50 mL of sorghum extract and then shaken at 150 rpm for 24 h. Lichenysin was extracted with methanol as reported.[25] The methanol-soluble fraction was concentrated to 1 mL by rotary evaporation. To determine lichenysin concentration, UPLC was performed with a Waters Acquity UPLC system equipped with a UV detector (Milford, MA). The chromatographic separation was performed on a Waters Acquity C18 column (2.1 × 50 mm). The injection volume was 10 μL. The mobile phase was a gradient prepared from methanol (component A) and water containing 0.1% formic acid (component B). Elution started with 15% B for 0.1 min, and the proportion of B was decreased linearly to 0% in 10 min and then returned to 15% in 1 min. The flow rate was 300 μL/min. The experiments were carried out in triplicate.

RESULTS AND DISCUSSION

***B. licheniformis* CGMCC 3961, 3962, and 3963 Produce Lichenysin Efficiently in Simulated Liquor Fermentation Process.** *B. licheniformis* CGMCC 3961, 3962, and 3963 were isolated in Chinese Maotai-flavor liquor-making process.[22,23] They showed the highest lichenysin productivity among the isolated strains by the hemolysis reaction method[21] and UPLC determination. There are seven different fractions, which we reported previously.[4] The concentration of lichenysin is the total amount of these different fractions. Time profiles of lichenysin production by these strains and the type strain ATCC 14580 in sorghum extract medium were determined and are shown in Figure 1. *B. licheniformis* CGMCC 3961, 3962, and 3963 grew much better than ATCC 14580 in this medium. This indicated the three producers had adapted to this medium after long-time survival in the environment for liquor fermentation. In addition, all three strains produced lichenysin efficiently, and *B. licheniformis* CGMCC 3963 had stronger producing activity than the other two, while the type strain *B. licheniformis* ATCC 14580, of non-liquor-making origin, did not produce lichenysin. Lichenysin increased quickly after 8 h, reached a maximum value at 32 h (386.3, 553.5, and 795.2 μg/L, respectively), and then decreased until the end of fermentation by *B. licheniformis* CGMCC 3961, 3962, and 3963. The decrease of lichenysin might be due to further degradation by the strains. In addition, lichenysin was produced 8 h after initiation of cell growth, since it was produced as a secondary metabolite.[15]

Lichenysin is an amphiphile and shows strong antibacterial activity. It could inhibit the growth of many strains, including *Pseudomonas*, *Staphylococcus*, *Escherichis coli*, *Acinetobacter*, *Alcaligenes*, *Micrococcus*, etc.[11,22,26] Among them, *Pseudomonas* and *Staphylococcus* have been discovered in Chinese liquor.[27] The antibacterial activity of lichenysin would not only be beneficial for the dominance of *B. licheniformis* in Maotai-flavor liquor making but could also prevent liquor fermentation from contamination by those harmful microbes, achieving a successful product.

Transcriptome Analysis between Three Producers and Nonproducer. To gain further insight into the metabolic mechanism of overproduction of lichenysin by *B. licheniformis* CGMCC 3961, 3962 and 3963, the mean global differences of gene expression levels of these three producers were compared with those of nonproducer ATCC 14580. Of the 4196 genes on the microarray, a total of 1574 genes (37.5%), with a change of at least 2.0-fold, were identified as differentially expressed genes: 803 genes were upregulated and 771 genes were downregulated. Metabolic pathways obtained from the KEGG databases were characterized from the 1574 genes. As shown in Table 1 and Table S1 (Supporting Information), 11 metabolic pathways had *P*-value <0.05. Among them, ABC transporters (bld02010) constituted the most significantly different pathway. This might be related to membrane transport of substance absorption and lichenysin secretion, as well as the phosphotransferase system (PTS) (bld02060). Inositol phosphate metabolism (bld00562) and methane metabolism (bld00680) were related to energy metabolism, which might supply energy for vigorous cell growth and lichenysin biosynthesis and secretion processes. Benzoate degradation (bld00362), naphthalene degradation (bld00626), and geraniol degradation (bld00281) might be responsive to the fermentation environment, since there were terpenes and aromatic compounds in liquor fermentation materials. Fructose and mannose metabolism (bld00051) might be responsive to the high oligosaccharide content in sorghum, since these sugars were the nutrient for cell growth. Certain amino acids in cells were not only nutrients for cell growth but also direct substrates for lichenysin synthesis. The responsive metabolic pathways of valine, leucine, and isoleucine degradation (bld00280) and tryptophan metabolism (bld00380) might be related to substance degradation for cell growth and providing substance for lichenysin synthesis.

Increased Expression Pattern of Lichenysin Synthetases and Certain Regulators. Compared with the type strain ATCC 14580, *B. licheniformis* CGMCC 3961, 3962, and 3963 showed strong lichenysin-producing activities, which was essentially due to the difference in expression pattern of lichenysin synthetases. Lichenysin was reported to be produced by a multienzyme peptide synthetase complex expressed by the *lchA* operon, consisting of *lchAA*−*AD*.[15,16] To gain further

J. Agric. Food Chem. 2015, 63, 888−893

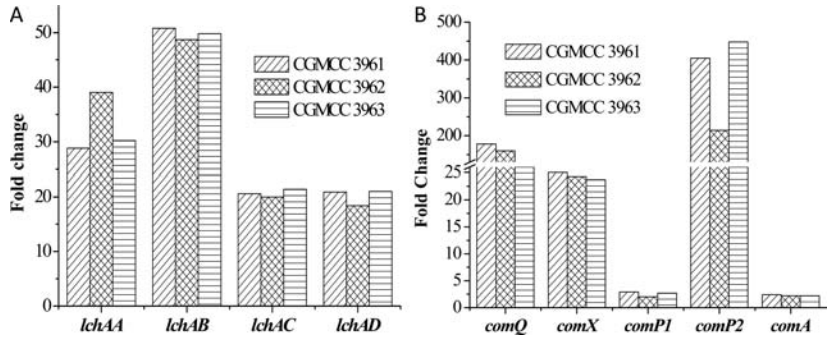

Figure 2. Expression pattern of lichenysin synthetases and regulators in *B. licheniformis* GMCC 3961, 3962, and 3963 compared with ATCC 14580. (A) *lchAA*−*AD*; (B) different regulators.

insight into the expression pattern of *lchA* operon in these three producers, the expression patterns of *lchAA*−*AD* were analyzed and are shown in Figure 2A. The average expression values of *lchAA*−*AD* in the three producers were 32.7-, 49.8-, 20.7-, and 20.1-fold greater than those of the type strain, respectively. The high expression level of lichenysin synthetase genes confirmed the overproduction of lichenysin.

LchAA is a three-module enzyme. The first module activated the acylation of the first amino acid, the second and third module assembled the following two amino acid residues, and the third module also converted L-amino acid into the D-isomer. LchAB and LchAC incorporated the following three and the last amino acids, respectively. LchAD is a repair enzyme.[28] The gene allele distribution of *lch* operon in the genome was analyzed in the genome of *B. licheniformis* CGMCC 3963.[23] It was found that *lchAA*−*AD* were in one gene cluster all with one copy in the genome level, which was the same as in ATCC 14580.[29] Therefore, the higher expression level in the producers might be due to the difference in transcription levels. However, the expression levels of *lchAA* and *lchAB* were higher than those of *lchAC* and *lchAD*. The sequence lengths of *lchAA* and *lchAB* were 10 757 and 10 766 bp, while the lengths of *lchAC* and *lchAD* were only 3848 and 740 bp in CGMCC 3963.[23] The long gene sequence of *lchAA* and *lchAB* might lead to weak transcription levels of the following genes, *lchAC* and *lchAD*. Since the reactions catalyzed by LchAA and LchAB were more complex, the higher expression levels of *lchAA* and *lchAB* would consequently increase the synthesis reaction and lichenysin yield. This represents the cell's economy of costs and benefits, which result from the adaptation evolution of this strain, due to long-term habitation in the liquor fermentation environment.

The expression levels of lichenysin synthetases were regulated by additional regulators. Therefore, it was necessary to find the expression pattern of the involved regulators. ComX was the initial regulator of surfactin (the homologue of lichenysin) biosynthesis in *B. subtilis*. It became active after being modified by ComQ and then controlled *srfA* expression when it interacted with ComP and ComA.[1,18] Therefore, in order to investigate whether the lichenysin synthesis regulatory pathway was the same in the producers, these related regulators were all analyzed, as shown in Figure 2B. Expression levels of *comQ* in these strains were more than 94.4-fold greater than that in the type strain, and the expression levels of *comX* were more than 23.7-fold. There were two histidine protein kinases ComP, but the expression pattern was significantly different: *comP2* expression in *B. licheniformis* CGMCC 3961, 3962, and 3963 was 404.9-, 214.3-, and 447.7-fold greater than that in the type strain, indicating ComP2 might be important for lichenysin synthesis. Although *comP1* and *comA* directly activate transcription of *lchAA*−*AD*,[17,18] the expression increase was only around 2.0−2.9-fold. This indicated that a small amount of *comP1* and *comA* would lead to the overproduction of *lchAA*−*AD*. The high expression of these regulators indicated that regulation of lichenysin biosynthesis might be also related to these regulators in the three lichenysin producers.

Increased Expression Pattern of Peptide Transport-Related Genes. ABC transporters (bld02010) constituted the most significant responsive metabolic pathway. Of the 29 upregulated genes, 14 of them were related to dipeptide and peptide transport, including *dppABCDE*, *appCDF*, *oppA*-like, *appBCDF*-like, and *ykfD* genes (Tables S1 and S2, Supporting Information). As shown in Figure 3, the expression level of

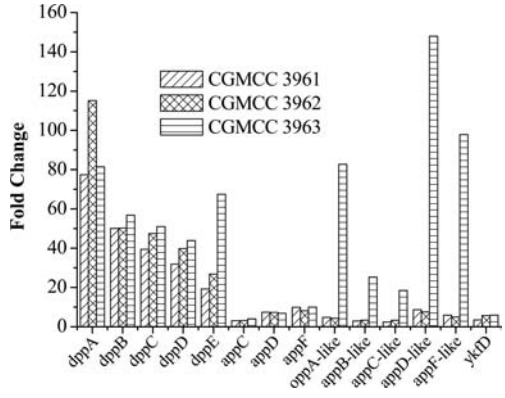

Figure 3. Expression pattern of genes related to peptide transport in the pathway of ABC transporters (bld02010) in *B. licheniformis* GMCC 3961, 3962, and 3963 compared with ATCC 14580.

dppABCDE increased more than 19.2-fold in CGMCC 3961, 3962, and 3963. In addition, the average upregulated expression level of *dppABCDE* in the three strains gradually decreased from 91.3- to 37.8-fold, although the expression level of *dppE* was higher than that of *dppBCD* in CGMCC 3963. Since the five genes were in the same operon, the subsequent gene expression gradually became weaker during the transcription process, due to premature termination of transcription of the subsequent genes by several attenuators.[30]

In addition, we found that the expression of *dppE*, *oppA*-like, and *appBCDF*-like genes was significantly higher in the highest lichenysin producer CGMCC 3963: about 67.5-, 82.7-, 25.3-, 18.4-, 147.9-, and 97.9-fold greater than in ATCC14580, respectively. These more highly expressed genes might be related to the higher productivity of lichenysin.

Table 2. Lichenysin Production in Synthetic Medium with Addition of Different Substrates[a]

	control	glucose	amino acids	casein hydrolysate
biomass, log(CFU/mL)	8.65 ± 0.03	8.75 ± 0.06	7.84 ± 0.08	8.51 ± 0.01
lichenysin yield (μg/L)	28.2 ± 2.6	42.7 ± 3.9	12.8 ± 2.1	47.5 ± 4.4

[a]*B. licheniformis* CGMCC 3963 was cultured in synthetic medium for 32 h. Control represents the culture in synthetic medium without additional substrates. The added concentrations of glucose, amino acids, and casein hydrolysate were all 20 g/L.

To confirm the microarray data, we analyzed the relative mRNA levels of two genes (*dppA* and *dppC*) in the three producers by qRT-PCR, and the results suggested that the expression levels of *dppA* in CGMCC 3961, 3962, and 3963 were 58.4-, 89.3-, and 66.2-fold greater than that in ATCC14580, respectively, while the expression levels of *dppC* in these three strains were 24.2-, 31.3-, and 30.5-fold greater, respectively (data not shown), which showed good agreement between the microarray and qRT-PCR analysis.

Relationship of Peptide Transport Genes to Lichenysin Production. It was reported that *Bacillus* will use glucose as the main substance to produce lichenysin.[15] However, we found that the average expression levels of the glucose transport-related genes *ptsG* (BLi01598) and *ypqE* (BLi02359) were both 0.4-fold in the three producers. Since lichenysin was mainly composed of amino acids, which would be hydrolyzed from peptides, the high peptide transporter expression value indicated peptide would also be a good candidate for the substrate of lichenysin synthesis. In order to investigate the relationship between lichenysin production and the substrates (glucose and peptide), we cultured *B. licheniformis* CGMCC 3963 (the most efficient among the three producers) in synthetic medium with different substrates, including glucose, five types of amino acids (the component unit of lichenysin), and casein hydrolysate (containing various types of peptides), respectively. As shown in Table 2, with the addition of amino acids, cell growth decreased slightly and lichenysin production also decreased. This implied that amino acids could not stimulate cell growth and lichenysin production. *Bacillus* species could utilize amino acids as the substrate to grow, however, some strains evolved to preferentially take up dipeptide or oligopeptide rather than amino acids. Although *B. licheniformis* CGMCC 3963 could grow with amino acids as the only nitrogen in our previous work (data not shown), it still preferred to utilize peptide in the environment full of peptides. With the addition of glucose and casein hydrolysate, lichenysin production increased significantly, from 28.2 to 42.7 and 47.5 μg/L, respectively. Since cell growth remained nearly the same between the control and the sample cultured with glucose or casein hydrolysate, it indicated that glucose and peptide would both improve the metabolic activity of lichenysin biosynthesis. It might be due to the increase of substrate supplements, such as glucose and peptide. In addition, glucose might also provide energy for lichenysin biosynthesis. Since the nonribosomal peptide synthetase and ABC transporter systems for lichenysin synthesis would both expend a lot of energy, glucose may benefit as a respiratory substrate to create energy.

In addition, we determined the expression levels of transport-related genes in the synthetic medium with the addition of these substrates. As shown in Table 3, the expression levels of *dppABCDE* remained nearly stable when glucose or amino acids were added in synthetic medium, but the expression of all these genes increased about 2-fold when casein hydrolysate was added. This indicated that peptide transport might be strengthened with the addition of casein hydrolysate, which was full of peptides. In addition, the expression levels of glucose-related genes, *ypqE* and *ptsG*, both increased about 2-fold with the addition of glucose, indicating glucose might induce higher expression of these two genes. However, the expression levels of these two genes both decreased to less than 0.21-fold with the addition of amino acids and casein hydrolysate. It was consistent with the transcriptome analysis result that the expression of the two genes decreased in sorghum extract. When it came to Chinese liquor fermentation, the fermentation environment was rich in peptide, and the concentration of glucose was at a relatively low level, because it is a simultaneous saccharification and fermentation process. This explained the high expression levels of peptide transporter genes (*dppABCDE*) and the low expression levels of glucose transporter genes (*ptsG* and *ypqE*) in the simulated liquor fermentation process. Since these producers were long-term inhabitants in an environment full of various types of peptides, then the strains might have evolved to preferentially take up peptides to synthesize lichenysin, rather than the in vivo pathway. This was also the energy and nutrition−cost principle, which was also the result of adaptation of long-term evolution. This would be a supplement for the previously reported substrate glucose.[15] On the other hand, the competition for nutrients and space was another way of exploitative competition by producers. The high efficiency of peptide transport by the producers competitively absorbed these available substances in this microbial community. It had stronger transport ability for substances for both cell growth and lichenysin biosynthesis. Then the high efficiency of peptide transport would be beneficial for both cell survival and lichenysin production, which turns out to be beneficial for cell competition.

Table 3. Expression of Substrate Transport-Related Genes in *B. licheniformis* CGMCC 3963 Cultures in Synthetic Medium with Different Additions[a]

gene	glucose	amino acids	casein hydrolysate
dppA	0.79	0.67	2.06
dppB	1.05	0.95	2.74
dppC	1.16	0.99	2.69
dppD	0.86	0.73	1.93
dppE	1.44	1.25	4.01
ypqE	2.87	0.08	0.21
ptsG	2.10	0.05	0.18

[a]*B. licheniformis* CGMCC 3963 was cultured in synthetic medium for 24 h. The concentrations of glucose, amino acids and casein hydrolysate were all 20 g/L. Strain cultured in the synthetic medium served as the control for qRT-PCR.

This work not only deepened insight into the mechanism for lichenysin biosynthesis but also found a new explanation of the biological mechanism of lichenysin produced by *B. licheniformis*. It should ultimately promote the production efficiency of lichenysin.

hydrolytic activity and transglycosylation toward lactose. Interestingly, a much higher synthetic ability of Bgal1-3 was observed in an organic−aqueous biphasic system than in aqueous system. To evaluate the effect of the immobilization as CLEAs on the GOS synthetic ability of the enzyme, its CLEAs were prepared. The enzymatic properties of Bgal1-3-CLEAs were investigated and compared with that of the free enzyme, including optimal pH, optimal temperature, pH stability, thermostability, storage stability, and kinetic parameters. The GOS synthesis of Bgal1-3-CLEAs was also conducted in the organic−aqueous biphasic system, and their reusability was evaluated by repeated consecutive batches. The aim of this study was to provide more information about the CLEAs of β-galactosidase and their potential application in the GOS synthesis.

MATERIALS AND METHODS

Strains, Vectors, and Chemicals. *E. coli* DH5α (Invitrogen, Carlsbad, CA, USA) was used as the host for gene cloning. A modified plasmid pUC19Δ*LacZ* was used to construct metagenomic libraries. The plasmid pUC19Δ*LacZ* was obtained by eliminating the *LacZ* fragment of plasmid pUC19 and replacing the ampicillin resistance gene with kanamycin resistance gene. *E. coli* BL21 (DE3) and pET-32a (+) (Novagen, Madison, WI, USA) were used for protein expression. Restriction endonucleases, DNA polymerase, and T4 DNA ligase were purchased from Thermo Fisher Scientific (Hudson, NH, USA). Lactose, glucose, and galactose were purchased from Sigma-Aldrich (St. Louis, MO, USA). All other chemicals and reagents were of analytical grade and purchased from commercial sources, unless indicated otherwise.

Construction and Screening of Metagenomic Library. Marine sediment samples were collected from Qiongdongnan basin of South China Sea (17°33′17″ N, 110°30′26″ E; water depth of 716.8 m) and stored at −80 °C until the DNA extraction was performed. The total genomic DNA from the marine sediment sample was extracted by using QIAamp DNA stool Mini kit according to the product manual (QIAGEN, Hilden, Germany). The genomic DNA was then partially digested with *Bam*HI and DNA fragments of 2.5−7.5 kb were purified using a QIAquick Gel Extraction Kit (QIAGEN) and inserted into the pUC19Δ*LacZ* vector, which had been previously digested with *Bam*HI and dephosphorylated with calf intestine alkaline phosphatase (CIAP). Next, the recombinant plasmid was transformed into *E. coli* DH5α and the transformants were cultured on LB agar plates containing 24 μg/mL isopropyl-β-D-1-thiogalactopyranoside (IPTG), 40 μg/mL 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-Gal), and 50 μg/mL kanamycin at 37 °C overnight. The positive colonies were visibly selected based on their blue color, which was caused by the hydrolysis of X-Gal.

Overexpression and Purification of the Target Protein. The overexpression and purification of the target protein in pET32a (+) and *E. coli* BL21 (DE3) were performed as previously described elsewhere.[8] After purification using a His Bind Purification Kit (Novagen) according to the product manual, the purified enzyme in the elution buffer (1 M imidazole, 0.5 M NaCl, 20 mM Tris-HCl, pH 7.9) was further dialyzed three times in phosphate buffer (50 mM, pH 7.0), and then stored at 4 °C for further study. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) was used to determine the molecular mass of the denatured recombinant protein with suitable size of protein markers (Thermo Fisher Scientific, Waltham, MA, USA) as standards. The concentration of the recombinant protein was determined by using CoomassiePlus (Bradford) Assay Kit (Thermo Fisher Scientific, Waltham, MA, USA) according to the product manual.

Enzyme Activity Assay. The enzyme activity was determined using lactose as substrate. Appropriately diluted enzyme solution (50 μL) was added into 450 μL of lactose solution (50 g/L in 50 mM phosphate buffer, pH 7.0). After being incubated for 15 min at 50 °C, the reaction mixture was boiled for 10 min to terminate the reaction. The concentration of glucose released from lactose was determined using a glucose oxidase-peroxidase assay kit (Sigma-Aldrich). One unit of enzyme activity was defined as the amount of enzyme required to release 1 μmol of glucose per min.

Preparation and Structure Analysis of Bgal1-3-CLEAs. The CLEAs of Bgal1-3 were prepared in a 25-mL flask with a magnetic stirrer bar. Initially, 9 mL of different protein precipitating agents including saturated ammonium sulfate, acetone, isopropanol, acetonitrile, and dimethyl sulfoxide (DMSO) was added into 1 mL of β-galactosidase solution, respectively. After keeping the mixture with stirring for 30 min at 4 °C for precipitation, glutaraldehyde was added to different final concentrations (10, 25, 50, 75, 100, and 125 mM) and stirred for 3 h at 25 °C. The pellets were collected by centrifugation at 12 000*g* for 10 min, washed twice with 10 mL of phosphate buffer (50 mM, pH 7.0), and stored in the same buffer at 4 °C.

The scanning electron micrographs (SEM) of CLEAs were recorded on a JSM-6330F field emission scanning electron microscope (Japan Electron Optics Laboratory Co., Ltd., Japan). The sample preparation consisted of freeze-drying by lyophilizer (Alpha 2-4/LSC, Christ, Germany) and coating with gold using an Emitech K550 sputter coater (Ashford, UK).

Effect of pH and Temperature on the Activity of the Free and Immobilized Bgal1-3. The optimal pH of the free and immobilized Bgal1-3 was determined using lactose as substrate in the pH range of 4.5−8.5 at 50 °C, respectively. The pH buffers were 50 mM citric acid−sodium citrate buffer (pH 3.0−6.0), 50 mM phosphate buffer (pH 6.0−8.0), and 50 mM Tris-HCl buffer (pH 8.0−9.0). The optimal temperature of the free and immobilized Bgal1-3 was determined by measuring the initial reaction rate in the temperature range of 35−65 °C in phosphate buffer (50 mM, pH 7.0). Moreover, the pH stability of the free and immobilized enzyme was investigated by measuring the residual activity after incubating the free and immobilized enzyme at 4 °C for 24 h in the above buffer systems, and the thermostability of the enzyme was measured by residual activity analysis after incubating the free and immobilized enzyme for various times intervals at 40 °C in 50 mM phosphate buffer (pH 7.0). All these reactions were performed according to the method in the Enzyme Activity Assay section.

The storage stability of the free and immobilized β-galactosidase was determined at 25 °C in 50 mM phosphate buffer (pH 7.0). After different storage times (0−90 days), the residual activities were tested. The activity of the free and immobilized enzyme after fresh preparation was defined as 100%, respectively.

Determination of Kinetic Parameters of the Free and Immobilized Bgal1-3. The kinetic parameters (K_{cat} and K_m) of the free and immobilized β-galactosidase were determined by assaying the enzymatic activity in 50 mM phosphate buffer (pH 7.0) at 50 °C with seven different concentrations (5, 10, 15, 20, 30, 50, and 100 mM) of lactose as substrate. The Michaelis−Menten equation was used to make all kinetic data fit to Lineweaver−Burk, and SigmaPlot software (Systat Software, Chicago, IL, USA) was applied to calculate the kinetic parameters.

Effect of Galactose and Glucose on the Activity of the Free and Immobilized Bgal1-3. The effect of galactose and glucose on the activity of the free and immobilized Bgal1-3 was determined according to the method reported by Husain et al.[28] In brief, the activity of the free and immobilized β-galactosidase was determined in the presence of increasing concentrations of galactose or glucose (100−500 mM) in 50 mM phosphate buffer (pH 7.0) at 50 °C using 5 mM *o*-nitrophenyl-β-D-galactopyranoside (oNPG) as substrate. Ten μL of enzyme solution was added into 490 μL of oNPG solution. After the reaction mixture was incubated for 10 min at 50 °C, 500 μL of 10% (w/v) sodium carbonate was added to terminate the reaction. The enzyme activity was quantified by following the *o*-nitrophenyl (oNP) release at 405 nm. The activity of enzyme without galactose or glucose was considered as 100%, respectively.

GOS Synthesis in Organic−Aqueous Biphasic System Using the Free and Immobilized Bgal1-3. The synthesis of GOS using lactose as substrate via the free and immobilized Bgal1-3 was performed in an organic−aqueous biphasic system. Ethyl acetate

DOI: 10.1021/jf504473k
J. Agric. Food Chem. 2015, 63, 894−901

(2.5 mL) was added into 22.5 mL of aqueous phase, which was prepared by adding 9 g of lactose and 450 U enzyme into phosphate buffer (50 mM, pH 7.0). The reaction mixture was added into a 100-mL flask and the reaction was carried out at 40 °C for 10 h in a shaking oscillator (250 rpm). The reaction was then terminated by boiling the mixture for 10 min. After centrifugation at 12 000*g* for 10 min, the supernatant of aqueous phase was collected for sugar analysis.

Sugar Analysis. Qualitative analysis of the GOS syrup was performed by thin-layer chromatography (TLC). Butanol−ethanol−water (5:3:2, v/v/v) was used as the mobile phase, and visualization was achieved by spraying a solution containing 20% (v/v) sulfuric acid and 0.5% (w/v) 3,5-dihydroxytoluene onto a plate (TLC Silica gel 60 F254, Merck, Germany) and heating it at 85 °C for 15 min. Further analysis of the individual oligosaccharide in the GOS syrup was investigated by high-resolution electrospray ionization mass spectrometry (HR-ESI-MS) via hybrid mass spectrometer LTQ Orbitrap Velos (Thermo Scientific, FL, USA). The detection was performed in the positive mode under the working conditions as follows: spray voltage of 3.5 kV, heated capillary temperature of 300 °C, and heated capillary voltage of 20 V with nitrogen used as sheath and auxiliary gas. Quantitative analysis of the GOS syrup was carried out by high-performance liquid chromatography (HPLC) with a refractive index detector via a system equipped with a degassing system (LC-20A SHIMADZU, Japan) and a pump (SHIMADZU). A Shodex SUGAR SP0810 column (8.0 × 300 mm, 7 μm, Shodex, Japan) was used for the HPLC analysis. HPLC-grade water was used as the mobile phase at a flow rate of 0.25 mL/min at 80 °C. The injection volume was 10 μL. Individual sugars in the mixtures were identified by comparison of their retention times with those of the standards (1% glucose, 1% galactose, 1% lactose; their response factors were 2.953×10^{-7}, 3.422×10^{-7}, and 3.376×10^{-7}, respectively) and quantified from the peak area calibrated against sugar standards.[29] The GOS yield was calculated according to the following formula:

$$\text{GOS yield (\%)} = \frac{\text{GOS formed}}{\text{total saccharides}} \times 100$$

Total saccharides is the sum of all sugars (glucose, galactose, residual lactose, and GOS), and it is approximately equal to the initial lactose content.

Reusability Assay of Bgal1-3-CLEAs. The reusability of Bgal1-3-CLEAs was assessed by carrying out the GOS synthesis for ten consecutive batches under the same synthetic condition described above. After each cycle of operation, the pellets were recovered by centrifugation at 12 000*g* for 10 min and washed twice with phosphate buffer (50 mM, pH 7.0). The recovered CLEAs and 2.5 mL of ethyl acetate were then added into 22.5 mL of phosphate buffer (50 mM, pH 7.0) which contained 9 g of lactose to initiate the next batch reaction. The residual enzymatic activity after each operation was compared with that of fresh CLEAs, which was defined as 100%. The GOS yield of each batch was determined according to the method in the Sugar Analysis section.

Statistical Analysis. All data were treated by analysis of variance (ANOVA) using IBM SPSS (Statistical Package for the Social Sciences, IBM SPSS. Inc., Chicago, IL, US). Significant differences were defined as $P < 0.05$.

Nucleotide Sequence Accession Number. The nucleotide sequence of *bgal1-3* has been submitted to GenBank, and its accession number is KC521353.

RESULTS AND DISCUSSION

***β*-Galactosidase Screening from Metagenomic Library and Sequence Analysis.** A plasmid metagenomic library containing nearly 3150 Mb of metagenomic DNA was successfully constructed using the DNA extracted from marine sediment samples of South China Sea for screening novel *β*-galactosidase. Twenty-eight positive clones were identified from the metagenomic library by functional screening, and one of the positive clones was finally selected for further study due to its high activity toward natural substrate lactose. Sequence analysis of the positive clone revealed an open reading frame (named *bgal1-3*) of 2202 bp which encoded a 733-amino-acid protein (Bgal1-3). A protein blast (Blastp) result showed that all its closest homologues were *β*-D-galactosidase. A search of Conserved Domains Database (CDD) revealed contained conserved regions of the glycosyl hydrolases family 2 sugar binding domain (1−140 aa, pfam02836) and glycosyl hydrolases family 2 triosephosphate isomerase barrel domain (249−547 aa, pfam02837), which indicated that this protein was a member of the glycosyl hydrolases family 2 (GH2).

Overexpression and Purification of the Recombinant Bgal1-3. The *bgal1-3* gene was inserted into the expression vector pET-32a (+) and overexpressed in a soluble protein fraction in *E. coli* BL21 (DE3). The recombinant Bgal1-3 was purified by affinity chromatography, and the activity of the pure protein toward lactose was 67.18 ± 1.22 U/mg. SDS−PAGE analysis revealed that the molecular mass of the recombinant Bgal1-3 was about 100 kDa (Supporting Information (SI) Figure S1), which agreed with the predicted size of Bgal1-3 (82.26 kDa) plus the N-terminal fusion protein of the expression vector (18 kDa).

Preparation and Structural Characterization of Bgal1-3-CLEAs. The preparation of CLEAs usually includes two procedures: precipitation of the enzyme from aqueous buffer as physical aggregates and cross-linking of the aggregates by bifunctional agent.[21] In this study, five kinds of protein precipitating agents were used for the precipitation of Bgal1-3 (Figure 1A). Activity assay demonstrated that ammonium sulfate (90% saturation) worked best among them. The activity recovery of the precipitated protein was 92.3 ± 3.7%. The optimum quantity of glutaraldehyde required for activity recovery was then investigated by adding glutaraldehyde to different final concentrations (10−125 mM), and the results showed that the CLEAs retained 96.2 ± 1.6% activity after cross-linking with 25 mM glutaraldehyde at 25 °C for 3 h (Figure 1B).

The scanning electron micrographs of Bgal1-3-CLEAs revealed a spherical structure of the aggregates. The enzyme molecules were packed together into "balls" with diameter of about 0.2 μm (Figure 2B), and then the "balls" were cross-linked to be aggregate clusters with the diameter of about 5 μm (Figure 2A). The structure of Bgal1-3-CLEAs was similar to that of the type 1 aggregates described by Schoevaart et al.[30]

Effect of pH and Temperature on the Enzymatic Activity and Stability of the Free and Immobilized Bgal1-3. The free and immobilized Bgal1-3 both showed an optimal pH of 7.0 (Figure 3A). However, the immobilized Bgal1-3 maintained higher pH stability than the free enzyme (Figure 3B), which was similar to the reports previously published.[18,25] The optimal temperature of the immobilized Bgal1-3 was 50 °C, the same as that of the free enzyme (Figure 3C). The thermostability of the immobilized enzyme was distinctly improved than that of the free enzyme, and its enzymatic activity stayed almost constant after incubation at 40 °C for 120 h, whereas the residual activity of the free enzyme was only about 60% under the same processing conditions (Figure 3D). This phenomenon has been observed in some previous studies. For example, the CLEAs of aminoacylase from *Aspergillus melleus* conserved about 52% activity after incubation at 47 °C for 24 h, while the free aminoacylase lost almost all activity;[31] the CLEAs of phenylalanine ammonia lyase from *Rhodotorula glutinis* maintained approximately 75% activity

when stored at 60 °C for 10 h, whereas its soluble counterpart maintained only 20% activity at the same temperature for 1 h;[25] the CLEAs of alpha amylase (CLARASE L-40,000), glucoamylase (OPTIDEX L-300) and pullulanase (OPTIMAX L-300) retained 85%, 70%, and 38% activity after the incubation at 65 °C for 3 h, while their free counterparts retained only 46%, 35%, and 15% activity, respectively.[32] The enhanced thermostability of the CLEAs indicated that cross-linking as aggregates provided more molecular conformation stability of these enzymes.[25,31,32]

The storage stability of Bgal1-3-CLEAs was also determined. After storage at 25 °C for 90 days, the residual activity of the immobilized enzyme was 79.5 ± 3.1%, whereas the free enzyme was only 16.2 ± 2.3% (Table 1). Therefore, the immobilization of Bgal1-3 as CLEAs conferred extended storage life of the enzyme.

Kinetic Parameters of the Free and Immobilized Bgal1-3. The kinetic parameters of the free and immobilized Bgal1-3 are listed in Table 2. The catalytic efficiency (K_{cat}/K_m) of Bgal1-3 decreased after the immobilization, which was mainly due to the increase of the K_m value (from 17.98 ± 0.35 mM to 19.39 ± 0.21 mM). Similar change of the kinetics parameters has also been reported in the cases of other enzymes. The K_m value of the immobilized aminoacylase was 1.497 mM, higher than that of free enzyme (0.964 mM);[31] the immobilized β-galactosidase from *Aspergillus oryzae* displayed higher K_m value (60.30 mM) than its soluble counterpart (52.13 mM).[33] The increase of K_m value of immobilized enzyme may be partially attributed to the occurrence of mass transfer resistance between the substrate and the immobilized enzyme.[34]

GOS Synthesis in Organic−Aqueous Biphasic System Using the Free and Immobilized Bgal1-3. To assess the GOS synthetic ability of the free enzyme in the organic−aqueous biphasic system, the reaction condition was optimized by a single factorial experiment (method and data are provided in detail in the SI). Ethyl acetate was chosen as the organic phase because its existence (10−90%, v/v) did not affect the thermostability of either the free Bgal1-3 or Bgal1-3-CLEAs (data not shown). The GOS synthesis of Bgal1-3-CLEAs was then conducted under the same condition in order to investigate the effect of the immobilization on the GOS synthetic ability of Bgal1-3. After the reaction, TLC was used for the preliminary analysis of the GOS syrups synthesized by the free enzyme and Bgal1-3-CLEAs. As shown in Figure 4A, the GOS content and composition of the two kinds of syrups were similar. The bands of the sugar distribution in Figure 4A also suggested the rich diversity of the oligosaccharide. Each individual oligosaccharide was then further distinguished by mass spectrometry. HR-ESI-MS analysis revealed that both of the GOS syrups synthesized by the free enzyme and Bgal1-3-CLEAs contained at least seven different oligosaccharides, with the degree of polymerization (DP) ranging between 3 and 9 (SI Figure S3 and SI Table S1). At last, the GOS yields were quantified according to the method in the Sugar Analysis section. (Figure 4B). Results showed that the GOS yield of Bgal1-3-CLEAs (59.4 ± 1.5%) was slightly higher than that of the free enzyme (57.1 ± 1.7%) ($n = 6$, $P < 0.05$, SI Figure S4, and SI Table S2). High GOS yield is an attractive property of the β-galactosidases that is of interest for the potential application. According to the reported literature, GOS yields were commonly achieved between 17.1% and 45%, only a few exceeded 50%.[35] Therefore, the high GOS yields of the free enzyme and CLEAs in this work would be very useful in the GOS production.

Although the CLEAs of a variety of enzymes have been applied to many different biochemical reactions, there is only one report on the GOS synthesis by using β-galactosidase CLEAs up to now. Gaur et al.[27] reported that the transglycosylation activity of the β-galactosidase from *Aspergillus oryzae* drastically dropped after it was immobilized as CLEAs, with the decrease of the GOS yield from 24.1% to 1.4%. In contrast, the GOS yield of Bgal1-3 increased after the immobilization. The possible reasons behind this were mainly ascribed to the following points: First, the conformational change of Bgal1-3 after immobilization may affect its trans-

glycosylation ability. The conformation of the enzyme molecular could be significantly changed in the process of precipitation and then the changed conformation was "locked" by the cross-linking, which would greatly affect the selectivity of the enzymes.[36] In line with this, the conformation "locked" by the CLEAs of Bgal1-3 may be more conducive to trans-glycosylation. Previous studies on the lipase CLEAs also showed that increased specific activity and/or enantioselectivity can be achieved by changing the conformation of the enzymes to more favorable forms.[36] Second, the enhanced galactose-tolerance of Bgal1-3-CLEAs might be another reason for the increased GOS yield. As shown in Figure 5, Bgal1-3-CLEAs showed glucose tolerance similar to that of the free enzyme; they both retained more than 90% activity in the presence of 500 mM glucose. Whereas, when the same concentration of

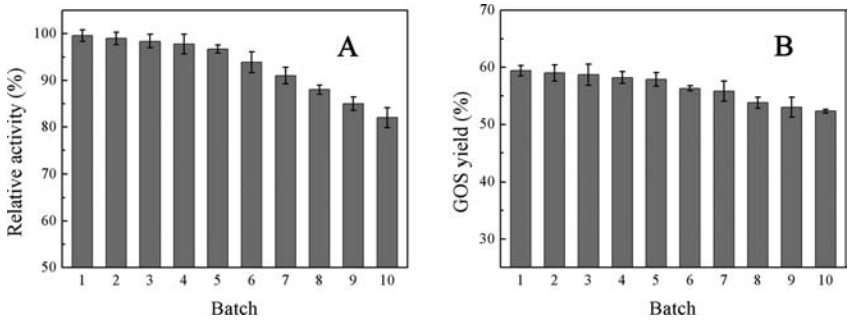

Figure 6. Reusability of Bgal1-3-CLEAs for GOS synthesis in organic−aqueous biphasic system. (A) Residual activity of Bgal1-3-CLEAs after each batch. (B) GOS yields of each batch. Data represent the means of three experiments and error bars represent standard deviation.

galactose existed, the residual activity of Bgal1-3-CLEAs was much higher than that of the free enzyme (92.3 ± 1.3% vs 68.1 ± 1.5%). The enhanced galactose-tolerance of Bgal1-3-CLEAs could relieve the inhibitory effect during the reaction and thus benefit the GOS synthesis.[37] Similar phenomena of other β-galactosidases have been reported before.[33,38] Last, it is worth noting that the organic−aqueous biphasic system used in this work may also contribute to the higher GOS yield of Bgal1-3-CLEAs. As mentioned above, Bgal1-3-CLEAs showed lower hydrolytic efficiency toward lactose than the free enzyme in aqueous phase, which may be partially attributed to the occurrence of diffusional limitations. However, when the Bgal1-3-CLEAs and the free enzyme were used for the GOS synthesis in the organic−aqueous biphasic system, higher GOS yield was achieved by Bgal1-3-CLEAs, which indicated undiminished catalytic efficiency and negligible diffusional limitations in the process of GOS synthesis. Similar phenomenon has been reported by Sheldon[21] when using CLEAs in colorimetric assays (aqueous system, diffusional limitations observed) and organic synthesis (nonaqueous system, no diffusional limitations observed). These results suggested that the catalytic property of CLEAs in aqueous and nonaqueous system was not fully corresponding. The activity of CLEAs based on colorimetric assays in aqueous system may lead one to underrate its real catalytic capability in nonaqueous system. Hence, more caution and attempts are needed when one tries to evaluate the suitability of CLEAs for the reactions in nonaqueous system.

Reusability of Bgal1-3-CLEAs. Reusability of the immobilized enzymes is a key factor in industrial applications, because it results in simplification of downstream processing and reduction in enzyme costs.[21] In this study, the reusability of Bgal1-3-CLEAs was evaluated through GOS synthesis for successive batches. As shown in Figure 6, Bgal1-3-CLEAs retained 82 ± 2.1% of their initial activity after ten batches; the GOS yield of the tenth batch was 52.3 ± 0.3%, which was still higher than that of the most former reports.[35] Considering the fact that the activity of Bgal1-3-CLEAs was almost constant after incubation for 120 h at 40 °C (Figure 3D) and the existence of ethyl acetate also did not affect their thermostability (data not shown), the decline of catalytic activity of CLEAs during repeated use might be mainly attributed to the washing and centrifugation.[39] This phenomenon was also supported by the determination of enzyme activity left in the supernatant (data not shown). These results demonstrated that CLEAs of Bgal1-3 had a robust reusability and good application potential in the GOS production.

In conclusion, a novel β-galactosidase Bgal1-3 was isolated from a marine metagenomic library, and its CLEAs were then successfully prepared. Furthermore, the enzymatic properties and GOS yields of the free and immobilized enzyme were also investigated. In comparison with the free enzyme, the immobilized enzyme displayed slightly higher GOS yield, much higher thermostability, and robust reusability, as well as good storage stability. These results open an attractive way toward the feasibility and high-efficiency synthesis of GOS by β-galactosidases-CLEAs.

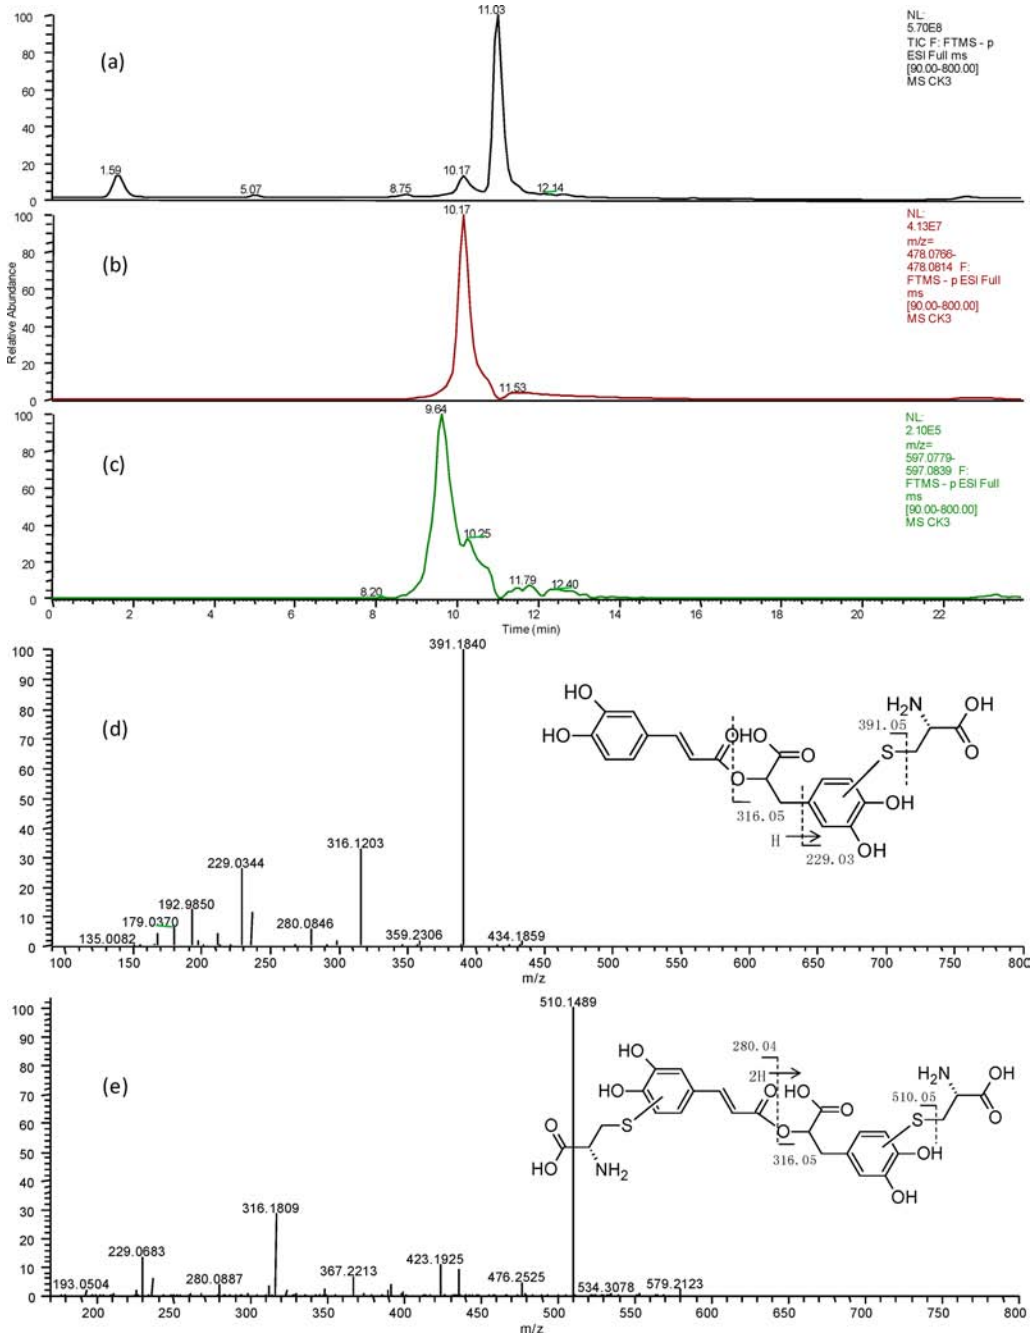

Figure 1. Cys (1.0 mM) and RosA (0.5 mM) incubated in maleic acid buffer (0.1 M) at pH 5.8, with $FeSO_4$ (0.1 mM) and H_2O_2 (30 mM) at 30 °C: (a) TIC of the incubation solution; extracted chromatograms of (b) M1 and (c) M2 from TIC; MS^2 fragmentation patterns of (d) M1 and (e) M2 show the structures of the products with fragmentation pathways noted.

distributed in Lamiaceae herbs.[22] The Lamiaceae herbs, including rosemary, sage, and melissa, are rich in RosA; these herbs are used as food additives in many food products.[23−26] Although Fujimoto[33] has demonstrated the addition reaction between RosA and 1-dodecanethiol, there are still questions about whether RosA can react with myofibrillar proteins, which is closely related to the quality of resulting meat products. As of this writing, little information is available to elucidate the effects of processing conditions, including stirring time, temperature, and oxidative stress, on the formation of adducts. Thus, the objective of this study was to identify the structures of adducts by the reaction of RosA and thiol compounds including cysteine (Cys), glutathione (GSH), and peptides digested from myosin; determine the occurrence of the adduction reaction between RosA and myosin, which is the main protein of myofibrillar proteins in meat; and investigate the influence of processing conditions on the formation of adducts.

MATERIALS AND METHODS

Materials. RosA (96%, MW 360.33), maleic acid, formic acid, Cys (96%, MW 121.15), and GSH (reduced Biotech grade, MW 307.32) were obtained from Sigma-Aldrich Inc. (St. Louis, MO, USA). Hydrochloric acid, sodium hydroxide, acetonitrile, sodium dihydrogen phosphate, sodium chloride, magnesium chloride, ethylenebis-(oxyethylenenitrilo)tetraacetic acid, and hydrogen peroxide (30%) were obtained from Sino Pharm Chemical Reagent Co., Ltd. (Shanghai, China). Water was purified by a Milli-Q system (Millipore,

Thermo, Bedford, MA, USA). The following three synthetic peptides (96% enrichment) were obtained from China Peptides Co., Ltd. (Shanghai, China): hexapeptide-1, Cys-Ala-Ser-Leu-Glu-Lys (MW 649.76); heptapeptide-2, His-Asp-Cys-Asp-Leu-Leu-Arg (MW 870.98); and nonapeptide-3, Leu-Glu-Asp-Glu-Cys-Ser-Glu-Leu-Lys (MW 1065.16).

Preparation of Model Solution Sample. The method used for generating adducts was based on the method formerly described;[10,27] thiol compounds including Cys, GSH, and peptides from myosin were diluted in 0.1 M maleic acid buffer adjusted to pH 5.8 with NaOH. The solutions were then separately incubated with RosA, $FeSO_4$, and H_2O_2 at 30 °C and stirred in the dark for 5 h. The concentrations of samples are presented in Table 1.

Preparation of Meat Samples. Freshly ground pork was purchased from Walmart supermarket, Nanjing, China. The meat was chopped and divided in two parts (100 g): to one part was added 50 mg of RosA, and the other part without RosA was used as the control. Aliquots of 5.0 g samples were transferred to plastic bags, which were filled with pure oxygen and sealed. The meat samples in triplicate were kept in storage in the dark at 4 °C for 6 days.

Extraction of MPI. MPI was extracted from the meat samples after 6 days of storage according to the method of Park et al.[28] with slight modifications. An aliquot of 4.0 g of meat was homogenized in 20 mL of isolation buffer (100 mM NaCl, 10 mM NaH_2PO_4, 2 mM $MgCl_2$, 1 mM EGTA, pH 7.0) in 50 mL centrifuge tubes. The homogenate was centrifuged at 2600*g* at 4 °C for 12 min, and the pellet was

J. Agric. Food Chem. 2015, 63, 902−911

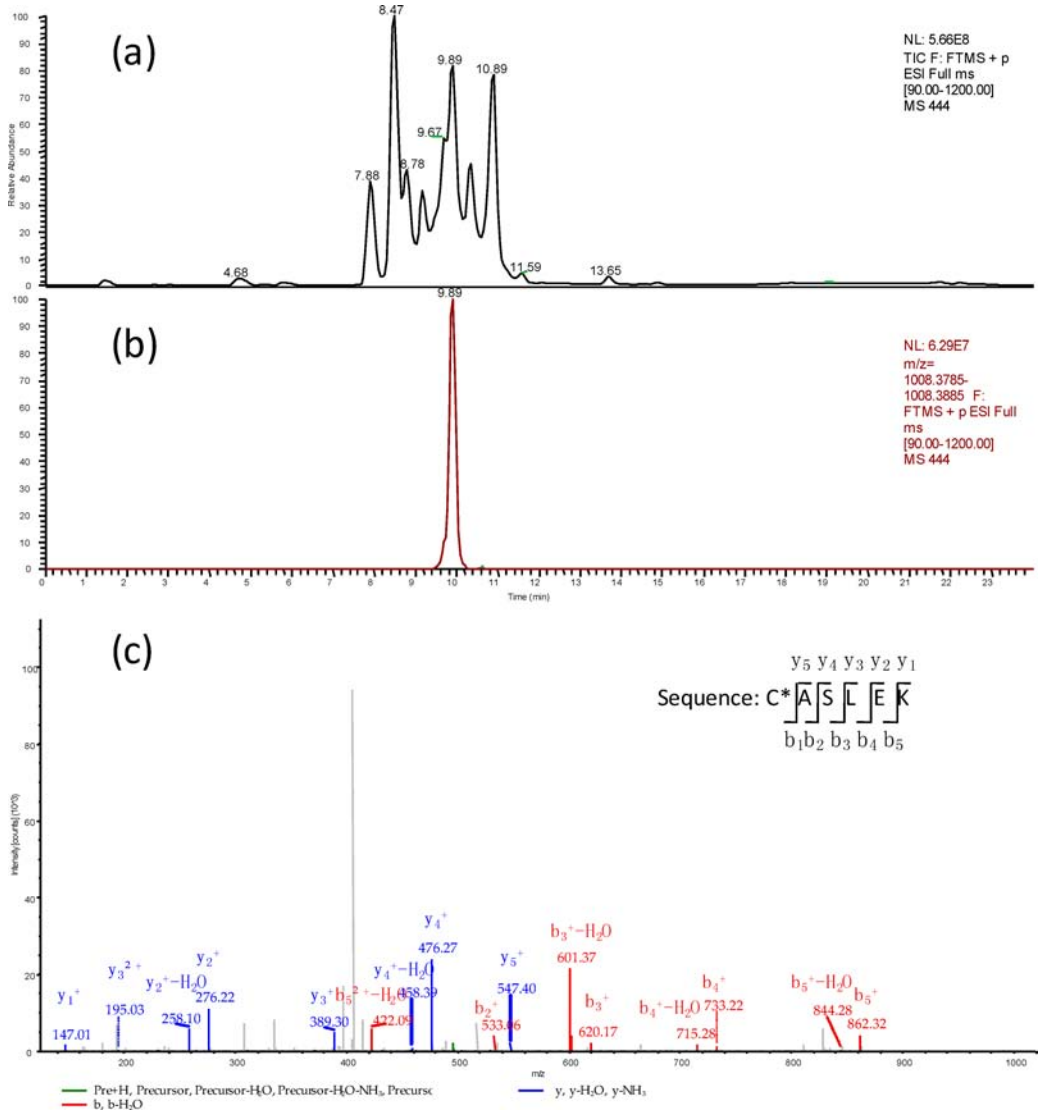

Figure 3. Hexapeptide (0.5 mM) and RosA (0.5 mM) incubated in maleic acid buffer (0.1 M) at pH 5.8, with $FeSO_4$ (0.1 mM) and H_2O_2 (30 mM) at 30 °C: (a) TIC of the incubated solution; (b) extracted chromatogram of M4 from TIC; (c) MS^2 fragmentation patterns of M4 show the structures of the products with fragmentation pathways noted.

resuspended in 10 mL of isolation buffer by homogenization and centrifugation, which was repeated three times. Before the last centrifugation, the suspension was filtered through cheesecloth, and the protein pellet was stored in ice for use.

Influence of Processing Condition on Adducts. To evaluate the effects of stirring time, temperature, and oxidizing intensity on adduct production, the above reaction mixtures were incubated at 30, 40, and 50 °C and stirred for either 1, 3, 5, or 7 h in the presence of 10, 30, 50, or 70 mM H_2O_2. Aliquots (10 mL) of each reaction were prepared in amber vials. Reactions were stopped by the addition of 50 mM potassium bisulfate solution. All reactions were performed in triplicate. The residue was filtered through a 0.45 μm membrane filter for mass spectrometer analysis.

UHPLC-LTQ-Orbitrap MS Analysis. The thiol sources, including Cys, GSH, and peptides of myosin, and their adducts with quinones oxidized from RosA were monitored by the UHPLC-LTQ-Orbitrap system, which consisted of UHPLC (Dionex, ThermoFisher Scientific, New York, USA) coupled with LTQ Orbitrap XL MS (Thermo Fisher Scientific). Instruments were charged by Tune 2.6.0 and Cheomeleon programs. The chromatographic column used was Hypersil GOLD C18 (100 mm × 2.10 mm, 3 μm particle size, Thermo Fisher Scientific). UHPLC mobile phase A was water with 0.1% formic acid, and UHPLC mobile phase D was 100% acetonitrile. Separations were performed in 20 min with a flow rate of 0.2 mL/min under the following programs: 0−4 min, 5% D; 4−12 min, 5−95% D; 12−15 min, 95% D; 15−15.5 min, 95−5% D; and 15.5−20 min, 5% D. The oven temperature of the column was set at 35 °C, and the injection volume was 5 μL.

MS was operated in negative mode to analyze adducts formed by Cys and GSH and monitor the calculated ions of $[M - H]^-$ = 478.0813 (Cys−RosA, M1), $[M - H]^-$ = 597.0854 (Cys−RosA−Cys, M2), and $[M - H]^-$ = 664.1454 (GSH−RosA, M3). The positive mode was used to analyze the adducts formed by peptides and monitor the calculated ions of $[M^+H]^+$ = 1008.3866 (hexapeptide−RosA, M4), $[M + 2H]^{2+}$ = 615.2428 (heptapeptide−RosA, M5), and $[M + 2H]^{2+}$ = 712.2767 (nonapeptide−RosA, M6).

MALDI-TOF/TOF MS Analysis. MALDI-TOF/TOF-MS equipped with a 355 nm laser was applied to examine the precise sites of adduct between RosA and myosin in MPI. The protein samples were reduced and alkylated by the routine method of Biotech Proteome kit (Shimadzu, Osaka, Japan). Finally, the sample (2 μg) was digested in 5 μL of 100 mM NH_4CO_3 (pH 8.0) containing 10 μg/mL trypsin for 10 h at 37 °C. After desalting by C18 Tip, 1 μL of sample solution was spotted on the MALDI plate (Shimadzu GLC, Osaka, Japan) with DHB as the matrix. The digests were analyzed on a MALDI-TOF/TOF

J. Agric. Food Chem. 2015, 63, 902−911

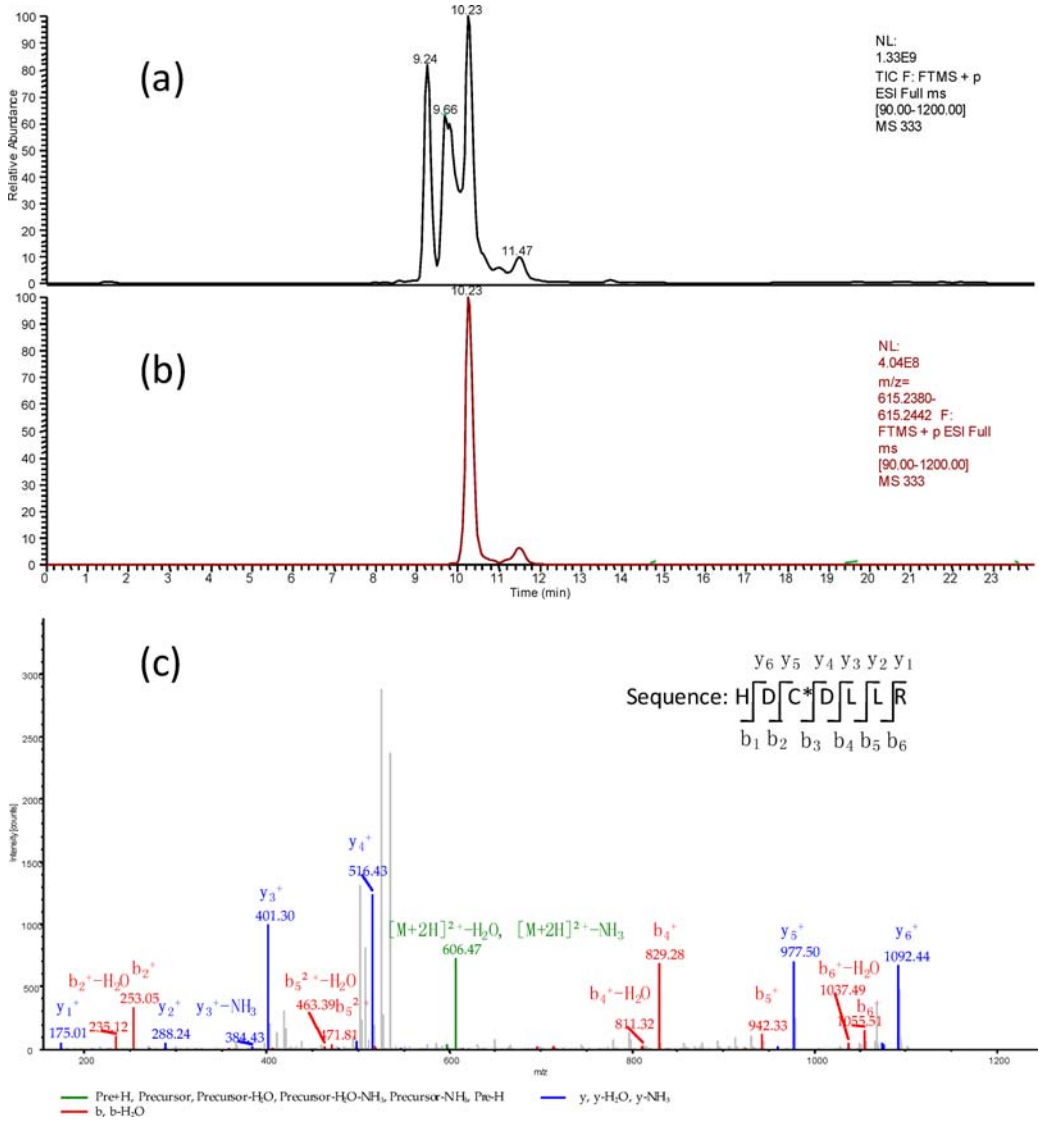

Figure 4. Heptapeptide (0.5 mM) and RosA (0.5 mM) incubated in maleic acid buffer (0.1 M) at pH 5.8, with $FeSO_4$ (0.1 mM) and H_2O_2 (30 mM) at 30 °C: (a) TIC of the incubated solution; (b) extracted chromatogram of M5 from TIC; (c) MS^2 fragmentation patterns of M5 show the structures of the products with fragmentation pathways noted.

instrument (AXIMA Performance; Shimadzu, Manchester, UK) with Kompact version 2.8.

Protein identification was operated by using the MS ion and MS/MS ion search of Mascot. The following parameters were set for searching peptides containing cysteine modified by rosmarinic acid: database, SwissProt; allowing one missed cleavage; enzyme, trypsin; peptide mass tolerance, 100 ppm; fragment mass tolerance, ±1.5 Da; fixed modification, carbamidomethyl (C); and variable modification, oxidation (M). A Mascot threshold of 63 was used to achieve a false identification rate of 5%.

RESULTS AND DISCUSSION

Identification of Adducts Formed between Cys and Quinone Derived from RosA. Two adducts formed between Cys and quinone derived from RosA were named quinone−RosA/Cys adduct (M1) and quinone−RosA/2Cys adduct (M2), respectively. A typical total ion chromatogram (TIC) for adducts in the solutions is presented in Figure 1a. Extracted chromatograms from the TIC with different accurate mass settings are shown in Figure 1b,c. M1 and M2 were identified using the exact mass of two peaks at retention times of 2.81 and 2.96 min, displaying the accurate mass of 478.0813 (Figure 1b) and *m/z* 664.1454 (Figure 1c) for each peak, respectively.

The structure of M1 was identified by the data-dependent MS/MS spectra and fragments for further examination (Figure 1d). The ratio of *m/z* 391.05 suggested the base peak of the RosA moiety with sulfur residue. Given the ester bond cleavage, *m/z* 316.05 was attributed to the 2-oxyphenylpropanoyl moiety with the conjunction Cys, which implied that the Cys residue occurred on the right benzene moiety of RosA. In M2 (Figure 1e), which consisted of RosA with two Cys residues caused by ester bond cleavage, *m/z* 316.05 was attributed to the 2-oxyphenylpropanoyl moiety with the conjunction Cys, and *m/z* 280.04 suggested the loss of the caffeoyl moiety with the conjunction Cys. The ion fragmentation patterns of the adducts were similar to those of RosA, which confirmed our results.[29−31]

According to the 1,4-Michael addition reaction, Cys could add to the 2- and 2′-positions (Scheme 1) of quinone derived from RosA. Cys reacts with 4-MC on the 2-position.[10] Caftaric acid, which is similar to the left benzene moiety of the RosA ring, also reacts with 3SH on the 2′-position.[32] However, RosA

DOI: 10.1021/jf5044713
J. Agric. Food Chem. 2015, 63, 902−911

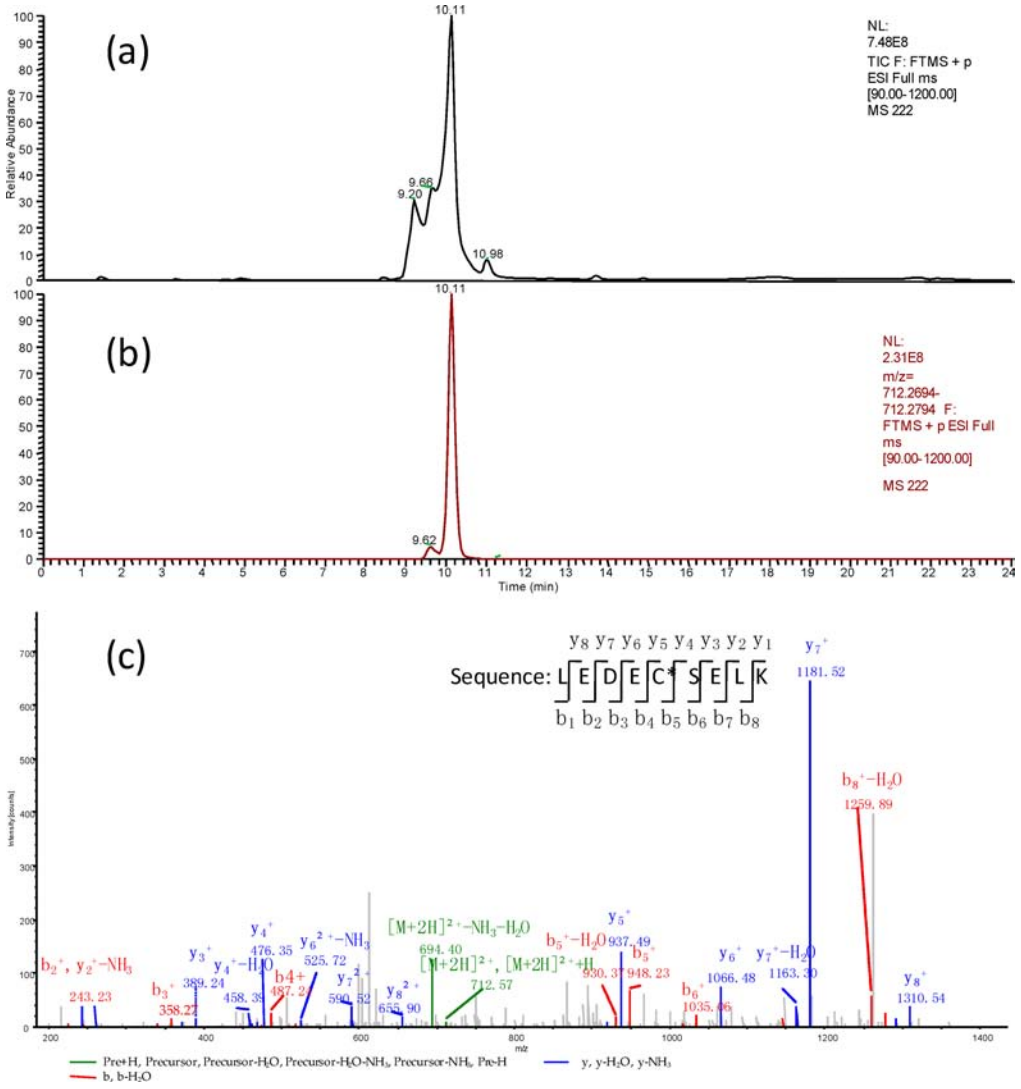

Figure 5. Nonapeptide (0.5 mM) and RosA (0.5 mM) incubated in maleic acid buffer (0.1 M) at pH 5.8, with $FeSO_4$ (0.1 mM) and H_2O_2 (30 mM) at 30 °C: (a) TIC of the incubated solution; (b) extracted chromatogram of M6 from TIC; (c) MS^2 fragmentation patterns of M6 show the structures of the products with fragmentation pathways noted.

reacted with 1-dodecanethiol to form three thiol adducts, in which the binding sites were on the 5-, 6-, and 2′-positions of the benzene rings.[33] Further research should be conducted to confirm the reaction position on the benzene moiety of the RosA ring.

Identification of Adducts Formed between GSH and Quinones Derived from RosA. M3, which was formed between GSH and quinones derived from RosA, was identified using the exact mass of the peak at a retention time of 10.23 min, and an accurate mass of 664.1413 was obtained (Figure 2b). Fragments were performed to identify the structure of M3 (Figure 2c). The ratio of m/z 502.09 suggested the 2-oxyphenylpropanoyl moiety with the conjunction of GSH. This finding indicates that the GSH residue occurred on the right benzene moiety of RosA. Given the fracture of the GSH thiol, m/z 391.05 was attributed to the base peak of RosA, and m/z 272.10 indicated the GSH residue with the removal of 2H. The ratio of m/z 353.10 suggested the loss of the glutamyl residue, and m/z 306.08 suggested the GSH residue.

Other quinones from 4-methylcatechol,[10] tocopherol,[34] and epigallocatechin gallate (EGCG)[35] were confirmed to undergo an adduct reaction with GSH. The structure of those adducts could not be understood because MS/MS ion fragmentation analysis was not accomplished in the current study. However, we can confirm that only one GSH reacted with the corresponding phenolics.

Identification of Adducts Formed between Peptides of Myosin and Quinones Derived from RosA. A series of trypsin-digested peptides of myosin with Cys residue were selected to evaluate the formation of adducts between quinones derived from RosA and myosin, and the positive mode was used for analyzing adducts. The results of peptides were CASLEK, HDCDLLR, and LEDECSELK, and RosA acted as a modification group on the Cys residues for analysis. Adducts were named M4, M5, and M6.

UHPLC-MS TICs for adducts in the solution are presented in Figures 3a, 4a, and 5a. As shown in Figures 3b, 4b, and 5b, the ions from the molecular masses of adducts (M4, M5, and M6) were determined to be $[M + H]^+$ = 1008.3835 m/z (retention time = 9.89 min), $[M + 2H]^{2+}$ = 615.2412 m/z (retention time = 10.23 min), and $[M + 2H]^{2+}$ = 712.2744 m/z (retention time = 10.11 min), respectively. The MS/MS spectra

J. Agric. Food Chem. 2015, 63, 902−911

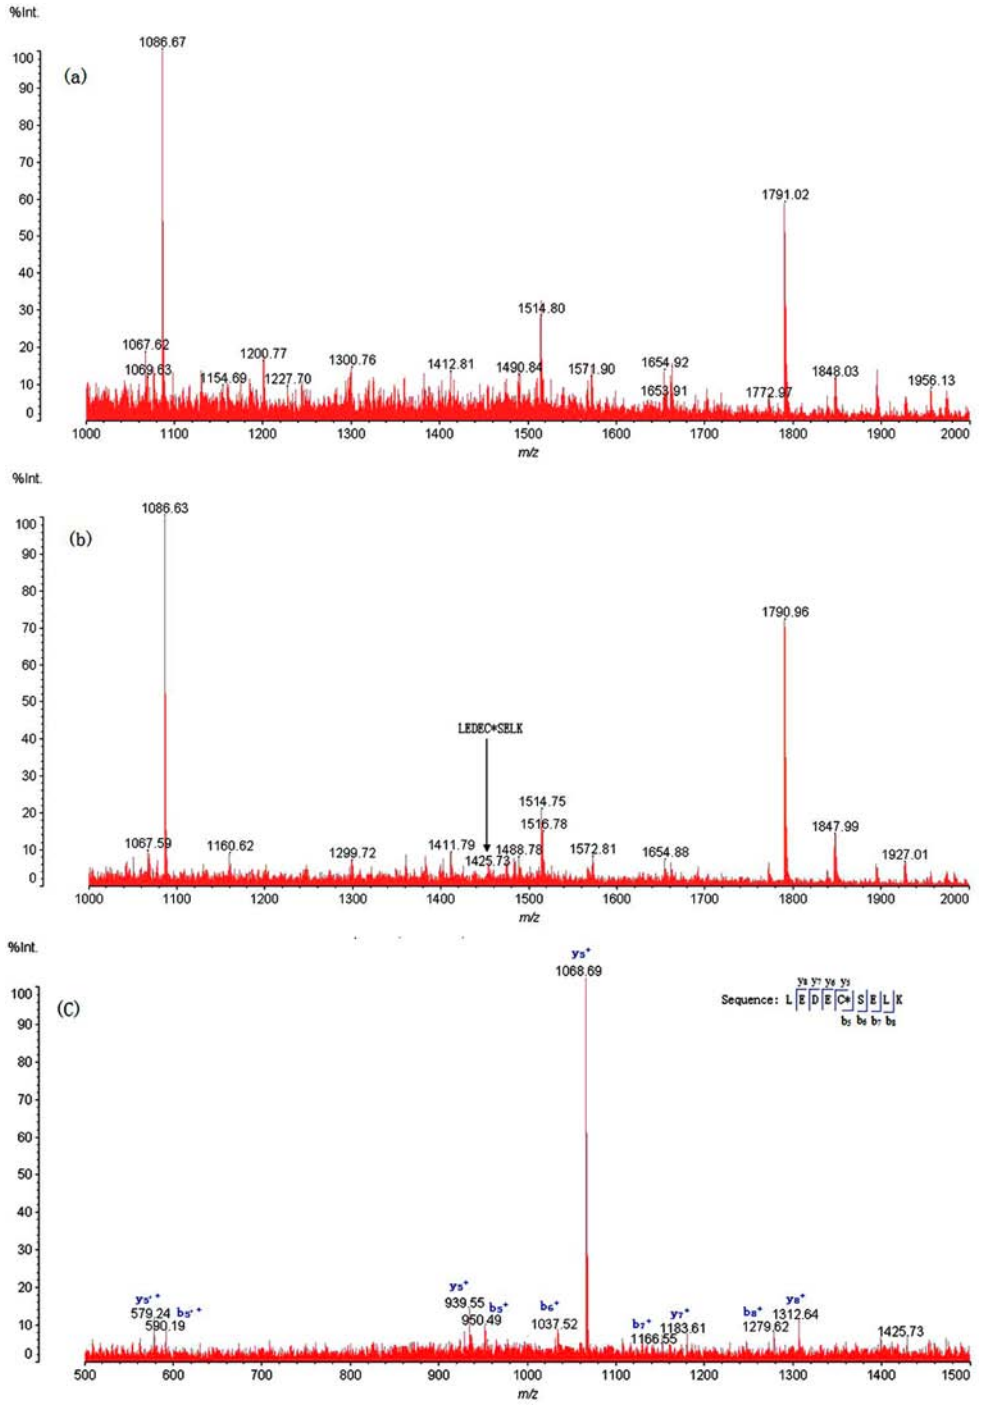

Figure 6. MALDI-TOF/MS spectrum of the tryptic digest of (a) myosin in MPI extracted from sample as control, (b) myosin in MPI extracted from sample with RosA (500 ppm), (c) MS/MS spectrum of m/z 1425.73 peptide (LEDEC*SELK) acquired with MALDI-TOF/TOF MS (C*, cysteines adducted with RosA).

and fragments were studied to identify the structures of M4, M5, and M6 (Figures 3c, 4c, and 5c), and Xcalibur 2.1.0 was used for analysis. Peptides were identified by peptide mass mapping using the Mascot database search program. We found the corresponding ions, from which we confirmed that RosA could react with peptides on the Cys residues.

The Cys−quinone adduct was determined to investigate the adduction reaction between MPI and 4-MC.[10] Rawel[38] found that whey proteins are modified by reactions with selected phenolic compounds using MALDI-MS. However, no study has identified and further analyzed the structures of adducts formed between RosA and peptides digested from myosin. To analyze the mechanism of adduction between phenolic compounds and proteins, structural identification of adducts is necessary.

However, quinones may also react with delta-amino groups located in the side chains of alkaline amino acids (e.g., lysine, proline, and arginine) to form the corresponding semialdehydes.[39,40] The outcome of this reaction is the carbonylation of that side chain, which may also influence the quality of muscle foods.[41,42]

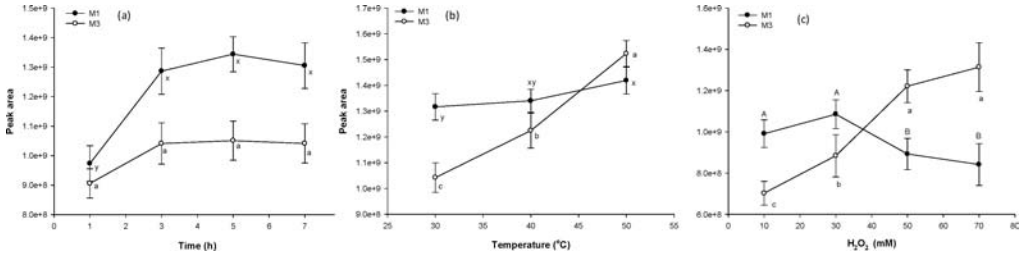

Figure 7. Stirring time effects of (a) oxidation reaction, (b) temperature, and (c) oxidation stress on the concentrations of M1 and M3. Data are expressed as the mean ± standard deviation (SD) (n = 3).

Identification of Adduction Reaction Sites between RosA and Myosin in MPI. To identify adduction sites between myosin and RosA, we performed MALDI-TOF/TOF analysis with PTM Finder. Figure 6a shows the spectrum of peptides digested from MPI sample as control. A Swissprot database search of the MS data yielded 11% sequence coverage with "MYH4-PIG". Figure 6b shows the spectrum of peptides digested from MPI sample with RosA, identifying the adduction peptide m/z 1425.73 LEDEC*SELK (C*, cysteines adducted with RosA). With the MS/MS spectrum of "LEDEC*SELK" in Figure 6c, we confirmed the peptide sequence of the observed fragment ions and demonstrated Cys949 was the adduction site. We herein, for the first time, managed to determine the accurate adduction site between RosA and myosin and to demonstrate the adduction between polyphenols and proteins during meat storage and processing.

Influence of Processing Condition on the Reactivity of RosA and Thiol Compounds. To understand the influence of processing conditions (stirring time, temperature, and oxidation stress) on the reactivity of RosA and thiol compounds, 1 mM Cys or 1 mM GSH was reacted with 1 mM RosA and incubated by chemical oxidation (30 mM H_2O_2). Adduct formation was determined by UHPLC-LTQ-Orbitrap with a proton detector for ion peak area. M2 was ignored because its contents were significantly lower than those of M1 and M3.

Different incubation times (1, 3, 5, and 7 h) were used. The effect of stirring time was examined, as shown in Figure 7a. The formation of M1 and M3 initially increased followed by a lag phase, and the maximum yield was observed at 3 h. In the study of adducts between oxidized grape phenolic compounds and odoriferous volatile thiol in grape wine, seven adducts showed similar increasing trends.[36] The chemical oxidation of RosA to yield peroxyl radicals results in the formation of quinones (Scheme 1).[37] Quinones, which are reactive electrophilic intermediates, are inclined to react easily with thiol compounds, including Cys and GSH, to form thiol−quinone adducts by 1,4-Michael addition reactions. However, the yield rate of M1 was faster than that of M3 from 1 to 3 h. Some similar findings were reported with EGCG[35] or quercetin,[43] in which Cys was more reactive than GSH. Nikolantonaki[44] explained that Cys, a primary thiol, is expected to have less sterically hindered sulfhydryl groups than GSH thiols; thus, Cys has greater reactivity with the quinones.

The effect of different temperatures on the formation of M1 and M3 was investigated. As shown in Figure 7b, two adducts presented an increasing trend as the temperature increased from 30 to 50 °C. The generation of M1 significantly increased with temperature (ion intensity of M1 increased by 46.15%), whereas that of M3 changed more gradually from 30 to 50 °C (M3 increased by only 7.58%). Besides accelerating RosA to quinone, an increase in temperature converted the autoxidation of thiol compounds to polymerization (Scheme 1, reaction I), which could hinder 1,4-Michael addition reactions to form the thiol−quinone adduct. Given its nucleophilic properties,[44] Cys autoxidation reacts faster than GSH, which hinders the formation of adduct 1. Thus, the addition reaction also increased with rising temperature. The order of the reactivity of the addition reaction was GSH > CYS.

The effect of different types of oxidation stress on the formation of M1 and M3 is investigated in Figure 7c. With increasing oxidation stress, M3 demonstrated an increasing trend. Growing oxidation stress can increase the oxidation of RosA to quinone and improve the addition reaction.[45] M1 showed a decreasing trend with higher oxidation stress (50−70 mM). Besides accelerated oxidation of RosA, high H_2O_2 concentration also induced the polymerization reaction of Cys to form the Cys−Cys dimer (Scheme 1, reaction I), which could inhibit M1 formation. Considering the less sterically hindered sulfhydryl group, M1 itself could further oxidize or polymerize, thereby causing the decreasing trend of M1. These findings indicate that oxidation potentials played an important role in adduct formation, and sulfhydryls of different molecular weights exhibited different reaction capacities to form adducts.

Overall, we successfully identified the structures of adducts between RosA and thiols under chemical oxidation conditions. The amount of adducts was regulated by chemical reaction conditions including stirring time, temperature, and oxidation stress. We further determined the accurate adduction site between RosA and myosin in meat samples. In addition, polyphenols and proteins were subjected to adduction reaction during meat storage and processing. Further studies are necessary to investigate how these adducts regulate the quality and nutritional value of food products in processing.

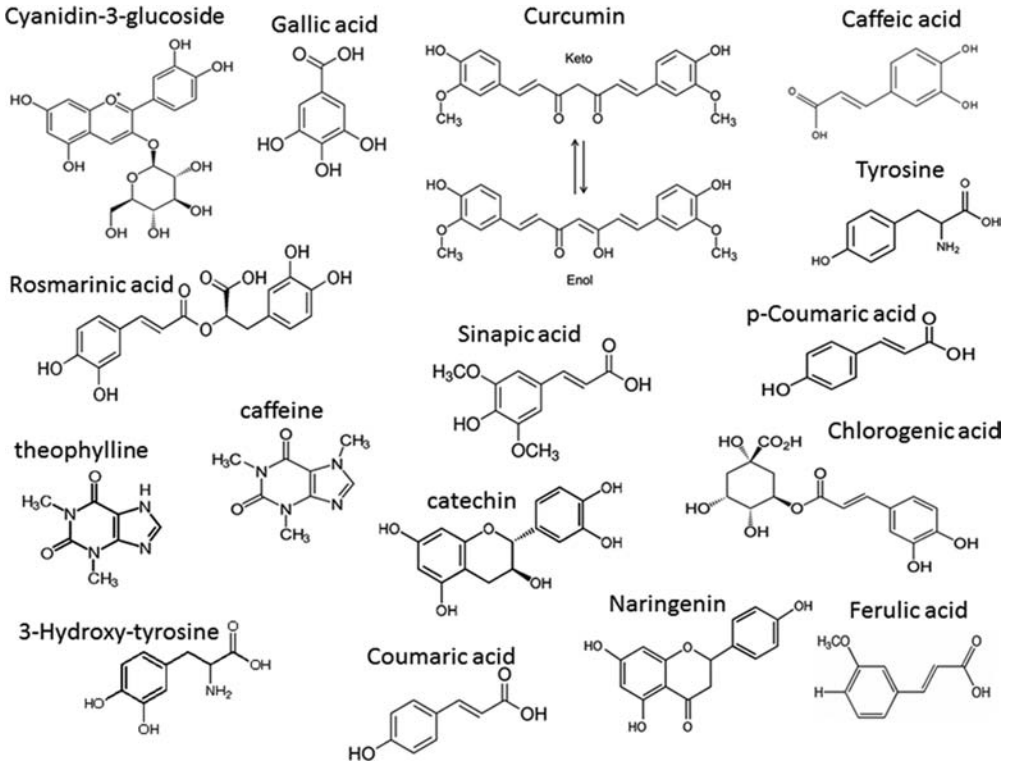

Figure 1. Molecular structures of phenolic compounds tested in the present experimental work.

bind weakly to nanoparticle surfaces and eventually desorb or exchange with bulk solution, affecting the stability of colloidal suspensions. In addition, processes to coat nanoparticles are often cumbersome, time-consuming, expensive, and characterized by low yield, limiting massive productions. Finally, nanoparticle coating reduces the average magnetic moment of the material by introducing a nonmagnetic component in the final nanoparticle.[4,10] Therefore, magnetic nanoparticles, to be a real competitor for standard technologies, need to respond to specific requirements, that is, colloidal stability, proper surface reactivity, and superparamagnetism.

Recently, we developed a novel synthetic procedure for nanostructured superparamagnetic material in the size range around 10 nm, constituted of stoichiometric maghemite (γ-Fe_2O_3) and showing peculiar surface chemical behavior, called surface active maghemite nanoparticles (SAMNs).[11,12] SAMNs present a high average magnetic moment and high water stability as colloidal suspensions without any superficial modification or coating derivatization. Because of their unique physical and chemical properties, these naked iron oxide nanoparticles are currently used to immobilize various biomolecules.[13−16] Biomolecule immobilization is carried out in water, without any chemical reactant, and the total derivatization process is mild, minimizing alteration/oxidation of ligands, low cost, ecologically green, and reversible. These peculiarities make SAMNs an elective competitor to standard methods for biomolecule purification.

In the present work, the binding properties of SAMNs were tested with different ligands of high interest in the pharmaceutical and food industries. Interestingly, among tested molecules, SAMNs displayed high specificity for curcumin binding.

Curcumin (IUPAC name, (1*E*,6*E*)-1,7-bis(4-hydroxy-3-methoxyphenyl)-1,6-heptadiene-3,5-dione; CAS Registry No. 458-37-7) is a homodimer of feruloyl-methane, containing a methoxy group and a hydroxyl group, a heptadiene with two Michael acceptors, and an α,β-diketone (see Figure 1).

Curcumin has shown significant efficacy as a chemopreventive in cell culture studies, as it elicits efficacy in various clinical studies.[17,18] Numerous experimental studies on in vitro and in vivo activities of this compound have been reported.[19] A special attribute of curcumin resides in its antioxidant potency,[20] namely, the ability to scavenge free radicals in blood and body tissues, helping the prevention of various cardiovascular, viral, and other chronic diseases.[21] In particular, curcumin's ability to affect gene transcription and induce apoptosis in preclinical models advocates its potential utility in cancer chemoprevention and chemotherapy.[22]

In *Curcuma longa* rhizome, a combination of substances called curcuminoids, namely, curcumin, demethoxycurcumin, and bis-demethoxycurcumin, can be found, curcumin being the major compound.

In the present work naked SAMNs were successfully applied for the purification of curcuminoids, and curcumin, from extracts of *C. longa* rhizome.

MATERIALS AND METHODS

Materials. Chemicals were purchased at the highest commercially available purity, and they were used without further treatment. Iron(III) chloride hexahydrate (97%), sodium borohydride ($NaBH_4$), and tetramethylammonium hydroxide ($N(CH_3)_4OH$) were obtained from Aldrich (Sigma-Aldrich, Italy), as well as catechin, tyrosine, hydroxytyrosine, ferulic acid, coumaric acid, rosmarinic acid, naringenin, curcumin, and cyanidin-3-glucoside.

A mixture of curcuminoids (curcumin, demethoxycurcumin, and bis-demethoxycurcumin) (purity ≥ 94.0%), being curcumin ≥80.0% (by TLC), was obtained from Aldrich (cod. C7727, Sigma-Aldrich, Italy).

DOI: 10.1021/jf504624u
J. Agric. Food Chem. 2015, 63, 912−920

The cultivations of *Eryngium fetidum* and *Curcuma longa* were carried out in a greenhouse in the experimental farm of the State University of São Paulo 'Júlio de Mesquita Filho' in Botucatu, São Paulo, Brazil (22°53′09″ S latitude, 48°26′42″ W longitude, and at 804 m altitude), with harvest at the optimal period. The soil used in the experiment showed the following characteristics: pH 6.3; M.O = 23 g dm^{-3}; P = 60 mg dm^{-3}; H + Al = 19 mmol dm^{-3}; K = 7 mmol dm^{-3}; Ca = 44 mmol dm^{-3}; Mg = 25 mmol dm^{-3}; SB = 77 mmol dm^{-3}; CTC = 95, V% = 80; B = 0.31 mg dm^{-3}; Cu = 2.2 mg dm^{-3}; Fe = 26 mg dm^{-3}; Mn = 2.4 mg dm^{-3}; Zn = 5.3 mg dm^{-3}.

Instrumentation. Optical spectroscopy measurements were performed in 1 cm quartz cuvettes using a Cary 50 spectrophotometer (Varian Inc., Palo Alto, CA, USA). Transmission electron microscope (TEM) micrographs were taken on a JEOL 2010 operating at 160 kV with a point-to-point resolution of 1.9 Å. A series of Nd−Fe−B magnets (N35, 263−287 kJ/m3 BH, 1170−1210 mT flux density by Powermagnet, Germany) was used for the magnetic driving of nanoparticles.

Synthesis of Surface Active Magnetic Nanoparticles. A typical synthesis of nanoparticles was already described[11,12] and can be summarized as follows: $FeCl_3{\cdot}6H_2O$ (10.0 g, 37 mmol) was dissolved in Milli-Q grade water (800 mL) under vigorous stirring at room temperature. $NaBH_4$ solution (2 g, 53 mmol) in ammonia (3.5%, 100 mL, 4.86 mol mol^{-1} Fe) was quickly added to the mixture. Soon after the reduction reaction occurrence, the temperature of the system was increased to 100 °C and kept constant for 2 h. Then, the material was cooled at room temperature and aged in water, as prepared, for another 24 h. This product was separated by imposition of an external magnet and washed several times with water. This material can be transformed into a red-brown powder (final synthesis product) by drying and curing at 400 °C for 2 h. The resulting nanopowder showed a magnetic response upon exposure to a magnetic field. The final mass of product was 2.0 g (12.5 mmol) of Fe_2O_3, and a yield of 68% was calculated.

The nanoparticulated resulting material was characterized by Mössbauer spectroscopy, FT-IR spectroscopy, high-resolution transmission electron microscopy, XRD, and magnetization measurements[12] and was constituted of stoichiometric maghemite (γ-Fe_2O_3) with a mean diameter (d_{av}) of 11 ± 2 nm, which can lead to the formation, upon ultrasound application in water (Bransonic, model 221, 48 kHz, 50 W), of a stable colloidal suspension, without any organic or inorganic coating or derivatization. The surface of these bare maghemite nanoparticles shows peculiar binding properties and can be reversibly derivatized with selected organic molecules. We called these bare nanoparticles surface active maghemite nanoparticles (SAMNs).

Quantitative Determination of Free Phenolic Acids and Curcuminoids by HPLC. Curcuminoids, chlorogenic acid, ferulic acid, *p*-coumaric acid, caffeic acid, gallic acid, cyanidin-3-glucoside, and synaptic acid were separated and quantified using an HPLC (model X-LC, Jasco, Japan). The liquid chromatography apparatus consisted of a PU-2080 pump, an MD-2015 diode array detector, an AS-2055 autosampler, and a CO-2060 column oven. ChromNAV chromatography software was used for chromatographic data analysis. The separation of phenolic acids was obtained on a Tracer Extrasil ODS2 (5 mm, 250 mm, Teknokroma, Spain) operating at room temperature. The mobile phase consisted of formic acid, pH 2.8 (A), and acetonitrile (B). Elution gradient was carried out in 50 min, and the flow rate was 0.8 mL min^{-1} (10−80% B). All standards were dissolved in 50% ethanol, and the calibration curves were built with standard concentrations ranging from 0.06 to 60 mg L^{-1}. Two wavelengths (325 and 310 nm) were used to detect phenolic acids. Measurements at 325 nm were used for the identification of chlorogenic acid, caffeic acid, and ferulic acid. The identification of *p*-coumaric acid was performed at 310 nm.

HPLC determination of curcuminoids (bis-demethoxy-curcumin, demethoxy-curcumin, and curcumin) was carried out according to a procedure derived from that of He with some modification.[23] A UHPLC system (Ultimate 3000 BioRS, Dionex-Thermo Fisher Scientific Inc., USA) equipped with a diode array detector was used. An Ace 5 C18 (Advanced Chromatography Technologies, UK) column (5 μm, 25 cm × 4.6 mm) was used for curcuminoid analysis, at 48 °C. The gradient profile of the mobile phase, (A) water (0.25% acetic acid, Mallinckrodt) and (B) acetonitrile (HPLC grade, Mallinckrodt), was as follows: 0−17 min, 40−60% B; 17−32 min, 60−85% B; 32−38 min, 85% B; 38−40 min, 85−40% B; 40−45 min, 40% B; the flow rate was 0.5 mL min^{-1}. The injection volume was 20 μL (full loop). All samples were filtered through 0.22 μm membrane filters before the injections. Curcuminoid peaks were identified by retention times and injections tests with standards (curcumin, demethoxy-curcumin, and bisdemethoxy-curcumin).

RESULTS

A list of biomolecules of interest for the pharmaceutical and food industries, namely, catechin, tyrosine, hydroxytyrosine, ferulic acid, coumaric acid, rosmarinic acid, naringenin, curcumin, and cyanidin-3-glucoside, was screened to test the recognition properties of SAMN surface toward different compounds. Thus, the binding efficiency and reversibility on SAMNs were evaluated by UV−vis spectroscopy. Moreover, with the aim of broadening the applicability spectrum of SAMNs in the field of biomolecule purification, a general approach for predicting SAMN suitability for selective magnetic separation of compounds of interest from complex matrices was studied. Selected molecules present chemical features potentially able to anchor, by metal chelation, on iron(III) available sites on the SAMN surface, the presence of which was recently demonstrated.[16] The comparison of the interactions of different molecular functionalities with SAMNs, from binding to desorption, allowed the individuation of chemical features required for stable and, at the same time, reversible binding on the SAMN surface.

Structural and magnetic properties of as-prepared iron oxide nanoparticles were investigated by zero-field and in-field Mössbauer spectroscopy and SQUID magnetization measurements.[12] In-field Mössbauer spectroscopy was used due to its unique ability to distinguish between structurally isomorphous maghemite and magnetite and also to quantify the distribution of cations in tetrahedral (T) an octahedral (O) sites of these spinel structures. The in-field Mössbauer spectrum, collected at 5 K in an external magnetic field of 5 T, corresponded with that reported for maghemite. Taking into account the maghemite stoichiometric formula, given by $(Fe^{3+})^{T}(Fe^{3+}_{5/3}\ o_{1/3})^{O}O_4$, where "o" stands for vacancies, the prepared maghemite was perfectly stoichiometric.

To monitor the magnetic response of SAMNs, hysteresis loops were measured at 2 and 300 K. At 2 K, the isothermal magnetization curve showed hysteresis with the values of coercivity and remanent magnetization comparable with those reported for bulk maghemite. As prepared SAMNs showed a maximum magnetization of 71.4 Am^2 kg^{-1}, which was similar to that of bulk maghemite[12] and higher than values reported for other magnetic nanoparticles in the literature.[24] The value of the maximum magnetization at 7 T was slightly lower than that reported for bulk maghemite, which was caused by a nanometer size of the particles. The hysteresis loop at 2 K was symmetric (i.e., equal values of positive and negative coercivity and positive and negative remanent magnetization), and no exchange bias phenomenon was present. Thus, the degree of magnetic disorder occurring at the surface layers of nanoparticles was not significant. Some misalignment of the surface atomic magnetic moments of each particle is present, in accordance with in-field Mössbauer data; however, it does not crucially govern the overall magnetic response of the system.

DOI: 10.1021/jf504624u
J. Agric. Food Chem. 2015, 63, 912−920

From the application point of view, it is important that a very high magnetization is achievable already at very low applied fields at room temperature. Thus, we can conclude that the prepared magnetic particles would act as an excellent magnetic carrier due to their well-defined stoichiometric structure, single-phase character, suitable magnetic properties, and uniform size distribution. Moreover, as a unique aspect of the preparation procedure, the particles exhibit colloidal behavior with no indications of the sedimentation and/or aggregation process even within several months.

Tentatively, phenolic compounds were incubated with aqueous suspensions of SAMNs, and the resulting nanoconjugates were extensively washed with water, by alternating magnetic separations, to eliminate loosely bound molecules. Finally, the release of the phenolic compounds from the nanoconjugate was tested under different conditions. All tested compounds present at least one phenol ring in their molecular structure (see Figure 1); thus, the whole process was easily followed by UV−vis spectroscopy. The characteristic wavelength of maximum absorbance and the molar extinction coefficients of tested compounds are reported in Table S1 in the Supporting Information. Because the focus of the present paper is providing a purification strategy for real applications, we aimed at obtaining the best compromise between yield and purity of phenolic compounds, minimizing the operations during the purification steps. For this last reason we avoided any other modification of the extracting and binding solutions, such as pH or ionic strength modifications.

First, because the tested substances could possibly be easily oxidized at room temperature, their stability was, as well, assessed by UV−vis spectroscopy. Optical spectra were acquired within 24 h, and the residual concentration of phenolics, with respect to freshly prepared solutions, is reported in Table S1 (in the Supporting Information, last column). Experimental data indicated that the stability of tested substances was acceptable, and, anyway, the magnetic purification tests carried out with SAMNs was performed within 2 h.

The tested phenolic compounds (10.0 μM) were incubated in the presence of SAMNs (0.5 g L^{-1}), and experimental results evidenced different behaviors in terms of efficiency and reversibility of the binding. In all of the explored cases, phenolic−SAMN nanoconjugates showed remarkable stability and no oxidation of bound phenolics was observed.

It is known that catechols and ene-diols, bearing multiple hydroxyl groups, as well as carboxylic groups, are able to form complexes with transition metals and metal oxide-based nanomaterials.[25,26] Recently, we demonstrated the presence of available under-coordinated iron(III) atoms on the surface of SAMNs,[27] and these phenolic ligands can lead to the formation of very stable complexes, as they convert under-coordinated iron atoms on the nanoparticle surface to a bulk-like lattice structure.[28]

Interestingly, most of the tested phenolic substances led to the formation of irreversible complexes with SAMNs, in agreement with Rajh, who reported, with bidentate ene-diol ligands, the formation of very stable complexes with metal oxide nanoparticles.[29] In fact, the protocol used for releasing ligands from the nanoparticle surface, consisting of an incubation of the complex in 0.5 M NH_4OH,[27] was inefficient with the tested group of molecules (see Table 1).

As an example, a remarkable binding efficiency on the SAMN surface was shown by catechin, and the subsequent incubation

Table 1. Binding and Release Efficiencies of Tested Compounds on the Surface of SAMNs[a]

[a]Incubations were performed with 50.0 μM of the tested compound in the presence of 1.0 g L^{-1} SAMNs. The releasing process from the nanoparticles was performed with 99.6% ethanol. Values are the mean of three experiments.

of the complex of SAMNs with catechin (SAMN@catechin) in 99.6% ethanol led to the release of only 4.7 ± 1.1% of the bound molecule, indicating that catechin formed stable complexes on the iron oxide surface, as it completed the dangling boundaries of truncated crystalline structure of the nanoparticle.[30] Moreover, the comparison between the behavior of tyrosine and 3-hydroxytyrosine highlighted the role of the catechol structure, with respect to simple phenolic groups. The catechol structure was responsible for a 160-fold increase of substance binding with respect to simple phenolic rings. As in the case of catechin, the catechol structure of 3-hydroxytyrosine generated an irreversible binding, and the incubation of its SAMN complex in 99.6% ethanol led to a releasing yield of 4.2 ± 0.6% (n = 5).

The strong intimate interaction between phenolics and the surface iron oxide nanoparticles was evidenced by UV−vis spectroscopy. The electronic absorption spectrum of bare SAMNs, acquired in water, showed a wide band with a maximum at about 400 nm (Figure 2, black line) characterized by an extinction coefficient of 1520 $M^{-1}cm^{-1}$, expressed as Fe_2O_3 molar concentration. Differently, the SAMN@catechin spectrum was characterized by a peak at 440 and a shoulder at 520 nm (see Figure 2, red line). The observed red shift and

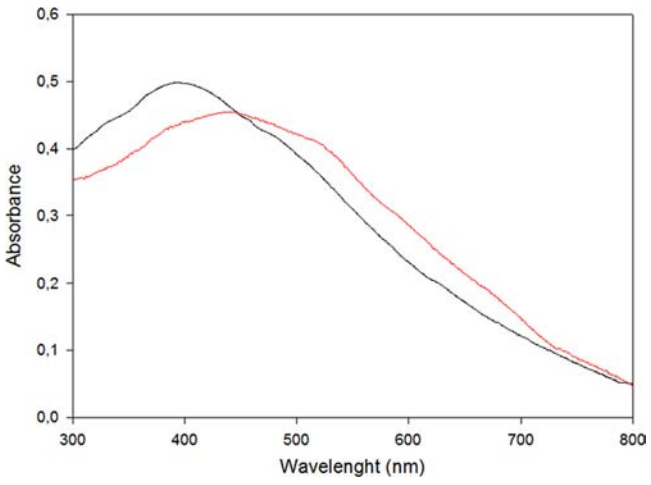

Figure 2. UV−vis spectra of naked and catechin-coated SAMNs (SAMN@catechin): (black line) SAMN; (red line) SAMN@catechin. Spectra were acquired in water. The concentrations in suspension were 40 and 200 μg mL^{-1} for SAMN and SAMN@catechin, respectively.

J. Agric. Food Chem. 2015, 63, 912−920

change in the absorption envelope (shape) of the SAMN spectrum upon catechin binding was not surprising. A similar phenomenon was observed with other biomolecules following their interaction with the nanoparticle surface.[14] We suggest that the recorded red shift in the absorption spectrum of modified nanoparticles was due to the excitation of localized electrons from the surface modifier to the conduction band of iron oxide nanoparticles.[29] In the present case, it was due to the presence of catechin on the SAMN surface.

Moreover, the SAMN@catechin complex was studied by electron transmission microscopy (see Figure 3). TEM

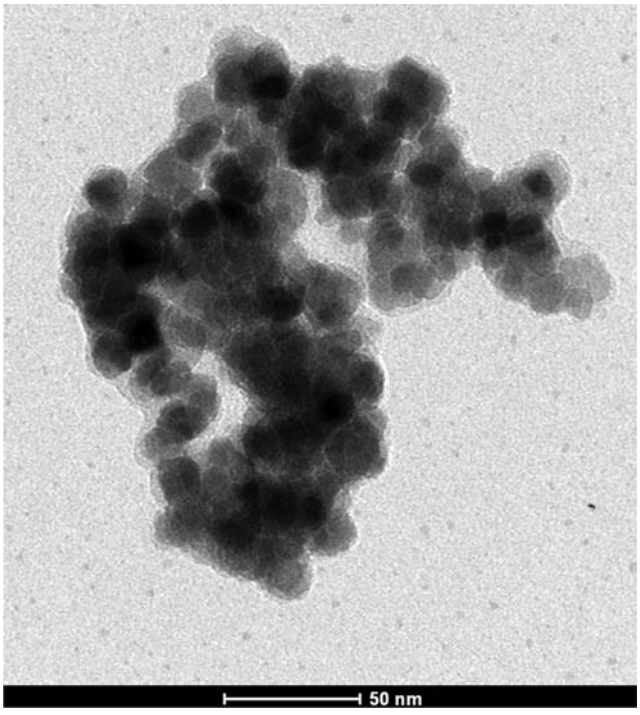

Figure 3. TEM micrograph of SAMN@catechin complex.

microscopy images of the SAMN@catechin complex indicated the presence of an organic matrix, forming a shell of about 2.0 nm around iron oxide nanoparticles, characterized by a lower electron density, attributable to catechin molecules layering on the SAMN surface. The resulting SAMN@catechin complex was extremely stable and, if stored at 4 °C, catechin remained firmly bound to the iron oxide nanoparticle surface for at least 12 months.

Considering the binding behavior of similar molecules (ferulic, coumaric, and rosmarinic acid), we observed the best binding efficiency on SAMN surface by rosmarinic acid, which presents two catechol moieties, with free hydroxyl groups, at the extremities of the organic chain (see Figure 1), therefore confirming that catechol-containing ligands showed a more efficient anchoring function on the SAMN surface with respect to simple phenol moieties and single-carboxylate ligands. Furthermore, the presence of a methoxy substituent ($-OCH_3$) in the aromatic ring, such as in the molecule of ferulic acid, led to a considerably less efficient ligand binding.

Narigenin and curcumin, presenting a keto−enol functionality, showed very good binding proclivity toward the SAMN surface. In particular, curcumin appeared as one of the best ligands for the SAMN surface (Table 1), confirming the literature reporting that curcumin has a remarkable ability to create stable complexes with iron(III).[31] In addition, its complex with SAMN (SAMN@curcumin) was completely reversible, and the molecule was completely released from the nanoparticle surface by incubation in 99.6% ethanol (see Table 1).

It should be mentioned that different solvent mixtures, based on ethanol, acetic acid, and ammonia, were tested for phenolic release from the SAMN surface (data not shown). Some of them were already used for controlling SAMN complex formation.[13] Ethanol was chosen for subsequent experiments aimed at the release of phenolic compounds from the SAMN surface. The use of ethanol for releasing oleic acid from iron oxide nanoparticles was already reported in the literature.[32]

Comparable binding efficiency on SAMNs with respect to curcumin was observed for cyanidin-3-glucoside, which presents a sugar ring as a distinctive chemical feature, a resorcinol, and a catechol moiety.

As a general result, substances characterized by catechol and/or keto−enol functionalities were able to efficiently bind on the SAMN surface, even if, at the same time, no easy general strategy for compound release from the nanoparticle surface was individuated. For comparison, as negative controls, two alkaloid molecules were tested, namely, caffeine and theophylline (Figure 1), both presenting no chemical features particularly prone to iron(III) chelation. Even at high concentration (1 mM), the incubation of these two substances with SAMNs did not lead to significant complex formation. In both cases, a negligible binding efficiency, with respect to previously tested phenolics, was observed (see Table 1).

As a first test on a real sample, SAMNs were subsequently used for the magnetic separation of biomolecules in water−ethanol extracts of *Eryingium fetidum* L. (Apiaceae family). *E. fetidum* is an aromatic plant, used as a spice and medicinal plant in tropical regions. The leaves are used to treat several diseases, such as fever, pains, and hypertension.[33−35] This species is also an important item in the perfumery and cosmetic industries due to the properties of its essential oil.[36,37] Several studies have reported the presence of phenolic compounds in leaves of *E. fetidum*.[38,39] However, researchers mainly focused their attention on the essential oil, and scarce information is available on other phytochemicals,[40] such as phenolic compounds.

The HPLC profiles of phenolic acids extracted from *E. fetidum* in 50% ethanol showed peaks attributable to chlorogenic, ferulic, *p*-coumaric, caffeic, gallic, and sinapic acid. All of these compounds may form complexes with undercoordinated iron(III) on the SAMN surface (see Figure 1). Ethanolic extracts of *E. fetidum* leaves (20 mg mL^{-1}) were incubated in the presence of 0.5 g L^{-1} SAMNs to test binding specificities. After magnetic separation, SAMN-bound molecules were removed by incubation in 99.6% ethanol, and supernatants were analyzed by HPLC for the determination of phenolic acids. No enrichment of a specific phenolic acid was evidenced, and the chromatographic profile was unaltered with respect to that of the untreated sample, demonstrating that phenolic acids were purified by magnetic purification with SAMNs, but without any specificity (see Figure S1 in the Supporting Information). This behavior can be attributed to the concomitant presence of the catechol function on most of the phenolic acids in the extract. Molecules bearing chemical features with similar affinity toward iron(III) chelation compete for complex formation with the SAMN surface, without showing particular selectivity.

Curcumin Purification from *Curcuma longa* Rhizome. Experimental results showed that curcumin stands out, among all tested molecules, in terms of both binding efficiency on SAMNs and complex reversibility. Therefore, the magnetic separation of this molecule by SAMNs was tested on real samples of *C. longa* rhizome.

HPLC analyses were performed to evaluate the efficiency of the magnetic purification and isolation yield of curcumin and curcuminoids as a function of experimental conditions and nanoparticle concentrations. As a control, commercial curcuminoid mixture, purified from *C. longa* rhizome at the highest commercial purity available, namely, a combination of curcumin, demethoxy-curcumin, and bis-demethoxy-curcumin, was subjected to chromatographic analysis.

Rhizomes of *C. longa* collected after 65 days of cultivation were manually finely ground and then dried at 45 °C in a ventilated oven. Dried and powdered *C. longa* rhizome was extracted (20 mg mL^{-1}) with different water−ethanol mixtures, where ethanol concentration was in the 0−100% range.

Then, the extracts were incubated with SAMNs, in the 1.25−10.0 g L^{-1} concentration range. After 1 h of incubation, SAMNs and the corresponding bound material were magnetically recovered. Then, SAMNs were resuspended in 99.6% ethanol for the release of bound curcuminoids. After 1 h of incubation and a further magnetic separation, SAMNs were finally removed, and the resulting supernatants were collected and characterized by HPLC.

As reported in the literature,[41] we found that curcumin represented the main curcuminoid compound in the *C. longa* rhizome (87.02% curcumin, 2.08% demethoxy-curcumin, and 10.90% bis-demethoxy-curcumin). As shown in Figure 4, the isolation yield of curcuminoids increased with ethanol concentration used during the extraction and depended, as well, on SAMN concentration. The best results were observed by extraction in 99.6% ethanol and using 10 g L^{-1} SAMNs for the magnetic purification. Under these conditions it was possible to isolate >80% of curcuminoids from *C. longa* rhizome extracts, namely, 155.37 mg L^{-1}. Notwithstanding the highest ethanol concentration (99.6%) represented the worst binding condition on nanoparticles, as it is used for the release of curcuminoids from SAMNs, it represented the best extraction condition in terms of yield. According to the le Chatellier principle, the high concentration of curcuminoids in the extract strongly favored the binding to the formation of the complex with nanoparticles; thus, under these conditions, curcuminoids successfully competed for SAMNs in the presence of extraction contaminants. Conversely, when curcuminoid-loaded nanoparticles were incubated in 99.6% pure ethanol, the equilibrium leads to the dissociation of the complexes.

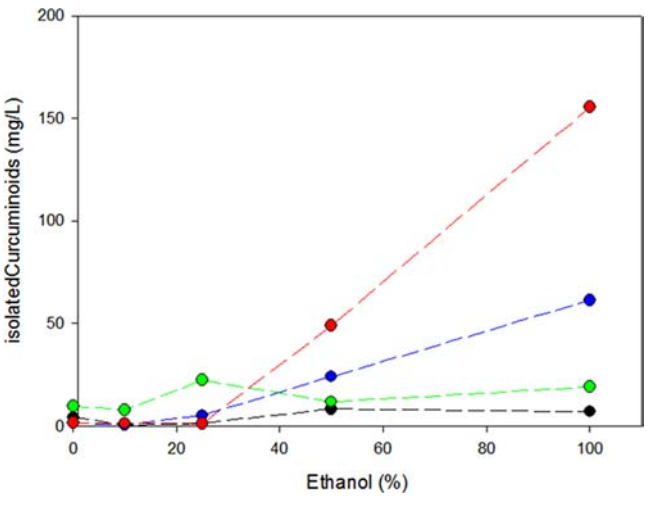

Figure 4. Isolation yield of curcuminoids as a function of ethanol and SAMN concentrations. Powdered *C. longa* rhizome was extracted (20 mg mL^{-1}) with different water−ethanol mixtures, and the resulting solutions were incubated with SAMNs. Recovered SAMNs and the corresponding bound material were resuspended in 99.6% ethanol for the release of bound molecules. SAMN concentrations used for the magnetic purification of curcuminoids were (black symbols) 1.25 g L^{-1}, (green symbols) 2.5 g L^{-1}, (blue symbols) 5.0 g L^{-1}, and (red symbols) 10.0 g L^{-1}.

Moreover, the curcumin purification yield, with respect to the total amount of curcuminoids, obtained from the magnetic purification, was assessed by comparison of chromatographic peak areas by HPLC. In Figure S2 in the Supporting Information the fractions of purified curcumin are reported as a function of ethanol concentration, for all of the tested concentrations of SAMNs. The highest yield of curcumin, with respect to total curcuminoids, was observed using 25% ethanol for extraction. Interestingly, the combination of 25% ethanol for *C. longa* rhizome extraction and 1.25 g L^{-1} SAMNs for magnetic purification, which is the lowest nanoparticle concentration tested, led to the highest curcumin/curcuminoid ratio (>80.0%). For other tested ethanol and SAMN concentrations, the curcumin/curcuminoid ratio was about 65%.

The proposed procedure for curcumin purification can be summarized as follows: dried powder of *C. longa* rhizome (10 g) was extracted with 99.6% ethanol (600 mL) with the aid of 5 min of sonication (Bransonic, model 221, 48 kHz, 50 W).

Control experiments showed that the extraction of the same amount of powdered *C. longa* rhizome with ethanol led to the isolation, after drying in a rotary evaporator, of 50.7 mg g^{-1} of a residual oil. As reported in the literature, *C. longa* rhizome contains a considerable amount of essential oil; thus, the separation of curcuminoids from this hydrophobic matrix represents a problematic task.[42]

After decantation (10 min), the supernatant was incubated with SAMNs (10 g L^{-1}) for 1 h, under stirring, at room temperature. The nanoparticle-containing suspension was subjected to magnetic separation, and the resulting supernatant was eliminated. The release of curcuminoids bound to nanoparticles was accomplished by subsequent incubation of SAMN@curcumin in 99.6% ethanol (600 mL) for 1 h, at room temperature. Released curcumin in ethanol was dried under low vacuum (100 torr) in a rotary evaporator at 40 °C, leading to 3.95 mg g^{-1} of a yellow powder, consisting of 64.0% curcumin, 17.0% demethoxy-curcumin, and 19.0% bis-demethoxy-curcumin (by HPLC), with a purity >98% with respect to the total dry mass of the extract. The total process can be accomplished within 80 min. The HPLC profile of curcuminoids after magnetic separation by SAMNs is shown in Figure 5. The amount of purified curcuminoids from *C. longa* extracts well agreed with literature values,[43] and a yield of 45% with respect to its total content in the first ethanol extract was calculated. It should be mentioned that the total amount of curcuminoids, as well as the curcumin/curcuminoids ratio, will depend on the original composition of the *C. longa* rhizome sample.

DISCUSSION

Novel maghemite nanoparticles (SAMNs) were studied for phenolic binding and were applied for the purification of curcumin from *C. longa* rhizome extracts. The peculiar properties of the SAMN surface, due to the presence of under-coordinated iron(III) sites, confer high specificity to select iron chelating molecules from complex matrices. These nanoparticles easily match with interests in biotechnology, revealing different surface characteristics from other reported magnetic nanoparticles, justifying the peculiar behavior of SAMN suspensions, their high colloidal stability in aqueous solutions, and their ability to reversibly adsorb biomolecules. These features led us to apply SAMNs as a novel tool to isolate and purify substances from natural matrices, which could be attractive for the pharmaceutical and food industries. SAMNs showed high specificity to reversibly bind curcumin and were used for isolating this biomolecule from *C. longa* rhizome extracts.

The present paper envisages new possibilities offered by SAMNs for the isolation of curcumin and, moreover, proposes an easy procedure based on magnetic purification of curcuminoids, which could be easily modified for scaling-up, moving from a laboratory scale to an industrial level. The complete purification process, from SAMN synthesis to application, is fast and ecologically green, avoiding the use of large volumes of solvents, as typically required by elution in standard chromatographic methods, and the ethanol employed for extraction is easily recyclable. As well, SAMNs can be easily regenerated after the purification process by sonication in water and reutilized for further purification cycles. Therefore, the proposed process is cost-effective and does not involve production of wastes, being based on green chemistry processes, suitable for scaling-up. In the present case an estimated yield of 45% of pure curcuminoids, characterized by a purity >98%, was obtained from *C. longa* rhizomes.

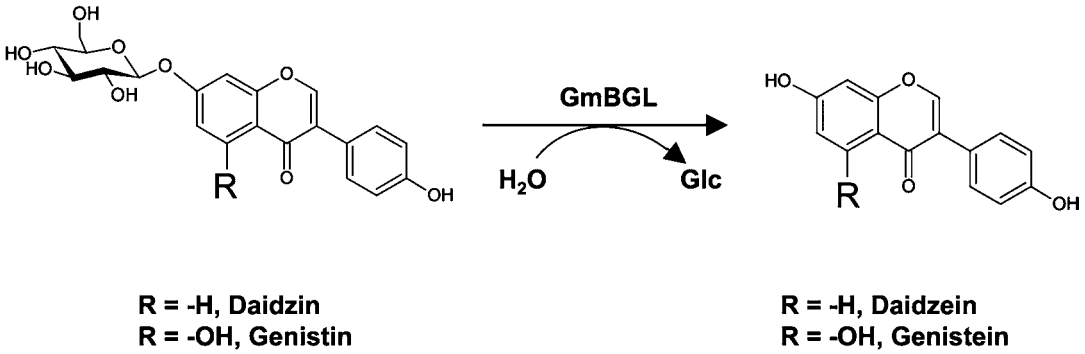

Figure 1. *Glycine max* β-glucosidase (GmBGL)-catalyzed hydrolysis of glycosyl isoflavones. Isoflavone 7-*O*-glucosides including daidzin and genistin are hydrolyzed by GmBGL into the corresponding aglycones. Glc, glucose.

been characterized. β-Glucosidase has been purified from soy cotyledons that hydrolyze isoflavone glucosides to release aglycones.[22,23] Suzuki et al.[24] reported cloning a gene encoding isoflavone conjugate-hydrolyzing β-glucosidase (GmICHG). GmICHG is a member of the glycoside hydrolase 1 (GH1) family, which can hydrolyze both malonylated and non-malonylated forms of isoflavone-7-*O*-β-D-glucosides.

In soybean, although β-glucosidase is believed to play an important role in the transformation and regulation of isoflavones, most of the biochemical and molecular properties remain unclear. In our previous study, we purified a novel β-glucosidase with high specificity toward glucosidic isoflavones (Figure 1), but not malonylglucosidic isoflavone from soybean okara, the byproduct of soy milk and tofu-making, and we determined the N-terminal amino acid sequence of the enzyme.[25] Here, we obtained and characterized the full-length *GmBGL* cDNA. Moreover, transgenic rice harboring *GmBGL* was created, and β-glucosidase activities toward isoflavone conjugate were determined. *GmBGL* may be a functional β-glucosidase for use in producing isoflavone aglycone-rich soybean by genetic engineering.

MATERIALS AND METHODS

Plant Materials and Chemicals. Soybean (*Glycine max* L.) Kaohsiung No. 12 was obtained from the agricultural research and extension station in Kaohsiung district, Taiwan. Soybean seeds were washed with running water, soaked in tap water overnight, and then ground in liquid nitrogen for RNA extraction. *Japonica*-type rice (*Oryza sativa* L.) Tainung 67 (TNG 67) was used for heterologous expression. *p*-Nitrophenol (*p*NP), dithiothreitol, and electrophoresis reagents were from Sigma-Aldrich Co. (St. Louis, MO, USA). CM-Sepharose CL-6B cation exchanger, Hiload 16/60 Superdex 75 columns, and protein standards were from GE Healthcare Bio-Sciences Co. (Piscataway, NJ, USA). Isoflavone standards were purchased from Sigma-Aldrich Co. Liquid chromatography grade acetonitrile, methanol, and *n*-hexane were from Merck (Darmstadt, Germany). DIAION HP-20 was from Mitsubishi Chemical Co. (Tokyo, Japan). All chemicals used were of analytical grade.

Rapid Amplification of cDNA ends (RACE). Total RNA was extracted from soybean seeds as described.[26] Purified RNA was used to construct the RACE library by use of the SMART RACE cDNA Amplification kit (Clontech, Palo Alto, CA, USA). Our previous paper[25] gave the partial N-terminal amino acid sequence for soybean β-glucosidase. To obtain the full-length cDNA encoding soybean β-glucosidase, pairs of degenerate primers were designed on the basis of this partial protein sequence and the conserved sequences of β-glucosidase from other plants in Genbank. After obtaining the gene's partial sequence, gene-specific primers (GmBGL-F1, 5′-GCTGCGACCTGGCAGCAAATGGTGAATC-3′; GmBGL-R1, 5′-CCGCAATGCATGGAGCAAAGACATACGG-3′) were designed by use of the PrimerSelect program of Lasergene 6 (DNASTAR, Inc., Madison, WI, USA) for 5′ and 3′ RACE. PCR involved a Mastercycler gradient thermal cycler (Eppendorf, Hamburg, Germany). The high-fidelity Platinum Taq DNA polymerase (Invitrogen, Carlsbad, CA, USA) was used for the amplification of the *GmBGL* cDNA. PCR products were cloned with use of the pGEM-T Easy Vector System II (Promega, Madison, WI, USA). An ABI Prism 3730XL DNA Sequencer (Applied Biosystems, Foster City, CA, USA) was used to determine the nucleotide sequences of positive clones. After sequencing, we obtained a full-length cDNA of the soybean β-glucosidase gene (*GmBGL*, GenBank accession no. KF740479).

Sequence and Phylogenetic Analysis. DNA sequences were analyzed by use of BLAST (http://www.ncbi.nlm.nih.gov/blast/) and InterProScan (http://www.ebi.ac.uk/Tools/pfa/iprscan/). The amino acid sequences of β-glucosidase from soybean and other plants including *Medicago truncatula*, *Zea mays*, *Arabidopsis thaliana*, *Hordeum vulgare*, *Nicotiana tabacum*, *Triticum aestivum*, *Tropaeolum majus*, and *Oryza sativa* deposited in GenBank were used for phylogenetic analysis. The alignment of the deduced protein sequences and phylogenetic tree were computed by use of Megalign in Lasergene 6 (DNASTAR, Inc., Madison, WI, USA) and MEGA5,[27] respectively, with standard parameters.

Rice Transformation and Growth Conditions. The maize ubiquitin 1 promoter together with its first intron was used to drive the overexpression of *GmBGL* in rice. The hygromycin phosphotransferase gene was chosen as a selectable marker. The cassette was cloned into the binary vector pCambia1302 and then transferred into *Agrobacterium tumefaciens* strain EHA101 by electroporation. Embryogenic calli from immature seeds of TNG67 were transfected as described.[28] Three independent T2 homozygous lines (oxBGL1, oxBGL2, and oxBGL3) were used for molecular and biochemical analysis. Seeds of wild-type and transgenic rice were hydroponically cultivated at 30/25 °C (day/night) in a phytotron (Agricultural Experimental Station, National Taiwan University, Taipei) with natural sunlight and 90% relative humidity.

Semiquantitative RT-PCR. Total RNA was isolated from 2-week-old rice leaves and soybean tissues by use of Trizol reagent (Invitrogen). RNA samples were treated with TURBO DNase (Ambion, Grand Island, NY, USA) at 37 °C for 30 min to avoid DNA contamination. First-strand cDNA was synthesized by use of MMLV high-performance reverse transcriptase (EPICENTRE Biotechnologies, Madison, WI, USA) according to the manufacturer's instructions. For amplifying the full-length cDNA of *GmBGL*, we designed a gene-specific primer pair (GmBGL-F2, 5′-ACTAGTAGTCCACTCAATTTTAGATTTTTAAGTGTCTGGT-3′; GmBGL-R2, 5′-ACTAGTAACAATAGTAATCAAAATGAAAAGTCTGCCCTAG-3′; *Spe*I underlined for subcloning). To quantify the relative amount of *GmBGL* transcripts in transgenic rice and soybean, we designed two pairs of gene-specific primers (OsActin-F, 5′-ATGCTCTCCCCCATGCTATC-3′; OsActin-R, 5′-TCTCCTTGCTCATCCTGTC-3′; GmEF-1-F, 5′-ACATCCCAAGCTGACTGTGC-3′; GmEF-1-R, 5′-TACCTGGCCTTGGAATACTTGG-3′) for rice

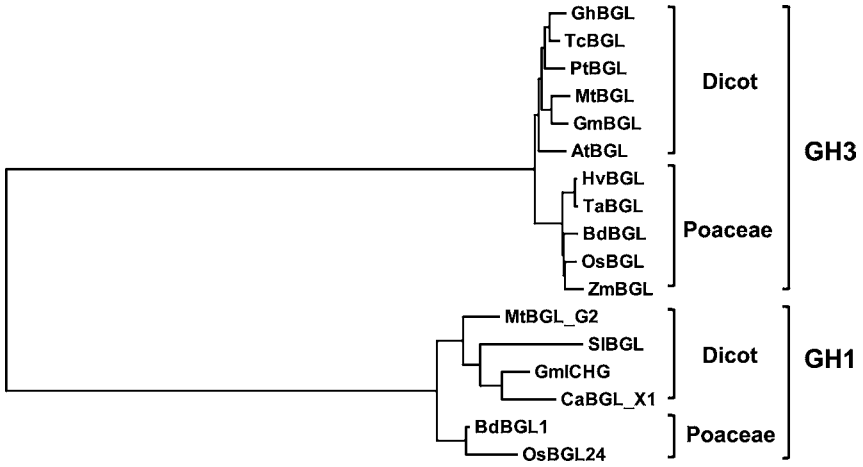

Figure 3. Phylogenetic tree of plant β-glucosidases. The tree was generated with the full-length BGL protein sequences by use of Clustal W and the neighbor-joining method (MEGA 5.0). The bar beneath the dendrogram represents a distance of 0.05 change per amino acid. Branches are labeled with species names as follows: *G. max* (GmBGL, KF740479; GmICHG, NP_001237501), *A. thaliana* (AtBGL, NP 197595), *Brachypodium distachyon* (BdBGL, XP 00355; BdBGL1, Bradi1g42690), *Cicer arietinum* (CaBGL_X1, XP_004507133), *G. hirsutum* (GhBGL, AAQ17461), *H. vulgare* (HvBGL, AAC49170), *Medicago truncatula* (MtBGL, XP 003601350; MtBGL_G2, ABW76287), *O. sativa* (OsBGL, Os03g0749300; OsBGL24, LOC_Os06g21570), *Populus trichocarpa* (PtBGL, XP 00231363), *Solanum lycopersicum* (SlBGL, Solyc08g044510), *Theobroma cacao* (TcBGL, EOY33198), *T. aestivum* (TaBGL, AAM13694), and *Z. mays* (ZmBGL, NP 001130296).

Actin1 and soybean *elongation factor-1α*, respectively, as normalization controls.

Enzyme Extraction and Activity Assay. Shoots from 2-week-old rice plants were ground to powder in liquid nitrogen, and 2 mM EDTA aqueous solution was added to a volume of approximately 10 mL g^{-1} fresh weight. After centrifuging at 13000*g* for 15 min, the supernatant was discarded to remove water-soluble parts. The residue was then extracted twice with 10 mL of 3% NaCl aqueous solution for 30 min at room temperature. The homogenates were centrifuged at 13000*g* for 15 min at 4 °C. The supernatant as crude β-glucosidase was assayed for GmBGL activity and protein content. β-Glucosidase activity was assessed by measuring *p*NP release from *p*-nitrophenyl-β-D-glucopyranoside (*p*NPG) at pH 9.5 by absorption spectrophotometry at 405 nm absorbance.[25] The enzyme reaction was initiated by mixing 20 μL of crude β-glucosidase with 25 μL of 10 mM *p*NPG and 55 μL of 50 mM acetate buffer, pH 4.5. After incubation at 45 °C for 15 min, 100 μL of 1 M sodium carbonate solution was added to stop the reaction, and the released *p*NP was measured. A quantitative curve was prepared for authentic *p*NP at 0−0.5 mM. β-Glucosidase activity was calculated from the angular coefficient of the linear slope and normalized to protein content by using the Bradford method.

Antiserum Preparation. The full-length coding region of *GmBGL* was cloned into the *pET32a* vector at the *Nco*I and *Xho*I sites for protein expression in the *Escherichia coli* BL21 (DE3) strain by induction with isopropyl-D-thiogalactopyranoside. For purification of recombinant protein, bacterial extracts were initially passed through an Ni^{2+} column (GE Healthcare Life Sciences) according to the manufacturer's protocol, and then purified recombinant GmBGL was used as the rabbit antigen for antibody production (LTK BioLaboratories, Taoyuan, Taiwan).

Western Blot Analysis. In total, 2 μg of crude extract from shoots was separated by 10% SDS-PAGE, and proteins were transferred to an Immobilon-P PVDF transfer membrane (Merck Millipore, Darmstadt, Germany), which was blocked with 5% skim milk for 1 h and incubated with primary antibody at a 1:500 dilution at 4 °C for 12 h and then with horseradish peroxidase-conjugated secondary goat anti-rabbit IgG antibody (GeneTex, Irvine, CA, USA) at 1:50000 dilution for 1 h. Immunoreactivity was detected by enhanced chemiluminescence (Amersham International PLC, Gloucester, UK). The positive control from soybean was purified as described.[25] Briefly, 200 g of okara was homogenized in 1 L of 3% (w/v) NaCl aqueous solution; after filtration, the filtrate was concentrated by ultrafiltration (Hollow Fiber Cartridge, MWCO 5 kDa, GE Healthcare Life Science), treated with dithiothreitol, and then further purified by CM-Sepharose CL-6B cation-exchange chromatography to obtain soybean β-glucosidase.

Hydrolyzing Test of Malonylglucosidic and Glucosidic Forms of Isoflavone. Malonylglucosidic and glucosidic forms of isoflavone were prepared as described.[29] Briefly, isoflavones were extracted from soybean with 60% methanol, and then solvents were removed under reduced pressure to obtain the crude extracts of isoflavone, which were further fractionated by passing through a column prepacked with Diaion HP20 resins. The HP20 adsorbed fraction was eluted sequentially with a bed volume of 40% methanol, 70% methanol, and pure methanol to obtain the corresponding fractions that contained the dominant constituent with malonylglucosidic, glucosidic, and aglycone forms of isoflavone, respectively. The isolated isoflavones in each of the eluents was identified by comparison with authentic isoflavone standards through high-performance liquid chromatography (HPLC). After evaporation to dryness under vacuum, the isolated fraction with dominant glucosyl isoflavone was used as the substrate for analyzing the enzyme activity of recombinant β-glucosidase. For evaluating the substrate affinity of enzyme, both malonylglucosidic and glucosidic forms of isoflavone were used as substrates. The hydrolysis was initiated by adding 100 μL of the substrate isoflavone at 3000 μg/mL into the reaction mixture, which consisted of 10 μg of crude extract protein and 100 μL of 50 mM acetate buffer, pH 4.5, with a final volume of 350 μL. After incubation at 45 °C for 60 min, the reaction was stopped by adding 350 μL of methanol containing 1000 μg/mL benzoic acid. The insoluble substances were removed by centrifugation, and the supernatant was used for analyzing isoflavone content by HPLC. HPLC involved the model 584 Solvent Delivery Module (ESA Biosciences, Chelmsford, MA, USA) equipped with a YMC-Pack ODS-AM C18 column (4.6 × 250 mm, 5 μm) and a Thermo SpectroMonitor 3200 digital UV−vis detector. The linear mobile phase gradient was obtained with 0.1% acetic acid in H_2O (solvent A) and 0.1% acetic acid in acetonitrile (solvent B). After injection of 20 μL of sample, solvent B was increased from 15 to 20% over 20 min, to 24% within the next 10 min, isocratic at 24% over 6 min, increased to 35% within the next 8 min, then isocratic at 35% over 6 min, and finally to decreased to 15% within 5 min and held at that percentage for the next 15 min. The flow rate was set at 1 mL/min. The eluted components were detected at 254 nm.

Statistical Analysis. Data are expressed as mean ± SE (n = 4). Comparisons involved ANOVA, and means were compared by Duncan's multiple-range test (P < 0.05).

RESULTS

Characterization of GmBGL Gene. After RACE analysis, we obtained a 2190 bp DNA fragment containing a poly-A signal region in the 3′-UTR. Sequence analysis revealed a single open reading frame of 1884 bp encoding a polypeptide of 627 amino acids. The open reading frame was designated the *G. max β-glucosidase* gene (*GmBGL*). The amino acid sequences for GmBGL shared 90% similarity with β-D-glucosidase of *Gossypium hirsutum* (GhBGL, GenBank accession no. AAQ17461). The cDNA and amino acid sequence of *GmBGL* have been deposited at GenBank (accession no. KF740479) (Figure 2).

GmBGL Is a Member of the Glycosyl Hydrolase 3 Family. A BLAST search of the soybean genome database (http://www.phytozome.net/soybean) revealed four highly homologous genes for *GmBGL*. Soybean clones Glyma10g15980.1, Glyma02g33550.1, Glyma02g43990.1, and Glyma14g04940.2 share 99, 96.5, 86.1, and 86.0% identity, respectively, to *GmBGL*, and all genes were annotated as members of the β-glucosidase family. However, N-terminal amino acid sequence analysis demonstrated that only the Glyma10g15980.1 was identical to the N-terminal sequence we identified previously.[25] As compared with Glyma10g15980.1, two single-nucleotide polymorphisms were found in the *GmBGL* cDNA sequence, which may result from different soybean genetic backgrounds.

Multiple sequence alignment of β-glucosidase among *G. max*, *A. thaliana*, *G. hirsutum*, *H. vulgare*, *N tabacum*, *O. sativa*, *T. aestivum*, *T. majus*, and *Z. mays* demonstrated that the GH3 family shared high similarity of the N-terminal domain (^{105}Leu−Val^{340}) and C-terminal domain (^{412}Leu−Thr^{621}) (Figure 2). Aspartic acid, located in the conserved motif ^{303}GFVISDW^{309} of all GH3 family members, was thought to be one of the active sites of amino acid residues. Another putatively catalytic residue of glutamic acid was located in E^{514}. The phylogenetic tree shown in Figure 3 summarizes the β-glucosidases identified in the soybean genome and other species. It revealed a clear divergence between GH1 and GH3 isoforms (Figure 3). Both GH1 and GH3 isoforms could be divided into dicot and Poaceae subgroups. The novel GmBGL belongs to the dicot GH3 subgroup. The sequences in this group are restricted to dicot plants and have been identified in *G. hirsutum*, *Theobroma cacao*, *Populus trichocarpa*, *M. truncatula*, and *A. thaliana*. No isoform from this group was found in the Poaceae genome. In contrast, another soybean β-glucosidase, GmICHG, is included in GH1 (Figure 3).

Expression of GmBGL Gene in Soybean Plants. We analyzed the spatial *GmBGL* gene expression in soybean by semiquantitative RT-PCR. The *GmBGL* transcript was present in both vegetative and reproductive tissues. Roots and leaves accumulated more *GmBGL* transcript than did other tissues (Figure 4).

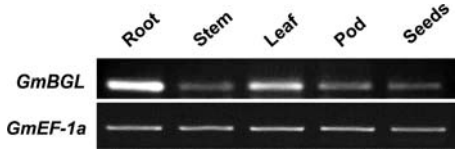

Figure 4. Semiquantitative RT-PCR of *GmBGL* transcript levels in root, stem, leaf, pod, and mature seeds. *G. max elongation factor-1α* (*GmEF-1α*) was used as an internal control.

Analysis of Transgenic Rice Plants Harboring the GmBGL Gene. Figure 5a illustrates the plasmid construct used for heterologous expression of *GmBGL* in rice. After *Agrobacterium*-mediated transformation, 15 independent transgenic lines were obtained. Three randomly selected transgenic lines were analyzed. RT-PCR analysis revealed increased *GmBGL* transcript in oxBGL1- and oxBGL3-overexpressing lines and markedly increased *GmBGL* transcript in the oxBGL2-overexpressing line, with no *GmBGL* transcript detected in nontransformants (WT) and plants transformed with empty vector (Figure 5b). To examine the translation of GmBGL in transgenic rice, we produced a polyclonal antibody to detect GmBGL protein. GmBGL protein highly accumulated in oxBGL1 and oxBGL2 lines and slightly in oxBGL3. Moreover, GmBGL antibody strongly bound to the purified soybean BGL protein, with no signal detected in the WT or rice plants transformed with empty vector (Figure 5c).

β-Glucosidase Activity in Transgenic Rice and Substrate Specificity toward Isoflavones. To examine the β-glucosidase activity of recombinant GmBGL in transgenic rice, we performed a chromogenic assay with *p*NPG as a substrate. As compared with the WT, oxBGL1 and oxBGL2 showed 6- and 31-fold increased activity, respectively (Figure 6). The β-glucosidase activity of oxBGL3 and the WT was similar. The substrate specificities of recombinant GmBGLs toward glucosidic and malonylglucosidic isoflavones are in Figure 7. Figure 7a shows the chromatogram for isoflavone substrate before hydrolysis. After hydrolyzation by crude GmBGLs from oxBGL1 and oxBGL2 at 45 °C and pH 4.5 for 30 min, the contents of daidzin and genistin were decreased to 42 and 46% of the original content with β-glucosidase from oxBGL1 (Figure 7b) and to 97 and 80% with β-glucosidase from oxBGL2 (Figure 7c), but the corresponding contents of daidzein and genistein with both treatments were increased. Daidzin and genistin contents were not reduced in oxBGL3, the WT, or the empty vector control (Figure 7d−f). Thus, both GmBGLs from transgenic rice oxBGL1 and oxBGL2 could effectively hydrolyze glucosyl-conjugated isoflavones into their corresponding aglycones. The content of malonylglucosidic isoflavones in all treatments remained relatively stable. Thus, the β-glucosidase activity of GmBGL from transgenic rice, which possesses high substrate specificity toward glycosyl isoflavones rather than malonylglucosidic isoflavones, could be markedly increased by overexpressing *GmBGL*.

DISCUSSION

We previously purified and characterized a β-glucosidase with isoflavone glucoside-hydrolyzing activity from soybean okara.[25] In this study, we isolated *GmBGL*, a novel gene encoding β-glucosidase, and validated the enzyme activity and substrate specificity in transgenic rice. *GmBGL* encodes for a polypeptide of 627 amino acids with molecular mass of 69 kDa. The deduced amino acid sequence had a high isoelectric point at pH 8.98, which agrees with our previous finding of native GmBGL from soybean okara being capable of separation by adsorption to CM-Sepharose CL-6B cation-exchange resin.[25]

GmBGL was transformed into the rice genome and could be transmitted to progenies. Among three randomly selected transgenic lines overexpressing *GmBGL*, oxBGL2 expressed the highest mRNA levels of β-glucosidase, and oxBGL1 and oxBGL3 expressed lower levels (Figure 5b). As well, oxBGL2 expressed the most abundant GmBGL protein, followed by oxBGL1, with the least by oxBGL3. Both oxBGL1 and oxBGL3

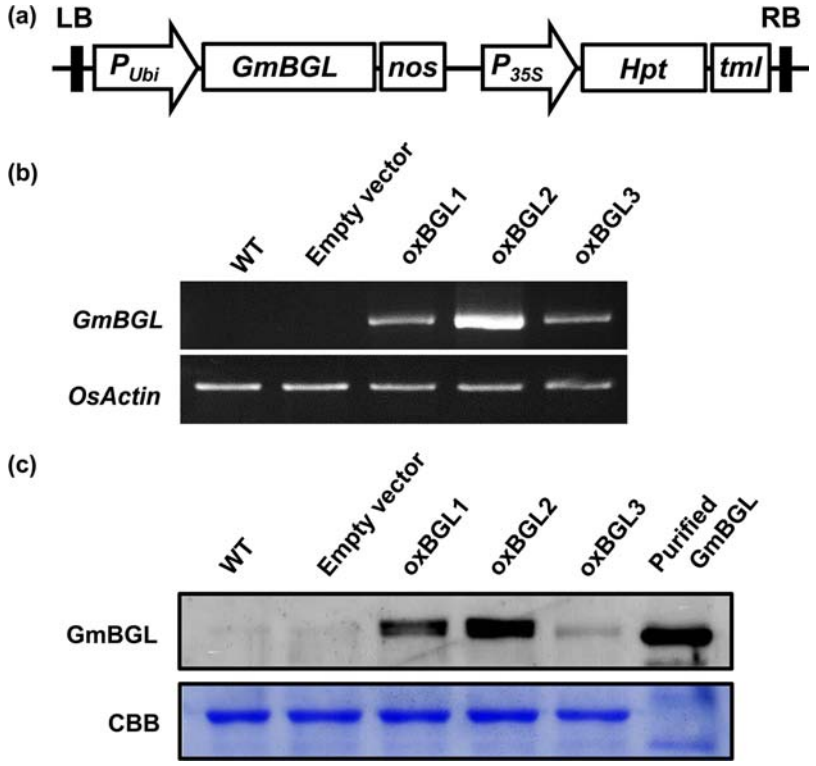

Figure 5. Heterologous expression of *GmBGL* in rice. (a) Schematic representation of the expression cassette used for rice transformation. LB, left border; RB, right border; P_{ubi}, maize ubiquitin 1 promoter together with its first intron; *nos*, terminator of the nopaline synthase gene; P_{35S}, CaMV 35S promoter; *hpt*, coding sequence of hygromycin phosphotransferase; *tml*, terminator of a tumor morphology large gene; oxBGL, overexpressing BGL line. (b) Semiquantitative RT-PCR of expression of *GmBGL* in the wild type (WT) and transformants. Semiquantitative RT-PCR was performed with gene-specific primers of *GmBGL* and the rice *Actin1* as a control. (c) Western blot analysis of GmBGL protein level in the WT and transformants. Equal loading of extracted proteins (2 μg each lane) is shown by Coomassie brilliant blue (CBB) R250 staining. Partially purified GmBGL protein from soybean was used as a positive control to demonstrate antibody specificity.

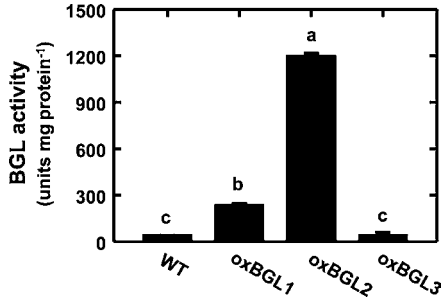

Figure 6. β-Glucosidase activity in transgenic rice plants. Proteins were extracted from shoots of WT and transgenic rice plants. Data are expressed as specific activity. β-Glucosidase activity was assayed with *p*-nitrophenyl-β-D-glucopyranoside (*p*NPG) as the substrate, and activity was calculated from measuring *p*NP release by absorbance at 405 nm. Data are the mean ± SE (n = 4). Bars with the same letter are not significantly different at $P < 0.05$.

expressed similar mRNA levels of *GmBGL*, but a very low protein level in oxBGL3 (Figure 5c). This suggests that mRNA levels of GmBGL in transgenes may, but not necessarily, contribute to corresponding protein levels.

The molecular mass of GmBGL in transgenic rice was slightly higher than that for β-glucosidase purified from soybean okara (Figure 5c). An explanation for the difference in molecular mass could be that recombinant GmBGL underwent post-translational modification such as glycosylation. Many foreign proteins, including soybean proteins, overexpressed in rice are glycosylated.[30,31] We found five potential N-glycosylation sites in the GmBGL amino acid sequence (Figure 2), so the higher molecular mass of GmBGL in transgenic rice than in soybean okara may be due to glycosylation.

The β-glucosidases have been characterized into five families—GH1, GH3, GH5, GH9, and GH30—by amino acid sequence similarity.[32] Most of the identified genes encoding β-glucosidases belong to the GH1 family. The first isoflavone-7-*O*-glucoside-specific β-glucosidase was isolated from chick pea (*Cicer arietinum*). Three isozymes, including R3, H1, and L1, were isolated from roots, hypocotyls, and leaves, respectively.[19] Among the isoflavone-related leguminous β-glucosidases, two members of the GH1 family, dalcochinin-8′-*O*-β-glucoside β-glucosidase (dalcochinase) from *Dalbergia cochinchinensis* and *Dalbergia nigrescens* β-glucosidase, have been cloned and characterized. Dalcochinase, showing high aglycone specificity for isoflavonoids, can hydrolyze both β-glucosides and β-fucosides, and *D. nigrescens* β-glucosidase can efficiently remove disaccharides from dalpatein 7-*O*-β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside and 7-hydroxy-2′,4′,5′,6-tetramethoxy-7-*O*-β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside. They can also remove a single glucose residue from isoflavonoid 7-*O*-glucosides such as daidzin and genistin.[33,34] Our phylogenetic analysis revealed that GmBGL is a novel GH3 protein in soybean (Figure 3). *GmBGL* is preferentially expressed in roots and leaves (Figure 4), which is a similar expression pattern as for the soybean GH1 gene *GmICHG*.[29] However, soybean GH1 and GH3 β-glucosidases show divergence in substrate specificity. The GmICHG (GH1 family) can hydrolyze both malonylated and nonmalonylated

J. Agric. Food Chem. 2015, 63, 921−928

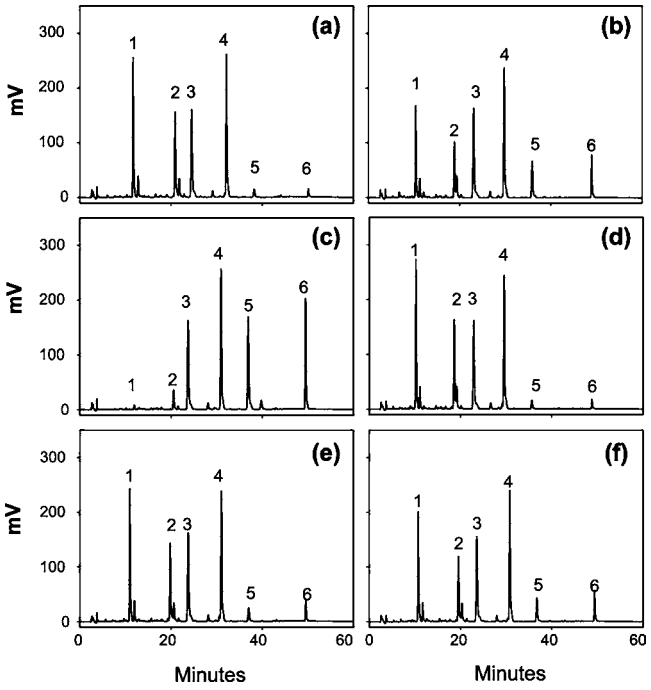

Figure 7. High-performance liquid chromatograms of substrate isoflavones after hydrolysis by crude β-glucosidases from transgenic rice oxBG lines at 45 °C and pH 4.5: (a) original substrate before hydrolysis as a blank control; (b–f) isoflavones were hydrolyzed for 30 min by the crude enzyme from oxBGL1, 2, 3, the WT (TNG 67), and the empty vector control, respectively. Peaks: 1, daidzin; 2, genistin; 3, internal standard (benzoic acid); 4, malonyl-genistin; 5, daidzein; 6, genistein.

forms of isoflavone-7-*O*-β-D-glucosides, the malonylated form being the preferred substrate. In contrast, the GmBGL (GH3 family) has strict substrate specificity toward glucosyl but not malonylglucosidic isoflavones.

GmBGL shares 72% sequence identity with a barley β-D-glucan exohydrolase isoenzyme *Exo*I, which also belongs to the GH3 family. The 3D structure of *Exo*I demonstrated that its first 357 residues represent an $(\alpha/\beta)_8$ barrel domain and the 374–559 residues, an $(\alpha/\beta)_6$ sheet.[35] Protein engineering predicted that GmBGL likely shares similar protein folding. According to Varghese et al.,[35] Asp^{285} and Glu^{491}, representing two conserved residues of the barley β-D-glucan exohydrolase, were suggested to be involved in the nucleophilic catalytic sites within general acid/base catalysis. We found these two conserved amino acids in GmBGL (Asp^{308} and Glu^{514}) and also in other GH3 family members (Figure 2).

Many studies have described the efficient transformation of isoflavone glycosides to aglycones by exogenous enzymatic hydrolysis and microbial fermentation, but only a few have characterized β-glucosidase from soybean. Because aglyconic isoflavones are considered practically to be the bioactive form of soy isoflavones, which could have a role as chemoattractants to attract nodule bacteria occurring in soy plant rhizosphere,[21,36] the amount of aglyconic forms of isoflavone in mature soybean seeds is actually negligible; the predominant forms of isoflavone are malonylglucosides and glucosides.[37] Therefore, most isoflavones in soybean have to undergo a hydrolysis process for their function while soybean seeds are sprouting and growing. We found greater *GmBGL* transcript level in roots and leaves than in other tissues of soybean seedlings (Figure 4), so GmBGL may play an important role in conversion of isoflavone conjugates into bioactive aglycones in soybean.

In conclusion, the cloning and identification of functional β-glucosidase helps us investigate its physiological role and provides the opportunity for genetic engineering of soybean seeds with high levels of aglycone.

been associated with consumer acceptance and can be promoted in the marketplace.[9]

Plant starches are synthesized by several enzymatic reactions.[10−12] ADP-glucose (ADPG) pyrophosphorylase (AGP) (also called glucose-1-phosphate adenyltransferase [EC 2.7.7.27]) activities generate a major source of the glucosyl donor ADPG for starch biosynthesis.[13−15] Starch synthase (SS) including soluble SS (SSS) [EC 2.4.1.21] and granule-bound SS (GBSS) [EC 2.4.1.242] add glucosyl units at the nonreducing end of linear chains through new $\alpha(1\rightarrow4)$ linkages. Starch branching enzyme (SBE) (also called 1,4-α-glucan branching enzyme [EC 2.4.1.18]) introduces branch linkages in the starch by cleaving interior $\alpha(1\rightarrow4)$ bonds and forming a new glycoside bond between the C1 reducing end of the released glucan and a C6 within an adjoining linear chain. Starch debranching enzyme (SDBE) including isoamylase [EC 3.2.1.68] and pullulanase [EC 3.2.1.41] hydrolyzes branch linkages and is needed for creation of normal branching patterns in amylopectin. Multiple isoforms exist for each enzyme, although their specific roles in starch biosynthesis generally are not known.[16] Starch biosynthesis is probably best studied in *Arabidopsis* leaves, potato tubers, and maize endosperm.[12,17,18] Maize (*Zea mays*) contains at least five different genes coding for SS,[19] three genes coding for SBE,[20] and two genes coding for SDBE.[21] In addition, ADPG is transported from the cytosol into amyloplasts by the adenylate transporter/adenylate translocator (ANT) coded for by the *brittle1* gene in maize endosperm.[15,22]

Starch biosynthesis has not been studied in chestnut. One study identified a homologue of *Arabidopsis* DSP4 (SEX4) involved in starch degradation in chestnut that was induced in response to cold and accumulated in stem amyloplasts during winter.[23] New technologies such as transcriptome and microarray have been used to uncover the genes involved in chestnut blight infection. A number of genes have been identified and characterized by comparative transcriptomes of American chestnut (*Castanea dentata*) and Chinese chestnut (*Castanea mollissima*) in response to the chestnut blight infection.[24] This technology has provided insightful information for chestnut resistance to blight disease.[25] cDNA microarray has also been used to monitor transcriptional responses of the chestnut blight fungus *Cryphonectria parasitica* to infection by virulence-attenuating hypoviruses.[26] However, there is no molecular level study of starch biosynthesis and sucrose metabolism in chestnut tree. This study evaluated metabolite profiles and identified genes coding for enzymes in starch and sucrose metabolism by transcriptome and quantitative real-time polymerase chain reaction (qPCR).

MATERIALS AND METHODS

Plant Materials. Chinese chestnut (*Castanea mollissima* Mill.) cultivar 'Yanshanzaofeng' was used in this study. The plants were planted in Qianxi county, Tangshan city, Hebei province, China. Chestnut fruits were collected from three 8-year-old trees at five developmental stages (30, 45, 60, 75, and 90 days after flowering, DAF). To ensure the same developmental stages of the seeds from different trees, we conducted controlled pollination on the three trees. Three chestnut fruits were removed from each of the south, east, west, and north directions of each tree, resulting in a total of 12 fruits per developmental stage per tree. Seeds were taken out of the fruits, and the seed coat and skin were removed. The endosperm was wrapped with silver paper and stored in liquid nitrogen immediately until being used for RNA extraction and metabolite analyses. No specific permit was required for sample collection because the trees were publicly owned, and the field studies did not involve protected species.

Seed Composition Analysis. The seed endosperms were dried in an 80 °C oven. Each dried sample was ground into fine powder with a homogenizer followed by filtration through a 0.5 mm filter before being used for seed composition analyses. Soluble sugar content was determined by the colorimetric Anthrone method.[27,28] Starch (amylose and amylopectin) content was determined by dual-wavelength spectroscopy with wavelength scans of the amylose−iodine and amylopectin−iodine complexes at 450−800 nm in a spectrophotometer (DU 800 Beckman Coulter).[3] Protein content was determined according to the Kjeldahl method based on nitrogen released after strong acid digestion.[29] Oil was extracted from powders by using the Soxhlet extraction method according to the standard protocol of "Determination of crude fat in foods" (State Standard of the People's Republic of China, GB/T 14772-2008).[29]

RNA Isolation. For cDNA library construction and transcriptome sequencing, total RNA was isolated from frozen endosperms of developmental seeds collected at 45 DAF (corresponding to the beginning of starch synthesis peak phase) and 75 DAF (corresponding to the end of starch synthesis peak phase) using a PureLink RNA Mini Kit (Life Technologies, USA). For qPCR analyses, all five stages of seed endosperms were used for RNA extraction using a Microto-Midi Total RNA Purification System according to the manufacturer's protocols (Life Technologies). The quality and quantity of the purified RNA samples were characterized initially by agarose gel electrophoresis and NanoDrop ND1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA) and further assessed by RNA Integrity Number (RIN) and rRNA ratio using an Agilent 2100 Bioanalyzer (Santa Clara, CA, USA) as described.[30] These RNA isolation kits resulted in high-quality RNA preparations with RIN larger than eight (data not shown).

cDNA Library Construction. Poly-A containing mRNA was purified from 2 μg of total RNA using oligo (dT) magnetic beads and fragmented into 200−500 bp pieces with divalent cations at 94 °C for 5 min using a similar procedure for tung tree seed transcriptome cDNA library construction.[31] The mRNA fragments were reverse transcribed into first-strand cDNA using SuperScript II reverse transcriptase and random primers (Life Technologies). After double-stranded cDNA synthesis, fragments were end-repaired and A-tailed. The final cDNA library was created by purifying and enriching the double-stranded cDNA by PCR.

Unigene Assembly and Analysis. The cDNA sequencing was performed using a paired-end flow cell with an Illumina Solexa HiSeq 2000 Sequencing System (Biomarker Technologies Co.). Clean DNA sequencing reads were de novo assembled using Trinity with default *K*-mers = 25.[32] The contigs without ambiguous bases were obtained by conjoining the *K*-mers in an unambiguous path. The clean reads were mapped back to contigs using Trinity to construct unigenes with the paired-end information. This program detected contigs from the same transcript as well as the distances between these contigs. Finally, the contigs were connected with Trinity, and sequences that could not be extended on either end were defined as unigenes for each library. Finally, the two sets of unigenes were integrated into one set of unigenes using the BLAST-Like Alignment Tool (http://genome.ucsc.edu/cgi-bin/hgBlat). The Kyoto Encyclopedia of Genes and Genomes (KEGG) protein databases were used to annotate unigenes using InterProScan software.[33] KEGG annotation was used initially to identify unigenes in starch and sucrose metabolism and glycosyltransferase pathways. Because there is a limitation of using bacterially derived KEGG maps for unigene annotation, a keyword search was performed to identify additional unigenes related to starch and sucrose metabolism.

Digital Analysis of Differentially Expressed Genes in Two Seed Developmental Stages. To compare differences in gene expression, tag frequencies of both libraries were analyzed by IDEG6 software (http://telethon.bio.unipd.it/bioinfo/IDEG6/) according to the method described by Audic and Claverie.[34] The false discovery rate (FDR) was used to determine the threshold *P* value for multiple testing. Calculation of unigene expression used the reads per kilobase

[a]A−U represent the sample ID of unigene analyzed by qPCR and correspond to those listed in Figure 3 and Table 5. REF represents the reference gene used for qPCR assays. [b]C and U represent the initials of "chestnut" and "unigene" followed by the ID of the unigene identified in the Chinese chestnut transcriptomes.

J. Agric. Food Chem. 2015, 63, 929−942
DOI: 10.1021/jf505247d

per million mapped reads (RPKM) method.[35] FDR <0.001 and absolute value of the log2 RPKM ratio >1 (or RPKM ratio more/less than 2-fold) were used as the threshold to determine significant differences in gene expression.

Quantitative Real-Time PCR Analysis of Gene Expression in Five Seed Developmental Stages. The expression patterns of 21 unigenes mostly in the starch and sucrose metabolism pathway in developing Chinese chestnut seeds were studied by qPCR using the SYBR Green method essentially as described in Cao and Shockey.[36] Elongation factor 1-α2 (*EF1-α2*) (C2Ug31919) was used as the reference gene (primer sequences were identical between Chinese chestnut unigene C2Ug31919 and Portuguese chestnut GenBank accession no. FK868440). PCR primers were designed with "Primer Express" software as used previously.[30] The names and primer sequences of the 22 unigenes are listed in Table 1. The qPCR assay was carried out with three replicates in each reaction using the Bio-Rad CFX system (Bio-Rad). PCR was performed in a 20 μL volume containing 2 μL of diluted cDNA, 250 nM of each primer and 1× SYBR Premix Ex *Taq*II (TaKaRa). The results were analyzed using the comparative Cq method, which uses an arithmetic formula, $2^{-\Delta\Delta Cq}$, to obtain results for relative quantification.[37] The significant difference of $2^{-\Delta\Delta Cq}$ among the different stages of seeds was analyzed using Duncan's multiple-range test with IBM SPSS Statistics 20.0. The correlation between gene expression levels and starch content was analyzed using the method of Pearson correlation coefficient with IBM SPSS Statistics 20.0.

RESULTS

Metabolite Profiles during Fruit Development in Chinese Chestnut Tree. During the developmental stages from 30 to 90 days after flowering, water contents in the fruits collected at 30, 45, 60, 75, and 90 DAF were 82.67 ± 3.23, 75.38 ± 1.12, 66.88 ± 2.30, 60.34 ± 2.21, and 52.89 ± 1.81%, respectively. Whereas water content in the nuts was gradually decreased, the dry mass of the chestnut fruits was rapidly increased from 0.5 to >4 g per fruit, an increase of 7.6-fold (Figure 1A). The increase of dry mass in the fruit was primarily due to starch accumulation in the endosperm (Figure 1B). The amylose portion of starch was increased 32.8-fold by weight (Figure 1B) and 5-fold by ratio (Figure 1C), whereas the amylopectin portion of starch was increased 22.9-fold by weight (Figure 1B) and 3-fold by ratio (Figure 1C). Amylopectin was the major component of starch with approximately 2−3 times the amylose content in the endosperm (Figure 1B). Other metabolites in the endosperm were also increased by weight (6.3-fold for soluble sugars, 4.3-fold for proteins, and 3.6-fold for lipids) (Figure 1B), but their ratios in the endosperm were decreased accordingly until 75 DAF followed by a slight increase at 90 DAF at the expense of amylose in the seeds (Figure 1C).

Identification of Starch and Sucrose Metabolism Genes in Chestnut Seed Transcriptome. RNA was extracted from chestnut seed endosperms collected at 45 and 75 DAF to achieve a broad survey of genes associated with seed development. These RNAs were reverse transcribed into cDNAs and sequenced by an Illumina paired-end sequencing platform. De novo assembly of Chinese chestnut seed transcriptomes generated a total of 56671 nonredundant unigenes (complete transcriptome analysis to be published elsewhere). Pathway-based analysis using KEGG annotation identified 6323 unigenes involved in 302 pathways (data not shown). The default starch and sucrose metabolism pathway contained 141 unigenes including 136 annotated unigenes (Table 2), 2 unannotated unigenes, and 3 unigenes with

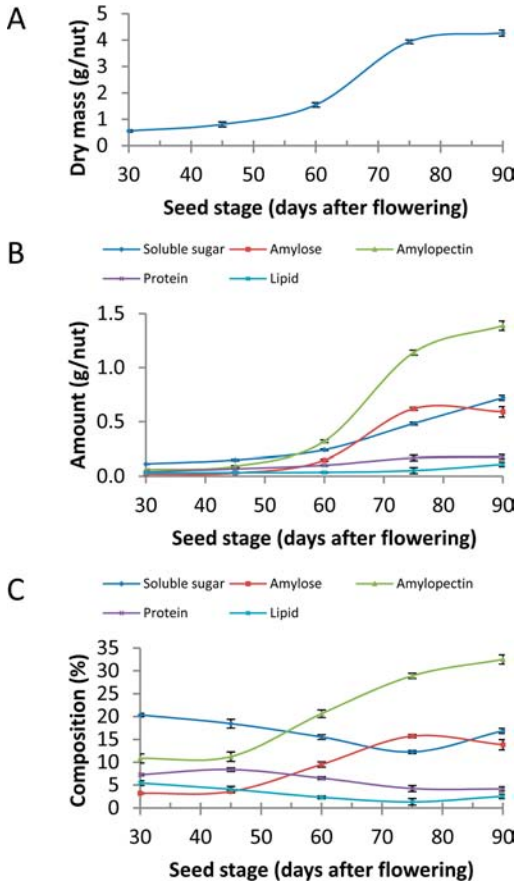

Figure 1. Developmental profiles of dry mass, soluble sugars, amylose, amylopectin, protein, and lipid contents in Chinese chestnut endosperm: (A) dry mass accumulation in developmental nuts; (B) major metabolite accumulation in developmental nuts; (C) composition profiles in developmental nuts (% of dried endosperm).

undetectable RPKM value in the seed transcriptomes (data not shown).

Examination of the unigene list in the KEGG annotated starch and sucrose metabolism pathway revealed that a significant number of known enzymes and transporters were not included in the pathway. Therefore, we manually searched additional unigenes with keywords in the glucosyltransferase family and the whole unigene databases. Glucosyltransferase family contained one unigene (C1Ug17153) coding for glycogenin glucosyltransferase (GLG) [EC.2.4.1.186] and four unigenes (C2Ug23993, C1Ug17740, C1Ug26954 and C1Ug98040) coding for GBSS in the seed transcriptomes (Table 2). Manual search was also used to identify if chestnut transcriptomes contained orthologues of maize Brittle1-type ADPG transporter and Brittle2/Shrunken2-type cytosolic AGP.[15,22,38,39] Keyword search of the annotated chestnut unigene database with "*brittle*" resulted in 4 unigenes related to "*brittle1*" of grape (C1Ug30622, C1Ug33748 and C1Ug29007) and castor bean (C1Ug39668) (Table 2) but none with "*brittle2*." Keyword search with "*shrunken*" did not yield any unigene. Additional keyword search of the annotated unigene database with "isoamylase" and "pullulanase" resulted in the identification of two unigenes for isoamylase-type (C1Ug44378 and C1Ug45762) and three unigenes for pullulanase-type (C1Ug30670, C2Ug20485 and C1Ug22898) of starch debranching enzyme in Chinese chestnuts (Table 2). [a]Unigene ID highlighted with yellow and green colors represent unigenes identified from "glycosyltransferases" categories according to the KEGG protein database, and manually searched, respectively. [b]The numbers under the "C1 (no.)" and "C2 (no.)" columns represent the number of total reads in each unigene identified in the chestnut transcriptomes. [c]Highlighted RPKM values under the "C1 (RPKM)" and "C2 (RPKM)"columns represent those almost exclusively expressed in the nuts collected 45 and 75 DAF, respectively. [d]Highlighted RPKM values under the "C2/C1 (expression)" column represent those 58 unigenes that showed ≥2-fold of expression difference between the 45 and 75 DAF seed stages.

search using keyword "maltose" identified one unigene (C1Ug35422) in the unigene database putatively coding for maltose exporter (Mex1), a transporter important for starch degradation.[40] Finally, one α-amylase/subtilisin inhibitor-like unigene (C2Ug26008), an orthologue of grape wine, was found in the 75 DAF transcriptome (Table 2). Taken together, 152 annotated unigenes with detectable RPKM values involved in starch and sucrose metabolism were identified from the Chinese chestnut transcriptomes (Table 2).

Digital Analysis of Differentially Expressed Genes in Two Seed Developmental Stages. The RPKM (reads per kb per million mapped reads) method was used to identify unigenes with significant differences in expression levels between the two libraries. A total of 1537 unigenes showed ≥2-fold change (complete transcriptome analysis to be published elsewhere). Among the 152 unigenes coding for starch and sucrose metabolism, 58 unigenes showed ≥2-fold of expression difference between the 45 and 75 DAF seeds including 11 up- and 47 down-regulated unigenes (Table 2). In addition, transcripts for 18 unigenes were almost exclusively detected in 45 DAF seeds whereas 15 unigene transcripts were exclusively detected in 75 DAF seeds as judged by apparent RPKM value in their respective nut stages (Table 2).

Digital Analysis of Major Expressed Genes in Two Seed Developmental Stages. Among the 152 unigenes discovered in starch and sucrose metabolism pathway, 13 unigenes from the 45 DAF cDNA library and 14 unigenes from the 75 DAF cDNA library had RPKM value over 100 (Table 3). Among them, 11 of the unigenes with PRKM values over 100 were presented in both 45 and 75 DAF cDNA libraries (C2Ug23993, C1Ug30240, C1Ug33458, C1Ug35570, C1Ug38445, C1Ug39284, C1Ug40932, C1Ug41886, C2Ug23382, C2Ug29836 and C2Ug30776) (Table 3). C2Ug23993 had the highest RPKM value at 994 and 2343 in the 45 and 75 DFA cDNA libraries, respectively. C2Ug23993 putatively coded for a GBSS, the most abundant transcript identified in the endosperms.

Classification of Starch and Sucrose Metabolism Genes in Chestnut Seed Transcriptome. The 152 starch and sucrose metabolism unigenes identified from the chestnut transcriptomes coded for 37 protein families (Table 4). The gene families coding for pectinesterase, α-1,4-galacturonosyltransferase, β-glucosidase, and SuS had the most unigenes with 17, 13, 12, and 11 unigenes identified from the transcriptomes, respectively (Table 4). These unigenes coded for well-known components in the starch and sucrose metabolism pathway, including 1 unigene for GLG, 1 unigene for Mex1, 4 unigenes for Brittle1-type ANT, 3 unigenes for AGP, 8 unigenes for SS (4 for SSS and 4 for GBSS), 2 unigenes for SBE, 5 unigenes for SDBE (2 for isoamylase and 3 for pullulanase), 11 unigenes for sucrose synthase (SuS), 3 unigenes for sucrose-phosphate synthase (SuPS), 3 unigenes for α-amylase (α-AMY), 2 unigenes for β-AMY, and 4 unigenes for starch phosphorylase (SP) (Table 4). These families of unigenes (red color) were mapped onto the generalized starch and sucrose metabolism pathway generated by KEGG protein database (black color) (Figure 2). Among the identified unigenes, 23 unigenes coding for AGP, ANT, GLG, SSS, GBSS, SBE, and SDBE were involved in starch biosynthesis, whereas 11 unigenes coding for AMY, SP, Mex1, and α-amylase/subtilisin inhibitor were involved in starch degradation (Figure 2). A total of 14 unigenes coding for SuS and SuPS were involved in sucrose metabolism and 9 unigenes coding for enzymes to convert sucrose into β-D-fructose (Figure 2). Ten unigenes converted UDP-glucose into α-D-glucose, whereas 13 unigenes were used to convert cellulose into β-D-glucose (Figure 2). In addition, 40 unigenes starting from UDP-glucose were committed to pectin and pectate biosynthesis (Figure 2). Finally, 11 unigenes starting from UDP-glucose were committed to trehalose biosynthesis and 6 unigenes encoding trehalase for pectate hydrolysis to glucose (Figure 2).

[a]The numbers under "C1 (no.)" and "C2 (no.)" columns represent the number of total reads in each unigene identified in the chestnut transcriptomes. [b]The numbers under "C1 (RPKM)" and "C2 (RPKM)"columns represent those most abundantly expressed unigenes with at least 50 RPKM in at least one of the two nut stages collected 45 and 75 DAF.

Digital Expression Analysis of Starch and Sucrose Metabolism Gene Families in Chestnut Seed Transcriptome. RPKM values of individual unigenes were pooled together according to the classified gene families (Table 4). Thirteen families of unigenes had RPKM values >100 in both 45 and 75 DAF seed transcriptomes (Table 4). The most abundantly expressed unigenes represented by total RPKM values were SuS (1159), GBSS (1001), pectinesterase (403), and AGP (399) in 45 DAF seed transcriptome, but the order of the abundance of expression was changed to GBSS (2345), SuS (1007), AGP (523), and pectinesterase (459) in 75 DAF seed transcriptome (Table 4). Soluble SS, isoamylase- and pullulanase-type SDBE, brittle1-type ANT, and Mex1 had <100 RPKM in either transcriptome, but SP had >200 RPKM in both seed stages (Table 4). GLG RPKM was extremely low in 45 DFA and undetectable in 75 DAF transcriptomes (Table 4). In addition, three unigenes were identified in the nut transcriptomes, which coded for phosphotransferase system (PTS), including one unigene for maltose- and glucose-specific IIC component and two unigenes for trehalose-specific IIC component.

Quantitative Analysis of Selected Genes Involved in Starch and Sucrose Pathways. We used qPCR to evaluate the expression profiles of 11 genes involved in starch and sucrose metabolism pathway as well as 10 other genes predicted to be important in chestnut tree carbohydrate metabolism using primers designed according to the sequences of the unigenes (Table 1). The qPCR results showed that five of these genes were significantly up-regulated and peaked at 75 DAF with >2-fold of increases in mRNA levels compared to those at 30 DAF (Figure 3E, C1Ug38445; 3H, C1Ug41228; 3Q, C2Ug26944; 3S, C2Ug29836; and 3T, C2Ug30790). These five genes were important enzymes for starch synthesis because they coded for AGP large subunit (C1Ug38445) and small subunit (C2Ug29836), GBSS2 (C1Ug41228), SSS1 (C2Ug26944), and SSS4 (C2Ug30790) (Table 1). Twelve of the genes were down-regulated during seed development (Figure 3A, C1Ug19275; 3B, C1Ug22044; 3C, C1Ug31955; 3D, C1Ug36303; 3F, C1Ug39763; 3G, C1Ug41090; 3I, C1Ug41886; 3J, C1Ug42679; 3K, C1Ug43056; 3M, C1Ug46084; 3N, C2Ug23382; and 3R, C2Ug29276). Five of the down-regulated genes coded for sucrose synthase (C1Ug41886, C1Ug19275, C2Ug23382, C2Ug29276, and C1Ug31955) (Table 1).

Correlation between Gene Expression Levels and Starch Content in Chestnut Seeds. The correlation between gene expression levels and starch content was performed by SPSS software (Table 5). Expression levels of five genes were highly correlated with the amount of starch including both amylose and amylopectin with correlation

[a]Gene families 18 and 19 were identified from "glycosyltransferases" categories according to the KEGG protein database; gene families 8, 9, 21, 22, and 28 were identified by keyword search of unigene database manually. [b]The numbers under "unigene no." column represent the total number of unigenes in each enzyme family identified in the chestnut transcriptomes. [c]The numbers under the "C1 (no.)" and "C2 (no.)" columns represent the total reads in each enzyme family identified in the chestnut transcriptomes. [d]The numbers under "C1 (RPKM)" and "C2 (RPKM)" columns represent the total values of unigene RPKM in each enzyme families identified in the chestnut transcriptomes.

coefficients >0.9 (boldfaced in Table 5). These five genes (C1Ug38445, C1Ug41228, 2Ug26944, C2Ug29836, and C2Ug30790) were identical to those genes for which mRNA levels were up-regulated in later stage of nuts (75 DAF) at least 2-fold relative to those in early stage of nuts (30 DAF) (Figure 3E, C1Ug38445; 3H, C1Ug41228; 3Q, C2Ug26944; 3S, C2Ug29836; and 3T, C2Ug30790). Similarly, all down-regulated genes were negatively correlated with starch content in the nuts (Table 5 vs Figure 3).

DISCUSSION

Chinese chestnuts are a major source of starch, but little has been reported about starch biosynthesis in the seeds. To our knowledge, no prior research has been conducted at the biochemical and molecular levels of starch biosynthesis in chestnuts. Our objectives in this study were to analyze composition profiles and characterize genes involved in starch biosynthesis in developing nuts. As expected, starch constituted approximately half of the dry mass including 33% of amylopectin and 14% of amylose in the seed endosperm collected 90 DAF. In addition, 17% of the dry mass was soluble sugars, but there were only 4% protein and <3% lipid in the nuts. The Chinese chestnut cultivar 'Yanshanzaofeng' used in this study contained less starch than most of the other Chinese chestnut cultivars.[3] The endosperm from this Chinese chestnut contained approximately 15% less starch and 1.5% more lipids than Portuguese chestnuts.[1] The ratio of amylose to amylopectin in Chinese chestnut was similar to that of

J. Agric. Food Chem. 2015, 63, 929−942

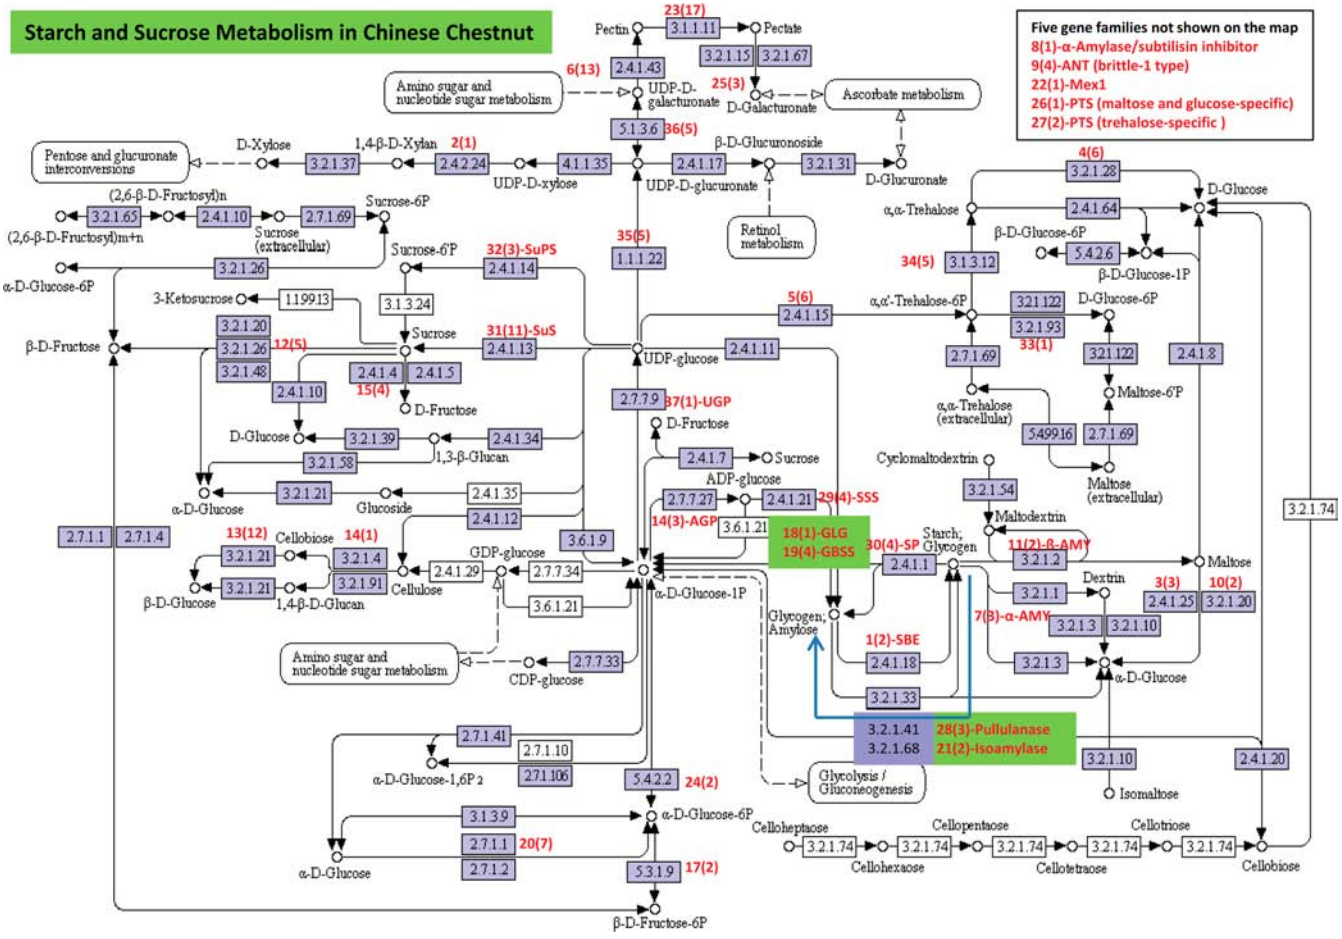

Figure 2. Starch and sucrose metabolism pathway in Chinese chestnut endosperm. The map represents a general starch and sucrose metabolism pathway and was generated from the KEGG pathway, which outlines the steps involved in starch and sucrose metabolism. The numbers in the rectangle represent the standardized international enzyme names in the pathway. The numbers next to the rectangle (in red) represent the family of enzymes corresponding to those in Table 4 followed by the total number of unigenes in that family discovered in the seed transcriptomes (in parentheses).

Portuguese chestnut.[4] The compositions of soluble sugars in Chinese chestnut were not determined as those in Portuguese chestnut.[5]

We coupled transcriptomic analysis with qPCR assays for selected genes to understand the global gene expression involved in starch and sucrose metabolism in Chinese chestnuts. Transcriptomic technology identified 152 unigenes in the starch and sucrose metabolism pathway and classified them into 37 protein families in which pectinesterase, α-1,4-galacturonosyltransferase, β-glucosidase, and SuS families had the most unigenes from the transcriptomes. We used this novel information to construct a general view of starch and sucrose metabolism in Chinese chestnuts (Figure 2). These unigenes coded for well-known components in starch biosynthesis (one unigene for GLG, four unigenes for Brittle1 type ANT, three unigenes for AGP, eight unigenes for SS, two unigenes for SBE, five unigenes for SDBE) and starch degradation (three unigenes for α-AMY, two unigenes for β-AMY, four unigenes for SP, one unigene for Mex1). Sucrose metabolism contained 11 unigenes for SuS, three unigenes for SuPS, four unigenes for fructokinase, and five unigenes for β-fructofuranosidase. In addition, 10 unigenes converted UDP-glucose into α-D-glucose and 13 unigenes converted cellulose into β-D-glucose (Figure 2). Pectin and pectate biosynthesis from UDP-glucose contained 40 unigenes in the transcriptomes. Finally, trehalose contained 11 unigenes for its biosynthesis from UDP-glucose and 6 unigenes for its hydrolysis to glucose (Figure 2). These high numbers of unigenes for glucose and fructose metabolism may represent its property of the nuts having a sweet taste, whereas significant numbers of unigenes for trehalose metabolism may represent the nuts being able to withstand prolonged periods of desiccation. Because there is a limitation of using bacterially derived KEGG maps for unigene annotation, it is possible that more unigenes could be identified in Chinese chestnut transcriptomes using plant-specific software such as MapMan and MetaCyc in the future.

Plant starches are synthesized by a series of enzymatic reactions.[41] Two major starch biosynthesis pathways have been proposed in plants based on the subcellular localization of generating ADPG, the major if not the sole sugar donor for starch biosynthesis. In cereal endosperm such as maize (*Zea mays*),[16] ADPG is mainly synthesized in the cytosol[42] by cytosolic AGP encoded by *brittle2* and *shrunken2* genes.[15,38] ADPG is transported into amyloplasts by brittle1 ADPG transporter.[15,22,39,43] In other plant tissues such as potato tubers, *Arabidopsis* leaves, and pea embryos, ADPG is mainly synthesized in the plastids by plastidic AGP and ANT is mainly used to exchange ATP/ADP across plastid envelopes.[12,44] Adenylate transporters in these tissues are probably divergent from maize brittle1 ADPG transporter because maize brittle1

[a]Bolded ID, unigene, and annotations represent those genes showing a positive correlation between their mRNA levels and starch content in the chestnuts. [b]"*" and "**"after the correlation coefficients represent positive correlation between their mRNA levels and starch content in the chestnuts differently at $P < 0.05$ and $P < 0.01$, respectively.

antibodies did not recognize any protein in a number of tissues as well as maize endosperm suspension cultured cells.[45,46] In Chinese chestnut transcriptomes, a keyword search of the annotated unigene database with "*brittle*" resulted in four unigenes related to "*brittle1*" of grape and castor bean but none with "*brittle2*." A keyword search with "*shrunken*" did not yield any unigenes. These results suggest that most if not all AGP resides inside the amyloplasts in Chinese chestnut endosperm cells and that chestnut brittle1 orthologues may function in ATP/ADP transport instead of ADPG transport into amyloplasts. This is the same biochemical mechanism used by *Arabidopsis* leaves and potato tubers.[12,44,47] The fact that high levels of gene expression related to starch degradation (α-AMY, β-AMY, SP, Mex1) were detected in the transcriptomes suggests that starch degradation is probably an active process to ensure sweetness of chestnuts upon harvest.

Digital expression analysis indicated that 13 families of unigenes had RPKM values >100 in both 45 and 75 DAF seed transcriptomes. The most abundantly expressed unigenes represented by total RPKM values were SuS (1159), GBSS (1001), pectinesterase (403), and AGP (399) in 45 DAF seed transcriptome, but the order of the abundance of expression was changed to GBSS (2345), SuS (1007), AGP (523), and pectinesterase (459) in 75 DAF seed transcriptome (Table 4). The altered key gene expression implies that sucrose metabolism is more active in the earlier stages of nut development and that starch accumulation becomes more predominant in the later stages. It is interesting to note that soluble SS, isoamylase- and pullulanase-type SDBE, brittle1 type ANT and GLG had <100 RPKM in either transcriptome but SP had >200 RPKM in both seed stages. These observations suggest that SSS, SBDE, ANT, and GLG are possibly limiting factors for starch biosynthesis, and SP is the major enzyme for starch degradation in the seeds. Future experiments will be needed to characterize the significance of PTS genes discovered from this transcriptome analysis.

Digital expression analysis showed that 58 of 152 unigenes in starch and sucrose metabolism exhibited ≥2-fold of expression difference between the two seed stages. Transcripts for 18 unigenes were almost exclusively detected in 45 DAF seeds, whereas 15 unigene transcripts were exclusively detected in 75 DAF seeds. Additional experiments will be required to understand the physiological significance of these stage-specific unigenes in the chestnuts. The expression profiles of 21 unigenes putatively coding for major enzymes in starch and sucrose metabolism were confirmed by qPCR using RNA from five seed stages. Expression profiles and correlation analyses indicated that the mRNA levels of AGP (large and small subunits), GBSS2, and soluble SS1 and SS4 were well-correlated with starch accumulation in the seeds. Interestingly, two of the most abundant transcripts with RPKM values >1000 in chestnut seed transcriptomes coded for GBSSII-1 (C2Ug23993) and fructose-bisphosphate aldolase (C1Ug33347). GBSS is responsible for amylose synthesis,[48] whereas fructose-bisphosphate aldolase is an important enzyme in the glycolytic pathway regulating carbohydrate metabolism.[49]

J. Agric. Food Chem. 2015, 63, 929−942

We also noted that gene expression profiles by RPKM and qPCR methods were generally in agreement. Ten of the 11 unigenes (C1Ug22044, C2Ug24779, C2Ug24961, C2Ug31317, C1Ug39763, C1Ug41090, C1Ug41886, C1Ug42679, C1Ug43056, and C1Ug46084) selected for qPCR assays exhibited similar patterns of expression to those estimated by RPKM. The expression of the other unigene (C1Ug36303) showed a similar trend between the two methods, but the expression levels were not significantly different among the seed stages (Figure 3). These results suggest that both methods are reliable and complementary to each other for estimating gene expression.

In conclusion, metabolite analysis showed that starch was the major component and rapidly accumulated during Chinese chestnut seed development. Amylopectin was approximately 3-fold of amylose content in chestnut starch. Transcriptome sequencing identified 152 unigenes involved in starch and sucrose metabolism, which are classified into 37 gene families including glycogenin glucosyltransferase, adenylate transporter, ADP-glucose pyrophosphorylase, starch synthase, starch branching enzyme, starch debranching enzyme, sucrose synthase, and sucrose-phosphate synthase. Among them, 58 unigenes showed a ≥2-fold expression difference between the 45 and 75 DAF seeds including 11 up- and 47 down-regulated unigenes. The expression of 21 unigenes putatively coding for major enzymes in starch and sucrose metabolism was validated by qPCR using RNA from five seed stages. Expression profiles and correlation analysis indicated that the mRNA levels of AGP, granule-bound SS2, and soluble SS1 and SS4 were well-correlated with starch accumulation in the seeds. Our data suggest that the starch biosynthesis pathway in Chinese chestnut endosperm is similar to that of potato tubers and *Arabidopsis* leaves and differs from that of maize endosperm. This study provides valuable metabolic and genetic resources for future research in starch and sucrose metabolism in the Chinese chestnut tree.

pepsin from porcine gastric mucosa (P7000, 561 U/mg solid), and all other chemicals were purchased from Sigma-Aldrich (Steinheim, Germany).

Citrobacter braakii and *Peniophora lycii* (variant optimized for intestinal and thermal stability[13]) phytases expressed in *Aspergillus oryzae* (trade names Ronozyme HiPhos (L) and Ronozyme NP (L), hereafter abbreviated to H and R, respectively), were kindly provided by DSM (Heerlen, The Netherlands) and Novozymes (Bagsværd, Denmark), respectively. *Escherichia coli* phytase expressed in *Pichia pastoris* (trade name Granular phytase), hereafter abbreviated to G, and *Aspergillus niger* phytase expressed in *A. niger* (trade name SukaPhy phytase), hereafter abbreviated to S, were kindly provided by Challenge Group (Beijing, China) and Sukahan Biotechnology (Weifang, China), respectively. Wheat phytase, hereafter abbreviated to W, was purchased from Sigma-Aldrich. *A. niger* phytase expressed in *P. pastoris*, hereafter abbreviated to N, was produced in house as described below.

Production of *Aspergillus niger* Phytase. *Vector and Strain Construction.* An *A. niger* phytase (GenBank accession no. Z16414.1) without the 21 amino acid long N-terminal signal peptide, but including a C-terminal c-myc epitope and a His_6-tag, was codon-optimized for expression in *P. pastoris* and synthesized by DNA2.0 (Menlo Park, CA, USA) (this codon-optimized nucleotide sequence has been deposited in the GenBank database; NCBI KP001509). The synthesized gene was inserted in the vector pJ912, generating a translational fusion to the α-factor signal sequence. The resulting plasmid, pJ912_AnPhy, was propagated in *E. coli* DH5α grown at 37 °C with shaking in low-salt LB medium (10 g/L tryptone, 5 g/L yeast extract, and 5 g/L NaCl) supplemented with 25 μg/mL Zeocin.

The *P. pastoris* strain X-33 (Life Technologies, Carlsbad, CA, USA) was used as the host strain. X-33 electrocompetent cells were prepared as follows. *P. pastoris* X-33 was grown in nonselective YPD medium to an OD_{600} of 1, centrifuged, and resuspended in PPD buffer (50 mM potassium phosphate, pH 7.5, 25 mM DTT). After 15 min of incubation at 30 °C without shaking, cells were washed three times with STM buffer at 25 °C (10 mM Tris-HCl, pH 7.5, 270 mM sucrose, 1 mM $MgCl_2$) and resuspended in ice-cold STM buffer. Cells were frozen in liquid nitrogen and stored at −80 °C until use. For each transformation, 60 μL of cells were mixed with 0.5−1 μg of *Sac*I-linearized plasmid DNA in a prechilled 2 mm electroporation cuvette. Electroporation was performed using a MicroPulser Electroporator (Bio-Rad, Hercules, CA, USA) with settings according to the manufacturer's instructions. Immediately after the pulse, 1 mL of ice-cold YPD was added to the cuvette, and the cells were incubated at 30 °C for 1 h without shaking. Cells were washed once with 0.68% YNB (without amino acids) supplemented with 20% dextrose and plated on YPDS plates supplemented with 100 μg/mL Zeocin followed by incubation at 30 °C for 2−3 days.

Protein Production and Purification. Of 20 Zeocin-resistant *P. pastoris* X-33 transformants harboring the pJ912_AnPhy, the clone expressing the enzyme of interest in highest amounts, was selected as follows: Transformants were grown for 3 days in 50 mL of BMMY (10 g/L yeast extract, 20 g/L peptone, 100 mM potassium phosphate, pH 6, 13.4 g/L yeast nitrogen base, 0.4 mg/L biotin, and 0.5% (v/v) methanol) during shaking at 28 °C. Protein synthesis was induced every 24 h by addition of methanol to a final concentration of 0.5% (v/v). After 72 h of expression, cells were removed by centrifugation and sterile filtration and the supernatants containing secreted proteins analyzed by SDS-PAGE. To test for N-glycosylation and determine the molecular mass of the nonglycosylated enzyme, the secreted protein fraction was treated with endoglycosidase H for 1 h at 37 °C.

For large-scale phytase expression, the strain identified to produce the highest levels of enzyme in small scale was selected for fermentation in a 5 L Sartorius Biostat Aplus fermentor as described previously.[14] The phytase was purified either (i) from the ultrafiltered cell-free extract from *P. pastoris* by Ni^{2+} affinity column chromatography using a HisTrap HP column (GE Healthcare, Uppsala, Sweden) or (ii) directly from the fermentation broth by Cu^{2+} affinity column chromatography using a Microradial flow column (Proxcys, Nieuw-Amsterdam, The Netherlands), charged with IDA Chelating Cellthru BigBead (Sterogene, Carlsbad, CA, USA). After purification, the enzyme was dialyzed overnight against 20 mM ammonium bicarbonate at room temperature, lyophilized, and frozen at −20 °C.

Determination of Protein Concentration. Protein contents of the phytase formulations were measured with the BCA assay according to the manufacturer's instructions (microplate scale). Bovine serum albumin was used as a standard. For circular dichroism (CD) measurements, protein concentration was determined by absorption at 280 nm (see below).

Phytase Activity Assay. Phytase activity was evaluated at 37 °C in 200 mM acetate buffer at pH 5.5 using 5 mM phytic acid[15] and an enzyme dose corresponding to 0.05% E/S (enzyme/substrate % weight/weight) based on the determined protein content of the enzyme formulations for the R, H, G, and S phytases and 0.3% E/S (w/w) for the N phytase. The higher inclusion level for the N phytase was due to the low specific activity of this enzyme. Three hundred and fifty microliters of substrate solution was preheated to 37 °C, after which 50 μL of phytase solution was added. Reaction was stopped by adding 50 μL of 3.6 M HCl and incubating at 99 °C for 10 min. Samples were diluted with Milli-Q water and analyzed for InsP6 by ion exchange chromatography[15,16] (see below). Activity was evaluated as initial rate of net (compared to control without phytase) inositol hexakisphosphate elimination in micromoles per minute per milligram of enzyme protein during the first minute of reaction.

Quantification of Inositol Phosphates. Inositol phosphates were resolved using an ICS-3000 ion exchange chromatography system from Dionex (Sunnyvale, CA, USA) equipped with a CarboPac PA100 guard column (4 × 50 mm) and a CarboPac PA100 analytical column (4 × 250 mm). Samples (100 μL) were loaded with an autosampler. Bis- to hexakisphosphates were resolved using a gradient from 5 to 95% 1 M HCl, and for analysis of hexakisphosphate only, 80% 1 M HCl was used isocratically.[16] The eluent (0.8 mL/min) was mixed in a postcolumn PTFE knitted open tubular reaction coil (4 m × 0.25 mm i.d.) (Biotech, Onsala, Sweden) with 0.4 mL/min 0.1% (w/v) $Fe(NO_3)_3{\cdot}9H_2O$ in 2% (v/v) $HClO_4$ pumped by an AXP Auxiliary Pump (Dionex). The inositol phosphates were detected with a photodiode array detector at 290 nm.

A reference hydrolysate of phytic acid was prepared by reflux boiling with 0.5 M HCl, evaporation of the acid solution, and reconstitution in Milli-Q water followed by filtration through a 0.22 μm filter. This sample was analyzed according to the bis- to hexakisphosphate method described above, and the chromatogram served as a reference for peak identification by comparison with assigned chromatograms from previous studies.[15,17] Ins(1,2,5,6)P4 and Ins(1,2,4,5,6)P5 standards were run as confirmation for correct assignment of postreaction peaks. InsP3, InsP4, and InsP5 were quantified as InsP6 equiv using the same quantification factor as for InsP6 (slope of standard curve of area under the curve versus molar concentration).

Thermostability of Phytases. The thermostability of the five different phytases (H, R, G, S, N) was tested by incubation (n = 2) of phytases for 2, 10, 20, and 30 min at 37, 45, 50, 60, and 70 °C in 200 mM acetate buffer, pH 5.5, after which the residual activity was assayed as described above.

pH Profiles of Phytases. The pH profiles (n = 3) were determined at 37 °C according to the method described above, except for the solvent of the assays, which was exchanged for a buffer cocktail consisting of 50 mM glycine, 50 mM acetic acid, and 50 mM Bis-Tris.[18] The pH was adjusted to 13 different values between pH 1 and 7. Activities were normalized according to the activity optimum for each phytase to simplify comparison between phytases, as the enzymes were dosed on a protein/substrate (w/w) basis rather than on specific activity.

Stability of Phytases to Pepsin and Low pH. Pepsin stability of the six different phytases (H, R, G, S, W, N) was tested by incubation of phytases (n =2) with 5000 U/mL pepsin (based on gastric conditions as simulated by Haraldsson et al.[19]) in 0.01 M HCl (pH 2) at 37 °C for 10, 20, 30, 60, and 120 min, after which 50 μL of the phytase/pepsin solution was transferred to 350 μL of substrate solution and the activity assayed as described above. Activities were compared with the activity before pepsin addition yielding the residual

DOI: 10.1021/jf5050469
J. Agric. Food Chem. 2015, 63, 943−950

activities. A corresponding assay was conducted to investigate the stability at pH 2 without pepsin (H, R, G, S, and N phytases). Activities were normalized according to the initial activities (for individual replicate series) for each of the phytases.

Degradation of InsP3−6 under Simulated Gastric Conditions. Degradation of inositol hexakis- to triphosphates was investigated at pH 1 (100 mM HCl), pH 2 (10 mM HCl), and pH 5 (200 mM acetate buffer) with and without pepsin (5000 U/mL) with five different phytases (H, R, G, S, N) using 4 mM phytic acid. Each reaction was stopped as described for the phytase assay.

Circular Dichroism. To ensure enzyme purity, commercial phytase formulations were filtered through 0.22 μm syringe filters. Subsequently, they were washed twice with Milli-Q water in Vivaspin 500 sample concentrators (VWR, Radnor, PA, USA) with a molecular weight cutoff of 30 kDa to retain the phytases. Phytases were reconstituted in Milli-Q water. Solutions were diluted with either 10 mM HCl at pH 2 or 10 mM acetate buffer at pH 5 to approximately 2 μM. Concentrations were verified by measuring baseline-corrected absorption using a UV-2401 PC spectrophotometer (Shimadzu, Tokyo, Japan) at 280 nm. Extinction coefficients were calculated from the amino acid sequence using the ProtParam tool.[20]

Baseline-corrected far-UV CD spectra of the five phytases (H, R, G, S, N) were obtained using a Jasco J815 circular dichroism spectropolarimeter (Jasco Inc., Easton, MD, USA) equipped with a temperature control unit. Measurements were performed at 37 °C and a path length of 0.5 mm. Mean residue ellipticities were calculated by normalizing for enzyme concentration and number of amino acids in the respective phytases. Secondary structure contents were estimated from the spectra using the software package CDSSTR[21] through the Dichroweb analysis Web server.[22]

Sequence Alignment and Homology Modeling. Primary sequences for the phytases were found in GenBank with accession numbers AJ310696.1 (*P. lycii*, R), AAS45884.1 (*C. braakii*, H), X05471.1 (*E. coli*, G), Z16414.1 (*A. niger*), and XM_746871.2 (*A. fumigatus*). Sequences were aligned using Clustal Omega.[23,24] The *P. lycii* sequence was submitted to Phyre[25] using the intensive modeling mode for construction of a homology model of the phytase.

Statistical Analyses. For the thermal and low-pH/pepsin data, regression analyses of logarithmically transformed data were done with the aid of Minitab 14 (State College, PA, USA). For significant ($p < 0.05$) regressions, half-lives were determined from the regression parameters. Significance ($p < 0.05$) of differences in decay constants between enzymes were tested in Minitab 14 using a one-way analysis of variance followed by Bonferroni's multiple-comparison test. For the InsP3−6 degradation data, regression analysis was carried out with nontransformed data. For the data from circular dichroism, principal component analysis (PCA) was used to extract a single value expressing the differences in molar ellipticities between the spectra at pH 2 and 5 for each phytase over the entire range of wavelengths.[26] R[27] was used for the PCA.

RESULTS AND DISCUSSION

Thermostability of Phytases. Generally, all tested phytases were stable for 30 min at 50 °C (Figure 1). A direct comparison of half-lives at 60 and 70 °C showed that the R phytase had a significantly longer half-life than the other phytases (Figure 1). Notably, no significant loss of activity could be observed for the R phytase at 60 °C, whereas the half-life of the H phytase was significantly higher than the half-lives of the G, S, and N phytases, and the half-life of the G phytase was significantly higher than that of the N phytase (Figure 1). At 70 °C, no significant differences between half-lives among the S, H, G, and N phytases were observed.

The high thermal stability of the *P. lycii* phytase, R, is supported by previous findings,[28] whereas other studies reported much lower stabilities.[29,30] Some of these discrepancies might be due to different assay conditions in studies or the use of a different, non-optimized variant of the *P. lycii*

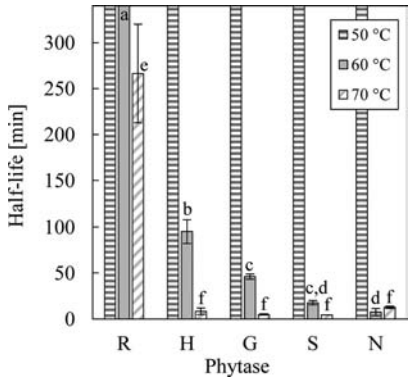

Figure 1. Average (n = 2) half-lives of different phytases (R, Ronozyme NP (L); H, Ronozyme HiPhos (L); G, Granular phytase; S, SukaPhy phytase; N, *A. niger* phytase) at 50, 60, and 70 °C. No decrease in activity of the phytases at 50 °C and, furthermore, the R phytase at 60 °C could be measured, so a half-life is plotted as out of range. Stability was tested in 200 mM acetate buffer, pH 5.5. Error bars correspond to the standard deviation for the duplicate measurements. Different letters correspond to significantly different half-lives ($p < 0.05$).

phytase. For the *A. niger* phytase (the N and S phytases of the present study), results similar to the present study have previously been reported,[29] except for a study that found the *P. lycii* phytase to be less stable than the *A. niger* phytase.[30] The thermal stabilities for the *E. coli* phytase found here are also similar to previously published results.[12,29] For the *C. braakii* phytase (the H phytase of the present study), thermal stability was a little higher than previously reported.[10]

pH Profiles of Phytases. The pH dependence of phytase activities (Figure 2) followed regular symmetrical response

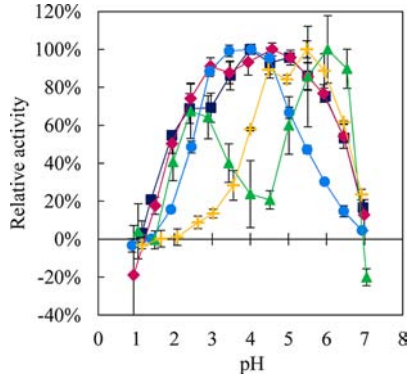

Figure 2. Relative activity of different phytases against pH: (dark blue squares) Granular phytase, G; (red diamonds) SukaPhy phytase, S; (blue circles) Ronozyme HiPhos (L), H; (yellow crosses) Ronozyme NP (L), R; (green triangles) *A. niger* phytase, N. Activity was evaluated as InsP6 elimination rate at 37 °C in a buffer consisting of 50 mM glycine, 50 mM acetic acid and 50 mM Bis-Tris. All activities have been normalized to the activity optimum for the given phytase. Error bars represent the standard deviations (n = 3).

curves for the H, G, and S phytases with pH optima at approximately pH 4, 4, and 4.5, respectively. Compared to the other phytases, the R phytase had a narrower pH profile with the curve slightly skewed toward the higher pH values and an optimum around pH 5.5. For the N phytase, the characteristic double-optimum profile believed to be due to interactions between acidic and alkaline amino acids in the substrate

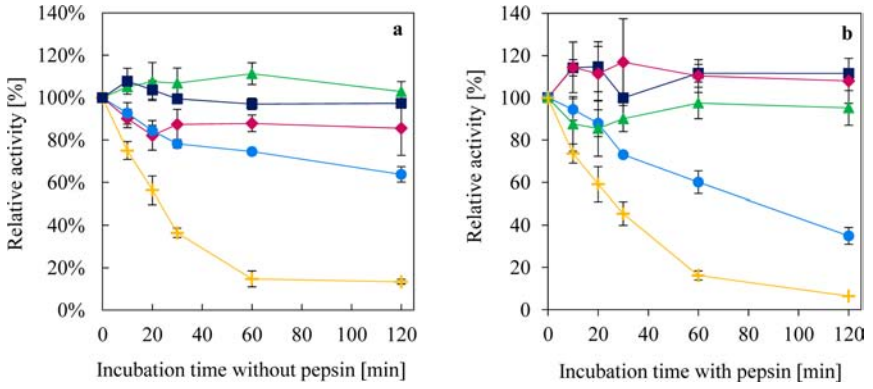

Figure 3. (a) Activity retention against incubation time at pH 2 of different phytases: (dark blue squares) granular phytase, G; (red diamonds) SukaPhy phytase, S; (blue circles) Ronozyme HiPhos (L), H; (yellow crosses) Ronozyme NP (L), R; (green triangles) *A. niger* phytase, N. (b) Activity retention against incubation time with pepsin (5000 U/mL) at pH 2 of different phytases (legend as for panel a). Activity was evaluated as InsP6 elimination rate at pH 5.5 and 37 °C, and all phytases have been normalized to their activity before pepsin incubation (0 min). Error bars represent the standard deviation (n = 2).

specificity site[31] was seen with optima around 3 and 6, respectively. The negative values of relative activities correspond to very small absolute activities with a high relative inaccuracy. As the S phytase was declared to be an *A. niger* phytase, it was surprising that the pH profile did not agree with the expected double optimum reported by previous studies.[32,33] This indicated that the enzyme might not be the wild type *A. niger* phytase, but instead a mutant (or perhaps an enzyme from a different source, e.g., *E. coli*, which has a similar pH profile).

For the R phytase, the pH profile found in these experiments was slightly more skewed toward the alkaline pH range compared with previous studies,[11,34,35] whereas another study using different assay conditions reported a similar pH activity profile.[30] For the *C. braakii* phytase (H phytase), the pH profile determined in the present work was similar to previous findings,[10,34] although the similarity was generally lower at the extreme ends of the pH profile (around pH 2 and 7). The pH activity profile for the G phytase found in the present study was similar, but broader than previously reported.[12]

Stability of Phytases to Pepsin and Low pH. The activities of the G, H, and R phytases decreased significantly when incubated at pH 2 in the absence of pepsin (Figure 3a), whereas the activities of only the H and R phytases decreased significantly in the presence of pepsin (Figure 3b). In agreement with previous findings,[36] the wheat phytase showed no activity after incubation at pH 2 with or without pepsin (data not shown). The wheat phytase was therefore not expected to exert measurable activity in gastric conditions and was not included in further experiments.

Initial rates (linear fit of first 30 min) of activity loss were 27% (R) and 11% (H) higher in the presence of pepsin compared to activity loss at pH 2 without pepsin (Figure 3). The rate of activity loss at pH 2 (no pepsin) was significantly higher ($p < 0.05$) for the R phytase than for the other phytases (half-lives in Table 1). These rates did not differ significantly among the remaining phytases (half-lives in Table 1).

For the S and G phytases, there was a slight tendency toward an increase in activity in the presence of pepsin. The activity increase following pepsin-catalyzed proteolysis was previously reported for the *E. coli* acid phosphatase and was speculated to be due to the presence of pepsin-resistant polypeptides internally in the phosphatase sequence with a higher phytase activity than the original protein.[37] This potential increase in activity might also obscure the activity loss due to low pH, which was observed in the experiment without pepsin (Figure 3a).

Table 1. Half-Lives (min) (± Standard Deviations, n = 2) of Phytases Incubated at pH 2 with or without Pepsin

phytase	without pepsin	with pepsin
G	1200 ± 144	NS[a]
H	205 ± 38	78 ± 7
R	40 ± 3	30 ± 0.3

[a]NS, regression was not significant.

When compared with other studies, it appears that the varying methods of testing pepsin resilience highly influence the conclusions. Other studies[29,38] conducted at pH 2 reported high activity losses of the *P. lycii* phytase, similar to the present study, whereas another study conducted at pH 3−5 reported much lower activity loss.[39] Similarly for the *E. coli* phytase, high pepsin stability was reported at pH 2,[29] similar to the present study, whereas a study using pH 1.2 reported extensive activity loss.[40] With respect to stability to pH 2 (without pepsin), the stability found in the present study agrees with previous results reported for *E. coli*.[12]

Previous studies disagree on pepsin resilience of *A. niger* phytase, with some[29,38] reporting lower pepsin stability than found in this study (Figure 3b) and others reporting similarly high stabilities.[36,37] This might be a result of the use of a different variant of the *A. niger* phytase or an entirely different source organism as mentioned in connection to the pH activity profiles. For the *C. braakii* phytase (the H phytase of the present study), a previous study[10] reported much higher pepsin stability than we found, but because neither pepsin activity nor pH were reported, comparisons are difficult.

Regardless of differences in assay conditions among the various studies, a comparison of different phytases using the same assay conditions is of interest to assess performance of the enzymes in question relative to each other.

Interestingly, in the present study it was observed that the phytases which were least stable at low pH also showed lower resistance toward proteolytic inactivation by pepsin (Figure 3). This could be explained by partial unfolding of the acid labile H and R phytases at low pH, which leads to a better accessibility for the protease pepsin.[35] This hypothesis was corroborated by the observed increase in activity decay rates upon pepsin

addition (H and R phytases). An exception was the G phytase as described above.

Finally, it was noted that there appeared to be no connection between pH/pepsin stability and thermostability (Figures 1 and

DOI: 10.1021/jf5050469
J. Agric. Food Chem. 2015, 63, 943−950

3), as the R phytase with the longest half-lives at 60 and 70 °C had the shortest half-lives when incubated at pH 2 with or without pepsin. In a similar fashion, stability toward heat and low pH/pepsin appeared to be inversely correlated for the other phytases.

Degradation of InsP3−6 under Simulated Gastric Conditions. At pH 2, the H, S, and G phytases significantly reduced InsP3−6 content (measured as InsP6 equiv) (Figure 4a) by >90% after 30 min, whereas no significant reduction was seen for the N and R phytases. For the N phytase, even negative average values were observed. The negative values are believed to be a result of minor inaccuracies of chromatography quantifications of small peak values compared to reference values that become magnified when multiplied by a dilution factor for diluted samples. As the R phytase in the pH profiling showed low activity at pH 2 (Figure 2) and in addition showed low activity retention after incubation at pH 2 with or without pepsin (Figure 3), this phytase was not expected to perform well with pepsin at pH 2. The N phytase having significant activity at pH 2 (Figure 2) and good stability toward low pH/pepsin (Figure3) was expected to demonstrate better performance in this assay. However, due to the low specific activity of this enzyme, the amount of enzymatic activity was not sufficient to compare with the other phytases, so a higher dosage would be required for this phytase.

At pH 5 (Figure 4b), all phytases except the N phytase reduced InsP3−6 content by at least 86% after 30 min. The R phytase performed significantly better at this pH compared to pH 2, but the H, G, and S phytases catalyzed a significantly higher degradation of InsP3−6 than the R phytase after 30 and 60 min. At 120 min degradation of InsP3−6 did not differ significantly between the R phytase and H, S, and G phytases (Figure 4b). The N phytase once again suffered from low specific activity, resulting in low InsP3−6 removal in these incubations. Given the high resistance to pepsin and low pH as well as reasonable activity retention at both pH 2 and 5, the N phytase is expected to perform well given a higher dosage. At pH 1, none of the phytases caused a significant reduction in InsP3−6 (data not shown), which was in coherence with the pH profiles showing very low activities for all of the phytases at this pH (Figure 2).

When considering the practical implication of these results, we can take a serving (50 g) of oatmeal as an example. Oatmeal contains ∼1 g phytic acid/100 g,[41] resulting in a total intake of ∼0.5 g of phytic acid. Using the same dosage of enzyme per substrate mass as in the present experiment, ∼0.25 mg of phytase protein would then be required to obtain the same degradation kinetics as seen in the present study (Figure 4). However, different kinetics may occur in the gastric ventricle in vivo due to lower substrate accessibility. Phytate in grains is incorporated in complex globoids,[15] and viscosity effects provided by the food components may lower mass transfer rates. These issues might be overcome by increasing phytase dosage.

As a final note on the practical applications of the results, it should be mentioned that the pH in the fed gastric environment is highly dependent on the nature of the recently consumed meal and is expected to be in a range of pH 3−6. Several studies[42−44] use 0.1 M HCl (corresponding to pH 1) as in vitro gastric medium. Therefore, gastric conditions were initially simulated at pH 1, but because none of the phytases showed activity at this pH value (Figure 2), only results at pH 2 and 5 are reported (Figure 4). Although the average pH value in the fed stomach is in the range of ∼3−6, phytases might experience considerably lower pH values locally due to the secretion of hydrochloric acid. Therefore, a high resistance to acid-induced denaturation is desirable for the optimal phytase. However, to allow for catalysis at the pH in the food chyme, some activity in the pH range of 5−6 and maybe even up to pH 7 is desirable. Finally, high pepsin resistance is desirable to continue catalysis throughout the retention of phytase in the gastric environment. Combining these demands for the optimal phytase, the *E. coli* (G) and SukaPhy (S) phytases appear to have a competitive edge in performance as compared to the other phytases tested. If thermostability is essential for the specific application (including, e.g., preparation of a food or feed product), *P. lycii* (R) and *C. braakii* (H) phytases are good candidates. Native *A. niger* phytase (the N phytase), being the only phytase approved for use in food,[8] appears to be a relatively poor choice due to the low activity between pH 3 and 6. This might be counteracted by increasing dosage as the acid and pepsin stabilities of this phytase are high (Figure 3).

Circular Dichroism. The CD spectra (Figure 5a−e) and estimated contents of secondary structural contents (Table 2) showed that the secondary structures of the H and R phytases changed more between pH 5 and 2 compared with the G, S, and N phytases. The ratio of unassigned (neither α-helix, β-strand, nor turn) secondary structure increased between pH 5 and 2 for the H and R phytases, but decreased or remained constant for the N, G, and S phytases. Using PCA, a principal component able to explain 98.4% of the variation over the entire spectra between pH 2 and 5 was extracted. This principal component appeared to correlate with the difference in activities displayed by the different phytases at pH 5 and 2 (Figure 5f), corroborating that the extent of loss in secondary structure correlates positively with the loss in enzymatic activity.

Table 2. Secondary Structural Contents (Percent) of the Five Phytases at pH 2 and 5[a]

phytase	pH	helix	strand	turn	unassigned
G	5	44	12	16	27
	2	50	20	17	13
H	5	49	12	14	25
	2	31	19	20	30
N	5	33	18	19	30
	2	25	30	15	30
R	5	31	20	19	30
	2	19	28	22	31
S	5	34	18	20	28
	2	37	17	19	27

[a]Numbers are estimated by the CDSSTR software package.

An investigation of potential correlations between secondary structure composition at pH 5 and stability toward heat, low pH, and pepsin indicated that helix content (at pH 5) correlated negatively with half-life at pH 2, whereas strand and turn contents correlated positively (Figure 6a; because no significant loss of activity was observed for S and N phytases, their half-lives have been plotted at 3000 min). On the other hand, higher helix content (at pH 5) and lower contents of

DOI: 10.1021/jf5050469
J. Agric. Food Chem. 2015, 63, 943−950

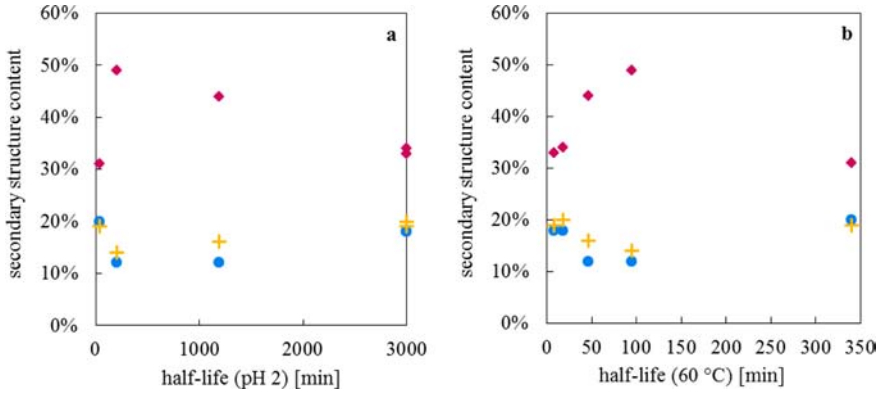

Figure 6. (a) Secondary structure contents against enzymatic activity half-life at pH 2: (red diamonds) helix; (blue circles) strand; (yellow crosses) turns. (b) Secondary structure contents against enzymatic activity half-life at 60 °C (legend as in panel a).

strands and turns appeared to imply a longer half-life at 60 °C (Figure 6b). These tendencies with regard to stability toward heat and low pH were observed for the G, S, N, and H phytases, whereas the R phytase apparently evaded these trends. It is believed that the *P. lycii* phytase (R), which is an optimized version of the native *P. lycii* phytase, differs significantly from the other phytases, for example due to single amino acid changes that may play a crucial role in the structural integrity of the enzyme.

In conclusion, the CD results clearly established a relationship between loss of secondary structure and loss of activity at a low pH. To our knowledge, this relationship has not previously been reported for these phytases.

Sequence Alignment and Homology Modeling. As expected, sequence alignment showed highest sequence identity within the fungal phytases and bacterial phytases, respectively (Table 3). Crystal structures are available for *E. coli* (G), *C. braakii* (H), and *A. niger* (S/N) phytases with PDB entries 1DKL, 3ZHC and 3K4P, respectively. No crystal structure is available for the *P. lycii* (R) phytase. Homology modeling rendered a model using phytases from *A. ficuum* (PDB entry 1IHP) and *A. fumigatus* (PDB entry 1QWO) as templates. Each *Aspergillus* phytase (the two templates, which had 65% sequence identity) had 40% sequence identity with *P. lycii*. The secondary structure contents of the modeled 3D structure for the *P. lycii* phytase were 43% helix, 11% strand, and 16% disordered, which correlates poorly with the secondary structure content determined from the CD spectra (Table 2). This poor agreement with experimental data points toward differences in structure of the homologous enzymes despite their moderate similarity in the amino acid sequence.

Overall, the stability and activity assessments using the soluble phytic acid substrate reported here have provided a decision base for conducting further trials, also including the use of a food model system with digestion.

Table 3. Sequence Identities As Determined from Sequence Alignment Carried out by Clustal Omega

% sequence identity	*C. braakii*	*E. coli*	*A. niger*	*P. lycii*
C. braakii		63.33	19.78	20.64
E. coli	63.33		20.11	21.23
A. niger	19.78	20.11		39.71
P. lycii	20.64	21.23	39.71

these compounds. Freezing has been shown as an effective method of minimizing the oxidative degradation of these compounds during storage.[4,10]

MATERIALS AND METHODS

Raw Materials. Vegetable seeds were donated by the Seminis Vegetable Seed Co., Inc., Woodland, CA. Six replicate samples were harvested from different randomly selected points along linear rows for each commodity. Commodities were harvested according to the times and locations listed in Table 1.

Table 1. Harvest Times and Locations for Each Commodity Studied

commodity	month and year	harvest location
spinach	December 2012	Full Belly Farm (Guinda, CA)
carrots	November 2012	UC Davis (Davis, CA)
broccoli	February 2013	UC Davis (Davis, CA)
blueberries	March 2013	California Coastal Blueberry Farms (Oxnard, CA)
peas	April 2013	Iacopi Farm (Half Moon Bay, CA)
green beans	June 2013	UC Davis (Davis, CA)
strawberries	July 2013	Driscoll's (Watsonville, CA)
corn	August 2013	UC Davis (Davis, CA)

All commodities were harvested at uniform maturity as determined by both color and approximate size, as recommended by the grower. All commodities were transported to the UC Davis (University of California, Davis) Food Science and Technology pilot processing plant in refrigerated Styrofoam coolers (Lifoam Industries, Hunt Valley, MD) and processed immediately.

Processing. Throughout the processing and storage chains, each of the six field replicates was maintained as discrete samples. All commodities were given a preliminary rinse with water prior to entering the pilot plant to avoid unnecessary contamination of the facilities. Commodities were then submerged in a flume wash (Food Science and Technology Machine Shop, Davis, CA) filled with water and rinsed thoroughly to remove any surface dirt. Some commodities received additional processing steps prior to blanching: carrots were diced into 1.5 cm cubes using an Urschel G-A dicer (Urschel Laboratories, Inc., Valparaiso, IN), strawberries had their crowns removed by hand, green beans and peas were destemmed by hand, broccoli was cut into 3−5 cm florets by hand, and individual corn kernels were removed from the cob by hand using a Zyliss corn stripper (Zyliss, Irvine, CA).

For each field replicate of each commodity, cleaned, prepared samples were randomized and separated into two parts. Half of each field replicate was then marked for fresh storage, while the other half was blanched and frozen. The samples to be blanched were loaded onto the steam blanching line (Food Science and Technology Machine Shop) in stainless steel baskets for the specified amount of time and temperature (Table 2). Following blanching, the samples were transferred onto wire mesh racks and placed immediately into a −32 °C walk-in freezer (Estes Refrigeration, Inc., Richmond, CA). After 1 h, the frozen commodity was divided into three 300 g storage samples which were packaged in UltraSource 3 mil polyethylene pouches (UltraSource LLC, Kansas City, MO) and stored at −27.5 °C (18 °F) for up to 90 days. Blueberries and strawberries were not blanched prior to freezing, in accordance with industry practices.

Table 2. Blanching Protocols for Each Commodity

commodity	blanch time (min)	blanch temp (°C)	commodity	blanch time (min)	blanch temp (°C)
blueberries	N/A	N/A	corn	3.5	93.3
strawberries	N/A	N/A	green beans	3.5	93.3
broccoli	1.5	90.5	peas	2	93.3
carrots	2	96.1	spinach	3	93.3

Stability Study. The fresh half of each field replicate was divided into three 300 g storage samples which were stored in breathable Tuf-R low-density polyethylene bags (U.S. Plastic Corp., Lima, OH) at 2 °C (35.6 °F) in a walk-in refrigerator (Estes Refrigeration, Inc.) for up to 10 days. The frozen half of each field replicate was divided into three 300 g storage samples which were packaged in UltraSource 3 mil polyethylene pouches (UltraSource LLC) and stored at −27.5 °C (18 °F) for up to 90 days. For each field replicate, one frozen pouch and one fresh pouch were analyzed within 24 h of harvest (day 0) and after each storage time: 3 and 10 days for fresh; 10 and 90 days for frozen. Upon completion of each storage period, samples were removed from storage and transported in refrigerated coolers to the UC Davis Analytical Laboratory facilities for analysis.

Minerals. *Acid Digestion.* A 0.5 g portion of dried, homogenized sample was weighed and transferred to a Teflon PFA double-wall digestion vessel with a 200 psi relief seal (CEM Corp., Matthews, NC). A 1 mL volume of nitric acid and 2 mL of hydrogen peroxide (Fisher Scientific Co., Pittsburgh, PA) were added and gently mixed with the sample. The vessel was capped tightly and allowed to predigest for 10−15 min. Samples were digested for 5 min at 40% power and 8 min at 90% power in a CEM MDS 2000 microwave digestion system (CEM Corp.). After cooling, the digest was transferred to a 15 mL centrifuge tube using deionized water to rinse the vessel. The volume was adjusted to 15 mL with deionized water. The test tube was mixed by being shaken vigorously and allowed to sit overnight to allow particles to settle out. A 1 mL aliquot of the digest was diluted with 3 mL of deionized water and analyzed on a Thermo iCAP 6500 inductively coupled plasma atomic emission spectrometer (Thermo Fisher Scientific, Hudson, NH).

Fiber. *Reagents.* Acid detergent solution was prepared by thoroughly mixing 2 L of Ankom acid detergent liquid (Ankom Technology, Macedon, NY) with 8 L of deionized water. Sulfuric acid solution was prepared by diluting 650 mL of concentrated sulfuric acid (Fisher Scientific Co.) to 2 L with deionized water.

Acid Digestion. Approximately 1 g of dried, ground sample material was weighed into an aluminum weigh dish (Fisher Scientific Co.). The sample was washed into a 600 mL refluxing beaker using acid detergent solution. Additional acid detergent solution was added to fill the beaker to the 100 mL mark. The sample solution was heated under reflux for 60 min and then filtered using a coarse porosity fritted glass crucible (Corning, Tewksbury, MA). The sample was rinsed twice with 90−100 °C water and twice with acetone, then dried for 3 h at 105 °C, cooled, and weighed.

Total Phenols. *Reagents.* Sodium carbonate solution consisted of 75 g of sodium carbonate (Fisher Scientific Co.) diluted in 1 L of deionized water. Gallic acid standards of 40, 100, and 2500 mg/L concentrations were prepared by mixing gallic acid (Arcos Organics, Geel, Belgium) with acetone to the appropriate concentration. Folin and Ciocalteu's phenol reagent (2 N) was obtained from Sigma-Aldrich, Buchs, Switzerland.

Folin−Ciocalteu Treatment. Samples were homogenized with 60% water by weight of sample. A 6.4 g mass of each of the blended samples was weighed into a 50 mL plastic centrifuge tube. Samples were homogenized with 27.6 mL of 76% (v/v) aqueous acetone (Fisher Scientific Co.) for 30 s using an Ultra Turrax T25 basic homogenizer (IKA Works, Inc., Wilmington, NC). After being shaken for 10 min, the samples were centrifuged at 2000 rpm for 10 min. To 1 mL of extract was added 0.36 mL of 2 N Folin reagent. The solution was vortexed and allowed to stand for 5 min, then 6 mL of sodium carbonate was added, and the solution was vortexed again. Deionized water (2.64 mL) was added, and the solution was vortexed and incubated at 50 °C for 5 min. After the solution was cooled to room temperature for 1 h, the absorbance was read at 760 nm and compared to a calibration curve of derivatized gallic acid.

Statistical Analysis. Statistical analysis was performed using JMP statistical software version 9.0.0 (SAS Institute Inc., Cary, NJ). A blocked analysis of variance (ANOVA) was run with storage time point and processing treatment as the treatments. Tukey comparisons

were used to determine the significance of differences between both fresh and frozen treatments and storage time points for each commodity and nutrient.

RESULTS AND DISCUSSION

The results of this study are presented in Table 3. The content of five minerals as well as fiber and total phenolics was evaluated in eight different commodities stored under either refrigeration (fresh) or frozen conditions over three storage points.

Minerals. Rickman et al.[4] and previous authors have found that minerals are unaffected by the thermal treatments implemented during conventional food processing.[12,13] In fact, leaching of minerals during blanching is the only significant cause of loss of minerals that has been reported that is relevant to the conditions of this study. Water-soluble minerals can be extracted into the water used during the blanching process, causing losses in mineral content of food blanched before further processing.[4,6,14]

While all commodities were washed and scrubbed thoroughly prior to sampling, it is possible that some soil may have remained on the samples, which would have artificially augmented the baseline fresh values and would have caused an apparent decrease in frozen values due to the fact that the mineral-rich soil had been removed during blanching. To evaluate this possibility, an extra set of carrot samples was analyzed. The carrots were peeled after washing and sampled according to the same experimental protocol as the other samples in this study. Half of the peeled carrot samples were stored fresh, and the other half were blanched and frozen. There were no significant differences in mineral content between the fresh and frozen peeled carrots. This suggests that some of the difference in mineral content of samples immediately after blanching is due to removal of residual soil particles.

Calcium. Calcium was one of the best-retained nutrients in the fresh and frozen stored commodities evaluated over the course of this study. In all commodities, there were no significant differences between the frozen samples and those that were stored fresh (Table 3). These results were consistent with the findings of Wills et al.[15] and Maklouf et al.,[16] who found that the calcium content of frozen vegetables was highly conserved, if not higher than in fresh-stored produce.

Magnesium. Magnesium was largely well conserved over both fresh and frozen storage in most commodities. Broccoli, carrots, blueberries, and strawberries showed no significant difference in magnesium content between fresh and frozen samples (Table 3).

Frozen peas, spinach, and corn contained between ~7% and 18% less magnesium when compared to fresh samples (Table 3). These changes were apparent immediately following processing, indicating that minor losses were most likely caused by leaching of magnesium into the blanching water.[16,17]

Zinc. The trends in retention of zinc in frozen fruits and vegetables were similar to those of magnesium. Broccoli, carrots, strawberries, green beans, corn, blueberries, and spinach showed no significant difference between fresh and frozen treatments, while peas showed small losses (~5%) in frozen samples (Table 3).

Copper. Copper, like calcium, was well retained in frozen as compared to fresh produce. In all commodities, there were no significant decreases in the frozen samples (Table 3). This indicates that there were no losses due to leaching of nutrients during blanching, which is the only reason cited in the literature for loss of minerals during the freezing process where no tissue is removed.[4,12,13]

Iron. Two general trends were apparent in the retention of iron in frozen and fresh produce. In green beans, broccoli, carrot variety B, blueberries, strawberries, and peas, there were no significant differences in the iron content between the two treatments. However, in spinach and carrot variety A, the frozen samples had between 10% and 45% less iron than the fresh samples (Table 3). This could be due to leaching of iron during blanching,[14,16,17] since as illustrated with spinach, the loss occurs immediately after blanching and freezing. It may also have been due to small traces of soil left on the surface of products that was washed off during blanching. The amount of surface area exposed to blanching may have also contributed, since the carrots were diced prior to blanching and the spinach had high surface area naturally.

Acid-Digestible Fiber (ADF). Most of the commodities (blueberries, strawberries, green beans, peas, spinach, and corn) showed no significant change in fiber content over the course of fresh or frozen processing and storage (Table 3); however, some commodities showed increases during storage or declines as a result of either blanching or frozen storage. Broccoli showed an increase (21.2%) in fiber content during fresh storage (Figure 1). This could be due to continued respiration

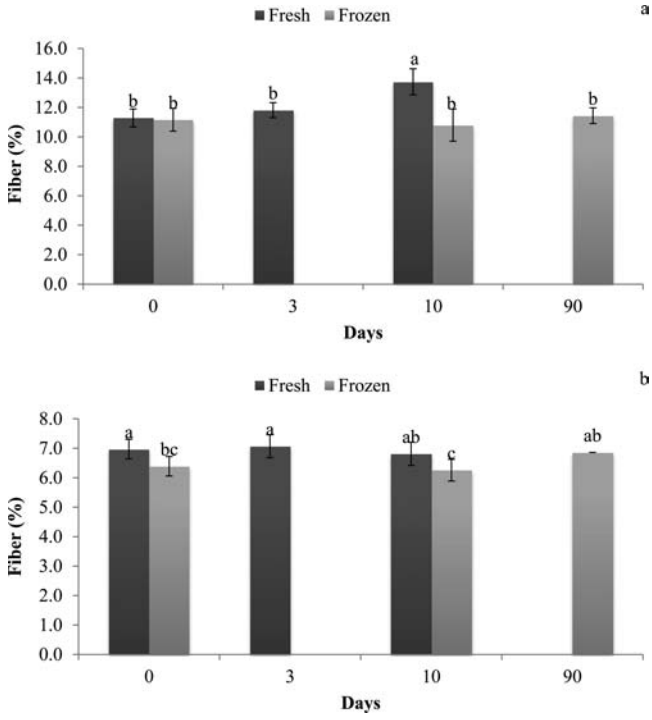

Figure 1. Fiber content of (a) broccoli and (b) blueberries during fresh and frozen storage. Values reported on a dry weight basis. Values that share the same letter (a, b, c) are not significantly different ($p \leq 0.05$).

and thickening of cell walls within broccoli tissue during storage.[18] Some commodities, such as bamboo shoots, have been known to exhibit such behavior during postharvest storage as a stress response.[19] It should be noted that while increases in fiber content were found in vegetables such as onions in previous studies,[20] the increases occurred over much longer periods of fresh storage than in this study. Onions respire

DOI: 10.1021/jf504890k
J. Agric. Food Chem. 2015, 63, 951−956

slower than broccoli, so that may be the reason for the difference. This increase in fiber content during fresh storage caused fresh broccoli to appear to have higher fiber content than frozen broccoli, even though the fiber content of frozen broccoli was unaltered during processing and storage.

Both varieties of carrots lost fiber (~25%) during frozen storage. This could be due to degradation of cell wall components such as cellulose, hemicellulose, pectin, and lignin, which is known to occur during frozen storage of some commodities.[21] Degradation of these polysaccharides in these tissues could have caused the apparent decrease in fiber over storage time.

Fiber losses in peas appear to be due to physical losses during the blanching and freezing process, as the decline occurs immediately after these processes on day 0. According to Kunzek et al.,[22] thermal processing can cause changes in the solubility of plant carbohydrates, which could account for the losses seen in peas, which were among the commodities blanched before freezing. This seems to be corroborated by the fact that two of the commodities with the best retention of fiber were strawberries and blueberries, the two commodities that received no blanching treatment prior to freezing.

Some variability in the method of analysis of fiber, or variability in the raw material, may have had an impact on these results, as frozen blueberries showed slight decreases in fiber levels initially (~8%), but by the end of the 90 day frozen storage period, the frozen product was not significantly different from the fresh product (Figure 1). Previous studies indicated little to no loss of fiber for any commodities during processing apart from methods that involved peeling or otherwise removing plant tissue.[4,14]

Phenolics. Overall, phenolics were well retained in both fresh and frozen produce, and some commodities retained higher concentrations with frozen storage. Spinach, green beans, and carrots showed no significant differences between fresh and frozen produce, while broccoli, corn, and peas had lower levels of phenolic compounds in frozen samples (Figure 2). This could be due to either oxidation of phenolic compounds or leaching of water-soluble phenolic compounds during blanching.[14,23] The decline in phenolic content of peas during frozen storage may be due to oxidation of sensitive phenolic compounds, which can occur nonenzymatically even at temperatures encountered in frozen storage.[4,14] The increases in phenolics in broccoli and peas over the fresh storage period contrast with the findings of Vallejo et al.,[23] who found large losses in phenolic content of fresh broccoli over a period of 10 days, but are supported by Olivera et al.,[24] who proposed that rupture of cellular compartments such as vacuoles during processing could lead to increased availability of phenolic compounds. Blueberries showed higher values of phenolics in frozen compared to fresh samples. This may be due to high oxidative enzymatic activity in fresh blueberries, which would have been minimized by frozen storage.[24,25]

Conclusions. With regard to the nutrients studied, frozen fruits and vegetables represent nutritionally viable alternatives to fresh produce subjected to typical postharvest holding times. Total phenolics, fiber, and minerals were for the most part well conserved in frozen samples as compared to fresh, and when there were decreases in frozen samples, they were usually small and may have been due to some variability in the raw material.

In this study we sought to evaluate the nutritional quality of fruits and vegetables as they arrived to the consumer. A logical progression to future studies would include evaluation of what happens to that nutrient content during preparation for consumption in the home. Knowledge about basic culinary practices involved in preparation of these commodities for consumption in the home would provide useful insight into how they can best be preserved.

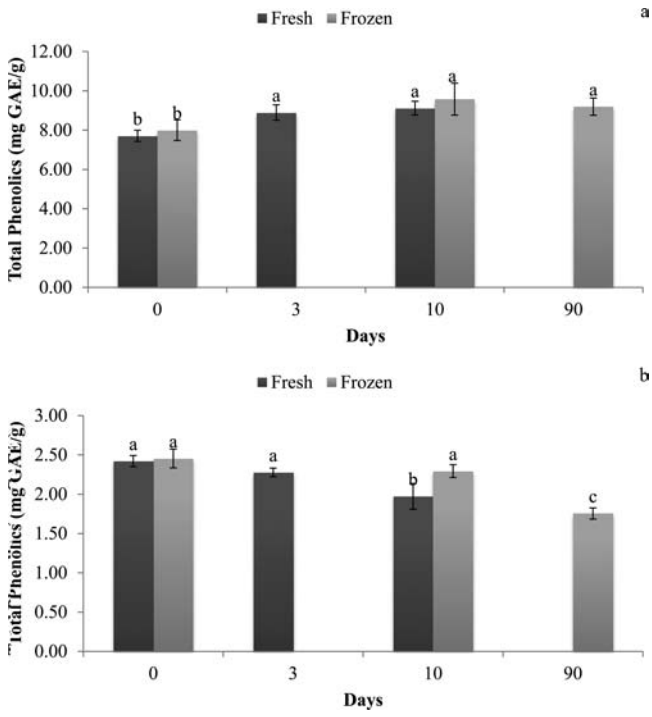

Figure 2. Phenolics content of (a) spinach and (b) corn during fresh and frozen storage. Values reported on a dry weight basis. Values that share the same letter (a, b, c, d, e) are not significantly different ($p \leq 0.05$).

While fat-soluble vitamin A is not normally found in fruits and vegetables, it can be indirectly obtained through consumption of the carotenoid compound β-carotene. β-Carotene is a metabolic precursor to vitamin A, and in fact, many dietary descriptions of plant-based foods report a vitamin A correlation that is based on the concentration of β-carotene in the product. β-Carotene does not leach out of produce during washing and blanching but is very sensitive to degradation due to oxidation. This potential for oxidation is dependent on the various processing and storage conditions which include exposure to high temperatures, light, and oxygen.[6,19] Retention of β-carotene in frozen storage seems to vary by commodity, with studies showing decreases to different degrees in β-carotene over a prolonged period of frozen storage.[6,20] This is in contrast to fresh storage, where there is reported to be little degradation.[13]

MATERIALS AND METHODS

Raw Materials. Vegetable seeds were donated by the Seminis Vegetable Seed Co., Inc., Woodland, CA. Six replicate samples were harvested from different randomly selected points along linear rows for each commodity. Commodities were harvested according to the times and locations listed in Table 1.

Table 1. Harvest Times and Locations for Each Commodity Studied

commodity	month and year	harvest location
spinach	December 2012	Full Belly Farm (Guinda, CA)
carrots	November 2012	UC Davis (Davis, CA)
broccoli	February 2013	UC Davis (Davis, CA)
blueberries	March 2013	California Coastal Blueberry Farms (Oxnard, CA)
peas	April 2013	Iacopi Farm (Half Moon Bay, CA)
green beans	June 2013	UC Davis (Davis, CA)
strawberries	July 2013	Driscoll's (Watsonville, CA)
corn	August 2013	UC Davis (Davis, CA)

All commodities were harvested at uniform maturity as determined by both color and approximate size, as recommended by the grower. All commodities were transported to the UC Davis (University of California, Davis) Food Science and Technology pilot processing plant in refrigerated Styrofoam coolers (Lifoam Industries, Hunt Valley, MD) and processed immediately.

Processing. Throughout the processing and storage chains, each of the six field replicates was maintained as discrete samples. All commodities were given a preliminary rinse with water prior to entering the pilot plant to avoid unnecessary contamination of the facilities. Commodities were then submerged in a flume wash (Food Science and Technology Machine Shop, Davis, CA) filled with water and rinsed thoroughly to remove any surface dirt. Some commodities received additional processing steps prior to blanching: carrots were diced into 1.5 cm cubes using an Urschel G-A dicer (Urschel Laboratories, Inc., Valparaiso, IN), strawberries had their crowns removed by hand, green beans and peas were destemmed by hand, broccoli was cut into 3−5 cm florets by hand, and individual corn kernels were removed from the cob by hand using a Zyliss corn stripper (Zyliss, Irvine, CA).

For each field replicate of each commodity, cleaned, prepared samples were randomized and separated into two parts. Half of each field replicate was then marked for fresh storage, while the other was blanched and frozen. The samples to be blanched were loaded onto the steam blanching line (Food Science and Technology Machine Shop) in stainless steel baskets for the specified amount of time and temperature (Table 2). Following blanching, the samples were transferred onto wire mesh racks and placed immediately into a −32 °C walk-in freezer (Estes Refrigeration, Inc., Richmond, CA). After 1 h, the frozen commodity was divided into three 300 g storage samples which were packaged in UltraSource 3 mil polyethylene pouches (UltraSource LLC, Kansas City, MO) and stored at −27.5 °C (18 °F) for up to 90 days. Blueberries and strawberries were not blanched prior to freezing, in accordance with industry practices.

Table 2. Blanching Protocols for Each Commodity

commodity	blanch time (min)	blanch temp (°C)	commodity	blanch time (min)	blanch temp (°C)
blueberries	N/A	N/A	corn	3.5	93.3
strawberries	N/A	N/A	green beans	3.5	93.3
broccoli	1.5	90.5	peas	2	93.3
carrots	2	96.1	spinach	3	93.3

Stability Study. The fresh half of each field replicate was divided into three 300 g storage samples which were stored in breathable Tuf-R low-density polyethylene bags (U.S. Plastic Corp., Lima, OH) and stored at 2 °C (35.6 °F) in a walk-in refrigerator (Estes Refrigeration, Inc.) for up to 10 days. The frozen half of each field replicate was divided into three 300 g storage samples which were packaged in UltraSource 3 mil polyethylene pouches (UltraSource LLC) and stored at −27.5 °C (18 °F) for up to 90 days. For each field replicate, one frozen pouch and one fresh pouch were analyzed within 24 h of harvest (day 0) and after each storage time: 3 and 10 days for fresh; 10 and 90 days for frozen. Upon completion of each storage period, samples were removed from storage and transported in refrigerated coolers to the UC Davis Analytical Laboratory facilities for analysis.

Homogenization and Sample Preparation. Fresh or frozen samples were blended in a blender (Vita-Prep 3, Vitamix, Cleveland, OH) with the addition of 6 g of deionized water for every 10 g sample.

Riboflavin. *Extraction.* Homogenized sample (3.2 g, equivalent to 2 g of sample) was weighed into 50 mL plastic centrifuge tubes. To this was added 20 mL of 0.1 M HCl (Fisher Scientific Co., Pittsburgh, PA), and the tubes were capped, shaken for 5 min, and then incubated at 100 °C for 30 min. Once cool, 2.5 mL of 2.5 M sodium acetate (Fisher Scientific Co.) was added, to an approximate pH of 4.87, and then 100 mg of amyloglucosidase (Sigma-Aldrich, St. Louis, MO) was added to each sample. The samples were shaken and incubated at 37 °C for 15 h. After cooling, 2 mL of trichloroacetic acid (Fisher Scientific Co.) was added to each tube, and the samples were heated to 60 °C for 15 min. After cooling, the samples were diluted with deionized water to a final volume of 40 mL, shaken, and centrifuged for 10 min at 4000 rpm. From the supernatant, 10 mL aliquots were taken, 50 μL of 10 ppm internal standard ($[^{13}C_4,^{15}N_2]$riboflavin, Sigma-Aldrich) was added, and the tubes were vortexed. A 10 mL sample aliquot was loaded onto an Oasis HLB 3 mL[3] (60 mg) extraction cartridge (Waters Corp., Milford, MA) which was prewashed with 1 column volume of methanol followed by 1 column volume of deionized water. The extraction column was washed with 2.5 mL of trichloroacetic acid and dried for 5 min under vacuum. The column was eluted with 1 mL of methanol (Fisher Scientific Co.) into glass test tubes. The extracts were filtered through 0.20 μm IC Millex-LG (EMD Millipore Corp., Billerica, MA) filters into autosampler vials. A 15 μL aliquot of sample was then injected onto the high-performance liquid chromatography (HPLC) column for liquid chromatography/mass spectrometry (LC/MS) determination.

Analysis. The samples were analyzed using HPLC in conjunction with MS. The apparatus consisted of a PerkinElmer LC-200 chromatograph (PerkinElmer, Waltham, MA) with a Sciex API 2000 mass spectrometer (AB SCIEX, Framingham, MA) in the positive ion ESI mode. The transition ions m/z 377 to m/z 243 (riboflavin) and m/z 283 to m/z 249 ($[^{13}C_4,^{15}N_2]$riboflavin, internal standard) were used. An isocratic mobile phase of 90% methanol with 0.2% acetic acid (Fisher Scientific Co.) and 10% water with 0.2% acetic acid (v/v) at 0.4 mL/min was used on a Waters XTerra RP18 column, 3.5 μm pore size, 4.6 × 150 mm (Waters Corp.).

Ascorbic Acid. *Extraction.* Homogenized sample (6.4 g) was mixed with 13.6 mL of 2% oxalic acid (Fisher Scientific Co.) and

J. Agric. Food Chem. 2015, 63, 957−962

homogenized for 30 s. From this mixture, 10 mL was transferred to a 15 mL centrifuge tube and centrifuged at 10 000 rpm for 10 min at 4 °C. A 1.8 mL aliquot was taken, 400 μL of 5% dithiothreitol (Sigma-Aldrich) was added, and the sample was filtered through a 0.2 μm filter. The filtered sample was transferred to an autosampler vial for HPLC analysis.

Analysis. The samples were analyzed using HPLC with UV/vis diode array detection at 261 nm. The apparatus consisted of a PerkinElmer 200 quaternary HPLC system with a PerkinElmer 200 diode array detector (PerkinElmer). A Phenomenex Luna C-18 HPLC column (100 mm × 4.6 mm, 100A) with a C-18 guard column (Phenomenex, Torrance, CA) was used. The mobile phase was 95% water and 5% methanol with 5 mM hexadecyltrimethylammonium bromide and 50 mM potassium dihydrogen phosphate (Sigma-Aldrich) at 1.2 mL/min.

α-Tocopherol and β-Carotene. *Extraction.* Homogenized sample (1.6 g) was weighed into a 50 mL glass centrifuge tube along with 5 mL of ethanol containing 6% (w/v) pyrogallol (Sigma-Aldrich), and the mixture was sonicated for 10 min. A 1 mL volume of 50% KOH (aqueous) (Fisher Scientific Co.) was added, the mixture was mixed by vortexing and heated at 70 °C for 10 min, and mixed and heated for an additional 10 min. The sample was cooled to room temperature, and 5 mL of 5% NaCl was added. The sample was extracted with 30 mL of extraction solvent (85:15 (v/v) hexane/ethyl acetate with 0.05% BHT, Sigma-Aldrich). A 7.5 mL aliquot was evaporated to dryness at 40 °C under nitrogen using a Zymark TurboVap LV. The extract was redissolved in 200 μL of ethyl acetate followed by 1.8 mL of methanol, mixed, and filtered into an autosampler vial for HPLC analysis.

Analysis. The samples were analyzed using HPLC with UV/vis and fluorescence detection. The apparatus consisted of a PerkinElmer 200 quaternary HPLC system with a PerkinElmer 200 UV/vis detector (PerkinElmer) and a Shimadzu 10Axs fluorescence detector (Shimadzu Scientific Instruments, Columbia, MD). Excitation and emission wavelengths of 295 and 340 nm were used to detect α-tocopherol, and an absorbance wavelength of 450 nm was used to detect β-carotene. A Phenomenex Kinetex C-18 HPLC column (100 mm × 4.6 mm, 100A) with a C-18 guard column (Phenomenex) and a mobile phase of 9:1 (v/v) acetonitrile/methanol (Fisher Scientific Co.) at 1 mL/min was used.

Statistical Analysis. Statistical analysis was performed using JMP statistical software version 9.0.0 (SAS Institute Inc., Cary, NJ). A blocked analysis of variance (ANOVA) was run with storage time point and processing treatment as the treatments. Tukey comparisons were used to determine the significance of differences between both fresh and frozen treatments and storage time points for each commodity and nutrient.

RESULTS AND DISCUSSION

The concentrations of four different compounds were evaluated in eight different commodities stored under either refrigeration (fresh) or frozen conditions over three time points (Table 3).

Ascorbic Acid. Ascorbic acid was degraded less in frozen-stored samples than in fresh-stored samples (Figure 1). None of the eight commodities showed losses during frozen storage. In strawberries, carrots, spinach, peas, and broccoli, the ascorbic acid content of fresh-stored products was not significantly different from that of frozen-stored products. In corn, green beans, and blueberries, significantly higher levels of ascorbic acid were found in frozen-stored samples when compared to fresh-stored samples, which could possibly be attributed to arrested enzymatic activity and slowed oxidative degradation of ascorbic acid in the frozen samples.[6] Extensive degradation of ascorbic acid in fresh-stored produce has been previously reported in vegetables, as compared to their frozen counterparts.[21−23]

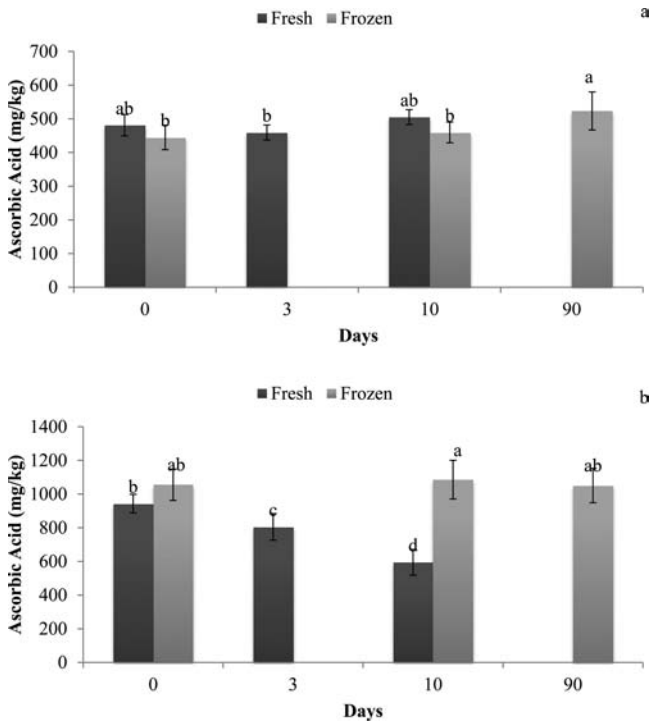

Figure 1. Ascorbic acid content of (a) strawberries and (b) green beans during fresh and frozen storage. Values reported on a dry weight basis. Values that share the same letter (a, b, c, d) are not significantly different ($p \leq 0.05$).

Riboflavin. Riboflavin was well conserved in most frozen samples. Carrots, corn, broccoli, blueberries, and green beans all followed the same trend, with fresh samples containing the same riboflavin content as frozen samples (Figure 2a). Of the eight commodities studied, only peas lost riboflavin during frozen storage (Figure 2b). The loss of riboflavin in peas is most likely due to oxidative degradation of the nutrient. Similar results were found by Gleim et al.,[24] who noted large decreases in riboflavin in asparagus and spinach.

Broccoli (Figure 2c) actually had higher riboflavin content in frozen-stored vs fresh-stored samples. This contrasts with the majority of the literature, such as Makhlouf et al.,[25] who found that, while riboflavin content was higher in frozen vegetables than canned, it was not higher in frozen vegetables than fresh. Similarly, while Van Duyne et al.[26] found riboflavin to be well retained in frozen peas, beans, and spinach, it was not found to be present in any higher amounts in frozen produce as compare to fresh produce.

α-Tocopherol. Of all of the nutrients determined in this study, the α-tocopherol content in fruits and vegetables benefited the most from blanching, freezing, and frozen storage, as compared to fresh storage. When stored fresh, peas, carrots, and corn showed significant decreases in α-tocopherol content (Figure 3). Fresh green beans had much lower levels of α-tocopherol than frozen, but the levels of α-tocopherol did not decrease over the course of fresh storage. In the remaining commodities blueberries, broccoli, green beans, spinach, and strawberries, no significant difference between fresh- and frozen-stored samples was observed (Figure 3). Frozen peas and green beans exhibited more than 2-fold higher levels of α-tocopherol, while blueberries, spinach, and corn also had significantly higher levels (12−39%) in frozen-stored samples, as compared to fresh-stored samples (Figure 3).

J. Agric. Food Chem. 2015, 63, 957−962

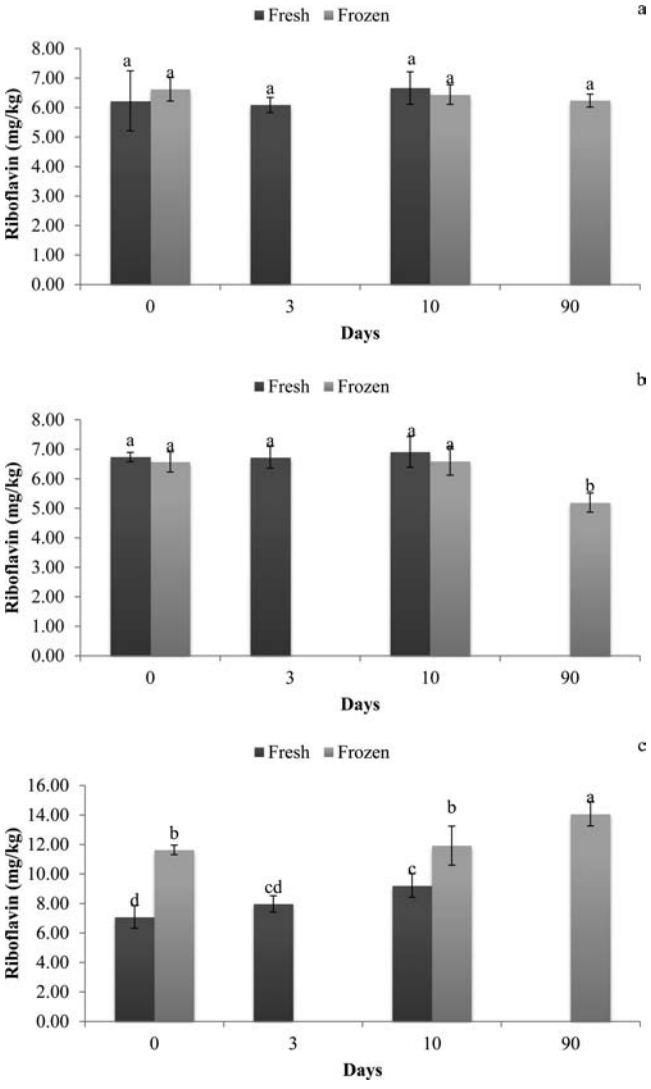

Figure 2. Riboflavin content of (a) green beans, (b) peas, and (c) broccoli during fresh and frozen storage. Values reported on a dry weight basis. Values that share the same letter (a, b, c, d) are not significantly different ($p \leq 0.05$).

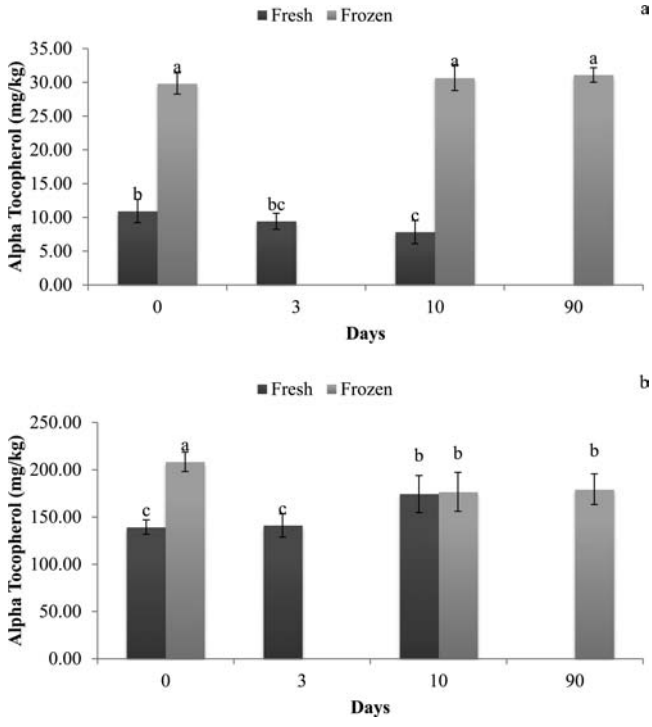

Figure 3. α-Tocopherol content of (a) peas and (b) broccoli during fresh and frozen storage. Values reported on a dry weight basis. Values that share the same letter (a, b, c) are not significantly different ($p \leq 0.05$).

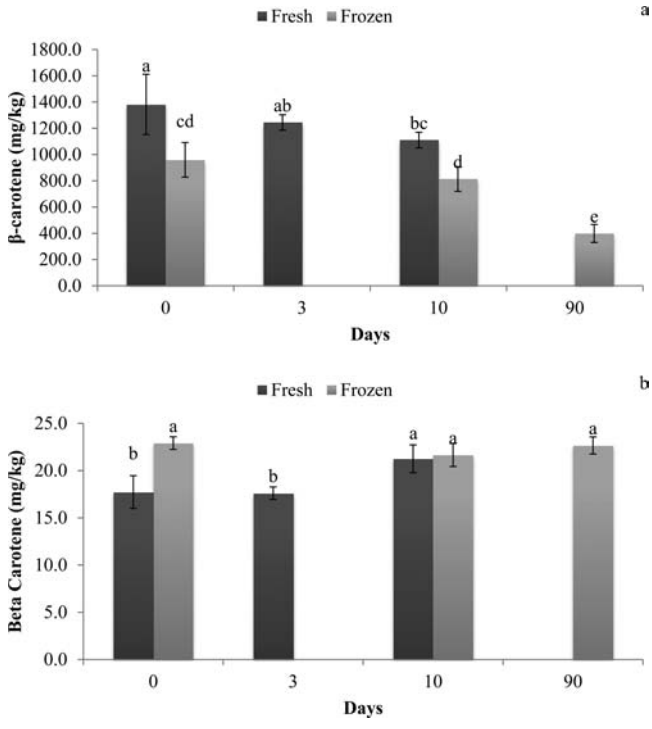

Figure 4. β-Carotene content of (a) carrots and (b) green beans during fresh and frozen storage. Values reported on a dry weight basis. Values that share the same letter (a, b, c, d, e) are not significantly different ($p \leq 0.05$).

The observed higher levels of α-tocopherol in some commodities, which is evident immediately after blanching and freezing on day 0, may be due to its increased availability after steam blanching.[26] α-Tocopherol levels in fresh broccoli were found to be more than 2-fold higher after heat treatments such as steaming or boiling by previous authors.[26] The heat treatment administered during blanching could have a similar effect on the commodities in this study. Previous authors have not studied the effects of freezing on peas in any detail, but lipid oxidation in peas caused by enzymatic or nonenzymatic pathways has been reported to consume α-tocopherol, a potent antioxidant.[27] Both of these oxidative pathways could have been responsible for preferentially lowering the levels of α-tocopherol in fresh samples. It is also unlikely that any leaching of fat-soluble α-tocopherol would occur during blanching in an aqueous environment.

***β*-Carotene.** β-Carotene was not found in any significant amount in blueberries, strawberries, and corn, even in fresh samples (<1.0 mg/kg). Over the course of frozen storage, peas, spinach, and carrots showed losses of more than 50% of the initial β-carotene content (Figure 4). Over the course of fresh storage, peas, green beans, and carrots lost at least 15% of the initial β-carotene content. Losses in β-carotene occurred both immediately after processing and over the course of frozen

DOI: 10.1021/jf5058793
J. Agric. Food Chem. 2015, 63, 957−962

storage. Losses during blanching are most likely not related to leaching because β-carotene is water insoluble,[6] but may be attributed to oxidation of β-carotene.[20] In all of the commodities that showed decreased levels of β-carotene, the 90 day frozen samples were by far the lowest levels detected. These decreases were most likely due to oxidation during frozen storage, which was found to occur in previous studies by Desobry et al.,[29] but these findings are contrary to some other previous findings.[20,26] One possible explanation for such a drastic decrease in β-carotene in carrots is that extensive cell damage and larger surface area after dicing encouraged oxidation of the tissue.[28] Green beans and broccoli showed no significant differences in β-carotene as a result of processing and storage (Figure 4).

Conclusions. For most nutrients in this study, frozen versions of a given commodity present viable substitutes for fresh in terms of nutritional value. While the results were highly dependent on commodity and nutrient, there were certain trends within the specific nutrients. In frozen samples of the commodities analyzed, riboflavin, α-tocopherol, and ascorbic acid were not only preserved in quantities equivalent to those of fresh samples, but in many cases were found in quantities much higher than those of the fresh samples. The most prevalent negative trend in the nutrient content of frozen fruits and vegetables is in β-carotene, which was drastically degraded over frozen storage in many of the commodities studied.

ethyl ether (447534, Carlo Erba) were used as reagents. Mixtures of pure FA (674, Nu-Chek Prep Inc., Elysian, MN, USA), bacterial acid methyl esters (BAMEs) (Sigma-Aldrich) plus CLA*c*9,*t*11 (UC-60M, Nu-Chek Prep Inc.), CLA*t*10,*c*12 (UC-61M, Nu-Chek Prep, Inc.), CLA*c*9,*c*11 (1256, Matreya LLC, Pleasant Gap, PA, USA), CLA*c*11,*t*13 (1259, Matreya LLC), and CLA*t*9,*t*11 (1257, Matreya LLC) were used as reference standards, whereas methyl-12-tridecenoate (U-35 M, Nu-Chek Prep Inc.) was used as internal standard.

Animals and Feeding Systems. The present study followed the "Guidelines for the Care and Use of Agricultural Animals in Agricultural Research and Teaching".[14] Data regarding growth performance and carcass traits of the lambs used in the current experiments are given in Pellattiero et al.[15] Briefly, the lambs were selected from the two largest flocks on an in situ conservation program. Given the need for breed conservation, the number of lambs included in the

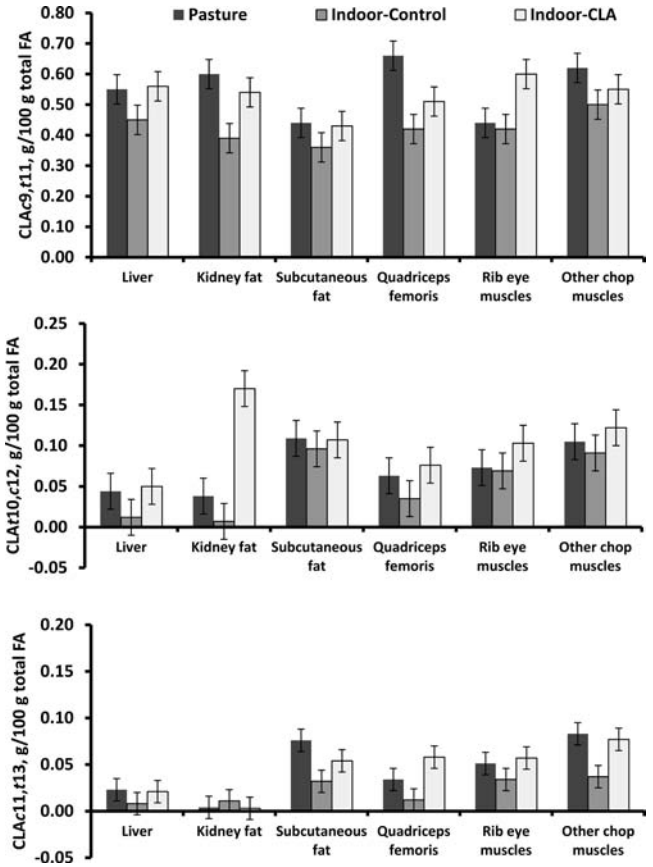

Figure 1. Effect of feeding system (pasture; indoor-control, based on hay and concentrates; indoor-CLA, based on hay and concentrates top dressed with 8 g/day of a commercial rumen-protected CLA mixture) on the content of CLA,*c*9,*t*11, CLA*t*10,*c*12, and CLA*c*11,*t*13 of six lamb tissues. Each bar is the least-squares mean from 12 observations; vertical bars indicate SEM. The level of significance of the feeding system × tissue interaction was $p = 0.07$, $p = 0.10$, and $p = 0.23$ for CLA,*c*9,*t*11, CLA*t*10,*c*12, and CLA*c*11,*t*13, respectively.

experiment was kept to a minimum yet was sufficient to attain adequate statistical power. In total, 36 weaned lambs of three breeds, Foza, Brogna, and Alpagota, were used (12 lambs/breed, 6 males and 6 females). To obtain carcasses with FA profiles varying according to the different feeding systems (FS) used in the Veneto region, lambs were divided into three groups (two males and two females of each breed in each group). All of the lambs in the first group were kept together in a fenced pasture on the experimental farm to ensure the same feeding conditions (pasture). The second group of lambs was kept indoors in an open barn and fed ad libitum hay plus 267 g/day of a commercial concentrate mixture (indoor-control), whereas the third group was also kept indoors on the same diet, but supplemented with 8.0 g/head of a commercial rpCLA product (SILA, Noale, Venice, Italy) providing 0.71 g/day of CLA*c*9,*t*11 and 0.69 g/day of CLA*t*10,*c*12 per lamb (indoor-CLA). The chemical compositions of the pasture, hay, concentrate, and rpCLA product are given in Table 1; further details on rpCLA are given in Schiavon et al.[16]

At the beginning of the trial, lambs were weighed and given a body condition score (BCS) on a scale from 1 (emaciated) to 5 (obese). Mean initial body weight (BW) was 20.1 kg for ewe lambs and 21.8 kg for ram lambs; initial BCS was 3.1 for ewe lambs and 3.0 for ram lambs. The trial lasted 113 days. The final average BW was 28.1 kg for ewe lambs and 31.7 kg for ram lambs. Average age, BW, BCS at slaughter, and carcass yields of the three groups are given in Table 2.

Tissue Sampling. Immediately after slaughter, liver and kidney fat samples were collected from all of the animals and stored at −20 °C. Each carcass was divided into two halves, which were weighed and

[a]Data are least-squares means (feeding system, $n = 72$; gender $n = 108$). [b]The asterisks (*, $p < 0.05$, or **, $p < 0.01$) on entries in pasture, CLA, or ram columns indicates that pasture differed from the average of the two indoors diets, indoor-CLA differed from indoor-control, or ram differed from ewes, respectively. [c]Standard error of the means.

cold stored at 4 °C. The day after slaughter, all semicarcasses were weighed again, and the right semicarcasses were divided into five cuts (hind leg, foreleg and shoulder, ribs−loin, withers, brisket). Each cut was weighed, and the ribs−loins and hind legs were collected and stored under vacuum for 6 days at 4 °C. These two cuts were then cut up and weighed. Ribs−loin was divided into ribs and loin. Ribs were divided into ribeye muscle, other chop muscles, bones, and subcutaneous fat and weighed. Only the inner part of the hind leg (quadriceps femoris) was separated and weighed. Samples of subcutaneous fat, ribeye muscle, other chop muscles, and leg muscle were collected and stored at −20 °C prior to analysis.

Sample Preparation. All of the tissues collected were ground and mixed for 10 s at 4500*g* (Grindomix GM200, Retsch, Haan, Düsseldorf, Germany). Fresh samples were weighed (liver, 3.26 ± 0.32 g; kidney fat, 2.24 ± 0.21 g; subcutaneous fat, 1.14 ± 0.35 g; leg muscle, 2.60 ± 0.28 g; ribeye muscle, 2.56 ± 0.04 g; other chop muscles, 2.65 ± 0.27 g) and homogenized with Hydromatrix (Phenomenex, Castel Maggiore, Bologna, Italy) and then transferred into 10 mL stainless steel extraction cells for ASE (Dionex ASE 350, Thermo Fisher Scientific Inc., Waltham, MA, USA) with petroleum ether as solvent. Extraction conditions as reported in ASE Application note 334 for meat samples (ASE, Dionex, Sunnyvale, CA, USA) were as follows: temperature, 125 °C; pressure, 10 MPa; static time, 2 min; number of static cycles, 2; rinse, 60%; and purge, 60 s of purge using 20 mL/sample of fresh solvent. Following extraction the solution was heated and maintained at 50 °C under N_2 stream for about 20 min to complete solvent evaporation and then placed in an oven at 60 °C for 15 min and cooled in a dryer; the resulting ether extract was weighed. About 40 mg of ether extract was transferred to test tubes to be methylated using sodium methoxide in methanol (1 M) at room temperature.[17] Briefly, 2 mL of *n*-hexane containing 2 mg/mL of methyl 12-tridecenoate as internal standard and 100 μL of sodium methoxide (1 M) in methanol was collected with a GC microsyringe (1701N, Hamilton, Bonaduz, Switzerland) and added to the ether extract. The solution containing the ether extract was mixed with the solvent for 10 min using a laboratory multimixer (717+, ASAL s.r.l., MI, Italy) at room temperature. After this step, 150 μL of oxalic acid in ethyl ether was added to stop the reaction and obtain the fatty acid methyl ester (FAME) solution. The solution was mixed for 30 s and centrifuged at 8000*g* for 10 min (Sigma Laborzentrifugen 3K15, Osterrode am Harz, Germany). The upper phase was collected (1 mL) and transferred to a vial for the GC×GC analysis. The resulting FAME solution was stored in GC vials at −20 °C prior to analysis.

Gas Chromatographic Analysis. FA profiles of the samples were obtained by GC×GC (Agilent 7890A, Agilent Technologies, Santa Clara, CA, USA) employing two columns in series and fitted with a modulator (G3486A CFT, Agilent Technologies), an automatic sampler (7693, Agilent Technologies), and a flame ionization detector (FID) connected to the chromatography data system software (Agilent Chem Station, Agilent Technologies). This instrument was chosen because the double column enables a much better two-dimensional separation and identification of FAs compared with the traditional one-column GC.[18] Between the two columns the modulator unit collects the analyte bands of the first column in a fixed volume channel, and these are successively launched into the short second column in narrow bands. The operating conditions of the GC apparatus were as follows: first column, 20 m × 100 μm (internal diameter) × 0.1 μm film thickness (J&W 127-0122, Agilent Technologies); H_2 carrier flow, 0.3 mL/min; second column, 5 m × 250 μm (internal diameter) × 0.15 μm film thickness (Agilent 19091N-030, Agilent Technologies); H_2 carrier flow, 24 mL/min. Planned oven temperature variation was an increase from 40 °C (held for 2 min) to 260 °C (held for 5 min) at 5 °C/min. Valves were set for a modulation delay of 0.115 min, a modulation period of 2.0 s, and a sample time of 1.75 s. Detector (FID) conditions were as follows: heater, 250 °C; H_2 carrier flow, 20 mL/min; air flow, 450 mL/min. Splitless inlet temperature was 250 °C and pressure, 37.758 MPa, with a septum purge of 3 mL/min and a split ratio of 15 mL/min.

[a]Data are least-squares means (feeding system, $n = 72$; gender $n = 108$). [b]The asterisks (*, $p < 0.05$, or **, $p < 0.01$) on entries in pasture, CLA, or ram columns indicate that pasture differed from the average of the two indoors diets, indoor-CLA differed from indoor-control, or ram differed from ewes, respectively. [c]Standard error of the means. [d]Found only in liver and kidney fat. [e]Co-eluted isomers. [f]Found only in liver.

The resulting two-dimensional chromatograms were analyzed with the comprehensive GC×GC software (GC Imagine Software, Zoex Corp., Houston, TX, USA) to ascertain the cone volume of each FA.

Identification and Quantification of FA. Identification was made first by comparing the cone position in the chromatogram with the cone position of the FA contained in reference standards. The second FA identification method was by elution order and position of each FA in the two-dimensional chromatogram produced by the comprehensive GC×GC software. Quantification of each FA was calculated from the cone volume of each FA peak compared to the volume of total FA, and FA content was expressed as grams per 100 g of total FA on the basis of the concentration in weight of the methyl 12-tridecenoate contained in the solution used as internal standard. Some peaks were excluded from the statistical analysis and from the tables (C4:0, C6:0, C7:0, C13:0$_{iso}$, C13:0$_{anteiso}$, C19:0$_{anteiso}$, C23:0, C24:0, C13:1 unknown isomer, ΣC14:1 unknown isomers, ΣC19:1 unknown isomers, ΣC20:1 unknown isomers, C23:1, C24:1) because they were absent from the large majority of samples. Some long-chain PUFAs are presented separately because they were detected in significant amounts in only liver and kidney fat.

Saturated FAs (SFA) were the sum of C8:0, C9:0, C10:0, C11:0, C12:0, C13:0, C13:0$_{iso}$, C13:0$_{anteiso}$, C14:0, C14:0$_{iso}$, C15:0, C15:0$_{iso}$, C15:0$_{anteiso}$, C16:0, C16:0$_{iso}$, C16:0$_{anteiso}$, C17:0, C17:0$_{iso}$, C17:0$_{anteiso}$, C18:0, C18:0$_{iso}$, C19:0, C19:0$_{iso}$, C19:0$_{anteiso}$, C20:0, C21:0, C22:0, C23:0, and C24:0. Monounsaturated FAs (MUFA) were the sum of C13:1 unknown isomer, C14:1*c*9, ΣC14:1 unknown isomer, ΣC15:1

[c]Standard error of the means. [d]Δ^9-desaturase indices: calculated according to the method of Kelsey et al.[22] [e]Thrombogenic index and atherogenic index were calculated according to the method of Ulbricht and Southgate.[23]

other, C16:1*n*5, C16:1*t*7, C16:1*c*7, C16:1*c*9, ΣC16:1 other, C17:1*c*10, ΣC17:1 other, C18:1*t*7, C18:1*t*9(+*t*11), C18:1*c*9, C18:1*c*7, C18:1n-3, ΣC18:1 other, C19:1*n*9*t*, C19:1*n*9*c*, ΣC19:1 unknown isomer, C20:1*n*7, C20:1*n*9, C20:1*n*11, C20:1*n*9*t*, ΣC20:1 unknown isomer, C23:1, and C24:1. Polyunsaturated FAs (PUFA) were the sum of ΣC16:2 unknown isomers, C18:2n-6, ΣC18:2 unknown isomers, ΣC19:2 unknown isomers, C20:2n-6, C20:2n-3, ΣC20:2 unknown isomers, ΣC16:3 unknown isomers, C18:3*n*-3, C18:3n-6, ΣC18:3 unknown isomers, C20:3n-3, C20:3n-6, ΣC20:3 unknown isomers, C18:4n-3, C20:4n-3, C20:4n-6, ΣC20:4 unknown isomers, C20:5n-3 (EPA), C20:5n-6, ΣC20:5 unknown isomers, C22:2n-6, C22:4n-6, C18:5n-3, C22:5n-6, ΣC22:5 unknown isomers, C22:6n-3 (DHA), CLA*c*9,*t*11, CLA*c*11,*t*13, CLA*t*10,*c*12, CLA*c*9,*c*11, CLA*t*9,*t*11, and ΣCLA unknown isomers. Unknown FAs are the sum of 10 peaks not identified by standard or by position in two-dimensional chromatograms.

Branched FAs, calculated according to Raes et al.,[19] were the sum of $C13:0_{iso}$, $C13:0_{anteiso}$, $C14:0_{iso}$, $C15:0_{iso}$, $C15:0_{anteiso}$, $C16:0_{iso}$, $C16:0_{anteiso}$, $C17:0_{iso}$, $C17:0_{anteiso}$, $C18:0_{iso}$, $C19:0_{iso}$, and $C19:0_{anteiso}$. Odd-chain FAs were calculated according to the method of Or-Rashid et al.[20] The sum of the identified CLA isomers was indicated as ΣCLA and was calculated as the sum of isomers identified by standard and position: CLA*c*9,*t*11, CLA*c*11,*t*13, CLA*t*10,*c*12, CLA*c*9,*c*11, and CLA*t*9,*t*11 plus the ΣCLA of other unknown isomers. The sums of omega-3 PUFAs (n-3 PUFA) and of omega-6 PUFAs (n-6 PUFA) were calculated according to Givens et al.;[21] as an example, n-3 PUFA was computed as the sum of C18:3n-3, C18:4n-3, C18:5n-3, C20:2n-3, C20:3n-3, C20:4n-3, C20:5n-3 (EPA), C22:5n-3, and C22:6n-3 (DHA).

The Δ^9-desaturase indices were calculated according to the method of Kelsey et al.[22] for four pairs of FAs representing products and substrates for Δ^9-desaturase. These FA pairs were 14:1*c*9 and 14:0, 16:1*c*9 and 16:0, 18:1*c*9 and 18:0, and CLA*c*9,*t*11 and C18:1*t*11. The desaturase index was defined as product of Δ^9-desaturase/(product of Δ^9-desaturase + substrate of Δ^9-desaturase). The atherogenic index (AI) and thrombogenic index (TI) were calculated according to the method of Ulbricht and Southgate[23] as AI = (C12:0 + 4 × C14:0 + C16:0)/(n-3 PUFA + n-6 PUFA + MUFA) and TI = (C14:0 + C16:0 + C18:0)/[0.5 × MUFA + 0.5 × n-6 PUFA + 3 × (n-3 PUFA/n-6 PUFA)].

Statistical Analysis. The 216 data obtained for each FA or FA category from the combination of 6 tissues (T) × 3 feeding systems (FS) × 3 breeds ×2 sexes ×2 lambs were analyzed using a linear mixed-effects model (MIXED) procedure in SAS[24] with T, FS, breed, and sex as fixed effects. The random effect of animal was used to test FS, breed, and sex, whereas the effects of T and the FS × T interaction were tested on the residual. Orthogonal contrasts between least-squares means were fitted to test pasture versus indoor diets and indoor-control versus indoor-CLA diets ($p < 0.05$). Further contrasts were fitted to test liver versus other tissues, fatty tissues versus muscles, kidney fat versus subcutaneous fat, leg versus chop muscles, and ribeye versus other chop muscles ($p < 0.05$). As a preliminary analysis revealed the effect of breed to be seldom significant and no interactions of breed with other sources of variation were found, breed was excluded from the model. Because the experimental design was balanced, only one standard error of the least-squares means (SEM) was reported for each source of variation.

RESULTS AND DISCUSSION

Two-Dimensional Gas Chromatography. The GC×GC system revealed the presence of 128 peaks, 56 of which were identified using standard references: 21 SFAs, 16 MUFAs, and 19 PUFAs. Seventy-two other FA peaks were found, but as identification was incomplete, they were placed into 6 family groups (ΣC15:1 other, ΣC16:1 other, ΣC17:1 other, ΣC18:1 other, ΣC16:2 other, and ΣC18:2 other) according to their

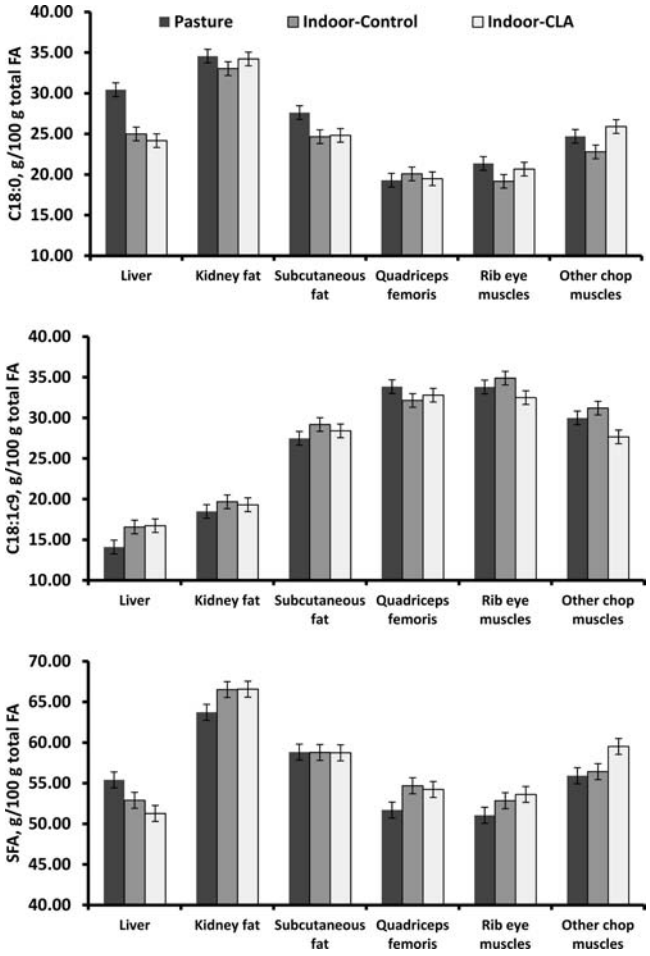

Figure 2. Effect of feeding system (pasture; indoor-control, based on hay and concentrates; indoor-CLA, based on hay and concentrates top dressed with 8 g/day of a commercial rumen-protected CLA mixture) on content of C18:0, C18:1*c*9, and saturated FA in six lamb tissues. Each bar is the least-squares mean from 12 observations; vertical bar indicate SEM. The significance of the feeding system × tissue interaction was $p < 0.01$, < 0.01, and 0.28 for C18:0, C18:1*c*9, and saturated FA, respectively.

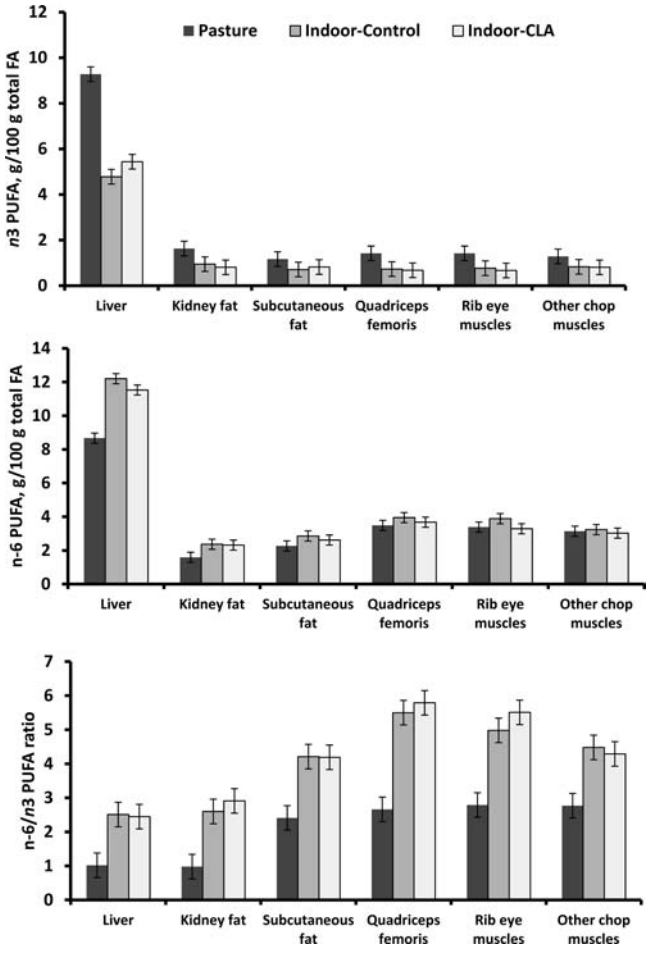

Figure 3. Effect of feeding system (pasture; indoor-control, based on hay and concentrates; indoor-CLA, based on hay and concentrates top dressed with 8 g/day of a commercial rumen-protected CLA mixture) on content of n-3 and n-6 fatty acids and on their ratio in six lamb tissues. Each bar is the least-squares mean from 12 observations; vertical bars indicate SEM. The significance of the feeding system × tissue interaction was $p < 0.01$, < 0.01, and 0.28 for n-3, n-6, and n-3/n-6, respectively.

elution time in the ordered GC×GC chromatograms. Identification of compounds is more reliable with GC×GC than with traditional GC, particularly in combination with columns with different polarities.[4] The various FAs are aligned in the chromatograms in grid form according to their number of carbon atoms and double bounds.[25] The GC×GC system therefore appeared to be well suited to the analysis of matrices containing complex mixtures of FAs, such as meat samples, in which a large number of FAs are present in very different concentrations. Some studies have shown that near-infrared spectroscopy (NIRS) is a useful technique for satisfactorily predicting some FAs in meat, particularly the major SFAs and MUFAs, but is less reliable in predicting PUFAs.[26] This NIRS technique is based on calibrations resulting from FA analysis conducted with a monodimensional GC. A tool such as the GC×GC, which is suitable for accurately detecting numerous FAs in very different concentrations, would be useful in improving NIRS calibration and prediction potential, particularly with regard to the less numerous but most biologically active PUFAs. GC×GC-based calibration of NIRS is desirable as it would allow NIRS to make measures at population levels, which would open up a variety of applications, including genetic selection and online meat quality evaluation at slaughterhouses.

Feeding System. Dietary manipulation is considered to be one of the most effective ways to improve the FA composition of sheep meat.[1,27,28] In the current experiment, the feeding system (FS) affected the average proportions of the large majority of individual FAs in tissues. The FA profile of lambs reared on pasture differed from those fed on the two indoor diets; the only quantitatively notable FAs not influenced by pasture were C14:0 among the SFAs (Table 3) and C16:1*c*9 and C18:1*c*9 among the MUFAs (Table 4). Tissues from lambs kept on pasture were fattier ($p < 0.01$) than those of lambs on indoor diets (Table 5), suggesting that, under the conditions of the current experiment, the lambs' net energy intake was greater from pasture than from the indoor diets. Despite the differences observed in individual FAs and in tissue fat content, FS had little influence on SFAs and MUFAs, although there was a slightly higher proportion of PUFAs in lambs reared on pasture than those on indoor diets ($p < 0.05$), mainly due to increased proportions of C18:3n-3, C20:5n-3 (EPA), and C22:6n-3 (DHA) in pasture-fed lambs ($p < 0.01$). Pasture

[a]Data are least-squares means (for tissue, $n = 36$; for FS × T, $n = 12$); a significant difference for a given FA is indicated as * ($p < 0.05$) or ** ($p < 0.01$) for each contrast and FS × T interaction. [b]KF, kidney fat; SF, subcutaneous fat; leg, leg inner muscle (quadriceps femoris); RE, rib ye muscle; OM, other chop muscles. [c]Standard error of the means.

increased the sums of CLA ($p < 0.05$) and n-3 PUFA ($p < 0.01$), reduced n-6 PUFA ($p < 0.01$), and lowered the n-6/n-3 PUFA ratio compared to the indoor diets ($p < 0.01$), the main reason for this being that grass is a rich natural source of C18:3n-3, a precursor of other n-3 PUFAs, whereas concentrates are rich in C18:2n-6, a precursor of other n-6 PUFAs.[27] Pasture feeding also increased long-chain FAs and reduced the proportions of medium- and short-chain FAs as well as the incidences of branched and odd FAs compared to the indoor diets. This would reflect greater rumen activity and lower rumen escape of intermediary products of biohydrogenation with pasture compared to concentrate-based diets.[29] The reduced proportions of odd FAs found in the tissues of lambs kept on pasture might also reflect a lower availability of propionic acid for lipogenesis in fat tissues.[30]

Compared to the indoor-control, the rpCLA diet did not alter the average tissue fat content and influenced only the proportions of individual CLA isomers ($p < 0.05$), the CLA sum ($p < 0.01$), and the desaturation index for CLA*c*9,*t*11 ($p < 0.05$). The CLA*c*9,*t*11 isomer is formed in the rumen or is synthesized in tissues from *trans*-vaccenic acid (C18:1*t*11).[31,32] The C18:1*t*11 is formed in the rumen from C18:1*n*9, C18:2n-6, and C18:3n-3[11] diets that promote the greatest activity of the stearoyl-CoA desaturase (SCD); that is, starchy concentrate diets are also associated with a lower duodenal flow of the C18:1*t*11 precursor, with forage-based diets resulting in the highest flow of this FA from the rumen.[27] This is consistent with the results of the current experiment, which showed that tissues of lambs on indoor diets contained lower proportions of C18:1*t*11 and CLA*c*9,*t*11 than those of lambs on pasture. Unfortunately, in the current experiment we were unable to achieve a good separation of the C18:1*t*11 isomer, as it was coeluted with C18:1*t*9. Separation of the two isomers is desirable, and in light of this a better combination of operative conditions and column characteristics of the GC×GC system needs to be studied.

The CLA*t*10,*c*12 isomer is produced in the rumen from biohydrogenation of linoleic acid (C18:2n-6), especially in cows, sheep, and lambs on starchy and low-fiber diets[33] or on diets supplemented with oils rich in linoleic acid.[34] There are generally low proportions of this CLA isomer in ruminant products,[2] and an rpCLA supplement is considered to be the most effective way of increasing its presence in ruminant tissues.[13] In the current study, the indoor diet with rpCLA increased the average content of CLA*c*9,*t*11 and CLA*t*10,*c*12 in tissues by about 30 and 100%, respectively, compared to the similar diet without rpCLA (Figure 1). The magnitude of response to rpCLA supplementation was broadly similar to that to pasture, except in kidney fat, where a notable increase in CLA*t*10,*c*12 was found when rpCLA was given to the lambs. Previous experiments on lambs found that CLA supplementation effected a dose-dependent increase in the content of these isomers in tissues, but had no influence on the proportions of the other FAs, as also found in the current experiment.[35,36] This suggests that rpCLA supplementation has a much smaller effect on the FA profile of tissue than was previously observed by others in milk.[33]

The relative proportions of CLA*c*11,*t*13 were highest in lambs kept on pasture and lowest in lambs on the indoor-control diet ($p = 0.03$), whereas rpCLA supplementation increased the

[a]Data are least-squares means (tissue, n = 36; FS × T interaction, n = 12); a significant difference for a given FA is indicated as * (p < 0.05) or ** (p < 0.01) for each contrast and FS × T interaction. [b]KF, kidney fat; SF, subcutaneous fat; leg, leg inner muscle (quadriceps femoris); RE, ribeye muscle; OM, other chop muscles. [c]Standard error of the means. [d]Found only in liver and kidney fat. [e]Co-eluted isomers. [f]Found only in liver.

amounts of this isomer in all tissues except kidney fat, even though the FS × T interaction was not significant (p = 0.23). This isomer was not present in the rpCLA mixture used in this trial, so the reason for the increase in CLA*c*11,*t*13 when rpCLA is added to the feed is unknown. To our knowledge, this effect has not been observed before, and it may be hypothesized that one or both of the two CLA isomers supplied with rpCLA is directly or indirectly involved in CLA*c*11*t*13 formation.

Depending on the circumstances, gender may be an important factor in FA composition, because of its relationship with carcass fatness.[37] However, in this study no significant or notable effect of gender was observed, likely because the fatness of males and females did not differ as they were slaughtered at the onset of puberty.[15]

Tissue. The FA profile of liver largely differed from that of the other tissues for the majority of single FAs or FA categories (Tables 6−8), as described in the literature.[30,38]

Liver tissue was the richest in PUFAs (21%), mainly due to the contribution of C18:2, C18:3, and FAs with chains longer than 18 C, including 5 FAs present in trace amounts or not detectable in other tissues, among them C20:4n-6, C20:5n-3, and C22:6n-3. Liver also contained high levels of very long

[a]Data are least-squares means (for tissue, $n = 36$; for FS × T interaction, $n = 12$); a significant difference for a given FA category or index is indicated as * ($p < 0.05$) or ** ($p < 0.01$) for each contrast and FS × T interaction. [b]KF, kidney fat; SF, subcutaneous fat; leg, leg inner muscle (quadriceps femoris); RE, ribeye muscle; OM, other chop muscles. [c]Standard error of the mean. [d]Δ^9-desaturase indices: calculated according to the method of Kelsey et al.[22] [e]Thrombogenic Index and Atherogenic Index were calculated according to the method of Ulbricht and Southgate.[23]

chain SFAs, C20:0, C22:0, and C23:0, and of n-3 and n-6 PUFAs and odd-chain FAs, but had the lowest n-6/n-3 PUFA ratio compared to all other tissues ($p < 0.01$). The Δ^9-desaturation index for C18 was lower in liver than in other tissues, but the opposite was found for the CLA*c*9,*t*11 desaturation index. The FA profile of liver is influenced by dynamic conditions caused by incoming and outgoing FAs. Ruminant liver has less effect on de novo synthesis than adipose tissues or muscles do; nevertheless, a low rate of de novo biosynthesis occurs when acetate is the main carbon source. However, the pool of long-chain FAs in the liver is mainly derived from plasma NEFA.[38,39]

The FA profiles of the two adipose tissues differed from those of muscles with respect to the large majority of single saturated and unsaturated FAs. Fatty depots had higher proportions of SFAs but lower MUFAs and PUFAs, higher proportions of n-3 PUFA, lower proportions of n-6 PUFA, a lower n-6/n-3 PUFA ratio, similar proportions of short-, medium- and long-chain FAs, and higher proportions of branched- and odd-chain FAs compared to muscles. Adipose tissues are considered to be the major sites of de novo FA synthesis, palmitic acid (C16:0) being the main product, which can be further elongated to stearic acid (C18:0) and desaturated to oleic acid by SCD.[27] Ward et al.[40] demonstrated that, in sheep, SCD is produced from a single gene, the expression of which is under hormonal control, independent of total fat synthesis, and the activity of which varies according to fat depot, being higher in subcutaneous fat that in internal depots. In the current experiment, subcutaneous fat and kidney fat differed substantially, the latter being richer in SFAs, particularly C18:0, but poorer in MUFAs, particularly C18:1*c*9.

Differences among the FA profiles of muscles were less pronounced than among those of fat depots; in general the three muscles contained higher proportions of C18:1*c*9 (32%) and C18:2n-6 (3.1%), a similar proportion of C16:0 (23.1%), and a lower proportion of C18:0 (21.5%) compared to subcutaneous fat. The general trend was that the other chop muscles tended to have an FA profile intermediate between that of the leg and ribeye muscles and that of the fatty depots. Differences among muscles are related to differences in the presence of fibers with different oxidative, glycolytic, or oxidoglycolytic properties. These fibers are present in various proportions in muscles depending on animal species, location of the muscle in the body, and other nutritional and physiological characteristics, such as physical movement. Red oxidative fibers have a higher proportion of phospholipids than white and, consequently, a higher percentage of PUFAs.[39]

Feeding System × Tissue Interaction. A significant FS × T interaction was observed for the fat content of tissue. Feeding system had a small or negligible effect on the fat content of liver and muscles, but the proportion of fat in the subcutaneous tissue was higher with pasture than with the two indoor diets (65.0 vs 49.8 g/100 g tissue, respectively). The fat content of kidney exhibited a consistent progressive decrease from 80.0 g/100 g of tissue for pasture to 68.0 g/g for indoor-control to 59.0 g/g for indoor-CLA. This suggests that the

DOI: 10.1021/jf504956x
J. Agric. Food Chem. 2015, 63, 963−974

muscles, the most valuable components of the carcass, have a lower response to changes in dietary energy supply in terms of fat content than other fat tissues, which are less important for human nutrition.

The FS × T interaction was significant for many FAs: a total of 41 single FAs, categories, and indices. The number and the complexity of these interactions made it impossible to go into all of these interactions in depth, so only some examples are presented and discussed.

In all tissues, the most highly represented FAs were C18:0 and C18:1*c*9, both of which exhibited a significant FS × T interaction ($p < 0.01$) (Figure 2). Compared to pasture, the indoor-control diet reduced by an average of 11% the relative proportion of C18:0 in all tissues, except the quadriceps femoris. Indoor-CLA increased the proportion of C18:0 by an average of 11% over indoor-control in ribeye muscle and in other chop muscles, but no differences were found in the other tissues. The trend observed for C18:1*c*9 in tissues, according to FS, mirrored that described for C18:0. Thus, the pattern of the FS × T interaction for SFAs largely reflected the patterns of their major FA constituents, C18:0 and C18:1*c*9. In pasture-fed lambs as opposed to indoor diets the proportions of SFAs decreased in liver (from 55.4 to 51.3 g/100 g total FA), were constant in subcutaneous fat (58.8 g/100 total FA), and increased in muscle (from 52.9 to 55.2 g/100 g total FA). The opposite pattern was observed for MUFAs, whereas PUFAs remained unchanged. These results suggests that different tissues would respond differently to a change in FS in terms of the relative presence of some FAs. However, for the large majority of FAs, the direction of the response to a change in FS was similar in the various tissues, although the relative amounts differed. For example, liver contained higher proportions of both n-3 and n-6 FAs, and in all tissues pasture effected an increase in the proportions of n-3 PUFA, and a decrease in the proportions of n-6 PUFA and in the n-6/n-3 PUFA ratio compared to the other FSs (Figure 3). The n-6/n-3 ratio was smaller with pasture than the other diets in all tissues. Irrespective of the FS, this ratio ranged from 1.0 to 2.5 in liver and from 2.5 to 6.0 in other tissues. Replacing pasture with indoor diets also increases branched and odd FAs in all tissues (Figure 4), but it is more pronounced in liver and kidney fat.

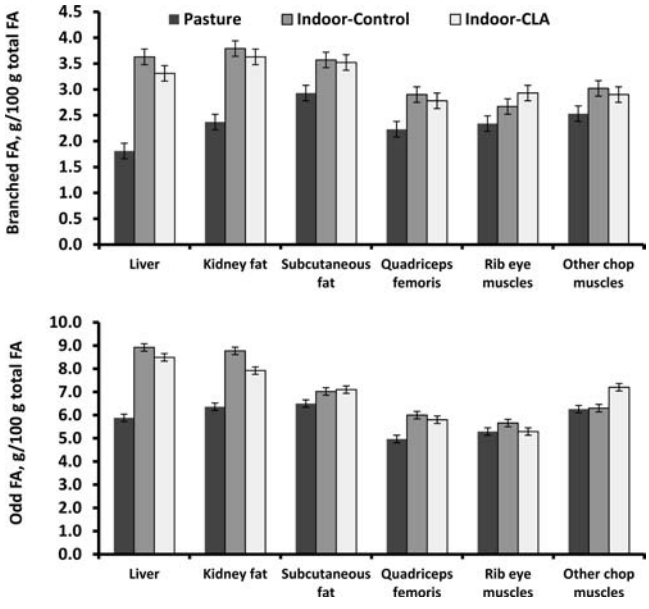

Figure 4. Effect of feeding system (pasture; indoor-control, based on hay and concentrates; indoor-CLA, based on hay and concentrates top dressed with 8 g/day of a commercial rumen-protected CLA mixture) on branched-chain and odd-chain fatty acid contents of six lamb tissues. Each bar is the least-squares mean from 12 observations; vertical bars indicate SEM. The significance of the feeding system × tissue interaction was $p < 0.01$ and < 0.01 for branched and odd FA, respectively.

In conclusion, the use of two-dimensional GC provided a very detailed FA profile of the lipid fraction contained in various tissues of lambs, with 128 single FAs quantified, making available new information on this issue and allowing for a deeper insight of the effect of nutrition on lipid metabolism of ruminants. Despite the relatively low number of observations, this technique allowed us to evaluate the effects of the FS × T interaction even for FAs present in low or very low concentrations, and in general the standard errors of the means were proportional to the value of the corresponding means. It was found that the replacement of pasture with indoor diets altered the FA profile, with an increase in the average n-6/n-3 PUFA ratio toward values that can still be considered acceptable.[38] A commercial CLA mixture containing CLA*c*9,*t*11 and CLA*t*10,*c*12 notably increased the CLA*c*11,*t*13 content in all tissues, except kidney fat, demonstrating the effectiveness of rumen-protected molecules in delivering specific bioactive substances to lamb tissues. The effects of feeding systems with or without rpCLA on the FA profiles were similar, but not identical, in almost all of the tissues analyzed.

[a]Ciders were categorized as European (EU) or Australia/New Zealand (ANZ). [b]Calculated according to the method of Brooks et al.[21]

cations and anions. The primary aim of this survey was to determine whether the techniques already established for beers[20] could be applied to identify the geographical origin of ciders and/or the addition of C_4 sugars. A further outcome of the study was to provide background data against which suspected substitute or counterfeit products can be compared.

MATERIALS AND METHODS

Sample Collection and Processing. Twenty bottled and one canned cider were purchased from licensed retail outlets in the Brisbane metropolitan area (Queensland, Australia). The packaging of each sample was examined to verify the integrity and authenticity of the product and to confirm the location of manufacture. As with many studies of food authenticity, it was difficult to obtain truly authentic samples. In obtaining the samples for this study our strategy was to seek out reputable vendors.

Prior to analysis, the samples were stored at room temperature. Once opened, samples were filtered through hardened ashless paper to remove the majority of the dissolved carbon dioxide and then through 0.45 μm Durapore filters (Merck Millipore, Billerica, MA, USA) into two 50 mL sterile containers for cation and anion determination. Degassed samples intended for δ^2H and δ^{18}O analysis were dispensed into 2 mL autosampler vials. To obtain a solid residue, approximately 5 mL aliquots of unfiltered ciders were heated in wide beakers at 102 °C until visibly dry.

Stable Isotopic Analysis. All isotopic measurements were performed using a Thermo Scientific (Bremen, Germany) Delta V^{PLUS} isotope ratio mass spectrometer (IRMS) coupled to a ConFlo IV interface for working gas introduction and sample dilution.

The carbon isotopic analysis of solid samples and hydrogen and oxygen isotopic analyses of liquid samples were performed using a Thermo Scientific Flash 2000 HT operated in Elemental Analyzer (EA) or Thermal Conversion EA (TC/EA) mode, respectively, as previously described.[20] The median standard deviations for replicate measurements of samples were 0.03‰ for solid ^{13}C measurements (n = 3) and 0.3 and 0.1‰, respectively, for aqueous ^{2}H and ^{18}O measurements (n = 5).

Solid samples intended for δ^{18}O analysis were measured into 4 × 3.2 mm silver capsules (IVA Analysentechnik, Meerbusch, Germany) and dried under vacuum, over phosphorus pentoxide for a minimum of 5 days. The ^{18}O composition was determined using the TC/EA with the same operating conditions used for liquid samples. Capsules were crimped closed prior to analysis and introduced into the reactor by a Zero-Blank autosampler (Costech Analytical Technologies Inc., Valencia, CA, USA). Each sample was analyzed in triplicate with a median standard deviations of 0.2‰.

Data were normalized to the international isotope scales (VPDB-LSVEC or VSMOW-SLAP) by two-point calibration; a list of the reference materials and quality control (QC) materials used is given in the Supporting Information (cider supp 2). No attempt was made to measure the δ^2H compositions of the solid residues as these samples contained exchangeable hydrogen and were highly deliquescent. In the face of ongoing controversy regarding the measurement of δ^2H values for materials with exchangeable hydrogen,[26] the authors considered that δ^2H_{VSMOW} data for these samples should not be compared to published data.

Cation Analysis. Aliquots of approximately 2 g of sample were accurately weighed into PTFE vessels and digested with 4 mL of high-purity nitric acid (69%, Seastar Chemicals, Sidney, BC, Canada) using a MarXpress microwave digestion system (CEM, Matthews, NC, USA). Digested samples were analyzed using a Vista Pro inductively coupled plasma−optical emission spectrometer (ICP-OES) (Varian Australia Inc., VIC, Australia) and a 7700 ICP-MS (Agilent Technologies Australia Pty Ltd., VIC, Australia) as previously described.[20] Reference materials and recovery spikes were used for quality control and assurance. Recoveries ranged from 77 to 119% and were deemed satisfactory (Supporting Information, cider supp 3).

Anion Analysis. Samples were diluted 500-fold and transferred to autosampler tubes. Anion concentrations were measured using a Compact ion chromatograph (Metrohm, Gladesvile, Australia) as previously described.[20] The recoveries for anions from spiked sample and aqueous solutions were satisfactory and >90% (Supporting Information, cider supp 3).

Sugar Analysis. Degassed, filtered samples were diluted 10-fold and transferred to autosampler vials. Sugars were separated and quantified using a Shimadzu UFLC-20A High-performance liquid

DOI: 10.1021/jf5030054
J. Agric. Food Chem. 2015, 63, 975−982

chromatograph (HPLC) system coupled to an RID-10A refractive index detector. Separation was achieved using a 150 mm × 4.6 mm Alltima NH_2 3 μm column (Grace, Archerfield, QLD, Australia) maintained at 30 °C with an isocratic mobile phase of water/acetonitrile (30:70). Standard solutions were prepared at concentrations of 10, 5.0, and 2.5 g/L from high-purity fructose, glucose, and sucrose (Sigma-Aldrich, Castle Hill, NSW, Australia).

Statistical Analysis. Data were analyzed and plotted using R 3.0.1 software environment for statistical computing and graphics.[27] Least absolute deviation (LAD) regression was applied to plotted data to determine the equation of robust fit and the correlation R^2 (observed vs predicted). Principal component analysis (PCA) was performed on the chemical data to determine which parameters accounted for the largest differences between samples. This was performed using the L_1-norm to increase robustness to outliers compared to traditional PCA.[28] Canonical discriminant analysis (CDA) was applied to both chemical and isotopic data to determine to what extent these parameters distinguish between the different regions of origin. These results represent the recognition ability based on the samples used to generate the model.

RESULTS

Overview of Samples. Although the number of samples in this study was limited, it was considered to be representative of the brands readily available within Australia at the time of the survey (October 2013). The analytical data are presented in the Supporting Information (cider supp 1).

The ciders obtained for this study are detailed in Table 1, categorized by country and region of origin and ingredients. Seven of the samples were produced in Australia, three in New Zealand (NZ), and 12 in European Union (EU) countries (Belgium, France, Ireland, Spain, Sweden, and the United Kingdom). Within Australia and New Zealand the composition of cider is controlled by the Food Standards Australia and New Zealand (FSANZ) code. There is no common EU legislation governing cider, but the majority of cider-producing countries adhere to the AVIC (L'Association des Industries des Cidres et Vins de fruit de l'U.E.) code of practice.

The declared alcoholic content of the ciders (reported in Table 1) ranged from 4.0 to 8.2% alcohol by volume (ABV) with a median value of 4.5% ABV. (For a product to be described as cider, FSANZ and AVIC codes require an alcoholic strength between 1.5 and 8.5% ABV.) Two of the ciders claimed to be manufactured from pears (samples 2 and 16) and one from apples and pears (sample 19). Both FSANZ and AVIC codes allow apple cider to contain up to 25% pear juice and vice versa. Three samples (1, 13, and 15) contained novel ingredients: strawberry, pomegranate, lime, or ginger. The authors assumed that these ingredients would be added in small amounts, principally for flavor, and, consequently, contribute little to the chemical or isotopic composition of the finished product. None of the analytical data acquired suggested differences between beverages produced from apples or pears or due to the inclusion of novel flavoring ingredients. This finding was in agreement with AIJN (The European Fruit Juice Assocaition) reference guides for apples and pears,[29,30] which indicate no significant differences between the juices of the two fruits. The sole sample of canned cider was not distinct from the bottled varieties other than containing the lowest concentration of sulfur. It was assumed that a canned product would be pasteurized, negating the need for added preservative.

Chemical Composition. All measured parameters that were below the limit of detection for the majority of the samples were removed from the overall data. Complete data are reported for nine cations (Na, Ca, K, Mg, Si, V, Mn, Sr, and Ba), four anions (Cl, NO_3, S, and P), the δ^2H and δ^{18}O compositions of the whole ciders (predominantly water), and the δ^{13}C and δ^{18}O compositions of the dry residues (predominantly sugar). A previous study[24] has identified the concentrations of a similar combination of cations (Na, Ca, K, Mg, Si, V, Mn, Sr, Ba, Al, Ti, Zn, As, Rb, and Mo) were sufficient to classify ciders according to country of origin, and the findings of this study were broadly in agreement with that conclusion.

A Pearson correlation matrix was determined for all of the measured parameters (Supporting Information, cider supp 1) and, in contrast to results previously reported for beers,[20] few strong correlations were observed. Correlations observed within the data for beer were attributed to the addition of brewing salts, such as calcium chloride and calcium sulfate, used to control the character of the brewing water and of the finished beer. There is no documented evidence for the addition of brewing salts to ciders, which may account for the general lack of correlations between anion and cation concentrations. In common with the data obtained for beer, significant correlations were observed between the concentrations of potassium, magnesium, and manganese. There was no apparent explanation for these relationships other than all three elements being important nutritional elements for plants.

PCA was applied to the combined anion and cation concentrations to determine which parameters accounted for the largest differences between samples. The loading factors for PC1 were dominated by potassium concentration, as was the case for an earlier study of beer, and the loading factors for PC2 were dominated by sulfur concentration. The latter finding could be explained because all but two of the ciders (samples 1 and 7) declared the preservative sulfur dioxide (or sulfite) as an ingredient. As confirmation, samples 1 and 7 contained the lowest concentrations of sulfur of the samples tested, 30 and 11 mg/kg, respectively, compared to a median concentration of 173 mg/kg. The loading factors for PC3 were predominantly the concentrations of phosphorus, sodium, and calcium. Overall, these finding were in broad agreement with an earlier study of beer,[31] which identified the concentrations of potassium and phosphate as important factors in distinguishing between styles of beers and the region of production.

Isotopic Composition. A Pearson correlation matrix (Supporting Information, cider supp 1) showed that a strong correlation existed between the δ^2H and δ^{18}O compositions of the liquid component of ciders. Both the δ^2H and δ^{18}O compositions of the liquid component correlated with the δ^{18}O composition of the solid residue and with the concentrations of potassium, magnesium, manganese, and silicon. A correlation was also observed between the δ^{13}C and δ^{18}O compositions of the solid residue.

Sugar in Cider. Figure 1 shows the distribution of the δ^{13}C compositions determined for the dry residues of the ciders (predominantly sugar). The majority of samples had $\delta^{13}C_{VPDB}$ values of approximately −26‰, which is typical of C_3 plant material, that is, unadulterated apple or pear sugars, consistent with AIJN guidelines. Other samples were, however, significantly enriched in ^{13}C, suggesting the inclusion of C_4 sugar. An estimate of the proportion of C_4 sugar present in the samples was calculated using the equation adapted from Brooks et al.[28]

$$\%C_4 \text{ carbon} = \frac{(\delta^{13}C_{cider} - \delta^{13}C_3)}{(\delta^{13}C_4 - \delta^{13}C_3)}$$

DOI: 10.1021/jf5030054
J. Agric. Food Chem. 2015, 63, 975−982

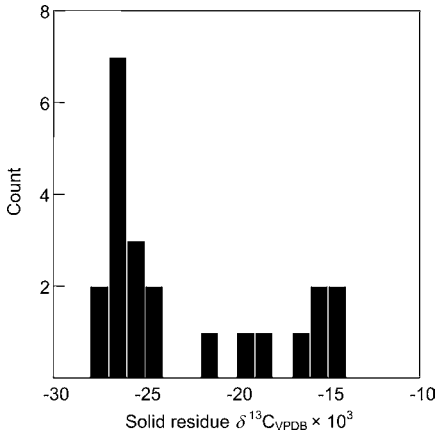

Figure 1. Histogram showing the distribution of $\delta^{13}C$ compositions for the solid residues from ciders.

in which $\delta^{13}C_3$ and $\delta^{13}C_4$ are the typical $\delta^{13}C_{VPDB}$ values for C_3 and C_4 plant material, respectively. (In this study $\delta^{13}C_3$ was taken to be the average value for the ciders that did not appear to contain C_4 sugar (−26.1‰): $\delta^{13}C_4$ was taken as the value reported by Brooks et al. (−12.5‰).) Applying this equation to the $\delta^{13}C$ compositions of the dry residues gave the results presented in Table 1 and revealed that seven of the nine ANZ samples contained C_4 sugar, in contrast to a single EU sample. The EU sample (sample 6) was produced in Spain and claimed to be made from "100% local ingredients". In France, the UNICID (L'Union Natioale Interprofessionnelle Cidricole) code distinguishes between products branded with the English or French spellings, *cider* or *Cidre*, and the addition of water or sugar to the latter is strictly prohibited. Reassuringly, the $\delta^{13}C$ composition of Normandy *Cidre* (sample 5) showed no evidence of adulteration with C_4 sugar.

Ciders that were considered to contain >25% C_4 sugar were analyzed by HPLC to identify the sugars present (Supporting Information, cider supp 1). It was assumed that most of the sugars originally present in the fruit juice would be consumed during primary fermentation and that the profile of the sugars present in the final product would reflect those added after the primary fermentation. The AIJN guidelines suggest that the glucose/fructose ratio of natural apple and pear juice should not exceed approximately 0.5 and, therefore, samples with ratios of approximately unity were deemed to contain HFCS. A single sample (sample 19) was found to have a glucose/fructose ratio >3 and was assumed to contain added glucose syrup. The AIJN guidelines also suggest that the sucrose/fructose ratio of natural apple and pear juice should not exceed approximately 0.4. Ciders with a sucrose concentration exceeding 0.5 (in combination with ^{13}C enrichment) were deemed to contain added cane sugar. On the basis of these guidelines the nature of the added sugar is reported in Table 1.

In this study ANZ and Spanish cider producers were found to use a variety of sugar types (cane sucrose, HFCS, and glucose) or combinations to sweeten their products. In contrast, manufacturers in other EU countries appeared to rely on natural fruit sugars. FSANZ, AVIC, and local Spanish codes (BOE-A-1979-21034) allow for the addition of sugar (and water) to ciders and do not restrict the source of added sugar. This practice makes it difficult to distinguish the origin of ciders based on $\delta^{13}C$ measurements and, although C_4 sweetened products may be indicative of an ANZ origin, it would not be possible to distinguish them from a Spanish cider sweetened with HFCS.

Figure 2a shows a scatter plot of the $\delta^{18}O$ composition of the solid residues against that of the corresponding whole ciders defined by

$$\delta^{18}O_{solid} = \delta^{18}O_{liquid} \times 0.59 + 33 \ (R^2 = 0.87)$$

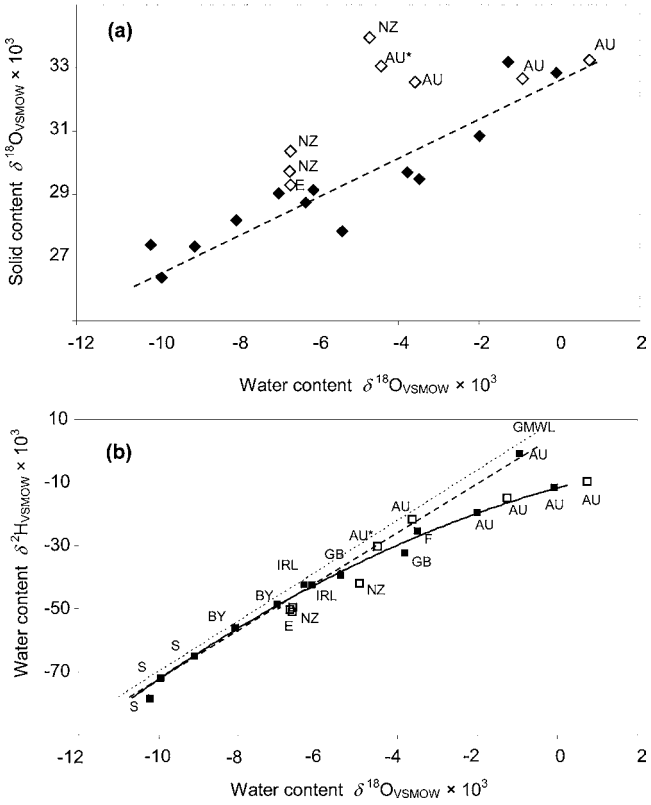

Figure 2. (a) Plot of $\delta^{18}O$ for solid residue against water content; (b) plot of δ^2H against $\delta\ ^{18}O$ for the water content of cider samples (Global Meteoric Water Line shown dotted). Open symbols indicate samples for which $\delta^{13}C$ results suggest the inclusion of C_4 sugars.

The enrichment in ^{18}O of the residues with respect to the whole ciders was consistent with biosynthesis.[32] The robust trend line shown was derived from the samples considered not to contain C_4 sugar (shown as solid symbols, ◆). All of the solid residues that were deemed to contain C_4 sugar (shown as open symbols, ◇) were observed to be enriched in ^{18}O with respect to the robust trend.

Water in Cider. Applying LAD regression to the δ^2H and $\delta^{18}O$ data for the whole ciders produced, the results shown in Figure 3a are defined by the relationship

$$\delta^2H = \delta^{18}O \times 7.6 + 4.3 \ (R^2 = 0.98)$$

with a slope that approximated to that of the Global Meteoric Water Line,[33] which defines all natural waters according to

$$\delta^2H = \delta^{18}O \times 8 + 10$$

The liquid components of all ciders were found to be enriched in ^{18}O with respect to meteoric waters. A recent study has demonstrated that an offset from the GWML develops during the manufacture of beer,[34] which was attributed largely to the boiling of brewery water. Although boiling should not occur during cider making, it is proposed that slower

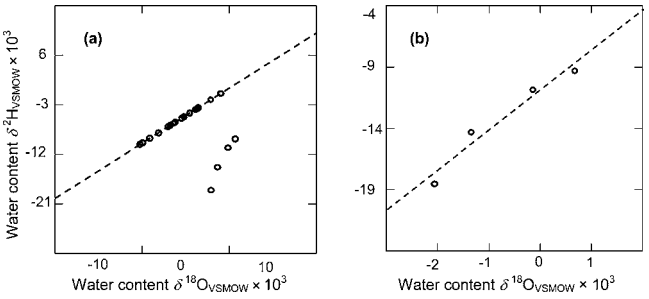

Figure 3. Least absolute deviation (LAD) regression plots of δ^2H against δ^{18}O for the water content of (a) all cider samples and (b) samples identified as outliers. Robust fit lines are shown dashed.

evaporation, from open vats, during initial fermentation may have a similar effect. Another possibility is that the observed offset results from the presence of alcohol and sugar in the analyte, of which cider typically contains more than beer.[35]

Four ciders produced in Australia (samples 13, 14, 17, and 18) deviated significantly from the robust trend line shown in Figure 3a. Applying LAD regression to these data alone produced the result shown in Figure 3b with a relationship defined by

$$\delta^2H = \delta^{18}O \times 3.3 - 11 \ (R^2 = 0.95)$$

This result is consistent with published δ^2H and δ^{18}O compositions of orange and grape juices,[36] which have been reported to have a relationship of approximately 4. This enrichment in ^{18}O with respect to groundwater was reported to result from evapotranspiration and to be more apparent in slow-growing fruits such as apples and pears, which are typically grown in cooler climates than grapes or oranges.

From Figures 2a and 3 it was apparent that the water content of ciders reflected the meteoric water available to the parent fruit tree but, when grown in warmer climates, such as Australia, isotopic enrichment occurred as a result of evaporation. It is also possible that some of the isotopic enrichment observed in the Australian samples resulted from evaporative enrichment of the waters used for irrigation or through water loss during storage or transportation of fruit.

DISCUSSION

Classification. The results of CDA applied to the chemical, isotopic, and combined compositions of the ciders in an attempt to distinguish the country of origin are summarized in Table 2. When considering the chemical data, it was possible to assign the ciders to their country of origin with 100% correct classification. In agreement with PCA, the discriminant functions were dominated by the concentrations of potassium, phosphorus, calcium, and magnesium. Although the concentration of sulfur dominated PC2, it did not feature strongly in the discriminant functions, most likely because the majority of sulfur was derived from an additive rather than from a natural component of the fruit juice. Combining the chemical and isotopic data again provided 100% correct classification.

CDA analysis of the isotopic data in isolation proved somewhat less successful in discriminating the country of origin, and some U.K. samples were variously misclassified as France or New Zealand possibly because these regions share similar geography and/or climate. All of the isotopic parameters contributed approximately equal weighting to the discriminant functions.

Table 2. Percentage Correct Classification by CDA

	country code[a]							
	AU	BY	E	F	GB	IRL	NZ	S
isotopic data	100	100	100	100	50	100	67	100

isotopic data	100	100	91
chemical data	100	100	100
all data	100	100	100

[a]Australia (AU), Belgium (BY), Spain (E), France (F), UK (GB), Ireland (IRL), New Zealand (NZ), Sweden (S).

Applying CDA to data composed of a large number of variables with only a small number of samples assigned to each class might be considered disingenuous. In an initial attempt to address this concern, CDA was applied to two broader groupings, ANZ and EU countries. This approach proved unsuccessful as it transpired the NZ ciders had many characteristics intermediate between those of the Australian and EU samples. CDA was, therefore, recalculated using NZ as a separate grouping, which gave the results shown in Table 2. Figure 4a shows the results of CDA applied to the isotopic data. Although Australian and EU samples formed discrete groupings, the NZ grouping overlapped both and encompassed the sample from Spain, clearly demonstrating why a single ANZ grouping was ineffective. All of the isotopic data contributed similar weighting to the discriminant functions. A similar pattern was observed for the chemical data (Figure 4b), the three classes forming discrete grouping with the Spanish sample correctly classified. In contrast to PCA results, the discriminant functions were dominated by the concentrations of strontium and barium. When the isotopic and chemical data were combined (Figure 4c), there was a clear distinction between Australian and EU samples. From this figure it was also apparent that the NZ samples had more in common with the EU samples than with those from Australia. The discriminant functions were again dominated by the concentrations of strontium and barium with significant contributions from manganese and chloride. In contrast to PCA results, the concentrations of potassium and phosphorus made little contribution; that is, the discriminatory information was not aligned with the direction of maximum variance.

It will be necessary to check the established discrimination functions with a new suite of samples to evaluate fully the real discriminating power.

Geo-location or *CyderSpace*. Figure 2b shows a scatter plot of the δ^2H and δ^{18}O compositions of the whole ciders. As discussed above, these parameters appeared to be controlled by two factors, groundwater and evaporation. To reflect this, two trend lines are shown in Figure 2b; the dashed line shows the robust trend determined by LAD regression (above), and the solid line shows a polynomial fit to all data according to

$$\delta^2H = -0.2 \times \delta^{18}O^2 + 3.7 \times \delta^{18}O - 10 \ (R^2 = 0.99)$$

Of note, the linear part of this equation was similar to the evapotranspiration line determined in Figure 3b ($\delta^2H = \delta^{18}O \times 3.3-11$).

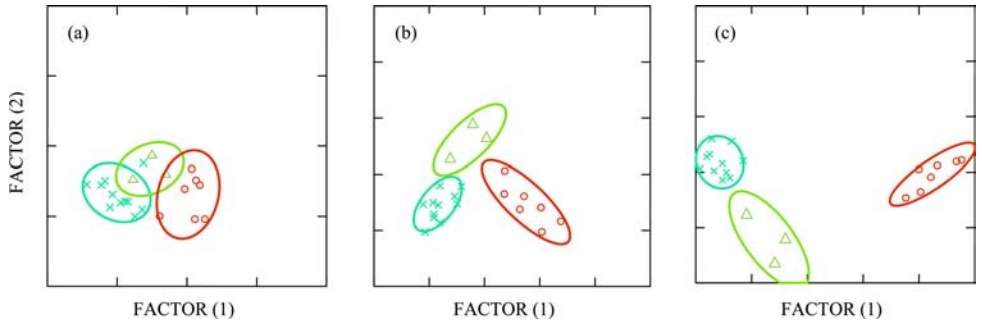

Figure 4. Factor plots derived from canonical discriminant analysis of (a) isotopic data, (b) chemical data, and (c) combined data: Australian (red, ○), EU (blue, ×), and NZ (green, △).

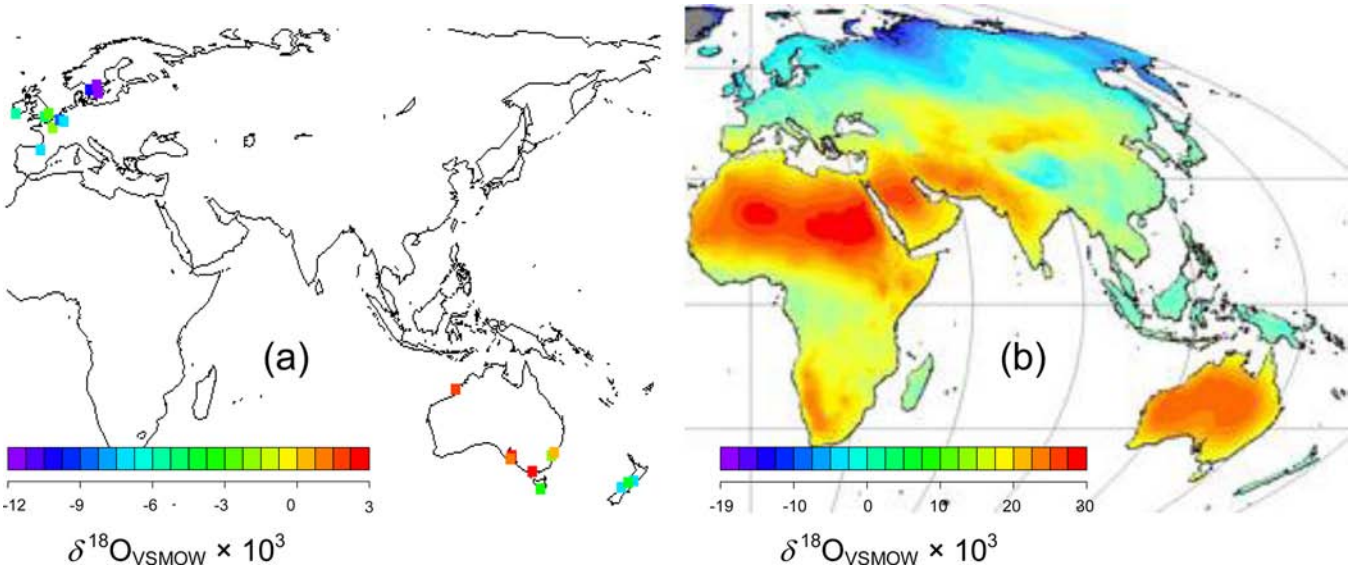

Figure 5. Isoscape of (a) the oxygen isotopic composition of whole ciders compared to (b) the predicted isotopic composition of leaf water. Reprinted with permission from ref 38. Copyright 2008 Public Library of Science.

It was possible to use these data to make inferences about geographical origin. Simplistically, from Figure 2b the most isotopically depleted samples originated from Sweden (S) or Belgium (BY), whereas the most enriched samples originated from Australia (AU). Although AIJN guidelines recommend a minimum $\delta^{18}O_{VSMOW}$ composition for both apple and pear juice of −6.5‰, it was clear that all of the Swedish samples fell below this value, but these guidelines do note that "lower values are possible due to the effects of geographical origins...".

It was difficult to interpret data in the central region of Figure 2b because samples from similar geographical regions such as the United Kingdom (GBR), France (F), or Ireland (IRL) had similar isotopic compositions, as did samples from regions with similar climates, EU, NZ, and Tasmania (AU*), especially Spanish and NZ samples.

Figure 5a shows the $\delta^{18}O$ composition of the whole ciders, color scaled and projected onto a map, often referred to as an *isoscape*[37] or, in this example, *CyderSpace*. This map was compared to a map in which records of the isotopic composition of precipitation were used to predict the $\delta^{18}O$ composition leaf water[38] (Figure 5b). The extent of isotopic enrichment of water within plant tissue is generally assumed to be leaves > fruit > stem > groundwater.[36] Although the water in fruit was expected to be less enriched than in leaves, it was possible to compare fruits and leaves in these maps because both were scaled to encompass the full range of data rather than presented on an absolute scale. Although limited data were available for ciders, the visual similarity between the two maps was apparent. A similar comparison was obtained when the $\delta^{18}O$ data derived from analysis of the dry residues were mapped, which might be expected given the strong correlation observed between the solid and liquid $\delta^{18}O$ data.

The presentation of data in a geo-spatial framework provided a more refined tool to determine country of origin by addressing the following question: Is the isotopic composition of a cider consistent with the claimed country of origin? Such an approach will allow an assessment of the authenticity of ciders for which no reference samples can be obtained. Caution, however, must be applied when the isotopic composition of ciders is compared to isoscapes derived from precipitation. First, ciders have been shown to be enriched in ^{18}O with respect to meteoric waters and, second, plants may be exposed to waters from a combination of precipitation and irrigation, which may vary with time.[39] As a further caveat, it should be noted that once harvested, apples, pears, juice, or sugar may be transported considerable distances, and the composition of a finished cider may not reflect the region of production of any single ingredient.

As with any comparison, it is vital to understand variability to know if differences are significant. The next goal of this study

DOI: 10.1021/jf5030054
J. Agric. Food Chem. 2015, 63, 975−982

will be to examine intraproduct heterogeneity as a function of time because growing conditions will vary from year-to-year and suppliers of fruit and sugar may change.

(21 °C) and verified to be isotropic using the below method were treated as microemulsions and used to construct a partial ternary phase diagram. Controls containing 1−6% (w/w) lecithin and 1% (w/w) peppermint oil without Tween 20 were also prepared by the same procedures stated above.

Determination of the Phase Inversion Temperature (PIT). *Viscosity Method.* Determination of the PIT based on viscosity data during cooling was adopted from a previous study.[16] Tests were conducted using a model AR2000 rheometer (TA Instruments, New Castle, DE) and a concentric cylinder geometry (bob outer diameter 28 mm, cup inner diameter 30 mm). A 13 mL volume of a mixture with 20% (w/w) Tween 20, 6% (w/w) lecithin, and 20% (w/w) peppermint oil after brief hand-shaking was loaded into the cup, heated to 95 °C, equilibrated for 2 min, and subsequently cooled to 25 °C at 3 °C/min using a fixed shear rate of 100 s^{-1}.

Turbidity Method. The turbidity of emulsions before and after heating at 20−90 °C for 5 min was measured for absorbance at 600 nm using a UV/vis spectrophotometer (model Evolution 201, Thermo Scientific Co., Waltham, MA).

Physicochemical Properties of Microemulsions. Microemulsions with the highest oil loading capability of various lecithin concentrations were used to characterize the following physical and chemical properties. The specific sample numbers and corresponding compositions are listed in Table 1.

Table 1. Sample Numbers and Their Corresponding Compositions Showing the Highest Content of Peppermint Oil Being Dissolved by the Surfactant Combinations as Microemulsions

	composition (%, w/w)		
sample no.	Tween 20	lecithin	peppermint oil
S1	20	1	5
S2	20	2	7
S3	20	3	9
S4	20	4	12
S5	20	5	16
S6	20	6	20

Particle Size Distribution. The particle size distribution of microemulsions was measured using a Delsa Nano C particle size/ζ potential analyzer (Beckman Coulter, Fullerton, CA). To fit the instrument sensitivity requirement, microemulsions were diluted 20−60-fold in diwater. All measurements were performed four times with two from each of two independent repetitions. Both volume fraction-length ($d_{4,3}$) and area-volume ($d_{3,2}$) mean diameters were calculated using eqs 1 and 2, respectively, where n_i is the number of particles with diameter d_i.

$$d_{4,3} = \frac{\sum_{i=1} n_i d_i^4}{\sum_{i=1} n_i d_i^3} \quad (1)$$

$$d_{3,2} = \frac{\sum_{i=1} n_i d_i^3}{\sum_{i=1} n_i d_i^2} \quad (2)$$

Rheological Property. The viscosity of microemulsions was determined using the above rheometer and concentric cylinder geometry. The shear rate ramps were performed from 0.1 to 100 s^{-1} at 25 °C.

Optical Microscopy. To verify the formation of isotropic microemulsions, samples were examined using an Olympus BX51 polarized light microscope and a 40× objective (Olympus Corp. of America, Hauppauge, NY).

Dilution Stability. Microemulsions were diluted 50-, 100-, and 200-fold in diwater. The chemical stability of peppermint oil components and physical stability of the mixtures were monitored at 240 and 600 nm, respectively, using the above UV/vis spectrophotometer during storage at room temperature (21 °C) for 72 h.

Storage Stability. The stability of microemulsions was evaluated after storage for 30 and 70 d at room temperature (21 °C) by measuring particle size changes.

Microemulsions with Dissolved Coenzyme Q_{10}. *Preparation of Microemulsions with CoQ_{10}.* Microemulsions containing CoQ_{10} were prepared using procedures similar to those described above. Briefly, 0.018 mg of CoQ_{10} and 0.54 mg of peppermint oil were mixed on a magnetic stir plate at room temperature (21 °C) until visually completely dissolved. Subsequently, the oil phase was mixed with the 12% (w/w) lecithin stock suspension, diwater, and Tween 20 to a total mass of 18 g containing 0.1% (w/v) CoQ_{10}, 3% (w/w) peppermint oil,

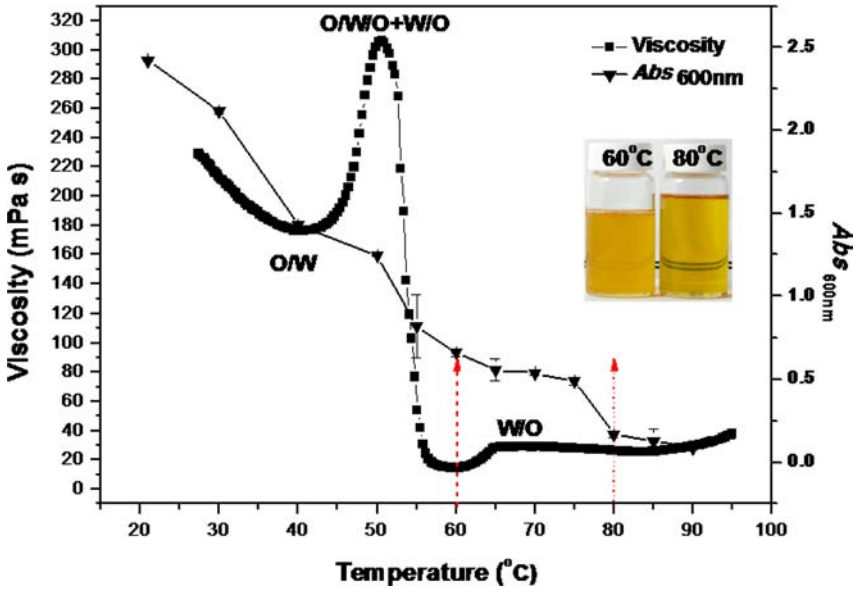

Figure 1. Changes of the viscosity of the coarse emulsion during cooling from 95 to 25 °C at 3 °C/min, in comparison to the absorbance at 600 nm (Abs_{600nm}) after heating of the coarse emulsion at a fixed temperature from 20 to 90 °C for 5 min and cooling in an ice/water bath. The coarse emulsion contained 20% (w/w) Tween 20, 6% (w/w) lecithin, and 20% (w/w) peppermint oil. The inset image compares the visual appearance of two samples heated at 60 and 80 °C for 5 min.

J. Agric. Food Chem. 2015, 63, 983−989

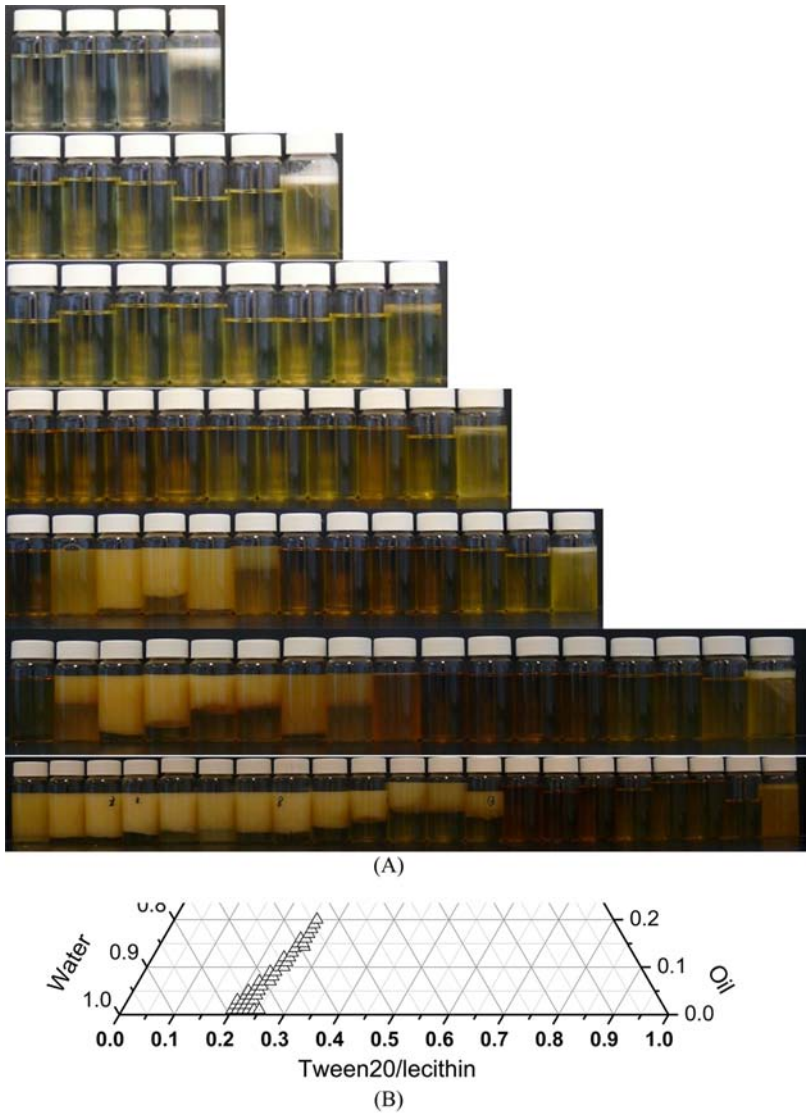

Figure 2. (A) Appearance of oil/water/surfactant mixtures after phase inversion by heating at 80 °C for 5 min. From the top to the bottom, the Tween 20 content was kept at 20% (w/w), while the lecithin content was 0%, 1%, 2%, 3%, 4%, 5%, and 6% (w/w), respectively. In each row, the peppermint oil content from left to right increased by 1% (w/w) successively from 1% (w/w). (B) Partial ternary phase diagram of Tween−lecithin, peppermint oil, and water mixtures confirmed to form transparent microemulsions.

20% (w/w) Tween 20, and 0% or 3% (w/w) lecithin. After brief hand-shaking, the coarse emulsion was heated at 80 °C for 5 min, followed by cooling in an ice/water bath. The CoQ_{10} control solution was prepared by dissolving CoQ_{10} at 0.1% (w/v) in ethyl acetate directly.

Kinetics of CoQ_{10} Degradation under UV Radiation. A 3.5 mL volume of the above microemulsions with CoQ_{10} and control solution in 4 mL clear glass vials were placed at 15 cm under a 15 W UV tube (254 or 302 nm) attached to an XX-15 series UV system from UVP, LLC (Upland, CA). After UV radiation at ambient conditions (21 °C) in the dark for up to 32 h, the samples were diluted 5-fold, and the absorbance at 420 nm was measured using a Biomate 5 UV/vis spectrophotometer (Thermo Scientific). The residual concentration of CoQ_{10} was then determined on the basis of a calibration curve established from standard solutions with 0.03125−1 mg/mL CoQ_{10} dissolved in ethyl acetate. The determined CoQ_{10} concentrations were fit to eq 3, where c_0 and c_t are CoQ_{10} concentrations before and after radiation for a duration of t (h), on the basis of the first-order degradation kinetics.[17,18] The degradation rate constant (k) and half-life ($t_{1/2}$), the duration corresponding to the reduction of the CoQ_{10} concentration to half its initial value (eq 4), were determined.

$$c_t = c_0 e^{-kt} \quad (3)$$

$$t_{1/2} = -(\ln 0.5)k^{-1} \quad (4)$$

Statistical Analysis. The data are reported as the mean ± standard deviation from replicates. Statistical analyses were performed using SAS software (version 9.3, SAS Institute Inc., Cary, NC). One-way ANOVA Tukey's test was used to compare the significant difference of mean values at a P level of 0.05.

RESULTS AND DISCUSSION

Determination of the PIT. The first set of experiments was to identify an appropriate temperature to form microemulsions. The coarse emulsion with 20% (w/w) Tween 20, 6% (w/w) lecithin, and 20% (w/w) peppermint oil was used to determine the PIT. There are several ways to determine the PIT, such as monitoring viscosity changes during cooling,[16,19] electrical conductivity at various temperatures,[20] and turbidity changes during/after heating.[20] In this study, viscosity changes during

cooling and turbidity changes after heating were used to determine the PIT.

Figure 1 demonstrates changes of the viscosities of the coarse emulsion during cooling from 95 to 25 °C. During cooling, the coarse emulsion can change from a water (W)/oil (O) emulsion to a W/O/W emulsion, with partial W/O emulsion, and finally to an O/W emulsion.[21] The PIT can be determined as the lowest temperature at which the emulsion converts from a fine W/O emulsion to a W/O/W emulsion.[21] On the basis of the viscosity data, the PIT was determined to be 60.7 °C (Figure 1). When the turbidity data were compared, samples heated at a higher temperature had lower turbidity (Figure 1). The sample heated at 60 °C showed some degree of phase inversion when compared to the coarse emulsion but had a higher absorbance than samples heated at 80 °C or higher, corresponding to turbid and transparent dispersions, respectively. Since the turbidity was similar at 80 °C and above, heating treatment at 80 °C for 5 min was chosen for further study.

Influence of the Lecithin Content on Microemulsion Formation. The impacts of the lecithin content on the phase behavior of oil/water/surfactant mixtures with a base composition of 20% (w/w) Tween 20 were studied after the samples were heated at 80 °C for 5 min. The sample appearance after ambient incubation overnight is shown in Figure 2A. Emulsions prepared with 1−6% (w/w) lecithin alone were turbid even with only 1% (w/w) peppermint oil, and treatments prepared with 1−3% (w/w) lecithin showed some creaming after overnight storage (data not shown). Tween 20 (20%, w/w) alone was able to dissolve 3% (w/w) peppermint oil. The combinations of 20% (w/w) Tween 20 and 1%, 2%, and 3% (w/w) lecithin increased the amount of dissolved peppermint oil to 5%, 7%, and 9% (w/w), respectively. With 4% (w/w) lecithin, the treatments with 1% (w/w) and 7−12% (w/w) peppermint oil were transparent, while the ones with 2−6% (w/w) oil showed phase separation. Similar observations were noted for treatments with 5% (w/w) lecithin, with higher peppermint oil levels in transparent samples (10−16%, w/w). At the highest lecithin content (6%, w/w) studied, 14−20% (w/w) peppermint oil was dissolved as transparent dispersions. For mixtures with 4−6% (w/w) lecithin, samples separated into a clear lower phase (O/W microemulsion) and a turbid upper phase (with excess lecithin) after storage have the characteristics of Winsor-I phase behavior.[22] When transparent samples were examined for sample homogeneity and birefringence using a polarized light microscope, all samples appeared completely dark (data not shown). Therefore, these samples were isotropic, which is a distinct feature of microemulsions.[23] Formulations resulting in isotropic transparent dispersions after confirming Newtonian viscosity and stable and small monodispersed droplets, as presented in the following sections, are treated as microemulsions and summarized in Figure 2B, and those with the highest peppermint oil content at different lecithin concentrations are listed in Table 1.

The hydrophile−lipophile balance (HLB) is commonly used to indicate the properties of surfactants emulsifying oils. Theoretically, surfactants with higher HLB values have better solubility in water,[24] and surfactants with HLB values higher and lower than 7 are usually used to form O/W and W/O emulsions, respectively.[24] The HLB of a surfactant mixture (HLB_{mix}) can be estimated using the summation of the product of HLB and mass percentage of individual surfactants.[25] When the HLB of a surfactant or surfactant mixture is similar to the required HLB of the oil phase, the system provides the minimum energy condition for microemulsion formation.[26] Tween 20 and soybean lecithin have respective HLB values of 16.7 and 8.[27] Assuming similar HLB of sunflower and soybean lecithin, HLB_{mix} decreases from 16.7 (of Tween 20) to 14.69 when the lecithin content increases from 0% to 6% (w/w). Therefore, the addition of lecithin decreased HLB_{mix} to be closer to 12.3, which was found to be the most appropriate HLB value to form O/W emulsions of peppermint oil.[28] Additionally, two long hydrocarbon chains of lecithin facilitate the dissolving of oil in the dispersed phase of O/W microemulsions.[29] These two factors may have resulted in a high loading of peppermint oil in the microemulsions of the present study.

Particle Size and Stability of Selected Microemulsions. Microemulsions are thermodynamically stable systems that typically contain particles with a dimension in the range from 2 to 50 nm.[30] The particle sizes of selected microemulsions containing 1−6% lecithin and 5−20% peppermint oil (Table 1) were tested. No significant differences ($P > 0.05$) were observed from the values of $d_{4,3}$ and $d_{3,2}$ of all samples before and after storage for 30 and 70 d at room temperature (21 °C, Table 2). Particle dimensions ranging from ∼7 to ∼11 nm enabled their transparent appearance. A single narrow peak was observed for all the measured transparent samples (data not shown). The nanoemulsions of peppermint oil typically show the growth of particle dimensions during storage due to Ostwald ripening.[31] Because a stable particle dimension and visible appearance were always observed for all transparent dispersions, it can be concluded that they are microemulsions.

Viscosity of Selected Microemulsions. Shear rate ramps of microemulsions in Table 1 are presented in Figure 3. Linear correlations between shear rate and shear stress, with R^2 values all greater than 0.99 (Table 3), and an intercept of zero indicate

S6	0.1969 ± 0.0011 a	0.9999 ± 0.0000

[a]Numbers are the mean ± standard deviation from three independent measurements. Different online Roman letters indicate the statistical difference in the mean ($P < 0.05$).

these microemulsions are Newtonian fluids. The Newtonian viscosity ranged from 0.0085 Pa s for the sample with 1% lecithin and 5% peppermint oil to 0.1969 Pa s for that with 6% lecithin and 20% peppermint oil (Table 3). A higher viscosity of microemulsions with higher contents of peppermint oil and lecithin is expected. The trend agreed with the literature microemulsion systems with isopropyl myristate dissolved by a soybean lecithin and Tween 80 mixture and orange oil by a sucrose laurate/soybean lecithin mixture.[29,32]

Stability of Microemulsions after Dilution. The stability of microemulsions diluted 50-, 100-, and 200-fold using diwater was monitored at 240 and 600 nm to indicate the chemical stability of peppermint oil and physical stability (turbidity), respectively, at 21 °C for up to 72 h. The wavelength of 240 nm, corresponding to the maximum absorbance of peppermint oil in the UV/vis regime, was used to monitor the amount of peppermint oil. All diluted samples showed no significant change in the absorbance at 240 nm (presented in Figure 4 for microemulsions after 200-fold dilution), indicating good chemical stability of peppermint oil in microemulsions after dilution. The absorbance at 600 nm of all detected samples after 50-, 100-, and 200-fold dilution using diwater was smaller than 0.1. The excellent dilution stability of microemulsions may be due to the close HLB values of surfactant mixtures and peppermint oil, as discussed above. Because flavor oils such as peppermint oil are used at low concentrations, the excellent

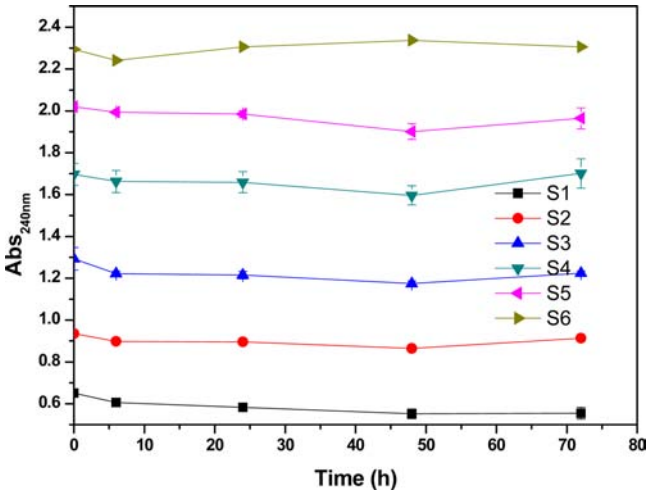

Figure 4. Absorbance of microemulsions S1−S6 at 240 nm (the maximum absorbance of peppermint oil) after 200-fold dilution and incubation at 21 °C for up to 72 h. The sample compositions are listed in Table 1.

dilutability of microemulsions is an important feature for practical applications.

Photostability of CoQ_{10} in Microemulsions. Microemulsions after dissolving CoQ_{10} had a $d_{3,2}$ smaller than 7 nm (Table 4), and there was no significant ($P > 0.05$) difference for

Table 4. Area-Volume Mean Diameters ($d_{3,2}$) of Microemulsions with 20% (w/w) Tween 20, 3% (w/w) Peppermint Oil, 0.1% (w/w) CoQ_{10}, and 0% or 3% (w/w) Lecithin before and after Treatment at 302 nm and Ambient Conditions (21 °C) for up to 32 h[a]

8	6.85 ± 0.69	4.69 ± 0.55
16	5.57 ± 0.67	4.85 ± 0.80
32	6.45 ± 1.56	4.29 ± 0.68

[a]Numbers are the mean ± standard deviation from two measurements from two independent repetitions. No significance difference ($P > 0.05$) was observed for all treatments.

the treatments with 0% or 3% (w/w) lecithin. These dimensions were similar ($P > 0.05$) to those of microemulsions without CoQ_{10} (Table 2). $d_{3,2}$ did not change significantly ($P > 0.05$) after UV radiation at 302 nm for up to 32 h (Table 4).

The UV stability of CoQ_{10} was studied at 254 and 302 nm. As demonstrated in Figure 5, no significant degradation of CoQ_{10} in the control solution was observed after radiation at 254 nm for 32 h ($P > 0.05$), which was the same as previously reported.[14] However, significant ($P < 0.05$) degradation of CoQ_{10} in the control solution was observed after radiation at 302 nm, decreasing to less than 25% of the initial concentration after 8 h of radiation. The energy of photons is proportional to the frequency of electromagnetic waves, and UV 254 nm, with a higher frequency (shorter wavelength) than UV 302 nm, is expected to cause a greater extent of structural degradation, including the mechanism related to heat after energy conversion.[33,34] Conversely, the electromagnetic energy (P) at

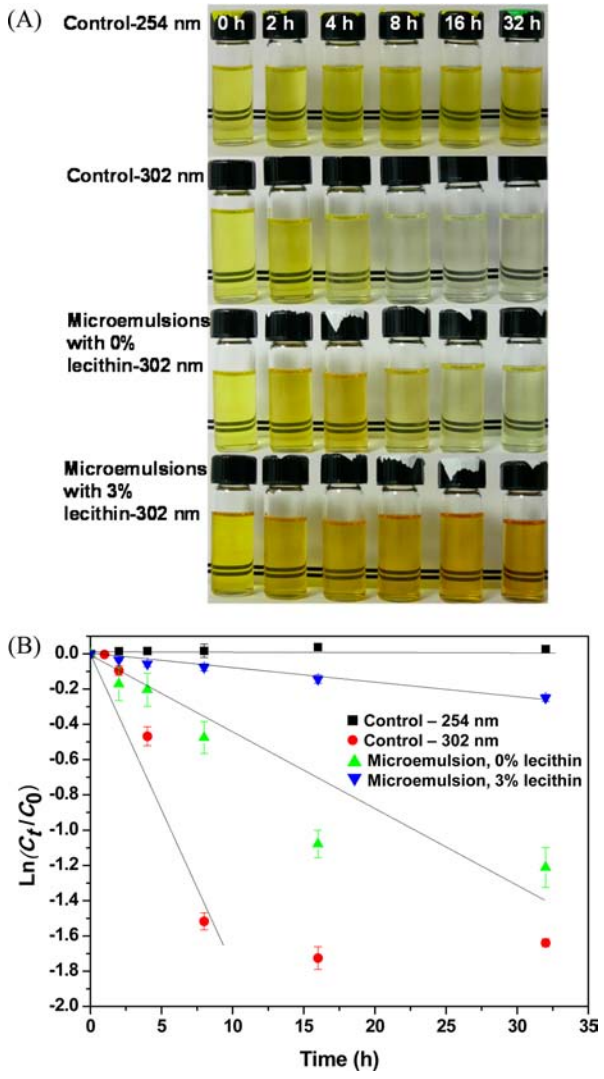

Figure 5. Appearance (A) and normalized residual concentrations (B) of 0.1% (w/w) CoQ_{10} dissolved in microemulsions with 20% (w/w) Tween 20, 3% (w/w) peppermint oil, and 0% or 3% (w/w) lecithin after radiation at UV 302 nm under ambient conditions in the dark for up to 32 h. The control solution contained 0.1% (w/w) CoQ_{10} dissolved in ethyl acetate and was treated at both 254 and 302 nm. Error bars are standard deviations (n = 4).

a depth z decays exponentially from the energy on the surface (P_0), as expressed in the well-known Beer–Lambert law:

$$P = P_0 e^{-\alpha z} \quad (5)$$

where α is a constant and equals $1/d_p$, with d_p being the penetration depth that corresponds to a z value where P becomes 1/e of P_0.[35]

UV 302 nm has a longer penetration depth[36] and therefore has a greater impact on reactions induced by radiation than UV 254 nm, despite the lower photon energy.[37] Therefore, a quicker degradation of CoQ_{10} at 302 nm than at 254 nm was observed in the present study, as well as others.[14,38] The stability of CoQ_{10} in microemulsions was therefore only tested for 302 nm treatments.

The appearance and residual CoQ_{10} concentration after UV 302 nm treatments are shown in Figure 5, and the estimated parameters according to eqs 3 and 4 are compiled in Table 5. The microemulsions improved the photostability of CoQ_{10}, and the improvement was more apparent for the treatment with lecithin. The first-order kinetic model fits the degradation data well, with coefficients of determination above 0.8, which agrees with previous reports.[17,18] The degradation rate constant decreased from 0.167 h^{-1} in the control solution to 0.0448 and 0.00825 h^{-1} in the microemulsion without and with lecithin, respectively. Accordingly, the half-life increased 3.7- and 20.3-fold, respectively, for CoQ_{10} in the microemulsion without and with lecithin.

It is well-established that Tween 20 does not have antioxidant capacity, while lecithin is a good antioxidant.[39] The improved photostability of CoQ_{10} in the microemulsion without lecithin likely resulted from the antioxidant capacity of peppermint oil.[40] The combination of antioxidant properties of lecithin and peppermint oil apparently improved the stability of CoQ_{10} dissolved in the microemulsion with lecithin. On the basis of a previous report,[39] Tween 20 at the O/W interface cannot prevent the diffusion of peroxyl radicals into the oil body, while the opposite is the case for lecithin. Because Tween 20 is present at a higher content than lecithin in the microemulsion (20% vs 3%), the much improved stability of CoQ_{10} in the microemulsion with lecithin further indicates that the two surfactants synergistically dissolved peppermint oil, as discussed previously.

Overall, the combination of sunflower lecithin and Tween 20 enabled the formation of stable microemulsions capable of dissolving high levels of peppermint oil, increasing from 3% to 20% when the lecithin content increased from 0% to 6%. Microemulsions were isotropic and transparent with particle sizes smaller than 12 nm and had relatively low Newtonian viscosity and excellent water-dilution and storage stability at ambient conditions. Additionally, microemulsions had the capability of dissolving CoQ_{10} and reducing its degradation under UV radiation at 302 nm, which likely resulted from the presence of both peppermint oil and lecithin. Our findings indicate that the microemulsions in the present study are promising systems to deliver both flavor oils and lipophilic bioactive compounds in transparent products such as beverages.

Table 5. Degradation Rate Constant (k), Half-Life ($t_{1/2}$), and R^2 When Fitting the Degradation Data at 302 nm (Figure 5) to the First-Order Kinetics Model[a]

sample	k (h^{-1})	R^2	$t_{1/2}$ (h)

purchased from Fisher Scientific Co. (Fair Lawn, NJ, USA). All other chemicals used were of analytical grade. Double-distilled water was used to prepare all solutions and emulsions.

Nanoemulsion Preparation. We carried out a study using three delivery systems with different compositions and structures.

Delivery System 1: Solubilized β-Carotene (Emulsion). β-Carotene crystals were dissolved in corn oil (digestible oil) and then converted into an oil-in-water nanoemulsion. This group simulates the consumption of functional foods or beverages containing solubilized carotenoids.

Delivery System 2: Crystalline β-Carotene (Emulsion). β-Carotene crystals were mixed with an oil-in-water emulsion immediately before introduction into the GIT model. This group simulates the consumption of crystalline forms of carotenoids (such as those in tablets, powders, cereals, or baked goods) with fatty foods.

Delivery System 3: Crystalline β-Carotene (Buffer). β-Carotene crystals were mixed with a phosphate buffer saline (PBS) solution immediately before introduction into the GIT model. This group simulates the consumption of crystalline forms of carotenoids without co-ingestion of fatty foods (e.g., a crystalline suspension taken with a glass of water).

Initially, an aqueous phase was prepared by mixing 0.5% (w/w) Tween 20 with aqueous buffer solution (10.0 mM PBS, pH 7.0).

β-Carotene-Enriched Nanoemulsion Preparation. An oil phase was prepared by dispersing 0.5% (w/w) of crystalline β-carotene into corn oil followed by mild heating at 50 °C for 5 min followed by stirring at ambient temperature for about 1 h to ensure full dissolution. A coarse emulsion was then formed by mixing the oil phase (4% w/w) with an aqueous phase (96% w/w) and then blending for 2 min at ambient temperature using a high-shear mixer (Tissue-Tearor, Biospec Products, Bartlesville, OK, USA). The coarse emulsion was then passed through a high-pressure microfluidizer (model 101, Microfluidics, Newton, MA, USA) three times at 9000 psi. The freshly prepared β-carotene nanoemulsions were then protected from light in a glass container and stored at 20 °C before digestion.

Nanoemulsion Preparation. Oil-in-water nanoemulsions were prepared by homogenizing 4% (w/w) corn oil with 96% (w/w) aqueous phase using the same method as described above. The freshly made nanoemulsions were then covered by parafilm in a glass container and stored at 20 °C before digestion.

Particle Characterization. The mean particle diameters (*Z*-average) and particle size distribution of the original nanoemulsion and samples at each digestion step were monitored using a dynamic light scattering instrument (Nano-ZS, Malvern Instruments, Worcestershire, UK). Prior to analysis, dilution (1:20) was carried out by adding 0.5 mL of sample to 9.5 mL of buffer solution with the same pH and ionic composition as the sample being analyzed. Dilution was necessary to avoid multiple scattering effects.

The electrical charges (ζ-potential) of the original nanoemulsion and the digesta were monitored using a microelectrophoresis instrument (Nano-ZS, Malvern Instruments). The same diluted samples used above were used for measuring electrical charge. The ζ-potential was determined by measuring the direction and velocity of droplet movement in an oscillating electric field.

Microstructural Analysis. The microstructural changes of the samples within the simulated GIT were observed using confocal scanning fluorescence microscopy. The physical changes of β-carotene crystals were observed using a cross-polarized lens (C1 Digital Eclipse, Nikon, Tokyo, Japan). Samples from each GIT step were dyed with Nile Red (0.1%) to highlight the location of the lipid phases. All images were taken using a 10× eyepiece and a 60× objective lens (oil immersion).

In Vitro Digestion. Three groups of samples were prepared: (1) solubilized β-carotene; (2) crystalline β-carotene (emulsion); (3) crystalline β-carotene (buffer). The β-carotene crystals were introduced into the nanoemulsions and buffer solutions just before the GIT model was started to mimic the way people may ingest nutraceutical tablets with food emulsions or water, respectively. The initial concentration of β-carotene in all three groups was the same. Each sample was passed through a three-step GIT model that consisted of mouth, gastric, and small intestine phases.

Mouth Phase. Simulated saliva fluid (SSF), containing 3% mucin and various salts, was prepared as described previously.[17,18] Ten milliliters of sample was placed in a beaker and mixed with 10 mL of SSF. The mixture was then adjusted to pH 6.8 and placed in a shaker at 100 rpm and 37 °C for 10 min to mimic oral conditions (Innova Incubator Shaker, 132 model 4080, New Brunswick Scientific, NJ, USA).

Gastric Phase. Simulated gastric fluid (SGF) was prepared according to a protocol described before.[19] The "bolus" sample from the mouth phase was mixed with SGF at a 1:1 mass ratio. The mixture was then adjusted to pH 2.5 and placed in a shaker at 100 rpm and 37 °C for 2 h to mimic gastric conditions.

Small Intestine Phase. Gastric digesta (30 mL) was incubated in a water bath (37 °C) for 10 min and then NaOH solution used to adjust the pH to 7.0. Then 1.0 mL of $CaCl_2$ solution, containing 110 mg of $CaCl_2$ (pH 7.0, PBS), was added into the 30 mL digesta. Then 4 mL bile extract, containing 187.5 mg of bile extract (pH 7.0, PBS), was added with stirring, and the resulting system was adjusted to pH 7.0. Finally, 2.5 mL of pancreatic suspension, containing 60 mg of lipase (pH 7.0, PBS), was added to the solution. At this point, titration was started automatically. The pH-stat (Metrohm, USA Inc.) was used to monitor and control the pH (at pH 7.0) of the digestion solution. As the triacylglycerol of fat was digested into free fatty acids (FFAs) by lipolysis, the NaOH solution (0.25 M) was added to neutralize the pH (7.0). The amount of FFAs released in the system was calculated from the volume of NaOH required to maintain neutral pH as described previously.[20] The small intestine digestion phase lasted for 2 h.

Bioaccessibility Determination. After in vitro digestion, digesta of each sample group was collected and centrifuged (14000 rpm, Thermo Scientific, USA) at 25 °C for 40 min. Centrifuged samples separated into three phases: sediment phase at the bottom, a relatively clear watery phase in the middle, and sometimes an undigested oil phase at the top. The middle phase was assumed to contain mixed micelles that entrapped the β-carotene, that is, the bioaccessible fraction. The micelle phase was passed through a syringe filter with the pore size of 0.45 μm. β-Carotene was extracted using organic solvent isopropanol/isooctane solution (1:1 v/v). The micelle phase and total digesta (0.2 mL) from the small intestine were added to 4.8 mL of isopropanol/isooctane solution and centrifuged at 14000 rpm at 25 °C for 10 min. The β-carotene concentrations were then analyzed using a UV−visible spectrophotometer (Ultrospec 3000 pro, GE Health Sciences, USA) at 450 nm. The concentration of β-carotene was calculated from the absorbance using a standard curve. The bioaccessibility was calculated using the following equation:

$$\text{bioaccessibility} = 100 \times \left(\frac{C_{\text{micelle}}}{C_{\text{digesta}}}\right)$$

In this equation, C_{micelle} stands for the concentration of β-carotene in the micelle fraction and C_{digesta} is the concentration of β-carotene in the overall sample (total digesta) after the pH-stat experiment.

Statistical Analysis. All measurements were performed at least three times on freshly prepared samples and were reported as calculated means and standard deviations.

RESULTS AND DISCUSSION

Impact of Physical State of β-Carotene on Gastrointestinal Fate. *Particle Size and Microstructure.* To investigate the influence of the physical state of β-carotene on its bioaccessibility, the three types of delivery system were passed through the GIT model: (1) solubilized β-carotene (emulsion); (2) crystalline β-carotene (emulsion); (3) crystalline β-carotene (buffer). The mean particle sizes (*Z*-average diameters) (Figure 1a), particle size distribution (Figure 1b,c), particle charges (Figure 2), and microstructures (Figures 3 and 4) of the initial nanoemulsions and the samples collected after each GIT stage were measured. Particle size and charge measurements are reported only on the

delivery systems initially containing nanoemulsion droplets, because the samples containing crystals in buffer solution could not be reliably analyzed using these analytical techniques.

(a) Initial Samples. The nanoemulsions used to form the solubilized β-carotene (delivery system 1) and the crystalline β-carotene (emulsion) (delivery system 2) had relatively small

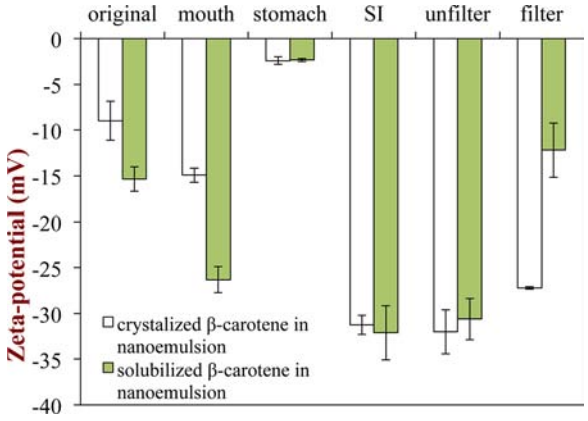

Figure 2. Influence of physical state of β-carotene and in vitro digestion on the charge (ζ-potential) of the particles in oil-in-water nanoemulsions subjected to a simulated gastrointestinal model.

mean particle diameters (d < 200 nm, Figure 1a) and monomodal particle size distributions (Figure 1b,c), which suggested that they were stable under initial solution conditions (pH 7). The confocal microscopy images indicated that the lipid droplets were relatively small and evenly distributed throughout the initial samples (Figure 3).

(b) Mouth Stage. The dynamic light scattering (DLS) measurements suggested that the particles in delivery systems 1 and 2 remained relatively small after passing through the simulated mouth stage, that is, d < 210 nm (Figure 1). However, this may have been an artifact of the DLS method (which is not sensitive to slow-moving large particles), because the confocal microscopy images indicated the presence of some relatively large particles (Figure 3). Droplet aggregation may have occurred as a result of the presence of mucin within the artificial saliva used in the mouth model. Mucin is a complex biopolymer that has previously been shown to be able to promote bridging or depletion flocculation of lipid droplets.[21,22] Nevertheless, the confocal images do suggest that a fraction of the lipid droplets did remain relatively small and evenly distributed (Figure 3). These droplets may have remained stable to aggregation due to the strong steric repulsion generated by the hydrophilic head groups of the nonionic surfactant coating them.[10,23,24] Only a fraction of the lipid droplets may have aggregated because of differences in droplet size (larger droplets are more prone to depletion flocculation than smaller ones) or polymer concentration (there may have been insufficient mucin present to promote bridging or depletion flocculation of all the droplets).

(c) Stomach Stage. After the stomach stage, the DLS measurements indicated that there was a slight increase in particle size, although the mean diameter remained relatively small, that is, d < 270 nm (Figure 1). Again, this appears to be an artifact of the DLS method, because the confocal microscopy images indicated the presence of some large aggregates (Figure 3). Droplet aggregation in the stomach may have been the result of bridging or depletion flocculation caused by the presence of mucin (from the mouth stage) or due to changes in the pH and ionic strength of the intestinal fluids in the stomach phase. The magnitude of the electrical charge on the particles was considerably smaller under stomach conditions than mouth conditions (Figure 3), which would have reduced the electrostatic repulsion between the lipid droplets.

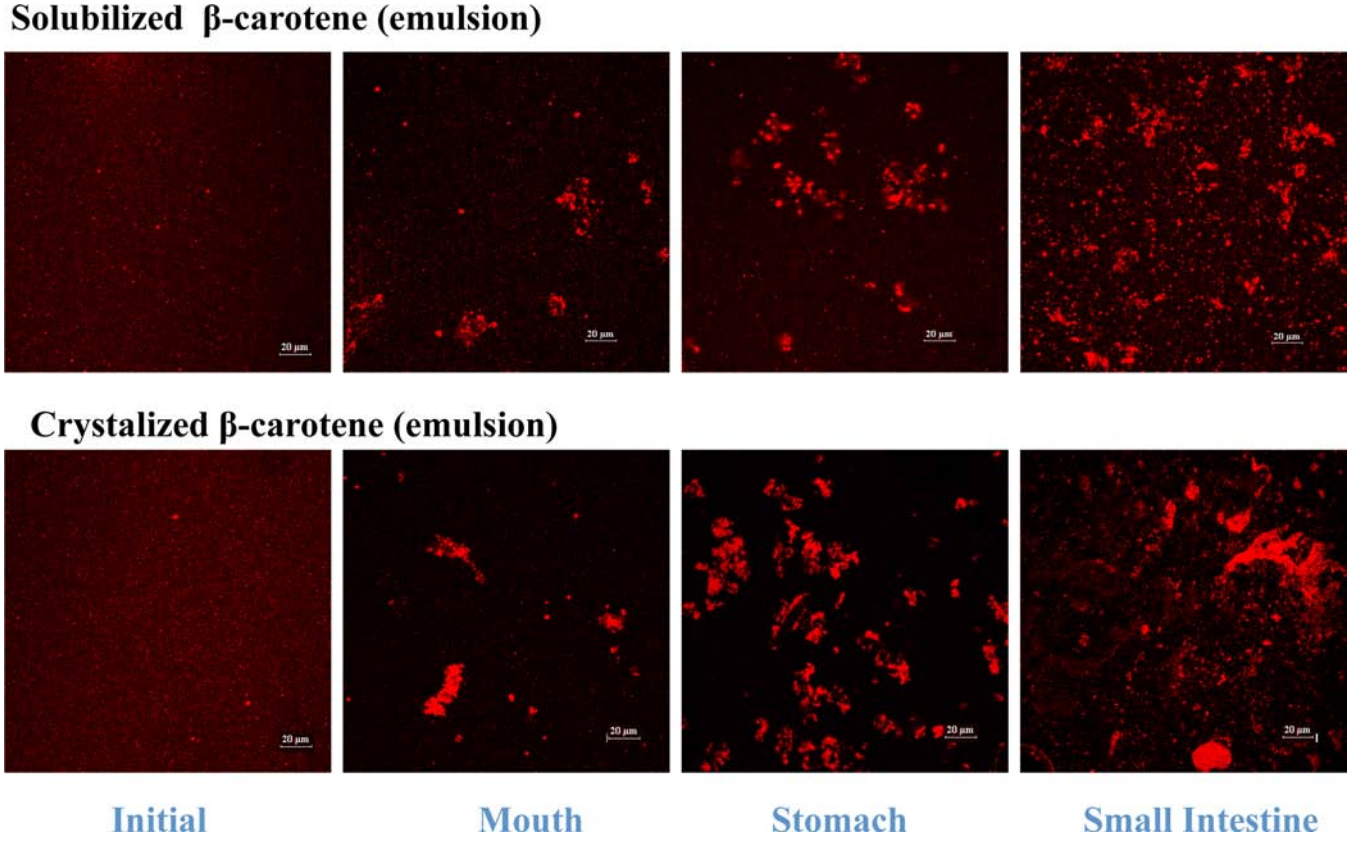

Figure 3. Influence of physical state of β-carotene on the microstructure of lipid measured by confocal microscopy at various stages in an in vitro gastrointestinal tract model. Scale bars = 20 μm.

DOI: 10.1021/jf504673v
J. Agric. Food Chem. 2015, 63, 990−997

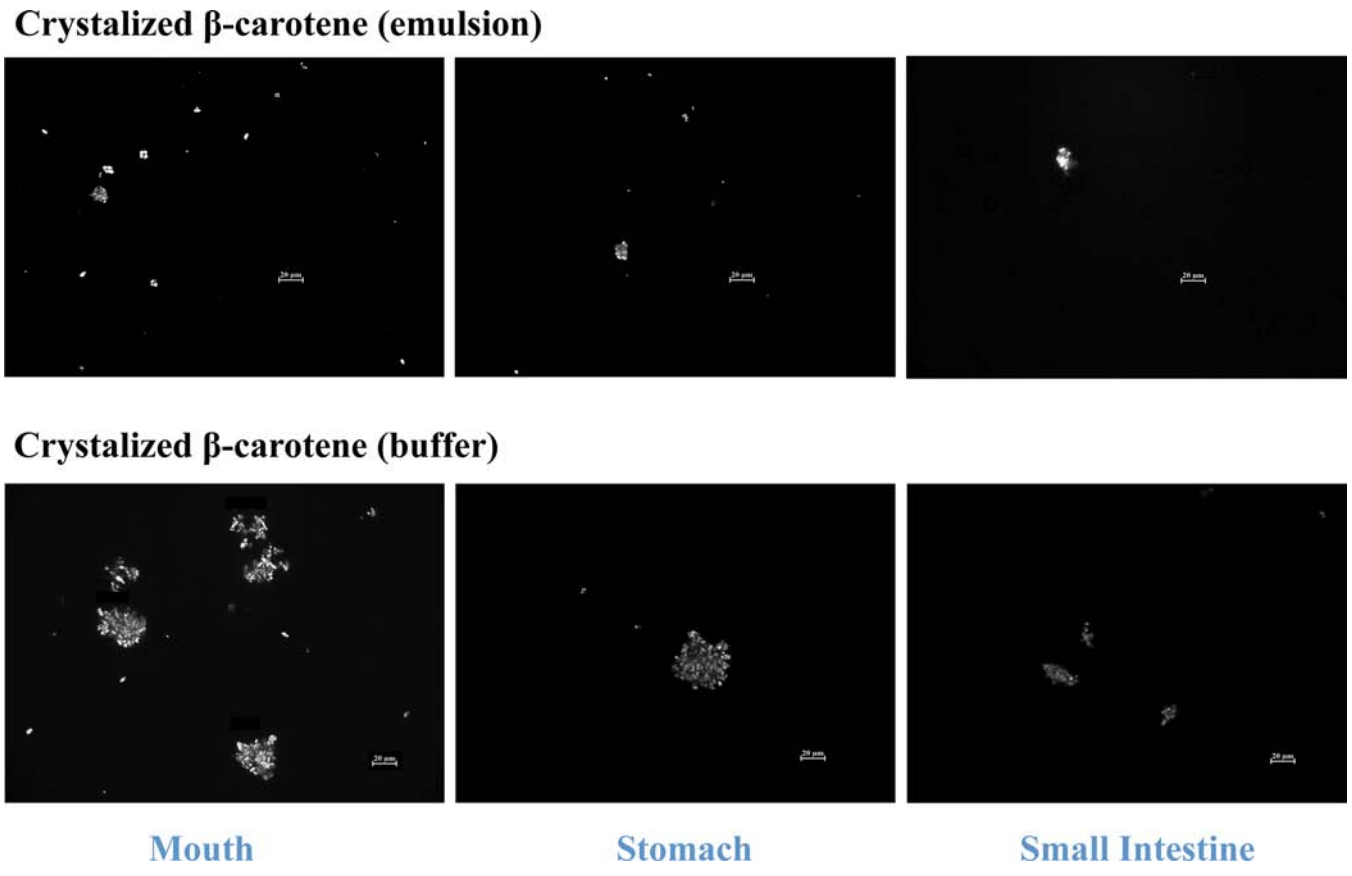

Figure 4. Influence of physical state of β-carotene on the microstructure of β-carotene crystals measured by optical microscopy with a crossed polarizer at various stages in an in vitro gastrointestinal tract model. Scale bars = 20 μm.

(d) Small Intestine Stage. After the small intestine stage, delivery systems 1 and 2 showed a large increase in particle size (Figures 1 and 3), which suggested that extensive droplet aggregation occurred. According to previous studies, several physicochemical mechanisms may have been responsible for this change in aggregation state.[18,23,25] First, the displacement of the original surface active species coating the droplets (i.e., Tween 20) with surface active species from the simulated GIT fluids (i.e., phospholipids, bile salts, FFAs, and monoacyglycerols) may have altered the colloidal interactions between the droplets, thereby promoting aggregation.[26−28] Second, the conversion of emulsified triacylglycerols into FFAs and monoacylglycerols by lipase changes the internal and surface composition of the lipid droplets, which will alter their morphology and aggregation stability.[25]

(e) Micelle Phase. The micelle phase was obtained by centrifuging the digesta from the small intestine phase. The properties of the micelle phase were then analyzed before ("unfiltered") and after ("filtered") they were passed through a 450 nm filter. The mean particle diameters of the unfiltered (228 and 279 nm) and filtered (107 and 205 nm) micelle phases measured by DLS were relatively small for delivery systems 1 and 2, respectively (Figure 1a). The sizes in the unfiltered groups were larger than those in the filtered groups, which indicated that some of the larger particles had been removed by the filter. The micelle phase would be expected to contain β-carotene solubilized within mixed micelles, which are actually a complex mixture of various colloidal structures, including micelles and vesicles.[29] Micelles are expected to be only a few nanometers big (<10 nm), whereas vesicles are much larger (10−1000 nm). Our results therefore suggest that the mixed micelle phase resulting from digestion of the nanoemulsions contained an appreciable amount of vesicles.

Overall, we did not find an appreciable difference between the behavior of the lipid droplets in the two delivery systems containing nanoemulsions (i.e., with either solubilized or crystalline β-carotene). This suggests that the physical state of the carotenoids did not have a major influence on the gastrointestinal fate of the nanoemulsions.

Crystal Structure. Images of the β-carotene crystals within the different delivery systems were captured using a crossed polarizer lens (Figure 4). No crystals were observed in the samples initially containing solubilized β-carotene (delivery system 1), which suggests that the carotenoids did not crystallize during passage through the simulated GIT (data not shown). The number of crystals appearing in the images of the samples initially containing crystalline β-carotene decreased as they were passed through successive stages of the simulated GIT (Figure 4). The most likely reason for this observation is that the samples were progressively diluted at each GIT stage. It is also possible that some of the crystals dissolved during passage through the GIT, but the results of the bioaccessibility study (discussed below) suggest that this was not an appreciable amount.

Particle Charge. We also measured the electrical charge of the particles in the samples after each stage of the GIT model to provide some information about changes in their surface characteristics. Initially, the lipid droplets in the nanoemulsions used to prepare delivery systems 1 and 2 had negative charges (Figure 2). Tween 20 is actually a nonionic surfactant and might therefore be expected to produce neutral lipid droplets. However, it is well established that lipid droplets stabilized by

DOI: 10.1021/jf504673v
J. Agric. Food Chem. 2015, 63, 990−997

this surfactant can have a substantial negative charge, which has been attributed to the presence of anionic impurities in the surfactant or lipids used to prepare them (e.g., phospholipids or FFAs) or due to preferential adsorption of hydroxide ions (OH^-) in water to the droplet surfaces.[10] The electrical charge became more negative when the delivery systems were exposed to the simulated saliva in the mouth (Figure 2), which may have been due to adsorption of anionic mucin molecules to the droplet surfaces. The magnitude of the negative charge on the droplets decreased appreciably after exposure to simulated gastric fluids, which can be attributed to the appreciable decrease in pH in the stomach environment. The particles in the samples had a large negative charge after exposure to the simulated intestinal fluids (Figure 2), which can be attributed to adsorption of anionic species to the droplet surfaces, such as surface active species from the simulated intestinal fluids (e.g., bile salts and phospholipids) or generated during triacylglycerol digestion (e.g., FFAs). The electrical charges on the unfiltered and filtered micelles are also highly negative (Figure 2) because they are primarily composed of anionic species, such as bile salts, phospholipids, and FFAs. The particles in the filtered micelle phase resulting from digestion of the nanoemulsions containing solubilized β-carotene appeared to be less negative than those initially containing crystallized β-carotene. The origin of this effect is unknown, but it suggests that there may have been some differences in the compositions of the mixed micelles in the different systems.

Influence of Physical States of β-Carotene on Lipid Digestion. In this section, the rate and extent of lipid digestion in the small intestine phase was monitored using an automatic titration method (pH-stat). This method measures the amount of alkaline solution required to neutralize the FFAs released from triglycerides during digestion by lipase.[30] As expected, there was little change in the pH of the sample that contained only β-carotene crystals dispersed in buffer solution, because there was no fat in the system and so no FFAs were released during digestion (Figure 5). The slight consumption of NaOH

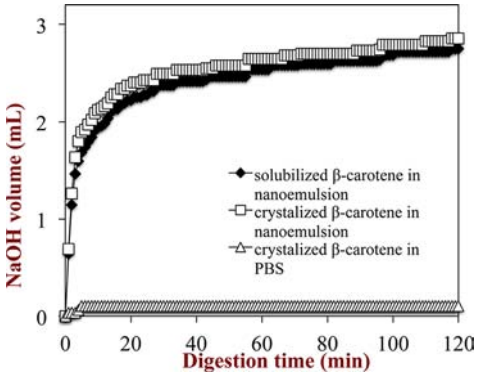

Figure 5. Influence of physical state of β-carotene on the pH-stat titration curves of oil-in-water nanoemulsions. The curves show the volume of 0.25 M NaOH solution that had to be added to the samples to maintain the pH at a constant value of 7.

observed may have been due to some digestible materials in the nonionic surfactant (present in buffer solution) or the chemicals used to prepare the gastrointestinal fluids, for example, phospholipids or proteins. A recent study showed that several nonionic surfactants have ester bonds that are susceptible to lipase digestion, leading to FFA release.[31,32]

In the two delivery systems containing digestible nanoemulsions, there was a steep increase in the volume of NaOH added during the first 20 min of digestion and then it leveled off (Figure 5). The FFA release profiles followed a similar trend as the NaOH consumption (Figure 6). These results suggested that

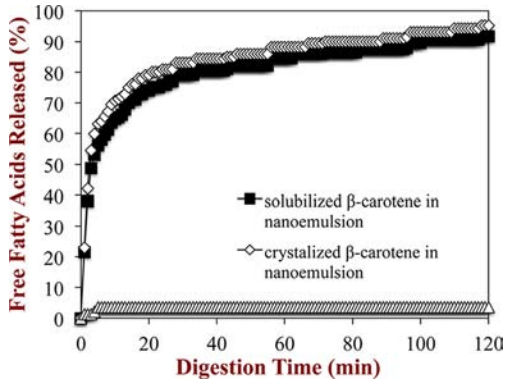

Figure 6. Influence of physical state of β-carotene on the pH-stat titration curves of oil-in-water nanoemulsions. The curves show the calculated percentage of free fatty acids (FFA) released from the nanoemulsions after digestion of the triacylglycerol phase by lipase.

lipase rapidly attached to the surface of the lipid droplets and promoted triacylglycerol digestion. There was no appreciable difference in the FFA release profiles for the solubilized β-carotene samples and for the crystallized β-carotene samples, which suggested that the physical state of β-carotene did not have a major impact on the rate or extent of lipid digestion.

Influence of Physical States of β-Carotene on Its Bioaccessibility. Finally, we measured the influence of the physical state and environment of β-carotene on its bioaccessibility after it passed through the simulated GIT model (Figure 7).

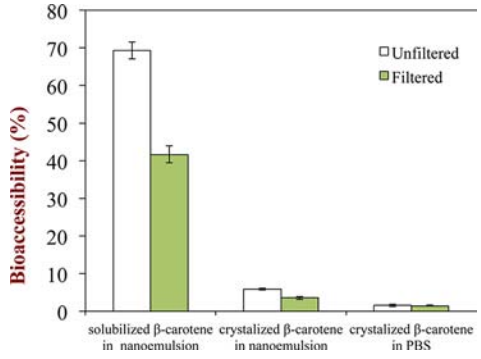

Figure 7. Effect of physical states of β-carotene on bioaccessibility of β- carotene measured after centrifugation of nanoemulsions passed through an in vitro digestion model.

The bioaccessibility was taken to be the amount of β-carotene in the "micelle" phase divided by the portion in the digesta collected after the small intestine phase. The bioaccessibility was measured for both unfiltered and filtered micelle phases. It was assumed that the data for the filtered samples would be more representative of the actual bioaccessibility because particles >~450 nm should not be able to pass through the mucus layer that normally coats the intestinal epithelium cells.[33]

The lowest bioaccessibilities were measured for the unfiltered (1.5%) and filtered (1.4%) samples that initially contained β-carotene crystals dispersed in buffer solution (Figure 7), which

DOI: 10.1021/jf504673v
J. Agric. Food Chem. 2015, 63, 990−997

can be attributed to the fact that there were few mixed micelles available to solubilize the carotenoid crystals. The carotenoid crystals are dense and relatively large (Figure 4) and therefore they sedimented to the bottom of the test tubes after the small intestine stage and did not appear in the micelle phase. The bioaccessibility was also relatively low for the samples that initially contained crystallized β-carotene in nanoemulsions: 5.9 and 3.6% for unfiltered and filtered samples, respectively. In this case, there would be a relatively high concentration of mixed micelles present because the lipid droplets were digested by lipase during the small intestine phase (Figure 5b). This result suggests that there was insufficient time for the β-carotene crystals to dissolve within the mixed micelles in the gastrointestinal fluids, as confirmed by the presence of crystals in the optical microscopy images (Figure 4).

The samples initially containing β-carotene fully dissolved within the nanoemulsions had by far the highest bioaccessibilities: 69 and 42% for unfiltered and filtered samples, respectively. This result suggests that the solubilized β-carotene molecules were able to be transported from the lipid droplets into the mixed micelles during the lipid digestion process, without any crystallization occurring. Overall, our results suggest that the most effective means of delivering β-carotene is by solubilizing it within digestible lipid droplets. Crystalline β-carotene appears to have a relatively low bioaccessibility, whether consumed with water or with an emulsion; however, co-ingestion with an emulsion does lead to an appreciably higher bioaccessibility.

In conclusion, this study showed the bioaccessibility of β-carotene is highly dependent on its physical state, that is, solubilized versus crystalline. Three delivery systems with different properties were tested: (1) solubilized β-carotene in a nanoemulsion; (2) crystallized β-carotene in a nanoemulsion; and (3) crystalline β-carotene in buffer solution. The bioaccessibility of solubilized β-carotene (delivery system 1) was much higher than that of crystallized β-carotene (delivery systems 2 and 3). However, co-ingestion of crystallized β-carotene with a nanoemulsion did lead to an appreciable increase in bioaccessibility. These results have important implications for the development of functional foods or beverages to deliver bioactive lipophilic compounds, such as carotenoids. Our results suggest that the most effective way to obtain a relatively high bioaccessibility is to dissolve the carotenoids in an emulsion. Nevertheless, the bioaccessibility of crystalline carotenoids can also be improved considerably by their consumption with an emulsion.

include degumming with different reagents (phosphoric acid, glacial acetic acid, oxalic acid, and citric acid), neutralization with alkali to remove the free fatty acids, bleaching with different individual adsorbents or their combinations (activated charcoal powder, kaolin light, Fuller's earth, cellulose powder, and purified chitin powder), and deodorization by vacuum distillation to remove the low molecular weight volatile compounds. The changes in ^{1}H NMR signal characteristics after degumming and bleaching processes were compared to those of the crude sardine oil. The volatile compounds distilled off during the deodorization process were evaluated by gas chromatography−mass spectroscopic (GC-MS) analysis.

MATERIALS AND METHODS

Preparation of Crude Sardine Oil. Fresh samples of *S. longiceps* (Valenciennes, 1847) (Indian oil sardine) were collected from the fishing harbors in Cochin (9.97° N, 76.28° E; southwestern coast of India) during the monsoon season and were brought to the laboratory in an icebox. After a washing in sterile water, the internal organs were removed and the edible tissues were cut into slices before being minced in a grinder. The minced edible tissue (100 g) was cooked in a pressure cooker for 30 min at 75 °C, and the cooked tissue was pressed in a screw expeller (PIC-106; Four Brothers Ex-Imp Pvt. Ltd., Chennai, India) before being centrifuged (8000*g*, 30 min) to afford the cooked and pressed crude sardine oil (CSO, 8.3 g).

Oil Refinement Methodology. The steps of the crude oil refinement process (degumming, neutralization, bleaching, and deodorization) were carried out by using the operating conditions as described as follows. Each stage of these refining processes was monitored by evaluating the percent recovery and quality parameters such as FFAs, peroxide (PV), *p*-anisidine (pAV), total oxidation (TOTOX), thiobarbituric acid reactive species (TBARS), Lovibond L^*, a^*, b^* color, chroma, hue angle, total color (ΔE) values, and fatty acid composition.

Crude sardine oil (100 g) was stirred in a temperature-controlled water bath (70 °C) for 20 min separately with 85% phosphoric acid (1 mL, DG_1), 99% glacial acetic acid (1 mL, DG_2), 10% oxalic acid (5 mL, DG_3), and 10% citric acid (5 mL, DG_4). The oil was then cooled to room temperature and centrifuged (10000*g*, 10 min) to remove the precipitated gum. The optimum method of degumming was found by studying the percent recovery and common physicochemical characteristics of the oil.

The degummed oil (100 g) obtained by optimum degumming method (i.e., with phosphoric acid DG_1) was further refined by caustic neutralization according to AOCS Official Method Ca 9b-52.[9] This was performed by the addition of NaOH solution (1 N, 30 mL) dropwise to the degummed oil with constant stirring and heating (65 °C) for 20 min until a pH of 7.0 was attained. This oil was then heated at 70 °C for 20 min, cooled to room temperature, and centrifuged (10000*g*, 10 min), and the oil was decanted to remove the precipitated soap. The oil thus obtained was washed three times with 10% deionized water (in relation to the oil mass) by agitation (500 rpm) and heating at 50 °C under vacuum. Water and other impurities were further removed by centrifuging (2500*g*, 10 min) to obtain the neutralized sardine oil (NSO). The quality of the degummed oil was studied by ^{1}H NMR spectroscopy. The proton integral as observed by the ^{1}H NMR analysis of the degummed oil vis-à-vis crude oil were compared to understand the reduction of the hydrocarbon residues from the externalities.

The neutralized sardine oil (NSO) was treated separately with activated charcoal powder (AC), kaolin light (KL), Fuller's earth (FE; fulmont 700C), cellulose powder (CP), and chitin purified powder (CH) to study the individual effect of different adsorbents (at 5%, w/w of oil) on the color and other quality parameters of the oil. The effect of different experimental combinations (at 5% w/w of oil) of the best adsorbents selected, (i.e., AC and FE) on bleaching of the oil was further evaluated. The five experimental combinations of AC and FE were BC_1, AC + FE (90:10); BC_2, AC + FE (75:25); BC_3, AC + FE (50:50); BC_4, AC + FE (25:75); and BC_5, AC + FE (10:90). The best adsorbent combination was optimized by studying their effects on the oil quality parameters such as FFAs, PV, pAV, TOTOX, TBARS, Lovibond L^*, a^*, b^* color, chroma, hue angle, and ΔE values after bleaching. For the above bleaching processes, the neutralized oil was stirred separately with the adsorbents at 300 rpm (using a magnetic stirrer) with heating at 60 °C for 10 min under N_2. The effect of the best adsorbent combination, that is, BC_4 (AC + FE, 25:75), was further studied for optimizing two experimental factors, namely, adsorbent amount and contact time of bleaching as shown in Table 1.

Table 1. Concentration of Different Adsorbents[a] and Contact Time of Bleaching of Crude Sardine Oil

	adsorbents			
treatment	AC (g)	FE (g)	amount of adsorbent (g in 100 g of oil)	contact time[b] (min)
BC_{4A}	1.25	3.75	5	20
BC_{4B}	1.25	3.75	5	40
BC_{4C}	1.25	3.75	5	60
BC_{4D}	0.75	2.25	3	20
BC_{4E}	0.75	2.25	3	40
BC_{4F}	0.75	2.25	3	60
BC_{4G}	0.25	0.75	1	20
BC_{4H}	0.25	0.75	1	40
BC_{4I}	0.25	0.75	1	60

[a]AC, activated charcoal; FE, Fuller's earth. [b]Contact time implies the time used for stirring the oil with the adsorbent combination by heating at 60 °C.

The optimum methodology of the bleaching process of the oil was validated through ^{1}H NMR spectroscopy conjugated with ^{13}C NMR methodology to understand the signals related to the coloring impurities at different regions.

The deodorization of the bleached sardine oil (BSO) was carried out using a modified method of Karahadian and Lindsay[7] with a laboratory distillation unit containing a round-bottom boiling flask (500 mL) having two outlets. One outlet was connected to a condenser, which was connected to a vacuum, and the other was connected to a thermometer. Aqueous acetic acid solution (0.25 N, 5 mL) was added with an aliquot containing the BSO in a round-bottom flask, and the contents were heated to 100 °C under vacuum (5 mmHg) for a period of 1 h. The vacuum line was turned off at different time intervals (5, 15, 30, and 60 min), and the distillates (designated DO_1−DO_4, respectively) were analyzed using GC-MS to estimate the traces of volatile compounds distilled off during the deodorization process. The traces of volatile compounds distilled off during the deodorization process of the degummed oil were analyzed at different intervals (5, 15, 30, and 60 min) using GC-MS analysis.

Analytical Methodologies. FFA (Ca 5a-40), PV (Cd 8−53), and pAV (Cd 18-90) values were determined according to American Oil Chemists' Society (AOCS) methodologies.[10] FFA value was expressed as percent oleic acid = (28.2 × 0.1 × volume of 0.1 N NaOH in mL) × 100/weight of oil in g, and PV was expressed as milliequivalents of O_2 (mequiv O_2)/kg oil. The pAV was calculated as $[25 \times (1.2A_S - A_B)]/W$, where A_S = absorbance of the oil solution after reaction with the *p*-anisidine reagent, A_B = absorbance of the oil solution, W = grams of sample, 25 mL = dilution volume, and 1.2 = correction factor. TOTOX value was calculated as TOTOX = (2 × PV) + pAV.[11] TBARS value was determined by using a spectrophotometric method[12] with a standard curve (with 0−10 ppm concentration) of 1,1,3,3-tetramethoxypropane (malondialdehyde; MDA) with thiobarbituric acid. TBARS values were expressed as milligrams of MDA equivalent compounds (MDAEQ) per kilogram of oil.

The oil color was determined using the Lovibond method (Lovibond Color Staler Tintometer, model F, UK), as described by Sathivel et al.[13] The results were expressed as L^*, a^*, and b^* values. The L^* values indicated lightness (0 = black and 100 = white),

DOI: 10.1021/jf505127e
J. Agric. Food Chem. 2015, 63, 998−1009

whereas a^* values represented redness (+) and greenness (−) and b^* values represented yellowness (+) and blueness (−). From a^* and b^*, the psychometric parameters, namely, hue angle (h_{ab}; actual color) and chroma (C^*_{ab}; intensity of color) were calculated as $h_{ab} = \tan^{-1}(b^*/a^*)$ and $C^*_{ab} = \sqrt{(a^*)^2 + (b^{*2})}$. The total color difference was calculated by $(\Delta E) = \sqrt{(\Delta L^{*2} + \Delta a^{*2} + \Delta b^{*2})}$. The UV−vis spectral scanning of the bleached and nonbleached fish oils in *n*-hexane (0.02% w/v) was performed on a UV−visible spectrophotometer equipped with a 1 cm cell (Varian Cary 50, USA).

Fatty acid profiles were evaluated by converting the triglycerides to their corresponding methyl esters.[14] The lipid (0.2 g) was saponified under reflux (20 min, 70−80 °C) with alkaline reagent (3 mL, 0.5 N KOH/MeOH). The saponifiable materials were reacted with methylating mixture (14% BF_3/CH_3OH, 1 mL) for 5 min, yielding fatty acid methyl esters (FAMEs), which were extracted in *n*-hexane/H_2O (1:2, v/v). The *n*-hexane layer was dried to be reconstituted in petroleum ether (40−60 °C) before being injected on a PerkinElmer (PerkinElmer, Shelton, CT, USA) AutoSystem XL gas chromatograph (HP 5890 series II) connected with an SP 2560 (crossbond 5% diphenyl−95% dimethyl polysiloxane) capillary column (100 m × 0.25 mm i.d., 0.50 μm film thickness, Sigma-Aldrich/Supelco, Bellefonte, PA, USA) using a flame ionization detector (FID) equipped with a split/splitless injector, which was used in the split (1:15) mode. FAMEs were identified by comparing the retention time of the samples with FAME standards (Supelco 37 Component FAME Mix, catalog no. 47885-U, Bellefonte, PA, USA), and the results were expressed as percent of total fatty acids (%). Chromatograms were analyzed using PerkinElmer Chromstation (version 4.02) software. The GC-MS analyses of the *N*-acyl pyrrolidides of fatty acids were performed using the electronic impact (EI) ionization mode in a Varian GC (CP-3800, Palo Alto, CA, USA) interfaced with a Varian instrument 1200L single-quadruple mass spectrometer for confirmation of fatty acid identification as described earlier.[14] Mass spectra were analyzed using Varian Workstation (version 6.2) software.

The ^{1}H NMR spectra of the fish oil were measured using the modified method on a Bruker Avance III, 400 MHz (Bruker Inc., Bremen, Germany) NMR spectrometer using tetramethylsilane (TMS) as an internal standard and $CDCl_3$ as solvent (in δ).[15,16] The acquisition parameters for ^{1}H NMR were as follows: time domain data points (TD) = 65536, number of scans (NS) = 64, number of dummy scans (DS) = 0, sweep width (SWH) = 8223.685 Hz, temporal resolution of the free induction decay (FIDRES) = 0.125483 Hz, acquisition time (AQ) = 3.9846 s, receiver gain (RG) = 16, dwell time (DW) = 60.800 μs, relaxation delay (D1) = 2 s.

The qualitative GC-MS analyses of the volatile components obtained during deodorization were performed using electronic impact (EI) ionization mode in a PerkinElmer Clarus 680 GC-MS instrument. The separation of volatile components was achieved on an Elite 5 MS nonpolar, bonded phase capillary column (50 m × 0.22 mm i.d. × 0.25 μm film thicknesses). Helium (He) was used as the carrier gas, and the flow rate used was 1 mL/min. The temperature was programmed at an initial temperature of 50 °C for 2 min, then raised at 10 °C/min to 180 °C, held for 2 min, and finally raised at 4 °C/min to 280 °C and held for 15 min. About 1 μL of the extract was injected into the column, in the splitless mode. Electron ionization energy was set at 70 eV. The mass range, electron multiplier voltage, and scan rates were set at 35−400 u, 1550 V, and 10 spectra/s, respectively. Ion source temperature was maintained at 200 °C. Mass spectra were analyzed using PerkinElmer Clarus software. The identity of the compounds has been confirmed by fragmentation analyses and by comparison with NIIST database.

Statistical Methodology. The means of all parameters were examined for significance by analysis of variance (ANOVA) and carried out with the Statistical Program for Social Sciences 13.0 (SPSS Inc., Chicago, IL, USA; ver. 13.0). The level of significance for all analyses was $p \leq 0.05$.

RESULTS AND DISCUSSION

Characteristics of Sardine Oil during Different Stages of Refining. *Degumming.* The yield of CSO obtained by cooking followed by pressing was found to be 8.3% (w/w). Degumming with phosphoric acid (DG_1) yielded a dark residue (14%, w/w) with 86% oil recovery (w/w), whereas oxalic acid treatment (DG_3) yielded a dark residue (9.8%, w/w) with 90.2% oil recovery (Table 2). An increase in FFA (5.6−7.8%) was observed for oil after degumming in relation to CSO (4.4%) (Table 2), which was expected due to the trace amount of acids added. PV exhibited maximum reduction for DG_1 followed by DG_3, DG_2, and DG_4. DG_{1-4} observed lesser pAV in relation to CSO with maximum percent reduction observed for DG_1 (16%). TBARS value showed 19.4% reduction for DG_1 in relation to the CSO. Initial L^*, a^*, and b^* values of CSO were recorded to be 50.25, 7.58, and 42.51, respectively, which indicated the brownish orange color of the oil due to the deposition of dietary carotenoids.[17] Increases in L^* and a^* (51.02 and 8.0, respectively) and a reduction in b^* value (42.0) were observed for DG_1, whereas other degumming modes showed no substantial changes in the L^*, a^*, and b^* values (Table 2). This increase in L^* and a^* values could be attributed to the increase in FFA content, resulting in the formation of lipid−protein complexes, thereby consequently increasing color.[18]

Fatty acid compositions of CSO before and after degumming (DG_1, DG_2, DG_3, and DG_4) are shown in Table 3. The saturated fatty acid (SFA) fraction of CSO was 41.0%, which remained unchanged after treatment with different degumming agents. The predominant SFA in CSO was 16:0, accounting for around 53% of total SFA fraction. The monounsaturated fatty acid (MUFA) fraction was 29.2% with predominant fatty acids being 16:1n-7 (13%) followed by 18:1n-9 (12%). The total PUFA of CSO was 26.5% with total n-3 PUFAs (18:3n-3, 20:5n-3, 22:5n-3, and 22:6 n-3) accounting for 83% of the PUFA fractions with a greater share of 20:5n-3 (15.5%) and 22:6n-3 (5%). No significant differences were apparent in MUFA or PUFA compositions after the degumming process ($p > 0.05$). However, a marginal reduction in EPA, ∑PUFA, and ∑n-3PUFA contents might be due to the involvement of heat during the process of degumming. Thus, evaluation of the quality parameters after degumming showed the greater quality of phosphoric acid as degumming agent of the crude sardine oil.

The ^{1}H NMR spectrum of the degummed sardine oil DG_1 was compared with that of CSO (control) for qualitative representation of the various functionalities present in them. The integrated areas of the characteristic regions of the ^{1}H NMR spectra of the oils studied were found to be linearly correlated with the fatty acid data, and ^{1}H NMR was proposed as a new method for determining the degree of degumming. The characteristic fatty acid signals of CSO as identified by ^{1}H NMR were confirmed using literature data[16,19] and by recording spectra of standard compounds. This revealed the presence of n-3 fatty acids as confirmed by a sharp triplet at δ 0.974, a structural feature for methyl proton (-C$\underline{\mathbf{H}}_3$) in n-3 PUFAs (Figure 1). The signals at δ 1.18−1.43 could be explained due to the methylene envelope ($-(C\underline{\mathbf{H}}_2)_n$) in the long alkyl chain. The sandwiched CH_2 bis-allylic protons (−CH═CH—C$\underline{\mathbf{H}}_2$—CH═CH−) were overlapped and displayed at δ 2.74−2.92 (multiplets). These bis-allylic peaks indicate the predominance of PUFA in the sardine oil. The proton integral as observed by the ^{1}H NMR analysis of DG_1 revealed significant reduction of the hydrocarbon residues compared with DG_3 and

[a]CSO, crude sardine oil; DG_1, DG_2, DG_3, and DG_4 represent the sardine oil degummed using phosphoric acid (85%, 1 mL), glacial acetic acid (99%, 1 mL), oxalic acid (10%, 5 mL), and citric acid (10%, 5 mL), respectively; NSO, neutralized oil; activated charcoal (AC), kaolin (KA), Fuller's earth (FE), cellulose powder (CE), and chitin (CH) were used individually (5% concentration to oil) as adsorbents; BC_1, BC_2, BC_3, BC_4, and BC_5 represent AC + FE used in the ratios 2.5:2.5, 4.5:0.5, 3.75:1.25, 1.25:3.75, and 0.5:4.5, respectively; BC_{4A}, BC_{4B}, BC_{4C}, BC_{4D}, and BC_{4E} represent AC/FE (1.25:3.75) at different contact times and temperatures as detailed in Table 1. Data are expressed as the mean ± standard deviation of three replicates. Means with different letters (a, b, c, etc.) in the same column indicate significant statistical difference ($p < 0.05$). Other notations are as represented under Materials and Methods.

DOI: 10.1021/jf505127e

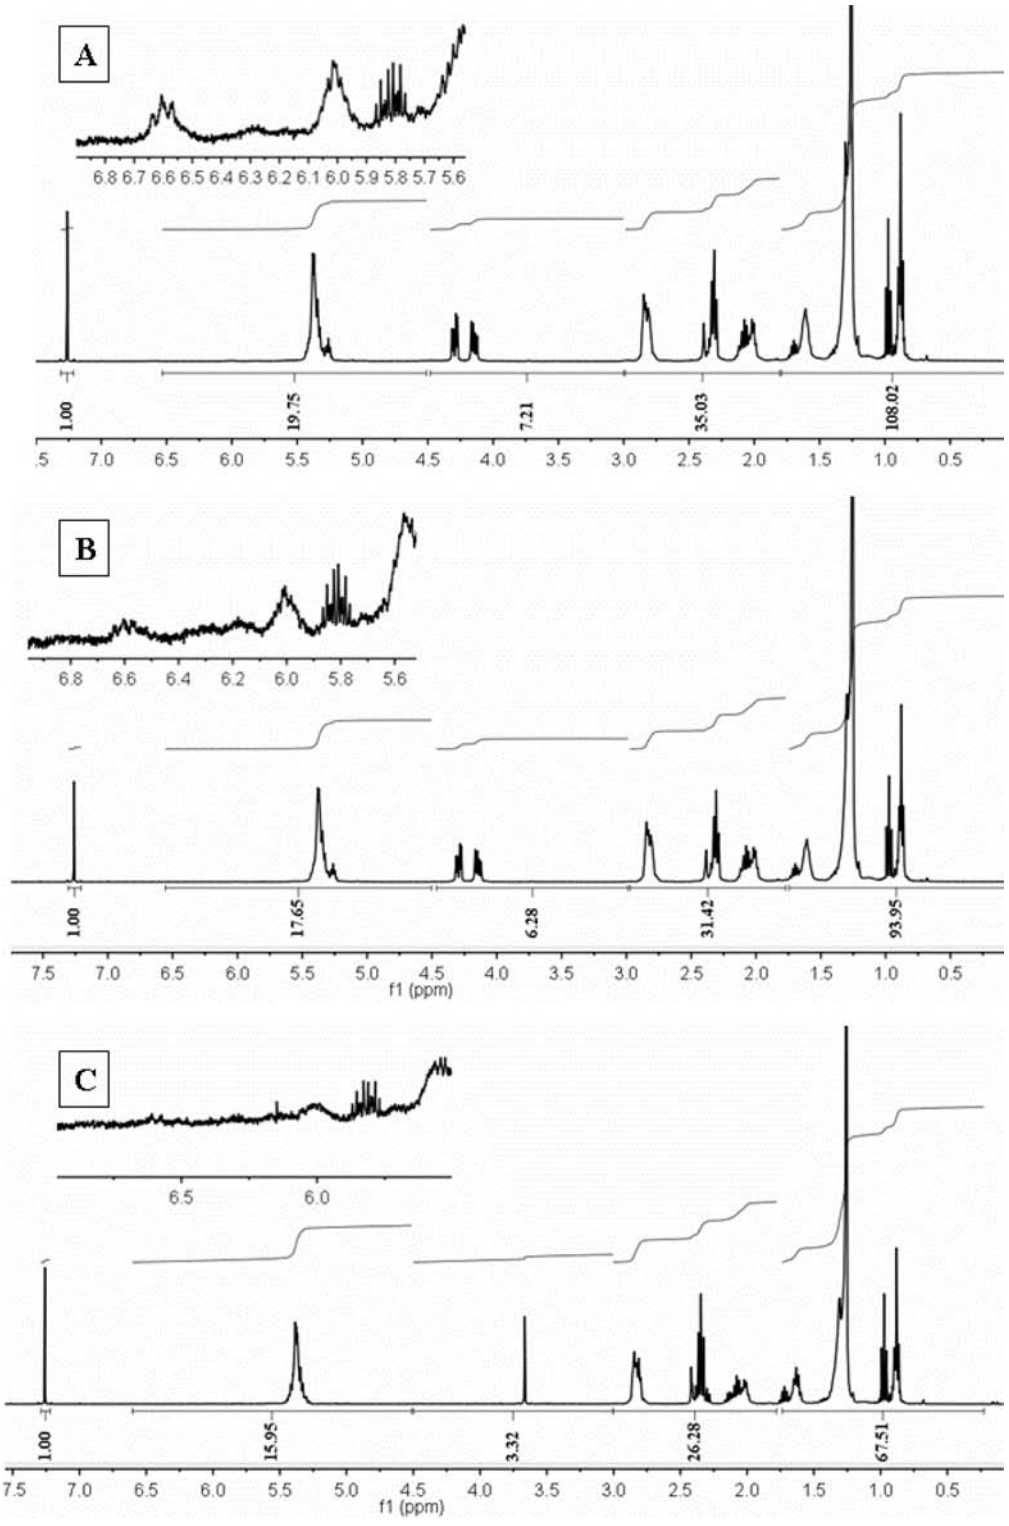

Figure 1. ^{1}H NMR spectra of the (A) crude (CSO), (B) degummed (DG_1), and (C) bleached sardine oils. (Insets) ^{1}H NMR proton signals at δ 5.2−7.0.

CSO (Figure 1). The effect of degumming using the phosphoric acid was determined by the ratio of the proton integrals of the degummed oil (DG_1) to the control oil (CSO) at the region δ 0.2−1.8 (signals exhibited by $-CH_3$ and $-CH_2-$ protons), δ 1.8−3.0 (−CH< and $-C(=O)CH_3$), δ 3.0−4.5 (free $-NH_2$ and −OH), and δ 4.5−6.5 (olefinic protons). A greater reduction in the proton integral was observed for DG_1 at these regions with 13.0 (δ 0.2−1.8), 10.3 (δ 1.8−3.0), 12.9 (δ 3.0−4.5), and 10.6 (δ 4.5−6.5) percent in relation to CSO. Overall, lesser intensity of the peak at δ 6−7 for DG_1 as compared to CSO was observed.

Neutralization of the Degummed Sardine Oil. The neutralization of DG_1 afforded a dark residue (6.6 g) with 80.4% oil yield (w/w) with respect to CSO. The neutralization step effectively reduced the FFA value of DG_1 to 3.21% (Table 2). Similarly, reduction in PV, pAV, and TOTOX values

DOI: 10.1021/jf505127e
J. Agric. Food Chem. 2015, 63, 998−1009

was observed after neutralization ($p > 0.05$) (Table 2). The reduction in the TBARS value of NSO in relation to CSO was approximately 35%. Neutralized oil was lighter ($L^* = 51.34$) and more yellowish ($b^* = 43.65$) in color than CSO. No reduction in redness ($a^* = 8.21$) indicated that the neutralization process might not have significantly removed the carotenoid pigments (Table 2). Neutralization increased the chroma values and decreased the hue angle values of the oil. The ∑SFA, ∑MUFA, and ∑PUFA did not show any significant difference ($p > 0.05$) after neutralization (Table 3).

Bleaching of the Neutralized Sardine Oil. The reduction in FFA content of NSO (13.1 and 1.6% reduction, respectively, with respect to NSO) when AC and FE were added individually indicated the effect of these adsorbents in removing the soap stock residues from NSO (Table 2). The FFA value was further reduced to <2.8% when the combinations of AC:FE at 4.5:0.5 and 1.25:3.75 (BC_2 and BC_4) were used. The FFA value exhibited a marginal increase from 2.8% (BC_4) to 3−3.1% ($BC_{4G\text{-}I}$) when a lower concentration of AC:FE (1%) was used. The reduction of PV, pAV, and TOTOX values after bleaching with individual adsorbents confirmed the capacity of AC and FE to adsorb primary and secondary oxidation products or similar compounds.[20,21] BC_4 showed maximum reduction in the PV and TOTOX values as compared to other combinations (BC_1, BC_2, BC_3, and BC_5). Similarly, maximum reductions in PV and TOTOX values were observed for BC_{4E}. Interestingly, the TOTOX value recorded an increase for $BC_{4G\text{-}I}$ that might be due to the adsorption of impurities together with the natural antioxidants present in the oil, thereby affecting the stability of the fish oil. List et al.[22] reported that the sunflower oil treated with bleaching earth (6%) had unacceptable flavor and oxidative stability relative to the bleached oil with a lower concentration of activated earth (2%). A lower TBARS value was observed when AC and FE were used individually as compared to other adsorbents studied. For the different combinations, TBARS values were in the order $BC_3 < BC_4 < BC_1 < BC_3 \sim BC_5$. Furthermore, the combination of AC and FE used at 3% as in BC_{4E} (with stirring time of 40 min at 40 °C) was found to be optimum for the TBARS reduction to the minimum.

Activated charcoal and Fuller's earth increased the lightness of the oil ($L^* = 75$ and 71, respectively). Besides, the adsorption process using AC and FE effectively reduced the a^* value (3.7), indicating a decrease in red pigment. The b^* value of the bleached oils was observed to be reduced (<40) when AC and FE were used. Among the different combinations, BC_4 exhibited an increment in L^* value and a reduction in a^* value compared to other combinations of AC and FE (Table 2). The highest L^* value (83.74) was achieved for BC_{4B} and BC_{4E}. The combination of chitosan and activated earth was earlier reported to increase the L^* value during the purification process of the salmon oil.[21] The lower a^* value of bleached oil reached ≤3.64 for 3 and 5% concentrations (BC_{4A-F}), which indicated a decrease in the red pigmentation pattern. As a consequence, the oil samples became lighter and more transparent. However, a lesser adsorbent concentration (1%) did not effectively reduce the a^* value (>5), whereas an increase in adsorbent concentration and adsorption time resulted in a more greenish color to sardine oil ($a^* \leq 3.64$). An earlier study in salmon oil revealed the reduction of carotenoid pigments such as astaxanthin and canthaxanthin during adsorption with a decrease in a^* value (redness) and an increase in $-a^*$ value (greenness) while using chitosan and activated earth as adsorbents.[21] Likewise, a greater reduction in b^* value was observed for BC_{4A-F}, which denotes a yellowish color of the bleached sardine oil. The chroma value, which represents the intensity of color, was found to be reduced for BC_{4E} (≤38), whereas the hue angle value increased with the concentration of the adsorbent. Hence, considering the above quality parameters, the combination of activated charcoal and Fuller's earth (1.25:3.75) at 3% concentration with 40 min of stirring time was found to be optimum for obtaining the BSO. The fatty acid profile of the BSO (BC_{4E}) is shown in Table 3. No significant differences were observed in the fatty acid composition of the bleached oil compared to the neutralized oil ($p > 0.05$) (Figure 2).

Spectroscopic Analyses of Sardine Oil after Bleaching. The extent of the bleaching process of the oil was further studied by ^{1}H NMR spectroscopy to understand the signals and proton integrals of the conjugated olefinic double-bond protons as impurities, which resonated at δ 4−4.5 (Figure 1). The region at δ 4−4.5 showing the peaks of conjugated double bonds were reduced for BSO. A greater reduction in the proton integral in the final bleached oil (BSO/BC_{4E}) at the ^{1}H NMR regions with 37.5 (δ 0.2−1.8), 25 (δ 1.8−3.0), 53.9 (δ 3.0−4.5), and 19.2 (δ 4.5−6.5) percent in relation to CSO was recorded. The reductions in proton integral with respect to the degummed oil were 28.1% (δ 0.2−1.8), 16.3% (δ 1.8−3.0), 47.1% (δ 3.0−4.5), and 9.6% (δ 4.5−6.5). These greater reductions in the proton integrals supported the bleaching ability of AC:FE (1.25:3.75) at 3% concentration with a stirring time of 40 min were further confirmed by their L^*, a^*, and b^* values as well as the spectral scanning data (Figure 3). The UV−vis spectra of BSO showed a reduction in their peak intensities in the region between 340 and 370 nm (Figure 3), which apparently signifies the reduction in the unsaturation and auxochromes bearing the electronegative groups. A characteristic absorption of control oil (NSO) in the visible range as shown in Figure 3 might be caused by the chromophores with conjugated π-electron systems resulting in red shifts, thereby giving an undesirable color to the fish oil. The bleaching process led to the removal of the color causing auxochrome and chromophoric systems in the treatment combinations. The absorption of the fish oils in the visible regions was apparently due to the lipid-soluble pigments or pigment-like substances bearing multiple unsaturations in their structures. This indicated that fatty acid glycerides with nonconjugated double bonds did not absorb significantly in the visible region (340−800 nm).

Deodorization of the Bleached Sardine Oil. The BSO on vacuum distillation for 1 h yielded 97.6 g of the deodorized oil with 73% yield (w/w) with respect to CSO. A reduction in FFAs after the deodorization step (DO_4) was observed (4.08%), and this might be due to the vaporization of odoriferous compounds and FFAs during the deodorization process.[8] The deodorization step reduced FFA content by up to 47% to afford an acceptable FFA level (i.e., between 1.8 and 3.5%)[13] for the refined oil. A reduction in PV, pAV, and TOTOX values was observed (Table 2) after the deodorization process. It is significant to note that PV was recorded below the threshold level of acceptance for human consumption (8 mequiv O_2/kg oil),[23] which indicated the oxidative quality index of the refined sardine oil. Thus, it is evident that the conditions used for the deodorization in the present study did not induce oxidative deterioration, which might involve the formation of ring cyclization of fatty acids and the formation of various forms of cyclic fatty acid analogues. An example of the formation of the cyclic fatty acid product 5-(2-((6-(prop-1-enyl)cyclohex-3-enyl)methyl)cyclopent-3-enyl)pentatonic acid

DOI: 10.1021/jf505127e
J. Agric. Food Chem. 2015, 63, 998−1009

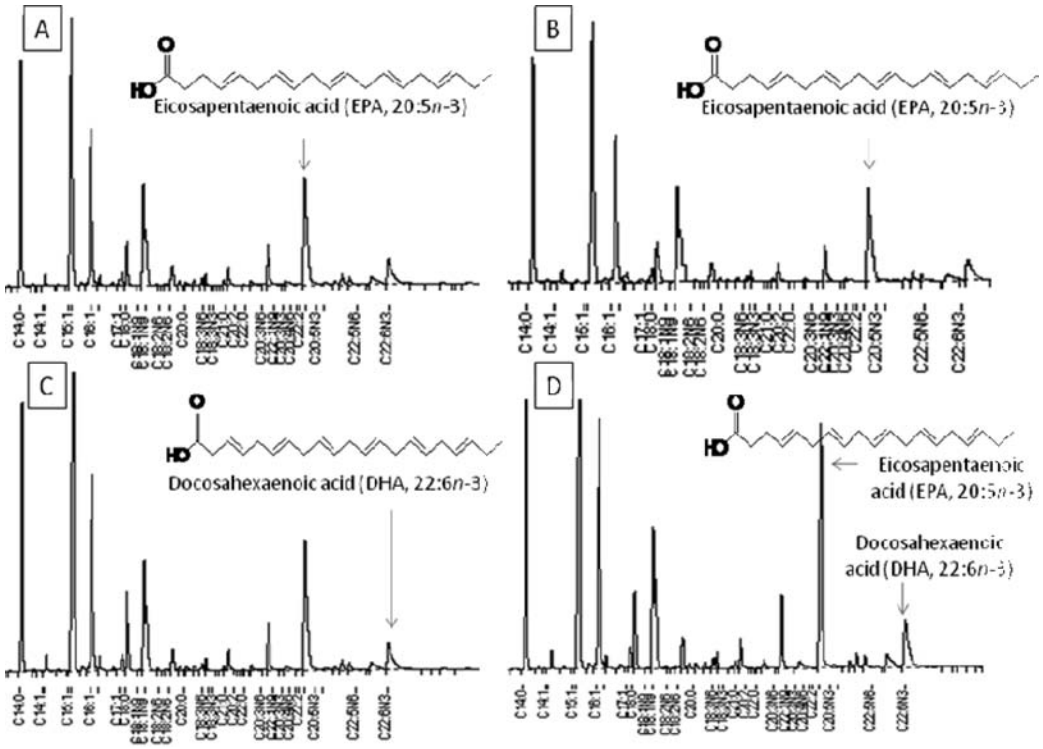

Figure 2. Fatty acid chromatogram of degummed and neutralized sardine oil treated with (A) activated charcoal (AC), (B) Fuller's earth (FE), (C) BC_4 [AC + FE in the ratio (25 g/75 g)], and (D) BC_{4E} [AC + FE in the ratio (25 g/75 g) at 3% concentration].

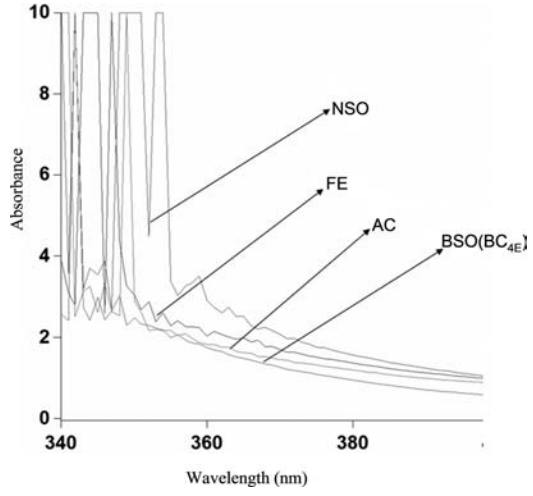

Figure 3. UV spectra of neutralized sardine oil (NSO), oil bleached with activated charcoal (AC), Fuller' earth (FE), and a combination of activated charcoal (0.75 g) plus Fuller's earth (2.25 g) at 3% concentration and 40 min of stirring time (BSO/BC_{4E}).

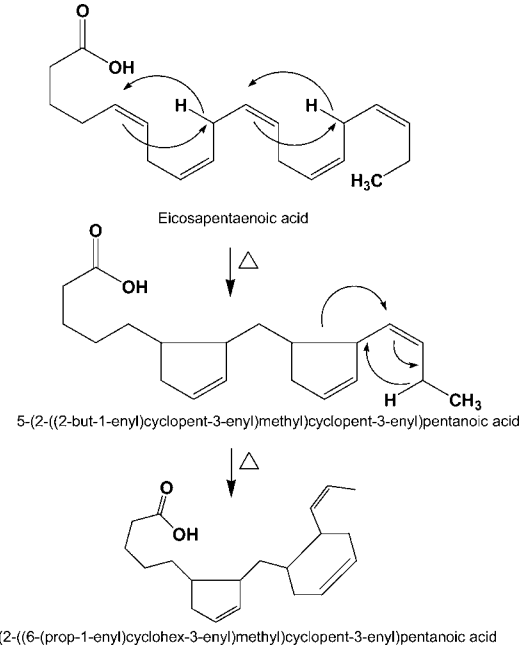

Figure 4. Poposed pathways of the formation of cyclic fatty acid analogue (5-(2-((6-(prop-1-enyl)cyclohex-3-enyl)methyl)cyclopent-3-enyl)pentanoic acid) from EPA.

via the intermediate 5-(2-((2-but-1-enyl)cyclopent-3-enyl)-methyl)cyclopent-3-enyl)pentanoic acid from eicosapentaenoic acid has been proposed under Figure 4. The reduction in the content of TBARS in the deodorized oil in relation to CSO was found to be about 40%. However, a lesser increment in L^*, a^*, and b^* values for the deodorized oil (DO_4) than in BSO confirmed the absence of formation of conjugation in the fatty acid double bonds due to heating.

The contents of ∑SFA, ∑MUFA, and ∑PUFA did not show significant difference ($p > 0.05$) between the CSO and deodorized (refined) sardine oil (Table 3). An insignificant reduction ($p > 0.05$) in n-3 PUFA (decrease of 2.4%) and DHA (decrease of 5.2%) contents was observed in DO_4 as compared with CSO. A study by Sathivel et al.[13] reported an approximate 19% reduction in the n-3 PUFAs of catfish viscera after the oil refining processes including degumming, neutralizing, bleaching, and deodorization. The share of EPA and DHA in the refined fish oil was 20%, which was greater than earlier cited[24] for crude oils of five commercially important species of Brazilian fish, namely, sardine, croaker, tilapia, curimbata, and

[a] DO_1, DO_2, DO_3, and DO_4, distillates obtained at 5, 15, 30, and 60 min, respectively, during the deodorization process of the sardine oil. The prefixes (*E*)- (*Z*)- denote *trans*- and *cis*-isomers, respectively. [b] Base peak in GC-MS spectra refers to the *m*/*e* peak with 100% intensity. [c] The siloxane derivatives of fatty acids were formed by reaction between the GLC column stationary phase and the fatty acid reaction products.

shrimps (11.6−13.4%). The increase in the content of *trans* fatty acids was statistically insignificant ($p > 0.05$) after the process of deodorization, which might be due to the exposure of fatty acid at the high temperature used during the deodorization step. The contents of *trans* fatty acids in the refined oil obtained in this study were recorded below the threshold limit (1.0%) as prescribed by EU guidelines.[8] An increase in the human dietary n-3/n-6 fatty acid ratio observed for deodorized oil showed its ability to prevent coronary heart disease by reducing plasma lipids and to reduce cancer risk.[16] In this study, the deodorized oil with superior qualities was obtained with the utilization of a lesser process time as compared to the conditions utilized by Fournier et al.[2]

Gas Chromatographic−Mass Spectroscopic Analysis of the Volatile Components during Deodorization. Table 4 lists the volatile components identified in the fish oil during the deodorization process with acetic acid treatment after 5, 15, 30, and 60 min of distillation. The distillate obtained after 5 min (as in DO_1) showed siloxane derivatives such as octamethyl cyclotetrasiloxane, decamethyl cyclopentasiloxane, dodecamethyl cyclohexasiloxane, tetradecamethyl cycloheptasiloxane, and hexadecamethyl cycloocatasiloxane (Table 4). The appearance of these siloxane derivatives could be attributed to the reaction between the stationary phases of the GC reverse phase column with the eluted components. GC-MS spectra of the distillate obtained after 15 min (DO_2) showed the presence of volatiles, mainly alkanes/alkenes (dodecane t_R 9.19 min, tetradecene t_R 11.81 min, tetradecane t_R 11.91 min, pentadecane t_R 13.16 min). The dodecane was earlier identified in menhaden fish oil, whitefish oil, and tuna oil,[6,25,26] whereas pentadecane was identified in the menhaden fish oil and salmon oil.[6,27] Pentadecane was the

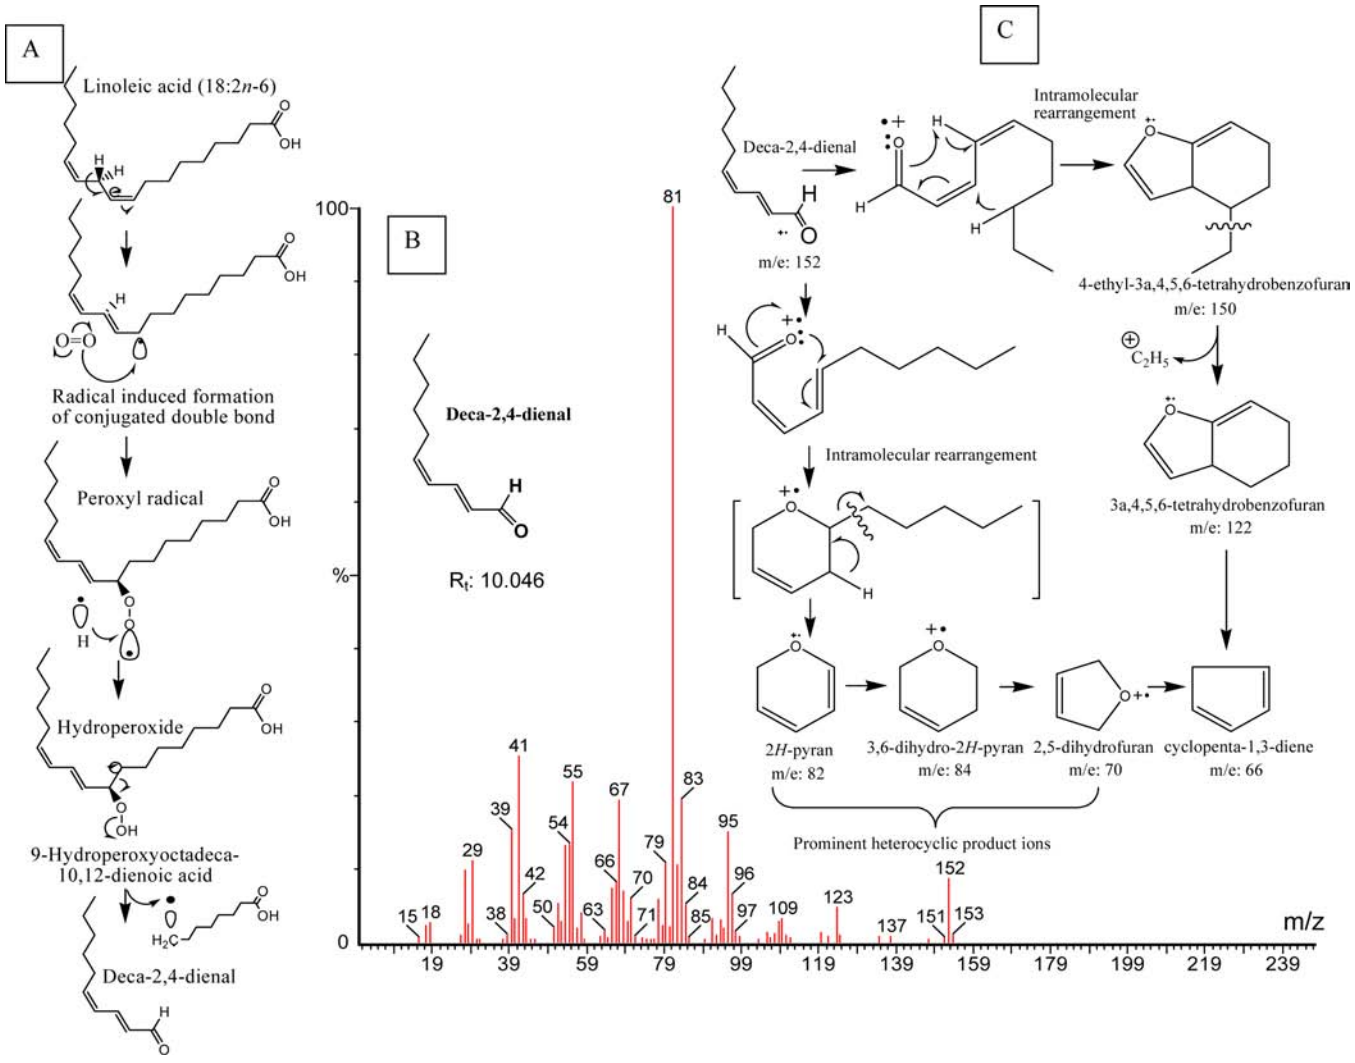

Figure 6. (A) Free radical induced formation of 2,4-decadienal from n-6 polyunsaturated fatty acids (linoleic acid, 18:2n-6); (B) GC-MS spectrum of 2,4-decadienal; (C) proposed GC-MS fragmentation pathways for generation of fragment ions during EI-MS analysis of 2,4-decadienal from DO-04.

major *n*-alkane found in oil sardines and horse mackerel oil.[28] GC-MS spectra of the distillate after 30 min (DO_3) showed four abundant aldehydic volatile compounds, namely, (*E*,*Z*)-2,6-nonadienal, (*E*,*E*)-isomers of 2,4-nonadienal and 2,4-decadienal, and an alcohol, *E*-2-octadecadecen-1-ol (Table 4). Aldehydes play an important role in many food products and are responsible for a wide range of oxidized flavors.[29] Milo and Grosch[30] demonstrated that (*E*,*Z*)-2,6-nonadienal and (*E*,E)-2,4-decadienal were the key aroma compounds of raw and boiled salmon. GC-MS spectra of the distillate obtained after 60 min (DO-04) demonstrated the presence of two prominent aldehydes, namely, (*E*,*E*)-isomers of 2,4-heptadienal and 2,4-decadienal. Rahimabadi[31] recorded (*E*,*Z*)-2,6-nonadienal and (*E*,*E*)-2,4-heptadienal on the distillation of raw narrow-barred Spanish mackerel (*Scomberomorous commerson*). Volatiles such as (*E*,*Z*)-2,6-nonadienal and (*E*,*E*)-2,4-decadienal were separated earlier from cod liver oil by means of deodorization at 200 °C for 2 h.[32] (*E*,*Z*)-2,6-Nonadienal was identified as the compound contributing to the green and melon flavors encountered in fish oils.[7] Furthermore, (*E*,*E*)-2,4-heptadienal was reported as strong fat odor and fish smell inducing compound in the oil.[33] The presence of these unsaturated volatile aldehydes in the fish oil was apparently due to the greater contents of PUFAs. A schematic representation of the peroxidation of polyunsaturated fatty acids (eicosapentaenoic and linoleic acids have been taken as a model systems) leading to the formation of aldehydes is shown in Figures 5 and 6.

It is challenging to characterize the long-chain fatty aldehydes (in free forms) within biological matrices, apparently due to their greater reactive properties. These highly unstable compounds react with nucleophiles in the matrix leading to their rapid metabolism. Of the fatty aldehydes, 2,4-decadienal (particularly from the n-6 fatty acids) and hepta-2,4-dienal (from n-3 fatty acids) are of greater importance due to their contribution to the characteristic unpleasant odor of the oil.

The hydroperoxides formed by free radical induced autoxidation process of n-3 polyunsaturated acids are highly unstable and undergo prompt β-scission to form carbonyl compounds such as hepta-2,4-dienal. For example, 14-hydroperoxyicosa-5,8,11,15,17-pentaenoic acid has been demonstrated to be formed from EPA (20:5n-3) by free radical induced formation of conjugated double bond, which thereafter form hepta-2,4-dienal as the predominant reaction product. EI-induced mass spectrometry of hepta-2,4-dienal with a conjugated diene system yields a characteristic molecular ion at *m*/*e* $[M]^+$ 110 and ragment ions at *m*/*e* 114 (heptanal), *m*/*e* 70 (pent-1-ene),

DOI: 10.1021/jf505127e
J. Agric. Food Chem. 2015, 63, 998−1009

and *m/e* 58 (prop-1-en-2-ol) due to reduction of the molecular ion followed by intramolecular McLafferty type rearrangement. The *β*-cleavage of heptanal (*m/e* 114) with the gain of *γ*-hydrogen atom led to the formation of pent-1-ene and prop-1-en-2-ol. Hepta-2,4-dienal generates prominent heterocyclic product ions with *m/e* 82 (2*H*-pyran), *m/e* 84 (3, 6-dihydro-2*H*-pyran), and *m/e* 70 (2,5-dihydrofuran) (Figure 5) by intramolecular rearrangement of the parent molecular ion.

The diene n-6 polyunsaturated fatty acids have been shown to be good precursors in some defined oxidative conditions to form deca-2,4-dienal along with other reaction products. To rationalize the formation of aldehydic products, as is the case for 2,4-decadienal, linoleic acid (18:2n-6) has been taken as an example. This n-6 dienoic fatty acid may undergo oxidation via 9-hydroperoxyoctadeca-10,12-dienoic acid, forming the fatty acid aldehyde with a conjugated diene system (2,4-decadienal) as the major product. The conjugated unsaturated aldehydes may undergo changes by autoxidation, producing shorter chain aldehydes and other volatile compounds (data not shown). EI-induced mass spectrometry of deca-2,4-dienal yields characteristic molecular ion at *m/e* $[M]^+$ 152 and fragment ions at *m/e* 150 (4-ethyl-3a,4,5,6-tetrahydrobenzofuran) due to intramolecular rearrangement and at *m/e* 122 (3a,4,5,6-tetrahydrobenzofuran) due to the loss of ethyl ion from the former. In particular, deca-2,4-dienal generates prominent heterocyclic product ions with *m/e* 82 (2*H*-pyran), *m/e* 84 (3,6-dihydro-2*H*-pyran), and *m/e* 70 (2,5-dihydrofuran), as demonstrated for hepta-2,4-dienal (Figure 6).

Other volatile decomposition products of hydroperoxides reported in severely oxidized fish oil were alkatrienals, mainly 2,4,7-decatrienal (PV > 70 mequiv/kg).[34] However, in the present study no trace of alkatrienal in the distillate was observed. Thus, a distillation period of 1 h could optimally be able to remove the major volatile components from the sardine oil.

The crude oil obtained from *S. longiceps* was refined by the stepwise process of degumming, bleaching, and deodorization. The effective degumming agent was found to be 1% phosphoric acid, which could keep the PV, pAV, TOTOX, and TBARS values below threshold limits. The utilities of NMR-based proton signal characteristics as new analytical tools to understand the signature peaks and relative abundance of different fatty acids and monitoring the refining process of fish oil have been demonstrated. The region between *δ* 4 and 4.5 in the ^{1}H NMR spectra was taken into account to explain the bleaching process of the oil, and the characteristic signals at *δ* 1.8−3.0, 3.0−4.5, and 4.5−6.5 were considered as indicator regions to explain the variability of the oil qualities under different treatment combinations during the degumming process. A significant reduction in the contents of hydrocarbon functionalities (as shown by the decrease in proton integral in the characteristic ^{1}H NMR region) was demonstrated by using 1% H_3PO_4 during the course of the degumming process. A combination of activated charcoal and Fuller's earth (1.25:3.75, 3% w/w, contact time of 60 min) was found to be efficient in bleaching the sardine oil and to eliminate the colored impurities. This study also demonstrated that unfavorable odor-causing components, particularly low molecular weight carbonyl compounds and alcohols, could successfully be removed by distillation under vacuum with 0.25 N acetic acid (100 °C). A four-stage refinement process of sardine oil resulting in a significant improvement in nutritional values and fish oil characteristics has been demonstrated in the present study. This study is significant in the quest to obtain refined marine fish oil with greater nutritional and oxidative quality for use in the food and pharmaceutical industries.

difficult to establish scientifically.[15,16,24,27] Moreover, comparative studies on the sensory quality of conventional and organic strawberries are rather scarce, and studies investigating strawberry chemical composition usually concentrate on restricted compound groups such as polyphenols or volatile compounds.

In this study, three strawberry cultivars grown both conventionally and organically were subjected to nontargeted metabolite profiling analysis with liquid chromatography connected with negative electrospray ionization in a quadrupole−time-of-flight−mass spectrometer (LC-qTOF-ESI-MS) and to descriptive sensory evaluation by a trained panel in a sensory laboratory. Metabolite and sensory data were tested statistically to investigate the dependence of strawberry metabolome on cultivar and farming practice and to examine the effects of cultivar, farming practice, and chemical composition on the sensory quality of strawberry.

MATERIALS AND METHODS

Strawberries. Samples from three strawberry (*Fragaria* × *ananassa* Duch.) cultivars, 'Bounty' (B), 'Jonsok' (J), and 'Polka' (P), were collected from both conventional (CON) and organic (OR) fields in northern Savonia, eastern Finland, in June−July 2013. The farming locations were Leppävirta (62.30° N, 27.475° E; J-CON and P-CON), Kaavi (62.586° N, 28.295° E; B-CON), and Lapinlahti (63.216° N, 27.232° E, B-OR, J-OR, and P-OR). Organic cultivation was implemented according to EU Council Regulation (EC 834/2007). The collected berries were in the same, fully mature stage and grown approximately in the same compass direction. Of each cultivar (conventional and organic), ∼7 kg was harvested; ∼2 and ∼5 kg were used for metabolome analysis and sensory evaluation, respectively. After harvesting, pooled whole berry samples were immediately placed on ice and frozen as soon as possible. Berries were stored at −20 °C until further processing.

Nontargeted Metabolite Profiling. *Sample Preparation.* For the metabolite extraction, 10 frozen berries (81.46−149.09 g) for each cultivar × farming practice combination were gently thawed in a microwave oven (defrost setting, 1.5 min; AM Kodinkoneet Inc., Helsinki, Finland) and homogenized with a stick blender. Chemical compounds were extracted from pureed strawberries with 80% methanol; for 10 g of strawberry puree, 30 mL of methanol was used. Suspensions were quickly vortexed and extracted in a horizontal shaker (Unimax 2010, Heidolph Instruments, Schwabach, Germany) at 400 rpm for 15 min at room temperature. Extracts were filtered through a gauze (Mölnlycke Health Care, Gothenburg, Sweden) and centrifuged (Centrifuge 5810R, Eppendorf, Hamburg, Germany) at 3220*g* for 5 min. The clarified supernatants were stored at −75 °C until analysis. Prior to the metabolite analysis, samples were again centrifuged and filtered (Acrodisc 0.22 μm PTFE filter, PALL, Port Washington, NY, USA).

The total phenolic contents of strawberry extracts were measured with the Folin−Ciocalteu method,[28] with some modifications. Briefly, 200 μL of strawberry extract dilution (1:10 or 1:20) was combined with 1000 μL of 10% (v/v) Folin−Ciocalteu reagent (VWR International, Darmstadt, Germany) and 800 μL of 7.5% (w/v) Na_2CO_3 (Sigma-Aldrich, St. Louis, MO, USA) solution; the reagent mixture was incubated at room temperature for 60 min and vortexed every 20 min. The mixture absorbance was measured at 765 nm (Ultrospec 2000, Pharmacia Biotech, Uppsala, Sweden), and the total phenolic content was calculated as gallic acid (GA) (Sigma-Aldrich) equivalent according to a standard curve (0.01, 0.03, 0.05, 0.07, and 0.1 mg GA/mL).

LC-MS Conditions. The samples were analyzed by LC-qTOF-ESI-MS (Agilent Technologies, Waldbronn, Karlsruhe, Germany) that consisted of a 1290 LC system, a Jetstream electrospray ionization (ESI) source, and a 6540 UHD accurate-mass qTOF spectrometer. The samples were analyzed with reversed phase (RP) chromatographic separation, and data were acquired in negative electrospray ionization (ESI−). The sample tray was kept at 4 °C during the analysis.

Two microliters of the sample solution was injected onto a column (Zorbax Eclipse XDB-C18, 2.1 × 100 mm, 1.8 μm) (Agilent Technologies, Palo Alto, CA, USA) kept at 50 °C. Mobile phases, delivered at 0.4 mL/min, consisted of water (eluent A) and methanol (eluent B) (Sigma-Aldrich), both containing 0.1% (v/v) of formic acid (Sigma-Aldrich). The following gradient profile was employed: 0−10 min, 2 → 100% B; 10−14.5 min, 100% B; 14.5−14.51 min, 100 → 2% B; 14.51−16.5 min, 2% B.

A Jetstream ESI source was operated in negative ionization mode. The conditions were as follows: drying gas temperature, 325 °C, and flow, 10 L/min; sheath gas temperature, 350 °C, and flow, 11 L/min; nebulizer pressure, 45 psi; capillary voltage, 3500 V; nozzle voltage, 1000 V; fragmentor voltage, 100 V; and skimmer, 45 V. For data acquisition, 2 GHz extended dynamic range mode was used, and the instrument was set to acquire over m/z 20−1600. For automatic data-dependent MS/MS analyses, precursor isolation width was 1.3 Da, and from every precursor scan cycle, the four most abundant ions were selected for fragmentation. Collision energies were 10, 20, and 40 V in subsequent runs. Continuous mass axis calibration was performed by monitoring two reference ions from an infusion solution throughout the runs. The reference ions were m/z 112.985587 and 966.000725.

Data Processing. Initial data processing was performed using MassHunter Qualitative Analysis B.05.00 (Agilent Technologies, Palo Alto, CA, USA). Ions were extracted to compounds exhibiting isotopic peaks, dimers, and common adducts. Mass Profiler Professional software (version 2.2, Agilent Technologies, Palo Alto, CA, USA) was used for compound alignment. Noise and low-abundance metabolites were removed from the data matrix according to their abundance and appearance frequency in the samples. The final data set contained 3669 molecular features. For the comparison of the sample groups, the data matrix was exported to Excel and filtered according to their maximum peak area value, indicating high relative abundance in one or more sample types focusing on the 131 most intense compound signals. After initial reduction, preliminary partial least-squares regression (PLS) analysis (Unscrambler 9.8, Camo Process AS, Oslo, Norway), using molecular features as *X*-variables, that is, predictors, and sensory properties as *Y*-variables, that is, responses, was performed to perceive the most relevant compounds in terms of sensory characteristics; this resulted in 60 final entities, which were then subjected to spectral inspection and identification.

Principal component analysis (PCA) (Simca 13.0, Umeå, Sweden) was utilized to monitor the relationship between samples and sample replicates in their metabolite profiles. Hierarchical clustering analysis with heat map representation (TM4Microarray Software Suite, available at www.tm4.org/mev.html; algorithm according to Eisen et al.[29]) was applied to analyze and display the similarity of sample replicates and compound accumulation patterns and to visualize the differences in normalized metabolite signal abundances between sample types.

The identification of metabolites was performed on the basis of the fragmentation patterns in the data-dependent MS/MS acquisition. The MS/MS data and the molecular masses were compared against The METLIN Metabolite Database (http://metlin.scripps.edu/), SciFinder (https://scifinder.cas.org), Dictionary of Natural Products (http://dnp.chemnetbase.com/), or earlier published work describing fragmentation patterns.

Sensory Analyses. *Sample Preparation.* For sensory analyses, 200 g of frozen strawberries/cultivar × farming practice combination was gently thawed in a microwave oven (defrost setting, 120 W, 2.5 min; Rosenlew, Stockholm, Sweden). Thawed berries were homogenized with a stick blender, and 30 g of strawberry puree was measured into 50 mL beakers. The beakers were covered with small watch glasses, and the samples were kept at room temperature to stabilize the headspace and to reach the serving temperature (∼20 °C).

Sensory Panel. The descriptive profiling was carried out with 15 voluntary assessors familiar with sensory profiling. Assessors were known to be able to rank taste solutions and recognize flavor differences and odor samples.

Table 1. Attributes, Definitions, and References Used in Sensory Evaluations

attribute	description	reference	intensity
orosensory			
total intensity of flavor	perceived first expression of flavor		
sourness	taste of acids	0.1% citric acid	8
bitterness	bitter taste	0.07% caffeine	8
astringency 1	soft, mouth-drying mouthfeel	0.1% $AlNH_4(SO_4)_2$	8
astringency 2	rough, sharp mouthfeel	0.1% $Al_2(SO_4)_3$	8
sweetness	taste of sugars and other sweeteners	2% sucrose	8
off-flavor	flavors that are not innate for strawberries		
odor			
total intensity of odor	perceived first expression of odor		
fruity	an ester-like odor	5 mL of 10 ppm ethyl butyrate	7
green	freshly cut grass, leaves, or vegetables	1 μL of 200 ppm *cis*-3-hexenol	9
strawberry-like		1 μL of wild strawberry aroma concentrate (Roberts, Turku, Finland)	8
off-odor	odors that are not innate for strawberries		

Panel Training. The panelists were trained according to ISO 8586 standard. Descriptions for strawberry samples were adapted from Hakala et al.[24] and Sandell et al.[30] In four 1 h sessions, assessors were trained to recognize and evaluate the intensity of seven orosensory attributes and five odor attributes in reference samples (Table 1) and in strawberry puree samples.

Intensity Evaluations. The sensory evaluations were performed in December 2013 in a sensory laboratory (ISO 8589). Three parallel evaluation sessions were organized, and each panelist assessed the same six-sample set in each session. The sample set consisted of three cultivars cultivated both conventionally and organically (B-CON, B-OR, J-CON, J-OR, P-CON, and P-OR). Sample cups were coded with three-digit numbers, and the sample order was randomized. The intensities of sensory attributes were rated with a line scale (from 0 = "none" to 10 = "very strong") in nonrandom order, using reference samples (Table 1) in every session. In addition, the possible off-flavors and off-odors were described freely in writing. Data were collected with Compusense *five* software (Compusense Inc., Guelph, Canada).

Statistical Analyses. Differences among the sensory attributes of strawberry samples were analyzed by ANOVA together with Tukey's *t* test and the Tamhane test ($p < 0.05$) (SPSS 16.0, SPSS Inc., H, Chicago, IL, USA). Relationships between sensory and chemical characteristics were tested with the PLS method (Unascrambler 9.8, Camo Process AS, Oslo, Norway). Cross-validation was used to estimate the number of principal components for a statistically reliable model. The reproducibility, agreement, and sensitivity of assessors were also tested (PanelCheck, Nofima, Tromsø, Norway).

RESULTS AND DISCUSSION

Sensory-Active Metabolites in Organic and Conventional Strawberries. From the 3669 molecular features observed in the strawberry metabolite profiling analysis, 60 compounds were selected for further analysis on the basis of preliminary partial least-squares regression (PLS) analysis: the peak areas of 131 molecular features having highest abundance of response in the LC-MS analysis were used as predictors, and the intensities of 7 orosensory attributes and 5 odor attributes (Table 1) evaluated from frozen, pureed strawberry samples were used as responses. The 60 major compounds found to be related to the sensory profile were tentatively identified on the basis of their accurate mass and product ion spectrum. This compound group included mainly flavonoids, hydrolyzable and condensed tannins, organic and phenolic acids, and fatty acids, as well as some terpenoids, furans, and a lactone derivative (Table 2).[6,8,21,31−37] The identified compounds are depicted in the total ion chromatogram of conventional 'Jonsok' sample (Figure 1).

The relatively good stability of 'Bounty" and 'Polka' chemical composition in different horticultural systems was demonstrated by the PCA separating individual sample replicates on the basis of the 60 tentatively identified metabolites: for these two cultivars, conventional and organic samples were closely accumulated (Figure 2). In the hierarchical clustering analysis, conventional 'Polka' (P-CON) and organic 'Polka' (P-OR) further indicated quite similar metabolite profiles regardless of cultivation system (Figure 3). The sample replicates of conventional 'Jonsok' (J-CON) and organic 'Jonsok' (J-OR) were clearly clustered according to farming practice, therefore demonstrating the most conspicuous intracultivar differences between organic and conventional samples (Figures 2 and 3). Especially many organic and cinnamic acids were markedly more abundant in J-CON in comparison to J-OR or to any other sample (Figure 3). When organic 'Bounty' (B-OR) and conventional 'Bounty' (B-CON) were compared, for example, isorhamnetin aglycone, tryptophan, salidroside, an epiafzelechin hexose, a sesquiterpenoid, and a dicaffeoylquinic acid were on average significantly more abundant in B-OR (Figure 3).

In general, the compositional differences between cultivars were much more pronounced than the differences caused by cultivation methods. For example, differing flavonoid glycosylation patterns between cultivars were visualized in the heat map (Figure 3). Both J-CON and J-OR totally lacked a kaempferol pentose. The abundances of some small carboxylic and/or aromatic compounds and salidroside were regulated in a cultivar-dependent manner. A sapogenin compound was found to be more abundant in all organic samples in comparison to conventional analogues, but no other consistent, significant differences were found according to farming practice within the selected compound group.

Earlier studies have shown that flavonoids (e.g., anthocyanins and quercetin glycosides), hydroxycinnamic acids, flavan-3-ols, hydrolyzable and condensed tannins, and triterpene-derived metabolites are important constituents in many strawberry tissues.[7−9,11,14,38,39] Several members of these compound groups were identified as orosensory-active features in this study. In nature, phenolic compounds and terpenoids are often associated with bitter taste perceived by a large family of receptors,[17,40] and the astringent mouthfeel of berries and other polyphenol-rich foods is a consequence of phenolic compounds binding to salivary proteins.[41] Bitterness and astringency, although important quality traits of many beverages (e.g.,

[a]Data were acquired in negative electrospray ionization (ESI−). t_R, retention time.

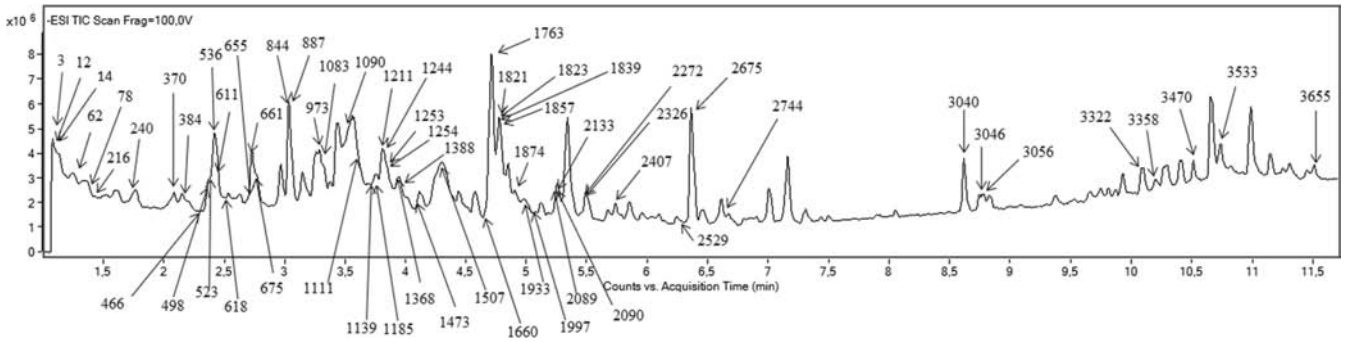

Figure 1. Total ion chromatogram of strawberry obtained in reversed phase liquid chromatography connected with negative electrospray ionization in qTOF-MS analysis. Sixty sensory-active strawberry metabolites are depicted. The peaks are marked by numbers, referring to the tentative identifications in Table 2.

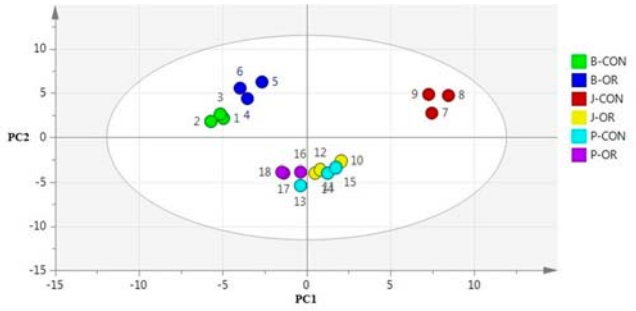

Figure 2. Principal component analysis (PCA) of the metabolite contents of three conventionally and organically grown strawberry cultivars. The PCA plot shows differences between strawberry sample replicates according to their metabolite profiles based on metabolite-specific signal abundances. Each replicate is a pool of 10 strawberry fruits. Numbered circles indicate sample replicates. 1−3, B-CON, conventional 'Bounty'; 4−6, B-OR, organic 'Bounty'; 7−9, J-CON, conventional 'Jonsok'; 10−12, J-OR, organic 'Jonsok'; 13−15, P-CON, conventional 'Polka'; 16−18, P-OR, organic 'Polka'.

wine, tea),[41] are frequently experienced as unpleasant properties of berries.[20]

For instance, citric, malic, and malonic acids were indicated to contribute to strawberry sensory quality in our analyses. Organic acids are an important compound group in strawberry and, indeed, participate and act in synergy with sugars in strawberry flavor formation and perception.[2]

Esters, alcohols, aldehydes, ketones, lactones, furanones, and terpenoids are dominant factors in the strawberry aroma profile.[22,26,42] In addition to furans, terpenoids, and a lactone derivative, many types of fatty acids were among the selected compounds considered in the present study. Several volatile aroma- and/or flavor-active plant secondary metabolites are, in fact, derived from primary metabolites:[17,22,32] for example, lactones are typical products of essential fatty acid degradation[17] and are known to participate in, for instance, the formation of strawberry fruity aroma.[25]

Environment × genotype interactions are important determinants of strawberry phenolic content and metabolite profile. Growth season temperature,[43] fertilization level,[15] harvesting time,[42] and growth location[1] may affect the strawberry metabolome in inter- and intracultivar manners, and some compounds show more plasticity according to environmental conditions.[1] Wounding, microbial attack, and UV radiation, for instance, may induce kaempferol derivative accumulation.[12] As 'Jonsok' samples contained all kaempferol derivatives analyzed in this study except the pentose derivative, it can be proposed that genotype-dependent patterns regulate the glycosylation of flavonols in response to a stress factor. Saponins are synthesized during normal plant development, but biotic threats can also trigger their accumulation.[13]

Total Phenolic Contents of Strawberry Samples. When compared to any other sample, J-CON showed significantly higher total phenolic (TP) values (199 ± 11 mg/100 g fw GAE). J-OR had the second highest TP content (176 ± 11 mg/100 g fw). B-CON had the lowest TP concentration (155 ± 6 mg/100 g fw). The TP contents of J-OR and B-CON differed significantly from each other. The TP contents of P-OR, P-CON, and B-OR were 165 ± 5, 170 ± 4, and 171 ± 2 mg/100 g fw, respectively.

The TP contents of our samples were in line with previous studies.[1,39] No consistent intracultivar alteration of TP content has been observed according to organic versus conventional production.[14,27] Cultivar-dependent, significant differences in the TP values as well as in absolute and relative concentrations of strawberry metabolites have been observed frequently in earlier studies.[1,10,25,27,39]

Strawberry Sensory Properties and Their Relationships with the Identified Metabolites. Some significant

DOI: 10.1021/jf505183j
J. Agric. Food Chem. 2015, 63, 1010−1019

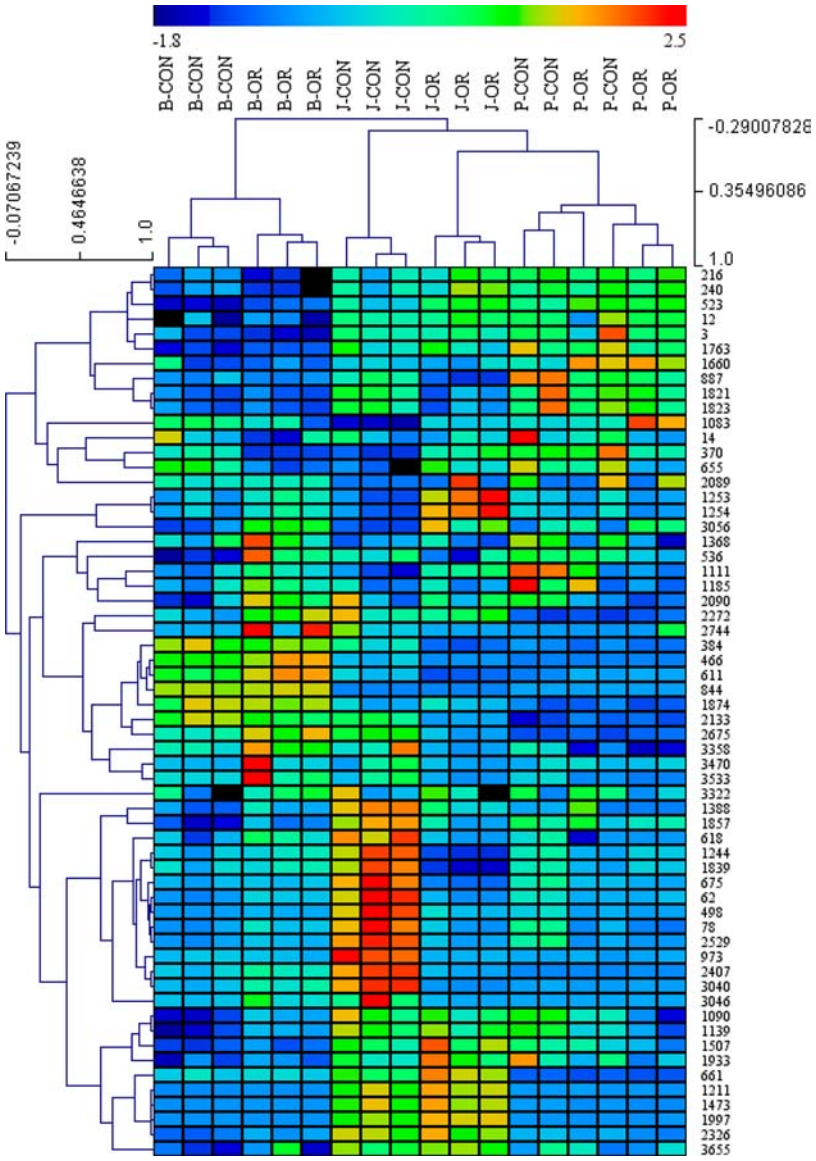

Figure 3. Heat map representation of the hierarchical clustering analysis based on Pearson correlation of the strawberry sample replicates. The analysis is based on the normalized signal abundances of the tentatively identified strawberry metabolites across all analyzed samples. The metabolites are marked by numbers, referring to the tentative identifications in Table 2. The color-coding scale indicates the relative abundance within each metabolite: blue, low abundance; red, high abundance; green/yellow, average abundance. Each replicate is a pool of 10 strawberry fruits. B, 'Bounty'; J, 'Jonsok'; P, 'Polka'; CON, conventional; OR, organic.

differences were detected in all orosensory attribute intensities evaluated from the frozen, pureed strawberry samples (Figure 4A). Nevertheless, there was no consistent correlation between cultivar or farming practice and orosensory property intensities. Sourness and sweetness were the dominating taste properties. J-OR showed both the lowest sweetness intensity and the highest sourness intensity, whereas B-OR was the sweetest and the least sour. B-OR had significantly lower type 1 astringency intensity in comparison to all other samples. Off-flavor was detected in every sample type in at least one evaluation session by at least one assessor.

Green and strawberry odors demonstrated statistically significant differences between samples (Figure 4B). With respect to strawberry odor intensity, J-CON and J-OR represented the extremes and were significantly different from each other; J-CON had considerably higher strawberry odor intensity than J-OR. B-OR had significantly higher green odor intensity than J-OR and P-OR. Off-odors were observed in all sample types with no significant intensity differences.

When the identified chemical compounds were used to explain the sensory attributes of strawberry samples in the PLS model (Figure 5), with three factors, 79% variation in the metabolome data explained 88% variation in the sensory profiles. Bitterness and astringencies were related to the sample-specific combinations of several flavonoid and flavan-3-ol derivatives, a salidroside conjugate, and a triterpenoid. Astringencies and bitterness, in turn, were important contributors in the total intensity of flavor. Two propelargonidin-derived products, citric and caprylic acids and methyl cinnamate, were related to both sourness and rough, sharp type 2 astringency. The aglycones of quercetin and isorhamnetin seemed to be somewhat meaningful in sweet taste intensity, whereas ellagic acid aglycone contributed to bitterness. Green and strawberry odors, as well as sweet taste, were connected

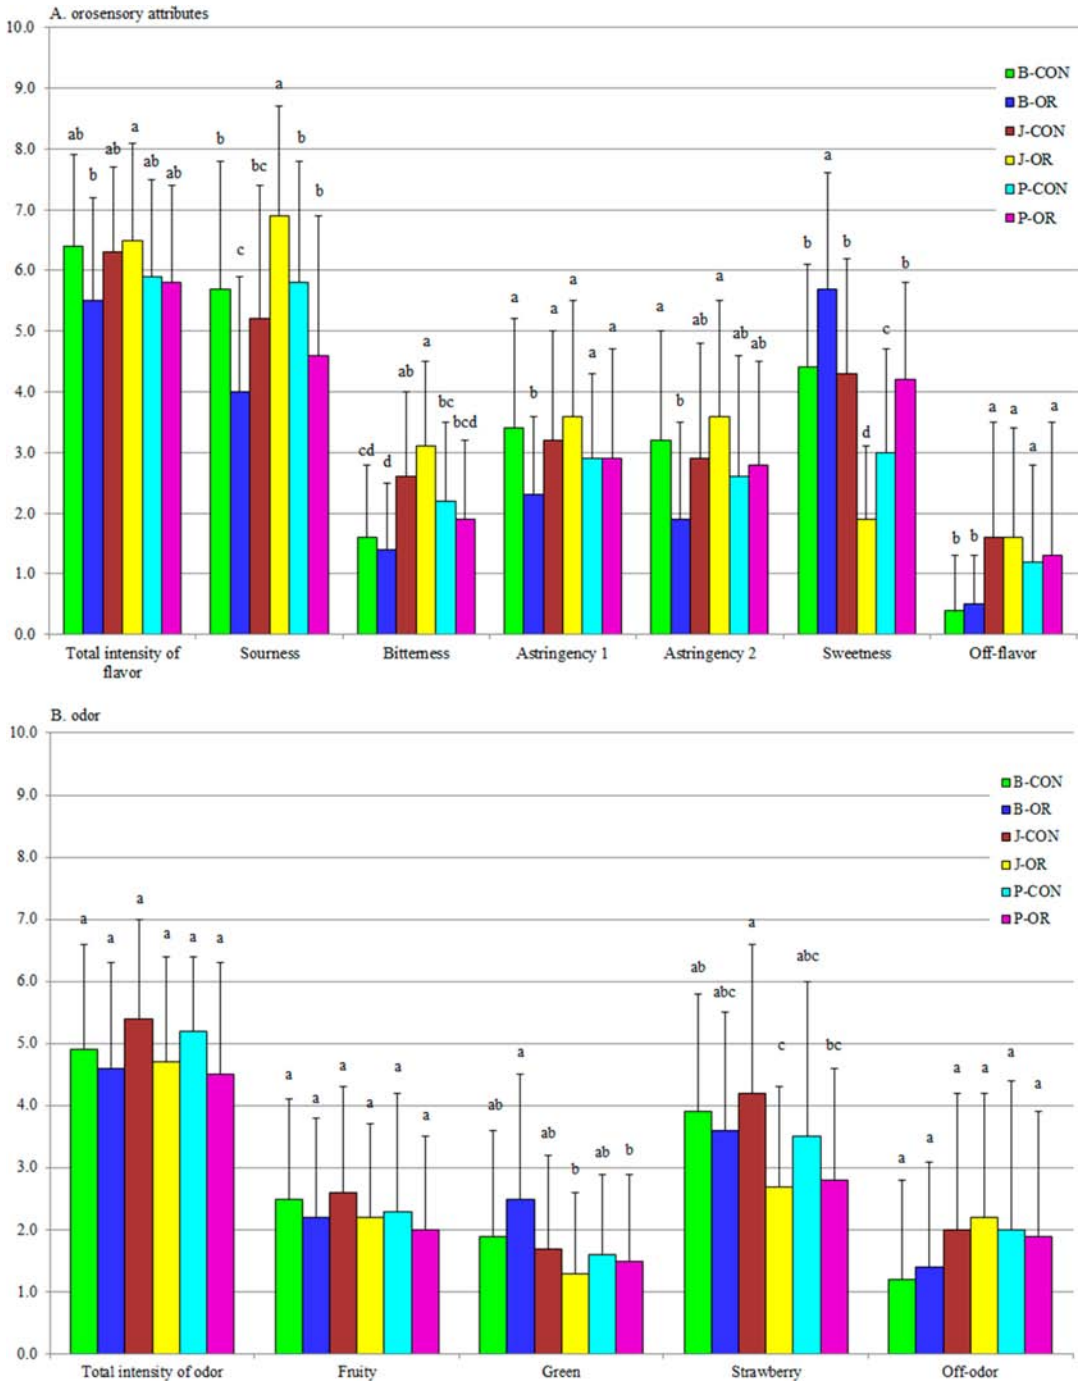

Figure 4. Mean intensities (±SD) of (A) orosensory attributes and (B) odor attributes of three strawberry cultivars (B, 'Bounty'; J, 'Jonsok'; P, 'Polka') cultivated conventionally (CON) and organically (OR). Samples with the same letters for each attribute do not differ significantly.

with fatty acids and fatty acid derivatives. Oleic and linoleic acids were related to green odor formation; an oleic acid derivative was a more determinant factor in strawberry odor. A sesquiterpenoid compound contributed to strawberry odor and salidroside to green odor.

Flavonol glycosides are strongly astringent and contribute especially to velvety, mouth-drying astringency.[20,44−46] Glycosylation patterns of different flavonols are, however, crucial for astringency detection thresholds, depending on the aglycone structure.[44,45] Proanthocyanidins, a compound group including propelargonidins, induce puckering and rough astringency at low concentrations.[45,46] Anthocyanins and proanthocyanidins may also form polymeric pigment compounds having astringent properties in a food matrix.[47] Many compounds having astringent properties may have bitter properties as well, depending on their structure, polymerization level, and concentration.[45,46] Because flavan-3-ols (e.g., (epi)catechin and (epi)afzelechin) tend to polymerize,[8] they possibly contribute to bitterness, along with astringency. Moreover, when chemical mixtures are assessed for their sensory quality, astringency and bitterness are easily linked.[45,46] In a previous study, flavonol aglycones have been observed to correlate with the bitterness of wine,[48] but in our data, flavonol aglycones seemed to be related to the sweetness of B-OR. As for

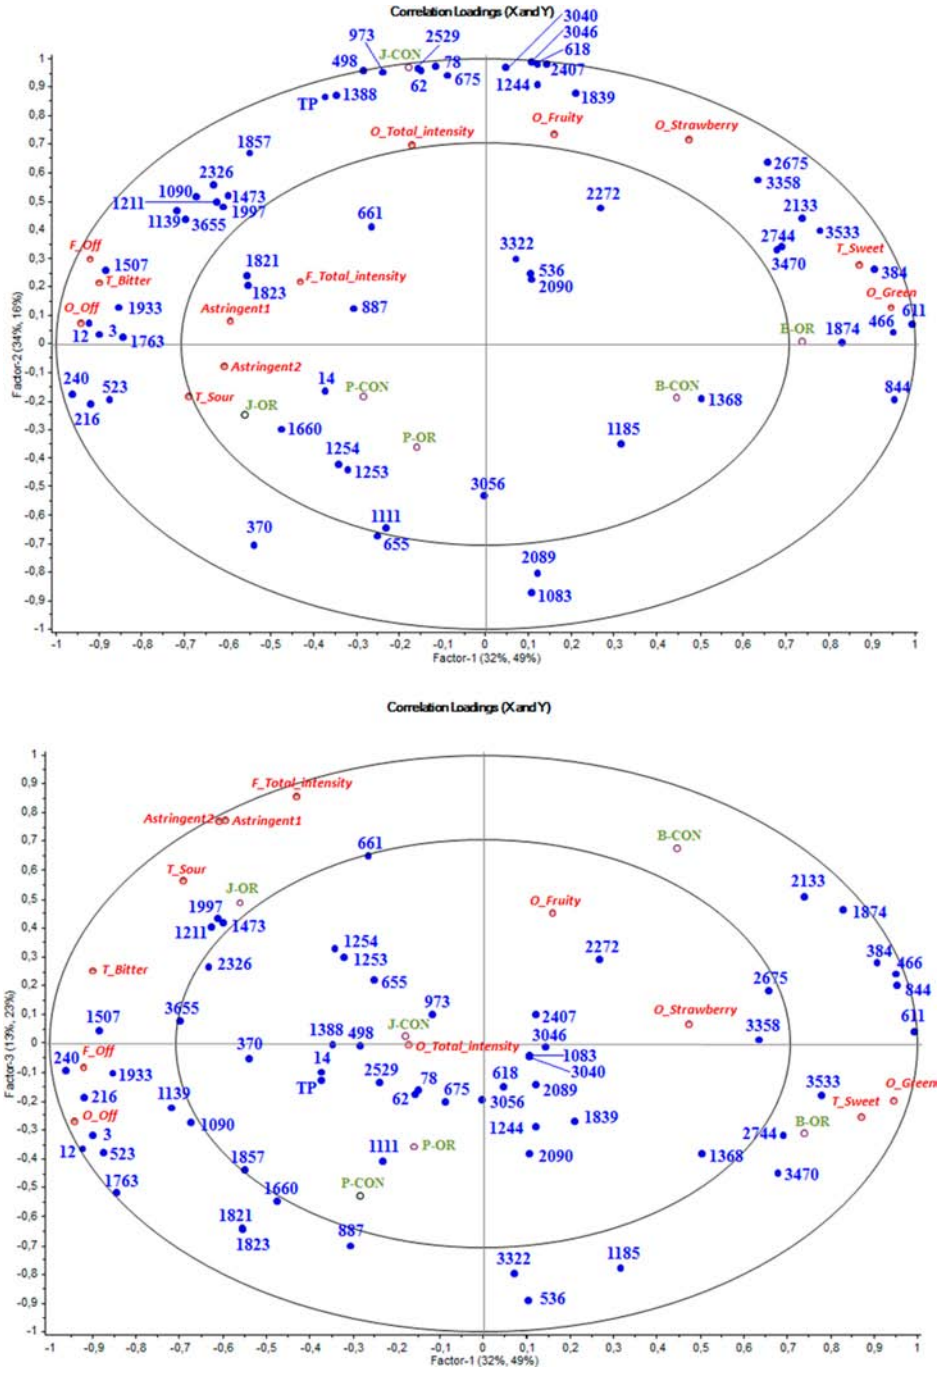

Figure 5. Partial least-squares regression (PLS) plots of the interactions between sensory and tentative metabolite profiles in three strawberry cultivars (B, 'Bounty'; J, 'Jonsok'; P, 'Polka') cultivated conventionally (CON) and organically (OR). Tentatively identified metabolites are used as *X*-variables (predictors) and sensory properties as *Y*-variables (responses). The metabolites are marked by numbers, referring to the tentative identifications in Table 2. Factors 1 and 2 are in the upper plot, and factors 1 and 3 are in the lower plot. Sensory attributes are in italics. O, odor; T, taste; F, flavor; TP, total phenolics.

terpenoids in general, they are well-known bitter, toxicity-implying defense compounds.[17]

Organic acids have been previously found to contribute to both sourness and astringency, two attributes having positive correlation with total acid content and titratable acidity and negative correlation with sugar content.[49] In sensory evaluations, astringency and sourness can be correlated with each other in a berry fruit sample,[49] and this makes distinguishing the effects of individual chemical compounds on fruit sensory properties more difficult.

Oleic and linoleic acids—being long-chained, *cis*-polymerized fatty acids—are distinctive precursors of volatiles involved in plant flavor formation.[17] The catabolism of essential fatty acids is also apt to cause off-flavors.[17] Salidroside is a glucoside of phenylethyl alcohol, and the cleavage of its moieties is likely to profit, for example, rosy odor.[50,51] Yet, the orthonasally perceived aroma of strawberry—derived from the balanced combination of hundreds of plant metabolites, their conjugates. and derivatives—is a complex, polygenic trait fluctuating from

J. Agric. Food Chem. 2015, 63, 1010−1019

one cultivar to the other and between plants cultivated under different environmental conditions.[22,50]

Sucrose content is a determinant factor in strawberry sweetness and also correlates positively with the total volatile content of strawberry; in addition, some volatile compounds have been observed to enhance sweet taste perception from strawberry samples.[22] The contents and ratios of strawberry sugars (i.e., fructose, glucose, and sucrose) vary according to cultivar, and this may affect the sweet taste perception because sugars differ in their relative sweetness.[2,52] Sweetness may decrease both astringency and bitterness: increased sucrose levels have been found to reduce these properties in polyphenol-rich solutions, and this can be explained both physiologically and cognitively.[53] In addition, sample color can modify flavor perception.[54]

The sugar contents or more accurate volatile profiles of frozen strawberries were not determined in this study, and overall, all samples had moderate sensory attribute intensities. Yet it can be concluded that either high sucrose content, the low concentrations of some flavonoid glycosides, distinct fatty acid metabolism, advantageous volatile profile, or all of these factors may explain the relatively high green odor and sweet taste intensities and relatively low astringency and bitterness intensities evaluated from B-OR (Figures 4 and 5). In this study, we have considered a small but prominent fraction of the strawberry metabolome. Adequate peak area, indicating metabolite abundance in the strawberry sample, was one of the criteria used for compound qualification in our analyses. Among the thousands of chemical compounds detected in our samples, there are yet many minor constituents that undoubtedly contribute to the taste, flavor, and odor of strawberries. Therefore, it is our aim to take a broader perspective in clarifying the relationship between the metabolome and sensory quality of strawberries.

The present results indicate that the stability of strawberry chemical composition and sensory quality in different horticultural systems vary mainly according to cultivar. Organic farming practices may enhance the accumulation of some health-related plant metabolites in specific strawberry genotypes. Hence, careful cultivar selection is a key factor in combining sustainable farming practices and the enhanced nutritional quality of strawberry. Furthermore, appropriate cultivar selection may help to increase the marketing value of organically grown strawberry. This study has further verified that strawberry cultivars differ in their chemical composition and sensory characteristics. Many types of flavonoids, hydrolyzable tannins, and flavan-3-ol derivatives are among the most abundant compounds in strawberries, and these compounds contribute to strawberry sensory attributes, as well.

[a]Data are means ± SE of three replications. For weight loss (%) study, $n = 10$. Different letters denote significant differences ($P < 0.05$) among treatments at each storage period for individual parameters.

MATERIALS AND METHODS

Plant Materials. 'Star Ruby' grapefruits of uniform size were harvested from a commercial grove on the southern coast of Israel (January 26, 2010). Each treatment included four cartons of 10 kg of grapefruits, i.e., 40 kg of fruit per treatment. In the current study, the "bag in box" method of MAP was used. Fruits were stored at 10 °C for 16 weeks, followed by 1 week of storage at shelf conditions (20 °C) with the following treatments: (a) control (untreated); (b) microperforated Xtend bag (MIPB; modified atmosphere and humidity); (c) macroperforated Xtend bag (MAPB; modified humidity). The relative humidity in the 10 °C cold storage room was between 80 and 85%. The optimum humidity for postharvest storage of citrus fruit is ∼90−95%.

The MIPB and MAPB liners used included 20 μm thick Xtend films (StePac LA, Tefen, Israel), which were used in our previously published report,[5] and the total area of pores as a percentage of the film surface area were 0.002% for MIPB and 0.06% for MAPB. The water vapor transmission rate of the film was 18×10^{-10} mol s^{-1} m^{-2} Pa^{-1}, and the oxygen transmission rate was 24×10^{-14} mol s^{-1} m^{-2} at 23 °C. The O_2 and CO_2 concentrations in the atmosphere surrounding the untreated control fruit were similar to those of the regular air (0.1−0.3% CO_2 and 20.5−21.0% O_2) (Table 1). In the MAPB, the atmospheric gas concentrations were also similar to those of regular air. In contrast, the fruit in the MIPB experienced a modified atmosphere with constant levels of 3.5% CO_2 and 18.2% O_2. The relative humidity inside both perforated bags was ∼97−98% as compared with ∼80% for the untreated control fruit. The approximate cost of an Xtend MAP bag for 10 kg of fruits (per carton) is ∼25 cents, and the cost of production will not increase significantly using this material.

Fruit samples were collected at intervals of 4 weeks and were further stored for 1 week at room temperature (20 °C) before analysis, to simulate market conditions. Three juice samples per treatment at each time interval were prepared by blending three peeled fruits from different cartons, i.e., a total of nine fruits for each time point. The juice samples were lyophilized and sent in plastic containers to the Vegetable and Fruit Improvement Center (Texas A&M University, College Station, Texas, USA) for quantification of phytochemicals. Lyophilized juice samples were stored at −20 °C until further phytochemical analysis.

Chemicals. Butylated hydroxytoluene (BHT), lycopene, β-carotene, narirutin, naringin, didymin, poncirin, limonin, and 6′,7′-dihydroxybergamottin (DHB) were procured from Sigma-Aldrich Co. (St. Louis, MO, USA). Analytical-grade solvents used for quantitative analysis were obtained from Fisher Scientific Research (Pittsburgh, PA, USA).

Fruit Quality Analysis. Fruit quality parameters such as total soluble solids (TSS), titratable acidity, ripening ratio (TSS/acidity), weight loss, and disease incidence were measured. TSS was determined using a digital refractometer (model PAL-1, Atago, Tokyo, Japan) and is expressed as °Brix. Titratable acidity was determined by titrating the juice with 0.1 M NaOH to pH 8.3 using a model CH-9101 automatic titrator (Metrohm, Herisau, Switzerland). Each measurement included five replications, and each replication included three fruits. Weight loss was determined by weighing fruits ($n = 10$) at intervals of 4 weeks (plus the subsequent 1 week of storage at 20 °C) and was expressed as percent weight loss compared to the prestorage weight. Decay incidence was determined by monitoring the number of fruits with disease symptoms and was expressed as the percentage of decayed fruit per carton.

Sensory Analysis. Fruit sensory quality was evaluated at 4 weeks intervals (plus the subsequent 1 week of storage at 20 °C). Fruits were peeled, and the separated segments were cut in halves and placed into covered glass cups. Each treatment included a mixture of cut segments from five different fruits. Sensory evaluations were conducted by a trained panel consisting of five males and five females aged between 25 and 62 years, who were well-trained and experienced in tasting citrus fruit. The sensory training included open panel sessions with tasting of reference standards. Each panelist assessed the various attributes of the three samples, according to an unstructured 100 mm scale, with anchor points "very weak" and "very strong" for each attribute, and the sensory data were recorded as distances (mm) from the origin. Overall flavor preference was recorded on a hedonic scale of 1 to 10. The samples were identified by randomly assigned three-digit codes.

Quantification of Ascorbic Acid. Direct titration of juice with 2,6-dichlorophenolindophenol (DCIP) was used to determine ascorbic acid content by measuring the reduction of DCIP with ascorbic acid in an acidic solution.[17] Titration volumes were compared with 0.1% ascorbic acid (Sigma-Aldrich, St. Louis, MO), and the results were expressed as mg of ascorbic acid per 100 mL of juice.

Quantification of Carotenoids. Carotenoids were extracted and analyzed using a previously described method.[18] Freeze-dried samples (1 g + 5 mL of water) were extracted using chloroform (15 mL) containing BHT (0.2%). The reconstituted juice was sequentially extracted three times under yellow light. The organic layer was allowed to separate, and extracts from each sample were pooled, filtered using Whatman grade 1 filter paper, and subjected to high-performance liquid chromatography (HPLC) analysis. Carotenoids were quantified by HPLC using a Gemini C-18, 5 μm column (250 mm × 4.6 mm i.d.) with a guard cartridge (Phenomenex, Torrance, CA, USA) on an Agilent 1200 series HPLC (Foster City, CA, USA). Acetonitrile (A) and isopropyl alcohol (B) were used for the mobile phase at the flow rate of 0.8 mL/min with 10 μL injection volume. External standards were used to quantify β-carotene and lycopene at 450 nm wavelength.

Quantification of Limonoids, Furocoumarins, and Flavonoids. *Sample Preparation.* Extraction of samples was carried out according to our previously published method.[18] Each freeze-dried juice sample was reconstituted (1 g + 5 mL of water) and extracted with 15 mL of ethyl acetate on a shaker for 4 h. The organic layer was separated; the residue was extracted twice and pooled; and the solvent was evaporated to dryness. The dried residue was reconstituted with acetone (4 mL), filtered using a 0.45 μm poly(tetrafluoroethylene) (PTFE) filter, and analyzed by HPLC for limonoids, flavonoids, and furocoumarins. In the current study, a common extraction solvent was used for measuring the levels of limonoids, flavonoids, and furocoumarins, to allow comparison and minimize the extraction errors caused by using different solvents.

Quantification of Limonoids and Flavonoids with HPLC. A Waters HPLC (Milford, MA, USA), spectra model with a photodiode array detector (2996), a binary HPLC pump 1525, and a 717 plus

DOI: 10.1021/jf505278x
J. Agric. Food Chem. 2015, 63, 1020−1028

autosampler, was used for quantification of limonoids and flavonoids. The chromatographic separations were performed according to a previously published method[18] on a Gemini C-18, 5 μm column (250 mm × 4.6 mm i.d.) from Phenomenex (Torrance, CA, USA). The limonoids and flavonoids were detected at 210 and 280 nm, respectively. Data analysis was carried out using the Empower pro software. The chromatographic separation was performed using a gradient mobile phase of 0.03 M phosphoric acid (A) and acetonitrile (B) with 1 mL/min flow rate. Each sample was injected three times, and all measurements were conducted in triplicate.

Confirmation of Limonoids and Flavonoids by Liquid Chromatography–Mass Spectrometry. The structures of limonoids and flavonoids in samples were confirmed by ultrahigh performance liquid chromatography–time-of-flight-mass spectrometry (UPLC-QTOF-MS) (maXis impact, Bruker Daltonics, Billerica, MA, USA). Limonoids and flavonoids were separated on an Eclipse Plus C18 LC-MS column (2.1 × 100 mm), 1.8 μm partical size, connected to an Agilent 1290 UPLC instrument (Agilent, Santa Clara, CA) at 70 °C with a flow rate of 0.2 mL/min using binary gradient elution of 0.1% formic acid and acetonitrile. Compounds were separated by a gradient of 98% A to 10% in 0–9 min followed by equilibration for 2 min before the next injection. The 1290 UPLC is equipped with auto sampler, binary pump, solvent degasser, thermostated column compartment, and diode-array detector (DAD). The LC peaks were monitored at 210 and 280 nm for limonoids and flavonoids, respectively. Mass spectral analyses were performed using the ESI-Q-TOF mass spectrometer equipped with an electrospray ionization. Both positive and negative modes were used for ionization. Mass spectrometer conditions are as follows: MS scan range, 50–1000 m/z; end plate offset, −500 V; capillary voltage, 3000 V; nebulizer gas (N_2), 4 bar; dry gas (N_2) flow rate, 12 L/min; dry gas temperature, 200 °C; ion transfer conditions funnel radio frequency (RF), 200 Vpp; multiple RF, 200 Vpp; quadruple low mass, 55 m/z; collision energy, 5.0 eV; collision RF, 600 Vpp; ion cooler RF, 50–250 Vpp ramping; transfer time, 121 μs; prepulse storage time, 1 μs. Calibration was done before each run through a loop injector of 20 μL of 10 mM sodium formate. The Bruker Compass Data analysis 4.1 software was used for data acquisition.

Quantification of Furocoumarins with HPLC. Furocoumarins were analyzed using our previously described method, with slight modifications.[19] A PerkinElmer HPLC system consisting of a series 200 pump, photodiode array (PDA) detector (235C), and autosampler (Norwalk, CT, USA) was used for analysis. The separations were carried out on a Gemini C-18, 5 μm column (250 mm × 4.6 mm i.d.), with a guard cartridge from Phenomenex (Torrance, CA, USA). The peaks were detected at 320 nm, and the data were integrated using Turbochrom software (PerkinElmer, Norwalk, CT, USA). The gradient mobile phase consisted of 0.03 M phosphoric acid (A) and acetonitrile (B) with 10 μL injection volume at the flow rate of 1 mL/min. Each sample was analyzed three times, and all measurements were conducted in triplicate.

Statistical Analysis. Statistical analysis was performed using one-way analysis of variance (ANOVA) with PASW Statistics 18 software (SPSS Inc., 2009). A general linear model was used to test significant differences, and means were compared using Tukey's HSD test at the 5% probability level. The results were expressed as means ± SE.

RESULTS AND DISCUSSION

Weight Loss. Overall, we observed no significantly detrimental weight loss in any of the three treatments, but in the control fruits, weight loss gradually increased during the postharvest storage from 1.7% after 4 weeks to 4.2% after 16 weeks of storage (Table 1). MIPB and MAPB significantly ($P < 0.05$) reduced weight loss during the 16-week storage period. Humidity, temperature, and storage period strongly affect weight loss in fruits.[20] Moisture loss from the peel, a primary reason for weight loss in citrus fruits, can lead to peel disorders and affect the fruit's appearance.[21,22] In the current experiment, the reduction in weight loss observed in grapefruits stored in MAP can be attributed to reduced transpiration due to the high humidity maintained in the MAP. Similar results were reported in previous experiments where individual film wrapping[22] and use of box liner bags[5] for storage of citrus fruits significantly reduced weight loss.

Visual Appearance and Color. At the time of harvest (January 26, 2010), the fruits were attractive, with an external yellowish color with red cheeks (Figure 1). During the prolonged storage at 10 °C, the control fruits gradually became more reddish as compared to time zero (at harvest). Packing the fruits in perforated bags slightly delayed the development of external color. Low oxygen and high carbon dioxide levels inhibit ethylene production and action,[23,24] which may cause the delay in peel color development in grapefruits stored in MAP.[25] Modified atmosphere storage delays ripening and color development in plums,[26] avocado,[27] and Marsh grapefruit.[22] With respect to internal appearance, the fruit flesh was red at harvest, and no further remarkable changes occurred during storage.

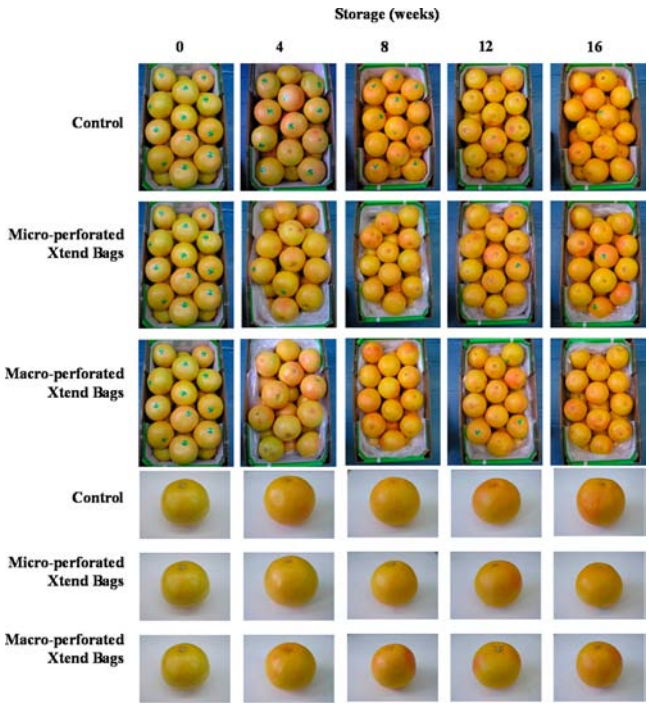

Figure 1. Effect of MAP on the appearance of 'Star Ruby' grapefruit. Fruits were untreated or kept in perforated bags, and pictures were taken after 4, 8, 12, and 16 weeks of storage at 10 °C, followed by 1 week of storage at shelf conditions (20 °C).

Juice TSS and Acid Percentages. Juice TSS was 12.2% at harvest and remained mostly constant during postharvest storage in all treatments (Table 2). By contrast, acidity levels were 1.9% at harvest and slightly decreased to 1.6–1.7% after prolonged storage. Overall, the observed changes in juice TSS and acidity levels resulted in a slight increase in ripening ratio from 6.5 at harvest to 8.0 after 16 weeks of storage. Fruit stored in perforated bags showed only a slight reduction in acidity levels. Similar results were observed in previous studies where MAP had no significant effect on TSS and acidity levels in citrus fruits.[5,28]

Decay Development. The incidence of decay was very low throughout the course of the experiment, and after 16 weeks of

storage only 3−4% decay was observed in all the treatments (data not shown). Thus, the increased humidity in the MAP did not increase the incidence of decay. MAP is recommended as it reduces various rind disorders in citrus fruits including oranges, tangerines, and grapefruit.[5,6]

Fruit Taste. At harvest, fruits achieved a high taste score of 8.8 on a scale of 1 to 10 (Table 2). Although the fruit taste remained good during the entire experiment, the taste score gradually decreased to 7.2−7.5 after 16 weeks of storage. Overall, storing the fruits in MAP had no significant effect on fruit taste or sensory acceptability (Table 2). Taste is an important factor in determining the quality of fruits, especially in fruits stored for prolonged periods. Sugars (TSS) and acids are the primary factors affecting taste, and MAP did not alter these in the current study. Other studies conducted using MAP have reported retention of taste for longer periods than control.[29] However, care must be taken to avoid very high CO_2 (>7−8%) or low O_2 (<14−15%), which can lead to anaerobic conditions and result in off-flavors.[5]

Ascorbic Acid. Ascorbic acid content was 40 mg per 100 mL of juice at harvest and was retained during postharvest storage in all three treatments (Figure 2). MAP had no significant effect on ascorbic acid levels during the storage period. Ascorbic acid levels increased in all three treatments at 8 weeks after storage; nevertheless, at the end of the 16-week storage period, fruits in all three treatments had ascorbic acid levels similar to initial levels. Ascorbic acid is a major antioxidant present in citrus fruits and acts as a first defense response against oxidative stress.[30,31] Increase in ascorbic acid up to 8 weeks can be attributed to de novo biosynthesis and regeneration of ascorbic acid due to increase in stress after harvest and during initial storage weeks of the fruits.[32] In another study in 'Cara Cara' navel orange, an increase in ascorbic acid was observed during prolonged storage of 105 days as a result of ripening of the fruit after harvest and reduced degradation due to lower metabolic rate.[33] Ascorbic acid was higher in broccoli stored in MAP due to its low autoxidation,[34] and MAP did not affect ascorbate peroxidase, the major enzyme involved in ascorbic acid degradation, in broccoli. In Valencia oranges, coating with different commercial waxes that modified their internal O_2 and CO_2 produced no significant difference in ascorbic acid levels between coated and noncoated fruits.[35] However, Valencia oranges showed a decrease in ascorbic acid with increasing storage period.[35] Nevertheless, in the present study, no significant differences were seen in ascorbic acid contents among the three treatments during the storage period.

Carotenoids. β-carotene levels gradually increased in grapefruit pulp during the storage period in all three treatments (Figure 2). At the end of 16 weeks of storage, β-carotene levels were higher in control fruits, followed by fruits stored in MIPB and MAPB. In addition, lycopene was significantly higher in control fruits at 4 and 16 weeks of storage. Fruits stored in MAPB had higher lycopene contents than fruit stored in MIPB at 4 weeks of storage; however, no significant difference was observed between MIPB and MAPB fruits at 8 and 16 weeks of storage. A sharp increase in lycopene levels was observed in the fruits stored in MIPB at 12 weeks of storage, although lycopene decreased after 16 weeks of storage. The current results indicate that MAP delayed color development in peel and carotenoid development, especially β-carotene, in fruit flesh. In plums, storage in MAP delayed anthocyanin and carotenoid development.[13,36] Another study conducted on shredded carrots showed similar results, where MAP (95% O_2 and 5% CO_2) reduced the carotenoid contents of both orange and purple carrots during storage.[37] Being nonclimacteric in nature, mature citrus fruit produce low levels of endogenous ethylene.[38] However, MAP affects ethylene biosynthesis and action and thus may delay carotenoid development.

Limonoids and Furocoumarins. Limonin levels increased sharply after 4 weeks of storage in all three treatments (Figure 3), but limonin was higher in control and in MIPB at 4 and 8 weeks after storage. However, control fruits had lower levels of limonin than MAP-treated fruits at 12 weeks of storage. No significant difference in limonin was observed among the treatments after 16 weeks of storage. LC-MS analysis was conducted to further confirm the increase in limonin observed

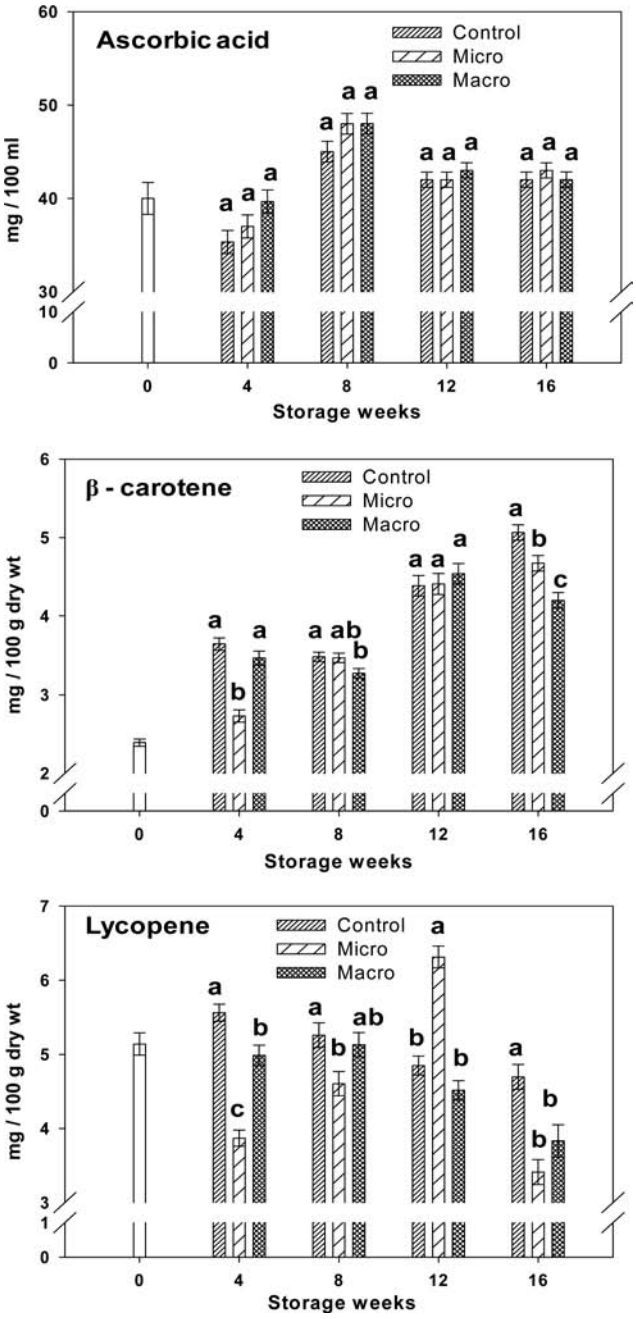

Figure 2. Effect of MAP on ascorbic acid and carotenoid contents of 'Star Ruby' grapefruit. Fruits were stored for 4, 8, 12, and 16 weeks in microperforated and macroperforated bags at 10 °C, followed by 1 week of storage at shelf conditions (20 °C). Data are represented as means ± SE of 3 replications, each from 3 different fruits. Different letters denote significant differences ($P < 0.05$) among treatments at each storage period.

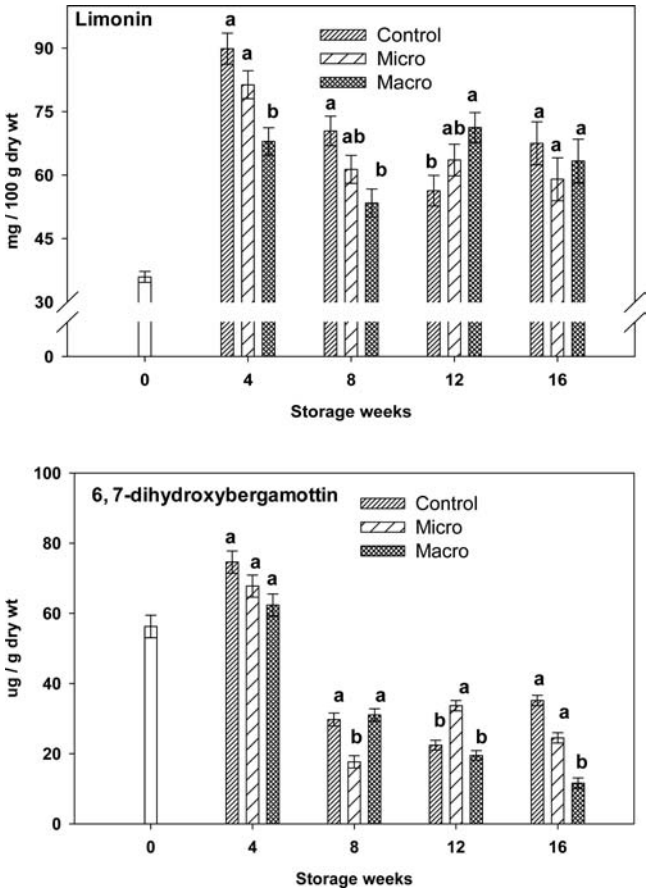

Figure 3. Effect of MAP on limonin (limonoid) and 6,7-dihydroxybergamottin (furocoumarin) contents of 'Star Ruby' grapefruit. Fruits were stored for 4, 8, 12, and 16 weeks in microperforated and macroperforated bags at 10 °C, followed by 1 week of storage at shelf conditions (20 °C). Data are represented as means ± SE of 3 replications, each from 3 different fruits. Different letters denote significant differences ($P < 0.05$) among treatments at each storage period.

at 0 days and 4 weeks. The total ion chromatogram (TIC) of mass spectral analysis of ethyl acetate extracts were illustrated in Figure 4A, and the mass spectrum of limonin shows the negative molecular ion m/z 469.1849 $[M+1]^-$ (mass error 1.39 ppm) (Figure 4B). The limonin levels were found to be more than 2-fold higher at 4 weeks, compared to at 0 days. In citrus fruits, limonin is the most abundant aglycone followed by nomilin.[39] Limonin is one of the compounds responsible for the bitter taste of grapefruit. Nomilin is the precursor of limonin, and limonin is further converted into limonin glucoside.[40]

Furocoumarin, namely, DHB, was quantified in the current study. DHB levels decreased in all three treatments with longer storage, after 4 weeks (Figure 3). No significant difference ($P < 0.05$) was observed in DHB levels among all three treatments up to 4 weeks of storage. At 8 weeks of storage, DHB was significantly lower in fruits stored in MIPB, but control and fruits stored in MAPB showed no difference. Fruits stored in MIPB then showed higher DHB levels at 12 weeks of storage than fruits in the other two treatments. Nevertheless, after 16 weeks of storage, no significant difference was seen between control and the fruits stored in MIPB, while the fruits stored in MAPB showed lower DHB levels. Furocoumarins are derived from the phenylpropanoid pathway, with umbelliferone being their main precursor.[41] Furocoumarins are affected by various factors such as environmental conditions, variety, season, storage period, and postharvest treatment.[19,42,43] A previous study by Girennavar et al.[42] reported a decrease in DHB levels during storage when Rio Red grapefruits were stored at 9 °C for 45 days. The current study is the first to report the effect of MAP on limonoids and furocoumarins in 'Star Ruby' grapefruit.

Flavonoids. The four flavonoids (narirutin, naringin, didymin, and poncirin) showed similar trends during storage

DOI: 10.1021/jf505278x
J. Agric. Food Chem. 2015, 63, 1020−1028

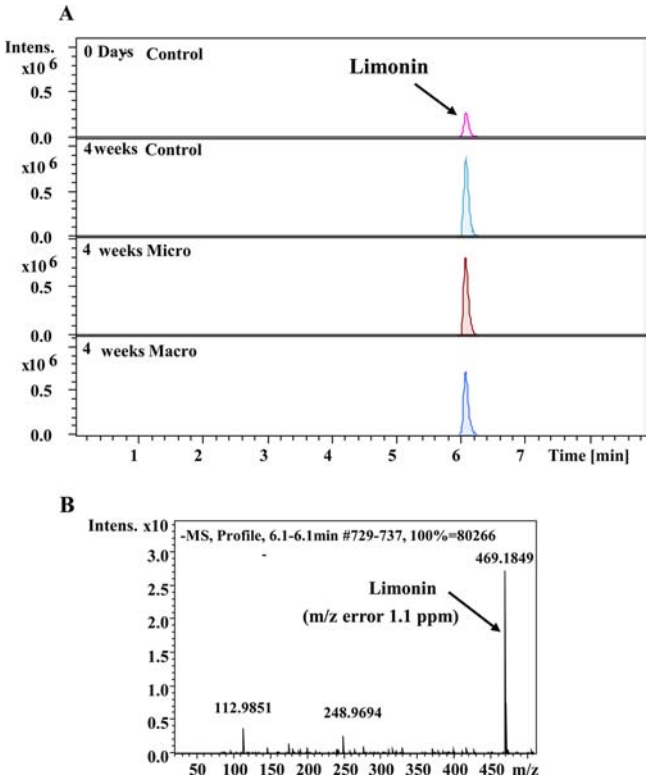

Figure 4. (A). Extracted ion chromatograms of limonin in control grapefruits and fruits stored in microperforated and macroperforated bags at 10 °C for 0 days or 4 weeks, followed by 1 week of storage at shelf conditions (20 °C). (B) ESI−MS spectrum of limonin confirmed by negative ionization mode.

(Figure 5). Their levels decreased gradually with storage up to 8 weeks, with a sharp increase at 12 weeks of storage in all three treatments. However, at the end of the 16-week storage period, initial flavonoid levels were maintained in fruits stored in MAPB, while flavonoids levels decreased slightly in the other two treatments. The sharp increase in flavonoids in all three treatments can be a response to physiological stress during storage. No significant difference was observed in narirutin and didymin levels at 8 weeks of storage in all three treatments. Naringin, didymin, and poncirin levels were higher in the control and in fruits stored in MAPB at 4 weeks of storage. At 8 weeks of storage, controls and fruits stored in MIPB had higher naringin and poncirin levels in comparison to the fruits stored in MAPB. In addition, mass spectral experiments were performed using electrospray ionization operated in negative mode for zero day control and 4-week samples of control and microperforated and macroperforated samples to validate the structural confirmation using high-resolution mass spectra. Figure 6A shows UPLC separation for four flavonoids eluted at 3.8, 3.9, 4.6, and 4.7 min. Figure 6B depicts the negative molecular ion mass spectra of narirutin, m/z 579.1676 (m/z error −5.6 ppm), naringin m/z 579.1705 (m/z error 0.57 ppm), didymin m/z 593.1970 (error 4.7 ppm), and poncirin m/z 593.1860 (error 3.5 ppm). A mass error of the molecular ion of each flavonoid is <5 ppm, which confirms the positive identification of measured mass compared to theoretical mass.

Flavonoids are phenolic compounds derived from the phenylpropanoid pathway, and phenylalanine ammonia lyase (PAL) is the first enzyme in this pathway. Various biotic and abiotic factors including ethylene, chilling injury, irradiation, and low temperature affect the activity of PAL.[44−47] A previous study in plum reported a delay in increase of total phenolics when fruits were stored in MAP for up to 35 days.[13] Delays in

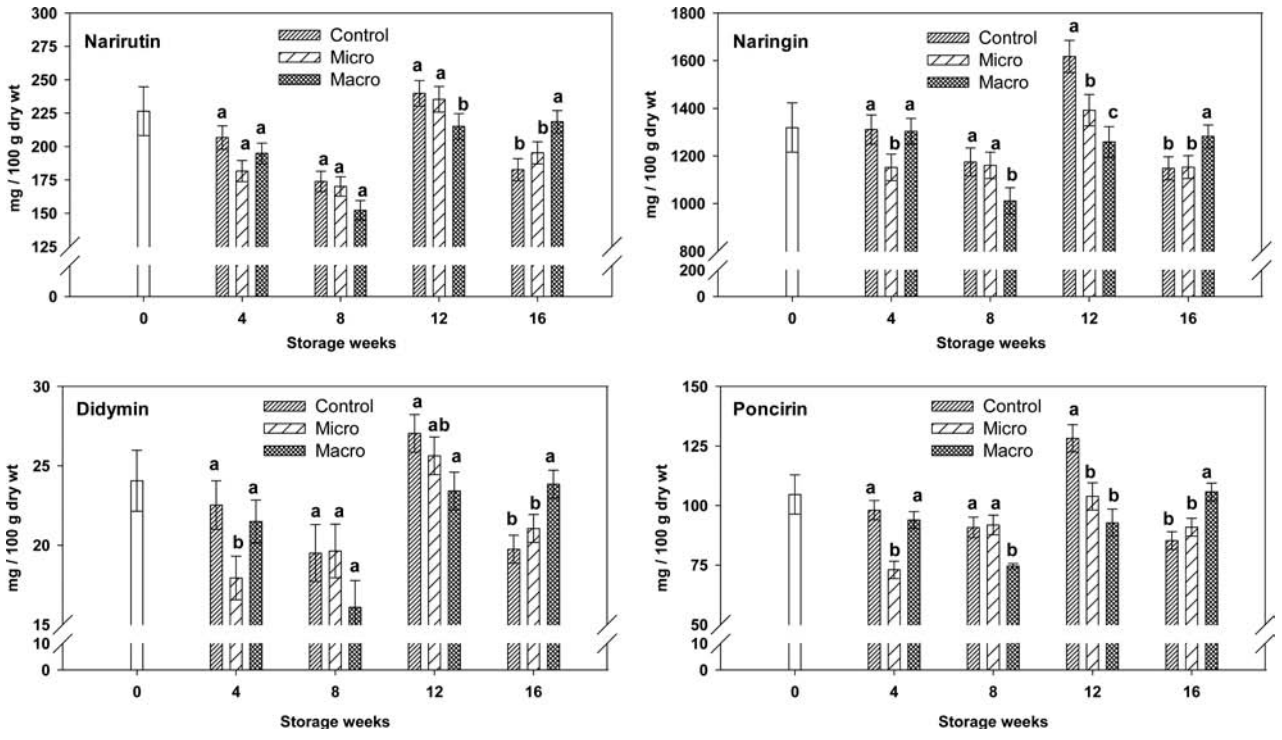

Figure 5. Effect of MAP on flavonoid contents of 'Star Ruby' grapefruit. ripening or ethylene inhibition due to MAP can affect flavonoid biosynthesis. In addition, grapefruits contain furocoumarins, phenylpropanoid compounds that can influence flavonoid biosynthesis. Further research on biosynthesis of flavonoid and furocoumarins is warranted to help us understand the mechanisms acting under different treatments and storage conditions.

In conclusion MAP can be used as a valuable approach to maintain postharvest quality of grapefruits and reduce the occurrence of disease and rind disorders. The present study demonstrates that, among the different phytochemicals evaluated, MAP has a significant effect on carotenoids, flavonoids, and furocoumarins. Overall, MAP produced no detrimental effects on fruit weight, color development, sensory taste, TSS, acidity, and ripening ratio. In addition, we observed no significant effects of MAP on the levels of ascorbic acid and limonoids among all three treatments at 16 weeks of storage. MIPB is recommended over MAPB, as it modifies the atmosphere and helped to retain certain phytochemicals in comparison to control. Further studies on grapefruits stored at temperatures below 10 °C will examine the effect of MAP on chilling injury and changes in phytochemicals.

isomer, and with a consistent ratio of producing strains (70−80%) regardless of where the strains are sampled.[15] Fumonisins originating from *A. niger* have previously been detected in wine and raisins[21−23] as well as Thai coffee beans where the whole fruit is used.[24] *Fusarium xylarioides* causes the Coffee Wilt Disease and thus could be another source of fumonsins because this species belongs to the *Gibberella fujikuroi* species complex that contains many fumonisin producers.[25]

The Quick, Easy, Cheap, Effective, Rugged, and Safe (QuEChERS) extraction method, originally developed for pesticides,[26] has in recent years been adopted for numerous analytical methods for mycotoxins.[1,10,27,28] The popularity lies in (i) fast sample preparation; (ii) the bulk part of contaminants are trapped in the water phase; and (iii) the possibility to mix with water for immuno-affinity or reversed phase column purification. A disadvantage is that basic and acidic mycotoxins cannot be coextracted in one step.[27]

We speculated that it was possible to change to a QuEChERS-based method and also to include the fumonisins in our OTA method for roasted coffee, currently based on immunoaffinity purification and LC-MS/MS. Looking at the functional groups, acidic QuEChERS was tested but it could not meet sensitivity requirements for OTA. Consequently, it was combined with anion exchange solid phase extraction (SPE) where mixed mode anion-exchange was the most promising.

MATERIALS AND METHODS

Chemicals. Acetonitrile (MeCN), methanol, 2-propanol, and formic acid were LC-MS grade and purchased from Sigma-Aldrich (St. Louis, MO). $MgSO_4$, NaCl, H_2PO_4, and KH_2PO_4 were analytical grade and purchased from Sigma-Aldrich. Water was purified with a Milli-Q purification system (Millipore, Bedford, MA). Fumonisin standards (a mixture of FB_1 and FB_2, both at 50 μg/mL), OTA (10 μg/mL), fully ^{13}C-labeled FB_2 ($^{13}C_{34}$−FB_2, 10 μg/mL) and OTA ($^{13}C_{20}$-OTA, 10 μg/mL) were purchased from Romer Laboratories (Tulln, Austria). FB_3 was acquired from Sigma-Aldrich as a 50 μg/mL solution. All toxin solutions were stored at −20 °C.

Roasting of Green Coffee. Selected green coffee samples of about 150 g were roasted in a Helios electrical oven (Struers, Denmark). The oven temperature was set at 200 °C, and the roasting level was controlled by regularly monitoring the coffee color changes for about 20 min until a color similar to medium roasted beans was obtained.

Extraction and Purification. Ground green (5.0 g), roasted (5.0 g), or instant coffee (2.0 g) was shaken with 40 mL of MeCN/water/formic acid (49:49:2, v/v/v) for 15 min at room temperature and centrifuged at 4500*g* for 10 min. The supernatant, approximately 30 mL, was transferred to a new tube, and 4.0 g of $MgSO_4$ and 1 g of NaCl were added. After 10 min of shaking, the tube was centrifuged at 4500*g* for 10 min and filtered through a Whatman No. 4 filter (Brentford, U.K.). From this mixture, 1.9 mL was transferred to a new tube, and 50 μL U−^{13}C-OTA (0.05 μg/mL), 50 μL U−^{13}C-FB_2 (0.05 μg/mL), and 9 mL of water were added, and the tube was centrifuged at 4500*g* for 10 min.

The sample was then transferred to a 200 mg Oasis Max 60 μm cartridge (Waters, Milford, MA, U.S.A.) and passed through the cartridge. The cartridge had previously been conditioned sequentially with 3 mL of methanol and 3 mL of water. Two other brands of mixed mode columns were also tested, also 200 mg: Bond Elute Plexa PAX (Agilent, Waldbronn, Germany) and Evolute AX (Biotage, Uppsala, Sweden).

Columns were sequentially washed by 4 mL of 0.1 M H_2PO_4/$KHPO_4$ (pH 7.2), 4 mL of methanol, and 4 mL of MeCN, and the toxins were eluted by 3 mL of MeCN containing 2% formic acid into a 4 mL acid washed glass vial (Scherf-Präzision Europa GmbH, Meiningen, Germany). Samples were evaporated to dryness with N_2 at 50 °C and kept at −20 °C until analysis.

UHPLC-MS/MS. Samples were vortexed with 400 μL of MeCN/water (1:1, v/v) and transferred directly to a 2 mL autosampler vial. UHPLC-MS/MS was performed on an Agilent 1290 system equipped with a cooled Agilent G4226A auto sampler (tray at 5 °C), a 100 mm × 2 mm inner diameter i.d. 2.6 μm, Poroshell C_6−Phenyl column (Agilent) held at 40 °C and coupled to an Agilent 6490 i-funnel triple quadruple mass spectrometer equipped with the Jet Stream ESI source.

Unless otherwise stated, 1 μL of extract was injected and eluted at a flow rate of 0.4 mL/min using a water (containing 20 mM formic acid)-MeCN (with 20% isopropanol) gradient system starting from 10% MeCN, with a linear increase to 75% in 7.5 min, then to 100% in 1.5 min, holding this for 3 min, then back to 10% MeCN in 0.1 min, holding this for 2.5 min. Other gradient compositions were initially tested.

To avoid carry-over, the Agilent 1290 auto sampler was operated in the flow-through-needle mode and further coupled to an Agilent Flex cube, which was used to back flush the needle seat for 15 s at a flow of 4 mL/min with each of these components: (i) isopropanol-0.2% NH_4OH (1:1 v/v); (ii) MeCN with 2% formic acid; (iii) water with 2% formic acid. To further lower carry-over, the auto sampler valve was switched between main and bypass twice prior to sample injection and further 12 times between 9.5 to 13.5 min while the gradient was at 100% organic and down to 10% at the start conditions.

Ion source conditions were the following: gas temperature 180 °C; gas flow 12 L/min; nebulizer 20 psi; sheath gas temperature 350 °C and flow 12 L/min; capillary 3500 V.

MS was operated in ESI^+ in the dynamic multiple reaction monitoring (MRM) mode using the $[M + H]^+$ ions as the precursor ions. The multiplier was raised 150 V from the autotune value, the ion-funnel fragmentor at 380 V, and all MRM analyses were done at unit resolution for both quadrupoles.

MRM settings were for FB_1, RT 4.48 min, precursor *m*/*z* 722.4 and fragments *m*/*z* 352.3 (collision energy, 37 eV) and *m*/*z* 334.3 (37 eV) ratio 125% (ratio of quantifier and qualifier ion peak areas); FB_6, RT 5.14 min, precursor *m*/*z* 722.4 and fragments *m*/*z* 370.3 (40 eV) and *m*/*z* 352.3 (38 eV) ratio 63%; FB_3, RT 4.97 min, precursor *m*/*z* 706.4 and fragments *m*/*z* 354.3 (35 eV) and *m*/*z* 318.3 (42 eV) ratio 65%; FB_2, RT 5.31 min, precursor *m*/*z* 706.4 and fragments *m*/*z* 354.3 (35 eV) and *m*/*z* 318.3 (42 eV) ratio 90%; U−^{13}C-FB_2, precursor *m*/*z* 740.5 and fragment *m*/*z* 354.3 (35 eV); FB_4, RT 5.79 min, precursor *m*/*z* 690.4 and fragments *m*/*z* 338.3 (34 eV) and *m*/*z* 320.3 (38 eV) ratio 100%; OTA, RT 6.74 min, precursor *m*/*z* 404.2 and fragments *m*/*z* 239.1 (25 eV) and *m*/*z* 102.1 (70 eV) ratio 42%; and U−^{13}C-OTA, precursor 424.2 and fragments 250.1 (25 eV).

Data were integrated in Agilent MassHunter Quant B6.00 Software and copied to Microsoft Excel for quantification. Chromatograms were smoothed using a Gaussian width of 5 scans.

Calibration. Matrix-matched calibration curves were used throughout this study by spiking blank whole samples of roasted, green, and instant coffee. The spike levels including the blank for each coffee type were 0, 2, 5, and 10 μg/kg of OTA and 0, 20, 50, and 100 μg/kg of FB_2, respectively. The spiked samples were stored uncapped overnight at room temperature to allow solvent evaporation and to achieve equilibrium between the analytes and matrix. The following day, all samples were passed through the entire cleanup process as described above. The calibration curves were constructed by plotting the peak area of the analytes divided by the peak area of the respective internal standards of $^{13}C_{20}$-OTA and $^{13}C_{34}$−FB_2 versus the analyte standard concentrations. For determination of OTA and FB_2 in real samples of roasted, green, and instant coffee, the peak area ratio between the analyte and its internal standard was used, and all concentrations were calculated by using the obtained linear calibration equation. The limits of detection (LOD) and quantification (LOQ) were calculated as 3 times and 6 times the standard deviation on the lowest points of the calibration curve for OTA and FB_2, respectively.

The addition of isotope-labeled internal standards before the extraction was not considered as an option in this study for determination of extraction recovery due to the high costs associated with the high amounts of internal standards needed.

Method Performance and Validation. Validation was done for each sample type of roasted, green, and instant coffee at the levels

described above, on 5−10 different days for each matrix using three different operators for the sample preparation.

The extraction recovery was assessed in eluates prepared by QuEChERS extraction of blank samples of roasted, green, and instant coffee followed by SPE purification on Oasis Max as described above. The eluates were then spiked with OTA and FB_2 within the same concentration range as for the not purified samples corresponding to the following levels: (i) 3.13 ng/mL of OTA and FB_2; (ii) 6.25 ng/mL of OTA and FB_2; (iii) 9.38 ng/mL of OTA and FB_2; and lastly with (iv) 12.5 ng/mL of OTA and FB_2. These standard calibration curves were used to measure the extraction recovery in each coffee type at the three spiking levels of OTA (2, 5, and 10 μg/kg) and FB_2 (20, 50, and 100 μg/kg), respectively.

Signal suppression and enhancement due to matrix effects was evaluated as the MS signal response areas between standards of OTA and FB_2 dissolved in MeCN containing 2% formic divided by the response area of the standards prepared in the blank eluates as described above.

A roasted coffee sample with a certified level of OTA of 4.36 μg/kg was obtained from the Food Analysis Performance Assessment Scheme (FAPAS, The Food and Environment Research Agency, Sand Hutton, U.K.) and was analyzed on 4 different days and processed in the same way as described for the samples. The Z-score specified by FAPAS is considered as satisfactory for $Z \leq 2$ (numeric value) corresponding to a concentration range between 2.44 and 6.27 μg/kg.

RESULTS AND DISCUSSION

Extraction and Purification. As a start, dry acidic MeCN was tested and it provided very clean extracts, but unfortunately the extraction recoveries were inconsistent. Using an acidic QuEChERS, it was visually apparent that the major part of the colored contaminants were present in the lower discardable water phase. Further initial tests comparing mixed mode versus normal silica based SAX columns showed that the mixed mode columns provided higher recoveries.

A strong ion exchanger compared to a wear anion exchanger was chosen because phospholipids, for example, known to induce ion-suppression,[13,29] are much more strongly bound than the carboxylic acid containing analytes that will become uncharged during elution with formic acid.

During method development, both phosphoric acid and formic acid were tested. The latter gave higher recoveries (>30%) on the Oasis MAX columns. Finally, we also tried to minimize the amount of water added to the QuEChER extract before cleanup on SPE columns. We found that addition of less than 4.5 mL water per mL of MeCN supernatant was the minimum. Thus, addition of less water decreased the recovery of FB_2 significantly, which shows that FB_2 is mainly retained by reversed-phase action. Two other brands of mixed mode columns (Agilent Bond Elute Plexa PAX and Biotage Evolute AX) were also investigated. However, both gave approximately 50% lower recoveries when tested at the same conditions as the Oasis MAX columns (results not shown). During method development, different glass and polypropylene vials were tested for evaporation of the SPE eluate. Loss of up to 75% of FB_2 was observed in single-use glass reagent tubes, whereas less but still up to 40% was lost on 15 mL polypropylene centrifuge tubes, with the lowest on acid washed and silanized glass vials. The loss of FB_2 was about half when the coffee matrix was present and insignificant for OTA with and without matrix. This suggested that the amine group of the fumonisins could be bound to the free silanol groups on the glass surface of the used test tubes. Interestingly, polypropylene was still not as good as acid washed glass and shows that for evaporation of fumonisin solutions, strict control with tubes/vials quality is necessary.

UHPLC-MS/MS Optimization. It was not possible to avoid the SPE purification by direct injection of the QuEChERS extract, but even with a reduced sample load compared to the SPE purified extracts, signal strength was much lower and many interfering peaks were observed. Even with the SPE purification, the relatively flat gradient was needed to elute polar impurities, especially interfering with OTA.

During the SPE fine-tuning, we also tested pure MeCN against MeCN with 20% isopropanol as LC solvent B (kindly suggested by Joachim Thiemann, Agilent Technologies). Here, the 20% isopropanol gave for green coffee 95−113% higher signal for OTA in the range 1−10 μg/kg (n = 8) range) and 55−75% higher signal for FB_2 in the range 10−100 μg/kg (n = 8)). In instant coffee tested at the same concentrations, the effect was less pronounced with 20−30% higher signal for OTA but the same 54−83% for FB_2. Finally, in roasted coffee tested at the same concentrations, the increase was 57−74% for FB_2 but only 20−40% for OTA. Besides better signals, the R^2 for signal versus concentrations of all the above-mentioned comparisons also increased typically from 0.998 to 0.999.

Due to the 50% MeCN in water (v/v) used for redissolving the sample, the maximum injection volume was 1 μL. When higher volumes were used, the eluted peaks were broader and ion-suppression was more pronounced. The elaborate injector

cleaning program using the extra Agilent flex-cube module was necessary, as the default methanol cleaning of the needle and flow during the gradient gave a carry-over of >1:5000 of both fumonisins and OTA, presumably the carry-over occurs in the valve system and to some extend in the needle seat. The chromatographic gradient could resolve all the fumonisins FB_1, FB_2, FB_3, FB_4, and FB_6. Standards of FB_4 and FB_6 were only available in very limited amounts and were therefore not validated. In the present study, the two compounds were quantitated using their peak areas relative to the FB_2 peak multiplied with the measured FB_2 amount in the sample. Eluting in a close window with almost the same percent organic solvent, and all having a free amino group where the charge resides,[30] fumonisins ionize almost equally. However, with MS/MS, FB_4 will probably be overestimated by 20−30% because it has one hydroxyl group fewer than FB_2 and thus less possible fragment ions due to one less possible water loss. Conversely, FB_6 can lose one more water molecule than FB_2, resulting in more fragment ions giving a lower response.

Validation. Because most coffee sold in Denmark is roasted ground, this was validated on 10 different days, whereas green and instant coffee were validated for only 5 days.

As seen in Table 1, the average deviation for OTA in roasted coffee was <6%, although with the maximum close to 13% (n = 10), which is fully acceptable. The deviation for fumonisin was very similar and surprisingly comparable to the results of the two other matrices. We have expected a lower amount in the green coffee as it contains fewer impurities.

The deviation can probably be lowered by adding the ^{13}C internal standards to the dry coffee prior to extraction (correcting for differences in losses during the QuEChERS extraction), but this would make the method much more costly due to a higher consumption of internal standards.

The sensitivity did vary considerably over 1 year due to instrument cleaning, a problem with the electronics controlling Q1 (required the unit to be changed), and numerous other projects running on the instrument. The LOD and LOQ values as listed in Table 1 were worst case determined limits. Actual values were in most cases much better (5−10-fold). However, with the regulatory limit of OTA being higher, no problem exists, and the slightly higher limits for fumonisins are not a problem as they are far less toxic than OTA.

Table 2 shows the recoveries of the sample preparation procedure including both the QuEChERS extraction and the SPE purification. As shown, the recovery was independent of the level for both target groups but depended on the matrix for FB_2, as the recovery was significantly lower in instant and roasted coffee than green coffee. This shows that quantification needs to be done from the spiked matrix.[31,32] Overall, the recovery of OTA was very satisfactory with a recovery above 75% in all sample matrices. For FB_2, it was 40% but reproducible, which has also been observed elsewhere.[33] The low recovery is corrected by the matrix-matched calibration, but the value is still below 60%, which is the requirement for EU methods. However, given the lack of regulatory limit for fumonisins in coffee, good recovery for the regulated compound OTA, as well as the possibility of adding ^{13}C-labeled internal standards, the method remains sound and is significantly cheaper than alternatives.

The loss must be due to the zwitterionic nature of FB_2 where it can be speculated that the amine binds to acid interfering substances in the aqueous water phase. In a recent study, QuEChERS combined with cleanup by immuno-affinity columns was described for the analysis of different mycotoxins in green coffee and other food products including OTA, FB_1, and FB_2.[1] The recovery for OTA was very similar to our findings with green coffee. However, no validation data was reported for FB_1 and FB_2 in their green coffee samples.[1]

All three matrices still showed a slight but consistent signal enhancement for OTA. This was 10−40% for instant coffee, 20−50% for roasted coffee, and 10−40% for green coffee. For FB_2, the matrix effect was more variable with −10 to +30% for instant coffee, 10−70% for roasted, and −10 to +60% for green coffee. This shows that it is necessary to use ^{13}C-labeled internal standards to correct for this effect.[31,32]

The trueness of the method was investigated by determining the OTA content in a roasted reference material obtained from FAPAS with an assigned value of 4.36 μg/kg. This sample was analyzed four times over a period of 6 months on different days.

DOI: 10.1021/jf504254q
J. Agric. Food Chem. 2015, 63, 1029−1034

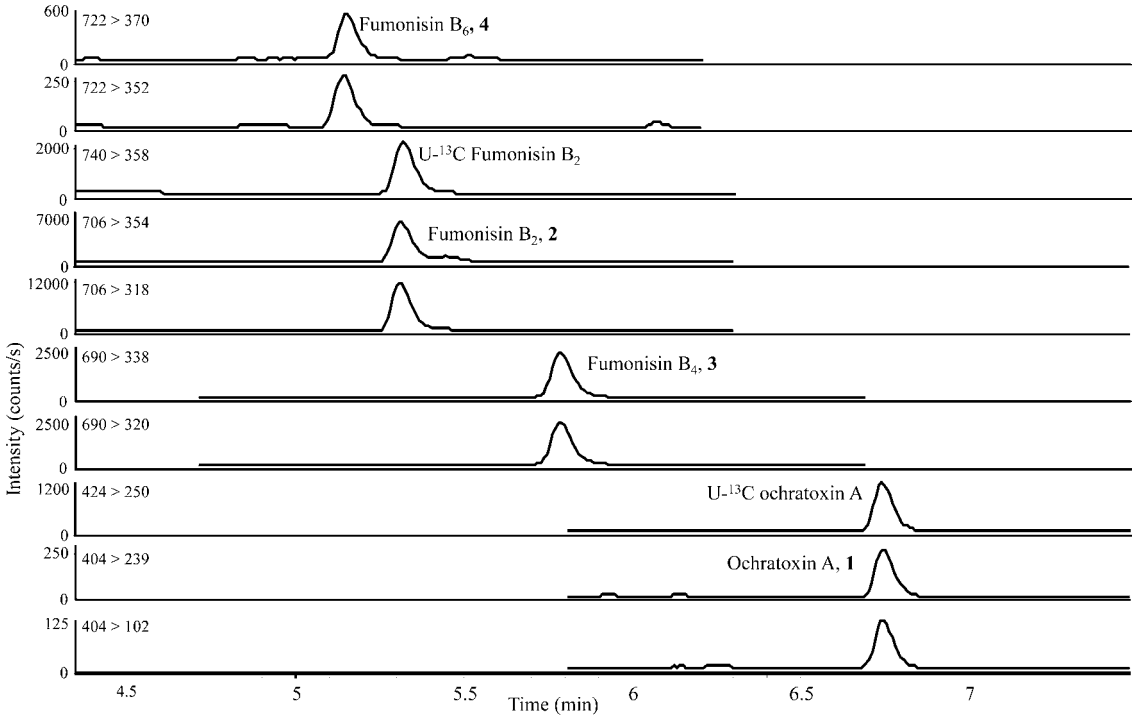

Figure 2. MRM chromatogram from naturally infected green coffee containing fumonisins B_6 (5 μg/kg*), B_2 (134 μg/kg), and B_4 (25 μg/kg) as well as ochratoxin A (2.4 μg/kg). *Below calculated LOQ of fumonisin B_2.

The concentrations of OTA were measured to be 6.04, 5.71, 5.47, and 6.67 μg/kg, respectively. The Z score specified by FAPAS is considered to be satisfactory if the measured result of OTA is between 2.44 and 6.27 μg/kg. This means that three of the results are within this range, whereas the latter was determined to be slightly high.

Retail Samples. In Table 3, an overview of the screened retail samples is listed. For the roasted samples, all purchased in Denmark, about 10% of the samples were above the regulatory level of 5 μg/kg.

Instant coffee did not contain levels above the regulatory limit for OTA and neither did the green coffees, but for the latter, almost half of the samples (purchased in Kenya and Tanzania) contained fumonisins in levels up to 164 μg/kg fumonisins (sum of the three isomers), as illustrated in Figure 2. The fumonisin profile of $FB_2 > FB_4 > FB_6$ and no FB_1 nor FB_3 showed that *A. niger* was the producing organism and not *Fusarium* spp.,[15] and thus, this is the widespread contamination presumably occurring when drying fruits are on/in the soil where *A. niger* is found.[34] This finding combined with the lack of fumonisins in the processed coffee samples suggested that the fumonisins decompose during roasting. This was confirmed by the roasting of a sample containing 164 μg/kg fumonisins, which after 20 min of roasting (medium roast as judged by the color) did not contain any measurable traces of fumonisins. Although the roasting process was not conducted at true production conditions, the OTA content in this sample was reduced from 2.4 to 0.5 μg/kg corresponding to a reduction of approximately 80%. This value is comparable to other studies of OTA reduction during green coffee roasting.[35]

To summarize, a method for the simultaneous analysis of OTA and fumonisins was developed for the three major coffee types using a combination of QuEChERS, mixed-mode anion exchange and UHPLC-MS/MS. Screening of 57 roasted coffee samples from nine countries showed that OTA is present in approximately half of the samples. The regulatory limit of 5 μg/kg was exceeded in five of these samples with a maximum obtained value of 21 μg/kg. Fumonisins were not detected in any of the roasted (n = 25) and instant coffee samples (n = 25). However, in green coffee, fumonisins were found in 44% of the analyzed samples (n = 18) with a maximum value of 164 μg/kg referred to the sum of fumonisin B_2, B_4, and B_6. A roasting study with several samples of the fumonisin-contaminated green coffee showed that they totally decomposed, which also explains the lack of detection in the roasted and instant coffee samples.

J. Agric. Food Chem. 2015, 63, 1029−1034

functions to break down food and nutrients to be absorbed into the body, and the intestinal epithelium is the first physiological barrier after oral intake of the compounds. In order to obtain a more comprehensive insight into the cytotoxicity and apoptotic mechanisms of 7-ketophytosterols, cell viability, cell cycle analysis, and cell apoptosis induced by these compounds were studied. For comparison, the cytotoxic effects of 7-ketocholesterol (7K-CH) were also assessed in the HIC cell line. In addition, several modulators of apoptosis (caspase-3 and Bcl-2) were investigated to determine whether these compounds were responsible for the intrinsic pathway of apoptosis in HIC cancer cells.

MATERIALS AND METHODS

Materials. 7K-CH was purchased from Sigma-Aldrich Company (St. Louis, USA). 7K-ST and 7K-MIX were separately chemically synthesized from stigmasterol (Sigma-Aldrich Company, St. Louis, MO, USA) and phytosterols (Cognis, Saint-Fargeau-Ponthierry, Seine-et-Marne, France) as described by Gao et al.[28] The other three individual POPs (7K-SI, 7K-CA, and 7K-BR) were not commercially available and therefore were separated by semipreparative HPLC and characterized as described in the literature.[28] Except 7K-BR and 7K-MIX, the purity of each individual 7-ketosterol compound was ∼95%. 7K-BR contained 52% 7-ketobrassicasterol and 48% 7-ketoavenasterol, whereas the blend of 7K-MIX contained 45% 7K-SI, 32% 7K-CA, 10% 7K-BR, and 9% 7K-AV. The profile of this mixture reflected the composition of related phytosterol oxides in the plant oil.[28] The chemical structures of these compounds are available in the literature.[28]

Cell Culture and Treatment. The HIC cell line was obtained from Chinese Academy of Medical Sciences Tumor Cell Culture (Beijing, China). HIC cells were cultured in DMEM/high glucose medium (Hyclone, Beijing, China) supplemented with 10% (v/v) fetal bovine serum (FBS), 100 U/mL penicillin G sodium, and 100 μg/mL streptomycin sulfate at 37 °C and 5% CO_2 in a humidified incubator. Cells were routinely harvested by treatment with a 0.25% trypsin-EDTA solution. Cultures were allowed to reach 80% confluence before experiments were performed.

For treatment, all above-mentioned 7-ketosterols were separately dissolved in 100% ethanol and added to the cells to a final concentration of 30, 60, or 120 μM. The concentrations used here were physiologically significant and shown in some published studies.[21,22,29] Equivalent quantities of ethanol were added to the control cells, and the final concentration did not exceed 0.5% (v/v) in the culture medium. Cells were then harvested after 24 h treatment for determination of cell viability, apoptotic effect, cell cycle, caspase-3 activity, and Bcl-2 content analysis.

Cell Viability. Cell viability was determined by using the Cell Counting Kit-8 (CCK8) assay (Dojindo, Kumamoto, Japan), which is based on a reaction catalyzed by dehydrogenase of the mitochondria. Within this assay, cells were adjusted to a density of 2×10^4 cells/well in 96-well plates. After incubation with different concentrations of 7-ketosterol oxides, the culture medium was discarded, cells were washed with PBS, and then 200 μL of 10% CCK8 in culture medium was added and incubated at 37 °C for 2 h. Absorbance was read at 450 nm with a Fluostar Optima microplate reader (BMG Labtech, Ortenberg, Germany) and expressed as the viable cell number as a percentage (%) of control cells. Measurements were made in triplicates.

Cell Apoptosis and Cell Cycle Assay. HIC cells (5×10^5) were seeded in the wells of a 6-well plate and harvested by trypsinization (0.25% trypsin with EDTA) after exposure to different doses of 7-ketosterol oxides for 24 h. With the Annexin V-FITC Apoptosis Detection Kit (BD Biosciences, Franklin Lakes, NJ, USA), cells were stained with fluorescein isothiocyanate (FITC)-conjugated annexin V and propidium iodide (PI) according to the manufacturer's protocol. Apoptotic cells were then analyzed by BD FACScan flow cytometry (BD Biosciences, Franklin Lakes, NJ, USA).

For cell cycle analysis, cells were centrifuged and fixed in 2 mL of methanol/PBS (9:1, v/v) at 0 °C overnight, washed twice in PBS, and resuspended in 200 μL of PBS containing 0.25 mg/mL RNase A for 30 min and then stained in 50 μL of PI (0.2 mg/mL in PBS) with incubation in the dark at 4 °C for 30 min. The fluorescence of 1×10^4 cells was then analyzed by BD FACScan flow cytometry (BD Biosciences, Franklin Lakes, NJ, USA).

Caspase Activity Assay. The measurement of caspase-3 activity was performed using a Caspase-3 Assay Colorimetric Kits (Sigma-Aldrich, Hamburg, Germany) according to the manufacturer's protocol with some modifications. Briefly, HIC cells (1×10^6) were seeded in 60 mm culture dishes and exposed to 7-ketosterol oxides for 24 h and then collected and lysed at 0 °C. Lysates were clarified by centrifugation at 10000*g* (4 °C) for 10 min, and the supernatants were carefully transferred to a new microcentrifuge tube without disturbing the cell-debris pellet in the collection tube. Protein (50−200 ng) was incubated with 50 μL of reaction buffer and 5 μL of caspase-3 (Ac-DEVD-pNA) colorimetric substrate at 37 °C for a further 4 h. The cleavage of the peptide substrate was monitored at 405 nm using a 96-well microplate reader (Bio-Rad, Hercules, CA, USA). The samples were analyzed in triplicate.

Bcl-2 Content. The Bcl-2 level in HIC cells exposed to 7-ketosterol oxides for 24 h was quantified using a Human Bcl-2 Platinum ELISA Kit (BMS244/3, eBioscince, San Diego, CA, USA). The supernatant from cells was removed; cells (5×10^6) were washed once with PBS and harvested by scraping and gentle centrifugation. PBS was aspirated, and an intact cell pellet was frozen at −80 °C for lysis at a later date. The cultured cells were resuspended in lysis buffer and incubated 60 min at room temperature with gentle shaking, and extracts were transferred to microcentrifuge tubes and centrifuged at 1000*g* for 15 min. According to the supplier's instructions, the supernatant was added to the wells of the ELISA plate. The absorbance was measured at 450 nm using a Fluostar Optima Microplate Reader (BMG Labtech, Ortenberg, Germany), and the data were expressed as a percentage of the untreated control sample.

Statistics. All data points represented the mean value (SE) of at least three independent experiments. One-way analysis of variance (ANOVA) and the LSD test were applied to determine differences in cytotoxic effects, apoptosis effects, changes of cell-cycle arrest, and changes in expression of caspase-3 and Bcl-2 between treated and control cultures. Statistical differences were considered significant at a value of $p < 0.05$ and reported as $p < 0.05$ and $p < 0.01$.

RESULTS

Cell Viability Effects of 7-Ketosterols on HIC Cells. CCK8 cell viability assay was used to evaluate the cytotoxicity of the tested compounds after 24 h of exposure. Viability of the control sample was set at 100%. As shown in Figure 1, as the positive control, 30 and 60 μM 7K-CH caused 50% and 38% HIC cell growth inhibition ($p < 0.01$), respectively, whereas 60 μM of five 7-ketophytosterol oxides only caused 10−20% growth inhibition. This indicated that HIC cells were more sensitive to 7-ketocholesterol than 7-ketophytosterols. After treatment with 120 μM 7-ketophytosterol oxides for 24 h, all individual test compounds induced a significant reduction ($p < 0.01$) of cell viability relative to the negative control, and the cell survival was 37%, 39%, 56%, and 79% for 7K-SI, 7K-CA, 7K-BR, and 7K-ST treated cells, respectively. In contrast, 7K-MIX caused no significant change in cell viability at all test concentrations.

7-Ketophytosterols Induce Apoptosis on HIC Cells. We then elucidated whether the cytotoxic effects of 7-ketosterols were mediated through apoptosis. At low dose of 30 μM, all 7-ketophytosterol oxides caused no obvious change in the percentage of apoptotic cells. At 60 μM, there was a significant increase ($p < 0.05$) in apoptotic cells by all tested compounds treatment compared with the control group. At

J. Agric. Food Chem. 2015, 63, 1035−1041

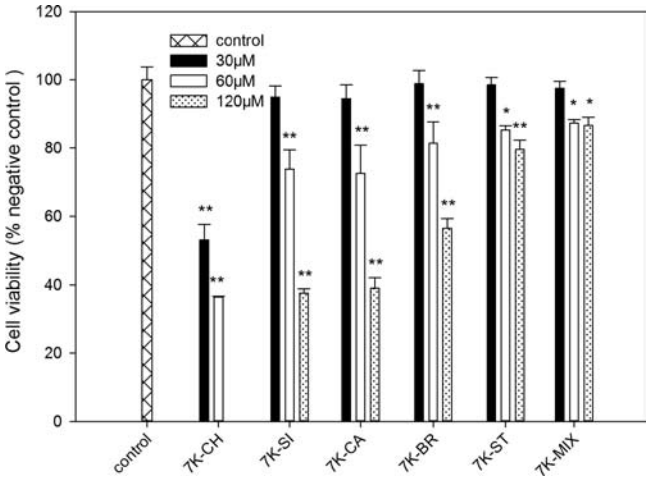

Figure 1. Cell viability measured by the CCK8-test. HIC cells were exposed to 0.5% ethanol (control), 30, 60, and 120 μM of 7-ketophytosterol oxides (7K-SI, 7K-CA, 7K-BR, 7K-ST, and 7K-MIX) or 30 and 60 μM of 7K-CH for 24 h. Values are mean ± SE of three separate experiments and are marked when significantly different from control levels (*p < 0.05, **p < 0.01).

high dose of 120 μM, 7K-SI, 7K-CA, 7K-BR, 7K-ST, and 7K-MIX caused early apoptotic cells to 64.0%, 53.6%, 17.5%, 15.9%, and 14.8%, respectively (Figure 2).

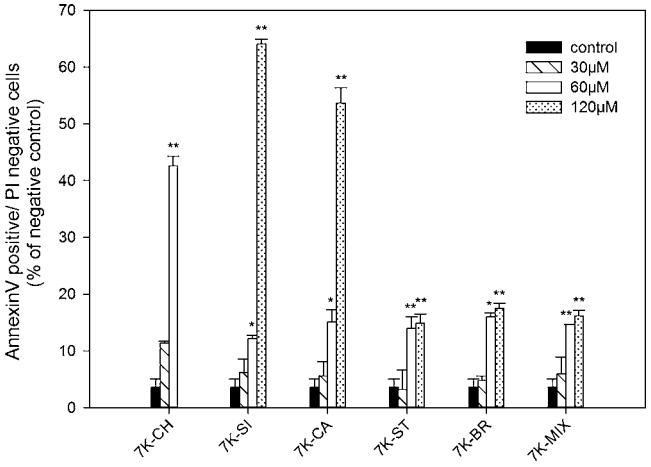

Figure 2. Percentage of apoptosis in HIC cancer cells following exposure for 24 h to 30, 60, and 120 μM of 7-ketophytosterol oxides (7K-SI, 7K-CA, 7K-BR, 7K-ST, and 7K-MIX) or 30 and 60 μM of 7K-CH. All compounds were dissolved in ethanol and equivalent quantities of ethanol were added to control cells. Apoptotic cells were assessed with fluorescein isothiocyanate (FITC)-conjugated annexin V and propidium iodide (PI). Values are mean ± SE of three separate experiments and are marked when significantly different from control levels (*p < 0.05, **p < 0.01).

Effect of 7-Ketophytosterols on Cell Cycle. The effect of 7-ketosterols on cell cycle progression was determined by flow cytometry with PI-based staining. Results showed that after 24 h of 7-ketosterol treatment, the normal cell cycle progression was disrupted in HIC cells (Figure 3). At 60 μM, 7K-CH increased the percentage of cells in G1 phase from 40.5% to 79.4% and decreased the percentage of cells in S phase from 43.5% to 25.8% (p < 0.05) (Figure 3A). In contrast, when the cells were exposed to 120 μM of 7K-SI (Figure 3B), 7K-CA (Figure 3C), or 7K-ST (Figure 3E), the proportion of cells in G1 phase decreased from 40.5% to 26.8%, from 40.2% to 34.5%, and from 39.9% to 35.3%, respectively, whereas 7K-SI and 7K-CA caused the accumulation of cells in S phase from 42.0% to 52.9% and from 41.0% to 51.5% (p < 0.05), respectively. At all concentrations tested, 7K-BR (Figure 3D) and 7K-MIX (Figure 3F) did not show a significant difference (p > 0.05) in G1 and S phases. In addition, all the tested compounds did not lead to increase in the sub-G1 phase population.

Effect of 7-Ketophytosterols on Caspase-3 Activity in HIC Cells. To assess whether 7-ketophytosterols induce caspase activation, which plays an important role in the execution phase of cell apoptosis, caspase-3 activity was evaluated. As shown in Figure 4, relative to the control group, significantly increased caspase-3 activity was observed in HIC cells treated with 60 and 120 μM 7K-SI, 7K-CA, and 7K-BR for 24 h in a dose-dependent manner. Caspase-3 activity was enhanced 3-, 2-, and 1.3-fold relative to control group in response to the incubation with 120 μM 7K-SI, 7K-CA, and 7K-BR, respectively (p < 0.01). In contrast, caspase-3 activity remained at a basal level when HIC cells were treated with 7K-ST and 7K-MIX at all of the concentrations tested.

Effect of 7-Ketosterols on Bcl-2 Protein in HIC Cells. To further verify the apoptotic effect, we investigated the changes in activity of the apoptosis-related proteins triggered by the tested 7-ketosterols. Results showed that, compared with control cells, the HIC cell protein levels of Bcl-2 declined after treatment with 60 μM 7K-CH, 120 μM 7K-SI, and 120 μM 7K-CA, which favors the induction of apoptosis (Table 1). The Bcl-2 protein level was increased after treatment with 7K-BR at 30 μM, while it was decreased after treatment at 120 μM (p < 0.01). Bcl-2 remained at a basal level in cells treated with 7K-ST and 7K-MIX (60 μM and 120 μM) relative to the untreated control.

DISCUSSION

The present study was focused on the biological implications of individual and mixed 7-ketophytosterol oxides on HIC cell line. A further objective was to assess the death pathways related to Bcl-2 and caspase-dependence induced by these phytosterol oxides.

We found that 7-ketophytosterol oxides displayed different cytotoxic and apoptotic effects on HIC cells. Except 7K-ST and 7K-MIX, other 7-ketophytosterol oxides (7K-SI, 7K-CA, and 7K-BR) were capable of inducing growth inhibition and apoptosis on HIC cells in a dose-dependent manner after 24 h treatment. At 120 μM, the order of 7-ketophytosterol oxide toxicity was 7K-SI > 7K-CA > 7K-BR > 7K-ST > 7K-MIX. 7K-SI was the most cytotoxic and apoptotic compound, exerting the strongest reduction in cell viability and inducing cell apoptosis, whereas 7K-ST (120 μM) resulted in decreased cell viability with low level apoptosis in HIC cells. The cytotoxicity of 7K-CA was demonstrated for the first time, in the present study: cell apoptosis was induced when HIC cells were exposed to 7K-CA (60 and 120 μM), but its cytotoxic and apoptotic effects were less than those of 7K-SI. In addition, 60 μM 7K-CH induced even higher cytotoxicity than 120 μM 7K-SI. This finding was in agreement with the results of Maguire et al.[19] and Ryan et al.[20] that β-sitosterol oxides had general toxic effects similar to COPs but higher concentrations of POPs were required to obtain comparable results.

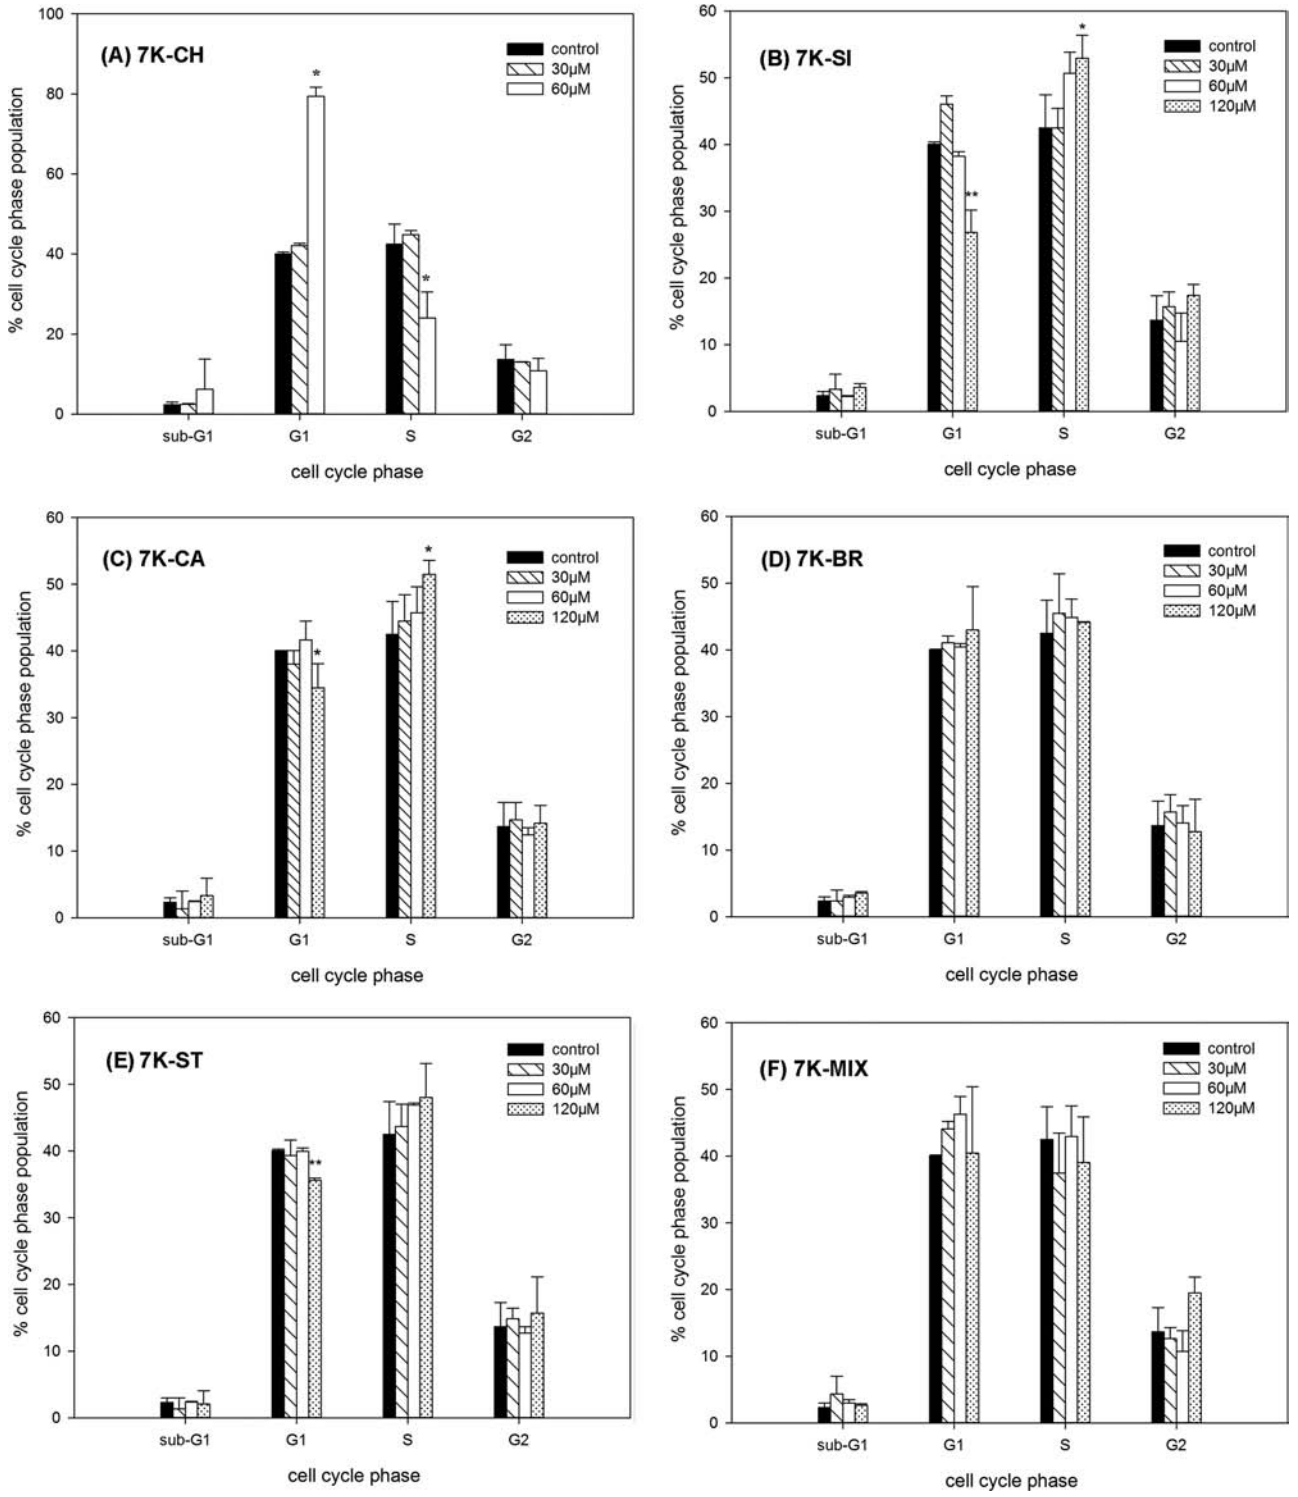

Figure 3. Changes in cell cycle phase populations of HIC cells exposed to 30, 60, and 120 μM of 7-ketophytosterol oxides (7K-SI (B), 7K-CA (C), 7K-BR (D), 7K-ST (E), and 7K-MIX (F)) or 30 and 60 μM of 7K-CH (A) for 24 h. Values are mean ± SE of three separate experiments and are marked when significantly different from control levels (*$p < 0.05$, **$p < 0.01$).

The differences in susceptibility of cells to sterol oxide treatment might be related to the chemical structures of sterol oxides and the genetic background of the cell lines.

7-Ketosterol oxides are structurally similar compounds that possess the same sterol nucleus (one double bond at C5−C6 and a ketone group at C7 in the B-ring) but a small difference in the side chain (such as substitution at C24 or an additional double bond between C22 and C23). We found that, in the present study, HIC cells were more sensitive to the 7-ketosterol oxides that had no double bond in the side chain (7K-CH, 7K-SI, and 7K-CA) than other oxides with a double bond between C22 and C23 in the side chain (7K-ST and 7K-BR). The substitution of the double bond in the side chain (7K-ST) might influence the equilibrium between the ketone form and

hydroxide adducts, which might be shifted by interaction with proteins at the intestinal epithelial level.[23]

Ryan et al. reported that β-sitosterol oxides produced different toxic effects in U937, Caco-2, and HepG2 cell lines, but without inducing apoptosis in either HepG2 or Caco-2 cells.[24] Koschutnig et al. reported a decrease in HepG2 cell viability upon exposure to single β-sitosterol oxide but little effects induced by the mixture of polar oxides.[21] Other studies indicated that 7-ketostigmasterol (30−120 μM) had no cytotoxic effects on U937 cells[24] and Caco-2 cells.[27,29] It is well-known that the U937 cell line can express the Fas antigen and is sensitive to TNF and anti-Fas antibodies.[30,31] Caco-2 cells express retinoic acid binding protein I and retinol binding protein II.[32] HepG2 cells retain many functions of the normal liver cell, express 3-hydroxy-3-methylglutaryl-CoA reductase and hepatic triglyceride lipase activities, have decreased expression of apoA-I mRNA, and have increased expression of catalase mRNA in response to gramoxone (oxidative stress).[33] Combined our experimental results that 7-ketosterol oxides displayed different cytotoxic and apoptotic effects on the HIC cell line, this suggested that the toxicity of sterol oxides on different cell lines depends on the physiological area in which they work.

In addition, synergistic as well as inhibitory effects of individual sterol oxides in mixtures had been noted.[34] Some studies indicated that oxysterols as a mixture did not elicit the same cytotoxic effects and defensive responses as the individual oxysterols.[35−37] They suggested that major oxysterols were not universally cytotoxic and the simultaneous presence of several different oxysterol species might reduce the adverse effects of individual oxysterols.[35] These finding were consistent with our results that 7K-MIX exerted a reduction of the toxic potential compared with the individual phytosterol oxides (7K-SI, 7K-CA, and 7K-BR).

The studies of cytotoxicity were also supplemented with cell cycle assay. Alemany et al. reported that exposure to neither 7K-ST nor 7K-CH led to increases in the sub-G1 phase population in Caco-2 cells.[23] Similar results were found in HIC cells treated by all the tested compounds in the present study. In addition, 7K-CH (60 μM) caused cell cycle arrest in the G1 phase and decreased the percentage of cells in S phases, whereas 7K-SI and 7K-CA (120 μM) led to an accumulation in S phase, and a simultaneous decrease of cells engaged in the G1 phase in HIC cells. Therefore, there is not definite relationship between 7-ketosterol structures and their effect on the cell cycle.

Apoptosis is a highly regulated physiologic cell death process that is critical for development, host defense, and the prevention of malignant transformation and inflammation throughout the body.[38,39] There are two major pathways regulating apoptosis: the intrinsic pathway mediated by the mitochondria,[40] and the extrinsic pathway induced by the death receptor.[41,42] Recently, new apoptotic mechanisms including caspase-independent pathway and granzyme-initiated pathways have been shown to exist in lymphocytes.[42,43]

Regarding the death pathway of oxide derivatives of sterols, Prunet et al. demonstrated that caspase-3 was essential to trigger 7-ketocholesterol- and 7β-hydroxycholesterol-induced apoptosis, and these oxysterols simultaneously activate caspase-3-dependent or -independent modes of cell death.[44] Roussi et al. reported that 7β-hydroxysitosterol and 7β-hydroxycholesterol followed different death pathways despite their structural similarity.[21] In the case of 7β-hydroxysitosterol, the intracellular caspase-9 and -3 was activated in Caco-2 cells. In contrast, 7β-hydroxycholesterol did not activate caspase-3.[21] They caused mitochondrial depolarization but not involve the Bcl-2 family proteins in Caco-2 cells.[21,22] In addition, caspase-8 was not activated in cells treated with both hydroxysterols.[21] Alemany et al. showed that 7K-CH regulate key enzymes HMG-CoA in cholesterol metabolism and cause alterations in mitochondrial membrane potential in Caco-2 cells.[27]

Considering the complexity of the sterol oxides involved in the death way, in our present study, Bcl-2 and caspase-3 were detected to preliminary confirm the intrinsic death pathway of

7-ketosterols. It is becoming clear that the Bcl-2 family proteins play an important role in the regulation of apoptosis at the mitochondrial level. Dysregulation of the Bcl-2 proteins was proved to induce the destruction of mitochondrial membrane, which result in the release of cytochrome *c* and apoptosis-inducing factors from the mitochondria and subsequently induces activation of the caspase cascade.[45,46]

Significant changes were found in expression of the apoptosis related Bcl-2 family proteins after treatment with phytosterol oxides. In the present study, 7K-CH (60 μM) and 7K-SI and 7K-CA (120 μM) caused a significant decrease in the level of antiapoptotic protein Bcl-2, which in turn resulted in the activation of caspase-3. Caspase-3 activity analysis showed that treatment of 7K-CH, 7K-SI, and 7K-CA did activate apoptosis proteins caspase-3 with dose-dependent manner. However, no significant changes in expression of Bcl-2 protein were found after 24 h treatment with 7K-ST and 7K-MIX in HIC cells. It might involve various apoptosis mechanisms or cell death pathway.

In conclusion, our study demonstrated that HIC cells were significantly more sensitive to 7K-CH, 7K-SI, and 7K-CA treatment than other 7-ketophytosterol oxides. The cytotoxicity of 7K-CA was demonstrated at first time and analogue to 7K-SI. 7K-SI and 7K-CA modulated cell viability, proliferation, and expression of apoptosis-related proteins. Since induction of cell cycle arrest was usually accompanied by growth inhibition, the research is required to identify which cell cycle regulators attribute to the alteration of specific phases of cells. Moreover, further study is required to clarify the precise pathway of POPs-induced apoptosis.

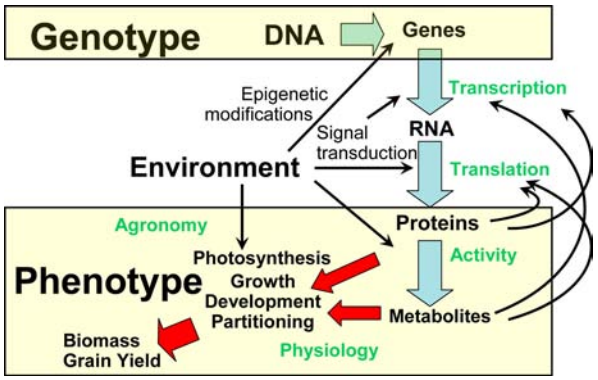

Figure 1. Model showing the large gap between genotype and phenotype. The functional link between DNA and yield is complex because the environment acts at many different levels. Genes can be modified epigenetically by methylation and histone acetylation, which are both affected by the environment. Some epigenetic states can be stably inherited and are therefore relevant for breeding. Multiple feed-forward and feedback signaling loops between metabolites, proteins, and small ribonucleic acids (RNAs) complicate the specific pattern of gene expression. Genes represent "potential", whereas transcripts reveal the short-term "strategy". Proteins and enzymes do the "work", whereas the final "results" are the metabolites that are accumulated in a certain storage organ (e.g., starch in seeds). From this model, it is apparent that metabolites are much closer to grain yield than any DNA sequence, and therefore, selection for biomarker metabolites should be more relevant for breeding than selection for molecular markers [e.g., microsatelites, single nucleotide polymorphisms (SNPs), quantitative trait loci (QTL), etc.].

analytical methods should be retailored to be faster, save reagents, reduce cost, and simplify/automatize data analysis.[6]

Mass spectrometry (MS) allows for the analysis of a large number of chemical compounds and is a promising tool for agricultural research.[5−7] Traditionally, qualitative separation and quantitative detection are performed in two steps: upstream separation, such as liquid chromatography (LC) and gas chromatography (GC) first filters molecules because of physicochemical differences (affinity to a stationary or mobile phase), and then detection of positive or negative ions is performed according to the mass-to-charge ratio (m/z). In GC−MS, post-chromatographic molecular fragmentation is performed by electron impact (EI), a hard ionization method that results in the fragmentation of the molecules.[8] MS methods combining different chromatographic and ionization technologies have been used for phenotyping purposes, such as liquid chromatography−electrospray ionization−mass spectrometry (LC−ESI−MS) and gas chromatography−electron impact−mass spectrometry (GC−EI−MS).[9−12] Metabolic profiling based on GC−EI−MS is the most widely used in plant biology, e.g., for the phenotypic characterization of mutants, transgenic plants, and recombinant inbred line (RIL) populations.[6,13−16] It has also been used to characterize the metabolic response of maize hybrids subjected to drought.[12]

UPLC−MS is too expensive to be implemented for routine breeding in agricultural institutions of the subtropics. GC−EI−MS is more affordable, but unfortunately, it has several technical limitations. Each single chromatographic run requires 30−60 min, and therefore, less than 24−48 samples can be analyzed daily. Besides low throughput, GC−MS-based metabolic profiling depends upon volatility and ionizability of molecules, with both aims being somehow in contrast. On the one hand, ionizable molecules have less propensity to escape from the liquid phase the more charged that they are. On the other hand, uncharged molecules are volatile but do not ionize efficiently. Therefore, GC−EI−MS samples need to be previously derivatized to increase chemical coverage. The most widely used procedure is the addition of trimetylsylyl (TMS) groups,[14] which makes highly hydrophilic compounds, such as amino acids and carboxylic acids, volatile in the gas phase. Unfortunately, biomolecules are derivatized to several possible TMS compounds, each having different retention times (RTs) in the GC column. One single metabolite, such as citric acid, can generate more than 10 different RT peaks in a GC−EI−MS chromatogram. The difficulty is to decide which chromatographic peak should be used to quantify citric acid in the original sample. It becomes even more difficult because GC−EI−MS data are split in two dimensions (RT and m/z). Therefore, sophisticated data processing workflows are needed for data integration and statistical interpretation.[12] Manual processing and intuitive decisions have to be made relying on recommendations of experienced users.[12] Each group may follow particular philosophies, and therefore, GC−EI−MS and LC−ESI−MS data analysis can be considered both mathematics and art.[12,17] The bottleneck of LC−ESI−MS and GC−EI−MS profiling is the manual processing and individual interpretation of chromatographic data by the final user. Typically, a student requires several months for training, and even when it learns to perform GC−EI−MS by himself, a single user cannot fully process and interpret more than 24 samples per day, much less produce publication-ready graphics in less than 1 week (final throughput is very low).

Given the previously mentioned considerations, we decided to implement a metabolic profiling strategy that overcomes the following problems: (1) time-consuming chromatographic separation, (2) limited compound volatility and inefficient ionization of hydrophilic metabolites, (3) generation of multiple peaks because of chemical derivatization (data redundancy), (4) reliable, sensitive, and quantitative detection, (5) manual handling of chromatograms, and (6) complex data workflow and statistical processing (e.g., automatic data reduction and visualization). Inspired by the requirements of plant breeders, we aimed to develop an analytical platform that allows for a high sample throughput, produces a vast amount of quantitative chemical information, and is at the same time cheap, robust, and easy to handle bioinformatically.

Therefore, we compared several analytical methodologies, with particular focus on direct-injection electrospray ionization mass spectrometry (DIESI−MS).[18] We documented the genotypic and environmental effects on the metabolic profile of maize stem extracts. Our leading questions were as follows: Is DIESI−MS data quantitative and repeatable? Can we detect specific ions that have larger variance because of the environment (E) or the genotype (G)? How large is the throughput and how expensive is DIESI−MS profiling compared to other methods? Does this metabolic phenotyping strategy work for other plant samples in addition to maize?

MATERIALS AND METHODS

Plant Materials and Growth Conditions. *Maize Experiments under Nitrogen Stress.* The low nitrogen (LN) and control trial (CT) were performed during the 2011 summer season in El Batán, Texcoco, Mexico [19° 30′ N latitude, 98° 53′ O longitude, 2247 m above sea level (masl) altitude]. It was performed according to the field management standards established by the International Maize and Wheat Improvement Center (CIMMYT).[2] The LN treatment consisted of suppressing nitrogen fertilization during the previous

DOI: 10.1021/jf504853w
J. Agric. Food Chem. 2015, 63, 1042−1052

~4 years (8 cycles), whereas the control field was fertilized chemically with urea at the usual frequency (3 times per growth cycle) and dose (~400 kg/ha). Planting density was 67 000 plants/ha in two rows of 5 m distributed in randomized blocks (α lattice).[2] Six plants were sampled per genotype for each treatment (LN and CT). The CIMMYT field trial HL2011-11-01-PVB-2 was harvested ~10 days after silking (~85 days after sowing), while the field trial HL2011-11-01-PVB-1 was harvested ~12 days after silking (~85 days after sowing). DIESI−MS results are shown for 684 maize samples: 19 genotypes, 2 conditions (LN and CT), and 18 replicates (6 maize plants extracted 3 times each). Figures show the number of n behind each boxplot. Each of the 684 DIESI−MS runs lasted for 60 s, and all MS spectra acquired were averaged to increase accuracy and precision. In total, 4104 individual MS spectra were processed for the maize experiments.

Maize Stem Juice Collection. Representative healthy plants from each genotype and treatment were selected in the field and processed within ~15 min after harvest. Morphological and physiological data were rapidly registered: total plant weight, plant height (up to the flag leaf), number of ears, and ear weight. The tassel and the leaf blades were removed, and the supporting stem (including leaf sheath) was weighted and cut into segments (~30 cm) for tissue homogenization. The stem juice (phloem sap + xylem sap + cellular extracts) was obtained using a mechanical extractor (industrial-scale juice extractor model EXS, International Co., Mexico). The stem juice (~80 mL) was collected in a plastic beaker, weighted accurately (±0.2 g), aliquoted (1 mL), and frozen in dry ice immediately (<30 s). Collected samples were stored at −80 °C for ~4 months in sealed deep well plates (96 well format). For analysis, the stem juice was unfrozen and kept on ice for short time periods (<1 h). Samples were first centrifuged (10 min at 5000g and 4 °C), and the supernatant was used directly for metabolite analysis (see below).

Other Plant Samples. Leaves from different coffee and tea species were obtained as described previously.[18,19] Strawberry fruits were divided in three levels of ripeness (see Figure S1 of the Supporting Information). The level of ripeness was determined according to the following parameters: fruit turgor, fruit color, and peduncle color (see Table S1 of the Supporting Information).

Metabolite Analysis. Analytical methods were evaluated considering costs, sample throughput, and the requirements of chromatographic separation and chemical derivatization. We also evaluated the required workflow for computational and statistical analyses of the generated data. We excluded NIRS because it is well-known that it can simultaneously detect/discriminate only 1−3 different compounds reliably,[20] whereas MS-based methods produce information on more than 300 different metabolites. We also excluded high-end UPLC−MS and nuclear magnetic resonance (NMR) because machine costs are prohibitive for routine plant breeding.

Enzyme-Coupled Spectrophotometry Assays. Soluble sugars were measured in microplate format.[21,22] The insoluble starch pellet was dissolved in 0.5 mL of 10 mM KOH at 99 °C and autoclaved for 30 min. Starch was hydrolyzed in 50 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) (pH 7.5) at 37 °C overnight by the addition of 10 units of α-amylase (EC 3.2.1.1, Roche) and 10 units of amyloglucosidase (EC 3.2.1.3, Roche). Samples were centrifuged (13000g for 5 min); the resulting supernatant was stored at 4 °C; and the pellet was hydrolyzed again for 30 min at 37 °C. Both supernatants were combined, and an aliquot was enzymatically assayed for glucose, as described above.

DIESI−MS. The DIESI−MS assay was performed as described previously,[18,19] with some adjustments (see below). The stem juice supernatant was filtered through a 0.45 μm polyvinylidene difluoride (PVDF) filter and diluted 1:100 with deionized water to avoid saturation of the capillary and cone soiling. To improve ionization, to 475 μL of diluted sample and 25 μL pure formic acid were added [final concentration of 5% (v/v) formic acid]. Control experiments were carried out to determine optimal parameters of sample pretreatment and dilution (data not shown). The diluted and acidified samples were analyzed by DIESI−MS in positive mode, employing a Micromass ZQ 2000 with a quadrupole analyzer (Waters) and MassLynx 4.0 as control software.[18] A constant volumetric flow rate (10 μL/min) was achieved using a syringe pump loaded with 100 μL of sample. Capillary voltage was set to 3 kV; the cone voltage was set to 60 V; the extractor voltage was set to 3 V; and the radio frequency (RF) lens was left at 0.5 V. The source temperature (80 °C) and desolvation temperature (150 °C) were used with a nitrogen gas flow of 250 L/h and a cone gas flow of 50 L/h. In the analyzer section, low-mass (LM) and high-mass (HM) resolution of 15.0 and ion energy of 0.5 were set. The multiplier was adjusted to a value of 650. Continuous spectra were collected in a range of m/z 15−2000, with a total run duration of 1 min, a scan time of 10 s, and a interscan time of 0.1 s, producing six spectra per sample.

Data Analysis and Script Optimization. The raw MS spectra files were converted to *.mzXML using masswolf, version 1.4. Analysis of mass spectra was performed with the OpenMS/TOPP suite, version 1.8.0, and later further processed with the free statistical software R (http://www.r-project.org).[23] A TOPPAS pipeline was written executing the following sequential tasks: file conversion to mzML, spectra merger with a block method (six replicate spectra), NoiseFilter sgolay with a frame length of 21 and polynomial order of 4, followed by a PeakPicker with a signal-to-noise ratio (S/N) of 1 and a peak width of 0.15. Finally, data tables were converted into TOPPAS out files using raw text format, containing tab-separated columns for genotype names, treatment factors, m/z values, and corresponding signal intensities of the individual ions. Individual data files were then automatically imported with a tailored script into R.[23]

Besides sample harvesting and DIESI−MS workflow optimization, other advantages/novelties presented in this paper are the improved algorithms for data processing. The new R script imported all text files from a given directory and allowed for the definition of analysis of variation (ANOVA) experimental factors based on the original file name. Variable assignment was performed inside the R environment and did not require additional software for file merging or renaming. The R script was also optimized to process the data of hundreds of samples in $^1/_{10}$ of the time of previous scripts.[18,19]

Instead of naming peaks by interval boundaries,[18,19] m/z peaks were named by their center of maximal intensities. Instead of defining mass bins across the entire m/z range,[18,19] only real occurring m/z peaks were transferred to the rectangular result matrix used for the heatmap graphics. Instead of defining bin boundaries centered at 0, a mass shift was introduced to reduce bin jumping. The m/z bin boundaries were adjusted according to the observed m/z pattern (metabolic space) in various extracts: in the mass range of 50−400 Da, m/z peaks were centered at +0.2 Da from the unitary mass. In the mass range of 400−700 Da, a mass shift of +0.3 Da was more accurate. Ions were less frequent in the mass range of 800−2000 and had more variability in mass shift, so that it was more convenient to define bin centers based on the occurrence of specific ion peaks (metabolic space).

The improved R script also allowed us to define variably the tolerance of m/z peak assignment (bin size). However, for our plant samples, there was little gain of information by defining mass bins smaller than ±0.25 Da, and therefore, bin size was conveniently defined in 1 Da intervals (±0.5 Da from the center) across the entire m/z range (30−2000 Da).

When double peaks appeared in the same bin (e.g., isotopic peaks), intensities were summed up and not averaged or deleted. The optimized R script produced separate tables documenting the number of peaks per bin, intensity of single peaks, and summed intensity of multiple peaks. Automatic quality control was carried out to detect double-peak occurrence in individual mass bins.

In addition to presenting metabolic data as colored heatmaps, the optimized R script produced gray heatmap biclusters and various boxplot figures showing statistics and quality controls. For example, in addition to reporting the intensity values for given m/z ion bins, the script also ploted the exact m/z value for each sample group. The m/z residual (difference between the real observed mass and the unitary mass) was calculated for each peak and sample and plotted in parallel to the intensity boxplots (e.g., panels D−F of Figure 8). From this approach, users can decide if a given m/z value in one plant sample corresponds to the same metabolite in another plant sample. Ideally,

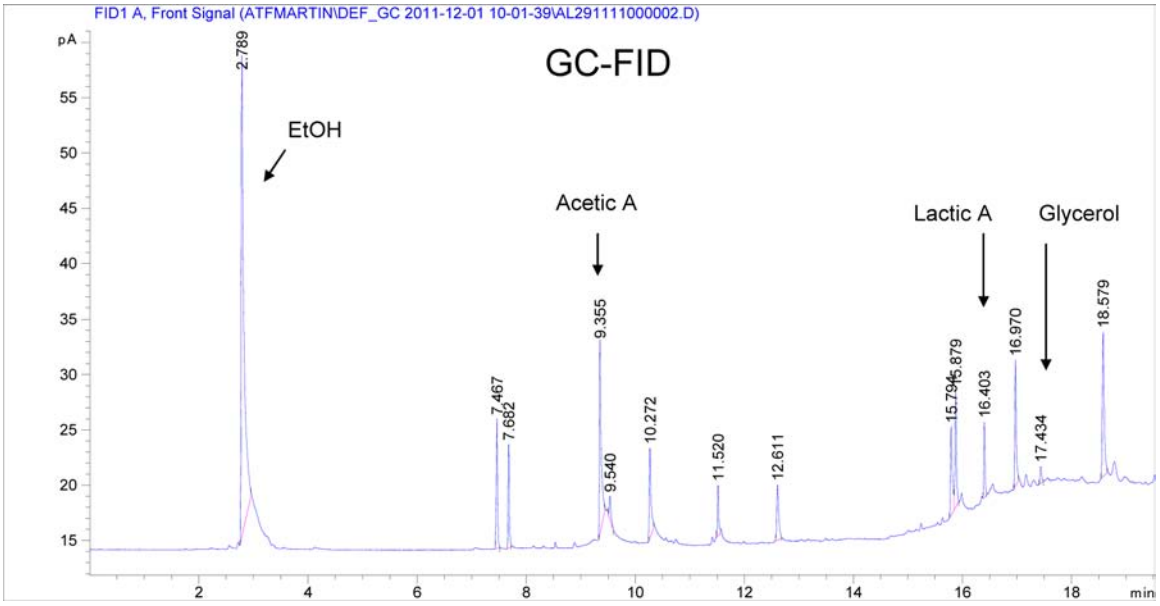

Figure 2. Typical GC−FID chromatogram of juice extracts of maize stem samples. Results correspond to the maize genotype CLQ-RCWQ83 harvested under well-watered conditions. RTs of standards were as follows: methanol, 2.53 min; ethanol, 2.78 min; acetic acid, 9.19 min; lactic acid, 16.38 min; and glycerol, 17.31 min.

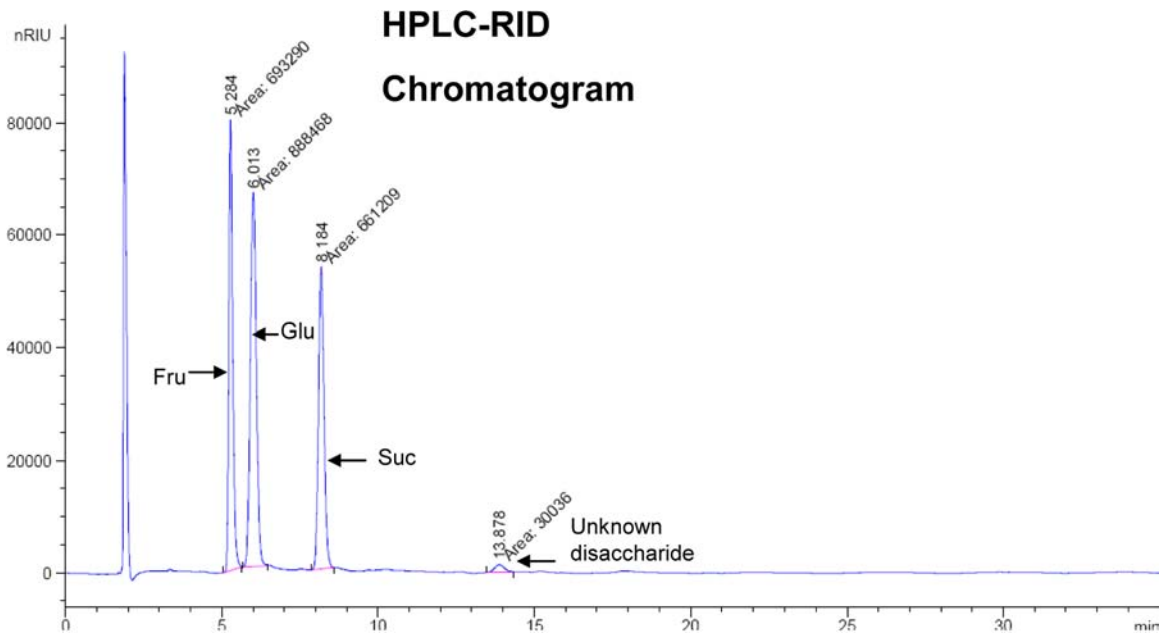

Figure 3. Chromatogram of juice extracts of maize stem samples acquired with HPLC−RID. The three main sugars were fructose, glucose, and sucrose. A fourth minor disaccharide of unknown nature was also observed in maize extracts. Other compounds rather than sugars are not detectable with this method.

m/z values of the same compound across samples should be similar, but in practice, they did vary ±0.2 Da with our quadropole MS equipment.

Overall, the optimized algorithm permitted automatic import of thousands of files, allowed for more rapid data processing, and also significantly increased reliability by diminishing "peak jumping" and eliminating the requirement of manual post-processing of data.

Statistical Procedures. All experiments were conducted using randomized complete block designs with an adequate number of controls and replicas (see the legends). ANOVAs and Tukey's least significant difference (LSD) test were applied with $p \leq 0.05$ (α = 0.05). Mixed effect linear models were used for the analysis of data, with separate factors for the effect of the G, E, development stage (DS), and their respective interactions. Bonferroni correction was used to address the false discovery rate. Statistical analysis was performed with R, version 2.10.[23]

RESULTS AND DISCUSSION

Comparison of Information Density Generated by Different Analytical Methods. Various samples were analyzed with the particular interest of determining the information density of different phenotyping strategies. Maize was grown under different environmental conditions under water and nitrogen stress.[12,18] Plants were harvested at the post-flowering stage, and stem juice aliquots were collected and

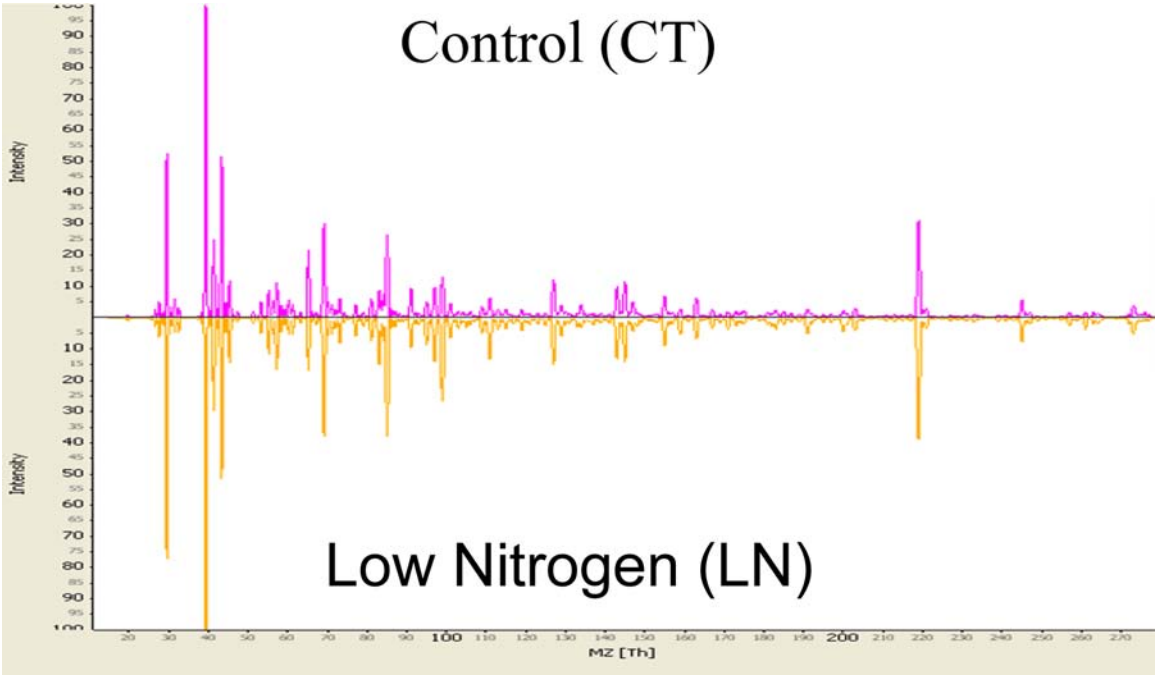

Figure 4. Mass spectrum of stem juice extracts of maize acquired with DIESI−MS showing ∼200 compounds. Maize were grown under normal CT and LN stress, and the stem was harvested ∼12 days after female flowering. Stem juice was extracted mechanically, and aliquots were frozen in liquid nitrogen until analysis. Data from a representative sample (genotype CV-702) are shown.

Table 1. Comparison of Analytical Platforms for Metabolic Phenotyping and Breeding Purposes with Respect to Throughput, Information Density, and Cost[a]

method/analytical platform	sample throughput per day technical/statistical	number of metabolites per assay	cost per sample ($ U.S./sample)	cost per metabolite data point ($ U.S./metabolite)
UV−vis enzymatic	384/384	1−3	∼10.00	3.33−10.00
UV−vis colorimetric	384/500	1	∼0.50	0.50
GC−FID	30/10	5−20	∼50.00	2.50−10.00
GC−EI−MS	24/2	50−100	∼80.00	0.80−1.60
UPLC−MS	48/2	200−1000	∼200.00	0.20−1.00
HPLC−DAD	24/10	3−15	∼80.00	5.30−26.67
NIRS	80/500	1−4	∼2.00	2.00−0.50
DIESI−MS	80/500	100−500	∼10.00	0.02−0.10

[a]Values were estimated from our experiences across several research projects at CINVESTAV and other institutes. Throughput is separated in technical (amount of samples that a laboratory can process) and statistical [amount of data files that an undergraduate student can analyze considering worktime for chromatogram integration, metabolite assignment, statistical analysis, etc. (∼human worktime)] throughput.

frozen for the simultaneous analysis with various analytical procedures [GC, HPLC, ultraviolet−visible (UV−vis), nano-assisted laser desorption ionization time-of-flight mass spectrometry (NALDI−TOF−MS), and DIESI−MS]. The gas chromatography with flame ionization detection (GC−FID) method allowed for the detection of ∼10 different peaks with satisfactory results (Figure 2). The chromatographic peaks had RTs of known alcohols and organic acids that are typically present in plant extracts (e.g., ethanol, acetic acid, lactic acid, glycerol, etc.) (Figure 2).

Using high-performance liquid chromatography with refractive index detection (HPLC−RID), ∼4 different peaks were detected with satisfactory results (Figure 3). The HPLC chromatographic peaks had retention times corresponding to glucose (glu), fructose (fru), and sucrose (suc) (Figure 3). Enzymatic assays coupled to NADPH using a UV−vis spectrophotometer (microplatte reader) specifically detected the three main sugars (glu, fru, and suc) that are typically present in plant samples. From this targeted method, the presence and amount of all sugars were confirmed in the maize stem extracts. The sugar ratio was dependent upon the G but also strongly dependent upon the DS and E conditions in which the maize plants were grown. Using ANOVA, the effects because of E, G, DS, and their interactions were discriminated. The variance effects because of G were in the range of 3−20% of the total phenotypic variance, which is excellent for breeding purposes in maize, because selection is only effective for the genetic variance.

We also employed analytical methods based on MS. NALDI−TOF−MS has the advantage to be relatively cheap if it is implemented routinely and further requires no previous chromatographic separation. With NALDI−TOF−MS we found ∼20 different peaks with a S/N of >10 (data not shown; see also ref 18). The information density generated with NALDI−TOF−MS did nor surpass the previous analytical methods, and therefore, we switched to another MS method that neither employs chromatography nor chemical derivatization: DIESI−MS. Using DIESI−MS in positive-ion mode, more

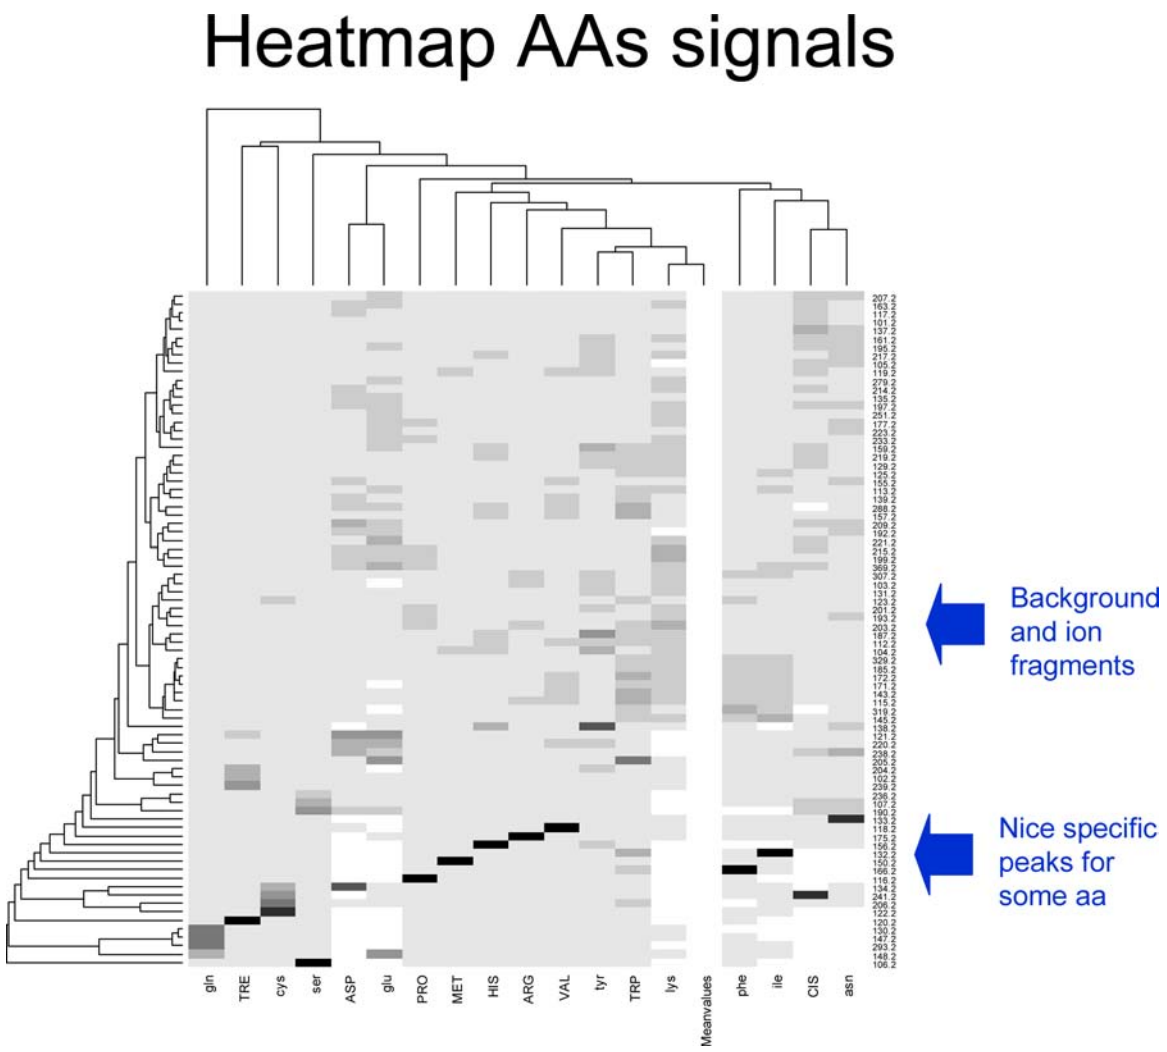

Figure 5. Heatmap profile of amino acid standards. Hierarchical clustering is presented for the ion fragments (horizontal rows) and amino acid standards (vertical rows).

than 200 different peaks were detected with an excellent S/N of >10 (Figure 4). Up to ~600 other ions could also be quantified with acceptable results (S/N > 3). DIESI–MS yielded 1–2 orders of magnitude more biochemical information at a fraction of the cost compared to other methods (Table 1).

DIESI–MS Generates a Metabolic Fingerprint Revealing Specific Ions Differing between Treatments. When samples from maize plants grown under different environmental conditions (normal CT and LN) are compared, many peak intensities were similar, the mass spectra appeared symmetrical, but detailed inspection revealed that there were also specific ions that increased or decreased (Figure 4). A similar response was also observed for maize plants subjected to drought stress and for plants grown at different localities and conditions (data not shown). Overall, the results confirmed our previous report on the possible application of DIESI–MS for the physiological evaluation of maize plants using stem extracts collected at the flowering time.[18]

Method Development and Optimization. The promising results motivated us to further optimize the DIESI–MS platform for high-throughput metabolic phenotyping of maize and other species. We simplified the extraction and sample preparation procedure, but more particularly, we improved the scripts, file handling, statistical procedures, and boxplot figure output compared to previous reports.[18] The statistical analysis of the DIESI–MS data using loop programming and the R scripts were optimized as described extensively in the methods. We also optimized sample treatment and handling, allowing for the realistic measurement of ~80 samples per day (Table 1).

Control Experiments: DIESI–MS Ion Pattern of Standards. We then asked: How repeatable and redundant is the DIESI–MS data? Do standard compounds ionize with the theoretical positive mass, or does our DIESI–MS method produce ions fragmenting other non-standard m/z peaks? To answer those questions, additional control experiments were performed. Candidate primary metabolites that might change under different stress conditions were evaluated. We focused on amino acids, because it could be expected that CT and LN treatments severely affects the nitrogen status of plants. Theoretically, they should all ionize well in positive-ion mode; therefore, the 20 standard amino acids and cistine were injected into the MS quadrupole, and the occurrence and the magnitude of ion fragmentation with electrospray ionization (ESI) was documented using gray heatmaps (Figure 5).

DIESI–MS produced an ion pattern (mass spectrum) that was highly specific for each amino acid (Figure 5). The most intense peaks (black bars) had indeed the expected m/z according to the theoretical mass of non-fragmented proto-

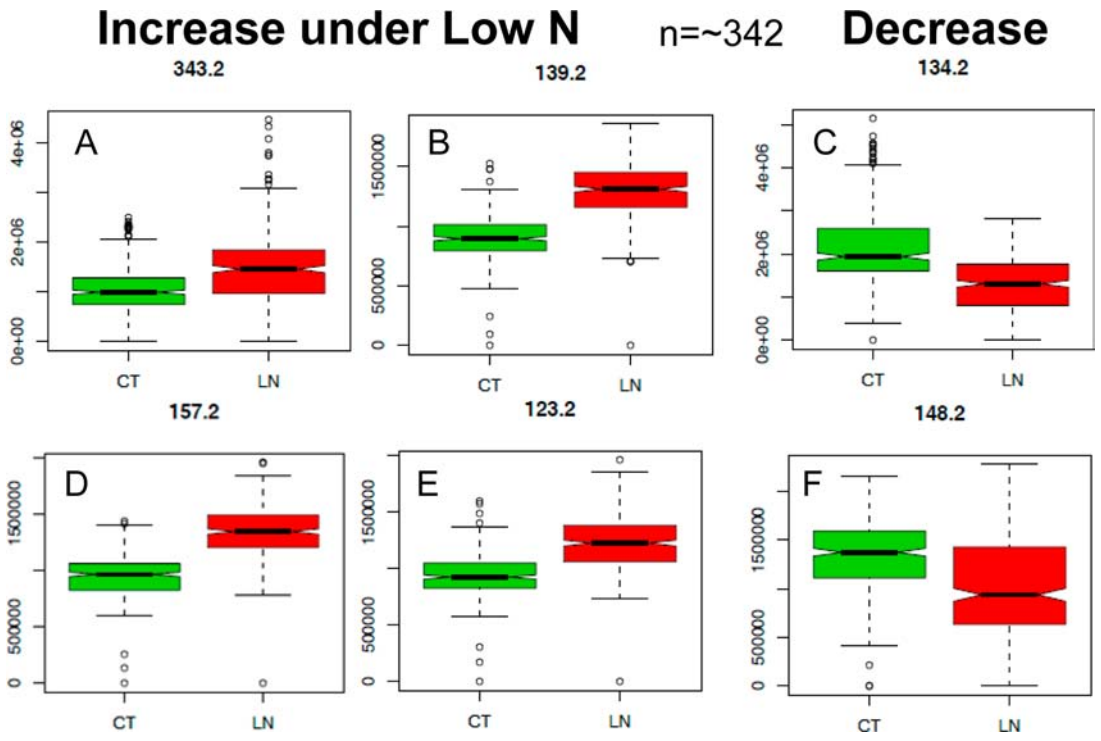

Figure 6. Intensity data of selected m/z ions quantified with DIESI−MS. Maize plants were grown under either normal CT (green) or LN (red) conditions, and stem juice extracts were sampled for DIESI−MS metabolic profiling. Boxplots summarize data from 19 genotypes, 6 biological, and 3 technical replicates (n = 342). Boxplot wiskers are shown for significant differences. (A, B, D, and E) Data from four representative ions that increase under LN conditions. (C and F) Data from two representative ions that decrease under LN conditions.

nated amino acids (AA + 1H) (Figure 5). Most amino acids ionized very well with our DIESI−MS protocol (e.g., Gly, Ser, Thr, Gln, Leu, and Ala). Unfortunately, other amino acids did not ionize equally well (e.g., His, Met, Arg, Asn, Tyr, Trp, Phe, Glu, and Asp), and the reason for this remained unknown. The atomic events that lead to ionization in ESI are complex, so that efficient ionization cannot be theoretically predicted nor explained by the chemical formula but must rather be confirmed by a trial and error approach.

In addition to the expected m/z peaks (main ion fragments), other minor ions of lower intensity also appeared in the DIESI−MS spectra (Figure 5). Minor accompanying peaks were both smaller and larger than the expected molecular mass of the unitary ion. These peaks could be ion fragments (smaller mass) or ion aggregates (larger mass) of the original molecules. Nevertheless, ion fragmentation with ESI was much less than that with EI, and the avoidance of chemical derivatization reduced the problem of data redundancy (e.g., with GC−TOF, citric acid and some amino acids generate more than six RT peaks across several fragmented masses).

Taken together, the control experiments indicated that DIESI−MS efficiently discriminates the chemical profile of samples and that data are repeatable and fairly non-redundant. However, because of fragmentation, aggregation, and matrix interaction, the assignment of a given m/z peak to a given biomolecule should be performed with extreme care. Even if a DIESI−MS peak has a m/z value that is identical to the theoretical mass of a standard known compound, we did not assume that the intensity value corresponded to the concentration of the known compound in the plant sample. In fact, direct-injection spectra provide a numeric phenotype of complex ion mixtures that reveals the physiological status of plants,[18] but it is not the best choice for metabolite identification, chemical discovery, and/or structural assignment as with other high methods, such as UPLC−MS−Orbitrap or NMR. For example, the DIESI−MS peak m/z 106.2 in theory corresponds to positively ionized serine, but other compounds could also generate signals or suppress ionization in that m/z range. A search in chemical databases yielded dozens of chemical compounds for that given m/z value. If the mass tolerance was increased to ±0.5 Da, then hundreds of theoretical compounds were listed. Many molecules are certainly absent in plants or living cells, but unequivocal assignment of m/z values to metabolites requires many control experiments that are out of the focus of the present paper. In the midterm, we will start building a biochemical database of DIESI−MS peaks that are frequently found in various plant extracts (we call it "metabolic space" of each species and tissue) (see also ref 19).

Given the previous limitations, we avoided assigning chemical names to DIESI−MS peaks but only named them by the numerical m/z value (center of maximal intensity of the positive ion). From the practical perspective of metabolic phenotyping for breeding purposes, it does not matter the exact identity or name of the compound but rather the following questions: Is it related to yield? Can we measure it cheaply? Is it quantitative? How much variance depends upon the E, and how much depends upon the G? Will it be useful for plant breeding? Which ions increase or decrease significantly under stress? Which peaks should be used as biomarkers for selection and/or screening?

Discrimination of Phenotypic Variance Because of E and G Effects. To answer above questions, we performed field trials using 18 maize hybrids grown under CT and LN conditions (see the Materials and Methods). The optimized DIESI−MS data analysis pipeline and the novel R scripts

DOI: 10.1021/jf504853w
J. Agric. Food Chem. 2015, 63, 1042−1052

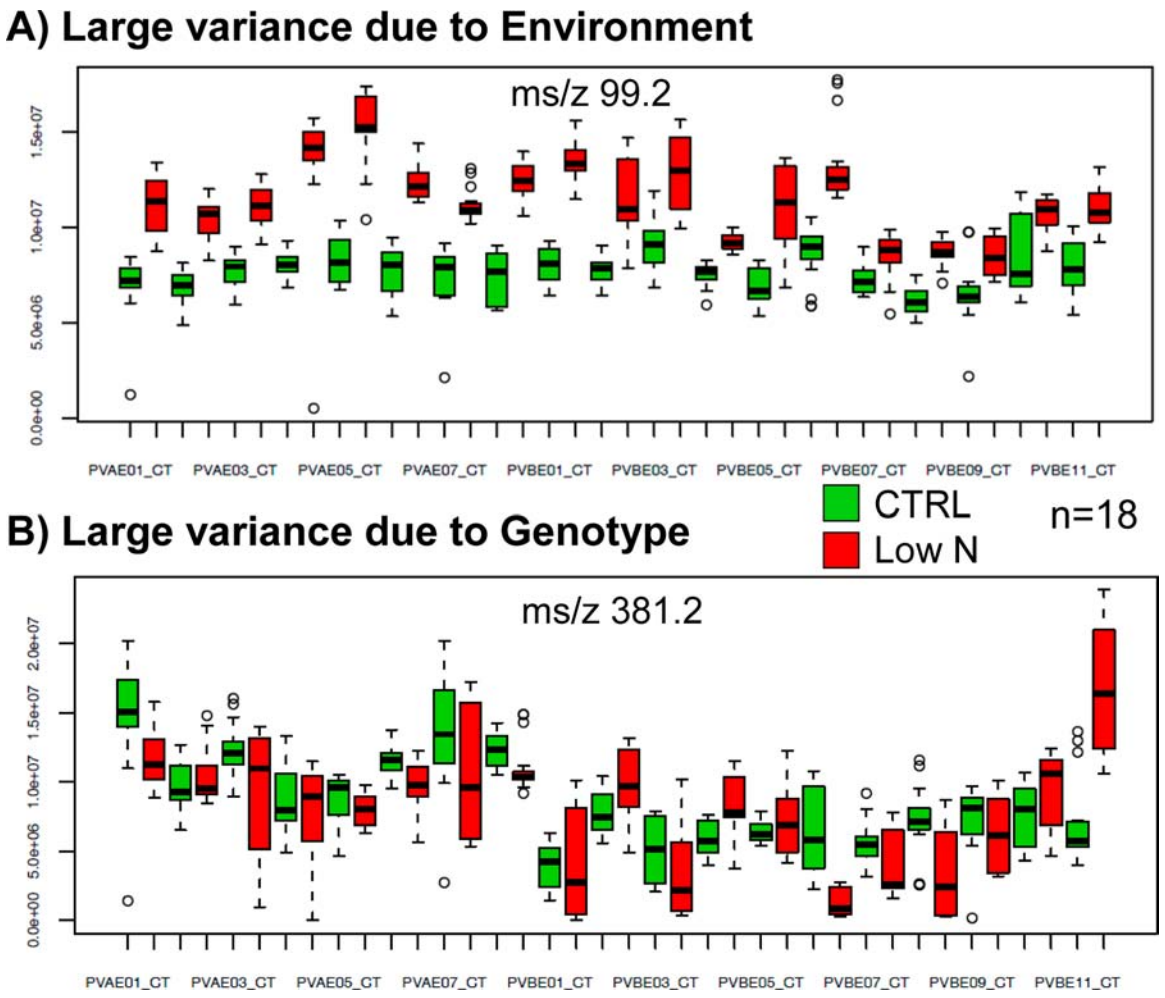

Figure 7. Evaluation of signals that primarily depend upon environmental or genetic factors. Intensity data of selected m/z ions were quantified with DIESI−MS. A total of 19 maize genotypes were grown under either normal CT (green) or LN (red) conditions, and stem juice extracts were sampled for DIESI−MS metabolic profiling. Boxplots summarize data from 6 biological and 3 technical replicates (n = 18). ANOVA was used to discriminate environmental and genotypic variance. (A) Representative m/z ion 99.2 with a large environmental effect. (B) Representative m/z ion 381.2 with a lower environmental effect but larger genetic effect.

allowed us to represent the data of given m/z peaks automatically as boxplots (Figure 6). The pooled data per environmental condition revealed several m/z peaks that significantly increased (panels A, B, D, and E of Figure 6) or decreased (panels C and F of Figure 6) under LN treatment.

When the data for each genotype were analyzed separately (Figure 7), several m/z signals, such as 99.2, displayed a strong dependence upon the environment (Figure 7A), while others, such as 381.2, were less dependent upon the growth conditions but rather presented large variance because of the genotype (Figure 7B). Such information is required for phenotyping purposes because it is important to identify candidate m/z peaks to be used as biomarkers for a given physiological condition or stress. Overall, DIESI−MS allowed for the partitioning of variance of individual peaks according to E and G effects and can be combined with standard agronomic measurements within yield trials to predict hybrid performance under variable conditions.

Comparison of the Cost−Benefit Analysis of Different Metabolic Profiling Strategies. For research purposes, it is attractive to find reliable quantitative biomarkers for genotypic selection, but a maize breeder with limited resources would ask the following questions: How expensive is DIESI−MS profiling? How much training and manual worktime is required? How many samples can a user process per week or season?

Systematic comparison of several analytical platforms revealed that DIESI−MS allowed for a high throughput of samples, required little time for statistical analysis, and was the cheapest method per metabolic data point (Table 1). The cost per metabolic data point was in the range of 2−10 cents in U.S. dollars. Among all metabolic profiling strategies, DIESI−MS had the greatest potential to be extensively used for plant phenotyping.

DIESI−MS Results from Various Plant Extracts. Because DIESI−MS was generating promising results, several colleges asked: does it work for other samples in addition to maize stems? To answer their questions, we combined the DIESI−MS data from different plant samples (Figure 8). We included previously obtained spectra from coffee leaves (*Coffea arabica* and *Coffea canephora*), red and black tea leaves (*Camellia sinensis*), and coca leaves (*Erythroxylum coca*).[18] Novel data were added from maize stem juice extracts (grown under CT and LN conditions) and also strawberry (*Fragaria vesca*) samples of different maturity stages. A pseudo-extract was also included as a blank control (Figure 8).

DOI: 10.1021/jf504853w
J. Agric. Food Chem. 2015, 63, 1042−1052

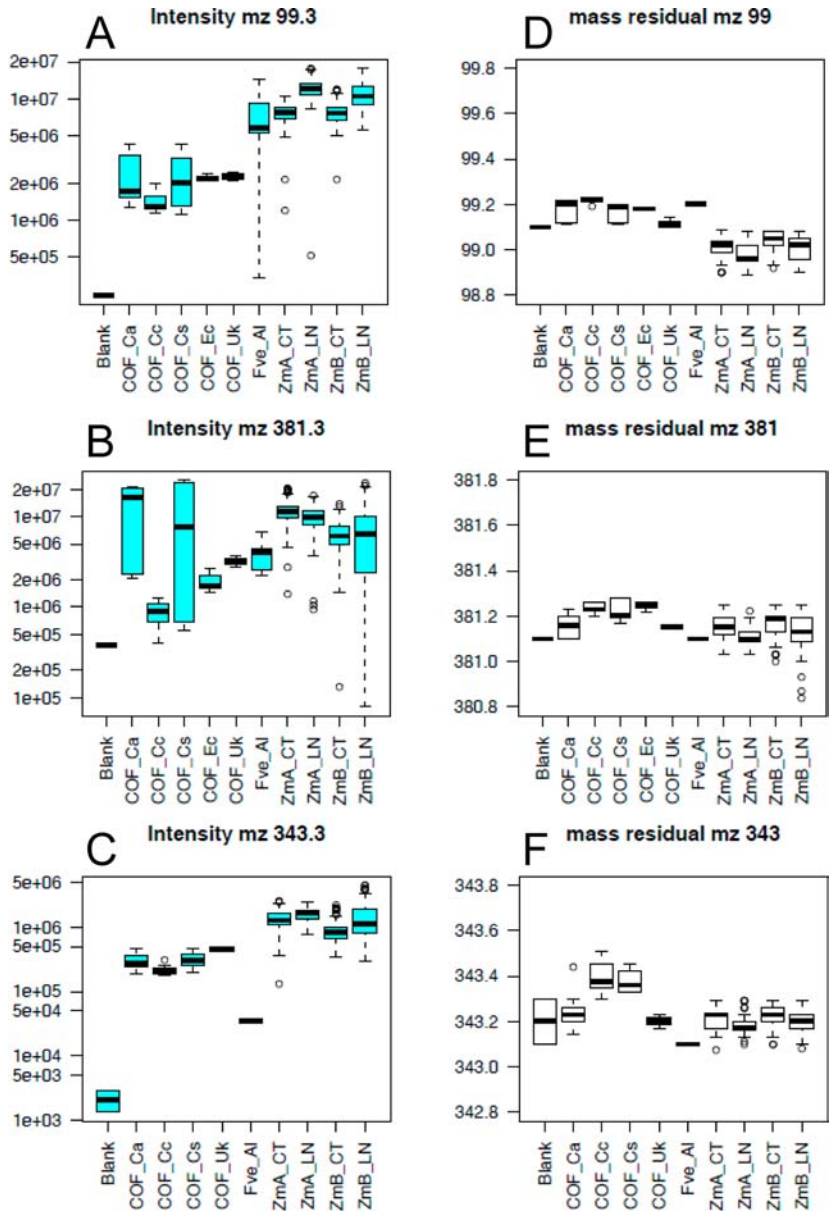

Figure 8. Ion intensity data of nine different plant samples. (A–C) Representative m/z ions. (D–F) Corresponding m/z values. (A) Ion 99.3 was low in leaves of tea samples but was equally abundant in strawberry fruits and maize stem. It increased under LN stress compared to CT but was similar among yellow (ZmA) and white (ZmB) maize hybrids. (B) Ion 381.3 did not change much because of environmental conditions but varied more according to genotype. (C) Ion 343.3 increased slightly because of LN stress in maize but was very low in strawberry fruits. *Zea mays* samples were pooled into white grain genotypes (ZmA) or yellow grain genotypes (ZmB) and grown under either normal CT or LN conditions. Boxplots summarize data from each species or treatment (n = 6–500). Data were from coffee leaves [*C. arabica* (COF-Ca) and *C. canephora* (COF-Cc)], tea leaves [*C. sinensis* (COF-Cs)], and coca leaves [*E. coca* (COF-Ec)][18] as well as strawberry (*F. vesca*) fruit samples of different maturity stages (Fve-Al). A pseudo-extract was used as a blank.

In addition to reporting the intensity values for given m/z ion bins (panels A–C of Figure 8), we also found it relevant to plot the exact m/z values (panels D–F of Figure 8). Peak m/z 99.3 was highest in all maize samples and strawberry fruits, whereas it was lower in all leaf samples (Figure 8A). In maize stem extracts, peak m/z 99.3 increased under LN compared to CT treatment (Figure 8A). The m/z values were similar across leaf samples (Figure 8D). There was a slight tendency that the m/z value was lower in maize, indicating that the metabolite is not necessarily the same in tea leaves or maize stems (Figure 8D).

Peak m/z 381.3 was high in maize stems, intermediate in strawberry fruits, and highly variable in leaves of different species (Figure 8B). It was higher in *C. arabica* than in *C. canephora* (Figure 8B). In maize stem extracts, peak m/z 381.3 did not change significantly under LN or CT conditions (Figure 8B). The m/z values were very similar across all species and treatments (Figure 8E).

Peak m/z 343.3 was high in maize, intermediate in leaves, and rather low in strawberry fruits (Figure 8B). This metabolite was high in maize stem extracts, particularly low in fruits, and totally absent in coca leaves (Figure 8C). No difference was found between LN or CT conditions for peak m/z 343.3 (Figure 8C). The m/z values varied across plant species, so that most likely intensity values correspond to different metabolites in different samples (Figure 8F).

DOI: 10.1021/jf504853w
J. Agric. Food Chem. 2015, 63, 1042–1052

The metabolite detected in *C. arabica* samples probably corresponds to the metabolite detected in maize and strawberry, but it might be different from the metabolite detected in *C. canephora* and *C. sinensis* (Figure 8F).

We conclude from these analyses that the boxplot figures provide useful quality controls for the DIESI−MS results. Our protocol worked for many different plant samples, and it even allowed for the study of phylogenetic relationships. Some specific ions allowed for the identification of plant organs or species. Other ions allowed for the specific identification of environmental variance or the selection according to genetic variance.

Potential Applications of DIESI−MS for Plant Breeding. It can be concluded that, among all metabolic profiling strategies, DIESI−MS generates a vast amount of information at the cheapest price (Table1) and, therefore, has the greatest potential to be routinely implemented for biochemical phenotyping of plant cultivars. Because metabolites are closer related to GY than DNA sequences (Figure 1), we postulate that metabolic phenotyping using DIESI−MS complements genome-wide selection (GWS) strategies.

In summary, DIESI−MS is a great phenotyping tool, which will assist plant research and breeding. We expect it will become common in the near future, because there is still large room for methodological improvements to increase information density, bring down cost, and further simplify procedures. Success will depend upon the establishment of strategic alliances between plant physiologists, biochemical researchers, biostatisticians, breeders, and agronomists.

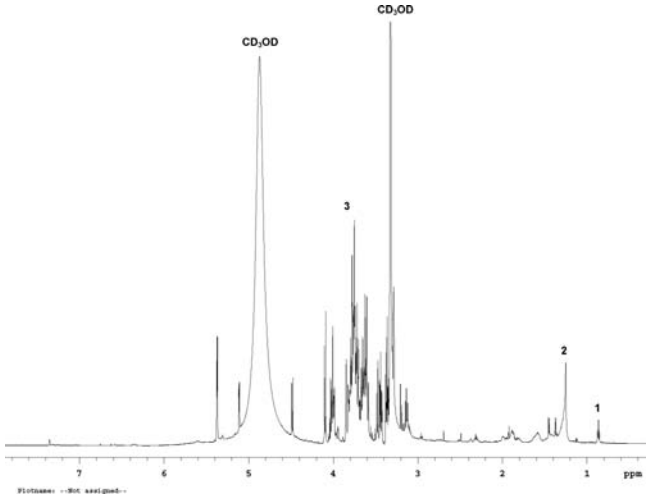

Figure 1. ^{1}H NMR in CD_3OD of the methanolic extract of lyophilized pawpaw fruit pulp. Peaks: 1: $-\mathbf{CH_3}$ 2: $-(\mathbf{CH_2})_n$ 3: **H**CO of sugars and acetogenins.

(ASE, ThermoFisher Scientific, Sunnyvale, CA). Then, methanol (CH_3OH) was added while the temperature and pressure were increased to 23, 60, or 100 °C and 10.3 MPa (1500 psi) over a 3 min time (static time). Next, the solvent was purged into a collection vessel. A total of four cycles were run to statically extract the sample, resulting in a total volume of about 160 mL. The solvent was evaporated off, and the oily residues remaining were weighed.

A portion of the residue remaining after the methanolic extraction at 100 °C was redissolved in methanol for LC-HRMS analysis using a Thermo Scientific HPLC with an Accela 1250 pump and Accela Open AS autosampler. A Waters Acquity UPLC C18 BEH column with 1.7 μm particle size and dimensions of 2.1 × 150 mm was used with a gradient elution. It started with CH_3OH and water containing 0.1% formic acid at a flow rate of 0.300 mL/min. For the first 25 min of the first gradient, an isocratic mobile phase of 4:1 CH_3OH:H_2O (v/v) was used. This was changed linearly to 49:1 CH_3OH:H_2O (v/v) from 25 to 30 min and held at this mixture from 30 to 35 min, followed by a step change back to 4:1 CH_3OH:H_2O (v/v) that was held from 35 to 45 min. An Orbitrap Exactive HRMS (Thermo Scientific, Sunnyvale, CA) was used with heated electrospray ionization (HESI) at 350 °C and a nitrogen gas sheath flow 45 arbitrary units, auxiliary nitrogen gas flow 12 arbitrary units. For negative ionization, the following parameters were used: spray voltage 2.60 kV, capillary temperature 325 °C, capillary voltage −35.00 V, tube lens voltage −80.00 V, skimmer voltage −18.00 V. For positive ionization, the following parameters were used: spray voltage 3.50 V, capillary temperature 325 °C, capillary voltage 32.50 V, tube lens voltage 100.00 V, skimmer voltage 16.00 V. Its resolution at m/z 400 was 100,000 full width at half-maximum peak height (fwhm). It used an internal mass lock. The mass range was 100−1000 m/z with a target of 1,000,000 charges and a maximum ionization time of 250 ms. It was able to rapidly switch between positive and negative ionization, so H^+, Na^+, and formate ($HCOO^-$) adducts could be detected. So, for annonacin, masses in the range of 597.47071−597.47549, 619.45251−619.45747, and 641.46397−641.46911 were monitored for $[M + H]^+$, $[M + Na]^+$, and $[M+HCOO]^-$, respectively. For squamocin, masses in the range of 623.48628−623.49126, 645.46808−645.47324, and 667.47985−667.48519 Da were monitored for $[M + H]^+$, $[M + Na]^+$, and $[M +HCOO]^-$, respectively. Annonacin and squamocin standards from Pierre Champy at the University of Paris were used to identify and quantify the peaks due to annonacin and squamocin that eluted at 19.74 and 22.51, min, respectively.

Calibration curves were obtained using 10−1000 ng/mL annonacin and squamocin, assuming that the standards were 100% pure. Samples were diluted until they produced peaks with areas that fell within the range of the calibration standards.

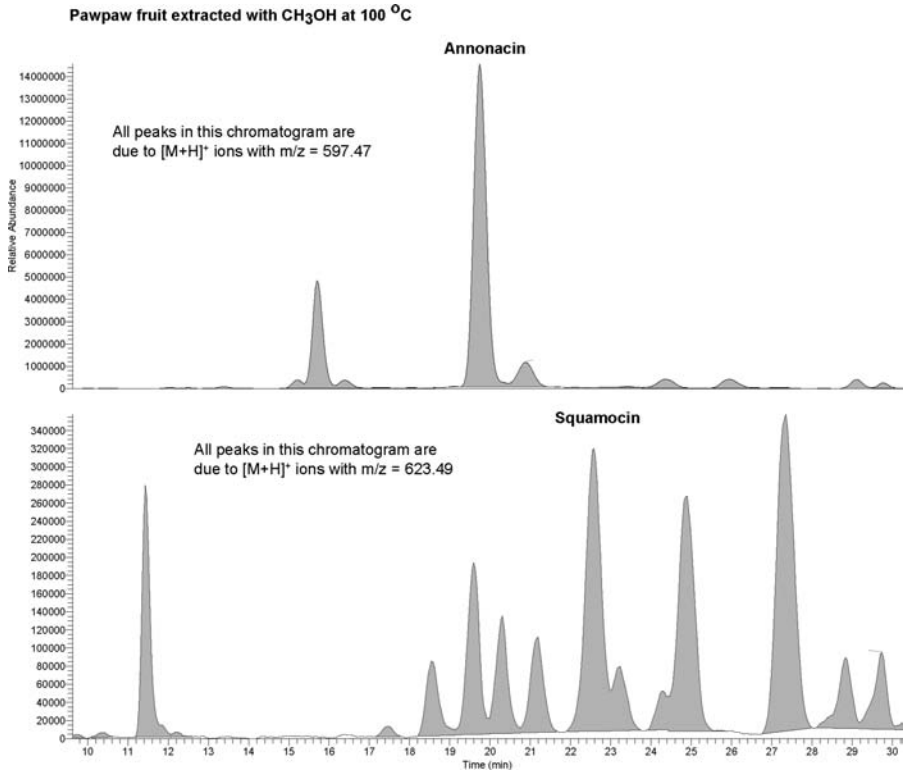

Figure 2. LC-HRMS of methanolic extract of lyophilized whole pawpaw fruits done at 100 °C and 10 MPa pressure in a sealed container. All of the peaks in the top chromatogram are due to $[M + H]^+$ ions that had a mass to charge ratio (m/z) of 597.47, like annonacin. All of the peaks in the bottom chromatogram are due to $[M + H]^+$ ions that had a mass to charge ratio (m/z) of 623.49, like squamocin.

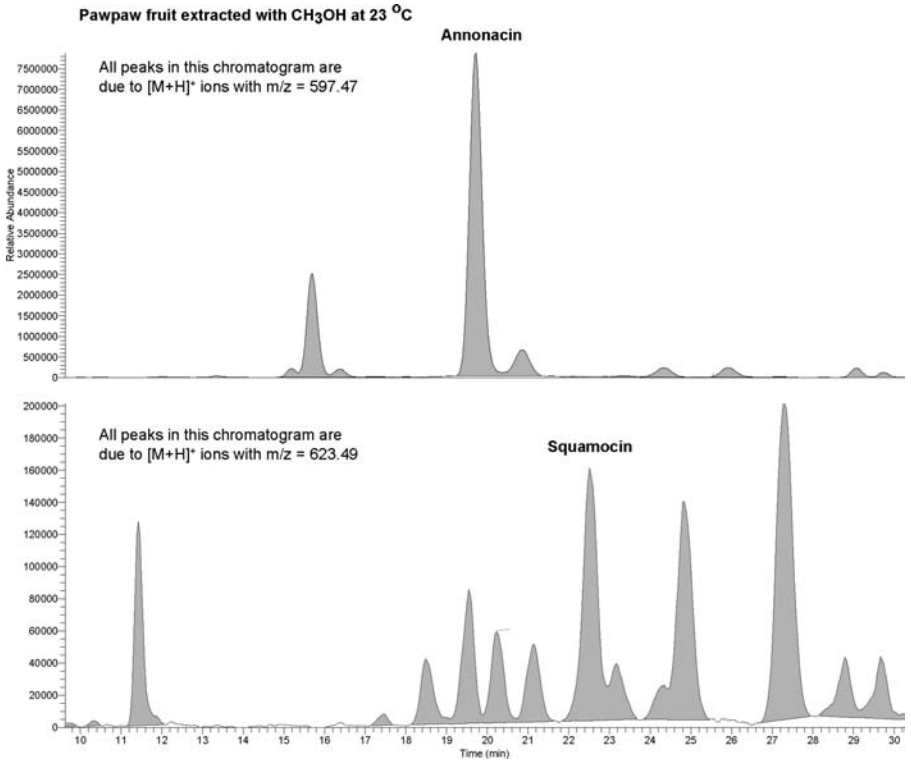

Figure 3. LC-HRMS of methanolic extract of lyophilized whole pawpaw fruits done at 23 °C and 10 MPa pressure in a sealed container. All of the peaks in the top chromatogram are due to $[M + H]^+$ ions that had a mass to charge ratio (m/z) of 597.47, like annonacin. All of the peaks in the bottom chromatogram are due to $[M + H]^+$ ions that had a mass to charge ratio (m/z) of 623.49, like squamocin.

Another portion of the residue remaining after the methanolic extraction at 100 °C was redissolved in CD_3OD for NMR analysis using an Agilent DD2 600 MHz NMR (Santa Clara, CA). A 30° pulse width and 1 s pulse delay were used for the ^1H NMR, while a 30° pulse width and 2 s pulse delay were used for the ^{13}C NMR spectra. Chemical shifts were referenced to the CD_3OD peaks at 3.35 and 4.78 ppm (for ^1H) and 49.3 ppm (for ^{13}C).

RESULTS AND DISCUSSION

About 59.3% of the lyophilized pawpaw fruit was solubilized by dry methanol at 100 °C, compared to 40.4 and 50.1% at 23 and 60 °C. This does not refer to the percent recovery, which is a term that refers to the recovery of standards that are spiked into a sample. It refers to the percentage of material in the fruit that was solubilized. Like the NMR spectra of the methanolic extracts of four other fruits in the Annonaceae family,[18] the pawpaw spectra are dominated by peaks due to fructose and other carbohydrates, as shown in Figure 1. There are no peaks due to triglycerides, which would be strongly retained on a C_{18} column. So, this extract was suitable for LC-HRMS analysis without any sample cleanup being required.

The LC-HRMS chromatograms of the methanolic extract of pawpaw detected not just annonacin and squamocin but also isomers of them, as shown in Figures 2 and 3. The chromatograms of the extracts obtained at 100 and 23 °C look almost identical, indicating that the same compounds were solubilized in about the same ratios. However, the peaks areas were larger in the chromatogram of the extract at 100 °C, and more material was solubilized at this higher temperature. So, the total concentration found in the 100 °C extract was higher than those found in the 23 and 60 °C extracts.

The concentrations of annonacin and squamocin found at each temperature are in Table 1. That is, 7724 and 162 μg/g annonacin and squamocin were found when the extraction was done at 100 °C, while only 3750 and 74 were found at 23 °C and 6370 and 128 were found at 60 °C. This compares to 70.1 μg/g annonacin and no squamocin found by others in fresh (not lyophilized) pawpaw fruit using MALDI-TOF MS analysis.[5] Since pawpaw fruit contains about 77% moisture,[15] this would correspond to about 304 μg annonacin per g of dry weight. There were not enough of the annonacin and squamocin standards to completely validate the method. That is, there was not enough to do the required analyses for percent purity. There was not enough for moisture analysis. Still, each standard produced only one peak in the LC-MS. They were also the same standards used in the previous study that found lower concentrations of them.[5] So, even though the exact concentrations were calculated based on the assumption that the standards were 100% pure (no moisture), they can be compared to the previous study.[5] The main reason why so much less was found in that study was because the extraction was done under ambient conditions and because there was so much moisture in the fresh pawpaw fruit. Annonacin, squamocin, and other acetogenins are lipophilic,[16] so they are extracted best from dry (lyophilized) fruit using dry methanol at 100 °C and 10 MPa pressure. However, if the extraction is

Table 1. Concentrations (in μg/g) of Annonacin and Squamocin Found at Three Different Extraction Temperatures in Lyophilized Whole Pawpaw Fruits from Missouri

temp	annonacin (μg/g)	squamocin (μg/g)
23 °C	3750	74
60 °C	6370	128
100 °C	7724	162

DOI: 10.1021/jf504500g
J. Agric. Food Chem. 2015, 63, 1053−1056

done under these conditions and then the extract is analyzed by MALDI-TOF MS, all the isomers of annonacin would coelute with each other, since no column was used to separate them. This is also true for isomers of squamocin. As a result, the apparent concentrations of annonacin and squamocin would be overestimated. In conclusion, a combination of high pressure liquid extraction using dry methanol at 100 °C and 10 MPa pressure and LC-HRMS is the preferred method.

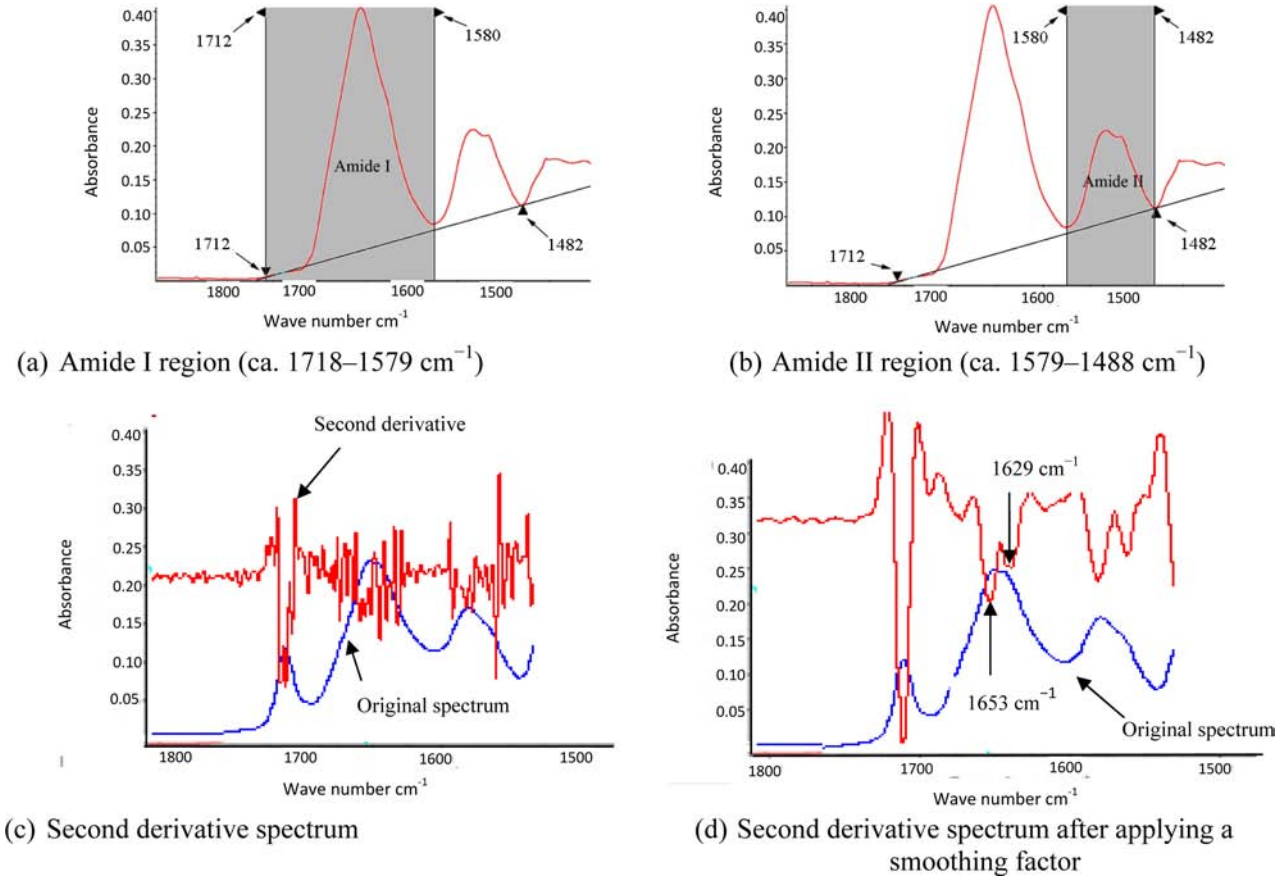

Figure 1. Typical Fourier tansform/infrared-attenuated total reflectance (FT/IR-ATR; Jasco Inc., Easton, MD) spectrum showing (a) amide I region at ca. 1712−1580 cm^{-1}; (b) amide II region 1580−1482 cm^{-1}; (c) original and second-derivative spectrum of the amide I and II region; and (d) second-derivative spectrum of the amide I and II region after applying smoothing factor. The intensities of α-helix (ca. 1653 cm^{-1}) and β-sheet (ca. 1629 cm^{-1}) were measured on the primary spectrum as the height below the first and second negative peak (d).

is vital to establish optimal heating conditions and understanding the changes in CP chemical profile and digestion in dairy cows.[11,14,15] Fourier transform/infrared-attenuated total reflectance (FT/IR-ATR) molecular spectroscopy can be used as a rapid, direct, nondestructive bioanalytical technique to detect heat-induced changes in protein molecular structures.[11,15]

The MIR, dry heating, and moist heating may induce different levels of alteration in feed protein molecular structures. To our knowledge, no systematic study has been conducted on the effect of these different heat-processing methods on protein inherent molecular structures of flaxseed in relation to changes in CP chemical profile, ruminal CP degradation, and intestinal digestibility of RUP. Thus, the objectives of the present study were to (1) determine changes in the protein molecular structure of flaxseed induced by MIR, dry heating, and moist heating, and (2) correlate these structural changes with changes in (a) CP chemical profile, (b) CP subfraction composition, and (c) *in situ* rumen CP degradation and intestinal digestibility of RUP. We hypothesized that these heat processing methods would affect flaxseed protein molecular structures to different extents, resulting in corresponding changes to protein nutritive value and digestibility.

MATERIALS AND METHODS

Chemicals. All the chemicals used for the study were of reagent grade. Sodium hydroxide (purity >99%), trichloroacetic acid (purity 99.6%), sodium tungstate ($Na_2WO_4 \cdot 2H_2O$; purity 100%), sulfuric acid (purity 70%), hydrochloric acid (purity 38%), ethyl ether (purity 99%), sodium borate ($Na_2B_4O_7 \cdot 10H_2O$; purity 99.5%), sodium phosphate ($NaH_2PO_4 \cdot H_2O$; purity 99.5%), kjeltabs (0.15 g $CuSO_4$ and 5.0 g K_2SO_4; $N < 0.005\%$), boric acid (purity >99.5%), acetone (purity ≥99.5%), potassium phosphate (purity >99%), sodium sulphite anhydrous (purity 98.4%), and potassium hydroxide (purity 85%) were purchased from Fisher Scientific (Ottawa, ON, Canada). Thymol ($C_{10}H_{14}O$; purity 99.5%) and enzymes pepsin and pancreatin were purchased from Sigma-Aldrich Co. (St. Louis, MO). Heat-stable α-amylase (17 400 liquefon units/mL); NDF solution containing 30 g of sodium dodecyl sulfate, 18.61 g of ethylenediamine-tetraacetic disodium salt, 6.81 g of sodium borate, 4.56 g of anhydrous sodium phosphate diabasic, and 10 mL of triethylene glycol; and ADF solution containing 20 g of cetyltrimethylammonium bromide in 1 N sulfuric acid were purchased from Ankom Technology (Macedon, NY).

Flaxseed Sample Collection and Heat Processing. Seeds from two varieties (CDC Bethune and CDC Sorrel) of flaxseed were evaluated. Seeds (~3 kg) were sampled from two replicate plots of each variety grown at two different locations: the Kernen Crop Research Farm (52°9′ N and 106°32′ W), managed by the Crop Development Centre (CDC; University of Saskatchewan, Saskatoon, SK, Canada), and Melfort Research Fields (52°8′ N and 104°59′ W; Melfort, SK, Canada), managed by Agriculture and Agri-Food Canada. A subsample (~700 g) of each sample was either kept as raw (control), heated by MIR for 5 min, toasted in an air-draft oven (dry heating) at 120 °C for 60 min, or heated by high pressure (15 lb/in^2) saturated steam (moist heating) in an autoclave (Amsco Eagle SG-3031, Steris Corp., Mentor, OH) at 120 °C for 60 min. The microwave oven (DMW904W, Findlay, OH) was operated at a power of 900 W (1.33 W/g of seeds) and an irradiation frequency of 2450

DOI: 10.1021/jf503575y
J. Agric. Food Chem. 2015, 63, 1057−1066

MHz. To avoid overheating (burning), the seeds were mixed after 2 min of MIR and cooled for 5 min. For dry heating and moist heating, the seeds were spread in aluminum pans (33 × 23 cm^2 area, and 5 cm high) for uniform heating. Heat processing was carried out in two replicate runs, with heated samples subsequently cooled at room temperature (20−22 °C) and stored at 4 °C until further processing.

Both raw and treated samples were ground using a laboratory mill (Retsch ZM-1, Brinkmann Instruments Ltd., Mississauga, ON, Canada) to 0.5 mm for molecular spectral analyses, to 1 mm for all other wet chemical analyses, and to 2 mm for *in situ* studies. Samples were kept cool and slowly fed to the grinder to minimize clumping and sticking, and to make sure that the seeds were crushed and not extruded.

Molecular Spectroscopy. Protein molecular spectral analyses were carried out in the molecular spectroscopy laboratory of the Department of Animal and Poultry Science, University of Saskatchewan (Saskatoon, SK, Canada). Spectral profiles were obtained in the mid-infrared region (ca. 4000−800 cm^{-1}) using a JASCO FT/IR-ATR-4200 (Jasco Inc., Easton, MD). The FT/IR was equipped with a ceramic infrared light source, deuterated L-alanine doped triglycine sulfate detector, and fitted with a MIRacle ATR (Pike Technologies, Madison, WI) sampling accessory equipped with ZnSe crystal plates and a pressure clamp. Each sample was run five times, and each spectrum was collected with 128 coadded scans at a spectral resolution of 4 cm^{-1} in transmission mode. Molecular spectral data were collected and processed (corrected against background and CO_2 noise) using Jasco Spectra Manager II software (Jasco Inc., Easton, MD). Primary protein structures were quantified using two absorbance bands in the amide I (1712−1580 cm^{-1}; Figure 1a) and amide II (1580−1482 cm^{-1}; Figure 1b) regions using OMNIC 7.3 software (Spectra-Tech Inc., Madison, WI). The bands were identified using values reported in the literature.[11] Secondary protein structure (α-helix and β-sheet) intensities were quantified in the amide I region as described by Yu[16] using the second-derivative function of OMNIC 7.3. Briefly, an FTIR/ATR spectrum was selected and corrected for baseline, and then the second derivative function was used to produce a secondary spectrum above the primary spectrum (Figure 1c). Noise in the secondary spectrum was corrected by repeatedly applying a smoothing factor until no further improvement was possible. After smoothing, the intensities of the α-helix and β-sheet were measured on the primary spectrum as the height below the center of the first and second negative peaks (ca. 1653 and 1629 cm^{-1}, respectively; Figure 1d) of the secondary spectrum.

***In Situ* Rumen Incubation.** Four lactating Holstein dairy cows (BW, 680 ± 10 kg), each fitted with permanent rumen fistula (10 cm internal diameter; Bar Diamond Inc., Parma, ID) were used for the *in situ* incubations. The fistulated cows were cared for and handled according to the relevant Canadian Council for Animal Care (CCAC) protocol (#19910012). The cows were individually fed a balanced total mixed ration twice daily (0800 and 1600) in equal portions. The ration contained 31% barley silage, 16% chopped alfalfa hay, and 53% dairy concentrate. The concentrate contained 56% barley grains, 33% dairy supplement pellets, 5% wheat grains, 5% oat grains, and 1% molasses. The dairy supplement pellets were prepared from a mixture of 36.4% soybean meal, 30.3% canola meal, 9.1% mineral and vitamin mixture (University of Saskatchewan), 6% wheat distillers grains, 6.1% corn gluten meal, 3.0% molasses, 2.5% barley, 2.1% canola oil, 1.8% cobalt-iodized salt, 1.8% sodium bicarbonate, and 0.9% Dynamate (K and Mg sulfate, University of Saskatchewan). The cows had 24 h/d access to fresh drinking water.

The standard protocol[17] for *in situ* rumen incubations was adopted to determine rumen degradation characteristics of the control (raw) and heated (dry, moist, MIR) flaxseed. In brief, 7 g of ground (2 mm) sample was weighed into preweighed and coded nylon bags (10 × 20 cm^2) with a pore size of 41 μm (Nitex 03-41/31 monofilament open mesh fabric, Screentec Corp., Mississauga, ON, Canada). The bags were tied ∼2 cm below the top, allowing 19 mg of sample per cm^2 of bag surface area. Each feed was randomly incubated for 48, 24, 12, 8, 4, 2, or 0 h in the four fistulated cows in two replicate runs. To obtain an adequate amount of residue for chemical analysis, multiple replicate bags were used for each incubation period (four bags for 48, 24, and 12 h incubation periods; two bags for 8, 4, 2, and 0 h incubation periods). Bags for different incubation periods were added at appropriately staggered intervals so that all could be extracted together at the end of 48 h (gradual addition, all out method). At the end of the 48 h incubation period, all bags were removed from the rumen and immediately washed (6 times) in a bucket with cold tap water to stop microbial/enzymatic degradation of the residues and remove adhering ruminal contents. The bags were subsequently dried at 55 °C for 48 h, cooled to room temperature (20−22 °C), and reweighed. Residues were pooled together as per incubation time and run, ground to 1 mm particle size, and stored at 4 °C for chemical analysis.

Rumen Degradation Kinetics. The first-order kinetics equation of Ørskov and McDonald,[18] modified for lag time as proposed by Tamminga et al.,[19] was used to compute the degradation kinetics of DM and CP

$$Y(t) = U + (100 - S - U) \times e^{-kd(t-T_0)}$$

where $Y(t)$ is the residue present after t hours of incubation, U is the undegradable fraction, S is the soluble fraction, kd is the degradation rate (%/h) of the potentially degradable fraction, and T_0 is the lag time (h). The nonlinear (PROC NLIN) procedure in Statistical Analysis System (SAS) software[20] was used to estimate degradation parameters from *in situ* data.

The rumen degradability of DM (RDDM) and CP (RDP) were computed from the degradation parameters according to the NRC 2001[21] dairy model

$$\text{RDDM/RDP} = S + D \times \left[\frac{K_d}{(K_d + K_p)}\right]$$

where D is the potentially rumen degradable fraction computed as $D = 100 - S - U$, and K_p is the passage rate of digesta from the rumen (estimate at 6%/h).[19] The rumen undegraded DM (RUDM) and CP (RUP) were calculated according to

$$\text{RUDM/RUP} = U + D \times \left[\frac{K_p}{(K_d + K_p)}\right]$$

Intestinal Protein Digestion Determination. The three-step *in vitro* method of Calsamiglia and Stern[22] was used to analyze the digestibility of RUP. Briefly, ∼0.4 g of dried residues of 16 h rumen incubated samples, containing ∼15 mg N, were transferred to 15 mL centrifuge tubes. Then, 10 mL of 0.1 N HCL solution, containing 1 g/L pepsin, was added to the tubes. The tubes were vortexed and incubated in a shaking water bath at 38 °C for 60 min. Subsequently, 0.5 mL of 1 N NaOH and 13.5 mL of phosphate buffer (pH 7.8) containing 37.5 mg of pancreatin were added to each tube to neutralize the pH. The tubes were vortexed and further incubated at 38 °C for 24 h. At the end of incubation period, 3 mL of 100% (wt/vol) trichloroacetic acid solution was added to precipitate the undigested protein and stop any further enzymatic digestion. The tubes were then vortexed and centrifuged at 10 000 × g for 15 min (at 20 °C), and the supernatant was collected and analyzed for (soluble/digested) N content (AOAC; method 984.13).[23]

Chemical Analysis. The contents of DM (method 930.15), ether extract (EE; method 920.39), CP (method 984.13 using a Kjeltec 2400 autoanalyzer; Foss Analytical A/S, Hillerød, Denmark), ash (method 942.05), acid detergent fiber (ADF; method 973.18), and acid detergent lignin (ADL; ADF method 973.18, followed by digestion with 72% H_2SO_4 for 3 h) were analyzed according to AOAC standard methods.[23] The NDF content was analyzed according to the method of Van Soest et al.[24] with heat-stable α-amylase but without sodium sulfite. The ADF and NDF procedures were adapted for an ANKOM 200 Fiber Analyzer (Ankom Technology Corporation, Fairport, NY) and for the high oil containing seeds as described by Peng et al.[12] Nonprotein nitrogen (NPN), neutral detergent-insoluble CP (NDIP), and acid detergent-insoluble CP (ADIP) content were determined according to methods described by Licitra et al.[25] Soluble protein (SP)

[f]$P < 0.1$; *, $P < 0.05$, **, $P < 0.01$; ***, $P < 0.001$.

was analyzed by the method of Roe et al.[26] with some modifications as described by Peng et al.[27] All samples were analyzed in duplicate and the analyses repeated if error exceeded acceptable levels.

Fractionation of Protein. The Cornell Net Carbohydrate and Protein System (CNCPS) was used to partition the CP into NPN denoted as subfraction PA, true protein as subfraction PB, and unavailable protein as subfraction PC.[28,29] Subfraction PA contains peptides, free amino acids, ammonia, amides, amines, ureides, nucleotides, and nitrates and is considered to degrade in the rumen at a rate of 200%/h.[30] The PB fraction was further fractionated into a rapidly degradable (10−40%/h) subfraction denoted as PB1, a moderately degradable (3−20%/h) subfraction denoted as PB2, and a slowly (4−9%/h) degradable subfraction denoted as PB3.[30] Subfraction PB1 was calculated as SP − PA, PB2 as CP − (PA + PB1 + PB3 + PC), and PB3 as NDIP − ADIP. Subfraction PC is the ADIP.

Statistical Analysis. Data with respect to chemical profile, CP subfractions, and protein molecular spectral characteristics were analyzed using the PROC MIXED procedure of SAS.[20] The model used for analysis was

$$Y_{ijk} = \mu + HT_i + V_j + e_{ijk}$$

where Y_{ijk} is an observation on the dependent variable *ijk*, μ is the overall population mean, HT_i is the fixed effect of heat treatment (control, MIR, dry heating, and moist heating), V_k is the random effect of variety (CDC Bethune and CDC Sorrel), and e_{ijk} is the random error associated with the observation *ijk*. The plots ($n = 4$) were used as replicates.

The *in situ* rumen degradation and intestinal digestibility data were analyzed using the model

$$Y_{ijkl} = \mu + HT_i + V_j + R_k + e_{ijkl}$$

where Y_{ijkl} is an observation on the dependent variable *ijkl*, μ is the overall population mean, HT_i is the fixed effect of heat treatment, V_k is the random effect of variety, R_k is the random effect of *in situ* experimental run, and e_{ijkl} is the random error associated with the observation *ijkl*. When significant ($P < 0.05$) differences were noted, posthoc analyses were carried out on the least-squares means using the Tukey−Kramer test adjusted for multiple comparisons to compute pairwise differences in the means. Values are presented as mean ± standard deviation.

DOI: 10.1021/jf503575y
J. Agric. Food Chem. 2015, 63, 1057−1066

The strength of relationships between the protein molecular spectral characteristics and chemical profile, CP subfractions, *in situ* CP degradation, and intestinal digestibility were analyzed by the PROC CORR procedure of SAS[20] using the Pearson correlation method. Stepwise multiple regressions analyses were performed using the PROC REG procedure of SAS[20] to obtain regression equations for prediction of chemical profile, CP subfractions, *in situ* degradation characteristics, and intestinal digestibility of RUP. The independent variables tested in the model were the amide I and amide II area, height, and their (height and area) ratio as well as the α-helix and β-sheet height and their ratio. Only variables contributing significantly ($P < 0.05$) to the estimation of the dependent variable were used in the final model.

Multivariate analysis, agglomerative hierarchical cluster analysis (CLA), and principal component analysis (PCA) were performed on the overall spectral data (n = 249 spectral bands) obtained from the fingerprint region (ca. 1732−1483 cm^{-1}) to classify and visualize the heat-induced changes in intrinsic protein molecular structures. Earlier works by our group describe the detailed procedure and concepts for using CLA and PCA for FTIR/ATR spectral analysis.[15]

RESULTS AND DISCUSSION

Heat-Induced Changes in Chemical Profile. Data on the effect of MIR, dry heating, and moist heating on chemical profile of flaxseed compared to the control (raw seed) are provided in Table 1. Microwave irradiation and dry heating significantly increased the DM content, indicating a decrease in the moisture holding capacity of flaxseed, consistent with earlier findings.[12,14] Ether extract content significantly increased with MIR and moist heating. Moist heating is often used to increase oil extraction in the bio-oil industry, and a significant increase in EE has been observed with moist heating of camelina[12] and sunflower[31] seeds. Our results show that MIR for 5 min is as effective as moist heating at 120 °C for 60 min for increasing the ether extractability of flaxseed. This increase could be related to heat-induced physicochemical reactions in the seeds, such as the denaturation of the protein matrix that encapsulates the oil bodies.[32] Moreover, heating can also denature the delicate membranes of oil bodies, thus allowing them to coalesce.[33] These heat-induced physicochemical changes in the protective membrane increase oil body exposure to solvents, resulting in the higher extraction of oil.[12]

Heat processing did not significantly alter the total CP content in flaxseed, in support of earlier findings.[12,31] Among the heating methods, moist heating was more effective in altering the CP chemical profile. Notably, moist heating markedly decreased (56.5% to 25.9% CP) the SP content. Previous studies have reported a similar decrease in the SP fractions of soybean (43.4% to 11.4% CP)[34] and camelina seeds (52.7% to 20.4% CP)[12] after moist heating (120 °C for 60 min). In contrast, dry heating and MIR did not significantly alter the SP content of flaxseed. In agreement with our findings, dry heating also did not alter the SP content of soybean or camelina seeds.[12,34] The NPN content of flaxseed did not significantly change with heat processing. Other studies have reported both increases[12] and decreases[31,34] in NPN content with heat processing of oilseeds. Discrepancies between results may be related to the differences in seed types as well as in the NPN methodology (e.g., trichloroacetic acid vs tungstic acid and filter paper pore size). The NDIP content increased with all heating methods, but only that for moist heating was statistically significant (16.5% to 28.7% CP). Heat induces cross-linkages between amino acids and sugar molecules that can increase the recovery of N in the NDF fraction.[12,34] Our results show that heat-induced changes in chemical profile of flaxseed depend on the type of heating, with moist heating more effective in altering protein chemical profiles than MIR or dry heating. These findings also show that the use of moist heating during oil extraction in the bio-oil industries can improve both oil extractability and the nutritive value of the protein in the coproducts (meals and oil cakes) for dairy cows.

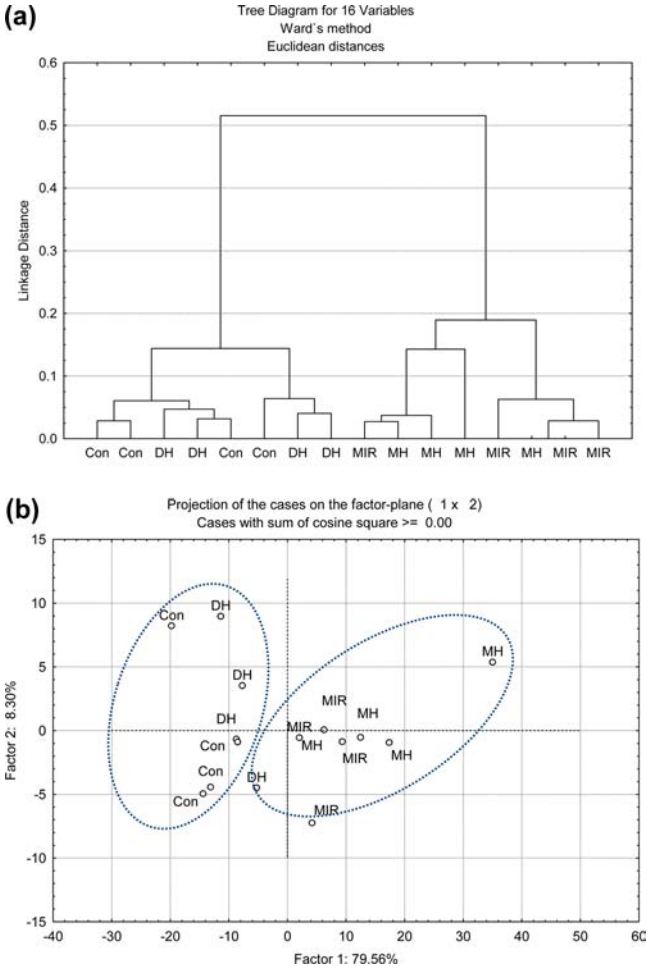

Figure 2. Agglomerative hierarchical cluster analysis (CLA) dendrograms (panel I) and principal component analysis (PCA) scatter plot (panel II) representing the overall spectral (n = 249 spectral bands) differences in the protein primary structures in the amide region (ca. 1712−1482 cm^{-1}) of raw (Con) and heat treated flaxseeds (MIR = microwave irradiation for 5 min; DH = heated in air-draft oven at 120 °C for 60 min; MH = heated in an autoclave by high pressure saturated steam at 120 °C for 60 min).

Heat-Induced Changes in Protein Subfractions. Data with respect to heat-induced changes in CNCPS CP subfractions of flaxseed are presented in Table 2. Moist heating significantly altered the content of PB1, PB2, and PB3 subfractions. The rapidly degradable (PB1) subfraction decreased (52.6% to 21.3% CP) with a subsequent increase (27.1% to 45.4% CP) in the intermediately degradable (PB2) subfraction. The major shift from the rumen degradable PB1 subfraction to the partially rumen degradable PB2 subfraction suggests a decrease in CP degradation in the rumen and a greater supply of RUP to the small intestine. Peng et al.[12] and Samadi and Yu[34] also observed a similar shift from PB1 to PB2 subfractions after moist heating (120 °C for 60 min) of camelina seeds and soybean. Moist heating increased (13.1% to 22.1% CP) the PB3 subfraction of flaxseed. Because of the slow

ruminal degradation rate (4%/h to 9%/h),[30] a large portion of the PB3 subfraction escapes degradation in the rumen and is instead digested in the small intestine. Therefore, the increase in the PB3 subfraction results in a contribution to the supply of digestible RUP to the postruminal tract. The MIR and dry heating of flaxseed did not significantly alter the CP subfraction profile, suggesting no significant change in ruminal CP degradation characteristics of flaxseed with these treatments. The three heating methods did not alter the PC subfraction. The proteins in the PC subfractions are bound to lignin or are heat damaged, and are thus considered nondegradable in the rumen and nondigestible in the postruminal tract.[28] This means that none of the heat processing method overprotected protein from intestinal digestion. Overall, heat processing method appears to have a major influence on heat-induced changes in CP subfractions.

Heat Induced Changes in Rumen Degradation and Intestinal Digestibility. Data on the effect of heating methods on ruminal DM and CP degradation kinetics and intestinal digestibility of RUP are presented in Table 3. Moist heating significantly increased the content of RUDM. The *S*-fraction of DM did not significantly change with moist heating. Therefore, the higher content of RUDM in the moist heated flaxseed could be related to the significantly lower *D*-fraction (76.3% vs 70.4% DM) and slightly lower kd (9.18% vs 8.09%/h) of the *D*-fraction compared with raw seeds. In agreement with our findings, moist heating (127 °C for 30 min) of sunflower seeds decreased the kd (9.3%/h to 5.2%/h) with a subsequent increase (31.6% to 42.4% DM) in RUDM.[31] The MIR did not alter the DM degradation kinetics. In contrast to our findings, a 5 min MIR increased the RUDM of cottonseed meal (39.7% to 48.3% DM)[35] and canola meal (33.5%/h to 45.9%/h).[36] This discrepancy in DM degradation kinetics could be related to the inherent differences in feed types, and industrial processing such as (defatted)-meals were used in the previous studies compared to full-fat flaxseeds in our study. Dry

heating did not significantly alter the DM degradation kinetics of flaxseed, consistent with earlier findings.[12,34]

With the exception of lag time and *D*-fraction, moist heating significantly altered the contents of all measured CP degradation parameters (Table 3). Notably, the content of RDP decreased (64.0% to 53.1% CP) with a concomitant increase in the supply of RUP (36.0% to 46.9% CP) to the postruminal tract. The higher content of RUP in the moist heated flaxseed could be related to the lower *S*-fraction (15.7% vs 9.27% CP) and lower kd (9.90% vs 7.53% CP) of the *D*-fraction. The higher RUP content in the moist heated flaxseed is also supported by observed changes in CP subfractions, such as the decrease in rapidly rumen degradable (PB1) subfraction and the increase in partially (PB2) and slowly (PB3) degradable subfractions. These results are consistent with the findings of Samadi and Yu[34] and Peng et al.,[12] who observed an increase in RUP content with moist heating (120 °C for 60 min) of soybean meal (13.8% to 33.6% CP) and camelina seeds (24.6% to 42.1% CP). Mustafa et al.[31] also observed a significantly higher RUP content (8.90% to 26.1% CP) with moist heating (127 °C for 30 min) of sunflower seeds. These findings demonstrate that moist heating of flaxseed can shift the site of CP digestion from the rumen to the postruminal tract. Digestion of feed protein in the small intestine results in lower losses of essential amino acids and protein.

Microwave irradiation increased the RUP content (36.0% to 40.4% CP) compared to raw seeds; this increase was not as large as that achieved with moist heating, but MIR requires less energy inputs and processing time. In agreement with our findings, earlier studies report that MIR for 6 min increased the RUP content of canola seeds (17.5% to 34.9% CP),[37] canola meal (34.8% to 53.9% CP),[36] and cottonseed meal (38.9% to 54.6% CP).[35] As MIR did not alter the kd, the higher RUP of the irradiated flaxseed could be related to the lower *S*-fraction and higher *U*-fraction compared to raw seeds. Dry heating did not significantly alter the RUP content (Table 3), consistent with earlier findings.[12,34] Notably, dry heating significantly decreased the intestinal digestibility of RUP, which implies that the seeds were partly overheated. In dry heating, the heat penetrates from the exterior to the interior and can result in the exterior feed being overheated and therefore overprotected from digestion in the postruminal tract.[15] The intestinal digestibility of RUP in the moist heated flaxseed was slightly higher than in the raw seeds (63.8% vs 61.0% RUP). The increase in RUP digestibility with moist heating of soybean and camelina seeds has been reported.[12,34] These results suggest that moist heating can increase the supply of digestible RUP to the postruminal tract. Steam heating, within the scope of the treatment used in this study, can be used for oil extraction in bio-oil industries to decrease CP degradation in the rumen, and improve the supply of metabolizable protein to dairy cows.

Heat Induced Changes in Protein Molecular Structure. Any heat-related processing that can modify the noncovalent interactions in protein molecules can potentially alter their pleated structures,[14] and exposes hydrophobic amino acids that can potentially reduce protein solubility.[36,38] The free (unbounded) amino acids also establish cross-linkages with reducing sugars and other (poly)peptides, resulting in reduced protein solubility and ruminal degradation.[12] Establishment of more complex cross-linkages due to heating for a longer duration or a higher temperature can make the protein molecules more resistant to rumen-microbial degradation and enzymatic hydrolysis.[12,15,38] Therefore, studying the heat-induced changes in protein molecular structures is vital to fully understand the changes in CP chemical profile and digestive behavior.

Amide I and II spectral intensities in terms of peak area and height characterize the protein primary structures.[27,39] Typically, the difference in the amide I and II spectral intensities reflects differences in protein content, whereas the amide I:II and α-helix:β-sheet ratios reflect differences in protein molecular makeup.[39,40] The data in Table 4 show that moist heating significantly decreases the α-helix:β-sheet ratio. This decrease is associated with a decrease in SP (56.5% to 25.9% CP; Table 1) and increases in RUP (36.0% to 46.9% CP; Table 3) and intestinal digestibility of RUP (61.0% to 63.8% RUP). The differences in α-helix:β-sheet ratio affect ruminal CP degradation and intestinal digestibility by altering protein solubility and the access of microbes and proteolytic enzymes.[14,27,41] Dry heating did not significantly alter the α-helix:β-sheet ratio. The lack of change in protein molecular structure with dry heating is associated with a lack of changes in protein subfraction composition and degradation characteristics in the rumen. These findings demonstrate that heat-induced changes in protein chemical profile and digestion are strongly related to heat-induced changes in protein molecular structure.

Multivariate Analysis. The CLA and PCA were performed on overall (n = 249 spectral bands) spectral data from the fingerprint region (ca. 1732−1483 cm^{-1}) to classify and visualize the heat-induced changes in protein molecular structural characteristics. Multivariate analysis is a useful tool for studying molecular structure differences of biopolymers. The CLA dendrograms (Figure 2a) show that protein molecular spectral data from moist heated and irradiated seeds can be distinguished from the raw and dry heated seeds at a linkage distance of <0.6, indicative of structural differences between these two groups. The mixed dendrograms of moist heated and irradiated flaxseed show that their protein molecular makeup is indistinguishable. Similarly, the mixed dendrograms of control (raw) and dry heated seeds show that the protein molecular makeup of dry heated and raw seeds are indistinguishable. The PCA results are presented as a scatter plot of the first two principal factors (Figure 2b). The scatter plot explained 87.9% of the total variation in protein molecular structures of the raw and heat-processed flaxseed. The protein molecular spectra of control and dry heated flaxseed were clustered into one ellipse, and those of MIR and moist heated flaxseed were clustered into another. Similar to the CLA dendrograms, these two groups could be completely distinguished from each other. The multivariate analyses results based on overall spectral data support the conclusion of the univariate spectral analyses (Table 4) that moist heating and MIR significantly alter protein molecular structures compared to raw seed. Moreover, CLA and PCA analysis were able to classify the overall differences in protein molecular makeup.

Correlations between Protein Molecular Structural Characteristics and Protein Availability and Utilization. Table 5 shows the coefficient of correlation (Pearson) and their level of significance between the α-helix:β-sheet ratio and protein chemical profiles, CP subfractions, *in situ* rumen CP degradation, and intestinal digestibility of RUP. Heat-induced changes in the α-helix:β-sheet ratio were negatively correlated with NDIP (r = −0.84), and positively correlated with SP (r = 0.86). These findings suggest that protein denaturation during heating increased the NDF-bound protein and decreased the SP. The α-helix:β-sheet ratio was positively correlated (r =

DOI: 10.1021/jf503575y
J. Agric. Food Chem. 2015, 63, 1057−1066

0.87) with the CNCPS PB1 subfraction, and negatively correlated with PB2 (r = −0.83) and PB3 (r = −0.74) subfractions. Among the *in situ* parameters, heat-induced changes in the α-helix:β-sheet ratio were positively correlated with kd (r = 0.80) and RDP (r = 0.87), and negatively correlated to RUP (r = −0.87) and intestinal digestibility (r = −0.68) of RUP. These results demonstrate the existence of a close relationship between heat-induced changes in α-helix:β-sheet ratio and the changes in protein chemical profile, CP-subfractions, and ruminal CP degradation characteristics.

Using Protein Molecular Spectral Parameters to Predict Protein Subfractions, Rumen Degradation Parameters, and Intestinal Digestibility. Table 6 shows the multiple regression equations, based on protein spectral parameters, and their predictive power for estimation of CP subfractions, *in situ* CP degradation parameters, and intestinal digestibility of RUP. The total CP content can be predicted (R^2 = 0.80) from the area ratio of amide I:II, which reflects differences in protein content of feeds.[38] Heat-induced changes in PB1 (R^2 = 0.64), PB2 (R^2 = 0.56), PB3 (R^2 = 0.60), kd (R^2 = 0.56), U (R^2 = 0.78), RUP (R^2 = 0.71), and intestinal digestibility of RUP (R^2 = 0.47) can be predicted from the α-helix:β-sheet ratio. The relatively high predictive power for estimation of CP subfractions and *in situ* parameters such as RUP could have important practical implications for feed evaluation because FTIR-ATR molecular spectroscopy is a noninvasive and nondestructive analytical technique that can rapidly analyze large numbers of feed samples. The findings of the present study support the suggestion of Yu and Nuez-Ortín[42] and Becker and Yu[43] that the α-helix:β-sheet ratio can be used as an indicator for changes in the protein nutritive value during heat-related processing. For example, the α-helix:β-sheet ratio was strongly correlated with protein solubility, rumen degradability, and intestinal digestibility of RUP. However, it is pertinent to mention that these prediction equations were derived from limited data based on only one type of oilseed. Further studies will be required to obtain predictive equations based on a large number of samples from diverse sources.

Overall, heat induced changes in CP chemical profiles, protein subfractions, rumen degradability, intestinal digestibility, and protein molecular structures of flaxseed clearly depend on the method of heating. Compared to dry heating and MIR, moist heating of flaxseed improves the nutritive value and utilization of protein in flaxseed by decreasing the SP content and the kd of the *D*-fraction, thus causing an increase in the supply of digestible RUP to the postruminal tract. These changes in CP chemical profile and digestive behavior are strongly associated with alterations in intrinsic protein molecular structures as measured by characteristics such as the α-helix to β-sheet ratio. Regression equations based on protein molecular structural features provide relatively good estimations for heat induced changes in SP content (R^2 = 0.62), RUP content (R^2 = 0.71), and intestinal digestibility of RUP (R^2 = 0.47).

studies on the isolation and pharmacological properties of the phenolic amides from the fruits of *L. barbarum* have been reported. In our preliminary chemical investigations on the fruits, phenolic amide constituents were detected. Therefore, the active components from the ethyl acetate part of ethanol extracts, especially the phenolic amides, were isolated and identified from the fruits of this plant with the help of activity-guided chromatography for antioxidants. The antioxidant activities of these phenolic amides isolated from the fruits of *L. barbarum* were also evaluated systematically in scavenging 2,2-diphenyl-1-picrylhydrazyl (DPPH) free radical and inhibiting lipid peroxidation in rat liver microsomes induced by ascorbate/Fe^{2+}, cumine hydroperoxide (CHP), or CCl_4/reduced form of nicotinamide-adenine dinucleotide phosphate (NADPH).

MATERIALS AND METHODS

Animals and Chemicals. Sprague−Dawley rats (male, weight = 180−220 g) were obtained from the Experimental Animal Research Center at the Fourth Military Medical University. All experimental procedures were carried out according to protocols approved by the Ethics Committee for Animal Experimentation of the Fourth Military Medical University (Xi'an, Shaanxi, China) and in accordance with the *National Institutes of Health Guide for the Care and Use of Laboratory Animals*.

CHP (85%), BHA (99%), BHT (99%), bovine serum albumin (BSA, 99%, fraction V, essentially fatty acid free, low endotoxin), and reduced form of nicotinamide-adenine dinucleotide phosphate tetrasodium salt ($NADPHNa_4$, 98%) were purchased from Sigma-Aldrich Chemie (Steinheim, Germany). DPPH was purchased from Fluka (Buchs, Switzerland). Phenolic acids and flavonoid standards, including gallic acid, caffeic acid, *p*-coumaric acid, chlorogenic acid, rutin, quercetin, and kaempferol, with purities of 98, 99, 98, 95, 95, 98, and 99%, respectively, were purchased from Sigma-Aldrich Chemie (Steinheim, Germany). Most of the other solvents and chemicals used in this research were also obtained from Sigma-Aldrich Chemie.

General Experimental Procedures. Optical rotations ($[\alpha]_D$) were measured on a PerkinElmer 343 polarimeter (PerkinElmer Instruments, Norwalk, CT, USA). ^{1}H (500 MHz), ^{13}C (125 MHz), and 2D NMR (500 MHz) spectra were recorded on a Bruker AVANCE-500 NMR spectrometer (Bruker Daltonik GmbH, Rheinstetten, Germany) using pyridine-d_5 or CD_3OD as solvent and tetramethylsilane (TMS) as internal reference. ESIMS, HRESIMS, and ESIMS/MS were carried out on a Micromass Waters Q-Tof Micro Mass Spectrometer Mass Spec QTOF. EIMS was carried out on a Waters AutoSpec Premier. Compounds were separated with a Dionex P680 liquid chromatograph equipped with a UV170 UV−vis detector and a YMC-Pack R&D ODS-A column (20 × 250 mm; YMC Co., Ltd., Japan) and monitored at 225, 250, 275, and 300 nm. Chromatographic materials for low-pressure chromatographies were silica gel (10−40 μm; Qingdao Marine Chemical Inc., China), reversed phase silica gel (Lichroprep RP-18, 40−63 μm; Merck Inc., Germany), and Sephadex LH-20 (GE-Healthcare, USA). Silica gel 60 F_{254} precoated aluminum sheets (0.25 mm, Merck Inc., Germany) were used for thin-layer chromatography (TLC). Fractions were monitored by TLC, and spots were visualized by spraying with 20% H_2SO_4−EtOH solution followed by heating.

Plant Materials. The fruits of *L. barbarum* used in this research were collected from Zhongning county of Ningxia province, the largest planation of goji berry in China, in September 2012. The plant materials were identified by one of the authors (H.T.). A voucher specimen (no. 11485) has been deposited in the Herbarium of the Department of Pharmacy, Xijing Hospital, Fourth Military Medical University, Xi'an, China.

Extraction and Activity-Guided Chromatographic Isolation of Antioxidants. The air-dried fruits of *L. barbarum* (20 kg) were extracted with 80 L of 85% EtOH at 85 °C for 2 h under reflux. This process was repeated three times. The combined extracts were concentrated under vacuum at 60 °C. The residue (540 g) was suspended in H_2O and extracted with petroleum ether and EtOAc (each 2 L × 3), successively. The EtOAc-soluble fraction (120 g) was subjected to column chromatography on silica gel (1400 g, 15 × 120 cm) and eluted with a $CHCl_3$/MeOH/H_2O gradient (100:1:0.1, 50:1:0.1, 20:1:0.1, 10:1:0.1, 8:1:0.1, and 6:4:0.4) to give six major fractions: fraction 1 (17.54 g), fraction 2 (12.83 g), fraction 3 (21.67 g), fraction 4 (20.56 g), fraction 5 (13.42 g), and fraction 6 (20.92 g). The abilities to scavenge the DPPH radical of these six fractions (each 0.1 mg/mL) were evaluated by the DPPH assay (calculated as radical-scavenging percentage, RSP), and the most active fractions were 3 and 4, with RSP values of 48.9 and 47.4%, respectively. The two fractions were evaluated by TLC compared with phenolic acids and flavonoid standards, including gallic acid, caffeic acid, *p*-coumaric acid, chlorogenic acid, rutin, quercetin, and kaempferol standards, and spots were visualized by spraying with 20% H_2SO_4−EtOH solution followed by heating. The TLC results showed that the spots displayed by fraction 3 were similar to those of flavonoids and phenolic acids

DOI: 10.1021/jf5049222
J. Agric. Food Chem. 2015, 63, 1067−1075

standards, but the spots displayed by fraction 4 were distinctively different from them. This suggested that the antioxidants of fraction 3 were mainly composed of flavonoids and phenolic acids,[14] but those of fraction 4 were of a different chemical structure. Accordingly, fraction 4 (20.65 g) was chromatographed on a silica gel column with a $CHCl_3$/MeOH/H_2O gradient (20:1:0.1, 15:1:0.1, 10:1:0.1, and 8:1:01) to give four major fractions: fraction 4.1 (2.24 g), fraction 4.2 (6.13 g), fraction 4.3 (2.68 g), and fraction 4.4 (1.15 g). Among all of these fractions (each 0.1 mg/mL), fraction 4.2 was the most potent in the DPPH assay with an RSP value of 72.3%. Accordingly, fraction 4.2 was submitted to Sephadex LH-20 column chromatography (1000 g, 5 × 120 cm) with MeOH and further purified by open column using reversed phase silica gel (RP-18, 300 g, 2 × 90 cm) eluted with an MeOH/H_2O gradient (4:6 and 7:3) to give two major subfractions: fraction 4.2.1 (3.87 g, 0.1 mg/mL) and fraction 4.2.2 (1.56 g, 0.1 mg/mL); fraction 4.2.1 was the main active part with an RSP value of 86.7%. Purification of fraction 4.2.1 by semipreparative HPLC (MeOH/H_2O, 65:35; 8.0 mL/min) afforded pure compounds **1** (25 mg, t_R 9.3 min), **2** (23 mg, t_R 11.8 min), **3** (15 mg, t_R 19.4 min), **4** (13 mg, t_R 16.6 min), and **5** (12 mg, t_R 14.2 min).

Structural Elucidation of Natural Products. *N-E-Coumaroyl tyramine (**1**):* faint yellow powder; ^{1}H NMR (pyridine-d_5, 500 MHz) and ^{13}C NMR (pyridine-d_5, 125 MHz) data, see Table 1; positive ESIMS m/z 306 $[M + Na]^+$; negative ESIMS m/z 282 $[M - H]^-$; positive HRESIMS m/z 306.1107 $[M + Na]^+$ (calcd for $C_{17}H_{17}NO_3Na$, 306.1106).

*N-E-feruloyl tyramine (**2**):* faint yellow powder; ^{1}H NMR (CD_3OD, 500 MHz) and ^{13}C NMR (CD_3OD, 125 MHz) data, see Table 1; positive ESIMS m/z 336 $[M + Na]^+$; negative ESIMS m/z 312 $[M - H]^-$; positive HRESIMS m/z 336.1213 $[M + Na]^+$ (calcd for $C_{18}H_{19}NO_4Na$, 336.1212).

*Lyciumamide A (**3**):* yellow powder; $[\alpha]^{22}_D$ − 9.4° (*c* 0.21, MeOH); ^{1}H NMR (CD_3OD, 500 MHz) and ^{13}C NMR (CD_3OD, 125 MHz) data, see Table 1; positive ESIMS m/z 647 $[M + Na]^+$; negative ESIMS m/z 623 $[M - H]^-$; positive HRESIMS m/z 647.2370 $[M + Na]^+$ (calcd for $C_{36}H_{36}N_2O_8Na$, 647.2369); negative ESIMS/MS of parent ion at m/z 623, m/z 177, 312, 417, 432, and 460; negative ESIMS/MS of parent ion at m/z 432, m/z 177, 283, 312, and 417; EIMS m/z 120 (41), 149 (16), 165 (8), 177 (100), 193 (81), 254 (23), 296 (16), 312 (34), and 328 (17) (Figure 2A).

*Lyciumamide B (**4**):* yellow powder; $[\alpha]^{22}_D$ − 8.6° (*c* 0.25, MeOH); ^{1}H NMR (CD_3OD, 500 MHz) and ^{13}C NMR (CD_3OD, 125 MHz) data, see Table 2; positive ESIMS m/z 647 $[M + Na]^+$; negative ESIMS m/z 623 $[M - H]^-$; positive HRESIMS m/z 647.2371 $[M + Na]^+$ (calcd for $C_{36}H_{36}N_2O_8Na$, 647.2369); negative ESIMS/MS of parent ion at m/z 623, m/z 283, 296 and 460; negative ESIMS/MS of parent ion at m/z 283, m/z 136 and 255.

*Lyciumamide C (**5**):* yellow powder; $[\alpha]^{22}_D$ − 7.9° (*c* 0.34, MeOH); ^{1}H NMR (CD_3OD, 500 MHz) and ^{13}C NMR (CD_3OD, 125 MHz) data, see Table 2; positive ESIMS m/z 514 $[M + Na]^+$; negative ESIMS m/z 490 $[M - H]^-$; positive HRESIMS m/z 514.1839 $[M + Na]^+$ (calcd for $C_{28}H_{29}NO_7Na$, 514.1842); negative ESIMS/MS of parent ion at m/z 490, m/z 312 and 356; negative ESIMS/MS of parent ion at m/z 356, m/z 163, 179, and 340.

Antioxidant Activities. *DPPH Radical-Scavenging Activity.* Radical-scavenging activities of chromatographic fractions, purified compounds, and reference compounds were determined using a DPPH assay.[23] The RSP was calculated as follows: RSP = $[(A_0 - A_1)/A_0] \times 100$, where A_0 is the absorbance of the control (BHA) at 30 min and A_1 is the absorbance of the sample at 30 min. All samples were analyzed in triplicate.

Preparations of Liver Microsomes. Rat liver microsomes were prepared by standard differential centrifugation techniques as described by the literature.[24] The microsomes were suspended in 0.1 M Tris-HCl buffer (pH 7.4) when used in the experiments. Protein concentration was determined according to the Lowry method[25] using BSA as the standard.

Ascorbate/Fe^{2+}-Induced Lipid Peroxidation. The assay of lipid peroxidation of microsomes was performed as described by the literature.[26] The microsomes (2 mg microsomal protein/mL) were preincubated with (I) or without (I_0) the sample (0.1 mM compounds **1**−**5**, respectively) in the presence of 0.1 M Tris-HCl buffer (pH 7.4) and $FeSO_4$ (50 μM). Lipid peroxidation was initiated by adding ascorbate (5 mM), and the sample was then incubated at 37 °C for 15 min. The extent of lipid peroxidation was detected by the TBA method using trichloroacetic acid (10%, w/v) and TBA (0.67%, w/v) to measure the absorbance at 535 nm. The thiobarbituric acid reactive substances (TBARS) were calculated as malondialdehyde (MDA) equivalents. BHT (0.45 mM) was used as a positive control. The inhibitory effect on vitamin C/Fe^{2+}-induced lipid peroxidation was calculated as (%) inhibition ratio = $(I_0 - I)/I_0 \times 100$.

CHP-Induced Lipid Peroxidation. The microsomes (2 mg microsomal protein/mL) were preincubated with (I) or without (I_0) pure compounds (all 0.1 mM) in the presence of 0.1 M Tris-HCl buffer (pH 7.4). Lipid peroxidation was initiated by CHP (1 mM), and the samples were then incubated at 37 °C for 15 min. Trichloroacetic acid (10%, w/v) was used to stop the reaction. TBARS were determined as described above. BHT (0.45 mM) was used as a positive control. The inhibitory effect on CHP-induced lipid peroxidation was calculated as (%) inhibition ratio = $(I_0 - I)/I_0 \times 100$.

CCl_4/NADPH-Induced Lipid Peroxidation. The reaction mixture contained 2 mg of microsomal proteins and a NADPH-generating system (0.2 mM $NADP^+$, 4 mM glucose 6-phosphate, and 0.8 unit of

glucose-6-phosphate dehydrogenase) in the 0.1 M Tris-HCl buffer (pH 7.4) with (I) or without (I_0) testing samples (all 0.1 mM). Lipid peroxidation was initiated by CCl_4/DMSO (1:4, v/v). After 15 min of incubation at 37 °C, TBARS were determined as described above. BHT (0.45 mM) was used as a positive control. The inhibitory effect on CCl_4/NADPH-induced lipid peroxidation was calculated as (%) inhibition ratio = $(I_0 - I)/I_0 \times 100$.

Statistical Analysis. Data were expressed as the mean ± SD. Statistical analysis was carried out by analysis of variance (ANOVA) followed by the LSD test for multiple comparisons. Data analysis was carried out using the SPSS v.11.0 software package. Differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

Isolation of Compounds from the Fruits of *L. barbarum*. The air-dried fruits of *L. barbarum* were extracted with EtOH under reflux. The petroleum ether extraction allowed removing the nonpolar components that showed low antioxidant activity. The EtOAc extract was fractionated by low-pressure column chromatography on silica gel to yield six major fractions. The six fractions were further purified with the help of activity-guided chromatography. Then the active antioxidants were isolated and identified as *N-E*-coumaroyl tyramine (**1**), *N-E*-feruloyl tyramine (**2**), lyciumamide A (**3**), lyciumamide B (**4**), and lyciumamide C (**5**), respectively (Figure 1). All of the compounds were isolated from the fruits of *L. barbarum* for the first time, and compounds **3**−**5** were identified as new compounds.

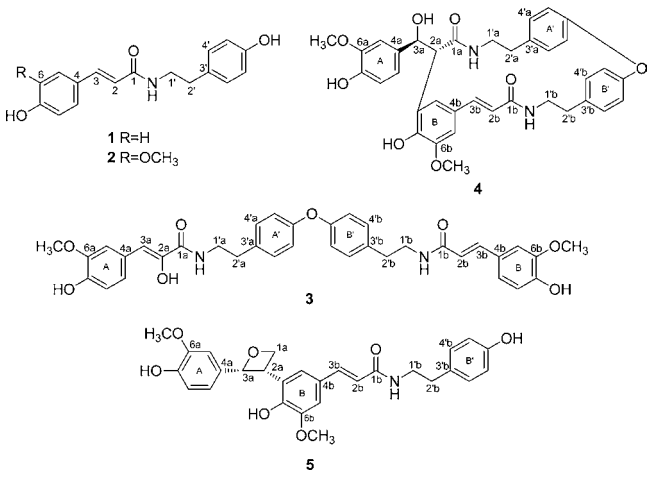

Figure 1. Structures of compounds **1**−**5**.

Structure Elucidation of the Five Purified Compounds. Two known compounds, *N-E*-coumaroyl tyramine (**1**) and *N-E*-feruloyl tyramine (**2**), were identified by comparaison of the observed ^{1}H and ^{13}C NMR data with literature values. The coupling constants between H-2 and H-3 (J = 15.6 and 15.7 Hz, respectively, for **1** and **2**) clearly indicated the *E* configuration of the double bonds. Compound **1** had been identified from *Asimina triloba*[27] and root bark of *Lycium chinense*.[17] Compound **2** had been reported as a natural product from the stem of *Piper argyrophylum*,[28] twigs of *Piper caninum*,[29] roots of *Solanum melongena*,[30] and stem of *Tinospora tuberculata*.[31]

Compound **3** was obtained as a yellow powder. The molecular formula of **3** was established as $C_{36}H_{36}N_2O_8$ from the $[M + Na]^+$ ion at m/z 647.2370 (calcd for $C_{36}H_{36}N_2O_8Na$, 647.2369) in the positive ion mode HRESIMS. This formula corresponded to a phenolic amide dimer consistent with 20 degrees of unsaturation. The ^{1}H and ^{13}C NMR data (Table 1) indicated that it was a dimer consisting of a *N-E*-feruloyl tyramine unit and a unit of its derivative.[32] On the basis of the EIMS fragment ions at m/z 254, 193, 177, and 312 (Figure 2A), the two units were suggested to be linked by an ether bond that was produced by the dehydration of two phenolic hydroxyl groups belonging to the two tyramine parts, that is, −C-6′a−O−C-6′b−. ESIMS data (Figure 2B) provided further evidence that the two tyramine parts were linked by an ether bond. In particular, the ion at m/z 432, which was equivalent to a loss of 191 Da in comparison to an ion at m/z 623, suggested the loss of a ferulic acid fragment, whereas an ion at m/z 283 was assigned as loss of a 2-methoxy-4-vinylphenol unit (149 Da) in comparison to the ion at m/z 432. In addition, the negative ESIMS/MS of parent ion at m/z 623 afforded representative fragmentations at m/z 177, 312, 417, 432, and 460 (Figure 3). The ion at m/z 432, which was equivalent to a loss of 191 Da in comparison to the parent ion at m/z 623, suggested the loss of a ferulic acid fragment, whereas an ion at m/z 417 was assigned as loss of NH (15 Da) in comparison to the ion at m/z 432, etc. The proposed fragmentation pathway of **3** is shown in Figure 3. This was also confirmed by the negative ESIMS/MS of parent ion at m/z 432 (representative fragmentations at m/z 177, 283, 312, and 417, Supporting Information). The assignments of all ^{1}H and ^{13}C NMR signals for the dimer were made by analyzing ^{1}H−^{1}H COSY, HSQC, and HMBC data. After analysis of ^{1}H−^{1}H COSY and HSQC, the ^{1}H NMR spectral data (Table 1) showed the presence of characteristic resonances in two distinct regions. The former, between δ_H 7.5 and 6.0, was produced by two sets of ortho-coupled aromatic protons at δ 7.07 and 6.61 (each 2H, d, J = 8.4 Hz) and δ 6.85 and 6.73 (each 2H, d, J = 8.4 Hz) from the AA′BB′-spin system of two 1,4-disubstituted aromatic rings (A′ and B′), two sets of aromatic protons at δ 7.30 (d, J = 1.2 Hz, H-5a), 6.73 (d, J = 8.0 Hz, H-8a), and 7.05 (dd, J = 8.0 and 1.2 Hz, H-9a) and at δ 7.24 (d, J = 2.0 Hz, H-5b), 6.72 (d, J = 8.0 Hz, H-8b), and 7.02 (dd, J = 8.0 and 2.0 Hz, H-9b), from the ABC-spin system of two 1,3,4-trisubsitituted benzene rings (A and B), two olefinic proton doublets at δ 6.53 and 7.49 (each d, J = 15.7 Hz, H-2b and H-3b), and an olefinic proton singlet at δ 7.26 (H-3a). The second region of the ^{1}H NMR spectrum of the dimer, between δ_H 4.0 and 2.0, indicated two A_2X_2 spin systems (δ 3.48, 4H, H_2-1′a and H_2-1′b; δ 2.77, 2H, H_2-2′a and δ 2.65, 2H, H_2-2′b) corresponding to protons of two isolated and deshielded ethylidene units, and two methoxy groups (δ 3.67, 3H, s, and δ 3.92, 3H, s). The HMBC correlations from protons of the two methoxy groups to C-6a (δ_C 147.5) and C-6b (δ_C 149.1), respectively, showed their positions on rings A and B. Additional ^{13}C NMR resonances in the dimer indicated the presence of two carbonyls of amide (δ 164.0, C-1a and δ 167.4, C-1b). In comparison with the chemical shifts of C-1a, C-2a (δ 140.1, quaternary carbon), C-3a, and C-4a with those of C-1b, C-2b (δ 119.6, tertiary carbon), C-3b, and C-4b, respectively, the variation of the δ values suggested that an active group was linked at C-2a. In consideration of the molecular formula of **3**, it should be a hydroxyl group. This was confirmed by the EIMS fragment ions (Figure 2A) at m/z 193 and 165 and the HMBC correlations H-3a/C-1a, H-5a/C-3a, and H-9a/C-3a. The HMBC interactions (Figure 4) also confirmed the interatomic connectivities and, thus, established the entire structure of **3**, named lyciumamide A.

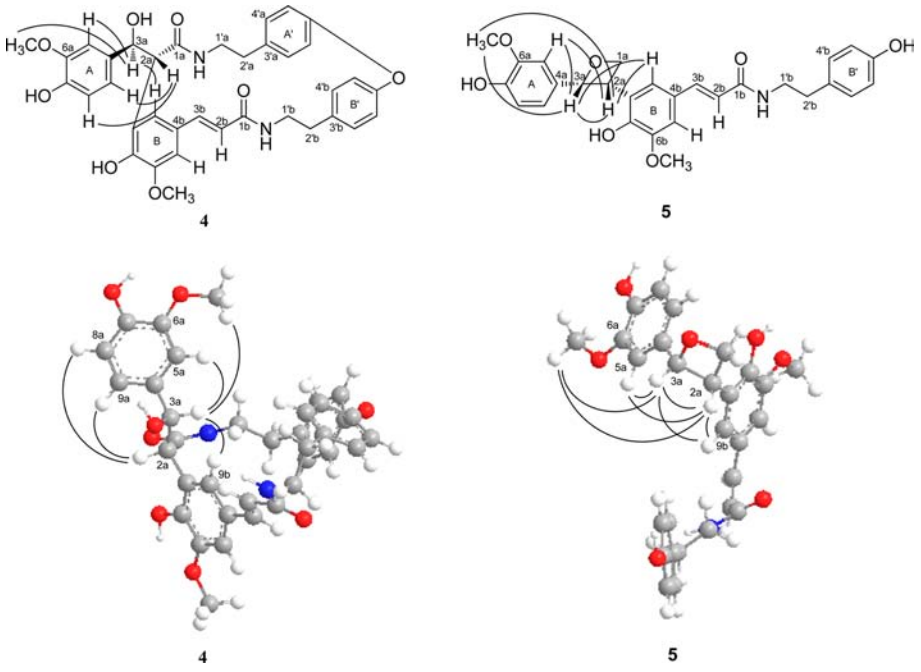

Figure 5. Key NOESY correlations for compounds **4** and **5**.

ments of the NMR signals were secured by analysis of $^{1}H-^{1}H$ COSY, NOESY, HSQC, and HMBC spectra. The ^{1}H and ^{13}C NMR spectral data of **4** (Table 2) were very similar to those of **3**, which indicated that **4** was also a dimer consisting of a *N-E*-feruloyl tyramine unit and a unit of its derivative. The negative ion mode ESIMS (Figure 2B) showed the same daughter ion peak at *m/z* 283 as for compound **3** deduced from the loss of a 340 Da unit (two ferulic acid fragments). Another ion at *m/z* 255, which was equivalent to a loss of 28 Da in comparison to the ion at *m/z* 283, suggested the loss of CO. In addition, the negative ESIMS/MS of parent ion at *m/z* 623 afforded representative fragmentations at *m/z* 283, 296, and 460, which could further confirm the linkage of compound **4**. The ion at *m/z* 296, which was equivalent to a loss of 164 Da in comparison to an ion at *m/z* 460, suggested the loss of CO and a 2-methoxy-4-methylphenol unit. The ion at *m/z* 283 was also assigned as loss of CH (13 Da) in comparison to the ion at *m/z* 296, and the proposed fragmentation pathway of **4** is shown in Figure 3. This was also verified by the negative ESIMS/MS of the parent ion at *m/z* 283 (representative fragmentations at *m/z* 136 and 255, Supporting Information). There were two distinctly distinguishable regions by careful comparison of the NMR data of **4** with **3**. In the former, the signals at C-2a (δ_H 4.16, d, J = 8.3 Hz; δ_C 58.8) in **4** suggested that it was a sp^3 methine instead of the olefinic quaternary carbon atom (δ_C 140.1) in **3**. The signals at C-3a (δ_H 5.90, d, J = 8.3 Hz; δ_C 90.1) in **4** suggested that it was also a sp^3 methine instead of the sp^2 methine (δ_H 7.26, s; δ_C 124.0) in **3**, and the upfield δ values of C-3a and H-3a in **4** indicated that an active group was linked at C-3a. In consideration of the molecular formula of **4**, it should be a hydroxyl group. In the second region, the DEPT and ^{13}C NMR spectra of **4** revealed that C-8b (δ_C 129.6) was a quaternary carbon atom instead of the tertiary carbon atom in **3** (δ_H 6.73, δ_C 115.0). The partial structure from C-1a to C-3a and the linkage of C-8b to C-2a were confirmed from the HMBC correlations from H-2a to C-4a, C-7b, and C-9b and from H-3a to C-1a, C-5a, C-9a, and C-8b, together with the $^{1}H-^{1}H$ COSY correlations between H-2a and H-3a (Figure 4). To infer the relative stereochemistry, a NOESY experiment was conducted (Figure 5). Clear cross peaks of H-2a and H-8a, H-2a and H-9a, H-3a and H-5a, H-3a and the methoxy protons, and H-3a and H-9b were observed. These NOEs indicated that the relative stereochemistry of the two protons H-2a and H-3a was *trans*. Thus, the structure of **4** was established and named lyciumamide B.

Compound **5** was obtained as a yellow powder. The molecular formula was established as $C_{28}H_{29}NO_7$ from the $[M + Na]^+$ ion at *m/z* 514.1839 (calcd for $C_{28}H_{29}NO_7Na$, 514.1842) in the positive ion mode HRESIMS. The assignments of the NMR signals were secured by analysis of $^{1}H-^{1}H$ COSY, NOESY, HSQC, and HMBC spectra. Careful comparison of ^{1}H and ^{13}C NMR data of **4** with those of **5** (Table 2) revealed that the NMR signals from C-1′a to C-8′a could not be observed in **5**, suggesting the absence of the phenethylamine group. Moreover, the NMR spectra of **5** displayed a sp^3 methylene (δ_H 3.84, 2H, m; δ_C 65.0, C-1a) instead of the carbonyl group in **4** ($\delta_{]C}$ 173.0). The upfield δ values of C-1a, H-1a, C-3a (δ_C 90.0), and H-3a (δ_H 5.58) in **5** indicated that C-1a and C-3a were oxygen-bearing atoms. The $^{1}H-^{1}H$ COSY correlations between H-1a and H-2a (δ_H 3.54) and between H-2a and H-3a confirmed the presence of the oxetane segment. The linkages of C-3a to C-4a and C-2a to C-8b were deduced from the HMBC correlations from H-1a to C-3a and C-8b, from H-2a to C-4a, C-7b, and C-9b, and from H-3a to C-5a, C-9a, and C-8b (Figure 4). Meanwhile, the structure of the oxetane segment was further confirmed by the key ESIMS fragmentation at *m/z* 340 and 356 (Figure 2B) and the ESIMS/MS of parent ion at *m/z* 490 (representative fragmentations at *m/z* 312 and 356, Figure 3) and the ESIMS/MS of parent ion at *m/z* 356 (representative fragmentations at *m/z* 163, 179, and 340, Supporting Information). To infer the relative stereochemistry, a NOESY experiment was conducted (Figure 5). Clear cross peaks of H-2a and H-3a, H-3a and H-5a, H-3a and the methoxy protons, H-3a and H-9b, H-2a and the methoxy protons, H-2a and H-5a, and H-2a and H-9b were

DOI: 10.1021/jf5049222
J. Agric. Food Chem. 2015, 63, 1067−1075

observed. These NOEs indicated that the relative stereochemistry of the two protons of oxetane (H-2a and H-3a) was *cis*. Therefore, the structure of **5** was established and named lyciumamide C.

Antioxidant Activities of the Five Purified Compounds. The assessment of antioxidant activity by a single method often underestimates the antioxidant potential of a molecule, and it reflects only the ability to inhibit a precise class of oxidants present.[33] The combination of several complementary analyses can give a clearer idea of the power of an antioxidant extract or a pure molecule. In this context, the antioxidant capacities of the five phenolic amides were evaluated using different antioxidant tests.

Scavenging of DPPH. Figure 6 shows the abilities of these pure compounds in reducing DPPH free radical. It could be noted that all of these pure compounds were effective in scavenging DPPH free radicals, whereas compound **1** showed the most prominent effect (96.3%), followed by compound **2** (96.1%), BHA (93.2%), compound **5** (90.3%), compound **3** (75.6%), and compound **4** (73.2%). In fact, compounds **1** and **2** exhibited better free radical scavenging activity than the reference BHA. The results suggested that phenolic amides isolated from the fruits of *L. barbarum* had good antioxidant activity, similar to that of other phenolic compounds such as phenolic acids and flavonoids from the fruits.[22]

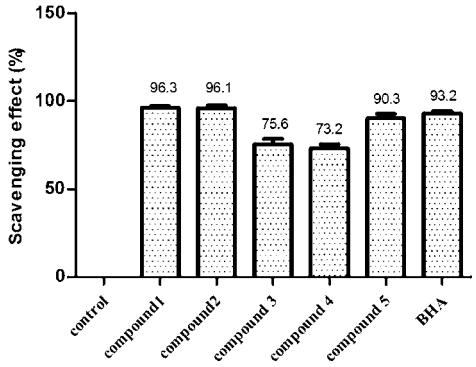

Figure 6. Effects of compounds **1**−**5** (0.1 mM) on DPPH absorption. The values are expressed as the mean ± SD (n = 3). Data with all compounds compared with the control group are significantly different at $P < 0.01$.

Inhibition of Lipid Peroxidation in Rat Liver Microsomes. Lipid peroxidation can be induced rapidly by the incubation of rat liver microsomes with ascorbate/Fe^{2+}, CHP, or CCl_4/NADPH at pH 7.4. Table 3 shows the activities of the pure compounds and BHT against lipid peroxidation. The extent of inhibition of lipid peroxidation was not uniform and varied among different compounds.

The analysis of results (Table 3) showed that the extent of TBARS formation was significantly decreased compared with the control group ($P < 0.01$) in the presence of the pure compounds, which exhibited lipid peroxidation inhibition activity. In the ascorbate/Fe^{2+}-induced lipid peroxidation system, compounds **1** and **2** exhibited the highest inhibiting activity of lipid peroxidation, and no significant difference was found between the two compounds ($P > 0.05$). Compound **5** showed significantly higher inhibitory activity of lipid peroxidation when compared with compounds **3** and **4** ($P < 0.01$), and no significant difference was found between compounds **3** and **4** ($P > 0.05$). In the CHP-induced lipid peroxidation system, compound **5** exhibited the highest inhibitory activity of lipid peroxidation, which was higher than those of the other dimers and the monomers ($P < 0.01$). The monomers **1** and **2** showed significantly higher inhibitory activities of lipid peroxidation when compared with the dimers **3** and **4** ($P < 0.01$). In the CCl_4/NADPH-induced lipid peroxidation system, all of the compounds exhibited excellent inhibiting activity of lipid peroxidation. Compound **5** showed the highest inhibiting activity, whereas there was no significant difference when compared with compounds **1** and **2** ($P > 0.01$). All of the results showed that the inhibition activity of compounds **1**, **2**, and **5** were significantly higher than the two dimers in the lipid peroxidation inhibitory assay.

In summary, the fruits of *L. barbarum* are a new source of natural phenolic amides. Lyciumamides A, B, and C, three new dimers of phenolic amides, along with two monomers, *N-E*-coumaroyl tyramine and *N-E*-feruloyl tyramine, were isolated from the fruits of *L. barbarum* for the first time. Their antioxidant activities were determined in scavenging DPPH free radical and inhibiting lipid peroxidation in rat liver microsomes induced by ascorbate/Fe^{2+}, CHP, or CCl_4/NADPH, and the data supported that these phenolic amides played an important role in the natural antioxidant properties of the fruits of *L. barbarum*, similar to those of other phenolic constituents such as flavonoids and phenolic acids of the fruits.[11] In conclusion, all of the results obtained here complemented the current knowledge of the antioxidative composition of the fruits of *L. barbarum* and confirmed that this agricultural product contained phenolic amide compounds, which might offer interesting potential applications in the food, cosmetic, and pharmaceutical industries.

Table 3. Effects of Compounds 1−5 on Lipid Peroxidation of Rat Liver Microsomes

	ascorbate/Fe^{2+}		CHP		CCl_4/NADPH	
	MDA[a] (μM)	I%[b]	MDA[a] (μM)	I%[b]	MDA[a] (μM)	I%[b]
control	7.16 ± 0.23		3.67 ± 0.18		5.13 ± 0.08	
compound **1**	0.53 ± 0.03**[c]	92.60	0.55 ± 0.04**	85.01	0.21 ± 0.01**	95.91
compound **2**	0.58 ± 0.03**	91.90	0.62 ± 0.04**	83.12	0.18 ± 0.01**	96.49
compound **3**	2.65 ± 0.07**	62.99	1.36 ± 0.07**	62.94	0.95 ± 0.04**	81.48
compound **4**	2.72 ± 0.07**	62.01	1.38 ± 0.08**	62.40	0.93 ± 0.04**	81.87
compound **5**	1.24 ± 0.05**	82.68	0.21 ± 0.02**	94.28	0.17 ± 0.01**	96.69
BHT	0.18 ± 0.01**	97.49	0.06 ± 0.01**	98.37	0.22 ± 0.01**	95.71

[a]Values are expressed as the mean ± SD (n = 3). TBARS (thiobarbituric acid reactive substances) were expressed by MDA (malondialdehyde) produced in the presence of 0.1 mM of pure compounds in the condition assays (see Materials and Methods). [b]Percentage of inhibition (I%) due to the pure compounds was calculated after deducting the basal level of peroxidation. [c]**, $P < 0.01$ compared with the control group (BHT).

Validation Sample Matrix. Canola seed used for method development and validation was purchased from a commercial source. Seed was ground using a centrifugal mill grinder (Retsch, Haan, Germany) to a particle size of ≤0.75 mm. Following preparation, ground seed was stored at approximately −20 °C.

Extraction. Extraction of vitamin K_1 from food matrices has been accomplished primarily via direct extraction with organic solvents or through enzymatic hydrolysis. Because vitamin K_1 is unstable under alkaline conditions, caustic saponification, commonly used for other fat-soluble vitamins such as A and E, is not appropriate.[7] Extraction was accomplished utilizing the procedure recommended by USP24/NF19.[8] Test portions (0.5 g) of ground canola seed were weighed into 15 mL plastic centrifuge tubes. Subsamples designated as laboratory-fortified samples were spiked with 0.07 mL of a 10 μg/mL vitamin K_1 standard solution, producing a fortified concentration of about 1.5 mg/kg. Laboratory-fortified samples were used to assess method accuracy through calculation of percent recovery. All test portions were spiked with 0.1 mL of a 10 μg/mL IS standard solution. To each test portion were added 4 mL of DMSO and 6 mL of hexane, and the contents were mixed on a vortexing apparatus for about 5 s. The samples were placed in an ultrasonic bath at 60 °C and sonicated for 45 min with vigorous hand shaking for 5 s approximately every 10 min. After centrifugation at 1800*g* for 10 min, the upper hexane layer was transferred to a 25 mL volumetric flask. Two additional extractions were performed by adding 6 mL of hexane followed by brief vortex mixing and shaking (sample tubes oriented horizontally) for 5 min at 300 rpm using a platform orbital action shaker. Following centrifugation at 1800*g* for 10 min, the hexane layer was drawn off and combined with the previous extract in the 25 mL volumetric flask. A 2.5 mL aliquot of the hexane extract was transferred to a 15 mL glass culture tube and evaporated to dryness under a stream of nitrogen using a heating block temperature of 30 °C. Sample residues were reconstituted by adding 1 mL of hexane to each culture tube and vortex mixing for about 5 s.

Silica Solid Phase Extraction (SPE) Cleanup. A SPE purification procedure followed recommendations outlined in AOAC method 992.27.[9] Silica SPE Sep-Pak cartridges, 500 mg/6 cm^3 (Waters Corp.), were mounted on a 12- or 24-position SPE vacuum manifold (Supelco, Bellefonte, PA, USA). Each cartridge was washed with 2 mL of hexane and then loaded with the sample solution (1 mL). The extract solution was allowed to drain via gravity flow until reaching the top of the column bed. The SPE cartridge was washed with 1 mL of hexane followed by 2 mL of 5:95 dichloromethane/hexane (v/v). Vacuum (<20 in. Hg) was applied for 5 min to completely dry the cartridge packing. The vacuum was stopped, and a 15 mL glass culture tube was placed under the cartridge inside the manifold. Vitamin K_1 was eluted by adding 2 mL of dichloromethane to the top of each column and allowing the solvent to drain by gravity to the top of the sorbent bed. Vacuum was then applied to remove the remaining dichloromethane from the column bed. The collected eluate was evaporated to dryness under a stream of nitrogen and reconstituted in 1 mL of isopropanol. The isopropanol sample solution was transferred to an amber HPLC autosampler vial and submitted for C_{30} HPLC-MS/MS analysis.

C_{30} HPLC-MS/MS Analysis. The HPLC-MS/MS analysis was based upon the methodology of Huang et al. and Schimpf et al.[10,11] Separation was accomplished on a C30 (3 mm × 150 mm i.d. × 3 μm) reversed phase column (YMC Co., Komatsu, Japan). The column was maintained at a temperature of 30 °C. Elution was carried out at a flow rate of 0.5 mL/min with the following solvent system: A = 0.1% formic acid in deionized water, B = dichloromethane/methanol, 5:95 (v/v). Following injection of 5 μL of sample or calibration standard solution, the solvent composition was held at 5% A/95% B for 0.1 min. A linear gradient to 100% B was then carried out over 5 min and held until 8 min. The mobile phase composition was returned to 5% A/95% B and allowed to equilibrate for an additional 4 min. The total run time was 12 min per injection. Approximate retention times were 7.2 and 7.7 min for *trans*- and *cis*-vitamin K_1, respectively. Mobile phase flow was diverted to waste for the first 6.5 min following injection and then redirected to the MS detector for 2 min to allow detection of the eluted analytes. The flow was again diverted to waste at 8.5 min. The MS detector scanned only during the 2 min retention time range of peak elution. The Quattro micro MS detector was operated in positive ion mode. Multiple reaction monitoring (MRM) was used to detect the vitamin K_1 and d_7-vitamin K_1 isomers. For vitamin K_1, the transition of the precursor ion at a mass to charge ratio (m/z) of 451.6 ($[M + H]^+$) and product ion at m/z 187.2 (451.6 → 187.2) was monitored. For the d_7-vitamin K_1 internal standard, the transition 458.8 → 194.3 was monitored. Source settings were 40 V for the sample cone, 25 (nominal) for the collision cell energy, 4.5 kV for the capillary, 0.00 V for the extractor, and 0.1 V for the RF lens. Source and desolvation temperatures were maintained at 150 and 450 °C, respectively. Cone gas and desolvation nitrogen gas flow rates were 30 and 550 L/h, respectively.

Calculation of Results. Calibration curves were generated for *trans*-vitamin K_1 ranging from 4.5 to 180 ng/mL. Internal standardization was utilized. Each calibration solution contained 90 ng/mL d_7-*trans*-vitamin K_1. A linear regression curve was constructed using peak area ratios (y-axis) and the standard solution concentration ratios (x-axis). A single injection of each calibration standard was carried out over the course of each analysis sequence. Sample solution concentrations (ng/mL) were calculated using the straight-line equation from the calibration curve. A weighting function of $1/x$ was used. Peak areas, calibration curves, and sample solution concentrations were calculated using the data system (Masslynx version 4.1).

Biological Materials. A total of seven conventional canola cultivars were evaluated from Locations in North and South America as listed in Table 1. The South American canola seed materials were grown at two locations (El Monte, Melipilla; and Paine, Maipo) in Chile during 2011/2012. The North American canola seed materials were grown in the United States and Canada (R. M. Corman Park, Saskatchewan, Canada; Portage la Prairie, Manitoba, Canada; R. M. MacDonald, Manitoba, Canada; Cass, ND, USA; Grand Forks, ND, USA; McHenry, ND, USA) during 2012. Various cultivars were planted at each location, with Ebony being planted at each location. Each location was planted in a randomized complete block design with four replicates of each variety. Seed samples were harvested at physiological maturity from all plots and shipped at ambient temperature to Monsanto Co. (Creve Coeur, MO, USA). A subsample for vitamin K_1 analysis was obtained from each sample collected. These subsamples were then ground and stored in a freezer set to maintain a temperature of −20 °C until their shipment on dry ice to EPL Bio Analytical Services for analysis.

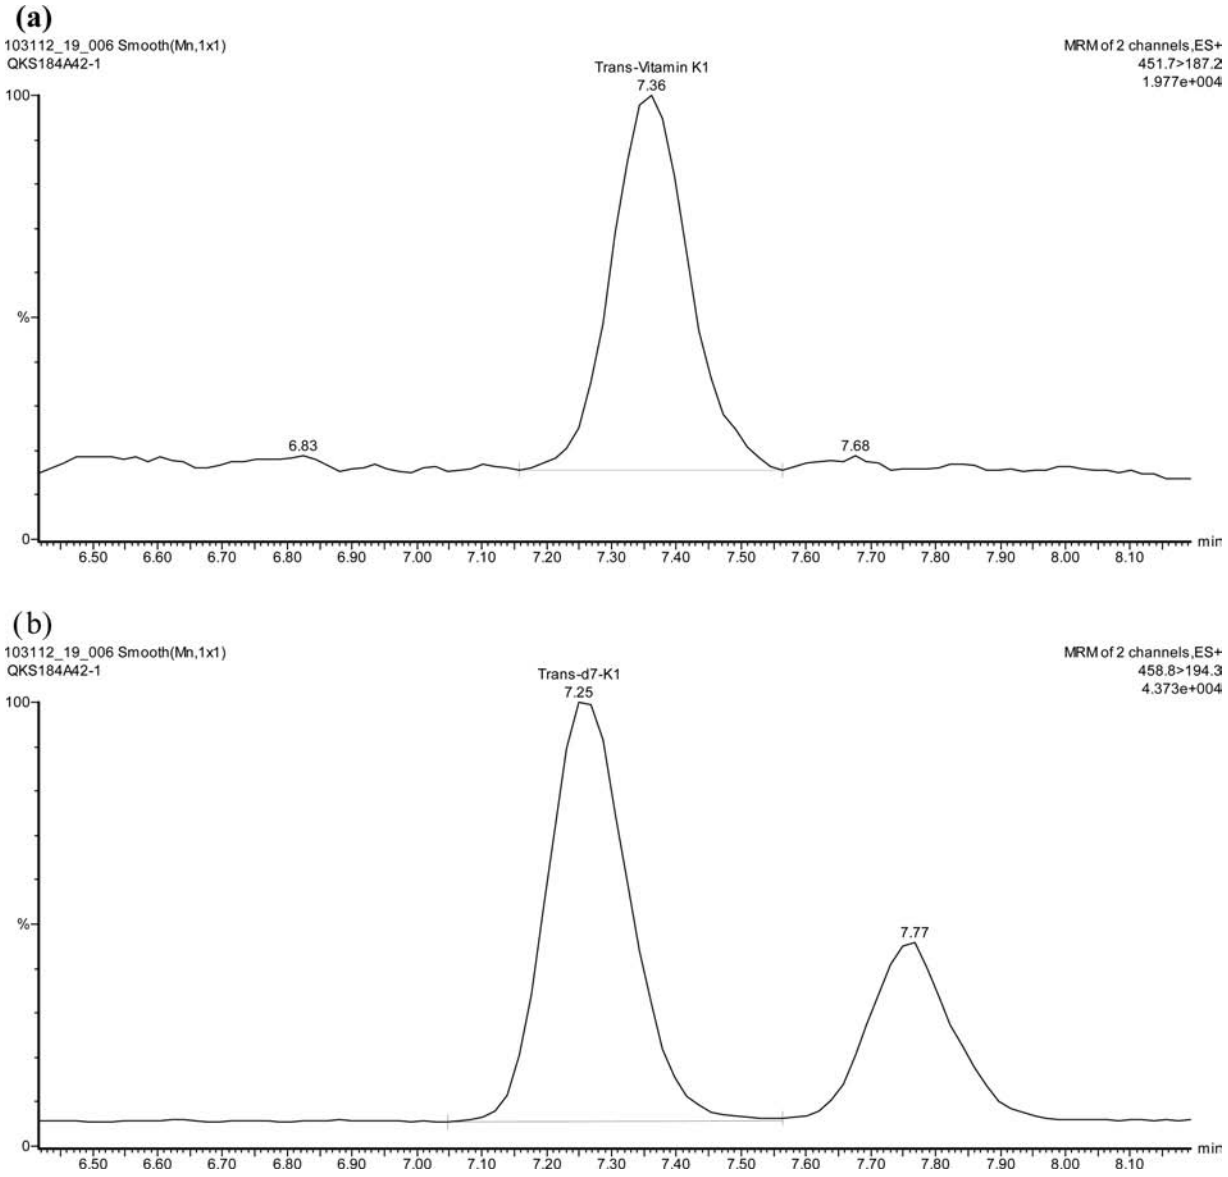

Figure 1. HPLC-MS/MS chromatogram of a canola seed extract showing *trans*-vitamin K_1 (a). *cis*-vitamin K_1 not detected (expected retention time = 7.88 min). HPLC-MS/MS chromatogram of a canola seed extract showing d_7-*trans*-vitamin K_1 internal standard (b). d_7-*cis*-Vitamin K_1 internal standard peak appears at 7.77 min (not integrated).

Statistical Analysis. The vitamin K_1 data were summarized (mean and range) by region (North and South America). In addition, statistical analysis of the data involved a comparison of vitamin K_1 concentrations between the North American sites and the South American sites to determine significant differences ($\alpha = 0.05$) by using the following fixed model to conduct analysis of variance (ANOVA). The model uses the term continent to refer to the North and South American locations.

$$Y_{ijk} = \mu + \tau_i + \lambda_k + (\tau\lambda)_{ik} + \beta_{j(k)} + \varepsilon_{ijk}$$

Y_{ijk} is the value of vitamin K_1 concentration of cultivar i in location j of continent k, μ is the overall mean, τ_i is the random effect of cultivar i, λ_k is the effect of continent k, $(\tau\lambda)_{ik}$ is the random effect of the interaction between cultivar i and continent k, $\beta_{j(k)}$ is the effect of location j nested within continent k, and ε_{ijk} is the residual error. Statistically significant differences between the North American and South American sites were declared at $\alpha = 0.05$.

Variance components analysis (VCA) was also conducted to estimate the proportion of each effect in the model contributing to the total variance. In this application, the effects of cultivar, continent, cultivar × continent interaction, and location (continent) in the ANOVA model were set as random effects. The SAS procedure PROC MIXED was employed to run the analysis. The output table of covariance parameter estimates from SAS PROC MIXED procedure gave estimates of the variance component parameters for each of the model components. The variance component parameters of each model component were divided by the total variance to get the variance proportions for each of the components.

RESULTS AND DISCUSSION

Method Validation. Prior to applying the HPLC-MS/MS methodology to the harvested materials, the method was validated. The method limit of quantitation (LOQ) for *trans*-vitamin K_1 was established at 0.09 mg/kg on the basis of peak signal-to-noise ratios (S/N) for seed extracts (S/N at the LOQ was at least 10). The limit of detection (LOD) was established at a level that was approximately equal to 30% of the LOQ. The LOD concentration was 0.03 mg/kg. It is unlikely that

concentrations in canola seed would approach the current LOQ as defined.

The linear concentration range for *trans*-vitamin K_1 was 4.5−180 ng/mL. The minimum acceptable correlation coefficient (r) was 0.990 for each calibration curve; values >0.995 were observed. The use of d_7-vitamin K_1 as an internal standard proved adequate for compensation for matrix-induced ion source suppression. The C30 column provided adequate resolution from any surrounding peaks (Figure 1).

Repeatability precision and spike and recovery accuracy data are presented in Table 2. The repeatability RSD (n = 7) was 7.39% with a mean spike recovery of 105% achieved. Additional analyses were conducted to provide intermediate precision data. Two sets of 10 replicate canola seed test portions were assayed on two different days by two analysts. The overall RSD (n = 20) was 8.53%. Individual analyst RSDs were 10.2 and 4.59% (Table 3). On the basis of these data, the methodology was deemed acceptable (RSD ≤ 15%) for use in determining vitamin K_1 levels in canola seed. Validation acceptance criteria were based on single-laboratory validation guidelines published by AOAC International.[12]

Canola Seed Vitamin K_1 Levels. As previously discussed, canola, soybean, and olive oils are considered to be major sources of vitamin K_1,[2,3] with canola oil containing 0.7−1.5 mg vitamin K_1/kg of oil.[4,5] Vitamin K_1 is a fat-soluble vitamin that is associated with the lipid fraction of the seed. Although there are few data on vitamin K_1, there have been several publications on fat and fatty acid contents of canola seed. Environmental effects on fat content of canola seed have been shown to be large relative to cultivar effects, with high fat levels being shown to be correlated with cooler spring temperatures and higher spring rainfall.[13] The climate of the typical North American canola cultivation region is considered subhumid to semiarid, with mean annual precipitation ranging from 300 to 600 mm

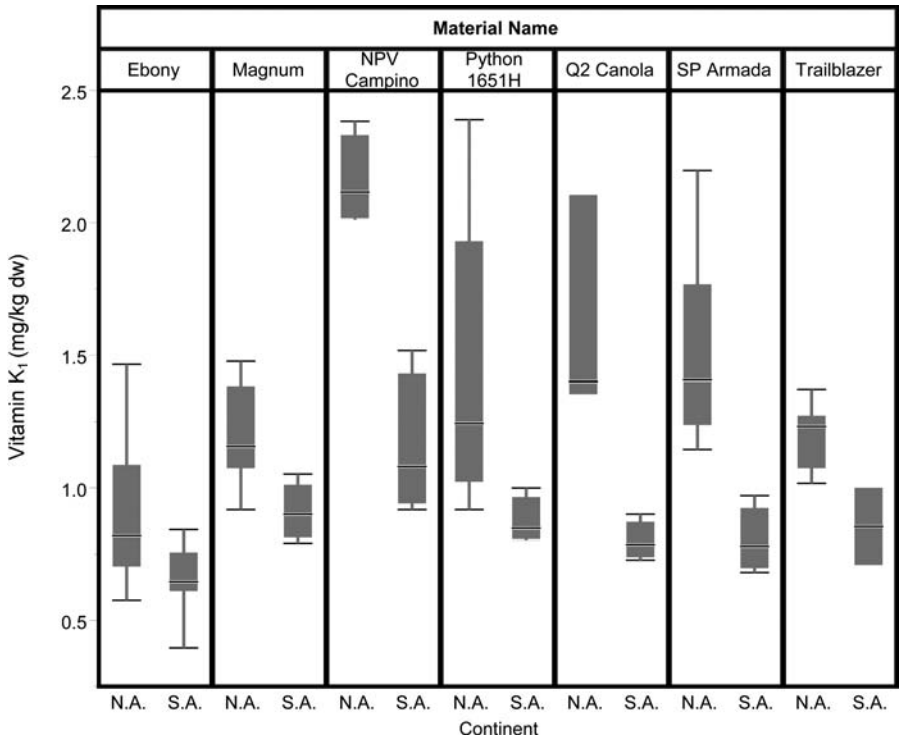

Figure 2. Comparison of vitamin K_1 concentrations in canola seed grown in locations in North America versus South America. Each box plot provides a graphical summary of the distribution of data from all cultivars grown at all locations in either North or South America. The box represents the distribution of the middle 50% of the data, whereas the horizontal line within the box represents the median sample value. Upper and lower lines represent the remaining distribution of the data. Concentrations of vitamin K_1 are expressed on a dry weight basis.

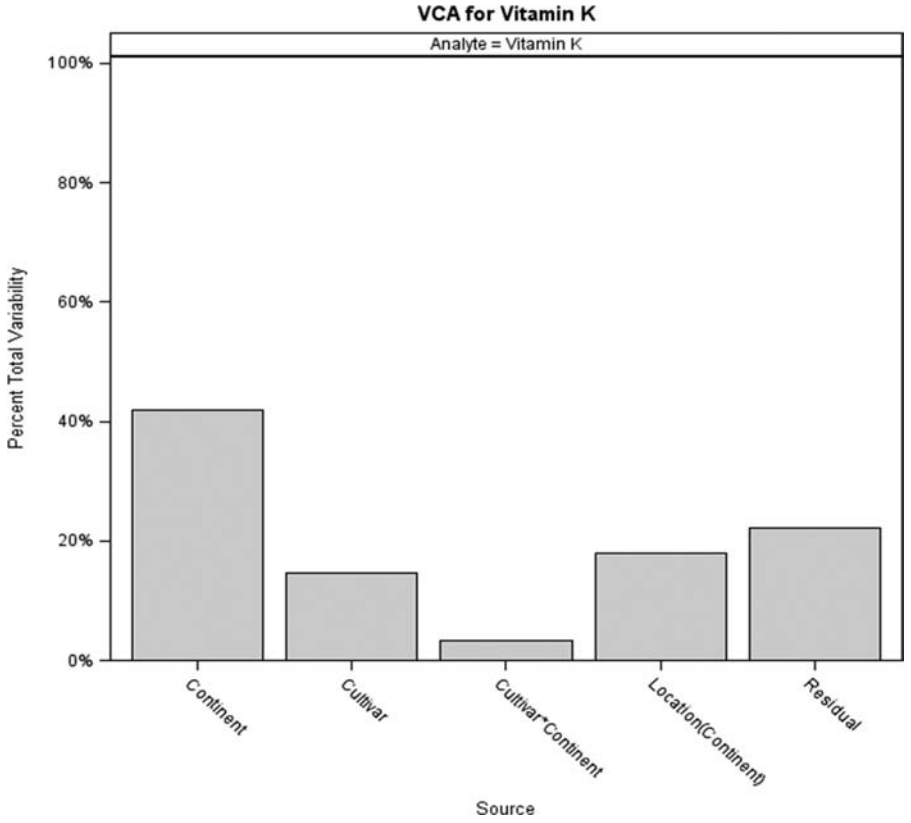

Figure 3. Sources of variation estimates from variance component analysis for vitamin K_1 in canola seed.

per year. In comparison, the climate of the Chilean central region is considered semiarid Mediterranean, with average precipitation of 100−300 mm.[14]

Comparison of mean vitamin K_1 values by cultivar and continent demonstrated that canola grown in locations in North America ranged from 0.25 (Ebony) to 1.01 mg/kg (NPV Campino) higher than the corresponding cultivars grown in locations in South America. The relative difference (difference in means/mean North American value) ranged from 24.2% difference for Magnum to 50.6% difference for Q2 canola. In all cases, numerically higher average vitamin K_1 levels were observed for locations in North America in comparison to those in South America. Figure 2 graphically compares the vitamin K_1 levels for each cultivar grown in locations in both North and South America. Across all cultivars, the individual replicate *trans*-vitamin K_1 values observed for locations in North America were between 0.58 and 2.39 mg/kg and for locations in South America were between 0.40 and 1.52 mg/kg. Statistical analysis included application of VCA to investigate the impacts of environment and cultivar on the variability of vitamin K_1 canola seed composition. Comparisons included data that were combined across all locations for each continent using ANOVA. The results showed there is a significant difference (0.0002, $p < 0.05$) of vitamin K_1 levels in canola seed between locations in North America and South America. These data demonstrated that environment, represented by continent and location effects, was the main contributor to vitamin K_1 level variation (Figure 3). In addition, these data also showed that variation in genetic background represented by cultivar effect to a lesser degree also influenced vitamin K_1 canola seed composition.

An accurate, sensitive, and selective method for the determination vitamin K_1 in canola seed was developed and applied to survey the levels of the biologically active *trans*-vitamin K_1 isomer in several commercial cultivars of canola seed grown in locations in North and South America. The research reported herein provides the first publication describing the variability of vitamin K_1 levels in commercial canola cultivars grown in relevant geographical locations. The data suggest that, similar to other canola components previously evaluated by others,[13] vitamin K_1 levels are influenced by cultivar and environment. Knowing that cultivar and environmental effects influence vitamin K_1 levels provides a context to assess compositional quality of new cultivars developed for market.

In general, multiple metal ions, such as Na^+, K^+, Ca^{2+}, and Mg^{2+}, are considered to change some zymogens into active enzymes or accelerate the enzymatic reaction rate. Gibberellin, a type of plant hormone, controls many plant developmental processes, such as germination, growth, and flowering.[30,31] Many studies suggest that aleurone cells could synthesize and secrete a range of hydrolytic enzymes in response to exogenous gibberellin through initiating PCD.[32] This process of PCD can also be initiated by all types of reactive oxygen species (ROS) including hydrogen peroxide.[33−36] Moreover, our previous experiments and previous report[37] revealed that solid−liquid ratio, incubation temperature, and incubation time also have obvious effects on endogenous phytase activity and phytate content in wheat bran.

Hence, we attempted to evaluate the influence of solid−liquid ratio, incubation temperature, and incubation time in this study. Meanwhile, gibberellin and hydrogen peroxide were used to induce PCD and then activate endogenous phytase and reduce phytate level in wheat bran.

MATERIALS AND METHODS

Materials and Reagents. Wheat bran (Xinong 979, hard wheat, harvested in 2014 June, Henan, and stored for 2 months) was purchased from COFCO (Zhengzhou, China). Experiments were performed immediately after milling.

Phytic acid (>95%) was obtained from Sigma-Aladdin (Shanghai, China). Standard sodium phytate were obtained from Sangon Biotech Co., Ltd. (Shanghai, China). Other chemicals were of analytical grade unless stated otherwise.

Incubation. Wheat bran samples (1 g) were incubated in 1−6 mL of working solution of different gibberellin concentrations (0−5000 mg/L), different hydrogen peroxide concentrations (0−1.0%), and different metal ions (0.1 mol/L Na^+, K^+, Ca^{2+}, and Mg^{2+}) in beakers at 4, 20, 38, 55, and 70 °C for 360 min. After 30, 80, 180, and 360 min, the mixtures were used to determine endogenous phytase activity and phytate content. The levels of gibberellin concentration, hydrogen peroxide concentration, and metal ion were chosen according to the previous studies with some modifications.[38−41]

Phytic Acid. Phytic acid was measured according to the bipyridine colorimetric method reported by Buddrick and Jones et al.[23] Phytic acid was used as internal standard. All analyses were carried out in sextuplicate.

Phytase Activity. Phytase activity was measured by determination the inorganic orthophosphate released from the phytic acid by phytase. Standard phytase activity assay was performed at 37 °C according to the method of Huang.[42] Half a gram of wheat bran sample was mixed with 15 mL of acetate buffer A (20.52 g of anhydrous sodium acetate, 0.5 g of Triton X-100, and 0.5 g of bovine serum albumin in 1000 mL of distilled water, pH 5.5 ± 0.01), extracted for 15 min under ultrasonic treatment, and stirred with a magnetic stirrer for 30 min at room temperature. Then the mixture was centrifuged (centrifuge TGL-16G, Shanghai Anting Scientific Instrument Factory, Shanghai, China) at 5000*g* for 4 min. The supernatant (0.2 mL) was incubated at 37 °C with 1.8 mL of buffer A for 5 min and added to 4 mL of 7.5 mmol/L standard sodium phytate. After mixing, the solution was incubated at 37 °C for 30 min, and the enzyme reaction was stopped by the addition of 4 mL of 5% TCA. Inorganic phosphate (P_i) was determined colorimetrically.[43] Two hundred microliters of the resulting solution was added to 5 mL of acetate buffer B (20.52 g of anhydrous sodium acetate in 1000 mL of distilled water, pH 5.5 ± 0.01), 200 μL of 10% ascorbic acid, and 200 μL of 10% ammonium molybdate. Its absorbance was measured at 700 nm after 30 min by a SpectraMax M5Multifunctional microplate reader (Molecular Devices, Sunnyvale, CA, USA). All determinations were performed in sextuplicate. One unit of phytase activity (1 FTU) was defined as the amount of enzyme that liberates 1 μmol of orthophosphate per minute from phytate at 37 °C and pH 5.5.[44]

Optical Microscope Observations. The raw wheat bran and incubated wheat bran were stained with hematoxylin−eosin staining solution and iodine solution and rinsed with distilled water. The samples were subsequently observed with an optical microscope (Nikon, T1-SAM, Japan).

Statistical Analysis. All determinations were performed in sextuplicate. The data obtained are expressed as the mean ± standard deviation. The data obtained in this study were analyzed by one-way analysis of variance (ANOVA), and the differences among means were determined through Dunnet T3 test by using the software SPSS 16.0 for Windows. $p < 0.05$ was considered to be significant.

RESULTS AND DISCUSSION

Solid−Liquid Ratio. Endogenous phytase activity and phytate content of wheat bran samples under various solid−liquid ratios (1:1, 1:2, 1:3, and 1:6) at 55 °C during 360 min of incubation with distilled water are presented in Figure 1. The

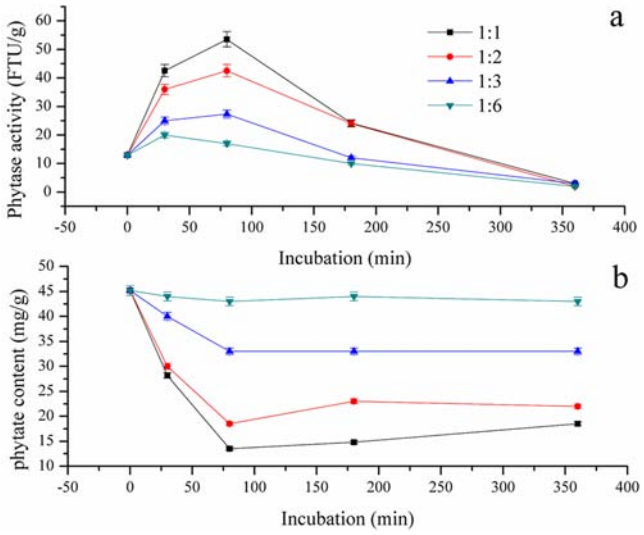

Figure 1. Effect of solid−liquid ratio (1:1, 1:2, 1:3, and 1:6) at 55 °C on endogenous phytase activity and phytate content of wheat bran samples: (a) effect of solid−liquid ratio on endogenous phytase activity; (b) effect of solid−liquid ratio on phytate content. Data values are based on sextuplicate measurements and shown as the mean ± SD.

results show that the solid−liquid ratio had an extremely significant ($p < 0.0001$) effect on endogenous phytase activity and phytate content of wheat bran, which respectively demonstrated an upward or a downward trend with the rising solid−liquid ratio. During incubation, every condition could obtain a better point with a maximum endogenous phytase activity (U^*) and a minimum phytate content (P^*). At high solid−liquid ratio (1:1), U^* (53.54 FTU/g) in wheat bran was higher than those incubated at the other lower solid−liquid ratios, which was about 4.13 times greater than raw material. U^* at solid−liquid ratios of 1:2, 1:3, and 1:6 were 3.28, 2.11, and 1.54 times, respectively, as high as raw material. In addition, P^* (13.52 mg/g) at a solid−liquid ratio of 1:1 was 29.91% of raw material, whereas at solid−liquid ratios of 1:2, 1:3, and 1:6 the values were 40.93, 70.01, and 95.13%, respectively.

Phytase was reported to be inactive in dry conditions, whereas it was activated in wet conditions to degrade phytate.[45] A moderate amount of water could well activate the endogenous phytase activity and reduce phytate, yet a high amount of water probably promoted aleurone cell swelling and rupturing to death. Therefore, a solid−liquid ratio of 1:1 was

DOI: 10.1021/jf504319t
J. Agric. Food Chem. 2015, 63, 1082−1087

selected in follow-up experiments. In addition, this ratio is favorable for subsequent drying.

Incubation Temperature. Endogenous phytase activity and phytate content of wheat bran samples under various temperatures (4, 20, 38, 55, and 70 °C) during 360 min of incubation with distilled water (solid−liquid ratio of 1:1) are shown in Figure 2. It could be found that there was a steadily

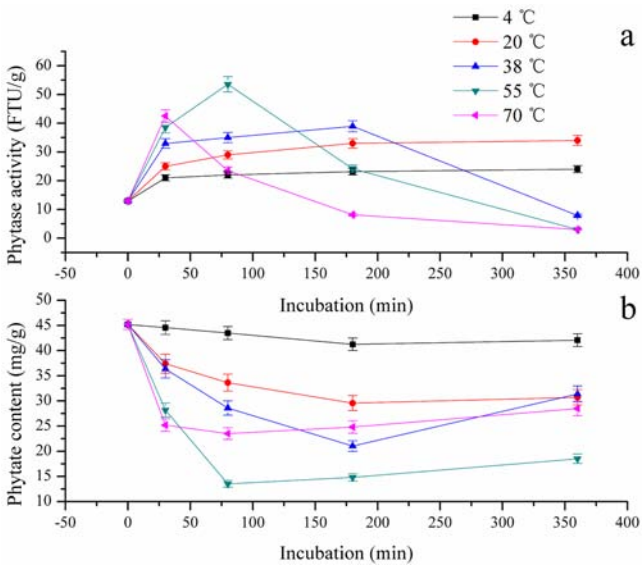

Figure 2. Effect of incubation temperature on endogenous phytase activity and phytate content of wheat bran samples: (a) effect of incubation temperature on endogenous phytase activity; (b) effect of incubation temperature on phytate content. Data values are based on sextuplicate measurements and shown as the mean ± SD.

increasing tendency of *U** from 4 °C (23.15 FTU/g) to 55 °C. However, at 70 °C, *U** revealed a sudden drop (42.51 FTU/g), only 79.40% of that at 55 °C but a little higher than that at 38 °C (38.92 FTU/g). *P**, as well, was extremely significantly ($p < 0.0001$) influenced by incubation temperature. When compared with raw wheat bran, *P** was decreased by 8.74% (41.25 mg/g), 34.60% (29.56 mg/g), 53.50% (21.02 mg/g), 70.09% (13.52 mg/g), and 47.96% (23.52 mg/g) at incubation temperatures of 4, 20, 38, 55, and 70 °C respectively, in comparison with that in raw wheat bran (45.20 mg/g). Obviously, higher incubation temperatures could decrease *P**, but extremely high incubation temperature (70 °C) induced a negative effect.

Appropriate increase in incubation temperature was helpful to promote phytase reaction in aleurone cells, but when the temperature was much higher than ambient temperature, aleurone cell vitality was subject to inhibition and a serious decline in endogenous phytase activity occurred. Loss of endogenous phytase activity at high temperature (70 °C) may be explained by conformational change and irreversible inactivation.[46]

Metal Ions. Four commonly used metal ion activators (Na^+, K^+, Ca^{2+}, and Mg^{2+}) were used to investigate their influence on endogenous phytase activity and phytate content in wheat bran samples during incubation at a solid−liquid ratio of 1:1 and 55 °C (Figure 3). Obviously, all of the metal ions had a negative impact on *U** and *P**. The most significant ($p < 0.0001$) factor was Mg^{2+} (*U**, 19.39 FTU/g; *P**, 39.20 mg/g), which when compared with raw wheat bran just increased the *U** by 49.58%, followed by Na^+ (78.34%), Ca^{2+} (82.19%), and K^+

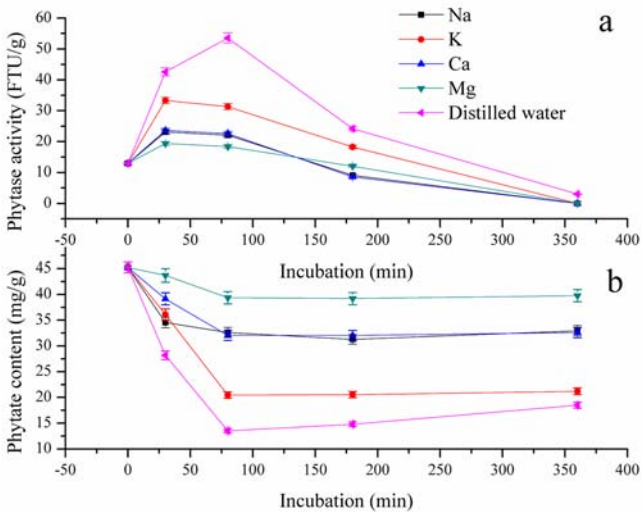

Figure 3. Effect of metal ions on endogenous phytase activity and phytate content of wheat bran samples: (a) effect of metal ions on endogenous phytase activity; (b) effect of metal ions on phytate content. Data values are based on sextuplicate measurements and shown as the mean ± SD.

(157.23%). Accordingly, it decreased the *P** by 13.27%, followed by Ca^+ (29.11%), Na^{2+} (30.78%), and K^+ (54.80%).

Phytate in wheat exists mainly in the form of phytin (calcium magnesium phytate). Thus, adding Ca^{2+} and Mg^{2+} would increase the concentration of enzymatic hydrolysates to inhibit the enzymatic reaction. Moreover, Ca^{2+} competed with phytate for the active site of endogenous phytase and inhibited its activity or formed Ca−phytate complexes that were insoluble and undegradable.[47] The results of this experiment are inconsistent with those from Zhang[48] and Yao,[41] in which the activity of β-propeller phytases (BPPs) were activated by a reasonable concentration of Ca^{2+}. This could be because BPPs were mainly from *Bacillus*, and their degradation mechanism was different from that of wheat endogenous phytase.

Gibberellin Concentration. Under the conditions of incubation temperature at 55 °C, a solid−liquid ratio of 1:1, and in the incubation solution, the effect of gibberellin concentration (0, 5, 50, 500, 2000, and 5000 mg/L) on the endogenous phytase activity and phytate content in wheat bran samples was measured, and the results are displayed in Figure 4. Generally, gibberellin was counterproductive on activation of endogenous phytase and phytate degradation. It was shown that gibberellin had little effect at low concentration (5 mg/L). However, with the increase of the concentration, the deleterious effect of gibberellin began to be revealed. When the gibberellin concentration was 50 and 500 mg/L, *U** fell to around 30 FTU/g and *P** rose to >40 mg/g. When the gibberellin concentration reached 2000 mg/L, *U** dropped to 20.60 FTU/g and *P** went up to 40.67 mg/g. When the gibberellin concentration reached 5000 mg/L, the results improved (*U** was 29.59 FTU/g, and *P** was 25.16 mg/g) but were still worse than those from incubation with distilled water.

Gibberellin was generally regarded as having positive effects on the PCD.[49] The barley aleurone layer and its protoplast treated by gibberellin would secrete large amounts of protease, nuclease, α-amylase, and other hydrolases.[50] However, our results indicated that secretion of endogenous phytase activity by aleurone had nothing to do with gibberellin's induction. This

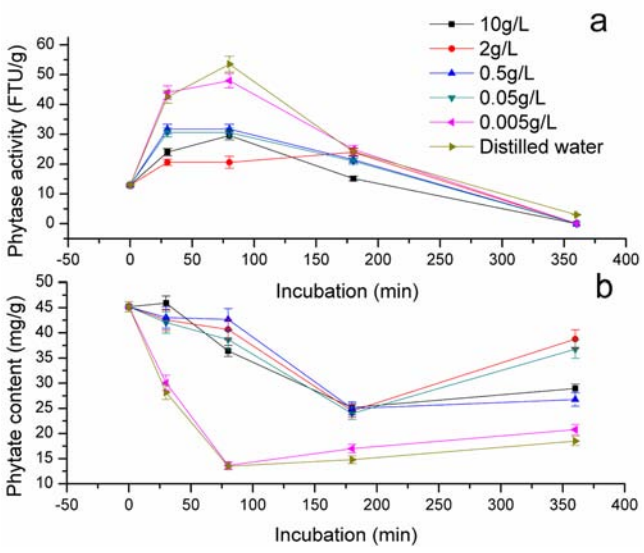

Figure 4. Effect of gibberellin concentration on endogenous phytase activity and phytate content of wheat bran samples: (a) effect of gibberellin concentration on endogenous phytase activity; (b) effect of gibberellin concentration on phytate content. Data values are based on sextuplicate measurements and shown as the mean ± SD.

may be because the main role of gibberellin was to awaken the dormant seed, whereas the selected raw material was fresh and had not yet entered the dormant period or generated adequate germination inhibitors. Thus, the aleurone cells were vital and could produce endogenous phytase by moderate water without gibberellin.[51]

Hydrogen Peroxide Concentration. Under the conditions of incubation temperature at 37 °C and a solid−liquid ratio of 1:1, the effect of hydrogen peroxide concentration (0, 0.2, 0.4, 0.6, 0.8, and 1.0%) on the endogenous phytase activity and phytate content in wheat bran samples was determined (Figure 5). It was found that the effect of hydrogen peroxide on

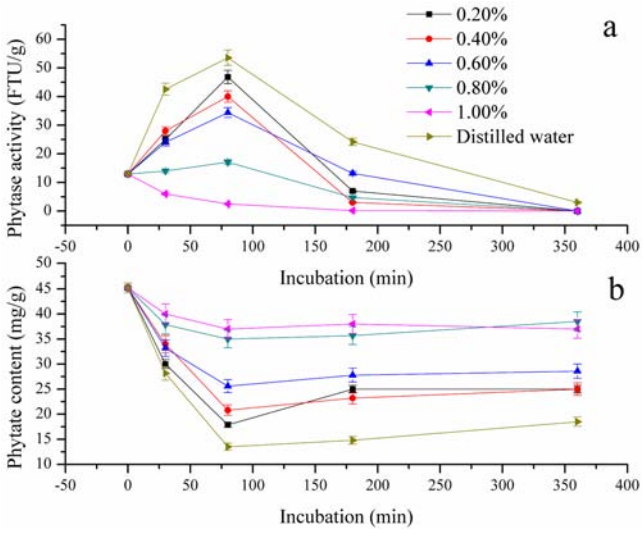

Figure 5. Effect of hydrogen peroxide concentration on endogenous phytase activity and phytate content of wheat bran samples: (a) effect of hydrogen peroxide concentration on endogenous phytase activity; (b) effect of hydrogen peroxide concentration on phytate content. Data values are based on sextuplicate measurements and shown as the mean ± SD.

U^* and P^* was significantly negative ($p < 0.0001$). With the rising hydrogen peroxide concentration, U^* gradually declined and P^* ascended when compared with distilled water. Notably, 1.0% hydrogen peroxide severely inhibited the phytase activity, which decreased rapidly to zero and induced almost no change in phytate content.

According to Golovina's report, reactive oxygen species (ROS) provided by moderate concentration of hydrogen peroxide could induce the PCD process,[52] whereas research carried out in this paper pointed the other way. This may be attributed to the selection of raw materials. In their previous study, wheat kernel was selected, whereas wheat bran was selected in this study.

Incubation Time. From Figures 1−5, it could be found that, in most cases, the endogenous phytase activity rose rapidly and reached the peak at about 80 min of incubation and then steadily declined to zero while the phytate content continuously decreased during the first 80 min of incubation and then slightly increased. The exceptions were the incubations at 4, 20, 38, and 70 °C or the incubation with 1.0% hydrogen peroxide. The lower the temperature was, the later the U^* and P^* occurred. In addition, a high concentration of hydrogen peroxide (1.0%) led to rapid inactivation of endogenous phytase; hence, phytate content had little change with the incubation time.

This study also highlighted that incubation time was a limiting factor for degradation of phytate in wheat bran during incubation. A short period of time might not achieve the peak of endogenous phytase secreted and synthesized by aleurone cells, and there was insufficient phytase in cells, whereas a long period of time would cause the enzyme activity to decrease gradually and lose its utilization value. Research showed that phytase in wheat belongs to 6-purple acid phosphatase (6-PAPhy) and its final enzyme hydrolysates are diphosinositide and phosphate,[53] which would not disturb results of phytate content by bipyridine colorimetric method.[54] Nevertheless, after 80 min of incubation and with the reduction of phytase activity, some substances such as IP3, IP4, and other complexes might be generated and would result in high phytate content.

Optical Microscope Observations. The photomicrographs of raw wheat bran sample and sample incubated with distilled water for 360 min at 55 °C are displayed in Figure 6. As shown in Figure 6a,b, the aleurone cell content had been stained crimson, whereas the cell walls were extremely thick and presented a transparent color. After incubation (Figure 6c−e), the aleurone cells almost disappeared (leaving only a thin layer of pink cell content and a thinner cell wall, Figure 6d), or aleurone cells disappeared completely (Figure 6e), where only neatly arranged long cylindrical transparent cells of intermediate layer were observed.

In cereal aleurone tissue, PCD preceded extensive vacuolation of PSVs. At the time of death, a highly vacuolated status occurred showing a single large vacuole occupied virtually all of the cytoplasm.[55] Then the cell wall became thinner or partial autolysis occurred, plasma membrane integrity was abruptly lost, and cellular autolysis occurred.[56,57] Although there was no vacuolization phenomenon found in this study, the incubated sample still indicated that the PCD and cell autolysis occurred in aleurone cells.

This work showed that endogenous phytase activity could be effectively activated to reduce phytate level in wheat bran during the process of activation for 80 min at 50 °C with a solid−liquid ratio of 1:1. Under this experimental condition,

gibberellin, hydrogen peroxide, and metal ions showed undesirable results. Compared with traditional phytate degradation, the method described in this paper is more effective, efficient, and suitable for industrial production.

components and the absorption of light in the infrared region.[27−29]

Ultraviolet−visible (UV−vis) spectroscopy relies on the detection of pi bonding and conjugated double bonds, so the predominant wine matrix does not have a significant signal, although the UV−vis portion of the electromagnetic spectrum contains valuable information regarding phenolic compounds where absorbance features are generated at specific regions. Garcia-Jares and Medina[30] applied UV−vis chemometrics methods in enological research. Despite the limitations of the analytical methods, related to a lack of selectivity,[8,9,31] such as the colorimetric assay used for tannin quantification, and the small sample set (n = 34), the results demonstrated the potential of this technique to predict tannins in red wine.[30] Other authors[32] applied partial least-squares regression (PLS) to the UV−vis spectra of 200 wines at various stages of fermentation. The development and validation of an ultraviolet spectral calibration for the rapid and robust prediction of wine tannin concentration was reported by Dambergs et al.[33] The authors used multiple linear regression (MLR) due its suitability to transfer calibration models between different instruments by means of slope and bias adjustment. The ability to objectively measure wine quality, in which wine tannins play a critical role, is an important requirement for the production of competitively priced high-quality wines by the South African wine industry. Little research has been done on tannin levels in a wide range of South African red wines, including those from different vintages and cultivars and produced on a commercial or experimental scale. It is difficult to compare tannin data from wines elaborated differently, due to the great impact that different locations and/or winemaking techniques have on final tannin concentration. The aim of this work was first to investigate the application of multivariate methods to the UV−vis spectra of South African red wine samples to develop predictive models for determining tannins over a wide range of grape cultivars, growing regions, and vintages. The second aim was to demonstrate the robustness of calibration models across different cultivars and vintages and between commercial and experimental wines to predict tannin concentration. BSA and MCP tannin assays were selected as the reference analytical methods, because they have proven to be robust procedures.[3,4,15,17,34] There also is a lack of studies dealing with PLS calibrations comparing two different wine tannin reference methods (BSA and MCP) and testing the robustness of the tannin concentration prediction by UV−vis spectroscopy in wines.

MATERIALS AND METHODS

Sample Collection. Two hundred and forty South African wine samples were used, including Cabernet Sauvignon (n = 49), Shiraz (60), Merlot (46), Pinotage (13), Sangiovese (5), Nebbiolo (1), Carmenere (2), Pinot Noir (3), Grenache Noir (2), Ruby Cabernet (9), Tempranillo (3), Tinta Barroca (1), Tinta Amarella (2), Monastrell (4), Barbera (1), Durif (4), and some blends (37), ranging in vintage from 2000 to 2012. Samples were from small-lot experimental fermentation trials (n = 121) ,elaborated in the experimental cellar of the Department of Viticulture and Oenology (DVO) at Stellenbosch University, and commercial, bottled wines (n = 119). The sample set was performed with wines from regions having diverse climates and soil types.

Spectral Data Collection. Wine samples were 51-fold diluted in 1 M HCl (Merck, Darmstadt, Germany) (100 μL of sample plus 5 mL of 1 M HCl). The diluted samples were incubated for 1 h in the dark at room temperature and then scanned in an Analytic Jena Specord 50 UV−vis spectrophotometer (Jena, Germany), using a 10 mm path length quartz cuvette, with 1 M HCl as the reference blank. Wine samples were scanned without temperature equilibration at 2 nm intervals over the wavelength range from 200 to 700 nm, therefore yielding 250 data points per spectrum.

Methylcellulose Precipitable Tannin Assay.[4,17] Methylcellulose solution (0.04% w/v; 1500 cP viscosity at 2%) was prepared in accordance with the manufacturer's instructions. Considering the expected high tannin concentration of some samples and with the aim of fitting the absorbance values within the working range (0.1−1.2 AU) for the spectrophotometer used in this study, a modified protocol of the MCP tannin assay was performed on wines using a 2 mL format. In a 2 mL microfuge tube, 600 μL of methylcellulose solution (Sigma-Aldrich Chemie, Steinheim, Germany) was mixed with 50 μL of wine diluted twice (25 μL of wine sample + 25 μL of distilled water), and the tube was capped, inverted several times, and allowed to stand for 2−3 min. Following the addition of 400 μL of saturated ammonium sulfate solution (Merck), the samples were made up to a final volume of 2 mL with distilled water (950 μL). Samples were after 10 min centrifuged at 9279g for 5 min (treatment sample). The same wine solution volume was added to the control sample. Following the addition of 400 μL of saturated ammonium sulfate solution, the sample was made up to final volume with distilled water (1550 μL), mixed, and allowed to stand for 10 min at room temperature before centrifugation. The difference in the A_{280} value obtained by subtracting the A_{280} value of the MCP treated sample from the control A_{280} sample was converted into epicatechin equivalents (mg/L) using a calibration curve (Sigma-Aldrich Chemie). The wine sample had a dilution factor of 80. The wine dilution effect was investigated with the analysis of eight different undiluted and twice-diluted red wine samples. The results showed a small effect of wine dilution on tannin concentration, with diluted samples having slightly higher concentrations. The twice-diluted protocol was therefore used throughout the study after observing that no underestimation of tannin concentration was obtained.

Bovine Serum Albumin Tannin Assay.[18] Wines were diluted twice, three times, and five times, respectively, in a model wine solution of 12% v/v ethanol containing 5 g/L tartaric acid that had been adjusted to pH 3.3 with HCl. The tannin protein precipitate was formed by mixing 0.5 mL of diluted wine and 1 mL of BSA solution (containing 1 mg BSA/mL dissolved in a buffer of aqueous 0.2 M acetic acid and 0.17 M sodium chloride adjusted to pH 4.9 with sodium hydroxide) for 15 min. The precipitate was centrifuged for 5 min at 18188g to form a pellet, and the supernatant was discarded. The pellet was washed twice with 1 mL of the pH 4.9 buffer. After the addition of 0.25 mL of the pH 4.9 buffer to wash the pellet a third time, samples were centrifuged for 1 min at 18188g. The rinsed pellet was redissolved in 0.875 mL of buffer (containing 5% w/v SDS and 5% v/v triethanolamine and adjusted to pH 9.4 with sodium hydroxide). The background (A^{back}) of 0.875 mL redissolved solution was measured in the spectrophotometer at 510 nm and was subsequently mixed with 0.125 mL of ferric chloride solution (10 mM ferric chloride in 10 mM aqueous HCl). The final absorbance at 510 nm (A^{FeCl3}) was measured after 10 min, and the tannin response was calculated as the background absorbance minus 0.875 times the final absorbance. Tannin responses between 0.3 and 0.75 were selected for the different dilutions, as suggested by Jensen et al.,[34] and the tannin concentration was calculated and expressed as milligrams of catechin (Sigma-Aldrich Chemie) equivalents.

Data Analysis. Chemometric analysis was performed using SIMCA version 13.0.3 software (www.umetrics.com). Principal component analysis (PCA) was performed before the PLS regression models were developed. PCA describes the maximal quantity of information present in the data set using a small number of latent variables.[35] Possible sample groupings and outlier visualization were the main aims in applying this technique. Analysis of variance (ANOVA) and coefficient of variation (CV) were also determined to study the variability present in the data set. High variability in the data set means that the data are suitable for PLS calibrations.[36] Calibrations were developed using partial least-squares (PLS) regression with leave-one-out cross-validation. In this way, one object of the training set is removed and a PLS model is built with the remaining objects, and then this model is used to predict the removed object.[37,38]

DOI: 10.1021/jf503412t
J. Agric. Food Chem. 2015, 63, 1088−1098

Of the overall sample set, 50% (n = 120) were used for cross-validation as calibration set, whereas the remaining 50% were used as external validation set. Selection of both the calibration and validation set was performed randomly. Moreover, to develop robust models and to test the effect of seasonal, cultivar, and winemaking (commercial vs experimental) variations on model performance, calibration models were developed on samples from each cultivar or vintage and used further to predict samples from the other remaining cultivars or vintage years. The ability of the tannin concentration of a single variable (single cultivar or year) to be predicted by the model was also determined (ability of the tannin concentration of the cultivar or year to be predicted by the model). The same approach was tested using the classifying variable experimental versus commercial wines. Calibrations for the tannins were developed using various combinations of the data set.

Statistics calculated for the calibrations included the coefficient of determination in calibration (R^2cal), the root mean standard error in cross-validation (RMSECV), the root mean standard error of prediction (RMSEP), and the coefficient of correlation in validation (R^2val). R^2cal estimates the percentage of variation in the training set explained by the model. It is a measure of how well the model fits the data. A large R^2 (close to 1) is a necessary requirement for a good model, but this alone is not sufficient. Poor models can be achieved (models that cannot predict) even with a large R^2cal. Poor R^2cal could be obtained when there is poor reproducibility (much noise) in the training data set or when the spectral information does not explain the chemistry for other reasons.

The RMSECV indicates the fit of the observations to the model estimated using the cross-validation procedure and is a measure of the average difference between the values determined by MCP or BSA and those predicted by the model. It provides an indication of the potential error associated with the future predictions of samples not included in the calibration set. RMSECV is expressed in the same units as the reference values and is influenced by the range of tannin concentrations. R^2val is the percent of variation of the validation set explained by the model. Moreover, the RMSEP, which is also influenced by the reference values range, is a measure of the average difference between the values predicted by the model and values determined by the laboratory method during independent validation of the model (average prediction error).[32] To counteract the effect of range in the RMSEP, the residual predictive deviation (RPD = SD/RMSEP) is used to standardize the predictive accuracy. RPD is defined as the ratio of the standard deviation of the population and the root-mean-square error of prediction. If the RMSEP is large compared to the spread of tannin concentration in all samples (SD), a relatively small RPD is achieved. This means that the model is not able to predict variability. The higher the RPD, the greater the probability of the model to predict chemical composition in samples outside the calibration set.

RESULTS

Reference Values. The tannin concentrations reported here are presented with the aim to compare the analytical methods, although the reported levels may be of interest, as some cultivars have not previously been analyzed for tannin content in South Africa. The data presented here thus offer the first indication of the range of tannin values in South African red wines that might be observed using the MCP and BSA methods (Figure 1). However, the values should be considered indicative, as the wines came from diverse origins, spanned a variety of climates and soil types, and also differed in the winemaking procedure. As has been reported by other authors,[39] a wide range of concentrations was observed for tannin concentrations in both tannin assays. This strengthens the idea that tannin concentration should be considered with caution, as tannin values might differ from site to site, even for the same variety.

ANOVA showed that MCP and BSA varied significantly (p < 0.001) in relation to the classifying variables: variety, commercial/experimental, and vintage for BSA (Table 1).

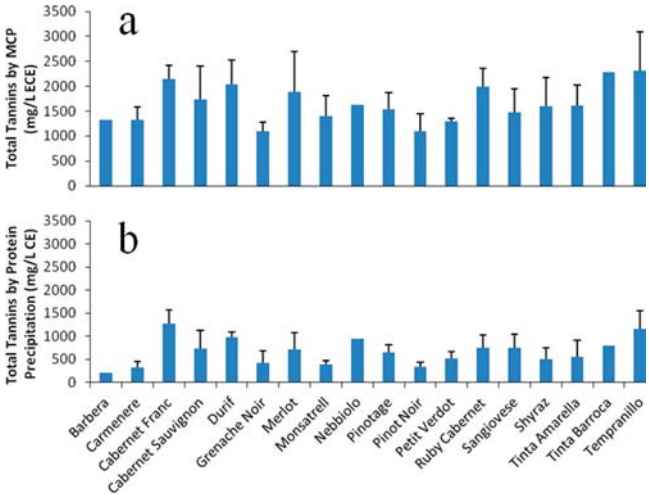

Figure 1. Total tannin levels of the 18 different grape cultivars analyzed, showing standard error bars: (a) tannins determined by methylcellulose precipitation calibrated against an epicatechin standard curve and expressed as mg/L; (b) tannins determined by protein precipitation (BSA) and expressed as mg/L catechin equivalents. The absence of error bars means that only one sample was available.

Significant variation also existed for the variable vintage (p < 0.05) when MCP was used as reference method. It was observed that tannin concentration was affected the most by the experimental/commercial classifying variable (Table 1). Harberston et al.[40] reported exceptional variability in the tannin concentration of commercial wines and stated that winemaking techniques play a critical role in wine tannin levels. A huge overlap in tannin concentrations between populations has also been reported, in agreement with the results observed in our study.

Table 1. ANOVA (ANOVA, F Ratio, and p Values) for MCP and BSA in Relation to Variety, Vintage, and Commercial/Experimental Wines

variable	factor	F ratio	p
MCP	variety	2.74	<0.001
	vintage	2.42	0.0123
	commercial/exptl	73.45	<0.001
BSA	variety	3.75	<0.001
	vintage	6.46	<0.001
	commercial/exptl	52.43	<0.001

Table 2 shows the mean, minimum, maximum, standard deviation, and coefficient of variation of the wines' tannin levels as determined by the reference methods. Tannin levels determined by protein precipitation ranged from 0.05 to 1.72 g/L. The mean of tannins determined by protein precipitation across all samples was 0.62 g/L (%CV = 52.63). The average level of tannins determined by methylcellulose precipitation was 1.64 g/L. The range of tannin values observed was between 0.31 and 3.21 g/L (%CV = 35.56). Although the CV in the samples analyzed by MCP was in accordance with the literature (35.5 vs 37.8%), higher CV values were found in BSA-analyzed samples regarding the study published by Seddon and Downey (52.63 vs 30.5%), even though the analysis was performed in skin grape samples instead of wine.[41] A higher coefficient of variation can also be considered as a source of variability in the tannin

concentrations of the sample set. The variability in the concentration of tannins in the analyzed samples was considered suitable for developing PLS calibration.

Linear regression analysis showed a good correlation (R^2 = 0.79) between the two tannin quantification techniques for 240 wine samples (Figure 2). The results are similar to those found by

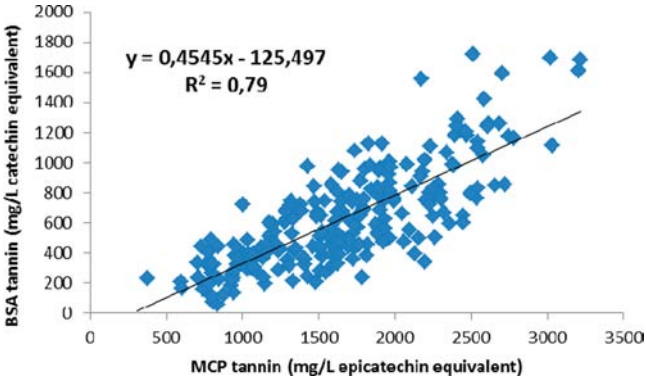

Figure 2. Linear regression analysis of wine tannin concentration determined using the MCP and BSA tannin assays (n = 240).

Mercurio and Smith[16] when 41 wine samples were analyzed by both methods (R^2 = 0.8). MCP and BSA tannin assays showed a slope of 0.45, indicating an almost 2.5-fold difference in tannin concentration. Moreover, the intercept of the line is not close to zero (−125.497), revealing that both methods are not measuring a similar amount of tannin material in the sample. The x-axis intercept of the line is relatively large, showing that the MCP tannin assay was measuring more tannin material, which is in accordance with Mercurio and Smith.[16]

Contradictory results are reported in the literature regarding the magnitude of the tannin concentration determined using both protein and polymer precipitation methods. Mercurio and Smith,[16] in accordance with the results reported here, observed approximately 3-fold higher tannin levels when using the MCP tannin assay in both grape and wine samples. On the other hand, other authors have stated the same magnitude for both analytical procedures in grape skin samples, but lower values were observed for the MCP tannin assay.[41] Furthermore, Harberston and Downey[39] also found lower tannin levels in grape skin and wine samples when the tannin precipitation was carried out with methylcellulose. The variation of the MCP method described by Mercurio et al.,[17] who reported that the methylcellulose concentration used by Sarneckis et al.[4] was suboptimal, may account for the differences in the results observed.

Moreover, the detection step has been proposed in the literature as a key factor that might explain the differences observed in tannin levels when using the two reference methods. The BSA precipitation method involves absorbance at 510 nm after the reaction of precipitated tannins with iron, whereas the MCP tannin assay measures the tannin concentration at 280 nm after precipitation with methylcellulose. Even though both precipitants might not be reacting with the same tannins, it is nowadays widely accepted that they both precipitate the same amount of tannin material.[16,39] Therefore, the detection step rather than the tannin precipitation appears as a crucial factor that could account for the observed differences. At this stage the exact type of tannins precipitated by BSA and MC is not well-known; further work in this area is required with the aim to fully understand the observed differences in tannin values.

The presence of some samples in the higher BSA concentration range that do not fit the regression curve should be highlighted. The spectra of some of the samples farther away from the regression curve were compared with those samples with similar MCP tannin concentrations but that did fit the regression curve, that is, were placed on or close to the regression curve. No differences were observed in the spectra of those samples in the region around 280 nm (the region where tannins show their absorbance features), although higher spectrum values were observed in the region around 520 nm, which corresponds to anthocyanins and polymeric pigments (Figure 3).

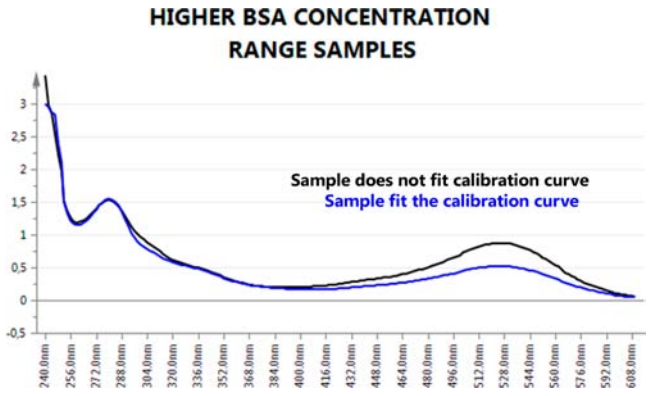

Figure 3. UV−vis spectra comparing a sample that does not fit the calibration curve (black) with a sample that fits the regression curve (blue).

The latter phenomenon of samples deviating at high concentrations could be explained by the inability of the MCP polymer to completely react and precipitate all of the polymeric pigment material in samples containing high levels of these compounds. However, Mercurio and Smith[16] stated that the MCP polymer is able to precipitate all tannins and polymeric pigments, whereas the BSA protein is not. It would seem that the portion of tannins not removed by BSA is representative of small polymeric pigments (SPP).[3] It remains unclear whether the ability to quantify these compounds is related to tannin size or whether other factors, such as difference in detection methods, might also have an effect on tannin quantification.[3] The contradictory results observed lead us to consider the hypothesis of suboptimal concentration, that is, the inability of the MCP to react with all of the polymeric pigments in samples very rich in these compounds.

Descriptive analysis showed that data on both measured tannin parameters (BSA and MCP) were normally distributed

DOI: 10.1021/jf503412t
J. Agric. Food Chem. 2015, 63, 1088−1098

around the mean, as indicated by the skewness. Normally distributed data should have skewness values ranging from −1 to +1, with the absolute of this statistical parameter as close to 0 as possible.[42] MCP and BSA tannin concentrations showed skewness values of 0.224 and 0.915, respectively, which are within the accepted range. Bellon-Maurel et al.[43] stated that RDP values can be affected in highly skewed sample sets because this parameter was developed for data sets showing normal distribution.

Principal Component Analysis. A preliminary study of the information contained in the spectral data set was carried out to detect possible sample grouping and to identify the presence of outliers. To this end, a principal component analysis (PCA-X) of the recorded spectra (260−610 nm) was used to describe the maximal quantity of information present in the data set using a small number of variables (principal components). The information contained in the data set reveals that two principal components explained 94.7% of the spectral variation of the samples (71.8% PC1, 23.9% PC2). No outliers were observed in the score plot (PC1 vs PC2) of the wine samples analyzed using UV−vis spectra. Moreover, PCA of the UV−vis spectra of the wine samples indicates that the variables vintage, variety, and experimental/commercial wines had no clustering effect on the data set. The absence of clustering supports the suitability of the UV−vis calibration for the measurement of tannins (results not shown). On the other hand, it is worth mentioning that a clear sample differentiation appeared in the PCA plot for the variables vintage and commercial/experimental wines (Figure 4).

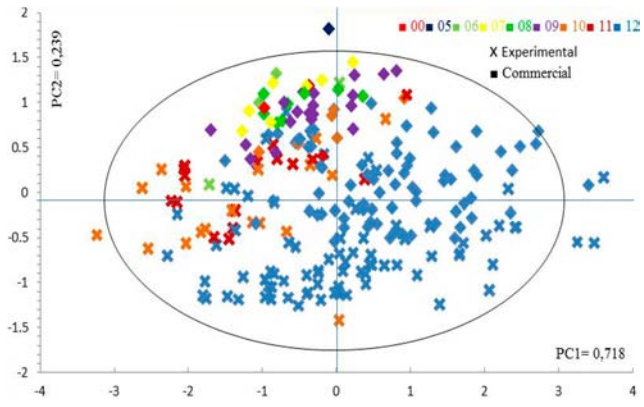

Figure 4. Principal component analyses of the UV−vis spectra of the analyzed wines classified by vintage year and commercial versus experimental wines.

Figure 4 shows the PCA plot for the wine samples identified by vintage (year). Wines included in the study ranged in vintage from 2000 to 2012. Wines elaborated in 2012 are located mostly in the lower right side of the graph, whereas the wines made from older vintages are placed mostly in the upper left side of the graph. The distribution observed in the PCA plot could probably be explained by differences in the phenolic composition, mainly anthocyanin and tannin, of the younger wines compared with that of the older wines. A great number of reactions involving phenolic compounds take place during wine aging. Oxidation and nucleophilic addition reactions, polycondensation with aldehydes, conversion of anthocyanins to pyranoanthocyanins, direct flavan-3-ol anthocyanin reactions, and other nucleophilic addition reactions have been reported in the literature.[44,45] The above-mentioned reactions are responsible for the organoleptic changes observed during wine aging, therefore playing an important role in the color and mouthfeel properties of wines.[46,47] Samples seem to be affected by both first and second components, explaining (PC1 and PC2) 95.7% of the variance. Young samples were positively correlated with PC1, although negatively correlated with PC2. On the other hand, samples of older wine vintages showed the opposite behavior, that is, appear positively correlated with PC2 and negatively correlated with PC1.

Furthermore, the separation of two groups also appeared in the PCA plot when the samples were classified according to commercial or experimental wines (Figure 4). Experimental wines appear in the lower part of the graph, whereas the commercially available wines are placed in the upper part. In this case, samples seem to be influenced more by PC2, where commercial and experimental wines are positively and negatively correlated, respectively. These differences might be due to the effect of winemaking techniques on the phenolic and tannin composition.

As far as we know, very little literature is available on the effect of fermentations at different scales on phenolic composition. It thus is not possible to explain at this stage whether the experimental vinifications carried out at smaller scale had a considerable effect on the phenolic composition. On the other hand, the well-known effect that wood aging and/or oxygen exposure have on phenolic and tannin composition could also explain the differences observed. Moreover, the fact that some of the wines elaborated on the experimental scale did not complete malolactic fermentation (MLF) might also explain some of the observed differences. Some studies have reported the effect of MLF on non-anthocyanin phenolic compounds and found an important decrease in the concentration of hydroxycinnamic acids and an increase in the concentrations of the free forms of caffeic, *p*-coumaric, and ferulic acids,[48] compounds that can act as copigments.[49−53] MLF therefore may influence wine color and phenolic composition.[54] MLF also leads to an increase in pH of between 0.1 and 0.45 unit in wine,[55] leading to subsequent changes in wine color. A decrease in the wine color and anthocyanin concentration takes place during MLF,[56] which could partially explain, together with the mentioned effect of the MLF on the non-anthocyanin phenolic compounds, the different locations of the experimental and commercial wines in the PCA plot.

Analysis of Loadings Plot. The influence of each wavelength on the variance is observed in the loadings plot (Figure 5). As shown in the loadings plot (Figure 5), two main zones highly influence the variance of the samples' spectra. The first region is observed at around 280 nm, a region that should be related to tannins and other phenolic compounds,[33] and the second region appears around 520 nm, where compounds such as anthocyanins or polymeric pigments absorb. Moreover, other regions of the spectra also explain some variance and must be taken into consideration in the development of PLS calibrations. For example, the second component also shows a region around 320 nm, highly influencing the variance of the spectra, and is possibly related to the hydroxycinnamic acids.

Quantitative Analysis: PLS Models. Statistics for the PLS calibrations developed for wine samples using UV−vis spectroscopy (260−610 nm) are shown in Table 3. Three wavelength regions were selected to develop PLS calibrations. First, a region containing all of the recorded spectra was tested (260−610 nm). However, Dambergs et al.[33] reported a robust method for the development and validation of a UV spectrum calibration for the prediction of the tannin concentration in red wines; therefore, a

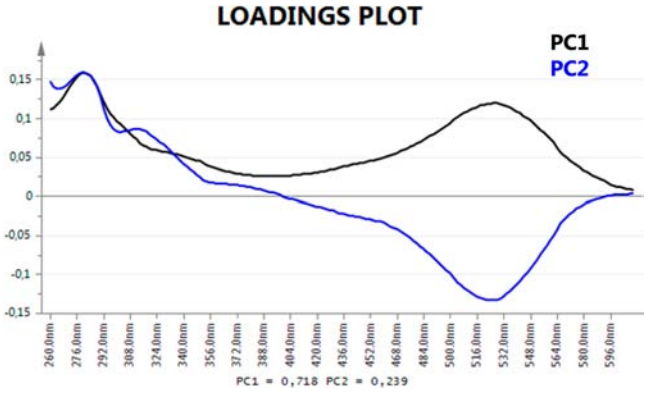

Figure 5. Loadings for the two principal components corresponding to the spectra of the 240 wine samples recorded in the UV−vis region of the electromagnetic spectrum.

section containing only the UV region was also selected. Finally, the region related to the maximum absorbance of anthocyanins and polymeric pigments (480−580 nm) was also considered in combination with the UV region following the results observed in the loadings plot. In addition, and following the study by Dambergs et al.,[33] a model was also built using only the spectral values corresponding to five wavelengths in the UV region (270, 280, 290, 300, and 314 nm). The use of a small number of wavelengths is beneficial when transferability of calibration models between instruments is taken into account. Moreover, wavelengths were selected on the basis of the absorption peak that tannins show in the UV region of the electromagnetic spectrum around 280 nm.

Slightly higher values were observed in the reported statistics when only the UV region (260−310 nm) was considered in the PLS calibrations. R^2val, RMSEP, and RPD were 0.89, 0.16 g/L (epicatechin equivalents), and 3.49 for MCP and 0.93, 0.08 g/L (catechin equivalents), and 4.07 for BSA, respectively. When BSA was used as reference method, slightly higher values were found. These results, together with the higher %CV observed for the BSA method, suggest an increase in the variability of tannins measured by protein precipitation and therefore an increase in the ability of the model to predict new samples outside the calibration set.

It has been reported by several authors that RPD values >2.5 are considered good enough for prediction purposes.[20,33,57,58] Fragoso et al.,[25] however, rated only RPD values >3 as sufficient for prediction purposes, whereas values between 2.5 and 3 were considered suitable only for rough screening.[25] Taking into consideration the complexity of wine tannin molecules, which are more complex than those found in grapes due to the acidic and oxidative nature of the vinification process,[2,39,55] and also the possibly greater variable interaction between wine tannins and methylcellulose or BSA compared to that of grape tannins, we considered RPD values >2.5 valid for prediction purposes.

Moreover, the model built using only five spectral absorbance values in the UV region showed lower RPD vales than those observed when the full UV region was included in the calibrations. In this specific case, MCP presented higher RPD values than BSA, although in both cases the RPD vales were >2.5 and the models were therefore considered suitable for prediction purposes.

Models for Individual Grape Varieties. On the basis of the good results obtained with the full data set (R^2val = 0.88 and 0.9 and RPD = 2.97 and 3.5 for MCP and BSA, respectively), we decided to check the ability of UV−vis spectroscopy to predict tannin concentration by devising models with each grape variety individually. Table 4a shows the statistics for the PLS calibrations developed for wine samples using UV−vis spectroscopy (260−610 nm). The calibration sets were developed using 49 Cabernet Sauvignon samples, 46 Merlot samples, 60 and 57 Shiraz samples, 15 and 14 Pinotage samples, and 60 and 59 samples spanning a wide range of varieties and some blends (called "remaining") for MCP and BSA tannin assays, respectively (five BSA values were missing and therefore were not included in the calibration models). In each case the remainder of the 240 samples was then used as a validation data set.

The ability of Cabernet Sauvignon and Merlot tannin models to predict new samples of all other cultivars was weak, as the RPD values were always <2. On the other hand, the predictive ability of Shiraz and the remaining sample set was relatively strong. Interestingly, although a small range (0.92−0.29 g/L), lower CV (26.61%), and a small calibration set were used (14 samples), the Pinotage model showed strong predictive ability when BSA was used as reference method, whereas weak predictive ability was observed when MCP was used as *Y* variable. A calibration set aimed at predicting the tannin concentration when only Pinotage samples are included therefore probably would need a wider range of Pinotage samples when MCP is used as reference

method. The differences observed for the Pinotage models could also be related to the different ability of the precipitants, methylcellulose polymer or bovine serum albumin protein, to bind and precipitate tannins from this variety, which is probably due to the unique phenolic composition of Pinotage wines.[59−61] Future work on establishing a MCP model for Pinotage should thus probably take into account the different abilities of both precipitants to react and precipitate tannins.[41] Only the model built with the Shiraz samples using BSA as reference method could be used for prediction purposes (RPD > 2.5). Moreover, the model built with the remaining samples, containing a great number of varieties, showed RPD values >2.5 and therefore is valid for tannin prediction purposes. This gives an idea of the robustness of the models, even though a wide range of varieties, different from Cabernet Sauvignon, Merlot, Syrah, and Pinotage, and a small calibration set were used to build the model (60 and 59 samples for MCP and BSA, respectively).

The results showed a great variability in tannin concentration and composition when building the calibration models. Models built with only single varieties did not cover the tannin variability observed in wines made from different *Vitis vinifera* varieties, therefore being unable to predict new samples. This is supported by the higher ability of the diverse pool of varieties model to predict the tannin concentration of new samples.

Table 4b shows calibration and validation statistics for the PLS models. The models were built with all of the samples from the other cultivars and validated against each individual cultivar; thus, the ability of the model to predict the tannin concentration of each cultivar was tested. The results show slightly higher RPD values where BSA was used as reference method, as has been observed for the full-range calibrations. The model aimed at predicting Cabernet Sauvignon tannin concentrations showed the strongest ability to predict new samples. Merlot and Shiraz, in this order, also showed RPD values considered suitable for prediction purposes, although these were slightly lower than those of the Cabernet Sauvignon model. However, this order was inverted when the ability of each cultivar to predict tannin concentration was tested (Table 4a).

It thus seems that lower variation in tannin composition leads to poorer ability of the cultivar to predict new samples' tannin concentrations. Moreover, the set of samples composed of the remaining cultivars showed R^2val and RPD values of 0.85 and 2.73 for MCP as reference method and 0.87 and 2.77 for BSA as reference method, respectively. These results display the ability

of four red varieties (Cabernet Sauvignon, Merlot, Syrah, and Pinotage) to predict samples spanning a wide range of other cultivars. On the other hand, poor statistics were again observed for the cultivar Pinotage for both reference methods. This indicates the poor ability of a diverse calibration set to predict Pinotage wine samples' tannin concentrations, which is probably due to the specific phenolic composition of this variety.[59−61]

Models for Individual Vintage Years. The ability of the 2012 and 2010 tannin model to predict tannin concentrations of samples from other vintages when MCP was used as reference method was considered good enough (RPD > 2.5) for prediction (Table 5a). However, 2011 and 2009 showed lower RPD values. Whereas the 2009 tannin model could be considered for screening purposes, the smaller sample set in the 2011 model could affect the ability of the model to predict tannin concentrations in samples outside the calibration set.

On the other hand, when BSA was used as reference method, the results showed lower accuracy, that is, lower ability to predict new samples, as the model is built with older samples, showing lower predictive ability when models were tested with new samples. A more qualitative interpretation of the RPD is given by other authors, where RPD values <1.5 were considered insufficient for most applications, whereas calibration models with values >2 were considered excellent.[57] In all of the models, RPD values were <1.5 and therefore could not be considered for rough screening.[36,62,63]

The results also show the poor ability of the older sample set (ranging in vintage from 2000 to 2008) to predict the tannin concentration of younger vintage samples. Therefore, when this result is taken into consideration, it is necessary to add samples of younger wines to the model to increase the reliability of the model.

Interestingly, different results were obtained depending on the reference method employed. It seems that BSA protein loses its ability to react with old wine tannins and polymeric pigments, which means that the ability of the models to predict new samples is compromised. However, this effect was not observed when MCP was used as reference method. In this case, the RPD values were 2.71, 1.94, 2.93, and 2.49 for the 2012, 2011, 2010, and 2009 models, respectively. These results, which are reported here for the first time, strengthen the fact that the tannin material is measured differently by MCP and BSA.[39,41]

Older wines exhibit lower astringency intensities together with smaller tannin size.[1,2] Furthermore, an increase in the ability of

the BSA protein to react with tannins based on their molecular size was reported recently.[64] The precipitation of tannin increased with increasing size, up to octamer. The authors report that around 100% of the decamer would be precipitated under the assay conditions. The effect of polymer mixtures for precipitating proteins was also studied, and a different protein precipitation efficacy was observed compared to that of individual polymers.[64] These findings could partially explain the inability of the BSA model composed of young 2012 samples to predict older samples, because lower mDP would be expected in older samples, leading to a decreased ability of the BSA to react and precipitate tannins.[64] In summary, the variability in tannin composition observed in the old samples would probably not be represented in the calibration model based on young samples. This model therefore is unable to predict older samples outside the calibration set. The different ability of tannin polymer mixtures to precipitate BSA could also affect the lower ability of the other models, which contain samples from different vintages, to predict new samples. Unfortunately, a similar study using MCP as a precipitating agent of different polymer size tannins has not yet been conducted.

RPD values between 2 and 3 were observed for all vintages and both reference methods when the model's ability to predict the tannin concentrations of specific years was tested (Table 5b). Wine samples from 2011 and 2010 for MCP as reference method showed satisfactory ability to be predicted by the model containing the remaining set of samples. Moreover, 2010 and the set of remaining vintage years could also be predicted by the model when BSA was taken as reference method (RPD values of 2.64 and 2.87, respectively). Thus, a possible explanation for the differences observed in the calibrations could be caused by the vintage year affecting tannin composition and also by interaction between the two precipitants. When samples from the youngest vintage (2012) were predicted by the model, R^2val and RPD values of 0.85 and 2.59 for MCP and 0.9 and 2.69 for BSA as reference method were achieved, respectively. This shows high predictability when new samples are predicted with a model built with samples from older vintage years. The results show that new samples should probably be added to the model as it becomes older (Table 5a), although new samples do not need to be added every year, because models built with all of the samples except the 2012 wines (latest vintage) and validated against samples from 2012 showed good predictive ability (RPD = 2.59 and 2.69 for MCP and BSA, respectively) (Table 5b).

Models for Commercial/Experimental Wines. Table 6 shows the statistics for the PLS calibrations developed for wine samples using UV−vis spectroscopy (260−610 nm). The calibration set was developed using the 121 commercial wine samples and 119 experimental wine samples for the MCP tannin assay and the 121 commercial and 115 experimental wine samples for the BSA tannin assay, respectively. In each case the remainder of the 240 samples was then used as a validation set. To test the ability of commercial wines to predict experimental wine samples and vice versa, models containing both variables as calibration set were developed. The R^2val and RPD values were 0.81 and 2.11 for MCP as reference method and 0.89 and 2.75 for BSA, respectively, when commercial wines were used as calibration set and experimental samples were used to validate the model. Thus, using BSA as reference method, the commercial wines had sufficient ability (RPD > 2.5) to predict samples outside the calibration set (experimental wines). Otherwise, RPD values <2.5 (2.29 and 2.28 for MCP and BSA, respectively) have been observed when experimental wines were used to predict commercial wines. Models built with experimental wines therefore could be used for the purpose of screening commercial wines, allowing a classification of the wines' tannin levels, but should not be used further for prediction purposes. As we have observed in the PCA-X plot, the effect of barrel aging or oxygen exposure together with the absence of MLF in experimental samples could explain the lower ability of the experimental wines to predict commercial wines, because the changes in the phenolic composition that occur during MLF and wine aging could account for the observed lower accuracy.

Conclusions. The results presented here clearly show the potential and robustness of rapid UV−vis predictive methods to quantify wine tannins in South African red wines. Models built using only the UV region presented slightly higher RPD values and hence better ability to predict new samples and, therefore, should be considered in terms of a reduction in the time of analysis. In addition, differences in the results obtained when the predictive ability of the classifying variables was studied suggest that tannin composition and concentration, and the ability of tannins to react and precipitate with both precipitants MCP and BSA, are affected to a great extent by several factors.

The tested cultivars showed different abilities to predict samples from other, new cultivars. Shiraz, Merlot, and Cabernet Sauvignon, in this order, showed a decreasing ability to predict the tannin concentration of new samples. However, this order was inverted when single-cultivar samples were predicted by a diverse cultivar model. A particular behavior was observed when Pinotage was used as calibration or validation test. The specific phenolic and tannin composition of this variety could perhaps explain the differences in the results observed. The results also showed that models built with older wine samples should also incorporate younger samples to increase their accuracy in predicting samples outside the calibration set when BSA is used

DOI: 10.1021/jf503412t
J. Agric. Food Chem. 2015, 63, 1088−1098

as reference method, an effect that was not observed when MCP was used as the *Y* variable. The different ability of the BSA protein to bind and precipitate tannins with different degrees of polymerization has been proposed as the possible reason for this behavior. Finally, samples from 2012 (last vintage tested) were predicted accurately by models constructed with samples spanning a number of older vintage years. This means that samples from the last vintage should not necessarily be added to the model to achieve prediction accuracy. Furthermore, experimental wines made without MLF and not submitted to barrel aging and oxygen exposure were not able to accurately predict commercial wines. A proposal for future work is that experimental wines subjected to MLF should be also included in the calibration set, as this might be able to increase model predictability. In addition, the distinctive phenolic, especially tannin, composition of Pinotage wines needs to be characterized extensively. Finally, the interaction between Pinotage tannins and BSA protein or MCP polymer needs to be also assessed to understand the ability of Pinotage tannin material and both precipitants to bind and form precipitable aggregates.

[a]All new CLs listed are proposed by Shim et al.,[46] except **3** and **7**. [b]The first positions of amino acid sequences are highlighted in Figure 1. Abbreviations are Met for methionine, Abu for 2-aminobutanoic acid, MetO for methionine *S*-oxide, and $MetO_2$ for methionine *S*,*S*-dioxide. [c]This work proposed the use of **3** and **7** for Abu-substituted forms **2** and **6**, respectively.

many physiological roles and pharmacological effects. One of its main functions is to regulate osmotic potential between the blood and tissues. It also plays a role in the maintenance of blood pH. Another very important role of albumin is its function as a transport molecule. This role is based on albumin's unique ability to bind a variety of exogenous and endogenous compounds, such as metal cations, fatty acids, amino acids, and diverse drugs.[24−26] The distribution, free concentration, and metabolism of various drugs can be significantly altered as a result of binding to HSA.[23] HSA has multiple binding sites that bind a wide range of different ligands with high affinity.[22] There are two Sudlow's sites, site I and site II, which have been shown to bind drug molecules, endogenous hormones, and ions.[27] Site I is composed of a pocket with hydrophobic walls and an opening lined with positively charged residues, allowing it to bind a variety of different ligands.[27] It binds dicarboxylic acid or bulky heterocyclic molecules with a negative charge in the middle.[27] Site II is smaller and less flexible than site I. It binds aromatic carboxylic acids with negatively charged acidic groups such as those present on nonsteroidal anti-inflammatory drugs.[27] Because the amino acid residues on CLs are primarily hydrophobic, it is probable that CL interacts with HSA when introduced to the human body.

The interaction of HSA with drugs has been investigated using fluorescence,[28,29] Fourier transform infrared spectroscopy,[30−32] and circular dichroism spectroscopy,[33] but the binding of CLs other than CL **1** to HSA has yet to be investigated. Investigation of the kinetics and equilibrium of CL/HSA binding and release is necessary as cyclic peptides are being considered as drug-delivery molecules.[34] For instance, binding information is essential to understanding how cyclic peptides can be delivered to a target environment or tissue. The information provided by surface plasmon resonance (SPR) is ideal for studying the association/dissociation kinetics of CL/HSA binding. One advantage of SPR is that the different binding kinetics of a number of different analytes to the immobilized ligand can be studied. Comparisons between the association/disassociation kinetics between different analytes can be made easily. The equilibrium constants of association (K_A) and dissociation (K_D) are determined from the association and dissociation rate constants.

MATERIALS AND METHODS

General. HSA (99% purity, fatty acid and globulin free) was purchased from Sigma-Aldrich Canada, Ltd. (Oakville, ON, Canada) and used without further purification. CLs were extracted and purified from flaxseed using previously reported procedures.[5,6,35,36] An amine coupling kit [0.4 M 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC), 0.1 M *N*-hydroxysuccinimide (NHS), and 1.0 M ethanolamine hydrochloride-NaOH (EA), pH 8.5], HBS-EP buffer [10 mM 4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid (HEPES), 150 mM NaCl, 0.005% (v/v) surfactant polysorbate 20, and 3.4 mM ethylenediaminetetraacetic acid (EDTA), pH 7.4], and a research-grade CM5 sensor chip were obtained from Biacore (GE Healthcare, Montreal, QC, Canada). The sensor chip CM5 has a 100 nm thick carboxylated dextran layer on a 50 nm thick gold layer surface. All other reagents were of analytical grade, and Milli-Q water (Millipore, Bedford, MA, USA) was used throughout the experiments.

Theoretical Aspects. The kinetic model for a 1:1 interaction is normally represented by eqs 1 and 2

$$A + B \xrightarrow{k_a} AB \quad (1)$$

$$AB \xrightarrow{k_d} A + B \quad (2)$$

where k_a and k_d represent the association and dissociation rates, respectively. The affinity constant K_A is the ratio of k_a and k_d,[37] shown in eq 3.

$$K_A = \frac{k_a}{k_d} = 1/K_D \quad (3)$$

The ligands are immobilized on the SPR sensing surface by passing HSA through a flow cell (Figure 2A). The immobilized ligands have different densities as well as different orientations on the sensor surface. The interactions are measured in real time in the flow cell (Figure 2B).

The affinity of interaction is estimated by first assuming that HSA binding sites are equally available and, second, that only high-affinity sites are occupied in the working concentration range.[38] Plots of the measured response versus different CL concentrations [CLs] are shown in Figure 3 and Figure S1A−H of the Supporting Information, respectively. K_A and the response values at the binding site saturation (R_{max}) were obtained by fitting the measured response values (R_{eq}) obtained with different CL concentrations to eq 4.

$$R_{eq} = R_{max}\frac{K_A[CLs]}{K_A[CLs] + 1} \quad (4)$$

Analyte and Buffer Preparation. Nine CLs with either 8 or 9 amino acids (915.17−1090.38 Da; Table 1 and Figure 1) were used. The CLs were purified to >98% homogeneity using reversed phase high-pressure liquid chromatography (HPLC). Analyte solutions were prepared by diluting CL stock solutions 20-fold into phosphate-buffered saline (PBS; 10 mM phosphate buffer, 2.07 mM KCl, 137 mM NaCl, pH 7.4), giving a final PBS buffer containing 5% (v/v) dimethyl sulfoxide (DMSO). The CL concentrations in the analyte solutions injected on the biosensor ranged from 40 to 150 μM. Preferably, analyte solutions were prepared just before use, but in some cases were stored at 4 °C. Running buffer for all experiments was PBS (pH 7.4) containing 5% (v/v) DMSO. Running buffers were

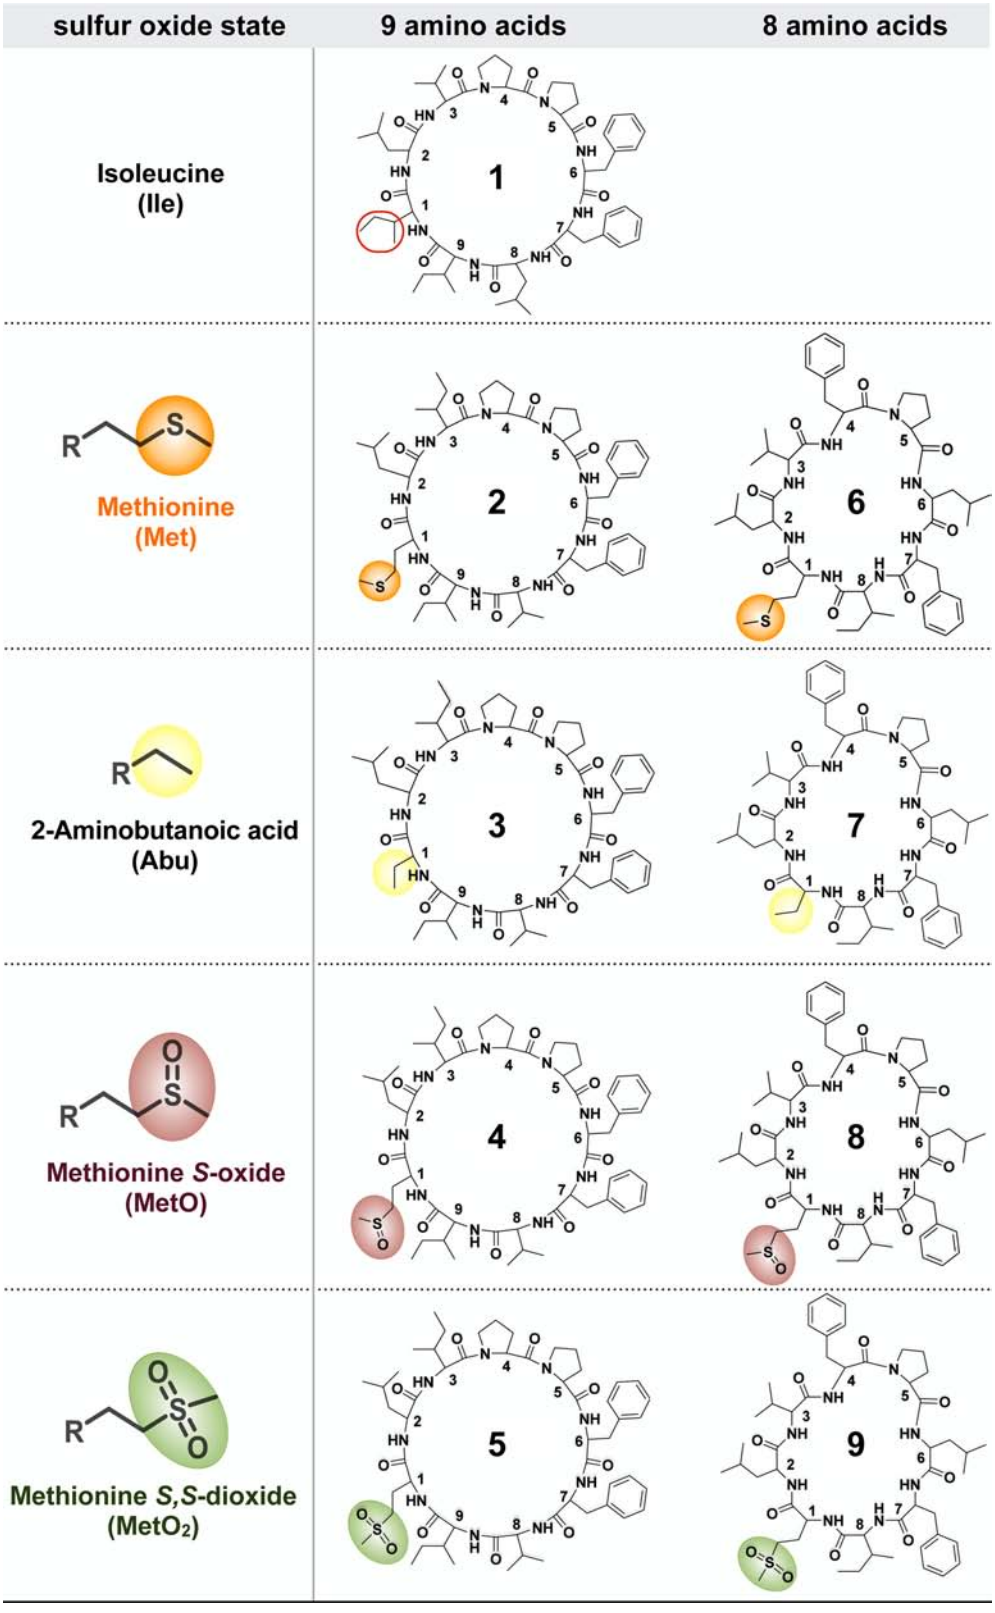

Figure 1. Structure of CLs used in the HSA binding studies.

filtered and degassed daily before use. A 10 mM sodium acetate buffer (pH 5.3) is generally adequate for immobilizing amine ligands onto a CM5 sensor chip and was used in all experiments. All buffer solutions were freshly prepared, degassed, and filtered with a 0.22 μm filter.

Surface Plasmon Resonance Analysis. SPR measurements were performed using a Biacore X instrument (Biacore AB, Uppsala, Sweden) equipped with an internal injection system (500 μL Hamilton syringe). This instrument has a flow injection system to enable real-time measurement of molecular binding. The SPR angle shift is used as a response unit (RU) to quantify the binding of biomolecules to the sensing surface (Figure 2B). The fluidic unit of the instrument was cleaned prior to experiments by injecting 0.5% sodium

J. Agric. Food Chem. 2015, 63, 1099−1106

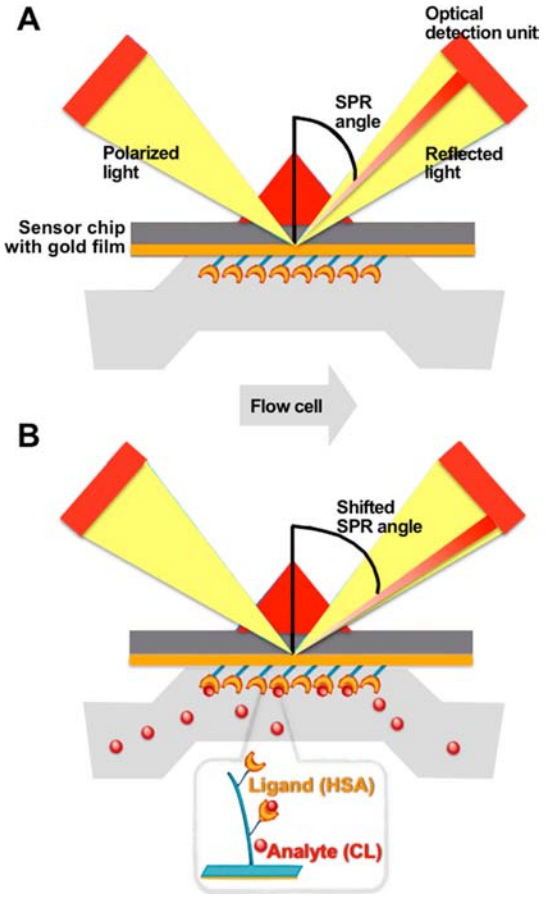

Figure 2. Principle of SPR phenomenon. (A) Polarized light is applied to the surface of the sensor chip and is reflected. The intensity of the reflected light is reduced at a certain incident angle, the SPR angle. (B) Interacting substances near the surface of the sensor chip increase the refractive index, which alters the SPR angle. The optical detection unit detects position changes in the wedge of the reflected light, corresponding to the SPR angle. The signals produced are measured in RU.

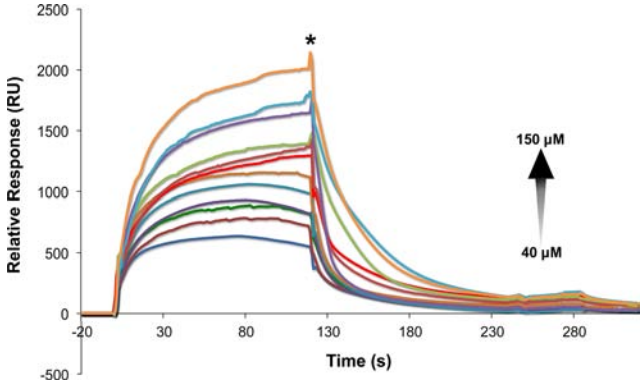

Figure 3. Concentration-dependent analysis of CL **1** complexes binding to HSA. All color plots indicate a spot exposed to 30 μg/mL HSA ligand and with various concentrations of CL **1** on the surface, respectively, with duplicates (omitting the regeneration stage). The response baseline is set to equal the level of HSA whereas time zero is set at the time of injection of CL **1**. One representative experiment is shown. All experiments are performed on the same sensor chip. The asterisk marks the end of the CL **1** injection and the beginning of CL **1** desorption.

dodecyl sulfate, followed by 50 mM glycine (pH 9.5). To reuse a chip for SPR analysis, bound analyte must be regenerated by stripping prior test compounds from the surface after each injection, usually with mild detergents. However, standard regeneration treatments did not effectively remove CLs from the HSA-immobilized chip. The only reagent that reproducibly did so was 6 M guanidine hydrochloride (GdnHCl) applied as a brief pulse (10 μL at 10 μL/min flow rate), followed by continued HBS-EP buffer flow (>5 min at 25 μL/min) to stabilize HSA prior to the next injection.

Immobilization of HSA. HSA was covalently immobilized onto a research-grade CM5 sensor surface at 25 °C using standard amine-coupling chemistry.[37] Briefly, CM5 sensor chips were preconditioned prior to HSA immobilization by priming the instrument three times with HBS-EP buffer, followed by three successive 1 min injections of 50 mM NaOH at 50 μL/min. Flow cell 1 (Fc1) and flow cell 2 (Fc2) were activated by a 7 min injection of a 1:1 mixture of 0.1 M NHS and 0.4 M EDC using a flow rate of 5 μL/min. HSA has an isoelectric point (p*I*) of 5.67 and is positively charged below this pH. Immediately after activation, HSA (30 μg/mL) was diluted in 10 mM acetate buffer (pH 5.3) to impart a positive charge on the HSA (Figure 4). Thereafter, the HSA is attracted to the negatively charged

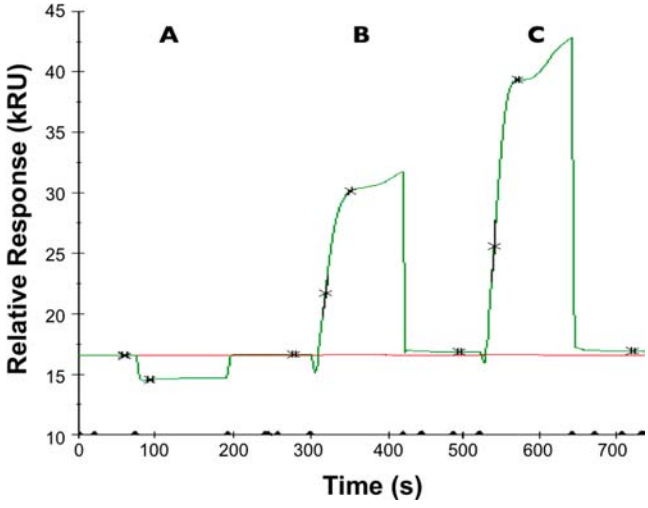

Figure 4. PH scouting of three successive electrostatic preconcentration assays for HSA (66 kDa MW and p*I* 5.67) as ligand. All HSA was diluted in 10 mM sodium acetate to a final concentration of 30 μg/mL, at three different pH values, (A) 5.5, (B) 5.3, and (C) 5.0, respectively.

matrix of the sensor chip and immobilized onto Fc2 (Figure 5). A solution of 10 mM acetate buffer without HSA was passed over Fc1, to act as the reference cell. A 7 min injection of 1.0 M EA (pH 8.5) using a flow rate of 5 μL/min was passed over Fc1 and Fc2 to deactivate unbound areas of the sensor surfaces. The thickness of the bilayer was calculated by assuming that 1 kRU corresponded to a 1 nm thick layer.[39] This bilayer was subsequently used as a model membrane surface to study the CL/HSA interactions. When kinetic analyses are performed, the ligand density should be as low as possible, provided signal-to-noise ratios are adequate. Direct detection of CL (ca. 1.0 kDa) binding to the immobilized HSA ligand (ca. 66 kDa) on a Biacore X generally requires immobilization responses.

CL Binding to HSA. For all CLs, 40 μL of analyte solution (40–150 μM) was injected, in duplicate, and flowed over reference and HSA surfaces for 2 min at a flow rate of 20 μL/min, followed by a dissociation phase of 2 min for all experimental conditions. At the end of the CL injection, the flow solution was switched to the running buffer, and a decrease in the response toward the baseline was observed within minutes. This decrease in response indicated that CLs were dissociating from the HSA immobilized to the sensor surface. All experiments were performed at 25 °C. When the baseline RU was not readily achieved, a short pulse of 50% (v/v) DMSO solution was injected at a high flow rate to remove any remaining CLs. Repeated

[a]All experiments were performed on the same HSA-immobilized CM5 chip. Values are means of SPR assays performed in duplicate. [b]The slopes were determined from curve-fitting dose-response curves in Figure 3 and Figure S1 of the Supporting Information.

experiments indicated that the regeneration procedure did not change the binding characteristics of the immobilized HSA (data not shown).

The sensorgrams were analyzed by the global fitting procedure using a 1:1 (Langmuir type) drifting baseline model-derived equation[26] available in the BIA evaluation software (version 4.2). RU curves taken from the sensorgrams 10−30 s after association and the dissociation were used in the model. The association rate constant (k_a), the dissociation rate constant (k_d), and the dissociation equilibrium constants (K_D) were determined from the model at the minimal chi-squared (χ^2) value.

RESULTS AND DISCUSSION

Preconcentration Assays. Preconcentration assays were performed to determine the best immobilization buffer. Different preconcentration pH values were used to determine optimal binding of HSA to the sensor chip surface (Figure 4). Using ca. 12 kRU as a reasonable immobilization level for the direct kinetic assay of CL binding to a HSA surface, pH 5.5 produces inefficient preconcentration, resulting in low levels of the ligand binding to the carboxymethyl-dextran matrix of the sensor chip. At pH 5.3, efficient HSA preconcentration occurred, producing a satisfactory final response level (Figure 4B). In contrast, HSA uptake by the surface is too rapid at pH 5.0, resulting in an excessive final response (Figure 4C). Thus, for immobilization of HSA via the amine coupling reaction, a preconcentration pH of 5.3 was chosen.

HSA Covalent Immobilization. Typical SPR response sensorgrams of HSA immobilization are shown in Figure 5. In a first stage (A), the EDC/NHS activating mixture is injected with the consequent increase in the SPR signal due to a change in the bulk refractive index. The HSA solution is then injected, and the binding event (B) can be followed in real time. Once an adequate binding level is reached, the remaining active carboxyl-NHS esters are blocked with ethanolamine hydrochloride (C), causing a significant change in the bulk refractive index. The biospecific HSA surface is then ready to be used (D). The final immobilized HSA response is 12−13 kRU at the sensorgram.

Binding of the Bioactive Compound CLs to HSA. Interactions between **1** and immobilized HSA were measured (Figure 3). As the concentration of **1** increased from 40 to 150 μM, the binding signal steadily increased in RU. This result was similar to that reported by Rempel et al., although the response is significantly stronger in this study.[40] Interestingly, when the chip surface was saturated with analyte, the response

DOI: 10.1021/jf504811x
J. Agric. Food Chem. 2015, 63, 1099−1106

normalized by the concentration-dependent analysis should have yielded equal maximum responses. A CL:HSA (1:1) binding stoichiometry was observed, using a drifting baseline model (Table 2 and Figure S1 of the Supporting Information). Residual values from Figure 6 also support the closeness of this

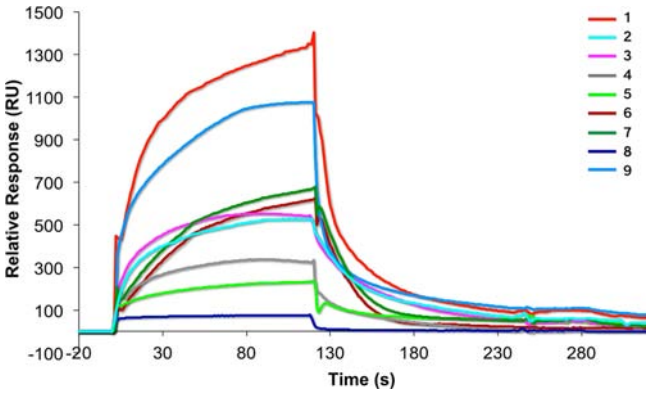

Figure 6. SPR sensorgram responses for 100 μM of different CLs binding to HSA. Colors of sensorgram traces are assigned in the legend.

1:1 ratio between the experimental and theoretical curves. All plots illustrated the experimental curve-fitting methodology for a simple binding model (1:1 Langmuir).

Data Processing and Evaluation. The concentration dependencies of different CLs binding to immobilized HSA for concentrations ranging between 40 and 150 μM were determined (Figure S1 of the Supporting Information). Sensorgrams corresponding to a nonspecific CL **8** injected on a HSA surface are shown in Figure 6 and Figure S1G. The sensorgrams are square-wave shaped due to a refractive index jump, which is confirmed by the fact that no CL **8** is bound to the HSA at the beginning of the dissociation phase: (1) CL **8** did not appreciably bind HSA; (2) the increase in RU caused by an increase in refractive index is largely the result of buffer injection; and (3) all other CLs examined formed HSA complexes as the association curve is relatively higher than observed in CL **8**.

In contrast, other sensorgrams correspond to a specific interaction between an injected CL and the immobilized HSA. Compared to the other CLs tested, CL **1** has slow association kinetics with HSA (Figure 6). At higher concentrations, the steady-state plateau was not reached after 120 s. The gradual increase of response to a steady state during CL **1** injection indicates slow recognition kinetics of CL **1** with the HSA binding site compared to other CLs tested (Figure 6). Quantitative kinetic data were initially extracted using the kinetics profiling within the Biacore Evaluation software. The slow recognition may be due to CL becoming available for interaction with HSA. It is likely that CL **1** has a large hydration sphere, which must dissociate before interaction with HSA is possible.

HSA has seven known fatty acid binding sites, each of which is known to bind other small, hydrophobic molecules. Two of the binding sites for small molecule drugs are known as Sudlow site I (warfarin binding site) and Sudlow site II (indole-benzodiazepine binding site).[41] Site I binds drug molecules that are structurally bulky, heterocyclic compounds with centrally localized negative polar/charges, and hydrophobic substitutions. It has been suggested that binding is through hydrophobic interactions between the analyte and a hydrophobic crevice within the binding cavity of site I.[42] The nature of CL binding was not proven in the present study.

The equilibrium parameters for several CL binding reactions with immobilized HSA were determined (Table 2). The K_A value indicated that the affinity tends to increase as the CL becomes more hydrophobic, although there are significant exceptions. The K_D showed more rapid dissociation of CLs **4**, **5**, and **8** than of CL **1** (Table 2 and Figure 6). This suggests that there is more binding of **1** at the highly hydrophobic crevice. All CLs tested were able to bind, showing more than an order of magnitude increase in the **8**/HSA binding (RU 71.0) and **1**/HSA, which was almost 20-fold higher (RU 1370.6) than **8**/HSA (Figure 6). Also, the oxidation state of the sulfur-containing amino acid residue in position 1 of CLs (**2**−**9**) was a component critical to binding. To examine the importance of this sulfur-containing residue (*S*), we synthesized CLs with 2-aminobutanoic acid (Abu) instead of methionine residues at this position (Table 1 and Figure 1). These modified compounds are named [1−9-NαC],[1-Abu]-CLB (**3**)[35] and [1−8-NαC],[1-Abu]-CLE (**7**)[36] according to established conventions. Each of the S-free [1-Abu]-CLs had similar binding strengths to their 2-Met-containing counterparts (Figure 6). Most strikingly, the conversion of methionine sulfoxide to the sulfone peptide [1−8-NαC],[1-MetO_2]-CLE (**9**) had the greatest effect on binding (Figure 6 and Figure S1 of the Supporting Information). It can be speculated that this was an effect of structural differences between CLs **6** and **9** and CLs **8** and **9** induced by the oxygen−sulfur bonds or the dipole moment of the *S*-oxide group. A similar but less pronounced effect was observed with CLs **2**−**5**. The conservative introduction of an oxygen group to **2** leads to a partial disruption of the HSA interaction and weak binding of compound **4**, whereas the addition of two oxygen groups results in **5** with 4-fold stronger binding than that of **4** (the most polar CL tested).

CLs are produced in plants via expression of genes that code for multiple CLs.[1] The peptides produced in the same reading frame are usually produced in constant ratios in the plant determined by transcription and post-translational modification of the peptide gene. In an attempt to observe the sensorgram of peptides encoded by the same gene after different post-translational modification, we compared three mixtures of three peptides each with a similar modification of methionine. The slow release of the stronger binding groups (CL mixtures **1_2_6**; **1_3_7**; and **1_5_9**) suggested that parameters would also be important in understanding their HSA binding (Figure 7). The fast dissociation of CL mixture **1_4_8** showed weak binding with HSA. This is due to the contribution from breaking of the solution complex and hydrophobic binding. It has been observed that CL mixture **1_2_6** is observed in flaxseed meal products with prolonged storage. This mixture is the major product of a single gene located on scaffold 1198 coded on the 3′ to 5′ strand bases 162067−161526 available via Phytozome portal (version 9.1). Flaxseed oil CLs **2** and **6** become oxidized to **4** and **8**, respectively. Finally, excessive oxidation will produce **5** and **9**.[43]

In conclusion, the K_D of CL/HSA solution is correlated with both the methionine oxidation state and polarity. The binding of methionine-containing CLs with HSA was similar to that of peptides that had Abu in place of methionine but greater than that of peptides with methionine *S*-oxide. The dipole moment of the *S*-oxide likely contributes to decreased affinity.

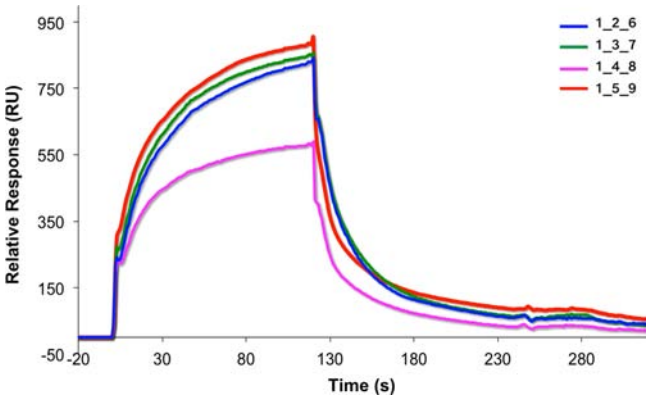

Figure 7. SPR sensorgram responses for 100 μM of each CL mixture binding to HSA.

Conversely, increased oxidation of the methionine *S*-oxide to form the *S*,*S*-dioxide produces a molecule with restored HSA binding. These findings show that cyclic peptides and particularly CLs can be used to study the discrete effects of changing a single amino acid on receptor binding. Other studies on more complex molecules may not allow the examination of a single substitution. For example, oxidation of methionine residues in human IgG2 Fc decreased SPR binding affinities to protein A.[44] Comparison of the equilibrium dissociation constants to other literature compounds indicates that CL binding to HSA is not comparatively strong when compared with that of other drugs, except that the values of K_D for **5** and **8** were similar to those reported for pyrimethamine and rifampicin bindings, respectively.[45] In this study the impact of sulfur oxidation and elimination was observed for orbitides containing methionine and its modified analogues.

predominantly pressure, temperature, and solvent type.[10] As a number of factors can influence the course of the extraction, the screening and optimization of the significant factors must be carried out to establish a reliable analytical PLE method. In the study described here, seven extraction factors were evaluated, namely, solvent composition, extraction temperature, pressure, flushing, static time, solvent purge, and sample weight.

In PLE the pressure generally acts by forcing liquid into the solid matrix.[14] In addition, an increase in pressure leads to an increase in the extraction rate because, if sufficient pressure is exerted on the solvent during extractions, temperatures above the boiling point can be reached while the solvent is maintained in the liquid state.[15]

Temperature plays a role in enhancing the extraction yield because higher temperatures can decrease the viscosity of liquid solvents, thus permitting faster diffusion rates and better penetration into the matrix. Furthermore, thermal energy can disrupt the strong interactions between the solute molecules and active sites on the matrix, and this can aid the release of target molecules. However, as melatonin is sensitive to temperature,[16] a preliminary study on its stability under different PLE temperatures was required to define the working temperature range for the optimization.

The extraction yields from plant samples are highly dependent on the nature of the solvent employed[17] because of the effects of both the solvent diffusivity and the solvent polar properties. The polarity of the solvent will affect the extraction depending on the polar properties of the target compound. On the other hand, the enhanced diffusivity of the solvent leads to an increase in extraction speed and efficiency.[18] The amphipathic structure of the melatonin molecule, which is composed of polar and nonpolar moieties, makes it difficult to select a solvent that yields complete recovery.[19] In the study described here, this constraint was therefore taken into account in a preliminary study by screening several solvents, including water, methanol, ethanol, and ethyl acetate, prior to the selection of the extraction solvents to be used in the optimization experiments.

A factorial design with a reduced number of runs is preferable to a full factorial design for more than four factors, particularly when the available resources are limited. Therefore, a chemometrical approach based on a fractional factorial design (FFD) is a reasonable option to evaluate the significance of the studied factors prior to optimization of the PLE conditions.[20,21] The particular focus of this study was on the optimization and validation of PLE for the extraction of melatonin from rice grains using an FFD.

MATERIALS AND METHODS

Chemicals and Reagents. HPLC grade methanol (MeOH), ethanol (EtOH), ethyl acetate (EtOAc), and acetic acid were purchased from Merck (Darmstadt, Germany). Melatonin standard was obtained from Sigma-Aldrich (St. Louis, MO, USA). Water was purified with a Milli-Q purification system (Millipore, Billerica, MA, USA).

Rice Sample Preparation. Red rice samples from Thailand were used in this study. A rice sample (20 g) was placed in a plastic cylinder, and the rice grains were milled with an Ultraturrax homogenizer (IKA T25 Digital, Germany) for 10 min prior to extraction. The milling process was stopped every minute to avoid excessive heating of the sample. The fine powder of rice grain was then homogenized by stirring, and the samples were stored at room temperature in a closed container until analysis (1−5 weeks depending on the sample). No specific humidity conditions were applied during storage. The final extraction method was applied to a wide range of rice products available in the market, and these covered the varieties of polished (short and long) grain, whole (short and semilong) grain, aromatic rice, black rice, black glutinous rice, red rice, and parboiled rice products. Samples were acquired in several different markets in Spain.

Extraction of Melatonin. Pressurized liquid extraction (PLE) of melatonin was performed in a Dionex ASE 200 extractor (Dionex, Sunnyvale, CA, USA) equipped with stainless steel extraction cells (11 mL volume) and collection vials (60 mL capacity). A cellulose filter (Dionex) was inserted at the outlet end of the extraction cell. Rice powder was accurately weighed and loaded into the extraction cell, and washed sea sand was used to complete the extraction cell. The extraction cell was then filled with the extraction solvent (80−100% EtOAc in MeOH), pressurized (100−200 atm), and heated (100−200 °C). The cell was heated for a fixed time to guarantee that the sample reached thermal equilibrium. The sample was then extracted in a static extraction cycle (5−10 min) with the solvent at the experimental temperature and pressure. After the extraction, the cell was rinsed with fresh solvent (50−100% of the extraction cell volume) and purged with a flow of nitrogen for 60−120 s. The extract was dried under vacuum in a rotary evaporator. The residue was reconstituted with methanol and adjusted to a final volume of 5 mL. The liquid was then passed through a 0.45 μm nylon filter prior to injection in the HPLC-FD system.

Determination of Melatonin. High-performance liquid chromatography (HPLC) analyses were carried out on an Alliance HPLC 2695 system with a fluorescence detector (Waters 474 fluorescence detector), controlled by an Empower Pro 2002 data station (Waters, Milford, MA, USA). Separations were performed in a reverse phase RP 18 Lichrospher Column [LiChroCART 250 × 4 (5 μm)] from Merck at a temperature of 25 °C.

The mobile phase was a binary solvent system consisting of phase A (2% acetic acid and 5% methanol in water) and phase B (2% acetic acid and 88% methanol in water) with a flow rate of 0.5 mL min^{-1}. The mobile phase was filtered through a 0.45 μm membrane filter (Millipore) and degassed for 15 min prior to use. The 25 min programmed gradient was as follows: (time, solvent B): 0 min, 0%; 5 min, 35%; 12 min, 40%; 15 min, 40%; 20 min, 45%; 25 min, 50%. After each extraction, the column was washed with 100% B for 5 min and equilibrated with 0% B for 5 min. The established conditions for the fluorescence detector were as follows: excitation wavelength, 290 nm; emission wavelength, 330 nm; gain, 1000; attenuation, 16; injection volume, 10 μL.

Performance of the Method. The chromatographic method used to determine melatonin was performed according to the suggestions of ISO 17025 and the recommendations of ICH Guideline Q2 (R1).[22,23] The range, linearity, recovery, precision, detection, and quantification limits of the method were evaluated.

Linearity was estimated to express how the method provides test results that are directly proportional to the melatonin concentration within the studied range. A series of dilutions from a stock solution of melatonin were carried out to give concentrations ranging from 0.75 to 15 μg L^{-1} and from 15 to 750 μg L^{-1}. Gnumeric 1.12.17 was used to generate the regression analysis of the calibration curves. The standard deviation estimated for the response and the slope from the regression were then used to calculate the limit of detection (LOD) and the limit of quantification (LOQ).

A certified reference material was not available for melatonin in rice matrices and, as a consequence, definitive statements cannot be made with regard to accuracy. Nonetheless, the extraction recovery (%R) was determined by comparing the absolute response of the analytes spiked in control samples before and after the extraction procedure.

The precision of the method was evaluated by studying the repeatability (intraday) and intermediate precision (extraday). Repeatability was assessed by nine independent analyses of the same samples on the same day, whereas intermediate precision was determined by three independent analyses on three consecutive days. Precision was expressed as the coefficient of variance (CV) of the retention time and peak height. The acceptable CV limit is ±10% according to the AOAC manual for the Peer-Verified Methods

DOI: 10.1021/jf505106m
J. Agric. Food Chem. 2015, 63, 1107−1115

Table 1. Analytical Characteristics for the Determination of Melatonin by HPLC-FD

						intraday, CV (%)			
						n = 9		n = 3 × 3	
linear range (μg L^{-1})	observations	linear eq	R^2	LOD (μg L^{-1})	LOQ (μg L^{-1})	RT	height	RT	height
0.75−15	6	y = 580.79x − 1806.8	0.996	1.15	3.84	0.99	0.93	1.23	2.05
15−750	6	y = 615.11x − 961.13	0.999						

program.[24] The CV values with reference to the peak height for both repeatability and intermediate precision were <10%, thus showing that the method has a satisfactory precision. The analytical properties for the chromatographic method for the determination of melatonin are listed in Table 1.

Experimental Design and Optimization. The effects of the tested independent factors on the response within the studied range were evaluated by performing a fractional factorial design (FFD), that is, a 2^{7-2} (quarter fraction) screening design with a central point analysis. The extraction factors included in the design were solvent composition (x_1), extraction temperature (x_2), pressure (x_3), flushing (x_4), static time (x_5), purge (x_6), and sample weight (x_7). Because the variables have different units and ranges, each of the variables was first normalized and forced to range from −1 to +1 to obtain a more even response.[25] Therefore, the factor levels were denoted −1 (low), 0 (central point), and 1 (high). The variables were coded according to the equation

$$x_i = \frac{x_i - x_0}{\Delta x} \quad (1)$$

where x_i is the coded value of the factor x_i, x_0 is the value of x at the center point, and Δx is the increment of x_i corresponding to a variation per unit of x_i. The factors included in the design are shown in Table 2 along with their respective levels. The whole design consisted of 33 runs carried out in random order, and these are presented in Table 3.

Table 2. Coding Table of Experimental Factors and Levels

factor	−1	0	+1	unit
x_1, solvent	80	90	100	% EtOAc in MeOH
x_2, temperature	100	150	200	°C
x_3, pressure	100	150	200	atm
x_4, flushing	50	75	100	%
x_5, static	5	8	10	min
x_6, purge	60	90	120	s
x_7, sample weight	2.5	3.75	5	g

The design of experiment (DOE) matrix was established with the highest possible resolution and the lowest level of aliasing. Thus, resolution (R) of IV and the effects of two factors confounded with high-order interactions between the four other factors was used. The 2^{7-2}_{IV} fractional factorial design allowed the first four variables (x_1−x_4) to be set, and thus the DOE was obtained by establishing the full 2^5 factorial as the basic design (with the four factors x_1, x_2, x_3, and x_4); factors x_6 and x_7 were subsequently equated to the $x_1x_2x_3x_4$ and $x_1x_2x_4x_5$ interactions, respectively. This particular design produced the following defining relationships: $I = x_1x_2x_3x_4x_6 = x_1x_2x_4x_5x_7 = x_3\ x_5\ x_6x_7$. The second order response function for this fractional factorial design is

$$y = \beta_0 + \sum_{k}^{i=1} \beta_i x_i + \sum \sum_{j<i} \beta_{ij} x_i x_j + \varepsilon \quad (2)$$

where β_i (i = 1, 2, ..., 7) is the parameter estimated for the factor i, β_{ij} (i = 1, 2, ..., 7; j = 1, 2, ..., 7) is the parameter estimated for the interaction between variables i and j; x_i is the coded form of factor i that influences the response y; and x_i is the coded form of factor i that influences the response y. This model provides information on only the linear and two-factor interaction effects and assumes that three-factor and higher factor interactions are negligible.

The experimental results in single-factor experiments were analyzed using Gnumeric 1.12.17. The analysis of variance (ANOVA) and least significant difference (LSD) test were used to determine the significance of differences between the means.

RESULTS AND DISCUSSION

Preliminary Study: Stability of Melatonin during the PLE. Extraction temperature is the most crucial factor that affects the stability of melatonin because the extraction process is carried out at high temperature, which can even be above the boiling point of the solvent at atmospheric pressure. The stability of melatonin at different PLE temperatures was evaluated prior to the analytical method development. The level of melatonin in a standard solution was assessed after heating at 50, 100, 150, 175, and 200 °C.

The effect of PLE temperature on the stability of melatonin was analyzed using single-factor ANOVA. The retained melatonin was expressed by the signal height (mV) of the melatonin peak. The ANOVA showed that the different levels of melatonin exposed to different PLE temperatures were all stable. The applied PLE temperatures did not have a significant effect (p = 0.05) on the stability of melatonin because $F_{calculated}$ (0.7) was less than $F_{critical}$ (5.1). As the melatonin levels remained unchanged under the PLE temperatures tested, the optimization range for the temperature factor was defined between 100 and 200 °C.

Solvent Selection. Due to its amphipathic behavior, the extraction of melatonin must be carried out using a specific solvent for a sample with certain characteristics. As a point of reference, the extraction of melatonin from *Juglans regia* L. was achieved using MeOH and chloroform,[26] EtOAc was employed to extract melatonin from *Lupinus albus* L. roots,[27] hot water was used for the extraction from the three flowers from *Tanacetum parthenium*, *Tripleurospermum disciforme*, and *Viola odorata*,[28] and EtOH was employed for extractions from 15 seeds of edible plants including rice.[29] As a result, different solvents have been reported to be useful for the extraction of melatonin from different sources, although previous reports on the extraction of melatonin using PLE were not found. The behavior of solvents during PLE can be rather different from their behavior under regular extraction conditions and, as a consequence, several solvents, namely, MeOH, EtOAc, water, and EtOH, were evaluated to select the most suitable solvent for the PLE of melatonin from rice samples. The extraction efficiencies for melatonin with different solvents are shown in Figure 2.

The results showed that EtOAc as the extraction solvent gave a better yield than MeOH and EtOH. In contrast, water was not a suitable solvent to extract melatonin from rice samples with the PLE system as it can lead to starch gelatinization during the extraction process. This phenomenon occurs due to the presence of starch and water, which, when subjected to heat, leads to swelling of the starch granules as the water is

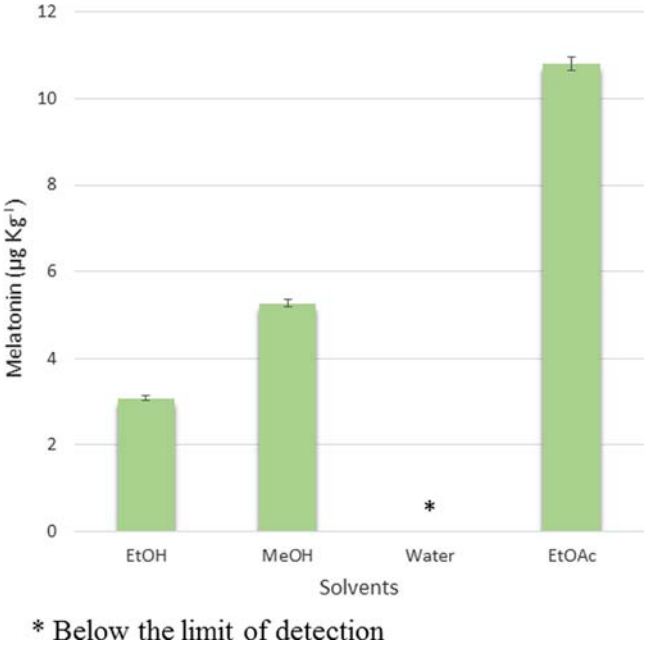

Figure 2. Effect of different solvents on the extraction efficiency.

gradually absorbed by the starch in an irreversible process. As a consequence, the extraction cell became blocked, and this led to an inefficient extraction process. Melatonin can be effectively extracted under PLE conditions using EtOAc, and the optimization was thus focused on obtaining the best concentration of EtOAc for the extraction solution. EtOAc was diluted in MeOH to adjust the concentration used for the optimization, and this was in the range of 80−100%.

2_{IV}^{7-2} Fractional Factorial Design Analysis. Once the working range for the extraction had been established by selecting the appropriate solvent and considering the stability of melatonin, the factors that were likely to influence the melatonin extraction were optimized. The factors considered were solvent composition (x_1; 80−100% EtOAc in MeOH), extraction temperature (x_2; 100−200 °C), pressure (x_3; 100−200 atm), flushing (x_4; 50−100%), static time (x_5; 5−10 min), solvent purge (x_6; 60−120 s), and sample weight (x_7; 2.5−5 g). The main response was the level of melatonin expressed as the value relative to the maximum yield of melatonin obtained (%). On the basis of the experimental design generated by the 2_{IV}^{7-2} fractional factorial design, 33 extraction processes were completed to extract melatonin from rice (Table 3), and the estimated effects of operating factors on the extracted melatonin were subsequently analyzed using the equation

$$\text{effect} = \frac{\Sigma y_+}{n_+} - \frac{\Sigma y_-}{n_-} \quad (3)$$

DOI: 10.1021/jf505106m
J. Agric. Food Chem. 2015, 63, 1107−1115

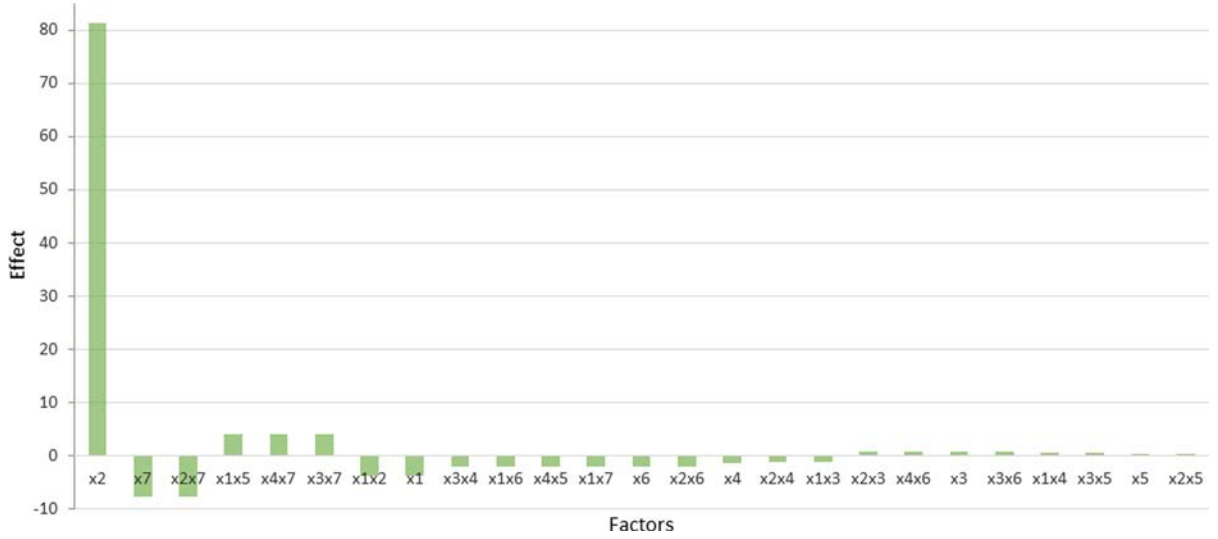

Figure 3. Estimated effects of the main and interaction factors on the recovery.

where n values refer to the number of data points collected at each level and y values refer to the associated responses. The values of the estimated main and interaction effects of factors in decreasing order of importance are plotted in Figure 3. The regression coefficients for the intercept, linear, and interaction terms of the model were calculated, and most of them were <2; only the regression coefficient for temperature showed a value much higher (38.734) than those calculated for the other extraction variables (1.65 as average value). Independent factors with a p value of <0.05 were defined as having a significant effect on the response.

The results shown in the chart for the main and interaction effects indicate that the most significant main effects (p < 0.00001) are extraction temperature (x_2) and sample weight (x_7). Another main factor that was reasonably prominent in terms of the extraction yield was the solvent (x_1) (p < 0.05). Furthermore, several effects caused by interactions of factors, including x_1x_2, x_1x_5, x_2x_7, and x_4x_7, were also found to be important (p < 0.05). Hence, the effects of extraction temperature (x_2) and sample weight (x_7) were the most important because a lower p value indicates a higher significance for the corresponding factors.[30]

The regression coefficients were then used to produce a final predictive equation for melatonin compounds in rice grain extracts by using significant variables. To avoid a high variability, it is advisible to keep the number of factors for an optimized design low by disregarding the nonsignificant factors (p > 0.05). The resulting equation for the fitted model is as follows:

$$y = 38.3273 - 1.82759x_1 + 38.7343x_2 - 3.71909x_7 - 1.84974x_1x_2 + 1.89794x_1x_5 - 3.68268x_2x_7 + 1.89501x_4x_7 \quad (4)$$

The efficiency of the model was checked by ANOVA, and the suitability of the model was judged by considering the coefficient of determination. The R^2 statistic obtained from the regression shows that the as-fitted model explains 0.9641 of the variability in melatonin levels. The adjusted R^2 statistic of 0.9416 indicates a high degree of correlation between the experimental and predicted values, and this is more appropriate when models with different numbers of independent factors are compared.

Optimization of the Significant Main Factors. Significant independent factors are essential to achieve the optimum yield for the melatonin extraction. According to the design analysis, as three main factors were significant, the best way to optimize the extraction yield is by increasing the extraction temperature (*estimated effect* +81.33), decreasing the weight of rice sample (*estimated effect* −7.7), and decreasing the percentage of EtOAc in MeOH (*estimated effect* −3.8).

The use of higher temperature increases the molecular motion and leads to a decrease in the solvent viscosity, resulting in an increase in the diffusivity. Furthermore, the walls of cells are broken more rapidly at higher temperature, and this facilitates the leaching of melatonin into the solvent, thus increasing the extraction efficiency. However, because the tested range includes the highest level (+1) for the maximum working temperature allowed by the system, optimization of the extraction process by increasing the PLE temperature was not possible. Thus, the optimum extraction temperature was set at 200 °C.

The amount of sample was oppositely correlated with the extraction yield, and this confirms that the higher solvent-to-solid ratio provides a higher driving force in transferring the desired analyte into the extraction solvent.[31] Nevertheless, the limitation in reducing the sample weight is the minimum concentration of melatonin in the extract that can be detected by the chromatographic system. Therefore, the lowest level (−1) for the tested optimization range in the design experiment was set as the optimum sample weight (2.5 g) to ensure a reliable quantification by the analytical method.

Solvent Optimization. The composition of the extraction solvent has a significant negative effect on the extraction yield. As a consequence, the solvent optimization should include a lower percentage of EtOAc than the range used in the experimental design. The proportion of EtOAc in MeOH was then examined at 60, 70, and 80% for further optimization (Figure 4). The yield of extracted melatonin increased significantly when the concentration of EtOAc in MeOH was decreased (single-factor ANOVA, p = 0.05) to give a yield of 70%. However, the amount of melatonin extracted was

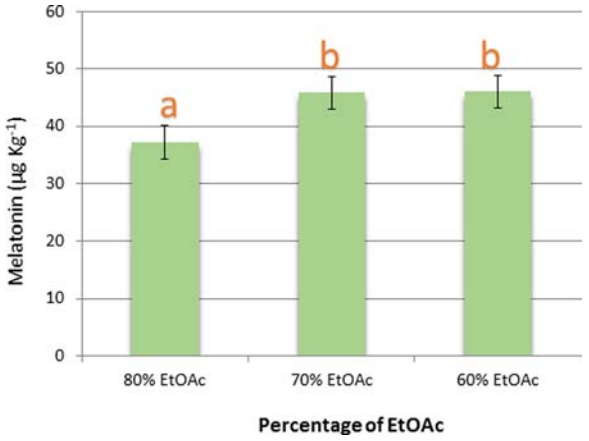

Figure 4. Level of extracted melatonin by different percentages of EtOH in MeOH. Means followed by the same letter are indicated as not significantly different (α = 0.05).

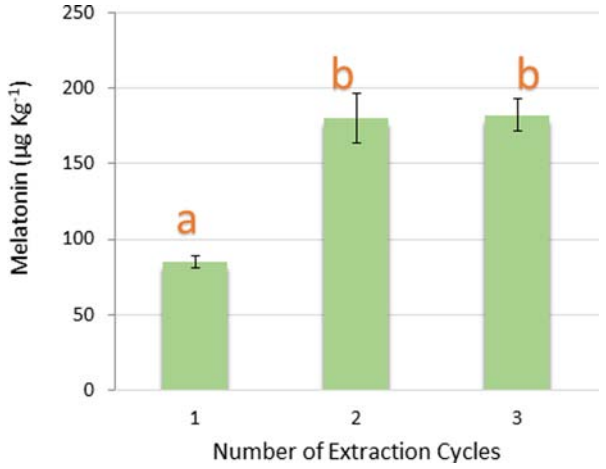

Figure 5. Level of extracted melatonin versus number of extraction cycles. Means followed by the same letter are indicated as not significantly different (α = 0.05).

comparable (LSD, p = 0.05) on decreasing the proportion of EtOAc to 60% in MeOH.

Melatonin has both hydrophilic and lipophilic properties, and it therefore requires a relatively complex solvent for extraction. In general, mixtures of solvents with different polarities lead to more efficient extractions than a single solvent when the analyte to be extracted has a wide range of polarities.[32] The use of solvent mixtures was found to improve the extraction yield by enhancing the solubility and encouraging interactions with the analyte.[33] Furthermore, a binary solvent mixture can effectively improve the extraction efficiency because one solvent may increase the solubility of the analyte, whereas the other may improve the analyte desorption.[10] Ethyl acetate is considered to be a medium-polar solvent that is appropriate for melatonin extraction, but the addition of MeOH to EtOAc increases the polarity of the mixed solvent, and this makes it easier to gain access into the ruptured cells to reach the melatonin. This advantage was exploited by selecting a mixture of 70% EtOAc in MeOH as the optimum PLE solvent for melatonin extraction.

Cycle Optimization. The major shortcoming of the static extraction mode in PLE systems is the limited volume of solvent that can be used to achieve a complete extraction. Nonetheless, an increase in the number of extraction cycles for the static process appears to be a reasonable solution that favors the solvent-to-analyte equilibrium.[34] Additionally, it is emphasized in the literature that the extractions of various compounds by PLE can be completed by employing multiple extraction cycles.[12,35,36] With this constraint taken into account, the number of cycles was also explored in this study to provide an adequate amount of solvent to obtain the maximum extraction efficiency (Figure 5).

The highest level of extracted melatonin was reached with multiple cycles, which increased the extraction yield by up to a factor of 2 when compared to the yield obtained with a single extraction cycle. However, the extraction with three cycles improved the level of extracted melatonin by only 1.15% in comparison to two cycles, and this change is not significantly different (LSD, p = 0.05). The number of extraction cycles dictates the static heating time, and the flushing processes are repeated. Hence, a process with two extraction cycles was selected for the extraction of melatonin with the purpose of saving time, solvent, and energy.

Optimized Conditions. The final conditions in terms of the significant factors ($p < 0.05$) that affect the extraction yield were as follows: extraction solvent (x_1, 70% EtOAc in MeOH), temperature (x_2, 200 °C), and sample weight (x_7, 2.5 g). Because the effects of the remaining factors (pressure, static time, flushing volume, and purging time) were not significant ($p > 0.05$), these operating conditions were set in keeping with the more favorable conditions for the extraction process. Pressure (x_3, 200 atm) was set at its maximum level (+1) to assist the rapid increase of temperature above the boiling point while maintaining the solvent in the liquid state. Flushing volume (x_4, 50% of extraction solvent), static time (x_5, 5 min), and purging time (x_6, 60 s) were selected according to the minimum point (−1) of the experimental domain (see Table 2) because the extraction efficiency was not affected and the extraction time and solvent cost were minimal. In addition, a two-cycle extraction was used to maximize the extraction efficiency.

Method Validation. Under the optimum experimental conditions, the validation of the proposed analytical method involving PLE followed by HPLC-FD was accomplished. The method precision was measured by considering the repeatability and intermediate precision of the analyses. Both measurements were conducted in accordance with ICH guidelines. The precision values, expressed as %CV, of the developed method were as follows: 1.53% for repeatability (n = 9) and 6.54% for intermediate precision ($n = 3 \times 3$). Because the %CV values for precision were lower than the acceptable limit (±10% refers to AOAC), the result confirmed that an excellent precision for the extraction method had been achieved.

On the basis of the calibration curve, LOD and LOQ for the solid sample can be calculated. Values found were LOD = 2.3 μg kg^{-1} and LOQ = 7.68 μg kg^{-1}.

The recovery (%R) of melatonin was evaluated using a standard addition method by comparing the absolute response of the analytes spiked in control samples before and after the extraction process. The average recovery obtained for the developed PLE was 98.9%. These results show that this particular PLE method is applicable for the assessment of melatonin content in real rice samples.

Application to Real Samples. The optimized and validated method was applied to the extraction of a number

	Parboiled rice *Processed rice, Spain*		Yes	28.33 ± 0.61

of real samples with the intention of evaluating its applicability. Various rice products composed of polished, whole grain, aromatic, black, black glutinous, red, and parboiled rice were extracted, and the melatonin contents were then analyzed in duplicate (Table 4). The results show that the melatonin contents are noticeably different between most of the pigmented and nonpigmented rice samples. The former include black glutinous, black, and red rice, and these have a higher melatonin content than the latter, that is, polished, whole grain, and parboiled rice. Variations in the melatonin contents are reasonable relative to the physical and chemical characteristics of different rice samples.

The cluster of pigmented rice grains has a higher concentration of melatonin as these samples contain a higher level of the vitamin B group.[37] It is widely recognized that niacin (vitamin B_3) prevents the breakdown of the melatonin precursor, whereas pyridoxine (vitamin B_6), a coenzyme in the one-carbon metabolism pathways, is involved in the synthesis of melatonin.[38,39] The level of melatonin may increase by >60% in the presence of pyridoxine during in vivo biosynthesis.[40]

The highest concentration of melatonin present in pigmented rice was 207.79 ± 3.18 $\mu g\ kg^{-1}$ (red rice), and this was followed by black rice (182.04 ± 2.79 $\mu g\ kg^{-1}$) and black glutinous rice (73.81 ± 1.13 $\mu g\ kg^{-1}$). The difference in melatonin contents between black rice and red rice was not as marked as that for black rice and black glutinous rice. Glutinous rice mainly differs from nonglutinous rice in that it has low (<5%) levels of or almost no amylose in its starch but is high in amylopectin.[41] The level of melatonin in black rice was roughly twice as high as that in its glutinous type. This finding is consistent with that reported by Li et al.,[42] who found that plant samples with high amylose contents exhibit better antioxidant activity than their glutinous genotypes. Despite significant research effort, the specific antioxidant enhanced by amylose has not yet been elucidated further, and melatonin is considered as a potential molecule that has a high antioxidant activity.[43]

In nonpigmented rice, the largest difference in the level of melatonin was between whole (from 42.95 ± 0.64 to 47.83 ± 0.12 $\mu g\ kg^{-1}$) and polished (from 28.33 ± 0.61 to 31.99 ± 0.31 $\mu g\ kg^{-1}$) grains. The melatonin content was reduced by as much as 33% on comparison to the whole and polished grains. The merits of the polishing step during rice production are the enhanced palatability and improved product appearance. Conversely, this step includes a bran removal process that causes a disadvantage due to the loss of melatonin from the grain, as shown by studies of the melatonin profile during rice production.[44]

composition of wine lees is subjected to a strong variability and depends on the winery procedures. Once the alcoholic fermentation has ended, autolysis of wine yeast starts, which is characterized by degradation of cell walls and release of some enzymes, mannoproteins, amino acids, and precursors of volatile compounds into wine as well as some phenolic and sulfur compounds that are adsorbed on wine lees.[17,18] Chassagne et al. established that the adsorption phenomenon is directly linked to the degree of autolysis, ethanol concentration, pH of wine, and temperature,[19] while Zea et al. found differences in the concentration of volatile compounds in cells and musts when different yeast races were used.[20−22]

To date, wine lees have been mainly exploited as a source of tartaric acid and calcium tartrate;[15] however, some attempts have also been made to use this raw material for feeding cattle, but these attempts have been discarded in view of the extremely poor nutritional value of wine lees.[23,24] Additionally, their use as a biosorbent for removal of undesirable compounds from wine has also been proposed,[25,26] since wine lees have been reported to retain part of the volatile compounds that oak wood transfers to wine, preventing wine from having an excessive and, thus, unpleasant woody flavor, as well as diminishing the impact of undesirable compounds such as toxins, pesticides, and antifoaming and volatile compounds such as 4-ethylphenol and 4-ethylguaiacol, which have been described as responsible for the associated horsy, medicinal, and spicy aroma of wines.[25−27] From the compositional point of view, some published research has focused on the pigment content of red wine lees, since their intense red coloration suggests a high anthocyanin and anthocyanidin content.[28,29] Some other studies have focused on the production of phenolic extracts from wine lees and the study of their phenolic content and their antioxidant activity.[30,31]

The aim of this research was to study and compare the composition profile of wine lees by independent analysis of imbibed wine from lees obtained by centrifugation and solid dried lees. For this purpose, ethanol−water extracts of solid lees were obtained by microwave-assisted extraction (MAE) as previously done by Pérez et al. and Delgado de la Torre et al.[29,30] Both fractions were subjected to liquid chromatography separation with tandem mass spectrometry detection using a quadrupole time-of-flight (QTOF) hybrid detector. Finally, both fractions were characterized and compared with the aim of studying the potential of these fractions to be recycled together or independently, depending on their composition. Multivariate analysis is a key tool to treat the large data sets provided by the QTOF detector and to understand the similar/dissimilar patterns among a range of samples provided from different wineries pertaining to the most characteristic denomination of origin wines in Spain.

MATERIALS AND METHODS

Samples. Wine lees as semisolid residue were provided in 2010 by 11 Spanish wineries from regions of Spain where different varieties of red grapes are used. The wineries correspond to the two most popular denominations of origin of red wines in Spain, namely, Ribera del Duero and Rioja (see Table 1). In all cases, wine lees were in contact with wine for three months during alcoholic fermentation, after which wine lees were isolated and used for this study. The sample from each winery was homogenized by agitation at room temperature for 15 min and centrifuged at 855*g* for 5 min. The solid phase was dried at 40 °C for 48 h in an oven, milled in a mortar, sieved to a 0.5 mm particle size, and stored at −20 °C until use. The liquid phase was directly stored at −20 °C until use.

Table 1. Samples Provided by Wineries from Two of the Most Characteristic Denominations of Origin in Spain

code	grape	location	denomination of origin
R1	Tempranillo	Azagra (Navarra)	Rioja
R2	Tempranillo	Haro (La Rioja)	Rioja
R3	Tempranillo	Haro (La Rioja)	Rioja
R4	Tempranillo	San Vicente de la Sonsierra (La Rioja)	Rioja
R5	Tempranillo (ecological)	Aldeanueva de Ebro (La Rioja)	Rioja
R6	Tempranillo, Garnacha	Gimileo (La Rioja)	Rioja
R7	Mazuelo	Haro (La Rioja)	Rioja
RD1	92% Tempranillo, 3% Cabernet, 5% Merlot	Gumiel de Mercado (Burgos)	Ribera del Duero
RD2	Tempranillo	Langa del Duero (Soria)	Ribera del Duero
RD3	Tempranillo	Fompedraza (Valladolid)	Ribera del Duero
RD4	Tempranillo	Anguix (Burgos)	Ribera del Duero

Reagents. Acetonitrile (ACN) and formic acid (MS grade) were from Scharlab (Barcelona, Spain). Deionized water (18 MΩ·cm) was obtained by a Milli-Q water purification system from Millipore (Billerica, MA). Ethanol (96%, v/v) PA from Panreac (Barcelona, Spain) and distilled water were used to prepare the extractant.

Apparatus and Instruments. A Microdigest 301 digestor of maximum power 200 W (Prolabo, Paris, France) furnished with a microprocessor programmer (Prolabo) to control the microwave unit was used for MAE.

Shaking and centrifugation of wine lees and extracts were carried out by an MS2 minishaker (IKA, Germany) and a Mixtasel (Selecta, Barcelona, Spain) centrifuge, respectively.

Analysis of the studied compounds was performed in an Agilent 1200 series LC system interfaced to an Agilent UHD accurate-mass QTOF-MS/MS detector (Palo Alto, CA) equipped with an Agilent Technology dual electrospray ion source (dual ESI).

Sample Preparation. A 6 g sample of dried lees was placed into the extraction vessel of the microwave-assisted digestor with 50 mL of 60:40 (v/v) ethanol−water adjusted to pH 4 with formic acid. The vessel was positioned at the suited zone for irradiation with focused microwaves. The auxiliary energy was applied at 140 W irradiation power for 10 min, after which the solid residue was removed by centrifugation and the liquid fraction filtered by a 20 μm pore size filter and 1:2 diluted with 60:40 (v/v) ethanol−water adjusted to pH 4 with formic acid.

LC−QTOF-MS/MS Analysis. Chromatographic separation was performed using a C_{18} Inertsil ODS-2 column (250 mm × 4.6 mm i.d., 5 μm particle size, Análisis Vínicos, Tomelloso, Ciudad Real, Spain) kept at 25 °C. The mobile phases in this case were water (phase A) and ACN (phase B), both LC−MS/MS grade and with 0.1% formic acid as the ionization agent. The LC pump was programmed at a flow rate of 0.9 mL/min, and the following elution gradient was carried out: hold from 0 to 2 min at 4% phase B, 2−7 min 10% phase B, 7−60 min 100% phase B, and hold to 70 min. A postrun of 4 min was included to equilibrate the column. The injection volume was 10 μL, and the injector needle was rinsed five times with 70% methanol. Furthermore, the needle seat back was flushed for 12 s at a flow rate of 4 mL/min with 70% methanol to clean it. The operating conditions of the mass spectrometer were as follows: gas temperature, 325 °C; drying gas, nitrogen at 10 L/min; nebulizer pressure, 40 psi; sheath gas temperature, 380 °C; sheath gas flow, nitrogen at 10 L/min; capillary voltage, 3500 V; skimmer, 65 V; octopole radiofrequency voltage, 750 V; focusing voltage, 175 V. MS and MS/MS data were collected in both polarities using the centroid and the profile modes at a rate of two spectra per second in the extended dynamic range mode (2 GHz). Accurate mass spectra in auto MS/MS mode were acquired in the MS

J. Agric. Food Chem. 2015, 63, 1116−1125

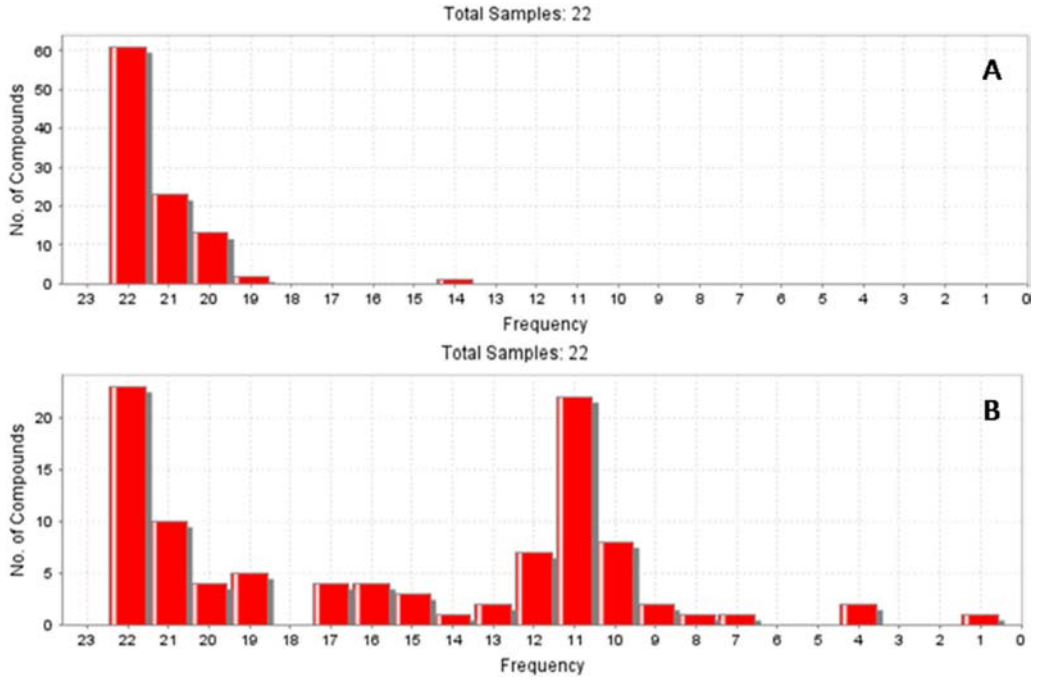

Figure 1. Alignment diagram corresponding to positive (A) and negative (B) ionization modes.

m/*z* range 100−3000 and MS/MS *m*/*z* range 100−3000. The auto MS/MS mode was configured with two maximum precursors per cycle and an exclusion window of 0.25 min after two consecutive selections of the same precursor. The collision energy selected was 22.5 eV. To ensure the desired mass accuracy of recorded ions, continuous internal calibration was performed during analyses by the use of signals at *m*/*z* 121.0509 (protonated purine) and *m*/*z* 922.0098 [protonated hexakis(1*H*,1*H*,3*H*-tetrafluoropropoxy)phosphazine, or HP-921] in positive ionization mode, while ions with *m*/*z* 119.0362 (proton abstracted purine) and *m*/*z* 966.0007 (formate adduct of HP-921) were used in negative ionization mode.

Data Treatment. The MassHunter Workstation software package (B.05.00) and MassHunter Profinder (B.06.00) from Agilent Technologies were used to process all data obtained by LC−QTOF in the auto MS/MS mode. The recursive feature extraction algorithm was used to extract and align potential molecular features in all the injection sets. This algorithm initially deconvolutes the chromatograms and aligns the molecular features across the selected raw data files in terms of *m*/*z* value and retention time; then it uses the mass and retention time of each feature for recursive targeted feature extraction in the raw data files. This two-step procedure reduces the number of both false negatives and false positives in the process of feature extraction. The target parameters for feature extraction included a threshold of 1500 counts and a maximum charge state of 2. In addition, the isotopic distribution for a valid feature had to be defined by two or more ions—with a peak spacing tolerance of 0.0025 *m*/*z*, plus 10.0 ppm. Adduct formation in the positive (+H, +Na) and negative (−H, +HCOO) ionization modes was also used to identify features of the same molecule. Features were aligned by using a tolerance window of 0.30 min and a mass accuracy of 10 ppm for retention times and *m*/*z* values, respectively, across all data files. The minimum absolute height required for feature extraction was set at 3000 counts, which was also used for 100% of samples in the recursive step. Thus, ions with identical elution profiles and related *m*/*z* values (representing different adducts or isotopes of the same compound) were extracted as molecular features (MFs) or entities characterized by RT, intensity in the apex of the chromatographic peak, and accurate mass.

The resulting data files after this treatment were created as comma-separated value files (.csv) for each sample and exported into the Mass Profiler Professional (MPP) software package (version 2.0, Agilent Technologies) for further processing. Compound identification was performed using the METLIN Metabolite and MS/MS (http://metlin.scripps.edu/), Massbank (http://www.massbank.jp/), MetFrag (http://msbi.ipb-halle.de/MetFrag/), and PlantCyc (http://plantcyc.org/) databases.

RESULTS AND DISCUSSION

Data Pretreatment. Wine lees are a complex matrix containing mainly polar and midpolar compounds, as revealed by the LC−MS/MS elution profiles obtained in the positive and negative ionization modes. The elution profiles represented by the base peak chromatograms (BPCs) show the predominance of polar compounds in imbibed wines from lees in both ionization modes, where the peaks were found almost exclusively in the elution time window from 1 to 28 min, while the extracts from the solid residues provided peaks characterized by the presence of less polar compounds, as most of the peaks were associated with compounds eluted at longer times (elution time window from 1 to 60 min), which support the adsorbent role of this residue during wine aging.

With the aim of ensuring the representativeness of the study, the data set obtained after alignment of molecular features was filtered to select a subdata set formed by the molecular features in all the samples of liquid and dried lees. This means that the data sets should contain molecular features present in all the samples analyzed for each class. This data mining operation reduced the data sets to 90 and 68 molecular entities for imbibed wine from lees and extracts, respectively, in the positive ionization mode and 34 and 67 molecular entities in the negative ionization mode. This pretreatment ended with mean-centering of the data set prior to statistical analysis. As the alignment diagram in Figure 1 shows, the positive ionization mode reported a data set formed by molecular features detected in most samples. On the other hand, the profile of molecular features in negative ionization mode allowed deduction of higher variability than in positive mode since a representative proportion of molecular entities were

DOI: 10.1021/jf505331f
J. Agric. Food Chem. 2015, 63, 1116−1125

detected in 50% of the samples. This high proportion of entities detected in half of the samples should be assigned to features detected exclusively in liquid or solid dried lees and, therefore, to differences in their composition.

Multivariate Analysis. The next step was the comparative analysis of samples pertaining to both classes of samples, imbibed wine from lees and extracts of dried lees. Qualitative comparison was carried out by application of Venn diagrams that allow the overlapping in compositional terms between both types of samples to be established. The diagrams illustrated in Figure 2 show a high similarity between the molecular entities found in imbibed wine from lees and in the extracts of dried lees in positive ionization mode, since 61 features were common to the two types of samples, while 7 and 29 features were exclusively detected in the extracts and imbibed wine from lees, respectively. Concerning the negative ionization mode (Figure 2B), the Venn diagram agreed with the alignment diagram (Figure 1B) about the observed variability in the composition of extracts and imbibed wine from lees. Thus, only 23 entities were common to the two types of samples, while 44 entities were exclusively detected in extracts from the solid residue. The different behaviors in positive and negative ionization could be explained by the influence of the chemical structure on the ionization efficiency. Therefore, it is evident that data sets from the two ionization modes should include molecular features corresponding tentatively to different compounds, which are preferentially ionized in one mode.

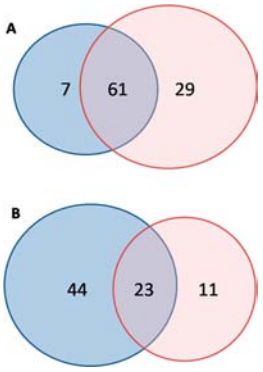

Figure 2. Venn diagram obtained by qualitative comparison of the molecular entities for imbibed wine from lees (right side) and extracts of dried lees (left side) after application of a 100% frequency filter in the positive (A) and negative (B) ionization modes.

Comparison of the compositional profiles of both fractions was made in terms of nonsupervised analysis using principal component analysis (PCA) to evaluate the distribution of the samples according to the variability sources. Figure 3 shows the PCA scores plot obtained for imbibed wine from lees and extracts of dried lees after data pretreatment. As can be seen, both ionization modes led to similar results since a clear discrimination was observed between the samples corresponding to imbibed wine from lees and extracts from dried solid wine lees. In negative ionization mode, PC1/PC2/PC3 explained 54.1% of the total variability, while, in positive mode, the variability explained by the three first components increased to 61.7%. In both cases, discrimination between the two types of samples was ascribed to PC1. Therefore, it is evident that the compositions of both separated materials were quite different. Apart from this discrimination, no trends were observed according to the origin of the wineries such as designation of origin or localization of wineries.

Identification of Compounds in Positive Ionization Mode. Characterization of representative families of compounds in the samples was carried out by tandem mass spectrometry in high-resolution mode. Tentative identification of compounds was supported on mass accuracy measurement of the precursor ion and representative product ions. The isotopic distribution of signals detected in full-scan mode was also taken into account. The combination of these data allowed tentative elucidation of the structure of the compounds listed in

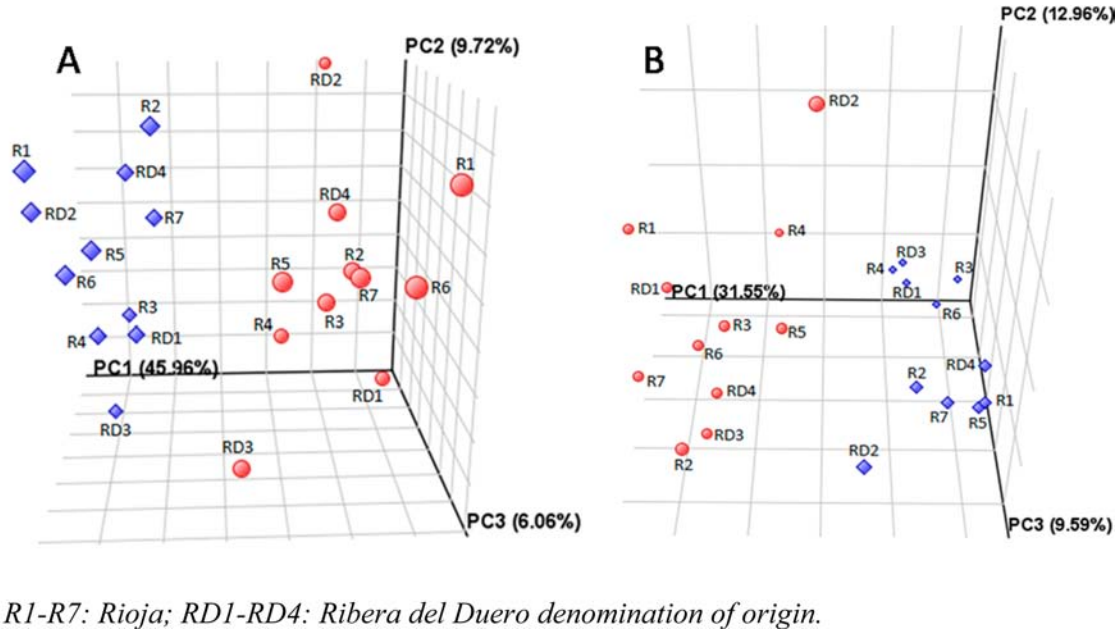

Figure 3. PCA scores plot obtained for imbibed wine from lees (tilted squares) and extracts of dried lees (circles) using the data set formed after data pretreatment for the positive (A) and the negative (B) ionization modes.

[a]Key for superscript letters: A, compounds found exclusively in imbibed wine from lees; B, compounds found exclusively in extracts; C, representative compounds common to both fractions.

Table 2, which are organized by families showing information about theoretical and experimental *m/z* values as well as characteristic fragment ions used to support identification.

Concerning the positive ionization mode, it is worth emphasizing the presence of compounds identified exclusively in imbibed wine from lees, those only identified in extracts of dried lees, and those common to both fractions. Few amino acids were identified in the analysis of wine lees. Thus, only one primary amino acid was detected exclusively in imbibed wine from lees in this polarity, aminocaproic acid, an analogue of the amino acid lysine. Two other compounds exclusively identified in imbibed wine from lees were 8-oxoguanosine monophosphate and ureidoglycolate. The former results from degradation of 8-oxoguanosine triphosphate, produced in nucleic acids during cellular metabolic processes and responsible for eliminating oxidized nucleotides in plants, thus preventing replicational and translational errors by misincorporation of 8-oxoguanosine triphosphate into DNA and RNA, which would cause mutation and phenotypic suppression.[32,33] On the other hand, ureidoglycolate is involved in purine metabolism and also in metabolic pathways and microbial metabolism in diverse environments. Particularly, it is present in *Saccharomyces cerevisiae*, where it is produced by degradation of allantoin with the concomitant production of urea.[34]

Concerning compounds found exclusively in extracts of dried lees, only two of them were tentatively identified as phenolic compounds, namely, 3,4,5-trimethoxyflavone and malvidin 3-(6-*p*-coumarylglucoside). The former elutes at 8.0 min with *m/z* at 335.0890 as the precursor ion, which corresponds to the $[M + Na]^+$ adduct. The most abundant fragments were at *m/z* 298.0187, 280.0701, and 252.0822, which is consistent with the results obtained by Huck et al. and explained by the loss of a CH_3 group from the original structure (−15 Da), the subsequent loss of a molecule of water (−18 Da), and the loss of a carbonyl group (−28 Da).[35] Malvidin 3-(6-*p*-coumarylglucoside) was found at 24.6 min, with $[M + H]^+$ as the precursor ion at *m/z* 639.1706. The consecutive loss of the coumaroyl and glucoside moieties explains the characteristic fragments found at *m/z* 477.1248 and 331.0786, respectively,

J. Agric. Food Chem. 2015, 63, 1116−1125

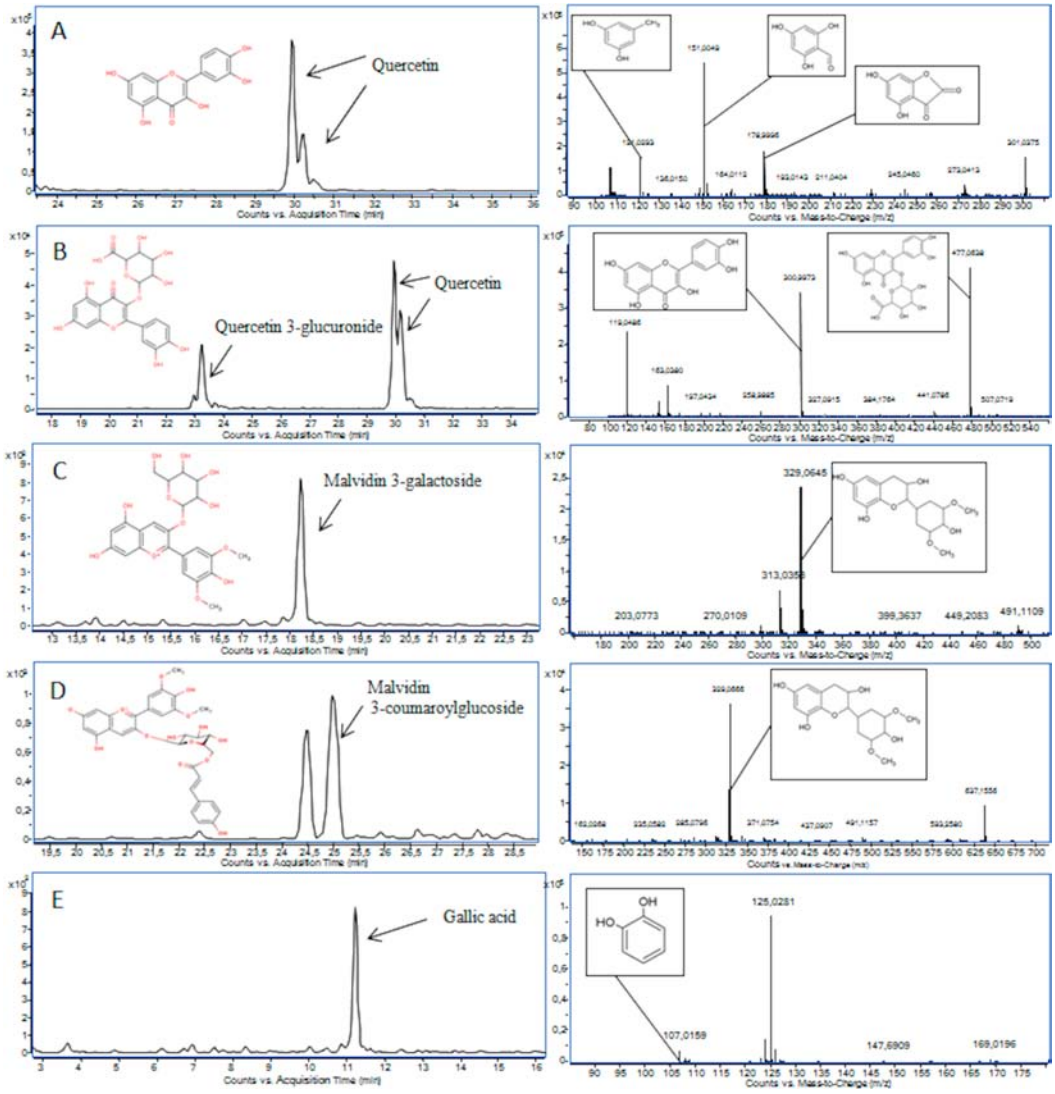

Figure 4. Extracted ion chromatograms for quercetin (A), quercetin 3-glucuronide (B), malvidin 3-galactoside (C), malvidin 3-(6-*p*-coumarylglucoside) (D), and gallic acid (E), with MS/MS spectra obtained by LC−MS/MS analysis in negative ionization mode.

where the fragment at 331.0786 corresponds to the malvidin aglycon.

Valine was the only primary amino acid found in all the samples analyzed in this polarity. It was found at 6.8 min elution time when the m/z ratio at 118.0857 was monitored as the $[M + H^+]$ precursor ion. Two phenolic compounds were tentatively detected in imbibed wine from lees and extracts from the solid residue: two flavanol isomers, catechin and epicatechin, naturally found in diverse plants such as cocoa, tea, apples, and berries, among others. Catechin and epicatechin elute at 17.5 and 21.1 min, respectively, with $[M + H]^+$ precursor ions at m/z 291.0856. Representative fragments supporting the tentative identification of both isomers were detected at m/z 147.0442, 139.0385, and 123.0410. According to Li et al., the fragment at 147.0442 is explained by heterocyclic ring fission and loss of a water molecule, the fragment at 139.0385 is produced by retro-Diels−Alder (RDA) reaction of the original molecule, and that at 123.0410 can be explained either by direct benzofuran-forming fission (BFF) or by loss of a water molecule following BFF.[36]

Other compounds tentatively identified in the positive mode in both types of samples were hypoxanthine, norfuraneol, 2-formamido-N^1-(5-phospho-D-ribosyl)acetamidine, hexanethiol, and 2,3-dihydroxy-3-methylbutanoate. The presence of all them was verified by using the Plantcyc database (www.plantcyc.org). Hypoxanthine is a naturally occurring purine derivative and a reaction intermediate in the metabolism of adenosine and in the formation of nucleic acids. It elutes at 8.5 min with an $[M + H]^+$ precursor ion at 137.0444. The MS/MS fragmentation of this precursor ion produces two characteristic fragments, one at m/z 119.0348 by the loss of a molecule of water (−18 Da) from the original structure and another fragment at 110.0346 by the loss of a CO unit (−28 Da). Norfuraneol is known for being one of the caramel descriptors in wine, together with furaneol and homofuraneol, as supported by Sarrazin et al.[37] This compound was tentatively identified eluting at 7.7 min by monitoring the m/z ratio at 115.0392 as the $[M + H]^+$ precursor ion, with two representative product ions at m/z 113.0244 and 110.9751. 2,3-Dihydroxy-3-methylbutanoate was identified by an $[M + H]^+$ precursor ion at m/z 135.0543 and with representative fragments at m/z 119.0429 produced by the loss of an oxygen unit (−16 Da) and 107.0455 produced by the loss of a CO unit from the original structure (−28 Da). According to the Yeast Metabolome Database (www.ymdb.ca),

DOI: 10.1021/jf505331f
J. Agric. Food Chem. 2015, 63, 1116−1125

2,3-dihydroxy-3-methylbutanoate is present in *S. cerevisiae*, one of the yeast more widely used for winemaking, baking, and brewing. According to Morata et al., the use of different strains of *S. cerevisiae* can have a strong influence on the content of wine in different compounds such as vitisin A and B, pyruvate, and acetaldehyde, among others.[38]

Identification of Compounds in Negative Ionization Mode. As Table 2 shows, only one amino acid derivative and one phenolic compound were tentatively identified as exclusively present in imbibed wine from lees in the negative ionization mode: namely, 3-hydroxy-L-tyrosine and kaempferol 3-(2′,3′-diacetylrhamnoside)-7″-rhamnoside. On the other hand, compounds exclusively detected in imbibed wine from lees were citric acid, *S*-adenosylmethioninamine, and 2-carboxy-2,3-dihydro-5,6-dihydroxyindole. Citric acid is commonly added during the winemaking process to improve the sensory characteristics of wine by increasing acidity to complement a specific flavor or prevent ferric hazes.[39] This acid was found at 9.2 min with an $[M - H]^-$ precursor ion at m/z 191.0240. The MS/MS spectrum associated with this compound presented characteristic fragments at 129.0239 and 111.0130, interpreted by the conversion of citric acid into itaconic acid by decarboxylation following the loss of a molecule of water to form the ion at m/z 111.0130. On the other hand, *S*-adenosylmethioninamine and 2-carboxy-2,3-dihydro-5,6-dihydroxyindole are related to the methionine and tyrosine metabolic pathways, respectively. The former is a precursor of spermine and spermidine, which are undesirable biogenic amines in wine.[40,41]

Regarding compounds exclusively detected in the extracts of wine lees, one other derivative of tyrosine is octadecyl ester, found at 40.6 min with a representative $[M - H]^-$ precursor ion at m/z 432.3442.

The abundance of phenolic compounds tentatively identified in the extracts of dried lees in negative ionization, which is justified by the adsorbent power of wine lees during aging, should be highlighted. As shown in Table 2, most of them are flavonoids, widely spread in wine and grapes, such as quercetin, myricetin, and conjugates such as malvidin 3-galactoside.

Quercetin was identified at 29.8 min with a characteristic $[M - H]^-$ precursor ion at m/z 301.0354 and with MS/MS fragments at 178.9996, 151.0049, and 121.0293 (Figure 4A). The fragment at m/z 151.0049 is produced by RDA reaction of the A ring and is a common product ion from flavonols, flavanones, and flavones. The fragment at m/z 121.0297 is produced by retrocyclation of the original structure of quercetin, with the mechanism proposed by Dubber et al.[41] Another representative fragment for quercetin used for its identification is the ion found at m/z 107.0137, a product of the cleavage of a CO_2 unit after RDA reaction takes place $[M - H - CO - CO_2]^-$. Quercetin was detected in free form, but also as a glucuronide derivative at 23.2 min showing an $[M - H]^-$ precursor ion at m/z 477.0638, as shown in Figure 4B, with a representative ion at m/z 300.9973 produced by the loss of the glucuronide moiety to form the corresponding aglycon.

Following a similar pattern, Figure 4C shows the MS/MS fragmentation pattern of malvidin 3-galactoside, eluted at 18.2 min with precursor ion $[M - H]^-$ at m/z 492.1252. The spectrum was marked by the presence of three representative product ions at m/z 329.0645, 313.0353, and 299.0128, where the ion at 329.0645 corresponds to the malvidin aglycon and the ion at 313.0353 is produced by the complete loss of the galactoside moiety (−179 Da).

Gallic acid was also tentatively detected in lees. This nonflavonoid phenolic compound is a final product in the hydrolysis of ellagitannins, which contribute to the astringent character of wines. Gallic acid elutes at 11.4 min as an $[M - H]^-$ precursor ion at m/z 169.0196. Its fragmentation produces representative product ions at m/z 107.0159 and 125.0281, as shown in Figure 4E, where the ion at m/z 125.0281 is explained by decarboxylation and the ion at 107.0159 is produced by the subsequent loss of an OH unit (−17 Da).

Additionally, two phenolic compounds were tentatively found in the two samples from all wineries, procyanidin B2 and pelargonidin 3-(6-*p*-coumaroylglucoside). Procyanidin B2 reported an $[M - H]^-$ precursor ion at m/z 577.1357, with representative fragments at m/z 407.0767, 289.0731, and 425.0932. This fragmentation pattern is consistent with the scheme proposed by Delgado de la Torre et al., where fragments at m/z 271.0 and 289.0 were explained by a quinone methide (QM) cleavage of the interflavan bond, while those at m/z 407.0 and 425.1 would correspond to the RDA reaction.[29]

Apart from these phenols, tartaric acid was also found in the two fractions of wine lees, a logical finding since this is one of the most concentrated organic acids in grapes and it plays a fundamental role in wine acidity. Tartaric acid was detected at 4.6 min, with an $[M - H]^-$ precursor ion at m/z 149.0086 and representative fragments at m/z 130.9981 and 105.0172. The fragment at m/z 130.9981 is explained by the loss of an OH group and the fragment at 105.0172 is obtained by the loss of a CO unit.

Attending to these results, it can be concluded that both fractions, imbibed wine from lees and extracts from dried lees, can be considered an exploitable source of various interesting compounds, where the former proved to be rich in primary amino acids and phenolic compounds, especially flavonoids, which can be ascribed to its adsorbent characteristics. On the other hand, a similar number of other uncommon compounds have been indentified in both fractions; thus, selection of a fraction for its exploitation would depend on the target product, since, for instance, citric acid was only found in imbibed wine from lees. On the basis of the number of compounds present in both fractions and those existing only in solid lees, this residue is proposed as the most adequate sample for exploitation, since the absence of water facilitates transport and storage. This study complements previous studies on wine lees and other enological byproducts.

Facultat de Farmàcia of the Universitat de Barcelona. Animals were kept in an environmentally controlled room with stable humidity (50 ± 10%) and temperature (22 ± 2 °C) and a 12 h light/dark cycle. A commercial diet (2014 Teklad Global 14%, Harlan, Barcelona, Spain) and water were supplied *ad libitum*. Rats were fasted overnight and anesthetized by intraperitoneal injection of 90 mg/kg of ketamine (Imalgene 1000, Merial Laboratorios S.A., Barcelona, Spain) and 10 mg/kg of xylacine (Rompun 2%, Química Farmacéutica Bayer S.A., Barcelona, Spain). All animal manipulations accomplished the requirements set by the European Community guidelines for the care and management of laboratory animals. In addition, the experiments were conducted in the morning to lessen the effects of circadian rhythms. The research protocol (reference 164/10) was approved by the Ethic Committee of Animal Experimentation of the Universitat de Barcelona.

Dose Administration and Sample Collection. Maslinic acid was administered to overnight fasted rats at a dose of 50 mg/kg of body weight by single oral gavage. Pentacyclic triterpene was dissolved in an aqueous solution of (2-hydroxypropyl)-ß-cyclodextrin (40%, w/v) and sodium carboxymethylcellulose (0.5%) as previously described.[12] After oral administration, blood was withdrawn from the saphenous vein[13] at 45 min and placed in tubes containing ethylenediaminetetraacetic acid (EDTA)−K_2 (Microvette CB300, Sarstedt, Granollers, Spain) to avoid coagulation. Samples were maintained on ice until centrifugation at 1500*g* (Centrifuge Megafuge 1.0R, Heraeus, Boadilla, Spain) for 15 min at 4 °C. Plasma was subsequently separated and stored at −20 °C until analysis. At 45 min post-administration, urine samples were directly collected from the urinary bladder of previously anesthetized animals and frozen at −20 °C until processing.

Preparation of Rat Plasma and Urine Samples. Plasma and urine were thawed before analysis, and urine was centrifuged at 25000*g* for 30 min at 2 °C (Centrifuge 5417R, Eppendorf Ibérica S.L.) to obtain a clear supernatant. A total of 200 μL of either plasma or urine was spiked with 10 μL of 50 μM betulinic acid [IS, dissolved in 80:20 (v/v) methanol/water] before being extracted with 2 mL of ethyl acetate. Each sample was strongly stirred in a vortex mixer for 3 min and then centrifuged at 1500*g* for 15 min at 4 °C (Centrifuge Megafuge 1.0R, Heraeus). The ethyl acetate layer was carefully removed and placed in a clean conical tube, and a second extraction of the residue was performed. The organic supernatants were gathered together and evaporated to dryness in a vacuum concentrator (Concentrator 5301, Eppendorf Ibérica S.L., San Sebastián de los Reyes, Spain) at 45 °C. The dry residue was dissolved by adding 100 μL of methanol/water (80:20, v/v), followed by vigorous shaking in a vortex mixer for 5 min. Samples were immediately sonicated for 1 min and centrifuged at 25000*g* for 15 min at 4 °C (Centrifuge 5417R, Eppendorf Ibérica S.L.). Finally, an amber vial was employed to place the clean supernatant before the analysis.

Metabolite Identification by LC−APCI−LTQ−Orbitrap. Samples were analyzed using an Accela liquid chromatograph (Thermo Scientific, Hemel, Hempstead, U.K.) equipped with a thermostated autosampler and a quaternary pump and coupled to a LTQ−Orbitrap Velos mass spectrometer (Thermo Scientific). The equipment was available at the Centres Científics i Tecnològics of the Universitat de Barcelona. Chromatographic separations was carried out on a Luna C_{18} column (150 × 2.0 mm, 5 μm) kept at 40 °C and protected with a security guard cartridge of the same packing material (Phenomenex, Micron Analítica S.A., Madrid, Spain). Gradient elution was performed with water (solvent A) and acetonitrile (solvent B) at a constant flow rate of 0.8 mL/min. The volume of injection was 10 μL. Separation was carried out within 19 min under the following conditions: 0 min, 95% A and 5% B; 4 min, 50% A and 50% B; 8 min, 40% A and 60% B; 12 min, 25% A and 75% B; 15 min, 0% A and 100% B; and 19 min, 0% A and 100% B. An additional period of 8 min was needed for re-equilibration of the column before the ensuing injection.

Mass spectrometric analysis was conducted using an APCI source in the negative-ion mode. Mass calibration was performed daily according to the guidelines of the manufacturer. The LTQ−Orbitrap was tuned to the optimal conditions for maslinic acid. Therefore, a 100 μM standard solution was delivered by the LTQ syringe pump at a constant flow rate of 10 mL/min in the presence of LC mobile phase under isocratic conditions of 25% A and 75% B. Operation parameters were set as follows: vaporizer temperature, 450 °C; sheath gas, 50 arbitrary units (au); auxiliary gas flow, 5 au; sweep gas, 0 au; discharge current, 5 μA; S-lens radio frequency (RF) level, 70%; and capillary gas, 300 °C. The data were acquired using Fourier transform full scan with a resolving power of either 60 000 or 100 000 (at m/z 400) and the microscan count fixed to unity. The automatic gain control (AGC) was set at 1×10^6. The mass spectrometric data were collected in a range of m/z from 100 to 1000.

MS Data Processing. Mass chromatograms and spectral data were acquired with the Xcalibur software 2.0 (Thermo Scientific). Maslinic acid metabolites were searched both manually with Xcalibur Qual Browser and also employing MetWorks software (version 1.3, Thermo Scientific). Qual Browser was employed for MS data processing and calculation of elementary compositions. The elemental composition was selected according to the accurate masses and the isotopic pattern. Mass accuracy was determined by the deviation of measured and theoretical masses relative to theoretical values and was expressed in millidaltons. MetWorks software allowed for the identification of metabolites by comparing the samples to controls, of either blank plasma or urine. The most commonly observed biotransformations in phase I and phase II metabolism were searched to find putative metabolites of maslinic acid with a mass deviation of less than 5 ppm from the predicted values.

Quantification of Maslinic Acid and Its Metabolites by LC−APCI−MS in Rat Plasma and Urine. After the identification of maslinic acid metabolites by LC−APCI−LTQ−Orbitrap, the compounds were quantified by LC−APCI−MS. The liquid chromatograph (PerkinElmer series 200, PerkinElmer, Norwalk, CT) included a quaternary pump and a refrigerated autosampler plate and was coupled to a single quadrupole mass spectrometer (PE Sciex API 150 EX, AB SCIEX, Spain) with an APCI source at 500 °C in negative-ion mode. The LC−MS system was controlled by the 1.4.2 Analyst software supplied by Applied Biosystems (Foster City, CA). The chromatographic conditions were the conditions described for the LC−APCI−LTQ−Orbitrap system. For the mass spectrometer, nitrogen was used as both curtain gas (12 au) and nebulizer gas (10 au) with a nebulizing flow of −3 au. The optimum LC−APCI−MS pre-collision cell voltages were −30 V for declustering potential, −100 V for focusing potential, and −5 V for entrance potential. The selected ion monitoring (SIM) mode was used for quantification of maslinic acid at m/z 471.3 and betulinic acid (IS) at m/z 455.3. The metabolites identified by LC−APCI−LTQ−Orbitrap were quantified at m/z 487.3 (M1−M4), 485.3 (M5), and 501.3 (M6 and M7). The dwell time was set at 165 ms. Concentrations of maslinic acid in plasma and urine samples were calculated from the ratio of the peak area of triterpene to the IS interpolated on an external calibration curve. Because of the absence of synthetic standards, it was assumed that LC−APCI−MS response to derivatives is similar to that of maslinic acid; thus, both plasma and urine metabolites were quantified using the standard curve of the parent compound. Results were expressed as micromoles per liter (μM).

The determination of maslinic acid in plasma and urine was validated for recovery, matrix effect, precision, accuracy, linearity, and sensitivity, according to the European Medicines Agency (EMA) Guideline on Bioanalytical Method Validation.[14] Calibration standards were freshly prepared by spiking 190 μL of rat blank plasma or urine with 10 μL of standard solutions of maslinic acid at different concentrations and were treated as previously indicated for the specimens collected from dosed rats. The post-extraction spiking method proposed by Matuszewski et al.[15] was used to establish the recovery and matrix effect. Briefly, recovery was assessed by comparing the peak areas of calibration standards to the peak areas obtained from blank plasma or urine spiked with maslinic acid after the extraction. The matrix effect was evaluated by comparing the peak areas obtained from blank plasma or urine spiked with pentacyclic triterpene after the extraction to those of a solution of 80% methanol spiked with the expected concentration. Recovery and matrix effect were determined

at four concentration levels (0.5, 1, 5, and 10 μM), while precision and accuracy were analyzed at 1, 5, and 10 μM. Linearity was assayed in the range of 0.005−10 μM, which included eight concentration levels that covered the expected amounts in the samples. The limit of detection (LOD) was considered as the minimum concentration of maslinic acid that could be recognized by the detector and produced a signal-to-noise ratio of 3:1. The lowest limit of quantification (LLOQ) was defined as the lowest concentration of the standard curve that could be accurately quantified and with a signal at least 10 times above the noise level.

RESULTS

LC−APCI−LTQ−Orbitrap Analysis of Maslinic Acid and Its Metabolites in Rat Plasma and Urine. Maslinic acid ($C_{30}H_{48}O_4$) was unambiguously identified in rat plasma and urine by comparing its retention time (9.22 min) and MS

[a]ND = not detected.

data to the standard reference. In addition, the injection into the high-resolution system LTQ−Orbitrap gave its accurate mass (m/z 471.3480) with an error of 0.4 mDa. The spectra generated for pentacyclic triterpene in plasma and urine showed the deprotonated molecule $[M - H]^-$ without the presence of any fragment (Figures 1A and 2A, respectively).

Possible derivatives of maslinic acid were first predicted on the basis of knowledge of metabolism and then searched in full-scan chromatograms of rat plasma and urine samples. Afterward, the formulas of potential metabolites were compared to that of the parent compound to refer metabolic pathways. The high mass accuracy of the LTQ−Orbitrap analyzer enabled an extraction of individual chromatograms in a narrow interval of the m/z scale (± 5 mDa), which is useful for discarding other compounds with similar masses.[16] The initial screening of plasma and urine samples obtained after the oral administration of maslinic acid revealed the formation of derivatives with mass shifts of +16, +14, and +30 Da in comparison to the parent compound. Mass shifts of +32 Da, which corresponded to a double hydroxylation, were searched but were not found in the analyzed plasma and urine samples. On the other hand, phase II metabolites of maslinic acid were not detected after screening with LC−APCI−LTQ−Orbitrap and MetWorks software, indicating that this compound undergoes mainly phase I metabolism.

Table 1 shows the list of metabolites identified through LTQ−Orbitrap analysis, along with retention times, accurate masses, molecular formulas, and mDa and ppm of error between the mass found and the accurate mass of each derivative. The observed and calculated masses agree to within less than 1 mDa, which demonstrates the high accuracy of the measured masses. Neither maslinic acid nor its metabolites were detected in plasma and urine of the control group at the corresponding retention times.

M1−M4 (m/z 487.3). Four polar metabolites, namely, M1−M4, were detected in plasma as deprotonated molecules at m/z 487.3 and a molecular formula of $C_{30}H_{48}O_5$, according to the Formula Predictor software (Table 1). The mass of these compounds was 15.9949 Da higher than that of maslinic acid, thus indicating that the biotransformation might be the addition of a hydroxyl group. All of the metabolites eluted earlier than the parent compound, showing retention times of 4.77, 5.33, 6.61, and 7.13 min for M1, M2, M3, and M4, respectively. As shown in Figure 1B, the peak of M1 was the most abundant, followed by M2 and M4 peaks, while that of M3 was less intense. The accurate mass of each of these metabolites differed by less than 1 mDa from the theoretical mass, and the respective spectra showed an isotopic distribution that was in accordance with the theoretical spectra of m/z 487.3, indicating a correct identification (panels B1−B4 of Figure 1).

On the other hand, in urine samples, only metabolites M1 and M4 were detected (Figure 2B). The compound M1 was the most abundant, as was observed in plasma. However, M2 and M3 were not present in any of the samples analyzed, and M4 appeared in urine with low intensities. The corresponding spectra are shown in panels B1 and B2 of Figure 2.

M5 (m/z 485.3). A single peak corresponding to a deprotonated molecule at m/z 485.3 was identified as M5. This metabolite had a retention time of 7.75 min and was found in both plasma (Figure 1C) and urine (Figure 2C) samples. The mass increment of 13.9792 Da with respect to maslinic acid (Table 1), together with the molecular formula ($C_{30}H_{46}O_5$) calculated by the Formula Predictor software, suggested that this biotransformation consists of the incorporation of a hydroxyl group and the loss of two hydrogen atoms. M5 was identified with an error of 0.23 mDa (Table 1) and a correct isotopic distribution pattern (Figures 1C1 and 2C1).

M6 and M7 (m/z 501.3). Two additional compounds (M6 and M7) eluting earlier than the parent compound yielded a deprotonated molecule at m/z 501.3. The retention times were 4.24 and 4.65 min for M6 and M7, respectively. Because the molecular formula of both metabolites was $C_{30}H_{46}O_6$, as calculated by the Formula Predictor software (Table 1) and the mass shift was +29.9442 Da, this biotransformation was attributed to dihydroxylation and dehydrogenation of maslinic acid. In plasma samples, M7 showed a higher relative abundance than M6 (Figure 1D), whereas in urine, only M6 was detected and with very low intensities, indicating small concentrations (Figure 2D).

Quantification of Maslinic Acid Metabolites by LC−APCI−MS in Rat Plasma. The mass chromatograms from LC−APCI−LTQ−Orbitrap were consistent with the LC−APCI−MS chromatograms and allowed for the identification of all of the metabolites, taking into account the relative retention times. The method was adequate for the quantification of maslinic acid in plasma samples, as indicated by the results obtained in the validation. The mean recovery and matrix effect

10	3.30 (n = 3)	3.54 (n = 3)	6.42 (n = 9)	5.10 (n = 6)	0.94 (n = 4)	14.5 (n = 3)

[a]Values are expressed as means ± SEM.

at the four concentration levels assayed were 99.1 and 119.1%, respectively (Table 2). The intra- and interday precision and accuracy are summarized in Table 3, showing that, at all concentrations, the results were well below the 15% limit established by the EMA Guideline on Bioanalytical Method Validation.[14] Calibration curves were linear within the concentration range from 0.005 to 10 μM, and a representative curve is $y = 2.39x + 0.25$. Correlation coefficients were above 0.99. The sensitivity was suitable, because the LOD and the LLOQ were 2 and 5 nM, respectively.

Maslinic acid was the main compound in plasma samples withdrawn at 45 min after the oral administration of 50 mg/kg of body weight with a concentration of 4.83 ± 0.85 μM (Figure 3A). The identified metabolites were found in plasma at much lower concentrations than the parent compound. The most abundant derivative was the monohydroxylated and dehydrogenated metabolite M5 (m/z 485.3) at 0.77 ± 0.18 μM, followed by the monohydroxylated metabolite M1 (m/z 487.3) that reached the amount of 0.15 ± 0.03 μM. The other monohydroxylated metabolites were found at concentrations of 57.0 ± 12.7, 22.6 ± 3.8, and 34.2 ± 10.9 nM for M2, M3, and M4, respectively (Figure 3). Similarly, the dihydroxylated and dehydrogenated compounds were present in plasma in minor amounts, of 25.1 ± 4.1 nM for M7 and 10.3 ± 2.3 nM for M6 (Figure 3).

Quantification of Maslinic Acid Metabolites by LC–APCI–MS in Rat Urine. The analytical method for the determination of maslinic acid in urine was also validated to ensure a reliable quantification of both the parent compound and its metabolites. Recovery and matrix effect were analyzed at concentrations of 0.5, 1, 5, and 10 μM (Table 2). The extraction method was appropriate for the analysis of maslinic acid in urine, because it yielded recoveries between 95.6 and 99.4% (Table 2) and matrix effect values from 109.7 to 112%. Table 3 displays the intra- and interday precision and accuracy, which were assayed by spiking blank urine at three concentrations (1, 5, and 10 μM). The method was precise, as evidenced by relative standard deviations (RSDs) of intra- and interday assays lower than 6.90 and 7.59%, respectively, which fall below the 15% limit stipulated by the EMA Guideline on Bioanalytical Method Validation.[14] The accuracy of the method met the same criterion. Linearity was observed over the concentration range assayed (0.005–10 μM), with a representative calibration curve of $y = 0.58x + 0.05$ and correlation coefficients that surpassed 0.99. The LOD was 2 nM, and the LLOQ was 5 nM, meaning appropriate sensitivity.

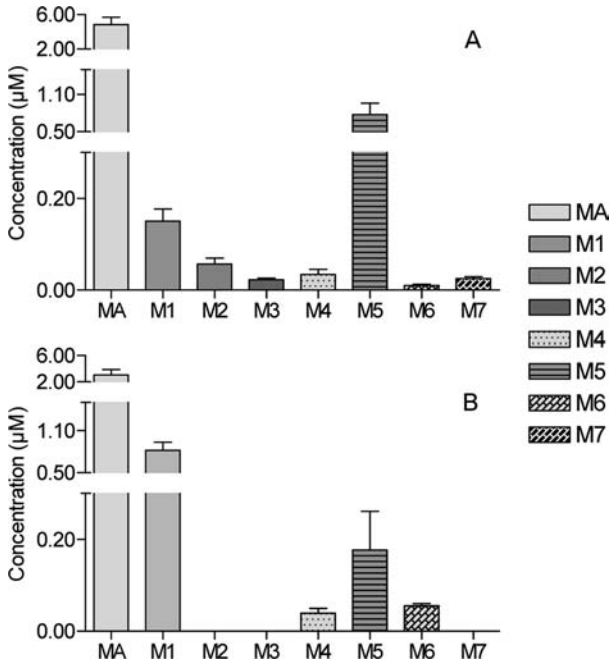

Figure 3. Concentrations of maslinic acid and its metabolites in (A) plasma and (B) urine collected at 45 min after the oral administration of 50 mg/kg of body weight of triterpene. Values are represented as means + SEM (n = 4–5).

Maslinic acid and its metabolites were quantified by LC–APCI–MS in urine samples obtained 45 min after the administration of triterpene (Figure 3B). As previously observed in plasma, maslinic acid was the major compound in urine (73.9%). However, the metabolite profile in this biological fluid differed from that found in plasma. The most abundant compound was the monohydroxylated derivative M1, representing 19.9%, whereas the monohydroxylated and dehydrogenated metabolite (M5) accounted for only 4.30%.

DOI: 10.1021/jf505379g
J. Agric. Food Chem. 2015, 63, 1126–1132

The other monohydroxylated metabolite (M4) and the dihydroxylated and dehydrogenated compound M6 represented only 0.71 and 1.23%, respectively.

DISCUSSION

A large variety of drugs and bioactive compounds from the diet, such as maslinic acid, are considered as xenobiotics by the organism. Consequently, a detoxification process is activated, consisting of the increase of its hydrophilicity via metabolism to facilitate their excretion.[17] The biotransformation of xenobiotics can take place through phase I reactions on the basis of oxidation, reduction, and hydrolysis processes and phase II reactions, which comprise glucuronidation, sulfation, methylation, acetylation, and glutathione conjugation.[1,18] To devise a comprehensive strategy for the detection in plasma and urine of maslinic acid and its metabolites, the derivatives arising from both processes were considered, but only phase I metabolites were found.

The analysis by LTQ−Orbitrap allowed the identification of a monohydroxylated metabolite with four isomers in plasma samples (M1−M4) and two in urine (M1 and M4). The metabolism of pentacyclic triterpenes has been scarcely assessed with only an *in vivo* study for boswellic acids.[19] In agreement with our study, Krüger et al.[19] found in plasma two monohydroxylated derivatives after the oral administration of 12.5 mg/kg of boswellic acids to female albino Wistar rats. The fact that hydroxylation is the principal metabolic route of pentacyclic triterpenes has been confirmed by *in vitro* assays consisting of incubations of oleanolic acid[20] or boswellic acids[19,21] with rat and human liver microsomes. With regard to maslinic acid, the biotransformation of this pentacyclic triterpene has only been investigated *in vitro* with the use of fungi, such as *Cunninghamella*[22] and *Rhizomucor*.[23] These species express cytochrome P450 (CYP) enzymes that enable equivalent phase I reactions to mammalian metabolism, thus being widely used in the assessment of the biotransformation of drugs and xenobiotics.[24] The results obtained with these microbial models of mammalian drug metabolism are in concordance with our findings. Feng et al.[22] described that maslinic acid was transformed by *Cunninghamella blakesleana* into three different monohydroxylated derivatives (7β-hydroxy, 15α-hydroxy, and 13β-hydroxy with double bond migration) and one dihydroxylated metabolite (7β,15α-dihydro derivative). Moreover, the bioconversion of maslinic acid by *Rhizomucor miehei* also yielded a monohydroxylated metabolite, but in this case, the addition of the hydroxyl group took place at the angular methyl group on position 30.[23] Taking into account these published data and considering that, in our study, four isomers of the monohydroxylated maslinic acid were detected in plasma, it could be suggested that the hydroxyl groups were added to the positions 7, 13, 15, and 30.

Maslinic acid underwent a biotransformation that yielded M5, which was detected in both plasma and urine. The mass shift of +14 Da exhibited by this metabolite was compatible with monohydroxylation, followed by dehydrogenation, which could be due to the oxidation of the corresponding secondary alcohol to a ketone. The pentacyclic ring skeleton of maslinic acid has two alcohols at the 2 and 3 positions, respectively, which are likely to be converted to a ketone. Up to now, this modification of maslinic acid has not been reported. However, this reaction has been described *in vitro* for boswellic acids after incubation with rat liver microsomes[19] and also for betulinic acid after incubations with different microbial models of drug metabolism.[25,26] Additionally, metabolites M6 and M7 showed a mass shift of +30 Da, which corresponded to the addition of two hydroxyl groups plus the conversion of a secondary alcohol to a ketone. This result is consistent with the biotransformation observed for boswellic acids[19] as well as ursolic acid after the incubation with the fungus *Pestalotiopsis microspora*.[27] Under our experimental conditions, no metabolites resulting solely from oxidation (−2 Da) or dihydroxylation (+32 Da) reactions were found in either plasma or urine.

Once the metabolites of maslinic acid were identified by LTQ−Orbitrap, their plasmatic concentrations were quantified to know the degree of the biotransformation of this compound by LC−APCI−MS. After the administration of 50 mg/kg of body weight of maslinic acid, this bioactive molecule was the prevalent compound in plasma and urine, where it accounted for 81.8 and 73.9%, respectively. Therefore, although the results indicate that maslinic acid undergoes phase I metabolism, yielding seven derivatives in plasma and four in urine, their contribution to the elimination of this pentacyclic triterpene is not preeminent, because the parent compound is excreted in urine mainly unaltered. These findings are consistent with our previous assessment of the pharmacokinetics of maslinic acid that indicated a low clearance that was attributed to minor hepatic and renal metabolism along with unchanged renal excretion.[10] Moreover, the oral bioavailability of 5.13% observed cannot be mainly attributed to metabolism. At present, experiments on the intestinal absorption of this compound are being conducted in our laboratory, and the results suggest poor absorption from the gastrointestinal tract (data not shown).

In summary, the present study thoroughly characterizes for the first time the metabolite profile of maslinic acid in rat plasma and urine. Although the oral bioavailability of similar pentacyclic triterpenes has been reported and the derivatives of some of them have been identified after incubation with different microorganisms[19,25−27] or rat and human microsomes,[19,20] none of these studies quantified the metabolites in biological fluids. Our results reveal that maslinic acid undergoes mainly phase I metabolism through hydroxylation and oxidation reactions but is not subjected to phase II biotransformations. A total of seven metabolites were identified in plasma, four monohydroxylated derivatives (M1−M4), one monohydroxylated and dehydrogenated metabolite (M5), and two dihydroxylated and dehydrogenated derivatives (M6 and M7). Only M1, M4, M5, and M6 were detected in urine. This study provides comprehensive insight into the metabolite profile of maslinic acid, thus increasing our knowledge about the bioavailability of this bioactive food component.

Endopep-MS method achieves limits of detection comparable to or below that of the historically used mouse bioassay.[21]

On the basis of our previous success in detecting and differentiating BoNT in clinical specimens and culture supernatants, we sought to extend the utility of the assay to foods. In this work, we used the Endopep-MS method to detect BoNT/A, /B, /E, and /F spiked into more than 50 foods. In all cases, BoNT/A, /B, /E, and /F were detectable at levels spiked below the limit of detection of the mouse bioassay. For 10 diverse types of foods, the limit of detection was determined. Many of the foods evaluated were submitted during suspected botulism outbreaks over the past several years, and the foods account for a wide variety of characteristics such as pH, viscosity, and fat content and are representative of cuisines from varied ethnic cultures.

MATERIALS AND METHODS

Materials. Monoclonal antibodies to BoNT/A (CR2 and RAZ1),[22] BoNT/B (2B18.2 and B12.1),[23] BoNT/E (4E17.1),[24] and BoNT/F (6F5)[25] were obtained from Dr. James Marks at the University of California at San Francisco and used for immunoaffinity purification. Dynabeads (M-280/Streptavidin) were purchased from Invitrogen (Carlsbad, CA). BoNT/A (3.5×10^7 mLD_{50}/mg), BoNT/B (1.1×10^7 mLD_{50}/mg), BoNT/E (3.0×10^7 mLD_{50}/mg), and BoNT/F (3.6×10^6 mLD_{50}/mg) complex toxins at a concentration of 1 mg/mL, where mLD_{50} is the mouse lethal dose, were purchased from Metabiologics (Madison, WI). Botulinum neurotoxin is very toxic and necessitates suitable safety measures (see below). All chemicals were from Sigma-Aldrich (St. Louis, MO) except where indicated. Peptide substrates for evaluation of BoNT activity are listed in Table 1 and were synthesized by Midwest Biotech Inc. (Fishers, IN). Sulfo-NHS-Biotin was purchased from Thermo Fisher Scientific (Waltham, MA). Kingfisher plates (deep well and traditional 96 well) and tip combs were purchased from Thermo Fisher Scientific (Waltham, MA).

Preparation of Food Extracts. Foods were purchased from local stores. For the spiking studies, extracts were made from solid foods prior to analysis. The solid food was weighed and placed into a standard 80 mL stomacher bag. A 1 mL amount of phosphate-buffered saline with 0.05% tween-20 (PBST) was added for every gram of food, with a minimum of 10 g and a maximum of 60 g of processed. Foods were processed using the Stomacher 80 Biomaster (Seward, Port Saint Lucie, FL) at maximum speed for 2 min. The mixture was then centrifuged at 12 000g in a refrigerated centrifuge (4 °C) for 20 min. The supernatant was recovered, and centrifugation continued until a clear supernatant was obtained. The clear supernatant was used for testing. Liquid foods were not processed prior to use. BoNT was pipetted into the clear supernatant or liquid food in volumes varying from 2 to 20 μL.

For foods from outbreak investigations, 5−10 g (or 5−10 mL if liquid) of sample was transferred to a container and 1 mL of gelatin phosphate-buffered collecting fluid (GBS) per 1 g (or 1 mL) of sample was added. After mixing, the sample was centrifuged at 4 °C for 20 min at 23 000 g. The supernatant was then transferred into a 6 or 10 mL sterile syringe and filtered through a 0.45 μm filter.

Preparation of mAb-Coated Beads. The mAbs (20 μg) were biotinylated with 4 μL of the 300 μM sulfo-NHS-biotin in water, prepared immediately before use. The mAb/biotin was incubated overnight at room temperature with no mixing. Biotin-labeled mAb (2 μg) was added to 100 μL of washed (two times with 1 mL of PBST; resuspended in 100 μL of PBST) streptavidin-coated beads and incubated at room temperature for 1 h with constant movement to keep the beads in solution. The beads then were washed twice in 1 mL each of PBST, and then the mAb bound beads were reconstituted in 100 μL of PBST. For a higher number of test samples, the volumes were increased proportionally.

Spiking Liquid Foods and Food Extracts with BoNT. Biosafety Level-2 practices, processes, and facilities were used to ensure safety while working with BoNT. Additionally, toxin stock material and all samples containing BoNT were processed in a Class II biosafety cabinet containing HEPA filters to minimize the potential for aerosol exposure.

An aliquot of the liquid food or food extract of 0.5 or 1 mL was placed into a deep well plate. BoNT/A, /B, /E, or /F complexes were serially diluted in PBST from 1000 mLD_{50}/μL down to 0.001 mLD_{50}/μL immediately prior to spiking using 2 μL of the stock solution and 18 μL of PBST. For milk, the following levels were spiked: 10 mLD_{50}, 1 mLD_{50}, 0.5 mLD_{50}, 0.25 mLD_{50}, 0.1 mLD_{50}, 0.05 mLD_{50}, and 0.01 mLD_{50} of BoNT. For infant formula, yogurt, broccoli, green bean liquid, salami, salmon, liquid egg, orange juice, and tomato juice, the following levels were spiked: 1 mLD_{50}, 0.75 mLD_{50}, 0.5 mLD_{50}, 0.25 mLD_{50}, 0.1 mLD_{50}, 0.05 mLD_{50}, 0.025 mLD_{50}, and 0.01 mLD_{50} of BoNT. The remaining foods were spiked with 0.75 mLD_{50}, 0.5 mLD_{50}, or 0.25 mLD_{50} of BoNT. The limit of detection was defined as the lowest level of toxin which could be detected during five separate analyses performed by a minimum of two analysts. Detection of the toxin consisted of the presence of mass spectrometric peaks with S/N of greater than 3 times above the S/N of the negative control (unspiked sample of same matrix).

Extraction of BoNT from Foods. For spiked foods, 10X PBST was added to achieve a final volume of 0.55 (for 0.5 mL of food extracts) or 1.1 mL (for 1 mL of food extracts). All spiked foods were tested in parallel with the same volume of blank food matrix, diluted to the same level with 10X PBST. For foods from outbreak investigations, an aliquot of 100 μL was placed into a deep well plate along with 400 μL of 1X PBST. A negative control consisting of 100 μL of blank food matrix and 400 μL of 1X PBST and a positive control consisting of 100

J. Agric. Food Chem. 2015, 63, 1133−1141

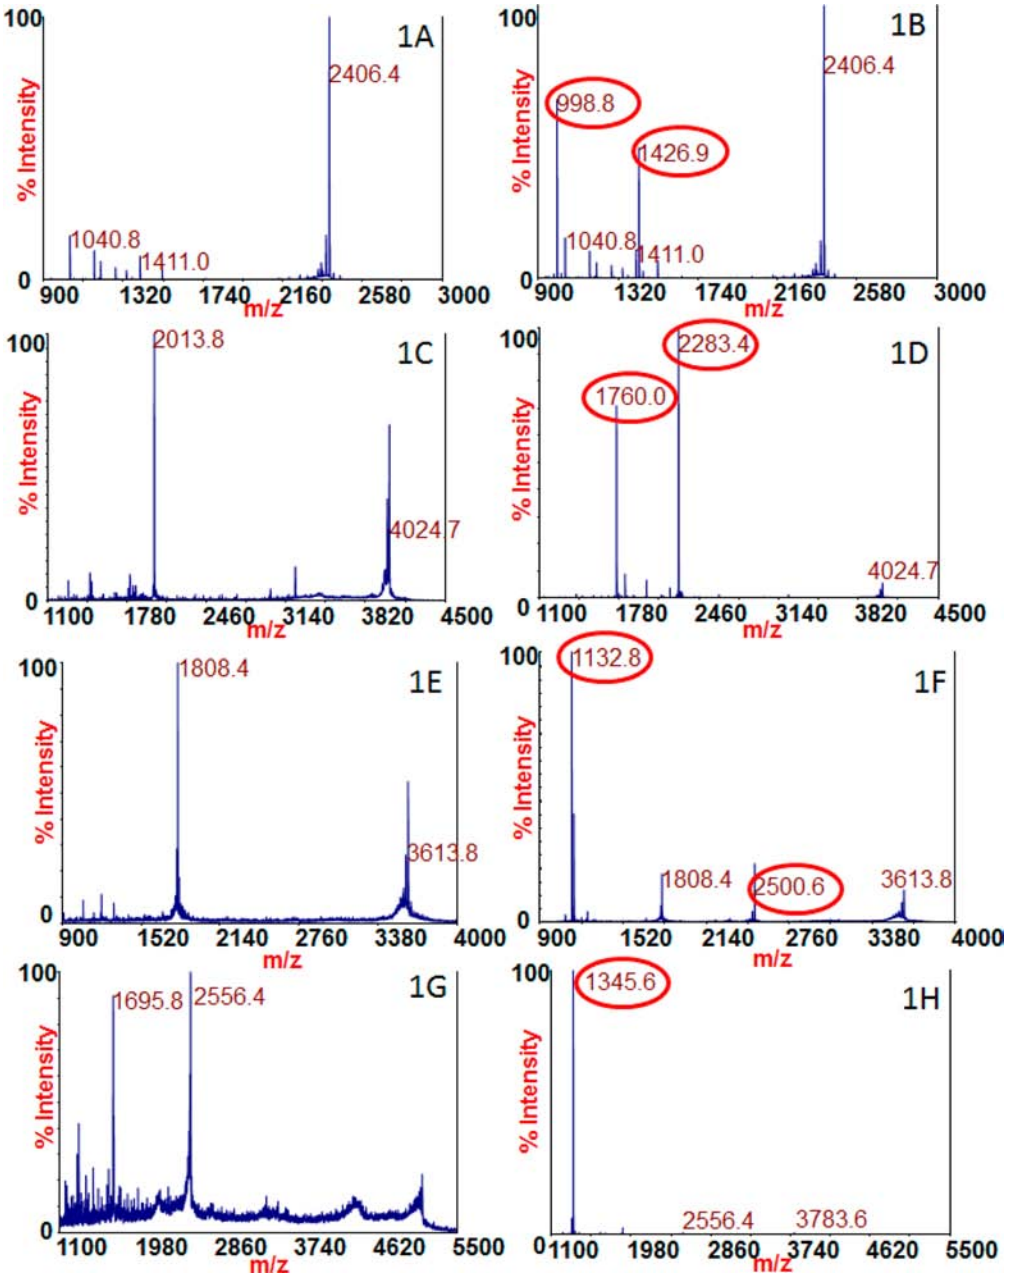

Figure 1. Mass spectra of 10 mLD_{50} of (B) BoNT/A, (D) BoNT/B, (F) BoNT/E, and (H) BoNT/F spiked into 1 mL of milk. Cleavage products indicating the presence of BoNT are circled in red. Negative controls consisted of 1 mL of milk tested for (A) BoNT/A, (C) BoNT/B, (E) BoNT/E, and (G) BoNT/F.

μL of blank food matrix, 400 μL of 1X PBST, and 1 mLD_{50} of BoNT were run in parallel with the food from the outbreak investigation. The foods from outbreak investigations included salmon, kim chi, sofrito, salsa, rice, juice, steak, pebre, corn cake, chili sauce, tomatoes, tomato paste, tofu, soup, fish, sauerkraut, relish, tea grounds, sour cream dip, yogurt, rice, vegemite, chili peppers, and baked potato. In addition, acidic matrices were adjusted to a pH of 7.0 with the addition of ammonium hydroxide unless otherwise noted.

Antibody-coated beads (20 μL) were added to the sample. The deep well plate was capped and placed on a plate shaker for 1 h at the minimal speed necessary to keep the beads in solution. The deep well plate was then uncapped and placed into a KingFisher flex magnetic particle processor (Thermo Fisher Scientific, Waltham, MA) for automated bead washing, which included two washes with 1 mL each of 2 M NaCl (or 1X PBST as specified) followed by two washes with 1 mL each of 1X PBST. The beads were eluted into 80 μL of water and removed from the KingFisher flex. Replicate extracts were incubated with each serotype of mAb coated beads.

Endopep-MS Reaction with MALDI-TOF Analysis. The aqueous extract was removed from the beads, and then the beads were reconstituted in 18 μL of reaction buffer consisting of 0.05 M Hepes (pH 7.3), 25 mM dithiothreitol, and 20 μM $ZnCl_2$ and 2 μL of peptide substrate specific for the antibody extract (SubA, SubB, SubE, or SubF, respectively). The final concentration of each substrate was 50 pmol/μL. All samples were incubated at 37 °C for 4 h with no agitation. A 2 μL aliquot of each reaction supernatant was mixed with 18 μL of matrix solution consisting of α-cyano-4-hydroxy cinnamic acid (CHCA) at 5 mg/mL in 50% acetonitrile, 0.1% trifluoroacetic acid (TFA), and 1 mM ammonium citrate. A 0.5 μL aliquot of this mixture was pipeted onto one spot of a 384-spot matrix-assisted laser desorption/ionization (MALDI) plate (Applied Biosystems, Framingham, MA). Mass spectra of each spot were obtained by scanning from m/z 900 to 5500 in MS-positive ion reflector mode on an Applied

Biosystems 5800 Proteomics Analyzer (Framingham, MA). The instrument uses an Nd:YAG laser at 355 nm, and each spectrum is an average of 2400 laser shots.

RESULTS AND DISCUSSION

Detection of BoNT/A, /B, /E, and /F in Whole Milk. The Endopep-MS method has been used successfully in the analysis of clinical specimens and culture supernatants for BoNT/A, /B, /E, and /F, demonstrating its potential to diagnose botulism, a potentially fatal disease. Although this method has limits of detection in clinical specimens and culture supernatants lower than that of the historically standard assay, the mouse bioassay, until now it was uncertain if the assay could be adapted to examine foods directly for the presence of BoNT/A, /B, /E, and /F. Detection of BoNT in foods is important as it allows for discovery of the vehicle of transmission in foodborne botulism cases, potentially preventing additional outbreaks. Foods represent a wider variety of different characteristics than clinical specimens. For example, foods can be protease rich, low pH, high fat, and very viscous, all properties which could negatively affect any assay for detection of BoNT. We therefore wanted to test the Endopep-MS method on a wide variety of foods with varying properties in addition to foods which have been known to serve as causative agents of botulism in the past.

We began with the analysis of BoNT/A in whole milk. Various levels of BoNT/A were spiked into whole milk and analyzed. Comparison of the mass spectra of whole milk

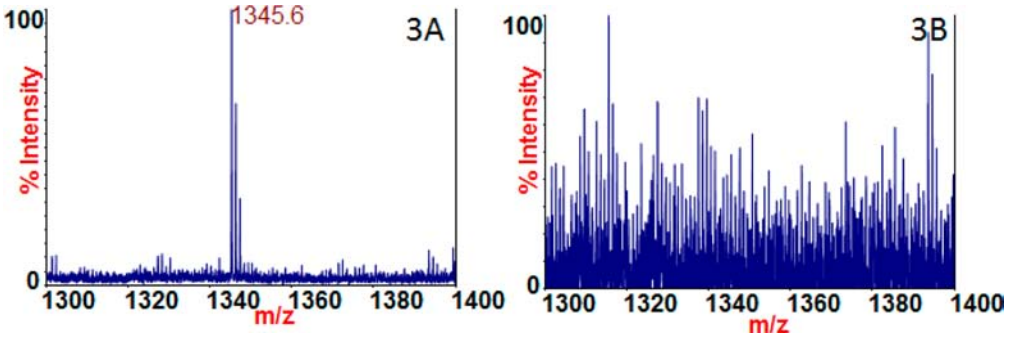

Figure 3. Mass spectra of Endopep-MS reactions containing (A) 0.01 mLD_{50} of BoNT/F spiked into cooked egg and (B) 0.01 mLD_{50} of BoNT/F in raw egg.

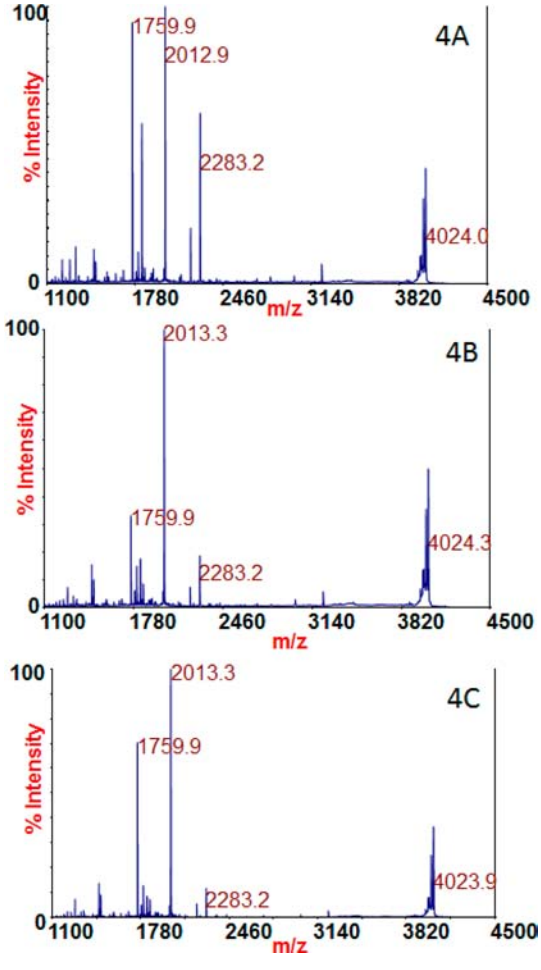

Figure 4. Mass spectra of Endopep-MS reactions containing BoNT/B spiked into (A) PBST, (B) orange juice with no neutralization, and (C) orange juice with neutralization. All were stored for 6 weeks at 4 °C prior to testing.

(Figure 1A) with whole milk spiked with 10 mouse LD_{50} (mLD_{50}) of BoNT/A (Figure 1B) shows two new peaks in the spiked sample which are absent in the untreated sample. These peaks circled in red at m/z 999 and 1427 correspond to the cleavage of SubA by BoNT/A, proving the presence of enzymatically active BoNT/A in the milk. The uncleaved substrate (SubA) is present at m/z 2406. Through repeated analysis, we could reliably detect as little as 0.25 mLD_{50} of BoNT/A spiked into 1 mL of whole milk (Figure 2B).

BoNT/B, /E, and /F were also spiked into whole milk. By examining the differences between untreated whole milk (Figure 1C, 1E, and 1G) and whole milk spiked with 10 mLD_{50} of BoNT/B (Figure 1D), BoNT/E (Figure 1F), and BoNT/F (Figure 1H), the spiked milk can be distinguished from the untreated milk in all cases. In the case of BoNT/B, the two peaks at m/z 1760 and 2283 in Figure 1D correspond to cleavage of SubB by BoNT/B, peaks at m/z 1133 and 2501 in Figure 1F correspond to cleavage of SubE by BoNT/E, and peaks at m/z 1346 and 3784 in Figure 1H correspond to cleavage of SubF by BoNT/F. The uncleaved substrates are present at m/z 4025 for SubB, 3614 for SubE, and 5511 for SubF. Replicate analysis of whole milk spiked with BoNT/B, /E, and /F determined that we could detect as little as 0.1 mLD_{50} of BoNT/B (Figure 2D), 0.1 mLD_{50} of BoNT/E (Figure 2F), or 0.01 mLD_{50} of BoNT/F (Figure 2H) spiked into 1 mL of whole milk. Intact SubF and the N-terminal cleavage product produced by cleavage of the substrate by BoNT/F are long peptides with molecular weights of 5510 and 3783 Da and historically are rarely seen by MALDI-TOF/MS. However, the doubly charged intact SubF is often visible at m/z 2556, using the analytical instrumentation listed here.

Detection of BoNT/A, /B, /E, and /F in Additional Foods. BoNT/A, /B, /E, and /F were spiked into infant formula, yogurt, broccoli, green bean liquid, salami, salmon, liquid egg, orange juice, and tomato juice. Through repeated analysis, we determined that the limits of detection of BoNT/A, /B, /E, and /F spiked into 1 mL of these matrices is below the limit of detection of the mouse bioassay, 1 mLD_{50}, as seen in Table 2. The limits of detection ranged from 0.01 mLD_{50} of BoNT/F in infant formula, yogurt, broccoli, green bean liquid, salami, and salmon up to 0.75 mLD_{50} of BoNT/A in liquid egg.

Additional foods which were of interest as they had been investigated in previous years as suspect agents of foodborne botulism were also tested with the Endopep-MS assay. For these foods, BoNT/A, /B, /E, and /F at levels below the limit of detection of the mouse bioassay were spiked into 0.5 mL of the liquid food or food extract. The results listed in Table 3 indicate that BoNT/A, /B, /E, and /F were successfully detected in 44 additional foods at levels below that of the historical standard, the mouse bioassay.

Many of the food matrices presented no challenges for the Endopep-MS assay. The results from many viscous matrices, such as corn syrup, honey, and molasses, looked identical to the results in PBST. On the basis of the similar results in buffer, it does not appear that the antibody-coated beads lacked sufficient mobility in the viscous matrix to capture the toxin nor does it seem that any of the toxin/antibody-coated beads

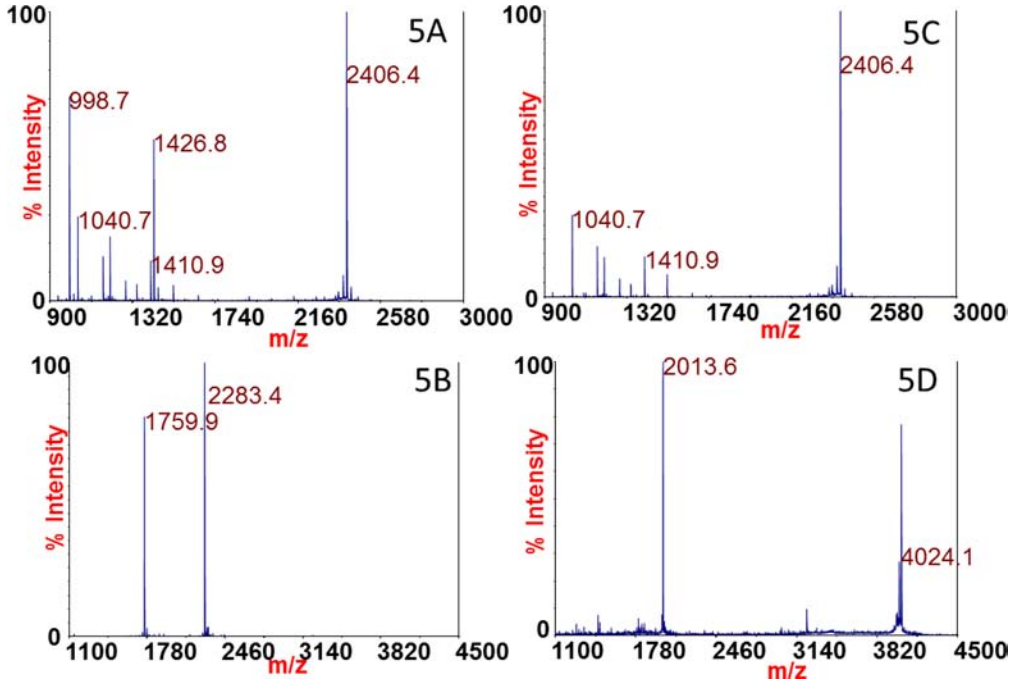

Figure 5. Mass spectra of Endopep-MS reactions testing for (A) BoNT/A and (B) BoNT/B in baked potato. Negative controls of baked potato were also tested for (C) BoNT/A and (D) BoNT/B.

remained in the viscous matrix. Samples with low pH such as tomato juice, salsa, chili sauce, kimchi, pickled peppers, and sauerkraut also looked similar to the results in PBST provided that the sample was neutralized with ammonium hydroxide to physiological pH prior to antibody−bead addition (data not shown).

Foods which were protease rich such as steak, dried beef, beef stew, and ham benefited greatly from washing the antibody-coated beads post toxin capture with 2 M NaCl to remove all nonspecific binding proteases from the antibody-coated beads. This technique was developed for the high protease environment of stool extracts,[26] so it is not surprising that it works for other protease-rich matrices. The high-salt washes however had a negative effect on high-fat matrices. Although it was possible to detect BoNT/A, /B, /E, and /F spiked into high-fat matrices such as mackerel, salami, salad dressing, and salmon when the antibody-coated beads were washed in 2 M NaCl post toxin capture, the limit of detection of the assay with these high-fat matrices was improved by washing the beads in PBST only (data not shown).

One of the more problematic matrices was the liquid egg matrix. Although the Endopep-MS assay could detect BoNT/A, /B, /E, and /F spiked into liquid egg at levels below the limit of detection of the mouse bioassay, the limit of detection in that matrix was elevated when compared to the other matrices for which a limit of detection was established (Table 2). It appeared that some of the antibody-coated beads remained behind in the matrix and the beads which were removed from the matrix had a clumpy appearance similar to the appearance of the beads from high-fat matrices when washed in 2 M NaCl. Altering the wash buffers from 2 M NaCl to PBST did not improve the appearance of the beads when used with the liquid egg matrix.

It was suspected that perhaps the high level of biotin in the liquid egg interfered with the antibody-capture process as the beads used for antibody-capture are streptavidin coated and biotin has a very strong affinity for streptavidin. Upon switching to protein-G-coated beads which do not contain streptavidin, however, similar limits of detection were obtained, indicating that the high level of biotin in eggs did not cause the bead retention or clotted appearance. Additionally, when BoNT was spiked into the extract of cooked eggs, lower levels of toxin could be detected. As little as 0.01 mLD_{50} of BoNT/F spiked into 1 mL of cooked egg extract produced a visible C-terminal cleavage product indicating the presence of active BoNT/F (Figure 3A); however, cleavage product was absent when the same level of toxin was spiked into 1 mL of liquid raw egg (Figure 3B). A level of 0.01 mLD_{50} of BoNT/F could be detected by diluting the liquid egg matrix 1:10 in PBST; however, this step would negatively impact the limit of detection by an order of magnitude in a real outbreak sample as the limit of detection would be increased to 0.1 mLD_{50}/mL of undiluted sample. Because as little as 0.05 mLD_{50} of BoNT/F could be detected in 1 mL of undiluted liquid egg (Table 2), a lower limit of detection was achieved by using 1 mL of liquid egg matrix with no dilution.

Another of the matrices with an increased limit of detection was orange juice (Table 2). Orange juice is very acidic, and it was thought that the low pH of the matrix had an effect on either the enzymatic activity of the toxin or the capture of the toxin by the antibody. An amount of one mLD_{50} of BoNT/B was spiked into 1 mL of orange juice or PBST and stored for 6 weeks at 4 °C. Endopep-MS of the samples proceeded both with and without neutralization of the pH of the orange juice immediately prior to antibody−bead addition. The peaks at m/z 1760 and 2283 in Figure 4 correspond to BoNT/B cleavage of SubB, illustrating that even after being stored for 6 weeks at 4 °C, active toxin remained in all three samples. However, comparison of the intensity of the cleavage product peaks (particularly the peak at m/z 1760) compared to the intensity of the uncleaved SubB peak (at m/z 4024 and especially 2013) indicates that there is either less toxin or less active toxin in the

DOI: 10.1021/jf505482b
J. Agric. Food Chem. 2015, 63, 1133−1141

untreated orange juice sample (Figure 4B) and, to a lesser degree, the neutralized orange juice sample (Figure 4C) when compared to the PBST sample.

Application of Endopep-MS to Foods Suspected of Causing Botulism Outbreaks. Thirty-one food extracts received for testing during botulism outbreak investigations were tested by Endopep-MS for BoNT/A, /B, /E, and /F in parallel with the mouse bioassay. Twenty-nine of these samples were below the limit of detection of BoNT/A, /B, /E, and /F with Endopep-MS as well as the mouse bioassay. One chili pepper sample tested positive for BoNT/B by Endopep-MS, and based on the intensity of the BoNT/B cleavage products, the level of toxin was very low, near the limit of detection for the Endopep-MS assay. This sample tested below the limit of detection of the mouse bioassay. The baked potato sample tested positive for both BoNT/A and /B by Endopep-MS as seen in Figure 5.

Peaks at m/z 999 and 1427 in Figure 5A indicate the presence of active BoNT/A in this sample, and peaks at m/z 1760 and 2283 indicate the presence of active BoNT/B in this same sample (Figure 5B), compared to the negative control of baked potato tested for BoNT/A (Figure 5C) and BoNT/B (Figure 5D). Mouse bioassay results on these food samples were identical to the Endopep-MS results. The finding of two serotypes of BoNT in a single sample is rare, although not completely unique as some strains of *C. botulinum* are known to make more than one BoNT serotype. These are called bivalent toxin producers and are named Ab, Ba, Af, or Bf, with the capital letter representing what is thought to be the main serotype produced. Upon the basis of the intensity of the BoNT/A and /B cleavage products, it would appear that the baked potato contained a Ba strain of *C. botulinum*. Alternatively, the potato could have been contaminated with 2 strains of *C. botulinum*.

In conclusion, we demonstrated that the Endopep-MS method is able to detect enzymatically active BoNT/A, /B, /E, and /F in a wide variety of foods. These foods represent different characteristics such as low pH, high viscosity, high fat, and varied ethnicities. Many of the foods were suspected of causing a botulism outbreak in the past, and others have definitively caused prior botulism outbreaks. The limit of detection varies and is matrix and serotype dependent, but all matrices tested were able to detect BoNT/A, /B, /E, and /F spiked into foods at levels below the limit of the historical standard assay for botulism, the mouse bioassay. The method accurately identified BoNT/A and BoNT/B in a baked potato associated with a recent case of botulism. The combination of the ability to detect BoNT/A, /B, /E, and /F in foods as well as clinical specimens such as stool extracts make this assay a concrete alternative to the mouse bioassay for BoNT detection.

Chemicals. We previously reported that the tomato glycoalkaloid referred to as tomatine consists of a 9:1 mixture of α-tomatine and dehydrotomatine.[14] This ratio differs for different parts of the tomato plant, ranging up to 3:1 for tomatine isolated from large stems.[15] The purity of the α-tomatine used in the present study as provided by the supplier is >75%. α-Tomatine ($C_{50}H_{93}NO_{21}$; mol wt 1034.2) has the following chemical name: *O*-[β-D-glucopyranosyl-(1→2)-[β-D-xylopyranosyl-(1→3]-β-D-glucoyranosyl-(1→4)-β-D-galactopyranoside]. Dehydrotomatine has the same structure as α-tomatine except for the presence of a double bond in the steroidal B ring of the aglycone part of the molecule. α-Tomatine has a tetrasaccharide (lycotetraose) attached to the aglycone tomatidine, whereas dehydrotomatine has the lycotetraose moiety attached to the aglycone tomatidenol (Figure 1).

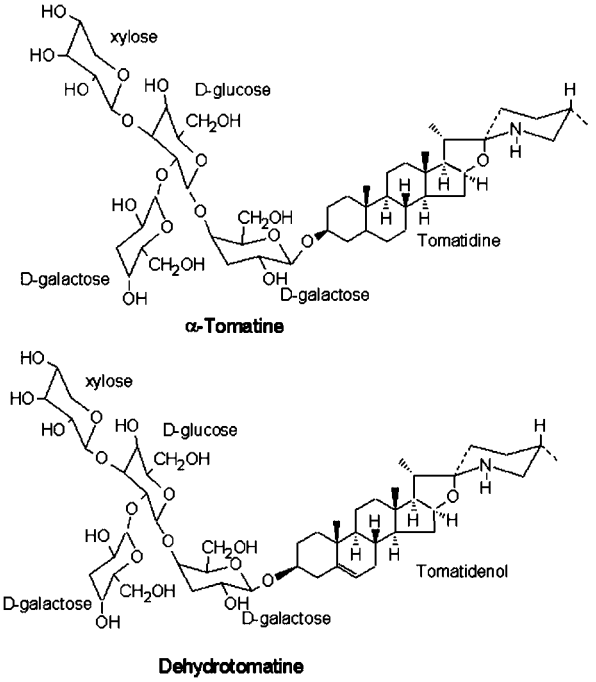

Figure 1. Structures of α-tomatine and dehydrotomatine. In α-tomatine, the tetrasaccharide (lycotetraose) side chain is attached to the aglycone tomatidine and in dehydrotomatine, to the aglycone tomatidenol.

α-Tomatine is soluble in methanol, ethanol, dioxane, and dimethyl sulfoxide (DMSO) and is fairly soluble in water. The experiments were carried out with solutions of 0.1% commercial tomatine in DMSO. This concentration is known not to induce cell toxicity. The term "tomatine" describes a mixture of α-tomatine and dehydrotomatine.

Cancer Cells and Mice. The CT-26 mouse colon cancer cell line from the American Type Tissue Culture Collection (Manassas, VA, USA) was cultured in DMEM supplemented with 10% heat-inactivated FBS containing penicillin (100 U/mL) and streptomycin (100 mg/mL). Cells were cultured at 37 °C in a humidified atmosphere with 5% CO_2.

Cytotoxicity Assay. Cell cytotoxicity was assessed by lactate dehydrogenase (LDH) release upon cell lysis following the method of Nachlas et al.[16] A CytoTox 96 Non-Radioactive Cytotoxicity Assay kit (Promega Corp., Madison, WI, USA) was used following the manufacturer's instructions. Briefly, the CT-26 cancer cells were seeded into a 96-well plate at a density of 1×10^5 cells/well and cultured for 24 h in 37 °C humidified air with 5% CO_2. The cells were then treated with α-tomatine under various concentrations (from 1 to 10 μM final concentration) for various time periods (from 3 to 48 h). After treatments, the supernatant from each well was transferred to the flat-bottom 96-well enzymatic assay plate. Released LDH in culture supernatants was measured with a 30 min coupled enzymatic assay, resulting in the conversion of a tetrazolium salt into a red formazan product. The absorbance of resultant colored products was read in a microplate reader (model 550, Bio-Rad, Hercules, CA, USA) at 490 nm. Cell cytotoxicity was expressed by the following formula:

$$\text{cytotoxicity (\%)} = 100 \times (\text{absorbance of } \alpha\text{-tomatine-treated cells} / \text{absorbance of maximum LDH-released control cells})$$

The concentration that results in ~50% cell death for 24 h treatment was 3.5 μM. We used this concentration and incubation time period to avoid any possible adverse effect of tomatine on the cells. In parallel, α-tomatine-induced cytotoxicity was also assessed by an MTT staining method as described in our previous publication.[3]

Apoptosis Assay by Flow Cytometry. Flow cytometry was carried out according to the method described by Vermes et al.[17] Briefly, CT-26 cancer cells (1×10^6) were seeded into a culture dish and cultivated for 3 h in serum-free DMEM. Serum starvation is needed for all cells to synchronize their cell cycle. This step reduces the background noise of the data. After serum starvation, the serum-free medium was replaced with complete medium. Cells were then treated with 3.5 μM α-tomatine. After incubation for each time period, cells were collected by detaching through trypsin digestion and subsequent centrifugation at 1000*g* for 5 min. Cell pellets were resuspended in a FACS binding buffer (0.1 mL; 10 mM HEPES, 150 mM NaCl, 2.5 mM $CaCl_2$, pH 7.4) with annexin V-FITC (1 μg) and PI (1 μg). After incubation for 15 min in the dark, flow cytometry was carried out in a FACSCaliber (Becton, Dickinson and Co., San Jose, CA, USA).

Mice and Treatments. All experiments were performed in compliance with the relevant laws and institutional guidelines. Pathogen-free female BALB/c mice (6 weeks old), weighing 20−25 g, were purchased from Orient Bio (Seongnam, Korea). The mice were hosted in a stainless steel cage under a 12 h light/dark cycle with a temperature range of 20−22 °C and a relative humidity of 50 ± 10%. The mice were fed pelletized commercial chow diet from Orient Bio (catalog no. 5L79) and sterile tap water ad libitum during the entire experimental period. After acclimation for 1 week, the mice were then randomly divided into two groups (n = 10), avoiding any intergroup difference in body weight. α-Tomatine was dissolved in 0.1% DMSO. After dilution with PBS to an appropriate dose, α-tomatine was given to mice via the intraperitoneal (ip) route at a dose of 5 mg/kg body wt (in 200 μL). Simultaneously, the mice were intracutaneously transplanted with 1×10^6 of CT-26 cancer cells in 200 μL of PBS into the lateral side of the back. The mice were then administered the α-tomatine dose once a day for 2 weeks. Control mice were administered the same volume of vehicle only. Mice were sacrificed by CO_2 inhalation at the end of the experimental periods for excision of tumor masses.

Preliminary experiments indicated that the mice frequently died 4 weeks after tumor transplantation, especially the vehicle-treated control mice without tomatine. To avoid this problem, we carried out the in vivo experiment for 2 weeks.

Tumor Growth. To evaluate the suppressive effect of α-tomatine on tumor growth, removed tumor masses from the control and experimental groups of mice were weighed using an analytical balance. Excised tumor masses were rinsed with ice-cold PBS and stored at −20 °C until use.
