rice starch, amylose, and amylopectin of 16 rice cultivars are isolated after the rice powder is hydrolyzed by lipase and protease first. The main retrogradation-related properties of starches are identified by correlating their retrogradation rates with average molecule weight (amylopectin), chain-length distribution (amylopectin), wavelength of maximum visible absorption (λ_{max}), IR, X-ray diffraction, and DSC of the native rice starches, amylose and amylopectin.

MATERIALS AND METHODS

Materials. Rice seeds were offered by Tianjin Crops Research Institute. Thermostable α-amylase (12 000 units/mL) from *Bacillus licheniformis*, microbial lipase from *Rhizopus chinensis*, and alkali protease from *Bacillus pumilus* were purchased from Tianjin Nuoao Technology Development Co., Ltd. Pullulanase microbial from *Bacillus subtilis* (Enzyme Commission Number 3.2.1.41; 5000 units/mL), maltose, maltotriose, maltotetrose, maltopentaose, maltohexaose, and maltoheptaose were purchased from Sigma-Aldrich Co., LLC. Butanol and ethanol were purchased from Tianjin Fuyu Fine Chemical Co., Ltd.

Methods. *Preparation of Rice Starch from Rice Seeds.* The rice seeds were first ground into a fine powder with a grinder, and the brans were removed by sieving with 80 mesh. Then, the rice powder (20 g) was dispersed in 0.085 M NaOH solution (100 mL) with rapid stirring, and the starch was extracted at 40 °C for 180 min, after which the crude starch was obtained by centrifugation at 5000*g* for 15 min. Purification of the crude starch was carried out by washing with deionized water for more than 3 times at room temperature. The purified rice starch was dried at 45 °C in the oven until a constant weight.

Hydrolysis of Rice Starches by Lipase and Alkali Protease. Hydrolysis of lipid and protein in rice starches were performed by dissolving 5 g of starch in 100 mL of water with stirring; after gelatinization at 95 °C for 30 min, the pH of the mixtures was adjusted to 7.0 for lipase and 8.0 for alkali protease by 2.0 M NaOH. Then, 10 mg of lipase (1500 units/g) or alkali protease (20 000 units/g) was added, and the starch solutions were kept for 24 h. The hydrolysis temperatures were set at 37 °C for lipase and 65 °C for alkali protease. The lipase and alkali protease were inactivated by being boiled for 10 min. Then, the starches hydrolyzed were obtained by centrifugation (3040*g* for 10 min). The dried starches for visible absorbance, IR, average molecule weight (amylopectin), chain-length distribution (amylopectin), X-ray diffraction, and DSC were obtained by removing water with hot air at the temperature of 55−60 °C in a drying oven until a constant weight.[16]

Preparation of Rice Amylose and Amylopectin from Rice Starch. The rice starch (10 g) was dispersed in deionized water (100 mL) with continuous stirring, and the slurry was poured into 0.15 M NaOH solution (1.3 L) slowly and kept for 5 min. Then, NaCl (5%) with a volume of 360 mL was added to the solution, and the pH of the solution was adjusted to 6.5−7.5 by 1.0 M NaOH with stirring. The solution was separated into two sections, and the up and down sections were crude rice amylose and amylopectin, respectively. Then, 100% *n*-butanol (at one-third the volume of the supernatant) was added to the up section. The mixture was stirred and held at room temperature for 4 h before centrifuging for 10 min at 5000*g* to precipitate amylose. The crude rice amylopectin was obtained by centrifugation at 5000*g* for 15 min and further purified by washing with 1% NaCl 4 times. The precipitates of amylose and amylopectin were washed with absolute alcohol, and the purified starches were dried in an oven at 45 °C until a constant weight.

Determination of Retrogradation Rates of Rice Starches. The retrograded rice starch was prepared according to our previous method.[17] A total of 10 g of rice starch blended with 100 mL of distilled water was gelatinized for 20 min at 95 °C by continuous stirring. Gelatinized starches were autoclaved at 120 °C for 30 min and retrograded at 4 °C for 24 h. Then, 0.6 mL of α-amylase (12 000 units/mL) was added to hydrolyze non-retrograded starch into soluble carbohydrates for 6 h at 90 °C. Crude retrograded rice starch was precipitated with a centrifuge (3040*g* for 5 min), and the supernatant fraction was discarded. The crude retrograded rice starch was washed with deionized water 3 times to remove soluble impurities, and the purified retrograded starches were dried with hot air at the temperature of 55−60 °C on an oven until a constant weight. The retrogradation rate (%) was calculated according to the following equation:

$$\text{retrogradation rate (\%)} = (m/m_0) \times 100\%$$

where m and m_0 are the weights of purified retrograded starch and native starch, respectively. All of the samples are duplicated 3 times.

Scanning of the Wavelengths of Maximum Absorbance (λ_{max}) of Samples. I_2/KI (1:3) solutions were prepared with a total of 5% (w/v) total iodine. A total of 5.0 mg of samples was first dissolved in 4.0 M NaOH with magnetic stirring, and then the pH of the solutions was adjusted to 7.0. After that, 0.25 mL of I_2/KI (1:3) solutions was added rapidly, and the solutions were sent to scan λ_{max} after 30 min. λ_{max} of samples was determined by UV-2501pc, ultraviolet−visible (UV−vis)-recording spectrophotometer (Shimadzu, Japan).

IR Spectra. All samples have been dried at 120 °C for 2 h first. Then, each sample was mixed with potassium bromide (KBr) at the rate of 1:60, and the mixture was compressed into slices by equipment. After that, samples were loaded on a slide holder, and spectral curves were obtained in transmission mode using a Bio-Rad FES135 IR spectrometer at 27 °C. The IR instrument is equipped with a deuterated triglycine sulfate (DTGS) detector using the Digilab attenuated total reflectance (ATR) accessory at 4 cm^{-1} resolution by 64 scans.

Molecular Weight Distribution (MWD) Profiles. MWD was determined by the method described in ref 18. Sweet potato amylose or amylopectin (100 mg) was added to 80 mL of deionized water and heated in boiling water with stirring for 20 min to make the samples dissolve. After filtration through 5 μm cellulose acetate filters, the dissolved samples were injected into a high-performance size-exclusion column chromatography system (HPSEC) with a multi-angle laser light scattering detector (MALS), a refractive index detector (RI), a pump (LC-10AT, Shimadzu Corporation, Kyoto, Japan), and an injector valve with a 100 μL loop (Rheodyne, Cotati, CA). Two series tandem columns (300 × 7.5 mm, PL aquagel-OH MIXED, 8 μm, Polymer Laboratories, Ltd., Shropshire, U.K.), a DAWN DSP-F laser photometer fitted with He−Ne laser (k = 623.8 nm) with a K-5 flow cell (Wyatt Technology, Santa Barbara, CA), and a RID-10A differential refractive detector (Shimadzu Corporation, Kyoto, Japan) were used. The flow rate was 0.5 mL/min. The mobile phase was $NaNO_3$ solution (0.1 M) containing 0.02% NaN_3, which had been passed through a 0.4 μm membrane filter (Membrane Solutions, LLC). A dn/dc value of 0.150 was used in molecular weight calculation, and data handling was carried out using ASTRA software (version 4.73.04, Wyatt Technology, Santa Barbara, CA).

Chain-Length Distribution Profiles. The chain-length distribution of sweet potato amylose or amylopectin was determined by high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC−PAD).[19] The samples (100 mg) were dissolved in 30 mL of 4.0 M KOH solution, and the pH of the solution was 6.0. Then, pullulanase (0.5 unit) was added to each solution for hydrolysis at 45 °C for 24 h with stirring. After that, the solution was heated in a boiling water bath for 10 min to deactivate the enzyme. The debranched sample solutions were first centrifuged at 21500*g* and filtered through a 0.45 μm membrane filter before being injected into the HPAEC−PAD system. The HPAEC−PAD system included a Dionex DX 600 equipped with an ED 50 electrochemical detector with a gold working electrode, a GP 50 gradient pump, a LC 30 chromatography oven, and an AS40 automated sampler (Dionex Corporation, Sunnyvale, CA). The standard triple potential waveform was used with the following period and pulse potentials: T1 = 0.40 s, with 0.20 s sampling time, E1 = 0.05 V; T2 = 0.20 s, E2 = 0.75 V; and T3 = 0.40 s, E3 = −0.15 V. The data were collected using Chromeleon software (version 6.50, Dionex Corporation, Sunnyvale, CA). The eluents were prepared in distilled deionized water with helium sparging, with eluent A consisted of 200 mM NaOH and eluent B consisted of 50 mM sodium acetate in 200 mM NaOH.

X-ray Diffraction Patterns. The X-ray patterns of the starches were obtained with copper, nickel foil filtered, Kα radiation using a diffractometer (D-500 Siemens, Madison, WI). The diffractometer was operated at 27 mA and 50 kV. The scanning region of the diffraction angle (2θ) was from 4° to 60° at 0.05° step size with a count time of 2 s.

[a]Values are means ± standard deviations. Where given, means and standard deviations are calculated from three samples. [b]The data are absent for a limited amount of rice seeds.

Retrograded starches were equilibrated at 100% relative humidity for 24 h at 25 °C prior to examination.

DSC. Thermal analysis of the complex was carried out with DSC (Q20, TA Instruments, New Castle, DE). The complex (6.0 mg) was placed in an aluminum DSC pan, and scanning was performed from 25 to 230 °C at a heating rate of 5 °C/min, with an empty pan as a reference. For each endothermic curve, the onset (T_o), peak (T_p), and conclusion (T_c) temperatures as well as the corresponding enthalpy changes (ΔH) associated with these transitions were computed with the universal analysis 2000 software (version 4.5A, TA Instruments—Waters, LLC, New Castle, DE).

Statistical Analysis. All samples were analyzed in triplicate. The statistical significance of observed differences among treatment means was evaluated by analysis of variance (ANOVA) and a least significant difference (LSD) test (Excel). The coefficients of correlation were calculated by Microsoft Excel. Regression equations were developed between retrogradation rates and λ_{max}, proportions of chains, molecular weight, and thermal index. Significance of correlations (r) was examined by SPSS 12.0 for Windows software using Pearson's correlation.

RESULTS AND DISCUSSION

Chain-Length Distribution Profiles. To reduce adverse effects of lipids, protein, and association of amylose and amylopectin on analysis of main retrogradation-related properties, all 16 rice starches have been hydrolyzed by lipase and protease and their amylopectin has been isolated to determine profiles of chain-length distribution. The results in Table 1 and Figure 1 show the correlation between retrogradation rate of rice starch and chain-length distribution of corresponding amylopectin. There is significant positive correlation (R^2 = 0.85; r = 0.926; $p < 0.01$) between proportions of chains with degree of polymerization (DP) > 10 of amylopectin from different rice cultivars and their corresponding starch retrogradation rates, which verifies the speculation in ref 20. Cereal cultivars having amylopectin structures with a lower proportion of long B chains are speculated to give improved quality products with lower rates of retrogradation and stalling. Such a coefficient of correlation (R^2) will decrease to 0.65 if proportions of chains with DP > 5 are investigated. Gidley and Bulpin[21] indicate that a minimum chain length of DP of 10 is required for formation of double helices. The results in the paper indicate that the minimum chain length of DP of 10 is also probably necessary for the occurrence of retrogradation. Such a chain length might be the minimum length for nucleation of starch retrogradaton, which might offer the stability of association among those chains in starch solutions. In other words, double helix (not too long) formation is probably necessary during the nucleation stage of starch retrogradation. The finding in the paper suggests that we can screen rice cultivars with a low rate of retrogradation by seeking the gene or enzyme in rice to control the proportions of chains with DP > 10 of amylopectin. Furthermore, the low-retrogradation cultivar will be obtained by transferring the identical gene to normal rice. There are similar cultivars in the ethnic residential area in China, called "soft rice", which have attracted the attention of many rice breeders. The cultivars ZP-35 and ZP-36 in the paper are of this kind. The average chain length is related to the melting temperature of retrograded waxy starch[22] but not to the retrogradation rate of rice starches. The results in Figure 1 and Table 1 also negate the speculation that the amylopectin molecule with a narrower chain-length distribution has a higher retrogradation tendency,[23] because the rice cultivars ZP-14, ZP-19, and ZP-35 have narrower chain-length distributions and a relatively low retrogradation rate.

The MWDs of amylopectin, as the main property of rice starch, are also measured to investigate their relationships with retrogradation rates. Such results are described in Figure 2 and Table 2. The results in Table 2 and Figure 2 show that there are various quantities of the distribution interval of molecule weights for those 16 rice cultivars: four intervals for ZP-32, ZP-33, and ZP-35, three intervals for ZP-3, ZP-12, ZP-13, ZP-15, and ZP-36, two intervals for ZP-26, and one interval for ZP-14 and ZP-19. The coefficient of correlation between those quantities and retrogradation rates is 0.0356 (R^2) (r = 0.189). Other coefficients between the weight-average molecular weights (M_w) in the first to the fourth intervals and retrogradation rates are 0.1445, 0.064, 0.0429, and 0.0091 (R^2) (r = −0.380, 0.253, 0.096, and 0.207), respectively, in Table 2. The results of the significant test suggest that there is no correlation between retrogradation rates and quantities of intervals or M_w. The polydispersity index (PDI) is another index that represents the weight distribution of macromolecules.

It can be calculated by M_w/M_n, M_n is the number-average molecular weight. Table 3 shows the correlation between rice starch retrogradation rates and corresponding PDI in different intervals. The coefficients in the first to the fourth intervals are 0.062, 0.021, 0.009, and 0.027 (R^2) (r = 0.249, −0.167, −0.095, and 0.244), respectively, in Table 3. Also, the correlation between them is not significant. Such results infer that the main factor to determine rice starch retrogradaion rates is proportions of chains with DP > 10 of amylopectin and not the narrowness or width of the MWD of rice starch. Such results also suggest that retrogradation is in essence the formation of crystals and the nucleation is the main factor to influence the extent of retrogradation.[24]

Figure 3. Visible absorbance of different rice (left) starches, (middle) amyloses, and (right) amylopectins: (o) ZP-36, (p) ZP-35, (i) ZP-15, (j) ZP-19, (f) ZP-12, (e) ZP-11, (a) IZDP-30, (h) ZP-14, (l) ZP-31, (k) ZP-26, (b) IZP-8, (n) ZP-33, (g) ZP-13, (c) ZP-3, (m) ZP-32, and (d) ZP-8.

The wavelength of maximum absorption (λ_{max}) of starch combined with iodine is sensitive to the presence and length of double helices in starches, which represents another important property of starch. λ_{max} of different rice starches, amyloses, and amylopectins with iodine in complex is shown in Figure 3 and Table 4. The coefficients of correlation between retrogradation rates and λ_{max} of different rice starches, amylose, and amylopectin are 0.2736, 0.3232, and 0.1573 (R^2) (r = 0.523, −0.386, and −0.809), respectively. The results of the significant test in Table 4 suggest that there is no correlation between λ_{max} of those starches and the corresponding retrogradation rates. There are no λ_{max} for the samples ZP-35 and ZP-36 with a low proportion of chains with DP > 10 of amylopectin and low retrogradation rates, verifying that a lot of amylopectin in those two cultivars is too short to form double helices. The absence and presence of λ_{max} in sample ZP-26 starch and amylose in Figure 3 indicate that the interaction of amylose and amylopectin in the sample might greatly influence the formation of double helices of the rice starch. The results of λ_{max} of different samples support the above point of view that the distribution of rice amylopectin determines the retrogradation rate of rice starches.

Although the degree of short-range molecular order in the retrograded state can be determined by FTIR,[4,25] few papers report the prediction of retrogradation tendency by IR spectra of native starch, amylose, or amylopectin. The IR spectra of

[a]Values are means ± standard deviations. Where given, means and standard deviations are calculated from three samples. [b]The data are absent for a limited amount of rice seeds.

different rice starches (up), amyloses (middle), and amylopectins (down) are shown in Figure 4 to discern their correlation with retrogradation property. The results show that no special peaks are present for low retrogradation rate or high retrogradation rate cultivars and all of the IR spectra of different rice starches are the same. Also, the difference of the intensities of different peaks in all of the samples is not obvious. Therefore, IR spectra are not suitable for discerning rice cultivars with a low or high retrogradation rate. The results agree well with ref 26.

Different starches fall into four crystal types, showing the strong reflections (2θ) at around 15°, 17°, 18°, 20°, and 23° for A-type crystallinity, 5.5°, 17°, 22°, and 24° for B-type crystallinity, 7.8°, 13.5°, and 20.7° for V-type crystallinity, and the mixture of reflections of A- and B-types for C-type X-ray diffraction pattern.[27−29] X-ray diffractions of different rice starches, amyloses, and amylopectins were determined to discern the correlation of those patterns and retrogradation rates of rice starches. Figure 5 shows the X-ray diffractions of different rice starches (up), amyloses (middle), and amylopectins (down). All of the native rice starches exhibit A-type X-ray pattern, which shows the strong diffraction peaks at about 15° and 23° (2θ) and an unresolved doublet at around 17° and 18° (2θ).[27] All rice amylose and amylopectin samples show ambiguous diffraction peaks between 15° and 23° (2θ) and an obvious peak at about 29° (2θ). They are not attributed to any types of X-ray pattern, inferring that the rice amylose/amylopectin forms crystals different from those of native rice starch. These results are also different from those in ref 30, which is probably caused by the presence of lipids and protein in those starches. There are no identical peaks or intensities of diffraction for rice cultivars with a low or high retrogradation rate in Figure 5; therefore, no correlation exists between the retrogradation rate and intensities of diffraction of different rice cultivars. Such results suggest that the patterns for crystal formation of native starch in the growth of plants are different from those of amylose/amylopectin in drying.

d	ZP-8	6.63 ± 0.02	*b*	*b*	*b*	*b*	

[a]Values are means ± standard deviations. Where given, means and standard deviations are calculated from three samples. [b]The data are absent for a limited amount of rice seeds.

0.0373 ($r = -0.125$, not significant) (for peak temperature), 0.0241 ($r = 0.193$, not significant) (for offset temperature), and 0.018 ($r = -0.043$, not significant) (for ΔH) in Table 7. The results of the significant test suggest that the correlation between rice starch retrogradation rates and their DSC characteristics, such as onset, offset, and peak temperatures or melting enthalpy ΔH (J/g) of different starches, is not significant at all.

The findings in the paper provide us with a new way to solve the retrogradation problem. On the basis of knowledge of rice starch synthesis,[32,33] we can easily screen those genes controlling synthesis of the starch branching enzyme and transfer them to proper cultivars to obtain the rice cultivars with a low retrogradation rate, high yield, and better taste.

1. The formation of insoluble and unstable dicalcium phosphate in water results in the formation of intermediate calcium phosphate phases and ultimately apatite (e.g., hydroxyapatite, HAP), the most stable form of calcium phosphate. The following equations[9] show the compounds formed between free calcium and phosphoric acid under slightly alkaline conditions:

$$Ca^{2+}(aq) + HPO_4^{2-}(aq) \rightarrow CaHPO_4(s)$$
(dicalcium phosphate) (1)

$$Ca^{2+}(aq) + 2H_2PO_4^{-}(aq) \rightarrow Ca(H_2PO_4)_2(s)$$
(monocalcium phosphate) (2)

$$3Ca^{2+}(aq) + 2PO_4^{3-}(aq) \rightarrow Ca_3(PO_4)_2(s)$$
(tricalcium phosphate) (3)

$$2CaHPO_4(aq) + 2Ca_3(PO_4)_2(s) \rightarrow Ca_8H_2(PO_4)_4(s)$$
(octacalcium phosphate) (4)

$$Ca_3(PO_4)_2(aq) + 2Ca^{2+}(aq) + HPO_4^{2-}(aq) + H_2O(l) \rightarrow Ca_5(PO_4)_3OH(s) + 2H^{+}(aq)$$ (hydroxyapatite) (5)

Amorphous tricalcium phosphate is the main compound that forms flocs in aqueous systems, including sugar solutions.[9]

The physicochemical properties of flocs influence the efficacy of solid−liquid separation processes. Colloidal particles in an aqueous solution are charged as a result of the dissociation of surface groups or adsorption of ions in solution, resulting in the electrical double layer surrounding the particle.[10] The electrical double layer of particles governs the electrostatic attraction between charged particles and determines the extent of floc formation. The nature and structure of flocs formed in an aqueous solution dictate how effective the solid−liquid separation process is in relation to floc size and settling velocity.[11] Loosely held or more open floc structures have fractal dimensions in the range of 1.6−2.4.[12] On the other hand, compact structures have fractal dimension values in the range of 2.5−3.0.[13,14] Generally, flocs with fractal dimension in the range of 2.0−2.5[13,14] are effective in trapping suspended particles and the adsorption of particles onto the floc network[13,14] (Figure 1), if the effect of impurities in the matrix

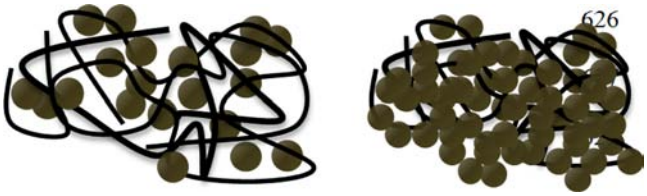

Figure 1. Formation of disordered, loosely attached, fine flocs (left) and tightly bound bridged flocs (right).

is neglected. As such, it was hypothesized that examining the effect of impurities on floc structure and size would provide information on strategies that could be adopted to improve solid−liquid separation processes in sugar and other systems. Typically, the floc structure is characterized by the fractal dimension; however, the measurement of size of primary particles is not directly proportional to the wavelength of the incident light, which consequently voids the Rayleigh−Gans−Debye (RGD) theory. In the current study, the term "scattering exponent" is used.

Studies on the various phases of calcium phosphate precipitates formed in sugar solutions have been reported to provide information on the mechanism of calcium phosphate formation and on the clarification process.[15−17] Greenwood et al.[15] studied the size and structural properties of calcium phosphate flocs formed in simple synthetic juice solutions using light scattering techniques. These flocs were reported to have scattering exponents (which are qualitative representations of the floc structures)[15] between 1.97 and 2.76 and average sizes of between 10.4 and 17.5 μm. Following the work conducted by Greenwood et al.,[15] the present study examined the effect of starch, Na^+ ions, SiO_2, and phosphate ion concentrations on floc structure and size of calcium phosphate particles formed in synthetic sugar solutions. These constituents were examined using small-angle laser light scattering technique, X-ray powder diffraction (XRD), and attenuated total reflectance Fourier transformed infrared (ATR-FTIR) spectroscopy. The investigations were conducted to provide explanations on how certain impurities influence the properties of calcium phosphate flocs and, hence, the clarification process of sugar cane juice. On the basis of the information derived from the initial study, further clarification studies were conducted using both cold and cold/intermediate liming techniques on juice expressed from prepared WC. These two liming techniques produce calcium phosphate flocs with different properties.[18] In addition, one-stage (i.e., conventional) and two-stage clarification processes using these techniques were examined.

MATERIALS AND METHODS

Preparation of Synthetic Cane Juices. The composition of the synthetic juice solution used in the study is shown in Table 1. Sucrose

Table 1. Composition of Synthetic Cane Juice Solutions

concentration (mg/kg)	substance	added as
120000	sucrose	white sugar
125	dextran	dextran
500	starch	soluble starch
75	SiO_2	sodium silicate pentahydrate
300	CaO	calcium hydroxide
1000	organic acid	*trans*-aconitic acid
265	P_2O_5	potassium dihydrogen phosphate
400	MgO	magnesium sulfate heptahydrate

(Sigma-Aldrich, Castle Hill, NSW, Australia), equivalent to 120 mg/kg, and Milli-Q water were used to prepare the solutions. Also, proportions of $Ca(OH)_2$, $Mg(SO)_4{\cdot}7H_2O$, KH_2PO_4, and aconitic acid (Chem-Supply, Gillman, SA, Australia); dextran, NaCl, and $NaSiO_3{\cdot}5H_2O$ (Sigma-Aldrich, Sydney, Australia); and AR grade soluble starch (Ajax Finechem, Seven Hills, NSW, Australia) were added to prepare the synthetic juice solution. Varying amounts of Na^+ ions, SiO_2, phosphate ions, and starch were added to the synthetic juice solution prior to liming to examine the influence of each component on the structure and size of calcium phosphate. For the addition of SiO_2, a correction was made to account for the total amount of Na^+ ions, as it was added in the form of $NaSiO_3{\cdot}5H_2O$. Lime saccharate was prepared with 725 mg/kg of sucrose and 50 mg/kg of $Ca(OH)_2$. This solution was used in the synthetic juice solution studies.

Preparation of Raw Cane Juices. Tully Sugar factory (Queensland, Australia) processed mechanically harvested green cane with all of the trash removed during the August−September 2012 crushing season. Factory juice (SJ) was collected directly from the incubator

DOI: 10.1021/jf502229f
J. Agric. Food Chem. 2015, 63, 1573−1581

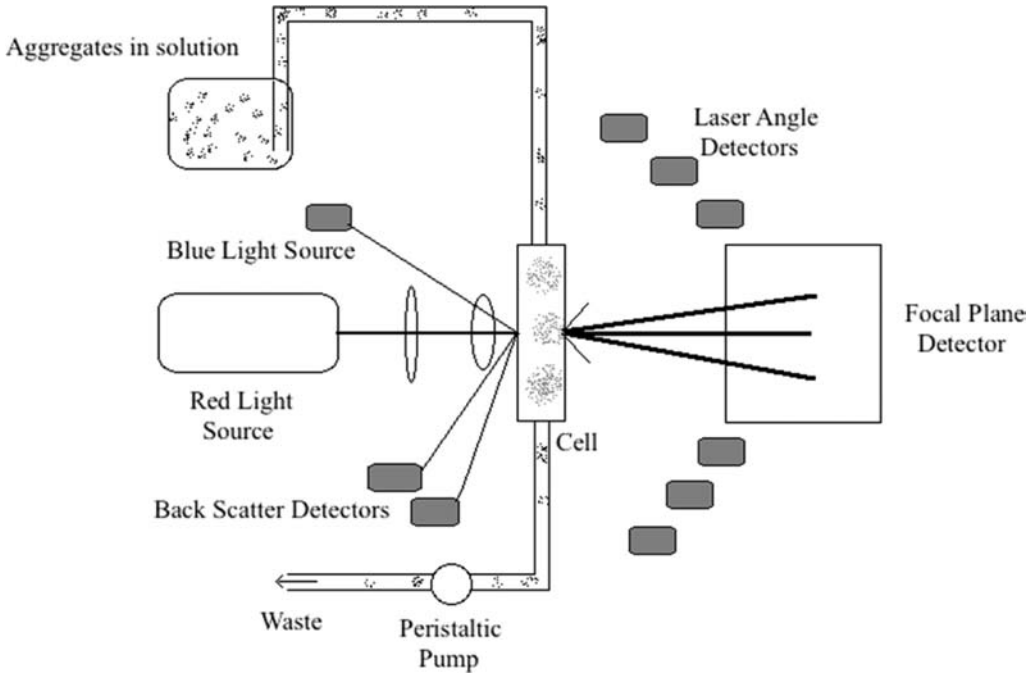

Figure 2. Schematic diagram of the Malvern Mastersizer S Particle Analyzer.

tank (76 °C) prior to the clarification process. Juice samples were collected every 0.5 h for 3 h, and composite samples were prepared to reduce the variability of the data. It was necessary to maintain the temperature of the collected juices at 76 °C to avoid changes in juice properties.

None of the sugar factories in Australia were processing WC at the time of the present study; thus, WC juice was not available. As a result, synthetic WC juice was prepared by mixing 850 mL of SJ juice with 150 mL of juice expressed from trash, for each clarification test. Several sugar cane plants in the fields in the vicinity of the Tully Sugar factory were hand-cut to obtain sugar cane trash. The trash was fibrillated using a cutter grinder, and the juice was expressed using a 20 tonne hydraulic press unit (Carolina Industrial Equipment, Charlotte, NC, USA).

Clarification Procedure. Clarification experiments (by sedimentation) were conducted using settling tubes (60 mm diameter, 460 mm high) in a Sugar Research Institute (SRI) designed heated illuminated batch settling kit.[19] Each tube was calibrated 0−400 mm with a 400 mm settling depth and volume of ∼1.0 L. Samples of sugar cane juices were clarified immediately after collection from the sugar factory. One-stage (i.e., conventional) and two-stage clarification processes were conducted to determine which process produces juice of better quality and fast-settling juice flocs. The lime saccharate used was a mixture of 100 g of a 200 g/kg solution of calcium oxide and 100 g of 68 °Brix factory syrup. The pH of the juices was measured using a portable pH meter (Hach H160, Cleveland, CO, USA) with a glass probe (model 93×218814, Eutech Instruments, Singapore) and a high-temperature probe (EC-FG-7350401B, Eutech Instruments).

Two liming techniques (cold and cold/intermediate) were selected for this study. Cold liming for the one-stage process was performed as follows: Lime saccharate was added to juice (50−55 °C) to provide free calcium ions, which reacted with the inorganic phosphates in the juice to form the calcium phosphate flocs. Enough lime saccharate was added to neutralize the juice to pH 7.1/7.8 (to examine the effect pH on turbidity and Ca^{2+} ion levels). The juice was heated to 76 °C and then boiled at ∼100 °C to remove entrained air, which can interfere with floc settling. A dose of 5 mg/kg of flocculant, poly(acrylamide-*co*-sodium acrylate) polymer (Magnafloc LT27 with a degree of hydrolysis of 27%, TD Chemicals, Robina, QLD, Australia), was added to the juice to bridge the calcium phosphate flocs, enhance agglomeration, and improve sedimentation. After 30 min of quiescent settling, the samples of clarified juice (CJ) were siphoned from the settling tubes for subsequent analyses. The experiments were performed in duplicate. For the cold/intermediate liming technique, the following modifications were made: juice was limed to pH 6.2 at 52 °C, then heated 76 °C, and further limed to pH 7.1/7.8. The limed juice was then boiled at ∼100 °C. The juice was then processed in a similar fashion as the cold liming technique.

The two-stage clarification process involved heating the juice (60 °C) followed by lowering the juice pH to 3.5 using 2 M H_2SO_4 (Ajax Finechem, Seven Hills, NSW, Australia) to facilitate precipitation of proteins and polysaccharides. A highly charged cationic coagulant (10 mg/kg, Magnafloc LT525 with a degree of hydrolysis of 46%, Chemiplas Australia Pty Ltd., East Melbourne, VIC, Australia) was also added to aid the precipitation process. After sedimentation, the supernatant, stage 1 juice, was collected for further clarification. The stage 1 juice was clarified using the process described for the one-stage normal clarification process. The pH of the juice was limed to pH 7.1/7.8. Both the cold liming and the cold/intermediate liming techniques were performed for the one-stage clarification process. All clarified juice samples were stored at −20 °C and thawed prior to compositional analyses.

The settling rate of calcium phosphate flocs provides a good indication of how effectively the flocs settle. It was determined by measuring the level of the mud interface at 0.5, 1.0, 2.0, 3.0, 4.0, and 5 min. The initial settling rate (cm/min) was obtained from the graphical analysis of the initial linear slope.

The final mud level was determined after 30 min of sedimentation by visual assessment, recording the height of the interface where the boundary line between the solid and liquid phase is evident. As the settled flocs were unstirred, the final mud levels were not indicative of values obtained in commercial clarifiers.

The turbidity of CJ was determined by measuring the absorbance (A) at 900 nm in 1 cm cuvette cells against Milli-Q water[20] using a Cintra 40 double-beam UV−visible spectrophotometer (GBC Scientific Equipment Pty. Ltd., Braeside, VIC, Australia). The turbidity was measured in triplicate and calculated as 100A. The error for turbidity determination was ±0.5%.

Compositional Analyses. The total soluble solids (i.e., the °Brix of the juice) was determined using a digital refractometer (RFM 342, Bellingham and Stanley Ltd., London, UK) accurate to ±0.01 °Brix. Total soluble polysaccharides were calculated according to the

DOI: 10.1021/jf502229f
J. Agric. Food Chem. 2015, 63, 1573−1581

procedure described by Roberts.[21] Proteins were isolated from the organic sugar cane juice by gel filtration using PD-10 desalting columns prepacked with Sephadex G-25 (GE Healthcare, Rydalmere, NSW, Australia), and the concentration was measured using the BCA protein assay kit (Thermo Scientific, Scoresby, VIC, Australia). Percentages of sucrose, glucose, and fructose present in the samples were determined using a Waters (Milford, MA, USA) high-performance ion chromatography system coupled to an electrochemical detector (model 2465, Waters), a pump (model 626, Waters), and a controller (model 600S, Waters). The carbohydrates were separated using a CarboPac PA-1 column (4 × 250 mm, Dionex, Idstein, Germany). The samples for HPIC analysis were prepared using ICUMSA method GS7/8/4-24.[22] Inorganic ions were determined using a Varian Vista-MPX CCD simultaneous inductively coupled argon plasma optical emission spectrometer (ICP-OES; Varian Inc., Mulgrave, VIC, Australia). All measurements were conducted in triplicate.

Floc Size and Structure. The synthetic juice test solutions were heated to 76 °C in a temperature-controlled water bath. Once the temperature was stabilized, lime saccharate was added to raise the pH to 7.8 ± 0.05. Floc size and structure measurements were conducted online using the small-angle laser light scattering instrument (Malvern Mastersizer S Particle Analyzer, Malvern Instruments, Southborough, MA, USA) using a circulation system (Figure 2). The inlet and outlet tubes were placed in the beaker of hot synthetic sugar solution. A peristaltic pump was used to deliver the solution through the tubes to flow through the flow cell. The gentle action of the peristaltic pump ensured minimum breakup of the aggregates while maintaining them in suspension. Pure sugar solution (maintained at 94 °C) was used to preheat the instrument. The silicon lines and top of the flow cell were insulated.

Prior to measurements, the alignment and background readings for the Mastersizer were conducted using Milli-Q water. Measurements were taken every 30 s for 5 min, and all measurements were repeated 10 times during each sequence to ensure that consistent results were obtained.

The floc structure (i.e., compactness), represented as the scattering exponent, was calculated (please refer to the Supporting Information) using the RGD scattering theory and by constructing a log−log plot of scattered light intensity versus scattering momentum.[23]

The measurement of particle size was within the range of 0.05−900 μm. The instrument consisted of a He−Ne laser light (λ = 632.8 nm) as the light source, an optic lens, and photosensitive detectors. The scattered light was collected at angles between 0° and 46°. An integration time of 40 s per curve was selected to provide both optimum rate of measurement and data quality. The light obscuration level of the samples was maintained between 10% and 30% to enhance the reliability of the measurements, and aliquots of the samples were injected into a small dispersion unit containing Milli-Q water. The variability in the scattering exponent for these measurements was generally ≤0.05, and for the average size distribution, the variability was ≤50 μm.

The XRD patterns were obtained for the calcium phosphate flocs using a PANalytical X'Pert MPD with Cu Kα radiation of wavelength 1.5418 Å.

Infrared spectra were collected using a Nicolet 870 Nexus Fourier transform infrared (FTIR) spectrometer equipped with an attenuated total reflection accessory (Madison, WI, USA). Spectra were collected in the spectral range from 4000 to 440 cm^{-1} and were the average of 64 scans at a resolution of 4 cm^{-1}. The spectra were plotted using the Galactic 187 Industries Corp. GRAMS/32 software package (Salem, NH, USA). The final FTIR spectra were normalized with respect to the reference peak located at 1007 cm^{-1}.

RESULTS AND DISCUSSION

Effect of Sodium on Calcium Phosphate Flocs. The scattering exponent and average size of the flocs formed in the presence of Na^+ ions are shown in Table 2. A linear decrease in the scattering exponent (from 2.50 to 2.25) with increasing Na^+ ion concentration is attributable to the increasing formation of looser flocs. Looser flocs exhibit lower packing density and, hence, slower settling rates. The changes in floc structure with increasing Na^+ concentration may be associated with the dispersive properties of Na^+ ions.[24] The floc size increased to a maximum of 280 μm before slightly dropping and leveling off. The general increase in size may be due to electrostatic repulsion between calcium phosphate particles and or electrostatic repulsion between the microflocs because of the dispersive action of Na^+ ions.[24]

Table 2. Scattering Exponent (±5%) and Average Size (±5%) of Flocs under the Influence of Na^+ Ions, Silica, Phosphate, and Starch Concentrations

	scattering exponent	av size (μm)

500	2.55	270

Effect of Silica on Calcium Phosphate Flocs. The effects of SiO_2 on the size and structure of the primary flocs formed in the synthetic cane juice solutions are also presented in Table 2. Increasing the SiO_2 concentration generally decreased the scattering exponent. This trend is similar to that obtained with the Na^+ ions. However, the drop in the scattering exponent value with increasing SiO_2 concentration was not as distinct as that obtained with Na^+ ions. The decline in the scattering exponent is likely to be, in part, due to increasing Na^+ concentration in solution, as SiO_2 was added in the form of $NaSiO_3 \cdot 5H_2O$. However, the absolute scattering exponent values were higher with the addition of SiO_2 relative to situations when Na^+ ions were added, possibly indicating that SiO_2 has less of an impact than Na^+ ions on floc structure. The size of the calcium phosphate flocs peaked at approximately 380 μm at 100 mg/kg and then declined with increasing SiO_2 concentration. The reason for this is not known.

Effect of Phosphate on Calcium Phosphate Flocs. Floc structure was not influenced by phosphate addition; however, the size of calcium phosphate flocs significantly increased from approximately 220 to 380 μm when >350 mg/kg P_2O_5 was added compared to the addition of 300 mg/kg P_2O_5 (Table 2). Supplying phosphoric acid to the sugar solution provided

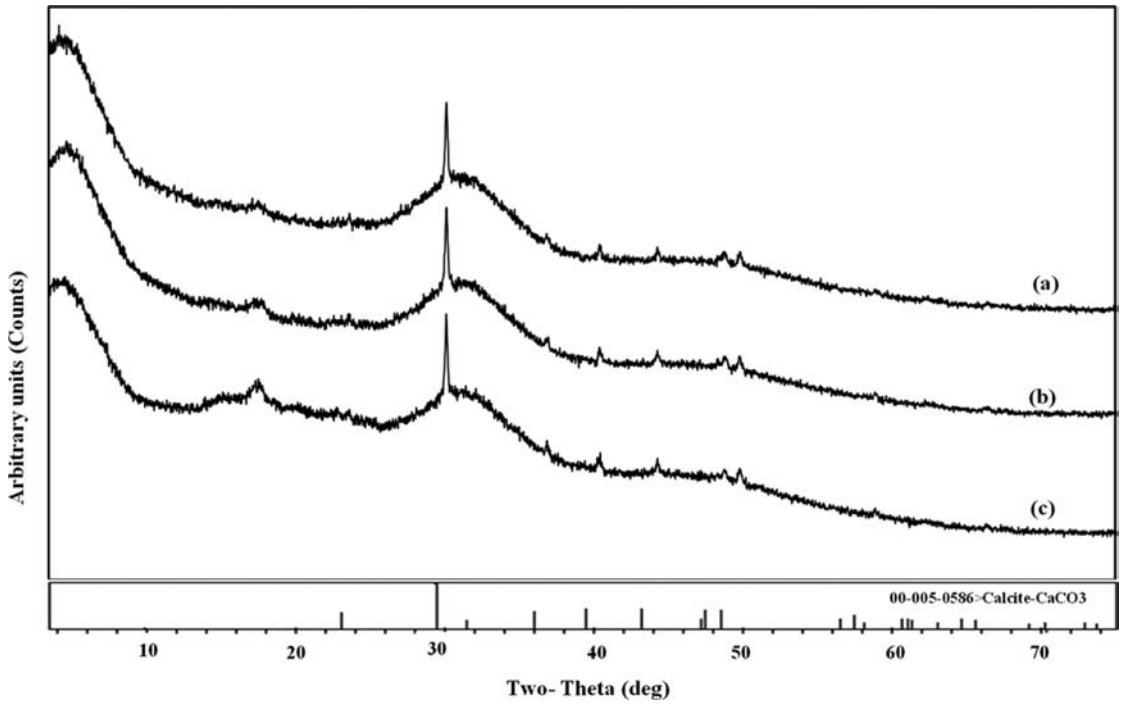

Figure 3. X-ray powder diffraction patterns of calcium phosphate flocs: (a) 5 mg/kg of NaCl added to synthetic juice; (b) synthetic juice; (c) 200 mg/kg starch added to synthetic juice.

additional phosphate ions, which interacted with calcium ions from lime saccharate and resulted in an increase in the growth of calcium phosphate particles. The results show that there is a wide P_2O_5 range over which there is stabilization of floc structure. It is unclear whether the stabilization is due to the changes in surface charge of the calcium phosphate, via changes in proportion of the phases that constitute the floc.[9] In a typical clarification process in a sugar factory, juice phosphate concentration >300 mg/kg as P_2O_5 does not influence clarification performance significantly.[9]

Effects of Starch on Calcium Phosphate Flocs. As shown in Table 2, increasing the amount of starch did not change the floc structure, but slightly affected the floc size. At the lowest dosage of starch (100 mg/kg), the floc size of the formed flocs was 390 μm. Increasing starch concentration to 500 mg/kg dropped the size to approximately 270 μm. The reduction in floc size may be associated with starch molecules adhering to the surface of microflocs inhibiting growth, without affecting packing arrangement.[25] Starch molecules when present to a significant extent in juice do affect sugar crystallization, so the same may occur with calcium phosphate.[25]

X-ray Powder Diffraction Results. XRD was used to identify the phases of calcium phosphate precipitates formed in the presence of Na^+ ions and starch, as these two components were shown to most strongly influence the scattering exponent and size of flocs. The XRD patterns of selected precipitates are shown in Figure 3. Calcite (2θ, 23.06°, 29.46°, 35.98°, 39.46°, 43.18°, 47.54°, 48.56°, and 57.40°) is the main crystal phase in all of the samples. The prominent halo in the 2θ region between 26° and 36° is characteristic of an amorphous compound,[26] which is presumably calcium phosphate, because energy dispersive spectroscopy gave a mass ratio of Ca to P similar to that of tricalcium phosphate. As was reported for SiO_2, the variation in the size of the halo may be a representation of the variation of the interatomic distances between P−O−P structural units, which is related to the arrangement of the phosphorus molecules.[14]

The addition of phosphate broadens the XRD halo relative to the control, indicating that the calcium phosphate phase is far less ordered (smaller particles, i.e., more amorphous) than that of the control. The increased amorphous nature of the calcium phosphate particles will increase the amount of impurities removed because of an increase in surface area.[18]

The crystalline peaks associated with starch at 2θ values of 15° and 17°, which is typical of the A-type pattern,[25] are highest when an increasing amount of starch was added prior to lime neutralization and lowest when the Na^+ level was increased prior to neutralization. Starch is electronegative, so cations attract starch hydroxyl groups and destabilize starch granules, whereas anions tend to repel starch hydroxyl groups and stabilize starch granules.[27] Chiotelli[27] and co-workers postulated that Na^+ ions tend to penetrate starch granules and replace hydrogen ions, which reduces the water phase. When the electrostatic driving force of the anions in solution exceeds the repulsive force associated with the Na^+ ions, the anions enter the starch granule and rupture the hydrogen bond between starch molecules. This results in gelatinization, and so the amount of starch trapped (or rather removed) by the calcium phosphate flocs is reduced. The presence of starch in sugar cane juice processed in the factory can create boiling and viscosity problems, filterability impairment, and poor molasses exhaustion.[28] As a consequence, high levels of Na^+ ions in juice have two negative effects on clarification: (i) increasing the amount of starch molecules present in the CJ and (ii) loosening the floc structure, thereby reducing the amount of suspended particles not trapped by the flocs.[12]

Attenuated Total Reflectance Fourier Transform Infrared spectroscopy. The ATR-FTIR spectra of calcium phosphate precipitate formed in the control synthetic juice and

DOI: 10.1021/jf502229f
J. Agric. Food Chem. 2015, 63, 1573−1581

in the presence of starch, SiO_2, NaCl, and phosphate are shown in Figure 4. The broad band observed at 3325 cm^{-1} is

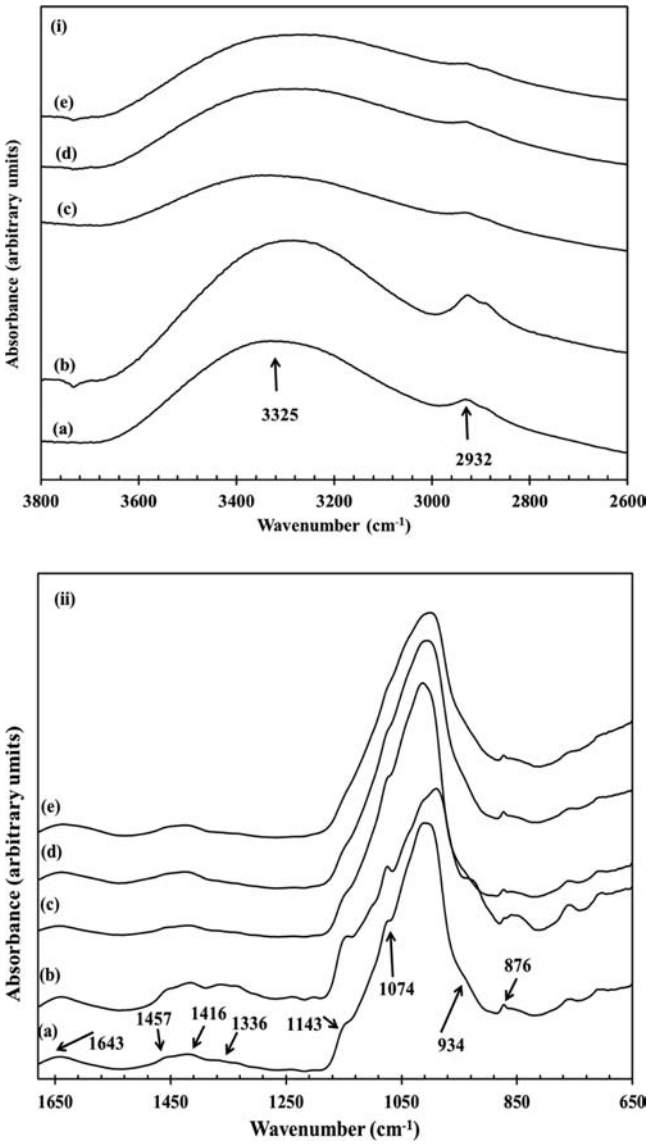

Figure 4. ATR-FTIR spectra ((i) 3800−2600 cm^{-1} and (ii) 1650−650 cm^{-1}) of calcium phosphate precipitate formed during juice flocculation of synthetic juice: (a) control; (b) 200 mg/kg starch; (c) 25 mg/kg SiO_2; (d) 5 mg/kg NaCl; (e) 250 mg/kg phosphate.

associated with the O−H group stretch vibration of calcium phosphate.[29] The presence of adsorbed water may also be associated with this peak. Figure 4I shows that the addition of SiO_2 significantly reduced the intensity of this broad peak. This peak was also reduced, albeit to a lesser extent, for the calcium phosphate precipitates derived from the synthetic juice in the presence of NaCl and phosphate ions. It is therefore likely that these added compounds affect the properties of calcium phosphate at differing extents. The band at 2932 cm^{-1} is related to the C−H stretching vibration of methyl groups, which is related to the presence of starch and/or dextran.[30] From Figure 4i, the intensity of this peak is highest in the synthetic juice obtained in the presence of starch (Figure 4i(b) followed by the control (Figure 4i(a) in comparison to the intensities of the other samples. This confirms that the addition of phosphate, NaCl, and SiO_2 reduces the amount of starch trapped by the calcium phosphate flocs.

The peak detected at 1643 cm^{-1} in the spectra (Figure 4ii) is correlated to the H−O−H symmetric bending vibration.[31] The bands observed at 1457, 1416, and 876 cm^{-1} are derived from two antisymmetric stretching and bending vibrations of CO_3^{2-}, respectively. The presence of these peaks is due to the formation of $CaCO_3$.[32] The partially resolved shoulder at 1336 cm^{-1} detected from the control and synthetic juice, in which starch was added, is assigned to the C−H bending of CH_2 groups in starch.[30] This peak was not detected in the spectra obtained from the analysis of other samples. The other peaks present as shoulders at 1143, 1074, and 934 cm^{-1}, characteristic of starch, were detected in the control (Figure 4ii(a) and calcium phosphate sample (Figure 4ii(b)). These peaks are associated with C−O, C−C stretching, C−O−H bending, and C−O−C vibrations in starch molecular structure, respectively.[29] Each spectrum shown in Figure 4ii reveals an intense peak between 1200 and 896 cm^{-1}, which is related to P−O stretching derived from the phosphate group.[32] The position of this peak shifted in the spectra of the samples, which may be related to the salt added during flocculation and the change in crystallinity of the calcium phosphate floc. In summary, the results obtained using ATR-FTIR correlate with the XRD data, in terms of the relative proportions of starch in the various calcium phosphate samples. The calcium phosphate flocs are not effective in trapping starch molecules. However, increasing the concentration of phosphate increases the floc size and presumably the amount of flocs formed to improve clarification performance.[6] Thai et al.[6] investigated the clarification performance of sugar cane juice derived from burnt cane (BE) and green cane with half of the trash removed (GE) and concluded that the latter can be clarified with acceptable juice turbidity when up to 100 mg/kg of P_2O_5 is added.

Clarification of Sugar Cane Juice Derived from Whole Sugar Cane Crop. The compositions of sugar cane juices obtained from the factory (SJ) and those prepared from factory juice and hand-cut trash material (prepared WC) are shown in Table 3. The inclusion of juice derived from trash contributed significantly to the level of soluble proteins, polysaccharides, reducing sugars, calcium, phosphate, magnesium, and silicon ions.

The polysaccharide content of juice derived from WC was higher than that of SJ by ∼36% (Table 3). Starch, polysaccharides, and proteins are polar and thus would influence the coagulation and flocculation processes of juice particles and their floccing ability.[18] Furthermore, if a higher proportion of these impurities is carried through the various processing stages, they would increase the viscosity of molasses (sugar syrup), reduce the rate of sucrose crystallization, and produce colored compounds.[33]

The results of the soluble inorganic ions (Table 3) show that Ca^{2+} and phosphate contents in the WC juices were higher than those in the SJ by ∼30% and ∼52%, respectively. As a result, Ca^{2+} and phosphate ions are expected to increase the coagulation of WC juice particles and hence improve clarification compared to juice expressed from SJ. However, it is important to note that the proportion of Ca^{2+} ions in WC juice that takes part in particle aggregation is not known.[24]

Clarification Performance. As shown in Table 3, the one-stage (i.e., conventional) clarification processes using cold and cold/intermediate liming resulted in relatively high CJ turbidities of 15.7 and 29.0 NTU, respectively. For good

clarification, this value is usually <20 NTU under Australian conditions.[34] In the two-stage clarification process (with or without LT525 addition), the cold liming technique improved CJ turbidity by 67−69% in comparison to the one-stage clarification process. With this process, cold liming gave lower CJ turbidities than the cold/intermediate liming technique.

The one-stage clarification process (both cold and cold/intermediate liming techniques) resulted in the formation of fine and small flocs (Table 3), which led to slow to moderate settling rates of the particles during sedimentation, similar to the results obtained by Kent et al.[35] Mud compaction was very poor at 30% for the cold liming technique. This will have implications with the clarifier size and the pol loss during mud filtration. If this liming process is to be adopted, then a suitable flocculant must be identified to improve mud compaction and reduce juice turbidity. However, the level of mud compaction reduced by half when the juice was treated using cold/intermediate liming. Again, a suitable flocculant should be identified if the process is to be used commercially.

In the two-stage process, the flocs formed in the second stage were significantly larger in size (than those formed in the one-stage process) but floated, rather than settled. The reason for this is that a significant portion of heavy insoluble impurities was removed during the first stage of the two-stage process, which would have assisted floc densification in the second stage of the process. An alternative method to gravity sedimentation is to use dissolved air flotation (DAF) system. This will readily remove the floating flocs. The DAF method is used in syrup clarification and is an efficient, practical, and reliable separation method for the removal of impurities.[36]

Significant protein removal was achieved when the juice was cold-limed as part of a two-stage clarification process (Table 3). The protein level in the CJ was remarkably low with 82% removed using the two-stage clarification process and 60% with the one-stage clarification process. The significantly higher amount of proteins removed in CJ obtained by the two-stage clarification process was a result of their partial removal during the pretreatment step (i.e., stage one). Polysaccharide removal was highest when the juice was cold limed. Liming to a lower pH level of 7.1 (instead of 7.8) reduced the proportion of the protein and polysaccharide contents in CJ. The reason for this is not known. It was observed that there was no benefit in using the coagulant during the first stage of the two-stage process.

Amino acids formed by protein denaturation in sugar cane juice react with reducing sugars (e.g., glucose and fructose) via the Maillard reaction to form undesirable high molecular weight dark colored compounds that become incorporated into the sucrose crystals.[37] Thus, the two-stage process, which reduced proteins (and polysaccharides) may thus affect the proportions of colored bodies formed during sugar manufacturing. Previous studies by Lindeman and O'Shea[38,39] revealed a strong association between colored compounds and polysaccharides in sucrose crystals.

In comparison to the one-stage clarification process, the two-stage clarification process resulted in CJ with higher reducing sugar content by ≤28% (≥2.0% on dry solids) and sucrose levels were lower by ≤4.5% (∼93% on dry solids) (please refer to the Supporting Information for glucose, fructose, and sucrose concentrations in WC juices). The results showed that sucrose degradation occurred, due to the use of acid to drop the juice pH to 3.5 during the pretreatment step.

Table 3 shows that lime consumption was notably higher using the cold/intermediate liming technique than cold liming because additional lime saccharate was required for neutralization. There were no changes in the proportion of Mg^{2+} ion concentrations irrespective of liming technique or clarification process. In general, cold liming resulted in lower inorganic ion levels than the cold/intermediate liming technique. For both cold and cold/intermediate liming techniques, there was an improved removal of phosphate and silicon using the two-stage clarification process compared to the one-stage clarification process by ≤53% and ≤23%, respectively, whereas, Ca^{2+} and sulfur levels were considerably higher by ≤136% and ≤200%, respectively. The higher the sulfur content in juice treated using the dual clarification process is due to the addition of H_2SO_4 during pretreatment.

The high levels of these inorganic components, particularly Ca^{2+}, phosphate, silicon, and sulfur, will cause severe scaling in

DOI: 10.1021/jf502229f
J. Agric. Food Chem. 2015, 63, 1573−1581

the evaporators,[40] as they are significantly higher than those present in burnt cane or green cane with the trash removed.[6] With the one-stage clarification process, predominantly calcium phosphate and silica scale (neglecting the contribution from calcium oxalate) will be deposited in the evaporators, and the proportion will be significantly higher with the juice obtained with cold/intermediate liming. However, the proportion of scale formed from the juice using the cold liming technique may be only marginally higher than the scale derived from juice expressed from green cane with half the trash extracted (GE).[6] This is because of the higher proportion of phosphorus and suspended particles (i.e., higher turbidity). As mentioned in the previous work by the authors, the cost of cleaning the evaporators increases if phosphate scale coprecipitates with calcium oxalate and amorphous SiO_2 in the no. 4 and 5 evaporators of a quintuple evaporator set.[41] A high proportion of phosphate level in CJ is usually associated with high raw sugar filterability.[4]

On the basis of the inorganic constituents of the CJ obtained by the two-stage process, the main scale compounds apart for calcium oxalate will be calcium phosphate, calcium sulfate, and SiO_2. The CJ obtained by the two-stage process contains 2 and 3 times as much Ca^{2+} and sulfur, respectively, than the CJ obtained in the one-stage clarification process. As such, an increase in scaling propensity will occur if this juice is processed compared to the juice obtained by the one-stage clarification process. As, the CJ obtained with the two-stage process resulted in significantly lower turbidity than that of the one-stage clarification process, scaling in the no. I and 2 evaporators of a quintuple evaporator set will be expected to be significantly less.[42]

An approach that needs to be explored to reduce Ca^{2+} ions present in the CJ obtained by the two-stage process is to use an inorganic acidic salt (e.g., alum) instead of H_2SO_4 to lower the juice pH and then use an alkali (e.g., soda ash or dolomite) to slightly raise it to the original value prior to liming. The removal of the flocs can be achieved with either the DAF process or the addition of higher density material microsilica or even dirt prior to the clarification via sedimentation. To reduce sucrose inversion, the pH level of the first stage should be lowered to between 4 and 4.5, not to 3.5 as was done in the present study. The removal of significant quantities of proteins and polysaccharides will reduce not only color bodies in sugar process streams but also the proportion that ends up in the sucrose crystal. This will reduce the color of the product sugar.

Also, the role of sucrose (apart from its free radical scavenging ability) in the degradation process of these acids in a mixture has not been reported.[22]

CaA, *p*CoA, and FeA are also the main color precursors present in sugar cane juice and are known to participate in reactions producing color that results in the raw sugar (sucrose) product.[23,24] In this study, a comprehensive investigation on the degradation of CaA, *p*CoA, and FeA in aqueous sucrose solutions containing the mixture of these HCAs was conducted. The degradation efficiencies and behaviors of individual HCAs were studied. The degradation conditions were optimized using central composite design (CCD) and multiresponse surface methodology (MRSM). Models were developed to predict the degradation of HCA mixtures in synthetic sugar cane juice solutions and examined by regression analysis.

MATERIALS AND METHODS

Reagents and Solvents. CaA, *p*CoA, FeA, fructose, glucose, lactose, and sucrose were obtained from Sigma-Aldrich (St. Louis, MO). Ferrous sulfate heptahydrate ($FeSO_4{\cdot}7H_2O$), glacial acetic acid, hydrogen peroxide (H_2O_2; 30%, w/w), sodium acetate, sodium hydroxide, and sulfuric acid were purchased from APS Ajax Finechem (Seven Hills, NSW, Australia). Ethanol (absolute) was supplied from Merck (Darmstadt, Germany). All chemicals were purchased of the highest purity grade available and used as supplied without any further purification. Stock solutions of HCAs (i.e., CaA, *p*CoA, and FeA, 10 mg/mL) were prepared individually by dissolution in degassed aqueous ethanol solution (50%, v/v) and stored at 4.0 °C in the absence of UV light.

Fenton Oxidation Reactions. Reactions were carried out in 10 mL glass scintillated reaction vessels housed in a Pierce Reacti-Therm heating/stirring module (Rockford, IL) with continuous magnetic stirring (280 rpm). In each run, predetermined amounts of high-purity water (18.2 MΩ·cm), sucrose, and each HCA were added to the reaction vessel. Consistent amounts of $FeSO_4{\cdot}7H_2O$ and H_2O_2 solutions were added to achieve a final volume of 5.0 mL and final concentrations of 0.5 and 7.50 mM, respectively. The optimum working molar ratio (Fe(II):H_2O_2) determined for the Fenton reaction by the authors was 1:15.[25] The reaction was initiated as soon as H_2O_2 was added. After 2 min, 3 mL of the solution was taken, diluted 10-fold to quench the reaction, and kept frozen. Table 1 gives the operating conditions used in the Fenton oxidation process. The reaction time was kept to 2 min to minimize sucrose degradation to allow treatment of sugar cane process streams, where the main objective is to preserve the sucrose content.

Table 1. Coded and Actual Values of the Experimental Design

			coded levels of parameters				
notation	factor	unit	−2	−1	0	+1	+2
A (X_1)	total HCA concn	mg/L	20	65	110	155	200
B (X_2)	sucrose concn	mass %	0	3.75	7.50	11.25	15
C (X_3)	pH		4.5	4.75	5.0	5.25	5.5
D (X_4)	temp	°C	25	31.25	37.5	43.75	50

Although it is well-known that ethanol is a scavenger for hydroxyl radical, in this study, ethanol had to be used for the dissolution of HCAs due to the low solubility of HCAs in water. As the ethanol concentration was at least 11 times higher than the concentrations of Fe (II) and H_2O_2 (0.5 and 7.5 mM, respectively), it was assumed that the effect of ethanol on the Fenton reaction was similar.

Instrumental Procedures and Analyses. The proportion of each HCA degraded was monitored by reversed-phase HPLC with UV/vis diode-array detection (DAD). The analysis was performed on a Hewlett-Packard HP/Agilent 1100 series HPLC system (Germany) using a Waters Symmetry C18 column (150 mm length × 3.9 mm diameter) with a Waters Guard-Pak Resolve C18 guard insert (10 μm) (Milford, MA). The mobile phase consisted of 1.0% (v/v) acetic acid in water (as eluent A) and methanol (as eluent B). The gradient program was as follows: 20% B to 25% B (5 min), 25% B to 50% B (15 min), and 50% B to 20% B (5 min). Simultaneous detection at specific wavelengths (280 and 320 nm) was subtracted against a reference wavelength (620 nm). The column temperature was ambient (25 °C), and the flow rate of the mobile phase was 1.0 mL/min. Aliquots of samples were membrane filtered (0.45 μm) prior to injection into the HPLC system. Sucrose and reducing sugar contents in the reaction mixtures were monitored by a Waters HPLC system (Milford, MA) equipped with a 626 pump, a 600S controller, a 717plus autosampler, and a 2465 electrochemical detector. A Dionex CarboPac PA-1 anion exchange column (250 mm × 4 mm) with a Dionex CarboPac PA-1 guard column (50 mm length × 4 mm diameter) (Waltham, MA) was used to separate the sugars at 27 °C with 150 mM sodium hydroxide as the mobile phase (a flow rate of 1.0 mL/min). The samples were diluted 100-fold and filtered through 0.45 μm membrane disk filters prior to HPLC analysis.

The efficiency of the Fenton process on the degradation of CaA, *p*CoA, and FeA was determined individually on the basis of the change in absorbance of the corresponding HPLC peak using the following equation:

$$\text{CaA, } p\text{CoA, or FeA degradation (\%)} = \left(\frac{A_0 - A_t}{A_0}\right) \times 100 \quad (1)$$

where A_0 is the initial absorbance of HCA (mAU) (i.e., t = 0 min) and A_t is the absorbance of HCA (mAU) at the time the aliquot was taken (i.e., t = 2 min).

Experimental Design and Statistical Analysis. The design of the experiments, mathematical modeling, and optimization of process parameters were evaluated using the Stat-Ease Inc. Design-Expert 7.0.0 software package (Minneapolis, MN). A rotatable circumscribed CCD was used to evaluate the main effect for each condition and the possible interactive effects on the residual stresses between two variables. The process parameters (independent variables) used in this study are the initial total HCA concentration (A), the initial sucrose concentration (B), the solution pH (C), and the reaction temperature (D). The selected response factors (dependent variables) for optimization are CaA degradation (y_1, %), *p*CoA degradation (y_2, %), FeA degradation (y_3, %), and total HCA degradation (y_4, %). The coded and actual values of each variable and their levels for the experimental design used in the study are shown in Table 1. The ranges for each parameter were determined by preliminary experiments based on previous work by the authors[23] and were selected to closely mimic operating parameters during the processing of sugar cane juice for raw sugar manufacture. Concentrations of HCAs varied from 20 to 200 mg/L to mimic the range of HCA and phenolic compound concentrations in sugar cane juice, which depends on the season, region, and type of cane and the method of harvesting (e.g., burnt cane, green cane, whole crop cane).

Analysis of variance (ANOVA) was used for model adequacy and analysis of the experimental data. The quality of the fit polynomial model was expressed by the regression coefficient R^2, and its statistical significance was checked using Fisher's F test.

Evaluation of the Interactions between Fe(II) and HCAs. Studies were conducted to investigate the interaction between Fe(II) and each of the HCAs in the presence and absence of sucrose using UV/vis and attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectroscopy. Sodium acetate (100 mM) and acetic acid (100 mM) solutions were used to make buffer solutions having pH values of 4.0−6.0. For each analysis, predetermined amounts of buffer, sucrose, and $FeSO_4{\cdot}7H_2O$ were added to achieve a final HCA concentration of 5.50 mM. Samples were diluted to the desired concentration and immediately membrane disk filtered (0.45 μm) for analysis. The pH of each solution was checked before and after dilution. The UV/vis spectra were recorded on a PerkinElmer Lambda

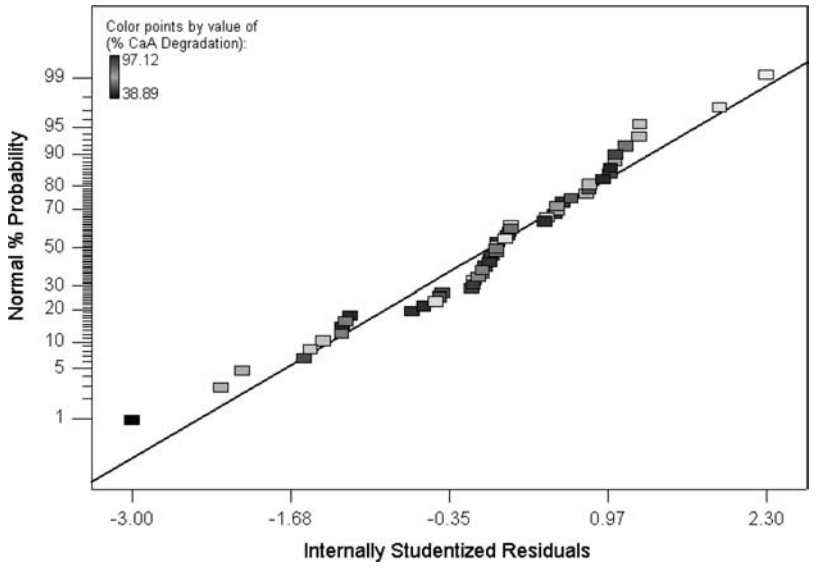

Figure 1. Normal probability plot of residuals for the fitted model using CaA degradation data before power transformation.

35 double-beam UV/vis spectrophotometer (Shelton, CT) using cells of 1.0 cm path length and at a wavelength range of 190−450 nm in 1.0 nm increments. Data acquisition was performed using the PerkinElmer UV WinLab (version 2.85.04) software package.

Infrared absorbance spectra were obtained using a Thermo Electron Nicolet Nexus 870 FT-IR instrument fitted with a deuterated triglycine sulfate (DTGS) detector (Madison, WI). Spectra were recorded over the 4000−650 cm^{-1} range at 4 cm^{-1} resolution for 64 scans with an optical path difference (OPD) velocity of 0.6329 cm/s. Data acquisition and processing was performed using the OMNIC 7.3 software package. The FTIR peaks were normalized with respect to the main peak at 1045 cm^{-1}.

A light brown precipitate was formed at pH ≥ 5 for all the acids with iron. No recoverable amount of precipitate was obtained at lower pH. This precipitate was filtered using a poly(vinyl chloride) (PVC) membrane filter (5 μm), and the retentate was analyzed by X-ray powder diffraction (XRD). Sample analysis was performed on a PANalytical X'Pert PRO multipurpose X-ray diffractometer (MPD) (Almelo, The Netherlands) using Cu Kα radiation (λ = 1.5406 Å) at 40 kV and 40 mA. Patterns were recorded in the 2θ range from 3.5° to 75° with a scan step size of 0.017° and a count time per step of 50 s. Data were acquired and processed using the X'Pert Data Collector 2.2 and MDI Jade 9.0 software packages, respectively.

RESULTS AND DISCUSSION

Optimal Data Transformation and Test for Normality. CCD and response surface methodology (RSM) were used to investigate the relationships between the response factors (dependent variables) and the process parameters (independent variables). To achieve this, an empirical second-order polynomial function for each response investigated with respect to the four process parameters was used to fit the experimental results obtained, as described in ref 26.

A normal probability plot of residuals based on the experimental data obtained for CaA degradation (Figure 1) indicates a nonlinear pattern in the middle of the trend line and short tails with the first and last few points showing increasing departure from the trend line. To address the nonlinearity of these plots, the Box−Cox power transformation was used to improve linearity. The power transformation on the predicted response can be described as follows:[27]

$$y^{\lambda} = \begin{cases} \dfrac{y^{\lambda} - 1}{\lambda} & \lambda \neq 0 \\ \ln(y) & \lambda = 0 \end{cases} \quad (2)$$

where λ indicates the power to which all data should be raised. The initial value of λ in the standard quadratic function (i.e., eq 2) is 1.00.

To determine the λ value for each response, a Box−Cox plot was used as a guide for the selection of the optimized λ value for the power transformation of the experimental data. Supplementary Figure 1 (Supporting Information) shows the Box−Cox plots for each response investigated. From the Box−Cox plots for the *p*CoA (Supplementary Figure 1b) and FeA (Supplementary Figure 1c) degradation data, the recommended λ values ranged from 0.70 to 2.40 and from 0.59 to 2.23, respectively, at a 95% confidence interval. On the other hand, the λ value range within the 95% confidence interval is not shown for CaA (Supplementary Figure 1) and total HCA (Supplementary Figure 1d) degradation data, due to the values being outside the λ = ±3.00 limits. Hence, the optimum λ values used to transform the CaA and total HCA degradation were both maximized at λ = 3.00. For *p*CoA and FeA degradation, the optimum λ values were determined by observing the minima of the curves, which were 1.56 and 1.43, respectively. Using the optimized λ values, the normal probability plot for each response surface model shown in Supplementary Figure 2 (Supporting Information) indicates improved linearity of data points. There are only a minimal number of data points deviating from the line of fit. The data for all fitted response surface models show good correspondence to a normal distribution and validate the normality assumption.

Regression Modeling and Statistical Analysis. On the basis of the sequential model sum of squares (type I), the power transformed response surface models for CaA (y_1), *p*CoA (y_2), FeA (y_3), and total HCA (y_4) degradation were selected on the basis of the highest order polynomial, where the additional model terms were significant and the models were not aliased. The data obtained for all four responses fit a quadratic polynomial function.

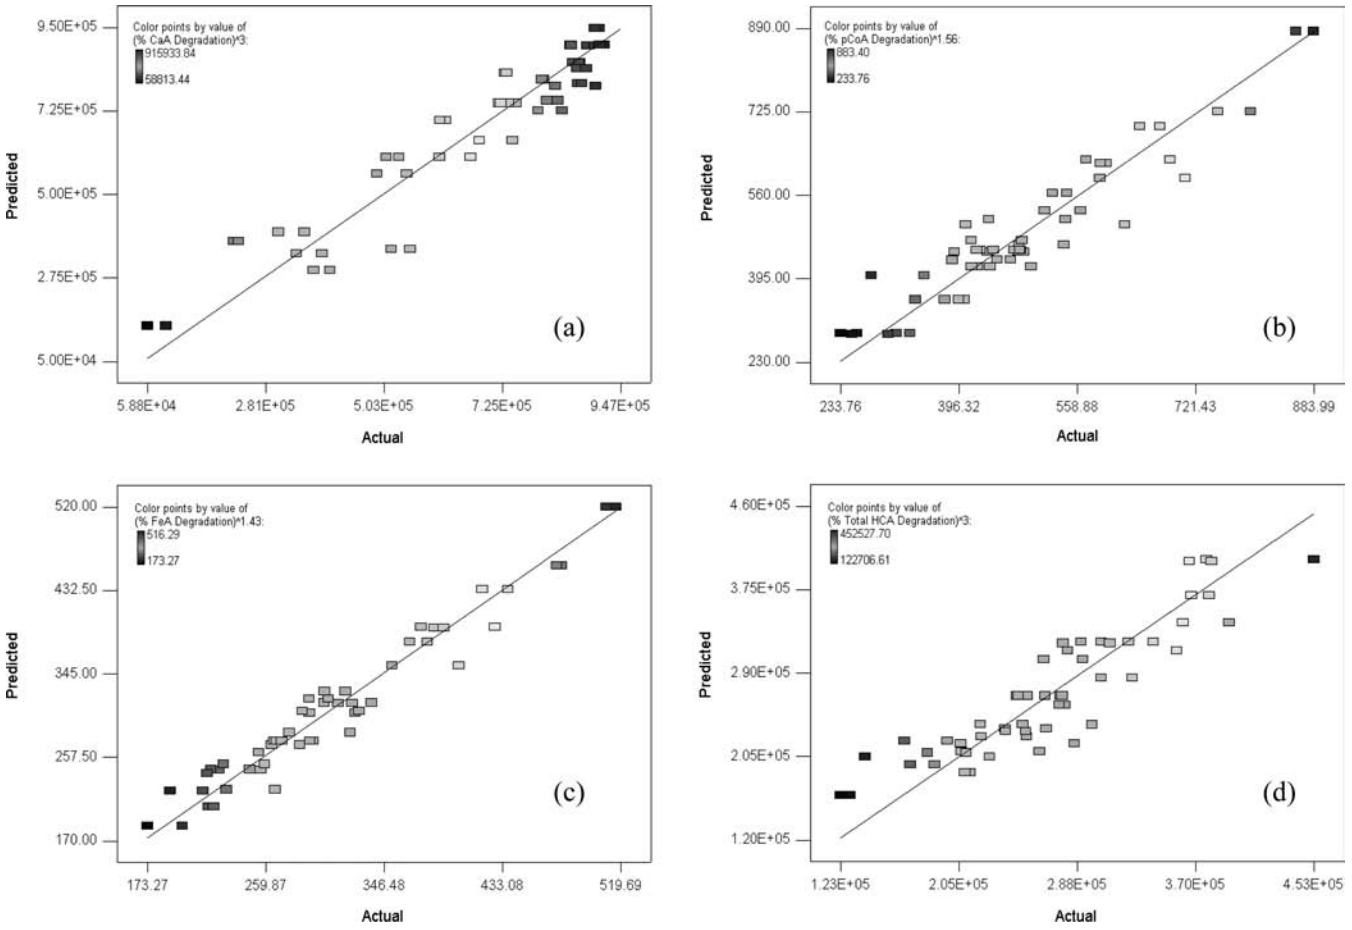

Figure 2. Predicted response and experimental (actual) values for the degradation (%) of (a) CaA, (b) *p*CoA, (c) FeA, and (d) total HCAs.

The ANOVA results for the partial sum of squares (type III) for the four response surface reduced quadratic models after stepwise regression are shown in Supplementary Table 1 (Supporting Information). The analysis indicates that most independent variables and some of the interactions are significant and contribute to the degradation of the HCAs. Model terms with a p value of <0.0500 are significant at the 95% confidence level. Values of >0.1000 indicate the model terms are insignificant at the 90% confidence level and are removed from the proposed models via stepwise regression, with the exception of the first-order temperature model term for all models. Temperature was regarded as statistically insignificant but was added to all models to make each model hierarchical. In other words, parent (i.e., first-order) model terms are added to the model to complete the family of any significant higher order (i.e., second-order) model terms.

The independent variables in the models were initial total HCA concentration, initial sucrose concentration, solution pH, and reaction temperature and were coded A, B, C, and D, respectively. The final empirical quadratic equations in terms of coded factors for each response are as follows:

CaA degradation (%)

$$y_1^{\,3} = 7.459 \times 10^5 - 22685.04A + 87649.64B - (1.893 \times 10^5)C - 2787.88D + 38875.43BC + 25613.66BD - 48866.47B^2 - 55229.82C^2 + 21771.66D^2 \quad (3)$$

*p*CoA degradation (%)

$$y_2^{\,1.56} = 452.03 - 25.39A - 112.96B + 56.46C - 9.29D + 25.34AB + 24.11CD + 51.51B^2 - 13.11C^2 \quad (4)$$

FeA degradation (%)

$$y_3^{\,1.43} = 274.79 - 14.82A - 69.60B + 25.99C - 3.36D + 24.97AB - 9.36BD + 6.34CD + 26.42B^2 + 9.46D^2 \quad (5)$$

total HCA degradation (%)

$$y_4^{\,3} = 2.670 \times 10^5 - 22911.69A - 49869.11B - 10752.76C - 4168.93D + 19018.79AB + 17344.68BC + 14113.81CD + 9351.73B^2 - 19861.54C^2 + 11289.82D^2 \quad (6)$$

The predicted R^2 values of all response surface models are in reasonable agreement with the adjusted R^2 values, which show that the fitted models are adequate. The accuracy of the models is shown in Figure 2, which compares the predicted responses against the experimental data. Reasonable linear relationships were obtained for predicting the degradation of *p*CoA and FeA (Figure 2b,c) but not CaA and total HCAs (Figure 2a,d), respectively. This may be related to complex formation as discussed in the section "Complex Formation".

DOI: 10.1021/jf504184u
J. Agric. Food Chem. 2015, 63, 1582−1592

On the basis of the coefficients of the first-order model terms in eqs 3−6, it is evident that the degradation efficiency of all HCAs decreases with the increase of the initial total HCA concentration (A). Sucrose concentration (B) is the most influential parameter with the highest coefficient in all equations and shows a negative influence on *p*CoA and FeA degradation but a positive influence on CaA degradation. Also, the degradation efficiency of *p*CoA and FeA increases with the solution pH (C), but the opposite is observed for CaA (refer to the section on complex formation). Temperature (D) has a negative effect on all responses, but its minuscule coefficient has little effect on the respective response. Hence, this model term is statistically insignificant and was only included in all of the equations to make the models hierarchical.

For the degradation of the mixture (i.e., the combined acids), there are strong interactions between total HCA concentration and sucrose concentration (AB), between sucrose concentration and pH (BC), and between pH and temperature (CD).

Perturbation Analysis. Perturbation plots were analyzed to further identify the most influential variables on the degradation of each HCA investigated in this study (Figure 3). Sucrose concentration and solution pH appeared to be the most influential parameters. Temperature showed an insignificant effect as expected, while the initial total HCA concentration exhibited a consistent effect for the degradation of each HCA.

As shown in Figure 3, the higher the initial total HCA concentration, the lower the amount of each HCA degraded. The reason behind the decrease in degradation efficiency is simply due to a higher uptake of $^{\bullet}$OH radicals by the increased amounts of HCA molecules.

The presence of sucrose significantly affected the degradation efficiency of the HCAs. The fate of sucrose during the degradation process was evaluated by high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD). The results showed up to 0.01% sucrose loss due to complete mineralization, as no glucose and/or fructose are detected. This is related to the effective scavenging ability of sucrose in removing $^{\bullet}$OH radicals[22] and accounts for the decrease in degradation efficiency with increasing sucrose concentration for *p*CoA and FeA (Figure 3b,c), but not for CaA (Figure 3a). The reason for the increased degradation efficiency of CaA with increasing sucrose concentration may be related, as will be shown in the next section, to a strong association between CaA and sucrose, which increased with increasing sucrose concentration, and precipitation of CaA out of solution.

Degradation of CaA decreases with increasing pH, whereas the opposite was observed for *p*CoA and FeA degradation. The reason for the results obtained with *p*CoA and FeA is not known but may be related to the various species that exist in the acid−base equilibria that influence the logarithmic acid dissociation constants (pK_a values) of these acids. The results obtained with CaA with increasing pH are again related to the precipitation of the latter as shown later.

Complex Formation. To obtain insights into the apparent differences in the behavior among the three HCAs, the UV/vis spectra of the individual acids, mixtures of each acid with Fe(II), and mixtures of each acid with Fe(II) and sucrose at pH 4.0−6.0 were obtained. The UV/vis spectra obtained with mixtures of FeA or mixtures of *p*CoA were not dissimilar compared to those of their corresponding acids. However, as Figure 4 shows, there is a significant difference between the

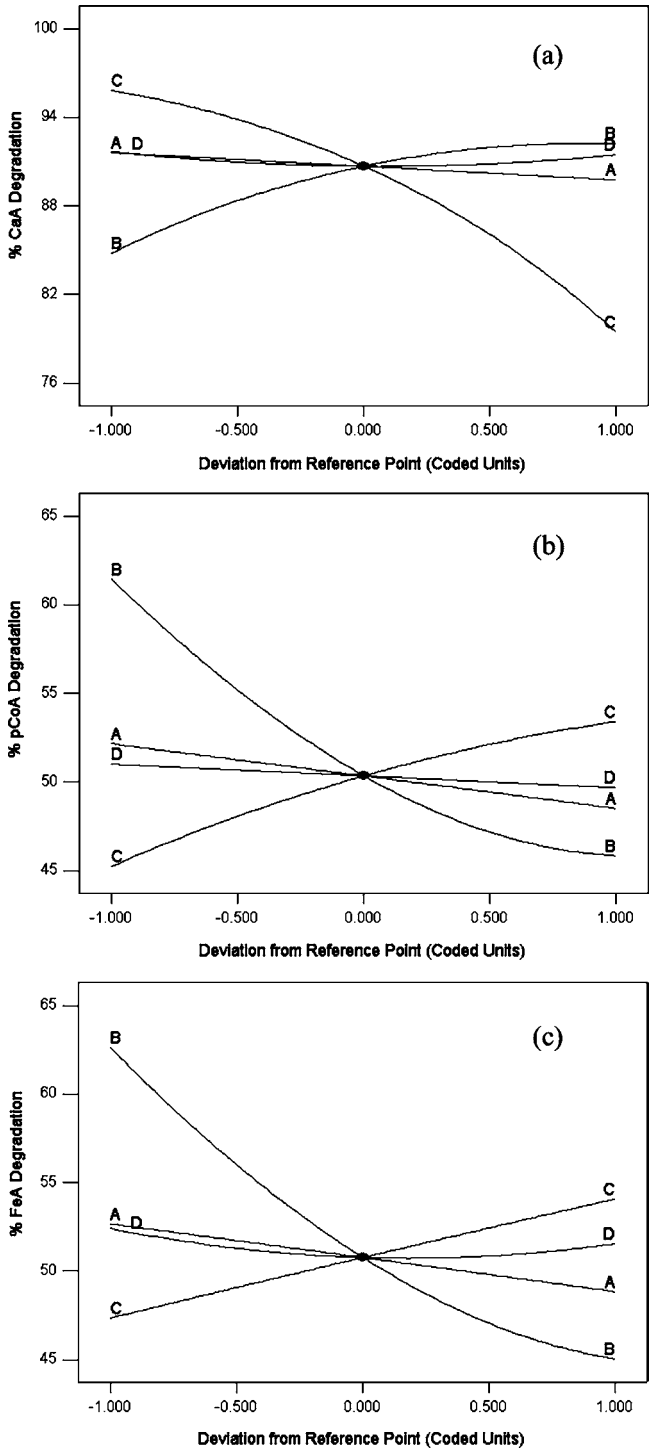

Figure 3. Perturbation plot for the degradation (%) of (a) CaA, (b) *p*CoA, and (c) FeA. Coded values are shown for each factor, total HCA concentration (A), sucrose concentration (B), pH (C), and temperature (D), and refer to actual values listed in Table 1.

spectra of CaA with Fe(II) and the spectra of CaA without Fe(II). In these acidic conditions, Fe(II) and Fe(III) will be present in equilibrium.[28] The change in the profile of the spectra is likely due to complexation between Fe(III) and CaA, as shown in the spectra obtained for Al(III)−CaA in aqueous acidic solutions by Cornard and co-workers.[29] In fact, Hynes and O'Coinceanainn[30] have reported the formation of a 1:1 complex between Fe(III) and CaA at pH between 1 and 2.5

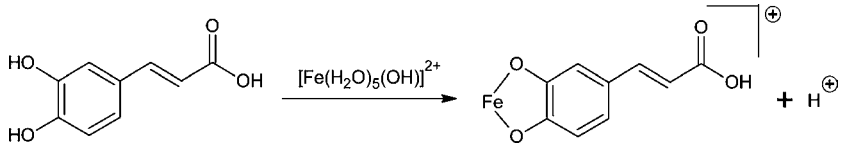
Scheme 1



(Scheme 1). Moreover, previous studies have shown the accelerated decomposition of H_2O_2 to $^{\bullet}OH$ radicals by Fe(III) complexes of analogous phenolic acids.[31]

There is a shape drop in peak intensities at pH ≥ 5 for CaA and Fe(III) mixtures (Figure 4b), likely associated with increased complex formation due to increasing amounts of caffeate ions with pH rise. As the pK_{a1} of CaA is 4.38, there is an increasing amount of deprotonation with increasing pH.[32] The drop in intensity may also be due to the removal of CaA by adsorption onto the iron precipitate formed under these pH conditions. The spectra of Figure 4b also show that there was no change in the shape of the curves with increasing pH, so it is probable that only one type of complex is formed between Fe(III) and CaA under the conditions investigated.

The CaA mixtures were further characterized using ATR-FTIR spectroscopy. From the FTIR data, a number of bands were used to monitor changes in CaA as a result of the presence of Fe(II) and the presence of Fe(II) and sucrose. The spectral bands of CaA and sucrose solutions and CaA mixtures containing Fe(II) or Fe(II) and sucrose are given in Table 2. Spectral bands were assigned on the basis of literature data for CaA,[33−36] similar phenolic acids,[37−40] and sucrose.[41−45] Bands attributable to aromatic ring vibrations are numbered using the Wilson notation adapted by Varsányi[46] The main differences between the spectrum of CaA and that of Fe(II)−CaA are shown in Figure 5. The $\nu(CC)_{ar}$ aromatic bands (i.e., 8a and 19a) that occur at 1554 and 1483 cm^{-1} [36] are of increased intensity in the Fe(II)−CaA mixture compared to CaA (Figure 5). The peak at ∼1386 cm^{-1} associated with $\nu(CC) + \beta(OH)_{ar}$ (i.e., 14)[36] is also of higher intensity in the spectrum containing both Fe(II) and CaA. These increases in intensity may be attributed to complex formation between the aromatic −OH group in CaA and Fe(III).[39] The peak at 1275 cm^{-1} attributable to ν(C−OH) for CaA[35,47] has shifted to a lower wavelength of 1265 cm^{-1} with an increase in intensity. This is a further confirmation of a strong association between Fe(III) and CaA and that the complex formed is between Fe(III) and the phenolic hydroxyl group.[30,31] There was no change in the band at 1672 cm^{-1} associated with ν(C═O), implying no evidence of Fe(III) bonding to the carboxylic acid group of CaA. Previous works have shown that, with other phenolic acids, linkages are formed with their carboxylic acid groups.[37−39]

[a]Symbols are denoted as follows: ν, stretching vibrations; β, in-plane bending modes; γ, out-of-plane bending modes.

The spectra for CaA, Fe(II), and sucrose (Figure 6) show that the broad band that occurs at 3495 cm^{-1} [ν(OH)][45] which is associated with sucrose has shifted by 94 cm^{-1} to a lower wavenumber of 3401 cm^{-1}. This implies hydrogen-bonding interactions between CaA, Fe(III), and sucrose and could well explain why CaA degradation increases with increasing sucrose concentration.[48] These interactions provide supporting evidence of the differences in the degradation behavior of CaA and the other two HCAs (viz., *p*CoA and FeA). It is also probable that sucrose−Fe(III)−CaA complex formation may result in the coprecipitation of CaA, causing its reduction in the system, and not due to its oxidation. As reported in the next section, XRD data showed the coprecipitation of CaA.

Response Surface Analysis. Graphical representations of the regression model in the form of three-dimensional surface plots were used to provide a pictorial view of the interactions between the independent variables on total HCA degradation. These plots are shown in Figure 7, where two independent variables were varied within the experimental ranges investigated while the remaining variables were kept constant. The interactions are significant as the curvature of the surfaces is obvious.

The variables of sucrose concentration and initial total HCA concentration were varied as shown in Figure 7a, while the other variables, namely, pH and temperature, were kept constant at 5.0 and 35 °C, respectively. These fixed values were chosen as they were similar to those typical of process sugar cane juice.[23] The total HCA degradation efficiency decreases with increasing sucrose concentration and the initial total HCA concentration. Increasing the initial total HCA concentration did not significantly decrease the degradation efficiency of the HCAs. This can be seen both by the coefficient of the first- and second-order model terms (eq 6) for total HCA concentration (i.e., A) and in Figure 7a where there was only a 5.9% discrepancy between 65 and 155 mg/L initial total HCA at 3.75 mass % sucrose. This discrepancy is not noticeable

at higher sucrose concentrations. It can be said from these observations that the optimal Fenton dosage is capable of degrading higher concentrations of HCAs and other components (similar to that of HCAs) than at the highest concentration studied (i.e., >200 mg/L).

Sucrose concentration showed a significant effect on the degradation of the HCAs (Figure 7b). Degradation increases smoothly with an increase in pH from 4.75 to 5.0 but decreases gradually when the pH exceeds 5.0 at any given concentration of sucrose. The negative effect on total HCA degradation at lower pH than the optimal may be attributed to the scavenging effect of H^+ or $^\bullet OH$ radicals, which can inhibit the reduction of Fe(III) to Fe(II) and prevent the further generation of $^\bullet OH$ radicals.[49,50] On the other hand, the negative effect at pH above the optimal may be attributable to the deactivation of the Fe(II) catalyst with the formation of iron(III) oxyhydroxide in lieu of being regenerated back to Fe(II).[51] The formation of iron(III) oxyhydroxides in the present study was confirmed by analyzing the precipitates obtained at pH 5.5 and 25 °C by XRD (Table 3). The *d* spacing values 6.21, 3.28, 2.46, and 2.36 Å correspond to lepidocrocite (i.e., iron(III) oxide hydroxide), FeO(OH), while the peaks at 5.20 and 2.04 Å are associated with CaA.[52] The formation of oxyhydroxide is derived from the following reaction equation:

$$Fe^{2+} + {}^1/_4O_2 + 2OH^- \rightarrow FeOOH + {}^1/_2H_2O \quad (7)$$

Figure 7c shows the interaction effects of pH and temperature on HCA degradation. The nonsignificance of the temperature variable is evident by the narrow range on the response axis (i.e., 57−64%). Despite this, the degradation trend on the HCAs in terms of temperature is still observable. Increasing temperature leads to less degradation of the HCAs. The decomposition of H_2O_2 by Fe(II) is not directly linked to the amount of HCA degraded. In addition to the formation of $^\bullet OH$ radicals by the Fenton process, nonreactive species such as H_2O and O_2 are also formed at higher temperatures (>40 °C).[53] The Fenton process was the only contributor to the degradation of HCAs as there was no thermal decomposition of any of the HCAs within the temperature range studied (25−50 °C).

Process Optimization and Model Validation. Numerical optimization was performed on the basis of the desirability function to determine the optimum process parameters for the degradation of the HCAs. The desirability function is expressed numerically from a scale of 0−1 (lowest to highest desirability) and denotes the degree of importance in obtaining the desired response value.[54] A desirability function value can be constructed by using five different goal optimization constraints: none, maximum, minimum, target, and within range. On the basis of the fitted quadratic models, an optimized response value can then be predicted by using the chosen goal optimization criteria that maximize the desirability function. To simultaneously optimize numerous responses (i.e., multi-response optimization), the desirability function values for each response (i.e., CaA, *p*CoA, and FeA) are combined into an overall desirability function by computing their geometric mean of different desirability values, as shown in the following equation:[55]

$$D = (d_1 d_2 d_3 ... d_n)^{1/n} = \left(\prod_{i=1}^{n} d_1\right)^{1/n} \quad (8)$$

where D is the overall desirability function, d_i is the desirability of the response, and n is the number of responses investigated.

To confirm the accuracy and robustness of the predicted models and assess their reliability to predict the degradation (%) of HCAs, additional experiments were carried out under those conditions, as well as selected conditions of process streams close to that of a typical Australian sugar mill.

For this study, the desirability functions for the three individual HCA degradation models were combined into one value and compared to the desirability function of the total HCA model (Table 4). The combined desirability function

DOI: 10.1021/jf504184u
J. Agric. Food Chem. 2015, 63, 1582−1592

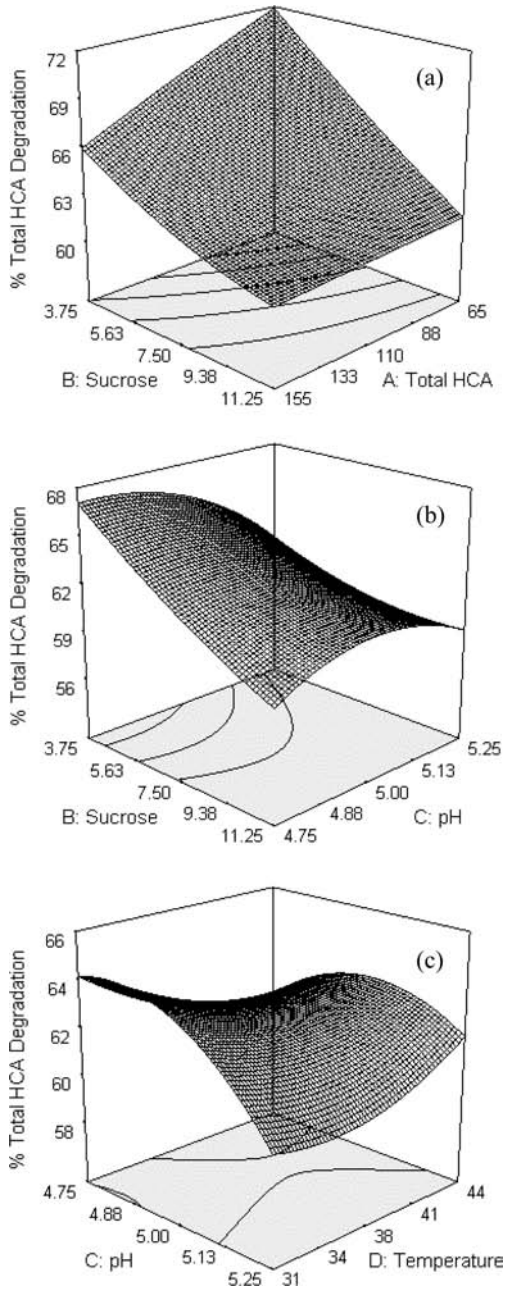

Figure 7. Three-dimensional surface plots of total HCA degradation (%) as a function of (a) total HCA and sucrose concentrations, (b) sucrose concentration and pH, and (c) pH and temperature (bottom). Variables: total HCA concentration (155 mg/L), sucrose concentration (7.5 mass %), pH (5.0), and temperature (35 °C).

values of the three individual HCA models for the experiments were relatively close to the desirability values produced for the single total HCA degradation model. This indicates that there is little variation between the simultaneously predicted values of each HCA degraded and the predicted value for the total HCAs degraded.

Table 4 shows the experimental and predicted (in parentheses) values for the degradation of each HCA and the total HCAs under specified constraints. The optimum conditions for maximum degradation of HCAs (200 mg/L) using the Fenton process (2.49 mM $FeSO_4 \cdot 7H_2O$ and 7.5 mM H_2O_2) are 0 mass % sucrose (i.e., aqueous), pH 4.73, and 25.15 °C. Under these conditions 92% CaA, 69% *p*CoA, and 70% FeA (total degradation of 77%) were degraded. The experimental values of the optimum conditions agree well with the predicted values deduced from each of the four models. The low error in the experimental and predicted values indicates good agreement of the results. The experimental values obtained for the worst conditions were also in good agreement with the predicted values. The good agreement between values is attributable to the high combined desirability function value. It is worth mentioning that the sum of the predicted degradation values of the individual HCA degradation models (i.e., CaA, *p*CoA, and FeA) is not equal to the predicted total HCA degradation value. Hence, the individual degradation models should only be used as a guide to predict the degradation of the total HCAs present in a mixture.

The best results for the synthetic juices are obtained with solutions having sucrose contents and operating temperatures similar to those of factory-mixed juice (synthetic juice 1) followed by factory no. 1 mill juice (i.e., juice expressed from the first mill of a quintuple set of mills) (synthetic juice 2). Despite a low desirability function value predicted under the synthetic juice 1 conditions, the experimental results were in close agreement with the predicted values for all four models. The lower desirability may be due to some of the constraints not being close to any of the design points of the CCD. On the other hand, a higher error was observed for synthetic juice 2, despite a reasonable desirability value. In addition, the experimental values obtained for *p*CoA and FeA degradation were significantly lower than the predicted values. Then again, the calculated total HCA degradation (76%) based on the predicted degradation values of CaA (68%), *p*CoA (75%), and FeA (84%) degradation models is higher than the model-predicted total HCA degradation (67%). It is highly probable therefore that the presence of sucrose may have contributed to the inaccuracy of this prediction as its concentration was outside the range used to develop the proposed models. Therefore, it is not recommended to use constraints outside the ranges studied for multiresponse optimization, as the responses are all dependent on each other.

From these results, the Fenton process can successfully be used to degrade HCAs (i.e., color precursor compounds) in a raw sugar manufacturing factory, as minimum sucrose breakdown occurred. However, the effectiveness of the Fenton process will be expected to be dependent on the type of sugar cane cultivar, harvesting conditions, cane maturity, and location. This is also because the proportion and ratio of free and conjugated phenolics will influence degradation. Despite this, the Fenton process will be particularly useful in processing juice expressed from the whole sugar cane biomass (instead of the stalk) because of the prevalence of color precursors in such

Table 4. Optimized Conditions under Specified Constraints for the Degradation of Total HCAs (200 mg/L) and Model Verification

				degradation[a] (%)				desirability	
experiment	sucrose concn (mass%)	pH	T (°C)	CaA	*p*CoA	FeA	total HCAs	combined	total HCAs
water	0	4.73	25.15	92 (90)	69 (68)	70 (64)	77 (73)	0.720	0.743
worst case	14.47	4.52	39.68	87 (90)	33 (37)	40 (46)	53 (49)	0.542	0.632
synthetic juice 1	13.00	5.39	35.98	73 (72)	48 (52)	51 (56)	57 (58)	0.383	0.332
synthetic juice 2	21.00	4.86	29.97	78 (68)	52 (75)	54 (84)	61 (67)	0.655	0.621

[a]Values in parentheses indicate the model-predicted degradation (%) of each individual HCA/total HCAs. Measurements were conducted in triplicate. The RSD was <5.0%.

juice types. As the sugar cane industry around the world is looking toward diversification by value-adding with the excess biomass produced from whole crop processing, the use of the Fenton or similar processes will allow juice expressed from the whole sugar cane plant to be cost-effectively processed. The advantages of the use of the Fenton process in the sugar manufacturing process include its simplicity, its nonspecific oxidation property, and the use of inexpensive equipment. Also, the sludge that is produced has the potential to remove colorants and other impurities (including proteins and polysaccharides), improving the quality of the juice feedstock.

traditional and alternative oak maturation regimens on the composition, sensory properties, quality, and consumer acceptability of wine. The knowledge gained from this study can be used by wine producers to both inform and justify their use of oak alternatives, in particular for the production of wines at certain price points and/or targeted toward specific segments of the wine market.

MATERIALS AND METHODS

Oak Maturation Trials. Two South Australian Cabernet Sauvignon wines were sourced from industry-based trials, involving a range of different oak maturation regimens (Table 1). Trial 1 involved a 12 month maturation of a 2009 Padthaway Cabernet Sauvignon in four types of 900 L Stakvats (Ausvat Pty. Ltd., Willunga, Australia), being (i) stainless steel, hereafter referred to as "SSVAT"; (ii) stainless steel with two 4.5 mm high-density polyethylene (HDPE) panels, hereafter referred to as "P1VAT"; (iii) stainless steel with two 1.5 mm HDPE panels, hereafter referred to as "P2VAT"; and (iv) stainless steel with two French oak wood panels, hereafter referred to as "FOVAT". French oak chips (medium toast) sourced from the same batch of oak wood were inserted in each of the stainless steel and plastic Stakvats (SSVAT, P1VAT, P2VAT), but not the oak-sided Stakvat (FOVAT), at a rate of 2 g/L. Trial 2 involved a 4 month maturation of a 2011 Eden Valley Cabernet Sauvignon in four different vessels, being (i) 1000 L plastic tanks with oxygen ingress of 17 mg O_2/L/year, hereafter referred to as "P1"; (ii) 1000 L plastic tanks with oxygen ingress of 12.6 mg O_2/L/year, hereafter referred to as "P2"; (iii) 4550 L stainless steel tanks, hereafter referred to as "SS"; and (iv) a combination of new, 1- and 2-year-old French oak barrels (medium plus toast), which were blended after maturation, hereafter referred to as "barrel". Maturation in plastic and stainless steel tanks comprised treatments with and without the addition of French oak staves (medium toast), sourced from the same batch of oak wood (hereafter designated "+ OAK" and "− OAK", respectively). Staves were added to achieve an area-to-volume ratio of 1.4 m^2/kL.

Following completion of each maturation trial, wines were bottled (using 750 mL bottles fitted with metal screw-cap closures for trial 1 and 375 mL bottles fitted with plastic screw-cap closures for trial 2) and stored at 15 °C prior to sensory and chemical analysis. Trial 1 wines were bottle aged for 3 years prior to analysis, whereas trial 2 wines were analyzed approximately 4 months after bottling.

Chemical Analysis of Wine. Wines were analyzed (in duplicate) to determine pH, titratable acidity (TA, as tartaric acid equivalents to an end point of pH 8.2), volatile acidity (VA, as acetic acid equivalents to an end point of pH 8.2), free and total SO_2 content (by the aspiration method), wine color density, and total phenolics, according to methods described previously.[19] Glucose and fructose concentrations were determined enzymatically (Boehringer-Mannheim/R-BioPharm, Darmstadt, Germany). Ethanol content (as % alcohol by volume) was measured with an alcolyzer (Anton Paar, Graz, Austria). Oak volatiles were quantified by gas chromatography−mass spectrometry (GC-MS) using stable isotope dilution analysis (SIDA) methods reported previously.[20−22] These publications describe the preparation of deuterated internal standards, method validation, and instrumental operating conditions. Analysis of oak volatiles was performed by the Australian Wine Research Institute (AWRI) Commercial Services Laboratory using an Agilent 6890 gas chromatograph coupled to a 5973 mass selective detector.

Sensory Analysis of Wine. Wines were equilibrated at 21 °C for 24 h prior to each sensory experiment. Wines were assigned a random three-digit code for descriptive analysis (DA), expert and consumer sensory assessments. Wine aliquots (30 mL) were presented in covered Viticole XL5 (ISO standard) 215 mL stemmed wine tasting glasses, using a randomized presentation order.

Descriptive Analysis. DA was undertaken using a panel comprising 10 University of Adelaide staff and students (seven females, three males). Panelists were recruited on the basis of their availability and previous participation on DA panels involving analysis of red wine. Prior to formal assessment, panelists underwent 9 h of training (comprising 6 × 1.5 h sessions held over 6 weeks) involving detection, identification, evaluation, and intensity rating of red wine aroma and palate (i.e., flavor, taste and mouthfeel) attributes. During the training sessions, the panel evaluated each wine at least twice, to generate appropriate aroma and palate terms and to gain familiarity in recognizing and scoring their intensity, according to previously published protocols.[23] The training sessions also included three practice evaluation sessions conducted in sensory booths, under the conditions used during formal assessment. Data were evaluated after each practice evaluation to assess panelist-by-sample interactions, to determine when formal assessment should commence. The panel agreed upon 15 aroma attributes and 16 palate attributes; when reference standards were used, their preparation is shown in Table 2. Because panelists were unable to perceive any differences in wine color, appearance was not evaluated. Three formal assessment sessions were held, with all 11 wines presented in each session, such that all wines were assessed in triplicate. Panelists assessed each wine in an isolated tasting booth at 22−23 °C under red lights, with a light temperature of 6500 K, and rated the intensity of each sensory

Table 2. Reference Standards Used in Descriptive Analysis of Cabernet Sauvignon Wines after Oak Maturation

descriptor[a]	reference standard
red fruit	two McCain frozen raspberries and one fresh strawberry
confectionary	$^1/_2$ Allens strawberries and cream lolly + 0.5 cm piece Coles banana lolly
dark fruit	two McCain frozen blackberries and two McCain frozen blueberries
herbaceous	0.5 cm cube of green capsicum, two small tomato plant leaves
mint/menthol	$^1/_2$ tsp eucalyptus solution (1 drop of eucalyptus oil (Bosisto's, Australia) in 2 L of water)
dusty[b]	3 cm square of Hessian, 3 sticks of white chalk crushed
earthy	1 tsp wet earth with moss
charry	1 tsp 4-ethylguaiacol solution (1 drop of 4-ethylguaiacol in 50 mL of water) and 2 tsp of oak solution (medium-toasted American oak wood (Oak Chips Inc., Waverly, OH, USA) prepared in 10% ethanol)
leather[b]	3 cm × 10 cm piece of leather
mocha	1 tsp of mocha solution (100 g of 70% Lindt chocolate + 20 coffee beans in 250 mL of water)
licorice	0.5 cm piece of Darrell Lea licorice
sweet oak	$^1/_8$ tsp of vanillin powder (Sigma-Aldrich) + $^1/_2$ tsp of oak solution
spice	$^1/_4$ tsp of McKenzie's mixed spice + $^1/_4$ tsp of freshly ground black pepper + 3 cloves
woody[b]	1 cm × 9 cm × 0.5 cm untoasted French oak wood (Oak Chips Inc.) + $^1/_2$ tsp of pencil shavings

[a]Samples prepared in 30 mL of Cabernet Sauvignon cask wine, unless otherwise stated. [b]Denotes samples that were prepared dry.

descriptor using a 15 cm unstructured line scale with anchor points of "low" and "high" placed at 10 and 90% on the scale, respectively. Sensory reference standards (Table 2) were developed during training sessions and provided to panelists at each formal assessment session in covered, opaque black glasses. Panelists were required to reacquaint themselves with the sensory reference standards and written definitions of attributes several times during each evaluation. Distilled water and crackers were provided as palate cleansers, and panelists were required to have a 1 min break between samples and a 5 min break every three samples. Sensory data were collected using FIZZ software (version 2.47b, Biosystemes, Couternon, France).

Consumer Acceptance and Expert Panel Testing. On the basis of the outcomes of DA, five wines (barrel, SS + OAK, P1 + OAK, P1 − OAK, and P2VAT), with distinct sensory profiles were selected for consumer acceptance and expert panel testing. Consumer acceptability tests were carried out in a sensory laboratory at a central location, with each participant assigned a random "taster" number and allocated to an individual booth. Participants were recruited using a variety of methods, including social networking sites (e.g., Facebook, LinkedIn, Twitter), distribution of a flyer (via a mailbox drop within a 6 km radius of the University of Adelaide's Waite campus, and distribution at local wine retail outlets) and e-mail. Participants were screened against inclusion criteria requiring consumption of red wine at least once a month and being of legal drinking age (i.e., ≥18 years of age); exclusion criteria precluded participation by wine industry professionals and university staff and students. One hundred and sixteen consumers were recruited and acceptability tests were performed in October 2012, approximately 3 months after DA was completed. Consumers were asked to rate their hedonic liking of each wine using a 9-point scale with anchors from 1 (dislike extremely) to 9 (like extremely). Prior to evaluation of wines, consumers were instructed on how to assess the wine and use the hedonic scale. Coded samples were presented monadically with consumers signaling the researchers for their next sample using a switch in the sensory booth. Crackers and distilled water were provided as palate cleansers. After wines were evaluated, consumers answered demographic questions regarding gender, age, education, household income, and wine consumption. Consumers also indicated their average spend per bottle of wine for home consumption.

The expert panel comprised 10 wine industry personnel (9 males and 1 female), who met the criteria of "expert" defined by Parr and co-workers.[24] Each panelist assessed 10 wines, that is, the subset of 5 wines in duplicate. Participants were asked to assess each wine according to the 20-point scoring system used in Australian wine show judging[25] and to provide informal comments describing what they liked or disliked about each wine. Tasting was conducted 4 months after consumer acceptability testing in an open-plan tasting room at a winery in the Barossa Valley.

Data Analysis. Data were analyzed using Senpaq v5.01 (Qi Statistics, 2012) and XLSTAT 2013.1.01 (Addinsoft, 2012). Consumer acceptance data were analyzed using a combination of descriptive and multivariate techniques, including analysis of variance (ANOVA) with post hoc Tukey's test, partial least-squares regression (PLSR), internal preference mapping, and principal component analysis (PCA). Hedonic clusters were identified using cluster analysis.

RESULTS AND DISCUSSION

Cabernet Sauvignon wines (a 2009 Padthaway and a 2011 Eden Valley) were matured using a range of traditional and/or alternative oak maturation regimens (Table 1). Various chemical and sensory analyses were subsequently performed to compare the influence of each maturation regimen on the composition, sensory properties, quality and consumer acceptability of wines.

Influence of Oak Maturation Regimen on Chemical Composition of Wine. The wine color density, wine hue, total phenolics, alcohol content, pH, TA and VA of wines are reported in Table 3. Wines from trial 1 (i.e., 2009 Padthaway wines) had slightly lower pH, TA and VA and slightly higher alcohol content than wines from trial 2 (i.e., 2011 Eden Valley wines). There were no meaningful differences between the basic wine parameters of trial 1 wines, but trial 2 wines showed greater variation, in particular for wine color density and phenolic content, which ranged from 9.7 to 10.2 and from 51 to 57 au, respectively. Increased phenolic content can influence the perception of astringency by enhancing the drying sensation,[26] but the relatively small differences observed

[a]Values are mean scores from one wine replicate (per treatment) presented to 10 judges in three replicate sessions. Means within a row (per trial) followed by different letters are significantly different (P = 0.05, one way ANOVA, Tukey's LSD post hoc). [b]A, aroma attribute; P, palate attribute.

between phenolic measurements obtained in the current study (i.e., 5−10%) would not be expected to lead to perceptible sensory differences.

Similar concentrations of oak volatiles were observed in each of the trial 1 wines, albeit SSVAT wines contained significantly lower levels of vanillin than the other wines from trial 1 (Table 4). Of the oak volatiles measured, only *cis*-oak lactone and eugenol occurred at concentrations above their detection thresholds, of 23 and 5 μg/L, respectively.[27,28] More significant differences were observed between trial 2 wines. Wines aged using maturation regimens without the addition of oak wood (i.e., SS − OAK, P1 − OAK, and P2 − OAK) contained low or undetectable (<1 μg/L) levels of oak volatiles, as expected. The barrel-aged wine contained the highest concentrations of *cis*- and *trans*-oak lactones (99 and 79 μg/L respectively), but comparatively lower levels of other oak-derived volatiles. The maturation regimens involving addition of oak staves yielded similar oak volatile concentrations, albeit P1 + OAK wines contained extremely low levels of furfural and 5-methylfurfural (i.e., <100 μg/L) compared to SS + OAK and P2 + OAK wines (which contained >1800 μg/L) and even the unoaked wines. Again, *cis*-oak lactone was detected (in oaked wines) at concentrations above its detection threshold. The guaiacol and vanillin levels of trial 2 wines aged using alternative oak maturation regimens also exceeded threshold concentrations, being 10 and 200 μg/L, respectively.[28]

DOI: 10.1021/jf5044025
J. Agric. Food Chem. 2015, 63, 1593−1600

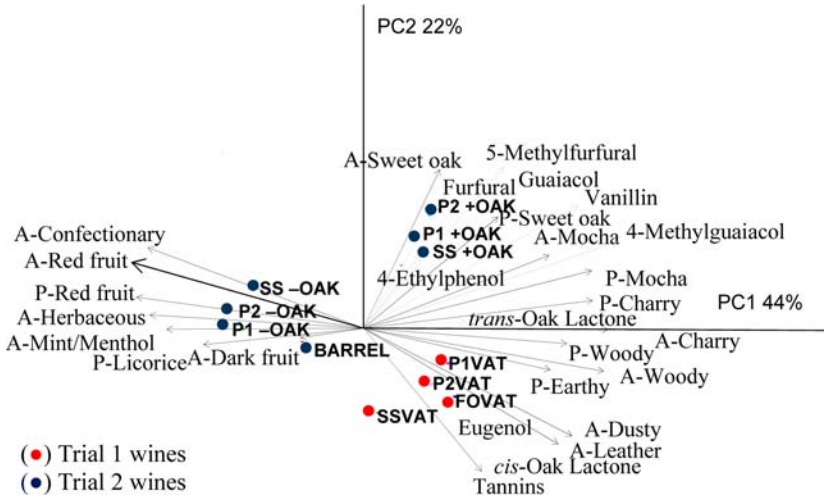

Figure 1. PCA biplot of oak volatile concentrations and sensory attribute ratings for Cabernet Sauvignon wines after oak maturation.

The differences observed between the oak volatile profiles of wines from trial 1 compared to those from trial 2 likely reflect differences in oak composition, in agreement with previous studies.[29−31] Interestingly, the oak wood used in trial 1 yielded a considerably higher proportion of *cis*-oak lactone (i.e., approximately 4-fold higher levels) than *trans*-oak lactone, whereas the oak used in trial 2 gave approximately equal concentrations of each isomer. Compositional differences can also be attributed to differences in the rate of oak addition, the surface area available for extraction, and the duration of oak maturation. Surprisingly, meaningful differences in wine color, phenolic and oak volatile profiles were not observed for the different maturation regimens, even when oxygen ingress varied considerably (Table 1).

Influence of Oak Maturation Regimen on Sensory Properties of Wine. ANOVA was performed on the DA data, and 19 of 31 attributes were found to significantly differentiate ($P < 0.05$) wines within each trial (Table 5).

Wines from trial 1 were generally rated higher in *dusty*, *charry*, *leather*, and *woody* characters than trial 2 wines, with FOVAT receiving the highest ratings for *charry* and *leather* aromas. Similar ratings were given to varietal attributes, that is, *red fruit*, *dark fruit*, and *herbaceous* attributes. That wines from this trial were perceived to be more complex, that is, to exhibit more intense oak- and age-related sensory attributes, reflects the extended period of oak maturation (12 months) and bottle aging (24 months) prior to sensory analysis. The duration of oak maturation directly influences the concentration of volatiles extracted from oak wood into wine,[32] but biochemical reactions continue to occur, for example, the conversion of furanic aldehydes into their corresponding alcohols.[33,34] This likely explains the lower levels of furfural (i.e., approximately 120 μg/L) and the absence of 5-methylfurfural observed in trial 1 wines, compared to trial 2 wines, in particular SS + OAK and P2 + OAK (Table 4).

The unoaked wines from trial 2 received similar ratings for most attributes and tended to exhibit more intense varietal characteristics, for example, *red fruit*, *dark fruit*, *herbaceous*, and *mint/menthol* attributes, than the oaked wines; the prominence of varietal characters is due to the absence of oak influence. Of the oak-treated wines, the barrel-aged wine received the lowest scores for most oak-related attributes, which was not surprising given the low levels of oak volatiles observed in this wine. The ratings for oak attributes in the barrel wine more closely resembled scores given to the unoaked wines, and instead, the barrel wine displayed more intense *red fruit* and *mint/menthol* aromas and *red fruit* on the palate. P1 + OAK exhibited the highest *charry*, *mocha*, *sweet oak*, and *woody* aromas and *charry*, *licorice* flavor, whereas P2 + OAK displayed *leather* and *sweet oak* on the palate. Previous studies have investigated the impact of micro-oxygenation (MOX) on wine sensory attributes, including the development of aged notes in MOX wines. For example, Cejudo-Bastante and colleagues observed an increase in nutty, tobacco, and spice notes in MOX-treated wines compared to wines stored in stainless steel tanks without oxygen addition.[35] Several of the maturation regimens used in trial 2 deliberately enabled oxygen ingress (Table 1), but the resulting wines did not exhibit overly apparent aged notes.

PCA was performed on the mean intensity ratings obtained for the sensory attributes that were perceived to be significantly different across the two trials (Figure 1), with PC1 and PC2 accounting for 44 and 22% of variation between wines, respectively. Clear separation was observed between oaked wines, which were predominantly located in the right quadrants, and unoaked wines, which were located in the left quadrants. The barrel-aged wine was located in close proximity to the unoaked wines, which again was not surprising given its relatively low levels of oak volatiles (Table 4). PC1 suggests separation of oaked and unoaked wines is primarily driven by the intensity of varietal (i.e., *fruit/green*) versus oak-related sensory attributes. Discrimination of trial 1 and 2 wines was also observed, with wines aged in vats clustered together in the bottom right quadrant and wines aged in stainless steel or plastic tanks (containing oak) clustered in the top right quadrant. Trial 1 wines were in part differentiated on the basis of *dusty* and *leather* aromas, which reflect the increased age of these wines. SS + OAK, P1 + OAK, and P2 + OAK each contained higher levels of vanillin (being 242−313 μg/L) than trial 1 wines (Table 4). These concentrations exceed the detection threshold reported for vanillin in red wine, that is, 200 μg/L.[28] Vanillin might therefore contribute to the *sweet oak* and *mocha* attributes that helped differentiate these wines. Differentiation of trial 1 and 2 wines may also have been influenced by guaiacol, *cis*-oak lactone, and eugenol, that is, the other volatiles observed in selected wines at concentrations above their threshold levels (Table 4).

J. Agric. Food Chem. 2015, 63, 1593−1600

Influence of Oak Maturation Regimen on Quality and Consumer Acceptance of Wines. A subset of five wines was selected for quality and acceptability ratings by wine experts and consumers, respectively. The expert panel used a 20-point scoring system to rate wine quality (Table 6); mean scores ranged from 13.8 (for the barrel-aged wines) to 14.8 (for P1 − OAK), which indicates all wines were technically sound. The experts informally described the unoaked sample as having "*varietal characters, fresh cherry nose, forest fruits, confectionary*" but "*lacking complexity and palate length*". The barrel-aged wine was considered to display "*dull, manufactured oak*" and "*lack fruit intensity*". P2VAT was described as "*savory, chocolate, dusty, earthy, lacking fruit flavor*" with "*softer tannins*" and "*more complex than the other wines*". In general, these comments were in good agreement with DA results.

Table 6. Consumer Liking and Expert Quality Ratings for Selected Cabernet Sauvignon Wines after Oak Maturation[a]

	hedonic ratings[b]				quality ratings[b]
treatment	total sample (n = 116)	cluster 1 (n = 35)	cluster 2 (n = 55)	cluster 3 (n = 26)	wine experts (n = 10)
barrel	5.7	5.11 b	6.35 a	4.85 b	13.75
SS + OAK	5.8	4.49 b	6.45 a	6.12 a	14.42
P1 − OAK	5.9	4.31 b	6.60 a	6.23 a	14.82
P1 + OAK	5.9	3.91 b	6.73 a	6.58 a	13.92
P2VAT	5.9	5.80 b	7.00 a	3.42 c	14.65

[a]Means within a row followed by different letters are significantly different (P = 0.05, one-way ANOVA, Tukey's LSD post hoc). [b]Hedonic ratings were determined using a 9-point scale and quality ratings using a 20-point scoring system.

One hundred and sixteen consumers participated in the acceptance test, and their demographic data are reported in Table 7. A similar proportion of male and female participants and a relatively even distribution of ages were achieved. Most consumers were regular wine drinkers and consumed wine at least once per week (i.e., 86%). There were no significant differences in the hedonic ratings given by the consumer cohort for the five wines (Table 6), with mean scores ranging from 5.7 to 5.9. However, as in previous research,[17] disparity in consumers' wine preferences was observed, and cluster analysis based on individual hedonic scores enabled the identification of three distinct consumer segments (Tables 6 and 7). The first cluster comprised 35 consumers, who were not overly accepting of any wine, but who liked P2VAT most and P1 + OAK least. Cluster 2, the largest cluster (n = 55), gave similar scores to each wine and quite closely resembled the total sample. Cluster 3 comprised 26 consumers, who did not like the barrel-aged or P2VAT wines, but equally liked the other wines. Surprisingly, the wine produced using traditional barrel maturation was not favored by any segment and actually received the lowest overall score, whereas P1 − OAK, the wine made without oak contact, was quite well liked by clusters 2 and 3.

Internal preference mapping was undertaken to investigate the sensory attributes driving consumer liking. PLSR was performed on the DA data and hedonic ratings for each consumer segment and the total sample (Figure 2). Sensory attributes with regression coefficients > ±0.2 are generally considered to influence consumer liking.[6] In the current study, there were neither positive nor negative drivers for either the total consumer sample or cluster 2. In contrast, strong positive drivers were observed for cluster 1, including *leather* aroma (0.34) and flavor (0.33), *licorice* flavor (0.24), and *astringent/dry* mouthfeel (0.26), whereas strong negative drivers included *mocha* (−0.47) and *charry* (−0.30) aromas. This explains cluster 1's preference for P2VAT, which exhibited more apparent aged characters relative to other wines. Positive drivers for cluster 3 included *red fruit* (0.42), *charry* (0.27), and *mocha* (0.56) aromas and *earthy* (0.61) and *woody* (0.31) flavors. The strong negative drivers for cluster 3 were *dusty* (−0.44) and *leather* (−0.64) aromas and *leather* flavor on the palate (−0.57). Consumers within this cluster tended to be younger, from households with higher incomes, who were willing to spend more for wine on average than consumers from clusters 1 and 2 (Table 7). On the basis of demographic data, hedonic scores, and the sensory attributes driving wine preferences, consumers from clusters 2 and 3 would be most likely to be receptive to wines made using alternate oak maturation regimens; indeed, consumers from cluster 2 were generally accepting of all wines (Table 6).

J. Agric. Food Chem. 2015, 63, 1593−1600

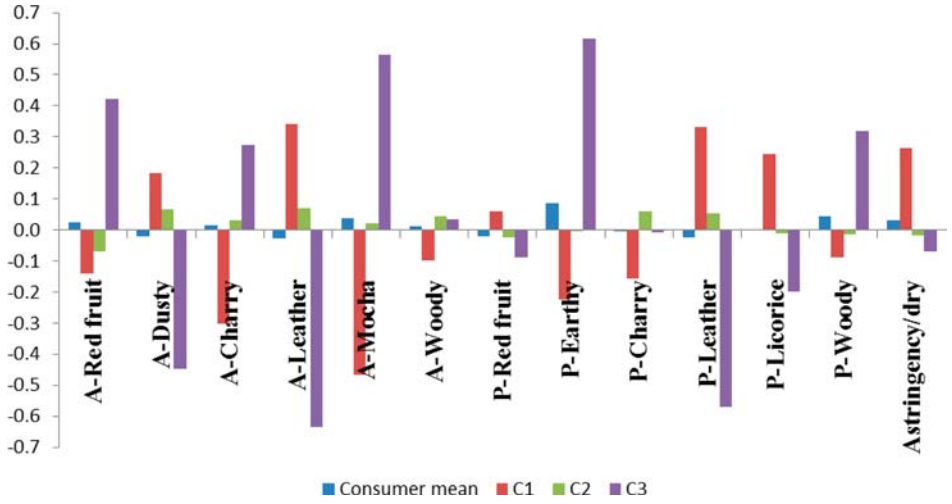

Figure 2. PLSR plot of consumer liking against wine sensory attributes for selected Cabernet Sauvignon wines.

and sensory analysis. Differences observed in the oak volatile concentrations and intensity of varietal versus oak-derived aromas and flavors of wines reflect differences in oak treatment, including the duration of oak maturation and the use of different oak woods. Quality rating scores ranged from 13.8 to 14.8, indicating wines were considered technically sound, but because wines aged using oak alternatives tend not to be premium quality wines, quality scores were always expected to be modest. Segmentation based on consumers' hedonic ratings demonstrated the variation in wine preferences of different consumers, but importantly, also demonstrated the appeal of wines made using alternative maturation regimens to consumers within different segments. These results justify wine producers' use of alternative oak maturation regimens, in particular for the production of wines targeted at certain price points and/or toward specific segments of the wine market. Furthermore, this study highlights the importance of combining compositional and descriptive sensory analyses with consumer research (e.g., hedonic ratings) to achieve a more substantial overview of the drivers of wine quality and acceptability.

patterns of these flavonoids during fruit development. In this study, anthocyanins, flavonols, and PAs were identified, quantified, and localized over fruit development in four pigmented-fruited (blue-purple) cultivars and one white-fruited cultivar of saskatoon. This study furthers our understanding of the developmental regulation of these three branches of the flavonoid pathway during saskatoon fruit development. Furthermore, these data can aid breeding efforts to optimize flavonoid content and specific flavonoid composition for the production of fruit with higher levels of health-beneficial flavonoids and aid in the targeting of specific developmental stages with an optimal flavonoid profile for the production of health-beneficial products.

MATERIALS AND METHODS

Plant Material. Saskatoon fruits from four purple-fruited cultivars (Northline, Pembina, Thiessen, and Honeywood) and one white-fruited cultivar (Altaglo) were collected from the University of Alberta Experimental Farm, Edmonton, Alberta, Canada. Fruit samples for chemical analyses were harvested onto dry ice in the field and were then sorted on dry ice in the laboratory into maturity classes according to a nine-stage system[10,11] (see Figure 1). After sorting, the fruits were immediately stored at −80 °C. Fruits for the histological studies were harvested onto ice in the field, transported on ice to the laboratory, and dissected immediately in the laboratory for tissue fixation.

Anthocyanin, Flavonol, and PA Analysis. For anthocyanin and flavonol quantitation, fruits were removed from −80 °C storage, and approximately 2−4 g of fruit per sample (with a minimum of four fruits per sample; see Table 1 for fruit size within each developmental stage) was ground in a commercial blender (New Hartford, CT). The ground tissue was weighed and then immediately extracted with 8 mL of an HPLC-grade solvent mixture (acetone/methanol/water/formic acid, 40:40:20:0.1, v/v/v/v), and further extraction and purification of anthocyanins and flavonols from saskatoon fruit were performed using a C18 column high-performance liquid chromatography (HPLC) diode array detector (DAD) method as outlined by Ozga et al.[7] and fully described in the Supplementary Materials and Methods in the Supporting Information. The quantitation of anthocyanins and flavonols was determined using absorption at 520 nm for anthocyanins and 350 nm for flavonols. Commercial authentic standards of anthocyanins and flavonols were used for comparison of HPLC retention times, and UV−vis absorption spectra and for construction of standard curves at the HPLC step for quantitation. Anthocyanin and flavonol quantitation data are the means of independent biological replicates (i.e., each replicate consists of a different fruit sample; the number of replicates ranged from 2 to 4, but in most cases, $n = 3$) ± the standard error of the mean (SE). Further identification of the putative quercetin triglycosides (HPLC peaks 2c and 2g, retention times of 10.5 and 32.7 min; Figure 2) was conducted using an Agilent 1100 liquid chromatography−mass spectrometry (LC−MS) system fitted with an electrospray ionization (ESI) interface. The LC−MS column and conditions were as reported by Ozga et al.[7]

For PA extraction, frozen fruit was ground to a fine powder in liquid nitrogen using a mortar and pestle. Ground samples (5−10 g with a minimum of four fruits per sample) were weighed and then immediately extracted with 66% (v/v) aqueous acetone (10 mL/g of tissue) as outlined by Kennedy and Jones[19] and fully described in the Supplementary Materials and Methods in the Supporting Information. The phloroglucinolysis reaction procedure was similar to that reported by Koerner et al.[18] with minor modifications as described in the Supplementary Materials and Methods in the Supporting Information. The phloroglucinolysis reaction times for monitoring free flavan-3-ols and flavan-3-ol−phloroglucinol adducts were as follows: 20 min for B-type and A-type (A_2; dimer made up of two flavan-3-ols linked together with an A-type linkage) terminal units, B-type phloroglucinol adducts, and grape skin PA standard extracts (no A-type PA linkages present), 120 min for A_2−phloroglucinol adducts for saskatoon fruit PA extracts, and 135 min for cranberry fruit PA standard extracts (containing abundant A-type PA linkages).

A 20 μL aliquot of the diluted reaction mixture was injected onto two Chromolith RP-18e (4.6 × 100 mm; Merck, Germany) columns connected in series, protected by a guard column (Chromolith RP-18e 4.6 × 10 mm; Merck, Germany), stabilized at 30 °C, using an Agilent 1200 HPLC system equipped with an Agilent G1315B DAD. The HPLC conditions were similar to that of Kennedy and Taylor[20] with minor modifications. The samples were eluted at 3 mL min^{-1} using a linear gradient with 1% (v/v) aqueous acetic acid (solvent A) and acetonitrile with 1% acetic acid (v/v; solvent B) as follows: isocratic at 3% B from 0 to 4 min, 3% to 18% B by 14 min, and 80% B from 14 to 18 min. Free flavan-3-ols, A_2 dimers, flavan-3-ol−phloroglucinol adducts (from extension subunits), and A_2−phloroglucinol adducts (from extension subunits) were monitored at 280 nm. PA terminal subunits were identified by comparison of HPLC-DAD retention times and absorbance spectra with commercially available flavan-3-ol standards. Phloroglucinol−PA adducts were identified by comparison of HPLC retention times with grape skin and cranberry fruit PA reaction products that were previously characterized by Koerner et al.[18] The mean degree of polymerization and conversion yields were calculated according to the method of Kennedy and Jones.[19] PA quantitation data are the means of independent biological replicates (the number of replicates ranged from 2 to 4, but in most cases, $n = 3$) ± SE.

To confirm the identification of the phloroglucinolysis products, LC−MS analysis was performed on the products using a 4000 Q-TRAP LC−MS/MS mass spectrometer (MDS SCIEX, Applied Biosystems) connected to an Agilent 1200 HPLC system as described by Zifkin et al.[21] PA terminal subunits (except for the terminal unit dimer, A_2) were identified by comparison of HPLC-DAD retention times, LC−MS fragmentation spectra, and absorbance spectra with commercially available flavan-3-ol standards. (−)-Epicatechin-(4β→2)-phloroglucinol (EC−P) was identified by comparison of HPLC retention times and the LC−MS fragmentation pattern with grape skin PA phloroglucinolysis reaction products. A_2 and the A_2−phloroglucinol (A_2−P) adducts were characterized by comparison of HPLC retention times and LC−MS spectra with cranberry fruit PA phloroglucinolysis products, which have been previously characterized.[18,19] The (+)-catechin-(4α→2)-phloroglucinol (C−P) standard was synthesized using taxifolin (see the Supplementary Materials and Methods in the Supporting Information). (−)-Epicatechin was used as an external standard for quantification of the free PA terminal subunits [(+)-catechin, (−)-epicatechin, and A_2] and phloroglucinol adducts. The relative molar and mass response factors from previous publications[18,19] were used for calculating PA subunit concentration, mDP, and conversion yield.

Histochemical Localization of PAs and Flavonols. Whole fruits were fixed for stages 1−4. For stages 5, 7, and 9, the top (pedicel end) and bottom (calyx end) parts of the fruit were removed, and approximately 5−10 mm of the central fruit tissue was used for tissue fixation. The fresh fruit sections were fixed, dehydrated, infiltrated, and embedded in Paraplast tissue embedding medium (Fisher Scientific, Houston, TX) as described by Zifkin et al.[21] Tissue blocks were sectioned to 10 or 20 μm thickness and affixed onto clean glass slides for microscopy.

For PA localization, the paraffin was removed from the tissue sections using two toluene (100%) washes at 5 min intervals. Tissue sections were stained with 0.1% 4-(dimethylamino)cinnamaldehyde (DMACA)/0.5 M H_2SO_4/1-butanol solution prepared as described by Gutmann and Feucht[22] (see the Supplementary Materials and Methods in the Supporting Information). For tissue staining, slides with fruit sections were covered with the DMACA solution and incubated at 60 °C on a hot plate for 15 min. The slides were subsequently washed with 100% ethanol to remove the excess staining solution and then dipped into two fresh toluene (100%) baths for 5 min each to remove moisture from the tissues. Cover slides were placed on slide-mounted tissue sections using DPX mounting media (BDH Chemicals, New York). Tissue sections were observed using a Zeiss AXIO scope A1 light microscope (Zeiss, Germany), and

DOI: 10.1021/jf504722x
J. Agric. Food Chem. 2015, 63, 1601−1614

micrographs were taken with a microscope-mounted Optronics camera (Optronics, United States) controlled by Picture Frame Application 2.3 software.

For flavonol localization, tissue sections were stained with 0.1% (w/v) diphenylboric acid 2-aminoethyl ester (DPBA) staining solution (containing 0.025% Triton X-100) for 5 min. The nearly dried sections were covered with cover slides using Fluoro Mount G (Electron Microscopy Sciences, United States) mounting medium. The micrographs of whole-fruit cross sections were taken with a Nikon camera (DXM1200, Japan) mounted on a Leica DMRXA microscope (Leica, Germany) (bright-field option). The fruit pericarp, placenta, and seed fluorescence micrographs were obtained using the same equipment described above under the fluorescence microscopy configuration (green; excitation filter, BP, 420–490 nm; dichromatic mirror, 510 nm; suppression filter, LP, 515 nm).

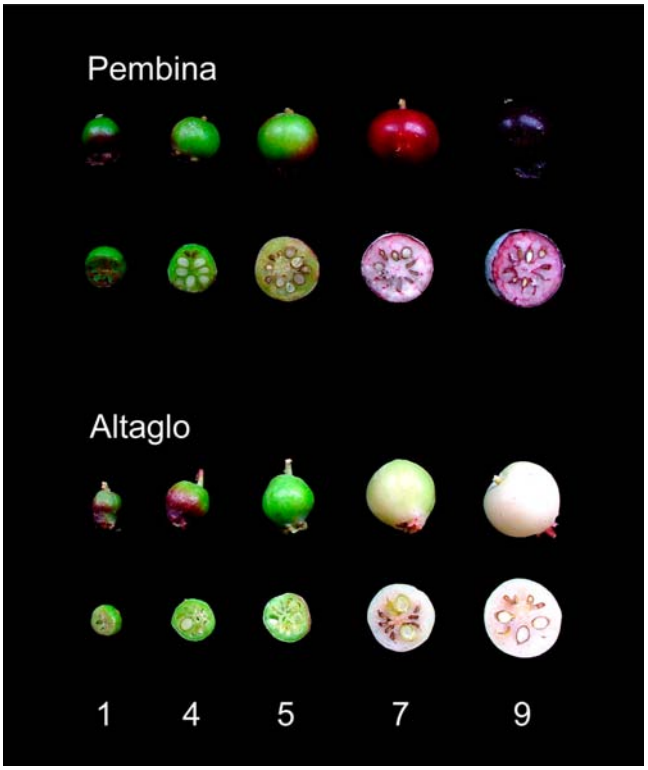

Figure 1. Whole and bisected saskatoon fruits (cultivars Pembina and Altaglo) over development. Stages for 'Pembina' fruit: 1, small green fruit; 4, larger green fruit; 5, light green fruit with slight pink mottling; 7, red fruit; 9, mature blue-purple fruit. Stages for 'Altaglo' fruit: 1, 4, and 5, green fruit in the order of ascending fruit size; 7, light green to white fruit; 9, white fruit. The fruit and pigment developmental patterns of saskatoon cultivars Honeywood, Northline, and Thiessen were similar to that of Pembina.

Chemicals. All HPLC-grade organic solvents (acetone, acetonitrile, methanol, ethyl acetate), acetic acid (ACS grade), and 1-butanol were purchased from Fisher Scientific (Ottawa, ON, Canada).The anthocyanin and flavonol standards (cyanidin 3-*O*-galactoside chloride, cyanidin 3-*O*-glucoside chloride, quercetin 3-*O*-glucoside, quercetin 3-*O*-galactoside, quercetin 3-*O*-rutinoside, and quercetin 3-*O*-arabinoglucoside) were purchased from Extrasynthese (Genay, France). (+)-Catechin hydrate, (−)-epicatechin, (−)-epicatechin gallate, (−)-epigallocatechin, (−)-gallocatechin, (−)-catechin gallate, (−)-epigallocatechin gallate, (−)-gallocatechin gallate, taxifolin, phloroglucinol, trifluoroacetic acid (TFA), L-(+)-ascorbic acid, hydrochloric acid (HCl; 36.5–38%), 5-*O*-caffeoylquinic acid (chlorogenic acid), diphenylboric acid 2-aminoethyl ester (DPBA), 4-(dimethylamino)cinnamaldehyde (DMACA), Triton X-100, and TOYOPEARL resin (HW-40F) were from Sigma (Oakville, ON, Canada). Glutaraldehyde and paraformaldehyde were purchased from Electron Microscopy Sciences (Hatfield, PA). The crude cranberry PA and grape skin PA standards were kindly provided by Dr. James Kennedy (Oregon State University).

RESULTS AND DISCUSSION

Fruit Development. Among the nine defined stages of saskatoon fruit development,[10] stages 1, 4, 5, 7, and 9 were selected to represent the major stages of fruit development (Figure 1). Saskatoon fruit increased in size throughout development, with the greatest increases in fruit fresh weight occurring at the latter stages of fruit development[23] (Table 1). Of the cultivars studied, Honeywood and Thiessen had the largest fruit fresh weight at maturity (Table 1). For the pigmented-fruit cultivars, from stages 1 to 4, the mainly green fruit increased in size. Stage 5 fruits were lighter green, and intermittent pink color occurred on the fruit surface. By stage 7, the fruit turned red and transitioned into the ripening stage. Fully mature fruits at stage 9 were blue-purple (Figure 1). For 'Altaglo', the early stages of fruit development (stages 1–5) were similar to those of the pigmented-fruit cultivars except for the substantially smaller fruit size at stage 1 (Figure 1, Table 1). However, with the transition to ripening (stage 7), minimal coloration occurred in 'Altaglo' fruits, and the fruits were white at maturity (stage 9; Figure 1). Saskatoon fruits have five locules as do other pome fruits such as apple, and each locule

Table 1. Fresh Fruit Weight and Diameter of Northline, Honeywood, Pembina, Thiessen, and Altago Saskatoon Fruit Cultivars over Development

cultivar	stage 1	stage 4	stage 5	stage 7	stage 9
			Fresh Fruit Diameter (mm)		
Northline	6.9 ± 0.3[a]	9.1 ± 0.1	10.4 ± 0.4	12.2 ± 0.3	13.4 ± 0.3
Honeywood	6.5 ± 0.2	8.7 ± 0.4	11.7 ± 0.1	13.2 ± 0.2	15.5 ± 0.4
Pembina	6.9 ± 0.2	7.6 ± 0.2	9.5 ± 0.3	11.5 ± 0.5	12.9 ± 0.2
Thiessen	7.8 ± 0.2	8.3 ± 0.4	11.1 ± 0.3	12.8 ± 0.3	13.8 ± 0.3
Altaglo	4.2 ± 0.0	9.2 ± 0.2	10.6 ± 0.3	11.6 ± 0.3	13.3 ± 0.3
			Fresh Fruit Weight (mg)		
Northline	181.3 ± 9.0	327.9 ± 23.2	475.3 ± 27.2	830.3 ± 14.1	1122.4 ± 27.4
Honeywood	153.7 ± 2.8	291.1 ± 23.2	642.8 ± 40.7	981.4 ± 66.8	1865.8 ± 19.2
Pembina	188.3 ± 4.2	242.3 ± 14.0	373.8 ± 21.6	666.3 ± 76.7	957.6 ± 27.5
Thiessen	234.2 ± 3.6	387.1 ± 61.5	623.2 ± 45.8	948.6 ± 23.1	1522.4 ± 126.3
Altaglo	52.0 ± 3.1	345.7 ± 17.7	521.4 ± 34.9	667.6 ± 35.2	1030.0 ± 92.1

can produce up to two seeds; however, at maturity the number of developed seeds is usually substantially lower than 10 (between 3 and 5; Figure 1).[23]

Anthocyanin Profiles in Developing Fruit. A typical HPLC-DAD chromatogram of a flavonoid extract from 'Pembina' stage 9 fruit monitored at 520 nm for anthocyanin detection is presented in Figure 2A. Four anthocyanin peaks were detected, cyanidin 3-*O*-galactoside (cyn-gal; 1a), cyanidin-3-*O*-glucoside (cyn-glu; 1b), cyanidin 3-*O*-arabinoside (cyn-arb; 1c), and cyanidin 3-*O*-xyloside (cyn-xyl; 1d), as previously determined for cultivars Honeywood and Smoky.[7] Cyn-gal, cyn-glu, and cyn-arb were detected throughout development in fruits from all pigmented-fruit cultivars tested (stages 1−9), with cyn-gal predominating in the profile throughout development (Figure 3B−E). Thus, cyn-gal is mainly responsible for the red coloration on the largely green-colored fruit skin early in development (Figure 1). As the fruit transitioned into the ripening phase (stage 7), the anthocyanin content dramatically increased, and cyn-xyl was detected (Figure 3B−E). Anthocyanin levels peaked at fruit maturity (stage 9) in all pigmented-fruit cultivars tested. Anthocyanin localization was carried out by cross sectioning whole fruits and visually observing tissue coloration. The typical red color of anthocyanins appeared on some parts of the fruit exocarp (skin) throughout the earlier developmental stages (stages 1−5; Figure 1). The red color on the fruit skin intensified as the fruit transitioned into the ripening stage (stage 7), and red-purple pigmentation was also observed in the cells of the mesocarp, vascular traces, and fruit locule margins. The fruit skin was dark purple at maturity (stage 9), with some purple coloration throughout the mesocarp tissue (Figure 1). The total anthocyanin concentration in the mature fruits of cultivars Honeywood, Pembina, Thiessen, and Northline ranged from 154 to 201 mg/100 g of fresh fruit weight (Table 2).

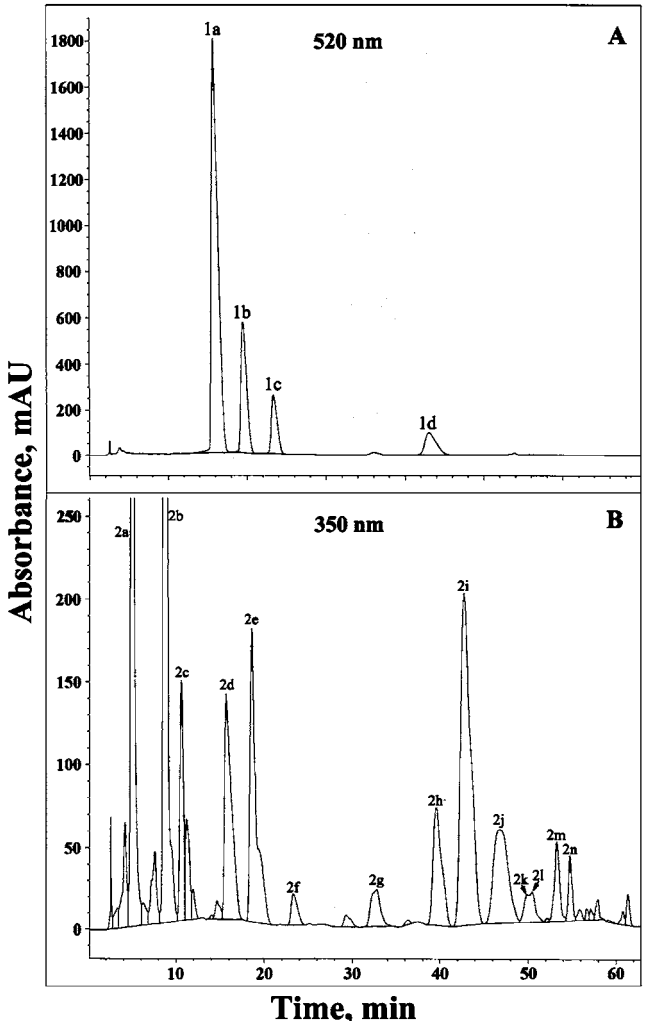

Figure 2. HPLC-DAD profiles of a stage 9 'Pembina' saskatoon fruit flavonoid extract. (A) Profile of anthocyanins monitored at 520 nm: peak 1a (15.7 min), cyanidin 3-*O*-galactoside; peak 1b (19.4 min), cyanidin 3-*O*-glucoside; peak 1c (23.3 min), cyanidin 3-*O*-arabinoside; peak 1d (43.0 min), cyanidin 3-*O*-xyloside. (B) Profile of flavonols and phenolics monitored at 350 nm: peak 2a (4.9 min), 3-*O*-caffeoylquinic acid; peak 2b (8.7 min), 5-*O*-caffeoylquinic acid; peak 2c (10.6 min), putative quercetin triglycoside; peak 2d (15.7 min), cyanidin 3-*O*-galactoside; peak 2e (18.6 min), unknown chlorogenic acid isomer; peak 2f (23.3 min), cyanidin 3-*O*-arabinoside; peak 2g (32.7 min), putative quercetin triglycoside; peak 2h (39.6 min), quercetin 3-*O*-arabinoglucoside; peak 2i (42.7 min), quercetin 3-*O*-galactoside; peak 2j (46.8 min), quercetin 3-*O*-glucoside; peak 2k + peak 2l (50.4 min), quercetin 3-*O*-robinobioside + quercetin 3-*O*-rutinoside; peak 2m (53.3 min), quercetin 3-*O*-arabinoside; peak 2n (54.7 min), quercetin 3-*O*-xyloside.

In the pigmented-fruit saskatoon cultivars, anthocyanin levels in the mature fruit were comparable to those found in other small fruits such as blackberry, cranberry, and sweet cherry (Table 2).[24] In general, saskatoon fruits have a relatively simple anthocyanin profile (four major anthocyanins that are monoglycosides of cyanidin) compared with blueberry fruits.[25] The dramatic increase in anthocyanin levels as the fruit transitions into ripening suggests that, as part of the ripening process, there is increased expression of transcription factors that up-regulate transcription of genes in the anthocyanin biosynthesis pathway, as observed in grape berries.[26,27]

In 'Altaglo' fruits (white fruit at maturity), cyn-gal and cyn-arb were found at levels comparable to those of the pigmented-fruit cultivars during early fruit development (stage 4; Figure 3, Table 2), demonstrating that the structural genes in the flavonoid pathway required to produce these anthocyanins are present during this developmental phase. However, as 'Altaglo' fruit continued to develop and transition into the ripening phase (stage 7), the dramatic increase in anthocyanin levels did not occur as observed in the pigmented-fruit cultivars, and only minimal levels of anthocyanins were detected in 'Altaglo' fruit at maturity (stage 9; Figure 3, Table 2). It is unlikely that the white fruits produced by 'Altaglo' at maturity are the result of a mutation in a key enzyme(s) for anthocyanin biosynthesis, as anthocyanins were detected in 'Altaglo' fruit at levels similar to those of the pigmented-fruit cultivars at earlier developmental stages. Furthermore, the presence of cyn-xyl in all the pigmented-fruit cultivars at stage 7 when the fruit is transitioning into ripening and subsequent cyn-xyl accumulation in these fruits through stage 9, and the lack of cyn-xyl in white-fruited 'Altaglo', lend support to the hypothesis that 'Altaglo' fruits lack a functional transcription factor(s) that up-regulates the transcription of genes for anthocyanin production as the fruit transitions into the ripening phase.

Flavonol Profiles in Developing Fruit. A representative HPLC-DAD chromatogram of a flavonoid extract from 'Pembina' stage 9 fruit monitored at 350 nm for flavonol detection is presented in Figure 2B. Seven main flavonols were detected in all pigmented-fruit cultivars studied (as previously determined in cultivars Honeywood and Smoky fruits by Ozga et al.[7]) as

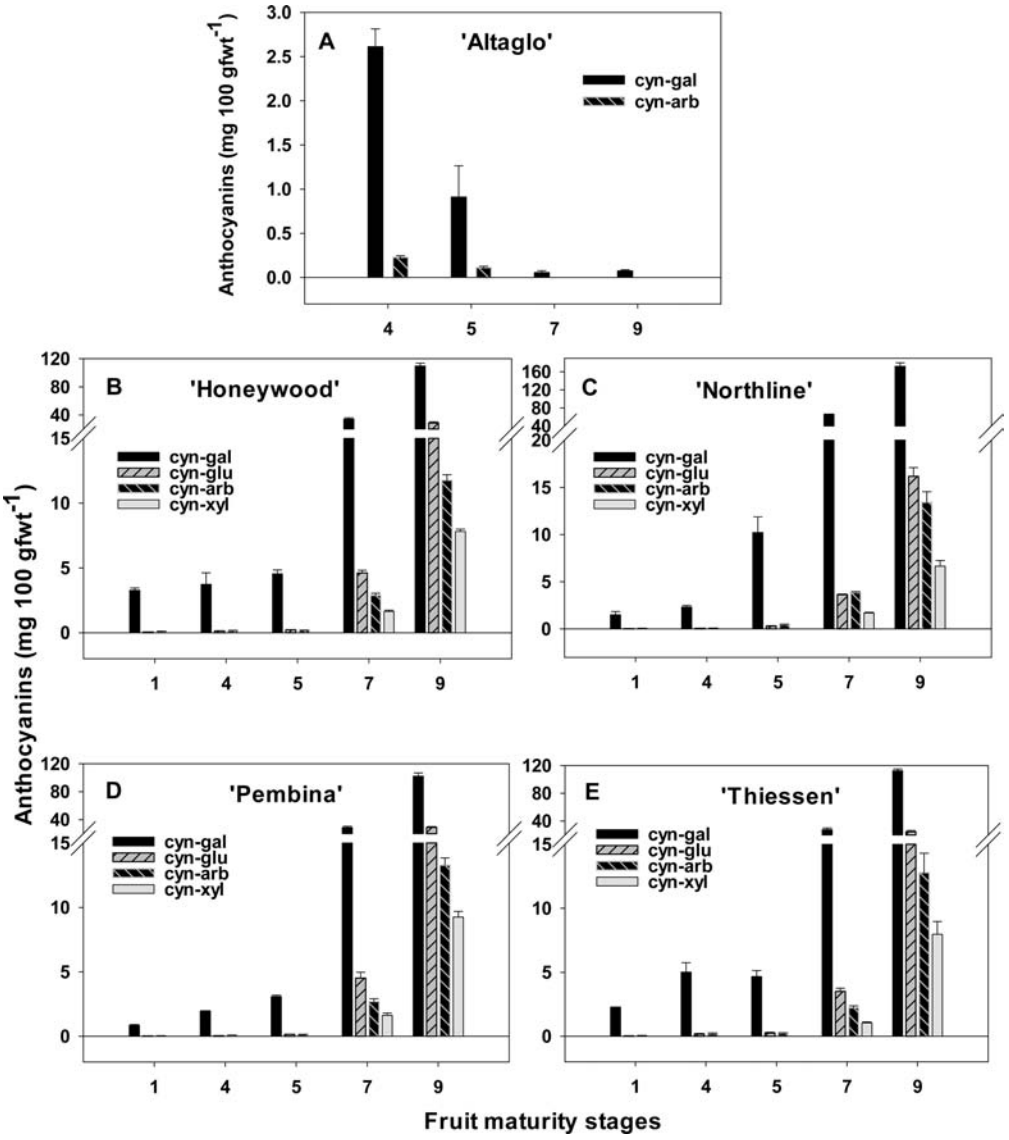

Figure 3. Type and content of anthocyanins in the fruits of cultivars (A) Altaglo, (B) Honeywood, (C) Northline, (D) Pembina, and (E) Thiessen over development (stages 1, 4, 5, 7, and 9). Abbreviations: cyn-gal, cyanidin 3-*O*-galactoside; cyn-glu, cyanidin 3-*O*-glucoside; cyn-arb, cyanidin 3-*O*-arabinoside; cyn-xyl, cyanidin 3-*O*-xyloside. Cyn-glu and cyn-arb were detected in cultivars Northline stages 1 and 4, Pembina stages 1 and 4, and Thiessen stage 1 fruits at <0.2 mg 100 gfwt^{-1}. Data are the means of independent biological replicates ± SE, n = 2−4.

follows: quercetin 3-*O*-arabinoglucoside (peak 2h), quercetin 3-*O*-galactoside (peak 2i), quercetin 3-*O*-glucoside (peak 2j), quercetin 3-*O*-robinobioside (peak 2k), quercetin 3-*O*-rutinoside (peak 2l), quercetin 3-*O*-arabinoside (peak 2m), and quercetin 3-*O*-xyloside (peak 2n). Additionally, in ripening and mature fruit (stages 7 and 9) of the pigmented-fruit cultivars, the presence of a strongly hydrophilic flavonol-type compound was observed (peak 2c; Figures 2B and 4) that had maximum absorbance at 343 nm (data not shown). LC−MS analysis was performed on HPLC fraction 2c. The MS fragmentation pattern suggested that peak 2c was a quercetin derivative with the characteristic quercetin aglycon ion mass of 303 (quercetin + H^+ ion; Table S1 and Figure S1, Supporting Information). Strongly polar quercetin triglycosides have been reported in Italian red onion and cauliflower.[28,29] These quercetin triglycosides were glycosylated at carbon 3, 7, or 4′. As the polarity of the peak 2c quercetin-type flavonol was much stronger than that of the other flavonols detected (eluted at 10.5 min in our HPLC system; Figure 2B), it is reasonable to propose that the glycosylation pattern of the peak 2c flavonol likely differs from that of the other saskatoon fruit flavonols identified, with a hexose sugar attached at carbons 3 and 7 or 4′. Another flavonol-type compound (peak 2g, Figure 2 B) was detected in cultivars Honeywood stage 1 fruits and Pembina fruits throughout development (Figure 4). This flavonol was further identified by LC−MS analysis as a quercetin triglycoside of rhamnose, hexose, and pentose with a molecular ion mass of 743 (302 + 146 + 162 + 132 + 1 = quercetin + rhamnose + hexose + pentose + H; Table S1 and Figure S2, Supporting Information). This compound (eluted at 32.7 min in the HPLC system) had a polarity similar to that of quercetin 3-*O*-arabinoglucoside; therefore, it is reasonable to postulate that this compound is a quercetin 3-*O*-triglycoside. The exact linkage of the three sugar units to quercetin cannot be determined by LC−MS analysis since internal monosaccharide loss might happen during the electrospray ionization process.[30] In general, the flavonol profiles of the pigmented-fruit cultivars were relatively similar, with quercetin 3-*O*-galactoside, quercetin

Table 2. Developmental Profile of the Total Anthocyanin Content of Cultivars Altaglo, Honeywood, Northline, Pembina, and Thiessen Saskatoon Fruits

	total anthocyanin content[a] (mg 100 gfwt^{-1})				
cultivar	stage 1	stage 4	stage 5	stage 7	stage 9
Altaglo	nd[b]	2.8 ± 0.2[c]	1.0 ± 0.4	0.06 ± 0.02	0.08 ± 0.01
Honeywood	3.4 ± 0.2	4.0 ± 0.9	4.9 ± 0.3	43.3 ± 2.2	157.9 ± 5.6
Northline	1.6 ± 0.4	2.5 ± 0.2	11.0 ± 1.8	75.4 ± 0.5	200.9 ± 14.5
Pembina	0.90 ± 0.07	2.1 ± 0.0	3.4 ± 0.1	37.4 ± 2.8	153.5 ± 6.9
Thiessen	2.4 ± 0.0	5.4 ± 0.8	5.2 ± 0.6	34.4 ± 2.9	157.5 ± 7.2

[a]Content estimated as cyanidin 3-*O*-galactoside (cyn-gal, cyn-arb, and cyn-xyl) and cyanidin 3-*O*-glucoside (cyn-glu) equivalents at the HPLC step. [b]nd = not determined. [c]Data are the means of independent biological replicates ± SE, n = 2−4.

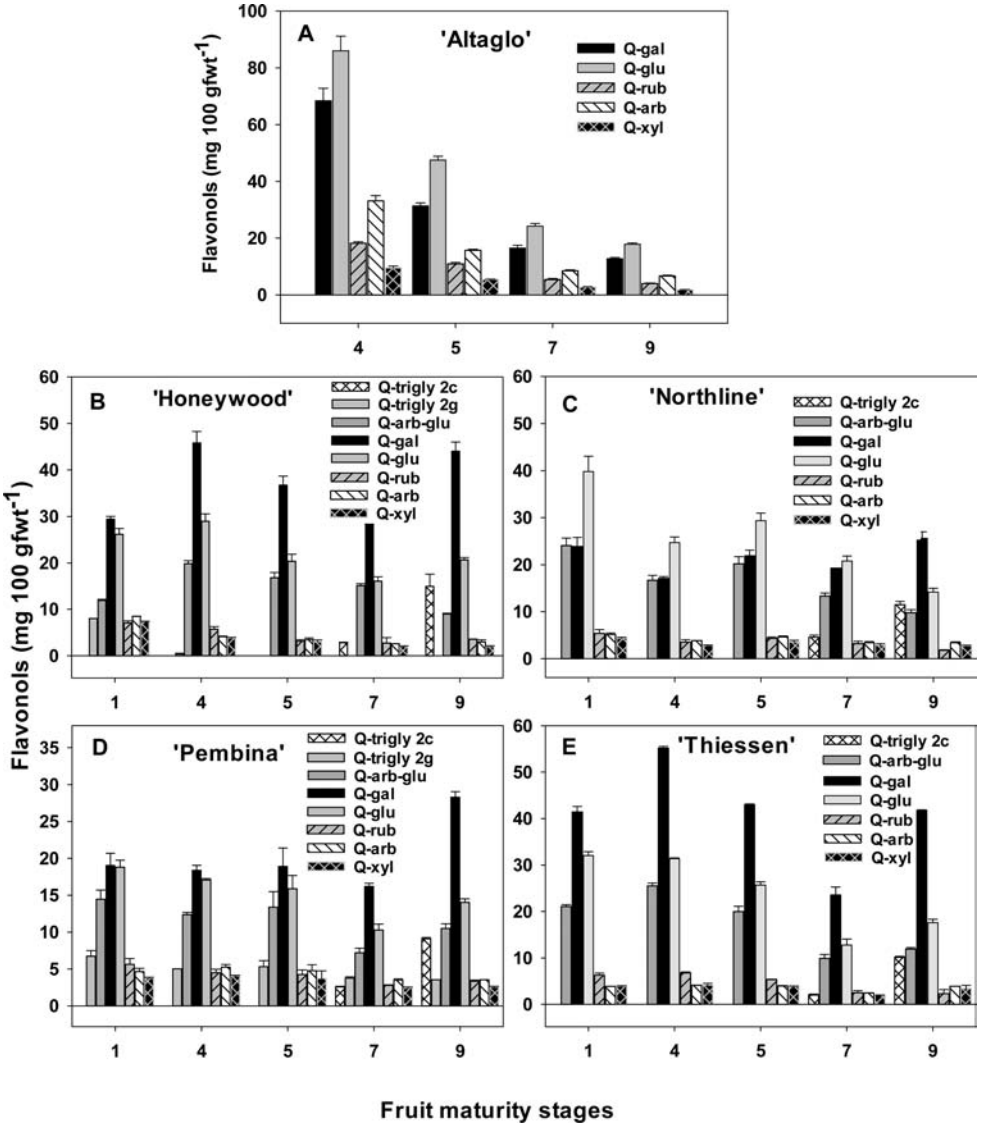

Figure 4. Type and content of flavonols in the fruits of cultivars (A) Altaglo, (B) Honeywood, (C) Northline, (D) Pembina, and (E) Thiessen over development (stages 1, 4, 5, 7, and 9). Abbreviations: Q-trigly 2c, putative quercetin triglycoside; Q-trigly 2g, putative quercetin triglycoside; Q-arb-glu, quercetin 3-*O*-arabinoglucoside; Q-gal, quercetin 3-*O*-galactoside; Q-glu, quercetin 3-*O*-glucoside; Q-rub, quercetin 3-*O*-robinobioside + quercetin 3-*O*-rutinoside; Q-arb, quercetin 3-*O*-arabinoside; Q-xyl, quercetin 3-*O*-xyloside. Data are the means of independent biological replicates ± SE, n = 2−4.

3-*O*-glucoside, and quercetin 3-*O*-arabinoglucoside dominating the flavonol profile throughout development (Figure 4). The flavonol profile of 'Altaglo' fruit differed from those of the pigmented-fruit cultivars in several ways. Quercetin 3-*O*-arabinoglucoside was not detected in 'Altaglo' fruits over development (Figure 4A), while this flavonol was relatively abundant in the other pigmented-fruit cultivars (Figure 4). Also, quercetin 3-*O*-glucoside was in greater abundance in 'Altaglo' fruits relative to other flavonols (Figure 4). In contrast, quercetin 3-*O*-galactoside was the most abundant flavonol in

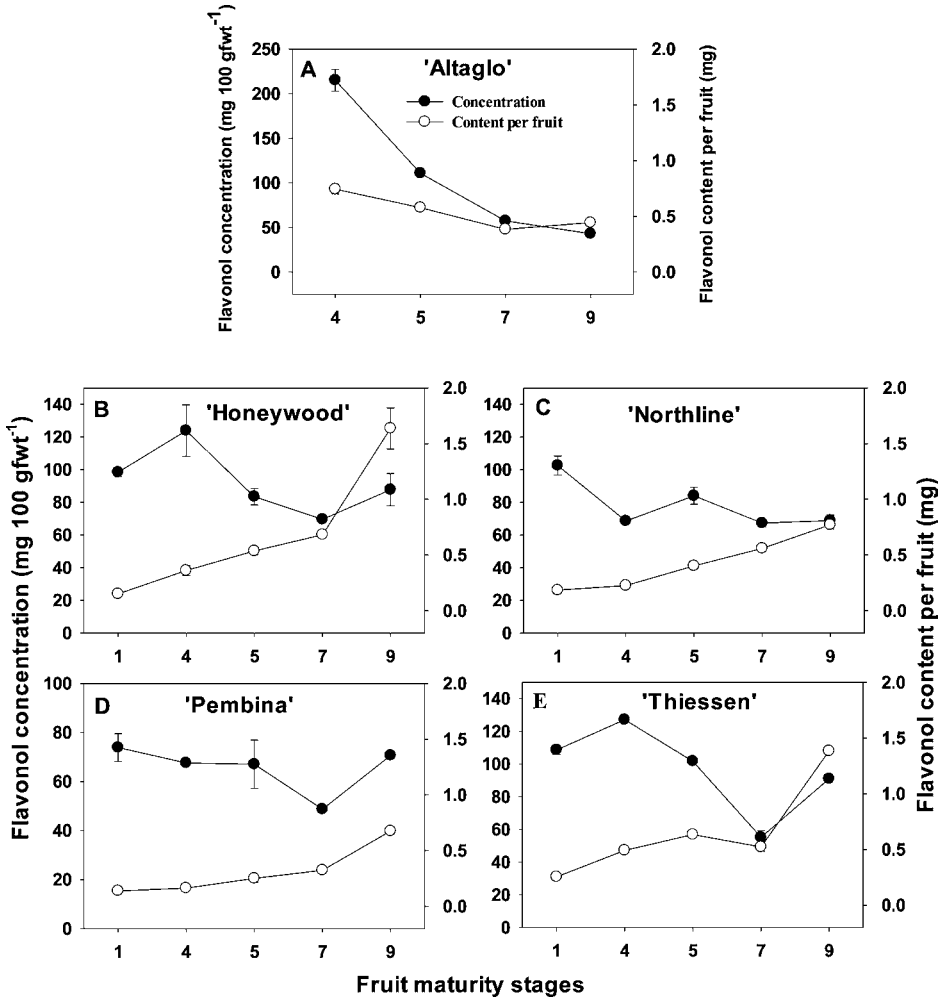

Figure 5. Total flavonol concentration and content of cultivars (A) Altaglo, (B) Honeywood, (C) Northline, (D) Pembina, and (E) Thiessen saskatoon fruits over development (stages 1, 4, 5, 7, and 9) expressed as milligrams per 100 g of fresh weight and milligrams per fruit. Data are the means of independent biological replicates ± SE, n = 2–4. Where standard error is minimal, error bars may be obscured by the symbols.

most pigmented-fruit cultivars (Figure 4). In flavonol biosynthesis, the glycosyltransferases, which catalyze the transfer of sugars to the flavonol aglycons, may have different preferences for sugars as substrates. The variation in flavonol type between the cultivars and over development within a cultivar may reflect the type and activities of specific glycosyltransferases.[31]

In the pigmented-fruit cultivars, in general, higher fruit flavonol concentration occurred earlier in fruit development (Figure 5B–E). In three of the four pigmented-fruit cultivars, the minimal flavonol concentration occurred as the fruit transitioned into ripening (stage 7; Figure 5B–E), followed by an increase in the flavonol concentration as the fruit completed development (stage 9; Figure 5B–E). The increase in flavonol concentration after transitioning into ripening may be related to the activity of transcription factors that up-regulate specific parts of the flavonoid biosynthesis pathway.[32] In blueberry (*Vaccinium corymbosum* L.) and bilberry (*Vaccinium myrtillus*) fruits, flavonol concentration decreased with increasing fruit maturity, with no increase in flavonol concentration following the transition to ripening.[21,33,34]

As the saskatoon fruit continued to increase in size throughout development, the total flavonol content per fruit increased during development in the pigmented-fruit cultivars (Figure 5B–E). This was not the case for 'Altaglo' fruits, where the total flavonol content decreased as the fruit matured (stages 4–9; Figure 5 A). In contrast, pink bilberry fruit (color mutant, pink fruits at maturity) had greater flavonol content at maturity compared with that in wild-type bilberry (dark-colored fruits at maturity).[34] The reduction in flavonol content per fruit in 'Altaglo' over development is consistent with the loss of function of a ripening-related transcription factor(s) that could act to up-regulate flavonoid biosynthesis, leading to flavonol accumulation over development in this cultivar. In addition to the flavonols, chlorogenic acid isomers were detected (peak 2a, neochlorogenic acid; peak 2b, chlorogenic acid; peak 2e, an unknown chlorogenic acid isomer), as previously described (Figure 2B).[7]

Flavonol Localization during Fruit Development. Flavonols autofluoresce, and the autofluorescence (yellow color) can be intensified by a flavonol-specific staining reagent, DPBA.[35,36] For flavonol localization, flavonol autofluorescence within fruit cross sections after histological fixation was monitored using fluorescence microscopy. To verify that the yellow-colored fluorescence signal was derived from flavonols, we stained sections with DPBA. After DPBA staining, the yellow-colored fluorescence signal dramatically intensified but retained the same pattern, confirming that the yellow autofluorescence was specific to the flavonols (Figure 6). Furthermore, we previously confirmed the autofluorescence emission wavelength range of

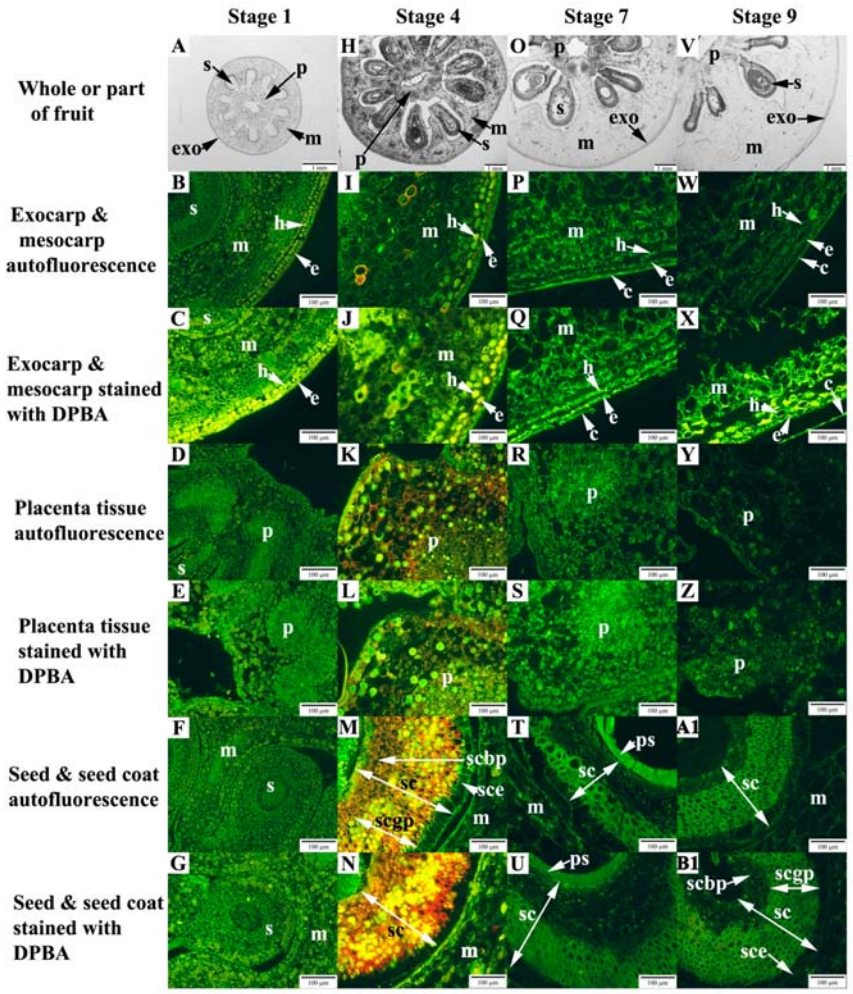

Figure 6. Fluorescence light micrographs showing flavonol localization in 'Altaglo' saskatoon fruit cross sections over development. Flavonols were visualized by autofluorescence and enhanced fluorescence after DPBA staining (yellow color). Panels are paired vertically, with the autofluorescence panel and corresponding DBPA-enhanced fluorescence panel shown immediately below. Micrographs from fruit stages 1 (A–G), 4 (H–N), 5 (O–U), and 9 (V–B1) are shown as columns. Panels A, H, O, and V are light micrographs that depict the entire fruit over development (size bar 1 mm). Exocarp and mesocarp tissues are depicted as autofluorescence (panels B, I, P, and W) and after staining with DPBA (panels C, J, Q, and X). Placental tissues are shown as autofluorescence (panels D, K, R, and Y) and after staining with DPBA (panels E, L, S, and Z). Seed tissues are shown as autofluorescence (panels F, M, T, and A1) and after staining with DPBA (panels G, N, U, and B1). Bars for fluorescence micrographs are 100 mm. Abbreviations: c, cuticle; e, epidermis; exo, exocarp; h, hypodermis; m, mesocarp; p, placenta; ps, perisperm; s, seed; sc, seed coat; scbp, seed coat branch parenchyma; sce, seed coat epidermis; scgp, seed coat ground parenchyma.

flavonols and the enhancement of the flavonol-specific fluorescence emission by DPBA using commercial standards of flavonols and a spectrofluorometer with an excitation wavelength within the range used for the fluorescence micrographs (420–490 nm).[21] These controls confirmed that flavonols autofluoresence and that DPBA enhances the fluorescence of flavonols within the expected wavelength range. This enhancement was not observed for chlorogenic acids, which are abundant nonflavonoid phenolic acids of saskatoon and blueberry fruits.[7,21]

Flavonol localization was determined over development in 'Pembina' and 'Altaglo' fruits. The same general pattern of flavonol localization was observed in the fruit of both cultivars. However, the minimal anthocyanin content of 'Altaglo' fruits throughout development allowed for better flavonol localization resolution. As demonstrated in 'Altaglo', flavonols were localized intracellularly (most likely in the vacuole) in the fruit (epidermis and hypodermis of the exocarp, mesocarp, and placental tissues) and the developing seed tissues of stage 1 fruits (Figure 6B–G). As the fruits and seeds developed, flavonol localization differed among the tissue types. The most intense flavonol staining was detected in the epidermal and hypodermal layers of stage 1 fruit (Figure 6B,C). At stage 4, flavonol localization remained high in the epidermal and hypodermal layers, but was substantially reduced in the mesocarp layer of the fruit wall (Figure 6I,J). As the fruit continued to mature, flavonols were observed mainly in the epidermal/hypodermal layer and cuticle of the fruit wall (Figure 6P,Q,W,X). Flavonol localization in the cuticle layer may be the result of flavonol migration from the epidermal to the cuticle layer to provide protection to fruits from UV light damage.[37]

Flavonols were detected in the placental tissues at all stages, with particularly intense staining in specific placental cells in stage 4 fruit (Figure 6D,E,K,L,R,S,Y,Z). In seed tissues, flavonols localized to the vacuoles of the ground parenchyma cells of the developing seed coats during early fruit development (stage 4; Figure 6M,N). As the seed coat matures, seed

DOI: 10.1021/jf504722x
J. Agric. Food Chem. 2015, 63, 1601–1614

coat cells undergo a programmed cell death.[38,39] Flavonols from the vacuoles are likely deposited on the cell walls of the seed coat ground parenchyma layer (Figure 6T,U,A1,B1) during this process, potentially to provide protection to the embryo from potential microbial attack during germination. This hypothesis is supported by the report that flavonols accumulated in the vacuoles and the cell walls of lisianthus (*Eustoma grandiflorum*) flower petals.[40] In addition, saskatoon seeds with viable embryos were found to contain a perisperm layer that also stained for the presence of flavonols (Figure 6T,U).

Characterization and Quantitation of PAs. Phloroglucinolysis (the method of HPLC analysis following acid catalysis in the presence of phloroglucinol)[41] was used to determine PA subunit composition and concentration by comparison of product retention properties with those of known products. Flavan-3-ols in the extension units form phloroglucinol adducts at their C-4 position, while terminal flavan-3-ol units are released as flavan-3-ol monomers or dimers (depending on subunit linkages). To determine the type of PA subunit linkages present in saskatoon fruit, we followed a procedure based on the property that PA polymers with a higher portion of A-type linkages are more resistant to the acid-catalyzed cleavage reaction than the PA polymers with only B-type linkages between the flavan-3-ol subunits.[18,42] Resistance to acid-catalyzed cleavage is likely due to the enhanced intermolecular forces resulting from the double linkages between the flavan-3-ol subunits characteristic of the A-type linkage group.[18,19] A kinetic study was conducted to determine the phloroglucinolysis reaction products produced over reaction time for saskatoon fruit PA extracts (from 'Thiessen' stage 1 fruits). The optimal reaction time was 20 min for the production of free A_2 dimer and epicatechin (EC) from terminal subunits and epicatechin-(4β→2)-phloroglucinol (EC−P) from the extension units of PAs from saskatoon fruits (the levels of these compounds were reduced at longer reaction times; Figure S3B−D, Supporting Information; see Figure S4 in the Supporting Information for depolymerized product structures). These data are consistent with PAs with B-type linkages from grape skin and seed, where a 20 min reaction time was optimal for releasing terminal subunits and production of phloroglucinol adducts (longer reaction times for PA extracts resulted in epicatechin terminal units forming undesirable C-2 phloroglucinol adducts).[19] Formation of A_2 dimer−phloroglucinol adducts (A_2−P) from the PA extension units was also detected in the phloroglucinolysis reaction products of saskatoon fruits, with approximately 80% of A_2−P production occurring within a 120 min reaction time (Figure S3A). In cranberry juice PA extracts, which contain higher levels of A-type PA linkages, 135 min was found to be the optimal reaction time for production of A_2−P in the phloroglucinolysis reaction.[18]

Typical HPLC chromatograms of the phloroglucinolysis products of PA extracts of saskatoon fruit ('Northline' stage 1) and grape skin and cranberry fruit standards are presented in Figure 7. The chemical structures of PA phloroglucinolysis products detected in the HPLC chromatograms are presented in Figure S4 in the Supporting Information. The major products from a 20 min phloroglucinolysis reaction in the saskatoon fruit and grape skin PA extracts are EC−P (peak 3), A_2−P (peak 5), EC (peak 7), and A_2 (peak 8) (Figure 7A). After the 120 min phloroglucinolysis reaction, the amount of EC (peak 7) was reduced, while that of A_2−P (peak 5) increased (compare 'Northline' chromatograms in panels A and B of Figure 7). These data demonstrate that the 120 min phloroglucinolysis reaction

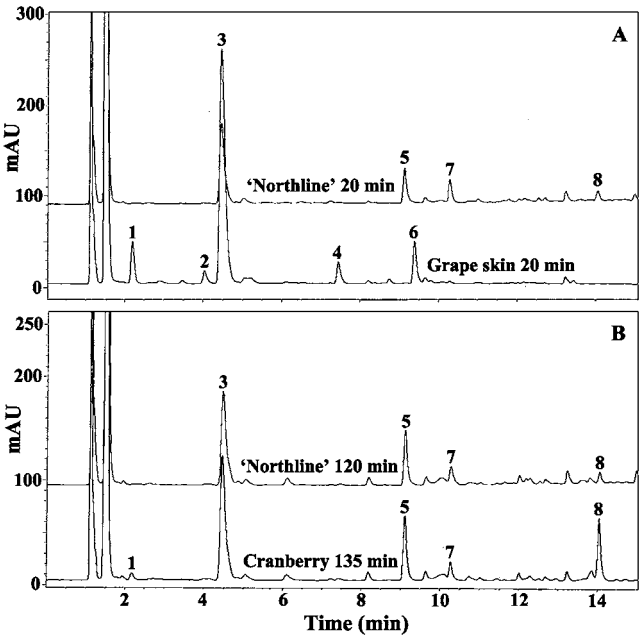

Figure 7. Reversed-phase HPLC chromatograms (monitored at 280 nm) of PA phloroglucinolysis products from 'Northline' stage 1 saskatoon fruit, cranberry fruit, and grape skin extracts: (A) comparison of 'Northline' 20 min reaction products with grape skin standard 20 min reaction products, (B) comparison of 'Northline' 120 min reaction products with cranberry standard 135 min reaction products. Peaks: 1, (−)-epigallocatechin-(4β→2)-phloroglucinol (EGC−P); 2, (+)-catechin-(4α→2)-phloroglucinol (C−P); 3, (−)-epicatechin-(4β→2)-phloroglucinol (EC−P); 4, (+)-catechin (C); 5, A_2−phloroglucinol (A_2−P); 6, (−)-epicatechin gallate-(4β→2)-phloroglucinol (ECG−P); 7, (−)-epicatechin (EC); 8, A_2. The two peaks detected prior to peak 1 are the reaction components ascorbic acid and phloroglucinol.

time is optimal for A_2−P quantitation but not for epicatechin quantitation. By comparing HPLC retention times and UV absorption spectra (data not shown) with those of known grape skin and cranberry fruit standards, saskatoon fruit PA flavan-3-ol extension units were confirmed to be nearly exclusively procyanidin (epicatechin; Figure 7, Table 3).

Our saskatoon PA composition data are consistent with those reported using fractionation with normal-phase semi-preparative HPLC followed by electrospray ionization coupled with tandem mass spectrometry (ESI-MS/MS) analysis of each PA oligomer fraction[43] and direct thiolysis of PA extracts with benzyl mercaptan followed by RP-HPLC analysis.[8] In the above-mentioned studies, PAs from mature saskatoon fruits were found to consist mainly of (−)-epicatechin subunits, with only B-type linkages reported. In this study, we found (−)-epicatechin−flavan-3-ol subunits were linked together by both B-type (peak 3, EC−P) and A-type (peak 5, A_2−P) linkages in the extension units, as well as the terminal units (peak 7, EC; peak 8, A_2) (Figure 7, Table 3). The abundance of A-type PA linkages varies with the cultivars, with 'Pembina' fruit having the greatest abundance of PA A-type linkages at most stages of fruit development (Table 3). Additionally, minimal amounts of (+)-catechin were detected in the PA extension subunits over fruit development in most cultivars (Table 3). The terminal subunits of PAs from saskatoon fruits consisted mainly of (−)-epicatechin (peak 7, Figure 7; Table 3), with a minor portion of (−)-epicatechin dimer in the A-type configuration (A_2, peak 8, Figure 7; Table 3). Only minimal

amounts of (+)-catechin (peak 4) from the terminal subunits were detected in saskatoon fruit over development (Table 3). These PA composition results suggest that either the flavonoid biosynthesis enzymes for synthesizing both (+)-catechin (leucoanthocyanidin reductase, LAR) and (−)-epicatechin (anthocyanidin synthase, ANS, anthocyanidin reductase, ANR) from leucocyanidin are present in saskatoon fruits or that (+)-catechin is produced by ANR epimerase activity.[44,45] Interestingly, the presence of (−)-epigallocatechin in the PA extension subunits was detected only in 'Thiessen' fruits, and it occurred at all developmental stages studied (Table 3). (−)-Epigallocatechin has three hydroxyl groups attached to the B-ring, whereas (−)-epicatechin has two (see Figure S4 in the Supporting Information). This suggests that both B-ring hydroxylases, flavonoid 3′-hydroxylase (F3′H) and flavonoid 3′,5′-hydroxylase (F3′5′H),[46] are present and active in 'Thiessen' fruits, where only F3′H is active in the other cultivars studied.

PA concentration (mg/100 g of fresh fruit weight) was higher during early fruit development and decreased as the fruit ripened in the saskatoon cultivars studied (Table 3, Figure 8). Similar PA accumulation patterns were observed over fruit development in bilberry,[34] strawberry,[47] and grape.[41] As supported by flavonoid gene expression data in blueberry fruit over development,[21] a likely scenario is that PA synthesis is limited to the early fruit developmental stages of saskatoon fruit, resulting in decreasing PA concentration as the fruit matures. The average PA polymer length (mDP) was relatively constant at 5−10 among all cultivars tested and over fruit development (Table 3). Our fruit PA mDP data are consistent with those of Bakowska-Barczak and Kolodziejczyk[8] for pigmented-fruit saskatoon cultivars at maturity. The PA composition and concentration of the white-fruited 'Altaglo' were similar to those of the pigmented-fruit cultivars (Table 3), suggesting that PA synthesis is not affected by the genetic modification(s) that result in the white fruit in 'Altaglo'. With respect to organoleptic properties, in general, PA polymers impart astringency to the fruit, while PA monomers are perceived as bitter.[48] The saskatoon PA mDP range is similar to that reported for blueberry fruit (7)[21] and apple fruit (4−8 in 14 of 16 varieties of French cider apples).[49]

The phloroglucinolysis reaction products of PAs from saskatoon fruit were further characterized by LC−MS/MS analysis. Saskatoon fruit C−P (RP-HPLC peak 2) and EC−P (RP-HPLC peak 3) had similar retention times, the same molecular ion mass of 413, and similar fragment ions compared to C−P and EC−P in the grape skin and cranberry fruit PA standards (Table 4). A_2−P (RP-HPLC peak 5) from saskatoon fruit had the same retention time and molecular ion mass of 699 and similar fragment ions compared to A_2−P in the cranberry fruit standard (Table 4), and these data are consistent with the RP-HPLC and positive ion mode LC−MS data for

A_2−P in cranberry fruit extracts.[18] A_2 (HPLC peak 8) from saskatoon fruit also had the same retention time, molecular ion mass of 575, and fragment ions as A_2 in the cranberry fruit standard (Table 4). Possible A_2−P and A_2 ion fragmentation patterns in negative ion mode LC−MS are presented in Figure S5 in the Supporting Information according to the major fragment ions we observed (Table 4).

Localization of PAs in Saskatoon Fruit. 'Altaglo' fruit PA levels were similar to those in the pigmented-fruit cultivars (Table 3), but Altaglo fruits do not accumulate high levels of anthocyanins in the later stages of development. Therefore, PA localization was performed in 'Altaglo' fruits to avoid anthocyanin interference in the later stages of fruit development, as the PA-specific stain DMACA changes PAs to a dark-blue color, similar to that of anthocyanins. PAs accumulated in all the fruit tissues of stage 1 'Altaglo' fruit (Figure 9A,B,F), with intense staining in the exocarp (hypodermal layer), seed coat, and placental tissues. By stage 4, PA accumulation was the greatest in the hypodermal layer of the exocarp and seed coat tissues (Figure 9C,D). At fruit maturity (stage 9), PA staining was still clearly observed in the exocarp, placenta, and seed coat tissues (Figure 9E). Interestingly, in the hypodermal, mesocarp, and placental stage 1 fruit tissue of 'Altaglo', small DMACA-staining vesicles were observed within some cells, along with cells that stained for PAs within one large vacuole (Figure 9B,F). Similar small DMACA-staining vesicles were observed in the same fruit tissues in 'Altaglo' stage 4 fruit and 'Pembina' stage 1 and stage 4 fruit (data not shown). Small PA vesicles have also been observed via transmission electron microscopy (TEM) in the endothelial cells of *tds4-1* mutant seeds.[50] The occurrence of small DMACA-staining vesicles in the cells of young saskatoon fruit tissue (stages 1 and 4) is consistent with the hypothesis that the process of vacuolar formation involves a combination of specific vacuolar docking and fusion events and that vacuolar formation and PA biosynthesis may be coupled processes in the cell.[50]

In young seed coats (stage 1), PAs were localized mainly intercellularly in the cells of the innermost cell layer of the seed coat, around vascular bundle tissue, and in the ground parenchyma layers of the seed coat (Figure 10A). At seed maturity, the PAs in the seed coat ground parenchyma cell layers were localized within or adjacent to the cell wall region (Figure 10B). In *Arabidopsis* seeds, flavonols are localized in proximity to PAs, where they both become imbedded into the mature seed coat by enzyme-catalyzed oxidative polymerization.[51]

Additionally, as noted in the fluorescence light micrographs (Figure 6T,U), a perisperm layer (residual endosperm) was observed in mature saskatoon seeds (Figure 10B).

Overall, saskatoon fruits have a relatively simple anthocyanin profile that consists of four major anthocyanins that are monoglycosides of cyanidin. The dramatic increase in anthocyanins in all pigmented-fruited cultivars contrasts with the lack of this ripening-associated increase in anthocyanins in the white-fruited 'Altaglo'. This difference is consistent with the

[a]Abbreviations: EC−P, (−)-epicatechin-(4β→2)-phloroglucinol; C−P, (+)-catechin-(4α→2)-phloroglucinol; A_2−P, A_2−phloroglucinol. [b]Retention time. The blueberry, grape skin, and cranberry samples were run at different times, leading to some variation in t_R between the same compounds in the different samples. [c]MS was run in the negative mode, and all the molecular ions are $[M-H]^-$. [d]The grape skin PA sample was processed as described by Kennedy and Taylor.[20] Fraction 5 was used (eluent from the solvent system consisting of (v/v/v) 20% acetone, 65% methanol, and 15% water with the solvent−water mixture containing 0.2% (v/v) formic acid). [e]The cranberry PA sample was processed as described by Koerner et al.[18]

loss of transcription factor activity in 'Altaglo' fruit that up-regulates the transcription of genes for anthocyanin production as the fruit transitions into the ripening phase, as documented in the flavonoid pathways of fruits of other plant species such as grape and apple.[26,27,34,52] High anthocyanin levels in the mature fruit might function to alleviate oxidative stress as the fruit ripens,[53] and the intense fruit coloration may function to attract animals for seed dispersal.[12]

Flavonols identified in saskatoon fruits were glycosides of quercetin. Previously identified flavonols in saskatoon fruit were confirmed, and two quercetin triglycosides were newly identified. PAs were composed mainly of (−)-epicatechin, with not only B-type, but also A-type, subunit linkages. Variation in PA flavan-3-ol subunit composition was also detected among the cultivars tested ['Thiessen' fruit PAs contained both (−)-epigallocatechin (three hydroxyl groups attached to the B-ring) and (−)-epicatechin (two hydroxyl groups attached to the B-ring), and only (−)-epicatechin was detected in the other four cultivars], making saskatoon fruit an interesting model for further understanding and manipulating flavonol B-ring hydroxylases for production of flavonoids with a specific compositional structure.

Flavonols and PAs were quantified and localized in saskatoon fruit over development. Our studies suggest that both flavonols and PAs are localized to similar tissues within the fruit, with higher levels, in general, observed during early fruit development. In the seed, both flavonols and PAs localized mainly to the seed coat. Flavonols and PAs are noted for their protective/defense function in plants. Our studies support that these

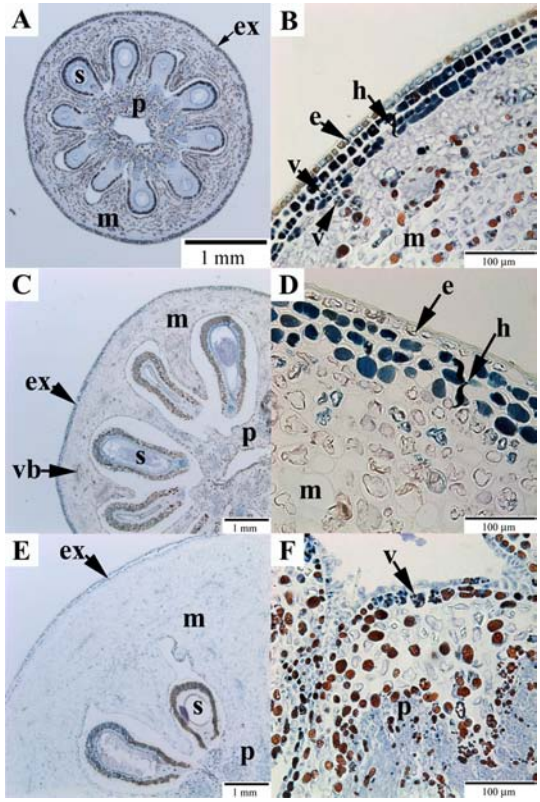

Figure 9. Light microscopic images of 'Altaglo' saskatoon fruit cross sections stained with DMACA for PA visualization: (A) stage 1 fruit, (B) stage 1 exocarp and mesocarp at 40× magnification, (C) stage 4 fruit, (D) stage 4 exocarp and mesocarp at 40× magnification, (E) stage 9 fruit, (F) stage 1 placenta at 40× magnification. Scale bars in panels A, C, and E are 1 mm, and panels B, D, and F are 100 μm. Abbreviations: e, epidermis; ex, exocarp (including cuticle, epidermis, and hypodermis); h, hypodermis; m, mesocarp; p, placenta; s, seed; v, small DMACA-staining vesicles with a cell; vb, vascular bundle.

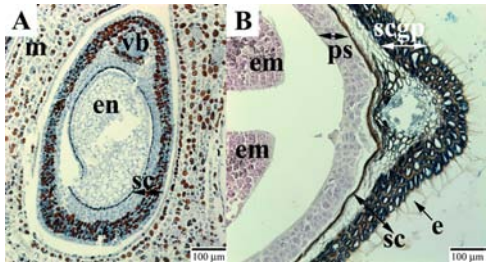

Figure 10. Light microscopic images of 'Pembina' saskatoon seed cross sections stained with DMACA for PA visualization: (A) Stage 1 seed at 20× magnification, (B) stage 7 seed at 20× magnification. Abbreviations: sc, seed coat; em, embryo; en, endosperm; ps, perisperm; vb, vascular bundle; m, mesocarp of fruit wall; e, epidermis of seed coat; scgp, ground parenchyma layers of seed coat staining for PAs.

compounds are developmentally regulated and tissue localized in the fruits and seeds of saskatoons to provide protection/defense during the reproductive and germination phase of this species. Also, their greater presence in immature fruit may also, through their astringency, help deter frugivores from consuming fruit prior to ripening.

The accumulation of anthocyanins, flavonols, and PAs in ripe saskatoon fruit, particularly in the fruit exocarp (skin) and the seed coats of seeds within the fruit, makes the consumption of these fruits a good source for flavonoids purported to impart

health-beneficial effects.[54] Future studies to understand the transcriptional mechanisms of the regulation of the flavonoid pathway during fruit ripening would be beneficial to provide further insight for further enhancing health-beneficial flavonoid content in saskatoon fruits.

(PEG 400), dimethyl sulfoxide (DMSO), ethanol (EtOH), methanol (MeOH), sodium dihydrogen orthophosphate ($NaH_2PO_4 \cdot 2H_2O$), anhydrous disodium hydrogen phosphate (Na_2HPO_4), and dichloromethane (CH_2Cl_2) were all purchased from Sinopharm Chemical Reagent Co., Ltd. (China). (+)-Limonene was purchased from J&K Scientific (New Jersey, USA). Mushroom tyrosinase (3130 units/mg), L-tyrosine, kojic acid, ascorbic acid (V_C), and 4-hexylresorcinol (4-HR) were purchased from Sigma Chemical Co (St. Louis, MO, USA). HPLC grade solvents were purchased from J&K Scientific. Norartocarpetin (NorA) was isolated from the wood of *A. heterophyllus* in our previous study.[3]

HPLC-DAD Analysis of NorA. The analytical HPLC system consisted of a Shimadzu LC-20AT series pumping system, an SIL-20A automatic injector, an SPD-M20A UV−visible detector, and Class-Vp chromatography data station software. All samples were analyzed by HPLC using a reverse-phase GraceSmart column (4.6 μm, 2.1 × 250 mm, Ryss Tech Ltd., China) at 25 °C with a Shimadzu HPLC system. Norartocarpetin was detected at 352 nm by a gradient elution with water containing 0.5% formic acid (solvent A) and methanol (solvent B) as a mobile phase. For the elution program, the gradient elution was as follows: initial, 20% B; 0−10 min, 20−60% B; 10−20 min, 60−100% B; 20−25 min, 100% B; 25−30 min, 100−20% B. The flow rate was set at 1.0 mL/min. The sample injection volume was 10 μL. Three injections were performed for each sample. The calibration curve of NorA in the concentration range of 3.125−50.0 μg/mL was linear with a correlation coefficient of 0.9995.

Solubility Studies. The solubility of NorA was determined in different oils, surfactants, and cosurfactants to find the appropriate constituents of microemulsions. An excess amount of NorA was added in 2 mL of ethyl butyrate, ethyl oleate, (+)-limonene, peppermint oil, Tween 80, Tween 40, Tween 20, ethanol, glycerin, PEG 400, 1,2-propanediol, and *n*-octanol. The mixtures were shaken reciprocally at 25 °C for 48 h to reach equilibrium using a magnetic stirrer (Genius 3 vortex and RW 20D magnetic stirrer, IKA Laboratory Technology, Germany). Each sample was centrifuged at 10000*g* for 20 min (Jintanshi Jinchengguosheng Shiyanyiqichang, Jiangsu, China), followed by filtering through a 0.45 μm membrane filter. The concentration of NorA was determined by HPLC analysis at appropriate dilution with methanol. The solubility was determined in triplicate.

Construction of Pseudoternary Phase Diagrams. Pseudoternary phase diagrams were constructed to obtain the concentration of all components of ME. Pseudoternary phase diagrams were constructed according to the water titration method.[18] Different weight ratios (S_{mix}) of surfactants and cosurfactants were mixed first, the S_{mix} ratio varying from 1:1 to 2:1 to 3:1. For each S_{mix} ratio, a pseudoternary phase diagram was elaborated by testing the weight ratios of oil/S_{mix} of 5:95, 10:90, 20:80, 30:70, 40:60, 50:50, 60:40, 70:30, 80:20, 90:10, and 95:5. Water was added drop by drop to each oily mixture under magnetic stirring (Genius 3 vortex and RW 20D magnetic stirrer, IKA Laboratory Technology) at room temperature. After being equilibrated, each sample was visually checked and determined as a clear microemulsion. The pseudoternary phase diagram was drawn by OriginPro for Windows version 9.0.

Preparation and Solubility Determination of NorA-Loaded ME. The selected formulas based on phase diagram and NorA solubility were prepared by mixing ethyl oleate, Tween 80, and PEG 400 together, and then the required quantity of water was added and stirred to form a clear and transparent dispersion. All ME were stored to achieve equilibrium at room temperature for at least 24 h before further investigation. To determine the maximum loading capacity of NorA in ME, increasing amounts of NorA were loaded to the base ME.[18,23] The mixture was stirred for 24 h at 25 ± 1 °C. The undissolved NorA was removed by centrifugation at 10000*g* (DL-5-B table model large capacity centrifuge, Shanghai Anting Scientific Instrument Factory, Shanghai, China) for 20 min, and then supernatant was taken and the encapsulation efficiency was quantified by HPLC-DAD at 352 nm after 100-fold dilution with methanol. The analyses were performed in triplicate.

Characterization of MEs. The appearance of ME was determined by visual inspection of clarity, turbidity, phase separation, and color. The conductivity, mean particle size, and polydispersity index (PI) were determined by three independent experiments.

Physical Properties. Physical properties of blank ME and NorA ME were characterized for pH and conductivity using a pH meter (Mettler Toledo, Shanghai, China) and conductivity meter (Mettler Toledo) at 25 ± 1 °C.

Particle Size Analysis. The mean particle diameter of the ME was determined by photon correlation spectroscopy using a Zetasizer Nano ZS (Marvern Instruments, Worcestershire, UK). Each size analysis lasted 180 s and was performed with an angle detection of 90°. The measurements of samples without dilution were performed at 25 ± 0.1 °C.

Morphology. Morphology of NorA ME was observed using a transmission electron microscope (TEM, JEOL JEM2100, Eindhoven, The Netherlands). One drop of NorA ME sample was deposited on a formvar film-coated copper grid and allowed to dry before TEM observation.

Stability Studies. The thermodynamic stability of ME systems was investigated visually for phase separation after their centrifugation at 10000*g* for 20 min at room temperature (25 ± 1 °C). Stability tests using accelerated condition by cooling−heating wee conducted at 4 and 40 °C for 24 h for six cycles. Long-term stability testing at room temperature (20−37 °C) for 8 weeks was also performed. Their chemical and physical stabilities were studied and recorded by monitoring the occurrence of phase separation, dispersed phase size, and NorA content before and after the stability tests. The particle size of the ME was evaluated by laser light scattering technique at 25 ± 0.1 °C. NorA content was measured by HPLC-DAD method.

Tyrosinase Inhibition Activity of NorA ME. The tyrosinase inhibitory activity of NorA ME was determined by spectrophotometric method (UV-5300PC spectrophotometer, Metash Instrument Co., Ltd., Shanghai, China) as described in our previous study.[3] Briefly, the prepared ME were first diluted to 20, 10, 5, 2.5, 1.25, and 0.625 μg/mL with deionized water. Each of the sample solutions (300 μL) was diluted with 700 μL of 0.05 mM sodium phosphate buffer (pH 6.8) in the test tubes, followed by the addition of 1 mL of 0.1 mg/mL L-tyrosine and finally 1.0 mL of mushroom tyrosinase solution (200 units/mL). Thirty microliters of DMSO and a kojic acid solution was used as the blank reference and positive control, respectively. The reaction mixtures (3.0 mL) were mixed by vortex, and the initial absorbance at 492 nm was measured. After incubation for 20 min at 37 °C, the final absorbance at the same wavelength was taken. The IC_{50} values, which represent the concentrations of ME at which 50% of the tyrosinase activity was inhibited, were determined. The percent inhibition of tyrosinase activity was calculated as follows:

$$\%\ \text{inhibition} = [(A_2 - A_1) - (B_2 - B_1)]/(A_2 - A_1) \times 100$$

A_1 is the absorbance at 492 nm of the blank at 0 min, A_2 is the absorbance at 492 nm of the blank at 20 min, B_1 is the absorbance at 492 nm of test sample at 0 min, and B_2 is the absorbance at 492 nm of test sample at 20 min.

Antibrowning Effects of NorA ME on Fresh-Cut Apple Slices. Apples of comparable size were cleaned and cut into 4 mm thick slices and then treated by dipping in 500 mL of the corresponding test solutions for 5 min and drained. Samples were then placed in plastic Petri dishes, sealed with parafilm, and stored at room temperature for 24 h. Replicate samples were prepared for each treatment, and the experiment was repeated three times. Test solutions used for the above samples included aqueous solutions of blank ME, 0.5% V_C, 0.01% NorA ME, 0.01% 4-HR + 0.5% V_C, and 0.01% NorA ME + 0.5% V_C. Visual assessment of color development in the samples was performed with a digital camera, whereas the relative extents of browning were measured with a tristimulus reflectance colorimeter. The center of the apple slices was in touch with the lens of the Minolta CR-400 Chroma meter (Konica Minolta Sensing, Inc., Japan) when the readings (a^* values) were taken. Measurements were made immediately following each treatment and at timed intervals of 3, 6, 12, and 24 h thereafter.

J. Agric. Food Chem. 2015, 63, 1615−1621

Statistical Analysis. All of the measurements were carried out in triplicate. An analysis of variance (ANOVA) of the data was performed using the SPSS 13.0 statistical analysis system. The treatments were considered to be significantly different at $p < 0.05$.

RESULTS AND DISCUSSION

Solubility Study in Various Vehicles. The solubility of NorA in different vehicles was determined and is listed in Table 1. On the basis of the results, NorA showed the highest solubility in ethyl oleate among four oils. It is considerably higher than its solubility in water, although the solubility in oils is limited. Among the three surfactants, Tween 80 showed the best solubility for NorA relative to Tween 20 and Tween 40, up to 3.63 mg/mL. The solubility values of NorA in surfactants are much higher compared to oils. Tween 80 is one of the polysorbates (ethoxylated sorbitan esters) belonging to a nonionic surfactant; it is widely used as an emulsifier and dispersing agent for pharmaceutical products and as an emulsifier in food products. Meanwhile, it is reported that the concentration of Tween 80 in the systems greatly affected the appearance and stability of the systems.[24] Low concentrations of Tween 80 (1−4% w/w) resulted in a milky white layer and relatively large droplets of the system, whereas higher concentrations of Tween 80 (>15% w/w) led to homogeneous transparent liquids and very small particles.[24] Although the content of Tween 80 is not clearly defined, it is necessary to reduce the content of surfactant to obtain ideal ME without potential side effects.[20,25] The content of Tween 80 was controlled in the range of 10−20% in this study to form the transparent ME. Among all of the cosurfactants, PEG 400 has the best solubility values of NorA. PEG 400 is a low-molecular-weight grade of polyethylene glycol. It is a clear, colorless, and odorless liquid, it is strongly hydrophilic, and it can be soluble in water, acetone, alcohols, benzene, glycerin, glycols, and aromatic hydrocarbons.[26] Due to its low toxicity, it is widely used in foods, pharmaceuticals, and personal and home care products as a solvent or solubilizing agent.[27] On the basis of these advantages and great solubility for NorA, PEG 400 was chose as cosurfactant for NorA ME. On the basis of solubility results, ethyl oleate, Tween 80, and PEG 400, which showed maximal solubilizing capacity for NorA, were selected for further NorA ME formulations.

Pseudoternary Phase Diagram Study and Determination of ME Formulation. To figure out the optimal proportion of the components in ME, pseudoternary phase diagrams were constructed using a water titration method.

The pseudoternary phase diagrams of ME systems contained ethyl oleate, Tween 80, PEG 400 at fixed ratios (w/w, S_{mix}) of 1:1, 2:1, and 3:1), and water. In the pseudoternary phase diagrams, the left area along the curve was referred to as the turbid region, whereas the right region was the ME region (Figure 1). All ME were isotropic, transparent dispersions, and no phase separation could be observed with all the ratios of oil/surfactant−cosurfactant/water after centrifugation at 10000*g* for 20 min at 25 °C. The previous study showed that the cosurfactant was arranged exactly among surfactant molecules and resulted in the formation of ME with maximum solubilizing capacity at the optimum ratio of surfactant and cosurfactant.[28] Therefore, the ratio of surfactant and cosurfactant (S_{mix}) was very important in the formation of stable ME. In this study, when the same oil phase (ethyl oleate) was fixed, the area of ME regions existing in various ratios of surfactant and cosurfactant in pseudoternary phase diagrams were in the order 2:1 > 3:1 > 1:1 (Figure 1).

On the basis of the above optimization, the formulation of NorA ME was composed of ethyl oleate (2% w/w), Tween 80 (12% w/w), PEG 400 (6% w/w), with a ratio of 2:1 of

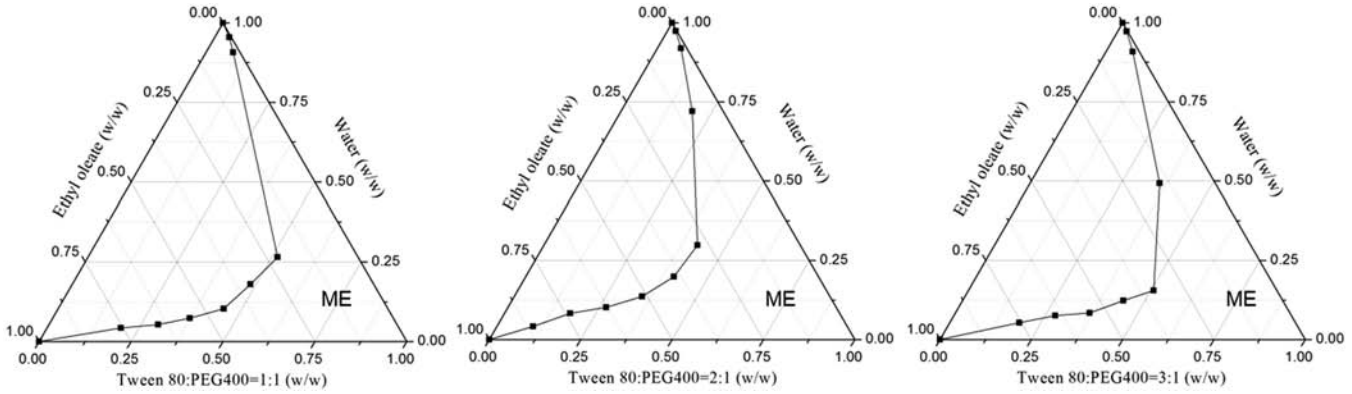

Figure 1. Construction of pseudoternary phase diagram of ethyl oleate/Tween 80/PEG 400/water system at a ratio of surfactant and cosurfactant (w/w) of 1:1, 2:1, or 3:1.

J. Agric. Food Chem. 2015, 63, 1615−1621

surfactant/cosurfactant, and water (80% w/w). The ME formulation exhibited the maximum solubility for NorA, up to 1.73 ± 0.21 mg/mL, increasing at least 1000 times its solubility in water.

Physicochemical Properties of ME. The selected ME base showed a colorless and transparent appearance, whereas NorA ME exhibited a light yellow and transparent appearance (Figure 2). The pH values of blank ME and NorA ME were

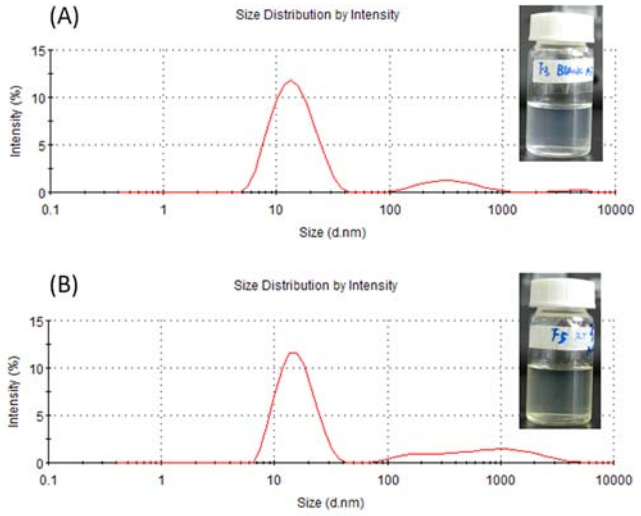

Figure 2. Particle size distribution and visual appearance of blank ME (A) and NorA ME (B).

5.56 and 5.51, respectively, a slight decrease after incorporation of NorA into ME. This may be induced by the phenolic hydroxyl groups in the structure of NorA. The mean particle sizes determined by the dynamic light scattering (DLS) measurements were 15.84 ± 0.02 and 16.01 ± 0.16 nm for the blank ME and NorA ME (Table 2), respectively. It can be

seen that the droplet sizes of ME and their homogeneity remain unchanged after the addition of NorA. The values of polydispersity indices were 0.270 ± 0.004 and 0.340 ± 0.020 for blank ME and NorA ME, respectively. The low values of PI indicated that the formulas had uniformity of narrow size distribution.[18] A lower diameter of the drops of oil (<100 nm) and the transparency of the system confirm the presence of microemulsions.[23] Conductivity is a certain correlation with the water content of ME, which can be used to categorize the ME area to w/o, o/w, and the bicontinuous structure between them.[29] The conductivity values of blank ME and NorA ME were 126.13 ± 0.21 and 129.13 ± 0.06 μS/cm, respectively. The results of high conductivity suggested that the ME were in o/w systems.[18,29]

TEM results confirmed the presence of droplets with size <30 nm (Figure 3). TEM analysis of NorA ME showed the presence of small spherical drops of oil with a mean diameter of 15−27 nm, coherent with particle sizes obtained by DLS.

Solubility Determination of NorA-Loaded ME. The solubility of NorA in the selected ME was 1.73 ± 0.21 mg/mL, which was improved considerably by loading it in ME. The solubility of NorA in the optimization ME was much higher than in water. On the other hand, it was found that the solubility of NorA showed little improvement when it was added in the oil phase first rather than directly adding it in the blank ME (Supporting Information). However, the latter was found to have a slight decrease in stability relative to the former one during long-term storage, and a trace of precipitate was found after 8 weeks of storage.

Stability Studies. Phase transitions are known to occur in ME structures as a result of changes in appearance, particle size, dilution, and so on, as well as the presence of guest molecules. To determine physical stability, the formulation was characterized by visual inspection, determinations of concentration, and particle size.

In stability tests, blank ME and NorA ME were stable during cooling−heating for six cycles (accelerated conditions) and long-term storage at room temperatures (20−37 °C) for 8 weeks (Table 3). Incorporation of NorA into ME did not affect the structure and the physical stability of the blank ME, because no significant changes in phase separation, clarity, and precipitation were observed after accelerated and long-term conditions. After accelerated and long-term conditions, the color and transparency of the blank ME and NorA ME were still the same as those freshly prepared. In addition, pH values decreased a lot after accelerated and long-term conditions for both blank ME and NorA ME. The decrease of pH values of NorA ME could be explained due to the large number of hydrogen protons ionized from phenolic hydroxyl groups, but it was strange that the pH values of blank ME also decreased by about 2−3 units. The optimum pH for PPO activity was between 5 and 7.[30] When pH values were <3, the enzyme activity could be effectively inhibited because hydrogen ions are noncompetitive inhibitors of apple PPO at pH <5.[31,32] The conductivities increased much from 126.13 to 208.67 and 294.0 μS/cm for blank ME and from 129.13 to 170.87 and 337.67 μS/cm for NorA ME after accelerated and long-term conditions, respectively. Both blank ME and NorA ME increased their conductivities about 2−4 times. The particle sizes of blank ME, after accelerated and long-term storage, slightly increased (from 15.84 to 17.36 and 21.62 nm) when compared with those of freshly prepared ME. However, the particle size of NorA ME slightly decreased compared to the fresh preparation after accelerated storage (from 16.01 to 15.44 nm), whereas it slightly increased after long-term storage (from 16.01 to 17.89 nm). All of the particle sizes were below 30 nm, suggesting both base and NorA ME were stable ME. The NorA contents of formulations were 1.71 ± 0.15 and 1.63 ± 0.14 mg/mL after accelerated and long-term stability testing, respectively, which were not significantly different compared with that of freshly prepared NorA ME (1.73 ± 0.21 mg/mL). These

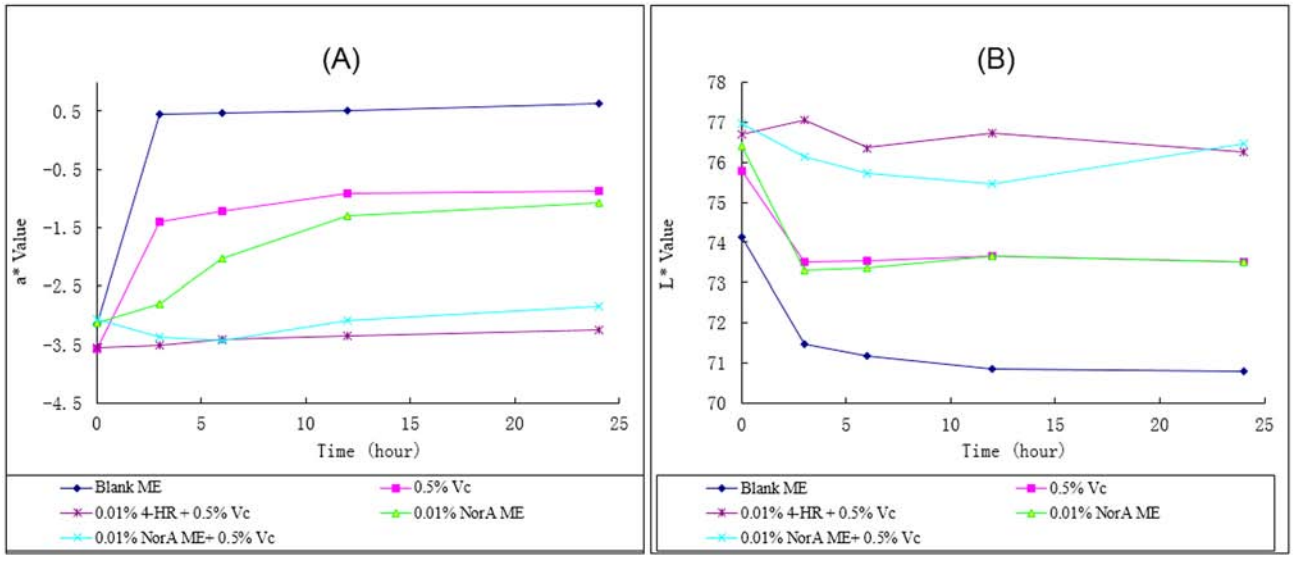

Figure 4. Reflectance measurement of a^* (A) and L^* (B) of apple slices treated with the different tested solutions and stored at room temperature.

results suggested that NorA was chemically stable in selected ME.

Tyrosinase Inhibition Activity and Antibrowning Effects of NorA ME on Fresh-Cut Apple Slices. To study whether the prepared NorA ME maintained good tyrosinase inhibitory activity and antibrowning effects, the NorA ME was diluted to different concentrations and tested for their inhibitory activities on tyrosinase. The IC_{50} of NorA ME was 1.43 ± 0.06 μM, which is similar to the IC_{50} obtained from using DMSO as a solubilizer,[3] suggesting the tyrosinase inhibitory activity of NorA does not decrease due to incorporation into ME.

Until today, there is still not a unified standard quantitative method for measurement of the extent of browning in foods. Usually, ΔE (total color difference), L^*, a^*, and b^* have been used as parameters for measuring the extent of browning reactions in fruits and vegetables. A decrease in L^* and an increase in a^* or ΔE indicate the occurrence of browning. Among them, the a^* value was reported to be more sensitive to browning and had been used to effectively monitor browning in fresh-cut pear and apple.[33−35] Moreover, it was found that plant extracts or compounds needed to be used in combination with V_C to exhibit better antibrowning effects.[35−37] In the present study, a^* and L^* values were chosen as parameters for estimation of the antibrowning activity of NorA ME on apple

DOI: 10.1021/jf5048805
J. Agric. Food Chem. 2015, 63, 1615−1621

slices, in addition to visual observation. Except for blank ME, V_C, and NorA ME alone, NorA ME and 4-HR combination with V_C were assayed for antibrowning effects on fresh-cut apple slices. According to the change of a^* value, blank ME almost did not show antibrowning effects even at 3 h in room temperature, whereas NorA ME and 4-HR in combination with 0.5% V_C, respectively, showed similarly better antibrowning effects than NorA ME and V_C alone, even at 3 h (Figure 4). NorA ME in combination with 0.5% V_C were not significantly different from apple slices treated with 0.01% 4-HR in combination with 0.5% V_C dipping solution in 24 h. The results of L^* values displayed the same trend according to the results obtained for the a^* values. The solutions of 0.01% NorA ME + 0.5% V_C and 0.01% 4-HR + 0.5% V_C exhibited higher L^* values than the solutions of NorA ME and V_C alone and much higher L^* values than base ME solution. According to the decrease in L^* value normally associated with browning, 0.01% NorA ME + 0.5% V_C and 0.01% 4-HR + 0.5% V_C could better inhibit browning for fresh-cut apple slices than NorA ME or V_C alone. Although the inhibitory effect of norartocarpetin on tyrosinase has been reported in our previous studies,[2,4] the mechanism of browning inhibition is still unknown. The above findings suggest that browning inhibition of norartocarpetin was achieved possibly through a mechanism similar to that of 4-HR. These results preliminarily suggest that NorA may be a potential candidate for 4-HR and V_C as antibrowning agents for fresh-cut fruit products. The visual assessment agreed with colorimetric measurements.

In conclusion, the results of this study suggest that the solubility of NorA was improved greatly in the food grade MEs. NorA ME retains good physicochemical stability after accelerated and long-term conditions. NorA ME still showed strong tyrosinase inhibitory activities and antibrowning effects on apple slices. On the basis of physicochemical characterization and antibrowning effect studies, the ME formulation may be employed to improve the solubility of insoluble tyrosinase inhibitors such as NorA. However, further studies on texture, sensory, nutritional values, aroma, and flavor of apple slices need to be performed before this formulation can be commercially exploited.

and a 250 × 10 mm i.d., 10 μm Cosnosil 5SL-II (Nacalai Tesque, Kyoto, Japan).

Plant Materials. Gac fruits were purchased at a local vegetable market in Vietnam.

Quantitative Analysis of Carotenoids. The total carotenoid content and the amount of carotenoids eluted by column chromatography were calculated using the extinction coefficient of $E^{1\%}_{cm}$ = 3450 at λ_{max}.[21] In the HPLC analysis, the relative amounts of individual carotenoids were calculated from the peak area detected at 470 nm.

Isolation of Carotenoids. The aril (980 g) of gac was extracted with acetone (Me_2CO) at room temperature. The Me_2CO extract was evaporated to dryness. The reddish residue was subjected to silica gel 60 (Nacalai Tesque, Kyoto, Japan) column chromatography (300 × 20 mm). The fraction (fr) eluted with 200 mL of ether−hexane (1:9 v/v, fr 1) was subjected to preparative HPLC on ODS (Cosmosil 5C18-II) with a CH_3CN flow rate of 2.0 mL/min to yield α-carotene, β-carotene, 9Z-β-carotene, γ-carotene, lycopene (**1**), 9Z-lycopene, and 13Z-lycopene.

The fraction eluted with ether-hexane (5:5 v/v, fr 2) was subjected to preparative HPLC on silica gel (Cosmosil 5Si) with acetone−hexane (15:85 v/v) to yield new carotenoid **3** (retention time 18.4 min) and 1,16-dehydro-2,6-cyclolycopene-5-ol A (rt 20.5 min).

The fraction eluted with ether−hexane (8:2 v/v, fr 3) was subjected to preparative HPLC on silica gel (Cosmosil 5Si) with acetone−hexane (25:75 v/v) to yield isocryptoxanthin (rt 9.4 min), β-cryptoxanthin (rt 10.4 min), and new carotenoids **11** (rt 12.0 min), **12** (rt 14.0 min), **6** (rt 16.0 min), and **7** (rt 17.0 min). The fraction eluted with ether (fr 4) was subjected to preparative HPLC on silica gel (Cosmosil 5 Si) with acetone−hexane (25:75 v/v) to yield new carotenoids **10** (rt 12.0 min) and **9** (rt 14.0 min), 2,6-cyclolycopene-1,5-diol B (rt 17.0 min) and 2,6-cyclolycopene-1,5-diol A (rt 20.0 min), lutein (25.0 min), and zeaxanthin (27.0 min).

Identification and Characterization of Carotenoids. α-Carotene, β-carotene, 9Z-β-carotene, γ-carotene (**8**), lycopene (**1**),

Ab Initio Molecular Orbital Calculation. Ab initio molecular orbital calculations were performed using the Gaussian 03 program (Gaussian, Inc., Wallingford, CT). The starting coordinates were generated by inspection of the molecular model and were fully optimized using a Fujitsu HX600 supercomputer at the Information Technology Center of Nagoya University. The position of methyl group and hydroxyl group were represented as follows. The position of methyl group was represented by the average of coordinates of three hydrogens that were obtained by the ab initio molecular orbital calculations. Similarly, the position of the hydroxyl group was represented by the coordinates of the base of a perpendicular line drawn from the hydrogen atom to the extension of the C-6 and O bond.

In Vitro Epstein−Barr Virus (EBV) Early Antigen Activation Induction Effect. EBV genome-carrying lymphoblastoid cells (Raji cells) derived from Burkitt's lymphoma were cultivated in RPMI-1640 medium with 10% fetal bovine serum (FBS). The Raji cells were incubated for 48 h at 37 °C in a medium containing *n*-butyric acid (4 nmol), TPA (32 pmol), and various amounts of test compounds. Smears were made from the cell suspension, and we employed an indirect immunofluorescence technique. Details of the in vitro assay on EBV-EA induction have been reported previously.[23,24]

J. Agric. Food Chem. 2015, 63, 1622−1630

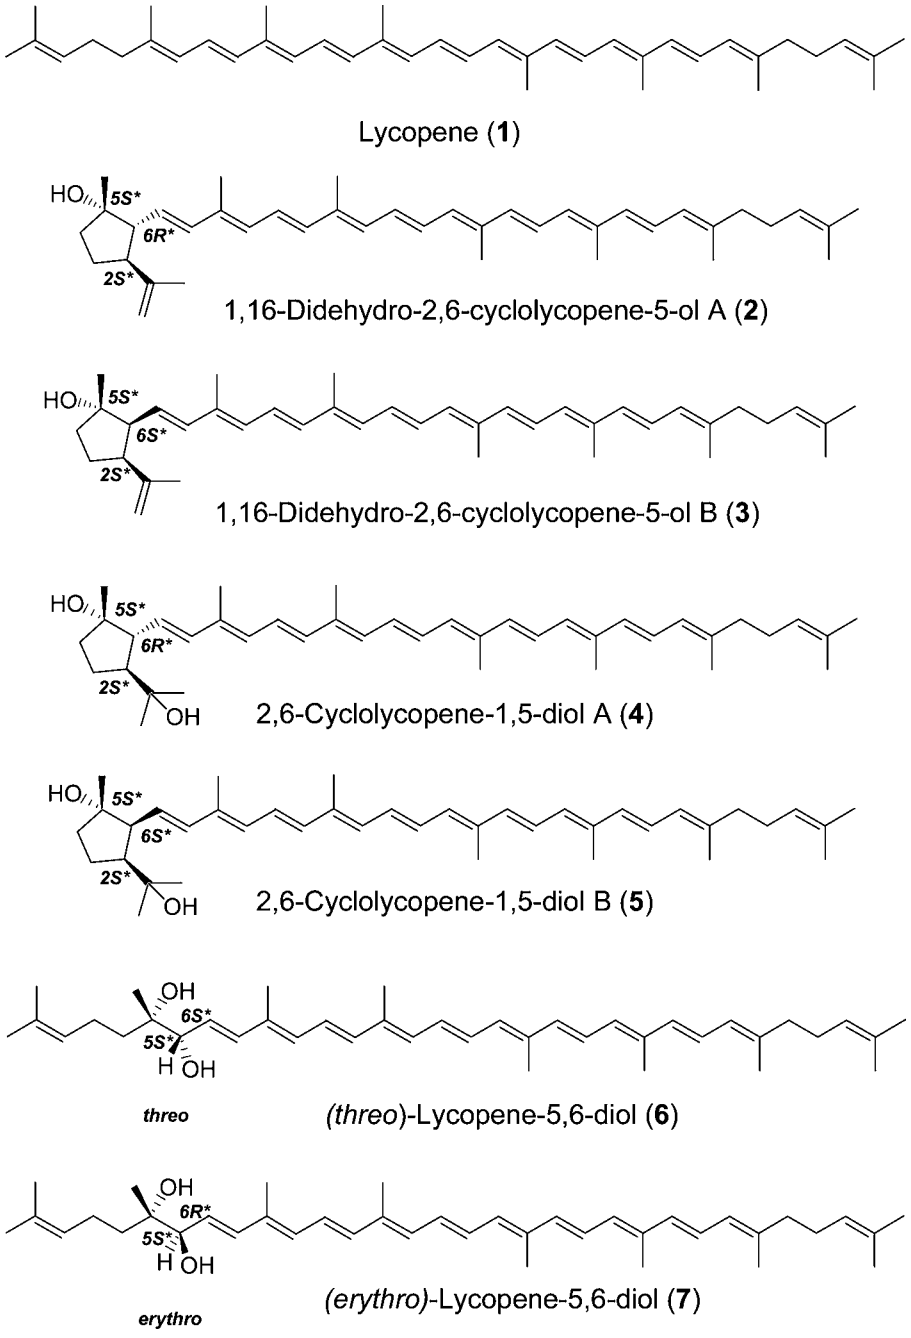

Figure 1. Lycopene (**1**) and its oxidative metabolites (**2**–**7**) in gac. The relative stereochemistry was indicated as *R** and *S**.

RESULTS AND DISCUSSION

Three new carotenoids, **3**, **6**, and **7**, were isolated as minor components along with lycopene (**1**), 1,16-didehydro-2,6-cyclolycopene-5-ol A (**2**), 2,6-cyclolycopene-1,5-diol A (**4**), and 2,6-cyclolycopene-1,5-diol B (**5**) from the aril of gac, as shown in Figure 1. Relative stereochemistry of these compounds is indicated as *R** and *S**.

The new carotenoid **3** showed absorption maxima at 431, 455, and 486 nm, indicating the presence of a decene conjugated double bond system.[22] The molecular formula of **3** was determined as $C_{40}H_{56}O$ by HR FAB MS. The ^{1}H NMR spectral data for **3**, assigned by COSY and NOESY analyses, are shown in Table 1. The ^{1}H NMR spectroscopic data were almost the same as those of 1,16-didehydro-2,6-cyclolycopene-5-ol A (**2**),[18] except for the H-5, H-6, H-7, and H-18 positions. This suggested that **3** might be an epimer of 1,16-didehydro-2,6-cyclolycopene-5-ol A (**2**), having a (2*S**,5*S**,6*R**) configuration. The relative configuration of **3** was elucidated by performing a NOESY experiment. In the case of **2**, a NOESY correlation for CH_3-18/H-7 was not noted. However, a NOESY correlation for CH_3-18/H-7 was observed in the case of **3** (Figure 2). This clearly indicated that **3** is a 6-epimer of **2**. Therefore, a (2*S**,5*S**,6*S**) configuration was postulated for **3**. Thus, compound **3** was named 1,16-didehydro-2,6-cyclolycopene-5-ol B ((2*S**,5*S**,6*S**)-1,16-didehydro-1,2,5,6-tetrahydro-2,6-cyclo-*ψ*,*ψ*-carotene-1′,5′-diol). This stereostructure was also confirmed using the ab initio molecular orbital method employing the Gaussian 03 program.

Both new carotenoids **6** and **7** showed the same absorption maxima at 431, 455, and 486 nm, indicating the presence of a

decene conjugated double bond system.[22] The molecular formulas of both **6** and **7** were determined as $C_{40}H_{58}O_2$ by HR FAB MS. Acetylation of both compounds yielded a monoacetate. The ^{1}H and ^{13}C NMR data for **6**, which were assigned by COSY, NOESY, HSQC, and HMBC analyses, are shown in Table 1. These ^{1}H and ^{13}C NMR spectroscopic data were almost the same as those of lycopene (**1**), except for the C-5, C-6, and C-18 positions. The presence of one secondary hydroxy group (δ_C 78.9 and δ_H 4.04) and tertiary hydroxy group (δ_C 75.0) in **6** was revealed by NMR data. The presence of a tertiary hydroxy group at C-5 and secondary hydroxy group at C-6 was determined by HMBC data. HMBC correlations for CH_3-18/C-5, CH_3-18/C-6, H-3/C-5, and H-7/C-6 were in agreement with this structure. Thus, the planar structure of **6**

DOI: 10.1021/jf505008d
J. Agric. Food Chem. 2015, 63, 1622−1630

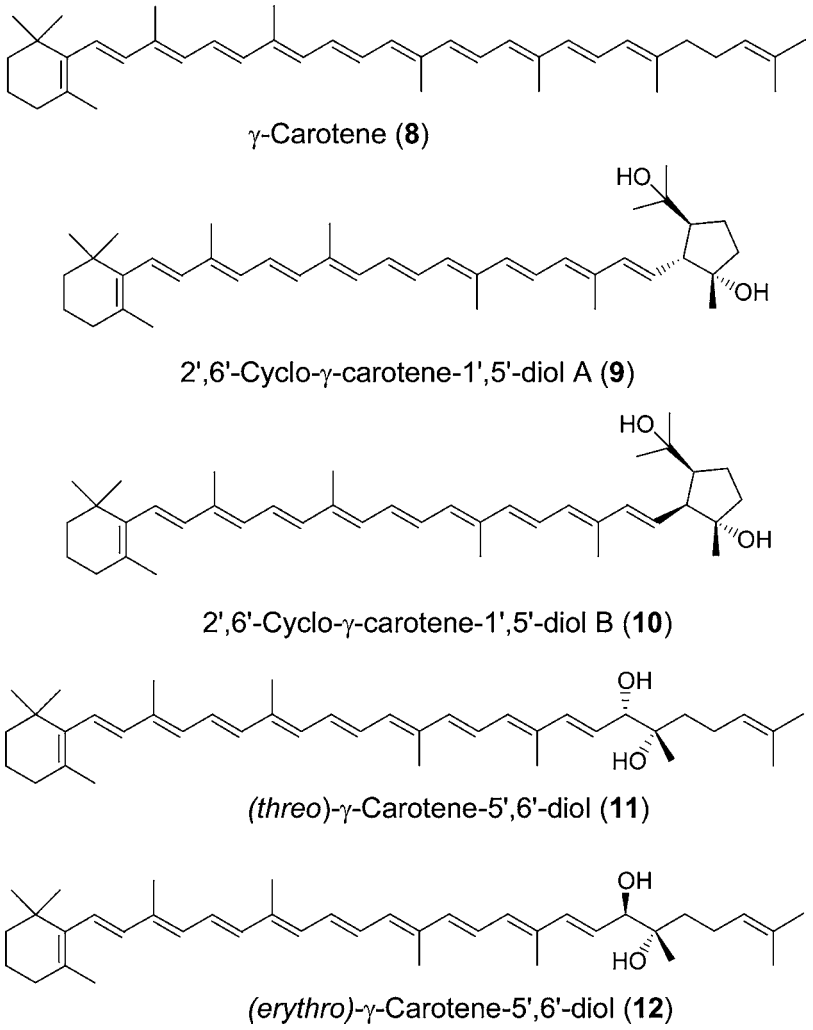

Figure 4. γ-Carotene (**8**) and its oxidative metabolites (**9**−**12**) in gac.

was determined as 5,6-dihydro-ψ,ψ-carotene-5,6-diol. The ^{1}H NMR data for **7** were almost the same as those for **6**, except for the H-6 and H-18 positions. The COSY experiment also revealed the planar structure 5,6-dihydro-ψ,ψ-carotene-5,6-diol for **6**. We decided on lycopene-5,6-diol to refer to the carotenoid of 5,6-dihydro-ψ,ψ-carotene-5,6-diol. Concerning the relative stereochemistry of lycopene-5,6-diol, the *threo* form (indicated as 5*S**,6*S** configuration) and *erythro* form (indicated as 5*S**,6*R** configuration) can be considered (Figure 1). The relative stereochemistry of **6** and **7** was elucidated by NOESY and NOE difference experiments. Strong NOE (>5%) was observed between protons of CH_3-18 and OH-6 in compound **6**, and NOE was not noted between protons of CH_3-18 and OH-6 in compound **7**. Furthermore, strong NOE between protons of CH_3-18 and H-6 was not observed in compound **6** but it was observed in compound **7**. Molecular calculation using the ab initio molecular orbital method employing the Gaussian 03 program indicated that, in the case of the *threo* isomer, distances of CH_3-18 to H-6 and CH_3-18 to OH-6 are 3.81 and 3.28 Å, respectively. Additionally, in the case of the *erythro* isomer the distances of CH_3-18 and H-6 and CH_3-18 and OH-6 are 3.16 and 3.91 Å, respectively. It has been reported that NOE is observed at both protons pairs, located within 3.5 Å.[25] Therefore, *threo* stereochemistry for **6** and *erythro* stereochemistry for **7** could be postulated. These stereochemistries were also confirmed with a synthetic approach. Namely, (5*S*,6*R*)-(*erythro*)-lycopene-5,6-diol was synthesized by a stepwise C_{15} + C_{10} + C_{15} double Wittig reaction. The key compound, (5*S*,6*R*)-C_{15}-dihydroxy aldehyde, was prepared via Sharpless asymmetric epoxidation of geraniol and subsequent acidic hydrolysis of the epoxide as shown in Figure 3. The enantiomeric purity of the epoxy geraniol was improved by recrystallization of its dinitrobenzoate. In the same procedure, (5*S*,6*S*)-(*threo*)-lycopene-5,6-diol was synthesized starting from nerol. The enantiomerically enriched compound was obtained by recrystallization of the dihdroxy dinitrobenzoate instead of the epoxy dinitrobenzoate. The outline of the total synthesis of (5*S*,6*R*)- and (5*S*,6*S*)- lycopene-5,6-diol is shown in Figure 3. The detailed synthetic procedures of these compounds will be described elsewhere.

The ^{1}H NMR and ^{13}C NMR data of **6** were identical to those of synthetic (*threo*)-lycopene-5,6-diol, and the ^{1}H NMR data of **7** were identical to those of (*erythro*)-lycopene-5,6-diol. Therefore, structures of **6** and **7** were determined to be (*threo*-) and (*erythro*)-lycopene-5,6-diol, respectively.

Four oxidative metabolites of γ-carotenes, **9**, **10**, **11**, and **12**, were isolated as very minor components. The new carotenoid **9** showed absorption maxima at 420, 445, and 472 nm. The molecular formula of **9** was determined as $C_{40}H_{58}O_2$ by HR FAB MS. The ^{1}H NMR data for **9** are shown in Table 2. The

γ-carotene-5′,6′-diol (**11**)	6.2 (70)	32.0	79.8	100	352

[a]Values represent the percentage relative to the positive control values (100%). [b]There are significant differences ($P < 0.01$) in inhibitory capacity in treatment groups of carotenoids **1**, **4**, **6**, **8**, **9**, and **11** with the control group. [c]TPA concentration was 20 ng (32 pmol/mL). [d]Values in parentheses are percentage viability of Raji cells. [e]Units are nmol.

^{1}H NMR spectroscopic data showed the presence of a β-carotene moiety (H-2 to H-20). The signals of the remaining part (H-2′ to H-20′) were the same as those of H-2 to H-20 positions of 2,6-cyclolycopene-1,5-diol A (**4**), having a (2*S**,5*S**,6*R**) configuration.[14] This structure was confirmed by COSY and NOESY experiments. Therefore, the structure of **9** was determined as (2′*S**,5′*S**,6′*R**)-1′,2′,5′,6′-tetrahydro-2′,6′-cyclo-β,ψ-carotene-1′,5′-diol. Like 2,6-cyclolycopene-1,5-diol, this structure corresponds to a cyclic oxidative metabolite of γ-carotene. Therefore, we referred to **9** as 2′,6′-cyclo-γ-carotene-1′,5′-diol A (Figure 4).

The new carotenoid **10** showed the same UV/vis and MS spectra as those of **9**. The ^{1}H NMR spectroscopic data were almost the same as those of **9** except for the H-2′ to H-6′ and H-16′ to H-18′ positions. This suggested that **10** might be an epimer of 2′,6′-cyclo-β,ψ-carotene-1′,5′-diol A (**9**). The ^{1}H NMR spectroscopic data of H-2′ to H-6′ and H-16 to H-18 were the same as those of H-2 to H-6 and H-16′ to H-18′ of 2,6-cyclolycopene-1,5-diol B (**5**), having a (2′*S**,5′*S**,6′*S**) configuration.[14] Therefore, the structure of **10** was determined as (2′*S**,5′*S**,6′*S**)-1′,2′,5′,6′- tetrahydro-2′,6′-cyclo-β,ψ-carotene-1′,5′-diol and was named 2′,6′-cyclo-β,ψ-carotene-1′,5′-diol B (Figure 4). Very recently, Crawford et al. synthesized 1,2,5,6-tetrahydro-2,6-cyclo-γ-carotene-1,5-diol, an oxidation product of γ-carotene.[26] This compound has the same relative stereochemistry as that of **9** and the spectral data of 1,2,5,6-tetrahydro-2,6-cyclo-γ-carotene-1,5-diol synthesized by Crawford et al. were identical to those of **9**.

Both compounds **11** and **12** showed the same absorption maxima at 420, 445, and 472 nm and the same molecular formula of $C_{40}H_{58}O_2$. ^{1}H NMR data of both compounds were similar to each other except for H-5′ and H-18′. ^{1}H NMR data of **11** indicated the presence of a β-carotene moiety (H-2 to H-20) and (*threo*)-lycopene-5,6-diol moiety (H-2′ to H-20′). Therefore, the structure of **11** was determined as (*threo*)-5′,6′-dihydro-β,ψ-carotene-5′,6′-diol, which was confirmed by COSY and NOESY experiments, and was named (*threo*)-γ-carotene-5′,6′-diol (Figure 4).

Similarly, the structure of **12** was determined as (*erythro*)-5′,6′-dihydro-β,ψ- carotene-5′,6′-diol by comparison of the ^{1}H NMR data with β-carotene and (*erythro*)-lycopene-5,6-diol (**7**), and was named (*erythro*)-γ-carotene-5′,6′-diol (Figure 4).

Based on the results of the present investigation and the previous literature,[13−18] possible metabolic conversion path-

ways of 1,16-didehydro-2,6-cyclolycopene-5-ols (**2** and **3**), 2,6-cyclolycopene-1,5-diols (**4** and **5**), and lycopene-5,6-diols (**6** and **7**) from lycopene (**1**) are proposed, as shown in Figure 5. Nevertheless, lycopene-5,6-epoxide was not detected in gac, and it was assumed that compounds **2**−**7** might be formed through lycopene-5,6-epoxide. Epoxidation of lycopene provided lycopene-5,6-epoxide. Lycopene-5,6-epoxide was reported as a reaction product of lycopene with MCPB,[14] but it has not been isolated and characterized by spectroscopy including NMR.[14−18] Lycopene-5,6-epoxide might be a very unstable compound and soon converted to other metabolites. Immediately, lycopene-5,6-epoxide was converted to 2,6-cyclolycopene-1,5-diols (**4** and **5**) through epoxy ring cleavage and cyclization of the end group by acid catalysis. Subsequently, dihydroxylation of the hydroxy group at C-1 in **4** and **5** yielded 1,16-didehydro-2,6-cyclolycopene-5-ols (**2** and **3**). However, hydrolytic cleavage of the epoxide ring in lycopene-5,6-epoxide led to two diastereomeric pairs of lycopene-5,6-diols, **6** and **7**. Similarly, 2′,6′-cyclo-γ-carotene-1′,5′-diols (**9** and **10**) and γ-carotene-5′,6′-diols (**11** and **12**) were assumed to be formed from γ-carotene through γ-carotene-5′,6′-epoxide, which was not detected in gac, like lycopene-5,6-diol.

The antitumor-promoting activity of lycopene (**1**), 2,6-cyclolycopene-1,5-diol A (**4**), lycopene-5,6-diol (**6**), γ-carotene (**8**), 2′,6′-cyclo-γ-carotene-1′,5′-diol (**9**), and γ-carotene-5′,6′-diol (**11**) was examined using the Epstein−Barr virus (EBV) activation assay in Raji cells. The results are shown in Table 3. These compounds showed inhibitory effects on the EBV-EA induction of Raji cells without significant cytotoxicity (more than 60% viability of Raji cells) in this assay. The lycopene oxidative metabolites 2,6-cyclolycopene-1,5-diol A (**4**) and lycopene-5,6-diol (**6**) showed slightly higher activity than lycopene (**1**), which is a well-known and excellent antitumor-promoter.[5−8] Similarly, 2′,6′-cyclo-γ-carotene-1′,5′-diol (**9**) and γ-carotene-5′,6′-diol (**11**) also showed slightly higher activity than γ-carotene (**8**). These results revealed that oxidative metabolites of lycopene and γ-carotene exhibit anticarcinogenic activity as well as lycopene and γ-carotene. Carotenoid contents and compositions in gac are shown in Table 4. Gac is a good dietary source of lycopene, as is tomato.[19,20]

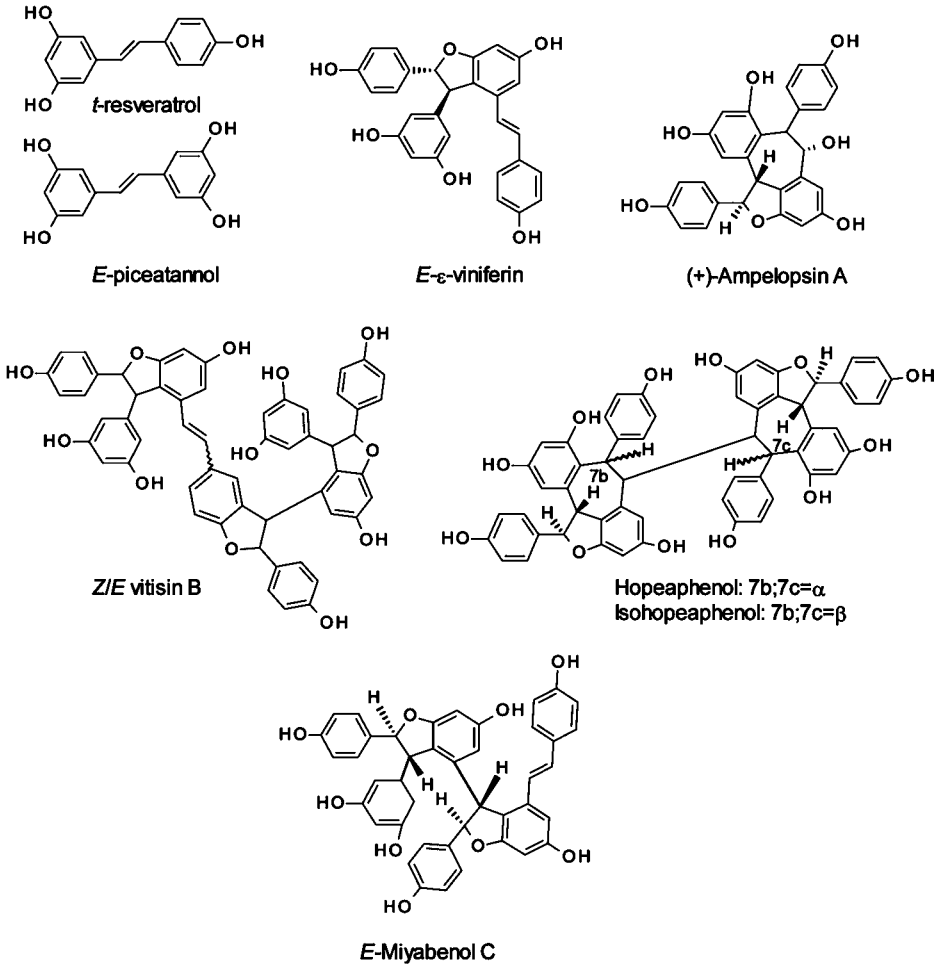

Figure 1. Selected structures of typical stilbenoids present in grape canes.

pharmacological properties of stilbenoids[31] and in agriculture as an alternative source of anti-phytopathogenic substances.[12]

Despite recent advances in the evaluation of stilbenoid composition of grape canes,[31−33] varying results have been reported. Several factors can explain this variability. First, the variety and provenance of the grape can greatly influence stilbenoid composition.[11,30,34] To note, *E*-resveratrol ranged from 0.022 mg kg^{-1} of dry weight (DW) in Turkish cultivars[35] to 6533 mg kg^{-1} of DW in canes from Chile.[30] Second, the extraction method is critical to ensure a good recovery of stilbenoids,[32,36] and the range of extraction methods tends to bias the results. Furthermore, an accurate quantification of stilbenoids relies on calibration curves with pure stilbenoid standards because the quantification of stilbenoids as a resveratrol equivalent leads to an underestimation of the concentrations of resveratrol oligomers.[11] Additionally, a disparity in stilbenoid composition of "Pinot Noir" grape canes has been observed during storage, i.e., the time elapsed between vine pruning and the phytochemical analyses.[37] An increase in the stilbenoid concentration (up to 5-fold) after 6 months at 20 °C was observed. Canes were enriched in *E*-resveratrol, whereas the level of *E*-ε-viniferin did not vary. Although an increase in stilbenoid concentrations has been found in "Pinot Noir" canes in response to storage, the determining factors controlling this accumulation remain unknown and the effect of storage on other grape varieties has not been determined systematically.

The aim of this study was to better characterize stilbenoid accumulation in pruned grape canes and particularly to (i) determine the optimal storage period for 8 grape varieties representative of the Loire valley, (ii) evaluate the influence of temperature storage on stilbenoid accumulation, and (iii) assess the potential biosynthetic activity in pruned grape wood.

MATERIALS AND METHODS

Plant Material. Grape canes of *Vitis vinifera* varieties, "Cabernet Franc", "Chardonnay", "Chenin", "Malbec" (Côt), "Gamay", "Grolleau", "Pinot Noir", and "Sauvignon Blanc", were collected in vineyards at the wine school of Amboise (France) in December 2012. The canes were cut into 10 cm long sections and stored in a controlled chamber at 20 °C for 10 weeks in the dark. In the same way, grape canes of *V. vinifera* var. "Malbec" were stored in additional controlled chambers at −20, 5, 15, 20, and 28 °C for 10 weeks in the dark. Heat shock treatment with intent to denature enzymes consisted of a treatment at 65 °C for 2 h immediately after cane harvest, followed by storage at 20 °C. After storage, samples were ground for 2 min with a cooled analytical grinder (Ika-Werke, Staufen, Germany), frozen in liquid nitrogen, and stored at −80 °C for stilbenoid and gene expression analysis. For time point zero, canes were cut in the vineyards, transported to the laboratory (1 h), and immediately ground, as described above.

Chemicals. *E*-Resveratrol, *E*-piceatannol, catechin, and epicatechin were purchased from Sigma-Aldrich (St. Louis, MO). *E*-ε-Viniferin, *Z*/*E*-vitisin B, ampelopsin A, and hopeaphenol were extracted from grape canes.[19] Acetonitrile and ethanol were purchased from Thermo Fisher

DOI: 10.1021/jf505316a
J. Agric. Food Chem. 2015, 63, 1631−1638

Scientific (Courtaboeuf, France). Ultrapure water was obtained from a Millipore Milli-Q water purification system.

Stilbenoid Analysis. A second grinding step was performed to obtain a powder with an average particle size of 1 mm using a cutting mill (Polymix PX-MFC 90 D, Kinematica AG, Switzerland). Stilbenoid extraction was adapted from the study by Karacabey and Mazza.[33] A total of 50 mg of lyophilized powder were extracted in 1 mL of ethanol/water solution (60:40; v/v), shaken for 30 min at 1400 rpm at 83 °C, and centrifuged at 18000*g* for 5 min. A high-performance liquid chromatography (HPLC) apparatus consisted of a Waters system equipped with a gradient pump (Waters 600 controller, Milford, MA), a cooled autosampler (Waters 717 plus), and a UV−vis photodiode array detector (Waters 996) set to acquire data from 200 to 400 nm. Empower 2 software from Waters was used for instrument control, data acquisition, and data processing. Analyses were performed on a column packed with 3 μm particles (250 × 4 mm, Multospher 120 RP18HP, CS-Service, Langerwehe, Germany) at 24 °C. The mobile phase consisted of aqueous phosphoric acid (0.1%, w/v, eluent A) and acetonitrile (eluent B) pumped at 0.5 mL min^{-1} into the HPLC system. The gradient started at 5% B and increased linearly to 72.5% in 60 min, followed by washing and reconditioning the column. Compounds in extracts were identified according to their UV spectra and retention time by comparison to external standards. Quantification was performed using pure reference standards of *E*-resveratrol, *E*-piceatannol, *E*-ε-viniferin, *Z*/*E*-vitisin B, ampelopsin A, and hopeaphenol and five-point calibration curves (0−100 ppm) using the Maxplot detection mode.

Gene Expression Analysis. Total RNA extractions were performed on ground grape canes (approximately 100 mg) using the improved RNA extraction protocol for woody plants,[38] with RNeasy Plant Mini Kit (Qiagen, U.K.). RNA quality and concentration were assessed both spectrophotometrically and on agarose gel. Reverse transcription of RNA was carried out using ThermoScript RT (Invitrogen) according to the instructions of the manufacturer. First-strand cDNA was synthesized using total RNA (200 ng) and oligo dT_{20} primer (2.5 μM) in the presence of RNaseOUT (Invitrogen). Gene expression was analyzed by quantitative real-time PCR on retro-transcribed RNA using the following primer pairs: 5′-GAAACCCAT-CAATTCCGAACC-3′ (forward) and 5′-GCACTGAGACAATCCA-GAAGAG-3′ (reverse) for phenylalanine ammonia lyase (PAL), 5′-AAAGCTCTGTTAGCGGTGTTCTG-3′ (forward) and 5′-TCAGGTGGTTCAAGTCATCCC-3′ (reverse) for cinnamate 4-hydroxylase (C4H), 5′-CCTGAAATTCCCATCTCCAACC-3′ (forward) and 5′-GACTTTGCGAGAAATGAGGTG-3′ (reverse) for 4-coumaric acid:CoA ligase (4CL), 5′-CAGCAGCCCAAACATT-TATTCC-3′ (forward) and 5′-GTTCCAATCGCTAATAC-CAAGTG-3′ (reverse) for stilbene synthase (STS), and 5′-CTTCTCCTGTATGGGAGCTGCG-3′ (forward) and 5′-GCCA-TAACAACTGGTACAATCGAC-3′ (reverse) for VATP16 reference gene, chosen according to Gamm et al.[39] A real-time polymerase chain reaction (PCR) was run on a CFX96 Touch real-time PCR system (Bio-Rad) using the SYBR Green I technology. Each PCR mixture of 15 μL of total reaction volume contained an equal amount of cDNAs, 0.2 μM forward and reverse primers, and 1× SsoAdvanced SYBR Green Supermix (Bio-Rad). The reaction was initiated by a denaturation step (95 °C for 7 min), followed by 40 cycles at 95 °C for 10 s and 60 °C for 30 s. Melt curve analysis was performed on the end products of PCR, to determine the specificity of reactions. Absolute quantification of the transcript copy number was performed using calibration curves (plasmid dilution series from 10^8 to 10^4 copies). The results are expressed as the copy number of cDNA normalized using VATP16 reference gene.

Statistical Analysis. Data were analyzed with Statistica, version 6.0 (StatSoft, Inc., Tulsa, OK). Statistical significance from different treatments was revealed after one-way analysis of variance (ANOVA), followed by Tukey's test.

RESULTS AND DISCUSSION

A total of 10 compounds were identified in grape cane extracts from the varieties "Cabernet Franc", "Chardonnay", "Chenin", "Malbec" (Côt), "Gamay", "Grolleau", "Pinot Noir" and "Sauvignon Blanc", corresponding to the flavonoids, catechin and epicatechin, and the stilbenoids, ampelopsin A, *E*-piceatannol, *E*-resveratrol, hopeaphenol, isohopeaphenol, *E*-ε-viniferin, *E*-miyabenol C, and *Z*/*E*-vitisin B (Figure 1). HPLC chromatograms of "Sauvignon Blanc" grape cane extracts before and after a 6 week storage period show striking changes in stilbenoid composition, particularly for *E*-resveratrol and *E*-piceatannol (Figure 2). To confirm those observations, a survey

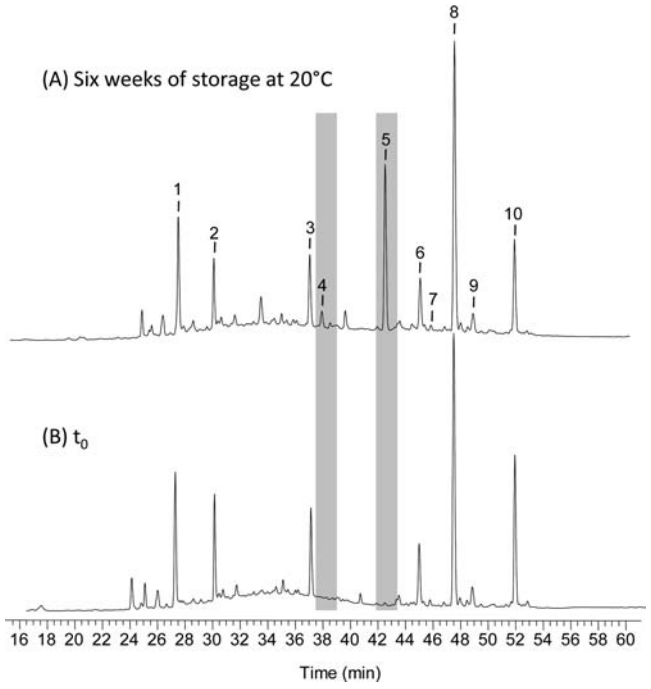

Figure 2. HPLC chromatograms measured in Maxplot detection of hydroalcoholic cane extracts of *V. vinifera* "Sauvignon Blanc". Grape canes were harvested in the vineyard and stored for 6 weeks at 20 °C (A) or were immediately ground for stilbenoid extraction (B). (1) Catechin, (2) epicatechin, (3) ampelopsin A, (4) *E*-piceatannol, (5) *E*-resveratrol, (6) hopeaphenol, (7) isohopeaphenol, (8) *E*-ε-viniferin, (9) *E*-miyabenol C, and (10) *Z*/*E*-vitisin B.

of stilbenoid accumulation in pruned wood was expanded to eight grape varieties stored for 8 weeks at 20 °C (Figure 3). The initial concentration of *E*-resveratrol contained in branches before any treatment was determined prior to storage. For this, the grape canes were ground and frozen at −80 °C within 1 h (maximum) after pruning in the vineyards. The *E*-resveratrol contents measured at t_0 in all varieties were shown to be very low (101 ± 77 mg kg^{-1} of DW) and corresponded to the values previously reported for unstored grape canes.[37] In contrast, an accumulation of *E*-resveratrol was observed in the eight tested grape varieties during storage, reaching a peak after 6 weeks (Figure 3A). On average, a 40-fold increase in *E*-resveratrol was observed with a range from 19-fold for "Pinot Noir" to 102-fold for "Chenin" (Table 1). At the same time, *E*-piceatannol increased in a similar fashion but on a smaller scale (Figure 3B). The accumulation of *E*-resveratrol during storage in these eight varieties confirms previous results obtained for "Pinot Noir",[37] with an additional increase in *E*-piceatannol (3-hydroxyresver-

Table 1. Changes in the *E*-Resveratrol Concentration in Grape Canes from Eight Varieties after a 6 Week Storage Period at 20 °C

	E-resveratrol concentration (mg kg^{-1} of DW)		
variety	0 weeks	6 weeks	fold induction
Sauvignon Blanc	60 (31)	2908 (552)	48
Chardonnay	96 (16)	3175 (508)	33
Côt	158 (23)	3316 (762)	21
Grolleau	41 (18)	3913 (704)	95
Chenin	45 (15)	4631 (926)	106
Pinot Noir	250 (112)	4725 (897)	19
Cabernet Franc	57 (15)	4762 (952)	83
Gamay	100 (33)	5100 (867)	51
Means	101	4066	40

atrol). Such an induction of monomeric stilbenoids was also observed in other postharvest plant materials.[40] Indeed, *E*-resveratrol and *E*-piceatannol were shown to accumulate in sugar cane billets within 7 days after harvest. Furthermore, it has been shown that red wines and table grapes can be enriched in stilbenoids by postharvest UV-C irradiation of grapes.[41−43] As for other stilbenoid-rich products, the present results highlight the importance of the postharvest process to obtain grape canes with enriched contents in *E*-resveratrol and *E*-piceatannol.

Nevertheless, the origin of the accumulated stilbenoids was not elucidated. They might be formed from the degradation of oligomeric stilbenoids or a biosynthetic activity. For this reason, the concentrations of resveratrol oligomers (ampelopsin A, hopeaphenol, isohopeaphenol, *E*-ε-viniferin, *E*-miyabenol C, and *Z*/*E*-vitisin B) were individually quantified during the storage period but no significant changes were observed (data not shown). In summary, Figure 3C presents the total concentration of resveratrol oligomers, which do not significantly vary during storage in any of the varieties tested. Therefore, the possibility that *E*-resveratrol and *E*-piceatannol originated from the degradation of resveratrol oligomers was ruled out. To test the hypothesis that the accumulation of *E*-resveratrol originated from a *de novo* biosynthesis, the influence of temperature storage on *E*-resveratrol accumulation was tested on the "Cabernet Franc" variety over 10 weeks (Figure 4). First, when the canes were stored at either 5, 15, or 20 °C, the *E*-resveratrol concentration increased to approximately 6384 ± 456 mg kg^{-1} of DW; however, the accumulation rate of *E*-resveratrol was shown to be delayed at lower temperatures. Second, at 28 °C, *E*-resveratrol accumulated rapidly during the first 2 weeks up to a peak of 3923 ± 584 mg kg^{-1} of DW; however, no further accumulation was observed in the weeks after. Finally, when a short heat-shock treatment (2 h at 65 °C) was applied to grape canes, no *E*-resveratrol accumulation was observed. Such a treatment with intent to denature proteins inhibits the accumulation of *E*-resveratrol during the storage period and suggests the involvement of active enzymes in this phenomenon. Similarly, when canes were stored at −20 °C, *E*-resveratrol was not induced. The temperature during the storage process of grape canes is therefore a determining factor for optimal *E*-resveratrol accumulation (observed at 20 °C). Moreover, whereas an excessive temperature (up to 28 °C) rapidly inhibits *E*-resveratrol accumulation, a decrease in the storage temperature only slows the induction rate and the optimal *E*-resveratrol content is still achieved, albeit at a later

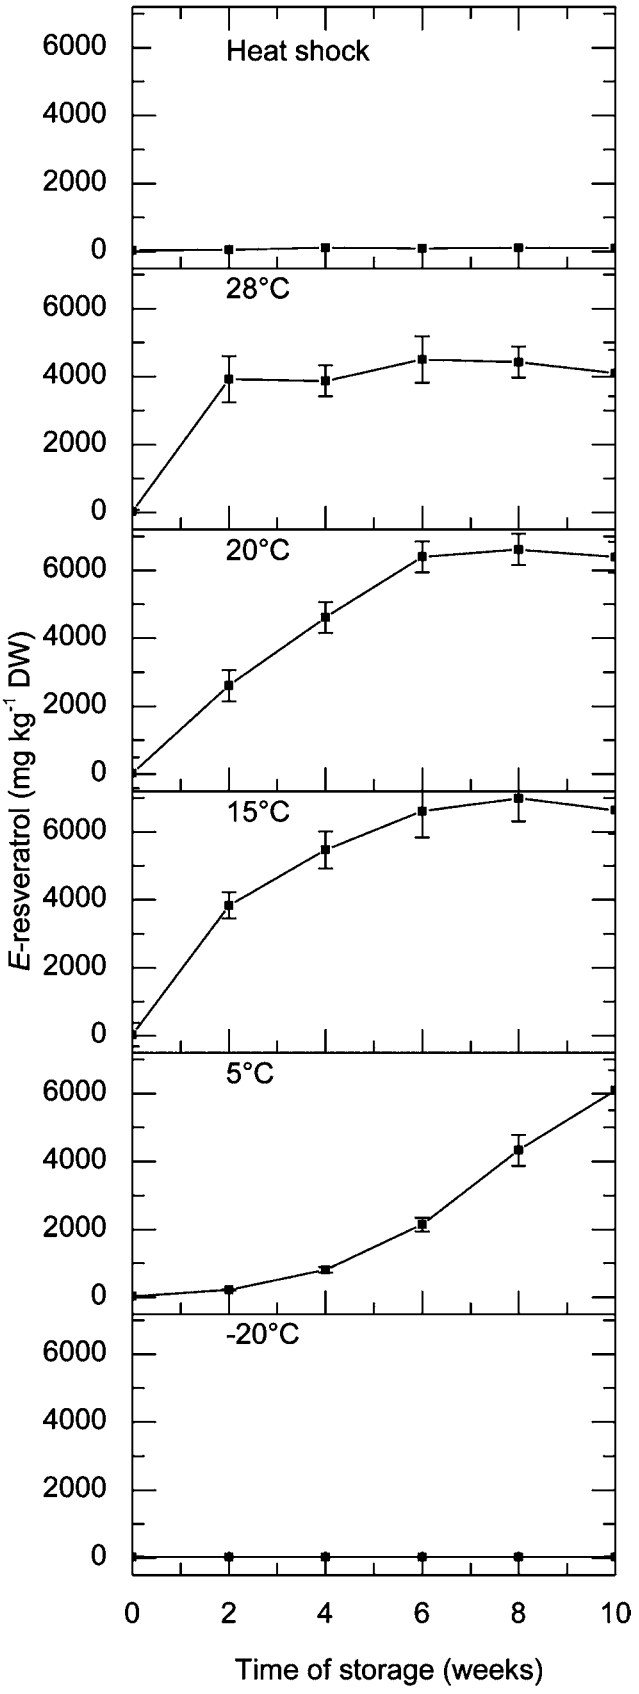

Figure 4. Effect of the temperature on *E*-resveratrol accumulation during cane storage of *V. vinifera* "Cabernet Franc". Grape canes were stored for a period of 10 weeks at −20, 5, 15, 20, and 28 °C. Heat shock consisted of a treatment at 65 °C for a period of 2 h immediately after harvest, followed by storage at 20 °C.

time period (Figure 4). These data prompt us to assume that the biosynthetic enzyme activities and, particularly, those involved in the stilbene pathway persist during storage and that the optimal period of storage is directly related to the storage temperature.

Given these data, we investigated by real-time PCR the transcriptional activity of key genes involved in the stilbene biosynthesis during the 6 weeks of *E*-resveratrol accumulation in pruned grape wood of the "Cabernet Franc" variety stored at 20 °C (Figure 5). The transcript abundance of the structural

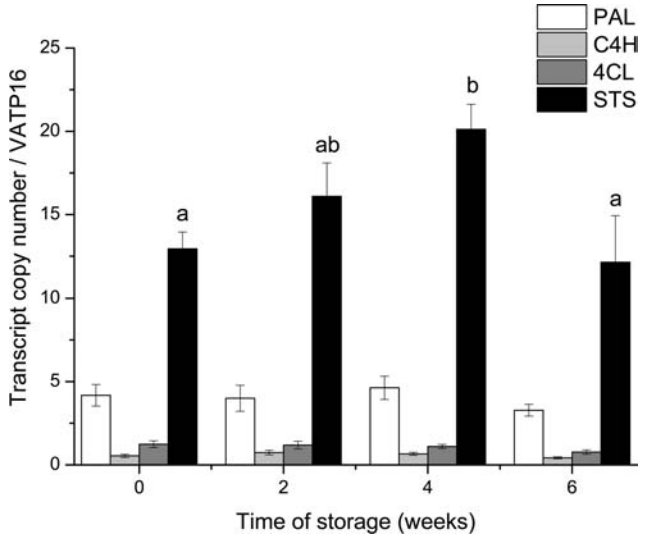

Figure 5. Transcript abundance of the stilbene biosynthesis pathway genes PAL, 4CL, C4H, and STS measured by quantitative real-time PCR during cane storage of *V. vinifera* "Cabernet Franc". Grape canes were collected in the vineyard and directly frozen at −80 °C (t_0) or stored at 20 °C for 2, 4, and 6 weeks. Transcript abundance of each gene was normalized against VATP16 reference gene. Different letters in the same group of bars indicate significant differences ($p < 0.05$).

genes PAL, 4CL, C4H, and STS were assayed by quantitative real-time PCR (Figure 5). PAL, 4CL, and C4H, the three genes of the general phenylpropanoid pathway, were constitutively expressed over the 6 weeks of storage, and in addition, STS (forming *E*-resveratrol) was induced during the first 4 weeks of storage. These results suggest that grape pruned wood is still transcriptionally active during the storage period.

In planta, *E*-resveratrol is a well-known phytoalexin, i.e., an antimicrobial substance that rapidly accumulates at the pathogen infection site. *E*-Resveratrol is induced in response to biotic and abiotic stresses, such as elicitors,[44] UV-C light,[45] ozone,[46] anoxia,[47] and wounding.[48] Following pathogenic infection, the STS transcripts are induced within 16−48 h[3,39] and the peak value for *E*-resveratrol accumulation occurs around 24−72 h.[6] In contrast, the induction of stilbene metabolism in postharvest material is poorly documented, and available data are restricted to grape berries. Pioneering work showing the induction of stilbene metabolism during the drying process of postharvest grape berries was reported by Versari et al.[49] Recently, complementary studies showed that both STS transcripts and *E*-resveratrol biosynthesis are induced in the epicarp of postharvest grape berries and the induction level depends upon the dehydratation rate.[50] Our study highlights a similar induction of stilbene biosynthesis in postharvest grape canes where the drying process during storage might be perceived as a stress signal by living tissues. Stilbene metabolism is thus induced, and *E*-resveratrol and *E*-piceatannol accumulate until the tissues are dry. Further investigations will help to evaluate the influence of the hygrometric conditions in relation to temperature on stilbenoid accumulation during grape cane storage.

In conclusion, at the pruning stage, grape canes contain high levels of oligomeric stilbenoids previously accumulated during the growing season but almost no monomeric stilbenoids. During the first 6 weeks of storage, *E*-resveratrol and *E*-piceatannol accumulate at various rates depending upon the storage temperature. This *E*-resveratrol accumulation resulted from a *de novo* biosynthesis with induction of STS expression during storage. Grape canes appear to be an original plant byproduct containing valuable stilbenoids. Because this pruned wood is still metabolically active during the drying process, the storage conditions have to be controlled to obtain stilbene-enriched material for further medicinal or agronomical applications. To further characterize the variability of stilbenoids in grape canes, the impact of grape diseases during the growing season will be required.

pathway is strictly regulated by Wnt antagonists, including Wnt inhibitory protein 1 (WIF1), Frizzled related protein (sFRP), and Dickkopf (Dkk). Binding of WIF to Wnts and binding of sFRP to both Wnts and Fzs cause negative modulation in both the canonical and noncanonical Wnt pathways. Binding of Dkks to the Fz−LRP complex impairs its function, acting as specific inhibitors of the canonical Wnt pathway.[18] Abnormal Wnt gene expression is associated with the epithelial-to-mesenchymal transition (EMT). Importantly, many oncogenic pathways may activate EMT, thus causing EMT metastatic potential in epithelial cancer cells,[19] which is related to the upregulation of mesenchymal markers, including Twist and fibronectin, in the majority of premetastatic tumors.[20] However, tissue fibrosis is tight EMT activation, which may also be initiated by tissue damage and inflammatory processes.[21] Furthermore, EMT has been suggested to result in the increases in the levels of fibroblasts, collagen, and other matrix components at chronic inflammatory sites, involving progressive organ fibrosis.[22] Furthermore, changes in the expression of Wnts, their receptors, and antagonists were demonstrated to be associated with renal interstitial fibrosis induced by unilateral ureteral obstruction.[14] Therefore, we hypothesized that nano-TiO_2-induced chronic renal inflammation may subsequently lead to renal fibrosis and is associated with the Wnt pathway in mouse kidney.

Nano-TiO_2 is a common additive in food and personal care products, and their presence in daily life is increasing. Dietary exposure to TiO_2 in Western populations is 1−3 mg of TiO_2 [kg of body weight (bw)]$^{-1}$ day^{-1} on average for children under the age of 10 years and approximately 0.2−1 mg of TiO_2 (kg of bw)$^{-1}$ day^{-1} for other age groups. Several reports (e.g., NIOSH) recommend exposure limits of 2−3 mg/m^3 for fine TiO_2 and 0.3−1 mg/m^3 for ultrafine (including nanoscale engineered) TiO_2.[22] Assuming that 36% of food-grade TiO_2 is smaller than 100 nm in at least one dimension, this exposure limit decreases to approximately 0.1 mg of nanoscale TiO_2 person^{-1} day^{-1}.[23] Therefore, the long-term oral ingestion of the smaller dose of TiO_2 may be associated with potential kidney toxicity. In this study, female mice were continuously exposed to 1.25, 2.5, or 5 mg of nano-TiO_2/kg administered by gavage according to FDA guidelines for 9 consecutive months. The expression levels of Wnt pathway-related markers and EMT markers in mouse kidney were investigated to determine the mechanism of renal fibrosis caused by chronic exposure to nano-TiO_2.

MATERIALS AND METHODS

Chemicals. The preparation of nano-anatase TiO_2 was described by Yang.[24] It was fully characterized as previously described by Yang et al.[24] and in our previous studies[25] and is listed in Table 1.

Table 1. Characteristics of Nano-TiO_2[24,25]

phase	particle size (nm)	surface area (m^2/g)	Man hydrodynamic diameter (nm)	ζ potential (mV)
anatase	5−6	174.8	208−330 (mainly 294)	9.28

Animals and Treatment. CD-1 (ICR) female mice (4 weeks old, 20 ± 2 g), obtained from the Animal Center of Soochow University (China), were used in this study and were fed with sterilized food and distilled water *ad libitum* and housed in stainless steel cages (five mice per cage). All mice were kept at standardized laboratory conditions (24 ± 2 °C, 60 ± 10% humidity, and a 12 h light/dark cycle). After being acclimated to the laboratory conditions for one week, the mice were fasted for 3 h prior to nano-TiO_2 administration. All experiments were conducted using the recommendations for the ethical conditions approved by the Care and Use of Animals Committee of Soochow University, which are consistent with international ethics for handling experimental animals.

One hundred mice were divided into four groups (n = 25 in each group): a control group treated with 0.5% (w/v) hydroxypropylmethylcellulose (HPMC) K4M (Sigma-Aldrich, St. Louis, MO) solvent and three experimental groups treated with 1.25, 5, or 5 mg of nano-TiO_2/kg of bw suspended in HPMC solvent. All mice were weighed, and the nano-TiO_2 suspensions of different doses were administered to mice by intragastric feeding every day for 9 months. Food and water intake was carefully recorded during the last week of the 9th months. Food and water intake was calculated according to the Drozdz method.[26]

Kidney Indices. After the 9 month study period, all mice were weighed and urine was collected in 50 mL conical tubes over 24 h. Urine volumes were measured, and the samples were stored at −80 °C. All mice were lightly anesthetized with ether; blood samples were collected from the heart, and the kidneys were quickly removed and placed on ice. After the kidneys had been weighed, the kidney indices were calculated as the ratio of kidney (wet weight, milligrams) to body weight (grams). Fresh kidneys from five mice in each group were quickly soaked in a 10% formaldehyde solution for histopathological examination. The remaining fresh kidneys were quickly stored in liquid nitrogen and subsequently assayed for titanium content and cytokine expression. Serum was collected by centrifuging the blood samples at 1200g for 10 min.

Analysis of Titanium Content. The frozen kidney tissues (n = 5 from each group) were thawed; approximately 0.3 g samples were digested, and titanium, sodium, magnesium, potassium, calcium, zinc, and iron concentrations were determined using inductively coupled plasma mass spectrometry (ICP-MS) (Thermo Elemental X7, Thermo Electron Co., Waltham, MA).[11,12]

Analysis of Kidney Toxicity Biomarkers. Urinary levels of kidney injury molecule-1 (KIM-1), clusterin (CLU), osteopontin (OPN), β2-microglobulin, and cystatin C were performed by enzyme-linked immunosorbent assays (ELISAs) using commercial kits (R&D Systems, Minneapolis, MN), following the manufacturer's instructions.

Analysis of Serum Biochemical Parameters. Uric acid (UA), blood urea nitrogen (BUN), creatinine (CR), and urinary protein excretion in serum (n = 10 in each group) were assessed using a clinical automatic chemistry analyzer (type 7170A, Hitachi, Tokyo, Japan).

Histopathological Observation of Kidneys. After being fixed in 10% neutral formalin and embedded in paraffin, kidney specimens from five mice in each group were sliced at a thickness of 5 μm, and the slices were placed on separate glass slides. After being stained with hematoxylin and eosin, the renal samples were routinely evaluated by a histopathologist unaware of the treatments for light microscopy (U-III Multipoint Sensor System, Nikon, Tokyo, Japan).

Assay of Cytokine Expression. Total RNA was extracted from individual kidneys (n = 5 in each group) with Tripure Isolation Reagent (Roche) according to the manufacturer's protocol. According to MIQE guidelines, probes and cycling conditions were optimized for polymerase chain reaction (PCR).[27] cDNA was reverse transcribed (RT) from total RNA samples using the TaqMan RT reagents (Applied Biosystems) and used for real-time PCR by employing primers designed using Primer Express Software according to its guidelines. Primer sets were used for real-time PCR assays and are listed in Table 2. The probes for *Wnt1*, *Wnt2*, *Wnt3*, *Wnt4*, *Wnt5a*, *Wnt6*, *Wnt7a*, *Wnt9a*, *Wnt10a*, *Wnt11*, *Gsk3β*, *Fz1*, *Fz5*, *Fz7*, *LRP5*, *LRP6*, *Dkk1*, *Dkk2*, *Dkk3*, *Dkk4*, *SFRP/FrzB*, *Abcb1b*, *cyclin D1*, *Myc*, *Col1a1*, *Fn* (fibronectin), *Twist*, and *α-SMA* in the kidneys (n = 5 in each group) were designed by the manufacturer and purchased from Shinegene Co. (Shanghai, China). As an endogenous reference for these PCR quantification studies, GAPDH gene expression was measured. According to the method of Schefe et al.,[28] the RT-qPCR data were processed with sequence detection software version 1.3.1.

The levels of Wnt1, Wnt2, Wnt3, Wnt4, Wnt5a, Wnt6, Wnt7a, Wnt9a, Wnt10a, Wnt11, Gsk3β, Fz1, Fz5, Fz7, LRP5, LRP6, Dkk1, Dkk2, Dkk3, Dkk4, SFRP/FrzB, Abcb1b, cyclin D1, Myc, Col1a1, Fn, Twist, and α-SMA in mouse kidney tissues were measured by an ELISA using commercial kits that were selective for each respective protein (R&D Systems), following the manufacturer's protocols.

Statistical Analysis. Values are presented as means ± the standard deviation (SD). One-way analysis of variance (ANOVA) was performed to compare the differences in means from the multigroup data using SPSS 19 software (SPSS, Inc., Chicago, IL). Dunnett's test was performed when each data set was compared with the solvent control data. The statistical significance for all tests was judged at the $P < 0.05$ probability level.

RESULTS

Food and Water Intake. The quantitative data regarding food and water intake of female mice after intragastric feeding with nano-TiO_2 during the last week of the 9 months are presented in Figure 1. It can be observed that the values of daily food and water intake from nano-TiO_2-exposed groups were decreased compared with those of the control, suggesting

body weight and increases in renal indices compared with those of the control group ($P < 0.05$). Furthermore, significant titanium accumulation occurred with an increased nano-TiO_2 dose (Figure 3; $P < 0.05$). The increased renal indices following exposure to nano-TiO_2 may be related to nephrotoxicity and renal injury.

Table 3. Effect of Nano-TiO_2 on the Level of mRNA Expression of Wnt Ligand Genes in Mouse Kidney after Intragastric Feeding with Nano-TiO_2 for 9 Consecutive Months

	x-fold change in the level of mRNA expression (treatment vs control)		
	1.25 mg of nano-TiO_2/kg of bw	2.5 mg of nano-TiO_2/kg of bw	5 mg of nano-TiO_2/kg of bw

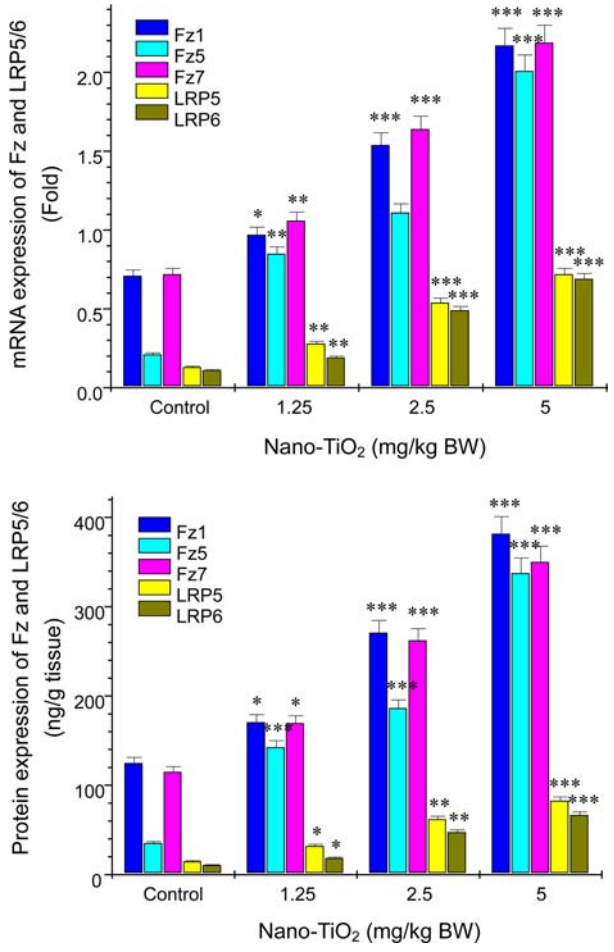

Figure 7. Effect of exposure to nano-TiO_2 on Fz and LRP5 and -6 expression in mouse kidney after intragastric feeding with nano-TiO_2 for 9 consecutive months. *$P < 0.05$. **$P < 0.01$. ***$P < 0.001$. Values represent means ± SD ($n = 5$).

respectively, whereas levels of β2-microglobulin and cystatin C showed no statistically significant change ($P > 0.05$).

Serum Biochemical Parameters. To confirm the effects of nano-TiO_2 on renal function, serum levels of CR, UA, and BUN were examined and are shown in Figure 5. It can be seen that the level of CR and the protein/CR ratio increased by 11.32−20.40 and 2.66−62.19%, respectively, and those of UA and BUN declined by 16.62−50.96 and 11.06−34.94% due to nano-TiO_2 ($P < 0.05$ or 0.01), respectively, compared with the control.

Histopathological Evaluation. The histological changes in the kidney specimens are shown in Figure 6. Unexposed kidney samples presented intact architecture and regularly arranged renal cells, while those from the mice exposed to increasing concentrations of nano-TiO_2 exhibited severe pathological changes, including infiltration of inflammatory cells, dilatation and filling proteinic liquids in the renal tubule, degeneration of tubular cells, tubular dilatation, fibrosis, cell abscission, and tissue necrosis. The results suggested that chronic exposure to TiO_2 NPs resulted in significant pathological changes in the kidneys, which may be related to expression of renal fibration-related markers.

Expression of Wnt Ligands. The effects of nano-TiO_2 on the expression of Wnt ligands are listed in Tables 3 and 4. The results suggested that the level of expression of all Wnt ligands in the nano-TiO_2-exposed kidneys, including Wnt1, Wnt2, Wnt3, Wnt4, Wnt5a, Wnt6, Wnt7a, Wnt9a, Wnt10a, and

Wnt11, was significantly elevated by 0.09−4.84-fold, whereas the level of Gsk3β expression was reduced by 14−64% with an increased nano-TiO_2 dose ($P < 0.05$).

Expression of Fz and Coreceptors LRP5 and -6. Figure 7 shows that exposure to nano-TiO_2 significantly induced the expression of all Wnt receptors Fz- and coreceptors LRP5 and -6-related markers in the kidneys, including Fz1, Fz5, Fz7, and LRP5 (0.37−8.57-fold) and LRP6 (0.73−5.27-fold).

Expression of Wnt and EMT Target Genes. Tables 5 and 6 show that with an increased nano-TiO_2 dose, the expression of all Wnt antagonist-related markers, such as Dkk1, Dkk2, Dkk3, Dkk4, and sFRP/FrzB, was notably inhibited by −0.06- to −0.87-fold. In addition, the levels of expression of Wnt and EMT target genes, such as Abcb1b, cyclin D1, Myc, Col1a1, Fn, Twist, and α-SMA, were markedly elevated by 0.03−2.73- and 0.06−5.80-fold in the kidneys with an increased nano-TiO_2 dose, respectively.

DISCUSSION

The FDA's Critical Path Initiative sought to identify more sensitive and predictive biomarkers of nephrotoxicity that can specifically detect adverse changes in renal integrity before kidney function is compromised. ELISA measurements can identify numerous urinary protein biomarkers (such as KIM-1, CLU, OPN, cystatin C, and β2-microglobulin) and serum parameters, including CR, UA, and BUN, which were qualified by the FDA and European Medicines Agency (EMA) as prognostic prepathological indicators of nephrotoxicity in preclinical rat studies.[29,30] The study presented here suggests that administration of 1.25, 2.5, and 5 mg of nano-TiO_2/kg of bw by intragastric feeding for 9 consecutive months increased the level of nano-TiO_2 accumulation in mouse kidney. This led to severe nephrotoxicity, shown by significant elevations in levels of urinary KIM-1, CLU, and OPN, serum CR and proteinuria, and reductions in serum UA and BUN, together with decreased body weight, inflammatory responses, fibrosis, and tissue necrosis. Reductions in levels of eating, drinking, and activity in mice caused by nano-TiO_2 were also observed; therefore, loss of body weight may be associated with loss of appetite. A decreased level of food intake is due to excessive ROS,[30] and exposure to nano-TiO_2 promoted the over-production of ROS in mouse kidney.[10−13] Our previous studies indicated that exposure to nano-TiO_2 for 3 or 6 consecutive months resulted in renal inflammation in mice; however, renal fibrosis was not observed.[9−13] Renal inflammation and fibrosis in mice following exposure to nano-TiO_2 for 9 consecutive months may be due to modulation of the Wnt pathway.[14]

The Wnt pathway has been shown to play an important role in kedney development; in adult mouse kidney, however, Wnts and their receptors (Fzs) are also expressed.[14] Therefore, we examined the alterations in Wnt ligands and Wnt receptors (Fzs) in mouse kidney following exposure to nano-TiO_2. Levels of all Wnt ligands, including Wnt1, Wnt2, Wnt3, Wnt4, Wnt5a, Wnt6, Wnt7a, Wnt9a, Wnt10a, and Wnt11, were elevated following exposure to nano-TiO_2. As suggested, Wnt3a may be involved in various cancers[31] and is associated with β-catenin activation, thus driving transcription from the LEF-1 promoter.[32] As secretory proteins, Wnts proteins can bind to their respective receptors and execute their function in a paracrine or autocrine manner. He et al. observed that Fz receptors are expressed in tubular epithelial cells in vivo and guessed that these receptors may be the main targets of Wnt signaling in renal fibrosis.[14] Our findings suggest that exposure to nano-TiO_2 markedly upregulated the expression of Fz1, Fz5, and Fz7 in the kidneys. These results support the hypothesis that nano-TiO_2 promotes renal inflammation and fibrosis by triggering the Wnt pathway as chronic exposure to nano-TiO_2 caused significant alterations in these Wnts and Fzs.

In this study, our data suggest that chronic exposure to nano-TiO_2 significantly decreased the level of expression of Dkk1, Dkk2, Dkk3, Dkk4, and sFRP/FrzB as antagonists of the Wnt pathway in the kidneys. As suggested, epigenetic silencing of Wnt antagonistic genes such as sFRP/FrzB,[33] Dkks,[34] and WIF1 is closely associated with poor prognosis in renal cell carcinoma patients.[35] The reduction in the level of antagonist expression in the kidneys caused by exposure to nano-TiO_2 may promote renal inflammation and fibrosis in mice.

As the expression of all Wnts and Fzs was greatly induced in the kidneys by nano-TiO_2, the question of whether β-catenin modulated transcription and the canonical Wnt pathway activated by nano-TiO_2 was also examined. Our findings indicate that nano-TiO_2 significantly elevated the level of expression of the Wnt genes c-Myc, cyclin D1, and Abcb1b in mouse kidney. It was previously demonstrated that both cyclin D1 and Abcb1b expression was involved in renal cancer and the aberrant Wnt/'β-catenin pathway.[36] As EMT markers, fibronectin, collagen I, and α-SMA are closely related to tissue regeneration or fibrosis; in particular, these EMT markers play

DOI: 10.1021/jf5034834
J. Agric. Food Chem. 2015, 63, 1639−1647

pivotal roles in the development of renal fibrosis under various stresses and chronic inflammation, while Twist is associated with cancer generation and cancer cell metastasis.[37−39] Expression of Twist and fibronectin was demonstrated to be modulated by the β-catenin pathway.[40,41] Because of the activation of the Wnt/β-catenin pathway caused by exposure to nano-TiO_2, we observed significantly increased levels of expression of fibronectin, α-SMA, and Twist in the kidneys. Importantly, collagen I has been shown to be very abundant in renal fibrosis[14] and to be a critical modulator of kidney fibrosis.[41] Our data also suggest that nano-TiO_2 significantly elevated the level of collagen I expression in the kidney.

In conclusion, this study shows that administration of nano-TiO_2 resulted in significant increases in urinary KIM-1, CLU, and OPN levels in mice. Furthermore, exposure to nano-TiO_2 activated the Wnt pathway through directly increasing the levels of expression of Wnts, Fz receptors, and EMT markers and decreasing the levels of expression of Wnt antagonists, thus resulting in renal inflammation and fibrosis.

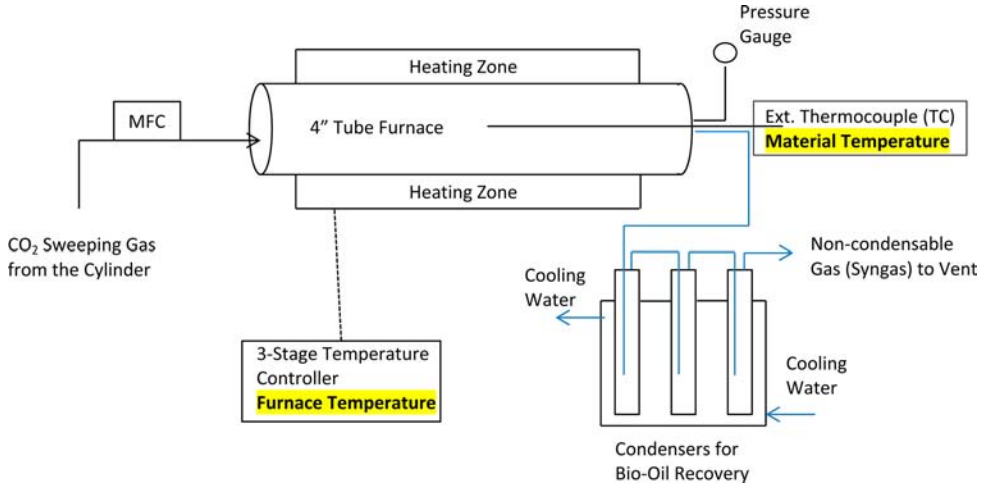

Figure 1. Slow pyrolysis experimental setup.

conditions, specifically temperature range and residence time, to obtain biochars with negligible PAH content. The impetus behind this work is the prospect of the existence and bioavailability of PAHs in the biochar, which are pyrolytic compounds produced during pyrolysis. This valid concern is hindering biochar's market acceptance with greenhouse growers and cooperators. This study will provide the applied knowledge required to ensure confidence (of cooperators/greenhouse growers) in biochar as a consistent, high-quality, well-documented, locally made greenhouse growing medium (substrate). This aspect has not been sufficiently studied or documented before, and the existing knowledge gap in the information is vital for commercial adoption of biochar as a benign growing medium for the greenhouse industry. The results of the proposed study will help fill the gap of assuring consistency in the quality and safety of biochar use for food production in greenhouses. The overall objective of this project is to make recommendations to the biochar producers and biochar end users (greenhouse growers) on what criteria biochars derived from thermomechanical pulp sludge (TMPS) can be considered safe for use in greenhouses for food production.

For this study the TMPS feedstock was sourced from Alberta Newsprint Co. (ANC), which was considering installing a 5000 tonne/year commercial biochar production facility at White Court, Alberta, Canada. ANC employs a thermomechanical pulping (TMP) process, wherein the wood chips are heated using steam to mechanically separate fibers (pulp) in a refiner. Wastewater generated from the pulping process is directed to a wastewater treatment system, where the remnant solids, termed sludge (TMPS), are separated. TMPS is essentially a combination of primary and secondary sludges. The primary sludge consists mainly of cellulose, hemicellulose, and lignin, whereas the secondary sludge is mainly composed of proteins, cellulose fibers, and lignin. Approximately 12000 oven-dried (OD) tonnes of sludge is produced by ANC annually. The main recycling and disposal routes for sludge are land-spreading or incineration. The conversion of TMPS, a negative-value effluent, into biochar, a high-value greenhouse growing medium, would be economically favorable to ANC.

MATERIALS AND METHODS

Feedstock. One hundred liters of TMPS was supplied by ANC, White Court, AB, Canada.

Feedstock Preprocessing. TMPS was manually delumped to improve heat transfer efficiency during drying and carbonization. It was dried at 110 °C overnight to obtain bone-dry homogeneous material, which was subsequently characterized and used in biochar production.

Feedstock Characterization. Proximate (volatile, ash, and fixed carbon), ultimate (CHNSO), and trace metal (36 element scan) analyses of TMPS were performed using the standard American Standard for Testing Materials (ASTM) and U.S. Environmental Protection Agency (EPA) methods.[11−20] All of the results and discussion in this study are presented on a dry weight basis (db).

Biochar Production. The laboratory-scale experimental setup employed to generate slow pyrolysis biochars from the TMPS feedstock is depicted in Figure 1. It comprises three components: (1) a tube furnace;,(2) a 4 in. stainless steel reactor, and (3) a three-stage programmable temperature controller.

To maintain uniform process conditions all through the TMPS feedstock, about 800 g of bone-dry TMPS was packed between two perforated metallic plates in the center of a tube reactor, which created a 10 in. void space on both/either ends of the reactor. The sealed reactor was inspected for leaks and placed in a split hinge tubular furnace. The tube furnace is equipped with three programmable temperature zones (left, center, right), which are regulated with the help of three thermocouples (TCs). In addition, a calibrated TC was placed directly into the center of the sludge sample, which was employed to measure the actual material temperature and was used to determine the process temperature and residence time in all of the experiments. In a typical run, the furnace was heated to a desired (material) temperature and maintained at that desired temperature for a desired time (residence time). Nine different kinds of biochars were made from TMPS by treating it at three different material temperatures (450, 500, 550 °C) and for three different residence times (30, 60, 120 min) under anoxic conditions (CO_2 purge). At the end of each experiment the tubular reactor was removed from the furnace and quenched rapidly (20 min) to cool the biochar to room temperature. Subsequently, the biochar was collected and weighed to calculate its yields.

Biochar Characterization. A composite aliquot of each biochar generated in this study was first ground and sieved to 0.25 mm size and then dried in the oven at 105 °C overnight. The dried samples were characterized by various techniques using standard ASTM and EPA methods,[11−23] with the exception of bioassays,[21] wherein as-produced biochars were employed. PAHs in biochar were extracted by Soxhlet extraction following EPA method 3540C. Extracts were further cleaned up using silica gel column according to EPA method 3630C prior to analysis by GC-MS operated in SIM as described in EPA methods 625 and 8270.[22] Soxhlet extraction employed 1 g of biochar and 10 g of sodium sulfate with hexane/DCM overnight (18 h). The extracts were concentrated to 1 mL and analyzed GC-MS (SIM) to determine PAH concentrations. Analyte recovery was determined by the addition of surrogate standards [2-fluorobiphenyl, 4-terphenyl, benzo(*g*,*h*,*i*)-

DOI: 10.1021/jf502556t
J. Agric. Food Chem. 2015, 63, 1648−1657

perylene] to the biochar sample prior to the Soxhlet extraction; typically recovery varies from 60 to 120%. Due to variability of the sample matrix the MDL was set at 1 ng/g to provide a high level of confidence in the data. The biochar exhibiting highest PAH content was submitted to PCDDs/PCDFs analyses, which was performed in accordance with EPA methods 1613 and 1668.[23]

Bioassay of Biochar Phytotoxicity and Effect on Plant Performance. A 5 day germination bioassay was performed to compare phytotoxicity differences on radish seeds between the various carbonized TMPS biochars, uncarbonized (raw) coconut coir (greenhouse industry standard growing medium), Sunshine (SS) commercial potting mix, and quartz sand by adapting the standard Organisation for Economic Co-operation and Development (OECD) methodology (1984).[21] Radish seeds (11) were plated on the substrate in a Petri plate, and each sample was tested in three replicated plates that were incubated in a humidity chamber at room temperature with 12 h of light for 5 days. Germination rate and root/shoot length were recorded for each treatment.

To assess the biochar's phytotoxicity and its effects on plant performance and human health, a growth chamber trial was conducted on a rapid-growing lettuce vegetable crop from July 31 to August 30, 2013. Six different biochar samples, coconut coir, and SS mix (controls) with six replicates each were employed in a 30 day growth chamber trial. Lettuce seeds (Burgia variety) were sown in 1 in. rockwool cubes and incubated in a growth chamber programed at 20/16 °C, day/night, and 16 h of light for 2 weeks. Seedlings were transplanted to biochar or coconut coir or SS mix in 4 in. plastic pots, one seedling per pot and six pots per treatment, watered with nutrient solution daily, and incubated under the same conditions for 30 days. The pH and EC of leachates were monitored and measured once a week. The foliage biomass yield was recorded, and lettuce tissue samples were subjected to Soxhlet extraction, cleanup, and PAH analysis as per EPA methods 3540C, 3630C, 8270, and 625, respectively (GC-MS analyses).[23]

RESULTS AND DISCUSSION

Feedstock Characterization. As-received TMP sludge contained about 65 wt % moisture content. It was manually delumped and dried overnight at 110 °C to obtain bone-dry TMPS feedstock, which was analyzed to evaluate its quality and was employed in the biochar production runs. The proximate composition, ultimate composition, and inorganic constituents of the TMPS are shown in Tables 1 and 2, respectively. In the TMP process, chipped soft woods (spruce, fir, pine) are pulped thermomechanically to extract cellulose fibers (pulp). During pulping most of the hemicellulose fraction of the wood is extracted into the liquid phase. The concentration of chemical compounds in TMP mill waste streams is usually rather low and constitutes a complex mixture of various substances such as hemicelluloses, extractives, inorganic ions, and suspended matter. These waste waters are directed to the waste treatment plant, where the remnant solids are separated, termed sludge, which is predominantly lignin, hemicellulose, protein, and cellulose remnants.[10] Table 1 compares the proximate and ultimate analyses values of typical clean wood and TMPS feedstock. As noted, it is evident that TMPS has characteristics similar to those of wood, except for high ash and lower oxygen contents. Removal of hemicellulose with significantly high oxygen content[24] during pulping results in lowering the oxygen content of TMPS, as evidenced from Table 1.[24] As noted from Table 2, the concentrations of specified metals such as As, Cd, Co, Cr, Cu, Hg, Mo, Ni, Pb, Se, and Zn were far below the stipulated guideline for maximum permissible metal concentration in biomass ashes, processed sewage, compost, and biosolids for land applications as regulated by European Union (EU) and Canadian Food Inspection Agency (CFIA) guidelines.[25] Furthermore, the TMPS also meets the specifications of clean biomass commonly employed in combustion and co-firing applications.[25] On the basis of the above finding TMPS can be designated a clean feedstock suitable for multiple applications ranging from land spreading to thermochemical processing (torrefaction, pyrolysis, combustion) applications. A recent study by Parikh's group[26] investigated trends in the biochar properties in relation to its feedstock material to develop guidelines for biochar use in agronomic systems. Special emphasis was given to ash content, C/N ratio, and surface area measurements. The overall exercise was intended to guide end users with feedstock selection tool for specific soil functions.[26]

Table 1. TMPS Feedstock Basic Analyses

feedstock[a]	TMPS	typical clean wood[b]	hemicellulose[24]
proximate analysis			
moisture content wt % (wb)	64.5	18.2

[a]db, dry basis; wb, wet basis. FC was computed by the following equation: FC (%) = 100 − [VM (%) + ash (%)]. Oxygen was computed by the following equation: O (%) = 100 − [N (%) + C (%) + H (%) + S (%) + ash (%)]. [b]For comparison, proximate/ultimate analyses of typical wood feedstock were referenced from *The Handbook of Biomass Combustion & Co-firing*, edited by Sjaak van Loo and Jaap Koppejan in 2008.

Biochar Production. Nine different biochars were generated by carbonizing the TMPS at three different material temperatures for three different residence (retention) times. The observed biochar yields are shown in Figure 2. As noted in Figure 2, biochar yields decrease with increasing carbonization (material) temperature and residence (material retention) time on account of a higher degree of devolatilization. The results reveal that the temperature increment has a more pronounced effect on the degree of devolatilization and associated weight loss than residence time.

Generally, in the demonstration-scale continuous operation, the feedstock is conveyed using augers or rakes and gravity and is under constant agitation and could also experience air penetration, which would potentially raise the material temperatures to ≥600 °C. In the current study, laboratory-scale batch equipment was selected for producing biochars at specific temperatures and residence times as it offers more accurate control over the process parameter than demonstration-scale equipment operated in continuous mode. In the current investigation, the biochar material temperatures were precisely regulated within ±5 °C tolerance and air infiltration/penetration was prevented by regulating a continuous CO_2 purge through the tube furnace.

Biochar Basic Characterization. All of the biochars generated in this study were analyzed for gross and elemental compositions by ASTM methods. The measurements obtained are presented in Table 3. As noted, the volatile matter decreases, whereas fixed carbon and elemental carbon contents increase

with increase in temperature and residence time. The effect is more pronounced in the case of temperature increment rather than with the residence time increment; these findings are in-line with a similar study reported on poultry manure biochars.[27] It is also evident from Table 3 that as the volatile matter content of biochars decreases so does their O/C atomic ratio. Furthermore, all of the biochars generated in this study possess O/C atomic ratios <0.2, with predicted half-lives of >1000 years from the literature.[28] From the data presented in Table 3, it is clear that all of the biochars except the one generated at 450 °C with 1 h residence time fall under the IBI class I biochar on account of their fixed carbon being >60 wt % (db) and H/C atomic ratio being <0.7.[7] The biochar generated at 450 °C temperature with a 60 min residence time exhibits H/C = 0.8 and therefore fails to meet the IBI biochar classification criterion.[7]

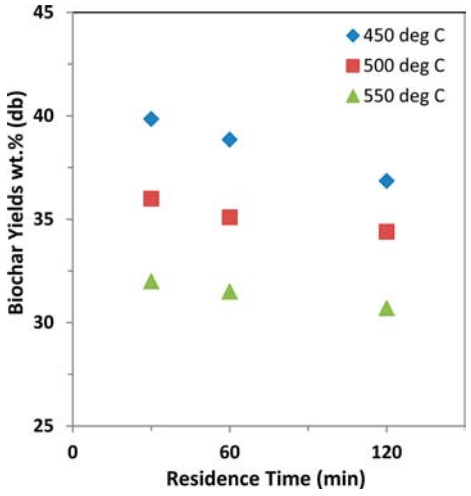

Figure 2. TMPS biochar yields versus process conditions.

Biochar Toxicity Characterization. *Polycyclic Aromatic Hydrocarbons (PAHs).* PAHs are a group of chemicals that are formed during the incomplete burning of coal, oil, gas, wood, garbage, or other organic substances. There are more than 100 different PAHs. PAHs generally occur as complex mixtures, not as single compounds. They can have a faint, pleasant odor. They are found throughout the environment in the air, water, and soil. They can occur in the air, attached to dust particles, or as solids in soil or sediment.[29,30]

Although the health effects of individual PAHs are not exactly alike, the following 17 PAHs are considered as a group in this profile:[29] acenaphthene, acenaphthylene, anthracene, benzo(*a*)-anthracene, benzo(*a*)pyrene, benzo(*e*)pyrene, benzo(*b*)-fluoranthene, benzo(*g*,*h*,*i*)perylene, benzo(*j*)fluoranthene, benzo(*k*)fluoranthene, chrysene, dibenzo(*a*,*h*)anthracene, fluoranthene, fluorene, indeno(1,2,3-*cd*)pyrene, phenanthrene, and pyrene.

These 17 PAHs were chosen to be included in this profile because[29] (1) more information is available on these than on the others; (2) they are suspected to be more harmful than some of the others, and they exhibit harmful effects that are representative of the PAHs; (3) there is a greater chance that you will be exposed to these PAHs than to the others; (4) of all the PAHs analyzed, these were the PAHs identified at the highest concentrations at hazardous waste sites; and (5) some of them are listed in EPA's Priority Chemical list such as benzo(*a*)pyrene, which is the most studied polycyclic aromatic hydrocarbon and is considered the most toxic and it is listed as a group 2a carcinogen by the International Agency for Research in Cancer (IARC).[31] The Group 2a carcinogenic chemical agent (or mixture) is probably carcinogenic to humans. This category is used when there is limited evidence of carcinogenicity in humans and sufficient evidence of carcinogenicity in experimental animals.[15] Benzo(*a*)pyrene [B(a)P] is often used as a human health risk indicator for PAH exposure and as a marker for the overall PAH exposure. The toxicity of dibenzo(*a*,*h*)anthracene is similar to that of benzo(*a*)pyrene; therefore, both have been assigned a TEF = 1.[32] The toxicity of other PAHs is converted into B(a)P equivalents by using their relative toxicity equivalency factors (TEFs). The EPA TEF values for the select PAHs available in the literature are presented in Table 4.[29]

The potentially toxic compounds in the biochars such as PAHs were determined by using a GC-MS technique. In all, 27 different PAHs were detected, and the corresponding results are shown in Table 4. The content of PAHs generated depended on the biochar production parameters (temperature and time) and varied from 0.4 to 236 μg/g biochar (Table 4). Per IBI guidelines, the maximum allowable threshold of PAHs in biochar should not exceed the 20 mg/kg biochar limit (≅20 μg/g biochar).[7] According to the above guideline, the biochars generated at 500 °C, 30 min; 500 °C, 120 min; 550 °C, 30 min; and 550 °C, 120 min meet the IBI criterion (Figure 3).[7]

Further insight into the relative compositions of PAHs revealed that the PAH in most detected quantities was retene (7-isopropyl-1-methylphenanthrene), which is a common combustion product of wood, a biotransformation product of a conifer resin (dehydroabietic acid) found in pulp and paper mill effluents. The detection of retene in high concentrations can be attributed to the origin of TMPS. It is not listed in the EPA 17 PAHs and does not have an assigned toxicity equivalency factor (TEF) associated with it, pointing to no toxicity in human health. After ignoring the retene content, the PAHs sum varied from 0.09 to 27.2 μg/g biochar as presented in Table 4. Per IBI guidelines, the maximum allowable threshold of PAHs in biochar should not exceed the 20 mg/kg biochar limit.[7] Among the nine biochars generated in the course of this study, except the one generated at 450 °C and 60 min, all other biochars pass the IBI criterion[7] if the retene content is ignored (Table 4).

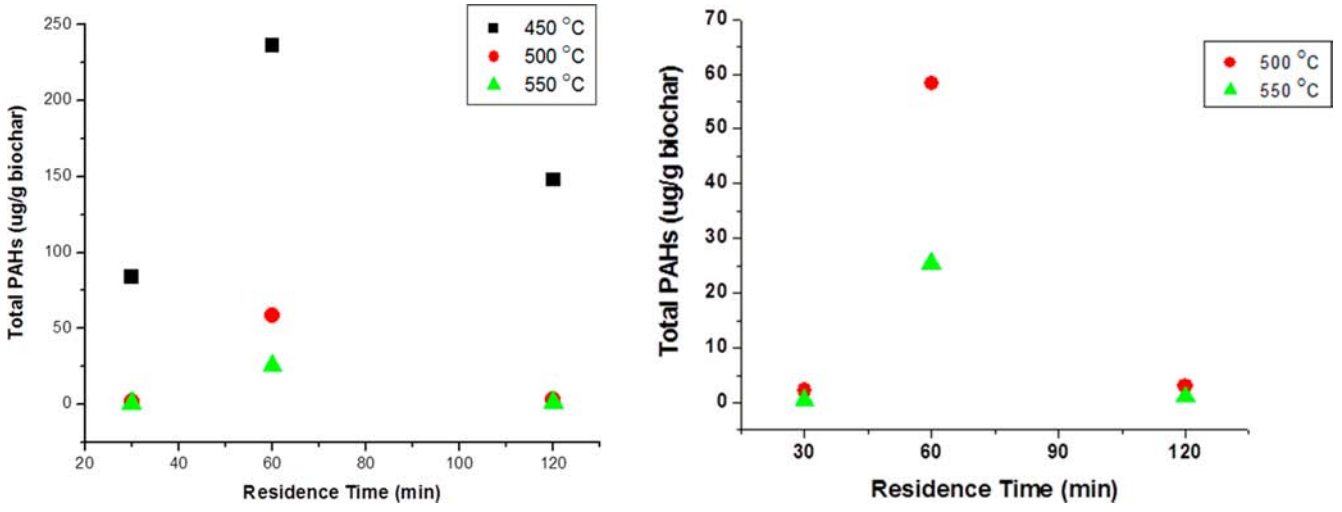

Figure 3. Cumulative PAHs (including retene) versus process conditions.

In a comprehensive study,[33] researchers evaluated four different biochars derived from wood, elephant grass (miscanthus), and coniferous/deciduous wood residues (carbonized at 600−750 °C) for 16 EPA PAHs (Σ16 EPA PAHs) and reported PAH concentrations ranging from 9 to 355 mg/kg biochar (db). According to their observation, both naphthalene (40−60%) and phenanthrene (10−30%) detected in high concentrations among the 16 EPA PAHs were produced during

pyrolysis process conditions and were not originally present in the feedstocks.[33]

The toxicity of the TMPS-derived biochars depended on the production (process) parameters such as material temperature and residence time. A significant correlation between the content of PAHs content and toxicity was noted and was matched to their production conditions. The total benzo(*a*)pyrene equivalents in each biochar sample was estimated on the basis of the detected probable carcinogenic PAHs[31] in the given biochar sample per the EPA TEF methodology (U.S. EPA 1993)[29] and is presented in the form of process toxicity relationships (PTRs) as detailed in a later section.

Polychlorinated Dibenzo Dioxins/Difurans (PCDDs/PCDFs). The biochar sample generated at 450 °C and 60 min was found to contain the highest concentration of PAHs (236 μg/g biochar) in this study. These detected high levels of PAHs prompted the need for PCDDs/PCDFs (dioxins/furans) analyses. The test results (not shown) indicate the absence of both PCDDs and PCDFs within the minimum detection limit (MDL) (0.1 pg/g) of the analytical method employed.[23] The nonformation of dioxins and furans can be attributed to the cleaner nature of the feedstock (free of chlorine and heavy metals).

Swift Radish Germination Bioassay. A 5 day radish germination test[34] was conducted to compare toxicity differences between the carbonized sludge feedstocks (biochars), uncarbonized coconut coir, SS mix, and quartz sand (controls). The germination test measures the effect of substrates on plant performance by measuring seed germination, initial shoot growth, and root development. Results in terms of number of germinated seeds, shoot length, and root length are shown in Table 5. Except for one biochar (produced at 450 °C for 60 min), all other biochars passed the radish seedling germination bioassay, and so did the quartz and coconut coir controls. The best radish performance, with the highest germination and root growth, was observed on seeds placed on biochar produced at 500 °C for 30 min. Interestingly, root zone development in biochar was different from the one noted in coconut coir and quartz. Extensive branching of roots was noted in the seedlings germinated in biochar, whereas long thin and unbranched roots were noted in seedlings germinated in quartz. In the current trials, substrate materials tested (biochar, coco, SS mix, and quartz) were not rinsed/washed in water (intentionally), which could be the reason behind the poor performance of coconut coir in comparison to other controls in this germination test. Coir media is known to contain high alkali content as most of it is sourced from coastal regions of Southeast Asia. Rinsing or washing could have potentially led to PAHs leaching, thus skewing the bioassay.

Growth Chamber Trial. To assess the biochar's phytotoxicity and its effects on plant performance, a 30 day growth chamber trial was conducted on a rapid-growing lettuce vegetable crop. The results obtained are presented in Table 5 and Figure 4. As noted from Table 5 and Figure 4, all of the

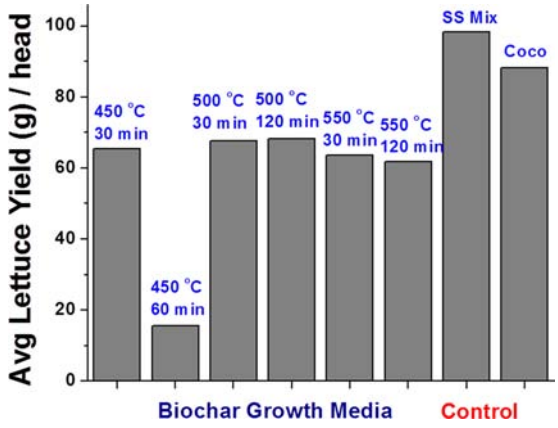

Figure 4. Average lettuce yield in TMPS biochars and controls.

biochar samples display very similar results in terms of lettuce growth and yield, except for the lettuce vegetable grown in biochar produced at 450 °C with a 60 min residence time. These results corroborate well the radish germination bioassay results, wherein except for the biochar produced at 450 °C with 60 min residence time, all other biochars passed the germination bioassay. Lettuce yields per head varied in the following order: commercial SS potting mix 1 (~100 g/head) > coconut coir (~90 g/head) > biochar (~65 g/head). Most of the lettuce plants grown (except those grown with 450 °C, 60 min medium) in the biochar display similar growth pattern and yielded similar weights of lettuce heads (average 65 g/head). The lettuce plants grown in biochar generated at 450 °C and 60 min exhibited stunted growth (~15 g/head), which is due to high

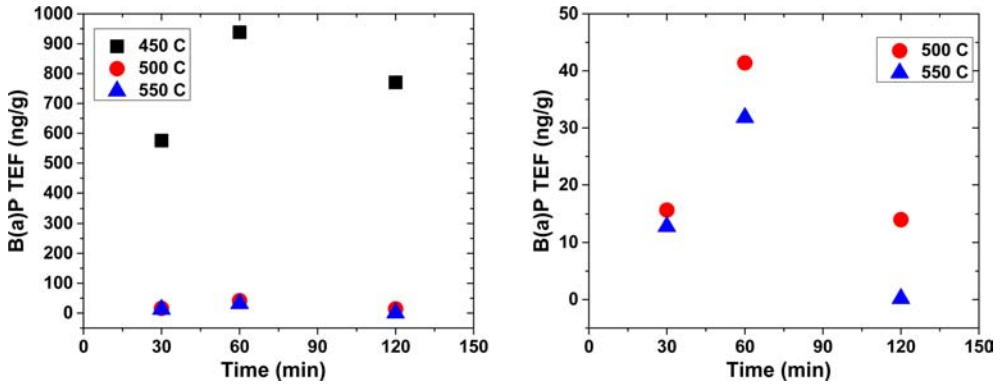

Figure 5. Biochar toxicity [B(a)P TEF] versus process conditions.

concentrations of PAHs identified in the biochar and their plausible bioavailability and translocatability.

The pH of leachate from biochar media was initially high (~8), but it was monitored, controlled, and maintained at about 6 throughout the test. The high initial pH (~8) of biochar is an important issue that may affect plant growth. A pretreatment, such as washing, is needed to reduce the pH of biochar and make it suitable and comparable with coco and SS mix growth substrates, which exhibit neutral pH (~7). Another option is to avoid prewash; instead, let the normal nutrient leaching as practiced with soilless production practices bring the pH down. Research trials conducted so far have shown that normal leaching practices with several daily watering cycles may be adequate for plants nutrient uptake needs.[3−5] As this study was focused on characterizing biochar toxicity, no attempts such as presoaking the biochar in nutrient solution (precharging) or water/nutrient washing (flashing) were done to improve the lettuce yields. In commercial greenhouses coconut coir bags are always presoaked in a calcium nitrate solution for 24−48 h so as to buffer it and replace sodium and potassium ions, which are present in high concentrations. In the early stages, fresh biochar has a high adsorption capacity for nutrients and there is a competition between the plant roots and the biochar media for the available nutrients, which initially hinders plant growth. Precharging the biochar with nutrients prior to its use in a greenhouse would likely bring lettuce yields up to levels similar to those seen with coconut coir media, but such work was beyond the scope of this study.

Lettuce Tissue Toxicity Analyses. Lettuce tissue samples were analyzed for the existence of PAHs; the results thus obtained are documented in Table 6. The results show the existence of PAHs in very minute proportions in the lettuce grown in the various biochars. Interestingly, PAHs were also detected in lettuce grown in commercial SS potting mix and coconut coir, however, in extremely low amounts. The PAH in greatest detected quantities is retene (7-isopropyl-1-methylphenanthrene), which is a common combustion product of wood. It is not listed in the EPA 17 PAHs and does not have an assigned toxicity equivalency factor (TEF) associated with it, pointing to its negligible toxicity to human health. The total benzo(*a*)pyrene equivalents in each lettuce tissue analyzed were estimated on the basis of the detected PAHs with probable human carcinogenicity

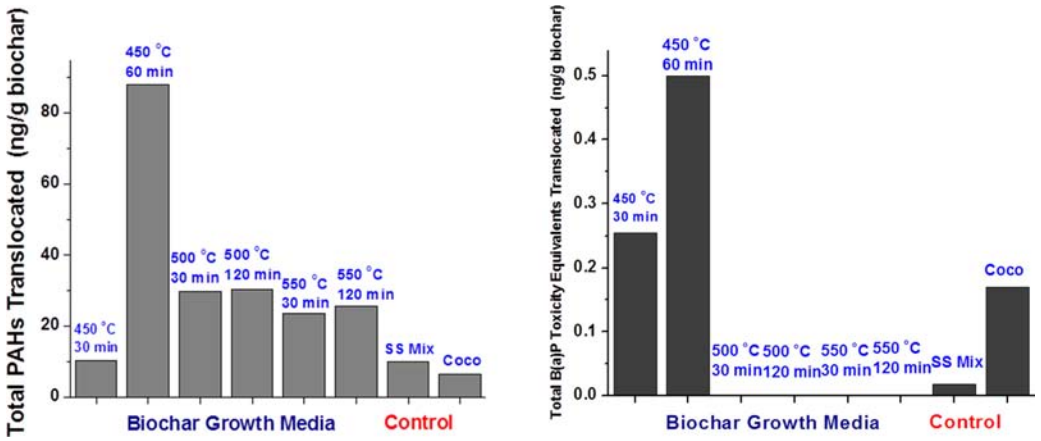

Figure 6. Total translocatable PAHs in lettuce (left) and total toxicity [B(a)P TEF] in lettuce (right).

(IARC class 2a)[31] using the U.S. EPA TEF methodology[29] (Table 6) and are presented in the form of process toxicity relationships (PTRs) as detailed in a later section.

Process Toxicity Relationships. All of the data generated during the course of the study were used in developing meaningful and realistic (slow pyrolysis) process/(biochar) toxicity relationships (PTRs). The PTRs would form the core applied knowledge base for developing future standards for biochar quality programs. PTRs generated in this study are shown in Figures 5 and 6. Figure 5 correlates toxicity in biochar to production (process) conditions. It can be observed from Figure 5 that biochars generated at 500 °C and beyond with an optimum residence time of 30 min exhibit very low B(a)P TEFs, which increase with prolonging the residence time to 60 min, on account of further breakdown of the lignin component of TMPS feedstock causing further PAH enrichment in the biochar. Prolonging the residence time to 120 min leads to thermal degradation/breakdown of the PAHs formed at 60 min as observed in Figure 5 (and also in Table 4). From process optimization and economic perspectives, minimal residence time would be favored for increased throughput. Figure 6 documents the translocatable PAH contents and the resulting toxicity in the lettuce tissue grown in the various TMPS-derived biochars generated at different process conditions. It is evident that the B(a)P TEFs noted in lettuce are extremely small and insignificant. From the learning garnered in this study, it is recommended that TMPS feedstock will yield benign quality biochar when processed at a minimum 500 °C material temperature for an optimum residence time of 30 min. The current study strengthens the fact that "*not all biochars are created equal*" and with proper feedstock selection and process optimization, it is possible to create a benign quality biochar suitable for safe greenhouse-based food production.

provided by Santa Cruz Biotechnology Co. (Paso Robles, CA). The purity of these standards is greater than 98.0%. Nonafluoropentanoic acid (NFPA, purity over 97%), HPLC grade methanol, and acetonitrile were obtained from J&K Chemical Co., Ltd. (Shanghai, China). Pure CML (purity over 95%) was synthesized by Qiangdao Vochem Co., Ltd. (Shandong, China). Ultrapure water was produced by a Superpure Water System (Shanghai, China). All other chemicals were of analytical grade and were provided by Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China).

Sample Collection. Fourteen Sprague−Dawley rats were housed in a specific pathogen-free room (temperature: 22−24 °C, 55−70% humidity, and a 12-h light-dark cycle). After 1 week of acclimatization, the rats were randomly divided into Control group and CML group (n = 7 each). Rats in the CML group were given pure CML by stomach gavage (60 mg kg^{-1} per day, dissolved in ultrapure water in the form of CML inner salt (10 mg/mL)), whereas rats in the Control group received an equivalent volume of water. All of the treatments were for 12 consecutive weeks. During the experimental period, rats were allowed free access to a normal diet and to water except as otherwise noted. The fasting body weight (FBW) and 24-h food and water intake of all rats were recorded every 2 weeks. Furthermore, fasting blood glucose (FBG) was measured with an Accu-Check Performa glucometer (Roche Diagnostics, Mannheim, Germany) at the same time each week. At the end of the experiment, all rats were weighed and anesthetized intraperitoneally with 40 mg kg^{-1} pentobarbital sodium after an overnight fast. Blood samples were collected from the heart and centrifuged at 1400g for 20 min. Each serum sample obtained was divided into two portions: one portion for measuring serum biochemical markers and the other stored at −80 °C for later determination of the serum protein-bound CML level. The kidney, liver, heart, lung, spleen, and pancreas were immediately removed, weighed, and frozen at −80 °C for determination of the protein-bound CML levels.

All study management and experimental procedures adhered to the Guide for the Care and Use of Laboratory Animals (issued by the Ministry of Science and Technology of the People's Republic of China in 2006 [398]) and were approved by the Ethics Committee of Jiangnan University, China (JN no. 28 2013).

Determination of Serum Biochemistry Values.[33] Serum samples were run on a Roche Modular-P800 automatic biochemistry analyzer (Roche Diagnostics GmbH, Mannheim, Germany) for measuring the following serum biochemistry values: (1) kidney function markers: blood urea nitrogen (BUN), creatinine (CREA); and (2) liver function markers: alanine aminotransferase (ALT), aspartate aminotransferase (AST).

Sample Preparation for Protein-Bound CML Analysis. All tissue samples were lyophilized and powdered by mortar. The protein-bound CML was extracted by means of a modified method developed by Zhang et al.[18] and Teerlink et al.[22] Approximately 100 mg of tissue sample was extracted three times with hexane to remove the sample fat. For each extraction, 2 mL of hexane was added to the tube, the mixture was vortexed for 1 min and centrifuged at 5000g for 5 min, and the hexane layer was removed with a Pasteur pipet. After the three extractions, the residue was dried with nitrogen gas and then reduced with 1 mL of 0.1 M sodium borohydride (dissolved in 0.2 M borate buffer, pH 9.2) at room temperature for 4 h. After reduction, 2 mL of 60% (w/v) trichloroacetic acid (TCA) was added to the reduced sample to a final concentration of 20% (w/v), the mixture was vortexed vigorously for 1 min and centrifuged at 4000g for 10 min. This step ensured the determination of only protein-bound CML. The protein pellet was washed twice with 2 mL of 20% (w/v) TCA, dissolved in 5 mL of 6 M HCl, and then incubated at 110 °C for 24 h for hydrolysis. The acid hydrolysate was then filtered with Whatman no. 1 qualitative filter paper (70 mm) and volumed with ultrapure water in a 10 mL volumetric flask. Five hundred microliters of diluted acid hydrolysate was evaporated to dryness under nitrogen gas at 50 °C, and the residue was reconstituted in 2 mL of 0.1 M HCl and spiked with 150 μL of CML-d_4 (475 ng/mL in ultrapure water) for solid phase extraction (SPE).

For the SPE, an Oasis MCX cartridge (3 mL, 60 mg; Waters, Milford, MA) was preconditioned with 3 mL of methanol and 3 mL of ultrapure water, followed by 3 mL of 0.1 M HCl at a flow rate of 1 mL/min. The reconstituted sample was loaded onto the preconditioned cartridge at a flow rate of <0.5 mL/min. The cartridge was washed, in sequence, with 3 mL of 0.1 M HCl and 3 mL of ultrapure water. Finally, the analyte was eluted with 3 mL of 5% ammonia/methanol (v/v) at a flow rate of <0.5 mL/min. The eluant was dried gently with nitrogen gas at 50 °C, reconstituted in 300 μL of 5 mM NFPA in ultrapure water, vortexed for 30 s, and then microfiltered through a 0.22 μm syringe needle membrane prior to analysis by LC-MS/MS.

A 80 μL amount of serum sample was directly reduced in accordance with the above procedures. All samples were performed in triplicate or duplicate if they were limited.

CML was quantified using standard addition methods employing CML-d_4. The peak area ratio of CML standard/CML-d_4 internal standard was used to establish the standard curve. Recovery studies were performed by six tissues samples (each sample from each tissue) and one serum sample. Each sample was spiked with a certain level of CML standard before SPE cleanup. All samples were performed in triplicate. Limit of detection (LOD) and limit of quantification (LOQ) were determined by diluting the same calibrator to a specified signal-to-noise (S/N) ratio (S/N = 3 and 10 for the LOD and LOQ, respectively).

LC-MS/MS Analysis. Chromatographic separation was performed on a Waters 2690 LC system equipped with a degasser, a binary pump, and an autosampler, coupled with an X-Bridge C18 column (Waters) at 35 °C. The binary mobile phase consisted of solvent A (100% acetonitrile) and solvent B (5 mM NFPA in ultrapure water). Five microliters of sample solution was injected with an autoinjector. The flow rate of the mobile phase was set to 300 μL/min. The gradient elution was performed as follows: mobile phase A was increased from 5% to 60% within 5 min and then to 100% within 2 min and was held for 2 min; it was changed to 5% over 1 min and was held for 10 min to equilibrate the column prior to the next injection.

The LC was directly interfaced to an electrospray ionization (ESI) source of a Micromass Quattro Micro triple quadrupole mass spectrometer (Waters). The triple quadrupole was operated in positive ESI mode with a capillary voltage of 3.55 kV. Temperatures of the source block and desolvation capillary were 110 °C and 400 °C, respectively. Nitrogen (99.9% purity) was used as the cone and desolvation gases, the flow rates of which were 50 L/h and 600 L/h, respectively. Argon (99.99% purity) was used as the collision gas. Data were acquired in multiple reaction monitoring (MRM) mode for quantitation and analyzed by MassLynx V 4.1 software. Optimized cone voltages and collision energy are as follows: cone voltages (CML: 25 V; CML-d_4: 20 V), collision energy (CML: m/z 130−12 eV, m/z 84.1−14 eV; CML-d_4: m/z 130−12 eV, m/z 88.1−15 eV). For CML, the product ion at m/z 84.1 was used for quantification and the other for confirmation (m/z 130).

Statistical Analysis. Data are expressed as mean ± standard deviation (SD). After confirmation of their normal distribution, between-group differences in measured variables were tested by one-way analysis of variance (ANOVA). Statistical significance for all analyses was accepted at a level of $p < 0.05$. All statistical analyses were performed with the SPSS statistical program (version 20.0 for Windows).

RESULTS AND DISCUSSION

Analytical Performance of the Method. LC-MS/MS chromatograms of standards solutions and a kidney sample are shown in Figure 1. The retention time of CML in the kidney sample was almost consistent with that in CML standard solution (Figure 1A,C). However, a split peak of CML appeared for the kidney sample compared with CML standard solution. This might be due to matrix effects, because when CML-d_4 was added into the kidney sample solution the same

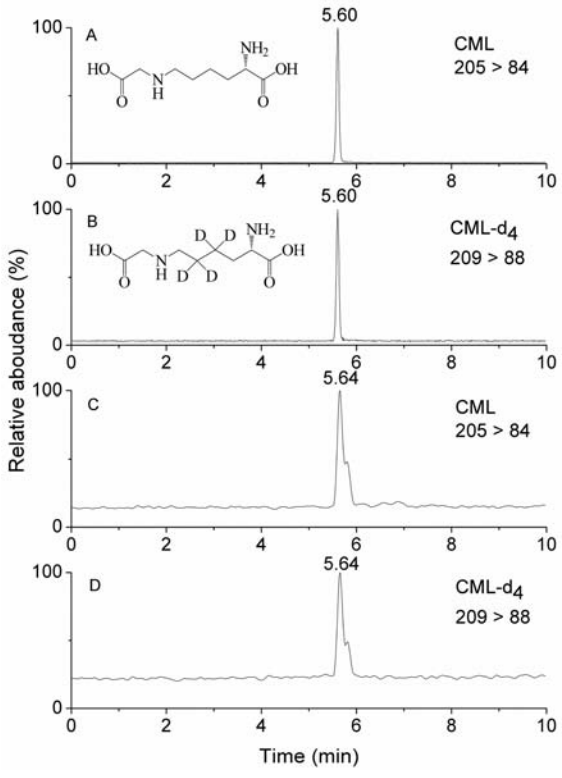

Figure 1. Typical LC-MS/MS chromatogram of CML standard solution (A), CML-d_4 internal standard solution (B), CML in kidney sample solution (C), and CML-d_4 added to kidney sample solution (D).

split peak also appeared compared with CML-d_4 standard solution (Figure 1B,D).

The method used in this work was verified by calibration, sensitivity, and recovery test. The correlation coefficient (R^2) of the CML calibration curve was 0.9995, and the linear range (41.21−5275 ng/mL) was wide enough to assess CML in biological samples. The LOD and LOQ were 8.5 and 28.34 ng/mL, respectively. The recoveries for CML were 94.93−105.74% for tissues and 107.22% for serum (Table 1). These data show that this method is suitable for determining the protein-bound CML level in biological samples.

Protein-Bound CML Levels in Serum and Tissue Samples. The dose of CML in this study was based on the studies of Somoza et al.,[26,32] aiming to reveal a potential biological effect of dietary CML on healthy tissues over a short period of time. Noteworthy, this dose is not representative of a normal exposure (0.034−0.252 mg kg^{-1} per day for adults).[34] In the present study, the protein-bound CML level in serum in CML-rats did not differ significantly from that in the Control group (CML: 1.40 ± 0.33; Control: 1.60 ± 0.52 μg/mL serum, $p > 0.05$). This finding was in good agreement with the results of recent studies,[29,31] further confirming that protein-bound CML in serum mainly comes from the in vivo glycation rather than the dietary intake of CML.

Up to now, a correlation between serum CML content and pathophysiological outcomes has not been found based on up-to-date methodology,[35,36] but it is reported that dietary AGE restriction could attenuate insulin resistance, oxidative stress, and endothelial dysfunction.[37] Therefore, tissue CML levels might be of greater relevance to chronic diseases.[36] Figure 2 shows the protein-bound CML levels in the tissues of rats in different groups. After oral CML administration for 12 consecutive weeks, the protein-bound CML contents in tissues of rats were increased in different degrees. In the kidney and liver (Figure 2A,B), the protein-bound CML levels were increased by 107% and 56%, respectively (kidney: CML 202 ± 17, Control 98 ± 1 μg/g dry matter, $p < 0.05$; liver: CML 217 ± 44, Control 140 ± 42 μg/g dry matter, $p < 0.05$). Liver and kidneys are the essential metabolic and blood-filtering organs, respectively.[38] In addition, kidneys also play a major role in AGE excretion.[26] Therefore, it is hypothesized that after entering the bloodstream, exogenous free CML is primarily transported to the liver and then partially transferred to the kidneys and other organs, which is consistent with Bergmann et

Table 1. Recovery Data for LC-MS/MS Analysis of Protein-Bound CML[a]

	protein-bound CML[b]			
sample	control sample	spiked sample	amount added	recovery (%)
kidney	97.7 ± 1.50	185 ± 10.8	83.7	106 ± 12.8
liver	99.9 ± 0.55	186 ± 8.11	91.6	94.9 ± 8.86
heart	158 ± 3.92	292 ± 11.0	138	98.9 ± 7.94
lung	92.0 ± 0.11	165 ± 4.48	74.6	97.6 ± 6.00

al.[39] When the free CML is conveyed to these organs, it would accumulate and bind to tissue certain proteins, thus elevating the protein-bound CML levels in these tissues. This study proved that the elevated protein-bound CML is due to exogenous free CML binding to tissue proteins. Since protein-bound CML is not cleared by the liver scavenger cells,[40] it would not be catabolized further in the organism.[39] Furthermore, it is reported that protein-bound CML is not easily excreted through the kidneys.[8] These factors explain the marked elevation in the protein-bound CML levels in the kidneys and liver.

In the heart (Figure 2C), the protein-bound CML level increased by 85% over that in the Control group (CML 167 ± 47, Control 90 ± 15 μg/g dry matter). This significant increase was consistent with the findings of Roncero-Ramos et al.,[29] who reported that CML in the rat heart increased significantly after rats were fed bread crust. In the lung (Figure 2D), the protein-bound CML level increased by 41% (CML 107 ± 4, Control 76 ± 18 μg/g dry matter). Protein-bound CML is reported to form only under aerobic conditions.[41] Thus, we suggested that the abundant oxygen in the lungs could accelerate the absorbed exogenous free CML binding to tissue proteins and thus elevate the protein-bound CML in vivo. However, in the spleen and pancreas (Figure 2E,F), there was no significant difference in the protein-bound CML levels between the two groups (spleen: CML 144 ± 23, Control 115 ± 15 μg/g dry matter; pancreas: CML 33 ± 7, Control 30 ± 4 μg/g dry matter), although the level tended to be higher in the CML group. Why did protein-bound CML increase markedly in the heart and lungs rather than the spleen and pancreas? One possibility is that blood flowing into the heart and lungs comes from aorta, while blood flowing into the spleen and pancreas comes from arterial branches. Thus, in the same time, more exogenous free CML is carried to the heart and lungs along with bloodstream. Another possibility is that the rate at which CML and proteins combine in the spleen and pancreas is slow, and thus protein-bound CML does not quickly accumulate in these tissues.

Notably, the formation of protein-bound CML generally reflects the level of oxygen stress in vivo;[42] therefore, we suggest that the oxygen stress level might have been higher in the tissues of the CML group rats than in those of the Control group rats, particularly in the kidney, heart, and liver tissues, which might induce chronic diseases in these organs.[43]

Serum Markers. Because the clearly accumulated protein-bound CML in body tissues might be a threat to the kidneys and liver, several serum markers of kidney and liver function were measured in this work. As shown in Figure 3, after oral CML treatment for 12 consecutive weeks, the serum BUN, CREA, ALT, and AST levels were all significantly elevated over those in the Control group. It is reported that serum BUN and CREA are regarded as diagnostic markers of renal function,[44] and the significantly elevated levels of BUN and CREA indicate renal dysfunction.[45] Similarly, serum ALT and AST are generally used to assess liver damage,[46] and a significant increase usually indicates abnormal liver function.[47] Therefore, we believe that chronic intake high level of CML contributes to functional impairment of the kidneys and liver in healthy individuals.

FBW, Food, and Water Intake and FBG Levels. To investigate the effect of chronic oral intake of CML on healthy rats, the FBW and food and water intake of all rats were recorded every other week. As shown in Figure 4A–C, there were no significant differences between the CML and Control

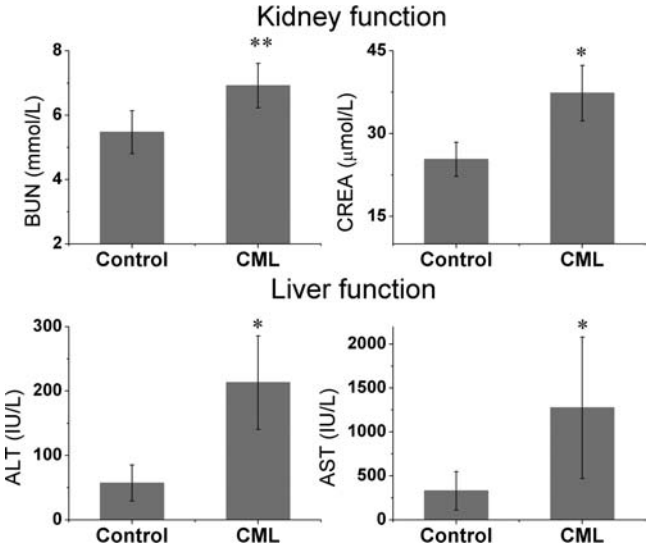

Figure 3. Serum markers of kidney and liver function (mean ± SD, n = 5). *p < 0.05 indicates a significant difference between Control and CML groups and **p < 0.01 indicates a highly significant difference between both groups.

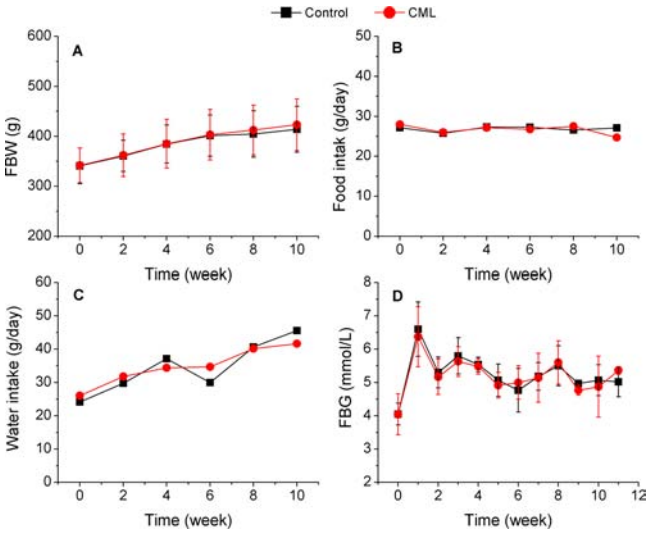

Figure 4. Biweekly FBW (A), 24-h food intake (B), 24-h water intake (C), and weekly FBG levels (D) in the Control and CML groups.

groups, indicating that chronic oral CML intake did not affect the appetite or weight of the rats. In addition, the FBG level was measured every week during the experiment (Figure 4D). During the first week, the FBG levels of the rats in both groups were elevated, which could have been caused by poor adaptation of the rats to stomach gavage. During the following week, the FBG levels were back to normal, indicating that the rats had adapted to the procedure. As time went on, no significant difference was observed between the CML and Control groups, and the trends in both groups were similar. Thus, we suggest that chronic oral CML administration does not affect the FBG levels of rats fed a normal diet.

In summary, the distribution of protein-bound CML in tissues of healthy rats after chronic oral administration of pure CML was investigated in this work. After entering the bloodstream, exogenous free CML is conveyed and accumulated in tissues along with the blood circulation and binds to

DOI: 10.1021/jf505063t
J. Agric. Food Chem. 2015, 63, 1658–1663

tissue proteins to form protein-bound CML, especially in the kidneys, heart, and liver, followed by the lungs. Conversely, no statistically excess protein-bound CML accumulated in the spleen or pancreas. Furthermore, serum BUN, CREA, ALT, and AST increased significantly. Our findings might be clinically meaningful, i.e., chronic intake of high level of CML could lead to kidney and liver toxicology and induce kidney and liver dysfunction in healthy individuals. In addition, chronic oral CML did not induce a rise in the FBG level. Thus, we emphasize that long-term consumption of CML-rich foods is a potential risk for healthy humans, especially in terms of kidney or liver function. This finding is of vital importance. We must realize the harm that can come from a daily diet rich in AGEs, and we must also realize the implications of an AGE-rich diet for timely prevention and diagnosis AGE-related chronic diseases.

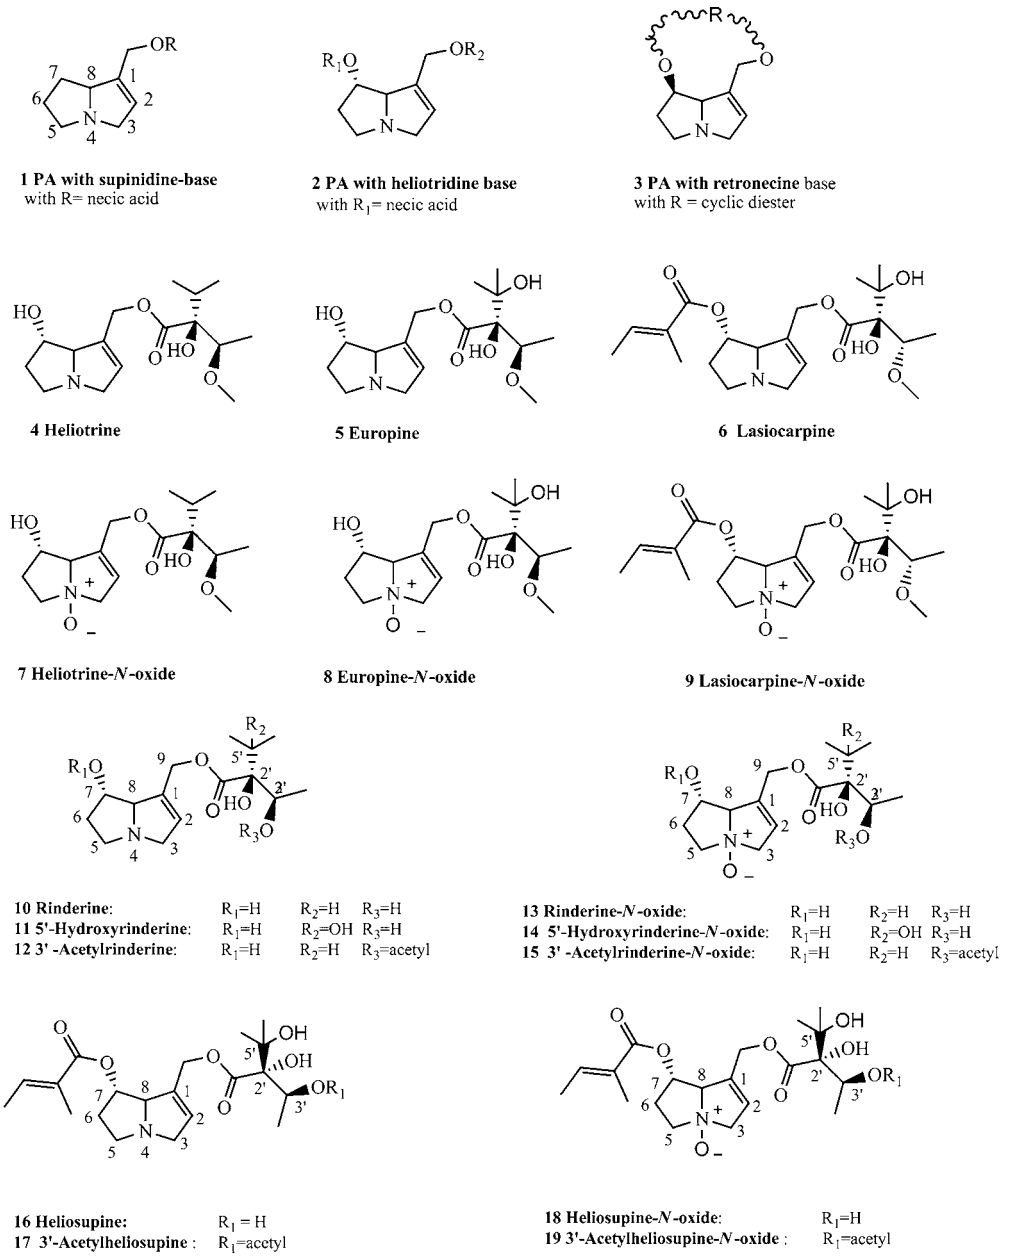

Figure 1. Classification of 1,2-unsaturated PA, commonly found in *Heliotropium* spp., into four subgroups according to their PA base-type and the number/type of ester bonds. The generic names are indicated in bold below each chemical structure.

literature.[9] A mortality rate of about 30% was recorded over a time period of 26 weeks. The surviving animals were eventually slaughtered after it was shown that some clinically normal calves had striking pathological lesions. Between March 14 and May 15, 2014, in a herd of 15−18-month-old replacement mixed-breed beef cattle (n = 73) from the Galilee region in Israel, a 33% mortality rate occurred, following ingestion of total mixed ration (TMR) containing hay that turned out to be contaminated with *H. europaeum*. The aims of the present work were to provide a detailed description of the chronic PA poisoning in cattle, including clinical signs, pathology, and histopathology in association with the total PA levels found in the feed, and to characterize the PA/PA-*N*-oxide composition in the contaminated hay in comparison to the PA and PA-*N*-oxide profile of the aerial portions of *H. europaeum* collected under similar conditions.

MATERIALS AND METHODS

Toxicosis Event. History of the herd: the affected cattle consisted of 73 mixed-breed beef cattle (15−18 months old, weighting 340−390 kg), which were reared in Kibbutz Gazit located in the Galilee region in Israel. The herd was held in a semiopen pen with a yard. The herd was fed from the beginning of February 2014 a TMR supplied by a local private company composed of 50% hay accidently contaminated with *H. europaeum*, 47.5% poultry litter, and 2.5% *Stevia rebaudiana*. Neither the feed producer, the farmer, nor the farm veterinarian considered the dried green plant material present in the hay a noxious weed. After 42 days of contaminated TMR consumption, followed by 1 week of rearing on a nearby pasture, as commonly practiced at the beginning of spring, two cows were found dead (March 14, 2014), and 2 days later two additional cows were found dead (Figure 2). The mortality cases were immediately reported to the Israeli Veterinary Institute, and of the four dead cows, three were submitted to the Department of Pathology for full necropsy and histopathological as well as parasitological and virological examination. Furthermore,

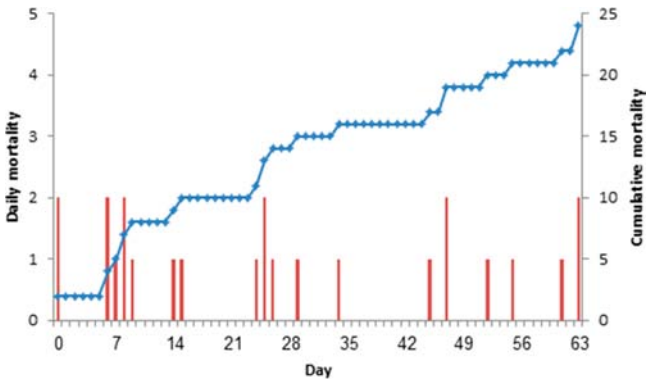

Figure 2. Daily mortality and cumulative mortality curve of mixed-breed beef cattle (15−18 months old) poisoned with *H. europaeum*. The time scale begins with the first mortality events (day 0) following 42 days of consumption of *H. europaeum*-contaminated feed and 7 days after cessation of feeding the affected herd with the contaminated hay.

leftovers of the suspected feed material were submitted to the Department of Toxicology and Bacteriology for toxicological and bacteriological evaluation. The sudden deaths occurred without any previously noticeable clinical signs according to the farmer's testimony. Noticeable clinical signs appeared only about 1 week after the first sudden death events and affected only a small proportion of the herd and included lethargy, staggering with dragging of the hind quarters, and tenesmus, invariably accompanied by varying degrees of rectal prolapse. In some cases, restlessness was a marked feature, sometimes coupled with circling within the perimeter of the yard. The course of all these manifestations was short, with affected animals invariably dying within 48 h with a significant loss of weight during this period. Over a period of 63 d counted from the first mortality event, 24 cows were found dead, yielding a mortality rate of 33%. As clinically normal cows revealed marked pathological liver lesions, the remaining 49 cows were slaughtered. The Israeli Veterinary Services decided to incinerate the meat of the affected cattle, due to an unknown risk associated with meat products possibly contaminated with PA residues. The suspected contaminated hay was stored for inspection in a closed confinement within the kibbutz.

Laboratory Investigations. *Total Mixed Ration (TMR) Analysis.* Samples of the TMR ingredients (hay, poultry litter, and *Stevia*) were screened for a wide range of pesticides, including organophosphates, carbamates, pyrethroids, and organochlorides as well as PAs by GC−MS (Agilent Technologies, Santa Clara, CA), according to an in-house-validated screening method published recently.[18] The TMR ingredients were also analyzed for doxycycline and oxytetracycline, as well as the ionophores monensin, lasalocid, salinomycin, maduramicin, semduramicin, and narasin by LC−MS/MS according to the previously described method.[19] The analysis of the TMR ingredients for aflatoxins B_1, B_2, G_1, and G_2 was performed by HPLC with postcolumn photochemical derivatization and fluorescence detection. Moreover, the TMR ingredients were analyzed for the elements As, Cd, Co, Zn, Cu, Fe, Pb, Mn, Hg, Mo, Se, Tl, and Zn by utilizing an ARCOS ICP-AES (Spectro Analytical Instruments, Kleve, Germany) according to the EPA method 6010c.[20]

LC−MS/MS Analysis for PA and PA-N-Oxides in Animal Feed and H. europaeum. Dried, ground plant material was extracted using a slightly adapted procedure.[21] Powdered material was extracted with 2% formic acid (Merck, Darmstadt, Germany) solution in a 1:100 ratio (w/v). The extract was then filtered and 5 μL was diluted 200 times with 2 mM NH_4OH solution (Merck). The contaminated hay material was extracted the same way, but in this case, 50 μL was diluted 20 times with 20 mM NH_4OH solution. PA composition and content of the samples were determined using an Acquity chromatographic system coupled to a Quattro Premier XE tandem mass spectrometer (Waters, Milford, MA), run in multiple reaction monitoring mode (MRM) with positive electrospray ionization. Cone voltage was set at 30 V, desolvation gas temperature at 450 °C, source block temperature at 120 °C, and the argon collision gas pressure at 4.0×10^{-3} mbar. Dwell time of the selected transitions was 10 ms with an interscan delay of 0.5 ms. The column used was a 150 × 2.1 mm i.d., 1.7 μm Acquity BEH RP-18 (Waters, Milford, MA), kept at 50 °C and run at 0.4 mL/min. A mobile phase consisting of 6.5 mM NH_4OH in water and 6.5 mM NH_4OH in acetonitrile was used. The gradient started at 100% water and was changed linearly to 50% acetonitrile in 12 min. After 0.2 min the composition was returned to the starting condition and the column was allowed to equilibrate for another 2.5 min. Mass spectrometric data were processed using Masslynx 4.1 software (Waters, Milford, MA).

Representative *H. europaeum* samples were screened for the presence of known and new PAs using parent ion scanning. Typical product fragments were selected, such as m/z 120, 122, 138, 156, 172, and 254. The mass scanning range was from m/z 200 to 500 with a mass resolution of 0.1 Da and a scan time of 800 ms. Spectra were recorded using a fixed cone voltage of 30 V and fixed collision energy of 30 eV. Compounds producing a protonated molecular ion with an even mass and displaying fragmentation behavior typical for specific types of PAs were tentatively identified as PAs. These potential PAs were further identified by collecting individual fragmentation spectra at a collision energy range of 20−40 eV. On the basis of their fragmentation spectra, tentative structures could be derived. These compounds have been included in the MRM method, by selecting two product ions, typically the most abundant ones. See Table 1 for the mass spectrometric settings selected for each compound. PAs were quantitated against a range of calibrant samples (0−500 ng/mL) containing available PA standards [heliotrine (**4**), europine (**5**), lasiocarpine (**6**), their corresponding *N*-oxides (**7**−**9**), lycopsamine, and echimidine (Phytoplan, Heidelberg, Germany)]. Echimidine-*N*-oxide was synthesized in-house by *N*-oxidation of echimidine. For a number of PAs, no reference standard was available. For those PAs, a semiquantitative result was obtained by comparison of the peak area with that of a structurally related standard, as indicated in Table 1. The available PA standards accounted for approximately 90% of the PA content in the hay and plant material. The limit of quantification in the *H. europaeum* plant material was 1 μg/g and in the hay approximately 0.1 μg/g.

Aflatoxin B_1, B_2, G_1, and G_2 Analysis by HPLC with Postcolumn Photochemical Derivatization and Fluorescence Detection. Homogenized hay was extracted and analyzed according to a previously published method with slight modifications.[22] In brief, a 5 g sample was extracted with 15 mL of acetonitrile:water 80:20 (v/v) and shaken for 1 h. The sample was centrifuged for 10 min at 4000*g* and 13 mL of organic supernatant was transferred into a new 15 mL Falcon tube and evaporated to dryness in a water bath (40 °C) under a stream of N_2. The dried residue was reconstituted with 0.5 mL of methanol:water 60:40 (v/v) in water and subjected to centrifugation for 10 min at 14 000*g* and finally injected into a HPLC-FLD equipped with a PHRED photochemical derivatization system (AURA Industries, New York, NY) installed before the fluorescence detector. The method utilized a model 1100 (Agilent Technologies, Waldbronn, Germany) liquid chromatography system (equipped with binary pump, degasser, column compartment, and autosampler) combined with a fluorescence detector with excitation and emission wavelengths of 360 and 455 nm, respectively. The column used was a 150 × 4.5 mm i.d., 3.5 μm, ZORBAX RP-18 (Agilent Technologies, Santa Clara, CA), and the following gradient program was utilized: separation was started with 70% water, 17% methanol, and 13% acetonitrile (0−7 min), followed by an increase of the organic phase to 55% water, 30% methanol, and 15% acetonitrile (7−10 min), holding at the latter conditions for an additional 6 min, and eventually returning to the initial mobile phase conditions (16−19 min). The flow rate was 1.0 mL/min and the injection volume 40 μL. A limit of quantitation of 1 and 0.3 μg/kg was achieved for AFB_1 and AFG_1, and AFB_2 and AFG_2, respectively.

Blood Samples. Blood samples were collected from the jugular vein of 27 randomly chosen live cattle during the intoxication event, counted from the first mortality event, over a time period of 63 d. Samples for complete blood count were collected in potassium-EDTA

[a]Coelutes with its structural isomer intermedine. [b]Coelutes with its structural isomer intermedine-*N*-oxide. [c]Tentative identification, based on fragmentation spectra, MW, retention time, and the presence/absence of *N*-oxides. The prefix iso indicates the presence of a structural isomer (e.g., 7-tigloyl or 7-senecioyl) instead of the 7-angeloyl ester moiety.

tubes and analyzed within 2 h of collection using an Advia 120 hematology analyzer (Siemens Medical Solutions Diagnostics, Erfurt, Germany). Samples for serum chemistry were collected in plain tubes with gel separators. Samples were centrifuged within 2 h of collection, and harvested sera were analyzed immediately using a Cobas Integra 400 Plus wet chemistry analyzer (Roche, Mannheim, Germany) at 37 °C, and reagents were supplied by the manufacturer. The serum was assayed for the enzymes creatine phosphokinase (CK), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and γ-glutamyltransferase (GGT) and for the concentrations of albumin, total protein, globulin, calcium, phosphate, magnesium, and urea. Whole blood was examined to determine the values of the red blood-cell count (RBC), mean cell volume (MCV), mean corpuscular hemoglobin concentration (MCHC), and white blood cell count (WBC).

Bacteriology and Virology. Fresh samples of lung, liver, spleen, and kidney from three dead cows were examined for evidence of bacteriological and viral infections. The analysis for botulism neurotoxin from feed, stomach content, and plasma was performed by the Israeli Reference Laboratory, Department of Bacteriology, The Kimron Veterinary Institute, Israel, utilizing in-house-validated mouse lethality assay.[23] Brain tissues were tested for rabies virus (RABV) at the Israeli Reference Laboratory, Department of Rabies, The Kimron Veterinary Institute, Israel, utilizing the direct fluorescent antibody test according to an in-house-validated method.[24]

Necropsy and Gross Pathology. Three cows were submitted to the Kimron Veterinary Institute for full necropsy on the first week of the intoxication event.

Histopathology. Tissues collected for histopathological examination from three cows included the entire heart, lung, liver, kidney, spleen, brain, both ventricular walls and the interventricular septum, and small intestine and were preserved in 10% buffered formalin. In addition, liver samples from 49 slaughtered cows were collected for

DOI: 10.1021/jf5052199
J. Agric. Food Chem. 2015, 63, 1664−1672

histopathological evaluation. Tissues were embedded in paraffin, sectioned at a 5 μm thickness, and stained with hematoxylin and eosin.

Ethical Animal Use. Blood sampling for diagnostic purpose was performed by the farm veterinarian in compliance with the Animal Disease Order, Article 11, 1985.[25] Cattle slaughtering was performed according to the Israeli Livestock Slaughter Regulations, Article 30, 1964.[26]

Statistical Analysis. The results of the blood tests were analyzed for differences between healthy (standard reference values) (Table 2) and intoxicated cows by Student's t test, with a level of significance of $p < 0.05$. The biochemical values of the healthy mixed breed cattle were provided by the Veterinarian Hospital, The Hebrew University, Beit-Dagan, Israel. The biochemical reference values were determined from dozens of healthy mixed-breed cattle over a time period of 5 years, weighting 300−400 kg.

Table 2. Serum Biochemical Markers of Intoxicated Mixed-Breed Beef Cattle in Comparison to Reference Values of Healthy Mixed-Breed Beef Cattle of the Same Age

biochemical marker[a]	mean (range) values of intoxicated cows	blood values outside the normal range[b] (%)	mean (range) values of healthy cows
AST	180 (68−811) U/L[c]	48	75 (45−110) U/L

[a]AST = aspartate aminotransferase, CK = creatinine kinase, GGT = γ-glutamyl transferase, and ALP = alkaline phosphatase. [b]The percent values are related to the number of cattle being outside the normal range. [c]Mean enzyme activity values of healthy vs intoxicated cows are significantly different according to the Student's t test ($p < 0.05$).

RESULTS

Necropsy and Gross Pathology. Necropsy was performed on three cows that were found dead 7−9 d after being allocated to a nearby grazing field free of any visible *Heliotropium* weeds. The findings in the three dead cows were consistent. Pathological abnormalities were mostly confined to the liver, which was pale-yellowish, firm, and smaller than normal, with fibrotic streaks in most cases (Figure 3). Furthermore, mild to moderate ascites and mesenteric edema were observed. The kidneys were mildly congested but retained normal architecture. The rest of the necropsy revealed no gross abnormalities within the rest of the body.

Histopathology. Histopathological examination of the livers revealed similar changes in all animals, with hyperplasia of bile ductulus and prominent periportal fibrosis. Megalocytosis was not consistently seen in all liver samples. Cirrhosis was observed in all livers, with fibroblasts infiltrating the liver parenchyma (Figure 4). Nodules of regeneration of hepatocytes were also recorded. No pathological changes were observed in the other organs examined.

Blood Analysis. Biochemical tests of blood samples collected from 27 live cows during the mortality event revealed extraordinarily high CK levels in all animals tested (125−4128 U/L), whereas the enzyme activities for AST (68−811 U/L), GGT (17−232 U/L), and ALP (51−439 U/L) were significantly elevated in more than 47% of all animals examined (Table 2). Serum urea, Ca^{2+}, Mg^{2+}, phosphate, albumin, total protein, and globulin were within the normal range (Table 2). Blood hemoglobin, hematocrit, red blood-cell count (RBC),

[a]Classification according to the PA necine base and the number and type of esterifying necic acids (Figure 1). [b]The chemical structure of the PAs without a bold compound number can be found in ref 5. [c]*n* = 3. [d]Tentative identification. The prefix iso indicates the presence of a structural isomer (e.g., 7-tigloyl or 7-senecioyl) instead of the 7-angeloyl ester moiety.

packed cell volume (PCV), and white blood cell count (WBC) were within normal limits.

Liver Analysis for Trace Elements. The elements analyzed in the liver samples by ICP-AES (As, Cd, Co, Zn, Cu, Fe, Pb, Mn, Hg, Mo, Se, Tl, and Zn) were within the normal limits.[27]

Bacteriology and Virology. No pathogenic bacteria (aerobic, anaerobic and *Salmonella*, *Clostridium*) and viruses of epidemiological significance were detected in the tissues examined.

Feed Analysis. The feed ingredients were concomitantly analyzed for ionophores, tetracycline antibiotics, pesticides, and aflatoxins. Only ionophore and tetracyclines, approved by the Ministry of Agriculture for use in farm animals, were included in the analysis.[19] The antibiotics and ionophores analyzed by LC−MS/MS were below the detection limit of 60 μg/kg. The feed ingredients analyzed for aflatoxins by HPLC-FLD were below the limit of quantitation (1 μg/kg).

Our routine qualitative multiresidue screening analysis utilizing GC−MS of the TMR ingredients did not reveal any pesticide contamination. However, in the hay samples analyzed, GC−MS clearly indicated the presence of three PAs, heliotrine (**4**), europine (**5**), and lasiocarpine (**6**). Hay inspection by the Department of Toxicology and by a certified botanist revealed the presence of aerial parts of dried *H. europaeum*, and therefore, a subsequent qualitative and quantitative PAs analysis of the contaminated hay samples together with the aerial parts

DOI: 10.1021/jf5052199
J. Agric. Food Chem. 2015, 63, 1664−1672

of *H. europaeum* collected in the fields used for the aforementioned hay harvest was carried out by LC−MS/MS.

The PA and PA-*N*-oxide composition and relative concentrations of the individual PAs in the contaminated hay and in *H. europaeum* overlapped strongly, yielding in both sample types 30 structurally different PAs [16 *N*-oxides and 14 tertiary amines containing supinidine (**1**) and heliotridine (**2**) as necine bases; see Table 3 and Figure 1]. PAs containing a heliotridine necine base (**2**) were classified into two subtypes, according to the number of esterifying necic acids [monoester heliotrine-type PAs (**4**) and diester lasiocarpine-type PAs (**6**); Figure 1]. The total PA content in the contaminated hay was 3.4 mg/g dried hay, while the aerial plant parts of *H. europaeum* contained 27.7 mg PA/g dried plant (Table 3). The most abundant tertiary PA bases found in *H. europaeum* and the contaminated hay were heliotrine (**4**) (170 and 1180 μg/g, respectively), followed by europine (**5**) (90 and 830 μg/g, respectively) and lasiocarpine (**6**) (56 and 240 μg/g, respectively) (Table 3). The PA-*N*-oxides constituted the major part of the total PA composition in the hay and in *H. europaeum* (90 and 91%, respectively), with heliotrine-*N*-oxide (**7**) and europine-*N*-oxide (**8**) being the most prevalent *N*-oxides (28−29% and 33−34%, respectively), followed by lasiocarpine-*N*-oxide (**9**) (21% and 13.6%, respectively) (Table 3).

The LC−MS/MS analysis of *H. europaeum* revealed the presence of trace amounts of 10 PAs containing rinderine (**10**−**15**) and heliosupine structures (**16**−**19**) (Figure 1). Putative assignments were made on the basis of retention time, protonated precursor mass, fragmentation behavior (such as the loss of characteristic fragments), the oxidation state of the nitrogen atom; and comparison with literature data and with additional plant extracts available at RIKILT. In this way, rinderine (**10**), 5′-hydroxyrinderine (**11**), 3′-acetylrinderine (**12**), rinderine-*N*-oxide (**13**), 5′-hydroxyrinderine-*N*-oxide (**14**), 3′-acetylrinderine-*N*-oxide (**15**), heliosupine (**16**), 3′-acetylheliosupine (**17**), heliosupine-*N*-oxide (**18**), and 3′-acetylheliosupine-*N*-oxide (**19**) could be identified (Figure 1 and Table 3). The supinidine-type PAs (**1**) exhibited low abundances in both the hay and the *H. europaeum* samples (Table 3).

DISCUSSION

Chronic PA poisoning of cattle in Israel due to consumption of hay contaminated with *H. europaeum* was first reported about 30 years ago.[9] The clinical manifestations and histopathological findings were similar to those described previously.[9] In general, the clinical manifestation of PA toxicosis is not pathognomonic and might have been indicative of aflatoxicosis, lead poisoning, or rabies. Rabies was eliminated by examination of brain slices, and lead poisoning was ruled out by liver lead determination; neither latter poisonings are associated with characteristic liver lesions. Aflatoxicosis, which in cattle often displays histopathological signs similar to those of PA toxicosis, was ruled out by the results of the feed analysis by HPLC-FLD. Routine bacteriological examinations eliminated possible causative infective bacteria, while chemical analysis of TMR ingredients excluded the involvement of common causes of poisoning previously reported in Israel (organophosphorus, carbamate, organochlorine pesticides). However, the inspection of the TMR ingredients by GC−MS led to the identification of three PAs in the hay: heliotrine (**4**), europine (**5**), and lasiocarpine (**6**). The discovery of PAs in the hay led us to examine the suspected hay, eventually revealing the presence of *H. europaeum*. Subsequent analysis of the contaminated hay and native *H. europaeum* by LC−MS/MS resulted in the identification of 30 different PA and PA-*N*-oxides, at a total level of 3.4 mg/g dry weight in the hay (Table 3).

In the literature there have been a number of descriptions of the histopathological changes of PA toxicosis, among which megalocytosis was often stated to be pathognomonic. However, the histopathological results of the present study indicate that megalocytosis was not a prominent and consistent feature, appearing only in one liver specimen and at a very low intensity, in agreement with the experimental trial results on cattle published previously.[17,28] The differences reported regarding the prominence of megalocytosis might arise due to intra- and interspecies variation in PA composition and duration of exposure, as well as varying degrees of susceptibility to PA toxicities among different cattle breeds. From the results of this study together with previous studies, the inconsistent appearance of megalocytosis in a biopsy specimen does not rule out PA toxicosis in a clinical situation.[17,28]

Measurement of specific serum enzyme activities, in conjunction with markers of renal activity and complete blood count, is a very useful tool in the diagnosis of hepatobilliary injury due to hepatotoxic xenobiotics such as PAs and aflatoxins. Concomitant increases of ALP with GGT raises the suspicion of hepatobilliary disease, as was demonstrated in more than 70% of all cows tested in the present study ($n = 27$) (Table 2). Elevated serum GGT activity can be found in liver, biliary system, and pancreas disorders. In this respect, it is similar to ALP in indicating biliary tract diseases. The main value of GGT over ALP is in verifying that ALP elevations are due to biliary disease, as ALP may increase in certain bone diseases, while GGT does not.[17] Increased AST activity in the serum is indicative of liver damage; however, in the present study only 48% of all examined cows revealed values above the normal AST range (Table 2); hence, according to the results presented herein, GGT and ALT are potentially more sensitive biomarkers for hepatobilliary injury due to PA toxicity.

CK is generally very useful in diagnosing skeletal or cardiac muscle degeneration.[17] In all examined cows, CK levels were substantially above the normal range over a time period of 63 d, indicating muscle trauma, most probably due to prolonged recumbancy, as histologically no marked myocardial damage was observed (Table 2).

Measuring serum GGT and ALP as diagnostic enzymes could be useful as a first screening test in suspected cases of PA toxicosis.[17] These enzymes, together with a histopathological examination of the liver, provide important information in diagnosing lethal exposure to hepatotoxic compounds such as PAs or aflatoxins. However, a differentiation between various hepatotoxic xenobiotics is only possible by direct determination of the noxious compound and/or its metabolites in the feed and/or organ tissues, such as the liver. The main obstacle in establishing a diagnosis of PA or aflatoxin intoxication is that in both cases the clinical symptoms and sudden death occur weeks or several months after chronic exposure, depending on the exposure level and animal species, age, and sex, so that often no samples of contaminated feed are available for chemical analysis.[9,29] Moreover, since PAs and aflatoxins are quickly metabolized to their corresponding reactive intermediates, the ability even of highly sensitive instruments such as LC−MS/MS to identify parent compounds as well as major metabolites

DOI: 10.1021/jf5052199
J. Agric. Food Chem. 2015, 63, 1664−1672

thereof diminishes rapidly within a few days.[12,30] On the other hand, protein and/or DNA adducts of PAs and aflatoxins have far longer tissue half-lives and therefore are currently the most promising biomarkers for establishing a conclusive diagnosis, even after several months of washout period.[12]

The average feed intake of 15−18-month-old mixed-breed cattle weighting 350 kg was estimated to be 7 kg feed/d, hence 20 g feed/d/kg body weight (BW). Taking into account an average total PA content of 3.4 mg/g hay and a dilution ratio of 1:2 with the other feed ingredients, the total mean PA intake leading to the observed high mortality rate and clinical and pathological signs was 34 mg/kg BW/d. This value is about twice as high as the lethal doses (15 mg PAs/kg BW/d) given as dried *Senecio jacobaea* for 14 d to four lactating cows and administered for 20 d to three calves in the form of dried *Senecio riddellii* (17 mg PAs/kg BW/d).[11,31] LD_{50} values reported for various PAs vary widely, but macrocyclic and diester PAs tend to be somewhat more toxic than monoester PAs.[5]

Careful inspection of weed species likely to thrive in pastures and meadows under certain environmental conditions, such as drought, could prevent future cases of PA intoxications both in livestock and humans. An inspection protocol must include collection and retention specimens of the suspected feed and feed analysis, preferably by utilizing highly sensitive instruments such as GC−MS or LC−MS/MS. Furthermore, the establishment of a future database of MS spectra and corresponding retention times together with the availability of sufficient PAs standards would facilitate rapid diagnosis.

To the best of our knowledge, this is the first study utilizing LC−MS/MS for qualitative and quantitative analysis of the PA content in *H. europaeum*. The high sensitivity of the LC−MS/MS analysis utilized for the determination of the PA and PA-*N*-oxide composition in the contaminated hay, as well as the possibility of measuring both forms of PAs simultaneously and the ease of sample preparation, enabled us to markedly expand the known PA profile of *H. europaeum* from 12 to 30 different PA and PA-*N*-oxides (Table 3).[3] A total of 10 PAs of the rinderine and heliosupine classes are reported for the first time to be present in this species. To the best of our knowledge, PAs derivatives of rinderine (**10**−**16**, Figure 1) and heliosupine (**16**−**19**, Figure 1) have so far been reported only in *Heliotropium indicum*, *Heliotropium peruvianum*, *Heliotropium transalpinum*, and *Heliotropium supinum*.[3] The definite assignment of the rinderine derivatives could not be made, because the obtained mass fragmentation spectra do not exclude the presence of echinatine structures. However, on the basis of the fact that (+)-trachelanthic acid, the necic acid in rinderine, has the same stereochemistry as heliotric acid, the necic acid in heliotrine, its presence was considered more likely than the echinatine structure, which is esterified with (−)-viridifloric acid and for which no heliotrine counterpart is known.

Utilizing LC−MS/MS analysis techniques is expected to expand substantially the PA composition of known PA-producing plants.[33]

In agreement with previous studies, the most abundant PAs found in *H. europaeum* were heliotrine (**4**), europine (**5**), and lasiocarpine (**6**).[3,32] In the investigated *H. europaeum*, the total PA level was 2.7%, being comparable to the levels found in *H. europaeum* grown in southeastern Australia at the same flowering stage.[34]

The total PA profiles of *H. europaeum* and of the contaminated hay strongly overlapped in terms of composition and relative abundance, with heliotrine-*N*-oxide (**7**) and europine-*N*-oxide (**8**) being the most abundant alkaloids in both samples (Table 3). This finding suggests that a selection of abundant PA and PA-*N*-oxides may be used as a fast and reliable tool for species identification.

In conclusion, a mortality rate of 33% in mixed-breed cattle was recorded, following ingestion of TMR contaminated with *H. europaeum* at a level of 12% dry weight. The toxicosis event was characterized by typical clinical and histopathological signs of PA toxicosis. LC−MS/MS analysis of the PA and PA-*N*-oxide profile in *H. europaeum* enabled a comprehensive composition determination, including 10 PAs of the rinderine and heliosupine classes reported for the first time in *H. europaeum*.

J. Agric. Food Chem. 2015, 63, 1664−1672

The aim of this study was to evaluate the influence of climatic variables such as temperature, solar radiation, relative humidity, and precipitation on the phenolic composition and color of three pigmented baby leaf lettuce varieties sampled during 16 consecutive weeks from February to May. In addition, possible color−anthocyanin composition relationships were studied by applying multivariate statistical analysis.

MATERIALS AND METHODS

Plant Material. Three pigmented baby leaf lettuces (*Lactuca sativa*), two Batavia cultivars (B1 and B2) and one red oak leaf (R), were cultivated under commercial conditions in Fuente Alamo (Murcia, Spain) by a commercial grower (Langmead, Murcia, Spain). The growing fields were located within an area of 20 km^2. The type of soil in the selected fields was mainly clay and clay loam. Sowing was performed directly from seeds on elevated beds using a density of 700 plants m^{-2}. Baby leaves at the commercial maturity stage (10−12 cm) were mechanically harvested during 16 consecutive weeks from February (week 5) to May (week 20) in 2012. Supplemental information regarding the dates of plantation and harvesting and the crop cycle schedule has been provided by Medina-Martínez et al.[24] After harvest, baby leaves were transported under refrigeration (approximately 35 km) to the CEBAS-CSIC laboratory (Murcia, Spain). On arrival, samples were characterized by measuring fresh weight, dry matter content, leaf area, and color, and the remaining leaves were frozen within 2 h of harvest and stored at −80 °C for the analysis. Twenty leaves per cultivar were characterized for fresh weight, dry matter content, leaf area, and color. Dry matter content was measured after drying the leaves in a ventilated oven at 70 °C until constant weight. Leaf area was measured by a horizontal photography and image treatment (ImageJ, Bethesda, MD, USA) of each leaf.

Color Measurements. Color was measured using a compact tristimulus colorimeter (Minolta CR-300, Ramsey, NJ, USA) with an 8 mm diameter viewing aperture. The parameters L^*, a^*, and b^* were used to calculate the hue angle $[\tan^{-1}(b^*/a^*)]$ and the chroma index $[(a^{*2} + b^{*2})^{1/2}]$. Hue angle was expressed on a 360° color wheel where 0° and 360° represents red, 90° represents yellow, 180° represents green, and 270° represents blue. Chroma indicates color purity or saturation (high values are more vivid).[25] Twenty leaves per cultivar and sampling date were measured.

Extraction, Identification, and Quantification of Phenolic Compounds. For the analysis of phenolic compounds, 100 g of leaves per cultivar were lyophilized. For the identification and characterization of phenolic compounds, 0.02 g of lyophilized leaf powder was extracted with 2 mL of methanol:water:formic acid (50:49:1,v/v) by sonication for 1 h. The resulting extract was centrifuged and filtered through a 0.45 PVDF filter. Chromatographic analyses were carried out on a Luna C18 100 Å column (150 × 1.0 mm, 3 μm particle size; Phenomenex, Macclesfield, U.K.). The mobile phase consisted of two solvents: water (1% formic acid) (A) and methanol (B). Elution was performed with a flow rate of 20 μL min^{-1} and an injection volume of 3 μL. The elution profile was as follows: gradient from 5 to 30% solvent B for 15 min, gradient from 30 to 50% solvent B for 15 min, isocratic solution 50% for 5 min, gradient from 50 to 60% solvent B for 1 min, gradient from 60 to 70% for 4 min, gradient from 70 to 90% solvent B for 5 min, and isocratic solution 90% for 5 min. Spectral data from all peaks were accumulated in the 200−400 nm range. Chromatograms were recorded at 320, 340, and 520 nm. The analyses were carried out by high-performance liquid chromatography (HPLC) coupled to diode array detection (DAD) and mass spectrometry (MS−MS) with an ion trap detector equipped with an electrospray ionisation interface (ESI). The HPLC−DAD−MS−MS/ESI analyses were carried out in an Agilent HPLC 1200 series (Agilent Technologies, Waldbronn, Germany) equipped with a binary pump (model G1376A), an autosampler (model G1377A) refrigerated at 4 °C (model G1330B), a degasser (model G1379B), and a photodiode array detector (model G1315D). The HPLC system was controlled by ChemStation software (Agilent, v. B.01.03-SR2). The mass detector was a Bruker ion trap spectrometer (model HCT Ultra) equipped with an electrospray ionization interface controlled by software (LCMSD, Agilent, v. 6.1). The ionization conditions were 300 °C and 4.0 kV for capillary temperature and voltage, respectively. The nebulizer pressure and flow rate of nitrogen were 5.0 psi and 3 L/min^{-1}, respectively. The full scan mass covered the range from m/z 100 up to m/z 1200, and the target mass was adjusted to m/z 350. Collision-induced fragmentation experiments were performed in the ion trap using helium as the collision gas, with voltage ramping cycles from 0.3 up to 2 V. Mass spectrometry data were acquired in the negative mode for phenolic acids and flavonoids and in the positive ionization mode for anthocyanins. MSn was carried out in the Selected Ion Monitoring (SIM) mode.

The identification of the peaks was carried out by the extracted-ion chromatograms of the ion current at m/z values corresponding to the $[M-H]^-$ ions of the individual investigated compounds, as well as their fragmentation. Quantification of the identified analytes was performed by HPLC-DAD using the external standard method with calibration graphs, as a function of concentration based on peak area, detected at the wavelength corresponding to the maximum absorbance (320 nm for phenolic acids, 360 nm for flavonoids, and 520 nm for anthocyanins). Phenolic acids were quantified as chlorogenic acid (5-*O*-caffeoylquinic acid) (Sigma, St Louis, MO, USA), flavonoids as quercetin-3-rutinoside (Sigma, St. Louis, MO, USA), and anthocyanins as cyanidin-3-glucoside (Polyphenols Laboratories AS Hanaveien, Sandnes, Norway). Three replicates per cultivar and sampling date were analyzed.

Climatic Variables. Climate data were obtained from the nearby Balsapintada climate station (37° 44′ 53,89″ N, 1° 7′ 45,14″ W) and El Campillo climate station (37° 41′ 56,52″ N, 1° 14′ 16,96″ W), located within 10 km of the fields, using the local climatological database.[26] Relevant climatic variables such as temperature, solar radiation, precipitation, and relative humidity were collected daily from the start to the end of the growing season. The climatic variables and their abbreviations are listed in Table 1.

Table 1. Climatic Variables Investigated and Their Abbreviations

abbreviations	climatic variable	units
Rw	radiation in the last week before harvest	MJ m^{-2}
Rgh	radiation from the start of the growing until harvest	MJ m^{-2}
Tw	temperature in the last week before harvest	°C
Tgh	temperature from the start of the growing until harvest	°C
T0w	hours with temperature below 0 °C in the last week before harvest	h
T0gh	hours with temperature below 0 °C from the start of the growing until harvest	h
T7w	temperature below 7 °C in last week before harvest	h
T7gh	hours with temperature below 7 °C from the start of the growing until harvest	h
RHw	humidity in last week before harvest	%
RHgh	humidity from the start of the growing until harvest	%
Pw	precipitation in last week before harvest	mm
Pgh	precipitation from the start of the growing until harvest	mm

Statistical Analysis. Two-way analysis of variance (ANOVA) was carried out to detect significant differences between cultivars and harvest weeks on the color and phenolic composition and content. Tukey's HSD test for the population with equal variances was used to carry out the multiple comparisons at $p < 0.05$. Principal component analysis (PCA) and Pearson's correlation coefficient analysis were carried out to study the influence of seasonal variability in the three pigmented baby leaf lettuces. Statistical analyses were performed using SPSS 20.0.0 (SPSS Inc., Chicago, IL, USA).

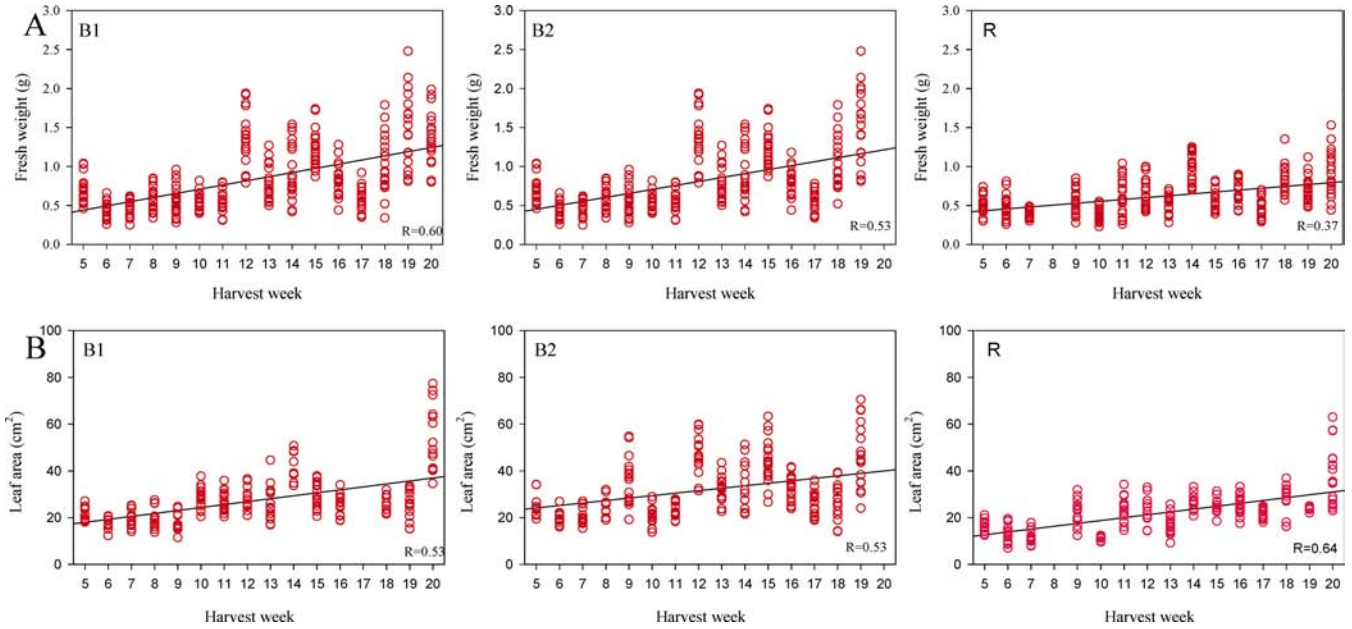

Figure 1. Scatter plots of growth parameters vs harvest week of baby leaf Batavia (B1 and B2) and red oak leaf (R) lettuces. (A) Fresh weight and (B) leaf area.

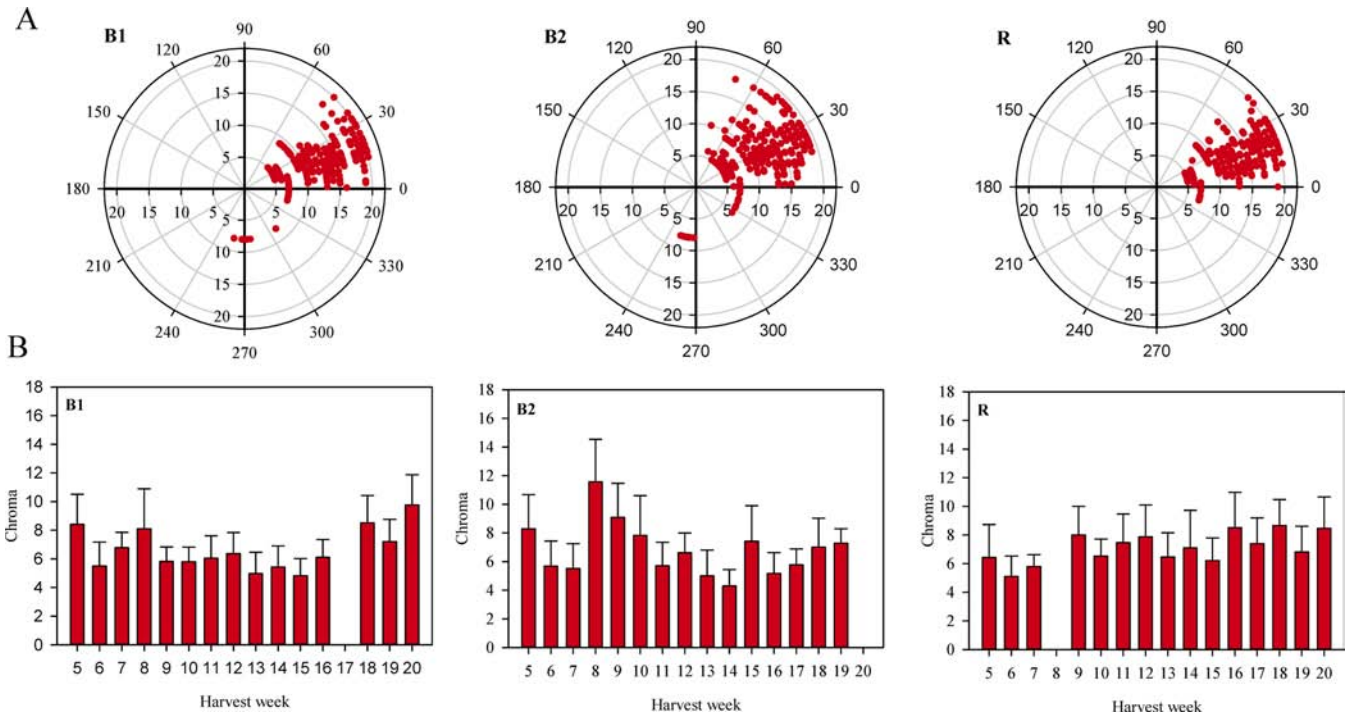

Figure 2. Hue angle vs harvest week (A) and chroma values vs harvest week (B) of baby leaf Batavia (B1 and B2) and red oak leaf (R) lettuces. In polar plot (A) 0° and 360° indicate red, 90° indicates yellow, 180° indicates green, and 270° indicates blue.

RESULTS

Effect of Seasonal Variability on Growth and Color Characteristics. Growth characteristics were significantly ($P \leq 0.001$) influenced by the cultivar and harvest week (Supporting Information, Table SI.1). In detail, the fresh weight and leaf area were higher in Batavia B2 (0.81 g and 32.27 cm^2), followed by Batavia B1 (0.72 g and 27.7 cm^2) and red oak leaf (0.67 g and 22.3 cm^2) (Figure 1). However, the fresh weight and leaf area increased slightly with harvest week for the three pigmented lettuce cultivars.

To determine which cultivar presented the reddest and most intense color, data of the three cultivars were combined and analyzed (Figure 2). Batavia B1 showed the lowest hue value (15.22°) followed by red oak leaf and Batavia B2, which had hue angles of 18.01° and 23.16°, respectively (Figure 2A). These data indicated that Batavia B1 showed the reddest color followed by red oak leaf and Batavia B2. The changes in the hue angle indicated the fluctuation with the growing season, and together with other genetic and agricultural implements, weather variability might be responsible for the lack in color

DOI: 10.1021/acs.jafc.5b00120
J. Agric. Food Chem. 2015, 63, 1673−1681

consistency as it was observed for the hue angle values of B1 and B2 for the harvest week 8. Regarding chroma values, red oak leaf showed the highest value (7.1) whereas Batavia B1 and B2 had the lowest values (6.6 and 6.7, respectively) with no significant differences between them (Figure 2B). With respect to the influence of harvest week on the hue angle, Batavia B1 and red oak leaf showed lower dispersion of hue angle values than Batavia B2 and therefore more homogeneous color throughout the season (Figure 2A). Moreover, Batavia B2 showed the highest chroma value for the harvest weeks 8 and 9 (Figure 2B).

Effect of Seasonal Variability on Individual Composition and Content of Phenolic Compounds. Figure 3 shows

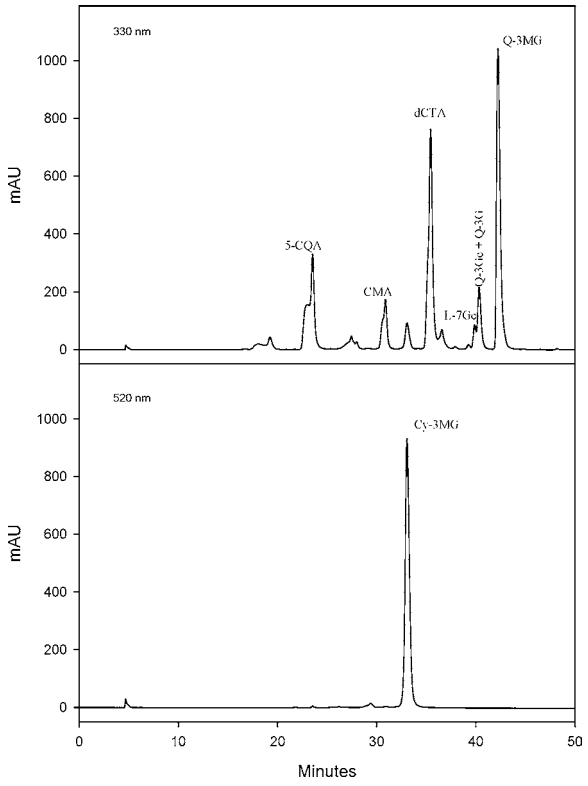

Figure 3. HPLC chromatograms of Batavia B1. Hydroxycinamics acids, flavonols, and flavone at 330 nm and anthocyanins at 520 nm. Abbreviations: Cy−3MG, cyanidin-3-*O*-(6″-*O*-malonyl)-glucoside; 5-CQA, 5-caffeoylquinic acid; CMA, caffeolylmalic acid; dCTA, dicaffeoyltartaric acid; L−7Gc, luteolin-3-*O*-glucuronide; Q−3Gc, quercetin-3-*O*-glucuronide; Q−3G, quercentin-3-*O*-glucoside; Q−3MG, quercetin-3-*O*-(6″-*O*-malonyl)-glucoside.

the HPLC chromatograms of Batavia B1 recorded at 330 and 520 nm. Identification of phenolic compounds was based on the chromatographic and mass spectral characteristics as well as the previous literature descriptions.[8] Three hydroxycinnamic acids were confirmed as 5-*O*-caffeoylquinic acid (5-CQA), *O*-caffeoylmalic acid (CMA), and di-*O*-caffeoyltartaric acid (dCTA), three quercetin glycosides (quercetin-3-*O*-glucuronide, quercetin-3-*O*-glucoside, and quercetin-3-*O*-(6″-malonyl)-glucoside), one luteolin glycoside (luteolin-7-*O*-glucuronide), and one cyanidin glycoside (cyanidin-3-*O*-(6″-malonyl)-glucoside). See legend of Figure 3 for abbreviations.

Throughout the season, the phenolic content was significantly ($P \leq 0.001$) influenced by cultivar and harvest week (Supporting Information, Table SI.1). Among the three pigmented lettuce cultivars, the same individual phenolic constituents were observed but with significant ($P \leq 0.001$) differences in their individual content (Supporting Information, Table SI.2). The flavonol Q−3MG was the main phenolic compound in the three cultivars, followed by Cy−3MG and the phenolic acids 5-CQA, dCTA, and CMA. The flavonols Q−3Gc and Q−3G coeluted and were quantified as the sum and the flavone L−7Gc was present at the lowest concentration. When the contents of the individual phenolic compounds for all the harvest weeks were combined, Batavia B1 and red oak leaf had similar but higher phenolic acid contents, except for CMA, than Batavia B2, which showed the highest phenolic acid content for dCTA (Supporting Information, Table SI.2).

To create an overview of the changes in the content of phenolic compounds with harvest week, the data of the three cultivars were combined and analyzed together (Figure 4). The three cultivars showed the same trend for phenolic acids throughout the season; the content of 5-CQA and dCTA increased while the content of CMA slightly decreased as the harvest week progressively advanced. Concerning flavonoids, Q−3MG showed marked differences between consecutive harvest weeks, particularly Batavia B2, but in general it increased as the growing season advanced. The content of Cy−3MG in Batavia cultivars was maintained or increased slightly throughout the season while this pigment tended to decrease slightly in red oak leaf (Figure 4).

Effects of Climatic Variables on Phenolic Compounds and Color. Principal component analysis (PCA) was conducted to give an overview of the impact of climatic variables on the content of phenolic compounds and color of the pigmented baby leaf lettuces (Figure 5). PCA resulted in five uncorrelated principal components (PC) for Batavia B1 and B2 and four PC for red oak leaf that accounted for 88.4, 90.2, and 85.6% of the total variability, respectively. Eigenvalues, loadings, and accumulated percentage of data variation of each PC are shown in Table SI.3 (Supporting Information). PC1 and PC2 explained 66.7, 67.1, and 64.1% of the variation in the content of phenolic compounds and color by climatic variables for B1, B2, and R cultivars, respectively. As it can be observed in Figure 5, phenolic compounds were located close to each other in the PCA plot arrangement and responded in a similar way to the changes in the climatic variables. PC1, which accounted for 45.6%, 47.7%, and 40.7% for B1, B2, and R cultivars, respectively, separated the different phenolic compounds by their sensitivity to the changes in temperature and radiation doses. PC2, which accounted for 20.8%, 19.4%, and 23.4% for B1, B2, and R cultivars, respectively, separated the different phenolic compounds by their sensitivity to the changes in humidity, precipitation, and the number of hours below 0 and 7 °C in the last week before harvest.

In addition to the general correlations observed via PCA analysis, correlations between climatic variables and individual phenolic compounds were also detected via Pearson's correlation coefficient analysis (Table 2). Batavia cultivars had similar correlations between climatic variables and individual phenolic compounds. Temperature and radiation during the growing cycle was positively correlated with Cy−3MG, 5-CQA, dCTA, L−7Gc, and Q−3MG (Table 2). However, a CMA showed higher correlation with the number of hours below 7 °C the week before harvest (correlation coefficients $r = 0.73$ and $r = 0.74$ for B1 and B2, respectively). In red oak leaf, the content of Cy−3MG showed a good correlation with the

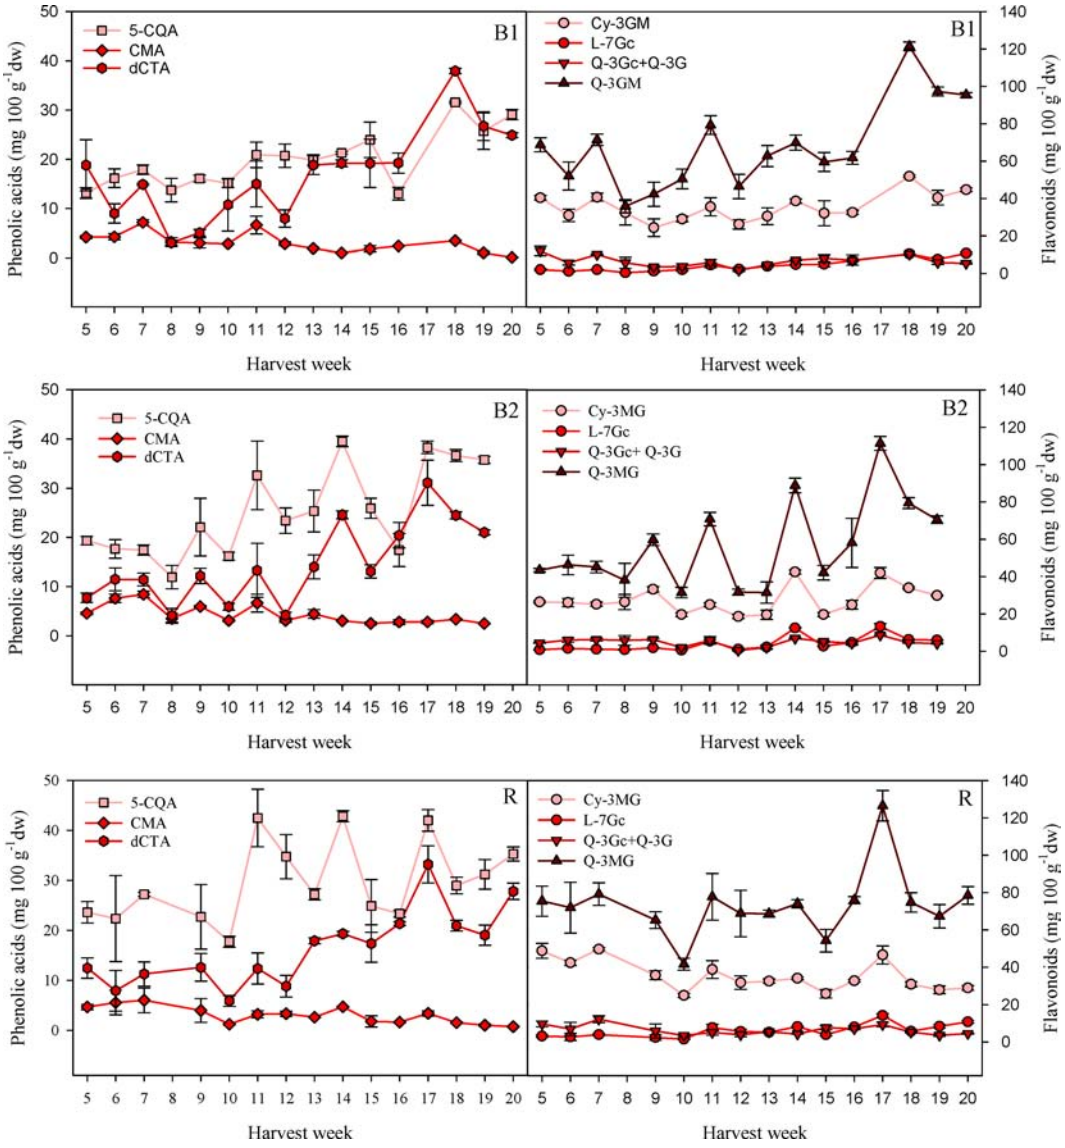

Figure 4. Phenolic compounds vs harvest week of baby leaf Batavia (B1 and B2) and red oak leaf (R) lettuces. Symbols represent the mean ± standard deviation of three replicates. See Figure 3 for abbreviations.

number of hours at a temperature below 0 and 7 °C (r = 0.50 and r = 0.62, respectively). At the end of the growing season, red oak leaf showed the lowest concentration of Cy−3MG. The same trend observed for the anthocyanin Cy−3MG was shown for CMA and the flavonols Q−3Gc + Q−3G (r = 0.44 and r = 0.59, respectively). With respect to the color, the hue angle was the parameter that best represented the color changes of these cultivars. PCA analysis showed that there was no correlation between anthocyanin content and hue angle in any of the cultivars studied (Figure 5). However, the hue angle was related with cold temperatures during the weeks before harvest and therefore showed the same trend as the CMA.

■ DISCUSSION

The changes observed in the phenolic content throughout the season agree with other studies in which the effect of variety, processing, and storage has been studied in whole pigmented lettuce heads.[27] We have previously observed that the individual phenolic composition depends on the genetic information[8,11] although the content is very much influenced by the growing conditions.[13,14,28] In the present study, we also observed that the climatic variables influenced the content of phenolic compounds; in particular, the increase in temperature and radiation during the season promoted the increase in the content of phenolic acids and flavonoids. In another study by Bunning et al.[29] it was observed that differences among lettuce cultivars appear to have a larger impact on sensory and phenolic profiles than environmental variation during the growing season. However, in green and white currants high radiation and temperature have been associated with low content of the major phenolic compounds.[30] In lettuce, most of the studies have evaluated the influence of light quality, light intensity, and temperature on the changes in the phenolic compounds but always under controlled conditions far from the environmental conditions in open fields. In previous studies under controlled conditions, light experiments have been carried out using different plastic films to allow the filtration of different doses of ultraviolet radiation.[12,21,31] In other studies, the influence of light quality was also studied but by using different supplemental light qualities such as UV-A, blue, green, red,

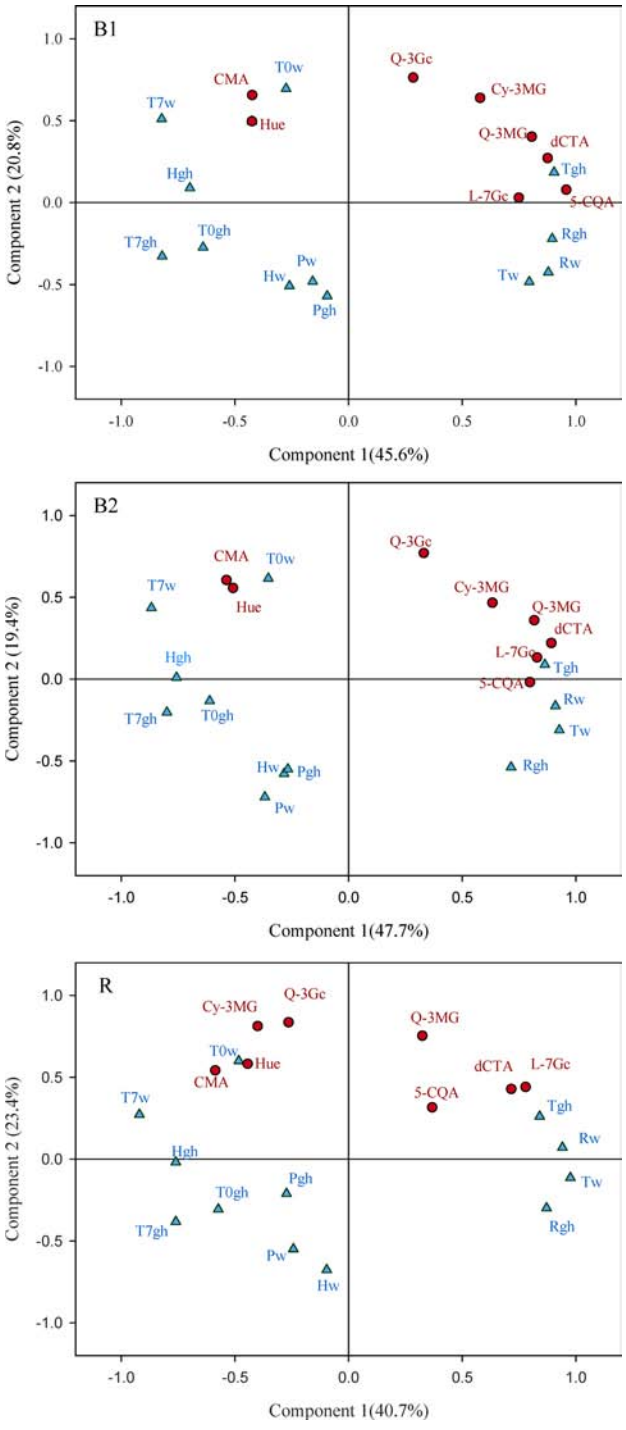

Figure 5. PCA plots of the correlations between phenolic compounds and hue angle and climatic variables. See Figure 3 and Table 1 for abbreviations.

and far-red-light-emitting diodes (LEDs).[23,32] In summary, radiation intensity has a definite influence increasing the phenolic metabolism in accordance with our results. The biosynthesis of flavonoids in pigmented leaf lettuce is enhanced by growing under plastic films that allows a higher exposure to UV radiation.[19] These authors observed that there was not a significant impact on the phenolic acids whereas the glycosides of quercetin and luteolin were significantly affected by the different radiation treatments. With the same approach, García-Macías et al.[12] showed that exposure to increased levels of UV radiation during cultivation caused the lettuce leaves to redden and increased the concentrations of total phenolics, particularly the main flavonoids, quercetin and cyanidin glycosides, as well as luteolin conjugates and phenolic acids. In a previous study, we could not study the variability of the content of anthocyanins among red-leafed lettuce genotypes because of the lack of color development when lettuces were protected by the greenhouse compared to that of lettuce grown in open fields.[13] Generally, the flavonoid content is much higher in field-grown than in glasshouse-grown plants, as in the case of a New Asia Salad (*Gynura bicolor*).[33]

Anthocyanin accumulation in plants is sensitive to environmental conditions, but depending on the crop, their impact can be different. In strawberries[34] and black currant[35] the content of the anthocyanins increases as temperature and radiation increase. In pomegranate, however, anthocyanins accumulate with cold temperatures.[36] In addition, foliar anthocyanin accumulation has been reported to be induced at high light intensities, in particular high-UV light, and low growth temperatures.[37,38] Our results showed that the climatic conditions prior to harvest had a great influence on pigmentation. The content of Cy−3MG increased with temperature and radiation in Batavia cultivars, and in red oak leaf it increased with cold temperatures. In lettuce, several studies have shown that low temperatures lead to an increase in anthocyanins due to the biosynthesis of phenylpropanoids by the increase in the PAL activity.[10,22] In the present study, the different response of Cy−3MG in Batavia and red oak leaf to the temperature and radiation may indicate genetic differences for the regulation of anthocyanin biosynthesis. Recently, Becker et al.[17]cdescribed that the light-related increase of flavonoid glycosides was structure- and growth-stage-dependent. In detail, an interaction was detected between plant age and low-level photosynthetic photon flux density (PPFD) regarding the cyanidin-3-*O*-(6″-*O*-malonyl)-glucoside concentration: the increase was strongest before head formation. Becker et al.[39] observed that the content of Cy−3MG was higher in cool-cultivated than in warm-cultivated lettuce heads. All major phenolic compounds decreased with plant age. Nevertheless, in our study baby leaves were harvested at the immature stage. The pigmented baby lettuces were harvested at the commercial maturity stage for baby leaves that varied between 8 and 12 cm leaf length depending on the season.[3] As expected, samples harvested in May showed shorter growing cycles than the ones harvested in winter. There was an increase mainly in the solar radiation and temperature with the transition from winter to spring. It is well-known that plant growth and development are regulated by light quality, light intensity, and photoperiod.[40] Our results showed that baby leaves harvested in May presented higher fresh weight and leaf area but lower dry matter content than those harvested in February. Researchers have reported that increased light intensity and extended photoperiods usually promoted the growth.[41] Li and Kubota[32] demonstrated that the growth of red baby leaf lettuce was significantly affected by light quality as fresh weight, dry weight, and leaf area increased with supplemental far-red light compared to those of plants grown in white light.

A clear seasonal variability was observed by the grower in agreement with the analytical results that showed the seasonal fluctuations in the content of individual phenolic compounds. However, our results indicate that it was not possible to establish a relationship between color measured by hue angle and the content of anthocyanins and, therefore, hue angle

cannot be considered a good indicator for anthocyanin accumulation. These results disagree with a previous publication that shows the good correlations between analytic, instrumental, and visual assessment of coloration in red lettuce.[15] These authors measured the pigment extract by spectrophotometer at 530 nm. However, in plant material where two or more pigments are present, close examinations of individual constituents are needed.[42] Other phenolic compounds (copigmentation) as well as the amounts and distribution of chlorophylls and carotenoids contribute significantly to leaf color. Therefore, it is very difficult to find a good correlation between color measurements and pigment content.

Lettuce breeders need to be assisted by agricultural and food chemistry specialists to select cultivars with improved color and phenolic constituents grown under commercial environmental conditions.

including organoclays,[14,15,20,23,25,26] polymer−clays,[16,17,24,27] and micelle−clays.[28−31] Several of the clay-based formulations were tested and found to reduce herbicide leaching through soils. However, these formulations were designed for herbicides with high solubility and extensive leaching to reduce their leaching of 10−100 cm, unlike the case of pendimethalin where the goal is to eliminate its leaching of 1−2 cm. A pendimethalin organoclay formulation was designed for enhanced herbicidal activity, but reduced leaching was not tested.[32]

Hence, the main goal of this study was to develop and examine slow-release formulations of pendimethalin for the reduction of root penetration into subsurface irrigation drippers. The formulations developed were based on pendimethalin solubilization in octadecyltrimethylammonium bromide (ODTMA) micelles adsorbed and unadsorbed on montmorillonite. We have characterized in detail the ODTMA (as monomer and as micelles)−clay interactions in previous studies applying adsorption isotherms, modeling, X-ray diffraction, freeze−fracture electron microscopy, herbicide solubilization measurements,[29] fluorescence studies,[19] and FTIR analysis.[33] The solubilization of several herbicides was further explored in our more recent studies.[25,34]

The novelty of this investigation covers three different aspects; formulation design, bioassay design, and application. More specifically the originality of this study involves the development of (1) two-mode formulations (in the past, unadsorbed micelles were considered not adequate for slow release[31,34] because the release was too fast, but here we demonstrate the advantage of having both modes of micelles, adsorbed and unadsorbed), (2) a bioassay to study herbicide migration at a refined scale of 1−2 cm, and (3) the application of slow release herbicide formulations for the reduction of root penetration into subsurface irrigation drippers.

MATERIALS AND METHODS

Materials. Wyoming sodium montmorillonite (SWy-2) (cation exchange capacity, 0.76 mmol/g; surface area, 700 m^2/g) was obtained from the Source Clays Repository of the Clay Mineral Society (Columbia, MO, USA). Octadecyltrimethylammonium bromide (ODTMA) and Triton X-100 were purchased from Sigma-Aldrich (Stenheim, Germany). Pendimethalin *N*-(1-ethylpropyl)-3,4-dimethyl-2,6-dinitrobenzenamine (technical grade 96%) and Stomp 330 (a commercial formulation containing 330 g/L pendimethalin) were from BASF Agro, Germany. Rehovot sandy soil (95.5% sand, 3.3% silt, 1.2% clay, 0.2% OM) was collected (top 20 cm) from the Faculty's experimental farm.The test plant for the bioassay was *Sorghum bicolor*.

Methods. *ODTMA Adsorption on Montmorillonite: Temperature Effect.* Throughout the study, the preparation of ODTMA micelle solutions included heating the solutions to a temperature exceeding the Krafft temperature, T_K (36 °C), and reaching a clear solution. The adsorption of ODTMA from a micelle solution (20 mL) to montmorillonite (10 mL) was studied in batch experiments (in duplicates) reaching final concentrationd of 1−10 mM and 0.56 or 1.67 g/L. The adsorption was studied at temperatures of 40 and 60 °C by agitating the tubes in a hot tub for 24 h (reaching equilibrium). Supernatants were separated by centrifugation at 15000*g* for 20 min (at 40 and 60 °C), and the precipitates were lyophilized. The percent of carbon in the precipitates was measured using a CHNSO analyzer, Carlo-Erba 1108. The concentration of ODTMA adsorbed was calculated by taking into account full cation exchange at concentrations above the cation exchange capacity of the clay.

ODTMA−clay samples were prepared (as described above) for scanning electron microscopy (SEM) analysis by adsorbing ODTMA (5 mM) to montmorillonite (0.56−5 g/L) at 27 °C and at 40 °C on 0.56 g/L montmorillonite (all concentrations are final).

The morphology of montmorillonite and the ODTMA−clay samples was studied by SEM and elemental analysis. Samples were prepared on Akulon stubs using double-sided sticky tape. The microphotographs are recorded using scanning electron microscope JEOL model JSM-5410 LV. The images were taken with an accelerating voltage of 20 kV, at low vacuum mode (28 Pa), and backscattered electron detection.

Pendimethalin Solubilization in Micelles and Adsorption to Montmorillonite. The solubilization of pendimethalin (50−900 mg/L, 0.18−3.2 mM) in ODTAM micelles (10 mM) was studied in batch experiments (final concentrations). The solutions were stirred for 24 h in covered glass tubes (to avoid photodegradation) at 40 °C. If complete solubilization of pendimethalin was not reached, its precipitation was observed. This precipitate was separated by centrifugation at 15000*g* for 20 min at 40 °C. The concentration of pendimethalin in solution was determined by using a UV−vis spectrophotometer (Evolution 300, Thermo Scientific, Waltham, MA, USA). For herbicide concentrations <50 mg/L the measurement was with a 1 cm glass cuvette at 200−800 nm with λ_{max} = 423 nm. For herbicide concentrations >50 mg/L the measurement was with a 0.2 cm glass cuvette (to avoid dilution and micelle decomposition). Pendimethalin solubilization was calculated by subtracting the solution concentration from the initial concentration. The contribution of pendimethalin in water, 0.275 mg/L, not solubilized in micelles, is negligible.

Pendimethalin (300 mg/L) adsorption on montmorillonite (3−10 g/L) via its solubilization in ODTMA micelles (10 mM) was studied at 40 °C in batch experiments in triplets. Pendimethalin solubilization was performed as described above. The herbicide−micelle solution was added to a clay suspension (final concentrations of 3−10 g/L) at 40 °C. The tubes were agitated for 24 h (equilibrium reached) in a hot tub, supernatants were separated by centrifugation at 15000*g* for 20 min, and pendimethalin concentration was measured by UV−vis spectrophotometer as described. The concentration of adsorbed pendimethalin was then calculated.

Herbicide−Micelle−Clay Formulation Preparation. Pendimethalin (300 mg/L) was solubilized in ODTMA (10 mM) as described above. To prepare the one-mode formulation the herbicide−micelle solution was added to a high clay concentration (7 g/L) at 40 °C, and to prepare the two-mode formulation the solution was added to a low clay concentration (2 g/L) at 27 °C. The tubes were agitated for 24 h (equilibrium reached) in a hot tub with the relevant temperatures, supernatants were separated by centrifugation at 15000*g* for 20 min, and the precipitates were lyophilized. For the greenhouse study a larger scale preparation included adding pendimethalin (800 mg/L 10 mLin acetone) to ODTMA (20 mM) and adsorbing the solubilized herbicide to a high clay concentration (16 g/L) at 40 °C and to a low clay concentration (4 g/L) at 27 °C for the preparation of the one- and two-mode formulations, respectively. The suspension was left to settle, and the concentrated suspension was centrifuged. Pendimethalin concentrations in the supernatants were determined by UV−vis spectrophotometer measurements, and the adsorbed pendimethalin was calculated. The percentages of active ingredient in the one- and two-mode formulations were 1.6−2.7 and 3.2−4.8%, respectively.

Pendimethalin Desorption from the Formulations. The one- and two-mode formulations were suspended in 20 mL for 24 h at 27 °C in batch experiments in triplets. Supernatants were separated by centrifugation at 15000*g* for 20 min, and pendimethalin concentration was measured by UV−vis spectrophotometer as described.

Pendimethalin Desorption and Leaching through Thin Soil Layers. The release and leaching of pendimethalin from the one- and two-mode formulations and from the commercial formulation, Stomp 330, was measured by applying the formulations on a thin sandy soil layer (160 g and approximately 1 cm) deposited on a filter paper (Whatman 1442-125) in a Buchner funnel (area of 7.85×10^{-3} m^2). No herbicide adsorption was detected on the filter paper. The formulations were applied in 30 mL of water at a rate of 1.4 mg of active ingredient (ai) per funnel, equivalent to 1.8 kg ai/ha. Water was applied as a control. A second filter paper was placed on top of the soil to ensure uniform water distribution and to minimize disruption of the

DOI: 10.1021/jf504839q
J. Agric. Food Chem. 2015, 63, 1682−1688

soil surface. The funnels were irrigated five times with 50 mm of water (40 mL per funnel) at uniform intervals between irrigations. The leachates were collected after each irrigation, and herbicide concentrations were measured by UV−vis spectrophotometer. Each treatment was performed in triplicate.

Bioactivity and Reduced Leaching of Pendimethalin in the Soil: Laboratory Essays. The release, leaching, and bioactivity of pendimethalin applied as Stomp 330 or one- and two-mode formulations were measured by applying the formulations (0.3 kg ai/ha) on sandy soil columns of 10 cm diameter and 5 cm height. Water was applied as control. Each treatment was performed in triplicates. The columns were irrigated with 60 mL of water, covered with paper to prevent photodegradation, and after 60 h, each centimeter of the top 3 cm was pushed from the bottom up and removed. The soil from each depth was transferred to Petri plates (in triplets). Ten *Sorghum* seeds were sown in each plate, and plates were covered, sealed with tape, and placed in a 27 °C dark room at a 45° angle to force roots to grow downward along the Petri dish cover. After 60 h, root length was measured for each treatment. Pendimethalin leaching and bioactivity were calculated by measuring the degree of root growth inhibition at each depth, which was calculated by comparison to untreated control.

Bioactivity and Reduced Leaching of Pendimethalin in Soil: Greenhouse Assays. The efficiency of the micelle−clay formulation and of Stomp 330 to reduce root penetration into the drippers was studied in a greenhouse setup. The study was conducted in large pots (1 m × 0.5 m and a depth of 0.35 m total volume of 175 L) filled with a soilless matrix of sand mix with compost 70/30% (Givat Adda, Israel). The subsurface irrigation drippers were buried at a depth of 15 cm, two rows per pot including 10 drippers per pot. Lettuce (*Lactuca sativa* L.) seedlings at the 13−14 BBCH growth stage were transplanted, 10 per pot, and grown by regular protocol. Each treatment was repeated five times. Three weeks from planting irrigation was reduced gradually to induce root penetration into the drippers. Five weeks after planting the two-mode formulation, Stomp 330, or water (as control) was applied at 0.06 g ai per dripper (10 g from the two-mode formulation in 100 mL of water or 2 mL of Stomp 330 in 100 mL of water). Three weeks after pendimethalin application, the drippers were removed and root penetration was evaluated. The penetration was ranked from 0 to 3 (low to high) and compared to the control.

A second greenhouse scale test (same setup) was performed to test an earlier application of the formulations. In this study tomato (*Lycopersicon esculentum* Mill.) seedlings at the 12−13 BBCH growth stage were planted and the growth period was extended to 4 months to increase the probability of root penetration into drippers. Three weeks from planting the one- and two-mode formulations were injected through the irrigation system (early application). Eight weeks after planting, irrigation was reduced gradually to induce root penetration. Ten weeks after planting, the one-mode and Stomp formulations were injected through the irrigation system (regular application).

Data Analysis. The statistical analysis was carried out using JMP 7.0.1 (SAS 2007) and $p = 0.05$. The bioactivity study at the laboratory scale was subjected to a two-way ANOVA model in a "split-plot" design, where the treatment (formulation), the depth, and root length were used as the main effects. Multiple comparisons were done using a *t* test. The bioactivity study at the greenhouse scale was subjected to the same analysis with treatment (formulation and application timing) and root penetration as main effects.

RESULTS AND DISCUSSION

Effect of Temperature on ODTMA Adsorption to Montmorillonite. The effect of temperature on ODTMA adsorption from a micelle solution (concentrations above the critical micelle concentration (CMC) and at temperatures above the T_k) to montmorillonite was explored (Figure 1). As previously reported for ODTMA adsorption from a micelle solution, adsorption was extremely high, reaching loadings of >2-fold the cation exchange capacity (CEC) of the clay, which

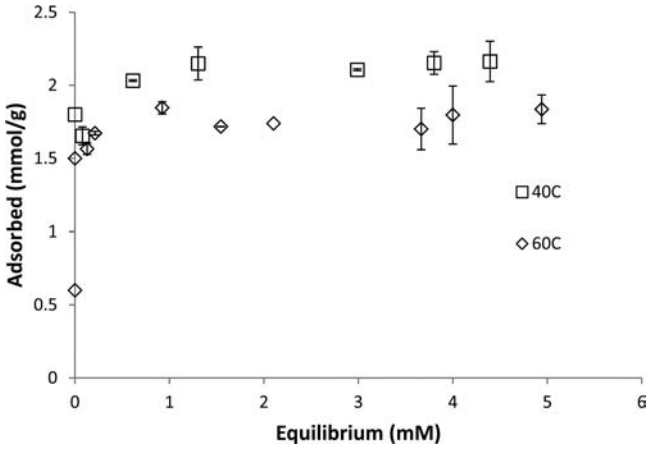

Figure 1. ODTMA (1−10 mM) adsorption on montmorillonite (0.56 and 1.67 g/L).

was explained in terms of micelle adsorption.[29] The adsorption was complete up to the CEC of the clay at both temperatures but decreased with temperature at adsorbed concentrations exceeding the CEC. These trends indicate that the adsorption reaction, exceeding the CEC, is most likely exothermic.[28] The adsorption reaction below the CEC, under the current experimental conditions, is complete and therefore cannot be determined; that is, it may be endothermic or exothermic.

Enthalpies of adsorption of organic molecules to clay minerals are generally exothermic,[28] because the molecules leaving the solution and attaching to the surface lead to a decrease in the dispersion of the energy, a decrease in the entropy.[32,35] Processes with decreasing entropy might be spontaneous only if they are exothermic (definition of Gibb's free energy). However, sorption of organic cations to montmorillonite are usually exchange processes, and the release of inorganic cations with their hydration shells may bring on an overall increase in entropy,[27] and endothermic adsorption processes have been reported in a few cases.[24,27,29] The adsorption of ODTMA monomers to the clay surface below the CEC is indeed due to cation exchange, that is, possibly an endothermic reaction. The adsorption of ODTMA from a micelle solution is driven by two forces; cation exchange (up to the CEC) and a bilayer that is formed on the surface due to hydrophobic interactions between the surfactants, which involve only confinement. The release of exchangeable cations (with their hydration shell) increases entropy, but this increase may be smaller than the loss of entropy due to both electrostatic and hydrophobic confinement, explaining the total decrease in enthalpy, that is, an exothermic reaction at adsorbed concentrations exceeding the CEC.

Little has been reported in the literature on the effect of temperature on monomer and micelle adsorption. Nevertheless, trends similar to those found in this study were reported for micelle adsorption of sodium dodecyl sulfate micelle to hydrotalcite.[36]

The effect of temperature on monomer versus micelle adsorption is expressed not only by their different reaction enthalpies but also by the adsorption mode, monomer conformation, and orientation.[37] It is well-known that a surfactant solution will spontaneously form micelles when prepared at concentrations above the CMC and above the T_k. The adsorption to montmorillonite of ODTMA at a concentration above the CMC (5 mM) and above (40 °C)

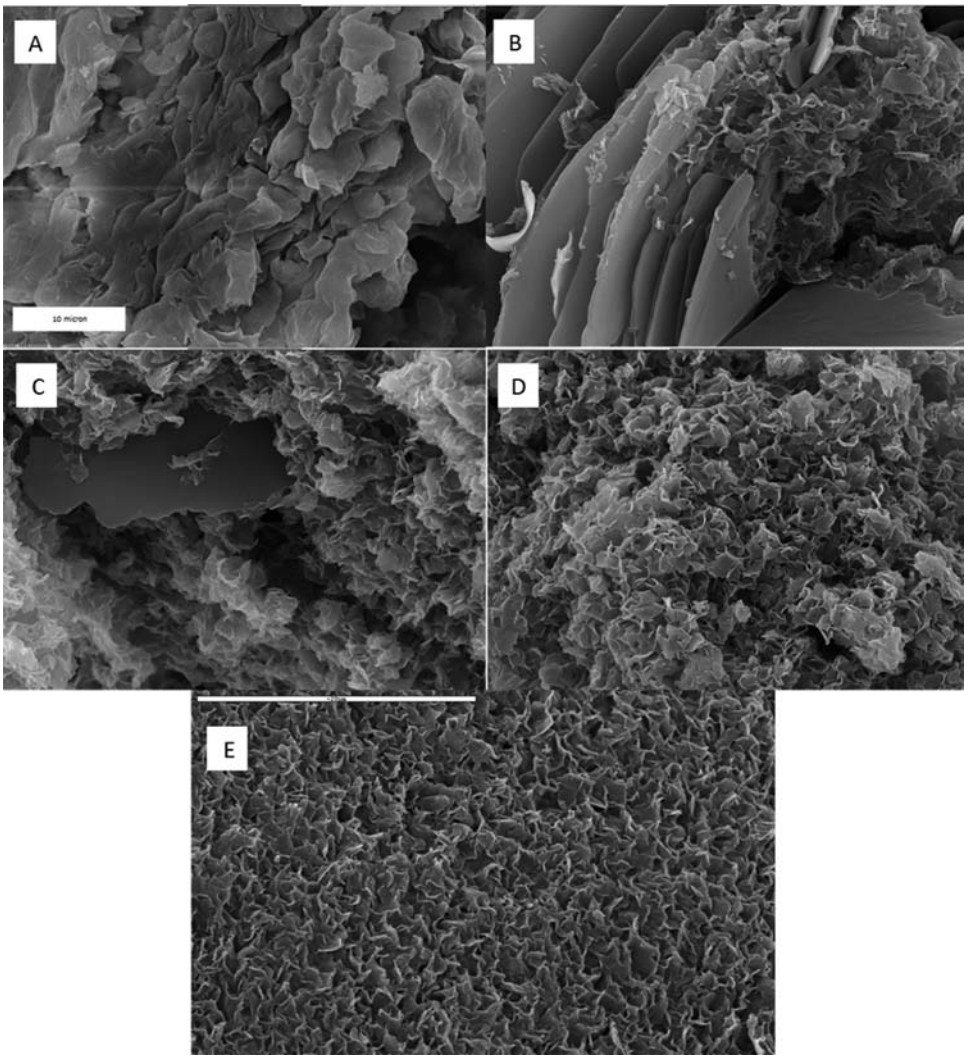

Figure 2. SEM images of (A) montmorillonite and ODTMA (5 mM) adsorption, (B) at 27 °C on 0.56 g/L montmorillonite, (C) at 27 °C on 4 g/L montmorillonite, (D) at 27 °C on 5 g/L montmorillonite, and (E) at 40 °C on 0.56 g/L montmorillonite.

or below (27 °C) the T_k was studied, and images of the precipitates were collected by SEM measurements (Figure 2).

ODTMA adsorption at 27 °C to a low clay concentration (0.56 g/L) resulted in high concentrations of ODTMA, which do not adsorb, and because the solution temperature is below T_k, the excess surfactant precipitates as an ODTMA salt with a platter morphology (Figure 2B). In contrast, ODTMA adsorption at 40 °C from a micelle solution resulted in homogeneous surfactant adsorption, and clay exfoliation was observed (Figure 2E). Because the temperature was above the T_k, the excess surfactant remained in the supernatant (was removed) and did not precipitate.

To increase ODTMA (5 mM) adsorption at temperatures below the T_k, the clay concentration was increased (0.56−5 g/L). As expected, fewer ODTMA platters were observed as the clay concentration increased, and uniform organoclay composites were observed upon the addition of ODTMA (5 mM) to high clay concentrations 5 g/L (Figure 2C,D).

Elemental analysis (eds) supports the identification of the platters as ODTMA salt precipitation with significant amounts of carbon, nitrogen, and bromine (55, 5, and 30%, respectively) The "fluffier" material was identified as organic−clay composite samples, containing carbon and nitrogen (of the surfactant) and aluminum and silica (characteristic of the clay) (55, 7, and 12%, respectively).

The identification of two modes of ODTMA in the samples, precipitate and adsorbed to clay, was further utilized to design two-mode pendimethalin formulations.

Pendimethalin Solubilization in Micelles and Adsorption to Montmorillonite. The first step to design pendimethalin−micelle−clay formulations was solubilizing pendimethalin, which has extremely low water solubility (0.275 mg/L), in a micelle solution of ODTMA (10 mM) to enhance its solubility (Figure 3). Pendimethalin solubilization in a 10 mM ODTMA solution was complete up to a concentration of 300 mg/L, and above this concentration the degree of solubilization decreased but the concentration increased, reaching 550 mg/L. Pendimethalin solubility increased by 3 orders of magnitude at a herbicide/surfactant ratio of only 0.2 mol/mol. High pendimethalin solubilization in ODTMA micelles enabled high active ingredient adsorption on the clay (via micelle adsorption).

Pendimethalin (300 mg/L) adsorption on montmorillonite (3−10 g/L) via its solubilization in ODTMA micelles (10 mM) was studied at 40 °C (Table 1). Surfactant/clay molar ratio (taking the cation exchange capacity into account) has a

5	48.2 ± 1.6	80
6	47.3 ± 0.5	95
7	42.7 ± 0.0	99
8	37.3 ± 0.0	99
10	29.9 ± 0.0	99

pronounced effect on surfactant loading and adsorption/precipitation mode. A high ratio will result in unadsorbed micelles (as obtained for a clay concentration of 3 g/L), whereas a slightly low ratio, with complete surfactant adsorption, will decrease the loading (mg/g) of pendimethalin (as obtained for clay concentration of 8–10 g/L). At a very low surfactant/clay ration, below 1, micelle decomposition and active ingredient release may occur.[19,34]

Complete pendimethalin adsorption on the clay (via micelle adsorption) and high herbicide loading were reached upon the addition of 10 mM ODTMA to 7 g/L montmorillonite. This surfactant/clay molar ratio of ~1.9 is in within the suggested optimal range.[34]

On the basis of the results of ODTMA adsorption on low and high clay concentrations and at temperatures above and below T_k (Figure 2) two types of micelle–clay formulations were designed. A one-mode formulation was prepared at 40 °C (above the T_k) by fully solubilizing the herbicide (300 mg/L) in micelles (10 mM) and at a surfactant/clay ratio in which surfactant adsorption is complete (7 g clay/L). A two-mode formulation was prepared by fully solubilizing the herbicide in micelles (like the one-mode) but at a surfactant/clay ratio at which surfactant adsorption is not complete (2 g clay/L) and the adsorption was at 27 °C. Due to the low temperature the unabsorbed pendimethalin, solubilized in micelles, precipitates. We hypothesized that the release from the one-mode formulation will be slower than from the two-mode and at a lower rate. The release from the two-mode formulation will be in two phases: a relatively fast phase, when the herbicide will release from nonadsorbed micelles, and a slower phase, when the herbicide solubilized in micelles adsorbed on clay will be released.

Pendimethalin Desorption from the Formulations. Pendimethalin desorption, in suspension, at 27 °C, after 24 h from the one-mode formulation was 0.13 ± 0.01%, whereas the release from the two-mode formulation was 10-fold higher, reaching 1.5 ± 0.3%. Higher desorption from the two-mode formulation was also observed when the desorption and leaching of pendimethalin through a thin layer of sand were studied (Figure 4). After irrigation of 5 pore volumes, 0.56 and

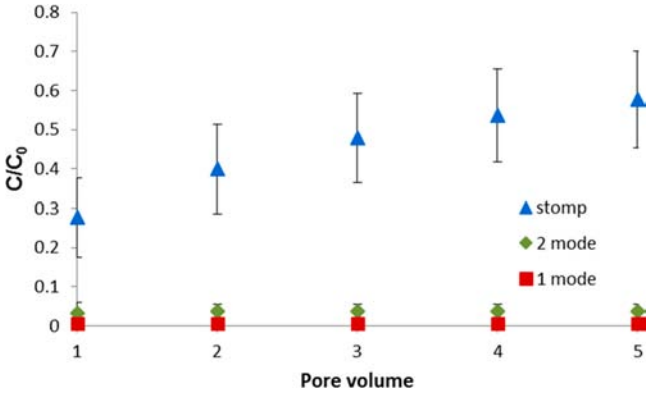

Figure 4. Pendimethalin desorption and leaching through a thin layer of sand applied as a commercial formulation or as the one- and two-mode micelle–clay formulations.

4% of the pendimethalin applied as one- and two-mode formulations leached through the soil, respectively. The leaching from the commercial formulation (Stomp) was significantly higher, reaching 57%.

Bioactivity and Reduced Leaching of Pendimethalin in the Soil: Laboratory Essays. Herbicide leaching in soil columns of several centimeters (10–100 cm) has been widely explored in bioassays. The challenge in the current study was to reach a leaching resolution of 1–2 cm. To test pendimethalin release from the formulations and leaching through 0–3 cm of soil, the formulations (and water as control) were applied to soil columns, irrigated, allowed to settle, and then sliced to depths of 0–1, 1–2, and 2–3 cm. Each soil layer was placed in a Petri dish, the test plants were sown, and root growth inhibition was measured (compared to the control) (Figure 5).

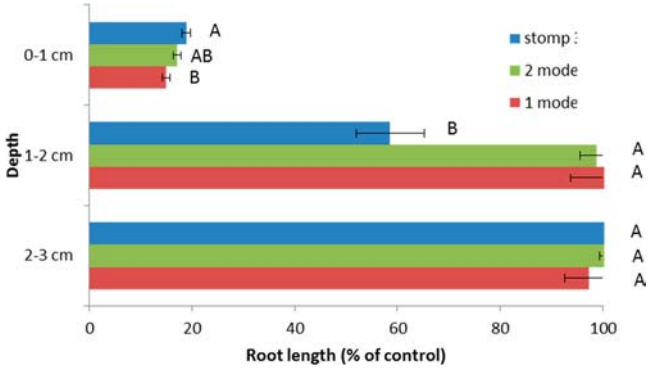

Figure 5. Effect of pendimethalin, applied as formulations one-mode, two-mode, and Stomp, on root growth of sorghum as a function of soil depth.

Pendimethalin did not leach beyond 2 cm. Its release and leaching from the commercial formulation to 1–2 cm depth was significant, resulting in nearly 60% root growth (percent of control), whereas no release and leaching from the micelle–clay formulations were observed (Figure 5). Efficient root growth inhibition was obtained for all three formulations at the top of the soil. Root growth inhibition by the one-mode formulation was significantly higher than by Stomp. This

DOI: 10.1021/jf504839q
J. Agric. Food Chem. 2015, 63, 1682–1688

leaching experiment indicates that the micelle−clay formulations demonstrate good root inhibition at the target location <1 cm from the point of application (in the case of the one-mode even better than the commercial formulation) while reducing pendimethalin leaching.

Bioactivity and Reduced Leaching of Pendimethalin: Greenhouse Assay. The efficiency of the micelle−clay formulation to reduce root penetration into the drippers was demonstrated in greenhouse studies (Figure 6). The

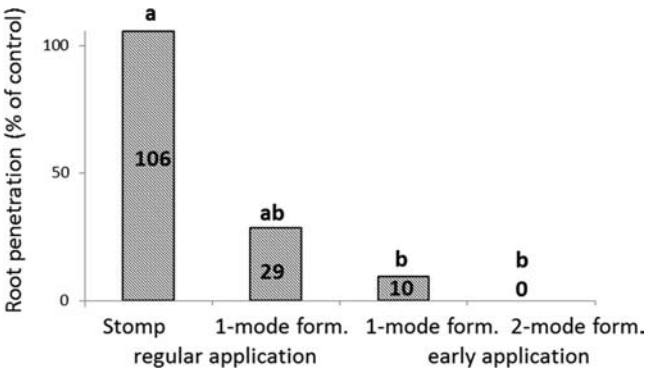

Figure 6. Root penetration (percent of control) in drippers treated with Stomp, one-mode, and two-mode formulations applied 3 weeks after tomato planting (early application) or 10 weeks after tomato planting (regular application).

commercial formulation and the two-mode formulation were applied as usually practiced, a few days (~14 days) after irrigation was gradually ceased. Lettuce root penetration (measured 8 weeks after planting) reached 50 and 37% (of control) for drippers treated with Stomp and the two-mode formulation. However, the difference was not significant.

In the second greenhouse study (Figure 7) tomatoes were planted and the growth period was extended to 4 months,

Figure 7. Image of greenhouse study.

increasing the probability of root penetration. In addition, an early application of the micelle−clay formulations (one- and two-mode formulations) was explored to test whether the activity and efficiency of the formulations indeed are for a longer period. The commercial and the one-mode formulations were applied as usually practiced. Prolonging the growth period indeed increased root penetration for the drippers treated with Stomp, reaching 100% (compared to control) penetration. In contrast, only 30% penetration was observed for the drippers treated with the one-mode formulation. An early application was extremely efficient with 10 and 0% penetration for drippers treated with the one- and two-mode formulations (between them, the difference was not significant).

To conclude, with the aim of inhibiting root penetration, slow-release pendimethalin formulations based on its solubilization in micelles adsorbed and unadsorbed to clay were developed (one- and two-mode formulations, respectively). The novelty of this investigation covers three different aspects: formulation design, bioassay design, and application. The two formulations were designed by controlling the temperature and ratio between the surfactant and clay. Although unadsorbed micelles were considered inadequate for slow release (release was too fast), we demonstrated the advantage of a two-mode release formulation. A bioassay to study pendimethalin leaching at a refined scale of 1−2 cm was developed, and reduced leaching from the micelle−clay formulations in comparison to the commercial formulation (Stomp) was exhibited. In a greenhouse study the application of the formulations by injection into the irrigation system was extremely efficient with 0−10% root penetration in comparison to 100% penetration upon Stomp injection. Reductions in root penetration and herbicide leaching upon application of the designed formulation were demonstrated.

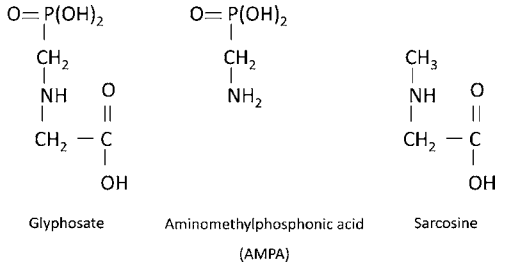

Figure 1. Chemical structure of glyphosate and its metabolites aminomethylphosphonic acid and sarcosine.

no established proof that metabolic degradation plays a role in either glyphosate tolerance or resistance in nontransgenic plants.

Enhanced metabolic degradation of herbicides is a common mechanism of resistance to many herbicide classes.[18] Because several plant species, including all *Ipomoea* species thus far studied, can metabolize glyphosate, we hypothesized that enhanced metabolism of glyphosate would be a likely response to strong selection with glyphosate (resistance) and could also explain biotype differences in susceptibility to glyphosate that are not due to selection with glyphosate (tolerance). The objectives of this research were to investigate (i) the variability in tolerance to glyphosate among *I. lacunosa* accessions, (ii) if there is any correlation between metabolism of glyphosate to AMPA or sarcosine and the level of tolerance, and (iii) the role of differential translocation as a potential mechanism of tolerance to glyphosate.

MATERIALS AND METHODS

Plant Material and General Experimental Conditions. During 2004 through 2006, seeds from *I. lacunosa* were randomly collected at multiple locations across the U.S. that had or had not been exposed to glyphosate for several years in GR crop management systems.[19] *I. lacunosa* seeds were stored at 10 °C until used. Germination of seed, transplanting of seedlings, growth of plants, and all experiments were conducted under greenhouse growing conditions (30/22 °C day/night, 12 h photoperiod under natural sunlight) unless otherwise described. Seeds were planted at 1 cm depth in 50 × 20 × 6 cm plastic trays with drain holes containing a commercial Metro-Mix 360 potting mix (Sun Gro Horticulture, Bellevue, WA). Two weeks after emergence, seedlings were transplanted into 6 × 6 × 6 cm pots containing the same soil mix. Plants were watered as needed. Plants were fertilized once by subirrigating the pots with a Miracle-Gro nutrient solution (The Scotts Company, Marysville, OH) containing 200 mg/L each of N, P_2O_5, and K_2O at 4 weeks after transplanting. All herbicide treatments were applied with an air-pressurized indoor spray chamber equipped with an 8002E flat-fan nozzle (Spraying Systems Company, Wheaton, IL) delivering 140 L/ha at 280 kPa and were made on plants of each accession at the four- to five-leaf stage (beginning to vine).

Glyphosate Dose Response in *I. lacunosa* Accessions. Fourteen *I. lacunosa* accessions were selected strictly on the basis of their response to preliminary screening, being the seven most tolerant (MS-WAS-8, MS-VJ, MS-SCO-1, MS-PAN-1, MS-YAZ-2, MS-COA-1, and MS-ITA-1) and the seven least tolerant (MS-LEE-2, MS-WAS-2, MS-MAR-1, MS-99, MS-90, MS-QUI-1, and MS-YAZ-1) accessions, among 76 initial accessions. Plants of each of the 14 accessions were treated with the Roundup WeatherMAX formulation of glyphosate (Monsanto Company, St. Louis, MO) at 0, 105, 210, 420, 840, and 1680 g of ae (acid equivalent)/ha. Shoot fresh weights were recorded at 2 weeks after treatment (WAT) only, as the separation of vines between control plants becomes problematic at later growth stages. Shoot fresh weight was expressed as a percent of nontreated plants. There were four replications per treatment, one plant per replication, in a completely randomized design, and the experiment was conducted twice.

Glyphosate Metabolism Studies in Intact Plants. The most tolerant (MT) (MS-WAS-8) and least tolerant (LT) (MS-YAZ-1) accessions were selected on the basis of the dose response assay described above and were analyzed for metabolism of glyphosate to AMPA and sarcosine as well as shikimate, the precursor of aromatic amino acids. Two experiments were conducted. In the first, five plants were treated with glyphosate at 420 g of ae/ha (0.5 × field rate) and harvested at 2 WAT, and the experiment was conducted twice. In the second, three plant replications were treated at their respective GR_{50} doses (MT, 151 g of ae/ha; LT, 58 g of ae/ha) and at 1, 3, and 6 days after treatment (DAT) plants were harvested. The GR_{50} rate for each plant accession was selected so that the two accessions would have the same level of phytotoxicity interfering with metabolism of glyphosate. There was one plant per replication in a completely randomized design, and the experiment was repeated over time. At harvesting, plants from both experiments were excised at the soil surface, washed with running water, rinsed with distilled water to remove glyphosate remaining on the leaf surface, and blotted dry with paper towels. Each sample consisted of all leaves from each single plant (replicate) and leaves were predried in a greenhouse and then oven-dried at 80 °C for 2 weeks, ground with a mortar and pestle, and analyzed for glyphosate, AMPA, shikimate, and sarcosine.

Extraction and derivation were performed for glyphosate and AMPA analysis according to previously reported procedures,[20,21] with modifications. Ground tissue (0.25 g) was extracted with 8 mL of water in a 20 mL scintillation vial, shaken, placed in a sonicating bath for 20 min, and then centrifuged at 5000*g*, 20 °C, for 20 min. The supernatant was collected, the remaining tissue sample pellet was extracted a second time by adding 4 mL of water, and procedures were performed as in the first extraction. The volume of the combined supernatant was measured and syringe-filtered (0.45 μm) into a new 20 mL plastic vial. Then, 45 μL of 12.1 N HCl was added to the supernatant and shaken. Four milliliters was transferred to a 20 mL scintillation vial with a Teflon-lined cap, shaken with 2 mL of CH_2Cl_2, and centrifuged at 300*g*, 25 °C, for 10 min. A portion (1.8 mL) of the top water layer was taken, and 200 μL of acidic modifier [(16 g of KH_2PO_4:160 mL of H_2O):13.4 mL of 12.1 N HCl] was added and vortexed. One milliliter was loaded to a cation exchange (CAX) resin column, 0.8 × 4 cm AG 50W-X8 Resin 200−400 mesh, H^+ (Bio-Rad Laboratories, Hercules, CA), previously equilibrated with two 5 mL portions of water. The sample was eluted until the column bed was reached. Seven hundred microliters of CAX mobile phase (160 mL of H_2O:40 mL of MeOH:2.7 mL of HCl) was added, eluted, and discarded. Twelve milliliters of CAX mobile phase was again added to the column to elute the analytes. The eluate was collected in a 20 mL vial and evaporated to dryness using a Savant speed vac. A 1.5 mL volume of CAX mobile phase was added to the dried sample, and then the vial was placed in a sonicating bath for 30 min. A 20 μL aliquot was syringe-filtered (0.2 μm) and added to 640 μL of a solution of 2,2,3,3,4,4,4-heptafluoro-1-butanol and trifluoroacetic anhydride (1:2, v/v) in a chilled 4 mL vial with a Teflon-lined lid in a duplicate extraction experiment. The mixture was equilibrated at room temperature for 10 min. The vial was transferred to a heating block at 90 °C for 1 h and then allowed to cool to room temperature. The solvent was evaporated under a stream of nitrogen at 50 °C, and the residue was dissolved in 80 μL of ethyl acetate containing 0.2% citral.

For the analysis of shikimate and sarcosine, a 1 g powdered sample was placed in a 20 mL scintillation vial and extracted with 15 mL of water, shaken, placed in a sonicating bath for 20 min, and then centrifuged at 5000*g*, 20 °C, for 20 min. A 4 mL aliquot of supernatant was removed to a new 20 mL vial. The tissue sample pellet was extracted a second time by adding 5 mL of water, and procedures were performed as in the first extraction. A 2 mL aliquot of supernatant was removed and combined with the previous 4 mL aliquot, totaling 6 mL of supernatant. Then, 30 μL of HCl was added to supernatant and shaken. One half of the total supernatant was transferred to a tared vial, frozen, and lyophilized. The dry product was recovered, and 5 mg of lyophilized extract was transferred to gas chromatography (GC)

J. Agric. Food Chem. 2015, 63, 1689−1697

vial, in a duplicate extraction experiment, to be treated with 50 μL of *N*,*O*-bis(trimethylsilyl)trifluoroacetamide and *N*,*N*-dimethylformamide (1:1, v/v) and vortexed. The vial was transferred to a heating block at 70 °C for 30 min, allowed to cool to room temperature, and centrifuged at 300*g*, 25 C, for 10 min. Then, 25 μL of clear liquid was transferred to a GC vial and analyzed by GC−mass spectrometry (MS).

Analysis of glyphosate and AMPA was performed by GC−MS on a 6890 GC gas chromatograph (Agilent, Santa Clara, CA) coupled to a JEOL GCMateII mass spectrometer (JEOL USA, Peabody, MA), using a 30 m length × 0.25 mm i.d., 0.25 μm film, DB-5 capillary column (Agilent Technologies, Foster City, CA). The GC temperature program: initialized at 80 °C, held for 2.5 min, raised to 160 °C at 30 C/min rate, raised to 270 °C at 40 C/min rate, raised to 300 °C at 35 °C/min rate, and kept at this temperature for 1.5 min. The carrier gas was ultrahigh purity helium at a 1 mL/min flow rate. The injection port was kept at 250 °C, and the GC−MS interface and the ionization chamber were kept at 230 °C. The volume of injection was 1 μL (splitless injection). The mass spectrum was acquired in the positive, low resolution, selected ion monitoring mode, with electron impact of 70 eV. AMPA was monitored using *m*/*z* 571, 502, 446, and 372 (t_R 5.97 min); glyphosate was monitored using *m*/*z* 611, 584, 486, and 460 (t_R 6.77 min). Glyphosate and AMPA in the samples were quantitated from a calibration curve of the respective standards: glyphosate, purity 99.5% (Chem Service, West Chester, PA), and AMPA, purity 99% (Sigma-Aldrich, Saint Louis, MO). Analysis was performed in duplicate. The LOD and LOQ for glyphosate were 19.9 and 160 pg on column (1 μL injection), respectively. The LOD and LOQ for AMPA were 4.16 and 12.61 pg on column (1 μL injection), respectively.

Analysis of sarcosine and shikimate was performed by GC-MS using the same conditions as in the analysis of glyphosate and AMPA, except the GC temperature program: initialized at 120 °C, held for 2 min and raised to 300 °C at 17 °C/min rate, and then held at this temperature for 0.5 min. Sarcosine was monitored using *m*/*z* 233, 218, 190, and 160 (t_R 5.58 min); shikimate was monitored at *m*/*z* 462, 447, 372, and 255 (t_R 8.67 min). Sarcosine and shikimic acid in the samples were quantitated from a calibration curve of the respective standards: shikimic acid, purity 99% (Sigma-Aldrich), and sarcosine (Sigma-Aldrich). Analysis was performed in duplicate. Sarcosine was not detected in any of the samples. The LOD and LOQ for shikimate were 929 and 2815 pg on column (1 μL injection), respectively.

Glyphosate Metabolism Studies in Leaf Discs. In a study to eliminate uptake and translocation effects, 4 mm diameter leaf discs were cut with a cork borer from uniform leaves of 18-day-old, greenhouse-grown-MT and LT plants. Three hundred discs were floated on 20 mL of aqueous solutions of technical grade glyphosate for 1 day in 10 cm diameter polystyrene Petri dishes. Treatments were quadruplicated. After incubation, samples were taken for analysis of shikimate, AMPA, and glyphosate content. The 300 discs from each dish were washed in a total of 1 L of Millipore filtered water and then frozen at −80 °C in 50 mL centrifuge tubes until analysis by the methods above. Relative shikimate content was also determined by the method of Shaner et al.[22]

Glyphosate Absorption and Translocation. MT and LT *I. lacunosa* plants were treated with glyphosate as described before at a rate of 840 g of ae/ha, except that the second youngest fully expanded leaf was covered with a water-resistant paper sleeve. This sleeve was removed immediately after herbicide treatment for subsequent (within 30 min of overspray) application of solutions containing ^{14}C-glyphosate, ^{14}C-methyl labeled with 2.0 GBq/mmol specific activity, 99.5% radiochemical purity in an aqueous stock solution of 7.4 MBq/mL (American Radiolabeled Chemicals, Inc., St. Louis, MO). A solution containing glyphosate at a final concentration equivalent to 0.84 kg/ha in 140 L was prepared using ^{14}C-glyphosate, a commercial formulation of glyphosate, and distilled water. A 10 μL volume of the treatment solution, containing 5 kBq of ^{14}C-glyphosate, was applied to the adaxial surface of the not oversprayed second true leaf of 15 cm tall plants in the form of 25 droplets with a microapplicator. Plants were harvested at 1, 4, 24, 48, 96, and 168 h after ^{14}C-glyphosate treatment (HAT) for absorption measurements carried out as described previously.[6]

MT and LT plants were processed for phosphorimaging prior to translocation analysis. The treated leaves from the plants were removed at respective harvest times to wash off unabsorbed radioactivity and set aside. The remaining above ground part of the plant was excised from the roots and mounted on a 27 × 21.25 cm piece of plain white paper. Shoot parts were evenly spread and kept in place with thin strips of clear office tape. Care was taken to avoid contact of the washed treated leaf with other parts of the plant. Roots were gently rinsed with water to remove soil, blotted dry with paper towels, and mounted on a separate sheet as with the shoot. The mounted plant parts were pressed between one or more layers of newspaper, and bookended with two hard cardboard sections. The assembled plant press was held together with large binder clips and stored at −20 °C for later drying. The plant samples were dried in a gravity convection oven set at 60 °C for 24 h. Phosphorimaging was used to develop an image of the plant samples. After the dried sample was cooled to room temperature, the plant was placed in a 20 × 40 cm exposure cassette (GE Healthcare Bio-Sciences Corp., Piscataway, NJ) and brought into contact with a BAS IPSR 2025 E storage phosphor screen (GE Healthcare Bio-Sciences Corp.) under diffused lighting. The apparatus was placed in a dark cabinet for 24 h. A Typhoon FLA 7000 phosphorimager (GE Healthcare) was used to detect distribution of ^{14}C-glyphosate and develop an image. Phosphorimaged plants were carefully removed from the mounting paper and divided into treated leaf, shoot above treated leaf (SATL), shoot below treated leaf (SBTL), and roots, and translocation was measured according to previously described procedures.[6] There were five replications per treatment (harvest) time per plant type (MT/LT).

Statistical Analysis. All data were analyzed by ANOVA via the PROC GLM statement using SAS software version 9.3 (SAS Institute, Cary, NC) to determine the main effects and interactions of the factors at $P < 0.05$. No significant experimental effect was observed in repeated experiments; therefore, data from experiments were pooled. Treatment means in selected experiments were separated using Fisher's Protected LSD test at $P < 0.05$.

Glyphosate dose response data were subjected to nonlinear regression analysis, and a sigmoidal log−logistic curve[23] of the form

$$y = L + \frac{U - L}{\left[1 + \left(\frac{D}{GR_{50}}\right)^{s}\right]} \quad (1)$$

where *y* represents shoot fresh weight reduction as compared to that of nontreated plants in percentage at herbicide rate *D*, *L* is the mean response at very high herbicide rate (lower limit), *U* is the mean response when the herbicide rate is zero (upper limit), *s* is the slope of the line at GR_{50}, and GR_{50} is the glyphosate rate required for 50% growth reduction of *I. lacunosa* plants, was fit to the data. The estimate of the four regression parameters was obtained using Sigma Plot version 11 (Systat Software, San Jose, CA) and tested for significance using the *t*-test method ($P < 0.05$). GR_{50} values of tolerant accessions were compared to that of the least tolerant accession according to the Student *t*-test at $P < 0.05$ with the open-source R software version 2.15.2 (R Foundation for Statistical Computing) using the drc package and drm function, and the comparisons were given by means of the selectivity index (SI) function.

In the glyphosate metabolism study, data variance was visually inspected by plotting residuals to confirm the homogeneity of variance prior to statistical analysis using SAS. The Shapiro−Wilk test was applied to verify if the data among accessions were normally distributed, and Hartley's F_{max} test was applied to verify if different populations have a similar variance using SAS. Means separation was performed using Fisher's Protected LSD test at $P < 0.05$.

RESULTS AND DISCUSSION

Glyphosate Dose Response in *I. lacunosa* Accessions. The F-test in the ANOVA was significant ($P < 0.0035$) for the pairing of dependent variable (fresh weight reduction) with

[a]The most tolerant (MT) was MS-WAS-8 and least tolerant (LT) was MS-YAZ-1. [b]SE represents the standard error of the mean where $n = 10$ (pooled data from two experiments of glyphosate at 420 g of ae/ha) and $n = 6$ (pooled data from two experiments of glyphosate at GR_{50} rate). [c]Values followed by the same letter (lowercase when MT and LT were treated with glyphosate at 420 g ae/ha, uppercase when MT and LT were treated with glyphosate at 151 and 58 g ae/ha, respectively) within each column are not significantly different at the 5% level as determined by the LSD test. [d]GR_{50} indicates the glyphosate dose required to cause a 50% reduction in plant growth, 151 g of ae/ha for the MT accession, and 58 g of ae/ha for the LT accession.

main effect terms (accessions and glyphosate dose) and interaction terms, indicating that the response to glyphosate varied among the 14 *I. lacunosa* accessions (data not shown). The accessions with less previous exposure to glyphosate in GR crops were the ones with numerically smaller GR_{50} values (MS-99 106, MS-90 91, MS-QUI-1 59, and MS-YAZ-1 58 g/ha glyphosate) (data not shown). Thus, the higher GR_{50} values of some accessions could be due to selection with glyphosate. If so, these more "tolerant" accessions may actually be categorized as resistant (genetically changed by selection with glyphosate). *I. lacunosa* went from the fifth to the second most common weed in Mississippi soybean six years after the introduction of GR soybean.[24] Therefore, it appears that the emergence of *I. lacunosa* as a major weed problem has coincided with the widespread adoption of GR crops. The tolerance/resistance of *I. lacunosa* may be a consequence of a mutation(s) arising after the introduction of the herbicide, or the resistance gene(s) may predate the widespread use of the herbicide with selection from preexisting genetic variation in the population.[11] Also, localized adaptations have probably resulted in the evolution of several variably glyphosate tolerant *I. lacunosa* ecotypes in North America, which could, in turn, be unrelated to exposure of the population to glyphosate.

Intersimple sequence repeat (ISSR) markers were used to study intraspecific population structure in *I. lacunosa*.[25] Subpopulation differentiations were detected in those accessions from proximal locations and clustered together populations with high similarity of agricultural environments, like Arkansas and Mississippi. However, intraspecific accessions almost always clustered together among various *Ipomoea* species.[26] Moreover, it is possible that the colonization of *I. lacunosa* in the southern U.S. started with only one genotype and evolved with time due to localized adaptations and hybridization with compatible species. Consequently, the morphological and genetic variance of *I. lacunosa* in the southern U.S. may impact the efficacy of weed management strategies.

The MS-YAZ-1 accession had the lowest GR_{50} value of 58 g/ha glyphosate and MS-WAS-8 accession had the highest GR_{50} value of 151 kg/ha glyphosate, resulting in a R/S (proportion of GR_{50} values of most and least tolerant accessions) ratio of 2.6. The 2.6-fold R/S ratio of glyphosate tolerance is more than that reported for other *I. lacunosa* accessions from the southern U.S., which was 1.9-fold less when their most tolerant and least tolerant populations were compared.[19] In weed species that have evolved glyphosate resistance, the resistance mechanisms thus far elucidated are target-site-based and non-target-site-based.[27,28] The following processes have been reported to provide different levels of resistance to glyphosate: reduced glyphosate absorption (~3-fold),[29,30] impaired glyphosate translocation (~3- to 13-fold),[31−34] sequestration to the vacuole (2.9−5.6-fold),[35] EPSPS mutations (~2- to 15-fold),[36,37] and overproduction of target enzyme (6−8-fold)[38] in weedy species.

Because legume species have been reported to metabolize glyphosate,[7,39] different sensitivities to glyphosate in certain populations of *I. lacunosa* may be due to differences in the levels of degradation of glyphosate to the much less phytotoxic metabolite of glyphosate, AMPA, or even sarcosine. To test this hypothesis, glyphosate, shikimate, AMPA, and sarcosine levels were measured in glyphosate-treated leaves of the MT and LT accessions.

Glyphosate Metabolism Studies. Two experiments were performed. In the first, the LT and MT accessions were each treated with 420 g/ha glyphosate (half the recommended field rate), after which shikimate, glyphosate, and AMPA levels in the entire plant shoot were determined at 14 DAT (Table 1). In the second experiment, the LT and MT bioptyes were treated with GR_{50} doses (58 and 151 g/ha, respectively), after which shikimate, glyphosate, and AMPA shoot contents were

DOI: 10.1021/jf5055722
J. Agric. Food Chem. 2015, 63, 1689−1697

measured at 1, 3, and 6 DAT (Table 1). Sarcosine was not detected in either accession in either experiment.

In the first experiment, shikimate levels were much more elevated (ca. 15-fold more) in the LT than the MT accession. There were no differences in AMPA levels between the two accessions, but glyphosate levels were more than twice as high in the LT than the MT accession. Such an experiment provides only pool sizes at one time point, without any information on flux of compounds through those pools. The higher glyphosate pool in the LT could be due to a slower rate of glyphosate metabolism in the LT than the MT accession. An alternative explanation could be the reduced metabolism of glyphosate in the LT accession caused by metabolic dysfunction, due to the fact that this accession was more severely affected by the herbicide. Also, reduced growth during the 14 DAT would mean that the glyphosate would be more concentrated in the LT accession.

The second experiment in which the two accessions should have been equally affected by the glyphosate treatment was designed to better assess whether glyphosate metabolism differs in the two accessions, as the higher rates used in the first experiment may have disrupted metabolic processes. By blocking EPSPS, glyphosate causes many-fold increases in shikimate levels in non-GR plants and, consequently, elevated shikimate levels are used as an early and highly sensitive indicator of glyphosate effects on glyphosate-sensitive plant tissue.[40,41] The nonsignificantly different levels of shikimate between the two accessions at 1, 3, and 6 DAT indicated that the GR_{50} doses for the two accessions had similar physiological effects (Table 1). The only signficant difference between the two accessions was a higher shikimate level at 1 DAT of the MT accession than at 6 DAT in the LT accession. Shikimate levels decreased from 1 to 6 DAT for both accessions, but the only statistically significant change with time for an accession was a reduction for the MT accession between 1 and 6 DAT (Table 1).

AMPA levels were the same in both accessions at all times after treatment (Table 1). Although AMPA levels trended upward from 1 to 6 DAT for both accessions, the increase was not statistically significant. However, glyphosate concentrations were higher at 1 and 6 DAT (ca. 3-fold and 5-fold, respectively) in the MT than the LT accession. Under different growth conditions, Reddy et al.[21] found that AMPA levels in treated soybean leaves were highest 1 DAT and decreased over a period of 22 days.

If there were enhanced metabolism of glyphosate in the MT accession, one would not expect the higher levels of glyphosate than LT observed above. If the uptake and translocation as a percentage of glyphosate applied were the same in the two accessions, one would expect about 2.6-fold more glyphosate in the MT than the LT accession when each is treated with their respective GR_{50} dose. This is approaching the 1 DAT result for both glyphosate and AMPA (2.75-fold and 2.13-fold more in the MT than the LT) (Table 1). The nonsignficant differences in the glyphosate to AMPA ratio between the two accessions at 1 and 3 DAT suggest similar levels of metabolism as a percent of glyphosate taken up. However, the 6 DAT glyphosate to AMPA ratio was significantly higher in the MT than the LT (ca. 3.7 fold), indicating that metabolism could be higher as a percent of glyphosate taken up in the LT accession (Table 1). Again, these data are only a snapshot in time of pool sizes that do not take into account flux through the pools due to the translocation of glyphosate and AMPA to roots and metabolic degradation of AMPA. Nevertheless, these data do not support the theory that metabolism of glyphosate explains the relative sensitivities to glyphosate in the two *I. lacunosa* accessions tested.

There has been no conclusive evidence of metabolic degradation as an important mechanism of evolved resistance to glyphosate.[8] The fact that *I. lacunosa* accessions with variable levels of tolerance accumulated the same amount of AMPA does not support the view that enhanced metabolism of glyphosate is involved in the tolerance of the MT accession. Gene mutation or amplification of plant genes for GOX-like enzyme activity or horizontal transfer of microbial genes for glyphosate-degrading enzymes could result in GR weeds.[16] This mechanism of tolerance could be combined with another mechanism such as differential absorption or translocation of glyphosate. This is supported by our results of increased glyphosate concentration from 1 to 6 DAT in the MT, suggesting that glyphosate may be slowly taken up in this accession. This hypothesis of single or multiple mechanisms of glyphosate tolerance was investigated using studies of absorption and translocation of glyphosate in the *I. lacunosa* accessions.

Metabolism in cut leaf discs was determined to avoid effects of potential differences in uptake and translocation between the two accessions. Glyphosate content was slightly higher in the MT than the LT accession at each glyphosate treatment concentration (Figure 2). AMPA levels rose with glyphosate dose for both accessions (Figure 2), but the percentage of AMPA as a fraction of glyphosate as glyphosate dose increased was 3.5, 7.2, and 8.7% for the MT accession vs 13, 9.7, and 10.4% for the LT accession. These data do not support the view that differences in glyphosate metabolism have anything to do with the differences in tolerance to glyphosate between these two accessions. Shikimate levels after 24 h of incubation in 0.1, 0.33, or 1 mM glyphosate were the same or slightly higher in the LT accession at the three concentrations (Figure 2). The differences in shikimate levels between MT and LT plants were not as great as in whole plants (Table 1). These results provide further support for the view that metabolism is not involved in the difference between the LT and MT accessions.

^{14}C-Glyphosate Absorption and Translocation. The absorption pattern of ^{14}C-glyphosate in the MT and LT accessions of *I. lacunosa* was similar throughout the time course of 168 HAT (Figure 3A). Glyphosate absorption amounts reported here (21−25%, 42−43%, and 45−46% of applied at 24, 48, and 96 HAT, respectively) are similar to previously reported estimates (23% and 43% of applied at 24 and 96 HAT, respectively),[6] but lower than levels (57−63%, 52−58%, and 53−59% of applied at 26, 50, and 74 HAT, respectively) reported for three different formulations of glyphosate in *I. lacunosa*.[42] In *I. cordatotriloba* Dennstedt (sharppod morningglory), glyphosate absorption was much higher (75% of absorbed at 72 HAT)[43] than for MT and LT accessions of *I. lacunosa* reported here.

The amount of ^{14}C-glyphosate that translocated out of the treated leaves of the MT and LT plants was similar up to 4 HAT (Figure 3B). Thereafter, the LT accession translocated more (41 and 53% of absorbed at 24 and 48 HAT, respectively) ^{14}C-glyphosate than the MT accession (26 and 38% of absorbed at 24 and 48 HAT, respectively) out of the treated leaf, with translocated amounts leveling off to similar levels in both populations by 96 HAT (49 and 51% of absorbed in LT and MT, respectively) and 168 HAT (48 and 49% of absorbed

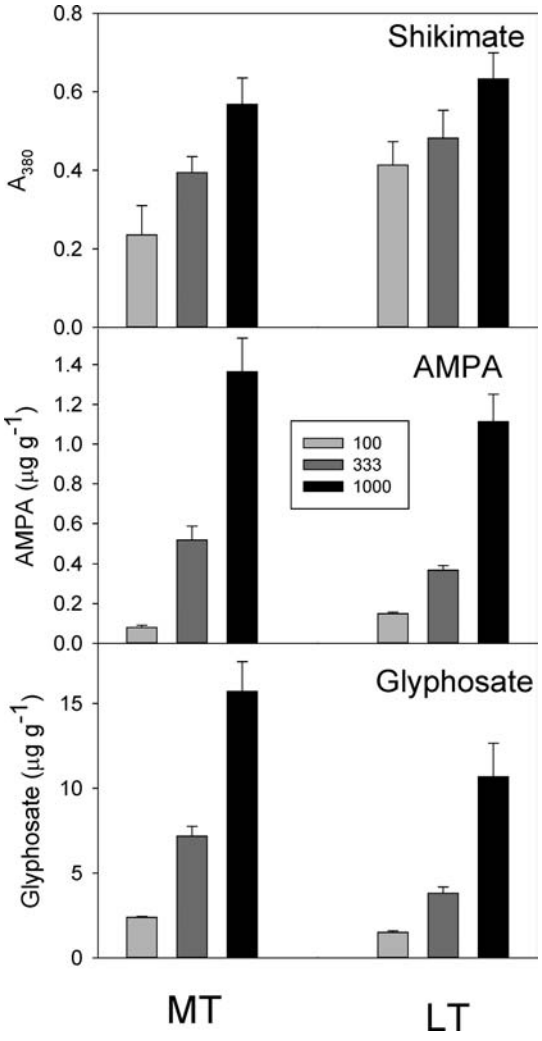

Figure 2. Shikimate, glyphosate, and AMPA levels in leaf discs of MT and LT *I. lacunosa* floating on 0.100, 0.333, and 1.000 mM glyphosate for 24 h.

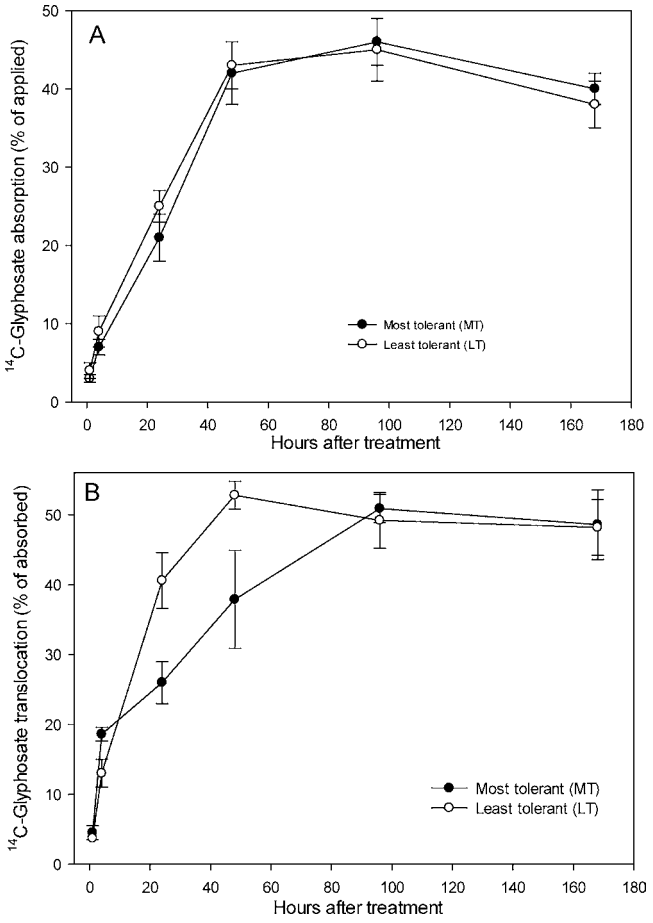

Figure 3. Absorption (A) and translocation (B) of ^{14}C-glyphosate in most (MT, closed circles) and least (LT, open circles) tolerant *Ipomoea lacunosa* accessions. Vertical bars represent standard error of mean (n = 5).

in LT and MT, respectively). The translocation levels of ^{14}C-glyphosate out of the treated leaf reported here (26–41%, 38–53%, and 49–51% of absorbed at 24, 48, and 96 HAT, respectively) are greater than those reported previously in *I. lacunosa* (5 and 23% of absorbed at 24 and 96 HAT, respectively)[6] and *I. cordatotriloba* (13% of absorbed at 72 HAT),[43] with the same formulation of the potassium salt of glyphosate used in all cases.

Distribution of absorbed ^{14}C-glyphosate in the MT and LT accessions is summarized in Table 2. The quantity of ^{14}C-glyphosate that remained in the treated leaf was higher in the LT (87% of absorbed) than in the MT plants (81% of absorbed) at 4 HAT. Thereafter, the MT accession retained more glyphosate in the treated leaf (74 and 62% of absorbed at 24 and 48 HAT, respectively) than the LT accession (59 and 47% of absorbed at 24 and 48 HAT, respectively). A similar trend was reflected in the SATL where the level of glyphosate in the MT plants was higher (15% vs 5% of absorbed at 4 HAT) and lower (14% vs 20% and 19% vs 25% of absorbed at 24 and 48 HAT, respectively) than the LT plants. The MT accession retained more ^{14}C-glyphosate in SBTL (12% of absorbed) than the LT accession (8% of absorbed) at 48 HAT. However, the LT accession roots contained more glyphosate (20% of absorbed) than those of the MT accession (7% of absorbed) at 48 HAT. Distribution of ^{14}C-glyphosate in the treated leaf and other parts of the plant was generally lower and higher, respectively, across the LT and MT accessions compared to previous reports in *I. lacunosa*[6] and *I. cordatotriloba*[43] within 24–96 HAT, which is an extension of translocation observations.

Phosphorimaging was used to generate autoradiographs of MT and LT plants treated with ^{14}C-glyphosate to visualize ^{14}C-glyphosate translocation patterns. ^{14}C-glyphosate movement was discernible in the SATL of the LT accession (Figure 4) at 24 HAT, but not the MT accession (Figure 5). The intensity of the autoradiograph of SATL was greater in the LT accession (Figure 4) at 48 HAT compared to that of the MT accession (Figure 5), reflecting the translocation and distribution data at 48 HAT. A closer examination of the colored plant specimen of the LT accession at 168 HAT indicated extensive chlorosis compared to the case of the MT population (data not shown) at the same harvest time. Inhibition of the apical meristems in the LT population may have caused a feedback inhibition of glyphosate loading, thereby resulting in numerically reduced glyphosate levels in SATL of LT plants (22 and 23% of absorbed at 96 and 168 HAT, respectively) compared to the level of the MT plants (30 and 34% of absorbed at 96 and 168 HAT, respectively). The progressive increase in intensity of the root in LT (data not shown) could be partly due to a switch to

[a]Abbreviations: LT, least tolerant; MT, most tolerant; ns, not significant; SATL, shoot above treated leaf; SBTL, shoot below treated leaf; TL, treated leaf. [b]Distribution represents partitioning of absorbed ^{14}C-glyphosate between the treated leaf, shoot above treated leaf, shoot below treated leaf, and root. [c]Number indicates significance at the 5% level of probability and ns indicates no significant difference between means within the same column and within the same plant part.

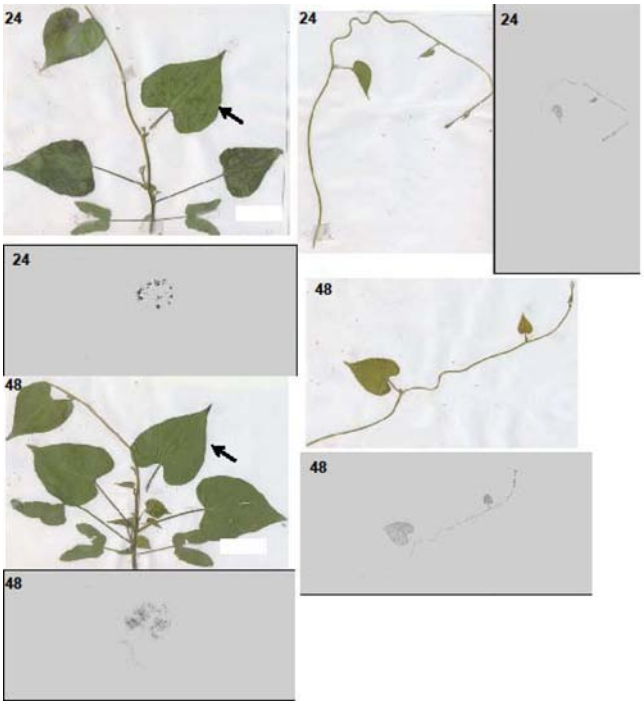

Figure 4. Above ground plant parts and corresponding phosphor-images of least tolerant (LT) *Ipomoea lacunosa* accession. Arrow indicates TL. A part of the SATL appears above the TL. Numbers indicate hours after treatment (HAT) with ^{14}C-glyphosate.

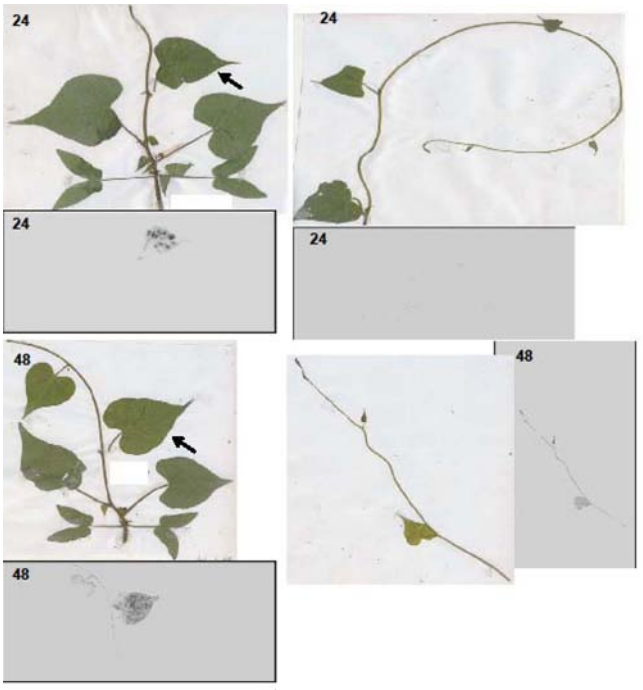

Figure 5. Above ground plant parts and corresponding phosphor-images of most tolerant (MT) *Ipomoea lacunosa* accession. Arrow indicates treated leaf. A part of the SATL appears above the TL. Numbers indicate hours after treatment (HAT) with ^{14}C-glyphosate.

basipetal translocation brought about by inhibition of aerial sinks by glyphosate.

In summary, glyphosate dose response studies were conducted on selected *I. lacunosa* accessions suspected to be tolerant to glyphosate. Results indicated variable tolerance with the most tolerant (MT) and least tolerant (LT) accessions exhibiting GR_{50} values of 151 and 58 g of ae/ha of glyphosate, with a resistance index of 2.6. Contrary to our hypothesis, metabolism of glyphosate to AMPA did not explain the tolerance mechanism. The absence of enhanced metabolic degradation of glyphosate as a resistance or tolerance mechanism of any case of resistance or tolerance thus far studied remains unresolved. ^{14}C-glyphosate absorption patterns were similar in the MT and LT accessions, but the LT accession translocated more glyphosate at 24 and 48 HAT than the MT accession. Differential glyphosate translocation may explain, at least in part, tolerance in the MT accession.

new groups of water protons according to their relaxation characteristics. In this work, the effect of freezing and thawing on water relaxation was followed as a means to probe the extent of nano-/microstructural changes resulting from seed germination. An interest was to assess the ability of relaxometry to distinguish the different phases of seeds' germination, particularly the onset of embryonic axis elongation.

In the present study, the model legume *Medicago truncatula* was chosen as an example because several of its germination characteristics are known.[32−34] Radicle protrusion is achieved within ∼20 h. It mobilizes proteins and reserves carbohydrates and involves cell wall loosening.[34] The endosperm cells of *M. truncatula* seeds contain cell wall galactomannan that is metabolized at the end of germination during radicle growth. Due to its hydrophilic nature, galactomannan likely participates in the water balance of the seed during imbibition.[35,36] In this work, NMR relaxometry was evaluated as a means to detect minor developmental perturbations during seed germination. Among the many small chemicals affecting plant biological processes, the growth modulators fusicoccin and oryzalin were added to the imbibition medium to test if relaxometry could differentiate seed germination alterations due to perturbed cell expansion or cell division and elongation.[37−40]

MATERIALS AND METHODS

Plant Material. Seeds of *M. truncatula* cv. Jemalong A17, harvested in 2009 were obtained from INRA UMR 1334 AGAP (Amélioration Génétique et Adaptation des Plantes méditerranéennes et tropicales).

For all conditions, seeds were germinated at 25 °C in darkness in 9 cm diameter Petri dishes on Whatman paper soaked with 4 mL of imbibition solution at pH 5.8. The latter was composed of 0.5 g L^{-1} of a salt solution (1 mM $CaCl_2$ (2 H_2O), 1 mM $MgSO_4$ (7 H_2O), 2 mM KH_2PO_4, 1 mM NH_4NO_3, 4 mM KNO_3, 100 μM $MnSO_4$ (H_2O), 30 μM $ZnSO_4$ (7 H_2O), 0.1 μM $CuSO_4$ (5 H_2O), 1 μM $NaMo_4$ (2 H_2O), 100 μM H_3BO_3, 5 μM KI, 0.1 μM $CoCl_2$ (6 H_2O), 25 μM Na_2Fe−EDTA). This salt solution was used alone (MS) or was complemented with 10 μM oryzalin (OR; Sigma-Aldrich) or 2 μM fusicoccin (FU; Sigma-Aldrich).

Different imbibition times were studied: 0, 1, 2.5, 5, 15, 21, 24, 38, and 48 h.

NMR Measurements. Seeds were packed in 10 mm diameter NMR tubes to reach 1 cm height. For measurement at 20 °C on the fresh seeds, the NMR tubes were immediately placed in the spectrometer and left 10 min for temperature stabilization. For measurement at −20 °C, NMR tubes were immersed in liquid nitrogen for 10 min, transferred to the spectrometer at −20 °C and allowed to equilibrate for 10 min. The frozen seeds were allowed to thaw in the NMR tubes at room temperature for about 4 h prior to measurement at 20 °C. For each condition (time of imbibition, temperature, and growth modulators), NMR measurements were made on five biological replicates. NMR analyses were done using a Minispec mq20 (Bruker) at 0.47 T (20 MHz proton resonance frequency) equipped with a thermostated (±0.1 °C) ^{1}H probe.

The longitudinal (T_1) relaxation times were determined using an inversion−recovery sequence. Recycle delay varied from 0.5 to 5 s, depending on temperature of measurement and imbibition time. Sixteen data points were acquired by incrementing (geometric series) the 180°−90° pulse spacing. Scans acquisition varied from 8 to 64 according to an experiment time of ∼15 min.

The transverse (T_2) relaxation times were determined using a Carr−Purcell−Meiboom−Gill (CPMG) sequence. Only even echoes were collected from 600 to 16000. The 180° pulse separation was 0.08 ms, and the acquisition was from 128 to 512 scans according to an acquisition time of about 15 min.

NMR Data Analysis. Relaxation curves obtained from T_1 and T_2 measurements were subjected to multiexponential nonlinear least-squares fitting (which minimizes the sum of quadratic deviations between fitted and experimental values) of signal amplitude $A_1(t)$ and $A_2(t)$ according to eqs 1 and 2, respectively,

$$A_1(t) = \sum_n P_{1n}(1 - C\exp(-t/T_{1n})) \quad (1)$$

$$A_2(t) = \sum_n P_{2n}\exp(-t/T_{2n}) \quad (2)$$

where P_{in} (i = 1 or 2) is the normalized amplitude/proportion ($\Sigma_n P_{in} = 1$) of the nth component, C is a constant that depends on the 180° pulse efficiency (ideally, $C = 2$), and T_{in} is the T_i value associated with the nth component. A standard F test was used to discriminate between models with different numbers (n) of exponentials.

Free Sugar Extraction. For each imbibition time, the five seed samples studied by NMR were pooled and then divided in three lots to have analytical repetitions. The three lots of seeds at each set of imbibition conditions were frozen and lyophilized. Each dried sample was ground to a fine powder (CryoMill, Retsch). Soluble sugars were extracted from 5 mg powders in 1 mL of deionized water at room temperature overnight with agitation. After filtration through 0.33 μm pore membranes (Millipore), the contents of α-galactosides, sucrose, fructose, and glucose in the filtrate were analyzed by HPAEC.

High-Performance Anionic Exchange Chromatography (HPAEC). Raffinose, stachyose, sucrose, fructose, and glucose were separated by anionic exchange chromatography using a ICS-3000 system (Dionex, Voisin Le Bretonneux, France) controlled by the Chromeleon software. The column used was a Carbopac PA1 analytical column (2 × 250 mm). The column was placed in an oven at 30 °C during the analysis. All mobile phases were sparged and pressurized with helium to prevent adsorption of atmospheric carbon dioxide and subsequent production of carbonate. The flow rate was set at 0.250 mL min^{-1}. The mobile phase consisted of a binary gradient of solvents A (water) and B (sodium hydroxide, 500 mM). Detection of eluted sugars was performed by amperometry using a pulsed electrochemical detector. Eluent B was constant (16%) during the 30 min of the whole process. Five external standards containing a mixture of glucose, fructose, sucrose, raffinose and stachyose in similar concentrations ranging from 0.1 to 50 μg mL^{-1} were used to calibrate the linear response of the detector.

Radicle Length Measurement. To follow the radicle growth, images were taken using a camera at the different imbibition times, inserting a ruler for length calibration, and processed with ImageJ software. The average length of 25 radicles was carried out for each imbibition time.

Statistical Analyses. Statistical analyses were performed using *R*.[41] Exploratory statistics consisted of principal component analysis (PCA). Significant differences between imbibition conditions were evaluated by a Student test from NMR and were set at a probability value of below 5%.

RESULTS

Water Uptake, Radicle Development and Unfreezable Water Evolution in MS Seeds. Water uptake during imbibition showed different events (Figure 1). A very fast uptake was observed up to about 2.5−5 h imbibition with significantly lower water contents for oryzalin-treated seeds. Water uptake of MS-imbibed seeds was constant from 5 h imbibition until the end of the observation after 48 h, with a rate of ∼0.6% h^{-1}. In the presence of fusicoccin and oryzalin, deviations in the water uptake rate were observed, although they were significant for the oryzalin-treated seeds only at 5 (p = 0.011), 21 (p = 0.046), and 48 h (p = 0.002) imbibition. At these times, the oryzalin-treated seeds contained less water than MS-imbibed seeds. After 48 h imbibition, fusicoccin-treated seeds also contained significantly less water than MS-imbibed seeds (p = 0.001). Irrespective of the medium of germination, the water content represented ∼69% (w/w) after 15 h of imbibition. Then a significant increase from 69% to 77% was observed for fusicoccin-treated seeds between

J. Agric. Food Chem. 2015, 63, 1698−1710

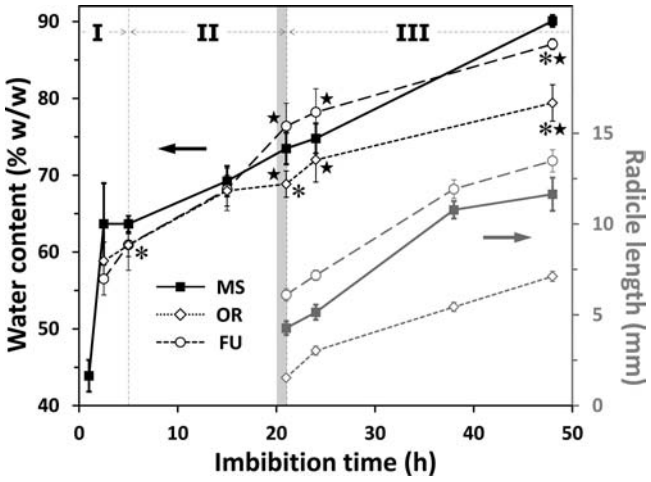

Figure 1. Water uptake and length of radicle after germination of seeds during imbibition in Murashig and Skog (MS) medium and supplemented by oryzalin (OR) or fusicoccin (FU). Bar: standard deviation, $n = 5$; symbols * and ★ indicate significant difference (t-test; $p < 0.05$) between OR and FU media with MS medium and between the two growth modulators, respectively. The shaded area corresponds to the radicle emergence period. At each time of imbibition, radicle length of oryzalin- and fusicoccin-treated seeds differed significantly from MS and between them (t-test, $p < 0.05$, $n = 8–25$). Vertical dashed lines mark the three imbibition phases (I, II, and III) as defined in the text.

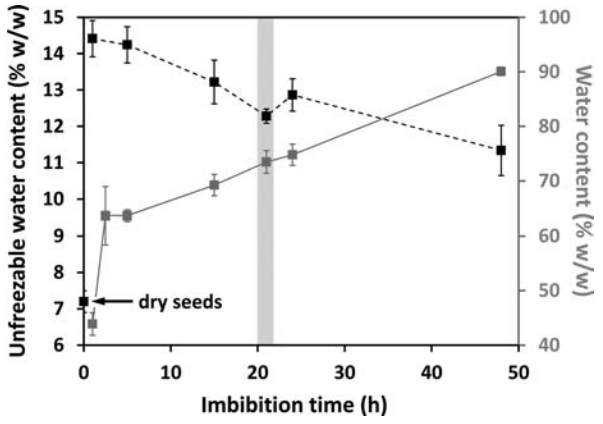

Figure 2. Unfreezable water content (black squares) and water content (gray squares) evolutions during MS seed imbibition. Bar: standard deviation, $n = 3$. The shaded area corresponds to the radicle emergence period.

15 and 21 h, but no major change was observed for oryzalin-treated seeds. This delay in water uptake was partially made up after 24 h of imbibition to reach a value of 76%, comparable to the 78.5% obtained at the same imbibition time for fusicoccin.

As previously reported, germination occurred after ∼20 h of imbibition.[34] Radicle length after emergence was significantly ($p < 0.01$) shorter for all seeds treated with oryzalin and longer under fusicoccin treatment (Figure 1). The rate of radicle development under MS medium was similar to that under fusicoccin medium, with a reduction of the growth rate after 38 h of imbibition, whereas under oryzalin medium, this growth rate was higher until 24 h, reduced during the 24–38 h period, and then similar until 48 h compared with the two other media.

The unfreezable water content was determined from the residual NMR signal obtained at −20 °C after freezing, compared with the fresh one and normalized to the total weight of the seeds. Between 1 and 48 h of imbibition, the unfreezable water content of MS-imbibed seeds decreased from about 14.5% to 11% w/w (Figure 2). A small increase (from 12.3% to 12.9% w/w) of this unfreezable water content was observed after the radicle emergence.

Water Dynamics in MS Seeds. *M. truncatula* seed germination phases were followed by NMR relaxometry. Longitudinal (T_1) and transverse (T_2) relaxation times were registered at 20, −20, and 20 °C after thawing. It was assumed that over the 4 h thawing period, enzymatic activities affected the composition and microstructure of seeds similarly for all imbibition conditions. Differences observed in the relaxation results from thawed seeds were attributed to the imbibition conditions. The results obtained at 20 °C on fresh, frozen, and freeze–thawed MS seeds are shown in Figure 3. The different relaxation time components and their normalized proportions resulting from the multiexponential fitting of T_1 and T_2 relaxation curves (with eq 1 and eq 2, respectively) are defined as follows: the three groups of letters a, b, c, d; i, j, k, l; and α, β, γ, used for T_2 and the three other groups x, y, z; q, r, s; and λ, μ, ν used for T_1 referred to the relaxation time components of fresh, freeze–thawed, and frozen seeds, respectively. In each group, the relaxation time values are sorted in alphabetical order in increasing order of value. The results are thereafter set out in terms of imbibition phases subdivided in noteworthy periods.

Dry seeds. Water in fresh dry seeds at 20 °C (about 9% w/w) gave two components for T_1 ($T_{1x,y}$) and three for T_2 ($T_{2a,b,c}$; Figure 3A,B, respectively). The latter corresponds to three pools of water molecules with different mobilities and environments. T_1 being more sensitive to molecular diffusion and chemical exchange than T_2 can be represented by a lower number of T_1 components than T_2.[42] As a consequence, the merged T_1 values partly lose specific physical/chemical environment information attached to the different proton populations. In the present case, it can explain the two components' behavior of T_1 instead of the three obtained for T_2. In the frozen state, two components for T_1($T_{1\mu,\nu}$) and three for T_2 ($T_{2\alpha,\beta,\gamma}$) were also observed (Figure 3E,F, respectively). The proportions' similarity to those obtained at 20 °C reflected that the three water pools in dry seeds were very little affected by freezing; however, compared with fresh dry seeds, the long $T_{1\nu}$ component was reduced by a factor of ∼2 while the short one remained unchanged ($T_{1\nu} \approx T_{1x}$). The two longest T_2 components, $T_{2\beta}$ and $T_{2\gamma}$, were reduced by a factor 10 compared with $T_{2b,k}$ and $T_{2c,l}$ and the shortest one, $T_{2\alpha}$, by a factor of 3 compared with $T_{2a,i}$ (Figure 3). The unfreezable water, tightly associated, was determined from the residual NMR signal after freezing to represent ∼80% of the water content of fresh dry seeds; that is, ∼7% w/w (see Figure 2). Compared with fresh seeds, no significant changes in the relaxation times values and proportions were observed for thawed seeds (Figure 3C,D), suggesting that the tissue structures of the seeds were essentially intact after the freezing process as a result of a negligible ice nucleation at this low water content.

Phase I: 0–2.5 h Imbibition Period. The first hour of imbibition induced marked changes in relaxation distribution. For fresh seeds, an additional water component appeared with long T_1 and T_2 values of about 950 and 850 ms for T_{1z} and T_{2d}, respectively, with similar proportions of about 43% (Figure 3A,B). A marked increase in time and proportion was observed for the short T_1 relaxation time (T_{1x}) until 2.5 h imbibition; T_2 values were less affected, except the significant increase and decrease in the proportions P_{2a} and P_{2d} of the shortest and longest T_2 components, respectively. The freeze–thawing process induced

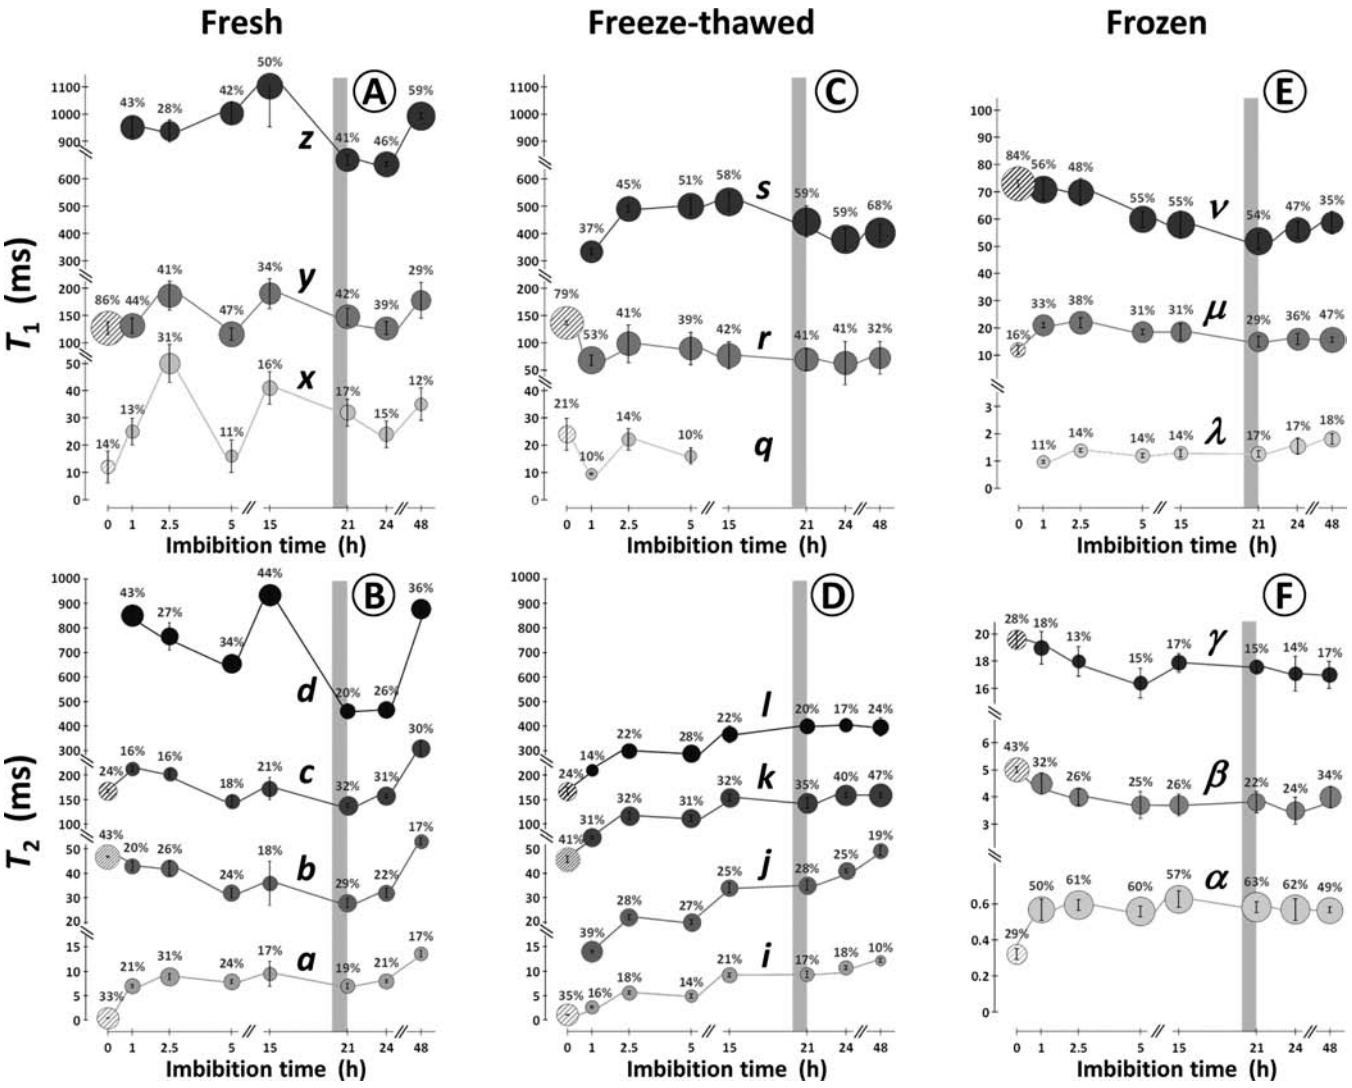

Figure 3. T_1 (A, C, E) and T_2 (B, D, F) components of germinating *M. truncatula* seeds on Murashig and Skog (MS) medium registered at 20 °C on fresh (A, B) and freeze−thawed (C, D) seeds and at −20 °C on frozen seeds (E, F) for different imbibition times. Circles of different gray densities denote different T_1 and T_2 components, indicated by different groups of letters: from the shortest to the longest relation time, T_1 components are identified by letters *x, y, z*; *q, r, s*; and *λ, μ, ν* for fresh, freeze−thawed and frozen seeds, respectively. In the same way, T_2 components are identified by letters *a, b, c, d*; *i, j, k, l*; and *α, β, γ*. The circle area and percentage refer to the proportion (P_1 or P_2) of the component to the overall T_1 or T_2 signal. The standard error on these proportions does not exceed an absolute value of 3% ($n = 5$). A bar represents standard error of time ($n = 5$). The striated circles are associated with fresh dry seeds, and the shaded area corresponds to the radicle emergence period. For each relaxation time component, the line is a guide to the eye.

an overall decrease in relaxation times by a factor of ∼2 (Figure 3C,D) by comparison with those of the fresh sample (Figure 3A,B), and an overall increase in relaxation times was observed until 2.5 h imbibition. At the frozen state, a short T_1 component of 1 ms ($T_{1\lambda}$), with a proportion of 11%, appeared (Figure 3E), and the shortest T_2 component ($T_{2\alpha}$) increased in value and markedly in proportion (Figure 3F).

Phase I: 2.5−5 h Imbibition Period. For the fresh seeds, all T_2 values decreased significantly as well as the two shortest T_1 components. Concerning the proportions P_1 and P_2 (circle area and percentage in Figure 3) of the T_1 and T_2 components, respectively, the major events were the increase in P_{1z} and P_{2d}, and the concomitant decrease in P_{1x} and P_{2a}. The freeze−thawed seeds showed no significant changes. In the frozen state, the only marked change consisted in the decrease in the longest $T_{1\nu}$ component.

Phase II: 5−15 h Imbibition Period. During this period, all relaxation time values of fresh seeds (Figure 3A,B) increased, as well as the contribution of more mobile water fractions (P_{1z} and P_{2d}). The T_2 values of freeze−thawed seeds also increased, but without marked changes in proportions, and the shortest T_{1q} component disappeared (Figure 3D). No noticeable changes were detected in the frozen state.

Phase II: 15−21 h Imbibition Period. The most significant changes concerned the fresh seeds (Figure 3A,B). With emergence of the radicle, the longest components T_{1z} and T_{2d} decreased markedly while the others decreased slightly. A marked redistribution of component proportions was also observed, with a decrease in the longest (P_{1z} and P_{2d}) and an increase in the intermediate (P_{1y}, P_{2c} and P_{2b}) ones.

Phase III: 21−48 h Imbibition. Whatever the temperature conditions, all relaxation time components remained relatively stable in values and proportions from the radicle emergence to 24 h of imbibition. For fresh seeds, a global increase in the water mobility was observed between 24 and 48 h, with a significant increase in the proportions P_{1z} and P_{2d} of the longest T_1 and T_2

[a]Standard deviations are indicated in parentheses. [b]In bold and bold underlined, significantly ($p < 0.05$) higher and lower values than MS ones, respectively. Φ denotes the three phases of imbibition (see Figure 1). The values associated with the radicle emergence at the end of phase II (21 h of imbibition) appear on a grey background.

components at the expense of others (Figure 3A,B). The latter was also observed for the freeze−thawed seeds, but without significant changes in relaxation time values (Figure 3C,D). At −20 °C, changes in relaxation time values were minor after 48 h of imbibition. The only significant differences lie in the component proportions with a marked decrease in $P_{1\nu}$ and $P_{2\alpha}$ and an increase in $P_{1\mu}$ and $P_{2\beta}$ (Figure 3E,F).

Growth Modulator Effects on Water Dynamics. Oryzalin and fusicoccin were used to modify cell division and development and consequently change tissue microstructure. These were expected to lead to different water relaxation behaviors in the freeze−thawed germinating seeds. Significant differences ($p < 0.05$) observed for relaxometry data between treated seeds compared with MS-imbibed seeds are specified in Tables 1 and 2 for frozen and freeze−thawed seeds, respectively.

Comparison with MS Medium in Frozen Seeds. Compared with MS-imbibed seeds, oryzalin-treated seeds showed the first main significant changes at radicle emergence (Table 1). The three T_1 relaxation time components were longer, with their first and third proportions ($P_{1\lambda}$ and $P_{1\nu}$) lower and the intermediate one ($P_{1\mu}$) higher. A very similar event was observed with fusicoccin treatment but at an earlier imbibition time (5 h), and it lasted up to 15 h. After radicle emergence (phase III), oryzalin-treated seeds differed from MS-imbibed seeds essentially by a shorter $T_{1\mu}$ and $T_{1\nu}$; higher $P_{1\nu}$ and lower $P_{1\lambda}$ and $P_{1\mu}$; shorter $T_{2\alpha}$ and $T_{2\gamma}$; and proportions $P_{2\beta}$ and $P_{2\gamma}$ that were higher and lower, respectively. For fusicoccin-treated seeds, differences were less marked. As for the oryzalin-treated seeds, $T_{1\mu}$ and $T_{1\nu}$ were shorter at 48 h of imbibition (as well as $T_{1\nu}$). In contrast, proportions $P_{2\alpha}$ and $P_{2\beta}$ at 24 h of imbibition were lower and higher, respectively. As illustrated in Figure 4, the $P_{2\alpha}$ and $P_{2\beta}$ proportions proved to be very closely correlated with the radicle length (removing the shortest value of radicle length associated with oryzalin-treated seeds at 21 h of imbibition), irrespective of the germination medium used (MS, oryzalin, or fusicoccin).

Comparison with MS Medium in Freeze−Thawed Seeds. Oryzalin treatment essentially affected the transverse relaxation parameters after radicle protrusion (Table 2). From 21 to 48 h of imbibition, the T_{2i} and T_{2j} components became shorter than those of MS seeds, with an increase in their proportions at 48 h, at the expense of P_{2k} and P_{2l}, which decreased.

Thawed fusicoccin-treated seeds showed significantly longer T_{1q} and T_{1r} during phase I of imbibition, with an increase in the proportion P_{1q} and at 21 and 24 h with longer T_{1r} values. Concerning transverse relaxation parameters, except for the longer T_{2k} at 48 h, fusicoccin treatment affected only the proportions P_2, with a decrease in P_{2l} and an increase in P_{2j} and P_{2k} at the early imbibition time of 2.5 h and, during the third phase, a decrease in P_{2i} at 24 h and then, as observed for oryzalin-treated seeds, higher P_{2j} and lower P_{2l} proportions at 48 h.

Furthermore, pooling the T_2 relaxation results obtained during phase III of imbibition for the three germination media, the three components $T_{2i,j,k}$ and their proportions $P_{2i,j,k}$ showed relatively good correlation, with radicle length as displayed in Figure 5A,B, respectively.

Direct Comparison between Oryzalin and Fusicoccin Media. The comparison between relaxation parameters obtained with oryzalin and fusicoccin treatments is reported in Figure 6 for frozen (Figure 6A,B) and freeze−thawed seeds (Figure 6C,D). No significant differences were noticed at 2.5 and 15 h of imbibition, whatever the relaxation parameter or the temperature considered. At the end of phase I (5 h), the two treatments differed only by their longitudinal relaxation parameters. Thawed fusicoccin-treated seeds revealed systematically significant higher T_1 values than those of oryzalin-treated seeds. At the frozen state, fusicoccin-treated seeds differ only by a longer $T_{1\nu}$ value and lower $P_{1\nu}$ and higher $P_{1\mu}$ proportions. Following the radicle

[a]Standard deviations are indicated in parentheses. [b]In bold and bold underlined, significantly ($p < 0.05$) higher and lower values than MS ones, respectively. Φ denotes the three phases of imbibition (see Figure 1). The values associated with the radicle emergence at the end of phase II (21 h of imbibition) appear on a grey background.

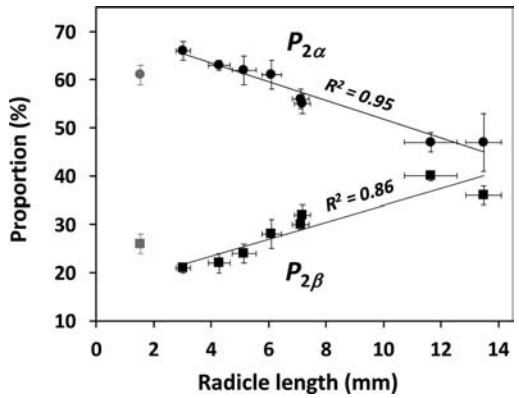

Figure 4. Evolution of T_2 relaxation proportions $P_{2\alpha}$ (circle symbol) and $P_{2\beta}$ (square symbol) determined at the frozen state (−20 °C) during the phase III of germination (refer to Table 1) as a function of radicle length of *M. truncatula* seeds for all germination media (MS, oryzalin and fusicoccin). The straight lines result from linear regression of data (excluding the shortest value of radicle length, identified by gray symbols), with the correlation coefficient R^2 mentioned for each regression.

emergence and thereafter, differentiation between the two growth modulators was clearly displayed in the freeze−thawed samples. The fusicoccin-treated seeds had systematically higher T_2 values from 21 to 48 h and higher T_{1l} values compared with oryzalin-treated seeds. In this third phase, the only significant differences in proportions were observed at 24 and 48 h for P_{2i} and P_{2k} with lower and higher values, respectively, for fusicoccin-treated seeds. Along phase III, the frozen seeds treated with fusicoccin also differed significantly from seeds treated with oryzalin by lower $P_{2\alpha}$ and greater $P_{2\beta}$ proportions at 24 and 48 h, shorter $T_{1\nu}$ and $T_{1\mu}$ at 21 and 48 h, and greater $P_{1\mu}$ and lower $P_{1\nu}$ at 24 h.

Free Sugars and Galactooligosaccharides. Along with water uptake, the composition in free sugars (glucose, fructose, sucrose) and oligosaccharides (α-galactoside: raffinose, stachyose) participating in water fluxes during cell development was determined in the germinating seed (Figure 7).

Evolution of Free Carbohydrate Contents in Seeds Germinating on MS Medium. Glucose was the major free sugar, and its content increased early on until 5 h of imbibition, then plateaued up to 21 h and rose again until 38 h of imbibition (Figure 7A). Fructose, which was a minor sugar at the beginning of germination, increased a little in content until 5 h, steeply from 15 to 24 h, and continued to increase until 48 h of imbibition, albeit at a slower rate (Figure 7B). Sucrose showed an evolution of content close to that of glucose until radicle protrusion, but with proportions divided by a factor of about 2 (Figure 7C). Between 24 and 38 h, sucrose concentration increased ∼3-fold and markedly decreased between 38 and 48 h imbibition, reaching a value close to zero.

As expected, stachyose was the major α-galactoside in *M. truncatula* seed.[43] Its content decreased particularly after 15 h of imbibition to reach a constant, low content after 24 h of imbibition (Figure 7E). The very low raffinose content displayed behavior very similar to that of the stachyose content until radicle protrusion, but a steep decrease was observed at 48 h of imbibition (Figure 7F).

Total free sugars (Figure 7D) increased slightly until 15 h of imbibition and then about three times as fast before stabilizing after 38 h of imbibition.

Effect of Oryzalin and Fusicoccin Treatments on Free Sugars and α-Galactosides Concentrations. The fate of free sugar and oligosaccharides in germinating oryzaline- and fusicocin-treated seeds was significantly different from that of seeds germinating on MS medium. Compared with MS-imbibed seeds and fusicoccin-treated seeds, oryzalin-treated seeds exhibited systematically a deficiency of free sugars after 2.5 h of

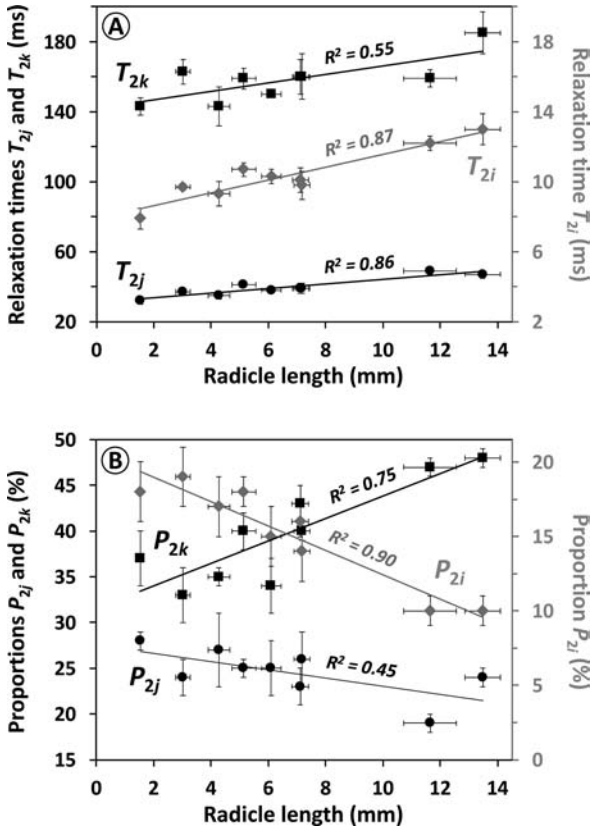

Figure 5. Evolution of (A) relaxation time components T_{2i}, T_{2j}, and T_{2k} and (B) their associated proportions P_{2i}, P_{2j}, and P_{2k} determined for freeze−thawed *M. truncatula* seeds (refer to Table 2) as a function of radicle length for all germination media (MS, oryzalin, and fusicoccin). The components *i*, *j*, and *k* are identified by the symbols ◆, ●, and ■, respectively. The straight lines result from linear regression of data, with the correlation coefficient R^2 mentioned for each regression.

imbibition. Subsequently, free sugars in oryzalin-treated seeds displayed an evolution similar to that observed in MS-imbibed seeds but with lower concentrations, except for a higher sucrose content at 48 h of imbibition. Regarding the fusicoccin effect, all free sugar contents were significantly higher than those of the oryzalin effect at 2.5 h of imbibition. Thereafter, the first marked significant differences in sugar contents appeared at 21 h of imbibition, with higher glucose and fructose concentrations compared with MS and oryzalin treatment. After 21 h, this highest glucose content steeply decreased to reach significantly lower values after 38 and 48 h of imbibition. At this last time, unlike what was observed at 2.5 h, the oryzalin treatment induced higher free sugar contents than the fusicoccin one, except for fructose.

Concerning the α-galactosides, the stachyose content was significantly lower after 15 h and higher after 24 h of imbibition in the presence of the two growth modulators compared with MS medium. After 48 h, the stachyose and raffinose contents were significantly higher with oryzalin treatment than with fusicoccin treatment.

■ DISCUSSION

The present study showed that NMR relaxometry allowed changes in seed chemistry and microstructure during the different phases of germination to be revealed. Variations in both T_1 and T_2 relaxation times and proportions displayed different dynamics of water diffusion and exchanges among *M. truncatula* seed tissues components (cell membranes, cell wall polysaccharide assemblies, vacuole, inclusion bodies, organelles, intercellular spaces, solutes, etc.) all along germination. These changes were observed within the three phases of germination and were likely associated with specific water diffusion events observed in other seeds by MRI.[4−8,21] They were also probably related to microstructural changes associated with the recovery of the metabolic processes of protein and α-galactosides as well as with endosperm cell wall galactomannan swelling and degradation after radicle protrusion. Evolutions of T_1 and T_2 relaxation times and proportions resulted from the combination of (i) higher water mobility associated with water uptake and macromolecular disassembly (cell wall, reserve protein bodies), (ii) lower water mobility due to interactions with the generated mobile solutes and newly synthesized macromolecules, and (iii) water exchange between the different cellular components and tissue compartments. Lowering temperature reduces the water self-diffusion coefficient and slows the exchange of water molecules among the various compartments. This changes the water relaxation time distribution into the slow exchange regime so that some compartments are potentially more easily resolved. The existence of multiple unfrozen water fractions at freezing temperatures can be attributed to mainly three effects: (i) the freezing point depression due to small solutes; (ii) the freezing point depression due to macromolecules, membranes, and other hydrophilic ultrastructure; and (iii) the effects of viscosity.[44,45] For example, changes in the distribution of water proton transverse relaxation times were used to monitor the subcellular compartmentation of water during freezing of apple, carrot, and tomato tissues.[46−48] This is possible because ice, which has short proton relaxation times of a few microseconds, is not detected on the millisecond time scales of the NMR pulse sequences classically used for the T_1 and T_2 measurements. However, it should be noted that information on some water compartments or environments will be partly lost as a result of the ice's forming.

The complexity of the overlapping events occurring during imbibition with the different seed tissue components makes it difficult to identify distinctive water relaxometric features as probes of cellular events, such as cell elongation or division in the whole seed. It also should be noted that the compartmental analysis is complicated because no direct relationship can be simply established between the relaxation time components T_{1n} and T_{2n}. Nevertheless, some specific periods of seed imbibition displayed particular water relaxation characteristics within the 0−48 h seed imbibition period, which can be associated with some noteworthy physiological and morphological events, as discussed in the two following sections.

Seed Imbibition Kinetics, Free Carbohydrates Evolution, and Water Dynamics in Seeds Germinating on MS Medium. The first specific period of imbibition is within the first half of phase I of germination. Between 0 and 2.5 h, changes in relaxation times and proportions were observed for both T_1 and T_2 components. The significant amount of water absorbed after 1 h of imbibition resulted in a 44% w/w water content (initially 9% w/w), while the proportion of unfreezable water was two times larger than in dry seeds (Figure 2) as a result of the hydration of matrixes, such as the cell walls and reserve biopolymers. The new markedly longest T_{1z} and T_{2d} components observed for fresh seeds (Figure 3A,B) reflect this rapid seed rehydration. These components correspond to new water species, with the highest mobility likely distributed in the first hydrated seed tissue during the early imbibition stage, such as the seed coat and endosperm. The freeze−thawing process induced a

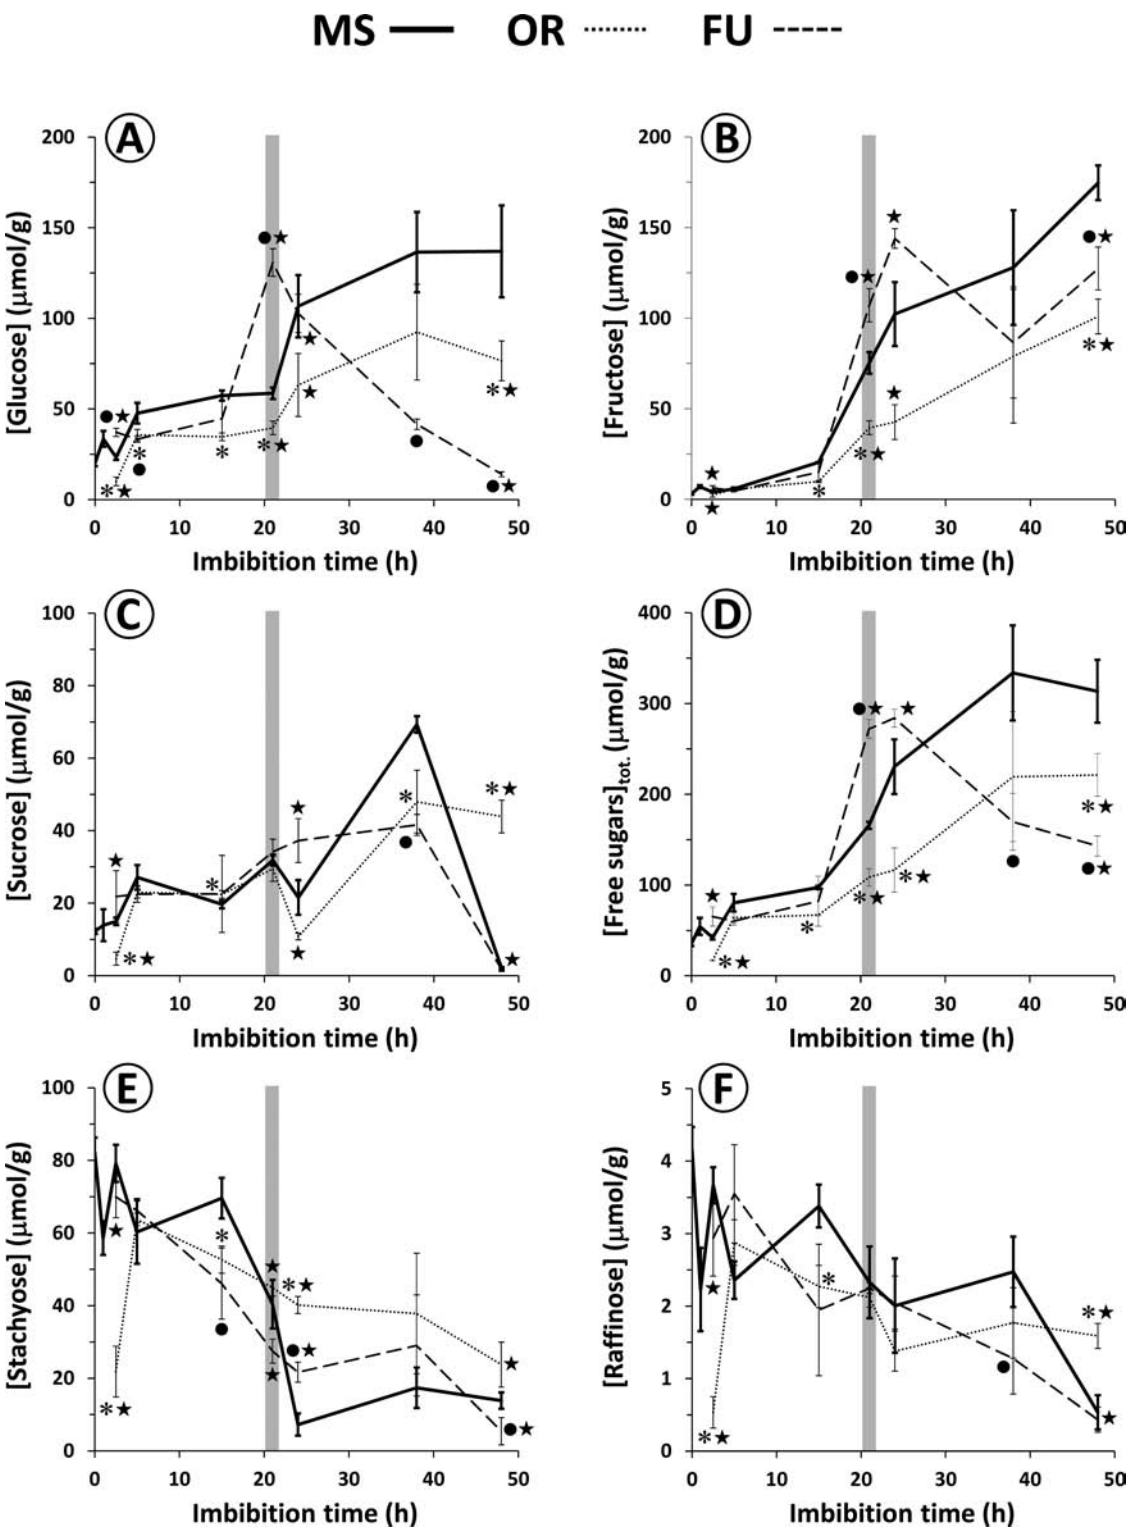

Figure 7. Free sugars (glucose (A), fructose (B), and sucrose (C)), total free sugars (D) and oligosaccharides (stachyose, E; and raffinose, F) concentration (in μmol/g) evolution of the germinating *M. truncatula* seeds on MS medium (solid line) and supplemented by oryzalin (OR, dotted line) or fusicoccin (FU, dashed line). Bar: standard deviation on three repetitions from a pool of five biological repetitions. Significant difference ($p < 0.05$) between OR and FU media with MS medium are indicated by symbols * and ●, respectively. The symbol ★ indicates significant difference between OR and FU media. The shaded area corresponds to the radicle emergence period.

drastic change in these two new components, shortening the T_{1z} component from 950 to 350 ms for T_{1s}, and leading to a new T_{2j} component of ~14 ms, instead of 850 ms for the new T_{2a}, but with a similar proportion for P_{2j} (39%) compared with P_{2a} (43%).

These results reflect an early "structural reorganization" due to solute and macromolecular rehydration. The freezing process causes ice crystal formation with a partial breakdown of cellular structures. The subsequent thawing modifies the concentration of solutes as a result of the redistribution of vacuolar, cytoplasmic,

DOI: 10.1021/jf505515n
J. Agric. Food Chem. 2015, 63, 1698−1710

and apoplastic fluids that probably led to local increases in viscosity, resulting in the short T_{2j} and T_{1s} values. The marked increases in the proportion $P_{2\alpha}$ from 29% to 50% of the shortest $T_{2\alpha}$ component in the frozen state (Figure 3F) can be attributed more specifically to the rehydration of macromolecules, such as reserve proteins and cell wall biopolymers. Compared with 1 h of imbibition, this last phenomenon was still observed after 2.5 h of imbibition but less marked. The water content reached approximately 64% w/w while the unfreezable water content (about 14% w/w; Figure 2) and the concentration of free sugars (Figure 7) remain unchanged. In addition, the marked decrease in P_{1z} from 43% to 28% (the latter being the lowest P_{1z} value observed during the 48 h imbibition period studied), the marked decrease in P_{2d} with a concomitant decrease in P_{2l} for the freeze−thawed seeds, and the marked increases in P_{1x} (from 13% to 31%) and P_{2a} (from 21% to 31%) observed for fresh seeds (Figure 3A,B) revealed a new mobilization and relatively large redistribution of water in seed tissues at 2.5 h of imbibition. This is likely related to the gradual resumption of energy metabolism.[1] This is corroborated by the significant increase in glucose and sucrose concentrations at the end of phase I (Figure 7) and an overall decrease in water mobility at 5 h of imbibition, irrespective of the thermal treatment of seeds (Figure 3).

The second noteworthy period of imbibition was during phase II within the 5−15 h time period. The overall increase in water mobility observed for fresh and freeze−thawed seeds (see, for example, the very marked increase in T_{2d} and P_{2d} values in fresh seeds; Figure 3B) following the moderate water uptake of about 5% w/w and a relative stability of carbohydrate concentrations, may be associated with the embryonic axis development and the concomitant clustering of cortical parenchyma cells in spindle-shaped form all along the embryo axes.[34] This was also accompanied by a higher water diffusivity inside or between the various seed tissues/compartments, as demonstrated by the significant increase in the three T_1 component values in fresh seeds (Figure 3A) and the permanent loss of the shortest T_{1q} component of lowest proportion ($P_{1q} \approx 10\%$ at 5 h imbibition) in freeze−thawed seeds (Figure 3C).

During the third period, between 15 h and the end of phase II (21 h imbibition), which corresponds to the emergence of the radicle (Figure 1), fructose and sucrose concentrations increased while that of the α-galactosides decreased (Figure 7). A similar peak in fructose and glucose was reported in the same germination phase of *Medicago sativa*, along with that of amino acids, such as proline, known to be part of the osmoregulators.[49,50] For fresh seeds, this third time period was characterized by a drastic decrease in the longest relaxation times, T_{1z} and T_{2d}, as well as their proportions P_{1z} and P_{2d}, with a concomitant increase in the proportions of P_{1y}, P_{2c}, and P_{2b} of the intermediate relaxation time components T_{1y}, T_{2c}, and T_{2b} (Figure 3A,B). These changes occurred while modifications of the cell wall polysaccharide chemistry related to cellulose-rich primary wall synthesis were observed along with an increase in embryonic axis size in the seed.[34] These changes were also likely related to water interactions with reallocated carbohydrates to cell wall polysaccharide and to increase osmolyte concentrations in vacuoles. The latter is particularly important for driving water into the cell for turgor pressure maintenance and build-up as cells in the embryonic axis elongate. Also remarkable was the very high similarity in the four T_{2n}−P_{2n} values between fresh and freeze−thawed seeds ($a \equiv i$; $b \equiv j$; $c \equiv k$; $d \equiv l$) at 21 h of imbibition (Figure 3B,D, respectively). Indeed, there is no controversy that the freezing−thawing process causes extensive damages in the cell structure, such as cell wall breakdown, damages which also depend on the cooling velocity.[51] Even if moderated by the cryoprotectant effect of some solutes, such as sugars and amino acids, freeze−thawing induces a morphological destructuring of tissue, leading to a redistribution of water to some extent. Despite this, the present results display that the $T_{2n} - P_{2n}$ values remained unchanged after the freezing−thawing process compared with fresh seeds, which means that each T_2−P_2 pair is more likely associated with a specific "class" of water interaction/environment, regardless of any link with tissue compartmentation. Thus, the concept very widely and usually used for the interpretation of the multicomponent behavior of NMR transverse relaxation in biological tissue that relates each T_2 component to a particular water compartment, such as vacuole (longest T_2 component), cytoplasm, or extracellular space (intermediate T_2 components) or cell wall (shortest T_2 component), proves to be most probably inappropriate or at least too simplistic.

To our knowledge, our results are the first experimental results that clearly demonstrate that no simple direct relationship exists between T_2 components and morphological compartments in biological tissue. The drastic decrease between 15 and 21 h of imbibition of the more mobile water proportion P_{2d} in fresh seeds from 44% to 20% (Figure 3B), water component usually associated with vacuolar water, supports this view. Indeed, a 2-fold decrease in the water content in vacuoles is unrealistic. In fact, the 24% reduction in P_{2d} proved to be mainly balanced by the 11% increase in both P_{2b} and P_{2c}, which means that these two components would also be partly present in the vacuole, reflecting, for example, the increase in sugar concentrations in vacuoles, as mentioned above. It should also be noted that the two T_1 components observed for the freeze−thawed seeds, instead of three for the fresh ones, show evidence of the destructuring effect of freezing, which promotes water exchange and diffusion phenomena and, contrary to T_2, allows discriminating between the two different temperature treatments of seeds and, thus, proved to be a valuable and complementary parameter for water dynamics characterization.

The last time period was during phase III, which consists of radicle elongation. Between 21 and 24 h, a slight increase in the unfreezable water content was observed for the first time from the beginning of seed imbibition (Figure 2). This could partly reflect a cell wall biosynthesis enhancement due to the activation of cell division in embryo axis, as revealed by the overexpression of the mitotic gene Cyclin B-1,2 and a peak activity of gene encoding cellulose synthase responsible for the synthesis of cell wall constituents at about 24 h after seed imbibition.[34] The significant increase in glucose and fructose concentrations (Figure 7A,B) could also contribute to this phenomenon. After 48 h of imbibition, fresh seeds displayed a marked increase in overall T_1 and T_2 relaxation time components and in proportions P_{1z} and P_{2d} of the longest ones (Figure 3A and 3B). Furthermore, during the 21−48 h imbibition period, the evolution of each of the three T_{2b}, T_{2c}, and T_{2d} relaxation times revealed an excellent linear positive correlation ($R^2 \approx 1$) with the radicle length (not shown). Along with the water uptake of ∼16%, this correlation could reflect the increase in the cell mean size from about 6 to 200 μm in the cortical parenchyma of the elongating radicle and, thereby, the development of large vacuoles during the protrusion-elongation phase, III.[34] In the frozen state, the significant decrease in the shortest T_2 proportion ($P_{2\alpha}$) from 62% to 49% and the concomitant increase in the intermediate one ($P_{2\beta}$) observed at 48 h (Figure 3F) likely reflected the cell wall loosening, as evidenced, at the same imbibition time, by the

DOI: 10.1021/jf505515n
J. Agric. Food Chem. 2015, 63, 1698−1710

highest expression of cell wall reshuffling enzymes and proteins, such as α-expansins involved in the cell wall expansion.[34] This wall loosening mechanism would promote turgor-driven polymer slippage by disrupting noncovalent binding between wall polymers (e.g., hydrogen bonding of matrix polysaccharides to cellulose microfibrils).[52] The water fraction involved in the hydrogen bonding of this complex would also be affected by this mechanism, as suggested by the marked change of $P_{2\alpha}$ and $P_{2\beta}$ water proportions. The decrease in the two shortest T_2 proportions (P_{2i} and P_{2j}) concomitantly to the increase in the two longest ones (P_{2k} and P_{2l}) observed at 48 h for freeze−thawed seeds (Figure 3D), as well as the increase in the longest T_1 proportion P_{1s} (Figure 3C), could also be related to this cell architecture weakening more specifically localized in the radicle.

Growth Modulator Effects on Free Sugars Evolution and Water Dynamics. Changes in the water status resulting from typical drugs affecting plant development, such as oryzalin and fusicoccin, were assessed by relaxometry on frozen and freeze−thawed seeds. Oryzalin, by blocking microtubule polymerization, inhibits cell division and alters cell elongation as a result of impaired cellulose deposition.[40,53] It was expected to alter water dynamics with respect to the MS-imbibed seeds because of a blockage of cell elongation prior to radicle protrusion and cell division in the developing hypocotyl. Fusicoccin, by promoting seed germination and increasing cell enlargement, was expected to modify the embryonic axis elongation stage and growth of the emerged radicle.[38,39]

The effect of the two drugs on the exact time of radicle protrusion was not determined in this study because we knew that it was likely to be slightly advanced with fusicoccin and very little affected by oryzalin compared with MS medium.[34,39] However, radicle elongation was observed in both drug treatments as well as for the MS medium from 21 h of imbibition. Fusicoccin accelerated the early elongation rate on the emergence of the radicle, leading to a significant increase in the radicle length. The opposite situation was observed with oryzalin, leading to a markedly shorter radicle (Figure 1). Despite minor variations in the rate of radicle elongation among the three germination media, the mechanisms involved in this elongation would not be very different. The two drugs modified α-galactosides and free sugar concentrations during seed germination and radicle growth (Figure 7). In the MS medium, α-galactosides were consumed early during seed imbibition and were partly transformed into free fructose and glucose. Of interest was a marked increase in the fructose content at radicle emergence, whereas the glucose content increase occurred after radicle emergence (Figure 7A,B). Fructose and glucose may contribute to turgor regulation, but the different kinetics in concentration changes of these two sugars may reflect different rates of use as a source of energy or as starting building blocks of cell wall polysaccharides. This is particularly emphasized with the fusicoccin-treated seeds, in which axis growth was faster. Glucose content peaked first after 21 h imbibition with radicle protrusion; maximum fructose content was observed after 24 h. Then glucose content particularly declined with active elongation of the radicle. In comparison with the MS medium, oryzalin-treated seeds displayed a parallel shift in the evolution of the total sugar content (Figure 7D), with significantly lower values along the imbibition, testifying for a perturbed seed metabolism. The latter may be delayed, as observed by the significantly higher sucrose content observed after 48 h of germination compared with MS and fusicoccin (Figure 7C).

Regarding T_1 and T_2 relaxation time components, fusicoccin and oryzalin affected water dynamics in both frozen and freeze−thawed samples (see Tables 1 and 2, respectively). The main significant differences between the two drugs occurred at 5 h and during the germinating phase III (Figure 6). At 5 h of imbibition, the overall longest T_1 relaxation times observed for fusicoccin-treated seeds compared with MS and oryzalin ones, could be related to the stimulation of osmotic efficiencies and transcellular water flux by the drug, thus promoting water exchange and diffusion phenomena.[38] Oryzalin affected the water dynamics, but at a later stage. The earliest significant differences were after 21 h of imbibition, indicating a possible influence of the drug on tubulin polymerization required for radicle cell elongation and, later on, for cell division for hypocotyl growth.

The cytoskeleton plays an important role in mitosis and in guiding cellulose deposition in expanding cells; both phenomena could contribute to reducing the radicle length after germination.[53] During the phase of radicle elongation (21−48 h imbibition period), the water dynamics associated with each of the two growth modulator media were quite well differentiated (Figure 6). In addition, relationships between relaxometric parameters and radicle length could be identified, regardless of the germination media. In the frozen state, proportions $P_{2\beta}$ and $P_{2\gamma}$ correlated well with radicle length (Figure 4). Regarding the cell wall loosening mechanism occurring during the radicle elongation, this supports the previous assumption of a significant contribution of water fractions closely associated with cell wall biopolymers to the cell elongation process. For freeze−thawed seeds, fairly good correlations between transverse relaxation parameters ($T_{2i,j,k}$; $P_{2i,j,k}$) and radicle length were also demonstrated (Figure 5). The increase in the three T_2 relaxation time values and the relative increase in P_{2k} likely reflected the weakening of the radicle cell wall and the increase in cell size during the period of radicle elongation. This set of linear relationships, determined without germination medium consideration, points out that growth modulators (oryzalin and fusicoccin) would not significantly affect the molecular composition after radicle protrusion.

In conclusion, comparing NMR relaxometric characteristics of water in fresh, frozen, and freeze−thawed germinating *M. truncatula* seeds allowed us to distinguish developmental phases and to detect further specific events occurring within them related to organ and tissue microstructural developments. It also allowed detection of the effects of growth modulators (oryzalin and fusicoccin) on cell development. The sensitivity of low-field NMR relaxometry in detecting physiological events makes this technique promising for characterizing seed quality and the impact of abiotic and biotic stresses on germination. With regard to the interpretation of the multicomponent relaxation, the similarity of T_2 relaxation results obtained during the radicle emergence period between fresh and freeze−thawed seeds clearly demonstrated the necessity for a reinterpretation of the classical analysis linking relaxations to cell structures in biological systems. It is proposed that the different T_2 components be preferentially assigned to specific "classes" of water interaction/environment rather than to individual tissue compartments, such as vacuole, extra-cellular space, or cell wall.

bioinformatics analyses, assay optimization, characterization, and in-house validation were conducted by the MBG Unit of the IHCP with the samples provided by IRRI. The characterization and validation of the two assays were performed in accordance with the European Network of GMO Laboratories (ENGL) minimum performance requirements (MPR) for analytical methods of GMO testing,[14] the requirements of the Codex Alimentarius for methods for detection, identification and quantification of specific DNA sequences,[25] and taking into account International Union of Pure and Applied Chemistry (IUPAC) harmonized guidelines for single-laboratory validation of methods of analysis.[26]

MATERIALS AND METHODS

Bioinformatics Analyses. Bioinformatics analyses were conducted on the JRC Central Core DNA Sequence Information System (CCSIS)[27] using PLD gene sequence (GenBank accession number NM_001064552.1) and sequence data for event Golden Rice 2-R (GR2-R) provided by IRRI for the two PLD-GR taxon-specific assays (Set1 and Set2) and the GR2 event-specific assays (LB-01 and RB-BS), respectively. Similarity searches were performed with BLASTN 2.2.15:[28] both primer sequences and the corresponding amplicon were used as query to scan the CCSIS DNA set, the plant sequence data section of the EMBL database, the NCBI nucleotide sequence and the rice TIGR databases, the vector sequences from synthetic (syn) division of GenBank, the NCBI patent nucleotide sequence, and the NCBI UniVec databases (web addresses available in the Supporting Information).

Genomic DNA and Plant Materials. Frozen leaves of non-GM rice (*Oryza sativa* ssp. Japonica, cv. Kaybonnet) and GM rice (homozygous for GR2-R, GR2-E, GR2-G, GR2-L, GR2-T, or GR2-W GR2 transformation events, cv. Kaybonnet), and genomic DNA extracted from 131 non-GM rice varieties (complete list available in Table S1, Supporting Information) were provided by IRRI. DNA from sorghum (*Sorghum vulgare*), barley (*Hordeum vulgare*), wheat (*Triticum durum*), triticale (*x Triticosecale*), and rye (*Secale cereale*) was extracted from ground seeds or leaves at the European Union Reference Laboratory for GM Food and Feed (EU-RL GMFF). Genomic DNA from non-GM soybean (*Glycine max*), rapeseed (*Brassica napus*), cotton (*Gossypium hirsutum*), sugar beet (*Beta vulgaris*), potato (*Solanum tuberosum*), and from the GM events listed in "Genomic DNA and plant materials", Supporting Information, was prepared by the EU-RL GMFF.

Genomic DNA Extraction and Evaluation of Quality and Quantity. Barley, rice, rye, sorghum, triticale, and wheat genomic DNA was extracted with either a CTAB DNA extraction method (modified from ISO 21571[29]) or a phenol-chloroform method optimized for rice leaves (modified from Sambrook and colleagues[30]). All extracted DNAs were tested for integrity using a 1% (w/v) agarose gel electrophoresis and for purity by assessing the presence of PCR inhibitors as described by Zel and colleagues[31] and the absence of contamination with the GR2-R event. DNA concentration was determined fluorimetrically with the Quant-iT PicoGreen dsDNA Assay Kit (Molecular Probes, Eugene, U.S.) with a five-point standard curve ranging from 1 to 500 ng/mL with a Biorad (Hercules, U.S.) VersaFluor fluorometer. Only pure, noninhibited high molecular weight DNA was used.

Sample Preparation. Samples for optimization and in-house testing of the taxon- and event-specific assays were prepared diluting DNAs in 0.1 × TE. Samples for the relative quantification were prepared in haploid genome equivalents (hge) ratio by mixing GM (GR2-R event) and non-GM (cv. Kaybonnet) rice DNA. Standard curve samples were prepared by serial dilution; test samples were prepared independently. Genome sizes taken into account for the calculation of hge contents are listed in "Genome Sizes", Supporting Information.

Specificity. For the taxon-specific assay (Set1 and Set2), all of the species mentioned in the section Genomic DNA and Plant Materials (except carnation) were tested with 200 ng DNA/reaction; reactions were performed in triplicate, and the resulting Cqs were averaged. Rice DNA was included as positive control at 100 ng/reaction, with six replicates. For the event-specific assay (RB-BS set), the events listed in "Genomic DNA and Plant Materials", Supporting Information, were tested, as well as non-GM DNA from the same species tested with the taxon-specific assay, with a DNA amount corresponding to 200 000 hge/reaction, up to a maximum of 200 ng of DNA. Reactions were performed in triplicate, and the resulting Cqs averaged. The DNA amount used for each event/species and the GM material used are reported in "Specificity", Supporting Information. DNAs used for the tests were previously checked for the absence of inhibition as described in ref 31 with a suitable taxon-specific assay.

Stability of the Taxon-Specific Assay. The variability of the Cqs obtained with the PLD-GR taxon-specific assay (Set1) with a fixed DNA concentration was evaluated on 131 rice varieties, selected by IRRI as representative of global genetic diversity, and the Kaybonnet variety. The variability between plates was maintained as low as possible by performing all qPCR experiments on the same day and the same instrument; the same baseline and threshold were used for the analysis of the results of all plates. The list of the varieties tested, subspecies they belong to, and the obtained Cq are available in Table S1, Supporting Information. The genomic DNA of each variety was diluted to 25 ng/reaction, corresponding to 50 000 hge; reactions were performed in triplicate, and the resulting Cqs were averaged.

Dynamic Range and LOQ. A set of standard curve and test samples was prepared for the PLD-GR (Set1) and one for the GR2 (RB-BS set) assay, with non-GM and GR2-R DNA, respectively. Table S2, Supporting Information, reports the hge and DNA content of the standard curve and the test samples. Each standard curve sample was analyzed in three plates in triplicate, for a total of nine replicates, and each test sample was measured in three plates with eight replicates, for a total of 24 replicates. The hge content of the test samples was estimated by interpolation from the standard curve constructed with the standard curve samples. The limit of quantification (LOQ) of the two assays was evaluated concurrently.

LOD. The limit of detection (LOD) of the two assays was first assessed with 10 replicates over a range of 3−50 hge/reaction, on the samples described in Table S3, Supporting Information. The 0.1, 0.5, and 1 hge samples were included in the test to verify the correctness of the dilution, by evaluating the number of negative replicates obtained. Samples D1−D9 were prepared by serial dilution of non-GM rice DNA or GR2-R GM DNA for the taxon- and event-specific assays, respectively; the 0.5 hge sample was prepared and assessed only for the event-specific assay. To reach the 95% level of confidence, on the basis of the pilot test, two hge levels were selected for each assay, which were then tested, together with the 0.1 and 1 hge samples, with 60 replicates. For the PLD-GR taxon-specific assay, the 4.5 and 3 hge levels were selected, for the GR2 event-specific assay, the 6 and 4 hge levels. The LOD was set at the lowest concentration yielding at least 59 positive results.[32,33]

Robustness. The robustness of the PLD-GR (Set1) and the GR2 (RB-BS set) assays was tested by introducing variations in the volume of reaction mix per reaction (21 μL or 19 μL instead of 20 μL), the concentration of Mastermix (±20%), the concentration of primers or probe (±30%), the annealing temperature (±1 °C), and the qPCR equipment: Roche (Basel, Switzerland) LightCycler (LC) 480, Stratagene (La Jolla, CA) Mx3005P, Applied Biosystems (ABI, Waltham, U.S.) 7500. RSD_r and bias were evaluated on quantification of three test samples chosen to cover the full dynamic range of the GR2 assay (from 40 to 200 000 hge) and almost all that of the PLD-GR assay (from 30 to 200 000 hge). Test samples were quantified in repeatability conditions, with 3 replicates over one run for each condition. Standard curve and test samples were prepared with non-GM DNA for the taxon-specific assay and with GM (GR2-R) DNA for the event-specific assay (Table S4, Supporting Information).

Relative Quantification. Three test samples with a GM % ranging from 0.1% to 4.5% were prepared on the basis of their hge content and quantified with two qPCR runs and 6 replicates for each GM-level on each plate, with the PLD-GR (Set2) and the GR2 (RB-BS set) assays,

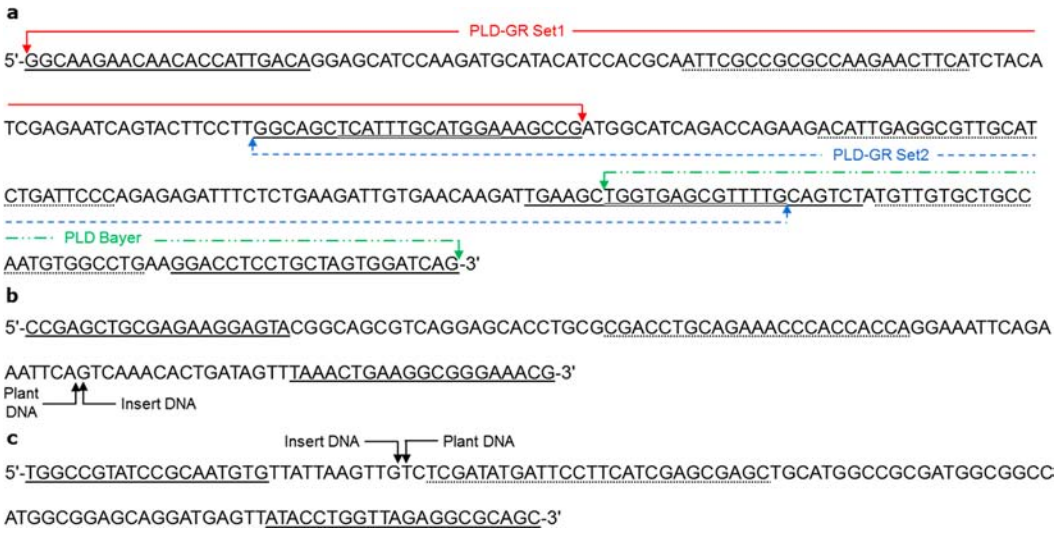

Figure 1. Amplicon sequence of PLD taxon-specific assays and GR2 event-specific assays. (a) PLD-GR Set1 and Set2, and PLD taxon-specific assay developed by Bayer;[22] (b) GR2 LB-01 primers/probe set; (c) GR2 RB-BS set. PLG-GR Set1 and Set2 overlap of 25 bp at their 5′ and 3′ ends, respectively; PLD-GR Set2 and PLD from Bayer overlap of 14 bp at their 5′ and 3′ ends, respectively; GR2 LB-01 set covers the 3′ plant-to-insert DNA junction; GR2 RB-BS set covers the 5′ insert-to-plant junction. Primer sequences are underlined with a single line, or a double line if two primers overlap, probe sequences are underlined with a dotted line; the junction between plant and transgenic insert DNA is indicated with arrows in GR2 amplicons; PLD-GR Set1 amplicon is indicated with a solid, red line, PLD-GR Set2 amplicon with a blue, broken line, and PLD amplicon developed by Bayer with a green broken and dotted line.

with a five-point standard curve with a GM % content ranging from 5% to 0.07%. The GR2 hge and PLD hge content of the standard curve and test samples were included in the dynamic range of the two assays. Hge and DNA content, dilution factor (standard curve only), and GM % of the standard curve and test samples are reported in Table S5, Supporting Information.

PCR Primers and Probes. Primers and TaqMan probes sequences were designed by IRRI using Primer Express Software (Life Technologies, Carlsbad, CA) and selected by the EU-RL GMFF on the basis of bioinformatics analyses. Primers were also tested against known plant genomes using the ePCR prediction tool.[34] The selected TaqMan probes are labeled with 6-carboxyfluorescein (FAM) fluorophore at 5′ and with tetramethylrhodamine (TAMRA) quencher at 3′. The sequence, annealing position of the primers and probes, and length of the obtained amplicons are reported in Table 1. Primers were purchased from Eurofins MWG operon (Ebersberg, Germany) and probes from ABI UK (Warrington, United Kingdom). The primers/probe concentration for PLD-GR taxon-specific assay and for GR2 event-specific assay was optimized by testing different primers/probe concentrations on a serial 4-fold dilution of DNA starting from 200 ng of non-GM DNA/reaction to 0.78 ng/reaction for the taxon-specific assay and from 100 to 0.39 ng of GM (GR2-R event) DNA/reaction for the event-specific assay. An optimal primer concentration was first selected, keeping the probe at 150 nM and testing the primers from 150 to 450 nM by 100 nM increases; probe concentrations tested ranged from 100 to 250 nM by 50 nM increases, with primers at 350 nM. The selection criteria were: profile and level of fluorescence of the amplification curves at different DNA concentrations, presence/absence of inhibition, and slope of the dilution. The final selection was 300 nM primers and 150 nM probe for the two primers/probe pairs tested for each of the two assays.

Real-Time PCR. The optimized qPCR reaction mixture for all four primers/probe sets tested contained the following reagents: 1x TaqMan universal master mix (ABI), 300 nM primer forward, 300 nM primer reverse, 150 nM probe, 5 μL of DNA sample, and nuclease free water (Promega, Madison, WI) up to a volume of 25 μL/reaction. All qPCR runs, except where specified for the robustness test, were performed with ABI 7900 platform (Life Technologies, Carlsbad, CA) with the following thermal profile: 50 °C for 2 min; 95 °C, 10 min; 45 cycles of 95 °C, 15 s and 60 °C, 60 s; fluorescence data were acquired at the end of each cycle.

DOI: 10.1021/jf505516y
J. Agric. Food Chem. 2015, 63, 1711−1721

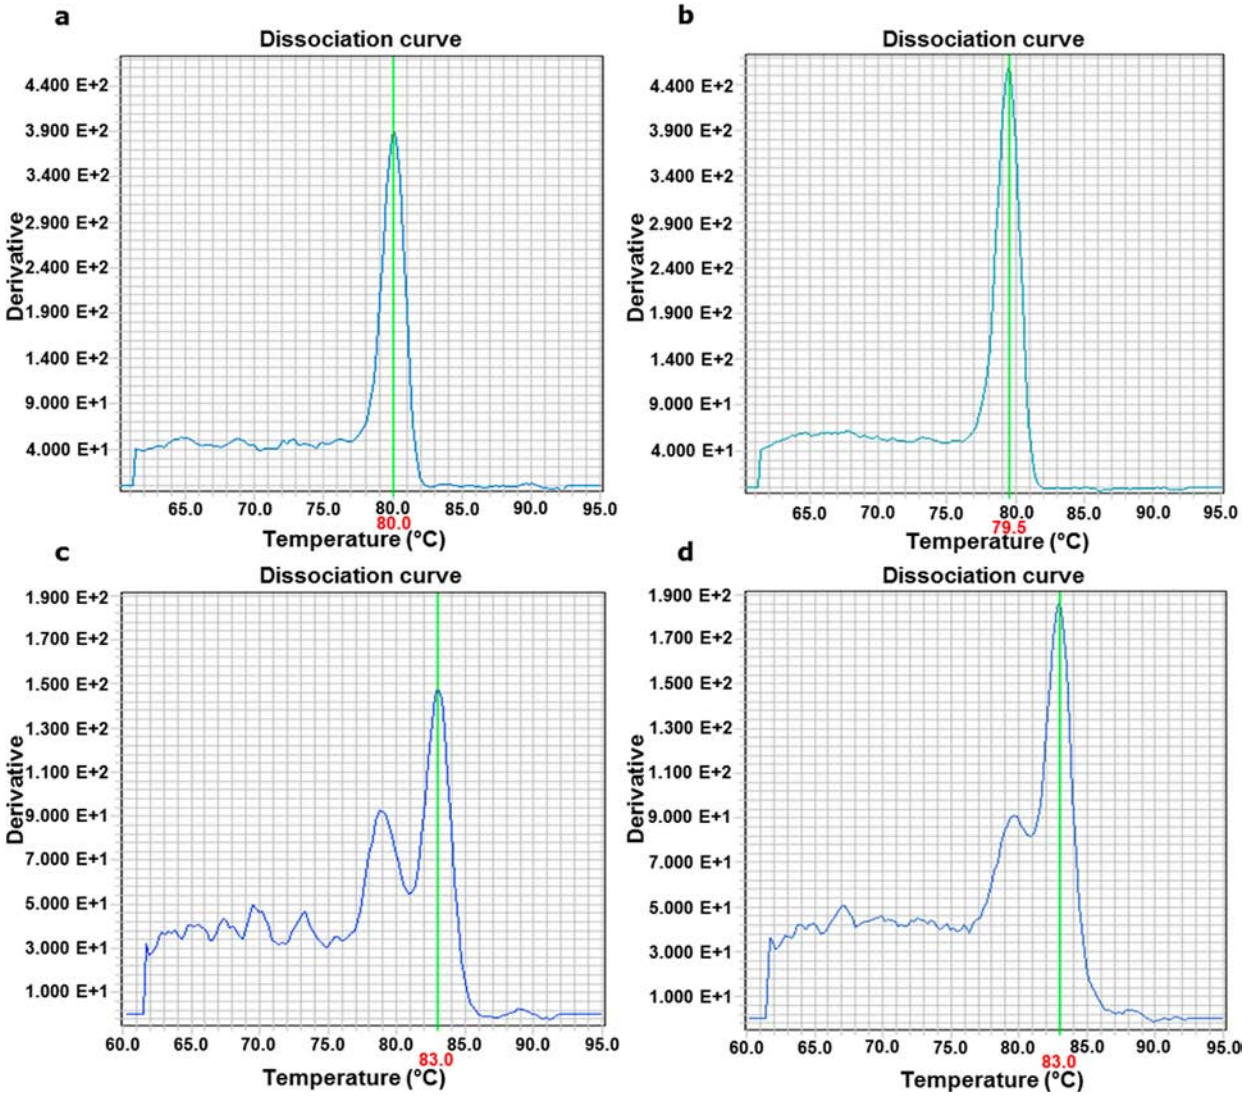

Figure 2. Melting curve profile of (a) PLD-GR taxon-specific assay, Set1; (b) PLD-GR taxon-specific assay, Set2; (c) GR2 event-specific assay, LB-01 set; and (d) GR2 event-specific assay, RB-BS set. A single peak is present in PLD-GR Set1 and Set2 assays melting profile; a weaker peak (lower melting temperature, putative primer dimers) and a stronger peak (higher melting temperature, specific amplification) are present in the GR2 LB-01 and RB-BS assays melting profile, the weaker peak being more evident in the LB-01 assay melting profile.

Melting curve analysis, Agilent microfluidic chip assay, sequencing, and digital PCR methods are described in the Supporting Information.

Data Analysis. Standard curves were generated by plotting the Cq values measured for the calibration points against the logarithm of the DNA hge content and by fitting a linear regression line into these data. The hge content of the test samples was then estimated by interpolation from the standard curve. Experiments performed on ABI 7900 qPCR equipment were analyzed with the SDS 2.4 software (Life Technologies, Carlsbad, CA); the baseline was set manually three cycles before the cycle number at which the threshold line crosses the first amplification curve; the threshold was set manually in the area where the amplification profiles appeared linear and there was no fork effect between replicates of the same sample. MIQE guidelines were taken into consideration when applicable to the present work.[35] Robust mean calculation and cluster analysis are described in the Supporting Information.

Performance Criteria. Performance parameters of the PLD-GR and GR2 assays were evaluated in accordance with ENGL MPR.[14] Specificity, dynamic range, accuracy, PCR efficiency, linearity, LOQ, LOD, and robustness were evaluated, as well as copy number and stability of the PLD-GR taxon-specific assay. Accuracy was evaluated on the basis of two parameters: trueness and precision. Trueness was expressed as mean percent bias (difference between the mean value of test results and the accepted reference value divided by the latter). Precision was expressed as relative repeatability standard deviation (RSD_r) in percent relative to the accepted reference value. Amplification efficiency was calculated from the slope of the standard curve using the formula: efficiency = $((10^{(-1/\text{slope})}) - 1) \times 100$. Linearity was expressed as coefficient of determination of the standard curve obtained by linear regression analysis. The criteria set for each of these parameters are discussed throughout the text.

RESULTS

Bioinformatics Analyses. The two sets of primers and probes for the PLD-GR taxon-specific assay (see Table 1 for primers and probes sequence and location) produced alignments only with exon 2 of the PLD α2 gene in *Oryza sativa* and with sequences from *Oryza glaberrima*, African rice (data not shown). Set1 and Set2 PCR amplicons overlap for 25 bp and Set2 overlaps for 14 bp with the amplicon of the PLD assay developed by Bayer (Figure 1a).[22] The two sets of primers and probes for the event-specific assay produced alignments with no other sequence than the GR2-R event. The LB-01 set is

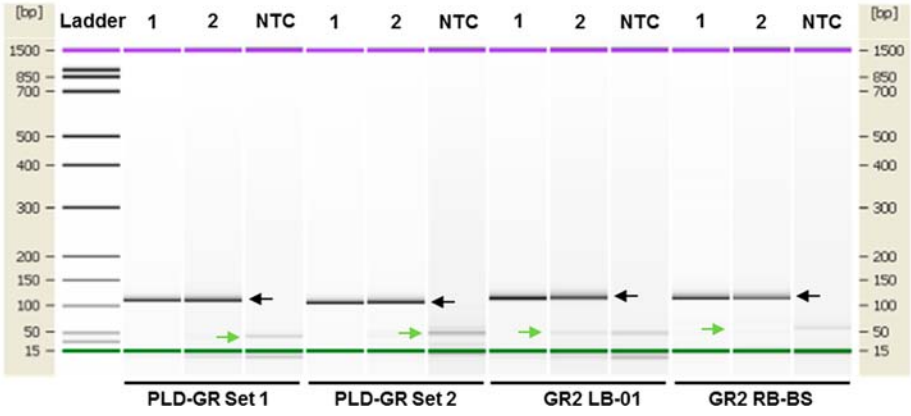

Figure 3. Virtual gel representation of capillary electrophoresis of the amplification products of PLD-GR taxon-specific assay Set1 and Set2, and GR2 event-specific assay LB-01 and RB-BS sets. PLD-GR Set1 and Set2 assays show one specific amplification product (black arrow, pointing left) for the two template DNA concentrations loaded (1, 40 000 hge; 2, 156 hge), and a lower band of putative primer dimers (green arrow, pointing right) only in the no template control (NTC). GR2 LB-01 and RB-BS sets show one specific amplification product for the two template DNA concentrations loaded and primer dimers in the no template control and with a weak (LB-01 set) and very weak band (RB-BS set) also in the amplification with lower template DNA concentration. bp, base pairs.

designed across the 5′ plant−insert DNA junction, the RB-BS set across the 3′ insert−plant DNA junction (Figure 1b,c).

Optimization and Characterization of the PLD-GR and GR2 Assays. We optimized and characterized the PLD-GR taxon-specific and the GR2-R event-specific qPCR assays independently. We defined the optimal concentration of primers and probes as described in the Materials and Methods, which resulted to be 300 nM primers and 150 nM probe for all sets. We characterized the PCR products of the four primers/probe sets with melting curve analysis, capillary electrophoresis, and amplicon sequencing. The melting temperature of the PLD-GR assay ranged, depending on the amount of DNA in reaction, from 79.7 to 80.3 °C with an average of 80.0 °C for Set1 and from 79.2 to 79.9 °C with an average of 79.5 °C for Set2; the profiles of the dissociation curves were indicative of specific amplification (Figure 2a,b). Capillary electrophoresis showed the presence of a single band of the expected size for both sets, on a clean background (Figure 3). The sequences generated on both strands of PLD-GR Set1 and Set2 amplicons showed 100% identity with PLD α2 gene, further confirming the specificity of the amplification. For the GR2 assay, the melting temperature ranged from 82.5 to 83.0 °C with an average of 82.8 °C for the LB-01 set and from 82.5 to 83.0 °C with an average of 82.9 °C for RB-BS primer set. The melting profiles of the two sets were indicative of specific amplification, although they showed peaks consistent with the formation of putative primer-dimers, more evident for the LB-01 set (Figure 2c,d). Capillary electrophoresis showed the presence of a single band of the expected size for both sets, and smaller bands barely visible, with a size consistent with primer-dimers (Figure 3). The sequences obtained for GR2 LB-01 and RB-BS amplicons showed 100% identity with the sequence of the GR2 event provided by IRRI. Because both melting curve analysis and capillary electrophoresis indicated that the formation of primer dimers was less evident for GR2 RB-BS primer set as compared to LB-01 primer set, we chose the RB-BS set for further analyses.

Specificity. We tested the specificity of the PLD-GR and GR2 assays experimentally, verifying their amplification with genomic DNA from other species and/or events. PLD-GR Set1 assay amplified only rice DNA, while PLD-GR Set2 produced unspecific amplification, with high Cqs, with DNA from barley, wheat, and rye (Table S6, Supporting Information). We thus selected Set1 primers and probe for further analyses, and discarded Set2. We tested the specificity of the GR2 assay on the same species listed for the PLD-GR assay and on DNA from all of the GM events, which were authorized or in the course of authorization in the EU at the moment of testing, plus all GR2 transformation events, rice events LL62 and LL601, and carnation event IFD-25958. We did not observe any unspecific amplification. A detailed list of the DNAs and the DNA amount tested is reported in the Materials and Methods and as Supporting Information, and the list of the species and events tested with the obtained Cqs is available in Table S7, Supporting Information.

Copy Number and Stability of the PLD-GR Taxon-Specific Assay. We performed the digital PCR experiment as described in the Supporting Information, and obtained a mean ratio between event-specific and taxon-specific amplification of 1.033, which, given that the 95% confidence interval of the mean spans around one, is not significantly different from the expected ratio of one (Table 2). We thus confirmed that the PLD-GR amplicon is present in single copy in the haploid genome of the transformed variety.

Table 2. Results of Digital PCR Analysis Conducted with the GR2 and PLD-GR Assays on GM DNA, 100% GM for GR2 Event

mean ratio (GR2/PLD-GR)	1.033
standard deviation	0.106
RSD$_r$, %	10.230
standard error of the mean	0.027
upper 95% CI of the mean	1.090
lower 95% CI of the mean	0.977

We then assessed the stability of the PLD-GR assay as described in the Materials and Methods. The results of the test are presented in Figure 4, where the Cq value obtained for each variety (Kaybonnet plus 131 varieties) is plotted, together with the overall mean, median, and robust mean (i.e., a mean whose estimate is less influenced by potential outliers in the data), and ±0.5 Cq intervals. According to ENGL MPR,[14] the range of

J. Agric. Food Chem. 2015, 63, 1711−1721

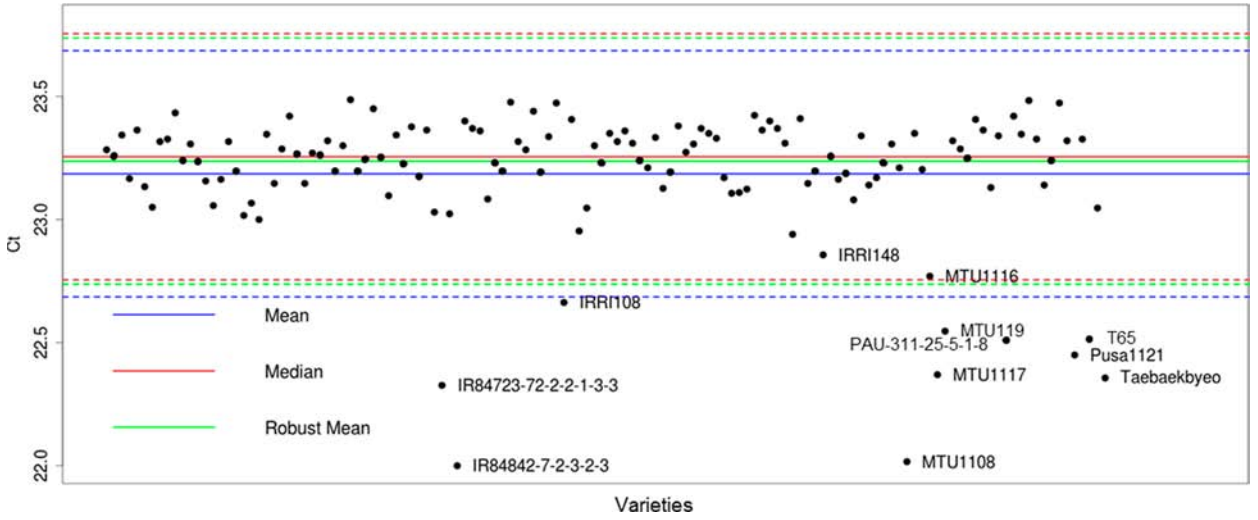

Figure 4. Results of the stability test for PLD-GR taxon-specific assay (Set1). The average Cq value obtained for each variety is plotted along the *x* axis; the mean of all measured Cq values (blue line), the median (red line), and the robust mean (green line) are represented; broken lines represent the mean (blue), median (red), and robust mean (green) plus or minus 0.5 Cq. Most varieties (122 out of 132) are distributed within ±0.5 Cq from the mean/median/robust mean. Twelve varieties, labeled with a text string, were identified as a cluster distinct from the other varieties.

variability of Cq values within the taxon should not exceed 1 Cq. As shown in Figure 4, most varieties (120 out 132) were comprised between 22.94 and 23.49 Cq with a maximum distance of 0.55 Cq (unlabeled varieties). To identify possible outlying varieties, we performed cluster analysis, a technique that aims at discovering groups of objects with similar characteristics in a set of data, and we labeled with a text string the varieties that were identified as a distinct cluster. Some of the labeled varieties were however comprised in the mean ±0.5 Cq interval (IRRI148 and MTU1116) or at least in an interval of 1 Cq from the variety with the highest Cq value (IRRI108, MTU1119, T65, and PAU-311-25-5-1-3). Only six varieties (Pusa1121, MTU1117, Taebaekbyeo, IR84723-72-2-2-1-3-3, MTU1108, and IR84842-7-2-3-2-3) were outside that 1-Cq interval. The Cq we measured for those varieties was lower than the accepted range, thus excluding the possibility that sequence variability in the region amplified by the PLD-GR assay would lead to lower PCR efficiency, and thus to a higher Cq value.

Dynamic Range of the Two Assays. We assessed the dynamic range of the two assays as reported in the Materials and Methods. Table 3 reports the hge content, RSD_r, and bias measured for each test sample, for the PLD-GR and the GR2 assays. For the PLD-GR taxon-specific assay, the RSD_r was acceptable between 200 000 and 30 hge per reaction, for the GR2 event-specific assay between 200 000 and 40 hge. Bias was below 25% for all test samples for both the PLD-GR and the GR2 assays. On the basis of these values of RSD_r and bias, and in accordance with ENGL MPR,[14] which establishes that the RSD_r and bias should be below 25% over the whole dynamic range, we defined the dynamic range of the PLD-GR taxon-specific assay to be between 30 and 200 000 hge and between

40 and 200 000 hge for GR2 event-specific assay. As reported in Table 4, for the PLD-GR assay and the GR2 assay, slope values were below −3.6; the average PCR efficiency was above 90% and the average R^2 coefficient was above 0.99. These values are within the limits established by ENGL MPR.[14]

LOQ and LOD. According to ENGL MPR,[14] the LOQ of a method should be equal to or below the lowest amount or concentration included in the dynamic range. In this study, we assessed the LOQ together with the dynamic range of the method, and it consequently corresponds to the lowest test sample included in the dynamic range. For the PLD-GR assay, we thus established the LOQ at 30 hge per reaction, with a RSD_r of 17.8% and a bias of 22.2%; for the GR2 assay at 40 hge per reaction, with a RSD_r of 20.0% and a bias of −8.6% (Table 3).

The LOD of a method should be below 25 hge with a level of confidence of 95%, ensuring less than or equal to 5% false negative results.[14] The results of the test are reported in Table S8, Supporting Information: the LOD was at 4.5 hge/reaction for the PLD-GR assay and at 4 hge for the GR2 assay. The 1 hge level had 36.7% and 33.3% negative results, respectively, for the PLD-GR and the GR2 assay, in line with the value of 36% that is expected taking into account the probability of distribution of the target DNA in the 60 replicates.[36]

Robustness. Robustness was evaluated as described in the Materials and Methods. The results of the quantification for the determination of the robustness are illustrated in Table 5 for the PLD-GR assay and in Table 6 for the GR2 assay. The measured RSD_r was below 25% for the three test samples with all of the conditions tested for both the PLD-GR and the GR2 assays, in line with ENGL MPR;[14] bias was within ±25% for all of the conditions and test samples for the PLD-GR assay, while for the GR2 assay there was only one value of bias below −25% for the test sample at the LOQ, with Roche LC 480 qPCR instrument. We also evaluated the efficiency and linearity of the two assays, and the results are reported in Table 7. The values of slope and linearity were within the ENGL MPR[14] for both assays; the PCR efficiency was above 90% for both assays with all conditions, with the exception of the experiments performed with the GR2 assay with a concentration of primers 30% lower and on ABI 7500, for which the efficiency was 89.5% and 89.9%, respectively.

Relative Quantification. The results of the relative quantification are reported in Table 8: for the three test samples, the measured RSD_r ranged from 9.9% to 13.1%, and bias ranged from −6.2% to 5.3%. Both parameters are below 25%. The slope, PCR efficiency, and linearity of the standard curves for the two runs and their average over the two runs are

DISCUSSION

In this study, we describe the development, optimization, and in-house validation of the two TaqMan qPCR assays that compose the method for the event-specific detection and quantification of GR2 with a new rice taxon-specific assay, PLD-GR. The GR2 event-specific assay amplifies a 121-bp fragment across the 3′ junction between transgenic insert and plant DNA; the new PLD-GR taxon-specific assay amplifies a 124-bp fragment of rice PLD gene. These two assays were validated independently, on hge basis, and their performance was evaluated following European guidelines[14] and taking into consideration IUPAC harmonized guidelines for single-laboratory validation of methods of analysis.[26] All performance criteria adopted in this study satisfy the requirements of the Codex Alimentarius for methods for detection, identification, and quantification of specific DNA sequences.[25]

According to the principle of modularity, different parts of an analytical procedure, for example, DNA extraction and qPCR, can be evaluated and validated independently, provided that specific performance requirements are satisfied for each module.[37−39] In this study, we developed and validated only the qPCR module, independently of the DNA extraction method, in line with the principle of modularity. This approach is also supported by a study that compared the results of 53 collaborative trials for the validation of qPCR methods and indicated that the standard deviation introduced by the DNA extraction step with respect to GM quantification is negligible when compared to the one introduced by the qPCR step.[40] Furthermore, we considered the taxon- and the event-specific assays that constitute the GR2 qPCR method as independent modules, as already discussed in Kagkli et al.[39] This strategy is advantageous because it offers increased flexibility and potentially lowers the cost of method testing and validation, allowing, for example, the use of the same taxon-specific assay in combination with different event-specific assays, without the need to revalidate the combination of assays. A GMO testing laboratory could select the best combination of taxon- and event-specific assays, depending on the availability of PCR reagents or of verified and implemented taxon-specific assays. When a detection method for a new GMO event would have to be developed, the taxon-specific assay would not need to be developed and/or validated a second time. This approach also allows a wider freedom in the GM percentages that can be tested, which are instead limited to the validated dynamic range when the qPCR method is treated as a single module, and on whether to use a delta Cq method or a two-standard curves method. The results of the relative quantification experiment performed with the GR2 method confirmed that the two assays can be used in combination to quantify GR2 relative content, with acceptable levels of trueness and precision (Table 8).

For the PLD-GR taxon-specific assay, bioinformatics analyses with PLD-GR primer sets and amplicons evidenced that perfect alignments were produced only with rice and African rice sequences. Our bioinformatics analyses showed that also the primers for the PLD assay from Bayer, the SPS, and the gos9 assays[17−22] may potentially amplify sequences from African rice, suggesting that sequence variability between rice and African rice is low, which restricts the possibilities to design primers specific for one of the two species. The production of African rice is however limited, and the color of the African rice grain normally ranges from red to brown, easy to distinguish from rice by eye inspection. The specificity of amplification of the selected event- and taxon-specific assays was confirmed by melting curve analysis, capillary electrophoresis, and amplicon sequencing. The specificity of the GR2 and PLD-GR assays was also verified against the DNA of a number of other species, representative of the most important GM crops and a selection of cereals and grasses; the GR2 assay was additionally tested on DNA from 53 GM events and from five independent GR2 transformation events. The GR2 and PLD-GR assays did not show unspecific amplifications with the species tested. The PLD-GR taxon-specific assay was designed taking into consideration the polymorphisms reported for the region.[41,42] We demonstrated that the newly developed PLD-GR taxon-specific assay is present in single copy in the rice genome of the Kaybonnet variety and that its amplification stability is good

DOI: 10.1021/jf505516y
J. Agric. Food Chem. 2015, 63, 1711−1721

across the 132 rice varieties tested, belonging to both the indica and the japonica subspecies. The Cq values obtained with DNA from 120 out of 132 varieties were within a range of 0.55 Cq, and only six varieties were outside a range of 1 Cq calculated from the variety with the highest measured Cq value (Table 2, Figure 4, and Table S1, Supporting Information). All of the outlying varieties showed a lower Cq, suggesting either the presence of a second amplicon for the PLD-GR assay or an incorrect quantification of the DNA that was added to the reaction. Both hypotheses were investigated, by sequencing the amplification products of these varieties, and by requantifying their DNA with Picogreen and spettrophotometric methods. However, we did not identify a second amplification product (which seems to exclude the hypothesis of the presence of a second PLD-GR amplicon) and did not obtain significantly different quantification results. We will further investigate these results, but given that the test on the stability of the PLD-GR assay did not indicate the presence of sequence polymorphisms in the primers/probe region negatively influencing the efficiency of amplification, and that less than 5% of the varieties tested were outside the established Cq range, the PLD-GR taxon-specific assay can be classified as having good performance in terms of stability.

We established that the dynamic range of the GR2 event-specific assay is between 200 000 and 40 hge, with the LOQ at 40 hge and the LOD at 4 hge, and the dynamic range of the PLD-GR taxon-specific assay is between 200 000 and 30 hge, with the LOQ at 30 hge and the LOD at 4.5 hge (Table 3 and Table S8, Supporting Information). These numbers are in line with the criteria set in the ENGL MPR document.[14] The RSD_r was generally higher at the lower end of the dynamic range for both assays, a trend common to most calibration systems;[43] the linearity of the standard curves for the event- and taxon-specific assays was in line with that measured for most calibration systems, while PCR efficiency was slightly below the average when compared to data from the EU Database of Reference Methods for GMO Analysis.[44] It has to be taken into consideration, however, that the data available on the EU Database of Reference Methods for GMO Analysis are the results of full validation experiments, while we presented the results of the in-house validation of the two assays.

We optimized the GR2 and the PLD-GR assays on ABI 7900HT qPCR equipment, chosen for being one of the most common qPCR equipment in GMO testing laboratories, and tested the robustness of the two assays on three other common qPCR instruments: Roche LC 480, Stratagene Mx3005P, and ABI 7500. The results of the quantification of three test samples distributed over the whole dynamic range showed that the two assays can be transferred to other qPCR equipment without losing their accuracy; only the sample at the LOQ reported a bias of −27.9% with Roche LC 480 for the GR2 event-specific assay (Tables 5 and 6). It was already observed that deviations from the expected performance occurred at low GM contents with some qPCR methods when Roche LC 480 was employed;[45] in this case, the deviation was small and only at the lower limit of the dynamic range of the assay. However, particular care should be taken when using this platform to perform the GR2 assay. The certification of GMO testing laboratories under ISO 17025[46] requires that validated methods be verified in-house before being implemented for routine analysis; we suggest performing this verification on all of the different qPCR platforms on which the method is planned to be used. The slope, efficiency, and linearity of the standard curves generated with the two assays on the three qPCR instruments were within the performance requirements,[14] with the only exception of the PCR efficiency of the GR2 assay on ABI7500, which was very near to 90%. This small deviation did not influence the quantification results, which showed a RSD_r between 1.1% and 11.6% and bias between −6.2% and −1.2%. We tested the robustness of the two assays also with deliberate and small changes to the reaction conditions and the quantification remained reliable, although as a general trend bias was higher for the samples with lower hge content, especially for the GR2 assay (Tables 5 and 6). It has to be taken into consideration that we tested the GR2 assay at its LOQ; it is thus more likely that changes to the reaction mix or the PCR program have a higher influence at the lower extreme of the dynamic range. The slope, efficiency, and linearity of the standard curves of the two assays were within the performance requirements[14] with the exception of the PCR efficiency of the GR2 assay with 30% lower primer concentration, for which a small decrease in efficiency led to a quantification that was still acceptable, with a RSD_r comprised between 5.1% and 7.3% and a bias between −11.5% and −1.9%. The two assays can thus be considered robust against small deviations from the protocol.

GR2 is intended for cultivation and consumption in developing countries that use rice as a staple crop, with the objective of fighting vitamin A deficiency, and at present its commercialization is not foreseen outside those countries. The humanitarian license that regulates its use and distribution establishes that only national sales of the product are allowed.[1,2,47−49] It cannot however be excluded that this rice will enter the EU, either as a contamination in food imports or as fortified food. In this view, the development of a qPCR detection method for GR2 is important to ensure the traceability of this GM event. The applicability range of the qPCR GR2 detection method that we developed is wide in terms of haploid genome equivalents that can be detected, also as a result of the choice of treating the event and taxon-specific assays that compose the method as independent modules. The method can thus be applied in different regions of the world, notwithstanding the diverse provisions set for the unintended presence of GMOs.[50]

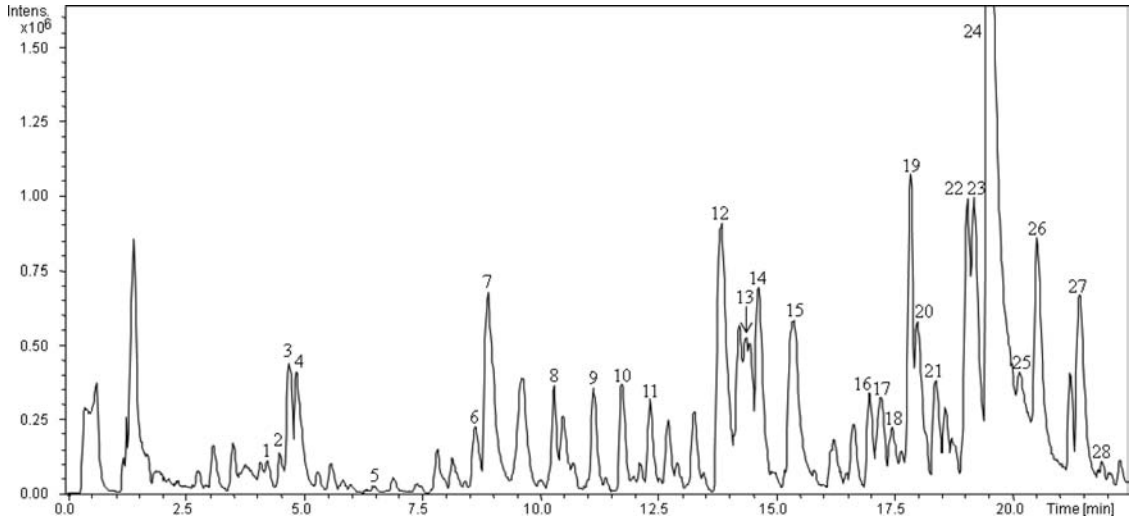

Figure 1. Base peak chromatogram (BPC) of 'Arbequina' olive leaf extract in December, obtained by HPLC-DAD-TOF-MS. See Table 1 for identification numbers.

some phenolic compounds in olive leaves, or the influence of factors such as water deficit, genetic factor, or seasonal period.[21−25]

In a previous work,[26] our group reported the phenolic composition of 'Sikitita' ('Chiquitita' in the U.S.), a newly bred olive cultivar.[27] In the present work, an exhaustive number of phenolic compounds and cultivars were considered with the main aim of providing further insights into the evolution of olive leaves phenolic compounds in different olive cultivars during their growth and the olive ripening period under the Andalusian climate. We also highlight the optimal sampling time to use olive leaves as a source of bioactive compounds.

MATERIALS AND METHODS

Chemicals and Reagents. Methanol, the reagent used for extracting the phenolic compounds from the olive-leaf samples, was purchased from Panreac (Barcelona, Spain), and HPLC-grade acetonitrile was purchased from Labscan (Dublin, Ireland). The acetic acid used was of analytical grade (assayed at >99.5%) and was purchased from Fluka (Switzerland). Water was purified using a Milli-Q system (Millipore, Bedford, MA). Standard compounds such as hydroxytyrosol, tyrosol, luteolin, and apigenin were purchased from Sigma-Aldrich (St. Louis, MO), and oleuropein was from Extrasynthèse (Lyon, France). The stock solutions containing these analytes were prepared in methanol. All chemicals were of analytical reagent grade and used as received. All of the solutions were stored in a dark flask at −20 °C until use.

Samples. Olive leaves (*Olea europaea* L.) from cultivars 'Arbequina', 'Arbosana', 'Changlot Real', 'Koroneiki', 'Picual', and 'Sikitita' were used in this study. These cultivars were selected as some of the most widely used in new orchards currently in Spain, highly productive, well adapted to modern olive growing techniques, and initially originated in different areas: 'Arbequina' and 'Arbosana' from Catalonia (Spain), 'Changlot Real' from Valencia (Spain), 'Picual' from Andalusia (Spain), 'Koroneiki' (Greece), and 'Sikitita', a new Spanish cultivar from cross-breeding between 'Arbequina' and 'Picual'. All cultivars were grown under the same agronomic and environmental conditions in the same olive orchards located at "IFAPA, Centro Alameda del Obispo" in Córdoba, Spain (37°51′36.5″ N 4°47′53.7″ W). Samples were processed at four times: mid-June (fruit-set), mid-August, mid-October, and mid-December (fruit-ripening) in 2012. Adult leaves were collected from three individuals of each cultivar, in 5 year old trees of these cultivars planted at 7 × 5 m spacing and trained as single-trunk vase. Standard cultural practices were followed, with minimal pruning to allow early bearing and irrigation by in-line drips with 2000 m^3/ha per year to avoid water stress of plants. All of the leaves collected from the same tree were pooled in a unique sample, immediately transferred to the laboratory, and dried outdoors. Finally, samples were stored at −80 °C until needed.

Extraction of Phenolic Compounds from Olive Leaves. Sample extraction was performed as described previously by Talhaoui et al.[26] Briefly, dry leaves (0.5 g) were crushed and extracted via Ultra-Turrax IKA T18 basic using 30 mL of MeOH/H_2O (80/20). After solvent evaporation, the extracts were reconstituted with 2 mL of MeOH/H_2O (50/50). Three replicates of each sample were processed.

Determination of Phenolic Compounds by HPLC-DAD-TOF-MS. Phenolic compounds were separated by a Poroshell 120 EC-C18 analytical column (4.6 × 100 mm, 2.7 μm) from Agilent Technologies, on an Agilent 1200 series rapid resolution liquid chromatograph (Agilent Technologies, CA). The gradient eluent, at a flow rate of 0.8 mL/min, was achieved using the method previously described by Talhaoui et al.[26] The column temperature was maintained at 25 °C, and the injection volume was 2.5 μL.

The HPLC system with diode-array detection was coupled to a micrOTOF (Bruker Daltonics, Bremen, Germany), an orthogonal-accelerated TOF mass spectrometer, using an electrospray interface (model G1607A from Agilent Technologies, Palo Alto, CA). The effluent from the HPLC column was split using a T-type phase separator before being introduced into the mass spectrometer (split ratio = 1:3). Analysis parameters were set using a negative-ion mode with spectra acquired over a mass range from m/z 50 to 1000. The optimum values of the ESI−MS parameters were: capillary voltage, +4.5 kV; drying gas temperature, 190 °C; drying gas flow, 9.0 L/min; and nebulizing gas pressure, 2 bar. The accurate mass data on the molecular ions were processed through the newest Data Analysis 4.0 software (Bruker Daltonics, Bremen, Germany), which provided a list of possible elemental formulas via the Smart Formula Editor. The Smart Formula Editor uses a CHNO algorithm, which provides standard functionalities such as minimum/maximum elemental range, electron configuration, and ring-plus double-bond equivalents, as well as a sophisticated comparison of the theoretical with the measured isotope pattern (Sigma Value) for increased confidence in the suggested molecular formula. Peak areas of phenolic compounds were integrated using Bruker Compass Target Analysis 1.2 software for compound screening (Bruker Daltonics, Bremen, Germany). All phenolic compounds showed good levels for quantification in the various samples on each date of sampling. Five standard calibration graphs were prepared for quantification of the phenolic compounds in the olive leaves using five commercial standards (oleuropein, hydroxytyrosol, tyrosol, apigenin, and luteolin).

[a]Group 1 (secoiridoid); group 2 (flavonoids); group 3 (simple phenols); group 4 (oleosides); group 5 (elenolic acids).

Statistical Analysis. All assays were run in triplicate. Values of different results were expressed as the means mg/g olive leaves. Results were tested for statistical significance by one-way ANOVA. Significant statistical differences among treatments ($p < 0.001$) were assessed by Tukey's honest significant-difference multiple comparisons. Statistica 8.0 software (2001, StatSoft, Tulsa, OK) was used for statistical determinations. Principal components analysis (PCA) was elaborated using the MatLab function "princomp ()" version R 2012a.

RESULTS AND DISCUSSION

Identification and Quantification of Phenolic Compounds. Samples of phenolic extracts from olive leaves picked at different times were analyzed by HPLC with UV−vis and MS detection. The identification of phenolic compounds from samples was carried out as previously reported by Talhaoui et al.[26] The compounds were identified by interpreting their mass spectra determined via TOF-MS and taking into account the data reported in the literature. All of these results were complemented with the UV spectra provided by DAD, which gave additional information about the family of compounds, in terms of the absorbance bands. However, quantification was performed using MS data. Twenty-eight compounds were detected in all of the samples and for all sampling times, except for 'Arbosana' in which tyrosol glucoside was only detected in December (Table a, Supporting Information). No qualitative differences in phenolic compounds were detected between leaves from the six different olive cultivars. Figure 1 shows the base peak chromatogram of 'Arbequina' cultivar in December as a representative example. The calibration plots indicated good correlations between peak areas and analyte concentrations, and regression coefficients were higher than 0.990 in all cases. Sensitivity (RSD, %), linearity (r^2), calibration ranges, calibration curves, and limits of detection and quantification are reported (Table b, Supporting Information). The limit of quantification (LOQ) was determined as a signal-to-noise ratio of 10:1, and the limit of detection (LOD) was determined as a signal-to-noise ratio of 3:1. LOD was found to be within the range 0.53−27.63 μg/L, while LOQ was within 1.76−92.10 μg/L. Intraday and interday precisions were developed to assess the repeatability of the method. An olive leaf extract was injected six times on the same day (intraday precision, $n = 6$) for 3 consecutive days (interday precision, $n = 18$). The intraday repeatability of the peak area, expressed by the RSD, was 1.03%, whereas the interday repeatability was 3.6%. Oleuropein and other secoiridoids were quantified with the calibration curve for oleuropein; hydroxytyrosol-hexose isomers were quantified with the calibration curve for hydroxytyrosol; tyrosol glucoside was quantified with the calibration curve for tyrosol; apigenin rutinoside was quantified with the calibration curve for apigenin and luteolin; and luteolin-diglucoside and the other flavonoids were quantified with the calibration curve for luteolin. All phenolic compound contents are reported as mg of compound/g dry olive leaves (Tables a, c, d, e, f, g, Supporting Information).

[a]Different letters indicate significant differences among cultivar by sampling time and phenolic group ($P < 0.001$).

Chemometric Approach. Because of the large amounts of data obtained, it was indispensable to adapt the appropriate statistical method so that it could facilitate discrimination between cultivars and/or sampling times. Hence, the data on the concentrations determined for the 28 compounds were grouped into five groups (Table 1): secoiridoids, group 1 (oleuropein aglycon, demethyloleuropein, three isomers of oleuropein diglucoside, two isomers of 2″-methoxyoleuropein, two isomers of oleuropein, oleuropein/oleuroside, and ligstroside); flavonoids, group 2 (luteolin diglucoside, luteolin rutinoside, apigenin rutinoside, two isomers of luteolin glucoside, luteolin, chrysoeriol-7-*O*-glucoside, and rutin); simple phenols, group 3 (hydroxytyrosol-hexose and isomer, and tyrosol glucoside); oleosides, group 4 (oleoside, secologanoside isomers a and b); and elenolic acids, group 5 (elenolic acid glucoside isomers a, b, and c). Subsequently, the statistical analysis was applied to a data set consisting of a matrix of 288 rows (one for each analysis) and 5 columns (one for each compound group).

Comparison of Total Phenolic Compounds among Sampling Times. The total concentration of phenolic compounds in the samples collected in June and December presented the highest mean concentrations, while those collected in August presented the minimum values. This general trend was also observed for most of the individual phenolic compounds (Table 1). The total concentration means of phenolic compounds for the six cultivars are in agreement with those reported for every single cultivar, except for 'Koroneiki' and 'Arbosana' cultivar samples, in which the variation in phenolic compound content did not show any significant difference from October to December (Tables a, c, d, e, f, g, Supporting Information). Considering the standard deviation (SD), there was little variability between cultivars in August and October. To evaluate whether the differences between sampling times were statistically significant or not, a matched Student's *t*-test was performed between the total concentrations from each pair of seasons. Highly significant differences were obtained for all seasonal pair comparisons ($p < 0.001$), except when comparing June and December ($p = 0.70$). In fact, the phenolic compound content of olive leaves is in general greatly influenced by the time of collection.[28] Indeed, studies carried out on different cultivars and in different seasons by Hashemi et al.[25] reported that the concentration of oleuropein, the major component of olive leaves, was significantly higher in the cold season than in the warm season. The same results have been confirmed by other authors, such as Brahmi et al.[22] for total *o*-diphenols and total flavonoids. Mert et al.[24] studied the annual variation in the quantity of oleuropein in the leaves of the 'Gemlik' cultivar and demonstrated the same pattern observed in the present study. Changes in oleuropein levels in different flower and fruit developmental stages have also been reported previously. Thus, Malik and Bradford[29] found a sharp decrease in oleuropein level during the transition from vegetative to flower buds, followed by a rapid increase at the initial stages of fruit development and again a sharp decrease with fruit maturity.

Seasonal Variability of Phenolic Compound Groups. To analyze the seasonal variability in the phenolic content in olive leaves, total concentrations for each compound group were averaged for all samples (individuals and replicas) for each sampling time and cultivar. Considering the general mean of each phenolic compound group for all cultivars per sampling time (Table 2), an evident reduction in concentrations was observed in August with respect to June. From August on, the concentrations gradually increased until December. In fact, the mean secoiridoids concentration decreased from 46.82 mg/g dry olive leaves in June to 11.97 mg/g dry olive leaves in August, before starting to increase up to a maximum value in December, 47.81 mg/g dry olive leaves. Regarding flavonoids, mean values decreased from 3.18 mg/g dry olive leaves in June to 1.45 mg/g dry olive leaves in August, but returned to increasing in December, reaching 2.61 mg/g dry olive leaves.

The mean concentrations of the simple phenols, oleosides, and elenolic acids groups decreased from 1.98, 1.36, and 0.39 mg/g dry olive leaves (June) to 0.35, 0.32, and 0.18 mg/g dry olive l leaves (August), respectively, while in December their concentrations reached 2.89, 1.09, and 0.41 mg/g dry olive leaves, respectively. The increase in elenolic acids content observed from August is likely the result of some oleuropein degradation that is accentuated in autumn.[30] The same behavior was observed in all cultivars for the five groups, although some exceptions were noted, especially between concentrations in October and December (Table 2). In fact, the concentration of the flavonoids group for 'Changlot Real' increased from June to December. The concentration of the flavonoids group for the 'Koroneiki' cultivar was decreased by one-half in December from its value in October. The concentration of the oleosides group showed a small decrease, by 8.2% and 8.9%, from October to December for the 'Koroneiki' and 'Arbosana' cultivars, respectively. Finally, the concentrations in the elenolic acids group decreased from October to December for the 'Koroneiki' and 'Arbequina' cultivars, displaying decreases of 20.8% and 42.6%, respectively. The large increase observed in winter in all phenolic groups probably occurred as a consequence of olive tree reaction to the low temperatures (Figure a, Supporting Information).

Comparison of Phenolic Compounds Groups among Cultivars. It is noteworthy that the concentration of each phenolic group was greatly dependent on the cultivar. In fact, the sum of squares (SS) distribution between sources of variation (cultivar and experimental error) showed a great influence of the cultivar on all sampling dates. Indeed, cultivar was responsible for 76%−99% of the variation in all groups. This result supports other studies reporting that genetic factors have a significant impact in the content of oleuropein in olive leaves.[21,31] Significant differences in phenolic compound composition have also been observed in the oils of different olive breeding selections.[32] In June, the 'Koroneiki' cultivar showed the highest concentrations of phenolic compounds for all cultivars and for all groups except the elenolic acid group, for which 'Arbosana' presented by far the highest concentration (Table 2). In August, the 'Arbosana' cultivar presented the highest values for secoiridoids, flavonoids, simple phenols (with 'Arbequina'), and elenolic acids, while 'Koroneiki' and 'Picual' showed the highest concentrations for oleosides. In October, the highest values for secoiridoids, oleosides, and flavonoids were registered for the 'Koroneiki' cultivar, whereas the highest value for simple phenols was registered for the 'Arbequina' cultivar. 'Arbosana' showed the highest concentration of elenolic acids. In contrast, the 'Sikitita' cultivar presented the lowest concentrations of flavonoids, oleosides, and elenolic acids in October. Except for simple phenols, the 'Picual' cultivar was the richest in terms of secoiridoids, oleosides, flavonoids, and elenolic acids among the studied samples in December. In addition, 'Changlot Real' also showed a high value of secoiridoids at that sampling time, with 73.25 mg/g dry olive leaves, insignificantly different from the 'Picual' cultivar with 70.69 mg/g dry olive leaves (Table 2). Previous studies have reported that oleuropein concentration in the 'Picual' cultivar decreases significantly in fruits while increasing in leaves during olive ripening.[33] Many studies also stipulate that antioxidant capacity, assumed to be almost entirely due to phenolic compounds, is greatly dependent on the severity of the stress as well as the species and developmental stage.[34] Hence, differences observed are probably associated with each cultivar's resistance or tolerance to environmental conditions for each season and the plants' need for protection against external pathogenic agents, which are according to the genetic endowment.

Principal Component Analysis (PCA) of the Phenolic Content. Even though the seasonal tendency was similar for all compounds groups and cultivars, the plots in Table 1 also show differences among cultivars or among compound groups. To study these differences, a principal component analysis (PCA) was applied to the data set containing the concentrations of the five previously described compound groups, including all 288 samples. Before applying the PCA, the data were preprocessed by applying a 10-base logarithm to the concentrations and mean and variance normalization. The logarithmic scaling puts the emphasis on relative variations in concentration (i.e., a change from 1 to 1.5 is more important than a change from 100 to 100.5), and the normalization equalizes the different components of the data vector. The PCA analysis was performed using the MatLab function "princomp()". Tables 3 and 4 show the variances of the principal components, the cumulative variance expressed as a percentage, and the coefficients providing the principal components as a function of the original components. As can be seen, the first and second principal components describe 88.4% of the data variability.

Table 3. Variances of Principal Components

	component				
	PC1	PC2	PC3	PC4	PC5
variance	3.63	0.79	0.31	0.19	0.08
cumulative variance (%)	72.61	88.44	94.63	89.41	100.00

According to the coefficients, principal components 1 and 2 can be computed from the normalized concentrations for different groups of compounds according to the following equations:

$$PC1 = -0.4899*C_{G1} - 0.3985*C_{G2} - 0.4333*C_{G3} - 0.4874*C_{G4} - 0.4194*C_{G5}$$

$$PC2 = 0.2266*C_{G1} - 0.5929*C_{G2} + 0.5101*C_{G3} + 0.2530*C_{G4} - 0.5224*C_{G5}$$

Under these equations, the first principal component is a weighted average of the normalized concentration for each group, where all of the original components contribute with a

Table 4. Coefficients of the Principal Components

	PC1	PC2	PC3	PC4	PC5
concentration group 1	−0.4899	0.2266	−0.2894	0.3299	0.7184
concentration group 2	−0.3985	−0.5929	0.6784	0.0710	0.1560
concentration group 3	−0.4333	0.5101	0.2705	−0.6914	−0.0299
concentration group 4	−0.4874	0.2530	0.0276	0.5309	−0.6449
concentration group 5	−0.4194	−0.5224	−0.6181	−0.3554	−0.2070

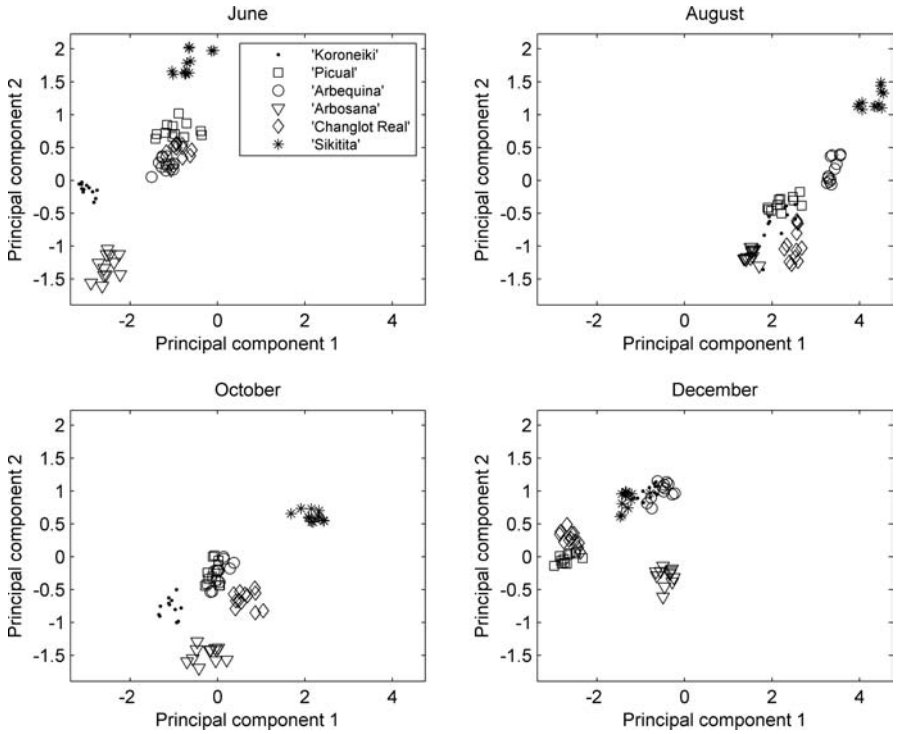

Figure 2. Scatter plots of the first and second principal components for sampling time.

negative coefficient to the first PC (and, therefore, a decrease in this principal component represents a global increase in the phenolic content of the sample). On the other hand, the second principal component is clearly dominated by the concentration of group 2 (although again with a negative coefficient; i.e., a decrease in PC2 can be roughly interpreted as an increase in the concentration of compounds in group 5).

Figures 2 and 3 represent scatter plots of the first and second principal components. To allow a detailed analysis of the PCA study, the scatter plots have been separated by seasons (Figure 2) and cultivars (Figure 3). As can be seen, different cultivars can be separated in the scatter plots: the separation becomes difficult only between 'Picual' and 'Arbequina' in October, with 'Koroneiki' in August and December, and between 'Picual' and 'Changlot Real' in December. This separation reveals a strong dependence of the phenolic profile's seasonal pattern on the cultivar. This dependence has already been described in the paragraph above.

Figure 3 reveals a strong dependence of the phenolic profile on the season, because the points corresponding to each season are clearly separable in each plot. In general, all of the cultivars showed global reductions in their phenolic contents in August (principal component 1 reaches its highest value at this sampling time for all cultivars). The largest increase in phenolic content (lowest value of PC1) was reached in June or December, depending on the cultivar. The plots in Figure 3 evidence again the differences in the seasonal changes associated with each cultivar. According to these results, it can be concluded that the principal component analysis enables separation of the phenolic profile in olive leaves for different seasons and cultivars. This separation capacity is notable because PCA does not aim to discriminate among classes but to represent the maximum variability in the data with the minimum number of components, and reveal changes in the phenolic profile associated with the season (or seasonal changes in the environment) and with the cultivar.

In summary, olive leaves from different cultivars grown in the same orchard under the same environmental conditions and collected at different times showed marked differences in individual and total phenolic compound content. Despite these differences observed among cultivars, all of them showed a similar trend during ripening. The differences among seasons and cultivars should be taken into account for understanding the availability of phenolic compounds in each cultivar and the importance of seasonal changes in the context of the plants' biochemistry. On the other hand, knowledge of the phenolic profile for each season and cultivar is useful when the olive leaves are considered as a source of specific phenolic compounds, because the availability of each compound depends on both the season and the cultivar. To our knowledge, the present study reports the seasonal variability of a large number of phenolic compounds for the first time. At the studied sampling times, June and December seem to be the best periods to use olive leaves as a source of phenolic

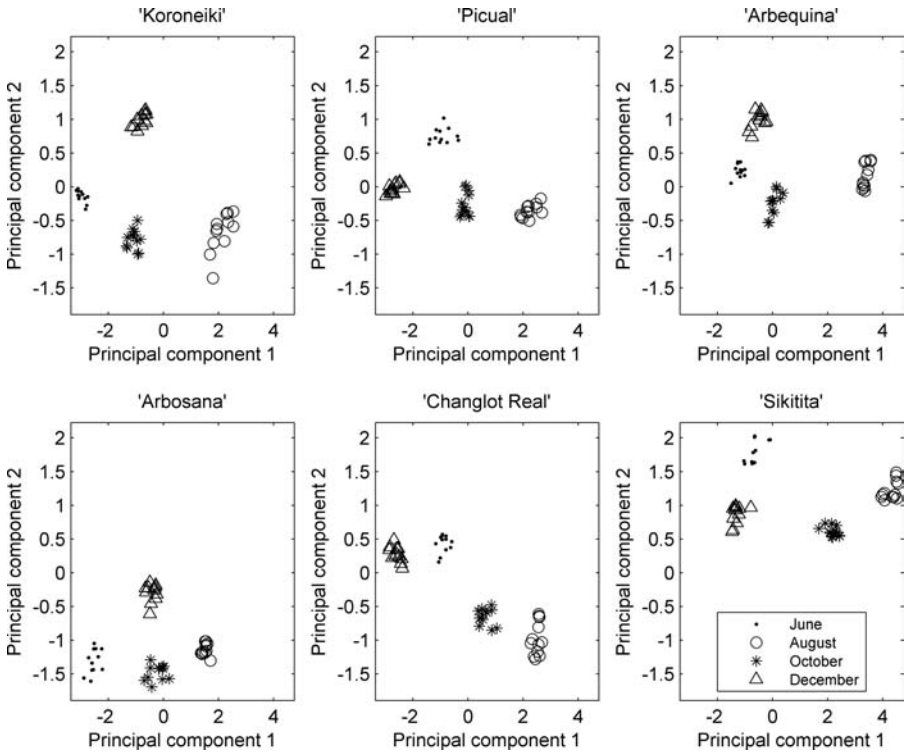

Figure 3. Scatter plots of the first and second principal components for cultivar.

compounds as both of them present similar concentrations of phenolic compounds. In practice, the results shown in December could be rewarding as it coincides with the fruit harvesting period in Andalusia (Spain), the region where the study was performed, during which 432 984 tons of olive leaves is produced annually.[16] In this period, olive leaves could be valorized efficiently as olive byproducts.

MATERIALS AND METHODS

Reagents and Antibodies. 6-Shogaol (6-SH) and 6-gingerol (6-GL) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). *Recombinant human* (*rh*) CCL2 protein was obtained from R&D Systems (Minneapolis, MN, USA).

Cell Culture. Human breast cancer MDA-MB-231, lung cancer A549, mouse mammary tumor 4T1, and Lewis lung carcinoma (LLC) cells were purchased from American Type Culture Collection (ATCC) (Manassas, VA, USA). The MDA-MB-231 cells were cultured in Leibovitz's L-15 medium supplemented with 10% fetal bovine serum (FBS), penicillin, and streptomycin in a CO_2-free incubator. The A549, 4T1, and LLC cells were cultured in F-12K medium (Kaighn's modification of Ham's F-12 medium) or RPMI1640 and DMEM containing 10% FBS in a 5% CO_2 incubator. For the conditioned medium (CM) collection, the MDA-MB-231 and A549 cells (1×10^6) were seeded in a 10 cm dish and the supernatants collected, filtered (0.22 mm), and defined as MDA-CM and A549-CM.

Isolation of $CD14^+$ Monocytes and Differentiation of Monocyte-Derived DCs (mdDCs). Monocytes were purified from peripheral blood mononuclear cells (PBMCs) obtained from healthy consenting donors. Mononuclear cells were isolated from the blood by the Ficoll–Hypaque gradient (GE Healthcare Bio-Sciences, Little Chalfont, UK). $CD14^+$ monocytes were purified using $CD14^+$ monoclonal antibody-conjugated magnetic beads (MACS MicroBeads, Miltenyi Biotec), according to the manufacturer's protocol. Monocyte-derived DCs (mdDCs) were generated by culturing $CD14^+$ monocytes in RPMI 1640 medium containing 10% FBS (Invitrogen, Carlsbad, CA, USA) and 20 ng/mL GM-CSF and 10 ng/mL IL-4 (R&D Systems) with or without 6-SH (1 or 10 μM) for 5 days. The medium was replaced with fresh medium containing GM-CSF and IL-4 on day 3. The hospital's Institutional Review Board approved the study, and all of the patients provided informed consent in accordance with the Declaration of Helsinki. A549 and MDA-MB-231 tumor-associated mdDCs (A549-TADCs) and MDA-MB-231-TADCs were generated by culturing $CD14^+$ monocytes in RPMI 1640 medium containing FBS, GM-CSF, and IL-4 presenting in A549-CM (20%) and MDA-MB-231-CM (20%) with or without 6-SH (1 or 10 μM) for 5 days. After washing, the supernatants were collected, frozen, stored at −80 °C, and thawed singly for the study.

Measurement of Secreted Factors. Supernatants from mdDCs, A549-TADC, MDA-TADCs, 6-shogaol-treated mdDC, and TADC were collected. $CD11c^+F4/80^-$ cells were isolated from mice and cultured in RPMI 1640 medium. After 24 h, the supernatants were harvested. CXCL1, CCL2, and CCL4 levels were quantified using human and mouse MILLIPLEX MAP kits.

Quantitative Real-Time PCR (qRT-PCR). Isolation of RNA was performed using the TRIzol reagent (Invitrogen). cDNA was prepared using an oligo (dT) primer and reverse transcriptase (Takara, Shiga, Japan) following standard protocols. Real-time PCR was performed using SYBR Green on the ABI *StepOnePlus* real-time PCR instrument (Applied Biosystems, Foster City, CA, USA). Each PCR reaction mixture contained 100 nM of each primer, 5 μL of 2× SYBR Green PCR Master Mix (Applied Biosystems, Foster City, CA, USA), 2.5 μL of cDNA, and RNase-free water for a total volume of 10 μL. The PCR reaction was conducted with a denaturation step at 95 °C for 10 min, and then for 40 cycles at 95 °C for 15 s and 60 °C for 1 min. All of the PCRs were performed in triplicate and normalized to internal control glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA. The relative expression is presented using the $2^{-\triangle\triangle CT}$ method.

Tumor Spheroid Formation. A549 and MDA-MB-231 cells were labeled with PKH67 (Sigma-Aldrich) following the manufacturer's procedures. The cells were seeded in ultralow-attachment wells with or without 6-shogaol preset conditioned media (20%) of mdDCs or TADCs for tumor sphere formation. On day 10, the tumor spheres were assessed by fluorescence microscopy or dissociated into single cells for ALDHFLOR analysis.

Flow Cytometry Analysis. Aldehyde dehydrogenases (ALDH) activity was assessed using an ALDHFLOR kit (Stem Cell Tech-

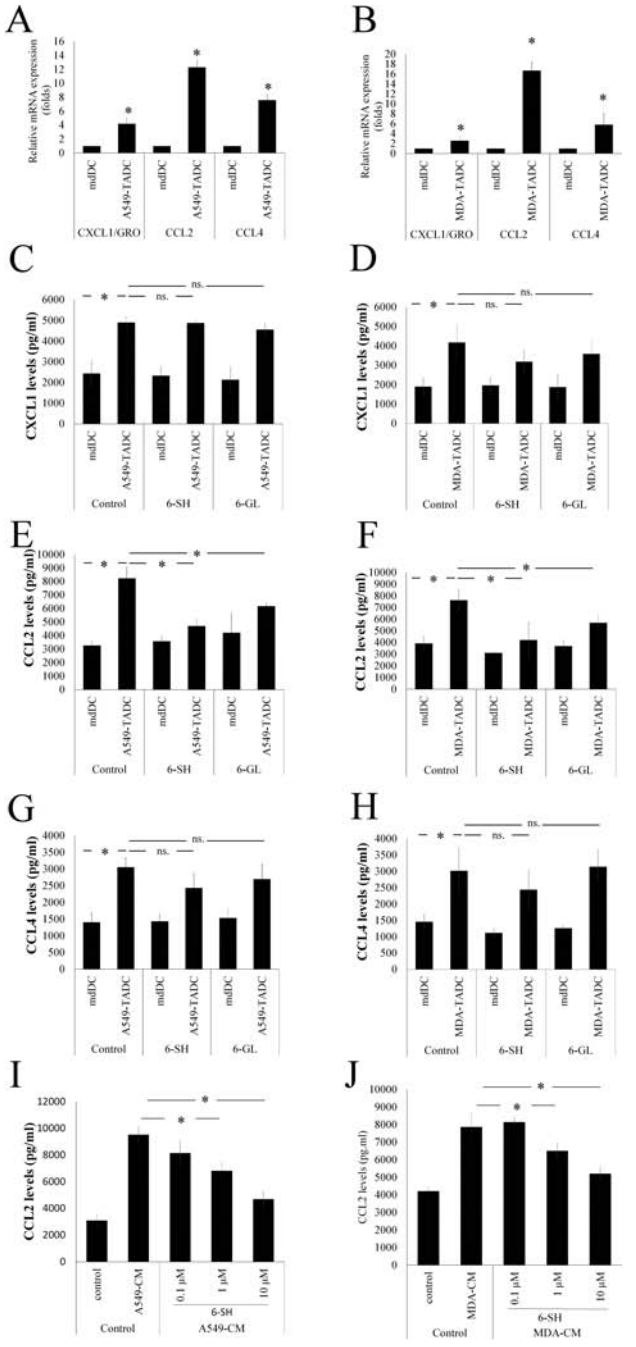

Figure 1. 6-Shogaol and 6-gingerol decreased the expression of CCL2 in TADC: Up-regulation of inflammatory chemokines in (A) A549- and (B) MDA-MB-231-derived TADC, as determined by qRT-PCR. The active components of ginger failed to inhibit the up-regulation of CXCL1 in both (C) A549- and (D) MDA-MB-231-derived TADCs. 6-Shogaol (10 μM) and 6-gingerol (10 μM) decreased the expression of CCL2 in (E) A549- and (F) MDA-MB-231-derived TADCs. 6-Shogaol (10 μM) and 6-gingerol (10 μM) did not affect the stimulatory effect of (G) A549 and (H) MDA-MB-231 cells on CCL4 expression of TADCs. 6-Shogaol decreased the expression of CCL2 in (I) A549 and (J) MDA-MB-231-derived TADCs in a dose-dependent manner. The expression of mRNA and protein was assessed by qRT-PCR and MILLIPLEX MAP kits. All results are representative of at least three independent experiments. The results are reported as the mean ± SD; (*) $p < 0.05$.

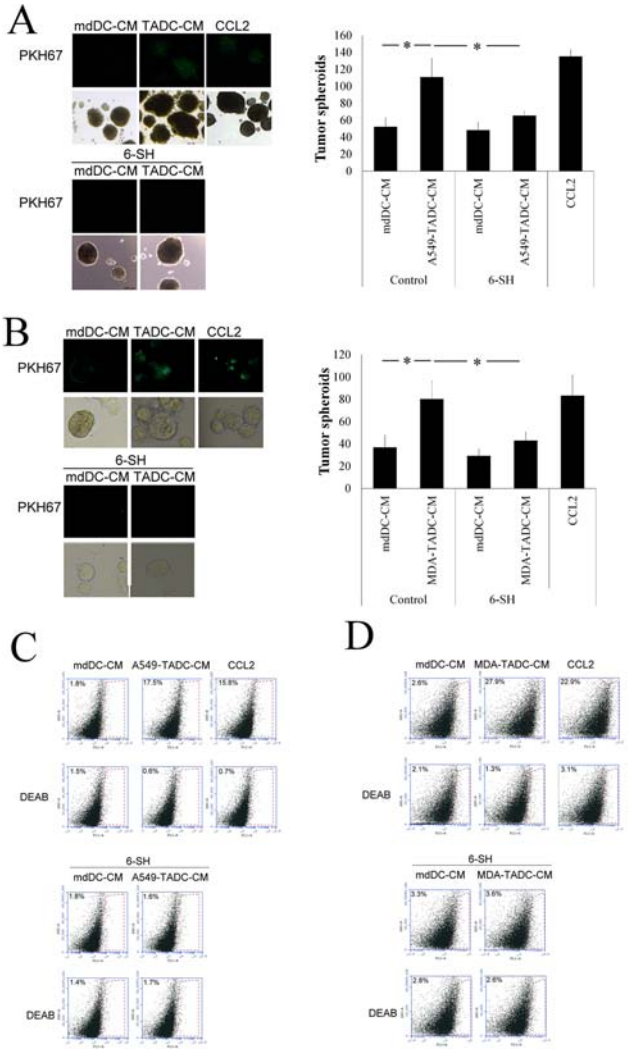

Figure 2. 6-Shogaol decreased TADC-mediated cancer tumorigenesis. 6-Shogaol (10 μM) reduced the stimulatory effect of TADCs on tumor spheroid formation of (A) A549 and (B) MDA-MB-231. 6-Shogaol (10 μM) decreased the up-regulation of TADCs on ALDH activity (C) A549 and (D) MDA-MB-231 tumor spheroids. mdDCs and TADCs (A549-TADCs and MDA-TADCs) were derived by culturing $CD14^+$ monocytes in RPMI 1640 medium containing GM-CSF and IL-4 with or without A549-CM or MDA-CM (20%) for 5 days. 6-Shogaol-treated mdDCs and TADCs were generated by using the same procedure but contained 6-shogaol (10 μM). The supernatants of various DCs were collected. A549 and MDA-MB-231 cells were treated with CMs (20%) of mdDCs, TADCs, 6-shogaol-treated mdDCs, or TADCs in ultralow-attachment wells for 10 days. The tumor spheroids were stained by PHK67 and counted by fluorescence microscope, and ALDH activity was determined by ALDHEFLUOR kit. All results are representative of at least three independent experiments. The results are reported as the mean ± SD; (*) $p < 0.05$.

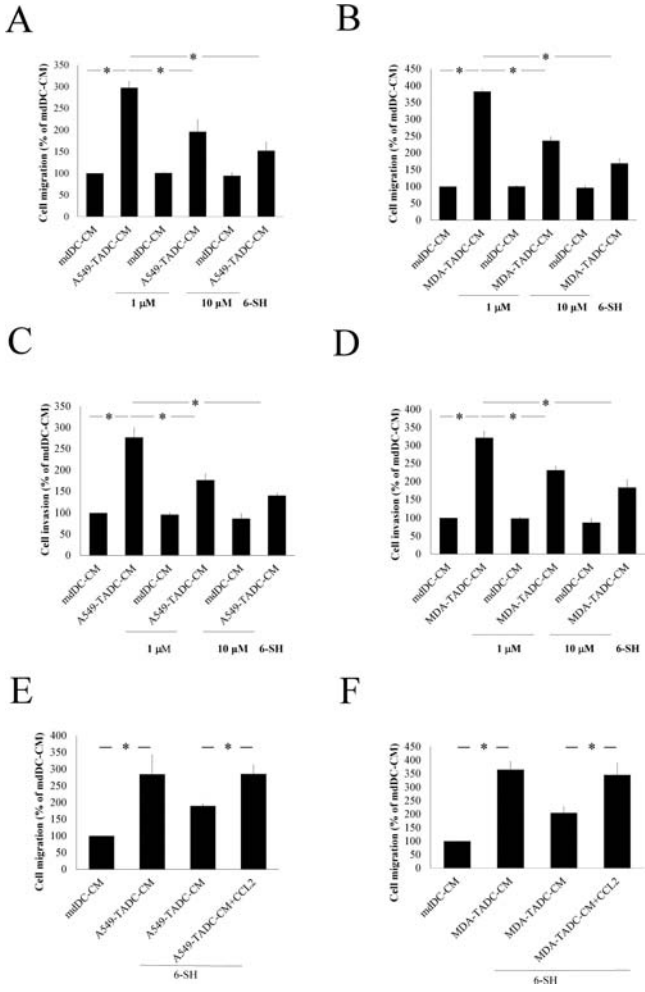

Figure 3. 6-Shogaol decreased TADC-mediated cancer progression. 6-Shogaol (1 and 10 μM) decreased the stimulatory effect of TADCs on migration of (A) A549 and (B) MDA-MB-231. 6-Shogaol reduced the enhanced effect of TADCs on the invasion of (C) A549 and (D) MDA-MB-231 cells. The addition of CCL2 reversed the inhibitory effect of 6-shogaol on TADC-mediated cell migration in (E) A549 and (F) MDA-MB-231 cells. mdDCs and TADCs (A549-TADCs and MDA-TADCs) were derived by culturing $CD14^+$ monocytes in RPMI 1640 medium containing GM-CSF and IL-4 with or without A549-CM or MDA-CM (20%) for 5 days. 6-Shogaol-treated mdDCs and TADCs were generated by using the same procedure but contained 6-shogaol (1 or 10 μM). A549 and MDA-MB-231 cells were seeded into the top transwell insert, and the various CMs of mdDCs, TADCs, 6-shogaol-treated mdDCs, or TADCs were added to the bottom cells as chemoattractant for 24 h (for migration) or 48 h (for invasion). The invasive and migration abilities of the A549 and MDA-MB-231 cells were quantified by CyQUANT GR dye. All results are representative of at least three independent experiments. The results are reported as the mean ± SD; (*) $p < 0.05$.

nologies, Vancouver, BC, Canada). Briefly, cells were incubated in Aldefluor assay buffer containing ALDH substrate (1 μmol l^{-1} per 1×10^6cells), with or without diethylaminobenzaldehyde (DEAB), a specific ALDH inhibitor. After incubation at 37 °C for 30 min, the cells were centrifuged and resuspended in cold Aldefluor buffer. ALDH activity was determined by an Acuri C6 flow cytometer (Becton Dickinson Immuno-cytometry Systems). The cells isolated from the lungs and mammary tumors of mice were stained by antibodies against mouse CD11b labeled by FITC (BD Biosciences, San Jose, CA, USA) and F4/80 labeled by allophycocyanin (APC) (Biolegend). The expression of each molecule was analyzed using an Acuri C6 flow cytometer (BD Biosciences).

Cell Migration and Invasion Analysis. A quantitative migration and invasion assay was conducted using the QCM 24-well Cell Migration Assay and Invasion System (Millipore Corp., Billerica, MA, USA). Briefly, 3×10^4 A549 or MDA-MB-231 cells were seeded into the top chamber, and CMs of mdDC, TADC, 6-shogaol-treated mdDC, and TADC were added to the bottom wells as chemoattractant for 24 h (for migration) or 48 h (for invasion). At the end of treatment, the cells were poststained with CyQuant GR dye in cell lysis buffer for 15 min at room temperature. Fluorescence

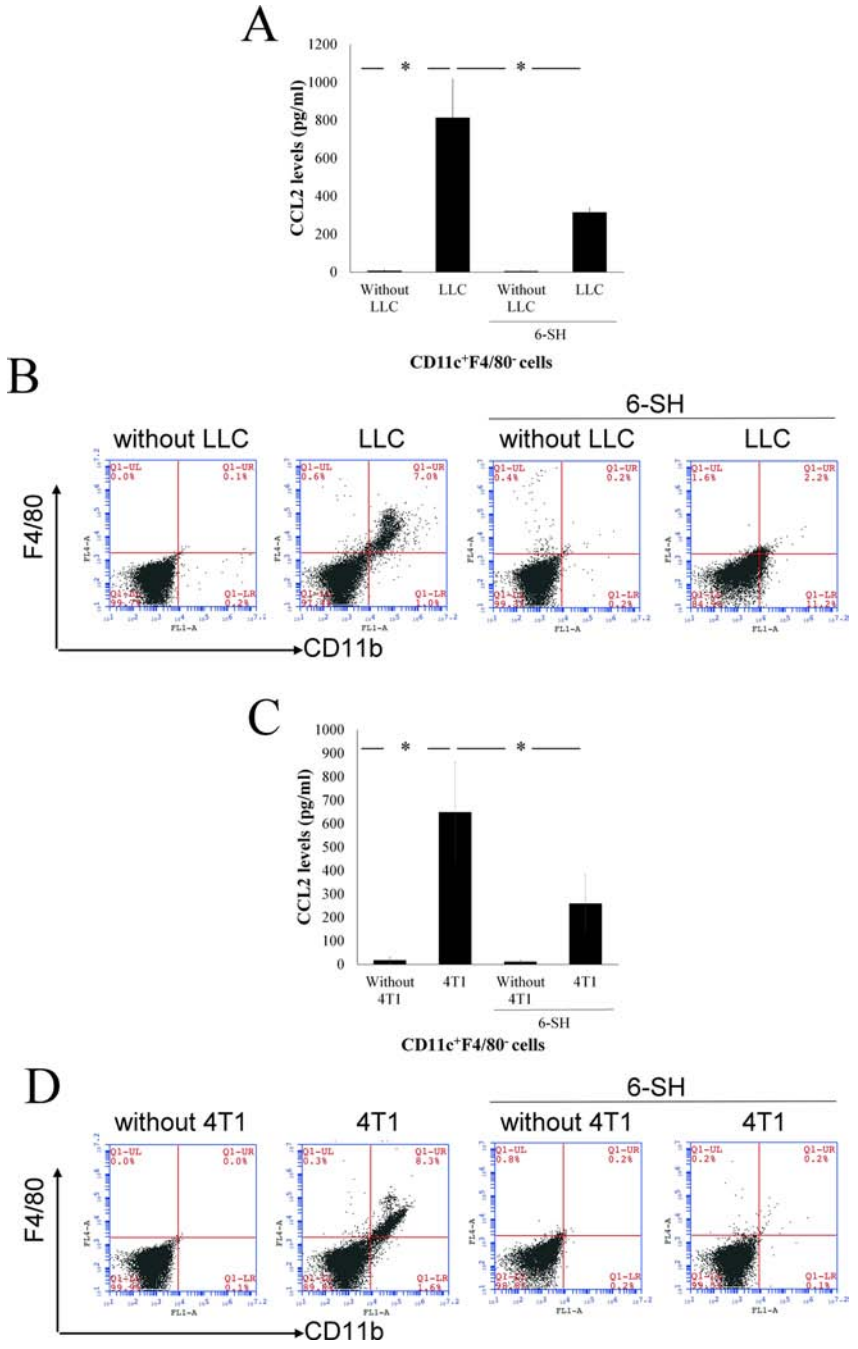

Figure 4. 6-Shogaol reduced CCL2-mediated immunosuppression in vivo. 6-Shogaol decreased the (A) CCL2 expression of CCL2 of TADCs and (B) TAM infiltration in LLC-transplanted mice. 6-Shogaol decreased the (C) CCL2 expression of TADCs and (D) TAM infiltration in 4T1-transplanted mice. 4T1 cells were implanted into mammary fat pads of BALB/c mice, and LLC cells were implanted into C57BL mice via tail vein injection. The mice were then randomly divided into two groups: the 6-shogaol-treated group was given ip daily with 6-shogaol (dose = 30 mg/kg of body weight), whereas the control group was given an equal volume of normal saline. Tumor-bearing mice were sacrificed 14 days after transplantation. TADC ($CD11c^+$, $F4/80^-$) and TAM ($CD11b^+$) cells were isolated from lungs (LLC) and mammary tumors (4T1). The subgroups of immune cells were determined by staining of surface markers and by flow cytometry analysis. All results are representative of at least three independent experiments. The results are reported as the mean ± SD; (*) $p < 0.05$.

of the migratory or invaded cells was read using a fluorescence plate reader at excitation and emission wavelengths of 485 and 540 nm, respectively.

Immunoblot Analysis. $CD14^+$ monocytes (4×10^6) were pretreated with 6-shogaol for 1 h and the A549- or MDA-MB-231-CMs were added for 30 min. Total cell extracts were prepared in RIPA lysis buffer (Millipore). Equivalent amounts of protein were resolved by the SDS-PAGE and transferred to PVDF membranes. After the membranes were blocked in Tris-buffer saline containing 0.05% Tween 20 (TBST) and 5% nonfat powdered milk, they were incubated with primary antibodies against p-STAT3, STAT3, and GAPDH (Cell Signaling Technology) at 4 °C overnight. After three washings with TBST, the membranes were incubated with horseradish peroxidase-labeled secondary antibody for 1 h and then rewashed. Detection was performed using an enhanced chemiluminescence blotting detection system (Millipore).

Chromatin Immunoprecipitation (ChIP). ChIP was conducted according to the protocol of the Pierce Agarose ChIP kit (Pierce, Thermo Scientific, Rockford, IL, USA). Immunoprecipitation was

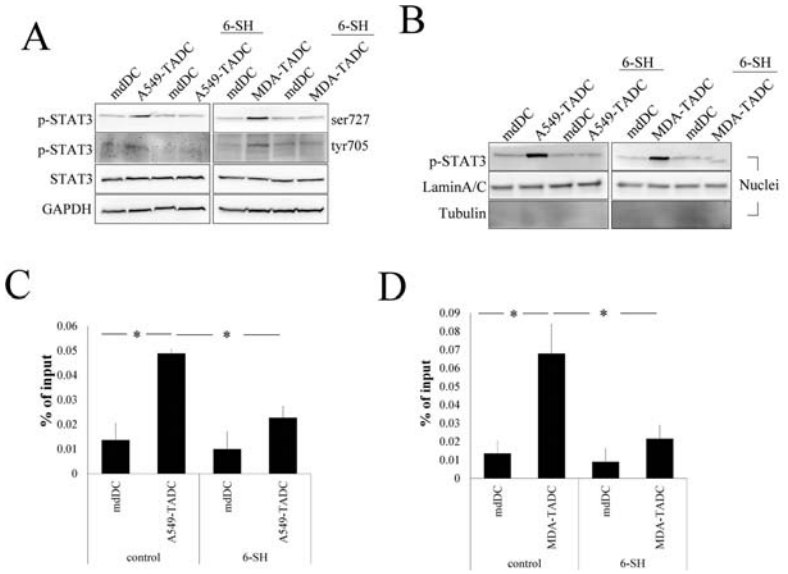

Figure 5. Effect of 6-shogaol on STAT3 activation in TADCs. 6-Shogaol (10 μM) decreased the phosphorylation of STAT3 in (A) A549-TADCs and MDA-MB-231-TADCs. (B) 6-Shogaol (10 μM) inhibited active STAT3 in the nuclear fraction in A549- and MDA-MB-231-TADCs. It also reduced the DNA binding of STAT3 on the promoter of CCL2 in (C) A549- and (D) MDA-MB-231-TADCs. $CD14^+$ monocytes were pretreated with 6-shogaol (10 μM) for 1 h, and then A549 or MDA-MB-231-CM was added for 30 min. The phosphorylation of STAT3 was assessed by immunoblot. STAT3 activity was assessed by ChIP analysis. All results are representative of at least three independent experiments. The results are reported as the mean ± SD; (*) $p < 0.05$.

conducted using anti-STAT3 transcription factors (Cell Signaling Technology) or by normal rabbit IgG (Cell Signaling Technology) as the negative control. Input DNA and immunoprecipitated DNA were analyzed by quantitative PCR. Primer sequences were obtained from Qiagen (GPH1005667(−)01A).

Lung Metastasis of Lung and Breast Cancer in Vivo. Male C57BL and female BALB/c mice (5−6 weeks old) from the National Science Council Animal Center (Taipei, Taiwan) were maintained in pathogen-free conditions. 4T1 cells (2×10^6) were implanted into mammary fat pads of BALB/c mice and LLC cells were implanted into C57BL mice via tail vein injection. The mice were then randomly divided into two groups: the 6-shogaol-treated group was given a daily intraperitoneal injection (ip) of 0.2 mL of 6-shogaol (dose = 30 mg/kg of body weight), whereas the control group was given an equal volume of normal saline. Tumor-bearing mice were sacrificed 14−21 days after transplantation. Lung (LLC-bearing mice) and mammary tumors (4T1-bearing mice) were collected and minced. Single-cell suspensions were obtained after enzymatic digestion (1 mg/mL collagenase A; Roche Diagnostics) and 100 IU/mL type I DNase (Sigma-Aldrich) for 2 h at 37 °C and 5% CO_2 in RPMI 1640 medium. A single-cell suspension was filtered through a 70 μm nylon mesh (BD Biosciences), and cells were washed twice by PBS. $CD11c^+$ and $CD11b^+$ cells were purified using anti-CD11c or CD11b monoclonal antibody-conjugated magnetic beads (MACS MicroBeads, Miltenyi Biotec). $F4/80^+$ cells were depleted from $CD11c^+$ cells by using $F4/80^+$ antibody−biotin beads (Miltenyi Biotec). Alternatively, the lungs were removed and the metastatic tumor nodules counted. All animal experiments were performed according to a protocol approved by the Institutional Animal Care and Use Committee of Kaohsiung Medical University Hospital.

Statistical Analysis. Data are expressed as the mean ± SD. Statistical analyses between control and experimental groups were analyzed by an unpaired Student's t test. Multiple comparisons were evaluated by a one-way ANOVA, and differences in the mean values among groups were conducted by a Fischer post hoc analysis. p values <0.05 were considered to be statistically significant.

RESULTS

Lung Cancer- and Breast Cancer-Derived TADCs Secrete High Levels of CCL2, Which Are Decreased by 6-Shogaol and 6-Gingerol. Previous studies and data show that lung cancer A549 and breast cancer MDA-MB-231 cells increase the expression of some inflammatory chemokines in TADCs.[6] This study therefore assessed whether the active components of ginger, 6-shogaol (6-SH) and 6-gingerol (6-GL), could decrease the expression of these cytokines/chemokines in TADCs. The qRT-PCR data demonstrated that A549- and MDA-MB-231-CMs (MDA-CM) increased levels of CXCL1 (chemokine (C-X-C motif) ligand 1), CCL2, and CCL4 (chemokine (C-C motif) ligand 4) mRNA transcripts in TADC, when compared to mdDCs (Figure 1A,B). As determined by ELISA, the CMs of lung and breast cancers increased the expressions of CXCL1, CCL2, and CCL4 in protein levels in TADCs (Figure 1C−H). 6-Shogaol decreased the production of CCL2 in TADCs in protein levels (Figure 1E,F). The inhibitory effect of 6-shogaol on CCL2 secretion in TADCs was greater than that of 6-gingerol. In addition, 6-shogaol decreased the expression of CCL2 in TADCs in a dose-dependent manner ranging from 0.1 to 10 μM (Figure 1I,J). Neither 6-shogaol nor 6-gingerol prevented the stimulative effect of cancers on the expression of CXCL1 and CCL4 in TADCs (Figure 1C,D,F,G). To eliminate the possibility of cytokines being reduced due to altered cell viability, we assessed the effect of 6-shogaol and 6-gingerol (0.1−10 μM) on the cell viability of TADCs. The data show that 6-shogaol and 6-gingerol do not affect the viability of TADCs (data not shown).

6-Shogaol Decreases the Effect of TADC-Derived CCL2 on the Formation of Tumor Spheroids, Migration, and Invasion. Because CCL2 has been reported to increase cancer-stem cell like property and enhance cancer progression,[20] this study assessed the effect of 6-shogaol on the bioactivities of TADC-derived CCL2. The stem cell-like phenotype is determined by tumor spheroid formation and aldehyde dehydrogenase (ALDH) activity. A549- and MDA-MB-231-TADC-CM increased tumor spheroid formation in A549 and MDA-MB-231 cell lines, respectively (Figure 2A,B). However, TADCs lost their inductive effect on tumor spheroid formation if they were generated in the presence of 6-shogaol

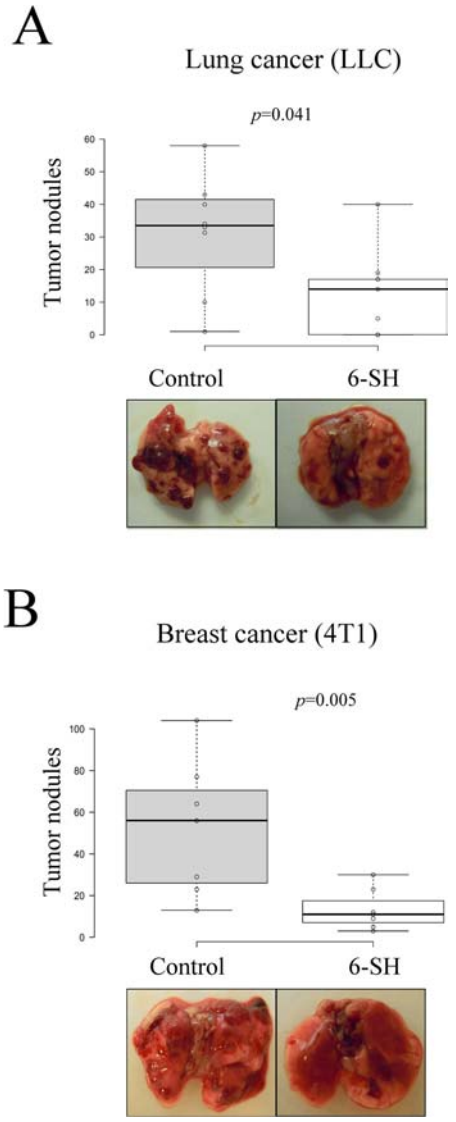

Figure 6. 6-Shogaol decreased cancer metastasis in vivo. 6-Shogaol decreased the metastasis of (A) LLC and (B) 4T1 in mice. 4T1 cells were implanted into mammary fat pads of BALB/c mice, and LLC cells were implanted into C57BL mice via tail vein injection. The mice were then randomly divided into two groups: the 6-shogaol-treated group was given ip daily 6-shogaol (dose = 30 mg/kg of body weight), whereas the control group was given an equal volume of normal saline. Tumor-bearing mice were sacrificed 14 (for LLC) or 21 (for 4T1) days after transplantation. Their lungs were removed and the metastatic tumor nodules counted. Each value is the mean ± SD of three determinations. (*) Significant difference between the two test groups, as analyzed by Student's *t* test ($p < 0.05$).

(Figure 2A,B). The PKH^{high} cells undergo fewer divisions during sphere formation, which implies they possess a stem cell phenotype, in contrast to high proliferation nonstem PKH^{low} cells. The ratio of PKH^{high} cells increased in tumor spheroids cultured in TADC-CMs when compared to those cultured in mdDC-CMs. 6-Shogaol treatment decreased the ratio of PKH^{high} cell population in tumor spheroids, revealing 6-shogaol reduces the stem cell characteristics in both lung and breast cancers (Figure 2A,B). Moreover, the activity of ALDH, a stem cell marker, was enhanced in tumor spheroids cultured in TADC-CMs when compared to those cultured in mdDC-CMs. However, the ALDH activity of tumor spheroids was reduced when the TADCs were generated in the presence of 6-shogaol (Figure 2C,D). We next assessed the effect of 6-shogaol on TADC-mediated cancer progression. A549- and MDA-MB-231-TADC-CM increased A549 and MDA-MB-231 cell migration, respectively. However, TADCs lost their inductive effect on cancer migration if they were generated in the presence of 6-shogaol (Figure 3A,B). Similarly, A549- and MDA-MB-231-TADC-CM increased cell invasion in A549 and MDA-MB-231 cells, but not if the TADC-CMs were derived in the presence of 6-shogaol (Figure 3C,D). In contrast, the addition of rhCCL2 reduced the inhibitory effect of 6-shogaol on TADC-mediated A549 and MDA-MB-231 cell migration (Figure 3E,F).

6-Shogaol Improves CCL2-Mediated Immunosurveillance in Lung and Breast Cancers in Vivo. Because CCL2 increases immunosuppressive response by decreasing macrophage infiltration in mice with cancer,[20] this study assessed if 6-shogaol could alter immunosurveillance in mice. LLCs were transplanted into mice by tail vein injection. The mice were sacrificed after 14 days, and TADC ($CD11c^+F4/80^-$) cells from metastatic tumor nodules in the lungs were isolated and examined. CCL2 expression in TADCs ($CD11c^+/F4/80^-$) of the lungs of mice with LLC transplantation was higher than the dendritic cells isolated from the lungs of normal mice. Administration of 6-shogaol decreased CCL2 levels in TADCs of the lungs of mice with LLC transplantation (Figure 4A). 6-Shogaol treatment also decreased tumor-associated macrophage (TAM) ($CD11b^+F4/80^+$) infiltration when compared to vehicle-treated mice with LLC transplantation (Figure 4B). To assess the effect of 6-shogaol on immunosurveillance in breast cancer in vivo, 4T1 was implanted in the mammary fat pads of mice. On day 14 post-tumor implantation, TAM and TADCs were isolated from both mammary tissue and lungs with metastatic 4T1 tumors. 4T1 breast cancer cells also had increased CCL2 expression in TADCs when compared to dendritic cells isolated from normal mammaries. This CCL2 up-regulation was inhibited by 6-shogaol administration (Figure 4C). Similarly, TAM infiltration also decreased in 6-shogaol-treated mice (Figure 4D).

6-Shogaol Decreases CCL2 Expression by Inhibiting STAT3 Activation in TADCs. Because STAT3 was reported to bind to and activate the promoter of *CCL2*,[20] this study assessed if 6-shoagol could decrease the activation of STAT3. The CMs of lung cancer A549 and breast cancer MDA-MB-231 cells increased the phosphorylation of STAT3 in TADCs more than in mdDCs (Figure 5A). The CMs of lung and breast cancers also enhanced the nuclear translocation of activated STAT3 (Figure 5B). These effects, including STAT3 activation and nuclear translocation, were inhibited by 6-shogaol in TADCs. ChIP analysis further revealed that CMs of A549 and MDA-MB-231 cancer increased the binding of STAT3 on the promoter of CCL2 gene, but this was inhibited by 6-shogaol treatment (Figure 5C,D).

6-Shaogol Decreases Metastasis in Lung and Breast Cancers in Vivo. To assess the activity of 6-shogaol on the metastasis of lung and breast cancers, LLC (by tail vein injection) and 4T1 (by mammary fad pad implantation) were transplanted into mice, which were sacrificed after 14 and 21 days, respectively. The tumors in the lungs of mice were collected and counted. 6-Shogaol treatment decreased the number of LLC tumor nodules in mice (Figure 6A). Similarly, 6-shogaol also reduced the lung metastasis of breast cancer 4T1 in mice (Figure 6B).

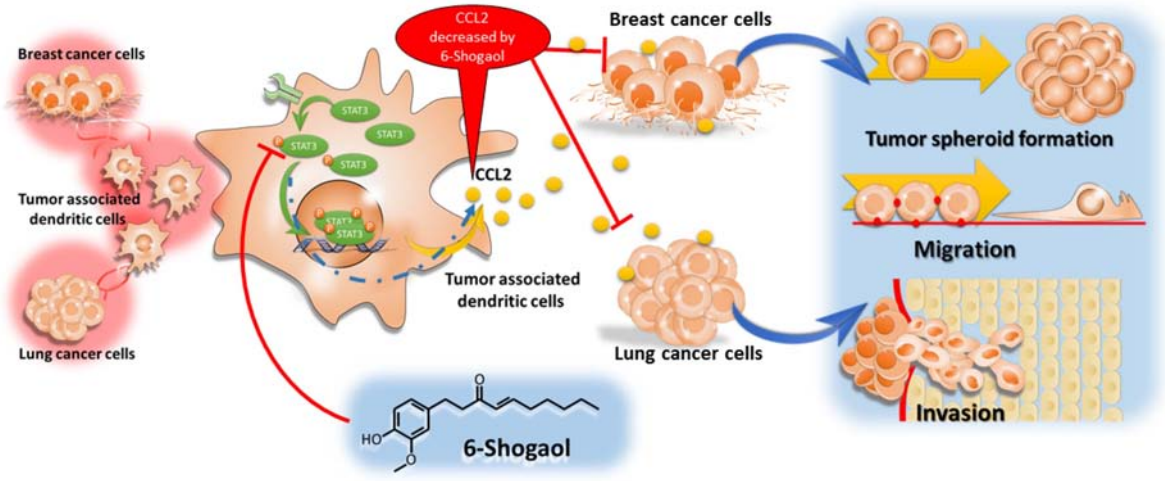

Figure 7. Scheme of proposed 6-shogaol impairment of cancer development and lung metastasis by inhibiting the secretion of CCL2 in tumor-associated dendritic cells.

DISCUSSION

Tumor microenvironment is characterized by a stroma of hematopoietic precursors, inflammatory immune cells, dysregulated vessel endothelial cells, and proteolytic enzymes.[21,22] TADCs have been shown to lose their antigen-presenting function and also to promote cancer progression by modulating multiple components in the cancer niche, thereby creating a permissive and supportive microenvironment for tumor survival, proliferation, and spread.[7,23,24] This study has two novel findings. It is the first study to demonstrate that TADCs facilitate lung and breast cancer metastasis in vitro and in vivo by secreting inflammatory mediator CCL2. It is also the first study to demonstrate that 6-shogaol decreases cancer development and progression by inhibiting the production of TADC-derived CCL2 (Figure 7).

CCL2 has been implicated in cancer progression and metastasis. Serum CCL2 levels are significantly correlated to the cancer stage and have been shown to have significant prognostic value for relapse-free survival.[25−27] CCL2 appears to play a dual role in regulating tumor immunosurveillance and in sustaining the development and advancement of established malignancy. CCL2 has also been implicated in directly affecting cancers by switching the cancer stem cell-like phenotype and by enhancing cancer cell survival, growth, angiogenesis, migration, and metastasis.[28,29] It has also been reported to indirectly facilitate carcinogenesis and metastasis by altering the host's immune response, including the accumulation of suppressive immune cells TAM, MDSCs, and regulatory DC and T cells.[20,30−32] CCL2 expression is modulated in the interaction between tumor and niche cells, including fibroblasts and adipocytes.[20,30]

This study demonstrates that cancer cells stimulate TADCs to express high levels of CCL2, which in turn increase tumorigenesis by increasing cancer stem cell-like properties. TADC-derived CCL2 also increases cancer migration and invasion, key characteristics of metastatic cancer. However, these enhancing effects of TADCs on cancer development are prevented by 6-shogaol treatment in vitro and in vivo. 6-Shogaol administration decreases immunosuppressive TAM infiltration in cancer, suggesting that 6-shogaol may restore the host's immune system.

Accumulating evidence supports a role for the STAT3 pathway in the establishment of the inflammatory microenvironment. Constitutively activated STAT3 can drive various pro-tumorigenic and inflammatory mediator expressions in cancer cells per se, as well as in niche cells.[20,33,34] Breast cancer stimulates fibroblasts to express high levels of CCL2 via a STAT3-dependent mechanism, resulting in increased tumorigenesis. In contrast, inhibition of STAT3 in DCs enhances its ability to prime T cells that have elevated IFNγ production,[35] suggesting that STAT3 is a potential target for developing a strategy that restores the host's immunity against tumors.

The results of this study reveal that cancer increases the activation and DNA binding activity of STAT3, which in turn enhances the expression of CCL2 in TADCs. 6-Shogaol decreases the cancer-induced activation of STAT3, subsequently reducing CCL2 levels in TADCs. According to the studies presented here, 6-shogaol may have a novel mechanism for inhibiting STAT3 activation in TADCs, resulting in decreased pro-tumorigenesis and inflammatory mediators in cancer niches.

In summary, this study provides novel insights for understanding the paracrine interaction initiated by cancer cells to induce CCL2 production by TADCs. TADC-derived CCL2 promotes cancer progression by regulating cancer stem cell-like properties, migration/invasion, and immunosuppressive immune cell infiltration. 6-Shogaol has also been demonstrated to inhibit the effect of TADCs on cancer tumorigenesis and progression by decreasing CCL2 production. 6-Shoagol also reduces the accumulation of immunosuppressive cells, suggesting that 6-shogaol may serve as a future therapeutic agent for efficiently blocking the cancer−DC interaction to overcome immune dysregulation and cancer progression.

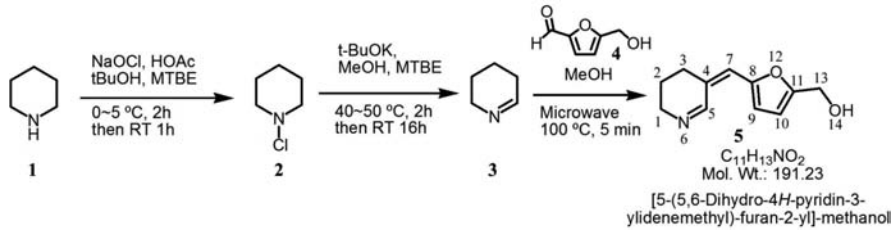
Scheme 1. Synthesis of F3-A



MATERIALS AND METHODS

Preparation and Separation of [5-(5,6-Dihydro-4*H*-pyridin-3-ylidenemethyl)furan-2-yl]methanol (F3-A). We repeated our original MR protocol to recover F3-A from a heated aqueous Glc-Lys MR mixture.[4] Briefly, D-glucose (0.8 mol/L) was mixed with L-lysine monohydrochlide (0.8 mol/L) in 100 mL of ddH_2O and adjusted to pH 7. The mixtures were autoclaved (Laboratory VMP, Cliton, NJ) at 121 °C for 60 min in screw-capped glass bottles and then rapidly chilled on ice and centrifuged at 3400×*g*. In a preliminary experiment to increase the yield of F3-A on extraction, MR mixtures were adjusted to pH 2, 6, and 12, respectively, and then extracted with chloroform. We found that F3-A was recovered in the chloroform fraction at a higher amount when the pH was adjusted to 12. Therefore, in the following experiment, the supernatant was adjusted to pH 12 using sodium hydroxide, followed by extraction with chloroform, three times using a 2:1 (v/v) ratio. Pooled chloroform fractions were collected and evaporated under reduced pressure using a rotary evaporator. The concentrated sample (around 1 g) was redissolved in 10 mL of dichloromethane (DCM) and loaded onto a glass column (3 × 25 cm) packed with 50 g of silica gel (32−63 μm, 230−400 mesh, Selecto Scientific, Georgia). The column was sequentially eluted with 200 mL of DCM, 90% DCM/10% MeOH, 80% DCM/20% MeOH, 70% DCM/30% MeOH, and 60% DCM/40% MeOH, respectively, using flash chromatography. Eluents (20 mL/per tube) were collected, and the presence of F3-A in the eluent was detected using both analytical thin layer chromatography (TLC) and HPLC. TLC was performed using aluminum plates precoated with silica gel 60F-254 (EMD Millipore Corporation, Billerica, MA). Plates were developed in DCM:MeOH (8:2, v/v) mixture and air-dried. F3-A with a retention factor (Rf) of 0.53 on the plate was visualized using a $KMnO_4$ staining solution, followed by air drying. The eluent containing F3-A collected from the silica column was combined and evaporated under vacuum. The concentrated crude extract was reloaded onto a newly prepared silica gel column and eluted with 100 mL of dichloromethane, 200 mL of 90% DCM/10% MeOH, 300 mL of 80% DCM/20% MeOH, and 100 mL of 70% DCM/30% MeOH, respectively. TLC analysis identified tube 19 containing F3-A which was used for NMR and high-resolution mass spectrometry analysis. This fraction was named F3-AC19. Purity of F3-A in the F3-AC19 fraction was greater than 95%, as determined by NMR.

Synthesis of [5-(5,6-Dihydro-4*H*-pyridin-3-ylidenemethyl)-furan-2-yl]methanol (F3-A). Scheme 1 shows the procedures to synthesize intermediate compounds and F3-A.

*N-Chloropiperidine (**2**).* In a 500 mL, 3-neck round-bottom flask was added methyl *tert*-butyl ether (MTBE, 160 mL), piperidine (5 mL, 50 mmol), and *t*-BuOH (2.4 mL, 25 mmol). The solution was cooled to 0 °C in an ice/water bath. Bleach (active ingredient NaOCl, nominal 5% active chlorine, 0.5 M, 110 mL) and acetic acid (3.2 mL, diluted with 3.2 mL of water) were added simultaneously from two dropping funnels, at a rate that maintained internal temperature below 10 °C. The mixture was stirred at 0 °C for 1 h, and the organic phase was separated leaving the aqueous phase which was extracted with MTBE (100 mL). The combined organic fractions were dried with Na_2SO_4 and filtered. This solution was used in the next step without isolation or purification.

*1,2-Dehydropiperidine (**3**).* To the above filtrate kept at 0 °C in an ice/water bath was added solid *t*-BuOK (11.2 g, 100 mmol) in one batch, followed by MeOH (80 mL, in 10−20 mL portions). The mixture was heated in a warm water bath (∼50 °C) for 2 h and then cooled in an ice/water bath overnight. The mixture was diluted with water to dissolve solids, and the aqueous layer was then extracted twice with MTBE (100 mL). The combined organic phases were dried with Na_2SO_4 and concentrated by rotary evaporation to yield an oily, pale yellow residue, 1,2-dehydropiperidine (dHP, **3**, ∼4 g). This crude material was stored in a −20 °C freezer and used in the next step without further purification.

*[5-(5,6-Dihydro-4H-pyridin-3-ylidenemethyl)-furan-2-yl]-methanol (**5**).* HMF (**4**, 160 mg, 1.3 mmol) was dissolved in MeOH (500 μL) in a BioTage 0.5−2 mL microwave vial, and dHP (**3**, 300 mg, 3.6 mmol) was added. The vessel was sealed and irradiated using microwave set at 100 °C for 5 min. In a separate reaction, HMF (**4**, 260 mg, 2.1 mmol) and dHP (**3**, 500 mg, 6.0 mmol) were reacted in the same manner. The two runs were combined and purified by dry-loading flash chromatography on a SiliCycle SiliaSep-HP 12 g cartridge performed on a BioTae Isolera instrument using a 2−20% MeOH/DCM linear gradient as the eluent. Fractions with significant 370 nm absorption were pooled and concentrated to thick oil, which solidified upon standing. Trituration in MTBE (∼2 mL) gave a crystalline powder that was filtered and washed with MTBE (total ∼10 mL in 3 portions). Drying on high vacuum at room temperature gave F3-A (**5**) as light brown powder, 186 mg (yield 29.2%). The synthesized F3-A was named F3-AS. ^{1}H NMR (500 MHz, DMSO) δ: 7.92 (s, 1 H), 6.62 (d, J = 3.3 Hz, 1 H), 6.53 (s, 1 H), 6.43 (d, J = 3.3 Hz, 1 H), 5.31 (s, 1 H), 4.42 (s, 2 H), 3.54 (td, J = 5.6, 1.8 Hz, 2 H), 3.33 (s, 4 H), 2.66 (td, J = 6.8, 1.9 Hz, 2 H), 1.74−1.49 (m, 2 H) ppm. ^{13}C NMR (126 MHz, DMSO) δ: 161.85, 156.97, 150.97, 128.29, 122.29, 114.23, 109.47, 55.77, 48.67, 24.28, 20.78 ppm.

Determination of Optimal Reaction Conditions for F3-A Production Using Taguchi Orthogonal Design. A four-factor /four-level (L16 (4^4)) Taguchi orthogonal array (Table 1) was chosen

Table 1. Taguchi Orthogonal Array and F3-A and HMF Yield[a]

exp. no.	S:AA ratio	pH	T (°C)	t (min)	F3-A (μg/g)	HMF (μg/g)

to investigate the effects of four different reaction conditions including sugar:amino acid ratio, pH, heating temperature, and heating time on the yield of F3-A in a Glc-Lys MR mixture. The experiments were performed in triplicate over three concessive days. Glucose was mixed with L-lysine (0.8 mol/L) at sugar to amino acid ratios (mole ratio) of 0.5:1, 1:1, 2:1, or 3:1 in ddH_2O, and pH was adjusted to 5, 6, 7, or 8, respectively, using concentrated HCl. The mixtures (100 mL) were put in capped glass bottles and heated in an oven (Blue M electronic company, Blue Island, IL) at 70, 80, 90, or 100 °C, for 30, 60, 90, or 120 min time periods, respectively, after which they were rapidly chilled on ice. An aliquot (15 mL) of sample was stored at −20 °C for further analysis, and the remainder was freeze-dried.

Effects of Reactants and Concentration and Heating Time on the Yield of F3-A. According to the optimal conditions from Taguchi design, glucose was mixed with L-lysine at sugar to amino acid (S:AA) mole ratios of 0.2:0.1, 0.4:0.2, 0.8:0.4, or 1.6:0.8 in distilled deionized water, and the pH was adjusted to 6 using 1 N HCl. The mixtures were heated at 100 °C for 1.5, 3, 6, 9, 12, and 24 h, respectively, in an oven (Blue M electronic company, Blue Island, IL) and then rapidly chilled on ice. The yield of F3-A was measured using HPLC, and F3-AS was used as standard. To determine if specific sugars produced relatively greater F3-A, we also compared yield derived from fructose, glucose, sucrose, and lactose (1.6 mol/L), respectively, mixed with lysine (0.8 mol/L) at an adjusted pH 6. The mixtures were heated at 100 °C for 4 h, and the yield of F3-A was measured using HPLC.

HPLC Analysis. F3-A was detected by analytical reverse phase HPLC using an Agilent 1100 LC system (Agilent, Santa Clara, CA) equipped with a Zorbax SB-C18 column (4.6 × 150 mm, 3.5 μm, Agilent, U.S.A.) and monitored with a diode array detector (DAD) at 370 and 385 nm. A linear gradient comprised of 5−20% MeOH/0.2% formic acid delivered at a flow rate of 1 mL/min for 6 min was used to separate the sample components. The column temperature was set at 30 °C.

FTIR and UV−Vis Spectrophotometry Analysis. F3-AC19 and F3-AS were dissolved in methanol, and Fourier transform infrared spectroscopy (FTIR) spectrum on both samples was measured by PerkinElmer Spectrum 100 FTIR spectrometer with a horizontal attenuated total reflectance (HATR) sampling accessory. For ultraviolet−visible (UV−vis) spectrophotometry, F3-AC19 and F3-AS were dissolved in MeOH or 0.002% formic acid/ddH_2O at a concentration of 0.02 mg/mL, respectively. UV-vis spectrum 200−700 nm was recorded using a spectrophotometer (Multiskan Ascent, Thermo-Labsystems, Finland).

HRMS. High-resolution mass spectrometry (HRMS) of F3-AC19 was conducted using a Bruker maXis Impact Ultra-High Resolution tandem time-of-flight (UHR-Qq-TOF) mass spectrometer, and the data was acquired using Compass 1.5 software. The MS condition was set as follows: ionization mode, positive electrospray ionization (+ESI), gas temperature, 180 °C; gas flow, 8 L/min, nebulizer, 2 bar; capillary voltage: 3800 V; mass scanning range, 50−1500 Da. For MS/MS, nitrogen was used as the collision gas, collision energy was 35 eV, and sodium formate was the accurate mass calibrant.

NMR. ^1H and ^{13}C NMR spectra were recorded with a Bruker Avance III 600 MHz spectrometer using a QNP Cryoprobe. NMR data processing was performed with Topspin3.1 software The spectra were referenced to the corresponding solvent signals.[12]

Cell Culture. Caco-2 cells (HTB-37, ATCC) were cultured in complete Minimum Essential Medium (MEM) containing Earle's salts and supplemented with 10% FBS (Invitrogen, Canada) and 100 units/mL of penicillin and 100 μg/mL of streptomycin (Sigma, St. Louis, MO). Cells were incubated at 37 °C under a 5% CO_2 atm. The medium was changed every 2−3 days. Caco-2 cells were subcultured weekly.

NO Inhibitory Activity in Caco-2 Cell. NO in Caco-2 cells was measured using the conditions reported by Chen and Kitts (2008).[11] Caco-2 cells seeded on 96-well plates (Sarstedt, Nümbrecht, Germany) at a density of 10^5 cells/cm^2 in complete MEM (100 μL) were cultured for 3 weeks. The fully differentiated Caco-2 cells were supplied with fresh MEM without FBS and incubated with, or without, experimental samples for 1 h followed by a treatment of inducer which consisted of 8000 U/mL IFN-γ + 0.1 μg/mL PMA for 48 h. NO levels in the culture medium were determined using the Griess reagent (50 μL of 1% sulfanilamide in 5% phosphoric acid and 50 μL of 0.1% *N*-(1-naphthyl)ethylenediamine dihydrochloride) after reducing nitrate to nitrite with nitrate reductase (Sigma, St. Louis, MO). The color change was measured by a spectrophotometer (Multiskan Ascent, ThermoLabsystems, Finland) at 540 nm. Nitrite and nitrate levels were determined using sodium nitrate as the standard. Percent inhibition was calculated using the following equation

$$(NO_{st} - NO_{sample})/(NO_{st} - NO_{blank}) \times 100\%$$

where NO_{st} is the NO concentration of the cell supernatant incubated with inducer; NO_{blank} is the NO concentration of the cell supernatant without samples and inducer; NO_{sample} is the NO concentration of cells incubated with samples and inducer.

Cell Viability. The cell viability was tested using MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, Sigma, St. Louis, MO) assay described by Chen and Kitts.[4] After cells were treated with sample and inducer, they were then incubated with 0.5 mg/mL MTT in complete MEM for 4 h, followed by an overnight incubation with 10% sodium dodecyl sulfate (SDS). Absorbance was read at 570 nm using a spectrophotometer (Multiskan Ascent, Thermo Labsystems, Helsinki, Finland).

RESULTS AND DISCUSSION

Effects of Reaction Conditions and Type of Reactants on the Yield of F3-A. In order to increase the yield of F3-A, two steps were performed to optimize the reaction conditions. First, a Taguchi design was used to determine the sugar to amino acid ratio, pH, temperature, and heating time. Previously, we have used Taguchi design to successfully optimize the inducers for NO production in differentiated Caco-2 cells[11] and to define the coculture conditions for Caco-2 and HT29-MTX cells.[13] Herein, a four-factor/four-level

Table 2. Yield (μg/g) of F3-A in Glc-Lys with Different Concentration and Heating Time[a]

	S:AA[b](mol/L: mol/L)			
time (h)	0.2:0.1	0.4:0.2	0.8:0.4	1.6:0.8

(L16) Taguchi design (Table 1) which includes 16 experiments in the orthogonal array was used to investigate the effects of four levels of the four reaction conditions (control factors) including S:AA ratio, pH, temperature, and heating time on F3-A production in glucose and lysine aqueous mixtures. Within the multiple conditions tested, F3-A concentration ranged from undetectable amounts to 11.1 ± 3.3 (μg/g) (Table 1). From the ANOVA table, the relative impact of the different factors tested to affect production of F3-A followed in descending order: sugar:amino acid (S:AA) ratio < temperature (T) < heating time (t) < pH. The optimal conditions for producing F3-A were determined to be S:AA ratio = 2:1, T = 100 °C, t = 90 min, pH = 6. The production of F3-A precursor, HMF, was also measured. The amount of HMF was positively significantly (P = 0.023) correlated with the yield of F3-A.

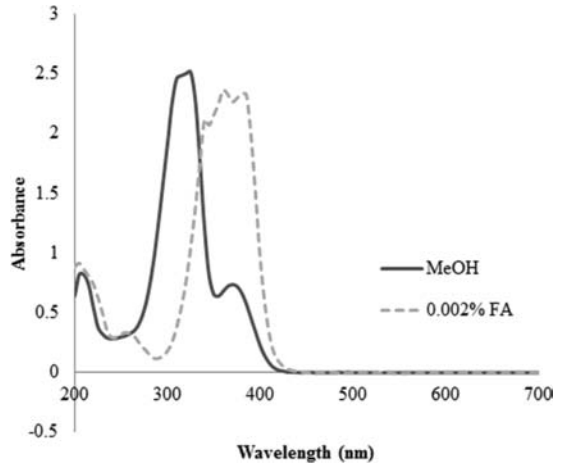

Figure 3. UV−vis spectrum of F3-A in MeOH and 0.002% formic acid at a concentration of 0.02 mg/mL.

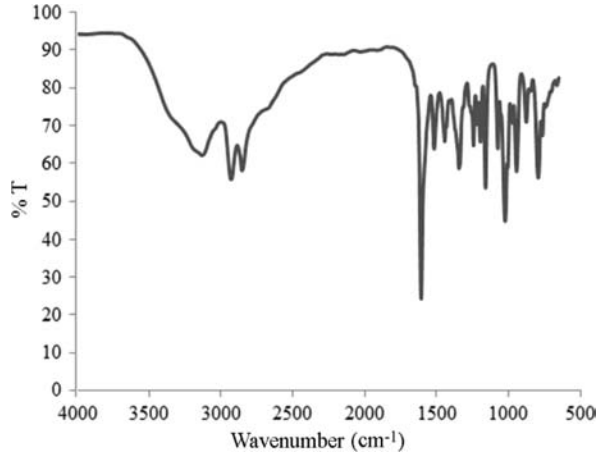

Figure 4. FTIR spectrum of F3-A.

Since the yield of F3-A was still low using conditions obtained from Taguchi design, in the second step, we held constant temperature, pH, and reactant ratio conditions that were obtained from the Taguchi design and varied the reactant concentration and the heating time, using a factorial design. The yield of F3-A from Glc-Lys mixture decreased as the reactant concentration was lowered, when keeping the molar ratio the same (Table 2). In general, more F3-A was produced when heating time was increased to 24 h. One exception existed when the sugar:amino acid ratio of 1.6:0.8 (mol/L: mol/L) was used; however, we attribute this to the gel like precipitates that were formed when reactants at these concentrations were heated for 24 h. Therefore, the optimal conditions used are Glc:Lys ratio set at 1.6:0.8 (mol/L: mol/L) and a heating duration of 12 h. The yield of F3-A increased more than 1000-fold when the Glu-Lys mixture (1.6:0.8, mol/L: mol/L) was heated for 12 h, compared to shorter heating times (e.g., 1.5 h).

In order to show the effects of various sugar types on the yield of F3-A, we conducted F3-A recovery experiments using fructose, glucose, lactose, and sucrose, respectively. Hence, hexoses or disaccharides comprised of hexose, known to generate HMF during heating and involving MR or caramelizing, were found to be necessary precursors to produce F3-A. Monosaccharides had a significantly (P < 0.05) greater affinity to produce F3-A compared to disaccharides containing hexose

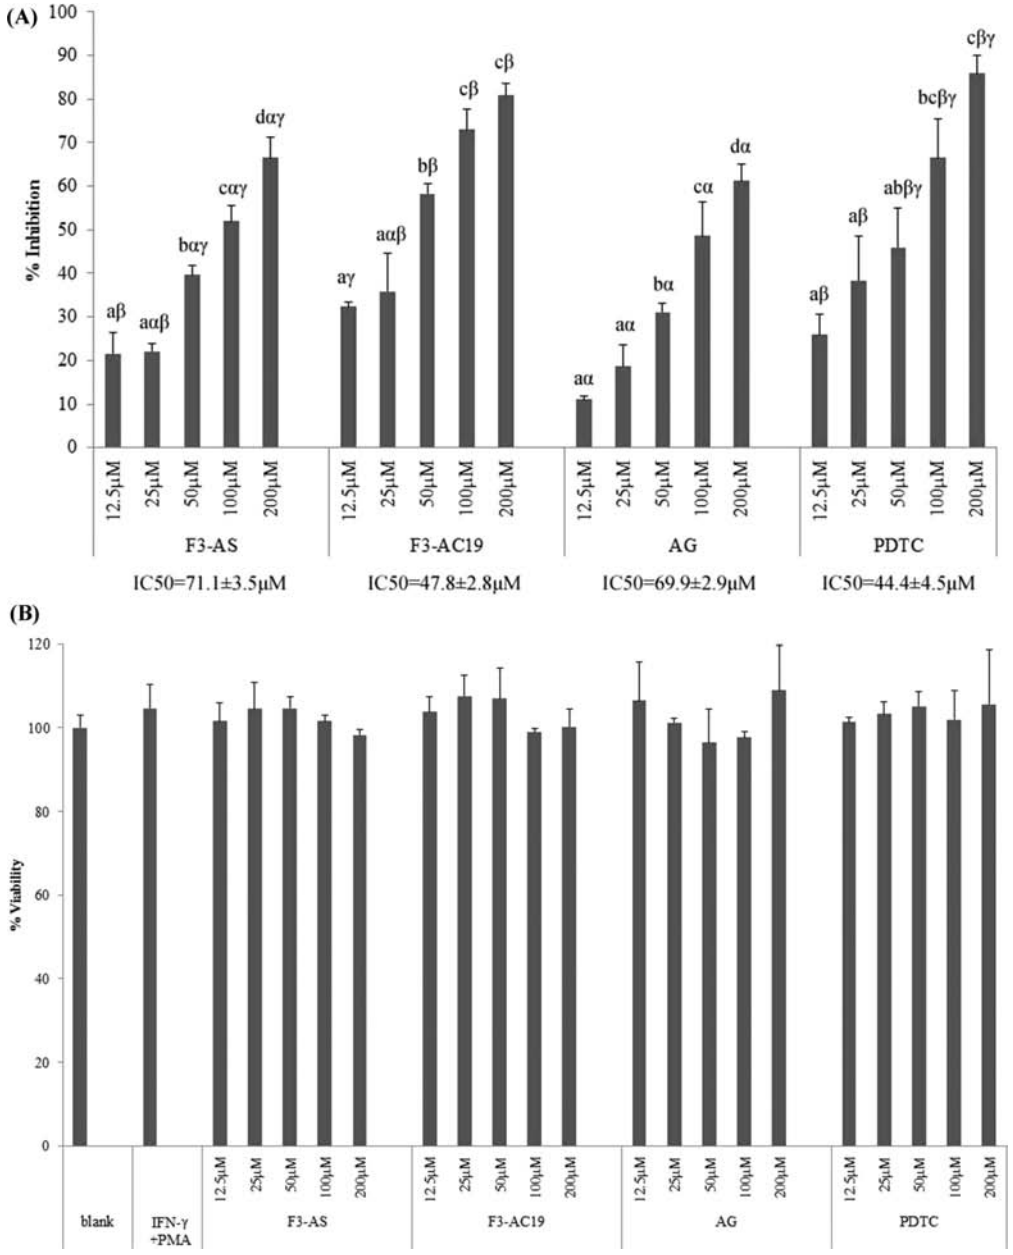

Figure 5. NO inhibitory (A) and cell viability (B) effects of F3-AS, F3-AC19, AG, and PDTC on Caco-2 cells. F3-AS: synthetic F3-A; F3-AC19: isolated F3-A from Glu-Lys MR mixture.

(Table 3). Nonenzymatic browning of aldohexoses in the presence of lysine has been reported to occur faster than that of ketohexoses in similar heat-processed, aqueous model systems.[14−16] This would explain the relatively higher production of F3-A from the glucose than the fructose MR model. Sucrose itself is a nonreducing sugar; hence, without hydrolysis there should not be a Maillard sugar−amino acid interaction. The fact that we detected a trace amount of F3-A from sucrose, compared to lactose, a reducing disaccharide, indicates sucrose hydrolyzed to glucose and fructose at 100 °C under pH 6. Results of Buera et al. (1987)[17] confirm this with their report that 10% hydrolysis of sucrose occurred when heated at 55 °C at pH 6 and produced yellow-brownish products. Alternatively, degradation of sucrose occurring with caramelizing will also result in HMF formation.[18] However, Lee and Nagy (1990)[19] showed that the rate of HMF formation in fructose is much faster than in sucrose followed by glucose when sugars were heated 50 °C under pH 3.5. The presence of amino acid increased HMF formation rate for glucose but not sucrose. Our results indicated that the production of F3-A precursor, HMF, is faster in glucose and lysine MR models than that of fructose and sucrose in our experimental conditions, the ultimate outcome being a higher F3-A production from glucose models.

Proposed Reaction Route for Synthesis of F3-A. We found that the chemical synthesis of F3-A favored acidic conditions and that both the alpha and epsilon amino groups of lysine were involved in the reaction.[20] A possible route for F3-A production in Glc-Lys can therefore be related to the production of HMF and reaction with compound **3**, 1,2-dehydropiperidine.[21] HMF is formed via various pathways, including the aldo−keto isomerization of aldohexose, followed by the dehydration of furanose tautomers,[22] decomposition from 3-deoxyhexosone produced by MR or by carameliza-

tion,[18,23] or methylglyoxal recombination with glyceraldehyde.[24] Under acidic conditions, glucose is isomerized to fructose through Lobry de Bruyn–Alberda van Ekenstein transformation, followed by three dehydration steps to produce HMF.[25] First, the furanose ring at C5 loses one H_2O molecule to form fructofuranosyl oxocation; this is followed by enolization to the enol of 2,5-anhydro-D-mannose after loss of a proton. Second, the second H_2O molecule is released to form a double bond in the furan ring. An additional H_2O molecule is lost to form HMF.[26] At pH 7, or acidic conditions, the Amadori product in Glc-Lys MR mixture undergoes 1,2-enolization to produce HMF.[27] L-Lysine also undergoes Strecker degradation during MR to produce 5-aminopentanal which can be cyclized to 1,2-dehydropiperidine. HMF and 1,2-dehydropiperidine undergo aldo condensation and dehydration to form F3-A.[21]

Chemical Properties and Chemical Structure of [5-(5,6-Dihydro-4*H*-pyridin-3-ylidenemethyl)-furan-2-yl]-methanol. The HPLC profile of Glc-Lys heated mixture is shown in Figure 1. The retention time of F3-A was 5.15 min. The accurate mass data for F3-A (Figure 2) gave a signal that corresponded to the protonated form of the compound at m/z 192.1021 Da with major fragments including m/z 175.0994, 146.0966, 121.9663, 91.0542, and 62.9290 Da. Most of the error values are within ±5 ppm except for a few fragment ions, thus confirming a formula $C_{11}H_{13}NO_2$. The unusual large number of fragment ions and the presence of multiple signals in one nominal mass such as m/z 123.0676 and 123.0441 are evidence of the m/z 192.1021 ion undergoing complex rearrangements in the fragmentation processes.

Small amounts of F3-AC19 were dissolved in CD_3OD; ^1H, ^{13}C, COSY, ^{13}C-APT, HSQC, and HMBC-NMR experiments were performed. The NMR data along with the molecular formula ($C_{11}H_{13}NO_2$) derived from the MS results were input in CMC-se software (version 2.0.10) for possible chemical structures which were ranked based on observed correlations and chemical shift predictions. The chemical shift and ^1H and ^{13}C NMR spectrum are shown in Table 4. After manual verification, F3-AC19 was identified as [5-(5,6-dihydro-4*H*-pyridin-3-ylidenemethyl)-furan-2-yl]methanol. The compound has a root-mean-square (rms) deviation of 4.6 ppm, indicating a good match between both proposed and actual chemical structures. This compound was also synthesized as described previously, and the ^1H and ^{13}C spectra were compared with the isolated compounds. The results confirmed that F3-AS and F3-AC19 had the same structure.

F3-A is easily soluble in MeOH and acidic ddH_2O. When dissolved in MeOH, F3-A gave two major absorbance peaks at 315 and 370 nm, with maximum absorbance peak occurring at 315 nm (Figure 3). Under acidic condition, the maximum absorbance (λ_{max}) of F3-A shifted to a higher wavelength (370 nm). This result indicated that protonation increased the solubility of F3-A in H_2O and therefore might have also caused the rearrangement of double bond resulting in the red shift of λ_{max}. In previous work, Totsuka et. al[28] and Miller et. al[20] identified F3-A from HMF-Lys and Glc-Lys MR models, respectively. The physiochemical properties, FTIR (Figure 4), MS, and NMR data of separated and synthesized compounds were identical in our experiments and similar to previous work.

NO Inhibitory Effects in Caco-2 Cells. The NO inhibitory effects of separated F3-AC19 and synthesized F3-AS were tested using Caco-2 cells. A NO inhibitor AG and a NF-κB inhibitor PDTC were chosen to compare the NO inhibitory effect with our samples. F3-AC19 and F3-AS both produced a dose dependent inhibition of NO production in Caco-2 cells (Figure 5 A) with an IC50 = 47.8 ± 2.8 and 71.1 ± 3.5 μmol/L, respectively. The cell viabilities of all treatments were comparable to the untreated cells (Figure 5 B). The IC50 of F3-AC19 was significantly ($P < 0.05$) lower than that of F3-AS, indicating that the isolated F3-AC19 had higher NO inhibitory affinity than the synthesized sample. We attribute this result to the possible trace amounts of other MRPs in F3-AC19 that could contribute to a higher NO inhibitory capacity. F3-A can exist at both Z and E configurations; thus, in aqueous conditions the isomers interconvert. It is possible that one of the configurations has a relatively higher activity than the other, and the production and separation process for F3-AC19 from Glc-Lys MR model possible tended to produce the isomer with a characteristically higher NO inhibitory activity. Of particular importance was the observation that the IC50 of F3-AS was similar to that of AG and that the IC50 of F3-AC19 was also equivalent to that of PDTC. AG is a selective iNOS inhibitor that prevents NO and iNOS synthesis in IFN-γ + PMA induced Caco-2 cells.[11] PDTC, a NF-κB inhibitor, prevents NF-κB activation, thus inhibiting both NO and iNOS in activated Caco-2 cells.[29] The results described herein indicate that F3-A has a similar NO inhibitory capacity to that of the iNOS and NF-κB inhibitors in inflamed Caco-2 cells. When the synthetic F3-A was coincubated with AG, it showed an additive NO inhibitory effect in Caco-2 cells (Figure 6), thereby further indicating that F3-A could be useful to increase activity of known anti-inflammation drugs.

Previous studies from our laboratory have reported that a fraction (F3) composed of small molecular weight components derived from a Glc-Lys MR mixture was effective at inhibiting inflammatory reactions in Caco-2 cells induced by IFN-γ and PMA cocktail.[5,6] Anti-inflammatory activity of F-3 was shown

DOI: 10.1021/jf505579m
J. Agric. Food Chem. 2015, 63, 1739−1746

to be mediated through iNOS inhibition and down regulation of genes in NF-κB signaling;[5] these activities correspond to NO inhibition. This study has elucidated the structure of the bioactive component present in F3, being [5-(5,6-dihydro-4*H*-pyridin-3-ylidenemethyl)-furan-2-yl]methanol, which was active at inhibiting NO in inflamed Caco-2 cells. We also found that process variables that influenced the yield of F3-A from a heated aqueous Glc-Lys reaction were lower pH and higher reactant concentration. Moreover, MR models comprised of aldohexose produce a higher amount of F3-A compared to ketohexose and disaccharides. The relative anti-inflammatory potency of F3-A corresponded to similar activity observed with AG, a selective iNOS inhibitor, and also PDTC, a Nf-κB inhibitor, both of which are involved in iNOS and NO inhibition.

have been reported since GSH was first quantified in grapes in 1989.[25] This may be because the food sample matrix is too complicated and needs laborious pretreatment procedures. Moreover, due to the easy autoxidation of GSH during the pretreatment, especially the centrifugal process, accurate measurement of GSH is arduous. Therefore, a simple and effective method for GSH detection in food samples is highly desirable.

It should be noted that a new type of graphitic carbon nitride quantum dot (g-CNQD) fluorescent materials have recently attracted significant research attention with promising biosensing application. The g-CNQDs emerge as a novel fluorescent probe for biological and environment detection with unique physicochemical properties, such as bright fluorescence, water solubility, biocompatibility, and nontoxicity.[26] As an ideal fluorescent probe, its fluorescence could be completely and specifically quenched by Hg^{2+} and reversed by GSH. On the basis of this phenomenon, the g-CNQDs have been utilized in this work to detect GSH in foods. Their preparation is according to a low-temperature solid-phase process with sodium citrate and urea as the precursors, which was energy-saving and environmentally friendly.[27]

Herein, a selective and rapid fluorescence probe via a "switch-on" strategy for GSH sensing in foods is demonstrated. The sensing system set out by quenching the fluorescence from g-CNQDs by Hg^{2+} through electron transfer. Interestingly, the quenching effect could be reversed by coordination of Hg^{2+} to GSH, thereby switching on the fluorescence of the chemosensor. Furthermore, the chemical response of g-CNQDs is specific toward GSH, relative to other different biomolecules or electrolytes. Furthermore, the g-CNQDs–Hg^{2+} probe was also successfully applied for the quantification and comparison of GSH level in various food samples.

EXPERIMENTAL PROCEDURES

Materials. Trisodium citrate, urea, and $HgCl_2$ were purchased from Tianjin Guangfu Chemical Reagents Co. Ltd. (Tianjin, China). NaCl, KCl, $MgCl_2$, and vitamin C were acquired from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China). All amino acids were bought from Shenggong Biological Engineering Co. Ltd. (Shanghai, China). All chemicals were of analytical reagent grade and used without further purification. The ultrapure water used throughout the experiments was purified through a 18202 V AXL water purification system (Asura Technology Development Co. Ltd., Chongqing, China).

Apparatus and Characterization. A TU-1901 double-beam UV–vis spectrophotometer (Purkine General Instrument Co. Ltd., Beijing, China) was used to record absorption spectra and measure absorbance. Fluorescent emission spectra were recorded on an RF-5301PC spectrofluorometer (Shimadzu, Kyoto, Japan). A Hitachi-600 transmission electron microscope (TEM, Hitachi, Kyoto, Japan) was used for measuring the morphology and size of g-CNQDs. The sample for TEM characterization was prepared by placing a drop of colloidal solution on a carbon-coated copper grid and dried at room temperature. FT-IR spectra were performed on a Nicolet Nexus 670 Fourier transform infrared spectrometer (Nicolet Instrument Co., Madison, WI, USA) using KBr pellets, scanning from 4000 to 400 cm^{-1} at room temperature.

Preparation of g-CNQDs. The process was according to the previously reported procedure with a little modification.[27] In typical synthesis, 0.081 g (0.28 mmol) of sodium citrate and 0.101 g (1.68 mmol) of urea were mixed in an agate mortar and ground into fine powder. The mixture was then transferred to a poly(tetrafluoroethylene) (Teflon)-lined autoclave and heated at 180 °C for 1 h. After the reaction was finished, the autoclave was naturally cooled to ambient temperature. The final yellowish product was dispersed in 5 mL of ultrapure water and centrifuged at 12000 rpm for 5 min. The supernatant was extracted by removing the precipitation and subsequently dialyzing against ultrapure water through a dialysis membrane (3 kDa) for 24 h. The as-synthesized g-CNQDs were stored at 4 °C for further detection and characterization.

Sample Pretreatment. The food samples were prepared according to a previous paper with a little modification.[15] All of the food samples were purchased in the local market in Lanzhou, China. First, all of the samples were cleaned with tap water and ultrapure water. Then, they were naturally dried in air and accurately weighed, followed by homogenization in a commercial blender. After centrifugation in a refrigerated centrifuge (to prevent oxidation caused by the high temperature produced by the centrifuge) at 3000 rpm for 15 min, the supernatant was filtered through a 0.45 μm pore size filter membrane and diluted to appropriate concentration in the detection range with ultrapure water. The final juices of tomatoes, cherry tomatoes, purple grapes, white grapes, spinach, and cucumber were diluted to 10, 20, 10, 1, 1, and 1 times, respectively. All of the samples were stored in a refrigerator at 4 °C for use.

Quantification of GSH in Food Samples. The GSH level in food samples was determined according to the following steps: (a) A 3.3 μM Hg^{2+} solution was incubated with 60 μL of g-CNQDs in 2.5 mL of 0.2 M phosphate buffer solution (PBS, NaH_2PO_4–Na_2HPO_4, pH 8.0) for 5 min so that the probe could be formed. (b) Five hundred microliters of sample solution was then added and mixed thoroughly. The resulting solution was maintained at room temperature for 5 min to hold the reaction completely. Finally, the spectra were recorded under excitation at 400 nm, and the slit widths were set at 5/5 nm. The recovery rate was calculated according to the following equation:

$$\text{recovery} = (c_{\text{measured}} - c_{\text{initial}})/c_{\text{added}}$$

RESULTS AND DISCUSSION

Characterization. As shown in Figure 1, the remarkable optical properties of the as-obtained g-CNQDs were confirmed

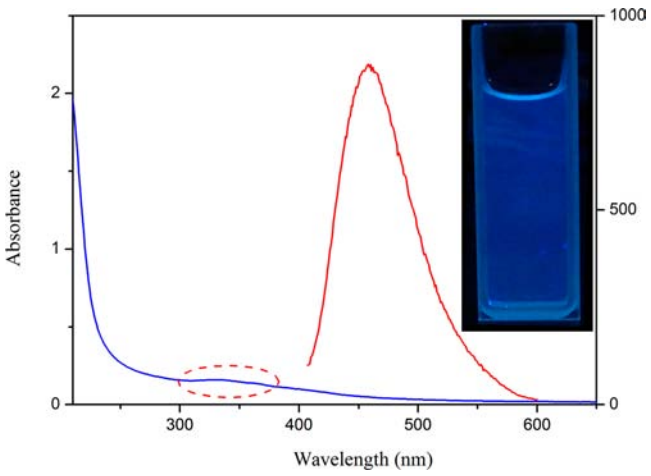

Figure 1. UV–vis absorption (blue line) and fluorescence emission (red line) spectra of the g-CNQDs. (Inset) Photograph of g-CNQD dispersion under UV light (365 nm).

by UV–vis absorption and fluorescent (FL) spectra of the aqueous dispersion. The UV–vis spectrum exhibited a characteristic absorption peak at 340 nm. The narrow and symmetrical fluorescence peak at 460 nm, resulted from their narrow size distribution, was observed when the aqueous solution was excited at 400 nm. The digital picture of the aqueous dispersions further showed that the obtained g-CNQDs are water-soluble and exhibit strong blue fluorescence under 365 nm UV light. The morphology and microstructure were identified by the typical TEM image of the prepared g-CNQDs solution. As shown in Figure 2, g-CNQDs are regular in shape and monodisperse, and their size is about 2.1–4.5 nm with an average diameter of 3.5 nm.

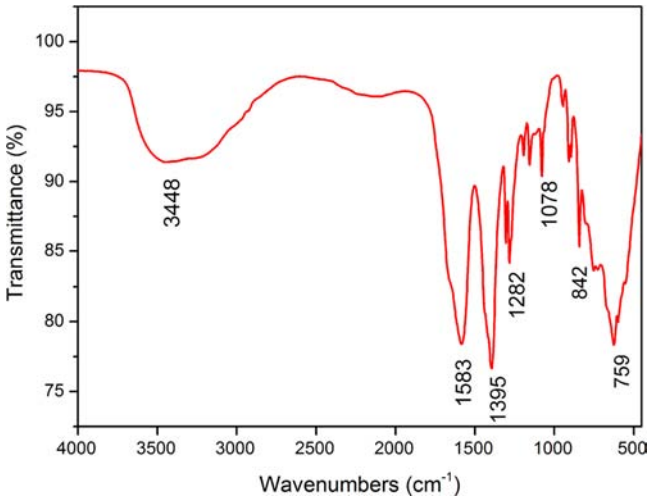

Figure 3. FT-IR spectrum of g-CNQDs.

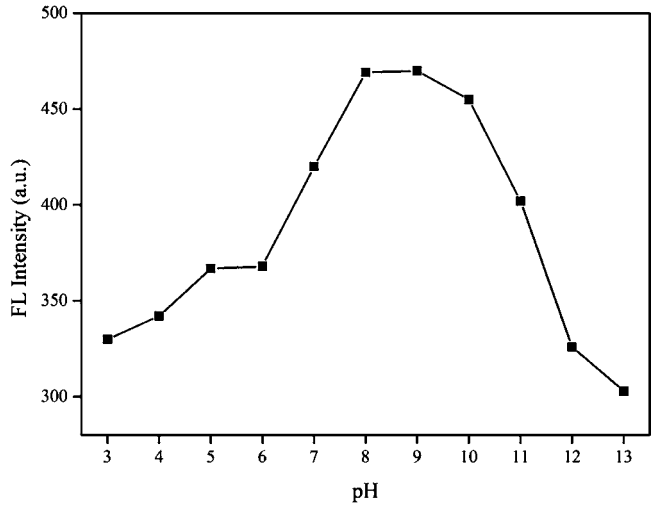

Figure 4. Fluorescence intensity of g-CNQDs at different pH values.

At least 50 particles were selected at random to characterize the size distribution of g-CNQDs. The FT-IR spectrum (Figure 3) was used to confirm the surface chemistry of the as-prepared g-CNQDs. The characteristic absorption broad bands at about 3100−3600 cm^{-1} corresponded to the stretching vibrations of O−H and N−H. The sharp peak at 1395 cm^{-1} was from the bending vibration of C−NH, and the peak at about 1000−1300 cm^{-1} was related to the C−OH stretching vibration.[28] The high intensity of the peak at 1583 cm^{-1} was ascribed to the asymmetric stretching vibrations of the carboxylate anions.[29] These abundant hydrophilic groups presented on the surface significantly improved the water solubility and stability of g-CNQDs. From the characterization results, we could confirm that the synthesized g-CNQDs with high performance were basically identified with that from the literature.[27]

The FL intensity of g-CNQDs at different pH values is presented in Figure 4, and as can be seen the FL intensity of the g-CNQDs was pH dependent. They have extremely poor stability and could be severely quenched in too acidic and alkaline solution due to the destruction of the surface groups. Such a phenomenon was in agreement with those of carbon nanoparticles modified with hydroxyl and carboxylic.[30,31] It is worthwhile mentioning that these pH-sensitive g-CNQDs have great potential for monitoring pH changes.

Design Principle and Mechanism Study of Chemosensor for GSH. As depicted in Scheme 1, the original fluorescence of g-CNQDs was quenched after the addition of Hg^{2+}. Upon the addition of GSH, Hg^{2+} was strongly captured by GSH and released from the surface of g-CNQDs. In other words, the structure of the g-CNQDs−Hg^{2+} probe was decomposed, and the fluorescence intensity of g-CNQDs was restored remarkably as the GSH concentration increased.

Quenching Mechanism. We, not unexpectedly, found that the FL intensity of g-CNQDs gradually decreased upon the successive addition of Hg^{2+}. The measurement of zeta potential indicated that the g-CNQDs are negatively surface charged.[27] On the basis of this result, we deduced that there perhaps existed an electrostatic interaction between the negative groups (carboxyl and hydroxyl groups) of g-CNQDs and Hg^{2+}. The capture of the nanomaterials with oxygen-containing groups to Hg^{2+} was specific.[29,32] Furthermore, electron transfer occurred between g-CNQDs and Hg^{2+}.[29,31,33] Both electrostatic interaction and electron transfer could lead to the decrease of g-CNQDs emission, but the latter effect may play a leading role.

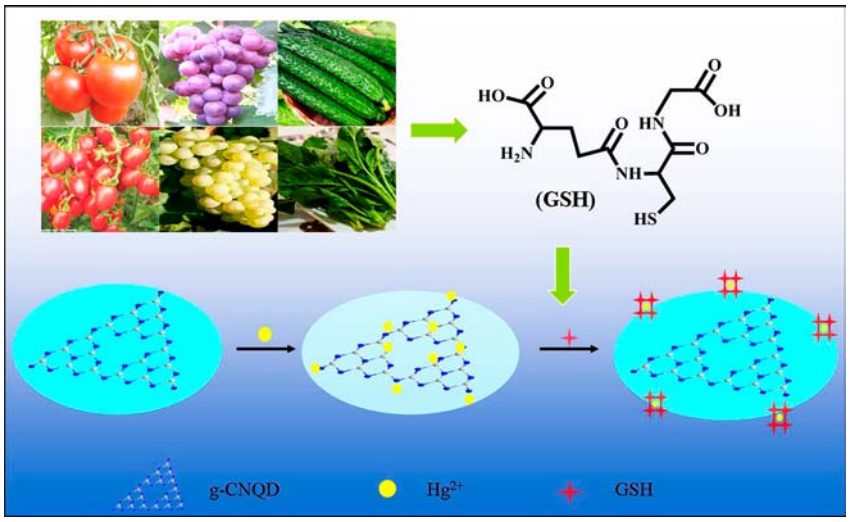
Scheme 1. Schematic Illustration of the Principle of the g-CNQDs−Hg^{2+} System Based Chemosensor for GSH



Restoration Mechanism. Evidently, a recovery of g-CNQDs was observed immediately upon addition of GSH to the g-CNQDs−Hg^{2+} system. At this stage, the fluorescence probe was switched to the "on" state. Negligible changes of the pure g-CNQD emission were observed after treatment with excess GSH (Figure 5). This illustrated that the enhancement in FL intensity of g-CNQDs should be ascribed to the interaction between GSH and Hg^{2+}, which is consistent with previous studies.[34,35] As we know, the Hg^{2+} cation, as a thiophilic metal ion, has a particular binding preference to GSH.[34] GSH has specific steric structure with several potential coordinating sites: sulfhydryl, amino group, and carboxyls.[36] Therefore, Hg^{2+} can be easily released from the surface of g-CNQDs after the addition of GSH, which leads to the dissociation of the g-CNQDs−Hg^{2+} probe. As mentioned above, we established the "switch-on" fluorescence sensor for sensitive, selective, and rapid determination of glutathione.

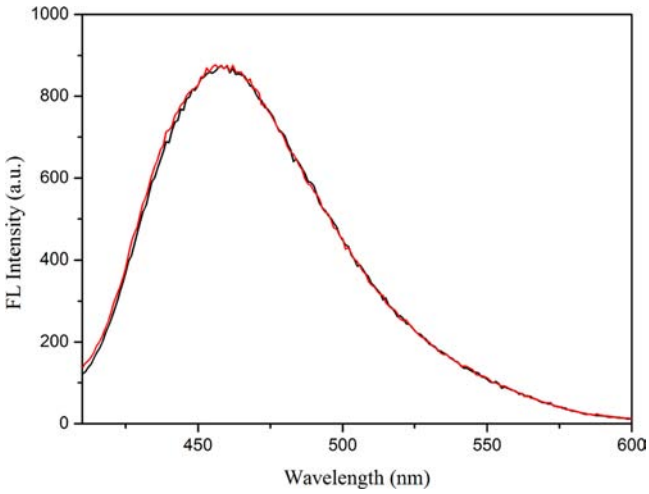


Figure 5. Fluorescence emission spectra of 60 μL of g-CNQDs (black line) solution and 60 μL of g-CNQDs solution with 100 μM GSH (red line). All experiments were conducted in 0.2 M PBS buffer and incubated for 5 min.

Optimization of Experimental Conditions. To further improve the detection sensitivity of the system, we systematically optimized the relative conditions and found that the Hg^{2+} concentration and the pH of the buffer solution remarkably influenced the assay sensitivity. Besides, the reaction time also has a certain effect.

Figure 6A displays the fluorescence restoration changes with increasing Hg^{2+} concentration. We noted that less Hg^{2+} cannot quench the fluorescence thoroughly and thus cause an inapparent FL restoration. However, an excess amount of Hg^{2+} leads to GSH binding with free Hg^{2+} in solution instead of Hg^{2+} on the surface of g-CNQDs, which resulted in poor sensitivity. From the above, we selected 3.3 μM as the optimum Hg^{2+} concentration.

The effect of pH on the assay performance was studied over a pH range from 5.0 to 10.0 with a universal PBS buffer (Figure 6B). On the one hand, the material had strong FL intensity and was stable in the range of pH 8.0−10.0 (Figure 4). On the other hand, $[Hg(GSH)_n]^{(2-3n)-}$ (n = 2 or 3) complexes, the dominant formations, have higher stability in alkaline solutions than in acidic solution.[37] Taking the two factors into account, pH 8.0 is recommended as the optimal pH value for further detection.

In addition to the Hg^{2+} concentration and pH, the kinetics of both the quenching and restoration processes were measured to optimize the required incubation times (Figure 6C,D). The test was performed with the optimized and typical assay protocol in 0.2 M PBS buffer (pH 8.0) with 3.3 μM Hg^{2+}. As demonstrated in Figure 6, the two procedures both leveled off after ∼5 min with the extension of incubation time, revealing the equilibrium of the two kinetic behaviors. Hence, considering the efficiency, an incubation time of 5 min was selected for both the two processes to achieve the rapid and sensitive determination of GSH in the subsequent experiments.

Analytical Performance for GSH Sensing. *Sensitivity.* The sensitivity of the sensing strategy was investigated by adding different concentrations of GSH into a 0.2 M PBS solution (pH 8.0), containing the same amount of g-CNQDs and 3.3 μM Hg^{2+}. The restoration rate was very fast within 5 min to reach the plateau. As indicated in Figure 7A, the enhancement of fluorescence intensity was closely relevant to the concentration of GSH. The inset image shows the linear plot of the logarithm of $\Delta F/F_0$ against the concentration of GSH over a range of 0.16−16 μM, where ΔF is the difference between F and F_0, corresponding to the fluorescence intensity after and before the

Fe_3O_4–ABTS–H_2O_2	colorimetry	3.0–30 μM	not given	time consuming	40
g-CNQDs–Hg^{2+}	fluorescence	0.16–16.0 μM	37 nM	high selectivity, sensitivity, fast, cost-effective	this work

Table 2. Comparison of the Analytical Performances of Different Concentration of Hg^{2+} for GSH Sensing (n = 3)

Hg^{2+} concn (μM)	linear range (μM)	regression eq[a]	LOD (nM)	R^2	RSD (n = 3, %)
1.6	0.33–5.0	$\log y = -1.318 + 0.157x$	54	0.9558	0.7–2.0
3.3	0.16–16.0	$\log y = -1.058 + 0.0995x$	37	0.9807	1.9–3.1
5.0	6.66–20.0	$\log y = -1.348 + 0.0788x$	178	0.9840	1.4–3.2

[a] y is $\Delta F/F_0$, where ΔF is the difference between F and F_0 (corresponding to the fluorescence intensity in the presence and absence of GSH, respectively); x is the concentration of GSH.

addition of GSH. The curve followed the standard regression equation $\log(\Delta F/F_0) = -1.058 + 0.0995[\text{GSH}]$ ($R^2 = 0.9807$). On the basis of three parallel determinations (n = 3), the repeatability ranged from 0.19 to 0.31% (expressed as the relative standard deviation, RSD), demonstrating the excellent reliability of this fluorescence chemosensor. Under the optimal conditions, the detection limit (LOD) was estimated to be 37 nM on the basis of the generalized 3σ method, which is comparable to or even better than the previous reports for GSH sensing (see Table 1).

The appropriate concentration of Hg^{2+} should be crucial to achieve a good analytical performance for the switch-on fluorescent sensing of GSH. To illustrate this, the other two

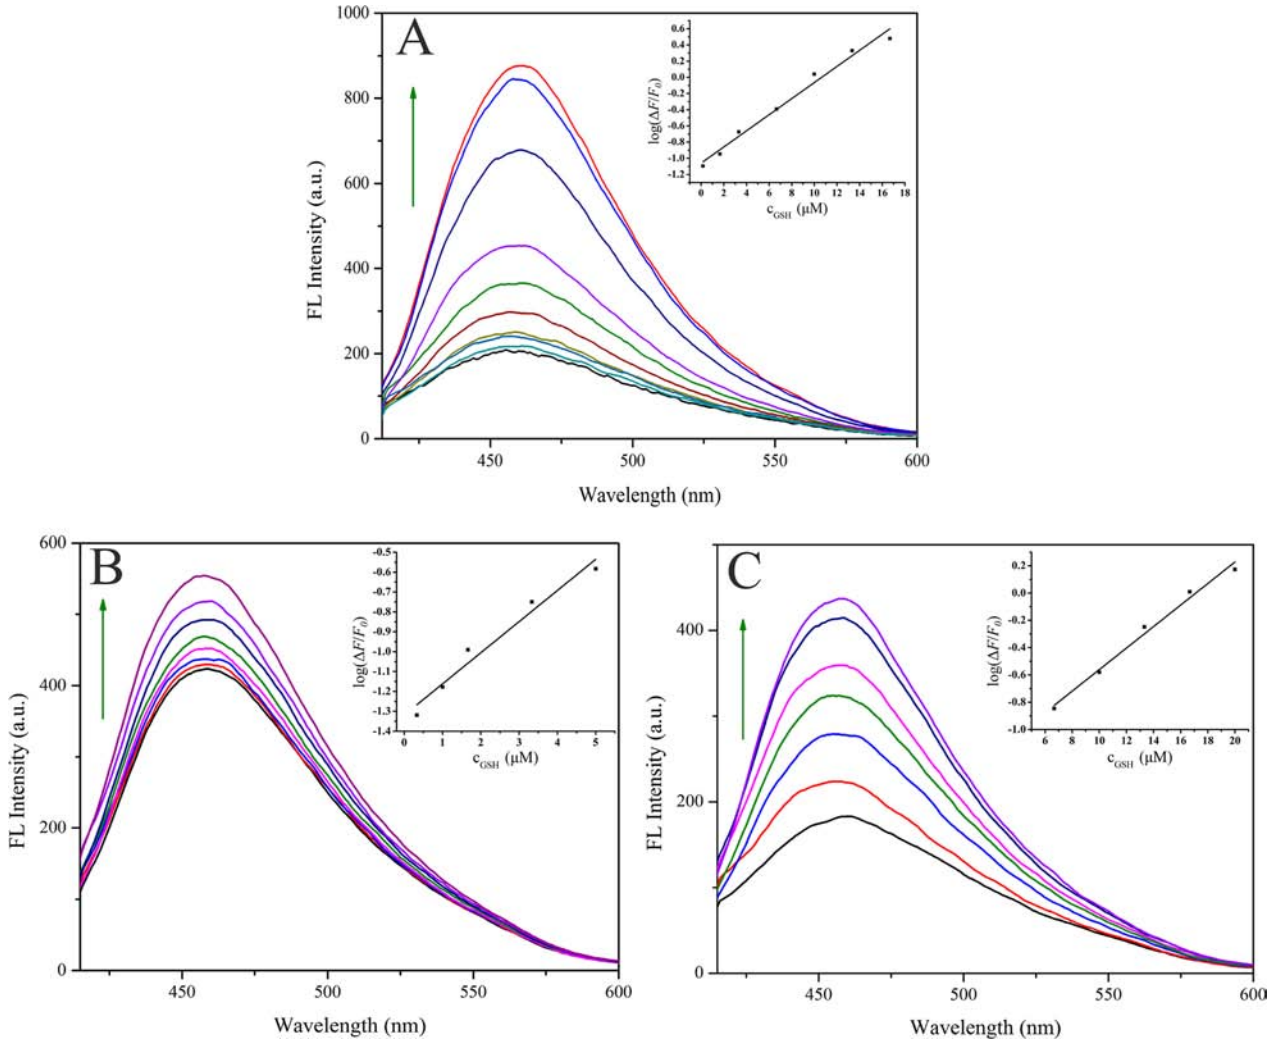

Figure 7. Fluorescence emission spectra of g-CNQDs with increasing concentration of GSH in the presence of 3.3 μM Hg^{2+} (A), 1.6 μM Hg^{2+} (B), and 5.0 μM Hg^{2+} (C). (Inset) Relationship between $\log(\Delta F/F_0)$ and concentration of GSH. The fluorescence emission intensity at 460 nm was measured with an excitation of 400 nm.

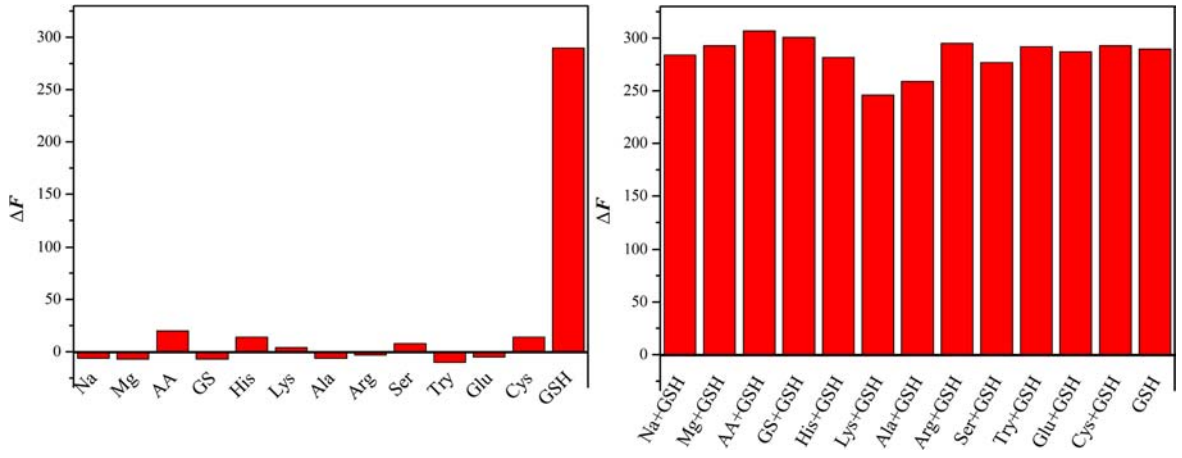

Figure 8. (A) Fluorescence emission intensity of g-CNQDs–Hg^{2+} to 0.5 mM GSH and 12 other analytes (10-fold concentration of GSH). (B) Fluorescence emission intensity of g-CNQDs–Hg^{2+} to GSH and 12 other analytes (0.5 mM) in the presence of GSH (0.5 mM).

concentrations of Hg^{2+} (1.6 and 5.0 μM, respectively) were added to the above system, replacing 3.3 μM Hg^{2+}. In Figure 7B,C, there were similar changes in the fluorescence intensity of the chemosensor with the increase of Hg^{2+} concentration as in Figure 7A. The calculated regression equation, correlation coefficient (R^2), LOD, and RSD are listed in Table 2. Obviously, 3.3 μM Hg^{2+} was optimum in terms of the wider linear range, higher sensitivity, and better repeatability.

DOI: 10.1021/jf505759z
J. Agric. Food Chem. 2015, 63, 1747–1755

Table 1 presented the characteristics of different sensors to detect GSH proposed in recent years, including quantum dots, nanocluster, Fe_3O_4, and carbon-based materials. No doubt, our proposed method is a highly sensitive and selective method for the detection of GSH. Although the detection limits of several reported sensors are better than ours, they need special equipment, a sophisticated technique, and complicated operations. Besides the simplicity in operation and inexpensive detection cost, the response speed of our switch-on chemosensor is much faster than that of most of the reported sensors.

Selectivity. To evaluate the selectivity of the present assay strategy, we have studied the effect of foreign substances. The potential interferences in fruits and vegetables consisted of a number of amino acids and mineral substances, especially vitamin C (AA), glucose (GS), and metal ions, such as Na^+ and K^+.

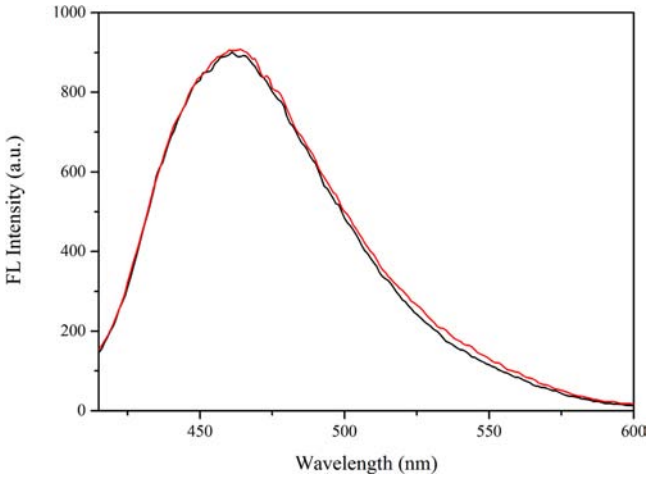

Figure 9. Fluorescence emission spectra of 60 μL of g-CNQDs solution (black line) and 60 μL of g-CNQDs solution with 500 μL of cucumber sample (red line). All experiments were conducted in 0.2 M PBS buffer and incubated for 5 min.

As the experimental data show in Figure 8A, under the same conditions, GSH showed a drastic enhancement of the fluorescence intensity against all other analytes at a 10-fold concentration of GSH, demonstrating that this detection system presented an excellent selectivity. Anti-interference experiments were also carried out to study the selectivity of the sensing toward GSH (Figure 8B). The recovery caused by the mixture of GSH (0.5 mM) with the other analytes (0.5 mM) was similar to that caused solely by GSH.

We have found that Cys has little effect on the recovery of the "switch-on" probe in the detection range, although it is well-known that the structure of Cys is similar to that of GSH. We inferred the following reasons: There exist abundant functional groups (carboxyl and hydroxyl) decorated on the surface of g-CNQDs. As a consequence, Hg^{2+} was tightly captured by g-CNQDs and required a very strong external force to remove. Considering the enormous differences in coordination ability between GSH and Cys due to the multidentate anchor along with the particular steric structure existing in GSH,[36] we deduced that Hg^{2+} can bind GSH preferably. Such results fully reflected the outstanding selectivity and specificity of the sensor platform.

Application in Food Samples. To examine the practical application of the proposed chemosensor, the detection of GSH concentration in various kinds of food was explored. Prior to the sample analysis, cucumber extract was selected as the model sample and used to investigate the effect of sample matrix on GSH sensing. A seen from Figure 9, FL emission spectra of g-CNQDs had no obvious change after the addition of a certain amount of cucumber extract. This was similar in other foods, pointing out no influence from sample matrix. Furthermore, we conducted the recovery test by spiking a series of different known concentration of GSH to ensure the accuracy of the sample test. As the results summarized in Table 3 show, the average recoveries of GSH in tomatoes, cherry tomatoes, purple grapes, white purples, cucumbers, and spinach were found to be in the ranges of 98.3−100.9, 96.5−99.7, 97.1−101.8, 99.5−114.3,

Table 3. Recovery Test of GSH in Various Food Samples

sample	initial amount (mg/100 g)	added amount (μM)	recovery (%)	av recovery (%)	RSD (n = 3, %)
tomato	6.24	3.33	98.6−102.4	100.9	2.0
		6.66	98.4−99.7	98.8	0.7
		10.0	97.4−99.2	98.3	0.9
cherry tomato	5.61	2.00	96.5−103.1	99.7	3.3
		4.00	94.7−100.0	96.5	3.2
		6.00	95.4−99.4	97.6	2.1
purple grape	1.89	1.00	98.5−102.0	101.8	3.2
		3.00	95.8−104.5	101.2	4.4
		5.00	94.3−100.5	97.1	3.0
white grape	1.00	2.50	108.0−120.0	114.3	5.3
		5.00	103.0−105.8	104.2	1.4
		10.0	99.4−99.6	99.5	0.6
cucumber	1.17	2.50	103.6−107.2	105.1	1.8

		10.0	94.9−96.8	96.0	1.0
spinach	2.77	1.00	105.1−115.0	111.0	4.7
		3.00	99.4−107.2	105.0	4.6
		5.00	103.8−105.3	104.5	0.7

DOI: 10.1021/jf505759z
J. Agric. Food Chem. 2015, 63, 1747−1755

96.0−105.1, and 104.5−111.0%, respectively. These results indicated that the restoration of fluorescence was entirely generated by GSH in the food samples.

The amounts of GSH in tomatoes, cherry tomatoes, purple grapes, white purples, cucumbers, and spinach determined by the proposed chemosensor are 6.24, 5.61, 1.89, 1.00, 1.17, and 2.77 mg/100 g, respectively. The detection results of GSH in tomatoes and grapes are respectively consistent with the result achieved from the book (7.0 mg/100 g)[38] and literature (1.89 mg/100 g),[25] which strongly proved the feasibility and reliability of our method. From the analytical results mentioned above, tomatoes and cherry tomatoes are two kinds of food rich in GSH. Therefore, they are excellent food sources for GSH supplements and benefit human health.

In summary, we have successfully developed a "switch-on" fluorescence chemosensor for glutathione detection in food samples. This method, based on the fluorescence recovery of the g-CNQDs−Hg^{2+} probe in the presence of glutathione, displayed several appealing properties, including low cost, quick response, high sensitivity, excellent selectivity, label-free measurement, and switch-on fluorescence response. We believe that such a fluorescence sensor not only would be suitable for GSH assay in food samples but also shows great potential in cell imaging and biological investigation.

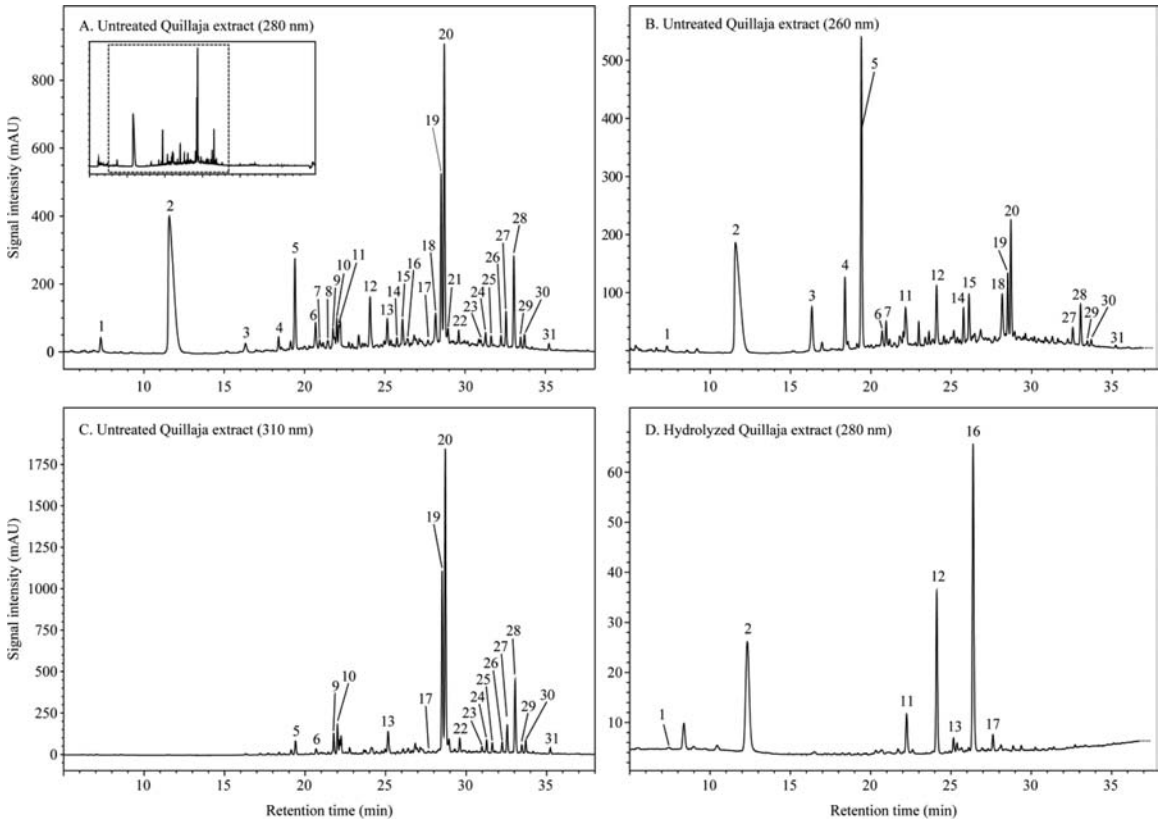

Figure 1. HPLC separation of phenolic compounds in aqueous *Q. saponaria* wood extracts (untreated) monitored at 280 nm (A), 260 nm (B), and 310 nm (C) and in an acid-hydrolyzed extract (D) at 280 nm.

Ultrapure water was used throughout the study (Milli-Q system, Millipore, France).

HPLC-PDA–ESI/MS^n Analyses. Dry commercial *Quillaja* powders and the liquid *Quillaja* preparation were dissolved and diluted in 1% (v/v) aqueous formic acid, respectively. All samples were membrane filtered (0.45 μm) prior to HPLC separation. HPLC-PDA analyses were performed on an 1100 series HPLC system (Agilent, Waldbronn, Germany) equipped with a 250 × 4.6 mm i.d., 5 μm particle size, 100 Å pore size, Kinetex C_{18} column fitted with a 4.0 × 2.0 mm i.d. guard column of the same material (Phenomenex, Torrance, Canada). The column was operated at 35 °C. The mobile phase consisted of 1% (v/v) formic acid in water (solvent A) and 1% (v/v) formic acid in methanol (solvent B), using the following gradient program: 5% B isocratic (10 min), 5–100% B (40 min), 100% B isocratic (5 min), 100–5% B (1 min), 5% B isocratic (4 min). The total run time was 60 min at a flow rate of 1.0 mL/min. Injection volumes of 10 and 20 μL were used. Phenolic compounds were monitored at 260, 280, 310, and 370 nm, and additional UV/vis spectra were acquired in the range of 200–600 nm, employing a model G1315A photodiode array (PDA) detector (Agilent).

For HPLC–ESI-MS^n analyses, the HPLC system described above was serially interfaced with a Bruker (Bremen, Germany) Esquire 3000+ ion trap mass spectrometer via an electrospray ionization (ESI) source operated in both positive and negative modes. Ion mass spectra of the column eluate were recorded in the range m/z 100–1400 at a scan speed of 13 000 m/z/s. Nitrogen was used as a drying gas at a flow rate of 11.0 L/min and as a nebulizing gas at a pressure of 60.0 psi. The nebulizer temperature was set at 365 °C. Helium was used as a collision gas for collision-induced dissociation (CID) at a pressure of 4.0×10^{-6} mbar.

Individual compounds were quantitated using linear calibration curves of authentic reference compounds (ferulic acid, *p*-coumaric acid, syringic acid, and vanillic acid). Derivatives of these phenolic acids were quantitated according to the calibration of the free compound using molecular weight correction factors. For quantitation of (+)-piscidic acid, the compound isolated from *Quillaja* extract was used. Quantitation experiments were performed in duplicate.

Preparative Isolation of Major *Quillaja* Extract Compounds. Four fractions containing major phenolic components as identified by HPLC-PDA–MS^n were isolated from the *Quillaja* extract Andean QDP ultra organic by preparative HPLC. The *Quillaja* extract was dissolved in water/methanol (90/10, v/v) containing 0.1% formic acid for the isolation of compounds **2** and **5** (Table 1 for peak assignment). For isolation of compounds **19** and **20**, the extract was adjusted to pH 2 with formic acid. After membrane filtration (0.45 μm), phenolic compounds were separated with an Ultimate 3000 preparative HPLC system equipped with two solvent delivery modules, a diode array detector (DAD-3000), and an automatic fraction collector (AFC-3000). Separation of compounds **2** and **5** was performed with a 150 × 21.0 mm i.d., 5 μm particle size, 175 Å pore size, Hypersil Gold silica column (Thermo Fisher Scientific, Waltham, MA). The mobile phase consisted of 0.1% (v/v) formic acid in water (solvent A) and 0.1% formic acid in methanol (solvent B) using a multistep gradient as follows: 10% B isocratic (10 min), 10–40% B (5 min), 40–100% B (0.5 min), 100% B isocratic (4.5 min), 100–10% B (1 min), 10% B isocratic (9 min). The total run time was 30 min at a constant flow rate of 15 mL/min. Using this method, the retention times of compounds **2** and **5** were 8.8 and 14.2 min, respectively. Monitoring and peak detection were performed at 256 nm.

Isolation of compounds **19** and **20** was performed with a preparative 250 × 21.1 mm i.d., 5 μm particle size, 125 Å pore size, Phenomenex Aqua C_{18} reversed-phase column. The mobile phase consisted of water (solvent A) and methanol (solvent B), which were both acidified to pH 2 with formic acid. The following gradient was used: 20% B isocratic (10 min), 20–40% B (18 min), 40% B isocratic (20 min), 40–100% B (2 min), 100% B isocratic (8 min), 100–20% B (2 min), 20% B isocratic (10 min). The total run time was 70 min at a constant flow rate of 8 mL/min. Using this method, the retention times of compounds **19** and **20** were 40.2 and 41.0 min, respectively. Monitoring and compound detection were performed at 310 nm.

J. Agric. Food Chem. 2015, 63, 1756–1762

Aliquots of 1000 μL of the *Quillaja* Andean QDP ultra organic extract were injected for each preparative HPLC run. The collected fractions were evaporated to dryness at 40 °C under reduced pressure (T_{max} = 40 °C), freeze-dried, and stored at −20 °C until further use. Compound purity was checked by HPLC-PDA−MS^n as described above.

Acidic Hydrolysis of Extracts and Individual Compounds. The *Quillaja* Andean QDP ultra organic extract, *p*-coumaric acid, and the isolated fractions containing compounds **2**, **5**, **19**, and **20** were dissolved in aqueous 4 N HCl, heated to ∼85 °C for 20−120 min, and subsequently neutralized with aqueous NaOH. Hydrolyzed samples were membrane filtered (0.45 μm) and analyzed with HPLC-PDA−MS^n as described above.

Determination of the Absolute Configuration of Compound 2 and Absolute Sugar Conformation of Compound 5. Specific rotation values for compound **2** were measured with a PerkinElmer model 341 polarimeter (PerkinElmer, Waltham, MA). Compound **5** (ca. 1 mg) was heated with aqueous 2 M TFA at 85 °C for 2 h. The reaction mixture was evaporated at 45 °C in vacuo, dissolved in pyridine (0.2 mL), and treated with L-cysteine methyl ester hydrochloride in pyridine (12 mg in 0.1 mL) at 65 °C for 1.5 h. Subsequent trimethylsilylation was carried out with the above-mentioned silylation mixture (0.3 mL) at 65 °C for 1 h. The reaction mixture was partitioned between hexane and H_2O (0.3 mL each), and the hexane layer was analyzed by GC−MS (column, 30 m × 0.25 mm i.d., d_f = 0.25 μm, HP-5 ms Agilent J&W; column temperature, 100 °C for 1 min, 15 °C/min to 200 °C, hold for 1.33 min, 2.5 °C/min to 240 °C, 15 °C/min to 300 °C, hold for 5 min; carrier gas, helium). The sugar derivative was identified as D-glucose with the retention time of 20.15 min, being identical to the respective retention time of derivatized authentic D-glucose. Under the same conditions, the L-glucose derivative revealed a retention time of 20.61 min.

NMR Spectroscopy. ^1H and ^{13}C NMR spectra of isolated compounds **2** and **5** were recorded on a Varian Unity Inova 500 MHz spectrometer (Darmstadt, Germany). Compound **2** was dissolved in MeOH-d_4 and compound **5** in D_2O. The ^1H and ^{13}C chemical shifts were referenced to residual solvent signals at δ_H 3.35 and δ_C 49.0 for methanol as well as δ_H 4.70 for deuterated water relative to TMS. Adiabatic 2D broad-band and band-selective gHSQC and gHMBC as well as gDQFCOSY spectra were recorded using CHEMPACK 4.0 pulse sequences (implemented in Varian Vnmrj 2.1B software). Coupling constants, *J*, were directly taken from the spectra and are not averaged.

Piscidic Acid, 2. ^1H NMR (CD_3OD, 500 MHz): δ 3.03 (1H, d, *J* = 13.8 Hz, 4-Ha), 3.18 (1H, d, *J* = 14.4 Hz, 4-Hb), 4.55 (1H, s, 2-H), 6.69 (2H, d-like, *J* = 8.8 Hz, 3′-H, 5′-H), 7.11 (2H, d-like, *J* = 8.8 Hz, 2′-H, 6′-H). ^{13}C NMR (CD_3OD, 125 MHz): δ 174.6 (C-1), 76.4 (C-2), 81.4 (C-3), 42.0 (C-4), 175.9 (C-5), 128.0 (C-1′), 132.5 (C-2′, C-6′), 115.7 (C-3′, C-5′), 157.2 (C-4′). NMR data of compound **2** were in agreement with previously published data for piscidic acid.[8]

Syringic Acid 4-O-β-D-Glucopyranoside (Glucosyringic Acid), 5. ^1H NMR (D_2O, 500 MHz): δ 3.29 (1H, ddd, *J* = 2.3, 5.3, 9.7 Hz, 5′-H), 3.42 (1H, t-like, *J* = 9.5 Hz, 4′-H), 3.48 (1H, t-like, 3′-H), 3.51 (1H, ov, 2′-H), 3.63 (1H, dd, *J* = 5.2, 12.5 Hz, 6′-Hb), 3.74 (1H, dd, *J* = 2.4, 12.6 Hz, 6′-Ha), 3.84 (6H, s, 8-H, 9-H, $-OCH_3$), 5.08 (1H, d, *J* = 7.4 Hz, 1′-H), 7.33 (2H, s, 2-H, 6-H). ^{13}C NMR (D_2O, 125 MHz): δ 127.2 (C-1), 107.5 (C-2, C-6), 152.2 (C-3, C-5), 137.6 (C-4), 170.1 (C-7, O−C═O), 56.3 (C-8,C-9, $-OCH_3$), 102.6 (C-1′), 73.6 (C-2′), 75.6 (C-3′), 69.3 (C-4′), 76.3 (C-5′), 60.4 (C-6′). This compound was previously reported by Wolfram et al.[9] and Liu et al.[10]

RESULTS AND DISCUSSION

Characterization of Phenolic Compounds. Typical chromatograms of an aqueous saponin-rich *Q. saponaria* extract are illustrated in parts A (280 nm), B (260 nm), and C (310 nm) of Figure 1. Acidic sample hydrolysis led to a simplified chromatogram shown in Figure 1D (280 nm). In both untreated and hydrolyzed extracts, vanillic acid (**11**), syringic acid (**12**), *p*-coumaric acid (**16**), and ferulic acid (**17**) were identified by comparison of their retention times, UV/vis spectra, and mass spectra to those of authentic reference substances (Figure 2). Furthermore, compounds **1** and **2** were

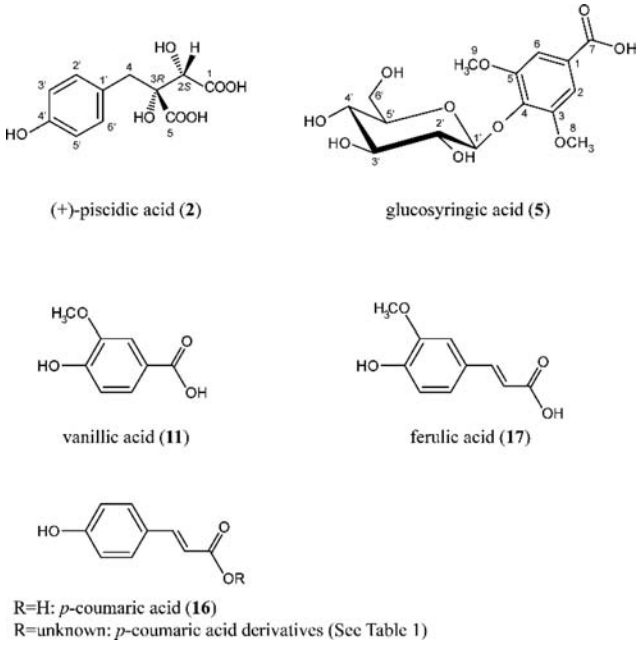

Figure 2. Major phenolic compounds in aqueous *Q. saponaria* wood extracts.

present in both untreated and hydrolyzed extracts. The minor compound **1** remained unidentified in our study. Compound **2** eluted at 11.4 min and represented the major phenolic component in all extracts, showing a UV absorption maximum at 275 nm. In negative ionization mass spectrometry, it produced a quasi-molecular ion, $[M - H]^-$, at *m/z* 255, while a corresponding sodium adduct ion, $[M + Na]^+$, at *m/z* 279 was produced in positive ionization mode (Table 1). The latter ion $[M + Na]^+$ at *m/z* 279 produced a dominant fragment, $[M + Na - 90]^+$, at *m/z* 189 after CID, possibly representing the simultaneous loss of two carboxyl groups. Fragmentation of the analogous negative quasi-molecular ion $[M - H]^-$ at *m/z* 255 yielded a strong signal, $[M - H - 90]^-$, at *m/z* 165. The predominant MS^3 fragments of this daughter ion at *m/z* 165 were observed at *m/z* 147, 135, and 107, indicating the loss of water, a CH_2O group, and a $C_2H_2O_2$ group, respectively. The presumably corresponding ion of the latter $C_2H_2O_2$ group was detected at *m/z* 58 at high signal intensity (Table 1). After isolation by preparative HPLC, NMR spectroscopic data allowed the identification of compound **2** as piscidic acid. Since a rotational value of $[\alpha]_D^{25}$ +41.0° (*c* 5.4, H_2O) was determined in good agreement with previously described data for (+)-piscidic acid ($[\alpha]_D^{24}$ +40.5° and $[\alpha]_D^{23}$ +42.5°),[11] compound **2** was unambiguously identified as (2*S*,3*R*)-(+)-piscidic acid (Figure 2), which was previously found in *Piscidia erythrina* L. (Jamaican dogwood).[12,13]

Compounds **3** and **4** exhibited highly similar UV absorption spectra and identical dominant MS^2 daughter ions at *m/z* 167, derived from parent ions at *m/z* 329 and 461, respectively. Moreover, MS^3 spectra of these ions at *m/z* 167 yielded similar major fragments at *m/z* 152, 123, and 108, being characteristic for the elimination of a methyl moiety, decarboxylation, and a combination of both losses, respectively. In agreement with

[a]The abbreviation "tr" means nonquantitated traces.

Fischer et al.[14] and data obtained by an authentic vanillic acid standard, both compounds were identified as vanillic acid derivatives. Compound **3** yielded the fragment $[M - H - 162]^-$ at m/z 167 after elimination of a putative hexose moiety from the molecular ion at m/z 329. The quasi-molecular ion of compound **4** at m/z 461 exhibited a loss of 294 Da, possibly representing a hexose−pentose moiety. Their UV absorption spectrum showed high similarity to that of vanillic acid (**11**). While esterification of vanillic acid with hexoses was reported to cause a bathochromic shift, the absorption bands remain mostly unaltered after glycosylation of the hydroxyl group.[14,15] Therefore, compounds **3** and **4** were tentatively identified as vanillic acid 4-hexoside and 4-hexosylpentoside, respectively. Compound **14** was also tentatively identified as a vanillic acid derivative, eluting at 25.8 min and exhibiting a characteristic UV absorption spectrum and a dominant CID fragment at m/z 167 (Table 1).

By analogy to compounds **3** and **4**, the quasi-molecular ions $[M - H]^-$ of compounds **5** (m/z 359) and **7** (m/z 491) showed identical losses of 162 and 294 Da, although both yielded a strong MS^2 signal at m/z 197. MS^3 spectra of the daughter ion at m/z 197 yielded characteristic fragments at m/z 182, 167, and 153, which allowed the tentative assignment of compounds **5** and **7** to syringic acid derivatives. After isolation of compound **5** by preparative HPLC, acidic hydrolysis resulted in the appearance of free syringic acid, supporting the tentative identification. In agreement, NMR spectroscopy allowed the complete elucidation of compound **5** as syringic acid 4-*O*-*β*-D-glucopyranoside (glucosyringic acid) (Figure 2). The absolute configuration of the sugar moiety of compound 5 was determined to be D-glucose by GC−MS. Since UV absorption and mass spectra indicated a high structural similarity of compounds **5** and **7**, except for the above-described difference in primary mass loss of 294 Da, compound **7** was tentatively assigned to be a yet uncharacterized syringic acid hexosylpentoside.

Compound **6** showed a UV absorption maximum at 280 nm and a quasi-molecular ion at m/z 451, which produced a strong signal, $[M - H - 162]^-$, at m/z 289 due to the putative loss of a hexose moiety after CID. Since the MS^3 fragmentation pattern of this daughter ion at m/z 289 was highly similar to the fragmentation pattern of an analytical (+)-catechin standard, compound **6** was tentatively identified as catechin hexoside. Compound **8** revealed a UV absorption spectrum similar to that of compound **6** and a quasi-molecular ion, $[M - H]^-$, at m/z 739. The main daughter ions obtained at m/z 587, 407, and 559 could not be specified, while the daughter ions at m/z 451 and 289 indicate a possible structural similarity to compound **6**, a catechin hexoside. Therefore, compound **8** was tentatively identified as a catechin hexosyl derivative.

A total of 11 different compounds (**9**, **10**, **19**, **20**, **22**−**26**, **30**, **31**) were assigned to *p*-coumaric acid derivatives. All of them showed a UV absorption spectrum highly similar to a *p*-coumaric acid standard, while ESI(−)-MS analyses yielded signals at uncommonly high m/z values. Compounds **20**, **22**, **24**, and **25** exhibited a quasi-molecular ion, $[M - H]^-$, at m/z 925, while $[M - H]^-$, ions at m/z 1007 were observed for compounds **9** and **10** and at m/z 1057 for compounds **19** and **23**. Irrespective of their parent ion, common fragment ions were observed at m/z 925, 779, and 633 for all of the above-mentioned compounds. Compounds **19** and **20** were isolated by preparative HPLC and subjected to acidic hydrolysis, yielding free *p*-coumaric acid (Figure 2) as identified by comparing the retention times and UV and mass spectra to those of an authentic standard. In agreement, the neutral loss of 164 Da (*p*-coumaric acid) to yield daughter ions $[M - H - 164]^-$ at m/z 893 and 761 for compound **19** and **20**, respectively, was observed during ESI(−) experiments (Table 1). Therefore, the above-mentioned compounds were assigned to yet uncharacterized *p*-coumaric acid derivatives (Table 1). Further investigations for their detailed characterization by NMR spectroscopy are ongoing.

Compounds **28** and **29** revealed quasi-molecular ions at m/z 1217 and 1071, respectively. Their fragmentation pattern yielded daughter ions at m/z 925, 779, and 633, highly similar to those of the above-described *p*-coumaric acid derivatives (e.g., compounds **19** and **20**). However, their UV absorption maximum was different (ca. 304 nm) as compared to that of *p*-coumaric acid and its derivatives (ca. 314 nm). Several other unknown compounds displaying analogous absorption spectra were found (compounds **13**, **21**, and **27**−**29**). While compounds **21**, **27**, **28**, and **29** disappeared after acidic hydrolysis, compound **13** was still retained in the hydrolyzed extract. Thus, compound **13** may represent a basic structural element of the above-mentioned compounds. In agreement, the quasi-molecular ion of compound **13** was detected at m/z 175, whereas compounds **21**, **27**, **28**, and **29** produced signals at higher m/z 313, 623, 1217, and 1071, respectively. The quasi-

molecular ion of compound **13**, $[M - H]^-$, at m/z 175 produced a single detectable fragment at m/z 131, indicating the elimination of CO_2 and, hence, the presence of a carboxyl function. However, we were unable to identify compound **13** and its tentative derivatives, compounds **21** and **27**−**29** (Table 1).

Quantification of Phenolic Compounds. The identified (+)-piscidic acid represented the major phenolic compound (75−87% of all phenolic compounds) in all *Quillaja* extracts, ranging from 22.09 ± 0.12 to 33.99 ± 0.15 mg/g of DM (Table 2). Although quantitative reports about the natural occurrence of piscidic acid are scarce, dried *Cimicifuga* rhizomes were reported to contain from 0.28 to 4.47 mg of piscidic acid/g of DM previously.[16]

Compounds **3**−**5**, **9**−**12**, and **14** were minor phenolic compounds at levels below 3 mg/g of DM (7% of the total identified phenolic compounds). The *p*-coumaric acid derivative contents (compounds **19** and **20**) ranged between 1.67 mg/g of DM (6.2%) and 8.54 mg/g of DM (18.8%) as shown in Table 2. Generally, all four *Quillaja* extract batches showed similar portions of their polyphenolics. However, both Andean QDP ultra organic batches revealed slightly higher total polyphenol concentrations (42.5 and 45.5 mg/g of DM, respectively) when compared to the batches of Andean QDP ultra and Andean Q ultra (27.8 and 27.1 mg/g of DM, respectively). Previously, the total phenolic content of a less purified *Q. saponaria* bark extract (20% sapogenins) has been assessed by the highly unspecific Folin−Ciocalteu assay to contain 72.14 mg of total phenolics/g of DM.[17]

Since the extracts investigated are frequently used for emulsification in commercial applications, we sought to compare the phenolic contents of *Quillaja* wood extracts with those of other polyphenol-rich emulsifiers. For instance, Rombouts and Thibault[18,19] reported a polyphenol content of 1−2% (DM) in the alcohol-insoluble residue (AIR) obtained from sugar beet pulp, containing feruloyl groups covalently linked to the pectin molecule. Cashew tree gum exudate, representing a natural emulsifier, has been found to contain less than 0.5% (DM) phenols.[20] Consequently, *Quillaja* extracts contain substantially higher levels of total phenolic compounds (up to 4.6%, w/w) than sugar beet pectin and cashew gum exudate.

Since a number of characteristic phenolic acids were present in *Quillaja* wood extracts, their occurrence might be useful for the detection of *Quillaja* extracts in foods, cosmetics, and pharmaceutical formulations. In particular, the high content of 2.2−3.4% (w/w, DM) piscidic acid in the dried extracts is highly characteristic. Due to its monohydroxylated benzene moiety, piscidic acid is most likely susceptible to enzymatic oxidation. Monophenol oxidases (tyrosinase, EC 1.14.18.1) from plants and microorganisms efficiently catalyze the hydroxylation of monohydroxy phenolics to *o*-dihydroxy phenolics. The latter are rapidly oxidized to *o*-quinones by *o*-diphenol:oxygen oxidoreductases (EC 1.10.3.2), which then nonenzymatically polymerize to yield commonly undesired brown or black melanins.[21,22] Oxidases originating from other starting materials should be completely inactivated to prevent undesired browning during *Quillaja* processing. However, (+)-piscidic acid was previously shown to effectively complex Fe^{3+} in pigeon pea root exudates[23] and, therefore, may also be capable of inactivating phenol oxidases by sequestering the copper cation cofactor of these enzymes. Besides enzymatic oxidation, autoxidation of *Quillaja* polyphenols might contribute to discoloration. The presence of catalysts such as excessive metal ions beyond the complexing capacity of piscidic acid as well as excessive oxygen and heat exposure might further accelerate the autoxidation of polyphenols.[24,25]

In addition, polyphenolic compounds with high affinity for iron ions were previously shown to exert an antimicrobial activity.[26] Besides their high content in saponins, the iron-sequestering piscidic acid may therefore represent a further antimicrobial and hemolytic agent of *Quillaja* extracts.[27,28]

In summary, the qualitative and quantitative characterization of phenolic compounds in different commercially available saponin-rich *Q. saponaria* extracts revealed a unique profile of polyphenols that might be applicable for their authentication. Furthermore, the high levels of polyphenols observed in the extracts might exert desired antioxidant properties but, at the same time, cause undesired browning reactions within the food matrix.

being extensively planted in Southern China. The fibers without bark were collected in this study. A fungal laccase (phenoloxidases, EC 1.10.3.2) originated from *Aspergillus oryzae* was purchased from Hubei Yuancheng Pharmaceutical Co., Ltd., China. One unit of laccase activity was defined as the amount of enzyme that oxidized 1 μmol of 2,2′-azinobis-3-ethylbenzthiazoline-6-sulfonate (ABTS)/min, under standard conditions of pH 4.0 and temperature 30 °C, respectively. The cellulolytic enzyme was Celluclast 1.5 L (Novozymes, filter paper activity, 100 FPU/g), containing hemicellulase activities. All chemicals used as received were of analytical or reagent grade.

Treatment of the Fibers. The *E. grandis* fibers were extracted with toluene/ethanol (2:1, v/v) in a Soxhlet apparatus for 6 h. The extracted fibers without exposure to any other processes were regarded as the control fibers (F_1). For the HCW treatment, 25 g of extracted fibers (dry weight, dw) was soaked in 750 mL of deionized water in a stainless-steel reactor with a magnetic stirrer. This reactor was sealed with a steel cover and autoclaved at 170 °C for 1 h. After the HCW treatment, the mixtures were cooled to about 30 °C, and then the treated fibers were filtered with a Buchner funnel. The treated fibers were washed repeatedly with deionized water until the filtrate was neutral and then dried for 24 h at 40 °C in a drying oven. The resulting dry samples were named hot-compressed water treated fibers (F_2). For the laccase-mediated treatment, the extracted fibers were treated with laccase in an aqueous suspension at 5% consistency with a dosage of 24 U/g fiber (dw) and with ABTS 1.5% (dw, w/w) at the saturated air bubbling atmosphere. They were held at approximately 25 °C and pH 4.0 for 2 h. After the laccase-mediated treatment, the mixtures were filtered, and the treated fibers were dried at 40 °C for 24 h. These samples were considered as the laccase-mediated fibers (F_3). Integrated fibers (F_4) were obtained by the same HCW treatment used to prepare the F_2 samples followed by the same laccase-mediated treatment used to prepare the F_3 samples. It should be mentioned that all the treatments were carried out in duplicate.

Isolation of MWL. Milled wood lignin (MWL) was prepared from the fibers according to the method of Björkman.[19] Approximately 15 g of fibers were milled (5 h) in a Fritsch planetary ball mill (Germany) according to previous literature.[20] The ball-milled sample was extracted with dioxane/water solution (96:4, v/v) for 24 h. The mixture was filtered, and then the filtrate was concentrated to ca. 30 mL. The dissolved lignin was isolated by precipitating the concentrated liquor into 10 volumes of acidified water (pH 2.0) adjusted by 6 M HCl. The precipitated MWL was obtained by first centrifugation, then washed with the same acidified water, and finally freeze-dried. The four fiber samples (F_1, F_2, F_3, and F_4) underwent the same processes, and the four resulting lignin samples were titled as L_1, L_2, L_3, and L_4, respectively.

Preparation of EHL. Enzymatic hydrolysis lignin (EHL) was isolated as described by Wen et al.[20] The ball-milled sample (0.3 g)

DOI: 10.1021/jf506042s
J. Agric. Food Chem. 2015, 63, 1763−1772

was subjected to enzymatic hydrolysis (100 FPU cellulase/g substrate) at 2% solid loading with 50 mM NaOAc buffer (pH 4.8). The mixed slurry was incubated in a rotary shaker (150 rpm) at 50 °C for 48 h. After the enzymatic hydrolysis treatment, the residue (named as EHL) was obtained by centrifugation and thoroughly washed with 70 °C water, and then freeze-dried. No further purification was conducted to preserve all structural features of the isolated EHL. The four fiber samples (F_1, F_2, F_3, and F_4) underwent the same processes, and the four resulting lignin samples were named EHL_1, EHL_2, EHL_3, and ELL_4, respectively. The freeze-dried sample (30 mg) was suspended in DMSO-d_6 (0.5 mL), and the mixture was ultrasonically processed at 45 °C for 5 h to complete dissolution.

Characterization of the Fibers. The composition of the four fiber samples was determined by the National Renewable Energy Laboratory (NREL) protocol using a two-step acid hydrolysis method.[21] FT-IR spectra of the fibers were collected in the range of 4000 to 700 cm^{-1} at 4 cm^{-1} resolution and 128 scans per sample.[20] Scanning electron microscopy images were carried out with a Hitachi S-3400N II (Hitachi, Tokyo, Japan) instrument at 15 kV. For each sample, five different surface areas on average were imaged on each single piece by the functionalized SEM tip. Ten sample pieces were imaged by different amplification factors, and 150 recognition images were randomly selected for the analysis. The crystallinity index of fiber samples was measured using an XRD-6000 instrument (Shimadzu, Japan) with a C_u K_α radiation source (λ = 0.154 nm) at 40 kV and 30 mA. Samples were scanned from 5° to 40° (2θ) at a speed of 2° /min.

Characterization of the Lignins. The carbohydrate moieties associated with the four lignin samples were determined by hydrolysis with dilute sulfuric acid according to a previous report.[22] The weight-average (M_w) and number-average (M_n) molecular weights of the acetylated lignin preparations were determined by GPC with an ultraviolet detector (UV) at 280 nm. The column used was a 300 mm × 7.5 mm i.d., 10 μm, PL-gel 10 μm mixed-B, with a 50 mm × 7.5 mm i.d. guard column of the same material (Agilent Technologies, Scotland, UK). For the quantitative ^{13}C NMR experiments, 140 mg of lignin was dissolved in 0.5 mL of DMSO-d_6, and 20 μL of chromium(III) acetylacetonate (0.01 M) was added as a relaxation agent to reduce the relaxation delay. For the quantitative 2D-HSQC spectra, approximately 90 mg of lignin was dissolved in 0.5 mL of DMSO-d_6. Functional groups of the lignin samples were determined by ^{31}P NMR spectra according to previous publications.[20,24] The detailed NMR analysis operation conditions have been given previously.[20,23,24]

RESULTS AND DISCUSSION

Chemical Composition of the Fibers. It should be mentioned that the OH groups in hemicelluloses and cellulose are mainly attributed to the hygroscopicity and dimensional changes of fiberboard. From the perspective of fiberboard performance standards, it is desired to simultaneously minimize the water-absorbing capacity and maximize the strength of the product as much as possible. A feasible solution for this challenge is to remove the hemicelluloses but keep the cellulose. In the present study, HCW treatment at a lower temperature of 170 °C for 1 h was performed to partially remove hemicelluloses and boost the fiberboard performance. The selection of the operational parameters employed in this work was based on our previous research and other published work.[25,26] The elevation of pretreatment temperature from 110 to 170 °C for 1 h and 170 to 230 °C for 0.5 h resulted a notable increase of the degradation and solubilization of hemicelluloses. However, the dissolving rate of the hemicelluloses tended to be slightly in the range of 170 to 230 °C for 0.5 h.[25] The similar fractionation of hemicelluloses could be achieved in the experiments performed under the mildest conditions assayed (175 °C, 1 h) according to the report of Romaní etc.[26] In addition, considering the energy consumption and the cost, the experimental condition of 170 °C for 1 h was chosen.

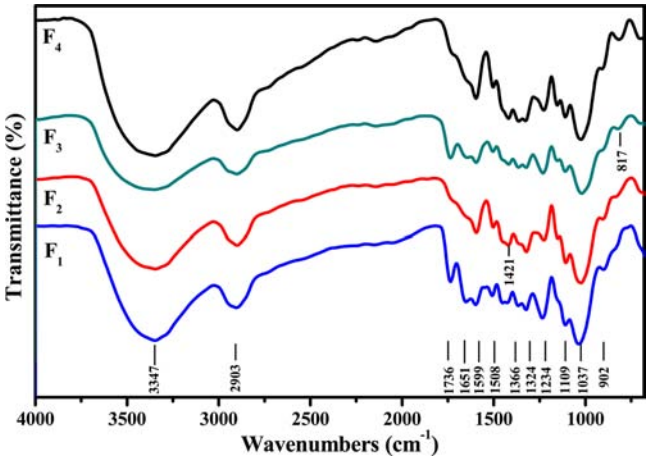

Figure 2. FT-IR spectra of the control and treated fibers.

As shown in Table 1, the yield of F_3 (97.5%) was relatively very high, whereas, the yields of F_2 (67.2%) and F_4 (62.8%) were decreased greatly due to the HCW treatments. The content of arabinose, galactose, mannose, and xylose, which are representative of hemicellulosic fractions, was significantly affected by the HCW treatment. A reduction of their total contents from 18.51% in the control fiber (F_1) to 12.66% in the HCW fiber (F_2) was observed. In particular, xylose presented a maximal decrease of 30.00%. It has been reported that the HCW treatment can cause a significant reduction of the proportion of hemicelluloses.[27] However, the content of glucose, the main constituent of cellulose, was relatively stable in this study, possibly explained by the less intensive HCW treatment conditions used. Furthermore, the lignin content slightly increased in all of the treated samples. This result could be explained by the fact that the hemicellulose content was reduced and the relative content of lignin was increased proportionally. The CrI of F_3 increased just 1.50% compared to that of the control sample, and F_1 was inferior to that of F_2 (4.63%). It was assumed that the increase of CrI could be ascribed to the partial removal of the amorphous portion, mainly hemicelluloses and to some extent of lignin. These results indicated that the HCW and laccase-mediated treatments could enhance the mechanical properties of fiber by increasing the CrI.

Surface Morphology of the Fibers. Scanning electron microscope images of the fibers revealed a rather conspicuous structure on the surface of the fibers (Figure 1). F_1 was observed to be relatively smooth, exhibiting a homogeneous surface that was covered by a thin layer of noncellulosic material. This smooth layer was probably due to the melted lignin spread on the surface of the fiber. It was logical to suppose that the lignin of the middle lamella was plasticized at a high temperature above its glass-transition-point during the thermo-mechanical pulping process and then spread over the nearby fiber surfaces. When the temperature cooled down, a surface coating was likely formed.[28] Fernando et al.[29] also reported a crust on the surface of the unbleached TMP fibers. However, it was obviously observed that the cellulose microfibril aggregates and granules on the surface of F_3 showed a rough and wrinkled mark. Simultaneously, it could be noticed that a large number of holes, which would enhance the accessibility of the enzyme, were present on the surface of F_2

M_w/M_n	1.64	1.68	1.64	1.83

and F_4 but not in the other two samples. The phenomenon could be ascribed to the hydronium ion (H_3O^+) initially causing depolymerization of xylose and cleavage of the acetyl group. At a high temperature, H_3O^+ is originated from water autoionization, causing hydrolysis and deacetylation of hemicelluloses. Meanwhile, H_3O^+ is reproduced from the released acetic acid with the further degradation of hemicelluloses. Since the abundance of side groups and the less uniform structure of the hemicelluloses would be easily solubilized and hydrolyzed

in water,[16,17,30,31] the formation of holes may have been promoted. The "granular" materials on the surface of F_4 after the integrated treatment were due to the deposition of lignin, which was in line with previous reports.[32,33] Through the analysis of the SEM and AFM images, Kristensen et al.[34] reported that the hydrothermal pretreatment could induce the formation and migration of spherical lignin deposits onto the surface of fibers. The incremental content of deposited lignin on the surface of the fibers increased the effect of the laccase-mediated treatment.

FT-IR Analysis of the Fibers. Figure 2 shows the FT-IR spectra of the four fiber samples with the bands assigned according to previous literature results.[4,6,35] The O−H stretching vibration in OH groups was observed as a wide absorption band at 3347 cm^{-1}, and the band at 2903 cm^{-1} was attributed to the C−H asymmetric vibrations in methyl and methylene groups. The signals at 1599, 1508, and 1421 cm^{-1} were originated from the aromatic skeletal vibrations and C−H deformation. The symmetric stretching of C−O−C presented at 1037 cm^{-1} was due to the presence of cellulose and hemicelluloses. Some different absorption peaks were clearly distinguished in the four FT-IR spectra. An evident signal at 1736 cm^{-1} could be found in the spectra of F_1 and F_3, which was originated from the carbonyl stretching in unconjugated ketone, carbonyl, and ester groups.[22] The intensity of this signal was decreased in the spectra of F_2 and F_4. The same trend was observed regarding the intensity of the band at 1651 cm^{-1} (carbonyl stretching in conjugated ketones). As mentioned above, the hydronium ions (H_3O^+) could cause depolymerization of hemicelluloses and cleavage of the acetyl group, which could decrease the content of carbonyl groups. Furthermore, the deposition of lignin on the surface of the fibers, which contains minor amounts of carbonyl groups as compared to hemicelluloses, may reduce the signals of carbonyl groups.

Yield and Carbohydrate Content in the Isolated MWL Samples. The yields and carbohydrate contents of the isolated MWL samples are given in Table 2. The yield of L_1, L_2, L_3, and L_4 was 9.8%, 11.3%, 9.4%, and 11.9%, respectively. MWL could act as a representative of native lignin,[36,37] but its yield is limited and extensively relies upon milling time and the nature of the lignocellulosic materials.[38] Although all MWL samples obtained have been purified, some carbohydrates still associated with the MWL samples. As shown in Table 2, glucose and galactose were the primary sugars, while the amounts of arabinose, rhamnose and xylose were slight. However, the glucose content decreased to 0.25% and 0.62% after HCW and laccase-mediated processes, respectively. Furthermore, xylose disappeared in L_2 and L_4, suggesting that most of the xylose that was attached to lignin was removed after the HCW treatment. This observation indicated that the HCW treatment was an effective method to remove hemicelluloses.

Molecular Weight Distributions of the Four MWL Samples. As can be seen from Table 3, the molecular weights of these four MWL samples ranged from 4030 to 4790 g/mol. As compared to the M_w of L_1, the other three lignin samples exhibited a decreasing tendency. Specifically, the M_w of L_4 after

DOI: 10.1021/jf506042s

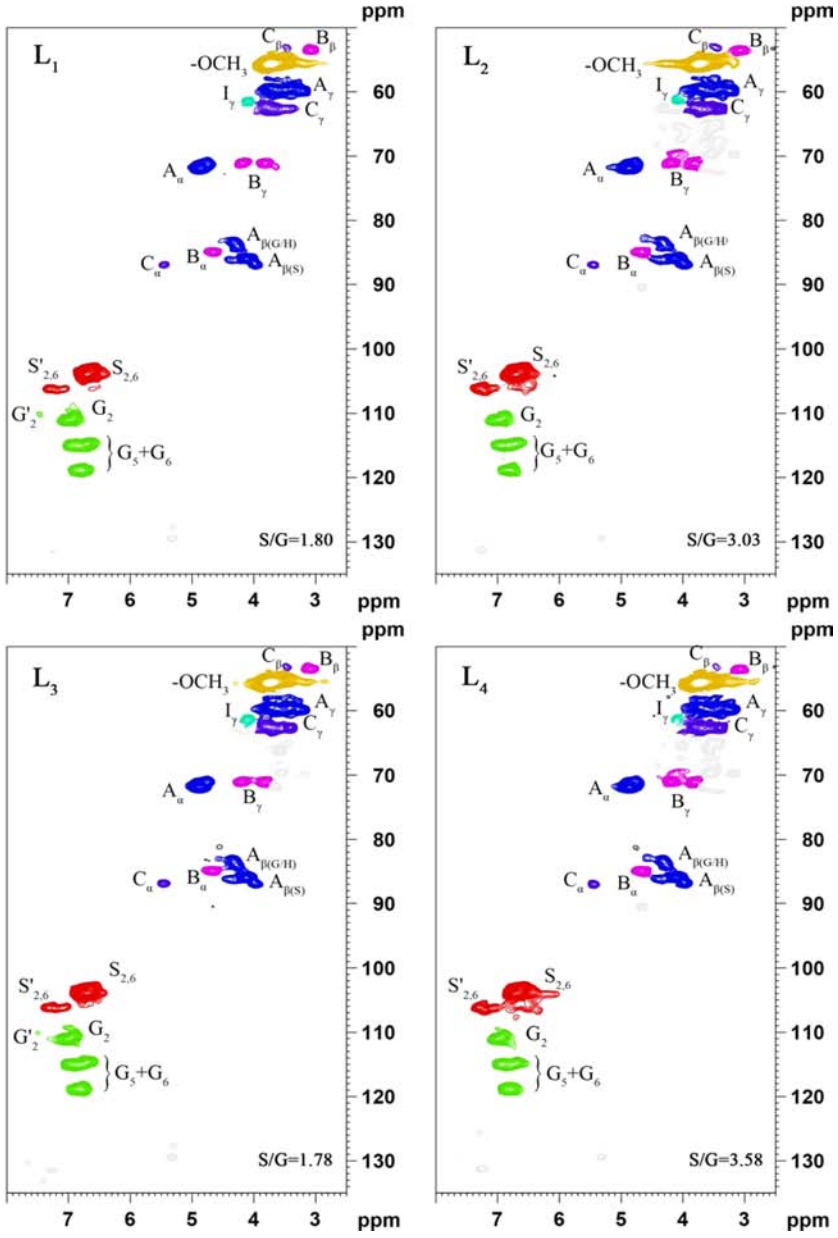

Figure 5. 2D-HSQC NMR spectra of the four MWL samples.

the integrated treatment was 4030 g/mol. The results revealed that the integrated treatment reduced the molecular weight of L_4, which was related to the depolymerization of lignin.[39] The difference in the carbohydrates contents could also be explained for this phenomenon.[23,36] In addition, the four lignin samples presented a relatively low polydispersity (M_w/M_n < 2). Furthermore, after a relatively short incubation with the laccase mediator, more activated sites and stable lignin fragments were obtained. Cleavage of linkages was the main reaction, and as a result, phenolic monomers were formed.[40]

Quantitative ^{13}C NMR Spectra of the Four MWL Samples. The quantitative ^{13}C NMR spectra of the four MWL samples are presented in Figure 3. The amount of specific substructures was calculated based on an aromatic ring (Ar).[23,24] The detailed assignments of the signals in the spectra have been given in previous literature.[24] The spectra of the MWL samples were similar to each other with the exception of several peaks. The low carbohydrate contents were verified by the diminished signals between 90 and 102 ppm, which was also confirmed by the aforementioned sugar analysis, and suggested that the lignin-carbohydrate complex linkages were partly cleaved after the treatments. The peak at 163.2 ppm originated from carboxyl groups was visible in L_1 and L_3, whereas its intensity was decreased in L_2 and L_4 due to the HCW treatment. The aryl ether bond (β-O-4′, δ 61.3−58.0) and the methoxy group (OMe, δ 58.0−54.0) regions were applied to calculate the quantitative information on the structural features. The value of OMe was decreased from 1.89/Ar in L_1 to 1.76/Ar (L_2) after HCW treatment and to 1.74/Ar (L_3) after laccase-mediator treatment, which was mainly as a result of the demethoxylation reactions that occurred in the G and/or S units. The content of β-O-4′ substructures was reduced after the treatments, and there was an especially marked decline from 0.60 to 0.50/Ar after the integrated treatment. It has been demonstrated that the predominant reactions in lignin were fragmentation rather

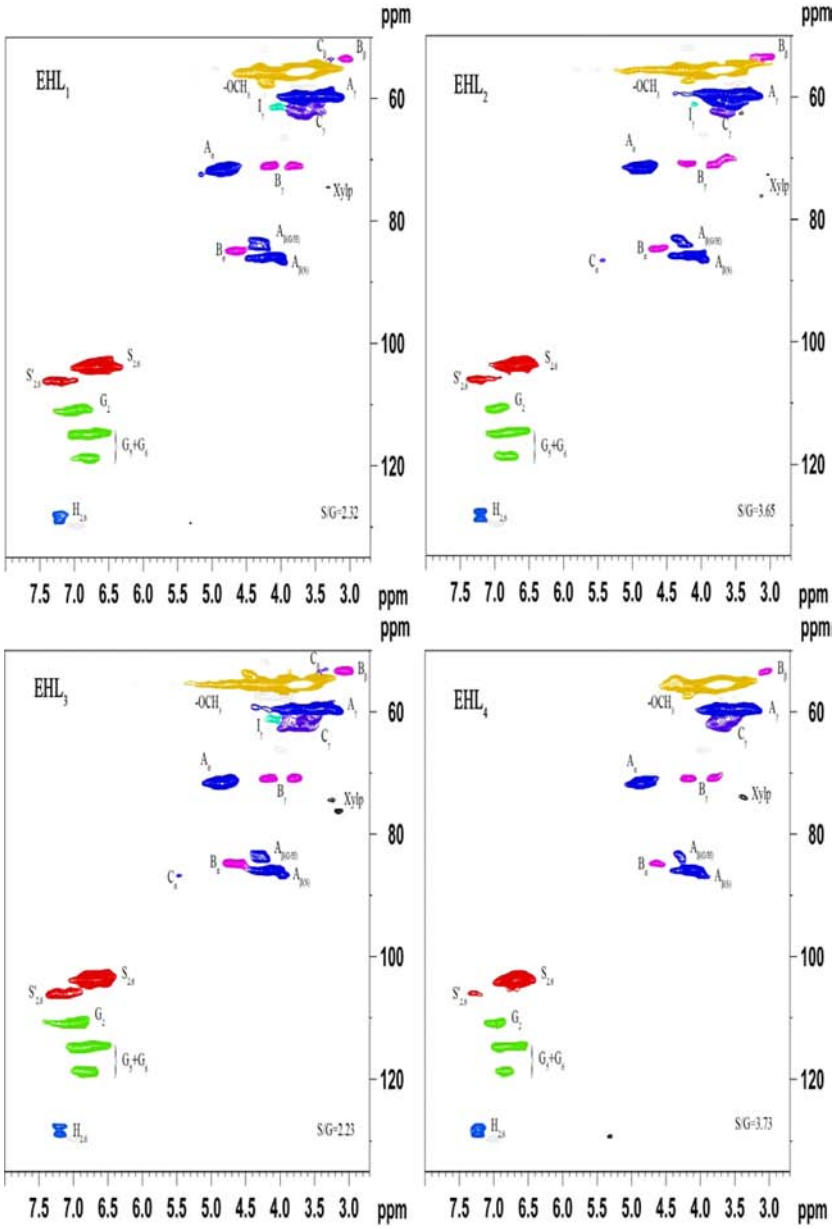

Figure 6. 2D-HSQC NMR spectra of the four EHL samples.

than polymerization. This fact was also confirmed by 2D NMR integration results.

Quantitative ^{31}P NMR Spectra of the Four MWL Samples. The reactivity of lignin is mainly defined by the OH groups, especially by the free phenolic OH groups.[41] ^{31}P NMR spectroscopy is an ideal technique for quantitating the major OH groups in lignin, such as aliphatic OH, condensed and uncondensed phenolic OH, and carboxylic acids groups.[23,42] The ^{31}P NMR spectra of L_1 to L_4 are shown in Figure 4, and the contents of different OH groups are given in Table 4. The amounts of noncondensed syringyl OH were calculated to be 0.38, 0.51, 0.38, and 0.66 mmol/g for L_1, L_2, L_3, and L_4, respectively. These results suggested that the HCW treatment could induce an augmentation of the noncondensed syringyl OH, revealing the split of *β*-*O*-4′ linkages. The content of noncondensed guaiacyl OH was gradually decreased after the HCW and laccase-mediator treatments; however, there was no obvious difference of the condensed guaiacyl OH content among these samples. This implied that parts of the guaiacyl-type lignin units were degraded and possibly released into the hydrolysate.[43] The amount of carboxylic groups in L_2, L_3, and L_4 were elevated, up to 0.92, 0.43, and 1.03 mmol/g, respectively, as compared to L_1 (0.22 mmol/g). This increment was likely attributable to the oxidation of lignin side chains during the HCW and laccase mediator treatments.[5]

2D-HSQC NMR Spectra of the Four MWL Samples. The four MWL samples were investigated by 2D-HSQC NMR techniques to reveal their detailed structures. The corresponding spectra are exhibited in Figure 5, and the main substructures are described in Figure 7. As shown in Figure 5, the prominent correlations observed in the side-chain region (δ_C/δ_H 50−90/2.5−6.0) of all of the four spectra were the *β*-*O*-4′ ether linkages (substructure A). Specifically, the correlations at δ_C/δ_H 71.7/4.85, δ_C/δ_H 83.4−85.9/4.10−4.30, and δ_C/δ_H 59.8/3.39−3.69 belong to the C_α-H_α, C_β-H_β, and C_γ-H_γ linkages of the *β*-*O*-4′ ether substructures, respectively. *β*-*β*′ (resinol, B) and *β*-5′

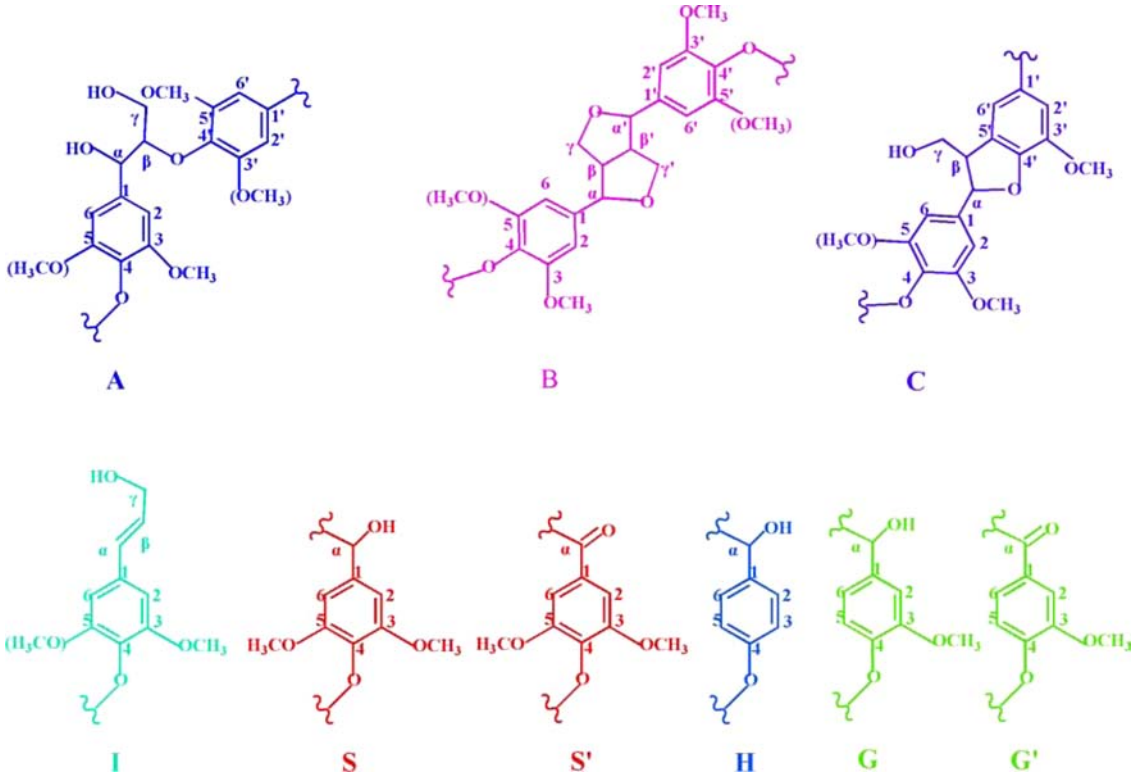

Figure 7. Main classical substructures, involving different side-chain linkages and aromatic units identified by 2D-NMR of MWL: (A) *β*-*O*-4′ aryl ether linkages with a free −OH at the *γ*-carbon; (B) resinol substructures formed by *β*-*β*′, *α*-*O*-*γ*′, and *γ*-*O*-*α*′ linkages; (C) phenylcoumaran substructures formed by *β*-5′ and *α*-*O*-4′ linkages; (I) *p*-hydroxycinnamyl alcohol end groups; (S) syringyl units; (S′) oxidized syringyl units with a C_α-ketone; (G) guaiacyl units; (G′) oxidized guaiacyl units with a C_α-ketone; (H) *p*-hydroxyphenyl units.

Table 5. Quantitation of the Four MWL and EHL Samples by the 2D-HSQC NMR Method

sample	*β*-*O*-4′[a]	*β*-*β*′	*β*-5′	S/G[b]
L_1	47.6	13.6	2.9	1.80
L_2	50.3	14.6	1.9	3.03
L_3	46.7	14.3	3.8	1.78
L_4	46.0	14.3	2.7	3.58
EHL_1	52.41	11.29	ND[c]	2.32
EHL_2	57.19	10.60	0.91	3.65
EHL_3	49.46	10.12	0.68	2.23
EHL_4	46.93	8.64	ND	3.73

[a]Results expressed per 100 Ar based on quantitative 2D-HSQC spectra. [b]S/G ratio obtained by the equation: S/G ratio = $0.5IS_{2,6}/IG_2$. [c]ND, not detected.

(phenylcoumaran, C) linkages could also be observed. Strong signals for resinol substructures B were detected at δ_C/δ_H 84.9/4.66 (C_α-H_α) and δ_C/δ_H 53.5/3.07 (C_β-H_β). The correlations located at δ_C/δ_H 71.0/3.80 and δ_C/δ_H 70.9/4.18 were ascribed to their *γ*-position. Phenylcoumaran substructures C presented relatively low levels, as shown by the correlations at δ_C/δ_H 86.97/5.46, 53.3/3.46, and 62.5/3.72 corresponding to C_α-H_α, C_β-H_β, and C_γ-H_γ, respectively.

In the aromatic region (δ_C/δ_H 100−135/5.5−8.5), the predominant correlations of S and G units could be observed in all of the spectra. The $C_{2,6}$-$H_{2,6}$ correlation for the normal S-type lignin units was found as a prominent signal at δ_C/δ_H 104.2/6.69, whereas the corresponding correlation in C_α-oxidized S′ units was shifted to δ_C/δ_H 106.3/7.21. The C_2−H_2, C_5−H_5, and C_6−H_6 correlations for the G units were identified at δ_C/δ_H 111.2/6.99, 114.5/6.82, and 118.8/6.79, respectively. The correlation for the C_2−H_2 in oxidized *α*-ketone G′ units (δ_C/δ_H 110.1/7.47) was only detected in the spectra of L_1 and L_3. Moreover, some condensed lignin structures could also be detected at $S_{2/6}$, especially for L_2 and L_4, but the formed mechanism was still not revealed.[44]

The absolute percentages of lignin substructures in the four MWL samples are listed in Table 5. The primary substructures were estimated to be *β*-*O*-4′ aryl ether linkages, ranging from 46.0% to 50.3%. The secondary substructures were detected to be *β*−*β*′ linkages (13.6−14.6%). The *β*-5′ linkages was present in lower proportions (1.9−3.8%). It could be found that the percentage of the *β*-*O*-4′ aryl ether linkages (A) decreased to 46.0% in L_4. Three different reactions have been considered to take place with the lignin polymers during the incubation period with the laccase mediator: (i) oxidation; (ii) partial polymerization with perhaps concomitant degradation and possible repolymerization; and (iii) cleavage of lignin carbohydrate bonds.[3,5,6,9,11] According to the present data, it could be concluded that a preferential degradation of lignin occurred after incubation with the laccase mediator. As can be seen form Table 5, the S/G ratio of L_1 was calculated to be 1.80. However, for L_2 isolated from HCW treated fibers and L_4 isolated from the integrated treated fibers the S/G ratio was estimated to be 3.03 and 3.58, respectively. The increased S/G ratios of L_2 and L_4 further confirmed the preferential degradation or removal of the G-type lignin in the treated fibers during hydrothermal pretreatment.[45] The correlations of the G′ units (oxidized G units with a C*α*-ketone) disappeared in the corresponding spectra of L_2 and L_4, which could only be seen at lower contour levels. In addition, the S/G ratio in L_3

DOI: 10.1021/jf506042s
J. Agric. Food Chem. 2015, 63, 1763−1772

(1.78) isolated from the laccase-mediator-treated fiber exhibited a slight reduction, which was also in line with the previous literature.[46]

2D-HSQC NMR Spectra of the Four EHL Samples. To further verify the structural transformations of lignin in the fibers, the EHL samples were isolated to make a comparison with the MWL samples. Undoubtedly, almost all lignin fractions in the materials could be obtained as EHL samples, which were more representative than the MWL samples. To preserve all structural features of the isolated EHL, no further purification was conducted. As shown in Figure 6, the four EHL samples exhibited clearly distinguishable spectra, which were similar to those of the corresponding MWL samples. The primary structural features of lignin, including S, G, and H units as well as various interunit linkages, such as β-*O*-4′, β-β′, and β-5′ linkages, can be clearly identified in the 2D-HSQC spectrum of EHL.

In the side chain region, however, the correlations at δ_C/δ_H 86.7/5.43, which originated from the C_α-H_α of the phenylcoumaran C (β-5′) substructures, could only be found in the spectra of EHL_1 and EHL_3, but still be observed at lower contour levels in the other two samples. In the aromatic region, the cross-signals from S, G, and H units could be clearly identified. The C_2−H_2 correlations in the G′ units (δ_C/δ_H 110.1/7.47) disappeared in all of the EHL samples. Whereas, the $C_{2,6}$-$H_{2,6}$ correlations from H units were clearly observed at δ_C/δ_H 127.8−128.7/7.23, which disappeared in all of the MWL samples. This phenomenon could be ascribed to MWL including a higher proportion of middle lamella material, containing few H units, and the enzymatic treatment removing most of the carbohydrates, preserving the inner H units.

The absolute percentages of β-*O*-4′, β-β′, and β-5′ linkages as well as S/G ratios of EHL samples are also listed in Table 5. Obviously, the contents of β-*O*-4′ linkages and the S/G ratios presented similar features to the corresponding MWL samples. The downtrend of the content of β-β′ linkages was observed after the hot-compressed water, laccase-mediator system, and integrated treatments. However, the content of β-5′ was very low, not even detected in the EHL_1 and EHL_4 samples. In general, the MWL and EHL samples display great similarity and either could be considered as a good representative of native lignin.

containing 12% dry matter. Then the concentrated microalgae were lyophilized to yield dry flakes containing 95−97% dry matter. The dry algae samples were stored at −26 °C and processed within 3 days.

Chemicals and Reagents. FAME mix standards (GLC 566) was purchased from Nu-Chek (Elysian, MN, USA). Cholesterol (≥99% GC), 5α-cholestane (≥97% GC), and hexadecane (99%) used in the determination of GC response factors were purchased from Sigma-Aldrich (St. Louis, MO, USA). Other analytical grade solvents (isopropanol, chloroform, and methanol) were purchased from Fisher Scientific (Fair Lawn, NJ, USA).

Proximate Analysis of Microalgae Biomass. Dry matter content was determined by weight difference after oven-drying at 110 °C for 5 h. Lipid content was determined gravimetrically after solvent extractions as described below, and protein content was determined by using the Dumas nitrogen combustion method with an ElementarVario MAXCN analyzer (Elementar Analysensysteme GmbH, Hanau, Germany) and a nitrogen-to-protein conversion factor of 4.36.[19] Ash content was determined by heating the dry algae samples at 550 °C for 5 h and then weighing the residual ash (AOAC Official Method 923.03). All of the algae samples were washed with DI water to remove growth media before drying/dewatering prior to ash determination.

Microalga Lipid Extraction. Dry algae sample (20 g) was first extracted with isopropanol (300 mL) for 1 h with continuous stirring (300 rpm) to deactivate hydrolytic enzymes that might be present. After isopropanol extract was recovered by filtration, the residual wet solids were mixed with chloroform/methanol (300 mL, 2:1, v/v) and then homogenized using an Ultra-Turrax T25 homogenizer (Ika Works, Wilmington, NC, USA) at 10,000 rpm for 3 min, followed by a 2 h continuous stirring at 300 rpm and then a sequential extraction with chloroform/methanol at ratios of 2:1, 1:1, and 1:2 (v/v). Each extraction used 300 mL of solvent, a 300 rpm stirring rate, and a duration of 1 h. The extracts from isopropanol and chloroform/methanol extractions were combined, and the solvent was removed by rotary evaporation at 45 °C. The crude lipid was subjected to the modified Folch wash[20] twice using a mixed solvent of chloroform, methanol, and water in a ratio of 8:4:3. The lipids obtained from the chloroform phase were filtered through a PTFE filter disk (0.45 μm) and then dried by rotary evaporation at 45 °C and vacuum oven at 23 °C for 12 h. The quantity of extracted lipids was determined gravimetrically. Four replicates of extractions were performed to determine lipid content. Then the lipids of each alga were combined and dissolved in a small amount of chloroform and stored at −26 °C until further analysis.

Fractionation of Neutral Lipid, FFA, and Polar Lipid by TLC. Algae total lipids (30−40 mg) dissolved in chloroform were applied on a preparative TLC plate (silica gel G, 500 μm, Analtech, Newark, DE, USA), and the plate was developed in a mixed solvent of hexane/diethyl ether/acetic acid (70:30:1, by vol). The separation was visualized under ultraviolet light after spraying with 0.1% (w/v) 2′,7′-dichlorofluorescein in methanol. The bands of TAG and FFA were scraped off the plate and extracted four times with 10 mL of chloroform/methanol (2:1). The bands of other lipid components (including polar lipids, sterols, and chlorophyll derivatives) that were located below the FFA band, referred to as the polar lipid fraction, were extracted twice with 10 mL of chloroform/methanol (2:1) and then twice with 10 mL of chloroform/methanol/water (5:5:1). The solvent of combined extracts of each fraction was removed by rotary evaporation at 45 °C. Residual water was removed with a small amount of isopropanol by rotary evaporation. The recovered lipids were converted to FAME in the presence of 1 mg of nonadecanoic acid (internal standard) and analyzed by GC following the procedure described below. Because only fatty acids' GC peaks were quantified, sterols and chlorophyll derivatives in the polar lipid fraction did not interfere with FAME quantification. The weight percentage of FAME was converted to TAG and FFA equivalents using the factors given in AOCS Official Method Ce 1i-07. Three replicates of total lipids from each alga were fractionated by TLC. Because polar lipids of the examined algae contained a variety of molecular species, which varied by the type of algae, estimation of polar lipid content based on GC-FAME result would be inaccurate if converting it to one type of polar lipid. Instead, the weight percentage of glycolipids and phospholipids obtained from LC-MS quantification was used in the calculation.

Fatty Acid Composition. The fatty acid composition of the total lipids and those of neutral and polar lipid fractions were determined by GC analysis of FAME. The lipids (10−20 mg) were methylated with 2% sulfuric acid in methanol (3 mL) by incubation at 65 °C for 18 h with occasional shaking. The resulting FAME were extracted with 3 mL of hexane and washed with 10 mL of water. The hexane extract (1 μL) was injected into an Agilent 7890 GC (Santa Clara, CA, USA) equipped with a DBWAXtre capillary column (30 m × 0.25 mm × 0.25 μm; Agilent, Santa Clara, CA). Helium was used as a carrier gas with a flow rate of 1 mL/min. The split ratio was 50:1. The temperature of the injector and FID detector was 260 °C. GC oven temperature was programmed from 100 °C (1 min) to 240 °C (15 min) at a rate of 4 °C/min. GC peaks were identified by the mixed FAME standard (GLC 566) and confirmed by GC-MS. The relative percentage of fatty acids was reported on the basis of the peak area without using correction factors. Three replicates of FAME samples were prepared from each alga.

The GC-MS system for the identification of fatty acids in each microalga included an Agilent 6890 GC and a Waters GCT time-of-flight mass spectrometer (Milford, MA, USA) operated in electron ionization (+) mode at 70 eV. Data were acquired with accurate mass precision (7000 resolution fwhm). The MS scanned from 45 to 650 Da each 0.5 s. Data were processed with MassLynx 4.0 (Waters Inc.) and compared with MS libraries Wiley 7th edition (2000) and NIST 2011. GC column specification, oven temperature program, injector temperature, carrier gas flow rate, and split ratio were the same as those used for fatty acid composition analysis.

Unsaponifiable Matters (USP). The percentage of USP in the total algae lipids was determined according to AOCS Official Method Ca 6b-53. Briefly, 2 g of total lipids was saponified with 95% ethanol and 50% KOH, and then the USP was extracted multiple times with diethyl ether. Total USP was determined by the weight of the ether extract after solvent removal and expressed as the weight percent of total lipids. The profile of USP was determined by GC-FID and GC-MS. For GC-FID analysis, USP dissolved in chloroform (3 mg/mL) was injected into an Agilent 7890 GC equipped with SAC-5 fused silica capillary column (30 m × 0.25 mm × 0.25 μm; Supelco, Bellefonte, PA, USA). The split ratio of GC injector was 50:1. The temperature of the injector and FID detector was 300 °C. GC oven temperature was programmed from 200 °C (1 min) to 300 °C (19 min hold) at a rate of 10 °C/min. The percentage of USP that were GC quantifiable was determined by using an internal standard, 5α-chloestane. GC response factors of hydrocarbons and sterols relative to 5α-chloestane were determined to be 0.862 for hexadecane and 0.775 for cholesterol, according to AOCS Official Method Ce 1j-07, and these factors were used in the calculations. Two replicates of microalgae total lipids were saponified.

The USP of *Chlamy*, *Chlorella*, *Nanno*, and *Scene* were fractionated on a silica gel TLC using a solvent system of hexane/diethyl ether/acetic acid (60:40:1, by vol). Six TLC fractions were collected from each microalga on the basis of their polarity or the position on the plates. Both the total USP and TLC fractionated USP of four green microalgae and the total USP of *Schizo* were then analyzed by GC-MS. The GC-MS unit for USP analysis was the same as that used for fatty acid analysis. GC column specification, oven temperature program, injector temperature, carrier gas flow rate, and split ratio in GC-MS were the same as those used for GC-FID analysis of USP.

Profiling of Polar Lipid (Glycolipids and Phospholipids) by TLC and ESI-MS/MS. A preliminary qualification of polar lipids was performed using normal phase TLC. First, the total lipids was applied on a normal phase SPE column (silica, 2000 mg, Alltech Extract-Clean column; Grace, Columbia, MD, USA), and then the cartridge was sequentially washed with 20 column volumes of hexane/diethyl ether (4:1), acetone, chloroform/methanol (1:1), and chloroform/methanol/water (5:5:1). The first fraction (hexane/diethyl ether) contained exclusively nonpolar lipids and was discarded. Other SPE fractions were applied on an analytical TLC plate (silica gel GHL, 250 μm;

J. Agric. Food Chem. 2015, 63, 1773−1787

Table 1. Microalgae Biomass Composition on a Dry Weight Basis[a]

	Chlamy	*Chlorella*	*Nanno*	*Scene*	*Schizo*
lipid	24.2 (0.1)	17.9 (3.3)	25.0 (0.4)	10.5 (0.4)	56.7 (0.8)
protein[b]	34.2 (0.3)	28.2 (1.4)	32.2 (0.1)	24.6 (0.3)	12.4 (0.3)
ash	6.1 (0.2)	10.5 (0.3)	5.5 (0.3)	29.5 (0.3)	5.6 (0.1)
carbohydrates[c]	35.5	43.4	37.3	35.4	25.3

[a]Values in parentheses are standard deviations of three replicates. [b]Nitrogen-to-protein conversion factor of 4.36 is used (Gerde et al.[19]). [c]Carbohydrate content is calculated by subtracting lipid, protein, and ash contents from 100%.

Table 2. Microalgae Lipid Class Composition (Weight Percent)[a]

	Chlamy	*Chlorella*	*Nanno*	*Scene*	*Schizo*
neutral lipids	51.3	57.2	14.5	31.5	78.2
TAG	24.5 (2.2)	26.6 (2.8)	8.6 (1.5)	4.1 (0.8)	77.5 (6.4)
FFA	26.8 (2.3)	30.6 (2.1)	5.9 (0.6)	27.4 (1.3)	0.7 (0.6)
polar lipids[b]	9.7 (0.3)	0.7 (0.0)	24.6 (0.4)	0.7 (0.1)	0.9 (0.2)
USP[c]	13.1 (0.1)	13.2 (0.4)	14.6 (0.4)	18.7 (0.6)	1.9 (0.0)
chlorophyllides[c]	16.8	14.6	5.8	14.3	
others[d]	9.1	14.3	40.5	34.8	19.1

[a]Values in parentheses are standard deviations of three replicates for TAG and FFA and differences of two replicates for USP and polar lipids. [b]Polar lipids in this table are glycolipids and phospholipids quantified by HPLC-MS. [c]The wt % of phytol chain of chlorophylls is included in USP (unsaponifiable matters). Chlorophyllide (nonphytol moiety of chlorophylls) is calculated on the basis of the assumption that all of the chlorophyll pigments had the same molecular structure as chlorophyll *a*. [d]"Others" represents the differences between 100 and the known components.

Analtech, Newark, DE, USA). The developing solvent system was methyl acetate/isopropanol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:4, v/v), which was based on a published method[21] with a minor modification of the ratio of aqueous KCl. Glycolipid standards MGDG, DGDG, and steryl glucoside (purchased from Matreya, Pleasant Gap, PA, USA), SQDG (purchased from Larodan, Sweden), phospholipid standards PC, PE, PG, and PI (purchased from Avanti, Alabaster, AL, USA), and soy lecithin (Fisher Scientific) were used in the comparison with microalgae lipid components. The spraying agent of 70% orcinol in sulfuric acid was used for the identification of glycolipids and steryl glucoside, and molybdenum blue was used for phospholipids.[20]

Polar lipid (i.e., glycolipids and phospholipids) analysis by LC-MS was performed by Kansas Lipidomics Research Center Analytical Laboratory (Manhattan, KS, USA). ESI-MS/MS analysis and quantification were conducted as described previously.[22] Microalgae lipid samples (total lipid extract) were introduced by continuous infusion into the electrospray ionization source on a triple-quadrupole MS/MS (API 4000; Applied Biosystems, Foster City, CA, USA). Lipid species were detected using sequential precursor and neutral loss scans. Lipids in each class were quantified in comparison with the two internal standards of that class using a correction curve determined between standards. The compositional data are presented as nanomoles (per weight) or weight percent of the total lipids analyzed. Two replicates of unfractionated total lipids of each microalga were analyzed.

Analysis of Chlorophyll Derivatives by TLC and LC/APCI-MS. The TLC fractionated polar lipid fraction of green microalgae were dissolved in iso-octane/toluene/acetone/methanol (5:5:1:1)[7] to a concentration of 1 mg/mL, and 2 μL was injected to an Agilent HPLC system equipped with the 1200 series Agilent binary pump system. A guard column (2.0 × 23 mm, s-0.5 μm; YMC, Allentown, PA, USA) and a YMC PVA-SIL column (150 mm × 2 mm, s-0.5 μm, 12 nm; YMC) were used in all separation experiments. The column temperature was maintained at 35 °C. The flow rate was 0.5 mL/min. The solvent composition and gradient program were modified on the basis of previous studies.[7,23,24] The solvent system consisted of isopropanol/hexane (2:98, by vol, with 0.1% of stoichiometric triethylamine/formic acid, solvent A1), isopropanol/acetonitrile/chloroform/acetic acid (84:8:8:0.025, by vol, solvent B1), and chloroform/isopropanol/methanol (39:21:40, by vol, solvent A2). The gradient elution program was as follows: 0−2.5 min, 100% A1; 2.5−40 min, 0−100% B1. After 40 min, the column was flushed with A2 (0−100%) for 15 min and reconditioned with A1 for 15 min. Mass spectrometry analysis was performed using the Agilent 6540 Accurate-Mass Q-TOF mass spectrometer with MassHunter Qualitative Analysis software for data acquisition and processing. The atmospheric pressure chemical ionization (APCI) source was set to operate in negative ion mode with a vaporizer temperature of 250 °C. Resolution was 40,000 fwhm, and mass accuracy was better than 2 ppm across the mass range. The instrument was tuned and calibrated with an Agilent tune mix prior to all LC-MS experiments.

Melting and Crystallization Temperatures of Microalgae Lipids and Their Methyl and Isopropyl Esters. The methyl and isopropyl esters of microalgae lipids were obtained by sulfuric acid (2%) catalyzed alcoholysis. The reaction conditions and purification procedure were the same as those used in FAME preparation described above. The melting and crystallization properties of lipid samples were determined by using a differential scanning calorimeter (Diamond DSC; PerkinElmer, Norwalk, CT, USA) equipped with an Intracooling II system. A sample of 3−5 mg was weighed in an aluminum pan (PerkinElmer) and sealed. Indium and *n*-decane were used as calibration standards. The temperature program started with a 1 min hold at 25 °C, followed by a rapid heating (40 °C/min) to 80 °C and a 5 min hold at 80 °C. Then the sample was cooled to −40 °C at a rate of 10 °C/min. After a 15 min hold at −40 °C, the sample was heated to 80 °C at a rate of 5 °C/min. The crystallization onset and completion of melting were recorded during the cooling and the last heating steps, respectively. Two replicates from each alga were measured.

Statistical Analysis. The number of replicates of each analysis was described above. Standard deviations were given for the mean values obtained with three or more replicates. Differences between two values were also given when there were only two replicates.

RESULTS AND DISCUSSION

Proximate Composition. Of the examined microalgae in this study, *Chlamy* (taxonomic class: Chlorophyceae), *Chlorella* (taxonomic class: Trebouxiophyceae), and *Scene* (taxonomic class: Chlorophyceae) are freshwater green algae; *Nanno* (taxonomic class: Eustigmatophyceae) is a saltwater green alga; and *Schizo* (taxonomic class: Thraustochytriaceae) is a saltwater heterotrophic alga.[25,26] Microalgae biomass composition is given in Table 1. *Scene* and *Schizo* had the lowest (11%)

DOI: 10.1021/jf5050603
J. Agric. Food Chem. 2015, 63, 1773−1787

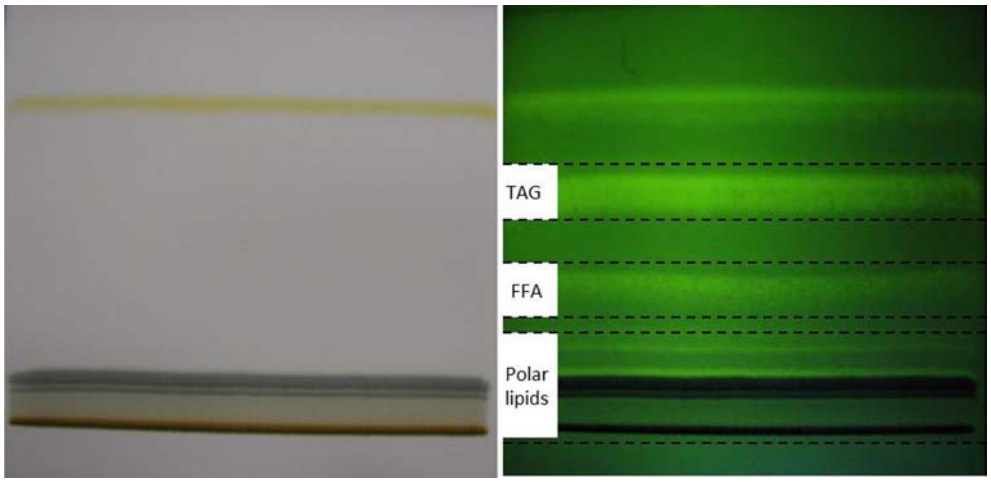

Figure 1. Separation of neutral and polar lipids of *Nanno*. The images on the left and right were taken before and after the fluorescence spray. The dashed lines illustrate how the fractions/silica strips were taken. The developing solvent was hexane/diethyl ether/acetic acid (70:30:1, by vol).

and highest lipid contents (57%), respectively. *Chlamy*, *Chlorella*, and *Nanno* had lipid contents in the range of 18−25%, similar to that of common oilseeds, such as soybeans. Their lipid contents were not unusual as compared to the literature.[3,5,7,25] *Scene* had an exceptionally high level of ash content (30%), followed by the 11% of *Chlorella*. The other three species contained 5−6% ash. Green microalgae contained higher protein contents (25−34%) than *Schizo* (12% proteins). Protein contents of *Chlamy*, *Chlorella*, and *Scene* were generally lower than the values summarized by Becker.[27] It is noted that protein content was not only affected by the growth conditions but also varied with the determination method.[19]

Microalgae Lipid Class Composition. *Nanno* contained the least amount of neutral lipids (15%) but the greatest amount of polar lipids (25%) among the green microalgae (Table 2). Because sterols and hydrocarbons are discussed separately, neutral lipids in this paper are defined as the simple acyl lipids, which include TAG and FFA. *Schizo* was mainly composed of TAG (78%) with <1% of polar lipids. All of the green microalgae had appreciable amounts of chlorophylls (6−17%) and USP (13−19%). *Chlamy* and *Chlorella* had similar lipid class compositions in terms of neutral lipids (51−57%), USP (13%), and chlorophylls (15−17%). Freshwater species were found to contain 27−31% FFA in this study, which more likely resulted from lipid degradation during storage and processing[28] rather than the algae responding to the change of or detrimental growth condition.[29] The relative ratio of TAG/FFA/polar lipids varied by algae species.[2,6] Even for the same species, the compositions of fatty acids and complex lipids in algae heavily fluctuate depending on growth conditions such as light, temperature, nitrogen level, salt stress and the growth stages at which they are harvested.[30,31] Detailed reviews on lipid metabolism in response to various growth factors were given by Harwood and Jones[2] and Guschina and Harwood.[3] For the above reasons, a compositional comparison of fatty acids and complex lipids of the microalgae examined with literature values is not given here. "Others" in Table 2 might include, but is not limited to, the acyl chains of sterol esters, carotenoids, and other polar lipids, such as diacylglycerol trimethylhomoserine ether (DGTS), which were reported as a major component in green algae, and chlorosulfolipids, which were found in freshwater species.[2] The polar lipid composition was very complex as seen by TLC. The lipid components with high polarity covered nearly the entire lower half of the TLC plate. The TLC images of separation of neutral and polar lipids of *Nanno* are given in Figures 1 and 2.

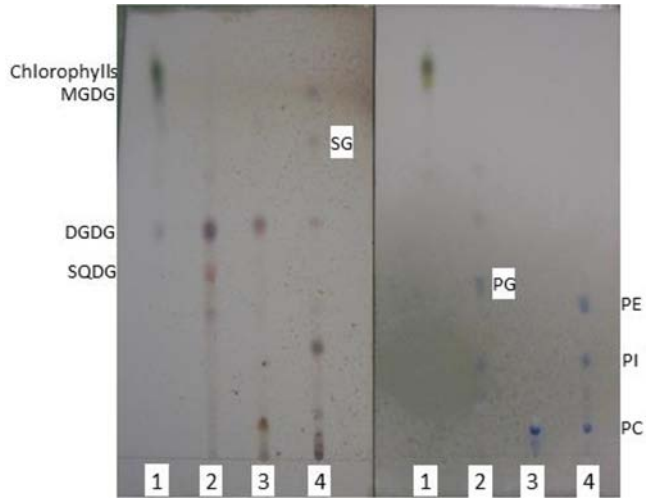

Figure 2. TLC separation of polar lipids of *Nanno*. The plates on the left and right were sprayed with 70% orcinol in sulfuric acid and molybdenum blue, respectively. The samples on the two plates were the same, which were the fractions collected after SPE separation of *Nanno* total lipids. Lanes: 1, acetone fraction; 2, chloroform/methanol (1:1) fraction; 3, chloroform/methanol/water (5:5:1) fraction; 4, soy lecithin. The developing solvent was methyl acetate/isopropanol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:4, by vol).

FAME Composition of Total Lipids, TAG, FFA, and Polar Lipids. Table 3 presents the FAME composition of unfractionated total lipids of five microalgae, as well as those in their TAG, FFA, and polar lipid fractions separated by normal phase TLC. Table 4 summarizes the distribution of saturated (SFA), monounsaturated (MUFA), and polyunsaturated fatty acids (PUFA) of five microalgae as well as their n-3 fatty acid contents.

Major fatty acids in *Chlamy* were C16:0 (27%), C16:4 (6%), C18:1*c* (16%), C18:2 (16%), and C18:3 (10%), representing 75% of total fatty acids. Although there were some differences in the proportion of individual fatty acids when TAG, FFA, and polar lipid fractions were compared with the total lipids of

C24:0	0.6 (0.0)		0.2	0.0				

[a]Values in parentheses are standard deviations of three replicates. Standard deviations of other fractions are generally <1% and are not presented. [b]"br" stands for "branched".

Table 4. Distribution of Saturated, Monounsaturated, and Polyunsaturated Fatty Acids, and n-3 Fatty Acids Content (Weight Percent) of Unfractionated Total Lipids

fatty acid	*Chlamy*	*Chlorella*	*Nanno*	*Scene*	*Schizo*
saturated (SFA)	33.6	23.2	27.5	37.2	68.1
monounsaturated (MUFA)	24.8	14.9	30.0	16.3	0.1
polyunsaturated (PUFA)	42.4	62.1	42.3	46.7	32.1
n-3	12.2	33.5	37.3	23.4	31.8

Chlamy, the general distributions of saturated versus unsaturated fatty acids and MUFA versus PUFA were the same. The polar lipid fraction contained slightly higher levels of C14:0 and C16:4, but reduced levels of C18:1*c* and C18:2, which was opposite to the TAG fraction. Fatty acid distribution in the FFA fraction was similar to that in total lipids.

Chlorella was rich in C16:0 (20%), C16:3 (13%), C18:1*c* (9%), C18:2 (23%), and C18:3 (21%), which accounted for 86% of the total. *Chlorella* contained the highest amount of PUFA and total unsaturated fatty acids. *Chlorella*'s TAG, FFA, and polar lipid fraction had similar fatty acid compositions.

Nanno was rich in C14:0 (6%), C16:0 (19%), C16:1 (24%), C20:4 (6%), and C20:5 (30%), totaling 85%. *Nanno* also contained the highest amount of n-3 fatty acids, at about 37%. There was a reduced level of C18 fatty acids in *Nanno*. Compared to the total lipids, the FFA fraction contained less C16:0 and C16:1, but had more than half of its fatty acids as C20:5. *Nanno*'s polar lipid and TAG fractions had fatty acid distributiond similar to its total lipids.

Scene was rich in C16:0 (31%), C16:4 (6%), C18:1*c* (11%), C18:2 (11%), and C18:3 (21%), accounting for 80% of the total. The unusual n-3 fatty acid C18:4 was present in *Scene* at 4% level. Studies have shown that C18:4 was as effective as marine oil derived long-chain n-3 fatty acids in providing the health benefits in humans relating to cardiovascular disease.[32] *Scene* had the highest amount of SFA among the four green microalgae. The FFA fraction of *Scene* had fatty acids similar to the total lipids. The TAG and polar lipids had lower levels of C16:0 and C16:4 and higher levels of C18 fatty acids.

Schizo has a narrow distribution of fatty acids, with 68% SFA and 32% PUFA. The main fatty acids were C14:0 (4%), C16:0 (60%), C22:5 (5%), and C22:6 (26%). The unique fatty acid distribution of *Schizo* made this species an ideal substrate for the production of functional lipids because its relatively simple fatty acid composition would facilitate the fractionation or purification of long-chain PUFA. The TAG, FFA, and polar lipid fractions all had high proportions of C16:0 and low levels of C22:5 and C22:6, which suggests that long-chain PUFA might have been oxidized during the TLC fractionation, or some of them might be present in other lipid classes that were not identified. The ability of efficient accumulation of DHA and DPA has made *Schizo* a commercial interest for producing purified long-chain n-3 PUFA as a nutritional ingredient in foods.[33]

The similarity of fatty acid composition of FFA to that of total lipids for most species suggests that these FFAs were released from lipid degradation as mentioned earlier. There are

others	2.7	8.4	11.1	8.9	9.8

[a]Values in parentheses are the differences of two replicates.

a few discrepancies; that is, fatty acids of the three fractions do not account for that in total lipid extracts. This suggests the presence of other acyl lipids, most likely in the "others" fraction in Table 2, that have contributed significantly to the total lipid fatty acid composition.

As reviewed by Harwood and Jones,[2] freshwater algae typically contain fatty acids similar to those of plants, but with a relatively high proportion of C16 fatty acids and a reduced level of C18 unsaturated fatty acids. Among the photosynthetic species examined, freshwater microalgae *Chlamy*, *Chlorella*, and *Scene* had low levels (<1%) of long-chain fatty acids that have more than 20 carbons, but an appreciable quantity (9−19%) of 16-carbon polyunsaturated fatty acids, which were not usually found in plant oils. The two saltwater microalgae, *Nanno* and *Schizo*, had much higher levels of PUFA of C20 (37%) and C22 (31%), respectively, than those found in fish oil, egg yolk, or other available sources. They are good sources of specialty oil. Small quantities of branched-chain fatty acids were found in *Chlorella*, *Nanno*, and *Scene*, in agreement with previous findings for *Chlorella* and *Scenedesmus* species.[34] All of the algae examined contained significant amounts of n-3 fatty acids (12−37%). In particular, *Chlorella*, *Nanno*, and *Schizo* had one-third of their fatty acids as n-3 fatty acids.

Polar Lipids (Glycolipids and Phospholipids) Composition by LC-MS and TLC. MGDG, DGDG, SQDG, and PG are the major components of chloroplast lipids in microalgae.[2,35] They function as membrane structural lipids and signaling molecules in the cells. These four classes of polar lipids represented 96, 79, 61, and 67% of the total polar lipids of the green microalgae *Chlamy*, *Chlorella*, *Nanno*, and *Scene*, respectively, as quantified by LC-MS (Table 5). TLC analysis confirmed the presence of MGDG, DGDG, SQDG, PC, PE, PI, and PG in the green microalgae by comparison with commercial standards and the literature.[20] The decrease of the ratio of water in the developing solvent from 9 (as used in the literature[20]) to 4 enabled the TLC separation of PG and SQDG and moved PE further below PG. An example of the separation of polar lipids of *Nanno* is given in Figure 2. Steryl glucoside, which was previously found in *Nanno*,[5] was not detected in the present work as examined by the TLC method.

Nanno contained the greatest amount of total polar lipids, 3 times more than that of *Chlamy*, the second ranked. It has been reported that phospholipids are generally present at minor quantities in microalgae,[6] as observed for *Chlamy* in this study. However, the two saltwater species, *Nanno* and *Schizo*, had more phospholipids than glycolipids. *Chlorella* and *Scene* had roughly the same amount of phospholipids as glycolipids. Unlike other species containing one or two types of major phospholipids, *Nanno* contained significant amounts of PC, PG, PI, and LPC. The high level of phospholipids in *Nanno* was suggested to relate to EPA biosynthesis.[3] The proportion of individual glycolipid varied with species. DGDG was dominant in *Nanno*. In addition, *Nanno* contained the highest level of SQDG (12%) among the microalgae examined. The ratio of MGDG to DGDG in *Chlamy* was close to 1, and SQDG represent only 5% of polar lipids in *Chlamy*. *Schizo* had a very low level of polar lipids, which were mainly phospholipids. The MS spectra of the polar lipids of *Nanno*, as an example, are given in the Appendix I (Supporting Information).

Glycolipids have been shown to have various biological properties including antiviral, antitumor, anti-inflammatory, and immune-suppressive activities.[36] Some of the biological properties of MDGD and DGDG might be dependent on the structure of sugar and acyl moieties.[37] Table 6 reports the molecular species of glycolipids and phospholipids determined by LC-MS. On the basis of the fatty acid composition in Table 3, we could reasonably infer the major acyl groups of each individual polar lipid. For *Nanno*, the dominant SQDG isoform (32:1) is composed mainly of the 16:1/16:0 diacyl group, in agreement with the result of He et al.[8] The principal MGDG isoform (34:5) mainly contains the 14:0/20:5 diacyl group. A minor MGDG isoform (36:5) contains the 16:0/20:5 diacyl group. DGDG is rich in 16:0/20:5, 16:1/20:5, and 14:0/20:5 fatty acids. The major PG isoform (36:6) mainly comprises 16:1/20:5. Two minor PG isoforms contain 16:1/16:0 and 16:0/20:5. The principal LPG, PE, and LPE contain the 16:1 acyl group. LPC mainly comprises 16:1 and 18:2 (minor) acyl groups. The major PC isoforms, 34:3 and 34:2, mainly comprise the 16:1/18:2 and 16:1/18:1 or 16:0/18:2 diacyl groups. The dominant PI isoform (32:1) is composed mainly of the 16:1/16:0 diacyl group.

For *Chlamy*, the major SQDG contains 16:0 fatty acid. The major DGDG and MGDG isoforms have 34 carbons and 1−6 double bonds distributed in two acyl groups, which covers all of the C16 and C18 major fatty acids in *Chlamy* total lipids.

The principal isoform (38:6) of PC, which is the most abundant polar lipid of *Schizo*, is composed of the 16:0/22:6 diacyl group, in agreement with the previous study.[38]

The acyl groups of polar lipids in *Chlorella* and *Scene* are not separately discussed here. In general, SQDG, LPG, PE, LPE, LPC, PC, and PI prefer SFA and MUFA, whereas MGDG, DGDG, and PG prefer PUFA, confirming previous results.[3,6,8]

Unsaponifiable Matters. *Scene* had the highest level of USP (19% of total lipids), followed by *Nanno* (15%), *Chlorella* and *Chlamy* (13% for both), and *Schizo* (2%) (Table 2). These values differed from the literature data to different extents.[5,9] The composition of USP was determined by GC-MS. Table 7 shows that a significant portion of USP was not GC quantifiable (with a SAC-5 column). GC-quantifiable USP of freshwater microalgae *Chlamy*, *Chlorella*, and *Scene* accounted for 68−80% of their total USP, much higher than the 37−48% of saltwater microalgae *Nanno* and *Schizo*. Wang and Wang[5] reported up to 70 and 30% of GC-unquantifiable USP in *Nanno* and *Schizo*, respectively. The GC-unquantifiable USP were nonvolatiles

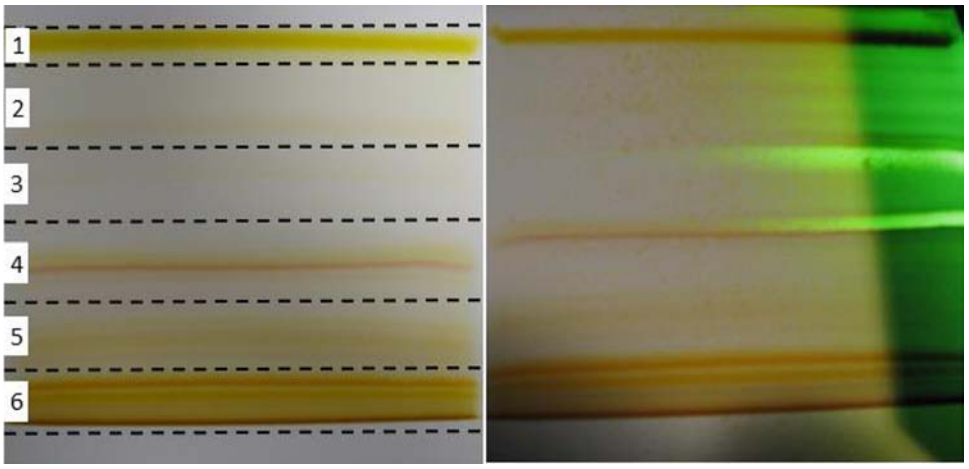

Figure 3. Preparative TLC image of unsaponifiables of *Nanno*. The image on the left was taken before fluorescence spray was applied. The dashed lines illustrate how the six fractions were taken. The image on the right was visualized under UV light after the right half of the plate was sprayed with fluorescence indicator. The developing solvent was hexane/diethyl ether/acetic acid (60:40:1, by vol).

under our GC conditions, present mainly in TLC fractions 5 and 6 (Figure 3), and had color from orange to red. They showed peaks upon HPLC normal phase elution (data not shown). Many of these unidentified USP were likely carotenoids. Carotenoids such as β-carotene and xanthophylls are commonly found in microalgae, as they are not only utilized in photosynthesis but also function as antioxidants.[7,9] The USP of *Scenedesmus quadricauda*, for example, contained 6% carotenoids and 0.5% β-carotene.[9] We did not further characterize these compounds, so the HPLC chromatograms are not included.

TLC fractionation of USP provided information on the relative polarity of the various compounds, which further assisted in structure identification. The preparative TLC separation of *Nanno* USP as illustrated in Figure 3 demonstrates the complexity of microalgae USP. A comparison of the USP of five examined microalgae is shown in the analytical TLC image of Figure 4.

The major USP components of green microalgae were hydrocarbons (TLC fraction 1, Figure 3), phytol (TLC fractions 2 and 3), and sterols (TLC fraction 4), in agreement with the findings of Paoletti et al.[9] Phytol is a diterpene alcohol and is the hydrocarbon tail of chlorophylls. The presence of phytol is attributed to the degradation of chlorophyll during saponification of the total lipids.[10] The level of phytol in the USP can be used as a quantitative indicator of the pigment. *Chlamy* and *Chlorella* contained the highest amount of phytol, representing 80−83% of their GC quantifiable USP, 2-fold higher than those of *Nanno* and *Scene*, which had phytol contents ranging from 40 to 50% (Table 7). *Scene* had the greatest amount of hydrocarbons (21%), whereas *Chlamy* and *Schizo* contained nearly no hydrocarbons. Sterols of the examined green microalgae accounted for 8−35% of total GC quantifiable USP. *Schizo* had a very different USP composition in that 90% of its GC-quantifiable USP was sterols despite the total USP of *Schizo* accounting for only 2% of its total lipids. In all of the species examined, higher amounts of sterols than hydrocarbons were found, in agreement with Paoletti et al.[9]

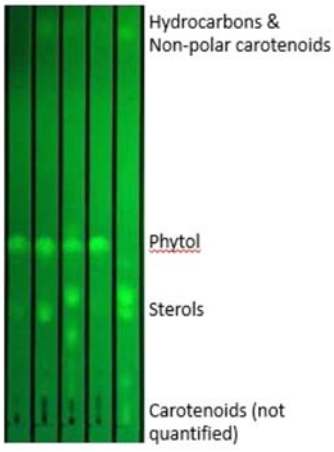

Figure 4. Analytical TLC image of unsaponifiables of microalgae. Lanes (from left to right): *Chlamy*, *Scene*, *Nanno*, *Chlorella*, and *Schizo*. The developing solvent was hexane/diethyl ether/acetic acid (60:40:1, by vol).

Table 8 presents the markedly different distribution pattern of hydrocarbons in these microalgae. Squalene was detected in all of the algae except for *Nanno* and was the only hydrocarbon found in *Schizo*, consistent with the previous result.[5]

Chlamy was mainly composed of odd-chain monounsaturated hydrocarbons, that is, 82% heptadecene and 18% nonadecene.

Chlorella had 88% of heptadecane and 13% of squalene. This differs from the previous result on a saltwater *Chlorella*, which had a wide range of hydrocarbons from C14 to C30 including branched-chain species.[7] However, two earlier papers showed that C17 alkane and alkene were the major components in *Chlorella* sp., albeit they were of different strains.

The major components in *Scene* were pentacosene (63%), heptadecane (6%), $C_{25}H_{48}$ (22%), and $C_{27}H_{54}$ (6%). The abundance of C25 hydrocarbons and the presence of a small amount of C_{27} alkene in *Scene* were also observed in previous studies except for the discrepancy on the level of unsaturation.[9,39]

Nanno had a variety of hydrocarbons from C14 to C30 including both saturated and unsaturated and even- and odd-chain species. The most abundant hydrocarbons in *Nanno* were heptadecane (8%), $C_{25}H_{48}$ (14%), hexacosene (7%), $C_{27}H_{52}$ (20%), and $C_{30}H_{44}$ (18%). Because *Nanno* had 35% sterols (mainly cholesterol) but no squalene, it is reasonable to consider the presence of certain types of biological precursor of

The sterol compounds are listed in the order of their GC retention time on the SAC-5 column. [d]Mass pattern similar to anthraergostatetraenol. [e]tr, trace.

sterols that have structures similar to squalene. This compound could be $C_{30}H_{44}$, which accounted for 18% of hydrocarbons in *Nanno* as shown in Table 8.

Sterol distribution in microalgae greatly varies with the microalgae classes, genera, and species.[40] The occurrence of sterols in these microalgae in relation to their evolutionary history and growth conditions has been extensively discussed in the literature cited.[40] Sterols are essential components of the membranes of eukaryotic organisms, having various biological functions.[40] Beneficial health effects of phytosterol have been reported.[41] A recent study has shown that sterol extract from *Schizochytrium* sp. had cholesterol-lowering activity.[42] The great diversity of sterol distribution in microalgae has long been recognized,[10,11,40] as observed in the present study. As shown in Table 9, saltwater microalgae *Nanno* and *Schizo* were rich in cholesterol, whereas freshwater microalgae *Chlamy*, *Chlorella*, and *Scene* were mainly composed of C28−C30 phytosterols, in agreement with previous reviews.[12,40] Both cholesterol and phytosterols were found in the species examined. Ergosterol (ergosta-5,7,22-trien-3β-ol) was the major sterol in *Chlamy* and *Chlorella*. *Chlamy*, *Chlorella*, and *Scene* contained 12−28% of γ-ergostenol (5α-ergost-7-en-3β-ol). Additionally, *Chlamy* contained 25% of Δ7-stigmasterol (stigmasta-5,7,22-trien-3β-ol), 5% of chondrillasterol (5α-stigmasta-7,22-dien-3β-ol), 3% of

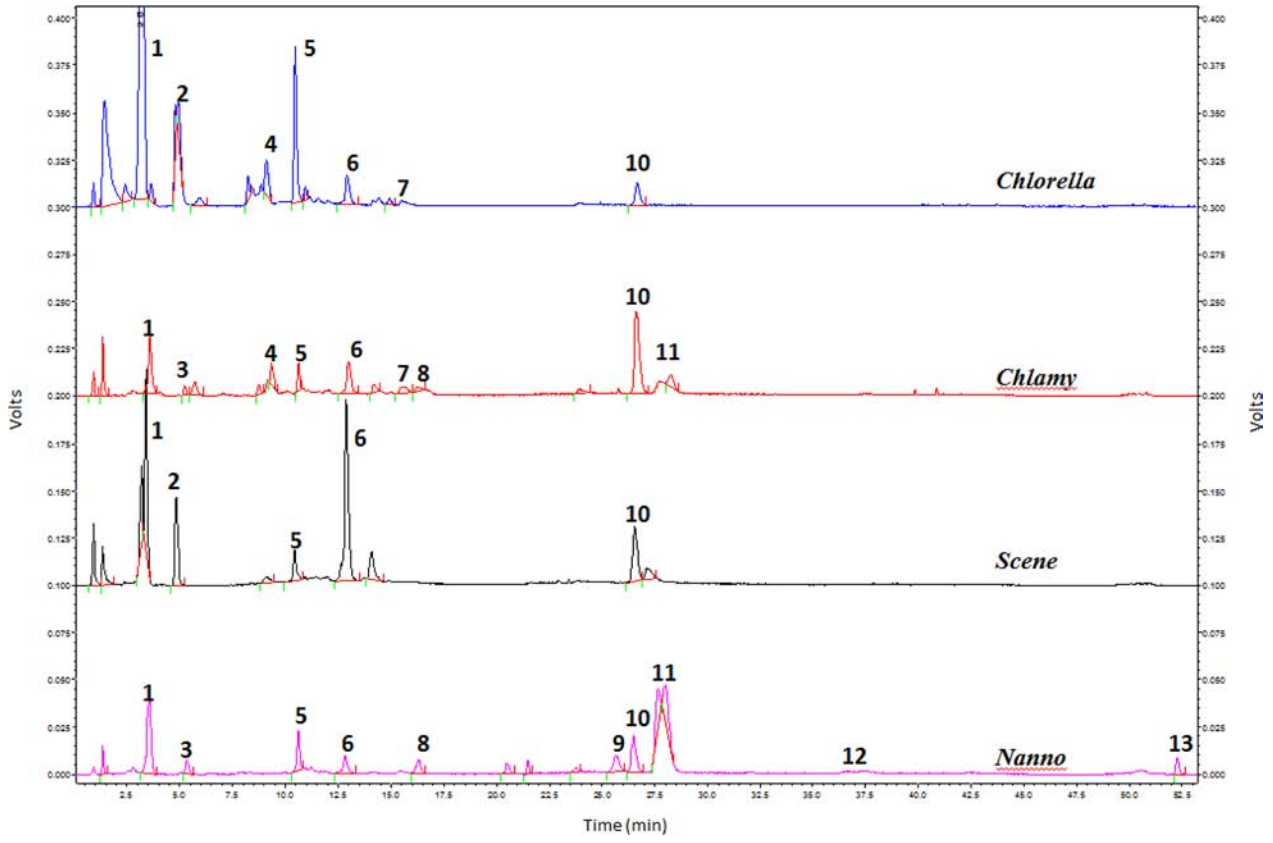

Figure 5. HPLC normal phase separation of polar lipid fractions of four green microalgae (qualitative). Peaks: 1, pheophytin *a*; 2, pheophytin *b*; 3, hydroxypheophytin *a*; 4, hydroxypheophytin *b*; 5, unidentified; 6, chlorophyllide *b*; 7, hydroxychlorophyllide *b*; 8, MGDG; 9, PG; 10, DGDG; 11, SQDG; 12, PI; 13, PC.

each of cholesterol and Δ7-chondrillastenol (stigmast-7-en-3-ol, (3*β*,5*α*,24S)-), and 5% of 5,6-dihydroergosterol (ergosta-7,22-dien-3*β*-ol), which is generally in agreement with the results of Paoletti et al.[10] on five Chlorophyceae. The characteristics of predominant chondrillasterol (68%) and *γ*-ergostenol (28%) of *Scene* in the present work are consistent with those found in *S. obliquus* examined by Patterson.[11] The principal sterols of *Chlorella* were ergosterol (66%) and *γ*-ergostenol (15%), differing from previous results showing the predominance of C29 sterols.[11−14,40] However, Rzama et al.[15] also found that ergosterol was the principal sterol in *C. vulgaris*. *Nanno* contained 84% of cholesterol as its major sterol, with the remaining being fucosterol and its isomer. Fucosterol was identified as the dominant sterol of brown algae,[11] but it was also found in some green algae in a small amount.[40] The other saltwater microalga, *Schizo*, had a more diverse distribution of sterols when compared to *Nanno*. Besides the dominant cholesterol (71%), *Schizo* contained a few C29 phytosterols as minor components. Although the relative percentages of sterols in *Schizo* differed from the reported values, the types of sterols were generally similar to those in the literature.[42]

Other GC-quantifiable USP in Table 7 included compounds having intermediate polarity (TLC fraction 2, Figure 3), such as 6,10,14-trimethyl-2-pentadecanone, which was found in *Chlamy*, *Nanno*, and *Scene* in small quantities, and some unidentified substances. A trace amount of *α*-tocopherolquinone was detected in the USP of *Nanno*. It is a membrane-bound quinone and previously found in blue-green algae.[43] Straight-chain alcohols as reported by Paoletti et al.[10] were not detected. Fatty amides were previously found in freshwater green algae.[44] In the present work, *m*/*z* 59 and 72 were observed in *Chlamy*'s USP (TLC fraction 5, Figure 3), which are the characteristic amide peaks resulting from McLaffery rearrangement of *γ*-cleavage,[45] indicating the presence of a trace of fatty amide in *Chlamy*.

Chlorophylls and Related Metabolites. Chlorophylls are the principal pigments involved in photosynthesis. They are natural food coloring agents and valuable bioactive compounds showing antimutagenic activity and other health benefits.[46,47] Green microalgae contain a great amount of chlorophyll and its metabolites for photosynthesis, suggesting a potential opportunity for value-added coproduct if an effective extraction and fractionation method is developed.[48] In addition, the separation of chlorophylls from the acyl lipids of microalgae also will improve the quality of the produced biodiesel.[49]

Pheophytins and chlorophyllides are derived from chlorophylls after loss of the central Mg atom and the phytol chain, respectively. They are both essential metabolites in chlorophyll biosynthesis and breakdown. The large amount of phytol that was detected in GC-MS analysis of USP suggested that chlorophylls were present in these green microalgae at a significant level. LC/APCI revealed the presence of the following degradation products of chlorophylls: pheophytin *a* [(*m*/*z* 870 ([M − H]$^-$)], pheophytin *b* [(*m*/*z* 884 ([M − H]$^-$)], hydroxypheophytin *a* [(*m*/*z* 886 ([M − H]$^-$)], hydroxypheophytin *b* [(*m*/*z* 900 ([M − H]$^-$)], chlorophyllide *b* [(*m*/*z* 627 ([M − H]$^-$)], and hydroxychlorophyllide *b* [(*m*/*z* 643 ([M − H]$^-$)] (Figure 5). The *m*/*z* values of the molecular ions found from the LC/APCI agreed with the reported values.[50,51] The detection of these compounds suggested that

Table 10. Temperature of Completion of Melting and Onset of Crystallization of Microalga Total Lipids and Their Methyl and Isopropyl Esters[a]

	methyl ester		isopropyl ester		total lipids	
	melting (°C)	crystallization (°C)	melting (°C)	crystallization (°C)	melting (°C)	crystallization (°C)
Chlamy	14.1	−1.0	−5.0	−12.5	48.0	10.0
Chlorella	10.8	−3.8	−4.1	−14.8	30.1	1.5
Nanno	5.4	−4.0	−10.3	−14.0	66.7	47.1
Scene	38.4	31.0	32.5	25.5	57.2	38.9
Schizo	26.2	17.5	13.2	1.8	53.8	25.9

[a]Values are the means of duplicate samples. All differences between the two replicates of melting temperature are <1 °C, and all differences between the duplicates of crystallization are <3 °C.

both chlorophyll *a* and chlorophyll *b* were present in these green microalgae. Peak 5 in Figure 5 was not identified. It had the same retention time as chlorophyll *a* [(m/z 928 ([M + Cl]$^-$)], but an m/z of 902. Quantification of these individual pigments was not carried out. Further structural confirmation with MS/MS is needed. None of chlorophylls or its metabolites were found in *Schizo*.

DSC Melting and Crystallization Temperatures of the Total Lipids of Microalgae and Their Methyl and Isopropyl Esters. Knowledge of the melting and crystallization behavior of microalgae lipids is useful in determining their suitable applications. Table 10 shows that melting points of total lipids of the microalgae examined ranged from 30 to 67 °C, with the highest melting temperature from *Nanno*. The high melting temperatures are caused by the saturated acyl lipids as well as the high melting components in USP such as sterols. When used as biodiesel, total lipids would be converted to methyl (or isopropyl) esters. Monoesters of fatty acids have lower melting and crystallization temperatures than triacylglycerides, phospholipids, and glycolipids. Methyl and isopropyl esters of the microalgae had much reduced melting temperatures compared to their total lipids. The greatest reduction was found in *Nanno*, with the lowest melting point of 5 °C. The current melting temperatures of the esters of these algae would not be satisfactory in biofuel application. The presence of sterols, chlorophyll, and other substances that are soluble in organic solvent would act as crystallization initiators, adversely affecting the quality of the fuels. Appropriate fractionation technology has to be developed to remove these high-melting components. The melting and crystallization behavior of microalgae lipids also have an impact on how they are utilized in food and functional health products.

In summary, lipid characterizations of five microalgae including freshwater and saltwater types are presented. A combination of instrumental analyses was used to obtain the complete lipid profile. All of the examined microalgae are good sources of n-3 fatty acids. *Nanno* and *Chlamy* contained significant amounts of bioactive glycolipids. Freshwater microalgae are rich in phytosterols, whereas saltwater species are rich in cholesterol. The compositional information and methodology presented in this paper are valuable references for future study on algae strain selection and algae cultivation optimization, as well as for the production of value-added coproducts from microalgae.

fragment identical to nucleotides 192−414 of *Ara h 2.01*.[10] Upon transcription, a 222 bp hairpin is formed by the sense and antisense fragments. The same construct also targets *Ara h 6* because *Ara h 2* and *Ara h 6* share 63% sequence identity overall[11] and 81% identity across the region used for the inverted repeat.[10] The RNAi construct was delivered by particle bombardment to 9 month old embryogenic clusters developed from mature zygotic embryos of peanut cultivar Georgia Green.

Testing Stability of Seed Allergen Content Across Three Transgenic Generations. In the field study, to test the stability of seed allergen content by silencing of *Ara h 2* and *Ara h 6* genes, seeds for T_4 and T_5 transgenic generations were raised in the greenhouse starting with bulked seeds of the T_2 generation. Transgenic generations T_3, T_4, and T_5 were grown in the field at the University of Georgia, Tifton Campus, from June 2010 to Oct 2010. There were four replications of T_3, T_4, and T_5 generations and three replications of non-transgenic segregants (similar to "Georgia Green") as controls. Each plot was 1.95 × 0.9 m in dimension, leaving 0.6 m between plots. A total of 66 seeds were sown in each plot, 33 in each of two rows at 16.2 plants/m (5 seeds/ft). Seeds were coated with Vitavax fungicide before sowing. Non-transgenic plants bordered the entire experimental area. The field test was conducted under notification (USDA-APHIS-BRS number 10-116-101n).

Testing Effects of Sulfur on Seed Allergen Content in Transgenic Lines Grown in the Greenhouse. To test the effect of sulfur on seed allergen content in the T_3 generation, seeds were planted in polyethylene containers 90 × 60 × 20 cm in dimension filled with a mixture of sand, vermiculite, and perlite in the ratio of 2:1:1. Each container had three transgenic and three non-transgenic plants. The planting mixture was irrigated with deionized water before planting. The nutrient solution for irrigation was prepared in deionized water with constant concentrations of macro- and micronutrients, except for sulfur (Table 1). Three concentrations of sulfur (S) were

Table 1. Composition of Nutrient Solution

medium S	0.3
high S	3.0
$MgCl_2{\cdot}6H_2O$	
low S	2.97
medium S	2.7
high S	0

provided as $MgSO_4$ at 3 mM (high S), 0.3 mM (medium S), and 0.012 mM (low S). The concentration of Mg was kept constant with $MgCl_2$ at 2.97 mM (in low S solution), 2.7 mM (in medium S solution), and 0 mM (in high S solution). The pH of the solution was adjusted to 5.8. There were five replications for each S treatment concentration (0.012, 0.3, and 3 mM). The plants were watered on alternate days with nutrient solution at 500 mL per plant. The potting medium was flushed with deionized water after every three applications of nutrient solution to prevent salt accumulation in the root zone.

Protein Extraction. In the study, to test stability across three transgenic generations, 15 seeds were pooled separately from three replications of T_3, T_4, and T_5 transgenic generations and non-transgenic control. To study the effect of sulfur on seed allergen expression, seeds were selected from each plant for protein extraction. Two seeds per plant were selected from low S treatment (0.012 mM) and pooled to obtain six seeds for each transgenic and non-transgenic genotype per replication. For medium (0.3 mM) and high (3 mM) S treatments, five seeds per plant were selected and pooled to obtain 15 seeds for each transgenic and non-transgenic genotype per replication. Thus, there were five pooled replicates from each sulfur treatment. Homogeneity of seed maturity within treatments was maintained by choosing the most mature seeds of nearly uniform size. A standard curve for quantitative westerns was derived using protein extracted from 15 seeds of field grown "Georgia Green". Seeds were weighed; testas were removed; and cotyledons were ground in liquid nitrogen. The seed powder was defatted with hexane at 1:35 (w/v) for 4 h, keeping the sample on ice. Defatted and air-dried seed powder was passed through a 30 mesh sieve. Seed protein was extracted using Tris-buffered saline (TBS, 150 mM NaCl and 50 mM Tris) at pH 7.4, containing ethylenediaminetetraacetic acid (EDTA)-free protease inhibitor (Roche Diagnostics, Indianapolis, IN). The defatted and air-dried peanut flour was mixed with ice-cold TBS in the ratio of 1:10 (w/v) and mixed overnight at 4 °C.[20] The mixture was centrifuged at 16060*g* for 15 min at 4 °C, and crude protein extract (CPE) was collected, aliquoted, and stored at −80 °C. Quantification of protein in the crude protein extract was performed using the Pierce bicinchoninic acid protein assay kit (Thermo Scientific, Rockford, IL) according to the protocol of the manufacturer.

Quantitative Western Blots. Seed protein was denatured at 95 °C for 5 min, resolved by running on 15% polyacrylamide gels for 1.5 h, and blotted onto Amersham Hybond-P polyvinylidene fluoride (PVDF) membrane (GE Healthcare, Piscataway, NJ) by electro-transfer at 100 V for 1 h. The PVDF membrane was dried at 37 °C overnight. To test for equal loading of proteins, the membrane was stained with SYPRO Ruby (Invitrogen, Grand Island, NY) as per the protocol of the manufacturer. Briefly, proteins on the PVDF membrane were fixed with a solution containing 10% methanol and 5% acetic acid, washed with deionized water 4 times for 5 min each, stained with SYPRO Ruby, and washed. Fluorescence detection and imaging were performed with a STORM molecular imager (Amersham Biosciences, Piscataway, NJ) at 450 nm excitation/520 nm emission. For western blotting, the membranes were blocked with 5% non-fat dry milk in Tris-buffered saline and Tween 20 (TBST) for 1 h, followed by incubation with anti-Ara h 1 (1:5000), anti-Ara h 2 (1:8000), anti-Ara h 3 (1:5000), or anti-Ara h 6 (1:5000) primary antibodies custom manufactured by Sigma Immunosys (Woodlands, TX). Subsequent to three washes with TBST, the membranes were reacted with alkaline phosphatase (AP)-labeled rabbit anti-chicken/turkey secondary antibody (Invitrogen) at 1:10 000 for $^1/_2$ h. Signal detection was performed with enhanced chemifluorescence (ECF) substrate (GE Healthcare, Piscataway, NJ) treatment for 5 min. Fluorescence was detected with a STORM molecular imager (Amersham Biosciences) at 450 nm excitation/520 nm emission.

Quantification of Allergens in Seed Protein Extract. The standard curve for allergen quantification was derived from "Georgia Green" protein at concentrations of 20, 10, 5, and 2.5 μg obtained by loading 5 μL per well of protein at 4, 2, 1, and 0.5 μg/μL, respectively. For Ara h 1 and Ara h 3 quantification, 5 μg of total protein of test samples was loaded. For Ara h 2 and Ara h 6 quantification, 20 μg of total protein of test samples was loaded. The volume of each band was quantified with Image Quant software after background correction by the object average method. Allergen band volume calculated for test samples was normalized with that of "Georgia Green".

Because allergens are quantified relative to "Georgia Green" total protein concentration, the concentration of individual allergens will be proportional to the total protein concentration. The mean allergen concentration was compared by Tukey's t test at $p \leq 0.05$ using SAS software.[21]

Carbon−Nitrogen−Sulfur (CNS) Analysis. In the sulfur study, CNS analysis was conducted on the same seed samples used for quantitative westerns. Replicate seed samples, four each from low, medium, and high sulfur treatments, were used. Analysis was

DOI: 10.1021/jf504892f
J. Agric. Food Chem. 2015, 63, 1788−1797

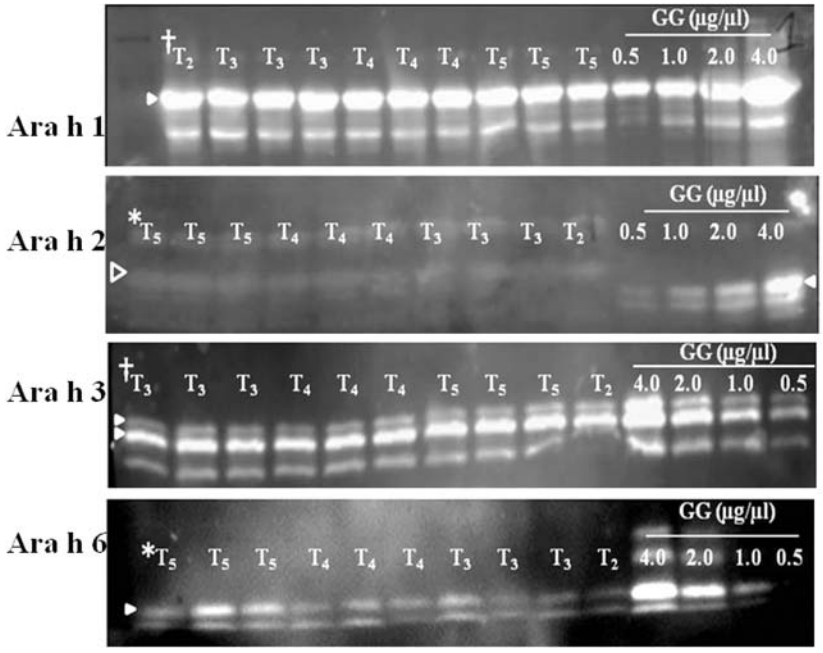

Figure 1. Western blot for allergen quantification in transgenic generations T_3, T_4, and T_5. A total of 5 μL of Tg and "Georgia Green" (GG) protein were loaded for SDS−PAGE. Western blotting was performed using a 1:5000 dilution of anti-Ara h 1, anti-Ara h 3, and anti-Ara h 6 and 1:8000 dilution of anti-Ara h 2 primary antibodies, followed by AP-labeled secondary antibody in 1:10 000 dilution. Signal detection of allergens was performed with ECF substrate with a STORM molecular imager at 450 nm excitation/520 nm emission. Allergen band selected for quantification was indicated by filled triangles. A standard curve was developed using the GG protein concentration and corresponding allergen band volume. The band volume for each allergen was calculated using Image Quant software. The control for protein loading in the Ara h 2 blot was performed with primary Ara h 3. A non-filled arrow in Ara h 2 blot corresponds to Ara h 3 detected with primary Ara h 3 antibody at 0.2:5000 dilution. (†) Transgenic (Tg) protein samples at 1 μg/μL. (∗) Transgenic protein samples at 4 μg/μL.

Table 2. Amount of "Georgia Green" Total Protein Equivalent Relative to Allergen Band Intensity in 1 μg/μL Total Protein from Transgenic Generations T_3, T_4, and T_5 and Non-transgenic (NTg) Null Segregants Grown in the Field

	"Georgia Green" protein equivalent corresponding to allergen band intensity (μg/μL)

[a]Band volume calculated for each allergen in total protein, by quantitative western blotting, was normalized with "Georgia Green" protein concentration used to develop a standard curve. Each value represents the average ± standard deviation from two technical replications of each of three biological replicates. Means were analyzed by Tukey's t test at $p \leq 0.05$. [b]Loaded 5 μL of protein at 1000 ng/μL. [c]Loaded 5 μL of protein at 4000 ng/μL. [d]Values within a column represented by the same letter are not significantly different.

performed with the dry combustion method in a Leco CNS 2000 analyzer at the Laboratory for Environmental Analysis, University of Georgia, Athens, GA. Carbon and sulfur were detected as CO_2 and SO_2, respectively, by infrared absorption measurement. Nitrogen was determined by thermal conductivity.

Amino Acid Analysis. Free and total amino acid analysis was conducted with one pooled seed sample each, from low-, medium- and high-sulfur plants of transgenic and non-transgenic genotypes. Seed samples (0.05 g each) were pooled from four pooled replicates (same as the replicates used for quantitative western blots) from each sulfur treatment. Amino acid analysis was conducted at the Molecular Structure Facility, University of California, Davis, Davis, CA. Briefly, for total amino acid detection, approximately 10 mg of seed meal was dissolved in 1 N HCl and heated to 56 °C for 15 min. The mixture was defatted with CH_2Cl_2 (2-chloromethane), and the supernatant was collected, dried, and hydrolyzed with 6 N HCl at 110 °C for 24 h. NorLeu dilution buffer was added, and samples were analyzed on a L-8800 Hitachi instrument. For analysis of cysteine and methionine, performic acid oxidation was performed prior to acid hydrolysis. For free amino acid determination, approximately 10 mg of seed meal was dissolved in 1 N HCl and heated to 56 °C for 10 min, proteins were precipitated with 10% sulfosalicylic acid, and supernatant was collected, dried, dissolved in AE-cysteine buffer and analyzed on a L-8800 Hitachi instrument.

RESULTS AND DISCUSSION

Germination, Extractable Seed Protein, and Allergen Expression in T_3, T_4, and T_5 Generations. The germination percentage of T_3, T_4, and T_5 generations and the non-transgenic control varied from 82.95 to 93.2%, although no statistically significant variation was observed ($p \leq 0.05$). The percentage of the total seed extractable protein varied from 6.09 to 10.4%, and no significant difference was detected among three transgenic and non-transgenic generations. Protein extraction efficiency differs with buffer, meal/buffer ratio,[22] and pH of buffer.[23] Peanut seed protein ranged from 20.7 to

DOI: 10.1021/jf504892f
J. Agric. Food Chem. 2015, 63, 1788−1797

28.1% in analysis of 64 peanut genotypes[24] and was reported as 21% in a comparative study of edible seed nuts.[25] Both of these studies measured protein by applying a conversion factor to total nitrogen content. In our study, only soluble protein was assayed, hence the variation from expected protein content per unit mass of defatted meal observed in this study.

No statistically significant difference was seen between "Georgia Green" and null segregants in quantitative western blots for Ara h 1, Ara h 2, Ara h 3, and Ara h 6 levels (results not shown). As shown by quantitative western blot (Figure 1 and Table 2), Ara h 1 and Ara h 3 levels in T_3, T_4, and T_5 generations were not significantly different from those of non-transgenics, although transgenics consistently showed numerically higher Ara h 1 and Ara h 3 than the null segregant. No signal for Ara h 2 proteins was detectable in RNAi lines, which was significantly different ($p \leq 0.0001$) from the non-transgenics. The concentration of Ara h 6 in all three transgenic generations was also significantly lower than in the null segregant ($p \leq 0.0001$).

The present study shows that inheritance and expression of the transgene are stable in T_3, T_4, and T_5 generations for both Ara h 2 and Ara h 6 under field conditions. This is in agreement with stable integration and inheritance of transgenes across multiple generations in other transgenic plants.[26,27] Because the transgene silencing of Ara h 2 was found to be stable across four generations (this study and the study by Chu et al.[10]), it is possible that the integration event may be near matrix attachment or hypomethylated chromosomal regions,[27] although this could only be determined with further molecular evidence.

Collateral changes in seed proteins were seen in soybean[28,29] and *Phaseolus vulgaris*,[30−32] where lines deficient in one seed protein showed an increase in other proteins and enzymes. The lack of a significant quantitative change in Ara h 1 and Ara h 3 probably would result in only minor changes in allergenicity because of these proteins. Mass spectrometry analysis of proteins from the same line did show a significant increase in 13-lipoxygenase and 11S Ahy-3 (Ara h 3-related) proteins.[19] This variation in detection efficiency is due to the sensitivity and ability of mass spectrometry to differentiate products of multiple gene families. In this study, a band was observed in transgenics alone when Ara h 3 primary antibody was used at dilution of 0.2:5000 with 4 μg/μL total protein (Ara h 2 in Figure 1). This band was not detectable with 1 μg/μL total protein used for Ara h 3 quantification in this study. A higher but statistically insignificant level of Ara h 3 in transgenics observed in this study could be attributed to differential detection of Ara h 3 isoforms by western blotting under the conditions employed in this study. Thus, the data from quantitative western blots of major allergens should be combined with more global proteomics platforms to develop a more comprehensive profile of differences between transgenic and non-transgenic lines.

An effect of the environment on silencing was not observed in this study, because both greenhouse-raised plants (T_3) and field-grown plants showed stable expression of the transgene. Environmental effects on transgene expression have been observed between field and greenhouse-grown *Gladiolus*,[33] in *Chrysanthemum* grown under different temperatures,[34] and in *Nicotiana* exposed to different light intensities.[35]

Of the four major allergens analyzed in this study, Ara h 1 and Ara h 2 constitute approximately 12−16 and 5.9−9.3% of the total seed protein, respectively.[12,13] Because there was no statistically significant difference in the extractable seed protein of field-grown transgenic compared to non-transgenic lines across generations, decreasing Ara h 2 and Ara h 6 proteins in seeds must be tempered by compensation with multiple proteins, including slight increases in Ara h 1 and Ara h 3.

Plant Morphology in the T_3 Generation under Varying Soil Sulfur Levels. Plants that received low sulfur nutrition (0.012 mM) showed clear symptoms of sulfur deficiency, including extensive yellowing, reduced vegetative growth, reduced seed number, and reduced seed weight, when compared to the plants grown under medium (0.3 mM) and high (3.0 mM) sulfur nutrition (Figures 2 and 3). Sulfur is an essential macronutrient for plants and impacts CO_2 assimilation, Rubisco enzyme activity, and photosynthesis.[36,37] Sulfur participates in several redox reactions and is essential for synthesis of amino acids methionine and cysteine, several proteins, co-enzymes, and iron−sulfur clusters. An adequate soil sulfur concentration is essential for nitrogen fixation.[38] Sulfur deficiency is associated with chlorosis, growth retardation, and reduced yield.[39,40] Reproductive growth was more affected than vegetative growth by sulfur deficiency in wheat.[40] Poor growth, reduced seed weight, and low yield under low sulfur were observed in this study and in other crops.[41−43]

Figure 2. Peanut plants 3 months after planting in two different soil sulfur levels.

Figure 3. Seed samples used for protein extraction and quantification of relative amounts of peanut allergens. For low S, two seeds were collected per plant from three plants per replication and pooled to obtain six seeds per replication of transgenic/non-transgenic seeds. For medium and high S, five seeds were collected per plant from three plants per replication and pooled to obtain 15 seeds per replication of transgenic/non-transgenic seeds.

Relative Concentrations of Allergens Ara h 1, Ara h 2, Ara h 3, and Ara h 6 in Peanut Transgenic Line B11.1.1 under Different Soil Sulfur Levels. Total extractable seed protein in greenhouse-grown seeds showed significant variation

Table 3. Extractable Seed Protein in T_3 Generation Transgenic (Tg) and Non-transgenic (NTg) Plants Grown in the Greenhouse under Three Soil Sulfur Levels

		total protein[a] (%)	observed F	observed p	F critical
sulfur (S)	0.012 mM	4.35 ± 0.84 b[b]	5.35	0.01	$F(2, 24) = 3.40$
	0.3 mM	4.66 ± 0.80 ab			
	3.0 mM	5.47 ± 1.05 a			
genotype	Tg	5.27 ± 0.93 a	9.13	0.005	$F(1, 24) = 4.25$
	NTg	4.39 ± 0.88 b			

[a]Seed protein was extracted from six pooled seeds of low S and 15 pooled seeds of medium and high S from each of the five replications and quantified by a bicinchoninic acid assay. Total protein values represent the average ± standard deviation from two technical replications of each of the five biological replicates. [b]Means were compared by Tukey's t test, and values with the same letter within a row (S and genotype) are not statistically significant at $p \leq 0.05$.

between transgenic plants (5.27%) and non-transgenic plants (4.39%) and between low S (4.35%) and high S (5.47%) treatments (Table 3). Contrary to results from field-grown seeds, there was a significantly higher percentage of extractable protein in transgenic versus non-transgenic plants, suggesting a possible environmental effect.

As tested by two-way ANOVA, relative levels of Ara h 1 in non-transgenic and T_3 generation transgenic seeds were not influenced by genotype or sulfur nutrition. Sulfur nutrition did influence seed Ara h 3 levels [$F(2, 18) = 3.55$; $p < 0.0001$)], but no effect of genotype or genotype × sulfur interaction was observed. The relative Ara h 3 protein concentration in seeds of plants grown under low sulfur status was reduced 9−10-fold compared to plants grown with medium- or high-sulfur nutrition (Figure 4). Effects of genotype [$F(2, 18) = 3.55$; $p < 0.0001$)], sulfur [$F(1, 18) = 4.41$; $p < 0.0001$)], and genotype × sulfur interaction [$F(2, 18) = 3.55$; $p < 0.0001$)] were significant for seed Ara h 2 and Ara h 6 levels. No Ara h 2 signal was detected in Ara h 2-silenced peanut at any sulfur level by quantitative western blot experiments (Figure 4). Quantitative westerns detected Ara h 6 in transgenics grown under medium- and high-sulfur nutrition but at significantly lower amounts than in non-transgenics (Figure 4). Non-transgenic plants grown under low-sulfur nutrition showed significantly lower concentrations of Ara h 2 and Ara h 6 proteins, lowered by ∼6 and ∼22 times, respectively, than those grown at medium- and high-sulfur levels.

The levels of Ara h 1 in low-, medium-, and high-sulfur treatments among transgenic and non-transgenic plants showed no significant variation, as might be expected for a protein that is not sulfur-rich. On the other hand, low levels of sulfur caused an approximately 10-fold reduction in Ara h 3 compared to high-sulfur levels. Ara h 3 belongs to the glycinin family of proteins. Glycinins comprise major 11S storage proteins in soybeans.[44] Increased legumin (glycinin) mRNA levels and higher legumin mRNA stability have been reported under high S conditions in pea.[45,46] Transcription and transcript stability were not tested in the current study. Ara h 3, like soy glycinin, has acidic and basic subunits covalently linked by disulfide bonds. C88 of the acidic subunit (residues 1−325) and C338 of the basic subunit (residues 326−510) of Ara h 3 are linked by disulfide bonds, as shown by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and mass spectrometry analysis.[47,48] Disulfide bonding in glycinin is important for stabilizing protein conformation.[49] Low sulfur levels in soil were found to reduce the cysteine and methionine contents in barley[41] and *Arabidopsis*.[50] A similar reduction of the cysteine content (Table 4) in seeds of peanut under low-sulfur nutrition was observed, thus lowering the concentration of glycinin Ara h 3, which has also conserved cysteine residues in acidic and basic polypeptides.

Lines silenced for Ara h 2 showed no chemifluorescence signal for Ara h 2 proteins in seeds from the T_3 generation at any sulfur level. These results confirm the stability of RNAi silencing in the T_3 generation and that variation in S nutrition does not alter the stability of transgene expression, even though significant interaction was seen between the sulfur level and genotype. The level of Ara h 2 reduction is consistent with other studies for detection of Ara h 2 proteins in seeds from the T_2 generation.[10] Statistically significant low levels of Ara h 6 detected in transgenics at medium and high S levels compared to non-transgenics also showed stability of transgene expression to added S. At low S, the available S was insufficient for the synthesis of Ara h 6 in the transgenic lines because no chemifluorescent signal was detected. The low level of Ara h 6 in transgenic peanut at medium and high sulfur levels should be the consequence of efficient post-transcriptional mRNA degradation through RNAi, which probably is unaffected by sulfur nutrition.

Free and Total Amino Acids. Because developing seeds can modulate the amino acid and protein composition based on nutrient availability,[51] the amino acid profile of the plants grown at different sulfur levels was tested. The proportion of each amino acid in the free and total amino acid pool under various S treatments (Tables 4 and 5) and total and free amino acids per unit seed mass (Table 6) was determined to assess any differences in amino acid profile among treatments. These unreplicated data are helpful only in deriving the trend in amino acid profile changes under different S levels in genotypes tested. Accordingly, in the present study, the highest total amino acid content was shown by low-S treatment. Wide variation was seen between low S and the two higher S levels for all amino acids. Under low S, the majority of amino acids was found in low proportions, except for six, namely, histidine, arginine, asparagine, ornithine, hydroxyproline, and glutamine. Among these six, histidine, ornithine, hydroxyproline, and glutamine were measurable only under low-S conditions. At low S, both free and total arginine levels were higher than in medium- and high-S treatments. Arginine represented 68% of the free amino acid pool and ∼18% of the total amino acid pool. Under higher S levels, it represented ∼5−9 and ∼7−9% of free and total amino acid pools, respectively. Except for arginine and asparagine, total amino acids (Table 4) did not vary much, for most amino acids, between S levels compared to the variation seen for free amino acids (Table 5). Arginine levels also were higher in non-transgenics under medium and high S levels. Cysteine and methionine levels were higher under

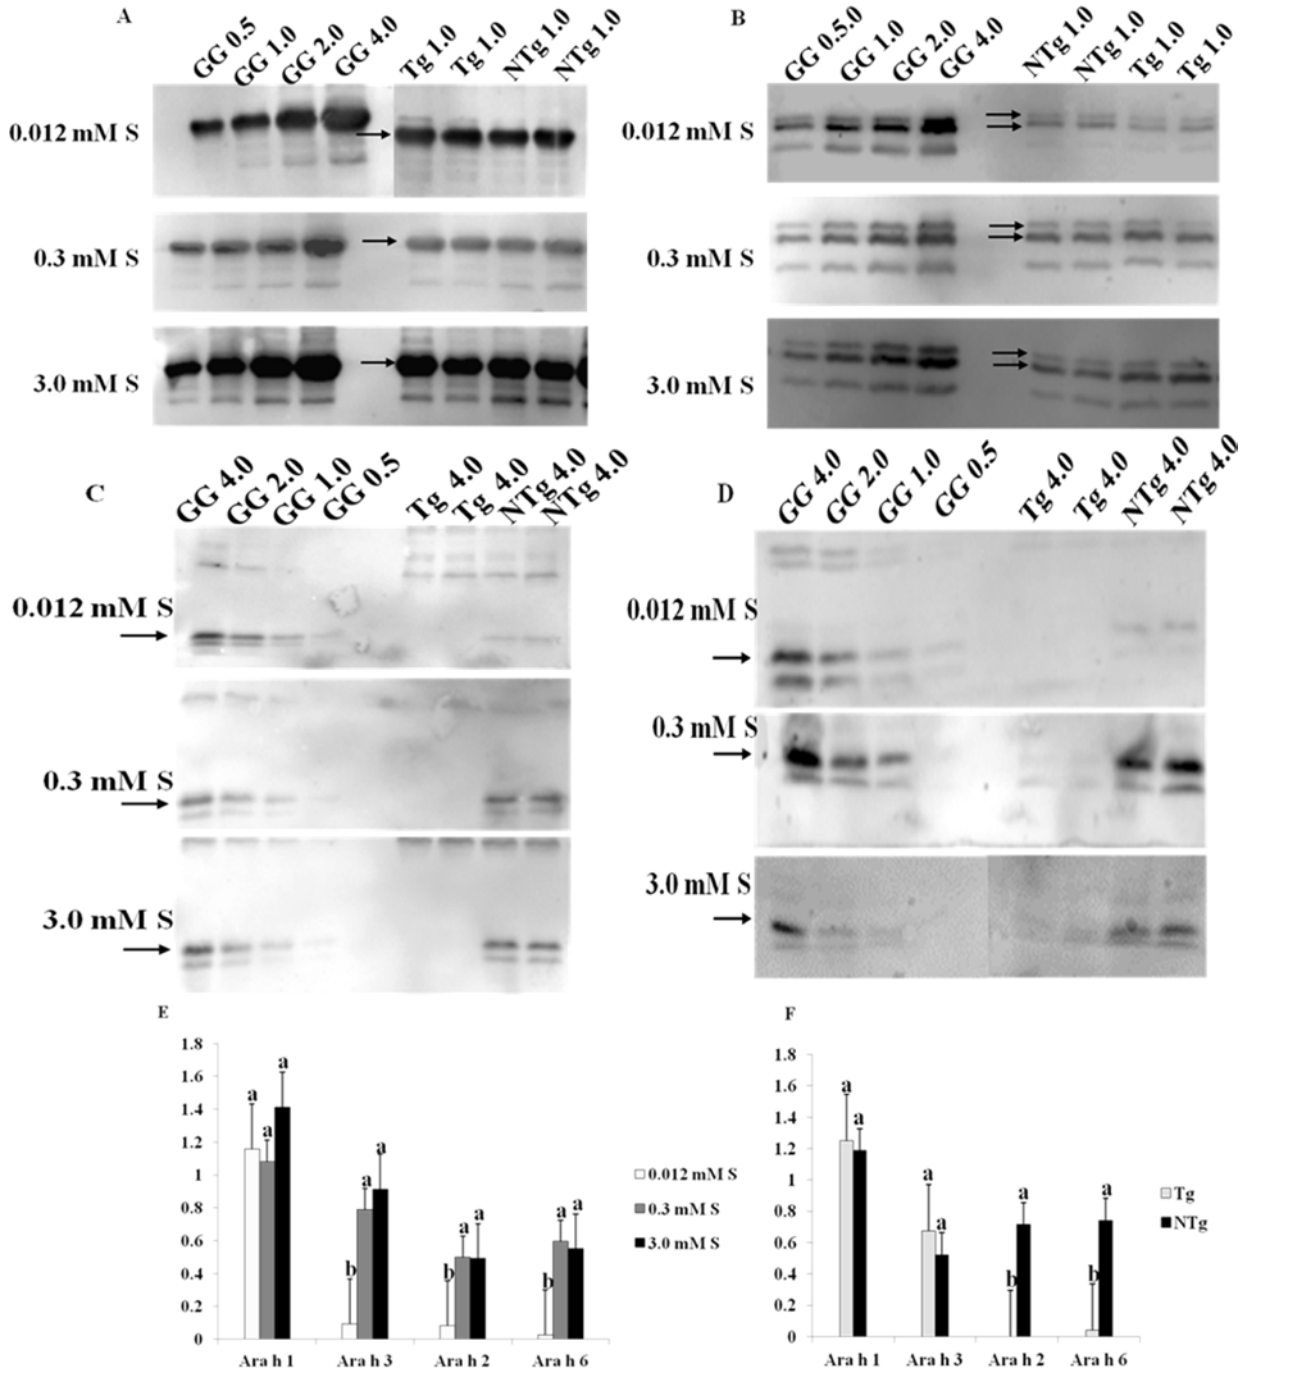

Figure 4. Western blot of allergens in T_3 generation transgenic (Tg) and non-transgenic (NTg) plants grown under three soil sulfur levels. A total of 5 μL of Tg, NTg, and "Georgia Green" (GG) protein was loaded for SDS−PAGE. Numbers corresponding to Tg, NTg, and GG indicate protein concentration in μg/μL. Western blotting was performed using (A) 1:5000 dilution of anti-Ara h 1 primary antibody, (B) 1:5000 dilution of anti-Ara h 3 primary antibody, (C) 1:8000 dilution of anti-Ara h 2 primary antibody, and (D) 1:5000 dilution of anti-Ara h 6 primary antibody, followed by AP-labeled secondary antibody in 1:10 000 dilution. Signal detection of allergen was performed using ECF substrate with STORM molecular imager at 450 nm excitation/520 nm emission. The allergen band selected for quantification is indicated by arrows in western blot images. The standard curve was developed using the GG protein concentration and corresponding allergen band volume. The band volume was calculated using Image Quant software. For Ara h1 and Ara h 3, band volume in 1 μg/μL of total protein was calculated. For Ara h 2 and Ara h 6, band volume in 4 μg/μL of total protein was calculated. (E) Effect of three soil sulfur levels on the allergen content. (F) Effect of genotype (Tg or NTg) on the allergen content. For panels E and F, error bars correspond to standard error, means were compared by Tukey's *t* test, and values with the same letter in bars for an allergen are not statistically significant at $p \leq 0.05$.

medium- and high-S treatments as well as higher in non-transgenics compared to transgenics under these two levels.

Abiotic stress[52−54] and unbalanced nitrogen metabolism[55−57] lead to accumulation of nitrogen-containing compounds, and members of the serine−arginine-rich protein family are found to be induced during abiotic stress.[58] This might explain the increased arginine and other amino acids in the free and total amino acid pools under low-S conditions, which can also lead

	NTg	1833.7	237.16
0.3	Tg	836.3	23.43
	NTg	1275.9	25.7
3.0	Tg	1006.2	22.46
	NTg	1552.1	25.55

[a]TAA and FAA per unit mass of defatted seed mass represent single measurements of four pooled samples, analyzed with a L-8800 Hitachi analyzer.

to a high nitrogen content, as seen in this study. Free amino acids are critical for the roasted flavor of peanut. Free amino acids react with the sugars in seed to produce organic compounds, which impart the typical roasted peanut flavor through the Maillard reaction.[59,60] Typical roasted flavor is attributed by glutamic acid, glutamine, asparagine, phenylalanine, aspartic acid, and histidine. Free arginine, tyrosine, lysine, and threonine are responsible for the atypical flavors.[60,61] Arginine, although beneficial to human health in multiple ways,[62] can be detrimental at high concentrations with regard to peanut-roasting quality. Hence, sulfur nutrition is important for maintaining the quality of peanut because low S levels showed higher arginine, irrespective of the plant genotype. Low levels of cysteine and methionine, in the total amino acid pool, in transgenics is due to the silencing of sulfur-rich Ara h 2 and Ara h 6 in these lines.

Seed CNS Content. The percentage of carbon in dry defatted meal varied from 49% in low-S treatment to 56% in high-S treatment (Table 7). Seed carbon was influenced by sulfur (p = 0.000 12); however, no significant variation in seed carbon was seen between transgenic and non-transgenic plants, and no genotype × sulfur effect was observed. Both genotype (p < 0.0001) and soil sulfur (p = 0.0002) levels showed significant effects on seed nitrogen in two-way ANOVA, although no effect of interaction was observed. Seed nitrogen content was significantly higher in the low-S treatment (8.62%), and no significant difference was shown between medium (7.13%) and high (6.92%) sulfur. Significant variation was observed between transgenic and non-transgenic plants in seed nitrogen content, with non-transgenics having higher nitrogen (8.31%) than transgenics (6.80%). Seed sulfur was influenced by sulfur nutrition (p < 0.0001) and genotype (p = 0.000 15),

[a]CNS values represent averages of four biological replicates analyzed using 0.2 g of defatted and lyophilized seed meal in a Leco CNS analyzer. [b]Means were compared by Tukey's t test, and values with the same letter in columns within a row (S, genotype, and S × genotype) are not significantly different at $p \leq 0.05$.

and no genotype × sulfur interaction was observed. The sulfur content in seeds ranged from 0.18 to 0.27% in the three S nutrient regimes. Non-transgenic plants grown under three S treatments showed significantly higher seed S content (0.27%) than transgenics (0.2%). The seed N/S ratio was influenced by sulfur alone ($p < 0.0001$). Nitrogen/sulfur ratios varied from 25.68 in high-S conditions to 49.67 in low-S conditions. The N/S ratio was higher in low-S treatment, and no difference was seen between transgenic and non-transgenic plants (Table 7)

Seeds from lupin plants carrying the sunflower seed albumin transgene showed higher total S and S amino acids than non-transgenic plants.[63] In the current study, transgenic peanuts showed significantly low seed S, a result expected to be contrary to that of lupins, given the difference between overexpressing and silencing S-rich proteins. Under abiotic stress, nitrogen-containing compounds accumulate, with the most common being amino acids, such as arginine, proline, amides (glutamine and asparagine), citrulline, and ornithine, which are formed as products of detoxification of excess ammonium produced under stress.[52−54] In barley grown under low sulfur, a high proportion of aspartic acid and asparagine and low levels of methionine and cysteine were found.[41] The difference in the percentage of N between transgenic and non-transgenic plants can possibly be due to the differences in the amino acid content in the two genotypes, with the non-transgenic controls having a high total amino acid content compared to transgenics (Table 6). Low S and high nitrogen contents of seeds resulted in high and unfavorable N/S ratios under S deficiency and varied significantly from plants under medium- and high-S nutrition. This is in accordance with reports where higher seed and plant S was seen with higher S nutrition in both high and low N levels.[64,65] Carbon, nitrogen, and sulfur contents in seeds result from interactions between carbon, nitrogen, and sulfur metabolic pathways. Sulfur is a component of chloroplast Fe−S cluster proteins, and low S concentrations lead to reduced chlorophyll, Rubisco level, photosynthesis, and CO_2 fixation in rice and barley.[37,52] A low seed carbon content in seeds of low-S treatment in this study may be a consequence of the reduced growth and photosynthesis under S deficiency. Also, when S is limited, activity of the nitrate reductase enzyme is reduced, leading to reduced nitrogen assimilation,[66,67] because the enzymatic activity of nitrate reductase depends upon S−Mo biochemistry.[68] Nitrogenase activity and nitrogen fixation in roots of white clover were also reduced under S deficiency[55] because S is an essential component of the Fe−Mo cofactor of the nitrogenase protein.[56] The unbalanced nitrogen metabolism results in accumulation of nitrogen compounds, especially nitrogen-rich amino acids.[55,57] Reduced S also impairs synthesis of sulfolipids and *S*-adenosyl methionine, required for photosynthesis. Thus, S limitation leads to reduced metabolism by its influence on photosynthesis and the carbon assimilation pathway.[57]

In summary, the stability of allergen gene silencing by RNAi was tested in the present study. Concentrations of Ara h 1, Ara h 2, Ara h 3, and Ara h 6 were analyzed relative to "Georgia Green" by quantitative western blotting. Silencing of Ara h 2 and partial silencing of Ara h 6 were stably inherited across three generations. Also, relative levels of Ara h 1 and Ara h 3 were slightly but not significantly higher in transgenics compared to non-transgenics. Soil sulfur had no effect on levels of completely silenced Ara h 2 and partially silenced Ara h 6, although high-sulfur nutrition increases Ara h 2 and Ara h 6 as well as cysteine and methionine in non-transgenic peanuts. Western blotting should be coupled with more sensitive proteomics techniques to develop a detailed protein profile of transgenic peanut line B11.1.1 across generations and under different environmental conditions. This transgenic line can also serve as a good experimental material for deducing the sulfur assimilation and metabolism pathways in perturbed and non-perturbed systems.

element content may have an adverse effect on human health; for example, accumulation of aluminum (Al) in tea infusion is associated with Alzheimer's disease.[19] Therefore, analytical methods for analyzing such samples must discriminate between different elements to properly assess the quality and safety of such preparations. Furthermore, the element determination of the entire plant is not adequate for risk assessment, and further attempts are made to determine the element composition of matured wild hawthorn fruit tea.[20]

The collection and analysis of medicinal herb components, especially those that are associated with human health and disease, provide data for food composition databases.[21] The aim of this study is a detailed metal characterization of hawthorn organs and tea preparations, including essential and toxic elements. Furthermore, the optimum decoction time for the diffusion of minerals into water was determined.

MATERIALS AND METHODS

Chemicals. For the experimental work, nitric acid (p.a.) and a multielement standard element analyzer (ICP Multielement Standard IV) from Merck (Darmstadt, Germany) were used. The standard reference material of strawberry leaves (LGC7162) was purchased from LGC Standards (Middlesex, UK). All glassware was cleaned with nitric acid prior to use. Ultrapure water produced in-house was used for all dilutions and blanks.

Samples. Fresh wild hawthorn whole fruits, leaves, and flowers were collected from hawthorn trees growing in Slunj, Croatia (N, 45.07°; E, 15.36°; A, 280 m) in 2011; leaves and flowers were sampled in spring, when the plant was in full blossom, and fruits in autumn, after reaching ripeness. All samples were dried at room temperature in paper bags and stored in a dry and dark room at ambient temperature in plastic bottles prior to analysis. The samples were then homogenized in a metal-free mortar.

Sample Preparation. The plant organs were digested using a microwave-assisted system, as commonly used for this kind of sample.[22]

For the microwave-assisted digestion of the samples, MWS-2 Microwave System Speedware from Berghof Laborprodukte GmbH (Eningen, Germany) was used, and the digestion procedure was conducted in three temperature steps (1, 110 °C/15 min; 2, 170 °C/15 min; and 3, 140 °C/15 min). Approximately 0.1−0.25 g (weighed to the nearest 0.1 mg) of the samples (leaves, flowers, and berries) was weighed into a Teflon reaction vessel (in duplicate). Different digestion mixtures were tested: I, 5 mL of HNO_3 (50:50 v/v); II, 5 mL of HNO_3 (25:75 v/v); and III, 5 mL of HNO_3 (25:75 v/v) + 2 mL of H_2O_2 (1 mol/L). The resulting clear solutions of the digestion procedure were then brought up to 10.0 mL with ultrapure water.

For the infusions, dried plant parts (approximately 2 g, weighed to the nearest 0.1 mg) were added to 98 mL of boiling water for different time periods (1, 5, 10, and 20 min). The infusions were then filtered with Whatman no. 541 filter paper.

If necessary, dilution of samples with diluted nitric acid was performed prior to elemental analysis.

ICP-AES Measurements. Mineral content of the digests and infusions was determined with a Prodigy High Dispersive ICP-AES spectrometer from Teledyne Leeman (Hudson, NH, USA) working in a simultaneous mode applying the instrumental conditions listed in Table 1.

All samples (infusions and blank solutions) were measured in triplicate. The quantitative determinations were carried out by external calibration using multielement standard solutions in the concentration range from 0.05 to the expected maximum concentration (5−20 mg/L) of the elements of interest. A multielement standard stock solution (1000 mg/L) was used for the preparation of standard solutions in 1% w/w HNO_3. Blank solutions were prepared in the same media.

The emission lines selected for the determination of the elements (wavelength in nm) were Al, 308.215; Ba, 455.403; Ca, 396.847; Cd, 214.441; Co, 228.615; Cr, 206.149; Cu, 224.700; Fe, 238.204; K, 766.491; Mg, 280.271; Mn, 257.610; Na, 589.592; Ni, 231.604; Pb, 220.353; Sr, 407.771; and Zn, 213.856.

Table 1. ICP-AES Operating Conditions

instrument	Prodigy High Dispersive ICP
spectrometer	high-resolution Echelle polychromator
	large-format programmable array detector (L-PAD)
RF generator	40 MHz "free-running"
output power	1.1 kW
argon flow	coolant: 18 L min^{-1}
	auxiliary: 0.8 L min^{-1}
	nebulizer: 1 L min^{-1}
peristaltic pump	1.0 mL min^{-1}
nebulizer	pneumatic (glass concentric)
spray chamber	glass cyclonic
plasma viewing	axial
replicates for each analysis run	3
sample uptake delay	30 s

ICP-MS. Elemental analysis was carried out on an Element 2 ICP-SFMS from Thermo Fisher (Bremen, Germany) equipped with the self-aspirating PFA microflow nebulizer (ESI) operated at a flow of 100 mL/min, a PC^3 cyclonic quartz chamber (ESI) operated at 4 °C, a quartz injector pipe and torch (Thermo Fisher), aluminum sampler, and skimmer cone (Thermo Fisher). The following operating conditions were applied: RF power of 1300 W and plasma gas flow of 16 L/min; sample gas and auxiliary gas flows were set to 1.06 L/min and 0.86 L/min, respectively.

The isotopes analyzed were, at low resolution, ^{7}Li, ^{82}Se, ^{88}Sr, ^{111}Cd, ^{208}Pb; at medium resolution, ^{52}Cr, ^{55} Mn, ^{56}Fe, ^{59}Co, ^{60}Ni, ^{65}Cu, ^{66}Zn, and ^{98} Mo; and at high resolution, ^{75}As.

^{115}Indium (1.1 μg/L) was used as internal standard at all resolutions. Nominal mass resolution values of the Element 2 ICP-SFMS for low resolution (LR), medium resolution (MR), and high resolution (HR) are 350, 4500, and 10000, respectively.

Optimization and Characterization of the Analytical Method. The trueness of the method for plant organs was determined by analyzing a standard reference material of strawberry leaves (LGC7162) using HNO_3 (50:50 v/v) for digestion. Recoveries of analytes from infusions were determined by spiking: Aqueous multielement standard solutions were added to a set of infusions at three concentration levels (1.0, 3.0, and 5.0 mg/L). All spiked samples were prepared and measured in triplicate.

To check the overall repeatability of the instruments, selected samples were analyzed after calibration on two different days. The precision was evaluated by measuring the solutions of all sample types five times and is presented as relative standard deviations (RSD).

The sensitivity of the method with respect to each metal was evaluated using the resultant slope of the calibration curves.

The limits of detection were calculated according to the method of Boumans using 3σ.[23] All standard deviations are based on measurements in triplicate.

Statistics. The variability of a food composition data point is best determined by looking at the standard deviation (SD).[21] Each sample is digested in triplicate and each digest measured three times. The resulting SD for each data point is thus based on nine results. The RSD values (RSD = SD/mean) are furthermore calculated for better comparison of data.

RESULTS AND DISCUSSION

Analytical Method. The limits of detection (LOD) for the digested flowers and leaves were below 2 μg/g for all analytes for ICP-AES and below 0.5 μg/g for ICP-MS.

The recoveries determined with the standard reference material of strawberry leaves (LGC7162) range from 94 to 129% for the digested plant material, from 92 to 115% for the

Zn	1.12	17.6	30.7	1.23

[a]nd, not determined.

infusions by ICP-AES, and from 89 to 109%, except for Zn (115%), for ICP-MS.

The sensitivity of the method was evaluated using the resultant slopes of the respective calibration curves. The correlation coefficients for calibration curves were all >0.9995.

The precision (expressed as %RSD) ranged from 0.02 to 1.5%. Within-day repeatability was found to be <2.3%.

The obtained figures of merit of both analytical methods are in the range for the determination of micro- and macroelements in biological samples.

The analytical parameters recovery, precision, and LOD for digest obtained for the three different acid mixtures applied were compared by applying a paired *t* test. Because only statistically insignificant differences were found ($p > 0.05$), mixture I (HNO_3 7 mol/L) was used for further experiments.

Elemental Analysis. Elemental compositions of hawthorn flowers, leaves, berries, and seeds are listed in Table 2 as mean values. For better clarity of results, the single standard deviations are not included in the table. For all samples and analytes, the %RSD values were in the range from 2 to 8%. Selenium was below the LOD (0.002 μg/g) in all samples.

Berries. Concentrations of macroelements in berries are given in μg/g dry matter: 4223 K; 3722 Ca; 987 Mg; 917 Al; 6.34 Na. In comparison to our results, Ozcan et al. found only 33 μg/g Al in berries, but higher concentrations of K (13531 μg/g), Mg (1502 μg/g), and Na (312 μg/g) and a similar concentration of Ca (3046 μg/g).[20]

Furthermore, in hawthorn berries, As, Ba, Cd, Co, Cr, Cu, Fe, Mn, Mo, Li, Ni, Pb, Sr, and Zn were found. Except for Cr (1.31 vs 1.1 μg/g) and Ni (1.89 vs 1.1 μg/g), lower concentrations were determined than reported by Ozcan, that is, Fe 2.4 vs 33 μg/g, Li 0.51 vs 1.62 μg/g, Pb (0.027 vs 0.71 μg/g), and Se (<LOD vs 0.56 μg/g).[20]

Hawthorn fruits collected in a polluted area in Transylvania contain much higher amounts of Cd, Cu, and Zn,[24] namely, 1.8, 6, and 60 μg/g, respectively.

Leaves. Only rare literature on white hawthorn leaves is currently available. Cd, Cu, and Zn contents in hawthorn leaves from a polluted area in Transylvania were found to be 1.9, 4.5, and 90 μg/g, respectively.[14] Except for Cu, these values are much higher than our results.

Leaves of other plants grown in nonpolluted areas are given below for comparison.

Leaves of poplar analyzed in Portugal were found to have the following concentrations: 2−3 μg/g for Pb, 0.1−0.2 μg/g for Cd, and 4−5 μg/g for Cu.[25] These values are similar to those determined in the present study, namely, 1.5−2 μg/g, 0.12−0.14 μg/g, and 6−7.5 μg/g for Pb, Cd, and Cu, respectively. Peppermint leaves, however, were found to contain 2.41 μg/g Pb, 0.09 μg/g Cd, and 12 μg/g Cu.[16]

With regard to the other elements determined, it was found that white hawthorn leaves contain lower amounts of metals than mint leaves:[16] Ba, 5−9 μg/g in comparison to 31 μg/g; Cr, 0.15−0.17 vs 0.94 μg/g; Mn, 9−13 vs 188 μg/g; Ni, 0.17−0.57 vs 2.99 μg/g; Sr, 1.2−1.7 vs 2.4 μg/g; and Zn, 15−18 vs 51 μg/g. Only Co is present in both leaves in the same order of magnitude, 0.13−0.16 vs 0.10 μg/g.

Cr	3.8	1.6	7.5
Cu	4.7	6.6	27
Fe	0.41	0.6	1.5
K	10	11.5	55
Mg	3.6	9.5	24
Mn	2.3	3.8	21
Mo	6.6	7.1	----
Na	9.2	8.9	23
Ni	7.9	6.1	44
Sr	2.7	2.5	----
Zn	10	9.7	37

Flowers. Trace elements in the flowers of white hawthorn were characterized by Goji and Dinulica,[24] but they analyzed samples harvested in a polluted area. Cd level in flowers were reported as 2.2 μg/g, Cu as 11 μg/g, and Zn as 90 μg/g. The flowers of the remote area in Croatia were found to contain only 0.069, 1.75, and 30 μg/g Cd, Cu, and Zn, respectively. By comparison of the data for hawthorn flowers with those for chamomile, it can be seen that the trace elements Al, Cd, Pb, and Zn were in similar concentration ranges. Higher values were found for Fe and Mn, but lower values for Cu, Cr, and Ni. The amounts of major elements (Ca, K, Mg, and Na) were found to be higher in hawthorn flowers. These elements mainly depend on the soil composition. Furthermore, each plant tends to accumulate various metals in different amounts. Chamomile is stated as an accumulator for only Ca, K, and Na.[26]

Seeds. Literature regarding the elemental composition of white hawthorn seeds is not available. The seeds of the berries analyzed show a similar pattern as the berries themselves for both major and minor elements, but differ from the values for the flowers and leaves (refer to Table 2).

Comparison of Different Organs. The major element K is present in berries, leaves, seeds, and flowers at approximately the same level. Mg is similar in berries, seeds, and leaves, but almost double the concentration is present in the flowers. Ca is mainly accumulated in berries and seeds, approximately 3 times higher than in leaves and flowers. Na shows a different pattern: this element is mainly present in leaves, followed by flowers (half concentration) and much less in berries and seeds. Al is present in berries and seeds at a relatively high level (mg/g) in comparison with leaves and flowers (μg/g). With regard to the microelements, it was found that Fe, Cd, Cu, and Ni are mostly accumulated in leaves, followed by flowers, then by seeds and berries. Mn is present in leaves and flowers at the same concentrations, whereas in the berries and seeds only about 10% of that amount is found. The Zn concentration is 10 times higher in leaves than in the berries and seeds, but only half of the level found in flowers. Cr is mainly present in berries and seeds. Ba is found with the same content in berries and leaves and double amount in flowers; seeds contain the lowest level. Co could be detected only in leaves, seeds, and berries, the latter having an even lower concentration. Amounts of Sr and Pb increase from berries and seeds to leaves and flowers.

Infusions. To obtain the optimum decoction time, periods from 5 to 30 min were examined, and 10 min was found to be adequate to prepare a good-quality tea beverage regarding element extraction. The element concentrations in the infusions did not significantly change after 5 min of extraction time. Already >90% of the maximum extracted concentration is reached after 5 min; thus, this period is considered to be the minimum recommended decoction time. The elemental

DOI: 10.1021/jf504474t
J. Agric. Food Chem. 2015, 63, 1798−1802

distributions of the infusions prepared from leaves and flowers are depicted in the Figures 1 and 2.

Hawthorn infusions are described also by Ozcan and co-workers,[27] but prepared from another species, *Crataegus orientalis*, instead of the *C. monogyna* used in this study. Except for Mn and Al, all metal concentrations found are lower than previously reported.

For all elements detected in the infusions, the extraction yield was calculated. Zengin et al.[28] used more plant material for the preparation of the teas (as compared to 2 g/100 mL used in this work), resulting in higher extraction yields, as shown in Table 3. Elemental analyses of different hawthorn organs is a valuable approach to study the nutritional value of trace elements or their potential harmful effects. Hawthorn berries and their derived infusions are a good dietary source of essential metals especially regarding K, Ca, Mg, Na, Ba, Mn, Zn, Cr, Cu, Sr, and Fe. The majority of metals were found to be extracted after a decoction time of only 5 min. The hawthorn infusions contained high amounts of K, Ca, Mg, and Na at concentration levels of mg/L, whereas Ba, Mn, Zn, Cr, Cu, Sr, and Fe are present at μg/L. The toxic elements Cd and Pb were not found in the final infusions, only in the berries in very low concentrations, and do not cause any risk to humans when consumed at such levels. The organs of white hawthorn show different elemental distribution, justifying its use as a valuable medicinal plant for the heart and cardiovascular system.

ACN composition in nasturtium flowers is very limited; only Garzón and Wrolstad[16] have reported the main ACN composition of orange flowers. Furthermore, there is no information on their non-ACN phenolic composition. The aim of this study was to evaluate the potential use of nasturtium flowers as a nutraceutical and pharmaceutical ingredient by outlining the ACNs and non-ACN phenolics profile in the petals of three different varieties, namely, red, orange, and yellow. Their total phenolics content (TPC), antioxidant activity, and antimicrobial activities were also assessed.

MATERIALS AND METHODS

Reagents. For the high-performance liquid chromatography (HPLC) work, cyanidin-3-glucoside (cy-3-glu) and pelargonidin-3-sophoroside (pg-3-soph) were purchased from Extrasynthese (Lyon, France), cyn-3-soph was from Polyphenols (Sandnes, Norway), and 5-caffeoylquinic acid (5-CQA) was from Sigma-Aldrich Chemie GmbH (Steinheim, Germany). The Folin−Ciocalteau reagent was purchased from MP Biomedicals, LLC (Illkirch, France). For the antioxidant studies, gallic acid, fluorescein sodium salt, and 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH) were obtained from Sigma-Aldrich (St. Louis, MO, USA); Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) was obtained from Acros Organics (Morris Plains, NJ, USA); and both sodium phosphate monobasic and sodium phosphate dibasic were purchased from Fisher Scientific (Fair Lawn, NJ, USA). For the antimicrobial studies, trypticase soy agar was purchased from Becton, Dickinson and Co. (Sparks, MD, USA). Various HPLC grade organic solvents for extractions and subsequent analyses were purchased from Fisher Scientific (Pittsburgh, PA, USA).

Plant Material. Petals of orange nasturtium flowers were collected from open fields around different locations in Bogotá, Colombia, in June of 2013, whereas petals of red and yellow flowers were collected from gardens in Geneva, NY, USA, during the summer of 2013. All petals were lyophilized and stored at −80 °C until analyzed.

Polyphenolic Extraction. For the extraction and isolation of ACNs and other polyphenolics, the freeze-dried plant material was milled. The powder (0.5 g) was placed in a centrifuge tube and mixed with 1:1 (w/v) 70% aqueous acetone under a nitrogen atmosphere. The tube was capped, and ultrasound-assisted extraction at a fixed frequency of 50 kHz was performed for 10 min in a chilled water bath (B-2200R-1; Branson, Shelton, CT, USA). The sample was centrifuged for 20 min at 4 °C at 3000*g* using an Eppendorf 5810 R centrifuge (Hamburg, Germany) to pellet the solids. The acetone extract was then transferred to a separate vial, and five successive re-extractions were performed on the pellet as described. The pooled extracts were partitioned with chloroform (1:2 acetone/chloroform, v/v) under nitrogen atmosphere. After centrifugation, the aqueous portion containing the ACNs and non-ACN phenolics was recovered and separated from the residual acetone in a Buchi rotoevaporator set at 40 °C and resolubilized in water. Extracts were stored under nitrogen at −80 °C until needed.

Determination of Monomeric Anthocyanin Content, and Total Phenolics. The extracted monomeric ACN pigment content was determined by the pH differential method.[17] Absorbencies were read at 490 and 700 nm for orange flowers and at 510 and 700 nm for red flowers. For comparison purposes, pigment content was calculated as cy-3-glu equivalents using an extinction coefficient (ε) of 26900 L cm^{-1} mol^{-1} and a molar mass of 449.2 g mol^{-1}. Measurements were performed in triplicate with standard deviations reported about the means.

Total phenolics content was determined as gallic acid equivalents (GAE)/100 g FW.[18] A 20 μL sample aliquot of extract or gallic acid standard (50−500 mg/L) was mixed with 1.58 mL of water followed by 100 μL of Folin−Ciocalteau's reagent. After vortexing and incubating at room temperature for 8 min, 300 μL of a 20% (w/v) aqueous sodium carbonate solution was added. Samples were vortexed and held at room temperature for 2 h. The absorbance of the blue solution was recorded at 765 nm on a Shimadzu UV−visible spectrophotometer, model UV 160 U (Kyoto, Japan), using 1 cm disposable cells. All measurements were performed in triplicate.

Acid Hydrolysis of Flavonols and Cleanup via Solid-Phase Extraction (SPE). Confirmative determination of non-ACN aglycones (kaempferol or luteolin) was achieved following a modification of the protocol described by Durst and Wrolstad[19] for acid hydrolysis of ACNs. Approximately 1 mg of the pigment was mixed with 15 mL of 2 M HCl in a screw-cap test tube. The mix was flushed with nitrogen, capped, hydrolyzed for 45 min at 100 °C, and subsequently cooled in an ice bath. The hydrolyzed extract containing the polyphenolics was cleaned using a 20 mL capacity high-load C-18 cartridge (Alltech Association, Inc., Deerfield, IL, USA). After methanolic conditioning and sample loading, the column was washed with water to remove sugars, acids, and other water-soluble compounds. The methanolic eluent containing the aglycones was subsequently evaporated using the Buchi rotoevaporator at 40 °C. The extract was freeze-dried until HPLC- photodiode array (PDA) analysis.

HPLC-PDA Analysis. All processed and freeze-dried extracts were reconstituted in 1 mL of 20% aqueous MeOH (v/v) and passed through a 0.2 μm nylon filter. For ACN, non-ACN phenolics, and aglycones, an Agilent 1260 Infinity series HPLC (Agilent Technologies, Santa Clara, CA, USA) was used. The equipment consisted of a G1322A inline degassing unit, a G1312B binary pump, a G1329B autosampler, a G1316A thermostated column compartment, a G4212B diode array detector fitted with a 10 mm path, and a 1 μL volume Max-Light cartridge flow cell. The instrument was controlled using an Agilent Chemstation software version B.04.02, service pack 1 with the spectral software module. Chromatographic separations were performed on a C_{18} Kinetex column (4.6 mm × 100 mm, 100 Å pore size, 2.6 μm particle size; Phenomenex, Torrance, CA, USA). The mobile phase composition for all analyses was (A) H_2O/H_3PO_4 (99.5:0.5) and (B) $ACN/H_2O/H_3PO_4$ (50:49.5:0.5). Chromatographic conditions for phenolic separations were as described previously.[20] ACNs were monitored at 520 nm, whereas non-ACN phenolics were monitored at 320 and 360 nm for hydroxycinammic acids (HCAs) and flavonols, respectively.

HPLC-Electrospray Ionization Quadrupole Time-of-Flight Mass Spectrometry. Initial reconstitution of the freeze-dried extracts followed similar protocols as described above. Separation of phenolic compounds was conducted under the following conditions: Detection was performed using a quadrupole/time-of-flight mass spectrometer (QTof Premier, Micromass Limited, Manchester, UK) equipped with an electrospray ionization (ESI) source operated in both positive and negative modes of polarity.

ESI conditions included a capillary voltage of 3.2 kV for positive mode, 2.8 kV for negative, a cone voltage of 35 V, ion guide at 1 V, source temperature of 100 °C, and nitrogen desolvation gas temperature of 400 °C flowing at 600 L/h. During experiments employing collisionally induced dissociation (CID), argon was held at a pressure of 3.0×10^{-3} mbar. To screen for potential parent/daughter ion relationships, both positive and negative ESI mode quadrupole time-of-flight mass spectrometry (QTOF-MS^e) runs were conducted.

For QTOF-MS^e experiments two functions were involved, one performed at low collision energy (LE) (5 eV) and the second at high collision energy (HE) to induce fragmentation (25 eV). Coincident retention times for a given pair of ions (one from LE, another from HE), where in HE the lower mass ion is enhanced and the higher mass ion is reduced, imply a parent/daughter MS/MS relationship. High-energy spectra for each of the ions in Table 3 with reported fragment ions are provided in the Supporting Information. The accurate masses of the parent and daughter ions combined with the ultraviolet−visible (UV−vis) spectra, retention times, and a comparison of these properties with those of available authentic standards and with those reported in the literature[16,21−23] lead to the tentative identifications of phenolics investigated in this study.

Quantification of Anthocyanins and Non-anthocyanin Phenolics. In addition to calculation of monomeric ACN concentration by the pH differential method, ACN quantification was based on peak areas extracted from HPLC-PDA monitored at 520

[a]Results are expressed as mean ± SD (n = 3). Values in rows with different letters are significantly different at the 95% confidence level. [b]Individual compounds presented as percentage of total peak area monitored at 520 nm. dp, delphinidin; cy, cyanidin; pg, pelargonidin; soph, sophoroside. [c]Calculated by HPLC-PDA. [d]Calculated by pH differential. [e]ND, nondetectable.

nm and external calibration curves. For comparison purposes, cy-3-glu was used as a standard. Quantification of total and individual flavonoids was based on peak areas extracted from HPLC-PDA monitored at 360 nm using external calibration curves of quercetin, kaempferol, and myricentin, whereas quantification of quinic acid esters was based on the peak area at 320 nm by external calibration curves of 5-CQA. Levels of all flavonoid derivatives were calculated using the calibration curve of the respective free flavonoids. All samples were analyzed in triplicate, and for comparison purposes, values are expressed as mg/100 g DW and mg/100 g FW.

Determination of Antioxidant Activity. The automated ORAC assay was conducted using 96-well microplates according to the method described by Prior et al.[24] with modifications. An aliquot (25 μL) of a petal extract or a trolox standard was mixed with 150 μL of 4 nM fluorescein in a 75 mM NaH_2PO_4 buffer at pH 7.4. Following 30 min of incubation at 37 °C, 25 μL of AAPH was added to each well and the fluorescence was recorded 485/528 nm (emission/excitation) once a minute for 3 h using a Synergy HT fluorescence microplate reader (Biotek Instruments, Winooski, VT, USA). The calibration curves consisted of various concentrations of Trolox (0−100 μM) made up in a phosphate buffer. Results were calculated on the basis of differences in areas under the fluorescence decay curve between the blank, samples, and standards. Final ORAC values were expressed as μmol of Trolox equivalents (TE)/100g DW and μmol of TE/100 g FW.

Antibacterial Activity. The antibacterial activity of the extracts against foodborne pathogenic strains including *Salmonella enterica*, serovar Hartford, *Escherichia coli* ATCC 43895, *Listeria monocytogenes* 104025, *Staphylococcus aureus* 9144, and *Bacillus cereus* F 4550 was determined using the spot-on-lawn assay.[25] A 50 μL aliquot of an overnight culture of the respective strain was inoculated in 7 mL of liquid TSB agar media (0.7% agar) and poured onto plates containing a TSA agar base. After the agar in the plates solidified, 20 μL of each extract was spotted onto this lawn, and plates were incubated overnight at 37 °C for 24 h. After incubation, the inhibition zones were evaluated.

Statistical Analyses. Quantitative data are presented as mean values with the respective standard deviation. Significant (P < 0.05) differences among means were identified using the least significant difference (LSD) multiple-range test after a multifactor analysis of variance (ANOVA). All analyses were performed with Statgraphics plus, version 2.1.

RESULTS AND DISCUSSION

Anthocyanin and Total Phenolics Content. The means of total ACN as determined by the pH differential method were 108.8 ± 37.2 and 168.0 ± 7.3 mg cy-3-glu/100 g FW in orange and red flowers, respectively (Table 1). These averages are comparable to the range of 70.3−201.0 mg cy-3-glu/100 g FW and the mean of 137 mg cy-3-glu/100 g FW for 21 blackberry samples taken from different origins as reported by Chiang and Wrolstad.[26]

The high SD for the average value in the orange flowers may be due to the varied geographic sampling site as the samples were collected from different locations across Bogotá, Colombia. Conversely, the yellow and red samples were collected in localized small gardens in the city of Geneva, NY, USA. This variability is expected as it has been reported that plant phenolics vary in response to environmental factors such as light intensity and nutrient availability.[27]

The TPC in red flowers was 908.7 ± 284.6 mg GAE/100 g FW, equivalent to the TPC in orange flowers (687.7 ± 161.3 mg GAE/100 g FW) and significantly higher than that one in yellow flowers (538.4 ± 6.5 mg GAE/100 g FW) (p < 0.01). The lower TPC content of yellow flowers is driven by the low content of ACNs.

The three samples showed TPC values comparable to tropical fruits with known elevated phenolic concentrations. Vasco et al.[28] tested 17 fruits from Ecuador, and Rufino et al.[29] studied 18 tropical fruits from Brazil. According to their classification, fruits with a TPC > 500 mg GAE/100 g FW are considered high.

According to Vasco's classification, at 1010 mg GAE/100 g FW, banana passion fruit (*Passiflora mollissima* L.) displayed the highest TPC. Likewise, Rufino et al. found that camu-camu (*Myrciaria dubia*) and acerola (*Malpighiae marginata*) had 1176 and 1063 mg GAE/100 g FW, respectively. Therefore, these fruits were placed at the top of the analyzed fruits as excellent sources of polyphenols.

Anthocyanin and Non-anthocyanin Polyphenolic Composition. Petals from red, orange, and yellow flowers shared similar ACN profiles (Figure 1). Delphinidin-3-dihexoside (dp-3-dihesoxide), cy-3-soph, and pg-3-soph were detected in each sample.

The results from the HPLC-ESI-QTOF-MS[e] analysis of ACNs are shown in Table 2. Delphinidin-3-dihexoside with parent ions at m/z 627.158, $[M + H]^+$, and m/z 625.146, $[M - H]^-$, resulted in HE delphinidin aglycone ion signals at m/z 303.051, $[M + H - X]^+$, and m/z 301.033, $[M - H - X]^-$, arising from a 324 amu loss, suggesting a dihexoside moiety. Accordingly, this compound was labeled delphinidin-3-dihexoside (dp-3-dihexoside). Cyanidin-3-soph was characterized by molecular ions at m/z 609.15, $[M - H]^-$, and m/z 611.162, $[M + H]^+$, with the resultant HE daughter ions at m/z 285.037 and 287.058, corresponding to the cyanidin aglycone. Identification of pg-3-soph was determined via molecular ions at m/z 595.168, $[M + H]^+$, and m/z 593.157, $[M - H]^-$, and aglycone ion signals at m/z 271.063, $[M + H - X]^+$, and m/z 269.042, $[M - H - X]^-$. These last two ACNs were also confirmed on the basis of congruence of retention time and UV−vis properties with authentic cy-3-soph and pg-3-soph standards. These findings confirm previous investigations on the ACN composition of orange nasturtium flowers (Garzón and

DOI: 10.1021/jf503366c
J. Agric. Food Chem. 2015, 63, 1803−1811

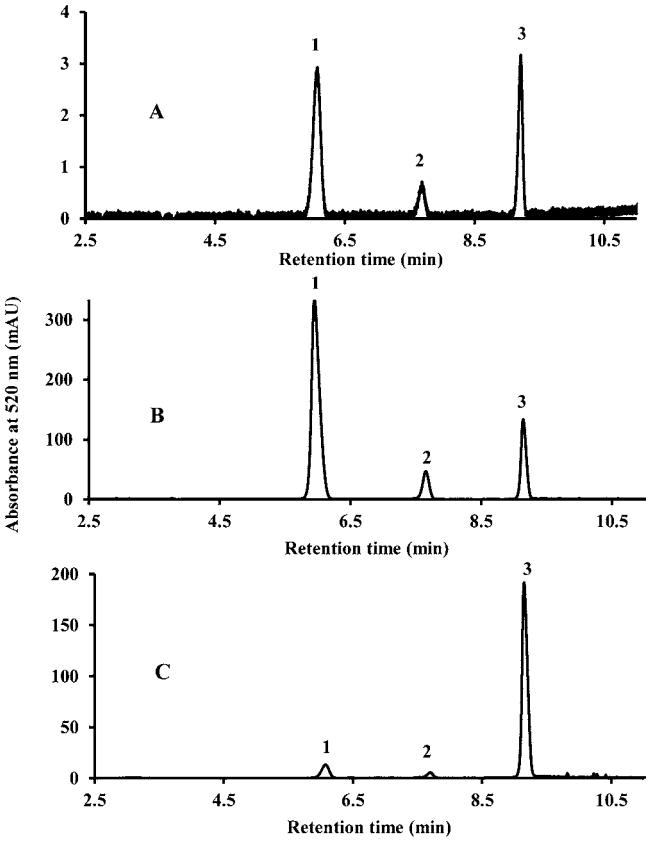

Figure 1. HPLC-PDA profile of anthocyanins in nasturtium flowers (*Tropaeolum majus*) detected at 512 nm: (A) yellow flowers; (B) orange flowers; (C) red flowers. Peaks: 1, delphinidin-3-dihexoside; 2, cyanidin-3-sophoroside; 3, pelargonidin-3-sophoroside.

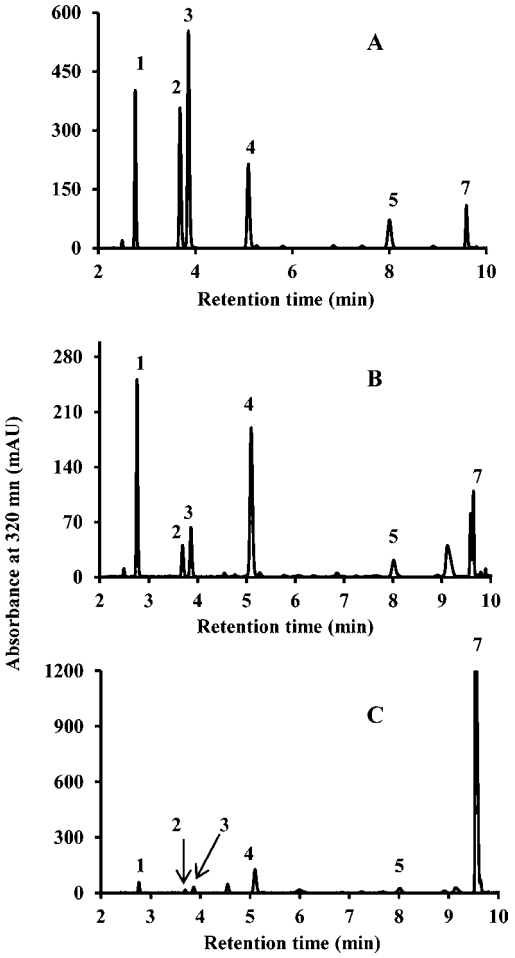

Figure 2. HPLC-PDA profile of hydroxycinnamic acids in nasturtium flowers (*Tropaeolum majus*) detected at 320 nm: (A) yellow flowers; (B) orange flowers; (C) red flowers. Peaks: 1, 3-caffeoylquinic acid (neochlorogenic acid); 2, *cis*-3-*p*-coumaroylquinic acid; 3, *trans*-3-*p*-coumaroylquinic acid; 4, 5-caffeoylquinic acid (chlorogenic acid); 5, *cis*-5-*p*-coumaroylquinic acid; 7, *trans*-5-*p*-coumaroylquinic acid.

Wrolstad[16]) and provide the first report of the ACN profile of red and yellow flowers.

The HPLC-PDA profile of non-ACN phenolics in flowers of *T. majus* is shown in Figure 2, whereas the HPLC-ESI-QTOF-MS^e results from the analysis of these compounds are shown in Table 3. Non-anthocyanin phenolics included HCAs and flavonols. Six HCAs belonging to chlorogenic acid family (esters of *trans*-cinnamic acids and quinic acid) were found. The first and fourth eluting compounds with λ_{max} 323 and 322 nm, respectively, and a difference in t_R of 1.56 min yielded molecular ions $[M - H]^-$ at m/z 353.087 and $[M - H + Na]^+$ and at m/z 375.069 with an HE fragment at m/z 191.053 identical to the 5-CQA standard. The fragment at m/z 191.053 corresponds to the loss of hydrogen from quinic acid typical of chlorogenic acids and their derivatives in tandem mass spectrum extracted ion chromatogram (EIC).[22] Because the order of elution between neochlorogenic acid (3-CQA) and chlorogenic acid (5-CQA) has been established in reverse-phase chromatography,[21] peaks 1 and 4 were identified as 3-CQA and 5-CQA, respectively.

Peaks 2, 3, 5, and 7 produced parent ions at m/z 337.092, $[M-H]^-$, which fragmented in HE daughter ions at m/z 163.037 ($[p$-coumaric acid-$H]^-$) and m/z 191.053 ($[$quinic acid-$H]^-$). On the basis of the strong signal at m/z 163.037, peaks 2 and 3 were tentatively labeled as *cis*-3-*p*-coumaroyl quinic acid (CoQA) and *trans*-3-*p*-CoQA, respectively.[21] In contrast, based on the prominent signal at m/z 191.053 and the later elution of compounds **5** and **7**,[21] they were labeled as *cis*-5-*p*-CoQA and *trans*-5-*p*-CoQA.[21]

Figure 3 is the HPLC-PDA profile of flavonols in nasturtium flowers. Myricetin conjugates (peaks 6, 8, and 10) with t_R = 7.16, 7.75, and 7.96 min, respectively, exhibited UV−vis absorption maxima at 354−356 nm. Compound **6** provided molecular ions at m/z 641.138, $[M - H]^-$, and m/z 665.135, $[M + H + Na^+]^+$. The HE fragment $[M - H - X]^-$ at m/z 317.03 was produced after cleavage of a dihexoside (324 amu)

moiety from the corresponding myricetin aglycon. As such, this peak was tentatively identified as myricetin dihesoxide. Peak 8, with a loss of 366 amu from a molecular ion at *m/z* 683.15, [M − H]$^-$, agrees with the loss of an acetyl-dihexoside moiety. Peak 10 yielded a molecular ion at *m/z* 479.083 in the negative ESI mode and a HE fragment at *m/z* 317.03. The loss of 162 amu from the aglycon revealed the cleavage of a hexose moiety.

Quercetin derivatives (peaks 9 and 13) showed UV−vis absorption maxima at 356 and 350 nm, respectively. Peak 9 with t_R = 7.77 and parent ions at *m/z* 625.144, [M − H]$^-$, and *m/z* 649.14, [M + H − X + Na$^+$]$^+$, had a typical HE fragment at *m/z* 301.033, [M − H − X]$^-$, and was identified as a quercetin dihexoside on the basis of the loss of a dihexoside moiety (324 amu). Peak 13 with t_R = 9.44 had a molecular ion at *m/z* 505.099 in the negative ESI mode and an HE fragment 301.033. The loss of 204 amu equates to the loss of an acetyl hexoside moiety.

For compounds **11**, **12**, **14**, and **15**, a λ_{max} between 344 and 350 nm was observed. The molar mass of kaempferol and luteolin is the same; therefore, they will yield the same parent ion mass fragmentation pattern in MS. Furthermore, whereas these two compounds, under certain conditions and columns, have been known to commonly coelute,[30] they did not under the conditions employed for this study. Therefore, acid hydrolysis is important when distinguishing between these two compounds. As such, this work unequivocally identified each of these compounds as kaempferol derivatives. From a bioactive prospective, it is essential to differentiate between these two flavonoids because their differential bioactivity may be attributed to their ability to react with reactive oxygen species and their interaction with membrane lipid bilayers. Tsuchiya[31] indicated that in the structure−membrane interactivity, 3-hydroxylation of the C ring and 5,7-dihydroxylation of the A ring provide flavonoids with the greatest ability to interact with membranes and protect them. Therefore, kaempferol would have a better protective effect on the lipid bilayer than luteolin.

The HE fragmentation of peak 11 led to the kaempferol aglycone at *m/z* 285.039 in a negative mode and *m/z* 287.05 in the positive mode. The loss of 32 amu is assumed to be from the cleavage of a dihexoside. A sodium adduct at *m/z* 633.145 was seen in the positive ESI mode. Peak 12 with t_R = 9.05 had [M − H]$^-$ at *m/z* 651.157 with a fragment at *m/z* 285.039

[a]Results are expressed as the mean ± SD (n = 3). Values in rows with different letters are significantly different at the 95% confidence level. [b]ND, nondetectable.

(acetyl-dihexoside moiety, 366 amu) and was identified as kaempferol acetyl dihexoside. Peak 14 had ions at m/z 447.092, $[M - H]^-$, and m/z 471.091, $[M + H + Na]^+$, which is consistent with kaempferol hexoside.

Compound **15** was tentatively assigned as kaempferol acetyl hexoside on the basis of its molecular ion ($[M - H]^-$) at m/z 489.105 as it showed a mass difference of 42 amu in relation to its nonacylated analogue kaempferol hexoside (peak 14).

The non-ACN phenolic composition of petals from nasturtium flowers is comparable with the composition of *T. majus* seeds. In 2013, Bazylko et al.[23] reported the presence of 3-*p*-CoQA, 4-CoQA, 5-CoQA, 3-CQA, 3-CQA, and 5-CQA in 60 aqueous ethanol extracts. With regard to the flavonoid composition, the authors found quercetin and kaempferol derivatives, but not myricetin conjugates. Seeds also contained a methoxyquercetin derivative, isoquercetin, and astragalin.

Quantification of Anthocyanins and Non-anthocyanin Polyphenolics by HPLC. Despite the similarity in constituent ACNs among petals with different colors, there were variations in total ACN concentration and amount of each pigment. A significant difference ($p < 0.05$) in the amount of ACNs as influenced by color was found. The highest amount of pigment was found in red flowers (114.5 ± 2.3 mg cy-3-glu/100 g FW), followed by orange flowers (58.2 ± 28.5 mg cy-3-glu/100 g FW) and yellow flowers (31.9 ± 21.7 mg cy-3-glu/100 g FW).

Whereas the value of ACN content as determined by HPLC was lower than the value determined by the pH differential method, similar results have been observed by other authors. Pacheco-Palencia et al.[32] found that the concentration of açai (*Euterpe oleracea*) ACNs quantified by spectrophotometry was 2.6 times higher than values for total anthocyanins determined by HPLC. The authors attributed these results to the presence of ACN polymers that influence color as well as copigmentation reactions that involve the formation of weak complexes between anthocyanin glycosides and other noncolored components such as phenolic acids, flavonoids, and flavonol derivatives. This results in a hyperchromic response that may result in an overestimation of total anthocyanins in spectrophotometric assays.

Orange flowers showed an abundance of pg-3-soph (52.7 ± 27.8 mg cy-3-glu equiv/100 g FW) and low concentrations of dp-3-dihesoxide and cy-3-soph. Conversely, red flowers presented high values of dp-3-dihesoxide (76.9.6 ± 6.9 mg cy-3-glu equiv/100 g FW) and pg-3-soph (27.7 ± 8.5 mg cy-3-glu equiv/100 g FW), whereas yellow flowers showed small concentration of each ACN with similar concentrations of pg-3-soph and dp-3-dihesoxide.

The concentrations of phenolic compounds in the extracts from petals with different colors as determined by peak area in the HPLC-PDA chromatogram are shown in Table 4. The highest level of flavonols was found in red flowers, with myricetin derivatives being the dominant flavonoids (315.1 ± 2.4 mg myricetin equiv/100 g FW or 2424.0 ± 18.3 mg myricetin equiv/100 g DW) followed by kaempferol derivatives (40.9 ± 10.6 mg kaempferol equiv/100 g FW or 314.4 ± 81.7 mg kaempferol equiv/100 g DW) and quercetin derivatives (16.1 ± 2.0 mg quercetin equiv/100 g FW or 123.6 ± 15.6 mg quercetin equiv/100 g DW). The quercetin content in red flowers is comparable with the amount present in food and medicinal plants with a very high concentration of this

DOI: 10.1021/jf503366c
J. Agric. Food Chem. 2015, 63, 1803−1811

compound. White onion (*Allium cepa*) contains 113.0 ± 6.0 mg quercetin equiv/100 g DW, *Ginkgo biloba* leaf has 136.0 ± 6.0 mg quercetin equiv/100 g DW, and *Calendula officinalis* flower has 112.0 ± 6.0 mg quercetin equiv/100 g DW.[30] On the other hand, the primary source of quercetin in the American diet (onions, tea, and apples) is either much lower or comparable to that of nasturtium flowers of any color.[31,33]

Quercetin has been shown to be an excellent antioxidant with anti-inflammatory, antiproliferative, and gene expression changing capacities in vitro.[34] In addition, antioxidative and anti-inflammatory effects have also been demonstrated in vivo, especially in people with hypertension and sarcoidosis.[34] This high antioxidant activity is attributed to its *o*-dihydroxy structure on the B ring and a −OH group at position 3, which results in the ability of quercetin to transfer a hydrogen atom to radicals.[35]

Kaempferol derivatives were the main flavonoids in orange flowers (167.0 ± 57.6 mg kaempferol equiv/100 g FW or 1,392.0 ± 480.3 mg kaempferol equiv/100 g DW). The second most abundant group of compounds in these petals were members of the chlorogenic acid family (81.2 ± 13.9 mg chlorogenic acid equiv/100 g FW or 550.6 ± 74.9 mg chlorogenic acid equiv/100 g DW), followed by small amounts of quercetin derivatives (9.7 ± 3.3 mg quercetin equiv/100 g FW or 80.5 ± 27.5 mg quercetin equiv/100 g DW) and myricetin conjugates (1.2 ± 0.6 mg myricetin equiv/100 g FW or 9.7 ± 4.7 mg myricetin equiv/100 g DW). Among 20 plant materials, *Rosa damascene* flower showed the highest kaempferol content (1480.0 ± 35.0 mg kaempferol equiv/100 g DW),[30] comparable to the kaempferol content in orange flowers. The high flavonoid content of this flower seems to be the primary reason for its protective effects on the cardiovascular system.[36]

Although kaempferol has only one OH group, accounting for a lower antioxidant activity than quercetin, epidemiologically, in vitro and in vivo studies show a positive association between the consumption of kaempferol and their glycosides, and subsequent pharmacological activities, including anti-inflammatory, antimicrobial, anticancer, cardioprotective, neuroprotective, antidiabetic, antiallergic, and antiasthmatic activities.[37] Several studies have explained that the presence of a double bond at C2−C3 in conjugation with an oxo group at C4 and the presence of hydroxyl groups or an acylated structure at C3, C5, and C4′ are the primary structural impetus for the antioxidant activity of kaempferol.[37] It has been estimated that the human dietary average intake of this polyphenol is approximately 10 mg/day.[38] Therefore, 10 g of fresh orange flowers would supply this intake.

Myricetin has been reported as a bioactive flavonoid during in vivo trials. Administration of aqueous and ethanolic extracts of myricetin glycosides from *Myrtus communis* L. showed significant antihyperglycemic, anti-inflammatory, and antinociceptive effects in albino mice as compared with control groups and reference drugs.[39] Similarly, the methanolic extract of *Cotinus coggygria* showed medicinal potential as an antigenotoxic and antihepatotoxic natural agent in albino Wistar rats. Because myricetin is the main flavonoid of this plant, the authors hypothesized that this compound could be responsible for the observed bioactivity and free radical scavenging activity.[40]

In contrast, the most representative polyphenolic compounds present in yellow flowers were hydroxycinammates. The total concentration of isomers of CQA and *p*-CoQA in this sample (235.6 ± 8.1 mg chlorogenic acid equiv/100 g FW) was significantly higher ($p < 0.05$) than the concentration in red and orange flowers. Conversely, as compared to yellow flowers, the amount of myricetin and quercetin conjugates was significantly higher ($p < 0.05$) in red petals, whereas the concentration of kaempferol conjugates was significantly higher ($p < 0.05$) in orange petals.

It has been reported that chlorogenic acid has antioxidant, anticarcinogenic, anti-inflamatory, and cholesterol-lowering activities[41] as well as protective properties against degenerative age-related diseases in animals.[42] Coffee is considered the main source of chlorogenic acids in the human diet; it is estimated that a 200 mL cup delivers 200 mg of total chlorogenic acids.[43] Thus, 100 g of fresh yellow petals would provide an amount of chlorogenic acid comparable to a 200 mL cup of coffee.

Generally, total phenolics, including ACNs and non-ACN polyphenols, were much lower in yellow flowers as compared with orange and red flowers. Mato et al.[44] stated that in edible flowers, an increased content of ACNs is correlated with high levels of total flavonoids. Terahara and Yamaguchi[45] explained that there is a common pathway of synthesis of flavonoids and ACNs; pale flowers lack enzymes such as flavanone 3-hydroxylase, dihydroflavonol 4-reductase,[44] and/or anthocyanidin synthase.[46]

Antioxidant Activity. The ORAC radical-scavenging activity of the red flowers (18719 ± 696 μmol TE/100 g FW) was significantly higher ($p < 0.05$) than those of the orange flowers (11790 ± 1570 μmol TE/100 g FW) and yellow flowers (7111 ± 3545 μmol TE/100 g FW).

ORAC values reflect the capacity of the cumulative extracted antioxidants present to donate a proton to the AAPH radical. When components with an important antioxidant capacity are present in high concentrations, the ORAC value is driven by these high-performing compounds. Furthermore, synergistic effects among components with high antioxidant properties have been found.[47] Red flowers exhibited the highest TPC and ACN concentrations as well as the highest antioxidant activity. This can be explained by the high concentration and specific chemical structure of phenolic compounds present in red flower extracts. It has been shown that cyanidin, delphinidin, and quercetin derivatives have a high radical-scavenging activity and an antioxidant capacity comparable to the activities of the well-known antioxidants α-tocopherol and Trolox.[48]

The extracts from *T. majus* petals did not exhibit any antimicrobial activity against any of the tested microorganisms. In a previous study,[23] the authors observed no effect of nasturtium seed extracts on *S. aureus* ATCC 9341 or *E. coli* ATCC 25922. The authors hypothesized that the low content of benzyl isothiocyante (a compound with antimicrobial activity and breakdown product of glucotropaeloin) in the extract was responsible for the lack of antimicrobial activity.

In conclusion, this comparative study revealed the profile of phenolic compounds in *T. majus* petals of different colors. Their antioxidant activity was also evaluated, and the results showed that they appear to be good sources of natural antioxidants that can be used as food additives or dietary antioxidants once their bioavailability and mechanism of action have been evaluated.

updating the body of lipid oxidation knowledge in low-moisture foods in an attempt to better understand oxidation mechanisms that can be instrumental in developing new antioxidant technologies. Ultimately, this work has broad and long-lasting implications on the development of stable foods that substitute heart-healthy polyunsaturated oils for saturated fats.

MATERIALS AND METHODS

Materials. Baking soda (Arm & Hammer; Princeton, NJ), iodized table salt (Morton; Chicago, IL), all-purpose flour (Gold Medal, original; Minneapolis, MN), traditional saltine crackers (Savoritz; Batavia, IL), and whole-wheat saltine crackers (Nabisco; East Hanover, NJ) were purchased from local (Amherst, MA) grocery stores. Interesterified soybean oil #762420 (henceforth referred to as ISO) was provided by Archer Daniels Midland Company (Decatur, IL) and selected for its recommended use in cracker applications. Dry goods were stored in closeable freezer bags; ISO was kept frozen (−20 °C) until use. The nonpolar dye Bodipy 493/503 ("Bodipy") was purchased from Invitrogen (Carlsbad, CA). The fluorescent probes Nile Red and Rhodamine B and all other chemicals were purchased from Sigma-Aldrich (St. Louis, MO). All solutions were prepared using double distilled water.

General Sample Manufacture and Preparation. Crackers were prepared by traditional baking methods and ingredients (Table 1).

Table 1. Ingredient Composition

ingredient	mass (g)	percentage (w/w)
flour	62.50	50.6
DI water	39.00	31.6
interesterified soybean oil	10.00	8.1
salt	1.50	1.2
baking soda	0.58	0.5
flour for sprinkling on surface	10.00	8.1
total	123.58	100

Sifted flour, baking soda, and salt were mixed together and then added to the ISO (∼1 min; speed 2 on a Kitchen Aid mixer, model #KSM95; Mississauga, Ontario) until an agglomerated powder formed. After exchanging the mixer's standard beater for a dough hook, water was added (speed 2; ∼1 min) to form dough. This dough was briefly kneaded by hand until all flour was visibly incorporated. A measured amount of additional flour was sprinkled on the surface of a baking mat to prevent sticking and was incorporated into the dough by kneading. The dough was flattened by twice by passing it through a pasta roller (Kitchen Aid KPSA attachment; thickness setting 2; Mississauga Ontario) to simulate industrial sheeting. The dough was then cut with a pizza cutter along the horizontal and vertical axes to form 2.5 cm × 2.5 cm crackers. The crackers were baked on an ungreased cookie sheet at 163 °C for 21 min in an electric oven (General Electric model JB350DFWW; Fairfield, CT). After baking, crackers were coarsely crumbled using a mortar and pestle, and 0.5 g was placed into acid-washed, 10-ml glass GC vials (Supelco Analytical; Bellefonte, PA), closed with aluminum caps containing PTFE/silicone septa (Supelco Analytical; Bellefonte, PA), and stored at 55 °C in the dark for 25−45 d depending upon lag phase. Treatments were produced in duplicate, and three samples were tested per treatment batch.

Addition of Confocal Dyes to Samples. Nile Red alone was added to some treatments, while a combination of Bodipy and Rhodamine B was added to other treatments. A stock solution of Nile Red was prepared at 0.5% (w/w) in ethanol, and 1 mL of this solution was mixed with the lipid (10 g) until even dispersal of colored dye was visually observed (∼20 s). Bodipy and Rhodamine B were added based on Matalanis and McClements.[13] Specifically, Bodipy (1.0 mg) was dissolved in 1 mL ethanol, and this entire amount was mixed with the lipid in the same manner as Nile Red. In contrast, 0.3 mg of Rhodamine B was dissolved in the double distilled water added directly to the dough when the dough hook was attached. One milliliter ethanol was added to control treatments to mimic the dye addition.

Addition of Iron. The iron content of the control dough was determined by Covance (Madison, WI) using inductively coupled plasma emission spectrometry. Crackers were then made with 1.0, 1.5, 2.0, 5.0, and 10 times the endogenous iron in the dough. Specifically, reduced elemental iron (product #R140100; 300 mesh) from Watkins (West Haven, CT) was mixed with the dry ingredients before adding liquids to make the dough as detailed above; this is the most common form of iron used to fortify most all-purpose flours.

Addition of FFA and Chelating Agents. Oleic acid was mixed directly into the lipid (∼20 s at mixer speed 1) before the addition of dry ingredients at concentrations of 0, 0.2, 0.4, 1.0, 2.0, or 3.0% of the total lipid. The chelating agents desferrioxamine (DFO), citric acid (CA), and ethylenediaminetetraacetic acid (EDTA) were dissolved in pH-adjusted solutions (pH 7.0) and added to the dough at a final molar mass of 0.2 mmol, which is equivalent to the maximum concentration of EDTA allowed in any food product (500 ppm in canned strawberry pie filling, CFR 21 [172.135]). They were added with the water when making the dough.

Basic Analyses. Cracker pH was determined by crushing crackers from each batch treatment and homogenizing the crackers with 10 parts distilled water to form a slurry. The pH of the slurry was measured during constant stirring using a Denver Instrument UB-10 pH meter ultraBASIC (Denver Instruments). Measurements were conducted in quadruplicate and averaged. Water activity on experimental and commercial crackers was determined at 24−25 °C using a Decagon Devices AquaLab Series 3 water activity meter (Pullman, WA) according to the manufacturer's instruction.[14] Measurements from each treatment batch were conducted in quadruplicate and averaged. Water content was determined using an A&D MX-50 digital moisture balance (Elk Grove, IL) according to the manufacturer's instructions.[15]

Measurement of Lipid Oxidation. Lipid hydroperoxides were measured in triplicate using a modified version of the International Dairy Federation method as described by Shantha and Decker.[16] Cracker samples (0.1 g) were pulverized using mortar and pestle and added to a mixture of chloroform and methanol (5 mL; 2:1 v/v), vortexed briefly, and centrifuged (3400*g*) for 10 min to extract the hydroperoxide fraction. This extract (200 μL) was mixed with 16.7 μL of a 50/50 solution (ferrous sulfate dissolved in double distilled water + barium chloride dissolved in 0.4 N HCl) and 16.7 μL of ammonium thiocyanate dissolved in water. The final mixture was vortexed, covered to prevent evaporation, and incubated for 20 min. Absorbance was measured at 500 nm on a Genesys 20 spectrophotometer (ThermoSpectronic; Waltham, MA). The concentration of hydroperoxides was calculated from a cumene hydroperoxide standard curve.

Headspace hexanal was measured in triplicate with a GC-2014 Shimadzu gas chromatograph equipped with an AOC-5000 autosampler (Shimadzu; Kyoto, Japan) based on the method by Panya et al.[17] A 50/30 μm divinylbenzene/carboxen/polydimethylsiloxane (DVB/Carboxen/PDMS) stable flex solid phase microextraction (SPME) fiber (Supelco, Bellefonte, PA) was inserted through the vial septum and exposed to the sample headspace for 10 min at 55 °C. The volatiles on the SPME fiber were desorbed at 250 °C for 3 min in the GC detector at a split ratio of 1:7. The chromatographic separation of volatile aldehydes was performed on a fused-silica capillary column (30 m × 0.32 mm inner diameter (i.d.) × 1 μm) coated with 100% poly(dimethylsiloxane) (Equity-1, Supelco). The temperatures of the oven, injector, and flame ionization detector were 65, 250, and 250 °C, respectively. Sample run time was 6 min. Peak integration was calculated using Shimadzu EZstart (version 7.4). Concentrations were calculated by using a standard curve made from cracker crush spiked with known hexanal concentrations (hexanal was diluted in methanol).

Imaging by Microscopy. A Nikon Confocal Microscope (C1 Digital Eclipse, Tokyo, Japan) with a PL FLUOTAR ELWD 20.0 × 0.45 objective lens was used to capture the confocal images. An air-cooled argon ion laser (Model 376 IMA1010 BOS; Melles Griot;

DOI: 10.1021/jf5048018
J. Agric. Food Chem. 2015, 63, 1812−1818

Carlsbad, CA) was used to excite Nile Red at 488 nm in the lipid phase, and emission spectra were collected at 515 ± 30 nm. Crackers containing both Bodipy (lipid soluble) and Rhodamine B (protein specific) were imaged sequentially, and the resulting images were overlaid. Bodipy was excited at 488 nm, and emission spectra were collected at 515 ± 30 nm; Rhodamine B was excited at 543 nm with a Melles Griot helium−neon laser (Model 05-381 LGP-193; Carlsbad, CA), and emission spectra were collected at 605 ± 75 nm. Bodipy was used instead of Nile Red in the experiments with Rhodamine B because the broad emission spectrum of Nile Red (525−605 nm) overlaps with that of Rhodamine B and prevented images from being overlaid. Detector pinhole size was always 150 μm. All resulting images consisted of 512 × 512 pixels, with a pixel size of 414 nm, and a pixel dwell time of 10.40 μs. Confocal microscopy images were analyzed using EZ-CS1 (version 3.8) software (Nikon; Melville, NY), while optical images taken on the same microscope were analyzed using NIS-Elements (version 3.0) software (Nikon, Melville, NY).

Statistical Analysis. Oxidation lag phases were defined as the first datum point that was significantly greater than the time-zero value with all subsequent data points also being significantly greater than the time-zero value. In all cases, comparisons of the means were performed using analysis of variance (General Linear Model with Tukey's Honestly Significant Difference test as a post hoc test for multiple comparisons). A significance level of $p < 0.05$ was defined as being statistically different. All calculations were performed using XLSTAT statistical software (version 2006.3, Addinsoft, New York, NY).

RESULTS AND DISCUSSION

Composition and Microstructure. The model crackers had a moisture content of 3.2% w/w and a water activity of 0.17. The water activity of commercial regular and whole wheat saltine crackers were both 0.22. The pH of the model crackers was 8.7 and did not vary significantly with the addition of chelators, confocal dyes, or oleic acid at any of the tested concentrations.

The ISO was selected based on its use in commercial manufacture of baked goods, making the model system a good representation of products currently available to consumers. According to the supplier's analysis, the ISO was comprised primarily of 10.9% (w/w) palmitic acid, 31.1% stearic acid, 13.8% oleic acid, 35.1% linoleic acid, and 4.9% linolenic acid. Saturated fatty acids accounted for 43.0% of the lipid, and 1.2% of the unsaturated fatty acids were present in the *trans* form. This composition meant the model system contained significant amounts of omega-6 fatty acids, which ensured that hexanal would be a major secondary lipid oxidation product in the later experiments.

Bodipy and Rhodamine dyes were added to view the lipid and protein fractions, respectively, under confocal microscopy. Starch granules were identified based on their size[18] and shape, nonabsorption of protein and lipid-specific confocal dyes, and ability to be stained with Lugol's iodine solution (visualized using the basic light microscopy function of the Nikon microscope; data not shown). Air bubbles were identified based on size and the absence of dye stain.

Samples were removed during each stage of cracker development, including after the lipid was mixed with dye; after water was added to the dry ingredient-lipid mixture to form the dough ball; after the final 10 g flour was incorporated but before the dough was sheeted through rollers; and after dough sheeting. Images of the lipid alone showed that the solid ISO was able to entrap air during mixing (Figure 1a) as would be expected from the solid fat fraction. Figure 1b shows images of the initial dough. At this point, lipid can be observed surrounding the starch granules and the protein shows a

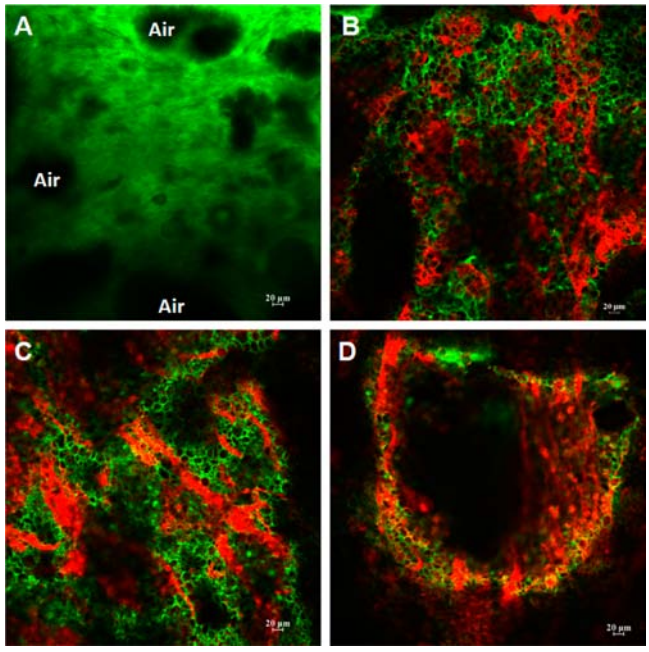

Figure 1. Confocal microscopy fluorescence of Bodipy 493/503 (green; lipid) and Rhodamine B (red; protein) in (A) the interesterified soybean oil; (B) dough before kneading; (C) kneading by hand and (D) after sheeting through pasta roller. All images taken before baking. Scale bar: 20 μm.

striated pattern typical of gluten formation. With the exception of slightly more striation due to gluten development, few changes are observed after kneading the final 10 g flour into the dough ball and sheeting the dough through the pasta roller (Figure 1c and d). Slade and Levine[19] and Kweon et al.[20] recently found that the low-sugar environment of crackers fosters gluten development during mixing and sheeting. Many of the structures developed during dough formation remain in the final, baked product (Figure 2).

It is important to understand the composition and microstructure of the crackers for several reasons. First, we wanted to understand how lipids were distributed in the cracker to see if lipid distribution was similar to other foods such as meats or emulsions. This information could provide clues on which lipids might be most susceptible to oxidation (e.g., high oxygen exposure); which prooxidants might easily access the lipids (e.g., aqueous phase metals that have an interface with the lipids as in emulsions); and how other components in the cracker associate with the lipids; and thus might influence oxidation reactions (e.g., the encapsulation of lipids with proteins. Alternatively air is quite hydrophobic, meaning that there could have been a tendency for lipid to partition to the air interface). However, the large number of examined confocal images (such as Figure 2) showed that the lipid was evenly distributed throughout the cracker and not highly associated with the air bubbles. The final water content of the crackers was low, and the confocal images confirmed that the crackers did not contain large water droplet that could be a site for lipid oxidation, especially via the metal-promoted reactions seen in emulsions.[21] The protein in the cracker formed striated bands that did not surround the lipid, with the latter more typical of meat or oil-in-water emulsions. This indicated that the protein would not provide a physical barrier on the surface of the lipid that might have influenced lipid oxidation. Finally, lipids

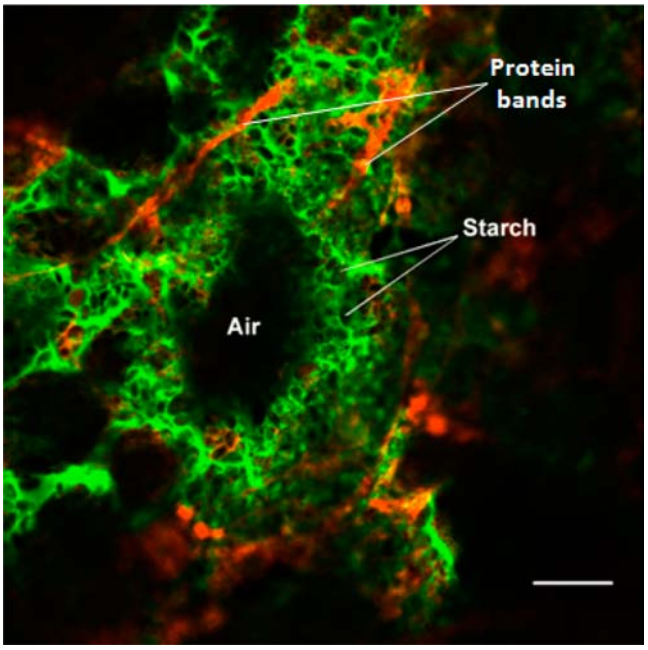

Figure 2. Confocal microscopy fluorescence of Bodipy 493/503 (green; lipid) and Rhodamine B (red; protein) in control crackers after baking. Scale bar: 50 μm.

produced a continuous phase that surrounded the starch granules, which is the opposite microstructure of most spray-dried powders where biopolymers (polysaccharides, proteins, gums) surround lipids, a structure that has been shown to reduce lipid oxidation rates.[22−24] Overall, protein−starch−lipid, lipid−air, protein−lipid, and starch−lipid interfaces were all observed within the cracker; that contrasts with other foods such as bulk oils with association colloids, oil-in-water emulsions, water-in-oil emulsions, and meat products that have only lipid−water interfaces, which are important sites for lipid oxidation.[21,25,26] This suggests that strategies to slow lipid oxidation in crackers might differ greatly from those strategies used with lipid dispersion oils.

Lipid Oxidation in Crackers. Primary (hydroperoxide) and secondary (hexanal) lipid oxidation products were both measured in the crackers during storage at 55 °C. Interestingly, the lag phases for these two measurements differed by approximately 23 d, and this trend was consistently seen in all experiments (Figures 3−6). In control crackers, the lipid hydroperoxide lag phase was 7 d. It is logical that hydroperoxides could exhibit a shorter lag phase since they are formed first and their breakdown produces secondary products. The difference in lag phases is likely due to greater lipid hydroperoxide stability in the low-moisture cracker environment than in bulk oils, meats, or emulsions where lipid hydroperoxides and hexanal lag phases differ by only a few days.[27,28] Hydroperoxides may have a longer life in crackers than in bulk oils, meats, or emulsions because the prooxidants (e.g., transition metals) that decompose lipid hydroperoxides are not readily diffusible in the low-moisture environment and so cannot readily interact with hydroperoxides. No secondary oxidation products can form if the hydroperoxides do not decompose. Hence, we needed to better understand the effects of iron in the system.

The most abundant ingredient in crackers is all-purpose white flour fortified with iron. Iron in the crackers is potentially

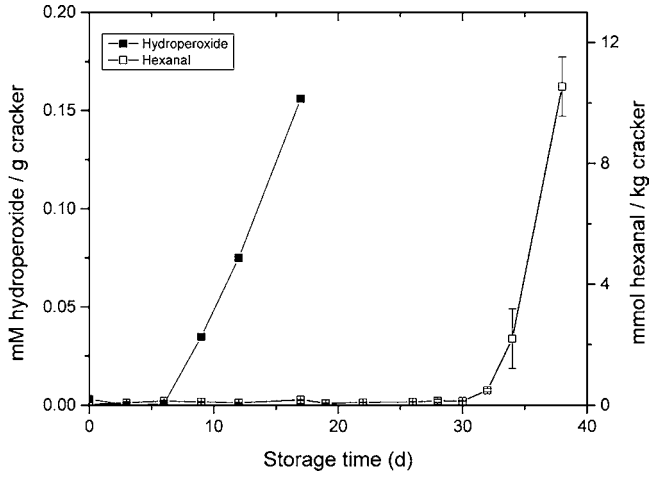

Figure 3. Lipid hydroperoxides and hexanal in control crackers stored at 55 °C in the dark. Standard error bars are smaller than data points in some instances.

an important prooxidant since it can decompose hydrogen peroxides and lipid hydroperoxides into free radicals through a redox cycling pathway.[11] Although iron can be detrimental from a shelf-stability standpoint, its fortification into flours is beneficial to consumer health by minimizing iron-based anemia in the population, which is why researchers are trying to genetically modify cereal grains to contain more iron.[29] Even traditionally bred, nonfortified wheat contains transition metals, which means presence of prooxidant iron will always be a challenge. Processing equipment containing iron or copper could also contaminate the dough with metal. Furthermore, most products are manufactured with tap water, another potential source of iron.[30] Thus, iron could contribute to the oxidation of low-moisture foods, although its role is not well understood.

To better understand the role of iron on the oxidative stability of the model cracker systems, increasing amounts of iron were added to the cracker dough. The cracker dough was found to contain 0.004% iron, which matches the USDA's reported value of 0.0046% iron in enriched, bleached, all-purpose flour.[31] Increasing the iron concentration up to 10-fold had no significant effect on either the hydroperoxides or hexanal lag phases (Figure 4).

To further determine the prooxidant effect of transition metals, metal chelators were added to the crackers. The chelator solutions (and the water for the control treatment) were pH-adjusted to 7.0. In addition, the cracker pH was 8.7, meaning that all chelators would be above their pK_a and thus would be charged and capable of binding metals. All chelator treatments exhibited the same lipid hydroperoxide (~7 d) lag phase (Figure 5a). Control crackers, DFO, EDTA, and CA treatments had similar hexanal lag phases (31 d), again supporting the hypothesis that iron is not an important prooxidant in the crackers. While EDTA did decrease the rate of hexanal formation after the lag phase, this is not important to the shelf life of a food because, at this point, the product is rancid.

The iron addition and chelator studies suggest that metals are not very active in the cracker system. A study using flour fortified with ferrous sulfate (0−75 ppm), EDTA, and folic acid to make naan flatbread showed that iron fortification significantly affected color, texture, flexibility, and chewability

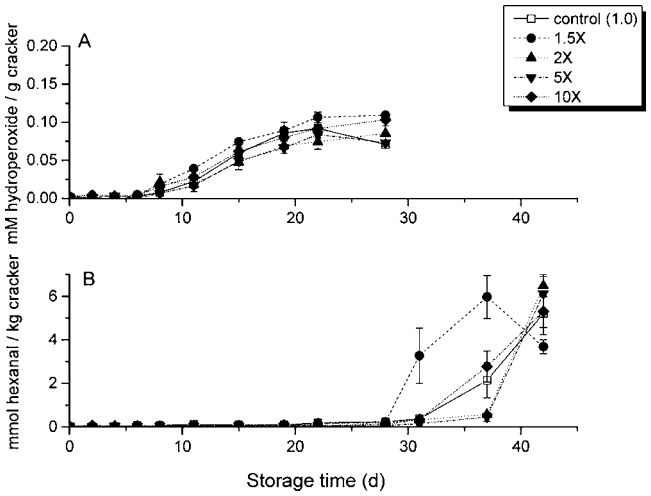

Figure 4. (A) Lipid hydroperoxides and (B) headspace hexanal in crackers made with 1, 1.5, 2.0, 5.0, and 10 times the amount of reduced iron found in the control cracker dough (0.004% iron) and stored in the dark at 55 °C. Standard error bars are smaller than data points in some instances.

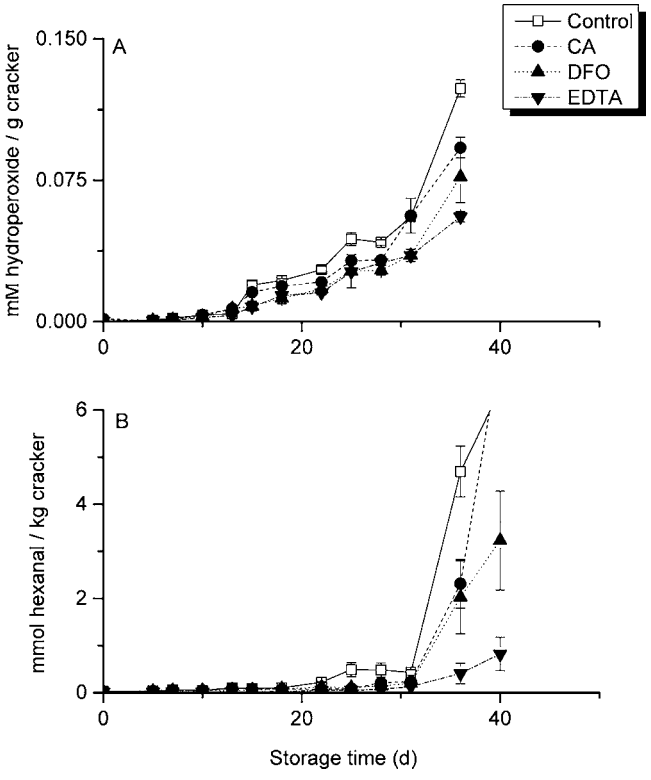

Figure 5. (A) Lipid hydroperoxides and (B) headspace hexanal in crackers made with citric acid (CA), desferrioxamine (DFO), and ethylenediaminetetraacetic acid (EDTA) and stored in the dark at 55 °C. Standard error bars are smaller than data points in some instances.

but not taste or flavor.[32] These latter two sensory attributes are most closely related to oxidative rancidity, suggesting that iron had little impact on lipid oxidation. In contrast, chelators, especially EDTA and DFO, can be very effective antioxidants in oil-in-water and water-in-oil emulsions, increasing secondary lag phases at least 4- and 3-fold, respectively.[33,34] The cracker's low water content and water activity likely limited iron diffusibility. This could explain why additional iron was not strongly prooxidative and why chelators were weaker antioxidants than seen in other foods. Of course, bulk oils also have a low water activity, but they do contain a fluid mobile phase unlike crackers and other low-moisture foods. In addition, iron could be a stronger prooxidant in bulk oils due to the presence of reverse micelles that can concentrate metals and serve as reaction centers.[21,26] The results in crackers suggest that iron fortification of low-moisture foods is an effective nutritional strategy since the iron in these products has minimal impact on product shelf life.

FFA are considered prooxidants because they can locate at water−lipid interfaces, and their negative charged is thought to attract positively charged iron to the reaction site.[35−37] In the case of crackers, both the flour and lipid are potential sources of FFA since enriched, bleached, all-purpose flour has been shown to contain free fatty acids.[31] Oleic acid was used in this study because it is a predominant fatty acid in soybean oil; it is liquid at room temperature and thus easy to distribute into the dough; and its monounsaturated and thus more oxidatively stable than polyunsaturated fatty acids, making it less likely to promote oxidation on its own. Figure 6 shows that the control, 0.2, 0.4,

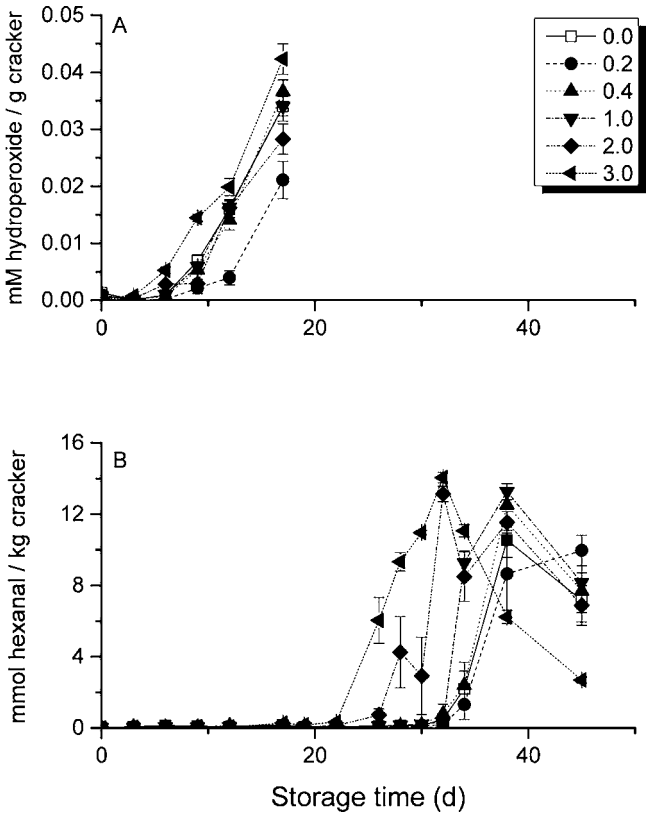

Figure 6. (A) Lipid hydroperoxides and (B) headspace hexanal in crackers made with 0−3% added oleic acid on a lipid basis and stored in the dark at 55 °C. Standard error bars are smaller than data points in some instances.

and 1.0% oleic acid in the lipids exhibited statistically similar lipid hydroperoxide (~6 d) and hexanal (~32 d) lag phases. In contrast, treatments with 2.0 and 3.0% oleic acid in the lipids exhibited significantly shorter lag phases at 3 d for hydroperoxides and ~22 d for hexanal. Crackers in general, however, are more stable to the prooxidant effects of FFA than bulk oil and emulsion systems. For instance, addition of oleic acid at concentrations as low as 0.25% decreased the lag phase of lipid

J. Agric. Food Chem. 2015, 63, 1812−1818

hydroperoxide and hexanal formation by over 30% in soybean-based oil-in-water emulsions.[38] Likewise, both saturated and unsaturated FFA were shown to accelerate lipid oxidation in walnut-based water-in-oil emulsions at concentrations as low as 0.05% oleic acid and 0.5% lauric, palmitic, or stearic acid, decreasing the oxidation lag phase by 15% and over 30%, repectively.[39] The prooxidant effect of FFA in emulsions and bulk oils is thought to be due to their ability to increase the prooxidant activity of metals and decompose lipid hydroperoxides. The shorter lipid hydroperoxide and hexanal lag phases of the cracker treatments containing 2.0 and 3.0% FFA suggests that, at great enough concentrations, the FFA may help solubilize metal, thereby increasing its accessibility to the lipid (Figure 6). This could also help explain why the FFAs had a greater effect on hexanal formation than hydroperoxide since the increased reactivity of iron would accelerate lipid hydroperoxide decomposition, which in turn would form hexanal.

The research in this study presented a systematic investigation of some of the factors influencing lipid oxidation in low-moisture foods. Ultimately, it was found that low-moisture foods differ in numerous ways from bulk oils and emulsions. From a microstructure standpoint, it was observed that lipid formed a continuous phase around the starch granules versus being dispersed as lipid droplets. The lag phases between lipid hydroperoxides and hexanal differed markedly—on the order of at least 20 d—whereas these lag phases tend to be similar in most other food systems. The lack of strong prooxidant activity of added iron and FFA, in addition to the low antioxidant activity of chelators, also suggested that transition metals are not a major prooxidant in the low-moisture crackers compared to meats, oil-in-water emulsions, and bulk oils. The limited diffusion of metals in the low-moisture system likely explains why they are not strong prooxidants even though the cracker had metal levels that would be strongly prooxidative in other food systems. This research suggests that free radical scavengers could be the best option for stabilizing lipids in low-moisture crackers.

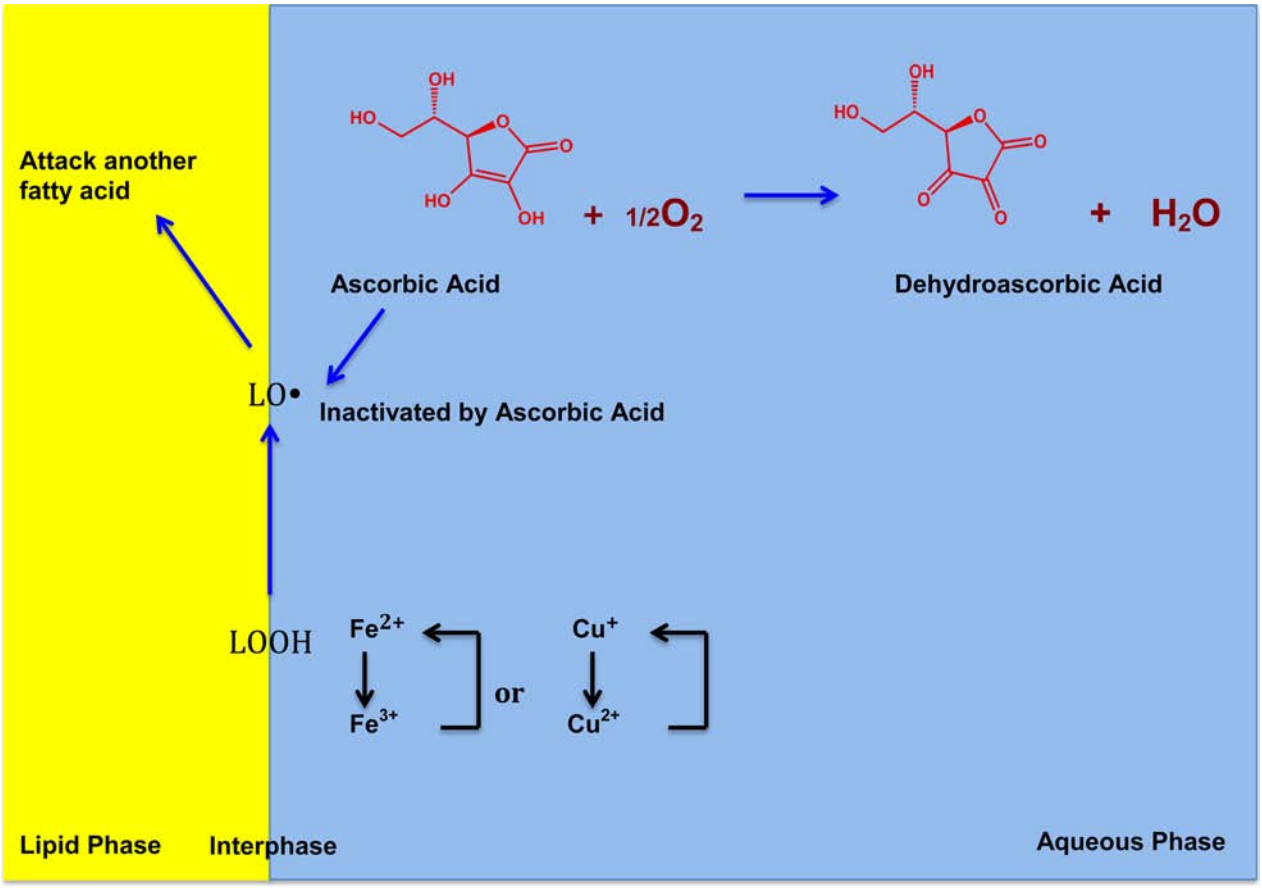

Figure 1. Potential reaction schemes for AA in an emulsion system.

lipid oxidation in food systems. These studies are important because AA can act as both an antioxidant and a prooxidant.

Oil-in-water (O/W) emulsions, such as salad dressing, beverages, and mayonnaise, are very susceptible to oxidative deterioration[24] and represent a food where AA could be added immediately prior to packaging to reduce oxygen concentrations. Therefore, the aim of this study was to investigate the conditions of oxygen reduction by AA in both a buffer system and O/W emulsions. Factors, such as AA concentrations, temperature, and presence of metals, were tested to determine optimum conditions for oxygen reduction. The ability of AA to both decrease oxygen concentrations and inhibit lipid oxidation was determined in O/W emulsions by determining lipid hydroperoxides and headspace hexanal.

MATERIALS AND METHODS

Chemicals and Materials. Soybean oil was purchased from a local grocer (Amherst, MA). Medium-chain triacylglycerols (MCTs, Miglyol) were obtained from Sasol North America, Inc. (Houston, TX). The fluorescent dye tris(4,7-diphenyl-1,10-phenanthroline) ruthenium(II) bis(hexafluorophosphate) complex was purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA). AA was purchased from Sigma-Aldrich (St. Louis, MO). All other reagents were of analytical or chromatographic grade.

Emulsion Preparation. The current study used two types of O/W emulsions. First, O/W emulsions were prepared using 1.0 wt % MCT in a 10 mM sodium acetate/imidazole buffer solution (pH 3.0 and 7) to produce emulsions that did not have oxidizable fatty acids. Tween 20 was used as an emulsifier at a 1:10 emulsifier/oil ratio. MCT, Tween 20, and sodium acetate/imidazole were added to a beaker, and a coarse emulsion was made by blending with a hand-held homogenizer (M133/1281-0, Biospec Products, Inc., Bartlesville, OK) for 2 min. The coarse emulsion was then homogenized with a microfluidizer (Microfluidics, Newton, MA) at a pressure of 9 kbar for three passes. The MCT O/W emulsion system was used for headspace oxygen analysis, and AA was added to the O/W emulsions at a final concentration ranging from 0.01 to 200 mM.

To represent a more realistic food matrix with oxidizable fatty acids, O/W emulsions were prepared using 1.0 wt % commercial soybean oil in 10 mM sodium acetate/imidazole (pH 4.0). Tween 20 was used as an emulsifier at a 1:10 emulsifier/oil ratio. Emulsion preparation was carried out as previously mentioned. The soybean oil O/W system was used to determine lipid oxidation products, and AA was added to the O/W emulsions at a final concentration ranging from 2.5 to 20 mM.

Measurement of the Particle Size of Emulsion. The sizes of the emulsion droplets were measured by dynamic light scattering (Zetasizer Nano-ZS, model ZEN3600, Malvern Instruments, Worchester, U.K.). Results were expressed as the *Z*-average mean diameter. Samples were diluted 50 times with the same buffer as the emulsion, mixed, and immediately measured by transferring the samples into 3 mL plastic cuvettes to determine the size. Measurements were performed on three replicates for each sample at room temperature. The emulsion droplet size averaged 174.1 ± 0.55 nm, and there was no significant change in the droplet size of each emulsion over the course of study (data not shown). In addition, there was no visual observation of creaming during storage in all treatments.

Headspace and Dissolved Oxygen (DO) Analysis. To measure headspace oxygen, the MCT O/W emulsion was first mixed with AA solution (final concentration of 0.01−200 mM) and the final emulsion (5 mL) was transferred to 10 mL of gas chromatography (GC) vials, sealed with (tetrafluoroethylene) butyl rubber septa, and then stored at 10, 20, 32, 37, and 45 °C in the dark. Headspace oxygen was determined using a headspace O_2/CO_2 anaylzer (Benchtop 902D Dualtark, U.S.A.).

DOI: 10.1021/jf5053942
J. Agric. Food Chem. 2015, 63, 1819−1824

The fluorescent dye, tris(4,7-diphenyl-1,10-phenanthroline) ruthenium(II) bis(hexafluorophosphate) complex, was used to determine DO in the buffer and O/W emulsion system using a $\lambda_{excitation}$ = 455 nm and a $\lambda_{emission}$ = 615 nm. Fluorescence intensity of the dye increased with a decrease in the oxygen concentration. A stock dye solution was prepared by dissolving 1 mg of the dye in 1 mL of methanol. This stock solution was then added to buffer and soybean oil O/W emulsions to achieve a final dye concentration of 50 μg/g in oil.[25] The samples were mixed with AA (0.01−200 mM final concentration in the solution), and the final samples (2 mL) were transferred to 10 mL GC vials, sealed with (tetrafluoroethylene) butyl rubber septa, and stored at 55 °C in the dark. Three vials of each treatment were sampled at each day of analysis. Standard fluorescence was used in the buffer model. Front-face fluorescence was used to measure DO in the O/W emulsion using steady-state measurements recorded with a PTI spectrofluorometer (PTI, London, Ontario, Canada). Spectral bandwidth for both excitation and emission slits was 2.0 nm; integration time was 30 s; and wavelength increment was 2.5 nm. Quantification of DO was calculated according the Stern−Volmer equation.[26]

Effect of Transition Metals on AA Degradation in Buffer. The ability of transition metals (e.g., copper and iron) to impact the ability of AA to reduce the DO concentration was determined in an acetic acid/imidazole buffer system (10 mM, pH 3). $FeSO_4$ and CuCl solutions were added to the buffer (final concentration of 2.5 or 10 μM) followed by the addition of AA (75 mM final concentration). The final solution (7 mL) was transferred to 10 mL GC vials, sealed with (tetrafluoroethylene) butyl rubber septa, and stored at 32 °C in the dark. Three vials of each treatment were analyzed for DO at each sampling time. Results were expressed as mean values ± standard deviation.

Determination of AA Degradation. Quantification of AA was determined directly in the buffer system or in the aqueous phase of the emulsion. The aqueous phase of the emulsified system was obtained by centrifuging at 38518*g* (17 000 rpm) for 1 h at 4 °C using a Fiberlite F40L-8 × 100 rotor with a high-speed centrifuge (Thermo Scientific WX Ultra 80, Asheville, NC). After the centrifugation, the lower aqueous phase was carefully removed using a syringe.

AA was analyzed according the method described by Acar et al., with minor modifications.[27] Briefly, 2,6-dichlorofenolindophenol (approximately 15 mg) was dissolved in double-distilled water until the absorbance was 0.800 ± 0.020 at 520 nm. Samples were diluted (1:100) with oxalic acid solution (0.04%, w/v) and mixed with the 2,6-dichlorofenolindophenol solution (1:100). The subsequent reaction results in non-oxidized AA reducing the indicator dye to a colorless compound. The absorbance was detected at 520 nm after vortexing for 10 s using an ultraviolet−visible (UV−vis) spectrophotometer (Genesys 20, Thermo Spectronic). AA concentrations were calculated from a standard curve prepared with reagent-grade AA. Results were expressed as mean values ± standard deviation.

Measurements of Lipid Oxidation Products. Lipid hydroperoxides and hexanal were measured as primary and secondary lipid oxidation products, respectively. Lipid hydroperoxide formation in emulsion samples was determined according to the method by Shantha and Decker.[28] Emulsion samples (0.3 mL) were mixed with 1.5 mL of isooctane/2-propanol solution (3:1, v/v) and vortexed (10 s, 3 times). The mixed solution was centrifuged at 3400*g* for 10 min (Centrific Centrifuge, Thermo Fisher Scientific, Inc., Fairlawn, NJ). The upper organic layer (200 μL) was mixed with 2.8 mL of methanol/butanol solution (2:1, v/v), followed by the addition of 15 μL of 3.94 M ammonium thiocyanate and 15 μL of Fe^{2+} solution. The Fe^{2+} solution was prepared freshly from the supernatant of a mixture of equal amounts of 0.132 M $BaCl_2$ in 0.4 M HCl and 0.144 M $FeSO_4$. The solution was vortexed and held 20 min at room temperature, and the absorbance was measured at 510 nm in a UV−vis spectrophotometer (Genesys 20, Thermo Fisher Scientific, Inc., Waltham, MA). Hydroperoxide concentrations were determined using a standard curve prepared from cumene hydroperoxide.

Headspace hexanal was measured according to the method described by Panya et al.[29] using a gas chromatograph (model GC-2014, Shimadzu Co., Tokyo, Japan) equipped with a solid-phase microextraction (SPME) auto injector (model AOC-5000, Shimadzu Co., Tokyo, Japan). Emulsions (1 mL) in 10 mL glass vials capped with aluminum caps with polytetrafluoroethylene (PTFE)/silicone septa were heated at 55 °C for 10 min in the autosampler heating sampler heating block before measurement. A 50/3 μm divinylbenzene (DVB)/carboxen/polydimethylsiloxane (PDMS) stable flex (SPME) fiber (Supelco Co., Bellefonte, PA) was then inserted into the vial headspace for 2 min to absorb volatiles. The fiber was transferred to the GC injector port (250 °C) for 3 min. The injection port was operated in split mode, and the split ratio was set at 1:7. Volatiles were separated on a fused-silica capillary Equity-1 Supelco column (30 × 0.32 mm inner diameter × μm) coated with 100% PDMS at 65 °C for 10 min. A flame ionization detector was used at a temperature of 250 °C. Hexanal concentrations were determined from peak areas using a standard curve made from authentic hexanal. Each measurement was performed in triplicate, and results were expressed as mean values ± standard deviation.

Statistical Analysis. All data result were analyzed by analysis of variance (ANOVA) using SPSS 20 (SPSS, Inc., Chicago, IL). The differences between mean values were compared using Duncan's multiple-range test with a level of significance of $p \leq 0.05$.

RESULTS AND DISCUSSION

Headspace Oxygen Analysis. Headspace oxygen concentrations in MCT O/W emulsions (pH 3 and 7) were only slightly decreased (<1%; data not shown) in the absence and presence of AA (0.01−200 mM), regardless of incubation temperature (10, 20, 32, 37, and 45 °C). In this closed O/W emulsion system, AA is located in aqueous phase and headspace oxygen exists above the emulsion. The AA and headspace oxygen reaction can be only occur at the limited surface area that exist between the emulsion and the headspace gas. Therefore, to obtain a decrease in headspace oxygen, DO concentrations would first have to be reduced and then headspace oxygen would have to diffuse into the emulsion. This observation is consistent with a previous report that showed headspace oxygen depletion by ascorbate occurred slowly.[30,31] While a small decrease in headspace oxygen may not seem significant, other reports suggested that reducing headspace oxygen by even a small percentage can lead to increased protection against lipid oxidation.[30,31] This is likely due to the fact that a large decrease in DO is needed to obtain a small decrease in headspace oxygen. Because of the lack of sensitivity of headspace oxygen, all further studies were performed using DO.

Effect of Transition Metals on AA Degradation and DO Concentrations. Copper and iron are common transition metals in food systems. These metals pose a serious threat to the oxidative stability of foods because they can accelerate lipid oxidation reactions.[2,31] However, transition metals have also been suggested to increase the ability of AA to decrease DO, meaning that they could allow AA to rapidly create an anaerobic environment in a food system.[32] Thus, it is important to determine the effect of metals on both AA degradation and DO depletion. Decreasing DO was determined in the buffer system, containing Fe^{2+} and Cu^{+} ions (2.5 and 10 μM) at pH 3 (Figure 2). The DO concentration in the presence of AA alone (75 mM) decreased quickly until day 10 as concentrations approached 0. Iron and copper only increased DO depletion rates, by 10.6−16.4% from day 1 to 7, with little difference in DO depletion occurring as a function of the metal concentration. These percentages are calculated in comparison to the control. By day 10, there was no statistical difference in DO among all samples.

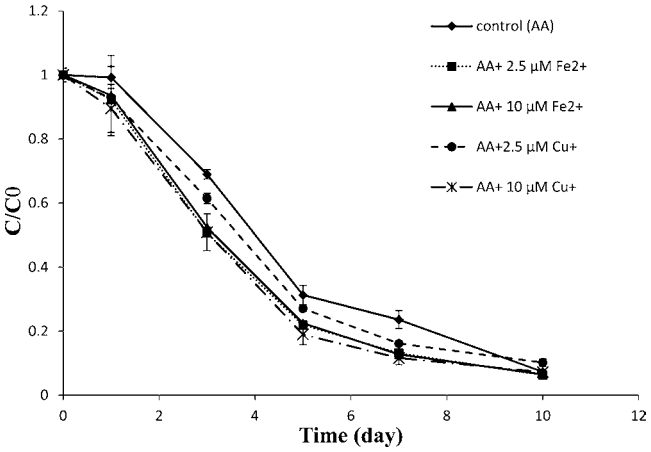

Figure 2. Reduction of dissolved O_2 by 75 mM AA in the presence and absence of Fe^{2+} and Cu^{+} (2.5 or 10 μM) in an acetic acid/imidazole buffer system (pH 3) during the storage at 32 °C. Data points and error bars represent means (n = 3) ± standard deviations.

Degradation of AA in the presence or absence of Fe^{2+} and Cu^{+} results is shown Figure 3. Both metals increased AA

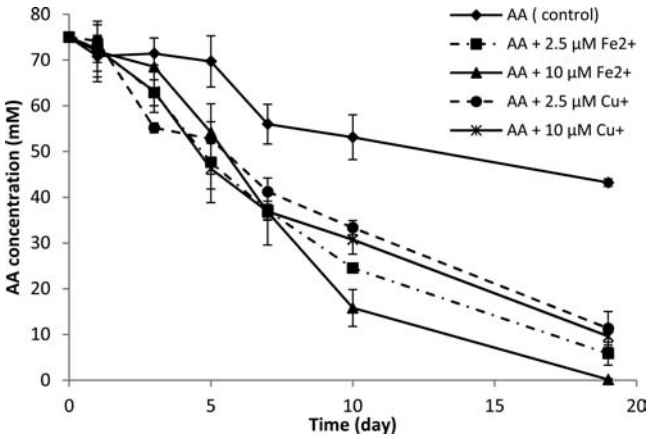

Figure 3. Degradation of AA by 75 mM AA in the presence and absence of Fe^{2+} and Cu^{+} (2.5 or 10 μM) in an acetic acid/imidazole buffer system (pH 3) during the storage at 32 °C. Data points and error bars represent means (n = 3) ± standard deviations.

degradation reactions compared to the control. After day 10, degradation of ascorbate was greatest in the presence of 10 μM iron. AA degradation rates were similar for both copper concentrations. Degradation of AA continued after day 10, even though DO was almost completely removed from the buffer (Figure 2). Previous studies suggested that anaerobic degradation of AA occurs at a much slower rate than the aerobic AA degradation at pH 2;[32] this condition was observed in the present study, because the rate of AA degradation was much higher in an aerobic environment than under an anaerobic environment. Copper has been reported by others[30] to degrade AA more rapidly than iron at pH 7. Lack of differences between iron and copper in this study could be due to the lower pH (3.0).

Effect of AA on DO and Lipid Oxidation in an O/W Emulsion. The ability of AA to both scavenge oxidation and inhibit lipid oxidation was determined in an O/W emulsion containing AA at varying concentrations to produce emulsions with reduced oxidation as well as low or high residual AA concentrations after DO depletion was complete. Lipid oxidation was monitored with lipid hydroperoxide and headspace hexanal in a soybean O/W emulsion at 55 °C. Degradation of AA and decreases in DO were also determined to evaluate the impact of AA and oxygen concentration on lipid oxidation kinetics.

Decreasing DO concentrations are shown at Figure 4, and degradation of AA results are shown at Figure 5. We again

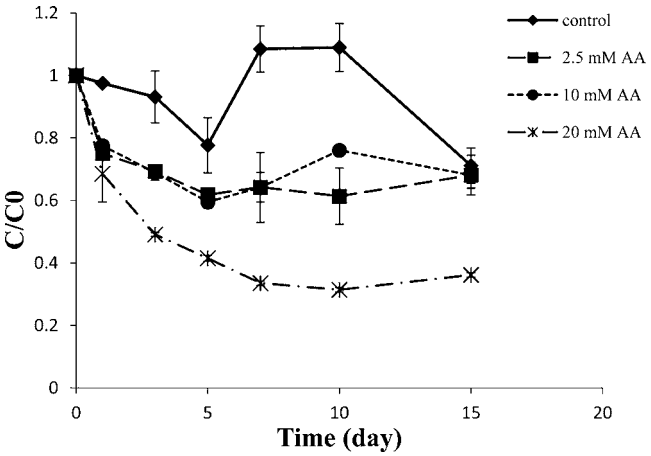

Figure 4. Reduction of dissolved O_2 in 1% soybean oil/Tween 20 emulsions (pH 4.0) at 55 °C in the presence of different concentrations of AA (2.5−20 mM). Data points and error bars represent means (n = 3) ± standard deviations.

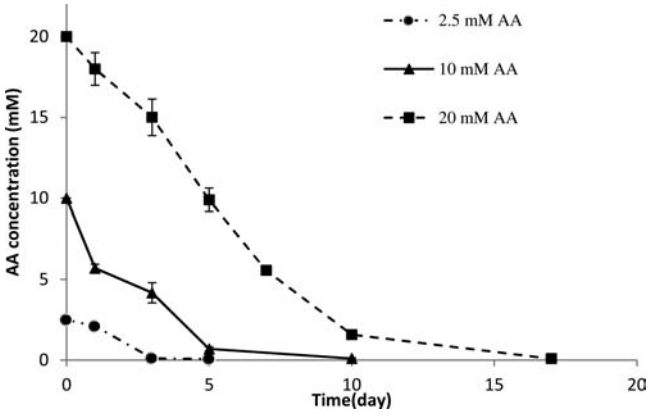

Figure 5. Degradation of AA in 1% soybean oil/Tween 20 emulsions (pH 4.0) at 55 °C in the presence of different concentrations of AA (2.5−20 mM). Data points and error bars represent means (n = 3) ± standard deviations.

attempted to increase the rate of DO removal with iron, but this was not effective (data not shown), which is similar to our observations in the buffer system. Both 2.5 and 10 mM AA decreased DO 32.0% after 5 days of storage, with no further decreases afterward. Decreasing the DO rate in the O/W emulsion system containing 20 mM AA was greatest with a maximal DO reduction of 64.0% after 10 days of storage. Samples with 2.5 and 10 mM exhibited a slight increase in DO after AA was depleted. This is likely due to diffusion of oxygen into the emulsion from the headspace and because there was no AA remaining to consume the oxygen. The lowest concentrations of AA were observed in the presence of 2.5, 10, and 20 mM AA after 3, 5, and 17 days, respectively. This was similar to

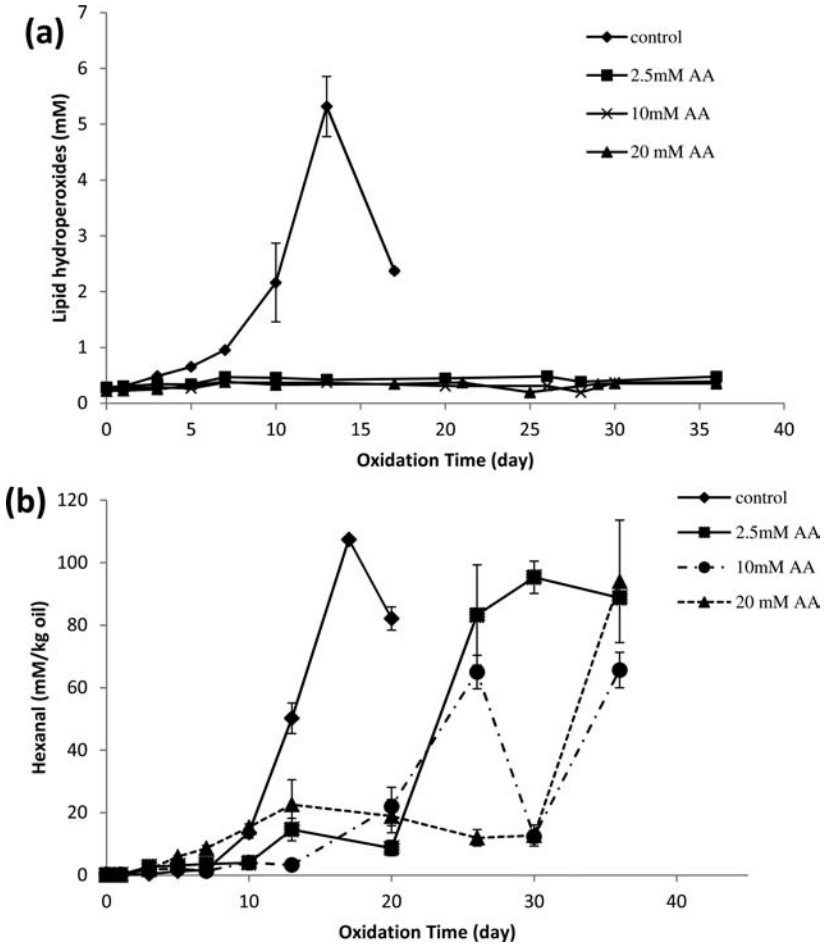

Figure 6. (a) Lipid hydroperoxide and (b) hexanal in 1% soybean oil/Tween 20 emulsions (pH 4.0) at 55 °C in the presence of different concentrations of AA. Data points and error bars represent means (n = 3) ± standard deviations.

the time to reach the lowest DO concentrations, suggesting that, once AA was consumed, no further reduction in DO was observed. Degradation of AA in an O/W emulsion system was faster than that in a buffer system (Figure 3). This could be due to AA degradation from both interactions with oxygen as well as free radicals generated by oxidizing lipids. DO depletion was also less than the buffer system (Figure 2), which can be explained by the more rapid loss of AA, which would result in lower amounts of AA being available for oxygen scavenging.

The formation of lipid hydroperoxides did not increase for any of the samples with AA (Figure 6a). This could be due to AA causing redox cycling of metals, making the metals more reactive. The reduced metals could then decompose hydroperoxides into secondary oxidation products, such as hexanal, faster than their formation, thus preventing their accumulation. A lack of hydroperoxide accumulation with the formation of secondary aldehydes has also been observed in sodium dodecyl sulfate-stabilized O/W emulsion at pH 3.0, where iron was added as a prooxidant.[33] The lack of hydroperoxide accumulation with the formation of secondary aldehydes has also been observed in a Tween-20-stabilized O/W emulsion at pH 3.0.[34] The lag phase for hydroperoxide formation in the control was 3 days, while the lag phase for hexanal formation was 7 days. It is not uncommon for aldehyde formation to occur later than hydroperoxide formation because the aldehydes are formed from the decomposition of the hydroperoxides.[35] The lag phase for hexanal formation was similar for 2.5 and 10 mM AA (20 days). This is somewhat surprising because residual AA in the emulsions with 10 mM AA was higher than samples with 2.5 mM AA during the first 5 days of storage. However, both 2.5 and 10 mM AA produced similar levels of DO reduction, suggesting that the observed inhibition could be due to the reduction of oxygen levels more than the ability of AA to scavenge free radicals. AA at 20 mM resulted in a hexanal lag phase of 26 days, which is only 1.3-fold longer than the 2.5 and 10 mM AA samples (Figure 6b). One might have expected that 20 mM AA would have been a more effective antioxidant because residual AA was observed in the emulsions for a much longer period of time and oxygen reduction was almost double that of the 2.5 and 10 mM samples. It could be possible that the unexpectedly low activity of 20 mM AA could be due to the ability of AA to act also as an prooxidant by reducing transition metals, and this prooxidant activity would decrease the effectiveness of its free radical scavenging and oxygen reduction.

In conclusion, AA can act as an edible oxygen scavenger, but its ability to reduce oxygen concentrations is less in O/W emulsions than a simple buffer system, which is likely to be due to the consumption of AA by both oxygen and free radicals in the emulsion system. At 2.5 and 10 mM AA, the ability of AA to inhibit hexanal formation was similar, which suggested that the antioxidant activity of AA was primarily due to its ability to decrease DO. The ability of 20 mM AA to inhibit lipid oxidation was better than 2.5 and 10 mM AA, but the improved

DOI: 10.1021/jf5053942
J. Agric. Food Chem. 2015, 63, 1819−1824

activity was only 1.3-fold greater, even though the concentrations of AA were much higher and DO reduction was much greater than the lower AA concentrations. These data suggested that the dual prooxidant and antioxidant role of AA could be decreasing its ability to increase oxidative stability. Overall, AA could be used to inhibit lipid oxidation in foods because of its dual ability to decrease DO and scavenge free radicals. However, these antioxidative properties could be diminished by the prooxidative activity of AA, and thus, the activity of AA could possibly be improved by metal chelators, which would bind metals and decrease the prooxidant activity of AA.

in over- or underestimation of gluten.[24] The gluten quantitation by ELISA can be further affected by thermal[25−27] and nonthermal[28−30] food processing conditions.

Since most ELISA methods use gliadin as a calibration standard, the calculated gluten content would be derived from the measured gliadin.[31,32] However, such quantitation may not give an accurate measure for other prolamins (secalin and hordein) and glutelins. Prolamins and glutelins differ in their proportions and molecular properties in wheat, rye and barley.[33,34] This will influence the availability of gluten epitopes, affecting antigen−antibody interaction in immunoassays and causing variability in gluten quantitation. Moreover, hydrolysis of gluten proteins may reduce the number of available epitopes leading to underestimation of gluten content. Hence, it is important to assess the contribution of prolamin and glutelin fractions and their hydrolysates to facilitate accurate gluten quantitation. So far, there is limited information available on the analysis of prolamins from rye and barley.[30] Furthermore, the quantitation of glutelin fractions from wheat, rye and barley is not well studied. The aim of this study was to assess the relative recovery of prolamin and glutelin fractions and their pepsin-trypsin (PT)-digests based on the gluten quantitation by various commercial ELISA kits.

MATERIALS AND METHODS

Materials. Pure grains of wheat, rye, barley, oats and corn were obtained from the Grain Inspection, Packers & Stockyards Administration (GIPSA), U.S. Department of Agriculture (USDA). Commercial gliadin (S1), wheat gluten (S2), casein (S3), pepsin and trypsin were from Sigma (St. Louis, MO). The sandwich ELISA kits used were RIDASCREEN Gliadin (R7001; R-Biopharm AG, Darmstadt, Germany), Wheat protein ELISA kit (gliadin) (181 GD; Morinaga Institute of Biological Science, Inc., Yokohama, Japan) and AgraQuant Gluten G12 (COKAL0200; Romer Labs UK Ltd., Cheshire, UK), whereas the competitive ELISA kits included RIDASCREEN Gliadin competitive (R7021; R-Biopharm AG, Darmstadt, Germany) and GlutenTox ELISA Competitive (KT-4758; Biomedal, Spain). BenchMark prestained protein ladder was purchased from Invitrogen (Grand Island, NY).

Methods. *Isolation of Gluten.* The grains of wheat, rye, barley, oats and corn were ground to flour and then independently subjected to Osborne fractionation as described by Tatham et al. (2000)[17] with minor modifications. Briefly, 100 g flour was suspended in 1000 mL 0.5 M NaCl and magnetically stirred for 1 h at room temperature (RT), followed by centrifugation at 5,000g for 10 min at 20 °C. The extraction was repeated again with the pellet by suspending in 0.5 M NaCl and the two supernatants (containing albumins and globulins) were pooled before dialyzing against distilled water for a total of 48 h with at least 6 water changes using an 8 kDa cutoff dialysis membrane. The globulins were separated by centrifuging at 10,000g for 15 min at 4 °C. Thereafter, all centrifugation steps were carried out at 5,000g for 10 min at 20 °C. The residual flour from NaCl extraction was washed with water for 10 min at RT followed by centrifugation. The washed residual flour was then resuspended twice in 1000 mL 70% ethanol (for oats, 50% ethanol) and magnetically stirred for 1 h at RT, followed by centrifugation. The pooled supernatant containing prolamins was precipitated overnight at 4 °C with 2 volumes of 1.5 M NaCl, centrifuged, resuspended the pellet in 100 mL 70% ethanol (for oats, 50% ethanol) and dialyzed against 0.1 M acetic acid for 48 h with at least 6 changes of 0.1 M acetic acid. Glutelins were finally extracted by resuspending the residual flour from ethanol extraction twice in 1000 mL 50% propan-1-ol containing 1% acetic acid and 2% β- mercaptoethanol for 1 h at RT, followed by centrifugation. The pooled supernatant was precipitated overnight at 4 °C with 2 volumes of 1.5 M NaCl, centrifuged, resuspended the pellet in 100 mL 50% propan-1-ol containing 1% acetic acid and 2% β- mercaptoethanol, followed by dialysis against 0.1 M acetic acid for 48 h with at least 6 changes of 0.1 M acetic acid. All the fractions were lyophilized and stored at −20 °C until further use. The protein content of all lyophilized fractions was analyzed by micro-Kjeldahl method (Micro-Analysis, Inc. Wilmington, DE) using the conversion factor of 5.83.

Pepsin-Trypsin (PT)-Digestion. Approximately 250 mg protein was dissolved in 2.5 mL pepsin solution (2 mg/mL prepared in 0.2 N HCl), followed by addition of 2.5 mL 0.2 N HCl. The enzyme to protein ratio was 1:50 (w/w). The tubes were incubated at 37 °C for 2 h in shaking water bath. The peptic digest was then adjusted to pH 7.4 with 2 M NaOH, followed by addition of 50 μL trypsin solution (100 mg/mL prepared in distilled water) to have an enzyme to protein ratio of 1:50 (w/w). The tubes were mixed and incubated at 37 °C for 4 h in shaking water bath. Thereafter, the tubes were transferred to a boiling water bath and incubated for 30 min to inactivate the enzymes. Appropriate controls (S1, Sigma gliadin; S2, Sigma gluten; S3, Sigma casein) were also used. Ten milligram aliquots of PT-digest were lyophilized and stored at −20 °C until further use.

Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE) and Western Blotting. Protein samples were boiled in 1x SDS-PAGE Laemmli sample buffer (Biorad, Hercules, CA) for 10 min, and suitable aliquots were loaded on large 1.5 mm thick 10−20% SDS-PAGE Tris-Glycine gel (Jule, Inc., Milford, CT). The gels were run at 50 mA current per gel for 1.5 h, and then reduced to 30 mA per gel until the dye reached the bottom edge of the gel. The gels were stained overnight with 0.25% w/v Coomassie Brilliant Blue R containing 50% v/v methanol and 10% v/v acetic acid. The gels were destained once with 50% v/v methanol containing 10% v/v acetic acid (destain buffer), followed by destaining buffer diluted with distilled water (∼1:1 v/v) until the background was clear.

For the Western blot analysis, the polypeptides were separated on 10−20% SDS-PAGE Tris-Glycine gels (Invitrogen, Grand Island, NY) by running at 100 V until the dye reached the bottom edge. The separated polypeptides were transferred to a polyvinylidene fluoride (PVDF) membrane at 0.4A current for 1.5−2 h at 8 °C. The transferred proteins were visualized by Ponceau S stain. The membrane was washed with Tris buffered saline containing 0.05% Tween 20 (TBS-T) to remove the stain and then blocked for 1 h at RT with 5% nonfat dried milk in TBS-T. The membrane was briefly washed with TBS-T and incubated with anti-gluten antibodies conjugated to horseradish peroxidase (HRP) overnight at 4 °C. The membrane was then washed thrice for 15 min each with TBS-T. The reactive bands on the membrane were developed on X-ray film using ECL substrate (Pierce).

Estimation of Gluten by Enzyme-Linked Immunosorbent Assay (ELISA). Both undigested and PT-digested prolamins and glutelins were quantified using sandwich and competitive ELISA kits as per the manufacturers' instructions. Briefly, lyophilized gluten fractions were dissolved in the extraction buffers of respective kits, and were used as stock solutions to prepare dilutions of appropriate protein content (10−100 ng/mL), based on calculated protein amounts analyzed by micro-Kjeldhal method. Appropriate controls (Sigma gliadin, S1; Sigma gluten, S2; Sigma casein, S3) were also used. The ELISA plates were read using a SpectraMax M5 microplate reader (Molecular Devices, Sunnyvale, CA). A four parameter standard curve was plotted using the SoftMax Pro 5.4 software, and was used to calculate the measured gluten/wheat protein. Further, the recovery was represented as a percent ratio of the measured gluten to the actual protein assayed. For all ELISAs, two samples of each protein fraction were analyzed in duplicate (n = 4), and the data were presented as mean ± standard error (SE).

RESULTS

Gluten Fractions and Their PT-Digests. The protein content of lyophilized prolamin and glutelin fractions from wheat, rye and barley were estimated by the micro-Kjeldahl method. Lower protein content was observed in oat (prolamin, 33% and glutelin, 59%) and corn (prolamin, 42% and glutelin, 64%) fractions as compared to wheat (prolamin, 68% and glutelin, 82%), rye (prolamin, 52% and glutelin, 71%) and

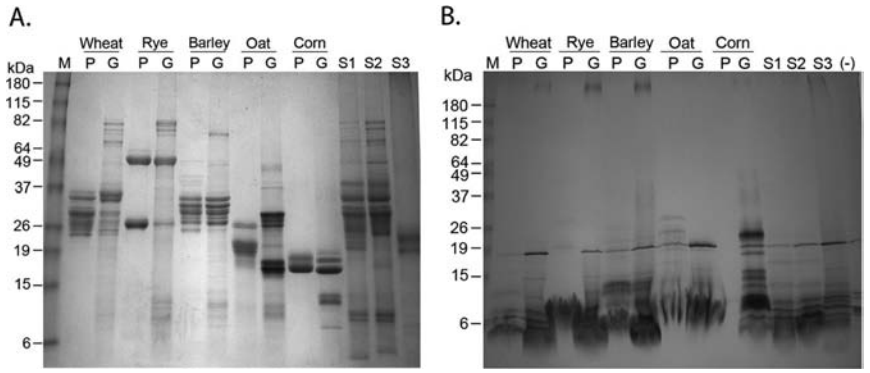

Figure 1. Coomassie stained SDS-PAGE gels of prolamin and glutelin fractions. Intact (A) and PT-digested (B) protein fractions. Protein load was 20 μg/lane for undigested and 50 μg/lane for PT-digested fractions. P, prolamin; G, glutelin; S1, gliadin; S2, gluten; S3, casein; M, MW marker; (−), pepsin-trypsin only.

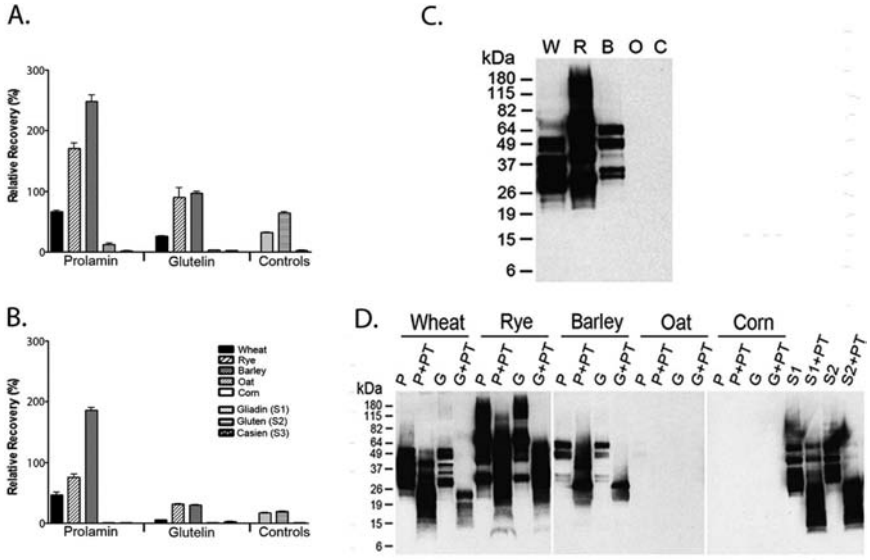

Figure 2. Analysis of gluten fractions and their PT-digests using the R-Biopharm sandwich ELISA kit and its antibodies. Recoveries of intact gluten fractions (A) and their PT-digests (B) in ELISA. Western blot analysis of flour proteins (C) and their gluten fractions (D) using the R-Biopharm kit antibodies. For ELISA, 25 ng/mL of sample extract was used, except that 100 ng/mL of PT-digests were used when the measured value was less than LOQ. W, wheat; R, rye; B, barley; O, oat; C, corn; P, prolamin; G, glutelin; PT, pepsin-trypsin.

barley (prolamin, 62% and glutelin, 71%). All experiments in this study were carried out based on the micro-Kjeldahl estimated protein contents. The yield of prolamin and glutelin proteins per 100 g of flour was 1.44 and 2.66 g (wheat), 0.61 and 0.81 g (rye), 1.41 and 1.7 g (barley), 0.79 and 2.78 g (oat), and 0.55 and 1.27 g (corn), respectively.

The purity and protein composition of the prolamin and glutelin fractions of different grains were analyzed on a 10−20% SDS-PAGE gel (Figure 1A). Gluten fractions of wheat, rye, barley and oats consisted of polypeptides in the expected molecular weight range in agreement with the previous reports.[2,17,35,36] Upon treating with pepsin and trypsin (PT), the gluten fractions from all grains were digested predominantly to low molecular weight polypeptides (<15 kDa) (Figure 1B). The corn prolamin exhibited poor solubility after PT-digestion. Aggregates were observed in the PT-digested glutelin fractions from wheat, rye and barley (Figure 1B).

ELISA

Three sandwich and two competitive ELISA kits employing anti-gluten antibodies (monoclonal or polyclonal) were used to measure the percent gluten recovery from various gluten fractions and their hydrolysates.

Sandwich ELISA. In general, the S1 and S2 controls behaved similar to wheat gluten fractions, as they are isolated from wheat. The average measured value for S3 and all oat and corn protein fractions used to calculate the percent gluten recovery was found to be lower than the limit of quantitation (LOQ) of the respective sandwich ELISA. The LOQs are 5 ppm gluten (R-Biopharm), 0.3 ppm wheat protein (Morinaga) and 4 ppm gluten (Romer Labs). Barley flour protein showed lower immunoreactivity than wheat and rye in Western blot. However, a high gluten recovery was observed with barley prolamin by ELISA. More detailed results on immunoreactivity of different grain protein fractions are described below.

With the R-Biopharm kit, the wheat gluten fractions showed a lower gluten recovery as compared to recoveries from rye and barley. The percent gluten recovery of prolamin and glutelin ranged from 65.8 (wheat) to 248.3 (barley) and 25.4 (wheat) to 97.0 (barley), respectively (Figure 2A). However, upon PT-digestion, the recovery was further reduced as compared to the undigested proteins, and it was 46.5 (wheat) to 185.8 (barley)

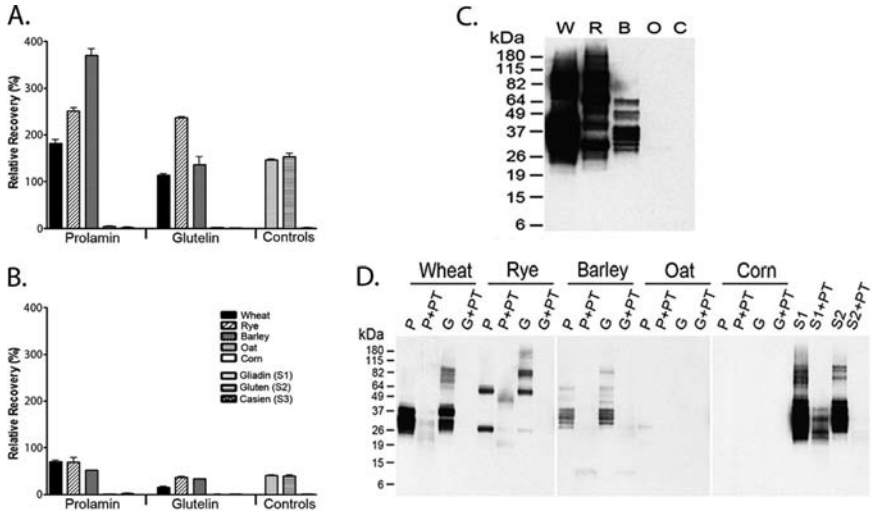

Figure 3. Analysis of gluten fractions and their PT-digests using the Morinaga sandwich ELISA kit and its antibodies. Recoveries of intact gluten fractions (A) and their PT-digests (B) in ELISA. Western blot analysis of flour proteins (C) and their gluten fractions (D) using the Morinaga kit antibodies. For ELISA, 10 ng/mL of sample extract was used, except that 40 ng/mL of PT-digested sample was used when the measured value was less than LOQ. W, wheat; R, rye; B, barley; O, oat; C, corn; P, prolamin; G, glutelin; PT, pepsin-trypsin.

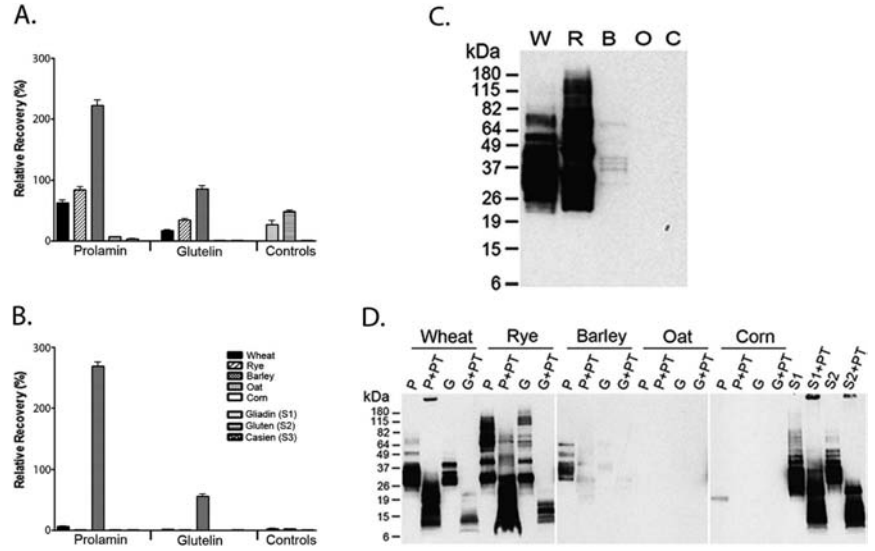

Figure 4. Analysis of gluten fractions and their PT-digests using the Romer Labs sandwich ELISA kit and its antibodies. Recoveries of intact gluten fractions (A) and their PT-digests (B) in ELISA. Western blot analysis of flour proteins (C) and their gluten fractions (D) using the Romer Labs kit antibodies. For ELISA, 50 ng/mL of sample was used, except that 100 ng/mL of PT-digested sample was used when the measured value was less than LOQ. W, wheat; R, rye; B, barley; O, oat; C, corn; P, prolamin; G, glutelin; PT, pepsin-trypsin.

for prolamin, and 4.9 (wheat) to 31.0 (rye) for glutelin (Figure 2B). The rye glutelin behaved similar to barley glutelin in both the undigested and digested samples. Interestingly, the recovery of S2 control (64.0%) behaved similar to that of wheat prolamin (65.8%), whereas a lower recovery was observed for the S1 control (31.5%). The average measured gluten level from 100 ng/mL PT-digests of wheat glutelin was lower than the LOQ. Since oat and corn flour proteins did not show any immunoreactivity with the R5-antibody (Figure 2C), it was likely that their fractions would not react in ELISA (Figure 2A and 2B) and Western analyses (Figure 2D).

With the Morinaga kit, the barley prolamin (369.4%) showed higher gluten recovery as compared to the prolamin of wheat (181.9%) and rye (251.3), while rye glutelin (237.1%) showed higher recovery as compared to the corresponding fractions in wheat (113.3%) and barley (135.9%) (Figure 3A). Among the PT-digested gluten fractions, gluten recovery was higher from the prolamin fractions as compared to their respective glutelin fractions (Figure 3B). Both S1 and S2 showed similar gluten recoveries, which were reduced upon PT-digestion. Oat and corn proteins did not react with Morinaga kit antibodies (Figure 3C). While the prolamin and glutelin fractions from wheat, rye and barley showed reactivity to Morinaga antibodies, their corresponding PT-digests had poor immunoreactivity (Figure 3D).

With the Romer Labs kit, gluten recovery was higher from the barley fractions as compared to those of wheat and rye. The percent recovery of prolamin ranged from 62.4 (wheat) to 222.5 (barley), while the glutelin ranged from 16.6 (wheat) to 84.9 (barley) (Figure 4A). The recoveries were substantially reduced upon PT-digestion for all fractions, except for barley (Figure 4B). Surprisingly, upon PT-digestion, the percent

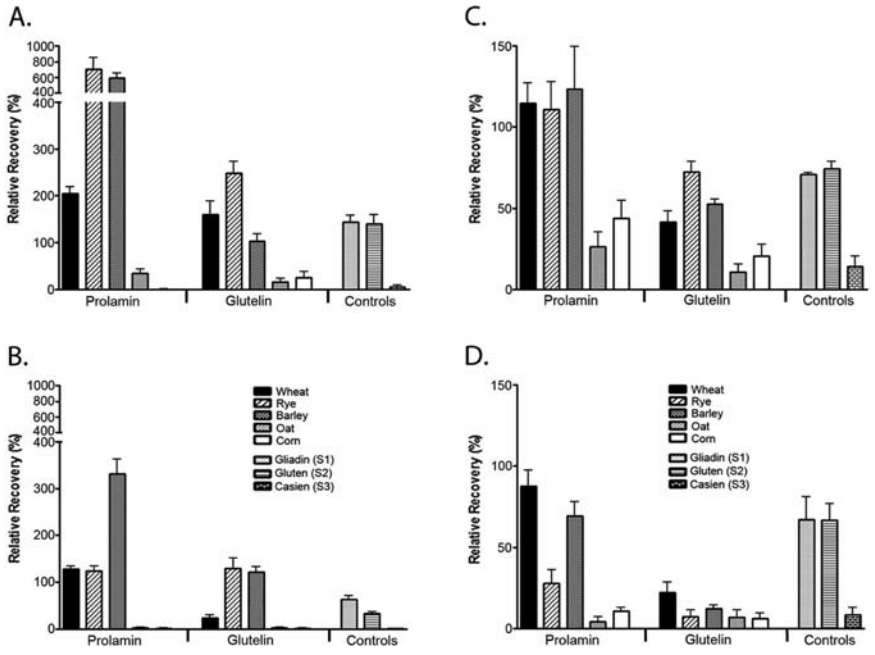

Figure 5. Analysis of gluten fractions and their PT-digests by competitive ELISA. Recoveries of intact gluten fractions (A and C) and their PT-digests (B and D) using the R-Biopharm (A and B) and the Biomedal Diagnostics (C and D) competitive ELISA kit. For ELISA, 25 ng/mL of sample was used, except that 100 ng/mL of PT-digested sample was used when the measured value was less than LOQ.

gluten recovery of barley prolamin (268.8) increased as compared to the undigested protein (222.5). The average measured gluten levels for 100 ng/mL of PT-digests of rye prolamin, wheat and rye glutelins, S1 and S2 were below the LOQ. The Romer Labs G12 antibodies did not show reactivity to oat and corn proteins (Figure 4C). Also, barley proteins showed poor immunoreactivity to G12 antibodies as compared to that of wheat and rye, as reported earlier.[37] The prolamin and glutelin fractions, including their PT-digests, from wheat and rye showed reactivity to G12 antibodies in Western blot, but only the prolamin fraction of barley was immunoreactive (Figure 4D).

Competitive ELISA. As observed with the sandwich format, the average measured gluten levels for S3 and all oat and corn protein fractions were lower than the LOQ of the respective competitive ELISA. The LOQ for the R-Biopharm R5-based competitive kit is 10 ppm gluten and the LOQ for the Biomedal G12-based competitive kit is 15 ppm gluten.

With the R-Biopharm competitive kit, the percent gluten recovery of prolamins ranged from 203.8 (wheat) to 703.5 (rye) and that of glutelins ranged from 102.6 (barley) to 247.4 (rye) (Figure 5A). As seen with the R5-based sandwich ELISA, the gluten recoveries from the rye and barley prolamins were higher than that of the wheat prolamin, even though the gluten recoveries were different between the two ELISA formats. Depending on the grain source of prolamin, the gluten recovery was at least 2 to 4 times higher with the competitive ELISA as compared to the sandwich ELISA (Figure 5A vs Figure 2A). The percent gluten recoveries of PT-digested prolamins were more than one hundred percent, ranging from 124.0 (rye) to 331.5 (barley), although recoveries were lower than those of the undigested prolamins (Figure 5B). The PT-digested glutelins showed percent gluten recoveries in the range of 23.0 (wheat) to 129.4 (rye). Reduced recoveries were observed for the PT-digests of S1 (2.3-fold) and S2 (4.2-fold) as compared to their respective undigested proteins.

The Biomedal competitive kit had similar gluten recoveries for wheat, rye and barley prolamins (110.9 to 123.5%). Even though the oat and corn prolamin fractions showed 26 and 44% recoveries, respectively, the measured value for the 25 ng/mL protein sample used in ELISA was below the LOQ. Among glutelins, only rye (72.2% recovery) had a measured value above the LOQ at 25 ng/mL of protein sample used in ELISA (Figure 5C). Similar recoveries were observed between S1 (70.6%) and S2 (74.2%). The PT-digested gluten fractions yielded lower recoveries when compared to the undigested proteins. Among the PT-digested prolamins, rye (27.8%) showed a significantly lower recovery as compared to wheat (87.7%) and barley (69.1%) (Figure 5D). The measured gluten level of the 100 ng/mL PT-digested protein sample was just above the LOQ when using the wheat glutelin fraction, while the gluten content of the rye and barley glutelin fractions were below the LOQ. The gluten recovery of S1 and S2 was not significantly reduced following the PT-digestion.

DISCUSSION

Gluten not only serves as a protein source but also imparts functional properties in many foods. Gluten is used in foods as either an intact protein or hydrolysate. We isolated prolamin and glutelin fractions from different grains and analyzed them by SDS-PAGE under reducing conditions (Figure 1A). Even though the polypeptide patterns of prolamins and glutelins on SDS-PAGE are different among wheat, rye and barley, all these proteins are linked to causing CD in genetically susceptible individuals. Gluten hydrolysis in the gastrointestinal tract is carried out by acid and digestive enzymes, such as pepsin and trypsin. Incomplete hydrolysis of gluten by PT-digestion, as observed in Figure 1B, allows the release of gluten peptides (<15 kDa), which can cause CD.

Gluten-free labeled foods are available as safe food choices for CD patients. Accurate gluten estimation (intact or hydrolyzed) in such foods is essential to comply with the

DOI: 10.1021/jf505716p
J. Agric. Food Chem. 2015, 63, 1825−1832

thresholds set for gluten-free labeling. ELISA offers rapid and sensitive quantitation of gluten, and many commercial kits are available in both sandwich and competitive formats. But, it is challenging to accurately quantitate gluten from different grains using ELISA because of differences in antibody affinity and calibration standards. For example, an ELISA kit that uses wheat prolamin as a calibration standard may not accurately estimate gluten from rye and barley, if the detection antibody does not have equal affinity for gluten from different grain sources. This may be circumvented by the use of grain-specific gluten calibration standards in ELISA, if the grain source of gluten contamination in food is known. Furthermore, the measurement of prolamin to quantitate gluten using a common multiplication factor of 2 may not accurately determine gluten content if prolamin and glutelin are not present in equal proportions.[34] Hence, it is important to assess the extent of immunoreactivity imparted by prolamin and glutelin fractions from wheat, rye and barley to facilitate gluten quantitation.

Both monoclonal (R-Biopharm and Romer Labs) and polyclonal (Morinaga) antibodies are used in ELISA for gluten quantitation. Monoclonal antibodies recognize one epitope, whereas polyclonal antibodies recognize many epitopes on a single protein. Among the different ELISA kits used in this study, variable results were observed in the recovery of both prolamin and glutelin fractions. Moreover, the glutelin fractions showed lower gluten recovery compared to their respective prolamin fractions from wheat, rye and barley. This could possibly be due to the reduced number of epitopes recognized in the glutelin fractions. The Morinaga polyclonal antibodies recognize many epitopes in gluten. Since there may be common amino acid sequences between prolamins and glutelins, the polyclonal antibodies aid in obtaining better recovery of glutelins compared to monoclonal antibodies (Figure 3A vs 2A and 4A). R-Biopharm (sandwich and competitive) ELISA uses the R5-monoclonal antibody, which was produced against secalin and recognizes amino acid sequences QQPFP, LQPFP, QQQFP and QLPFP as epitopes in wheat, rye and barley.[38] Hence, it is expected that the R5 antibody would react strongly to rye, and less so toward wheat and barley (Figure 2C). An NCBI database search of the four epitopes recognized by R5 antibody in the gluten sequences showed their presence in higher number in rye and barley, as compared to wheat. Among the gluten proteins (GenBank accession no. in parentheses following the protein type), one of the high affinity R5 epitopes (QQPFP) was repeated 33 times in rye [14 times each in ω- (ACQ83628.1) and γ-75k- (ABY71029.1), and 5 times in γ-40k- secalin (AEW46837.1)]; 20 times in barley [13 times in C- (AAA92333.1), 4 times in B- (AAZ76368.1) and 3 times in γ-1- hordein (AAA32955.1)]; and 8 times in wheat [5 times in γ- (AAA34272.1), 2 times in ω- (AAT01617.1) and once in α-gliadin (AFX69628.1)]. The repetitive epitopes could enhance antibody binding, resulting in the overestimation of rye and barley in the R5-based ELISA using gliadin as a calibration standard.

The G12 monoclonal antibody (used in the Romer Labs and Biomedal ELISA kits) was raised against the immunotoxic 33-mer peptide of α-2 gliadin, and it recognizes amino acid sequences QPQLPY, QPQLPF, QPQLPL and QPQQPY as epitopes in the reducing order of affinity.[39] The high affinity G12 epitope (QPQLPY), in the above-mentioned GenBank sequences, was found only in α-gliadin (repeated thrice). However, QPQLPF occurred once in wheat (γ-gliadin), twice in rye (one each in γ-40k- and ω-secalin) and once in barley (C hordein). Further, QPQQPY was present 3 times in γ-75k secalin and once in C hordein. It is interesting to see that despite having a lower number of epitopes, the gluten content of barley was overestimated when compared to that of wheat and rye (Figure 4A). A similar high sensitivity of the G12 antibody toward barley gluten has been reported earlier.[39] This suggests that there may be other factors involved in the overestimation of barley that would need further investigation.

Our observations show that the recovery of gluten in most PT-digested prolamin and glutelin fractions was reduced drastically as compared to the recoveries of their respective intact proteins in the sandwich ELISA. Competitive ELISA is more suitable for hydrolyzed proteins because it requires only one epitope, as compared to the sandwich format that would require at least two epitopes for target analyte detection. The competitive format may be useful for gluten estimation in fermented foods, such as beer and malt extracts.[30,40] We observed higher recoveries of intact gluten fractions as compared to their respective PT-digests with both competitive ELISA kits used in this study (Figure 5). Furthermore, acceptable gluten recoveries were obtained with PT-digested prolamins, with the exception of barley prolamin (high recovery) in the R5-based (Figure 5B) and rye prolamin (low recovery) in the G12-based (Figure 5D) competitive ELISAs. However, the suitability of a competitive format for intact proteins may be dependent upon the calibration standards used in the assay. For example, gluten peptide fragments used as calibration standards may undergo nonspecific cleavage of some epitopes, causing inaccurate estimations of intact gluten. Moreover, the gluten recovery may vary among fermented foods since various hydrolytic enzymes (for example, from plant seed germination, or of microbial or fungal origin) can hydrolyze gluten differentially and generate a set of gluten peptides that are different from those used as the ELISA calibration standards.

In summary, high variability in gluten quantitation by ELISA was observed depending upon the grain source, gluten protein and its level of hydrolysis. Based on the ELISA kit used for gluten quantitation, some intact prolamins and glutelins were overestimated. In particular, the recovery of barley prolamin was higher than that of wheat and rye prolamins by the sandwich ELISA. Even when the same antibodies (R5 or G12) were used, we observed different gluten recoveries between corresponding sandwich and competitive formats. This could be due to the differences in their assay conditions and calibration standards. Other non-immuno-based methods such as mass spectrometry,[41,42] polymerase chain reaction[43] and high pressure liquid chromatography[44] can be used to complement ELISA for a robust gluten analysis. Moreover, the availability of standard reference material may help to achieve consistency in gluten quantitation among different analytical methods. Thus, it is important to understand the effect of grain source (wheat, rye and barley), gluten protein (prolamin and glutelin), food ingredients (e.g., hydrolyzed gluten) and food processing methods (e.g., fermentation) in selecting a suitable ELISA for accurate gluten estimation.

MATERIALS AND METHODS

Plant Material and Extract Preparation. Sample provenance and voucher codes (CHR (Christchurch) kept at the Landcare Herbarium, Lincoln, others at Plant & Food Research, Dunedin) are shown in Table 1. The *L. oleraceum* plants for tasting and postharvest treatment experiments were originally sourced from a near-shore rock stack near Te Akau (Waikato) with the plants supplied by Forest Flora Plants, Ngaruawahia, and a second line purchased (Sept 2, 2010) from Taupo Native Nursery. They were cultivated in an unheated greenhouse with the controlled release fertilizer Osmocote Plus (Scotts Europe BV, Heerlen, The Netherlands). The fertilizer nutrient content included NPK (17:1.6:8.7), 0.6 Mg + trace elements (0.01 B, 0.25 Cu, 0.2 Fe, 0.03 Mn, 0.01 Mo, 0.01 Zn) + 9.0% organic resin coating based on vegetable oils. It was applied to the surface of the pots (5 g/pot) on Sept 2 and Nov 18, 2010. After the first harvest (Nov 18, 2010) the plants were moved to a shade house (80% shaded) until the second harvest (Feb 25, 2011). Te Akau rock stack material (sample 12) was harvested on Nov 15, 2009. The Landcare Research collection (samples 1, 2, 5−11, and 13−15) was harvested on Nov 16, 2009. *Lepidium banksii* samples 3 and 4 (Table 1) were harvested on April 3, 2014. Frozen leaves from the harvested plants were freeze-dried and ground to a powder using a mortar and pestle prior to analyses. Whole leafy lateral shoots of the *L. oleraceum* plants for tasting and postharvest treatment experiments were harvested using a pair of hand pruning clippers and then dried for 48 h either in a forced air cabinet drier at 45 or 75 °C or in a Virtis 12 sl (Gardiner, NY) freeze-drying unit. The dried herb material was ground to a powder using a ZM100 Retsch ultracentrifugal mill (Haan, Germany) screened to 0.75 or 0.20 mm and stored frozen (−20 °C) prior to analyses.

Glucosinolates by LC−MS. A subsample of freeze-dried leaf powder (200 mg) was weighed into a 15 mL tube, extracted with boiling H_2O (10 mL), and placed in a simmering H_2O bath for 10 min (cf. blanching[18]). We found a negligible difference in *Lepidium* glucosinolates by this method compared to using heated MeOH. Extracts were then centrifuged at 20817*g* for 10 min, and the supernatant was diluted to a final volume of 25 mL with H_2O. An aliquot was filtered (0.22 μm) into glass vials for LC−MS analysis. The LC−MS system consisted of a Thermo Electron Corp. (San Jose, CA) Finnigan Surveyor MS pump, Finnigan MicroAS autosampler, and Finnigan Surveyor PDA detector and a ThermaSphere TS-130 column heater (Phenomenex, Torrance, CA). A 2 μL aliquot of each prepared extract was separated with a mobile phase consisting of 0.1% formic acid in H_2O (A) and 0.1% formic acid in MeCN (B) by reversed-phase chromatography. The column used was a 150 × 3 mm i.d., 3 μm, 80 Å, Luna C18(2) with a 4 × 2 mm i.d., 10 μm, guard column of the same material (Phenomenex), maintained at 30 °C with a flow rate of 200 μL/min. A gradient was applied: 0−3 min, 98% A; 15 min, 85% A; 20 min, 60% A; 25 min, 50% A; 30−33 min, 2% A; followed by a return to the starting condition over 5 min. The eluent was scanned by PDA (190−390 nm) and LTQ 2D linear ion-trap API-MS (Thermo-Finnigan, San Jose, CA) with electrospray ionization (ESI) in the negative mode. Data were acquired for precursor masses from m/z 250 to m/z 1000 with Pulsed Q collision-induced dissociation (PQD) fragmentation at 40 arbitrary units. PQD fragmentation at MS^2 allowed collection of lower m/z data (<1/3 of the precursor), thus m/z 96 and m/z 97 ions (sulfate fragments) indicating glucosinolates as used by Mellon et al.[19] Data were processed with the aid of Xcalibur 2.05 software (Thermo Electron Corp.). The concentration of the glucosinolates was calculated relative to an external standard of sinigrin, **3**, 99% (Sigma-Aldrich, St. Louis, MO).

Gluconapin, 1, Content of the Flavor Evaluation Samples by LC−MS. A subsample (30−40 mg) of the cultivated *L. oleraceum* plants was extracted and analyzed as above, with the following changes: A standard of **1**, 87% (PhytoLab, Vestenbergsgreuth, Germany), stock solution (100 μg/mL) was diluted with H_2O to give external standards ranging from 0.1 to 20 μg/mL. Using the HPLC systems described above, the following solvent gradient was applied: 0−2 min, 75% A; 6−8 min, 5% A; 8.5−11 min, 75% A. The flow rate was stepped from 200 to 400 μL/min between 8.5 and 10.9 min. Data were acquired by selective ion monitoring (SRM) based on **1** with precursor isolation of m/z 372, and an applied collision energy (CE) of 35 (arbitrary units), measuring the area response for product ions of m/z 259, 275, and 195 at t_R = 6.70 min.

Isolation of Gluconapin, 1. Freeze-dried ground *L. oleraceum* (500 mg) was extracted in 70% MeOH (5 mL) by shaking overnight. The dried extract (103 mg) was applied in H_2O to an IST Isolute (Hengoed, Mid-Glamorgan, U.K.) prepacked C18 column (500 mg) eluting with 0−100% MeCN in H_2O followed by EtOAc. **1** eluted with 20% MeCN and was identified by comparison of the ^1H NMR spectrum (D_2O, 400 MHz) with published data.[20]

Reaction of Gluconapin, 1, and Myrosinase. Endogenous *L. oleraceum* myrosinase activity was shown to hydrolyze the glucosinolate completely by mixing freeze-dried material, as used for the quantification procedure, with H_2O at room temperature (18 °C) and at 37 °C for 2 h with periodic mixing.

HS-SPME-GC−MS Analysis of Isothiocyanates. Ground dried *L. oleraceum* leaf (10 mg) was weighed into a 20 mL SPME autosampler vial, which was closed until analysis. Before analysis a 20 μL internal standard solution consisting of 5 μL of allyl isothiocyanate, **4**, 95% (Sigma-Aldrich), in 50 mL of H_2O and pH 4 0.1 M citrate buffer (0.5 mL) were added. The sample was equilibrated at 35 °C for 1 min, followed by head space absorption onto a preconditioned 65 μm PDMS−DVB SPME fiber (Supelco, Bellefonte, PA), with agitation throughout. Analyses were performed on an Agilent 7890A gas chromatograph with a CTC Analytics PAL system autosampler and an Agilent 5975C inert XL MSD with triple axis detector (under the control of Enhanced ChemStation software). A 30 m J&W HP-5 ms column with a 0.25 mm i.d. and 0.25 μm film was used for analyses. The SPME fiber was desorbed for 1 min into the injector (splitless, 260 °C), with a purge flow of 50 mL/min. The carrier gas was H_2 at 1.7 mL/min. The oven was held at 40 °C for 4 min and then heated to 120 °C at 10 °C/min. The MS transfer line was at 300 °C, the MS source at 230 °C, and the MS quadrupole at 150 °C. Peaks were

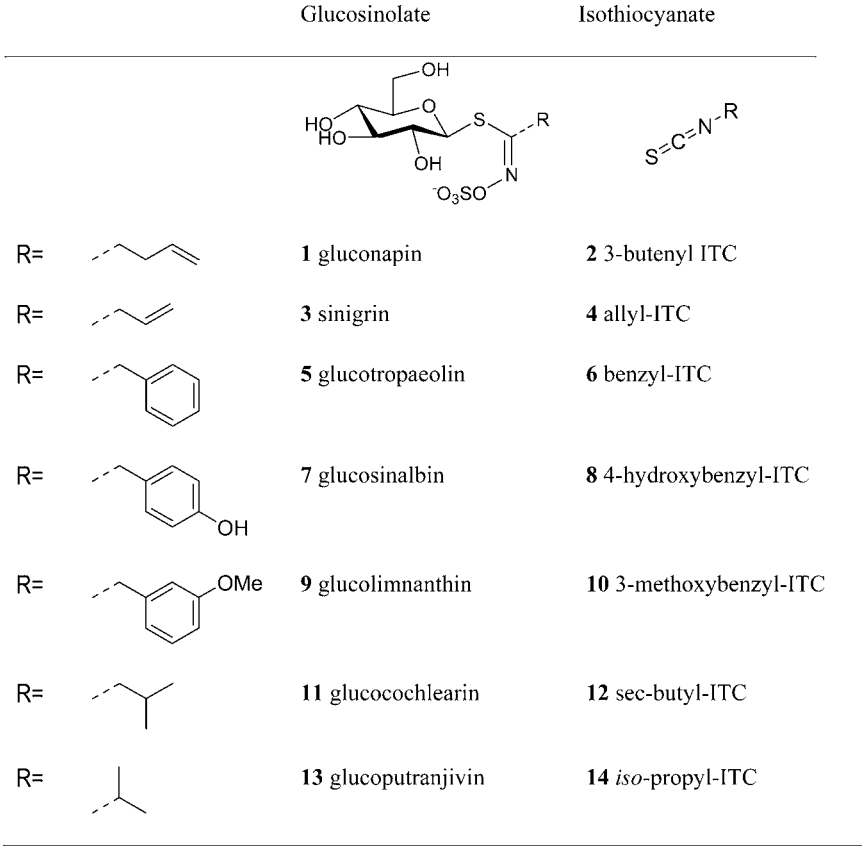

Figure 1. Compound structures

detected as total ion current, monitoring from m/z 35 to m/z 300 and identified by comparison with the NIST MS library and retention indices. 3-Butenyl isothiocyanate, **2**, was quantitated relative to the **4** internal standard peak, expressed as "relative units" based on TIC area and corrected for sample mass.

Free Isothiocyanate by GC−MS. Ground *L. oleraceum* plant material (100 mg) was extracted with EtOAc (0.5 mL) containing allyl isothiocyanate, **4** (216 μg/mL), as the internal standard. The solution was mixed thoroughly and then kept for 2 h, followed by a second mixing and filtering through a 0.45 μm PTFE filter before analysis. Analysis was by GC−MS using the method above but with direct 1 μL injection. A calibration curve was made using **4**.

Informal Sensory Evaluation. The samples assessed in this study were obtained from two harvests of the cultivated *L. oleraceum*. Water activity measurements were taken for food safety consideration, and all samples were less than 0.7a_w. Plant & Food Research staff experienced in food evaluation, but not considered trained descriptive sensory panelists, informally evaluated the color, flavor, and texture of the samples. Samples from the first harvest date were evaluated by three assessors, and samples from the second harvest date were evaluated by six assessors. *Lepidium* leaf material was tasted undiluted in a powdered form, and samples were blinded with a three-digit code for the evaluations. Assessors tasted each sample and recorded the flavors, aromas, and textures that they perceived. All comments were then tabulated and discussed as a group.

RESULTS AND DISCUSSION

Freeze-dried ground leaves of cultivated *L. oleraceum* plants (Table 1) were extracted with boiling water (to inactivate myrosinase) and analyzed for glucosinolates by LC−MS. The glucosinolate peaks were identified by characteristic m/z 96 and 97 sulfate fragments.[19] The predominant glucosinolate had an $[M - H]^-$ ion at m/z 372, suggesting a C_4H_7 side chain. By far the most common glucosinolate with this structure is gluconapin, **1**[10] (see Figure 1 for the structures of the compounds). Partial purification by reversed-phase chromatography gave a fraction dominated by glucosinolate signals in its ^{1}H NMR spectrum, matching the published data for **1**.[20] A commercial reference sample of **1** was purchased, and its LC retention and MS fragmentation were also matched.

Gluconapin, **1**, is widely distributed, but only one report from a *Lepidium* species was listed in a 2001 review,[10] at a low concentration in seeds of *Lepidium subulatum* from Spain.[21] However, there are more recent reports, for example, from perennial pepperweed, *Lepidium latifolium*, at highly variable concentrations up to 0.05 mg/g fresh weight.[22] We found concentrations of **1** in *L. oleraceum* leaves of 7−22 mg/g dry matter (DM), which is in the high range compared to reported concentrations in other Brassicaceae, e.g., 0.25−9.09 mg/g DM (assuming 90% H_2O) in Brussels sprouts, a *Brassica oleracea* cultivar.[23]

The flavor chemistry of Brassicaceae is complicated: the dynamic release of isothiocyanates and other compounds by myrosinase activity during processing and consumption gives pungency at pain receptors,[24] plus volatile aroma compounds reaching olfactory receptors. For example, the main pungent component of wasabi is allyl isothiocyanate, **4**, but the fresh green aroma is due to ω-(methylthio)alkyl isothiocyanates.[25] Endogenous myrosinase activity in *L. oleraceum* was shown to hydrolyze gluconapin, **1**, completely by mixing ground freeze-dried leaves with water. As expected, the predominant volatile product was 3-butenyl isothiocyanate (3BITC), **2**, but no free **2** was detected from an EtOAc extraction of dry leaf material.

3-BITC, **2**, is pungent,[25] but we could not find any quantitative comparisons of isothiocyanate pungency (i.e., no

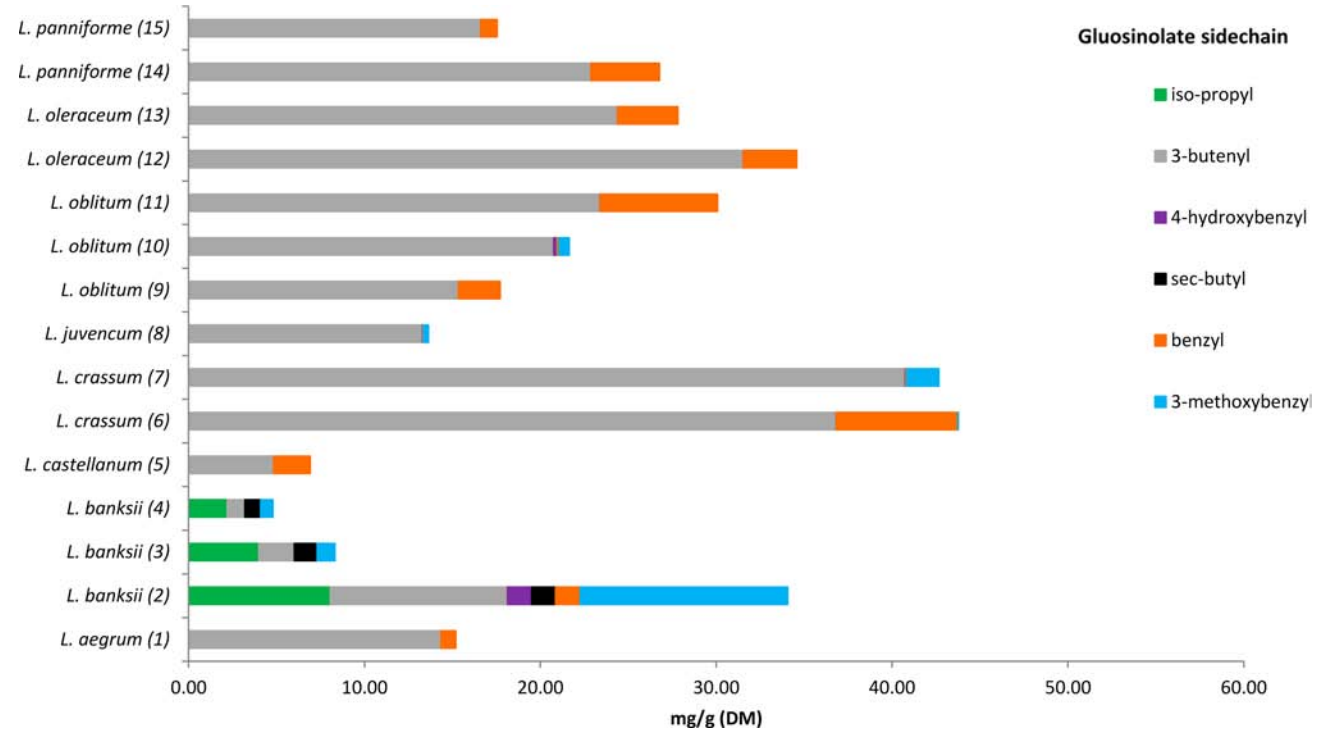

Figure 2. Glucosinolate concentrations in the leaves of New Zealand *Lepidium* species.

analogy of the Scoville scale used for pungent capsaicinoids[26]). Buttery et al.[26] studied the aroma impacts of isothiocyanates by sniffing the headspace above water solutions and found the odor threshold of **2** to be 380 ppb. This was practically the same as the odor threshold of allyl isothiocyanate (375 ppb), whereas other isothiocyanates had much more potent aromas; e.g., the ω-(methylthio)butyl isothiocyanate odor threshold was 3.4 ppb.[27] Therefore, minor glucosinolates in *Lepidium* may be important for aroma, although no other glucosinolates were detected in this *L. oleraceum* sample.

Various conditions inactivate myrosinase in different Brassicaceae.[25,28,29] To understand the parameters for *L. oleraceum*, different postharvest treatments were used to prepare dry leaf powders as potential flavor products. These were tasted and analyzed for gluconapin, **1**, and we also used an HS-SPME-GC−MS method to check the myrosinase activity by release of 3BITC, **2**. HS-SPME-GC has been used to analyze isothiocyanates from various Brassicaceae, e.g., mustard,[30] but we could not find any reports of using HS-SPME to monitor isothiocyanate release by immediate myrosinase action. Dried leaf powder was mixed with buffer solution at 35 °C for 1 min with agitation (cf. chewing) and then exposed to the SPME fiber for 10 s (cf. retro-nasal aroma sniffing[31]).

L. oleraceum leaves were dried at 0 (freeze-dried), 45, or 75 °C and ground to pass through 0.75 or 0.2 mm sieves. Samples from the higher temperature treatment were brown-green, while all other samples remained green. Chemical analyses and informal tasting results for this harvest 1 are presented in Table 2. All the samples had the grassy, green flavor that is typical of the fresh plant. Low amounts of wasabi-like pungency flavor were detected in nau leaf powders air-dried at 45 °C or freeze-dried, but not in samples dried at 75 °C. These flavor differences were not explained by differences in the concentrations of gluconapin, **1**. There were significant differences in the concentrations of **1** between drying treatments ($p < 0.001$, ANOVA), but the concentrations in the nonpungent 75 °C samples were higher than in the pungent freeze-dried samples (Table 1). The difference is in the myrosinase activity, shown by the nonpungent 75 °C samples releasing significantly ($p < 0.001$) lower amounts of

DOI: 10.1021/jf505859u
J. Agric. Food Chem. 2015, 63, 1833−1838

isothiocyanate **2** than the pungent freeze-dried and 45 °C samples (Table 1). There was also a significant ($p < 0.001$) effect of grinding size on release of **2** in this experiment, with the larger particles retaining more myrosinase activity (Table 2). However, this particle size effect was only seen for the 75 °C dried material in harvest 2 (Table 2).

We analyzed samples from a second harvest to check these results, but without the freeze-drying treatment, since this would be expensive commercially and gave lower concentrations of gluconapin, **1**, and 3BITC, **2**. The overall concentration of **1** was significantly ($p < 0.001$) higher in the nau leaves from this second harvest (Table 2). This was presumably due to seasonal variation, as has been reported for glucosinolates in various *Brassica*.[29] The overall release of **2** was also significantly ($p < 0.001$) higher from the nau leaves of this second harvest (Table 2) and disproportionately higher (about 10 times) than the rise in glucosinolate concentrations (about 1.3 times) (Table 2). Since the postharvest treatments were as similar as we could make them, this could be due to an increase in myrosinase concentration and/or activity and/or stability. This second experiment confirmed the highly significant ($p < 0.001$) difference in release of **2** between drying at 45 and at 75 °C, reflected by the lack of pungent wasabi-like flavor in the higher temperature samples (Table 2). A range of thermal stabilities have been reported for myrosinase from *Brassica*, from "up to 30 °C" to "up to 90 °C".[29]

These experiments showed that the pungent wasabi-like flavor of nau leaf powders is due to release of 3BITC, **2**, in the consumer's mouth due to the action of plant myrosinase, since there is no free **2** in leaf powders and no pungency if myrosinase is heat deactivated. Wasabi is generally used freshly grated to get the best flavor, but dried wasabi powders have been tested. These lost pungency on storage, but this could be slowed by readdition of L-ascorbic acid to preserve myrosinase activity.[25]

For this study we collected samples of nau as *L. oleraceum* sensu lato[7,32] from its geographic range across New Zealand: North Island, South Island, and off-shore islands (Table 1). We also collected *L. banksii* Kirk, which has long been recognized as a distinct species and called coastal peppercress.[7,32] However, the taxonomic revision published[8] during our work elevated most of these collections to distinct species, as shown in Table 1. Freeze-dried ground leaves from the full range of samples were analyzed for glucosinolates by LC−MS of boiling water extracts and for isothiocyanates, released by endogenous myrosinase, by HS-SPME-GC−MS.

The concentrations of glucosinolates in the leaves of eight New Zealand *Lepidium* species are shown in Figure 2. The major glucosinolate in seven of these species, all *L. oleraceum* sensu lato, was gluconapin, **1**, with benzyl glucosinolate, **5**, glucotropaeolin, the next most common component. Compound **5** has been reported from many other *Lepidium* species,[10] and the corresponding isothiocyanate, **6**, has a "chemical, pungent" odor with a threshold similar to that of 3BITC, **2**.[33] All three samples of *L. banksii* had a very distinct glucosinolate profile (Figure 2) and stood out as having a high proportion of isopropyl glucosinolate, **13**, plus *sec*-butyl glucosinolate, **11**, which were not detected in any of the other *Lepidium* species. 3-Methoxybenzyl glucosinolate, **9**, was also found in *L. banksii* and some of the other *Lepidium* species (Figure 2) and has been reported along with glucosinolates **5** and **7** as important components of *Lepidium meyenii*,[34,35] a South American tuber crop known as maca. Therefore, *L. banksii*, which is already being cultivated to save it from extinction,[7] could provide an alternative flavor crop. Further investigation on the chemical variability of New Zealand *Lepidium* species, especially using the rapid HS-SPME-GC−MS technique, could add to the studies of genetic variation under way using DNA markers.[17]

elimination of a fatty acid to form a cyclic acyloxonium cation reactive intermediate, followed with a nucleophilic substitution with a chlorine anion to form 3-MCPD diesters.[15] However, no direct evidence was provided to support the hypothesis. Whether TAG could be the precursor for 3-MCPD monoester formation also remained unknown.

The present study aimed to investigate whether TAG may serve as precursors for 3-MCPD di- and monoesters and to explore possible chemical mechanisms for their formation. TAG and selected chlorine-containing compounds were reacted under a high-temperature and low-moisture condition for 3-MCPD ester formation. An electron spin resonance (ESR) spectrometer was utilized to detect free radicals, whereas Fourier transform infrared spectroscopy (FT-IR) was used to examine the possible involvement of carbonyl group(s). The results from this study may serve as the scientific foundation for reducing the level of 3-MCPD esters in refined edible oils and other food products.

MATERIALS AND METHODS

Materials. Tristearoylglycerol (TSG) and lindane were purchased from J&K Scientific (Beijing, China). Sodium acetate (MS grade), iron chloride, DMPO, ferric sulfate, and ferrous sulfate were purchased from Sigma-Aldrich (St. Louis, MO, USA). Hexadecane and iron dichloride were purchased from Aladdin Reagent (Shanghai, China). Sodium hydroxide, toluene, sodium chloride, potassium chloride, copper chloride, zinc chloride, and concentrated HCl were bought from Ambrosia Pharmaceuticals (Shanghai, China). High-purity nitrogen (99.999%) was purchased from Ruili Chemical Gas Co., Ltd. (Shanghai, China). 2-Propanol and methanol (LC-MS grade) were obtained from Merck (Darmstadt, Germany). GHP membrane (0.2 μm) was purchased from Pall Corp. (New York, NY, USA). The refined palm oil was a gift from the Yihai Kerry/Wilmar Biotechnology Research and Development Center (Shanghai, China).

Model Reaction between TSG and Selected Chlorine-Containing Compounds. For the reaction between solid chloride agents and TSG, 2 mg of NaCl, KCl, $FeCl_2$, $CuCl_2$, $ZnCl_2$, $FeCl_3$, or lindane was added into 10 mL of 0.5 mg/mL TSG solution in hexadecane, respectively, according to a previous study.[14] HCl gas was prepared by heating concentrated HCl, followed by drying through 98% H_2SO_4, and introduced into 10 mL of a 0.5 mg/mL TSG solution. To examine whether Fe^{2+} or Fe^{3+} could catalyze the formation of 3-MCPD esters, 2 mg of $FeSO_4$ or $Fe_2(SO_4)_3$ was added into the mixture of 2 mg of KCl, $CuCl_2$, or lindane and 10 mL of 0.5 mg/mL TSG solution, respectively. Each reaction was refluxed with stirring for 20 min under ambient temperature or 120 or 240 °C, respectively. The nonpolar reaction system was low in moisture content. After cooling to ambient temperature, the mixture was diluted to 1/100 (v/v) with methanol, filtered through a GHP 0.2 μm membrane, and subjected to UPLC-Q-TOF-MS analysis (Waters Xevo G_2 Q-TOF-MS, Milford, MA, USA).[14]

ESR Determination of Radical Signals. To determine whether free radical was generated in the formation of 3-MCPD esters from TSG at different temperatures, TSG solution, TSG solution containing DMPO, TSG solution containing DMPO and $FeCl_3$, and TSG solution containing DMPO, KCl and $Fe_2(SO_4)_3$ were kept at ambient temperature or 60, 80, or 120 °C, respectively, for 20 min and measured on a Bruker EMX-8/2.7C spectrometer equipped with a variable-temperature system (Bruker Optics, Karlsruhe, Germany) in a 0.1 mL quartz tube for their ESR signals.[14] The concentration of TSG solution was 0.5 mg/mL in toluene. The final DMPO concentration was 20 mmol/L in the reaction mixture, whereas the concentration of $FeCl_3$ or $Fe_2(SO_4)_3$ was 0.2 mg/mL. The ESR conditions were the same as described before.[14]

FT-IR Measurements. TSG was directly applied onto the attenuated total reflectance (ATR) crystal and scanned immediately at 25 °C and then heated to 120 °C and scanned immediately.[14] FT-IR spectra were recorded on a Spectrum 100 FT-IR spectrometer (PerkinElmer, Waltham, MA, USA) equipped with a pressure application device, combined with a deuterated triglycine sulfate (DTGS) detector and a single bounce diamond temperature controller.

Effect of Chelating Agent. Two milligrams of $FeCl_3$ was added into 5 mL of 0.5 mg/mL TSG solution, followed by ultrasonic oscillation for 30 min after the addition of a series of different amount of EDTA-2Na (1.2, 2.3, 4.6, 9.2, and 23.0 mg). The control reaction contained no EDTA-2Na. The reaction was carried out at 120 °C for 20 min with continuous stirring. When the mixtures were cooled to ambient temperature, they were diluted with 50-fold of methanol/2-propanol (1:1, v/v) and examined by UPLC-Q-TOF MS after filtration.[14]

The experiment was also conducted using refined palm oil under a high-temperature and low-moisture condition. $FeCl_3$ (400 mg) was added into 80 g of refined palm oil and mixed well, then 0, 0.938, or 4.655 g of EDTA-2Na was added, respectively, for the control reaction and low and high levels of EDTA-2Na. The mixture was kept at 240 °C for 1 h with a nitrogen flow rate of 2 L/min at a pressure of about 5 mbar. After the reaction, inlet N_2 was stopped, and vacuum was released when the temperature was below 100 °C. The mixture was diluted with 2-propanol, filtered through a GHP 0.2 μm membrane, and analyzed by UPLC-Q-TOF MS.

Q-TOF MS Examination of DMPO Radical Adducts. TSG solutions (0.5 mg/mL in toluene) with $Fe_2(SO_4)_3$ and DMPO were heated to 120 °C and kept for 20 min. The final concentrations of $Fe_2(SO_4)_3$ and DMPO in the TSG solutions were 0.2 mg/mL and 20 mmol/L, respectively. After cooling to ambient temperature, the TSG solution was further diluted with methanol for 100-fold and injected directly into the Q-TOF mass spectrometer for analysis according to a method described previously.[14] Briefly, an ESI positive mode was selected with lockspray as an internal standard; capillary voltage for positive ion mode was 3.0 kV; sampling cone voltage was 30.0 kV; source temperature was 120 °C with a desolvation temperature at 450 °C; cone gas flow and desolvation gas flow were 50 and 800 L/h, respectively; scan range was m/z 50−1000 Da; scan time was 0.1 s. Data were collected and analyzed using Masslynx 4.1 software, and all peak areas were determined using the total ion counts in the extracted ion chromatogram.

Statistical Analysis. Data were expressed as the mean ± standard deviation (SD) for each experiment. Differences between means were determined by the analysis of one-way ANOVA and Tukey's test, using SPSS software (SPSS for Windows, version rel. 16.0, SPSS Inc., Chicago, IL, USA). Statistical significance was declared at $P < 0.05$.

RESULTS AND DISCUSSION

Potential of Forming 3-MCPD Esters from TSG. NaCl, KCl, $FeCl_2$, $CuCl_2$, $ZnCl_2$, $FeCl_3$, and dry HCl gas were examined as the inorganic chlorine donors, whereas lindane was selected as an organic chloride-containing compound to react with TSG because they were able to react with *sn*-1,2-stearoylglycerol (DSG) to form 3-MCPD fatty acid diester.[14] UPLC-Q-TOF-MS analysis of the reaction products showed that only $FeCl_2$ and $FeCl_3$ at 120 and 240 °C and HCl gas at 240 °C formed 3-MCPD diesters. It was reported that NaCl, KCl, $FeCl_2$, $CuCl_2$, $ZnCl_2$, $FeCl_3$, HCl gas, and lindane were able to react with DSG at 240 °C to form 3-MCPD diester.[14] It was also reported that only HCl gas, $FeCl_2$, and $FeCl_3$ were able to react with DSG and form detectable amounts of 3-MCPD diester at 120 °C.[14] Taken together, these results suggested that TSG might be less active in reacting with chlorine-containing compounds to form 3-MCPD diesters compared to DSG. Also, $FeCl_2$ and $FeCl_3$ might have greater reactivity with TAG/TSG and DAG/DSG than HCl gas and other inorganic and organic chlorine compounds to generate 3-MCPD esters.

In addition, 3-MCPD fatty acid monoester was also generated in the reaction of $FeCl_3$ and TSG at both 120 and

240 °C, suggesting that TSG or other TAGs might also serve as precursors for 3-MCPD fatty acid monoester formation under the same high-temperature and low-moisture condition. Interestingly, no detectable amount of 3-MCPD monoester was formed in the reactions of DSG with all of the tested chlorine-containing compounds in an earlier study.[14] To our knowledge, this was the first time that TAG was found to form 3-MCPD monoester under a high-temperature and low-moisture condition. The fact that only $FeCl_2$ or $FeCl_3$ could react with TAG to form 3-MCPD esters under a high-temperature and low-moisture condition, similar to that during oil deodorization, also raised the question of whether Fe^{3+} or Fe^{2+} could play a role in 3-MCPD ester formation.

Possible Role of Fe^{3+} or Fe^{2+} in 3-MCPD Ester Formation. To examine the possible role of Fe^{3+} or Fe^{2+} in the formation of 3-MCPD fatty acid esters from TAG, $Fe_2(SO_4)_3$ and $FeSO_4$ were tested as the Fe^{3+} and Fe^{2+} donors, respectively. TSG was reacted with both inorganic chlorides including KCl and $CuCl_2$ and an organic chlorine compound lindane in the presence of Fe^{3+} or Fe^{2+} at room temperature and 120 and 240 °C, respectively. Figure 1 reports the 3-MCPD ester formation in the reaction mixture of TSG and lindane at 120 °C. No detectable amount of either 3-MCPD

diester (Figure 1A) or monoester (Figure 1B) was observed under the experimental conditions. Significant amounts of 3-MCPD diesters at the retention time of 7.71 min with an m/z value of 665.5248 (calculated as 665.5252) were detected with the presence of $Fe_2(SO_4)_3$ or $FeSO_4$ (Figure 1, panels C and E, respectively), with significant levels of the monoester at 3.45 min with m/z 399.2640 (calculated as 399.2642) (Figure 1D,F). The structures of the 3-MCPD fatty acid mono- and diesters were confirmed with high-resolution MS analysis (data not shown). The possible catalytic effect of Fe^{3+} or Fe^{2+} in 3-MCPD ester formation was also confirmed with an inorganic chlorine compound KCl (Figure 2). No 3-MCPD esters were detected in the reaction mixture of TSG and KCl (Figure 2A,B), whereas significant contents of 3-MCPD diester at 7.69 min and monoester at 3.42 min were detected when $Fe_2(SO_4)_3$ was added (Figure 2C,D) or $FeSO_4$ was added in the reaction (Figure 2E,F). Furthermore, no difference in catalytic activity was observed between $Fe_2(SO_4)_3$ and $FeSO_4$. Interestingly, the ratio of 3-MCPD monoester to diester was approximately 10:1 when TSG reacted with KCl in the presence of $Fe_2(SO_4)_3$ or

DOI: 10.1021/jf5061216
J. Agric. Food Chem. 2015, 63, 1839−1848

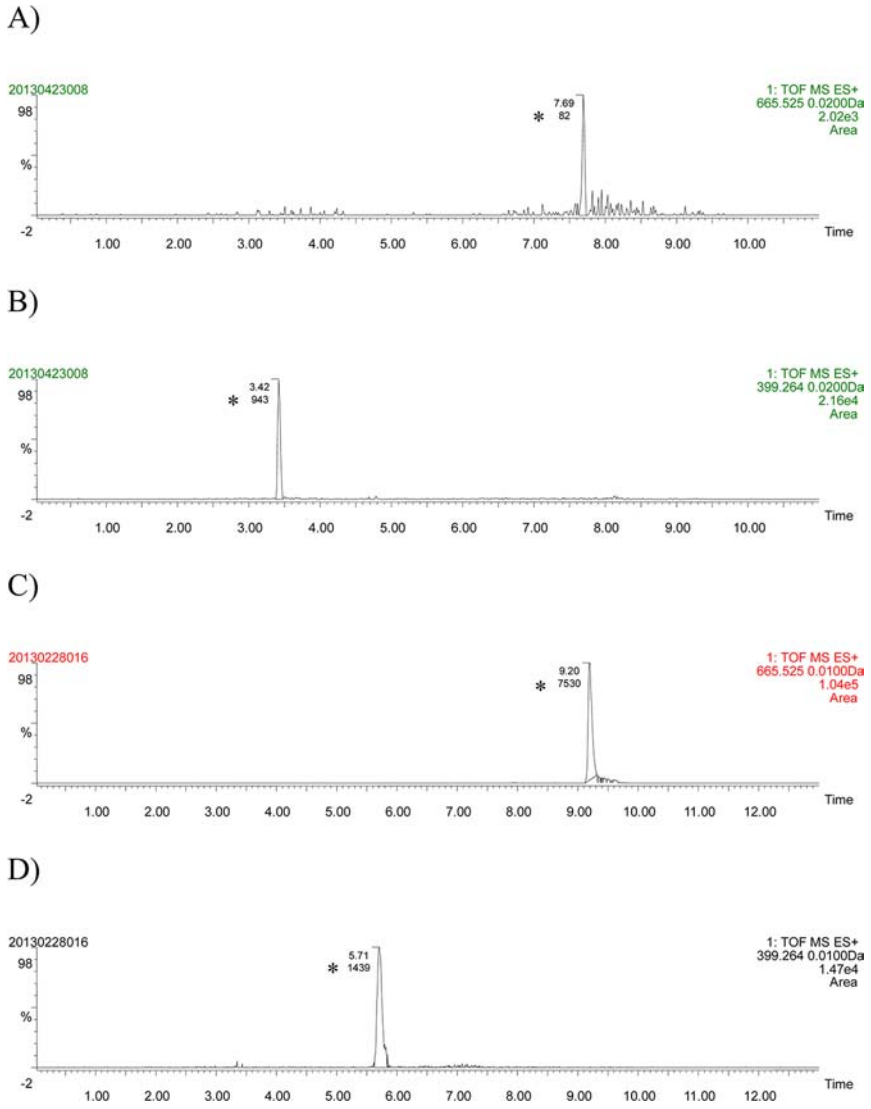

Figure 3. UPLC-QTOF MS extracted-ion chromatograms for the reaction products of TSG and different chlorine sources: (A) 3-MCPD diester ion with KCl and $Fe_2(SO_4)_3$; (B) 3-MCPD monoester ion with KCl and $Fe_2(SO_4)_3$; (C) 3-MCPD diester ion with $FeCl_3$; (D) monoester ion with $FeCl_3$. The retention times of both diester and monoester are different between injections because the UPLC columns were different. The concentration was 0.5 mg/mL for TSG the and reaction temperature was 120 °C. The concentration was 0.2 mg/mL for $Fe_2(SO_4)_3$ and $FeSO_4$. * indicates the peak area for a 3-MCPD di- or monoester ion.

$FeSO_4$ (Figure 2D−F, respectively), whereas the ratio was 1:10 when TSG reacted with $FeCl_3$ (Figure 3). The results suggested that both Fe^{3+} and Fe^{2+} were able to catalyze the formation of 3-MCPD fatty acid di- and monoesters from TAG and might favor the formation of 3-MCPD monoesters under a high-temperature and low-moisture condition, indicating their important role in forming 3-MCPD esters during the oil deodorization process. The results also suggested that the overall amount and profile of 3-MCPD esters also depended on the type of chlorine sources. This was the first report about the possible catalytic effect of Fe^{3+} or Fe^{2+} in 3-MCPD ester formation from TAG, suggesting a possible approach to mitigate 3-MCPD esters in refined oils through reducing the Fe availability. This was also the first report that chlorine source ($FeCl_3$ vs KCl with $Fe_2(SO_4)_3$ or $FeSO_4$) may alter the final 3-MCPD ester profile.

In addition, the two facts that 3-MCPD esters were formed through the reaction of lindane and TSG in the presence of Fe^{3+} or Fe^{2+} and that lindane is an organic chlorine compound also suggested a possible free radical mediated mechanism for 3-MCPD ester formation from TAG. It was interesting why or how Fe^{3+} or Fe^{2+} was able to facilitate the 3-MCPD ester formation under a low-moisture and high-temperature condition.

Electron Spin Resonance Examination of Possible Free Radicals. ESR examination was performed to examine and confirm the presence of free radicals under the experimental conditions, because our previous study showed a free radical mediated mechanism for 3-MCPD fatty acid diester formation from diacylglycerol.[14] As shown in Figure 4A, heating TSG with DMPO, a spin trapping agent, at 60 °C for 20 min did not result in any detectable level of free radicals, whereas significant ESR signal was detected in TSG with DMPO kept at 120 °C for 20 min (Figure 4B), indicating the generation of free radicals due to the thermal treatment. To test the role of Fe^{3+}, the mixture of TSG and DMPO with $Fe_2(SO_4)_3$ or $FeCl_3$ was heated for 20 min under the same conditions and examined for possible ESR signals. Weak ESR

DOI: 10.1021/jf5061216
J. Agric. Food Chem. 2015, 63, 1839−1848

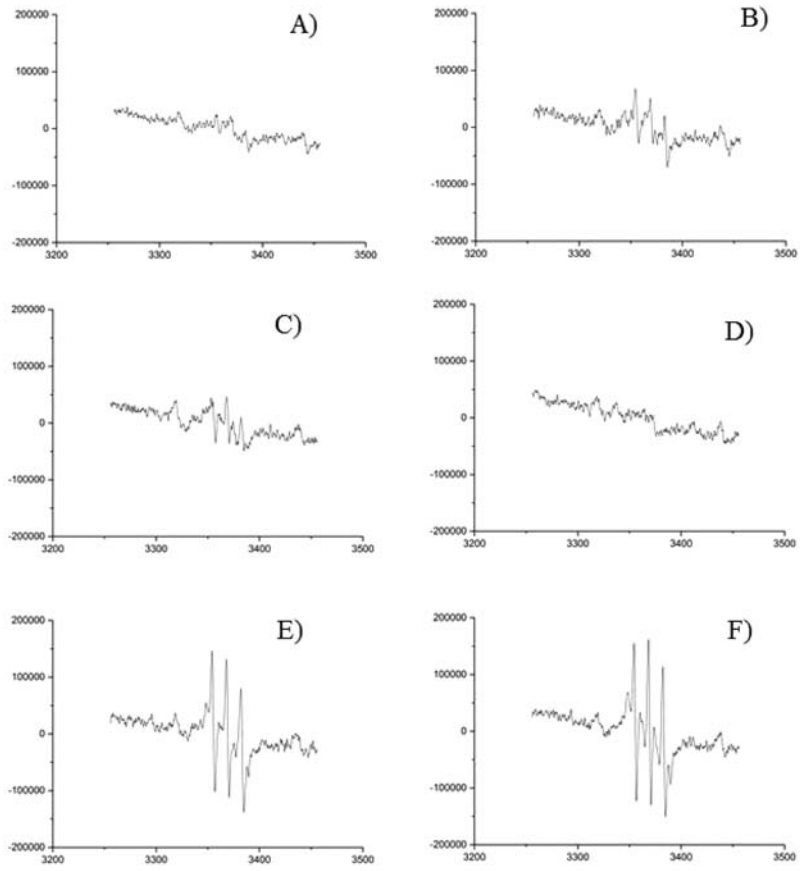

Figure 4. ESR examination of TSG mixtures. The TSG reaction mixtures were kept at (A) 60 °C without Fe, (B) 120 °C without Fe, (C) 60 °C with $FeCl_3$, (D) 120 °C with $FeCl_3$, (E) 60 °C with $Fe_2(SO_4)_3$, and (F) 120 °C with $Fe_2(SO_4)_3$. All TSG reaction mixtures contained 0.5 mg/mL TSG and 20 mmol/L DMPO, as well as different chlorine compounds. The concentration was 0.2 mg/mL for $FeCl_3$ and $Fe_2(SO_4)_3$. All reactions were carried out for 20 min in toluene at the temperature before ESR analysis.

signal was observed when the mixture of $FeCl_3$, TSG, and DMPO was heated at 25 °C (Supporting Information, Figure S1) and 60 °C (Figure 4C), but no significant ESR signal was detected in the mixture kept at 80 °C (Figure S1) and 120 °C (Figure 4D). Interestingly, the mixture of $Fe_2(SO_4)_3$, TSG, and DMPO kept at 60 °C (Figure 4E), 80 °C (Figure S2), and 120 °C (Figure 4F) had significant levels of ESR signals. These results suggested that $Fe_2(SO_4)_3$ might promote radical generation at a high-temperature and low-moisture condition and consequently stimulate 3-MCPD ester formation from TSG or other TAGs when a chlorine source is also available. The absence of ESR signals in the mixture of TSG, DMPO, and $FeCl_3$ at a relatively higher temperature might be explained by the availability of chlorine in $FeCl_3$, which immediately reacted with the radical intermediate(s) to form the 3-MCPD ester final product(s) under the experimental conditions. The catalytic activity of Fe^{3+} or Fe^{2+} in generating free radicals might depend on their electronic structures and electron availability. The weaker ESR signals detected in the $FeCl_3$ and TSG reactions might also be partially explained by the lesser electron availability of $FeCl_3$ compared to that of $Fe_2(SO_4)_3$.

Effect of Chelating Agent. To further examine the role of Fe^{3+} or Fe^{2+} in forming 3-MCPD esters, a chelating agent, EDTA-2Na, was selected and investigated for its possible influence on 3-MCPD ester formation in the presence of Fe^{3+}. Figure 5A shows that EDTA-2Na at a molar ratio to $FeCl_3$ of 1:1 or greater significantly decreased 3-MCPD diester formation from TSG in a dose-dependent manner, but had little effect on the monoester amount (data not shown).

The effect of EDTA on 3-MCPD ester formation was also investigated using refined palm oil. As shown in Figure 5B, the addition of EDTA in the reaction mixture was able to suppress the formation of 1-palmitoyl, 1-oleoyl, and 1-linoleoyl 3-MCPD esters in a dose-dependent matter. The levels of other 3-MCPD esters were not estimated as their levels were low in the reaction mixture and could not be accurately quantified. The result further confirmed the catalytic role of Fe^{3+} or Fe^{2+} in forming 3-MCPD fatty acid esters from TAG under a high-temperature and low-moisture condition and suggested that chelating agents might suppress 3-MCPD fatty acid formation from TAG through reducing Fe^{2+} or Fe^{3+} availability.

Taken together, the data in Figure 5 indicate that the oil composition might alter the 3-MCPD ester formation and modulate the catalytic effect of Fe^{3+} or Fe^{2+}, suggesting that 3-MCPD ester formation during oil refining could be very complicated and warrant additional research. This finding was partially supported by the earlier observation that the oil composition or type of oil might alter the generation of 3-MCPD esters.[19]

FT-IR Determination of TSG at 25 and 120 °C. To further examine the proposed free radical mechanism(s) for 3-MCPD di- and monoester formation, TSG kept at 25 and 120 °C was measured for FT-IT spectra. As shown in Figure 6A, because the carbonyl ester groups at C-1 and C-3 positions have the same chemical environment, TSG exhibited two

DOI: 10.1021/jf5061216
J. Agric. Food Chem. 2015, 63, 1839−1848

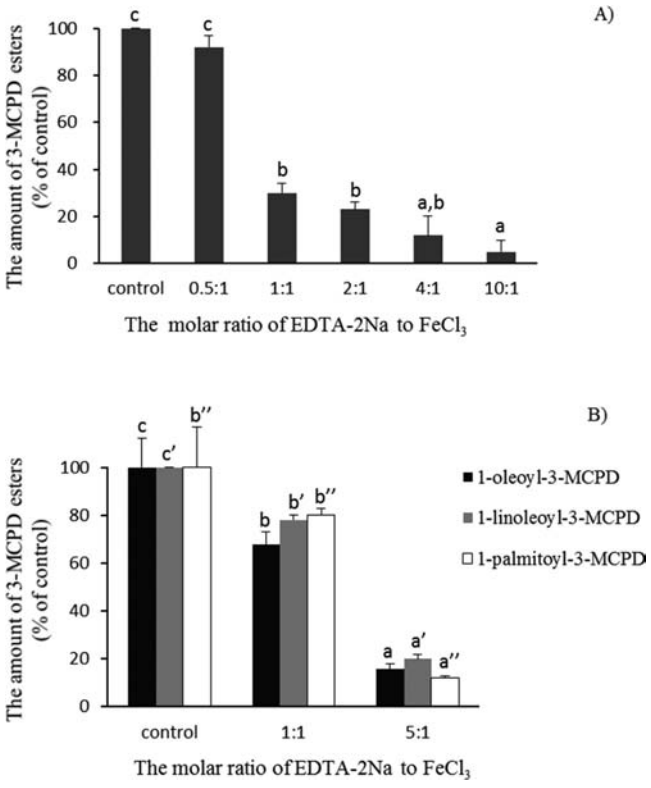

Figure 5. Effect of EDTA on 3-MCPD ester formation: (A) 3-MCPD diester formation from TSG; (B) formation of the three 3-MCPD monoesters from a refined palm oil. The relative amounts of 3-MCPD esters are reported. Different letters (a–c) in panel A reflect significant differences in the relative amount of 3-MCPD diester in TSG ($P < 0.05$), whereas different letters (a–c, a′–c′, and a″–c″) in panel B represent significant difference in relative amount of 1-oleoyl, 1-linoleoyl, and 1-palmitoyl 3-MCPD esters in the palm oil, respectively ($P < 0.05$).

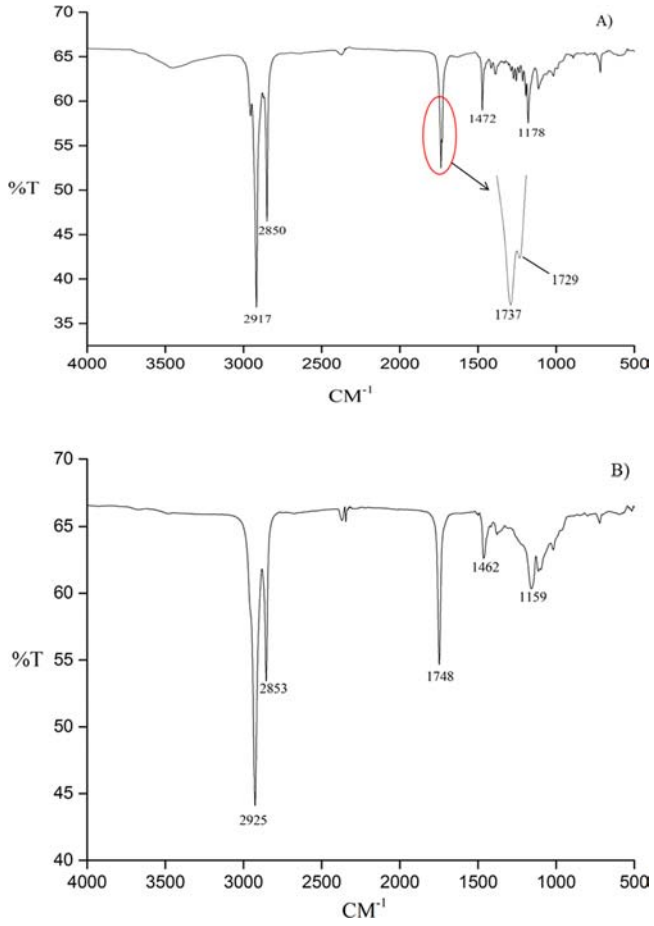

Figure 6. FT-IR spectra of TSG kept at (A) 25 °C and (B) 120 °C.

carbonyl absorbance bands at 25 °C, one centered at 1737 cm^{-1} and the other centered at 1729 cm^{-1}. However, when heated to 120 °C, only one carbonyl absorbance band centered at 1748 cm^{-1} was detected, reflecting a hypochromic shift of the carbonyl group (Figure 6B). The results indicated the involvement of the carbonyl ester group at the C-2 position or two of the three carbonyl groups at a high temperature in forming 3-MCPD esters.[14]

Proposed Mechanism for 3-MCPD Ester Formation from TAG. On the basis of the data, a new mechanism was proposed for 3-MCPD ester formation from a triacylglycerol under a high-temperature and low-moisture condition. As shown in Figure 7, the reaction might be initiated by the formation of a carbon-centered radical (**I**) by eliminating a RCOO$^{\bullet}$ from C-1 or C-3 of TSG (TAG) in step a due to the thermal treatment and/or the catalytic effect(s) of Fe^{3+} or Fe^{2+}. The carbon-centered radical was not stable and might immediately attack the ester carbonyl group located at the C-2 and form a cyclic acyloxonium free radical (**II**, CAFR) through step b or form a epoxide ring free radical (**III**, ERFR) through step c. CAFR and ERFR could be relatively stable because of the dislocation of the unpaired electron among multiple atoms within the ring structures. CAFR could either react with a chlorine radical or extract a chlorine radical from a chlorine-containing compound, such as HCl, Cl_2, NaCl, KCl, $FeCl_2$, $FeCl_3$, $CuCl_2$, or $ZnCl_2$, to form 3-MCPD diesters through step d or e, respectively, whereas EAFR could undergo a similar reaction to form 3-MCPD monoesters (Figure 7). The proposed mechanism(s) could explain the formation of both 3-MCPD fatty acid diesters and monoesters under a high-temperature and low-moisture condition, such as that during the deodorization procedure in the oil-refining process. The mechanism(s) could also explain the copresence of 3-MCPD and glycidol fatty acid esters in the refined edible oils.[20]

It was reported that both Fe^{2+} and Fe^{3+} were associated with free radical generation[21] and lipid peroxidation.[22] Fe^{2+} and Fe^{3+} may serve as a detrimental catalyst in 3-MCPD and glycidol fatty acid ester formation through promoting radical generation and forming complexes with the radical intermediates to enhance their stability. These might be explained by their special electron structures. For instance, Fe^{2+} and Fe^{3+} have been proposed to form iron–oxygen complexes such as preferred ion (Fe^{2+}–O_2 or Fe^{3+}–O_2) or ferryl ion (FeO^{2+}) to facilitate lipid peroxidation.[22]

To further examine the proposed radical mechanism(s), TSG was heated with $Fe_2(SO_4)_3$ and DMPO to 120 °C for 20 min, and the reaction mixtures were examined using Q-TOF MS. However, neither the intermediate free radical–DMPO adducts nor other possible product ions of the intermediates were detected.

Possible Role of Thermal Treatment on 3-MCPD Ester Formation. The effect of thermal treatment degree on 3-MCPD ester formation was also investigated by reacting TSG with $FeCl_3$ at 120 and 240 °C, and the concentrations of products were semiquantified on the basis of the peak areas of

DOI: 10.1021/jf5061216
J. Agric. Food Chem. 2015, 63, 1839–1848

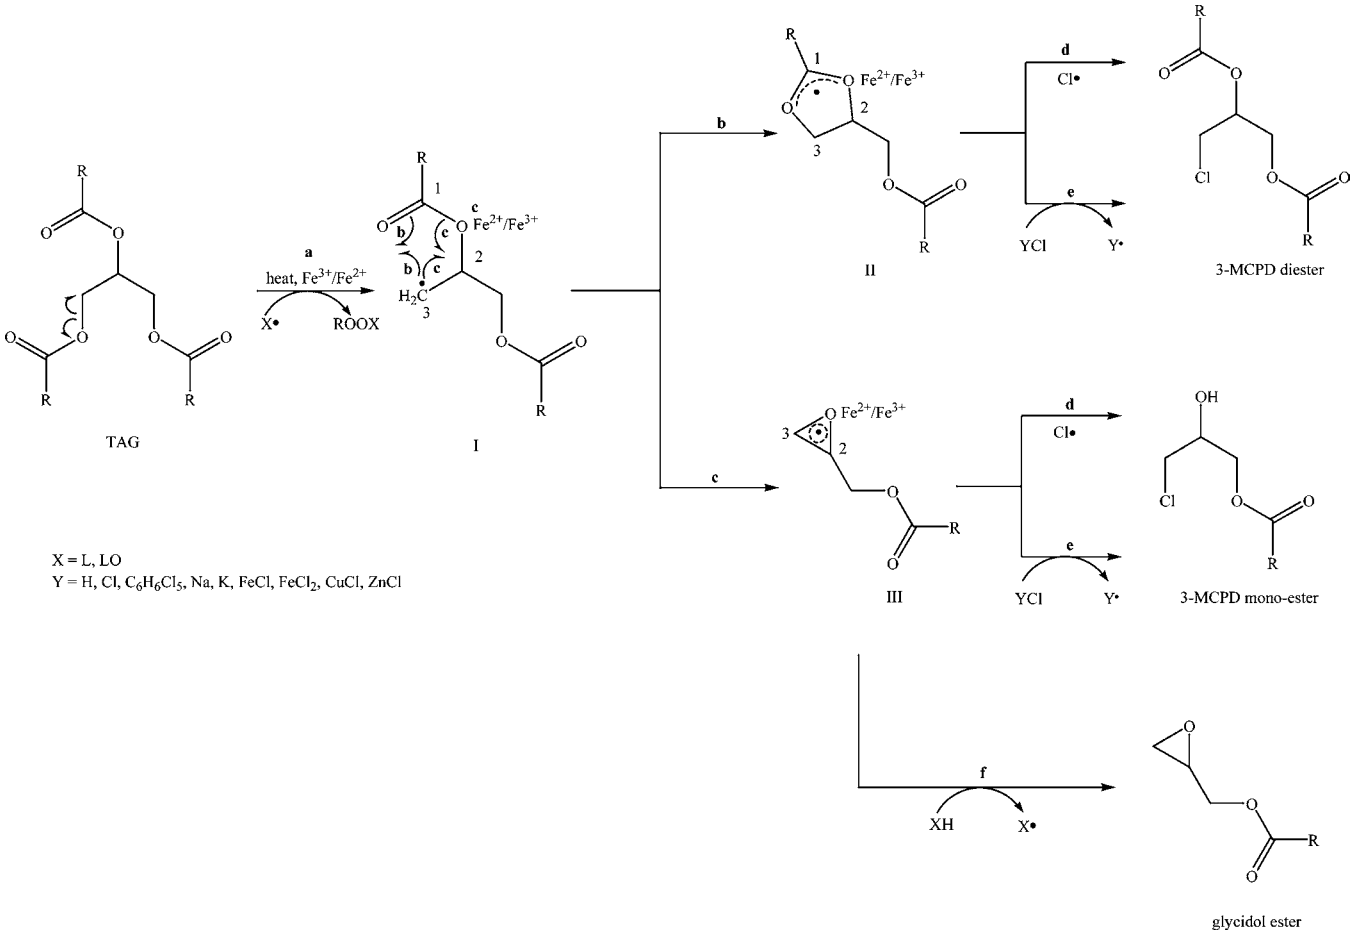

Figure 7. Proposed chemical mechanisms for 3-MCPD ester formation from triacylglycerol (TAG).

their extracted ion chromatogram. At 120 °C, the total ion count for 3-MCPD di- and monoesters was 8969 and was 5588 when the reaction was carried out at 240 °C, suggesting that a higher degree of thermal treatment might result in a lower overall 3-MCPD ester amount in the oil products (Figure 8). The finding was further confirmed with the reactions of TSG and KCl in the presence of either Fe^{3+} or Fe^{2+}. Compared to the reactions carried out at 240 °C, greater levels of total 3-MCPD esters were detected at 120 °C, regardless of the form of Fe (Supporting Information, Figures S3 and S4). This finding was in contrast to the observation by Svejkovská and others that MCPD ester concentration was proportional to the reaction temperature,[23] but supported an earlier observation that 3-MCPD esters undergo thermal degradation with the rate proportional to the thermal treatment degree.[24]

In addition, the ratio of 3-MCPD diester to monoester was more than 5:1 at 120 °C, whereas the ratio became about 1.3 when reacted at 240 °C (Figure 8), suggesting the possible influence of thermal treatment degree on the ratio of 3-MCPD di- and monoesters. Also noted was that TSG with KCl and Fe^{3+} also resulted in an ion count of 943 for 3-MCPD monoester and 82 for diester at 120 °C, respectively, whereas the reaction generated an ion count of 788 for 3-MCPD monoester without detectable diester (Supporting Information, Figure S3). For the reaction of TSG with KCl and Fe^{3+}, the ratios between diester and monoester were 1:10.6 and 1:14.5 at 120 and 240 °C, respectively (Figure S4). These data suggested the thermal degradation of 3-MCPD esters might include both dechlorination and deacylation, and deacylation may be more preferred under the experimental conditions. This finding was in contrast to the conclusion by Ermacora and Hrncirik that dechlorination was preferred over deacylation for 3-MCPD dipalmitate and dilaurate.[24] The degradation experiment was conducted with the residues of two 3-MCPD diesters in a temperature-controlled oven and kept at 180, 240, and 260 °C for 20 min. The conclusion was based on the analysis of 3-MCPD diesters and their degradation products. In the present study, the overall amounts for 3-MCPD di- and monoesters from TSG reacting with a chlorine compound were the results of both formation and degradation reactions. Taken together, these data suggested a possibility to reduce final 3-MCPD ester concentration in the refined oils through an extended thermal treatment degree. It needs to be pointed out that the thermal treatment may promote lipid oxidation and other chemical changes in the edible oil products through reducing their 3-MCPD ester contents.

In summary, the possible mechanisms behind the formation of 3-MCPD mono- and diesters from triglycerides might involve either a cyclic acyloxonium or a glycidol ester radical intermediate under a high-temperature and low-moisture condition. This study also reported that glycidol esters might be a coproduct from TAG during 3-MCPD ester formation under the experimental conditions. In addition, Fe^{2+} and Fe^{3+} might catalyze both 3-MCPD and glycidol esters' formation from TAG. These results suggested that reducing the availability of Fe^{2+} and Fe^{3+} through controlling ingredients,

extraction buffers,[9,11] food matrices,[10,12] and processing methods,[11,13−15] and the outcomes of these studies confirm that a wide variation in the recovery of peanut proteins exists among different kits.

Moreover, the reference material used to prepare the kit standards is not always known and is not standardized between ELISA kits, which is another source of variability between different kits. The National Institute of Standards and Technology (NIST) has developed a standard reference material (SRM) for peanut (2387), a peanut butter. However, a comparison of commercial peanut ELISA kits for their sensitivity of detection of peanut from SRM 2387 peanut butter is yet to be accomplished. Furthermore, although all peanut ELISA kits detect peanut proteins, no study has compared the specificity of recognition of individual peanut allergens by the antisera used in these kits.

Several peanut proteins have been identified as being major allergens including the seed storage proteins, Ara h 1, Ara h 2, Ara h 3, and Ara h 6. Both Ara h 1 and Ara h 3 belong to the cupin superfamily of proteins. Ara h 1 is a 7S vicilin-type protein, while Ara h 3 is an 11S legumin-type protein. Ara h 2 and Ara h 6 are both 2S albumins that show close homology to each other.[16,17] Although Ara h 1 and Ara h 3 are the more abundant peanut proteins, several studies have proven that Ara h 2 and Ara h 6 bind more strongly with IgE from peanut allergic patients and release mediators more efficiently from basophils, which confirm that these are also more potent allergens in in vitro systems[18−21] and in vivo.[20,22,23] Moreover, it has been observed that both Ara h 2 and Ara h 6 are recognized more strongly and more frequently than Ara h 1 and Ara h 3 by peanut allergic children with almost all of them showing IgE reactivity to these two allergens.[24] Other peanut allergens have been identified,[25,26] but their clinical significance remains to be firmly established.

Therefore, in the current study, we used the reference peanut butter SRM 2387 from NIST to compare the performance of six commercial peanut ELISA kits, and we applied purified peanut allergens Ara h 1, Ara h 2, Ara h 3, and Ara h 6 to assess the specificity of these ELISA kits.

MATERIALS AND METHODS

Reference Material and Peanut Allergens. SRM 2387 peanut butter was purchased from NIST. The purified peanut allergens Ara h 1, Ara h 2, Ara h 3, and Ara h 6 were obtained from lyophilized stock preparations made as described earlier.[19,20,22]

Peanut ELISA Test Kits. Six commercial ELISA test kits were used in this study: Veratox for peanut allergen from Neogen, Lansing, MI, USA; BioKits peanut assay kit from Neogen, Lansing, MI, USA; AgraQuant peanut assay from Romer Laboratories UK Ltd.; RIDASCREEN fast peanut from R-Biopharm, Germany; Peanut protein ELISA kit from Morinaga Institute of Biological Science, Inc. Japan; and Peanut residue from ELISA Systems Pty Ltd. Australia.

Preparation of Reference Material and Peanut Allergens. *Reference Material.* An initial stock sample containing 50 000 ppm (mg/kg) peanut butter was prepared both as a suspension and an extract. Grinding or homogenization of the sample as instructed in the kit inserts was not required since SRM 2387 is of a creamy consistency. The suspension was prepared by mixing 1 g of SRM 2387 peanut butter with 20 mL of sample extraction buffer of each respective ELISA kit and vortexing to obtain a uniform suspension of 50 000 ppm peanut butter in extraction buffer. For the extract, 1 g of peanut butter was mixed with 20 mL of preheated (at RT with the Morinaga kit) extraction buffer and extracted at RT (Morinaga, BioKits) or at 60 °C (Veratox, Romer, R-Biopharm and ELISA Systems) for 10 min (R-Biopharm) or 15 min (Veratox, BioKits, Romer, Morinaga and ELISA Systems). Following extraction, samples were centrifuged at 3000 *g* for 15 min at 25 °C, and the resulting supernatant containing 50 000 ppm peanut butter was obtained. Any extraction additives supplied by the kit manufacturers (i.e., Veratox) were added to the initial extract but not to the initial suspension. A series of dilutions ranging from 10−500 ppm were prepared with both the initial suspension and extract for all six kits. Each of the initial stocks and the series of dilutions were prepared in duplicate. Protein extraction from each of these dilutions was carried out as per manufacturers' instructions for each kit. Following protein extraction, an aliquot of the extract was transferred to a 1.5 mL Eppendorf tube and centrifuged at 14 000 rpm for 5 min with the resulting supernatant used for subsequent testing by ELISA.

Peanut Allergens. With each purified allergen, 1.5 mg was dissolved in either 1 mL of phosphate buffered saline (PBS), pH 7.4 containing 20 mM phosphate, 150 mM NaCl (Ara h 1 and Ara h 2), or distilled water (Ara h 3 and Ara h 6). Absorbance was measured at 280 nm (Thermo Scientific NanoDrop 2000c Wilmington, Delaware, USA), and the protein concentration (mg/mL) was determined by dividing the absorbance value by the absorbance coefficient for each allergen as can be found in the Uniprot database using ProtParam (0.657, 0.59, 0.77, and 0.21 for Ara h 1, Ara h 2, Ara h 3, and Ara h 6, respectively). Subsequently, the final protein concentration of each allergen was adjusted to 1 mg/mL by adding an appropriate volume of the primary dissolving fluid. Sample aliquots were put into screw-top Corning cryogenic tubes, frozen by snap-freezing in liquid nitrogen, and stored at −80 °C until further use. Prior to testing by ELISA, further dilutions of the 1 mg/mL allergens were prepared in each kits' extraction buffer. On the basis of the sensitivity of the test kit and reactivity of the allergen, dilutions ranging from 0.001−100 μg/mL were prepared for each allergen. The extraction and dilution procedure outlined in each kit was followed for extraction of proteins from each of the prepared dilutions. An aliquot of the extracted sample was centrifuged at 14 000 rpm for 5 min, and the resulting supernatant was used for subsequent testing by ELISA.

ELISA Test Procedure. ELISA was performed in duplicate for each sample according to the instructions supplied by each kit manufacturer. Where appropriate, extracted sample dilutions of the SRM 2387 peanut butter were further diluted in extraction buffer prior to testing by ELISA in order for the sample to be within the range of the kits' quantification. The purified allergens were tested directly by ELISA without any further dilutions other than dilutions specified by the kit manufacturers (BioKits and Morinaga test kits). The absorbance of the samples as well as the kit standards was measured at the wavelength specified by each kit using a microtiter plate reader (BioTek Instruments Inc. USA). To allow for uniform comparison between test kits, the concentration of kit standards of each kit were converted to μg/mL peanut protein. For the SRM 2387 peanut butter, the peanut concentration in each sample dilution was interpolated from the standard curve using the software supplied by the kit manufacturers (Veratox, Romer Laboratories and R-Biopharm) or the GraphPad Prism 4 software (BioKits, Morinaga and ELISA Systems). By taking into account any dilutions and conversion factors, the total peanut protein recovered (in ppm) was calculated as a percentage relative to expected recovery for each dilution and test kit.

SDS-PAGE Analysis. The SRM 2387 peanut butter and the purified allergens Ara h 1, Ara h 2, Ara h 3, and Ara h 6 were analyzed under reducing conditions (β-mercapotoethanol) using Mini-Protean TGX Precast 4−20% gradient gels (Biorad, Veenendaal, The Netherlands). For the purified allergens, 5 ug per lane was loaded. For the SRM 2387 peanut butter, an amount of protein was loaded (20 μg) such that the multiple bands of the allergens could be visualized. Gels were run for 90 min at 120 V and stained with Coomassie Brilliant Blue R-250 (Sigma-Aldrich, Germany). Molecular weight (MW) markers were Precision Plus Protein (all blue standard, 10−250 kDa, Bio-Rad).

Statistical Analysis. SRM 2387 peanut butter samples and dilutions were prepared in duplicate and each dilution analyzed in duplicate ELISA wells. Tests on peanut allergens were repeated twice, and for each trial, all concentrations were tested in duplicate by ELISA.

Peanut Residue (ELISA Systems)	1/10	none	1/4	40	4−60	0.1−1.5

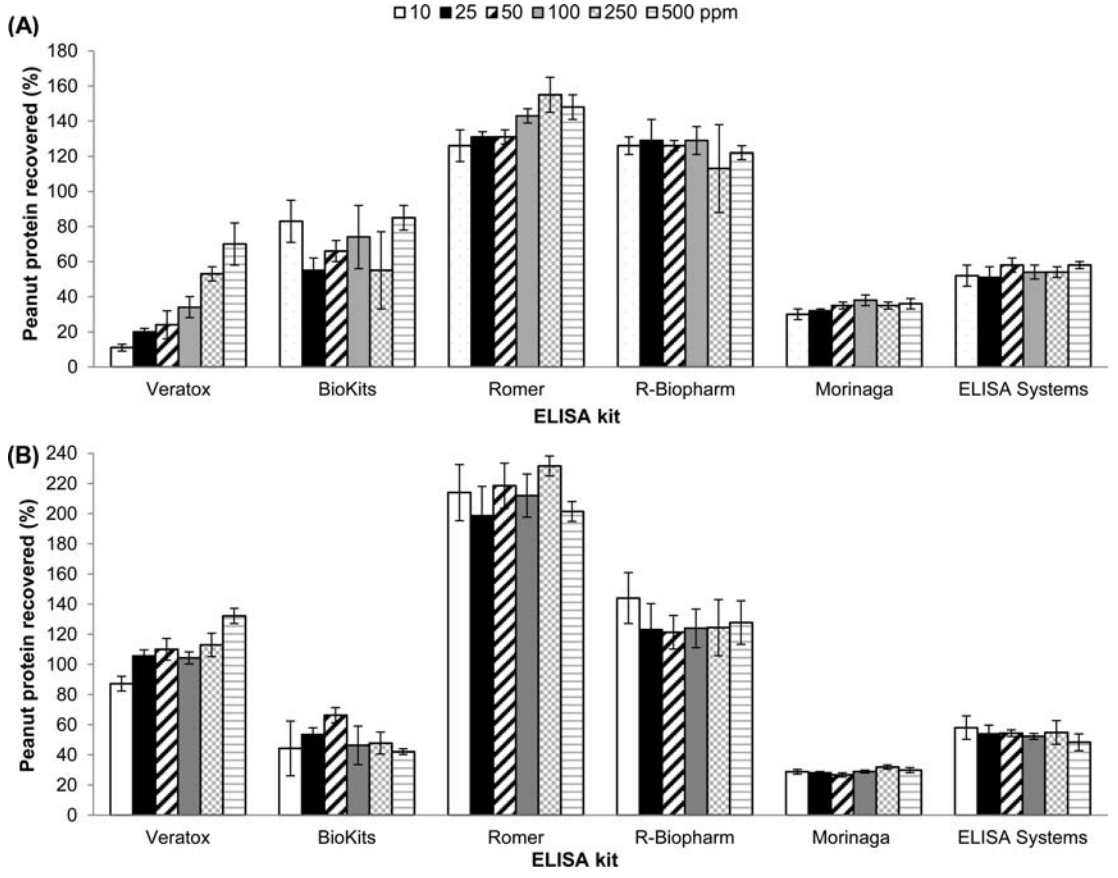

Figure 1. Comparison of percentage peanut protein recovered from an initial suspension (A) and extract (B) of SRM 2387 peanut butter by six different commercial peanut ELISA kits at sample concentrations ranging from 10−500 ppm. Protein extraction for each sample concentration was performed twice, and each extract was analyzed in duplicate by ELISA. Data are expressed as mean ± standard deviation (n = 4).

All statistical analyses were performed using the SAS 9.2 software package. Fisher's protected least significant difference (LSD) test and matched pairs t test were used to determine statistical significance, and the level of significance was set at $p \leq 0.05$.

RESULTS

Comparison of the Sensitivity of the ELISA Kits. The six peanut ELISA test kits used in this study differed from one to another in detection range, detection limit, unit of quantification as well as on the sample to extraction buffer ratio and the dilutions used. In four of the kits, results are expressed as ppm of total peanut (Veratox, BioKits, Romer and R-Biopharm). In the ELISA Systems test kit, results are expressed in ppm peanut protein, while in the Morinaga assay, the results are given in ng/mL of peanut protein. To allow for a comparison of the sensitivity between different kits, we calculated the range of quantification of each of the test kit standards in μg peanut protein/mL (Table 1). Since peanut kernels contain ~25% protein,[27] we used a conversion factor of 0.25 to calculate for peanut protein from total peanut for five of the test kits. For the R-Biopharm kit, a conversion ratio of 0.1 was used since the kit manufacturer states that a peanut raw material containing 10% protein was used for the preparation of their standards. As can be seen from Table 1, the six ELISAs were different in sensitivity. In particular, the sensitivity of one of them (Peanut Residue from ELISA Systems) seemed to be

DOI: 10.1021/jf504741t
J. Agric. Food Chem. 2015, 63, 1849−1855

about 10-fold lower than that of the other kits. By applying different dilutions, as specified in the kit, this ELISA also reached a sensitivity range (relative to the unextracted food products) similar to that of the other kits, that is, 4−60 ppm.

Efficacy of Recovery of Peanut Protein from Peanut Butter. The percentage of peanut protein recovered from both the peanut butter suspension and extract at sample dilutions ranging from 10−500 ppm was widely variable with the different kits as displayed in Figure 1. Of the six ELISA kits compared, the highest percentages of recovery of peanut proteins were obtained with the Romer and R-Biopharm kits with both methods of sample preparation. With the Veratox and Romer kits, a higher percentage of peanut was recovered when the sample was prepared as an extract rather than a suspension ($p < 0.05$). However, recovery was comparable with both methods of sample preparation with the BioKits, R-Biopharm, and ELISA Systems kits ($p > 0.05$). Recovery of peanut differed widely within the same test kit at different sample dilutions especially with the Veratox kit (11−70%) and to a lesser extent with the BioKits kit (55−85%) when the initial sample was prepared as a suspension. This effect of sample concentration on peanut recovery was not evident with the remaining test kits with either method of sample preparation.

Recognition of Individual Peanut Allergens by ELISA. The polypeptide profiles obtained with the individual peanut proteins (Ara h 1, Ara h 2, Ara h 3, and Ara h 6) and SRM 2387 peanut butter are shown in Figure 2. The gel profile and

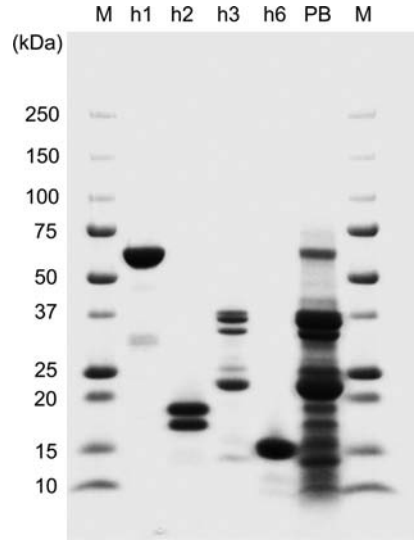

Figure 2. SDS-PAGE analysis of purified peanut allergens and SRM 2387 peanut butter under reducing conditions. M, molecular weight marker (indicated in kDa in left margin); h 1, Ara h 1; h2, Ara h 2; h3, Ara h 3; h6, Ara h 6; PB, SRM 2387 peanut butter from NIST. The protein load in each lane was 5 μg for the purified proteins and 20 μg for SRM 2387 peanut butter.

molecular sizes of the allergens Ara h 1 (63 kDa), Ara h 2 (17−20 kDa doublet), Ara h 3 (a series of polypeptides ranging from 14−45 kDa), and Ara h 6 (15 kDa) are in line with previously published findings.[20,22] Furthermore, the gel profile confirms the purity of allergens and that none of the allergens contain other allergen types except perhaps as minor contaminants. The protein profile of SRM 2387 peanut butter indicates that Ara h 3 is the most abundant protein and that the other three allergens are also present but in lower amounts.

When the specificity and sensitivity of recognition of purified peanut allergens, Ara h 1, Ara h 2, Ara h 3, and Ara h 6, at concentrations ranging from 0.001−100 μg/mL by the six commercial peanut ELISA test kits were compared, five of the kits were most sensitive in the recognition of Ara h 3, while their reactivity for the other allergens was substantially lower (Figure 3). Initially, each allergen was screened against each of the test kits in order to identify the range of sensitivity for each allergen−test kit combination. On the basis of this preliminary data, the range of dilutions tested was adjusted accordingly to span the range from nonreactivity to maximum reactivity. In four of these five kits (the exception being ELISA Systems), Ara h 3 was more reactive than the respective kit standards provided by each kit. The Morinaga kit was significantly different from the other five kits in that Ara h 3 was the least recognized allergen by this kit. Moreover, while the other five kits were least sensitive in the recognition of Ara h 2 and Ara h 6, the Morinaga kit showed the highest sensitivity of recognition for these two allergens. Thus, the Morinaga kit stands out from the other five kits in being the most sensitive in detecting Ara h 2 and Ara h 6, the two allergens that were least recognized by the other kits.

Except for Morinaga, in the other five kits, Ara h 1 was the second most reactive allergen, and in all five, reactivity of this allergen was less than the kit standard. However, the reactivity of Ara h 1 did show differences between these kits (Figure 3), most notably that the reactivity between Ara h 3 and Ara h 1 was approximately two-fold for the ELISA Systems kit, while it was about 300-fold in the Romer kit.

When Ara h 2 was considered, the signal was found to increase at very low allergen concentrations (0.003−0.03 μg/mL) but then level off at a low plateau with the R-Biopharm and ELISA Systems kits. This observation of being recognized at low concentrations and at the same time showing very low reactivity could most probably be due to having a low concentration of highly reactive antibodies against Ara h 2. However, with the Veratox and especially the Morinaga kits, the signal of Ara h 2 continued to increase with increasing concentrations of the allergen. In contrast, for both the BioKits and Romer kits, the signal remained at a low plateau for the entire range of concentrations where Ara h 2 seemed to show a low binding affinity for the antibodies.

Most of the kits reacted at higher concentrations of Ara h 6 ($\geq$ 0.03 μg/mL), although Veratox did show some reactivity at 0.01 μg/mL. The exception was the Morinaga kit where the kit reacted to the allergen at a concentration as low as 0.001 μg/mL. At the same time, other than for the Romer and Veratox kits where reactivity plateaus off, in all of the other kits, reactivity of Ara h 6 showed an increase with increasing allergen concentrations. However, compared to the reactivity of Ara h 3, reactivity of Ara h 6 was about 1000−10 000-fold lower in the R-Biopharm, BioKits, and Romer kits. Moreover, in comparison to the other kits, the kit from Romer Laboratories was found to be the least sensitive in the detection of Ara h 1, Ara h 2, and Ara h 6.

Some variations in kit specificity occurred among the kits. The Veratox, Romer, and Morinaga kit manufacturers do not indicate that their peanut ELISAs are targeted against specific peanut proteins/allergens. For the BioKits ELISA, it is stated that this kit specifically detects the peanut allergen, Ara h 1. Both the R-Biopharm and the ELISA Systems kits specify that

J. Agric. Food Chem. 2015, 63, 1849−1855

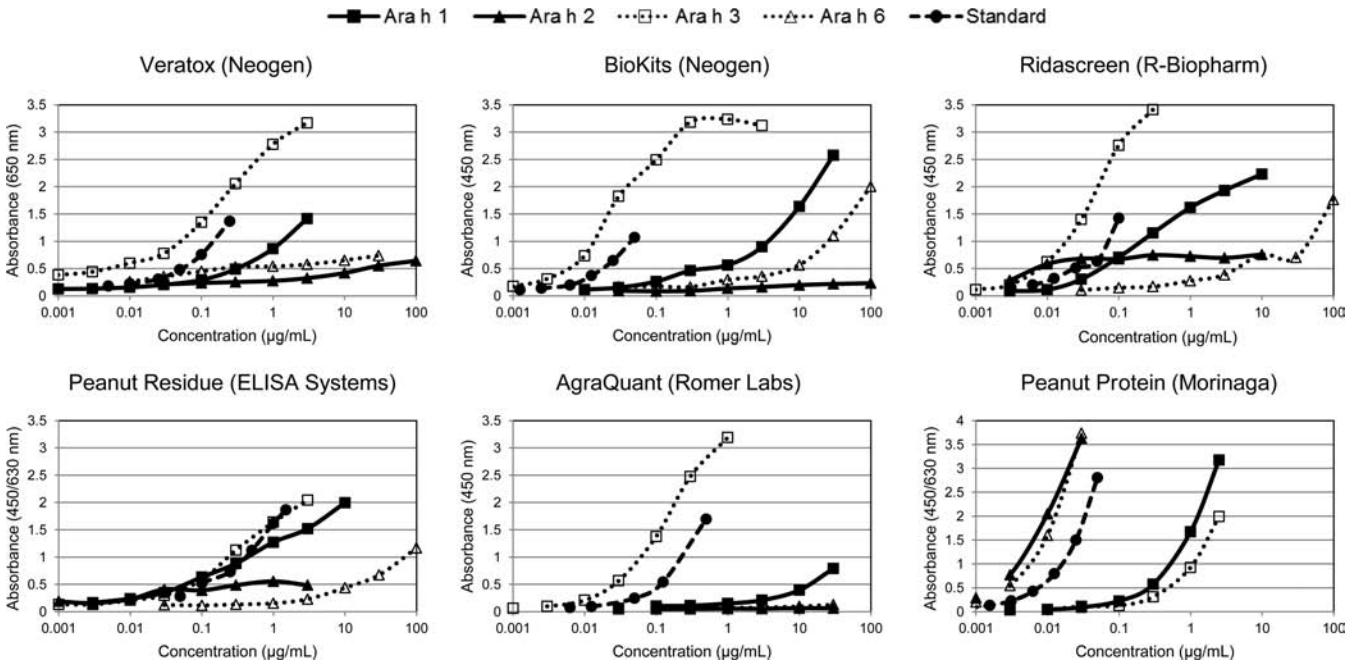

Figure 3. Recognition of the peanut allergens Ara h 1, Ara h 2, Ara h 3, and Ara h 6 by six ELISA kits at sample (peanut allergen) concentrations ranging from 0.001−100 μg/mL. The *x*-axis in logarithmic scale indicates sample concentration in the ELISA well. Standard refers to the calibration standards included in each respective ELISA kit.

their antibodies target peanut proteins including the allergens Ara h 1 and Ara h 2. As this study indicates, although these three kits do show reactivity against the specified allergens, they are most sensitive in the detection of Ara h 3. Importantly, the quantification of individual allergens within the same kit as well as between kits is not easy due to several reasons. First, other than the BioKits and R-Biopharm kits, in which the standards are calibrated with SRM 2387 peanut butter, none of the other kits specify the source or type of peanut used in the preparation of the kit standards, and as such this may vary between kits. Second, the reactivity curves of the individual allergens are not completely parallel with the standard curve or with each other.

DISCUSSION

Several ELISA kits for the detection and quantification of peanut residues in food products are commercially available. In this study, we compared the recovery of standard peanut butter (NIST SRM 2387) with six commercial sandwich ELISA kits and tested their ability to recognize individual peanut allergens.

All six test kits gave reasonably good recoveries with SRM 2387 peanut butter even though percentage recoveries varied widely between test kits. Given the differences in extraction buffers and the likely differences in the sources of peanut used to raise antibodies, which would translate into differences in the amount of protein extracted and differences in the antigens recognized by the antibodies, respectively, this is not unduly surprising. Overall, a low recovery of peanut was observed with the Morinaga kit with both methods of sample preparation (Figure 1). The kit manufacturers of Morinaga indicate that their kit gives 100% reactivity with dry peanuts and 60.3% reactivity with roasted peanuts. Since roasted peanuts are used in the manufacture of SRM 2387 peanut butter, this could at least partially explain the low recovery observed with the Morinaga kit. Poms et al.[11] suggest that antibodies raised against raw peanuts would have a lower affinity to heat-treated antigens, although none of the manufacturers of the six kits provide information about the sources of peanut used to raise antibodies.

Two kits, namely BioKits and R-Biopharm, indicate that their standards have been calibrated with SRM 2387 peanut butter. The high recovery observed with the R-Biopharm kit could be largely because it has already been standardized using SRM 2387 peanut butter. Nevertheless, as demonstrated by this study, the method of preparation of the peanut extracts influences the protein content in the extract. Thus, use of the same source to prepare the standard material does not necessarily guarantee uniform recoveries (compare BioKits vs R-Biopharm in Figure 1).

The underestimation of protein content in heat-treated peanut samples by ELISA is well documented.[13−15,28] Since the SRM 2387 peanut butter is heat-treated, the underestimation of peanut content from this peanut butter with some of the kits is supported by those previous observations. Accordingly, the kit manufacturers have optimized extraction procedures used with their kits, provided instructions intended to optimize extraction, and in some cases included an extraction additive to increase the recovery. Indeed, these steps are helpful for some of the kits (Figure 1).

The Morinaga kit differs significantly from the rest in containing the reducing agent, β-mercaptoethanol (2%), in its extraction buffer. This same manufacturer has developed a similar ELISA to detect egg albumin where they use an extraction buffer containing both a surfactant (SDS) and a reducing agent (β-mercaptoethanol), and the antibodies are also raised against denatured proteins.[29] Such an ELISA has the advantage of detecting denatured proteins in heat-processed samples as the reducing agent helps to redissolve aggregated proteins as was shown for an ELISA for soy earlier.[30]

In contrast to the Morinaga kit, the other five kits were highly sensitive in the recognition of Ara h 3 but recognized Ara h 2 and Ara h 6 only at high protein concentrations or at sensitivities about 1000-fold lower than that for Ara h 3. Both

J. Agric. Food Chem. 2015, 63, 1849−1855

Ara h 2 and Ara h 6 are 2S albumins containing up to five disulfide bonds, which makes them resistant to heat and digestive enzymes.[31] Moreover, Ara h 2 and Ara h 6 have been identified as being major peanut allergens that also share homologous regions.[18−20,24,32] However, a study on immune responses to peanut allergens has shown that upon oral exposure, Ara h 1 and Ara h 3 induce a comparatively higher IgG response, while Ara h 2 and Ara h 6 induce much lower responses.[33] Thus, this study confirms that Ara h 1 and Ara h 3 would be better immunogens for raising an IgG antibody response than Ara h 2 and Ara h 6. Accordingly, this would support our observation that five of the kits showed the highest recognition for Ara h 3 followed by Ara h 1, while recognition of Ara h 2 and Ara h 6 was much lower. Additionally, of the total protein content of peanut kernels, Ara h 3 is the most abundant and Ara h 1content is about 12−16%, while both Ara h 2 and Ara h 6 are present in approximately the same concentration, 6−9%.[20,34,35] Although none of the kit manufacturers provide information regarding the peanut extract/type used in the production of antibodies, the relative content of each allergen in peanut kernels could also contribute to the significantly lower sensitivity of recognition of Ara h 2 and Ara h 6 by five of the test kits.

Another reason that antibodies against both Ara h 2 and Ara h 6 seem under-represented in five out of the six kits may lie in the stable core structure of both Ara h 2 and Ara h 6. Processing of these two allergens by antigen presenting cells (APCs) in the laboratory animals used to raise antibodies would be less efficient. Thus, immunization to produce antibodies would lead to a response against other proteins, particularly Ara h 3. Reduction of the disulfide bonds of these two allergens will denature Ara h 2[36] as well as Ara h 6,[37] which would perhaps make these allergens more susceptible for processing by APC and consequently into better immunogens. Thus, the approach used with the Morinaga kit, that is, under conditions that reduce the disulfide bonds, would indeed increase detection of Ara h 2 and Ara h 6 especially since the antibodies are also produced against reduced peanut proteins.

The Veratox ELISA has been shown to have a low sensitivity in the detection of both Ara h 1 and Ara h 2.[38] Compared to a sensitivity of 30 ng/mL for a monoclonal antibody-based ELISA that specifically targets Ara h 1, Veratox showed a sensitivity of only 2−4 μg/mL for Ara h 1. This observation is in agreement with that of the present study where the Veratox ELISA is primarily specific for the detection of Ara h 3.

Additionally, the peptide profile of SRM 2387 peanut butter in Figure 2 shows that although all four allergens are represented, Ara h 3 appears the most intense, while Ara h 1 is much lower in intensity. Several previous studies have shown that heating/roasting of peanuts results in a decrease in Ara h 1 levels[28,39,40] presumably owing to a loss of solubility. The loss of Ara h 1 due to heating/roasting would be a disadvantage with a kit that was oriented to the specific detection of Ara h 1. However, the five test kits that predominantly recognized Ara h 3 showed a high recovery of peanut from SRM 2387 peanut butter. In contrast, the Morinaga kit, with a low reactivity to Ara h 3, showed low recovery of peanut protein from peanut butter in the present study.

Therefore, five of the commercial kits show the highest reactivity to the most abundant peanut protein, Ara h 3, a protein that also happens to be an excellent immunogen. In contrast, the Morinaga kit shows the highest reactivity to the more potent and therefore more relevant peanut allergens, Ara h 2 and Ara h 6. Given that Ara h 2 and Ara h 6 are less susceptible to denaturation and aggregation than other peanut proteins, these allergens may be better targets than Ara h 1 or Ara h 3 for quantification of peanut in processed food.

In conclusion, the present study proved that SRM 2387 peanut butter is recognized by all six commercial ELISA kits, but recovery was not uniform across different kits or at different sample concentrations. With regard to purified allergens, regardless of what is specified by some of the commercial kit manufacturers, five of the kits were most sensitive in the detection of Ara h 3, the most abundant protein in peanut kernels. The Morinaga kit was unique in that it showed the highest sensitivity in the detection of Ara h 2 and Ara h 6, the most relevant allergens in terms of allergenicity. Thus, while the detection of peanut residues in processed food products can likely be accomplished with any of these kits, comparable results should not be expected when analyzing the same sample across more than one kit. Surprisingly, this marked difference in specificity does not preclude kits recognizing heat labile proteins from quantifying peanut in peanut butter.

Sangon Biological Engineering Technology and Services Co. (Shanghai, China), and the Beijing Solarbio Science & Technology Co. (Beijing, China).

Fish Maintenance and Toxicity Testing. In this study, adult male (mean weight: 0.33 ± 0. 01 g, mean length: 2.48 ± 0.02 cm) and female (mean weight: 0.27 ± 0. 01 g, mean length: 2.47 ± 0.03 cm) zebrafish (*Danio rerio*) were purchased from the Qixin tropical fish aquarium (Taian, Shandong, China). Fish were separated by sex and acclimatized for 2 weeks prior to the experiments. The fish were then divided into separate groups of 100 males and females and were housed in 12 L fish tanks. Fish were maintained according to Du et al.[18] with the following parameters: a 12:12 h light/dark cycle, a temperature of 26 ± 1 °C, oxygen saturation greater than 70%, and pH 7.4 to 8.1. The fish were fed twice a day with commercial dry flakes. Feeding ceased 24 h before the fish were tested to avoid interference from fecal matter during the assays. The stability of imidacloprid in water has been reported,[19−21] and a semistatic exposure system was used. Half of the fish water was changed every 2 days to maintain the concentration of imidacloprid, and uneaten food and feces were cleared away from the fish water in a timely manner using a siphon. In this study, all males and females were exposed to the same treatment concentrations of imidacloprid (0, 0.3, 1.25, and 5 mg/L). The fish were sampled in triplicate at days 7, 14, 21, and 28 and used to determine the levels of SOD, CAT, ROS, MDA, and DNA damage.

Enzyme Extraction and Measurement of Protein Content. Enzymes were extracted from the zebrafish livers using the method described by Shao et al. with slight modifications,[22] and the enzyme protein concentrations were determined using the method described by Bradford.[23]

Measurement of Enzyme Activities (SOD, CAT, and GST), ROS Production, and MDA Content. SOD, CAT, and GST activities were measured according to the methods described by Song et al.,[24] Xu et al.,[25] and Habig et al.,[26] respectively. The ROS production and MDA content were determined according to the methods described by Zhang et al.[27] Six fish (including three females and three males) from each treatment were sampled to detect protein concentration, enzymatic activity and MDA content. Ten fish (female/male = 1:1) were selected to test ROS levels. Three repeat experiments were completed.

Measurement of DNA Damage. DNA damage was evaluated by single-cell gel electrophoresis (SCGE). The cell suspensions of livers were obtained from four fish (including two females and two males) according to the noninvasive approach described by Diekmann et al.[28] The livers dissected from the anesthetized zebrafish were rinsed and processed in a tube containing 0.1 M PBS (0.14 M NaCl, 2.68 mM KCl, 0.01 M Na_2HPO_4, and 1.76 mM KH_2PO_4, pH 7.4) (1 mL). Liver suspensions were then filtered through 74 μm sieve, and the interstitial fluid obtained was centrifuged at 180*g* for 10 min at 4 °C. Afterward, the supernatant was decanted, and the precipitation was resuspended using 0.1 M PBS prior to the comet assay. The SCGE assay was performed according to Shao et al.[22] Finally, Olive Tail Moment (OTM) was used to determine the extent of DNA damage caused by imidacloprid to zebrafish. OTM is the distance between the center of the head and the center of the tail, and the percent of tail DNA was used to evaluate the extent of DNA damage.[29]

Statistics. Each treatment was conducted in triplicate, and the means and standard errors were considered in the calculation. SPSS 18.0 was used to analyze biochemical responses by a bifactorial analysis of variance (ANOVA) according to the concentration, the time of exposure, and their interaction. A posthoc test using a least significant difference (LSD) calculation at $p < 0.05$ preceded bifactorial ANOVA results. One-way ANOVA analyses ($p < 0.05$) were conducted to evaluate the significant effects of all data among the treatments at the same sample times. Final results were expressed as the mean ± SD (standard deviation).

RESULTS

Effects of Imidacloprid on ROS Levels in Zebrafish (*Danio rerio*). The ROS levels in zebrafish exposed to imidacloprid is depicted in Figure 1.

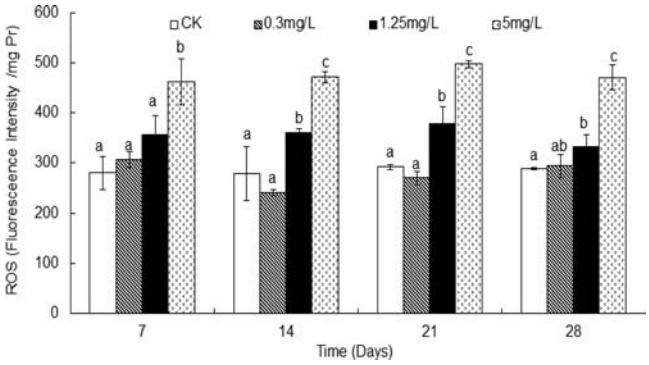

Figure 1. Effect of imidacloprid on ROS levels in the zebrafish liver (Pr = protein). Data represent means ± standard deviation ($n = 3$). Different labels above bars indicate significant differences at $p < 0.05$ between treatments.

Compared with the controls, no significant difference in ROS levels was detected in zebrafish exposed to 0.3 mg/L imidacloprid throughout the exposure period (7, 14, 21, and 28 days). However, the ROS levels of the high-concentration imidacloprid (1.25 and 5 mg/L) in fish were higher than those of the controls at days 14, 21, and 28. A higher ROS value compared with controls was also detected in fish treated with 5 mg/L imidacloprid during the entire exposure period.

SOD Activities. Changes in zebrafish SOD activities during imidacloprid exposure are described in Figure 2.

As shown in Figure 2, only the first week of exposure showed dose-dependent changes in SOD activity. Noticeably, there was

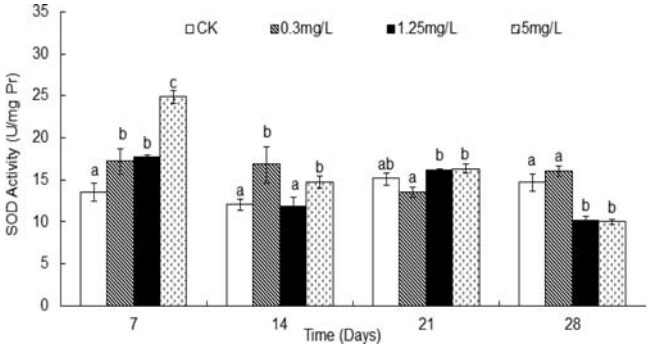

Figure 2. Effect of imidacloprid on SOD activity in the zebrafish liver (Pr = protein). Data represent means ± standard deviation ($n = 3$). Different labels above bars indicate significant differences at $p < 0.05$ between treatments.

DOI: 10.1021/jf504895h
J. Agric. Food Chem. 2015, 63, 1856−1862

a significant increase in SOD activity on day 14 in all treatment groups except the 1.25 mg/L group. At 21 days, no statistically significant differences in SOD activities between any exposure concentration and the control were observed. On the 28th day, SOD activities in the low concentration (0.3 mg/L) treatment group were the same as those in the control group. In addition, there was a significant decrease in SOD activity in the 1.25 and 5 mg/L treatment groups at day 28, which suggests inhibition of the SOD enzyme.

CAT Activities. The effects of imidacloprid on CAT activity in zebrafish are illustrated in Figure 3.

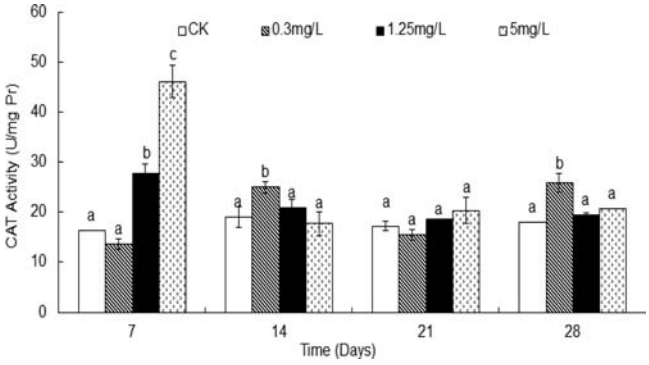

Figure 3. Effect of imidacloprid on CAT activity in the zebrafish liver (Pr = protein). Data represent means ± standard deviation (n = 3). Different labels above bars indicate significant differences at $p < 0.05$ between treatments.

Significant differences in CAT activity between the imidacloprid-exposed fish and the controls were observed only in the first week of exposure. After this time point, no differences were observed among the treatment groups except the 0.3 mg/L treatment group on days 14 and 28. Obvious increases in CAT activities in the 0.3 mg/L treatment group compared with controls were detected at days 14 and 28. No significant difference among the treatment groups was observed at day 21. In this case, no inhibition of CAT was observed at any time point.

GST Activities. The results of GST activities are depicted in Figure 4.

As indicated in Figure 4, on day 7, GST activities in zebrafish were not significantly different between any treatment group and the control group. A significant increase in GST activity relative to the control group could be observed on day 21. However, there were no difference among treatments (except in the 1.25 mg/L treatment group) compared with the control on day 14. GST activity was slightly higher in zebrafish exposed to imidacloprid (1.25 mg/L) than in controls. A dose-dependent decrease in GST activity was observed in all treatment groups at day 28.

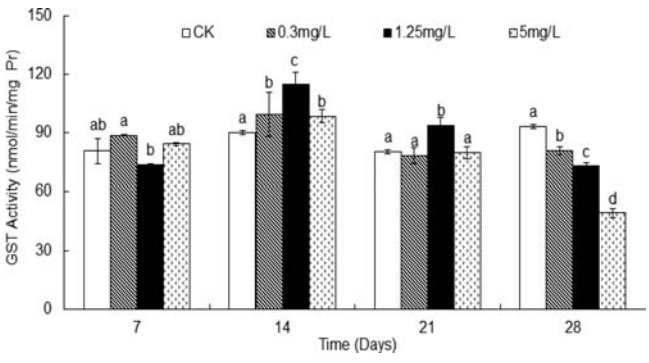

Figure 4. Effect of imidacloprid on GST activity in the zebrafish liver (Pr = protein). Data represent means ± standard deviation (n = 3). Different labels above bars indicate significant differences at $p < 0.05$ between treatments.

MDA Content. In this assay, the zebrafish MDA content was used to evaluate the level of lipid peroxidation caused by imidacloprid, and the results are illustrated in Figure 5.

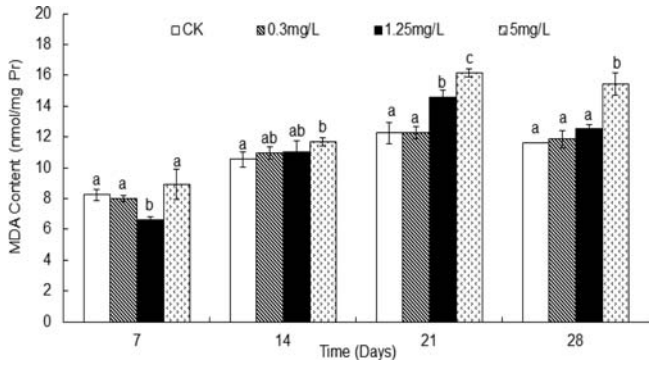

Figure 5. Effect of imidacloprid on MDA content in the zebrafish liver (Pr = protein). Data represent means ± standard deviation (n = 3). Different labels above bars indicate significant differences at $p < 0.05$ between treatments.

The MDA contents in zebrafish treated with different concentrations of imidacloprid were not significantly different at day 7, except in the 1.25 mg/L treatment group. Similarly, no obvious increase was found in the low concentration (0.3 and 1.25 mg/L) groups on days 14 and 28, when there was a significant difference in the highest treatment (5 mg/L) group compared with the control. On day 21, MDA production increased only in the highest concentration treatment (1.25 and 5 mg/L) groups compared with controls, whereas no significant difference was observed in the low concentration treatment (0.3 mg/L) group compared with control.

DNA Damage. The OTMs in zebrafish treated with different doses of imidacloprid are shown in Figure 6.

All of the OTMs obtained from the imidacloprid-exposed fish were significantly different from the control, which indicated that imidacloprid caused dose-dependent DNA

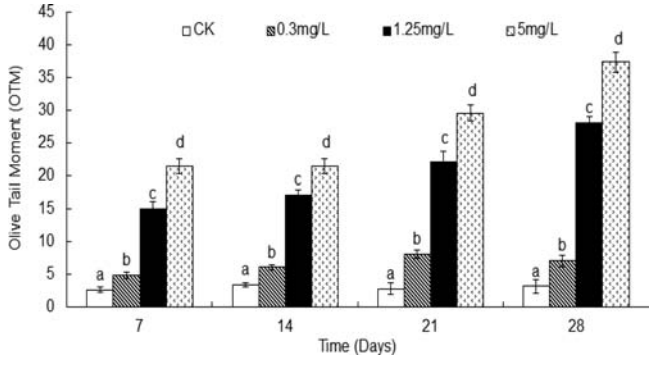

Figure 6. Effect of imidacloprid on DNA damage in the zebrafish liver. Data represent means ± standard deviation (n = 3). Different labels above bars indicate significant differences at $p < 0.05$ between treatments.

Table 1. ANOVA Results for the Biochemical Responses of Zebrafish Exposed to Imidacloprid on Days 7, 14, 21, and 28

	dose			time			dose* time		
biomarkers	df	*F*	*p*	df	*F*	*p*	df	*F*	*p*
SOD activity	3	20.78	0.000*	3	72.54	0.000*	9	33.14	0.000*
CAT activity	3	58.49	0.000*	3	54.04	0.000*	9	75.17	0.000*
GST activity	3	10.48	0.000*	3	57.49	0.000*	9	16.81	0.000*
ROS level	3	127.49	0.000*	3	1.06	0.385	9	1.31	0.280
MDA content	3	53.55	0.000*	3	290.93	0.000*	9	10.71	0.000*
DNA damage	3	25716.93	0.000*	3	2809.04	0.000*	9	799.44	0.000*

*Indicates a significant effect of imidacloprid concentration, time of exposure and their interaction on biochemical responses ($p < 0.05$).

damage in zebrafish. In the same treatment group, the OTM values in zebrafish increased distinctly with the extended exposure duration, and the level of DNA damage in zebrafish was also dependent upon the exposure time, which showed a time−effect relationship.

Bifactorial ANOVA Results of Biochemical Responses. A significant interaction between imidacloprid concentration and exposure time was found for all biomarkers assessed, except the ROS level (Table 1), which indicated that changes in these biomarkers in zebrafish livers were due to the combined effects of dose and exposure time. In addition, imidacloprid concentration had a significant effect on all biomarkers tested, and exposure time had an important influence on all biomarkers except ROS. Followed by bifactorial ANOVA (Table 2), the post hoc test results showed that changes in exposure dose or time could significantly affect the biomarker levels compared with controls.

Table 2. Results of Post-hoc Test by LSD after Bi-factorial ANOVA for Biochemical Responses of Zebrafish Exposed to Imidacloprid on Days 7, 14, 21, and 28

	dose (mg/L)				time (days)			
biomarkers	0	0.3	1.25	5	7	14	21	28
SOD activity	a	b	a	b	a	b	c	d
CAT activity	a	b	c	d	a	b	c	b
GST activity	a	a	a	b	a	b	a	c
ROS level	a	a	b	c	a	a	a	a
MDA content	a	ab	b	c	a	b	c	d
DNA damage	a	b	c	d	a	b	c	d

Different letters indicate significant differences at $p < 0.05$ between different dosages and exposure time.

The results of CAT activity and DNA damage were significantly different in each imidacloprid concentration treatment group. SOD activity, MDA content, and DNA damage were significantly different at each time point. These results were also reflected in the one-way ANOVA results that indicated the significant differences among various imidacloprid concentrations at the same exposure time.

DISCUSSION

Effects of Imidacloprid on ROS Levels. Many studies have demonstrated that intracellular oxidative stress is triggered due to excess ROS, which can be induced by toxicants, and that this excess is the main cause of cell damage.[30] In this assay, the ROS levels increased in a dose-dependent manner throughout the trial period. This may be because the antioxidant systems in zebrafish liver cannot completely remove excess ROS from the body, and thus, the dynamic equilibrium between ROS levels and the antioxidant defense system is destroyed, eventually leading to oxidative stress. Though the ROS levels of zebrafish exposed to 0.3 mg/L of imidacloprid remained stable, there was no significant difference between these fish and the controls. These results showed that a low concentration (0.3 mg/L) of imidacloprid was insufficient to cause significant changes in ROS content.

Effects of Imidacloprid on SOD Activities. SOD activity increased at different concentrations of imidacloprid during the early exposure period (7 and 14 days). On the basis of the study by Liu et al.,[31] we inferred that an increase in oxygen free radical production occurred in zebrafish under light stress. Consequently, excessive ROS may have induced the synthesis of more SOD or increased its activity to protect against oxidative stress. Increased SOD activity in organisms indicated that ROS levels were still in the range in which SOD could resist the oxidative stress. As the exposure time increased (21 and 28 days), SOD activity decreased to or below the levels detected in the control groups. This may be because the increased oxygen free radicals in zebrafish rendered SOD inactive by oxidation. Previous research demonstrated that SOD activity was activated under mild adverse stress and declined under more intense stress.[22] Our results confirm those findings. The inhibition of SOD activity can be explained by the metabolism of imidacloprid over time, which may have reduced the toxicant concentrations during prolonged exposure, and the adverse effects exerted on SOD synthesis and its activity were induced by excess ROS. These results show that the toxic effect of imidacloprid on SOD activity is much more obvious at higher concentrations.

Effects of Imidacloprid on CAT Activities. In this assay, CAT activities in zebrafish exposed to different imidacloprid concentrations increased during the first week of exposure and then decreased to control levels at later time points. A study by Olga et al.[32] showed that ROS levels were increased in crustaceans following imidacloprid treatment but then gradually decreased, which is in agreement with our results. Imidacloprid can induce CAT synthesis in zebrafish in response to scavenging H_2O_2 into H_2O and O_2 to maintain free radical balance. On day 7, the CAT activity in zebrafish exposed to a low imidacloprid concentration (0.3 mg/L) remained near the control level. At 14 days, both SOD activity and CAT activity were elevated, and CAT activity was significantly higher than SOD activity, which may be because the CAT was required to remove H_2O_2 generated by the oxidated environment and SOD catalysis. At the end of the exposure period (28 days), CAT activity was elevated, whereas SOD activity declined to control levels and was even inhibited. This illustrated that the CAT enzyme was needed to eliminate the excess H_2O_2 to maintain the balance of H_2O_2 in the cell. The CAT activities and SOD activities in zebrafish exposed to medium high (1.25 mg/L) and

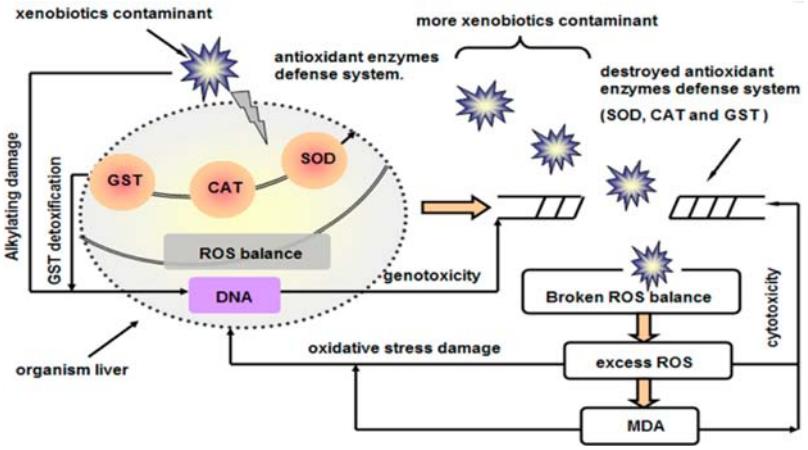

Figure 7. Relationship between each indicator. The connection among SOD, CAT, GST activities, ROS level, MDA content, and DNA damage in liver tissue.

high concentrations (5 mg/L) of imidacloprid treatments exhibited similar trends, in which both enzyme levels increased at first and then declined. CAT activity returned to control levels, whereas SOD activity was suppressed during the late exposure time point (28 days). This demonstrated that SOD was more sensitive than CAT to the same level of oxidative stress. These results show that during mild oxidative stress, SOD is activated earlier than CAT.

Effects of Imidacloprid on GST Activities. Glutathione S-transferase (GST) is a phase II biotransformation enzyme that can detoxify ROS.[33] In our study, the GST levels did not significantly change during early exposure (7 days). A possible reason for this phenomenon might be that the converted products of the phase I enzyme failed to reach adequate levels to activate GST. In addition, ROS levels might not have been sufficiently high to elevate GST activity. The GST activities in zebrafish exposed to all concentrations of imidacloprid were slightly activated by day 14 and were then suppressed by 28 days of exposure. When GST detoxifies ROS, its own activity can be impacted by exogenous substances. A study by Svensson et al.[34] showed that the sulfhydryl of microsomal GST's 49th cysteine could specifically combine with hydrogen peroxide (alkylating agent, etc.), thus enhancing GST activity. Therefore, in this assay, GST activity was possibly elevated because imidacloprid induced detoxification through the combination of intracellular GSH and harmful metabolites, such as membranous peroxide and DNA oxidative degradation products. Excess ROS induced by imidacloprid and imidacloprid itself could also have activated GST. At 28 days, the GST activity of every imidacloprid-exposed treatment group was inhibited. According to Egaas et al.,[35] this decline in enzymatic activity seems to be connected to excessive consumption of GSH as substrate and the change in GST composition triggered by many intermediate metabolites. Another correlative factor is the possible competitive inhibition between GST and its substrate (such as CDNB). Our research results have shown variations in GST activity in imidacloprid-exposed zebrafish, which is similar to previously reported studies.[22,36]

Effects of Imidacloprid on MDA Content. The free radical intermediate and the final breakdown products of lipid peroxidation, such as MDA, may severely damage cell membranes. Therefore, the measurement of MDA content can indirectly reflect the degree of lipid peroxidation. At present, many researchers have used MDA as a biomarker to detect the environmental effect of pollutants (such as polycyclic musk and textile wastewater) to earthworms or zebrafish, and some valuable results have been reported.[37,38] In our study, the MDA content in zebrafish treated with imidacloprid showed no significant differences from controls on days 7 and 14 but increased significantly afterward in the highest treatment groups. A possible reason for this observation is connected to ROS content and GST activity. For instance, the ROS content in zebrafish increased at 1.25 and 5 mg/L imidacloprid concentrations of imidacloprid. By 7 days, the GST activities of all imidacloprid-exposed zebrafish remained near the control levels and then increased after 14 days. The lack of significant variations in MDA content may have occurred because the ROS increase induced by these relatively low concentrations of imidacloprid was inadequate to initiate the lipid peroxidation that can be inhibited by GST detoxification. Certainly, the GSH-Px and other enzymes that are briefly discussed in our study may accelerate the catabolism of MDA. At prolonged exposure times, the MDA content in fish exposed to high concentrations (5 mg/L) of imidacloprid increased gradually. This can be interpreted as a reduction or inhibition of GST activity to increase the degree of lipid peroxidation, leading to the increase of MDA content ultimately. Because lower ROS levels and relatively lower levels of GST activity were induced by lower concentrations of imidacloprid, excessive accumulation of MDA was avoided. Moreover, the unchanged MDA content indicates that low doses of imidacloprid do not cause obvious lipid peroxidation damage to zebrafish, which further explains that MDA has no obvious indicative function during low concentrations of imidacloprid stress.

DNA Damage in Zebrafish. The single-cell gel electrophoresis assay (comet assay) is widely used to detect the genotoxicity of environmental pollutants to assess the DNA damage. The results showed that imidacloprid caused dose-dependent DNA damage to zebrafish livers. Additionally, a time−response relationship was observed under the same exposure conditions. Some studies have reported the dose−effect relationship between pollutants and DNA damage in organisms.[24,39,40] Pollutants that contain alkyl radicals can cause alkylation of DNA, thus inducing DNA damage. The reaction product of free radicals not only causes damage to base exchange (DNA−protein cross-linking and DNA chain rupture) but may lead to lipid peroxidation and generate lipid superoxide free radicals and alkyl radicals. This may further

DOI: 10.1021/jf504895h
J. Agric. Food Chem. 2015, 63, 1856−1862

intensify DNA damage or even change gene expression. The significant induction of GST activity could protect against DNA damage indirectly by inhibiting lipid peroxidation. In our assay, the ROS levels were increased and persisted as the imidacloprid concentration and exposure time increased; however, the MDA content at higher concentrations of imidacloprid increased during the later stages of exposure, and DNA damage also increased during the entire exposure to imidacloprid, which is in accordance with the study of Cooke et al.[41] Therefore, we infer that the accumulation of MDA is correlated with the production of ROS and the induction of DNA damage. During the exposure period, although GST activity increased slightly at day 14, the DNA damage could not be fully repaired. Additionally, the variations in ROS levels and MDA content were not in line with that of the DNA damage. It is possible that DNA damage could also be affected by other biochemical processes. The DNA damage observed in zebrafish livers may originate from the combined accumulation of reactive oxygen species and lipid peroxidation products, cell apoptosis, and the direct effects of imidacloprid. Compared with other indicators, DNA damage detected by comet assay was more sensitive and stable in our study.

Association Analysis Concerning the Results of Each Indicator. The production and elimination of ROS in the liver tissue was in a dynamic equilibrium under normal physiological conditions (Figure 7).

As shown in Figure 7, when exogenous pollutants enter the body, they induce organisms to generate ROS in abundance, and the antioxidant enzymes (SOD, CAT, and GST) are activated to scavenge the excess ROS to minimize the adverse effects caused by exogenous pollutants. With internal pollutant levels increasing over time during continuous exposure, the excess ROS generated cannot be scavenged entirely, and the ROS balance is broken thus causing cytotoxicity. This is reflected in a reduced, or even inhibited, activity of the detoxification system (e.g., SOD, CAT, and GST enzymes).[42] Additionally, the accumulation of ROS can induce lipid peroxidation and may lead to accumulation of the end-product MDA. Moreover, MDA is cytotoxic and can exert an adverse effect on the performance and synthesis of antioxidant enzymes. Furthermore, MDA and excess ROS may result in DNA strand breakage and base swaps, which can lead to DNA damage in liver tissue. Damaged DNA, as a result of alkylation or oxidative stress, can also inhibit the synthesis of detoxifying enzymes (genotoxicity). Moreover, GST can not only eliminate ROS, but it can also detoxify the liver tissue that has been directly damaged by exogenous pollutants.[43] Thus, detoxification by GST plays a significant role in protecting cells from DNA damage.

Our results indicated that very high concentrations of imidacloprid induced a marked increase in ROS levels in the zebrafish liver, and the activities of SOD, CAT, and GST were elevated to scavenge excess ROS. When excess production of ROS reached a certain level beyond the typical function of the antioxidant system, a decrease in antioxidant enzymes activity was induced. As time progressed, ROS attacked cell membranes leading to an increase in MDA, which caused DNA damage and was scavenged by the increased GST activity. After an analysis of these results, the protective capability of GST against DNA damage was not obvious. The DNA damage induced by imidacloprid increased with exposure concentrations and time, whereas GST activity in zebrafish livers decreased, even to the point of inhibition.

postharvest storage. The chemical profiles of broccoli microgreens were monitored for different growth periods and different shelf time after harvest. The goal of this study was to identify the differences in the chemical profiles for each experimental factor different group of samples and to further validate the findings quantitatively.

MATERIALS AND METHODS

Chemicals. Formic acid and high-performance liquid chromatography (HPLC)-grade methanol and acetonitrile were purchased from VWR International, Inc. (Clarksburg, MD). HPLC-grade water was prepared from distilled water using a Milli-Q system (Millipore Lab., Bedford, MA, USA). (−) Sinigrin hydrate (≥99.0%), sulfatase (from *Helix pomatia*), imidazole, and Sephadex A-25 chloride form were purchased from Sigma−Aldrich (St. Louis, MO, USA). Glucoerucin potassium salt, glucoiberin potassium salt, and glucoraphanin potassium salt were purchased from Chromadex (Irvine, CA, USA).

Plant Materials and Sample Preparation for Metabolomic Study. Broccoli microgreens were grown in a growth chamber (25 °C) as previously described.[15] Hydroponic "Sure seeds" were then spread evenly over the damp pad. The trays were kept in a growth chamber at 25 °C. During the first four days, the trays were covered, and the seeds were germinated in the dark. For the next six days, the seedlings were exposed to light with the light intensity of 42 μmol s^{-1} m^{-2} for 12 h/12 h (light/dark). The seedlings were sprayed once a day with H_2O (pH 5.6) only or 10 mM $CaCl_2$. Each treatment of microgreens has three trays as triplicate. Three trays of the microgreens were collected at the fourth day after sowing from each treatment group and labeled as "Preharvest Day 4". All of the rest of the microgreens, including hypocotyl and cotyledons, were harvested on 10 days after sowing (labeled as "Harvest Day") by cutting near the bottom of each hypocotyl with a pair of sterilized scissors. Harvested broccoli microgreens (0.01 kg each) were packaged in sealed bags (0.1 m × 0.1 m) prepared with polyethylene films of 16.6 pmol s^{-1} m^{-2} Pa^{-1} oxygen transmission rate (OTR). The film OTR was determined by the film manufacturer (Packaging Concept Inc., Salinas, CA, USA). Packaged microgreens were stored at 5 °C and collected on 4, 7, and 14 d postharvest and labeled as "Postharvest Day 4", "Postharvest Day 7", and "Postharvest Day 14", respectively.

All samples were lyophilized and then ground. Powdered samples (300 mg) were extracted with 5.00 mL of methanol−water (60:40, v/v) using sonication for 60 min at room temperature and then centrifuged at 1000*g* for 15 min (IEC Clinical Centrifuge, Damon/IEC Division, Needham, MA, USA). The supernatant was filtered through a 17 mm (0.45 μm) PVDF syringe filter (VWR Scientific, Seattle, WA, USA), and 10 μL of the extract was used for each HPLC injection.

Extration and Desulfation of GLs. The extraction of GLs was performed following the ISO9167-1 method with slight modification. A 200 mg amount of broccoli microgreen powder was weighed into screw-top graduated glass tubes and extracted with 5 mL of methanol, and then, the liquid level was marked . The tube was heated at 70 °C for 20 min using a water heating bath and then centrifuged at 5000 rpm for 10 min. After waiting for the tube to cool down, methanol was added to bring the liquid level back to the mark. A 200 μL amount of 5 mM 2-propenyl-glucosinolate (sinigrin) was added to the tube as an internal standard. A 1 mL volume of the extract was transferred to a prepared Sephadex A-25 column without disturbing the resin surface, and draining was allowed. Then, two 1 mL portions of sodium acetate buffer (pH = 4) was added, and the buffer was allowed to drain after each addition. Purified sulphatase (100 μL) was added to the column, and desulphation was done overnight (12 h) at room temperature. The resultant desulfo-GLs were eluted with two washes of 500 μL of water prior to separation by ultra-high-performance liquid chromatography with mass spectrometry (UHPLC-HRMS) analysis.

UHPLC-PDA-ESI/HRMS/MS^n Conditions for Metabolomic Study. The UHPLC-HRMS system used consisted of an LTQ Orbitrap XL mass spectrometer with an Accela 1250 binary pump, a PAL HTC Accela TMO autosampler, a PDA detector (ThermoFisher Scientific, San Jose, CA, USA), and a G1316A column compartment (Agilent, Palo Alto, CA, USA). Separation was carried out on a Hypersil Gold AQ RP-C_{18} UHPLC column (200 mm × 2.1 mm i.d., 1.9 μm, ThermoFisher Scientific) with an UltraShield precolumn filter (Analytical Scientific Instruments, Richmond, CA, USA) at a flow rate of 0.3 mL/min. The mobile phase consisted of a combination of solution A (0.1% formic acid in water, v/v) and solution B (0.1% formic acid in acetonitrile, v/v). The linear gradient was from 4% to 20% B (v/v) at 40 min, to 35% B at 60 min, to 100% B at 61 min, and held at 100% B to 65 min. The MS parameters were optimized using a standard solution of sinigrin (100 ng/mL) infused with mobile phase at a flow rate 0.3 mL/min. The optimized conditions were set as follows: sheath gas at 70 (arbitrary units), aux and sweep gas at 15 (arbitrary units), spray voltage at 4.8 kV, capillary temp at 270 °C, capillary voltage at 15 V, and tube lens at 70 V. The mass range was from 100 to 1500 amu with a resolution of 15 000, FTMS AGC target at 2×10^5, FT-MS/MS AGC target at 1×10^5, isolation width of 1.5 amu, and max ion injection time of 500 ms. The most intense ion was selected for the data-dependent scan to offer their MS^2 to MS^5product ions, respectively, with the normalization collision energy at 35%.

Qualitative and Quantitative Analysis of GLs. GLs were determined using a UHPLC-HRMS method that simultaneously separates intact GLs and other phenolics. The separated intact GLs, hydroxycinnamic acids (chlorogenic acid derivatives and sinapic acid derivatives), and flavonols were identified following their $MS^2 \sim MS^4$ fragmentations, UV−visible spectra, and the order of elution previously described for similar acquisition conditions.

The PDA signal at 229 nm was used to quantify the desulfo-GLs.The type and amount of desulfo-GLs in microgreen broccoli were calculated using known concentrations of standard sinigrin and recommended relative response factors.[25] The major GL compounds were quantified by integration of the peak areas using Xcalibur 2.1.

LC-MS Data Pretreatment and Handling. Acquired UHPLC-HRMS raw files were converted into mzXML format using Proteowizard 3.0. 3569 (http://proteowizard.sourceforge.net/), and then XCMS[26] was employed for peak detection, noise filtering, and peak alignment. A two-dimensional data matrix was generated from XCMS including variable index (paired m/z−retention time), sample names (observations), and peak intensities. Multivariate analysis was performed on the output table from XCMS using Sigma 13 (Umetrics, Umeå, Sweden), where principal component analysis (PCA) was performed to visualize group clustering, trends, or outliers among the observations, and then, supervised orthogonal projection to latent structural discriminate analysis (OPLS-DA) was performed. Pareto scaling was used for data normalization before multivariate data analysis (MVDA). PC1 and PC2 scores were used for the PCA models as these principal components seemed to reflect the main variation and separation in data. The score plot of PCA was used to observe clustering and trends among all samples. The loadings plot of the first two principle components was applied to evaluate the variables causing the separation between the groups. The structures of the marker compounds were annotated by searching free databases of Scripps Metlin (http://metlin.scripps.edu/) using exact mass and MS/MS spectra and structures. Available standards were used for the confirmation of the identity of the compounds.

RESULTS AND DISCUSSION

Profiling of the Major Compounds in Broccoli Microgreens. GLs and hydroxycinnamic acid derivatives are two major groups of compounds found in microgreen broccoli, which were reported in the matured broccoli.[27,28] In our previous study of other brassica microgreens,[9] it was found that hydroxycinnamic acid derivatives have good response under negative ionization mode. GLs are hydrophilic compounds with a sulfonate moiety in structure, which occur in nature as the anionic form. The most diagnostic ions were observed at m/z 259 and 275 in MS^2 or MS^3 spectra, produced by intraring rearrangement. This typical fragmentation can be used for fast characterization of GLs.[29−31] An UHPLC-MS profiling method

under negative ionization mode with a data-dependent scan was developed for a comprehensive study of the GLs and other phenolic components, and it leads to the identification of 15 GLs, 3 acylated flavonolglucosides, 1 flavan 3-ol, 6 hydroxycinnamic acid derivatives, and 2 sugars in broccoli microgreens.

A total of 15 GLs including 11 aliphatic GLs and 4 indolic GLs were identified (Figure S1, Supporting Information). The major ones were glucoerucin (ERN), glucoraphanin (RPN), glucoiberin (IBN), glucoiberverin (IVN), 4-hydroxyglucobrassicin (OHGBRN), gluconasturtiin (GSN), pentyl glucosinolates (PGN), hexyl glucosinolate (HXG), glucobrassicin (GBRN), and 4-methoxyglucobrassicin (MGBRN). Six hydroxyl cinnamoyl derivatives, including 1,2-disinapoylgentiobiose, 1,2-bis-*O*-sinapoyl-*β*-D-glucoside, 1,2,2′-trisinapoylgentiobioside, 2-feruloyl-1,2′-disinapoylgentiobiose 1-*O*-sinapoylglucose, and their isomers were identified by comparing the HRMS data with the previous reports for broccoli or other brassica vegetables.[32−34] Other compounds such as catechin, acylated-kaemperol glycosides,[35] and sugars were also found. Detailed accurate mass and mass fragmentation information can be found in Table S1 (Supporting Information).

Metabolomic Analysis of Different Stages of Microgreen Samples between $CaCl_2$ Treated and Control Groups. As shown in Figure S1 (Supporting Information), it would be very difficult to find the differences by visual examination of the chromatograms between the $CaCl_2$ treated microgreens and the control (H_2O) group. A metabolomic approach was employed for characterization of the chemical difference between the groups. The original UHPLC-HRMS raw data led to 5107 ion features from 30 samples. The PCA based on the relative intensities of these ion features revealed the effects of $CaCl_2$ treatment after pareto scaling (Figure 1A). The first two components accounted for 79.4% of the total variance. It showed no significant difference between the $CaCl_2$ group and the control group (H_2O) on the fourth day after sowing. They are grouped closely on the right of the PCA scoreplot. Another PCA was performed with postharvest samples only, as shown in Figure 1B. They are separated into two groups according to the postharvest times. The samples from harvest day (Day 0) and postharvest day 4 are clustered closely against the postharvest day 7 and day 14 groups on PC1, and the $CaCl_2$ treated samples are separated with H_2O treated samples on PC2. It suggested that the sampling time is another import factor for chemical composition of the samples. In order to define the effects on the $CaCl_2$ treatment and to minimize other factors, a supervised OPLS-DA statistical model was utilized to focus on the discrimination of the $CaCl_2$ treatment and H_2O spray only. The OPLS-DA approach has been widely used in metabolomic studies on botanical materials with different growth conditions, species, locations, harvest times, and so forth.[36−41] The OPLS-DA model resulted in one predictive and one orthogonal (1 + 1) component with the cross-validated predictive ability $Q^2(Y)$ 98.2% and the total explained variance ($R2(X)$) 58.0% (Figure 1C). In addition, a permutation test (n = 100) was carried out to evaluate the overfitting of the model. The discriminatory ion features were picked out by a variable importance projection (VIP) plot. The ion features with larger VIP values (more than 4) were

DOI: 10.1021/jf504710r
J. Agric. Food Chem. 2015, 63, 1863−1868

considered more relevant for sample classification in this study, as shown in Figure 1D. After filtering out the ion features for adduct ions, isotope ions, and fragment ions, 12 constituents including 9 GLs, 2 sinapinic acid derivatives, and a hexose were considered as major marker compounds responsible for the group classification, as shown in Table 1. For example, ion feature (m/z 420.0448, t_R = 5.74 min) has a calculated elemental composition of $C_{12}H_{23}NO_9S_3$ (3.4 ppm). The diagnostic ions at m/z 259 and 275 were observed in the MS^2 spectrum. It was identified as glucoerucin, a compound previously reported in broccoli.[42−44] Using the same approach, we conclude that the marker GL compounds are ERN, RPN, IBN, IVN, GBRN, neoglucobrassicin (NGBRN), OHGBRN, HXG, and PGN.

Table 1. Discriminatory Metabolites Responsible for the Group Classification between the $CaCl_2$ and H_2O Treated Groups

ion feature (m/z, t_R)	VIP value	formula	possible identification
420.0448, 5.74	20.63	$C_{11}H_{20}O_{10}NS_3$	glucoerucin
436.0398, 1.93	16.16	$C_{12}H_{22}O_{10}NS_3$	glucoraphanin
215.0317, 1.71	13.84	$C_6H_{12}O_6Cl$	hexose
959.2774, 46.75	11.49	$C_{45}H_{51}O_{23}$	1,2,2′-trisinapoylgentiobioside
422.0244, 1.83	9.75	$C_{11}H_{20}O_{10}NS_3$	glucoiberin
406.0295, 3.56	9.26	$C_{11}H_{20}NO_9S_3$	glucoiberverin
477.0632, 17.17	8.05	$C_{17}H_{21}O_{10}N_2S_2$	neoglucobrassicin
753.2228, 40.01	7.77	$C_{34}H_{41}O_{19}$	1,2-disinapoylgentiobiose
463.0473, 3.49	7.37	$C_{16}H_{19}N_2O_{10}S_2$	4-hydroxyglucobrassicin
402.0883, 14.24	5.57	$C_{13}H_{24}NO_9S_2$	hexyl glucosinolate
447.0523, 6.90	4.85	$C_{16}H_{19}N_2O_9S_2$	glucobrassicin
388.0727, 7.48	4.18	$C_{12}H_{23}NO_9S_2$	pentyl glucosinolate

Verification of the Marker GLs by Targeted GL Analysis. The metabolomic approach suggested that the major marker compounds, which changed significantly by $CaCl_2$ treatment, were GLs. However, the comparison of marker compounds is based on peak area of the marker compounds. In order to confirm the findings from the nontargeted metabolomic approach, the targeted analysis of GLs in microgreen broccoli was carried out according to the guidelines established in ISO 9167-1.[45] ISO 9167-1 specifies the method for the determination of GL content in rapeseed by quantifying the desulfo derivatives, using HPLC after sulfatase hydrolysis and anion ion-exchange concentration.

Because of the lack of reference standards, the desulfo-GLs are confirmed using HRMS. The product ion at m/z 195.03 ($C_6H_{11}O_5S^-$) that represents the thioglucose group was used for fast identification of desulfo-GLs. Figure S2 (Supporting Information) shows the typical chromatogram for GL determination using the ISO method, and a total of 10 different GLs was identified together with the internal standard

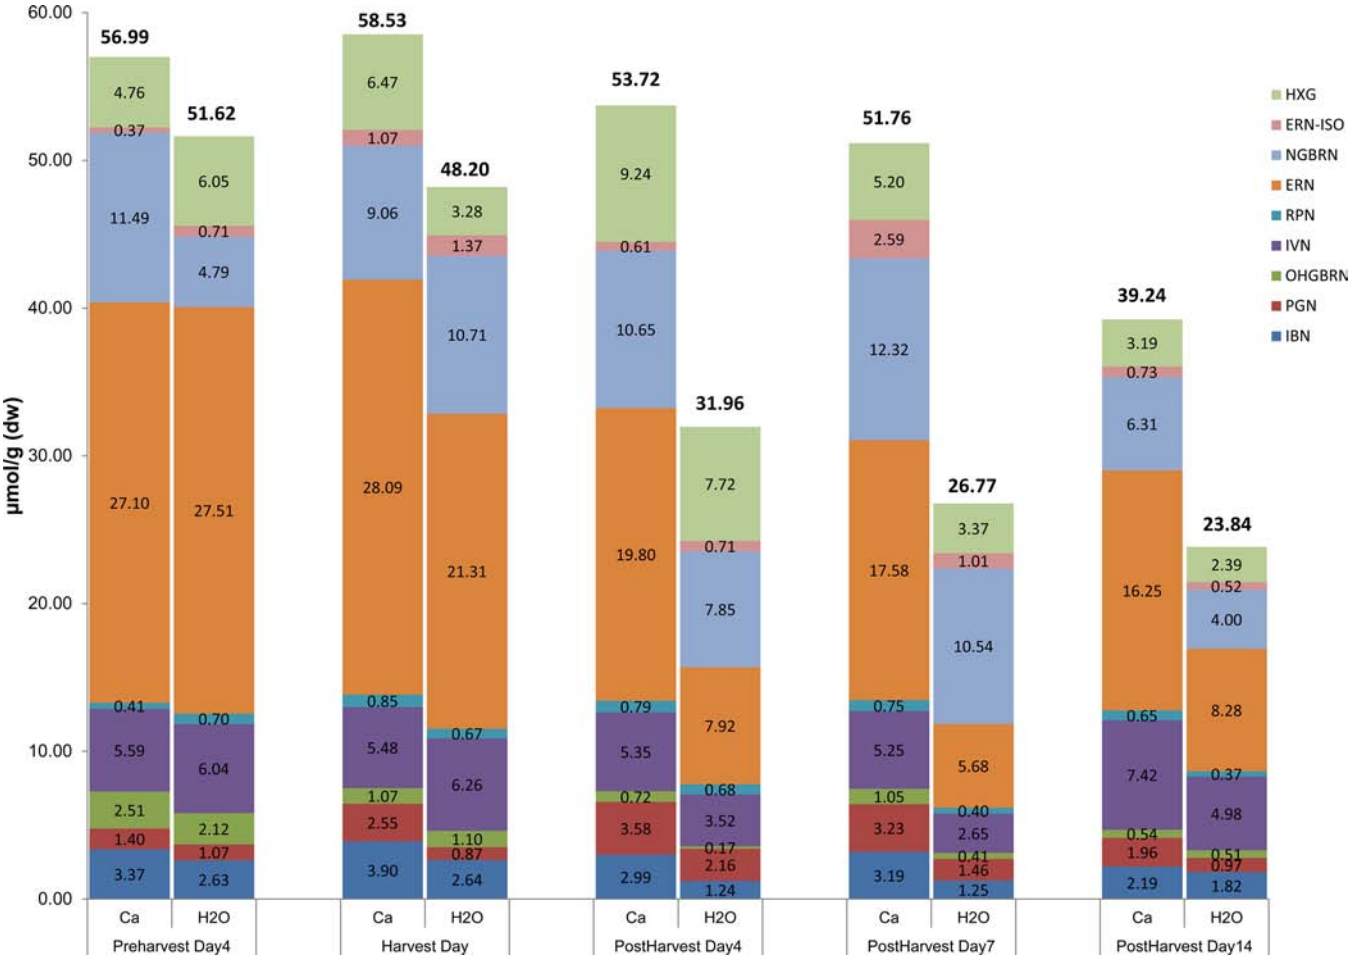

Figure 2. GL content in $CaCl_2$ (Ca) treated and control (H_2O) groups on different days.

J. Agric. Food Chem. 2015, 63, 1863−1868

sinigrin. They were desulfo-IBN, desulfo-IVN, desulfo-RPN, desulfo-ERN, desulfo-PGN, desulfo-HXG, desulfo-OHGBRN, and desulfo-NGBRN. The desulfo forms of two indolic marker GLs, GBRN and MGBRN, detected in the HPLC-HRMS profiling were not found using the ISO method. It may be due to that UV detection is much less sensitive compared to MS detection. The most abundant GLs are ERN followed by NGBRN and IVN. The GL profile in microgreen broccoli is different from that of broccoli sprouts but shows comparable total GL content.[46−48]

In comparison with the metabolomic approaches, the results show that aliphatic and indole GLs increase significantly after harvest but not for the preharvest samples in $CaCl_2$ treated samples. As shown in Figure 2, the highest GL concentration was observed at preharvest samples for both $CaCl_2$ and H_2O treated samples. The total GLs are 56.99 μmol/g dry weight (dw) and 51.62 μmol/g dw detected in the $CaCl_2$ treated and the control sample in the preharvest samples, respectively. After harvest, both the $CaCl_2$ treated and the control group showed decreasing of total GLs. For the $CaCl_2$ treated samples, the total GLs decreased to 39.24 μmol/g (by 33.0%) at day 14, while the GL samples in the control samples dropped to 23.84 μmol/g (by 50.5%). At each time point after harvest, the $CaCl_2$ treated samples showed an elevated level of total GLs together with the higher individual GLs such as ERN, IBN, RPN, IVN, OHGBRN, HXG, NGBRN, and PGN.

Accumulating evidence indicates that GL biosynthesis in plants can be upregulated by environmental stress signals and pathogen attacks.[3,4] Calcium has been shown to be an important secondary messenger in the relay of developmental, environmental, and hormonal signals that regulate plant growth and development as well as responses to biotic and abiotic stresses.[49−51] It has been reported the overexpression of a calcium/calmodulin-binding IQD1 leads to the expression of multiple genes with roles in GL metabolism.[52]Knockout of another calcium/calmodulin regulated transcription factor AtSR1/CaMTA3 resulted in the decreased GL levels and plant defense against insect herbivory.[53] Previously, we observed that calcium treatment retarded the broccoli microgreen decay during storage and extended shelf life.[15] This could be contributed, at least partially, by the increased GL levels thereby enhancing the microgreen stress tolerance and defense.

trometry (MS)-based proteomic techniques have been developed. Among them, two-dimensional electrophoresis (2-DE) and label-free liquid chromatography (LC)-MS/MS shotgun analysis are mostly applied.[12] In 2-DE, separated proteins are detected by staining and isolated from the gel, followed by matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) or surface-enhanced laser desorption/ionization mass spectrometry (SELDI-MS).[13] Shotgun proteomics performs the mass spectrometry in data-dependent acquisition mode. In this mode, peptide fragmentation is guided by the abundance of detectable precursor ions. The specific detected peptide ions are further selected for collision induced dissociation (CID) and fragment ion (MS2) spectra. The recorded information is then searched against protein sequence database to deduce the peptide sequences and corresponding proteins.[14] Compared with 2-DE, shotgun proteomics shows higher sensitivity, protein throughput, quantitative accuracy, proteome coverage, and reproducibility.[15]

Although several studies have been performed to investigate the effect of high-fat diet on hepatic proteomics, rats or mice were chosen instead of hamsters.[16−19] Hamsters are considered a better model for the study of metabolic diseases because they respond consistently to dietary modulation and show close similarity to the human lipoprotein profile compared to other rodents.[20] The aim of this study was to explore the differences in hepatic protein expression between hamsters fed control diet and high-fat diet by shotgun proteomic analysis. We hypothesized that a set of differentially expressed proteins will be identified as molecular markers for elucidating the pathological mechanism of high-fat diet.

MATERIALS AND METHODS

Antibodies. Antiaconitate hydratase, antixanthine dehydrogenase, and antiannexin 5 were purchase from Epitomics (Burlingame, CA). Antiadenosine kinase was obtained from Novus (Littleton, CO). Anti-HADHA (trifunctional enzyme subunit α, mitochondria) and antiannexin 3 were purchased from Proteintech Group (Chicago, IL). Goat antirabbit peroxidase-conjugated antibody was purchased from Jackson ImmunoResearch (West Grove, PA).

Animals and Diets. Male eight-week-old Syrian hamsters purchased from National Laboratory Animal Breeding and Research Center (Taipei, Taiwan) were maintained at 22 ± 2 °C and 12-h light/dark cycle. After 1 week of acclimation, animals were randomly assigned to the control group or the high-fat diet group (n = 7). The diets and water were provided *ad libitum*. Feed intake and body weights were measured daily and once a week, respectively. The ingredients of the control diet are (g/kg) corn starch, 452; sucrose, 200; casein, 200; soybean oil, 50; AIN-76 mineral mix, 35; AIN-76 vitamin mix, 10; methylated cellulose, 50; DL-methionine, 3. In the high-fat diet, 170 g of lard and 2 g of cholesterol per kilogram were supplemented to replace part of the corn starch. At the end of 8 weeks, all animals were sacrificed. Bloods and livers were collected for biochemical and proteomic analysis (Supporting Information Figure 1). This protocol was approved by Shih Chien University Animal Care and Use Committee.

Determination of Serum Lipids, Uric Acid, AST, and ALT. Serum TG, total cholesterol (TC), and HDL-cholesterol (HDL-C) were determined by using commercial kits (Fortree Diagnostics, Antrim, U.K.). Serum uric acid (UA), aspartate aminotransferase (AST), and alanine aminotransferase (ALT) were also quantified by the kits (Randox, Antrim, U.K.).

Determination of Liver Lipids. Liver lipids were measured according to the method of Folch et al. with modification.[21] In brief, the livers were homogenized with Folch reagent (chloroform/methanol = 2:1, v/v) at the ratio of 20:1. The homogenates were centrifuged at 936g for 10 min. Equal volumes of supernatant and triton-100 (Sigma, St. Louis, MO) were mixed and left in the fume hood to remove organic solvent before the contents of lipids were measured by commercial kits (Randox, Antrim, U.K.).

Liver Histoloty. Liver tissues were fixed in 10% buffered formalin overnight, embedded in paraffin, sectioned at 5 μm thickness, and stained with hematoxylin and eosin (H&E). The slides were examined with histopathological findings recorded by a veterinary pathologist who was blinded to the treatments.

SDS-PAGE and In-Gel Digestion. Total proteins of each sample (50 μg) were fractionated by SDS-PAGE (dodecyl sulfate polyacrylamide gel electrophoresis), and the gel was stained with Coomassie Brilliant Blue G-250 (Bio-Rad, Hercules, CA). The proteins in each lane were separated and sliced into 10 fractions based on molecular weight, followed by destaining in a solution of 25 mM NH_4HCO_3 and 50% (v/v) acetonitrile (1:1). After drying in a Speed-Vac (Thermo Election, Waltham, MA), all the gel slices were incubated with 25 mM NH_4HCO_3 and 1% β-mercaptoethanol in the dark for 20 min to reduce the disulfide bonds, followed by the incubation with solution consists of 5% 4-vinylpyridine in 25 mM NH_4HCO_3 and 50% acetonitrile (1:1) for 20 min for alkylation of the cysteine residues. Subsequently, the slices were dried in the Speed-Vac for 20 min. The in-gel digestion by the action of modified trypsin (Promega, Mannheim, Germany) in 25 mM NH_4HCO_3 (1%, w/v) was performed at 37 °C overnight. The digested peptides were removed from the gel, washed by 25 mM NH_4HCO_3 for 10 min, dried by Speed-Vac, and then kept at −20 °C until further analysis. The peptides were resuspended in 0.1% formic acid immediately prior to subsequent analysis.[22]

Mass Spectrometric Analysis. The tryptic peptides were analyzed by a nanoflow high-performance liquid chromatography system (Agilent Technologies 1200 series, Waldbronn, Germany) coupled to an LTQ-Orbitrap Discovery hybrid mass spectrometer with a nanoelectrospray ionization source (Thermo Electron, Waltham, MA). An analytical column (100 × 0.075 mm, 3.5 μm, Angilent C18) was operated at a flow rate of 0.5 μL/min in conjunction with a gradient elution solvent system using solvent A (0.1% formic acid in water) and solvent B (0.1% formic acid in acetonitrile). The course of gradient elution was programmed as a 30 min linear gradient of 5% to 35% solvent followed by 95% solvent B for a duration of 10 min. After each full scan at the m/z range 200−2000, a data-dependent acquired MS/MS scan for precursor ions was selected on the basis of conventional MS spectra performed at high resolution (M/DM, 60000 full width half-maximum). From each spectrum, the precise mass value and the charge state of the precursor ions were obtained. Following MS_1, the fragment ions were generated on the basic of collision-induced dissociation (CID) spectrum.[23]

Database Search. The spectra generated from nano-LC/MS/MS were analyzed by Xcalibur 2.0 SRI software (Thermo Electron, Waltham, MA). The TurboSequest algorithm was used to identify the peptide sequences against the hamster database in Universal Proteins Resource knowledgebase (UniProt; http://www.unipro.org/).[24] The peptides were filtered by Xcorr versus charge state with a significance level of 0.05. Xcorr was used for a match with 1.9 for singly charged ions, 2.2 for doubly charged ions, and 3.75 for triply charged ions. The proteins were identified as hepatic proteins when more than two peptides from a single protein met the Xcorr score. The mass spectra of candidate biomarkers were analyzed by our in-house post-translational modification (PTM) finder programs PTM-Miner and PTM-Q for identification of PTM peptide sequence, site of PTM, and quantification. Fix modification on the cysteine residues (carboxyamidomethylation, 57 Da), variable modification on the methionine residues (methionine, 16 Da), fragment mass tolerance at 1 Da, and peptide mass tolerance at 1.5 Da were not considered as specific PTM. The fragmented ions obtained were labeled as b, y, y-NH_3, and b-H_2O ions.[22,25]

Ingenuity Pathways Analysis. Accession numbers of proteins expressed differently in high-fat group were uploaded as an Excel file into the Ingenuity Pathway Analysis (IPA) software (http://www.igenuity.com). The proteins were grouped by known relationships into "functional analysis" and "canonical pathway analysis" of a network.

DOI: 10.1021/jf506118j
J. Agric. Food Chem. 2015, 63, 1869−1881

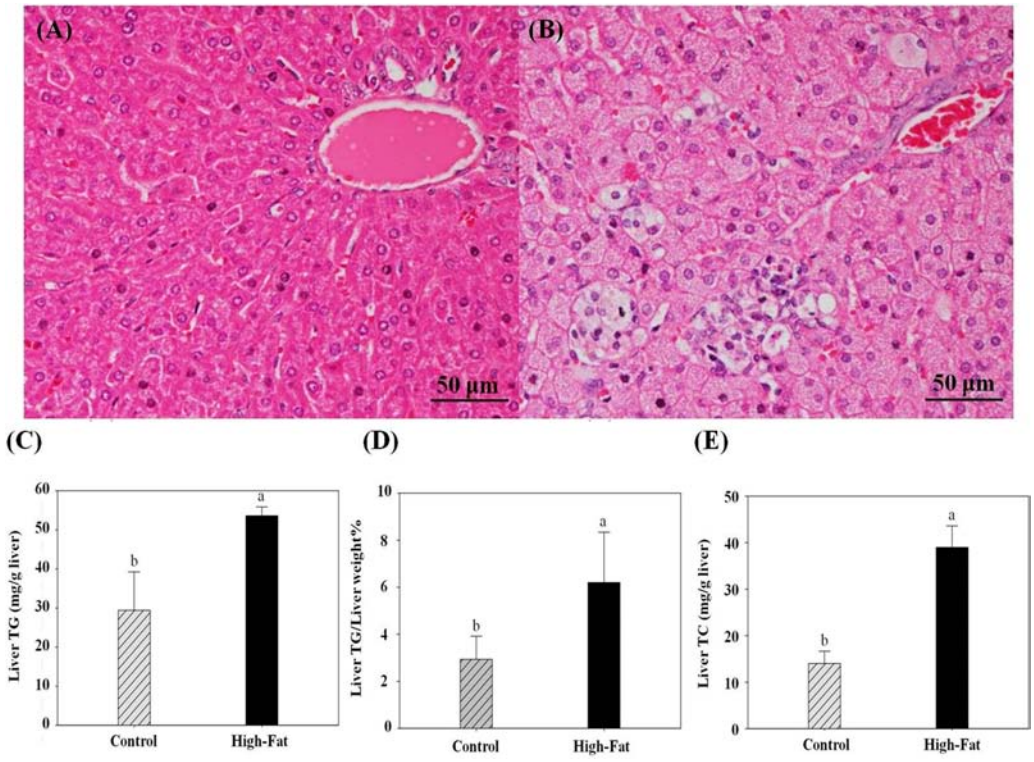

Figure 1. H&E stain of liver tissues from (A) control and (B) high-fat groups (400×). Panels C, D, and E show liver TG, relative weight of TG in liver (%), and liver TC, respectively. Hamsters were sacrificed after 8 weeks of feeding on the control diet or the high-fat diet. TG, triglyceride; TC, total cholesterol. Groups with the same letter are not significantly different (α = 0.05).

The significance of association between proteins and functional/canonical pathways was computed by Fisher's exact text (α = 0.05). IPA calculates a *p*-score as $-\log_{10}(p\text{-value})$ to rank networks. A score of 3 or higher indicates that the proteins are not clustered in a pathway by random chance at the confidence level of 99.99% or higher.[21,26]

Western Blotting. Livers were thawed on ice and homogenized in 25 mM Tris-HCl, pH 7.5, containing 250 mM sucrose and 1 mM ethylene-diaminetetra-acetic acid (10%, w/v). The homogenate was centrifuged at 105 000*g* for 30 min. After centrifugation, the supernatant was collected for analysis and its protein content was determined by Dc Protein Assay Kit (Bio-Rad, Hercules, CA). An equal amount of proteins from each sample was separated by SDS-PAGE before being transferred to polyvinylidene fluoride (PVDF) membranes (PerkinElmer, Waltham, MA). The membranes were blocked with 5% nonfat dry milk in Tris-buffered saline containing Tween (TBST) (20 mM Tris-HCl, pH 8.3, 137 mM NaCl, and 0.1% Tween-20) for 1 h before being sequentially incubated with primary antibody overnight in a cold room and horseradish peroxidase-conjugated secondary antibody for 1 h at room temperature. Immunoreactive proteins were detected using an enhanced chem-iluminescence kit (ECL, PerkinElmer, Waltham, MA), and the film was analyzed by ImageQuant software (Molecular Dynamics, Sunnyvale, CA). For stripping and reprobing, the membrane was incubated with stripping buffer (0.2 M glycine, 3.5 mM SDS, 0.1% Tween-20, pH 2.2) at room temperature for 10 min. After the buffer was discarded, the membrane was incubated with fresh stripping buffer for another 10 min followed by two 10 min washes by PBS buffer and two 5 min washes by TBST buffer. After striping, the blocking and probing were performed as mentioned above.[22]

Statistical Analysis. Statistical analysis was performed using the Statistical Analysis System (SAS Institute, Cary, NC). The *t*-test was used to determine significant difference among control group and high-fat group (α = 0.05).

RESULTS AND DISCUSSION

Hepatic proteomics is an important parameter for the studies of metabolic diseases. The animal model and the diet both have significant influences on the results of proteomic analysis. In most of the hepatic proteomic studies, rats or mice were chosen as models.[16−19] However, hamsters that show closer similarity to human lipid metabolism compared to rats/mice were used as the model in this present study. Hamsters and other rodents respond differently to dietary fats. Similar to humans, hamsters were hyper-responsive to the dietary cholesterol whereas rats were hypo-responsive.[27] Moreover, the effect of dietary cholesterol on lipoprotein profile in hamsters is similar to that of humans.[28] It is clear that hamsters could be a better model to study the physiological effect of dietary fats.

In addition to the difference in animal model, the composition of diet in current study is different from those in other proteomic studies. In this study, 17% lard and 0.2% cholesterol were supplemented to the diet (42.27% of calories from fats) to induce hyperlipidemia and accumulation of lipids in liver. In Zhang et al.'s proteomic study, 60% fructose was used to induce fatty liver in hamsters.[29] In a rat proteomic study, 2% cholesterol, 7% lard, and 10% yolk powder were used to formula a high-fat diet.[16] Luo et al. used a commercial 60% fat diet to study changes in hepatic protein abundance in mice.[18] Baiges et al. used bacon, sweets, biscuits with foie gras, cheese, muffins, carrots, and milk with sugar to formulate a cafeteria high-fat diet.[17] Different diet formulas lead to different results in proteomic analysis. The diet of this current study closely lines up with the Western pattern diet, which typically contains high amounts of saturated fat and sugar.

In our present study, we used label-free nano-LC/MS/MS (shotgun proteomics), a high-throughput proteomic tool, to

[a]High-fat group. [b]High-fat group/control group. [c]Significant level =0.05.

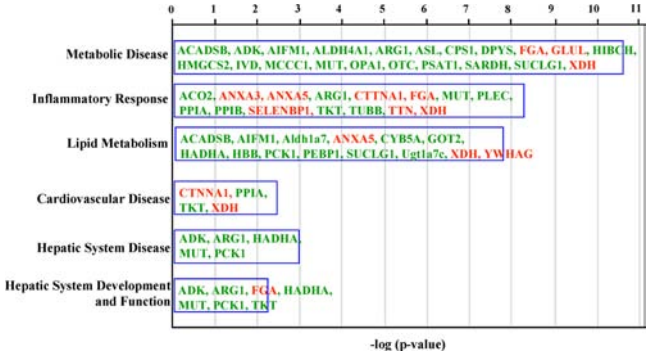

Figure 2. Proteins that were altered by the high-fat diet challenge and involved in metabolic diseases. Proteins marked green were down-regulated by the high-fat diet while those marked red were up-regulated. The full names of proteins are listed in Supporting Information Table 2. IPA computes a p score as $-\log_{10}(p\text{-value})$. A score of 3 or higher indicates that the proteins are not clustered in a pathway by random chance at the confidence level of 99.99% or higher.

perform the quantification of protein instead of two-dimensional electrophoresis (2-DE) as described in most studies.[16,29,30] Compared with 2-DE, label-free LC/MS/MS keeps the cost down and works more efficiently, allowing us to compare the expression of whole proteomics at a time. In addition to the changes in protein abundance, we also investigated the PTM of ANXA3, ANXA5, and XDH, three proteins that expressed differentially by the challenge of high-fat diet.

Body Weight and Organ Weight. Compared to control group, animals in high-fat group had lower daily feed intake; however, their weight gain, organ weight, and relative organ weight were higher than those of control group (Supporting Information Table 1).

Serum Lipids, AST, and ALT in Animals. Hamsters in the high-fat diet group had significantly ($p < 0.05$) higher serum TC and HDL-C (Supporting Information Figure 2). The level of serum TG was also higher in the high-fat group (Supporting Information Figure 2A), but not statistically significant ($p > 0.05$). The ratio of HDL-C to TC (Supporting Information Figure 2D) was lower in the high-fat group ($p > 0.05$). The activities of serum AST and ALT (Supporting Information Figure 2E and F), two clinical markers of liver damage, were significantly higher in animals maintained on the high-fat diet ($p < 0.05$).

Liver Lipids and Histopathology. Figure 1A shows the liver tissue of an animal in the control group while Figure 1B shows the liver tissue of an animal in the high-fat group. Microscopically, the liver from high-fat group revealed diffuse hepatocellular swelling with intracytoplasmic accumulation of lipid droplets (microvesicular steatosis). There were also multifocal, well-delineated ballooned hepatocytes in the periportal area. Some ballooned hepatocytes had pyknotic nuclei concurrent with varying degrees of neutrophils and lymphocytes infiltration.

Animals of high-fat group had significantly ($p < 0.05$) more hepatic TG and TC accumulation than those of control group (Figure 1C and E). Moreover, the average percentage of TG accumulated in the livers of high-fat group is higher than 5% (Figure 1D), which meets the clinical definition of fatty liver.[31]

Proteomic Analysis. Hepatic proteins were separated by electrophoresis and digested by trypsin before being analyzed by tandem mass spectrometry. The spectra generated were analyzed by TurboSequest to identify the peptide sequences against hamster database in UniProt. The results of analysis were scored using Xcorr. The proteins were regarded as hepatic proteins if more than two peptides from a single protein met the threshold of Xcorr score. On the basis of this criterion, 1191 proteins in liver were identified and 135 of them were altered by the challenge of high-fat diet (names of proteins and normalized spectrum counts of each protein were listed in Supporting Information Table 2). Table 1 shows the protein name, accession number, molecular function, and fold of change (high-fat/control) of all 135 proteins. Among these 135 proteins, 33 were up-regulated with the high-fat diet. The FDR (false discovery rate) of this analysis is 2.36%, higher than the minimal requirement of 5%. For some proteins that were not detected, it may result from their low abundance or the methodology of TurboSequest algorithm. By TurboSequest's specific algorithm, a protein will be ignored if it shares common sequences with other proteins that possess unique a peptide.

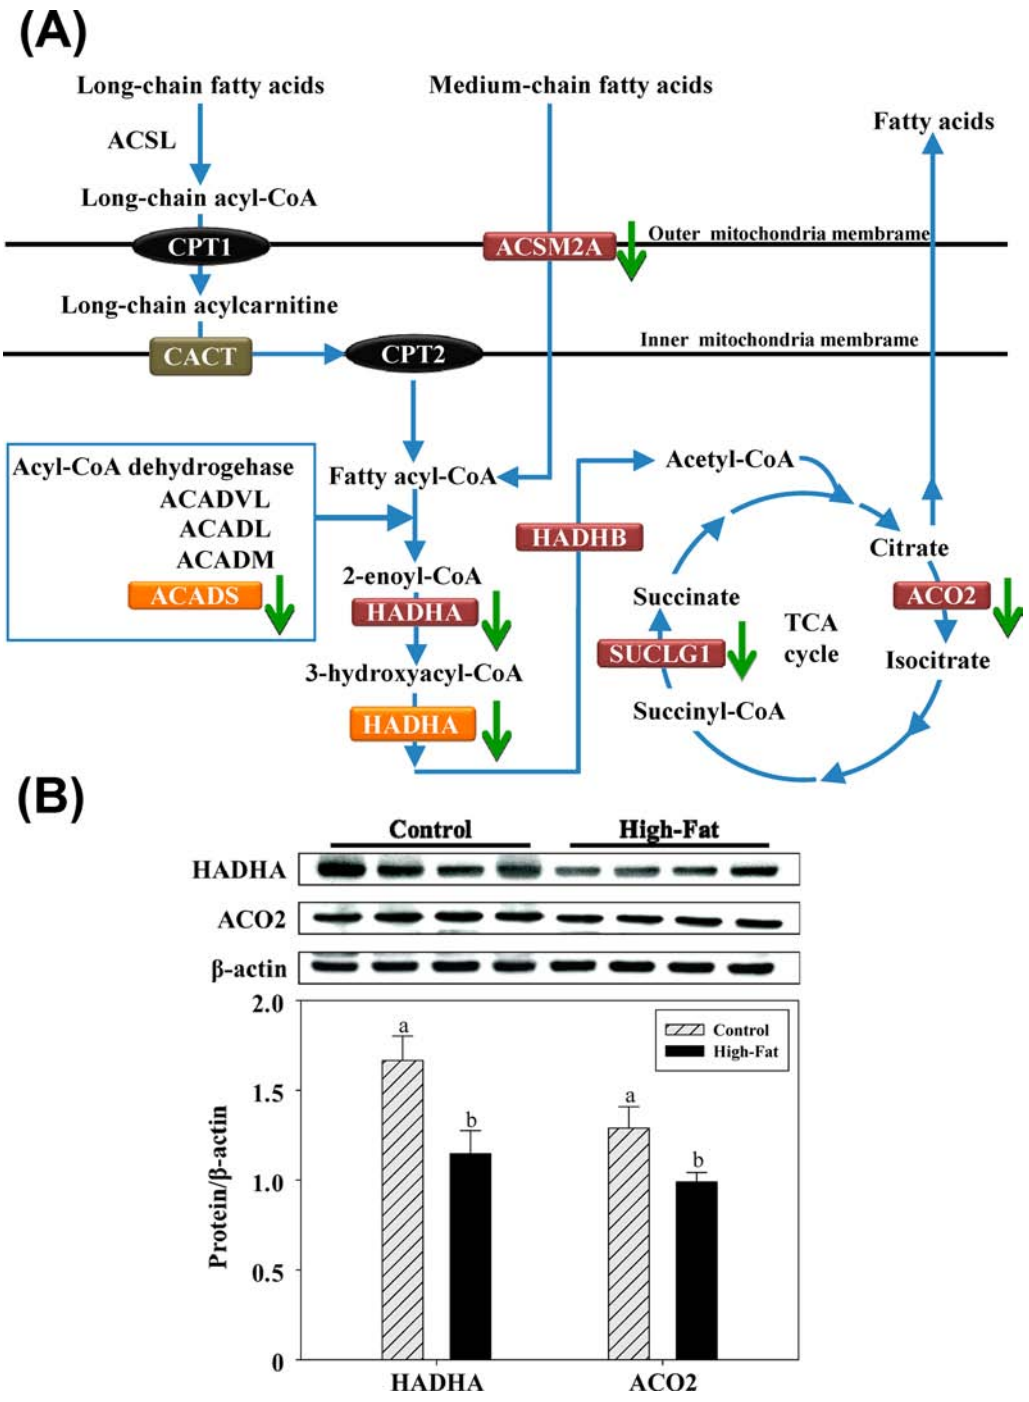

Figure 3. (A) Pathway of β-oxidation and TCA cycle. (B) Expression of HADHA and ACO2. Values are means of three replicated experiments. Groups with the same letter are not significantly different ($\alpha = 0.05$). Green arrows indicate down-regulation of proteins. ACSL, long-chain acyl-CoA synthase (ACSM refers to medium-chain acyl-CoA synthase); CPT, carnitine palmitoyltransferase; CACT, carnitine-acylcarnitine translocase; ACADS short-chain acyl-CoA dehydrogenase (VL, L, and M refer to very long-chain, long-chain, and medium-chain, respectively); HADHA, α-unit of mitochondrial trifunctional protein, containing the activities of enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase actvities; HADHB, β-unit of mitochondrial trifunctional protein, containing the activity of 3-ketoacyl-CoA thiolase. ACO2, aconitate hydratase 2; SUCLG, succinyl-CoA ligase.

Ingenuity Pathways Analysis. The proteins with altered expression were assessed through IPA. IPA calculates a p score as $-\log_{10}(p\text{-value})$ to rank networks. A score of 3 or higher indicates that the proteins are not clustered in a pathway by random chance at the confidence level of 99.99% or higher. Because high-fat diet significantly contributes to the etiology of metabolic diseases, proteins grouped into the related interactions by IPA are shown in Figure 2 (the full names of proteins are listed in Supporting Information Table 3). Proteins marked green were down-regulated by the high-fat diet, while those marked red were up-regulated. For proteins involved in metabolic diseases, 18 were down-regulated and 3 were up-regulated. For those that play a role in inflammatory response, 8 were down-regulated and 7 were up-regulated. With regard to

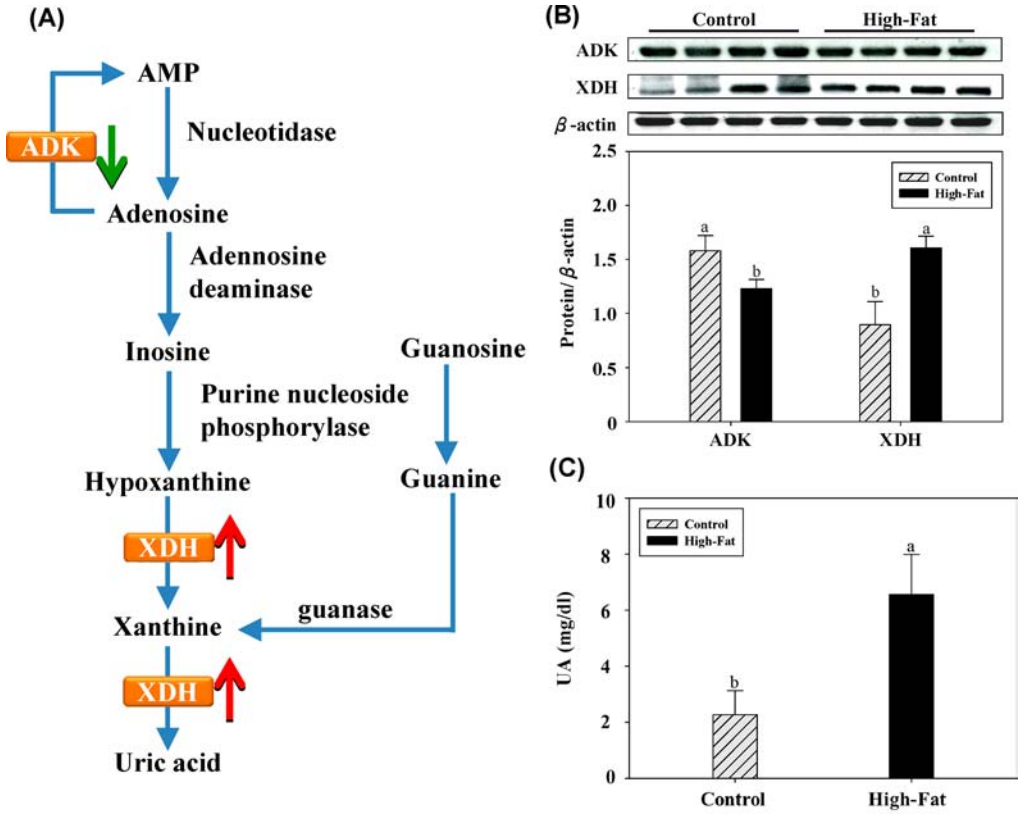

Figure 4. (A) Pathway of uric acid synthesis. (B) Expression of ADK and XDH. (C) Serum concentration of uric acid. Values are means of three replicated experiments. Groups with the same letter are not significantly different (α = 0.05). Green arrows indicate down-regulation of proteins and red arrows indicate up-regulation of proteins. ADK, adenosine kinase; XDH, xanthine dehydrogenase; UA, uric acid.

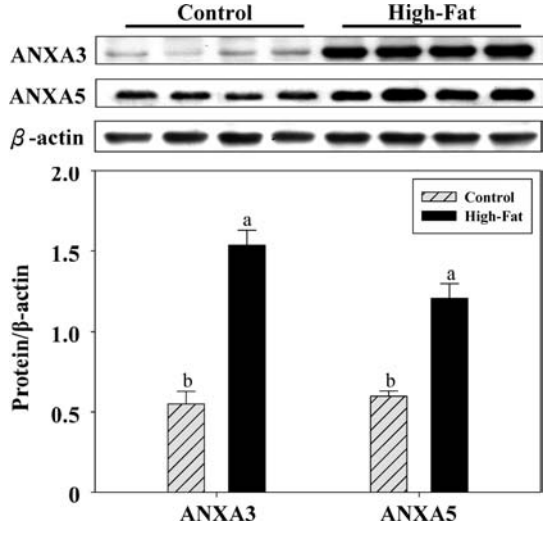

Figure 5. Expression of ANXA3 and ANXA5. Values are means of three replicated experiments. Groups with the same letter are not significantly different (α = 0.05). ANX, annexin.

lipid metabolism, 11 proteins were down-regulated and 3 were up-regulated. For proteins related to the development of cardiovascular disease, 2 were up-regulated and 2 were down-regulated. In the pathways involved in hepatic functions and diseases, 6 were down-regulated and 1 was up-regulated. Further Western blotting analysis was carried out to confirm the expression of some proteins mentioned above.

Expression of Enzymes Involved in Fatty Acid β-Oxidation. Mitochondrial β-oxidation is the main route for metabolism of fatty acids.[32] Prior to the translocation into mitochondria for β-oxidation, free long-chain fatty acids (LCFAs) must be activated by acyl-CoA synthetase long-chain (ACSL) (Figure 3A). After being activated to the CoA derivative, LCFAs translocate into a mitochondrion via the carnitine transacylation pathway, but medium-chain fatty acids can enter mitochondria without the carnitine shuttle. ACSs are classified as short-chain ACS (ACSS), medium-chain (ACSM), and ACSL according to their specificities for fatty acids of varying length.[33] Proteomic analysis shows that the expression of ACSM2A (medium-chain acyl-CoA synthetase family member 2A) was down-regulated by the high-fat diet (Table 1). Attenuated expression of ACSM2A decreased the opportunity for medium-chain fatty acids being transported into mitochondria for β-oxidation.

The first reaction within mitochondrial matrix is the acyl-CoA dehydrogenation catalyzed by acyl-CoA dehydrogenase (ACAD) (Figure 3A). Nine members were identified in the ACAD family, including the four members that are involved in β-oxidation: short, medium, long, and very long chain acyl-CoA dehydrogenase (ACADS, ACADM, ACADL, and ACADVL, respectively).[34] Following dehydrogenation, enoyl-CoA hydratase catalyzes the formation of 3-hydroxyacyl-CoA, which is further followed by the formation of 3-ketoacyl-CoA. Finally, acetyl-CoA is generated through a thiolysis reaction. The last three steps of reactions are catalyzed by mitochondrial trifunctional protein (MTP), which is composed of an α-unit (HADHA) and a β-unit (HADHB). HADHA contains long-chain enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydro-

genase actvities, whereas HADHB contains the 3-ketoacyl-CoA thiolase activity.[35]

Proteomic analysis shows that the expression of ACADS and HADHA was down-regulated by the high-fat diet challenge (Table 1 and Figure 3B). Down-regulation of ACAD and HADHA would limit the capacity of mitochondria to oxidize fatty acids, leading to hepatic steatosis. Mice deficient in short-chain ACAD (ACADS) develop a fatty liver upon dietary fat challenge.[36] Medium-chain acyl-CoA dehydrogenase (ACADM) is the most common inherited disorder of mitochondrial β-oxidation in humans. Mice deficient in ACADM also develop a fatty liver.[37] MTP consists of four α and four β subunits that catalyze the final three steps of long-chain fatty acid β-oxidation. Newborn mice with MTP α subunit (HADHA) null allele ($Mtpa^{-}/^{-}$) revealed rapid development of hepatic steatosis after birth and significant necrosis of cardiac myocytes later.[35] In the aging heterozygous $Mtpa^{+}/^{-}$ mice, significantly higher hepatic triglyceride content and serum ALT activity were measured compared with the $Mtpa^{+}/^{+}$ littermates.[38] Rats with a high-fat diet induced hepatic steatosis had reduced level of enoyl-coenzyme A hydratase. Down-regulation of enoyl-coenzyme A hydratase in mice significantly exacerbated high-fat diet induced hepatic steatosis.[16]

In this study, decreased expression of ACSM2A, ACADS, and HADHA in the high-fat group (Table 1 and Figure 3B) may attenuate the oxidation of fatty acids, increasing the availability of fatty acids for synthesis of TG. This finding may explain the development of fatty liver as observed in the high-fat group.

Expression of Enzymes Involved in TCA Cycle. Acetyl-CoA enters TCA cycle by condensing with oxaloacetate to form citrate (Figure 3A). The citrate is then converted to isocitrate through the action of aconitate hydratase (ACO, also named as aconitase). Isocitrate undergoes dehydrogenation and decarboxylation to form α-ketoglutarate. Ketoglutarate is further decarboxylated to form succinyl-CoA. To continue the cycle, succinyl-CoA is converted to succinate by the action of succinyl-CoA ligase (also called succinate synthetase or succinate thiokinase). Succinate is further metabolized to fumurate, followed by the formation of malate. Malate is then converted to oxaloacetate through dehydrogenation reaction.[39]

Proteomic analysis showed the ACO was down-regulated by high-fat diet (Table 1 and Figure 3B). Mammals express two isoforms of ACO, ACO1 (soluble), and ACO2 (mitochondrial). Cui et al. found a significant decrease of ACO2 expression in splenic lymphocytes of mice that were fed a high-fat diet for 10 weeks.[40] Loss of ACO activity limits TCA cycle activity, which will favor the translocation of citrate from mitochondria to cytosol to undergo fatty acid synthesis.[41]

Proteomic analysis showed that SUCLG1 was also down-regulated by high-fat diet (Table 1). SUCLG converts succinyl-CoA to succinate and free coenzyme A, and converts adenosine diphosphate (ADP) to adenosine triphosphate (ATP) or guanosine diphosphate (GDP) to guanosine triphosphate (GTP). SUCLG is composed of two subunits, and the α-subunit is encoded by *SUCLG1* gene with specificity for GDP. Liver biopsy of subjects with SUCLG1 deficiency showed both micro- and macrosteatosis.[42]

Expression of Enzymes Involved in Uric Acid Synthesis. Uric acid is the final breakdown product of purine metabolism. In the metabolism of purine nucleotide, adenosine is first deaminated to inosine in the reaction catalyzed by deaminase or phosphorylated to AMP by the action of adenosine kinase (ADK) (Figure 4A).[43] Catalyzed by purine nucleotide phosphorylase, inosine and guanosine are converted to hypoxanthine and guanine, respectively. Hypoxanthine and guanine next form xanthine in reactions catalyzed by xanthine dehydrogenase (XDH) and guanase, respectively. Xanthine is then oxidized to uric acid by the second reaction catalyzed by XDH.[44]

In the present study, the high-fat diet down-regulated ADK but up-regulated XDH (Table 1 and Figure 4B). ADK is highly expressed in liver. It is essential for maintaining normal level of adenine nucleotides and S-adenosylmethionine-dependent transmethylation process.[43] A decreased level of ADK decreases the recycle of adenosine to AMP, leading to more adenosine available for the biosynthesis of uric acid and reduced level of

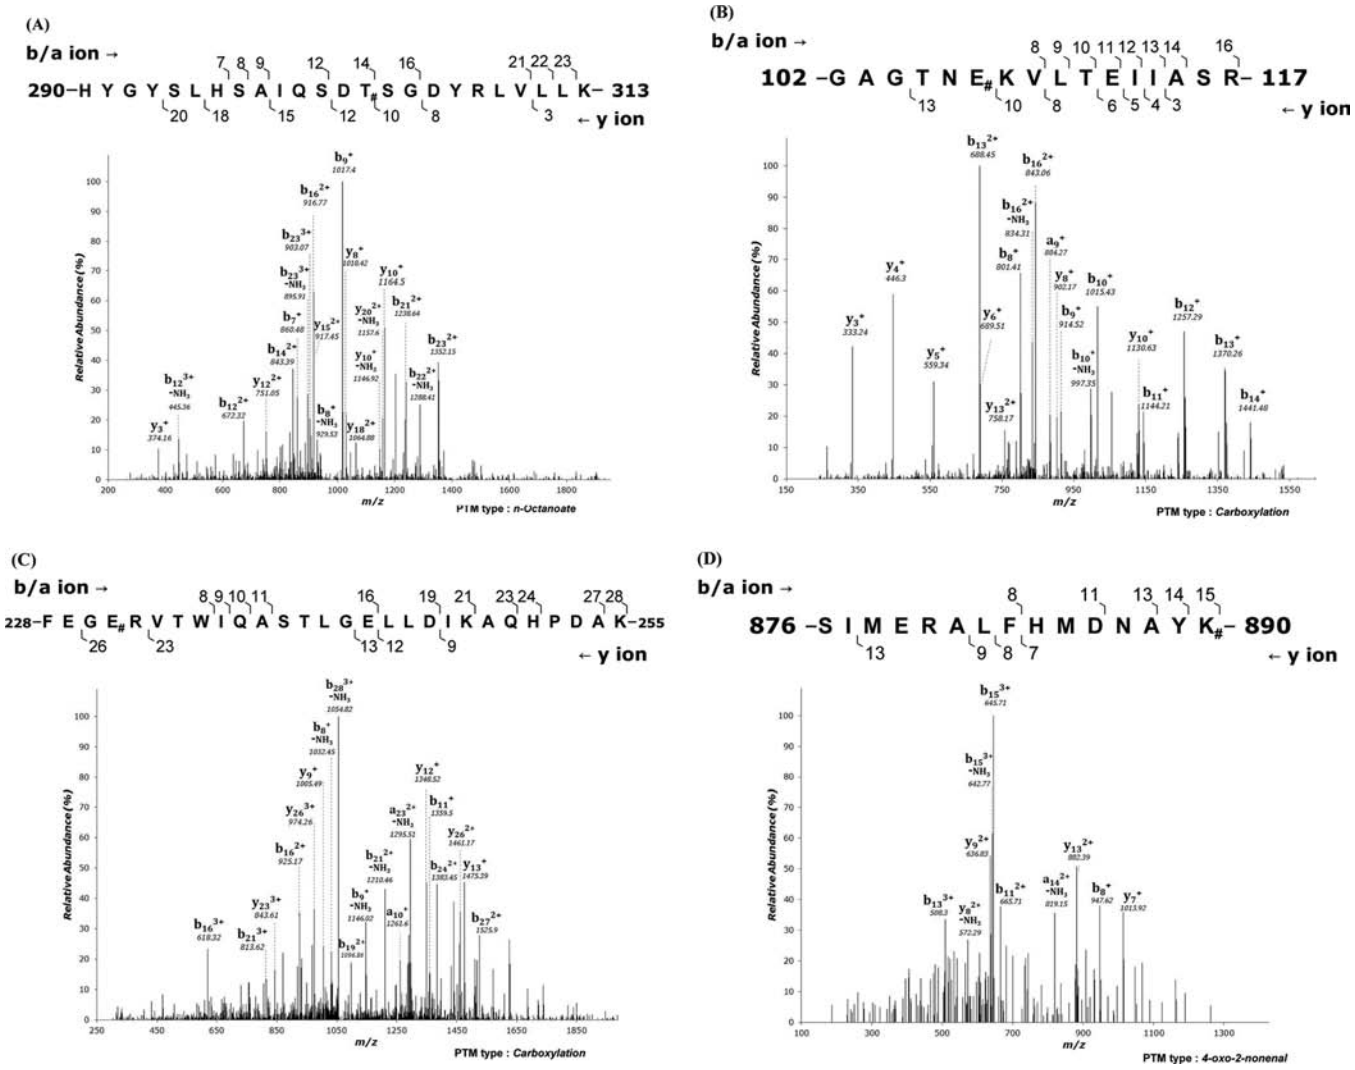

Figure 6. (A) Tandom mass spectrum of the *n*-octanoate peptide with the sequence 290-HYGYSLHSAIQSDT#SGDYRLVLLK-313 on ANXA3. (B) Tandom mass spectrum of the carboxylation peptide with the sequence 102-GAGTNEKVLTEIIAS#R-117 on ANXA5. (C) Tandom mass spectrum of the carboxylation peptide with the sequence 228-FEGE#RVTWIQASTLGELLDIKAQHPDAK-255 on XDH. (D) Tandom mass spectrum of the 4-oxo-2-nonenal peptide with the sequence 876-SIMERALFHMDNAYK#-890 on XDH. ANX, annexin; XDH, xanthine dehydrogena.

adenine nucleotides. Because the metabolic rate in liver mitochondria is proportional to the level of adenine nucleotides, a decreased amount of adenine nucleotides in the liver would lead to an impairment of mitochondrial function. Newborns with $Adk^{-/-}$ displayed microvesicular hepatic steatosis and died within 14 days with fatty livers.[44]

Xanthine oxidoreductase, a member of molybdoenzyme family, has two interconvertible forms, xanthine dehydroenase (XDH) and xanthine oxidase (XO). Both XDH and XO catalyze the conversion of hypoxanthine to xanthine and xanthine to uric acid.[45] Under physiological conditions, the enzyme is primarily present as XDH. Up-regulated expression of XDH by the challenge of a high-fat diet in the current study (Figure 4B) promoted the formation of uric acid, as indicated by the increased serum concentration of uric acid in animals of high-fat group (Figure 4C). Because high uric acid levels may cause frequent attacks of gout, it is reasonable to infer that high-fat diet is associated with etiology of gout.

Expression of Annexin A3 and Annexin A5. In this present study, proteomic analysis indicated that the challenge of a high-fat diet up-regulated both annexin A3 (ANXA3) and annexin A5 (ANXA5) (Table 1 and Figure 5). ANXs are a family of Ca^{2+}-regulated membrane- and phospholipid-binding proteins that have been implicated in many cellular processes including inflammation, apoptosis, proliferation, and differentiation.[46] Annexin A3 is a novel angiogenic factor that induces vascular endothelial growth factor (VEGF) production through the hypoxia-inducible factor-1 (HIF-1) pathway.[47] Poloxamer P-407 hyperlipidemia mouse is a nondiet-induced and genetically unaltered model of atherosclerosis. Kuzman et al. detected an up-regulation of annexin A3 in this mouse model.[48] By using an experimental model of tumor necrosis factor-α (TNF-α)-mediated inflammation, Pitroda et al. reported increased expression of ANXA3 in four types of human cancer and several human diseases associated with chronic inflammation.[49]

ANXA5 is associated with the development and progression of breast cancer, prostate cancer, cervical cancer, colorectal adenocarcinoma, gastric cancer, pancreatic adenocarcinoma, sarcoma, bladder cancer, and glioma. ANXA5 is considered as a predictive marker for tumor development and a therapeutic target for early diagnosis and treatment of tumors.[50] In the

present study, up-regulation of ANXA3 and ANXA5 implies an inflammatory and procarcinogenic status induced by high-fat diet.

Expression of Enzymes Involved in Urea Synthesis. The urea cycle is the major pathway for detoxification of ammonia in mammals. In the present study, proteomic analysis showed that several enzymes involved in urea synthesis were down-regulated by high-fat diet, including carbamoyl-phosphate synthetase 1 (CPS1), ornithine transcarbamoylase (OTC), argininosuccinate synthetase (ASS), argininosuccinate lyase (ASL), and arginase 1 (ARG1) (Table 1 and Supporting Information Figure 3).

CPS1 and OTC are mitochondrial enzymes catalyzing the first and second steps of the urea cycle, respectively. The expression of both enzymes is higher in hepatocytes than in other tissues.[51] Deficiency and reduced activity of CPS1/OTC cause hyperammonaemia.[52,53] ASS catalyzes the reversible condensation of citrulline with aspartate to form argininosuccinate. Argininosuccinate is then split into arginine and funarate in a reaction catalyzed by ASL. ASS is a highly conserved enzymes expressed in various tissues. Decreased expression of ASS attenuates the metabolism of ammonia and formation of argininosuccinate, resulting in abnormally higher concentration of ammonia and citrulline in the blood.[54] Patients with ASL deficiency were detected with increased blood ammonia.[55] ARG is the final enzyme of the urea cycle, catalyzing the metabolism of arginine to urea and ornithine. ARG1 knockout mice exhibited severe symptoms of hyperammonemia and hepatocyte abnormalities.[56,57]

Post-translational Modification of ANXA and XDH. PTMs are site specific amino acid side chain alterations taking place after translation of mRNA into a protein. It affects the folding, conformation, and functions of proteins. More than 300 different types of PTMs have been characterized to date, including carboxylation, methylation, phosphorylation, glycosylation, carboxylation, ubiquitination, prenylation, and sulphation. PTMs lead to higher structural and functional protein diversity, playing significant roles in physiological process and disease progression.[58,59] Identification of PTM on ANXA3, ANXA5, and XDH were carried out by our in-house PTM finder programs PTM-Miner and PTM-Q. The identified peptides and corresponding modified sites are listed in Table 2.

Four representative spectra for ANXA3, ANXA5, and XDH are shown in Figure 6. Figure 6A is the fragment ion spectrum for the modified peptide 290-HYGYSLH-SAIQSD**T**$_{\#}$SGDYRLVLLK-313 of ANXA3. The spacing of b and y ions was used to decipher the sequence of modified peptide. The novel *n*-octanoate site was detected based on the unmodified b14 ion and the mass shift of 126.10 Da for the y12 ion on modified peptide. The matched peaks were labeled according to the Biemann nomenclature. Figure 6B shows the fragment ion spectrum for the modified peptide 102-GAGTN**E**$_{\#}$KVLTEIIASR-117 of ANXA5. The novel carboxylation site was detected based on the unmodified y10 ion and the mass shift of 43.99 Da for the b8 ion on modified peptide. Figure 6C is the fragment ion spectrum for the modified peptide 228-FEG**E**$_{\#}$RVTWIQASTLGELLDIKAQHPDAK-255 of XDH. The novel carboxylation site was detected based on the unmodified y23 ion and the mass shift of 43.99 Da for the b8 ion on modified peptide. Figure 6D shows the fragment ion spectrum for the modified peptide 876- SIMERALFHMD-NAY**K**$_{\#}$-890 of XDH. The novel 4-oxo-2-nonenal site was detected based on the unmodified b14 ion and the mass shift of 136.09 Da for the y7 ion on modified peptide.

Proteomics is a powerful tool in monitoring the changes of protein profile induced by dietary manipulation. The findings of this study show that the challenge of a high-fat diet for 8 weeks impairs β-oxidation and ammonia metabolism; moreover, the high-fat diet up-regulates expression of inflammatory markers and synthesis of uric acid.

Alternative splicing and differential promoter usage results in two isoforms of PPAR γ, PPAR γ1 and PPAR γ2, differing for the additional 28 amino acids in the N terminus present in PPAR γ2 and not in PPAR γ1.[24,25] PPAR γ1 is expressed generally in multiple tissues, including the lower intestine, macrophages, and white adipose tissue (WAT), whereas PPAR γ2 expression is almost exclusively restricted to WAT.[21] PPAR γ is a master regulator of adipogenesis as well as a potent modulator of insulin sensitivity, lipogenesis, and adipocyte survival and function.[26−28] Moreover, PPAR γ has been considered as a molecular target for cancer chemoprevention[29−31] and has been shown to be involved also in the regulation of genes contributing to hypertension and atherosclerosis.[32]

PPAR γ could exert pleiotropic effects by ligand-dependent transactivation of specific genes. Following ligand binding, the conformation of PPAR γ is changed and then causes the release of histone deacetylase corepressors, thus enabling PPAR γ to heterodimerize with RXR. RNA polymerase II and coactivators with histone acetyl transferase activity are then recruited to this complex, which binds to PPREs in the promoter region of the respective target genes, leading to chromatin remodeling and ultimately to increased transcription. On the other hand, PPAR γ can also down-regulate the expression of its target genes by interfering with other proteins and transcription factors such as nuclear factor kappa B (NF-κB) and activator protein-1 (AP-1) through a transrepression mechanism.[31,33] In addition to their transactivating and transrepressional activity, the PPAR family also exerts nongenomic actions, which are too rapid to involve gene expression modulation.[34]

The transcriptional activity of PPAR γ could be mediated by agonist and antagonist. Fatty acids and prostanoids, as the endogenous ligands for PPAR γ, can bind and activate PPAR γ.[35,36] However, they are weak agonists compared to the strong synthetic thiazolidinedione agonists with robust insulin-sensitizing activities.[37] The transcriptional activity of PPAR γ is also regulated by post-translational modifications including phosphorylation, sumoylation, and ubiquitination, providing additional possibilities for fine-tuning.[34]

MODULATION OF PPAR γ BY CLA IN OBESITY

The prevalence of obesity and its associated comorbidities has grown to epidemic proportions worldwide. Thus, developing safe and effective therapeutic approaches against these widespread and debilitating diseases is important and timely.[38] Since Park et al. (1997) demonstrated that CLA modulated body fat in mice, interest in CLA as a weight loss treatment has increased.[39] The antiobesity activity of CLA has been extensively studied, and multiple animal studies and some human studies have confirmed that supplementation with a CLA mixture (i.e., equal concentrations of the *trans*-10,*cis*-12 CLA and *cis*-9,*trans*-11 CLA isomers) or the *trans*-10,*cis*-12 CLA isomer alone decreases body fat mass.[4,40] Of the two major isomers of CLA, the *trans*-10,*cis*-12 CLA isomer is specifically responsible for the antiobesity effects[41−44] and mechanisms involved in its impact on energy metabolism, adipogenesis, inflammation, lipid

metabolism, and apoptosis.[43] In the present review, the regulation of adipogenesis, lipogenesis, and inflammation through modulation of PPAR γ by *trans*-10,*cis*-12 CLA (Figures 1 and 2) is discussed.

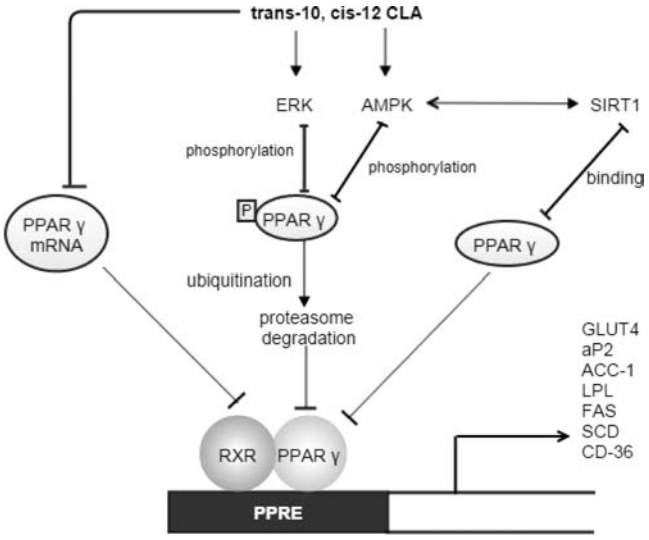

Figure 1. Proposed mechanism of action of CLA in adipogenesis and lipogenesis by modulation of PPAR γ. *trans*-10,*cis*-12 CLA reduced adipogenesis and lipogenesis by (1) regulating the expression PPAR γ and its target genes and (2) modulating the transactivating activity of PPAR γ, thereby reducing the expression of PPAR γ target genes. Ligand-dependent PPAR γ transactivating activity is antagonized by *trans*-10,*cis*-12 CLA, possibly via PPAR γ phosphorylation by ERK and AMPK. There is cross-regulation between SIRT1, AMPK, and PPAR γ. The transactivating activity of PPAR γ is attenuated by SIRT1 via binding directly or indirectly to PPAR γ. SIRT1 and AMPK activity are stimulated by one another and repressed by PPAR γ via a nontranscriptional mechanism.

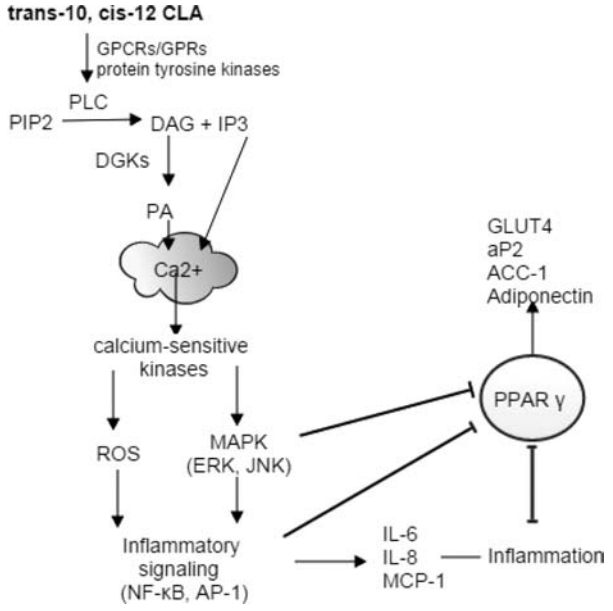

Figure 2. Proposed mechanism of action of CLA-mediated inflammation by modulation of PPAR γ. The *trans*-10,*cis*-12 CLA activates the specific cell surface receptors, including G protein coupled receptor, G protein receptor, or protein tyrosine kinases, and consequently stimulates the translocation of PLC to the plasma membrane, thereby generating DAG and IP3 from PIP2. DGKs convert DAG into PA and, together with IP3, stimulate calcium release from ER. Increased intracellular calcium accumulation activates calcium-sensitive kinases, such as CaMKII, which promotes ROS production and MAPK activation. MAPK subsequently activates inflammatory signaling, NF-κB, and AP-1. These inflammatory signals lead to a rise of secretion of inflammatory proteins, such as IL-6, IL-8, and MCP-1 and antagonize PPAR γ abundance and activity, thereby suppressing the expression of PPAR γ target genes and lipogenesis.

Regulation of Adipogenesis and Lipogenesis through PPAR γ by CLA. PPAR γ was originally described as a factor induced during adipocyte differentiation and function as a master regulator of adipocyte differentiation and metabolism.[26,45−47] Adipogenesis has been studied extensively in vitro, in particular using the murine 3T3-L1 preadipocyte cell line.[28,48−50] The regulation of adipogenesis through PPAR γ by CLA also has been investigated by using the 3T3-L1 preadipocyte cell line. CLA suppresses preadipocyte differentiation in animal[51−56] and human preadipocytes[57,58] by attenuating the expression and activity of adipogenic transcription factors such as PPAR γ and CAAT/enhancer binding protein α (C/EBP α).

PPAR γ is best known for its role in regulating adipogenic and lipogenic pathways[59] and is also crucial for controlling gene networks involved in lipid metabolism and glucose homeostasis, including adipocyte fatty acid binding protein (aP2),[60] insulin-dependent glucose transporter 4 (GLUT4),[61] lipoprotein lipase (LPL),[62] and the fatty acid translocase (CD-36/FAT).[63] *trans*-10,*cis*-12 CLA has been shown to reduce triglyceride (TG) accumulation in adipocyte cell culture models[42,52,53,64] and in the mouse[65] by attenuating the expression and activity of PPAR γ and its target genes such as LPL, acetyl-CoA carboxylase (ACC), fatty acid synthase (FAS), and stearoyl-CoA desaturase (SCD).

CLA and the Expression of PPAR γ and Its Target Genes. The expression of PPAR γ was decreased after *trans*-10,*cis*-12 CLA supplementation in rodents.[66−69] The expression and activity of PPAR γ and PPAR γ target genes and lipid content were also decreased substantially after *trans*-10,*cis*-12 CLA treatment in mature in vitro differentiated primary human adipocytes[51,70] or in mature 3T3-L1 adipocytes.[57] On the other hand, direct effects of CLA isomers on the PPAR γ expression were investigated by using a luciferase reporter assay system in a number of studies. These studies found that the *cis*-9,*trans*-11 CLA isomer was a PPAR γ agonist, whereas the *trans*-10,*cis*-12 CLA isomer appeared to be a partial antagonist or weak agonist.[58,64,71,72] However, Brown et al. showed that treatment with either *cis*-9,*trans*-11 CLA or *trans*-10,*cis*-12 CLA led to a slight decrease in luciferase activity by using 3T3-L1 cells transiently transfected with a luciferase reporter construct containing a PPRE, suggesting that these two isomers may antagonize PPAR γ activity in adipocytes.[58] There is no clear consensus regarding the activation or antagonism of PPAR γ by *trans*-10,*cis*-12 CLA, indicating that the way in which *trans*-10,*cis*-12 CLA affects PPAR γ expression is still unclear.

The inhibitory effect in PPAR γ-induced gene expression could be due to reduced PPAR γ expression or post-translational inhibition of PPAR γ activity per se.[43] Reduced PPAR γ activity could inhibit the expression of PPAR γ because PPAR γ directly or indirectly induces its own expression. Therefore, it is difficult to determine the levels at which inhibition occurs.[43]

CLA and the Activity of PPAR γ. PPAR γ activity can be modulated directly and indirectly at different levels (Figure 1). Several mechanisms are involved in the regulation of PPAR γ activity by supplementation with *trans*-10,*cis*-12 CLA. Phosphorylation, which can be mediated by the mitogen-activated protein

DOI: 10.1021/jf505050c
J. Agric. Food Chem. 2015, 63, 1883−1895

kinase (MAPK) pathway,[73,74] is the most investigated post-translational regulatory mechanism of PPAR γ.[21] The Ser82 in PPAR γ1 and Ser112 in PPAR γ2 in the mouse and the corresponding serines 84 and 114 in the human PPAR γ isoforms have been described to be phosphorylated by all MAPKs (extracellular signal-related kinase, ERK; cJun-NH2-terminal kinase, JNK, and p38), resulting in the inhibition of both ligand-dependent and -independent transactivation activity of the receptor.[21,34] Phosphorylation of PPAR γ may decrease its activity via ubiquitination and proteasome degradation.[75] Kennedy et al. demonstrated that 24 h of treatment with *trans*-10,*cis*-12 CLA increased PPAR γ phosphorylation and ERK 1/2 phosphorylation without significantly decreasing its protein levels, suggesting that the down-regulation of PPAR γ target genes is due to decreased transactivating activity in primary cultures of human adipocytes.[70] These suggested that *trans*-10,*cis*-12 CLA antagonizes ligand-dependent PPAR γ transactivating activity, possibly via PPAR γ phosphorylation by ERK.[70] A similar inhibitory effect on PPAR γ transactivating activity has been found for AMP-activated protein kinase (AMPK) via the phosphorylation of specific sites of PPAR γ.[76] AMPK was directly or indirectly responsible for the increased phosphorylation at Ser112 of PPAR γ in *trans*-10,*cis*-12 CLA treated adipocytes.[77]

The activity of PPAR γ could also be modulated by sirtuin 1 (SIRT1). SIRT1, a histone/protein deacetylase, is particularly involved in regulating cell energy metabolism, cell stress, and cell fate.[78] SIRT1 could directly bind directly or indirectly to PPAR γ to repress PPAR γ transactivating activity, inhibit adipogenesis, and promote fat loss in adipocytes.[79] After treatment with *trans*-10,*cis*-12 CLA, cross-regulation between SIRT1, AMPK, and PPAR γ occurred in 3T3-L1 adipocytes.[77] SIRT1 stimulated AMPK activity and attenuated PPAR γ activity, whereas AMPK stimulated SIRT1 activity and attenuated PPAR γ activity in *trans*-10,*cis*-12 CLA treated 3T3-L1 adipocytes. That PPAR γ has a repressive effect on the activities of AMPK and SIRT1, which is consistent with the opposing roles of PPAR γ in stimulating lipid biosynthesis and the catabolic energy-generating roles of AMPK and SIRT1.[51,80] PPAR γ achieved these inhibitory effects via a nontranscriptional mechanism because PPAR γ affected the activity levels of SIRT1 and AMPK without changing the total amounts of these proteins in the response to *trans*-10,*cis*-12 CLA. Besides the well-known transactivating and transrepressional activity of PPAR γ, these results suggested an emerging role for PPAR γ in regulating nongenomic processes.[34,81]

Regulation of Obesity-Related Inflammation through PPAR γ by CLA. *CLA and Obesity-Related Inflammation.* To date there is no clear consensus regarding anti-inflammatory effects of CLA. It is likely that the effects of CLA on inflammation of adipose tissue are isomer-dependent. *cis*-9,*trans*-11 CLA reduces adipose tissue inflammation in ob/ob mice,[82] whereas *trans*-10,*cis*-12 CLA reduces adiposity without improving or worsening insulin resistance and adipose tissue inflammation in hamsters and mice.[67,83]

Obesity is characterized by a chronic low-grade inflammation, primarily due to an imbalance between production/secretion of pro-inflammatory cytokines versus anti-inflammatory cytokines.[84] Adipose tissue is not simply an energy reservoir, thermal regulator, or protective padding for important organs but also a metabolically active endocrine organ.[85] Adipose tissue has the ability to produce a number of pro-inflammatory adipokines including tumor necrosis factor-alpha (TNF-α), interleukin-1 beta (IL-1β), interleukin-2 (IL-2), interleukin-6 (IL-6), interleukin-8 (IL-8), monocyte chemoattractant protein-1 (MCP-1), plasminogen activator inhibitor-1 (PAI-1), and resistin.[86,87] Adipose tissue can also produce anti-inflammatory cytokines such as adiponectin and interleukin-10 (IL-10).[87] These pro-inflammatory adipokines produced by adipose tissue can cause insulin resistance, thereby suppressing lipid synthesis and increasing lipolysis in adipocytes.[43]

The expression of PPAR γ and its target genes could be directly down-regulated by *trans*-10,*cis*-12 CLA supplementation. In contrast, PPAR γ and its target genes also could be indirectly inhibited by cytokines induced by *trans*-10,*cis*-12 CLA.[62,84−86] ERK[57] and NF-κB[67,88] in adipocytes could be activated by *trans*-10,*cis*-12 CLA supplementation and, consequently, these signaling pathways increased the expression or secretion of cytokines, for example, IL-6 and IL-8[57,67,68,70,88] and TNF-α and IL-1β,[89] which are known to antagonize PPAR γ target gene expression and insulin sensitivity.[69,90−92]

trans-10,*cis*-12 CLA supplementation increased PGF 2α secretion in human adipocytes in vitro.[93] *trans*-10,*cis*-12 CLA treatment also increased the levels of inflammatory prostaglandins (PGs) and C-reactive protein in humans in vivo.[94] Supplementation with an oil mixture with *trans*-10,*cis*-12 CLA (5.5 g/day for 16 weeks) exhibited higher levels of C-reactive protein in serum and 8-iso-PGF 2α in urine of healthy postmenopausal women, compared with *cis*-9,*trans*-11 CLA.[94] Inflammatory PGs such as PGF 2α have been reported to block adipogenesis through activation of MAPK, resulting in inhibitory phosphorylation of PPAR γ in 3T3-L1 preadipocytes.[95] PGF 2α has also been demonstrated to inhibit adipogenesis through normoxic activation of the hypoxia-inducible factor-1 (HIF-1) signaling pathway during 3T3-L1 preadipocyte differentiation under normal oxygen conditions.[96] HIF-1 decreases the expression of PPAR γ and C/EBP α via the increased expression of the DEC1 transcriptional repressor.[97] In addition, PGF 2α could inhibit adipogenesis by activating pro-inflammatory transcription factors that can antagonize PPAR γ.[43]

CLA and Inflammatory Signaling Cascade. The inflammatory signaling cascade is also involved in CLA-reduced adiposity (Figure 2). *trans*-10,*cis*-12 CLA mediated suppression of adipogenesis and lipogenesis and adipocyte delipidation were dependent on inflammatory signaling[57,88,98] and linked to endoplasmic reticulum (ER) release of calcium and increased intracellular calcium ($[Ca^{2+}]$ i) accumulation.[99] Up-regulation of inflammatory pathways by *trans*-10,*cis*-12 CLA increased the activities of NF-κB, AP-1, and MAPK,[57,88,98] which led to inhibition of PPAR γ abundance and activity,[58,70,100] reduction of glucose and fatty acid uptake, and de novo lipogenesis.[42,57,58] The molecular mechanisms by which NF-κB inhibits PPAR γ activity are not completely understood. However, unlike suppression of the PPAR γ transactivating activity by MAPK-induced growth factor signaling through phosphorylation of PPAR γ, NF-κB blocked PPAR γ binding to DNA by forming a complex with PPAR γ and its AF-1-specific coactivator PGC-2 in the bone marrow stromal cell line ST2.[90]

Up to now, the upstream signals activated by *trans*-10,*cis*-12 CLA that initiate this inflammatory signaling cascade were investigated by a number of studies.[99,101−103] One possible upstream mediator of *trans*-10,*cis*-12 CLA induced inflammation is $[Ca^{2+}]$ i, which is a vital second messenger for the activation of proteins involved in adipocyte proliferation, differentiation, and metabolism.[101] *trans*-10,*cis*-12 CLA increased $[Ca^{2+}]$ i levels, leading to the production of reactive oxygen species (ROS), NF-κB, JNK, ERK1/2, and, ultimately, the induction of inflammatory

genes and PGs and insulin resistance in human adipocytes.[99] Possible upstream signals of *trans*-10,*cis*-12 CLA mediated increased $[Ca^{2+}]$ i and inflammation included phospholipase C (PLC)[102] and diacylglycerol kinases (DGKs).[103] PLC, as an upstream enzyme that produces diacylglycerol (DAG), a substrate for DGK, and inositol-3-phosphate (IP3), an inducer of calcium release from the ER, was found to play an important role in *trans*-10,*cis*-12 CLA mediated activation of $[Ca^{2+}]$ i accumulation, inflammatory signaling, delipidation, and insulin resistance in human primary adipocytes.[102] DGKs are a family of kinases that phosphorylate DAG, resulting in the conversion of DAG into phosphatidic acid (PA). DAG and PA acted as second messengers that activated an array of target proteins, resulting in significant changes in cellular signaling.[104] DGKs, particularly DGK η, may also be involved in the regulation of *trans*-10,*cis*-12 CLA mediated inflammatory signaling, insulin resistance, and delipidation in primary human adipocytes.[103] On the basis of the studies by Shen et al. and Martinez et al., the mechanism of CLA-mediated inflammation and PPAR γ activity could be proposed (Figure 2).[102,103] *trans*-10,*cis*-12 CLA may activate the specific cell surface receptors, including G protein coupled receptor, G protein receptor, or protein tyrosine kinases, and consequently stimulate the translocation of PLC to the plasma membrane, thereby generating DAG and IP3 from PIP2. DGKs convert DAG into PA and, together with IP3, stimulate calcium release from ER. Increased intracellular calcium accumulation activates calcium-sensitive kinases, such as CaMKII, which promotes ROS production and MAPK activation. MAPK subsequently activates inflammatory signaling, NF-κB and AP-1. These inflammatory signals lead to a rise of secretion of inflammatory proteins, such as

DOI: 10.1021/jf505050c
J. Agric. Food Chem. 2015, 63, 1883−1895

IL-6, IL-8, and MCP-1, and antagonizes PPAR γ abundance and activity, thereby suppressing insulin-stimulated glucose uptake and lipogenesis.[102,103]

MODULATION OF PPAR γ BY CLA IN IBD

Inflammatory disorders including IBD, rheumatoid arthritis, atherosclerosis, metabolic syndrome, and ischemia/reperfusion injury are recognized as a major health problemd worldwide.[105] One common characteristic of these diseases is excessive production of pro-inflammatory mediators such as TNF-α, GM-CSF, IL-1, IL-6, IL-8, leukotriene B4, and PAF; the presence of highly activated inflammatory cells such as neutrophils, monocytes, and macrophages; and excessive production of ROS.[106] IBD is characterized by inflammation of the gastrointestinal tract and the most common IBD including ulcerative colitis and Crohn's disease and some atypical forms such as collagenous colitis and intractable colitis. Conventional therapies for IBD patients are represented by salicylates, steroids, immunosuppressants, and anti-TNF-α drugs. However, conventional therapies showed variable response rates and potential side effects. IBD patients tend not to adhere to conventional pharmacological therapy, mainly due to the fear of long-term side effects.[107] Thus, exploring novel therapeutic and preventive approaches for IBD is important and increasingly interesting.[108,109]

PPARs are the receptors for endogenous lipid molecules representing promising new targets for the treatment and prevention of inflammatory disorders such as IBD. The colon is a major tissue that expresses PPAR γ in epithelial cells and, to a lesser degree, in macrophages and lymphocytes. PPAR γ plays a role in the regulation of intestinal inflammation. Animal studies suggested that PPAR γ ligands have beneficial effects in different models of experimental colitis, with possible implications in the therapy of IBD.[109] Synthetic PPAR γ ligands such as troglitazone and rosiglitazone, have been proven effective in rodent models of IBD,[110,111] and their therapeutic efficacy is being tested in IBD clinical trials.[112,113] However, the universal application of rosiglitazone or rosiglitazone for the management and treatment of IBD is unlikely due to the reported serious side effects such as weight gain, increased bone fracture, fluid retention, and heart failure.[114] Interestingly, the use of dietary supplements such as CLA, CLNA, and probiotics (VSL#3) has proved beneficial on animal models of intestinal inflammation through the activation of PPAR γ.[115]

CLA has potent immunomodulatory effects in a wide range of inflammatory-based disorders including IBD,[116,117] atherosclerosis,[118,119] and diabetes.[120,121] The potent immunomodulatory effect of CLA is exhibited in an isomer-specific manner. Evidence suggested that *cis*-9,*trans*-11 CLA is responsible for the anti-inflammatory effect attributed to CLA, whereas *trans*-10,*cis*-12 CLA appears to be responsible for antiadipogenic effects.[122] The anti-inflammatory potential of *cis*-9,*trans*-11 CLA has been demonstrated in animal models of IBD and human study. For animal studies of IBD, two main standardized methods are used to produce an experimental animal model of IBD: (1) oral administration of dextran sulfate sodium (DSS) in drinking water; (2) intracolonic administration of trinitrobenzenesulfonic acid (TNBS).[123] A number of studies showed that CLA ameliorates experimental IBD in mice and pigs (Table 2).[116,117,124−127] CLA also was shown to ameliorate the IBD in humans. In this open-label study, oral CLA administration (6 g/day, 50:50 mixture of the *cis*-9,*trans*-11,*trans*-10,*cis*-12 CLA isomers) was well tolerated and suppressed the ability of peripheral blood T cells to produce pro-inflammatory cytokines, decreased disease onset, and increased the quality of life of patients with mild to moderate Crohn's disease.[128]

The protective effect of CLA against IBD could be mediated though PPAR γ activation.[116,124] Dietary CLA supplementation suppressed colonic inflammation and up-regulated colonic PPAR γ expression in pigs with bacterial-induced colitis.[124] Activation of colonic PPAR γ by CLA mediated protection from experimental IBD in mice with a targeted deletion of PPAR γ in immune and epithelial cells.[116] Furthermore, dietary CLA ameliorated disease activity, decreased colitis, and prevented adenocarcinoma formation in the PPAR γ-expressing floxed mice but not in the tissue-specific PPAR γ-null mice, suggesting that CLA ameliorates colitis and prevents tumor formation in part through a PPAR γ-dependent mechanism.[125] Indeed, besides induction of PPAR γ in vivo, other studies confirmed the increase of PPAR γ expression and activity in adipocytes,[129] skeletal muscle,[130] and macrophages[131,132] with CLA or CLA-rich diets. In contrast to the reduction in PPAR γ expression by *trans*-10,*cis*-12 CLA, treatment with *cis*-9,*trans*-11 CLA or mixtures of *cis*-9,*trans*-11 CLA and *trans*10,*cis*-12 CLA activated the expression of PPAR γ. This may be due to cell-type specificity of the response to CLA or isomer specificity because the *trans*-10,*cis*-12 CLA was able to reduce PPAR γ expression in adipocytes, but the *cis*-9,*trans*-11 CLA failed to show the same suppressive effect on PPAR γ activity.[133]

Trefoil peptides (TFF) were found to be involved into CLA-mediated DSS-induced colitis.[127] TFFs are small protease-resistant proteins characterized by a conserved cysteine-rich domain and comprise the gastric peptide (TFF1), the spasmolytic peptide (TFF2), and the intestinal trefoil factor (TFF3).[134] TFFs could be involved in IBD pathogenesis, and they could be a potential treatment option.[135] The colonic levels of TFF3 was increased after dietary supplementation of CLA-enriched diet, and the activation of TFF3 by CLA is mediated by PPAR γ, suggesting that the DSS-induced injury in mice is ameliorated by CLA through the colonic activation of PPAR γ, which in turn will increase the levels of TFF3.[127]

Interestingly, VSL#3 probiotic bacteria produce CLA locally in the gut and were shown to suppress colitis by targeting macrophage PPAR γ.[126] VSL#3 is a multistrain, high-potency probiotic preparation composed of four strains of lactobacilli (*Lactobacillus casei*, *Lactobacillus plantarum*, *Lactobacillus bulgaricus*, and *Lactobacillus acidophilus*), three strains of bifidobacteria (*Bifidobacterium longum*, *Bifidobacterium breve*, and *Bifidobacterium infantis*), and *Streptococcus thermophilus*. VSL#3 has been demonstrated to ameliorate colitis,[126] prevent colitis-associated colorectal cancer in animal models of colitis,[136,137] and induce remission in patients with ulcerative colitis.[138,139] VSL#3 treatment could produce *cis*-9,*trans*-11 CLA in vivo,[126,140] and a high concentration of *cis*-9,*trans*-11 CLA was found only in the mouse colon, but without systemic distribution in blood.[126] The loss of PPAR γ in myeloid cells abrogated the protective effect of VSL#3 and CLA in mice with DSS colitis, suggesting that PPAR γ possibly plays a vital role in VSL#3 and CLA amelioration of the colitis in mice. VSL#3 could suppress intestinal inflammation by altering colonic microbial diversity and enhancing microbial CLA production locally that in turn activates PPAR γ.[126] The CLA-producing probiotics may offer an alternative approach to conventional therapy in IBD by altering the intestinal microflora and enhancing CLA concentration; further exploration of the role of these bacteria in preventing human IBD is encouraged.

PUA-enriched PSO (approximately 80%)	male ICR CD-1 mice	0.5 wt % diet, 4 weeks	↓ perirenal and epididymal adipose tissue weight	143
genetically modified rapeseed oil containing PUA (2.5%)	male ICR CD-1 mice	0.25 wt % diet, 4 weeks	↓ perirenal and epididymal adipose tissue weight	143
PUA-enriched PSO (64.79%)	male CD-1 mice with high-fat feeding	61.79 mg/day PSO, 14 weeks	↓ body weight ↓ weight gain	144
PUA-enriched PSO (ND)	male C57BL/6J mice with diet-induced obesity	1% PSO wt diet, 12 weeks	↓ body weight ↓ body fat mass	145
α-ESA-enriched BGO (50%)	male C57BL/6J mice with diet-induced obesity	7.5 wt % diet, 5 weeks	↓ 21% body fat	146
α-ESA-enriched BGO (50%)	male C57BL/6J mice with diet-induced obesity	2.5, 5, and 7.5 wt % diet, 11 weeks	↓ 32, 35, and 65% of body fat	147
PUA-enriched PSO (70%) or α-ESA-enriched tung seed oil (70%)	male Golden Syrian hamsters	1.22−1.27 wt % diet, 6 weeks	no Δ body weight	148
α-ESA-enriched BGO (54.1%) or PUA-enriched PSO (76.1%)	male ICR mice	1 wt % diet, 6 weeks	no Δ body weight no Δ perirenal or epididymal adipose tissues	149
PUA-enriched PSO (ND)	male Wistar rats fed an obesogenic diet	0.5 wt % diet, 6 weeks	no Δ body weight no Δ white adipose tissue or interscapular brown adipose tissue weights	150

[a]PSO, pomegranate seed oil; BGO, bitter melon seed oil; PUA, punicic acid; α-ESA, α-eleostearic acid; ND, not determined; change; ↓ decrease.

MODULATION OF PPAR γ BY CLNA IN OBESITY

The effect of CLNA isomers on body weight showed inconsistent outcomes in animal obesity models (Table 3). CLNA mixtures prepared by alkaline isomerization reduced perirenal adipose tissue weight to a larger extent when compared with linoleic acid, CLA, and α-linolenic acid in Sprague−Dawley rats.[141] A PUA-enriched pomegranate seed oil (PSO) dietary supplement also reduced omental WAT weights, but not abdominal WAT weights in obese and hyperlipidemic OLETF rats.[142] Supplementation with PSO or genetically modified rapeseed oil containing PUA decreased the weight of perirenal adipose tissue in ICR CD1 mice in a dose-dependent manner.[143] Dietary supplementation with 61.79 mg/day of PSO significantly lowered the body weight and weight gain in mice with high-fat feeding, compared with the control.[144] In another study, dietary supplementation with 1% of PSO ameliorated high-fat diet induced obesity and insulin resistance in mice, independent of changes in food intake or energy expenditure.[145] Supplementation with α-ESA enriched bitter gourd seed oil (BGO) was shown to be more potent than soybean oil in attenuating high-fat diet induced body fat deposition in mice.[146,147]

In contrast, dietary supplementation with 1.22−1.27 or 1% of CLNA (α-ESA or PUA) for 6 weeks did not significantly change the body weight of hamsters or mice, respectively.[148,149] A recent paper also showed that dietary supplementation of 0.5% of PUA did not lead to decreased fat accumulation in adipose tissue, liver, or skeletal muscle when rats were fed an obesogenic diet.[150]

The potential mechanism by which CLNA isomers exert the antiobesity effect is not clear. Because *cis*-9,*trans*-11 CLA has no antiadiposity activity,[2,43] the antiadiposity potential of PUA and α-ESA cannot be attributed to CLA derived from α-ESA in vivo, because PUA and α-ESA are proved to be metabolized into *cis*-9,*trans*-11 CLA, rather than *trans*-10,*cis*-12 CLA.[151,152] PUA, α-ESA, and *trans*-10,*cis*-12 CLA might share a common metabolic or signaling pathway, leading to a qualitatively similar outcome in the WAT.[147] Similarly to *trans*-10,*cis*-12 CLA, CLNAs might exert their antiadiposity effect by induction of the expression or secretion of cytokines and inhibition of adipogenesis and preadipocyte differentiation through the regulation of PPAR γ.[141,146,153,154] BGO and CLNA mixtures were shown to elevate the TNF-α level in C57BL/6J mice with diet-induced obesity and Sprague−Dawley rats,[141,146] respectively, which are known to antagonize PPAR γ target gene expression.[90] PSO was also shown to inhibit the adipogenesis and differentiation and decrease the protein level of PPAR γ in 3T3-L1 preadipocytes.[153] Moreover, sustained activation of the ERK/MAPK signaling pathway, accompanied by PPAR γ phosphorylation, caused by α-ESA in the 3T3-L1 cell differentiation model might not only contribute to apoptosis but also have an inhibitory effect on adipogenesis.[154]

MODULATION OF PPAR γ BY CLNA IN IBD

PUA and IBD. Several in vivo studies assessed the anti-inflammatory effects of PSO and PUA on IBD intestinal inflammation and the model of necrotizing enterocolitis (NEC) (Table 2). Oral administration of pure PUA (400 μg/day) or 0.5 mL/day of PUA-enriched PSO for 10 days before TNBS injection in a colitis rat model ameliorated ulceration status and tissue damage, limiting neutrophil activation and lipid peroxidation.[106] Supplementation with 1% of dietary PUA ameliorated spontaneous pan-enteritis in an IL-10$^{-/-}$ mouse model of IBD for 42 days and in mice with experimental IBD during a 7 day challenge with DSS.[155] PSO has also been shown to be effective in a model of NEC. Oral administration with 1.5% of PSO decreased the incidence of NEC from 61 to 26% and the severity of necrotizing colitis, protecting the epithelial barrier and preserving the intestinal integrity in a neonatal model of NEC rats.[156] These results suggested that PUA- or PUA-enriched PSO could ameliorate intestinal inflammation and damage.

The underlying mechanisms by which PUA ameliorates experimental IBD are incompletely understood. Similarly to *cis*-9,*trans*-11 CLA, PUA was suggested as a potential PPAR γ agonist.[155,157,158] PUA was shown to robustly bind and activate PPAR γ, therefore increasing PPAR γ-responsive gene expression and ameliorating diabetes and gut inflammation.[159] PUA ameliorated spontaneous pan-enteritis in IL-10$^{-/-}$ mice and

DOI: 10.1021/jf505050c
J. Agric. Food Chem. 2015, 63, 1883−1895

DSS colitis, up-regulated Foxp3 expression in T-cells, and suppressed TNF-α, but the loss of functional PPAR γ or δ impaired these anti-inflammatory effects. The deletion of PPAR γ in macrophages completely abrogated the amelioration effect of PUA on experimental colitis, whereas the deletion of PPAR δ or intestinal epithelial cell-specific PPAR γ decreased its anti-inflammatory efficacy. These results strongly suggested that PUA ameliorates experimental IBD by regulating macrophage and T-cell function through PPAR γ- and δ-dependent mechanisms.[155]

α-ESA and IBD. α-ESA was also identified as a natural PPAR γ agonist by using complementary computational and experimental methods and found to be effective in ameliorating disease-associated phenotypes in mice with DSS colitis.[160] Activation of PPAR γ by α-ESA could play an important role in amelioration of DSS-induced IBD. The anti-inflammatory actions of α-ESA may be both PPAR γ-dependent and -independent responses that ameliorated disease activity and intestinal lesions in mice with DSS colitis.[160]

Targeting PPAR γ represents a promising avenue for developing novel prophylactic and therapeutic interventions for IBD[161,162] and obesity.[163] Due to the side effects of full thiazolidinedione agonists of PPAR γ, there is a demand for naturally occurring PPAR γ modulators from edible items with minimum adverse effect and high tolerance to the human body.[164] *trans*-10,*cis*-12 CLA has demonstrated antiobesity effects through regulation of expression and activity of PPAR γ, which is involved in reducing adipogenesis and lipogenesis and increasing inflammation. CLA (*cis*-9,*trans*-11 CLA or mixtures of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA) was also effective in ameliorating the experimental IBD though activation of PPAR γ. However, the safety of CLA is still of utmost concern and has been evaluated in numerous animal studies and human clinical trials.[4] A minority of studies have reported ambiguous or deleterious effects of CLA supplementation with regard to liver functions, milk fat depression, insulin resistance, and oxidative markers.[94,165−167] Although the safety of Clarinol and Tonalin TG 80, two oils with approximately 80% of the CLA 50:50 mixture of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 isomers, has been established for the proposed uses and daily doses (3.75 g of Clarinol and 4.5 g of Tonalin TG 80 corresponding to approximately 3 and 3.5 g of CLA, respectively) for up to 6 months by the EFSA Panel on Dietetic Products, Nutrition and Allergies. However, the safety of CLA consumption for periods >6 months has not been established under the proposed conditions of use.[168] These observations must be carefully considered, and further investigation is necessary before the widespread use of CLA as a functional food component.

PUA and α-ESA, which were identified as natural agonists of PPAR γ, have proven beneficial effect on animal models of intestinal inflammation. PUA and α-ESA also exerted an antiadiposity effect through regulation of PPAR γ. Acute toxicological studies have demonstrated that PUA is safe in rats.[169] Therefore, these plant-derived natural products are safer and may open the possibility to be used as functional foods and nutraceuticals. However, the exact mechanism by which PUA and α-ESA exert their physiological roles and human intervention studies are necessary to determine their beneficial effects on individuals with obesity or IBD.

In summary, CLA (*cis*-9,*trans*-11 CLA and *trans*-10,*cis*-12 CLA) and CLNA (PUA and α-ESA) play an important role in modulating the expression or activity of PPAR γ and that could in turn be employed as complementary treatment for obesity and IBD. Available evidence suggested that *trans*-10, *cis*-12 CLA reduces adipogenesis and lipogenesis in adipocytes and rodents by (1) regulating the expression PPAR and PPAR γ target genes and (2) modulating the transactivating activity of PPAR γ. Ligand-dependent PPAR γ transactivating activity is antagonized by *trans*-10,*cis*-12 CLA, possibly via PPAR γ phosphorylation by ERK and AMPK. The transactivating activity of PPAR γ could also be modulated by SIRT1 via binding directly or indirectly to PPAR γ in adipocyte. In addition, up-regulation of inflammatory signaling pathways by *trans*-10,*cis*-12 CLA increases the expression or secretion of cytokines and the activity of NF-κB, AP-1, and MAPK, which lead to inhibition of PPAR γ abundance and activity. Besides their antiobesity effect, CLAs also ameliorate experimental IBD through activation of PPAR γ. PUA and α-ESA are identified as natural agonists of PPAR γ and exert beneficial effects on animal models of intestinal inflammation through the activation of PPAR γ. In addition, PUA and α-ESA might exert their antiadiposity effect by induction of cytokine and inhibition of adipogenesis and preadipocyte differentiation through regulation of PPAR γ.

Some issues remain to be resolved before CLAs and CLNAs can be recommended to humans with confidence to improve health and quality of life, particularly regarding mechanisms and safety concerns. More well-controlled clinical trials with defined subject characteristics, study duration, and doses and preparations on the safety and physiological effects are urgently needed. Moreover, further studies are necessary to identify the diversified molecular signaling pathways and the crosstalk among these signaling pathways mediated by CLAs and CLNAs to provide valuable information on the efficacy, specificity, and potential side effects of CLAs and CLNAs.

ABBREVIATIONS USED

AMPK	AMP-activated protein kinase
ACC	acetyl-CoA carboxylase
AP-1	activator protein-1
aP2	adipocyte fatty acid binding protein
BGO	nitter gourd seed oil
CD-36/FAT	fatty acid translocase
C/EBP α	CAAT/enhancer binding protein α
CFA	conjugated fatty acid
CLA	conjugated linoleic acid
CLNA	conjugated linolenic acid
DAG	diacylglycerol
DGK	diacylglycerol kinases
DSS	dextran sulfate sodium
ER	endoplasmic reticulum
ERK	extracellular signal-related kinase
α-ESA	α-eleostearic acid
FAS	fatty acid synthase

DOI: 10.1021/jf505050c
J. Agric. Food Chem. 2015, 63, 1883−1895

GLUT4	insulin-dependent glucose transporter 4
HIF-1	hypoxia-inducible factor-1
IBD	inflammatory bowel disease
IL-1β	interleukin-1 beta
IL-2	interleukin-2
IL-6	interleukin-6
IL-8	interleukin-8
IL-10	interleukin-10
IP3	inositol-3-phosphate
JNK	cJun-NH_2-terminal kinase
MAPK	mitogen-activated protein kinase
MCP-1	monocyte chemoattractant protein-1
NEC	necrotizing enterocolitis
NF-κB	nuclear factor kappa B
PUA	punicic acid
PA	phosphatidic acid
PAI-1	plasminogen activator inhibitor-1
PLC	phospholipase C
PGs	prostaglandins
PPRE	PPAR-responsive regulatory element
PPAR	peroxisome proliferator-activated receptor
PSO	pomegranate seed oil
ROS	reactive oxygen species
SCD	stearoyl-CoA desaturase
SIRT1	sirtuin 1
TNF-α	tumor necrosis factor-α
TFF	trefoil peptides
TFF1	gastric peptide
TFF2	spasmolytic peptide
TFF3	intestinal trefoil factor
TG	triglyceride
TNBS	trinitrobenzenesulfonic acid
$[Ca^{2+}]$ i	intracellular calcium

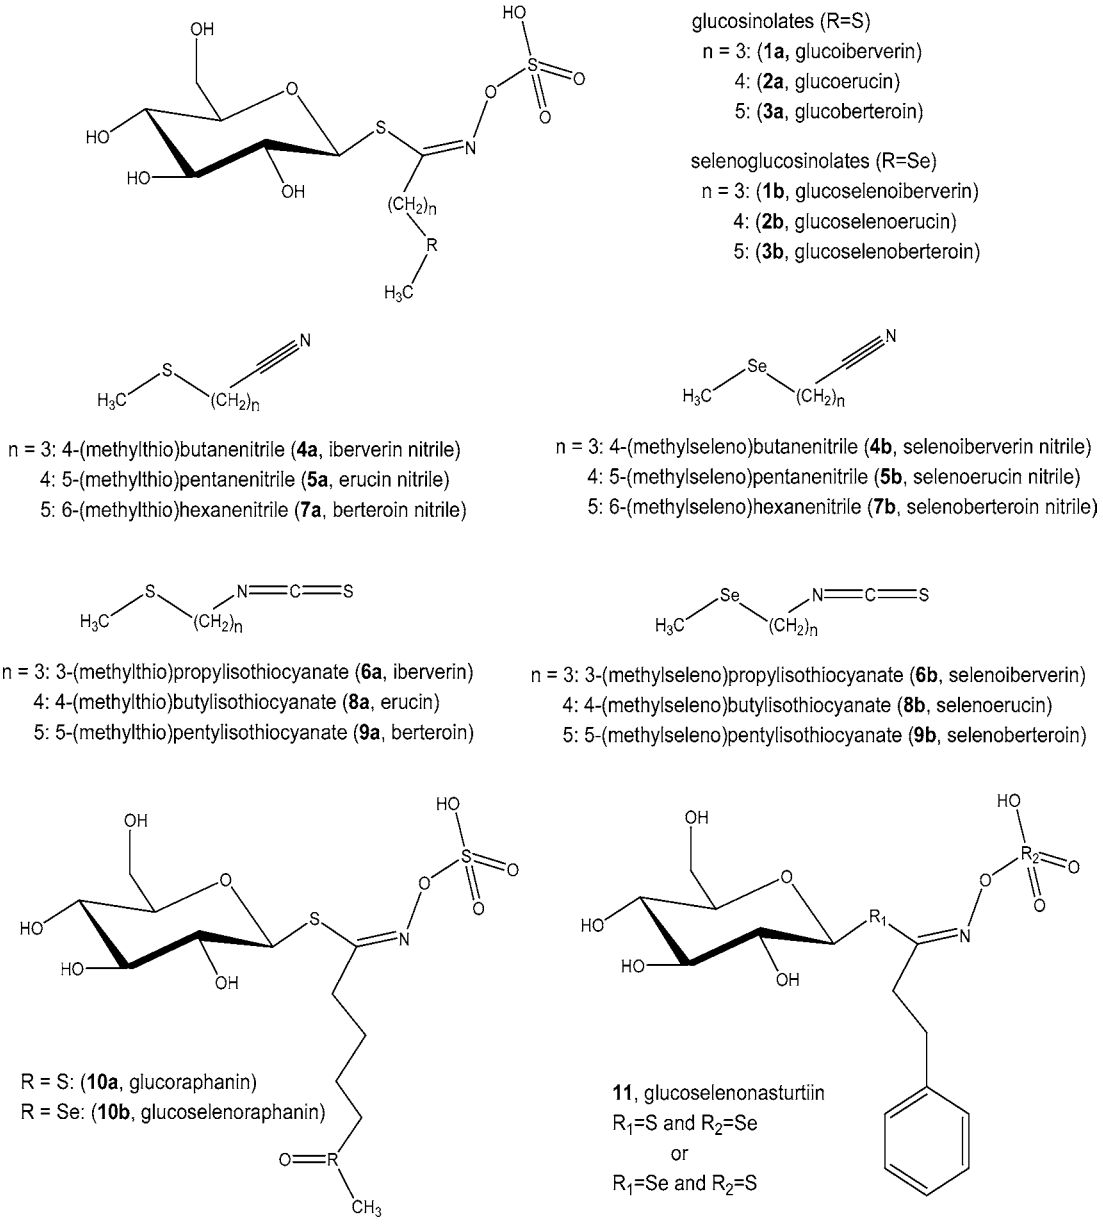

Figure 1. Structures of the glucosinolates and their modified aglycons (myrosinase enzyme hydrolysis products).

the only selenoamino acid incorporated into animal selenoproteins under direct genetic control. Selenoproteins are important in the control of cellular redox balance.[15] Additionally, the Brassicaceae contain the Se-specific enzyme selenocysteine methyltransferase, which catalyzes methylation of SeCys to methyl selenocysteine (3-(methylseleno)-L-alanine) and the downstream production of γ-glutamylselenomethyl selenocysteine (γ-glutamyl-3-(methylseleno)-L-alanine). Both of these modified amino acids have reported anticancer properties in mammals, the latter compound not directly so but as methyl selenocysteine to which it hydrolyzes in the intestinal tract.[14] At the cellular level it is proposed that the active cancer chemopreventative agent is actually methylselenol, which arises from the β-lyase hydrolysis of methyl selenocysteine.[14] The Brassicaceae are therefore of increasing interest for health benefits associated with their production of S-containing glucosinolates and selenoamino acids.

Recently, we reported several new Se-containing glucosinolates, and their aglycons, in the florets of broccoli and cauliflower and the tap roots of forage rape plants treated with sodium selenate fertilizer.[16] The selenoglucosinolates were of the methylseleno class (MeSe-GSLs), most likely derived from SeMet, and their downstream metabolites were methylseleno nitriles and isothiocyanates. In these experiments, the incorporation of Se into MeSe-GSLs, in the different tissues, appeared poorly correlated with the amounts of GSLs present. For example, forage rape tap roots had much higher concentrations of MeS-aglycons than the broccoli and cauliflower florets, yet the forage rape tap roots did not have correspondingly higher concentrations of the MeSe-aglycons.[16] Furthermore, broccoli is reported to have its highest total and aliphatic GSL concentrations in the florets,[17,18] but the highest concentrations of the major MeS-GSL glucoerucin[16,19] were found in the tap roots.[18] If incorporation of Se into glucoerucin is as efficient in the tap roots as it is in the florets, then the broccoli tap roots might produce higher concentrations of MeSe-GSLs.

Other workers have synthesized a number of isoselenocyanates: selenosulforaphane and several alkyl and phenylalkyl isoselenocyanates.[20,21] These synthetic compounds were reported as more bioeffective than their S analogues at reducing the incidence and progression of carcinogenesis. However, in these synthetic organoselenides the Se atom would have been located in the glucose moiety (e.g., compound **11**, R_1 = Se) of the parent GSL, in contrast with the methylseleno compounds found in planta, where the Se atom has been found only in the position derived from methionine.[16]

We were therefore interested in investigating which *Brassica* plant tissues had the highest concentrations of GSL compounds capable of incorporating Se, whether they also had the highest concentrations of the newly discovered methylseleno compounds, and also whether Se-GSLs with the Se incorporated into the thioglucose group could also be produced in *Brassica*.

MATERIALS AND METHODS

Plant Growth and Harvesting. The two broccoli (*B. oleracea* L. var. *italica*) cultivars chosen were a high-GSL-producing cultivar ('Booster', hereafter referred to as high-GSL broccoli) and a moderate- to low-GSL-producing cultivar ('Triathlon', hereafter referred to as low-GSL broccoli). Cauliflower (*B. oleracea* L. var. *botrytis* cv. 'Liberty') and forage rape (*B. napus* cv. 'Maxima') were also selected. Plants were grown from seed in separate 8 L bags of potting mix in a glass house at Plant & Food Research, Palmerston North, New Zealand. Plants were watered once daily via watering spikes for 1 min. Selenium feeding was commenced for broccoli and cauliflower following the emergence of immature floret material from the meristem and for forage rape once the plants had a well-established stem (ca. 16 cm from the soil to the top of the meristem) and approximately 10 fully expanded leaves. Plants were fed via the soil with 20 mL of 5.0 mM sodium selenate twice weekly, for 4 weeks, after watering. This Se application is equivalent to ca. 15 kg/ha, which is considerably higher than the 3−76 g/ha applied to agricultural and forage crops.[11] Broccoli produced at this high rate of Se application contained at least 500-fold more Se than control samples[22] but suffered no adverse effects upon its growth. Following the Se feeding, the leaves, stems, and lower stem/tap root (3−4 cm long) were harvested from all of the plants, after four months of growth, as well as mature floret tissue from the broccoli and cauliflower plants. For the forage rape roots, the outer fibrous ring was removed and only the inner pith was sampled. All material was immediately frozen in liquid nitrogen before storage at −80 °C until extraction.

Extraction of Glucosinolates for LC−MS Analysis. Triplicate extractions were performed on the tissue from selenized and duplicate extractions from control (nonselenized) plants, with each replicate comprising tissue from a separate plant. In the case of the leaves, for each replicate the two most recently expanded leaves were harvested from each of two separate plants (four leaves per replicate). For each replicate frozen tissue (2−10 g FW) was accurately weighed, ground with dry ice to a powder in a coffee grinder, and poured into boiling 70% ethanol (10 volumes (v/w)), which was refluxed for 5 min to inactivate the myrosinase.[8] Samples were cooled to 5 °C and concentrated in vacuo at 40 °C to volumes of ca. 5 mL. Pigments were removed from the concentrates by washing with an equal volume of dichloromethane (2× for the leaf and floret extracts), and solids were removed by centrifugation at 1000*g* for 1 min in a Hema-C centrifuge (Jouan, Saint Herblain, France). A cold (ice−water) acidic (0.5% AcOH) methanol extraction of GSLs was also performed on the high-GSL broccoli florets, based upon the method of Hsu et al.[23] The extracts were colorless, so pigment removal was not necessary. The amounts of glucoselenoraphanin in two replicates were compared with those in two parallel hot ethanolic extracts.

Extraction of Glucosinolate Hydrolysis Products (Modified Aglycons) for GC−MS Analysis. The same number of replicates was used as above for the glucosinolate extractions. For each replicate 3−5 g FW was accurately weighed and ground with dry ice to a powder in a coffee grinder. The sample was combined with 2 volumes (v/w) of prechilled diethyl ether on ice in a Schott bottle, which was sealed and left at 1 °C for a week with daily mixing before the solid material was frozen at −20 °C and the solvent poured off. The solvent extracts were dried ($MgSO_4$) and their volumes reduced to ca. 1.5 mL under a gentle stream of nitrogen.

LC−MS Analysis of Glucosinolates. Separations were performed on an Ultimate 3000 rapid separation liquid chromatograph (Dionex, Germering, Germany) with a micrOTOF-Q II mass spectrometer (Bruker Daltonics, Bremen, Germany) fitted with an electrospray source operating in negative mode. Sample injections (1 μL) were made onto a 50 mm × 2.1 mm i.d., 1.8 μm, Zorbax SB-C18 (Agilent) analytical column maintained at 50 °C and with a flow of 400 μL/min. Solvent A was H_2O/MeOH (10:90, v/v), and solvent B was HCO_2H/H_2O (0.5:99.5, v/v). The solvent ramp was 1:99 (solvent A:solvent B) from injection to 0.5 min, followed by a linear gradient to 30:70 (0.5−8 min), to 75:25 (8−13 min), and to 100:0 (13−15 min) and holding at 100:0 (15−17 min). The micrOTOF-Q II source parameters were as follows: 200 °C; drying N_2 flow, 8 L/min; nebulizer N_2, 4 bar (400 kPa); end plate offset, −500 V; capillary voltage, +3500 V; mass range, 100−1500 Da; 2 scans/s. Postacquisition internal mass calibration used sodium formate clusters with the sodium formate delivered by a syringe pump at the start of each analysis. MS data were processed by Compass DataAnalysis (Bruker Daltonics). The external standard used for quantitation (using $[M - H]^-$ current peak areas) was glucoerucin, **2a** ([4-(methylthio)butyl]glucosinolate) (Cfm Oskar Tropitzsch, Marktredwitz, Germany). The external standard and the plant extracts were spiked with an internal standard, epicatechin (Sigma-Aldrich, Auckland, New Zealand), to enable correction for sample volumes and for changes in LC−MS system responses. Identification of the S- and Se-GSLs by high-resolution LC−MS/MS has been described previously.[16]

Total Elemental Se Present as GSLs in the Plant Tissues. The total concentration of elemental Se present as MeSe-GSLs in each plant part was calculated by summing the concentrations of elemental Se in each of the individual MeSe-GSLs, using the molecular weight of the GSLs and the percentage of that MW that was constituted by elemental Se.

GC−MS Analysis of Glucosinolate Hydrolysis Products (Modified Aglycons). Separations were performed on an Agilent 6890N gas chromatograph coupled to a Waters GCT time-of-flight (ToF) mass spectrometer with an EI energy of 70 eV and a scan time of 0.4 s. Splitless injections of 1 μL over 30 s were made at 220 °C onto a 20 m × 0.18 mm i.d. × 0.18 μm film, Stabilwax (Restek, Bellefonte, PA) capillary column with a He flow of 0.9 mL/min. The oven temperature program was 1 min at 35 °C, 3 °C/min to 100 °C, and 7 °C/min to 240 °C, which was held for 5 min. Compounds were quantitated (using M^+ peak areas) against the synthetic[16] external standard selenoerucin nitrile, **5b**, $CH_3SeC_4H_8CN$, at concentrations of 0.02, 0.08, and 0.5 μL/L, to provide a response calibration curve. To keep the concentrations of compounds in the solvent extracts in the linear range of the MS detector, samples were injected neat and at 10- and 50-fold dilutions. All external standards and plant extracts were spiked with an internal standard (pentadecafluorooctanol) (Pierce Chemicals, Rockford, IL) to enable correction for extract sample volumes and changes in GC−MS system responses.

GC−MS Data. 6-(Methylseleno)hexanenitrile, $CH_3SeC_5H_{10}CN$ (Figure 1). RI (Wax) 2109. HR-ToF-EIMS: *m/z* 191.0194 (−1.9 mDa), $[M]^+$. Figure 2. Comparison between the mass spectra (EI, 70 eV) of (A) 6-(methylthio)hexanenitrile (berteroin nitrile, **7a**) and (B) its Se analogue 6-(methylseleno)hexanenitrile (selenoberteroin nitrile, **7b**), the latter compound being newly reported.

of the number of replicates. Statistical differences between sample means were analyzed using Student's *t* test.

RESULTS AND DISCUSSION

New Se-Containing Metabolites. This study targeted the methylthio-containing family of glucosinolates (MeS-GSLs) and their aglycons, which represent about 10% of the total glucosinolate content of the *Brassica* investigated and are the glucosinolates known to assimilate Se.[16] In addition to nine previously discovered organoselenides, **1b**–**9b** (Figure 1),[16] we have identified three new Se-containing metabolites. Glucoselenoraphanin, **10b**, was identified in high-GSL broccoli florets, and a Se-containing isomer of gluconasturtiin, **11** ((2-phenylethyl)glucosinolate), was tentatively identified in forage rape tap roots. These compounds are the Se analogues of the most abundant GSLs in these tissues. In addition, selenoberteroin nitrile, **7b** (6-(methylseleno)hexanenitrile), was tentatively identified in the tap roots and stem of forage rape.

New Compound Identification. Glucoselenoraphanin, **10b**, was identified from its pseudomolecular ion $C_{12}H_{22}NO_{10}S_2Se$, $[M - H]^-$, with a distinctive Se isotope pattern. It eluted 0.6 min after glucoraphanin and 4.1 min before glucoselenoerucin, **2b**, on the reversed phase LC column. **10b** constituted less than 0.08% of the glucoraphanin and 1.3% of the **2b** present in broccoli florets. Several diagnostic MS/MS daughter ions were obtained for glucoselenoraphanin by fragmentation of the pseudomolecular ion:[24] the thioglucose group $C_6H_{11}O_5S^-$, which precluded the attachment of the Se atom to glucose; the glucose sulfate ion $C_6H_{11}O_6SO_3^-$, from rearrangement and neutral loss of $CH_3Se(O)C_4H_8N{=}C{=}S$; $C_6H_{11}O_5SSO_3^-$, from rearrangement and neutral loss of $CH_3Se(O)C_4H_8N{=}C{=}O$; $C_{11}H_{18}NO_9S_2$, from neutral loss of CH_3SeOH. These fragments all indicated that the Se was located neither in the thioglucose nor in the sulfate moieties but was present as a selenoxide derived from SeMet as observed for the other major selenoglucosinolates discussed here.

Glucoraphanin, the parent GSL of sulforaphane, is the most abundant S-containing GSL in broccoli[8] and seriously overloaded the detector of the mass spectrometer for the broccoli florets we analyzed. Despite these very high levels of glucoraphanin, we did not identify its selenoxide analogue **10b** in any of the selenized *Brassica* in our previous study in which a low-GSL broccoli was selenized.[16] Selenoxides are generally considered to be thermally unstable;[25] hence, it was surprising to identify glucoselenoraphanin. Thermal instability may however explain the extremely low levels of selenization (<0.08%) observed for this particular glucosinolate. Given that the glucosinolates were extracted in boiling 70% ethanol, the concentration of glucoselenoraphanin in the broccoli may be higher than we have measured. Another possibility is that it accumulates due to autoxidation of glucoselenoerucin in the sample during cold storage prior to analysis.

The glucoraphanin aglycons sulforaphane ($CH_3S(O)$-C_4H_8NCS) and sulforaphane nitrile ($CH_3S(O)C_4H_8CN$) are well-known in *Brassica*,[26,27] but were not identified in this study as these compounds eluted after the 45 min run time used on the polar GC column employed here. Considerable amounts of both compounds were identified in samples run on a less polar (DB-5) GC column (data not shown), but their selenoxide analogues were not detected as expected due to their thermal instability.

Given the interest in sulforaphane as a compound associated with inhibition of carcinogenesis and the potential importance of its Se analogue, we investigated the effect of cold acidic methanolic versus hot ethanolic extractions of GSLs from high-glucoraphanin broccoli tissues to determine if there exist significant concentrations of glucoselenoraphanin, **10b**, and thus possibly selenosulforaphane, in selenized *Brassica*. The two replicate cold acidic methanol extracts contained concentrations of glucoraphanin similar to those in the hot ethanolic extracts. However, only one of the cold methanolic extracts contained detectable glucoselenoraphanin, which occurred at about 20% of the concentrations found in the two hot ethanolic extracts. Selenoxides are used as mild oxidizing agents, the reaction generally taking place under mildly acidic conditions.[28] Therefore, extraction with acidic methanol was counterproductive, possibility having resulted in the reduction of the glucoselenoraphanin to glucoselenoerucin. There was also approximately 14-fold more glucoselenoerucin in the hot-extracted samples than in the cold acidic extracts, whereas there was only 25% more glucoerucin in the hot-extracted samples. Clearly there is a problem with the acidic extraction of the selenoglucosinolates, and the question of whether there exist substantial quantities of glucoselenoraphanin and selenosulforaphane in selenized broccoli remains to be answered.

Glucoselenonasturtiin, **11**, $C_{15}H_{20}NO_9SSe$, $[M - H]^-$, was the other glucosinolate identified, with a distinctive Se isotope pattern, eluting 0.5 min after gluconasturtiin. The site of selenization remains unknown as the samples were too dilute for LC–MS/MS analysis. This Se-GSL constituted less than 0.04% of the total gluconasturtiin and was a very minor contributor to the Se-GSL content of the forage rape.

We did not unambiguously detect any GSLs, or their aglycons, containing the Se atom in the isothiocyanate moiety, as produced in synthetic selenosulforaphane and alkyl and phenylalkyl isoselenocyanate compounds.[20,21] There have been other reports of the incorporation of trace amounts of Se into *Brassica* glucosinolates and their aglycons. Radioactive selenosinigrin was identified in the sinigrin (2-propenylglucosinolate) fraction isolated from horseradish (*Armoracia lapathidolia)* leaves treated with radioactive $Na_2{}^{75}SeO_4$.[29] Similarly, selenized gluconasturtiin was identified in the hairy

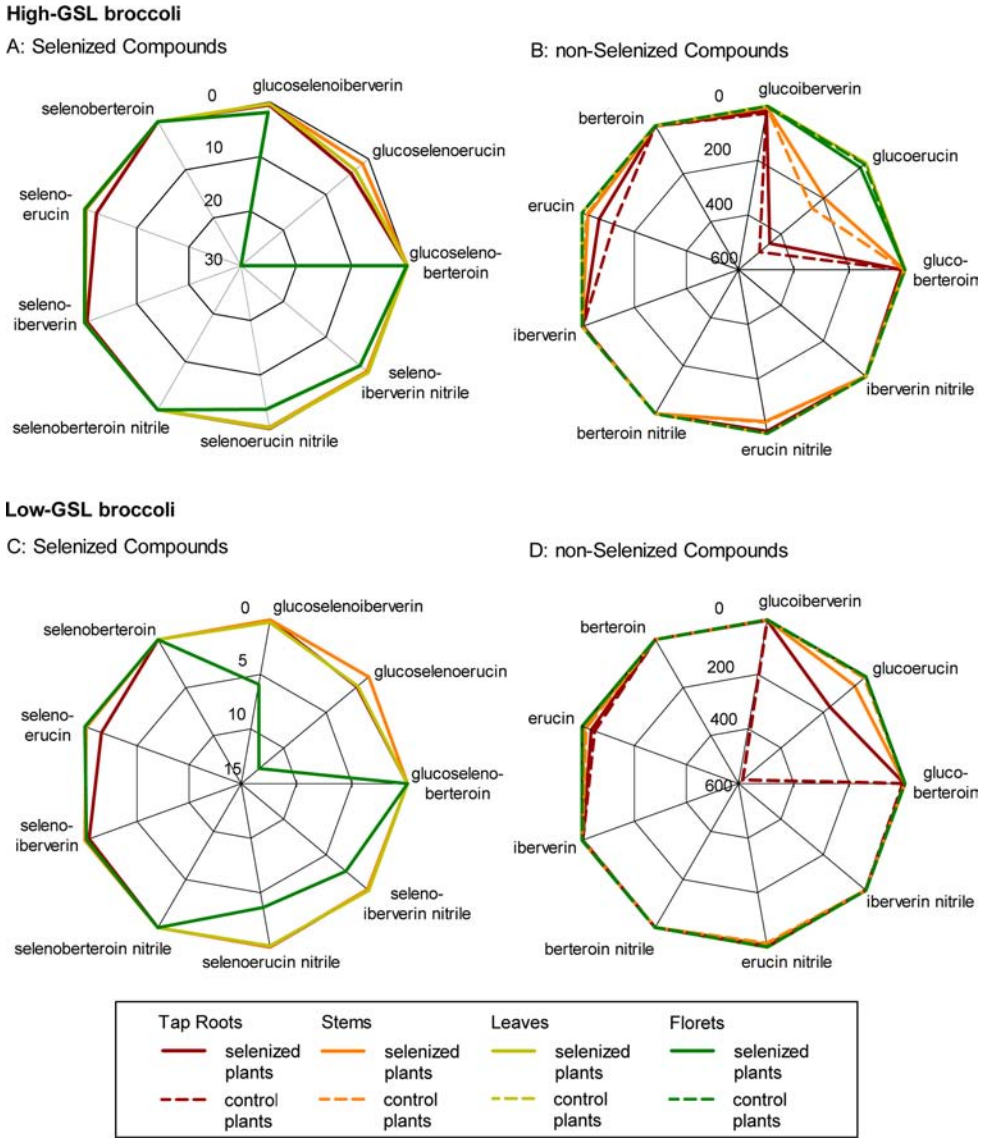

Figure 3. Glucosinolates and their nitrile and isothiocyanate hydrolysis products (modified aglycons) in the tap roots, stems, leaves, and florets of broccoli fertilized with 5 mM sodium selenate. (A) Selenized compounds in high-GSL broccoli: concentrations (mg/kg FW) of glucoselenoiberverin, glucoselenoerucin, and glucoselenoberteroin and their modified aglycons. (B) Nonselenized compounds in high-GSL broccoli: effect of Se fertilization on the concentrations (mg/kg FW) of glucoiberverin, glucoerucin, and glucoberteroin and their aglycons. (C) Selenized compounds in low-GSL broccoli: concentrations (mg/kg FW) of glucoselenoiberverin, glucoselenoerucin, and glucoselenoberteroin and their modified aglycons. (D) Nonselenized compounds in low-GSL broccoli: effect of Se fertilization on the concentrations (mg/kg FW) of glucoiberverin, glucoerucin, and glucoberteroin and their aglycons. Quantitation of the GSLs was by LC−MS as glucoerucin equivalents, and that of the modified aglycons was by GC−MS as erucin nitrile equivalents. Values are the average of three samples for selenized plants and two samples for the control plants, each replicate from a separate plant.

root cultures of *Nasturtium officinale* treated with a growth medium containing inorganic Se.[30] In neither case was it determined whether the Se was in the thioglucose or the sulfate group. A confident determination of the location of selenization in a glucosinolate was made in *Stanleya pinnata* plants grown hydroponically with Na_2SeO_3. The researchers identified 3-butenyl isoselenocyanate, but with a very low level of Se incorporation.[31] Even though similar concentrations of S and Se were applied, the Se aglycon was at less than 0.05% of the concentration of its S analogue. This is similar to the very low incorporation of Se into gluconasturtiin and glucoraphanin reported here and suggests that biosynthesis via SeMet provides the only efficient route for incorporation of Se into *Brassica* glucosinolates.

Selenoberteroin nitrile has not been reported in the literature, and our identification was based upon its order of elution in the gas chromatograph (after berteroin nitrile) and its mass spectrum shown in Figure 2, along with that of berteroin nitrile, **7a**. Berteroin nitrile has been reported in broccoli and cauliflower[32] and in forage rape roots[10,33] and buds.[34] We have previously identified both glucoberteroin and glucoselenoberteroin in broccoli and forage rape.[16]

Methyl thiocyanate and methyl selenocyanate were also identified in broccoli and cauliflower leaves and florets,[16] and methyl thiocyanate was identified in the leaves of forage rape (data not shown). We could not identify a parent GSL for these compounds nor find a literature reference for the occurrence of such a GSL. These two compounds may result from the

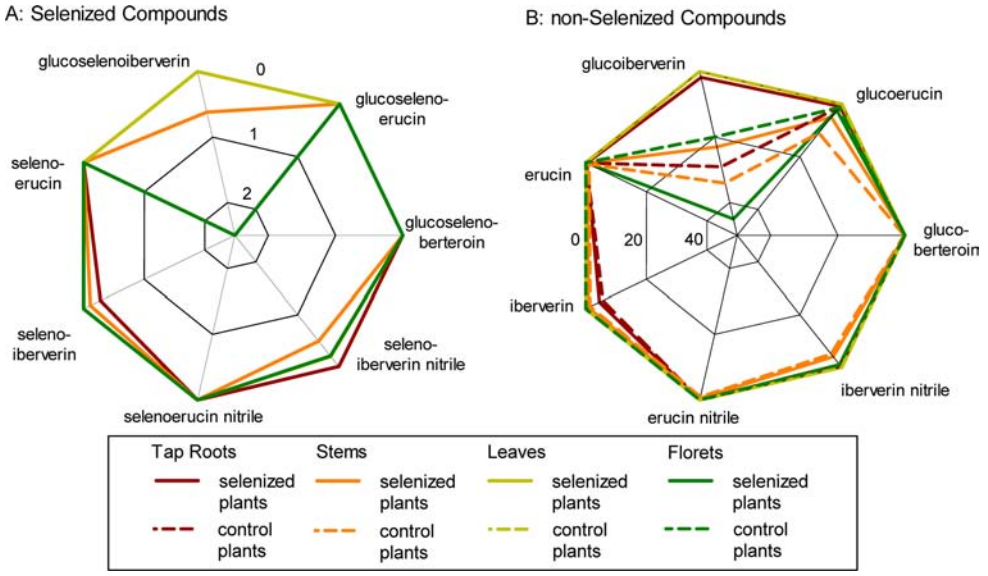

Figure 4. Glucosinolates and their nitrile and isothiocyanate hydrolysis products (modified aglycons) in the tap roots, stems, leaves, and florets of cauliflower fertilized with 5 mM sodium selenate. (A) Selenized compounds: concentrations (mg/kg FW) of glucoselenoiberverin, glucoselenoerucin, and glucoselenoberteroin and their modified aglycons. (B) Nonselenized compounds: effect of Se fertilization on the concentrations (mg/kg FW) of glucoiberverin, glucoerucin, and glucoberteroin and their modified aglycons. Quantitation of the GSLs was by LC−MS as glucoerucin equivalents, and that of the modified aglycons was by GC−MS as erucin nitrile equivalents. Values are the average of three samples for selenized plants and two samples for the control plants, each replicate from a separate plant.

methylation of thiocyanate and selenocyanate ions by a thiol methyltransferase (TMT).[35]

MeSe-GSL Concentrations in Broccoli. A high-GSL-producing cultivar ('Booster') and a moderate- to low-GSL-producing cultivar ('Triathlon') were chosen to examine the effect of Se fertilization on GSL production and to determine if high Se incorporation was peculiar to high-GSL-producing cultivars. In the high-GSL broccoli the concentrations of selenizable GSLs in the tap roots were 70 and 2200 times higher than in the florets and leaves, respectively (Figure 3B). The low-GSL cultivar had no detectable selenizable GSLs in the florets. Despite this, the florets had the highest MeSe-GSL concentrations, the predominant compound being glucoselenoerucin, **2b** (Figure 3A,C). The leaves and florets of the low-GSL broccoli also contained glucoselenoiberverin, **1b**, as a significant proportion of the MeSe-GSL content, which was not the case in high-GSL broccoli, possibly because when the latter was selenized, it showed a very large increase in its glucoerucin concentrations. In both cultivars, MeSe-GSL concentrations in the tap roots, leaves, and stems were about 10% of those in the florets (Figure 3A,C). Glucoselenoerucin and glucoerucin, **2a**, were the main MeSe- and MeS-containing compounds in all tissues (Figure 3A,D).

The MeS-GSLs of the stems and tap roots were around 1% selenized, the florets were 50% and 97% selenized (high-GSL and low-GSL broccoli, respectively), and the leaves were around 70% selenized. Thus, even though the concentrations of selenizable GSLs were low in the leaves, the measured MeSe-GSL concentrations were similar to those in the roots and stems. Treatment of these plants with Se did not commence until the florets started to emerge from the meristem, when the plant was diverting resources to the development of floret and leaf tissue. This may explain the greater accumulation of MeSe-GSLs in the growing florets and leaves than in the stems and tap roots. In accord with this result, sulfur fertilization of broccoli gave consistently higher assimilation and incorporation of S into GSLs in the florets and leaves compared to the roots.[17] This selective accumulation of MeSe-GSLs into the florets could be used to most economically produce high-Se broccoli.

Differential Alteration of the Total Concentrations of MeS-GSLs in Broccoli by Selenization. In selenized high-GSL broccoli, the total concentrations of the MeS/Se-GSLs were slightly, but not significantly, lower in the roots and stems but significantly higher in the leaves (20-fold) and florets (8-fold) than in the control plants, due to the presence of glucoselenoerucin and higher concentrations of glucoerucin (Figure 3A,B). In a study of floret GSL concentrations, Se fertilization caused an average 36% reduction in total GSL concentrations, which was mostly due to lower glucoraphanin levels, which we did not examine.[19] Robbins et al.[36] reported that very high levels of Se fertilizers reduced the concentrations of the aliphatic but not the indole GSLs. Kim and Juvik[37] reported that different broccoli cultivars displayed different responses to Se fertilization, with one of the five cultivars studied showing a small nonsignificant increased aliphatic GSL accumulation while the other four cultivars showed decreases.

MeSe-GSL Concentrations in Cauliflower. The highest concentrations of cauliflower MeSe-GSLs were in the florets (Figure 4A), but Se incorporation was much lower than in broccoli. MeSe-GSLs in the cauliflower florets totaled 2.5 mg/kg FW compared with 32.4 and 18.8 mg/kg FW, respectively, in the high- and low-GSL broccoli. While the major MeSe-GSL in broccoli was glucoselenoerucin, **2b**, the single MeSe-GSL in cauliflower florets and stems was glucoselenoiberverin, **1b**. Its sulfur analogue glucoiberverin, **1a**, is the major cauliflower MeS-GSL, which predominated in all tissues apart from the leaves in which GSLs were not detected.[8,9]

The cauliflower stems had more MeS-GSLs than low-GSL broccoli and less than the high-GSL broccoli stems, but with similarly low Se incorporation. MeSe-GSLs were not found in cauliflower tap roots whose MeS-GSL concentrations were

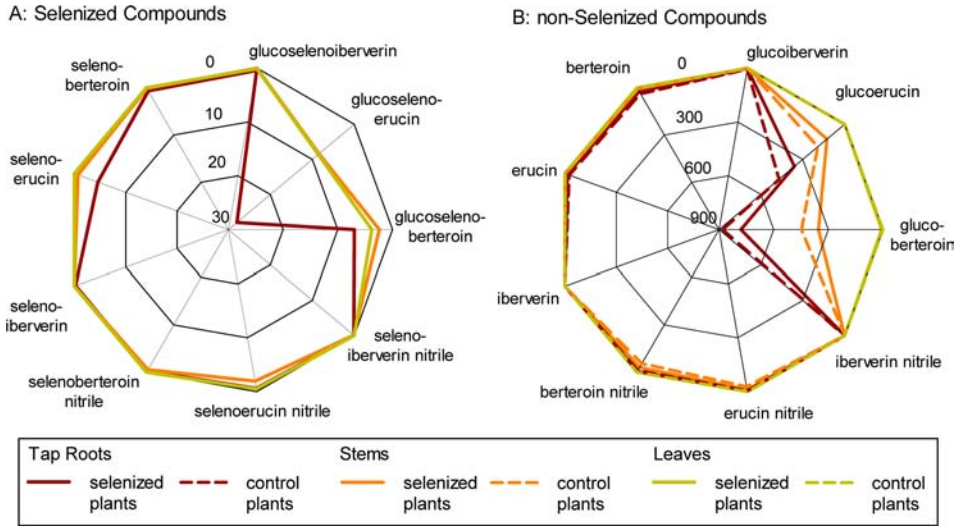

Figure 5. Glucosinolates and their nitrile and isothiocyanate hydrolysis products (modified aglycons) in the tap roots, stems, and leaves of forage rape fertilized with 5 mM sodium selenate. (A) Selenized compounds: concentrations (mg/kg FW) of glucoselenoiberverin, glucoselenoerucin, and glucoselenoberteroin and their modified aglycons. (B) Nonselenized compounds: effect of Se fertilization on the concentrations (mg/kg FW) of glucoiberverin, glucoerucin, and glucoberteroin and their modified aglycons. Quantitation of the GSLs was by LC−MS as glucoerucin equivalents, and that of the modified aglycons was by GC−MS as erucin nitrile equivalents. Values are the average of three samples for selenized plants and two samples for the control plants, each replicate from a separate plant.

similar to those in the stems and florets (Figure 4A) and at a mere 5% of the concentrations found in the broccoli tap roots. We did not detect Se analogues of the cauliflower GSLs glucoerucin and glucoberteroin (Figure 4B). The major cauliflower GSL is the indolic glucobrassicin in contrast to glucoraphanin in broccoli.[8,9]

Differential Alteration of the Total Concentrations of MeS-GSLs in Cauliflower by Selenization. In the selenized cauliflower both the tap roots ($P < 0.08$) and stems had lower concentrations of MeS-GSLs than the control plants, while the florets had higher, but not significantly so, concentrations of MeS-GSLs (Figure 4B). Most of this increase was due to glucoiberverin, although the variance in these data was high.

MeSe-GSL Concentrations in Forage Rape. Selenium incorporation into the forage rape tap root GSLs was low (3%, Figure 5, part A vs part B) as seen previously,[16] but 3 times higher than in the broccoli. Also, the total concentration of MeS-GSLs (1360 mg/kg FW) in the forage rape tap roots was 2 times that measured in broccoli and 40-fold higher than in cauliflower tap roots. Therefore, the forage rape tap roots had MeSe-GSL concentrations similar to those in the broccoli florets, with the major compound in both cases being glucoselenoerucin. The major GSL in forage rape tap roots is gluconasturtiin, **11**, which has been measured at 1900 mg/kg FW,[10] and which only incorporated trace amounts of Se.

The concentrations of MeS-GSLs and MeSe-GSLs in the forage rape stems and leaves were both higher than found in the other *Brassica*, so overall, forage rape plants had higher total concentrations of MeSe-GSLs than the other *Brassica* studied, despite not having the floret structure which contained most of the MeSe-GSLs in broccoli and cauliflower. The summed concentrations of all MeSe-GSLs, in all tissues studied, were 59.1 mg/kg (forage rape), 42.1 mg/kg (high-GSL broccoli), 21.7 mg/kg (low-GSL broccoli), and 3.1 mg/kg (cauliflower).

Glucoberteroin, **3a**, was the most abundant MeS-GSL in forage rape at 2 times the concentration of glucoerucin, **2a** (Figure 5B). The reverse was observed for the MeSe-GSLs with glucoselenoerucin at up to 4 times the concentration of glucoselenoberteroin (Figure 5A), indicating a differential incorporation of Se. Glucoiberverin and glucoselenoiberverin were both present as minor GSLs. The three GSLs glucoberteroin, glucoerucin, and glucoiberverin have previously been reported as the main MeS-GSLs in the roots of other forage rape cultivars.[10,38]

Modified Aglycons from Hydrolysis of the GSLs. A new selenium-containing aglycon, selenoberteroin nitrile, **7b** (6-(methylseleno)hexanenitrile) (Figure 1), in forage rape is reported for the first time (Figure 2). Se aglycons were present in extracts of all tissues of the Se-fed plants, though varying considerably in numbers of compounds and concentration (Figures 3−5). They loosely reflected the presence and concentration of the parent MeSe-GSL, but there were occurrences of MeSe aglycons without their MeSe-GSL precursors being detected and vice versa, viz., the aglycons selenoiberverin and selenoerucin in low-GSL broccoli without either of their GSL parents and glucoselenoberteroin in high-GSL broccoli florets without any of its aglycons. Similarly, in cauliflower the presence of the Se aglycons in all plant parts infers the presence of their corresponding Se-GSLs even though we did not identify them in the tap roots or leaves. Conversion of GSLs to the modified aglycons is influenced considerably by the conditions operating during tissue disruption.[27,39,40] We have not attempted to optimize this conversion, but breakdown of the MeSe-GSLs into the MeSe aglycons appears to occur at an efficiency similar to the formation of MeS aglycons.

The aglycon organosulfides identified here have previously been reported from broccoli florets,[32,41] although most interest has been in sulforaphane and sulforaphane nitrile because of the putative anticancer properties of the former[26,42] and possibly because it is the main aglycon from broccoli.[26] Comparisons between the amounts of particular aglycons, such as sulforaphane, have been conducted from different parts of broccoli plants,[43,44] but we have not been able to find reports that discuss the range of compounds from the different tissues. We recently identified the MeSe aglycons from broccoli

DOI: 10.1021/jf505963c
J. Agric. Food Chem. 2015, 63, 1896−1905

florets,[16] these tissues being of interest because they are the most consumed parts of these plants. The current study is the first we are aware of in which the distribution of MeS- and MeSe-GSL aglycons produced from different parts of broccoli plants has been examined.

All the cauliflower MeS aglycons reported in the present study (Figure 4B) are well-known.[32,41,45,46] However, as with broccoli, there is little information reporting the range of aglycons from different parts of cauliflower plants. In steam distillates of cauliflower florets and leaves, the summed nitrile and isothiocyanate concentration was higher in the florets,[46] as we observed. The MeS aglycons reported by these workers were iberverin, iberverin nitrile, erucin, and erucin nitrile. We have not been able to find other reports of MeS aglycons from plant parts of cauliflower and no reports of MeSe aglycons, apart from our previous paper.[16]

The complement of nitrile and isothiocyanate MeSe aglycons identified in extracts from forage rape tap roots (Figure 5A) reflected the presence of all three MeSe-GSLs in this tissue. Previously, we reported aglycons from forage rape tap roots, but not from the stems or leaves.[16] Erucin, erucin nitrile, berteroin, and berteroin nitrile have been reported by other workers from the tap roots, but not from the leaves and stems of forage rape.[10] We also identified iberverin and iberverin nitrile from the tap roots and iberverin nitrile, erucin nitrile, berteroin nitrile, erucin, and berteroin from the stems and leaves: these compounds have not previously been reported from forage rape.

Differential Alteration of the Concentrations of GSL Hydrolysis Products by Selenization. The total concentrations of modified aglycons in plant parts of some *Brassica* responded to selenization similarly to those of their GSLs. There were significantly higher summed concentrations of nitriles and isothiocyanates in the broccoli leaves (28-fold) and florets (7-fold), while there was a reduction, but not significantly, in their concentrations in the broccoli tap roots (ca. 40%) and in forage rape tap roots (35%) and stems (40%). The other plant parts did not display notable changes in the concentrations of these compounds as a result of selenization. While high-Se broccoli florets contain more MeS/Se aglycons, the reverse is reported for sulforaphane. In very high Se broccoli florets, Robbins et al.[36] measured lower concentrations of glucoraphanin and concentrations of sulforaphane reduced to 20% of those in the control plants. As a consequence, the biological activity of such broccoli with respect to sulforaphane may be reduced. In a study on the effect of selenized broccoli extracts upon mouse hepatoma cells, the selenized broccoli inhibited oxidative DNA damage, but the concomitant low sulforaphane concentrations reduced the ability of the broccoli extract to induce phase II detoxification proteins, which also exhibit antioxidant activity.[47] In broccoli with total selenium concentrations at edible levels, these complications may not arise. In a recent study glucoraphanin and sulforaphane concentrations were not adversely affected under more modest Se fertilization regimes which produce edible broccoli.[48]

Use of Selenized *Brassica* in Biological Experiments. Table 1 estimates the amounts of elemental Se present as Se-GSLs in each plant tissue. Cauliflower and broccoli had the highest concentrations of GSL-derived Se in their florets, between 4- and 10-fold higher than in their other tissues. For forage rape, the tap roots had the highest concentration of GSL-derived Se, at around 3-fold higher than in its other tissues. Therefore, the forage rape roots and the broccoli florets would be the best sources for Se-GSLs. A 100 g portion of selenized high-GSL broccoli floret, produced in this experiment, would however contain 550 μg (5.5 ppm) of elemental Se as Se-GSLs. This amount of selenium is above both the recommended minimum and recommended maximum daily Se intake levels of 55−90 and 400 μg/d, respectively.[49,50] Selenium is present in *Brassica* in several other chemical forms, and Finley et al., who used a similar fertilization regime for broccoli, measured a total elemental Se concentration of 500 μg/g DW. A 100 g (FW) portion would contain approximately 5 mg of elemental Se.[22] For biological testing, extracts of this plant material could be used to ensure suitable levels of MeSe-GSLs and of Se, particularly if they are shown to be beneficial to human health. Alternately, florets of broccoli grown with low-Se fertilization, to produce total Se at levels safe for human consumption, also contain smaller amounts of glucoselenoerucin and glucoselenoiberverin and some of their selenium isothiocyanate and selenium nitrile products.[48] The precise concentrations of glucoselenoraphanin and selenosulforaphane in these *Brassica* remain uncertain, and further work is required to develop "gentle" extraction methods for their quantitation. Discovery of these Se-GSLs, together with knowledge of their capacity to produce Se-containing nitriles and isothiocyanates, and of their distribution in planta, provides new opportunities for investigating how consumption of *Brassica* vegetables may impact human health.

Table 1. Concentrations of Elemental Se Present as Se-GSLs in the Plant Parts of Broccoli, Cauliflower, and Forage Rape (mg/kg FW)[a]

plant part	high-GSL broccoli Se	low-GSL broccoli Se	cauliflower Se	forage rape Se
florets	5.5 (0.8)	3.3 (1.2)	0.44 (−)	
leaves	0.58 (0.41)	0.26 (0.24)		2.2 (1.2)
stems	0.84 (0.35)		0.11 (−)	1.8 (0.98)
roots	0.79 (0.2)	0.24 (0.03)		6.0 (2.5)

[a]Values for each tissue are the sums of the elemental Se present in each of the selenized glucosinolates and were calculated from the concentration and molecular weight of each Se-GSL. Values in parentheses are the standard errors of the means.

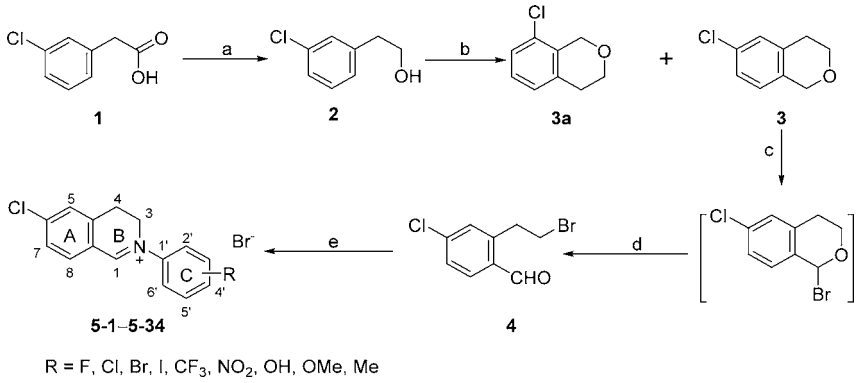
Scheme 1. General Synthetic Route of Compounds 2-Aryl-6-chloro-3,4-dihydroisoquinolin-2-ium Bromides[a]



[a]Reagents and conditions: (a) $NaBH_4$, I_2, dry THF, overnight; (b) HCHO, TFA, 0 °C to r.t.; (c) Br_2, CCl_4, reflux; (d) 40% HBr, reflux; (e) Ar-NH_2, dioxane.

MATERIALS AND METHODS

Chemicals. Azoxystrobin, a commercial fungicide, was purchased from Jiangsu Frey Agrochemical Co. Ltd. (Jiangsu, China). Sanguinarine iodide (>98%) and chelerythrine iodide (>99%) were obtained in our laboratory by isolation from the whole plant of *M. microcarpa* (Maxim) Fedde. Dimethyl sulfoxide (DMSO) and the starting material, 2-(3-chlorophenyl)acetic acid, were purchased from J&K Chemical Ltd. (Beijing, China). Other reagents and solvents were obtained locally and of analytical grade or purified according to standard methods before use. The water used was redistilled and ion-free.

Fungi. The plant pathogenic fungi, *Alternaria alternate* (*A. alternate*), *Curvularia lunata* (*C. lunata*), and *Valsa mali* (*V. mali*), were provided by the Center of Pesticide Research, Northwest A&F University, China. These fungi were grown on PDA plates at 28 °C and maintained at 4 °C with periodic subculturing.

Instruments. Melting points were determined on a digital melting-point apparatus and uncorrected. Infrared spectra (IR) were recorded on a Bruker TENSOR 27 spectrometer with KBr disks. Ultraviolet spectra (UV) were obtained using a Thermo Scientific Evolution 300 UV−vis spectrophotometer. Nuclear magnetic resonance spectra (NMR) were performed on a Bruker Avance III 500 MHz instrument. Chemical shifts (δ values) and coupling constants (J values) were given in ppm and Hz, respectively. High resolution mass spectra (HR-MS) were carried out with a Micromass Auto Spec-3000 instrument. Low resolution mass spectra (LR-MS) were carried out with a Thermo Fisher LCQ Fleet instrument.

Synthesis. The synthetic route of target compounds **5-1** to **5-34** was outlined in Scheme 1 using 2-(3-chlorophenyl)acetic acid as a starting material.

*Synthesis of 2-(3-chlorophenyl)ethan-1-ol (**2**).* $NaBH_4$ (21.7 g, 0.57 mol) was added portion-wise in 30 min to a solution of 2-(3-chlorophenyl) acetic acid (**1**, 49.0 g, 0.29 mol) in 300 mL dried THF under ice bath, and then a solution of iodine (72.9 g, 0.29 mol) in 100 mL dried THF was dropwise added into the mixture over a period of 3 h with stirring. The reaction solution was stirred at room temperature for several hours until the reaction was completed according to TLC analysis. The solution was evaporated under reduced pressure. To the residue was added 100 mL saturated brine, extracted with ethyl acetate (3 × 100 mL), sequentially washed with saturated solution of Na_2SO_3 (3 × 60 mL) and saturated saline solution (2 × 60 mL), and finally dried over anhydrous $MgSO_4$. After filtration, the solution was evaporated under vacuum to yield 2-(3-chlorophenyl) ethan-1-ol (**2**) as colorless oil (44.5 g, yield 99%). The crude intermediate **2** was directly used in the following step. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.16 (3H, d-like, J = 7.2 Hz), 7.04 (1H, d, J = 6.7 Hz), 3.67 (2H, t, J = 6.8 Hz), 3.26(1H, s), 2.73 (2H, t, J = 6.8 Hz); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 140.9, 134.2, 129.8, 129.1, 127.3, 126.5, 63.0, 38.7.

*Synthesis of 6-chloroisochromane (**3**).* Paraformaldehyde (10.2 g, 0.34 mol) and trifluoroacetic acid (30 mL) were added into a round flask, and vigorously stirred at 50 °C for 30 min to provide a clear solution, and then cooled to 0 °C. To the resulting solution was added 2-(3-chlorophenyl) ethan-1-ol (**2**, 44.5 g, 0.28 mol) and stirred for 1 h at 0 °C and then for 2 h at room temperature. Trifluoroacetic acid was removed under vacuum. To the residue was added 60 mL ice−water, extracted with diethyl ether (3 × 70 mL), washed with water (1 × 40 mL), aqueous saturated $NaHCO_3$ (3 × 40 mL) and saturated saline solution (1 × 40 mL), finally dried over anhydrous $MgSO_4$. After filtration, the solution was evaporated under vacuum. The residue was purified by column chromatography on silica gel eluting with petroleum ether−ethyl acetate (V:V = 150:1) to afford 6-chloroisochromane (**3**) as colorless oil (22.5 g, yield 47%)and 8-chloroisochromane (**3a**) as colorless oil (23.1 g, yield 48%). **3**: ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.12(2H, d-like, J = 8.6 Hz), 6.90(1H, d, J = 8.0 Hz), 4.72(2H, s), 3.94(2H, t, J = 5.7 Hz), 2.82(2H, t, J = 5.7 Hz); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 135.2, 133.3, 129.6, 128.8, 126.2, 125.8, 67.6, 65.0, 28.2. **3a**: ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.17 (1H, d, J = 7.8 Hz), 7.10 (1H, t, J = 7.8 Hz), 7.02 (1H, d, J = 7.8 Hz), 4.76 (2H, s), 3.92 (2H, t, J = 5.6 Hz), 2.84 (2H, t, J = 5.6 Hz); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 135.8, 132.6, 131.0, 127.3, 127.2, 126.8, 66.3, 64.8, 28.3.

*Synthesis of 2-(2-bromoethyl)-4-chlorobenzaldehyde (**4**).* Bromine (21.3 g, 0.13 mol) was added slowly to an ice-cooled solution of 6-chloroisochromane (**3**, 22.5 g, 0.13 mol) in carbon tetrachloride (50 mL) in 10 min with stirring. After the exothermic reaction subsided, the mixture was refluxed for 2 h to obtain a pale yellow solution. The solvent was evaporated under vacuum. To the residue was added aqueous hydrobromic acid (40%, 32.4 g) and was refluxed for 20 min. The solution was extracted with diethyl ether (3 × 40 mL). The combined organic phase was washed with water (2 × 30 mL), aqueous saturated $NaHCO_3$ (2 × 30 mL) and dried over anhydrous $MgSO_4$. After filtration, the solution was evaporated under vacuum to yield orange oil. The obtained crude product was chromatographed on silica gel eluting with petroleum ether−ethyl acetate (V:V = 50:1) to afford 2-(2-bromoethyl)-4-chloro benzaldehyde (**4**) as brown liquid (24.4 g, yield 74%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 10.10 (1H, s), 7.76 (1H, d, J = 8.2 Hz), 7.45 (1H, dd, J = 8.2, 2.0 Hz), 7.34 (1H, d, J = 2.0 Hz), 3.60 (2H, t, J = 6.5 Hz), 3.54 (2H, t, J = 6.5 Hz); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 191.6, 142.4, 140.1, 135.6, 132.4, 132.2, 128.0, 35.8, 32.2.

*Synthesis of compounds **5-1** to **5-34**.* According to our previously reported method,[8] compounds **5-1** to **5-34** were prepared through the direct condensation of 2-(2-bromo ethyl)-4-chlorobenzaldehyde (**4**) with aniline or substituted aromatic amine. General procedure was as follows. Compound **4** (350 mg, 1.4 mmol) was slowly added to a solution of aniline or substituted aniline (1.4 mmol) in 1,4-dioxane (6 mL) under stirring. The resulting solution was stirred overnight at room temperature to yield colored precipitate. The solid was collected by filtration and repeatedly washed with a small volume of diethyl ether and recrystallized in a mixed solution of methanol and 1,4-dioxane to provide the desired compounds (**5-1** to **5-34**).

*6-Chloro-2-phenyl-3,4-dihydroisoquinolin-2-ium bromide (**5-1**).* Yield, 72%; yellow powder; mp 167.4−168.3 °C; IR, υ_{max} (KBr) cm^{-1}:

Antifungal Assay. The antifungal activities *in vitro* of all the synthetic compounds against three plant pathogenic fungi (*A. alternate*, *C. lunata* and *V. mali*) were assayed by the mycelium linear growth rate method as previously reported.[5,8,9,11] The test fungi maintained on potato dextrose agar (PDA) medium slants were subcultured for 48 h in Petri dishes prior to testing and used for inoculation of fungal strains on PDA plates.

The tested compound was completely dissolved in 0.5 mL of DMSO and then added to 9.5 mL of sterile water. The resulting solution was added to 90 mL of melted PDA agar at 50 °C and, after quickly and completely mixing, poured into a Petri dish in a laminar flow chamber. The final concentration of the test compound in the culture medium was 50 or 25 μg/mL for the activity screening test, and the final concentration of DMSO was 0.5%, which was proven to have no significant effect on the growth of tested fungi. Azoxystrobin (50 or 25 μg/mL) in the culture medium containing 0.5% DMSO (v/v) and 0.5% DMSO in culture medium were used as a positive control and a blank control, respectively. When the medium in the plate was partially solidified, a 5 mm thick and 4 mm diameter disc of fungus cut from beforehand subcultured Petri dishes was placed at the center of the semisolid medium. The dishes were kept in an incubator at 28 °C for 72 h. Each experiment was carried out in triplicate. The diameters (in mm) of inhibition zones were measured with a caliper in three different directions, and the growth inhibition rates were calculated according to the following formula and expressed as means ± S.D.

$$\text{Inhibition rate } (\%) = [(d_c - d_0) - (d_s - d_0)]/(d_c - d_0) \times 100$$

where d_0 is the diameter of the fungus cut, d_c is the diameter of a fungal colony in the blank test, and d_s is the diameter of a fungal colony in the compound-treated test.

Based on the results of *in vitro* antifungal activity, the more active compounds were selected to determine their median effective concentration (EC_{50}) according to the same method described above. The stock solution was mixed with the autoclaved PDA medium to prepare a set of mediums containing 70, 50, 35, 25, 12.5, 6.25, and 3.125 μg/mL of the tested compound. Similarly, 0.5% DMSO in culture medium was used as a blank control. Each test was performed in triplicate. EC_{50} values and their confidence intervals at 95% probability (95% CI) were calculated by using PRISM software ver. 5.0 (GraphPad Software Inc., San Diego, CA, USA).

RESULTS AND DISCUSSION

Chemistry. The synthetic route of compounds **5-1** to **5-34** was outlined in Scheme 1, and their substitution patterns are listed in Table 1. Commercially available 2-(3-chlorophenyl)-acetic acid (**1**) as a starting material was reduced with $NaBH_4$ in anhydrous THF in the presence of an equimolar amount of iodine to obtain **2** in 99% yield. Compound **2** reacted with paraformaldehyde in trifluoroacetic acid to obtain 6-chloroisochromane (**3**) and a byproduct 8-chloroisochromane (**3a**) in 95% yield in an approximately equimolar ratio, similar to the results reported elsewhere.[12,13] The mixture of **3** and **3a** was subjected to column chromatography over silica gel to yield the desired compound **3**. 2-(2-Bromoethyl)-4-chlorobenzaldehyde (**4**) as a key intermediate was obtained in 74% by α-bromination of 6-chloroisochromane (**3**) followed by the treatment with aqueous hydrobromic acid. Compound **4** reacted with various primary aromatic amines in 1,4-dioxane to obtain the desired 2-aryl-3,4-dihydroisoquinolin-2-ium bromides (**5-1** to **5-34**).

The structures of the synthesized compounds were confirmed by spectroscopic analysis including UV, IR, HR-MS, ^{1}H NMR and ^{13}C NMR. Due to the structural similarity, all compounds **5-1** to **5-34** showed similar spectroscopic characteristics. Each of them showed a wavelength of maximum absorption in the range of 227 to 426 nm in UV spectra due to the presence of the conjugated system, a strong absorption (C═N$^+$) in the range of 1617 to 1642 cm^{-1} in IR spectra, a characteristic ion peak at m/z [M − Br]$^+$ in positive ESI-HR-MS spectra, and the ion peaks at m/z [^{79}Br$^-$] and [^{81}Br$^-$] in negative ESI-MS spectra. In ^{1}H and ^{13}C NMR spectra, all the compounds revealed one singlet signal in the range of δ_H 9.40 to 9.92 ppm due to the proton of HC═N$^+$ and one signal in the range of δ_C 164.1 to 171.2 ppm due to C-1.

Antifungal Activity. According to the mycelium linear growth rate method reported by us, the antifungal activities *in vitro* of compounds **5-1** to **5-34** were screened against three plant pathogenic fungi (*A. alternate*, *C. lunata*, and *V. Mali*) at 50 and 25 μg/mL. The results listed in Table 1 showed all the compounds displayed the activity in varying degrees against each of the test fungi. For each fungus, at the test concentration of 25

or 50 μg/mL, part or most of the synthesized compounds were more active than their natural model compounds, sanguinarine and chelerythrine, and the positive control azoxystrobin. Especially for *C. lunata*, almost all the compounds except **5-21**, **5-27**, and **5-31** showed higher activity at 25 or 50 μg/mL than azoxystrobin, with inhibition rates of 44.2% at 50 μg/mL and 35.6% at 25 μg/mL. For all the synthesized compounds, 88% of all the test items at 50 μg/mL (90/102) and 52% at 25 μg/mL (53/102) revealed good to excellent activity with inhibition rates of 50% to 97.1%. In general, these compounds showed higher activity on *C. lunata* followed by *A. alternate* and *V. mali*.

In order to further explore the antifungal potential and structure−activity relationship, the compounds with inhibition rates >50% at 25 μg/mL were further examined to determine their median effective concentrations (EC_{50}) against three strains of fungi. The results are shown in Table 2.

From Table 2, it was clearly seen that all of the 28 tested compounds showed excellent activity, with EC_{50} values of 4.6−24.8 μg/mL against *C. lunata*, much higher than the positive control azoxystrobin (EC_{50} = 71.9 μg/mL) and the reference compound sanguinarine (EC_{50} = 35.6 μg/mL); EC_{50} values of 12 out of 28 were below 10.0 μg/mL. For *A. alternate*, all 16 tested compounds showed good activity, with EC_{50} values of 10.3−24.9 μg/mL, and **5-4** showed the highest activity, with an EC_{50} value of 10.3 μg/mL, superior to azoxystrobin (EC_{50} = 12.8 μg/mL), sanguinarine (EC_{50} = 53.0 μg/mL), and chelerythrine (EC_{50} = 49.5 μg/mL). Regarding *V. mali*, all of the 9 tested compounds showed higher activity, with EC_{50} values of 3.9−24.8 μg/mL, than azoxystrobin (EC_{50} = 37.2 μg/mL), sanguinarine (EC_{50} = 25.6 μg/mL), and chelerythrine (EC_{50} = 39.7 μg/mL). The above results indicated that the susceptibility order of three strains of fungi to these compounds was *C. lunata* > *A. alternate* > *V. mali*, which was in agreement with the screening results in Table 1.

From comparison of the EC_{50} values of various compounds in Table 2, in conjunction with the inhibition rates at 25 μg/mL in Table 1, it was concluded that the type and position of substituents on the C-ring had significant effects on the activity (Figure 2). The general trend is that the presence of 2′-F, 4′-F, or 2′-CH_3 always leads to an increase of the activity against all three

Figure 2. Structure−activity relationship of compounds **5-2** to **5-34**.

test fungi compared with compound **5-1** (R = H), whereas the effects of other substituents on the activity depend on their positions and the species of the fungi. For *A. alternate*, the presence of a monohalogen atom (F, Cl, Br, I) (**5-2** to **5-13**) or a trifluoromethyl group (**5-23** to **5-25**) at the 2′, 3′, or 4′ position improves the activity in most cases, whereas the introduction of a methoxy group (**5-20** to **5-22**), a hydroxy group (**5-26** to **5-28**), a methyl group (**5-32** to **5-34**), or a nitro group (**5-29** to **5-31**) generally decreases the activity; as to *C. lunata*, although most of the compounds showed higher activity than the reference azoxystrobin, only 4′-F, 2′-F, and 2′-CH_3 substituted compounds (**5-2**, **5-4**, and **5-34**) showed higher activity than **5-1** (R = H), indicating that the presence of the various substituents on the C-ring generally led to reduction of the activity against *C. lunata*. A similar case was observed for *V. mali*, where only the minority of the compounds were slightly more active than **5-1**, showing that the introduction of substituents to the C-ring was of less importance for enhancement of the activity against *V. mali*. The structure−activity relationships above are different from the case of 2-aryl-3,4-dihydroisoquinolin-2-ium bromides[8] and 2-aryl-6,7-methylenedioxy-3,4-dihydroisoquinolin-2-ium bromides[9] reported by us. For 2-aryl-3,4-dihydroisoquinolin-2-ium bromides, the presence of halogen atoms (F, Cl, Br, or I) or CF_3 groups at any site in the C-ring as well as 4′-OH remarkably enhances the activity against *A. alternate*, *C. lunata*, and *V. mali*, whereas the introduction of CH_3 or OCH_3 to the 2′-, 3′-, or 4′-site as well as 2′-OH leads to a decrease of activity.[8] Similar cases were observed for 2-aryl-6,7-methylenedioxy-3,4-dihydroisoquinolin-2-ium bromides.[9]

The noteworthy compounds were fluorinated (**5-2** to **5-4**), methyl-substituted (**5-32** to **5-34**), and nitro-substituted (**5-29** to **5-31**) isomers. Among all the synthesized compounds, **5-2** and **5-4** not only showed the top three activities on almost all of the three tested fungi, but also were more active than **5-1** for all the fungi. This result suggested that the presence of 2′-F and 4′-F was beneficial to the improvement of the activity. Compound **5-34** (2′-CH_3) showed the highest activity (EC_{50} = 3.9 μg/mL) against *V. mali*, the third highest activity (EC_{50} = 5.8 μg/mL) against *C. lunata* among all the synthesized compounds. This result indicated that the introduction of 2′-CH_3 could significantly improve the activity against both *C. lunata* and *V. mali* but have less influence on the activity against *A. alternate*. This case was completely different from the results observed for 2-aryl-3,4-dihydroisoquinolin-2-ium bromides[8] and 2-aryl-6,7-methylenedioxy-3,4-dihydroisoquinolin-2-ium bromides,[9] where the presence of 2′-, 3′-, or 4′-CH_3 lead to a decrease of the activities. For nitro-substituted compounds, the presence of 2′-NO_2 (**5-31**) caused reduction of the activities against all three fungi, and the presence of 3′-NO_2 (**5-30**) could lead to an increase of the activities against *A. alternate* and *V. mali*, similar to that observed for 2-aryl-3,4-dihydroisoquinolin-2-ium bromides[8] and 2-aryl-6,7-methylenedioxy-3,4-dihydroisoquinolin-2-ium bromides.[9] However, 4′-NO_2 in three series of the compounds has different effects on the activity. For **5-29**, the introduction of 4′-NO_2 led to a decrease of the activities against all three fungi, whereas for 2-(4-nitrophenyl)-3,4-dihydroisoquinolin-2-ium bromides and 2-(4-nitrophenyl)-6,7-methylenedioxy-3,4-dihydroisoquinolin-2-ium bromides, the presence of 4′-NO_2 could increase the activities against both *A. alternate* and *V. mali*. The above results obviously showed that there was an interaction effect between substituents on the A-ring and the C-ring, and the activity of compounds depended on the combined effect of substituents on the A-ring and the C-ring. This observation proved to be useful for the design of new 2-aryl-3,4-dihydroisoquinolin-2-iums with more potent antifungal activity.

Additionally, compared with compounds **5-2** to **5-13**, with one halogen atom on the C-ring, compounds **5-14** to **5-19**, containing two halogen atoms on the C-ring, did not improve the activities in most cases. This result indicated, to a certain degree, that the increase of halogen atom number on the C-ring made no contribution to the improvement of activity.

Our previous research proved that the iminium moiety (C═N^+) in sanguinarine and chelerythrine was a key structural moiety for their antimicrobial, acaricidal, and anticancer activity.[5−7,14] A similar case was also observed in 2-aryl-3,4-dihydroisoquinolin-2-ium compounds on the basis of the fact that reduction of the iminium moiety (C═N^+) led to loss of the activity (unpublished). The facts above suggested that the bioactivity of 3,4-dihydroisoquinolin-2-ium compounds should be related with the electron density of their iminium moiety. Our

previous research on 2-aryl-3,4-dihydroisoquinolin-2-ium compounds showed that the introduction of electron-withdrawing groups such as halogen atoms or CF_3 and NO_2 groups to C-ring could significantly increase the antifungal activity, indicating that the low electron density of the iminium moiety was a benefit to the improvement of the activity. However, for the present compounds (**5-2** to **5-34**), the electron density of the iminium moiety not only depends on the substituent in the C-ring but also on the chlorine atom in the A-ring. Therefore, the activity of **5-2** to **5-34** depends on the combined electron effect of substituents in the A-ring and the C-ring. This is the reason that **5-2** to **5-34** showed different SAR from 2-aryl-3,4-dihydroisoquinolin-2-ium bromides and 2-aryl-6,7-methylenedioxy-3,4-dihydroisoquinolin-2-ium bromides.

In conclusion, we reported the synthesis of a new series of 2-aryl-6-chloro-3,4-dihydroisoquinolin-2-ium bromides and the evaluation of their antifungal activity *in vitro* against three plant pathogenic fungi. All the synthesized compounds showed the obvious growth inhibition activity against all the tested fungi, and most of them were more active than azoxystrobin. Among all the tested compounds, **5-2** and **5-4** showed higher activity against all the tested fungi, with EC_{50} values of 4.6−24.8 μg/mL, and **5-34** showed the highest activity against *V. mali* with an EC_{50} value of 3.9 μg/mL and the third highest activity against *C. lunata* with an EC_{50} value of 5.8 μg/mL. Some of the compounds, especially **5-2**, **5-4**, **5-7**, **5-13**, **5-25**, and **5-34**, were of great potential to be developed as new antifungal agents for plant protection. SAR analysis showed that the C-ring was a highly sensitive structural moiety to the activity and the type as well as position of substituents on C-ring could make significant effects on the activity. In most cases, the introduction of monohalogen atom to the C-ring could enhance the activity, whereas the presence of −OH, -OMe, $-NO_2$ or $-CF_3$ caused decrease or slight increase of the activity. The presence of 2′-Me could significantly enhance the activities, especially on *C. lunata* and *V. mali*, but 3′- or 4′-Me caused decrease of the activities. Thus, the present results were of great importance for the design, synthesis and development of novel isoquinoline antifungal agents. Further research was necessary on the more extensive structural modification, the determination of an antifungal spectrum and the *in vivo* activity of these compounds.

phy−mass spectrometry (MDGC-MS) techniques, novel VSCs were synthesized and characterized. In addition, aroma extract dilution analysis (AEDA) by gas chromatography−olfactometry (GC-O) was applied to assign flavor dilution (FD) factors to the odor-active compounds in the lemon extract.

MATERIALS AND METHODS

Materials. Conventional Lisbon lemons (SK Choice grade, large size) were ordered from Saticoy Lemon Associates and Sunkist Growers in Oxnard, CA, USA. Upon arrival, the lemons were worked up immediately. A microplane zester (OXO, Chambersburg, PA, USA) was used to zest the peel.

Chemicals. The following reagents were purchased from Sigma-Aldrich (St. Louis, MO, USA): dichloromethane (DCM), methanol (MeOH), hexane, anhydrous magnesium sulfate ($MgSO_4$), 1,5-dibromopentane, 1,3-dibromopropane, Li_2CuCl_4, 2-pentylmagnesium bromide−diethyl ether solution, and 2-propionylthiophene. The following compounds were purchased from the FCH Group (Ukraine): 3-methylundecanal and 3-methyldodecanal. Finally, the following Grignard reagents were purchased from Novel Chemical Solutions (Crete, NE, USA): 2-hexylmagnesium bromide−THF solution, 2-heptylmagnesium bromide−THF solution, 2-octylmagnesium bromide−THF solution, 2-nonylmagnesium bromide−THF solution, 2-decylmagnesium bromide−THF solution, and 2-undecylmagnesium bromide−THF solution.

Synthesis of 6-Methylnonanal 136. The synthesis of **136** involved a four-step pathway (Figure 1) and is described in detail as an example of the 6-methyl and 4-methylalkyl aldehydes synthesized in this study.

*1-Bromo-6-methylnonane (**3a**).* Under N_2, a 1 L, four-necked flask, equipped with a mechanical stirrer, was charged with 1,5-dibromopentane (**1a**; 5.1 g, 25 mmol), THF (50 mL), and Li_2CuCl_4 (2.5 mL, 250 mmol) in 0.1 M THF and cooled to 0 °C. A 2-pentylmagnesium bromide−diethyl ether solution (**2a**; 100 mL, 25 mmol) was added to the reaction and stirred for 45 min at 0 °C under argon. The mixture was allowed to reach ambient temperature and quenched with water (200 mL) and 1 M HCl (25 mmol). The aqueous layer was extracted with hexane (3 × 100 mL), and the combined organic phases were washed with a 5% solution of $NaHCO_3$ (100 mL) and brine (100 mL). The organic phase was dried over $MgSO_4$, and **3a** was concentrated under partial vacuum to remove the solvent and used as-is in the next step.

*6-Methylnonyl Acetate (**4a**).* A 250 mL, four-necked flask was charged with the crude mixture of **3a** (16.0 g, 61 mmol) and DMF (50 mL). To this mixture was added sodium acetate (9.9 g, 120 mmol) in excess, and the reaction was run for 10 h at 100 °C. The reaction mixture was allowed to reach ambient temperature, followed by the addition of water (300 mL). The mixture was then extracted with hexane (3 × 100 mL), and the combined organic fractions were washed with water (2 × 100 mL) and brine (100 mL) and dried over $MgSO_4$. The solvent was evaporated under reduced pressure to produce **4a** and used as-is in the next step.

*6-Methylnonanol (**5a**).* A 1 L, four-necked flask was charged with the crude mixture of **4a** (10.0 g, 41 mmol), along with MeOH (200 mL) and a catalytic amount of K_2CO_3 (1.0 g, 7 mmol) and run for 5 h at ambient temperature. The MeOH was evaporated off and hexane (100 mL) and water (100 mL) were added to the residue. The phases were allowed to separate, and the organic phase was washed with water (50 mL) and brine (50 mL), dried over $MgSO_4$, and evaporated. The raw product mixture was purified by column chromatography (silica; hexane/ethyl acetate) giving **5a** (2.0 g) as a clear oil.

*6-Methylnonanal **136**.* A 1 L, four-necked flask was charged with **5a** (2.0 g, 10 mmol), KBr (0.1 g, 1 mmol), $NaHCO_3$ (1.7 g, 20 mmol), and DCM (150 mL). 2,2,6,6-Tetramethyl-1-oxylpiperidine (TEMPO; 16 mg, 100 mmol) was added to the flask, followed by water (5 mL), and allowed to cool to 0 °C. A 15% solution of NaClO (8.9 g, 13 mmol, d = 1.2) was added dropwise at 5 °C and stirred for 1 h at 10 °C. A 5 g solution of L-ascorbic acid (30% in water) was added and heated to reflux for 2 h. After cooling, the phases were allowed to separate, and the organic phase was washed with water (100 mL) and brine (100 mL) and dried over $MgSO_4$. After filtration and concentration, **136** (0.4 g, 20%) was obtained by column chromatography (silica; ethyl acetate/hexanes). The total yield based on the four-step synthesis beginning with **1a** was 10%. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 9.76 (t, J = 1.9 Hz, 1H), 2.42 (td, J = 7.4 Hz, 1.9 Hz, 2H), 1.56−1.67 (m, 2H), 1.21−1.42 (m, 7H), 1.04−1.17 (m, 2H), 0.88 (t, J = 7.3 Hz, 3H), 0.84 (d, J = 6.6 Hz, 3H). EI-MS: 156 (0, M^+), 95 (100), 43 (78), 71 (63), 70 (60), 69 (60), 41 (54), 57 (49), 55 (47), 96 (42), 84 (38).

The synthesis of 6-methyldecanal **215** followed a similar procedure but instead used a 2-hexylmagnesium bromide−THF solution as the Grignard reagent. The 4-methylalkyl aldehydes were prepared in a similar fashion except using 1,3-dibromopropane instead of 1,5-dibromopentane, along with the associated Grignard reagent.

*6-Methyldecanal **215**:* yield (14%); ^{1}H NMR ($CDCl_3$, 400 MHz) δ 9.77 (t, J = 1.9 Hz, 1H), 2.39−2.48 (m, 2H), 1.53−1.74 (m, 2H), 1.19−1.40 (m, 9H), 1.06−1.16 (m, 2H), 0.88 (t, J = 6.8 Hz, 3H), 0.84 (d, J = 6.5 Hz, 3H)' EI-MS 170 (0, M^+), 43 (100), 95 (84), 69 (67), 41 (67), 57 (66), 85 (61), 84 (59), 55 (46), 96 (44), 29 (39).

*4-Methyloctanal **86**:* yield (25%); ^{1}H NMR ($CDCl_3$, 400 MHz) δ 9.77 (t, J = 1.9 Hz, 1H), 2.35−2.49 (m, 2H), 1.55−1.72 (m, 1H), 1.36−1.49 (m, 2H), 1.19−1.34 (m, 5H), 1.04−1.19 (m, 1H), 0.89 (t, J = 6.6 Hz, 3H), 0.88 (d, J = 6.4 Hz, 3H); EI-MS 142 (0, M^+), 56 (100), 57 (56), 43 (49), 70 (44), 41 (43), 29 (36), 85 (33), 55 (27), 27 (22).

*4-Methylnonanal **140**:* yield (20%); ^{1}H NMR ($CDCl_3$, 500 MHz) δ 9.77 (t, J = 1.9 Hz, 1H), 2.30−2.48 (m, 2H), 1.57−1.73 (m, 1H), 1.35−1.50 (m, 2H), 1.21−1.34 (m, 7H), 1.04−1.20 (m, 1H), 0.89 (t, J = 6.6 Hz, 3H), 0.88 (d, J = 6.4 Hz, 3H); EI-MS 156 (0, M^+), 57 (100), 56 (83), 41 (47), 55 (33), 43 (31), 29 (23), 85 (20), 69 (19), 84 (17) 112 (16).

*4-Methyldecanal **217**:* yield (20%); ^{1}H NMR ($CDCl_3$, 400 MHz) δ 9.77 (t, J = 1.9 Hz, 1H), 2.35−2.48 (m, 2H), 1.55−1.71 (m, 1H), 1.35−1.50 (m, 2H), 1.22−1.34 (m, 9H), 1.04−1.20 (m, 1H), 0.89 (t, J = 6.6 Hz, 3H), 0.88 (d, J = 6.4 Hz, 3H); EI-MS 170 (0, M^+), 56 (100), 57 (97), 41 (53), 43 (52), 69 (43), 29 (43), 55 (43), 71 (43), 85 (34), 82 (28).

*4-Methylundecanal **274**:* yield (18%); ^{1}H NMR ($CDCl_3$, 500 MHz) δ 9.77 (t, J = 1.9 Hz, 1H), 2.32−2.50 (m, 2H), 1.56−1.76 (m, 1H), 1.38−1.56 (m, 2H), 1.22−1.33 (m, 11H), 1.03−1.20 (m, 1H), 0.89 (t, J = 6.6 Hz, 3H), 0.88 (d, J = 6.4 Hz, 3H); EI-MS 184 (0, M^+), 56 (100), 57 (87), 85 (56), 43 (55), 41 (53), 69 (49), 29 (46), 55 (45), 71 (39), 82 (39).

*4-Methyldodecanal **321**:* yield (20%); ^{1}H NMR ($CDCl_3$, 500 MHz) δ 9.77 (t, J = 1.9 Hz, 1H), 2.32−2.50 (m, 2H), 1.56−1.76 (m, 1H), 1.38−1.56 (m, 2H), 1.22−1.33 (m, 13H), 1.03−1.20 (m, 1H), 0.89 (t, J = 6.6 Hz, 3H), 0.88 (d, J = 6.4 Hz, 3H); EI-MS 198 (0, M^+), 56 (100), 57 (98), 41 (57), 43 (56), 85 (50), 55 (49), 69 (44), 82 (37), 29 (31), 81 (28).

*4-Methyltridecanal **370**:* yield (15%); ^{1}H NMR ($CDCl_3$, 400 MHz) δ 9.77 (t, J = 1.9 Hz, 1H), 2.35−2.48 (m, 2H), 1.56−1.76 (m, 1H), 1.38−1.48 (m, 2H), 1.21−1.33 (m, 15H), 1.04−1.20 (m, 1H), 0.89 (t, J = 6.6 Hz, 3H), 0.88 (d, J = 6.4 Hz, 3H); EI-MS 212 (0, M^+), 57 (100), 56 (87), 85 (58), 43 (47), 55 (47), 41 (45), 82 (44), 69 (43), 95 (31), 81 (31).

Synthesis of 3-Mercapto-3,7-dimethyl-6-octenyl Acetate 378. The multistep synthesis of **378** is shown in Figure 4.

*S-(3,7-Dimethyl-1-oxooct-6-en-3-yl)ethanethioate (**2b**).* Under N_2, a 1 L, four-necked flask was charged with citral (**1b**; 50.0 g, 330 mmol) and piperidine (2.8 g, 30 mmol). Thioacetic acid (37.5 g, 490 mmol) was added dropwise to the mixture and heated to 60 °C for 3 h. The mixture was then cooled to room temperature, and methyl *tert*-butyl ether (MTBE; 200 mL) was added followed by a wash with brine (100 mL), a 5% solution of $NaHCO_3$ (100 mL), and brine (100 mL) successively. The solvent was removed under vacuum, and the crude of **2b** (10.0 g) was used as-is for the next step.

*3-Mercapto-3,7-dimethyl-6-octenyl Acetate **378**.* Under N_2, a 1 L, four-necked flask was charged with $NaBH_4$ (2.5 g, 66 mmol), which was dissolved in ethanol (40 mL) and water (10 mL). The temperature of the reaction was lowered to 0 °C, and **2b** (10.0 g,

DOI: 10.1021/jf505177r
J. Agric. Food Chem. 2015, 63, 1915−1931

44 mmol) was added dropwise to the reaction flask, keeping the temperature below 10 °C. After addition, the reaction mixture was stirred at room temperature for 30 min. The mixture was then poured into a 10% solution of NH_4Cl (100 mL), transferred to a separatory funnel, and extracted with MTBE (200 mL). The organic layer was washed with brine (2 × 100 mL). The solvent was removed under vacuum, and **378** (8.2 g, 81%) was obtained by column chromatography (silica; ethyl acetate/hexanes): ^{1}H NMR ($CDCl_3$, 400 MHz) δ 5.00−5.14 (m, 1H), 4.21−4.30 (m, 2H), 2.07−2.15 (m, 2H), 2.04 (s, 3H), 1.92−1.96 (m, 2H), 1.68 (s, 3H), 1.62 (s, 3H), 1.56−1.70 (m, 3H), 1.38 (s, 3H); EI-MS 230 (3, M^+), 121 (100), 69 (31), 93 (20), 109 (15), 136 (13), 81 (13), 101 (13), 122 (12), 67 (10), 43 (9).

Synthesis of 2-(5-Isopropyl-2-methyltetrahydrothiophen-2-yl)ethanol 304 and 307. The multistep synthesis of **304** and **307** is shown in Figure 4, where intermediate **2b** was synthesized in a similar fashion as above and was used as-is for the next step.

*3-Mercapto-3,7-dimethyl-6-octenol (**3b**).* Under N_2, a 1 L, four-necked flask was charged with $LiAlH_4$ (3.3 g, 88 mmol), which was dissolved in THF (200 mL) at room temperature. The temperature of the reaction mixture was then lowered to 0 °C, and **2b** (20.0 g, 88 mmol) was added dropwise to the reaction flask, maintaining the temperature below 10 °C. After filtration and concentration, the crude of **3b** (15.0 g) was used as-is for the next step.

*2-(5-Isopropyl-2-methyltetrahydrothiophen-2-yl)ethanol **304** and **307**.* Crude **3b** (15.0 g, 80 mmol) was dissolved in THF (200 mL), refluxed for 1 h, and poured into a 10% solution of NH_4Cl (200 mL). The mixture was then transferred to a separatory funnel and extracted with MTBE (400 mL). The organic layer was washed with brine (2 × 100 mL), and the solvent was removed under vacuum. **304** and **307** (8.3 g, 50%) were obtained by vacuum distillation (bp 130 °C/1.0 mmHg): ^{1}H NMR ($CDCl_3$, 500 MHz) δ 3.72−3.86 (m, 2H), 3.24−3.32 (m, 1H), 2.59 (br, 1H), 1.56−2.18 (m, 7H), 1.41 (s, ∼50% of 3H), 1.38 (s, ∼50% of 3H), 0.92−0.98 (m, 6H); EI-MS 188 (20, M^+), 101 (100), 69 (42), 93 (41), 41 (27), 81 (21), 143 (21), 55 (20), 99 (16), 145 (15), 67 (13).

Synthesis of 2-(5-Isopropyl-2-methyltetrahydrothiophen-2-yl)ethyl Acetate 373 and 375. Compounds **304** and **307** (0.6 g, 3 mmol) were added to DCM (5 mL) at room temperature. The reaction mixture was cooled to 0 °C, and triethylamine (0.5 g, 5 mmol) and acetyl chloride (0.3 g, 4 mmol) were added as shown in Figure 4. After 1 h, 1 M HCl (5 mL) was added, and the reaction was extracted with DCM (2 × 5 mL), washed with water (10 mL) and brine (10 mL), and dried over $MgSO_4$. The solvent was removed under vacuum, and **373** and **375** (0.5 g, 90%) were obtained by column chromatography (silica; hexanes/ethyl acetate): ^{1}H NMR ($CDCl_3$, 500 MHz) δ 4.12−4.33 (m, 2H), 3.17−3.36 (m, 1H), 2.07−2.20 (m, 1H), 2.04 (s, 3H), 1.64−2.03 (m, 6H), 1.42 (s, ∼50% of 3H), 1.40 (s, ∼50% of 3H), 0.91−0.98 (m, 6H); EI-MS 230 (22, M^+), 93 (100), 43 (84), 127 (83), 69 (66), 41 (39), 99 (36), 81 (34), 143 (30), 55 (26), 67 (23).

Synthesis of 2-(2-Methyltetrahydrothiophen-2-yl)ethyl Acetate 281. The multistep synthesis of **281** is shown in Figure 5.

*Methyl 2-(2-Methyltetrahydrothiophen-2-yl)acetate (**2c**).* 2-(2-Methyltetrahydrothiophen-2-yl)acetic acid (**1c**; 5.1 g, 32 mmol), synthesized according to the procedure described by Bunce et al.,[25] was dissolved in MeOH (100 mL). *p*-Toluenesulfonic acid monohydrate (0.6 g, 3 mmol) was added, and the mixture was refluxed for 3 h. The solvent was removed under vacuum, and ethyl acetate (100 mL) was added to the residue. The organic layer was washed with a 5% solution of $NaHCO_3$ (100 mL) and brine (100 mL) and then dried over $MgSO_4$. After filtration and concentration, the crude of **2c** (5.0 g) was obtained and used as-is in the next step.

*2-(2-Methyltetrahydrothiophen-2-yl)ethanol (**3c**).* $LiAlH_4$ (1.1 g, 29 mmol) was dissolved in THF (100 mL). Under N_2, a solution of **2c** (5.0 g, 29 mmol) in THF (40 mL) was added dropwise to the reaction flask. After addition, the mixture was allowed to stir for an additional 2 h at room temperature. The mixture was then added to a 10% solution of NH_4Cl (200 mL) and extracted with ether (200 mL). The organic layer was washed with brine (100 mL) and dried over $MgSO_4$. After filtration and concentration, **3c** (3.8 g, 81%) was obtained by column chromatography (silica; ethyl acetate/hexanes).

*2-(2-Methyltetrahydrothiophen-2-yl)ethyl Acetate **281**.* **3c** (3.8 g, 26 mmol) and triethylamine (3.2 g, 32 mmol) were dissolved in DCM (100 mL) and cooled to 0 °C. With stirring, a solution of acetyl chloride (2.5 g, 32 mmol) in DCM (20 mL) was added dropwise to the reaction flask. After addition, the reaction was stirred for an additional 2 h at room temperature. The mixture was transferred to a separatory funnel and washed with a 10% solution of NH_4Cl (100 mL), a 5% solution of $NaHCO_3$ (100 mL), and brine (100 mL) and then dried over $MgSO_4$. After filtration and concentration, **281** (3.4 g, 70%) was obtained by column chromatography (silica; ethyl acetate/hexanes): ^{1}H NMR ($CDCl_3$, 400 MHz) δ 4.17−4.29 (m, 2H), 2.88−3.01 (m, 2H), 1.98−2.12 (m, 4H), 2.05 (s, 3H), 1.73−1.89 (m, 2H), 1.42 (s, 3H); EI-MS 188 (17, M^+), 101 (100), 43 (27), 113 (25), 67 (12), 81 (9), 59 (9), 41 (7), 102 (7), 79 (6), 100 (6).

Synthesis of 2-[5-(1-Hydroxy-1-methylethyl)-2-methyltetrahydrothiophen-2-yl]ethyl Acetate 401 and 406. This five-step synthesis is shown in Figure 6.

*6,7-Epoxyneral **246**.* Citral (**1d**, 100.0 g, 660 mmol) was dissolved in DCM (400 mL) and cooled to 0 °C. With stirring, a solution of *m*-chloroperbenzoic acid (136.0 g, 790 mmol) in DCM (200 mL) was added dropwise to the reaction flask. After addition, the reaction mixture was stirred for an additional 2 h at 0 °C. The organic layer was washed with a 5% solution of $NaHCO_3$ (2 × 100 mL) and brine (2 × 100 mL) and then dried over $MgSO_4$. After filtration and concentration, the crude of **246** (111.0 g) was obtained and used as-is for the next step.

*S-[1-(3,3-Dimethyloxiran-2-yl)-3-methyl-5-oxopentan-3-yl]-ethanethioate (**2d**).* **246** (111.0 g, 660 mmol), thioacetic acid (60.0 g, 790 mmol), and piperidine (5.6 g, 70 mmol) were mixed and heated at 60 °C for 6 h under N_2. The reaction mixture was dissolved in ether (500 mL) and washed with a 5% solution of $NaHCO_3$ (100 mL) and brine (100 mL) and then dried over $MgSO_4$. After filtration and concentration, the crude of **2d** (160.0 g) was obtained and used as-is in the next step.

*2-[5-(2-Hydroxypropan-2-yl)-2-methyltetrahydrothiophen-2-yl]-acetaldehyde (**3d**).* **2d** (17.5 g, 70 mmol) was dissolved in THF (200 mL) and cooled to 0 °C. With stirring, a solution of NaOH (2.9 g, 70 mmol) in water (10 mL) was added dropwise to the reaction flask and allowed to stir for an additional 10 min at 0 °C. The mixture was added to ethyl acetate (200 mL), transferred to a separatory funnel, washed with a 10% solution of NH_4Cl (100 mL) and brine (100 mL), and then dried over $MgSO_4$. After filtration and concentration, **3d** (10.2 g, 70%) was obtained by column chromatography (silica; ethyl acetate/hexanes).

*2-[5-(2-Hydroxypropan-2-yl)-5-methyltetrahydrothiophen-2-yl]-ethanol (**4d**).* $NaBH_4$ (3.0 g, 80 mmol) was dissolved in ethanol (60 mL) and water (40 mL). The mixture was cooled to 0 °C. With stirring, the solution of **3d** (16.0 g, 90 mmol) in ethanol (20 mL) was added dropwise to the reaction flask. After addition, the reaction mixture was stirred for an additional 30 min at 0 °C. The mixture was then added to ethyl acetate (200 mL), transferred to a separatory funnel, washed with a 10% solution of NH_4Cl (100 mL) and brine (100 mL), and dried over $MgSO_4$. After filtration and concentration, **4d** (10.7 g, 66%) was obtained by column chromatography (silica; ethyl acetate/hexanes).

*2-[5-(1-Hydroxy-1-methylethyl)-2-methyltetrahydrothiophen-2-yl]ethyl Acetate **401** and **406**.* **4d** (3.0 g, 15 mmol) and triethylamine (1.5 g, 15 mmol) were dissolved in DCM (100 mL), and the mixture was cooled to 0 °C. With stirring, a solution of acetyl chloride (1.2 g, 15 mmol) in DCM (10 mL) was added dropwise to the reaction flask and stirred for an additional 10 min at 0 °C. The mixture was then transferred to a separatory funnel, washed with a 10% solution of NH_4Cl (100 mL), a 5% solution of $NaHCO_3$ (100 mL), and brine (100 mL), and dried over $MgSO_4$. After filtration and concentration, **401** and **406** (3.4 g, 94%) were obtained by column chromatography (silica; ethyl acetate/hexanes): ^{1}H NMR ($CDCl_3$, 500 MHz) δ 4.15−4.32 (m, 2H), 3.63−3.72 (m, 1H), 2.49 (br s, 1H), 1.98−2.12 (m, 7H), 1.79−1.96 (m, 2H), 1.41−1.44 (m, 3H), 1.18−1.24 (m, 6H); EI-

MS 246 (1, M^+), 101 (100), 43 (82), 59 (35), 100 (28), 99 (25), 69 (22), 93 (16), 41 (16), 113 (14), 128 (13).

Synthesis of 2-(5-Isopropylidene-2-methyltetrahydrothiophen-2-yl)ethyl Acetate 395. Compounds **401** and **406** (7.9 g, 32 mmol) were mixed with *p*-toluenesulfonic acid monohydrate (1.2 g, 6 mmol) in toluene (100 mL) and refluxed for 30 min (Figure 6). The mixture was then transferred to a separatory funnel, washed with a 5% solution of $NaHCO_3$ (100 mL) and brine (100 mL), and dried over $MgSO_4$. After filtration and concentration, **395** (4.1 g, 56%) was obtained by column chromatography (silica; ethyl acetate/hexanes): ^{1}H NMR ($CDCl_3$, 400 MHz) δ 4.17−4.30 (m, 2H), 2.61−2.71 (m, 2H), 2.06 (s, 3H), 1.85−2.10 (m, 4H), 1.64−1.74 (m, 6H), 1.45 (s, 3H); EI-MS 228 (74, M^+), 43 (100), 141 (68), 85 (47), 41 (45), 67 (44), 59 (32), 79 (31), 99 (30), 125 (27), 107 (26).

The mass spectra for each of the synthesized VSCs and branched aliphatic aldehydes are detailed in the Supporting Information.

CAS Registry Numbers for identified compounds: 2-(5-Isopropyl-2-methyltetrahydrothiophen-2-yl)ethanol **304** and **307**, 1612888-42-2.

Extraction of Lemon Peel. The peels from 100 lemons were zested over a microplane grater and collected in 1 L jars. The peel (2.0 kg) was steeped in DCM (600 mL) for 24 h in a refrigerator (4 °C). The solvent extract was passed through filter paper, dried over $MgSO_4$, and concentrated using a Zymark Turbovap (Biotage, Uppsala, Sweden) to 100 mL. It was then further reduced under a stream of N_2 to obtain a 25 mL concentrated extract.

Fractionation of Lemon Peel Extract. The peel extract (5.0 g) was diluted in hexane (5.0 g). The diluted extract was fractionated using a Biotage Isolera Prime, which was equipped with a 40 × 150 mm FLASH 40+M silica cartridge (Biotage). The first solvent gradient started with hexane/DCM at a ratio of 100:0. When the ratio reached 0:100, a second gradient of DCM/MeOH began at 100:0 and increased to 0:100. The flow rate was continuous at 25 mL/min, and the collection mode was set to "collect all". A total of 105 fractions were collected. On the basis of GC and GC-MS analyses from a selection of the individual fractions, the fractions were combined chronologically in groups of 10. The resulting 11 fractions were each concentrated using a Zymark Turbovap to 15 mL and further reduced under a stream of N_2 to 1 mL.

Supercritical Fluid Extraction. A Spe-ed Supercritical Fluid Extraction Prime (Applied Separations, Allentown, PA, USA) instrument was used to extract the lemon peel oil. The chiller was turned on 12 h prior to extraction, and the system lines were prepressurized by liquid CO_2 1 h before the extraction. Freshly zested lemon peels (20.0 g) were packed into a 50 mL high-pressure cell. The dead volume in the cell was filled with glass beads and then capped with PTFE frits before the ends were secured with threaded steel end-caps. After the sample cell had been connected to the unit, the cell temperature was set to 40 °C and prepressurized with CO_2. The compressed air was set to 120 psi, and the sample was pressurized with compressed air after the prepressurization process. The flow valve was opened to the metering valve, which then slowly opened to the recovery vial (placed in a dry ice/acetonitrile trap at −50 °C). The metering valve was opened enough to maintain a sample cell flow of approximately 1−2 L/min. Once stable flows were established, the peel was extracted for 45 min.

Gas Chromatography. The peel extract and its fractions were analyzed on apolar and polar phases using an Agilent 7890A GC (Santa Clara, CA, USA). The apolar capillary column had dimensions of 50 m × 320 μm × 0.52 mm (Restek RTX-1 F&F), and the polar capillary column was 50 m × 320 μm × 0.5 mm (Varian CP-Wax 58 FFAP CB column). Samples were introduced to the GC using an autosampler at a volume of 1 μL with a split ratio of 5:1. For the apolar column, the hydrogen carrier gas flow rate was held constant at 2 mL/min, and the temperature program started at an initial temperature of 40 °C and then increased at 2 °C/min to 310 °C with a 10 min hold at 310 °C. The temperature program for the polar column had the same initial temperature and 2 °C/min ramp, but the final temperature reached only 250 °C with a 10 min hold at 250 °C. The GC was calibrated using a homologous series of C1−C18 ethyl esters to generate index values for the observed peaks. The index values were calculated on the basis of previous work by van den Dool and Kratz,[26] which takes into account the GC oven temperature program and non-alkane-based calibrants, specifically ethyl esters. Although this is an industry standard, it is commonly expected to report Kovats retention indices (RI), which are based on a calibration with a homologous series of *n*-alkanes. A linear relationship between the ethyl ester values and Kovats RI is found when the measured values for the homologous series of the ethyl esters are plotted versus the Kovats values. On the basis of this relationship, linear equations were derived for both polar and apolar phases, which allowed for the calculated Kovats values reported herein.

Gas Chromatography−Olfactometry. The peel extract and its fractions were analyzed on the same apolar column described above using an Agilent 6890A GC. All samples were introduced to the GC inlet using an autosampler at 1 μL with a split ratio of 5:1. For all samples, the following parameters remained constant. The hydrogen carrier gas flow rate was 2 mL/min, and the temperature program started at an initial oven temperature of 40 °C, then increased at 6 °C/min to 80 °C, at 4 °C/min to 150 °C, at 2 °C/min to 200 °C, and finally at 10 °C/min to 310 °C with a 5 min hold. In addition, two olfactory detection ports (ODP, Gerstel, Inc., Linthicum, MD, USA) were equipped on the GC. The effluent was split 4:4:1 (ODP:ODP:FID), and the ODP transfer lines were heated to 225 °C. Olfactory comments were recorded using Dragon Naturally Speaking, Speech Recognition Software 12.0 (Nuance Communications, Inc., Burlington, MA, USA) in conjunction with the ODP software. The GC was calibrated using a homologous series of C1−C18 ethyl esters to generate index values for the observed peaks and then converted to Kovats values using the aforementioned equation.

Aroma Extract Dilution Analysis. To obtain dilutions of the original extract, the lemon peel extract was diluted stepwise, 3-fold, with DCM (1:3 by volume).[27] Two experienced assessors simultaneously conducted GC-O on these dilutions until no odorant could be detected. Each odorant was therefore assigned a FD factor that represented the last dilution in which the odorant was detected.

Gas Chromatography−Chemiluminescence. The peel extract and its fractions were analyzed on an Agilent 6890 GC equipped with an Antek 7090 sulfur/nitrogen chemiluminescence detector (PAC, Houston, TX, USA; CLSD) in the sulfur detection mode. All samples were introduced to the GC inlet using an autosampler, at a volume of 1 μL in the splitless mode. The apolar, 50 m × 320 μm × 0.52 μm, column (Restek RTX-1 F&F) was split two ways to two detectors. The hydrogen carrier gas flow rate was 2 mL/min, and the temperature program had an initial oven temperature of 40 °C, then increased at 2 °C/min to 270 °C with a 10 min hold at 270 °C. The FID and CLSD were calibrated using a homologous series of C1−C18 ethyl esters to generate index values for the observed peaks and then converted to Kovats values.

Gas Chromatography−Mass Spectrometry. The chromatographic conditions were the same as described for the GC analyses. All data were acquired using a Waters GCT-Premier orthogonal acceleration time-of-flight mass spectrometer (Milford, MA, USA) in electron ionization (EI) mode. The ion source was operated at 150 °C with an electron energy of 70 eV and a trap current of 50 μA. The temperature of the transfer line was 250 °C. Spectra were acquired between 27 and 400 Da in a time of 0.05 s and a delay of 0.01 s (approximately 20 spectra/s). Exact mass spectra were obtained using a single-point lock mass (m/z 218.9856 from perfluorotri-*n*-butylamine) infused into the ion source continuously during the run. Mass spectral library identification was achieved using in-house and commercial libraries, including Wiley 8 and NIST. Standard relative retention data were used for confirmation, which was obtained by calibrating the instrument with a homologous series of ethyl esters.

An Agilent 6890 GC, coupled to a Waters Quattro Micro triple-quadrupole mass spectrometer, was used to develop a method operating in the multiple reaction monitoring (MRM) mode. The instrument was equipped with a Varian CP-Wax 58 FFAP CB column (50 m × 320 μm × 0.20 μm) and a Varian VF-1 ms column (50 m × 320 μm × 0.40 μm). The oven ramp was set to an initial temperature

DOI: 10.1021/jf505177r
J. Agric. Food Chem. 2015, 63, 1915−1931

of 75 °C with an increase of 3 °C/min to 240 °C. The collision energy was set to 10 eV, and the following transitions were monitored as the major mass intensities from the spectrum: m/z 110.0 to 95.0 and 95.0 to 67.0 were monitored for 6-methylnonanal **136**; m/z 188.0 to 101.0 and 145.0 to 101.0 were monitored for 2-(5-isopropyl-2-methyltetrahydrothiophen-2-yl)-ethanol **304** and **307**.

Multidimensional Gas Chromatography−Mass Spectrometry. A Shimadzu GCMS-QP2010 system (Shimadzu Corp., Kyoto, Japan), which consisted of two GC2010 GCs, was equipped with a Deans switch transfer device, an MS-QP2010 quadrupole mass spectrometer, and an AOC-20i autosampler. The first GC, where the initial split/splitless injections take place, contained the apolar, 50 m × 320 μm × 0.50 μm, column (Restek RTX-1 F&F), a transfer line to a FID, and a transfer line to the Deans switch. An advanced pressure control (APC) system is utilized to supply carrier gas at constant pressure, in this case helium, to the Deans switch. The Deans switch serves as a means to transfer effluent from the first GC to the second GC, which is equipped with an orthogonal column phase to achieve advanced second-dimensional separation. The instrument parameters were as follows: the 300 °C inlet was held at a constant pressure of 220 kPa, and samples were introduced to the inlet using an autosampler at 1 μL with a 10:1 split ratio. The first-dimension oven temperature program started at an initial temperature of 40 °C and then increased at 2 °C/min to 310 °C. The transfer line between the two GCs was 150 °C, and the APC, operating in the constant pressure mode, was held at 180 kPa. The second GC was equipped with a Sol−Gel Wax polar, 60 m × 320 μm × 0.25 μm, column (SGE Analytical Services). The oven was set to an initial temperature of 30 °C and increased at a rate of 4 °C/min to 260 °C. The end of the second column was inserted into the mass spectrometer source, which was operated under EI conditions. The source temperature was 200 °C, with the interface temperature at 230 °C. The mass scan range was set to scan from m/z 33 to 250 with a scan speed of 800 u/s, and the EI energy was set to 70 eV.

Nuclear Magnetic Resonance. NMR spectra were recorded at 26.8 °C in deuterated chloroform (containing 0.05% v/v tetramethylsilane) on a Bruker Avance III 400 MHz or a Bruker Avance 500 MHz spectrometer (Billerica, MA, USA), with 5 mm BBO probes. ^{1}H chemical shifts are expressed as parts per million (ppm) with residual chloroform (δ 7.26) or tetramethylsilane (δ 0.00) as references and are reported as chemical shift (δH), relative integral, and multiplicity (s, singlet; br, broad; d, doublet; t, triplet; higher multiplicities as, e.g., dd, doublet of doublets; m, multiplet), and coupling constants (J) are reported in hertz.

RESULTS AND DISCUSSION

Aroma-Active Compounds in Lemon Peel Extract. Peel oil can be obtained commercially by cold-pressed or distillation techniques, as well as in the laboratory by hand-pressing or grating. For the grated peel, different organic solvents are available to preferentially extract the volatile constituents from the grated peel. The Lisbon lemon peels in this research were zested and extracted with DCM, an organic solvent with a high extraction capacity and affinity for a wide range of volatile constituents. Using paper blotters, the aroma of the lemon peel extract was described as bright, aldehydic, and citrus-like with subtle sulfurous notes. Identifying and characterizing the odor-active compounds in lemon oil has been completed in the past.[28,29] To the best of our knowledge, this was the first attempt to perform AEDA and assign FD factors to the aroma-active compounds from laboratory-extracted lemon peel oil.

In the lemon extract, 27 odor-active regions were detected by GC-O with FD factors of at least 3 (Table 1). Four of the odor-active areas with the highest dilution factors included limonene **80**, linalool **106**, neral **202**, and geranial **216**. The fifth area with an equally high dilution factor had a "sulfurous, skunk-like" aroma. At this particular area, no peak appeared by FID or CLSD runs. The concentration at which this presumed VSC was found in the lemon extract must therefore be below the limit of detection for the sulfur chemiluminescence detector, which is 0.1 ppm of sulfur. With knowledge of the RI from the odor from two orthogonal columns by GC-O, prenyl mercaptan was proposed as the source of the odor. This compound has been identified as a highly odorous compound in other natural products, including beer,[30] coffee,[31] wine,[32] durian,[33] and most recently virgin olive oil,[34] but never in citrus fruits. This compound was subsequently spiked into the lemon extract at a concentration high enough to produce a signal on the GC. The RI and odor descriptors from the two GC-O runs on orthogonal columns of this spiked extract matched that of the original extract. Although there is no GC-MS evidence to support this claim, prenyl mercaptan, which can be formed from cysteine via free radical mechanisms,[35] appears to be found in the lemon peel extract in the parts per billion or parts per trillion range and significantly contributes to the aroma of the extract.

Relative flavor activity (RFA), which is a measure of the log of the FD factor divided by the weight percent of the compound, can be a valuable calculation to understand which

[f]Required MRM to confirm presence on polar column.

flavor components contribute to the aroma of a sample.[36,37] These values are not shown in Table 1 mainly because of the difficulty of calculating this value when compounds do not have a measured weight percentage. For example, prenyl mercaptan and 3-mercapto-3,7-dimethyl-6-octenyl acetate **378** did not have measured weight percentages by GC, but would have two of the highest RFA values due to its FD factor and extremely low concentration, which is quite remarkable and unique for lemons. A similar conclusion could be made for 8-methylnonanal **143** (green, peely, citrus) and 8-methyldecanal **220** (green, woody, cucumber), which were found at trace levels in the fractions and possess low odor thresholds.[38]

Composition of Volatile Compounds in the Lemon Peel Extract. Due to the complexity of natural product extracts, fractionation has become a primary technique to circumvent peak coelution and identify lower concentration compounds by selectively separating compound classes using gradient elution. Specifically for lemons, fractionation on both the juice[39] and the peel[10] has led to novel findings. To separate and enhance the trace volatiles from the complex volatile lemon peel matrix and to assist with properly linking GC-O data, the peel extract in this study was fractionated into its different chemical classes. Furthermore, monodimensional analysis has its limitations in citrus extracts as terpenes and sesquiterpenes interfere with lower concentration potentially odor-active components. Therefore, MDGC-MS was utilized for the analysis of the peel extract and its fractions. Unresolved peaks on the primary column were heart-cut onto a secondary (orthogonal) column using the Deans switch.[40] A summary of the volatile compounds in the peel extract and fractions is listed in Table 2 in order of elution on an apolar column. Known compounds were identified using RI from apolar and polar columns, coupled with mass spectral data. Several unknown compounds were postulated, synthesized, and confirmed in the lemon extract by comparing the RI of two orthogonal column phases and mass spectral data. The major components of the peel extract included limonene (63.7%), β-pinene (14.5%), and γ-terpinene (9.9%). The composition of the major chemical classes in the peel extract represented 94.8% hydrocarbons, 2.0% aldehydes, 1.6% alcohols, and 1.3% esters.

Aldehydes are known to play a key role in the aroma of citrus fruits, especially lemons. The medium-polarity fractions from the lemon extract comprised a series of 2-methyl, 3-methyl, 4-methyl, 6-methyl, and 8-methyl branched aliphatic aldehydes, many of which were synthesized and confirmed for the first time in lemons, citrus fruits, or any other botanical species. Only the branched aldehydes 4-methylnonanal **140** and 4-methylundecanal **274** have been previously identified in lemons.[10] It should be noted that 6-methylnonanal **136** required MRM for confirmation in one of the lemon fractions, where the transitions of m/z 110.0 to 95.0 and 95.0 to 67.0 were monitored for the fraction, the standard solution of **136**, and the fraction spiked with the standard. The synthesis scheme for **136** is shown in Figure 1. A similar mechanism was used for the synthesis of 6-methyldecanal **215** and the series of 4-methyl branched aliphatic aldehydes.

Identification of Volatile Sulfur Compounds. As each of the fractions was analyzed, it was increasingly evident that there were several unknown VSCs present. Formed through biochemical and enzymatic pathways,[41] as well as thermal processing,[42] VSCs are rarely reported in citrus research literature. The Lisbon lemons were purchased in early spring, the main harvest season for this lemon variety in the state of California. An elemental specific analysis for VSCs in the peel extract was carried out using a GC coupled to a CLSD in the sulfur mode only. Supercritical fluid extraction (SFE) of the peel was used to compare and validate the chromatographic results from the CLSD trace of the lemon peel DCM extract. Figure 2 shows the chromatograms obtained for both extraction techniques. Because the two chromatograms mirrored one another, the peel extract that was steeped in DCM was chosen for further research due to the large amount of extract, an

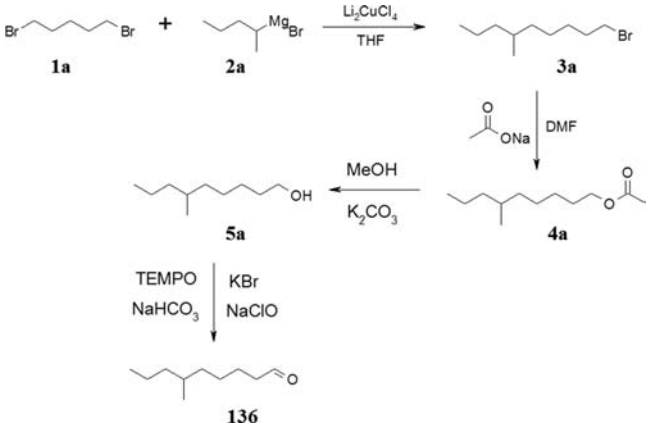

Figure 1. Synthesis of 6-methylnonanal **136**.

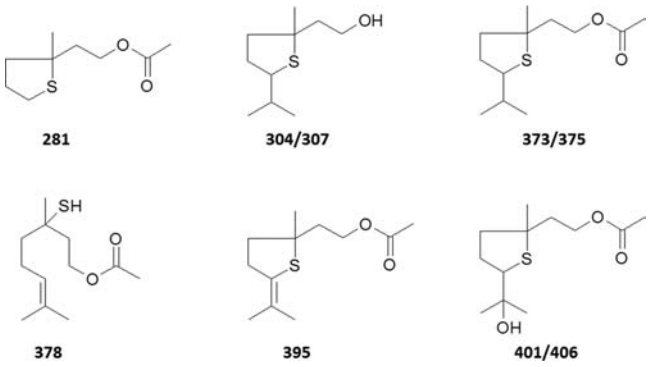

Figure 3. Chemical structures of synthesized VSCs.

important factor when multiple analytical techniques are used. Three well-known sulfur compounds were identified in the fractions: sulfur dioxide **1**, 2-propionylthiophene **152**, and methional **31**. First identified in black tea,[43] **152** is new to lemons and has been described in reaction mechanisms involving ascorbic acid and cysteine.[44] The medium-polarity fractions led to the identification of **31**, which is also new to lemons.

There were several novel VSCs identified in the peel extract (Figure 3), including one VSC that was present at a high enough concentration in the extract to produce a mass spectral signal. On the basis of the fragmentation pattern and accurate mass measurements of that peak, the structure was postulated as 3-mercapto-3,7-dimethyl-6-octenyl acetate **378**. This structure was synthesized (Figure 4) and confirmed by NMR. During the sodium borohydride reduction to produce **378**, it should be noted that a clean acetyl moiety migration occurred, as careful analysis of the crude did not yield the intermediate (**4b**). The RI on two orthogonal columns and the mass spectrum for the synthesized structure supported the presence of this compound in the peel extract. Even though the synthesized structure is highly unstable, **378** produced the strongest signal on the CLSD, as shown in Figure 2, and is considered stabilized by the antioxidants and tocopherols in the matrix of the peel extract. This was confirmed experimentally as

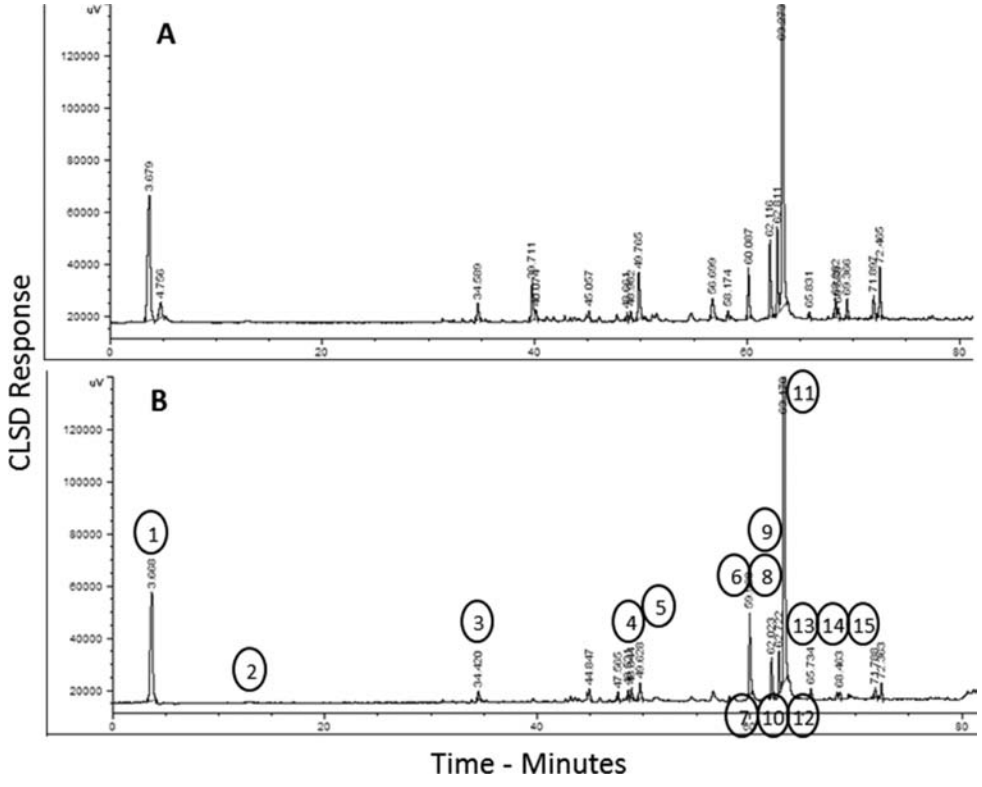

Figure 2. Comparison of the CLSD chromatograms by SFE (A) and DCM extraction (B). Peak identification from the DCM extraction (B) is as follows: (1) sulfur dioxide **1**; (2) methional **31**; (3) 2-propionylthiophene **152**; (4) 2-(2-methyltetrahydrothiophen-2-yl)ethyl acetate **281**; (5) 2-(5-isopropyl-2-methyltetrahydrothiophen-2-yl)ethanol **304** and **307**; (6) 2-(5-isopropyl-2-methyltetrahydrothiophen-2-yl)ethyl acetate (isomer 1) **373**; (7) 2-(5-isopropyl-2-methyltetrahydrothiophen-2-yl)ethyl acetate (isomer 2) **375**; (8) 3-mercapto-3,7-dimethyl-6-octenyl acetate **378**; (9) 2-(5-isopropylidene-2-methyltetrahydrothiophen-2-yl)ethyl acetate **395**; (10) 2-[5-(1-hydroxy-1-methylethyl)-2-methyltetrahydrothiophen-2-yl]ethyl acetate (isomer 1) **401**; (11) 2-[5-(1-hydroxy-1-methylethyl)-2-methyltetrahydrothiophen-2-yl]ethyl acetate (isomer 2) **406**.

DOI: 10.1021/jf505177r
J. Agric. Food Chem. 2015, 63, 1915−1931

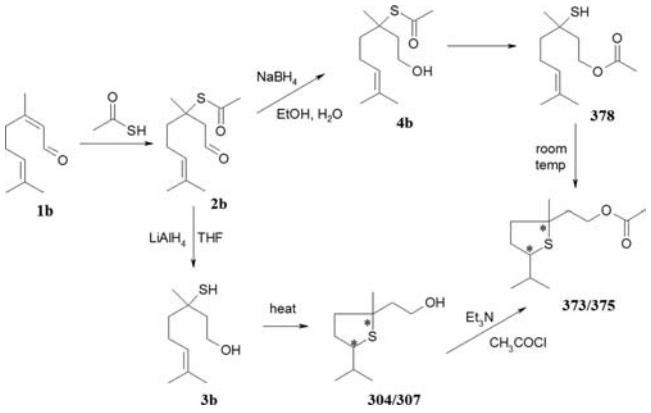

Figure 4. Synthesis of 2-(5-isopropyl-2-methyltetrahydrothiophen-2-yl)-ethanol **304** and **307**, 3-mercapto-3,7-dimethyl-6-octenyl acetate **378**, and 2-(5-isopropyl-2-methyltetrahydrothiophen-2-yl)-ethyl acetate **373** and **375**. The asterisks in the final product of both lemon VSCs indicate there are a set of unresolved chiral centers from the diastereomeric mixtures.

the addition of tocopherols at the end of the synthesis of **378** produces a stable material in a shelf-life study (data not shown). The biochemical or enzymatic mechanism by which this VSC forms is still under investigation. There is evidence that the amino acids cysteine and methionine, the precursors from which VSCs could form, are present in lemons.[45−48] In addition, hydrogen sulfide has been quantitated in the headspace of fresh lemon juice.[23] It was postulated that **378** could form from the reaction of hydrogen sulfide and neryl acetate, which tends to comprise a larger percentage of the volatile constituents in lemons compared to other citrus fruits.

To identify the other peaks on the CLSD chromatogram, the fractions were studied in-depth by GC-MS and MDGC-MS. Two unknown peaks in two of the polar fractions appeared to be isomers of each other with the same molecular weight and elemental formula as **378**. With NMR and mass spectral data from the synthesis and instability of **378** (Figure 4), there was a clear understanding that these two unknown isomers were 2-(5-isopropyl-2-methyltetrahydrothiophen-2-yl)ethyl acetate **373** and **375**. The thiol group from **378** readily attacks the double bond and undergoes internal cyclization to form **373** and **375**. This internal cyclization occurs rapidly, as **378** is unstable even at cooler temperatures.

Also in the polar fractions were what appeared to be two unknown isomeric VSCs that produced a clear signal on a polar column. After further investigation from data on the mass intensities and the elemental composition, the structure was proposed as 2-(5-isopropyl-2-methyltetrahydrothiophen-2-yl)-ethanol **304** and **307** and synthesized (Figure 4). Using a Waters Quattro Micro triple-quadrupole MS, a method operating in the MRM mode was developed to identify this compound in the lemon extract using the synthesized structure. The collision energy was set to 10 eV, and the transitions, *m*/*z* 188.0 to 101.0 and 145.0 to 101.0, were monitored as the major mass intensities from the spectrum of **304** and **307** for the fraction, a standard solution of **304** and **307**, and the fraction spiked with the standard. Similar to the formation of **373** and **375**, it was proposed that **304** and **307** could form in the lemon peel from the internal cyclization from 3-mercapto-3,7-dimethyl-6-octenol (the reaction of hydrogen sulfide and nerol; not observed) or from the hydrolysis of the corresponding esters **373** and **375** in acidic conditions.

Interestingly, there was another sulfur peak with the same molecular weight and similar mass spectral fragmentation as **304** and **307** that eluted earlier on both columns (see mass spectral data in the Supporting Information). From the analysis of the elemental composition, this sulfur peak had a different molecular formula and double bond equivalency. The postulated structure, 2-(2-methyltetrahydrothiophen-2-yl)ethyl acetate **281**, was synthesized as shown in Figure 5 and

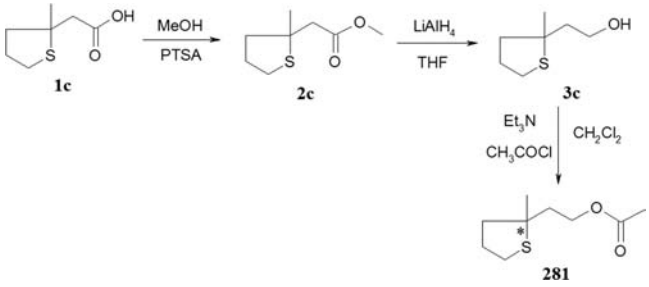

Figure 5. Synthesis of 2-(2-methyltetrahydrothiophen-2-yl)ethyl acetate **281**. The asterisk in the final product of **281** indicates there is an unresolved chiral center from the enantiomeric mixture.

confirmed as matching RI and mass spectral data for the peak in the lemon extract. The mechanism of formation for **281** is very difficult to understand, as the earlier mentioned VSCs can partly be explained through the internal cyclization of the citral-like backbone, but **281** appears to have derived through another pathway.

The final VSCs identified in the polar fractions included 2-[5-(1-hydroxy-1-methylethyl)-2-methyltetrahydrothiophen-2-yl]-ethyl acetate **401** and **406** and 2-(5-isopropylidene-2-methyltetrahydrothiophen-2-yl)ethyl acetate **395**. Similar to **304** and **307**, the synthesis of these compounds involved an internal cyclization step, but, unlike **304** and **307**, which used citral as the starting material, 6,7-epoxyneral **246** was chosen as the starting material to generate the final tertiary alcohol for **401** and **406** (Figure 6). In the lemon peel, however, the mechanism of formation is unknown for these compounds, although it appears as if **395** could form from the dehydration of **401** and **406**.

As shown in Figures 4−6, the lemon VSCs are a mixture of diastereomers. Unfortunately, the authors cannot comment on

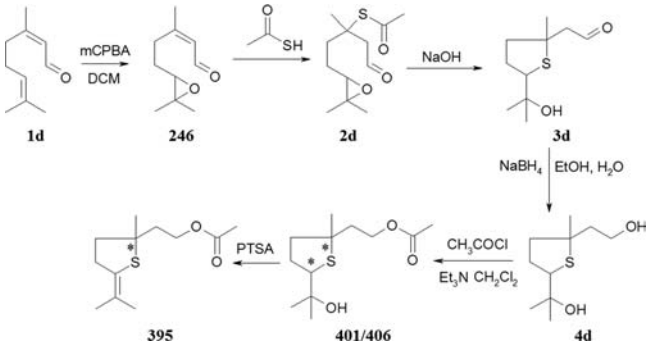

Figure 6. Synthesis of 2-(5-isopropylidene-2-methyltetrahydrothiophen-2-yl)ethyl acetate **395** and 2-[5-(1-hydroxy-1-methylethyl)-2-methyltetrahydrothiophen-2-yl]ethyl acetate **401** and **406**. The asterisks in the final product of both lemon VSCs indicate there are a set of unresolved chiral centers from the diastereomeric mixtures.

[a]Orthonasal evaluations were conducted using paper blotters at a 0.1% solution in ethanol. [b]Retronasal evaluations were conducted at various concentrations in water.

the identity or quantity for each of the chiral compounds as it was outside the scope of this work.

Organoleptic Evaluation of Synthesized VSCs. The novel VSCs were synthesized to not only confirm their presence in lemons but to gain a better understanding of the orthonasal and retronasal properties of each compound. The orthonasal evaluations were completed on paper blotters, and the retronasal evaluations were completed in water (Table 3).

■ ACKNOWLEDGMENTS

We are grateful for the following members of the IFF team who assisted in all aspects of this research: Susan Joseph, Stephen Toth, Sharon Brown, Dennis Swijter, Danielle Dinallo, Ubaideen Hassan, Jerry Kowalczyk, Mauricio Poulsen, Kurt Nordman, Kelly Carroll, Dennis Kujawski, Jung-A Kim, and Cynthia Vuich. We are also thankful for Dr. Russell Rouseff's recommendation for analyzing lemons as a potential source for VSCs.

■ ABBREVIATIONS USED

AEDA, aroma extract dilution analysis; CLSD, chemiluminescence detector; DCM, dichloromethane; FD, flavor dilution; GC, gas chromatography; GC-MS, gas chromatography–mass spectrometry; GC-O, gas chromatography–olfactometry; MDGC-MS, multidimensional gas chromatography–mass spectrometry; MRM, multiple reaction monitoring; ODP, olfactory detection port; RI, retention index; RFA, relative flavor activity; SFE, supercritical fluid extraction; VSC, volatile sulfur compound

biotransformations in vivo. We report here the synthesis of a series of deuterium-labeled standards and the use of these as internal standards in GC-MS to compare the evolution of several guaiane derivatives during in vitro aerial oxidation of α-guaiene (**1**) and α-bulnesene (**5**) over time at ambient temperature and on a submilligram scale.

MATERIALS AND METHODS

Chemicals. Acetic anhydride (≥98%, ACS reagent grade), pyridinium dichlorochromate (PDC), *tert*-butyl hydroperoxide (5−6 M in decane), selenium dioxide (SeO_2), cerium chloride heptahydrate ($CeCl_3{\cdot}7H_2O$), sodium borohydride ($NaBH_4$), lithium aluminum deuteride ($LiAlD_4$), deuterium oxide (D_2O), d_6-ethanol, triethylamine (Et_3N), palladium acetate ($Pd(OAc)_2$), 4-dimethylamino pyridine (DMAP), sodium sulfite (Na_2SO_3), and anhydrous magnesium sulfate were purchased from Sigma-Aldrich. Deuterated benzene (C_6D_6) and deuterated chloroform ($CDCl_3$) were purchased from Cambridge Isotope Laboratories, Inc. (Tewksbury, MA, USA). Anhydrous aluminum trichloride ($AlCl_3$), silver nitrate ($AgNO_3$), AR-grade hexanes, methanol, ethyl acetate, acetonitrile, tetrahydrofuran, toluene, and HPLC-grade dichloromethane were purchased from Merck. Sodium ethoxide solid was prepared freshly by dissolving sodium metal in absolute ethanol under N_2 followed by solvent removal and drying in vacuo. Guaiac wood essential oil (steam distilled from Bulnesia sarmientoi, Paraguay) was purchased from the Australian Botanical Products Co. as viscous oil.

General Experimental Procedures. All reagents were purchased from commercial sources and used directly unless otherwise stated. Solvents for synthesis were purified according to known procedures wherever needed.[12] NMR data were recorded on Varian-Inova 500/600 MHz spectrometers. $CDCl_3$ and C_6D_6 were used as solvents for NMR experiments. All ^1H and ^{13}C NMR spectra were calibrated utilizing residual ^1H and ^{13}C signals of deuterated solvents set at 7.26 and 77.0 ppm for $CDCl_3$ and 7.16 and 128.06 ppm for C_6D_6, respectively. GC-MS quantitative analysis was performed with an Agilent 6890 GC- 5973N MSD equipped with a DB-Wax capillary column (30 m × 250 μm I.D. × 0.25 μm film thickness, Agilent technologies). GC-MS analysis was performed with the following acquisition parameters: oven temperature was initially set at 100 °C and increased to 200 °C at 8 °C/min and then to 240 °C at 20 °C/min and held at 240 °C for a further 3 min; injection was in splitless mode with a purge flow of 6 mL/min in 0.05 min; front inlet temperature was set at 240 °C with a pressure of 12.92 psi; injection volume was 2 μL, and gas flow rate was 1.2 mL/min; MSD was in selective ion monitoring (SIM) mode. The ions 204 (for **1**, **5**), 220 (for **2a**, **2b**, **6a**, **6b**), 211 (for **10**, **15**), 218 (for **3**, **7**), 225 (for **11a, 11b**, **16**), and 223 (for **9**, **14**) were selected as quantifiers. Qualifier ions selected for the corresponding quantifiers were 105, 147, and 161 for **1**, 105, 163, and 205 for **2a** and **2b**, 105, 147, and 203 for **3**, 107, 147, and 161 for **4**, 147, 163, and 204 for **6a** and **6b**, 147, 161, and 203 for **7**, 108, 165, and 208 for **9**, 108, 165, and 196 for **10**, 108, 165, and 208 for **11a** and **11b**, 111, 163, and 208 for **14**, 112, 150, 166 for **15**, and 111, 165, 208 for **16**. The dwell times for all selected ions were set at 100 ms, gain factor was 1 and EI 70 eV, transfer line temperature was 240 °C, MS source was at 230 °C, and MS quadrupler was at 150 °C. Whatman grade 1 filter paper was the support medium for oxidation of **1** and **5**. Silica column chromatography (SCC) was performed using either LC60A 40−63 μm silica (Grace Davison) or Silica gel 60 (0.015−0.040 mm, Merck). TLC was conducted with TLC silica gel 60 F_{254} plates (Merck KGaA) using standard vanillin stain for visualization. Silver nitrate impregnated silica (SNIS) was prepared according to the literature.[13] Rotundone (**3**) and the rotund-2-ols (**2a**/**b**) were prepared as described previously.[3,5]

Synthesis of Deuterium-Labeled Standards for GC-MS. *d_5-Rotundone (**9**).* **9** was prepared as described previously with slight modification.[14] Rotundone (**3**) (180 mg, 0.83 mmol) was dissolved in a 1 M solution of NaOEt in d_6-ethanol (1 mL) in a vial (4 mL), which was capped under N_2 and left at room temperature overnight (ca. 20 h). Brine (2 mL) was added, and the resulting mixture was extracted with Et_2O (4 × 5 mL). The combined ether layers were concentrated, dried over anhydrous $MgSO_4$, and filtered, and the filtrate was concentrated in vacuo. The residue was purified with silica (15−40 μm) column chromatography (Et_2O/hexanes, 8%), affording **9** (75 mg, 42%) as a pale yellow oil. Spectroscopic data of **9** including NMR and MS was in accord with those reported in the literature.[14]

*d_7-α-Guaiene (**10**).* $LiAlD_4$ (42 mg, 1 mmol) was suspended in dry ether (1 mL) at room temperature under N_2. To the above solution was added dropwise a solution of anhydrous $AlCl_3$ (159 mg, 1.19 mmol) in dry ether (1 mL) with stirring. After 10 min, a premixed solution of d_5-rotundone **9** (32.1 mg, 0.14 mmol) in dry ether (0.5 mL) and anhydrous $AlCl_3$ (133.5 mg, 1 mmol) in dry ether (0.5 mL) was added dropwise. After stirring for 1 h, the reaction mixture was chilled in an ice bath before being quenched by slow addition of D_2O (2 mL) followed by 6 N H_2SO_4 (2 mL). The resulting mixture was extracted with ether (3 × 20 mL), and the combined ether layers were washed with brine (10 mL), dried over anhydrous $MgSO_4$, and filtered. The filtrate was concentrated in vacuo, and the residue was purified by SNIS chromatography (hexanes) to yield **10** (27.2 mg, 88%). ^1H NMR (600 MHz, $CDCl_3$) δ 4.68 (br s, 1H, H_{12a}), 4.62 (dq, 1H, J = 2.4, 1.5 Hz, H_{12b}), 2.34 (m, 1H, H_{10}), 2.11 (m, 1H, H_7), 1.72 (s, 3H, H_{13}), 1.71−1.67 (m, 3H, $H_{8a,\ 8b,\ 9a}$), 1.59 (m, 1H, H_{9b}), 1.01 (d, 3H, J = 6.6 Hz, H_{15}), 0.92 (s, 3H, H_{14}); ^{13}C NMR (150 MHz, $CDCl_3$) δ 152.4 (C_{11}), 140.5 (C_1), 138.5 (C_5), 107.9 (C_{12}), 46.4 (C_7), 33.8 (C_9), 33.7 (C_{10}), 31.0 (C_8), 20.4 (C_{13}), 19.7 (C_{14}), 18.6 (C_{15}). See Supporting Information for the mass spectra of **10** and other deuterium-labeled compounds.

*d_5-2R-Rotundol (**11a**) and d_5-2S-rotundol (**11b**).* **11a** and **11b** were synthesized from d_5-rotundone using the same protocol as described for preparing d_0-rotundols (**2a**/**b**)[5] except that d_5-rotundone (**5**, 40 mg, 0.18 mmol), $CeCl_3{\cdot}7H_2O$ (70 mg, 0.19 mmol), MeOH (5 mL), and $NaBH_4$ (10 mg, 0.27 mmol) were used. d_5-2*R*-Rotundol (**11a**, 23 mg, 65%, based on 87% conversion) and d_5-2*S*-rotundol (**11b**, 4 mg, 11% based on 87% conversion) were obtained as a white solid and a colorless liquid, respectively, with d_5-rotundone (5 mg, 13%) recovered after purification by silica (15−40 μm) column chromatography (Et_2O/hexanes, 8%−12%). **11a**: ^1H NMR (600 MHz, C_6D_6) δ 4.79 (dq, 1H, J = 1.8, 1.5 Hz, H_{12a}), 4.73 (dq, 1H, J = 2.0, 1.4 Hz, H_{12b}), 4.38 (s, 1H, H_2), 2.50 (qdd, 1H, J = 7.2, 4.2, 3.6 Hz, H_{10}), 1.95 (m, 1H, H_7), 1.84 (dddd, 1H, J = 13.8, 12.0, 11.4, 2.4 Hz, H_{8a}), 1.73 (dddd, 1H, J = 13.8, 6.0, 2.7, 2.3 Hz, H_{8b}), 1.65 (s, 3H, H_{13}), 1.60 (dddd, 1H, J = 13.8, 6.0, 4.2, 2.4 Hz, H_{9a}), 1.56 (m, 1H, H_{9b}), 1.21 (d, 3H, J = 7.2 Hz, H_{15}), 0.96 (s, 3H, H_{14}); ^{13}C NMR (150 MHz, C_6D_6) δ 151.7 (C_{11}), 144.1 (C_1), 142.4 (C_5), 108.3 (C_{12}), 80.5 (C_2), 46.5 (C_7), 33.6 (C_9), 31.7 (C_{10}), 31.1 (C_8), 20.7 (C_{14}), 20.0 (C_{13}), 18.2 (C_{15}); EI-MS m/z (rel. intensity) 225 ($[M]^+$, 30), 206 (14), 191 (15), 179 (19), 167 (100), 148 (26), 135 (21), 121 (36), 108 (42), 95 (45), 81 (30), 67 (24), 55 (21). **11b**: ^1H NMR (600 MHz, C_6D_6) δ 4.80 (br s, 1H, H_{12a}), 4.74 (dq, 1H, J = 2.4, 1.8 Hz, H_{12b}), 4.57 (br s, 1H, H_2), 2.65 (qdd, 1H, J = 7.2, 4.2, 3.6 Hz, H_{10}), 2.14 (m, 1H, H_7), 1.75−1.71 (m, 2H, $H_{8a,\ 8b}$), 1.70−1.69 (m, 1H, H_{9a}), 1.64 (s, 3H, H_{13}), 1.61 (m, 1H, H_{9b}), 1.01 (d, 3H, J = 7.2 Hz, H_{15}), 0.83 (s, 3H, H_{14}); ^{13}C NMR (150 MHz, C_6D_6) δ 152.2 (C_{11}), 144.5 (C_5), 143.2 (C_1), 109.0 (C_{12}), 79.0 (C_2), 47.1 (C_7), 34.8 (C_9), 31.7 (C_8), 30.8 (C_{10}), 20.8 (C_{13}), 20.6 (C_{14}), 18.4 (C_{15}).

Forty Seven Percent α-Bulnesene Hydrocarbons. The guaiacwood oil mother liquor containing ca. 47% α-bulnesol (**12**) was obtained after repeated recrystallization of guaiol with MeCN and used for the synthesis of bulnesene-enriched hydrocarbons employing acylation followed by pyrolysis as described for the synthesis of **1**.[15] To the guaiacwood oil mother liquor (33 g) was added acetic anhydride (100 mL) and DMAP (330 mg). The resulting mixture was heated under reflux at 150 °C under N_2 for 6 h. After being cooled to room temperature, the reaction products were extracted with hexanes (4 × 200 mL) and the combined hexane layers washed with substantial water, and brine and dried over anhydrous $MgSO_4$. The hexane extract was filtered through filter paper, and solvent removal gave a crude product (40 g) containing 47% bulnesyl acetate (**13**, GC-MS). Crude bulnesyl acetate (23 g) was heated to ∼220 °C under N_2 for 3.5 h, while the acetic acid generated was condensed and collected in a

DOI: 10.1021/jf505537s
J. Agric. Food Chem. 2015, 63, 1932−1938

receiving flask. The reaction was terminated and its temperature lowered to room temperature when no more acetic acid was being generated. To this reaction mixture was added hexanes (100 mL) and silica (ca. 30 g). The resulting suspension was filtered through a bed of silica (ca. 100 g) and further eluted with hexanes (3 × 100 mL). The combined filtrates were concentrated in vacuo to afford the bulnesene-rich hydrocarbons (47% by GC-MS, 15.6 g, 90% from **12**). Pure α-bulnesene (**5**) was obtained as a colorless oil after repeated SNIS chromatography (hexanes) of the 47% bulnesene hydrocarbon mixture. α-Bulnesene (**5**): ^{1}H NMR (600 MHz, $CDCl_3$) δ 4.66 (br s, 1H, H_{12a}), 4.64 (dq, 1H, *J* = 2.0, 1.5 Hz, H_{12b}), 2.47 (dd, 1H, *J* = 12.0, 7.2 Hz, H_5), 2.33 (m, 1H, H_{2a}), 2.23−2.15 (m, 2H, $H_{9a,\ 2b}$), 2.13−2.08 (m, 2H, $H_{4,\ 7}$), 2.01 (br dd, 1H, *J* = 15.0, 7.2 Hz, H_{9b}), 1.73−1.69 (m, 1H, H_{8a}), 1.71 (br s, 3H, H_{13}), 1.67 (br s, 3H, H_{15}), 1.65 (m, 1H, H_{3a}), 1.62 (m, 1H, H_{6a}), 1.35 (dq, 1H, *J* = 12.0, 7.8 Hz, H_{3b}), 1.26 (dddd, 1H, *J* = 13.2, 11.4, 11.4, 1.5 Hz, H_{8b}), 1.03 (ddd, 1H, *J* = 12.6, 12.0, 12.0 Hz, H_{6b}), 0.90 (d, 3H, *J* = 7.2 Hz, H_{14}); ^{13}C NMR (150 MHz, $CDCl_3$) δ 152.4 (C_{11}), 142.0 (C_1), 128.8 (C_{10}), 108.0 (C_{12}), 50.8 (C_7), 46.8 (C_5), 38.8 (C_4), 34.6 (C_9), 33.1 (C_3), 32.6 (C_6), 31.7 (C_8), 30.4 (C_2), 22.2 (C_{15}), 20.9 (C_{13}), 15.4 (C_{14}). EI-MS *m*/*z* (rel. intensity): 204 ([M]$^+$, 27), 189 (55), 161 (18), 147 (36), 133 (35), 119 (35), 107 (100), 93 (86), 79 (55), 67 (28), 55 (28). ^{1}H NMR data are consistent with that reported in the literature.[16]

*2S-Bulnesol (**6b**).* SeO_2 (1.38 g, 0.5 equiv, 12.5 mmol) was suspended in CH_2Cl_2 (100 mL) under N_2, and the suspension was cooled down to 0 °C. To the stirred suspension at 0 °C was added dropwise a solution of TBHP (5−6 M in decane, 10 mL, 50−60 mmol) in CH_2Cl_2 (15 mL) followed by a solution of α-bulnesene (47% by GC-MS, 5.1 g, 25 mmol) in CH_2Cl_2 (10 mL). After stirring at 0 °C for 3.5 h, the reaction was quenched with saturated aq Na_2SO_3 (50 mL). The resulting mixture was allowed to stir for an additional 0.5 h before being extracted with CH_2Cl_2 (3 × 100 mL), and the combined organic layers were further washed with brine, dried over anhydrous $MgSO_4$, and filtered. The filtrate was concentrated in vacuo, and the residue was purified by SCC (Et_2O/hexanes, from 4% to 12%) to furnish **6b** (1.54 g, 57%) as a white solid. Spectroscopic data was in agreement with those reported in the literature.[17]

*α-Bulnesone (**7**).* α-Bulnesone was synthesized by oxidation of **6b** using palladium-catalyzed oxidation with molecular oxygen.[18] To a stirred solution of **6b** (660 mg, 3 mmol) in THF/toluene (15%, 30 mL) was added $Pd(OAc)_2$ (20.2 mg, 90 μmol) and Et_3N (20 μL, 0.14 mmol). The solution was stirred under an O_2 atmosphere at 45 °C after being evacuated and refilled with O_2 three times. The oxidation was terminated after 52 h by filtration of the reaction mixture through a silica plug (ca. 10 g), which was further rinsed with Et_2O (3 × 20 mL). The combined filtrates were concentrated in vacuo, and the residue was purified by SCC (Et_2O/hexanes, from 4% to 16%) to yield **7** (347 mg, 53%) as a colorless oil. Spectroscopic data of **7** was in agreement with those reported in the literature.[19]

*d_5-Bulnesone (**14**).* Ketone **7** (326 mg, 1.5 mmol) was dissolved in a 1 M solution of NaOEt (102 mg, 1.5 mmol) in d_6-ethanol (1.5 mL), and the resulting mixture was left at room temperature overnight. After ca. 24 h brine was added (5 mL), the aqueous solution was extracted with Et_2O (3 × 15 mL), and the organic layers were combined, dried over anhydrous $MgSO_4$, and filtered. The filtrate was concentrated in vacuo and purified by SCC (Et_2O/hexanes, 8%) to give **14** (293 mg, 88%) as a colorless oil. ^{1}H NMR (600 MHz, $CDCl_3$) δ 4.68 (br s, 2H, $H_{12a,b}$), 2.86 (dd, 1H, *J* = 12.0, 7.2 Hz, H_5), 2.30 (m, 0.6H, H_{9a}), 2.28 (q, 1H, *J* = 7.2 Hz, H_4), 2.25 (ddd, 0.9H, *J* = 14.4, 9.6, 7.8 Hz, H_{9b}), 2.21−2.18 (m, 1H, H_7), 1.80 (m, 1H, H_{8a}), 1.74 (dd, 1H, *J* = 13.2, 3.6 Hz, H_{6a}), 1.70 (br s, 3H, H_{13}), 1.33 (m, 1H, H_{8b}), 1.22 (m, 1H, H_{6b}), 0.94 (d, 3H, *J* = 7.2 Hz, H_{14}); ^{13}C NMR (150 MHz, $CDCl_3$) δ 207.2 (C_2), 154.9 (C_1), 150.8 (C_{11}), 137.0 (C_{10}), 108.8 (C_{12}), 49.3 (C_7), 44.6 (C_5), 36.6 (C_9), 32.5 (C_6), 31.6 (C_4), 29.8 (C_8), 20.9 (C_{13}), 16.0 (C_{14}).

*d_7-α-Bulnesene (**15**).* d_7-Bulnesene was synthesized using the same procedure as that for d_7-α-guaiene except that $LiAlD_4$ (48 mg, 1.12 mmol), anhydrous $AlCl_3$ (159 mg 1.19 mmol), and the mixture of d_5-bulnesone (80 mg, 0.36 mmol) and $AlCl_3$ (133.5 mg, 1 mmol) were utilized. The crude reaction products were purified by repeated SNIS chromatography to yield d_7-bulnesene (33 mg, 44%) as a colorless oil. **15**: ^{1}H NMR (600 MHz, $CDCl_3$) δ 4.66 (br s, 1H, H_{2a}), 4.64 (br s, 1H, H_{12a}), 2.45 (dd, 1H, *J* = 12.0, 7.2 Hz, H_5), 2.19 (br dd, 0.6H, *J* = 15.0, 11.4 Hz, H_{9a}), 2.11−2.06 (m, 2H, $H_{4,\ 7}$), 2.01 (m, 0.9H, H_{9b}), 1.71 (br s, 3H, H_{13}), 1.70 (m, 1H, H_{8a}), 1.62 (ddd, 1H, *J* = 13.2, 1.8, 1.5 Hz, H_{6a}), 1.26 (m, 1H, H_{8b}), 1.03 (ddd, 1H, *J* = 13.2, 12.0, 10.8 Hz, H_{6b}), 0.90 (d, 3H, *J* = 7.2 Hz, H_{14}); ^{13}C NMR (150 MHz, $CDCl_3$) δ 152.4 (C_{11}), 141.9 (C_1), 128.8 (C_{10}), 108.0 (C_{12}), 50.8 (C_7), 46.1 (C_5), 38.7 (C_4), 34.4 (C_9), 32.7 (C_6), 31.8 (C_8), 20.9 (C_{13}), 15.4 (C_{14}).

*2R-Bulnesol (**6a**).* Compound **6a** was synthesized employing Luche reduction as used for the synthesis of 2*R*-rotundol (**4a**)[5] except that α-bulnesone (**7**, 14 mg, 64 μmol), MeOH (3 mL), $CeCl_3{\cdot}7H_2O$ (13 mg, 35 μmol), and $NaBH_4$ (9 mg, 243 μmol) were used, and the reaction was conducted at 0 °C. Purification of the reaction mixture by SCC (Et_2O/hexanes, 10%) yielded 2*R*-bulnesol (6.8 mg, 48%) as a colorless oil. ^{1}H NMR (500 MHz, C_6D_6) δ 4.81 (dq, 1H, *J* = 3.0, 0.8 Hz, H_{12a}), 4.78 (dq, 1H, *J* = 2.0, 1.5 Hz, H_{12b}), 4.53 (dd, 1H, *J* = 6.5, 4.5 Hz, H_2), 2.35 (br dd, 1H, *J* = 12.0, 7.5 Hz, H_5), 2.12 (br dd, 1H, *J* = 15.0, 11.5 Hz, H_{9a}), 2.02 (dddd, 1H, *J* = 12.0, 10.5, 3.0, 2.0 Hz, H_7), 1.94 (qd, 1H, *J* = 7.0, 6.5 Hz, H_4), 1.91 (ddd, 1H, *J* = 15.0, 7.0, 1.5 Hz, H_{9b}), 1.81 (dd, 1H, *J* = 13.0, 6.5 Hz, H_{3a}), 1.79 (ddd, 3H, *J* = 1.5, 1.0, 0.5 Hz, H_{15}), 1.75 (m, 1H, H_{6a}), 1.71 (m, 1H, H_{8a}), 1.68 (dd, 3H, *J* = 1.5, 0.8 Hz, H_{13}), 1.46 (dddd, 1H, *J* = 13.0, 6.5, 4.5, 0.5 Hz, H_{3b}), 1.28 (dddd, 1H, *J* = 13.5, 11.5, 10.5, 1.5 Hz, H_{8b}), 1.22 (ddd, 1H, *J* = 13.0, 12.0, 12.0 Hz, H_{6b}), 1.02 (d, 3H, *J* = 7.0 Hz, H_{14}); ^{13}C NMR (125 MHz, C_6D_6) δ 151.9 (C_{11}), 145.3 (C_1), 135.5 (C_{10}), 108.8 (C_{12}), 74.0 (C_2), 51.3 (C_7), 46.6 (C_5), 43.5 (C_3), 36.3 (C_4), 35.7 (C_9), 34.0 (C_6), 32.1 (C_8), 22.1 (C_{15}), 21.0 (C_{13}), 17.0 (C_{14}). EI-MS *m*/*z* (rel. intensity): 220 ([M]$^+$, 23), 205 (16), 187 (21), 177 (13), 163 (42), 138 (28), 119 (47), 108 (100), 95 (64), 79 (42), 67 (37), 55 (38). ^{13}C NMR data was in agreement with those reported.[4]

*d_5-2R-Bulnesol (**16**).* d_5-Bulnesone was synthesized using the same procedure as that for 2*R*-bulnesol except that d_5-bulnesone (16.7 mg, 75 μmol), $CeCl_3{\cdot}7H_2O$ (16 mg, 43 μmol), and $NaBH_4$ (8 mg, 216 μmol) were used. Purification of the reaction products by SCC (Et_2O/hexanes, 10%) gave d_5-2*R*-bulnesol (10.2 mg, 61%) as a colorless oil. ^{1}H NMR (500 MHz, C_6D_6) δ 4.81 (dq, 1H, *J* = 3.0, 0.8 Hz, H_{12a}), 4.78 (dq, 1H, *J* = 2.0, 1.5 Hz, H_{12b}), 4.52 (s, 1H, H_2), 2.35 (br dd, 1H, *J* = 12.0, 7.5 Hz, H_5), 2.12 (br dd, 0.6H, *J* = 15.0, 11.5 Hz, H_{9a}), 2.02 (dddd, 1H, *J* = 12.0, 10.5, 3.0, 2.0 Hz, H_7), 1.94 (dq, 1H, *J* = 7.5, 7.0 Hz, H_4), 1.91 (m, 0.9H, H_{9b}), 1.75 (m, 1H, H_{6a}), 1.71 (m, 1H, H_{8a}), 1.68 (dd, 3H, *J* = 1.5, 0.8 Hz, H_{13}), 1.28 (m, 1H, H_{8b}), 1.22 (ddd, 1H, *J* = 13.0, 12.0, 12.0 Hz, H_{6b}), 1.02 (d, 3H, *J* = 7.0 Hz, H_{14}); ^{13}C NMR (125 MHz, C_6D_6) δ 151.9 (C_{11}), 108.8 (C_{12}), 73.9 (C_2), 51.2 (C_7), 46.5 (C_5), 43.5 (C_3), 36.3 (C_4), 35.7 (C_9), 34.0 (C_6), 32.1 (C_8), 21.0 (C_{13}), 17.0 (C_{14}).

Preparation and Validation of Calibration Curves. Stock standard solutions in EtOAc were prepared from more concentrated solutions of synthetic standards as follows: Solution A contained **1** (160 μg/mL) and **2a**, **2b**, and **3** (each 80 μg/mL); solution B contained **5**, **6a**, **6b**, and **7** (each 160 μg/mL); solution C contained **9** and **10** (each 80 μg/mL), **11a** (32 μg/mL), and **11b** (128 μg/mL); solution D contained **14**, **15**, and **16** (each 80 μg/mL). Solution A was diluted with EtOAc to a scale of eight concentration levels and each spiked with an equal volume (250 μL) of diluted solution **C** (1:10 dilution) to make up the final concentrations of 0, 0.625, 1.25, 2.5, 5.0, 10.0, 20.0, and 40.0 μg/mL for **2a**, **2b**, and **3** and 0, 1.25, 2.5, 5.0, 10.0, 20.0, 40.0, and 80.0 μg/mL for **1** with corresponding labeled IS at 4.0 μg/mL for **9** and **10**, 1.6 μg/mL for **11a**, and 6.4 μg/mL for **11b**. In a similar fashion, solution B was diluted with EtOAc to a scale of eight concentration levels and each spiked with an equal volume (250 μL) of diluted solution D (1:10 dilution) to make up final concentrations of 0, 1.25, 2.5, 5.0, 10.0, 20.0, 40.0, and 80.0 μg/mL for **5**, **6a**, **6b**, and **7** with corresponding labeled IS at 4.0 μg/mL for **14**, **15** and **16**. The above concentrations of analytes were prepared in duplicate and analyzed by the GC-MS method outlined in the General Experimental Procedures. For generating the calibration curves, the ratios of response areas of selected ions at their corresponding retention times at each concentration [204/211 (**1**/**10**), 220/225 (**2a**/**11a**), 220/225 (**2b**/

DOI: 10.1021/jf505537s
J. Agric. Food Chem. 2015, 63, 1932−1938

11a), 218/223 (**3a**/**9**), 204/211 (**5**/**15**), 220/225 (**6a**/**16**), 220/225 (**6b**/**16**), and 218/223 (**7**/**14**)] were plotted against the ratios of concentrations of analytes versus those of labeled IS [c(**1**/**8**), c(**2a**/**11a**), c(**2b**/**11b**), c(**3**/**9**), c(**5**/**15**), c(**6a**/**16**), c(**6b**/**16**), c(**7**/**14**)]. Samples for quantitative analysis were each spiked with deuterium-labeled IS mixed solutions C or D to make up the final concentrations as those of IS in the preparation of the calibration curves. The concentrations of analytes in the samples were calculated based on calibration equations listed in Table S1, Supporting Information. The method was verified by linearity, relative standard deviation of quantitative analysis, limit of detection (LOD), and limit of quantitation (LOQ). LOD and LOQ are defined as the concentration giving a signal-to-noise (S/N) ratio of 3:1 and 10:1, respectively (Table S1, Supporting Information).

*Oxidation of α-Guaiene (**1**) and α-Bulnesene (**5**).* An α-guaiene solution (ca. 92 mg/mL) was prepared by dissolving **1** (ca. 92 mg) with EtOAc to a total volume of 1.0 mL. An aliquot (5 μL) of the above solution was added to a 1 cm^2 filter paper each in an empty vial (SAMCO specimen tubes 50 × 19 mm). The vials were left uncapped to allow contact with air at room temperature, and the changes of concentrations of **1**, **2a**, **2b**, and **3** at different time points were quantitated for duplicate samples at each time point by SIDA with GC-MS. For determining analyte concentrations, EtOAc (1 mL) was added to each sample vial. An aliquot of the analyte solution (80 μL) was diluted with EtOAc and spiked with solution of labeled IS mixture to make up a total volume of 0.5 mL of solution containing 4 μg/mL labeled IS with a dilution factor of 6.25 for analytes. This solution was analyzed by GC-MS using the parameters described in the General Experimental Procedures, and concentrations of analytes were obtained based on the calibration curves generated above. α-Bulnesene solution was prepared by dissolving α-bulnesene-enriched essential oil containing no **6a**, **6b**, or **7** (ca. 80% bulnesene by GC-MS, 150 mg) in EtOAc (1 mL). Oxidation of α-bulnesene (**5**) and determination of analytes were performed using the same procedure as that described for α-guaiene (**1**).

RESULTS AND DISCUSSION

Synthesis of Deuterium-Labeled Internal Standards (IS). On the basis of the readily synthesized d_5-rotundone (**9**), d_5-rotund-2-ols (**11a**/**b**) could be easily prepared by Luche reduction of **9**. Employing the stronger reducing reagent AlD_3 generated in situ by $LiAlD_4$ and anhydrous $AlCl_3$ realized the reduction of the enone carbonyl to furnish desired **10** in an excellent 88% yield, Figure 2. Our initial attempts to access

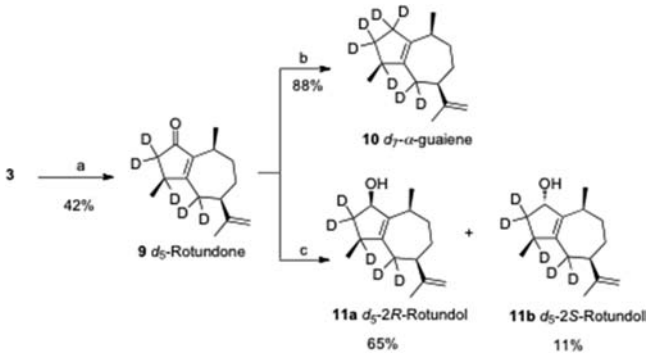

Figure 2. Synthesis of d_7-α-guaiene (**10**) and d_5-rotund-2-ols (**11a**/**b**).

deuterated α-bulnesene **15** via simple isomerization of d_7-α-guaiene **10** under various group VIII metal-catalyzed (e.g., $PdCl_2$, $Pd(OAc)_2$, $RhCl_3$), strongly acidic or basic conditions proved to be ineffective. Therefore, our focus was shifted onto constructing a carbonyl moiety at C2 within α-bulnesene **5** itself to enable initial deuterium exchange followed by removal of the carbonyl moiety by reduction to allow for the preparation of d_7-α-bulnesene (**15**), Figure 3. Direct attempts

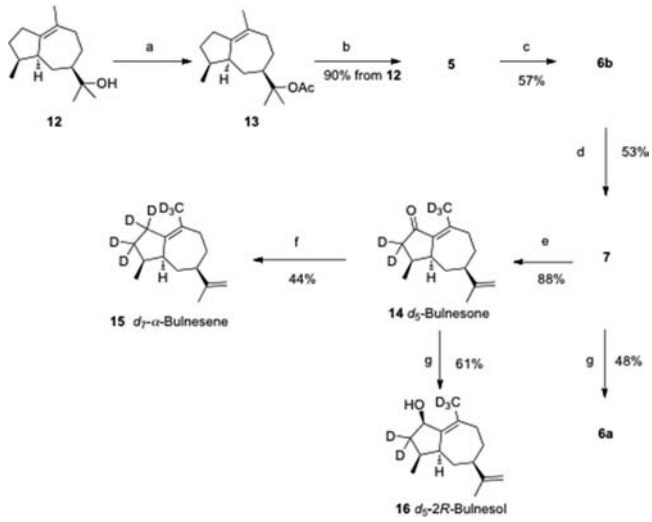

Figure 3. Synthesis of d_5-bulnesone (**14**), d_7-α-bulnesene (**15**), and d_5-2-bulnesols (**16**).

at allylic oxidation of **5** into α-bulnesone (**7**) in a single step exploiting chromium- and cobalt-based oxidants coupled with TBHP were unsuccessful, but allylic oxidation of **5** with SeO_2 and TBHP furnished 2*S*-bulnesol (**6b**) in a moderate 57% yield. Palladium-catalyzed oxidation of **6b** afforded ketone **7** again in moderate yield, which was subjected to deuterium exchange under basic conditions to furnish the desired d_5-bulnesone (**14**) in an excellent yield of 88%. d_5-2*R*-Bulnesol (**16**) and d_7-α-bulnesene (**15**) were successfully synthesized by reduction of **14** in similar fashions as those utilized for the synthesis of the d_5-rotund-2-ols (**11a**/**b**) and d_7-α-guaiene (**10**). Deuterium incorporation by hydrogen exchange is an equilibrium and will always yield a mixture of deuterium-labeled compounds with various degrees of deuterium incorporation at different sites of the substrates depending on the ease of exchange of the hydrogen atoms. For example, deuterium exchange of α-bulnesone **7** was found to be incomplete after the exchange equilibrium was reached, with a very small percentage of α-bulnesone **7** still existing in the labeled d_5-bulnesone **14** mixture. Consequently, this undeuterated analogue was carried through to the d_5-2*R*-bulnesol (**16**) after direct Luche reduction with $NaBH_4$. The nomenclature used here for the deuterium standards **9**, **10**, **11a**/**b**, **14**, **15**, and **16** and their structures are depicted in Figures 2 and 3 and represent the number of exchangeable hydrogens that are mainly substituted with deuterium. A low incorporation of deuterium onto C_9 was apparent for **14**−**16**. The determined deuterium incorporation percentages for all the synthetic standards are presented in Table 1. Approximately 0.6% of **14** and **16** had no deuterium incorporation when equilibrium of exchange had been reached, but the d_0 ions from spiked IS were negligible compared to those for the analytes during GC-MS. The various standard solutions for analysis were prepared at room temperature, stored under N_2, and kept in a freezer before and after each usage but allowed to attain ambient temperature immediately before usage. These standard solutions were found to be stable during handling and under the analysis conditions. Importantly, no autoxidation of the solutions was evident during use.

Evolution of Sesquiterpene Products under Aerial Oxidation Conditions. Employing these deuterium-labeled analogues in GC-MS we were able to monitor the rate of degradation of α-guaiene **1** and α-bulnesene **5** when exposed to air at ambient temperature. To better mimic the oxidation of **1** and **5** on dry herbs and plant materials we used cellulose filter paper as the supporting medium by coating **1** (ca. 380 μg) and **5** (ca. 600 μg) onto filter paper (1 cm^2), respectively. Aerial oxidation of both **1** and **5** produced the corresponding C2 alcohols and ketones, suggesting that oxidation of **5** could follow a similar oxidative pathway to that of **1** via the generation and decomposition of the C2 hydroperoxide epimers as recently described.[3,5]

As shown in Figure 4, some 99% of the α-guaiene **1** was consumed within 48 h. By contrast, the α-bulnesene **5** reacted

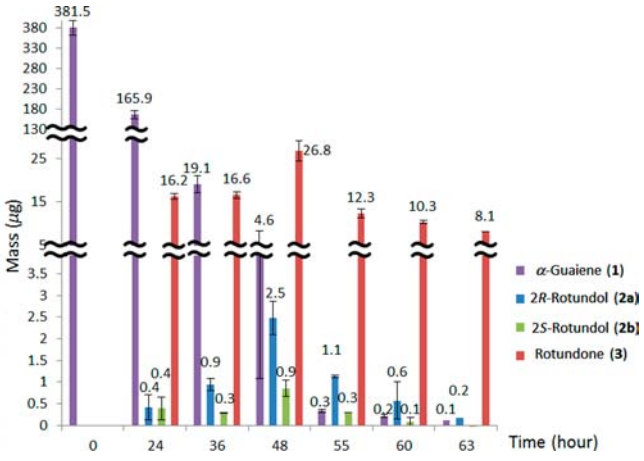

Figure 4. Formation of products from the aerial oxidation of α-guaiene (**1**).

more slowly with 80% remaining after this period. Only a very small quantity of α-bulnesene **5** (ca. 2 μg) was lost over the first 24 h, suggesting that evaporation was not significant under these conditions and indicating that the loss of α-guaiene **1** was due to facile chemical reactions rather than evaporation, based on their similar physical properties. The accelerated degradation of **1** and **5** after the first 24 h can be ascribed to a buildup of reactive radical species following initiation of the autoxidation reactions.

Previously,[3,5] we showed that aerial oxidation of α-guaiene, either in solution or when adsorbed onto filter paper, produced a complex array of products, observable by GC-MS, that could be isolated by column chromatography on deacidified silica or by multi-layer coil counter-current chromatography and identified by spectroscopic methods and X-ray crystallography. These included rotundone **3** (as a major product), the rotundols **2a**/**2b**, and the hydroperoxide **4b**. This last compound decomposed to **3** and **2b** on GC. Therefore, while **3** and **2a**/**2b** are undoubtably genuine autoxidation products of α-guaiene, the peaks observed in the GC could be augmented by decomposition products of hydroperoxides present in the reaction mixture during analysis. Thus, the concentration values for **3**, **2a**/**2b**, **7**, and **6a**/**6b** shown in Figures 4 and 5 could be greater than actually present in the reaction mixtures.

The amount of rotundone measured by GC-MS reached a peak of 26.8 μg (6.6% yield) at the 48 h time point, but this then decreased to 8.1 μg (2% yield) as the reaction progressed further. These figures accord with a previous yield of rotundone (5%) isolated by column chromatography after the reaction was conducted in a similar way but on gram scale and at higher temperature.[5] We had earlier monitored the effect of temperature on the progress of α-guaiene autoxidation by comparing the ratio of α-guaiene:rotundone, showing that this ratio increased faster at higher temperature.[3] The data in Figure 4 indicates that this ratio was due to a rapid degradation of α-guaiene rather than a continuing formation of rotundone. The possibility of rotundone being further oxidized in the reaction mixture was supported by the isolation of oxidized forms of rotundone during the earlier study. In pure form, rotundone **3** is relatively stable to air with only 26% being lost after contact with pure oxygen over 46 days. This suggests that the formation of oxidized forms of **3** will only take place over a short time period when in the presence of a pool of reactive oxygen species or other radical intermediates generated from more reactive substrates such as α-guaiene.

The generation of the products **6a**/**6b** and **7** from autoxidation of α-bulnesene **5** was significantly slower than **2a**/**2b** and **3** from α-guaiene, with the measured amount of the former products reaching a maximum after 108 h. The overall pattern of autoxidation of **5** resembles that of **1** but at a lower overall reaction rate. Interestingly, the formation of the rotund-2-ols (**2a**/**b**) and bulnes-2-ols (**6a**/**b**) over time displayed discrepant stereochemical preferences with the formation of the rotund-2-ols favoring the β-orientation (**2a**) over α-(**2b**) and the bulnes-2-ols favoring the formation of the opposite α-orientation (**6b**) over β-(**6a**).The formation ratio of **2a** vs **2b** was ca. 1:1 in 24 h, increased to ca. 3:1 at 36 h through 48 h, and further rose to ca. 4:1 and 6:1 at 55 and 60 h, respectively, whereas that of **6a** vs **6b** stayed at approximately 1:3. Consequently, it appears that the 2*S*-rotundol **2b** undergoes further oxidation into rotundone **3** in a much more facile fashion when compared to its 2*R*-counterpart **2a** under the specific oxidative conditions outlined herein.

This study has demonstrated that, in a similar fashion to the formation of rotundone (**3**) from α-guaiene (**1**), α-bulnesene (**5**) will generate the aroma compounds 2*R*/2*S*-bulnesol (**6a**

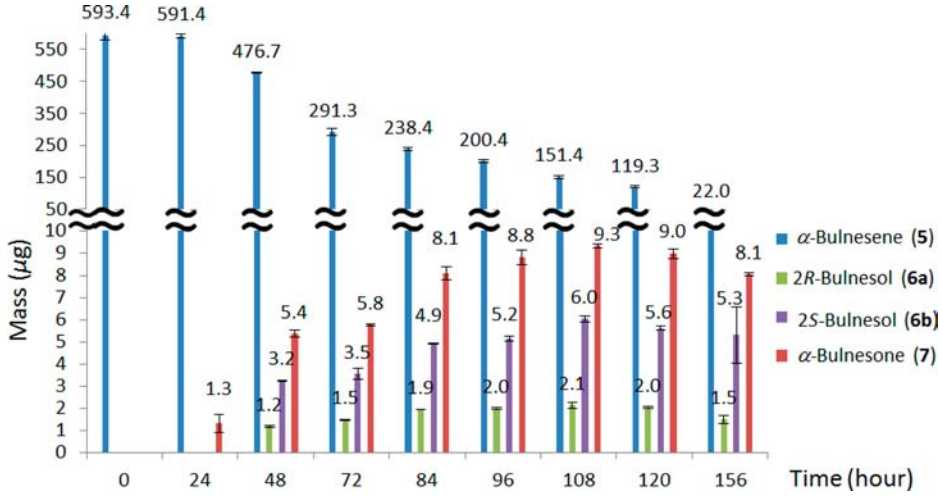

Figure 5. Formation of products from the aerial oxidation of α-bulnesene (**5**).

and **6b**) under simple aerial oxidation condition but that the latter process is much slower than the former. Furthermore, it was found that the formation of 2*R*/2*S*-rotundols (**2a** and **2b**) and 2*R*/2*S*-bulnesols (**6a** and **6b**) displayed stereochemical preferences, which is undoubtedly related to (a) the initial stereochemical preference for formation of the C2-hydroperoxide intermediates from the C2 requisite free radicals followed by decomposition into the observed C2-alcohols with retention of stereochemistry[5] and (b) the unequal consumption of these C2-alcohols by downstream oxidative processes. This study also provides further evidence on how various oxygenated sesquiterpenes may be formed from their precursor hydrocarbons under simple aerial oxidative conditions, shows that for some substrates such transformations can be rapid, even under ambient conditions, and may have implications on the storage and processing of herbs and spices originating from plant materials that contain these sesquiterpene hydrocarbons. Finally, the deuterium-labeled analogues prepared herein may be used to develop more sensitive quantitative analysis methods for the analysis of more complex plant-based matrices.

durian wines; and (3) to establish the relationship between samples, sensory attributes, and aroma compounds using multivariate analysis of PLSR. A better understanding of these points will be helpful for improving the characteristic aroma of durian wine by adjusting fermentation parameters or compensating for typical aroma compounds after alcoholic fermentation.

MATERIALS AND METHODS

Yeast Strains. Five different commercial yeast (*Saccharomyces cerevisiae*) strains were used in this research. Strains GRE (Y1), Lalvin RC212 (Y3), and Lalvin D254 (Y4) were supplied by Lallemand (France). The result showed that strain GRE was capable of producing high amounts of volatile esters, whereas strains RC212 and D254 showed excellent capability in the production of alcohol compounds.[9] Two strains were isolated from Sichuan province, China, named CGMCC2.23 (Y2) and CGMCC2.4 (Y5), and preserved in the Northeast Institute of Science.

Chemicals. Acetaldehyde, methanethiol, ethanethiol, dimethyl sulfide, 1-propanol, 2,3-butanedione, propane-1-thiol, ethyl acetate, 2-butenal, acetic acid, 1-butanol, 2-pentanone, dimethyl disulfide, methyl propanoate, (*Z*)-2-but-2-ene-1-thiol, methyl butanoate, 3-methylbutanol, 2-methylbutanol, 2-octanol (internal standard), 2-methyl-2-butenal, ethyl 2-methylpropanoate, butanoic acid, 2,3-butanediol, ethyl butanoate, propyl propanoate, butyl acetate, 3-methylbut-2-ene-1-thiol, 2-methyl-2-pentenal, methyl ethyl disulfide, ethyl 2-butenoate, ethyl thiolacetate, ethyl 2-methylbutanoate, ethyl 3-methylbutanoate, diethyl disulfide, propyl 2-methylbutanoate, 3-methylbutyl propanoate, 3-methylthio-1-propanol, ethyl hexanoate, propyl 2-methyl-2-butenoic acid, ethyl 2-hexenoate, propyl hexanoate, ethyl heptanoate, dipropyl disulfide, ethyl 2-methylhexanoate, methyl octanoate, 3,5-dimethyl-1,2,4-trithiolane, diethyl trisulfide, and ethyl octanoate were purchased from Sigma-Aldrich (St. Louis, MO, USA). All of them were analytical reagents.

Durian Musts. Fresh durian fruits (*Durio zibethinus* L.) cultivar 'Monthong' originating in Malaysia were purchased from Wal-Mart Stores in Shanghai. Only fully ripened fruits without any split on the husk were selected for the study. Five kilograms of durian fruits was washed in clean water to remove plant residue. Next, the pulp was extracted manually by mechanical pressure. Seeds and pulp residue were separated from the juice by centrifugation (RCF = 11000, 12 min, 18 °C).

Then, the musts were pasteurized for 30 min at 65 °C, cooled, and poured into 10 L bottles. The initial values of musts were as follows: total sugars, 163 g/L; pH, 6.3. The fruit musts were mixed with a sucrose solution to adjust the total sugars to 210 g/L. The pH was adjusted to 3.5 with 1 mol/L DL-malic acid. Sulfur dioxide, in the form of potassium pyrosulfite, was added into the musts to maintain the concentration of 50 mg/L free SO_2 to inhibit bacterial growth. All experiments were carried out in triplicate.

Durian Wine Production. The fermentation temperature for durian wine production was approximately 20 °C, and no stirring was performed during any stage of the fermentation. Yeast strains were grown in YPG medium (1% yeast extracts, 2% peptone, and 2% glucose). With a platinum loop, yeasts were inoculated into tubes containing 200 mL of YPG broth at 20 °C until the cell density reached approximately 10^7 cells/mL. The cells were counted, and an equal amount of cells per strain was resuspended in the same medium for the fermentation. Each vat was then inoculated with 10 mL of prepared suspension to obtain the final cell density of 10^6 cells/mL. Four liters of durian musts was utilized for durian wine production. All vinifications were carried out in a 10 L bioreactor at 20 °C. Fermentation was monitored through measuring viable cells and total reducing sugars. The fermentation was considered to be ended when the sugar content was below 1 g/L. After fermentation, fermented durian musts were transferred to the 10 L bottles and stored at 5 °C for biomass sedimentation. After 24 h, the durian wines were transferred to new bottles without aeration. After 10 days, wines were then filtered with cellulose filters and stored at 5 °C in sealed glass bottles to avoid oxygen entrance.

Standard Chemical Analysis. The official methods of the Office Internationale de Vigne et Vin (OIV)[10] were employed for the conventional determinations, such as pH, ethanol content, total acidity, free SO_2, and total reducing sugar. To analyze glycerol, the Boehringer-Mannheim (Germany) test kit was used. Yeast growth was followed spectrophotometrically (Shimadzu, Kyoto, Japan) by absorbance at 600 nm. Viable cells were determined by plating and counting of colonies on YPG agar.

SBSE Adsorption of Aroma Compounds. Each wine sample (5 mL) was placed in a 20 mL vial, in which 20 μL of internal standard solution (2-octanol, 50 mg/L in the ethanolic solution) was added. A stir bar (Twister) coated with polydimethylsiloxane (PDMS) phase (1 cm length, 0.5 mm thickness, Gerstel Inc., Baltimore, MD, USA) was used to extract the aroma compounds from the sample. The Twister bar was constantly stirred for 50 min at a speed of 600 rpm and 40 °C for extraction temperature. After sampling, the Twister bar was rinsed with distilled water, dried with a Kimwipe tissue paper, and placed into the sample holder of the thermal desorption unit (TDU) (Gerstel, Inc.).

The analyses were performed using a TDU sampler (Gerstel, Inc.) mounted on an Agilent GC-MS system (7890-5975, Agilent Technologies, Santa Clara, CA, USA). The analytes were thermally desorbed at the TDU in splitless mode, ramping from 45 to 240 °C at a rate of 5 °C/min, and held at the final temperature for 5 min. The desorbed analytes were cryofocused (−80 °C) in a programmed temperature vaporizing (PTV) injector (CIS 4, Gerstel, Inc.) with liquid nitrogen. After desorption, the PTV was heated from −80 to 240 °C at a rate of 10 °C/s and held at 240 °C for 5 min. The solvent vent injection mode was employed.

GC-MS Identification of Aroma Compounds. The analyses were performed using a Hewlett-Packard 7890 GC with a 5975 mass selective detector (MSD) (Agilent Technologies) instrument operating under electron ionization (EI) mode (70 eV, ion source temperature 230 °C) with the quadrupole in a scanning mode (scan range was m/z 30−450 at a scan rate of 1 scan/s). Separation of compounds was achieved on Innowax-Wax (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies) and DB-5 (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies). Helium (purity = 99.999%) was used as a carrier with a constant flow velocity of 1 mL/min. The quadrupole mass filter was at 150 °C. The transfer line temperature was operated at 250 °C. The oven temperature was held at 35 °C for 3 min, then ramped to 60 °C at the rate of 2 °C/min, and ramped at the rate of 6 °C/min to 240 °C for the last 5 min. The volatile compounds were identified by comparing retention indices and retention times with those obtained for authentic standards, or those of literature data, or with mass spectra in the Wiley and NIST11 libraries. The RIs were determined via sample injection with a homologous series of alkanes (C5−C30) (Sigma-Aldrich, St. Louis, MO, USA).

GC-MS Quantitation of Aroma Compounds. To obtain a matrix similar to that of durian wine, model wine was prepared containing 15.0 g/L malic acid, 0.5 g/L lactic acid, 2.0 g/L citric acid, 10.0 g/L fructose, 8.0 g/L glucose, and 12% of ethanol in Milli-Q deionized water. The pH was adjusted to 4.0. Quantitation of the major aroma compounds was carried out by standard curves obtained by each compound from six different concentrations in ethanol. The levels of the aroma compounds were normalized by 2-octanol equivalents. The ethanolic solution of internal standard 2-octanol (20 μL of 50 mg/L) was introduced to the 5 mL of model wine in a 20 mL vial and then extracted by SBSE, as was performed for the durian wines.

The standard curves were shown in the research, where y represented the peak area ratio (peak area of volatile standard/peak area of internal standard) and x represented the concentration ratio (concentration of volatile standard/concentration of internal standard). The calibration curves were obtained from Chemstation software (Agilent Technologies Inc.) and used for calculation of volatiles in juices and durian wines.

[a]Values with different letters (a–d) in the same row are significantly different according to the Duncan test ($p < 0.05$).

Gas Chromatography–PFPD. A HP-5890 series II GC from Agilent equipped with a 5380 PFPD detector from OI Analytical (College Station, TX, USA) was used in the sulfur mode. Separation of compounds was achieved on Innowax-Wax (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies) and DB-5 (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies) columns. The oven temperature was held at 35 °C for 3 min, then ramped to 60 °C at the rate of 2 °C/min, and ramped at the rate of 6 °C/min to 240 °C for the last 5 min. GC was operated in a constant flow mode (1 mL/min) with helium as the carrier gas. The PFPD detector was set at 250 °C, and the PMT voltage was set at 500 V. The sulfur-containing compounds were confirmed by comparison with authentic standards on both columns and RI value matching. The quantitation method was identical to the GC-MS analysis as described in the above section. The samples were run in triplicate.

Sensory Analysis. A quantitative descriptive sensory analysis was applied for evaluating five fruit wine samples using a 18 cm line scale by a well-trained panel consisting of 20 members (10 females and 10 males, ages 20–30 years). Before the quantitative descriptive analysis, 30 mL of fruit wine was put in a 100 mL volume white china cup covered with a plastic Petri dish and was served to a panelist in a laboratory at a room temperature (25 °C). Twenty judges had discussed aroma compositions of samples through three preliminary sessions (each needs 3 h), until everyone agreed to use them as the attributes. Then, the quantitative descriptive analysis was executed using five sensory attributes ("fruity", "sulfur", "sweety", "off-flavor", and "harmony") for all five samples that were randomly divided into two sessions. In every session, samples were randomly presented for every member to avert causing a so-called order effect. All of the samples were evaluated in triplicate.

Odor Activity Values (OAV). The contribution of each odor to the overall fruit wine aroma was evaluated by the OAV, which was measured as the ratio of the concentration of each compound to its detection threshold. The threshold values were taken from information available in the references (shown in Table 3).

Statistical Analysis. The chemical data and quantitative descriptive sensory analysis were submitted to variance analysis (ANOVA). Duncan's multiple-comparison tests were applied to determine significant differences between the samples and sensory attributes. All of the analyses was carried out employing XLSTAT ver. 7.5 (Addinsoft, New York, NY, USA).

Partial least-squares regression (PLSR) was employed to explore the correlations between samples, aroma compounds, and sensory attributes using Unscrambler version 9.7 (CAMO ASA, Oslo, Norway). All variables were centered and standardized (1/SD) so as to make each variable have a unit variance and zero mean before applying PLS analyses to finally obtain the unbiased contribution of each variable to the criterion. All PLSR models were validated using full cross-validation.

RESULTS AND DISCUSSION

Microvinifications. The five *S. cerevisiae* (Y1, Y2, Y3, Y4, and Y5) commercial fruit wine yeast strains showed growth indication when incubated at 20 °C (Figure 1). Fermentation parameters were calculated for these strains. Among the five strains, the growth rate of strain Y1 was higher than that of the other strains, and the cell density reached 6.4 × 10^7 cells/mL on day 6 of growth (Figure 1A). Then the viability decreased, and viability loss was measured at 25.8% after day 8 in culture Y1. Strains Y3 and Y5 presented a cell density increase in the first 4 days of incubation and reached their maximum cell densities of 5.1 × 10^7 and 4.9 × 10^7 cells/mL,respectively;thereafter, the cell densities remained almost constant at 1 × 10^7 cells/mL. Strain Y4 had a 2 day adaptation period (lag phase) and then started to grow at a slower rate than the other strains. Although strain Y4 showed delayed growth, it remained a strain with a rapid growth rate overall.

The sugar values in five *S. cerevisiae* strains displayed similar patterns of rapid initial reduction (Figure 1B). Strains Y1, Y2, and Y5 showed a gradual reduction in sugar value over the 10 day fermentation period and reached a stable sugar level around 1.1–1.2 g/L, indicating that almost all of the sugars were consumed and that the fermentation process was considered to

have ended. Both strains Y3 and Y4 showed a similar behavior; that is, a 14 day fermentation period was noted.

Different strains of *S. cerevisiae* showed significantly different growth rates and different abilities in metabolizing sugars as a result of their biochemical mechanisms and metabolic activity during alcoholic fermentation. Furthermore, it had been suggested that differences in the genes of *S. cerevisiae* strains play a central role in explaining the diversity of aroma profiles produced by each different strain.[11] Therefore, the choice of the proper yeast strain could be critical for the development of the desired flavor and aroma of such fruit wines.

Table 1 presents the values of each major parameter (mean ± standard deviation, $n = 3$) of durian wines fermented with the five yeast strains. The statistical analysis demonstrated that the yeast strains showed significant differences in the values of important parameters, such as the values of pH, total acidity, reducing sugar, free SO_2, and glycerol. The alcohol content of the fruit wines varied a little between 11.2 and 11.5% (v/v): the highest content was measured in a fruit wine fermented with strain Y5 and the lowest content in that produced by strain Y1. However, on the basis of Duncan's multiple-comparison tests, the fruit wines fermented with those two strains showed no significant difference in alcohol content. The highest concentration (17.8 mg/L) of free SO_2 was found in the Y5-derived fruit wine, and the lowest concentration (13.8 mg/L) was detected in the Y3-derived fruit wine. As shown in Table 1, the fruit wine fermented with strain Y1 presented the lowest concentration of reducing sugars of 0.64 g/L. The results indicated that strain Y1 possessed the highest capability to ferment reducing sugar.

Strain Y3 was an efficient producer of glycerol (1.6 g/L), which was produced from dihydroxyacetone phosphate in the initial fermentation stage. In this stage, the excessive NADH generated during biomass formation would be converted into NAD^+ by the yeast cells.[12] Besides ethanol and carbon dioxide, glycerol was quantitatively the most important fermentation product, and it was considered to contribute positively to the sensory quality of fruit wine.[12,13]

Identification of Volatile Compounds in Durian Juices and Wines. SBSE with GC-MS and GC-PFPD was applied for the first time in the analysis of the aroma fraction of durian juices and wines. The main parameters that were known to influence the methodology were investigated, such as extraction time, extraction temperature, and sample volume. According to the results obtained (data not shown), optimized SBSE experimental conditions were established, that is, 50 min of extraction time, 40 °C extraction temperature, and a sample volume of 5 mL.

In the present work, 38 and 43 aroma compounds in durian juices and wines were analyzed by GC-MS and GC-PFPD with the aid of SBSE, respectively. The aroma compounds with higher concentration detected in the juice included alcohols (1-propanol, 2,3-butanediol, and 3-methylbutanol), esters (ethyl acetate and methyl propanoate), and sulfur-containing compounds (dimethyl sulfide, dimethyl disulfide, methyl ethyl disulfide, and diethyl disulfide). Compared with the juice, the content of compounds such as ethyl octanoate, ethyl 2-hexenonate, ethyl hexanoate, and ethyl 2-methylbutanoate predominated in durian wines.

Among the aroma compounds present in fruit wine, only a subset was sensorily detectable. Thus, to evaluate the influence of compounds on the formation of aroma characteristics of durian wines, the selection of specific compounds from GC

analysis to represent the attributes in samples might be useful. As reported by previous literature,[14] the low concentrations of several fermentative aroma compounds could not actually reflect the influence on the perceived aroma intensity in samples due to their low detection thresholds. This phenomenon was particularly evident in tropical fruits. Therefore, the OAV was usually used to provide a rough evaluation of the real contribution of each aroma compound to the global aroma.[15] Compounds with OAVs > 1 were commonly at the perception level and considered important aroma compounds contributing to fruit wine aroma.[16]

According to OAVs (Table 3), only 11 and 15 aroma compounds were analyzed with the OAVs > 1 in juice or durian wines: dimethyl sulfide, 2,3-butanedione, ethyl acetate, dimethyl disulfide, ethyl propanoate, methyl butanoate, 3-methylbutanol, ethyl 2-methylpropanoate, ethyl butanoate, propyl propanoate, methyl ethyl disulfide, ethyl 2-methylbutanoate, diethyl disulfide, 3-methylbutyl propanoate, ethyl hexanoate, 3,5-dimethyl-1,2,4-trithiolane, and ethyl octanoate. Among these compounds, 2,3-butanedione, 3-methylbutanol, dimethyl sulfide, dimethyl disulfide, methyl ethyl disulfide, ethyl 2-methylbutanoate, ethyl butanoate, and ethyl octanoate were major contributors to aroma of juices and wines.

3-Methylbutanol, which was responsible for vinous, herbaceous, and cacao aromas, is formed during fermentation by deamination and decarboxylation reactions from isoleucine.[17] Compared to five durian wines, the concentration (30.734 mg/L) of this compound only slightly surpassed the odor threshold (30 mg/L) in durian juice. In other words, this compound decreased with the progress of fermentation. Obviously, the conclusion was in contradiction with other literature.[17] The reason might be that 3-methylbutanol was consumed by the esterification reaction. Correspondingly, the concentration of ethyl 3-methylbutanoate increased during the fermentation process.

Ester compounds were responsible for the fruity aroma in fruit juice and wines; in particular, those compounds were correlated with the freshness and fruitiness of new wines.[13] These compounds in fruit wines were mainly synthesized from their corresponding precursors by enzymatic ethanolysis with the aid of acyl-CoA during yeast fermentation. Their concentrations were influenced by many parameters, such as yeast strain, fermentation temperature, degree of aeration, and sugar content.[18]

On the one hand, propyl propanoate, ethyl 2-butenoate, ethyl 2-methylhexanoate, 3-methylbutyl propanoate, propyl 2-methyl-2-butenoic acid, ethyl 2-methylhexanoate, and propyl hexanote were detected only in the fermented wines. The phenomenon demonstrated that the function of yeasts in the production of aroma was to synthesize yeast-derived aroma compounds during fermentation. On the other hand, as shown

DOI: 10.1021/jf505666y
J. Agric. Food Chem. 2015, 63, 1939−1947

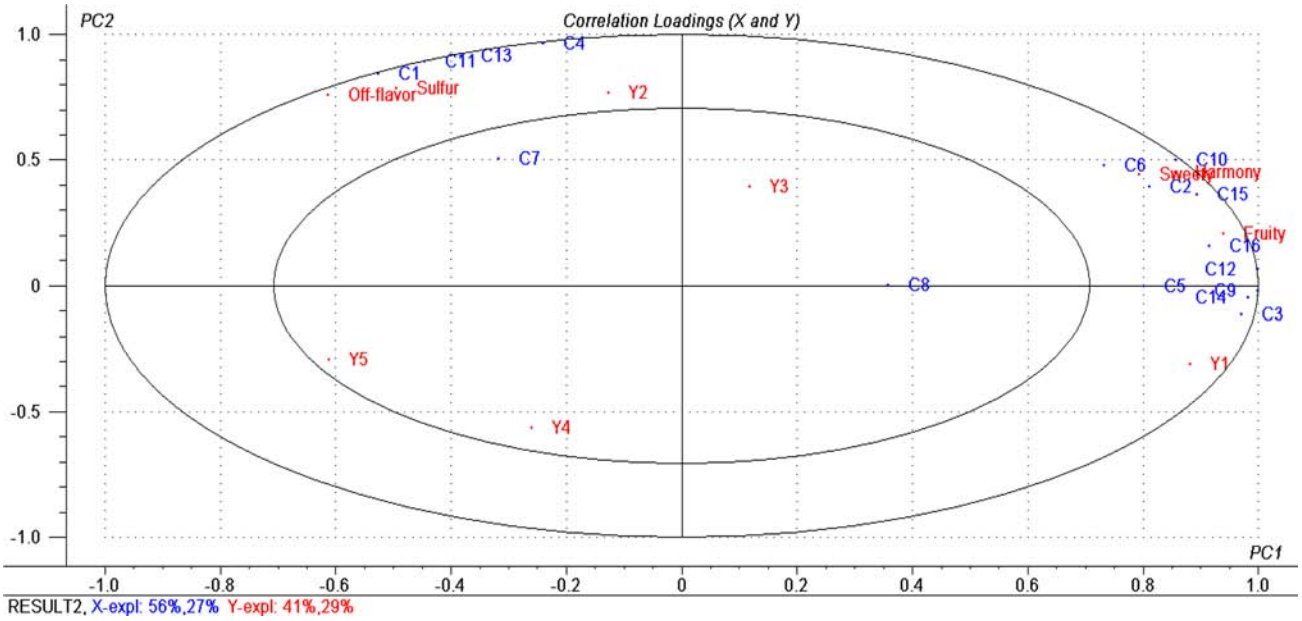

Figure 3. Overview of the variation found in the mean data from partial least-squares regression (PLSR) correlation loading plot for five samples. The model was derived from aroma compounds (OAV > 1) as the *X*-matrix and samples and sensory variables as the *Y*-matrix. The concentric circles represent R^2 = 0.5 and 1.0, respectively.

in Table 3, ethyl 2-methylbutanoate presented the highest value of OAVs, which ranged from 14.603 to 171.807 in juice and five durian wines. As a result, this compound contributed to the juices and wines with banana and pear aroma.[17] Another important ester compound was ethyl octanoate, which was far above its threshold in durian wines, indicating that this compound was a significant contributor to fruity aroma of durian wines. Ethyl octanoate showed its highest OAV (25.749) in Y1-derived durian wine. From the above-mentioned, major aroma compounds such as ethyl 2-methylbutanoate and ethyl octanoate were synthesized during the fermentation process. Moreover, strain Y1 led to durian wines with the highest OAVs of ester compounds, suggesting that Y1 strain possessed a relatively higher ability for ester synthesis.

Five sulfur-containing aroma compounds were identified across the range of durian wines analyzed, including dimethyl sulfide, dimethyl disulfide, methyl ethyl disulfide, diethyl disulfide, and 3,5-dimethyl-1,2,4-trithiolane. Most of those compounds (dimethyl sulfide, dimethyl disulfide, and diethyl disulfide) decreased rapidly with the progress of fermentation. The reduction of sulfur-containing compounds varied with fermentations, where strain Y1 had the slowest reduction followed by strains Y4 and Y5. The result was according with the findings of literature, which showed that most sulfur-containing compounds might be consumed or degraded to other compounds during the fermentation.[19]

Despite the fact that some sulfur aroma compounds were present in only low relative concentrations, as in the case of dimethyl sulfide and diethyl disulfide in this study, these compounds contributed a strong onion-like odor to the fruit wines due to their extremely low thresholds, 0.027 and 0.0043 μg/L, respectively. The sulfur aroma compounds found in this study might serve as character-impact compounds in durian that contributed to its sulfur note.[7,20] Dimethyl sulfide was considered as a beneficial compound in low concentrations. The formation of dimethyl sulfide in juice and wine existed not only from its fruit and fruit wine maturation but also during fermentation, which had also variously been linked to cysteine, cystine, or glutathione metabolism in yeast.[18]

What is worth mentioning was that 3,5-dimethyl-1,2,4-trithiolane seemed to make a significant contribution to the durian wine, but it was likely an artificial compound formed during the desorption process with the method of SBSE.[21−23] Thus, the compound 3,5-dimethyl-1,2,4-trithiolane had been excluded as an aroma-active compound in the juices and wines.

From Table 2, methanethiol, ethanethiol, propanethiol, and (2*Z*)-but-2-ene-1-thiol were present only in juices. Although the concentrations of these compounds were relatively low, the contribution to the aroma of the juice might be great due to the low threshold. The result was consistent with the findings of the literature,[19] which showed that these sulfur-containing compounds presented a significant contribution to durian juice aroma. The reason that these compounds were absent from fermented durian wines might be the result of strong volatilization or utilization by the yeast strains.

Although sulfur compounds were character-impact compounds for durian fruit, these compounds were usually perceived as offensive due to the unpleasant aroma.[7,18] On the one hand, it is well-known that the quality and value of fruit wines was strongly related to the characteristic aroma profile developed during fermentation process, which contributed to the strengthening of its characteristic organoleptic aroma. On the other hand, there is no doubt that the off-flavor compounds should be controlled in the fermentation process. Therefore, the balance between characteristic aroma and off-flavor attribute was the key to durian fermentation.

Sensory Analysis. Sensory analysis was performed by the evaluation of the organoleptic qualities of durian wines fermented by the different *S. cerevisiae* strains, using five descriptors including "fruity", "sulfur", "sweety", "off-flavor", and "harmony" for their aromas. ANOVA was used to distinguish different durian wines by their sensory evaluation scores. The statistical analysis demonstrated that samples fermented by yeast strains showed significant differences in

DOI: 10.1021/jf505666y
J. Agric. Food Chem. 2015, 63, 1939−1947

all attributes, which indicated that these fruit wines had different aroma intensities ($p < 0.001$).

Although judges exhibited significant subjectivity in their use of "fruity", "sulfur", "sweety", "off-flavor", and "harmony" as attribute descriptors, this result was inevitable in such a quantitative descriptive analysis. The reason might be because the judges expressed their perceptions against different scoring criteria, due to their differences in age, background, and olfactory sensitivity. From the research, no significant interaction between judge and replication was found, indicating that all of the judges were reproducible with regard to the scoring of all attributes in triplicate. Similarly, there was no significant interaction between sample and replication (in any attribute).

However, according to the statistical analysis, the interaction between sample and judge showed significant differences for the "fruity" ($p < 0.01$), "sulfur" ($p < 0.001$), "off-flavor" ($p < 0.01$), "sweety" ($p < 0.01$), and "harmony" ($p < 0.001$) attributes. This result suggested that the judges were scoring samples not consistent with each attribute.

Sensory analysis highlighted that some descriptors were statistically influenced by yeast starters (Figure 2). The durian wines fermented by strains Y1 and Y3 were accompanied by fruity notes more than in other strains. This phenomenon indicated that strains Y1 and Y3 yielded the highest content of compounds able to influence the fruity aroma of the corresponding fruit wine. It is common knowledge that the "fruity" attribute was the fundamental part of the overall perception of the aroma of durian wine. Therefore, the "fruity" attribute was an important symbol of fruit wine quality. The durian wines fermented by strains Y1 and Y2 were mostly associated with a greater "sweety" attribute than wines produced by other strains. The fruit wines fermented by strains Y2 and Y3 were rated as having the highest values of sulfur aroma, whereas durian wine produced by strain Y1 presented low sensorial scores for sulfur aroma. Traditionally, this sulfur aroma was typically associated with a negative sensory contribution to fruit wine (5).[7] However, the "sulfur" attribute remained the characteristic aroma of tropical fruit, which could obviously be distinguished from other fruits by this specific property. In addition, a similar behavior was observed for the "off-flavor" attribute in five fruit wines. The reason might be that sulfur-containing aroma compounds were typically perceived as offensive, they had very low detection thresholds, and they generally conferred a negative sensory contribution to fruit wine.[5,7,18] The result was consistent with findings of the literature,[24] which showed that the sulfur-containing aroma compounds were the main source of "off-flavor" attributes in fruit wines. The highest score under the "harmony" attribute was found in fruit wine produced by strain Y1, whereas the lowest score was found in that produced by strain Y5. Interestingly, by comparing the sensory analysis of "harmony" and "off-flavor" attributes, we found that these two attributes presented completely opposite scores when evaluated by our judges.

Relationship between Samples, Aroma Compounds, and Sensory Attributes. PLSR was used to process the mean data accumulated from sensory evaluation by the judges, aroma compounds (OAVs > 1), and samples. The *X*-matrix was designated as representing the aroma compounds of fruit wines; the *Y*-matrix was designated as representing the sensory variables and fruit wine samples. The derived PLSR model included two significant PCs explaining 83% of the cross-validated variance (Figure 3). The result demonstrated that the optimal number of components in the PLSR model presented was determined as two principal components (PC2): the issue of PC2 versus PC3 results was not presented here, as no additional information was gained by its examination.

The estimated regression coefficients from the jack-knife uncertainty test showed that all of the aroma compounds, except 3-methylbutanol (C7) and ethyl 3-methylpropanoate (C8), were significant for one or more of the five samples and five significant sensory descriptors. Five of the sensory attributes were placed between the inner and outer ellipses, $R^2 = 0.5$ and 1.0, respectively. The result indicated that they were well explained by the PLSR model.

From Figure 3, samples appeared to be divided into three groups according to strain. Among these samples, the fruit wine fermented by strain Y1 was located on the positive region of PC1 and the negative region of PC2. The fruit wines produced by strains Y4 and Y5, which were located on the negative region of PC1 and PC2, were clearly differentiated from samples fermented by other strains. The wines fermented by strains Y2 and Y3 lay in upper part of PC2.

The first PC was mainly defined by the aroma descriptors showing a contrast between "fruity", "harmony", and "sweety" attributes on the positive dimension and "sulfur" and "off-flavor" attributes on the negative dimension. The fruit wines produced by strains Y4 and Y5 were negatively correlated to all of the sensory variables and all aroma compounds even though they showed a certain aroma profile in the judges' evaluations thereof. This phenomenon might have been caused by sensory evaluation error, or it might be that those fruit wines could not possess characteristic, or distinguishing, aromas marking them apart from other fruit wines.

As compared with other wines, fruit wine fermented by strain Y1 was highly correlated with the sensory attributes of "fruity", "harmony", and "sweety". This was related to aroma compounds such as 2,3-butanedione (C2), ethyl acetate (C3), ethyl propanoate (C5), methyl butanoate (C6), ethyl butanoate (C9), ethyl 2-methylbutanoate (C12), and ethyl octanoate (C16). This phenomenon indicated that strain Y1 should have a higher ethyl acetate yield ability. Some aroma compounds are directly derived from chemical components of the musts, whereas many fruit-derived compounds were released or modified by the action of aroma-active yeast, and a further substantial portion of fruit wine aroma substances resulted from the metabolic activities of these fruit wine microbes.[2,25] Therefore, the selection of yeasts was central to the development of fruit wine aroma.

In contrast, "sulfur" and "off-flavor" attributes were strongly correlated with each other and showed high loadings in the opposite direction from other attributes. These attributes, which were pronounced in fruit wines fermented by strains Y2 and Y3, were strongly connected with the following compounds: dimethyl sulfide (C1), dimthyl disulfide (C4), methyl ethyl disulfide (C11), and diethyl disulfide (C13).

commercial Cognac by application of the AEDA and to identify the most odor-active compounds. Aroma compounds with the highest flavor dilution (FD) factors should be quantitated using stable isotope dilution assays, their OAVs (ratio of concentration to odor threshold) should be calculated on the basis of their odor thresholds in water/ethanol, and the results should finally be confirmed by means of an aroma recombinate. In addition, an AEDA was applied on a German brandy to find differences in the key odorants, which may be useful to distinguish Cognac from brandies.

MATERIALS AND METHODS

Cognac. According to the label, the commercial Cognac investigated (Hennessy) was labeled VS and had been stored in Limousin oak barrels for two years. This selection was not done for advertising purpose, nor does it imply any research contract with the manufacturer, but was done on the basis of a hedonic preference test performed by a group of 16 trained panelists (average age = 30 years; 60% women). The grape variety used for the production of the Cognac was Ugni Blanc, and the product was manufactured according to the regulation of the AOC Cognac. Several batches of the same production of the Cognac year were bought in a German supermarket. The German brandy (Mariacron) was selected because it showed the clearest difference in the overall aroma when compared to the Cognac.

Reference Odorants. These were obtained from the following commercial sources: 4-Allyl-2-methoxyphenol, α-damascenone, 1,1-diethoxyethane, ethyl acetate, ethyl hexanoate, 4-ethyl-2-methoxyphenol, ethyl 3-methylbutanoate, ethyl octanoate, 4-ethylphenol, ethyl 2-phenylacetate, 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone, 2-isopropyl-3-methoxypyrazine, methylpropanal, 3-methylbutanal, 3-methylbutanol, 3-methylbutyl acetate, (*E*)-2-nonenal, phenylacetaldehyde, 2-phenylacetic acid, (3*S*,4*S*)-*cis*- and (3*S*,4*R*)-*trans*-whiskey lactone, ethyl butanoate, ethyl methylpropanoate, ethyl pentanoate, ethyl propanoate, methylpropanol, (*E*)-2-nonanal, ethyl (*S*)-2-methylbutanoate, ethyl decanoate, octanoic acid, acetic acid, 2-methylbutanoic acid, 3-methylbutanoic acid, 2,3-butanedione, (*Z*)-3-hexenol, ethyl 2-hydroxy-3-methylbutanoate, and 2-phenylethanol were from Sigma-Aldrich Chemie (Taufkirchen, Germany). Acetaldehyde, ethanol, 4-hydroxy-3-methoxybenzaldehyde, and 2-methoxyphenol were from Merck (Darmstadt, Germany), and 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone was from SAFC (Hamburg, Germany). Cyclohexanoyl acetate was supplied by Lancaster (Griesheim, Germany); 1-hexanol by Fluka (Buchs, Switzerland), 4-vinyl-2-methoxyphenol from Alfa Aesar (Karlsruhe, Germany), and hexanoic acid from Acros Organics (Geel, Belgium). (*E*)-β-Damascenone was a gift from Symrise (Holzminden, Germany).

Isotopically Labeled Internal Standards. Most of the isotopically labeled internal standards were synthesized as listed in a previous study:[11] In addition, [$^2H_2$]-methylpropanol,[12] [$^2H_2$]-(*Z*)-3-hexenol,[13] [$^2H_2$]-butanoic acid,[14] [$^2H_5$]-ethyl pentanoate,[15] [$^2H_3$]-hexanoic acid,[16] [$^{13}C_2$]-3-hydroxy-4,5-dimethyl-2(5*H*)-furanone,[17] [$^2H_2$]-3-methylbutanoic acid,[18] [$^2H_2$]-octanoic acid,[19] and [$^{13}C_2$]-phenylacetaldehyde[20] were synthesized as previously reported. [$^{13}C_2$]-Phenylacetic acid was bought from Merck.

Isolation of the Volatiles. For volatile isolation, the spirit (25 mL) was diluted with brine and extracted with diethyl ether (3 × 50 mL), and the combined extracts were washed three times with brine (25 mL). Nonvolatile compounds were separated by high-vacuum distillation using the SAFE distillation;[21] the distillate was washed with brine (3 × 25 mL) and concentrated to ∼100 μL using a Vigreux column (60 cm × 1 cm i.d.) followed by microdistillation.[22] The distillate was separated into a fraction containing the neutral/basic volatiles (NBF) and the acidic volatiles (AF) by treatment with an aqueous sodium bicarbonate solution as previously described.[22]

Fractionation of the Neutral/Basic Volatiles by Column Chromatography. The neutral/basic fraction was concentrated to ∼1 mL and was applied onto a water-cooled glass column (30 cm × 1 cm) filled with silica 60 (30 g) in *n*-pentane. Using six *n*-pentane/diethyl ether mixtures (v/v) of increasing polarity (100 mL each; fraction A, 100:0; fraction B, 95:5; fraction C, 90:10; fraction D, 80:20; fraction E, 50:50; fraction F, diethyl ether), the compounds were separated and each fraction was concentrated to ∼1 mL as described above. These fractions were used to relocate the odor-active compounds for identification by GC-MS.

Gas Chromatography−Flame Ionization Detector (GC-FID) and Gas Chromatography−Olfactometry (GC-O). The analyses were performed by means of a gas chromatograph type 8000 (Fisons Instruments, Mainz, Germany) equipped with the following capillaries: DB-5 (30 m × 0.25 mm i.d.; 0.25 μm film thickness) (Varian, Palo Alto, CA, USA) and DB-FFAP (30 m × 0.32 mm i.d.; 0.25 μm film thickness) (J&W Scientific, Folsom, CA, USA). For GC-O, the end of the capillary was connected to a deactivated Y-shaped glass splitter dividing the effluent into two equal parts, which were transferred via two deactivated but uncoated fused silica capillaries (50 cm × 0.25 mm) to a sniffing port and an FID, respectively. The sniffing port was held at 180 °C, whereas the temperature of the FID was at 240 °C; nitrogen was used as the makeup gas. Sample injection (0.5 μL) was done at 40 °C, and after 2 min, the temperature were raised at 6 °C/min to 230 °C and held for 10 min. All aroma-active areas annotated by three panelists were marked in the chromatogram, and the odor qualities were described. For the original extracts, sniffing time was ∼15 min; that is, the entire chromatogram were sniffed 0−15, 15−30, and 30−45 min. Linear retention indices (RI) of the compounds were calculated from the retention times of a series of *n*-alkanes C-8−C-24.

Aroma Extract Dilution Analysis. The distillate was stepwise diluted with diethyl ether to obtain the dilutions 1:1, 1:2, 1:4, 1:8, 1:16, etc., and finally 1:2048 of the original extract.[22] Each odorant was, thus, assigned an FD factor representing the final dilution in which the odorant could be detected. Sniffing was continued until no odorant was detectable by GC-O. Odor qualities were assigned on the basis of a flavor language previously developed in our group.[23] The AEDA was performed in parallel by at least three panelists, and the results were averaged.

Gas Chromatography−Mass Spectrometry (GC-MS). Mass spectra were recorded by means of a gas chromatograph 5890 series II (Hewlett-Packard, Waldbronn, Germany) connected to an MAT 95 S sector field mass spectrometer (Finnigan, Bremen, Germany). Mass spectra in the electron ionization mode (MS-EI) were recorded at 70 eV, and mass spectra in the chemical ionization mode (MS-CI) were measured at 115 eV with isobutane as the reactant gas.

Quantitation by Stable Isotope Dilution Assays in Combination with Two-Dimensional High-Resolution Gas Chromatography (TDGC-MS). The labeled internal standards (2−10 μg; depending on the amounts of the respective analyte estimated in a preliminary trial) dissolved in diethyl ether (0.5 mL) were added to aliquots of the spirit. After the addition of brine (50 mL) and diethyl ether (50 mL), the solution was stirred for 1 h. The combined extracts were dried over anhydrous sodium sulfate and concentrated to ∼100 mL at 37 °C using a Vigreux column (50 cm × 1 cm i.d.). The nonvolatile material was removed by SAFE distillation at 40 °C, and the distillate was concentrated to 100 μL by means of microdistillation.[22]

For TDGC-MS a gas chromatograph Trace 2000 (ThermoQuest, Mainz, Germany) coupled via a moving column stream switching system (ThermoQuest, Mainz, Germany) to a gas chromatograph CP 3800 (Varian, Darmstadt, Germany) was used. In the first dimension, the separation of the distillate was achieved on the FFAP column. First, the retention time of the analyte under investigation was determined by means of reference substances. Then, at the respective elution time, the effluent was quantitatively transferred into a cold trap (−80 °C) and, after the cooling was turned off, the trapped material was transferred onto the DB-5 column in the second oven. The effluent was finally monitored using an ITD Saturn 2000 ion trap mass spectrometer (Varian, Darmstadt, Germany). Mass spectra in the chemical ionization mode (MS-CI) were generated at 70 eV using methanol as reagent gas. The peak areas of the selected ions of the labeled standard and the analyte were separately determined in the mass chromatogram by using either the molecular ions or selected

J. Agric. Food Chem. 2015, 63, 1948−1956

fragments given in Table 1. Concentrations were calculated and corrected using response factors obtained by measuring defined mixtures of the respective labeled and the unlabeled compound.[20]

Table 1. Selected Ions (m/z) ($M^+ + 1$; MS-CI) of Analytes and Isotopically Labeled Standards (ILS) Used in the Stable Isotope Dilution Assays

Quantitation of Ethanol. Ethanol was determined on the basis of density by weighing exactly 20 mL of a steam distillate of Cognac.

Separation of (*S*)-2- and (*R*)-2- and -3-Methylbutanol. Due to coelution on the DB-FFAP column, the separation of the three methylbutanols was achieved on a chiral BGB 174 E column (30 m × 0.25 mm i.d., 0.25 μm film thickness) (BGB Analytic, Anwill, Switzerland) by means of TD-HRGC/MS with the DB-FFAP column in the first and the BGB 174 E column in the second dimension.

Determination of Odor Thresholds. First, the purity of the reference odorants was checked by GC-O. For the determination of the odor thresholds, a defined amount of the purified aroma compound in ethanol (10 μL) was then pipetted into a Teflon vessel containing 25 mL of ethanol/water (6:4, v/v). After stepwise dilution (1:1, v/v), the samples were judged by 16 trained assessors. Triangular tests were performed using 25 mL of water/ethanol (6:4, v/v) as the control, and the odorants were presented in Teflon vessels (45 mL) with lid in decreasing concentrations. The assessors were recruited from the German Research Center for Food Chemistry, and sensory evaluations were performed in a sensory panel room at 21 ± 1 °C. Odor thresholds were calculated according to the method of § 64 LFGB, methods 00.90-7 and 00.90-9.[24]

Descriptive Profile Tests. The panelists were asked to rate the odor intensity of the aroma attributes of Cognac from 0 to 3 (0, not perceivable; 1, weak; 2, significant; and 3, strong) using a seven-point scale of 0, 0.5, 1, 1.5, up to 3.0. Eight suprathreshold aqueous solutions (25 mL in Teflon vessels) of 3-methylbutanol (malty), (*E*)-β-damascenone (cooked apple-like), ethyl 3-methylbutanoate (fruity), 2-phenylethanol (flowery), 4-hydroxy-3-methoxybenzaldehyde (vanilla-like), phenylacetic acid (honey-like), 2-methoxy-4-vinylphenol (clove-like), and (3*S*,4*S*)-*cis*-whiskey lactone (coconut-like) were used for the weekly training of the sensory panel. For the evaluation of the Cognac aroma, the panelists had to evaluate the intensities of the eight odor qualities represented by solutions of the reference aroma compounds on a seven-point intensity scale. The results of the aroma profile analysis were displayed in a spider web diagram.

For the aroma recombinate, a mixture consisting of 34 reference key odorants in the concentrations determined in the Cognac and showing OAVs ≥ 1 was dissolved in water/ethanol (6:4, v/v), and the pH was adjusted to 3.9 with aqueous H_2SO_4 (1 mol/L) (recombinate A). For the second aroma recombinate (recombinate B) aliquots of the same 34 compounds were added to an odorless Cognac matrix. To obtain this matrix, a Cognac sample (100 mL) was sequentially extracted with diethyl ether and distilled using the SAFE apparatus. The residue obtained was treated with water followed by *n*-pentane and finally freeze-dried until odorless. An aliquot of the residue, representing 100 mL of Cognac, was dissolved in water/ethanol (6:4, v/v) and was added to 100 mL of the recombinate. An overall aroma profile of both recombinates was determined in the same way as described above for Cognac. Separately, the similarity of the overall aromas of the Cognac and the Cognac recombinates were compared. The similarity was ranked using a seven-point scale from 0 (no similarity) to 3 (100% identical).

RESULTS AND DISCUSSION

In a first experiment, a sensory panel was asked to perform an aroma profile analysis of the Cognac. On the basis of eight odor qualities agreed to in a preliminary session, the panel evaluated fruity, malty, and baked-apple like attributes as the important odor qualities, followed by clove- and honey-like impressions (Figure 1). To assess the odorants responsible for these aroma

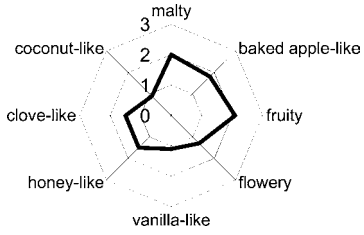

Figure 1. Aroma profile analysis of the Cognac Hennessy.

qualities, first, the most appropriate solvent for volatile extraction was selected from pentane/diethyl ether (1:1, v/v), dichloromethane, and diethyl ether. The diethyl ether extract exhibited the most similar aroma compared to the original Cognac when a drop of the extract was evaluated on a strip of filter paper, and thus this solvent was used for further analyses.

Identification of Odor-Active Compounds. A distillate of 25 mL of Cognac prepared by extraction/SAFE distillation was subjected to GC-O after concentration. A total of 39 odor-active areas could be detected in the FD factor range of 8−2048. Among them, the cooked-apple-like odor, which was smelled at position **26** (Figure 2) showed the highest FD factor followed by a fruity (**5**) and a malty (**12**) odor. Further

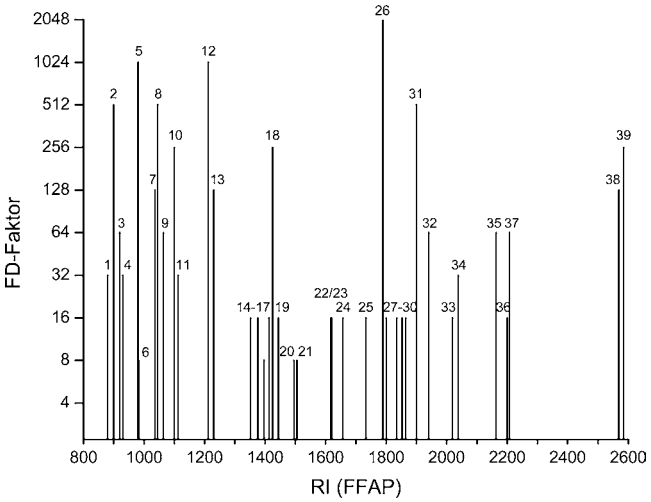

Figure 2. Flavor dilution (FD) chromatogram obtained by application of the aroma extract dilution analysis on a distillate of the volatiles isolated from the Cognac.

compounds with fruity notes (**2**, **8**, and **18**) showed somewhat lower FD factors. In addition, a flowery-smelling odorant (**31**), the malty smelling odorant (**10**), and the vanilla-like smelling odorant (**39**) showed quite high FD factors of 256.

To identify the compounds responsible for these odors, first, the retention indices of the odor-active areas were compared to an in-house database, suggesting potential structures for each odorant. To confirm these, the compounds present in the neutral/basic volatiles fraction were separated on silica gel. This procedure was necessary to avoid coelution of trace odorants with volatiles present in high amounts in the extract. The odor-active areas were then relocated in the respective fractions by GC-O, and mass spectra in the electron impact mode (MS-EI) and the chemical ionization mode (MS-CI) were recorded.

Compound **26** with the highest FD factor was, thus, identified as (*E*)-*β*-damascenone (Figure 3). Compound **12** with the second highest FD factor consisted of two compounds, (*S*)-2-methylbutanol (ee > 99%) and 3-methylbutanol, both of which could be separated on a chiral BGB E 174 column. The

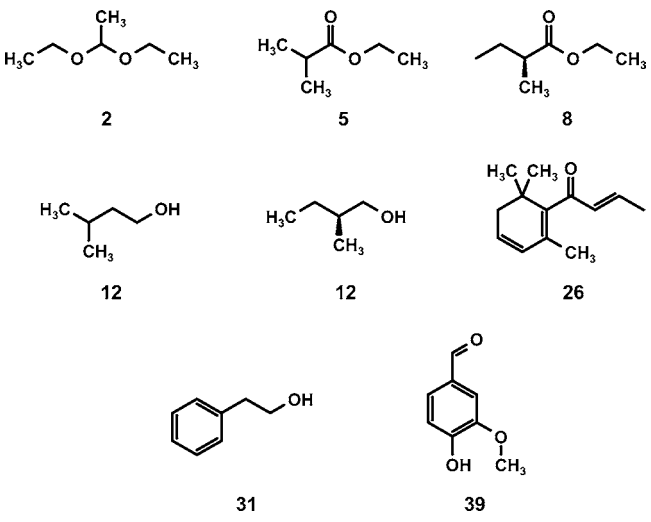

Figure 3. Structures of the most odor active compounds identified in Cognac. The alcohol isomers (12) could not be separated on the GC stationary phase used in GC−O.

ratio was determined to be 84% 3-methylbutanol and 16% (*S*)-2-methylbutanol. The fruity odors (**2**, **5**, and **8**) were evoked by diethoxyethane, ethyl methylpropanoate, and ethyl (*S*)-2-methylbutanoate. The flowery smell (**31**) was caused by 2-phenylethanol, and the vanilla-like odor was attributed to vanillin (**39**). The results of the further identification experiments are summarized in Table 2. Besides phenylacetic acid (**38**) with an FD factor of 128, other odor-active acids were detected, hexanoic acid (**28**), acetic acid (**19**), butanoic acid (**23**), and 2- and 3-methylbutanoic acid (**24**), all with an FD factor of 16.

Compounds with clove-like and phenolic aroma constituents were 4-allyl-2-methoxyphenol (**35**) with an FD factor of 64, and 2-methoxyphenol (**29**), 4-ethyl-2-methoxyphenol (**33**), and 2-methoxy-4-vinylphenol (**36**), all with FD factors of 16 (Table 2). Compounds **30** and **32** with a coconut-like odor were identified as (3*S*,4*S*)-*cis*- and (3*S*,4*R*)-*trans*-whiskey lactone.

α-Damascone (**25**) was another norisoprenoid eliciting a cooked apple-like smell. This odorant and also cyclohexanoyl acetate (**16**), 2-isopropyl-3-methoxypyrazine (**17**), 2-isobutyl-3-methoxypyrazine (**20**), (*E*)-2-nonenal (**21**), 2-methoxy-4-vinylphenol (**36**), 3-hydroxy-4,5-dimethyl-2-(5*H*)-furanone (**37**), and phenylacetic acid (**38**) were detected for the first time in a Cognac or brandy, respectively.

Quantitation by Stable Isotope Dilution Assays. The AEDA is an appropriate method to find odorants potentially contributing to the overall aroma of foods. However, this method does not permit conclusions on the influence of the food matrix, for example, on odorant binding, or on the interactions of odorants at the receptor level when matching the overall odor impression of a given food. For this reason the odor activity values were calculated as a next step.[7] For this purpose, the 37 aroma compounds that had shown the highest FD factors (Table 2) were quantitated using stable isotope dilution assays. In addition, ethyl pentanoate was quantitated, because it was found to be an important marker to differentiate brandies from Cognac samples.

The results of the quantitative measurements (Table 3) revealed ethanol (316 g/L) and 3-methylbutanol (1044 mg/L) as compounds with the highest concentrations, followed by methylpropanol, acetic acid (126 mg/L), 2-methylbutanol (107 mg/L), acetaldehyde (52 mg/L), hexanol (41 mg/L), 1,1-diethoxyethane (16.7 mg/L), and hexanoic acid (12.4 mg/L). Most odorants were, however, present in low amounts between 170 and 0.5 μg/L (Table 3).

Aroma compounds showing the lowest concentrations were (*E*)-2-nonenal (9.0 μg/L), 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone (5.7 μg/L), cyclohexanoyl acetate (6.0 μg/L), ethyl pentanoate (3 μg/L), and 2-isobutyl-3-methoxypyrazine (0.5 μg/L).

Odor activity values (ratio of concentration to odor threshold) are a valuable tool to correlate quantitative data with the volatility of a compound from the respective matrix,[6] but it is necessary that the thresholds of single components are determined in a matrix as close as possible to the food itself. Thus, for Cognac the odor thresholds were determined in water/ethanol (6:4, v/v) as previously reported in a study on whiskey aroma.[11] To indicate the importance of the matrix, Table 4 shows a comparison of odor thresholds for selected odorants in water and in water/ethanol (6:4, v/v). With the exception of phenylacetic acid, all odorants showed higher odor thresholds in water, with (*E*)-*β*-damascenone, 3-methylbutanol,

[a]Retention index. [b]Odorants were consecutively numbered according to their elution order from the FFAP column. [c]Odorants were identified by comparing them with reference compounds on the basis of the following criteria: (i) retention indices on the FFAP and DB-5 capillary columns, (ii) mass spectra obtained by MS-EI and MS-CI; and (iii) odor quality and odor threshold determined by GC-O. [d]Odor quality as perceived at the sniffing port during GC-O. [e]Column chromatography fractions A–F and AF (acid fraction) in which the odorant was detected. [f]FD factor, flavor dilution factor. [g]An unequivocal mass spectrum could not be obtained. The identification is based on the resting criteria detailed in footnote *b*.

and methylpropanol showing the largest difference between both media.

Using the odor thresholds in water/ethanol, the OAVs for 34 Cognac odorants were calculated (Table 5). The highest OAV was obtained for ethanol (12690) and confirmed the dominating aroma contribution of ethanol in spirits as recently found also for whiskey[11] or pear brandy.[25] The concentrations of all 34 aroma compounds clearly exceeded their thresholds in water/ethanol, and among them (*E*)-β-damascenone, due to its low odor threshold of 0.14 μg/L, had the second highest OAV. Quite high OAVs were also calculated for the fruity-smelling odorants ethyl (*S*)-2-methylbutanoate (195), ethyl methylpropanoate (120), ethyl 3-methylbutanoate (100), ethyl hexanoate (97), ethyl butanoate (69), and ethyl octanoate (61). Ethyl butanoate and ethyl hexanoate have also previously been suggested by Webb et al.[26] as important aroma compounds in Cognac.

To confirm the contribution of the 34 key aroma compounds to the overall aroma of the Cognac, an aroma recombinate was prepared containing reference chemicals of all odorants that had shown OAVs ≥ 1 in water/ethanol (6:4, v/v) in the concentrations measured in Cognac (Table 3). First, a recombinate in water/ethanol (6:4, v/v) was evaluated by the sensory panel. As shown in Figure 4A, in particular the flowery and fruity quality was somewhat weaker than determined for Cognac (Figure 4B), and the overall similarity was only rated 2.2 on scale from 0 to 3.

[a]Odor thresholds recently determined.[11]

If all aroma compounds were identified and quantitated, it can be assumed that nonvolatile compounds may interact with the odorants in Cognac, thus influencing the overall aroma perception. This was also recently proven for red wine.[27] Thus, to evaluate the influence of the nonvolatile fraction from Cognac, deodorized, nonvolatile material was isolated from Cognac, then added to the recombinate, and again a descriptive profile analysis against the original Cognac was performed. Now, the aroma profile of the recombinate (Figure 4C) was nearly identical with the aroma profile of the Cognac (Figure 4B), and in the similarity test this recombinate received 2.6 of 3.0 points.

Nordström[28] suggested the formation of ethyl esters from lower fatty acids during fermentation with *Saccharomyces cerevisiae*, and ethyl esters have been described as the largest group among the volatile compounds in Cognac.[2] Our study corroborated that ethyl esters make an important contribution to the aroma of Cognac, because high OAVs were calculated for ethyl (*S*)-2-methylbutanoate, ethyl methylpropanoate, ethyl 3-methylbutanoate, and ethyl hexanoate. The concentrations

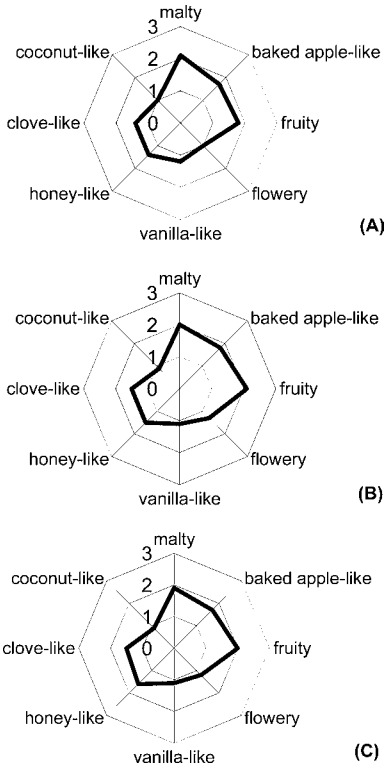

Figure 4. Aroma profile analysis of (A) the aroma recombinate in water/ethanol (6:4, v/v), (B) the Cognac, and (C) the aroma recombinate with a nonvolatile matrix prepared from Cognac added.

measured in the Cognac for ethyl 2-methylbutanoate, ethyl 3-methylbutanoate, and ethyl hexanoate were in good agreement with data reported earlier by Schreier et al.[3]

Janacova et al.[9] suggested methylpropanol, 2-methylbutanol, and 3-methylbutanol to be important in the aroma of Slovac brandies, and Webb et al.[26] also quantitated 3-methylbutanol, 2-methylbutanol and methylpropanol in Cognac with quite similar values as found here (3-methylbutanol, 1650−2190 mg/L; 2-methylbutanol, 330−430 mg/L; and 2-methylpropanol, 910−1100 mg/L). These alcohols have long been known as amino acid metabolites of yeast by the Ehrlich mechanism and have been detected in many fermented foods. They were also recently shown by us to be key odorants in whiskey,[11] Williams Christ brandy,[25] or wheat beer, respectively.[29]

Guichard et al.[30] quantitated whiskey lactones in different brandies. From the four possible stereoisomers they only found the (3*S*,4*S*)-*cis*-whiskey lactone and the (3*S*,4*R*)-*trans*-whiskey lactone, which is also in agreement with the result found here. Mosandl and Kustermann[31] reported that both enantiomers were mainly present in American white oak (*Quercus alba*). Maga[32] and Guymon and Crowell[33] investigated brandies aged in American and French oak barrels and found both whiskey lactone isomers in quite high concentrations in brandies aged in American oak, but in lower concentrations in French oak aged brandies. The Cognac used in this study was stored in French oak barrels, and, thus, the concentrations of these whiskey lactones were rather low, thus supporting the literature results.

In the present study a total of eight aroma compounds were detected for the first time in the volatile fraction of Cognac, namely, 2-methoxy-4-vinylphenol, phenylacetic acid, (*E*)-2-nonenal, 3-hydroxy-4,5,-dimethyl-2(5*H*)-furanone, ethyl cyclohexanoyl acetate, 2-isopropyl-3-methoxypyrazine, 2-isobutyl-3-methoxypyrazine, and α-damascone (Table 2). Among them, in particular, 2-methoxy-4-vinylphenol, phenylacetic acid, and (*E*)-2-nonenal showed quite high odor activity values.

Compared to wine[34] and other spirits,[25] the concentration of (*E*)-β-damascenone was quite high in the Cognac. Therefore, the odorant was quantitated in further Cognacs from different manufacturers, and interestingly the concentrations were quite high in all spirits, ranging from 108 to 330 μg/L (Table 6). By contrast, the norisoprenoid was much lower in seven German brandies (3−31 μg/L) as well as in Spanish (8−12 μg/L) and two French brandies (30−40 μg/L).

Odorants in a German Brandy. For a first comparison of the key odorants in a German brandy, the AEDA was applied on a distillate from the German brandy Mariacron. The data revealed distinct differences, but in particular ethyl pentanoate was higher in the German brandy (Table 7). The quantitation of this ester in the 12 Cognacs and the 7 German brandies revealed clear differences in their concentrations (Table 6). The same was true for two Spanish and two French brandies. Whereas only 3−13 μg/L of the ester was present in the 12 Cognacs analyzed, 68−320 μg/L of the odorant was present in the 7 German brandies (Table 6).

By calculating the ratio of the β-damascenone concentration to that of ethyl pentanoate, the German and Spanish brandies could easily be differentiated from the Cognacs. Even two French brandies (Dujardin and Napoleon) could easily be differentiated on the basis of these data, suggesting the pair (*E*)-β-damascenone/ethyl pentanoate as a possible indicator for the differentiation of Cognac from other brandies.

[a]The odorant was identified by comparing it with the reference compound on the basis of the following criteria: (i) retention indices on the capillary; (ii) mass spectra obtained by MS-EI and MS-CI; and (iii) odor quality and odor threshold determined by GC-O. [b]Odor quality perceived at the sniffing port.

Compared to data reported on the key odorants in other spirits, the results showed that the differences in the overall aromas of most distilled spirits aged in oak barrels are obviously caused by differences in the concentrations of odor-active constituents rather than by specific compounds present in the overall set of key odorants. This is, however, not a general rule, because for some spirits, such as pear brandy,[25] so-called specialists[7] among the key aroma compounds, such as ethyl decadienoate, can be the cause for overall differences in the aroma profile. Further studies will be undertaken to examine the influence of single processing steps as sources of the key aroma compounds in brandies by means of systematic studies on intermediates of the manufacturing process.

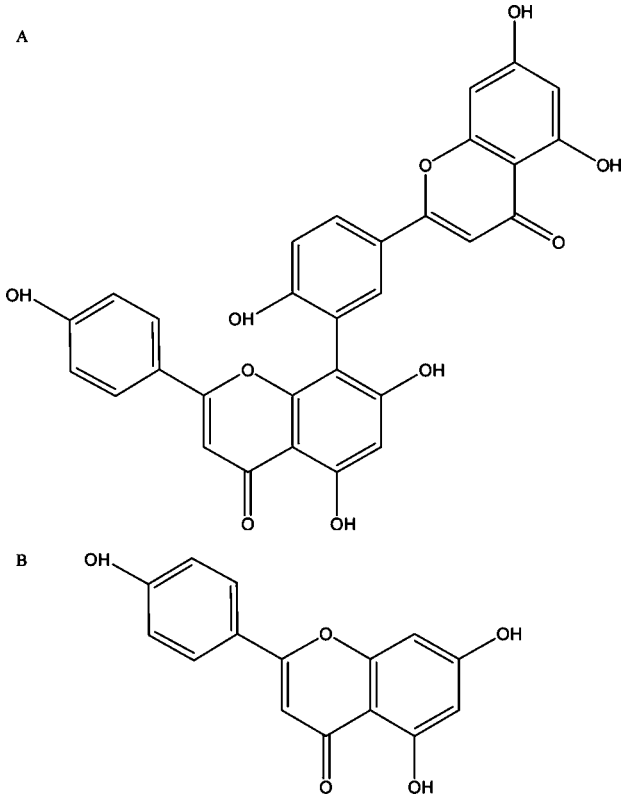

Figure 1. Chemical structure of amentoflavone AMF (A) and the internal standard (B).

inhibitors of cytochrome (CYP) 2C9, CYP 3A4, and especially CYP 1A2/1A1,[14−16] the other flavones present in the herbal extracts used in these studies could potentially alter the metabolism and disposition of AMF. On the other hand, because of simultaneous quantitation of multiple free and total biflavone components, including AMF, in rat plasma and human urine, respectively, the short cycle time and limit of detection were sacrificed for sufficient separation and accurate quantification of multicomponents in both methods. To improve understanding of the bioactivity and role of AMF beyond that provided by previous pharmacodynamics studies,[17,18] we developed a new specific, sensitive, and rapid liquid chromatography−tandem mass spectrometry (LC−MS/MS) method to detect the total content of AMF following β-glucuronidase/sulfatase hydrolysis. The present method had the advantages of a shorter detection time and lower limit of detection than the two published methods.[7,8] We used this method to generate a full pharmacokinetic profile for AMF in rats by administering a single dose by various routes, and then fully analyzing the conjugate metabolites of AMF, including its glucuronide/sulfate forms. Further, the pharmacokinetic differences between AMF administered to rats via alternative routes and the bioavailability of the compound were investigated. The resulting data are very useful for developing an improved understanding of the pharmacological profile of AMF in vivo, which will be beneficial for preclinical research and clinical use of AMF.

MATERIALS AND METHODS

Chemicals. AMF (98.0%) and apiolin (internal standard, 99.0%) were obtained from the National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). Methanol (HPLC grade) was purchased from Sigma-Aldrich (St. Louis, MO). β-Glucuronidase (type H-1 from *Helix pomatia*, which contained 300 units of β-glucuronidase and 15.3 units of sulfatase/mg), was purchased from Sigma-Aldrich. Formic acid was purchased from J.T. Baker. Wahaha deionized water (Hangzhou, China) was used throughout the study. Ethyl acetate and other chemicals were of analytical grade and obtained from Beijing Chemical Co. (Beijing, China).

Animal Treatment and Pharmacokinetic Analysis. Male Sprague−Dawley (SD) rats (190−210 g) were supplied by Beijing Vital River Laboratories Animal Technology Co. Ltd. All the experimental protocols were approved by the Animal Ethics Committee of Beijing Institute of Pharmacology and Toxicology (No. 11400700031602). Fifteen SD rats were randomly divided into three groups and were fasted overnight with free access to water prior to AMF administration. Animals in the first group received a single 10 mg/kg intravenous (iv) dose of AMF via the tail vein. Animals in the second group received a single 10 mg/kg intraperitoneal (ip) dose of AMF suspended in 0.1% Tween 80. Animals in the third group received a single 300 mg/kg dose of AMF suspended in 1% Tween 80 by oral gavage (po).

Blood samples were obtained via retro-orbital puncture with a glass capillary at 0, 0.033, 0.083, 0.167, 0.25, 0.5, 1, 2, 4, 6, 9, 12, and 24 h after iv and ip administration and at 0, 0.017, 0.5, 0.75, 1, 1.5, 2, 2.5, 3, 4, 6, 8, 12, and 24 h after po administration. The blood samples were collected into heparinized plastic tubes, and the plasma was separated by centrifugation at 4000 rpm at 4 °C for 10 min. The resulting plasma samples were stored frozen (−30 °C) until analyzed.

LC−MS/MS Method. The LC method employed a Thermo Syncronis C18 column (2.1 mm × 50 mm, 5 μm) equipped with an online filter and maintained at room temperature. Using a Finnigan Surveyor HPLC system, peaks were separated using a mobile phase of methanol, water, and formic acid (70:30:0.1, v/v/v) at a flow rate of 0.2 mL/min. The injection volume was 5 μL, and the run time was 3 min. A triple-stage quadrupole mass spectrometer (TSQ Quantum Discovery, ThermoElectron, San Jose, CA) equipped with an electrospray ionization (ESI) source was used for AMF detection. Xcalibur version 1.4 software (Thermo-Fisher, USA) controlled the HPLC system, mass spectrometer, and autosampler, and data analyses were completed using LCQuan software (Thermo Finnigan, USA). The mass spectrometer was operated in the negative ion detection mode, and quantification was performed using selected reaction monitoring (SRM) of the transitions of m/z 537.1 → m/z 374.9 for AMF (Figure 2A) and of m/z 269.2 → m/z 224.9 for apiolin (as an internal standard, Figure 2B) with a scan time of 0.1 s per transition. The optimum ion source parameters were as follows: ESI source temperature, 300 °C; spray voltage, 3500 V; sheath gas pressure, 43 psi; auxiliary gas pressure, 20 psi.

Standard and Quality Control (QC) Sample Preparation. Stock solutions of AMF and the internal standard were prepared individually by dissolving 10 mg of AMF or 20 mg of apiolin in 100 mL of methanol. Ten working standard solutions containing 9.3, 18.6, 37.2, 93.0, 186, 465, 930, 1860, 4650, and 9300 nmol/L of AMF were prepared by serial dilution of the stock solution using appropriate volumes of methanol. A working solution of the internal standard was prepared by diluting the stock solution with ethyl acetate by a factor of 1000 to a final concentration of 700 nmol/L. All stock solutions were stored at 4 °C, and all working solutions were freshly prepared each week. Plasma calibration standards were prepared by spiking 45 μL of fresh rat plasma with 5 μL of the appropriate working solution to achieve AMF concentrations of 0.93, 1.86, 3.72, 9.30, 18.6, 46.5, 93, 186, 465, and 930 nmol/L. QC samples containing three concentrations of AMF (low, 2.79 nmol/L; medium, 37.2 nmol/L; and high, 744 nmol/L) were prepared similarly.

Sample Preparation. The utilization of a mixture of β-glucuronidase/sulfatase to hydrolyze glucuronidated/sulfated conjugates has been successfully applied for the quantification of drugs in plasma.[19−23] In brief, prior to the determination of the total AMF (including free AMF plus its conjugated metabolites), plasma samples were treated with β-glucuronidase/sulfatase (type H-1) in vitro,

DOI: 10.1021/jf5019615
J. Agric. Food Chem. 2015, 63, 1957−1966

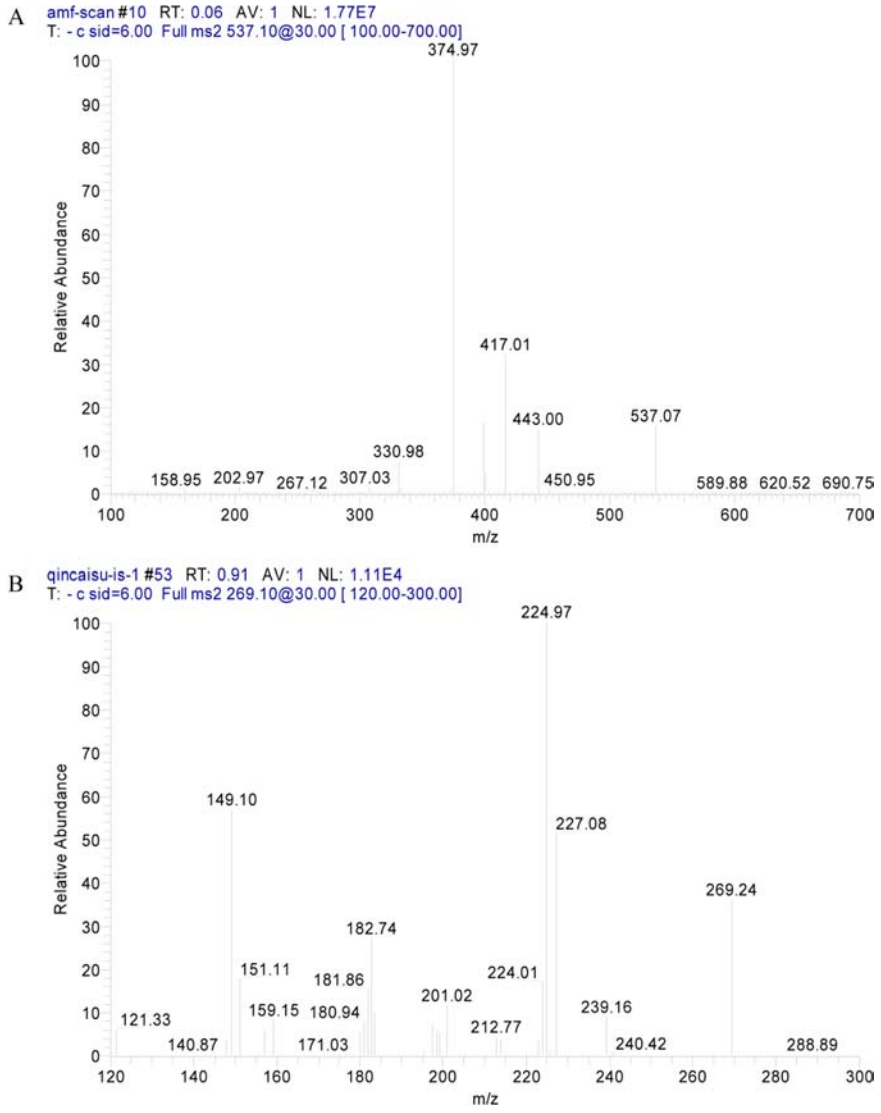

Figure 2. Product ion mass spectra of deprotonated molecules of amentoflavone (AMF, A) and the internal standard (B).

whereas no enzyme treatment was used before determination of free AMF. However, extensive efforts were made to optimize the conditions used in this first enzymatic step prior to liquid−liquid extraction (Supporting Information). Based on these results, we established the following optimal enzymolysis conditions: For enzymolysis, 50 μL plasma samples were mixed with 50 μL of β-glucuronidase/sulfatase solution in 0.1 M acetate buffer, pH 5 (500/16.6 units/mL for samples from rats dosed po and 5,000/166 units/mL for samples from rats dosed iv and ip), and 10 μL of ascorbic acid (200 mg/mL), followed by incubation at 37 °C for 12 h under anaerobic conditions in the dark with gentle shaking. After hydrolysis, the plasma was partitioned using 1 mL of ethyl acetate containing 700 nmol/L of the internal standard. The mixture was vortexed for 3 min and centrifuged at 4000*g* for 10 min at 4 °C. The ethyl acetate layer was then evaporated to dryness under N_2 gas and reconstituted with 50 μL of methanol. For determination of free AMF, 50 μL plasma samples were processed in the same manner, except that no enzyme was included in the 0.1 M acetate buffer.

To prepare calibrator samples, 45 μL of plasma was mixed with 5 μL of the appropriate AMF working solution. The mixture was added to 50 μL of 0.1 M acetate buffer (pH 5) and processed in the same way as the other samples.

Method Validation. The method was validated for selectivity, linearity, precision, accuracy, recovery, matrix effect, and stability. The validation assays were carried out in accordance with currently accepted U.S. Food and Drug Administration (FDA) guidelines for use in industry.[24]

Specificity. The specificity of the LC−MS/MS method was investigated by comparing blank rat plasma from six different rats with the corresponding rat plasma samples spiked with AMF at the lower limit of quantification (LLOQ, 0.93 nmol/L). This enabled evaluation of the influences of endogenous substances in rat plasma on AMF quantification.

Recovery and Matrix Effect. The extraction recovery of AMF from rat plasma was determined at the LLOQ (0.93 nmol/L) and at 2.79, 37.2, and 744 nmol/L for QC samples. Extraction recovery was defined as the ratio of the analyte peak area from extracted QC plasma to the mean peak area from extracted blank plasma spiked with AMF. Matrix effects were quantified as the ratio of the analyte peak area from an extracted plasma blank spiked with AMF to the mean peak area observed during analysis of the standard AMF solution, at the same concentration, prepared in methanol.

Linearity and LLOQ. Calibration curves were calculated by linear regression analysis of the peak area ratio of AMF to internal standard plotted against the normalized concentration of AMF, with a weighting factor of $1/x^2$. Curve fits were not forced to intersect the origin. The LLOQ of the assay was defined as the lowest concentration of AMF detected with precision and accuracy lower than 20% (n = 6).

Precision and Accuracy. QC samples were processed (n = 6) at the LLOQ and at 2.79, 37.2, and 744 nmol/L in rat plasma for each run

DOI: 10.1021/jf5019615
J. Agric. Food Chem. 2015, 63, 1957−1966

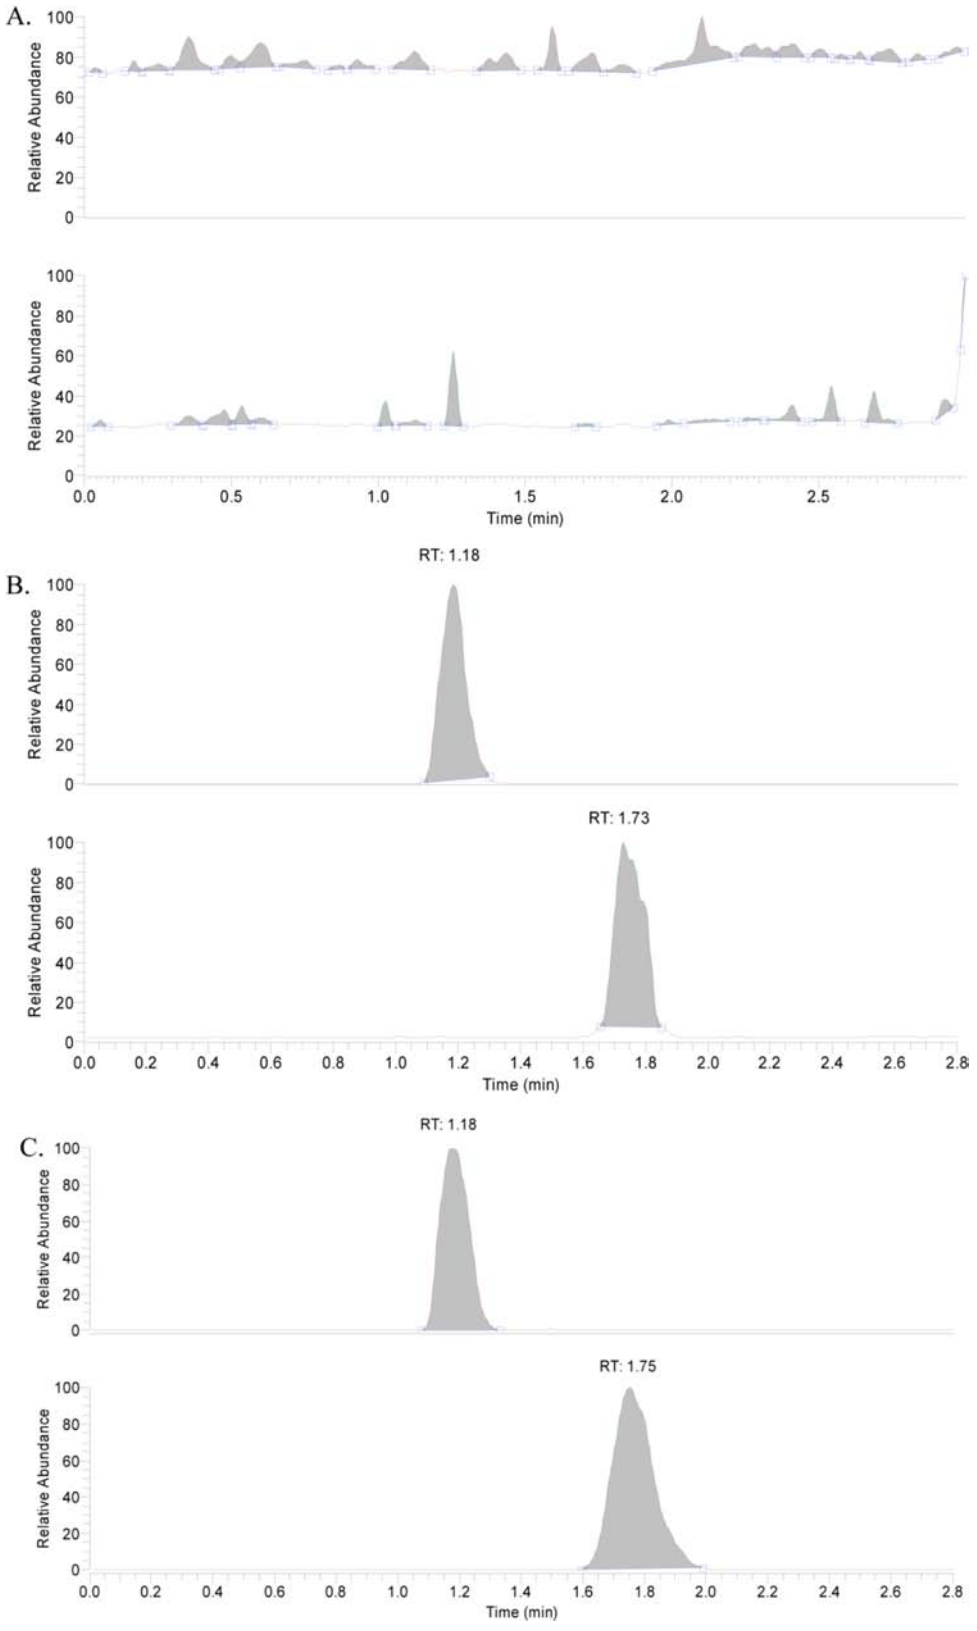

Figure 3. Representative selected reaction monitoring (SRM) chromatograms of amentoflavone (AMF, I) and internal standard (II) in rat plasma: (A) blank plasma sample; (B) blank plasma sample spiked with AMF at the lowest limit of quantification (0.93 nmol/L) and the internal standard (700 nmol/L); (C) plasma sample obtained from a rat 3 h after oral administration of AMF, when the concentration of AMF was found to be 0.16 nmol/mL.

over 3 days. The concentrations in the QC and the unknown samples were calculated from the equation of the calibration curve. Accuracy was measured by the deviation or bias (%) of the mean calculated concentration from the actual concentration. Precision was defined as

DOI: 10.1021/jf5019615
J. Agric. Food Chem. 2015, 63, 1957−1966

the coefficient of variation (CV, %). Precision and accuracy were determined within each day for the LLOQ and three concentrations of QCs, with six replicates and one calibration set prepared each day. Precision and accuracy between different days were evaluated for each QC concentration and for the LLOQ using 18 replicates obtained over three different days.

Stability and Dilution. The stability of AMF in rat plasma at the LLOQ and at the three QC concentrations was determined at room temperature (24 °C for 6 h), after three freeze−thaw cycles (−30 °C to room temperature), at the storage temperature (14 days at −30 °C), and in the autosampler at 4 °C. Five aliquots were analyzed for each condition, and the stability was calculated according to a published procedure.[25] The analyte was considered stable when the accuracy bias was within ±15% of the nominal concentration. Notably, some samples obtained from animals receiving iv AMF were observed to have AMF levels exceeding the highest concentration of the calibration curve. Therefore, to accurately evaluate the precision and accuracy for these samples, 25- and 5-fold more concentrated QC samples were diluted into blank matrix and analyzed in the same way as the other samples.[26] For these samples, accuracy was within ±15% and precision was ≤20%.

Carry-Over. To evaluate carry-over between samples, a blank sample was tested immediately after testing an AMF standard at the upper limit of quantitation (ULOQ).[27]

Data Evaluation and Statistics. The concentrations of the conjugate metabolites of AMF in plasma were calculated by comparing samples treated with β-glucuronidase/sulfatase to samples with no enzyme treatment, as follows:

$$\text{glucuronidated + sulfated AMF} = \text{AMF after β-glucuronidase/sulfatase treatment} - \text{free AMF} \quad (1)$$

The pharmacokinetic parameters were calculated using the Drugs and Statistics 2.0 software program (DAS 2.0, Shanghai, China), assuming a noncompartmental model. The area under the plasma concentration−time curve (AUC) was calculated using the trapezoidal method; the maximum plasma concentration (C_{max}) and the time to reach the maximum plasma concentration (t_{max}) were obtained by visual inspection of the experimental data; the terminal half-life ($t_{1/2}$) was calculated as 0.693/k, with k defined as the slope of the terminal regression line. The bioavailability (F) of AMF after ip and po administration was calculated using the following equation:

$$F = \frac{\text{po, ip AUC}_{0-t}}{\text{iv AUC}_{0-t}} \times \frac{\text{iv dose}}{\text{po, ip dose}} \quad (2)$$

where AUC_{0-t} represents the AUC from time 0 to the last time point.

The results were analyzed using Student's t-test to detect significant differences between the AMF and AMF conjugate pharmacokinetic data. Comparisons with $p < 0.05$ were considered to be significantly different. All results were expressed as the mean ± standard deviation (SD) for all replicates.

RESULTS

Method Development. A new LC−MS/MS method was optimized for the determination of plasma concentrations of AMF and its metabolites. We found that AMF could be measured in the positive- or negative-ion mode, but the mass response of AMF under positive mode was not sensitive enough to enable quantitative pharmacokinetic analysis. The most abundant molecular ion for AMF was $[M - H]^-$ (m/z 537.1). This was chosen for fragmentation analysis, and MS optimization was then performed by automatic tuning of the instrument to detect the product ion m/z 374.9. The fragment ion (m/z 224.9) of the internal standard (m/z 269.2) was obtained in a similar way. The product ion spectra of AMF (m/z 374.9) and the internal standard (m/z 224.9) are shown in Figure 2.

We found that changing the methanol:water ratio from 90:10 to 50:50 (v/v) improved the MS response area and peak symmetry and also reduced the run time for the target ions. For chromatographic separation, we found that a mobile phase of 70% methanol at a flow rate of 0.2 mL/min gave an ideal retention time of less than 3 min, which enabled rapid analysis of multiple samples. We also observed that, compared to lower percentages, 70% methanol enhanced the peak signal, most likely by enhancing ionization. Like most biflavonoids, AMF contains a carboxylic acid group, making the pH of the solvent critical for mass response. When 0.1% formic acid was included in the mobile phase, the peaks of both AMF and the internal standard were symmetrical and sharp.

The sample preparation method was also optimized to ensure reproducibility, minimal matrix effects, and a low cost. Apiolin was chosen as the internal standard because it has similar chemical structure, physicochemical properties, and mass spectrometric behavior to those of AMF. A single-step liquid−liquid extraction procedure was used to enrich and clean the target compound from plasma. Although several organic solvents, including ethyl acetate, acetonitrile, methanol, and diethyl ether, were investigated as extraction solvents, ethyl acetate produced the highest recovery and cleanest samples.

Method Validation. *Selectivity.* The SRM chromatograms of blank rat plasma, blank plasma spiked with AMF at the LLOQ (0.93 nmol/L) and with the internal standard (700 nmol/L), and plasma samples obtained 3 h after po administration of 300 mg/kg AMF are shown in Figure 3. No endogenous interference was observed in the chromatograms of control blank rat plasma ($n = 6$) over the period when AMF and the internal standard eluted, indicating that the analysis was highly selective.

Linearity and Sensitivity. The LLOQ for this method was 0.93 nmol/L for AMF in rat plasma. The standard curve was obtained by plotting the ratio of AMF to internal standard peak area versus the concentration of AMF added (0.93−930 nmol/L). Linear regression to $1/x^2$ yielded a correlation coefficient ≥0.9955, and the slope of each regression line was reproducible, with a relative standard deviation of <2% (Table 1). Calibration standards showed good precision (% CV between 4.9% and 11%) and accuracy (% bias between −8.2% and 6.7%) over the range of 0.93−930 nmol/L (Table 2).

Accuracy and Precision. The intra- and interassay accuracy (% bias) and precision (% CV) of the assay at the LLOQ and for three QCs at concentrations of 0.93−744 nmol/L are summarized in Table 3. The values for intra- and interday QC accuracy ranged from −5.55% to −1.25% and from −0.38% to −4.57%, respectively. The accuracy at the LLOQ was within

3%, with a CV of <8%. The intra- and interday precision ranged from 5.17% to 11.6% and 5.66% to 10.1%, respectively. The accuracy and precision for AMF were within ±15% for all QCs and ±20% at the LLOQ. These parameters indicated that the LC−MS/MS assay provided accurate and precise detection of AMF over the 0.93−930 nmol/L range, and that detection could be extended to higher concentrations.

Extraction Efficiency and Matrix Effects. The AMF extraction efficiency from rat plasma was determined at the LLOQ and at three QC concentrations: 2.79, 37.2, and 744 nmol/L. Extraction efficiency ranged from 88% to 98% (Table 3), and it was consistent, precise, and reproducible. Analysis of the matrix effect of AMF at the LLOQ and at the three QC concentrations (n = 6; Table 3) indicated that there was no significant matrix effect on AMF extraction from rat plasma.

Stability and Dilution. The stability of AMF in rat plasma at the LLOQ and at the three QC concentrations was investigated under a variety of storage and processing conditions that simulated sample handling during the entire protocol (Table 4). These results indicated that AMF was stable over three freeze−thaw cycles, at room temperature for 24 h, in the autosampler for 24 h at 4 °C, and frozen at −30 °C for 15 days. In addition, we evaluated the CV and accuracy after dilution in rat plasma, since some of the early pharmacokinetic samples required dilution due to having concentrations above the ULOQ. We found that the precision and accuracy were unaffected by 25- or 5-fold dilution.

Carry-Over. To ensure that there was no carry-over between samples, we washed the syringe and injection port multiple times with 50% methanol between samples, and we also directly confirmed that no carry-over was observed using a plasma blank sample.

Pharmacokinetic Application. Although AMF has previously been administered iv, ip, or po in studies evaluating its efficacy,[17,18,28] detailed pharmacokinetic analyses of AMF have not been reported. We used our sensitive and specific LC−MS/MS method to evaluate AMF pharmacokinetics in rats after a single po, iv, or ip dose (Figure 4). The pharmacokinetic parameters of the conjugated and free forms of AMF are listed in Tables 5 and 6.

After iv dosing, AMF and its conjugates showed biexponential clearance kinetics (Figure 4A), with the

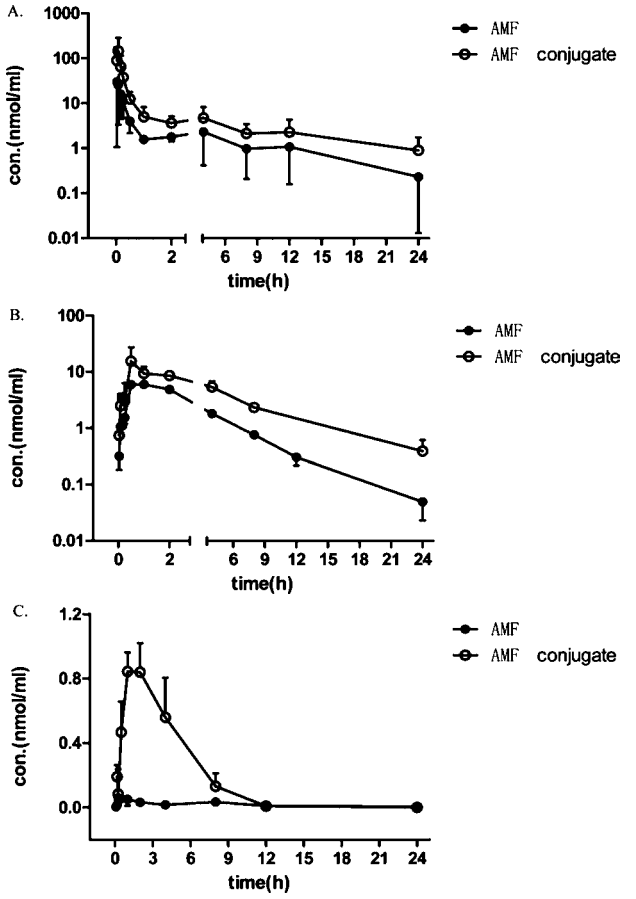

Figure 4. The pharmacokinetic profiles of amentoflavone (AMF) and its conjugates. Plasma concentration of AMF and its conjugates are shown after administration of (A) 10 mg/kg intravenous (iv) AMF, (B) 10 mg/kg intraperitoneal (ip) AMF, and (C) 300 mg/kg oral (po) AMF (mean ± standard deviation, n = 5).

conjugates present at higher concentrations throughout. Based on the AUC, 26.8% of the total AMF detected was nonconjugated, and 73.2% was conjugated (Table 6). Moreover, in plasma samples treated with the glucuronidase/sulfatase enzymes in vitro, the measured plasma AMF concentrations increased by ~2.0 to 5.6-fold, consistent with the measured ratio between conjugated and nonconjugated forms. Based on noncompartmental modeling of the data, both species had essentially the same (p >0.05) mean residence time (MRT_{0-t}), $t_{1/2}$, and t_{max} (Table 5). These data collectively suggested that AMF was rapidly conjugated (glucuronidated and/or sulfated) in the bloodstream, which may explain its rapid clearance time and high volume of distribution.

After a 300 mg/kg po dose, a low level of the free form of AMF was detected in the bloodstream throughout the analysis period (Figure 4C and Table 5). In contrast, higher concentrations of the AMF conjugates were detected, representing 90.7% of the total AMF, based on the AUC_{0-t} (Table 6). Comparison of the AUC_{0-t} values following po and iv doses indicated that the absolute oral bioavailability of total AMF was low (~0.13% ± 0.04%).

The pharmacokinetic profile and bioavailability were further assessed following ip administration of 10 mg/kg (Figure 4B and Table 5). The ratio of conjugate to the free form of AMF after ip dosing was similar to the ratio observed following iv administration, indicating that rapid conjugation still occurred

Table 6. Ratios of AUC_{0-t} of Free AMF and Its Conjugates to the Total AUC_{0-t} of AMF after Iv, Ip, or Po Administration to Rats ($n = 5$)[a]

param	10 mg/kg iv	10 mg/kg ip	300 mg/kg po
free AMF (%)[b]	26.8 ± 4.65	29.8 ± 3.27	9.33 ± 4.11
AMF conjugates (%)[c]	73.2 ± 6.29	70.2 ± 5.18	90.7 ± 8.32

[a]All values are mean ± SD. The data shown represent the ratios of the areas under the plasma concentration−time curves (AUC) for free and conjugated AMF to total AMF following intravenous (iv), intraperitoneal (ip), or oral (po) administration, respectively. [b]AMF (%) = 100 × (AUC_{0-t} of free AMF)/(AUC_{0-t} of free AMF + AUC_{0-t} of AMF conjugates). [c]AMF conjugates (%) =100 × (AUC_{0-t} of AMF conjugates)/(AUC_{0-t} of free AMF + AUC_{0-t} of AMF conjugates).

after ip dosing. The bioavailability of total AMF was higher for the 10 mg/kg ip dose (66.9%) than it was following the 300 mg/kg po dose. Similar to iv injection, free AMF and AMF conjugates showed similar time courses, with no significant differences in t_{max} and $t_{1/2}$ observed between AMF and AMF conjugates ($p > 0.05$).

DISCUSSION

Herein, we report the development and validation of a method for the accurate determination of plasma concentrations of the free and conjugate metabolized forms of AMF, an important bioactive biflavonoid derived from various herbal sources. Since no authentic standards exist for the glucuronide or sulfate metabolites of AMF, the method included in vitro treatment with β-glucuronidase/sulfatase, liquid−liquid extraction, centrifugation, and analysis by LC−MS/MS. Compared with the previously reported methods,[7,8] the present assay showed excellent performance in terms of sensitivity (increased by about 4-fold) and throughput (3 min per sample versus 6−10 min per sample). Using this method, we could accurately detect both the conjugated and nonconjugated forms of AMF. The high sensitivity and accuracy, as well as the rapid sample analysis, make this method suitable for routine evaluation of AMF pharmacokinetics. We used the method to compare pharmacokinetic behavior following administration by three different routes and to study the bioavailability of AMF in rats.

Although encouraging efficacy data has been reported for AMF in rats,[17,18] there have been no careful analyses of the drug metabolism and pharmacokinetic (DMPK) properties of AMF. Previous analyses of related compounds demonstrated that the biflavonoid glycoside moiety can undergo extensive biotransformation in vivo,[29,31] and that the glucuronide and sulfate conjugates are actually the predominant forms found in the bloodstream, urine, and bile. Hence, it is reasonable to assume that the conjugates are the bioactive forms.[30] Our preliminary investigations of the biotransformation of AMF after po dosing in rats revealed that glucuronide, sulfate, and sulfate/glucuronide conjugates predominated over the parent compound in the urine and feces, and an in situ perfused rat intestine−liver model also confirmed this result (unpublished data). Thus, like other biflavonoids, the conjugated form of AMF is most likely to be the bioactive form.

The dose of AMF used in this study was based on previously reported levels, as well as on our recent pharmacodynamics studies of efficacy. We have previously observed that AMF (20, 10, and 5 mg/kg iv and ip, and 300 mg/kg po) protected from the sperm damage induced by microwave radiation in rats (unpublished data). There are at least two published papers that have reported pharmacological effects of AMF at doses similar to those employed in the present study. Sakthivel et al.[18] reported that AMF (10 mg/kg, ip and iv) protected against acetic acid induced ulcerative colitis. Kim et al.[17] reported that AMF showed anti-inflammatory and analgesic activities when it was administered po at 100 mg/kg. As oral administration is more convenient than injection, we characterized the pharmacokinetics fates of free AMF and its conjugates in rats after po administration.

These results of the present study also suggested that AMF metabolism occurred very rapidly in rats. Several pathways for flavonoids have been previously described;[32,33] glucuronidation and sulfation are well-known mechanisms for increasing the polarity of compounds to aid detoxification.[34] Spencer et al.[35] and Piskula[33] proposed that the first conjugation step for dietary biflavonoids is glucuronidation in the intestinal mucosa. After entering the bloodstream as the glucuronidated form, sulfation occurs in the liver or kidneys. Our finding that oral dosing led to higher levels of conjugation than ip or iv dosing was consistent with this model, and this suggested that glucuronidation and sulfation are critical to biflavonoid metabolism and absorption. Our results also suggested that the activity reported for unmodified AMF in vitro may not fully explain its activity in vivo. Future characterization of the in vitro activity of AMF conjugates could help to clarify this.

Our study also confirmed that AMF showed very low bioavailability after oral dosing. Although the reasons for this are not entirely clear, it is generally thought that large, highly polar molecules are not absorbed efficiently following oral administration.[36,37] Consistent with this hypothesis, the apical transporter multidrug resistance-associated protein 2 (MRP2) can efflux some flavonoids, resulting in a dramatically reduced uptake.[9] At any rate, oral administration is clearly not the preferred route for AMF delivery. It is expected that further investigation of AMF DMPK using our method, combined with a better understanding of the antioxidant properties of the AMF conjugates, will help to advance the potential application of this important phenolic antioxidant constituent of a number of medicinal herbs. In addition, we are working on a pharmaceutical formula that may improve the absorption of AMF.

In this study, we report the development and validation of a reliable, rapid, and accurate LC−MS/MS method to quantify AMF and its conjugate metabolites in rat plasma. We used the method to evaluate the pharmacokinetics of AMF following its iv, ip, and po administration to rats. The resulting data have improved understanding of the DMPK properties of AMF and provided guidelines for further evaluation and development of AMF as a bioactive antioxidant.

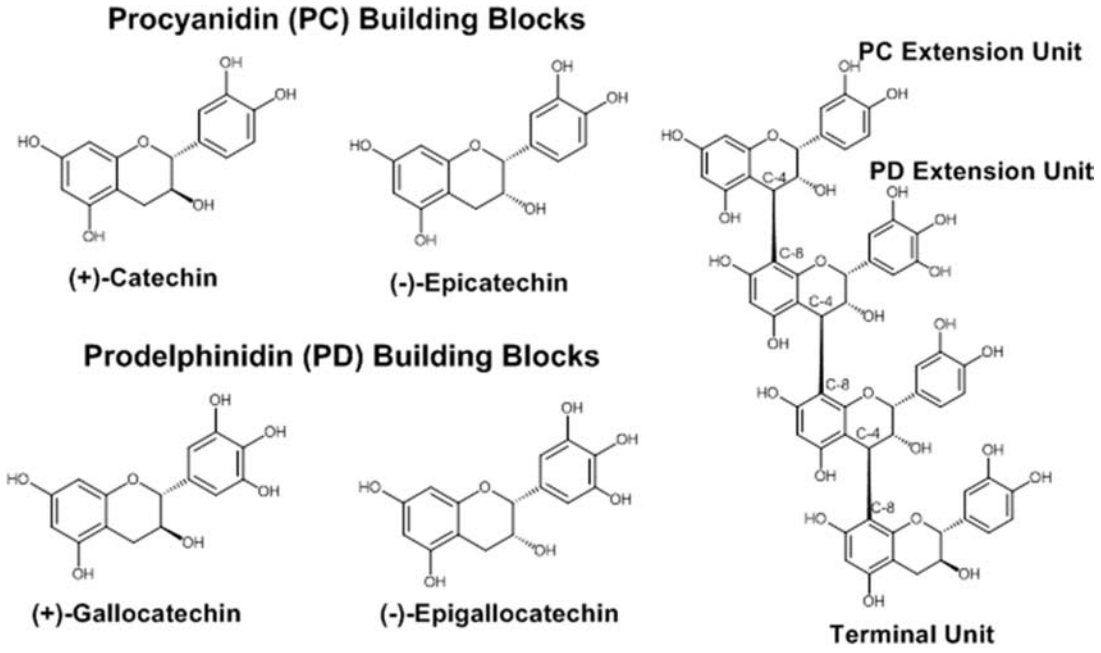

Figure 1. Structures of common flavan-3-ol monomeric subunits found in condensed tannins (left) and a condensed tannin tetramer (right) showing C4−C8 (B-type) linkages, PC and PD extension units, and a terminal unit.

monomeric flavan-3-ol adducts. In this method, extension units are converted into stable C-4 thio ethers, whereas terminal units of the polymers are liberated as intact flavan-3-ol monomers. HPLC analysis of the mixtures obtained from these depolymerization studies allows qualitative and quantitative assessment of CT composition in terms of ratios of PC/PD and *cis*/*trans* subunits and overall mDP. It can thus be used to calculate the purity of isolated CT samples on the basis of the total flavan-3-ol yield. Currently, thiolysis represents one of the most useful techniques available for the analysis of CT composition.

One-dimensional (1D) NMR spectroscopic studies have been used previously to determine the compositional aspects of isolated condensed tannin samples by either solution state ^{13}C NMR spectroscopy[18−27] or cross-polarization magic angle spinning (CPMAS) solid state ^{13}C NMR spectroscopy.[28−31] Solution state ^{13}C NMR spectroscopy has been utilized for the determination of PC/PD[18−20,22−27] and *cis*/*trans* ratios,[18,19,22,24−27] estimations of mDP,[18−20,22,24,26,27] and the identification of C4−C6 and C4−C8 linkages.[20,21] These NMR techniques, however, suffer from broad and often unresolved signals, long acquisition times, and low signal-to-noise ratios, which hamper an accurate assessment of CT composition. Solid phase studies of CT-containing plant material have been conducted using ^{13}C CPMAS NMR techniques.[28−31] Although this technique provides good signal-to-noise ratios, signals in the spectra are still broad and frequently overlap with non-CT signals. In addition, ^{13}C CPMAS requires the use of highly specialized equipment.

By contrast, common two-dimensional (2D) NMR techniques have not been extensively explored for assessing the composition of either purified CTs or CTs present in whole plant materials.[32] Here we report the use of ^{1}H−^{13}C HSQC NMR spectroscopy as a means to determine PC/PD and *cis*/*trans* ratios of isolated CT samples.

MATERIALS AND METHODS

General Procedure for the Purification and Characterization of Condensed Tannins. Condensed tannins were purified from dried and milled plant material and analyzed for CT composition and purity as previously described.[15,16] Briefly, dried plant material was milled (typically using a cyclone mill) containing a 1 or 0.5 mm screen, and the resulting ground material was extracted with 7:3 acetone/water (3 × 10 mL/g of dried material) and filtered. The combined filtrates were concentrated on a rotary evaporator (<40 °C) to remove acetone, and the resulting aqueous layer was extracted with a half volume of dichloromethane (2 times) and was freeze-dried. The freeze-dried residue was purified in one of two ways. The first method involved dissolving the freeze-dried residue in water and applying the resulting mixture to the top of a Sephadex LH-20 column prepacked in water. The column was eluted with water, removing a majority of the carbohydrates present. Column elution was continued with 3:7 acetone/water (providing sample fraction 1) followed by elution of the column with 1:1 acetone/water to give sample fraction 2, which typically contained CTs of highest purity. Alternatively, the dried extraction residue is adsorbed onto Sephadex LH-20 as a 1:1 methanol/water solution to provide a mixture with the consistency of wet sand. This material is then placed in a Buchner funnel and consecutively rinsed with methanol/water (1:1) followed by a series of acetone/water mixtures (1:1, 7:3, 9:1) with each rinsing conducted three times with 5 mL of solvent per gram of Sephadex LH-20. The three rinse filtrates for each solvent were pooled, concentrated on a rotary evaporator (<40 °C) to remove the volatile solvent, and freeze-dried. In both purification methods, the freeze-dried samples were analyzed by ^{1}H−^{13}C HSQC NMR spectroscopy to assess relative purity and/or thiolysis to provide a numerical purity.

NMR Spectroscopy. ^{1}H, ^{13}C, and ^{1}H−^{13}C HSQC NMR spectra were recorded at 27 °C on a BrukerBiospin DMX-500 (^{1}H 500.13 MHz, ^{13}C 125.76 MHz) instrument equipped with TopSpin 2.1 software and a cryogenically cooled 5 mm TXI ^{1}H/^{13}C/^{15}N gradient probe in inverse geometry. Spectra were recorded in DMSO-d_6/pyridine-d_5 (4:1) mixtures and were referenced to the residual signals of DMSO-d_6 (2.49 ppm for ^{1}H and 39.5 ppm for ^{13}C spectra). ^{13}C NMR spectra were obtained using 5000 scans (acquisition time of 4 h and 30 min each). For ^{1}H−^{13}C HSQC experiments, spectra were obtained using 128 scans (acquisition time of 18 h 30 min each) obtained using the standard Bruker pulse program (hsqcegtpsi) with

[a]% purity refers to g tannins/100 g fraction; % PD = 100 − % PC; % *trans* = 100 − % *cis*. nd, not detected.

the following parameters: acquisition, TD 1024 (F2), 320 (F1); SW, 10.0 ppm (F2), 160 ppm (F1); O1, 2500.65 Hz; O2, 11,318.20 Hz; D1 = 1.50 s; CNST2 = 145; acquisition time, F2 channel, 102.55 ms; F1 channel, 7.9511 ms; processing, SI = 1024 (F2, F1), WDW = QSINE, LB = 1.00 Hz (F2), 0.30 Hz (F1); PH_mod = pk; baseline correction ABSG = 5 (F2, F1), BCFW = 1.00 ppm, BC_mod = quad (F2), no (F1); linear prediction = no (F2), LPfr (F1). Samples sizes used for these spectra ranged from 10 to 15 mg providing NMR sample solutions with concentrations of 20−30 mg/mL.

Calculating Procyanidin/Prodelphinidin (PC/PD) and *cis*/*trans*-Flavan-3-ol Ratios. The percentage of PCs in the CT sample was calculated using eq 1

$$\%PC = PC\text{-}6'/[(PD\text{-}2'6'/2) + PC\text{-}6'] \times 100 \quad (1)$$

where PC-6′ is the integration of the contour for the H/C-6′cross-peak of the PC units and PD-2′6′ is the integration of the contour for the H/C-2′,6′ cross-peak of the PD units. The PD-2′6′ value is divided by 2 to account for the signal arising from two sets of correlated nuclei. The percentage of *cis* isomers present in the CT sample was calculated through integration of the respective H/C-4 *cis*- and *trans*-flavan-3-ol cross-peak contours centered around $^{1}H/^{13}C$ chemical shifts of 4.5−4.8/36.0 and 4.4−4.65/37.5 ppm, respectively, and used in eq 2:

$$\%cis\text{-flavan-3-ols} = cis\text{-flavan-3-ols}/[cis\text{-flavan-3-ols} + trans\text{-flavan-3-ols}] \times 100 \quad (2)$$

Integrations of cross-peaks were performed in triplicate, and the values were averaged. Integration of the peaks was performed using Topspin 2.1 software.

RESULTS AND DISCUSSION

We have recently shown that $^{1}H-^{13}C$ HSQC NMR spectroscopy can be a useful tool when assessing the presence of CT in forages and detection of CT left in residues after HCl−butanol treatment,[16] demonstrating the power of 2D NMR techniques. The current study included examining the $^{1}H-^{13}C$ HSQC NMR spectra of 22 purified CT samples prepared from 9 different plant species. The CT samples had PC/PD ratios ranging from 0/100 to 99/1, *cis*/*trans* ratios ranging from 58/42 to 95/5, and a CT content of 44−∼100% as determined by thiolysis (Table 1). As an example, the $^{1}H-^{13}C$ HSQC NMR spectrum of CT purified from *Lotus pedunculatus* (big trefoil, sample 6, Table 1) is given in Figure 2A along with cross-peak assignments. The absence of significant cross-peak NMR signals from non-CT organic compounds in this spectrum also confirms a high degree of purity of this sample.

Determination of PC/PD Ratios. Quantification of signals arising from polymeric materials by $^{1}H-^{13}C$ HSQC NMR spectroscopy is often hampered by nuclei having differing *T1* and *T2* relaxation times and differences in coupling constants and resonance offset effects.[33] The presence of these effects results in skewing of cross-peak signal contour volumes and thus typically limits the utility of these contours for quantifying structural information. Usually these effects require special spectroscopic treatments and alterations in NMR acquisition parameters, such as changes in pulse sequences or increased relaxation delays, before reliable quantification can be made.[34−36]

(A) Signal assignments for the $^{1}H-^{13}C$ HSQC NMR spectrum (500/125 MHz, DMSO-d_6/pyridine-d_5, 4:1) of purified condensed tannin sample (Table 1, sample 6) from *Lotus pedunculatus* (big trefoil) leaves. (B) B-Ring aromatic region cross-peak signals including H/C-2′,6′ PD signal and the H/C-2′,5′ and 6′ signals from procyanidin units. (C) H/C-4 *cis*- and *trans*-flavan-3-ol cross-peak signals. Contours were integrated as indicated by boxes. Non-tannin-related signals arising from impurities are noted and are not included in the integration.

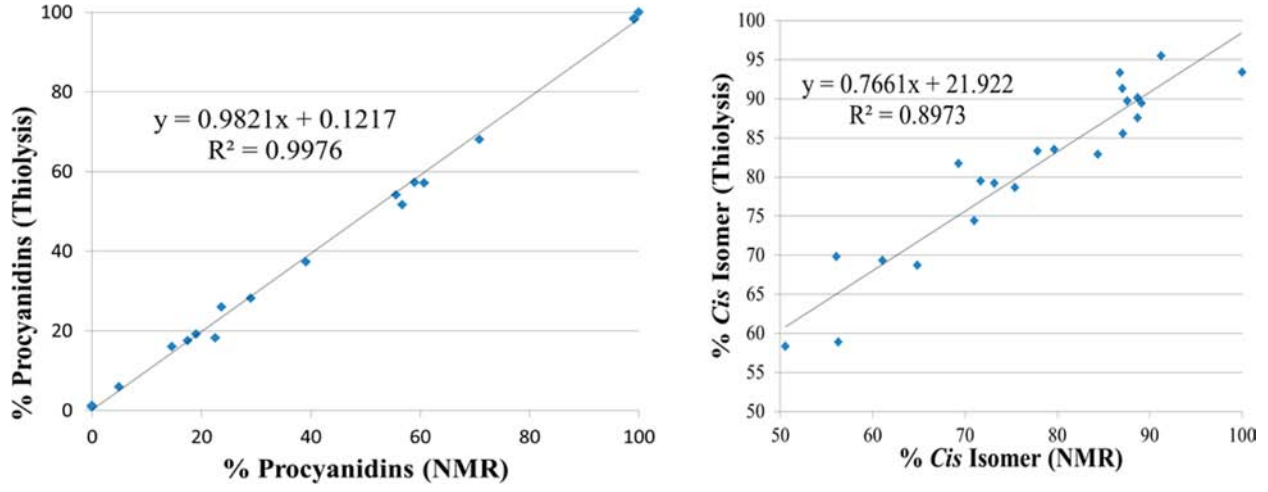

Figure 3. Proportion of procyanidin subunits (left) and *cis* subunits (right) *cis* subunits in 22 isolated condensed tannin samples as determined by thiolysis versus $^{1}H-^{13}C$ HSQC NMR.

In the $^{1}H-^{13}C$ HSQC NMR spectra of these samples, a combination of the nuclei *T1* and *T2* relaxation and resonance offset effects can be observed for most cross-peak signals. The results of these effects lead to cross-peak contours in the spectra the volumes of which are not proportional to the corresponding nuclei ratios. As a prime example, integration of the contours for signals arising from H/C-2′,5′ of PC units versus those from H/C-6′ of PC units would normally provide a ratio of 2:1 if

[a]% PC = percentage of procyanidins in CT sample; % *cis* = percentage of *cis*-flavan-3-ols in CT sample. Percentages for prodelphinidins (PD) and *trans*-flavanols are not shown as % PD = 100 − % PC and % *trans* = 100 − % *cis*.

none of the above-mentioned effects were observed (Figure 2B). However, the integration ratios of H/C-2′,5′ versus H/C-6′ cross-peak contours in PC containing samples from this study showed wide variability with a range from 2.37:1 to 3.86:1 (n = 17, av = 3.15, SD ±0.48). Most of the signals in the ^{1}H−^{13}C HSQC NMR spectra of these purified CT samples followed this trend. A comparison of integration values obtained from the cross-peak contours could not be directly correlated with theoretical relative intensities of the nuclei giving rise to the signal. Similarly, in an attempt to assess the mDP of these samples, integration of the terminal methylene unit versus any of the other CT cross-peak signals in the spectra also led to no obvious correlation with the thiolysis data of this study. It is worth noting that even integrations of the C-4 methylene units of the flavan-3-ol monomers catechin, epicatechin, and epigallocatechin under identical conditions only integrate, on average, to 72% of other signals present in the ^{1}H−^{13}C HSQC NMR spectrum.

However, integration ratios of H/C-6′ cross-peak signals from PC units and the H/C-2′,6′ cross-peak signal from PD units did show an extremely strong and unbiased relationship with PC/PD estimates from thiolysis determinations (Figure 3). Thus, this is the first time that ^{1}H−^{13}C HSQC NMR data from purified CT samples have been corroborated with data from an alternative method (thiolysis) to quantify compositional characteristics of CTs. Separate NMR analyses conducted on a limited set of other purified CT samples at the University of Reading confirmed this method as providing reliable PC/PD ratios.

It is not clear how all of the parameters controlling contour intensities are interrelated: Do the nuclei involved impart the same or similar *T1* and *T2* relaxation times, coupling constants, and resonance offset effects, allowing for accurate comparison of the two contours, or is this simply a coincidence of cancellation of the effects? Answers to these questions remain to be determined.

To test for variability in sample-to-sample preparation and data acquisition, we prepared duplicate NMR solutions from the same CT samples and obtained NMR spectra of these preparations on different days. These results are given in Table 2. As shown, there is excellent reproducibility of the method between these duplicate runs. In all, these experiments prove that this is a robust method for the estimation of PC/PD ratios in purified CT samples.

Determination of *cis*/*trans*-Flavan-3-ol Ratios. To assess *cis*- and *trans*-flavan-3-ol ratios (i.e., ratio of epicatechin and epigallocatechin versus catechin and gallocatechin) in these samples, we focused on the H/C-4 cross-peak signal (Figure 2C). It has been reported[32] that this signal is segregated into two cross-peaks with ^{1}H/^{13}C chemical shifts of ∼4.5−4.8/36.0 and ∼4.4−4.65/37.5 ppm for the *cis*- and *trans*-flavan-3-ol subunits, respectively. The integration of cross-peak signals in ^{1}H−^{13}C HSQC NMR spectra of the same nuclei with the same connectivity in nearly identical electronic environments should be straightforward as they should possess similar, if not identical, *T1* and *T2* relaxation times and pose little or no differences in coupling constants and resonance offset effects. Thus, we should be able to use the data obtained from these ^{1}H−^{13}C HSQC NMR spectra to directly measure this structural element of isolated CTs. The percentage of *cis* isomers present in the CT sample was calculated through integration of the respective H/C-4 *cis* and *trans* cross-peak contours (Figure 2C). Integration ratios from these contours provided strongly related but biased estimates of *cis*/*trans* ratios relative to thiolysis (Figure 3). A literature search revealed that this segregation of the *cis* and *trans* signals of flavan-3-ol moieties is most likely not absolute, and this could provide an explanation for the bias in *cis*/*trans* estimates relative to thiolysis. NMR spectroscopic data from epicatechin (*cis*) oligomers report ^{13}C chemical shift in the range of 37.5 ppm, overlapping into the previously designated "*trans*" signal region.[37,38] The lack of signal segregation is more pronounced in structures containing C4−C6 interflavanyl linkages.[38,39] Thus, overlapping of signals from *cis*- and *trans*-flavan-3-ol subunits is the most likely contributing factor for slightly larger discrepancies between the thiolysis/NMR correlations for *cis*/*trans*-flavan-3-ol subunit assessments and may also be responsible for the biased regression fit (Figure 3).

Precautions. The first issue here, as with most analytical techniques, is to obtain a spectrum with strong signal-to-noise ratio before the integration of data is attempted. If sample size is limited, extended acquisition times need to be considered. When using this technique on samples of low purity, it is imperative that the user be able to recognize any non-CT impurity signals present and avoid incorporating them into the integration values. For PC/PD ratio evaluations, we have found that the signals indicated in Figure 2B are the most common impurity signals which may interfere in obtaining reliable results. These signals most likely arise from trace amounts of non-CT polyphenols present in the sample. For the assessment of *cis*/*trans* ratios, the problem of integration of non-CT impurities does not seem to be an issue. The H/C-4 cross-peak signals appear, even in spectra of whole plant material, in an area void of other non-CT signals. The major issue in the *cis*/

DOI: 10.1021/jf504743b
J. Agric. Food Chem. 2015, 63, 1967−1973

trans ratio assessment is the resolution of the two signals. In some cases these signals are not well resolved (Figure 2C), and care needs to be taken in selecting the integration areas.

In conclusion, the method developed now permits analytical assessment, via 2D $^{1}H-^{13}C$ HSQC NMR spectroscopy, of two specific chemical properties of purified CT samples: PC/PD and *cis*/*trans* ratios. The purified CT samples examined encompass the entire range of procyanidin/prodelphinidin ratios from 0/100 to 99/1 and a substantial range of *cis*/*trans*-flavan-3-ol ratios from 58:42 to 95.5:4.5. The observations outlined here also provide validation of thiolysis data for analysis of CT composition. In contrast to thiolysis, NMR spectroscopy represents a nondestructive analytical tool, which can be important when sample quantities are limited. Thiolysis requires ca. 4 mg for a single determination, whereas NMR analysis requires only 10 mg for an 18 h acquisition time using the described instrumentation. No additional straightforward correlations were found upon examination of other cross-peak signals in these $^{1}H-^{13}C$ HSQC NMR spectra. Additional spectroscopic examination of these samples is warranted to investigate whether other significant structural information can be obtained using quantitative $^{1}H-^{13}C$ HSQC NMR data[34−36] or alternative NMR techniques.

[a]Determination of $\delta^2H_{tissue\ water}$ was not possible. Values calculated using OIPC (cf. Hydrogen Isotope Fractionation and Correlation between Tissue Water and Plant Matter Methoxyl Groups). [b]Isotope fractionation was calculated according to eq 3.

application, the following questions should be investigated by suitable experiments. (1) How does the δ^2H value of methoxyl groups correlate with the original plant tissue water, and does the value remain unchanged and constant during the evaporative processes? (2) How do the δ^2H and the $\delta^{18}O$ values of plant tissue water behave and correlate during the evaporative processes? (3) How do the δ^2H and the $\delta^{18}O$ values of tissue water correlate to the loss of water from biomass as measured by weight loss? (4) What is the potential of the methodology for the practical assessment of freshness of fruits and vegetables?

These questions will be investigated in a model experiment by measuring the δ^2H values of methoxyl groups, the δ^2H and the $\delta^{18}O$ values of tissue water, and the weight loss under controlled conditions from apples, carrots, and potatoes.

EXPERIMENTAL PROCEDURES

Chemicals. Hydriodic acid (puriss. p.a., 55−60%, not stabilized) and methyl iodide (99.5%) were purchased from Sigma-Aldrich (Seelze, Germany, and Gillingham, U.K., respectively).

Fruit and Vegetable Samples. Apples (*Malus domestica* var. Jonagold, 31 apples from a single tree) were harvested on September 29, 2009, at a local farm in Germany (geographic position, 49°57′34″N, 08°12′50″E; altitude, 190 m). Carrots (40 carrots per set) were provided from three different locations. One sample set, purchased at the local market in Mainz on August 17, 2010, had been grown nearby (geographic position, 49°58′17″N, 8°21′17″E; altitude, 86 m). The two other carrot sample sets were obtained from Umeå, Sweden (63°49′N, 20°15′E), and Belfast, Northern Ireland (54°35′N, 5°56′W). After being harvested, both sample sets were stored under controlled conditions at 4 °C and processed within 2 days.

Three apples and carrots were selected to represent a sample (to be analyzed after different storage time periods). The samples were stored at 22 °C and a relative humidity of 55%. Water loss relative to the fresh weight was calculated from the difference between the initial weight and that after storage before squeezing. Every 4 and 7 days, samples of carrots and apples, respectively, were processed by being squeezed in a commercial juice extractor; tissue water was collected and the residual organic matter lyophilized. Both samples were stored at −20 °C until stable isotope ratio analysis was conducted.

Moreover, during a sample campaign from Gibraltar, Spain, to Mainz, Germany, in May 2009 at different locations, several carrot and potato samples were collected along a south−north gradient covering a latitude range of ∼14° (36°−50°N) (see Table 1). These samples were stored at 4 °C and analyzed in the same manner described above.

Isotope Ratio Analysis of Samples. *Sample Preparation and Instrumentation for the ^2H Analysis of Methoxyl Groups.* Hydrogen isotope signatures of the methoxyl groups from fruit and vegetable matter were measured as CH_3I released upon treatment of the lyophilized samples with HI by the procedure of Greule et al.[12] HI (0.5 mL, 55−60%) was added to the sample (150−300 mg) in a crimp glass vial (1.5 mL). The vials were sealed with crimp caps containing PTFE-lined butyl rubber septa (thickness of 0.9 mm) and incubated for 30 min at 130 °C. After being heated, the samples were allowed to equilibrate at room temperature (22 ± 0.5 °C, air-conditioned room) for at least 30 min before an aliquot of the headspace (10−90 μL) was collected and directly injected into the analytical system.

The δ^2H values (see below) of CH_3I released from methoxyl groups in the samples ($\delta^2H_{OCH_3}$) were measured using an HP 6890N gas chromatograph (Agilent, Santa Clara, CA) equipped with an

DOI: 10.1021/jf505192p
J. Agric. Food Chem. 2015, 63, 1974−1981

autosampler (A200S, CTC Analytics, Zwingen, Switzerland), coupled to a Delta^{PLUS}XL isotope ratio mass spectrometer (ThermoQuest Finnigan, Bremen, Germany) via a thermo conversion reactor [ceramic tube (Al_2O_3), length of 320 mm, 0.5 mm inside diameter, reactor temperature of 1450 °C] and a GC Combustion III Interface (ThermoQuest Finnigan). The gas chromatograph (GC) was fit with a HP-5MS capillary column (Agilent) (30 m × 0.25 mm inside diameter; d_f = 0.5 μm), and the following conditions were employed: split injection (4:1), initial oven temperature of 30 °C for 3.8 min, ramp at 30 °C/min to 100 °C. Helium was used as the carrier gas at a constant flow of 0.6 mL/min.

A tank of high-purity hydrogen (hydrogen 5.0, Linde, Höllriegelskreuth, Germany) with a known δ^2H value of −295‰ (V-SMOW) was used as the working reference gas. The H_3^+ factor, determined daily during the measurement period, was in the range of 4.1−4.4. Samples were analyzed five times (n = 5), and the average standard deviations of the Gas chromatography-high temperature conversion-isotope ratio mass spectrometry (GC-HTC-IRMS) measurements were in the range of 0.3−4.2‰. All $\delta^2H_{OCH_3}$ values were mathematically corrected by adjustment for an offset derived from the difference between the nominal and measured δ^2H values of a single CH_3I working standard relative to V-SMOW. The δ^2H value of CH_3I was calibrated against international reference substances [IA-R002 ($\delta^2H_{V\text{-}SMOW}$ = −111.2‰), IAEA-CH-7 ($\delta^2H_{V\text{-}SMOW}$ = −100.3‰), and NBS-22 ($\delta^2H_{V\text{-}SMOW}$ = −118.5‰)] using an offline EA-IRMS (elemental analyzer-isotopic ratio mass spectrometer, Iso-Analytical Ltd., Sandbach, U.K.). The calibrated δ^2H value versus V-SMOW for CH_3I was −179.0 ± 2.9‰ (n = 15; 1σ). The standard was measured after every fifth sample injection.

As this procedure represents solely a one-point calibration, it has to be pointed out that the δ^2H data might be affected by an additional error ("scale compression"). Unfortunately, CH_3I working standards with distinct isotopic signatures spanning the full range of measured δ^2H values were not available for this study to eliminate or minimize such an error. The authors are very aware that traceability and therefore international comparability of stable isotope abundance measurements ideally require a two-scale anchor calibration with accepted isotope abundance values as recommended by the IUPAC guidelines.[14,15]

δ^2H and δ^{18}O Analysis of Tissue Water. Stable isotope analysis of tissue water was conducted at Isolab (Laboratorium für Stabile Isotope, isolab GmbH, Schweitenkirchen, Germany). In brief, samples of tissue water were homogenized, and the liquid was separated from solids by centrifugation. This liquid was subsequently used to measure δ^2H (after distillation) and δ^{18}O (after equilibration and dual inlet measurement) values of tissue water. A homemade equilibration unit coupled to a dual-inlet IRMS (Thermo MAT 250) was employed for oxygen isotope analysis and an equilibration unit based on platinum-catalyzed hydrogen exchange between water and hydrogen gas for hydrogen isotope analysis. The reliability of the isotopic analyses was checked by measuring in-house reference water of a known isotopic content (δ^{18}O, −10.3‰; δ^2H, −72‰) regularly in each sample batch. The reference water had been calibrated versus V-SMOW and V-SLAP international standard waters. To prevent microbial degradation of the dissolved organic compounds (CO_2 formation) during oxygen isotope analysis by equilibration, sodium azide was added to the samples before they were placed into the equilibration vessels.

Definition of δ Values and Calculation of Isotope Fractionation ε. Throughout this paper, the "delta" (δ) notation, the relative difference of the isotope ratio of a material to that of a standard V-SMOW (Vienna Standard Mean Ocean Water), is used. Values of δ^2H and δ^{18}O relative to that for V-SMOW are defined by the following equations:

$$\delta^2H = ({}^2H/{}^1H)_{sample}/({}^2H/{}^1H)_{standard} - 1 \quad (1)$$

$$\delta^{18}O = ({}^{18}O/{}^{16}O)_{sample}/({}^{18}O/{}^{16}O)_{standard} - 1 \quad (2)$$

However, for practical reasons, we use δ values in ‰, and as our method has originally been developed and is still preferably applied for geochemical questions, definitions for ε and Δ are as usual in this discipline.[8,16] Therefore, the hydrogen isotope fractionation between plant tissue water (index w) and methoxyl groups (index m) during the synthesis of biomass, the "isotope enrichment", is (R is here the isotope ratio)

$$\begin{aligned}\varepsilon_{m/w} &= R_m/R_w - 1\\ &= ({}^2H/{}^1H)_m/({}^2H/{}^1H)_w - 1\\ &= (\delta^2H_m + 1)/(\delta^2H_w + 1) - 1\end{aligned} \quad (3)$$

The authors are aware that this is an approximation and would like to refer to the studies of Coplen et al. and Schmidt et al. for further reading.[14,17] Throughout the paper, we use the short form $\varepsilon_{m/w}$ for $\varepsilon_{methoxyl/water}$.

RESULTS AND DISCUSSION

Hydrogen Isotope Fractionation and Correlation between Tissue Water and Plant Matter Methoxyl Groups. In our initial experiments, we determined the hydrogen isotope fractionation between tissue water and methoxyl groups of fresh potatoes and carrots, collected in different geographic locations in Europe (cf. Fruit and Vegetable Samples).

For some samples (carrot samples C4−C9), it was not possible to analyze the δ^2H values of tissue water as the amount of juice obtained was not sufficient to allow isotope analysis. For these samples, δ^2H values of tissue water were calculated using the Online Isotope Precipitation Calculator [OIPC (http://www.waterisotopes.org/)], employing the IAEA database and interpolation algorithms.[18−20] For this approach, we made the simplification and/or assumption that the δ^2H values of the water taken up by the potatoes and carrots were similar to that of the annual precipitation at the sampling site.

The mean isotope fractionations between tissue water and methoxyl groups ($\varepsilon_{m/w}$) were −184 ± 13‰ and −158 ± 13‰ for the carrots and potatoes, respectively (Table 1). This shows the necessity of determining the isotope fractionation for each species of fruit and vegetable separately. The slopes of the linear regressions for data of both potatoes and carrots are close to 1 with coefficients of determination (R^2) close to 0.6 (Figure 1a; for carrots, R^2 = 0.59, n = 11, and p < 0.006; for potatoes, R^2 = 0.56, n = 13, and p < 0.003). Furthermore, the mean isotope fractionation $\varepsilon_{m/w}$ of the potato samples is in excellent agreement with data previously been reported by Keppler et al. ($\varepsilon_{m/w}$ = −161 ± 11‰).[21] Via combination of the latter data with this data set (Table 1 and Figure 1b), R^2 increases to ∼0.85 (R^2 = 0.85, n = 30, and p < 0.001), highlighting the importance of larger data sets.

Relationship between δ^2H and δ^{18}O in Tissue Water of Fruits and Vegetables. The δ^2H and δ^{18}O values of meteoric water show a linear correlation, well-known as the "meteoric water line" (MWL) roughly expressed by the equation $\delta^2H = 8 \times \delta^{18}O + 10$.[22] Because of transpiration, tissue water in plants becomes enriched in δ^2H and δ^{18}O relative to source water.[23] This isotope enrichment is transferred to fruits and vegetables[24] but shows, as compared to MWL, a relative larger enrichment of ^{18}O and then of ^{2}H, which might be due to the relative mass difference of the water isotopologues that is twice as large for oxygen [$H_2{}^{18}O$ (mass of 20) − $H_2{}^{16}O$ (mass of 18) = 2] as it is for hydrogen [^{2}HHO (mass of 19) − H_2O (mass of 18) = 1]. More probably, however, different diffusion constants of the stomata lead to the observed difference in the enrichments of ^{18}O and ^{2}H. Thus, the slope of the resulting relationship

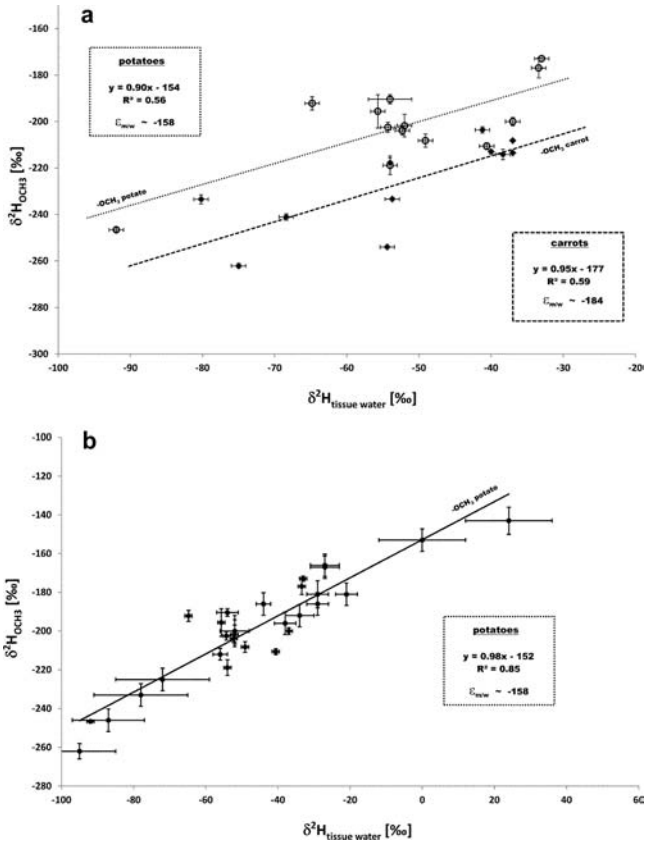

Figure 1. (a) Relationship between δ^2H values of tissue water and organic matter methoxyl groups of potatoes (○) and carrots (■) harvested at different geographic locations. Error bars indicate (i) for methoxyl groups the standard deviation of mean values (n = 4) and (ii) for δ^2H values of tissue water the confidence intervals calculated by the Online Isotope Precipitation Calculator (OIPC). (b) Relationship between δ^2H values of tissue water and organic matter methoxyl groups of potatoes harvested at different geographic locations. Combination of the current data set and that from a previous study.[10] Error bars indicate (i) for methoxyl groups the standard deviation of mean values (n = 4) and (ii) for δ^2H values of tissue water the confidence intervals calculated by the OIPC.

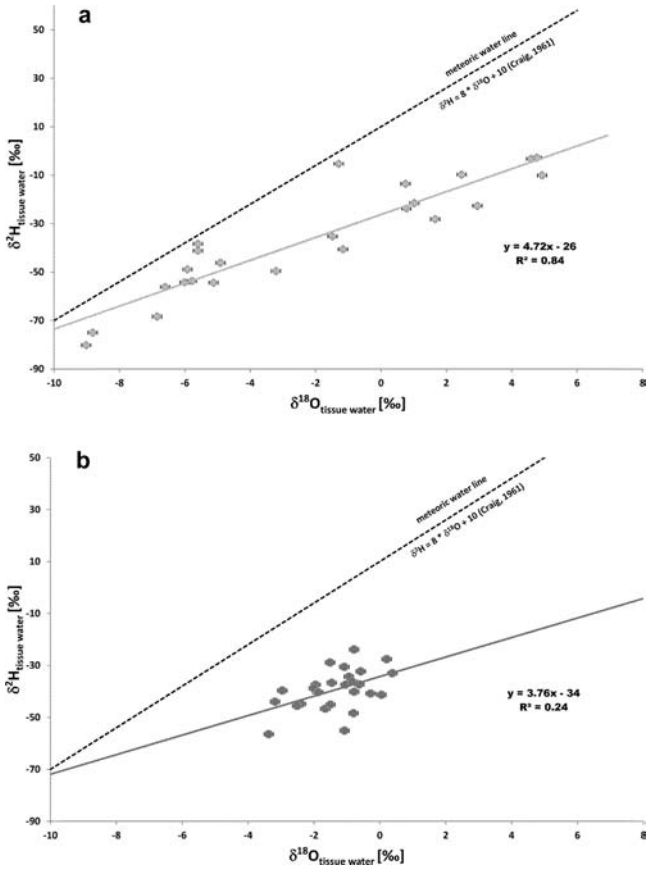

Figure 2. Relationship between δ^2H and δ^{18}O values in tissue water of (a) carrots and (b) apples. In analogy to the meteoric water line, we refer to the relationship as the "fruit water line". Error bars show the precision of sample measurement.

between δ^2H and δ^{18}O in tissue water that we define as the "fruit water line" is lower than the meteoric water line: in the literature, slopes of 2−4 can be found.[24−27] Although the "fruit water line" must be determined individually for each of the different fruits and vegetables, once it has been established the isotopic signatures of ^{2}H and ^{18}O of tissue water can be deduced from one another. Nevertheless, we cannot completely rule out the possibility that storage conditions might have an influence on the relationship between δ^2H and δ^{18}O in tissue water ($\delta^{18}O_{tw}$ and δ^2H_{tw}) and thus on the slope of the "fruit water line". This possibility should be further considered and investigated in the future.

Here, we determined δ^2H and δ^{18}O values of the "fruit water line" of carrots and apples. The slopes of the linear regressions for data of both carrots and apples are significantly lower than the MWL {4.72 and 3.76, respectively [panels a (carrots) and b (apples) of Figure 2]} and in good agreement with literature data (*Lupinus angustifolius*, 3.1;[26] grapes, 3.9[24]). The carrot samples showed an R^2 (R^2 = 0.84, n = 24, and p < 0.001) considerably higher than that of the apple samples (R^2 = 0.24, n = 27, and p < 0.01).

Relationship among δ^{18}O and δ^2H of Tissue Water, δ^2H of Methoxyl Groups, and Storage Time. A main factor to be controlled during the storage of fruit and vegetable is the loss of water by evaporation. The degree of water loss depends on storage time, temperature, and humidity. In this study, the controlled conditions were 22 °C and a relative humidity of 55%. Details of sample storage and measurement of the δ^{18}O and δ^2H values of tissue water of carrots and apples and the respective δ^2H values of the methoxyl groups during storage are described in the Experimental Section.

Our results (Figure 3) show that with storage time and water loss both $\delta^{18}O_{tw}$ and δ^2H_{tw} of the residual tissue water become more positive, because of the preferred loss of the lighter isotopes during transpiration. As described in the previous section, $\delta^{18}O_{tw}$ correlates significantly better with water loss than δ^2H_{tw}, for both carrots (R^2 = 0.90 ↔ 0.49) and apples (R^2 = 0.92 ↔ 0.18). No significant change in the δ^2H values of the methoxyl groups ($\delta^2H_{OCH_3}$) was observed for the same samples during storage for up to 20 and 69 days for carrots and apples, respectively (Figure 4). Thus, methoxyl groups of fruit and vegetable can be considered a plant archive that records the δ^2H values of the plant tissue water before harvest.

The results further prove that the hydrogen atoms remain fixed to the nonpolar C−H bond of the methoxyl groups and do not exchange with water once they are bound, and hence, their isotope value remains stable. At this point, it is important to note that this is not the case for the CO−H bond of carbohydrates. These results would indicate that most reliable

and promising use for the reconstruction of the tissue water loss would be a combination of $\delta^2H_{OCH_3}$ and $\delta^{18}O_{tw}$. In the subsequent sections, we will demonstrate in detail how this can practicably be undertaken.

Application of the Method for the Determination of the Initial $\delta^2H/\delta^{18}O$ Ratios of Tissue Water from the δ^2H Values of Methoxyl Groups. The complete isotopic signature of tissue water of plant tissue prior to harvest can be deduced from the δ^2H values of its methoxyl groups. The δ^2H value can be calculated from the correlation between the isotope signatures of methoxyl groups and tissue water (Figure 1a,b), and the $\delta^{18}O$ value from the "fruit water line" that is derived from δ^2H and $\delta^{18}O$ values of tissue water (eq 5 and Figure 2a,b). Because water loss is best reconstructed from $\delta^2H_{OCH_3}$ and $\delta^{18}O_{tw}$ in the first step, it is necessary to calculate the initial δ^2H value of tissue water (δ^2H_{twi}) using the respective food specific constant isotope fractionation between the δ^2H values of tissue water and methoxyl groups (eq 4).

$$\delta^2H_{twi} = \delta^2H_{OCH_3} - \text{isotope fractionation } \varepsilon_{m/w} \quad (4)$$

Then the next step is to determine the initial $\delta^{18}O$ value of tissue water ($\delta^{18}O_{twi}$) from the "fruit water line", the relationship between $\delta^{18}O$ and δ^2H values in fruits and vegetables (eq 5).

$$\delta^{18}O_{twi} = (\delta^2H_{twi} - \text{axis intercept}_{\text{"fruit water line"}}) / \text{slope}_{\text{"fruit water line"}} \quad (5)$$

As an example, this procedure is graphically illustrated in Figure 5.

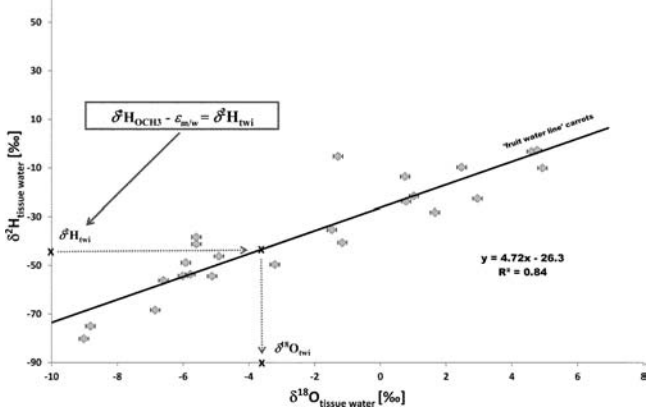

Figure 5. Calculation of the initial $\delta^{18}O$ value of tissue water from the δ^2H value of tissue water and the corresponding "fruit water line".

Deduction of Relative Water Loss from $\delta^{18}O$ of Tissue Water and δ^2H of Methoxyl Groups. Two further steps are necessary to calculate the relative water loss of fruits and vegetables during storage. First, we need to calculate the oxygen isotope discrimination $\Delta^{i18}O_{twm/twi}$ ("delta over baseline, DOB") or "isotopic difference" between the $\delta^{18}O$ value of tissue water measured at an unknown stage of storage time ($\delta^{18}O_{twm}$) and the initial value of the water present during biosynthesis ($\delta^{18}O_{twi}$) as obtained from the δ^2H value of the corresponding methoxyl group (cf. eq 5) and its correlation to the $\delta^{18}O$ value:

$$\Delta^{i18}O_{twm/twi} = (\delta^{18}O_{twm} - \delta^{18}O_{twi})/(1 + \delta^{18}O_{twi})$$

or, as

$$\delta^{18}O_{twi} << 1$$

$$\Delta^{i18}O_{twm/twi} = \delta^{18}O_{twm} - \delta^{18}O_{twi} \quad (6)$$

Finally, when $\Delta^{i18}O_{twm/twi}$ is divided by the slope of the food specific linear regression, this will yield the percentage water loss (eq 7):

$$\%\text{water loss} = \Delta^{i18}O_{twm/twi}/\text{slope} \quad (7)$$

A graphic illustration of the last step is shown in Figure 6. Via application of the procedure described above, the correlation

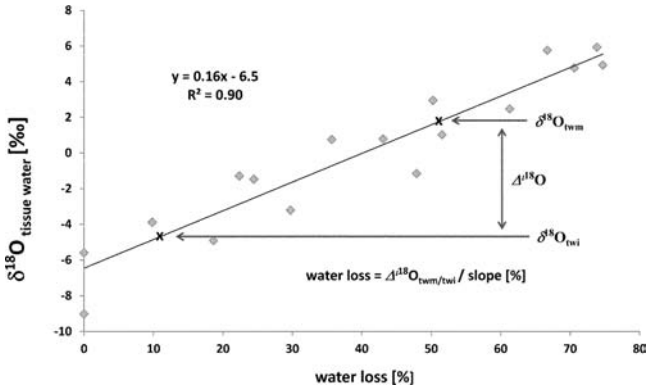

Figure 6. Calculation of water loss (%) using the calculated initial $\delta^{18}O$ value of tissue water (cf. Figure 5) and the measured $\delta^{18}O$ value of tissue water.

line of Figure 3a, and the equations given above, the relative water loss from an actual sample (carrot; measured values, $\delta^2H_{OCH_3} = -236.4 \pm 2.4‰$, $\delta^{18}O_{twm} = 1.02 \pm 0.14‰$, and $\varepsilon_{m/w} = -184‰$) after storage for 16 days at 22 °C and a relative humidity of 55% was found to be 40.8 ± 11.8%. The error was calculated using a Gaussian error propagation including uncertainties of $\delta^{18}O$ and δ^2H measurements, the regression equation of the relationship between δ^2H of tissue water and methoxyl groups [isotope fractionation (cf. Figure 1)], and the regression equation of the carrot "fruit water line" (cf. Figure 2a). The rather high error can most likely be explained by the small data sets on which the linear regressions have been calculated. Nevertheless, because our intention was to demonstrate the principle of this new method, we did not place too much emphasis on minimizing the uncertainties at this stage because we were aware that it was well beyond the capabilities of one study to provide such an extensive data set.

For comparison, the gravimetrically measured water loss for the same sample was found to be 46.6%, which is in reasonable agreement with the water loss determined by this new approach (40.8 ± 11.8%).

Conclusion. Postharvest alterations of plant tissue water, as water loss during storage or illegal tap water addition, decrease the quality of plant products. The aim of this study was therefore to investigate an easy and reliable method for the detection of such changes.

As shown in this study and previous studies, methoxyl groups of organic samples are very easily converted to CH_3I. From this investigation, the δ^2H value of the latter compound was found to be a stable and reliable biomarker for the isotope characteristics of plant tissue water prior to harvest. The

model experiments conducted with apples, carrots, and potatoes under controlled storage conditions revealed that water loss during storage was accompanied by an enhancement of the δ^2H and δ^{18}O values of tissue water. The correlations of these values were distinct for the individual plants and differed from the MWL. δ^{18}O values were better correlated to water loss, as measured by weight, than δ^2H values.

Therefore, for assessment of postharvest tissue water loss of fruits and vegetables, we suggest that a procedure should be based on the determination of the δ^2H values of the methyl groups of the organic matter and the δ^{18}O value of the actual tissue water. The extension of this procedure to the practical control of fruit or vegetable freshness would require investigation of samples stored under normal commercial conditions. For this, we would envisage that the range of isotopic data from such samples would be wider than those found in the model experiment, and therefore, calibration with several isotope standards covering this expanded range would be necessary. Moreover, as we would also expect the isotopic shifts under commercial storage conditions to be smaller than those observed in this study, it would be necessary to undertake considerably more development and refinement of the current protocol.
