JOURNAL OF AGRICULTURAL AND FOOD CHEMISTRY

Editorial

pubs.acs.org/JAFC

Future Has Tradition in *JAFC*, but Tradition, Too, Has a Future!

The landscape of scientific publishing is continually changing. A vast number of new journals are sprouting out of the ground. Many of these new journals are miniaturized in scope or limited by a narrow readership. In comparison, the *Journal of Agricultural and Food Chemistry* (*JAFC*) is firmly rooted in a long tradition of publication excellence in the broader chemistry and (bio)technology of agricultural and biobased materials all the way up to food products including bioactivity, nutritional, and health aspects. Since its foundation in 1953 with Walter J. Murphy as the first Editor-in-Chief, *JAFC* has become the most influential journal in agricultural and food chemistry. Over 5500 world-leading scientists serve as peer reviewers each year. In 2013, the journal had over 82000 citations, over 2 million article requests, and published more than 1500 papers, the most ever.

As new Editor-in-Chief, there is no better purpose for my first Editorial than to acknowledge the contributions of Jim Seiber to *JAFC*. Jim successfully navigated *JAFC* for 15 years; under his tenure the journal developed greatly with an increase of yearly manuscript submissions by more than 300%, yearly published article content by more than 45%, total number of citations to *JAFC* by nearly 375%, and a rise of the impact factor to 3.107. Backed with the excellent support of the ACS, Jim decreased the time it took accepted papers to reach our global readership.

Acting in wise foresight, Jim and *JAFC*'s passionate Associate Editors widened the scope of the journal and reacted flexibly to the ever-changing multidisciplinary arena of agricultural and food chemistry by timely introduction of new categories such as metabolomics, new formats such as Letters, and new author recognition tools such as the *JAFC* Research Article of the Year Award. Not only has the number of Associate Editors grown from 5 to 12, but also the global presence of *JAFC* has increased significantly. As cutting-edge research in *JAFC* continues to become more global, the composition of the team of Associate Editors is more international than ever before, and I expect this trend to continue: Hanne Christine Bertram (Denmark), Zhen-Yu Chen (China), John W. Finley (USA), Chi-Tang Ho (USA), Yoshinori Mine (Canada), Russell Molyneux (USA), Peter Schieberle (Germany), Taka Shibamoto (USA), Veronika Somoza (Austria), Francisco Tomás-Barberán (Spain), Elisabeth Waters (Australia), Liangli (Lucy) Yu (USA). Jim and the Associate Editors could always build on the contributions of the engaged members of the Editorial Advisory Board supporting *JAFC* in agenda setting and manuscript decision making. In an extraordinary show of service to the journal, Fereidoon Shahidi, Gow-Chin Yen, and Michael Clifford have provided more than 30 manuscript reviews over the past 3 years. Backed by all of these active supporters and continually refreshed with new science and innovative features, it is not surprising that *JAFC* retained leadership as the most cited journal in the three ISI categories "Agriculture", "Applied Chemistry", and "Food Science and Technology". Jim deserves our hearty thanks for these achievements!

So, as a welcome to 2015, first let me share an Editor's overarching goal for the coming year - that the Associate Editors and I will work hard to ensure that *JAFC* remains the premier journal in which to publish authors' most impactful and innovative science. Although submissions are increasing from all around the globe, the submitted manuscripts will be handled by an Associate Editor having the appropriate expertise, no matter where the authors are from or where the Editor is geographically located. Thus, while we have an increasingly international team of excellent Associate Editors, the defining aspect of the manuscripts we publish should be their outstanding science, not the country of origin. *JAFC* will further expand its tradition to develop strong, largely ramified roots. These will help our fundamental knowledge to continuously flourish, while concurrently germinating internationally to reach best-in-class scientists developing and applying new molecular tools and technologies to solve global challenges in agricultural and food research. *JAFC* is more than ever on the spot. Here's to an exciting 2015!

Thomas F. Hofmann, Editor

Reviewer List 2014

The Editor and Associate Editors gratefully acknowledge the following scientists for reviewing manuscripts during 2014. Many of these individuals reviewed several manuscripts. We thank all of the reviewers for their contributions of time and talent. Note: this list reflects reviews received between November 11, 2013, and November 30, 2014.

ABSTRACT: This review analyzes bottle-fermented sparkling wine research at each stage of production by evaluating existing knowledge to identify areas that require future investigation. With the growing importance of enological investigation being focused on the needs of the wine production industry, this review examines current research at each stage of bottle-fermented sparkling wine production. Production phases analyzed in this review include pressing, juice adjustments, malolactic fermentation (MLF), stabilization, clarification, *tirage*, lees aging, disgorging, and *dosage*. The aim of this review is to identify enological factors that affect bottle-fermented sparkling wine quality, predominantly aroma, flavor, and foaming quality. Future research topics identified include regional specific varieties, plant-based products from vines, grapes, and yeast that can be used in sparkling wine production, gushing at disgorging, and methods to increase the rate of yeast autolysis. An internationally accepted sensory analysis method specifically designed for sparkling wine is required.

KEYWORDS: *sparkling wine, wine production, aroma, flavor, foaming*

INTRODUCTION

Bottle-fermented wine production is increasing on a global scale, and there is a growing focus on alternative grape varieties in emerging sparkling wine regions that can produce quality sparkling wine. The more famous sparkling wines include Champagne and crémants from France, cava from Spain, prosecco from Italy, sekt from Germany, Cap Classique from South Africa, and sparkling icewine from Ontario (made with grapes picked by hand and pressed in their natural frozen state at approximately −10°C). Semi-sparkling wines such as Frizzante are found in Italy and white Vinho Verde in Portugal. Bottle-fermented sparkling wine quality, defined as flavor, aroma, and foaming height and stability, can be affected both positively and negatively at every stage of production. Factors that affect the quality of sparkling wine include grape variety, yeast strain, oxygen management, malolactic fermentation (MLF), fining, filtration, *tirage* recipe, length of lees aging, *dosage* recipe, and lees aging post-disgorging. The current literature has been critically analyzed to identify previous research regarding bottle-fermented/méthode champenoise/traditional method sparkling wine at every stage of production (Figure 1). Additionally, the authors aim to identify areas of future research that will benefit winemakers, contribute to increased wine quality, and advance scientific knowledge.

VITICULTURAL EFFECTS ON SPARKLING WINE QUALITY

This section of the review is a summary of viticultural effects of grape variety, clone, grape maturity, leaf removal (specifically fruit exposure), and yield and their impact on sparkling wine flavor, aroma, and foaming of sparkling wine.

The selection of grape variety for sparkling wine takes into consideration climate, foaming properties of the juice, the base wine composition (sugar, acidity, and pH levels), aging ability, and the wine style required. Cava wine is predominantly produced from white varieties, Macabeo/Viura, Xarel.lo, Parellada, and Verdejo with a small proportion of Chardonnay and Malvasia Riojana/Subirat Parent. Red varieties in cava wine production include Monastrell, Pinot noir, Garnacha, and Trepat.[1,2] The traditional Champagne grapes are Chardonnay, Pinot noir, and Pinot meunier, but a revival in interest of varieties such as Petit meslier, Arbane, Pinot blanc, and Pinot gris in Champagne is taking place.[3] An increase in the use of alternative grape varieties for sparkling wine is underway. Research has recently focused on varieties such as Albariño, Verdejo, Godello, Garnacha, and Prieto Picudo in Spain,[4] Baga and Ferñao-Pires in Portugal,[5] Italian Riesling/Welschriesling, Manzoni Bianco, and Moscato Embrapa in Brazil[6,7] Mieli in China,[8] and Emir and Dimrit in Turkey.[9,10] This increase in monovarietal sparkling wines is resulting in cultivar-specific, regionally focused research at various stages of the sparkling wine process.

Chardonnay clones in California, used for sparkling wine, were compared to Champagne clones in a 4 year study.[11]

Figure 1. Simplified flowchart of bottle-fermented wine production stages.

American clones had higher acidity at harvest, which was attributed to climatic differences of the two regions. The significant difference between reproductive factors was greatest between the American clones.[11] Pinot noir clone performance in California was found to be significantly different in a 3 year study, with some clones suffering from excessive vegetative growth and others from high yields.[12] Making a viable comparison of the performance of clones for sparkling wines in different countries is extremely difficult because studies rarely have more than a few clones in common.[11] Vine spacing, row orientation, training system, canopy management, and soil and climate differences in each country or region or even from one vineyard to another are all factors that influence clone and rootstock performance.[11,12]

A study in Portugal investigated the impact of soil type and grape maturity on sparkling wine aroma quality. More herbaceous notes were apparent in sparkling wines made from grapes picked one week before commercial harvest. Unfortunately, sugar levels, acidity, and pH values of the grapes were not presented in the study.[13] Esteruelas et al.[14] recently reported that sparkling wines produced from early harvested Macabeo/Viura, Xarel.lo, Parellada, and Chardonnay vines had higher foaming properties compared to those harvested later. However, the first grape harvest was determined by acidity levels and the second harvest by sugar levels, so alcohol differences also contributed to differences in foaming properties.

Viticultural Effects on Phenolic Compounds. Several studies have investigated the effect of viticultural practices on phenolic compounds in sparkling wines due to their importance on rosé, red, and white sparkling wine color and their impact on foaming and flavor.[15,16] Preflowering leaf removal resulted in higher levels of hydroxycinnamates in Chardonnay base wines and increased anthocyanin levels in Pinot noir base wines in Tasmania, Australia.[15] Hydroxycinnamates are the major class of phenolic compounds in Champagne and cava wines. They affect the texture and mouthfeel of sparkling wines, thereby affecting quality.[1,14,16−19] With regard to yield effects, Parellada sparkling wines from high-yielding vineyards in Spain had higher levels of phenolic compounds and fusel alcohols compared to low-yielding ones.[17] Sensory panelists preferred wines from the low-yielding vineyard, although this may have been due to the spontaneous malolactic fermentation that took place in the high-yielding wines, making direct comparison to low-yielding wines difficult.

Phenolic compounds in grape skins and seeds can be a result of environmental factors, vintage, training system, clonal selection, light, temperature, canopy management, and water availability.[5,14−16] Tastes and textures elicited by the presence of phenolic compounds in still white table wines are more prominent at lower alcohol levels and at moderate pH levels, indicating that the presence of phenolics is more important in the context of lighter bodied wines.[20] This could have implications for the quality of sparkling wines with low alcohol levels.

Nineteen phenolic compounds were identified in both Chardonnay and Pinot noir monovarietal Champagne wines from 2000 and 2001 vintages, although the quantity of each varied between the grape varieties.[16] In agreement with a previous study, the variation between phenolic concentrations in the wines was due to variety and vintage, but press pressure (which affects phenolic extraction) was not considered.[14,15]

Although common in many regions, mechanical harvesting is banned in Champagne. This is due to detrimental anthocyanin extraction from red grapes destined for white sparkling wine. Limited space between the grapevine rows in the Champagne region prohibits mechanical access, so this is unlikely to change in the future. Excessive anthocyanin extraction from mechanical harvesting can result in juice requiring charcoal or polyvinylpolyprrolidone (PVPP) treatment and can cause a loss of aromas and foamability in the final wine.[4] Additionally, an increase of pathogensis-related (PR) proteins from mechanically harvested white grapes compared to hand-picked fruit has been reported.[21−23] Results were attributed to their exraction from skins as opposed to physiological wounding response by the berry. PR proteins are largely responsible for protein haze, have low isoelectric points (p*I*) and molecular weights (MW), and are resistant to low pH as well as enzymatic and non-enzymatic proteolysis.[23] Phenolic compounds negatively affect foaming properties and have been implicated in "gushing" during disgorging (see Gushing).[1,24]

Recently, a comprehensive review regarding viticulture for sparkling wine production was published that highlights viticultural research including grape varieties, clones, rootstocks, soil impact on flavor, precipitation in cool/cold climates, and training systems as part of climate change adaptations.[25]

PRESSING

Traditional Champagne wine production uses gentle whole bunch pressing due to the use of red grapes for white wine production to prevent excessive anthocyanin extraction. A study in 1980 compared musts pressed by screw press, cylindrical Willmes press, and Willmes press with pressing aids and reported pressing effects on aroma constituents.[26] It is known that high pressures at pressing increase proteins and polyphenol

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

oxidase (PPO) and that oxidation of phenolic compounds is the main source of browning in wines due to PPO activity.[27] An increase in browning of cava wine (measured at 420 nm) due to the oxidation of phenolics has been previously reported.[18] A comparison of three presses, two traditional basket presses (with and without an outflow central star, respectively), and a pneumatic press, revealed that oxidation level of musts obtained from traditional Champagne presses were high as early as the press exit.[27] Crushed and destemmed juice from Spanish Albariño, Verdejo, Godello, Garnacha, and Prieto Picudo grapes was found to have high levels of phenolic compounds, which were later removed from base wines with PVPP.[4]

A study of a central membrane press compared to a side membrane press on red grapes for still table wine found that the central membrane press produced a higher juice yield as well as lower phenolic levels in juice fractions.[28] Few studies have compared flavor, aroma, and foaming properties of sparkling wines processed using different presses, yet this technology has vastly improved in the past decade. Additionally, comparisons of press performances have been discussed but not with specific regard to sparkling wine quality.[29] The addition of pressing aids, such as rice hulls, to the press with the grapes has been found to increase free run juice from 5 to 15%.[29,30] However, their addition may influence aroma development in sparkling wine, and their use may be dependent on the type of press being used as well as the press cycle program.[29]

Recent grape processing innovations have been developed that include automatic grape box unloading in Champagne in addition to the separation of press fractions partitioned into distinct juice trays using gravity flow with automatic SO_2 addition.[31] Further technological methods to preserve potential grape aromas and quality of the wine have been developed and are currently used in Champagne wine production. These include vibrating hoppers that deliver grapes directly to the press and inert gas (nitrogen) to protect grapes from oxidation in press.[31]

PRESS FRACTIONS

The main objective of grape pressing, as previously mentioned, is to use minimal rotation to avoid oxidation and minimal mechanical pressure on the grapes to minimize total insoluble solids that negatively affect wine quality. Studies have found a decrease in protein concentration and an increase in browning of the juice in the crumbling cycle of a Willmes press.[32−35] This oxidation could affect the foaming ability of the final wine if these fractions are included in the *cuvee* (first press fraction) or *taille* (subsequent press fractions referred to as first *taille* and second *taille* in Champagne). Further studies identified *Vitis vinifera* proteins including a class of IV chitinase, thaumatin-like proteins, putative thaumatin-like protein, and several uncategorized proteins in Pinot noir press fractions of *Botrytis*-contaminated grapes.[34−37] These proteins decreased in the return/retroussé cycle, which could have a negative impact on foaming. Most proteins have a p*I* ranging from 2.5 to 4.5 and MWs of 12−65 kDa.[36−38] Some grape-derived proteins may not survive two fermentations. However, grape pathogenesis (PR)-related proteins, found in high concentrations in grapes, are thought to be the main contributors to protein haze in still white table wines.[38−40] Although if numerous proteins were isolated and characterized according to their MW, p*I*, hydrophobicity, glycans, amino acid composition, and origin, there would still be little information concerning foaming properties of specific proteins or those responsible for foaming height and stability.[38−42] Turbidity levels decreased during the pressing but increased at the return/retroussé stage.[35] In the same study, post-pressing and after 24 h of flocculation, the early fractions had settled and decreased dramatically, from 300 to 20 nephelometric turbidity units (NTU), whereas the return/retroussé fractions were only marginally reduced. Foamability decreased during pressing, probably due to protein reduction or proteins binding to phenolic compounds.[35] Acidity decreased during sparkling grape pressing and pH increased. Additionally, phenolic extraction increased during the length of the pressing with increased pressure of each press cycle.[35] Press-fractioning impact on base wine and sparkling wine chemical composition will depend on grape variety, type of press, the pressure exerted during each cycle, and the length of each cycle.

CHAPTALIZATION, ACIDIFICATION, AND DEACIDIFICATION

Chaptalization. Chaptalization (sugar addition to increase final alcohol level) using cane or beet sugar is common in some cool-climate sparkling wine production regions, that is, Champagne and England. It is often suggested that 17 g/L additional sugar is required for white wines to reach 1% volume increase in alcohol content.[44] However, for low-temperature fermentations such as sparkling base wines, 16 g/L sugar likely contributes 1% volume of alcohol to the wine.[39] Guidelines regarding the level of chaptalization and its timing are controlled by regulatory bodies in each wine region. Sugar addition is not permitted in cava production, but rectified grape must (RGM) is allowed, but only in difficult years when climate conditions have affected grape ripeness.[14,44] Brazilian legislation allows the addition of sugar to grape must during the initial fermentation to increase ethanol content by up to 3 °GL [Gay-Lussac (GL) is the volumetric percentage of alcohol in a beverage].[42] However, in California, legislation permits sugar addition only for the second fermentation.[42] One study found that juice chaptalization had a significant influence on the perceived sweetness, body, and balance between acidity and flavor in still table wines.[45] The study investigated fruit ripeness and juice chaptalization on the sensory properties and typicality of Sauvignon blanc wines in Marlbourough, New Zealand. Since Goresline and Champlin,[46] there have been few studies regarding the effect of sugar type (i.e., cane, beet, dextrose) added prefermentation on sparkling wine quality. Chemical analysis of sparkling wines pre- and post-sugar addition, at first and/or secondary fermentation, investigating its effect on aroma, flavor, and wine quality has not been completed. However, it is likely that any required sugar addition prior to first fermentation will not affect aroma but increase alcohol and enhance the balance of acidity and sweetness.

Acidification. Acidification of juice is carried out by the addition of tartaric acid or, in some countries, cation exchange and is legal in some warm wine regions (i.e., California, Australia). Tartaric acid addition decreases the potassium ions and increases equivalently the concentration of hydrogen ions.[47] The pH reduction from acid addition is not directly related to the amount of acid added due to variations in the buffering capacity of different wines.[44] However, it is possible to make calculations for additions based on the level of pH reduction required.[44] Tartaric acid has also been found to positively affect foaming.[43,47−49] Lowering the pH without lowering titratable acidity requires the addition of calcium

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

sulfate ($CaSO_4$).[47] However, this is more suited to juice, and wines, to be aged prior to bottling and is not authorized by OIV regulations (except in Jerez, Spain, for historical reasons). The effect of acidification with tartaric acid on long-term sparkling wine quality and flavor remains unclear due to a lack of studies. However, any long-term effect on sparkling wine is likely to be minimal due to high tartaric acid being beneficial for sparkling wine foaming and stability.

Deacidification. Uncommon in cool and cold climates except in exceptionally poor growing seasons, the removal of tartaric acid or excess L-malic acid before or after fermentation may be necessary to balance wine acidity and stability.[4] Blending wines with high-acid wines or musts is not always possible, and amelioration (water addition) is detrimental.[50] Double-salt precipitation treatment (Acidex or DICALCIC) uses a 1% calcium tartrate and malic acid salt mixture as a seeding agent and is used to treat a small quantity of the wine, which is blended back into the untreated sample.[50] Boulton[51] advocated that treatment of juice is preferable to treatment of wine and stated that a juice with a pH of >3.8 and a titratable acidity of >10 g/L requires addition of tartaric acid after the double-salt method. This encourages potassium bitartrate crystal (KHTa) precipitation during and after fermentation, to lower the extent of exchange and pH.[46] Further details of deacidification can be found in a review by Volshenck et al.[50]

Malolactic Fermentation (MLF). MLF carried out post-first fermentation or simultaneously with alcoholic fermentation [cofermentation of yeast with lactic acid bacteria (LAB)] is common among winemakers in Champagne but results in a change in acid that may contribute to a reduction in aging.[52] Nonetheless, in difficult years in some wine regions when juice has high acidity, or for stylistic reasons, wineries might consider MLF. MLF not only reduces the acidity but improves the biological stability of the wine and modifies sparkling wine texture.[53] *Oenococcus oeni* is the main LAB that conducts MLF by the decarboxylation of L-malic to L-lactic acid.[54] *Lactobacillus* and *Pediococcus* LAB can conduct MLF but can be associated with wine spoilage and off-flavors.[54] Malic acid has been found to positively affect foaming height but negatively affect foam stability,[1,24,55,56] whereas lactic acid has been found to be beneficial for foaming stability but negatively affects foaming height.[24,56] Furthermore, malic acid and citric acid have both been found to inhibit calcium tartrate precipitation in model wine.[57] Several extensive reviews regarding MLF chemistry have been published but are not the subject of this review.[58,59] They detail bacterial strain performance, inoculation timing, and factors that affect MLF, those being ethanol, sulfur dioxide (SO_2), medium-chain fatty acid MLF inhibition, pH, temperature, nutritional requirements, and phenolic compounds as well as effects on wine aroma and lysozyme.

To prevent MLF, hen egg lysozyme (peptidoglycan *N*-acetylmuramylhydrolase, EC 3.2.1.17) can be used to reduce SO_2 levels in must or wine and prevents MLF due to the sensitivity of *O. oeni* to it. It is not permitted for use in all wine regions (i.e., Canada), and its high cost can be prohibitory.[60,61] Two genetically modified yeasts for MLF have been released onto the market but have limited availability in only a few countries due to public perception and lack of acceptance.[62,63]

Anecdotally, manufacturers of LAB are investigating the use of region-specific strains for MLF by identifying strains in vineyards/wineries, isolating suitable candidates and testing them on wines prior to their manufacture. MLF technological innovations include a study that used a two-stage nanofiltration technique (demalication) and compared its efficiency to inoculated MLF in six grape varieties, including Chardonnay.[64] Further research is required, though, because volatile aroma compounds, flavor analysis, and sensory analysis were not carried out in the study. Provided that aroma and flavor are not negatively affected, and beneficial compounds such as proteins for foaming are not removed in this process, it could have application in sparkling wine production.

An immobilized lactic acid bacterium continues to be investigated for MLF due to its ability to perform MLF in a low-pH environment.[65,66] Materials used to suspend lactic acid bacteria have included grape skins, corn cobs, and delignified cellulosic material (DCM) from sawdust, but they are not yet available commercially.[65,66] Sequential alcoholic and MLF using immobilized cells have been found to increase the speed of wine production, but fermentations were influenced by the pH of the medium, with higher pH levels being less successful.[67] This method may be more suitable for large-scale wineries, but further research is required regarding the flavor and aroma profile of the finished sparkling wines. The selection criterion for LAB has been highlighted and includes stress resistance, technological performance, and safety.[68] With recent progress being made on the stress adaptations, survival rate of *O. oeni*, and proteome map of *O. oeni*, future research is focused on decreasing the time and improving the success rate of MLF in high-acid wines to improve production efficiency.[69]

Recently, *Schizosaccharomyces pombe* yeast with malic dehydrogenase activity that metabolizes malic acid with the production of ethanol has been trialled.[47,63,70] Traditionally described as wine spoilage yeast, *S. pombe* has malic dehydrogenous activity, produces pyruvic acid, breaks down ethyl carbamate precursors, and has a cell wall structure that ensures the autolytic release of mannoproteins and polysaccharides during lees aging, yet only a limited number of commercial strains are available.[63,70] Its main drawback is the strong acetic acid production from unselected strains currently used in wine research.[70] However, it has potential use in sparkling wine production including the partial reduction of malic acid in wine. Instead of using it for a complete MLF, it could be used to start MLF, which could be followed by inoculation with *O. oeni* when acidity is reduced. Additionally, sequential inoculation with selected *Saccharomyces cerevisiae* strains at fermentation and the selection of low acetic acid forming strains for sparkling wine are further options. Further information regarding MLF and LAB can be found in published reviews.[50,59,71] The effect of these various deacidification methods on long-term sparkling wine flavor, aroma, and quality remain unclear due to a lack of comparative published research.[47]

ALCOHOLIC FERMENTATION OF SPARKLING BASE WINES

Alcoholic fermentation wine kinetics has been extensively investigated.[62,71] The key metabolic process during winemaking is alcoholic fermentation, the conversion of sugars into ethanol and carbon dioxide by yeast: $C_6H_{12}O_6 \rightarrow 2CH_3CH_2OH + 2CO_2$.[72] Base wine flavor composition, aroma, and foaming potential are influenced by many factors that include grape variety, clone, rootstock, yield, the health of the grapes (i.e., disease severity), sugar levels, acid levels, nutrient levels, choice of yeast, and press fractions. The alcohol level of sparkling wine has been found to have a negative effect on foam. Chardonnay and Parellada wines made from less ripe grapes in Spain had

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

higher foamability, due to lower sugar levels at harvest, compared to the grapes picked later.[14] Fermentability of botrytized base wine is reduced because of compositional effects including grape metabolites and protein composition of the *Botrytis*-affected berries.[73] *Botrytis* has been implicated in the destabilization of sparkling wine foam in several studies as well as organoleptic properties, thereby affecting final wine flavor and quality.[73−76] *Botrytis*-affected grapes also require higher SO_2 additions during pressing, which itself is known to negatively affect foaming.[1,49,56,77] The addition of a mixture of potassium caseinate, bentonite, and microcrystalline cellulose mixture to Parellada and Macabeo/Viura juice prefermentation produced wines with lower polyphenol content (less browning capacity), high foam stability time, less foamability, and foam collar persistence than the ones treated with bentonite.[78] It was reported that volatile aroma profiles of the wines treated with the caseinate mixture were different in comparison to the bentonite-treated wines, even though the study did not report any effect on sparkling wine quality.

Enzymatic preparations are used in winemaking to increase color extraction and filterability and improve aroma release due to β-glycosidase activity.[76] Pectolytic enzymes (added to juice during or after pressing) can increase juice yield and are used to settle solids in juice by breaking down pectins to smaller compounds. Grape protopectin and pectin levels are affected by climatic conditions and affect extraction of phenolic compunds. Insoluble protopectin is high in unripe grapes and is converted to pectin by hydrolyzation during ripening. Pectins are linear polymers of galacturonic acid, often possessing multiple esterified methyl groups, and complexed to various degrees with rhamnogalacturonan and chains consisting of arabinans and arabinoglactan.[29] However, pectolytic enzyme addition to Macabeo/Viura, Xarel.lo, and Parellada juice had a negative impact on foaming, possibly due to the settling and removal of solids that included polysaccharides and/or proteins.[79]

Few comparative published studies exist regarding the effect of oak barrels, steel tanks, and cement eggs and their impact on the final sparkling wine flavor and aroma, undoubtedly due to the number of vessels required and the length of time needed from base wine to finished wine for comprehensive chemical and sensory wine analysis. House style (reductive/oxidative) will dictate percent of oak used during production, which ranges from 10 to 100% depending on style. However, a study of the phenolic profiles of Chardonnay and Picapoll varieties of still wines fermented in stainless steel and American oak barrels has been published.[80] Unsurprisingly, total phenolics were found to be higher in wines fermented in oak, which may have detrimental effects on the finished wine foam qualities.[55,79] Several aromatic volatile compounds were reported in the oak-fermented wines [coniferaldehyde, sinapinaldehyde, syingaldehyde, 4-ethylguaiacol, 4-vinylphenol, eugenol, β-methyl-γ-octalactone, furan compound, and a coumarin (scropoletin)] but not in the stainless steel wines, but their impact on sparkling wine aroma and flavor by sensory analysis was not examined.

The effects of six commercial yeast strains were investigated using Macabeo/Viura, Xarel.lo, and Parellada base wines.[81] Yeasts produced wines with different aroma concentrations of esters, glycerol, phenylethanol, terpenes, isoamyl acetate, medium-chain fatty acids, and alcohols. The study illustrates chemical compositional changes attributed to yeast strain. The dynamics of *S. cerevisiae* in controlled and spontaneous fermentations, of two base wines from wineries in Franciacorta, Italy, were investigated.[82] The highest level of biodiversity of yeast isolates was found in the spontaneous fermentation, but the study did not investigate the sensory impact on the final wines. Although it is known that *pied de cuvée* is carried out in some sparkling wine regions (grapes are picked earlier and used to inoculate the first fermentation), there remains a lack of published studies concerning this inoculation method on yeast profile and its effect on sparkling wine foaming, flavor, or aging ability. The potential benefits of non-*Saccharomyces* yeasts (i.e., *Torulaspora delbrueckii*, *Pichia kluyveri*, *Lachancea thermotolerans*, *Candida/Metschnikowia pulcherrima*) on still table wine are well-known.[83] Nevertheless, their effect on bottle-fermented sparkling wines (if used for first fermentation) remains unclear, particularly in regard to their effect on glycerol (important for mouthfeel) that affects wine viscosity, foaming, and volatile aroma compounds.

Low nitrogen concentration in must and excessive ammonium addition have both been found to affect fermentation length, volatile acidity, and glycerol content and wine aroma profile.[84] A study in Australia with Chardonnay investigated nutrient concentration effects on fermentation kinetics and composition.[85] The project surveyed Chardonnay juice composition from cool and warm climates destined for still and sparkling wines, so there was a wide range of pH and acidity levels. They found that low potassium concentrations at low pH negatively affected fermentation performance of some yeasts, thereby affecting the wine quality due to acetic acid production. However, the study did not include the effect of yeast strain or type of nutrient addition on aroma compounds. Grape variety has an influence on nitrogen concentrations, which influences the fermentation kinetics and aromatic profile of the wines.[86] For instance, cava wines manufactured from Monastrell grapes had lower concentrations of fatty acids and ethyl esters as well as different nitrogen concentrations compared to wines produced from Trepat and Macabeo/Xarel.lo/Parellada blend.[86]

Alternatives to SO_2 addition to wine to prevent oxidation and microbial instability are a major focus of current enology research, and studies have used ascorbic acid, glutathione, yeast lees, and yeast autolysate.[87] The yeast derivative glutathione (GSH) (a tripeptide composed of glutamic acid, cysteine, and glycine) was found to be the one additive that performed most like SO_2 in a base wine in Prosecco DOCG when added to Pinot noir and Chardonnay must and base wine.[88] The study found that addition to must had greater oxidation protection than base wines, but addition to base wines resulted in retained free SO_2 levels. Phenolic levels were found to be lower in the sparkling wine that had GSH addition to must. The authors suggest further studies to assess the influence of GSH on MLF and to elucidate the effect of GSH on the levels of free SO_2. These preliminary results indicate that GSH has a promising role in future sparkling wine production, particularly due to the possible reduction of SO_2 use. However, studies into its effect on sparkling wine flavor, aroma, and lees aging are also needed. Additionally, the consequences of oxygenation of must and base wines on the synthesis and preservation of varietal aromas in the finished sparkling wine remain unclear, despite a comprehensive review of wine aroma aging in still wines by Ugliano.[89]

With regard to sparkling base wine aroma, different yeasts produce wines with different base wine aromas, particularly ethyl esters of fatty acids, depending upon yeast strain, fermentation temperature, oxygen management, and sugar

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

contents.[90] They are predominantly produced during alcoholic fermentation from reactions between alcohols and acetyl-CoA catalyzed by alcohol acetyltransferase.[13] The most important ethyl esters found in Chardonnay base wines were ethyl butanoate, ethyl hexanoate, ethyl octanoate, ethyl decanoate, ethyl lactate, and diethyl succinate.[90] Higher molecular weight alcohols found in Brazilian Chardonnay base wines included the aliphatic alcohols propanol, hexanol, dodecanol, 2,3-butanediol, and 2-phenylethanol.[90]

Grape variety has an effect on the aroma of base and sparkling wines. As an example, Ferñao-Pires grapes produced sparkling wines with higher aroma potential than Baga grapes in Portugal.[13] Although there are differences in the aroma compounds between base and sparkling wines, the main volatile compounds that differed between Brazilian Chardonnay base wines and the finished sparkling wines were C_{13}-norisprenoids (TDN, vitisparine, and β-damascenone), esters (laurate, 2-hydroxybutanoate, decanoate, 2-hydroxypropanoate, pentanoate ethyl esters), alcohols (4-butoxybutanol, 1-propanol, methaniol), aldehydes (3-phenyl-2-propenal, nonanal, undecanal), acids (acetic, 2-ethylhexanoic, butanoic), ketones (acetoin, diacetyl), and phenols (4-vinylguaiacol, 4-ethylphenol).[91] With regard to the color of wines after the first fermentation, Girbau et al.[92] suggested that base wine color intensity of white wines produced from black grapes should be similar to that of wines made from white grapes, between 140 and 160 absorbance units (AU).

STABILIZATION, CLARIFICATION, FINING, AND FILTRATION

Blending of base wines has not been an area of scientific research because the blends are specific to the winery style, so in-house trials are usually conducted. Post-blended wines are stabilized to test for tartrate and protein stability, and several studies have investigated methods to assist in wine stability prior to fining (if required) and filtering.

Stabilization and Clarification. In grape juice and wine, tartaric acid (H2T) and its salt, potassium hydrogen tartrate (KHT), are naturally present.[93] Tartrate instability leads to crystal formation in wine bottles, and the most common method to avoid crystals is cold stabilization (chilling wines to −4° for 10 days to 3 weeks using jacketed blankets or seeding crystals).[95] Other methods include electrodialysis, ion exchange, yeast mannoproteins, metartaric acid, and carboxymethylcellulose (CMC).[93,95] Stabilization and clarification along with the first 6 months on lees reduced polyphenol concentrations in sparkling wines, but the reduction was reversed by 9 months of lees aging, probably because some phenolic compounds were released back into the wine.[96] Cross-flow microfiltration is becoming more widely used for clarification and microbiological stabilization in wine production, although its effect on sparkling wine quality is unclear, particularly the effect on foaming ability and stability.[97,98] Clarification of Champagne base wines using wheat, alfalfa, and lupine proteins reported improved clarification compared to bentonite treatment. Pea protein is now commercially available and is currently being used by some English winemakers and so could be considered.[98]

CMC was authorized in 2008 by the International Organisation of Vine and Wine (OIV) at a concentration limit of 100 mg/L tartrate stabilization. It is made of polymers of β-D-glucose units on which the primary or secondary alcohol groups are esterified by sodium acetate groups (−CH_2−COONa).[99] However, it is not yet available or permitted in all wine regions.[93,100] The use of CMC can decrease winery energy costs due to a reduction in cooling while also preventing the loss of acidity. Yet CMC has been found to remove phenolics and proteins if CMC is added in high quantities, which may affect foaming. The stabilizing effect of CMC on tartrate salt precipitation results from its capacity to reduce the transfer of bitartrate molecules from the wine supersaturated with salt to the growing crystals and to decrease the speed with which crystals grow.[94,99] The effect of CMCs with different degrees of substitution and molecular weights on tartaric stability, tartaric acid, mineral content, phenolic compounds, and chromatic and sensory charactersistics of white still wines was recently investigated.[101] All CMCs significantly reduced conductivity, and a higher addition of CMCs resulted in higher tartaric stability. In wines with high tartaric instability associated with tartaric acid and potassium concentrations, CMC is beneficial. However, a deeper understanding is necessary with regard to their structure. This will allow winemakers to choose the appropriate CMC for a given tartaric acid instability issue.[101]

Flotation is a solid−liquid separation process used when the density of the particles is lower than the liquid containing them and is commonly used in wastewater treatment.[99] It has grown in popularity for wine production in recent years for must clarification due to the subsequent reduction/elimination of fining. Flocculating agents are used to bind particles including mineral adjuvants and proteins isolated from plants.[99] It has been suggested that natural plant-based vegetable compounds can replace animal products, for example, gelatin, and could reduce phenolic content and browning in white juices destined for base wines prior to fermentation.[98,99,102] Chitine derivatives are new biopolymers recently described as good flotation adjuvants.[103]

Fining. Grape variety, vintage, grape maturity, pH, and processing techniques affect must and wine proteins.[99] Trials on still wines to remove proteins using carrageenan, wheat proteins, lupine proteins, pea proteins, pectin, laccase, aspartic acid protease, and zirconium have taken place.[99,104−108] Aspartic acid protease BcAP8, from the fungal pathogen *Botrytis cinerea*, has recently been found to remove heat-precipitated proteins from Semillon still wines but not adequately in Sauvignon blanc still wines.[109] Nonetheless, Marchal et al.[110] showed that *Botrytis* protease negatively affects wine foaming by removing proteins, although a direct causal relationship between *Botrytis* proteases and wine protein content has not yet been found.[109] It is unlikely that sparkling winemakers would use *Botrytis*-associated enzymes due to possible effects on foamability and flavor.

The foamability of still base wines (Pinot noir and Chardonnay) decreases when the dose of bentonite increases. Generally speaking, base wine for the production of sparkling wine should have no proteoic haze risk, so bentonite fining is not required. Overfining with bentonite causes large bubbles and poor bubble stability and will affect wine aroma.[99] Bentonite treatment has a deleterious effect on wine foaming properties as the foamability of wines obtained from musts treated with bentonite at the concentration of 50 g/hL decreased by 40−60% and, correlatively, the protein content of the same wines diminished by 20−60%.[77] Bentonite, although commonly used by winemakers in the production of sparkling wines, should be avoided for sparkling base wines. This is because of its concentration of heavy metals potentially released over time and its negative effect on foaming, and it

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

should not be used for fining if bentonite is to be used as a riddling agent. The most commonly used protein stability test is the one referred to by Pocock and Rankine.[105,106] Wine is subjected to 80 °C for 6 h, cooled, and then visually checked for haze with a strong beam of light.[105,106] Unfortunately, there is currently no recommended protein level in base wines at bottling, probably due to the many variables involved including grape variety and production techniques. Unlike bentonite treatment, fining with gelatin−tannins or gelatin−silica gel significantly increases the foaming properties of the fined wines when compared to the nontreated wines.[111] The current interest in natural, plant-based winemaking products means further studies in this area are likely in the future.

Many sparkling base wines produced with Pinot noir and Pinot meunier grapes are pink in color. This is especially true for the wines produced with (1) grape berries having a high maturity level (less common in cool regions where the potential alcohol is between 8 and 10.5% v/v) or (2) the grape juice obtained in the second part of the pressing cycle. In the Champagne area, Pinot noir and Pinot meunier grape berries represent approximately two-thirds of all grapes, and many winemakers use vegetable charcoal for base wine color removal. Treatments with charcoal always diminish the Pinot noir base wine foamability.[77,114,115] It has been shown that 40 g/hL charcoal, used to remove color from Pinot noir base wines, was required for sufficient color removal.[114] The amount of charcoal needed to treat base wines will depend on the type of charcoal used, the wine chemical composition, and timing of addition. Charcoal contains a large quantity of air, and oxidation can occur from charcoal use due to the reduced protection that can occur when the protective phenolic compounds have been removed.[101] Wine oxidation can be reduced and prevented if the charcoal is rapidly and meticulously removed.[101] As with all fining agents, winery trials using different types of charcoal to determine the final type and quantity of charcoal addition are recommended.

A logarithmic relationship was found between the pink color and wine protein content. Foamability decreased by 54% with charcoal addition, and protein content decreased by 20%, suggesting that proteins in Pinot noir base wines are not solely responsible for foam quality. Nicolini et al.[115] found that a smaller amount of active carbon (20 mg/L) added during fermentation to still white wines produced from Chardonnay and Pinot gris did not negatively affect wine color or aroma. Differences in the grape color, charcoal product, analysis method, grape variety, vintage, and ripeness parameters (pH, TA, sugar level, phenolic composition) could all contribute to the difference in results. Some considerations that should be given to base wine charcoal additions include the timing of addition (must or base wine), the grape variety, and whether during alcoholic fermentation or to the blend before bottling. Additionally, it was not established whether the color from some red grapes would diminish during bottle fermentation and/or lees aging because phenolics are absorbed by yeast cells, with tannins being absorbed before anthocyanins.[112] This could mean charcoal addition to base wine is unnecessary for some varieties, especially as carbon used to remove color has been shown to be detrimental to wine foaming ability.[114]

Studies into the impact of specific grape (endogenous and exogenous) phenolics on foaming, phenolic characterization of different grape varieties, and their foaming ability, along with products capable of removing anthocyanins without removing beneficial proteins, could be areas of future study.[114] Occasionally carbon can also be used to reduce base wine off-flavors (mushroomy/moldy/earthy odors), but the carbon used for color removal and that used for off-flavor treatments have different characteristics. Not all forms of charcoal can absorb aroma compounds and polyphenols.

New fining agents include yeast protein extracts for clarification and stabilization including phenolic removal but are not yet available for trials on sparkling base wines.[116] PVPP is a high molecular weight fining agent made of cross-linked polypyrrolidone and attracts phenolic compounds by adsorption.[99] It is used to decrease bitterness in wine and oxidative browning in white wines. Potassium caseinate, either alone or in combination with other fining agents (gelatin or bentonite), was studied using Parellada juice for cava wine production. Juice filtration was found to be the most effective form of clarification, but potassium caseinate had less influence on aroma compounds and removed more phenolic compounds than other fining agents.[113] More recently, chitine derivatives have been described as interacting with some polyphenols and transition metals such as iron and copper so they could act as a preservative in regard to the wine oxidation process.[117,118]

Filtration. After cold stabilization and fining (if required), the turbidity of the wine is generally too high for bottling or secondary in-bottle fermentation so it is necessary to filter it (except for some rare wines vinified/produced and/or matured in barrels). Filtration is important for the brilliance of white wines, but results show that it modifies the turbidity of the sparkling wine. Additionally, foam formation depends on the type of filtration the wine has been subjected to.[48] Different foaming behavior has been reported in sparkling wine after different types of filtration.[119] Two base wines were laboratory filtered (0.2, 0.45, 0.65, and 3 μm and unfiltered), and it was found that foaming substantially decreased with filtering, no doubt due to removal of compounds required for foaming. The 0.2 μm filtered wine had very poor foam, and 0.45−3 μm range results were less clear, but the 0.45 μm filtered wine had the least foam collapse and best collar stability. It has been demonstrated that the smaller the filter pore size, the lower the foaming properties.[48] These differences are due to a different rate of film rupture. Foam expansion (E) is defined as the ratio of foam volume on liquid volume under standard conditions. During foam formation, the films are still thick and are drained mainly by gravity. Assuming that the nucleation is constant, the difference of slopes (during foam formation) depends on filtration.[48] These different coalescence rates occur because during foam formation, bubbles trap substances such as proteins to stabilize their interfaces.[120,121] If these components are lacking, the films are not stable and the surface tension is high, so coalescence takes place more easily.[48,122]

A comparison of diatomaceous earth (DE) filtration to cross-flow filtration in the food and drink industry found that DE filtering requires a low skill level and low maintenance and is cost-effective, but it is a risk to workers due to dust exposure from fine diatomaceous earth.[123] Apart from storage space for the DE filter and earth, consideration must be made for the spent cake disposal. Cross-flow filtration has a cost implication. It has been suggested that wine flavor and aroma can be lost in wines filtered by a cross-flow system.[123] However, a recent study in California using red and white still wines found minimal sensory differences between cross-filtered and unfiltered white wines.[124] Yet the red unfiltered wine changed after 2 months of post-filtration. A study of three membranes for cross-flow membrane filtration found that 0.1 μm was the

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

optimum cut-off point for white Riesling wines.[125] Filtering base wines to such a low level will most likely negatively affect foaming due to removal of foam-active compounds such as proteins. A review of cross-flow microfiltration in enology includes wine composition, membrane fouling, and membrane characteristics.[126] However, the effect of cross-flow filtration on sparkling wine foam, flavor, and volatile aromas remains unclear. Lenticular filtration is a relatively recent innovation rapidly replacing DE filtration in Champagne. It has no moving parts and fewer health hazards for workers than DE due to lack of dust inhalation risk and fewer disposal issues. These filters have large internal surfaces capable of retaining considerable volumes of turbid liquid (up to 3 L/m^2).[127] A comparative study using the same sparkling base wine filtered using different filtration methods would increase our knowledge and understanding of how the filtration systems affect sparkling wine volatile aroma compounds, foaming, and flavor.

BOTTLING AND *TIRAGE* (BOTTLING FOR BOTTLE FERMENTATION)

After fermentation, the sugar level at bottling affects the bottle pressure, especially with the more permeable crown caps available to producers.[128] An amount of 22−24 g/L sugar is used in the *tirage*, although in commercial wineries it may be 22−23 g/L to avoid excess pressure that can be high if the CO_2 loss is low from a crown cap. Depending on the crown cap permeability, the loss or transfer of CO_2 from inside the bottle to the outside can be from 0.12 to 0.68 mL/day. This CO_2 permeability is correlated with the O_2 intake.[129,130] Crown caps have been designed with seals with a range of permeability related to the desired O_2 intake depending on the quality objectives requested by the winemakers; that is, if the *cuvée* is to have long lees aging, the winemaker will choose a "closed to oxygen" crown cap to avoid oxidation during aging of the wine in the cellar. With the current crown caps on the market, the scale of O_2 intake ranges from 500 ppb to >3000 ppb (accumulated oxygen over 2 years).

All sparkling wines, but particularly rosé wines, are photosensitive and suffer from degradation over time on shelves, resulting in color, flavor, and aroma changes. Several studies have investigated the role of bottle color in wine quality.[131−133] Low-density polyethylene films (LDPE) have been found to protect wines for 60.4% longer than bottles without photoprotection, increasing the wine's shelf life from 6 to 12 months.[131] During storage Chardonnay still wine has been shown to be affected by temperature and light. The order of protection reported is Flint < Arctic Blue < French Green and Antique Green with low-wavelength visible, ultraviolet light being primarily responsible for the color changes.[132] Bottle weight was found to have only a minor impact on rosé sparkling wine color development.[133] These results have implications for producers of bottle-fermented sparkling wine when choosing colored bottles for wines, especially rosé sparkling wines, when color, flavor, and aroma retention is required for quality wine.

Tirage. *Tirage* ingredients are a closely guarded secret in many wineries, but the *tirage* recipe from two studies were *S. cerevisae* var. *bayanus* yeast (0.30 g/L) with sucrose (23 g/L) and bentonite (0.10 g/L) as a riddling aid.[96,134] This level of bentonite addition (at 0.10 g/L) is not reflective of all commercial wineries because if a winery uses bentonite as a riddling aid, it is more likely to be between 0.01 and 0.04 g/L.[34,35] Nutrient additions such as diammonium phosphate (DAP) and/or thiamin can be made along with tannin to prevent reductive notes and provide structure to sparkling wine while increasing antioxidant ability of the wine.[135] Other studies have not included *tirage* or *dosage* ingredients in their experimental design, making comparisons of chemical analysis results difficult.[136,137] The CIVC has demonstrated that the initial oxygen level at the *tirage* stage is not a limiting factor for yeast growth and fermentation kinetics. However, the initial CO_2 level in the mixing tank can be problematic for the normal development of the cells during *prise de mousse* (secondary fermentation in bottle).[139,140] A study of the influence of the method of starter culture preparation and level of inoculation with viable yeast assessed the kinetics of yeast growth and sugar utilization in *tirage* found that starter cultures prepared aerobically (in juice or wine) started fermentations that finished at similar times.[141] At similar levels of inoculation, the anaerobically prepared culture resulted in fermentations being completed 8−10 h earlier, due to the short period of exponential growth and earlier onset of linear growth, where 65−90% of the total sugar is utilized. Consideration must be given to alcohol level prior to sugar addition to ensure the required bottle pressure at the end of secondary fermentation is reached.[135] Researchers used a stable carbon isotope method to detect sugar additions in sparkling wines from Chile, Australia, Brazil, the United States, and Europe (France, Germany, Portugal, and Spain).[43] They identified sugar beet as being used for secondary fermentation in European and Chilean wines as opposed to sugar cane in Brazilian and Argentinian sparkling wines. There is unikely to be any effect on wine flavor or volatile aroma compounds from these two forms of sugar (see Chaptalization).

Winemakers generally use active dried yeast for bottle fermentation, and many suitable strains are available on the market. The direct yeast preparation for *tirage* avoids the risk of contamination compared to a multiplication procedure from one initial batch of yeast. Yeast flocculation ability is an important consideration to facilitate sediment removal at disgorging. This explains why some companies have developed "agglomerated yeast" to avoid riddling agents and to facilitate the riddling step.[142,143] However, the use of this particular yeast is decreasing due to some negative organoleptic effects on sparkling wine generated by some agglomerated yeast strains.[144]

Some researchers blend bottles of sparkling wines to allow for bottle variation prior to volatile aroma analysis, whereas others use two to three separate bottles for replication without opening and blending them.[137,145,146] Standardizing representative bottle numbers (i.e., three to five) to reduce bottle variation factors in addition to reporting *tirage* and *dosage* ingredients would improve direct comparisons of wines, research results, their treatments, and other factors associated with quality sparkling wines.

RIDDLING AIDS/ADJUVANTS

Bentonite. Bentonite not only is used as a fining agent for still wines (see Fining) but is also the most frequently used riddling agent for bottle fermentation. This clay efficiently removes proteins from wine due to the cation exchange capacity of the bentonite (a negatively charged adsorbent that at wine pH binds the positively charged grape proteins).[108] Calcium bentonite produces more compact lees than sodium bentonite and so is the preferred riddling agent for wineries that choose to use it in their Champagne sparkling wines.[99] A

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

study carried out by Jeandet et al.[146] investigated suspended particles (*voltigeurs*) thought to be bentonite in Champagne wines post-riddling. The particles were larger than bentonite, not protein related, but due to the concentration of aluminum and silicon concentration were found to be of a similar atomic composition to bentonite used in the *tirage liqueur*; however, it remains unclear why these particles did not settle during *remuage*. The use of bentonite as a riddling aid was investigated in cava monovarietal sparkling wines.[147] It decreased foaming height and stability in Chardonnay, Macabeo/Viura, and Xarel.lo. This was because bentonite removed favorable foaming proteins in the wine, although no significant differences were reported in Parellada and Pinot noir wines. The protein fraction, F2 and F3, which comprised proteins with molecular weights of 60 kDa (F2) and between 20−30 kDa (F3), were most affected by bentonite treatment, eliminating >80% of total soluble proteins.[147] These results are in agreement with another study that reported an almost complete removal of low molecular weight proteins from Chardonnay wines, illustrating that bentonite effects are different depending upon grape variety and the blend of grape varieties of the bottled sparkling wine.[148,149] A study found that just 3 g/hL of sodium bentonite added to cava sparkling wine (blend of Macabeo/Viura, Parellada, and Xarel.lo) did not greatly affect the volatile aroma compounds.[144] Nevertheless, sensory analysis showed that panelists preferred the wines produced without bentonite, in agreement with Martinez-Rodriguez and Polo.[150] It was found that even an addition of 3 g/hL bentonite reduced the foaming capacity of cava sparkling wines, which affected the visual and sensorial properties of the wine although the grape varieties in the wines were not mentioned.[150] This suggests bentonite affected mouthfeel, flavor, and aroma, possibly due to the change in nitrogen content, ethyl octanoate, and ethyl decanoate concentrations and other smaller volatile aroma compounds.

Bentonite and Alginate. Some other riddling agents can contain a percentage of potassium alginate. This polysaccharide has the ability to form gel in acidic conditions or very stable gels with calcium cation.[150] This enables a rapid formation of film-type sediments allowing quicker riddling. This particular riddling agent is often dedicated to mechanical riddling, and a pure bentonite riddling agent is used for manual riddling.

Immobilized Yeast. Methods for encapsulated yeast in alginate matrix dedicated to the bottle fermentation were patented in the mid-1970s.[151−154] Valade[155] conducted a study into riddling methods and compared (1) classical yeast and hand riddling, (2) classical yeast and mechanical riddling, (3) mechanical riddling and agglomerated yeast, (4) technique using included yeasts, and (5) the "Millispark" cartridge (developed by Micropore in 1993). The author found no difference in the wines, and no negative effect was observed on the sparkling wine flavor quality. More recently, a study compared the use of biocapsules (co-immobilization of filamentous fungi *Pencillium chrysogenum* and *S. cerevisiae* yeast), calcium alginate beads (immobilized *S. cerevisiae* yeast trapped in calcium alginate beads), and free yeast cells with bentonite.[156] Calcium alginate beads completed riddling in 15 s, biocapsules in 2 min, but free yeast with bentonite took several days. Yeast cells with bentonite produced wines with reduced foaming in agreement with other studies.[146] Calcium alginate wines had slightly higher foamability values than those made with biocapsules. This was attributed to the matrix support of the biocapsules formed by fungus hyphae that may have absorbed proteins required for foaming. Several studies have investigated the use of different support casings for immobilized yeasts in the beer and bioethanol industries, and these include clay and poly(potassium acrylate), but their effectiveness and impact on sparkling wine have not been investigated.[157,158]

SECONDARY FERMENTATION

Yeast chosen for secondary fermentation can sometimes be the same as the first fermentation (depending on wine style and the preference of the winemaker). Invariably, yeast is chosen for its ability to ferment wines high in acid, with low pH and possessing a high ethanol tolerance. *S. cerevisiae* strains able to carry out secondary fermentation in bottle were isolated from spontaneously fermenting Macabeo/Viura, Xarel.lo, and Parellada musts in El Penedes, Spain.[159] The use of non-*Saccharomyces* yeast is becoming more common in winemaking, but less so for secondary fermentation in bottle. There is a lack of published research regarding their use in sparkling winemaking, possibly due to an expected increase in glycerol, which could affect viscosity (that can affect foaming), mouthfeel, and wine flavor.[160] The effect of conventional versus non-conventional selected wild yeast for secondary fermentation was investigated with isolated yeasts from Sicilian Malvasia delle Lipari wine.[161] The yeasts produced sparkling wine with different aroma profiles easily distinguished in a triangle test. Further studies using wild yeast are likely to be a focus of future research, particularly with alternative varieties.

The kinetics of a second fermentation has been monitored using Attenuated Total Reflectance−Fourier Transform Infrared (ATR-FTIR) microspectroscopy to observe the degradation of lipids, proteins, and polysaccharides in Chardonnay base wine.[162] These authors suggested the technique could be used to select yeast strains according to their autolytic capacity, but wineries are unlikely to have this technology. The transcriptome profiling of secondary fermentation included the expression of genes involved in respiratory metabolism, oxidative stress response, autophagy, and peroxisomal function consistent with ethanol being the main environmental factor influencing transcriptional responses to winemaking conditions.[163] The majority of genes down-regulated during secondary fermentation are related to cell growth, linked to the biosynthesis of nucleic acids and proteins, and gene expression.[163] The study found that low pH or CO_2 pressure was not a relevant constraint for the adaptation of wine yeast cells as expected. However, phenolic compounds suppress yeast metabolism during the secondary fermentation in the bottle, which can cause gushing problems for sparkling red, rosé, and white wines.[164] The lower the temperature of a solution, that is, after secondary fermentation, the higher the gas solubility. After secondary fermentation, a standard 75 cL Champagne bottle has close to 9 g of dissolved CO_2 molecules.[72]

AGING ON YEAST LEES

The lees present in still wine during aging are composed of tartaric acid salts, organic residues, and cells of various species of yeasts and bacteria. In contrast, sparkling wine lees are mainly composed of cells from a single species of yeast, along with the technological co-adjuvants, which help to flocculate and eliminate the yeast lees at the end of aging. The aging of sparkling wine in the bottle on yeast lees is generally longer than still wine aging, and yeast autolysis occurs under pressure

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

commonly at 6 standard atmospheres (atm). Yeast autolysis is considered a lytic event. It is an irreversible process catalyzed by yeast intracellular enzymes. Autolysis generally takes place at the end of the stationary phase of growth and is usually associated with cell death. The scientific basis of yeast autolysis has been the subject of numerous reviews and is not the subject of this paper.[165−168]

Natural autolysis takes time. This is especially true in wines, in which the autolytic conditions from pH 3 to 4, aging temperature of 15°C, and presence of ethanol (12% v/v) are not the ideal conditions of 45°C at pH 5.[168] In sparkling wines, yeast autolysis does not begin until 2−4 months after the completion of secondary fermentation.[165,169] Yeast autolysis can be promoted by using a mixture of "killer" and sensitive yeast for the secondary fermentation. In these conditions, the sensitive yeast cells rapidly die in the presence of the killer strains.[169]

Hydrolytic enzymes play a major role in autolysis. Proteases are the most extensively studied of all the enzymes involved in autolysis. In sparkling wines, proteolytic activity decreases during active bottle fermentation and in the following months, but after 9 months of fermentation and aging, it gradually increases.[170] Leroy et al.[171] reported that proteolytic activity during Champagne aging may also depend on the yeast strain used.

The yeast cell wall is degraded during autolysis, but few studies have investigated the enzymes involved in this process during wine production. In still wines aged on lees, it has been shown that glucanases are involved in yeast cell wall degradation.[172,173] Cell wall degradation during autolysis results in the release of both amino acids and macromolecules, suggesting that both proteolytic and polysaccharides are involved in the degradation of enzymes.[176] However, in sparkling wine conditions, these activities have not been studied. A recent study investigated the evolution of polysaccharides and their molecular weights during sparkling winemaking.[96] The highest amount of mannoproteins and polysaccahrides with high concentrations of arabinose and galactose with a shift to low molecular weights was reported after 6 months of lees aging, which could positively effect foaming.

Recently, it was reported that the addition of enzyme preparation rich in β-glucanase increases aging characteristic of sparkling wine and would also enhance the antioxidant properties of sparkling wine.[174,175] Indeed, addition of exogenous β-glucanases promotes release of yeast components in sparkling wine during aging.[176] The optimal temperature for proteolysis in the Champenoise method has been reported to be between 10 and 12°C.[114] Another factor that influences yeast autolysis is the yeast strain. One study suggested that yeast strains with a high autolytic capacity would produce better quality sparkling wine than yeasts with a low autolytic capacity.[178] They also suggested that autolytic capacity and foaming analysis should be used for selecting yeasts for sparkling wine production. The importance of the autolytic capacity of yeast strains for sparkling wine quality was confirmed by Nunez et al.[179] A mutant strain with accelerated autolysis was used to conduct the secondary fermentation. The resulting wine had better foaming properties than that produced with the control strain. The aging period was also reduced from 9 to 6 months with this mutant, potentially decreasing production costs.

The use of high-pressure homogenization (HPH) to accelerate yeast autolysis in sparkling wines in Franciacorta, Italy, was investigated. Results showed that HPH-treated yeast strains (except L951) significantly modified the ester profile with lower medium- and long-chain fatty acid concentrations compared to wines without HPH treatment.[138] HPH reduced aging time for most yeast strains without enzyme addition. Its role in reducing medium- and long-chain fatty acids could be utilized in the future to reduce high levels of medium-chain fatty acids to prevent stuck MLF.[59] Although the volatile aroma profile of sparkling wine is dependent upon the kinetics of volatile retention and release by yeast lees during aging, further research is needed to study the effects of HPH on sensory attributes of sparkling wine and foaming ability.[76]

YEAST AUTOLYSIS COMPOUNDS AND THEIR IMPACT ON SPARKLING WINE QUALITY

The autolysis of yeast during aging results in the release of various compounds that modify the physical and organoleptic properties of sparkling wine.

Changes in the Nitrogen Compounds Present at Different Stages in the Traditional Method. Nitrogen release is thought to reflect the autolytic activity of the yeast-proteolytic activity in particular. Yeast autolysis does not begin until 3−4 months after the end of the secondary fermentation. The total amino acid concentration increases before the increase in free amino acid concentration. Thus, peptides are released into the medium and then broken down into amino acids. The change in the various nitrogen fractions during bottle-fermented sparkling wine aging has been studied.[180] Between 3 and 9 months after addition of the *tirage* solution, no change in free amino acid concentration had been observed, regardless of the grape variety used. Free amino acid concentration increased after 9 months, indicating the start of autolysis, and these results have been confirmed.[179] Peptide content fluctuates, peaking after 12−15 months of aging on the lees and decreasing thereafter. This behavior may reflect an initial release of peptides that are subsequently broken down. The amount of peptides released by yeast autolysis during sparkling wine aging is variable and depends on grape variety and aging time.[181] The nature of the peptides released also changes with aging; the length of the peptides released decreased with increased aging time.[182,183]

The amino acid composition of the peptides present in sparkling wines has been investigated.[180−184] The peptides mostly originate from the breakdown of yeast proteins rather than grape juice proteins. An increase in protein and polypeptide levels during the first 3 months, followed by a decrease attributed to protease activity, has been reported.[182] Protein and peptide contents then increased again after 6 months. Amino acid enrichment of the medium may improve the aromatic potential of sparkling wine, as amino acids are the precursors of aroma compounds. Aroma compounds may be generated by the deamination or decarboxylation of amino acid.[165] The levels of one lactone compound, 3-hydroxy-4, 5-dimethyl-2(5*H*)-furanone, also known as sotolon (green nut, curry odor), gradually increase during the aging of sparkling wine. Pham et al.[185] showed that sotolon is generated from threonine, which is transformed into α-ketobutyric acid that reacts with acetaldehyde. Vitispirane, a norisoprene-derived compound imparting eucalyptus aromas, is synthesized from methionine and has been detected in aged cava wine.[186]

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

The characteristics of foam are an extremely important property of sparkling wine that is usually measured for foam height, foam area, and foam collar.[179] Moreno-Arribas et al.[187] suggested that the hydrophobicity of peptides might account for the foaming properties of sparkling wine. A few years later it was found that foam characteristics were positively correlated with the concentrations of most free amino acids and proteins, confirming the results of Malvy et al.[183,188] However, no relationship was found between foam characteristics and the concentration of wine peptides.

Polymers. Glucanases and proteases release polysaccharides from the yeast cell wall during autolysis in sparkling wines. These macromolecules contain mainly glucose (74%) and mannose (26%). Polysaccharide concentrations in wines vary. An increase in polysaccharide content from 366 mg/L in base wine to 602 mg/L after 9 months of aging has been reported.[189] The effect of colloids (macromolecules) on foam quality has also been investigated.[190] Neutral polysaccharides are important for foam quality due to their highly significant, positive effect on foam stability.[187] A recent study investigated the impact of polysaccharides from Spanish varieties (Verdejo, Macabeo/Viura, Malvasía, Albarín, Godello, Prieto Picudo, Tempranillo, and Garnacha) on foaming properties.[184] Polysaccharides (mannoproteins, polysaccharides rich in arabinose and galactose, homogalacturons, glucans, and rhamnogalacturons type II) did not correlate with foamability [maximum height reached by foam after CO_2 injection (HM) or foam stability height during CO_2 injection (HS)].[184] The model to explain HS in the study was only predicted by polysaccharides rich in arabinose and galactose. However, there were positive correlations between all of the wine polysaccharides and foam stability time [defined as the time that elapsed before bubble collapse and the appearance of liquid after the interruption by CO^2 (TS)], except for rhamnogalacturonans type II. The optimum aging time for obtaining a high-quality, stable foam appears to be 18 months. Foam quality decreases after 18 months, which coincides with an increase in the level of monomeric compounds, such as fructose, that probably arise from the hydrolysis of grape components by yeast enzymes released during autolysis.[55]

Lipids are important components of sparkling wines because they are a major source of flavor compounds and affect foam stability.[191] Changes in the lipid content of sparkling wine have been the focus of several studies. Lipid content increases during the secondary fermentation, and qualitative changes occur during aging in the bottle in contact with the lees.[192,193] The concentration of polar lipids decreases, whereas the concentration of neutral lipids increases (monoglycerides, diglycerides, triglycerides). Conflicting results have been published concerning the influence of lipids on foam. Octanoic and decanoic fatty acids have been found to reduce foam stability, but it was also reported that the addition of a lipid mixture did not affect the foam.[77,194] It has been noted that linolenic and palmitoleic acid levels were the best indicators of foam stability, and the effect of fatty acids on the foaming properties of wine was investigated.[49,195] The C8, C10, and C12 acids had a negative effect on foam quality, whereas ethyl esters of hexanoic, octanoic, and decanoic acids had a positive effect.

RNase is active during autolysis in Champagne, but data on the extent of nucleic acid degradation should be interpreted with caution because organic acids, phenolic compounds, peptides, and other compounds in wine can interfere with the measurement of nucleotides.[171] Monophosphate nucleotides (5′-UMP, 5′-GMP, and 5′-IMP) have unequivocally been identified in Champagne wine aged on lees.[196,197] Nucleotide monophosphate concentration ranged from 50 to 500 μg/L. Recently it was demonstrated that aging on lees leads to an increase in uridine concentration, whereas purines appear as fermentative catabolites, which are derived from nucleosides or ATP degradation.[198] The nucleotides, especially monophosphate nucleotides, are used as flavorings in the food industry, but further studies are required to evaluate their impact on wine flavor.[199]

Volatile Compounds Released during Autolysis. Heavy acyl chain esters have been identified in model and sparkling wines.[177] Terpenic alcohols and higher alcohols are also released during autolysis. Geraniol and α-terpineol, citronellol, and farnesol have all been identified. These compounds are perceived by tasters at low concentrations, from 100 to 300 μg/L. Molnar et al.[177] suggested that farnesol could greatly contribute to the aromatic quality of sparkling wine, and Loyaux et al.[200] suggested that nerolidol makes a similar contribution to Champagne wines. Approximately 10 aldehydes have been identified in sparkling wines.[168] Methyl-3-butanal is the most abundant, accounting for 40% of all aldehydes present, and may be formed through a mechanism involving isoamyl alcohol oxidation. Most of the aldehydes identified are present at levels close to, or greater than, the detection threshold of the human nose for aqueous solutions, but their odor active values in ethanolic solution with CO_2 (sparkling wine) is unknown.

Volatile aroma compounds released during autolysis were characterized in 221 cava wines (classified into four groups according to their aging time), and diethyl succinate was identified as a possible age marker throughout the aging period.[201] Acetates appeared to decrease during aging, whereas diethyl succinate, vitispirane, and 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN) levels increased over time. Hexanol and 2-phenylethanol were also released during autolysis. Compounds such as vitispirane, TDN, and diethyl succinate may be good age markers and can discriminate between young and aged sparkling wines. Similar results have been obtained, and the researchers reported that some high molecular weight acetates and ethyl and isoamyl esters are typical aroma compounds in young cava wines, whereas vitispirane, diethyl succinate, TDN, hexenol, and ethyl acetate are typical aroma compounds in cava wines aged over a prolonged period.[202] The release of these aromas by yeast enzymes acting on glycoside precursors has been identified as a possible mechanism for their formation, with C13-norisoprenoids and vitispirane being derived from glycoside-bound carotenoids and megastigma, respectively.[202]

The concentration of esters has been found to decrease with aging in the presence of lees, especially 5-hydroxymethyl-2-furfural (5-HMF), synthesized from the dehydration of sugar (mainly fructose) and formed from the intermediate stage of the Maillard reaction.[203−205] This stage begins with the Amadori/Heyns products leading to sugar fragmentation products, that is, 5-HMF, in aged bottled-fermented sparkling wines.[204−206] 5-HMF has been described as contributing caramel, butter, musty, sharp, animal, and soap aromas to wines.[204,208,209] However, its odor activity threshold in sparkling wine and contribution to aged sparkling wine aroma, flavor, and quality remain to be determined. Fedrizzi et al.[210] found that different lengths of time on lees did not affect sulfur compounds in Chardonnay or Chardonnay/Pinot noir sparkling wines, but ethyl pyroglutamate was found to be

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

much higher in lees aged wines than still table wines aged on lees, which correlated with aging. Still table wines can age on lees in stainless steel tanks or oak barrels, depending on wine style and variety, but bottled-fermented sparkling wines age on lees that are in the bottle from secondary fermentation.

Benzenemethanethiol, 2-furanmethanethiol, and ethyl 3-mercaptopropionate were found in concentrations higher than their perception thresholds in aged wines, suggesting an important role in the aroma of aged Champagne wines.[211] In the study 3-mercaptohexan-1-ol (3MH) in aged Champagne wines was 4−10 times its perception threshold, which can contribute to the fruity aroma of Champagne wine. Differences in the phenolic concentration of various sparkling wine grape varieties have been reported.[211] However, lees aging did not significantly affect phenolic composition; rather, viticultural effects, vintage variation, and grape variety are responsible for phenolic differences in wines.

RIDDLING/*REMUAGE*

Prior to riddling, "Le Coup de Poigné" or "Poignettage" was used in Champagne but is less common today.[207] The process involves taking the bottle and shaking it to stir up yeast lees and then placing it on its side so that lees are dispersed over 80 cm^2.[207] This practice may break apart tartaric crystals if cold stabilization was not carried out on the base wine and could possibly assist with loosening yeast "streaks" to consolidate lees sediment.

Lees aging in bottle can be from 9 months to several years, depending on the regulations of the wine region and the wine style, and is followed by *remuage* (riddling) to move sediment to the neck of the bottle.[176] The gradual and controlled turning of the slanted and inverted bottles brings the yeast and adjuvants (bentonite or bentonite/alginate) together.[146] Riddling time has been reduced to 3−4 days with free yeasts and to 2 days with agglomerated yeasts, using automated riddling machines with 504 bottles in each cage.[146] The method of riddling does not affect O_2 intake. A recent promising innovation in sparkling wine technology has been developed.[212] Researchers attached to yeast cells magnetic iron oxide maghemite (γ-Fe_2O_3) that did not penetrate the yeast cell wall. These magnetized yeasts increased secondary fermentation time, and simplified and accelerated yeast removal from the bottle.[212] The iron oxide nanoparticles are considered nontoxic and are approved by the U.S. Food and Drug Administration (FDA) for in vivo medical applications and did not exceed the permissible iron limit in European wine regulations.[212] However, the effect on sparkling wine quality as well as yeast multiplication, foaming, oxidative potential, and long-term lees aging is currently unclear. This new magnetized yeast removal method could have a significant impact on production costs by removing the need for riddling, gyropalette equipment, and freezing bottleneck in glycol, decreasing riddling time and production costs (especially equipment and energy costs) of bottle-fermented wine production.

DISGORGING/*DÉGORGEMENT*

Disgorging is the removal of the yeast sediment and adjuvants from the bottle. It is currently performed by inserting the neck of the bottle into a glycol or calcium chloride solution, which freezes (−25°C) the yeast sediment in the *bidule* (a small plastic cap that fits inside the crown cap to catch yeast sediment).[76] Bottles are then picked up and quickly placed neck up; the crown cap is removed, and pressure ejects the *bidule* along with the iced sediment.[76] Marks and Morris investigated the use of ascorbic acid and SO_2 additions at disgorging on *V. vinifera* Chardonnay and Riesling sparkling wines and four sparkling wines made from hybrid cultivars (Cayuga white, Vidal, Chancellor, and Chardonnel) in Arkansas (USA). The aim was to assess the efficiency of ascorbic acid, SO_2, and a combination of the two on the oxidation of sparkling wine post-disgorging after 11 months of lees aging. SO_2 levels declined in all cultivars after the storage period, but there was no added benefit of including ascorbic acid in the *dosage*. Higher acetaldehyde levels were reported in wines after storage with SO_2 only added. Wines made from Cayuga white and Chancellor grape varieties had reduced browning and reduced color intensity when ascorbic acid was added compared to Chardonnay, Riesling, Vidal, and Chardonnel. The results indicated that ascorbic acid could be used in sparkling wine production to prevent oxidation, but only for certain cultivars.[213] Some studies suggest that closure is mainly responsible for the SO_2 decline and post-bottling oxidation.[214−216,218−220] In addition to the closure effect, the presence of the yeast (*sur lattes* bottles) in the traditional method can explain the rapid decrease of SO_2 over time. Some CO_2 is also lost at disgorging, but rapid closing with traditional cork, technical cork, or other closures prevents excessive CO_2 loss. After corking the bottle, dissolved and gaseous CO_2 quickly recovers equilibrium.[72]

"Gushing". Gushing during disgorging has been attributed to a number of factors, specifically tannin from red grape varieties, bottle shaking, ambient temperature during disgorging, insufficient bottle cleaning, cork dust, ultraviolet (UV) lighting in the disgorging area (especially natural sunlight from open doors or through windows on bottles waiting to be disgorged), incomplete riddling, lack of tartaric stabilization, and protein instability.[217,221,222] However, there is a lack of published studies fully investigating the causes in sparkling wine.[221,222] The effect of gushing causes financial loss due to reduction of wine and a decrease of bottling-line speed and efficiency, but its impact on foam, volatile compounds, and flavor in the finished product has not been researched (gushing can generate various levels of O_2 intake before corking.[220] Recent studies focused on beer gushing found that some proteins (hydrophobins and LTP) can be responsible even at very low levels (ppb scale) for beer gushing.[223−225] These particular compounds, the hydrophobic biopolymers of medium MW, are excreted from some fungi (*Fusarium* and other barley contaminants) and remain stable during beer production process. No evidence exists of work being conducted into the link between hydrophobic biopolymers and gushing in sparkling wine. It is likely that some grape contaminants could exhibit the same behavior as that previously described in beer. This would provide further information about "unexplainable gushing" in sparkling wines that lack tartaric crystals, turbidity, MLF in bottle, or riddling issues as suggested by Liger Belair et al.[226,227] The beer foaming gene, *CFG1*, has been isolated from *Saccharomyces pastorianus*, and similar fermentation foaming genes in *S. cerevisiae* are *Awa1p* and *Fpg1p*. These are cell wall mannoproteins, although their contribution, if any, to gushing and effervescence in sparkling wine remains unknown.[228,229]

"Jetting". Oxygen is a major contributor to wine quality; therefore, managing oxygen ingress is of utmost importance during bottle-fermented sparkling wine production.[230] Jetting has been developed to reduce flavor and aroma bottle variability

DOI: 10.1021/jf504268u
J. Agric. Food Chem. 2015, 63, 19−38

from the oxygen in the neck of the bottle at disgorging.[231] The beer industry has used this technology for several decades to avoid air intake (beer is very sensitive to oxidation). Immediately after disgorging when the headspace is 25 mL, there is potentially >7 mg of O_2 per bottle.[232] When the wine is removed, there is potentially >10 mg of O_2 per bottle. Jetting is the insertion of 100 μL of wine into the bottleneck to induce foaming and is being used in some Champagne wine production at bottling.[231] The foam acts as a piston, reducing oxygen ingress in the neck space because the cork is then inserted when the foam is high. Results of a blind test sensory analysis in Champagne found that 31 of 41 panelists preferred the jetted samples, describing them as *fresh* and *fruity*.[230,231]

Liqueur d'Expedition/Dosage. Prior to corking, the *liqueur d'expedition* (*dosage* solution) is inserted into each bottle, and it can give each wine its own unique flavor, for example, ice wine *dosage* in Ontario. The recipe for the *dosage* varies among wineries but can consist of sugar (cane or beet), the oldest sparkling wine in the cellar, oaked/unoaked still Chardonnay wine, wines aged in stainless steel, oak, or/and concrete vessels, with SO_2, citric acid, and very occasionally brandy (now illegal in Champagne), tannins, and/or copper sulfate.[19,76] To date there are no published studies regarding sugar types/sources in *dosage* on sparkling wine quality. *Zero-dosage* is becoming more popular and contains no added sugar. This type of "no-*dosage*" is reserved for special *premium* wines in Champagne. However, it has also recently been used in a scientific study of alternative varieties for sparkling wine. In the study *liqueur d'expedition* was not added to any of the research wines. Each bottle was filled with the same wine to produce Brut Nature wines for the laboratory and sensory analysis.[4] A recent study that used a range of wine styles in the *dosage* solutions found no difference in ethyl ester concentrations in brut sparkling wines (8 g/L residual sugar) by 15 weeks post-disgorging.[232] Interestingly, the *zero-dosage* wines (same wine inserted without sugar) showed an increase in ethyl isovalerate (fruity/minty), which the sugar added wines lacked. The wines with the same wine inserted but with sugar addition (8 g/L) showed slight increased in ethyl butyrate (artificial fruit/candy/strawberry) and ethyl isobutyrate (apple/tropical fruit/citrus). However, the effect on volatile wine compounds when aging under cork post-disgorging or the effect on sensory properties of the wines was not studied. Higher sugar additions may have more of an impact on volatile aroma compounds in sparkling wine than the 8 g/L residual sugar in the trial wines. The contribution of fusel alcohol pathways (anabolic and catabolic) that arise primarily from hexoses in wine fermentation has recently been studied.[233] The rate of sugar hydrolysis has been found to differ between grape varieties. It has been suggested that the natural hydolysis of a 10 g/L sucrose addition to a still wine (pH 3−3.4) devoid of invertase acitivity will take 2.5−5.5 months.[234] The length of time between disgorging and release of sparkling wine for sale is a decision by the wine producer, but the flavor of sparkling wine during the post-disgorging time is known to differ from 1 to 3 months and continuously in bottle thereafter. However, further flavor analysis of sparkling wine aging post-disgorging will clarify the aroma and flavor chemistry occurring in the bottle. It has been demonstrated that disgorging leads to a significant increase in the concentrations of thiols, specifically 2-furanmethanethiol (toasty aroma), benzenemethanethiol (smoky aroma), and ethyl 3-mercaptopropinate (foxy aroma), in two Champagne wines across a range of vintages.[235] Oxygen ingress at disgorging can negatively affect sparkling wine quality, and comprehensive reviews about oxidation mechanisms in wines have already been published.[219,236,237]

SENSORY ANALYSIS OF SPARKLING WINES

There is no internationally accepted or recognized sensory analysis method that has been specifically designed for sparkling wine and no published criteria to evaluate effervescence and foam of sparkling wines.[238] Hedonic scales following panelist training to obtain consensus-based descriptors have been used by visual assessment of foam formation and effervescence as well as questionnaires during tastings, but the method utilized depends on the aims and objectives of the research.[136,238−240] Although serving temperature, bottle opening method, pouring method, room temperature, and lighting are controlled, studies lack attention to glass type, sample order effect on foam and flavor, and the time between opening bottles and then pouring and imbibing.[90,240,242] Sparkling wine descriptors have been generated in studies and used in sparkling wine sensory analysis that includes olfactory intensity, equilibrium, fruity, full body, vegetal, acidity, persistence, floral, varietal, bitterness, freshness, and astringency.[96,243] Foam attributes have included initial foam, foam collar, bubble size, effervescence, and foam and require panelists to be trained in the use of these descriptors.[96,244] A fixed-choice profiling (FCP) method was used whereby each descriptor definition was built from the consesus of the panelists.[245] Initially 64 descriptors were generated, but this was reduced to 19. Wines were poured 5 min before panelists entered the room, so foaming height and stability were not included in the sensory analysis, which are essential to sparkling wine quality. A modified-descriptive analysis method for sparkling wine sensory analysis using calibrated glasses (cm/mm) to measure foam height would help with standardizing a sparkling wine sensory method. Criteria suggestions for consideration include (1) a specific time between opening pouring and tasting the wines or (2) immediate assessment of each wine by panelists as soon as their sample is poured, (3) set room and bottle temperature, (4) storage guidelines before tasting, (5) standardized bubble and foam classifications including persistence, stability, and collar, (6) agreed visual, aroma, and palate descriptors for sparkling wine styles, and (7) number of times to taste the same wine while minimizing bottle variation by allowing panelists to taste at least three bottles for replication purposes.

The odor activity value (OAV) of an aroma compound is an indication of the importance of a specific compound to the aroma of a wine, calculated as the ratio between the concentration of an individual compound and the perception thereshold described in the literature.[7] Until perception thresholds of volatile aroma compounds are determined in a range of sparkling wines (monovarietal and blends) for each compound, it is difficult to state with any certainty their contribution to sparkling wine aroma profile. For instance, the two 3MH enantiomers, *R* and *S*, have different aromas: *R* is fruitier with a grapefruit aroma, and *S* produces aromas reminiscent of passion fruit, which are likely to contribute differently to sparkling wine aroma profiles.[211] However, although OAVs can provide important information, they do not take into account the interactions between volatile compounds and other wine compounds that can enhance or suppress aromas.[241] It is also likely that CO_2 affects odor detection when compared to the same aroma compound in an aqueous or ethanolic solution.

J. Agric. Food Chem. 2015, 63, 19−38

This review of sparkling wine production has discussed current knowledge and highlighted areas for future research that include grape varieties, *tirage* and *dosage* effects on sparkling aroma and flavor chemical composition, the need for a specific sensory analysis method for sparkling wine, markers associated with sparkling wine quality (especially fermentation byproducts from secondary fermentation), and reducing the time and efficiency of MLF.[62] Future studies are likely to include chemical and sensory analysis related to post-disgorging aging effects on wine flavor and aroma, research related to red and rosé sparkling wines, length of lees aging for *zero-dosage* wines, low-SO_2 wines, SO_2 alternatives for sparkling wines, the effect of using different yeasts for first and secondary fermentations, acceleration of yeast autolysis, reduction of time for MLF, and enzymes involved in yeast autolysis. The mechanism for induction of yeast autolysis remains elusive as are the kinetics of glucanase activity linked to wine quality by its ability to release mannoproteins and the effect on the release of nucleotides, nucleosides, and lipids. If the chemical profile of Chardonnay including acids, genes, and proteins can be identified, then similar varieties with similar traits, and therefore aging characteristics, could be sought in sparkling wine regions. Research regarding phenolic compounds in sparkling wine is likely to focus on different grape varieties to provide information for phenolic management techniques to wine-makers, especially for color stability of rosé and red sparkling wines. Research is likely to focus on "alternative" or "resurrected" varieties for sparkling wines and is likely to include the impact of non-*Saccharomyces* yeast on sparkling wine aroma, flavor, and foaming. Studies that investigate natural plant-based products from vines/grapes/yeast for use in the production process are already underway and likely to continue. The authors are aware of an international sensory analysis method currently being developed with a team of international sensory scientists, specifically for sparkling wine assessment. Although not covered in this review, organic and biodynamic effects on sparkling wine quality, plus the economical, financial, and ecological sustainablility of sparkling wine production practises, are likely to be a focus of future research.

Colorimetric Assay for Heterogeneous-Catalyzed Lipase Activity: Enzyme-Regulated Gold Nanoparticle Aggregation

ABSTRACT: Lipase is a neglected enzyme in the field of gold nanoparticle-based enzyme assays. This paper reports a novel colorimetric probe to rapidly visualize lipase activities by using Tween 20 functioned GNPs (Tween 20-GNPs) as a reporter. The present strategy hence could overcome the limitations caused by the heterogeneous interface in lipase assay. Catalytic hydrolytic cleavage of the ester bond in Tween 20-GNPs by lipase will trigger the rapid aggregation of GNPs at a high salt solution. The color change from red to purple could be used to sense the activity of lipase. The detection limit (3σ) is as low as 2.8×10^{-2} mg/mL. A preliminary enzyme activity screening was carried out for seven commercially purchased lipase samples. It also has been successfully applied to detecting lipase in fermentation broth of *Bacillus subtilis* without any pretreatment.

KEYWORDS: *assays, enzymes, gold nanoparticles, tween 20*

INTRODUCTION

Lipases constitute the most important groups of biocatalysts for biotechnological applications, such as the synthesis of pharmaceuticals, agrochemicals, flavouring compounds, biopolymers, and biodiesel.[1−6] Developing technically simple yet effective assays for real-time lipase activity is of critical importance both for the industrial lipases optimization and for the drug discovery and medical diagnosis of diseases. In traditional lipase engineering, fluorogenic or chromogenic substrates and indicator assays have been used as the main screening tool.[7−9]

Gold nanoparticles (GNPs) have been used for a variety of enzyme assays.[10−17] In particular, GNP-based colorimetric assays have become excellent candidates for in vitro measurements[18] because of simple and rapid measurement, cheap instrumentation, robustness, and potential for high-throughput assay.

In the field of GNP-based enzyme assays, the lipase activity assay is still virgin ground.[19,20] Unlike the bond-cleaving enzymes, such as protease or endonuclease which work in homogeneous aqueous phase, the lipases are one such class of enzymes that catalyze hydrolysis of hydrophobic substrates at the lipid−water interface. The assay for lipase is complicated by difficulties associated with emulsifying the lipid substrates, which often produce signal interference and/or compound−lipid interactions.[21]

Tween 20 (polysorbates 20) is an amphipathic, nonionic surfactant composed of fatty acid esters of polyoxyethylene sorbitan monolaurate, the stability, biocompatibility, and relative nontoxicity of which allow it to be used as emulsifier in a number of scientific and pharmacological applications.[22,23] Although Tween 20 was previously investigated, such as in stabilizing gold nanoparticles,[24−28] and in synthesis nanomaterial,[29,30] as well as in turbidimetric assay of lipolytic enzymes,[31] no work has reported their multifunctional roles in the fabrication of GNP-based probe for lipase activity.

Herein, we developed a GNP-based colorimetric assay, which allows real-time measurement of lipase activity/kinetics. The presented strategy exploits the multifunctional properties of Tween 20 as an amphiphilic stabilizing agent as well as substrate for lipase and hence could overcome the limitations caused by the lipid−water interface in lipase assay. By using Tween 20-modified gold nanoparticles (Tween 20-GNPs) as substrate, the system can easily perform in homogeneous phase like the bond-cleaving enzymes did. It exhibits the possibility of overcoming the limitations of traditional lipase assay caused by lipid−water interface. To our knowledge, this is the first use of Tween 20-GNPs as colorimetric indicators to evaluate lipase activity. We believe that the research of screening lipase activity would not only broaden the spectrum of GNP-based enzyme assays but also stimulate the development of GNP-based assays for new targets.

Colorimetric lipase activity assay was performed under the following procedures. The lipases with different activities were added to the above Tween 20-GNP solution consisting of PBS (20 μL, 0.5 M, pH 6.5) and NaCl (50 μL, 2 M). Immediately, the mixture solutions were incubated at 50 °C for 5 min, and the UV−vis spectra were recorded.

For real sample detections, we conducted a preliminary screening using the developed strategy to test the activity of seven commercial purchased lipase samples (BCL, CRL, PPL, RNL, ANL, TLL, and PCL). We also evaluated whether Tween 20-GNPs would respond to lipase in living bacterial cells using inactivated and activated fermentation broth of *Bacillus subtilis*.

RESULTS AND DISCUSSION

Scheme 1 describes the sensing mechanism employed in this study. The GNPs were modified by Tween 20. We used Tween 20 here to act not only as the substrate for lipase but also as the stabilizer for GNPs. Tween 20-GNPs are stable at high salt concentrations (e.g., 0.1 M NaCl) because of the electrostatic and steric stabilization provided by tethered negatively charged Tween 20 polymers. The hydrolytic cleavage of the ester bond in Tween 20 catalyzed by lipase will trigger the rapid aggregation of GNPs at the same salt solution. The color change from red to purple associated with this event can therefore be used to sense the activity of the lipase.

The UV−vis spectroscopy was monitored to reveal the functional roles of Tween 20 in the assay. As shown in Figure 1, GNPs in aqueous solution were monodispersed (Eppendorf

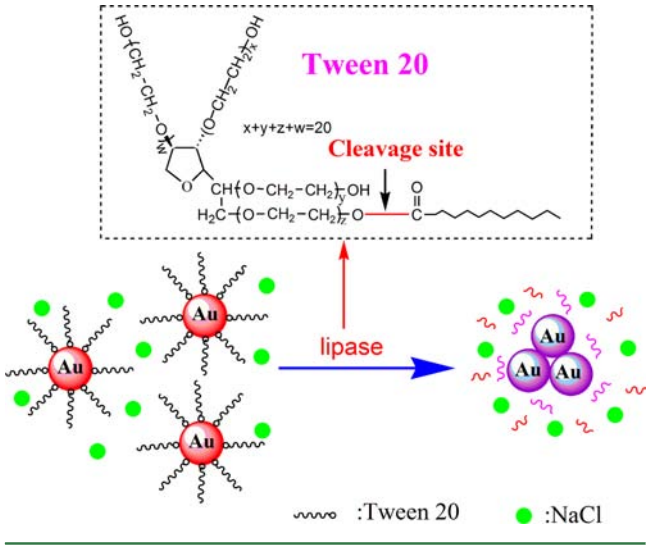
Scheme 1. Schematic Illustration of the Mechanism of Sensing the Activtiy of Lipase Based on Tween 20-GNPs



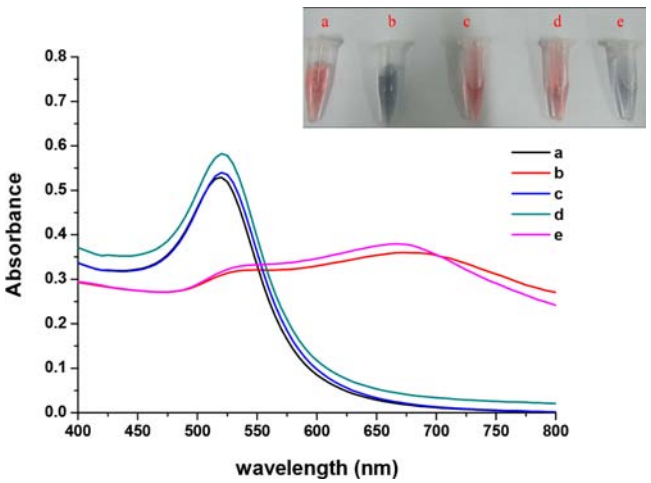


Figure 1. UV−vis spectra of solutions of (a) GNPs in aqueous solution, (b) GNPs, in 0.1 M NaCl, (c) Tween 20-GNPs, 0.1 M NaCl, (d) Tween 20-GNPs, 0.1 M NaCl, and 2 mg inactivated lipase, and (e) Tween 20-GNPs, 0.1 M NaCl, and 2 mg lipase. The phosphate in solution is at pH 6.5, and the incubation time is 5 min. (Inset) Corresponding visual color of these solutions.

tube a, curve a), and they aggregated in 0.1 M NaCl (Eppendorf tube b, curve b). However, for Tween 20-GNP solution, the position of the SPR maxima exhibited almost no change, indicating that the steric repulsion of Tween 20 can resist high salt strength (Eppendorf tube c, curve c). This result is consistent with previous reports that Tween 20 can be adsorbed onto the surface of GNPs to shield the citrate ions and prevent the aggregation of GNPs.[32−35] The addition of lipase can result in the aggregation of Tween 20-GNPs due to the catalysis of hydrolytic Tween 20 on the surface of GNPs (Eppendorf tube e, curve e). In the case of inactivated lipase, which was deactivated in high temperature (100 °C), there is no color change and no peak red shift (Eppendorf tube, curve d), demonstrating that the lipase catalysis cleavage of the ester bond in Tween 20 causes the GNP aggregation. The aggregation of the Tween 20-GNPs was also confirmed by TEM (Supporting Information, Figure S1).

Effects of salt concentration, Tween 20 concentration, GNP size, pH, and reaction temperature were investigated. The ratio value (E_{650}/E_{520}) of the extinction is used to quantify the aggregation process or color change. The optimal detection conditions for salt concentration, Tween 20 concentration, GNP size, pH, and reaction temperature were 0.1 M NaCl, 82.28 μM, 13 nm, 6.5, and 50 °C, respectively, for sensitive and rapid detection (Supporting Information, Figures S2 and S3). This result is also confirmed by zeta-potential experiments. The zeta potentials of Tween 20-GNP solution without NaCl were found to be −9.86 ± 0.50 and −3.52 ± 0.65 mV with 0.1 M NaCl, indicating that the electrostatic repulsion between Tween 20-GNPs was screened by NaCl.

Kinetic studies of the color change in the presence of various amounts of lipase were carried out (Supporting Information, Figure S4). It was found that the rate of color change was directly related to the amount of lipase used in the assay; faster color changes were observed when more lipase was used. The red shift was found to gradually increase on the lipase concentration (Figure 2A) and the rate of color change was directly related to the amount of lipase used in the assay. According to the calibration curve (Figure 2B), the response to the increasing amounts of lipase was linear in the range of from 0.15 to 1.80 mg/mL (R^2 = 0.9934). The detection limit (3σ) of this assay is as low as 2.8 × 10^{-2} mg/mL. One important feature of this assay is that the color change is sensitive and rapid. A comparison was made between our system and

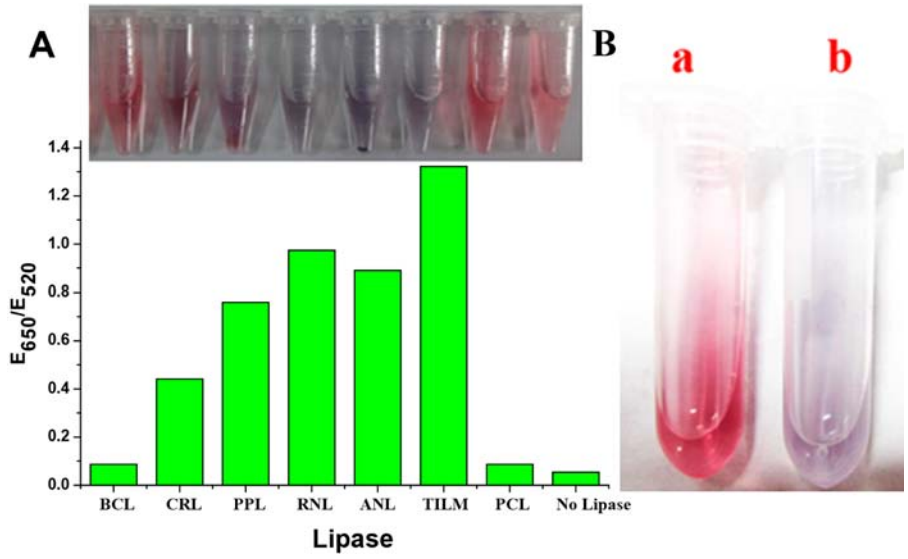

Figure 3. (A) Plot of E_{650}/E_{520} intensity of Tween 20-GNPs upon the addition of a fixed concentration (1 mg/mL) of commercial lipase samples, respectively, and within a interval of 10 min. (Inset) Corresponding visual color. (B) Visual color of Tween 20-AuNP solutions upon adding (a) inactivated and (b) activated fermentation broth of *Bacillus subtilis* after 10 min of incubation.

turbidimetric assay for lipase activity using Tween 20 as substrate.[31] The results showed that at the same lipase concentration our system is 1000 times more sensitive than the turbidimetric assay. The time to reach maximum color change was just 5 min in our system, whereas the turbidimetric assays required around 30 min (Supporting Information, Figure S5).

A preliminary screening was carried out using this system to test the activities of seven commercial purchased lipase samples (BCL, CRL, PPL, RNL, ANL, TLL, and PCL). The color and the E_{650}/E_{520} value of Tween 20-GNP solution in the presence of a fixed concentration (1 mg/mL) of lipase samples were monitored, respectively, within a fixed time interval. As shown in Figure 3A, Tween 20-GNPs incubated with TLL, ANL, and RNL led to significant color changes, whereas with PCL and BCL no color changes were observed. Moreover, the different color changes (violet blue in TLL, ANL, and RNL and reddish purple in CRL and PPL) were attributed to the different lipase activities. With UV−vis spectroscopy quantitative detection, we conclude that the lipase activity decreases in the following order: TLL > RNL > ANL > PPL > CRL > BCL > PCL. This order is consistent with the results detected with a pH-stat method (Supporting Information, Table S1), demonstrating the possibility that the colorimetric assay protocol can be used as an alternative to conventional methods for a sensitive assay of lipase activity.

The assay was also applied to fermentation broth of *B. subtilis*. The supernatant of the crude sample without any pretreatment was incubated with Tween 20-GNPs. A pronounced color change from red to blue was observed (Figure 3B-b), but inactivated sample solution, which was deactivated by boiling, did not lead to any color change (Figure 3B-a). This shows that the Tween 20-GNPs system provides a particularly useful probing approach for real samples that usually have significant background activities, which might cause false-positive signals during the measurements. The new Tween 20-GNP colorimetric assay has potential in the routine quantification of lipase in biochemistry industrial and medical applications.

In conclusion, we have developed a new colorimetric assay for screening lipase activity; it does not require specific instrumentation or complicated experimental steps. Furthermore, as opposed to a fluorogenic or chromogenic derivative of the substrate, it is desirable to carry out the assay without emulsification.

Effect of 5-*n*-Alkylresorcinol Extracts from Durum Wheat Whole Grain on the Growth of Fusarium Head Blight (FHB) Causal Agents

Roberto Ciccoritti, Marina Pasquini, Daniela Sgrulletta, and Francesca Nocente*

Consiglio per la Ricerca e la sperimentazione in Agricoltura, Unità di Ricerca per la Valorizzazione Qualitativa dei Cereali (CRA-QCE), Via Cassia 176, 00191 Roma, Italy

ABSTRACT: In an approach toward the identification of ecofriendly compounds for fusarium head blight biocontrol, the in vitro antifungal activity of 5-*n*-alkylresorcinol (AR) extracts, obtained from durum wheat intact kernels, was tested. In comparison with ethyl acetate and acetone extracts containing AR, total inhibition of *Fusarium graminearum* spore germination was observed with cyclohexane extract, which also exhibited a significant fungistatic activity against *F. graminearum*, *Fusarium culmorum*, *Fusarium avenaceum*, and *Fusarium poae*. Additionally, the study of the influence of such variables as predrying of seeds and durum wheat genotype on AR cyclohexane extract properties allowed the association of its highest antifungal activity with the AR homologue composition and, in particular, with the presence of a higher C21:0/C23:0 ratio. The interesting finding of this study suggests a potential application of the AR homologues in crop protection systems and could be an important step toward the development of commercial formulations suitable to the prevention of fungal diseases.

KEYWORDS: *5-n-alkylresorcinols, antifungal activity, AR extraction, AR homologue composition, durum wheat*

INTRODUCTION

Fungal diseases are by far the most serious threat to global crop production and cause heavy losses that can result in enormous socioeconomic hardship. Presently, it has been estimated that each year fungal infections destroy at least 125 million tons of the top five food crops (rice, wheat, maize, potatoes, and soybeans), which provide the majority of calories consumed by people. Among fungal diseases, fusarium head blight (FHB) is considered the most serious disease of common and durum wheat and other small-grain cereals worldwide, resulting in significant quality, safety, and yield reductions. The disease is caused by various filamentous fungi including *Microdochium nivale* and many *Fusarium* species; in Europe *Fusarium graminearum*, *Fusarium culmorum*, *Fusarium avenaceum*, and *Fusarium poae* are predominant.[1,2] Moreover, under favorable environmental conditions, the scabby grain is often contaminated by tricothecene mycotoxins (e.g., deoxynivalenol, T-2, HT-2, and zearalenone), making it unsuitable for human foods or animal feeds.

The control of FHB has relied on the use of resistant varieties and chemical fungicides. As resistant cultivars are very rare, the chemical fungicides have an important role in an integrated FHB control program,[3] but they represent a serious threat leading to disturbed biodiversity, outbreaks of secondary pests, development of resistance in the pathogens, and contamination of the food chain in the ecosystem.[4] In consideration of the environmental and economical implications associated with the use of chemical fungicides, there has been an increased interest in discovering biologically active natural compounds and extracts from higher plants as new classes of pesticides. Plant secondary metabolites, once not considered important compounds, are now thought to mediate chemical defense mechanisms by providing chemical barriers against animal and microbial predators and have enormous potential to inspire and influence modern agrochemical research.[5−8] Among the secondary plant constituents, alkylresorcinols (ARs) and their derivatives are considered to serve as phytoanticipins and allelochemicals, although direct evidence is still lacking.[9] ARs belong to an extensive family of bioactive compounds, referred to as nonisoprenoid phenolic lipids, which occur primarily in plants, fungi, and bacteria.[10] Structurally the 5-*n*-alkylresorcinols of cereals are characterized by two hydroxyl groups, at positions C1 and C3 of the aromatic ring, and a lipophilic alkyl chain at the C5 position. The amphiphilic nature of their structure could be responsible for their ability to interact with biological membranes, nucleic acids, or enzymes[11] and related to their antimicrobial, antiparasitic, antitumor, and antifungal activities.[10−14] In cereal grains, 99% of resorcinolic lipids occur only in an intermediate layer of caryopsis, including the hyaline layer, inner pericarp, and testa and are not detected in other parts of the grain, including endosperm and germ.[15] The localization of ARs at the surface of plant tissues could enhance their protective effect as a chemical barrier to infection; in fact, they are constitutively present in plants, but their biosynthesis may be triggered during seedling stage by fungal infection.[16] Antifungal activity of 5-*n*-alkylresorcinols extracted from rye has been reported against *Aspergillus niger*, *Aspergillus versicolor*, *Penicillium chrysogenum*, *Penicillium roqueforte*, *Rhizoctonia solani*, *Rhizoctonia cerealis*, and *F. culmorum*.[17−19] The resistance of barley seeds to the pathogenic fungi *A. niger* and *P. crysogenum* was attributed to resorcinolic lipids present in the seed epicuticular wax.[20] Alkylresorcinols isolated from etiolated rice seedling showed antifungal activity against spore germination of *Pyricularia oryzae*.[21] The occurrence of 5-*n*-(heptadec-12-enyl) and 5-*n*-pentadecylresorcinols in the peel was considered to be responsible for the resistance of mango fruits to fungal infections

by *Alternaria alternata*.[22,23] The capability of these natural compounds to inhibit fungal growth could be exploited to control plant diseases, avoiding the presence of fungicidal residues.

This work has been carried out with the aim to evaluate the antifungal activity of durum wheat whole grain extracts containing 5-*n*-alkylresorcinols against four species of *Fusarium* (*F. graminearum* Schwabe, *F. culmorum* (W.G. Smith) Sacc, *F. avenaceum* (Fr.) Sacc., and *F. poae* (Peck) Wollenw.) using in vitro assays. To the best of our knowledge this is the first study that examines the inhibitory effect of different alkylresorcinol extracts on the in vitro vegetative growth of four important *Fusarium* fungi. In addition, the possibility of using these extracts in seed treatment to control *Fusarium* diseases has been evaluated. The effects of variability factors such as the wheat genotype used and the seed-drying process on AR content, relative homologue composition, and antifungal activity of the durum wheat extracts are also discussed.

MATERIALS AND METHODS

Chemicals. All organic solvents used for AR extraction and pyridine were purchased from Carlo Erba (Italy). Methyl behenate (C22:0, methyl docosanoate) and 4-hexylresorcinol (4-hexyl-1,3-dihydroxybenzene) were purchased from Sigma-Aldrich (Milan, Italy). Trimethylchlorosilane (TMCS), which was used to prepare the trimethylsilyl ether derivates of AR extracts, was purchased from Restek (Milan, Italy). Standards 5-*n*-pentadecylresorcinol (C15:0), 5-*n*-heptadecylresorcinol (C17:0), 5-*n*-nonadecylresorcinol (C19:0), 5-*n*-heneicosylresorcinol (C21:0), 5-*n*-tricosylresorcinol (C23:0), and 5-*n*-pentacosylresorcinol (C25:0) were purchased from ReseaLife Chem. Science (Burgdorf, Switzerland).

Plant and Fungal Materials. For AR extraction, experimental plant material consisted of seeds of two commercial durum wheat cultivars, Tirex, grown during the crop years 2012 and 2013, and Simeto, grown during 2013. In addition, cv. Iride was used for the seed treatment with wheat extract for FHB protection. Kernels were kept at 4 °C until extraction and analysis.

Four isolates of *F. graminearum* (Fg_QCE2, Fg_QCE3, Fg_QCE5, Fg_QCE11) and of *F. culmorum* (Fc_QCE1, Fc_QCE2, Fc_QCE3, Fc_QCE7) and one isolate of *F. avenaceum* (Fav_QCE8) and of *F. poae* (Fp_QCE3), collected throughout Italy from infected durum wheat seeds from 2009 to 2011, were maintained and used in this study. Each isolate was cultured on potato dextrose agar (PDA) (Formedium, Hunstanton, UK) supplemented with neomycin and streptomycin sulfate (0.3 g L^{-1}) and incubated at 22 °C with a 12 h photoperiod for 7−14 days. The mycelium was then transferred onto fresh PDA plates and placed under near-ultraviolet for 10 days under 12/12 h alternate cycles of light and darkness to favor sporulation. All *Fusarium* isolates were identified on the basis of conidial morphology[24,25] and PCR analysis using species-specific primers for *F. graminearum*,[26] *F. culmorum*,[27] *F. avenaceum*,[27] and *F. poae*.[28]

For the bioassays, conidia or mycelial disks from 7-day-old cultures were used. Conidial concentration was adjusted with the aid of a hemocytometer to a concentration of 1×10^5 conidia/mL.

Extraction of Alkylresorcinols. Three organic solvents (acetone, ethyl acetate, and cyclohexane) were used to extract ARs from intact kernel at a ratio 1:4 (w/v) by continuous mechanical shaking for 24 h at 28 °C temperature. The extraction was repeated one more time with fresh solvent, and the products of the two consecutive extractions were combined. The extracts were filtered through Whatman no. 42 paper and used for gas chromatography−mass spectrometry (GC-MS) analysis and antifungal assays.

A successive test was carried out to increase AR extraction yield. Briefly, kernels of cultivars Tirex and Simeto (from 2013 harvest) were weighed and placed in a hot air oven at 50, 105, and 130 °C for 90 min and at 105 °C for 180 and 300 min. The decrease in moisture amount was evaluated as weight difference before and after heat treatment. Seeds were immediately used for AR extraction with cyclohexane or acetone as described above.

Chemical Analysis by GC−MS. Total AR content and relative homologue composition in wheat extracts were determined by GC-MS analysis, according to Landberg et al.[29] using 200 μg of methyl behenate as internal standard (IS). AR extracts (10 mL) were dried under nitrogen and silylated with a mixture (400 μL) of pyridine and TMCS (9:1 v/v). The mixture was then shaken and heated at 70 °C for 60 min. GC-MS analysis was performed with the gas chromatograph GC Clarus 600 series coupled to a mass spectrometer Clarus 580D (PerkinElmer, Milan, Italy) equipped with a split/splitless injector, an RTX-5MS column (0.25 mm × 30 m, 0.25 μm film thickness, Restek, Milan, Italy), and a quadrupole mass spectrometer (Clarus 580D, PerkinElmer) operating in electronic impact (EI) ionization mode (70 eV). Helium was used as the carrier gas (1 mL min^{-1}). The column temperature was programmed from 250 to 320 °C (hold for 2 min) at a 3.5 °C min^{-1} heating rate and then to 330 °C at a 1.1 °C min^{-1} heating rate. Ion source and detector temperatures were 250 and 350 °C, respectively. The injector temperature was 325 °C. Total ion current (TIC) mode was used to record the positive ion mass spectra of the samples in the range between m/z 40 and 620. AR homologue content was quantified according to the method of Ross et al.,[30] using a fragment ion m/z 268, which is characteristic for 5-*n*-alkylresorcinol homologues.

Antifungal Activity of AR Extracts. Extracts obtained from cv. Tirex (from 2012 harvest) by using acetone, cyclohexane, and ethyl acetate were evaporated to dryness at 60 °C in a rotary evaporator (Buchi R-114, Switzerland) and redissolved in the respective solvent to obtain 1100 μg/mL ARs. PDA plates (60 mm) were prepared, according to the method of Yin et al.,[31] by spreading 500 μL of acetone, ethyl acetate, or cyclohexane extracts from wheat whole grain, respectively, after solidification of medium (10 mL for plate). Media plates spread with 500 μL of solvents served as controls.

The antifungal activity was evaluated by considering the inhibiting effect of the AR extracts both on spore germination and on mycelial growth.

In the first experiment, 4 μL of a conidial suspension (1×10^5 mL^{-1}) of Fg_QCE2 isolate was used to inoculate the central surface of the plates and incubated in the dark at 22 °C. Three replications were prepared for each treatment, and each treatment was replicated twice. The spore germination was evaluated on the basis of the fungal ability to form a colony at 4 days after inoculation, compared with the control. The colony diameter was measured by electronic digital calliper (0−150 mm), and all values were recorded in two directions at right angles to each other; then the colony average diameter was calculated. Data are expressed as percentage growth inhibition in reference to the growth of untreated control.

Control experiments were carried out under similar conditions by using the standard 4-hexylresorcinol (positive control). A concentrated acetone stock solution of 4-hexylresorcinol was made and progressively diluted to obtain a 1 mg/mL solution. From this solution 10, 50, and 100 μL were brought to a volume of 500 μL with acetone and spread on PDA plates (60 mm).

The three extracts were also bioassayed to test their effect on conidial germination of *F. graminearum* using the method of Belding et al.[32] About 100 μL of the three extracts was applied respectively onto glass coverslips and then air-dried to form a film. Acetone, ethyl acetate, cyclohexane, and sterile distilled water were used as negative control. All of the coverslips were inoculated with 2 μL of 1×10^5 spores mL^{-1} of Fg_QCE2 isolate and placed in the lid of an inverted Petri dish filled with 0.95 M NaCl−2% agar, to maintain the relative humidity (RH) at 97.5% at 22 °C, and the coverslips were positioned about 3 mm below the agar surface. Two coverslips per treatment were used. Petri dishes were then incubated for 18 h in the dark at 22 °C. The number of germinated spores was examined by light microscope.

The second assay was carried out to evaluate the fungistatic activity of cyclohexane extract on the mycelial growth of four isolates of *F. graminearum* and *F. culmorum*, respectively, one isolate of *F. avenaceum*, and one isolate of *F. poae*. One 4 mm diameter plug of each isolate growing on PDA was placed in the center of 60 mm PDA plates, prepared as previously described. The plates were incubated at 22 °C in

the dark, and at 4 and 6 days after inoculation the colony diameters were measured and the percentage growth inhibition was calculated. Three replications were prepared for each treatment, and each experiment was replicated twice.

Antifungal Activity Assay of Mixtures of Standard Homologue Chains of ARs. Two mixtures of AR homologue chains were obtained by dissolving different quantities of standard homologues in acetone to have 1100 μg/mL total AR. The objective was to reproduce similar qualitative and quantitative compositions in AR homologue in comparison with the natural extracts isolated from durum wheat whole grain by using cyclohexane and acetone solvents.

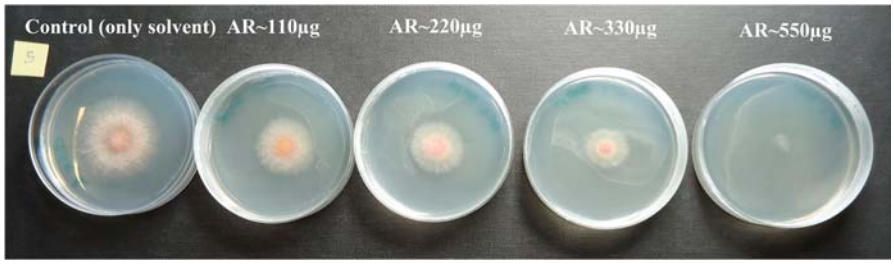

Figure 2. Growth of *F. graminearum* on PDA plates, containing different quantities (from 100 to 500 μL) of cyclohexane AR extracts.

The effect on fungal growth was evaluated by spreading 500 μL of both AR solutions on PDA plates. The center of air-dried plates was inoculated with 4 μL of a conidial suspension (1×10^5 mL^{-1}) of Fg_QCE2 isolate, and after 4 days, the inhibition percentage of mycelial growth was calculated as previously described.

A further experiment was performed to assess the effect of the addition of synthetic C21:0 homologue on the antifungal activity of acetone and ethyl acetate natural extracts. The solutions were prepared by adding 250 and 500 μg of C21:0 homologue standard to 1 mL of acetone or ethyl acetate natural extract, containing about 1100 μg of total AR. The antifungal activity assay against Fg_QCE2 isolate was performed as described above.

Seed Treatment with Cyclohexane AR Extract. One hundred seeds of the durum wheat cv. Iride, susceptible to FHB, were surface-sterilized by washing with 2% sodium hypochlorite for 10 min, followed by three water rinses (5 min each), and dried under a laminar flow hood. Ten milliliters of the cyclohexane extract (3 mg/mL of AR) obtained from the cv. Tirex were previously dried and redissolved in 10 mL of acetone. The extract was added to the seeds with stirring at room temperature until acetone was evaporated. Seeds treated with 10 mL of acetone or 10 mL of distilled sterile water were used as control. Seed infection with Fg_QCE2 isolate was performed using 10 mL of a macroconidia suspension at the concentration of 2×10^4 spores mL^{-1}. After 15 min of incubation, the conidial suspension was removed, and the seeds were plated on a paper disk kept in 90 mm Petri plates containing agar 0.5% (w/v) (10 seeds for plates). Seeds were incubated in a growth chamber at 22 °C, for 6 days under 12/12 h alternate cycles of light and darkness. The experiment was repeated twice. Recording of the infected seeds was done 4 and 6 days after infection using a stereomicroscope.

Statistical Analysis. The analysis of variance (ANOVA) performed with the MSTATC program (Michigan State University, East Lansing, MI, USA) was used to evaluate the significance of the antifungal activity of the AR extracts.

RESULTS

GC-MS Characterization of AR Extracts. ARs extracted from cv. Tirex (grown during 2012) with ethyl acetate, acetone, and cyclohexane were analyzed by GC-MS. The TIC chromatograms of the three extracts are shown in Figure 1. The mass spectra of alkylresorcinols show Mclafferty base fragment at m/z 268, and the identity of the ARs was confirmed by molecular ion at m/z 478 (C15:0), 492 (C17:0), 534 (C19:0), 548 (C21:0), 576 (C23:0), and 604 (C25:0). The three solvents exhibited different abilities to extract ARs, and the highest amount of ARs was found in ethyl acetate. The hierarchy of the AR content in the three extracts was ethyl acetate ≫ acetone ≫ cyclohexane. Moreover, the GC-MS analysis showed that the cyclohexane extract was characterized by lower contents of ballast substances or other unidentified compounds (Figure 1). Ethyl acetate and acetone extracts furnished comparable results for homologue chain composition, whereas the cyclohexane extract contained a significantly higher proportion of C21:0 homologue, representing 59.9 ± 2.2% of AR homologues, and significantly lower percentages of the other homologues, if compared with acetone and ethyl acetate extracts (Table 1).

Antifungal Activity of AR Extracts. The in vitro assay results showed that all of the AR extracts were able to inhibit the growth of *F. graminearum*, although presenting different levels of activity (cyclohexane, 100 ± 0%; acetone, 27 ± 3%; ethyl acetate, 17 ± 2%). As a matter of fact, a total inhibition of spore germination was observed only with cyclohexane extract in the dose between 300 and 500 μL, containing about 330−550 μg of ARs (Figure 2). In this study the 4-*n*-hexylresorcinol was used as positive control to verify the assay conditions; as expected, a total inhibition of spore germination was observed at amounts <10 μg. In addition, the efficacy of the three extracts to inhibit the spore germination of *F. graminearum* was estimated by using the method of Belding et al.[32] Germination of 90 ± 4% of conidia was observed in the presence of ethyl acetate extract and 70 ± 5% in the presence of acetone extract, whereas the presence of cyclohexane extract completely inhibited spore germination.

The relationship between homologue composition of AR extracts and their antifungal activity was also tested by using two homologue standard solutions, containing the same qualitative and quantitative compositions identified in crude durum wheat cyclohexane and acetone extracts. The results showed a different inhibition activity of the two solutions against Fg_QCE2 isolate. In particular, the solution reproducing cyclohexane homologue composition, containing a higher percentage of C21:0 chain, showed a greater antifungal efficacy (growth inhibition of 37 ±

DOI: 10.1021/jf5054518
J. Agric. Food Chem. 2015, 63, 43−50

1%) in comparison to the solution reproducing the acetone extract (growth inhibition of 19 ± 1%).

The role of C21:0 homologue on the AR antifungal activity was evaluated by adding synthetic C21:0 to the acetone and ethyl acetate natural extracts. At 4 days after inoculation, the addition of C21:0 standard in the acetone extract determined a complete inhibition of Fg_QCE2 isolate spore germination, already at the lowest concentration (250 μg). No significant variation of antifungal activity of ethyl acetate extract enriched with synthetic C21:0, at both concentrations, was observed (23 ± 1% of growth inhibition) with respect to natural extract (22 ± 0%).

The fungistatic activity of cyclohexane extract on mycelial growth of *F. graminearum*, *F. culmorum*, *F. avenaceum*, and *F. poae* was also tested and statistically evaluated. The analysis of variance (ANOVA) performed on the colony diameter, measured 4 and 6 days after inoculation, showed statistically significant differences in the effect of the extract against the pathogens compared with the controls (Figure 3). In particular, the mean values of growth inhibition percentage were 47 ± 4% for *F. graminearum*, 41 ± 5% for *F. culmorum*, 55 ± 6% for *F. avenaceum*, and 40 ± 3% for *F. poae*.

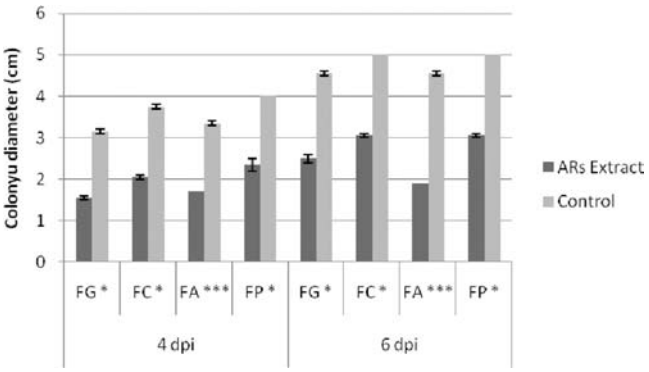

Figure 3. Effects of cyclohexane AR extract (~500 μg of AR) on mycelial growth of *Fusarium* spp. (FG, *F. graminearum*; FC, *F. culmorum*; FA, *F. avenaceum*; FP, *F. poae*): colony diameter (cm) 4 and 6 days after inoculation (mean values of triplicate experiments are given). (***) P = 0.001; (**) P = 0.01; (*) P = 0.05.

The antifungal activity of the extract against the four isolates of *F. graminearum* and the four isolates of *F. culmorum* is shown in Table 2. The AR extract exhibited antifungal activity against all of the tested *Fusarium* isolates, although some significant differences among the isolates were observed. The *F. graminearum* isolates showed the major variability of growth inhibition that ranged from 51 ± 1% for Fg_QCE2 to 32 ± 5% for Fg_QCE11 isolate. With regard to *F. culmorum* isolates, the highest antifungal activity was observed against Fc_QCE1 (growth inhibition = 45 ± 2%).

Protective Role of AR Cyclohexane Extract on Durum Wheat Seeds. The efficacy of the cyclohexane extract to protect seeds was evaluated. Seeds of the durum wheat cv. Iride were preliminarily treated with this extract and successively infected with a conidial suspension of Fg_QCE2 isolate. At 4 and 6 days after inoculation, respectively 77 ± 4 and 55 ± 5% of the treated seeds were not infected compared with untreated seeds, all completely infected after 4 days (Figure 4). The effect of this treatment on seed germination was evaluated by a static-type germinability assay. Four days after treatment, a reduction of 13 ± 4% of germinability was observed compared to the control seeds (2 ± 1%), treated with the solvent. Furthermore, in the treated seeds a slowdown in germination, with a day of delay compared to the control seeds, was observed.

Table 2. Antifungal Activity of AR Cyclohexane Extract versus Different Isolates of *F. graminearum* and *F. culmorum*[a]

	colony diameter (cm)		
	ARs	control	growth inhibition (%)
Fg_QCE2	1.55 ± 0.05	3.15 ± 0.05	50.79 ± 1.20

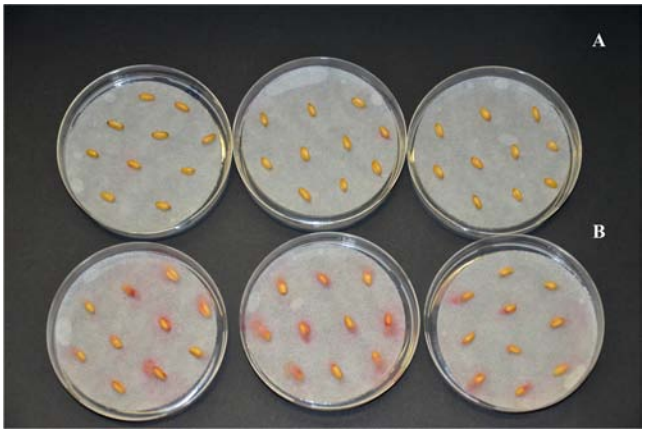

Figure 4. Effect of seed treatment with cyclohexane AR extract (A) and with solvent (B) on *F. graminearum* infection at 4 days after inoculation.

Effect of Seed-Drying Treatment and Durum Wheat Genotype on Antifungal Activity of AR Extracts. To increase the accessibility of cyclohexane solvent to the AR compounds, seed matrices (moisture content about 11.5%) of two durum wheat cultivars (Tirex and Simeto) were treated with high temperatures to reduce the moisture amount under 8% and facilitate AR extraction.[33] Measurements of AR content in acetone and cyclohexane extracts from predried seeds showed that an increased temperature (from 50 to 130 °C, moisture content about 9.4 and 5.2%, respectively) always resulted in increased AR content, and 105 °C for 90 min appeared to be the optimum conditions for an efficient AR extraction (Figure 5); in fact, in these conditions a proper seed moisture reduction (moisture content about 6.7%) was obtained, without undesirable variations in raw material. Changes in homologue profiles in the extracts obtained from predried and not dried seeds were also observed. In particular, the GC-MS data showed that the AR homologue profile presented a consistent decrease of C19:0 and C21:0 homologues and a significant increase of C23:0 chain in predried seeds; in addition, increased amounts of saturated ARs were evidenced in predried extracts (data not reported).

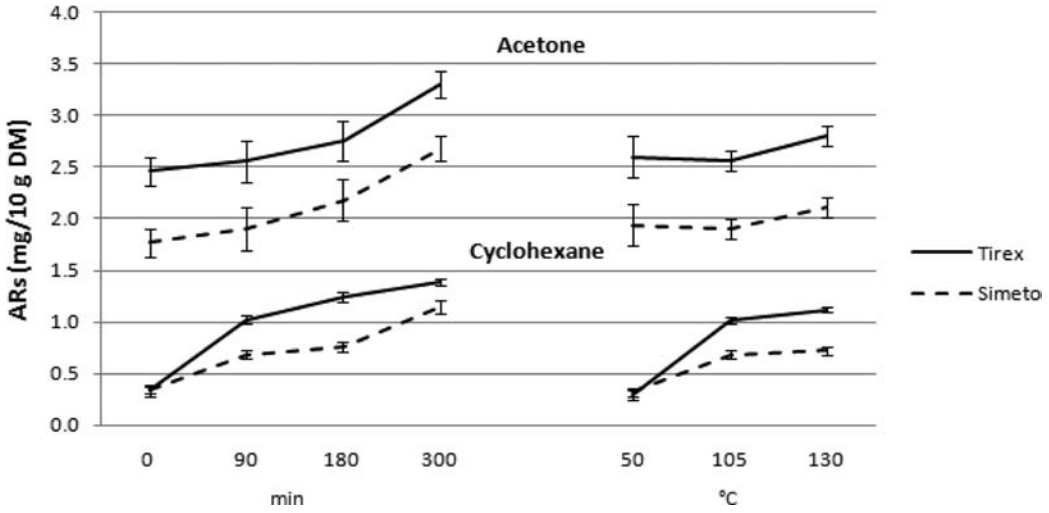

Figure 5. Effect of drying time and temperature on AR extractability with acetone and cyclohexane solvent from two durum wheat cultivars (Tirex and Simeto). (Mean values of triplicate experiments are given.)

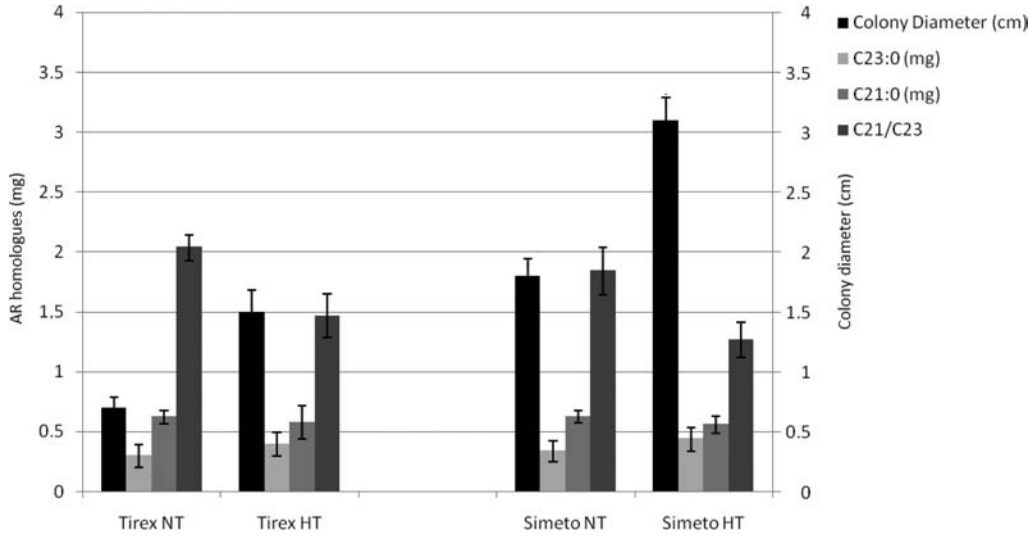

Figure 6. Effect of seed-drying treatment on the amount of C21:0 and C23:0 homologue of the AR cyclohexane extracts, obtained from the cultivars Tirex and Simeto, and on their antifungal activity against *F. graminearum* (colony diameter). NT, not dried seed; HT, dried seed.

The effect of predrying process on the antifungal activity of AR cyclohexane extract against *F. graminearum* is shown in Figure 6. At 4 days after inoculation, the AR extract obtained from predried seeds showed a lower antifungal activity with respect to the extract obtained from untreated kernels; the significant decrease in antifungal activity in dried samples always matched a decrease of the C21:0 and an increase of C23:0 homologue. In addition, as represented in Figure 6, significant differences in fungal growth inhibition activity between the extracts obtained from the two durum wheat cultivars were observed (82 ± 2% Tirex and 53 ± 7% Simeto).

DISCUSSION

The beneficial antifungal and antibacterial activities have led to the general assumption that alkylresorcinols play a defensive role during plant growth. Our results demonstrate the antifungal activity of durum wheat grain extracts, suggesting AR homologue composition as target of this activity. It is difficult to extract alkylresorcinols free of contaminants from cereal grain;[34] among the suggested organic solvents, in the present investigation ethyl acetate, acetone, and cyclohexane were chosen as extractants of 5-*n*-alkylresorcinols. According to previous papers,[35,36] intact kernels were preferred for the extraction. The results of GC-MS showed that the durum wheat grain extracts were always a mixture of contaminating coextracted compounds, soluble in the solvents used for the experiments. The data also indicated significant differences in AR content among ethyl acetate, acetone, and cyclohexane likely due to the different polarities of these solvents.[37] Zarnowski and Suzuki,[34] examining the efficiency of various solvents for the best total alkylresorcinols yield, also stated higher extraction ability of acetone and ethyl acetate with respect to cyclohexane, although this last extract was characterized by low ballast substances. Nevertheless, the interesting finding of this study was that only the relative amount of the C21:0 homologue increased using cyclohexane. This might be due to the middle chain length of lipophilic tail of C21:0 that could favor its solubility in the hydrocarbon solvent; on the other hand, the biological matrix and the individual cellular environment in which C21:0 and other ARs were embedded could affect their release depending on the protocol of

DOI: 10.1021/jf5054518
J. Agric. Food Chem. 2015, 63, 43−50

extraction. Moreover, the data confirmed cyclohexane as the most efficient solvent for minimizing coextraction of interfering compounds, which may have reduced the inhibitory effects of 5-*n*-alkylresorcinols on fungal growth. In fact, the antifungal activity was found to differ among the extracts, and the order of activity was cyclohexane ≫ acetone ≫ ethyl acetate. The high fungistatic activity of the cyclohexane extract was evidenced against *F. graminearum*, *F. culmorum*, *F. poae*, and *F. avenaceum*, this last species appearing to be the most sensitive one to AR activity. Moreover, the results of tests with different *F. culmorum* and *F. graminearum* isolates confirmed the antifungal properties of ARs despite the capacity of some *Fusarium* species to metabolize these molecules as previously described by Zarnowski et al.,[18,38] who suggested for *F. culmorum* a possible mechanism of tolerance to ARs. Therefore, studies on AR biosynthesis and biodegradation into fungal metabolism will be also needed in future projects concerned with the improvement of their applicability for fungal biocontrol.

The study on the influence of the predrying of seeds and the durum wheat genotype used on AR properties has further allowed the highest antifungal activity of the cyclohexane extract to be associated with the presence of a higher C21:0/C23:0 ratio. In fact, the predrying treatment significantly enhanced the recovery of total and saturated ARs, in agreement with the data of Agil et al.[39] In addition, significant modifications of the homologue composition in the AR cyclohexane extract with significant variations in C21:0 and C23:0 chains were evidenced. These changes in homologue composition appeared critical for the described antifungal activity, and the experiment with the standard homologues of AR supported this hypothesis. As part of the review process of this research, the results of the new tests showed that the addition of synthetic C21:0 increased the antifungal activity of the acetone extract, whereas no variation in the ethyl acetate extract activity was evidenced. In this last case likely the undesired interactions between ARs and coextracted compounds could also affect the activity of added C21:0 homologue. Accordingly, the data suggested that the higher antifungal activity of the cyclohexane extract might be due to the reduced presence of contaminants and the different AR composition, characterized by a higher amount of C21:0 homologue chain. These results were in agreement with Stasiuk and Kozubek,[40] who observed a higher ability to solubilize the erythrocyte membranes of homologue C21:0 extracted from rye compared to the other homologues. Moreover, previous studies on fatty acids proved the importance of the chain length in relation to antimicrobial activity.[41,42] On the basis of the trends of this study, AR antifungal activity seemed to be also influenced by factors such as genetic and environmental variables;[43−45] the choice of the durum wheat cultivar used for AR extraction and/or crop environment appeared to be important for optimizing and improving both the content of alkylresorcinols and their biological properties. However, our data did not exclude that other compounds present in the extracts might also play a role in the antifungal activity.

The role of ARs in plant defense is recognized, and their potential application in crop protection systems could appear as an alternative to chemical pesticides, in particular in "conscious agriculture". Our results indicated that seed treatment with cyclohexane extract could reduce the infection incidence of about 50%, suggesting the AR extract as potential control agent of *Fusarium* fungi. However, other agroecological aspects must be considered. In fact, the application of these compounds could affect chemical-mediated communication in the rhizosphere, both between plants and between plants and the soil microbial consortium,[46] that is a crucial contributor to soil quality, favoring long-term sustainability and resistance to perturbation.[47] Thus, the behavior of these molecules in crop field conditions will request future experiments to evaluate their stability and activity and their effects on soil communities.

In conclusion, the identification of the most effective AR homologue composition in inhibiting *Fusarium* growth suggested a potential application of the AR homologues in crop protection systems and could be an important step toward the development of commercial formulations suitable to prevent fungal diseases. Moreover, these findings supported the idea to include ARs in innovative cereal breeding programs to obtain new genotypes with increased resistance to fungal diseases and enhanced bioactive compounds.[44]

ABSTRACT: The quality of fruit from PPV (*Plum pox virus*)-infected plum (*Prunus domestica* L.) trees was investigated during the last 3 weeks of ripening using healthy tree (T3), tree with short-term infection (T2), and tree with long-term infection (T1). The pomological variables (presence of necrosis on fruit, color of fruit, color of flesh, firmness, soluble solids content, and fruit weight) and composition of nutritive compounds (sugars and organic acids) and bioactive compounds (phenolics: anthocyanins, flavonols, and hydroxycinnamic acids) were evaluated. The results indicated that the PPV infection modified the ripening process (the most in T1) and the composition of nutritive and bioactive compounds in the healthy-looking part of the fruit. Long-term infected tree (T1) yielded fruit with the poorest pomological traits and with the most modified composition of nutritive and phenolic compounds. The short-term PPV infected tree also produced fruit with significantly altered phytochemicals composition, although the pomological traits had not changed significantly.

KEYWORDS: *Plum pox virus, Prunus domestica, pomological characteristics, phytochemicals, nutritive compounds, phenolics, composition data analysis*

INTRODUCTION

Sharka (plum pox), caused by the *Plum pox virus* (PPV), is the most serious viral disease threatening the stone fruit industry, particularly because it causes severe losses in susceptible cultivars and is spread efficiently by aphids.[1] Over an approximately 80-year period since the description of the sharka disease, PPV has been thoroughly studied at various stages of the infection cycle.[2] On unripe fruit, shallow depressions of darker color appear. During ripening, these develop into deep rings and irregular lines, which cause deformation of the fruit. The epidermal tissue and underlying cells become necrotic, and the flesh turns brownish-red. The necrotic tissue often extends down to the seed. These fruits are tasteless and fibrous.[3] The diseased fruits contain more organic acids but less sugar and, especially, less sucrose. The fruits of infected susceptible varieties are also smaller in size.[4]

The influence of viruses on trees depends on the pathogen and its strain, as well as the fruit species, cultivar, rootstock, nutrition supply, time and mode of infection, vector species, and age of the tree when infected.[5] Trees newly infected with PPV show minor symptoms, usually only on one part of the tree, but with passing years infection of the tree increases.[6] The 'Požegača' cultivar is known to be very susceptible to PPV. This cultivar is widely distributed in Europe and has many synonyms, like 'Vânăt Românesc', 'Vinete Românești', or 'Bistrițene' in Romania; 'Kiustendilska' in Bulgaria; 'Vengerka' in Moldova; 'Quetsche' in France; 'Hauszwetsche' in Germany; 'Madjarica' in Croatia; 'Domača češplja' in Slovenia; etc.[7] Severe premature fruit drop (80−100%) has been reported for this cultivar. The dropping of the fruit begins 30−40 days before ripening.[4]

A number of physiological, biochemical, and structural changes occur during the ripening of plum,[8] resulting in modifications to pomological traits as well as to phytochemicals, which are dependent on the species,[9,10] cultivar,[9,11−13] ripening stage,[11−15] part of the fruit,[13,16] and rootstock.[17,18] Phytochemicals, particularly phenolics, are also good indicators of changed plant metabolism, owing to stress caused by infection; however, there has been no report about the effect of the PPV infection on phytochemicals in plum fruit.

In this study the effect of the PPV-Rec strain on external and internal quality of 'Brkinska češpa' was studied during the last 3 weeks of ripening. The quality of fruit from a tree that has been infected with PPV for at least 5 years and from a recently infected tree was compared to that of fruit from a healthy tree grown at the same location. To our knowledge this is the first report about the effect of PPV infection on composition of sugars, organic acids, and phenolics (anthocyanins, flavonols, and hydroxycinnamic acids) in plum fruit during the last stages of ripening. The results will improve the knowledge regarding the impact of PPV infection on the ripening process, the pomological traits, and especially the composition of phytochemicals in the healthy-looking part of the susceptible *Prunus domestica* plum fruit.

MATERIALS AND METHODS

Sample Collection. Fruit of 'Brkinska češpa', the local biotype of 'Domača češplja' (*Prunus domestica* L.), were collected from August 20

[a]M^+ (m/z) anthocyanins were obtained in the positive ion mode; other phenolics were obtained in the negative ion mode.

to September 19 in 2013 from a plum orchard in the southwestern part of Slovenia (45°32′ latitude, 14°15′ longitude; 600 m altitude), with 1500 mm of average annual precipitation. Three trees growing on their own roots in close vicinity were selected based on the abundance of symptoms.

All the trees were over 30 years old and propagated through root suckers. The rate of infection on leaves and fruits was estimated visually on each sampling time. One tree showed severe symptoms of PPV infection on almost all fruit and severe premature dropping of fruit, and it was infected by PPV for at least 5 years (T1) (long-term infection), since the owner discovered symptoms on the leaves in spring 2009. The sharka symptoms on the recently infected tree were less severe. Mild symptoms were observed on few fruits. The first symptoms of PPV infections on leaves of this tree were observed by the owner in 2012 (T2) (short-term infection). On the third tree symptoms of PPV infection were absent (T3) (control).

The visual observations of PPV symptoms were confirmed by laboratory analyses. The presence/absence of PPV and other viruses that might cause similar symptoms or aggrevate the symptoms of PPV was checked on March 12, 2014, in buds collected throughout the canopy using double-antibody sandwich enzyme-linked immunosorbent assay (DAS-ELISA). Antibodies (Bioreba AG, Reinach, Switzerland) for detection of *Plum pox virus* (PPV), *Prune dwarf virus* (PDV), *Prunus necrotic ringspot* virus (PNRSV), *Apple chlorotic virus* (ACLSV), and *Apple mosaic virus* (ApMV) were used. Total RNA isolated from the two PPV positive samples was used in reverse transcriptase polymerase chain reaction (RT-PCR) using PPV3MODIF/P3M and PPV3MODIF/P3D primer pairs.[19,20] Obtained amplicons were directly sequenced. Strain designations of all sequences were determined based on the 99% nucleotide identity to sequences in the National Center for Biotechnology Information (NCBI) database using the blastn tool.

Fruits were picked at 8−13-day intervals through the last 3 weeks of ripening—August 20 (*d0*; in figures, 0), August 29 (*d9*; in figures, 9), September 11 (*d22*; in figures, 22), and September 19 (*d30*; in figures, 30, only T3)—and immediately transferred to the laboratory for further analytical determinations. For each sampling date and each tree, 30 fruits were selected randomly. The sample of 30 fruits was randomly divided into five repetitions (subsamples). The percentage of premature dropping of fruit was estimated for each tree and each sampling date.

Pomological Variables. Pomological variables (color of fruit, color of flesh, firmness, fruit weight, and soluble solids content (SSC)) were measured, and the presence of necrosis on plum fruit was assessed visually on each fruit using the following scale: 0 = without symptoms, 1 = symptoms covering <10% of the fruit skin, 2 = symptoms covering 10−30% of the skin, 3 = symptoms covering >30% of the skin. Using a Konica Minolta Portable Color Reader CR-10 (Konica Minolta, Inc., Osaka, Japan; measuring diameter 8 mm), hue (h^*) was measured in fruit with an uninjured blush on two sides of each fruit and the values were averaged (h_{peel}) and in flesh (h_{flesh}). With a penetrometer (Chatillon penetrometer model DFG 50, John Chatillion & Sons, New York, U.S.A.; insertion depth 5 mm), equipped with a round jagged stainless steel probe (diameter 6 mm), firmness was measured on two sides of each fruit immediately after the measurement of h_{peel}, and the values were averaged. SSC was measured in fruit juice with a digital refractometer (WM-7, Atago Co. Ltd., Tokyo, Japan).

Fruit weight was measured only on September 11 and September 19. The water content of the edible part was calculated as a difference from the fresh and dry weight of each subsample.

Samples (peel + flesh) for further determination of sugars, organic acids, and phenolic compounds were taken on four sides of each fruit with a round stainless steel probe (diameter 6 mm). In fruit with necrosis, the healthy-looking part of the fruit was taken for analyses. Fruit tissue of each subsample (4 parts of 6 fruits) was frozen and kept at −20 °C until the extraction. The extraction was made for each subsample at once: from one part of the fruit tissue for determination of sugars and organic acids and from the other part for determination of phenolic compounds. Determination of sugars, organic acids, and phenolic compounds was therefore made on the same plant material.

Sugars and Organic Acids. One g of plum tissue was homogenized in 5 mL of twice-distilled water and left for 30 min at room temperature with frequent stirring. The extracts were centrifuged at 12 800*g* for 7 min at 10 °C (Eppendorf Centrifuge 5810R, Hamburg Germany). The supernatants were filtered through a 0.20 μm cellulose ester filter (Macherey-Nagel; Düren, Germany) and transferred into a vial, and 20 μL of the sample was used for the analysis.

The analysis of sugars was carried out using a Surveyor high-performance liquid chromatography (HPLC) system with a refractive index (RI) detector (Thermo Finnigan). Separation of sugars was carried out using Rezex-RCM-monosaccharide column (300 × 7.8 mm; Phenomenex, Torrance, CA) operated at 65 °C. The mobile phase was double distilled water. The flow rate was 0.6 mL/min. The run time was 30 min.

Organic acids were analyzed with the same HPLC system, equipped with a UV detector set at 210 nm using a Rezex ROA column from Phenomenex HPLC (Thermo Scientific, Finnigan Spectra system, Waltham, MA, U.S.A.) operated at 65 °C. The elution solvent was 4 mM sulfuric acid at a flow rate of 0.6 mL min^{-1}. The duration of the analysis was 30 min.

The concentration of an individual metabolite was calculated according to a calibration curve of corresponding standard solution. The concentrations of sugars and organic acids were expressed as grams per kilogram of fresh weight (g kg^{-1} of FW). From the data of individual sugars and individual organic acids, sum of sugars (SUG) and sum of acids (ACID) and their ratio SUG/ACID were calculated.

[a]a–f = No statistically significant differences between averages denoted with the same letter.

Phenolics. Plum tissue was ground to a fine paste in a mortar chilled with liquid nitrogen. One gram was extracted with 2.4 mL of methanol containing 3% (v/v) formic acid and 1% (w/v) 2.6-di-*tert*-butyl-4-methylphenol (BHT) in a cooled ultrasonic bath for 1 h. BHT was added to the samples to prevent oxidation during the extraction and formic acid was added for anthocyanin stabilization. After extraction, samples were centrifuged at 12 800*g* for 5 min at 4 °C and filtered through Chromafil A0-20/25 polyamide filters (Macherey-Nagel; Düren, Germany).

The analysis was performed immediately after extraction on a Surveyor HPLC system with a photodiode array (PDA) detector (Thermo Scientific, San Jose, CA, U.S.A.). The column was a Gemini C_{18} (150 × 4.6 mm; 3 μm; Phenomenex, Torrance, CA, U.S.A.) protected with a Phenomenex security guard column and operated at 25 °C. The elution solvents were aqueous 0.1% formic acid in double-distilled water (A) and 0.1% formic acid in acetonitrile (B). Samples were eluted using a linear gradient from 5 to 20% B in the first 15 min, followed by a linear gradient from 20 to 30% B for 5 min, then an isocratic mixture for 5 min, followed by a linear gradient from 30 to 90% B for 5 min, and then an isocratic mixture for 15 min before returning to the initial conditions[21] with some modifications, with an injection amount of 20 μL and a flow rate of 0.6 mL min^{-1}. Detected and quantified were hydroxycinnamic acids at 280 nm, flavonol derivatives at 350 nm, and anthocyanins at 530 nm.

Phenolic compounds were identified using a mass spectrometer (Thermo Scientific, LCQ Deca XP MAX) with an electrospray ionization (ESI) operating in positive (anthocyanins) and negative (all the other phenolics) ionization mode. Analyses were carried out using full-scan, data-dependent MS^n scanning from m/z 100 to 1000. The MS data are presented in Table 1. The capillary temperature was 250 °C, the sheath gas and auxiliary gas were 60 and 15 units, respectively, and the source voltage was 3 kV for negative and 4 kV for positive ionization.

The identification of compounds was confirmed by comparing retention times and their spectra as well as by adding the standard solution to the sample and by fragmentation. The concentrations of phenolics were calculated from peak areas of samples and corresponding standards. For compounds lacking standards, quantification was carried out using similar compounds as standards (Table 1). Concentrations were expressed in milligrams per kilogram fresh weight (mg kg^{-1} of FW). For the general presentation of the results, the sum of four hydroxycinnamic acids (HCA), the sum of five flavonols (FLAVO), and the sum of four anthocyanins (ANTH) were calculated.

Chemicals. The following standards were used for the quantification of sugars, organic acids, and phenolic compounds: sucrose, fructose, glucose, sorbitol, citric acid, malic acid, fumaric acid, *p*-coumaric acid, quercetin-3-*O*-galactoside, quercetin-3-*O*-glucoside, kaempferol-3-*O*-glucoside, cyanidin-3-*O*-galactoside, and peonidin-3-*O*-glucoside from Fluka Chemie GmBH (Buchs, Switzerland); shikimic acid, neochlorogenic (3-caffeoylquinic) acid, chlorogenic (5-caffeoylquinic) acid, and rutin (quercetin-3-*O*-rutinoside) from Sigma–Aldrich Chemical (St. Louis, MO, U.S.A.), and isorhamnetin-3-*O*-glucoside from Extrasynthese (Genay Cedex, France). Methanol for the extraction of phenolics was acquired from Sigma–Aldrich Chemical. The chemicals for the mobile phases were HPLC–MS grade acetonitrile and formic acid from Fluka Chemical GmBH. Water for the mobile phase was twice distilled and purified with the Milli-Q system (Millipore, Bedford, MA, U.S.A.).

Statistical Analysis. The data were analyzed as a two-factor experiment design, with the first factor expressing the level of PPV infection with three levels: T1, T2, and T3; the second factor expresses the time during ripening and also has three levels (*d0*, *d9*, and *d22*). In the case of pomological variables, there were 30 replications, and one plum represents an experimental unit. In the case of sugars, organic acids, and phenolic compounds, there were 5 replications; samples of flesh + peel were prepared from 6 plums. The impact of two fixed factors on pomological and chemical variables was examined on the basis of statistical analysis, performing linear models with one categorical explanatory variable (PPV infection) and one numeric explanatory variable (time). In most cases the interaction between PPV infection and time was statistically significant, indicating differing time trends for variables at different levels of PPV infection. The influence of PPV infection during the last stage of ripening on sugars, organic acids, and phenolic composition (relative values) was examined on the basis of compositional data analysis.[22] Three out of the four components in the four-part subcompositions of sugars, acids, and groups of phenolic components were first transformed using isometric log-ratio transformation (*ilr*) based on sequential binary partition. Multivariate and further univariate analysis of variance (MANOVA and ANOVA) was performed on *ilr* coordinates. Statistical analysis was done with the R program.[23] For compositional data analysis, the "compositions" package was used.[24,25]

RESULTS/DISCUSSION

DAS-ELISA testing showed the absence of all tested viruses with the exception of PPV. The presence of PPV was confirmed in both trees showing sharka symptoms (T1 and T2). The symptomless tree (T3) proved to be PPV-free. Owing to the absence of other viruses that can affect stone fruit, all the differences found can be ascribed to the effect of PPV. The 1226 nucleotide long sequences from both PPV-positive trees obtained with the primers PPV3MODIFIED[19] and P3M[20] were found to be identical and to belong to the PPV-Rec strain. Strain identification is important, because PPV isolates are diverse and have been assigned to 9 strains,[26] which differ in

[a]a–d = No statistically significant differences between averages denoted with the same letter. For the variables with statistically significant infection/time interaction, only small letters are used for indication of differences between treatments. If the interaction was not statistically significant, small letters indicate differences between rates of infection and capital letters indicate the differences between different time points.

their pathogenicity, host range, aphid transmissibility, and geographic distribution. The results show that premature fruit drop is higher in infected trees and that it increases with the duration of infection (Table 2).

Pomological Variables. Our results show the effect of PPV infection on the pomological characteristics during the final phases of ripening (Table 2). The analysis of variance for all pomological characteristics show that the interaction between infection and ripening stage (time) was statistically significant. This means that the level of PPV infection does influence the process of ripening.

The medians of the necrosis score evaluated for 30 plums of each tree/time combination differed from 0 only for T1 (Table 2). At the first sampling date, no necrosis was found on T2 and T3 fruit, but all fruit from T1 showed necrotic symptoms: score 1, 12 plums; score 2, 12 plums; and score 3, 6 plums. At the second sampling (*d9*), 12 plums from T1 got a score of 2 and 18 plums a score of 3. Two fruit from T2 got a score of 1, all others 0. At the last sampling (*d22*), 10 plums from T1 got a score of 1, 14 plums a score of 2, and 5 plums a score of 3; 5 plums from T2 got a score of 1, 1 a score of 2, and 1 a score of 3. This shows that the severity of symptoms increases with the duration of infection. These results also confirmed our estimation of infection rate done in the field. It is known that the infection of trees and the symptom expression increases with years;[6] thus, the relative differences in the rate of infection among trees of the same cultivar and rootstock on the same location can be estimated based on the abundance of symptoms on the leaves and on the fruit.

Significantly the lowest average values of h_{peel} were observed in T1 at first measurement (*d0*) (Table 2). The color of T1 at *d0* was magenta–blue and did not change significantly over the next 22 days. Ripening of T2 fruit resulted in changed color of fruit peel from magenta (*d0*) to magenta–blue (*d22*). The color of T3 changed to magenta–blue at *d30*. When plums become more highly colored, the h_{peel} decreases.[15] These results show the faster process of fruit ripening in fruit from infected trees (T1 and T2) and confirm the observations of Atanassov (cited in ref 4) that plums from PPV infected trees ripen from 10–15 days or more ahead of fruit from healthy trees.

Color intensity of flesh (h_{flesh}) significantly decreased during ripening (the color changed from green to yellow), more evidently in T2 and T3 than in T1 fruit. The fruit of T1 on *d22* had significantly higher values of h_{flesh} than T2 and T3, showing a more greenish flesh. The h_{flesh} of T3 decreased the most from

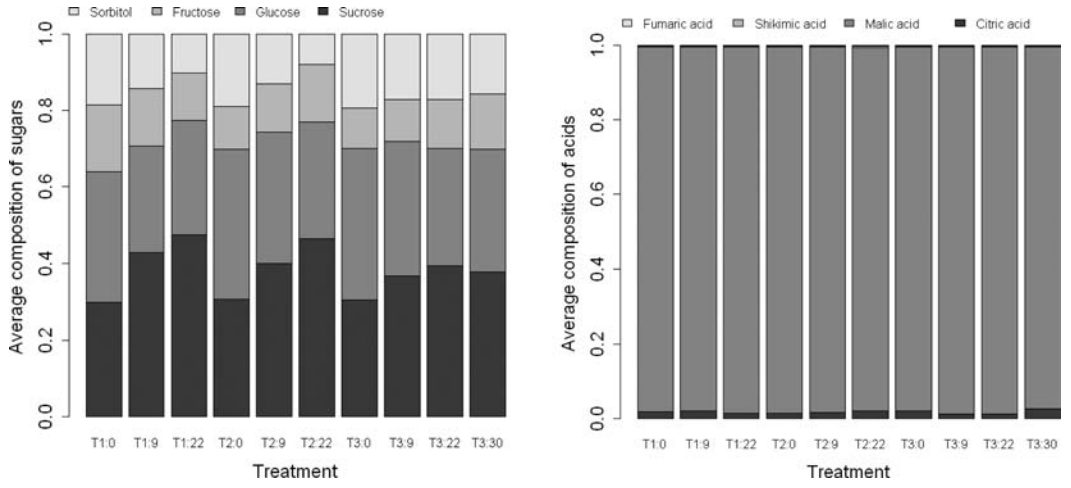

Figure 2. Effect of PPV infection (T1, long-term infection; T2, short-term infection; T3, control) on the average composition of sugars (left) and organic acids (right) of plum 'Brkinska češpa' during the last stages of fruit ripening (day) (0; 9; 22; 30, only T3).

d22 to *d30*. Assessment of ripeness using flesh color is consistent with the results of other pomological characteristics.

Our results show variation in reduction of firmness among fruit with various levels of infection. At the first measurement (*d0*), fruit from the PPV-free (T3) and from the tree infected for only a short time (T2) showed equal levels of firmness. Fruits from the long-term infected tree (T1) were statistically softer. After 9 days, differences in firmness among the fruit almost disappeared, but after 22 days the firmness of T1 and T2 fruit decreased to almost the same level, while T3 fruit remained firmer. The results for firmness also show that a high level of PPV infection causes earlier ripening of fruit, since during the final ripening phases a change in firmness is the only useful indicator of plum maturity.[15]

Ripening did not change soluble solids content (SSC) in T1 but increased it significantly in T2 between *d9* and *d22* and in T3 between *d22* and *d30*. Given that ripening increases SSC,[11] it can be assumed that PPV infection caused earlier ripening of T1 and T2 fruit. SSC is an essential quality variable in stone fruit,[27,28] which has been proposed as the most reliable maturation parameter for plums.[29,30] The average SSC of 10 selections of 'Brkinska češpa' varied from 16.2 to 19.8.[31]

Infection had no impact on the water content of the edible part of the plum fruit (Table 2). The level of PPV infection did influence average fruit weight, which was measured only on *d22* and *d30*. The fruit of T1 and T2 on *d22* had a similar fruit weight (10.8 and 11.1 g), which was much lower compared to T3 (15.9 g). By the last sampling day (*d30*), the average fruit weight of T3 had increased to 16.5 g. The ripening process increases fruit weight.[11] The average fruit weight of 10 selections of 'Brkinska češpa' varied from 17.4 to 21.4 g.[31]

Nutritive Compounds. Our results show the effect of PPV infection on the composition of nutritive compounds in the plum fruit of 'Brkinska češpa' during the final ripening phases. Two groups of nutritive compounds were identified: sugars and organic acids. In general, the relative content of sugars increased and the relative content of acids decreased during ripening (Figure 1 and Tables 3 and 4). T1 fruit had significantly less SUG than T2 and T3 fruit (Table 3).

The average content of individual sugars is shown in Table 3, and their average composition is shown in Figure 2. Glucose, fructose, sorbitol, and sucrose were detected.[13] Relative content of sucrose during the final phases of ripening generally increased (30.0% to 47.5%), but it decreased in the case of

[a]a–d = No statistically significant differences between averages denoted with the same letter. For the variables with statistically significant infection/time interaction, only small letters are used for indication of differences between treatments. If the interaction was not statistically significant, small letters indicate differences between rates of infection and capital letters indicate the differences between different time points.

glucose (39.5% to 27.8%), fructose (17.4% to 10.5%), and sorbitol (19.4% to 8.0%).

The interaction between infection and time was significant for sucrose; the increase of sucrose during ripening was the slowest for T3. The average glucose content significantly linearly decreased during ripening, with the same rate for all levels of infection. At first measurement (*d0*), there was a significant difference in average glucose between T1 and the other two infection rates; T3 had on average 10.4 g/kg more and T2 had on average 7.3 g/kg more glucose than T1. The average content of fructose increased during ripening in T2 and T3 and decreased in T1. Only in T1 and T2 did ripening significantly decrease sorbitol.

In general, the results for sugars show similarities between T2 and T3, but in the case of sucrose at *d22* there are similarities between T1 and T2. Fruit of T1 had less total sugars, glucose, and sorbitol than T2 and T3. Fruit of T1 and T2 had at *d22* more sucrose than T3 (Table 3).

To examine relative changes in the composition of sugars, the analysis was also done on the *ilr* (isometric log-ratio transformation) transformed four-component sugar composition (Figure 2). The MANOVA for the *ilr* coordinates shows that the infection/time interaction was statistically significant. This means that sugar composition changes during ripening are not the same for all levels of PPV infection. The three *ilr* coordinates were calculated: ilr_1 represents the balance between glucose and sucrose $ilr_1 = c_1 \times \ln(\text{glucose}/\text{sucrose})$; ilr_2 represents the balance between fructose and the group of sucrose and glucose) $ilr_2 = c_2 \times \ln(\text{fructose}/g(\text{sucrose} \times \text{glucose}))$; and ilr_3 represents the balance between sorbitol and the other three components $ilr_3 = c_3 \times \ln(\text{sorbitol}/g(\text{sucrose} \times \text{glucose} \times \text{fructose}))$. The constants c_1, c_2, and c_3 are determined on the basis of sequential binary partition and play a normalization role. The function $g(\,)$ represents the geometric mean of the composition components. The univariate ANOVA for ilr_1 showed a significant influence of infection and time; the highest occurred in T3 and the lowest in T1, and it decreased with time, owing to increased sucrose content relative to glucose. The infection/time interaction was statistically significant for ilr_2. The ilr_2, which for T1 at *d0* was significantly higher than T2 and T3 during ripening, decreased significantly in T1, but in T2 and T3 it increased slightly. The ilr_3 differed among levels of infection (the highest was in T3) and decreased over time—the most in T1 and T2, owing to a reduction in sorbitol concentration relative to the other sugars. The ilr_1 and ilr_2 coordinates show more similarities between T2 and T3, but the ilr_3 coordinate shows similarity between T1 and T2.

The average content of individual organic acids and the sum of acids (ACID) are shown in Table 4, and their average composition is shown in Figure 2. In general, the relative concentration of acids during ripening decreased:[11,13] from 98.4% to 97.5% malic acid, from 2.0% to 1.2% citric acid, from 0.3% to 0.2% shikimic acid, and from 0.2% to 0.1% fumaric acid.

The infection/time interaction was significant for ACID (Table 4). Fruit of T2 and T3 had significantly higher average ACID (20.0 and 15.4 g/kg, respectively) than T1 (9.3 g/kg) at first measurement (*d0*). Ripening decreased organic acids in plum, the most in T1 and T2. Fruit of T3 had significantly higher average ACID than T1 and T2 at *d22*. There is evident decrease of ACID in T3 between *d22* and *d30*.

The ANOVA for each acid separately (Table 4) showed that the citric acid content of T3 was significantly higher compared to T1. During ripening the content significantly decreased, the most in T2. The ANOVAs for average levels of malic acid, shikimic acid, and fumaric acid show that the infection/time interaction was statistically significant. The content of malic acid and shikimic acid of T2 and T3 was significantly higher than that of T1. The negative time trend (from *d0* to *d22*) was significant for all acids. There was an evident decrease in the main organic acid, malic acid, and ACID in T3 between *d22* and *d30*.

In general, the results for organic acids show that PPV infection causes earlier ripening of fruit. More similarities were between T1 and T2.

Four-component organic acid composition (Figure 2) was transformed into three *ilr* coordinates: $ilr_1 = c_1 \times \ln(\text{malic}/\text{citric})$, $ilr_2 = c_2 \times \ln(\text{fumaric}/\text{shikimic})$, and $ilr_3 = c_3 \times \ln(g(\text{citric} \times \text{malic})/g(\text{shikimic} \times \text{fumaric}))$. MANOVA showed that the infection/time interaction was statistically significant for all *ilr* coordinates. The ilr_1 was, at first measurement, lowest in T3 and highest in T2, but at *d22* it was highest in T3, owing to the higher relative concentration of malic acid against citric acid, and it was lowest in T2. There were significant differences among the levels of infection in ilr_2;

[a]a–d = No statistically significant differences between averages denoted with the same letter. For the variables with statistically significant infection/time interaction, only small letters are used for indication of differences between treatments. If the interaction was not statistically significant, small letters indicate differences between rates of infection and capital letters indicate the differences between different time points.

it was higher in T1 and T2, thus explaining the higher relative concentration of fumaric acid against shikimic acid. Ripening decreased the ilr_3 of T2 and T3 due to decreased relative concentrations of malic acid and citric acid.

The coordinates ilr_1 and ilr_2 show more similarities between T1 and T2, but ilr_3 shows similarity between T2 and T3. Additionally, the ratio SUG/ACID (Table 4) shows that the level of PPV infection influences the process of ripening. To consider the assumptions of ANOVA, the log-ratio was analyzed. The average SUG/ACID ratio of T1 increased significantly between *d9* and *d22* to 19.1 (95% CI is 15.5–21.7); the average SUG/ACID ratio of T2 increased linearly from *d0* to *d22*, and the average SUG/ACID ratio of T3 increased slowly between *d0* and *d22* and then jumped to 22.1 (95% CI is 18.4–25.8) by d30, owing to the increase in SUG and the decrease in ACID between *d22* and *d30*.

Phenolics. Three main groups of phenolics were detected in the edible part of 'Brkinska češpa' fruit: anthocyanins, flavonols, and the most abundant, hydroxycinnamic acids. The average composition according to these groups (sum of anthocyanins (ANTH), sum of flavonols (FLAVO)m and sum of hydroxycinnamic acids (HCA)) is shown in Figure 1 (right). Average concentrations, along with standard errors for individual phenolics inside groups, are shown in Tables 5–7, and the average composition within the phenolic group is shown in Figure 3.

Two *ilr* coordinates were calculated: $ilr_1 = c_1 \times \ln(\text{FLAVO}/\text{HCA})$ and $ilr_2 = c_2 \times \ln(\text{ANTH}/g(\text{HCA} \times \text{FLAVO}))$. The MANOVA for the *ilr* coordinates showed that the infection/time interaction was statistically significant. The phenolic composition of T3 was significantly different from that of T1 and T2. Ripening significantly increased the ilr_1 of T1 and T2, owing to the decreased relative content of HCA and increased FLAVO. This resulted in significantly higher ilr_1 in T1 and T2 than in T3 at *d22*. The ilr_2 was significantly increased during ripening, owing to increased ANTH and decreased HCA, evidently more in T1 and T2 than in T3 (Figure 1).

The four hydroxycinnamic acid derivatives were identified in 'Brkinska češpa' fruit: the main neochlorogenic acid,[13,31] *p*-coumaroylquinic acid, chlorogenic acid, and cryptochlorogenic acid, in accordance with the results of Slimestad et al.[10]

The ANOVA for each hydroxycinnamic acid separately shows that infection/time interaction was statistically significant for the average HCA and neochlorogenic acid prevailed: T2

DOI: 10.1021/jf505330t
J. Agric. Food Chem. 2015, 63, 51–60

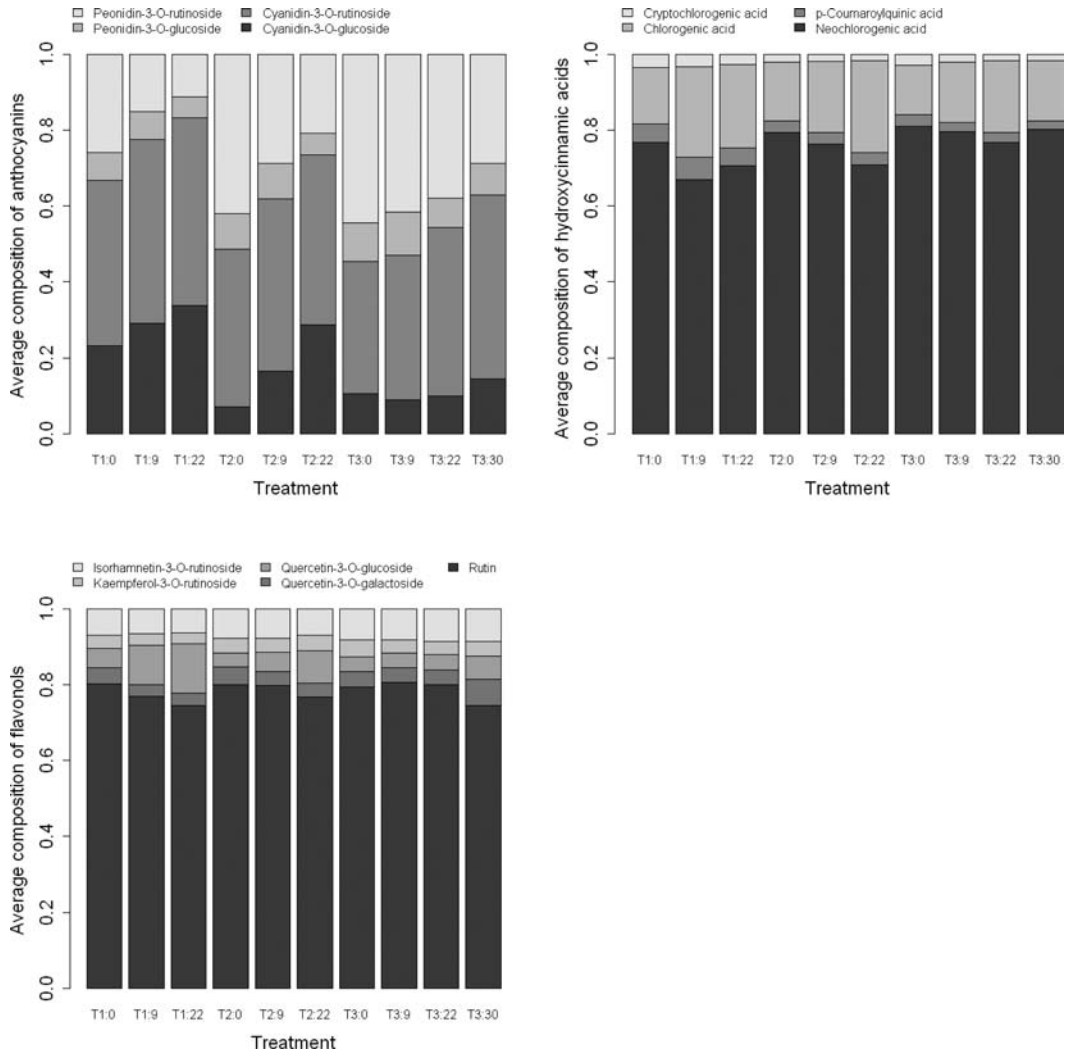

Figure 3. Effect of PPV infection (T1, long-term infection; T2, short-term infection; T3, control) on the average composition of hydroxycinnamic acids (top left), flavonols (top right), and anthocyanins (bottom right) of plum 'Brkinska češpa' during the last stages of fruit ripening (day) (0; 9; 22; 30, only T3).

and T3 had significantly more HCA than T1 (T2 more than T3) at *d0*. Ripening significantly decreases HCA and neochlorogenic acid only in T2. At the last sampling (*d22*), T3 had a significantly higher content of neochlorogenic acid and HCA than T2 and especially T1 (Table 5).

The PPV infection significantly influenced the average content of *p*-coumaroylquinic acid. Fruit of T1 had a significantly higher average content of *p*-coumaroylquinic acid than T2 and T3. There was no time trend.

Infection and time significantly influenced average content of chlorogenic acid. Fruit of T2 and T3 had significantly more chlorogenic acid than T1. Analysis shows a positive time trend.

There were no significant differences among the levels of infection in content of cryptochlorogenic acid. The content significantly decreased during ripening (the most in T3).

In the case of HCA (Figure 3), three *ilr* coordinates were calculated: $ilr_1 = c_1 \times \ln(p\text{-coumaroylquinic/neochlorogenic})$, $ilr_2 = c_2 \times \ln(\text{cryptochlorogenic/chlorogenic})$, and $ilr_3 = c_3 \times \ln(g(\text{neochlorogenic} \times p\text{-coumaroylquinic})/g(\text{chlorogenic} \times \text{cryptochlorogenic}))$. The MANOVA for *ilr* coordinates showed that the infection/time interaction was statistically significant. The coordinate ilr_1 was significantly influenced by infection—the greatest in T1 and the lowest in T3, owing to the higher relative content of neochlorogenic acid. Ripening had no significant influence on ilr_1.[13] The coordinate ilr_2 was significantly influenced by infection (the greatest in T1 and the lowest in T2) and time (ripening decreased the ilr_2). Our results show a negative time trend for the ilr_3 coordinate, with no significant effect from infection. The coordinates ilr_1 and ilr_3 show similarities between T2 and T3, but ilr_2 shows similarity between T1 and T3 on *d0* and *d9* and similarity between T2 and T3 on *d22*.

Four anthocyanins, cyanidin-3-*O*-glucoside, cyanidin-3-*O*-rutinoside, peonidin-3-*O*-glucoside, and peonidin-3-*O*-rutinoside, were identified in 'Brkinska češpa' fruit, which is in accordance with previous reports.[13,32] The relative concentration ranges were 34.8−49.4% for cyanidin-3-*O*-rutinoside, 11.1−44.4% for peonidin-3-*O*-rutinoside, 7.0−33.8% for cyanidin-3-*O*-glucoside, and 5.6−11.5% for peonidin-3-*O*-glucoside (Figure 3). Cyanidin-3-*O*-rutinoside was ascertained as the main anthocyanin in *Prunus domestica* plum.[10,12,13]

Ripening significantly increased ANTH,[11−13] in T1 and T2 more than in T3. At the beginning of the measurements, the highest content of ANTH was measured in T1. A higher content of ANTH in infected fruit shows a stress-protective role of anthocyanins in plant tissue given that they are acting as

DOI: 10.1021/jf505330t
J. Agric. Food Chem. 2015, 63, 51−60

general antioxidants in various stress situations. The measurement of h_{peel} shows similar results; T1 fruit was colored more than T2 and T3 at *d0*.

The ANOVA for each anthocyanin separately shows that infection/time interaction was statistically significant for the average cyanidin-3-*O*-glucoside and cyanidin-3-*O*-rutinoside. The highest content of both compounds was measured in T1 and T2. Ripening from *d0* to *d22* increased the content of both compounds significantly only in T1 and T2. In T3 the content of both cyanidins increased between *d22* and *d30*. The content of peonidin-3-*O*-glucoside, which increased with time, was significantly higher in T1 and T2 than in T3. The infection/time interaction was statistically significant for peonidin-3-*O*-rutinoside; the content increased with time, the most in T2 and T3.

In the case of ANTH (Figure 3), three *ilr* coordinates were calculated: $ilr_1 = c_1 \times \ln$(cyanidin-3-*O*-rutinoside/cyanidin-3-*O*-glucoside), $ilr_2 = c_2 \times \ln$(peonidin-3-*O*-rutinoside/peonidin-3-*O*-glucoside), and $ilr_3 = c_3 \times \ln(g$(cyanidin-3-*O*-glucoside × cyanidin-3-*O*-rutinoside)/g(peonidin-3-*O*-glucoside × peonidin-3-*O*-rutinoside)). The infection/time interaction was statistically significant for the ilr_1; the log-ratio of T1 and T2 during ripening decreased because of a relative increase in cyanidin-3-*O*-glucoside, but that of T3 increased slightly, owing to a relative increase in cyanidin-3-*O*-rutinoside. The ilr_2 was significantly affected by infection; the least effect was in T1 and the greatest was in T3, owing to the higher relative content of peonidin-3-*O*-rutinoside. The infection/time interaction was statistically significant for the coordinate ilr_3; ripening increased the log-ratio and resulted in a higher relative content of cyanidins in T1 and T2 but not in T3. The ilr_1, ilr_2, and ilr_3 coordinates show significant differences in the composition of anthocyanins between T1 and T3. T2 shows more similarities with T1.

The following five flavonols were identified in 'Brkinska češpa' fruit: rutin, quercetin-3-*O*-galactoside, quercetin-3-*O*-glucoside, kaempferol-3-*O*-rutinoside, and isorhamnetin-3-*O*-rutinoside. Rutin was the main flavonol compound (Figure 3).[13,32] Quercetin-3-*O*-galactoside and quercetin-3-*O*-glucoside have been previously identified in plums of *Prunus domestica*[32] and *Prunus salicina*.[33] Two novel compounds in plum fruit were identified: kaempferol-3-*O*-rutinoside and isorhamnetin-3-*O*-rutinoside (Table 1).

Infection and time significantly influenced average FLAVO (Table 7). T1 had a significantly higher content of FLAVO than T2 and T3. The increase in FLAVO during ripening was highest in T1 and lowest in T3. The levels of PPV infection, which represent various levels of stress, do influence the content of FLAVO. A higher content of FLAVO in infected fruit shows the stress-protective role of flavonols.

The ANOVA for each individual flavonol shows that infection and time significantly influenced the average content of rutin and quercetin-3-*O*-galactoside. T1 had a significantly higher content of rutin and quercetin-3-*O*-galactoside than T3. The time trend for both compounds was positive.

The infection/time interaction was statistically significant for quercetin-3-*O*-glucoside. The content was significantly the highest in T1. Ripening increased quercetin-3-*O*-glucoside—the most in T1 and the least in T3.

Infection had no significant effect on kaempferol-3-*O*-rutinoside and isorhamnetin-3-*O*-rutinoside. A positive time trend was significant for both compounds. The content of kaempferol-3-*O*-rutinoside increased the most in T2 and the least in T3. The content of isorhamnetin-3-*O*-rutinoside increased the most in T1 and the least in T3.

In the case of FLAVO (Figure 3), four *ilr* coordinates were calculated: $ilr_1 = c_1 \times \ln$(quercetin-3-*O*-galactoside/rutin), $ilr_2 = c_2 \times \ln$(kaempferol-3-*O*-rutinoside/quercetin-3-*O*-glucoside), $ilr_3 = c_3 \times \ln(g$(quercetin-3-*O*-glucoside × kaempferol-3-*O*-rutinoside)/isorhamnetin-3-*O*-rutinoside), and $ilr_4 = c_4 \times \ln(g$(quercetin-3-*O*-glucoside × kaempferol-3-*O*-rutinoside × isorhamnetin-3-*O*-rutinoside)/g(rutin × quercetin-3-*O*-galactoside)). There was no statistically significant effect of infection on the coordinate ilr_1, which from *d0* to *d22* decreased due to decreased relative content of rutin (Figure 3). The infection/time interaction was statistically significant for the ilr_2, ilr_3, and ilr_4 coordinates. The ilr_2 coordinate decreased during ripening in T1 and T2 owing to a higher increase in quercetin-3-*O*-glucoside. In T1 and T2, the ilr_3 and ilr_4 coordinates decreased significantly during ripening due to increased relative content of quercetin-3-*O*-glucoside and decreased relative content of rutin. Evident changes in the ilr_3 and ilr_4 of T3 occurred only between *d22* and *d30*, when the relative content of rutin decreased but quercetin-3-*O*-galactoside and quercetin-3-*O*-glucoside increased. These results confirm the other data; T3 fruit was ripe by *d30*, but the infection forced the process of ripening—T1 and T2 fruit ripened earlier.

Our results show that the level of PPV infection did modify the ripening process, especially fruit coloration, fruit softening, and fruit weight. The ripening process was the most forced in the long-term infected tree (T1) but resulted in inferior pomological traits. The fruits from the short-term infected tree (T2) were softer, smaller, and riper than fruit from the healthy tree (T3), but the percentage of fruit showing serious symptoms on fruit peel and in the flesh was lower than for T1.

PPV infection significantly modified the composition of nutritive and phenolic compounds, the most in fruit from the long-term PPV-infected tree (T1). The long-term infected tree (T1) yielded fruit with less glucose, malic acid, shikimic acid, sum of organic acids, neochlorogenic acid, and sum of hydroxycinnamic acids, but with more anthocyanins and flavonols than both T2 and T3. The healthy tree yielded fruit with more neochlorogenic acid and sum of hydroxycinnamic acids and less cyanidin-3-*O*-glucoside, cyanidin-3-*O*-rutinoside, peonidin-3-*O*-glucoside, and sum of anthocyanins than the short-term infected tree (T2).

Additionally, the short-term PPV infected tree produces fruit with a significantly changed phytochemicals composition. The visual appearance of such fruit has not changed significantly, but the composition of phytochemicals has, and this does determine the taste of plum, the quality of products processed from fruit, and, ultimately, human health.

Supporting Information

ABSTRACT: Ergot alkaloid pathway reconstruction in *Aspergillus nidulans* is an approach used to better understand the biosynthesis of these mycotoxins. An engineered strain named *A. nidulans* WFC (expressing ergot alkaloid synthesis genes *dmaW*, *easF*, and *easC*) produced the established intermediate *N*-methyl-4-dimethylallyltryptophan, as well as an uncharacterized ergot alkaloid. We investigated the chemical structure of the new metabolite and its role in the ergot alkaloid pathway. Mass spectrometry, labeling, and NMR studies showed that the unknown ergot alkaloid, designated here as ergotryptamine, differed from *N*-methyl-4-dimethylallyltryptophan by the loss of the carboxyl group, addition of a hydroxyl group, and shift in position of a carbon−carbon double bond. Feeding studies with *Aspergillus* mutants did not show ergotryptamine turnover, suggesting it is a pathway byproduct as opposed to an authentic intermediate. Several *Epichloë* species also produced this metabolite, and further investigations revealed the equivalency of ergotryptamine with an *Epichloë*-derived ergot alkaloid provisionally described as 6,7-secolysergine.

KEYWORDS: *ergot alkaloids, mycotoxins, ergotryptamine, 6,7-secolysergine, Aspergillus, Epichloë, NMR*

INTRODUCTION

Ergot alkaloids are a class of indole-derived mycotoxins with agricultural and pharmaceutical significance. Several fungi in the family Clavicipitaceae (order Hypocreales) and a few fungi in the distantly related family Trichocomaceae (order Eurotiales) produce these secondary metabolites.[1,2] The *Epichloë* spp. (Clavicipitaceae) are endophytes of turf and forage grasses (Poaceae, subfamily Poöideae) and synthesize a variety of compounds toxic to vertebrates and invertebrates.[3] Ergot alkaloids in these grass symbionts cause toxicoses in grazing animals and are responsible for significant economic loss to livestock industries.[4,5] The phylogenetically divergent fungus *Aspergillus fumigatus* (Trichocomaceae) is a common saprotroph and opportunistic human pathogen that causes spoilage of feed in agricultural settings.[1,6,7] Compared to the *Epichloë* spp., *A. fumigatus* produces a different subset of ergot alkaloids but can serve as a prominent model organism for studying ergot alkaloid biosynthesis.[8−12]

There is considerable diversity in the later steps of the ergot alkaloid pathway due to genetic variation within ergot alkaloid gene clusters of different fungi; however, there is strong evidence that the early steps of the pathway leading to the formation of intermediate chanoclavine I, **7**, are conserved (Figure 1).[1,2,13] It was recently discovered that four genes, *dmaW*, *easF*, *easC*, and *easE*, amplified from the *A. fumigatus* genome are sufficient to direct synthesis of **7** when transgenically expressed in *Aspergillus nidulans*, a model fungus that does not contain ergot alkaloid-synthesizing genes or produce ergot alkaloids.[11] DmaW performs the determinant step of ergot alkaloid synthesis by prenylating tryptophan, **2**, to produce dimethylallyltryptophan, **3**.[9,10,14] The *easF* gene encodes a methyltransferase responsible for converting **3** into *N*-methyl-4-dimethylallyltryptophan, **4**.[12] The exact reactions catalyzed by EasE and EasC have not yet been determined, but genetic analyses demonstrate that these two genes are required to convert **4** to **7**.[8,11,15] Bioinformatics suggest that EasC is a catalase, whereas EasE is an oxidoreductase.[8,11,15] A scheme of conversion from **4** to **7** has been proposed by Kozikowski et al.[16] (Figure 1).

Previously Ryan et al.[11] investigated the roles of EasC and EasE, as well as the intermediates they produced, by reconstructing the early steps of ergot alkaloid synthesis in *A. nidulans*. A mutant strain named *A. nidulans* WFC (containing the genes *dmaW*, *easF*, and *easC* from *A. fumigatus*) accumulated ergot alkaloid pathway intermediate **4** as well as an uncharacterized ergot alkaloid of *m*/*z* 259 (referred to here as alkaloid X) not seen in control strains or the nearly isogenic transformant *A. nidulans* WFE (expressing *dmaW*, *easF*, and *easE*), which synthesized **4** but no unusual metabolites. On the basis of the genetic background of the modified *A. nidulans* strain that produces this compound and the compound's chromatographic and fluorescence properties, alkaloid X was proposed to be a derivative of **4**. In this study, we investigated the chemical structure of this new ergot alkaloid, its role as a

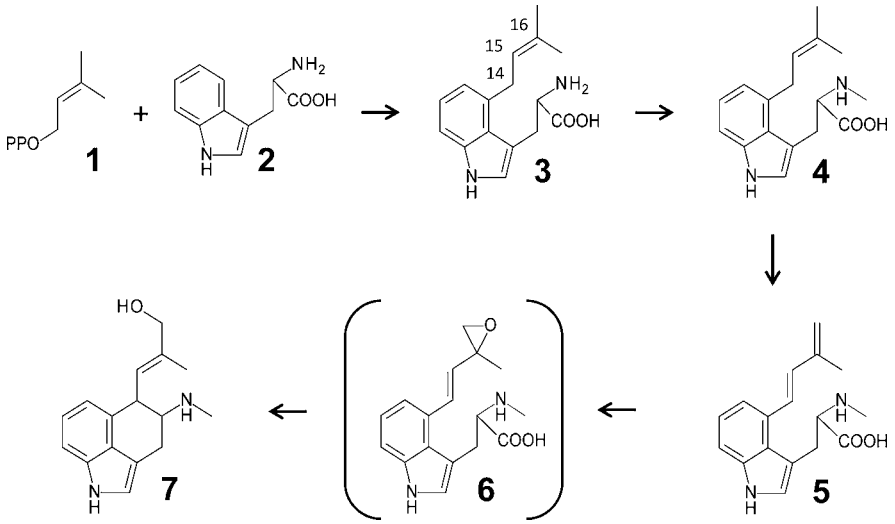

Figure 1. Early steps of ergot alkaloid synthesis (modified from Kozikowski et al.):[16] **1**, dimethlyallylpyrophosphate; **2**, L-tryptophan; **3**, dimethylallyltryptophan; **4**, *N*-methyl-4-dimethylallyltryptophan; **5**, dienyl tryptophan intermediate; **6**, hypothetical epoxide-containing intermediate; **7**, chanoclavine I.

pathway intermediate or byproduct, and whether natural ergot alkaloid producers accumulated this metabolite.

MATERIALS AND METHODS

Large-Scale Extraction and Isolation of Ergot Alkaloids. *Aspergillus nidulans* strain WFC was previously generated by Ryan et al.[11] Cultures were grown on modified ST medium (20 g/L sucrose, 20 g/L tryptone, 1 g/L $MgSO_4$, 2 mL/L trace element solution,[17] 50 mg/L nicotinic acid, 1 g/L tryptophan, 20 mL/L corn steep liquor, and 15 g/L agar) for 7 d at 37 °C. Ergot alkaloids were extracted by incubating fungal mats in 10% aqueous ammonium carbonate (25 mL of solvent per 100 × 15 mm Petri dish) for 2 h, followed by centrifugation at 5000 rpm for 10 min to pellet spores and mycelium. The extract was purified over an Isolute C18 SPE column (500 mg/3 mL) (Biotage, Charlotte, NC) as described previously.[19] Alkaloid X was eluted in 3 mL of 98% methanol/2% (v/v) glacial acetic acid for NMR spectroscopy or in 99.95% methanol/0.05% (v/v) glacial acetic acid for *Aspergillus* feeding studies. For NMR analyses, alkaloid X was purified in batches by analytical high-performance liquid chromatography (HPLC), reapplied to an Isolute C18 column, and, after elution, dried under vacuum. For *Aspergillus* feeding studies, eluate was concentrated to a final volume of 10 μL.

Feeding Studies with Labeled Tryptophan and *A. nidulans* WFC. Ten milligrams of L-tryptophan-d_5 (indole-d_5) or L-tryptophan-*1*-^{13}C (both from Sigma–Aldrich, St. Louis, MO) was dissolved in 1 mL of water, filter-sterilized through a 0.22-μm filter, and added to 99 mL of SYE agar (20 g/L sucrose, 20 g/L yeast extract, 1 g/L $MgSO_4$, 50 mg/L nicotinic acid, and 2 mL/L trace element solution) after autoclaving but prior to solidification of the medium. This medium was inoculated with *A. nidulans* WFC and incubated for 1 week at 37 °C. No deleterious effects of growing *A. nidulans* on these labeled derivatives of tryptophan were noted. Ergot alkaloids were extracted by repeatedly washing the fungal culture surface with 2 mL of methanol. The suspended cultures were incubated in methanol for 30 min, clarified by centrifugation, concentrated in a vacuum centrifuge to 50 μL, and analyzed by electrospray ionization liquid chromatography/mass spectrometry (ESI LC/MS).

Feeding Study with Alkaloid X and *Aspergillus* Mutants. *A. nidulans* strain WFE was described in Ryan et al.,[11] and *A. fumigatus easC* and *easE* knockout mutants were previously generated by Goetz et al.[8] A total of 1 × 10^6 spores was inoculated in 200 μL of liquid sucrose malt medium (15 g/L malt extract broth and 20 g/L sucrose) supplemented with 50 μmol alkaloid X and incubated for 5 days at 37 °C. Ergot alkaloids were extracted by addition of 200 μL of methanol, vortexed briefly, and incubated for 30 min at room temperature, followed by centrifugation for clarification. Samples were then analyzed by HPLC.

Yield of Alkaloid X. *A. nidulans* strain WFC was grown on ST agar for 10 days at 37 °C. One square centimeter (surface area) of fungal culture was vortexed in 400 μL of methanol and incubated for 30 min. The number of spores per microliter of suspension, which is a measure of fungal growth, was counted on a hemacytometer (Hausser Scientific, Horsham, PA). Samples were centrifuged to remove fungal matter, followed by HPLC analysis. Metabolite yield was calculated by comparison of peak areas to an ergonovine (Sigma, St. Louis, MO) standard curve and normalized to the concentration of conidia per microliter.

Extraction of Ergot Alkaloids from *Epichloë* sp.-Infected Grasses. An *lpsA* knockout strain of *Epichloë festucae* var. *lolii* × *Epichloë typhina* isolate Lp1 (henceforth called *E.* sp. Lp1), was previously generated and inoculated into perennial ryegrass (*Lolium perenne*).[18,19] Other *Epichloë* spp.-infected grasses were provided by Christopher Schardl (University of Kentucky). The *Epichloë* species studied included several species recently realigned from the genus *Neotyphodium* that have previously been known by their *Neotyphodium* sp. names.[20] Ergot alkaloids were extracted from fungal-infected grass pseudostems as previously described.[21]

High-Performance Liquid Chromatography. Samples were loaded onto a 150 mm × 4.6 mm i.d., 5-μm ODS3 Prodigy C18 column (Phenomenex, Torrance, CA) and subjected to a gradient of mobile phases A (5% acetonitrile/95% 50 mM ammonium acetate, v/v) and B (75% acetonitrile/25% 50 mM ammonium acetate) as previously described.[21] Ergot alkaloids were detected by their fluorescence at two detector settings: 272 nm excitation and 372 nm emission or 310 nm excitation and 410 nm emission. For purification of alkaloid X, *A. nidulans* WFC extracts purified by Isolute column chromatography were applied to the analytical HPLC column and runoff was collected for 30 s after alkaloid X was visualized by the detectors. Multiple batches (>10) were processed, and runoff was concentrated together for a final yield of 200 μg.

Electrospray Ionization Liquid Chromatography/Mass Spectrometry. For most analyses (other than comparison of alkaloid X from *A. nidulans* WFC to compounds extracted from *Epichloë* sp.-infected grasses), 10 μL of concentrated fungal extract was injected into a Finnigan LCQ DecaXP plus mass spectrometer equipped with a Surveyor HPLC system. Analytes were separated on a 150 mm × 2 mm i.d., 4 μm polar-RP C18 column (Phenomenex) maintained at 30 °C, by combining mobile phases A (5% acetonitrile/0.1% formic acid/94.9% water) and B (75% acetonitrile/0.1% formic acid/24.9% water) as described by Ryan et al.[11] The flow rate was 200 μL/min. Analytes

DOI: 10.1021/jf505718x
J. Agric. Food Chem. 2015, 63, 61−67

were ionized by electrospray ionization in positive mode and were detected by scanning for ions between m/z 200 and 400. MS^2 scans for compounds exhibiting m/z 259.0 also were conducted. For isotope incorporation, m/z intensities were recorded at peak retention time (alkaloid X retention time = 22 min; **4** retention time = 33 min) for the following peaks: m/z 259.0 $[\text{alkaloid X} + \text{H}]^+$; m/z 260.0 $[\text{alkaloid X} + 1 + \text{H}]^+$; m/z 263.0 $[\text{alkaloid X} + 4 + \text{H}]^+$; m/z 287.0 $[\mathbf{4} + \text{H}]^+$; m/z 288.0 $[\mathbf{4} + 1 + \text{H}]^+$; and m/z 291.0 $[\mathbf{4} + 4 + \text{H}]^+$. Eight intensity readings for each metabolite were recorded around peak intensity. Student's t test was performed with JMP (SAS, Cary, NC) to compare sample means of m/z intensity ratios for alkaloid X and **4** between samples grown on labeled **2** supplemented medium and unsupplemented medium.

Analyses of alkaloid X from *A. nidulans* WFC in comparison to compounds extracted from *Epichloë* sp.-infected grasses were conducted with different instrumentation and methods. Concentrated sample (20 μL) was analyzed on a ThermoScientific Q Exactive mass spectrometer (ThermoScientific, Waltham, MA). Analytes were separated on a 50 × 2.1 mm i.d., 1.9-μm particle size, end-capped, Hypersil Gold column (Thermo Scientific) maintained at 30 °C, by combining mobile phases A (5% acetonitrile/0.1% formic acid/94.9% water) and B (75% acetonitrile/0.1% formic acid/24.9% water) over a 10 min linear gradient of 0−100% B. The flow rate was 300 μL/min. Analytes were ionized by electrospray ionization in positive mode and were detected by scanning for ions between m/z 200 and 400. Alkaloid X had an accurate mass of 258.17337 Da, which deviated by only 0.62 ppm from the theoretical mass of $C_{16}H_{22}N_2O$.

NMR Measurements. One- and two-dimensional (1D and 2D) NMR spectra were recorded on a Varian Inova 600 MHz spectrometer at 25 °C operating at 599.67 and 150.79 MHz for proton and carbon, respectively, and equipped with a triple-resonance z-axis pulsed field gradient 5-mm probe. Sample concentration was 0.2 mg/0.7 mL (0.001 M). The free induction decays (FIDs) of the 1D and 2D NMR spectra were processed by use of the commercially available NMR software package ACD/SpecManager, Product Version 12 (Advanced Chemistry Development, Inc., Toronto, Ontario, Canada). ^{1}H NMR chemical shifts are reported relative to the tetramethylsilane (TMS) internal standard peak at 0 ppm. ^{13}C NMR chemical shifts are reported in deuterated dimethyl sulfoxide (DMSO-d_6) relative to the central peak of the septet set to 39.5 ppm. Typical parameters for acquiring ^{1}H NMR spectra were as follows: spectral width 7807.16 Hz, acquisition time 4.0 s, pulse width 3.16 μs (45°), relaxation time 2 s, and number of transients 128. The parameters for the gradient-selected 1D total correlation spectroscopy (TOCSY) were applied by use of the TOCSY1D program with spectral width 7807.16 Hz, acquisition time 4.0 s, pulse width 9.5 μs (90°), relaxation time 1 s, mixing time 80 ms, and number of transients 128. The FIDs were processed with a line broadening (lb) function of 1 Hz. The gradient-selected gCOSY spectra were acquired over both $F2$ and $F1$ with spectral width 7807.16 Hz, pulse width 9.0 μs (90°), relaxation delay 1 s, and 512 time increments of 64 transients each in magnitude mode. The FIDs were zero-filled to give a 4K × 4K data matrix, and a sine-bell function was applied in both dimensions ($F1$ and $F2$) prior to Fourier transformations giving a digital resolution of 3.81 Hz. Adiabatic versions of gradient-selected heteronuclear single quantum coherence (gHSQCAD) and heteronuclear multiple-bond correlation (gHMBCAD) spectra were acquired in phase-sensitive mode with spectral widths of 7807.16 kHz for ^{1}H ($F2$ dimension) and 37 700 Hz for ^{13}C ($F1$ dimension) by using a 2048 × 512 data matrix size and 128 transients for each $t1$ value. The carbon decoupler 90° pulse width was 10.4 μs, and one-bond coupling *j1xh* was set to 145 Hz. For evolution of long-range correlation, the multiple-bond CH coupling constant *jnxh* was set to 8 Hz and relaxation delay was set to 1.5 s. The FIDs of proton-detected gHSQCAD were processed with a Gaussian weighting function in both dimensions, whereas the FIDs of proton-detected gHMBCAD were processed with a sine-bell weighting function in $F2$ and with a Gaussian weighting function in $F1$ (carbon dimension).

NMR parameters (chemical shifts and coupling constants) for alkaloid X were determined by iterative analysis by use of the gNMR program. As starting data, the iterative process used ^{1}H NMR chemical shifts and coupling constants estimated from the experimental spectra.

RESULTS AND DISCUSSION

Insights on the Structure of Alkaloid X. *Aspergillus nidulans* WFC cultures grown on ST medium with or without d_5-labeled tryptophan, **2**, were analyzed by ESI LC/MS for the incorporation of deuterated **2** into alkaloid X as well as into the known ergot alkaloid intermediate *N*-methyl-4-dimethylallyltryptophan, **4**. During the first step of ergot alkaloid synthesis, DmaW replaces a deuterium on indole carbon 5 with a prenyl group, resulting in accumulation of ions with m/z values consistent with $[\text{M} + 4 + \text{H}]^+$ rather than $[\text{M} + 5 + \text{H}]^+$ in cultures supplemented with d_5-labeled **2**. Fungal cultures grown on medium supplemented with d_5-labeled **2** contained a significantly higher ratio of intensity values of m/z 291.0 $[\mathbf{4} + 4 + \text{H}]^+$ to m/z 287.0 $[\mathbf{4} + \text{H}]^+$ compared to control cultures grown on medium lacking d_5-labeled **2** (Figure 2). Similarly,

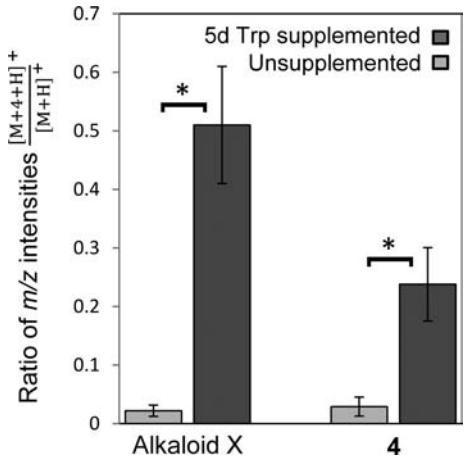

Figure 2. Derivation of alkaloid X, **8**, from L-tryptophan, **2**. Incorporation of four **2**-derived deuterium atoms into alkaloid X and *N*-methyl-4-dimethylallyltryptophan, **4**, was measured by recording intensity values for compounds with m/z 259.0 and 263.0 (for alkaloid X) and m/z 287.0 and 291.0 (for **4**). Error bars represent the standard error. Statistical significance in Student's t test is represented by * ($P < 0.05$).

extracts from fungi grown on medium supplemented with d_5-labeled **2** had a significantly higher ratio of intensity values of m/z 263.0 $[\text{alkaloid X} + 4 + \text{H}]^+$ to m/z 259.0 $[\text{alkaloid X} + \text{H}]^+$, compared to controls (Figure 2). In conjunction with genetic data that demonstrated accumulation of alkaloid X is dependent on expression of three ergot alkaloid biosynthesis genes,[11] the incorporation of deuterated **2** into alkaloid X confirms the new alkaloid is a derivative of **2**, and the accretion of m/z values consistent with $[\text{M} + 4 + \text{H}]^+$ rather than $[\text{M} + 5 + \text{H}]^+$, similar to what was observed with **4**, supports its membership in the ergot alkaloid family.

Based on high-resolution ESI LC/MS analyses, alkaloid X has a molecular formula of $C_{16}H_{22}N_2O$. When considered in relation to **4**, the molecular formula of alkaloid X is consistent with loss of the carboxyl group and addition of an oxygen. The absence of the carboxyl group in alkaloid X was tested by culturing *A. nidulans* WFC on medium supplemented with L-tryptophan-*1*-^{13}C. The presence of **4** in these cultures provided a positive control for incorporation of L-tryptophan-*1*-^{13}C. ESI LC/MS analyses of extracts from these cultures showed a

DOI: 10.1021/jf505718x
J. Agric. Food Chem. 2015, 63, 61−67

significantly greater ratio of intensity values of m/z 288.0 $[\mathbf{4} + 1 + H]^+$ to m/z 287.0 $[\mathbf{4} + H]^+$ compared to extracts from nonsupplemented control cultures (Figure 3), consistent with

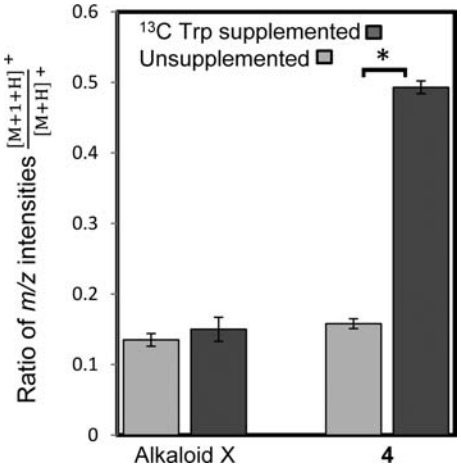

Figure 3. Lack of a carboxyl group derived from L-tryptophan, **2**, in alkaloid X, **8**. The presence of the carboxyl group was investigated by recording intensity values for compounds of m/z 259.0 and 260.0 (for alkaloid X) and compounds of m/z 287.0 and 288.0 (for **4**). Error bars represent standard error. Statistical significance in Student's t test is represented by * ($P < 0.05$).

presence of the **2**-derived carboxyl group in **4**. However, there was no difference in the ratio of intensity values of m/z 260.0 [alkaloid X + 1 + H]$^+$ to m/z 259.0 [alkaloid X + H]$^+$ in cultures grown on supplemented medium compared to controls (Figure 3). The lack of increased ^{13}C isotope incorporation into alkaloid X demonstrated the absence of the carboxyl group derived from **2** in the compound.

When genetic data on the origin of alkaloid X[11] are considered along with mass spectrometric, labeling, and fluorescence data, certain aspects of the structure of the compound can be proposed. The compound appears to be a derivative of **4**, containing a double bond conjugated to the indole ring, and lacking the carboxyl group. The compound also has an additional oxygen, which we hypothesized was located on the dimethylallyl-derived carbon 16 (customarily called carbon 8 in ergot alkaloids) as seen in **8** (Figure 4). Oxidation of **4** at this position would result in the double bond shifting

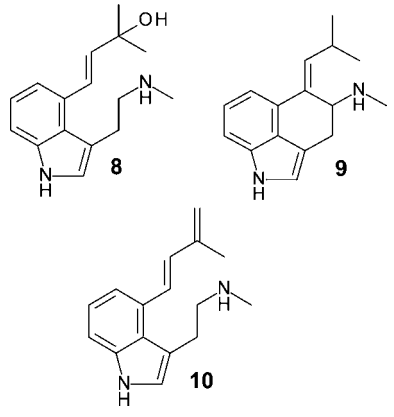

Figure 4. Chemical structures of alkaloid X or ergotryptamine, **8**; the previously proposed[19] 6,7-secolysergine, **9**; and the dehydrated derivative, **10**, of ergotryptamine.

from the 15,16 position to the 14,15 position (conjugated to the indole ring), accounting for the fluorescent properties of the molecule.

Structural Elucidation of Alkaloid X by NMR Techniques. Both 1D and 2D NMR techniques, including ^{1}H 1D TOCSY, gradient-selected ^{1}H−^{1}H gCOSY, and adiabatic versions of proton-detected gHSQCAD and gHMBCAD experiments, were used to investigate the chemical structure of alkaloid X, more specifically to identify the positions of the hydroxyl group and carbon double bond. In order to support the structural integrity of the new metabolite, ^{1}H and ^{13}C NMR spectra of **2** acquired in DMSO-d_6 were accomplished with the aid of 2D NMR techniques including gCOSY, gHSQCAD, and gHMBCAD. The lack of downfield proton H5 (δ 7.57) of the indole moiety of **2** confirms H5 substitution by the prenyl group (Figure 5). The ^{13}C NMR spectrum of alkaloid X was not acquired due to insufficient quantities (concentration 0.001 M). *A. nidulans* WFC cultures produced a low concentration of alkaloid X, with an average yield of 58 fg/spore.

The ^{1}H NMR spectrum (Figure 5) of alkaloid X in DMSO-d_6 exhibited four distinct aromatic protons downfield of the indole moiety at δ 7.10 (doublet, J = 2.4 Hz), δ 7.20 (doublet of doublets, J = 7.5, 0.8 Hz), δ 6.99 (doublet of doublets, J = 7.9, 7.5 Hz), and δ 7.01 (doublet of doublets, J = 7.9, 0.8 Hz) assigned as H2, H6, H7, and H8, respectively. Proton−proton connectivity (H6−H7−H8) through three bonds deduced from gCOSY spectrum was supported by 1D TOCSY experimental subspectra. Similarly, the contour plot of the gCOSY spectrum revealed cross peaks between the doublets, integrating for one proton each at δ 6.20 and δ 7.17 with a coupling constant of $^3J_{trans}$= 15.8 Hz, which were assigned to H14 and H15, respectively. Two upfield singlets integrating for six and three protons at δ 1.31 and 2.33, respectively were assigned to H13, H17, and H18. In the ^{1}H NMR spectrum, two aliphatic methylene (CH_2) protons appeared at δ 2.77 (triplet, J = 7.5 Hz) and δ 2.98 (triplet, J = 7.5 Hz). The chemical shift assignments of these methylene protons (10-CH_2 and 11-CH_2) were based on the observed two- and three-bond gHMBCAD correlations. The methylene protons at δ 2.98 showed long-range correlations to the carbon resonances C2, C3, and C4 of the indole moiety at δ 123.75, 113.80, and 124.24, respectively, and this peak at δ 2.98 was immediately assigned to the 10-CH_2. Due to unresolved coupling between 16-CH_3 and H15, the doublet lines at δ 7.17 were broadened and it was assigned to H15. Similarly, the doublet of doublets at δ 7.01 is broadened due to unresolved small couplings ($^5J_{HH}$) and was assigned to H8. Unambiguous assignments of H6 and H8 can be also accomplished by use of double pulsed field gradient spin echo nuclear Overhauser effect (DPFGSE NOE) spectra. Since the concentration of alkaloid X was very low (0.001 M, or 0.2 mg/0.7 mL), this experiment was not performed. NH (position 12) and OH protons are exchangeable with water in solution and consequently did not appear in the ^{1}H NMR spectrum. However, the NH (position 1) proton of the indole ring showed a broad singlet at δ 10.80. The assigned NMR parameters [^{1}H and ^{13}C chemical shifts (δ, in parts per million, ppm) and coupling constants (J, in hertz, Hz)] are listed in Table 1.

Utilization of gradient-selected 1D TOCSY experiment permitted a sequential assignment of the spin systems for different structural segments [(C_{10}−C_{11}), (C_6−C_7−C_8), and

(C_{14}−C_{15})] of alkaloid X by means of bond connectivities. Use of the 1D TOCSY technique removed all undesired proton frequencies and gave a clean, selective excitation ^{1}H NMR subspectrum. All selective excitation subspectra showed only those hydrogens that are in the same ^{1}H coupling network.

Once all proton connectivities were established, an iterative procedure was used to extract precise values of coupling constants for resonances of each proton (Figure 5). The determined values of couplings derived from the experimental ^{1}H NMR spectrum were used as starting couplings for an iteration of multiplicity patterns for each proton peak, generating accurate values of coupling constants. A good match between calculated and experimental splitting patterns of these protons confirmed their chemical shift assignments are correct.

A gradient version of proton-detected gHSQCAD spectrum was recorded to identify proton-bearing carbons (2-CH, 6-CH, 7-CH, 8-CH, 10-CH_2, 11-CH_2, 13-CH_3, 14-CH, 15-CH, 17-CH_3, and 18-CH_3) on the basis of one-bond correlations. The assignment of five quaternary carbons (C3, C4, C5, C9, and C16) was extracted on the basis of two ($^2J_{H-C}$) or three ($^3J_{H-C}$) gHMBCAD correlations. The contour plot of the gHMBCAD spectrum revealed a two-bond correlation between 16-CH_3 at δ 1.31 and carbon peak at δ 69.62, which is a typical chemical shift for tertiary carbon atom connected to OH group.

Complementary to the MS data, the analysis of 1D and 2D NMR spectra confirm that alkaloid X is compound **8** (Figure 4). This unique ergot alkaloid produced by *A. nidulans* WFC, (3*E*)-2-methyl-4-{3-[2-(methylamino)ethyl]-1*H*-indol-4-yl}-but-3-en-2-ol, was given the trivial name ergotryptamine due to its origin in the ergot alkaloid pathway and its structural similarity to tryptamine.

Role of Ergotryptamine (Alkaloid X) in the Ergot Alkaloid Pathway. Ergotryptamine, **8**, is a new member of the ergot alkaloid family. Genetic data[11] indicate that **8** is derived from **4**. Structural data reveal that **8** is a bicyclic ergot alkaloid lacking the carboxyl group found in precursor **4**. The biochemical scheme proposed for synthesis of chanoclavine I, **7** (Figure 1), suggests that decarboxylation coincides with closure of the third ergoline ring.[16] Here we show that decarboxylation can occur without ring closure, revealing that under some conditions these events may occur via independent reactions. Through comparison of ergot alkaloid profiles of *A. nidulans* WFE and *A. nidulans* WFC (which differ only in the presence of EasC versus EasE and the accumulation of **8** exclusively in *A. nidulans* WFC), we propose that decarboxylation of **4** or its oxidized derivative requires EasC. Enzymatic studies need to be performed to test the hypothesis that EasC can act as a decarboxylase.

DOI: 10.1021/jf505718x
J. Agric. Food Chem. 2015, 63, 61−67

The role of **8** as a pathway intermediate or byproduct was tested by feeding the metabolite to *Aspergillus* mutants, followed by HPLC analyses for the detection of downstream pathway products. *A. nidulans* WFE transformants and *A. fumigatus easC* knockout (ko) and *A. fumigatus easE* ko strains, all of which contain downstream pathway enzymes, failed to turn over **8**. These data indicate that **8** accumulates as a pathway byproduct (or spur product) that is incapable of being enzymatically converted to **7** or other pathway products.

Accumulation of Ergotryptamine in *Epichloë* Species and Equivalency with Provisional 6,7-Secolysergine. HPLC analyses revealed that ergotryptamine, **8**, displayed the same retention time (41 min) and fluorescence properties as a molecule previously observed in *E.* sp. Lp1 and provisionally named 6,7-secolysergine, **9**.[19] (Figures 4 and 6). This molecule

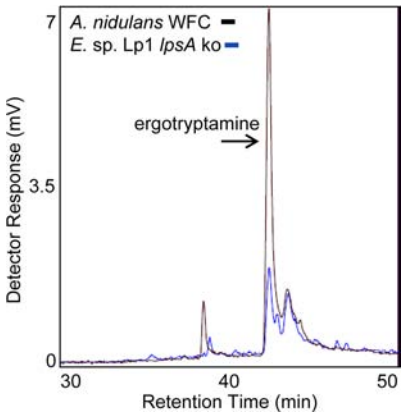

Figure 6. Accumulation of ergotryptamine, **8**, in *E. sp.* Lp1 *lpsA* ko. Ergot alkaloids produced by *A. nidulans* WFC (black) and *E.* sp. Lp1 *lpsA* ko-infected perennial ryegrass (blue) were analyzed by HPLC with fluorescence detected via 310 nm excitation and 410 nm emission.

accumulated twice as abundantly in *E.* sp. Lp1 *lpsA* ko as compared to wild-type *E.* sp. Lp1,[19] so extracts of that mutant were studied to test the identity of **8** with provisional **9**. Extracts from *E.* sp. Lp1 *lpsA* ko-infected grasses were analyzed by ESI LC/MS to further investigate potential accumulation of **8**. The Q Exactive high-resolution ESI LC/MS revealed coeluting peaks from *A. nidulans* WFC and *E.* sp. Lp1 *lpsA* ko-infected grasses with near-identical m/z values of 259.18065 and 259.18066 (Figure 7). Ionization of **8** from *A. nidulans* WFC and the coeluting molecule from *E.* sp. Lp1 *lpsA* ko led to an abundance of ionized fragment of m/z 241.17, corresponding to $[\mathbf{8} - H_2O + H]^+$ (Figure 7) and also to the apparent molecular ion previously observed for **9**.[19] This fragment was also visualized during analyses of **8** on the Finnigan LCQ LC/MS used previously and was found to be the dominant ion formed from selective fragmentation of **8**. Extracts from *E.* sp. Lp1 *lpsA* ko-infected grasses displayed similar ratios of m/z 259 parent ion to m/z 241 fragment ion (3.5:1) when compared to **8** from *A. nidulans* WFC (3.7:1). These results demonstrate the accumulation of **8** as a natural product in the fungal endophyte *E.* sp. Lp1 and provide support for the identity of **8** with the provisionally identified **9**. We propose that the apparent molecular ion detected by Panaccione et al.[19] was the dehydrated fragment of ergotryptamine, **10** (Figure 4), and that a provisional structure was proposed for the m/z 241 compound without considering bicyclic ergot alkaloids.

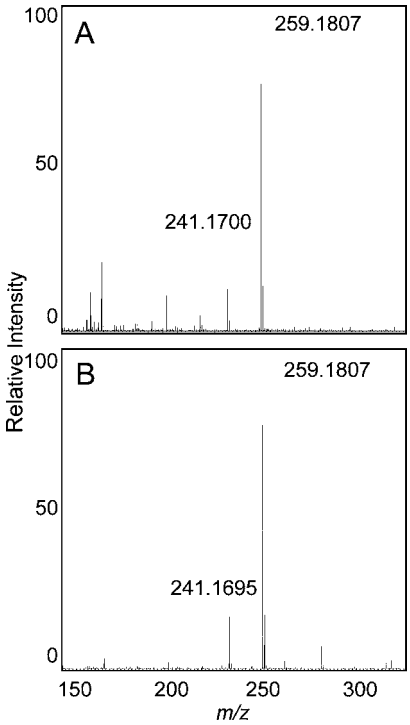

Figure 7. High-resolution ESI LC/MS spectra of ergotryptamine, **8**, in (A) *A. nidulans* WFC and (B) *Epichloë* sp. Lp1 *lpsA* ko-infected perennial ryegrass.

Several other *Epichloë* species contained a metabolite that coeluted with **8** when analyzed by fluorescence HPLC (Table 2). Fungal extracts from two asexual hybrid species, *Epichloë coenophiala* in tall fescue (*Lolium arundinaceum*) and *Epichloë funkii* in sleepy grass (*Achnatherum robustum*), contained an analyte characteristic of **8**. The sexual nonhybrid *Epichloë elymi* produced **8** in its host Canadian wild rye (*Elymus canadensis*). Although the genes necessary for synthesis of **8** are common to all ergot alkaloid producers, the accumulation of this metabolite appears to be species-specific, as we did not detect **8** in multiple extracts of *Epichloë gansuensis* in drunken horse grass (*Epichloë inebrians*) or *Epichloë festucae* var. *lolii* in perennial ryegrass (*Lolium perenne*).

Table 2. Concentrations of Ergotryptamine, 8, in Plants Containing Various *Epichloë* Species

host plant	*Epichloë* species and isolate	no. of samples	**8** (μg/g; mean ± SE)[a]
Lolium arundinaceum	*E. coenophiala* 4163	3	0.16 ± 0.04
Lolium arundinaceum	*E. coenophiala* e19	23	0.27 ± 0.08
Achnatherum robustum	*E. funkii*	5	0.32 ± 0.03
Elymus canadensis	*E. elymi*	2	1.76 ± 0.22
Lolium perenne	*E.* sp. Lp1	3	0.90 ± 0.20
Achnatherum inebrians	*E. gansuensis*	9	nd[b]
Lolium perenne	*E. festucae* var. *lolii*	8	nd

[a]All assays were conducted in the same way with same instrumentation, though tissues were of different ages and harvested at different times of year. [b]nd, not detected.

Agricultural Perspective. Ergot alkaloids cause toxicoses in livestock by interacting with multiple neurotransmitter receptors. The biological activities of ergotryptamine, **8**, are unknown, yet they remain of interest due to the accumulation

DOI: 10.1021/jf505718x
J. Agric. Food Chem. 2015, 63, 61−67

of this metabolite in prominent grass endophytes in the genus *Epichloë*. Feeding preference studies utilizing various mutant *E.* sp. Lp1-infected grasses have shown that rabbits prefer to feed on non-ergot-alkaloid-producing *E.* sp. Lp1 *dmaW* ko infected grasses rather than *E.* sp. Lp1 *lpsA* ko-infected grasses, which contained significant quantities of **7** and **8**.[22] The relative contributions of **8** relative to **7** in this feeding deterrence is unknown. Further research into the biological effects of this metabolite are needed to assess its bioactivity.

Supporting Information

ABSTRACT: The methanol extract of the aerial part of *Triumfetta grandidens* (Tiliaceae) was highly active against *Meloidogyne incognita*, with second-stage juveniles (J2s) mortality of 100% at 500 μg/mL at 48 h post-exposure. Two 4-quinolone alkaloids, waltherione E (**1**), a new alkaloid, and waltherione A (**2**), were isolated and identified as nematicidal compounds through bioassay-guided fractionation and instrumental analysis. The nematicidal activities of the isolated compounds against *M. incognita* were evaluated on the basis of mortality and effect on egg hatching. Compounds **1** and **2** exhibited high mortalities against J2s of *M. incognita*, with EC_{50} values of 0.09 and 0.27 μg/mL at 48 h, respectively. Compounds **1** and **2** also exhibited a considerable inhibitory effect on egg hatching, which inhibited 91.9 and 87.4% of egg hatching, respectively, after 7 days of exposure at a concentration of 1.25 μg/mL. The biological activities of the two 4-quinolone alkaloids were comparable to those of abamectin. In addition, pot experiments using the crude extract of the aerial part of *T. grandidens* showed that it completely suppressed the formation of gall on roots of plants at a concentration of 1000 μg/mL. These results suggest that *T. grandidens* and its bioactive 4-quinolone alkaloids can be used as a potent botanical nematicide in organic agriculture.

KEYWORDS: *Meloidogyne incognita, nematicidal activity, Triumfetta grandidens, 4-quinolone alkaloids*

INTRODUCTION

Nematode infestation is one of the major stresses affecting crop production worldwide. Plant parasitic nematodes, the most devastating pest groups responsible for insidious disease symptoms in different crops, are causing significant economic losses. Estimated annual yield losses in the world's major crops because of plant parasitic nematodes is about 12.3%.[1] Root knot nematodes (RKNs; *Meloidogyne* spp.), plant parasitic nematodes, have caused an estimated annual loss to world crop yields of U.S. $118 billion.[2] *Meloidogyne incognita* (Kofoid and White) Chitwood is regarded as one of the most important species in RKNs.[3] They cause plants to wither through inducing the formation of giant cells in roots of infected plants and taking nutrients from host plant roots. In addition, they cause physiological plant disorders by aiding infection of pathogenic microorganisms.

It is difficult to control RKNs because they spend their lives in the soil or plant roots. The nematode cuticle and other surface organizations make it difficult for many organic molecules to pass through.[4] Even though many synthetic nematicides, such as methyl bromide, aldicarb, and oxamyl, can be used to control RKNs, most of them are considerably toxic or volatile. Methyl bromide, the most widely used fumigant, faces prohibition of use in 2015 because of its ozone depletion and human health concern in most countries.[5,6] The demand for environmentally acceptable nematicides that can be applied in organic farm is increasing.[7] Thus, a search for alternatives, such as botanical nematicides, has recently received much attention, even though their toxic effects should be carefully evaluated before commercialization.

Plants are capable of resisting the invasion of plant parasitic nematodes by producing active substances because they live in the soil as stationary organisms.[8] These compounds can be directly used as botanical nematicides or served as templates for chemically synthesized derivatives to enhance their activity and reduce their environmental impact.[4] Plant-derived nematicidal metabolites were chemically classified into aldehydes, ketones, alkaloids, glycosides, glucosinolates, isothiocyanates, limonoids, quassinoids, saponins, phenolics, flavonoids, quinones, piperamides, polyacetylenes, polythienyls, and terpenes.[8] Research on developing phytochemical-based nematicides was attempted

for control of nematodes. Recently, bionematicides derived from plants, such as Sincocin and NemaKILL, were developed using plant extracts and essential oils, respectively.[9] Sincocin, an environmentally friendly pesticide, is able to control citrus nematode, reniform nematode, and cyst nematode. However, it has weak activities against *M. incognita*.[9] NemaKILL, an organic nematicide for the control of soil nematodes of crops, is highly active to RKN and root lesion nematode.

In the search for botanical nematicides from Vietnamese plants, a methanol (MeOH) extract of the aerial part of *Triumfetta grandidens* Hance (Tiliaceae) showed strong activity against *M. incognita*. *Triumfetta* species, widespread across tropical regions, is reported to produce biologically active metabolites, such as triterpenoids, ceramides, alkaloids, triterpenes, polyols, steroids, lupeol, tormentic and oleanolic acids, heptadecanoic acid, β-carotene, and glycosides.[10−17] However, whether they have nematicidal compounds was not clear. Therefore, the purpose of this study was to isolate and identify nematicidal compounds from *T. grandidens* and evaluate their *in vitro* and *in vivo* activities against *M. incognita*.

MATERIALS AND METHODS

Chemicals. Abamectin was purchased from Supelco (Bellefonate, PA). Tween 20 was obtained from Sigma-Aldrich (St. Louis, MO). Sunchungtan 150EC (active ingredients: 30% fosthiazate and 70% surfactant) was purchased from Dongbu Farm Hannong (Daejeon, Korea). All organic solvents used in the study, such as MeOH, ethyl acetate (EtOAc), *n*-butanol (BuOH), chloroform ($CHCl_3$), and acetone, were of analytical grade. They are commercially available from E. Merck (Darmstadt, Germany) or Daejung Chemicals (Siheung, Korea).

Plant Materials. The aerial part of *T. grandidens* was collected by the Department of Phytochemistry, Vietnam Institute of Industrial Chemistry, and dried. Plant species was identified, and voucher specimens were deposited in the laboratory.

Extraction and Isolation of Nematicidal Metabolites. The dried material of *T. grandidens* (100 g) was chopped and then extracted twice with 70% MeOH (2 × 3 L) for 24 h at room temperature. The extracts were filtered through a Whatman No. 2 filter paper and concentrated using a rotary evaporator under vacuum to yield crude extracts (11.26 g). The MeOH extract was dissolved in 500 mL of distilled water and then successively partitioned twice with EtOAc and BuOH. The three layers were assayed for nematicidal activity against second-stage juveniles (J2s) of *M. incognita*. Of the three layers, the EtOAc layer showed the strongest nematicidal activity against *M. incognita*. Therefore, the EtOAc layer was used for further isolation of active compounds.

The EtOAc fraction (3.19 g) was subjected to chromatography on a silica gel column (3.5 × 60 cm, Kieselgel 60, 200 g, 70−230 mesh, E. Merck) with elution with $CHCl_3$/MeOH (95:5, v/v), yielding 11 fractions, F1−F11. The fractions were monitored using thin-layer chromatography (TLC) with the developing solvent $CHCl_3$/MeOH (9:1, v/v). The TLC plate used was a Kieselgel 60GF 254 with 0.25 mm layer thickness (E. Merck). The nematicidal activity of the fractions were also performed using the second-stage juvenile (J2s) of *M. incognita*. The active spot was detected by ultraviolet (UV) light (254 nm) at a R_f value of 0.4. Five fractions (F4−F8) containing the active spot were combined. The combined F4−F8 fractions (454.5 mg) were subjected to Sephadex LH 20 column chromatography. The column used was a 62 × 2.8 cm inner diameter, glass column, which was packed with 70 g of Sephadex LH20 resin (70−100 μm, Sigma-Aldrich, Vienna, Austria) and eluted with methylene chloride/*n*-hexane/MeOH (5:5:1, v/v/v). It yielded four fractions named F4-1−F4-4. The four fractions were combined (49.3 mg) and injected into Shimadzu LC-6AD prep-high-performance liquid chromatography (HPLC) equipped with a SPD-M10AVP photodiode array detector (Shimadzu, Tokyo, Japan). The column for prep-HPLC was a C_{18} reversed-phase column (Atlantis T3, 5 μm, OBD 19 × 250 mm, Waters, Co., Ireland). The solvent system was isocratic of MeOH/0.05% trifluoroacetic acid in water (55:45, v/v) at a flow rate of 3.5 mL/min. Peaks were collected for nematicidal activity bioassays. Eventually, two pure compounds **1** (8.5 mg) and **2** (9.0 mg) were isolated as nematicidal metabolites.

Structure Determination of Nematicidal Metabolites. Chemical structures of the isolated compounds were determined by one- and two-dimensional nuclear magnetic resonance (NMR) spectroscopy and electrospray ionization mass spectrometry (ESI−MS) analyses. ^{1}H and ^{13}C NMR spectra were measured in $CDCl_3$ (Cambridge Isotope Laboratories, Inc., Woburn, MA) with a Bruker AMX-500 spectrometer (Bruker Analytiche Messtechnik Gmbh, Rheinstetten, Germany) at 500 MHz for ^{1}H NMR spectra and 125 MHz for ^{13}C NMR spectra. Chemical shifts were calculated using tetramethylsilane (TMS) as the internal standard. ^{1}H and ^{13}C NMR assignments were supported by ^{1}H−^{1}H correlation spectroscopy (COSY), heteronuclear multiple-quantum coherence (HMQC), nuclear Overhauser effect spectrometry (NOESY), and heteronuclear multiple-bond correlation (HMBC) experiments. ESI−MS analyses were performed on a MSD1100 single-quadruple mass spectrometer equipped with ESI (Hewlett−Packard Co., Palo Alto, CA). The high-resolution molecular mass values of the two compounds were determined by a Synapt G2 HDMS quadrupole time-of-flight (QTOF) mass spectrometer equipped with an electrospray ion source (Waters, Milford, MA).

Nematode Juveniles. *M. incognita* was reared on tomatoes (*Lycopersicum esculentum* Mill. cv. Seokwang) for 2 months in a greenhouse at 25 ± 3 °C. Eggs were collected from infected tomato roots and extracted with 1% NaOCl solutions. The nematode eggs were obtained by passing through a 45 μm sieve. Eggs were collected on a 25 μm sieve. Surface-sterilized eggs were allowed to hatch in modified Bearmann funnels[18] at 28 °C within 5 days to obtain J2s.

Mortality Bioassay. Stock solutions of test materials obtained from aerial parts of *T. grandidens* were prepared using MeOH or acetone as the solvent. The final concentration of organic solvents did not exceed 1% of the volume. In all cases, working solutions were prepared 2 times higher than the test concentration. Nematicidal activities of the MeOH extract and solvent layers were tested at a concentration range of 7.8−500 μg/mL. Purified compounds were tested at a concentration range of 0.02−10 μg/mL. Distilled water containing MeOH or acetone alone was used as a negative control. Abamectin, a natural nematicide, was used as a positive control. Freshly hatched J2s were used within 24 h for the bioassay using 96-well tissue culture plates (Becton Dickinson, Franklin Lakes, NJ). Aliquots of 25 μL of J2s suspensions (about 50) were placed in each well. Working solutions were then added at a ratio of 1:1 (v/v). Plates were smoothly shaken and exposed to 100% of humidity in a plastic box to avoid evaporation of each well. Plates were incubated in the dark at 28 °C. Juveniles were observed under a light microscope after 24, 48, and 72 h after treatment. Nematodes were judged as dead if their bodies were straight with no movement even if physically stimulated with a fine needle. The experiment using pure compound was conducted twice with five replicates, and the other experiments using solvent layers and the fractions obtained during isolation were performed once with three replicates. The value was presented as a percentage of corrected mortality (±standard deviation). Mortality values were corrected according to Abbott's formula.[19]

$$\text{mortality (\%)} = [(\text{mortality percentage in treatment} - \text{mortality percentage in control}) / (100 - \text{mortality percentage in control})] \times 100$$

Hatching Bioassay. Egg suspension was obtained using a sieve combination of 45 and 25 μm mesh sizes. Eggs on the 25 μm sieve were collected in a beaker using distilled water. Approximately 150 eggs in 25 μL of egg suspension were transferred to each well of a 96 well plate, followed by the addition of the working solutions of purified compounds at a ratio of 1:1. Plates were gently mixed and covered with a film to prevent evaporation. The plates were incubated in the

dx.doi.org/10.1021/jf504572h | J. Agric. Food Chem. 2015, 63, 68−74

dark at 28 °C. Nematode egg hatch inhibition rate was assessed with the aid of a light microscope at 3, 7, and 14 days after treatment. Experiments were conducted twice with five replicates. Hatch inhibition (HI) was calculated using the following formula:[20]

$$\mathrm{HI}\ (\%) = [(C - T)/C] \times 100$$

where C and T represented the percentages of egg hatch in the control and treatment, respectively.

Egg hatch was calculated as follows:

$$\text{percentage of egg hatch} = 100 \times \text{juveniles}/[\text{eggs} + \text{juveniles}]$$

***In Vivo* Experiment.** Pot experiments were performed in a greenhouse at 25 °C. A total of 400 g of air-dried and steam-sterilized soil (sand/nursery soil, 1:1, v/v) was added in 9 cm plastic pots. Tomato seedlings grown on clay−loam soil in a greenhouse for 2 weeks were transplanted into the pot. Eggs of *M. incognita* were obtained from the 2 month old tomato roots. About 5000 eggs were applied to the roots of tomato seedlings using a micropipette. The MeOH extract obtained from the aerial part of *T. grandidens* was dissolved in MeOH and then diluted with 0.025% (v/v) Tween 20. Sunchungtan 150EC (active ingredients: 30% fosthiazate and 70% surfactant) was diluted 2000-fold (150 μg/mL fosthiazate) with distilled water and served as a positive control. Negative controls were treated with 0.025% (v/v) Tween 20 containing 5% MeOH. Each sample was treated at a rate of 20 mL/pot by root drench application after inoculating eggs of *M. incognita*. Experiments were performed twice with five replicates. Pots were treated after 2 weeks with 50 mL of a 0.1% solution of 20−20−20 (N−P−K) fertilizer. Experiments were terminated 6 weeks after inoculation. Galling index (GI) was assessed, and a 0−5 galling scale was used, where 0 represents no galls on roots, 1 refers to 1−2 galls per root, 2 indicates 3−10 galls per root, 3 indicates 11−30 galls per root, 4 indicates 31−100 galls per root, and 5 indicates more than 100 galls per root.[21] On the other hand, phytotoxicity, such as deformation, discoloration, and reduced growth of the plant treated, was observed.

Statistical Analysis. One-way analysis of variation (ANOVA) with Turkey's honest significant difference (HSD) test was used for multiple comparisons ($p = 0.05$). The median effective concentration (EC_{50}) values were calculated using Microsoft Excel (version 2010 software). Regression analyses were conducted using a linear regression model implemented in Excel. Statistical analyses were performed using SAS software (version 12.0, SAS Institute, Cary, NC). Statistical difference was considered when a p value was less than 0.05.

RESULTS AND DISCUSSION

Isolation and Identification of Compounds from *T. grandidens*. The MeOH extract of the aerial part of *T. grandidens* exhibited strong nematicidal activity against J2s of *M. incognita*, with 100% mortality at a concentration of 500 μg/mL after 48 h of exposure (Figure 1). To our knowledge, the biological activity of *T. grandidens* has not yet been reported. In this study, we report nematicidal activity of the MeOH extract from the aerial part of *T. grandidens* against *M. incognita*.

To isolate active nematicidal compounds, the MeOH extract was sequentially fractionated with EtOAc and BuOH. Two organic layers and one aqueous layer were tested for their nematicidal activity against *M. incognita* together with MeOH extract. Their activities against J2s of *M. incognita* are summarized in Figure 1. The MeOH extract and the EtOAc and BuOH layers showed dose-dependent activity against J2s. However, the water layer was virtually inactive. The EtOAc layer showed the strongest activity against J2s of *M. incognita*. The EC_{50} values for the EtOAc layer, MeOH extract, and BuOH layer were 8.35, 56.62, and 120.18 μg/mL, respectively.

Bioassay-guided column chromatography with instrumental analyses led to the isolation of two nematicidal compounds

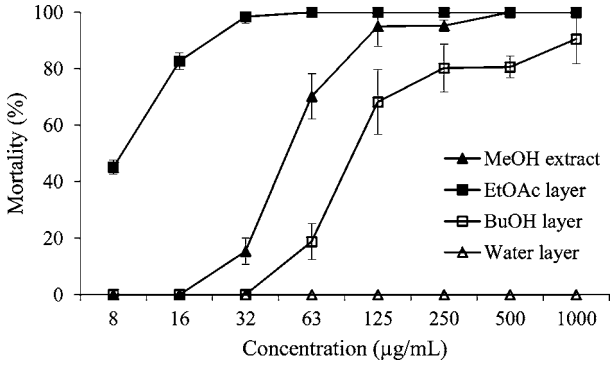

Figure 1. Nematicidal activities of the MeOH extract of the aerial part of *T. grandidens* and its three solvent extracts against the J2s of *M. incognita*. The mortalities were measured 48 h after treatment. Each value represented the mean ± standard deviation from three replicates.

(waltherione A and a new analogue named wlatherione E) from the EtOAc layer of the aerial part of *T. grandidens*.

Compound **1** was obtained as a white amorphous powder. $[\alpha]_D^{25}$ −29.0 (*c* 0.003, $CHCl_3$). ESI−MS *m/z*: 422.06 $[M - H]^-$. ^1H and ^{13}C NMR data are summarized in Table 1, which are similar to those of waltherione A and its analogues.[22−24] Compound **2** was obtained as a white amorphous powder. $[\alpha]_D^{25}$ −25.1 (*c* 0.004, $CHCl_3$). ESI−MS *m/z*: 394.26 $[M + H]^+$. ^1H and ^{13}C NMR spectra are listed in Table 1. These data were in agreement with those of waltherione A reported previously.[22,23]

^{13}C and ^1H NMR, COSY, HSQC, and HMBC spectra and the specific rotation value of compound **2**, waltherione A, were consistent with its reported literature values.[19] High-resolution ESI−QTOF mass spectrometry gave the molecular formula $C_{23}H_{23}NO_5$ ($[M + H]^+$, calcd., *m/z* 394.1654; found, *m/z* 394.1652). ^1H and ^{13}C NMR data of isolated compounds **1** and **2** are summarized in Table 1.

Compound **1**, waltherione E, was obtained as an off-white solid. High-resolution ESI−QTOF mass spectrometry gave the molecular formula $C_{24}H_{25}NO_6$ ($[M + H]^+$, calcd., *m/z* 424.1760; found, *m/z* 424.1756). ^{13}C NMR, distortionless enhancement by polarization transfer (DEPT), and HMQC spectra indicated the presence of 14 aromatic carbons between δ 111.43 and 153.06, carbonyl carbon at δ 171.06, two oxygenated methine carbons at δ 75.62 and 80.11, an oxygenated quaternary carbon at δ 78.06, two methylene carbons at δ 22.22 and 34.06, and three methoxy groups at δ 55.42, 55.86, and 60.46. The ^1H NMR spectrum of compound **1** revealed the presence of five aromatic hydrogens between 5.89 and 7.66 ppm. The ^1H NMR spectrum also revealed four methyl singlets [three at δ 3.95, 3.78, and 3.54 (3C−OMe, 2′C−OMe, and 5′C−OMe) and one at δ 2.46 (2C−Me)], two diastereotopic methylene groups at δ 2.03/2.43 and 2.01/2.33, and two methine hydrogens at δ 4.69 and 6.61. The ^1H NMR spectrum allowed for the assignment of one hydroxyl group at δ 5.12. There was no signal as a result of an amino group, probably because of rapid proton exchange rates. The ^1H and ^{13}C NMR data of compounds **1** and **2** were very similar to each other. However, compound **1** had an additional methoxy group attached to C-5′ (Table 1). ^1H NMR spectra of compound **1** indicated the presence of a trisubstituted benzene spin system, H-3′, H-4′, and H-6′, showing a doublet of a doublet, doublet, and doublet, respectively. In comparison, compound **2** showed a disubstituted benzene spin system. The homonuclear $^1H-^1H$

COSY spectrum of compound **1** did not show a vicinal coupling between C-5′ and C-6′ (at δ 6.70/6.88 ppm), which was observed in compound **2** (Figure 2). Furthermore, HMBC correlation of C-5′ was not observed. The relevant COSY and HMBC correlations in compounds **1** and **2** are shown in Figure 3. Thus, compound **1** was identified as 5-methoxywaltherione A and named waltherione E (Figure 2). It is reported for the first time in this study.

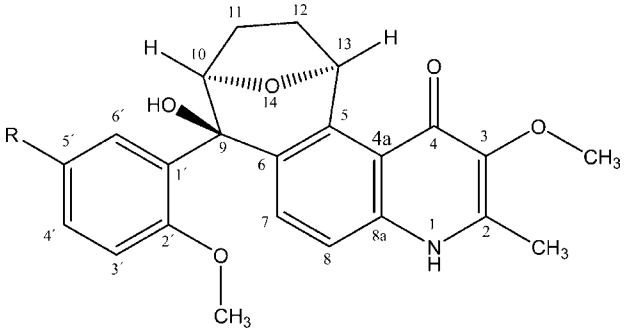

Figure 2. Chemical structures of nematicidal metabolites isolated from the aerial part of *T. grandidens*.

Waltherione A, a 4-quinolone alkaloid compound previously isolated from *Waltheria douradinha*, *Melochia chamaedrys*, and *Melochia odorata*,[23−26] has only been isolated from the Hermannieae tribe of the Sterculiaceae family. To our knowledge, the isolation of 4-quinolone alkaloids, such as waltherione A and E from *T. grandidens* of Tiliaceae, is reported for the first time in this study.

J2s Mortality and Hatch Inhibition of Compounds 1 and 2. The time course effects of the purified nematicidal metabolites on J2s are summarized in Table 2. The two compounds isolated from the aerial part of *T. grandidens* exhibited very strong nematicidal activity at 48 h post-exposure, with EC_{50} values of 0.09 μg/mL for waltherione E and 0.27 μg/mL for waltherione A, which were comparable to the abamectin positive control (EC_{50} = 0.13 μg/mL; Table 2). Nematicidal activities were increased when the exposure time increased to

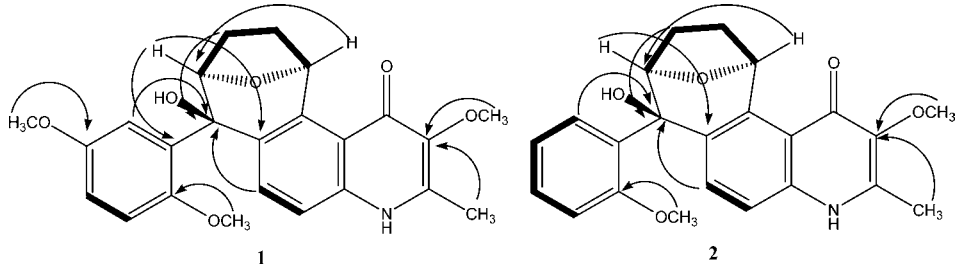

Figure 3. Significant correlation in COSY (solid lines) and HMBC (arrows) spectra of compounds **1** and **2**.

dx.doi.org/10.1021/jf504572h | J. Agric. Food Chem. 2015, 63, 68−74

Table 2. EC_{50} and R^2 Values of Purified Nematicidal Metabolites of *T. grandidnes* and Abamectin against *M. incognita* at 24, 48, and 72 h after Treatment

	EC_{50} (μg/mL)		EC_{50} (μg/mL)		EC_{50} (μg/mL)	
	24 h	R^2	48 h	R^2	72 h	R^2
waltherione E	0.15	0.96	0.09	0.94	0.08	0.96
waltherione A	0.26	0.94	0.27	0.96	0.18	0.95
abamectin	0.96	0.91	0.13	0.95	0.11	0.96

72 h, with EC_{50} values of 0.08 μg/mL for waltherione E and 0.18 μg/mL for waltherione A. The EC_{50} value for abamectin was 0.11 μg/mL at 72 h. These results revealed that waltherione E isolated from *T. grandidens* had a stronger activity than abamectin against J2s of *M. incognita*.

The two 4-quinolone alkaloids isolated from the aerial part of *T. grandidens* have stronger activities compared to other plant-derived compounds based on data reported in the literature. Caboni et al.[5] reported that phthalaldehyde, the most active aldehyde among selected aromatic aldehydes, showed a LC_{50} value of 11 ± 6 μg/mL against J2s of *M. incognita*, followed by salicylaldehyde and cinnamic aldehyde, with LC_{50} values of 11 ± 1 and 12 ± 5 μg/mL, respectively. Le Dang et al.[27] reported that squamosin G among various annonaceous acetogennins from *Annona squamosa* seeds showed nematicidal activity against *M. incognita*, with a LC_{50} value of 0.287 μg/mL after 72 h of exposure.

The two purified compounds in this study also displayed a significant inhibitory effect on egg hatching, with an inhibitory effect of over 90% at a concentration of 1.25 μg/mL on day 7 compared to the negative control (Figure 4), which was similar

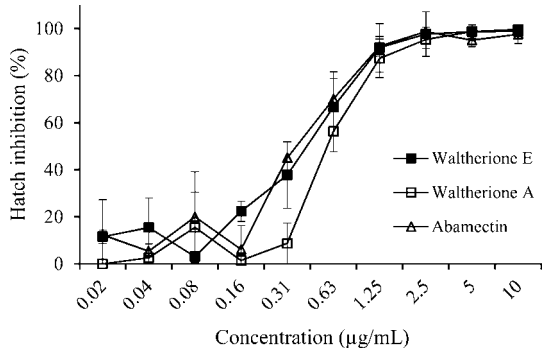

Figure 4. Inhibitory effects of waltherione E and waltherione A on egg hatching of *M. incognita* 7 days after treatment. Each value represented the mean ± standard deviation of two runs with five replicates each.

to that of abamectin. In this study, we clearly demonstrated *in vitro* that the two 4-quinolone alkaloids produced by *T. grandidens* possessed strong killing activities against J2s and an inhibitory effect on egg hatching of *M. incognita*.

Waltherione A was reported to possess antifungal activity against *Candida albicans*, *Cryptococcus neoformans*, and *Saccharomyces cerevisiae* and acetylcholinesterase inhibitory activity.[26,28] In addition, waltherione A and its analogue waltherione C displayed *in vitro* anti-human immunodeficiency virus (HIV) activity.[24] The killing effect on J2s and inhibitory effect on egg hatching of waltherione A and E from *T. grandidens* are reported for the first time in this study. The nematicidal activity of quinolone alkaloids has not been previously reported. Only thiazolidinones based on fluoroquinolone is known to have activities against *Ditylenchus myceliophagus* and *Caenorhabditis elegans*, with LD_{50} values of 210 and 240 μg/mL, respectively.[29]

The mode of action of 4-quinolone alkaloids on nematicidal activity is likely to involve acetylcholinesterase inhibition. Nematode locomotion depends upon an array of various neurons and interneurons employing the neurotransmitters acetylcholine and γ-aminobutyric acid. The effects of acetylcholine can be reduced by numerous acetylcholinesterase inhibitors, such as carbamate and organophosphate nematicides.[30−32] Even though the degree of acetylcholinesterase inhibition and nematicidal activity of the carbamate and organophosphate pesticides does not always correlate,[33,34] there is a general agreement that their toxic action upon nematodes is caused by their ability to inhibit acetylcholinesterase.[31,35,36] However, other mechanisms of the two 4-quinolone alkaloids involved in their nematicidal activity against *M. incognita* should also be considered.[33,34]

***In Vivo* Experiments.** Disease control efficacy of the MeOH extract of the aerial part of *T. grandidens* was evaluated *in vivo* using the GI index and compared to Sunchungtan, a commercial nematicide with fosthiazate as the active ingredient. The crude extract of *T. grandidens* at concentrations of 500, 1000, and 2000 μg/mL effectively reduced the formation of gall on roots of tomato plants (Figure 5). At concentrations of 1000 and 2000 μg/mL, the MeOH extract completely suppressed gall formation, which was comparable to the efficacy of Sunchungtan. In contrast, control plants had heavily galled roots (Figure 5). No phytotoxic effect of the crude extract to

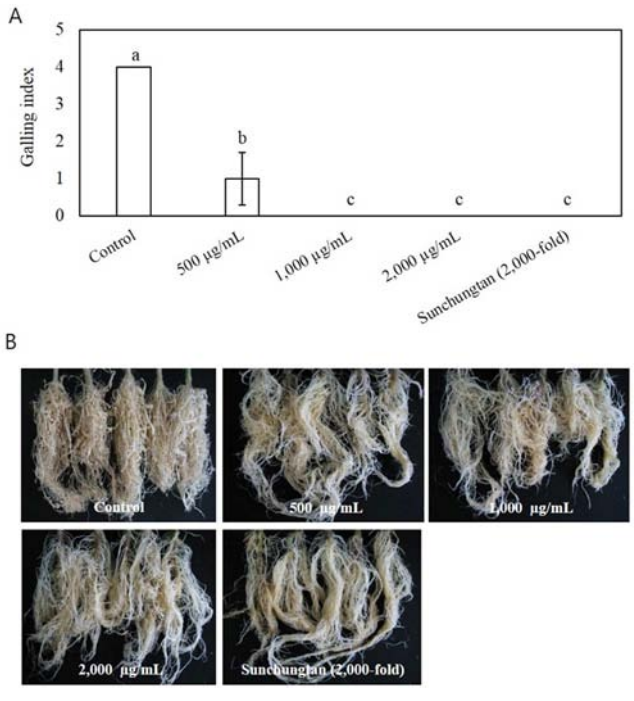

Figure 5. Effect of the MeOH extract from the aerial part of *T. graindidens* at concentrations of 500−2000 μg/mL on (A) gall formation on tomato plant roots by *M. incgonita* and (B) treated plants 6 weeks after inoculation. Sunchungtan (active ingredient 30% fosthiazate), a commercial nematicide, was diluted 2000-fold (150 μg/mL fosthiazate) as a positive control. Values were the mean ± standard deviation of combined results from two experiments with five replicates. Relationships among means were analyzed with one-way ANOVA and Turkey's HSD test (p = 0.05). Means with the same letter were not significantly different.

dx.doi.org/10.1021/jf504572h | J. Agric. Food Chem. 2015, 63, 68−74

the plants was observed. These results indicate that the crude extract of *T. grandidens* has potential as a botanical nematicide.

For the first time, our research has provided potent nematicidal activities of the crude extract of the aerial part of *T. grandidens* and its compounds waltherione E and waltherione A against *M. incognita*. The crude extract of *T. grandidens* effectively suppressed gall formation on tomato plant roots. Thus, our results suggest that the solvent extract of the aerial part of *T. grandidens* and their 4-quinolone alkaloids could be used as botanical nematicides for the control of RKNs.

Potential Toxicity of Phthalic Acid Esters Plasticizer: Interaction of Dimethyl Phthalate with Trypsin in Vitro

Yaping Wang, Guowen Zhang,* and Langhong Wang

State Key Laboratory of Food Science and Technology, Nanchang University, Nanchang 330047, China

ABSTRACT: Dimethyl phthalate (DMP) is widely used as a plasticizer in industrial processes and has been reported to possess potential toxicity to the human body. In this study, the interaction between DMP and trypsin in vitro was investigated. The results of fluorescence, UV−vis, circular dichroism, and Fourier transform infrared spectra along with cyclic voltammetric measurements indicated that the remarkable fluorescence quenching and conformational changes of trypsin resulted from the formation of a DMP−trypsin complex, which was driven mainly by hydrophobic interactions. The molecular docking and trypsin activity assay showed that DMP primarily interacted with the catalytic triad of trypsin and led to the inhibition of trypsin activity. The dimensions of the individual trypsin molecules were found to become larger after binding with DMP by atomic force microscopy imaging. This study offers a comprehensive picture of DMP−trypsin interaction, which is expected to provide insights into the toxicological effect of DMP.

KEYWORDS: *dimethyl phthalate, trypsin, interaction, spectroscopy, molecular docking, atomic force microscopy*

INTRODUCTION

Phthalic acid esters (PAEs), also known as dialkyl or alkyl aryl esters of 1,2-benzenedi-carboxylic acid, are a class of refractory organic compounds frequently added to plastics to enhance the flexibility of the materials. PAEs also serve as solvents and emulsifiers used in pharmaceuticals, pesticides, health and beauty products, and children's toys.[1,2] Because of their wide applications and growing demand, PAEs have become one of the highest yielding chemicals in the world. Their worldwide production amounts to approximately 6 million tonnes per year.[3] Because of the existence of noncovalent bonds between the phthalate plasticizers and their parent materials, PAEs can be significantly leached into the environment and lead to environmental contamination, which may cause common exposures in the general population.[4] As a kind of environmental endocrine disrupting chemical, PAEs show estrogen effects and a variety of biological toxicity. Investigations have shown that PAEs can reduce fertility and pregnancy rates in humans and animal models and can increase miscarriages and other gestational complications.[5] Epidemiologic studies have also found that early phthalate exposure can induce neurodevelopmental damage.[6] Moreover, they are suspected to cause liver, kidney, and thyroid gland tissue damage.[7] Some PAEs, such as dimethyl phthalate, diethyl phthalate, dibutyl phthalate, benzylbutyl phthalate, and di(2-ethylhexyl) phthalate, have been classified as priority environmental pollutants by the U.S. Environmental Protection Agency, European Union, and the China National Environmental Monitoring Center.[8] In recent years, excess of some PAEs has been detected sometimes in liquor and beverage in China, and their safety has attracted much attention, thus most PAEs have been listed as kinds of illegal food additives by the Ministry of Health, China.

Dimethyl phthalate (DMP, structure shown in Figure 1A) is one of the most frequently used PAEs. The impact of this chemical on the environment and its toxicity to living organisms is of great concern. DMP and its intermediates are suspected to be responsible for functional disturbances in the nervous systems and liver in animals.[9] Known for endocrine-disrupting and estrogenic activity, it may also promote chromosome injuries in human leucocytes and can interfere with the reproductive system and normal development of animals and humans.[10] Dillingham et al. have reported that DMP exhibited teratogenicity, mutagenicity, and cellular toxicity.[11] Additionally, repeated inhalation of the vapor of DMP will cause irritation of the nasal mucous membrane and lead to noticeable kidney damage.[12]

Proteinases are a kind of important protein that can cleave the covalent peptide bond between amino acids and play an important role in many biologically relevant processes.[13] As a water-soluble globular protein, trypsin belongs to a serine protease that cleaves peptide bonds at the carboxylic groups of lysine, arginine, and ornithine. This enzyme is excreted by the pancreas into the small intestine and takes part in the digestion of food proteins and other biological processes in vertebrates. Trypsin is a medium-sized protein owning 223 amino acid residues, with a molecular weight of 23.5 kDa,[14,15] and contains two domains of nearly equal size connected by six disulfide bonds. Every domain has six antiparallel β-foldings, and the active sites of trypsin are the catalytic triad, His 57, Asp 102, and Ser 195, located between the two domains.[16,17] Trypsin is often used as an important model of the digestive proteases to investigate the interactions of small molecules with proteins; it plays an essential role in digestion deconstruction of food. When DMP enters the human gastrointestinal tract, the digestive proteases may be the indirect binding targets, and there might be interaction between DMP and trypsin. The binding of some exogenous environmental pollutants with

trypsin can affect the conformation as well as the activity of trypsin and then cause the pathological changes in human body.

Wang et al. reported that the in vitro interaction of a widely used dye acid yellow 23 with trypsin induced the conformational changes of trypsin and led to the inhibition of enzyme activity.[18] To the best of our knowledge, no investigation on the interaction of DMP with trypsin has been previously reported; thus, exploring the DMP–trypsin interaction is significantly important because of the contribution to the understanding of the toxicity mechanism of DMP at the molecular level.

The present study was focused on the binding interaction between DMP and trypsin in physiological buffer (pH 7.4) with the use of a combination of spectroscopic, atomic force microscopy (AFM), cyclic voltammetric (CV), and molecular modeling approaches. The binding mode, binding site, and thermodynamic parameters of DMP with trypsin were characterized, and the conformational changes of trypsin induced by DMP were determined.

MATERIALS AND METHODS

Materials. Trypsin from bovine pancreas was purchased from Sigma Chemical Co., (St. Louis, MO); its stock solution (1.0 × 10^{-4} mol L^{-1}) was prepared by dissolving its crystals (11.8 mg) in 5 mL of Tris–HCl buffer (0.05 mol L^{-1} Tris base, 0.05 mol L^{-1} HCl, and 0.1 mol L^{-1} NaCl, pH 7.4) and then diluted to the required concentrations with the buffer. DMP (purity ≥99.5%) obtained from Aladdin Industrial Co. was prepared as a 1.0 × 10^{-2} mol L^{-1} solution in anhydrous methanol. *N*-α-Benzoyl-*L*-arginine ethyl ester (BAEE, from Aladdin Industrial Co., Shanghai, China) was dissolved in pH 7.4 Tris–HCl buffer to form a 6.0 × 10^{-3} mol L^{-1} solution. All other chemicals were of analytical reagent grade and used without further purification. Ultrapure water was used throughout the experiment.

Fluorescence Measurements. Fluorescence measurements were performed on a Hitachi spectrofluorimeter (Model F-7000, Hitachi, Japan) using a 1.0 cm path length quartz cuvette placed in a thermostat bath. A 3.0 mL solution containing 1.5 × 10^{-6} mol L^{-1} trypsin was titrated by successive additions of 1.0 × 10^{-2} mol L^{-1} DMP stock solution. After the solutions were mixed thoroughly and kept for 5 min, the fluorescence spectra of the solutions were measured in the wavelength range of 300–500 nm upon exciting the samples at 280 nm using 2.5/2.5 nm slit widths. The corresponding emission spectra of free DMP were measured as blanks (i.e., successive addition of DMP solutions into 3.0 mL Tris–HCl buffer) to eliminate background signal. Additionally, fluorescence intensities were corrected for the inner-filter effect before analysis of the binding and quenching data using the relationship[19]

$$F_c = F_m e^{(A_1+A_2)/2} \quad (1)$$

where A_1 and A_2 are the absorbance of DMP at excitation and emission wavelengths, and F_c and F_m represent the corrected and measured fluorescence, respectively. The intensity of fluorescence used in this paper was the corrected fluorescence intensity.

Synchronous fluorescence spectra of trypsin in the absence and presence of DMP were measured by setting the excitation and emission wavelength interval ($\Delta\lambda$) at 15 and 60 nm. The appropriate blank corresponding to the free DMP and buffer was subtracted to correct for background fluorescence.

UV–vis Absorption Measurements. The UV–vis absorbance spectra of trypsin, DMP, and DMP–trypsin mixtures were recorded at room temperature on a Shimadzu UV–2450 spectrophotometer (Shimadzu, Japan) at wavelengths between 200 and 320 nm.

The enzyme activity was measured spectrophotometrically by continuously measuring *N*-α-benzoyl-*L*-arginine (BA) formation at a wavelength of 253 nm with BAEE as the substrate.[20] A series of assay solutions dissolved in 0.05 mol L^{-1} Tris–HCl buffer (pH 7.4) containing different concentrations of DMP and a fixed concentration of trypsin (1.5 × 10^{-6} mol L^{-1}) was prepared and incubated for 3 h at

37 °C (the concentration of methanol was less than 0.03% in the total reaction volume). The assay was initiated by adding the DMP−trypsin complex solution to the substrate (BAEE, 7.0 × 10^{-4} mol L^{-1}), and the absorbance of the mixture at 253 nm was then determined every 20 s at room temperature. The enzymatic activity without DMP was defined as 100%. Relative enzymatic activity (%) = (slope of reaction kinetics equation obtained by reaction with inhibitor)/(slope of reaction kinetics equation obtained by reaction without inhibitor) × 100.[21]

Molecular Simulation. Molecular modeling of the DMP−trypsin complexation was performed using AutoDock 4.2 and AutoDockTools 1.5.6 (ADT). The crystal structure of trypsin (PDB code 2ZQ1) was taken from the Protein Data Bank (http://www.rcsb.org/pdb).[22] Water molecules were removed, polar hydrogens were added, and Kollman united atom partial charges were assigned during protein preparation. The 3D structure of DMP was constructed in Sybyl ×1.1 (Tripos Inc., St. Louis, U.S.), and its energy-minimized conformation was obtained with the help of the MMFF94 force field using MMFF94 charges. During the docking study, a grid box defined to enclose the entire binding site of trypsin with dimensions of 126 Å × 126 Å × 126 Å and a grid spacing of 0.375 Å was used. The Lamarckian genetic algorithm (LGA) was applied to search binding conformations, and a total of 100 runs were carried out during docking simulation.

Atomic Force Microscopy (AFM) Measurements. AFM measurements were carried out in tapping mode using an Asylum Research atomic force microscope (MFP-3D SA) at room temperature. Silicon nitride probes from Olympus (USA) with spring constants of 0.3−4.8 N m^{-1} were used. The tip radius of the probes was 9 ± 2 nm, and rectangular cantilevers with a length of 240 μm were used. The scanning rate was set at 1 Hz. Samples imaged in air were prepared by a drop 5 μL of the trypsin solution in the absence and presence of DMP on freshly cleaved mica at the required concentrations and dried overnight. Images were processed with the Igor Pro 6.3 software package and were presented unfiltered.

Cyclic Voltammetric (CV) Experiments. CV experiments were carried out on a CHI-660B electrochemical workstation (Chenhua Instrumental Company, Shanghai) with a three-electrode system. The working electrode was a glassy carbon disk electrode; an Ag/AgCl electrode was selected as the reference electrode with a Pt wire as the counter electrode. The concentration of DMP was kept at 1.0 × 10^{-5} mol L^{-1}, and the trypsin solution was added at different concentrations in the range of 0−1.5 × 10^{-6} mol L^{-1}. All test solutions were thoroughly deoxygenated by bubbling high-purity nitrogen for 10 min. A stream of nitrogen was blown gently across the surface of the solution in order to maintain the solution anaerobic throughout all the experiments.

Circular Dichroism (CD) Spectra. CD spectra in the far-UV region (190−250 nm) were recorded at room temperature on a Bio-Logic MOS 450 CD spectrometer (Bio-Logic, Claix, France) using a quartz cell with 1 mm path length in pH 7.4 Tris−HCl buffer under constant nitrogen flush. The concentration of trypsin was kept at 1.5 × 10^{-5} mol L^{-1}, while the DMP concentration was varied by keeping the molar ratios of DMP to trypsin as 0:1, 2:1, and 5:1. All of the obtained CD spectra were corrected for buffer signal. The online SELCON3 program (http://dichroweb.cryst.bbk.ac.uk/html/home.shtml) was used to analyze the CD spectroscopic data to obtain the contents of different secondary structures of trypsin.

Fourier Transform Infrared (FT-IR) Measurements. FT-IR spectra were performed on a Thermo Nicolet-5700 FT-IR spectrometer (Thermo Nicolet Co., USA) equipped with a germanium attenuated total reflection (ATR) accessory and a DTGS KBr detector. All spectra were taken via the ATR method with resolution of 4 cm^{-1} and 60 scans. The FT-IR spectra of free trypsin (1.5 × 10^{-5} mol L^{-1}) and DMP−trypsin complex (the molar ratio of DMP to trypsin was kept at 5:1) were recorded in the range of 1800−1400 cm^{-1} at room temperature. The corresponding absorbance contributions of buffer and free DMP solutions were recorded and subtracted with the same instrumental parameters.

RESULTS AND DISCUSSION

Fluorescence Quenching of Trypsin by DMP. Fluorescence quenching of protein usually attributed to a variety of molecular interactions including excited-state reactions, energy transfer, ground-state complex formation, and collisional quenching.[23] As shown in Figure 1, panel A, trypsin displayed a strong emission peak at 347 nm on excitation at 280 nm, and the peak intensity of trypsin decreased gradually with increased amounts of DMP. When the added concentration of DMP reached 1.64 × 10^{-4} mol L^{-1}, nearly 51.7% decrease in the fluorescence intensity of the peak accompanied by a 4 nm red shift was observed, which suggests that DMP interacted with trypsin, and the microenvironment of the fluorescence chromophore of trypsin was altered upon binding with DMP.

Quenching of protein fluorescence induced by a quencher can be classified as either dynamic quenching or static quenching, and the quenching mechanism can be distinguished based on their temperature dependence.[24] To speculate the fluorescence quenching mechanism, the fluorescence titration experiments were carried out at 298, 304, and 310 K, and the data were analyzed by the well-known Stern−Volmer equation:

$$\frac{F_0}{F} = 1 + K_{SV}[Q] = 1 + K_q\tau_0[Q] \quad (2)$$

where F_0 and F represent the fluorescence intensities in the absence and presence of DMP, K_{SV} is the Stern−Volmer dynamic quenching constant, and its value can be determined by linear regression of a plot of F_0/F against $[Q]$. K_q is the quenching rate constant of the biomolecule, $K_q = K_{SV}/\tau_0$. τ_0 is the average lifetime of the fluorophore without quencher (τ_0 = 2.80 × 10^{-9} s),[25] and $[Q]$ is the concentration of DMP.

The Stern−Volmer plots (Figure 1B) obtained at different temperatures showed a good linear relationship, which suggests a single quenching procedure between DMP and trypsin occurred, and the corresponding K_{SV} values for the DMP−trypsin complex are listed in Table 1. An inverse correlation between K_{SV} and temperature (decrease tendency of K_{SV} with increasing temperatures) was observed, which indicates that the probable fluorescence quenching mechanism of trypsin by DMP was initiated by complex formation, namely, static quenching.[26] Moreover, larger K_q values (1.45 × 10^{12}, 1.39 × 10^{12}, and 1.20 × 10^{12} L mol^{-1} s^{-1} at 298 K, 304 K, and 310 K, respectively) for the DMP−tryspin complexation compared to the reported maximum scatter collision quenching constant (2

dx.doi.org/10.1021/jf5046359 | J. Agric. Food Chem. 2015, 63, 75−84

$\times 10^{10}$ mol L^{-1} s^{-1}) also indicated that the quenching process was mainly governed by a static quenching procedure.[27]

Binding Constants and Number of Binding Sites. To further characterize the binding properties of DMP with trypsin, the binding constant K and the number of binding sites n for the DMP−trypsin complex were determined using the following equation:[28]

$$\log \frac{F_0 - F}{F} = n \log K - n \log \frac{1}{[Q_t] - \frac{(F_0 - F)[P_t]}{F_0}} \quad (3)$$

where F_0 and F are the same as in eq 2. $[Q_t]$ and $[P_t]$ stand for the total concentration of the ligand and the protein, respectively. From the intercept and slope of the regression curve of $\log (F_0 - F)/F$ versus $\log 1/([Q_t] - (F_0 - F)[P_t]/F_0)$ (Figure 1C), the values of K and n at the three temperatures were calculated (Table 1). Because of the n values approximately equal to 1, it can be inferred that there was a single class of binding sites on trypsin for DMP. The increasing trend of K with rising temperature suggested that the DMP−tryspin interaction was an endothermic reaction and that the increasing temperature was in favor of this binding.[29] The K value at 298 K was 3.92×10^3 L mol^{-1}, which was similar to that of a previous report on DMP interaction with HSA.[30]

Prediction of Binding Site of DMP on Trypsin. As a serine protease, the enzymatic mechanism of trypsin is similar to that of other serine proteases, with a catalytic triad (His57, Asp102, and Ser195).[31] Trypsin contains the primary substrate-binding pocket (S1 binding pocket) formed by amino acid residues 189−195, 214−220, and 225−228.[32] To predict the binding site of DMP on trypsin, the molecular modeling was employed to simulate the binding mode between DMP and trypsin.

Cluster analysis of 100 docking runs showed a total of nine multimember conformational clusters at a root−mean−square deviation (rmsd) tolerance of 2.0 Å (Figure 2A). The cluster with the lowest binding energy (red histogram in Figure 2A) was found to contain the highest number of the analyzed conformations (38 out of 100), which was the most energetically favorable. Thus, the cluster possessed the lowest energy (−5.12 kcal mol^{-1}), and the most frequent locus was used for binding orientation analysis; the obtained energy information is given in Table 2. The calculated binding Gibbs free energy ($\Delta G_{binding}$ = intermolecular energy + torsional energy) was −5.12 kcal mol^{-1}, which was equal to the predicted binding energy (−5.12 kcal mol^{-1}), which indicates that the docking result was credible.

As shown in Figure 2, panel B, DMP did not bind into the S1 binding pocket of trypsin, while it had a high affinity very close to the active site pocket, especially adjacent to the catalytic residues (His 57, Asp 102, and Ser 195). It was observed that DMP was surrounded by the amino acid residues including Phe41, Cys42, Ala56, His57, Tyr59, Asp102, Met104, Gly193, and Ser195. Moreover, two hydrogen bonds were formed between the oxygen atoms of DMP and the hydrogen atoms on Ser195 and Gly193 of trypsin, and their bond lengths were 1.712 and 2.187 Å, respectively, which suggested the involvement of hydrogen bonding in the DMP−tryspin interaction. The docking results indicated that DMP actually interacted with the catalytic residues located in the region close to the S1 binding pocket of trypsin, and the binding may affect the enzymatic activity.

Thermodynamic Parameters and Binding Forces. A thermodynamic process was considered to be responsible for the formation of a complex considered from the dependence of binding constant on temperature.[33] Therefore, the thermodynamic parameters including enthalpy change ($\Delta H°$), entropy change ($\Delta S°$), and free energy change ($\Delta G°$) of the interaction were analyzed to further characterize the bonding force between DMP and trypsin using the following equations:

$$\log K = -\frac{\Delta H°}{2.303RT} + \frac{\Delta S°}{2.303R} \quad (4)$$

$$\Delta G° = \Delta H° - T\Delta S° \quad (5)$$

where R is the gas constant (8.314 J mol^{-1} K^{-1}), T is the experimental temperature (298, 304, and 310 K), and K is the binding constant at the corresponding temperature. The calculated values of $\Delta H°$, $\Delta S°$, and $\Delta G°$ are summarized in Table 1. The negative signal for $\Delta G°$ showed that the interaction process was spontaneous. The positive $\Delta H°$ and $\Delta S°$ values indicated that hydrophobic interactions played a major role in the binding of DMP to trypsin based on the rule generalized by Ross and Subramanian.[34] It was obvious that the $\Delta G°$ value (−4.91 kcal mol^{-1}) at 298 K was a little larger than the calculated $\Delta G°$ value from molecular modeling. This difference could be explained by the fact that X-ray structure of the protein from crystals was different from that of the aqueous system used in this study.[35]

Table 2. Binding Free Energies of DMP−Trypsin Interaction with the Most Favorable Docking Gesture

complex	intermol energy (kcal mol^{-1})	internal energy (kcal mol^{-1})	torsional energy (kcal mol^{-1})	binding energy (kcal mol^{-1})	$\Delta G_{binding}$ (kcal mol^{-1})
DMP−trypsin	−6.31	−0.53	1.19	−5.12	−5.12

Effect of DMP on Trypsin Activity. As shown in Figure 3, trypsin activity decreased with the incremental addition of DMP, and the enzymatic activity decreased to 62.3% of the initial level when the concentration of DMP reached to 1.0×10^{-4} mol L^{-1}, which indicates that the interaction of DMP with trypsin can inhibit the enzymatic activity. There are two fundamental characteristics about the active site region of trypsin: (i) the catalytic triad composed of amino acid residues His 57, Asp 102, and Ser 195; (ii) the S1 binding pocket was near Ser 195, which can define the cut position of the peptidic bond.[36] If a ligand enters into the hydrophobic pocket or locates near this pocket, the enzymatic activity could be affected.[37] This experimental result further supported the molecular docking studies.

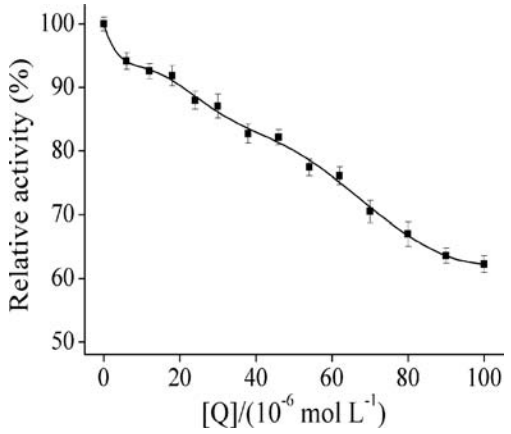

Figure 3. Trypsin activity in the absence and presence of DMP at different concentrations. c(trypsin) = 1.5×10^{-6} mol L^{-1}, and c(BAEE) = 7.0×10^{-4} mol L^{-1}.

Changes in Trypsin Topography. AFM is a very useful imaging technique in visualizing the interaction between small molecules and protein owing to its high resolution. To study the changes in trypsin topography following by the addition of DMP, AFM was performed on the free trypsin and the DMP−trypsin complex in pH 7.4 Tris−HCl buffer.

As shown in Figure 4, panel A, the trypsin was adsorbed evenly on the mica surfaces, and its topography image can be clearly observed. Cross-sectional images of two single trypsin molecules are given. After the widths of 50 single trypsin molecules were averaged, 5.0 nm was obtained for the mean width. The mean height of the individual trypsin molecules adsorbed on mica was determined to be 0.8 nm. This average width was larger than the reported data (3.8 nm) based on X-ray diffraction studies.[38] Upon complexation with DMP, trypsin molecules appeared to be more swollen on the mica substrate (Figure 4B), and the mean width and height of the individual trypsin molecules reached 12.0 and 2.5 nm, respectively. The increase in the size indicated that DMP interacted with trypsin and that a DMP−trypsin complex was formed. After binding with DMP, the stable dispersion of the protein aggregation became more evident in the AFM photograph, which suggests that the formation of the DMP−trypsin complex may cause a major destabilization of the native conformation of trypsin. From the three-dimensional graph of free trypsin and the DMP−trypsin complex (Figure 4C,D), it was clearly observed that the interaction between DMP and trypsin induced the topography image changes of trypsin and aggregation, which may be due to the changes of microenvironment around the trypsin molecule and the enzyme molecule exposing to a more hydrophobic environment after interaction with DMP. To minimize the number of unfavorable factors to form a stable structure, the trypsin molecule reduced its surface area in contact with water by molecular aggregation. The results suggested that hydrophobic interactions existed between trypsin and DMP, which was consistent with that of above thermodynamic analysis.

Electrochemical Behavior of DMP in the Presence of Trypsin. The cyclic voltammograms of DMP in the absence and presence of trypsin are shown in Figure 5. DMP exhibited a deoxidization peak at −0.98 V in pH 7.4 Tris−HCl buffer, which was the characteristic of the electroactive moiety of DMP. When trypsin was added to the DMP solution, a positive shift of the deoxidization peak along with a decrease in peak current was found, and no new peak was observed in the same scan potential range. These results indicated that the binding interaction between DMP and trypsin occurred and the electro−inactive complex was formed.[39] It was difficult for DMP in the complex to make contact with the electrode surface, and the free DMP concentration on the electrode surface was reduced after bonding with trypsin; thus, the peak current was decreased.[40]

Effect of DMP on the Conformation of Trypsin. UV−vis absorbance spectroscopy is widely used to explore the conformational changes of protein and to investigate ligand−protein complex formation. Figure 6 shows the difference of absorption spectra of trypsin after interaction with DMP, which were obtained by subtracting the corresponding absorption spectra of free DMP from those of DMP−trypsin complex. Trypsin has two main absorption peaks located at 205 and 280 nm. The stronger absorption peak at 205 nm reflects the peptide bond absorption peak that is due to the $\pi \rightarrow \pi^*$ transition of trypsin's characteristic polypeptide backbone structure C═O, and the weaker one at 280 nm appears to be due to the absorption of aromatic amino acids.[41] With the addition of DMP to trypsin solution, the peak at 205 nm shifted obviously toward the longer wavelength, and the intensity decreased sharply, which suggests that the binding of DMP to trypsin may cause the conformational change of trypsin. Moreover, decrease in the peak intensity at 280 nm also suggested that the polarity of the microenvironment around Trp and Tyr residues of trypsin was affected by the interaction with DMP.

Alteration in the microenvironment around the fluorophores (Tyr and Trp) of trypsin was further explored by synchronous fluorescence spectra. Figure 7, panels A and B display the effect of the increasing concentrations of DMP on the synchronous fluorescence spectra of trypsin when the scanning interval $\Delta\lambda$ was fixed at 15 and 60 nm, respectively. Upon the addition of DMP, the maximum emission wavelength of Tyr residue at $\Delta\lambda$

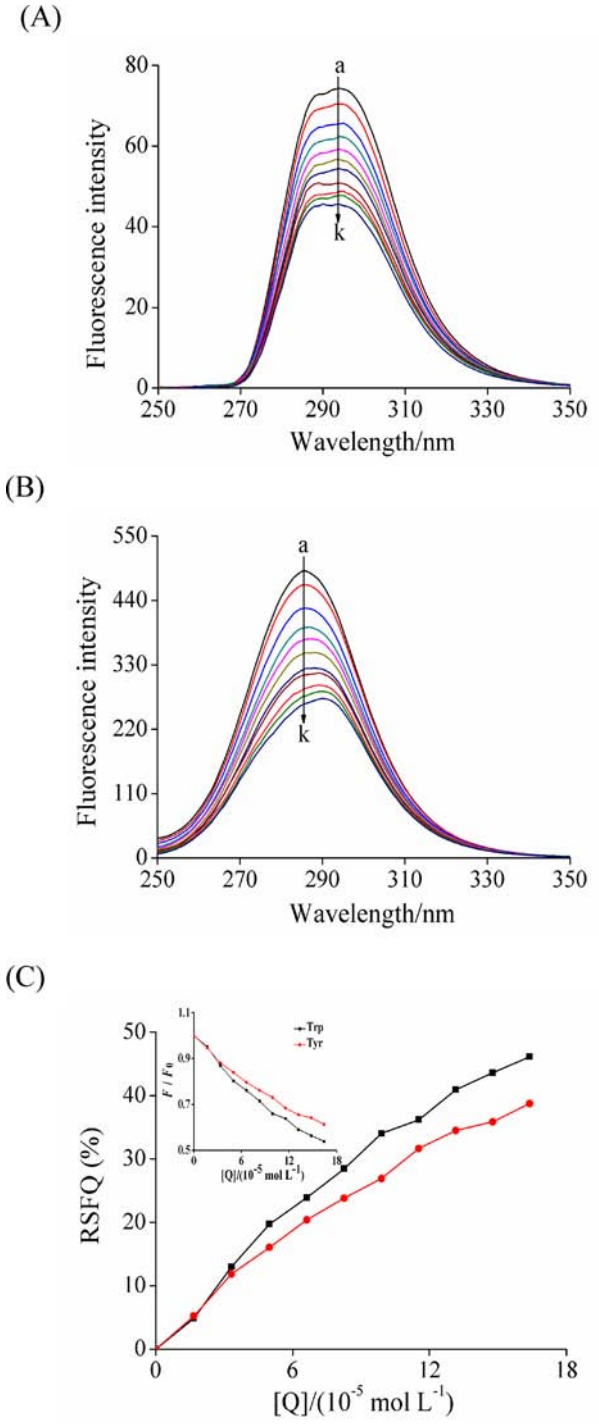

Figure 7. Synchronous fluorescence spectra of trypsin with different concentrations of DMP at (A) $\Delta\lambda$ = 15 nm and (B) $\Delta\lambda$ = 60 nm. c(trypsin) = 1.5 × 10^{-6} mol L^{-1}; c(DMP) = 0, 1.66, 3.32, 4.98, 6.62, 8.26, 9.90, 11.53, 13.16, 14.78, and 16.39 × 10^{-5} mol L^{-1} for curves a → k, respectively. (C) Comparative evaluation of DMP effect on the ratios of synchronous fluorescence quenching (RSFQ) of trypsin.

$\Delta\lambda$ = 60 nm displayed an obvious red shift (from 286−290 nm, shown in Figure 7B), which suggests that the hydrophobicity decreased and the polarity increased around the Trp residue.[42]

The RSFQ were calculated by using the equation RSFQ = 1 − F/F_0 (F_0 and F are the fluorescence intensities of trypsin in the absence and presence of DMP, respectively).[29] As shown in Figure 7, panel C, the data of RFSQ at $\Delta\lambda$ = 60 nm were a little higher than the corresponding ones at $\Delta\lambda$ = 15 nm at the same DMP concentrations, which may be due to more contribution of Trp residue to the quenching of the intrinsic fluorescence, and DMP was closer to Trp compared to Tyr residue.

To detect the possible influence of DMP binding on the secondary structure of trypsin, CD measurements were performed in the absence and presence of different amounts of DMP (Figure 8). The CD spectrum of trypsin exhibited only

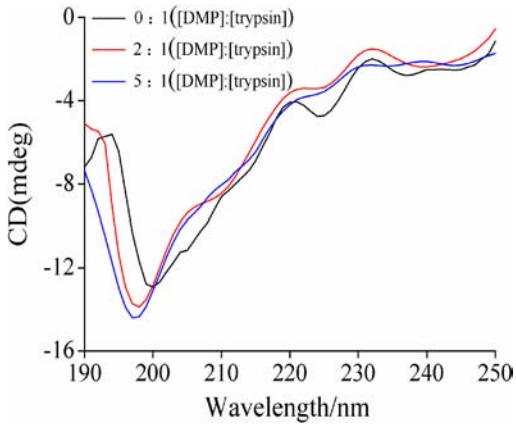

Figure 8. CD spectra of trypsin in the presence of increasing amounts of DMP. c(trypsin) = 1.5 × 10^{-5} mol L^{-1}; the molar ratios of DMP to trypsin were (a) 0:1, (b) 2:1, and (c) 5:1, respectively.

one negative band at 200 nm. Generally, the β-sheet shows a CD band at 210−220 nm; however, the irregular strands in trypsin structure may cause the negative CD band shift from the ideal β-sheet position toward the 200 nm region.[43] With the addition of DMP, the intensity of the negative peak increased with obvious blue shift; similar findings have been reported for the interactions of oxytetracycline and tetracycline with trypsin.[14,44] Then, the CD spectra data were analyzed by the online SELCON3 software, and the contents of different secondary structure of trypsin were obtained and listed in Table 3. The results showed that the β-sheet structure was predominant with a high percentage in trypsin, which was identical to the literature.[45] When the molar ratios of DMP to trypsin increased, a decreasing tendency of the β-sheet and β-turn contents were observed, while the α-helix and random coil contents tended to increase, which indicated that DMP induced the secondary structure changes of trypsin and thus may influence the function of the enzyme.

Infrared spectroscopy is a powerful means for investigating the secondary structures of proteins. The amide I band (1600−1700 cm^{-1}, mainly C═O stretch) and the amide II band (1600−1500 cm^{-1}, C−N stretch coupled with N−H bending mode) are main vibrational bands of the peptide moiety associated with the secondary structure of proteins,[46] and the amide I band is more sensitive to the change of secondary structure of protein than the amide II band.[47] Upon DMP interaction, the FT-IR difference spectra of trypsin [(DMP−trypsin solution) − DMP solution] were obtained to monitor the variation of these vibrations (Figure 9A). It was apparent that the peak position of amide I of trypsin moved from 1640−1646 cm^{-1}, and the one of amide II shifted from 1550−1552 cm^{-1} after addition of DMP, which suggests that DMP interacted with the C═O and C−N groups in the protein polypeptides and caused the rearrangement of the polypeptide carbonyl hydrogen bonding network.[48]

Table 3. Secondary Structural Analysis of Free Trypsin and DMP−Trypsin Systems from CD Data

molar ratio [DMP]:[trypsin]	α-helix (%)	β-sheet (%)	β-turn (%)	random coil (%)
0:1	13.8	43.8	20.6	21.8
2:1	15.9	40.9	20.1	23.1
5:1	17.1	39.1	19.8	24.0

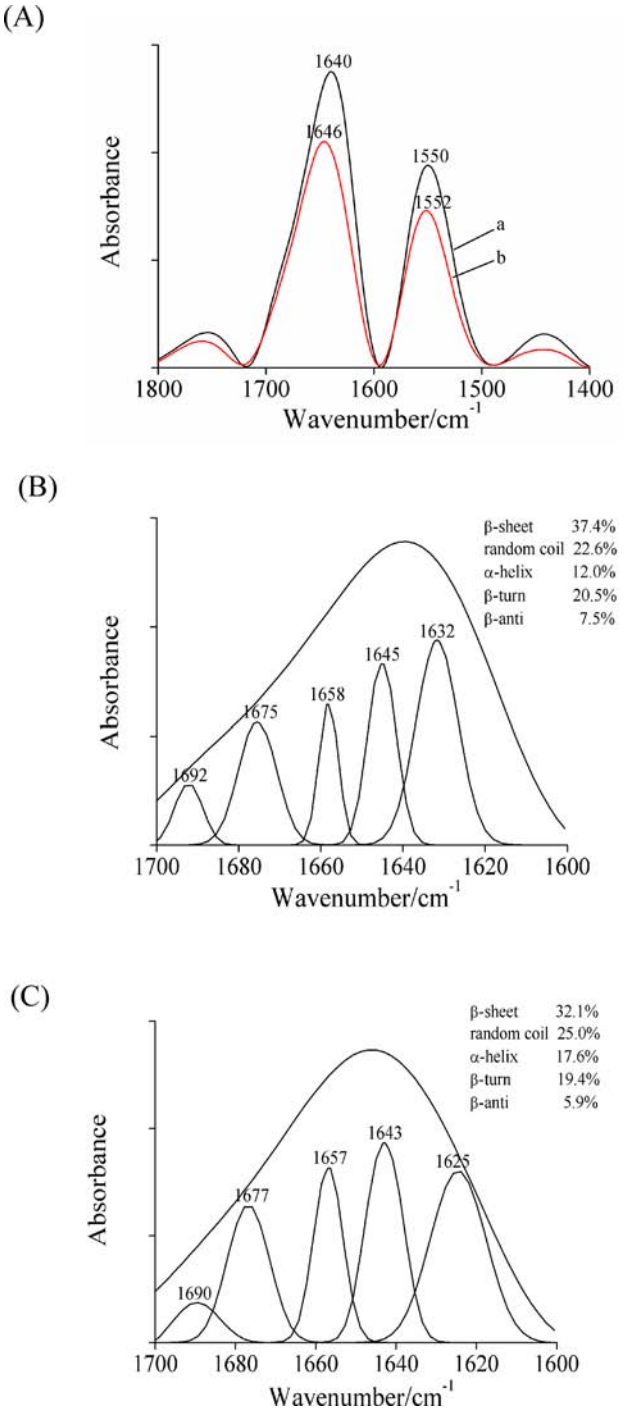

Figure 9. (A) The FT-IR spectra of (a) free trypsin and (b) difference spectra [(DMP−trypsin solution) − DMP solution] at pH 7.4 in the region of 1800−1400 cm^{-1}. c(trypsin) = 1.5 × 10^{-5} mol L^{-1}, c(DMP) = 7.5 × 10^{-5} mol L^{-1}. The curve-fitted amide I region of (B) free trypsin and its (C) DMP complex.

The curve-fitted spectra of trypsin infrared amide I bands before and after the binding with DMP were analyzed to further characterize the secondary structure change of trypsin according to the literature.[49] As shown in Figure 9, panel B, the free trypsin contained β-sheet 37.4% (1632 cm^{-1}), random coil 22.6% (1645 cm^{-1}), α-helix 12.0% (1658 cm^{-1}), β-turn 20.5% (1675 cm^{-1}), and β-antiparallel 7.5% (1692 cm^{-1}). After interaction with DMP ([DMP]:[trypsin] = 5:1), the contents of β-sheet, β-turn, and β-antiparallel reduced from 37.4−32.1%, from 20.5−19.4%, and from 7.5−5.9%, respectively, while the α-helix structure and random coil increased from 12.0−17.6% and from 22.6−25.0%, respectively (Figure 9C). The results indicated that the binding of DMP to trypsin led to the conformational changes of trypsin with an increase of α-helix and random coil stability and loss of β-structure content.

In summary, humans are exposed to thousands of different chemicals each day, and the chemicals may gather in organisms through the food chain and induce acute and chronic toxicity. The contaminants may show their toxicity by interacting with the biological macromolecules and affecting the structure as well as the function of the macromolecules after entering organisms. Hence, exploring the toxic effects and mechanism of contaminants at a molecular level is helpful to perfect the toxicity evaluation system of the contaminants and forecast the related effects on macroorganisms or populations. Also, it will be useful to provide reference and technical support for formulating a reasonable standard to protect human health. Investigation of DMP−trypsin interaction by a combination of fluorescence, UV−vis absorption, circular dichroism, Fourier transform infrared spectroscopic and atomic force microscopy, and cyclic voltammetric and molecular docking approaches revealed that DMP can bind with trypsin to form the DMP−trypsin complex. DMP actually interacted with the catalytic residues (His 57, Asp 102, and Ser 195) located within the region close to the S1 binding pocket of trypsin and resulted in the inhibition of the enzymatic activity. The binding process was primarily driven by hydrophobic interactions, as the values of $\Delta H°$ and $\Delta S°$ were found to be 4.16 kJ mol^{-1} and 82.80 J mol^{-1} K^{-1}, respectively. The binding of DMP to trypsin induced an increase in α-helix and random coil contents and a decrease in β-sheet and β-turn structure and caused the change of surface morphology of trypsin and its molecular aggregation. Additionally, the DMP binding to trypsin weakened the electrochemical signal of DMP to some extent, which confirmed the formation of the DMP−trypsin complex.

Park et al. have reported that exposure of *C. riparius* to a most commonly used plasticizer Di-(2-ethylhexyl) phthalate (DEHP) induced the decrease of the serine-type endopeptidase (SP) gene expression, and the *C. riparius* SP was putatively classified as a chymotrypsin-like protein that was primarily expressed in the gut where pollutants are frequently encountered.[50] Since trypsin belongs to the chymotrypsin superfamily of serine endopeptidases, the changes in gene expression might cause some adverse effects on trypsin by DEHP. Our experimental results indicated that DMP, an analogue of DEHP, can bind to trypsin and affect the structure and function of the enzyme under simulative physiological conditions. Although in vitro results could not completely

dx.doi.org/10.1021/jf5046359 | J. Agric. Food Chem. 2015, 63, 75−84

represent what happens in vivo and the fully biochemical properties of DMP, this study will be helpful to comprehensively understand the mechanism of DMP that affects the conformation and activity of trypsin in biological processes and its toxicity assessment in the environment.

Supporting Information

ABSTRACT: Ferruginol has antifungal activity against wood-rot fungi (basidiomycetes). However, specific research on the antifungal mechanisms of ferruginol is scarce. Two-dimensional gel electrophoresis and fluorescent image analysis were employed to evaluate the differential protein expression of wood-rot fungus *Trametes versicolor* treated with or without ferruginol. Results from protein identification of tryptic peptides via liquid chromatography−electrospray ionization tandem mass spectrometry (LC−ESI-MS/MS) analyses revealed 17 protein assignments with differential expression. Downregulation of cytoskeleton *β*-tubulin 3 indicates that ferruginol has potential to be used as a microtubule-disrupting agent. Downregulation of major facilitator superfamily (MFS)−multiple drug resistance (MDR) transporter and peroxiredoxin TSA1 were observed, suggesting reduction in self-defensive capabilities of *T. versicolor*. In addition, the proteins involved in polypeptide sorting and DNA repair were also downregulated, while heat shock proteins and autophagy-related protein 7 were upregulated. These observations reveal that such cellular dysfunction and damage caused by ferruginol lead to growth inhibition and autophagic cell death of fungi.

KEYWORDS: *antifungal activity, autophagy, basidiomycete, ferruginol, proteomics, Trametes versicolor*

INTRODUCTION

Ferruginol, a phenolic diterpene, is present in resins/exudates and heartwood of many plants, particularly coniferous trees such as *Calocedrus macrolepis* var. *formosana*,[1] *Cryptomeria japonica*,[2] *Taiwania cryptomerioides*,[3] and *Thuja plicata*.[4] In addition, an increasing number of reports revealed that ferruginol has excellent antifungal activities against fungi belonging to the family of basidiomycetes.[3,5,6] The general mechanisms of antifungal actions reviewed by Odds et al.[7] indicated that antifungal agents interfered with the cellular integrity of fungi via several targets including cell wall, cell membrane, microtubule assembly, sterol synthesis, protein synthesis, and DNA/RNA synthesis. Moreover, Ramsdale[8] reported that antifungals/fungicides can induce cell death via programmed cell death (PCD) pathways in pathogenic fungi. These findings revealed that antifungal agents can target specific cellular molecules and further mediate cell-death pathways to inhibit the growth of fungi. Chang et al.[3] examined the antifungal activities of five compounds—ferruginol, helioxanthin, savinin, taiwanin C, and hinokiol—isolated from *T. cryptomerioides* heartwood. They reported that ferruginol has the best antifungal performance against the basidiomycete fungus *Trametes versicolor*. However, specific study on the antifungal actions of ferruginol against basidiomycete fungus is limited.

Proteomics is a research tool for surveying comprehensive information on molecular networks within the living cells. Fungal proteomics has been intensively studied in the last 10 years, and many fungal genomes have been sequenced.[9,10] This tool can be further employed to identify the proteins that participate in regulation networks upon treatment with antifungal reagents or stress conditions.[11] Cagas et al.[12] investigated the proteomic response of an antifungal agent (caspofungin) against ascomycete fungus *Aspergillus fumigatus*. Shimizu et al.[13] used a proteomic differential display technique to identify the responses of basidiomycete fungus *Phanerochaete chrysosporium* to the addition of vanillin. These findings revealed that many cellular enzymes and metabolic shifts were regulated by specific stimulation. The objective of this study is to assess the regulation of cellular molecules at the proteome level of basidiomycete fungus *T. versicolor* upon addition of ferruginol. A proteomic differential display technique using two-dimensional electrophoresis (2DE) was adopted to profile the mechanism.

MATERIALS AND METHODS

Compound and Fungal Strain. Ferruginol was isolated from ethanolic heartwood extracts of a 40-year-old *Taiwania cryptomerioides* Hayata. The wood samples were harvested from the Experimental Forest of National Taiwan University in Nan-Tou County. Air-dried heartwood samples were soaked in 95% ethanol for 7 days. Crude extract was filtered, concentrated, and then lyophilized (yield 6.3%, based on dry weight of heartwood). The ethanolic extracts were fractionated by liquid−liquid partition to yield *n*-hexane-soluble fraction (50.8%), ethyl acetate-soluble fraction (27.0%), *n*-butanol-soluble fraction (1.6%), and water-soluble fraction (9.5%). The *n*-hexane-soluble fraction was divided into nine subfractions (H1−H9) by open-column chromatography (230−400-mesh silica gel; Merck, Darmstadt, Germany) and then eluted with a stepwise gradient of ethyl acetate/*n*-hexane from 0% to 100% (v/v). According to our previous study,[14] ferruginol was purified from subfraction H2 via a HPLC system equipped with a semipreparative silica column (mobile

phase ethyl acetate/*n*-hexane = 5/95; flow rate 4 mL/min; retention time = 9.8 min).

Trametes versicolor (Linnaeus: Fries) Pilat (BCRC 35253), a wood-rot test strain in JIS K 1517, ASTM D1413, and EN113, was obtained from the Bioresource Collection and Research Center (BCRC) of Food Industry Research and Development Institute in Taiwan.

Antifungal Assay. Agar dilution test was employed to evaluate the antifungal activity of ferruginol. Ferruginol was dissolved in 150 μL of 99.5% methanol and added into sterilized potato dextrose agar (PDA, 15 mL) in a 9 cm Petri dish with final concentrations of 25, 50, 100, 200, and 400 μg/mL. Methanol served as a control treatment. A 3 mm plug of mycelium was transferred to tested dishes and then incubated at 25 ± 2 °C and 70% relative humidity (RH). When the mycelia of the control group reached the border of the plate, the growth diameter was recorded to calculate the antifungal index (AI) as a percentage:

$$\mathrm{AI} = (1 - D_t/D_c) \times 100$$

D_t is the mycelium diameter of test groups, and D_c is the mycelium diameter of the control.

Liquid Culture of Fungal Cells for Proteomic Analysis. For proteomic analysis, *T. versicolor* was incubated in a liquid medium [700 mL of potato dextrose broth (PDB) in a 1-L Erlenmeyer flask] at 25 ± 2 °C under air. Cultures were incubated on an orbital shaker at 100*g* in darkness. After a 7-day preincubation, ferruginol in ethanol (1500 μL) and Tween 20 (350 μL) was added into the liquid medium with a final concentration of 100 μg/mL. For the control, only ethanol (1500 μL) and Tween 20 (350 μL) were added in the culture. At the 11th incubation day, cultured mycelia were filtered and weighed (100 °C dry weight).

Extraction and Quantification of Fungal Proteins. *T. versicolor* was treated with ferruginol for 4 days, and its mycelia were filtered, washed with chilled ultrapure water, and frozen in liquid nitrogen. The frozen mycelia (2 g, fresh weight) were ground into a fine powder in liquid nitrogen with a mortar and pestle and extracted with precooled (−20 °C) buffer containing 10% trichloroacetic acid and 20 mM dithiothreitol (DTT) in acetone. The mixture was precipitated at −20 °C for 50 min and centrifuged at 6000*g* (4 °C) for 30 min. Pellets were washed with precooled acetone containing 20 mM DTT, washed twice with 100% precooled acetone, and then dried in a freeze-dryer.

The lyophilized pellets (500 mg) were solubilized by urea buffer containing 7 M urea, 2 M thiourea, 4% (w/v) 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonic acid (CHAPS), and 1% (w/v) DTT, and the supernatant was collected by centrifugation at 12000*g* (25 °C) for 10 min. The protein concentration was quantified by the Bradford method[15] with bovine serum albumin (BSA) and protein assay dye reagent (Bio-Rad Laboratories, Inc.).

Two-Dimensional Electrophoresis. Figure 1 illustrates the experimental process of proteomic differential analysis. Proteins from *T. versicolor* were separated by two-dimensional electrophoresis (2DE) and stained with fluorescent dye (SYPRO Ruby), and the gel images were analyzed with ImageMaster software. For all tested groups, 300 μg of protein was mixed with rehydration solution (urea buffer, 2% ampholyte, and trace bromophenol blue) and then rehydrated with immobilized pH gradient (IPG) strips (17 cm, nonlinear gradient, Bio-Rad) for 12 h. The voltage of the isoelectric focusing (IEF) was programed from 100 to 8000 V to reach a total of 40000 V·h (50 μA for each strip). After IEF, the strips were immediately equilibrated with reduction solution [2% (w/v) DTT in equilibration buffer containing 50 mM Tris-HCl (pH 8.8), 6 M urea, 30% (v/v) glycerol, 2% (w/v) sodium dodecyl sulfate (SDS), and a trace of bromophenol blue] for 15 min, followed by the alkylation solution [2.5% (w/v) iodoacetamide (IAA) in equilibration buffer] for 15 min.

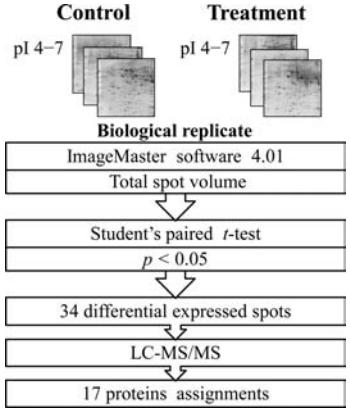

Figure 1. Workflow for studying differential protein expression of *T. versicolor* treated with or without ferruginol (100 μg/mL).

The second-dimension separation was performed by SDS−12% polyacrylamide gel electrophoresis (PAGE). After the 2DE separation, all gels were washed three times with deionized water to remove the residue of SDS. Gels were stained with SYPRO Ruby (Invitrogen) and digitalized with Typhoon 9400 scanner (Amersham Bioscience) at 200 μm pixel size. The images were analyzed with ImageMaster Platinum software v4.01 (Amersham Bioscience). Spot detection, matching, background subtraction (average on boundary), and image normalization were performed by this software. Only spots present in at least two biological replicates were taken as true signals. The volume of spots was normalized to the total volume of all spots in the analysis to compensate for slight differences in sample loading and gel staining. Protein spots with significantly changed levels (*t*-test, $p < 0.05$) were selected for protein identification.

Identification of Proteins and Database Search. Selected spots from both control and treatment gels were excised manually and washed three times with double-distilled H_2O. Gels were destained with 50% acetonitrile (ACN)/25 mM ammonium bicarbonate (37 °C), reduced with 10 mM DTT/25 mM ammonium bicarbonate (56 °C, 1 h in dark), and alkylated with 55 mM IAA/25 mM ammonium bicarbonate (room temperature, 45 min in dark). Gels were dehydrated with 100% ACN and rehydrated with trypsin (Promega, Madison, WI) (37 °C, 16 h). Oligopeptides were extracted twice in 5% formic acid (FA)/50% ACN with agitation (on ice, 20 min) and then dried via a centrifugal evaporator. Tryptic peptides were analyzed on a nano-HPLC system (LC Packing, Netherlands) with a 75-μm inner-diameter/15 cm C_{18} microcapillary column (Agilent Technologies). The HPLC system was connected with an ion-trap mass spectrometer (LCQ DECA XP plus, Thermo Finnigan, San Jose, CA) equipped with an electrospray ionization source (spraying voltage 1.8 kV). Elution conditions included a 40 min linear gradient from 100% to 40% buffer A (buffer A, 5% ACN/0.1% formic acid; buffer B, 80% ACN/0.1% formic acid; flow rate, 0.2 mL/min). Spectra were acquired by a full scan (m/z 450−2000).

Mascot software (www.matrixscience.com) was used for protein identification and comparison with the National Center for Biotechnology Information (NCBI) nonredundant protein sequence database and Swiss-Prot database against fungi taxonomy. Two missed tryptic cleavages per peptide and variable modification of carboxymethylation on cysteine and lysine, oxidation on methionine, and deamidation on asparagine or glutamine residues were permitted during the identification process. The identified proteins whose MOWSE (molecular weight search) scores exceeded 51 (NCBI) or 35 (Swiss-Prot) were taken as significant hits ($p < 0.05$). Sequences of identified proteins are listed in Tables S1 and S2 in Supporting Information.

RESULTS AND DISCUSSION

Antifungal Ability of Ferruginol. An agar dilution test was performed to assess the antifungal activity of ferruginol against *Trametes versicolor* (white-rot fungus) at concentrations of 25, 50, 100, 200, and 400 μg/mL. Results (Figure 2A) show that the antifungal indexes were 26%, 34%, 41%, 42%, and 43%, respectively. The antifungal activity of ferruginol reached a maximum at the dosage of 100 μg/mL and then leveled off.

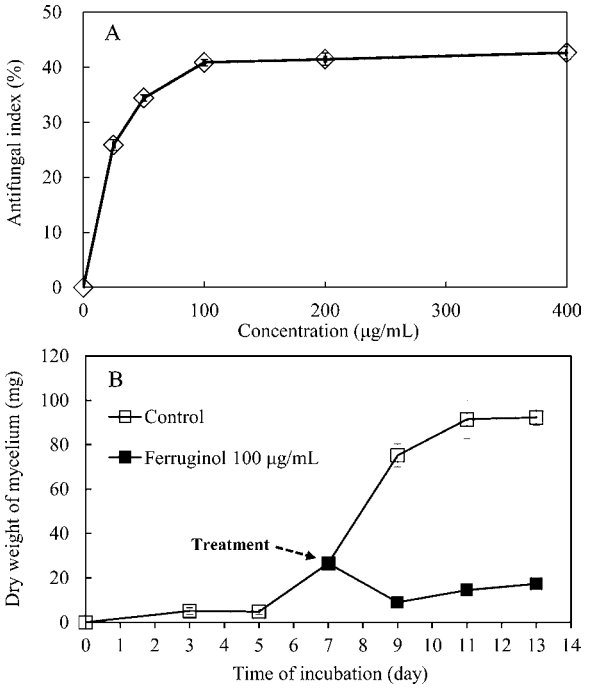

Figure 2. (A) Antifungal activity of ferruginol against *T. versicolor* on agar plate tests. (B) Dry weight of mycelium of *T. versicolor* on liquid culture test treated with (■) or without (□) ferruginol (100 μg/mL). Results are mean ± SD (n = 4).

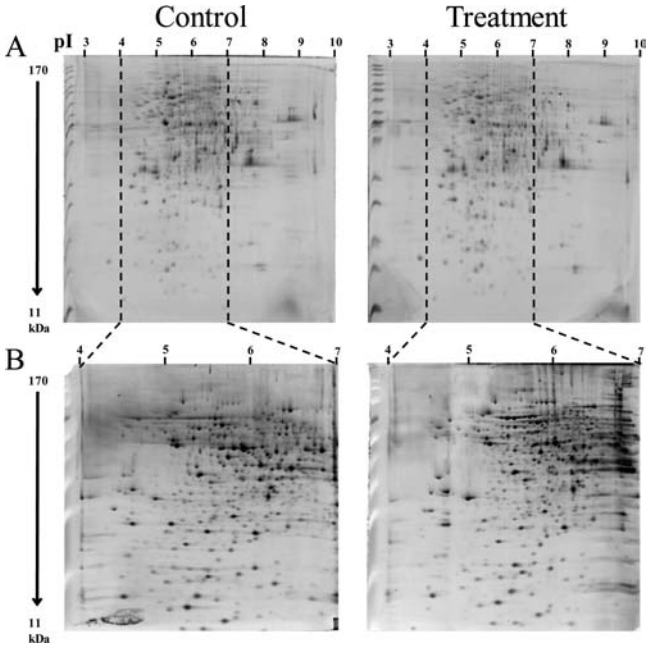

Figure 3. Two-dimensional electrophoretic analysis of *T. versicolor* proteins (300 μg) extracted from control and ferruginol-treated (100 μg/mL) groups. Proteomics analysis was carried out with (A) wide-range (pH 3−10) IPG strips and (B) narrow-range (pH 4−7) IPG strips. p*I*, isoelectric point.

To investigate the mechanisms of ferruginol on inhibition of *T. versicolor* growth, a liquid culture test was performed at the concentration of 100 μg/mL (Figure 2B). The dry weights of nontreated mycelia (control) increased slightly for 5 incubation days (lag phase, about 5 mg), increased linearly from the fifth to the 11th day of incubation (log phase), and exhibited stationary-phase fungal growth after the 11th day of incubation (about 90 mg). However, the dry weights of treated-mycelia decreased to lower than 20 mg after treatment with ferruginol at the seventh day. To analyze the protein expression patterns of ferruginol-treated *T. versicolor*, the mycelia were harvested at the end of the growth log phase (11th day) for further electrophoretic analysis.

Two-Dimensional Electrophoresis and Differential Display Analysis. Total proteins were extracted from mycelia with or without ferruginol treatments and used for quantitative comparison in the 2DE analysis (Figure 3). The average fluorescence intensity of each protein spot was measured to determine the protein expression level. The gels showed major spots between pH 4 and 7 in the wide-range (pH 3−10) immobilized pH gradient (IPG) strips (Figure 3A). To further separate the overlapping spots, narrow-range (pH 4−7) IPG strips were used, and the results revealed more detectable spots on a 2D gel (Figure 3B).

Approximately 360 spots were visualized in each 2D gel separated from the pH 4−7 IPG strip. The protein spot volumes from the control and treatment groups were statistically compared (t-test). A total of 34 protein spots, including 19 spots from nontreated (control) samples and 15 spots from ferruginol-treated samples, showed differential protein expression levels ($p < 0.05$) (Figure 4). A total of 17 nonredundant proteins and two not-identified proteins were identified among these proteins: 12 were downregulated (Table 1) and 7 were upregulated (Table 2) upon ferruginol treatment.

Downregulated Proteins upon Ferruginol Treatment. Exposure of *T. versicolor* cells to ferruginol showed decreased expression volumes in manganese ion homeostasis-related protein (spot 473) (Figure 5 and Table 1). Manganese homeostasis in the budding yeast *Saccharomyces cerevisiae* is under intensive investigation.[16,17] Reports indicated that manganese is both an essential trace element to living cells and a cofactor for metalloproteins. These findings suggest that an array of metalloproteins, such as oxidoreductases, DNA/RNA polymerases, peptidases, kinases, decarboxylases, and sugar transferases, of *T. versicolor* may function abnormally in transcription, glycolysis, and sugar transformation regulation upon ferruginol treatment.

To survive in natural environments, microorganisms possess two major transporter proteins, ATP-binding cassette (ABC) and major facilitator superfamily (MFS), for active secretion of endogenous and exogenous toxicants. Nelissen et al.[18] carried out a computer-aided genome analysis of 186 MFS transporters from the budding yeast *S. cerevisiae*, and their results showed that a total of 28 proteins confer a role in multidrug-efflux pumps with multiple drug resistance (MDR) function. Remarkably, the potential MFS−MDR transporter (spot 584) of *T. versicolor* was downregulated after ferruginol treatment (Figure 5 and Table 1). Thus, it was hypothesized that the first-line defense barrier, active secretion of toxins, of *T. versicolor* cells was reduced or dysfunctional. This might cause further damage within *T. versicolor* cells. Del Sorbo et al.[19] also suggested that the inhibitory activity of the two types of transporters (ABC and MFS) could be developed as an antifungal strategy. Taken together, these results suggest that downregulation of MFS−MDR transporter is an antifungal strategy of ferruginol against *T. versicolor*.

Removal of hydrogen peroxide, alkyl hydroperoxides, and various oxidative stresses by peroxiredoxin TSA1 (spot 503), a thiol-specific antioxidant enzyme (thioredoxin peroxidase), had

dx.doi.org/10.1021/jf504717x | J. Agric. Food Chem. 2015, 63, 85−91

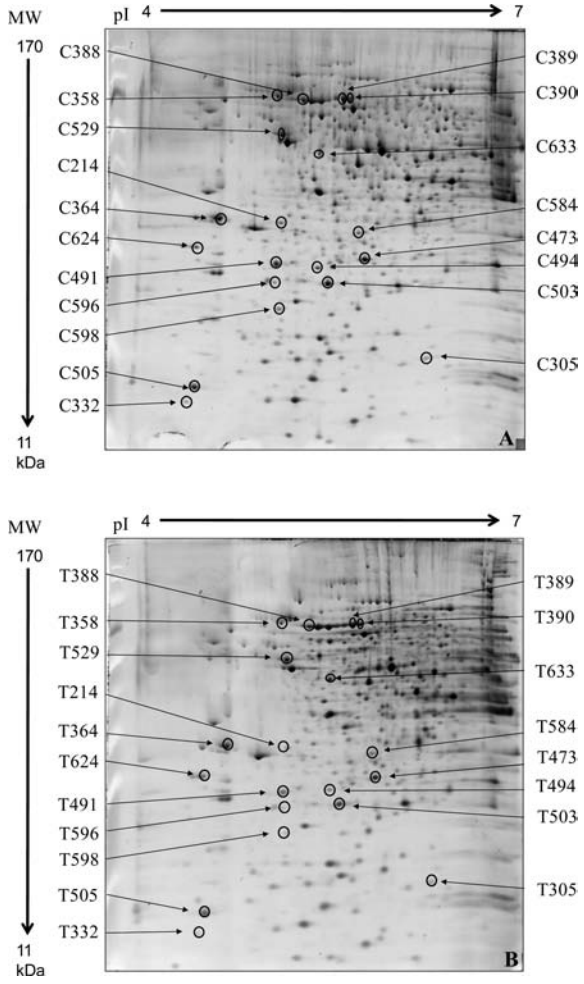

Figure 4. Two-dimensional gel images of (A) nontreated (control) and (B) ferruginol-treated *T. versicolor* protein expression patterns.

been demonstrated.[20,21] Iraqui et al.[22] further indicated that TSA1 maintains genome stability and avoids cell death of *S. cerevisiae*. Taken together, the downregulations of MFS−MDR transporter and peroxiredoxin TSA1 suggested that ferruginol reduced the defensive capabilities of *T. versicolor* cells. This may further result in the nonintegrity of *T. versicolor* cellular molecules such as cytoskeleton, polypeptide, and DNA.

The downregulated DNA polymerase ζ catalytic subunit (spot 494) of ferruginol-treated *T. versicolor* cells also corroborates the aforementioned damage situations. DNA polymerase ζ is an error-prone polymerase and comprises both Rev3 (catalytic subunit) and Rev7 (accessory subunit) in *S. cerevisiae*.[23] Downregulation of DNA polymerase ζ catalytic subunit (Figure 5 and Table 1) might result in dysfunction of DNA polymerase ζ. Lawrence[24] reviewed that the cellular functions of DNA polymerase ζ are participating in an extension step as a mismatch extender in translesion synthesis (TLS). For severe injuries caused by DNA damage, TLS is an important damage tolerance system and rescues cells for survival.[25−27] Hence, these findings suggest that the damage tolerance system of *T. versicolor* cannot function normally to assist cells in recovery from DNA damage caused by ferruginol.

In this study, β-tubulin 3 (spot 529) of *T. versicolor* was identified with a decrease in expression volume (Figure 5 and Table 1), suggesting that the ferruginol-treated *T. versicolor* cells might reduce cell motility, arrest the cell cycle, and inhibit cell growth/division.[28−30] Kiso et al.[31] screened antifungal agents and their results revealed that 2,5-dihydrophenylalanine (DHPA), a phenylalanine analogue, induced selective loss of both α- and β-tubulins in the filamentous fungus *Aspergillus nidulans*. According to the liquid culture test of *T. versicolor* treated with ferruginol, the growth of *T. versicolor* cells was inhibited. Average dry weights of treated mycelia were significantly lower than that of nontreated one (control) (Figure 2B). These findings suggest that ferruginol may be a type of microtubule-disrupting antifungal agent.

In addition, this study identified two downregulated proteins with uncertain functions, including hypothetical protein NCER_101469 (spot 491) and protein kinase C substrate (spot 305) of ferruginol-treated *T. versicolor* cells. The ratios of expression volumes (treatment/control) are 0.4 and 0.1, respectively (Table 1). Their functions await further investigation.

Among the 12 downregulated proteins, spots 596, 332, 598, and 214 were identified as phosphoenolpyruvate carboxykinase AcuF, nascent polypeptide-associated complex subunit β, mitochondrial protein involved in sorting of proteins in the mitochondria, and DNA damage checkpoint protein Rad24,

[a]Protein identified against NCBI, except spots 633 and 358 against Swiss-Prot. [b]Ratio of treatment/control upon addition of ferruginol. [c]Coverage of protein sequence/matched peptide number. [d]Not identified.

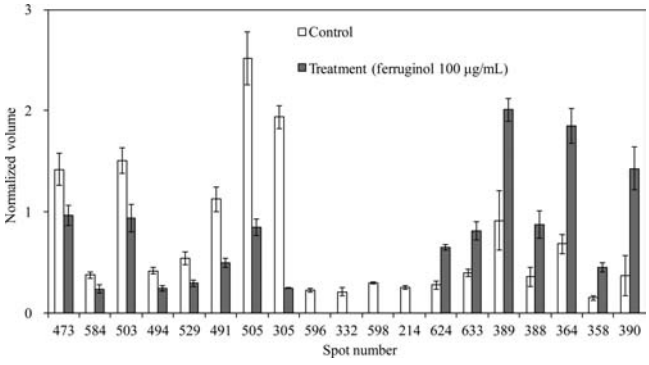

Figure 5. Comparison of expression patterns from nontreated (control) and ferruginol-treated *T. versicolor* protein by statistical analysis. Results are mean ± SE (n = 3). Protein expressions are significantly different at the level of $p < 0.05$ according to the student's paired t-test.

respectively. They were detected in nontreated (control) *T. versicolor* cells only. Phosphoenolpyruvate carboxykinase AcuF (spot 596) is a key enzyme associated with gluconeogenesis for producing hexose sugars of filamentous fungi via the tricarboxylic acid cycle to metabolize carbon sources.[32] This result suggests that ferruginol-treated *T. versicolor* cells cannot regulate glucose content normally via the processes of gluconeogenesis and tricarboxylic acid cycle.

Simultaneous observations of a drastic decrease in nascent polypeptide-associated complex subunit β (spot 332) and mitochondrial protein involved in sorting of proteins in the mitochondria (spot 598) (Figure 5 and Table 1) suggested that ferruginol-treated *T. versicolor* cells diminished the flux of nascent polypeptides and the capacity for correct translation. Nascent polypeptide-associated complex (NAC) is a heterodimer composed of α- and β-subunits and has a chaperone role in cells.[33,34] It also has a central role as a proteostasis sensor to control the folding state of the cellular proteome.[35] These results suggest that the proteostasis of ferruginol-treated *T. versicolor* cells is not under control.

In this study, expression of the DNA damage checkpoint protein Rad24 (spot 214) of *T. versicolor* cells was observed only in nontreated control (Figure 5 and Table 1). This finding supports the idea that ferruginol-treated *T. versicolor* cells might arrest the processing of the cell cycle and result in functionally defective DNA replication. Hartwell and Weinert[36] reported that eliminating the checkpoint control functions of eukaryotic cells may result in chromosome transmission infidelity. Aylon and Kupiec[37] further indicated that Rad24 plays a critical role in coordination of the response to repair chromosomal damage in *S. cerevisiae*. Taken together, the downregulation of peroxiredoxin TSA1, DNA polymerase ζ catalytic subunit, and DNA damage checkpoint protein Rad24 of *T. versicolor* cells strongly suggest that ferruginol is potentially involved in DNA damage or mutation, which might account for DNA nonintegrity and further cell death.

Upregulated Proteins upon Ferruginol Treatment. Six proteins are upregulated, including ATP-dependent RNA helicase eIF4A (spot 633), heat shock protein (spot 389), heat shock protein HSS1 (spot 388), tpis_emeni triosephosphate isomerase (spot 364), autophagy-related protein 7 (spot 358), and heat shock protein 70 (spot 390, Table 2). Eukaryotic translation factor 4A (eIF4A) participates in the initial step of mRNA translation. This ATP-dependent RNA helicase can unwind the secondary structure of mRNA at the 5′ untranslated region (UTR).[38] It is a critical stage of translational control. Upregulation of eIF4A suggests that *T. versicolor* cells appear to rescue cells by increasing their protein synthesis ability. However, the correct folding structure of protein is essential to such function. In this study, the nascent polypeptide-associated complex subunit β (spot 332, Table 1) and mitochondrial protein involved in sorting of proteins in the mitochondria (spot 598, Table 1) of *T. versicolor* cells were downregulated. These findings suggest that *T. versicolor* cells attempt to enhance the translation processes but the actions of protein sorting and folding cannot function normally. Taken together, *T. versicolor* cells might produce dysfunctional proteins and cause a massive stress.

Among these upregulated proteins, there are three heat shock proteins (HSPs). The ratios of expression volumes (treatment/control) of HSP (spot 389), HSS1 (spot 388), and HSP70 (spot 390) are 2.2, 2.5, and 3.8, respectively (Table 2). HSPs are highly conserved from bacteria to animals and function as molecular chaperones against stress. Jolly and Morimoto[39] reviewed the functions of HSPs and indicated that HSPs may control signal transduction at multiple checkpoints in the apoptosis pathways (type I programmed cell death, PCD). Moreover, among these HSPs, the small HSPs and HSP70 possess antiapoptotic activity for promoting cell survival. Matsuzaki et al.[40] investigated the proteomic responses of the white-rot fungus *Phanerochaete chrysosporium* to exogenous benzoic acid, and their results exhibited a similar stress response that the HSP70 was upregulated. These findings suggest that exposure of *T. versicolor* cells to ferruginol activates a defensive response via induction of HSPs.

Triosephosphate isomerase (spot 364) regulates the equilibrium of triosephosphates between dihydroxyacetone phosphate and D-glyceraldehyde 3-phosphate in glycolysis metabolism. Organisms convert glucose into pyruvate via glycolysis and release high-energy compounds, including ATP and NADH. In this study, the ratio of expression volumes (treatment/control) of triosephosphate isomerase was 2.7

(Figure 5 and Table 2). This upregulation of glycolytic protein suggests that *T. versicolor* cells appear to enhance energy production against stress conditions. Parente et al.[41] investigated the proteomic responses of dimorphic fungus *Paracoccidoides brasiliensis* under iron deprivation, and their results exhibited a similar response that glycolytic proteins were upregulated against stress. Upregulation of these proteins seems to indicate that *T. versicolor* cells can activate defense and rescue responses against ferruginol. However, the current results showed upregulation of a key autophagy-related protein (Atg7, spot 358, Table 2) of *T. versicolor* cells upon addition of ferruginol, inferring that those rescue reactions may be insufficient to reduce the toxic effects caused by ferruginol. This idea is consistent with the liquid culture test result of *T. versicolor* that the growth of mycelium was inhibited after treatment with ferruginol (Figure 2B).

Autophagy (self-eating, type II PCD) leads aberrant organelles and misfolded proteins for breakdown in autophagosomes, and the cells recycle these molecules for energy generation in response to aging or starvation conditions.[42] Nevertheless, excessive autophagy will induce a total collapse of cellular functions due to autophagic-type cell death. In this study, the ratio of expression volumes (treatment/control) of Atg7 is 3.0 (Figure 5 and Table 2). Atg7 is a unique ubiquitin-activating enzyme involved in the ubiquitin-like conjugation systems for processing the formation of autophagosomes.[43] This evidence demonstrates that *T. versicolor* cells had massive autophagy. Garrido et al.[44] further indicated that HSP70 is a decisive regulator that blocks the mitochondrial apoptotic pathway (type I PCD). In summary, upregulation of both HSP70 and Atg7 supports the idea that ferruginol induces *T. versicolor* cells toward cellular demise via type II PCD.

In this study, the downregulation of DNA damage checkpoint protein Rad24 (spot 214, Table 1) and DNA polymerase ζ catalytic subunit (spot 494, Table 1) suggests that the cell cycle of *T. versicolor* was arrested and the DNA damage cannot be completely repaired. In addition, the downregulation of peroxiredoxin TSA1 (Table 1) also suggests that *T. versicolor* cells suffered an abnormal accumulation of reactive oxygen species, contributing to irreversible damage that might cause cell death. Similar evidence that catalase, a key antioxidant enzyme, was selectively eliminated during autophagic cell death was reported.[45] Hence, ferruginol caused *T. versicolor* cells to move toward autophagic cell death in the current study.

In conclusion, antifungal processes of ferruginol against the basidiomycete *T. versicolor* at the proteome level were investigated. Results indicated that the defensive capabilities of *T. versicolor* cells were reduced. DNA and nascent polypeptides of *T. versicolor* cells might be attacked. The current results suggest that ferruginol induced destruction of vital cell organelles or proteins and caused cellular dysfunction. This process may further contribute to cell death of *T. versicolor*.

Supporting Information

ABSTRACT: This study investigated the herbicide isoproturon (IPU) residues in soil, where wheat was cultivated and sprayed with salicylic acid (SA). Provision of SA led to a lower level of IPU residues in rhizosphere soil compared to IPU treatment alone. Root exudation of tartaric acid, malic acid, and oxalic acids was enhanced in rhizosphere soil with SA-treated wheat. We examined the microbial population (e.g., biomass and phospholipid fatty acid), microbial structure, and soil enzyme (catalase, phenol oxidase, and dehydrogenase) activities, all of which are associated with soil activity and were activated in rhizosphere soil of SA-treated wheat roots. We further assessed the correlation matrix and principal component to figure out the association between the IPU degradation and soil activity. Finally, six IPU degraded products (derivatives) in rhizosphere soil were characterized using ultraperformance liquid chromatography with a quadrupole-time-of-flight tandem mass spectrometer (UPLC/Q-TOF-MS/MS). A relatively higher level of IPU derivatives was identified in soil with SA-treated wheat than in soil without SA-treated wheat plants.

KEYWORDS: *isoproturon, soil, salicylic acid, organic acids, microbial degradation*

INTRODUCTION

Isoproturon [3-(4-isopropylphenyl)-1,1-dimethylurea] (IPU) is a phenylurea herbicide widely used for controlling pre- and postemergence weed in soils with cultivation of various food crops.[1] While in agronomic practice IPU is applied to crop fields, not all administrated herbicide is absorbed by its targets. Instead, the left herbicide (or residue) may accumulate in soils, crops, or runoff into the adjacent ecosystems. Due to its high water solubility, IPU has been on the list of the 33 priority substances that have great potential to contaminate surface and groundwater.[2,3] As IPU is moderately hydrophobic and weakly absorbed by soils, it tends to accumulate in plants and consequently risks crop production and food safety.[4,5]

Soil is considered as a major sink for the bulk globally used herbicides, because more than 80% of the chemicals reside in soils after field administration.[6] The fate of soil herbicides is determined by chemical, physical, and biological processes, each of which individually or coordinately influences degradation, sediment, or transformation of herbicide within soils or soil-crop systems.[7,8] Among these, degradation is a fundamental process for soil herbicides.[9] Soil microbes are thought of as a dominant contribution to dissipation of organic contaminants.[10] IPU degradation involves biotic and abiotic processes, but bacterium-facilitated biodegradation in soil is of particular interest, because it undergoes a complete mineralization to harmless inorganic products.[11] Microorganism-based decay of IPU is possibly promoted by plant root growth in rhizosphere soil, because plants provide favorable conditions for soil microorganisms to live. The rhizo-degradation of IPU may depend on plant−soil microbe interactions. Recently, many efforts have been made to investigate the degradation of herbicides in plant and soil.[12−16] The efficiency of herbicide degradation in soil relies on environmental factors such as dissolved organic matter (including low-molecular-weight organic acids, LMWOAs), microbial community, soil enzyme activity, and soil structure.[17−19] Several bacterial strains have been isolated from soils with the capability of mineralizing IPU.[1,11] This makes it possible that IPU can be potentially decayed under an appropriate condition. To date, only a few documents are available on the rhizo-degradation of IPU.

Salicylic acid (SA) is a signal molecule involved in regulation of a wide range of plant growth, development, and responses to biotic and environmental stresses.[20−22] Our recent studies have shown that IPU-induced toxicity in wheat plants could be attenuated by external SA.[22] However, whether SA-regulated low accumulation of IPU in plants is associated with the IPU degradation in soils is unknown. Wheat (*Triticum aestivum*) is one of the most important crops, as it provides a staple food for more than half of the world population. As an essential crop, wheat is one of the targets of herbicide contamination.[23] Understanding the mechanisms for herbicide degradation in wheat and its surrounding soils is critical to minimize the environmental risk and ensure the safety of crop production. In

this study, we examined whether exogenous provision of SA stimulated LWMOAs efflux from wheat roots when exposed to IPU. We also investigated the effects of SA on soil microbial activities (microbial community and soil enzyme activities), which might be responsible for accelerating the degradation of IPU in soil. Using ultraperformance liquid chromatography−tandem mass spectrometry (UPLC-MS/MS), we further characterized the degraded products of IPU in rhizosphere soil. Our analysis provided evidence that IPU degradation in rhizosphere soil was enhanced by SA application on wheat plants. With cultivation of SA-treated wheat, the soil microbial population, enzyme activity, and microbial metabolites (e.g., phosphplipid fatty acids, as biomarkers) in rhizosphere soil were greatly improved. Thus, the aims of the study were to identify whether provision of SA affected the degradation of IPU residue in soil in which wheat plants were cultivated and to support the hypothesis that SA-accelerating IPU degradation in the soil rhizosphere fractions was through stimulation of root exudation of organic acids and enhancement of microbial population and activity. This study will help uncover a role of SA in modulating the IPU catabolism in wheat-planted soil and the intrinsic relationship between root exudation, microbial activity, and IPU degradation.

MATERIALS AND METHODS

Materials and treatments. Isoproturon (purity of 96.9%) and wheat seeds (*Triticum aestivum*, cv. Yangmai 13) were provided by the Academy of Agriculture Science in Jiang Su, Nanjing, China. IPU-free soil (organic carbon, 2.13%; total N, 1.26 g kg^{-1}; available P, 34.3 mg kg^{-1} and available K, 91.5 mg kg^{-1}; pH 7.6) was collected from the Experimental Station of Nanjing Agricultural University, Nanjing, China (Euric Gleysols, N 32.03°; E 118.84°). The soil was sampled from the surface layer (0−20 cm depth), air-dried, and sieved through a 3 mm mesh.[14]

Sterilized wheat seeds were germinated, and the uniformly germinating seeds were transferred to a plastic pot (1 L) containing 1,120 g of prepared soil. Seedlings were grown in a growth chamber (PGX-350D, SAFE Co.) under a light intensity of 200 μmol m^{-2} s^{-1} with a light/dark cycle of 14/10 h at 25/20 °C and watered to keep 70% relative water content in soils. Wheat was planted in the soil mixed with IPU at 4 mg kg^{-1} dry soil. For SA treatment, wheat leaves were sprayed with 5 mg L^{-1} SA and the SA treatment was undertaken once a day and lasted for 6 days. Water was sprayed for control seedlings. Soils adhered tightly to roots were collected as rhizosphere soil, while those shaken off from roots were collected as nonrhizosphere soil.[14,15] The bulk soil was the mixture of rhizosphere and nonrhizosphere soils.[16] When harvested, fine root fragments were carefully teased out to avoid any influence of cutoff roots. The fresh samples were used for measuring enzyme activities and phospholipid fatty acids (PLFAs), microbial population, and other parameters.

Determination of IPU and its degradation products. Isoproturon and its metabolites in soil were analyzed based on the method of Liang et al.[22] with slight modification. Samples in the soil (10 g) were ultrasonically extracted three times with mixed acetone−water (3:1, *v*/*v*) (each time 10 mL extraction solution for 30 min), followed by centrifugation at 4,000*g* for 10 min and filtration. The filtrate was pooled and concentrated to remove acetone with a rotary vacuum evaporator at 40 °C. The residual water was loaded onto an LC-C_{18} solid phase extraction (SPE) column (Supelclean, 300 mg). The elute was discarded, and the column was washed with 4 mL of high performance liquid chromatography (HPLC) grade methanol. The methanol solution was collected for analysis.

Fresh plant tissues (1.0 g) were homogenized with 15 mL of extraction solvent (acetone/water, 3:1, *v*/*v*) and ultrasonicated for 30 min. The homogenate was centrifuged at 5000*g* for 10 min and filtrated. The process was repeated in triplicate. The supernatant was concentrated to remove acetone by rotary vacuum evaporator at 40 °C. The residual water was extracted by petroleum ether for three times (each time with 10 mL). The organic phase was collected, dried on anhydrous sodium sulfate, and evaporated to dryness. The residue was redissovled in 10 mL of distilled water. The dissolved solution was transferred to an LC-C_{18} SPE column. The elute was discarded. Then, 2 mL of petroleum ether-diethyl ether (98:2, *v*/*v*) was passed through the column at 2.5 mL min^{-1}, and the eluted solution was removed. The residue in the column was washed with 4 mL of chromatographic grade methanol, and the washing solution was collected and quantified by HPLC. As seen in Supporting Information Table S1, the recoveries for the spiked soil and plant samples were in the range of 89.8−117.3%, with the relative standard deviations (RSDs) (n = 3) from 1.9% to 4.8%, confirming a convenient performance of analytic technique for determination of IPU in soil and plant tissues.

Liquid chromatography/mass spectrometer (LC/MS) analysis of soil extracts was performed with an ultraperformance liquid chromatography (UPLC) apparatus equipped with a Waters Acquity photodiode array (PDA) detector (Waters, USA) connected to a Waters SYNAPT SYNAPT Quadrupole-time-of-flight (Q-TOF) Mass Spectrometer (Waters, USA) (UPLC/Q-TOF-MS/MS). Chromatographic operation was set under conditions as follows: XBridge C_{18} columns (2.1 × 100 mm, granulation of 3.5 μm, Waters); injection volume, 4 μL; mobile phase with two solvents: A (100% Acetonitrile) and B (99.9% H_2O/0.1% formic acid, *v*/*v*) at a 0.3 mL min^{-1} flow rate. The elution steps were followed: 0−0.1 min linear gradient from 0 to 15% of A, 0.1−15 min linear gradient from 15 to 35% of A, 15−25 min linear gradient from 35 to 100% of A and 25−27 min isocratic at 100% of A. After returning to the initial conditions, the equilibration was achieved within 3 min.

The electrospray (ESI) in positive mode and TOF-MS parameters were optimized to reach the best sensibility on isoproturon and its metabolites ion $[M + H]^+$ for the m/z range from 50 to 1,000. The ESI source was operated at 50 °C with the desolvation temperature of 400 °C. The desolvation gas flew at the rate of 500 L h^{-1}. A capillary voltage was set at 3.5 kV. The cone voltage was set at 30 V. In order to achieve high fragmentation of protonated and deprotonated molecules ($[M + H]^+$), the collision energy was between 6 and 15 eV. IPU-derived metabolites were detected by comparison of the exact molecular masses and fragmentation pathway of the precursor $[M + H]^+$ ions recorded during LC-MS experiments. The targeted MS/MS experiments were performed using a collision energy ramp of 8 to 18 eV (positive ion mode).

Leucine enkephaline at the concentration of 2 ng μL^{-1} (exact mass of 556.2771 Da $[M + H]^+$) was infused at the flow rate of 10 μL min^{-1} in the lock spray channel. A spectrum of 0.3 s was acquired every 15 s and allowed exact mass determination during UPLC-MS and UPLC-MS/MS experiments. All acquisition and analysis of data were controlled by MassLynx V 4.1 software.

Assaying of soil enzyme activity. Catalase (CAT, E.C. 1.11.1.6) activity was measured by back-titrating residual H_2O_2 with $KMnO_4$.[24] Soil samples (2 g) were weighted into a 100 mL conical flask, which was added with 40 mL of distilled water and 5 mL of 3% hydrogen peroxide solution. The mixture was shaken at 120 rpm for 30 min at 30 °C, and 5 mL of 3 M H_2SO_4 was introduced immediately after shaking to end the reaction. The filtrate (25 mL) was titrated with 0.02 M $KMnO_4$ consumed g^{-1} dry matter.[25]

Dehydrogenase (DHA, EC 1.1.1.1) activity was determined using the reduction of 2,3,5-triphenylteterazolium chloride (TTC) method.[26] Samples of 5 g of soil and 50 mg of $CaCO_3$ were mixed thoroughly and transferred into three test tubes (1.6 × 15 cm). To each tube with stopper, 2 mL of 1% TTC and 2.5 mL of deionized water were added. The samples were mixed on a vortex and incubated at 30 °C. After 20 h, trephenylformanzan, a product from the reduction of TTC, was extracted by adding 25 mL of methanol and shaken in an orbital shaker (150 rev min^{-1}) under dark conditions for 15 min. The samples were collected in a volumetric flask. The tube was washed with methanol until the red color disappeared. The filtrate was diluted with additional methanol to a final volume of 100 mL. The color intensity was measured at 485 nm with methanol as a blank.

[a]Control, unplanted soil; RS, rhizosphere soil; BS, bulk soil; NRS, nonrhizosphere soil; BCF: fresh weight ratio of isoproturon concentration in plant to the bulk soil; TF: ratio of shoot BCF to root BCF. Seedlings grew in soils with IPU (4 mg kg^{-1}) for 4 d. After that, the leaves were sprayed with 5 mg L^{-1} SA once a day for 6 d. The control soil also contained 4 mg kg^{-1} isoproturon. Values are the means ± standard deviations (n = 3). Data of soil with different letters are significantly different ($p < 0.05$, Turkey's test). Asterisks indicate the significant differences between IPU and IPU+SA ($p < 0.05$).

Activities of phenol oxidase (PO, EC 1.10.3.2) were determined according to the method of Carine et al.[27] with some modifications. The PO activity was assayed by adding 5 mL of modified universal buffer (MUB) solution (pH 2.0) and 200 μL of a 0.01 M ABTS solution to the mixture. The mixture was incubated at 30 °C for 5 min and centrifuged at 11,300g at 4 °C for 2 min. The oxidation rate of ABTS to ABTS$^{\bullet+}$ released in the supernatant was measured at 420 nm (ε = 18460 M^{-1} cm^{-1}).

Analysis of organic acids. Root exudates in rhizosphere soil were collected according to the methods of Tuason and Arocena[28] and Gao[29] with minor modification. Fresh soil samples (10 g on dry-weight basis) were packed in a 50 mL plastic centrifuge tube, followed by addition of 10 mL of 0.1% H_3PO_4 (v/v) and shaken in a thermostat reciprocating shaker at 25 ± 0.5 °C for 2 h. Soil suspensions were mixed with 10 mL of 0.1 M NaOH and shaken again at 4 ± 0.5 °C for 10 min. The suspension was centrifuged at 10,000g for 30 min, acidified with 1 M HCl, and filtrated to remove precipitated humic acids. The filtrates were extracted three times with 10 mL of ethyl acetate. The organic phase containing organic acids was obtained by evaporation of the solvent in a rotary evaporator at 35 °C and redissolution of the residue in 1 mL of double-distilled water. The solution was filtered through a 0.45 μm filter (Millex-HV, Millipore). The quantitative determination of organic acids was carried out using a HPLC (Supporting Information Table S2).

Measurement of soil microbial biomass C and N in soil. The fumigation extraction method was used for determining soil microbial biomass carbon (SMBC) and nitrogen (SMBN).[30] Ten grams of soil was fumigated with alcohol-free chloroform at 25 °C for 24 h. Excess chloroform was removed by repeated evacuation. Samples were extracted by 60 mL of 0.5 M K_2SO_4 on a rotary shaker at 220 rpm for 60 min and filtered through Whatman qualitative filter paper. The samples from each treatment were placed for 24 h at 25 °C without fumigation and immediately extracted and filtered as described above. Soil filtrates were stored at −20 °C prior to analysis for SMBC and SMBN.[31] The concentrations of soluble organic carbon (SOC) in soil fractions were determined according to Gao et al.[29] SMBN was determined at 280 nm using a UV-1700 spectrophotometer (Shimadzu, Japan) by the method of Turner et al.[32] and Guo et al.[18]

Extraction and analysis of phospholipid fatty acids. PLFAs were determined based on the method of Hammesfahr et al.[33] The details of PLFAs extraction, esterification reaction, and quantification were presented in Supporting Information Table S3.

Statistic analysis. All the experiments were performed at least three repetitive independent treatments. The values were expressed as means ± standard deviation. Statistical analysis of the results was performed using SPSS statistics 20 for Windows. The statistical significance of the results was determined through analyses of variance post hoc test (ANOVA, Tukey's test) at the 95% confidence level ($p < 0.05$). Principal component analysis (PCA) was used to classify treatments according to their PLFAs using SIMCA-P 13.03 software.

RESULTS

Effect of SA on IPU degradation in soil. Compared to the soil without wheat planting (unplanted soil), the wheat-planted soil accumulated a lower level of IPU (Table 1). The concentration of IPU was always higher in nonrhizosphere soil (NRS) than in rhizosphere soil (RS). The bulk soil (BS) had a moderate concentration of IPU. When the wheat plants were exposed to IPU and/or treated with SA, the IPU residues in RS, BS, and NRS with IPU treatment alone were 1.21-, 1.16-, and 8.14-fold higher than that of IPU+SA treatment, indicating that SA application was able to reduce IPU residues in wheat-planted soil.

SA provision to plants gave rise to much less accumulation of IPU in roots and aerial parts (64.4% down in roots and 29.9% down in shoots) relative to the control (IPU treatment alone) (Table 1). To get an insight into the effect of SA on IPU accumulation, we analyzed the bioconcentration factor (BCF) and translocation factor (TF) for wheat under IPU-exposure. The BCF refers to the quotient between the organism and medium substance concentrations.[14] In the absence or presence of SA, the value of BCF_{shoot} was always higher than that of BCF_{root}, pointing out that more IPU was accumulated in the above-ground than in the root. Surprisingly, both BCF_{shoot} and BCF_{root} with IPU+SA treatment were found to be lower than those with IPU treatment alone. We further assessed the translocation factor (TF), the ratio of IPU concentration in aerial part to root, which is often used to evaluate the plant capability of translocating xenobiotics from root to shoot.[14] Although TF_{IPU} and TF_{IPU+SA} were above one (implying a potential for IPU accumulation in the above-ground of wheat), the TF value was higher for IPU+SA treatment than that for IPU treatment, pointing to the fact that IPU moved more rapidly in the IPU+SA-treated wheat than in the IPU-treated wheat.

Effect of SA on exudation of organic acids in wheat roots. Because SA provision led to more IPU degradation in wheat-planted soil, we inferred that root exudation might be altered. The extractable tartaric, malic, and oxalic acids are important organic acids liberated from roots to the rhizosphere.[20] Analysis of the organic acids in roots and planted soils showed a large variation under different conditions. Tartaric and malic acids were only detected in root tissue and rhizosphere soil (Figure 1). In rhizosphere soil, exudation of tartaric acid was drastically promoted by SA and IPU+SA treatment, which were 1.69- and 1.95-fold higher than the control; in contrast, no significant increase in tartaric acid was found in the IPU-exposed rhizosphere soil as compared to the

DOI: 10.1021/jf505117j
J. Agric. Food Chem. 2015, 63, 92−103

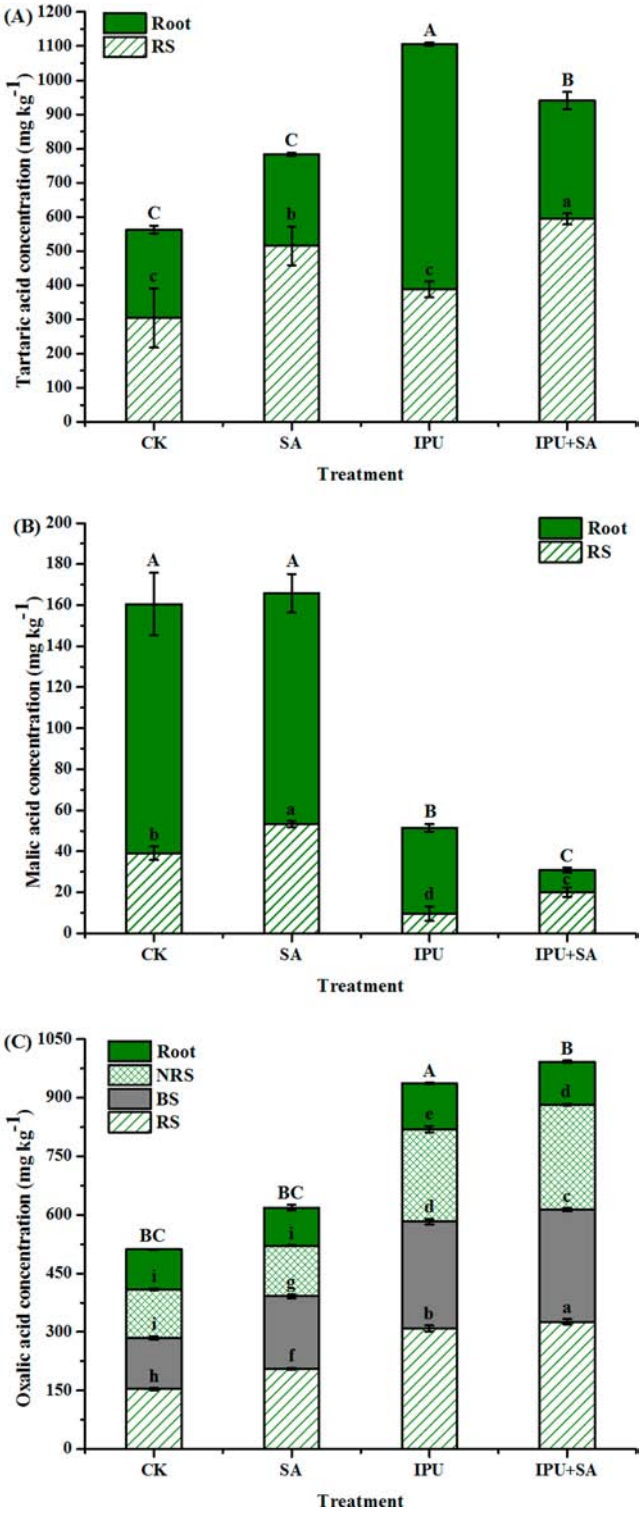

Figure 1. Concentrations of tartaric acid (A), malic acid (B), and oxalic acid (C) in rhizosphere (RS), nonrhizosphere (NRS), and bulk soils (BS) and wheat roots. Seedlings grew in soils with IPU (4 mg kg^{-1}) and without IPU (CK, control) for 4 d. After that, the leaves were sprayed with 5 mg L^{-1} SA once a day for 6 d. Values are the means ± standard deviations (n = 3). Data with different capital letters (wheat root) and lower case letters (soil) are significantly different (p < 0.05, Turkey's test).

control; however, more tartaric acid appeared to accumulate in IPU-treated roots (Figure 1A).

IPU treatment inhibited accumulation of malic acid in roots and rhizosphere soil (Figure 1B). While SA application stimulated the secretion of malic acids to soil with IPU, much less malate was accumulated in the root. The tartaric and malic acids in NRS and BS were assessed but undetectable. For oxalic acid, it could be detected in any of the compartments. Compared to control, provision of SA increased the levels of oxalic acid in BS and RS (Figure 1C). Treatment with IPU enhanced the content of oxalic acid in the BS and RS. In addition, oxalic acid in the NRS was also found to accumulate. Under the IPU exposure, the SA-regulated increase in oxalic acid was limited.

Effect of SA on soil enzyme activities in IPU-polluted soil. Catalase (CAT) is an intracellular enzyme involved in microbiological redox capacity.[34] Its activity in RS, BS, and NRS appeared to change slightly with all treatments (Figure 2A). Soil dehydrogenase activity (DHA) serves as an effective parameter for assessing the side effect of herbicide treatments on the soil microbial biomass.[35] Compared to the control, provision of SA alone did not affect DHA in rhizosphere soil (or BS), but IPU exposure resulted in the significant decrease in DHA (Figure 2B). For IPU+SA treatment, the DHA was largely recovered in rhizosphere soil. The DHA in BS and NRS was reduced with IPU relative to the control, and application of SA could hardly affect the DHA in the presence of IPU. We finally determined the activity of phenol oxidase (PO), a soil microoganism excreted enzyme catalyzing the oxidation of recalcitrant aromatic compounds.[27] In the three compartments, treatment with IPU led to the lower activity of PO compared to the control or SA alone; however, the rebound of PO activity was displayed in the presence of SA (Figure 2C).

Effect of SA on soil microbial nutrition in the presence of IPU. Soil microbial biomass carbon (SMBC), microbial quotient, and soil microbial biomass N (SMBN) are crucial biological indexes, representative of soil quality, deterioration, and correlation with degradation of herbicides.[36] Under all circumstances, concentrations of SMBC, microbial quotient, and SMBN progressively decreased in the following order: RS > BS > NRS (Table 2). The content of SMBC was drastically increased in the soil with IPU compared to control. Unexpectedly, much higher SMBC contents were examined with IPU+SA treatment. The change of microbial quotient demonstrated a similar trend to the change of SMBC (Table 2).

Effects of SA on the microbial community. PLFA is a group of phosphorus-containing fatty acids, which are frequently used for monitoring soil microbial community structure and their relative abundance under a certain environmental condition.[37,38] To investigate the microbial population and microbial biomass in the soil fractions, we determined phospholipid fatty acids from various microbial communities including $Gram^+$ bacteria, $Gram^-$ bacteria, actinomycetes, fungi, arbuscular mycorrhizal fungi (AM fungi), and eukaryotes. Soil with wheat-cultivation usually had a higher level of PLFA than that of the control (CK, soil with no wheat-cultivation) (Table 3). RS usually had the highest level of PLFA, whereas NRS had the lowest level of PLFA. SA had a potent effect on PLFA accumulation in the microbial community, particularly in RS. For example, SA provision significantly increased PLFA contents in Gram-negative (7.41) and -positive (7.26) bacteria compared to the controls (5.24 and 5.69, respectively). The enhancement of PLFA contents by SA could be found in the presence of IPU. Similarly, SA provision alone and IPU+SA treatment increased the PLFA

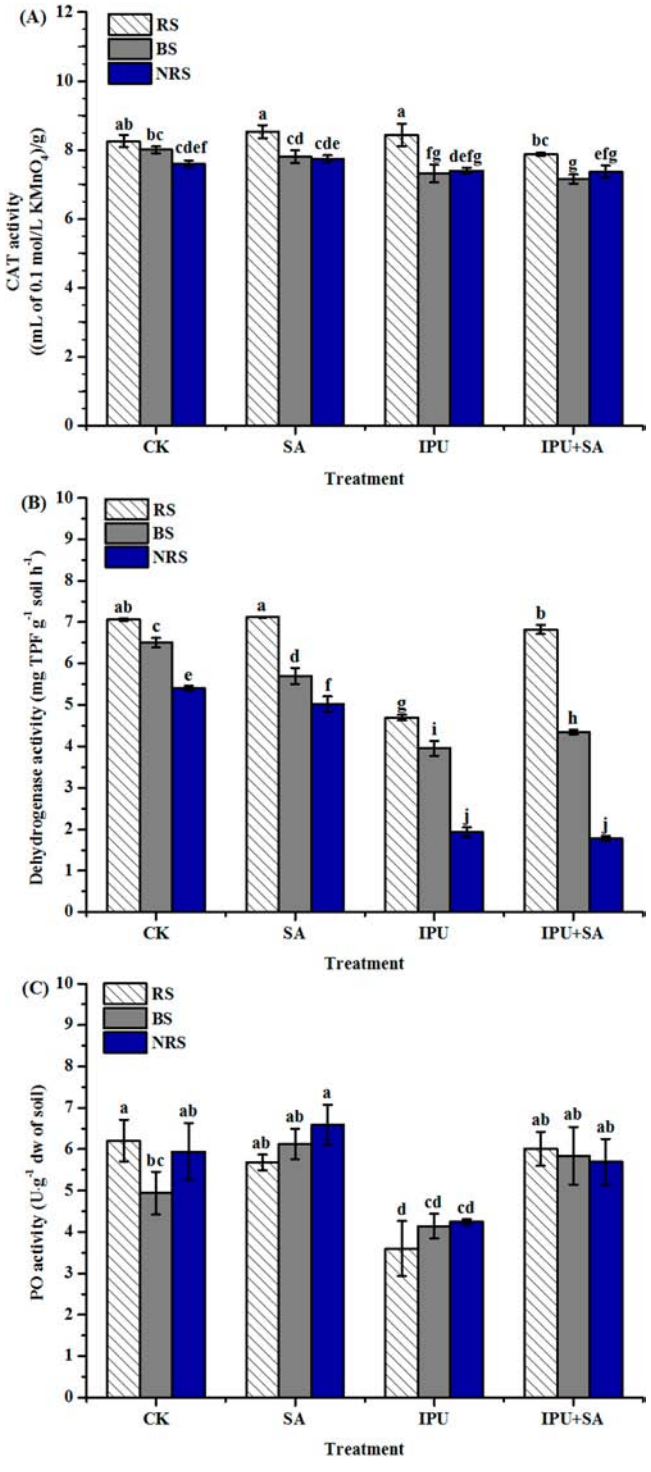

Figure 2. Effect of isoproturon (IPU) on catalase (CAT), dehydrogenase, and phenol oxdase (PO) activities in rhizosphere (RS), nonrhizopheric (NRS), and bulk (BS) soils with wheat planted for 10 d. Seedlings grew in soils with IPU (4 mg kg^{-1}) for 4 d. After that, the leaves were sprayed with 5 mg L^{-1} SA once a day for 6 d. Values are the means ± standard deviations (n = 3). Data with different letters are significantly different (p < 0.05, Turkey's test).

contents in fungi by 3.84- and 3.12-fold over the controls, respectively. The SA-promoted increase in PLFA accumulation was also detected in actinomycetes and eukaryotic microorganisms. These results suggest that SA application prompted the root exudates (e.g., organic acids), leading to the increase of soil microbial population. However, in the most bacteria, treatment with IPU did not induce accumulation of PLFA, except for eukaryote that had a positive response to IPU stress.

More than 70 PLFAs were assessed in this study. Microbial biomass, represented by the total PLFA, ranged from 8.48 to 22.01 nmol g^{-1} and was typically higher in RS than other soil fractions in all treatments (Figure 3A). The change of PLFA is indicative of a stressful environment for the soil microorganisms.[39] The major shifts in the microbial community under the IPU and/or SA treatment could be ascertained using the percentage of stress indicator (the ratios of bacterial to fungal PLFAs and Gram-negative to Gram-positive bacteria). The stress level of microbes in the unplanted and IPU-treated soils was significantly higher than that in the control samples (Figure 3B). The RS had a marginally lower stress compared to the IPU-free plant soils, while the stress was lower than that in both BS and NRS. Remarkably, the stress was increased by IPU treatment alone, especially in RS, BS, and NRS.

IPU treatment increased the ratio of bacterial to fungal PLFA (B/F), but the ratio decreased significantly in the presence of SA. No significant difference in B/F PLFAs was observed between the unplanted soil and planted soil (RS, BS, and NRS) without SA and IPU treatment (Figure 3C). Interestingly, the B/F PLFAs in the presence of SA progressively declined in the following sequence: NRS > BS > RS; meanwhile, the opposite trend was observed in samples without SA application (Figure 3C). Lower B/F ratios are considered to be indicative for a more sustainable agro-ecosystem, in which organic matter decomposition dominates the provision of plant nutrients.[40,41] The SA treatment had a stimulatory effect on the content of fungal PLFA in both the IPU-free and IPU-treated soils (Table 3).

The ratio of Gram-negative bacteria/Gram-positive bacteria (GN/GP) in the IPU-exposed unplanted soil was lower than that of the unplanted control (decreased by 27.4%) (Figure 3D). Meanwhile, the ratio of GN/GP was increased by application of SA in RS of SA and IPU+SA treatment. Additionally, the SA application also increased the amount of specific microbial PLFAs to some extent (Table 3). The content of $Gram^+$ PLFAs was higher than that of $Gram^-$ PLFAs in RS and NRS soils, revealing that $Gram^+$ was more resistant to the IPU toxicity. Taken together, although PLFAs in different microbial community and soil fractions varied under IPU exposure, provision of SA could promote accumulation of PLFAs in bacteria with or without IPU.

Principal component analysis and correlation matrix of multivariate. Using principal component analysis (PCA), the experimental data can be transformed into a new coordinate system by analyzing the variance. As shown in Figure 4, the first two principal components explained 0.747 of the total variance (R^2), with 50.8% and 23.9% for the first (PC1) and the second (PC2) components, respectively. The model can be considered valid, because the prediction goodness parameter (cum Q^2) was 0.475 (Supporting Information Table S4) and R^2 was not more than 2 units of cum Q^2.[42]

Soil samples with IPU were on the positive side of PC2, and samples without IPU were on the negative side of PC2 (Supporting Information Figure S1A), indicating a remarkable difference between the two treatments and that PC2 was markedly influenced by IPU exposure. The SA- and IPU+SA-treated RS was clearly distinguished by positive PC1 values, indicating that provision of SA had the largest effect on the first

principal component. Within RS, samples associated with IPU treatment alone and IPU+SA were significantly different.

The loading scatter plot showed the contribution of each variation to the first two principal components, which disclosed the dominating correlation structure among the variables. The plot can be divided into four colored regions, where the variables in the same tinctorial region are positively correlated (Supporting Information Figure S1B). The total PLFA had the highest contribution to PC1 and was positively correlated with variables in the red region as well as the yellow and blue regions, but negatively correlated with the stress indicator, the concentration of IPU (C_{IPU}), and the ratio of bacteria/fungi (B/F). This observation suggests that the soil microbial biomass had an important role in IPU degradation and was facilitated by release of organic acids. Likewise, the soil enzyme activities were located in the diagonal direction of the green zone, illustrating that the enzyme activities were negatively associated with the IPU (C_{IPU}) concentration and the ratio of bacteria/fungi (B/F) (Supporting Information Figure S1B).

The biplot indicated the effect of variables on the observations (Figure 4), showing that the soil microbial biomass and IPU concentration had the main contribution to the discrimination among the differently treated samples. The RS with SA and IPU+SA treatments was close to the variables of soil microbes and organic acids, but situated on the opposite side of the concentration of IPU. This indicated that application of SA prompted the soil microbial biomass, secretion of organic acids from wheat root, and degradation of IPU.

The correlation matrix was additionally used to assess the inner relationship among variables. The activities of soil enzymes were positively related to the tartaric and malic acids and some soil microbes (G^-, G^+, fungi, and AM fungi) but were negatively related to the stress indicator and concentration of IPU (Table 4). These results indicated that SA-promoted organic acids stimulated the growth of bacteria and fungi following the enhancement of soil enzyme activities and leading to the accelerated degradation of IPU.

Analysis of IPU residues and derivatives in rhizosphere soil. In the positive mode, $[M + H]^+$ ions of IPU and its metabolites in the rhizosphere sample were identified by high resolution/full-scan MS detection, and the registration of mass spectra was allowed to achieve a mass accuracy better than 5 ppm error (ppm) for all protonated $[M + H]^+$ molecules from a single analysis. LC-MS/MS spectra of IPU metabolites were obtained via fragmentation of molecular ions. The fragmentation pattern of IPU was subsequently used for the confident structural identification of metabolites. The full scan mass spectra of fragment ions of rhizosphere soil treated with IPU were compared to those of the blank soil to find out the potential metabolites. The parent herbicide and its main five

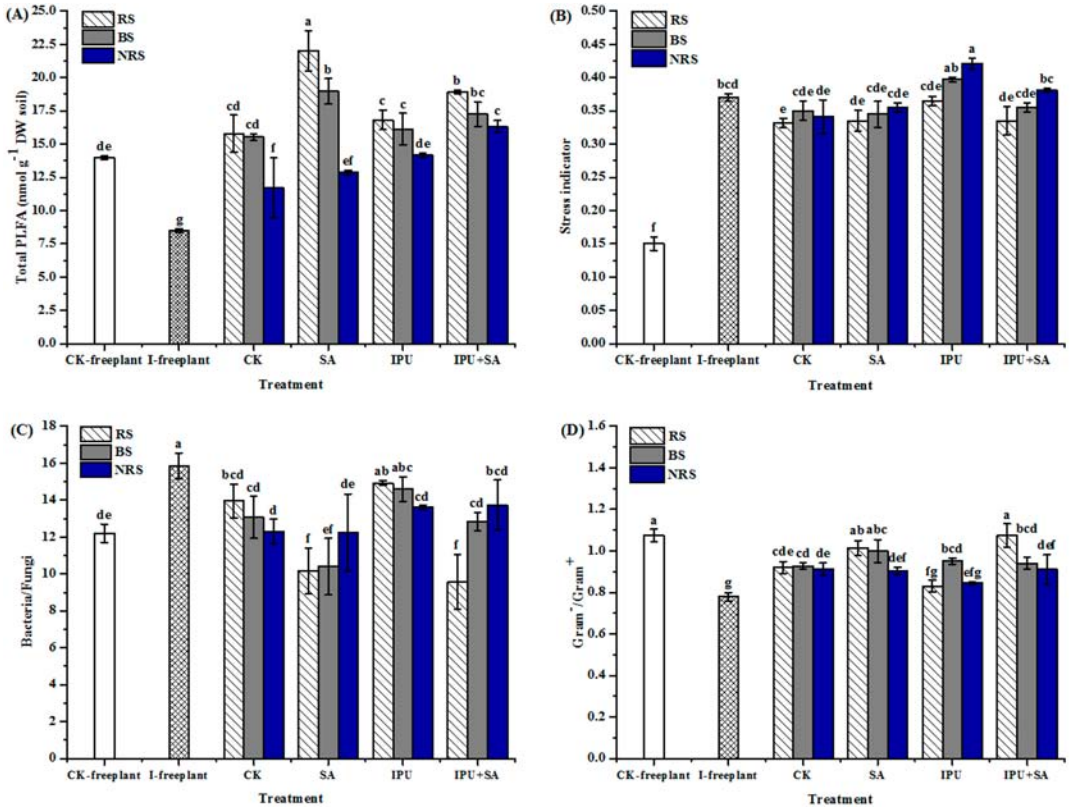

Figure 3. Total PLFA concentration (A), stress indicator (B), bacteria/fungi (C), and $Gram^{-}/Gram^{+}$ (D) of rhizosphere (RS), nonrhizosphere (NRS), and bulk soils (BS) with or without IPU and/or SA exposure. PLFA, the phospholipid fatty acid; $Gram^{-}/Gram^{+}$, Gram-negative bacteria/Gram-positive bacteria. Values are the means ± standard deviations (n = 3). Data with different letters are significantly different ($p < 0.05$, Turkey's test).

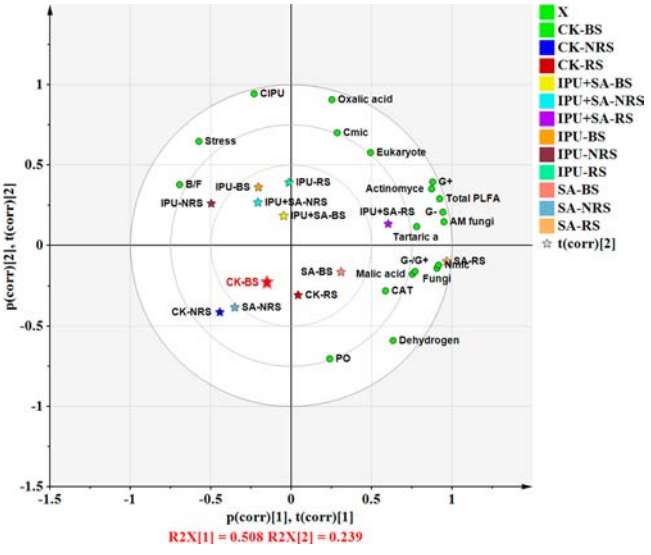

Figure 4. Biplot of 19 detected indexes of three parts of rhizosphere (RS), nonrhizosphere (NRS), and bulk soils (BS) with wheat planted for 10 d. Seedlings grew in soils with IPU (4 mg kg^{-1}) for 4 d. After that, the leaves were sprayed with 5 mg L^{-1} SA once a day for 6 d. PCA axes explained 50.8% and 23.9% of the total variation for sediment 1 and 2 microcosms, respectively.

metabolites (2# to 6#) were detected, and the mass data of IPU and its 5 metabolites of IPU were summarized in Table 5.

The extract MS^2 spectra of the molecular ion of m/z 207 occurred at the retention time of 8.07 min (Supporting Information Figure S2A). Fragmentation of IPU led to two product ions at m/z 165 and 134. The most abundant product ion at m/z 165 was generated by the loss of an isopropyl group (42 Da). The product ions at m/z 134 was 31 Da less than m/z 165, indicating the loss of a $-N(CH_3)_2$ group (Supporting Information Figure S3A). These characteristic product ions above were important for identification of IPU-metabolites.

The mass spectrum of metabolite 2# peaked at 5.76 min, and the fragment ion of m/z 223 was produced by addition of 17 Da (hydroxy group) from IPU (Supporting Information Figure S2B). Its main product ions were m/z 205 and 165, which were the same as the two fragment ions of IPU. Thus, metabolite 2# was identified as hydroxylated IPU (2-OH-isopropyl-IPU) with the addition of a hydroxyl group (Supporting Information Figure S3B; Table 5).

2-OH-Monodemethyl-IPU (metabolite 3#) was eluted at 5.32 min with protonated molecular ion $[M + H]^+$ of m/z 209 in the full-scan MS (Supporting Information Figure S2C). In the MS^2 spectrum, it had the typical and most abundant fragment ion at m/z 191 (loss of a hydroxy group), which further lost a neutral moiety of $O{=}C{-}NH{-}CH_3$ to form ion at m/z 134 (Supporting Information Figure S3C; Table 5).

Metabolite 4# peaked at 6.92 min and had a protonated molecular ion $[M + H]^+$ at m/z 195 (Supporting Information Figure S2D). The MS/MS spectra gave prominent ions at m/z 178 and 150, which were produced by the loss of $-NH_2$ via doffing-amidogen and further loss of $C{=}O$, respectively (Supporting Information Figure S3D; Table 5). Thus, we tentatively elucidated metabolite 4# to be formed by N-dealkylation of metabolite 2#.

[a]R_t: retention time. [b]MS^2 m/z: Base peaks of MS^2 fragment ions are shown in the table.

Metabolite 5# eluted at 7.91 min with a protonated molecular ion $[M + H]^+$ at m/z 193 and was 14 Da less than its parent IPU and formed by a loss of methyl group (Supporting Information Figure S2E). The corresponding fragment ions at m/z 151 were generated by loss of the isopropyl group and m/z 136 through cleaving of an amino C−N bond. The fragment ion of m/z 136 further lost an isopropyl group and gave rise to the ions at m/z 94, which represented the rest anilin moiety (Supporting Information Figure S3E; Table 5). Thus, metabolite 5# could be characterized as *N*-dealkylation products of parent IPU.

The molecular ion at m/z 179 (metabolite 6#) was eluted at 7.56 min (Supporting Information Figure S2F). The MS/MS spectra showed that elimination of C_3H_7, NH_2, and O═C-NH_2 groups led to occurrence of fragment ions at m/z 137, 120, and 94, from which Metabolite 6# was defined as didesmethyl-IPU (Supporting Information Figure S3F; Table 5).

The residual concentration of parent IPU and IPU-derived metabolites in the presence and absence of SA was determined. The concentrations of IPU in rhizosphere soil with SA application were moderately decreased by 14.5% compared to those without SA application (Figure 5). Furthermore, the relative intensities of IPU-metabolites in rhizosphere soil were much greater in the presence of SA than those in the absence of SA. IPU-metabolites with m/z 195, 193, and 179 under the IPU +SA treatment were increased by 52.7%, 9.1%, and 31.8% compared to the IPU treatment alone, respectively. The other two IPU-derivatives (m/z 223 and 209) were slightly increased by SA application but were not significantly different with IPU treatment alone (Figure 5).

DISCUSSION

Our recent study has demonstrated that SA was able to reduce the accumulation of IPU and improve the antitoxic capacity against IPU in wheat plants.[22] Such an observation allowed for the assumption that SA-regulated low levels of IPU in wheat plants are most likely associated with the degradation of IPU in soils, although the chemical and biological mechanisms for SA

J. Agric. Food Chem. 2015, 63, 92−103

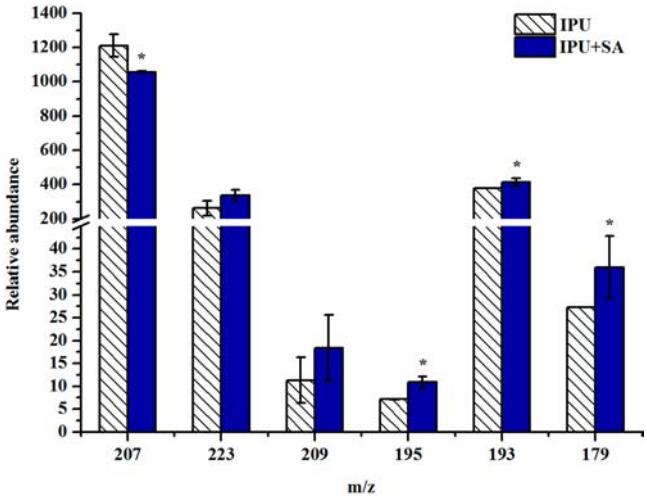

Figure 5. IPU-derived degradation products extracted from IPU-treated rhizosphere soil planted with wheat for 10 d under SA treatment or untreatment. Seedlings grew in soils with IPU (4 mg kg^{-1}) for 4 d. After that, the leaves were sprayed with 5 mg L^{-1} SA once per day for 6 d. Vertical bars represent three replicate measurements ± standard deviations. Asterisks indicate the significant differences between the treatments of SA+IPU and IPU ($p < 0.05$).

action in the plant are largely unknown. To investigate the role of SA in regulating IPU degradation in plants, we in detail characterized the IPU residues and their degradation products in wheat using UPLC-TOF-MS/MS.[43] Most detected IPU-derivatives were sugar-conjugated. Degradation and glycosylation of IPU-derivatives could be enhanced by applying salicylic acid (SA). While more sugar-conjugated IPU-derivatives were identified in wheat with SA application, lower levels of IPU were detected, indicating that SA is able to accelerate intracellular IPU catabolism. Because SA can promote IPU decay in wheat plants, this prompted us to assume that SA could also affect IPU degradation in soil through cultivation of wheat plants. Thus, we located the IPU residues in three soil fractions including RS, BS, and NRS, and we chemically characterized IPU degradation products in the major region of rhizosphere soil. Using UPLC/Q-TOF-MS/MS, more IPU-derivatives have been detected in the soil with SA-treated plants, indicating that SA can also enhance IPU catabolism in soil. To figure out the process of IPU degradation, we performed a comprehensive study by analyzing exudation of three major organic acids in roots and examining soil microbial population, biomass, nutrition, enzyme activities, group-specific PLFAs, and their correlations, all of which are closely associated with degradation of IPU. SA provision could promote the IPU degradation in soil because IPU concentrations with SA in RS, BS, and NRS were much lower that those without SA treatment (Table 1). SA-improved IPU degradation in the soil was most likely through enhancement of exudation of organic acids from roots, soil microbial population, and consequently acceleration of removal of IPU. To our knowledge, this is the first report on the comprehensive analysis of IPU degradation in soil fractions promoted by SA.

It is well-known that degradation of organic compounds in soils is mainly executed by microorganisms, but the efficacy of the degradation relies on the activity of the microbial community. Many environmental factors influence the processes, including root exudates, soil structure, nutrient conditions, and others.[19,44,45] One of the most active sites for organic compound degradation is the rhizosphere, where many root exudates are liberated from plants. In this study, only three organic acids, tartaric, malic, and oxalic acids, were detected in wheat, although we simultaneously examined several other organic acids, such as citric and succinic acids, but all of them were undetectable. This could be the result of different plant species that secrete only some kinds of dominant organic acids, particularly under toxic substances. For example, buckwheat (*Fagopyrum esculentum*), a monocot, predominantly secretes oxalic acids when challenged by excess aluminum (Al).[46] By contrast, *Cassia tora*, a dicot, tends to release citric acids when exposed to Al.[20] Root exudation of organic acids such as oxalate and malate induced by toxic organic compounds was also reported in several crops, such as maize, wheat, ryegrss, and *Cucurbita pepo*.[47,48] However, tartaric and malic acids were only detected in root tissue and rhizosphere soil, while oxalic acid occurred in root tissue and rhizosphere soil, nonrhizosphere, and bulk soil. One of the possible reasons is that both tartaric and malic acids were more favorably degraded in rhizosphere soil than oxalic acid, making less tartaric and malic acids accumulated in nonrhizosphere and bulk soils. Meanwhile, a large amount of oxalate could efflux to the rhizosphere that possibly diffused to nonrhizosphere and bulk soil. Alternatively, oxalate can also be generated by some microorganisms because some types of microbes are able to use soil-existing organic compounds (e.g., DOM) to release oxalate.[49]

The negative correlation between the exudation of organic acids and the concentration of IPU in the presence of SA indicated that the organic acids affected the IPU degradation by a biological process. Recent studies have demonstrated that dissolved organic matter (DOM) or organic acids in soil were observed to enhance the dissolution of prometryn,[50] chlorotoluron,[12] and isoproturon.[51] Therefore, the biodegradation of IPU could be promoted by the organic acids. In fact, organic acids released from plant roots provide the necessary nutrition and energy for survival and proliferation of rhizosphere microbes.[52] For instance, malate secreted from *Arabidopsis* roots selectively signaled and recruited the beneficial rhizobacterium *Bacillus subtilis* FB17.[53] The present study showed that exudation of tartaric and malic acids in the presence of SA increased soil microbial PLFA concentrations in rhizosphere soil, consistent with the evidence that soil microbial carbon (C_{mic}), nitrogen (N_{mic}), and microbial quotient were improved. Thus, the wheat growth may influence the soil microbial biomass by altering the spatial distribution and content of available substrates from rhizodeposition in the presence of SA.

Soil microbes play an important role in soil formation, nutrient cycling, and contaminant degradation, and the rate of herbicide metabolism was directly related to the microbial biomass.[10] In our case, total PLFAs concentration, as a biomarker of soil microbial biomass, showed a negative correlation with IPU residues (Figure 3A; Table 1). Moreover, soil microbes are sensitive to the changing environment.[54] It was found that the ratio of B/F was higher at IPU than that at IPU+SA, suggesting that a higher proportion of fungi occurred in the presence of SA. The proportion of fungi prompted by SA in soil was conducive to accelerate the degradation of IPU. $Gram^-$ bacteria were known to be sensitive to the utilizable carbon[55] and generally stimulated by plant root exudation in soil.[56,57] It was also found that the proportion of $Gram^-$ bacteria with IPU+SA was significantly higher than that with IPU, implying that a more utilizable carbon source was available

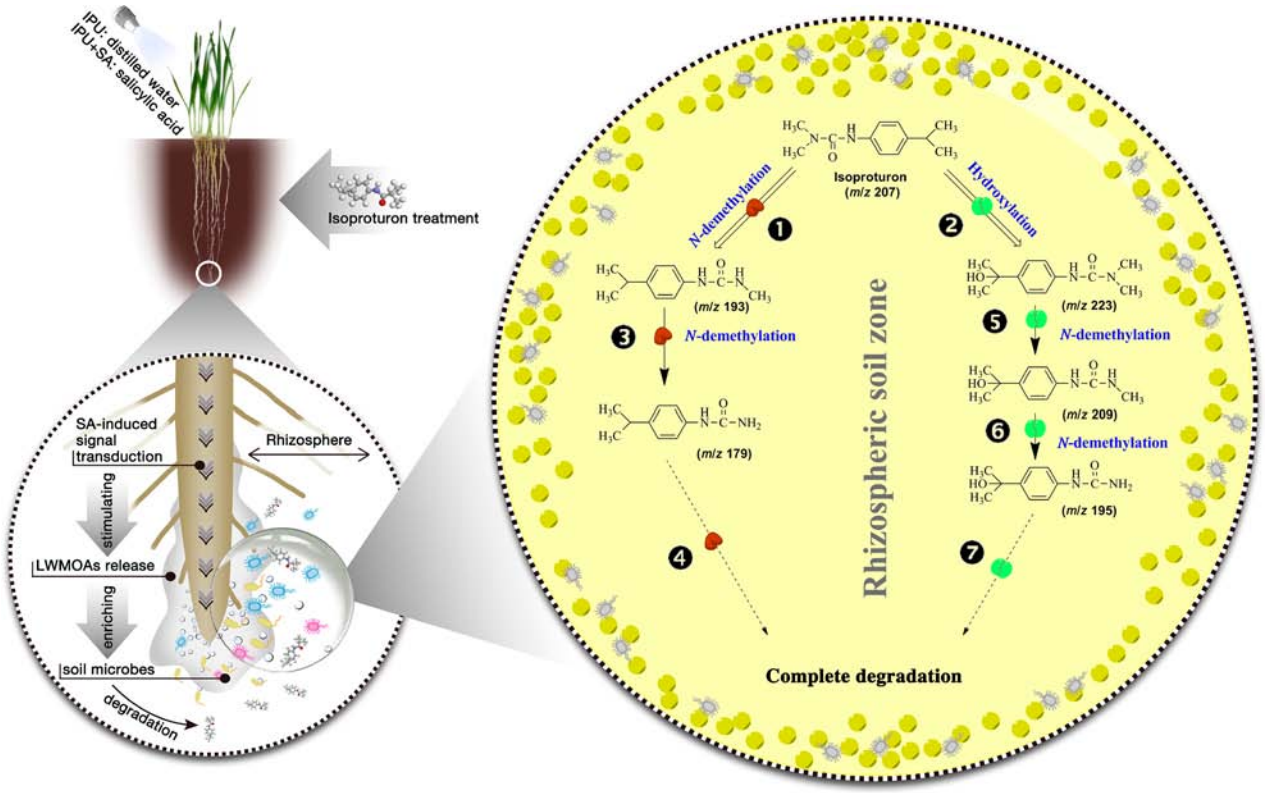

Figure 6. Proposed pathway of degradation in soil with wheat planted for 10 d.

in the presence of SA. Taken together, the SA-responsive release of organic acids promoted microorganism growth by improving C_{mic}, N_{mic}, and microbial quotient, thus making more IPU degraded.

Soil enzyme activities are also thought of as sensitive to pollutants and have been proposed as biomarkers for soil organic pollution degradation.[16,18] Herbicide residues disturb soil microbial communities by negatively affecting soil enzyme activities.[35] The activities of DHA were inhibited by IPU as a result of IPU toxicity to soil microbes (Figure 2) but were recovered in the presence of SA, pointing to the role of SA in alleviating the toxicity of IPU. PO is an extracellular enzyme and is also involved in biodegradation and detoxification of some aromatic xenobiotics such as organochlorinated compounds or polycyclic aromatic hydrocarbons (PAH).[27] By examination of PO, we found that its activity changed similarly to DHA in RS. However, the activity of CAT with IPU+SA was lower than that with IPU in RS. CAT is an intracellular enzyme found in most bacteria and can split hydrogen peroxide into molecular oxygen for preventing cells from damage by reactive oxygen species (ROS).[23,58] Notably, SA was well demonstrated to suppress the ROS production under environmental stresses.[59,60] The CAT activity was down-regulated, possibly due to the SA-induced decrease in ROS production.

The pathway of IPU degradation in rhizosphere soil was investigated by identifying intermediate metabolites. UPLC-TOF-MS/MS analysis resulted in characterization of five intermediate metabolites, including 2-OH-isopropyl-IPU (Metabolite 2#), 2-OH-monodemethyl-IPU (Metabolite 3#), 2-OH-didemethyl-IPU (Metabolite 4#), monodemethyl-IPU (Metabolite 5#), and didemethyl-IPU (Metabolite 6#). Unlike detoxified herbicide derivatives by means of conjugation with polar donor metabolic molecules,[61] microbial-meditated decay of IPU was associated with the catabolic pathway, leading to the direct degradation. Based on the finding, we proposed two main catabolic pathways of IPU in the present study. As shown in Figure 6 (Step 1, 3), one of the IPU-degradation pathways proceeds by consecutive *N*-demethylation to monodemethyl-IPU (Metabolite 5#) and didesmethyl-IPU (Metabolite 6#). This pathway has been studied mainly in bacterial cultures.[62,63] The other parallel pathway was initiated by hydroxylation of the isopropyl side chain of IPU to 2-OH-isopropyl-IPU (Metabolite 2#), which was subsequently *N*-demethylated to 2-OH-monodemethyl-IPU (Metabolite 3#) and 2-OH-didemethyl-IPU (Metabolite 4#) (Figure 6; Step 2, 5, 6). These IPU hydroxylated derivatives were commonly produced by soil fungi.[11] The detected intermediates can be further broken down by aerobic microbes, of which the process was divided into three stages—ring hydroxylation, cleavage of aromatic ring, and oxidation of the aliphatic moiety to Krebs cycle intermediates—and could be finally broken down to CO_2 and H_2O (Figure 6; Step 4, 7).[64] In a nutshell, provision of SA stimulated exudation of organic acids in rhizosphere soil. The increased organic acids enriched the soil microbial communities, modified the soil enzyme activity, and consequently accelerated the degradation of IPU (Figure 6).

Supporting Information

ABSTRACT: The present study investigates aroma transfer from commercial nursing tea, consumed in the maternal diet, into human milk by correlating sensory assessments with quantitative analytical data. The target terpenes were quantified in milk (expressed before and after tea consumption) and tea samples via gas chromatography−mass spectrometry (GC-MS) using stable isotope dilution assays (volunteer donors $n = 5$). Sensory analyses were carried out on different milk samples from a single donor, sampled before (blank) and at different times after tea ingestion. Quantitative analysis revealed that no significant odorant transfer into milk was observed after lactating women drank the tea. The comparative sensorial analysis of milk samples expressed before and after tea consumption confirmed that tea ingestion had no significant influence on the odor profile of human milk.

KEYWORDS: *human milk, odorant transfer, herbal tea, SAFE (solvent-assisted flavor evaporation), sensory*

INTRODUCTION

The potential transfer of odorants into breast milk attracts increasing attention in scientific research. There are several indications that odorants are transferred from the maternal diet into mother's milk and may influence the nursing behavior and later dietary habits of infants. As one example, infants whose mothers consumed carrot juice during pregnancy or nursing accepted carrot-flavored cereals better than babies without this prior exposure.[1] Thus, breast-fed children may perceive an array of different flavor impressions with the odor of human milk consecutively changing due to variable maternal nutrition. This assumption is supported by a study from Hausner et al., who showed that breast-fed infants, in contrast to formula-fed children, have high initial acceptance of caraway-flavored purée irrespective of whether previously exposed to *d*-carvone through mother's milk or not, suggesting that the process of breastfeeding itself facilitates acceptance of novel flavors.[2] There are many studies focusing the research on sensorial effects of odorants transferred into human milk.[2−5] Mennella et al. evaluated the odor change of human milk after lactating women ingested garlic,[3] beer,[4] or carrot juice[5] but did not characterize the alteration either by description of the smell or by chemical analysis of the milk's odorants. Studies aimed at investigating the molecular aspects of odorant transfer into human milk are thus few. Hausner et al. demonstrated the transfer of d-carvone from the maternal diet into breast milk.[2] These authors observed that several orally ingested volatiles are transferred according to specific time profiles and in relatively low percentages into mother's milk.[6] Similar results were obtained by Kirsch et al. for the orally ingested odorant 1,8-cineole.[7] Contrarily, Sandgruber et al. observed that the sensory profile of breast milk from women consuming fish oil capsules remained unmodified in relation to the control human milk with regard to their content of specific fish oil marker substances.[8]

Overall, odorant transfer from the maternal diet into human milk is not yet fully understood. The general problem of studies in this field is that investigators either are dealing with complex food matrices with often variable natural odorant values that are mostly in very low concentration ranges or perform highly controlled studies with odorant model applications that are, at times, difficult to relate to general real-life situations. Food containing naturally concentrated components may be represented by nursing tea, which is often consumed during pregnancy and nursing as the herbal constituents are traditionally known to foster lactation. The main ingredients of this product are fennel, anise, and caraway. Previous analyses of our group have shown that the main aroma compounds of fennel−anise−caraway tea (Meßmer) are limonene, 1,8-cineole, fenchone, estragole, d-carvone, *trans*-anethole, *p*-anisaldehyde, and anisketone. Accordingly, the focus of this study was on the investigation of odorant transfer of these selected terpenes from nursing tea into human milk. Specifically, the aim was to elucidate if characteristic and potent odorants in nursing tea are transmitted into the milk, on both qualitative and quantitative bases, and to relate this molecular analytical data to the respective sensory impact of nursing tea consumption on breast milk aroma profiles.

MATERIALS AND METHODS

Chemicals. Unlabeled (*R*)-(+)-limonene, 1,8-cineole, (1*R*)-(−)-fenchone, estragole, (*S*)-(+)-carvone, *trans*-anethole, *p*-anisaldehyde, anisketone, methyl octanoate, and $NaHCO_3$ were purchased from Aldrich (Steinheim, Germany). Dichloromethane (DCM) was obtained from ACROS Organics (Geel, Belgium). Na_2SO_4 was

purchased from VWR International BDH PROLABO (Lutterworth, UK). Deuterium-labeled limonene-d_2, 1,8-cineole-d_3, estragole-d_4, carvone-d_4, *trans*-anethole-d_3, *p*-anisaldehyde-d_3, and anisketone-d_3 were provided by aromaLAB AG (Freising, Germany).

Human Milk Samples. Human milk samples were provided by volunteer donors (A−E) who gave written informed agreement to participate in the experiment, which was obtained prior to sample collection and analysis after a full explanation of the intent and nature of the test procedure. Withdrawing from the experiment was possible at any time. The experiment was approved by the Ethical Committee of the Medical Faculty, Friedrich-Alexander-University Erlangen-Nürnberg. Five lactating women, one multiparous, four primiparous, were recruited for the aroma transfer experiment. They ranged in age from 22 to 35 years (mean 29.8 years), and their infants ranged from 6 to 55 weeks of age (mean 33.4 weeks). None of the mothers was allergic to any of the tea ingredients. The subjects had no acute medical complaints during the experiment, normal breast milk production, and no breast infection. All mothers produced milk in excess of their baby's needs. The sampling took place according to each mother's preference and with their own systems, by manual expression or the usage of either a mechanical or electrical breast pump. Sample volumes ranged from approximately 10 to 80 mL. The fresh milk samples were analyzed within 4 h after expression, with samples stored in a refrigerator in the meantime, or after a maximum of 4 days of storage at −20 °C.

Human Milk Samples for the Odorant Transfer Experiment. The experimental setup consisted of three different blocks, each of which comprised a period of 6 days. During these days the subjects were not allowed to consume herbs, aliments including herbs, and especially fennel, anise, or caraway. They also were advised not to use cosmetic or sanitary products containing herbal ingredients. The first 4 days of each block were used as wash-out days. At the fourth day of each block, the women had to collect a milk sample, the control sample. On day 5, the mothers were instructed to drink 950 mL of customary fennel−anise−caraway tea (Meßmer, Ostfriesische Tee Gesellschaft Laurens Spethmann GmbH & Co. KG, Seevetal, Germany) within 30 min. The preparation of the tea was according to the following instructions: the mothers had to incubate four tea bags with exactly 1 L of boiling water for 6 min. Then the tea bags had to be removed without squeezing them. A smallish leftover (about 70 mL) should be cooled to room temperature, and then 50 mL thereof was bottled for analysis. The remaining cool tea should be drunk. The participants were required to express milk 30 min (first block), 1 h (second block), and 2 h (third block) after total tea ingestion. In each case, control samples were taken as blanks prior to tea ingestion; these samples are, accordingly, named blank 0.5 h, blank 1 h, and blank 2 h. Due to various degrees of lactation, not all subjects participated in every block and some mothers repeated single blocks.

Human Milk Samples for Sensorial Analyses. To examine if adults could discriminate differences in odor of mother's milk as a function of fennel−anise−caraway tea ingestion, a sensory panel orthonasally evaluated the respective human milk samples. These samples were from a donor who expressed several small milk samples (25−40 mL) directly before and 30, 105, 155, and 225 min after tea ingestion and stored them in the refrigerator until sample collection. Time points of sampling were, on the one hand, dictated by the breastfeeding regimens and, on the other hand, defined according to previous evidence on systemic bioavailability of odorants after ingestion obtained from a range of studies from our and other groups as monitored via blood, breath, and urine.[9−12] All in all, the sum of these studies clearly shows systemic appearance of odorants to take place roughly between 30 and 120 min. Sample collection took place immediately after expression of the last sample, followed by immediate sensory analysis, thereby ensuring that the samples were stored for no longer than 5 h in total. For sensory evaluation, samples were adjusted to room temperature directly before testing.

Extraction of Milk Sample Odorants by Solvent-Assisted Flavor Evaporation (SAFE). For a fast and careful isolation of the volatiles from human milk (12.31−81.00 g), in this case potential nursing tea terpenes, SAFE[13] was used. Each milk sample was thawed if necessary, weighed in a flask, spiked with the respective internal standards (range of the concentrations of the labeled substances in the internal standard solutions for milk in DCM: limonene-d_2, 5.61−7.30 μg/mL; 1,8-cineole-d_3, 1.30−2.39 μg/mL; estragole-d_4, 0.45−0.64 μg/mL; (*R*)-(−)-carvone-d_4, 1.06−1.55 μg/mL; *trans*-anethole-d_3, 0.58−7.73 μg/mL; *p*-anisaldehyde-d_3, 1.45−2.36 μg/mL; anisketone-d_3, 7.64−11.17 μg/mL) according to the sample volume (approximately 1−2 μL of each internal standard solution per gram of milk), and stirred at room temperature for 10 min to homogenize with the standard. Subsequently, DCM (50% v/v) was added to the respective milk sample, and the solutions were equilibrated by stirring for 30 min until a stable phase had formed. These emulsions were immediately distilled using the SAFE apparatus at 50 °C and approximately 1×10^{-4} mbar. Evaporated volatiles were frozen with liquid nitrogen, and after thawing, the two distillate phases (DCM and water from the sample) were extracted three times with 25 mL of DCM. The combined DCM phases were dried over anhydrous Na_2SO_4 and concentrated by means of Vigreux distillation at 50 °C. Subsequently, the concentrate was extracted twice with $NaHCO_3$ solution (50% v/v) to remove carboxylic acids, dried over Na_2SO_4, and finally concentrated to a total volume of approximately 100 μL at 50 °C by means of microdistillation. The prepared sample extracts were stored at −20 °C until measurement, but no longer than 4 days.

Extraction of the Tea Samples by Liquid−Liquid Extraction. For each time-dependent odorant transition experiment, samples of the consumed tea were analyzed. Compared to the other terpenes, the contents of *trans*-anethole and carvone in the tea beverage were very high; thus, these compounds had to be determined separately in diluted tea. Therefore, 0.5 mL of tea beverage was placed in a 100 mL measuring flask that was then filled with water; 150 μL of the internal standard solution in DCM, containing carvone-d_4 (c = 3.83−92.79 μg/mL) and *trans*-anethole-d_3 (c = 4.07−22.79 μg/mL), was added to 10 mL of this solution, and subsequently the sample was stirred at room temperature for 10 min to homogenize with the standard. Afterward, the diluted tea was extracted three times with 30 mL of dichloromethane. The combined organic phases were dried over anhydrous Na_2SO_4 and concentrated by means of Vigreux distillation and microdistillation. For analysis of the undiluted tea, 25 mL of the beverage was spiked with 50 μL of the internal standard solution in DCM comprising 1,8-cineole-d_3 (c = 2.00−2.37 μg/mL), estragole-d_4 (c = 40.84−50.27 μg/mL), *p*-anisaldehyde-d_3 (c = 18.02−294.64 μg/mL), and anisketone-d_3 (c = 2.91−50.27 μg/mL) and with 25 μL of the internal standard solution containing limonene-d_2 (c = 1.87−2.36 g/mL). The tea was stirred for 10 min at room temperature, then the sample was extracted three times with 75 mL of DCM, and the further preparation was as described for the diluted tea. The prepared tea extracts were stored at −20 °C until measurement, but no longer than 4 days.

Quantification by Stable Isotope Dilution Assay (SIDA). The quantification of the terpenes in human milk and tea was carried out by means of stable isotope dilution assays.[14] SIDA is the most precise quantification technique at hand in modern aroma analytics and is the optimum methodology that can rule out potential losses of target odorants during isolation, workup, and analysis.[15] During this procedure, defined amounts of the respective stable isotope-labeled analytes were added prior to sample preparation to act as internal standard. This quantification technique has the advantage that the added labeled analytes behave similarly to the unlabeled analytes in the sample; both, analyte and labeled standard, experience the same losses or other changes during sample preparation, so that errors from such processes are automatically compensated. According to the analytical requirements, pentane solutions containing the respective labeled analytes were diluted in DCM. The resulting concentrations of the labeled analytes, limonene-d_2, 1,8-cineole-d_3, estragole-d_4, carvone-d_4, *trans*-anethole-d_3, *p*-anisaldehyde-d_3, and anisketone-d_3, were subsequently confirmed using methyl octanoate as an internal standard and solutions of the respective unlabeled analytes to establish a three-point calibration curve.[7] The measurements were performed using a gas chromatograph with flame ionization detector (GC-FID) system. Because the concentrations of the labeled substances might change

dx.doi.org/10.1021/jf504073d | J. Agric. Food Chem. 2015, 63, 104−111

over time, for example, because of partial evaporation of the solvent when the bottles are opened for usage, determination of the concentrations was repeated approximately every 4 weeks. Different calibration solutions for the quantification of the analytes in human milk and tea samples were prepared in DCM, comprising various concentrations of all unlabeled analytes but always the same concentrations of the respective isotopically labeled analytes. The concentrations of analytes in the samples were calculated by inserting the signal ratio from gas chromatography−mass spectrometry (GC-MS) analysis of the unlabeled to labeled molecules in the resulting calibration equations. The concentration of fenchone in the samples was determined using carvone-d_4 as respective labeled standard. For each calibration curve (X, ratio of concentrations; Y, ratio of areas) several weighting factors were evaluated to find the one that matched best.[16] The coefficient of determination of all calibration curves was always >0.99.

Gas Chromatography. *GC-FID.* For the determination of the concentrations of the labeled analyte solutions, a GC-FID system (Trace GC Ultra, Thermo Scientific, Dreieich, Germany) was used together with a DB-FFAP (30 m length, 0.32 mm inner diameter, and 0.25 μm film thickness; Agilent J&W GC columns, Munich, Germany) as analytical capillary. An uncoated, deactivated fused silica capillary was used as a precolumn (0.32 mm inner diameter, 0.5−3.5 m length) and changed regularly to avoid accumulation of any contaminants. Helium was used as a carrier gas, and a constant flow of 2.80 mL/min was applied. The temperature program started with an oven temperature of 40 °C that was held for 2 min followed by an 8 °C/min increase to 170 °C and a 40 °C/min increase to 230 °C, which were held for 5 min. Injections were carried out manually with an injection volume of 1 μL.

GC-MS. The GC-MS with a quadrupole system (GC 7890A with MSD 5975C, Agilent Technologies, Waldbronn, Germany) was used together with a DB-FFAP (30 m length, 0.25 mm inner diameter, and 0.25 μm film thickness; Agilent J&W GC columns, Munich, Germany) for the measurement of milk and tea sample extracts and for the respective calibration solutions. The mass spectrometer was operated in electron ionization mode at 70 eV. Helium was used as carrier gas, and a constant flow of 1.3 mL/min was applied. The temperature program started with an oven temperature of 40 °C that was held for 2 min followed by a 4 °C/min temperature increase to 170 °C and a 40 °C/min temperature increase to 230 °C; the end temperature was held for 10 min. The injection volume was 2 μL. Temperatures used were 200 °C for the MS transfer line, 200 °C for the ion source, and 150 °C for the quadrupole. The analytes in milk and tea samples were identified by comparison of the mass spectra and retention indices according to the method of Van den Dool and Kratz[17] with those of the commercially available substances.

Sensory Analysis. A trained sensory panel evaluated fennel−anise−caraway tea and the respective human milk samples orthonasally to assess if the odor of breast milk changed after the woman consumed fennel−anise−caraway tea. Before the sensory analysis of the samples, a trained panel (eight females, two males; 24−39 years of age, mean = 27.64 years) established in a preliminary test the attributes for milk and fennel−anise−caraway tea with the help of exemplary samples of tea and human milk. For the evaluation of the samples, the panelists were subsequently asked to score the intensities of these attributes on a scale from 0 (no perception) to 3 (strong perception); intermediate steps of 0.5 were allowed. The sensory analysis of the nursing tea was performed by a trained panel of 12 females and 3 males (24−40 years of age, mean = 28.33 years); the evaluation of the human milk samples took place on another day by a slightly different panel of 12 females and 1 male (22−39 years of age, mean = 27.46 years).

Method Validation and Investigation of Potential Storage Effects on the Investigated Terpenoid Substances in Human Milk. Detailed information about the method validation and the investigation of potential storage effects on the investigated terpenoide substances in human milk can be found in Appendix A of the Supporting Information.

Statistical Analyses. By means of a Mandel test, the calibration curves were tested for linearity. Few curves were linear; the other curves were found to be quadratic. However, differences in linear and quadratic curves were extremely low, so that for all calibrations the linear regression was chosen. Outliers were detected by the Nalimov test. For the comparison of different means, Student's t test was used. The results of the sensorial experiments were tested by two-way analysis of variance (ANOVA) followed by Fisher's least significant difference (LSD) test in the case of normally distributed values or by the Scheirer−Ray−Hare test, followed by the Schaich−Hamerle test, if values were not normally distributed.

RESULTS

Quantification of Odorants in Fennel−Anise−Caraway Tea. The results of the analyzed tea samples demonstrated that the mean concentrations of limonene (8.36 ± 4.83 μg/L) and 1,8-cineole (1.24 ± 0.53 μg/L) were low compared to the concentrations of the other terpenes (range ∼ 30−200 μg/L), especially carvone (238 ± 308 μg/L) and *trans*-anethole (858 ± 1973 μg/L), which showed relatively high concentrations (Table 1). There were also significant differences between the concentrations of the single tea preparations as shown by the large standard deviations and wide ranges (Table 1).

Table 1. Mean and Range of the Content of the Analyzed Terpenes of 16 Tea Samples

substance	mean content (μg/L)	range of content (μg/L)
limonene	8.4 ± 4.8	1.8−19.2
1,8-cineole	1.2 ± 0.53	0.60−3.0
fenchone	39.6 ± 30.6	7.2−141.8
estragole	26.6 ± 17.5	4.0−76.7
carvone	238.4 ± 308.4	12.6−1208.3
trans-anethole	858.1 ± 1973.2	83.2−7266.4
p-anisaldehyde	187.5 ± 187.5	75.0−454.3
anisketone	39.7 ± 17.9	16.7−80.2

Concentrations of Selected Terpenes in Human Milk before and after the Ingestion of Fennel−Anise−Caraway Tea. The mean concentrations of the terpenes limonene, 1,8-cineole, fenchone, estragole, carvone, *trans*-anethole, *p*-anisaldehyde, and anisketone in each group of analyzed human milk samples, that is, expressed before (blanks) and at different times after ingestion of fennel−anise−caraway tea, are shown in Figure 1. The mean concentrations of all analyzed terpenes of the milk samples, collected after tea ingestion, were comparable to those of the blank samples. Overall, the concentrations were very low, irrespective of whether the samples belonged to the blank or the tea ingestion group; furthermore, quite pronounced variation was present within each group (Figure 1). There were no significant differences between the mean values of samples obtained before or at different times after tea consumption ($p > 0.05$). Because averaging the data might obscure significant changes in individual participants, the obtained quantitative data were also analyzed on an individual basis (data of mother C are shown in Table 2; for the data of mothers A, B, D, and E see Table B2b-2e in the Supporting Information). Here it can be seen that the variation of the terpene content in all blank samples of one mother is quite large; for example, the concentration of 1,8-cineole in samples from mother C ranged from 1.07 to 54.2 μg/kg. Furthermore, changes in concentrations after tea ingestion did not follow a time-dependent

[a]Percentages of concentrations in human milk relative to the amount in the corresponding tea samples are given in parentheses.

dx.doi.org/10.1021/jf504073d | J. Agric. Food Chem. 2015, 63, 104−111

pattern. In some samples after tea ingestion the concentrations of the respective odorants were even lower than in the blanks (e.g., the *trans*-anethole content in human milk samples of mother C was 32.5 μg/kg for the blank sample compared to 2.11 μg/kg at 2 h after tea ingestion; Table 2). In other samples the content of some terpenes, for example, limonene, was higher after tea ingestion than in the blanks (e.g., the limonene content in human milk samples of mother C was 2.48 μg/kg for the blank sample compared to 37.1 μg/kg at 1 h after tea ingestion; Table 2). Some mothers repeated parts of the experiment; thus, for some times and participants, duplicate samples were available. The repetition experiments, especially those of the 1 h sample of mother B and the 0.5 h sample of woman C, showed that the concentrations of at least some odorants varied strongly in the samples from different days (Table 2, Table B2c). Comparing the *trans*-anethole content of the milk sample from mother C 0.5 h after tea ingestion (9.09 μg/kg) with the respective blank sample (2.05 μg/kg) (Table 2), one might suppose the transfer of the odorant from consumed tea into human milk. However, a repetition of this experiment shows in contrast that there was no odorant transfer (blank milk sample, 11.2 μg/kg; milk sample, 0.5 h after tea ingestion, 10.2 μg/kg) (Table 2). Although the participants were advised to drink a distinct amount of tea infusion prepared in a defined way, the absolute intake of terpenes was highly different for every woman and every sampling day, because the exact composition of the final beverage varied due to natural variations in the plant raw material and the influence of even small changes in the preparation process (Table 1). To compare human milk samples after tea consumption depending on the time of expression, the quantified values were additionally normalized to the absolute amount of each terpene ingested via the infusion; these normalized values are listed in Table 2 and Table B2b-2e. Also for these normalized values, no significant differences were present between the groups of human milk samples from different sampling times after tea consumption ($p > 0.05$). For fenchone, estragole, carvone, *trans*-anethole, *p*-anisaldehyde, and anisketone, the concentrations in the tea beverage, ranging from 4.02 μg/L to >7.27 mg/L, were much higher than in the milk samples, whereas for limonene and 1,8-cineole, with concentrations in the tea sample from 0.60 to 19.2 μg/L, the milk samples showed higher contents. Table 3 illustrates this by giving the mean percentual amount of terpenes in milk, calculated under the assumption that all terpenes in milk result from tea intake. The values for *p*-anisaldehyde demonstrate that only a negligible amount of 1−2% (Table 3) could be theoretically transferred from herbal tea into human milk, whereas in part >700% (Table 3) of limonene could be theoretically transferred from the beverage into breast milk; this is impossible and shows that the high limonene content has to originate from other sources.

Table 3. Percentual Amounts of Terpenes in Milk, on the Assumption That All Terpenes in Milk Result from Tea Intake[a]

substance	0.5 h	1.0 h	2.0 h
limonene	205	758	318
1,8-cineole	262	290	163
fenchone	5	19	3
estragole	1	8	3
carvone	1	32	2
trans-anethole	3	30	10
p-anisaldehyde	1	2	1
anisketone	3	5	7

[a]The percentual values of the terpene contents in human milk dependent on tea ingestion were calculated from the of six milk samples 0.5 h after tea consumption, five milk samples 1.0 h after tea ingestion, and five milk samples 2.0 h after tea ingestion compared to the average terpene content of the corresponding tea samples.

Sensory Analysis of Fennel−Anise−Caraway Tea and of Human Milk Samples Expressed before and after Tea Ingestion. In the pretest of the tea beverage, the sensory panel rated the following odor qualities with intensities above 1, which means that these attributes were perceived at least with a weak or clearly perceivable odor impression: fennel (2.41), anise (2.09)/licorice (1.23), caraway (1.50), chamomile (1.32), and sweet (1.14). These attributes together with the characteristic milk odor attributes,[18] hay-like, fatty, like boiled milk, metallic, fishy, rancid, like butter, and like egg white, were thus chosen to evaluate the fresh human milk samples. Due to a similar odor impression of anise and licorice, these attributes were combined for the sensorial analysis of the milk. Figure 2 shows the results displayed as sensory profiles of the five different samples. The odor qualities sweet (0.54−0.77), fatty (0.46−0.65), like boiled milk (0.69−1.00), and like butter (0.35−0.58) were perceived as very weak for all five breast milk samples. The intensities of the other nine attributes were even lower than 0.5, which means that these odors were practically unnoticeable. Thus, the panel detected only characteristic milk odors, and none of the tea attributes was distinctly perceived. Statistical analyses demonstrated for all odor qualities that the slight differences in intensity ratings between all samples and panelists, respectively, were not significant ($p > 0.05$).

Method Validation and Investigation of Potential Storage Effects on the Investigated Terpenoid Substances in Human Milk. The limit of decision, limit of determination, and recovery for each of the analytes in human milk are listed in Table A1 in Appendix A (Supporting Information). Quantification of odorants in human milk dependent on storage time under freeze-storage conditions could successfully rule out any degradations or losses under the given experimental conditions (Table A3). Details are provided in Appendix A.

DISCUSSION

Concentrations of Selected Terpenes in Human Milk before and after Ingestion of Fennel−Anise−Caraway Tea. The tea was chosen as this product represents an example of a beverage often consumed by breastfeeding women. In comparison to other transfer studies based on relatively high dosages of single odorants (e.g., 30−100 mg of *d*-carvone and 100 mg of *trans*-anethole, respectively[2,6]), the consumed odorant concentrations in the present study were relatively low (approximately 1−1000 μg) and the odorant profile was rather complex. The study design was thus targeted at real-life conditions and is of special relevance for the topic of odorant transfer into human milk. The analysis of the blank human milk samples demonstrated that nearly all analyzed milk samples contained each of the analyzed volatiles in trace amounts (approximately 0.35−20 μg/kg). Large inter- and intra-individual variations in odorant content were observed. Likely explanations are that milk is a biological matrix with constantly varying composition, for example, with regard to fat content.[19] The monitored terpenes are ubiquitous in everyday cuisine and sanitary and cosmetic products, so it can be assumed that these

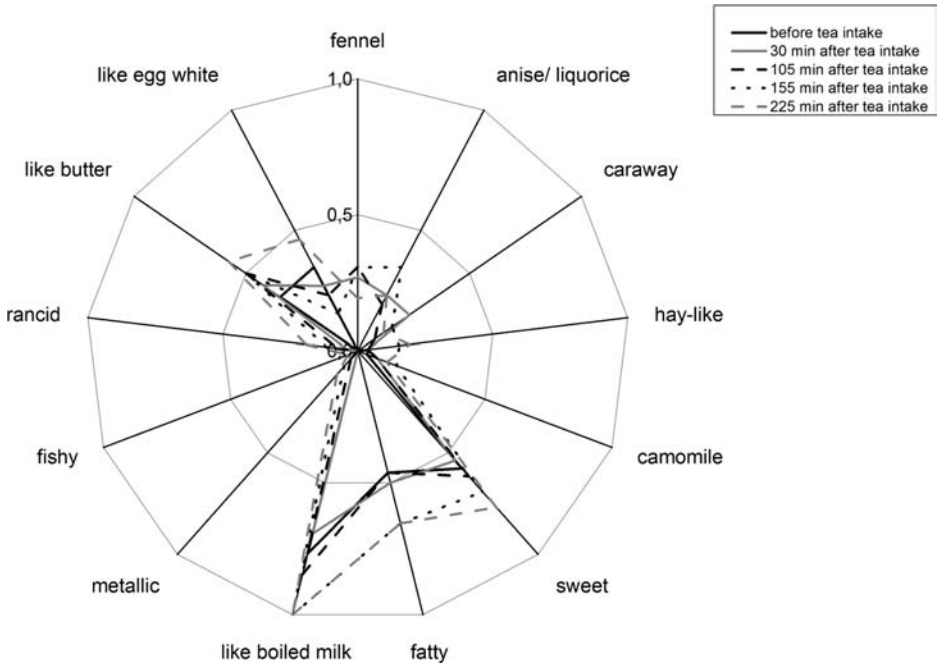

Figure 2. Orthonasal odor profile of fresh human milk samples before and after ingestion of fennel–anise–caraway tea.

terpenes are regularly consumed and absorbed in detectable amounts.[20] With regard to this observation, the present study is accordingly well in line with previous findings. Traces of terpenes have been reported in milk samples several times.[21,22] The present results of the comparison of the respective odor concentrations in tea and in the related human milk samples demonstrate that the ingestion of a typically consumed amount of fennel–anise–caraway tea had no significant influence on the concentrations of the analyzed odorants in human milk samples. Thus, it can be concluded that there was either no transfer of the analyzed odorants from ingested tea into the human milk or that the transferred amounts were so low that the basic terpene content, as monitored in the blanks, was predominant and the small transferred amount was negligible. The obtained data were also analyzed on an individual basis: On the one hand, the concentrations of some terpenes in the blanks were in some cases higher than in the respective milk samples expressed after tea ingestion, and on the other hand the comparison of all blanks of the same participant showed high variations in the respective terpene concentrations. Taking these variations into consideration, a slightly higher content of an odorant in a single measurement of a milk sample expressed after tea ingestion compared to the blank must be deemed as insignificant. This is especially true in view of the fact that the respective odorants were present in the milk samples independent of tea ingestion, as shown by the blank measurements. With regard to the above-said, one might deduce that significant odorant transfer into human milk might occur only either (I) if sufficient concentrations of the respective odorants are consumed, (II) if the substances are relatively stable and are not prone to strong biotransformation under physiological conditions as discussed in more detail in Buettner,[23] or (III) if the represented substances are not commonly found in human milk as a kind of "background profile". This might directly relate to the observations of Hausner et al.,[6] who reported in a study involving higher odorant dosages that the transfer of orally ingested odorants into human milk seemed to be dependent on the chemical structures of the molecules and that relatively low amounts were transferred into the milk despite the relatively high intake. Compared to the average contents of d-carvone and *trans*-anethole in milk samples after odorant ingestion from the studies of Hausner et al., the average concentrations of the terpenes in the milk samples of the present study after tea ingestion were only slightly lower. However, in the studies by Hausner et al. the blank values were lower than in the present study, and thus the differences between blanks and samples after odorant ingestion were much more pronounced. The reason for these low blank values probably was the strict diet that the subjects of the Hausner studies had to follow. In contrast, the mothers that participated in the present experiments were instructed to stay with their normal diet and to avoid overdoses of food that contained the analyzed terpenes. Summarizing both studies, the concentrations of potentially transferred substances detected in the milk samples was about a factor 1000 lower than in the ingested supplement or food. Consequently, when considering common odorant concentrations in foods, the likelihood of odorant transmission into human milk with association to sensory relevance seems to be at least limited with regard to many common food flavors (see also Buettner[23]).

Sensory Analysis of Fennel–Anise–Caraway Tea and of Human Milk Samples Expressed before and after Tea Ingestion. A further objective of our study was to characterize potential sensorial changes of the breast milk in relation to the tea consumption. Therefore, the sensorial analysis was arranged with milk samples of one mother with various expression times. The results of the sensorial experiment demonstrated that the ingestion of normal quantities of commercial fennel–anise–caraway tea showed no significant influence on the odor profile of human milk. Different results concerning a sensorially relevant odorant transfer into human milk were provided by the studies from the working group of Mennella and Beauchamp. These authors reported that the consumption of garlic capsules (1.5 g of garlic extract), alcohol (0.3 g/kg body weight), or carrot juice (500 mL) slightly altered the aroma profile of

dx.doi.org/10.1021/jf504073d | J. Agric. Food Chem. 2015, 63, 104–111

human milk. In the respective samples, the odor intensity peaked 2 h after the intake of garlic capsules and carrot juice and 1 h after alcohol consumption.[3−5] However, it is not clear if the panel only perceived a sensory difference with a rather diffuse character that might also have been induced by other parameters such as short periods of storage during the experiments or could actually smell the specific flavor in the human milk. Apart from that, with the only exception of the alcohol study, no chemical-analytical parameters were analyzed to monitor a potential odorant transfer into human milk. Overall, the occurrence of an odor change of human milk due to the transfer of flavors from the diet appears to be important not only concerning immediate reactions of the nursling to the altered flavor but also with regard to later associative effects, specifically related to possible influences on food preferences. However, the presumably much more prevalent influence of smells that nurslings encounter while being associated with their mothers in everyday life have to the best of our knowledge been basically neglected. The odor dosages from such "external" sources may drastically exceed what is delivered via the milk. This aspect might be another promising area of research for future studies into the field of odorant learning.

Method Validation and Investigation of Potential Storage Effects on the Investigated Terpenoid Substances in Human Milk. A detailed discussion of the method validation as well as the investigation of potential storage effects on terpenoid substances in human milk samples is provided in Appendix A (Supporting Information).

Supporting Information

ABSTRACT: The most potent aroma-active components of Sprite (SP), Sierra Mist (SM), and 7UP (7UP) were identified. Aroma extracts were prepared by liquid−liquid continuous extraction/solvent-assisted flavor evaporation (LLCE/SAFE). Twenty-eight compounds were detected by gas chromatography−olfactometry (GC-O) with linalool (floral, lavender), octanal (pungent orange), and 2,3-dehydro-1,8-cineole (minty) determined to be predominant aroma compounds based on their high flavor dilution (FD) factors by aroma extract dilution analysis (AEDA). The data indicate that lemon-lime flavor is composed of a small number of compounds (22 at the most in SM), and only a subset of these may be important because many compounds were detected only at low FD factors. Predominant aroma compounds (23) were quantified using static headspace solid phase microextraction (SPME) combined with stable isotope dilution assays (SIDA). In contrast to FD factors, the calculated odor-activity values (OAVs) indicate that octanal and limonene make the greatest contribution to the overall aroma of lemon-lime carbonated beverages, followed by nonanal, decanal, linalool, 1,8-cineole, and geranyl acetate. The results demonstrate that lemon-lime carbonated beverages share many of the same compounds but the relative abundance of these compounds varies by brand.

KEYWORDS: *lemon-lime, flavor chemistry, carbonated beverage, aroma extract dilution analysis (AEDA), stable isotope dilution assay (SIDA), odor-activity value (OAV), linalool, octanal, 2,3-dehydro-1,8-cineole, limonene*

INTRODUCTION

The first carbonated beverages came from natural sources in the form of effervescent mineral springs and yeast fermentation.[1] Early scientific investigations of carbon dioxide in water date back to 1741, when carbonated water was produced using bicarbonate salts, and by the late the 1760s and 1770s, scientists had developed ways of dissolving carbon dioxide in water under pressure.[1] The first commercial manufacture of carbonated water occurred in the late 1770s when Thomas Henry, a chemist and apothecary in Manchester, England, designed an apparatus that could carbonate up to 12 gal per batch and sold the product in corked glass bottles.[1,2]

The intended use of carbonated water changed as new carbonation technologies were developing. Although artificially carbonated mineral water was originally used for medicinal purposes and was required to contain sodium bicarbonate, it became a source of refreshment; soda was eliminated, and flavorings were added.[2] The early flavorings used in carbonated water for refreshment were largely from fruits and included sarsaparilla, lemon, pineapple, orange, strawberry, vanilla, peach, grape, almond, ginger, and cloves, among others.[2]

The volume of carbonated beverage sales has been declining since 2003. Yet, despite this trend, carbonated beverages accounted for $76.3 billion in 2013 sales for the United States.[3] Lemon-lime was among the top 10 carbonated beverage types in 2013, with Sprite taking the sixth largest market share.[3] Considering the market value of this product, it is important to understand the flavor profile and chemistry of lemon-lime flavor. Current details regarding the composition and chemistry of lemon-lime flavor in a beverage system are limited.

A review of the literature on essential oils indicates that certain oils from *Aloysia citriodora* Palau (lemon verbena)[4] and *Citrus aurantifolia* (Christm.) Swingle (lime) are important to the food industry.[5] Much work has been done to identify and quantify the composition of various oils for the purposes of detecting oil adulteration[6] or determining the antimicrobial activity of the oil.[7] It is also well-known that terpenes, the largest class of compounds in lemon oils, are unstable in acidic environments and undergo rearrangements.[8−12] Acid-catalyzed reactions of terpenes can occur at even mildly acidic pH (pH < ∼6).[8]

Numerous citrus varieties exist, and there is subsequently variation in the most abundant compounds in citrus. However, limonene is most abundant in lime oils on a percent by weight basis.[4,8,13] Neral and geranial (citral isomers) have been found to be very abundant in some varieties of lemon verbena.[4] Although acid-catalyzed reactions have been extensively studied, particularly in the case of citral, it is interesting to look at a real food system, namely, lemon-lime carbonated beverages, and find out which flavor compounds are important. Due to the large commercial value of lemon-lime carbonated beverages, this research has great potential to benefit the

beverage industry. When a consumer reaches for their favorite lemon-lime beverage, the flavor of the product they drink is distinctly different from that which was manufactured at the plant. Our ultimate goal is to understand the changes that take place as a result of the dynamic nature of the complex lemon-lime beverage system. Furthermore, this research aims to identify the key flavor compounds common to lemon-lime.

MATERIALS AND METHODS

Materials. Sprite (Coca-Cola Co., Atlanta, GA, USA), Sierra Mist (PepsiCo, Inc., Purchase, NY, USA), and 7UP (Dr. Pepper/Seven Up, Inc., Plano, TX, USA) were purchased in January 2009 and June 2010 at a local grocer (Urbana, IL, USA).

Chemicals. Unless otherwise stated, chemicals and reagents were obtained from Sigma-Aldrich Co. (St. Louis, MO, USA) for unlabeled standards. Nerol and geraniol were obtained from Bedoukian Research, Inc. (Danbury, CT, USA), and acetic acid was obtained from Fisher Scientific (Fair Lawn, NJ, USA). The isotope 4-([$^2H_3$]-methyl)-phenol was purchased from C/D/N Isotopes Inc. (Quebec, Canada). Published methods were used for the synthesis of (*E*)-4,5-epoxy-(*E*)-2-decenal,[14] 2,3-dihydro-5-hydroxy-6-methyl-4(*H*)-pyran-4-one (dihydromaltol),[15] [$^2H_2$]-limonene,[16] and [$^2H_2$]-linalool.[17] The Supporting Information provides synthetic procedures or references with modified procedures for the following compounds: 2,3-dehydro-1,8-cineole, [$^2H_3$]-2,3-dehydro-1,8-cineole, [$^2H_3$]-1,8-cineole, [$^2H_4$]-octanal, [$^2H_4$]-nonanal, [$^2H_4$]-decanal, [$^2H_3$]-isoborneol, [$^2H_6$]-neral, [$^2H_3$]-borneol, [$^2H_6$]-geranial, [$^2H_6$]-nerol, [$^2H_6$]-geraniol, [$^2H_7$]-4-terpineol, [$^2H_3$]-α-terpinyl acetate, [$^2H_3$]-α-terpineol, [$^2H_2$]-neryl acetate, and [$^2H_2$]-geranyl acetate. The structures of all isotope standards used can be found in Figure 1. All unlabeled compound purities were >90% (neat, hot split, 250 °C, GC-FID) except in the case of the isotope mixtures listed here: neral and geranial, 35.8 and 59.9%, respectively; [$^2H_6$]-neral and [$^2H_6$]-geranial, 21.8 and 52.3%, respectively; [$^2H_6$]-nerol and [$^2H_6$]-geraniol, 32.8 and 59.3%, respectively; and [$^2H_3$]-isoborneol and [$^2H_3$]-borneol, 48.3 and 47.0%, respectively.

Preparation of Aroma Extracts. Volatile components were isolated by liquid–liquid continuous extraction (LLCE). For each extraction, 500 mL of a carbonated beverage, 100 mL of deodorized deionized–distilled water, and 20 μL of an internal standard solution (417 μg/mL of 6-undecanone in methanol) were placed in the LLCE apparatus (Z101567, Sigma-Aldrich Co.). The device was connected to a 250 mL round-bottom flask containing the extraction solvent (200 mL of diethyl ether), which was subsequently refluxed by heating the flask in a 47 °C water bath, whereas the condenser of the LLCE apparatus was held at 5 °C. After extraction for 18 h at ambient temperature (~23 °C) with constant stirring in the sample chamber, the ether layers were recovered and concentrated to 50 mL using a Vigreux column at 43 °C. Solvent-assisted flavor evaporation (SAFE) was performed for 2 h according to the method described by Rotsatchakul et al.[18] The resulting aroma extract was further concentrated to 10 mL using a Vigruex column at 43 °C, dried over anhydrous sodium sulfate, and concentrated to a final volume of 500 μL using a gentle stream of nitrogen. Each aroma extract was stored in a 2 mL vial equipped with a PTFE-lined screw cap at −70 °C until analysis.

Gas Chromatography–Olfactometry (GC-O) and Aroma Extract Dilution Analysis (AEDA). The relative potency of individual odorants was determined using AEDA according to the method previously described.[19] Serial dilutions (1:3, v/v) of each aroma extract were prepared in diethyl ether and stored in a 2 mL vial equipped with a PTFE-lined screw cap at −70 °C until analysis. The GC-O system consisted of a 6890 GC (Agilent Technologies Inc., Palo Alto, CA, USA) equipped with a FID, an on-column injector (3 °C temperature tracking mode), and an olfactory detection port (DATU Technology Transfer, Geneva, NY, USA). Dilutions and concentrated extracts were analyzed on a polar capillary column (RTX-Wax, 15 m × 0.32 mm i.d.; 0.5 μm film; Restek, Bellefonte, PA, USA). Concentrated aroma extracts were also analyzed using a nonpolar capillary column (RTX-5MS, 15 m × 0.32 mm i.d.; 0.5 μm film; Restek) for calculation of retention indices (RI). For GC-O, column effluent was split 1:5 between the FID and olfactory detection port using deactivated fused silica tubing (1 m × 0.25 mm i.d.; Restek), with both detector temperatures held at 250 °C. The GC oven temperature was programmed from 40 to 225 °C at a rate of 10 °C/min with initial and final hold times of 5 and 30 min, respectively. Helium was used as

[i]Compound tentatively identified based on odor property and RI on RTX-Wax and RTX-5 columns.

a carrier gas at a constant flow rate of 2.2 mL/min. Other conditions of GC-O have been previously described.[20]

Gas Chromatography–Mass Spectrometry (GC-MS). The GC-MS system consisted of a 6890 GC/5973N MSD (Agilent Technologies Inc.) equipped with a cool on-column injector (3 °C temperature tracking mode). Separations were performed on 1 μL injections of each extract using either a polar capillary column (RTX-Wax, 30 m × 0.25 mm i.d.; 0.5 μm film; Restek) or a nonpolar column (RTX-5SLIM, 30 m × 0.25 mm i.d.; 0.5 μm film; Restek). The oven temperature was programmed from 35 to 225 °C at a rate of 4 °C/min with initial and final hold times of 5 and 20 min, respectively. Helium was used as carrier gas at a constant rate of 1.0 mL/min. The MSD conditions were as follows: capillary direct interface temperature, 280 °C; ionization energy, 70 eV; mass range, 35–300 amu; electron multiplier voltage (Autotune +200 V); scan rate, 5.27 scans/s.

Compound Identification. Compound identification was based on matching retention indices (on two different GC column phases), odor descriptions, and mass spectra of unknowns with those of authentic standards. Tentative identifications were based on one or more, but not all, of the above criteria. A homologous series of *n*-alkanes was used for the determination of retention indices according to the method of van Den Dool and Kratz.[21]

Quantification of Aroma-Active Compounds. *Stable Isotope Dilution Analysis (SIDA).* The aroma compounds presented in Tables 2 and 3 were categorized into three groups for quantification purposes.

(1) Compounds **3**–**5**, **8**, **12**, **14**, **16**, **18**, **24**, **30**–**35**, **37**, and **38**: The lemon-lime carbonated beverage (~5 mL) was poured into the 20 mL screw-top headspace (HS) vial equipped with a Teflon-coated stir bar and Teflon-lined silicon cap. The exact weight of sample was calculated by weight difference. The appropriate amounts of isotopically labeled standards used as internal standards were individually spiked through the septum. The sample was vigorously stirred by vortex, and then sodium chloride (1 g) was added. The vial was recapped with a new cap before analysis by solid phase microextraction (SPME). The sample vial was agitated at 250 rpm and incubated at 40 °C for 10 min. The HS volatiles were then extracted at the same temperature for 20 min using 50/30 μm DVB/Carboxen/PDMS StableFlex fiber (Supelco, Bellefonte, PA, USA). The aroma compounds were desorbed at 260 °C in the hot splitless injector of the GC-MS and separated on a Stabilwax column using the GC oven program described above.

(2) Compounds **29** and **36** (high concentration): Each isotope compound was spiked into 1 mL of lemon-lime carbonated beverage prepared in the HS vial. Odor-free water (9 mL) was added and stirred using vortex. The diluted sample (0.5 mL) was transferred to the new HS vial containing 4.5 mL of odor-free water and 1 g of sodium chloride. The concentrations of limonene (**29**) and α-terpineol (**36**) were then analyzed by SPME as described above.

(3) Compounds **2**, **10**, **13**, and **15** (pH-dependent stability): Approximately 150 mL of lemon-lime carbonated beverage was poured through a condenser at 0 °C into a three-neck flask, equipped with a pH meter and stir bar. The pH of the sample was adjusted to 7 with 2 M aqueous sodium hydroxide solution. The weight differences of carbonated beverage and sodium hydroxide solution were recorded to calculate the exact ratio. Approximately 5 mL of the mixture was prepared in the HS vial. The labeled standards were individually

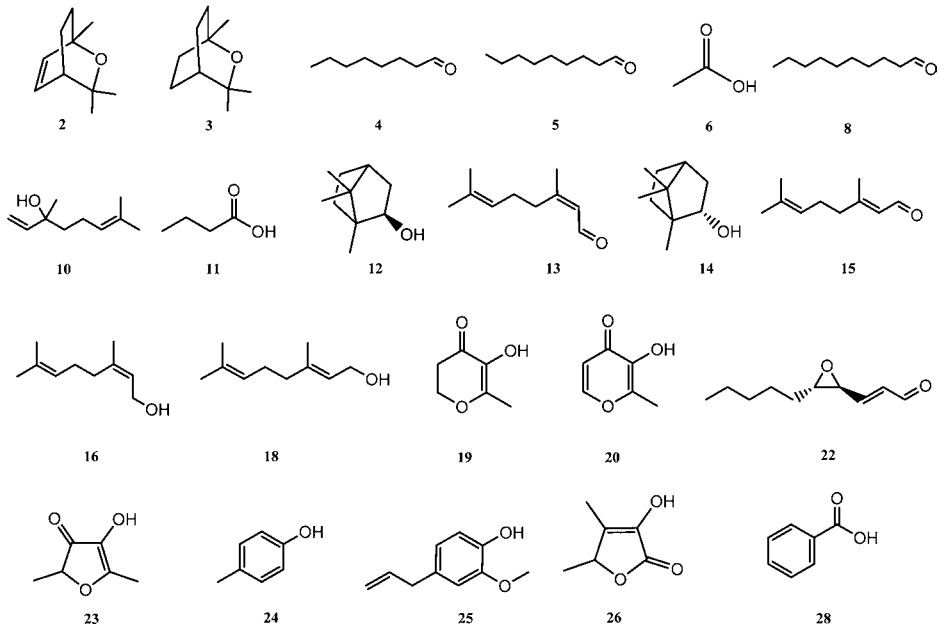

Figure 2. Structures of the aroma-active compounds identified in three commercial brands of lemon-lime carbonated beverages (compound numbers correspond to those in Tables 1−3).

spiked, and then 1 g of sodium chloride was added before quantification by SPME as before.

Calculations. The concentration of each odorant was calculated from the response factor (R_f), mass ratio, and area ratio of the selected ions presented in Table 2. The response factor was determined by plotting the area ratio of the unlabeled to labeled standard against the mass ratio and taking the inverse of the slope. The mass ratios chosen were 10:1, 5:1, 1:1, 1:5, and 1:10. The equation used to calculate the concentration of selected aroma compounds is

$$C = A_{\text{unlabeled}}/A_{\text{isotope}} \times R_f \times M_{\text{isotope}}/(M_{\text{soda}} \times B)$$

where C = concentration of aroma compound in the decarbonated soda (ng/g), $A_{\text{unlabeled}}$ = area of the extracted ion chromatogram for the unlabeled compound, A_{isotope} = area of the extracted ion chromatogram for the isotope compound, R_f = response factor, the inverse of the slope when the area ratio versus mass ratio are plotted, M_{isotope} = mass of the isotopically labeled standard (ng), M_{soda} = mass of the just-out-of-the-can carbonated beverage (g), and B = correction factor to convert the mass to a decarbonated basis. The correction factors B can be found in Table S1 of the Supporting Information.

Statistical Analysis. Quantifications of aroma compounds were run in triplicate. The analysis of variance (ANOVA) was performed by SAS program (SAS institute Inc., Cary, NC, USA). The least significant difference (LSD) was then tested if there was a significant difference (p value < 0.05) among the lemon-lime carbonated samples.

Determination of Odor Threshold. The odor detection threshold in water of a compound was determined orthonasally following published procedures.[22,23] All test samples (50 mL each) were presented in 125 mL Teflon sniff bottles (Nalge Nunc International, Rochester, NY, USA) in an ascending concentration series consisting of six samples (1:3 dilution series). The number of panelists for evaluation of odor threshold of 2,3-dehydro-1,8-cineole (**2**) and isoborneol (**12**) was 12 (7 females and 5 males; 22−52 years) and 12 (8 females and 4 males; 22−47 years), respectively. It is also important to note that the isoborneol (**12**) standard consisted of a racemic mixture of the two enantiomers (*d*- and *l*-).

Calculation of Odor Activity Values (OAVs). The OAV of a compound was calculated as the ratio of its concentration in lemon-lime carbonated beverage to its odor threshold in water, which was obtained from the literature or determined in our laboratory.

RESULTS

Aroma Extraction Dilution Analysis (AEDA). A combined total of 28 aroma-active compounds were detected in the three brands using gas chromatography-olfactometry (GC-O), as shown in Table 1 and Figure 2. The identification data for the aroma-active compounds in SP, SM, and 7UP indicated that linalool (no. **10**) was the single most potent aroma compound in lemon-lime carbonated beverages, while octanal (no. **4**) and 2,3-dehydro-1,8-cineole (no. **2**) were moderately potent aroma-active compounds. The data indicate that lemon-lime is composed of a small number of compounds (22 at the most, in SM) and only a subset of these may be important since many compounds have low FD factors.

Notably, lemon-lime carbonated beverages contain several groups of compounds with both similar odor properties and close retention indices on the polar GC column, as evidenced in Table 1. Specifically, these include 2,3-dehydro-1,8-cineole (**2**) and 1,8-cineole (**3**) with piney and eucalyptus notes; isoborneol (**12**) and borneol (**14**) with camphorous notes; neral (**13**), geranial (**15**), nerol (**16**), and geraniol (**18**) with lemony/lemon cleaner notes. Three aliphatic, straight-chain (*n*-) aldehydes, octanal (**4**), nonanal (**5**), and decanal (**8**), with similar pungent citrusy notes were also detected. The compounds in each group are structurally similar to one another, which provides a strong indication that compounds have undergone reactions and rearrangements. The original flavoring is derived from lemon oil, and it is well-known that terpenes undergo acid-catalyzed reactions.[8,24]

Linalool, determined to be the single most potent aroma compound by FD factor, is commonly found in lemon and lime oils,[4,25] as well as other citrus oils.[26,27] Furthermore, it can also be produced by structural rearrangements of other compounds (e.g., geraniol and nerol) frequently found in lemon/lime oils.[8] In an acidic model (pH 2.9) geraniol and nerol have been found to rearrange to form linalool in only 1 or 2 h, respectively, at 25 °C.[28] Furthermore, linalool itself is not stable in an acidic environment, converting into α-terpineol after only 2 h at pH 2.9.[28]

[a]Compound numbers correspond to peak numbers in Tables 1 and 3 and Figure 2. [b]Selected ion. [c]The letter "I" means isotopically labeled compound followed by the compound number. [d]Response factor. [e]A structurally similar compound was selected as the internal standard.

The three aliphatic straight-chain (*n*-) aldehydes, octanal (**4**), nonanal (**5**), and decanal (**8**), are present in the original citrus oil used to produce the lemon-lime flavorings.[29−31] On the basis of the results of AEDA, octanal is the second most potent odorant in SM with an FD factor of 243, whereas it is also important in SP and 7UP with FD factors of 81 in both beverages. The odor properties of *n*-aldehyrdes change slightly as a function of increasing chain length. Sensory work on carbon chain length shows that subjects were able to distinguish between pairs of *n*-aldehydes of differing chain lengths; however, octanal could not be distinguished from nonanal, nor could nonanal be distinguished from decanal.[32] This indicates that the *n*-aldehydes are important to the overall aroma of lemon-lime carbonated beverages collectively but not necessarily individually.

Another important potent odorant identified in lemon-lime carbonated beverages was 2,3-dehydro-1,8-cineole (dehydrocineol, **2**). This minty, eucalyptus-smelling compound had an FD factor of 81 in all three products. Dehydrocineol has been reported as a degradation product of citral.[8,11,33,34] Kimura et al.[33] monitored citral degradation in a citric acid solution and reported dehydrocineol as a degradation product of *p*-mentha-1,5-dien-8-ol and *p*-mentha-1(7),2-dien-8-ol. Results from our previous study[34] confirmed the above to be true and further demonstrated that dehydrocineole is highly unstable under acidic conditions. Dehydrocineole has been reported in numerous essential oils, including lemon grass,[35] lime,[5] licorice root,[36] and garden lovage,[37] among others. This compound may be present in the essential oil used for making the lemon-lime flavorings as well as formed from citral in the acidic environment of the carbonated beverage.

As expected, the citral isomers, geranial (**14**) and neral (**12**), were among the aroma-active components in the lemon-lime carbonated beverages. The levels of these isomers can be quite high in lemon oil; for example, 29.0% geranial and 20.0% neral were reported in lemon verbena oil.[4] The presence of high levels of citral can be used as a measure of essential oil quality.[4,38] Yet, although these aldehydes are clearly important in lemon and lime oils, they did not emerge as predominant aroma components in lemon-lime carbonated beverages, as indicated by their relatively low FD factors. This can be explained by their tendency to readily undergo acid-catalyzed rearrangements. A study that followed the degradation of citral over 2 weeks in an acidic buffer solution (pH 3.0; stored in the dark at 40 °C) demonstrated that nearly all of the geranial and neral was transformed into other compounds in only 3 days.[10]

An unknown compound (**7**) with a retention index (RI) of 1451 (wax) and contributing a fresh, melony aroma was detected at FD factors of 27 in SM and 9 in both SP and 7UP. It is hypothesized that this compound is a low threshold nonenal isomer. A number of the unsaturated C_9 aldehydes have green, cucumber-like ((*Z*)-3- and (*Z*)-4-nonenal) or melon-like odors ((*Z*)-5-, (*E*)-6-, (*Z*)-6-, (*E*)-7-, and (*Z*)-7-nonenal).[39] Some of these compounds have odor detection threshold values in the low parts per billion (ppb) range, such as (*Z*)-4-nonenal with an odor threshold of 80 ppb and (*E*)-6-nonenal with an odor threshold of 4.6 ppb (thresholds determined in paraffin oil).[39] In the present study, no mass spectral data were available for this compound because it was below the GC-MS detection limits. This further supports the hypothesis that the unknown has a very low threshold. In the identification work done up until this point, two unsaturated nonenal isomers were eliminated, specifically (*Z*)-6-nonenal or 8-nonenal, as neither compound had the same odor properties or RI values when compared to the unknown. Further

investigation of the other possible isomers of nonenal could lead to the identification of this compound.

Odor Activity Values (OAVs). OAVs are an alternative method to AEDA for determining the importance of aroma compounds and have the advantage of taking some matrix effects into account, that is, flavor release from water. Agreement between AEDA and OAVs gives confidence to ranking of odorant importance. In this study, both aroma-active compounds and high-abundance volatiles were quantified; the latter were chosen due to their potential to affect flavor release. All volatiles quantified are given in Table 2, along with the isotope standard used for quantitation, ion choice, and response factor.

The concentrations and OAVs of aroma compounds in lemon-lime carbonated beverages are shown in Table 3. To the greatest extent possible, the thresholds used were determined using similar methodology (Teflon sniff bottles) to reduce variation caused by methodology. Among 23 aroma compounds, octanal (**4**) and limonene (**29**) had the highest OAVs in all three brands. Notably, the OAV of octanal is 836 in 7UP, much higher than the corresponding values for octanal in SP and SM (274 and 209, respectively). Due to its relatively high FD factor in all brands and because of distinct brand differences in octanal concentration, it is likely that octanal is one of the main distinguishing compounds among the brands.

The OAVs for limonene are high in 7UP and SM, at 322 and 298, respectively (OAV of 120 for SP). Limonene was considered to have high potency by means of its OAV, but it was not even detected by GC-O. Limonene, as well as α-terpineol (**36**), is present at approximately 1 order of magnitude higher concentration that the other volatiles quantified. The high abundance and moderately low odor detection threshold in water account for limonene's importance. Limonene is a major compound in lemon and lime oils.[4,13,40,41] It also emerged as an important aroma-active compound in sensory-directed research of fresh lemon oil.[12]

In addition, the OAVs of 1,8-cineole (**3**), nonanal (**5**), decanal (**8**), linalool (**10**), and geranyl acetate (**38**) in all lemon-lime carbonated beverages were >10. Linalool was determined to be the most potent aroma compound on the basis of its high FD factor. Differences in odor potency, as determined by FD factor and OAV, can be related to the difference of thresholds in air and water. FD factors depend on each compound's odor threshold in air, whereas the calculated OAVs depend on each compound's threshold in water, which is a better indication of the perceived flavor, taking the matrix into account. A compound's threshold may be different in water and in air, as observed with linalool. The threshold of linalool in air is 0.4−0.8 ng/L (ppt),[42] whereas linalool's threshold in water is 6 μg/L (ppb).[43] Thus, the higher threshold in water helps explain why linalool appears to be less significant.

Notably, two of the most important aroma-active compounds, limonene and linalool, are chiral. In the case of both of these compounds, the odor property remains the same, regardless of the enantiomer.[44] For limonene, the published thresholds in air are similar for both the (*R*) and (*S*) enantiomers, 135 and 270 ppb, respectively. However, the threshold in air is significantly different for the linalool enantiomers, with a threshold 80 times lower for the (*R*) isomer, 0.036 ppb, compared to 2.9 ppb for the (*S*) isomer. (*R*)-Linalool has previously been reported to be in 13.6% enantiomeric excess in lemon oil.[45] Certainly, chiral analysis of

DOI: 10.1021/jf504852z
J. Agric. Food Chem. 2015, 63, 112−119

these aroma-active compounds, with linalool in particular, would refine the estimates provided by OAV. The thresholds available for comparison of enantiomers were in air, whereas those used for the calculation of OAVs in Table 3 are in water.

The quantitative data indicate that low levels of citral (neral and geranial) remained in the lemon-lime carbonated beverages. Geranial is the more abundant isomer present at levels of 359, 874, and 129 ng/g in SP, 7UP, and SM, respectively. The lemon-lime carbonated beverage was neutralized before analysis of these compounds to prevent the labeled standards from rearranging. Much lower concentrations of the citral isomers were found when the pH was not controlled in an earlier study in our laboratory.[46] These compounds likely do not play an important role in the overall aroma of lemon-lime carbonated beverages due to their low abundance. This result is intriguing given the importance of citral in fresh lemon oil.[12]

GC-O data culminating in FD factors for compounds by brand were determined for beverages from different lots used for quantification, and reasonable agreement in trends is seen from these two data sets. Neither FD factors nor OAVs are able to account for compound interactions that may affect flavor release. Furthermore, despite the relatively simple matrix of carbonated beverages, the acid, carbonation, and sugar could also affect release. Aroma reconstitution models can verify the predictions made by these analytical tools and would be an important area for future work.

Conclusion. The popularity of lemon-lime carbonated beverages, along with the complex chemistry arising from acid-catalyzed rearrangements of terpenes, makes this an important system to study. By investigating the three most popular brands of lemon-lime carbonated beverages, octanal and limonene were determined to be the most important aroma-active compounds by considering the OAVs, whereas linalool, 1,8-cineole, nonanal, decanal, and geranyl acetate were also moderately important. Meanwhile, the aroma contribution of citral was limited.

Preparation and Characterization of a Laboratory Scale Selenomethionine-Enriched Bread. Selenium Bioaccessibility

María Sánchez-Martínez, Teresa Pérez-Corona, Carmen Cámara, and Yolanda Madrid*

Department of Analytical Chemistry, Faculty of Chemical Science, Complutense University of Madrid. Avenida Complutense s/n, 28040, Madrid, Spain

ABSTRACT: This study focuses on the preparation at lab scale of selenomethionine-enriched white and wholemeal bread. Selenium was supplemented either by adding selenite directly to the dough or by using lab-made selenium-enriched yeast. The best results were obtained when using fresh selenium-enriched yeast. The optimum incubation time for selenomethionine-enriched yeast preparation, while keeping formation of selenium byproducts to a minimum, was 96 h. Selenium content measured by isotope dilution analysis (IDA)-ICP-MS in Se-white and Se-wholemeal bread was 1.28 ± 0.02 $\mu g\ g^{-1}$ and 1.16 ± 0.02 $\mu g\ g^{-1}$ (expressed as mean ± SE, 3 replicates), respectively. HPLC postcolumn IDA-ICP-MS measurements revealed that selenomethionine was the main Se species found in Se-enriched bread, which accounted for ca. 80% of total selenium. In vitro gastrointestinal digestion assay provided selenium bioaccessibility values of 100 ± 3% and 40 ± 1% for white and wholemeal Se-enriched bread, respectively, being selenomethionine the main bioaccessible Se species in white bread, while in wholemeal bread this compound was undetectable.

KEYWORDS: *selenium, selenium-enriched bread, yeast, biotransformation, bioaccessibility*

INTRODUCTION

Selenium (Se) is an essential trace element for humans. Supplementation of Se at supranutritional doses, in a population with low selenium status, may help to prevent or reduce different types of tumors,[1] e.g., lung, kidney, pancreas, or prostate cancer. However, the role of selenium in cancer prevention is not well understood yet and should be carefully examined to establish whether supplementation is advisible for treatment or prevention of a specific disease. Se deficiency can affect immune and reproductive systems and thyroid function, and it has been also associated with the occurrence of Keshan and Kaschin−Beck diseases.[2] The recommended dietary allowance (RDA) of this element has not been clearly established yet, because its requirement is highly dependent on several factors such as age, gender, eating patterns, country, etc.[3] The United Kingdom Expert Group on Vitamins and Minerals[4] set the RDA at 60 and 70 μg/day for women and men, respectively, while the Spanish Agency of Food Security and Nutrition[5] set it at 55 μg/day for women and 70 μg/day for men.

In areas where Se concentration in soil is low, its content in cereals and vegetables is also low and consequently the intake by the population is below the RDA.[6,7] With the aim of preventing Se deficiency, two main strategies have been applied: development of Se-enriched foods and agronomic biofortification of crops by using Se-fertilizers. Several Se-enriched food products such as wine,[8] beer,[9] yogurt,[10] or sauerkraut[11] have been developed in recent years. However, biofortification of crops with selenium through foliar and soil application has been the most widely used technique,[12−18] wheat being the main cereal selected when performing this agronomic practice. Although bread intake has decreased in recent years as a result of changing eating patterns,[5,19] it is still the main component of the diet in countries such as Spain, Italy, and Greece[20] and an important source of Se in the United States[21] with selenomethionine (SeMet) as the predominant selenium species.[22,23] Wheat from North America and Canada, with high Se concentrations,[24] was imported to Europe until the mid-1970s,[25] but nowadays, since regional wheat is being used to a higher extent, a decrease of Se intake has been observed among the general population.

Since biofortification is a laborious and expensive process, the aim of this work was to prepare lab-scale Se-enriched breads by using laboratory-made selenized yeast as source of selenium. Evaluation of Se biotransformation and stability of selenium species during baking was carried out by using HPLC postcolumn isotope dilution analysis (IDA)-ICP-MS.[26] Homogeneity studies were also performed to select the most suitable technology for preparing Se-enriched breads with a homogeneous distribution of selenium. Finally, Se bioaccessibility in the resulting Se-enriched white and wholemeal breads was assessed by applying an in vitro digestion assay. The main novelty of the current study involves a rigorous control of all the variables affecting the preparation of Se-enriched bread with the aim of scaling up the process from the laboratory to the industrial or commercial field. The results obtained on selenium bioaccessibility in white and whole bread are also of great interest from the nutritional point of view.

MATERIALS AND METHODS

Chemicals. Chemicals and reagents were of analytical grade, and solutions were prepared with deionized water (18 MΩ cm) from a Milli-Q water purification system unit (Millipore, USA). Stock

standard solutions of selenomethionine (SeMet), selenomethylselenocysteine (MeSeCys), and selenocystine ($SeCys_2$) purchased from Sigma-Aldrich (Germany) were prepared by dissolving each in 3% hydrochloric acid (37%, Merck, Germany). Inorganic Se solutions were prepared by dissolving sodium selenite (Na_2SeO_3) and selenate (Na_2SeO_4), purchased from Merck (Germany), in 2% HNO_3 (60%, Sharlau, Spain). Stock solutions were stored at 4 °C, and working solutions were prepared daily by dilution. Selenomethionine-Se-oxide (SeMetO) was obtained by oxidation of a SeMet standard using hydrogen peroxide (35%, Panreac, Spain).

Culture medium for yeast growth was "yeast extract peptone dextrose" (YEPD), composed of 1% of yeast extract (Sigma, Germany), 2% glucose (Fluka, Germany), and 2% peptone water (10 mM peptone from Sigma, Germany; 5 M NaCl from Merck, Germany; at pH 7.2).

Acid digestion of samples was carried out with HNO_3 and H_2O_2. For gastrointestinal simulated digestion, α-amilase (Merck, Germany), $NaHCO_3$ (Sigma, Germany), and intestinal solution (consisting of 1.5% of porcine pancreatin from Merck, Germany; 0.15% of biliary salts from Sigma, Germany; and 0.15 M NaCl) and gastric solution (consisting of 6% porcine pepsin from Merck, Germany; 0.15 M NaCl at pH 1.8 adjusted with 2 M HCl) were used.

Enzymatic hydrolysis was performed by using a nonspecific enzyme, protease XIV, from *Streptomyces griseus* (Sigma, Germany). Tris-HCl solution was prepared with Trizma base (Fluka, Germany) dissolved in water, and the pH was adjusted to 7.5 with HCl.

The ^{77}Se-enriched standard (Cambridge Isotope Laboratories, USA) was purchased as a powder, dissolved in a minimum volume of sub-boiled HCl, and diluted to the corresponding final volume with Milli-Q water. The resulting ^{77}Se-enriched solution was used for quantifying total Se and Se-species concentration.

Selenium species separation by anionic-exchange chromatography was achieved by using 10 mM citric acid (Sigma, Germany) in 2% MeOH (99.9%, Scharlau, Spain) adjusted to pH 5 with ammonium hydroxide (Fluka, Germany) as the mobile phase. The mobile phase used for reversed-phase chromatography was 0.1% trifluoroacetic acid, TFA (Sigma-Aldrich, Germany), in 2% MeOH. The mobile phase employed for size exclusion chromatography (SEC) was 50 mM Tris-HCl and 0.05 mM KCl (Fluka, Germany) at pH 6.8.

The ingredients (white flour, whole-meal flour, and yeast) for baking were purchased from a traditional bakery in Madrid, Spain. Se-enriched yeast certified reference material (CRM) SELM-1 (NRCC, Canada) was used to validate the method.

Instrumentation. For bread-making, dough was fermented in an incubator (Heraeus D-6450, Germany) followed by baking in a thermostatic oven (Digitronic, JP Selecta, Spain). Yeast selenization was performed in an Optic Ivymen System provided with a constant temperature incubator shaker (Comecta S.A., Spain). For homogeneity studies ingredients were mixed in a V-shaped laboratory mixer with dimensions of 415 × 400 × 415 mm (Venus FTLMV, Filtra, Spain).

For total selenium analysis, samples were digested in an analytical microwave oven (CEM, Matthews, USA). For the selenium species extraction, enzymatic hydrolysis was performed by using a Sonoplus ultrasonic homogenizer (Bandenlin, Germany) fitted with a titanium 3 mm diameter microtip and a GM200 HF generator. Extracts from enzymatic hydrolysis were centrifuged in an Eppendorf centrifuge 5804 R F34-6-38 (Germany).

Elemental detection was carried out by using an ICP-MS (Agilent HP-7700 series, USA) equipped with an octopole reaction cell for monitoring ^{76}Se, ^{77}Se, ^{78}Se, ^{79}Br, ^{80}Se, ^{81}Br, ^{82}Se and ^{83}Kr isotopes. Argon-based polyatomic interferences were reduced using H_2 as cell gas at an optimized flow rate of 4.5 mL min^{-1}. A commercial Meinhard nebulizer was used as sample introduction system device for the ICP-MS

Chromatographic separation was performed with a high-pressure pump (Jasco PU-2089, Italy) fitted with a six-port sample injection valve (Rheodyne 7725i, Rohnert Park, CA, USA) with a 100 μL loop. Different columns were coupled to ICP-MS for selenium speciation analysis: anionic exchange PRP-X100 (250 × 4.1 mm, 10 μm) (Hamilton, Switzerland); reversed-phase ion pairing C8 Zorbax R_x-C_8 (250 × 3.0 mm, 5 μm) (Agilent, USA); and SEC BioBasic-Sep 60 from 0.1 to 6 kDa (300 × 7.8 mm, 5 μm) (Thermo Fisher, Spain).

Methods. *Preparation of Se-Enriched Bread.* Bread pieces of around 3 × 3 × 3 cm were prepared. For that purpose, 5.00 g of wheat flour (with 13% moisture content and 10.3% of protein) or wholemeal flour (with 11% moisture content and 9.6% of protein), 0.10 g of sodium chloride, yeast (0.15 g of fresh yeast or 0.05 g of lyophilized yeast), and 2.5 mL of deionized water were used, as described in the literature.[13,27] With the aim of preparing bread with approximately 1 μg g^{-1} of Se, 5 μg of selenium was added. Selenium was supplemented either by adding selenite directly to the dough or by using lab-made Se-enriched yeast. The dough was first mechanically mixed during 5 min and then hand-kneaded during five more minutes. Parameters such as temperature and time of fermentation for dough rising and baking were optimized; the optimal conditions were 20 min of dough fermentation at 30 °C in an incubator, followed by baking at 200 °C during 25 min in a thermostatic oven. When using selenite for baking, selenium was incorporated into the water and mixed with all the ingredients. In this case, fermentation times from 20 min to 24 h were assayed in order to allow the complete transformation of selenium by yeast. Once the baking process was finished, bread was cooled at room temperature. Se-enriched bread was lyophilized, minced, and kept at −80 °C until analysis. Control bread was prepared similarly to Se-enriched bread but without adding Se.

Saccharomyces cerevisiae was growth in an incubator shaker under sterile conditions and by using a volume of 2.5 mL of YEPD and 5 μg of sodium selenite at 28 °C Different incubation times (16, 17, 96 h) were tested with the aim of achieving the highest yield of the selenization process.[8,28,29]

Total Se Determination by IDA-ICP-MS. Total Se content in the samples was determined by IDA-ICP-MS. For this purpose, an appropriate amount of ^{77}Se spike solution, 1.00 mL of nitric acid, and 0.25 mL of hydrogen peroxide were added to 0.15 g of yeast and 0.10 g of bread, dough, or flour. Afterward samples were digested in an analytical microwave oven at 130 °C for 15 min with a ramp temperature of 10 min, following the conditions described elsewhere.[30] The resulting solutions were diluted to 10.00 mL with Milli-Q water, and measurements were performed by IDA-ICP-MS

To apply IDA-ICP-MS, isotope intensities were corrected by using a detector dead time of 30 ns. The interferences caused by SeH^+ were corrected with a Se factor (f_{Se}) ranging between 2.2 and 2.4% of the Se signal, which is in agreement with data reported by other authors.[31,32] Next, mass bias in ^{78}Se/^{77}Se and ^{80}Se/^{77}Se isotope ratio was corrected by the exponential model.[32] Mass bias discrimination was computed every five analyses, and a mass bias factor (K) of ca. −4% per mass unit, similar to those reported before,[14,31] was obtained. Se concentration was calculated using the IDA equation described by García-Alonso et al.[26]

Determination of Se Species by HPLC Coupled to Postcolumn IDA-ICP-MS. Se speciation in the proteolytic extracts of the raw ingredients and baking products was carried out by HPLC-IDA-ICP-MS by using species-unspecific mode. Selenium species were extracted by means of applying enzymatic hydrolysis by adding 30 mg of protease XIV and 3.0 mL of 30 mM Tris-HCl solution (pH 7.5) to 0.15 g of yeast and 0.10 g of bread, dough, or flour. The resulting extracts were centrifuged for 20 min at 10000 rpm, and supernatants were filtered through a 0.22 μm nylon filter. A comparative study of Se-species extraction methodologies was performed by using microwave-assisted extraction (MAE) (37 °C, 30 min), incubation in a thermostatic bath (37 °C, 24 h), and ultrasonic probe sonication (37 °C, 2 min). In addition, acid hydrolysis with diluted HCl was used as an alternative to enzymatic hydrolysis.[33] Different chromatographic separation mechanisms, anionic exchange PRP-X100, reversed-phase ion pairing C8 Zorbax R_x-C_8, and SEC BioBasic-Sep 60 from 0.1 to 6 kDa were used for performing Se speciation. Identification of Se species was achieved by matching retention times and by spiking experiments. The analytical methodology used was validated by analyzing a reference material certified for SeMet (SELM-1).

Table 1. Total Se and SeMet Content in Raw Ingredients and Baked Products[a]

	total Se (μg of Se/g d.m.)	extracted Se (μg of Se/g d.m.)	% recovery	SeMet (μg of Se/g d.m.)	% recovery
control					
white wheat flour	0.28 ± 0.01	0.26 ± 0.02	93 ± 1	0.22 ± 0.01	84 ± 3
white dough	0.28 ± 0.02	0.28 ± 0.02	100 ± 2	0.23 ± 0.02	83 ± 3
white bread	0.28 ± 0.03	0.28 ± 0.02	102 ± 2	0.22 ± 0.01	80 ± 4
whole meal flour	0.10 ± 0.01	0.10 ± 0.01	100 ± 2	<LOD	<LOD
wholemeal bread	0.10 ± 0.01	0.10 ± 0.01	100 ± 2	<LOD	<LOD
Se-enriched					
fresh yeast	34.0 ± 0.1	35.0 ± 0.1	103 ± 5	24.1 ± 0.1	71 ± 2
dried yeast	28.0 ± 0.1	9.52 ± 0.05	34 ± 4	6.47 ± 0.03	68 ± 1
white dough[b]	1.29 ± 0.03	1.29 ± 0.06	100 ± 5	0.95 ± 0.03	74 ± 3
white bread[b]	1.28 ± 0.02	1.29 ± 0.02	101 ± 2	1.04 ± 0.02	81 ± 3
wholemeal bread[b]	1.16 ± 0.02	1.10 ± 0.02	95 ± 2	0.86 ± 0.05	78 ± 4

[a]Mean ± SE/ $N = 3$ replicates. LOD determined by analyzing ten solutions of the lowest point of calibration ($N = 3$), calculated from 3σ of the signal, and then referred to the regression line. [b]Samples were prepared by dosing selenium as selenized fresh yeast.

Extraction efficiency was calculated as the amount of selenium extracted relative to the total selenium concentration obtained after acid digestion. Blank analysis was also performed for estimating the occurrence of selenocompounds in the protease used for performing enzymatic hydrolysis.

Quantification of Se species was carried out by postcolumn IDA-ICP-MS. For this purpose, a ^{77}Se-enriched standard solution of the appropriate known concentration was added, at a constant rate (0.1 mL min^{-1}), through a T piece placed at the end of the column; afterward the resulting mixture was nebulized into the plasma for ICP-MS measurements. The conventional intensity chromatograms (counts s^{-1}) were converted into mass flow chromatograms (ng min^{-1}) by applying the online isotope dilution equation. Peak area measurements were performed to obtain the amount of Se.

In Vitro Gastrointestinal Digestion Assay. The in vitro gastrointestinal digestion method employed was based on that described by Luten et al.[34] Briefly, approximately 1.00 g of the dried sample and 5.0 mL of water containing 5 mg of α-amylase were mixed by shaking for 1 min and incubated for 15 min at 37 °C. Next, 3.0 mL of gastric juice (see Chemicals) was added, and the resulting mixture was shaken for 1 min before incubation at 37 °C for 4 h. Subsequently, the pH was adjusted to 6.8 with saturated sodium bicarbonate to stop the gastric process. After that, 2.0 mL of intestinal juice (see Chemicals) was added, and the mixture was energetically shaken for 1 min and left at 37 °C for 4 h, with periodical stirring. Then, samples were centrifuged at 6000 rpm for 30 min at 4 °C. The supernatant was filtered through a 0.22 μm nylon filter and was kept at 4 °C until analysis. Blanks of gastrointestinal digestion were prepared in parallel.

Se Homogeneity in the Bread Rolls. The homogeneous distribution of Se in bread was assessed by simulating an industrial baking process. For that purpose, dough of 100.0 g of wheat flour, 2.0 g of NaCl, 50.0 mL of distilled water, and 3.0 g of selenized fresh yeast was prepared, and then it was divided into 20 pieces of approximately 5.0 g each. The ingredients used to prepare the dough were mixed both by hand kneading and by mechanical mixing in a V-shaped laboratory mixer to compare selenium distribution in terms of homogeneity. Total Se concentration was determined in each piece (3 replicates for each) by using ICP-MS following the above-mentioned procedure.

RESULTS AND DISCUSSION

Method Validation. Detection (LOD) and quantification limits (LOQ) were determined by analyzing, in triplicate, ten solutions of the lowest point of calibration. They were calculated from 3σ and 10σ, respectively, of the signal and then referred to the regression line. Reproducibility was calculated as % RSD (relative standard deviation) from five measurements of two independent standard solutions of 20 and 100 μg L^{-1} of Se(IV), carried out on three nonconsecutive days. A LOD and LOQ of 0.001 μg L^{-1} and 0.004 μg L$^{-1,}$ respectively, were achieved for total selenium for ICP-MS. For SeMet, LOD was 0.7 μg L^{-1} and LOQ was 2.2 μg L^{-1}. Precision was determined in terms of repeatability and reproducibility, which were better than 2% RSD for ICP-MS.

The analytical methodology used was validated by analyzing a reference material certified for SeMet (SELM-1). Since at 95% confidence no significant differences were observed between the certified value (3448 ± 146 mg kg^{1-}) and the experimental value (3215 ± 122 mg kg^{1-}), the method was considered accurate for performing speciation.

Selenium Accumulation and Biotransformation during Baking. With the aim of optimizing baking conditions, ingredients were mixed at different ratios and were kneaded until elastic doughs were attained. In addition, different times of fermentation (from 15 min to 24 h) at a temperature of 30 °C were tested. Different baking times (from 5 to 30 min) and temperatures (from 180 to 200 °C) were also assayed in order to achieve a browned crust and spongy crumb, avoiding overbaking. All conditions were optimized in terms of obtaining breads with taste, flavor, texture, and color appropriate for human consumption. As a result, 20 min of dough fermentation at 30 °C, followed by baking at 200 °C for 25 min, was selected as optimal conditions for baking.

ICP-MS methodology was employed to determine total selenium concentration in flour (wheat flour or wholemeal flour), yeast (fresh and lyophilized), and bread samples. The results are shown in Table 1. Se levels in control white and wholemeal bread were 0.28 ± 0.03 μg g^{-1} and 0.10 ± 0.01 μg g^{-1}, respectively. Se content in the yeast used for baking was negligible, which means that Se found in control samples comes from the flour used for baking. Data in Table 1 also suggest that selenium remains unaltered under the high temperature conditions used during baking, as has been pointed out by other authors.[13,35] Se levels were clearly higher in control white bread than in control wholemeal bread. However, studies from biofortification of crops by using Se-rich fertilizers have reported lower Se content in white flour than in wholemeal flour because selenium is preferentially accumulated in embryo,[36] which is partially lost during milling. However, the provenance of the flour (wholemeal and white) used in this work cannot be assigned to the same wheat since they were purchased in a local store. Therefore, differences in Se levels between white and wholemeal control breads cannot be linked to a single factor. Wholemeal and white bread enriched with 1

J. Agric. Food Chem. 2015, 63, 120−127

μg of Se g^{-1}, as Se-enriched yeast, contained 1.16 ± 0.02 and 1.28 ± 0.02 μg g^{-1} of Se, respectively. Considering the concentration of Se present in control bread, the recovery of the added Se was over 99%. Similar results were obtained when selenium was directly added as selenite. Thus, it can be assumed that selenium was incorporated into the bread regardless of the method of supplementation used (either by adding selenite directly to the dough or by using a Se-enriched yeast for rising the dough).

Determination and quantification of Se species in the proteolytic extracts was performed by HPLC coupled to postcolumn IDA-ICP-MS. The extraction of Se species in food samples is usually carried out by enzymatic hydrolysis using protease XIV.[8,9,31,37] Conventionally enzymatic hydrolysis required incubation times of 17−24 h.[8,31,37,38] In recent years, the use of ultrasound and microwave energy[11,31,39] has been proposed as alternative methods to speed up sample treatment procedures.

In the present work, Se-species extraction in Se-enriched bread was carried out with and without enzymes. The extraction of species without enzymes resulted in low recovery values: only 17 ± 1% of the total Se was extracted while quantitative extraction (101 ± 2%) was achieved by using enzymatic hydrolysis with protease in Tris-HCl. In order to speed up the sample treatment process, ultrasonic probe sonication (USP) and microwave assisted extraction (MAE) were used. Regarding the amount of Se extracted, no significant differences were observed between the use of MAE (103 ± 3%), incubation (101 ± 2%), and USP (105 ± 3%). However, the methodology based on the use of ultrasonic probe was chosen for further experiments because it significantly reduces the extraction time (2 min in comparison with 30 min and 24 h for MAE and incubation, respectively). As a result, enzymatic hydrolysis with protease XIV in 30 mM Tris-HCl buffer by USP was chosen to perform Se extraction from both raw ingredients and baking products.

Figure 1 shows that SeMet is the main Se species detected in bread samples by LC-ICP-MS, using both anionic exchange and reversed-phase separation columns. Due to the lack of Se-labeled standards, quantification of the Se species was performed by using postcolumn IDA-ICP-MS, by means of continuous mixing of ^{77}Se spike solution with the effluent coming out of the column. SeMet concentration in Se-enriched white and wholemeal bread represents around 80% of total Se level present in the sample. On the other hand, the similarity between SeMet values obtained in Se-enriched bread and in the Se-enriched white dough (Table 1) indicates that SeMet integrity is not affected by baking. This finding is in agreement with data reported by Hart et al.[13] Contrarily, Warburton and Goenaga-Infante[22] observed a decrease in SeMet content after bread processing and production, although this could be due to differences in the recipe used for baking.

Despite the good results obtained using protease, the presence of Se species in the enzyme[40] employed to extract Se compounds may have a negative impact on the detection limit, and therefore, special control of the blanks is required. The use of acid hydrolysis as an alternative to enzymatic hydrolysis[33] was tested by using incubation bath, USP, and MAE; unfortunately only ca. 7% of the total Se content was extracted. The success of acid hydrolysis in releasing selenoamino acids is highly dependent on the sample matrix. D'Ulivo[41] reported that SeMet and SeCys standards were broken down and remained stable up to 22 h, whereas the

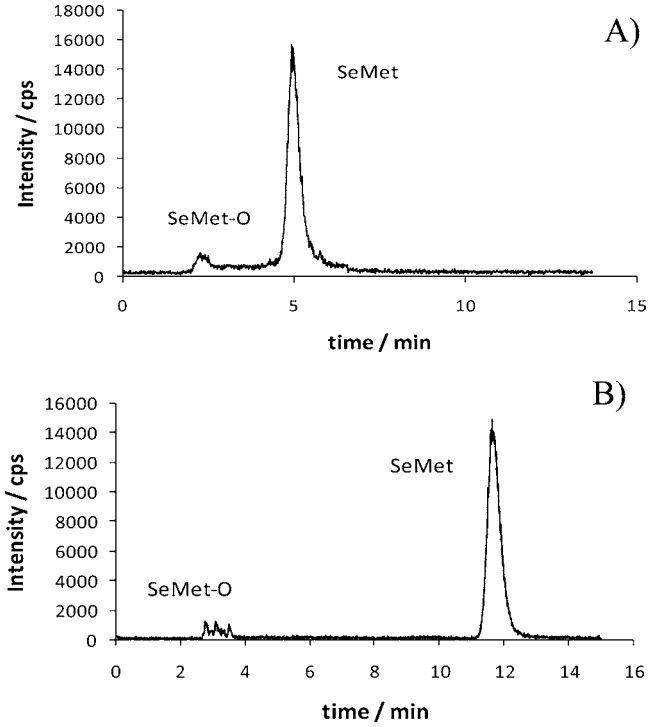

Figure 1. Typical chromatograms of Se-enriched bread prepared using Se-yeast after enzymatic hydrolysis achieved at m/z 78 by (A) anionic exchange PRP-X100 column and (B) reversed-phase C8 Zorbax column, coupled to ICP-MS.

extraction efficiency observed by Montes-Bayón et al.[42] for SeMet in *Brassica juncea* was very low. Acid hydrolysis is a harsh treatment that can lead to degradation of Se species or to some matrix degradation, which can hinder the determination of the species of interest. Therefore, since acid hydrolysis did not provide a reasonable recovery of SeMet, the optimized enzymatic hydrolysis was selected for all the experiments. However, protease blank analysis was always performed because selenium level in the enzyme could vary between batches.

The supplementation of Se for making Se-enriched bread was achieved either by adding selenite directly to the dough or by using laboratory-made selenized yeast. When dosing selenite directly to the dough, Se was quantitatively incorporated into the bread; however, the content of SeMet found was similar to that present in the flour (Table 1). The low amount of SeMet found could be attributed to an incomplete transformation of selenite into SeMet during fermentation. As was evidenced by size exclusion chromatography-ICP-MS (Figure 2), Se was biotransformed into low molecular weight (<5 kDa) Se species, which were not detected when using anion exchange or reversed-phase HPLC-ICP-MS. The results obtained are in disagreement with those published by other authors. Lazo-Vélez et al.[43] reported a complete transformation of selenite into selenomethionine when adding selenite directly. The differences could be explained by differences in the baking process used. Lazo-Velez et al. include sugar as an ingredient, which may help yeast to grow and, therefore, improve the biotransformation of selenium.

Se-enriched bread was successfully obtained by using selenized yeast, which was made in the lab following the protocol described in Methods. Selenized yeast preparation requires a careful control of experimental conditions[44]

DOI: 10.1021/jf505069d
J. Agric. Food Chem. 2015, 63, 120−127

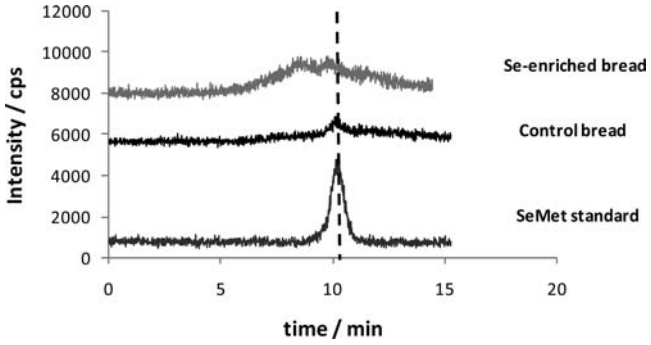

Figure 2. Size exclusion chromatograms achieved at m/z 78 by using BioBacic-Sep 60 column after enzymatic hydrolysis of control and Se-enriched bread obtained by direct addition of Se in the dough before kneading.

(temperature control, stirring, ventilation, and incubation time) to ensure that SeMet is the primary selenium species produced. In this study, selenized yeast (*Saccharomyces cerevisiae*) was prepared in YEPD culture medium in the presence of 5 μg of selenite. The resulting selenium species were monitored by HPLC-ICP-MS over 96 h of incubation (at 3 different time points, 12, 24, and 96 h). After 96 h, selenomethionine accounted for approximately 70% of the added Se (Table 1). A typical anion exchange-ICP-MS chromatogram of Se-enriched yeast at different incubation times is shown in Figure 3.

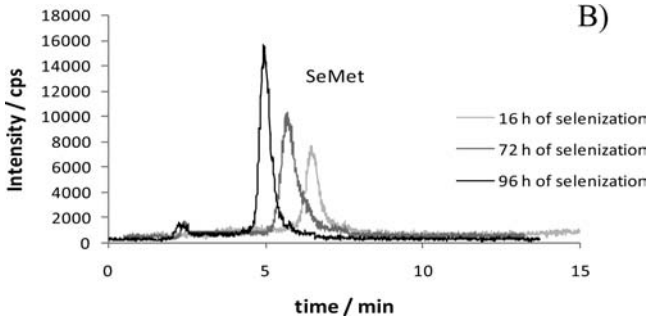

Figure 3. HPLC-ICP-MS chromatogram achieved at m/z 78 by anionic exchange column of Se-enriched yeast produced under controlled conditions of temperature (28 °C), stirring (280 rpm), and different times of incubation (16, 72, and 96 h).

During the experiments, it was observed that the use of fresh baker's yeast after it has been stored for 2 weeks leads to problems associated with variations in flavor, odor, and rate of fermentation, originating bread with bad flavor. It is well-known that one of the most satisfactory methods for preserving yeast is the use of dried yeast. So, in the current work the preparation of Se-enriched yeast was also performed by using dried yeast commercially available. Thus, dried yeast, acquired from a local market, was rehydrated and then cultured in the presence of 5 μg of selenite (in order to have 1 μg g^{-1} in the resulting bread) following the procedure already described when using fresh yeast. Analysis of total Se concentration in the resulting selenized yeast provided concentration values accounting for 103% and 34% of the added Se, when using fresh and dried yeast, respectively (Table 1). Either dried or fresh yeast is able to accumulate and biotransform selenium; however, fresh yeast accumulates higher amounts of Se than dried yeast. Therefore, we decided to prepare Se-enriched bread by using fresh yeast but keeping in mind that it should not be stored longer than 2 weeks. With the aim of overcoming this difficulty, one approach to be tested in the future could be to grow the yeast under the selected conditions to get SeMet, and then drying and using it like normal dry yeast.

From results obtained, selenium was added to the dough through the yeast, which is about 3% of the total weight of bread; therefore a homogeneous distribution of this ingredient is crucial to get selenium uniformly distributed in the resulting bread. Common baking practices consist of preparing the dough and then dividing it into small dough rolls. With the aim of scaling up the process from the lab scale to the pilot scale, dough preparation was carried out by mixing the ingredients either by hand (for up to 20 min) or mechanically (first mechanically mixed during 5 min and then hand-kneaded during five more minutes) following the procedure described in Methods. The resulting dough was divided into 20 pieces of approximately 5 g each and baked. The resulting bread pieces underwent microwave assisted acid digestion for Se concentration determination by IDA-ICP-MS. Figure 4 illustrates that the distribution of Se in the resulting pieces prepared by hand kneading is less homogeneous, and therefore, it provides higher standard deviation values than those prepared by mechanical mixing of the ingredients.

Bioaccessibility of Se in Se-Enriched Bread and Estimated Human Intake. Results from in vitro simulated gastrointestinal digestion of Se-enriched bread (white and

	Se	SeMet	Se	SeMet
control white bread	0.21 ± 0.02	<LOD	0.25 ± 0.01	<LOD
Se-enriched white bread[b]	0.89 ± 0.01	0.85 ± 0.03	1.25 ± 0.02	1.21 ± 0.02
control wholemeal bread	0.04 ± 0.01	<LOD	0.04 ± 0.01	<LOD
Se-enriched wholemeal bread[b]	0.44 ± 0.01	<LOD	0.42 ± 0.01	<LOD

[a]Mean ± SE. $N = 3$ replicates. LOD determined by analyzing ten solutions of the lowest point of calibration ($N = 3$), calculated from 3σ of the signal, and then referred to the regression line. [b]Samples were prepared by dosing selenium as selenized fresh yeast.

wholemeal) are shown in Table 2. Soluble Se fractions after simulated gastric and gastrointestinal digestion in Se-enriched white bread were 75% and 89% of total Se, respectively, whereas in Se-enriched wholemeal bread the amount of extracted Se was much lower (ca. 40%). Selenium species in the bioaccessible fractions were determined by HPLC-IDA-ICP-MS (Table 2). SeMet was the main selenium species found in the bioaccessible fraction of Se-enriched white bread. Se species in the bioaccessible fraction of Se-wholemeal bread were below the LOD. Differences in Se bioaccessibility between white and wholemeal bread could be attributed to the presence of dietary fiber, an unavailable carbohydrate[17] present in higher amounts in wholemeal than in white bread. High contents of fiber can lower both protein and starch digestibility[45] and, therefore, decrease the capability of enzymes to release Se from those compounds. These results highlight the low bioaccessibility of SeMet found in whole bread, which is of interest from the nutritional point of view because of the relatively high consumption of whole wheat products.

Based on these results, an estimation of Se intake was carried out. A daily consumption of approximately 60 g of Se-enriched white bread, following the Guidelines for Healthy Nutrition,[46] would provide 70 μg of Se per day, which is within the recommended range (RDA is 55−70 μg day^{-1}), although the amount of selenium supplied by other food sources should be also taken into consideration. However, according to the World Health Organization,[47] an intake of 400 μg day^{-1} is considered safe.

To the best of our knowledge, this is the first time that homogeneous Se-enriched bread is obtained by using selenized fresh yeast, with good recoveries of SeMet. The simple, cheap, and fast procedure used could be considered as an alternative to the more expensive and more extended procedure of agronomic biofortification of crops using Se-fertilizers. A scale-up development for Se-enriched bread is also proposed. Almost all (99%) of the added Se by using selenized fresh yeast was incorporated in the bread with SeMet accounting for 80% of total Se. Se-enriched bread, with SeMet as the main species, can be a suitable source of this element for people with Se deficiency. The bioaccessibility of selenium in Se-enriched bread was 100 ± 3% and 40 ± 1% for white and wholemeal bread, respectively.

Supporting Information

ABSTRACT: Attenuated total reflection infrared spectroscopy (ATR-IR) proved to be a promising detection technique for 2,4,6-trichloroanisole (TCA), which confers organoleptic defects to bottled alcoholic beverages, allowing the proposal of a criterion for cork plank acceptance when meant for stopper production. By analysis of a significant number of samples, it was proved that the presence of TCA, even in very low concentrations, imparts subtle changes to the cork spectra, namely, the growth of two new bands at ∼1417 (νC═C of TCA ring) and 1314 cm^{-1} (a shifted νCC of TCA) and an increase in the relative intensities of the bands at ∼1039 cm^{-1} (δCO of polysaccharides) and ∼813 cm^{-1} (τCH of suberin), the latter by overlapping with intense bands of TCA. These relative intensities were evaluated in comparison to a fingerprint of suberin (ν_{as}C−O−C), at 1161 cm^{-1}. On the basis of those spectral variables, a multivariate statistics linear analysis (LDA) was performed to obtain a discriminant function that allows classifying the samples according to whether they contain or not TCA. The methodology proposed consists of a demanding acceptance criterion for cork planks destined for stopper production (with the guarantee of nonexistence of TCA) that results from combining the quantitative results with the absence of the two TCA correlated bands. ATR infrared spectroscopy is a nondestructive and easy to apply technique, both on cork planks and on stoppers, and has proven more restrictive than other techniques used in the cork industry that analyze the cleaning solutions. At the level of proof of concept, the method here proposed is appealing for high-value stopper applications.

KEYWORDS: *cork, trichloroanisole, infrared spectroscopy, ATR-IR, wine stoppers*

INTRODUCTION

Cork is a natural, renewable, and biodegradable raw material; its unique physical properties have stimulated the broadening of application fields.[1,2] This is particularly true in Portugal, which is the largest worldwide producer.[3,4] Cork has a very complex composition, but the main constituent is suberin, defined as a glycerolipid polyester, or a mixture of fatty acids and heavy organic alcohols that form a macromolecular network, insoluble in all common solvents.[5] Another important constituent is lignin, with a less known structure than other natural and synthetic polymers, built by phenylpropane units randomly organized, having characteristic side chains with para-substituted phenolic hydroxyl groups, either free or etherified.[6,7] The 2D representations of proposed structures for suberin and lignin are schematized in Figure 1.

Recent studies on the chemical composition of cork from *Quercus suber* L. (oak), the main natural source of cork, point out that the determining variation factor is the individual tree rather than the geographical origin.[8] The average chemical composition of natural cork from *Q. suber* L. is approximately suberin 40%, lignin 22%, polysaccharides 18%, total extractives 15%, and ash below 1%.[9] The oak cork natural variability with location is mainly reflected in the amounts of extractives and polysaccharides, whereas the relative contents in suberin and lignin are not much affected.[9]

Traditionally, the growth of filamentous fungi in cork was considered beneficial, but currently the detection of volatile compounds, namely, chloroanisoles and chlorophenols, is associated with the incidence of some fungi.[10,11] Those volatiles can also be produced by different sources of phenol and

chlorine, such as some cleaning products and sanitizers (that contaminate surface waters). The honeycomb-type structure can provide adequate reservoirs for holding these volatile compounds in the cork core.[1,12]

The presence of volatiles is a critical problem in the food industry, because chloroanisoles and chlorophenols are associated with "musty" off-flavors and odors. Because cork materials are widely used to seal bottles of alcoholic beverages, the migration of chloroanisoles from the stoppers may result in those undesirable odors or tastes.[13] In fact, the production of chloroanisoles by fungi in cork slabs is considered the most frequent cause of organoleptic defects of wines.[14,15] The strongest chloroanisole is 2,4,6-trichloroanisole (TCA),[16] formed mainly due to the microflora associated with corks.[15,17] It is usually considered to be primarily responsible for economical losses in the wine industry, due to the increase of cork taint in bottled wine.[18] Several analytical techniques can now be employed to detect the presence of TCA, and numerous processes have been developed to reduce its quantity in cork.[19−24] Bleaching is the most used, but it does not remove all of the TCA. Moreover, when chlorinated products are used in the process, the formation of chlorophenols can be induced.[3]

The sensitivity of the olfactory receptor cells to TCA is extremely high: the threshold in wine can be low as 1.4−4.6 ng/L (or parts per trillion, ppt),[25] which is a detection limit difficult to match by analytical methods. Given the dimension of this problem, it is now settled that a preventive action is a main priority, starting with the detection of these compounds in the cork planks before stoppers are produced.

In the present work, a systematic analysis of attenuated total reflection infrared spectroscopy (ATR-IR) spectra of a substantial number of natural cork stoppers was performed to establish a safe criterion for TCA absence that may eventually be used for acceptance of cork planks intended for stoppers production.

EXPERIMENTAL PROCEDURES

Samples. Natural cork stoppers for wines that need to age in the bottle, from the *Q. suber* L. variety, were obtained from one manufacturer (the name is undisclosed for confidentiality reasons). The information provided consisted of whether the corks came from batches containing detectable traces of TCA in the last cleaning solution or not. No particular information was specified about the detection method, except that it was by chromatography. The stoppers, cut out directly from natural cork planks, were cylindrical single pieces, a total of 50. Two series of samples were provided: series A (15), from batches in which TCA was not detected in the last cleaning solution and, therefore, allegedly without TCA; and series R (30 five), from batches in which TCA was detected in the last cleaning solution and therefore expected to have TCA.

A 0.01 M solution of 2,4,6-trichloroanisol (Sigma-Aldrich, 99%) in ethanol (absolute, ≥99.8%, Sigma-Aldrich) was prepared to artificially embed TCA onto clean cork. Different amounts were deposited onto the cork surface to obtain a variety of low TCA concentrations upon solvent evaporation.

Infrared Characterization. All of the infrared spectra were scanned in a Mattson FTIR spectrometer RS1, equipped with a wide band MCT detector (400−4000 cm^{-1}). The spectra, with 4 cm^{-1} resolution, are presented without baseline or smooth corrections.

For analyzing pure TCA and cork powder from different regions of the same stopper, diffuse reflectance infrared Fourier transform (DRIFT) spectra were recorded using a Graseby/Specac selector. The samples were diluted in KBr (from Aldrich, FTIR grade) in a weight proportion of 1:4. The spectra were the ratio of 500 single-beam scans for the sample to the same number of scans for pure KBr, used as background. The spectra were transformed to Kubelka−Munk units using FIRST software.

The external surfaces of the stoppers were analyzed by infrared attenuated total reflection (IR-ATR) spectra, with a horizontal Pike Technologies (HATR) accessory. A slim slice of the stopper external surface was cut and placed on a SeZn ATR crystal (4 mm thick and 80 mm long) with 10 reflections and an incidence angle of 45°. Conditions for an "ideal contact" between the sample and the crystal were guaranteed, so that the band intensities remained constant as contact slightly changed.[26] The spectra were also obtained as a ratio of 500 single-beam scans of the sample to the same number of background (clean ATR crystal) scans. The spectra were transformed to $\log_{10}(1/R)$ using FIRST software.

A Bruker Hyperion 2000 microscope coupled to a Vertex 70 FTIR spectrometer was used to map the distribution of TCA in some of the samples. The spectra of very thin cork slices were acquired in transmission mode, with a spatial resolution of 15 μm.

RESULTS AND DISCUSSION

Infrared Spectrum of TCA. The infrared spectrum of 2,4,6-trichloroanisole is known, but the detailed analysis has not been published so far. It is shown in Figure 2, in DRIFT.

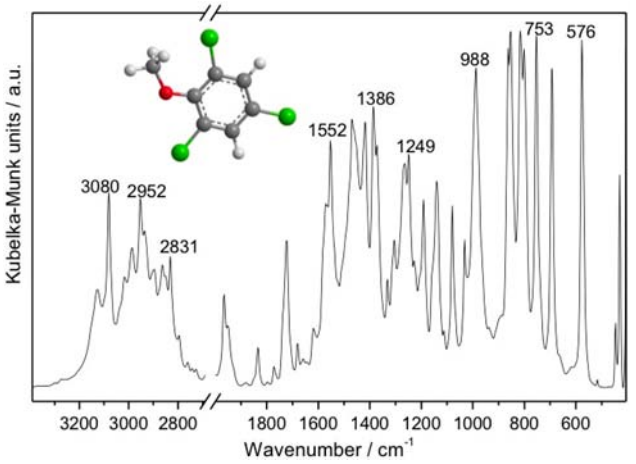

Figure 2. DRIFT spectrum of pure 2,4,6-trichloroanisole.

Two groups of very strong bands are observed, in the ∼1600−1370 and ∼1000−600 cm^{-1} regions, respectively, plus a number of strong ones in the 2900−3200 cm^{-1} region. A detailed assignment was made mainly by comparison with the parent molecules 2,4,6-trichlorophenol and anisole[27,28] and is presented in Table 1.

Cork Infrared Characterization. In general, the cork stoppers have a light color and, after bleaching, the external surface becomes more whitish. Both the heterogeneities of natural cork and the bleaching process may lead to differences in the infrared absorption bands. To assess these possibilities, several regions of a bleached cork stopper from a batch where no TCA was detected in the cleaning solution (sample A1) were characterized by DRIFTS. The spectra are compared in Figure 3.

The spectra in Figure 3, normalized to the strongest suberin band (ν_{as}COC, at 1161 cm^{-1}), show only changes in the bands' relative intensities, confirming some variability in the chemical components' proportions. The differences associated with the presence or absence of spots (sites a and b) are very small, whereas those related to the influence of bleaching (mostly site d) are clearer, pointing to bleaching as the main cause for adjustments in chemical proportions: the intensities of the

bands at 2924, 1739, 1464, and 1240 cm^{-1} decrease in comparison to the suberin fingerprint, at 1161 cm^{-1}, whereas those at 1093 and 1039 cm^{-1} appear to increase. For the systematic study that follows, the inner surfaces of cork stoppers will be analyzed.

The ATR spectra of two slides of stoppers from a bleached batch (A1 and A4) were used to establish the standard "clean" cork and are shown in Figure 4.

The spectra in Figure 4 were also normalized to the characteristic suberin band ν_{as}COC, at 1161 cm^{-1}, and correlate well with ATR infrared spectra of cork stoppers in the literature.[29−31] The assignment of the main bands is summarized in Table 2.[6,32−34]

The band shifts observed between the two samples are within the spectral resolution, and the changes in relative intensities are probably due to heterogeneities, as expected in natural samples. In fact, the amount of lignin in natural cork can vary from 19 to 24%, probably being the chemical component with less variability. In the case of suberin, its content varies from ~30 to almost 50%.[8]

Cork with TCA Embedded in Situ. The objective of characterizing cork samples with TCA embedded in the laboratory was to establish spectral regions unambiguously assignable to TCA on cork. The ATR infrared spectra were obtained only after complete evaporation of the solvent. The spectra of the same stopper, clean and with embedded TCA, are compared in Figure 5.

The presence of TCA induces the appearance of new bands at 3078, 1550, 1417, 1383, 987, 796, and 752 cm^{-1}, which can be considered as fingerprints of TCA in cork. Other strong modes of TCA can alter the band shape of the cork spectrum due to overlapping, as in the case of the bands at 1138, 1080, 854, and 692 cm^{-1}. Moreover, in the region between 1470 and 1415 cm^{-1}, the shoulder at 1468 cm^{-1} and the maximum at 1452 cm^{-1} invert their relative intensities, and the cork band at 1236 cm^{-1} splits into two components (1259 and 1248 cm^{-1}),

dx.doi.org/10.1021/jf503309a | J. Agric. Food Chem. 2015, 63, 128−135

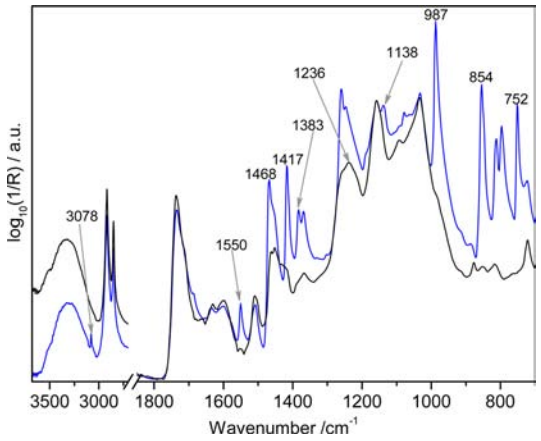

Figure 5. ATR infrared spectra of a clean cork stopper (black line) and the same sample after incorporation of TCA (blue line). The spectra were not baseline corrected and were normalized to the suberin band at 1161 cm^{-1}.

the first shifted from the maximum observed for the pure TCA doublet (1265 and 1249 cm^{-1}).

Evaluation of the Presence of TCA in Stoppers from Natural Cork. Taking into account that the natural amount of TCA expected in stoppers is very low, we are aware that only the very strong vibrational bands of TCA will probably be observed in the tainted samples. On the other hand, because TCA is formed within natural cork, it is possible that the interactions with the medium lead to conformational changes and thus to spectral differences regarding pure or artificially added TCA and also that a heterogeneous spatial distribution throughout the sample occurs. This effect is well illustrated in Figure 6A, which refers to one stopper of series R (from a batch in which TCA was detected in the last cleaning solution): the honeycomb-like cork structure is observed over an area of 0.02 mm^2, as well as the corresponding 3D mapping of the integrated intensity of the band at 1417 cm^{-1} (the strong νC=C of TCA). The ATR spectra of seven cork stopper slices of series R are presented in Figure 6B. Only the region 1800−700 cm^{-1} is shown, because the main differences are observed in this wavenumber region.

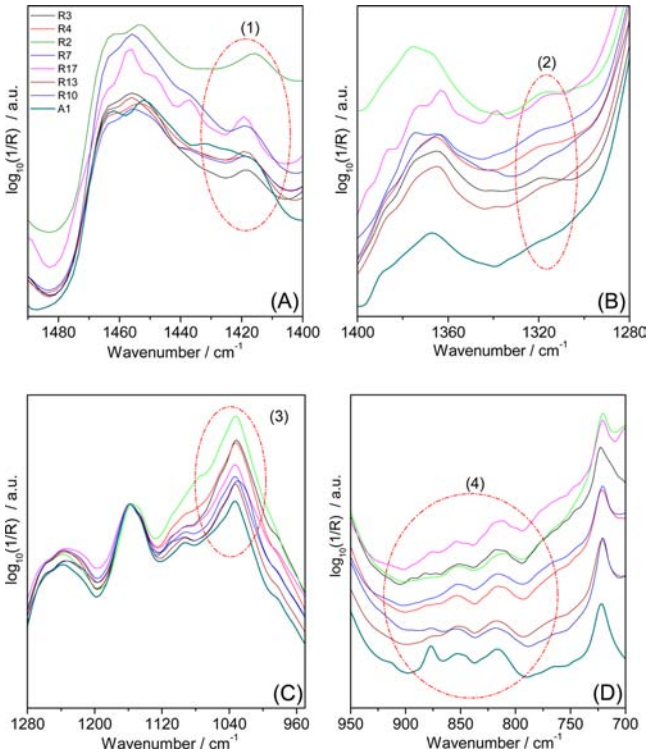

Figure 7. Details of the ATR infrared spectra of cork stopper slices in which TCA was detected in the cleaning solution, compared to a "clean" sample (A1). The spectra are baseline corrected and normalized at 1161 cm^{-1}.

As expected, the changes in the overall spectral shape are much more subtle than when TCA was embedded in situ. However, some effects are clear, and the corresponding regions are labeled (1−4) in Figure 6B. These spectral regions are enhanced in Figure 7, where the same samples are compared with one from a "TCA clean" stopper (A1).

Analysis of Figure 7 establishes spectral characteristics inherent to corks with TCA:

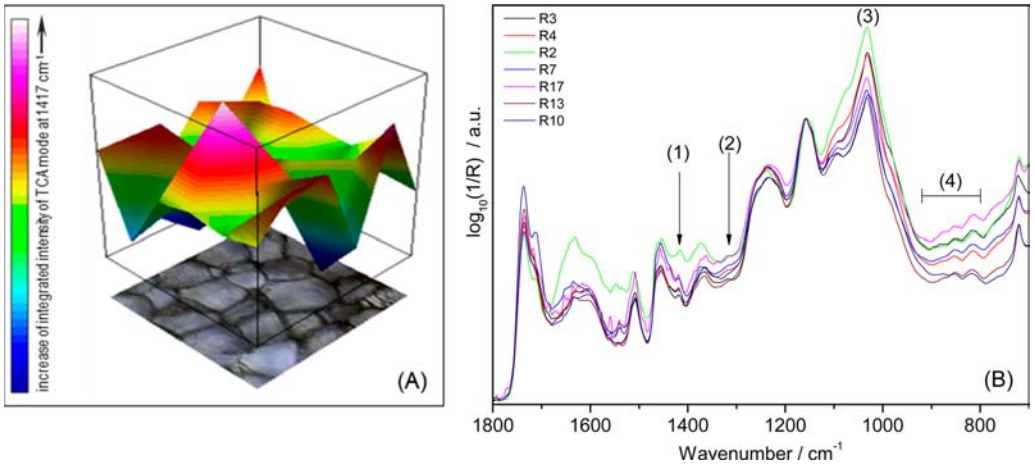

Figure 6. (A) Image of a 0.02 mm^2 area of a stopper slice in which TCA was detected in the cleaning solution (sample R2) and corresponding 3D distribution of the integrated intensity of the TCA mode at 1417 cm^{-1}. (B) ATR infrared spectra of cork stoppers in which TCA was detected in the cleaning solution (series R): highlighted bands at 1417 cm^{-1} (1), ∼1314 cm^{-1} (2), and ∼1039 cm^{-1} (3) and the spectral region between 950 and 800 cm^{-1} (4). The spectra are baseline corrected and normalized at 1161 cm^{-1}.

dx.doi.org/10.1021/jf503309a | J. Agric. Food Chem. 2015, 63, 128−135

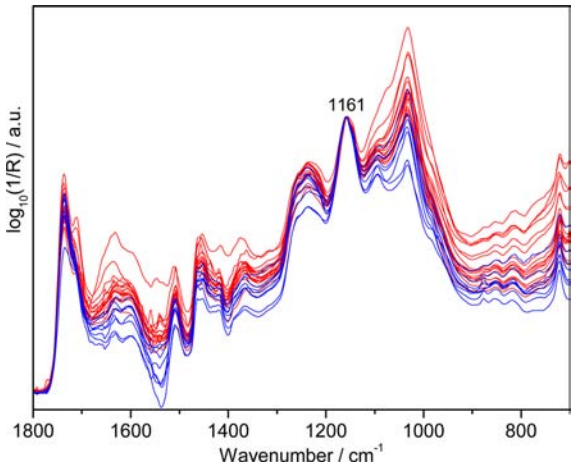

Figure 8. ATR infrared spectra of cork stopper slices: series A, from batches in which TCA was not detected (blue spectra); series R, from batches in which TCA was detected (red spectra). The spectra were baseline corrected and normalized at 1161 cm^{-1}.

In region 1, the TCA band near 1417 cm^{-1} grows, coincident with the observed for the sample with TCA embedded in the laboratory.

In region 2, a very small band at ∼1314 cm^{-1} (almost a shoulder) is present; this new band was neither observed in the spectra of cork with incorporated TCA nor does it corresponds to a pure TCA band, but it may result from $\pi-\pi$ interactions between the aromatic ring of TCA formed in situ and those of the suberin or lignin molecules.

In region 3, the relative intensity of the band at ∼1039 cm^{-1} (δCO of polysaccharides) is much higher than in the spectrum of the sample without TCA. As referred to above, these polysaccharides may originate from natural cork or from fungi cells walls. Because TCA can be synthesized by cork fungi, this band may be an indirect indication of contamination.

In region 4, the spectra between 950 and 800 cm^{-1} have a higher relative intensity that can be easily related with the presence of TCA, because its spectrum has very strong bands in this region, namely, the νCCl mode (that appears as a doublet at 815 and 801 cm^{-1} in pure TCA).

In summary, the appearance of bands at ∼1417 and ∼1314 cm^{-1} and the intensity increase of the spectral region 950−800 cm^{-1} are direct indications of the presence of TCA in a cork stopper. The relative increase of the polysaccharide band at ∼1039 cm^{-1} in comparison to the suberin fingerprint at 1161 cm^{-1} can be an indirect sign.

The observation of these four effects, although subtle, attests to the presence of TCA in cork, even in low concentrations, and ATR appears as a good candidate method for TCA detection. However, the purpose of the present work is to use this technique to establish criteria for guaranteeing the absence of TCA in cork, consequently allowing the approval of cork planks intended for the manufacture of high-value wine stoppers. To establish these criteria, further spectra were analyzed for the two complete series of samples provided (A and R). The ATR spectra are shown in Figure 8.

In the regions named above as 3 and 4, the TCA effects were tentatively quantified by the ratio between the intensity of a particular band to that of the 1161 cm^{-1} band: I_{1039}/I_{1161} and I_{813}/I_{1161}, respectively. About 50 specimens (of the two series of samples A and R) were considered an acceptable number to carry out an analysis of variance (ANOVA) of those two intensity ratios. The extreme points were excluded from the statistical analysis, based on the modified Thompson Tau test for outlier determination.[35] The Tukey test proved that the means difference between A and R series is significant at the 0.05 level, and the confirmation of equal variance for the two populations was obtained by using the Brown−Forsythe test. The samples used in the calculations, the results of the Brown−Forsythe test and ANOVA, are summarized in Table S1 in the Supporting Information. Because the two populations' means are significantly different, the ratios I_{1039}/I_{1161} and I_{813}/I_{1161}, the mean values, and corresponding confidence intervals are shown in Figure 9. The average intensity ratio I_{1039}/I_{1161} is 0.96 ± 0.06 for the samples allegedly without TCA and 1.15 ± 0.06 for the samples with TCA, and the average ratio I_{813}/I_{1161} is 0.42 ± 0.03 and 0.50 ± 0.04, respectively (95% confidence level). Accordingly, cork samples definitely not contaminated with TCA are expected to present simultaneously a I_{1039}/I_{1161} ratio below 0.96 ± 0.06 and a I_{813}/I_{1161} ratio below 0.42 ± 0.03.

Cork being a natural product, the ideal sampling would consist of a larger number of specimens, identified by production region and pretreatments. The limitations of the previous statistical analysis on the data from spectral regions 3 and 4 may be partially overcome by complementing with the information from regions 1 and 2. A complete evaluation of the spectral effects of TCA is indispensable to establish the final criteria for deciding on the acceptance of a cork plank. The four effects are combined in Figure 10A.

In the absence of the bands at 1417 and 1341 cm^{-1} (quadrant I) and only within the shaded area (limited by $I_{1039}/I_{1161} \leq 1.02$ and $I_{813}/I_{1161} \leq 0.45$), all of the spectral observations point to safely concluding the nonexistence of TCA in the cork stoppers. In line with this conclusion, all of the samples within the shaded area come from batches in which TCA was not detected in the last cleaning solution. When the bands at 1417 and 1341 cm^{-1} are both present (quadrant III), the cork stoppers are probably contaminated with TCA. Clearly, most of the samples included in this quadrant also present high values of the band ratios I_{1039}/I_{1161} and I_{813}/I_{1161} and therefore have a high possibility of TCA presence. Indeed, only one sample within this quadrant comes from A batches. If only the band at 1314 cm^{-1} is observed (quadrant IV), the

dx.doi.org/10.1021/jf503309a | J. Agric. Food Chem. 2015, 63, 128−135

conclusions can be more difficult. Only two samples are in these conditions, and both come from A batches. However, because the I_{1039}/I_{1161} and I_{813}/I_{1161} band ratios are high, the possibility of contamination in those cork stoppers may not be excluded. When only the band at 1417 cm^{-1} is observed (quadrant II), it is so unequivocal that it constitutes a strong enough indication of the presence of TCA in the cork. In this case, even if the band ratios do not support this hypothesis, the cork stoppers should be considered contaminated.

To further discriminate samples with and without TCA, a multivariate statistics linear discriminant analysis (LDA) was applied to the ATR infrared data. The two data categories A and R were used, as previously, and the four spectral effects were considered as independent variables: X_1 (the ratio I_{1039}/I_{1161}), X_2 (the ratio I_{813}/I_{1161}), X_3 (the TCA band at 1417 cm^{-1}), and X_4 (the TCA band at 1314 cm^{-1}). The dummy variables X_3 and X_4 were assigned either as 1 or 0, to account for the presence or absence of the bands, respectively. The output results (OriginPro 9.1) are summarized in Table 3, and the training data are reported in Table S2 in the Supporting Information. Equality of covariance matrices within groups is attested by similar log determinants and p value (0.319) of the likelihood-ratio test. Only one discriminant function and one eigenvalue accounting for 100% of the variance in the relationship are obtained, along with good canonical correlation between the discriminant function and the dependent variables. Statistical significance of the discriminant function is withdrawn from the low p value of the Wilks' lambda test. According to the LDA analysis, the intensity ratio X_1 (I_{1039}/I_{1161}) is the most relevant variable for the discrimination (canonical coefficient 0.886), followed by X_3, X_4, and X_2 (I_{813}/I_{1161}). Strong validity of the variables chosen to distinguish between R and A samples is given by the absence of error in the classification (Table 3) and corresponding post probabilities obtained for the training data. Cross-validation (Table S2 in the Supporting Iinformation) evidences a higher error rate, most probably due to misclassification of some observations, namely those of group A that contain the relevant band at 1417 cm^{-1} (X_3), pointing to a better allocation in group R. This corroborates the previous analysis, with the possibility of exclusion of some A samples. The canonical scores obtained for the ATR data along with the group centroids for A and R and the corresponding separation boarder line are represented in Figure 10B, confirming good quality of the discrimination attained. On the basis of this LDA, cork planks or stoppers can be safely rejected whenever they are allocated in the centroid region of group R. For acceptance of cork samples (guarantee of inexistence of TCA), however, the strong physical meaning of the bands at 1417 and 1341 cm^{-1} must be taken into account: the allocation in the centroid region of group A should be combined with the absence of both bands directly related with TCA. This leads to rejecting all of the samples already rejected by other methods, usually performed on the cleaning solutions, plus some accepted by those methods. Thus, the result is a more restrictive method in terms of acceptance of cork planks for stopper manufacture, especially adequate for cases when the economical damage for TCA-contaminated stoppers is more significant, namely, when high-value wines are at stake. Besides, it is a direct method, nondestructive, simple, rapid, and applicable both on the cork planks and on the cork stoppers.

Although the application of the proposed method renders valuable information, it is a proof of concept, and, prior to implementation, we are aware that a significantly larger number of samples should be tested.

Supporting Information

ABSTRACT: A hypotoxic immunosorbent assay for the detection of zearalenone (ZEN) was developed, by identifying a single-stranded DNA (ssDNA) aptamer with high specificity and affinity for a ZEN monoclonal antibody (mAb-ZEN). ssDNA aptamers, which could mimic ZEN epitopes, were identified using the modified systematic evolution of ligands by an exponential enrichment (SELEX) technique. The purified mAb-ZEN was coated on microtiter plates as a target recognized by the random oligonucleotide ssDNA library. The binding affinity between the aptamers and mAb-ZEN during each round was measured by the biotin−streptavidin−horseradish peroxidase system. During 15 rounds of screening, an increasing binding affinity was observed. The enriched ssDNA library binding to mAb-ZEN with high affinity was cloned, sequenced, and analyzed. One aptamer (number 46), which displays the highest affinity and specificity for the mAb-ZEN, was used to establish an indirect competition enzyme-linked oligonucleotide assay (ELONA) to measure the ZEN concentration in corn. Under optimal conditions, the regression equation for quantification of ZEN was $y = -0.0778x + 0.713$ ($R^2 = 0.9981$). The detection limit and IC_{50} were 0.01 and 0.2 ng/mL, respectively, with a working range of 0.03−2.5 ng/mL. The recovery rates of the spiked samples in the ELONA ranged from 95 to 105%. Aptamers, which can mimic many types of low-weight analytes in agricultural products, could serve as surrogates for the development of hypotoxic, environmentally friendly immunological detection methods.

KEYWORDS: *aptamer, zearalenone, monoclonal antibody, affinity, ELONA*

INTRODUCTION

Zearalenone (ZEN) is a secondary metabolite produced by fungi belonging to the genus *Fusarium*, including *Fusarium graminearum* and *Fusarium roseum*, and a mycotoxin that contaminates various agricultural products worldwide.[1,2] ZEN is estrogenic and carcinogenic, causes DNA damage, and is reproductively toxic to humans and animals.[3] Infants and children are reported more vulnerable to the effects of ZEN than adults.[4] To decrease the incidence of ZEN-based toxicity in infants and children, the European Commission regulations specify a maximum ZEN level of 20 μg/kg in cereal-based foods manufactured for consumption by children.[5] This upper limit is considerably lower than the maximum amount permitted in cereals (100 μg/kg) for adults. The need for more stringent limits of ZEN levels in the foods of infants and young children has necessitated more sensitive measures. To this end, highly sensitive, rapid, and simple methods to monitor the ZEN content in food and feed products have been recently developed.

Currently, low-molecular-weight analytes (both free and conjugates) are widely used in quantitative chromatographic and immunologic assays to detect mycotoxin in agriculture commodities for production of food and feed products. However, some low-molecular-weight analytes are quite toxic (such as pesticides and mycotoxins), and the use of an analyte and/or it is conjugate in an assay may be harmful to the operator and/or environment. Furthermore, analytes are expensive to produce, and the efficiency of chemical conjugation between low-molecular-weight analytes and a carrier, such as a protein or enzyme, is low.[6] To improve the analytical methods, anti-idiotypic antibodies[7] and phage-displayed peptides[8] have been developed to mimic antigenic epitopes on analyte surfaces. However, screening of anti-idiotypic antibodies is costly and time-consuming. In addition, phage-displayed peptides can fail because of their inherent cytotoxicity. The systematic evolution of ligands by exponential enrichment (SELEX) technology was developed in the 1990s[9] to generate highly specific nucleic acid sequences (aptamers) with high affinity for various ligands. Recently, aptamers have

ACS Publications © 2014 American Chemical Society

been widely used in diagnosis, detection, and chemical analysis of various substances, such as thrombin,[10] *Mycobacterium tuberculosis*,[11] and cocaine.[12] Aptamers have also been employed to mimic antibodies for detection of mycotoxins, such as ochratoxin A,[13,14] fumonisin B1 (FB1),[15] and ZEN.[16] In light of less expensive screening procedures, aptamers can now be used to mimic analytes and are more suitable than phage-displayed peptides and anti-idiotypic antibodies for hypotoxic analysis. To date, however, there have been no studies to develop aptamers as specific binding antibodies for the detection of low-molecular-weight analytes in agricultural products. In this study, we identified and charactierzed a single-stranded DNA (ssDNA) aptamer, which recognizes a monoclonal antibody against ZEN with high specificity and affinity. A hypotoxic immunoassay to detect ZEN was developed using this ssDNA aptamer to replace the ZEN conjugation, thereby avoiding environmental and operator exposure to toxin. Multiple low-molecular-weight analytes can be analyzed simultaneously using aptamers and an enzyme-linked oligonucleotide assay (ELONA) in the future, which offers several advantages over other methods, such as high sensitivity, rapidity, and safety.

MATERIALS AND METHODS

Materials. ZEN and FB1 were purchased from Sigma Chemical (St. Louis, MO). Monoclonal antibodies (mAb) against ZEN (2C9, mAb-ZEN) and FB1 (6H3, mAb-FB1) were generated in our laboratory.[17,18] Aflatoxin B1 (AFB1), deoxynivalenol (DON), and mAbs against DON (mAb-DON) or AFB1 (mAb-AFB1) were obtained from Huaan Megnech (Beijing, China). EasyTaq PCR MasterMix and a 50 base pair (bp) DNA ladder were purchased from CWbio (Beijing, China). A 20 bp DNA ladder was purchased from Thermo Scientific (Bremen, Germany). A UNIQ-10 column polyacrylamide gel electrophoresis (PAGE) gel extraction kit was purchased from Sangon Biotech (Shanghai) Co., Ltd. (Shanghai, China). Dynabeads M-280 streptavidin was purchased from Invitrogen (Grand Island, NY). Horseradish peroxidase (HRP)-conjugated streptavidin was purchased from AnaSpec (Fremont, CA), and the pMD18-T vector was purchased from TaKaRa Bio, Inc. (Tokyo, Japan). A plasmid extraction kit was purchased from Omega Bio-Tek (Norcross, GA). A random ssDNA library with strands of an overall length of 71 nucleotides (nt) containing a 35 nt random sequence flanked by two 18 nt constant sequences (5′-CGGAATTCTT-GATGTTGC-[35 nt]-CAACTTAGTAGGATCCCG-3′), a forward primer (P1, 5′-CGGAATTCTTGATGTTGC-3′), a reverse primer (P2, 5′-CGGGATCCTACTAAGTTG-3′), and a biotin-labeled forward primer (biotin-P1, 5′-biotin-CGGAATTCTTGATGTTGC-3′) used for amplification of double-stranded DNA (dsDNA) were synthesized by Sangon Biotech (Shanghai, China). The ZEN-free corn samples were provided by the Shanghai Entry−Exit Inspection and Quarantine Bureau (Shanghai, China).

Equipment. A NanoDrop 1000 spectrophotometer and 37 °C incubator were purchased from Thermo Scientific (Bremen, Germany); microtiter plates were purchased from Greiner Bio-One GmbH (Frickenhausen, Germany); and a microplate reader was purchased from BioTek Instruments, Inc. (Winooski, VT).

SELEX Screening Procedure. The purified anti-ZEN mAb (mAb-ZEN) was diluted to 10 μg/mL with coating buffer (50 mM carbonate buffer at pH 9.6). Three antibodies (mAb-FB1, mAb-AFB1, and mAb-DON) were mixed with equal concentrations and volumes and diluted to 10 μg/mL with coating buffer. Antibody solution (100 μL) was added to each microtiter plate well, followed by incubation at 4 °C overnight. The antigen-coated microtiter plate was washed 3 times with 10 mM phosphate-buffered saline (PBS) containing 0.05% Tween-20 (PBST) then blocked with 3% bovine serum albumin (BSA) at 37 °C for 2 h, followed by washing with PBST 3 times. The 20 μL original random ssDNA pool was dissolved in 500 μL of binding buffer (pH 7.4, containing 20 mM Tris−HCl, 100 mM NaCl, 5 mM KCl, 1 mM $CaCl_2$, and 2 mM $MgCl_2$), denatured at 94 °C for 10 min, and immediately cooled on ice for 10 min, followed by incubation at room temperature for 10 min. The denatured 100 μL ssDNA pool solution was added to blank wells coated with 3% BSA only as a negative control and incubated at 37 °C for 1 h to remove residual ssDNA bound to the BSA. Then, 100 μL of the counter BSA-treated ssDNA solution was added to the antibody mixture wells and incubated at 37 °C for 1 h to further subtract the residual ssDNA bound to the three antibodies (mAb-FB1, mAb-AFB1, and mAb-DON) as a second counter selection to increase the specificity and affinity of the selected ssDNA pool. Thereafter, the counter BSA and three antibody-selected ssDNA solution was moved to the mAb-ZEN-coated wells and incubated at 37 °C for 1 h. After washing with washing buffer (0.02−0.05% Tween in binding buffer) 5 times to remove unbound ssDNA, 100 μL of elution buffer (20 mM Tris-HCl, 4 M guanidine thiocyanate, and 1 mM dithiothreitol) was added to the wells and the plates were incubated at 80 °C for 10 min to dissociate the ssDNA from the antibodies. The eluted ssDNA was extracted using phenol/chloroform/isoamyl alcohol and precipitated with ethanol. Finally, the selected ssDNA was dissolved in 20 μL of TE buffer (10 mM Tris-HCl and 1 mM ethylenediaminetetraacetic acid at pH 8.0) and stored at −20 °C for future use. To improve the specificity and affinity of the selected ssDNA pool, the amounts of ssDNA and mAb-ZEN, incubation time of the ssDNA with the target IgG, and Tween concentration in the washing buffer were changed in subsequent selection rounds, as shown in Supplementary Table 1 of the Supporting Information.

Optimization of Symmetry and Asymmetry Polymerase Chain Reaction (PCR). To enrich the eluted ssDNA pool of each round of selection, dsDNA was generated by PCR in 25 μL reactions consisting of 12.5 μL of 2× EasyTaq PCR MasterMix, 1.0 μL of eluted ssDNA as a template, 1.0 μL of forward primer (biotin-P1), 1.0 μL of reverse primer (P2), and 9.5 μL of deionized water. Amplification consisted of a pre-denaturation cycle at 94 °C for 5 min, followed by denaturation at 94 °C for 30 s, annealing at 50 °C for 30 s, and extension at 72 °C for 20 s. One sample was taken out at each 5, 8, 12, 16, 20, and 25 cycle for amplification analysis. All remaining samples underwent a final extension cycle at 72 °C for 2 min. The PCR products were then separated by 12% PAGE and stained with silver nitrate.[19]

After generation of the dsDNA via symmetry PCR, asymmetry PCR was employed to produce a sufficient amount of ssDNA for affinity assays. The asymmetry PCR was performed in a 25 μL reaction volume consisting of 12.5 μL of 2× EasyTaq PCR MasterMix, 1.0 μL of dsDNA as a template, 1.0 μL of forward primer (biotin-P1), 1.0 μL of reverse primer (P2), and 9.5 μL of deionized water. To optimize the yield of ssDNA, the ratios of forward and reverse primers were tested at 1:0, 10:1, 30:1, 50:1, 80:1, and 100:1. The amplification conditions for the asymmetry PCR were performed as described above for the symmetry PCR. All PCR samples were separated on denaturing 8% PAGE containing 7 M urea, and the ssDNA band was extracted from the gel using the UNIQ-10 spin column DNA gel extraction kit as described in the manual. Purified ssDNA was stored at −20 °C until use in the ELONA to determine the optical density (OD) in 450 nm.

OD Values in ELONA and Specificity Assay of ssDNA in Each Screening Round. Each well of the microtiter plate was coated with 100 μL (1 μg/mL) of mAb-ZEN and incubated at 4 °C overnight. After washing with PBST 3 times, the coated wells were blocked with 3% BSA. Then, 50 μL of biotinylated ssDNA aptamer (100 pM), which was generated in the asymmetry PCR assay, was mixed with 50 μL of binding buffer, added to the antibody-coated wells, and incubated at 37 °C for 1 h. After washing, 100 μL of 1 μg/mL HRP-conjugated streptavidin was added to the wells and the plate was incubated at 37 °C for 1 h. After washing 3 times, 100 μL of substrate solution [3,3′,5,5′-tetramethylbenzidine (TMB)] was added to the wells and the plates were incubated at 37 °C for 10 min. Finally, 50 μL of 2 M H_2SO_4 was added to stop the reaction, and the absorbance of the wells was determined using a microplate reader at 450 nm. The ELONA was performed in triplicate.

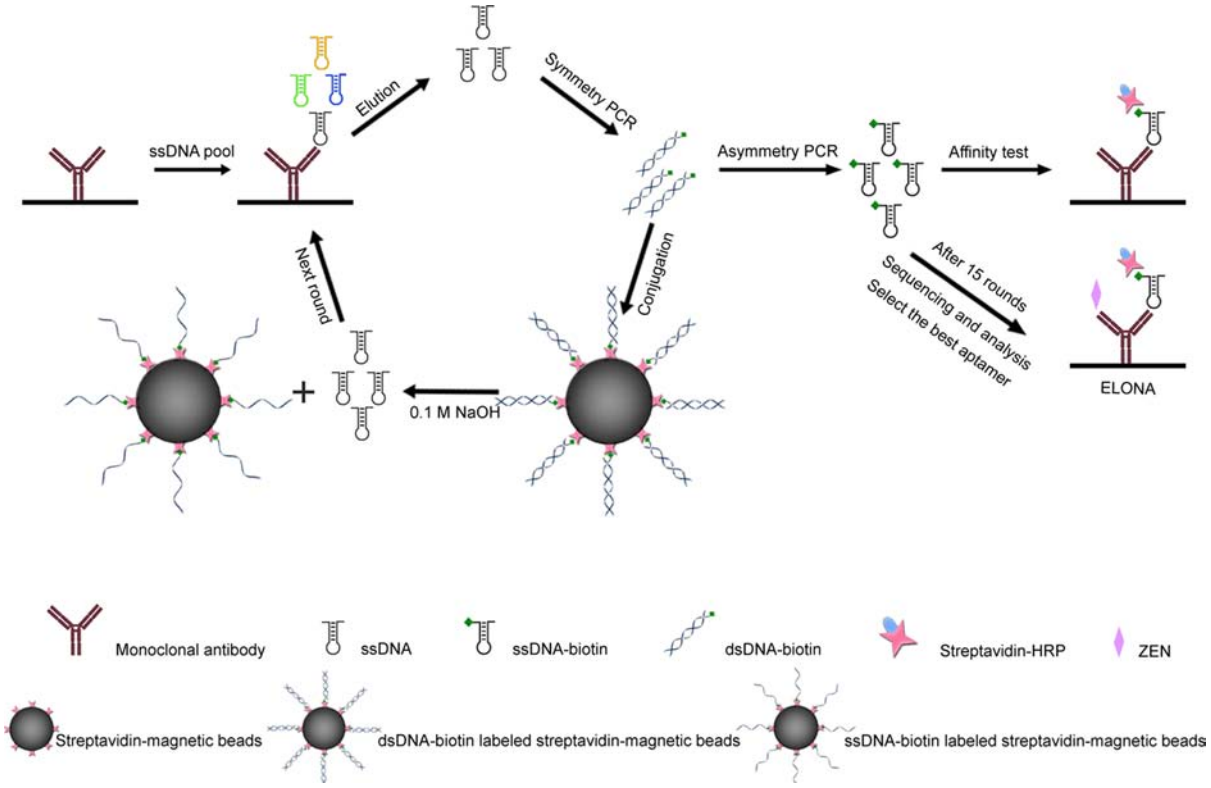

Figure 1. Schematic illustration of ssDNA screening and ELONA.

Preparation of a ssDNA Library Using Streptavidin-Coated Magnetic Beads. To yield a sufficient quantity of ssDNA for use as a seed pool in the next screening round, the selected ssDNA pool from each round of screening was used as a PCR template to generate dsDNA with primer pair biotin-P1 and P2 under the PCR reaction conditions as described above. Two strands of the PCR products were separated and the non-biotinlated ssDNA was recovered using streptavidin-coated magnetic beads. Briefly, the magnetic beads (100 μL containing about 6−7 × 10^7 Dynabeads) were separated from the storage buffer (PBS at pH 7.4 with 0.1% BSA and 0.02% sodium azide, v/v) in a magnetic field and washed 3 times with 2× binding and washing buffer (BW buffer, 10 mM Tris-HCl at pH 7.5 with 1 mM ethylenediaminetetraacetic acid and 2 M NaCl). A total of 200 μL of dsDNA was mixed with the magnetic beads and shaked gently for 20 min at room temperature. Then, the tube containing the mixture was placed under a magnetic field; the supernatant was removed; and the beads were washed 3 times in BW buffer. A total of 50 μL of 0.1 M NaOH was added to the tube containing beads and incubated at 37 °C for 30 min to uncoil the dsDNA. After the tube was placed in a magnetic field, non-biotinylated ssDNA was separated, while biotinylated ssDNA remained bound to the streptavidin beads. The supernatant containing the non-biotinylated ssDNA was recovered.

Aptamer Sequence Analysis. After the final selection round, the eluted ssDNA aptamer was used as a template to generate dsDNA by PCR amplification. The purified dsDNA was cloned into the pMD-18T. A total of 96 clones was randomly selected and sequenced by Sangon Biotech (Shanghai, China). The sequences were analyzed for homology and secondary structures using DNAMAN software (Lynnon Corporation, Pointe-Claire, Quebec, Canada). The clones with the correct sequences were used to prepare biotinylated ssDNA via asymmetry PCR amplification. The affinity and specificity of the ssDNA were also detected as described above.

The binding of the selected ssDNA to mAB-ZEN was determined in a way similar to that used in the SELEX screening procedure. Briefly, the plate was coated with 100 μL per well of diluted mAb-ZEN and blocked with 3% BSA. Then, different concentrations of ssDNA aptamer (from 0 to 1000 nM) were added in the wells and incubated at 37 °C for 1 h. After washing with washing buffer 5 times, 100 μL of elution buffer was added to the wells and the plates were incubated at 80 °C for 10 min to dissociate the ssDNA from mAb-ZEN. The eluted ssDNA was quantified using a NanoDrop 1000 spectrophotometer. Each concentration of ssDNA was determined in triplicate. The data were analyzed by GraphPad Prism 5 to fit the nonlinear specific binding curve, and the equilibrium dissociation constant (K_d) was calculated.

ELONA Development To Determine the ZEN Content. The ELONA was developed on the basis of the selected ssDNA aptamer, which had a relatively higher specificity and affinity. The concentrations of coating antibody, aptamer, and HRP-conjugated streptavidin were optimized by chessboard titration. The optimal ELONA contitions were as follows: a 100 μL aliquot of mAb-ZEN diluted to 1 μg/mL was added to each well of a microtiter plate and incubated at 4 °C overnight. After washing, 3% BSA was added to each well and the plate was incubated at 37 °C for 2 h. ZEN standard solutions (50 μL; 50, 10, 1, 0.1, 0.01, 0.001, 0.0001, and 0 ng/mL) were mixed with an equal volume of biotinylated ssDNA aptamer (100 pM). Each concentration of the standard was added to the plate in triplicate, which was incubated at 37 °C for 1 h and then washed 3 times. Afterward, 100 μL of HRP-conjugated streptavidin (1 μg/mL) was added to each well, and the plate was incubated at 37 °C for 1 h. After washing, 100 μL of TMB buffer was added to each well and the plate was incubated at 37 °C for 10 min. To stop the reaction, 50 μL of 2 M H_2SO_4 was added. The OD of the wells at 450 nm was recorded in a microplate reader. The standard curves were prepared using Origin 8.0 software (Northampton, MA). The log-transformed ZEN concentration was used as the x axis of the standard curve, and the y axis (B/B_0) represents the OD value of the standard solutions divided by the OD value at 0 ng/mL.

A schematic of ssDNA screening and the principle of ELONA is shown in Figure 1.

Specificity Study of the ELONA. To evaluate the specificity of the ssDNA-based ELONA, cross-reactivity of other mycotoxins (AFB1, FB1, and deoxynivalenol) with the anti-ZEN mAb was

dx.doi.org/10.1021/jf503733g | J. Agric. Food Chem. 2015, 63, 136−141

determined using the following formula (IC_{50} indicates the 50% inhibiton):

$$\text{cross-reactivity (\%)} = \frac{IC_{50} \text{ for ZEN}}{IC_{50} \text{ for other mycotoxins}} \times 100\%$$

Recovery Study. The extracts of corn samples were prepared as described previously,[20−25] and ZEN concentrations in the spiked samples were determined using a mAb-2C9-based enzyme-linked immunosorbent assay (ELISA)[17] and ssDNA-based ELONA. ZEN-free corn samples were ground and dried in a 60 °C incubator overnight. Standard ZEN solution was added to 10 g corn samples (1, 10, and 50 μg/kg for the ELONA and 50, 100, and 150 μg/kg for the ELISA) and allowed to incubate at room temperature overnight. Then, 40 mL of methanol/water (70:30, v/v) was added to each sample and shaken vigorously for 30 min at room temperature on a horizontal shaker. After an additional 10 min incubation period, the supernatant was centrifuged at 4000*g* for 20 min. For the 2C9-based ELISA, the supernatant was diluted 5-fold with 10 mM PBS, and for the ELONA, the supernatant was diluted 5-fold with binding buffer before analysis. Then, the extracts of the spiked samples were analyzed by ELISA and ELONA to determine the ZEN recovery rates. All spiked samples were analyzed in triplicate.

RESULTS AND DISCUSSION

Optimization of PCR Reaction Conditions. For the symmetry PCR, after 5, 8, 12, 16, 20, and 25 cycles of amplification, the dsDNA was analyzed by 12% PAGE. The results showed that, after 20 cycles, the yield of dsDNA reached a maximum and, after 25 cycles, the amount of non-specific DNA was greatest. Thus, 20 cycles were chosen for subsequent amplifications. Meanwhile, the annealing temperature (50−60 °C) had no effect on PCR amplification.

For the asymmetry PCR, different ratios of forward and reverse primers (1:0, 10:1, 30:1, 50:1, 80:1, and 100:1) were evaluated to generate higher amounts of ssDNA. As shown in Supplementary Figure 1 of the Supporting Information, the optimal ratio of forward and reverse primers was 80:1, giving the highest yield of ssDNA. The cycles of the asymmetry PCR were also optimized, and 30−35 cycles were the optimal amplification cycles to produce the highest amount of specific ssDNA (see Supplementary Figure 2 of the Supporting Information).

Selection of the ssDNA Aptamer Recognizing the Monoclonal Antibody. The affinity of each round of ssDNA for the anti-ZEN mAb was evaluated using a biotin−streptavidin−HRP-based ELISA. The OD values from rounds 1−15 are shown in Figure 2. The results indicate that affinity increased more than 5-fold after 15 rounds of screening, with OD values reaching a maximum after round 12.

Aptamer Sequence Analysis, Affinity, and Specificity. After 15 rounds of selection, the enriched ssRNA pool was amplified by PCR and cloned into the pMD-18T vector. A total of 96 clones were selected for sequencing. Of these, 63 clones had a complete genome length of 71 nt covering a 35 nt random sequence flanked by two 18 nt constant sequences.

Biotin-conjugated ssDNA aptamers were generated by asymmetric PCR using the 63 clones as templates. The affinities and specificities of 63 ssDNA aptarmers for mAb-ZEN as well as mAb-AFB1, mAb-FB1, and mAb-deoxynivalenol were determined by ELONAs using $OD_{450\ nm}$ values as readouts. All 63 aptamers show no specific binding to mAb-AFB1, mAb-FB1, and mAb-deoxynivalenol (data not shown), and 10 ssDNA aptamers with higher affinity in ELONA are listed in Table 1. The free energy (ΔG), which indicates the stability of the ssDNA, was predicted using DNAMAN software, and the results are also shown in Table 1.

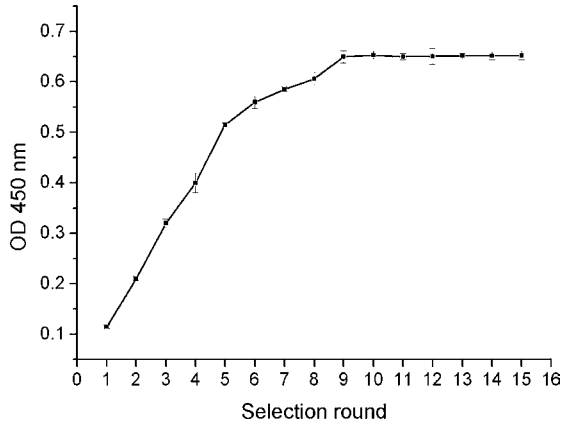

Figure 2. OD value of each round of ssDNA library screening using the biotin−streptavidin−HRP-based ELISA. The error bars indicate the interday standard deviation.

The putative secondary structures of these 10 aptamers were predicted using DNAMAN software and are shown in Supplementary Figure 3 of the Supporting Information. The main structure was a stem loop, which may bind antibody using this specific structure or through additional folding.

Development of an ELONA To Determine the ZEN Content Based on the Selected Aptamer. On the basis of sequence structure, affinity, and specificity analyses in ELONA, aptamers 46, 54, and 72 were used to develop the ELONAs to determine the ZEN concentration in samples. Aptamer 46, which shows better sensitivity and detection limit, was chosen for further studies and optimization of the ELONA. The K_d between aptamer number 46 and mAb-ZEN was 50.5 ± 5.4 nM. The binding saturation curve is shown in Supplementary Figure 4 of the Supporting Information. The optimal concentrations of coating antibody and HRP-conjugated streptavidin were 1 and 3 μg/mL, respectively, and the optimal dilution ratio of the aptamers was 1:10 (100 pM). The standard curve of this ELONA is shown in Figure 3. The regression equation for ZEN quantification was $y = -0.0778x + 0.713$ ($R^2 = 0.9981$). The detection limit and half maximal inhibitory concentration (IC_{50}) were 0.01 and 0.2 ng/mL, respectively, with a working range of 0.03−2.5 ng/mL. The intra- and interday standard deviations were 7.6 and 9.3% (data not shown), respectively, which indicates that this method had good reproducibility. Moreover, there were no competitive combining abilities of AFB1, FB1, and DON with the anti-ZEN mAb (cross-reactivity < 0.01%) in the ELONA using ssDNA aptamer number 46. These results indicate that this method has good specificity for ZEN. Thus, the best aptamer should be considered with the comprehensive factors, such as K_d values, OD values in ELONA, free energy, and detection sensitivity.

Recovery Rates of the ZEN Content in ELONA and ELISA. Previously, we showed that the limit of detection and IC_{50} are 0.051 and 1.9 ng/mL in ELISA, respectively.[17] Thus, the sensitivity of the ELONA (0.01 and 0.2 ng/mL for detection limit and IC_{50}, respectively) is greater than that of ELISA (Table 2). The 1, 10, and 50 μg/kg spiked corn samples were analyzed by ELONA, while 50, 100, and 150 μg/kg were determined by ELISA. As shown in Table 2, the recovery rates of the spiked samples in the ELONA ranged from 95 to 105%. Both the ELONA and ELISA could accurately detect ZEN

from the spiked samples and showed similar sensitivity in determining the ZEN content in the 50 μg/kg spiked sample.

As shown in Supplementary Table 2 of the Supporting Information, many highly sensitive analytical methods have been proposed to detect mycotoxins in agricultural products. Because the ELONA is an easy, rapid, and hypotoxic method, it is a significant improvement in detecting mycotoxins compared to other highly sensitive methods, including electrochemical sensor, immunoassay, and surface plasmon resonance. In addition, the ssDNA aptamer method has several advantages over the phage-displayed peptide technology, which can also mimic an antigenic epitope in a hypotoxic method,[8] including no requirement for bacterial transformation and protein expression.[12,13] Preparation of ssDNA aptamers is relatively easier, less expensive, and less time-consuming than phage-displayed peptides, and aptamers usually have greater specificity and affinity for their targets.

In conclusion, in this study, ssDNA aptamers against ZEN mAb were selected and identified. Aptamer number 46, which had a lower ΔG and higher affinity, specificity, and sensitivity than other aptamers, was chosen as a ZEN substitute to develop an ELONA for determination of the ZEN content in corn. This ELONA is less expensive and has greater sensitivity than previous hypotoxic screening technologies. The sensitivity and stability may be improved further by new detection platforms and optimization. Other aptamer-based hypotoxic analytical methods, such as fluorescent strip sensors,[14] electrochemical immunoassays, and chemiluminescence immunoassays could be developed in the future.

ABSTRACT: A novel, robust and fast ultrahigh performance liquid chromatography−multiple reaction monitoring mass spectrometry method has been developed for the simultaneous quantification of reduced glutathione (GSH), oxidized glutathione (GSSG), grape reaction product (GRP) and hydroxycinnamic acids in wine. The method was evaluated in terms of linearity, precision, accuracy, limits of detection and quantification, stability and matrix effects. Quantitative recovery (74−110%) and satisfactory interday precision (RSD <14%) were achieved for all target compounds. No significant matrix-dependent suppression/enhancement effects were observed. To demonstrate the method applicability, white, rosé and red wine samples with different levels of oxidation were analyzed. Levels of GSH and GSSG varied from 1.63 to 9.91 mg/L and from 0.32 to 3.33 mg/L, respectively. Levels of caftaric acid ranged from 2.57 to 293.07 mg/L. Levels of GRP were between 28.35 and 114.20 mg/L.

KEYWORDS: *glutathione, hydroxycinnamic acids, UPLC-MRM-MS, method validation*

INTRODUCTION

Wine phenolics have been recently gaining interest because of their biological effects, including free-radical scavenging, metal chelation, inhibition of cellular proliferation, and modulation of enzymatic activity and signal transduction pathways.[1] Hydroxycinnamic acids, and especially the tartaric esters of caffeic acid (caftaric acid) and of *p*-coumaric acid (coutaric acid), are the major phenolic compounds in grape flesh and consequently in juices and wines made with minimal skin contact.[2] During crushing and pressing, both of these molecules are oxidized to caftaric acid *O*-quinone under the action of grape polyphenoloxidase unless care is taken to avoid oxidation. The discovery of Grape Reaction Product (GRP),[3] identified as 2-S glutathionyl caftaric acid,[4] has provided evidence that grape also contains large amounts of glutathione (L-γ-glutamyl-L-cysteinyl-glycine, GSH), as GRP results from nucleophilic addition of glutathione onto caftaric acid quinone. Glutathione in plants is maintained in the reduced form by the ascorbate−glutathione cycle, and it is involved in the cell redox balance.[5−7] The ratio of caftaric and coutaric acids relative to GSH is a varietal characteristic and determines must susceptibility to oxidative browning. Glutathione, originating from the grape berry or from yeast metabolism, is also found in wines, where it occurs in both the reduced (GSH) and oxidized (GSSG) forms. Glutathione is attracting increasing interest because of its role as antioxidant in wine, limiting browning and protecting aroma compounds, as recently reviewed.[8] This role can be exerted through reduction of quinones and formation of GSSG, or via nucleophilic addition of glutathione on quinones, on aldehydes and/or on aldehyde condensation products with flavan-3-ols.[9]

Despite substantial interest in GSH and GSSG determination, the best protocol for sample preparation and analysis and quantification of these molecules is still investigated. Previously reported methods for the analyses of GSH and GSSG in wine musts include enzymatic assay,[10,11] high performance liquid chromatography (HPLC) with electrochemical detection,[12] without sample derivatization, and thiol derivatization followed by HPLC with UV detection[13−15] or fluorimetric detection.[16,17] Fluorimetric detection has been proved to be a fast and accurate method[18] but gives access only to GSH (or total glutathione after reduction of GSSG). Simultaneous detection of GSH and GSSG can be achieved by HPLC after derivatization of free amino groups.[19] In general, these methods are relatively complex and time-consuming and provide additional sources of variability and bias.[20] More recent methods involving mass spectrometry (MS) detection after HPLC separation of GSSG and GSH have been developed and applied to analyze both forms of glutathione in wine.[20,21] However, to the best of our knowledge, no method is available to analyze GSH, GSSG and hydroxycinnamic acids simultaneously. Therefore, the aim of this study is to provide a single, sensitive and rapid ultrahigh performance liquid chromatography-multiple reaction monitoring mass spectrometry (UPLC-MRM-MS) method without glutathione derivatization for the analysis of GSH, GSSG, GRP and hydroxycinnamic acids (ferulic, *p*-coumaric, caffeic, coutaric, fertaric and caftaric acids)

in white, rosé and red wines. The UPLC-MRM-MS method offers improved sensitivity, speed and resolution for analytical determinations, and it combines the advantage of high resolution chromatography and specific detection.

MATERIALS AND METHODS

Standards and Reagents. Methanol and formic acids were purchased from VWR Prolabo (Fontenay sous Bois. France). Caffeic, caftaric, ferulic and *p*-coumaric acids, GSH and GSSG were purchased from Sigma (Saint-Louis, MO, USA). Purified p-deionized water was used (Milli-Q purification system, Millipore, France) for the preparation of all solutions. All the standards were prepared with 1% formic acid in water.

Samples. The wines were provided by the INRA experimental winery at Pech Rouge (Gruissan, France). All selected wines were made from grapes harvested at commercial maturity, in September 2013, from the INRA Pech Rouge vineyard. The white and rosé wines were made from Viognier and Syrah varieties, respectively, using three processes differing in the extent of must oxidation. For each variety, the grapes were machine-harvested in two lots (1000 kg), either protected from oxidation (i.e., maintained under dry ice pellets from harvest through all the must processing stages) or nonprotected. After crushing and destemming, each grape lot was pressed by a 10 hL pneumatic press (Bucher Vaslin SA, Chalonnes sur Loire, France), to yield 60−65% must. The musts obtained by pressing each grape lot were supplemented with pectolytic enzymes (Rapidase clear, La Littorale, Montpellier, France) (2g h/L) and allowed to decant overnight at 10 °C in stainless steel tanks. A subsample (100 L) of the musts protected from oxidation was submitted to flash pasteurization (20 s, at 84 °C) to inhibit grape polyphenoloxidase (PPO). The six must samples (3 whites/3 rosés, without oxygen protection/with oxygen protection/with oxygen protection and flash pasteurized) were then inoculated with Fermicru rosé and Fermicru LVCB yeasts (Oenobrands SAS, Montpellier, France) (20g h/L) for rosé and white musts, respectively, and fermented to dryness.

The red wines were obtained from the same mechanically harvested Grenache noir grapes by traditional soaking (control) or flash détente, as described earlier.[22]

Characterization and Quantification of GSH, GSSG, GRP and Hydroxycinnamic Compounds. UPLC-MRM-MS analyses were carried out using an Acquity UPLC system (Waters, Saint-Quentin-en-Yvelines, France) hyphenated to a triple quadrupole (QqQ) TQD mass spectrometer (Waters, Saint-Quentin-en-Yvelines, France) operating in MRM mode with electrospray ionization (ESI) either in positive or negative ionization modes. The spectrometer was operated in the negative ion mode for the hydroxycinnamic acids and GRP and in the positive ion mode for the GSH and GSSG. The diode array detection (DAD) spectra were recorded in the range of 210−600 nm (resolution 1.2 nm).

The UPLC system included a binary pump, a cooled autosampler maintained at 7 °C and equipped with a 5-μL sample loop, a 100-μL syringe and a 30-μL needle, and a DAD. MassLynx software was used to control the instruments and to acquire the data and TargetLynx software was used to process the data. The column used for chromatographic separation was a reversed-phase Acquity HSS T3 1.8 μm 1.0 × 100 mm (Waters, Saint-Quentin-en-Yvelines, France) protected by a 0.2 μm in-line filter and maintained at 40 °C. The mobile phase consisted of 1% (v/v) formic acid in Milli-Q water (solvent A) and 1% (v/v) formic acid in methanol (solvent B). The elution program was as follows: isocratic for 8 min with 0% B, 0−35% B (2 min), 35−99% B (4 min) followed by washing and reconditioning of the column. The source and desolvation temperatures were respectively set at 120 and 450 °C. Nitrogen was used as desolvation (500 L/h) and cone (50 L/h) gas. Argon was used as collision gas at a flow rate of 0.16 mL/min. Capillary voltage was set at 3.5 kV in positive mode and 2.8 kV in negative mode.

Samples were diluted 2:3 (v/v) with 1% formic acid in water, filtered through a 0.22 μm PTFE filter (Waters) and injected into the column by using the Partial Loop with Needle Overfill injection mode with an injection volume of 1 μL. The flow rate was 0.170 mL/min and the oven temperature maintained at 40 °C. Two detectors were used: DAD and the QqQ detector. Validation of the method was carried out through standard addition method. GRP, coutaric and fertaric acids were quantified as mg equivalent caftaric acid.

Analytical Method Performances. The method was validated following the "Bioanalytical Method Validation" of the U.S. Department of Health and Human Services (Food and Drug Administration).[23] Validation assays were performed by means of standard-addition method in one red wine, one rosé wine and one white wine. The analytical method was checked for linearity, limit of detection (LOD), limit of quantification (LOQ), recovery, precision, stability and matrix effects.

Statistical Analysis. Statistical calculations were made using the GraphPad Prism version 5.0 package (GraphPad Software, San Diego, CA). Wine samples were analyzed in triplicate. Unless otherwise specified, data are presented as the mean ± SD. Statistical comparisons were performed using paired two-tailed Student's *t* test with the level of significance set at $p < 0.05$.

RESULTS AND DISCUSSION

Optimization and Validation of an UPLC-MRM-MS Method for the Analysis of GSH, GSSG, GRP and Hydroxycinnamic Acids. The main objective of the present work was to develop a rapid and simple method based on UPLC-MRM-MS for simultaneous determination of GSH, GSSG, GRP, and hydroxycinnamic acids in wine. Therefore, experiments were carried out in order to optimize their chromatographic separation and also their MRM detection. MRM is the method of choice for quantification in MS; it is both very sensitive and highly specific because it is based on the analysis of parent and fragment ions that are characteristic of each target molecule.[24]

The polar nature of GSH and GSSG requires the use of highly aqueous mobile phases to obtain a suitable retention under reversed-phase conditions. However, the loss in retention time may occur over time as a consequence of pore dewetting when using the conventional reversed-phase columns at 100% aqueous conditions. The selected column HSS T3 uses a trifunctional C_{18} phase bound at an intermediate ligand density, specially designed to be used with 100% aqueous mobile phases. Moreover, it was necessary to use an acidic mobile phase to improve the chromatographic behavior of the targeted compounds. Therefore, formic acid was selected because of its compatibility and volatility with ESI sources.[24] Two different proportions were tested (0.1% and 1%), and the best results were obtained using 1% formic acid in water. The optimized chromatographic conditions are detailed in the Materials and Methods.

For all target compounds, separation was achieved in less than 12 min. The UPLC-MRM-MS profiles obtained for all target compounds after injection of a white wine are presented in Figure 1 and Table 1. Direct infusion of standards in water 1% formic acid provided the fragmentation pattern and collision energy suitable for the sensitive detection of target analytes. For the compounds that are not available as standards, additional experiments have been performed by injecting the wines. ESI provided singly charged positive $[M + H]^+$ precursor ions for GSH and GSSG and singly charged negative $[M - H]^-$ ions for GRP and hydroxycinnamic acids. Two MRM ion transitions were selected for each compound (Table 1); the most intense transition was used for quantification, while the other one was employed for identification. For hydroxycinnamic acids, the main observed transition corresponded to a neutral loss of 44 u, i.e. CO_2, which is typical of compounds

having a carboxylic acid moiety. For hydroxycinnamic esters and for GRP, the main fragment ion corresponds to tartaric acid (m/z 149). Consequently, caftaric acid was used for calibration of coutaric acid, fertaric acid and GRP. For GSH and GSSG, the main transitions are neutral losses of 129 u, which is characteristic of glutathione (loss of glutamate).[25] Identifications were achieved by comparing the retention times and UV−visible and MS spectra with those of available standards

Method Validation. In order to assess the performance of the proposed method, the main analytical method performances were thoroughly evaluated (Table 2). The linearity of the method was tested using standard solutions at seven concentration levels from 0.5 to 100 mg/L for GSH, GSSG, caffeic, *p*-coumaric and ferulic acids. For caftaric acid, the linearity was checked from 0.5 to 500 mg/L. The method yielded linear responses up to 100 mg/L for GSH, GSSG, caffeic, *p*-coumaric and ferulic acids and up to 500 mg/L for caftaric acid. These are improved concentration ranges compared with those previously reported.[18,26,27] The weighted $(1/x)$ calibration curves $(y = ax + b)$ were found to be linear in the studied range with determination coefficients (R^2) ≥0.9889 and RSDs $(n = 3) \leq 5\%$.

Recovery and Precision. Recovery pertains to the efficiency of an analytical method within the limits of variability. Analyte recoveries were assessed by analyzing the percentage of recovery of each compound in wines. The samples were spiked at three concentration levels (2, 10, and 50 mg/L) of each compound before analysis. The spiked samples were prepared in triplicate and analyzed under the previously established optimal conditions. The percentage of recovery was calculated for each compound, while the corresponding relative standard deviation (R.S.D.) was representative for intraday precision. The interday precision (intermediate precision) was calculated from analyses performed in triplicate over three consecutive days, with five replicates per day. Each day, samples were prepared. The prepared concentration ranges were in accordance with the concentration ranges established in the linearity.

Quantitative recoveries at all three concentration levels tested in white, rosé and red wines ranged from 72% to 110% (Table 2). Both intra- and interday precision studies presented satisfactory results for all compounds in the three matrices tested, with RSDs below 7% and 13%, respectively, for white wine; below 12% and 14% for rosé wine, and below 9% and 14% for red wine (Table 2). For the values analyzed, recovery and precision were within the accepted values for the Bioanalytical Method Validation.[23]

Table 1. UPLC-DAD-MRM-MS Parameters for GSH, GSSG, GRP and Hydroxycinnamic Acids

Analytes	rt[a] (min)	ESI MODE	MRM transitions[b]	Collision energy (V)	Cone voltage (V)	UV−visible spectrum (max. wavelength)

Limits of Detection and Quantification. The sensitivity of the method was evaluated determining the LODs and LOQs. Regarding the two MRM transitions, the quantifier transition was used for quantitative purposes, while the confirmation transition was used for qualitative analysis and for the method limits. The LOD was calculated as the quantity of analyte able to produce a chromatographic peak three times higher than the noise of the baseline in a chromatogram (S/N = 3) of a sample. The LOQ was set at ten times higher than the noise of the baseline in a chromatogram (S/N = 10).[23] The LOD for GSH was 0.0014 and 0.0018 mg/L in white and rosé wines, respectively, whereas in red wines it was 0.0045 mg/L. For GSSG, the LOD ranged from 0.0038 to 0.0054 mg/L in white, rosé and red wines. The values of LOD and LOQ obtained in

DOI: 10.1021/jf504383g
J. Agric. Food Chem. 2015, 63, 142−149

our method are lower than those reported by other authors using MRM-MS. Du Toit et al.[21] reported a LOD of 0.2 mg/L in grape juice and wine for GSSG, while Mattivi et al.[20] reported LODs of 0.05 and 0.03 mg/L for GSH and GSSG, respectively. Our LODs and LOQs values are also lower than those reported using fluorescence detection after derivatization.[27,28] Marchand and de Revel[27] reported a LOD of 2.45 mg/L in white wine and 3.06 mg/L in red wine for GSSG. Janes et al.[28] reported a LOD and LOQ of 0.06 and 0.2 mg/L, respectively, in white grape juice and wine for GSH. However, Kritzinger et al.[29] reported similar LODs in white and red grape juice and wine to our method. For GSH, the LOD was 0.002 mg/L, and for GSSG, it was 0.001 mg/L.

The LODs for hydroxycinnamic acids in white wine ranged from 0.0014 mg/L for caffeic acid to 0.0037 mg/L for caftaric acid. In rosé and red wines, LODs were higher. The highest values were obtained for ferulic and caftaric acids. The LOD for ferulic acid was 0.0294 mg/L and 0.0203 mg/L in rosé and red wines, respectively. For caftaric acid, LODs were 0.0051 mg/L and 0.0246 mg/L in rosé and red wines, respectively, and similar to those reported by other authors.[30,31]

Stability. The chemical stability of an analyte under specific conditions for given time intervals can be assessed in several ways. Stability evaluations should cover the expected sample handling and storage conditions during the study. The stabilities studied were freeze and thaw stability and sample stability.

For the freeze/thaw stability, three freeze−thaw cycles were assessed in a mixture of the standards and on two wine samples (one rose and one white) used for the validation. No significant reduction of analyte concentrations in the standards or in wine samples was observed after the cycles.

The stability of the processed sample was studied from the moment the standards were prepared until the time the samples were analyzed in the autosampler, in this case about 24 h. There was a slight decrease in GSH (13%) and GSSG (7%) levels, while hydroxycinnamic acids remained stable over 24 h at 4 °C. Thus, it is recommended to prepare standards daily, at least for GSH and GSSG.

One area of concern in sample analysis is the introduction of relatively large amounts of salts or nonvolatile pollutants into the ion source, which may degrade the performance of the instrument. However, no deterioration in absolute sensitivity was observed over the course of each batch or between batches, and other assays run on the same instrument were unaffected after injection of wine samples. Moreover, no significant ($P > 0.05$) shift (±0.02 min) in retention times was observed over the course of the method development, validation, and subsequent application to real wine samples.

Matrix Effects. Finally, suppression/enhancement effects were also evaluated by calculating the ratio of the peak area of the analytes recorded for the sample spiked with the standards and the peak area of analytes recorded for the standard solution (expressed in percentage). Analyses were carried out in triplicate. In our study, no significant matrix-dependent suppression/enhancement effects were observed in the three matrices under the proposed UPLC-MRM-MS conditions (Table 2). In the evaluation of matrix effects, values lower than 100% indicate that matrix-dependent signal suppression occurs, while values higher than 100% indicate matrix-dependent signal enhancement. The eventual suppression and enhancement effects are generally matrix, analyte, method, and ion source dependent.[32]

Application to Wine Samples. The applicability of the proposed method was demonstrated by analyzing eight different wine samples: two red, three rosé and three whites wines. The three wines in the white and rosé series differed by the must preparation: nonprotected from oxygen exposure, protected from oxygen, protected from oxygen, and flash pasteurized to inhibit grape PPO. The two red wines were prepared from the same grapes by fermentation on pomace, respectively after destemming and crushing (control) or after flash détente. The latter process, which consists of rapidly heating the grapes in a closed tank and suddenly applying strong vacuum to induce fragilization of the grape cell walls and instant cooling of the grapes, enhances phenolic extraction. Two to 14-fold increases in hydroxycinnamic acid contents have been reported in wines obtained using this technique compared to the corresponding control wines.[22]

Results are reported in Table 3. GSH ranged from 1.63 mg/L in the control red wine to 9.91 mg/L in rosé wine made from must protected from oxidation and treated with flash pasteurization. Significant differences ($p < 0.05$) in GSH levels were found among the three types of wine and the different treatments. Marchand and de Revel[27] reported levels of GSH between 1.1 and 7.1 mg/L in white wines and between 0.3 and 0.7 mg/L in red wines whereas Fracasseti et al.[26] described that the content of GSH in wines varied from not detected to 27.4 mg/L. GSH levels strongly depend on the variety,[15] type of wine, exposure to oxygen, tyrosinase activity, grape skin maceration, yeast strain and fermentation conditions.[21,33,34] In the case of GSSG, significant differences between the three types of wine were also found. The highest content, 3.33 mg/L, was found in white wine made without protection from oxidation and the lowest, 0.32 mg/L, in rosé wine made from musts treated with flash pasteurization. Mattivi et al.[20] reported GSSG levels in wines to range from not detected to 16.2 mg/L.

Differences in GSH and GSSG contents within the rosé wine series can be attributed to different levels of must oxidation. Indeed, must protection against oxidation resulted in higher concentration of GSH and lower concentration of GSSG, as described earlier.[21] However, in our study, the concentrations of GSSG, ranging from 0.32 to 1.77 mg/L, represented only a few percent of the loss of GSH. This suggests that, during must oxidation, GSH was predominantly converted to nucleophilic addition products, including GRP, rather than oxidized to GSSG, as shown earlier.[3] In contrast, in the white wines series, the GSH level was not correlated with that of oxygen protection and no significant difference ($p > 0.05$) was found for GSSG levels. This is likely due to the different grape variety, yeast strains, and wine-making conditions used for the white and rosé wines.[21,33,34] Moreover, GSH has been shown to react with other compounds, such as aldehydes and their condensation products with catechin in wine.[35] The flash détente red wine contained significantly higher ($p < 0.05$) levels of both GSH and GSSG than the control, suggesting increased extraction of glutathione in the flash detente process.

Large variations were also observed in the wine phenolic composition. Wines prepared from musts that were not protected from oxidation presented higher GRP values and lower caftaric and coutaric acid levels in both the rosé and white wine series. The ratio of caftaric acid to GRP was much higher in the white wines, probably reflecting a much higher ratio of caftaric acid to glutathione in Viognier than in Syrah. Red wines contained higher levels of hydroxycinnamic esters than the white and rosé wines, owing to both the particularly high

[a]Superscript letters in the columns represent significant statistical differences ($P < 0.05$).

content of the Grenache grape variety and extraction from skins in the red wine-making process. They also showed lower amounts of GRP, which is in agreement with the low ratio of GSH to hydroxycinnamic (i.e., caftaric and coutaric) acids in the Grenache grapes and limited extent of oxidation in the red wine-making process.[36] Flash détente also resulted in higher levels of caftaric acid, coutaric acid and GRP, indicating that this process increases the extraction rate of both hydroxycinnamic esters and glutathione. Martinez-Pinilla et al.[37] reported levels of caftaric acid between 33.93 and 42.96 mg/L whereas Mattivi et al.[20] reported values in the range 42.5−316.8 mg/L. The fertaric acid levels were significantly higher ($p < 0.05$) in the red wines than in the whites and lower in the rosé wines and showed no difference ($p < 0.05$) within each series, meaning that they depended on the variety and increased with maceration but were unaffected by oxidation.

Free hydroxycinnamic acids were present in low amounts. The highest values for ferulic were found in red wines (0.90−0.92 mg/L) due to the increase of extraction. Levels in white and rosé wines were not significantly different ($p > 0.05$) between wines without oxygen protection, wines protected from oxidation, and wines with oxygen protection and flash pasteurization. The concentrations of *p*-coumaric and caffeic acid were higher in the wines protected from oxidation but lower after flash pasteurization. They were also significantly lower ($p < 0.05$) in the red wine obtained by flash détente than in the control. The values are within the range reported for white wines by other researchers.[37−40]

In this work, a simple and single run UPLC-MRM-MS approach was developed for the analysis of GSH, GSSG, GRP and hydroxycinnamic acids in wines. The method was completely validated providing a sensitive analysis for compound detection and showing satisfactory data for all parameters tested. Good results were obtained with respect to linearity and recovery as well as an excellent level of precision. The proposed method minimized sample preparation and solvent consumption and increased sample throughput. The applicability of the proposed method was assessed through the analysis of real wines.

Supporting Information

ABSTRACT: *Nostoc commune* has been traditionally used in China as a health food and medicine. The water stress proteins (WSP) of *Nostoc commune* are the major component of the extracellular matrix. This study purified and identified the water stress proteins (WSP1) from *Nostoc commune* Vauch., which could inhibit the proliferation of human colon cancer cell lines. The IC_{50} values of WSP1 against DLD1, HCT116, HT29, and SW480 cells were 0.19 ± 0.02, 0.21 ± 0.03, 0.39 ± 0.05, and 0.41 ± 0.01 μg/μL, respectively. Notably, it displayed very little effect on the normal human intestinal epithelial FHC cell line. The IC_{50} value of WSP1 against FHC cells was 0.67 ± 0.05 μg/μL. Moreover, the growth of DLD1 xenografted tumors in nude mice were significantly suppressed in the WSP1 treated group. Mechanistically, the cell-cycle analysis revealed that WSP1 induced growth inhibition by G1/S arrest. Meanwhile, Western blotting and immunohistochemistry assays showed WSP1 could activate caspase-8, -9, and -3, along with subsequent PARP cleavage. Furthermore, the pan-caspase inhibitor, z-VAD-FMK, partly reversed the effect caused by WSP1, confirming that WSP1 induced cell apoptosis through caspase-dependent pathway. Collectively, WSP1 has targeted inhibition for colon cancer proliferation both in vitro and in vivo and it is valuable for future exploitation and utilization as an antitumor agent.

KEYWORDS: *Nostoc commune Vauch, water stress protein 1 (WSP1), colorectal cancer (CRC), apoptosis, nude mice*

INTRODUCTION

Colorectal cancer (CRC) is a worldwide disease with an annual incidence of 1 million cases. It is the second most common cause of cancer mortality and comprises 9% of the cancer burden globally.[1] In China, CRC ranks fourth among the most common cancers and the mortality rate is 57.5%.[2] Chemotherapy is used in the treatment of cancer with one or more antineoplastic drugs. Patients often receive the combination of chemotherapy with various chemical agents.[3] However, the toxicity and side effects greatly restrict the application of chemotherapeutic agents.[4] Efforts have focused on developing effective therapeutic regimens to combat colon cancer with low toxicity and side effects.

A large number of previous studies have shown that many extracts from plants or microorganisms have exhibited strong inhibitory properties on several types of cancers, especially on colon epithelial tumors.[5] For example, compounds from color-fleshed potatoes have shown pro-apoptotic properties in human colon cancer cells,[6] major metabolites of 6-gingerol had cytotoxic effects on human cancer cells,[7] and dietary black and brown rice bran displayed antitumor effects in tumor-bearing mice.[8] *Nostoc commune* Vauch. (NCV) is an edible terrestrial cyanobacterium and is a photosynthetic prokaryote. In China, NCV is a popular food and is rich in protein, calcium, iron, vitamin C, and other nutrients.[9,10] Accumulated evidence indicates that substances from NCV could prevent fatty liver, kidney stones, and heart diseases.[11,12] The bioactive fractions from NCV showed multiantioxidant and antitumor activities;[13,14] however, the molecular mechanisms remain poorly understood.

In the present study, we purified active proteins from NCV, which had remarkable inhibitory effects on cell proliferation of colon cancer. Mass spectrometry analysis indicated that the protein belonged to the water stress proteins (WSP). *Nostoc commune* typically synthesizes water stress proteins when they are subjected to acute water stress in nature. WSP is a group of acidic polypeptides with cryptic functions and PI values between 4.3 and 4.8. WSP is a major extracellular matrix protein, which maintains the structure and function of the extracellular matrix.[15] The WspA from *Nostoc commune* possesses β-D-galactosidase activity[16] and is associated with 1,4-β-D-xylanxylanohydrolase activity.[17] Previous reports have shown that *wspA* is a single copy gene,[18] while WspA has microheterogeneity characterized by two or more proteins of 30−40 kDa but with identical N-terminal sequence.[19] These

isoforms may arise from deamidation, covalent modification, protease degradation, etc. In this study, we purified three predominate proteins (39, 37, and 35 kDa). They were all identified as WSP by MALDI-TOF analysis and were named WSP1. On the basis of the above data, the single copy gene (accession KF003026) that encoded the water stress protein (WSP1) was cloned into pET28a, and the recombinant protein of WSP1 (GI: 530891432) was obtained by genetic engineering technology.[20] The molecular weight of the recombinant WSP1 was found to be 39 kDa and could significantly inhibit the proliferation of human colon cancer cells.[20]

We report that WSP1 possessed potent antitumor effects on human colon cancer cell lines (DLD1, HCT-116, HT-29, and SW480). More importantly, WSP1 could suppress DLD1 xenografted tumors in nude mice. The results further indicated that the WSP1 treatment induced colon cancer cell apoptosis by triggering the caspase-dependent pathway and suppressed cell growth by G1/S arrest. Interestingly, WSP1 specifically suppressed proliferation and induced apoptosis in colon cancer cells in vitro and in vivo but not in normal human colon epithelial cells. The data presented in this study provides evidence for the potential of WSP1 as an antitumor agent against colon cancer.

MATERIALS AND METHODS

Chemicals. RPMI-1640 medium and fetal bovine serum (FBS) were obtained from GIBCO (Grand Island, NY). 3-4,5-Dimethylthiazol-2-yl-2,5-diphenyltetrazolium bromide (MTT) and DAPI (4′,6′-diamidino-2-phenylindole) were obtained from Sigma (St. Louis, MO). 5,5′,6,6′-Tetrachloro-1,1′,3,3′-tetraethyl-imidacarbocyanine iodide (JC-1) and the pan-caspase inhibitor (z-VAD-FMK) were provided by Beyotime Institute of Biotechnology (Haimen, China). The annexin V-FITC apoptosis detection kit was purchased from Oncogene (San Diego, CA). The antibodies used in this study were as follows: GAPDH and β-actin antibodies were purchased from Abmart (Arlington, MA); pRb was obtained from Cell Signaling Technology (Danvers, MA); c-Myc, cyclineD1, and cyclineE1 antibodies were obtained from Bioworld Technology (Minneapolis, MN); AIF, Bax, Bcl-2, caspase-3, -8, and -9, and polymerase (PARP) antibodies were obtained from the Beyotime Institute of Biotechnology (Haimen, China).

Isolation and Purification of WSP1 Polypeptides from *Nostoc commune* Vauch. Desiccated colonies of NCV were collected from Shanxi, China, in 2012. Then 20 g of desiccated colonies (unground) were cleaned with double distilled water, then suspended in 1000 mL of PBS (phosphate-buffered saline, pH 7.4, containing 1 mM PMSF) for 48 h, followed by centrifugation at 12000 rpm for 25 min at 4 °C. Then, the supernatant was precipitated with acetone (V/V = 1:2) at −20 °C for 2 h. The obtained precipitation was dissolved with appropriate volumes of PBS and subjected to ammonium sulfate fractionation. The precipitation from 30−60% ammonium sulfate was resuspended in PBS, dialyzed, and concentrated by ultrafiltration through a 10 kDa MWCO hollow fiber membrane (Millipore, USA). Proteins were analyzed with a 10% SDS-PAGE and a 10% nondenature PAGE. The collected active fractions showed three bands on both the SDS-PAGE and nondenature PAGE gels. Gels were stained using CBB R-250. The relative gray value of WSP1 was calculated using Image-J software.

Mass Spectrometry Analysis and Protein Identification. The purified target proteins were resolved using a 10% SDS-polyacrylamide gel. The SDS-PAGE was performed using standard methods on a Mini-Protean II system 3 (Bio-Rad, USA). The target protein band was cut from the SDS-PAGE gel and sent to Shanghai Applied Protein Technology Co. Ltd., China, for protein identification. Protein identification was performed using a matrix-assisted laser desorption/ionization-time-of-flight method (MALDI-TOF, Applied Biosystems USA), a peptide mass fingerprint (PMF), and the NCBI database.

Cloning of the WSP1 Gene. Specific primers for PCR amplification of the full-length *WSP1* gene in NCV were designed according to the *wspA* gene sequence of *Nostoc commune* (accession no. AB518000). The primer sequences were as follows:

Forward: 5′-CGCGGATCCATGGCTCTTTACGGCT-3′.

Reverse: 5′-CCGCTCGAG TTATTCATTAACAATCGT-3′.

PCR was performed under the following conditions: initial denaturation at 95 °C for 3 min, followed by 30 cycles of 95 °C for 1 min, 60 °C for 1 min, 72 °C for 1 min, and a final extension step at 72 °C for 10 min.

Cell Culture. Human colon cancer cell lines (DLD1, SW480, HT-29, and HCT116) and a normal colonic epithelial cell line (FHC) were obtained from the Chinese Type Culture Collection. Human colon cancer cell lines were cultured in RPMI 1640 medium supplemented with 10% (v/v) heat-inactivated FBS. The FHC was cultured in F12 medium with 10% FBS. All media were supplemented with 100 U/mL penicillin (Sigma, Germany) and 100 mg/mL streptomycin (Sigma, Germany). All cultures were incubated at 37 °C with 5% fully humidified CO_2.

MTT Assay. Growth inhibitory effects of WSP1 on DLD1, HCT116, SW480, HT-29, and FHC were determined using a MTT assay. Cells (1×10^4) were seeded into 96-well plates and allowed to grow for 24 h for acclimatization. The cells were then incubated with treatments of 0, 0.05, 0.15, and 0.25 μg/μL WSP1 for 48 h. Then 20 μL of MTT (5 mg/mL) was added to each well and further incubated for 4 h. The blue formazan produced was dissolved by DMSO, and the absorbance was measured at 570 nm with an ELISA plate reader. The percentage of cell growth inhibition was calculated with the formula: (A570 Control − A570 Experiment/A570 Control) × 100%. After the preliminary screening, in order to determine the time-dependent manner of WSP1 induced cell growth inhibition, DLD1 was treated with 0.05, 0.15, and 0.25 μg/μL WSP1 for 24 and 48 h. Assays were performed in triplicate independent experiments. The 50% inhibitory concentration (IC_{50}) of 48 h was determined as the anticancer drug concentration, causing a 50% reduction in cell viability and calculated by regression analysis.

Clonogenic Survival Assay. DLD1 cells were counted and plated onto 6-well tissue culture plates (1000 cells/well) in 1640 medium supplemented with 10% FBS. After attachment, the cells were treated with 0.15 μg/μL WSP1 for 10 days. The cells were then fixed with immune dye fixative and stained with 0.1% crystal violet. The results were observed under a stereomicroscope (OLYMPUS SZX16, Japan). The number of clones (more than 50 cells each) counted in 10 different microscopic fields were used to calculate the colon formation rate: Colon Formation Rate = (Clones/Seeded Cells) × 100%.

DAPI Staining and Quantification of Apoptotic Cells. To examine the effects of WPS1 on cancer cell apoptosis, a DAPI nuclear staining assay was performed. DLD1, HCT116, and FHC cells were plated in 6-well plates with glass slides (1×10^6 cells/well). After treatment with 0.15 μg/μL WSP1 for 48 h, the cells were fixed with immunostaining fixative for 60 min at 4 °C. Fixed cells were washed twice with PBS and incubated with DAPI for 1 h at 4 °C in the dark. Then the slides were washed with PBS to remove the excess DAPI and the cell nuclei were observed under a laser confocal scanning microscope (LCSM; OLYMPUS FV1000, Japan). The apoptosis rate of colon cancer cells treated with WSP1 was determined by scoring the number of cells with nucleus phenotypic changes in 20 different microscopic fields under LCSM.

Analysis of Cell Apoptosis and Cell Cycle by Flow Cytometry. WSP1 induced apoptosis in DLD1 was analyzed by flow cytometry using the Annexin V-FITC and propidium iodide (PI) double staining method. Briefly, after incubation with 0.15 μg/μL WSP1 for 48 h, cells were trypsinized and washed with PBS. Cells were then stained with 200 μL of Annexin V solution (10 μL of Annexin V + 200 μL of binding buffer) and 300 μL of PI (5 μL PI + 300 μL binding buffer) in the dark (RT) for 30 min. The population of Annexin V positive cells was examined using a FACSort flow cytometer. The cell cycle of DLD1 cells was assessed with a cell

cycle detection kit by FACScan. DLD1 cells were plated into 60 mm dishes (1×10^6 cells/dish) and incubated overnight. Cells were treated with 0.15 μg/μL WSP1 for 48 h and then trypsinized. These cells were washed with PBS and fixed in 70% ethanol at −20 °C for 12 h. The ethanol was removed after centrifugation, and the cells were resuspended in 1 mL of PBS, 100 μL of ribonuclease A (100 μg/mL PBS), and 400 μL of propidium iodide (400 μg/mL PBS) in the dark (RT) for 30 min. The percentages of cells in different cell cycle phases were analyzed using FACScan, and experiments were performed in triplicate.

Measurement of Changes of Mitochondrial ($\Delta\psi m$). Measurement of mitochondrial transmembrane potential was performed with DLD1 cells. First, 5×10^5 cells/well were seeded into 6-well plates. After treatment with WSP1 (0.15 μg/μL) for 48 h, the cells were then harvested and stained with 10 mg/mL JC-1 at 37 °C for 10 min. Then, the stained cells were washed, resuspended with PBS, and analyzed for their red and green fluorescence from JC-1 using a flow cytometer. Data are reported as the percentage of cells with depolarized mitochondrial membranes, and experiments were performed in triplicate.

Western Blotting Analysis. The human colon cancer cell line DLD1 (1×10^6) was treated with 0.15 μg/μL WSP1 for 24 and 48 h. After the treatment, cells were incubated with lysis buffer for 30 min on ice and then centrifuged for 10 min at 13000 rpm. Protein concentrations were measured with Bradford reagent (Bio-Rad, USA), and an equal amount of protein (60 μg) from each sample was separated by 10% SDS-PAGE and then transferred to PVDF membranes. The membranes were blocked using Tris-buffered saline with 0.1% Tween-20 and 5% skimmed milk for 1.5 h at room temperature. The membranes were probed with primary antibodies at 4 °C overnight. The membranes were then washed three times with Tris-buffered saline containing 0.1% Tween-20 and probed for 2 h at room temperature with HRP conjugated secondary antibodies. Protein bands were visualized using enhanced chemiluminescence, and experiments were performed in triplicate.

In Vivo Studies in Nude Mice. All animal experiments were carried out following procedures approved by the Institutional Animal Care and Use Committee of China Institute for Radiation Protection. The review board and ethics committee of the institution specifically approved this study.

Sixteen BALB/c nude mice (five-week old, female, weighing between 18 and 21 g) were purchased from the Institute of Zoology, Chinese Academy of Sciences. The nude mice were maintained under specified-pathogen free (SPF) conditions in the laboratory animal service center of the China Institute for Radiation Protection. DLD1 cells in 0.2 mL of PBS (5×10^6) were injected subcutaneously into the right oxter of each nude mouse. Fourteen days later, solid tumors were apparent in all injected nude mice and the 16 nude mice were randomly divided into two groups (each group with 8 nude mice) with no significant difference of tumor volumes between the groups. Mice in the WSP1 group received an intraperitoneal injection of 60 μg WSP1/g body weight every 3 days (total six injections), and the control mice were treated with PBS. The body weight and tumor diameters of nude mice were measured twice a week. Tumor volumes were calculated using the formula: tumor volume (cm^3) = 0.5 tumor length (cm) × tumor width^2 (cm^2). Then 21 days later, all mice were sacrificed according to ethical demands and tumors were excised, weighed, and frozen at −80 °C for further Western blotting and immunohistochemical analysis.

Immunohistochemical Analysis. Tumors were fixed in 10% formalin, embedded in paraffin wax, and used for immunohistochemical analysis. The paraffin sections were dewaxed in xylene and dehydrated in serially diluted ethanol. Antigen retrieval was carried out using citrate buffer (pH 6.0). All sections were stained with antihuman K_i-67, activated-caspase-8, activated-caspase-9, and PARP. Staining was performed using a universally labeled streptavidin−biotin kit according to the standard protocol. The percentage of cells was calculated by Imagepro-Plus 6.0 software.

Statistical Analysis. Data analysis was carried out using SPSS 17.0 software. Results were expressed as mean ± SD. IC_{50} values were calculated by regression analysis. Differences in means between the control and treatment groups were determined using a two-tailed unpaired Student's t test or a One-Way ANOVA followed by Tukey's multiple comparison tests. Values of less than 0.05 ($p < 0.05$) and 0.01 ($p < 0.01$) were considered statistically significant and highly significant, respectively.

RESULTS

Purification and Identification of WSP1. Total extracellular matrix proteins of NCV were prepared by 100% (m/v) ammonium sulfate precipitation (Figure 1A). After ammonium sulfate grading precipitation, three proteins (39, 37, and 35 kDa) dominated in both the SDS-PAGE (Figure 1B) and the nondenaturing PAGE gels (Figure 1C). The three proteins were all identified as WSP1 by MALDI-TOF analysis

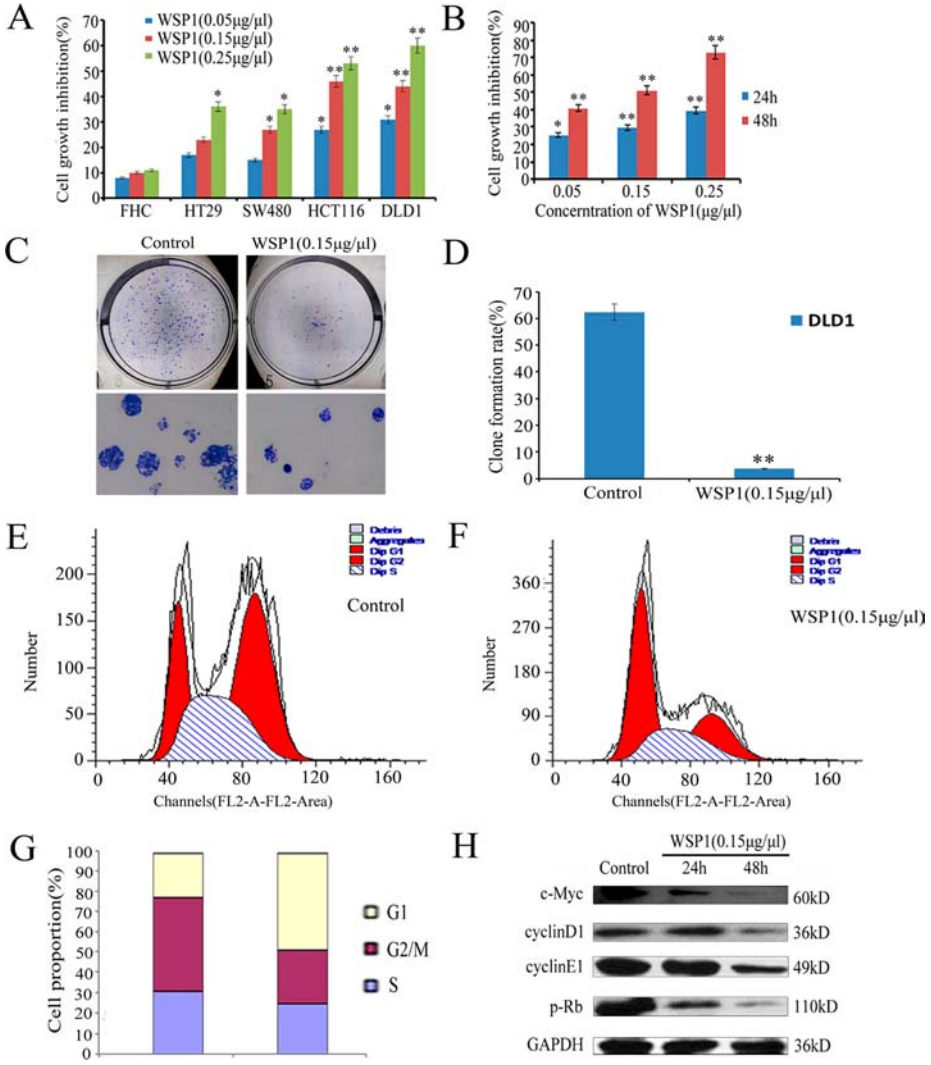

Figure 2. WSP1 antiproliferative activities. (A) Dose-dependent cell proliferation assays. FHC, HT29, SW480, HCT116, and DLD1 cells were treated with different doses (0, 0.05, 0.15, and 0.25 $\mu g/\mu L$) of WSP1 for 48 h, and cell proliferation was measured by MTT assay. (B) Time-dependent cell proliferation assays. DLD1 cells were seeded in the presence of WSP1 for 24 and 48 h. (C) Clonogenic survival assays. DLD1 cells (1000/well) were seeded in 6-well plates in the absence or presence of WSP1 for 10 d, then the clonogenic assay was carried out. (D) Colon Formation Rate = (Clones/Seeded Cells) × 100%. (E,F) Effects of WSP1 on cell cycle distribution in DLD1 cells. Cells were treated with WSP1 (0.15 $\mu g/\mu L$) for 48 h. DNA content was analyzed by cytometry. Accumulated cells in the G1 phase were compared with the control. (G) The percent of cell population in G0/G1, G1, S, and G2/M phases of the cell cycle. (H) Effects of WSP1 treatment on cell cycle proteins as shown by Western blotting. Antibodies were used against cyclin D1, cyclin E1, c-Myc, and pRb. GAPDH antibody was used as an internal control. The results represent mean ± SD of three independent experiments. $^*p < 0.05$, $^{**}p < 0.01$ compared with untreated cells.

(Supporting Information, Figure S1), and the three peptide fragments with identical amino acid sequences were detected at 55.8% (39 kDa), 45.3% (37 kDa), and 42.8% (35 kDa) coverage to WSP1 (GI: 530891431) of NCV (Supporting Information, Figure S1). The microheterogeneity of WSP1 was consistent with previous reports.[18,19] On the basis of the band intensity analysis, the three bands of WSP1 in Figure 1B were estimated to account for 31.5% (39 kDa), 23.6% (37 kDa), and 28.6% (35 kDa) of the total purified protein (Figure 1D). Additionally, the amino acid sequence of WSP1 protein of 39 kDa is shown in Figure 1E.

Cloning of WSP1 Gene. The full-length coding sequence of *WSP1* gene was amplified by PCR from the total cDNA of NCV. The identified *WSP1* gene sequence has been submitted to GenBank under accession number KF003026. It encoded a polypeptide of 337 amino acids (GI: 530891431) with an 83% sequence identity to WspA of *N. commune* KU002 (accession no. AB518000).

WSP1 Suppresses Cell Growth of Human Colon Cancer. This study investigated the sensitivity of colon cancer cells (HT29, SW480, DLD1, and HCT116) and normal colon epithelial cells (FHC) to WSP1. The proliferation of those cells treated with various concentrations of WSP1 for 24 or 48 h was monitored using a MTT assay. As shown in Figure 2A,B, WSP1 markedly suppressed colon cancer cells growth in a time- or dose-dependent manner; however, it displayed less effect on FHC cell proliferation. The IC_{50} values of WSP1 for DLD1, HCT116, HT29, and SW480 cells were 0.19 ± 0.02, 0.21 ± 0.03, 0.39 ± 0.05, and 0.41 ± 0.01 $\mu g/\mu L$, respectively, and the IC_{50} against FHC was 0.67 ± 0.05 $\mu g/\mu L$ (Table 1). The ability of individual cells to aggregate into viable colony clusters can be measured by a clonogenic survival assay; therefore, this assay was performed with DLD1 cells to evaluate the long-term

J. Agric. Food Chem. 2015, 63, 150−159

Table 1. Cytotoxic Activity of WSP1 against Various Human Cell Lines

cell lines	IC_{50} ($\mu g/\mu L$) ± SD
DLD1 (colon cancer cell)	0.19 ± 0.02
HCT116 (colon cancer cell)	0.21 ± 0.03
HT29 (colon cancer cell)	0.39 ± 0.05
SW480 (colon cancer cell)	0.41 ± 0.01
FHC (colon epithelial cell)	0.67 ± 0.05

effects of WSP1 on cell survival. The results showed that the clone formation rate of each group was 62.2 ± 5.1% in control group of 10 days, 2.8 ± 0.1% in WSP1-treated group of 10 days (Figure 2D). The data showed that the cell clone formation inhibiting effect of all the WSP1-treated groups were extremely significantly different from the control groups ($p < 0.01$). The result showed that clonogenicity was significantly inhibited in colon cancer cells cultured in the presence of WSP1 (Figure 2C).

WSP1 Inhibits Colon Cancer Cell Growth by G1-Phase Arrest. To determine the mechanisms by which WSP1 inhibits the proliferation of colon cancer cells, analysis of cell cycle by flow cytometry was applied with WSP1 treated DLD1 cells. As shown in Figure 2E,F, DLD1 exposed to WSP1 resulted in a time-dependent cell percentage reduction in the S-phase and accumulation in the G1-phase. The percentage of cells in different phases is shown in Figure 2G.

The expression levels of cell cycle associated proteins were analyzed by Western blotting. Compared with the control, the levels of c-Myc, cyclin D1, cyclin E1, and p-Rb decreased in DLD1 cells with the WSP1 treatment (Figure 2H), suggesting that the induced G1 phase arrest was attributed to the inhibition of c-Myc expression, followed by decreased cyclin D1, cyclin E1, and Rb phosphorylation expression.

Treatment of WSP1 Induces the Apoptosis of Human Colon Cancer Cells. Because many chemotherapeutic drugs have been used to treat tumors by inducing apoptosis,[21,22] we questioned whether WSP1 inhibited the colon cancer cell proliferation by inducing apoptosis. DLD1, HCT116, and FHC cells were treated with 0.15 $\mu g/\mu L$ WSP1 for 48 h, and apoptotic bodies were detected by DAPI staining. The results showed WSP1-treated cells exhibited the apoptotic characteristics of chromatin condensation with typical apoptotic bodies. The number of apoptotic nuclei significantly increased in the group of colon cancer cells with the WSP1 treatment. In contrast, the WSP1-treated FHC cells did not display any obvious apoptotic bodies (Figure 3A,B).

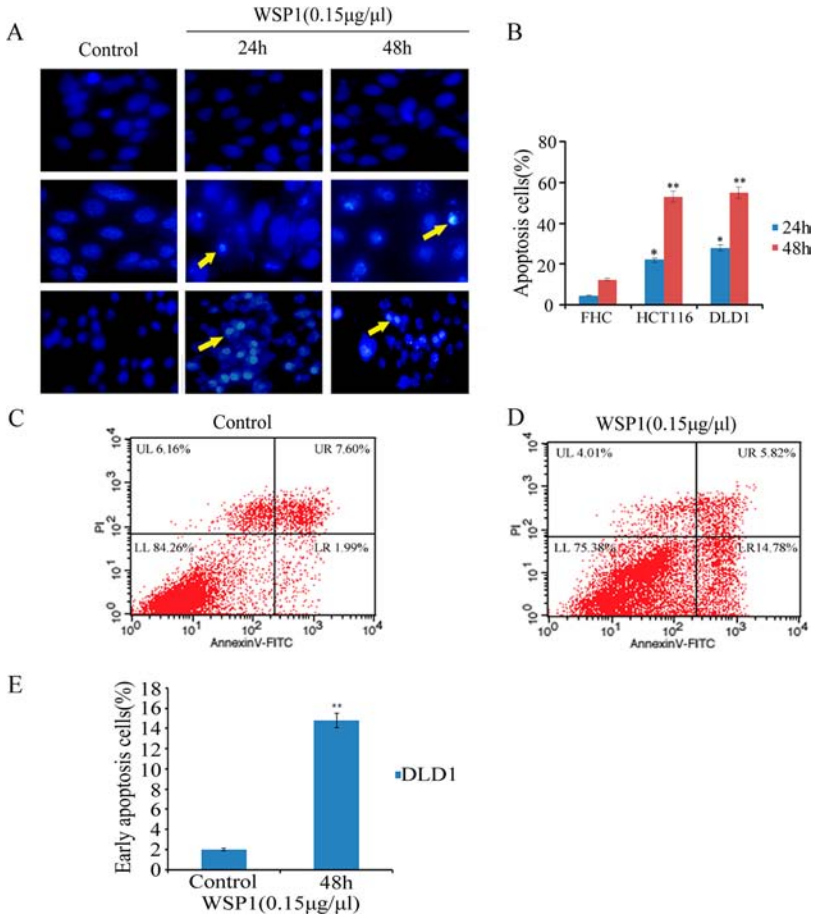

Figure 3. Effects of WSP1 on apoptosis. (A) DLD1 and HCT116 were treated with WSP1 (0.15 $\mu g/\mu L$) for 24 or 48 h, and monolayer cultures were stained with DAPI to reveal apoptotic changes in the cell nuclei. Apoptotic bodies were pointed out by arrows. (B) Apoptotic cells of DLD1 and HCT116 were calculated. (C,D) DLD1 cells were either untreated or treated with WSP1 (0.15 $\mu g/\mu L$) for 48 h. Effects of WSP1 on cell apoptosis induction assessed by Annexin V/PI method using flow cytometry. The bottom right quadrant represented cells stained mainly by Annexin V (early apoptotic cells). (E) The early apoptosis ratio of DLD1 was shown in the bar graph. All experiments were performed at least three times in independent cell culture. *$p < 0.05$, **$p < 0.01$ compared cells untreated with WSP1.

DOI: 10.1021/jf503208p
J. Agric. Food Chem. 2015, 63, 150−159

The degree of apoptosis was further determined by monitoring Annexin V-stained cells. DLD1 cells were treated with WSP1 for 48 h and then subjected to a flow cytometry analysis using Annexin V/propidium iodide double-staining. Compared to the control group, the ratio of Annexin V-stained cells was significantly increased in the group in the WSP1 treatment (Figure 3C,D). The early apoptotic cell percentage increased from 1.99 ± 0.38% to 14.78 ± 1.37% for DLD1 cells in the WSP1 treatment (Figure 3E).

WSP1 Alters Mitochondrial Membrane Potential and Induces Cell Apoptosis. Mitochondrial membrane depolarization[23] usually occurs in the stage of cell apoptosis. The collapse of mitochondrial membrane potential ($\Delta\psi m$), which reflects changes in mitochondrial membrane permeability, plays a vital role in the apoptotic process. Next, the changes of mitochondrial membrane potential were measured using JC-1 by flow cytometry. Under normal circumstances, JC-1 accumulates in active mitochondria in which it fluoresces red. A reduction in mitochondrial membrane potential results in the replacement of red fluorescence by green JC-1 monomers. The result indicated that there was an elevated percentage of DLD1 cells with depolarized mitochondrial membranes (time-dependently) after treatment with WSP1 for 48 h (Figure 4A). The fluorescent intensity ratio of red and green is shown in Figure 4B.

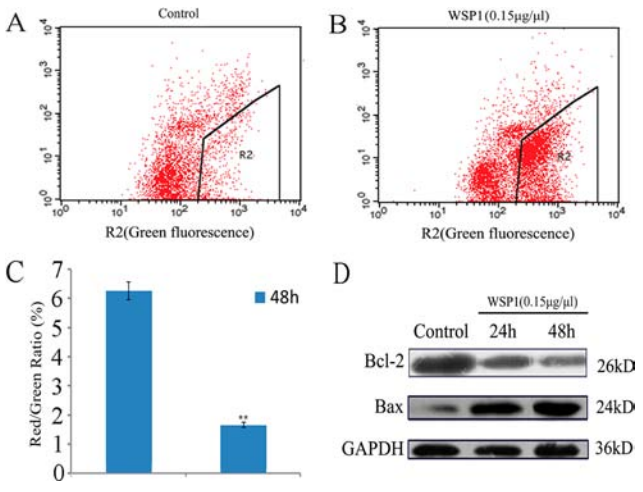

Figure 4. WSP1 induced mitochondrial membrane depolarization and releases of apoptotic factors in DLD1 cells. (A,B) Cells treated with WSP1 (0.15 $\mu g/\mu L$) for 48 h were harvested and subjected to flow cytometric analysis of mitochondrial membrane potential by JC-1 staining. Results were shown as mean values from three independent experiments. Treatment caused significant increases in the percentage of cells with depolarized mitochondrial membrane compared with the control (*$p < 0.05$, **$p < 0.01$). (C) Red and green fluorescence ratio of DLD1 cells treated and untreated by flow cytometric analysis. (D) Expressions of Bax and Bcl-2 were analyzed by Western blotting. GAPDH was used as the loading control. Representative Western blotting from two independent experiments was shown.

It is recognized that Bcl-2 family proteins regulate the mitochondrial membrane potential and the Bax/Bcl-2 ratio determines the cellular survival or apoptotic cell death.[24] The results showed that WSP1 could inhibit the antiapoptotic Bcl-2 protein and elevate the pro-apoptotic Bax protein (Figure 4D). With this, the Bax/Bcl-2 ratio was significantly increased (Figure 4D) and there was a subsequent reduction of mitochondrial membrane potential (Figure 4B,C). These data suggested that WSP1 caused mitochondrial dysfunction and the alteration of the Bax/Bcl-2 ratio that accounted for the WSP1-induced decline of $\Delta\psi m$.

WSP1 Treatment Induces the Caspase-Dependent Apoptosis in DLD1 Cells. To further explore the molecular mechanisms of WSP1 to induce cell apoptosis, the detection of PARP cleavage[25] was performed using Western blotting. The result showed WSP1 induced proteolytic inactivation of PARP and the extent of cleavage was elevated time-dependently (Figure 5A). Because PARP is a substrate of executioner caspases, its cleavage indicates that caspases might be activated during the cell death process. It is been known that caspase activation is involved in the cleavage of its pro-caspase.[26] After the WSP1 treatment, there were more pro-caspases-8 and -9 cleaved into caspases-8 and -9 (Figure 5A). In addition, the caspase-3 was further activated and led to apoptosis in DLD1 cells with the WSP1 treatment (Figure 5A). Moreover, the pan-caspase inhibitor, z-VAD-FMK, could partially reverse WSP1-inhibited cell proliferation in a dose dependent manner (Figure 5B); 20 μM z-VAD-FMK had inhibitory effects on the activation of caspase-9 (Figure 5C). These results confirmed that WSP1 induced apoptosis can be at least partially attributed to the activation of the caspase signaling pathway.

WSP1 Inhibits DLD1 Xenografted Tumor Growth in Nude Mice. To determine the anticolon cancer effects of WSP1 in vivo, we performed xenograft studies with DLD1-bearing nude mice. The nude mice received intraperitoneal injections of 60 μg WSP1/g body weight every 3 days. As shown in Figure 6, the WSP1-treatment for five injections resulted in a significantly reduced tumor volume and mass compared with the untreated group ($p < 0.01$). This phenomenon achieved a higher significance ($p < 0.01$) after six times injections. Furthermore, histology analyses revealed that WSP1-treated tumors had massive growth inhibition and apoptosis, as indicated by the significant reduction of K_i-67 and increase of actived-caspase-8, -9, and PARP (Figure 7). In addition, no mice died during the experiment. The body weights of the control group and the experimental group had no obvious difference (Figure 6A).

DISCUSSION

Studies have revealed that microorganisms serve as rich sources of anticancer therapeutics.[27−30] Previous studies have shown that *Nostoc commune* Vauch. contains various nutritional ingredients and has been used as food and medicine for centuries in China.[12] In this study, we found that the WSP1 from *Nostoc commune* Vauch. has anticolon cancer activity both in vitro and in vivo.

To prepare WSP1, *Nostoc commune* Vauch. does not need to be ground because water stress protein is the major component of the extracellular matrix.[16,18] The proteins obtained in this study had a relatively high purity. As shown in Figure 1D, WSP1 accounted for 83.6% of the total extracellular matrix protein. The three proteins of different molecular weights in the SDS-PAGE were all identified as WSP1 by mass spectrum. These isoforms may arise from deamidation, covalent modification, protease degradation, etc.[19] On the basis of our previous studies,[20] the WSP1 of 39 kDa was the main anticolon cancer protein and its amino acid sequence is shown in Figure 1E.

Malignant tumor growth is due to the abnormality of cell proliferation or regulation defects of cell death. Cell cycle arrest and apoptosis induction are concurrent.[31] The occurrence of

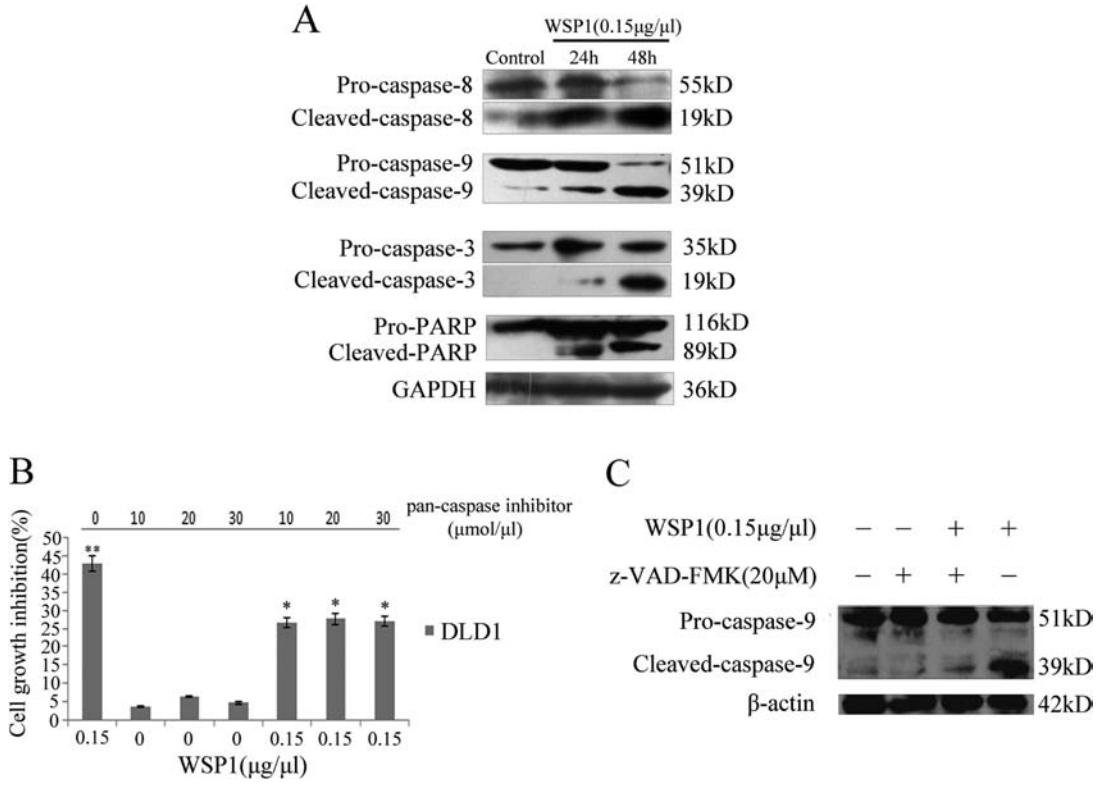

Figure 5. WSP1 induced caspase-dependent apoptosis in DLD1 cells. (A) Caspases and PARP were determined by Western blotting after treatment with WSP1 (0.15 μg/μL). GAPDH was used as the loading control. (B,C) The pan-caspase inhibitor reversed WSP1-suppressed cell proliferation. DLD1 cells were preincubated for 1 h in the absence or presence of 20 μM pan-caspase inhibitor, z-VAD-fmk, and were treated with WSP1 (0.15 μg/μL) for 48 h. Proliferation inhibitions of DLD1 cells were calculated by MTT, and the expression of caspase-9 was analyzed by Western blotting. $^{**}p < 0.01$ vs cells untreated with WSP1.

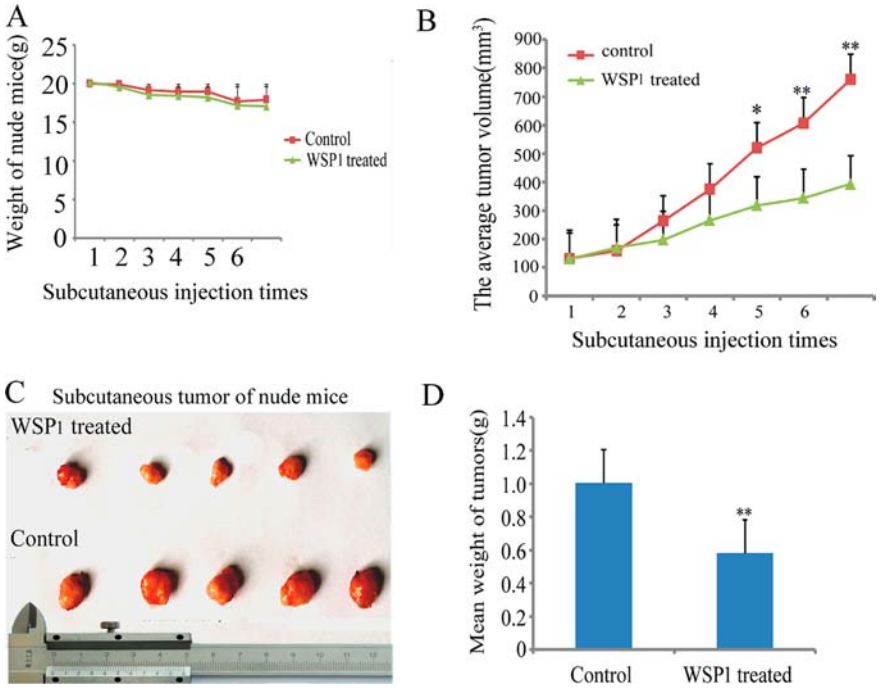

Figure 6. Effects of WSP1 on the growth of xenografted tumor in nude mice. DLD1 cells (5×10^6) were injected subcutaneously into the right oxter of the nude mice. After tumor formation, the mice were divided into two groups and treated with WSP1 (60 μg/g body weight) every 3 days or with PBS as control. (A) Curve of average body weight in two groups within 21 days. (B) Tumor volumes of both groups were calculated. (C) After six treatments with WSP1, mice were sacrificed and five representative tumors of each group were shown. (D) Mass of dissected tumors was excised. Results represent mean ± SD (n = 8). $^{**}p < 0.01$ vs control group.

J. Agric. Food Chem. 2015, 63, 150−159

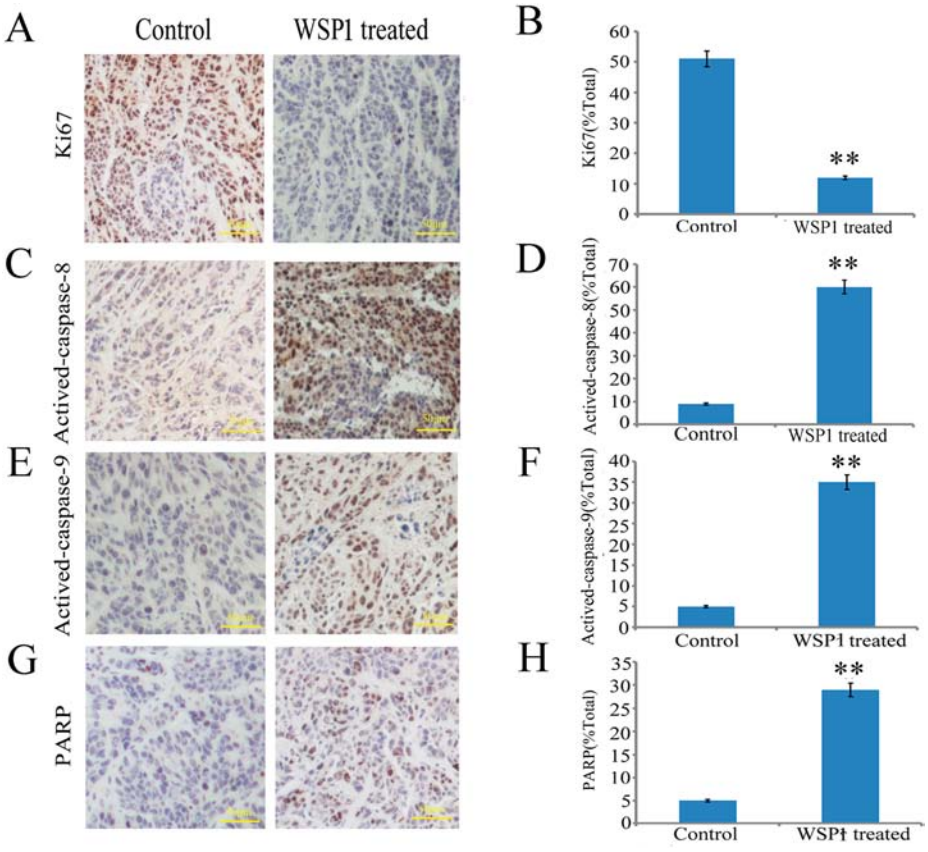

Figure 7. Immunohistochemical analysis of the expression of K_i-67, activated-caspase-8, activated-caspase-9, and PARP in the dissected tumor tissues by WSP1 treatment or control. There were significant differences between control and WSP1-treated group (**$p < 0.01$).

cell death is not caused by biochemical abnormalities but rather to completely split cell cycle events. Morphological change is considered the most reliable standard of apoptosis. The results showed that WSP1 dramatically inhibited proliferation of CRC cells in vitro, and the typical morphological changes of apoptosis were observed with WSP1 treatment (Figure 3A). Especially, WSP1 could induce the cell cycle arrest and apoptosis significantly. Moreover, it exerted obvious negative effects on normal colonic epithelial cell FHC, suggesting WSP1 has targeted antitumor effects on colon cancer cells.

It is known that c-Myc plays an important role in the cell cycle by activating cyclin D1 and cyclin E1, which in turn lead to phosphorylation of the retinoblastoma protein (Rb) and facilitate the cells entering the G1 phase.[32] Here, WSP1 induced cell cycle arrest at the G1/S phase in DLD1 cells. The corresponding Western blotting demonstrated that c-Myc expression was reduced, followed by the down regulations of cyclin D1, cyclin E1, and pRb expression. Thus, WSP1 could induce cell growth inhibition through the induction of G1-arrest in colon cancer cells (Figure 8).

Tumor formation often results from an increase in cell proliferation and a decrease in cell apoptosis.[33] The ability to induce apoptosis in tumor cells is as important as antitumor drugs.[34] Apoptosis usually initiated by caspase activation, even though not all cell apoptosis is linked to caspase activation.[35] Furthermore, PARP, a nuclear enzyme involved in DNA repair, is a well-known substrate for caspase-3 cleavage during apoptosis. Studies showed that PARP cleavage reduced DNA repair function and is considered to be a hallmark of apoptosis.[36] In the process of identifying the pathways by

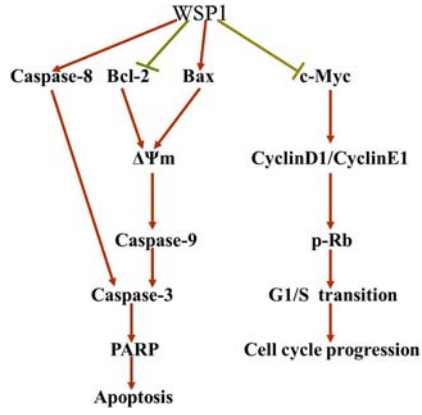

Figure 8. Proposed the possible signal pathway for growth inhibition and apoptosis induced by WSP1 in DLD1 cells.

which WSP1 induced colon cancer cell apoptosis, PARP was found to be cleaved and mediated by a cascade of caspases, including caspase-8 of the extrinsic apoptosis pathway and caspase-9 of the intrinsic pathway. These initiator caspases then lead to the activation of capsase-3. The present study showed that caspase-8, -9, and -3 in DLD1 cells were all activated with the WSP1 treatment. Consistently, WSP1-induced DLD1 cell apoptosis was partially suppressed and the cleavage of pro-caspase-9 was reversed by the addition of the pan-caspase inhibitor. The immunohistochemistry of DLD1 xenografted nude mice further confirmed that actived-caspase-8, -9, and PARP had strong expression in the cells treated with WSP1. These data confirmed that the caspase-dependent pathway was

DOI: 10.1021/jf503208p
J. Agric. Food Chem. 2015, 63, 150−159

responsible for the apoptotic process caused by WSP1 (Figure 8).

Cell survival depends on the maintenance of mitochondrial membrane potential.[37] The Bcl-2 family members consist of pro- and antiapoptotic proteins, which work together with other proteins to maintain a dynamic balance between the survival and death of cells by regulating the function of mitochondria. In human tumors, the expressions of Bcl-2, Bcl-xL, or other antiapoptotic homologues are up-regulated and the expression of pro-apoptotic protein Bax or Bak is down-regulated.[38] This study showed that WSP1 induced precocious apoptosis in DLD1 cells, as evidenced by a decrease in the expression of Bcl-2 and an increase in Bax, accompanied by a decrease in $\Delta\psi m$ (Figure 8).

The water stress protein, WSP1 from *Nostoc commune* Vauch. was prepared and studied in the present investigation. It indicated that WSP1 could suppress the growth of colon cancer cells by inducing cell cycle G1-phase arrest. Its apoptosis-promoting activity is attributed to the activation of caspase-dependent pathway. In agreement with the in vitro data, WSP1 could also suppress the growth of xenografted DLD1 tumors in vivo, indicating that it may be developed as an effective therapeutic agent for patients with colon cancers.

Intraperitoneal injection was applied in vivo in our study. It is an effective administration method for protein drugs in mice models. However, although it has good clinical characteristics such as a good curative effect and low side effects, the bioavailability of protein drugs is only a small percentage of their short half-life, they have large molecular weights and poor trans-membrane ability using methods other than injection. In contrast, using intravenous injection, protein drugs easily cause an immune response. Therefore, it has been an urgent task for scientists to research and develop protein drugs that are stable, have a long half-life, and have good biocompatibility and easy absorption. Studies[39−41] have shown that a chemical modification or a prodrug, such as an enzyme inhibitor, working as an absorption accelerator, could improve the absorption and reduce the immune response of protein drugs delivered via intravenous injection. For example, PEG (polyethylene glycol) is often used to carry modified protein structures and it could prolong the half-life of protein drugs and control their velocity into the blood. In addition, the injectable microspheres can achieve slow-release effects. Other non-injection methods such as nasal and pulmonary routes of administration can also improve the absorption and utilization of protein drugs. To improve the bioavailability of protein drugs, new biotechnology such as nanoliposomes are being used as oral and transdermal protein drug delivery carriers.

Collectively, WSP1 has specific antitumor activities on colon cancer and may have great potential for medicinal applications.

ABSTRACT: Alginate has notably diverse pharmacological activities. The present study investigated the anti-inflammatory activity of the guluronate oligosaccharides prepared by oxidative degradation (GOS-OD) from alginate. GOS-OD significantly attenuated the production of nitric oxide (NO), prostaglandin E_2 (PGE_2), and reactive oxygen species (ROS), the expression of inducible nitric oxide synthase (iNOS) and cyclooxygenase (COX)-2, and the secretion of pro-inflammatory cytokines in lipopolysaccharide (LPS)-activated murine macrophage RAW 264.7 cells. Moreover, GOS-OD potently decreased the binding of LPS to the cell surface and LPS-induced Toll-like receptor 4 (TLR4) and cluster of differentiation (CD) 14 expression. Additionally, GOS-OD could remarkably inhibit the LPS-induced activation of nuclear factor (NF)-κB and mitogen-activated protein (MAP) kinase pathways in RAW 264.7 cells. These results indicate that GOS-OD may reduce the LPS-stimulated inflammatory responses through blocking the activation of NF-κB and MAP kinases, suggesting that GOS-OD may be considered as a potential nutraceutical for inflammation.

KEYWORDS: *alginate oligosaccharides, lipopolysaccharide, Toll-like receptor 4, nuclear factor-κB, mitogen-activated protein kinases*

INTRODUCTION

Increasing evidence has confirmed that inflammation is associated with various diseases, such as cancer, obesity, and cardiovascular diseases.[1,2] Hence, the study of anti-inflammatory pathways is crucial to the development of new nutraceuticals or drugs for the treatment of inflammatory-mediated diseases. Lipopolysaccharide (LPS)-stimulated inflammatory models have been widely used to study the anti-inflammatory activity of various naturally derived substances.[3,4] Toll-like receptors (TLRs) play important roles in the molecular mechanisms of inflammation, particularly TLR4.[5] TLR4 has been shown to be the predominant modulator of the pro-inflammatory responses induced by LPS.[6] Cluster of differentiation (CD) 14 acts as an important cofactor for the binding of LPS to TLR4, an interaction that plays a critical role in the innate immune system response.[7] Recent works have demonstrated that LPS-stimulated inflammation is mainly mediated by TLR4 and CD14.[8] TLR4 signaling triggers a cascade of pro-inflammatory events that lead to the activation of the transcription factor, nuclear factor (NF)-κB, cellular kinases, such as mitogen-activated protein (MAP) kinases, protein kinase B (Akt), and phosphoinositide 3-kinase (PI3K), and the induction of the overexpression of inflammatory-related mediators, including nitric oxide (NO), prostaglandin E_2 (PGE_2), reactive oxygen species (ROS), pro-inflammatory proteins, such as inducible nitric oxide synthase (iNOS) and cyclooxygenase (COX)-2, and pro-inflammatory cytokines.[9,10] Therefore, naturally derived extracts/compounds that can efficiently reduce the LPS-induced activation of NF-κB and MAP kinase pathways should be considered as potential nutraceuticals or drugs for the treatment of inflammatory diseases.[11,12]

Although the anti-inflammatory activity of natural polysaccharides has been widely investigated to find anti-inflammatory agents that work through suppressing the production of NO and PGE_2 and down-regulating the expression of iNOS and COX-2,[11−13] wide application of those polysaccharides is difficult due to their high molecular weights and low solubilities. Therefore, the depolymerization of polymers may possibly overcome the limitation. The anti-inflammatory activity of naturally derived oligosaccharides, such as lactulose oligosaccharides,[14] mannan oligosaccharides,[15] and chitosan oligosaccharides,[16] have been widely investigated in recent years using in vitro and in vivo models of inflammation. Alginates are natural polysaccharides found in brown seaweed and are copolymerized alternatively by the two monomers α-1,4-L-guluronic acid (G) and β-1,4-D-mannuronic acid (M). They are used in a wide variety of industries, such as the food, textile, and pharmaceutical industries.[17] Alginate oligosaccharides (AOS) depolymerized by different methods from polymers show various phamacological activities. In previous works, we have reported that the different bioactivities of AOS can be attributed to the different structures. Unsaturated AOS that have been prepared by enzyme degradation possess various

bioactivities such as the induction of cytokine production,[18] neuroprotective activities,[19,20] macrophage bactericidal activity, and immunostimulatory activity,[21,22] whereas the saturated AOS prepared by acid hydrolysis have low bioactivities. AOS produced by the oxidative degradation method have been used as tissue engineering agents.[23] However, to the best of our knowledge, the anti-inflammatory activities of AOS prepared by oxidative degradation have not been reported.

In this study, we investigated the effect of AOS produced by different degradation methods on LPS-induced NO production in RAW 264.7 cells and found that only GOS-OD significantly reduced the LPS-induced excessive secretion of NO. Next, we provide key insights into potential mechanisms for the anti-inflammatory activity of GOS-OD in LPS-activated RAW 264.7 cells.

MATERIALS AND METHODS

Chemicals and Reagents. Alginates (1000 cps grade) were obtained from Nuotai (Shanghai, China). Fetal bovine serum (FBS) was purchased from Biontex (Planegg, Germany). RPMI-1640 culture medium was from Thermo Scientific (Hudson, NH, USA). Anti-mouse iNOS antibody, anti-mouse COX-2 antibody, anti-mouse NF-κB antibody, and antibodies for MAP kinases including p38, JNK, and ERK were all obtained from Cell Signaling Technology (Beverly, MA, USA). Anti-mouse TLR4 antibody and anti-CD14 were purchased from Abcam (Cambridge, UK). 2′,7′-Dichlorofluorescein diacetate (DCF-DA) was provided by Beyotime Inst. Biotech. (Jiangsu, China). NG-nitro-L-arginine methyl ester (L-NAME) and FITC-conjugated LPS were obtained from Sigma-Aldrich (St. Louis, MO, USA). The other reagents were all commercially available.

Preparation of Alginate Oligosaccharides. First, we prepared polyguluronate (PG) and polymannuronate (PM) (DP = 20−24) using methods previously described.[24] Second, AOS (GOS-OD, MOS-OD, GOS-AH, MOS-AH, GOS-ED, and MOS-ED) were obtained from PG and PM by oxidative degradation,[25] acid hydrolysis,[26] and enzymatic degradation,[27] respectively. Finally, alginate saccharide samples were sterilized by filtration using 0.22 μm filter membranes (Millipore Co., Billerica, MA, YSA) prior to the experiments.

Cell Culture and Viability Assays. Murine RAW 264.7 cells were purchased from the Shanghai cell bank of the Chinese Academy of Sciences (Shanghai, China). These cells were incubated in RPMI-1640 medium plus 10% FBS, 100 U/mL penicillin, and 100 μg/mL streptomycin sulfate in a humidified incubator with 5% CO_2. Cell viability was examined by a WST-8 assay (Beyotime Inst. Biotech.) according to the manufacturer's instructions. In brief, the cells were seeded onto 96-well plates (2×10^5 cells/well) and incubated with all various saccharide samples (GOS-OD, MOS-OD, GOS-AH, MOS-AH, GOS-ED, MOS-ED, PG, and PM) or GOS-OD (0.1−2 mg/mL) for 24 h. One hundred microliters of CCK-8 reagent (0.5 mg/mL) was added to the wells. The absorbance was examined at 540 nm by a Spectra Max microplate reader (Molecular Devices, LLC, Sunnyvale, CA, USA).

Measurement of NO, PGE_2, and ROS. For NO and PGE_2 measurements, RAW 264.7 cells were seeded onto 96-well plates (2×10^5 cells/well). Then, the cells were incubated with saccharide samples (1 mg/mL) or GOS-OD (0.1−2 mg/mL) for 2 h and treated with or without 1 μg/mL LPS for 24 h. The nitrite concentration was detected as an indicator of NO secretion via the Griess reaction.[28] Fifty microliters of supernatant was mixed with 50 μL of Griess reagent. The absorbance of the mixture was detected by a microplate reader (Molecular Devices, LLC). Levels of PGE_2 in the supernatant were quantified by an enzyme-linked immunosorbent assay (ELISA) kit (Cayman Chemical Co., Ann Arbor, MI, USA) according to the manufacturer's instructions.

The fluorescent probe DCFH-DA (Beyotime Inst. Biotech.) was used to measure ROS. RAW 264.7 cells (5×10^5 cells/well) were treated with GOS-OD (0.1−2 mg/mL) for 2 h and then incubated with or without LPS (1 μg/mL) for 24 h. Then, the cells were washed twice with PBS and incubated with a 10 μM DCFH-DA solution at 37 °C for 30 min. After three washings with PBS, the cells were harvested. The fluorescence intensity of the cell suspensions was measured using a fluorescence-activated cell sorting (FACS) system (Becton Deckinson, San Jose, CA, USA).

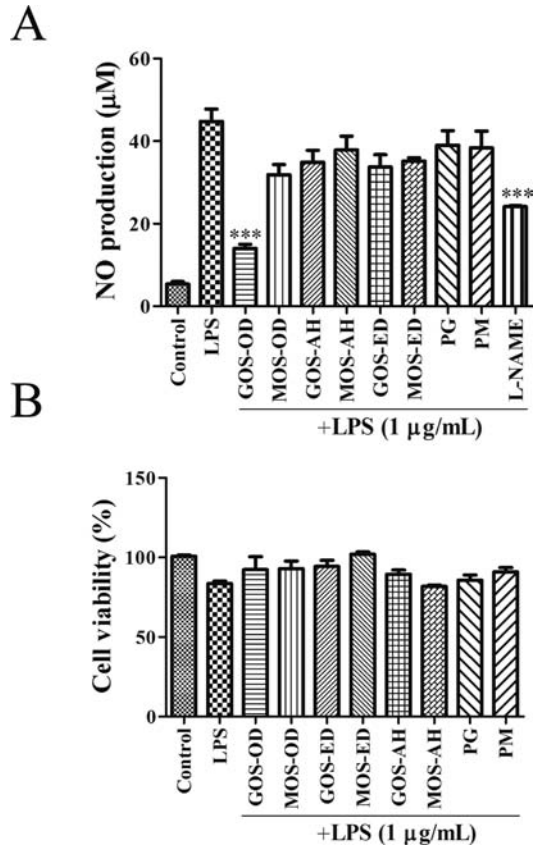

Figure 1. Effects of GOS-OD, MOS-OD, GOS-AH, MOS-AH, GOS-ED, MOS-ED, PG, and PM on NO production and cell viability in LPS-activated RAW 264.7 cells. (A) RAW 264.7 cells preincubated with 1 mg/mL saccharides for 2 h were treated with 1 μg/mL LPS for 24 h. The nitrite concentration in the culture supernatant was detected to indicate NO production. L-NAME (1 mM), a NOS inhibitor, was used as a positive control. (B) Cells preincubated with 1 mg/mL saccharides for 2 h were treated with 1 μg/mL LPS for 24 h. The cell viability was measured using a CCK-8 assay. Values are the mean ± SD of three independent experiments. (***) $p < 0.001$ indicates significant differences compared to the LPS-treated group.

Measurement of TNF-α, IL-1β, and IL-6. RAW 264.7 cells were seeded onto 96-well plates (2×10^5 cells/well). Then, the cells were preincubated with 0.1−2 mg/mL GOS-OD for 2 h and treated with or without LPS (1 μg/mL) for 24 h. Levels of TNF-α, IL-1β, and IL-6 in the supernatant were quantified by an ELISA kit (NeoBioscience Technology Co., Ltd., Shenzhen, China) according to the manufacturer's instructions.

Reverse Transcription Polymerase Chain Reaction (RT-PCR). RAW 264.7 cells (1×10^6 cells/well) pretreated with 0.1−2 mg/mL GOS-OD were stimulated with or without 1 μg/mL LPS for 12 h. Total RNA was extracted from the treated cells using Trizol reagent ($RNA_{fast200}$, Fastagen, China). For each sample, 1 μg of RNA was used for reverse transcription. The PCR primers are as follows: forward strand iNOS, 5′-CAA CCA GTA TTA TGG CTC CT-3′; reverse strand iNOS, 5′-GTG ACA GCC CGG TCT TTC CA-3′; forward strand COX-2, 5′-CCA CTT CAA GGG AGT CTG GA-3′; reverse strand COX-2, 5′-AGT CAT CTG CTA CGG GAG GA-3′; forward strand β-actin, 5′-GGA GAA GAT CTG GCA CCA CAC C-3′; reverse strand β-actin, 5′-CCT GCT TGC TGA TCC ACA TCT GCT GG-3′. β-Actin was used as an internal standard.

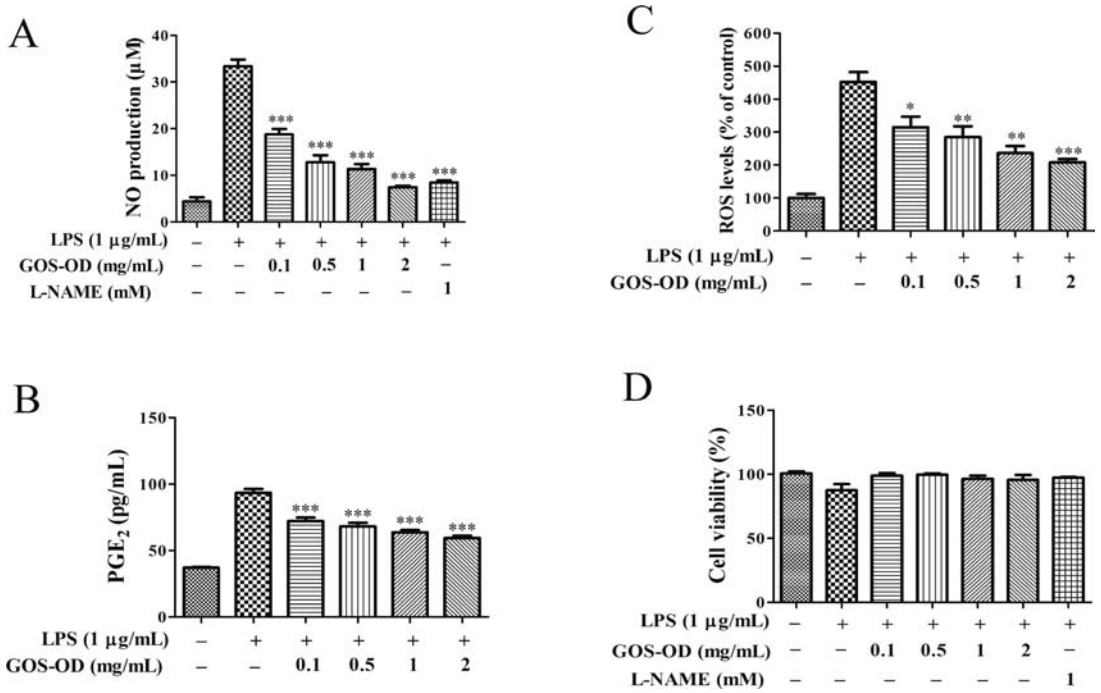

Figure 2. Effects of GOS-OD on the production of NO, PGE_2, and ROS in LPS-activated RAW 264.7 cells. Cells preincubated with 0.1−2 mg/mL GOS-OD for 2 h were treated with 1 μg/mL LPS for 24 h. NO (A) and PGE_2 production (B) in the culture supernatant was detected by ELISA. ROS production was measured by FACS analysis (C). The viability of cells preincubated with 0.1−2 mg/mL GOS-OD and treated with LPS was measured by the CCK-8 assay (D). L-NAME (1 mM) was used as a positive control. Values are the mean ± SD of the three independent experiments. (∗) $p < 0.05$, (∗∗) $p < 0.01$, and (∗∗∗) $p < 0.001$ indicate significant differences compared to the LPS-treated group.

Western Blot Analysis. RAW 264.7 cells were seeded onto 6-well plates (1×10^6 cells/well). Then, the cells were pretreated with GOS-OD (0.1−2 mg/mL) for 2 h and incubated with or without 1 μg/mL LPS for 24 h. Next, the cells were washed three times with ice-cold PBS. Cellular lysates were prepared in lysis buffer (Biocolors, Shanghai, China) at 4 °C for 30 min and centrifuged at 12000 rpm. After the quantification of proteins by a bicinchoninic acid (BCA) protein assay kit (Auragene Bioscience Corp. Inc., Changsha, China), 50 μg of cellular proteins was resolved using a 12.5% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) and transferred onto a polyvinylidene difluoride (PVDF) membrane (Amersham Pharmacia Biotech., UK). The membranes were treated with 10% skimmed milk in Tris-buffered saline containing 0.1% Tween 20 (TBST) to block the nonspecific binding. Thereafter, the membranes were washed adequately and hybridized with anti-mouse iNOS antibody (dilution 1:1000) or anti-mouse COX-2 antibody (dilution 1:1000) in 5% skimmed milk in TBST overnight at 4 °C. After three washings with TBST, the membranes were incubated with a horseradish peroxidase-conjugated secondary antibody at 37 °C for 2 h. The expression levels of iNOS and COX-2 proteins were observed by an LAS3000 luminescent image analyzer (Fujifilm Life Science, Tokyo, Japan). The density of the Western blot bands was analyzed using Quantity One software (Bio-Rad).

To analysis the expression of TLR4 and CD14, RAW 264.7 cells (1×10^6 cells/well) were preincubated with 2 mg/mL GOS-OD for 2 h and treated with or without 1 μg/mL LPS at 37 °C for 24 h. After protein preparation, the Western blot analysis was carried out using anti-TLR4 and anti-CD14 antibodies.

To test NF-κB/p65 expressions, RAW 264.7 cells (1×10^6 cells/well) pretreated with 2 mg/mL GOS-OD for 2 h were incubated with 1 μg/mL LPS for 30 min. Then, the nuclear and cytoplasmic proteins were extracted by a KeyGEN Nuclear and Cytoplasmic Protein Extraction Kit (KeyGen Biotech., Nanjing, China). After protein quantitation, the Western blot analysis was performed using an anti-NF-κB/p65 antibody, similar to the method described above.

To determine the expression levels of MAP kinases, RAW 264.7 cells (1×10^6 cells/well) were preincubated with 2 mg/mL of GOS-OD for 2 h and stimulated with or without LPS (1 μg/mL) at 37 °C for 10 min. After the suitable proteins were obtained, the Western blot analysis was carried out as described above using corresponding antibodies, including phosphorylated and nonphosphorylated p38, JNK, and ERK MAP kinases.

Fluorescence Analysis. To observe the effect of GOS-OD on the binding of FITC-conjugated LPS (FITC-LPS) to RAW 264.7 cell surfaces, cells were seeded onto glass coverslips (Corning Inc. Life Sciences, MA, USA) in 6-well plates for 24 h. The cells were preincubated with 2 mg/mL GOS-OD for 2 h and then stimulated with 10 μg/mL FITC-LPS for 1 h. Finally, the cells were washed three times with PBS and fixed in 4.0% (w/v) paraformaldehyde for 15 min at room temperature. The samples were observed using a Fluoview FV1000 laser scanning confocal microscope (Olympus, Tokyo, Japan).

Flow Cytometry Analysis. To further verify the effect of GOS-OD on the binding of FITC-LPS to RAW 264.7 cell surfaces, the cells were preincubated with 2 mg/mL GOS-OD for 2 h and treated with 10 μg/mL FITC-LPS for 30 min. Then, the cells were harvested and resuspended in RPMI-1640 medium and subjected to FACS for analysis.

Immunofluorescence Analysis. To examine TLR4 expression and nuclear NF-κB in RAW 264.7 cells, cells were seeded onto glass coverslips in 6-well plates for 24 h. Then, the cells were pretreated with 2 mg/mL GOS-OD for 2 h and treated with LPS (1 μg/mL) for 1 h. Thereafter, the cells were fixed with 4.0% (w/v) paraformaldehyde at room temperature for 15 min. After three washes with PBS, the cells were permeabilized in 0.2% (v/v) Triton X-100 for 30 min and washed three times. Next, the cells were blocked in 1% (w/v) goat serum in PBS for 60 min. Then, the cells were treated with mouse monoclonal anti-TLR4 antibody or anti-NF-κB/p65 antibody diluted in 1% goat serum/PBS (1:400) overnight at 4 °C. After removal of the primary antibodies and three washings, the cells were treated with Alexa Fluor 488-conjugated secondary anti-mouse antibody/PBS (1:200) for 2 h at 37 °C. Finally, the nuclei were stained with DAPI (5 μg/mL).

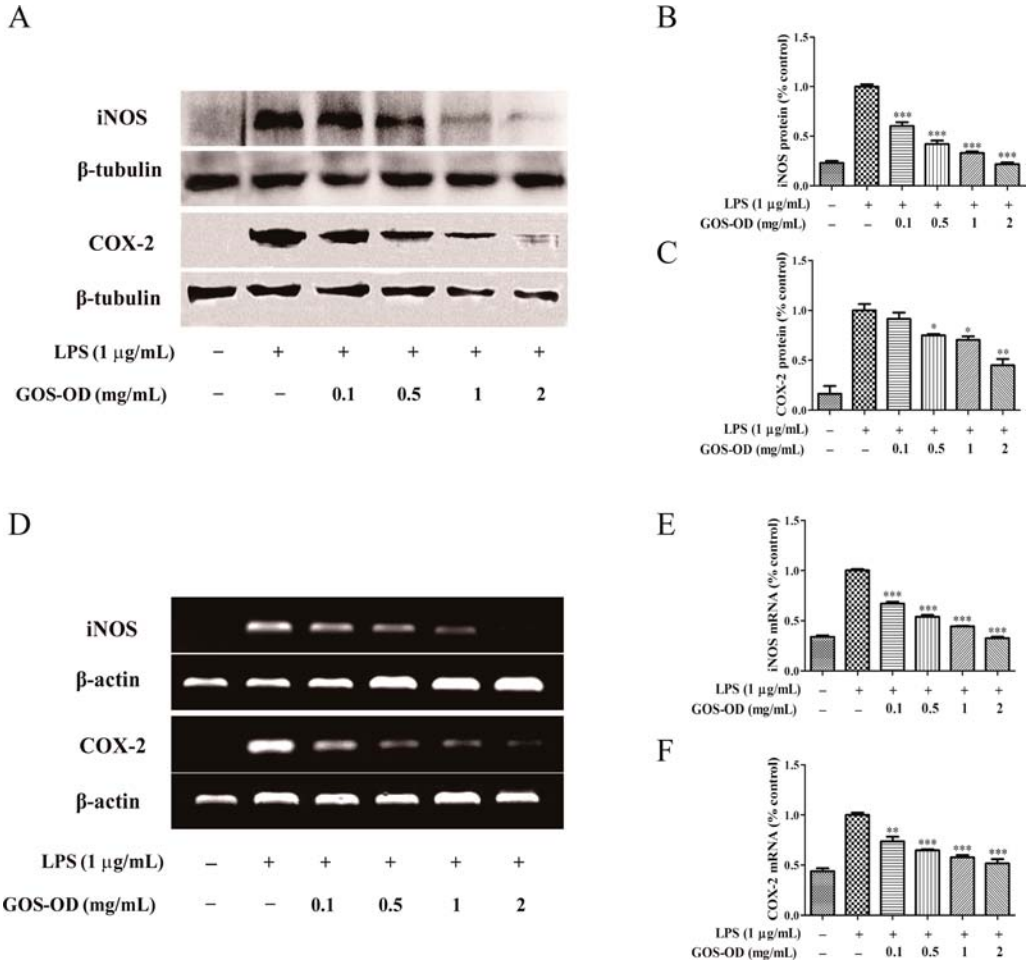

Figure 3. Effects of GOS-OD on iNOS and COX-2 expressions in LPS-activated RAW 264.7 cells. (A) Cells preincubated with 0.1−2 mg/mL GOS-OD for 2 h were treated with 1 μg/mL LPS for 24 h. The expressions of iNOS, COX-2, and β-tubulin proteins were detected by Western blot analysis. Relative iNOS (B) and COX-2 (C) protein levels were calculated with reference to the LPS-treated group. (D) Cells preincubated with 0.1−2 mg/mL GOS-OD for 2 h were treated with 1 μg/mL LPS for 12 h. Then, whole RNA was extracted for RT-PCR. Relative iNOS (E) and COX-2 (F) mRNA levels were calculated with reference to the LPS-treated group. Values are the mean ± SD of three independent experiments. (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ indicate significant differences compared to the LPS-treated group.

The immunofluorescence analysis was performed using a Fluoview FV1000 laser scanning confocal microscope (Olympus).

Cell Morphology of RAW 264.7 Cells. Dark field microscopy was performed on an upright optical microscope Olympus BX51. RAW 264.7 cells (4×10^5 cells/well) were cultured on a coverglass placed in a plastic culture dish and were pretreated with GOS-OD (1−2 mg/mL) for 2 h. After 24 h of incubation without or with LPS (1 μg/mL), the cell morphology of RAW 264.7 cells was monitored by dark field microscopy. Cell morphology was observed using a 40× objective and then captured by a color CCD camera (DP70, Olympus). The images were processed by ImageJ software.

Statistical Analysis. The data were processed as the mean ± standard deviation (SD). One-way analysis of variance (ANOVA) and Student's t tests were performed to determine any significant differences. p values <0.05 were considered to be significant.

RESULTS

Effect of Alginate Polysaccharides and Oligosaccharides on the Production of NO. We measured the effect of different types of saccharides on LPS-stimulated production of NO in RAW 264.7 cells. L-NAME is an analogue of arginine that inhibits NO production and was used as a positive control. Figure 1A shows that NO production was increased significantly by LPS treatment compared with control. Among all of the tested alginate saccharides, GOS-OD remarkably reduced the LPS-stimulated overproduction of NO as well as L-NAME treatment, whereas all other saccharides showed no statistically significant decreases. Figure 1B shows that none of the AOS, polysaccharides, or other reagents had a cytotoxic effect on RAW 264.7 cells. Thus, it is suggested that the changes in NO production may not be due to the cellular toxicity of AOS. NO-inhibitory effects have been commonly used as an indicator of the effectiveness of anti-inflammatory agents.[11,12] Thus, we focused on exploring the anti-inflammatory activity and molecular mechanisms of GOS-OD in subsequent studies.

Effect of GOS-OD on the Production of Inflammatory Mediators (NO, PGE_2, and ROS). The effect of GOS-OD on the LPS-activated secretion of NO, PGE_2, and ROS was examined. Panels A−C of Figure 2 show that GOS-OD notably suppressed the LPS-induced secretion of NO, PGE_2, and ROS at concentrations of 0.1−2 mg/mL. Cell viability results show that GOS-OD treatment with LPS stimulation did not have any cytotoxicity (Figure 2D). These results demonstrate that the inhibitory activity of GOS-OD on LPS-induced NO, PGE_2, and ROS productions cannot be induced by cytotoxic effects.

dx.doi.org/10.1021/jf503548a | J. Agric. Food Chem. 2015, 63, 160−168

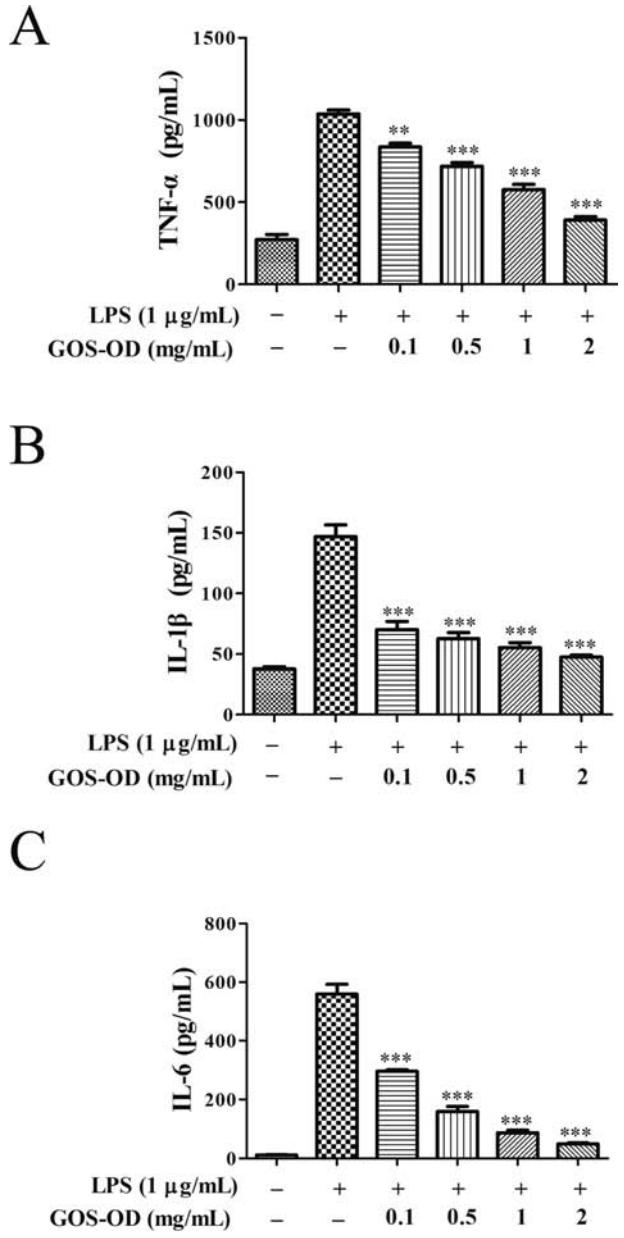

Figure 4. Effects of GOS-OD on pro-inflammatory cytokine productions in LPS-activated RAW 264.7 cells. Cells preincubated with 0.1−2 mg/mL GOS-OD for 2 h were treated with 1 μg/mL LPS for 24 h. Using an ELISA kit, TNF-α (A), IL-1β (B), and IL-6 (C) in the supernatant were detected. Values are the mean ± SD of three independent experiments. (**) $p < 0.01$ and (***) $p < 0.001$ indicate significant differences compared to the LPS-treated group.

Effect of GOS-OD on the Expression of iNOS and COX-2. It is well-established that iNOS and COX-2 are the most important enzymes for the synthesis of NO and PGE_2, respectively. Thus, the protein and gene expressions of iNOS and COX-2 were detected in LPS-activated cells. According to Western blot analysis and RT-PCR, LPS activation clearly increased the protein (Figure 3A) and mRNA (Figure 3D) expressions of iNOS and COX-2 when compared with controls in RAW 264.7 cells. However, GOS-OD prominently inhibited LPS-induced iNOS and COX-2 protein (Figure 3B,C) and mRNA (Figure 3E,F) expressions in a concentration-dependent manner.

Effect of GOS-OD on the Production of TNF-α, IL-1β, and IL-6. The effects of GOS-OD on the secretion of inflammatory cytokines, such as TNF-α, IL-1β, and IL-6, were evaluated in LPS-activated RAW 264.7 cells. As shown in Figure 4, the production of TNF-α (Figure 4A), IL-1β (Figure 4B), and IL-6 (Figure 4C) was significantly increased with LPS stimulation. However, the overproduction of TNF-α, IL-1β, and IL-6 was considerably reduced by 0.1−2 mg/mL GOS-OD treatment, indicating that GOS-OD is able to suppress the LPS-induced production of inflammatory cytokines in RAW 264.7 cells.

Effect of GOS-OD on the Binding of LPS and the Expression of TLR4 and CD14. The effect of GOS-OD on the binding of LPS to the surface of RAW 264.7 cells was examined by FITC-LPS. As shown in Figure 5A, LPS fluorescence was observed outside the cell membrane in RAW 264.7 cells when cells were stimulated with FITC-LPS alone. However, treatment with LPS in the presence of GOS-OD significantly prevented the binding of LPS to the RAW 264.7 cell surface. This phenomenon was further confirmed by FACS analysis (Figure 5B). These results indicate that GOS-OD exerts an antagonistic effect of GOS-OD against LPS binding to receptors on the cell surface, such as TLR4 and CD14. Therefore, the effect of GOS-OD on LPS-activated TLR4 and CD14 expressions was further evaluated. According to immunofluorescence results, GOS-OD pretreatment significantly blocked the LPS-induced expression of TLR4 (Figure 5C). Panels D and E of Figure 5 show that GOS-OD effectively decreased LPS-stimulated overexpression of TLR4 and CD14 proteins, respectively. Our results suggest that GOS-OD may suppress the initiation phase of LPS-activated intercellular signaling pathways by inhibiting the binding of LPS to cell surface receptors and the expressions of TLR4/CD14 on RAW 264.7 cells.

Effect of GOS-OD on the Activation of NF-κB. NF-κB is one of the crucial transcription factors that control the expression of inflammatory enzymes and inflammatory mediators.[29] Thus, the effect of GOS-OD on the activation of NF-κB was measured in LPS-activated cells using immunofluorescence microscopy and Western blot analysis. Figure 6A shows that LPS stimulation obviously induced the translocation of the NF-κB/p65 subunit from the cytosol to the nucleus, whereas GOS-OD treatment noticeably inhibited the nuclear translocation of NF-κB/p65. Similar results were found by Western blot analysis (Figure 6B).

Effect of GOS-OD on the Activation of MAP Kinases. The critical roles of MAP kinase signaling pathways in LPS-activated RAW 264.7 cells have been well established.[4] Therefore, the effect of GOS-OD on the phosphorylation levels of p38, ERK, and JNK MAP kinases was determined in LPS-activated cells (Figure 7). As expected, the LPS-induced phosphorylation of p38, ERK, and JNK MAP kinases was effectively suppressed with GOS-OD treatment. These results suggest that the LPS-stimulated activation of MAP kinases might be blocked by GOS-OD.

Reduction of LPS-Stimulated Irregular Cell Morphology by GOS-OD. We observed the effect of GOS-OD on the morphology of RAW 264.7 cells without or with LPS treatment using dark field microscopy. The control RAW 264.7 cells (Figure 8A) showed a round shape and smooth cell membrane, as did those subjected to GOS-OD treatment alone (1 and 2 mg/mL) (Figure 8B,C). However, the LPS-stimulated cells exhibited an irregular and rough form with enhanced spreading

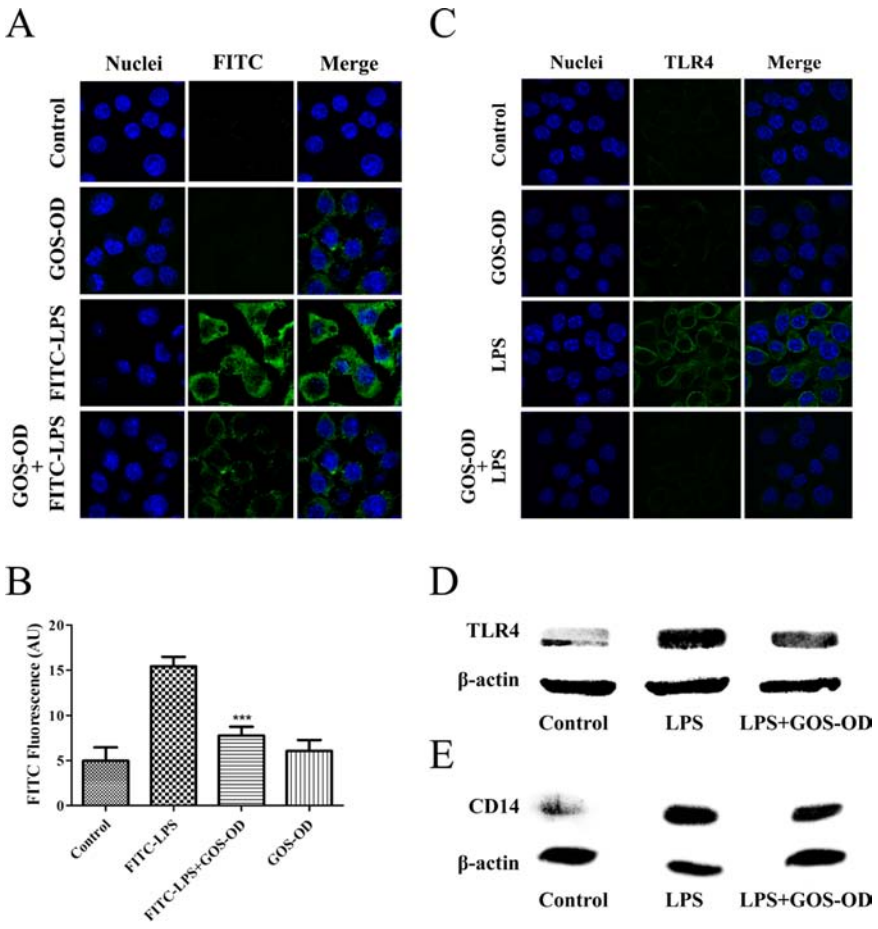

Figure 5. Effects of GOS-OD on the binding of LPS on RAW 264.7 cell surfaces and TLR4 and CD14 expressions in LPS-activated RAW 264.7 cells. (A) RAW 264.7 cells preincubated with 2 mg/mL GOS-OD for 2 h were treated with 10 μg/mL FITC-LPS for 1 h, and then the binding of LPS was detected by confocal microscopy. (B) RAW 264.7 cells preincubated with 2 mg/mL GOS-OD for 2 h were treated with 10 μg/mL FITC-LPS for 30 min, and then the binding of LPS was measured by FACS analysis. (C) RAW 264.7 cells were preincubated with 2 mg/mL GOS-OD for 2 h and then treated with 1 μg/mL LPS for 1 h. The immunofluorescence analysis was performed with anti-TLR4 antibody. DAPI was used to label the nuclei. The images were observed by confocal microscopy (60×). RAW 264.7 cells were preincubated with 2 mg/mL GOS-OD for 2 h and then treated with 1 μg/mL LPS for 24 h. TLR4 (D) and CD14 (E) protein expressions were detected by Western blot analysis. The representative images and results from three independent experiments are shown here. (***) $p < 0.001$ indicates significant differences compared to the LPS-treated group.

and reduced cell number (Figure 8D) in comparison with the control (Figure 8A). It is clear that 1 mg/mL GOS-OD pretreatment can reduce the LPS-stimulated cell morphology change (Figure 8E), with a higher inhibition effect at 2 mg/mL (Figure 8F). The cell numbers in average images were measured by using ImageJ software. We observed that LPS decreased macrophage proliferation by 50% compared with the proliferation of macrophages in control group (Figure 8G). GOS-OD did not have any effect on macrophage morphology but may act as a promoter to macrophage proliferation (Figure 8G), suggesting that GOS-OD specifically affects macrophage functions. Quantification revealed that 81.8 ± 8.7% of cells exhibited activated morphology (larger nuclei, cytoplasm with increased granularity, accelerated spreading, and forming pseudopodia) upon LPS induction and 49 ± 8.3 and 29 ± 8.3% upon GOS-OD treatment with LPS stimulation, compared to 1.2 ± 0.7% of untreated cells (Figure 8H). These results have demonstrated that GOS-OD pretreatment could reduce the LPS-stimulated irregular cell morphology.

DISCUSSION

In recent years, the anti-inflammatory activities of natural oligosaccharides have been widely studied. Chitosan oligosaccharides were found to be effective in the treatment of LPS-simulated inflammatory mediators in RAW 264.7 cells and intestinal inflammation in a mouse model through inhibition of NF-κB signaling.[16,30] Lactulose oligosaccharides showed excellent inhibition effect on pro-inflammatory cytokines such as interleukins (IL) 1, 6, and 12 in rat colitis.[14] Alginates are natural polysaccharides derived from brown seaweed.[17] AOS that are depolymerized by different methods display a wide variety of pharmacological activities; however, the anti-inflammatory activities of AOS remain uncertain. We believe this is the first work to investigate the anti-inflammatory activities of AOS depolymerized by oxidative degradation in LPS-stimulated inflammation model.

LPS-activated macrophage produces redundant inflammatory mediators (NO, PGE_2, and ROS) and pro-inflammatory cytokines (TNF-α, IL-1β, and IL-6) and serves as a general inflammation model for evaluating the anti-inflammatory activities of agents in vitro.[4,11,12] In the present work, we

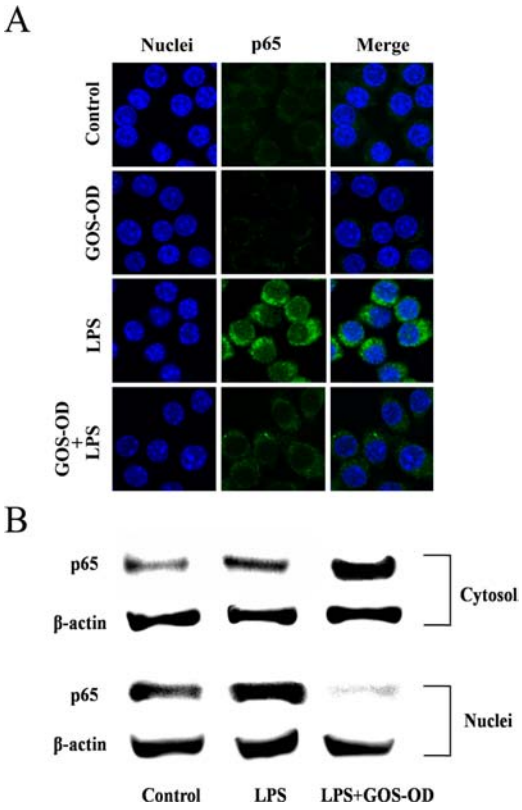

Figure 6. Effect of GOS-OD on the activation of NF-κB in LPS-activated RAW 264.7 cells. (A) Cells preincubated with 2 mg/mL GOS-OD for 2 h were treated with 1 μg/mL LPS for 1 h. The immunofluorescence analysis was performed with anti-NF-κB/p65 antibody. DAPI was used to label the nuclei. The images were captured by confocal microscopy (60×). The representative images from three independent experiments are shown here. (B) Cells preincubated with 2 mg/mL GOS-OD for 2 h were treated with 1 μg/mL of LPS for 30 min. Expression of NF-κB/p65 protein was detected by Western blot analysis. The representative Western blot bands from three independent experiments are shown here.

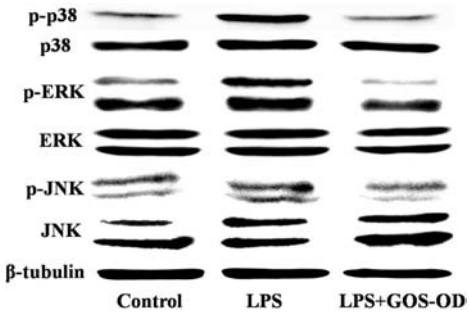

Figure 7. Effects of GOS-OD on the phosphorylation of MAP kinases. (A) Cells were preincubated with 2 mg/mL GOS-OD for 2 h and then treated with 1 μg/mL LPS for 10 min. For the detection of phosphorylated and nonphosphorylated MAP kinases, total cell lysates were extracted and measured by Western blot analysis. The representative Western blot bands from three independent experiments are shown here.

found that GOS-OD effectively suppressed the overproduction of inflammatory mediators in LPS-activated RAW 264.7 cells. In addition, the LPS-induced expression of iNOS and COX-2 mRNA was notably inhibited by GOS-OD treatment, indicating that the inhibitory activity of GOS-OD on the expression of iNOS and COX-2 proteins occurs at the pretranslational or transcriptional level.

Previous works have demonstrated that TLRs, especially TLR4, play a critical role in innate immune responses by activating the downstream signaling pathways of inflammatory responses.[5,31] CD14 is an important cofactor for TLR4-mediated signal transduction.[10] Upon binding of LPS to TLR4/CD14, the complex leads to downstream signal transduction through the NF-κB-mediated inflammatory cascade.[6] Here, we found that pretreatment with GOS-OD markedly inhibited LPS binding to the cell surface (Figure 5A,B). Then, GOS-OD was found to effectively attenuate LPS-induced TLR4 and CD14 expressions (Figure 5C−E), demonstrating that GOS-OD may inhibit the initial steps of signal transduction cascades through preventing the binding of LPS to the cell surface receptors and suppressing TLR4 and CD14 expressions in LPS-activated RAW 264.7 cells.

NF-κB and MAP kinase are the most important signaling pathways in LPS-stimulated inflammatory responses.[4,32,33] NF-κB transcription factor is retained in an inactive form in the cytoplasm by interaction with IκB proteins. Activation of NF-κB leads to phosphorylation of IκB proteins and induces the nuclear translocation of NF-κB/p65 units and transcription of target genes.[29] In this work, we observed that preincubation with GOS-OD could effectively reverse the LPS activated nuclear translocation of NF-κB/p65 (Figure 6), indicating that GOS-OD may affect the degradation and phosphorylation of IκB proteins. Furthermore, evidence has shown that MAP kinase signaling pathways are involved in the production of inflammatory mediators and the expression of iNOS and COX-2 proteins in LPS-activated RAW 264.7 cells through NF-κB activation.[34,35] Thus, the inhibitory activity of MAP kinases may be another important molecular mechanism to study in anti-inflammation. Western blot analysis shows that the phosphorylation of p38, ERK, and JNK MAP kinases induced by LPS was remarkably attenuated with GOS-OD treatment (Figure 7). These findings suggest that the inhibitory activity of GOS-OD on the activation of the MAP kinase signaling pathway may involve the GOS-OD-mediated suppression of NF-κB signaling pathway in LPS-induced RAW 264.7 cells.

Our previous study found that GOS-ED effectively induced NO production and that other AOS showed very low or no such activities.[21] However, we found that GOS-OD was a stronger inhibitor of NO production than other AOS in this work. These results indicate that the structure of AOS plays an important role in their activities. GOS-OD, which has a carboxyl group at the 1-position of the reducing end,[25] differs in structure from AOS-ED and AOS-AH. The existence of the carboxyl group may play an important role in the inhibitory effect of GOS-OD on LPS-stimulated NO production. In conclusion, GOS-OD was found to effectively suppress the overproduction of inflammatory mediators (NO, PGE_2, and ROS), inflammatory proteins (iNOS and COX-2), and pro-inflammatory cytokines (TNF-α, IL-1β, and IL-6) in a dose-dependent manner in LPS-activated RAW 264.7 cells. Additionally, GOS-OD inhibited the binding of LPS to the cell surface and attenuated LPS-induced TLR4 and CD14 expressions. Finally, we demonstrated that the anti-inflammatory activity of GOS-OD may be attributed to the suppressed activation of NF-κB and MAP kinase signaling pathways. Therefore, in the future, GOS-OD may be developed as a potential nutraceutical for inflammatory-mediated diseases.

Phytochemical Profiles and Antioxidant Activity of Different Varieties of *Adinandra* Tea (*Adinandra* Jack)

Yongsheng Chen,[†] Gu Chen,*[,†] Xiong Fu,[†] and Rui-Hai Liu*[,†,‡]

[†]College of Light Industry and Food Sciences, South China University of Technology, 381 Wushan Road, Guangzhou, Guangdong 510641, People's Republic of China

[‡]Department of Food Science, Cornell University, Ithaca, New York 14853, United States

ABSTRACT: Consumption of plant foods has been negatively associated with the risk of developing chronic diseases, which is partly attributed to their rich and diverse phytochemicals. To promote the rational and effective application of *Adinandra* tea (*Adinandra* Jack), a traditional Chinese tea (Shiyacha) widely consumed as a health beverage, the complete phytochemical profile and antioxidant activity of four varieties of *Adinandra* tea were analyzed. They were rich in phenolics and flavonoids, ranging from 71.29 to 140.54 mg of gallic acid equivalent/g and from 19.13 to 88.72 mg of catechin equivalent/g, respectively. Their antioxidant capacities were high, as revealed by oxygen radical absorbance capacity, peroxyl radical scavenging capacity, and cellular antioxidant activity (CAA) assays. An obvious antiproliferation effect was observed in HepG2 and MCF-7 cells, with EC_{50} ranging from 1.05 to 6.44 mg/mL and from 2.26 to 8.02 mg/mL, respectively. Among the four varieties compared, Nitida and Millettii had a higher CAA value and antiproliferation activity, while Latifolia contained considerable bound phenolics.

KEYWORDS: *Adinandra tea, phytochemicals, phenolics, flavonoids, antioxidant activity, antiproliferation activity*

INTRODUCTION

Epidemiological and interventional studies have shown that regular consumption of fruits, vegetables, whole grain, and other plant foods is negatively associated with the risk of developing chronic diseases.[1−3] The health benefits of plant foods are partly attributed to their rich and diverse phytochemicals, such as phenolics, carotenoids, alkaloids, etc.[4,5] Therefore, consumers are suggested to obtain nutrients and bioactive compounds from a wide variety of plant foods for optimal nutrition and health benefits.[2,4] Tea beverage rich in phytochemicals is a good source for dietary phytochemicals.[6]

Adinandra tea, famous as Shiyacha in Chinese, is a traditional Chinese tea consumed widely in south China. Different from tea of the tropical evergreen plant *Camellia sinensis*, *Adinandra* tea is an infusion made from leaves picked from plants belonging to *Adinandra* Jack. *Adinandra* tea has been consumed as a health tea beverage in China for hundreds of years and is reported to have many curative effects, such as reduction of blood pressure, anti-inflammatory, antibacterial, antitumor, antitoxic, and analgesic effects.[7,8] Over the past few decades, limited reports have been published about *Adinandra* tea. Chemical analysis of *Adinandra nitida* revealed that it was rich in flavonoids, such as camellianin A, camellianin B, and apigenin,[9−14] with high 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging activity.[10] An antiproliferative effect of camellianin A, camellianin B, and apigenin from *A. nitida* was reported in cancer cell lines, such as A431,[15] HepG2, and MCF-7[16] cells, although their mechanism remained elusive. However, thus far, there is no report on the phytochemical profiles and antioxidant activity of different varieties of *Adinandra*. Therefore, we performed the following studies to (1) determine the phytochemical profiles of four *Adinandra* varieties, namely, *Adinandra nitida* Merr. ex H. L. Li, *Adinandra glischroloma* Hand.-Mazz. var. *jubata* (H. L. Li) Kobuski, *Adinandra millettii* (Hook. & Arn.) Benth. & Hook. f. ex Hance, and *Adinandra latifolia* L. K. Ling, hereafter as Nitida, Jubata, Millettii, and Latifolia, respectively, (2) analyze the total antioxidant activity of four varieties *in vitro* and *in vivo*, and (3) compare the antiproliferation activity of four varieties on HepG2 and MCF-7 cells. Results here may contribute to the more rational and effective application and use of *Adinandra* tea.

MATERIALS AND METHODS

Chemicals and Reagents. Catechin, 2,6-dichloroindophenol sodium salt hydrate, chloranil, 2,2′-azobis-amidinopropane (ABAP), Folin−Ciocalteu reagent, gallic acid, and dichlorofluorescin diacetate (DCFH-DA) were purchased from Sigma (St. Louis, MO). Vanillin was purchased from Aladdin (Shanghai, China). Williams' medium E (WME), insulin, and other cell culture reagents were purchased from Gibco U.S. Biotechnology Co. The other chemicals were purchased from Sangon (Shanghai, China).

***Adinandra* Samples and Sample Preparation.** Four *Adinandra* varieties used are described in Table 1. Samples of Nitida and Jubata were obtained from Shiwandashan and authenticated by the Guangxi Institute of Chinese Medicine and Pharmaceutical Science. Samples of Latifolia and Millettii were supplied by the Kunming Institute of Botany, Chinese Academy of Sciences, and the Institute of Environmental Protection and Design, Huaqiao University, respectively. Samples were collected in autumn of 2013 and stored at −25 °C until use.

Extraction of Free Phenolic Compounds. Free phenolic compounds in *Adinandra* samples were extracted using the method reported previously.[17,18] Briefly, 2 g of samples were blended with 150 mL of 80% chilled acetone for 5 min and then homogenized for 5 min. After centrifugation at 4500 rpm for 10 min, residue was extracted 2

Table 1. Descriptions of the Four *Adinandra* Varieties Used in This Study

variety	description	moisture content (%)
Nitida	no hair, normal size leaves, long pedicel (10−20 cm)	12.64
Jubata	stem and leaves densely covered with long and bristle-like hairs, normal size leaves	11.59
Millettii	no hair, normal size leaves, short pedicel (2 cm)	16.55
Latifolia	no hair, large leaves, short pedicel (1 cm)	19.08

more times. Pooled supernatants were filtered through filter paper and evaporated at 45 °C. The extract was finally reconstituted with water to 10 mL and stored at −40 °C until use.

Extraction of Bound Phenolic Compounds. Bound phenolics in *Adinandra* samples were extracted using the method reported previously.[18,19] Briefly, the residue of the free phenolic compound extraction were flushed with nitrogen gas, sealed, and digested with 20 mL of 4 M sodium hydroxide at room temperature for 90 min with shaking. The mixture was acidified with hydrochloric acid to pH 2.0 and extracted 10 times with ethyl acetate. Pooled ethyl acetate fractions were evaporated at 45 °C to dryness. The extract were reconstituted in 10 mL of water and stored at −40 °C until use.

Determination of the Phenolic Content. The total phenolic content in extract was determined using the modified Folin−Ciocalteu colorimetric method.[20,21] Gallic acid was used as a standard, and the total phenolic content was expressed as milligrams of gallic acid equivalent per gram of dry weight (DW). Briefly, diluted extracts or standard were mixed with Folin−Ciocalteu reagent for 6 min and then neutralized by sodium carbonate. The absorbance of the resulting solution was measured at 760 nm after 90 min of incubation.

Determination of the Flavonoid Content. The total flavonoid content was determined using the sodium borohydride/chloranil protocol (SBC) developed by our group.[22] Catechin was used as a standard, and the total flavonoid content was expressed as milligrams of catechin equivalent per gram of DW. Briefly, extracts were dried under nitrogen gas and reconstituted in 1 mL of terahydrofuran/ethanol (THF/EtOH, 1:1, v/v). Catechin hydrate standard was prepared fresh in 1 mL of THF/EtOH (1:1, v/v). Extracts or standard were mixed with 0.5 mL of 50 mM $NaBH_4$ solution and 0.5 mL of 74.6 mM $AlCl_3$ solution. Then, they were shaken in an orbital shaker at 180 rpm at room temperature for 30 min. An additional 0.5 mL of 50.0 mM $NaBH_4$ solution was added with shaking continued for another 30 min. Chilled 2.0 mL of 0.8 M acetic acid solution was added and kept in the dark for 15 min after being thoroughly mixed. Then, 1 mL of 20.0 mM chloranil was added and heated at 99 °C with shaking for 60 min. The reaction solutions were cooled using tap water, and the volume was brought to 4 mL using methanol. Then, 1 mL of 16% (w/v) vanillin was added and mixed. A total of 2 mL of 12 M HCl was added and kept in the dark for 15 min after a thorough mix. After centrifugation at 2500 rpm for 10 min, the absorbance of the supernatant was immediately measured at 490 nm.

Quantification of the Total Antioxidant Activity by the Oxygen Radical Absorbance Capacity (ORAC) Assay. The total antioxidant activity was determined using the ORAC assay described by Huang et al. and modified by our group.[23,24] Briefly, 20 μL extracts or Trolox were mixed with 200 μL of fluorescein (final concentration of 0.96 μM) and incubated at 37 °C for 20 min. Then, 20 μL of freshly prepared 119.4 mM ABAP was added to each well using an eight-channel pipetter. The fluorescence was measured immediately at 485 nm excitation and 535 nm emission for 35 cycles every 4.5 min using a Fluoroskan Ascent fluorescent spectrophotometer (Molecular Devices, Sunnyvale, CA) at 37 °C. Using a standard curve of Trolox, ORAC values were presented as micromoles of Trolox equivalent (TE) per gram of DW of the sample.

Determination of the Total Antioxidant Activity by the Peroxyl Radical Scavenging Capacity (PSC) Assay. The total antioxidant activity was measured using the PSC assay.[25] Peroxyl radicals generated by thermal degradation of ABAP can oxidize non-fluorescent DCFH to fluorescent dichlorofluorescein (DCF). The antioxidant activity of antioxidants to scavenge peroxyl radicals was calculated on the basis of the reduction of DCF fluorescence in the reaction. DCFH-DA was prehydrolyzed with 1 mM KOH to remove the diacetate moiety just prior to use. Fluorescence was monitored at 485 nm excitation and 535 nm emission with a Fluoroskan Ascent fluorescent spectrophotometer (Molecular Devices, Sunnyvale, CA). Vitamin C was used as a standard, and results were presented as micromoles of vitamin C equivalent per gram of sample.

Cell Culture. Human liver cancer cells HepG2, grown in WME [supplemented with 5% fetal bovine serum (FBS), 10 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES), 2 mM L-glutamine, 5 μg/mL insulin, 0.05 μg/mL hydrocortisone, 50 units/mL penicillin, 50 μg/mL streptomycin, and 100 μg/mL gentamycin], were maintained at 37 °C and 5% CO_2. Human breast cancer cells MCF-7 were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 50 units/mL penicillin, 50 μg/mL streptomycin, 100 μg/mL gentamicin, and 10% FBS at 37 °C and 5% CO_2.

Cellular Antioxidant Activity (CAA) of *Adinandra* Extracts and CAA Quantification. The CAA assay was performed as previously described.[26] Briefly, HepG2 cells were seeded at a density of 6×10^4 cells/well in a 96 well microplate. At 24 h after seeding, the growth medium was removed and the wells were washed with PBS. Then, the cells were treated for 1 h with 100 μL of medium containing *Adinandra* extracts plus 50 μM DCFH-DA. Certain wells were washed with 100 μL of phosphate-buffered saline (PBS) (PBS wash protocol), and certain wells were not washed (no PBS wash protocol). ABAP (600 μM) in 100 μL of Hanks' Balanced Salt Solution (HBSS) was added to the cells. PBS wash protocol indicated that cells were pretreated with *Adinandra* extracts before ABAP was added, and no PBS wash indicated that cells were co-treated with *Adinandra* extracts and ABAP. Fluorescence was monitored at 485 nm excitation and 535 nm emission every 5 min for 13 circles using a Fluoroskan Ascent fluorescent spectrophotometer (Molecular Devices, Sunnyvale, CA) at 37 °C. It was calculated as CAA (units) = $1 - (\int SA/\int CA)$, where $\int SA$ is the integrated area under the fluorescence versus time curve of the sample and $\int CA$ is the integrated area under the fluorescence versus time curve of the control. The median effective dose (EC_{50}) of the *Adinandra* extracts was calculated from the median effect plot of $\log(f_a/f_u)$ versus log(dose), where f_a is the fraction affected by the treatment (CAA unit) and f_u is the fraction unaffected by the treatment (1 − CAA unit). The EC_{50} values were expressed as the mean ± standard deviation (SD) of triplicate data obtained from the same experiment. EC_{50} values were converted to CAA values, which were expressed as micromoles of quercetin equivalent (QE) per 100 g of *Adinandra* extracts, using the mean EC_{50} value for quercetin from three separate experiments.

Antiproliferation Test. The antiproliferative effects of *Adinandra* extracts were assessed as previously described.[27] Briefly, cells were seeded at a density of 2.5×10^4 calls/well in the central wells of the 96 well microplate. After 4−6 h of incubation to allow for sufficient attachment, growth medium was changed to 100 μL of fresh medium containing different concentrations of *Adinandra* extracts. The wells receiving fresh medium without extracts served as the control. After 72 h of incubation, the number of the viable cells were counted by the methylene blue assay.[28] The antiproliferative effects were assessed by the EC_{50} values, which were expressed as milligrams of *Adinandra* extracts per milliliter.

High-Performance Liquid Chromatography (HPLC) Analysis. On the basis of the method reported previously,[29] phenolic compounds of *Adinandra* extracts were separated in a Waters C_{18} column (5 μm, 250 × 4.6 mm) on a Waters HPLC system (Waters Corp., Milford, MA). The binary mobile phase consisted of solvents A (acidified water at pH 2 and trifluoroacetic acid) and B (methanol).

The mobile-phase gradient used was 0−10 min, 35% B; 10−11 min, 35−45% B; 11−26 min, 45−55% B; 26−27 min, 55−72% B; 27−40 min, 72−100% B; 40−44 min, 100−35% B; and 44−50 min, 35% B. The injection volume was 20 μL for each sample, and the flow rate was 1.0 mL/min. The peaks were identified by their retention times by comparing the ultraviolet−visible (UV−vis) spectra. Pure standards used for the identification were quercitrin, camellianin A, camellianin B, and apigenin. The recovery rates of camellianin B, quercitrin, camellianin A, and apigenin were 108.16 ± 7.19, 92.68 ± 6.17, 97.56 ± 2.54, and 102.30 ± 2.00% from the extracts, respectively. The contents of quercitrin, camellianin A, camellianin B, and apigenin were determined and expressed as milligrams per gram of DW according to the standard curve.

Statistical Analysis. Data were presented as the mean ± SD from at least three replicates per samples. Analysis of variation (ANOVA) and Tukey's test were performed using SPSS (SPSS, Inc., Chicago, IL), and dose−effect analysis was performed using Calcusyn software, version 2.0 (Biosoft, Cambridge, U.K.). Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Phenolic Content of *Adinandra* Varieties. Expressed as milligrams of gallic acid equivalent per gram of sample on a DW basis, the free, bound, and total phenolic contents of four *Adinandra* varieties are shown in Figure 1. The highest free

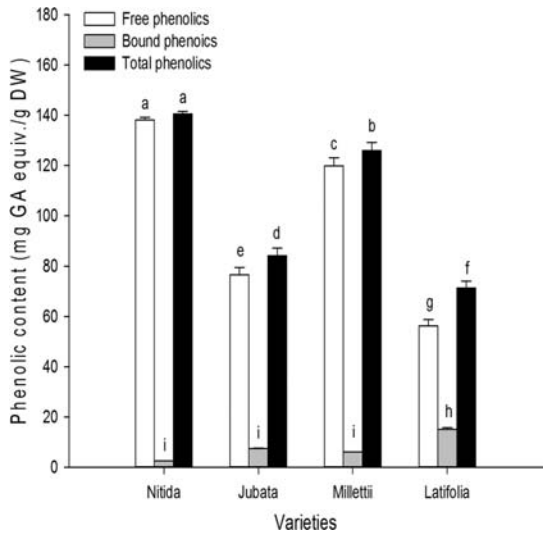

Figure 1. Free, bound, and total phenolic contents of the four *Adinandra* varieties. Bars with different letters differ significantly at $p < 0.05$.

phenolic content was found in Nitida (138.09 ± 1.08 mg/g), followed by Millettii (119.89 ± 3.14 mg/g), and then Jubata (76.62 ± 2.89 mg/g). Latifolia had the lowest free phenolic content (56.25 ± 2.52 mg/g). There were significant differences in the free phenolic contents among the four *Adinandra* varieties ($p < 0.05$). The highest bound phenolic content was observed in Latifolia (15.04 ± 0.65 mg/g), followed by Jubata (7.52 ± 0.08 mg/g), and then Millettii (6.07 ± 0.05 mg/g). Nitida had the lowest bound phenolic content (2.45 ± 0.05 mg/g). Overall, the bound phenolic content was significantly lower than the free phenolics. Therefore, the highest total phenolics were found in Nitida (140.54 ± 1.04 mg/g), followed by Millettii (125.96 ± 3.19 mg/g), and then Jubata (84.14 ± 2.97 mg/g). Latifolia had the lowest total phenolic content (71.29 ± 2.69 mg/g). The differences of total phenolics were significant among the four varieties ($p < 0.05$).

Although the contribution of bound phenolics to total phenolics might be ignored in Nitida (1.74%) and quite small in Millettii (4.82%) and Jubata (8.94%), it accounted for about one-fifth of the total phenolics in Latifolia (21.09%). It is suggested that the bound phytochemicals are resistant to digestion in the stomach and small intestine, and they may reach and be released in the colon after fermented by gut micribiota.[30] Here, the relatively high percentage of bound phenolics in Latifolia might have similar application.

Flavonoid Content of *Adinandra* Varieties. Expressed as milligrams of catechin equivalent per gram of samples on a DW basis, the free, bound, and total flavonoid contents of *Adinandra* varieties were shown in Figure 2. The free flavonoid content of

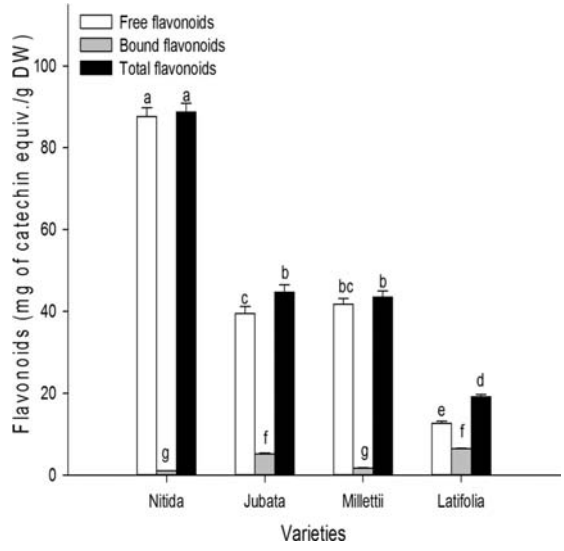

Figure 2. Free, bound, and total flavonoid contents of the four *Adinandra* varieties. Bars with different letters differ significantly at $p < 0.05$.

Nitida (87.66 ± 2.17 mg/g) was higher ($p < 0.01$) than those of the other varieties. The free flavonoid contents of Jubata (39.54 ± 1.66 mg/g) and Millettii (41.85 ± 1.43 mg/g) were similar ($p > 0.05$) and higher ($p < 0.05$) than that of Latifolia (12.64 ± 0.54 mg/g). For the bound flavonoid content, both Jubata (5.20 ± 0.25 mg/g) and Latifolia (6.49 ± 0.10 mg/g) had higher contents ($p < 0.05$) than Nitida (1.06 ± 0.05 mg/g) and Millettii (1.72 ± 0.08 mg/g). There was no significant difference in bound flavonoid contents between Jubata and Latifolia or between Nitida and Millettii. The contribution of bound flavonoid to total flavonoid contents was ignorable in Nitida (1.19%) and Millettii (3.95%), but it was 11.62% in Jubata and 33.92% in Latifolia. The total flavonoid content was highest ($p < 0.01$) in Nitida (88.72 ± 2.13 mg/g). The total flavonoid contents of Jubata (44.74 ± 1.79 mg/g) and Millettii (43.54 ± 1.48 mg/g) were similar ($p > 0.05$) and both higher ($p < 0.05$) than that of Latifolia (19.13 ± 0.54 mg/g).

Percentage Contribution of Flavonoids to Phenolics. On the basis of a micromole basis, the percentage contribution of flavonoids to phenolics was calculated and presented in Figure 3. The contributions of free flavonoids to free phenolics and bound flavonoids to bound phenolics ranged from 13.2 to 37.21% and from 16.6 to 40.51%, respectively. Total flavonoids accounted for 15.75 to 37% of the total phenolics, indicating flavonoids were one of the major phenolics in *Adinandra*. The contribution of free flavonoids to free phenolics was the highest

dx.doi.org/10.1021/jf503700v | J. Agric. Food Chem. 2015, 63, 169−176

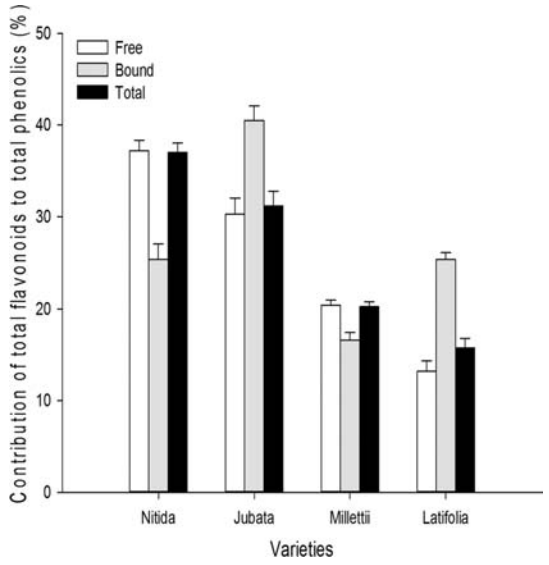

Figure 3. Percent contribution of flavonoids to phenolics (mean ± SD; n = 3).

in Nitida (37.21%), followed by Jubata (30.28%), and then Millettii (20.44%), while it was lowest in Latifolia (13.2%). The contribution of bound flavonoids to bound phenolics was highest in Jubata (40.51%), followed by Nitida (25.32%), and Latifolia (25.31%), while it was lowest in Millettii (16.6%). The contribution of total flavonoids to total phenolics was highest in Nitida (37%), followed by Jubata (31.19%), and then Millettii (20.26%), while it was lowest in Latifolia (15.75%).

***In Vitro* Antioxidant Activity Measured by ORAC and PSC.** The *in vitro* antioxidant activities were evaluated by ORAC and PSC assays. Expressed as micromoles of TE per gram of sample DW, the ORAC values of *Adinandra* are shown in Figure 4. Free phenolic extracts of Nitida had the highest ORAC value (2170.1 ± 197.22 μM TE/g of DW), followed by Latifolia (585.76 ± 53.21 μM TE/g of DW), Millettii (452.46 ± 72.38 μM TE/g of DW), and then Jubata (358.63 ± 25.18 μM TE/g of DW). The ORAC value of bound phenolic extract was highest in Latifolia (156.75 ± 11.34 μM TE/g of DW),

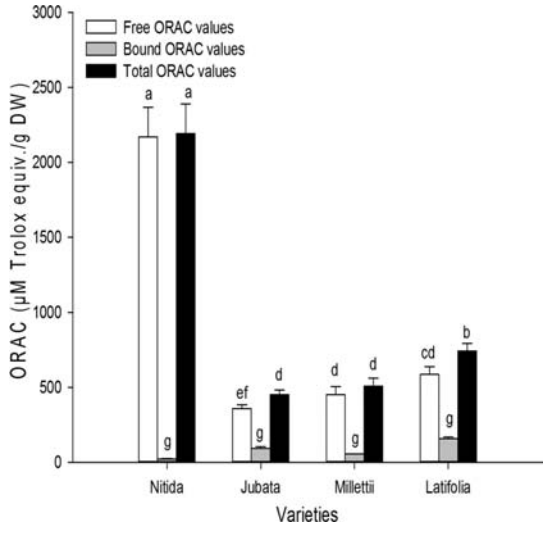

Figure 4. ORAC values of the four *Adinandra* varieties (mean ± SD; n = 3). Bars with different letters differ significantly at $p < 0.05$.

followed by Jubata (93.00 ± 11.59 μM TE/g of DW), Millettii (54.96 ± 1.04 μM TE/g of DW), and then Nitida (21.25 ± 3.53 μM TE/g of DW). Although the bound ORAC value accounted for only 0.97% of the total ORAC value in Nitida, their contributions should not be ignored in the total ORAC value of Millettii (10.83%), Jubata (20.59%), and Latifolia (21.11%). The total ORAC value of Nitida (2191.4 ± 199.43 μM TE/g of DW) was the highest ($p < 0.01$) of the varieties tested. The total ORAC values of Jubata (451.64 ± 30.63 μM TE/g of DW) and Millettii (507.42 ± 54.41 μM TE/g of DW) were similar ($p > 0.05$) but lower ($p < 0.05$) than that of Latifolia (742.51 ± 51.36 μM TE/g of DW).

The PSC value was expressed as micromoles of vitamin C equivalent per gram of sample DW. The PSC values of *Adinandra* varieties were presented in Figure 5. Free phenolic

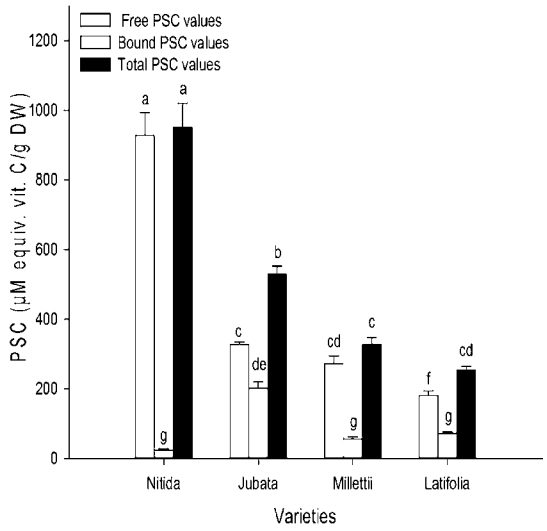

Figure 5. PSC values of the four *Adinandra* varieties (mean ± SD; n = 3). Bars with different letters differ significantly at $p < 0.05$.

extracts of Nitida had the highest PSC value (927.23 ± 66.93 μM vitamin C/g of DW), followed by Jubata (327.57 ± 6.65 μM vitamin C/g of DW), Millettii (272.19 ± 22.36 μM vitamin C/g of DW), and then Latifolia (181.44 ± 12.34 μM vitamin C/g of DW). The PSC value of bound phenolic extract was highest in Jubata (201.20 ± 18.50 μM vitamin C/g of DW), followed by Latifolia (71.75 ± 4.60 μM vitamin C/g of DW), Millettii (55.85 ± 5.82 μM vitamin C/g of DW), and then Nitida (24.05 ± 3.21 μM vitamin C/g of DW). The contribution of the bound PSC value to the total PSC value in Nitida was as small as 2.53%. However, the contribution of bound PSC values to the total PSC value in Millettii (17.03%), Latifolia (28.34%), and Jubata (38.05%) should not be underestimated. The total PSC value of Nitida (951.28 ± 70.13 μM vitamin C/g of DW) was the highest ($p < 0.01$) of the varieties tested. The total PSC values of Latifolia (253.19 ± 10.82 μM vitamin C/g of DW) and Millettii (328.04 ± 19.73 μM vitamin C/g of DW) were similar ($p > 0.05$) but lower ($p < 0.05$) than that of Jubata (528.77 ± 22.60 μM vitamin C/g of DW). The highest total PSC value was found in Nitida (Figure 5), which was consistent with the highest total phenolics, flavonoids, and total ORAC values observed in Nitida (Figures 1, 2, and 4). There were significant correlations between PSC values and total phenolics (R^2 = 0.800; $p < 0.05$) and between PSC values and total flavonoids (R^2 = 1.000; $p < 0.01$). This

Table 2. Average Phytochemical Content, ORAC, and PSC Values of the Four *Adinandra* Varieties

	free	bound	total
phenolics (mg of gallic acid equiv./g of DW)	97.71 ± 34.26	7.77 ± 4.80	105.48 ± 29.96
flavonoids (mg of catechin equiv./g of DW)	45.42 ± 28.19	3.62 ± 2.39	49.03 ± 26.24
ORAC (μmol of TE/g of DW)	891.74 ± 780.77	81.49 ± 53.04	973.24 ± 749.01
PSC (μmol of vitamin C equiv./g of DW)	427.11 ± 308.0	88.21 ± 70.98	515.32 ± 285.08

revealed that total phenolics and flavonoids had significant contribution to the PSC values of the samples tested.

The average phenolic and flavonoid content, ORAC, and PSC values of the four *Adinandra* varieties were analyzed and presented as the mean ± SD in Table 2. On average, *Adinandra* varieties had high phenolic content (105.48 ± 29.96 mg of gallic acid equiv./g of DW) and flavonoid content (49.03 ± 26.24 mg of catechin equiv./g of DW). Their antioxidant activities were also high in the ORAC value (973.24 ± 749.01 μmol of TE/g of DW) and the PSC value (515.32 ± 285.08 μmol of vitamin C equiv./g of DW). However, the big standard deviations indicated the diversity among these four varieties.

***In Vivo* Antioxidant Activity Measured by CAA.** The antioxidant activity of free phenolic extracts was further measured *in vivo* by the CAA assay. *Adinandra* extracts inhibited the increase in fluorescence from the formation of DCF in a dose-dependent manner, whether the cells had been washed with PBS or not between the antioxidant and the ABAP treatments. As shown in Figure 6, the EC_{50} values of four

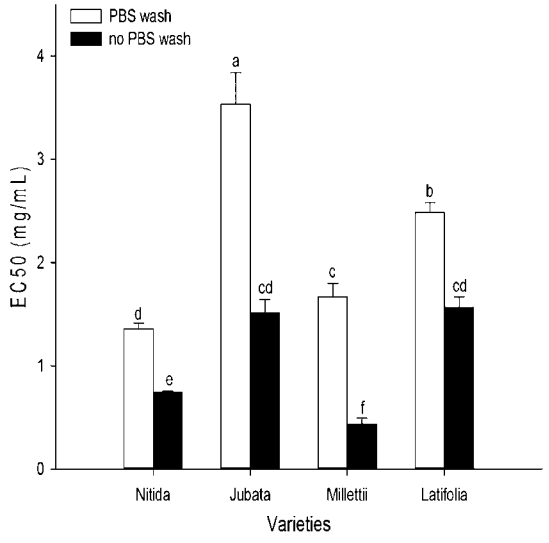

Figure 6. EC_{50} of free phenolic extracts from four *Adinandra* varieties (mean ± SD; $n = 3$). Bars with different letters differ significantly at $p < 0.05$.

varieties ranged from 0.43 to 1.56 mg/mL in the no PBS wash protocol and from 1.35 to 3.53 mg/mL in the PBS wash protocol. In the no PBS wash protocol, Millettii had the lowest EC_{50} values (430.87 ± 62.57 μg/mL), followed by Nitida (744.58 ± 10.65 μg/mL), Jubata (1509.4 ± 135.20 μg/mL), and then Latifolia (1562.8 ± 106.32 μg/mL). In the PBS wash protocol, which focused more on the intracellular antioxidant activity, Nitida had the lowest EC_{50} values (1359.3 ± 56.75 μg/mL), followed by Millettii (1668.2 ± 132.97 μg/mL), and then Latifolia (2482.2 ± 97.11 μg/mL). Jubata had the highest EC_{50} values (3533.2 ± 304.85 μg/mL).

On the basis of the comparison of EC_{50} values of samples and quercetin, the CAA value was expressed as micromoles of QE per 100 g of *Adinandra* and shown in Figure 7. CAA values

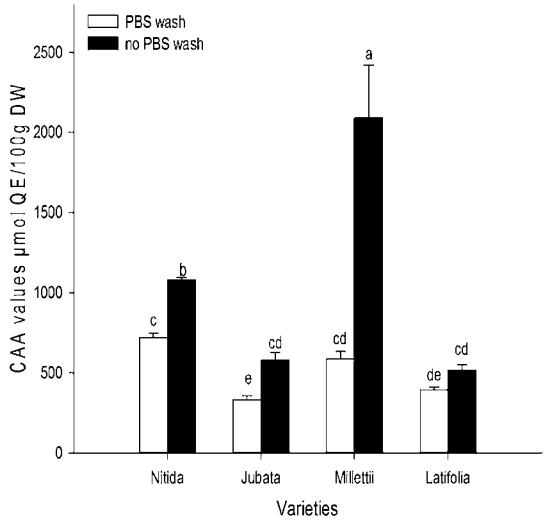

Figure 7. CAA values of the free phenolic extracts from four *Adinandra* varieties (mean ± SD; $n = 3$). Bars with different letters differ significantly at $p < 0.05$.

ranged from 516.06 to 2090.0 μmol of QE/100 g in the no PBS wash protocol and from 331.13 to 722.29 μmol of QE/100 g in the PBS wash protocol. In the no PBS wash protocol, Millettii had the highest CAA value (2090.0 ± 330.95 μmol of QE/100 g), followed by Nitida (1080.1 ± 15.36 μmol of QE/100 g). Jubata (580.31 ± 50.06 μmol of QE/100 g) and Latifolia (516.06 ± 33.89 μmol of QE/100 g) had lower CAA values. In the PBS wash protocol, Nitida (722.29 ± 29.71 μmol of QE/100 g) had the highest CAA value, followed by Millettii (587.26 ± 45.77 μmol of QE/100 g), Latifolia (395.49 ± 15.83 μmol of QE/100 g), and then Jubata (331.13 ± 27.64 μmol of QE/100 g).

The CAA assay reflects the absorption, metabolism, and distribution of antioxidants at the cellular level, and it is more accurate in evaluation of cellular antioxidant activity.[26,31] The CAA values were negatively correlated with EC_{50} values. Regardless of the protocol and expression method used, Nitida and Millettii showed higher antioxidant activity, which was consistent with higher phenolic contents in Nitida and Millettii (Figure 1).

The cellular antioxidant quality of free phenolic extracts was calculated from their CAA values, phenolic contents, and flavonoid contents and expressed as micromoles of QE per 100 μmol of flavonoids or phenolics. In the no PBS wash protocol, Millettii had the highest CAA value relative to the free phenolics (2.97 ± 0.47 μmol of QE/100 μmol of free phenolics), followed by Latifolia (1.56 ± 0.10 μmol of QE/100 μmol of free phenolics), Nitida (1.33 ± 0.019 μmol of QE/100 μmol of free phenolics), and Jubata (1.29 ± 0.11 μmol of

dx.doi.org/10.1021/jf503700v | J. Agric. Food Chem. 2015, 63, 169−176

Table 3. Cellular Antioxidant Quality of the Four *Adinandra* Varieties

variety	CAA quality of free phenolics (μmol of QE/100 μmol of phenolics)		CAA quality of free flavonoids (μmol of QE/100 μmol of flavonoids)	
	no PBS wash	PBS wash	no PBS wash	PBS wash
Nitida	1.33 ± 0.019	0.89 ± 0.037	3.58 ± 0.051	2.39 ± 0.098
Jubata	1.29 ± 0.11	0.74 ± 0.061	4.26 ± 0.37	2.43 ± 0.20
Millettii	2.97 ± 0.47	0.83 ± 0.065	14.50 ± 2.30	4.08 ± 0.32
Latifolia	1.56 ± 0.10	1.20 ± 0.048	11.84 ± 0.78	9.07 ± 0.36

QE/100 μmol of free phenolics). Millettii also had the highest CAA value relative to the free flavonoids (14.50 ± 2.30 μmol of QE/100 μmol of free flavonoids), followed by Latifolia (11.84 ± 0.78 μmol of QE/100 μmol of free flavonoids), Jubata (4.26 ± 0.37 μmol of QE/100 μmol of free flavonoids), and Nitida (3.58 ± 0.051 μmol of QE/100 μmol of free flavonoids). In the PBS wash protocol, Latifolia had the highest CAA value relative to the free phenolics (1.20 ± 0.048 μmol of QE/100 μmol of free phenolics), followed by Nitida (0.89 ± 0.037 μmol of QE/100 μmol of free phenolics), Millettii (2.97 ± 0.47 μmol of QE/100 μmol of free phenolics), and Jubata (0.74 ± 0.061 μmol of QE/100 μmol of free phenolics). Latifolia also had the highest CAA value relative to the free flavonoids (9.07 ± 0.36 μmol of QE/100 μmol of free flavonoids), followed by Millettii (4.08 ± 0.32 μmol of QE/100 μmol of free flavonoids), Jubata (2.43 ± 0.20 μmol of QE/100 μmol of free flavonoids), and Nitida (2.39 ± 0.098 μmol of QE/100 μmol of free flavonoids).

Inhibition of Proliferation in Human Cancer Cells. The antiproliferation effects of free phenolic extract from four varieties were tested against liver cancer cell HepG2 and breast cancer cell MCF-7. The *Adinandra* free phenolic extract effectively inhibited the cancer cell proliferation dose-dependently. Their inhibition of EC_{50} ranged from 1.05 to 6.44 mg/mL for HepG2 cells and from 2.26 to 8.02 mg/mL for MCF-7 cells (Table 4). For the HepG2 cells, Millettii extracts had the strongest inhibitory effect and the lowest EC_{50} (1.05 ± 0.089 mg/mL), followed by Nitida (1.49 ± 0.023 mg/mL), Jubata (1.85 ± 0.056 mg/mL), and finally Latifolia (6.44 ± 0.46 mg/mL). For the MCF-7 cells, Nitida (2.26 ± 0.19 mg/mL) and Millettii (2.43 ± 0.23 mg/mL) had a similar inhibitory effect, both stronger than Latifolia (4.01 ± 0.12 mg/mL). Jubata had the weakest effect and highest EC_{50} value (8.02 ± 0.32 mg/mL). Similar to the comparison in antioxidant activity by EC_{50} of CAA and CAA values (Figures 6 and 7), a higher antiproliferative effect was found in Nitida and Millettii (Table 3), which was consistent with and could be explained by their higher phenolic contents (Figure 1). Further investigation of individual phenolic compounds will shed light on the contribution and mechanism of their antiproliferative activities.

Table 4. Antiproliferative Activities of the Free Phenolic Extract from Four *Adinandra* Varieties toward Cancer Cells[a]

variety	antiproliferative capacity to HepG2 EC_{50} (mg/mL)	antiproliferative capacity to MCF-7 EC_{50} (mg/mL)
Nitida	1.49 ± 0.023 bc	2.26 ± 0.19 c
Jubata	1.85 ± 0.056 b	8.02 ± 0.32 a
Millettii	1.05 ± 0.089 c	2.43 ± 0.23 c
Latifolia	6.44 ± 0.46 a	4.01 ± 0.12 b

[a]Values in the same rows with different letters differ significantly at $p < 0.05$.

HPLC Analysis. The phenolic compounds of *Adinandra* varieties were further analyzed by HPLC (Figure 8). Camellianin B, quercitrin, camellianin A, and apigenin were reported to be the main components of Nitida;[9−12] therefore, their contents were determined using standards and presented in Table 5. In Nitida, camellianin B, quercitrin, and camellianin A were mainly detected in the free phenolic extracts, while apigenin was found in bound phenolic extracts. These four compounds in total were about 183 mg/g of DW and might account for most of the phenolics in Nitida. The recrystallized camellianin A extract from Nitida was reported to inhibit 33.8 and 8.7% of MCF-7 and HepG2 cells at 200 μM.[16] Here, a relatively higher antiproliferative effect was observed in the Nitida extract in MCF-7 and HepG2 cells (Table 4), which suggested that its antiproliferative effect might be attributed to the synergy or interactions of different phenolic compounds.

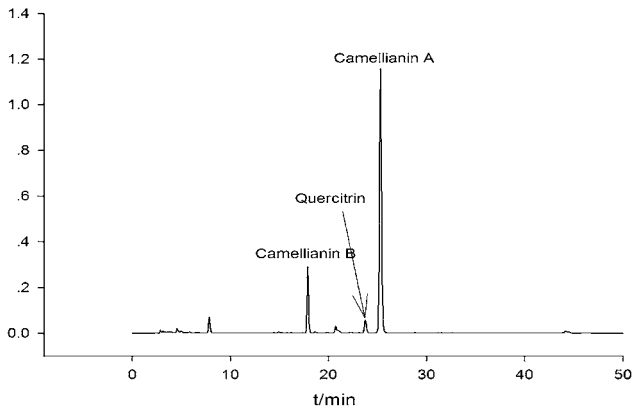

Figure 8. HPLC for Nitida free extracts.

In Latifolia, quercitrin and camellianin A were mainly detected in the free phenolic extracts, while camellianin B in the bound phenolic extract contributed more than 50% to the total camellianin B, which was consistent with its high content of bound phenolics (Figure 1). Among the four components quantified, only little amounts of camellianin B (3.89 ± 0.17 mg/g of DW) and quercitrin (1.99 ± 0.30 mg/g of DW) were detected in Jubata. Trace levels of camellianin B (0.58 ± 0.05 mg/g of DW) and quercitrin (0.18 ± 0.02 mg/g of DW) were detected in Millettii. These results suggest that phenolics other than these four components contribute to the total phenolics and antioxidant and antiproliferation activities of Jubata and Millettii, which deserved further investigation.

In summary, results here have revealed that four *Adinandra* varieties are rich in phytochemicals and have high antioxidant and antiproliferation activities. Thus, they are good source of natural antioxidants and antiproliferative compounds with further application in food and pharmaceutical industries. Among the four varieties compared, higher antioxidant and

variety		camellianin B (mg/g of DW)	quercitrin (mg/g of DW)	camellianin A (mg/g of DW)	apigenin (mg/g of DW)
Nitida	free	34.11 ± 4.97	6.43 ± 0.48	142.71 ± 21.20	ND
	bound	0.22 ± 0.00	0.43 ± 0.00	ND	0.01 ± 0.00
	total	34.33 ± 4.97	6.86 ± 0.48	142.71 ± 21.20	0.01 ± 0.00
Jubata	free	3.53 ± 0.17	1.99 ± 0.30	ND	ND
	bound	0.35 ± 0.00	ND	ND	ND
	total	3.89 ± 0.17	1.99 ± 0.30	ND	ND
Millettii	free	ND	0.18 ± 0.02	ND	ND
	bound	0.58 ± 0.05	ND	ND	ND
	total	0.58 ± 0.05	0.18 ± 0.02	ND	ND
Latifolia	free	3.27 ± 0.09	0.32 ± 0.02	5.17 ± 0.001	ND
	bound	3.98 ± 0.16	0.04 ± 0.00	ND	ND
	total	7.25 ± 0.18	0.36 ± 0.02	5.17 ± 0.001	ND

antiproliferation activities were found in Nitida and Millettii, which was consistent with and could be explained by their higher phenolic contents. The main phenolic components in Nitida were camellianin A, camellianin B, quercitrin, and apigenin, while the main phenolics in Millettii await further identification. Nitida contained ignorable bound phenolics, but the bound phenolics in other varieties, especially Latifolia, should not be underestimated and can be used in the future to provide additional health benefits.

Supporting Information

ABSTRACT: Recent evidence suggests an important role for natural honey in modulating immune response. To identify active components responsible, this study investigated the immunomodulatory properties of glycoproteins and glycopeptides fractionated from *Ziziphus* honey. Honey proteins/peptides were fractionated by size exclusion chromatography into five peaks with molecular masses in the range of 2−450 kDa. The fractionated proteins exhibited potent, concentration-dependent inhibition of reactive oxygen species production in zymosan-activated human neutrophils (IC_{50} = 6−14 ng/mL) and murine macrophages (IC_{50} = 2−9 ng/mL). Honey proteins significantly suppressed the nitric oxide production by LPS-activated murine macrophages (IC_{50} = 96−450 ng/mL). Moreover, honey proteins inhibited the phagocytosis latex bead macrophages. The production of pro-inflammatory cytokines IL-1β and TNF-α by human monocytic cell line in the presence of honey proteins was analyzed. Honey proteins did not affect the production of IL-1β; however, TNF-α production was significantly suppressed. These findings indicated that honey glycoproteins and glycopeptides significantly interfere with molecules of the innate immune system.

KEYWORDS: *honey, glycoprotiens, immunomodulatory, phagocytosis, oxidative burst*

INTRODUCTION

Natural honey is a well-known neutraceutical that is mainly composed of fructose, glucose, sucrose, and maltose. Small amounts of oligosaccharides, proteins, amino acids, minerals, trace elements, vitamins, aroma compounds, and polyphenols are also present (reviewed in ref 1). Honey exerts a number of pharmacological effects including antimicrobial, immunomodulatory, prebiotic, antinematodal, anti-inflammatory, and antinociceptive activities.[1−9] It showed both bacteriostatic and bactericidal potentials against pathogenic bacteria including drug-resistant strains.[5] Honey was found to exert anti-inflammatory effects via inhibiting (a) thrombin-induced reactive oxygen species (ROS) production[6] and (b) myeloperoxidase-dependent oxidative burst by professional phagocytes.[7] It inhibited nitric oxide (NO) production in a carrageenen-induced inflammatory rat model.[10] In addition, manuka, pasture, and jellybush honeys were found to reduce ROS production[11] and stimulate monocytes (MonoMac-6 cell line) to produce tumor necrosis factor-α (TNF-α), interleukin (IL)-1β, and IL-6, which are known to play vital roles in tissue repair.[12] The effect of honey on cytokine production was found to be associated with a 5.8 kDa component isolated from manuka honey, which interacted with TLR-4.[13] Natural honey exhibited antitumor activity by inhibiting the growth of Lewis lung carcinoma/2 cells.[14] An immunostimulatory effect of honey on antibody production against thymus-dependent (sheep red blood cells) and thymus-independent (*Escherichia coli*) antigens in mice has also been observed.[15] Likewise, honey also inhibited mitogen-activated T cell proliferation in vitro.[16] Moreover, honey regulates homeostasis by inhibiting human platelet aggregation and blood coagulation proteins.[17]

Natural honeys have a low protein content, which varies from type to type. Characterization of honey proteins from various sources was found to be valuable in determining the floral and geographical origin.[18] A number of studies pointed out the immunomodulatory potential of honey proteins. Four immunologically characterized IgE-binding glycoproteins (belonging to the major royal jelly protein-1 (MRJP-1) family) were identified in honey, and N-linked glycosylation in these proteins played an important role in binding of IgE.[19,21] Ultracentrifugation of royal jelly (RJ) revealed that the MRJP1 was the most abundant protein of RJ present in monomeric (55 kDa) as well as oligomeric (ca. 450 kDa) forms.[20] Honey contains MRJP1 protein as well, which exerts its immunostimulatory effect by stimulating TNF-α production in murine peritoneal macrophages, and the protein moiety of this glycoprotein was found be responsible for this property.[22] Recently, highly glycosylated arabinogalactan proteins (AGPs) with molecular masses of ∼110 kDa have been characterized from New Zealand kanuka honey.[23] AGPs are proteoglycans that contain type II arabinogalatans and 2−10% covalently attached protein that is typically rich in hydroxyproline and serine. AGPs are compact molecules consisting of a protein core to which highly branched polysaccharide chains are attached.[24] AGPs are found in the female sexual tissues of flowers and thus could be a potential source of AGPs in honey. AGPs and type II arabinogalactans from different sources have been shown to exert immunomodulatory properties.[25] As a

continuation of our research, we have elaborated the role(s) of honey glycoproteins and glycopeptides in the modulation of innate immune systems.

MATERIALS AND METHODS

Fractionation and Characterization of Honey Proteins. *Honey Samples.* Monofloral *Ziziphus* species honey samples produced by *Apis mellifera* in bee farms located in Himalayan and Pothohar plateau regions in northern Pakistan were used during this study.

Ammonium Sulfate Precipitation. Honey samples were diluted in buffer A (20 mM Tris-HCl, 150 mM NaCl, and 0.05% sodium azide, pH 7.4) and centrifuged at 2500*g* for 20 min at 4 °C to remove particulates, particularly pollens. The supernatants were collected and processed for ammonium sulfate precipitation at 4 °C with 80% saturation. The solution was kept on a stirrer for 1−2 h followed by centrifugation at 8300*g* at 4 °C. The pellets were dissolved in buffer and stored at −20 °C until use.

Gel Filtration Chromatography (GFC). GFC of crude honey proteins was carried out by using a Hiload 16/60 Superdex 200 Prep grade column (GE Healthcare, Uppsala, Sweden) with buffer A as mobile phase. Chromatography was done using an AKTA FPLC system (GE Healthcare) at the flow rate of 1 mL/min, and fractions of 2 mL were collected. The resultant five chromatographic peaks were termed GFC-P1−GFC-P5. Fractions containing a high molecular mass peak, GFC-P1, were pooled and treated with 8 M urea (Sigma-Aldrich, Steinheim, Germany) followed by rechromatography in the same conditions. Peaks GFC-P1−GFC-P3 were concentrated by ultrafiltration (MWCO 10 kDa, Millipore, Darmstadt, Germany), whereas peaks GFC-P4 and GFC-P5 were freeze-dried (Alpha 1-2/LD plus, Suarlee, Belgium) and resuspended in buffer A. Protein estimation was carried out by using a modified Lowry's protein assay kit (Thermo Scientific, Rockford, IL, USA).[26] The molecular masses of proteins were estimated by using a Gel Filtration Calibration Kit HMW (GE Healthcare BioSciences AB, Uppsala, Sweden), which contains five proteins and Blue dextran 2000 (ovalbumin M_r 43000; conalbumin M_r 75000; aldolase M_r 158,000; ferritin M_r 440,000; thyroglobulin M_r 669,000; and Blue dextran 2000 M_r 2,000,000).

Reverse Phase HPLC of GFC Peaks. The gel chromatography peaks GFC-P1 and GFC-P5 were subjected to reverse phase HPLC using a C-18 column (Purospher STAR, RP-18 end-capped (5 μm, 150-4.6, Merck, Darmstadt, Germany). The column was equilibrated with 0.1% TFA, and 100 μL of filtered protein sample was applied with a flow rate of 1.0 mL/min. Gradient elutions were made with acetonitrile as 5 min/0%, 40 min/70%, and 45 min/0%. Peaks were collected, concentrated, and stored at −20 °C until next use.

Mass Spectrometry. MALDI-TOF analysis of peaks obtained by RPLC was carried out as follows. Half a microliter of peptide suspension was mixed with 0.5 μL of matrix solution (sinapinic acid in 1:1 0.1% TFA/acetonitrile). The matrix/analyte solution was applied to the sample plate. Mass spectra were recorded on a Bruker Ultraflex III TOF/TOF spectrometer. Two hundered shots of light from a smart beam laser were irradiated to record mass spectra. Bioinformatics analysis of mass spectrometric data was done by using Glycosuite Database and GlycoMod tool of ExPASy server (www.expasy.org).

Immunomodulatory Activity Assays. *Isolation of Phagocytic Cells.* Polymorph nuclear leukocytes (PMNLs) were collected from human blood by using Ficoll paque gradient centrifugation. For this purpose, blood was drawn from healthy human volunteers (36−45 years old) who had not received any medication for 1 week. Blood was mixed with equal volumes of lymphocyte separation medium (MP Biomedical, Inc., Kaysersberg, France) and Hank's balanced salt solution (HBSS) without calcium and magnesium (Sigma-Aldrich, Steinheim, Germany). The diluted blood was kept undisturbed at room temperature for 30−45 min. When red blood cells (RBCs) settled, supernatant was layered onto 5 mL of LSM in a separate centrifuge tube and centrifuged at 400*g* for 20 min at 4 °C. Supernatant was discarded, and pellet was resuspended in HBSS free from calcium and magnesium and washed at 300*g* for 15 min at 4 °C. In the presence of RBCs contamination, RBCs were lysed with sterile distilled water; finally, pellet was resuspended in HBSS containing calcium and magnesium. Cell viability was determined using trypan blue dye, and cell count was adjusted to 1,000,000 cells per milliliter.

In addition, murine peritoneal macrophages were collected after the injection of 10 mL of sterile phosphate buffer saline (PBS) into mouse peritoneum (immunized with 1 mL of sterile fetal bovine serum 72 h earlier). Cells were spun at 300*g* for 15 min at 4 °C. Pellet was resuspended in 1 mL of sterile PBS, viability was checked with trypan blue exclusion method (cells were >95% viable), and count was adjusted as 1,000,000 cells per milliliter.

Chemiluminescence Assay for Oxidative Burst. The effect of honey protein fractions on ROS production was measured on PMNLs and mouse peritoneal macrophages. In brief, cells were plated in flat-bottomed 96-well plates and activated by serum opsonized zymosan-A (Sigma-Aldrich) at 250 μg/mL final concentration. Protein/peptide/glypeptide samples added at various concentrations (0.125−2.0 μg/mL) and plates were incubated for 20 min at room temperature. Luminol (3-aminophthalhydrazide) (Alfa Aesar, Karlsruhe, Germany) was added at 1.5 μg/mL final concentration. Plates were immediately kept in the thermostated chamber of a Luminoskan, and chemluminescence kinetics of ROS production was monitored as relative light units (RLUs) for 50 min in the Luminoskan (Labsystem, Helsinki, Finland) with repeated scans.[27]

Nitric Oxide Assay. The murine macrophage cells (J774.2 cell line) were purchased from the European Collection of Cell Cultures (Salisbury, UK). Cells were cultured in complete DMEM (Sigma-Aldrich) supplemented with 10% heat-inactivated fetal bovine serum (FBS), 100 U/mL penicillin, and 100 μg/mL streptomycin. The effect of honey proteins on NO production was monitored according to the method of Inoue et al.[28] Briefly, cells were seeded in a 96-well plate as 1.8×10^5 cells/well and activated by 30 μg/mL of LPS (*Escherichia coli* serotype 0111:B4, DIFCO Laboratories, Detroit, MI, USA) for the production of nitric oxide. Protein samples were added at various concentrations, and the plate was incubated at 37 °C for 48 h. Supernatants (50 μL) from each well were mixed with an equal amount of Griess reagent (0.1% naphthylethylenediamine dihydrochloride in distilled water and 1% sulfanilic acid in 5% H_3PO_4 in 1:1 ratio) (Fisher Scientific, Leicestershire, UK), and absorbance was recorded at 550 nm using a Spectra Max plus 340 (Molecular Devices, Synnyvale, CA, USA).

Phagocytosis Assay. Phagocytosis assay was performed according to the method of Foukas et al. with some modifications.[29] The murine macrophage cells (J774.2 cell line) were cultured in complete DMEM and seeded into a 96-well tissue culture-treated plate with 5×10^4 cells/well. Culture reaction plate was incubated in CO_2 environment at 37 °C with 5% CO_2 for 24 h. The next day, latex beads (fluorescent coated carboxylated modified polystyrene beads, 1 μm, Sigma-Aldrich) were added as 100 beads/cell. Protein samples were added as 800 ng/mL final concentration, and the plate was further incubated for 24 h at 37 °C in a CO_2 environment. Afterward, supernatant was removed and wells were washed twice by gently inverting the plate with 1× PBS. Trypan blue (1×, 50 μL) was added to each well, and the plate was kept at room temperature for 1 min. The trypan blue was removed, and fluorescence was recorded at 575−610 nm using a fluorescence reader (Molecular Devices).

Cytokine (TNF-α and IL-1β) Production Assay. THP-1 cell line (human monocytic leukemia cells) was purchased from the European Collection of Cell Cultures. Cells were cultured in a 75 mm^2 tissue culture flask with complete RPMI-1640 medium (MP Biomedical, Solon, OH, USA) supplemented with 10% FBS, 10 mM HEPES, 1 mM sodium pyruvate, 2 mM L-glutamine, 5.5 mM D-glucose, 50 μM β-mercaptoethanol, and 1% penicillin and streptomycin. Cells were seeded into a 24-well polystyrene sterile culture plate with 20 ng/mL PMA (SERVA, Heidelberg, Germany), which causes differentiation of monocytes to macrophages. The culture plate was incubated at 37 °C for 24 h. The next day, cells were activated with 50 ng/mL LPS, protein samples were added in various concentrations, and the plate was incubated at 37 °C with 5% CO_2. Supernatants were collected after 6 h, and levels of TNF-α and IL-1β were estimated using an

ELISA kit (R&D System, Minneapolis, MN, USA). Absorbance was recorded at 450 nm using a microplate reader (DIA Reader, Gmblt, Wr. Neudorf, Austria).[30]

Statistical Analysis. All experiments were run in triplicates, and data are presented as the statistical mean ± standard deviation (STD). A one-way analysis of variance (ANOVA) was applied to measure the significant difference between the results of test proteins and controls. Significance level was set as $P < 0.05$, $P < 0.01$, and $P < 0.005$.

RESULTS AND DISCUSSION

Separation and Characterization of Honey Glycoproteins and Glycopeptides. Previously, we have reported

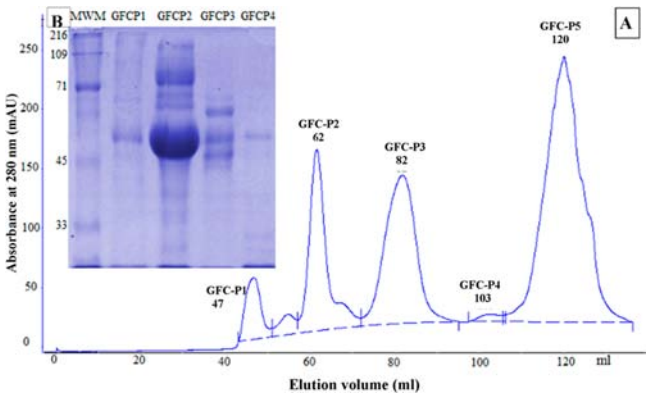

Figure 1. (A) Gel filtration chromatogram of *Ziziphus* honey proteins and peptides using AKTA FPLC system and Hiload 16/60 Superdex 200 prep grade column. Peak names and elution volumes (mL) are given. (B) SDS-PAGE of gel filtration peaks 1−4 designated GFC-P1, GFC-P2, GFC-P3, and GFC-P4 (MWM, protein molecular weight marker).

immunomodulatory activity of honey.[6,8] In the present study, we characterized immunomodulatory properties of proteoglycans, glycoproteins, and glypeptides from *Ziziphus* honey. We and others have already reported that honey proteins can be separated into five or six peaks by size exclusion chromatography.[19,31,32] Here, we report the role of fractionated honey proteins on the innate immune response. For this purpose, crude proteins extracted from *Ziziphus* honeys (produced by *A. mellifera* in bee farms located in northern Pakistan) were subjected to size exclusion chromatography using a Hiload Superdex 200 prep grade column and AKTA FPLC system. Consistent with previous findings, size exclusion chromatography separated honey proteins and peptides into five peaks (namely, GFC-P1−GFC-P5) (Figure 1A). In agreement with previous results,[19,31] we found an array of proteins with molecular masses in the range from 10 to ∼450 kDa in peaks GFC-P1−GFC-P4 as revealed by nondenaturing (i.e., GFC) as well as reducing/denaturing (SDS-PAGE) conditions (Figure 1B), whereas peak GFC-P5 contained low molecular mass peptides/glycopeptides (2−5 kDa).

The high molecular mass protein peak GFC-P1 was treated with 8 M urea followed by rechromatography with the same column (Hiload Superdex 200 prep grade). Untreated and 8 M urea treated peak GFC-P1 eluted at the same time (Supporting Information, supplementary Figure 1), whereas SDS-PAGE of this peak (Figure 1B) showed a band at 55 kDa, which indicated that high molecular mass proteins in the peak were dissociated into smaller subunits. Reverse phase liquid chromatography (RPLC) of GFC-P1 showed two distinct peaks (Supporting Information, supplementary Figure 2). These peaks were eluted during the start of the gradient, which indicated their hydrophilic nature. Typically, proteins show λ_{max} at 280 nm, whereas the UV spectra of RPLC peaks determined by diode array detector showed λ_{max} at 266 nm (Supporting Information, supplementary Figure 2). These observations pointed out covalently attached glycans, polyphenols, and other natural products to the protein core. Manuka, kanuka, and clover honeys have been reported to contain type II arabinogalactan proteins with molecular masses of >100 kDa.[23−25] Hence, high molecular mass protein peak (GFC-P1) presumably contained MRJP1 proteins. Molecular masses of proteins in peaks GFC-P2−GFC-P4 were found to be in the range of 10−200 kDa.[19] SDS-PAGE of GFC-P2 showed multiple bands with an intense band of 50−55 kDa, whereas GFC-P3 contained proteins of 45−70 kDa masses.

Peptides and glypeptides in peak GFC-P5 were further separated by RPLC, which resulted in 13 fractions (Figure 2). Peaks 8, 12, and 13 of RPLC were found to possess potent ROS production inhibitory activity (see below). MALDI mass spectrometric analysis of these peaks was carried out (Figure 3 and Supporting Information, supplementary Figure 3). Mass spectra were analyzed using the GlycoMod tool (www.expasy.org), which showed that peak 8 contained highly glycosylated peptide(s) with a molecular mass of 1157 Da (Figure 3A). A number of possible structures of O-linked glycopeptides(s) were found. This glycopeptide was characterized as O-linked glypeptide with a glycan structure of (Hex)3 (HexNAc)1 (Deoxyhexose)2 (Sulph)1 (HexA)1 (Figure 3A). Peak 12 was found to be a hybrid type N-linked glycoconjugate with the core region consisting of two *N*-acetylglucosamine residues and three mannose residues (Figure 3B). The peptide mass was calculated as 1066 Da, whereas the mass of the glycosylated peptide was 3086 (Figure 3B). The MALDI MS spectrum of relatively nonpolar peak 13 showed a single mass peak corresponding to peptide mass 1939 Da (Supporting Information, supplementary Figure 3). $[M + H]^+$, $[M + Na]^+$, and $[M + NH_4]^+$ adducts were expected to form during mass spectrometry; therefore, possible structures of these adducts were considered using GlycoMod. We used proteins and peptides fractionated by gel filtration chromatography for immunomodulatory assays.

Effect of Honey Glycoproteins/Glycopeptides on ROS Production. Activation of immune cells by any antigen induces the respiratory burst that results in ROS release. The

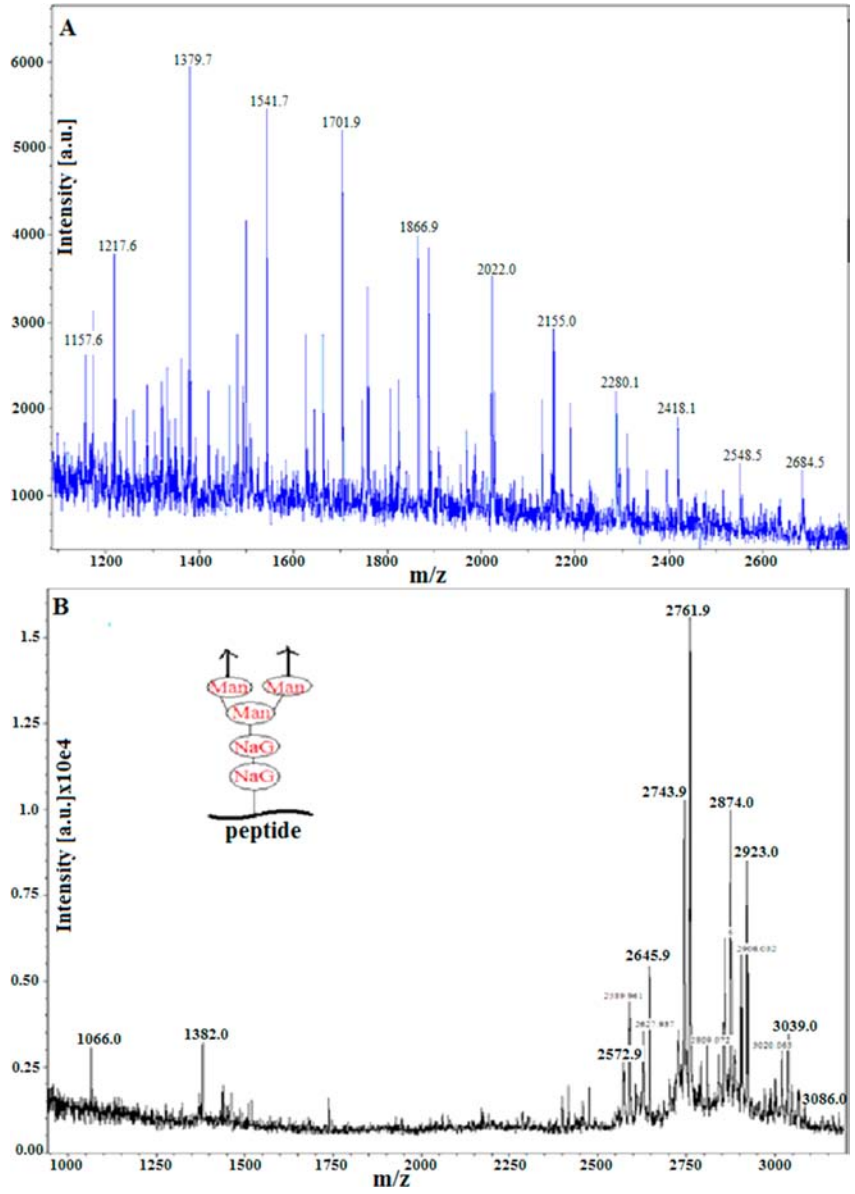

Figure 3. MALDI-MS spectra of peaks 8 (A) and 12 (B) from Figure 2.

ROS are known to play a crucial role in the pathogenesis of various inflammatory diseases including cardiovascular diseases, rheumatoid arthritis, and other inflammatory diseases. The manuka and pasture honeys were reported to have potential to reduce the production of ROS in MM-6 cells.[11] We previously reported the ability of natural honey to inhibit thrombin-induced ROS production[6] as well as myeloperoxidase-dependent oxidative burst of professional phagocytes.[7] The current experiments revealed that ROS production by human polymorph nuclear cells and mouse peritoneal macrophages was significantly suppressed by honey proteins/peptides of different molecular masses, that is, peaks GFC-P1−GFC-P5 (Figure 4; Table 1). Production and level of ROS were detected by luminol probe, which captures intracellular ROS (mainly HOCl besides the H_2O_2 and OH^- species) and converts them into a luminescent product, which was detected and recorded by luminoskan in the form of RLUs. All protein peaks showed potent inhibition of ROS production by neutrophils (IC_{50} = 6−14 ng/mL) and macrophages (IC_{50} = 2−9 ng/mL) stimulated with serum opsonized zymosan (SOZ). Zymosan is a fungal cell wall component, when coated with serum; it binds to cell surface phagocytosis receptors and serves as a potent activator of NADPH oxidase. The activation of NADPH oxidase results in the production of superoxide ($O_2^{\bullet-}$), which is a major player of host defense against bacteria and fungi. However, superoxide and other ROS must be controlled, and their continuous and excessive production can lead to inflammation.[33] The SOZ elicits phagocytosis through the Fcγ receptors on phagocytic cells.[34] Therefore, inhibition of ROS by honey proteins can be linked to the interference with or down-regulation of Fcγ receptors.

Among different fractions of peak GFC-P5 that were separated by RPLC, peaks RP-8, RP-12, and RP-13 suppressed ROS generation by neutrophils. These peptides showed significant inhibition of ROS production with IC_{50} values of 120 nM (RP-8), 50 nM (RP-12), and 150 nM (RP-13) (Figure 5). These results revealed that the proteins and peptides of honey play vital roles in ROS inhibition.

Effect of Honey Glycoproteins and Glycopeptides on Phagocytosis. Phagocytosis is the foremost mechanism of

proficient phagocytes. The binding of bacterial molecules to receptors on phagocyte surface elicits them to engulf and wipe out the invaders through the professional killing mechanism that includes respiratory burst process. In the current study, we investigated the effect of honey proteins on receptor-mediated phagocytosis of red fluorescent coated polystyrene modified unopsonized latex beads by J774.2 mouse macrophage cells. Honey proteins/peptides exhibited significant inhibitory effect at 800 ng/mL (Figure 6A; Table 1). Peaks GFC-P3 and GFC-P4 presented the highest degree of inhibition on phagocytosis (70%), whereas the other honey protein peaks showed moderate inhibitory effects.

Phagocytosis of unopsonized particles involves a number of cell surface receptors including scavenger receptors (MARCO, SR-A, SR-B, SR-C, LOX-1, etc.) and nonscavenger receptors (β-integrin, mannose, CD-48, β-glucan, asialoglycoproteins receptors, etc.).[35] Among these macrophage receptors, MARCO has been extensively studied for its role in latex beads and other inert and unopsonized environmental particles phagocytosis.[36,37] In the present study, honey proteins might inhibit phagocytosis through interfering with one or more of these receptors. Hence, honey proteins exerted their anti-inflammatory potential by interfering with phagocytotic process.

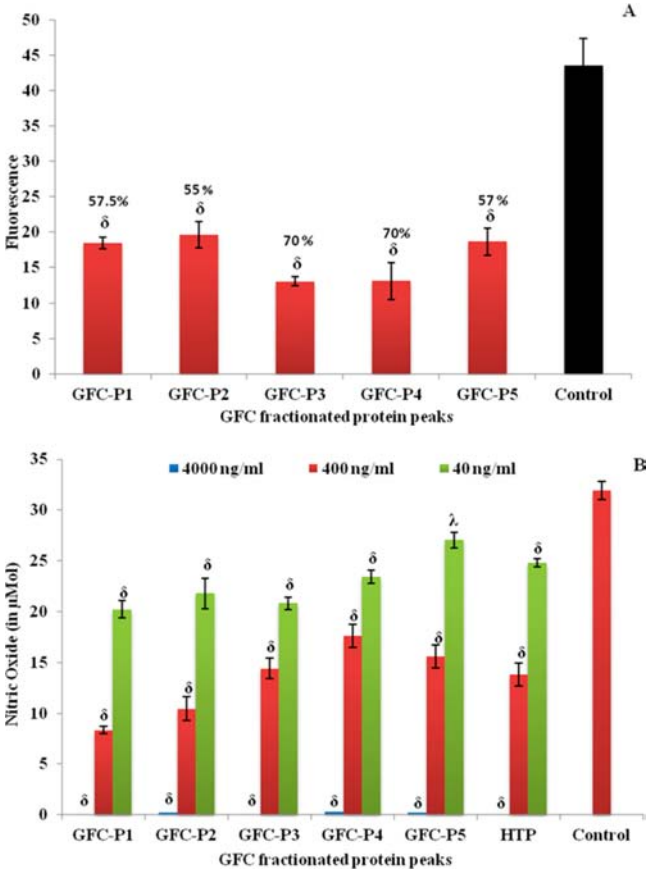

Figure 6. (A) Effect of honey protein fractions on phagocytosis. Macrophage phagocytosis was performed by using carboxylated modified latex beads and murine macrophage cell line J774.2. Control represents the cells with latex beads. The values on the bars show the percent inhibition of the phagocytosis by the respective protein fraction. Bar graph represents the statistical mean ± standard deviation. (B) Effect of honey protein fractions on NO production by J774.2 macrophages. Cells were activated by bacterial LPS for NO production. Control represents cells treated with LPS. Bar graph represents the statistical mean ± standard deviation. HTP referred as honey total proteins. One-way ANOVA was applied with significance levels <0.005, <0.01, and 0.05, which are represented as δ, λ, and ε, respectively.

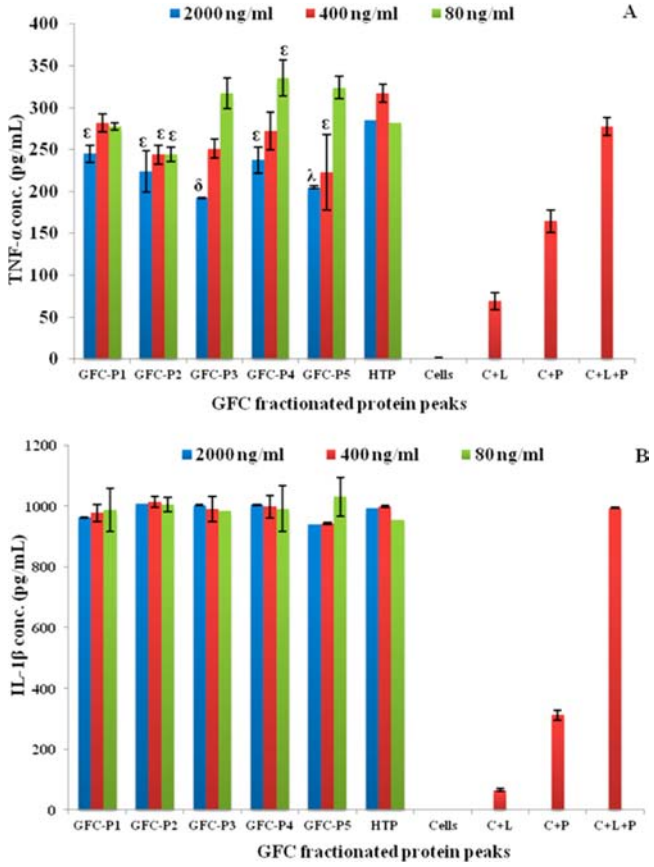

Figure 7. Effects of honey protein fractions on pro-inflammatory cytokine IL-1β (A) and TNF-α (B) production by human monocytic cells (THP-1 cells). Controls used during these assays were (a) cells only, (b) cells treated with LPS (C+L), (c) cells treated with PMA (C+P), and (d) cells treated with both LPS and PMA (C+L+P), which served as positive control. Bar graphs represent the statistical mean ± standard deviation. One-way ANOVA was applied with significance levels <0.005, <0.01, and 0.05, which are represented as δ, λ, and ε, respectively.

Effect of Honey Glycoproteins and Glycopeptides on Nitric Oxide Production. Effect of honey proteins on NO production by macrophages was also evaluated. Nitric oxide, the product of inducibe nitric oxide synthase, is a key modulator of immune response. The increase in NO production results in inflammation and progression of various chronic inflammatory diseases including rheumatoid arthritis, septic shock, inflammatory bowel disease, cardiovascular diseases, and several autoimmune disorders.[38] Nitric oxide inhibition is required in the treatment of many inflammatory disorders. Natural honey was reported to inhibit NO production in carrageenen-induced inflammatory rat model.[10,39] In the current study, the inhibitory effect of honey proteins on NO production was investigated using murine macrophage cells J774.2 that generate the inducible form of nitric oxide (Figure 6B; Table 1). All protein peaks showed a significant inhibition of NO production (IC_{50} = 130−450 ng/mL) by murine macrophage cells J774.2, which were stimulated with bacterial LPS. As a component of bacterial outer cell membrane, LPS serves as a potent activator of macrophage immune response. It binds to the macrophages through the CD14 and Toll-like receptors, which in turn activate NF-κB transcription factor. The NF-κB regulates a large number of genes involved in inflammation, cell proliferation, cell survival, and apoptosis.[40,41] Honey proteins might inhibit NO production by either binding to these receptor(s) or down-regulating the NF-κB gene expression.[42,43]

Effect of Honey Proteins and Peptides on Pro-inflammatory Cytokine Production. We further investigated the effect of honey proteins on pro-inflammatory cytokine production using THP-1 human monocytic cells. Pro-inflammatory cytokines, mainly TNF-α and IL-1β, play a central role in the establishment of inflammatory processes. Honey has been shown to stimulate the production of TNF-α, IL-1β, TGF-β, and matrix metalloproteinases (MMP-9) by human monocytes[12] and keratinocytes.[44] Moreover, the protein content of the honey glycoproteins was found to be responsible for stimulation of pro-inflammatory cytokine production.[22] In the current study, honey proteins were tested at different concentrations for their effects on the production of TNF-α and IL-1β by human monocyte cell line (THP-1 cells). For cytokine production, these cells were first differentiated into macrophages by PMA and then activated by LPS for the

dx.doi.org/10.1021/jf505131p | J. Agric. Food Chem. 2015, 63, 177−184

production of cytokines. In our experiments, honey proteins did not affect the production of IL-1β at the concentrations tested (Figure 7B) but exerted significant effects on TNF-α production (Figure 7A). We found that the production of pro-inflammatory cytokine TNF-α production was 10−20% down-regulated by peak GFC-P2. Peaks GFC-P3−GFC-P5 showed suppression of TNF-α production at higher protein concentration (2000 ng/mL) and stimulation at lower concentration (80 ng/mL). These results pointed out the involvement of TNF-α in the immunomodulatory activity of honey proteins and peptides. The high molecular mass glycoproteins/proteoglycans of honey might exert their effects by binding with cell surface receptors followed by activation of signaling pathway(s), whereas (glyco)peptides in peak GFC-P5 might be effective by interaction with intracellular receptor(s) after an internalization mechanism.

A Novel Triterpenoid Isolated from Apple Functions as an Anti-mammary Tumor Agent via a Mitochondrial and Caspase-Independent Apoptosis Pathway

Aimin Qiao,[†] Yihai Wang,[§] Limin Xiang,[§] Chunhua Wang,[§] and Xiangjiu He*[,§]

[†]School of Biosciences and Biopharmaceuticals and [§]School of Pharmacy, Guangdong Pharmaceutical University, Guangzhou 510006, China

ABSTRACT: A novel triterpenoid, named 3β-*trans*-cinnamoyloxy-2α-hydroxy-urs-12-en-28-oic acid (CHUA), was one of the main components of apple peels and showed potent in vitro antitumor activity against human tumor cells. In vivo antitumor experiments showed that CHUA could significantly inhibit the growth of mammary tumor in a nude mouse xenograft model at a dose of 50 mg/kg/day without body weight loss and mortality. In vitro, CHUA could induce apoptosis in MDA-MB-231 cells through the detection of DNA fragments and LDH activity. Simultaneously, mitochondrial transmembrane potential was markedly reduced and the release of cytochrome *c* was increased after CHUA treatment. It also up-regulated the expression ratio of mitochondrial Bax/Bcl-2 regulated by SIRT1 and p53. Interestingly, z-VAD-fmk and z-DEVD-fmk augmented cell death after CHUA treatment. Other protease(s) different from caspase-3 might be responsible for the degradation of PARP. These results suggested that the pro-apoptotic activity of CHUA may be adjusted by mitochondrial and caspase-independent pathways.

KEYWORDS: *apple, caspase-3-independent apoptosis, MDA-MB-231 cells, 3β-trans-cinnamoyloxy-2α-hydroxy-urs-12-en-28-oic acid*

INTRODUCTION

Apple (*Malus pumila*) is one of the most widely cultivated tree fruits. Epidemiological studies have shown that the consumption of apples may be related to a significantly reduced risk of many diseases such as carcinogenesis,[1,2] cardiovascular disease,[3] cognitive impairment,[4] acute inflammatory disease,[5] and diabetes.[6] Moreover, apple extracts have been shown to protect against gastrointestinal mucosa alterations[7] and have antitumor activity. Therefore, apples as an important part of consumption of plant foods could be beneficial for human health.

The bioactive compounds and antitumor activities of apple were investigated in our previous study. Twenty-two triterpenoids, including eight novels, have been purified from the peels of Red Delicious apple. It was found that the triterpenoids of apples exhibited pronounced in vitro antitumor activities and may be responsible for the antitumor activities of whole apples.[8,9] The total triterpenoids (ATT) of apples showed antitumor activity and could initiate apoptosis of breast cancer cells through mitochondrial pathway.[10]

Apoptosis is a fundamental cellular response, which plays a crucial role in regulating tissue homeostasis by removing unused cells. It is a well conserved cell death pathway executed by caspases including initiator and executioner. Caspases, a family of cysteine proteases, have the main function as central regulators of cell death during apoptosis.[11,12]

Cell apoptosis is mainly induced by intrinsic and extrinsic pathways involving either mitochondria or death receptors. The mitochondria-dependent apoptosis pathway is mainly regulated by pro-apoptotic factor Bax and the anti-apoptotic factor Bcl-2 family. The balance between Bax and Bcl-2 or Bcl-xL in the mitochondrial may determine cell survival or death. These proteins can also promote mitochondrial outer membrane permeabilization by regulating Mfn1, a GTPase involved in mitochondrial fusion.[13,14]

p53, a known tumor suppressor, induces cell cycle arrest and apoptosis related to DNA damage. It can also activate its downstream target genes, including Bcl-2 and Bax, for apoptosis. SIRT1 is a highly conserved nicotinamide adenine dinucleotide (NAD)-dependent histone deacetylase that plays an important role in promoting cell survival through regulating p53 in response to DNA damage.[15,16]

A new compound named 3β-*trans*-cinnamoyloxy-2α-hydroxy-urs-12-en-28-oic acid (CHUA) was isolated and identified from apple in our previous study.[8] CHUA is the one of main triterpenoids of apple and has been shown to significantly inhibit the growth of a number of malignant cell lines in a former preliminary study, especially breast cancer cells. In the present work, CHUA was extracted and purified from red apple, and its antitumor activities in vivo were investigated using the nude mouse xenograft model. The proposed mechanisms of CHUA-induced MDA-MB-231 cell apoptosis were studied through mitochondrial and caspase-independent pathways in vitro.

MATERIALS AND METHODS

Plant Material and Reagents. Red Fuji apples, which were harvested in October 2009, were bought from Wuhan Shahu Fruits Market (Wuhan, China).

All analytical and HPLC grade chemicals were purchased from Mallinckrodt Chemicals (Phillipsburg, NJ, USA). D101 macroporus resin was purchased from Xi'an Lanxiao Resin Corp. Ltd. (Xi'an,

China). Cell culture medium, Dulbecco's modified Eagle medium (DMEM), and fetal bovine serum (FBS) were products of Gibco Life Technologies (Grand Island, NY, USA). Bax, ICAD, PARP, cytochrome *c*, p53, Bcl-2, Bcl-X_L, SIRT1, and secondary antibody were bought from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Z-Ile-Glu-Thr-Asp-FMK (Z-IETD-FMK) and Z-Leu-Glu(OMe)-His-Asp(OMe)-FMC (Z-LEHD-FMK) were purchased from ICN (Aurora, OH, USA). Z-Asp(O-Me)-Glu(O-Me)-Val-Asp(O-Me) fluoromethyl ketone (Z-DEVD-FMK) and benzylocarbonyl-Val-Ala-Asp-fluoromethyl ketone (Z-VAD-FMK) were purchased from Calbiochem (Gibbstown, NJ, USA). RNase A, rhodamine 123, proteinase K, and MTT were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA).

Extraction and Purification of CHUA from Apples. The fresh apple peels of red Fuji variety (20 kg) were dried under vacuum at 60 °C and then smashed into powder, which was refluxed using 10 volumes of 95% ethanol for 2 h twice. The solvent was recovered under vacuum at 45 °C, and the residue was suspended in 2 L of water and subjected to a D101 macroporus resin column (100 × 1500 mm). The column was eluted with 10 L of 60% ethanol and then with 10 L of 95% ethanol, respectively. The fraction of 95% ethanol elution was concentrated and dried, getting the total triterpenoids (96.0 g). The total triterpenoids (92.0 g) was subjected to a silica gel column (230–400 mesh, 420 × 80 mm), gradiently eluted with CH_2Cl_2/MeOH (the CH_2Cl_2/MeOH ratios were from 100:0 to 0:100). The CH_2Cl_2/MeOH (50:1) elution (5.1 g) was purified by a Sephadex LH-20, followed by a HPLC (250 × 22 mm, 5 μm, Alltima C_{18}) using 82% methanol (adding 0.1% CF_3COOH, pH 2.0) as mobile phase, and CHUA (810.2 mg) were obtained.

The purity of CHUA was determined according to a HPLC method using a Waters HPLC system (equipped with a 600 pump and PDA detector) (Milford, MA, USA). The column was LiChrospher 100 RP-100e 5 μm (4.6 × 250 mm), and detection was at 210 nm. The mobile phase was $CH_3CN/H_2O/CF_3COOH$ (80:20:0.1) with a flow rate at 1.0 mL/min. The column temperature was set at 40 °C.

Nude Mouse Xenograft Model. Six-week old female nude mice (Balb/c-nu/nu) were bought from Guangdong Medical Experimental Animal Center. All animal experiment protocols were confirmed by the Animal Ethics Committee of Wuhan University. CHUA was dissolved in DMSO. Mice were randomly allocated to two groups with 10 animals per group. One hundred microliters of exponential MDA-MB-231 cells (3×10^6 cells) was injected subcutaneously into the backs of mice. When tumors become apparent after 9 days, 100 μL of DMSO containing CHUA was administered intraperitonelly to the therapy group at a dose of 50 mg/kg/day; the vehicle group was treated by only 100 μL of DMSO in the same way. Mice were sacrificed on day 10 post-CHUA treatment, and the tumor tissues were collected and weighed. The length and width of the tumors were measured, and the tumor volume was calculated using the following equation: volume = (length × width^2)/2.

Antiproliferative Effects of CHUA against Cancer Cell Line. Human breast cancer (MDA-MB-231, MCF-7), human liver cancer (HepG2), human colon cancer (Caco-2), human cervical cancer (HeLa), and human lung adenocarcinoma (A549) cell lines were purchased from ATCC. The MTT method was utilized to evaluate the bioactivity of CHUA. Briefly, tumor cells were cultured in DMEM with 10% FBS and maintained at 37 °C in 5% CO_2. A total of 2.5×10^4 cells were seeded in each well of a 96-well plate before the experiment day. After incubation overnight, the cells were treated by various concentrations of CHUA for 48 h. Cell viability was determined by the MTT assay. Experiments were performed in triplicate for each sample.

DNA Ladder Assay. DNA extraction and electrophoresis were performed as described previously.[17] Briefly, MDA-MB-231 cells (2×10^5) were seeded into a 100 cm dish for 24 h before the experimental day, and then the cells treated by 3.5 μM CHUA at indicated times were incubated with 0.25% trypsin for 10 min at 37 °C. The enzymatic digestion was terminated by mixing the suspension with an equal volume of DMEM supplemented with 10% FBS. Then floating cells were collected by centrifugation at 1000*g* for 10 min. The cell pellet was washed twice in ice-cold PBS. To detect the DNA fragments, an apoptotic DNA Laddering Kit (Shanghai Xinle Institute of Biotechnology, China) was used according to the manufacturer's protocol. The DNA fragments were separated by 2% agarose gel containing 0.2 mg/mL EB. The gel was photographed using an ultraviolet gel documentation system (UVI Tec Ltd., Cambridge, UK).

Lactate Dehydrogenase (LDH) Activity-Based Cytotoxicity Assays.[17] The MDA-MB-231 cells (2×10^5) were seeded into a 6-well plate for 24 h before CHUA was added. On the next day, the prepared cells were treated by 3.5 μM CHUA at different time courses or the cells were treated with or without z-VAD-fmk, z-DEVD-fmk, z-IETD-fmk, z-LEHD-fmk at given concentrations for 1 h and then treated with CHUA for 24 h. After treatment, floating cells were collected from cultured medium by centrifugation at 4 °C for 5 min. The LDH released in the cultured supernatant was used as an index of necrotic death, the LDH content in the cell pellets lysis was used for the apoptotic death, and the LDH present in the adherent viable cells was used as intracellular LDH. The LDH activities of the cell lysis and the cultured supernatant were measured according to the reference with a slight modification.

Measurement of Mitochondrial Transmembrane Potential ($_\Delta\Psi_m$). To measure the mitochondrial transmembrane potential ($_\Delta\Psi_m$), MDA-MB-231 cells (2×10^5) were seeded into a 100 cm dish for 24 h before the experimental day, and then the cells treated by 3.5 μM CHUA at the indicated time were incubated with 0.25% trypsin for 10 min at 37 °C. The enzymatic digestion was terminated by mixing the suspension with an equal volume of DMEM. The cells were collected by centrifugation (240*g*) at 4 °C for 5 min, then the cells were gently washed with 1 mL of cold PBS one time, and the cells were resuspended in rhodamine 123 staining solution (1 μg/mL) in the dark for 30 min. The samples were analyzed by flow cytometry.

Effects of Caspase Inhibitor on MDA-MB-231 Cells Treated by CHUA. The effects of caspase inhibitor on MDA-MB-231 cells were measured by MTT assay described above. The cultured cells were seeded in a 96-well plate with a density of 2.5×10^4 cells/well without or with z-VAD-fmk, z-DEVD-fmk, z-LEHD-fmk, and z-IETD-fmk at given concentrations for 1 h and then treated with 3.5 μM CHUA for another 24 h. After the treatment, the cell viability was measured by MTT assay.

Western Blot Analysis. MDA-MB-231 cells were treated with 3.5 μM CHUA for different time courses as indicated. All of the cells were harvested according to the method described by Laetitia et al.[18] Briefly, the cells were gently washed with ice-cold PBS and lysated by RIRA buffer containing proteinase inhibitor. Protein concentrations were determined by the Bio-Rad DC protein assay. Fifteen mirograms of proteins for each channel was separated by 12% SDS-PAGE and transferred to a nitrocellulose membrane. The membranes were incubated with appropriately diluted primary antibodies, followed by horseradish peroxidase-conjugated secondary antibodies against the corresponding species. Labeling was detected using the ECL system (Amersham Biosciences).

Statistical Analysis. Experimental values were expressed as the mean ± SEM. The differences between groups were assessed by one way-analysis of variance followed by multiple comparisons. Statistical significance is expressed as follows: *, $p < 0.05$; **, $p < 0.01$.

RESULTS AND DISCUSSION

Structure Identification of CHUA. CHUA was a white powder. The ESI-MS gave the $[M - H]^-$ ion at *m/z* 601, and its molecular formula was drawn as $C_{39}H_{54}O_5$ from HR-MS and ^{13}C NMR. In its ^1H NMR, there were three groups of characteristic signals of monosubstituted benzene, which showed at 8.12 (2H, br d, *J* = 8.6 Hz), 7.53 (2H, br t, *J* = 8.6 Hz), and 7.17 ppm (H, br t, *J* = 8.6 Hz), respectively. There was a pair of *trans*-conjugated olefinic protons, which appeared at 8.00 (H, d, *J* = 16.0 Hz) and 6.65 ppm (H, d, *J* = 16.0 Hz). There were 12 sp^2-hybrid carbons in the lower field of ^{13}C NMR, which included 2 carbonyl carbons. From its ^1H and ^{13}C

DOI: 10.1021/jf5053546
J. Agric. Food Chem. 2015, 63, 185–191

NMR and DEPT spectra, a *trans*-cinnamic acid part could be deduced. In the ^{13}C NMR spectra, there were a carbonyl signal at 180.1 ppm and two olefinic carbons at 139.7 and 126.1 ppm, which implied there was a carbon−carbon double bond in the molecule. The results showed that CHUA was a triterpene possessing an ursane skeleton. Compared with our former study,[8] the triterpenoid was identified as 3β-*trans*-cinnamoyloxy-2α-hydroxy-urs-12-en-28-oic acid (CHUA), which was a novel triterpenoid isolated from apple. The chemical structure of CHUA is shown in Figure 1.

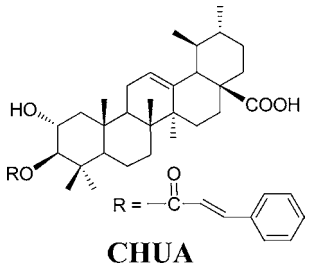

Figure 1. Chemical structure of CHUA.

The purity of CHUA was 97.3 ± 5.1%, determined by HPLC method. CHUA was used for in vivo and in vitro antitumor studies. It was dissolved in DMSO, and the stock solution was diluted with cell culture medium to keep the concentration of DMSO <0.1%.

Effect of CHUA on Cell Growth and Proliferation of Human Tumor Cells. To examine the in vitro antitumor effects of CHUA, a series of human tumor cell lines were treated with various doses of CHUA (1, 2, 4, 8, 16, and 32 μM) for 48 h, and cell viability was assayed by MTT method. The inhibitory rates of CHUA against human tumor cell lines are shown in Figure 2A. The results suggested that CHUA significantly inhibited the cell growth and proliferation of MDA-MB-231, MCF-7, and A549 cell lines with IC_{50} values of 2.57 ± 0.11, 5.45 ± 0.23, and 6.37 ± 0.29 μM, respectively. In particular, it should be noted that CHUA achieved the best inhibitory effect for MDA-MB-231 cell lines among the six tumor cell lines. On the basis of these results, MDA-MB-231 was selected to investigate the in vivo antitumor effects and mechanisms of CHUA in subsequent research.

In Vivo Antitumor Activity. CHUA was tested for anti-mammary tumor activity in nude mice on the basis of its potent inhibitory activity against the MDA-MB-231 cell line in vitro. To evaluate the in vivo antitumor effect of CHUA, growth inhibition of MDA-MB-231 xenografts in nude mice was further investigated. Administration of CHUA resulted in significant growth suppression of MDA-MB-231 xenografts compared to the control group. As shown in Figure 2B, tumor growth in the CHUA-treated group was significantly inhibited compared to the control group. The average tumor weight in the CHUA-treated group was significantly lighter than that in the control group ($p < 0.01$) at the end of the experiment (Figure 2C). Also, there were no statistical significant differences in body weights between the CHUA-treated and control groups, indicating a low general toxicity of CHUA.

Characterization of CHUA-Induced Cell Death in MDA-MB-231 Cells. To determine the characteristics of CHUA-induced MDA-MB-231 cell death, DNA fragmentation was examined. DNA fragmentation was obviously observed in CHUA-treated MDA-MB-231 cells (Figure 3).

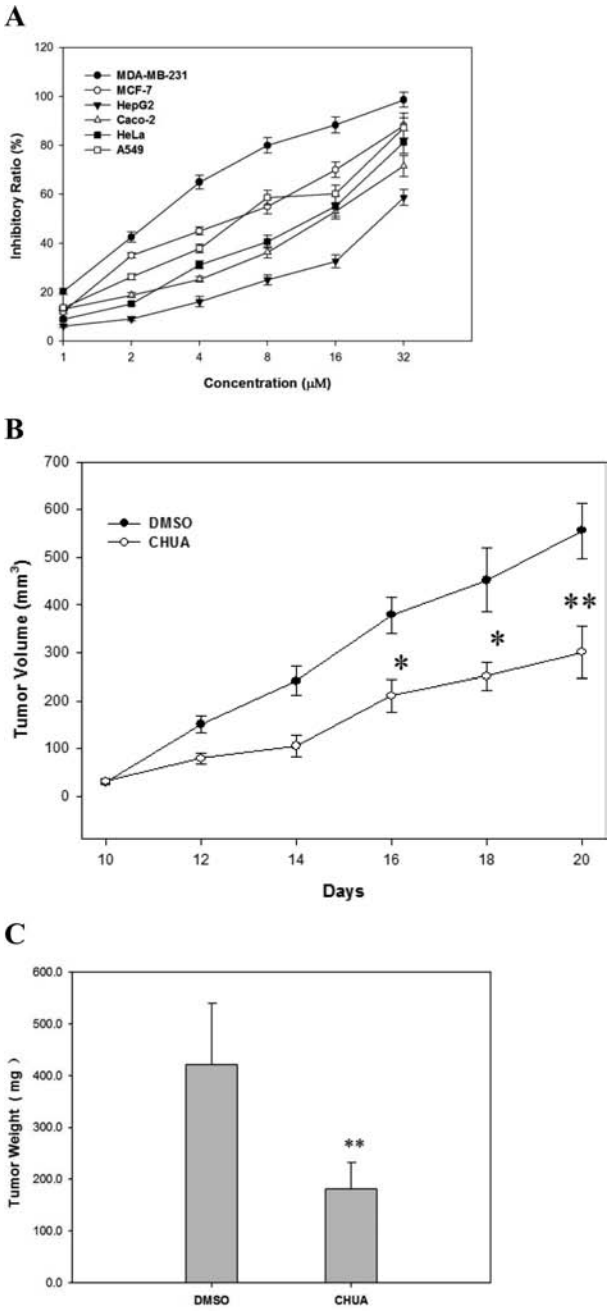

Figure 2. In vitro and in vivo antitumor effects of CHUA. (A) Antiproliferative effects of CHUA against human tumor cell lines. Different tumor cells were treated by various concentrations of CHUA for 48 h, and then the MTT method was used to evaluate the cell viability. The values presented are the mean ± SEM (n = 3). (B) Growth curves of subcutaneous tumors in mice treated with CHUA or DMSO. After succeeding in making this model, the mice were treated with 50 mg/kg/day CHUA 100 μL or the same volume of DMSO. Tumor size was measured every day after treatment. The values presented are the mean ± SEM (n = 10 in each group). (*) $p < 0.05$; (**) $p < 0.01$. (C) Weights of tumors in mice after 10 days of drug treatments. (**) $p < 0.01$. After the last day's drug treatment, the mice were sacrificed and the burdened tumors were removed carefully, and weighed. The values presented are the mean ± SEM (n = 10 in each group).

In the LDH activity assay, the ratio of apoptotic MDA-MB-231 cells increased from 12.0 to 41.1% in a time-dependent manner. The maximal apoptosis happened at 36 h and then

reduced quickly; however, the necrosis ratio continued to increase (Figure 4).

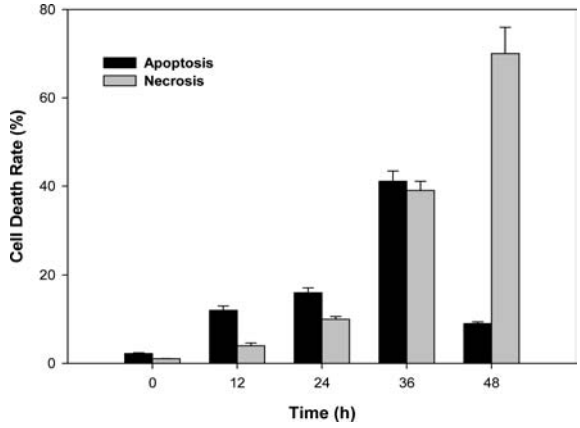

Figure 4. Apoptotic and necrotic ratios in CHUA-treated MDA-MB-231 cells. The cells were treated with 3.5 μM CHUA at the indicated time. The ratios of LDH released from floating dead cells and the culture medium were used to distinguish the proportion of apoptotic and necrotic cells. Results are represented as the mean ± SEM (n = 3).

Mitochondrial Transmembrane Potential ($\Delta\Psi_m$) Was Markedly Reduced by CHUA Treatment in MDA-MB-231 Cells. Lots of apoptotic signals are initiated by mitochondria to transduce cell death. Depletion of the mitochondria membrane potential ($\Delta\Psi_m$) is an early marker of the apoptotic process. Changes in the mitochondrial transmembrane potential in CHUA treated with MDA-MB-231 cells were analyzed by flow cytometry using the dye rhodamine 123, a specific fluorescent probe for analysis of mitochondrial transmembrane potential. Compared with the control group, the mitochondrial transmembrane potential was reduced after CHUA treatment correlated with time increasing, and the maximal decrease happened at 36 h (Figure 5), implying that CHUA-induced MDA-MB-231 cell apoptosis through mitochondrial pathway.

Enhanced Bax/Bcl-2 Expression Ratio in CHUA-Treated MDA-MB-231 Cells. It is well-known that the mitochondrial pathway is regulated by Bcl-2 family members to trigger downstream signaling. To understand the potential antitumor mechanism, the apoptosis-related proteins were detected using Western blot method. The data showed that the expression of pro-apoptotic Bax and the release of cytochrome c began to increase in response to CHUA treatment, whereas the expression levels of anti-apoptotic Bcl-2 and Bcl-X_L were down-regulated after 12 h of treatment. These results indicated that CHUA induced apoptosis, resulting in an increased ratio of Bax/Bcl-X_L, accompanied the translocation of cytochrome c from the mitochondria (Figure 6).

Expressions of SIRT1 and p53 in CHUA-Induced MDA-MB-231 Cell Death. SIRT1 can bind p53 and deacetylates its C-terminus, resulting in inhibition of p53- or Bax-mediated apoptosis. To test whether SIRT1 and p53 take part in CHUA-induced MDA-MB-231 cell death, Western blot analysis was used to detect the expressions of SIRT1 and p53. As shown in Figure 6, the expression level of SIRT1 began to attenuate after CHUA treatment for 24 h. As expected, p53 expression was up-regulated in a time-dependent manner.

Caspase Protected against CHUA-Induced MDA-MB-231 Cell Death. Many studies have shown that caspases are required in apoptosis. In this study, it was found that the inhibitor of pan-caspase (z-VAD-fmk) and the inhibitor of

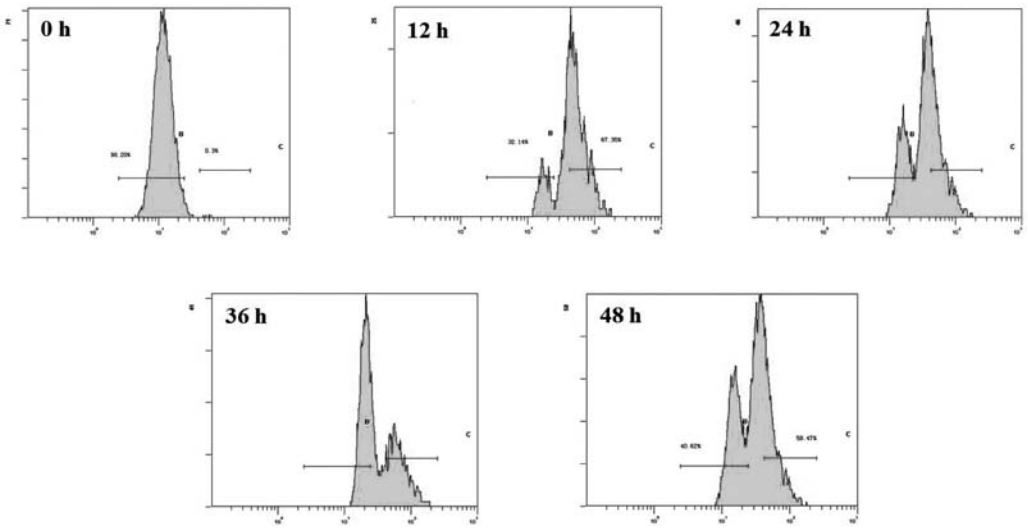

Figure 5. Effect of CHUA on the loss mitochondrial membrane potential on MDA-MB-231 cells. The cells were treated with 3.5 μM CHUA at the indicated time. Both adherent and floating cells were collected and incubated with PBS containing 1 μg/mL rhodamine 123. The mitochondrial membrane potential was detected by FCM.

J. Agric. Food Chem. 2015, 63, 185−191

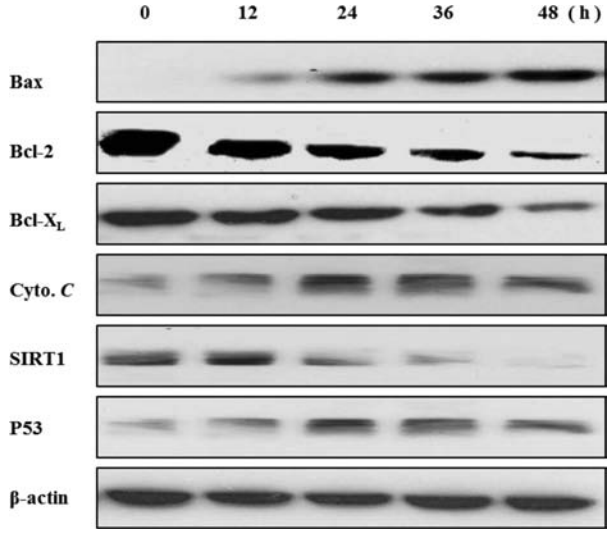

Figure 6. Release of cytochrome *c* and expressions of Bax, Bcl-2, Bcl-X, p53, and SIRT1 in CHUA-induced MDA-MB-231 cells. Cells were treated with 3.5 μM CHUA for 0, 12, 24, 36, or 48 h, the cell lysates (15 μg of protein for each channel) were separated by 12% SDS-PAGE, and the protein expressions were detected by Western blot analysis.

caspase-3 (z-DEVD-fmk) augmented the cell death to a significant difference. However, the inhibitor of caspase-8 (z-IETD-fmk) and the inhibitor of caspase-9 (z-LEHD-fmk) had no effect on the MDA-MB-231 cell death (Figure 7A).

In the LDH-based assay, it was found that the inhibitor of pan-caspase can significantly increase apoptosis; however, the caspase-3 inhibitor significantly increased necrosis on CHUA-treated MDA-MB-231 cells (Figure 7B). These results suggested that caspase-3 plays a protective role against CHUA-treated MDA-MB-231 cells.

Expressions of Caspase-3, ICAD, and PARP in CHUA-Induced MDA-MB-231 Cell Death. Caspase exists in normal cells as an inactive enzyme and is activated by removal of an aspartic acid residue. Activated caspase exerts the function related with apoptosis. Among them, caspase-3 is a common downstream apoptosis effector, which is processed and activated by caspase-9 or -8. To further investigate the influence of caspase on cells, apoptosis was challenged by CHUA. Western blot analysis was carried out to detect whether or not the participation of caspase-3 was involved in this process. As we expected, the 32 kDa band of procaspase-3 remained with no significant change after treatment with CHUA; also, no active form of caspase-3 was found. Moreover, ICAD is a classical substrate of caspase-3 and executes the characteristic fragmentation of DNA. ICAD is expressed as two isoforms, one is 45 kDa (ICAD-L/DFF45) and another is 35 kDa (ICAD/DFF35). The two isoforms have been reported to bind and inhibit CAD, but only ICAD-L/DFF45 has been reported to be functional.[19,20] Thus, the ICAD-L/DFF45 expression in MDA-MB-231 cells was examined. Interestingly, after exposure to CHUA for different time courses, the expression of ICAD-L remained with no change, too. Another characteristic associated with the execution phase of the apoptosis pathway is the specific PARP cleavage by the caspase. This cleavage leads to inactivation of the enzyme, thus preventing futile DNA repair cycle. It has been reported that caspase-3 is the most efficient processing enzyme for PARP.[21] Cleavage of PARP was examined after treatment with CHUA.

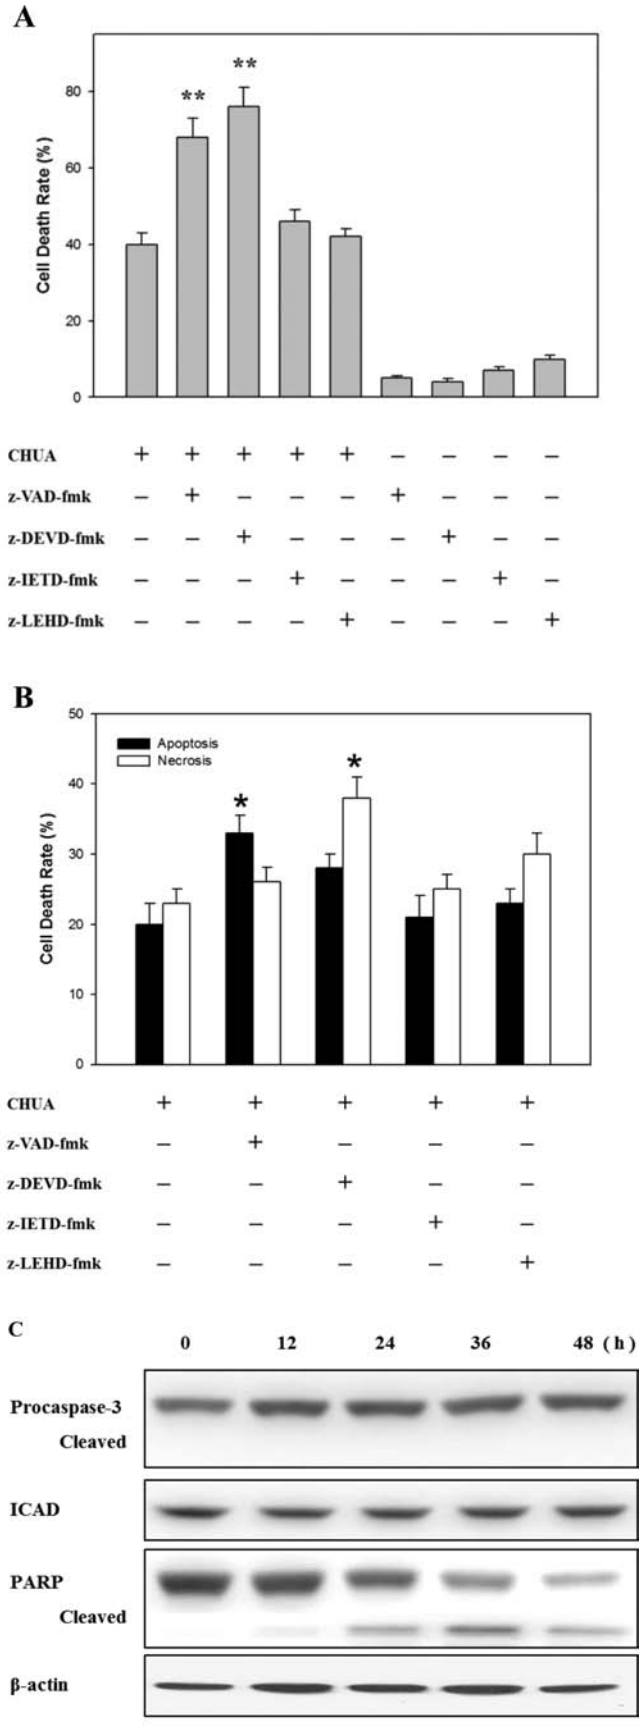

Figure 7. Effects of caspase on CHUA-induced MDA-MB-231 cell death. (A) Cells were pretreated without or with z-VAD-fmk 10 μM, z-DEVD-fmk 20 μM, z-IETD-fmk 20 μM, or z-LEHD-fmk 20 μM for 1

Figure 7. continued

h and then treated with 10 μM CHUA for another 24 h, and the cell death rate was measured by MTT assay. Mean ± SEM (n = 5). (**) p < 0.01. (B) Cells were treated as in (A), and then the characteristics of cell death were determined by LDH activity-based assay. Mean ± SEM (n = 5). (*) p < 0.05. (C) Involvement of caspase-3 independent pathway during CHUA-induced apoptosis in MDA-MB-231 cells. The cells were treated with 3.5 μM CHUA for the indicated times. The substrates of caspase-3, ICAD, and PARP were detected using Western blot analysis.

Surprisingly, PARP was activated and formed the 85 kDa isoform, which was digested from its 116 kDa precursor in a time-dependent manner, indicating that other enzyme(s) activated PARP (Figure 7C).

CHUA is a novel triterpenoid isolated from apple, which has showed potential antitumor activity against many types of tumors, especially breast cancer cells.[10] The aim of this study was to investigate the effects of CHUA as a chemopreventive agent in a nude mouse xenograft model and in vitro experiment. Although CHUA and other plant-derived triterpenoids have attracted a lot of interest for cancer study, there has, so far, been no study published about CHUA as a dietary supplementation for chemopreventive purposes. In this study, CHUA significantly inhibited the cell growth and proliferation of different tumor cell lines. In particular, it should be noted that CHUA achieved best inhibitory effect for MDA-MB-231 cell lines with the IC_{50} value of 2.57 ± 0.11 μM. In vivo antitumor experiments showed that CHUA could substantially reduce the occurrence and growth of mammary tumor in a nude mouse xenograft model at a dose of 50 mg/kg/day without body weight loss and mortality. The inhibition of CHUA on solid tumor may be stronger than HBA (natural triterpenoid analogue) with the same dose and the same treatment method.[22] As we know, apples are the most common fruit in our daily life, and apple peels are a waste product of apple sauce and canned apple manufacture. Rich in triterpenoids, they could be of benefit to our health. Triterpenoids form 3 kg of apple peels could contribute a sufficient amount of CHUA for chemoprevention for a 100 lb human according to animal experiments in vivo. Therefore, CHUA should undergo drug special preparations before use as a potential drug.

The antitumor mechanism of CHUA in MDA-MB-231 cells was further investigated. Apoptosis is characterized by a fragmentation of nuclear chromatin and dilatation of the endoplasmic reticulum. Results of DNA fragmentation and LDH activity assay suggested that CHUA-induced MDA-MB-231 cell death involved a mechanism of apoptosis. The mitochondrial transmembrane potential is a characteristic feature of apoptosis. Normally, mitochondria play the central role in supplying cells with ATP for survival. Dysfunction of mitochondria has been frequently reported in human cancera related with apoptosis because of the changes in membrane integrity that resulted in the disruption of the mitochondrial transmembrane potential.[23] In this research, the mitochondrial transmembrane potential on MDA-MB-231 cells treated by CHUA was decreased in a time-dependent manner. This result implied that the mitochondrial pathway might be involved in MDA-MB-231 cell apoptosis.

As we know, the collapse of the mitochondrial membrane potential correlates with an increased expression of Bax/Bcl-2 ratio, which is followed by cytochrome c release. Therefore, the ratio between Bcl-2 and Bax or Bcl-XL and Bax is a decisive factor to activate cell death.[13,24,25] Were these proteins involved or not in this apoptotic process? The results showed that MDA-MB-231 cells treated with CHUA exhibited the elevated ratio between Bax and Bcl-2 or Bcl-XL. Meanwhile, the release of cytochrome c was obviously up-regulated followed by the increased ratios. These results strongly suggested that the mitochondrial pathway was activated in CHUA-induced apoptosis on MDA-MB-231 cells.

p53 is a major regulator of apoptosis through different points. It may transcriptionally activate genes that are essential to growth arrest and DNA damage. It can also activate the pro-apoptotic Bcl-2 family number Bax.[26,27] As Bax expression increased, our attention was drawn to p53 because Bax is a gene promoter containing a p53-binding domain and is up-regulated by p53 in response to DNA damage. Moreover, Bax links p53 with apoptotic machinery of mitochondia, which results in the release of cytochrome c and activation of caspases. In this study, CHUA induced rapid accumulation of p53, which was positively correlated with subsequent up-regulation of Bax. These results indicate that p53 plays a pivotal role in the initiation phase of CHUA-induced MDA-MB-231 cell apoptosis.

SIRT1 has been proposed to promote tumor development and progression; also, SIRT1-mediated deacetylation suppresses the functions of several tumor suppressors, including p53. It also inhibits apoptotic cell death by deacetylating the DNA repair factor Ku70 that is tightly associated with Bax, resulting in the change of the mitochondrial permeability.[28] In this study, CHUA attenuated SIRT1 expression and triggered the activation of p53 and Bax, suggesting that SIRT1 inactivation was associated with p53- and Bax-mediated cell death by CHUA.

UV irradiation and some chemotherapeutic agents cause release of mitochondrial cytochrome c, which binds to Apaf-1, and the complex mediates recruitment of procaspase-9 and activates caspase-3. Caspases, a family of proteases, are one of the essential executioners of apoptosis, and their cleavage and subsequent activation are considered the primary hallmarks of apoptosis; however, there have been other reports that cell death is increased even when its function is shut down.[29,30] To further confirm the participation of caspase in cell death, different caspase inhibitors were used in the experiment. Interestingly, the results of this study showed that pretreatment with the caspase inhibitors z-VAD-fmk (pan-caspase inhibitor) and z-DEVD-fmk (caspase-3 inhibitor) significantly enhanced CHUA-induced MDA-MB-231 cell death, but the z-IETD-fmk (caspase-8 inhibitor) and z-LEAD-fmk (caspase-9 inhibitor) had almost no effect on cell viability, which implied that caspase-independent apoptosis happened. In the LDH assay, pretreatment with z-DEVD-fmk (caspase-3 inhibitor) significantly enhanced CHUA-induced MDA-MB-231 cell death after CHUA treatment. With this special question, we further examined the protein expression of caspase-3 and its substrates of ICAD and PARP. ICAD was left unaffected because no active form of caspase-3 was detected after CHUA treatment; however, cleaved PARP was detected, indicating that other proteins contribute to cell death and PARP activation in part. All data here allowed us to speculate that other enzymes existed to induce the apoptotic signals on MDA-MB-231 cells treated by CHUA.

DOI: 10.1021/jf5053546
J. Agric. Food Chem. 2015, 63, 185−191

Taken together, CHUA induced apoptosis in MDA-MB-231 cells via mitochondrial pathways, and some proteases different from caspase-3 might be responsible for the degradation of PARP. A more detailed mechanism of CHUA-induced MDA-MB-231 cell apoptosis remains to be elucidated.

Monascus Secondary Metabolites Monascin and Ankaflavin Inhibit Activation of RBL-2H3 Cells

Yu-Ying Chang, Wei-Hsuan Hsu, and Tzu-Ming Pan*

Department of Biochemical Science and Technology, College of Life Science, National Taiwan University, No. 1, Sec. 4, Roosevelt Road, Taipei 10617, Taiwan

ABSTRACT: *Monascus*-fermented products have been used as dietary food and traditional medicine due to their beneficial effects on circulation and digestive systems in Asia for thousands of years. Besides, monascin and ankaflavin, secondary metabolites from *Monascus*-fermented products, have proven anti-inflammatory and immunomodulatory effects. In previous research, monascin and ankaflavin ameliorated ovalbumin-induced airway allergic reaction often used as a type I allergy asthma model. Additionally, mast cells play critical roles in type I allergy. Therefore, RBL-2H3 cells were used as the mast cell model to determine whether the improving effects on asthma of monascin and ankaflavin came from influencing mast cells. PMA and ionomycin are common activators of mast cells because they stimulate the main signaling molecules during mast cell activation. Forty micromolar monascin and ankaflavin inhibited PMA/ionomycin-induced mast cell degranulation and TNF-α secretion through suppressing the phosphorylation of PKC and MAPK family ERK, JNK, and p38. Consequently, monascin and ankaflavin affected the activation of mast cells and may have the potential to improve type I allergy.

KEYWORDS: *mast cell, monascin, ankaflavin, allergy, PPARγ*

INTRODUCTION

Allergy is defined as the over-reaction that some people show toward nontoxic substances such as peanuts and pollens.[1] On the basis of the mechanism of allergy and the mainly participative cells, allergies are classified into four types. Type I allergy includes asthma, allergic rhinitis, food allergy, and so forth. Its mechanism begins with antigen presenting cells (APCs) contacting allergens, and then APCs recognize, engulf, and present antigens to naïve T cells, which make T cells activated and differentiated. In allergic patients, T cells tend to differentiate into T helper 2 (Th2) cells. Th2 cells release cytokines including interleukin-4 (IL-4), IL-5, and IL-13 that turn B cells into IgE-releasing plasma cells. The produced IgE bind to IgE receptors on mast cells. As a result, the next time allergy patients contact the same allergen, the allergen would cross-link with IgE previously bound on mast cells, followed by triggering biochemical reactions including activation of tyrosine kinase, PKC, mitogen-activated protein kinase (MAPK), calcium influx, and cytoskeleton remodeling.[2] After this signaling process, the mast cells activate and secrete inflammatory mediators with different effects on human. For instance, mast cells degranulate and release histamine, which would increase cell permeability, promote mucus production, and boost smooth muscle constriction.[1,3] TNF-α induces adhesion molecules expressed on endothelial cells and then recruits more immune cells to exaggerate the inflammatory reaction. The process of TNF-α release is also induced by PKC activation, calcium elevation, and MAPK phosphorylation. Furthermore, there are two forms that secrete TNF-α. One is the same as histamine, which is previously stored in the mast cell granules and is released upon exocytosis. The other is that MAPK phosphorylation induces the translocation of transcription factors into cell nucleus, and then TNF-α is transcribed and newly synthesized.[4] Finally, these mediators lead to patients displaying symptoms of bronchial constriction, diarrhea, and wheal-and-flare reaction.[1,3]

The prevalence of type I allergy increases with modernized and industrialized lifestyles (WAO), but there is no effective medicine with low side effects. Therefore, more and more groups investigate relative research to resolve the problems. *Monascus*-fermented products are natural and have been consumed for more than a thousand years, so their side effects may be less. Monascin and ankaflavin isolated from *Monascus* are secondary metabolites and have been determined to have antioxidative,[5−8] anti-inflammatory,[9,10] antidiabetes,[11−13] and immunomodulatory effects.[14,15] Additionally, monascin and ankaflavin have been proven to improved ovalbumin-treated BALB/c mice airway inflammation, which is a commonly used model of asthma.[10,16] Our previous study further examined whether monascin and ankaflavin affect participative cells in allergy. We found that monascin inhibited the maturation of dendritic cells, which belong to APCs. Without full maturation, dendritic cells could not present antigens to downstream T cells, and then allergy may be ameliorated. Monascin also interfered with EL4 T cells releasing Th2 cytokines, which are critical factors in allergic reaction.[14] However, the effects of monascin and ankaflavin on the activation of mast cells have not been studied.

Peroxisome proliferator-activated receptor γ (PPARγ) is a member of the nuclear receptor superfamily. After binding with its ligands, PPARγ translocates from cytoplasm into nucleus and recruits coactivators to modulate the expression of target gene.[17] PPARγ ligands have been shown to repress the

activation of mast cells.[18] In addition, monascin and ankaflavin both are PPARγ ligands.[5,19] They may have the same effect as other ligands.

In this study, we tested whether monascin and ankaflavin have beneficial effects on RBL-2H3 cells, which are often seen as mast cells. The RBL-2H3 cell is activated by PMA and ionomycin, which would induce protein kinase C phosphorylation and calcium concentration elevation, respectively.[20,21] These two responses are principal signaling molecules during the activation of mast cells.[22] We demonstrated that both monascin and ankaflavin suppressed the degranulation and TNF-α release of RBL-2H3 mast cells and that they achieved the effects through inhibiting the phosphorylation of the significant signaling molecules PKC, MAPK family ERK, JNK, and p38. Therefore, monascin and ankaflavin may possess the ability to be applied to the treatment of type I allergy patients.

MATERIALS AND METHODS

Chemicals and Reagents. Phorbol 12-myristate 13-acetate (PMA), ionomycin, PPAR-γ antagonist GW9662, rosiglitazone, bovine serum albumin (BSA), sodium dodecyl sulfate (SDS), dimethyl sulfoxide (DMSO), 4-nitrophenyl *N*-acetyl-β-D-glucosaminide (pNAG), Triton X-100, and dichlorodihydrofluorescein diacetate (DCFH-DA) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Minimum essential medium (MEM), fetal bovine serum (FBS), trypsin−EDTA,and nonessential amino acids were purchased from HyClone Laboratories (Logan, UT, USA). Sodium bicarbonate and sodium pyruvate were purchased from Caisson Laboratories (North Logan, UT, USA). Polyvinyldiene difluoride (PVDF) was purchased from Pall Corp. (Port Washington, NY, USA). Enhanced chemiluminescent (ECL) reagent was purchased from Advansta Inc. (Menlo Park, CA, USA). Anti-GAPDH antibody, anti-PKC, anti-p-PKC, anti-p-JNK, and anti-p-p38 were purchased from Abcam Co. (Cambridge, UK). Anti-p-p44/42 MAPK antibody and anti-COX-2 were purchased from Cell Signaling Technology (Beverly, MA, USA). Anti-rabbit antibody (secondary antibody) was purchased from GeneTex (San Antonio, TX, USA). Fura-2-acetoxymethyl ester (Fura-2 AM) was purchased from Invitrogen (Carlsbad, CA, USA). TNF-α ELISA kit was purchased from BioLegend Inc. (San Diego, CA, USA). Protein extraction solution was purchased from iNtRON Biotechnology, Inc. (Sangdaewon-Dong, Korea). The Bio-Rad protein assay dye was from Bio-Rad Laboratories (Hercules, CA, USA). Monascin and ankaflavin were isolated from *Monascus*-fermented rice (red mold rice) by SunWay Biotechnology Co. (Taipei, Taiwan).

RBL-2H3 Cell Culture. Rat basophilic leukemia (RBL)-2H3 cells were purchased from the Bioresource Collection and Research Center (Hsinchu, Taiwan). RBL-2H3 cells were cultured in MEM supplemented with 15 g/L sodium bicarbonate, 0.1 mM nonessential amino acids, 1.0 mM sodium pyruvate, and 15% heat-inactivated FBS. Cells were cultured at 37 °C in a humidified atmosphere of 5% CO_2.

Cell Viability Assay. The toxicity of monascin and ankaflavin to RBL-2H3 cells was evaluated with the crystal violet assay. After seeding into a 24-well plate overnight, the cells were cultured with different concentrations of tested samples for 24 h. Cells were washed with PBS and incubated with 0.5% crystal violet dye (dissolved in PBS solution) for 30 min. The cells were rinsed to remove the excess of dye and then air-dried overnight. Finally, 2% SDS was used to dissolve the dye, and the dye intensity was monitored at the wavelength of 600 nm.

β-Hexosaminidase Assay. The β-hexosaminidase assay was performed as described previously with some modification.[23] Treated with monascin, ankaflavin, and rosiglitazone for 24 h, the RBL-2H3 cells were cultured with Tyrode's buffer (135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1.8 mM $CaCl_2$, 5.6 mM glucose, 20 mM HEPES, and 0.1% BSA, pH 7.4) with 10 μM ionomycin for 30 min. After collection of cell supernatants for the released form of β-hexosaminidase, Tyrode's buffer with 0.5% Triton X-100 was added to destroy cell membrane and collect the β-hexosaminidase, which is inside the cells. For quantitation, to 5 μL samples was added 50 μL of 0.1 M citrate buffer (pH 4.5) with β-hexosaminidase substrate 4-nitrophenyl pNAG at 37 °C for 90 min. Finally, treatment with 150 μL of 0.1 M carbonate buffer (pH 9.0) stopped the reaction, and the intensity of absorption at 405 and 630 nm was measured. Before calculation with the following equation, subtract the background intensity of 630 nm from the intensity of 405 nm: (absorption of supernatant of the stimulated cells − absorption of supernatant of control)/(absorption of total amount of β-hexosaminidase in the cells − absorption of supernatant of control) × 100.

Quantification of TNF-α by ELISA. Before cells were induced with 50 nM PMA and 500 nM ionomycin for 3 h, they were treated with 40 μM monascin, ankaflavin, and rosiglitazone for 24 h. The cell medium was collected and stored at −80 °C until tested. The levels of TNF-α released into culture medium were determined with ELISA kits from BioLegend.

Immunoblot Analysis. After cell collection and extraction with the protein extraction solution (iNtRON Biotechnology, Inc.), the protein samples were subjected to 10% SDS−polyacrylamide gel electrophoresis (PAGE). The protein spots were electrotransferred to a PVDF membrane, and then the membrane was incubated with blocking buffer (phosphate-buffered saline (PBS) containing 0.05% Tween-20 and 5% w/v nonfat dry milk) for 1 h and washed with PBST (PBS containing 0.05% Tween-20) three times, each time for 5 min, followed by a diluted solution of anti-p-PKC, anti-PKC, anti-p-p38, and anti-p-JNK antibodies (Abcam) and anti-p-ERK, anti-COX-2 antibodies (Cell Signaling Technology) overnight at 4 °C. In addition, the blots probed with a 1:1000 diluted solution of anti-GAPDH (Abcam) antibody were used as internal control to keep each well loading with the same amount of protein. The membrane was washed three times, each time for 5 min in PBST, shaken in a solution of horseradish peroxidase (HRP)-linked anti-rabbit or anti-mouse IgG secondary antibody, and washed three more times, each time for 5 min in PBST. The expressions of proteins were detected by enhanced chemiluminescent (ECL) reagent (Advansta Inc.A) and image reader (ProteinSimple FluorChem M, ProteinSimple, Santa Clara, CA, USA). The intensity of blots were analyzed and quantitated with ImageJ software.

Measurement of Intracellular Calcium Level. Investigating intracellular calcium used a calcium-sensitive fluorescent Fura-2 AM, and the assay was as described previously with some change.[24] The cells were seeded in 12-well plates (1×10^5/mL) and cultured with samples for 24 h. After incubation with 2 μM Fura-2 AM for 1 h, the cells were washed two times with Tyrode's buffer and then cleaved by trypsin. Cells were collected and loaded into 96-well black-bottom, black-wall microplates. The cells were induced with PMA/ionomycin for 15 min. Finally, the fluorescent ratio of Fura-2 AM fluorescent (emission 490 nm) was monitored by 340 and 380 nm excitation, respectively. The intensity of wavelengths was calculated as a percentage compared to that of control and PMA/ionomycin groups: intracellular calcium level (%) = (Fura-2 AM fluorescence of samples − Fura-2 AM fluorescence of control)/(Fura-2 AM fluorescence of group PMA/ionomycin − Fura-2 AM fluorescence of control) × 100.

Measurement of Intracellular ROS Level. Intracellular ROS amount was investigated with ROS reactive fluorescent DCFH-DA. The cells were seeded into 6 cm plates (1×10^5/mL) overnight, treated with samples for 24 h, and then stimulated with PMA/ionomycin for 1 h. Cleavage by trypsin and three washings with Tyrode's buffer were followed by incubation with 45 μM DCFH-DA for 45 min at 37 °C. After that, the cells were washed three times with Tyrode's buffer to remove the fluorescence that did not penetrate into cells. After suspending cells in the buffer, cells were assayed by flow cytometer (BD, FACSCanto II, Becton-Dickinson Bioscience, San Jose, CA, USA).

Statistical Analysis. Each experiment was determined at least three times. Results are expressed as the mean ± standard deviation (SD). Data were compared by one-way analysis of variance (ANOVA) using the general linear model procedure of SPSS software (SPSS Institute, Inc., Chicago, IL, USA) followed by ANOVA with Duncan's test. The value of $p < 0.05$ was considered statistically significant.

RESULTS

Effects of Monascin and Ankaflavin on Degranulation and TNF-α Release. First, we examined the cytotoxic effects of monascin and ankaflavin on RBL-2H3 cells by using the crystal violet stain assay. As shown in Figure 1A, 10, 20, and 40 μM monascin and ankaflavin did not cause significant cytotoxicity to cells. Therefore, we further investigated whether monascin and ankaflavin under this concentration could influence the activation of RBL-2H3 mast cells. After activation, mast cells would degranulate and secrete lots of pro-inflammatory cytokines such as TNF-α and IL-4. Mast cells would release histamine, β-hexosaminidase, protease, and so on, which were previously stored in the granules before degranulation. Thus, the β-hexosaminidase release assay is commonly used as a marker of mast cell degranulation.[23] Cells were pretreated with monascin, ankaflavin, and PPARγ ligand rosiglitazone for 24 h, and then they were induced with PMA/ionomycin. As shown in Figure 1B, the effects of monascin and ankaflavin on RBL-2H3 degranulation are dose-dependent. Twenty micromolar monascin and 40 μM monascin, ankaflavin, and rosiglitazone significantly ameliorated mast cell degranulation. On the other hand, 20 μM monascin and ankaflavin and 40 μM monascin, ankaflavin, and rosiglitazone remarkably decreased the TNF-α secretion of RBL-2H3 cells (Figure 1C).

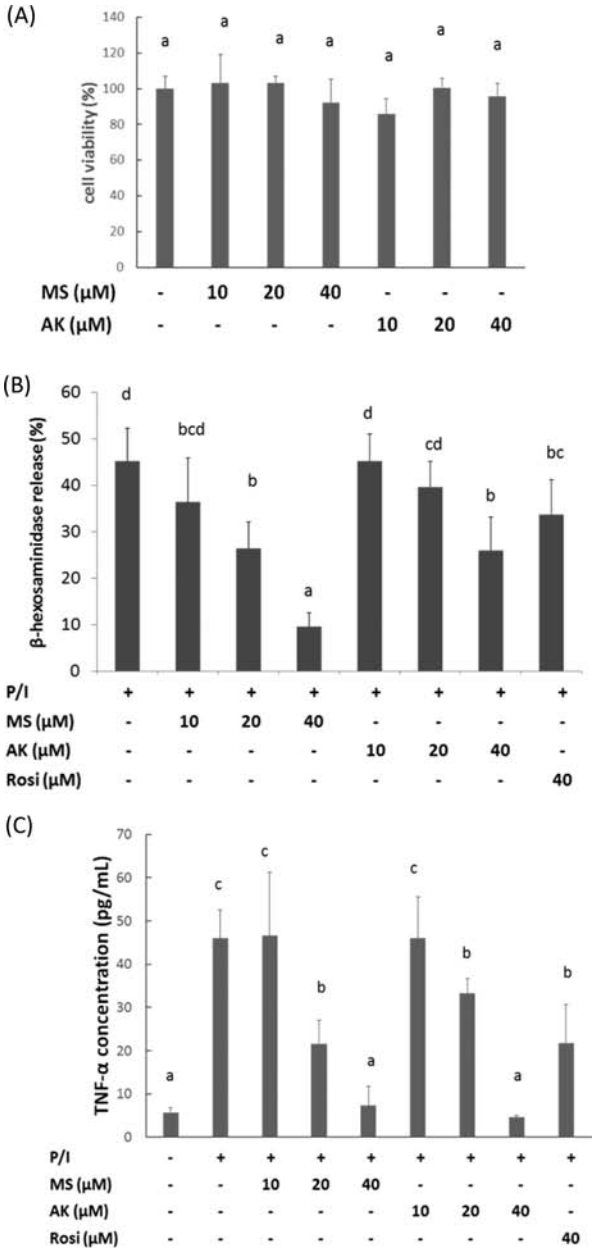

Figure 1. Effects of monascin and ankaflavin on (A) cell viability, (B) degranulation, and (C) TNF-α release in RBL-2H3 cells. Different letters above the bars indicate significant difference at $p < 0.05$ level. MS, monascin; AK, ankaflavin; Rosi, rosiglitazone; GW, GW9662 (PPARγ antagonist); P/I, PMA/ionomycin.

Roles of PPARγ, Monascin, and Ankaflavin on the Activation of Mast Cells. Monascin, ankaflavin, and rosiglitazone are PPARγ ligands.[16] In addition, many PPARγ agonists have been proven to possess an improving effect on the activation of mast cells.[18] To verify whether the ameliorative expressions of monascin, ankaflavin, and rosiglitazone on activation are achieved by PPARγ activation, we added the PPARγ antagonist GW9662 with samples to the cells for 24 h, and then we stimulated cells with PMA/ionomycin. As shown in Figure 2, degranulation and TNF-α secretion of RBL-2H3 had no effect after the addition of GW9662. These represented that even if PPARγ binds with GW9662, which would block PPARγ activation, inhibition effects of monascin, ankaflavin, and rosiglitazone on RBL-2H3 cell activation were still exhibited. Therefore, monascin, ankaflain, and rosiglitazone influenced the activation RBL-2H3 cells in a PPARγ-independent pathway.

Effects of Monascin and Ankaflavin on the Phosphorylation of MAPK. Because monascin, ankaflavin, and rosiglitazone achieved the inhibition of mast cell activation through a PPAR-unrelated mechanism, there would be some other mechanism to fulfill the amelioration effects. To elucidate that, we first investigated the phosphorylation of the MAPK family, which is critical during cytokine formation, such as TNF-α;[24] we examined the phosphorylation of MAPK family ERK, JNK, and p38 after sample treatments for 24 h and PMA/ionomycin induction for 10 min. As shown in Figures 3A−C, after stimulation with PMA/ionomycin, ERK, JNK, and p38 phosphorylations were apparently up-regulated. Incubation with monascin, ankaflavin, and rosiglitazone down-regulated the phosphorylation level of ERK, JNK, and p38 in RBL-2H3 cells. COX-2, the essential role during inflammatory mediator prostaglandins, has been reported to be regulated by p38 activation.[25] As shown in Figure 3D, we found a similar effect between p38 phosphorylation and COX-2 expression. Monascin, ankaflavin, and rosiglitazone all reduced the phosphorylation of p38 and the expression of COX-2 at the same time.

Effect of Monascin and Ankaflavin on the Phosphorylation of PKC, Intracellular Calcium, and ROS Level. We have investigated the alternation of monascin and ankaflavin on MAPK phosphorylation, and we further wondered whether samples could vary the upstream signaling molecules PKC activated by stimulant PMA.[20] As shown in Figure 4A, monascin and ankaflavin reduced the phosphorylation states of PKC. This indicated that samples influenced the activation of PKC. Furthermore, ionomycin is an ionophore, which increases intracellular calcium level. It is vital during mast cell activation.[21] The calcium-reactive fluorescent Fura-2 AM was used to detect intracellular level after culture with monascin, ankaflavin, and rosiglitazone for 24 h and then the incubation with PMA/ionomycin for 15 min. As shown in Figure 4B, monascin, ankaflavin, and rosiglitazone were ineffective on

intracellular calcium amount. Additionally, it has been reported that reactive oxygen species (ROS) are not only upstream but also downstream of calcium influx. In the beginning of mast cell activation, ROS induced an elevated calcium concentration through activation of NADPH oxidase. Later, the increased calcium level stimulated ROS by mitochondria.[26] Because there is no influence on calcium level, we investigated whether samples also had no effects on intracellular ROS level. The ROS amount was observed by ROS-sensitive fluorescent DCFH-DA. We found that monascin, ankaflavin, and rosiglitazone did not affect the intracellular ROS level (Figure 4C).

DISCUSSION

The activation of mast cells is a prominent process in type I allergic reaction. In addition, mast cells release a variety of pro-inflammatory substances including histamine, IL-4, TNF-α, prostaglandins, and leukotrienes, which are potent, multifunctional mediators. Finally, these mediators contribute to the allergic symptoms of patients.[1]

In this study, we verified that monascin, ankaflavin, and rosiglitazone improved degranulation and TNF-α release in RBL-2H3 mast cells in a PPARγ-independent mechanism. In fact, there are some improving effects of PPARγ ligands that are PPARγ independent. Okuyama et al. found that PPARγ agonist ciglitazone could inhibit inflammatory mediator leukotriene release in RBL-2H3 cells.[27] After incubation with GW9662, the

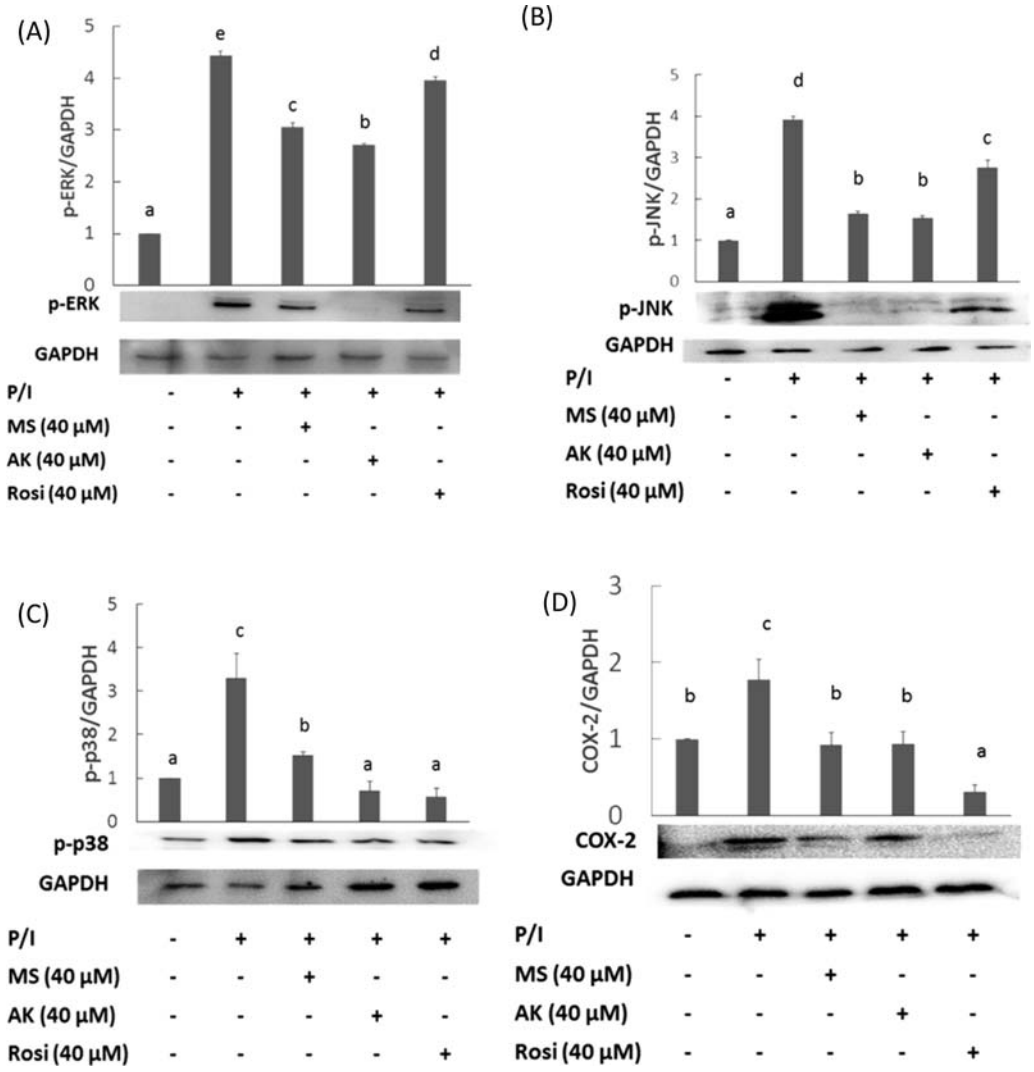

Figure 3. Effects of monascin and ankaflavin on the phosphorylation of (A) ERK, (B) JNK, (C) p38, and (D) COX-2 expression in RBL-2H3 mast cells. Different letters above the bars indicate significant difference at $p < 0.05$ level. MS, monascin; AK, ankaflavin; Rosi, rosiglitazone; GW, GW9662 (PPARγ antagonist); P/I, PMA/ionomycin.

reducing effect of ciglitazone on leukotriene secretion did not disappear. Additionally, the location of PPARγ still stayed at cytoplasm, indicating that the effect did not depend on the activation of PPARγ.[27] Besides, not all PPARγ ligands could influence mediator release in mast cells. For instance, in human cultured mast cells, histamine release was down-regulated by 15d-PGJ_2 but not down-regulated by troglitazone and ciglitazone.[28] The PPARγ-independent mechanism has also been reported in other kinds of cells. Furthermore, the concentration of PPARγ is much higher than the dissociation constant (K_d) of PPARγ. Therefore, there may still be other mechanisms to realize these phenomena.[18]

MAPK family ERK, JNK, and p38 are serine/threonine protein kinases and significant to cytokine and lipid mediator production in mast cells.[24,29] TNF-α formation is regulated by the activation of ERK.[30] Also, ERK controls the activity of phospholipase A_2 (PLA_2), which catalyzes the phospholipids in the membrane into arachidonic acid (AA). AA is the material needed in the manufacture of lipid mediators such as prostaglandins and leukotrienes.[30] We validated that monascin and ankaflavin diminished the phosphorylation level of ERK. Consequently, they may also have the potential to decrease the production of the lipid mediators, which would cause smooth muscle constriction, vasodilation, mucus overproduction, and nerve stimulation.[1]

PKC and intracellular calcium level are important to mast cell degranulation. We have found that monascin and ankaflavin inhibited the activation of PKC but did not affect the calcium concentration (Figure 4). These appearances could also be discovered in another study. Hide et al. determined that 10 μM azelastine had an effect on PKC phosphorylation but not on calcium level.[31] By comparison of their structures, monascin, ankaflavin, and azelastine are polycyclic. Therefore, this polycyclic structure may play a critical part in interfering with PKC activation. Now, azelastin has been developed into allergic rhinitis medicines in some counties, but it comes with some side effects such as nose burning, somnolence, and so on.[32,33] Monascin and ankaflavin had similar improving effects. Due to their natural properties, they would have lower side effects. Thus, they may be much safer to allergic patients.

In conclusion, PPARγ activators monascin, ankaflavin, and rosiglitazone ameliorated the pro-inflammatory mediator release of mast cells through a PPARγ-independent mechanism. As shown in Figure 5, monascin and ankaflavin influenced the

previous work, monascin and ankaflavin improved the ovalbumin-induced BALB/c airway allergic inflammation.[10,16] Monascin also down-regulated the maturation of dendritic cells and Th2 cytokine production.[16] We suggest that monascin and ankaflavin could suppress allergic reaction. To sum up these observations, monascin and ankaflavin may have a relieving effect on type I allergy patients and thus have potential for development into medicine s such as azelastine.

[§]College of Food Science and Pharmacy, Xinjiang Agricultural University, Urumqi, People's Republic China

ABSTRACT: Three new phenolic compounds, coretinphenol (**1**), coretincone (**2**), and coretinphencone (**3**), were isolated from the buds of *Coreopsis tinctoria* Nutt., together with nine known compounds, including butein (**4**), okanin (**5**), isoliquiritigenin (**6**), maritimetin (**7**), taxifolin (**8**), isookanin (**9**), marein (**10**), sachalinoside B (**11**), and 2-phenylethyl-β-D-glucoside (**12**). The chemical structures of these compounds were elucidated by extensive spectroscopic analysis and on the basis of their chemical reactivity. This work represents the first recorded example of the isolation of compounds **1**−**3**, **6**, **7**, **9**, **11**, and **12** from *C. tinctoria*. Compounds **5**−**9** showed strong diphenyl(2,4,6-trinitrophenyl)iminoazanium (DPPH) radical-scavenging activity, with IC_{50} values of 3.35 ± 0.45, 9.6 ± 2.32, 4.12 ± 0.21, 6.2 ± 0.43, and 7.9 ± 0.53 μM, respectively. Compounds **2** and **8** exhibited angiotensin I-converting enzyme inhibitory activity, with IC_{50} values of 228 ± 4.47 and 145.67 ± 3.45 μM, respectively. The activities of phenolic compounds isolated from *C. tinctoria* support the medicinal use of this plant in the prevention of cardiovascular diseases.

KEYWORDS: *Coreopsis tinctoria, structural identification, flavonoids, antioxidant activity, angiotensin I-converting enzyme inhibitory activity*

INTRODUCTION

Cardiovascular diseases (CVDs) are the leading cause of death worldwide, causing 17.3 million deaths per year.[1,2] It has been estimated that by 2030, there will be more than 23.6 million deaths annually resulting from CVDs all over the world.[2] Hypertension, one of the major risk factors related to CVDs, may be induced by many causes, for example, the imbalance of the renin angiotensin aldosterone system (RAAS), the kallikrein kinin system, and the sympathetic nervous system and genetic influences.[3] Among these causes, the angiotensin I-converting enzyme (ACE) plays a significant role in the RAAS, by converting the precursor angiotensin I into angiotensin II, a potent vasoconstrictor that is responsible for increasing blood pressure.[4] Therefore, finding potential ACE inhibitors from diverse natural resources has become a major target.[5] In particular, edible and medicinal plants have played important roles in functional food and drug development and continue to represent a promising source of new and interesting ACE inhibitors against hypertension.

Coreopsis tinctoria Nutt., which belongs to the Asteraceae/Compositae family, is a small, glabrous, aromatic annual plant distributed all over the world.[6,7] In China, it grows in the Karakorum Mountains at altitudes above 3000 m in southern Xinjiang. It is known as "snow chrysanthemum" or "snow tea" locally[8] and is traditionally used not only as a tea-like beverage but also as a folk medicine for the treatment of hypertension and hyperlipidemia in Uyghur folk medicine.[9] According to historical records, the decoction of *C. tinctoria* has been described by Huá Shòu as a traditional Chinese formula for diabetes as early as during the Yuan Dynasty (1271−1368 AD).[6] In North America and Romania, *C. tinctoria* was commonly cultivated in a variety of garden settings as an ornamental plant,[10] whereas the indigenous people of North America employed it as a therapeutic agent for several diseases, for example, diarrhea, internal pain, and bleeding, to strengthen blood, and as an emetic.[6] In Portugal, an infusion of two cups per day of *C. tinctoria* flowering tops, known as "Estrelas-do-Egipto", has been traditionally used to control diabetes.[10]

Previous studies have shown that *C. tinctoria* contains a diverse range of bioactive phytochemicals, including flavonoids,[6,11] phenolics,[12] phenylpropanoids,[13] polyacetylene glycosides,[8] and sterols,[14] with flavonoids being the major phytochemical present.[15] Although several investigations have been conducted on *C. tinctoria*, the precise nature of all of its bioactive components in antioxidant and antihypertensive activities remains unclear.

It is reported that the alcoholic extract of *C. tinctoria* buds showed the strongest antioxidant and antihypertensive effects.[9] Furthermore, in our preliminary studies, the methanol extract of *C. tinctoria* buds exhibited significant DPPH radical-scavenging activity and ACE inhibitory activity. It was for this reason that methanol was selected as an extraction solvent for the buds of *C. tinctoria*. An investigation of the chemical constituents in the bioactive extract led to the isolation of three new phenolic glycosides, together with nine other known compounds, and

evaluations of the antioxidant and ACE inhibitory activities of these compounds were performed.

Herein, we describe the experimental details of the separation process, as well as provide information pertaining to the elucidation of the structures of these compounds based on their spectroscopic properties and chemical reactivity.

MATERIALS AND METHODS

Chemicals. Dimethyl sulfoxide-d_6 (DMSO-d_6) and $CDCl_3$ were obtained from Merck (Darmstadt, Germany). Diphenyl(2,4,6-trinitrophenyl)iminoazanium (DPPH), ACE (EC 3.4.15.1), hippuric acid, and captopril were purchased from Sigma-Aldrich (St. Louis, MO, USA). All of the chemicals and solvents used in the current study were of analytical grade.

Materials. The aerial parts of *C. tinctoria* were purchased in September 2012 from the Beiyuanchun farmers market in Urumchi city of the Xinjiang Uygur Autonomous Region, China. The herbariums of *C. tinctoria* were deposited in the Key Laboratory of Food Processing and Quality Control, Nanjing Agricultural University, under number XJ8126. Thin-layer chromatography (TLC) analysis was performed on plates precoated with silica gel GF254 (10−40 μm). Column chromatography (CC) was performed over silica gel (300−400 mesh, Qingdao Marine Chemical Factory, Qingdao, China), reversed phase C18 (octadecylsilyl, ODS) silica gel (Silicycle, 50 μm, Canada), or Sephadex LH-20 (Sigma-Aldrich, St. Louis, MO, USA).

Instruments. UV spectra were recorded on a Beckman DU640 spectrophotometer (Beckman Coulter, Beijing, China). IR spectra were taken from KBr disks on a Nicolet Nexus 470 spectrophotometer (Thermo Scientific, Beijing, China). All of the ^1H and ^{13}C NMR spectra were recorded on Bruker Avance 300, 400, and 500 spectrometers (Bruker BioSpin GmbH, Beijing, China), using tetramethylsilane (TMS) as an internal standard. Two-dimensional NMR spectra include correlation spectroscopy (COSY), heteronuclear singular quantum correlation (HSQC), and heteronuclear multiple-bond correlation (HMBC). The chemical shifts in the NMR spectra were recorded as δ values. Electrospray ionization mass spectrometry (ESI-MS) analyses were measured on a Q-Tof Ultima Global GAA076 LC mass spectrometer (Waters Asia, Ltd., Singapore).

Extraction and Isolation. Dried buds of *C. tinctoria* (3 kg) were homogenized using a Polytron homogenizer prior to extracting three times with 80% acetone (1:6, v/v) at ambient temperature for 24 h. The resulting solution was then filtered, and the filtrate was combined and concentrated under vacuum at 30 °C until approximately 90% of the solvent had been evaporated. The remaining solution was then extracted sequentially with equal volumes of ethyl acetate (EtOAc) and methanol (three times), and the methanol solution was collected and concentrated under vacuum to give the methanol extract (15.8 g).

The methanol extract was separated into five fractions (A−E) by normal-phase silica gel column chromatography (CC) (100 g of silica gel, 300−400 mesh) using a stepwise gradient elution of cyclohexane/EtOAc/MeOH (from 100:0:0 to 0:100:0 to 0:0:100, v/v/v).

Fracton A (2.1 g) was separated into two subfractions (A-1 and A-2) on a normal-phase silica gel column using a stepwise gradient elution of petroleum ether/acetone (from 100:0 to 0:100, v/v). Fraction A-1 was then passed through a Sephadex LH-20 column with a $CHCl_3$/MeOH eluent (1:1, v/v) to yield compound **1** (3.5 mg). Fraction A-2 was purified on a silica gel column with a cyclohexane/EtOAc eluent (50:1, v/v) to produce compound **2** (3.7 mg).

Fraction B (3.4 g) was also purified by silica gel column chromatography with a cyclohexane/EtOAc eluent (50:1, v/v) to give three subfractions, B-1, B-2, and B-3. Fraction B-1 was passed through a Sephadex LH-20 column using a $CHCl_3$/MeOH eluent (1:1, v/v) to yield compound **3** (3.6 mg). Fraction B-2 was purified by silica gel column chromatography with a cyclohexane/EtOAc eluent (95:1, v/v) to give fraction B-2-1, which was separated through a Sephadex LH-20 column using a $CHCl_3$/MeOH eluent (1:1, v/v) to produce compound **4** (8.3 mg). Fraction B-3 was purified by column chromatography over silica gel with a cyclohexane/EtOAc eluent (200:1, v/v) to afford compound **5** (12.3 mg).

Fraction C (2.5 g) was separated into two subfractions (C-1 and C-2) by silica gel CC using petroleum ether/acetone (100:1, v/v) as an eluent. Fraction C-1 was subsequently purified by silica gel CC using petroleum ether/acetone (50:1, v/v) as an eluent to afford compound **6** (9.3 mg). Purification of fraction C-2 by silica gel CC eluting with a cyclohexane/EtOAc (10:1, v/v) gave compound **7** (11.3 mg).

Fraction D (5.8 g) was purified by normal-phase CC over silica gel, eluting with a petroleum ether/acetone eluent (15:1, v/v), to produce two subfractions, D-1 and D-2. Fraction D-1 was subjected to CC over silica gel with a petroleum ether/acetone eluent (100:1, v/v) to give compound **8** (10.5 mg), and fraction D-1-1. Fraction D-1-1 was subsequently purified over a Sephadex LH-20 column with a $CHCl_3$/MeOH eluent (1:1, v/v) to give compound **9** (13.4 mg). Fraction D-2 was purified by reversed-phase chromatography over silica gel using a stepwise gradient elution of MeOH/H_2O (80:20−0:100, v/v) to give fraction D-2-1, which was further purified using a Sephadex LH-20 column with a $CHCl_3$/MeOH eluent (1:1, v/v) to give compound **10** (51.9 mg).

Fraction E (2.0 g) was subjected to CC over silica gel using a stepwise gradient elution of petroleum ether/acetone (100:1 to 0:100, v/v) to provide two subfractions, E-1 and E-2. Fraction E-1 was subsequently purified by CC over a silica gel column using a petroleum ether/acetone eluent (10:1, v/v) to afford faction E-1-1, which was purified using a Sephadex LH-20 column with a $CHCl_3$/MeOH eluent (1:1, v/v) to give compound **11** (8.9 mg). Fraction E-2 was purified by silica gel CC, eluting with petroleum ether/acetone (60:1, v/v) to give compound **12** (21.5 mg).

Acid Hydrolysis of the Saponins and Determination of the Absolute Configuration of the Monosaccharides. The assay used to determine the absolute configuration of the monosaccharides was performed as described in the literature with minor modifications.[15] Briefly, a solution of the pure compound (2 mg) in 2 M HCl (2 mL) was heated at 85 °C for 15 h, and the resulting mixture was then evaporated under vacuum to give a residue, which was repeatedly distilled to dryness from H_2O under vacuum to produce a neutral residue. Then, the residue obtained and 2 mg of L-cysteine methyl ester hydrochloride were dissolved in 1 mL of anhydrous pyridine, and the resulting mixture was stirred at 60 °C for 1 h. A 3:1 mixture of HMDS−TMCS (hexamethyldisilazane−trimethylchlorosilane) was then added (300 μL), and the solution was stirred for 30 min. Hexane (3 mL) and water (1 mL) were then added to the solution. The hexane layer was dried over anhydrous Na_2SO_4 and subjected to GC-MS analysis under the following conditions: capillary column, HP-5MSi (30 m × 0.25 mm, with a 0.25 μm film, Agilent, USA); detection, FID; injection temperature, 250 °C; initial temperature, 160 °C, raised to 250 °C at 15 °C/min; final temperature maintained at 250 °C for 10 min.

Assay of DPPH Radical Scavenging. The DPPH radical-scavenging assay was performed according to the method described by Rivero-Pérez et al.[16] with slight modifications. Briefly, 1 mL of 0.2 mM DPPH ethanol solution was added to 2.5 mL of the sample solutions at different concentrations, and the resulting mixtures were shaken vigorously in the absence of light for 30 min. The absorbance values were then measured at 517 nm. Vitamin E (VE) was employed as a positive control. The antioxidant activity of the test compounds was expressed as IC_{50}, with the IC_{50} being defined as the concentration of test compounds required to inhibit the formation of DPPH radicals by 50%. All of the samples were analyzed in triplicate.

Measurement of Inhibitory Activity toward ACE. The measurement of inhibitory activity toward ACE was performed according to the method described by Cushman and Cheung,[17] which was slightly modified. The enzyme was added last to initiate the reaction, and tubes were incubated, usually for 10 min at 37 °C. One milliliter of ethyl acetate was added to the tubes and mixed by vortex for 15 s to extract hippuric acid from the acidified solution. The hippuric acid was redissolved in 3 mL of water, and the amount formed was determined by its absorbance at 228 nm. Captopril was employed as a positive control. The inhibitory activity of the test compounds was expressed as IC_{50}, with the IC_{50} being defined as the concentration of test compounds required to inhibit the ACE activity by 50%. All of the samples were analyzed in triplicate.

Statistical Analysis. All of the assay results reported in the present work were analyzed according to Duncan's multiple-comparison test ($p < 0.05$), using version 18.0 of the SPSS software package. The resulting data were presented as the mean ± standard deviation.

RESULTS AND DISCUSSION

Elucidation of the Structures of the New Phenolics. Compound **1** was isolated as a yellow amorphous powder. Its molecular formula was determined to be $C_{21}H_{32}O_9$ on the basis of HRESIMS analysis of the pseudomolecular ion peak at m/z 451.1952 $[M + Na]^+$ (calculated as 451.1944), indicating six degrees of unsaturation. The UV spectrum of compound **1** revealed three strong absorption bands at 207, 230, and 280 nm. The IR spectrum displayed strong absorption bands at 3421, 1650, 1399, and 1047 cm^{-1}, corresponding to hydroxyl, olefinic, alkyl, and glycosidic functionalities, respectively. The ^{1}H NMR and ^{13}C NMR spectra of compound **1** revealed the presence of one benzene ring, one double bond, and one sugar unit in the molecule. Analysis of the ^{1}H−^{1}H COSY, HSQC, and HMBC spectra of compound **1** allowed for the complete assignment of the ^{1}H and ^{13}C NMR spectral data (Table 1). The sugar unit sequence from an anomeric proton H-1″ to oxymethylene proton H-6″ through oxymethine protons H-2″, H-3″, H-4″, and H-5″, as well as H-1′ to H-5′, was established by ^{1}H−^{1}H COSY. HMBC analysis of compound **1** displayed several key correlations, including the 3-CH_3 group with the C-2, C-3, and C-4 carbons, H-1′ with the C-2′, C-3′, and C-6 carbons, H-2′ with the C-5 and C-6 carbons, and the 6′-CH_3 group with the C-5′, C-6′, and C-7′ carbons. Key correlations from H-1″ to C-1 were observed in the HMBC experiments, indicating that the sugar moiety was connected directly to the C-1 position of the benzene ring. The anomeric configuration of the pyranosyl sugar unit was identified as a β-glucopyranosyl group on the basis of its $^3J_{\text{H-1″, H-2″}}$ coupling constant of 7.08 Hz. Acid hydrolysis of compound **1** with 2 M HCl liberated aglycone and D-glucose, which were identified by gas chromatography−mass spectrometry (GC-MS) analysis of the corresponding trimethylsilyl L-cysteine derivative and a direct comparison with an authentic sample of the same material that had been prepared in the same manner. The results revealed that the acid hydrolysate of pure compound **1** contained a D-glucose derivative. This result was confirmed through a comparison of the retention time of this derivative with that of the authentic D- (t_R, 20.254) and L-glucose derivatives (t_R, 20.705), respectively, with both samples providing a retention time of 20.254 min. Consequently, the structure of compound **1** was determined to be 2,4-dihydroxy-3-methyl-6-(7-hydroxy-6-methylhep-5-en-2-yl)-β-D-glucopyranoside and informally named coretinphenol (Figure 1).

Compound **2** was isolated as a yellow amorphous powder, and its molecular formula was determined to be $C_{21}H_{22}O_{10}$ on the basis of HRESIMS analysis of the pseudomolecular ion peak at m/z 433.1142 $[M - H]^-$ (calculated as 433.1135). The UV spectrum of compound **2** revealed strong absorption bands at 212, 267, and 383 nm. The IR spectrum displayed strong absorption bands at 3421, 3254, 1656, 1399, and 1062 cm^{-1}, which are characteristic of flavonoid-glycoside type structures. Analysis of its 1D NMR data suggested the presence of an aglycone moiety and a sugar unit (Table 2). The aglycone resonances showed a β-unsaturated ketone olefinic proton at δ 7.78 (d, J = 8.88 Hz, 1H, H-β), an ABX spin system at δ 6.60 (d, J = 2.44 Hz, 1H, H-3′), 6.65 (dd, J = 2.44 Hz, 8.92 Hz, 1H, H-5′), and 8.22 (d, J = 8.96 Hz, 1H, H-6′), and an ABCX spin system at δ 7.40 (d, J = 2.08 Hz, 1H, H-2), 7.78 (d, J = 8.88 Hz, 1H, H-4), 6.93 (d, J = 8.20 Hz, 1H, H-5), and 7.26 (dd, J = 2.08 Hz, 8.16 Hz, 1H, H-6), as well as a broad proton singlet at δ 13.50 (s, 1H) attributable to 2′-OH. The ^{13}C NMR of compound **2** revealed the presence of 21 carbon signals, with 6 of these being assigned to the sugar moieties, 15 to the aglycone including 12 aromatic ring carbons, 2 olefinic carbons, and a characteristic carbonyl group at δ 192.3. These data revealed that the structure of compound **2** closely resembled that of compound **4**, which has been previously isolated from this plant.[18] A direct comparison of the ^{1}H and ^{13}C NMR data of these two compounds revealed that they share the same skeleton. The ^{1}H NMR spectrum of compound **2** revealed that the resonance signals corresponding to the H-4 at δ 7.78 and α-OH protons in compound **2** had been

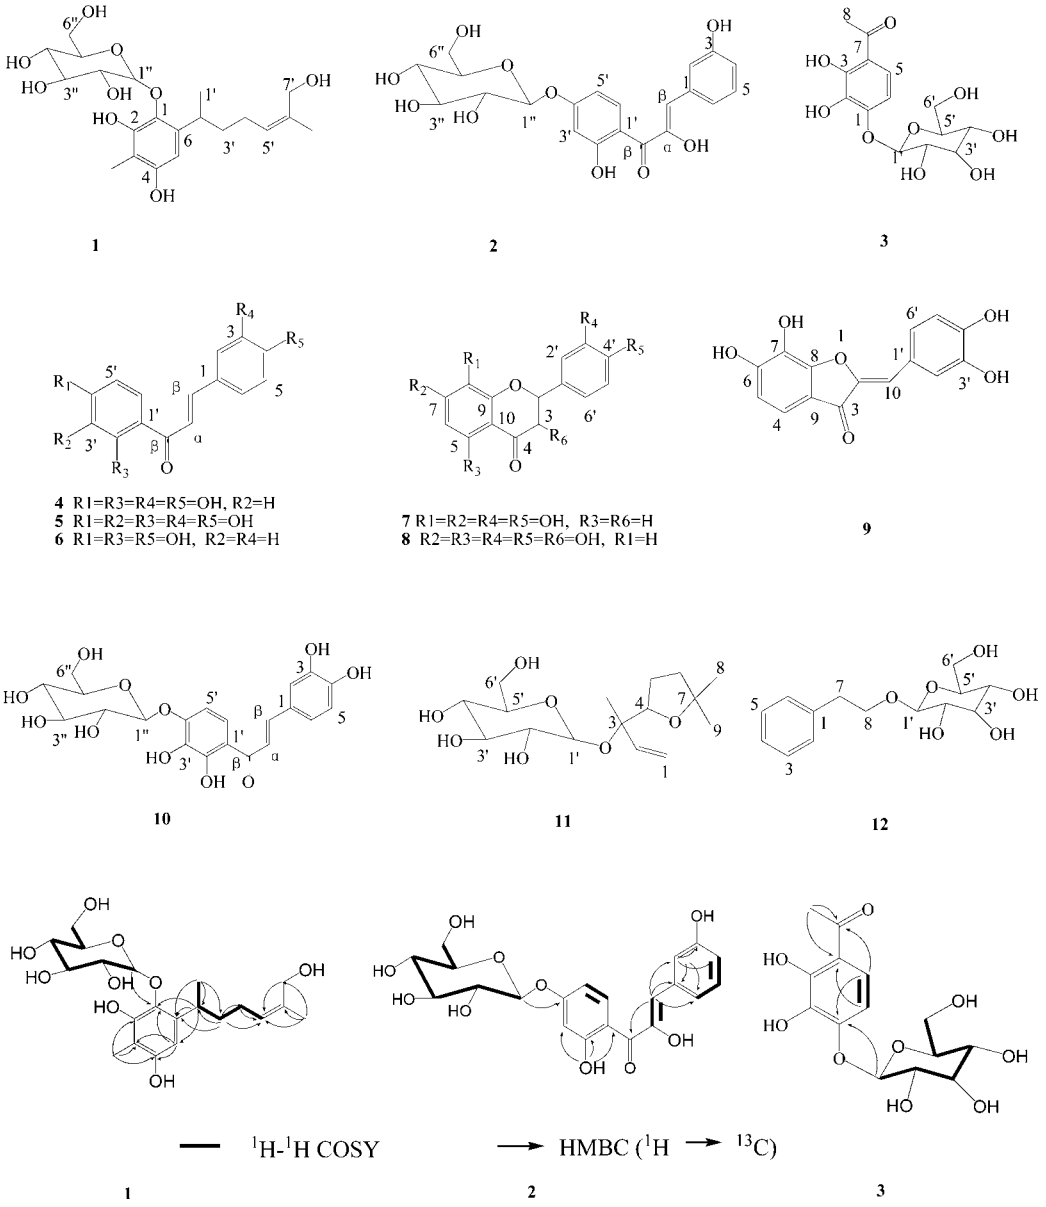

Figure 1. Chemical structures of the 12 compounds isolated from the methanol extract of *C. tinctoria*: **1**, coretinphenol; **2**, coretincone; **3**, coretinphencone; **4**, butein; **5**, okanin; **6**, isoliquiritigenin; **7**, maritimetin; **8**, taxifolin; **9**, isookanin; **10**, marein; **11**, sachalinoside B; **12**, 2-phenylethyl-*β*-D-glucoside. Key ^{1}H−^{1}H COSY and HMBC correlations for compounds **1**, **2**, and **3** are also shown.

replaced by a hydroxyl group and one olefinic proton at δ 7.65 in compound **4**. This difference was also supported by the presence of a methine carbon at δ 117.3 (C-4) and a quaternary carbon at δ 145.5 (C-α) in the ^{13}C NMR spectrum of compound **2**. These signals were replaced by the carbon signals at δ 148.8 and 117.3 in the spectrum of compound **4**, respectively. This assignment was further supported by HMBC correlations from the 2′-OH to C-1′, C-2′, and C-3′ and H-β to C-1, C-2, C-6, and C-β′. The full structure of compound **2** was further confirmed by ^{1}H−^{1}H COSY, HSQC, and HMBC experiments (Table 2). The anomeric proton of the glucopyranosyl sugar moiety at δ 5.15 (d, J = 7.52 Hz, 1H, H-1″) coupling to the C-4′ at δ 163.9 suggested the sugar moiety connected directly to C-4′ of aglycone. The anomeric configuration of the sugar unit was determined as a β-glucopyranosyl group from its $^{3}J_{\text{H-1″, H-2″}}$ coupling constant of 7.52 Hz. Following the hydrolysis of compound **2** with 2 M HCl and its subsequent trimethylsilylation for GC-MS analysis, the retention time of the sugar was found to be the same as that of an authentic sample of D-glucose. On the basis of this evidence, the structure of compound **2** was characterized as α,3,2′-trihydroxy-4′-*O*-β-D-glucopyranosylchalcone and informally named coretincone (Figure 1).

Compound **3** was isolated as a colorless amorphous powder. Its molecular formula was established as $C_{14}H_{18}O_9$ on the basis of HRESIMS analysis of the pseudomolecular ion peak at m/z 329.0881 $[M - H]^-$ (calculated as 329.0873), indicating six degrees of unsaturation. The UV spectrum showed strong absorption bands at 217, 283, and 343 nm. The IR spectrum displayed strong absorption bands at 3415, 1638, 1508, and 1074 cm^{-1}, corresponding to hydroxyl, carbonyl, aromatic, and glycosidic functionalities, respectively. The ^{1}H and ^{13}C NMR spectra were typical of a glycosidic type compound. The ^{1}H NMR spectrum revealed the presence of an AB spin system at δ 7.39 (d, J = 9.05 Hz, 1H) and 6.75 (d, J = 8.95 Hz, 1H), an

anomeric proton at *δ* 4.87 (d, *J* = 7.15 Hz, 1H), and a methyl at *δ* 2.57 (s, 3H). The ^{13}C NMR spectrum of compound **3** revealed the presence of 14 carbon signals, with 8 of these signals being assigned to the aglycone and 6 to the sugar moieties. The signals at *δ* 150.5, 134.2, and 151.1, connecting to three oxygen atoms, were attributed to the C-1, C-2, and C-3 carbons, respectively, and a signal at *δ* 203.8, corresponding to a carbonyl group, was assigned to the C-7 carbon. This assignment was further confirmed by HMBC correlations from H-5 to C-1, C-3, and C-7, from H-6 to C-1, C-2, and C-4, and from H-8 to C-4 and C-7. The full structure of compound **3** was further confirmed by ^{1}H−^{1}H COSY, HSQC, and HMBC experiments (Table 3). Key correlations from H-1′ to C-1 were observed in the HMBC experiments, indicating that the sugar unit was connected directly to the C-1 position of the aromatic ring. The anomeric configuration of the sugar unit was determined as a *β*-glucopyranosyl group from its $^3J_{\text{H-1′, H-2′}}$ coupling constant of 7.15 Hz. The *β*-glucopyranosyl group for compound **3** was also identified as D-glucose by the same procedures as for compounds **1** and **2**. Consequently, the structure of compound **3** was characterized as 2,3-dihydroxy-4-formoxyl-1-*O*-*β*-D-glucopyranoside and informally named coretinphencone (Figure 1).

Nine known compounds (Figure 1) were identified as butein (**4**),[18] okanin (**5**),[19] isoliquiritigenin (**6**),[18] maritimetin (**7**),[20] taxifolin (**8**),[21] isookanin (**9**),[22] marein (**10**),[11] sachalinoside B (**11**),[23] and 2-phenylethyl-*β*-D-glucoside (**12**),[24] respectively, by comparing their physical and spectroscopic data with those reported in the literature.

Antioxidant Activity of the Pure Compounds Isolated from *C. tinctoria*. The antioxidant activities of the 12 pure compounds were tested using the DPPH radical-scavenging assay. The results of these experiments are shown in Figure 2A. DPPH radical-scavenging activity of compounds **1**−**12** ranged from 13.2 to 89.4% at the concentration of 100 *μ*M. Compounds **5**−**9** displayed powerful DPPH radical-scavenging activity compared with the positive control vitamin E, followed by compounds **1**−**4** and **10**, whereas compounds **11** and **12** had the lowest activity. These compounds were further tested to calculate their IC_{50} values at different concentrations ranging from 1 to 100 *μ*M, and the results are shown in Table 4. The IC_{50} values of compounds **5**−**9** were 3.35 ± 0.45, 9.6 ± 2.32, 4.12 ± 0.21, 6.2 ± 0.43, and 7.9 ± 0.53 *μ*M, respectively, and were much lower than

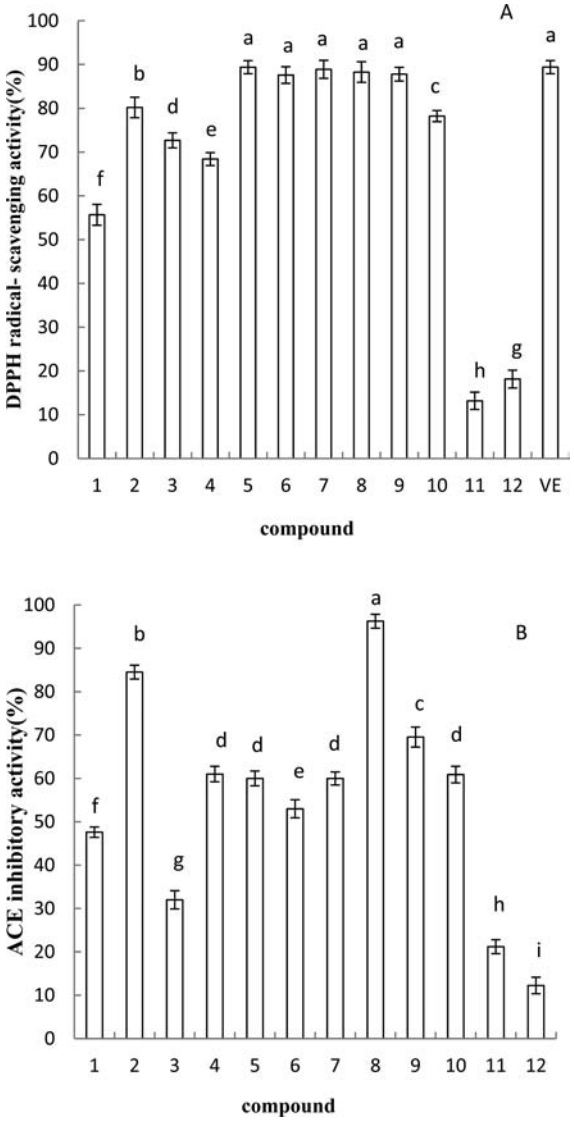

Figure 2. DPPH radical-scavenging activity (A) and ACE inhibitory activity (B) of the isolated compounds at concentrations of 100 and 400 μM, respectively. Coretinphenol (**1**), coretincone (**2**), coretinphencone (**3**), butein (**4**), okanin (**5**), isoliquiritigenin (**6**), maritimetin (**7**), taxifolin (**8**), isookanin (**9**), marein (**10**), sachalinoside B (**11**), and 2-phenylethyl-β-D-glucoside (**12**). Each value has been presented as the mean ± standard deviation of three experiments. (a–i) Results with a different letter differ significantly ($p < 0.05$).

those of vitamin E; these results are consistent with the values previously reported.[22,25−28]

ACE Inhibitory Activity of the Pure Compounds Isolated from *C. tinctoria*. The ACE inhibitory activities of the 12 pure compounds at the concentration of 400 μM were assessed, and the results are reported in Figure 2B. Among the pure compounds isolated from *C. tinctoria*, compound **8** exhibited strong ACE inhibitory activity, followed by compounds **2**, **4**−**7**, **9**, and **10**, whereas other compounds had weak ACE inhibitory activity. To further characterize the ACE inhibitory effect of these compounds, all of the compounds at different concentrations, ranging from 10 to 400 μM, were tested. Compounds **2** and **8** in particular possessed ACE inhibitory activity with IC_{50} values of 228 ± 4.47 and 145.67 ± 3.45 μM, respectively, whereas other compounds exhibited no inhibitory effect on ACE (Table 4). The IC_{50} value of captopril was

determined to be 0.009 ± 2.32 μM, similar to the value previously reported in the literature.[29] Previous studies have demonstrated that flavonoids have the potential to inhibit ACE activity in vitro by developing complexes with metal ions, which is an active center of ACE. Therefore, the metal ions of ACE are reduced and ACE activity decreases.[30,31] It has been reported that the ability of flavonoids to chelate metal ions varies depending on the position of the hydroxyl group in the molecular structure, where a hydroxyl group attached to the 3,5- and 3′,4′-positions are crucial to the inhibition of ACE activity.[32,33] The structure of compound **8** is consistent with this characteristic; therefore, compound **8** showed potent ACE inhibitory activity.

NMR and ESI-MS Spectroscopic Data. Coretinphenol (1): yellow amorphous powder; ^{1}H NMR and ^{13}C NMR data, see Table 1; ESI-MS m/z 451.1952 $[M + Na]^+$.

Coretincone (2): yellow amorphous powder; ^{1}H NMR and ^{13}C NMR data, see Table 2; ESI-MS m/z 433.1142 $[M - H]^-$.

Coretinphencone (3): colorless amorphous powder; ^{1}H NMR and ^{13}C NMR data, see Table 3; ESI-MS m/z 329.0881 $[M - H]^-$.

Butein (4): yellow amorphous powder; ^{1}H NMR (300 MHz, acetone-d_6, TMS) δ 7.27 (d, J = 1.71 Hz, 1H, H-2), 6.82 (d, J = 8.13 Hz, 1H, H-5), 7.20 (dd, J = 1.74, 8.19 Hz, 1H, H-6), 6.27 (d, J = 2.22 Hz, 1H, H-3′), 6.40 (d, J = 2.16, 8.82 Hz, 1H, H-5′), 8.14 (d, J = 8.91 Hz, 1H, H-6′), 7.65 (s, 2H, H-α, β); ^{13}C NMR δ 126.6 (C-1), 115.7 (C-2), 145.5 (C-3), 148.8 (C-4), 115.7 (C-5), 122.3 (C-6), 113.0 (C-1′), 164.8 (C-2′), 102.5 (C-3′), 165.6 (C-4′), 108.0 (C-5′), 132.7 (C-6′), 117.3 (C-α), 144.6 (C-β), 191.4 (C-β′); ESI-MS m/z 271.1 $[M - H]^-$.

Okanin (5): yellow amorphous powder; ^{1}H NMR (400 MHz, DMSO-d_6, TMS) δ 7.26 (d, J = 1.95 Hz, 1H, H-2), 6.82 (d, J = 8.13 Hz, 1H, H-5), 7.20 (dd, J = 2.01, 8.22 Hz, 1H, H-6), 6.44 (d, J = 8.88 Hz, 1H, H-5′), 7.68 (d, J = 8.22 Hz, 1H, H-6′), 7.65(s, 2H, H-α, β); ^{13}C NMR δ 126.2 (C-1), 115.7 (C-2), 145.5 (C-3), 148.8 (C-4), 115.6 (C-5), 122.2 (C-6), 113.3 (C-1′), 153.5 (C-2′), 132.4 (C-3′), 152.5 (C-4′), 107.6 (C-5′), 117.3 (C-6′), 122.2 (C-α), 144.4 (C-β), 191.9 (C-β′); ESI-MS m/z 287.1 $[M - H]^-$.

Isoliquiritigenin (6): yellow amorphous powder; ^{1}H NMR (400 MHz, acetone-d_6, TMS) δ 7.77 (dd, J = 2.44, 6.64 Hz, 2H, H-2, 6), 6.96 (d, J = 8.64 Hz, 2H, H-3, 5), 6.50 (dd, J = 2.44, 8.88

J. Agric. Food Chem. 2015, 63, 200−207

Hz, 1H, H-3′), 6.38 (dd, J = 2.24, 8.88 Hz, 1H, H-5′), 8.16 (d, J = 8.80 Hz, 1H, H-6′), 7.84 (d, J = 11.96 Hz, 2H, H-α, β); ^{13}C NMR δ 126.6 (C-1), 130.9 (C-2, 6), 115.8 (C-3, 5), 160.1 (C-4), 113.6 (C-1′), 164.7 (C-2′), 102.8 (C-3′), 166.7 (C-4′), 107.7 (C-5′), 132.4 (C-6′), 117.3 (C-α), 144.2 (C-β), 191.9 (C-β′); ESI-MS m/z 255.1 $[M - H]^-$.

Maritimetin (7): yellow amorphous powder; ^{1}H NMR (500 MHz, acetone-d_6, TMS) δ 5.42 (dd, J = 2.84, 12.88 Hz, 1H, H-2), 2.67 (dd, J = 2.88, 16.80 Hz, 1H, H-3), 3.04 (dd, J = 12.88, 16.76 Hz, 1H, H-3), 7.33 (d, J = 8.60 Hz, 1H, H-5), 6.62 (d, J = 8.64 Hz, 1H, H-6), 7.06 (d, J = 1.80 Hz, 1H, H-2′), 6.88 (d, J = 8.80 Hz, 1H, H-5′), 6.89 (dd, J = 1.76, 8.80 Hz, 1H, H-6′); ^{13}C NMR δ 145.9 (C-2), 182.4 (C-3), 116.4 (C-4), 112.2 (C-5), 155.4 (C-6), 130.6 (C-7), 154.6 (C-8), 115.0 (C-9), 113.0 (C-10), 123.9 (C-1′), 118.8 (C-2′), 146.3 (C-3′), 148.3 (C-4′), 115.6 (C-5′), 124.9 (C-6′); ESI-MS m/z 287.1 $[M - H]^-$.

Taxifolin (8): yellow amorphous powder; ^{1}H NMR (400 MHz, acetone-d_6, TMS) δ 5.05 (d, J = 11.44 Hz, 1H, H-2), 4.64 (d, J = 11.44 Hz, 1H, H-3), 5.96 (d, J = 2.16 Hz, 1H, H-6), 6.00 (d, J = 2.16 Hz, 1H, H-8), 7.08 (d, J = 2.08 Hz, 1H, H-2′), 6.88 (d, J = 8.08 Hz, 1H, H-5′), 6.94 (dd, J = 2.08, 8.16 Hz, 1H, H-6′); ^{13}C NMR δ 83.6 (C-2), 72.2 (C-3), 197.3 (C-4), 166.9 (C-5), 96.1 (C-6), 164.1 (C-7), 95.1 (C-8), 163.8 (C-9), 100.6 (C-10), 128.8 (C-1′), 114.8 (C-2′), 144.8 (C-3′), 145.6 (C-4′), 114.8 (C-5′), 119.9 (C-6′); ESI-MS m/z 303.1 $[M - H]^-$.

Isookanin (9): yellow amorphous powder; ^{1}H NMR (300 MHz, DMSO-d_6, TMS) δ 7.41 (s, 1H, H-2′), 7.36 (d, J = 8.46 Hz, 1H, H-6′), 7.10 (d, J = 8.46 Hz, 1H, H-4), 6.84 (d, J = 8.34 Hz, 1H, H-5′), 6.72 (d, J = 8.10 Hz, 1H, H-5), 6.58 (s, 1H, H-10); ^{13}C NMR δ 145.9 (C-2), 182.4 (C-3), 116.4 (C-4), 112.2 (C-5), 155.4 (C-6), 130.6 (C-7), 154.6 (C-8), 115.0 (C-9), 113.0 (C-10), 123.9 (C-1′), 124.9 (C-2′), 115.6 (C-3′), 148.3 (C-4′), 146.3 (C-5′), 118.8 (C-6′); ESI-MS m/z 285.1 $[M - H]^-$.

Marein (10): yellow amorphous powder; ^{1}H NMR (500 MHz, DMSO-d_6, TMS) δ 7.29 (d, J = 2.05 Hz, 1H, H-2), 6.81 (d, J = 8.15 Hz, 1H, H-5), 7.22 (dd, J = 2.10, 8.25 Hz, 1H, H-6), 6.77 (d, J = 9.20 Hz, 1H, H-5′), 7.73 (d, J = 9.20 Hz, 1H, H-6′), 13.12 (s, 1H, 2′-OH), 4.90 (d, J = 7.30 Hz, 1H, H-1″), 3.33 (m, 1H, H-2″), 3.20 (m, 1H, H-3″), 3.39 (m, 1H, H-4″), 3.50 (dd, J = 5.95, 11.85 Hz, 1H, H-5″), 3.49 (dd, J = 5.95, 11.85 Hz, H, H-6″), 3.73 (dd, J = 2.00, 11.85 Hz, 1H, H-6″), 7.66(s, 2H, H-α, β); ^{13}C NMR δ 126.1 (C-1), 115.7 (C-2), 145.5 (C-3), 148.9 (C-4), 115.8 (C-5), 122.5 (C-6), 115.9 (C-1′), 152.4 (C-2′), 134.4 (C-3′), 150.4 (C-4′), 106.3 (C-5′), 121.4 (C-6′), 101.0 (C-1″), 73.2 (C-2″), 69.8 (C-3″), 75.8 (C-4″), 77.3 (C-5″), 60.5 (C-6″), 145.9 (C-α), 117.4 (C-β), 192.6 (C-β′); ESI-MS m/z 449.0 $[M - H]^-$.

Sachalinoside B (11): colorless amorphous powder; ^{1}H NMR (500 MHz, acetone-d_6, TMS) δ 4.94 (dd, J = 1.60, 10.80 Hz, 1H, H-1α), 5.21 (dd, J = 1.28, 17.40 Hz, 1H, H-1β), 6.01 (dd, J = 10.80, 17.40 Hz, 1H, H-2), 1.24 (s, 3H, 3-CH_3), 4.06 (t, J = 7.00 Hz, 1H, H-4), 1.77 (m, 2H, H-5), 1.85 (m, 1H, H-6α), 1.99 (m, 1H, H-6β), 1.23 (s, 3H, H-8), 1.20 (s, 3H, H-9), 4.60 (d, J = 7.70 Hz, 1H, H-1′), 3.10 (t, J = 8.40 Hz, 1H, H-2′), 3.39 (d, J = 8.35 Hz, 1H, H-3′), 3.29 (m, 1H, H-4′), 3.29 (m, 1H, H-5′), 3.64 (m, 1H, H-6′α), 3.80 (m, 1H, H-6′β); ^{13}C NMR δ 111.3 (C-1), 145.5 (C-2), 79.0 (C-3), 84.2 (C-4), 38.3 (C-5), 27.5 (C-6), 83.5 (C-7), 23.8 (C-8), 22.4 (C-9), 97.9 (C-1′), 75.2 (C-2′), 78.1 (C-3′), 71.8 (C-4′), 77.2 (C-5′), 63.1 (C-6′); ESI-MS m/z 331.2 $[M - H]^-$.

2-Phenylethyl-β-D-glucoside (12): colorless amorphous powder; ^{1}H NMR (500 MHz, acetone-d_6, TMS) δ 7.18−7.30 (m, 5H, H-2, 3, 4, 5, 6), 3.23 (t, J = 8.56 Hz, 2H, H-7), 4.06 (m, 2H, H-8), 4.36 (d, J = 7.72 Hz, 1H, H-1′), 2.95 (m, 1H, H-2′), 3.39 (m, 1H, H-3′), 3.40 (m, 1H, H-4′), 3.41 (m, 1H, H-5′), 3.68 (m, 1H, H-6′α), 3.85 (m, 1H, H-6′β); ^{13}C NMR δ 139.0 (C-1), 128.2 (C-2, 6), 128.9 (C-3, 5), 126.0 (C-4), 36.0 (C-7), 70.0 (C-8), 103.5 (C-1′), 73.9 (C-2′), 76.6 (C-3′), 70.8 (C-4′), 77.0 (C-5′), 62.1 (C-6′); ESI-MS m/z 283.3 $[M - H]^-$.

Purification of the methanol extract of *C. tinctoria* allowed for the isolation of three new phenolics, coretinphenol (**1**), coretincone (**2**), and coretinphencone (**3**), and nine known compounds, including butein (**4**), okanin (**5**), isoliquiritigenin (**6**), maritimetin (**7**), taxifolin (**8**), isookanin (**9**), marein (**10**), sachalinoside B (**11**), and 2-phenylethyl-β-D-glucoside (**12**). The structures of these compounds were elucidated using a combination of spectroscopic methods and chemical analysis. To the best of our knowledge, this is the first report concerning the isolation of compounds **1**−**3**, **6**, **7**, **9**, **11**, and **12** from *C. tinctoria*. Compounds **5**−**9** exhibited strong antioxidant activity against DPPH radical, and compounds **2** and **8** showed ACE inhibitory activity. It is worth mentioning, however, the bioactivities of these compounds in vitro are not necessarily equal to their actual beneficial effects in vivo. These mainly depend on the bioaccessibility and bioavailability in vivo, where they are mostly mixed with biomacromolecule such as carbohydrates, lipids, and proteins to form the complex matrix. Several factors interfere with the real effects of a compound, such as food source and chemical interactions with other phytochemicals and biomolecules present in the food matrix.[34] Further studies should be carried out to assess the bioactivities of these compounds in animal experiments, as well as to validate their real effects in the human body in the future.

In conclusion, 12 compounds have been identified from the buds of *C. tinctoria*, and 8 of these compounds have been isolated for the first time. In particular, three of these compounds have been identified as novel phenolics: coretinphenol (**1**), coretincone (**2**), and coretinphencone (**3**). The findings in the current research may explain, in part, the antioxidant function and antihypertensive effect of *C. tinctoria* as a tea beverage and a folk medicine. Further studies are warranted to confirm the antihypertensive effect of *C. tinctoria* in vivo and elucidate the mechanism of ACE inhibition.

Supporting Information

ABSTRACT: Hepatocellular carcinoma (HCC) has become one of most common malignancies and a leading cause of cancer mortality worldwide. Previous study has shown that 4-acetylantroquinonol B (4AAQB) isolated from *Antrodia cinnamomea* (or niu-chang-chih) was observed to inhibit HepG2 cell proliferation via affecting cell cycle. However, the in vivo effects and antimetastatic activity of 4AAQB have not yet been addressed. This study found that 4AAQB inhibited HepG2 and HuH-7 hepatoma cell growth in both in vitro and in vivo models and exhibited pronounced inhibitory effects on HuH-7 tumor growth in xenograft and orthotopic models. 4AAQB efficiently inhibited the phosphorylation of mTOR and its upstream kinases and the downstream effectors and decreased the production of VEGF and activity of Rho GTPases in HuH-7 cells. Furthermore, 4AAQB inhibited in vitro HuH-7 cell migration and in vivo pulmonary metastasis. The results suggested that 4AAQB is a potential candidate for HCC therapy.

KEYWORDS: *hepatocellular carcinoma, Antrodia cinnamomea, 4AAQB, RhoGTPase, mTOR, metastasis, VEGF*

INTRODUCTION

Hepatocellular carcinoma (HCC) has become one of the most common malignancies and a leading cause of cancer mortality worldwide. It causes more than a million fatalities each year worldwide, and it is prevalent in Asia, including Taiwan; however, the increasing incidence of HCC has also been reported in Western countries.[1,2] The predominant risk factor in Asia and Africa is chronic hepatitis B viral (HBV), which, however, in Western countries and Japan is chronic hepatitis C viral (HCV) infection.[3,4] Although surgery is the most effective therapeutic approach for HCC, tumor invasiveness, intrahepatic spread, and extrahepatic metastasis are the key factors affecting HCC prognosis.[5] Therefore, it is important to elucidate the molecular pathogenesis of HCC to develop new strategies against this devastating disease.

There are many signaling pathways involved in tumor cell growth and metastasis.[6] The phosphatidylinositol 3-kinase (PI3K)/Akt pathway was demonstrated to play a major role in these processes. PI3K can then activate Akt that subsequently phosphorylates several other cytoplasmic proteins and mammalian target of rapamycin (mTOR). mTOR phosphorylates the translational regulators p70S6 kinase (p70S6K) and eukaryotic initiation factor (eIF) 4E-binding protein 1 (4E-BP1), resulting in cell growth promotion and cell cycle progression.[3,7] The PI3K/Akt/mTOR signaling pathway has recently become a promising target owing to its frequent activation and dysregulation in HCC. The mTOR pathway is activated in >50% patients with HCC, and phosphorylation of Akt has also been detected in up to 71% of HCC samples. This aberrant signaling is associated with invasion and metastasis of HCC and correlated with poor outcome.[8]

Antrodia cinnamomea (niu-chang-chih) is a well-known medicinal mushroom and grows naturally only in Taiwan. It has been applied in traditional Chinese medicine for the treatment of diarrhea, food poisoning, drug intoxication, abdominal pain, itchy skin, hypertension, and cancer therapy.[9,10] The biological activities of *A. cinnamomea* have been described, including antioxidant, anti-inflammatory, hepatoprotective, and antitumor activities.[11−13] *A. cinnamomea* has recently become more popular as a therapeutic agent for several human cancers.[9,11,14]

Several pure compounds in the fruiting body and mycelium of *A. cinnamomea* with antitumor activity have been isolated and identified,[12] particularly for hepatoma via the inhibition of cell growth and induction of apoptosis in human liver cancer cell lines.[15,16] Lin et al. isolated 4-acetylantroquinonol B (4AAQB) from the mycelium of *A. cinnamomea*, which potently inhibited the proliferation and growth of the hepatocellular carcinoma cell line (IC_{50} = 0.1 μg/mL).[17] A previous study showed that 4AAQB exerted an inhibitory effect on tumor growth by decreasing the expression of CDK2 and CDK4 and increasing the expression of p27, p53, and p21, resulting in cell cycle arrest.[18] However, to the best of our knowledge, there

have been no studies reporting that 4AAQB and other related antroquinonol compounds exhibit anticancer efficacy in in vivo models. In this study, we found that 4AAQB inhibited the PI3K/Akt/mTOR pathways in the human hepatocellular carcinoma cell line HuH-7. In addition, 4AAQB displayed prominent antitumor and antimetastatic effects in xenograft and lung metastasis models.

MATERIALS AND METHODS

Materials. 4-Acetylantroquinonol B was isolated from the mycelium of *A. cinnamomea* as described previously.[17] Lactate dehydrogenase (LDH) assay reagents were purchased from Promega (Madison, WI, USA). Antibodies to phospho-Akt (Ser473), phospho-mTOR (Ser2448), were purchased from Epitomics (Burlingame, CA, USA). Antibody to phospho-ERK1/2 (Thr202/Tyr204), ERK1/2, phospho-p70S6K (Thr389), and β-actin were purchased from Cell Signaling Technologies (Boston, MA, USA).

Cell Culture. Human hepatocellular carcinoma cell lines HepG2 and HuH-7 were obtained from the American Type Culture Collection. HepG2 and HuH-7 cells were cultured at 37 °C in HEPES-buffered Dulbecco's modified Eagle's medium (DMEM), containing 10% fetal bovine serum (Gibco) supplemented with $NaHCO_3$, glutamax I (Gibco), 100 IU/mL penicillin G (sodium salt), 100 μg/mL streptomycin, and 0.25 μg/mL amphotericin B (antibiotic−antimitotic solution, Gibco).

Cell Viability Assay. Hepatoma cells (HepG2 and HuH-7, 5×10^3 cells/well) were subcultured onto 96-well plates and starved with serum-free DMEM for 48 h. Then hepatoma cells were incubated in DMEM with 10% FBS in the absence or presence of various concentrations of 4AAQB (0.1, 0.3, 1, 3, and 10 μg/mL) for 48 h. After treatment, the medium was discarded first. To fix the adherent cells, 100 μL of trichloroacetic acid (10% (w/v)) was added to each well and incubated at 4 °C for 1 h. Then the plates were washed with deionized water and dried in the air. To each well was added 50 μL of sulforhodamine B (SRB) solution (0.4% w/v in 1% acetic acid) and incubated for 5 min at room temperature. To remove unbound SRB in the plates, the plates were washed with 1% acetic acid and then air-dried. The residual bound SRB was solubilized with 100 μL of 10 mM Tris base buffer (pH 10.5) and then read using a microtiter plate reader at 495 nm.

Cell Cycle Analysis. HuH-7 cells were pretreated with vehicle and different concentrations of 4AAQB for 24 h. Cell cycle experiments were performed with HuH-7 cells treated with vehicle as a control. According to the manufacturer's protocol (Apoptosis and Cell Proliferation Kit; BD Biosciences, San Jose, CA, USA), the experiment was conducted and analyzed by flow cytometry.

Oligonucleotide Microarray Analysis. HuH-7 cells were pretreated with vehicle or 4AAQB (3 μg/mL) for 24 h. Microarray experiments were performed with HuH-7 cells treated with vehicle as a control. According to the manufacturer's guidelines, the synthesized cDNA was synthesized and hybridized onto Human OneArray microarrays (Phanlanx Biotech Group, Hsinchu, Taiwan). Data analysis was conducted also according to the manufacturer's guidelines. Target preparation was performed using an Eberwine-based amplification method with an Amino Allyl Message Amp II aRNA Amplification Kit (Ambion, AM1753) to generate amino-allyl antisense RNA. Labeled aRNA coupled with NHS-CyDye was prepared and purified prior to hybridization. Purified coupled aRNA was quantified using a NanoDrop ND-1000. All array results were verified by the CyDye incorporation efficiency at >10 dye molecules/1000 nt. After duplicate sample analysis, there were 1177 up-regulated genes and 791 down-regulated genes.

Western Blotting. Western blotting was performed as previously described.[19] HuH-7 cells were pretreated with vehicle of various concentrations of 4AAQB (0.3, 1, 3, and 10 μg/mL) for 12 h. For the Rho/Rac1 pull-down assay, cells were harvested as described above and processed according to the manufacturer's protocol (Rho/Rac1 Activation Assay kit; Millipore, Billerica, MA, USA). The binding active Rho/Rac1 proteins were detected by Western blotting.

ELISA. HuH-7 cells (10^5 cells/well in 96 wells) were treated with various concentrations of 4AAQB or vehicle for 24 h, and then the supernatant was collected to examine the amount of vascular endothelial growth factor (VEGF) protein. A VEGF Human ELISA Kit (Novex, Invitrogen) was used according to the manufacturer's instructions.

Migration Assay. Migration assay of HuH-7 cells was measured by Coaster Transwells (polycarbonate filter, 8 μm pore size), which were coated with 0.2% gelatin. HuH-7 cells (5×10^4 cells/well) were treated with vehicle or different concentrations of 4AAQB (1, 3, ad 10 μg/mL), and then cells were seeded into the upper chamber. To the bottom chamber was added DMEM supplemented with 10% FBS. After incubation at 37 °C for 16 h, all nonmigrant cells were removed from the upper face of the Transwell membrane with a cotton swab, and the HuH-7 cells that had transmigrated through the micropore and that were still bound to the membrane were fixed with 4% paraformaldehyde in PBS solution and stained with 0.5% toluidine blue in 4% paraformadehyde. Migration was quantified by counting the number of stained cells on the membrane under a light microscope (Nikon, Japan) at a magnification of 200× in three random fields and then photographed. All determinations were obtained by replication in at least three independent experiments.

Animals. Male NOD SCID mice (8−10 weeks old) were used in all studies. All of the experimental protocols regarding animal study have been approved by the Institutional Animal Care and Use Committee at College of Medicine, Tzu-Chi University.

Subcutaneous Xenograft Models. HepG2 or HuH-7 (2×10^6) cells in a volume of 100 μL were injected subcutaneously into the right flank of the male NOD SCID mice. After 9 days, when tumors reached 2 mm in diameter, the mice were randomly given vehicle or 4AAQB at a dosage of 0.2 or 2 mg/kg for the HepG2 model and at a dosage of 0.5 or 2 mg/kg for the HuH-7 model once daily by intraperitoneal injection. Tumor size and body weight were measured every day. The tumor volume was calculated according to the following formula: $V = (\text{length} \times \text{width}^2/2)$. In accordance with the Animal Ethics Committee, the experiments should be stopped when an unbearable situation appeared in animals.

Immunohistochemistry Study. Paraffin embedded tumor were cut in 25 μm sections and then immunolocalized with ROCK1. The sections were incubated with 1% H_2O_2 and washed three times in PBS containing Triton X-100 (0.4%) and 2% BSA. Blocking was performed with 10% BSA and then incubated on a rocking table with Rock1 monoclonal antibody at 4 °C overnight. Sections were washed with PBS, incubated with the biotinylated anti-mouse IgG, washed with PBS again, and then incubated with 0.2% ABC solution (Vector Laboratories, Burlingame, CA, USA). After a washing with PBS, sections were treated with DAB (Sigma) for 15 min. Sections were mounted on gelatinized slides, air-dried overnight, and coverslipped.

Orthotopic Tumor Models. An orthotopic tumor model was created by intrahepatically injecting 2×10^6 HuH-7 cells in a volume of 100 μL into 8−10-week-old male NOD SCID mice. Seven days after implantation, mice were randomly divided into two groups (vehicle and 4AAQB). 4AAQB-treated groups received 2 mg/kg by intraperitoneal injection every day. The tumor-bearing mice were sacrificed by CO_2 asphyxiation on day 25 after administration of 4AAQB, and the livers were excised. Tumor-bearing liver lobes were fixed in formalin (10%). The orthotopic hepatocarcinoma area of liver surface was white and the background was dark red. White area was quantified using ImageJ software.

Experimental Metastasis Analysis. Metastasis analysis was performed as previously described.[20] Briefly, HuH-7 cells (2×10^6 cells) were slowly injected into the lateral tail vein of NOD SCID mice to initiate tumor metastasis. 4AAQB (0.5 or 2 mg/kg) was intraperitoneally administered to mice everyday from 3 days before tumor cell injection to 21 days after tumor cell injection (the day sacrificed).

Statistical Analysis. All values are presented as the mean ± SEM. Differences between groups were assessed by one-way ANOVA and Newman−Keuls multiple-comparison test when appropriate. p values <0.05 ($p < 0.05$) were considered to be significantly different.

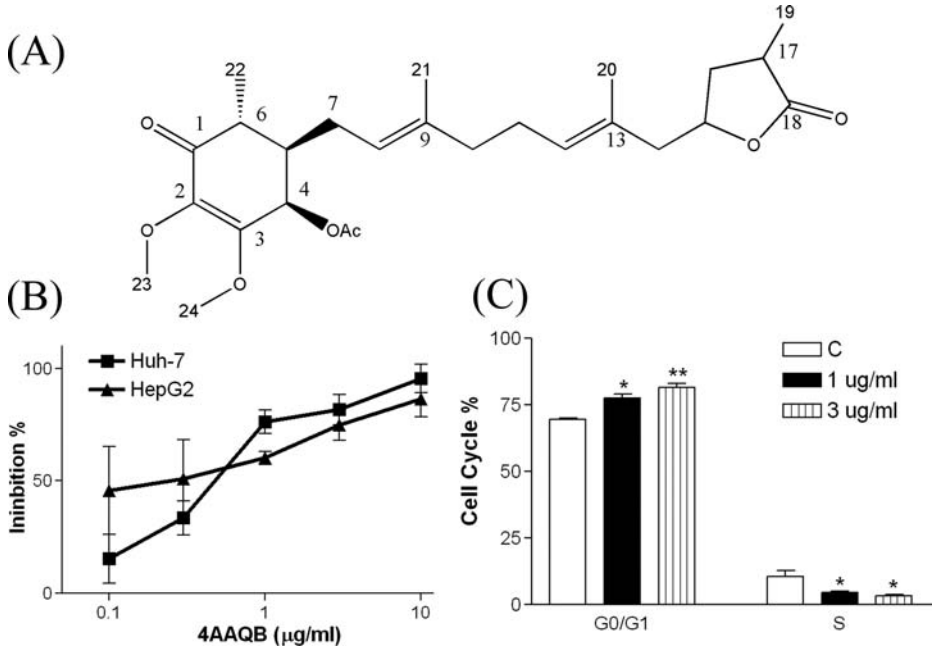

Figure 1. Structure of 4AAQB and its effect on hepatoma cell viability and cell cycle. The structure of 4AAQB is shown in panel A. HepG2 (B) and HuH-7 (C) cells were seeded onto plates for 24 h and starved for another 48 h with serum-free DMEM. Quiescent cells were cultivated with DMEM containing 10% FBS in the absence or presence of various concentrations of 4AAQB. After 48 h, cell viability was detected by the SRB assay. The results are presented as percentages of inhibition (mean ± SEM, $n = 4$). (D) HuH-7 cells were treated with vehicle or 4AAQB (1 and 3 μg/mL) for 24 h and analyzed by flow cytometry. Cell cycle distribution is shown as percentage in cell cycle phase.

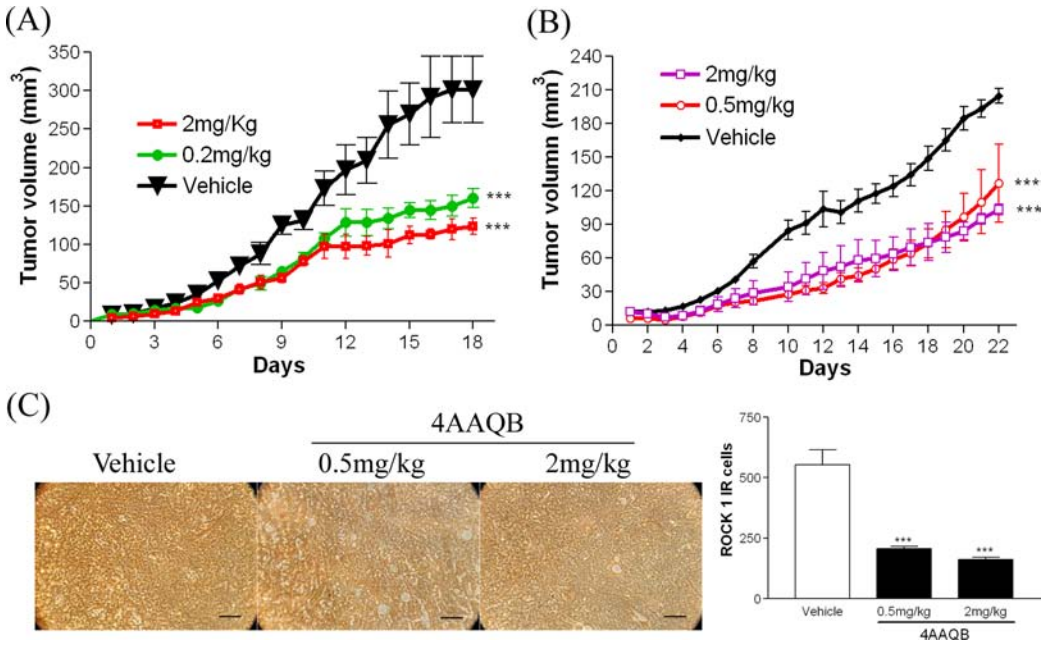

Figure 2. Effect of 4AAQB on HepG2 and HuH-7 tumor xenograft in vivo. SCID mice were sc inoculated with 2×10^6 cells of HepG2 (A) or HuH-7 (B). When tumors reached 2 mm in diameter, mice were administered vehicle or indicated dosage of 4AAQB by intraperitoneal injection once daily (QD). The tumor volumes of HepG2 and HuH-7 xenograft models were measured and plotted daily in 4AAQB-treated or control mice: points, mean tumor volume (mm^3). (C) Expression of ROCK1 in HuH-7 tumor xenograft was studied, and the ROCK 1 immunoreactive (IR) cells were counted. Scale bar = 10 μm, SE; (*) $p < 0.05$ and (***) $p < 0.001$.

RESULTS

Effects of 4AAQB on the Inhibition of HepG2 and HuH-7 Hepatoma Cell Proliferation. The structure of 4AAQB is shown in Figure 1A. A previous study reported that 4AAQB displayed a great growth inhibitory effect on HepG2 cells.[17] Because hepatocellular carcinoma is the major type in hepatoma and HepG2 is a hepatoblastoma, we used another hepatocellular carcinoma cell line, HuH-7, to examine the inhibitory effects of 4AAQB in this study. We first determined the effect of 4AAQB on hepatoma cell proliferation. HepG2 and HuH-7 cells were treated with 4AAQB for 48 h, followed by SRB assay. As shown in Figure 1B,C, 4AAQB inhibited the

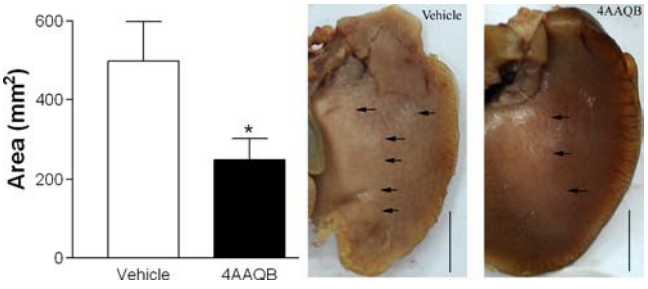

Figure 3. In vivo effect of 4AAQB on human hepatocellular carcinoma (HCC) growth in orthotopic xenograft models. SCID mice were intrahepatically inoculated with 2×10^6 cells of HuH-7. After 7 days, the mice were treated intraperitoneally with 4AAQB or vehicle once daily. Arrow bar is used to point out the orthotopic hepatocarcinoma area, which was quantified using ImageJ software. Scale bar = 2.5 mm.

proliferation of HuH-7 cells in a concentration-dependent manner, with a similar potency in HepG2 cells (IC_{50} = 0.57 μg/mL, ≈1.9 μM, in HuH-7 and 0.365 μg/mL, ≈1.22 μM, in HepG2).

Effects of 4AAQB on HuH-7 Cell Cycle. In light of a previous study showing that 4AAQB causes cell cycle arrest in HepG2 cells, we further examined the effects of 4AAQB on cell cycle and apoptosis in HuH-7 cells. Here we found that after treating the cells with 4AAQB, the proportion of cells in the G0/G1 phase is increased and that in the S phase decreased (Figure 1D). However, 4AAQB did not induce cell apoptosis in HuH-7 cells (data not shown).

Antitumor Effects of 4AAQB in in Vivo Models. To assess the antitumor effects of 4AAQB in vivo, HepG2 and HuH-7 cells were subcutaneously injected into the right flanks of NOD/SCID mice to establish a xenograft model. Tumor-bearing mice were intraperitoneally administered 4AAQB at a dosage of 0.2 or 2 mg/kg/day for the HepG2 model and at a dosage of 0.5 or 2 mg/kg/day for the HuH-7 model. Tumor volume rapidly increased in the vehicle group in both models. The administration of 4AAQB significantly suppressed tumor growth in a dose-dependent manner in both models (Figure 2). In addition, ROCK-1 expression was studied by DAB staining. The 4AAQB-treated group significantly decreased ROCK1 expression in the HuH-7 tumor cell (Figure 2C). Therefore, we examined whether 4AAQB elicits antitumor activity when HuH-7 tumor cells are orthotopically transplanted. Seven days after tumor transplantation, mice were intraperitoneally administered vehicle or 4AAQB at a dosage of 2 mg/kg/day. In this intrahepatic model, 4AAQB also exhibited a pronounced inhibitory effect on tumor growth (Figure 3). These results clearly showed that 4AAQB displayed antitumor activity in vivo.

Effects of 4AAQB on mRNA Expression. To determine whether 4AAQB treatment induces transcriptomic changes, a microarray using the Human OneArray system were performed. The top 10 enrichment pathway terms from gene set enrichment analysis are shown in Supplementary Table 1 in the Supporting Information. The top-scoring network was linked with the ECM pathway. In this pathway, there were six genes that were significantly down- or up-regulated (MAPK1, TGB1, RAF1, ROCK1, ARHGAP5, and GSN). These genes are known to be associated with cell shape changes during cell spreading or migration, in which both ERK and PI3K are known to be important. In addition, we found that the expression of epithelial-mesenchymal transition (EMT)-asso-

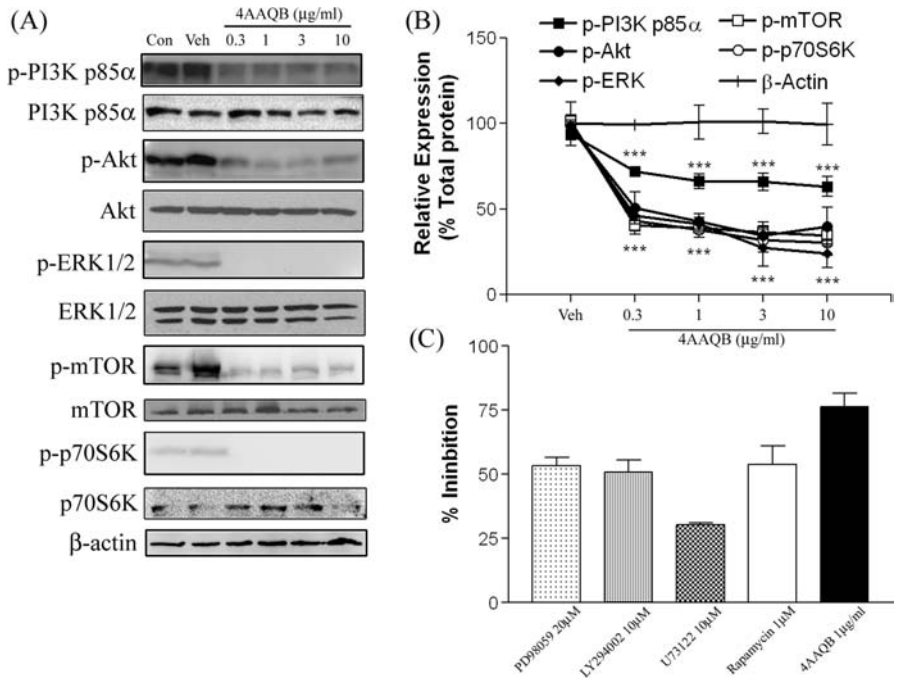

Figure 4. Effect of 4AAQB on PI3K/Akt/mTOR and ERK pathways. (A) HuH-7 cells were incubated in the absence or presence of 4AAQB (0.3−1 μg/mL) for 30 min. Then, the cells were harvested and lysed for the detection of the PI3K/Akt/mTOR and ERK pathway activation by Western blot. β-Actin expression is protein loading control. (***) $p < 0.001$ compared with the vehicle (CTL) group.

ciated genes was altered after 4AAQB treatment (Supplementary Table 2).

4AAQB Inhibits the PI3K/Akt/mTOR and ERK Pathways in HCC Cells. Given that the cell cycle was partly affected by 4AAQB and that the microarray data showed that the expression of EMT-associated genes was altered after 4AAQB treatment, we validated this observation to further understand the underlying mechanism of action of 4AAQB. The PI3K/Akt/mTOR and RAS/RAF/MAPK pathways, well-known signaling pathways, are important in HCC development. Thus, followup experiments to determine whether 4AAQB affects the phosphorylation of these proteins in HuH-7 cells were performed. Western blot experiments showed that 4AAQB suppressed the phosphorylation of PI3K, Akt, mTOR, p70S6K, and ERK (Figure 4). However, the total expression of these proteins was not affected after 4AAQB treatment. These results indicated that the anticancer activity of 4AAQB against HuH-7 cells is associated with the PI3K/Akt/mTOR and ERK pathways. We further compared 4AAQB's inhibitory activity on cell proliferation with the well-characterized inhibitors of these pathways to determine their correlation in HuH-7 cells. HuH-7 cells were treated with either 20 μM PD98059 (ERK-specific inhibitor), 10 μM LY294002 (PI3K-specific inhibitor), 10 μMU73122 (PLC inhibitor), or 1 μM rapamycin (mTOR inhibitor), followed by SRB assays. As shown in Figure 4B, PD98059, LY294002, and rapamycin resulted in approximately 50% inhibition of cell growth, indicating that ERK, PI3K, and mTOR are involved in HuH-7 cell growth, whereas 4AAQB (1 μg/mL) resulted in an inhibition to a greater extent. However, U73122 resulted in only a 25−30% inhibition.

4AAQB Inhibits VEGF Release. As per previous study, high VEGF expression is associated with hepatocellular carcinoma progression.[21] The PI3K/Akt/mTOR pathway increases the synthesis of transcript factors to regulate the expression and production of VEGF. Therefore, we examined the effect of 4AAQB on VEGF release in HuH-7 cells. After a 24 h treatment with various concentrations of 4AAQB, the supernatant was collected for analysis. 4AAQB was observed to suppress VEGF release in a concentration-dependent manner in HuH-7 cells (Figure 5A).

Effects of 4AAQB on Rho and Rac1 Activation. The Rho GTPase signaling cascade, including Rho and Rac which are activated by VEGF, is a key regulator of cytoskeletal dynamics and affects various cellular processes such as vesicle trafficking, cytoskeleton regulation, and migration.[22] As shown in Figure 5B, we found that 4AAQB inhibited the activation of Rho and Rac1 in a concentration-dependent manner, indicating that Rho GTPases are involved in the inhibitory actions of 4AAQB.

4AAQB Inhibits in Vitro Cell Migration and in Vivo Pulmonary Metastasis in HuH-7 Cells. Because of the EMT-associated genes that were altered after 4AAQB treatment (Supporting Information, Supplementary Table 2), we further examined whether 4AAQB affects cell migration in HuH-7 cells. As shown in Figure 6A, HuH-7 cell migration was inhibited by 4AAQB in a concentration-dependent manner. Finally, we investigated the effect of 4AAQB in the HuH-7 lung metastasis model in NOD/SCID mice. In this model, a single intravenous bolus injection of 2×10^6 HuH-7 cells resulted in lung metastases. 4AAQB (0.5 or 2 mg/kg) was intraperitoneally administered to the mice from 3 days before tumor cell injection. Twenty-one days later, the mice were sacrificed, and lungs were removed. Mice treated with 4AAQB result in a significant dose-dependent reduction in lung metastases (Figure 6B).

■ DISCUSSION

A. cinnamonea has been widely used to treat cancer and inflammation. Various components isolated from the fruiting bodies and mycelia of *A. cinnamomea* have been reported to exhibit some biological activity.[23] Antroquinonol, a ubiquinone derivative isolated from the mycelia of *A. cinnamomea*, shows potent anticancer activity against various human malignant carcinoma cell lines; it is particularly potent against Hep3B (IC_{50} = 0.13 ± 0.02 μM).[24] Morever, it has been reported to display hepatoprotective effects both in vitro and in vivo.[25] Lin and Chiang further investigated the mechanism of action of 4AAQB and found that it potently inhibits HepG2 cell

J. Agric. Food Chem. 2015, 63, 208−215

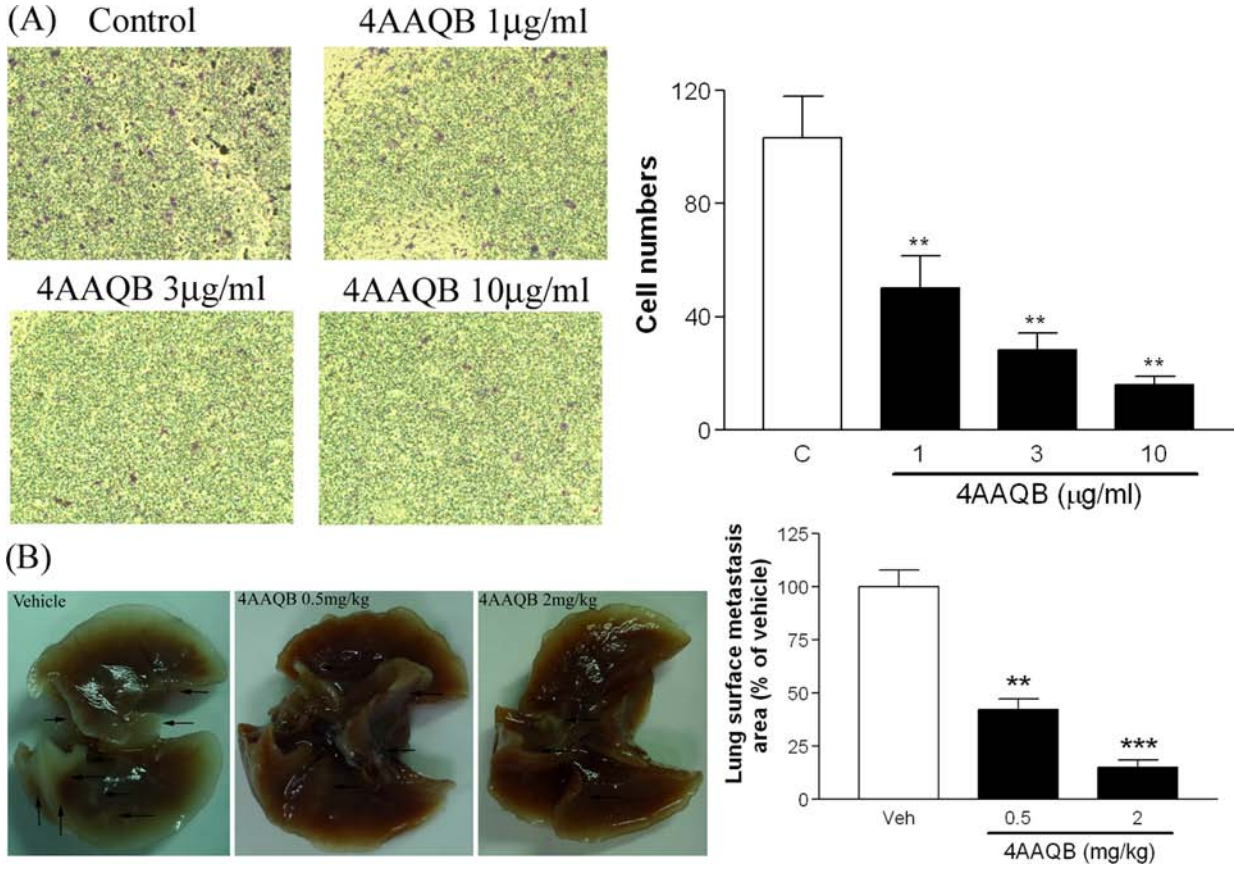

Figure 6. Effects of 4AAQB on cell migration and experimental lung metastasis. (A) HuH-7 cells were treated with various concentrations of 4AAQB and migrated through gelatin-coated transwell for 16 h. The migrated cells were counted, and data are expressed as the mean ± SEM of three independent experiments. (**)$p < 0.01$ compared with control (CTL) group. (B) HuH-7 hepatocellular carcinoma cells (10^6) were injected into the lateral tail vein of a SCID mouse. Twenty-one days later, the lungs were removed, and surface-visible tumors were counted in the absence and presence of 4AAQB treatment. The hepatocarcinoma metastasis area of lung surface is white and the background is dark red. The white area was quantified using ImageJ software. A corresponding bar graph is expressed as percentage of vehicle ($n = 8$).

proliferation by exerting various effects on cell cycle regulators.[18] The present study reveals that 4AAQB significantly suppresses HuH-7 cell proliferation, with a similar inhibitory effect on HepG2 cells, and exhibits potent antitumor effects in vivo. To the best of our knowledge, this is the first study to demonstrate the antitumor effect of 4AAQB in vivo.

Aberrant activation and deregulation of the PI3K/Akt/mTOR pathway occurs in various human cancers. This pathway has become one of the most important therapeutic targets for anticancer drug development because of its integral role in the regulation of various important cellular processes.[3,7,26] Currently, targeting mTOR signaling pathways for chemotherapy for cancer, including HCC, is investigated because of its aberrant activation in approximately 50% patients.[27] Microarray data also showed that various genes were affected by 4AAQB treatment, especially linking with the ECM pathway (Supporting Information, Supplementary Table 1), indicating that the effect of 4AAQB may be associated with this pathway. We further found that 4AAQB effectively inhibited the phosphorylation of mTOR and its upstream kinases, PI3K and Akt, and the downstream effectors (p70S6K) in HuH-7 cells (Figure 4). It has been shown that p70S6K activity is essential for G1 progression.[28] This result may be supported by the fact that 4AAQB induced G1 arrest in HepG2 cell in a previous study[18] and in HuH-7 cells in our study. However, 4AAQB did not induce apoptosis in HuH-7 cells, indicating that its antiproliferative activity excluded an apoptotic effect. The mTOR signaling pathway is also regulated by a PI3K/Akt-independent pathway, such as ERK, p38 MAPK, and AMPK[29] (Figure 4). We also use these kinase inhibitors to evaluate the importance of these protein kinases involved in cancer cell growth. Because 4AAQB significantly inhibited the phosphorylation of the ERK/PI3K/mTOR signaling pathway and ERK/PI3K/mTOR inhibition is correlated with cancer cell growth inhibition, the anticancer effect of 4AAQB may dependent on PI3K/Akt/mTOR pathway blockage.

In addition, mTOR plays a key role in angiogenesis, that is, the formation of new blood vessels to provide oxygen and nutrients to growing and dividing cells. mTOR activation through the PI3K/Akt pathway is associated with increased translation of hypoxia-inducible factor (HIF)-1α, therefore driving the expression of angiogenic growth factors.[30] VEGF is spontaneously produced by hepatoma cells; after a 24 h treatment with 4AAQB, VEGF production decreased in concentration-dependently in HuH-7 cells (Figure 5A), indicating that a downstream effector of mTOR was also inhibited by 4AAQB. VEGF, acting directly through the VEGF receptor (VEGFR), leads to the activation of a downstream signaling pathway and phenotypic changes such as an increase in cell migration and invasion.[31] A growing body of evidence indicates that one of the signaling cascades activated by VEGF, Rho GTPases including Rho, Rac1, and Cdc42, plays a crucial

DOI: 10.1021/jf504434v
J. Agric. Food Chem. 2015, 63, 208−215

role in controlling a variety of cellular processes such as cell proliferation, actin cytoskeleton reorganization, and gene expression.[32,33] The aberrant activity of GTPases has been implicated in cancers and other diseases.[34,35] In the present study, 4AAQB inhibited the activation of Rho and Rac1 in a concentration-dependent manner (Figure 5B).

Various therapeutic approaches, including resection, hepatic artery injection sclerotherapy, ethanol injections, and ablation therapy, have had remarkable effects on primary lesions in HCC. However, HCC prognosis remains poor because of tumor invasiveness, intrahepatic spread, and extrahepatic metastase.[36] Pulmonary lesions are the most common extrahepatic HCC metastases, accounting for 50−60% of the total metastases that occur.[37,38] Therefore, more aggressive treatments for extrahepatic metastases need to be considered. In the in vivo pulmonary metastasis model, 4AAQB dose-dependently reduced lung metastasis foci (Figure 6B), indicating that 4AQQB exhibited not only antitumor but also antimetastatic activities toward HCC.

In conclusion, we demonstrated that 4AAQB inhibited tumor growth in vitro by inducing cell cycle arrest and blocking the PI3K/Akt/mTOR and ERK pathways. The production of VEGF and activity of Rho GTPase were also decreased after 4AAQB treatment. More importantly, 4AAQB exhibited antitumor activity in vivo, including xenograft and orthotopic tumor models in addition to pulmonary metastasis. Taken together, our results suggest that 4AAQB is a potential anticancer agent for treating HCC. Although no clinical studies have been conducted with 4AQQB, two studies with *A. cinnamomea* have been approved. One study was aimed to determine the MTD/DLTs and safety/tolerability profiles of antroquinonol (pure compound purified from *A. cinnamomea*); no treatment-emergent adverse events (TEAEs) were reported as determined.[39] There are only mild side effects including stomach upset, dry mouth, and diarrhea, which can be alleviated by stopping use or taking the supplement with meals to relieve stomach upset and diarrhea. Further clinical trials are required for a full evaluation of this valuable medicinal mushroom for potential clinical applications.

Supporting Information

ABSTRACT: Prolamins from grains have attracted intensive attention in recent years due to their potential in satisfying the demand for environmentally friendly (biodegradable), abundantly available (sustainable), and cost-effective biomaterials. However, for kafirin, the prolamin from sorghum, its composition, structure, morphology, and self-assembly behaviors have not been fully characterized. In this paper, kafirin was extracted from the whole sorghum grain and found to contain 68, 14, 6, and 12% of α-, β-, and γ-fractions and cross-linked kafirin, respectively. Freeze-dried kafirin contained ~49% α-helix in the solid state. When dissolved in 65% (v/v) isopropanol, 60% (v/v) *tert*-butanol, and 85% (v/v) ethanol aqueous solvents, the relative α-helix content in kafirin increased with the decrease of solvent polarity. Structural analysis using small-angle X-ray scattering (SAXS) indicated that kafirin (2 mg/mL) took stretched and extended conformations with dimensions of 118 × 15 × 15 and 100 × 11 × 11 Å in 60% *tert*-butanol and 65% isopropanol, respectively. More elongated conformation of individual kafirin with high-order assembly was observed in 85% ethanol. Protein aggregation occurred as protein concentration increased in its good solvent. The morphology of kafirin assemblies captured by atomic force microscopy (AFM) revealed that kafirin protein took uniform particle morphology at low concentration, and disk-like or rod-like structures resulting from solvent evaporation induced particle interactions emerged at high concentrations. These results suggest that both protein concentration and solvent polarity can effectively regulate kafirin assemblies from thick rod-like to slim rod-like structures, a convenient way to tune the fibrillation of prolamin-based biomaterials.

KEYWORDS: *kafirin, SDS-PAGE, secondary structure, morphology, self-assembly, SAXS*

INTRODUCTION

Growing research interest in protein-based biomaterials has been stimulated by the demand for alternatives to traditional synthetic polymers that have expanded functional properties to accommodate a broader spectrum of applications.[1] Among various protein candidates, zein, the prolamin protein in maize, has received increasing research attention.[2,3] The composition, structure, dissolution, and gelation behavior of zein have been extensively studied.[4−7] Due to its unique properties, such as its solubility in aqueous alcohol, highly hydrophobic and non-allergenic nature, excellent oxygen barrier property, reduced susceptibility to proteolytic degradation, and ability to withstand gastric pH, zein is considered superior to other proteins, especially in the food packaging and drug delivery applications. Currently, research projects intended to explore its applications in tissue scaffolding, active ingredient encapsulation, and drug delivery are in full swing.[8−10]

Kafirin, the sorghum prolamin protein, resembles zein in its solubility, molecular weight, amino acid composition, and structure of polypeptides.[11,12] Compared to zein, kafirin is relatively more hydrophobic and less digestible,[13,14] which enables more stable films with superior gas and water vapor barrier characteristics. It is a more effective encapsulation vehicle with stronger protective function.[15] Therefore, kafirin has the potential to be an alternative to zein in biomaterial applications. Nevertheless, the effort to fulfill its potential is still seriously lacking. Of all the available research papers, only a few report kafirin's satisfying performance in film casting application.[16−19]

Many factors, such as protein composition, purity, concentration, secondary and tertiary structures, morphology, and self-assembly behavior, are known to affect the processing performance and functional properties of protein-based biomaterials.[20] To develop biomaterials from kafirin, it is necessary to understand the physical properties of kafirin in the first place. Although extraction methods and digestibility of kafirin received adequate research attentions, a clear view of the secondary structure, morphology, and self-assembly phenomena of kafirin and their relationship with processing properties is still absent.

In this presented work, we carried out a detailed investigation of kafirin on its composition, structure, morphology, and self-assembly behavior. The components of kafirin extracted from sorghum grain using 60% *tert*-butanol were identified on the basis of sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE). The secondary structure was characterized using Fourier transform infrared (FTIR) and circular dichroism (CD) in solid and liquid states. The morphology and self-assembly behavior of kafirin in different alcohol solutions were studied by synchrotron small-angle X-ray scattering

(SAXS) and atomic force microscopy (AFM). Key parameters affecting kafirin structure based on these measurements were obtained, and the results are very relevant in guiding future investigation of kafirin-based biomaterials with designed quality.

MATERIALS AND METHODS

Materials. Whole food-grade retail sorghum grain (*Sorghum bicolor* Moench) was purchased from Northern Food Inc. (Hicksville, NY, USA). Commercial zein (260-01283) was purchased from Wako Pure Chemical Industries, Ltd. (New York, NY, USA). Tris-alkali, sodium dodecyl sulfate (SDS), *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED), 2-mercaptoethanol (2-ME), bromophenol blue, Coomassie brilliant blue G-250, and prestained protein markers (broad range protein maker) were purchased from Bio-Rad Laboratories, Inc. (Hercules, CA, USA). Milli-Q water was used throughout the experiments.

Preparation of Kafirin by Ultrasound-Assisted *tert*-Butanol Extraction. Whole sorghum grain was milled to 40 mesh, and lipid was first removed from milled grain with *n*-hexane. The defatted flour was then extracted at room temperature with water followed by 0.5 M NaCl (the ratio of raw material to extract solution is 1:10) three times each (1 h each). At the end of each extraction cycle, the dispersion was centrifuged at 8000 rpm for 10 min and the supernatant was discarded to fully separate out the albumin and globulin proteins. The residue was then washed with distilled water three times in a similar way to remove salt. The remnants were then extracted by using 60% *tert*-butanol twice for 2 h each and 10 min of ultrasonication using an FS-28 solid-state ultrasonicator (bath type with sonic power, 225 W; sweep frequency, 40 kHz) (Fisher Scientific, Pittsburgh, PA, USA) at the interval of 30 min. The extract fraction was then centrifuged at 8000 rpm for 15 min, and the supernatant was then freeze-dried directly. Because the first extraction fraction contains pink color due to the coextraction of alcohol-soluble impurities, only the second extraction fraction was kept for further analysis. The second extract fraction powder has a white color, and the protein content was determined as 87% by combustion method with a nitrogen analyzer (FP-428, Leco Corp., St. Joseph, MI, USA) calibrated with analytical reagent grade EDTA (a factor of 6.25 was used to convert the nitrogen to protein).

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS-PAGE). Three milligrams of protein was denatured and reduced by heating samples at 95 °C for 5 min in 1 mL of loading buffer containing 0.01 mol/L Tris-HCl buffer (pH 6.8), 2% (w/v) SDS, 10%(v/v) glycerol, and 5% (v/v) β-mercaptoethanol (2-ME). The prestained protein marker (molecular weights ranging from 6.5 to 110.3 kDa) was used. Commercial zein was run under reducing condition as a control. Each sample solution (10 μL) or protein marker was loaded onto discontinuous sodium dodecyl sulfate polyacrylamide gel with 4% stacking gel and 12% separating gel. Migration was done in a Bio-Rad Mini-Protean II system under 90 V for 2 h. Gel was stained with 0.1% Coomassie brilliant blue G 250 in 45% methanol and 10% acetic acid and destained in solution with the composition ratio of methanol/acetic acid/water = 1:1:8, v/v/v. Gel was scanned by Bio-Rad Universal Hood II gel imaging system, and densitometry analysis was performed using Image J 2.1.4.7 software.

Amino Acid Composition Analysis. Seventy-five milligrams of kafirin was placed in a 20 mL ampule and mixed with 10 mL of 6 M HCl. After sealing, the protein was hydrolyzed at 110 °C for 22 h under vacuum. The hydrolysate was then dried under vacuum at 60 °C. The dried sample was dissolved in 3−5 mL of 0.2 M sodium citrate buffer (pH 2.2) to yield an amino acid concentration of 50−250 nmol/mL. The protein solution was filtered through a 0.2 μm syringe filter and loaded onto a Hitachi L-8800 amino acid analyzer (Tokyo, Japan) equipped with a Hitachi 2622SC ion-exchange column for amino acid composition analysis.

Attenuated Total Reflectance Fourier Transform Infrared (ATR-FTIR) Spectroscopy. ATR-FTIR spectra were collected by a Thermal Nicolet Nexus 670 FTIR spectrometer (Thermo Electron Corp., Madison, WI, USA). Kafirin protein powder was wrapped in aluminum foil and pressed into a flat pellet by hand to ensure good contact with the ATR crystal. Each spectrum was collected at wavenumber range from 4000 to 600 cm^{-1} and averaged over 256 scans with 4 cm^{-1} resolution. With the aid of OMNIC 7.2 software, the original FTIR spectrum was then smoothed with smoothing points (11, 21.213 cm^{-1}). Second-derivative (Savitsky−Golay derivative) analysis in the wavenumber ranging from 1700 to 1520 cm^{-1}, which covered the typical amide I and amide II peaks, was then conducted to identify positions of individual component peaks. With the assistance of Origin 9.0 software, multiple-peak fitting was conducted by fitting peak positions obtained from second-derivative to Gaussian functions. On the basis of the attribution relationship between component peaks and types of secondary structure, the ratio of secondary structure was determined by calculating the peak area ratio.

Circular Dichroism (CD) Spectroscopy. CD spectra were collected at 25 °C using an AVIV model 400 circular dichroism spectrometer equipped with 0.1 cm path length quartz cuvettes (model 110-OS, Hellma, USA). Wavelength scans were conducted from 190 to 260 nm with a bandwidth of 1 nm. Samples, with protein concentration of 0.2 mg/mL, were filtered by 0.45 μm membrane (Millipore, Ireland) before testing. Three scanning acquisitions were gathered, and one representative set of spectra was collected. For each spectrum, the medium baseline was subtracted and mean residue ellipticity (MRE) (mdeg·cm^2/dmol) versus wavelength was plotted.[21] It was calculated as $[\theta]\lambda = \mathrm{MRW}\theta\lambda/10dc$, where the average molecular weight of an amino acid residue is 109.867 g/mol, $\theta\lambda$ is the measured ellipticity at the specific wavelength in mdeg, c is the concentration of protein in g/mL, and d is the path length in cm. Secondary structure estimation was processed by curve fitting with reference CD curves of α-helix, β-sheet, random coil, and β-turn conformations.

Synchrotron Small-Angle X-ray Scattering. SAXS data were collected at Bio-CAT, 18-ID beam line section, at the Advanced Photon Source, Argonne National Laboratory. Freshly prepared kafirin (2 mg/mL) in 60% (v/v) *tert*-butanol, 65% isopropanol, and 85% ethanol aqueous solutions was examined. The X-ray wavelength was 1.033 Å, and the experimental setup included a 3 m sample-to-detector length camera and another 0.3 m sample-to-detector length camera with the high-sensitivity CCD detector. A quartz capillary flow cell of 1.5 mm diameter was fitted to a brass block; this sample holder was maintained at 25 °C in all experiments. A Microlab 500 Hamilton pump was used to load samples into the flow cell at a constant rate (10 mL/s) during X-ray exposure to minimize radiation damage. A single exposure of 1 s was used to acquire the scattering data, 15 curves were collected for each sample, and their averaged curves were utilized for further analysis. Identical measurement configurations were used for solvent backgrounds and sample solutions for proper background subtraction.

Small-Angle X-ray Scattering Data Analysis. The total scattering intensity, $I(Q)$, for a monodisperse protein can be expressed as[22]

$$I(Q) = n_p(\Delta\rho)^2 v^2 P(Q) S(Q) \quad (1)$$

where n_p is the number density of colloidal particles per unit volume in the solution, v is the specific volume of protein that can be predicted through the empirical equation proposed by Fischer et al.,[23] $Q = (4\pi/\lambda)\sin(\theta/2)$ is the scattering vector, where λ is the wavelength of the X-ray beam, θ is the scattering angle, and $\Delta\rho$ is the contrast of electron densities between proteins and solvent, $P(Q)$ is the form factor of a given protein that reflects the shape of individual protein, and $S(Q)$ is the structure factor that probes the structure of proteins in the solution. For an ellipsoidal particle with a parallel radius a and a perpendicular radius b of the equivalent ellipsoid of protein, the form factor can be expressed as[24,25]

$$P(Q) = \int_0^1 \left[\frac{3(\sin u - u\cos u)}{u^3}\right]^2 \mathrm{d}x \quad \text{with} \quad u = Qb\left[\frac{ax}{b} + (1-x)^2\right] \quad (2)$$

DOI: 10.1021/jf504674z
J. Agric. Food Chem. 2015, 63, 216−224

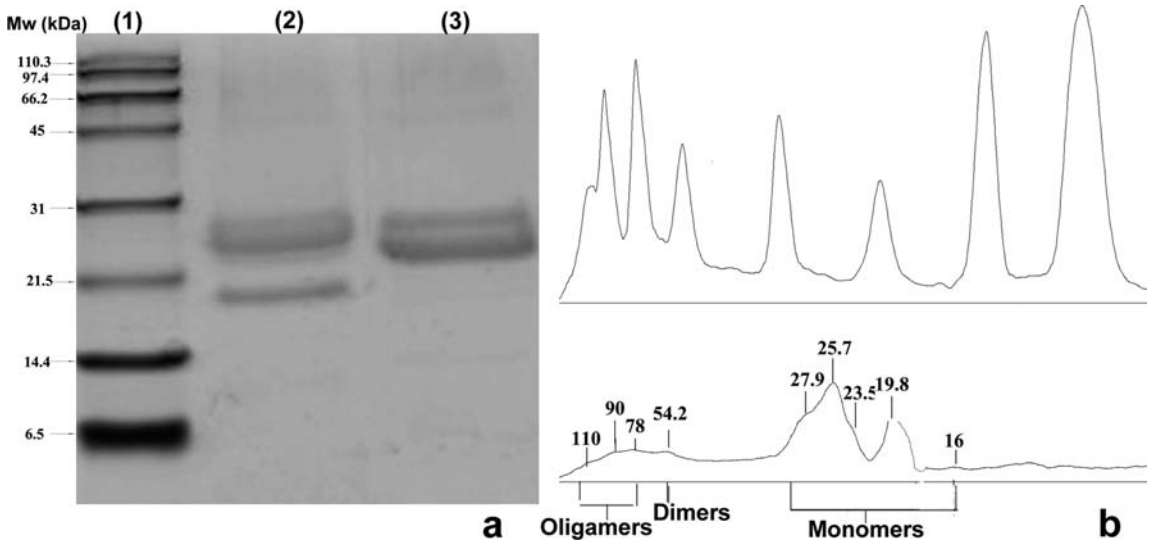

Figure 1. (a) Electrophoretic pattern of kafirin and zein under reducing conditions. Lanes: 1, protein marker; 2, kafirin under reducing condition; 3, commercial zein under reducing condition. (b) Plot fit curves for protein standard (upper) and kafirin (lower) under reducing conditions.

The protein aggregation and protein−protein interaction upon concentration increase in solutions can be described by using the effective structure factor $S(Q,C)$:[26]

$$S(Q, C) = \frac{C_0 I(Q, C)}{C I(Q, C_0)} \quad (3)$$

Here $I(Q,C)$ is the scattering intensity profile from a protein solution with concentration C, and C_0 corresponds to dilute solution in which protein aggregation is negligible.

Guinier analysis and pair distribution function (PDF) were used to obtain the radius of gyration R_g, cross-section radius of gyration (R_c), and size distribution, respectively. The Guinier approximation was given by

$$I(Q) = \alpha\pi Q^{-\alpha} A \exp\left(-\frac{R_\alpha^2 Q^2}{3-\alpha}\right) \quad (4)$$

where $\alpha = 0$ for a solid sphere, $\alpha = 1$ for a rod-like object, and $\alpha = 2$ for a sheet-like object. When the classic Guinier fit ($\alpha = 0$) was performed, A was equal to $I(0)$, the scattering intensity at $Q = 0$, and R_g equaled R_α. When rod-like Guinier fit was performed, R_c was equivalent to $\sqrt{2}R_\alpha$. When sheet-like Guinier fit was performed, T, the thickness, was equivalent to $(12)^{1/2}R_\alpha$.

GNOM package was used to generate the PDF $P(r)$, which displayed the probability of finding one point within the particle dimension D_m at a distance r from a given point.[27] The low-resolution structures (2−3 nm^{-1}) of kafirin in aqueous medium were restored by using the algorithm DAMMIN.[28,29] The program DAMMIN produced the model as an ensemble of densely packed beads inside a spherical search volume with a diameter D_{max}. The simulated annealing was utilized to find a compact conformation that had a minimum discrepancy between the experimental and calculated scattering curves. For each model body, five independent DAMMIN restorations were performed. Then, the program DAMAVER was used to generate the averaged model that represented the common features of all restorations at low resolution.

Atomic Force Microscopy (AFM). Tapping mode AFM images were collected with a NanoScope IIIA Multimode AFM (Veeco Instruments Inc., Santa Barbara, CA, USA) equipped with a silicon-etched RTESP7 cantilever (Veeco Nanoprobe, Camarillo, CA, USA). A silicon tip with nominal spring constant of 40 N/m was used. Before tip engagement, the drive frequency of the silicon tip was tuned to a frequency range of 300−320 kHz. Kafirin solutions (0.2 mL, dissolved in 60% butanol) with different initial concentrations of 0.1, 0.2, and 0.5 mg/mL were dripped onto a freshly cleaved mica surface; after 30 min of absorption, samples were dried under a stream of nitrogen gas. All of the collected images were flattened before further analysis. Section and bearing analyses, which were incorporated in the Nanoscope 5.30 software, were utilized to obtain the quantitative information of kafirin protein self-assembly morphology.

RESULTS AND DISCUSSION

Kafirin Composition. Kafirin and zein showed typical electrophoretic patterns as described by previous researchers[30,31] (Figure 1a). Under reducing conditions, kafirin showed major bands with M_r of 23.8 and 25.1 kDa, indicating the presence of α1-, α2-kafirin polypeptides. Bands at 19.8 and 27.9 kDa were identified as β- and γ-kafirin polypeptides. In addition, one light band was found at 54.2 kDa, suggesting the presence of stable dimers. A few faint bands of higher molecular weight were also present, indicating soluble oligomers. As a comparison, commercial zein showed predominately α1- and α2-zein bands at M_w of 22.1 and 25.4 kDa.

According to the calculated peak areas from the gel run under reducing conditions (Figure 1b), α-, β-, and γ-fractions and cross-linked kafirin (dimer and oligomers) account for 68, 14, 6, and 12% of the total detected kafirin, respectively. As a percent of total monomers this is equivalent to 77, 16, and 7% of α-, β-, and γ-fractions, respectively. Previous studies indicated that α-kafirin comprised 80−84%, whereas β- and γ-kafirin constituted 7−8 and 9−12% of the total monomers, respectively.[32−34] The main differences in the results, namely, decreased proportion in α- and γ-kafirin fractions and increased presence of β-kafirin, may have been due to the higher extraction yield of oligomers, which were composed of γ- and α- kafirins linked together by disulfide bonds.[35] Because γ- and β-kafirins and protein oligomers encapsulated α-kafirin in a disulfide-bound polymeric network in the protein body,[36] the ultrasound treatment with intense agitation and friction forces may effectively disrupt the cross-linked matrix, leading to a higher dissolution yield of cross-linked kafirin and soluble oligomers.[37]

Amino acid compositions of the extracted kafirin protein together with previously reported results of kafirin obtained by similar extraction procedures[38,39] are presented in Table 1.

[a]Analysis results reported by work of our laboratory. [b]Analysis results reported by work of R. W. Jones [c]Analysis results reported by work of R. Jambunathan.

Paired two-tail t tests showed p values of 0.88 and 0.78 compared with Jones's and Jambunathan's papers, respectively, indicating our sample has no significant difference with those reported samples. The uncharged or nonpolar neutral amino acids, namely, glycine, alanine, valine, methionine, leucine, tyrosine, phenylalanine, proline, and isoleucine, made up 60.1% of the total amino acids, which contributed to the highly hydrophobic nature of prolamin. Glutamic acid, leucine, alanine, and proline were the most abundant amino acids, accounting for about 28.2, 17.5, 11.8, and 10.2%, respectively, of the total amino acids. The protein contained low levels of lysine, glycine, and histidine. Although most of the amino acid contents of our extracted kafirin were consistent with previous results, the contents of methionine and cysteine were found to be much higher than their counterparts. These differences may be related to the higher fractions of β- and γ- kafirins and their disulfide cross-linked oligomers, all containing rich amounts of cysteine and methionine.[40,41] Therefore, this peculiar property could render a greater propensity to form intermolecular disulfide cross-linking and possibly additional protein aggregates.[42]

Secondary Structure of Kafirin. Because changes in secondary structure affect the properties of kafirin, such as surface hydrophobicity and film-forming properties,[43] the FTIR spectrum of kafirin in solid state (Figure 2a) was collected and analyzed. Typical amide I and amide II absorption peaks appeared at 1653 and 1541 cm^{-1}, respectively. Stretching vibrations of the C═O bond of the amide together with the weakly coupled in-plane N−H bending and C−N stretching contribute to the amide I absorption.[44] Because both C═O and N—H bonds were involved in the hydrogen bonding between different elements contributing to secondary structure, amide I bond was an ideal wavenumber range for secondary structure analysis of protein. Previous studies have systematically correlated proteins of known secondary structure with the shape of the amide I band, and the following secondary structure in this band has been suggested:[45,46] β-turn, 1678−1682 cm^{-1}; α-helix, 1648−1659 cm^{-1}; random coil, 1638−1640 cm^{-1}; and β-sheet, 1625−1635 cm^{-1}. Figure 2b shows the second-derivative plot of the amide I peak of kafirin. Four major components of kafirin were identified in the amide I region at 1681, 1658, 1644, and 1627 cm^{-1}, respectively. The most prominent bands at 1658 and 1644 cm^{-1} originated from α-helical structures, followed by those in the 1681 and 1627 cm^{-1} regions, which correspond to β-turn and β-sheets, respectively. Figure 2c shows the multiple peak fitting at the four wavelengths using Gaussian function. By calculation of the individual component peak areas, the composition of kafirin secondary structure was determined as 49% α-helix, 27% β-turn, and 24% β-sheet, respectively.

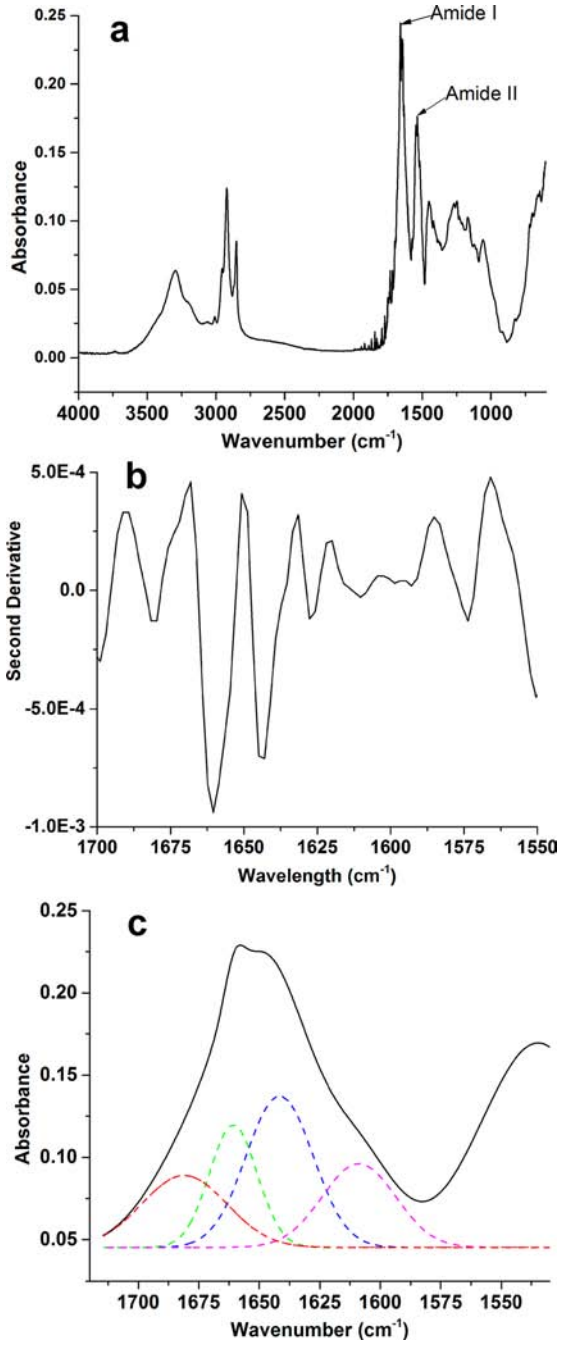

Figure 2. (a) FTIR spectrum of kafirin; (b) second-derivative FTIR spectrum of amide I and II bands of kafirin; (c) best fit for the FTIR spectrum using Gaussian multiple peaking fitting analysis for the peaks associated with protein secondary structure.

The secondary structure contents of kafirin in liquid solutions with different polarities were then determined via far-UV CD spectra. The CD profiles of kafirin in 60% *tert*-butanol, 65% isopropanol, and 85% ethanol are shown in Figure 3. In all cases, the CD spectra of kafirin exhibited the characteristics of α-helix with two strong negative ellipticity values at 208 and 222 nm. CD ellipticity at 222 nm has been widely used to estimate α-helix content in proteins.[47] The CD profiles of kafirin in different solvents show that the unshifted band at 222 nm has noticeable changes in the ellipticity. Consensus values of the relative α-helix content in 65% isopropanol, 60% *tert*-butanol, and 85% ethanol are 53.1, 57.9, and 68.4%, respectively. The change in α-helix content suggested that kafirin underwent solvent-induced conformational transformations as a combination result of differences in polarity index and proton-accepting ability of different solvents. Dielectric constants of these solvents were then calculated as 40.0, 39.5, and 32.7 by linear combination of dielectric constants of organic solvents and water (dielectric constants of *tert*-butanol, isopropanol, ethanol, and water are 12.4, 18.3, 24.3, and 80.1, respectively, under ambient condition). Because the polarity of a solvent is proportional to the value of the dielectric constant, it can be seen that the α-helix content increases as solvent polarity decreases. Furthermore, the α-helix content is in agreement with early study that reported the α-helix content of native kafirin to be 50−60%.[42] Compared with the value measured in dry state, the α-helix contents were higher in solutions. This result may be either due to the difference in sensitivities to α-helix structures under different analyzing techniques or further evidence of the solvent polarity induced conformational changes. Dry powder form is the extreme circumstance of polarity changes: the *tert*-butanol evaporated before water during the lyophilization process, causing kafirn to undergo a media change from a highly hydrophobic to a highly hydrophilic environment. Because water is more polar than *tert*-butanol, it, again, suggested that

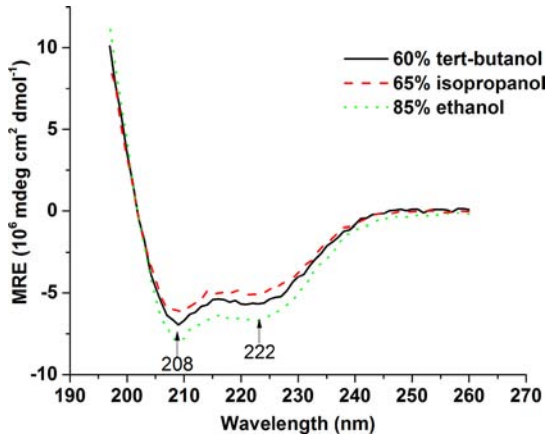

Figure 3. Far-UV CD spectra of kafirin in 60% *tert*-butanol, 65% isopropanol, and 85% ethanol.

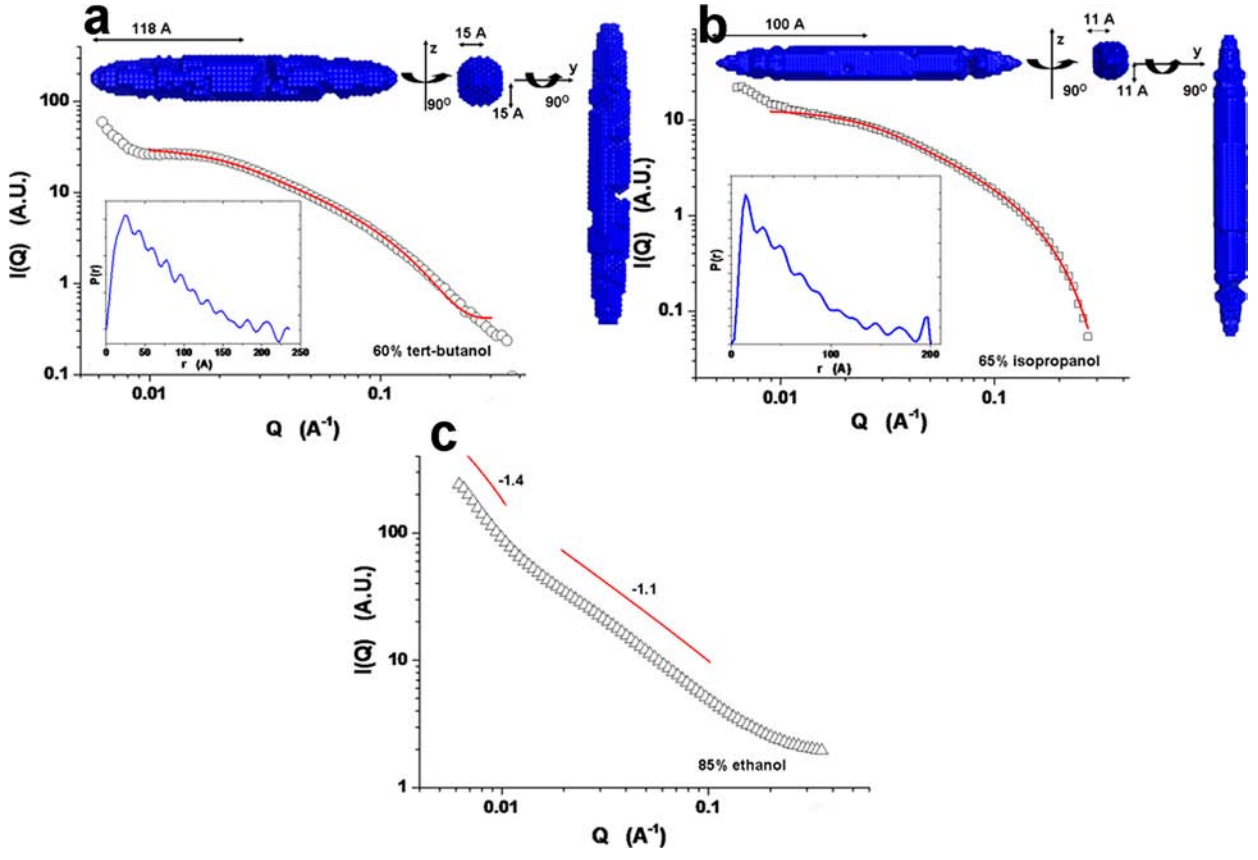

Figure 4. Small-angle X-ray scattering (SAXS) profiles of 2 mg/mL kafirin in (a) 60% *tert*-butanol, (b) 65% isopropanol, and (c) 85% ethanol. The SAXS data of kafirin in (a) 60% *tert*-butanol and (b) 65% isopropanol were best fitted with ellipsoidal form factor. The insets of panels a and b are corresponding pair distribution function (PDF) curve (below) and ab initio modeling performed by DAMMIN. Power law was used to fit both the low and intermediate Q regions of (c) kafirin in 85% ethanol.

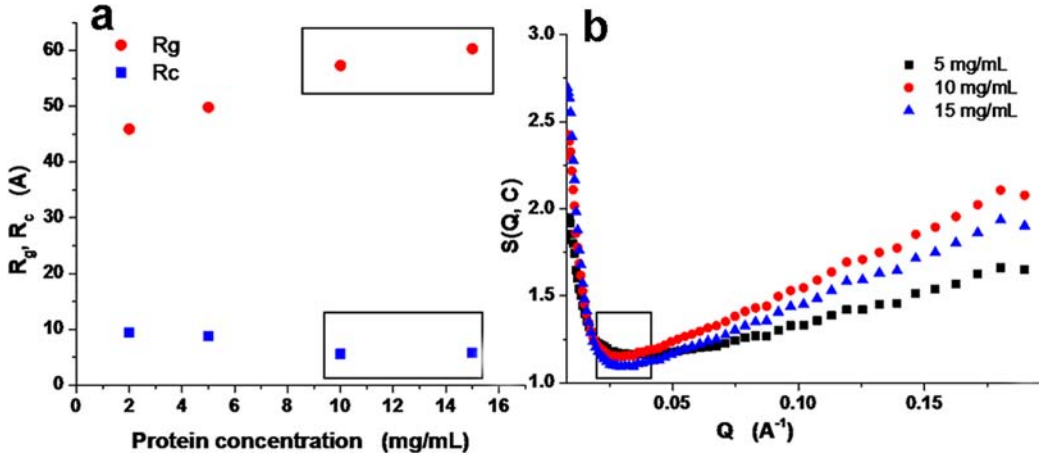

Figure 6. (a) Radius of gyration (R_g) and cross-section radius of gyration (R_c) of kafirin in 60% *tert*-butanol; (b) effective structure factor of 5−15 mg/mL kafirin in 60% *tert*-butanol.

increasing the polarity of kafirin surrounding media could decrease the α-helix content. In-depth understanding of changes in the secondary structure of kafirin with processing conditions can help develop new methodologies to optimize properties of kafirin-based materials.

Structure and Self-Assembly Behavior of Kafirin in Solutions. The shape and size of kafirin in different solvents were extracted on the basis of the SAXS data via form factor fitting, pair distribution function, and ab initio modeling. Figure 4 presents the SAXS profiles of 2 mg/mL kafirin in 60% *tert*-butanol, 65% isopropanol, and 85% ethanol aqueous solutions, respectively. Among the fittings using solid sphere, cylinder, and ellipsoid models, the last delivered the best fit, and we only discuss it later. Kafirin in 60% *tert*-butanol and 65% isopropanol showed prolate ellipsoid, with dimensions of 118 × 15 × 15 and 100 × 11 × 11 Å, respectively (Figure 4a,b). The slightly skewed PDF curve also verified this elongated conformation with a typical fingerprint of a maximum at small distance, and the location of the maximum is corresponding to the radius of the cross-section (insets, below).[26] On the basis of the PDF curve, ab initio modeling of kafirin showed a stretched and extended conformation (insets, above). Compared with 60% *tert*-butanol, kafirin in 65% isopropanol aqueous solution exhibited a more compact structure with a smoother surface (insets, above). Different from 60% *tert*-butanol and 65% isopropanol, kafirin in 85% ethanol showed a straighter profile (Figure 4c). Thus, only the power-law relationship was used to fit the low and intermediate Q regions. The exponents of −1.4 at low Q region and −1.1 at intermediate Q region suggested that either the individual kafirin or its assembly has extended conformation with a high-order elongated structure.

Figure 5 shows the scattering profile of kafirin in 60% *tert*-butanol at concentrations of 2, 5, 10, and 15 mg/mL, respectively. On the basis of Guinier plots of globular and rod-like particles (Supporting Information, Figures S1 and S2), the radius of gyration (R_g) and cross-section radius of gyration (R_c) of kafirin in 60% *tert*-butanol were extracted and plotted against kafirin concentration in Figure 6a. As protein concentration increased from 2 to 5 mg/mL, R_g increased from 46 to 50 Å and R_c slightly decreased from 9.4 to 8.8 Å. Further increase of kafirin concentration to 15 mg/mL resulted in R_g increase to 60.3 Å, and R_c slightly decreased to 5.8 Å, respectively. The increase of R_g and decrease of R_c resulted in a dramatic increase of axial ratio [calculated by $4/3(R_g/R_c)^3$] from 155.2 to 1498.3 upon protein concentration increasing from 2 to 15 mg/mL, which clearly indicated the aggregation of kafirin at high concentration with an elongated format.

The aggregation behavior of kafirin in 60% *tert*-butanol upon concentration increase was further analyzed via effective structure factor. The effective structure factors $S(Q,C)$ of kafirin in 60% *tert*-butanol, calculated on the basis of eq 3, are shown in Figure 6b by taking the scattering intensity profile at C_0 = 2 mg/mL as dilute condition. The values of $S(Q,C)$ in the entire Q region were >1, suggesting an aggregation of kafirin in a given correlation length range. An inverted peak was found at low Q region, which reciprocally corresponded to correlation length ($d = 2\pi/Q^*$, the average separation of proteins). When kafirin concentration increased from 5 to 10 mg/mL, the

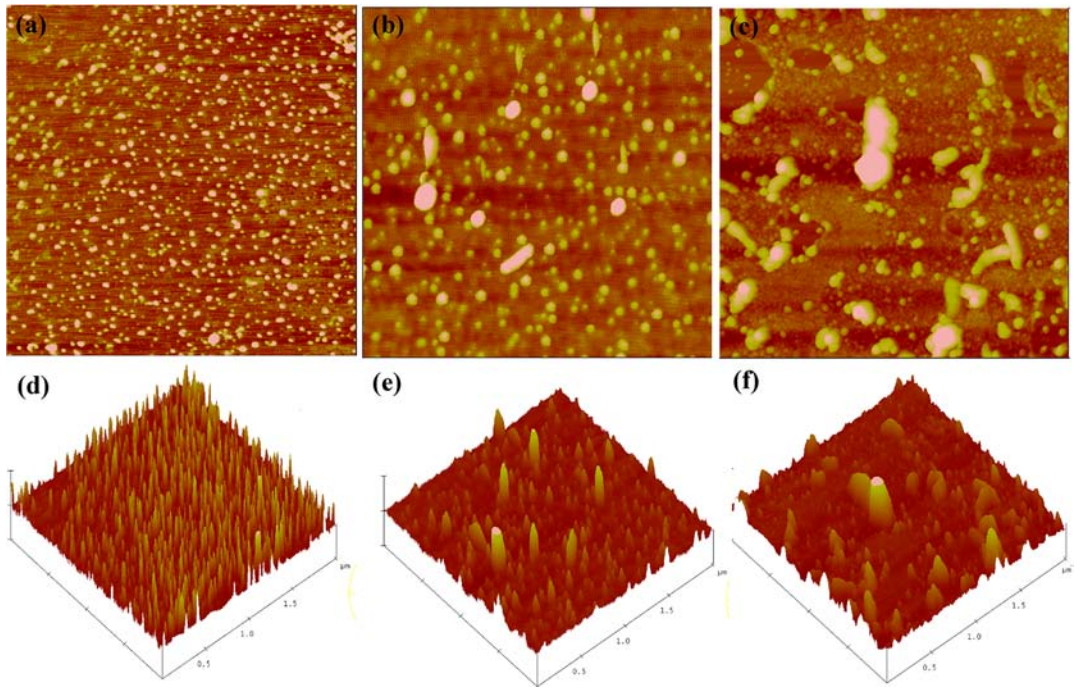

Figure 7. Morphology of kafirin on mica using tapping mode−atomic force microscopy (AFM) height images with casting solutions of 0.1 mg/mL (a), 0.2 mg/mL (b) and 0.5 mg/mL (c) and their corresponding 3D images in panels d, e, and f. The scale size is 2 μm × 2 μm, and the z scales for each concentration are 10, 20, and 80 nm, respectively.

correlation length was kept at 249 Å. However, further increase of kafirin concentration to 15 mg/mL resulted in a decrease of correlation length to 213 Å due to the concentration-dependent aggregation of kafirin. It is unlike concentration-independent correlation length of zein in aqueous ethanol solution,[48] but similar to the case of zein in acetic acid,[49] which indicates this solvent is good enough to fully dissolve karfirin.

Morphology and Solvent Evaporation Induced Self-Assembly of Kafirin. AFM is an effective tool to capture the morphology and self-assembly of either individual proteins or their aggregates. Figure 7 exhibits the height and 3D images of kafirin casting from 60% *tert*-butanol solution with different initial protein concentrations. During solvent evaporation, kafirin concentration in solution increased dramatically, and the remaining solvent became increasingly hydrophilic due to the lower boiling temperature of *tert*-butanol. Protein particles were expected as results of the intramolecular contact of individual proteins, and butanol evaporation triggered hydrophobic protein−protein interactions.

It was observed that kafirin dispersed well in forms of either ellipsoidal or disk-like particles at initial protein concentrations of 0.1 mg/mL, as shown in Figure 7a,d. On the basis of section analysis and statistical bearing analysis, most of individual proteins self-assembled into uniform particles with vertical size between 12 and 17 nm and horizontal size between 20 and 40 nm. Further dilution did not change the particle size (data not shown), which indicated that kafirin presented a rather stable aggregation state when prepared from dilute alcohol solution. This finding is analogous to the observation reported by Yamada et al [50] in the case of zein. The uniformly distributed protein aggregates had also been reported by McMaster et al.[51] using AFM. When the initial protein concentration was increased to 0.2 mg/mL, apart from the presence of individual spherical particles, large disk-like and rod-like particles began to emerge as shown in Figure 7b,e. Under section analysis, a typical disk-like particle had the three axis lengths of 115 nm (x-axis), 106 nm (y-axis), 13 nm (z-axis), and a typical rod-like particle had three axis lengths of 246 nm (x-axis), 86 nm (y-axis), 12 nm (z-axis), respectively. Significant protein aggregation continued, and even larger disk or rod-like structures were formed when the initial protein concentration was further increased to 0.5 mg/mL, as shown in Figure 7c,f. Additionally, the standard deviation for particle size was much larger at 0.5 mg/mL than at 0.2 mg/mL, indicating a more heterogeneous distribution of kafirin aggregates. Combining the results of both SAXS and AFM, the observed morphology of kafirin in dry state may be explained as individual protein with quite prolate dimension in the dilute solution aggregated into stable ellipsoid particles as the concentration increased and the hydrophobicity of the solvent decreased during the solvent evaporation process. As the initial protein concentration continued to increase, chances for individual prolate protein to interact with neighboring proteins enhanced, and small aggregates grew into disk or rod-like aggregates in a larger scale.

Key parameters affecting kafirin structure based on our investigations included the chemical compositions, solvent polarity, protein concentration, and solvent-induced evaporation process. Results gained in this work are relevant in guiding the development of kafirin-based biomaterials. The high propensity of protein aggregation due to the higher proportion of β- and γ-fractions and cross-linked kafirin is the basis for understanding its physical nature and rheological property in solution state. Clarification of the conformational changes of kafirin protein along with changes in protein concentration and solvent polarity is vital for designing the sample preparation and formulation process for kafirin-based biomaterials. The self-assembly behavior of kafirin under solvent-induced evaporation process lays the foundation for the understanding of its film-forming properties and the preparation of kafirin-based fibrillar materials.

Structural Characterization of Two Water-Soluble Polysaccharides from Black Soybean (*Glycine max* (L.) Merr.)

Jun Liu,* Xiao-yuan Wen, Juan Kan, and Chang-hai Jin*

College of Food Science and Engineering, Yangzhou University, Yangzhou 225127, Jiangsu, China

ABSTRACT: Black soybeans (*Glycine max* (L.) Merr.) have been widely used as a health food and medicinal herb in oriental medicine. In the present study, the chemical structures of two water-soluble polysaccharides (black soybean polysaccharide 1 (BSPS-1) and black soybean polysaccharide 3 (BSPS-3)) isolated from black soybeans were characterized by high performance size-exclusion chromatography (HPSEC), methylation analysis, and 1D (^{1}H, ^{13}C) and 2D (COSY, TOCSY, HSQC, NOESY, and HMBC) NMR spectra. The molecular weights of BSPS-1 and BSPS-3 were 1.95×10^5 and 1.88×10^5 Da, respectively. Methylation analysis and NMR spectra indicate that BSPS-1 is composed of 1,6-α-D-glucopyranosyl residues. By contrast, BSPS-3 is mainly composed of a 1,3-β-D-galactopyranosyl residue backbone with side chains substituted at the O-6 position consisting of large content of T-α-L-Ara*f*-(1→ residues, and small contents of →5)-α-L-Ara*f*-(1→, →2)-α-L-Rha*p*-(1→, and 4-*O*-Me-β-D-GlcA*p*-(1→ residues. Our results suggest that BSPS-1 is a linear (1→6)-α-D-glucan, whereas BSPS-3 is a type II arabinogalactan. The unique structures of BSPS-1 and BSPS-3 indicate that they might have wide applications in food and pharmaceutical industries.

KEYWORDS: *black soybean, NMR, structural characterization, polysaccharides*

INTRODUCTION

Black soybeans (*Glycine max* (L.) Merr.) are soybeans with black seed coats, which have been widely used as a health food and medicinal herb in oriental medicine. The pigmentation on the black soybeans is due to the abundance of anthocyanins in the seed coat.[1] Several studies suggest that black soybeans comprise various classes of bioactive compounds, including oil, isoflavones, anthocyanins, saponins, polysaccharides, and proteins.[2−5] Among these compounds, anthocyanins have been demonstrated to have a wide range of beneficial health effects, such as antioxidant, anti-inflammatory, antiobesity, antidiabetic, and antimutagenicity properties.[6−11]

Although polysaccharides have been reported as one of the secondary metabolites of black soybeans, information on the structure characterization and biological activities of black soybean polysaccharides (BSPS) is still limited. Liao et al. revealed that (1,6)-α-D-glucan might be the major component of BSPS. The polysaccharide component could inhibit proliferation and induce differentiation in human leukemic U937 cells by activating the immune response of mononuclear cells.[12] Moreover, BSPS could promote myelopoiesis activity in the bone marrow, stimulate production of various hematopoietic growth factors from spleen cells, and reconstitute bone marrow that has been myelosuppressed by irradiation and 5-fluorouracil.[13] Wu et al. reported that BSPS could stimulate granulocyte colony-stimulated factor production in peripheral blood mononuclear cells.[14] Recently, we reported the extraction, preliminary characterization, and in vitro antioxidant activity of BSPS.[15] Two main water-soluble polysaccharide fractions (black soybean polysaccharide 1 (BSPS-1) and black soybean polysaccharide 3 (BSPS-3)) were obtained. These two fractions have been demonstrated to be composed of different monosaccharides and possess potential superoxide anion and DPPH radical scavenging activities.

In order to establish the structure−function relationships of BSPS and further facilitate its applications in food and pharmaceutical industries, the main objective of this study was to characterize the detailed structure features of BSPS-1 and BSPS-3 by high performance size-exclusion chromatography (HPSEC), methylation analysis, and nuclear magnetic resonance (NMR) spectra.

MATERIALS AND METHODS

Materials and Reagents. Black soybean (*G. max* (L.) merr.) seeds were obtained from Heilongjiang Beizhen Food Co., Ltd. (Heilongjiang, China). Crude polysaccharides were isolated from black soybean flour and further purified on chromatography of DEAE-52 and Sepharose CL-4B.[15] Two main purified fractions of BSPS-1 and BSPS-3 were used in this study. Deuterium oxide (D_2O) was purchased from Sigma Chemical Co. (St. Louis, MO, USA). All other reagents were of analytical grade.

Monosaccharide Composition Analysis. The monosaccharide compositions of BSPS-1 and BSPS-3 were determined as described previously.[15] The trimethylsilyl derivatives of polysaccharide hydrolyzate were analyzed on a Trace GC Ultra gas chromatograph (Thermo Fisher Scientific, Waltham, MA, USA) equipped with flame ionization detector (FID) and a CP-Sil5 capillary column (30 m × 0.25 mm × 0.25 μm). Nitrogen gas was used as the carrier gas. Temperature-programmed GC measurements were carried out from 100 °C (held for 5 min), to 150 °C (held for 5 min) at a rate of 5 °C/min, and then to 240 °C (held for 2 min) at a rate of 5 °C/min.

Determination of Purity and Molecular Weight. The purity and molecular weight (MW) of BSPS-1 and BSPS-3 were determined by HPSEC on an Agilent 1200 system (Agilent Technologies, Palo Alto, CA, USA) equipped with a TSK gel G4000 PW_{XL} column (30

cm × 7.8 mm × 10 μm, Tosoh Corp., Tokyo, Japan) and an evaporative light scattering detector (ELSD). Sample solution (20 μL) was injected and eluted with distilled water at 50 °C with a flow rate of 0.7 mL/min. The molecular weights of polysaccharide samples were calculated from the calibration curve of T-series dextran standards (T-500, T-200, T-100, T-50, and T-10).

Methylation and GC−MS Analysis. For glycosyl linkage analysis, uronic acid residues of BSPS-1 and BSPS-3 were first reduced as described previously.[16] Then, methylation of BSPS-1 and BSPS-3 was carried out according to the method of Ciucanu and Kerek.[17] The complete methylation was confirmed by the lack of hydroxyl peak on a Varian 670 FT-IR spectrometer (Varian Inc., Palo Alto, CA, USA). The permethylated polysaccharide was then hydrolyzed with trifluoroacetic acid at 120 °C for 2 h, reduced with $NaBH_4$, and acetylated with acetic anhydride. The resulting partially methylated alditol acetate derivatives were analyzed on a Thermo Trace DSQ II GC-MS (Thermo Fisher Scientific, Waltham, MA, USA) equipped with a TR-5MS capillary column (30 m × 0.25 mm × 0.25 μm). The initial column temperature was set at 100 °C, and programmed to 250 °C (held for 5 min) at 6 °C/min. Helium was used as the carrier gas at the rate of 1 mL/min. The partially methylated alditol acetates were identified by their retention times and electron ionization spectra.

NMR Analysis. The fine chemical structures of BSPS-1 and BSPS-3 were analyzed by an AVANCE-600 NMR spectrometer (Bruker Inc., Rheinstetten, Germany). For NMR measurements, the dried sample (20 mg) was dissolved in 0.5 mL of D_2O and kept at room temperature for 3 h. ^1H (600 Hz) and ^{13}C (150 Hz) NMR spectra were recorded at 25 °C. Then, the 2D NMR spectra including $^1H/^1H$ homonuclear correlation spectroscopy (COSY), total correlation spectroscopy (TOCSY), heteronuclear single quantum coherence (HSQC), heteronuclear multiple-bond coherence (HMBC), and nuclear Overhauser enhancement spectroscopy (NOESY) were recorded.

RESULTS AND DISCUSSION

Structural Characterization of BSPS-1. Monosaccharide composition analysis showed that BSPS-1 was made up of arabinose, rhamnose, galactose, glucose, and mannose in the molar ratio of 1.79:1.00:2.59:26.54:1.01.[15] Thus, BSPS-1 can be mainly regarded as a glucan. To determine the monosaccharide linkages, BSPS-1 was methylated and converted into the corresponding alditol acetates for GC−MS analysis. As shown in Table 1, the major derivative of BSPS-1 was 1,5,6-tri-*O*-acetyl-2,3,4-tri-*O*-methyl-D-glucitol, indicating that BSPS-1 is mainly composed of (1→6)-linked glucopyranosyl residues. The purity and molecular weight of BSPS-1 was measured by HPSEC system. As shown in Figure 1a, BSPS-1 exhibited only one symmetrical sharp peak, indicating that this fraction was a homogeneous polysaccharide. According to the calibration curve of standards, the molecular weight of BSPS-1 was determined as 1.95×10^5 Da.

Table 1. Partial Methylated Alditol Acetates and Deduced Glycosidic Linkages of BSPS-1 and BSPS-3

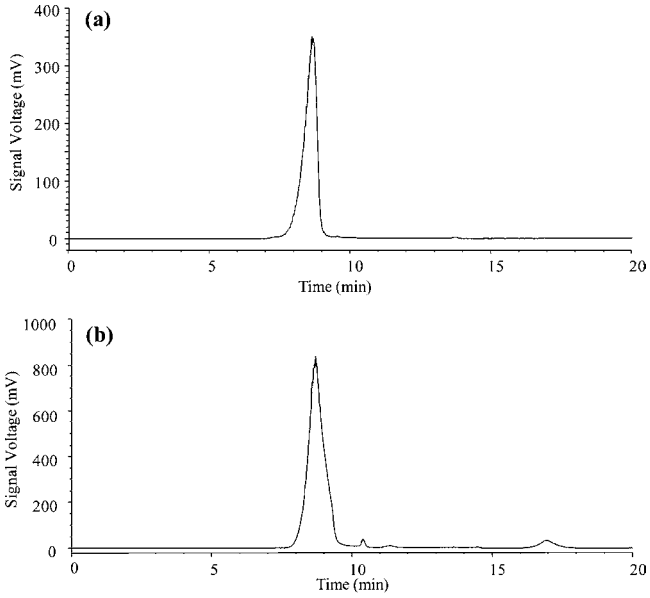

Figure 1. HPSEC elution profile of purified fractions BSPS-1 (a) and BSPS-3 (b).

As shown in Figure 2a, the ^1H NMR spectrum of BSPS-1 shows only one dominant peak at δ 4.92 ppm in the anomeric region, indicating that these glucosyl residues are α-glycosidically linked. Combining the result of methylation analysis and literature data,[18−22] this peak is assigned to the H-1 of →6)-α-D-Glc*p*-(1→. The chemical shift of H-2 can be assigned from the COSY spectrum based on the principle that H-2 correlates with H-1 (Figure 2b). Similarly, H-3 to H-6 can also be assigned. Therefore, the chemical shifts at 3.53, 3.66, 3.45, 3.85, 3.70, and 3.93 ppm can be attributed to H-2, H-3, H-4, H-5, H-6, and H-6′ of the glucosyl residues, respectively. All the proton chemical shifts can also be confirmed by TOCSY spectrum (Figure 2c). In the high field region of the ^1H NMR spectrum, a small methyl signal at 1.24 ppm should be assigned to the H-6 of rhamnose residue. However, the signals of sugar residues such as arabinose, galactose, and mannose are not clearly detected in the ^1H NMR spectrum of BSPS-1, which is probably due to the low contents of these residues.

The ^{13}C NMR spectrum of BSPS-1 is shown in Figure 3a. The chemical shift at 97.65 ppm is attributed to the anomeric carbon atoms of →6)-α-D-Glc*p*-(1→. The other carbon signals (C-2 to C-6) are identified from cross peaks in the HSQC spectrum (Figure 3b) as well as the literature data.[18,19,22] Accordingly, the carbon chemical shifts at 71.29, 73.40, 69.53, 70.23, and 65.66 ppm can be assigned to C-2, C-3, C-4, C-5, and C-6 of glucosyl residue. However, no typical signal is observed for uronic acid groups, which is in agreement with the result of the *m*-hydroxydiphenyl colorimetric method.[15] All the ^1H and ^{13}C chemical shifts for BSPS-1 are listed in Table 2 and are consistent with previous reports.[18−24] To confirm the sequence of glucosyl residues in the polysaccharide, HMBC and NOESY experiments were carried out. The cross peaks of H1−C6 and H6′−C1 are observed in the HMBC spectrum (Figure 3c). In the NOESY spectrum (Figure 3d), the cross peaks of H1−H6′ and H1−H6 are detected. These results all suggest that the glucosyl residues are linked by α-(1→6) glycosidic linkage.

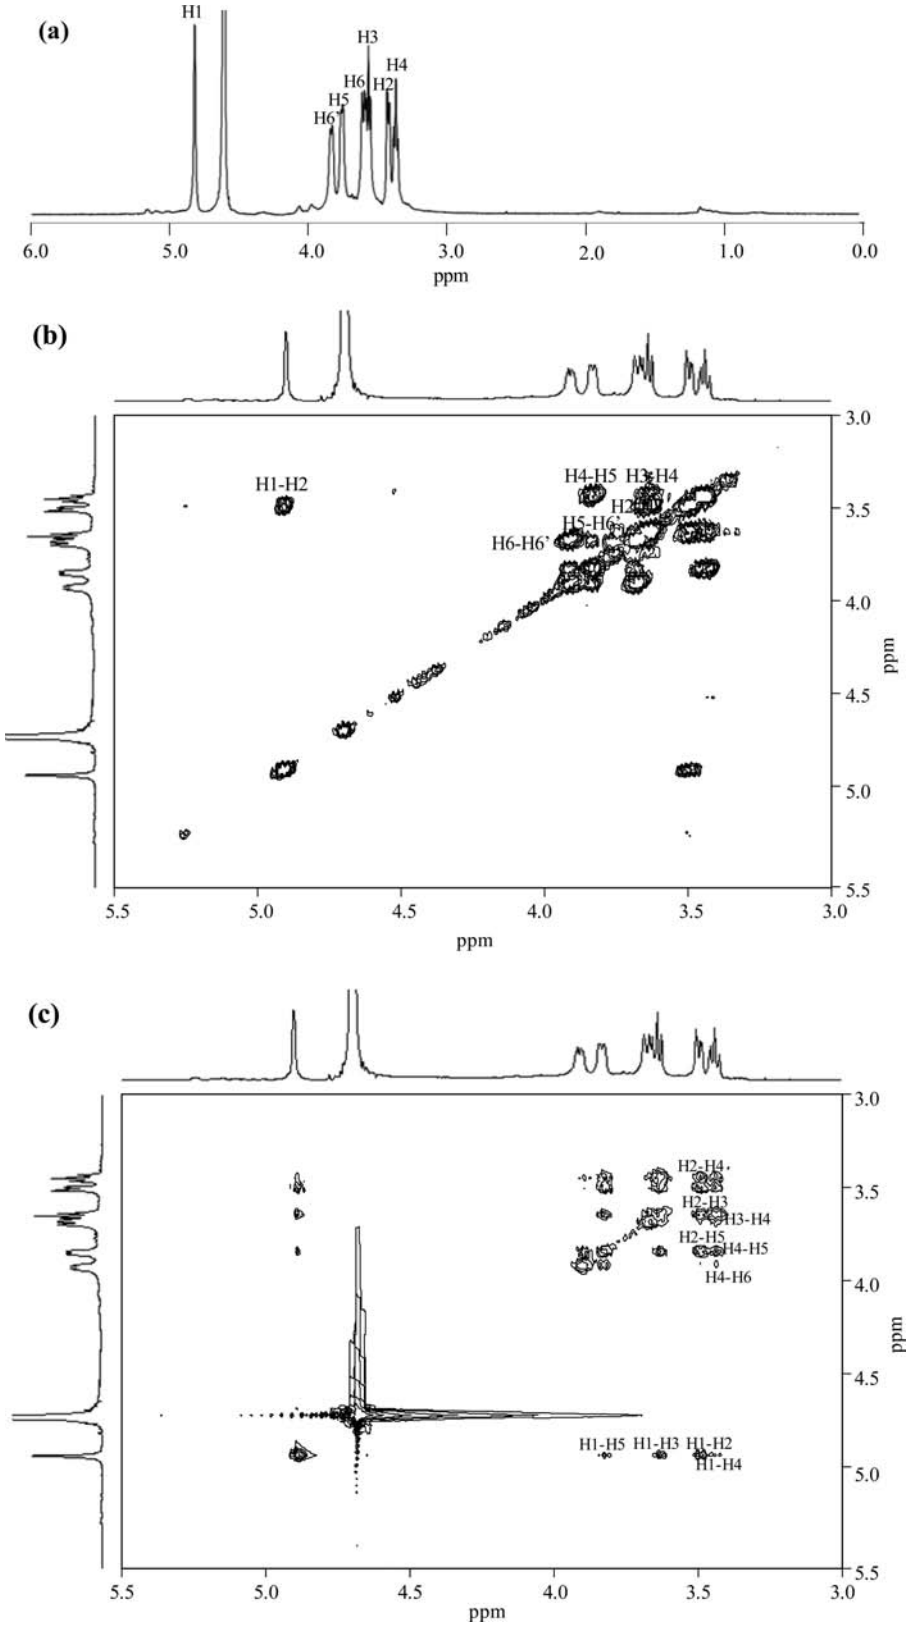

Figure 2. ^{1}H NMR (a), ^{1}H/^{1}H-COSY (b), and TOCSY (c) spectra of BSPS-1. In ^{1}H/^{1}H-COSY and TOCSY spectra, H1−H2 represents correlation between H-1 and H-2 of →6)-*α*-D-Glc*p*-(1→ residue, etc.

On the basis of above results, BSPS-1 is determined as a linear (1→6)-*α*-D-glucan. Until now, only few plants including *Ipomoea batatas*, *Cistanche deserticola*, *Angelica sinensis*, *Pueraria lobata*, *Panax ginseng*, and *Dimocarpus longan* have been reported to produce (1→6)-*α*-D-glucan. Zhao et al. reported that the (1→6)-*α*-D-glucan isolated from the root of *Ipomoea batatas* had strong immunostimulatory activity in a mouse model.[24] Wu et al. found that three polysaccharides from the

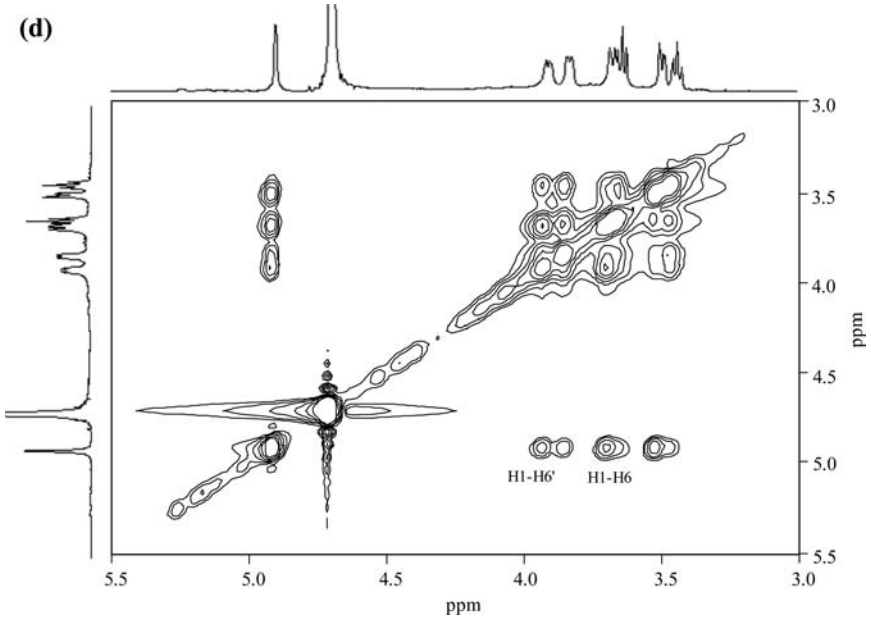

Figure 3. ^{13}C NMR (a), HSQC (b), HMBC (c), and NOESY (d) spectra of BSPS-1 in D_2O at 25 °C. In the HSQC spectrum, H1−C1 represents the cross peak between H-1 and C-1 of →6)-α-D-Glc*p*-(1→ residue, etc. In the HMBC spectrum, H1−C6 represents the heteronuclear coherence between H-1 and C-6 of adjacent →6)-α-D-Glc*p*-(1→ residues. In the NOESY spectrum, H1−H6′ represents the NOE contacts between H-1 and H6′ of adjacent →6)-α-D-Glc*p*-(1→ residues.

Table 2. Summary of ^{1}H and ^{13}C Chemical Shifts for BSPS-1

glycosidic linkage	H1/ C1	H2/ C2	H3/ C3	H4/ C4	H5/ C5	H6,H6′/ C6
→6)-α-D-Glc*p*-(1→	4.92	3.53	3.66	3.45	3.85	3.70, 3.90
	97.65	71.29	73.40	69.53	70.23	65.66

stem of *Cistanche deserticola* had a backbone of (1→6)-α-D-glucan with different molecular weights.[21] Cao et al. characterized a (1→6)-α-D-glucan from the root of *Angelica sinensis* (Oliv.) Diels.[18] Cui et al. extracted (1→6)-α-D-glucan from the root of *Pueraria lobata* (Willd.) Ohwi, and found that the sulfated derivative of glucan could significantly attenuate PC12 cell damage caused by hydrogen peroxide.[19] Sun et al. reported the structural characterization and immunostimulatory activity of a linear (1→6)-α-D-glucan isolated from *Panax ginseng* C. A. Meyer.[20] Recently, Zhu et al. isolated a (1→6)-α-D-glucan from flesh tissues of *Dimocarpus longan* Lour and demonstrated that the polysaccharide had anticancer activity against the growth of HepG2 cells.[22] In our previous study, BSPS-1 as a novel resource of (1→6)-α-D-glucan has been demonstrated to have potential superoxide anion and DPPH radical scavenging activities.[15] From the above literature, it could be concluded that (1→6)-α-D-glucan could be a health beneficial polysaccharide and might have wide applications in food and pharmaceutical industries.

Structural Characterization of BSPS-3. In our previous study, GC analysis showed that BSPS-3 was composed of arabinose, rhamnose, galactose, and mannose in the molar ratio of 16.80:3.60:33.66:1.00.[15] This indicated that BSPS-3 was probably an arabinogalactan. Methylation analysis (Table 1) further showed that the dominant linkage types of BSPS-3 were T-α-L-Ara*f* -(1→, →3,6)-β-D-Gal*p*-(1→, and →3)-β-D-Gal*p*-(1→, accompanied by small amounts of →5)-α-L-Araf-(1→, GlcA*p*-(1→, →2)-α-L-Rha*p*-(1→, and →6)-α-D-Glc*p*-(1→. As shown in Figure 1b, the molecular weight determination of BSPS-3 exhibited one major symmetrical sharp peak and another two small peaks. The molecular weight of main peak in BSPS-3 was determined to be 1.88×10^5 Da.

In the ^{1}H NMR spectrum of BSPS-3 (Figure 4a), the chemical shift at 5.18 ppm should be assigned to an α-linked residue (residue A). The corresponding chemical shift of this residue at 109.26 ppm in ^{13}C NMR spectrum (Figure 4b) can be confirmed by the HSQC spectrum (Figure 4c). According to the results of methylation analysis and literature data,[25−28] this residue can be identified as T-α-L-Ara*f* -(1→. From the TOCSY spectrum (Figure 5a), H-2 can be assigned at 4.16 ppm which correlates with H-1. H-3, H-4, H-5, and H-5′ can be assigned to the shifts at 3.88, 4.07, 3.80, and 3.67 ppm as shown in the COSY spectrum (Figure 5b). The corresponding ^{13}C chemical shifts of T-α-L-Ara*f* -(1→ can be assigned from the HSQC spectrum (Figure 4c) and are listed in Table 3. The assignments are consistent with the literature.[25−31]

From the ^{1}H NMR spectrum of BSPS-3 (Figure 4a) and the literature,[26−28] the H-1 signal at 5.02 ppm can be assigned as →5)-α-L-Araf-(1→ (residue B). The assignment of H-2 for →5)-α-L-Araf-(1→ at 4.05 ppm can be obtained by its correlation with H-1 in the TOCSY spectrum (Figure 5a). However, the other proton signals for →5)-α-L-Araf-(1→ are not detected in both TCOSY and COSY spectra, which is due to the low content of this residue. By comparing with literature data,[26−28] all the ^{1}H and ^{13}C chemical shifts of →5)-α-L-Araf-(1→ are identified from the cross peaks in the HSQC spectrum (Figure 4c).

As shown in Figure 4a, the H-1 signal at 4.62 ppm can be assigned to →3,6)-β-D-Gal*p*-(1→ (residue C), which is consistent with literature.[25,26,28,32] The assignment of H-2 (3.64 ppm) can be confirmed by its correlation with the H-1 signal in COSY and TOCSY spectra (Figure 5). The chemical shift of H-3 can be attributed to 3.83 ppm from its correlation with H-2. Comparing HSQC spectrum with the literature[25,26,28,30,32] allows the signals of H-4, H-5, and H-6 to be

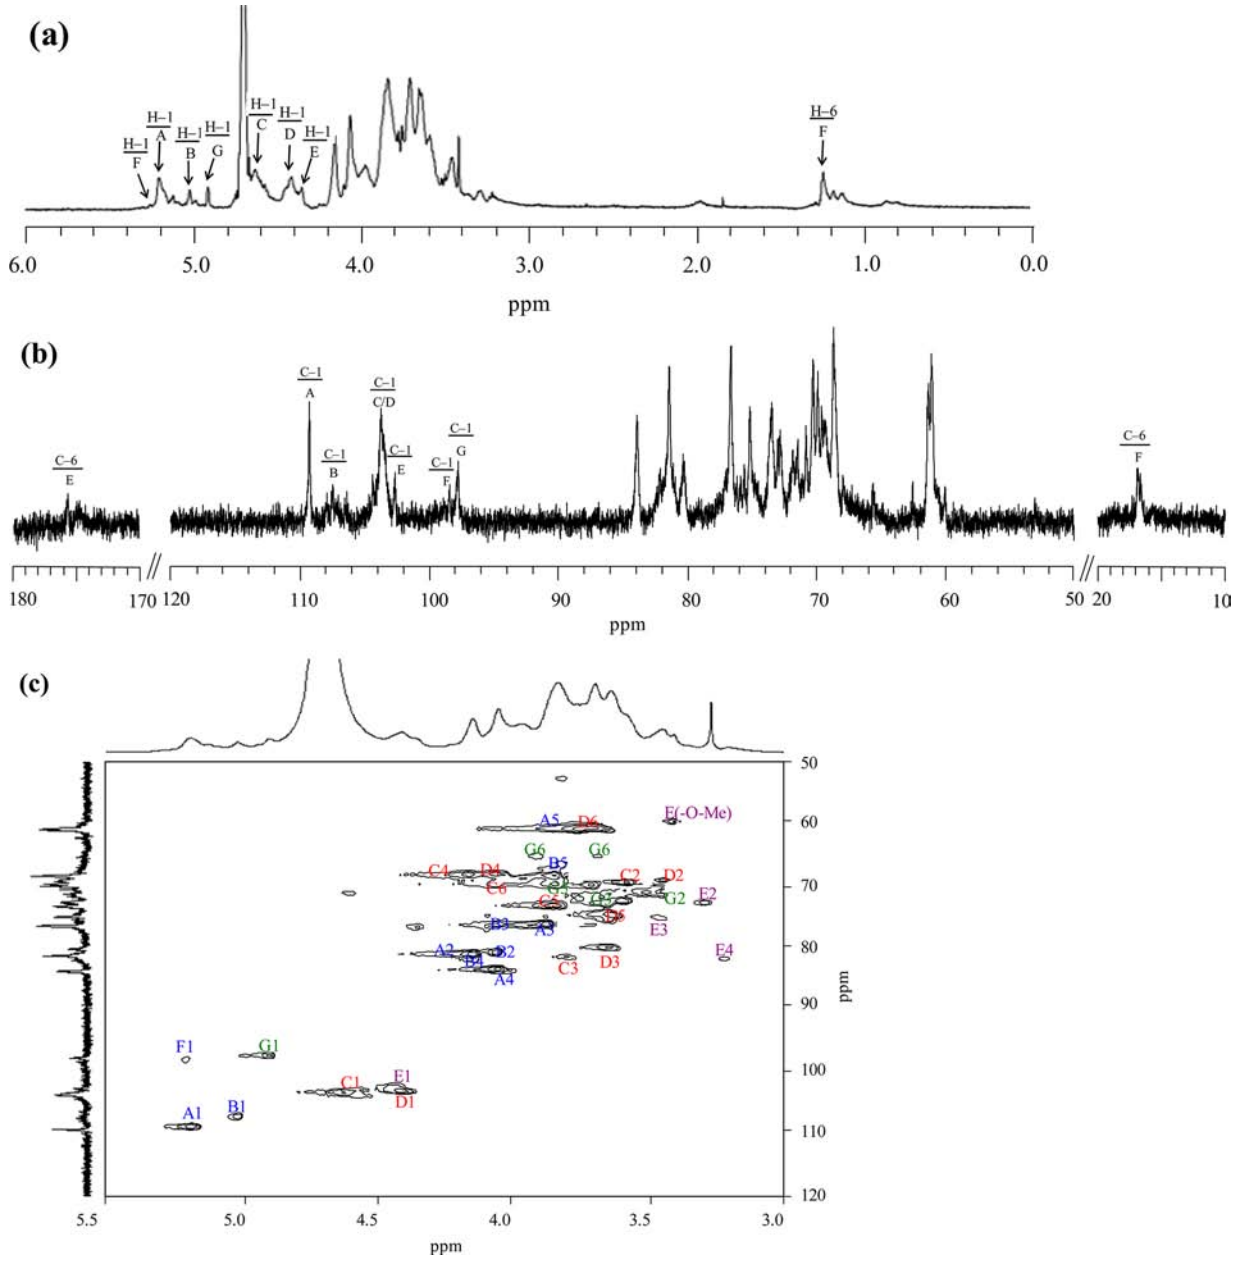

Figure 4. ^{1}H NMR (a), ^{13}C NMR (b), and HSQC (c) spectra of BSPS-3 in D_2O at 25 °C. A, B, C, D, E, F, and G represent the residues of *α*-L-Ara*f*-(1→, →5)-*α*-L-Ara*f*-(1→, →3,6)-*β*-D-Gal*p*-(1→, →3)-*β*-D-Gal*p*-(1→, 4-*O*-Me-*β*-D-GlcA*p*-(1→, →2)-*α*-L-Rha*p*(1→, and →6)-*α*-D-Glc*p*-(1→, respectively. In the HSQC spectrum, A1 represents the cross peak between H-1 and C-1 of residue A, etc.

assigned to chemical shifts at 4.18, 3.90, and 3.99 ppm, respectively. In addition, all the ^{13}C chemical shifts of →3,6)-*β*-D-Gal*p*-(1→ can also be identified from the cross peaks of HSQC spectrum (Figure 4c). Similarly, the H-1 signal at 4.38 ppm can be assigned to →3)-*β*-D-Gal*p*-(1→ (residue D). The ^{1}H and ^{13}C chemical shifts of this residue can be identified from COSY, TOCSY, and HSQC spectra. The corresponding chemical shifts are listed in Table 3 and are also consistent with previous reports.[29−32]

The signal at *δ* 102.6 ppm in the ^{13}C NMR spectrum can be attributed to C-1 of 4-*O*-Me-*β*-D-GlcA*p*-(1→ (residue E) according to the literature.[33,34] A small peak observed at 175.30 ppm is a typical signal of carboxyl group from uronic acid. A cross peak at 3.40/59.90 ppm is shown in the HSQC spectrum (Figure 4c), which is assigned to the $-OCH_3$ group of this residue. The other ^{1}H and ^{13}C chemical shifts of 4-*O*-Me-*β*-D-GlcA*p* are identified from the cross peaks in the COSY (Figure 5b) and HSQC spectra (Figure 4c). The chemical shifts identified are also consistent with literature data.[33,34] In addition, the small anomeric signal at 5.21 ppm can be assigned to the H-1 of →2)-*α*-L-Rha*p*-(1→ (residue F) according to the literature.[26,27,35,36] The signal at 1.24 ppm should be attributed to H-6 (exocyclic $-CH_3$ group) of →2)-*α*-L-Rha*p*-(1→in the ^{1}H NMR spectrum (Figure 4a). In the ^{13}C NMR spectrum, signals at 16.54 and 98.30 ppm belong to the $-CH_3$ and C-1 of →2)-*α*-L-Rha*p*-(1→, respectively (Figure 4b). These chemical shifts can be confirmed by the HSQC spectrum (Figure 4c). Other chemical shifts are assigned acorrding to the ^{13}C NMR spectrum and literature data.[26,27,36] Notably, BSPS-3 also contains a small amount of →6)-*α*-D-Glc*p*-(1→ (residue G) as confirmed by the ^{13}C NMR and

HSQC spectra. The chemical shifts of this residue are identical with that of BSPS-1.

The sequence of glycosyl residues for BSPS-3 was determined by NOESY experiment. As shown in Figure 5c, H-1 of T-α-L-Ara*f* -(1→ and →5)-α-L-Araf-(1→ have strong NOE contacts with H-6 of →3,6)-β-D-Gal*p*-(1→, indicating that these two residues are linked to the O-6 position of →3,6)-β-D-Gal*p*-(1→. Similarly, T-α-L-Ara*f* -(1→ is also linked to the O-5 position of →5)-α-L-Araf-(1→, →3,6)-β-D-Gal*p*-(1→ is linked to the O-3 position of →3)-β-D-Gal*p*-(1→, and →3)-β-D-Gal*p*-(1→ is linked to the O-3 position of →3,6)-β-D-Gal*p*-(1→ as assigned from the NOESY spectrum. However, →6)-α-D-Glc*p*-(1→ has no significant NOE contact with other residues. This suggests that BSPS-1 is not absolutely separated from BSPS-3 in the purification step, thus, a small amount of BSPS-1 is contained in BSPS-3. The NOE contacts of →2)-α-L-Rha*p*-(1→ and 4-*O*-Me-β-D-GlcA*p*-(1→ with other residues are not observed in the NOESY spectrum due to their low contents.

Combining all the information obtained above, the complete assignments of all the linkage patterns can be determined as listed in Table 3. The backbone of BSPS-3 is mainly composed of 1,3-β-D-galactopyranosyl residues with side chains substituted at the O-6 position consisting of large content of T-α-L-Ara*f* -(1→ residues, and lesser contents of →5)-α-L-Araf-(1→, →2)-α-L-Rha*p*-(1→ and 4-*O*-Me-β-D-GlcA*p*-(1→ residues. Therefore, BSPS-3 can be considered as a type II arabinogalactan. Till now, type II arabinogalactan has been isolated from various plants including *Andrographis paniculata*, *Anogeissus latifolia*, *Chrysanthemum morifolium*, *Centella asiatica*, *Endopleura uchi*, *Plantago major*, *Stevia rebaudiana*, *Viscum album*, etc., and demonstrated to possess many valuable bioactivities such as antitussive, antitumor, anticomplementary, antiviral, antioxidative, and immunological activities.[16,28,30,31,37−41]

In conclusion, our results suggest that BSPS-1 is a linear (1→6)-α-D-glucan, whereas BSPS-3 is a type II arabinogalactan. On the basis of methylation and NMR spectra analysis, the possible structural schemes for BSPS-1 and BSPS-3 are proposed in Figure 6. Notably, the unique structures of BSPS-1 and BSPS-3 indicated that they might possess many valuable bioactivities and have wide applications in food or pharmaceutical industries. Further works on the biological activities of these two polysaccharides are in progress.

ABSTRACT: Protocatechuic acid (PCA) has been implicated in the progression of atherosclerosis. The proliferation of vascular smooth muscle cells (VSMC) may play a crucial role in the pathogenesis of atherosclerosis. Adenosine 5′-monophosphate-activated protein kinase (AMPK) additionally exerts several beneficial effects on vascular function and improves vascular abnormalities. The current study sought to determine whether PCA has an inhibitory effect on VSMC proliferation under oleic acid (OA) treatment. A7r5 cells were treated with OA (150 μM) or cotreated with OA and PCA (150 μg/mL) for 24 and 48 h. PCA-treated cells were found to cause an increase in G0/G1 cell cycle arrest. Western blotting showed that PCA increased the expressions of p53 and $p21^{Cip1}$, subsequently decreasing the expression of cyclin E1 and Cdk2. In addition, PCA induced phosphorylation of AMPK and inhibited the expression of fatty acid synthase, Akt-p, and Skp2 after stimulation with OA. After treatment with AMPK inhibitor, the effects of PCA mentioned above were reversed. Taken together, PCA inhibited OA-induced VSMC proliferation through AMPK activation and down-regulation of FAS and AKT signals, which then blocks G0/G1 phase cell cycle progression. These findings provide a new insight into the protective properties of PCA on VSMC, which may constitute a novel effective antiatherosclerosis agent.

KEYWORDS: *Akt, AMP-activated protein kinase, cell cycle, protocatechuic acid, vascular smooth muscle cell proliferation*

INTRODUCTION

Atherosclerosis is a chronic inflammation and proliferative process of the arteries. The abnormal proliferation of vascular smooth muscle cells (VSMCs) is the key pathological factor in the initiation and progression of vascular disorders, including arteriosclerosis.[1] VSMC activation promotes a synthetic phenotype that underlies vessel growth disorders causing in-stent restenosis, transplant vasculopathy, and vein bypass graft failure.[2] The best way to control the proliferation of VSMCs has been a major focus in the development of new therapeutic strategies. Recently, adenosine 5′-monophosphate-activated protein kinase (AMPK), a cellular fuel sensor, has emerged as a therapeutic target for atherosclerosis.[3]

AMPK, a physiological sensor of cellular energy, has been reported to play a key role in energy metabolism and to exert a cardiovascular protective function under physiological conditions and diseases of the vascular system.[4] It has also been reported that AMPK activation by 5-aminoimidazole-4-carboxamide ribonucleoside inhibits PDGF-BB-induced human VSMC proliferation.[5] In addition, AMPK activation has been reported to lead to improved endothelial function,[6] attenuation of myocardial ischemia injury in mice,[7] and suppression of neointimal formation in a balloon injury rat model.[8] In particular, the deletion of AMPK has been reported to reduce the level of p21, probably through S-phase kinase-associated protein 2 (Skp2)-mediated degradation, thereby causing neointimal hyperplasia.[9] Recently, it has been reported that AMPK plays a significant role in cell growth arrest,[10,11] making it an ideal candidate for studies targeted at reducing VSMC growth.

Protocatechuic acid (PCA) is chemically known as 3,4-dihydroxybenzoic acid and is widely distributed and present in most edible plants.[12] It is also commonly found in the human diet including in bran, brown rice, and onions.[13] PCA is also found in many fruits such as plums, gooseberries, and grapes[14] and plants including Sudan mallow (*Hibiscus sabdariffa* L.)[15] and Japanese ginkgo.[16] Its pharmacological effects have been reported including antioxidant,[17] antibacterial,[18] anticancer,[19] antidiabetic,[20] antiaging,[21] and anti-inflammation[22] activities. Natural and synthetic polyphenols that stimulate AMPK have shown protective and antiatherogenic properties in aortic atherosclerotic lesions.[23] In the present study, we hypothesized that PCA would attenuate oleic acid (OA)-induced VSMC proliferation, and we attempted to explore the molecular mechanisms underlying the protective effect of PCA.

Data are represented as the mean ± SD (n = 3). (#) $p < 0.05$ versus the control group; (◊) $p < 0.05$ versus the OA group; (∗) $p < 0.05$ versus the OA+PCA group.

MATERIALS AND METHODS

Cell Culture. The cell line A7r5, a smooth muscle cell line derived from rat thoracic aorta, was obtained from the American Type Culture Collection (ATCC no. CRL-1444; Manassas, VA, USA). The A7r5 cells were cultured in DMEM supplemented with 10% fetal bovine serum (FBS), 2 mmol/L glutamine, 1% penicillin−streptomycin, and 1.5 g/L sodium bicarbonate (all from Gibco/BRL, Gaithersburg, MD, USA). All cell cultures were maintained at 37 °C in a humidified atmosphere of 5% CO_2.

Cell Growth and MTT Assay. The effect of OA (Sigma, St. Louis, MO, USA) on cell growth was determined in the A7r5 cells. The A7r5 cells were seeded in 24-well culture plates at a density of 4×10^4 cells/well, incubated for 48 h, treated with OA (150 μM) bound to BSA to stimulate cell growth as the control, or cotreated with OA and PCA (50−150 μg/mL) (Alfa Aesar, Ward Hill, MA, USA) for 48 h and 150 μg/mL of PCA for the indicated time. To measure cell viability, 0.2 mg/mL MTT (Sigma) was added to each well and incubated at 37 °C in a humidified atmosphere of 5% CO_2 for another 4 h and solubilized with isopropanol. The viable number of cells was directly proportional to the production of formazan measured spectrophotometrically at 563 nm. Cell viability was determined using an MTT assay.[24]

Cell Cycle Analysis Using Flow Cytometry. A7r5 cells were seeded in 6-well plates, treated with compound **C** (10 μM), OA (150 μM) alone, or cotreated with OA and PCA (150 μg/mL) for 48 h. The OA-treated cells were harvested with trypsin−EDTA, washed with cold PBS, and fixed with cold 70% alcohol for 4 h at −20 °C. The fixed cells were then removed from the alcohol and stained with 50 μg/mL propidium iodide (Sigma) solution containing 10 μg/mL RNase A in darkness for at least 30 min on ice. The distribution of cells in different cell cycle phases characterized by specific amounts of DNA (G0/G1 = diploid, S = DNA synthesis between diploid and tetraploid, and G2/M = tetraploid, preceding cell division) was determined using flow cytometry (FACS Calibur; BD Biosciences). A minimum of 10000 cells per sample was counted, and DNA histograms were analyzed using CellQuest software (BD Biosciences) for cell cycle analysis.[25]

Western Blot. Following appropriate treatment, A7r5 cells were lysed and equal amounts of cell lysates (50 μg of protein) were separated by electrophoresis on 8−12% SDS polyacrylamide gel and transferred to nitrocellulose membranes (Millipore, Bedford, MA, USA). The membranes were incubated with Tris-buffered saline containing 1% (w/v) nonfat milk and 0.1% (v/v) Tween-20 for 1 h to block nonspecific binding, washed with Tween-20 for 30 min, and then incubated with the appropriate primary antibody at 4 °C overnight. Specific antibodies were used to evaluate the expressions of p-AMPK, fatty acid synthase (FAS), Cip1/p21, cyclin E1, cyclin-dependent kinase 2 (Cdk2), p-Akt,p53,p-p53, and skp2 (all from Santa

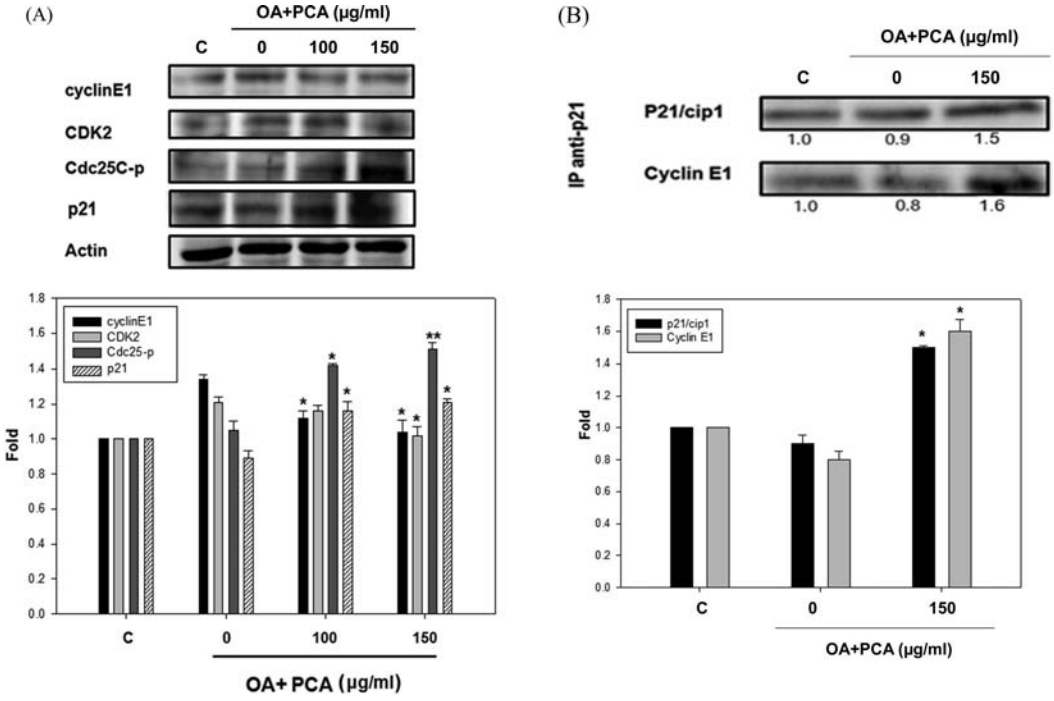

Figure 2. Inhibition of cell cycle related protein in VSMCs by PCA. A7r5 cells were cotreated with OA (150 μM) and PCA (100 and 150 μg/mL) or vehicle-treated control. (A) After treatment, the cell lysates for protein extraction were prepared and adjusted for Western blot analysis. Proteins were detected by specific antibodies (cyclin E1, CdK2, Cdc25C-p, p21), and β-actin was used as a loading control. (B) After treatment of cells with PCA 150 μg/mL, the formation of the cyclin E1−p21 complex was assayed by immunoprecipitation analysis. Each mean value is the average of three independent experiments ± SD. (*) $p < 0.05$ versus the OA group.

Cruz Biotechnology, Santa Cruz, CA, USA), Cdc25 (Cell Signaling, Beverly, MA, USA), and β-actin (Sigma). The membranes were then incubated with horseradish peroxidase-conjugated second antibody (Sigma) for 1 h and developed using ECL chemiluminescence (Millipore), and the densitometry was analyzed using AlphaImager Series 2200 software.[26] The results were representative of at least three independent experiments.

Immunoprecipitation Analysis. A7r5 (4×10^4/mL) cells were seeded into 10 cm plates and treated with OA (150 μM) alone or cotreated with OA and PCA (150 μg/mL) for 48 h. The A7r5 cells were then lysed and transferred to a new tube, followed by the addition of 25 μL of protein A/G plus agarose, incubation for 30 min on ice, and centrifugation. The supernatant was removed, and the protein quantity was determined. Eight micrograms of Cip1/p21 antibody was added per 0.5 mg of protein, and the samples were incubated for 2 h before the addition of 20 μL of Ultralink immobilized A/G bead slurry (Pierce, Rockford, IL, USA) for another 2 h. The samples were centrifuged, and the precipitate was washed more than five times. The remaining steps were the same as for the Western blot analysis.

AMPK Inhibitor. Compound **C**, an AMPK inhibitor, was purchased from Sigma. The cells were treated with 10 μmol of compound **C** for 30 min, followed by treatment with PCA. Specific antibodies were used to evaluate the expressions of AMPK-p, FAS, Akt-p, p53-p, p21, and skp2

Statistical Analysis. All data are expressed as the mean ± SD of three independent experiments, and statistical comparisons were evaluated using one-way analysis of variance (ANOVA). A p value <0.05 was considered to be statistically significant.

RESULTS

Effect of OA, PCA, and AMPK Inhibitor on VSMC Proliferation. Several studies have shown that OA is the active component of free fatty acid and that it can induce VSMC proliferation. Treatment with OA (150 uM) was found to lead to induction of the proliferation of VSMCs compared with the controls by MTT assay (Figure 1A). The proliferative potency of OA was inhibited by PCA ($p < 0.05$). Treatment with PCA (150 μg/mL) alone did not cause cytotoxicity in the cells. In addition, the cotreatment of OA and PCA (150 μg/mL) caused a time-dependent inhibition of the growth of VSMCs (24 to 48 h) (Figure 1B).

To investigate whether PCA treatment imparts an antiproliferative effect against A7r5 cells, the effect of PCA cotreatment with OA on cell cycle distribution was determined by flow cytometry. Stimulation of VSMCs with PCA (150 μg/mL) was characterized by an increase in the percentage of the G0/G1 phase and reduced S phase in comparison with the control cells. Thus, cells treated with PCA had a delay in cell cycle progression. After treatment with compound **C** (AMPK inhibitor), the stimulatory effect of PCA on VSMCs was reversed (Figure 1C).

Effect of PCA on Cell Cycle-Related Protein Expression. The cyclin E/Cdk2 complex performs an important role in controlling the G0/G1 phase. Western blot analysis showed that OA treatment for 48 h caused a moderate increase in the protein levels of cyclin E and Cdk2. Cells cotreated with OA and PCA (100 and 150 μg/mL) had decreased expressions of cyclin E and Cdk2 ($p < 0.05$). In addition, the treatment of cells with PCA significantly increased the phosphorylation of Cdc25C compared with OA at 48 h (Figure 2A). We further investigated the effect of PCA on the Cdk inhibitor (CDKI) $p21^{Kip1}$; PCA treatment dose-dependently increased the protein levels of $p21^{Cip1}$ compared with OA treatment. We then assessed whether PCA causes an increased interaction between induced p21 and cyclin E1. To assess the effect of PCA on binding, the cell extracts were subjected to immunoprecipitation, and the results indicated an increased binding of $p21^{Cip1}$

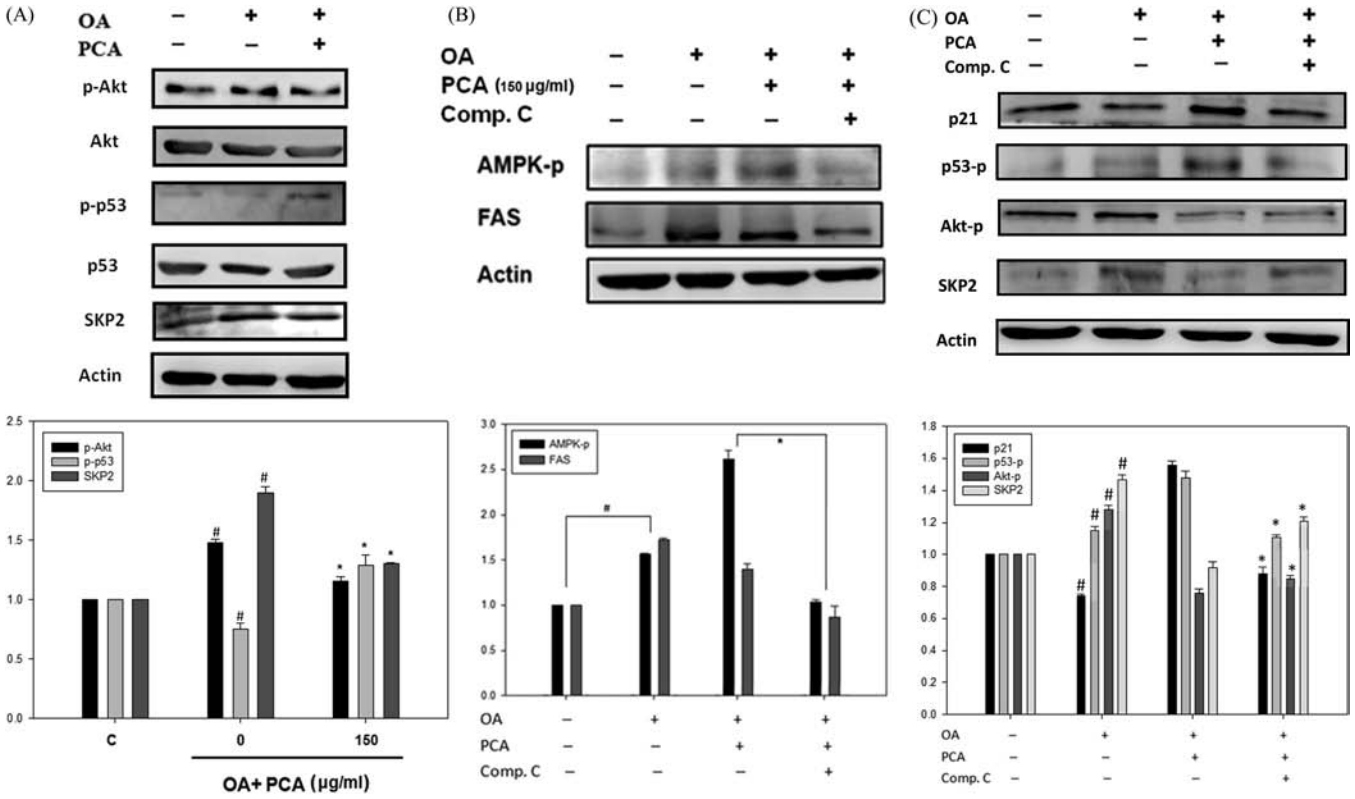

Figure 4. Effects of compound **C** (AMPK inhibitor) on the expressions of AMPK-p, FAS, and downstream proteins. (A) Cells were treated with OA (150 μM) and PCA (150 μg/mL) for 48 h. The cell lysates for protein extraction were prepared and adjusted for Western blot analysis. Proteins were detected by specific antibodies (p-Akt, p-p53, SKP2). (B, C) Cells were pretreated with compound **C** (10 μM) for 30 min and then with OA (150 μM) and PCA (150 μg/mL) for 48 h. The cell lysates for protein extraction were prepared and adjusted for Western blot analysis. Proteins were detected by specific antibodies (AMPK-p, FAS, p21, p53, Akt-p, and SKP2). Comp. C, compound **C**. Each mean value is the average of three independent experiments ± SD. (#) $p < 0.05$ versus the control group; (*) $p < 0.05$ versus the OA+PCA group.

and cyclin E in PCA-treated A7r5 cells compared with the OA group (Figure 2B).

Effect of PCA on AMPK Phosphorylation. Several physiological and pharmacological stimuli can activate AMPK, such as shear stress, statins, and adiponectin.[27] The effect of PCA stimuli on the phosphorylation of AMPK Thr-172 with the cotreatment with OA in the VSMCs was determined first. Cotreatment with OA and PCA (150 μg/mL) increased the phosphorylation of AMPK Thr-172 at 24 and 48 h and decreased the protein level of FAS until 48 h (Figure 3A). In addition, the protein level of FAS was decreased and phosphorylation of AMPK (Thr-172) was increased in a dose-dependent manner after PCA treatment for 48 h (Figure 3B). We further determined whether the AMPK pathway is involved in the process by which PCA causes Skp2, p-Akt, and p-p53 expression. The OA-induced increased expression of Skp2 was inhibited by PCA. The phosphorylation of Akt was markedly increased by incubation of the cells with OA. This effect was attenuated by treatment with PCA. In contrast, the phosphorylation of p53 was increased by treatment with PCA (Figure 4A). To clarify the role of AMPK phosphorylation in PCA-treated VSMCs, we used an AMPK inhibitor (compound **C**) to reduce the phosphorylation of AMPK. The PCA-stimulated expression of FAS was impaired in VSMCs pretreated with compound **C** (Figure 4B). After treatment with AMPK inhibitor, the PCA-induced increased expressions of p21 and p53-p were significantly reduced. Besides, the PCA-induced decreased expressions of Akt-p and Skp2 were increased significantly (Figure 4C).

DISCUSSION

It is well-known that nutrition plays a vital role in some chronic diseases. Epidemiological evidence has shown that dietary intake of vegetables and fruits rich in polyphenols is associated with a reduction in coronary heart disease.[28] Increasing interest has been paid to the phenolic acid, PCA, due to the recognition of a variety of biological effects. PCA was reported to inhibit monocyte adhesion/infiltration and reduces atherosclerosis in apolipoprotein E-deficient mice.[29,30] Besides, PCA was also reported to have an inhibitory effect on oxidation of low-density of lipoprotein (LDL).[31] In this study, we demonstrate for the first time that PCA suppresses A7r5 cell proliferation through the activation of AMPK-induced pathways including inhibition of protein synthesis (FAS, Akt-p, Skp2) and regulation of the cell cycle in VSMCs. Our findings also suggest that AMPK inhibits VSMC proliferation through the induction of a p53/p21^{Cip1} pathway or through a Skp2 pathway, which then blocks G0/G1 phase cell cycle progression.

AMPK activation has been shown to inhibit neointimal formation.[32] However, to the best of our knowledge, no studies have yet clarified the effects of PCA on AMPK in A7r5 cells. In the present study, we focused on the effects of PCA on AMPK and the subsequent consequences in A7r5 cells. Persistent activation of AMPK has been shown to accelerate p53-dependent senescence in mammalian cells,[33] and p53 is a well-recognized tumor suppressor protein, which regulates the cell cycle and apoptosis.[34] p21^{Cip1}, a CDKI, has been reported to bind and inhibit the activity of cyclin−Cdk complexes and to be

DOI: 10.1021/jf505303s
J. Agric. Food Chem. 2015, 63, 235−241

required for efficient G1 arrest.[34] The Akt family of serine threonine kinases is of critical importance with regard to growth factor signaling, cell proliferation, survival, and oncogenesis.[35] Park et al. reported an analogue of resveratrol-inhibited rat aortic VSMC proliferation by blocking Akt signaling.[36] OA was thought to be the active component of free fatty acid that induces VSMC proliferation,[37,38] and it has been also reported that OA can enhance VSMC proliferation via PI3K/Akt signaling pathway, thus inducing atherosclerosis.[39] Akt can phosphorylate MDM2 on S166 and S186, thus promoting translocation of MDM2 to the nucleus, where it negatively regulates p53 function.[40] In this study, we found that the inhibition of Akt phosphorylation by PCA was involved in blocking OA-induced VSMC proliferation. Besides, cell cycle regulation by PCA-induced AMPK was mediated via up-regulation of the p53- $p21^{Cip1}$ axis.

AMPK activators have been shown to suppress VSMC proliferation through the induction of $p53/p21^{Cip1}$, subsequently causing cell cycle arrest.[8,41] This is consistent with our results, which showed that PCA significantly activated AMPK Thr-172 phosphorylation and its downstream targets p53 and $p21^{Cip1}$ in A7r5 cells. These findings suggest that PCA exerts an antiproliferative effect, at least in part, via an AMPK-p53-$p21^{Cip1}$ signaling pathway.

AMPK was also reported to inhibit the glucose-activated expression of FAS gene in rat hepatocytes.[42] Metformin, an oral antidiabetic drug, was reported to inhibit hepatic gene expression of FAS, thus reducing hepatic free acid production, via activation of AMPK.[43] Previous study has showed that mulberry leaf polyphenol extracts can reduce hepatic lipid accumulation through activation of the AMPK and suppression of FAS.[44] Skp2, a well-characterized E3 ubiquitin ligase, has been reported to play important roles in cell proliferation,[45] differentiation,[46] senescence,[47] and cancer metastasis.[48] Blockade of FAS was reported to induce tumor cell cycle arrest by down-regulation of Skp2.[49] Song et al. demonstrated that AMPK2 deletion causes aberrant VSMC migration by increasing Skp2-mediated E-cadherin down-regulation.[50] In addition, Skp2-mediated p21 reduction has also been shown to regulate VSMC proliferation.[9] In the present study, we found that AMPK activation by PCA increased the expression of p21 through disruption of the p21−Skp2 complex.

In conclusion, this is the first study to show that PCA effectively suppressed cell proliferation and cell cycle progression of VSMCs through activation of AMPK. The growth suppression effect may be attributed to the activation of AMPK−p53−$p21^{Cip1}$ signaling and the inhibitory effect on cell cycle progression by AMPK−FAS−Skp2 signaling. Our results provide preliminary evidence that PCA exerts an inhibitory effect on OA-induced A7r5 cell proliferation.

Protective Effects of Selenium-Enriched Probiotics on Carbon Tetrachloride-Induced Liver Fibrosis in Rats

Yunhuan Liu, Qing Liu, Gengping Ye, Alamzeb Khan, Jin Liu, Fang Gan, Xian Zhang, Shahnawaz Kumbhar, and Kehe Huang*

Institute of Nutritional and Metabolic Disorders in Domestic Animals and Fowl, Nanjing Agricultural University, Nanjing 210095, People's Republic of China

ABSTRACT: This study aimed to investigate the effects of Se-enriched probiotics (SP) on the liver fibrosis induced by CCl_4 in rats. The results showed that SP significantly decreased serum alanine aminotransferase (87.0 ± 1.96 U/L), aspartate aminotransferase (101 ± 3.13 U/L), hepatic hydroxyproline (898 ± 72.5 μg/g), and malondialdehyde (2.39 ± 0.34 nmol/mg) levels, but increased glutathione peroxidase (37.2 ± 3.19 U/mg), superoxide dismutase (201 ± 19.2 U/mg), and glutathione levels (3.32 ± 0.25 mg/g) ($P < 0.05$) in rats treated by CCl_4. SP suppressed hepatic inflammation and necrosis induced by CCl_4. Moreover, SP significantly reduced the expression of α-smooth muscle actin, collagen, TGF-β1, TIMP-1, and inflammation-related gene and induced apoptosis of activated hepatic stellate cells ($P < 0.05$) in rats treated by CCl_4. Our results suggest that SP could protect the liver from fibrosis by attenuating hepatic oxidative stress, suppressing hepatic inflammation, and inducing apoptosis of hepatic stellate cells.

KEYWORDS: *liver fibrosis, selenium-enriched probiotics (SP), oxidative stress, inflammation, apoptosis*

INTRODUCTION

Hepatic fibrosis is a general pathological basis for hepatic cirrhosis and liver cancer, which is induced by a variety of etiological factors.[1] So, prevention and treatment of fibrosis is one of the crucial therapeutic goals in hepatology. Some studies have shown that reduction of oxidative stress is beneficial to ameliorate liver fibrosis.[2] Therefore, radical scavengers and antioxidants have emerged as effective antifibrotic agents to prevent liver fibrosis. It was generally believed that inflammation could initiate a series of events which lead to liver fibrosis.[3] The activated hepatic stellate cells (HSCs) are major targets for antifibrotic therapy. It has been shown that inducing the apoptosis of activated HSCs was an effective method to treat established experimental fibrosis.[4]

Selenium (Se) is an essential element for human and animals.[5] It is an essential component of some antioxidant enzymes and plays a pivotal role in the antioxidant defense system.[6] There is evidence that indicates that Se was decreased in chronic liver diseases.[7] Probiotics have also been considered as possible additive therapy in treating liver diseases caused by viral infection, alcoholism, and metabolic disorders.[8−10] In addition, probiotics such as *Lactobacillus* and *S. cerevisiae* could prevent oxidative stress induced liver injury.[11,12]

In our labratory, a newly developed Se-enriched probiotics (SP) product was produced by culturing *Lactobacillus acidophilus* (*L. acidophilus*) and *Saccharomyces cerevisiae* (*S. cerevisiae*) with sodium selenite being added into the culture medium under suitable conditions of the microenvironment. Both strains have a strong ability to convert sodium selenite into organic Se. Previous studies of dietary SP supplementation for livestock, poultry, and mice showed that the SP has the combined effects of selenium and probiotics.[13−15]

Until now, there have not been any reports concerning the effects of SP on liver injury in rats. CCl_4 is one of the classic hepatotoxicants used to induce liver injury. Long-term treatment of CCl_4 can cause chronic liver damage and is also a commonly recognized model for inducing hepatic fibrosis.[16] The aim of the current study was to investigate the effect of SP on CCl_4-induced liver fibrosis and further explore the underlying mechanisms.

MATERIALS AND METHODS

Chemicals. GSH-Px, SOD, GSH, MDA, and hydroxyproline assay kit was obtained from the institute of Jiancheng Biotechnology (Nanjing, China). The kit of assay total protein was purchased from the Biyuntian company (Nanjing, China). α-SMA monoclonal antibody were purchased from Abcam (Cambridge, U.K.). CCl_4 was purchased from the institute of Shoude (Nanjing, China).

Selenium-Enriched Probiotics and Probiotics. Both the Se-enriched probiotics (SP) and probiotics (P) products consist of two probiotic strains, *L. acidophilus* and *S. cerevisiae*. The colony-forming units (CFU) of *L. acidophilus* and *S. cerevisiae* in both products was about 10^{11}/mL and 10^9/mL, respectively. The content of total Se in the SP is 10.0 mg/L, with >90% being organic Se and >75% being selenomethionine, which were detected by AF-610A atomic fluorescence spectrometer.[17]

Animals and Feeding. The study was carried out according to protocols approved by the Animal Care and Use Committee of Nanjing Agricultural University, (Certification No.: SYXK (Su) 2011-0036).

Forty male Wistar rats weighing (200 ± 20g) were purchased from the Center of Laboratory Animals, Yangzhou University (Yangzhou, China). The rats were housed in a controlled condition at 25 ± 2 °C and a 12 h light/dark cycle. The rats were acclimatized for more than 1 week to use. The content of selenium in the basal diet was 0.05 mg/kg. The sodium selenite (SS), probiotics (P), and Se-enriched probiotics (SP) diets were made by grinding the basal diet into powder, which was then

mixed with SS, P, and SP. The doses of SS, P, and SP were calculated and mixed with the basal diet to obtain three different kinds of new diets and then supplied to the rats.

Experimental Procedure. Forty male Wistar rats were randomly divided into five groups of 8. Each group had 4 replicates, with 2 rats per replicate. The groups were as follows: (A) control group, (B) CCl_4 group, (C) CCl_4 + P group, (D) CCl_4 + SS group, and (E) CCl_4 + SP group. Group (A) received an intraperitoneal injection of olive oil (2 mL/kg body weight) twice weekly for 7 weeks. Groups (B−E) received intraperitoneal injection with CCl_4 (2 mL/kg body weight, 1:1 in olive oil) twice weekly for 7 weeks. Groups (A−B) were fed the basal diet containing 0.05 μg/g of Se per day. Groups (C−E) were fed the P diet, SS diet, SP diet per day, respectively. The number of viable microbial cells was approximately 10^9 CFU/g in the SP and P diets. The final total Se concentration was 0.3 μg/g in the SS and SP diets. During the experimental period, no rats died. Blood and liver samples were collected at the end of 7 weeks and immediately stored at −70 °C.

Biochemical Analysis of Serum Enzymes. Serum was obtained from blood by centrifugation at 5000*g* for 5 min at 4 °C. Serum ALT and AST were measured using an automated chemistry analyzer.

Measurement of GSH, GSH-Px, SOD, and MDA in Liver Tissue. Liver samples were weighed and homogenized with nine volumes of ice-cold buffer (1 mmol/L EDTA, 0.32 mol/L sucrose and 10 nmol/L Tris-HCl, pH = 7.4). The homogenates were centrifuged at 5000*g* for 5 min. The activities of GSH-Px and SOD and the levels of GSH and MDA in liver tissues were determined using a commercial assay kit, according to the instructions.

Assay of Hepatic Hydroxyproline in Liver Tissue. Hepatic hydroxyproline was detected using a commercial assay kit. The content of hepatic hydroxyproline was represented as μg of hydroxyproline per g of wet liver tissues.

Histopathological Examination and Immunohistochemical Staining. Liver samples from rats were fixed in 10% formalin. Hematoxylin-eosin (H&E) and Sirius red stains were performed using standard procedures. The Sirius red staining was used for analysis of hepatic fibrosis. A computerized image-analysis system was used to quantifiy the liver fibrosis (Image-Pro Plus version 6.0; Media Cybernetics, MD, U.S.A.). Data for liver fibrosis were shown as the mean percentage of the total hepatic area in the liver sections. For immunohistochemical examination, the liver tissues were incubated with monoclonal antibody of α-SMA and then incubated with streptavidin−peroxidase complex. The peroxidase conjugates were subsequently visualized using diaminobenzidine (DAB) solution. The liver sections were counterstained using hematoxylin, and then the liver sections were mounted on a coverslip.

RNA Extraction and Real-Time Polymerase Chain Reaction (Real-Time PCR) Assay. The mRNA expression levels of Collagen I, α-SMA, TNF-α, IL-6, MCP-1, TGF-β, Bcl-2, Bcl-xL, Bax, and TIMP1 were determined by real-time PCR. The primers were designed by Primer 5.0 online software and shown in Table 1. The isolation of RNA and synthesis of cDNA were carried out as previously reported.[15] Quantitative real-time PCR was performed on an ABI Prism 7300 Detection System (Applied Biosystems, U.S.A.). Relative gene expression was determined by the $\Delta\Delta C_T$ method using β-actin as an internal control. All reactions were performed in duplicate.

Statistical Analysis. Data were analyzed statistically using SPSS 19.0 for Windows. Experimental results were expressed as mean ± SD. Statistical significance was tested with one-way ANOVA followed by the Student−Newman−Keuls post hoc test. *P*-values <0.05 were considered statistically significant.

RESULTS

Effects of SP on General Features and Liver Function. The changes in the body and liver weight, liver index, food intake, and biochemical parameters of control and treatment groups during experimental period are given in Table 2. Treatment with CCl_4 caused a significant decrease in the body weight compared with control group ($P < 0.05$). The body weight in the P, SS, or SP group was significantly increased ($P < 0.05$) compared with the CCl_4-treated group. However, there was no significant difference in the body weight between the SS and P groups. The SP group showed a significant increase ($P < 0.05$) in the body weight compared with the SS or P group.

There was a significant increase in liver weight in the CCl_4-treated group compared with the control group ($P < 0.05$). The liver weight in the P, SS, or SP group was significantly decreased ($P < 0.05$) compared with the CCl_4-treated group. However, there was no significant difference in the liver weight of the P, SS and SP groups. As shown in Table 2, there was a significant increase in liver index of CCl_4-treated group compared with control group ($P < 0.05$). The liver index in the P, SS, or SP group was significantly decreased ($P < 0.05$) compared with the CCl_4-treated group. However, there was no significant difference in the liver index between the SS and P groups. The SP group showed a significant decrease ($P < 0.05$) in the liver index compared with the SS or P group. P, SS, and SP supplementation did not affect the food intake in the CCl_4-administered rats (Table 2). In addition, there was a significant increase in the level of serum ALT and AST in the CCl_4-treated group compared with control group ($P < 0.05$). The serum level of ALT and AST in the P, SS, or SP group was significantly decreased ($P < 0.05$) compared with the CCl_4-treated group. However, there was no significant difference in the level of serum ALT and AST between the SS and P groups. The SP group showed a significant decrease ($P < 0.05$) in the level of ALT and AST compared with the SS or P group.

Effects of SP on Histopathologic Change in Liver Tissues. In the control group, liver sections showed normal lobular architecture and cell structure (Figure 1A). In CCl_4-treated group, there were many micro nodules separated by fibrous septa, necrosis, inflammation, and hepatocyte ballooning, indicated by HE staining (Figure 1B). P and SS groups showed moderate inflammation and necrosis (Figure 1C,D). However, treatment with SP markedly reduced liver inflammation and necrosis induced by CCl_4. (Figure 1E).

Effects of SP on Collagen Accumulation in Liver Tissues. To assess the impact of P, SS, and SP on liver fibrosis

[a]Data are represented as mean ± SD (n = 8). Different letters above the values within each test parameter indicate significant differences between groups (P < 0.05).

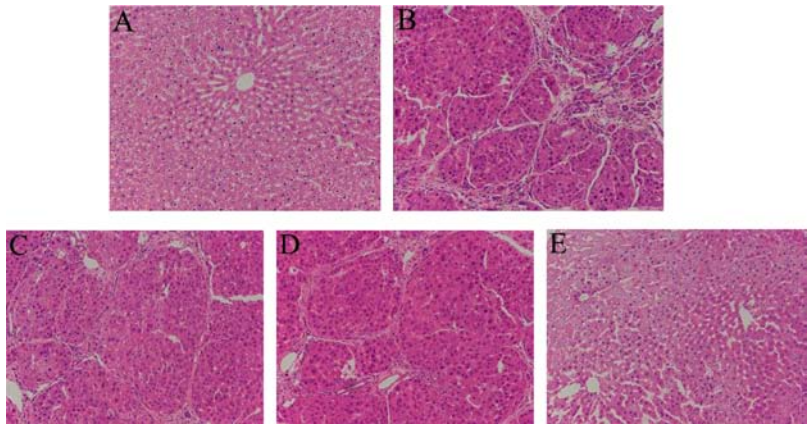

Figure 1. Liver sections were stained with H&E (original magnification 100×). (A) Control group, (B) CCl_4 group, (C) CCl_4 + P group, (D) CCl_4 + SS group, and (E) CCl_4 + SP group.

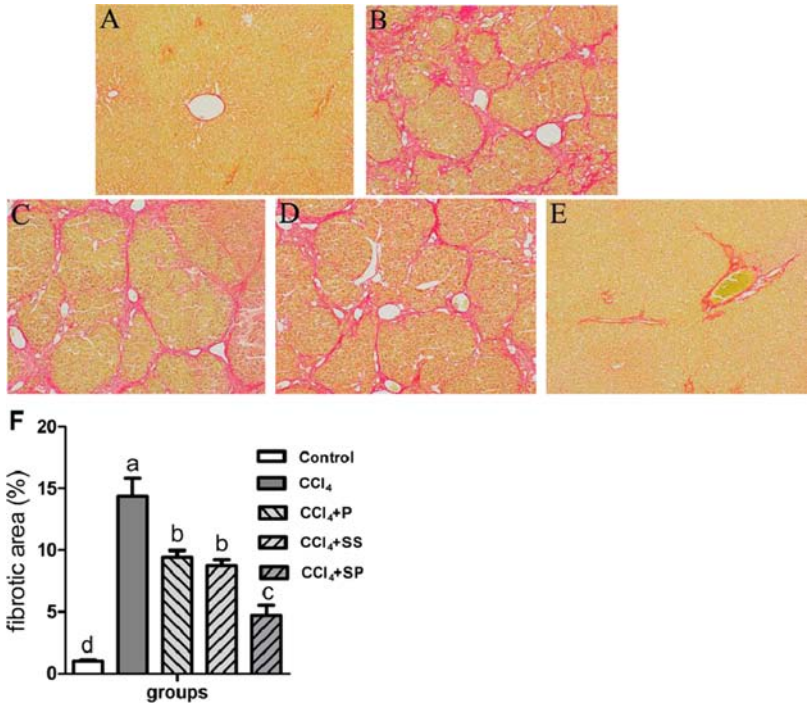

Figure 2. Liver sections were stained with Sirius red (original magnification 100×). (A) Control group, (B) CCl_4 group, (C) CCl_4 + P group, (D) CCl_4 + SS group, and (E) CCl_4 + SP group. Area ratio of stained collagen was quantified and shown in (F). Values of each bar are means ± SD (n = 8). Columns with different letters differ significantly (P < 0.05).

induced by CCl_4, liver samples were stained with Sirius red to determine the deposition of collagen. Liver sections from CCl_4 groups showed obvious red staining in the fibrotic septa compared with the control group. In P and SS groups (Figure 2C,D), liver fibrosis was mildly diminished. However, treatment with SP markedly reduced the degree of liver fibrosis (Figure 2E).

DOI: 10.1021/jf5039184
J. Agric. Food Chem. 2015, 63, 242−249

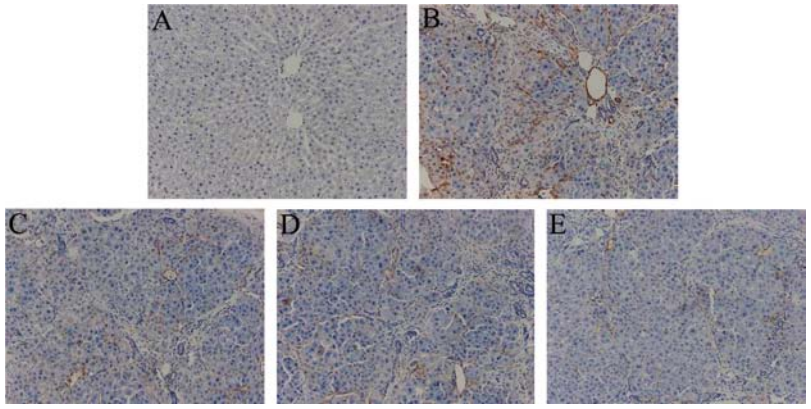

Figure 3. Immunohistochemical staining for activated HSC in liver sections (original magnification 200×). (A) Control group, (B) CCl_4 group, (C) CCl_4 + P group (D) CCl_4+SS group, and (E) CCl_4+SP group.

These results were consistent with the fibrosis area shown in Figure 2F. P, SS, and SP decreased fibrosis area to different extent.

Effects of SP on HSC Activation in Liver Tissues. We detected the activation degree of HSCs in the livers using immunohistochemical staining for α-SMA (Figure 3), a marker of activated HSCs. α-SMA expressions were more distinctly observed in the portal tracts, fibrous septa, and sinusoids in the livers from CCl_4-treated group compared with the control group (Figure 3A). Less α-SMA-positive HSCs were seen in P and SS groups compared with the CCl_4-treated group (Figure 3C,D). However, treatment with SP markedly ameliorated α-SMA expression in the fibrous areas (Figure 3E).

Effects of SP on Hydroxyproline Content in Liver Tissues. The content of hepatic hydroxyproline was an important indicator of liver fibrosis. After CCl_4 administration, The hydroxyproline content was significantly increased compared with control group (P < 0.05, Figure 4). The

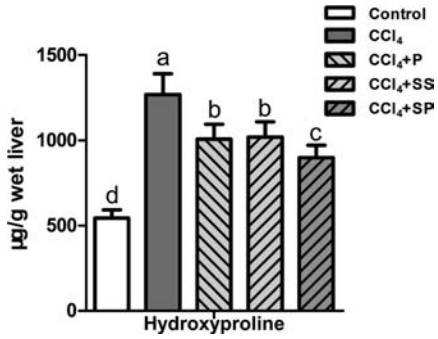

Figure 4. Effects of SP on hepatic hydroxyproline content. Data are represented as mean ± SD (n = 8). Columns with different letters differ significantly (P < 0.05).

hydroxyproline content in the P, SS, or SP groups was significantly decreased compared with the CCl_4-treated group (P < 0.05, Figure 4). However, there was no difference in the hydroxyproline content between the SS and P groups. The SP group showed a further decrease in the hydroxyproline content compared with the SS or P group (P < 0.05, Figure 4).

Effects of SP on GSH and MDA Levels, GSH-Px, and SOD Activities in Liver Tissues. The levels of GSH, the activities of GSH-Px and SOD were decreased highly in the CCl_4-treated group compared with the control group (P < 0.05, Figure 5). The antioxidant activity of GSH-Px in the P group was not higher than that in the CCl_4-treated group, but there was a significant increase in the SS and SP groups compared with the CCl_4-treated group (P < 0.05, Figure 5A). However, the SP group showed a further increase in the activity of GSH-Px compared with the SS group (P < 0.05, Figure 5A). After CCl_4 administration, the SOD activities were significantly decreased compared with the control group (P < 0.05, Figure 5B). The SOD activities in the P, SS, or SP groups were increased compared with the CCl_4-treated group (P < 0.05, Figure 5B). There were no significant differences in SOD activities between the SS and P groups. However, the SP group showed a further increase compared with the P group (P < 0.05, Figure 5B). After CCl_4 administration, the GSH level was significantly decreased compared with control group (P < 0.05, Figure 5C). The GSH level in the P, SS, or SP group was significantly enhanced compared with CCl_4-treated group (P < 0.05, Figure 5C). However, there was no difference in the GSH level between the P and the SS groups. The SP group showed a further increase compared with the P group (P < 0.05, Figure 5C). Treatment with CCl_4 caused a significant increase in the MDA contents compared with control group (P < 0.05). The MDA contents in the P, SS, or SP groups significantly decreased compared with the CCl_4-treated group (P < 0.05, Figure 5D). However, there was no difference in the MDA contents between the SS and P groups. The SP group showed a further decrease in the MDA content compared with the SS or P group (P < 0.05, Figure 5D).

Effects of SP on the Expression of α-SMA, Collagen-I, and Profibrogenic Markers in Liver Tissues. The mRNA expression levels of α-SMA, collagen-I, TGF-β1, and TIMP-1 genes were significantly increased in the CCl_4-treated group compared with control group (P < 0.05, Figure 6). These genes in the P, SS, or SP groups were significantly decreased compared with the CCl_4-treated group (P < 0.05, Figure 6). However, there was no difference in the mRNA expression levels of these pro-fibrogenic markers between the SS and P groups. The SP group showed a further decrease in the mRNA expression levels of these pro-fibrogenic markers compared with the SS or P group (P < 0.05, Figure 6).

Effects of SP on the Expression of Inflammation-Related Genes in Liver Tissues. To determine whether SP could suppress inflammation induced by CCl_4, we detected the expression of TNF-α, IL-6, and MCP-1 genes in the liver. The mRNA levels of TNF-α, IL-6, and MCP-1 were highly increased in the CCl_4-treated group compared with the control group (P < 0.05, Figure 7). But the mRNA expression levels of these

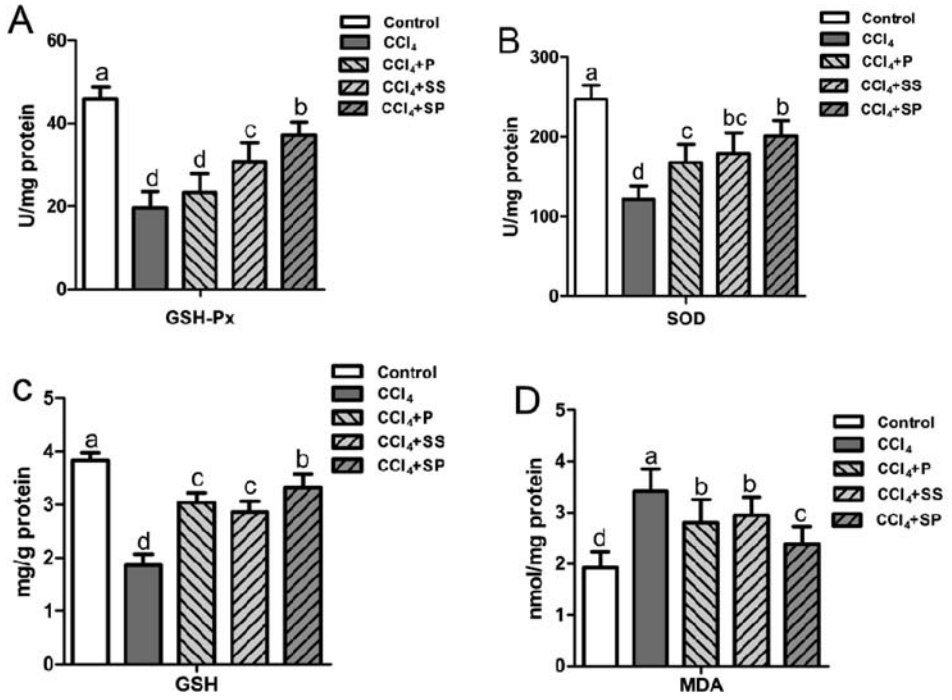

Figure 5. Effects of SP on hepatic oxidative stress parameters. (A) the activities of GSH-Px; (B) the activities of SOD; (C) the levels of GSH; and (D) the levels of MDA. Data are represented as mean ± SD (n = 8). Columns with different letters differ significantly (P < 0.05).

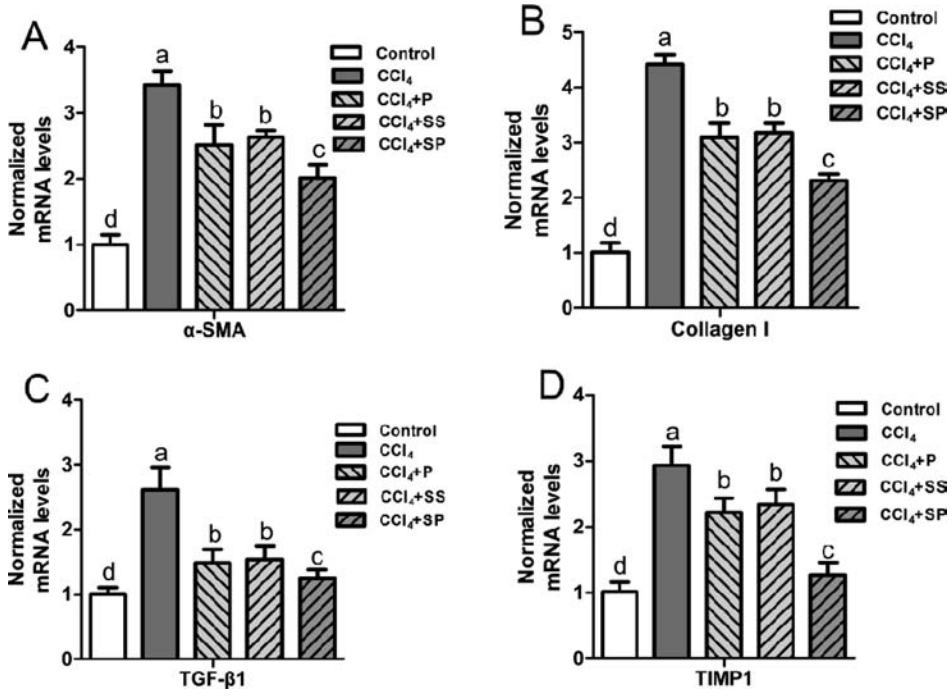

Figure 6. Effects of SP on fibrosis-related gene expressions. Real-time PCR analysis detected the mRNA expression levels of (A) α-SMA, (B) pro-collagen-I, (C) TGF-β1, and (D) TIMP-1 in liver. β-actin served as an internal control. Data are represented as mean ± SD (n = 8). Columns with different letters differ significantly (P < 0.05).

inflammation-related genes in the P, SS, or SP groups were significantly reduced compared with the CCl_4-treated group (P < 0.05, Figure 7). However, there was no difference in the mRNA expression levels of these inflammation-related genes between the SS and P groups. The SP group showed a further decrease in the mRNA expression levels of these inflammation-related genes compared with the SS or P group (P < 0.05, Figure 7).

Effects of SP on the Expression of Apoptosis-Related Genes in Liver Tissues. To further investigate the possible mechanisms by which SP induced apoptosis of activated HSCs, the mRNA levels of apoptosis regulating genes were analyzed. As shown in Figure 8, the mRNA levels of the antiapoptosis genes Bcl-2 and Bcl-xL were highly increased in the CCl_4-treated group compared with the control group (P < 0.05). The mRNA levels of these antiapoptosis genes in the P, SS, and SP groups were

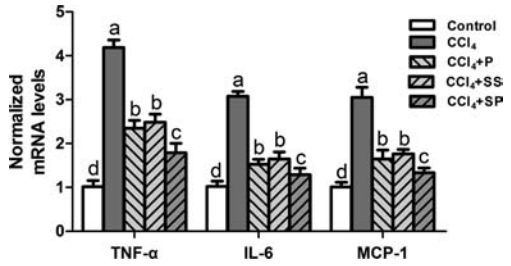

Figure 7. Effects of SP on inflammation-related gene expressions. Real-time PCR analysis detected the mRNA expression levels of TNF-α, IL-6, and MCP-1 in liver. β-actin served as an internal control. Data are represented as mean ± SD (n = 8). Columns with different letters differ significantly (P < 0.05).

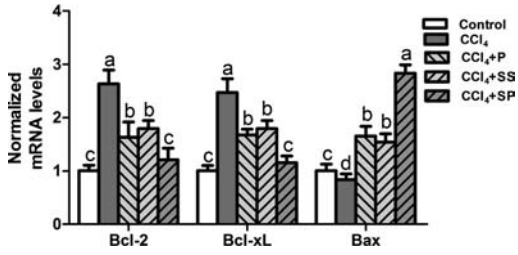

Figure 8. Effects of SP on apoptosis-related gene expressions. Real-time PCR analysis detected the mRNA expression levels of Bcl-2, Bcl-xl, and Bax in liver. β-actin served as an internal control. Data are represented as mean ± SD (n = 8). Columns with different letters differ significantly (P < 0.05).

significantly decreased (P < 0.05) compared with the CCl_4-treated group. However, there was no difference in the mRNA levels of these apoptosis-regulating genes between the SS and P groups. The SP group showed a further decrease in the mRNA expression levels of these antiapoptosis genes compared with the SS or P group (P < 0.05). As shown in Figure 8, the mRNA level of pro-apoptotic gene Bax was decreased highly in CCl_4-treated group compared with control group (P < 0.05). The mRNA expression level of the pro-apoptotic gene Bax in the P, SS, and SP groups was significantly increased compared with the CCl_4-treated group (P < 0.05, Figure 8). However, there was no difference in the mRNA expression levels of the pro-apoptotic gene Bax between the SS and P groups. The SP group showed a further increase in the mRNA levels of the pro-apoptotic gene Bax compared with the SS or P group (P < 0.05, Figure 8).

DISCUSSION

Liver fibrosis is a general consequence of chronic liver injury induced by different mechanisms, including viral infection, xenobiotics damage, and some genetic diseases.[18,19] However, the treatment programs to reverse liver fibrosis have not yet been well established. Currently, the urgent need in hepatic fibrosis management is to find some effective products related to low-toxicity.[20,21] Some studies have demonstrated that hepatic fibrosis induced by CCl_4 was ameliorated by dietary supplementation of Se.[22,23] A recent study showed that probiotics were beneficial in treating chronic liver diseases.[24] In our laboratory, we developed an SP product that has the combined effects of selenium and probiotics. The present study showed that treatment of SP was effective in reducing CCl_4-induced liver injury. This research is the first to investigate the effect of SP on CCl_4-induced liver fibrosis in rats and explore the underlying mechanisms.

Serum marker enzymes, such as ALT and AST, are generally recognized indicators of liver damage, and they are elevated in hepatocellular necrosis. The present study showed that the activities of ALT and AST were increased in CCl_4-treated rats, suggesting serious hepatocellular injury. Supplementation of SP significantly attenuated the increased activities of the serum enzymes. The histological results also demonstrated that the normal lobular architecture was damaged and pseudolobules were formed in CCl_4-treated rats. Collagen and hydroxyproline contents were also obviously increased in CCl_4-treated rats. Liver fibrosis is the progressive accumulation of ECM in the liver.[25] Collagen is a main component of ECM in fibrotic tissue. Hydroxyproline is a main component of the collagen and plays a key role in collagen stability.[26] SP could effectively reduce the content of these biomarkers. The result suggested that SP could ameliorate liver fibrosis induced by CCl_4.

Oxidative stress was a main contributor in the pathophysiologic process of liver fibrosis.[27] To verify the effect of SP on oxidative stress in hepatic fibrogenesis, some oxidative stress indicators were determined, including GSH, GSH-Px, SOD, and MDA. Consistent with the earlier studies, decreased liver GSH level, GSH-Px, and SOD activities and increased liver MDA levels were shown in the CCl_4-treated rats.[28,29] Our previous studies demonstrated that dietary SP supplementation for livestock, poultry, and mice could increase the activities of GSH-Px and SOD and the level of GSH.[14,15,17] In our study, we found that SP supplementation could significantly increase the GSH level and the activities of GSH-Px and SOD and markedly decrease the MDA level in livers, compared with that in CCl_4-treated rats. In addition, oxidative stress, especially lipid peroxidation, could induce collagen synthesis to exacerbate liver fibrosis.[30] Thus, the reduction of the extracellular matrix in the SP group may be attributed to its antioxidant activity.

It has been demonstrated that HSCs play a key role in the development of liver fibrosis.[31] In response to liver injury, HSCs undergo a process of activation by the accumulation of extracellular matrix (ECM) proteins.[32] Hence, liver fibrosis could be resolved by inducing apoptosis of HSCs, reducing the in-liver collagen and decreasing the expression of tissue inhibitors of metallo-proteinases (TIMPs).[33] In the current study, the mRNA expession levels of collagen I, α-SMA, and TIMP-1were increased in the CCl_4-treated group compared to the control group, but the administration of SP significantly decreased them. The present data showed that the inhibition of HSC activation contributed to a decrease in the excess accumulation of extracellular matrix (ECM) in the SP-treated rats.

Inflammation plays a critical role in the initiation and progression of liver fibrosis.[32] Kuppfer cells and monocytes could produce many pro-inflammatory cytokines, including TNF-α and IL-6, in response to stimuli.[34] In addition, the infiltration of inflammation could regulate the HSC activation and ECM deposition by secretion of growth factors and cytokines, especially MCP-1 and TGF-β1.[35,36] The expression level of MCP-1 is high in activated HSCs. MCP-1 also plays a pivotal role in activation of inflammatory cells, while TGF-β1 has been characterized as a key cytokine that mediates hepatic fibrogenesis.[35,37] Previous work showed that probiotics had a protective role in LPS/D-GalN-induced-induced liver damage, which contributed to their anti-inflammatory property.[24] Selenium-enriched lactobacillus could also decrease the plasma TNF-α level compared with CCl_4-treated rats.[38] Indeed, our results showed that SP supplementation could significantly decrease the gene expression of pro-inflammatory cytokines in

DOI: 10.1021/jf5039184
J. Agric. Food Chem. 2015, 63, 242−249

livers, compared with those of CCl_4-treated rats. Accordingly, the potential mechanism of SP in protecting CCl_4-induced hepatotoxicity could be related to a suppression of inflammatory responses.

Inducing apoptosis of activated HSCs is an emerging therapy for hepatic fibrosis.[39] Survival of cells is regulated by pro-apoptotic and anti-apoptotic Bcl-2/Bad family proteins.[40] Previous work showed that selenium supplementation could decrease CCl_4-induced hepatic fibrosis in mice by inducing apoptosis of activated HSCs.[23] Our results showed that the expression of Bcl-2 and Bcl-xL was significantly decreased, and the expression of Bax in the SP group compared with that of the CCl_4 group. Our study suggested that SP could ameliorate liver fibrosis by inducing the apoptosis of activated HSCs.

The protective effect of probiotics against CCl_4-induced liver injury has also been reported.[12] The combination of different probiotics has a significant effect in modulating the intestinal flora and decreasing the level of endotoxins in the liver compared with single probiotics.[41,42] So, in our study, SP and P products containing two probiotic strains, *L. acidophilus* and *S. cerevisia* were used. The dosages of probiotics ranged from 10^9 CFU/day to 10^{11} CFU/day in each rat in the related studies.[43−46] In our experiment, the dosage of probiotics was approximately 10^{10} CFU/day. Some studies used the probiotics by gavage,[11,45] others by food supplement.[46] In our study, we mixed probiotics with the basal diet and administered them by food supplement, for the sake of operational ease and because of the lower risk of damage to the rats. Our results indicated that administrating probiotics by food supplement is viable.

In conclusion, the present study showed that administration of SP was effective in attenuating CCl_4-induced liver injury and fibrosis. The primary mechanisms of this effect could be due to attenuating hepatic oxidative stress, suppressing hepatic inflammation, and inducing apoptosis of activated HSCs. Our study suggested that SP might be a potential dietary agent for prevention of hepatic fibrosis.

China

Supporting Information

ABSTRACT: This study was designed to investigate the effect of cooking on *in vitro* digestibility and peptide profiling of pork protein. We simulated gastrointestinal digestion of cooked pork that was treated with pepsin alone or followed by trypsin treatment. Digested products were identified using matrix-assisted laser desorption/ionization−time-of-flight mass spectrometry and liquid chromatography−mass spectrometry analyses. Cooking led to a reduction ($p < 0.05$) in digestibility and band intensities on sodium dodecyl sulfate−polyacrylamide gel electrophoresis gels. Peptide profiling and identification analyses also showed significant difference ($p < 0.05$) in the m/z ranges and number of peptides from the pepsin-digested products between raw (4 °C) and very well done samples (100 °C). Peptides sequenced from pepsin-digested samples under lower degrees of doneness disappeared as the temperature increased. Meanwhile, the trypsin cleavages appeared more consistent among different degrees of cooking. Further work may be needed to evaluate the bioavailability of the digested products under different cooking temperatures.

KEYWORDS: *cooking, in vitro digestibility, peptidomics, sequencing*

INTRODUCTION

Cooking is the way to convert raw meat into edible meat. The degree of cooking affects palatability and consumer acceptability differing with primal cuts and cooking methods.[1−4] Generally speaking, people in western countries prefer roasting and grilling with medium doneness, but Asian people prefer stewing and stir-frying with very well doneness. In recent years, the degree of doneness has been associated with the production of heterocyclic aromatic amines and the risk of colorectal cancer in the clinic.[5,6] However, meat has played and will continue to play a crucial role in the supply of high-quality protein, vitamins, and minerals.[7] Notably, it should be paid more attention to how cooking affects the bioavailability of nutrients in meat, especially proteins. However, few data are available.

A French group have performed much work on the effect of cooking on *in vitro* digestibility of meat, and they found that heat-induced oxidation and increased surface hydrophobicity of myofibrillar proteins could result in protein aggregation, which further decreased the pepsin digestion rate.[8−11] However, the nutritional quality of meat proteins should not only be associated with digestibility or amino acid composition but also with peptide size and sequences,[12−14] which may affect protein digestibility after cooking. It is known that oligopeptides can be degraded by the brush border peptide hydrolases and taken up into intestinal epithelial cells where the size of oligopeptides may be critical.[15] It is crucial to characterize the digested products from meat proteins when they go through the stomach and the gut to evaluate the effect of cooking on meat protein bioavailability.[16]

The objective of the present study was to characterize the *in vitro* digested products with pepsin and trypsin from cooked pork under different cooking temperatures by mimicking gastrointestinal digestion in the human body.

MATERIALS AND METHODS

Samples and Cooking Procedure. Pork longissimus dorsi muscles ($n = 8$; muscle pH 5.83 ± 0.18) were obtained at 36 h postmortem from a commercial meat packing company. After all visible fat and connective tissue were removed, each pork muscle was cut vertically into five 2 cm thick pieces (weighing 90−110 g each). Three of these pieces were packed in retort pouch and cooked in a 72 °C water bath (Julabo, TW 20, Germany) to different center temperatures, i.e., 60 °C (cooking time of 12−16 min), 65 °C (cooking time of 21−29 min), and 70 °C (cooking time of 33−37 min), individually. The fourth piece was packed in retort pouch and cooked in a 100 °C water bath (Julabo, TW 20, Germany) to the center temperature of nearest to 100 °C (cooking time of 3 h). The fifth piece was not cooked (4 °C) as the control (raw). During cooking, the center temperature of the samples was monitored using a digital, hand-held thermometer (Testo108, Testo AG, Germany). After cooking, the samples were cooled to the room temperature (20 ± 2 °C). Eight repeats were applied for each temperature point.

***In Vitro* Digestion.** Cooked meat was *in-vitro*-digested according to the procedure by Escudero et al., with some modifications.[14] Briefly, meat samples (0.5 g, each) were homogenized in 2 mL of double-distilled water for 2 × 30 s at 9500 rpm and 2 × 30 s at 13 500 rpm with 30 s cooling between bursts. The homogenate was adjusted to pH 2.0 with 1 mol/L HCl, and pepsin (≥400 units/mg of protein, from porcine gastric mucosa, product number P7125, Sigma-Aldrich, St. Louis, MO) was added 0.016 g each at a ratio of 1:31.25 of the substrate based on the weight of meat. The mixture was incubated at 37 °C for 2 h with continuous shaking, and then the enzyme was inactivated by adjusting the pH to 7.5 with 1 mol/L NaOH on ice. A total of 1 mL of the resulting

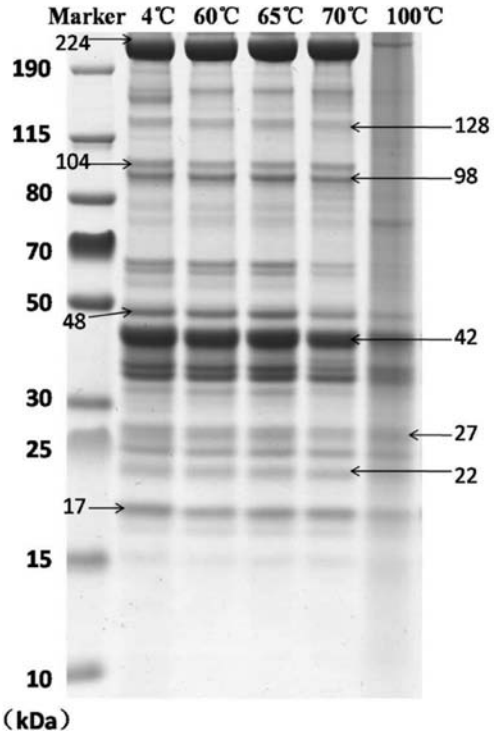

Figure 1. SDS−PAGE profiling of total proteins from cooked pork under different cooking temperatures. Proteins of bands with different numbers on the right five lanes were quantified and identified, with more details seen in Table 1.

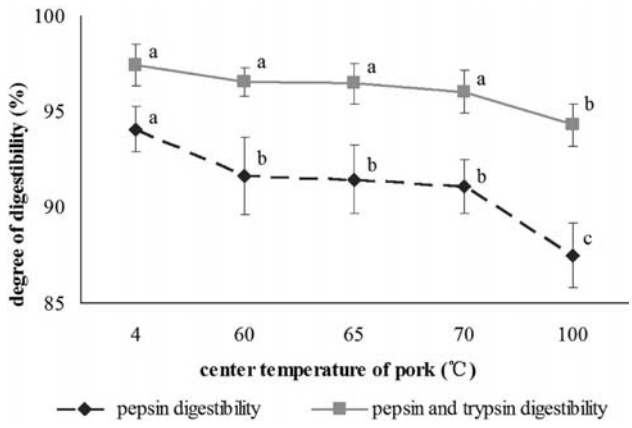

Figure 2. *In vitro* digestibility of pork under different cooking temperatures. Diamond, samples were treated with pepsin; black box, samples were treated with pepsin followed by trypsin. Different letters indicate statistically significant difference among the values.

digestion mixture was removed for peptide profiling, and the remaining (approximately 1.5 mL) was kept at 37 °C for trypsin digestion. Trypsin (1645 units/mg of protein, from porcine pancreas, lyophilized powder, type II-S, product number T7409, Sigma-Aldrich, St. Louis, MO) was added 0.006 g each at a ratio of 1:50 substrate based on the mass of meat left. The reaction mixture was maintained under the same conditions as above. After 2 h of trypsin digestion, enzyme activity was terminated by heating at 95 °C for 5 min and then 1 mL of the resulting digestion mixture was taken out for peptide profiling. Both the pepsin digests and pepsin/trypsin digests were deproteinized by adding three volumes of ethanol and storing for 12 h at 4 °C. The samples were then centrifuged at 10000*g* for 20 min at 4 °C. The supernatant and precipitate were separated and stored at −18 °C.

***In Vitro* Digestibility.** Two portions of meat sample weighing 1 g were taken from each piece. One portion was only treated with pepsin, and the other one was treated with pepsin, followed by trypsin. The digestion procedures were the same as above. After digestion, the digest was centrifuged at 10000*g* for 20 min at 4 °C and the supernatant was discarded. The precipitate was dried until the weight was constant. The degree of digestibility was calculated by the weight change of insoluble protein as the following equation:

$$DT = \left(1 - \frac{W_i}{W_t}\right) \times 100\%$$

where DT is the digestibility, W_i is the weight of dried insoluble protein, and W_t is the total weight of meat before digestion.

Gel Electrophoresis and Protein Identification. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) was performed to characterize the total protein profiles before and after cooking to different center temperatures.

A total of 1 g of cooked meat was homogenized in 4 mL of extraction buffer (2% SDS and 0.01 mol/mL sodium phosphate buffer at pH 7.0) with an Ultra Turrax homogenizer (IKA T25 Digital, Germany). The homogenate was centrifuged (Allegra 64R, Beckman Coulter, Brea, CA) at 1500*g* for 15 min at 4 °C. The protein concentration of the supernatant was determined with a BCA protein assay kit (catalog number 23225, Thermo Scientific, Waltham, MA).

Appropriate volumes of protein samples were mixed with 12.5 μL of XT sample buffer (Bio-Rad, Hercules, CA) and made up to a total volume of 50 μL with ultrapure water to a final protein concentration of 0.5 μg/μL. Protein samples were denatured by heating at 95 °C for 5 min. A total of 10 μL of each sample was loaded on 4−12% Bis-Tris Criterion precast gels (catalog number 345-0125, Bio-Rad, Hercules, CA). The gels were run in 900 mL of XT MES running buffer (Bio-Rad, Hercules, CA) at 150 V for approximately 1 h, until the bromophenol blue dye front just disappeared. After electrophoresis, proteins were stained with Coomassie Blue R250 for 3 h and destained until the bands were clear.

Gel images were captured using an image scanner (GE Healthcare, Little Chalfont, U.K.), and the band intensities were quantified with the Quantity One software (Bio-Rad, Hercules, CA). The intensity of each band was calculated as its actual intensity relative to the intensity of the 190 kDa band in the prestained calibration marker (catalog number 161-0377, Bio-Rad, Hercules, CA).

A total of 12 different bands were picked up and further identified by matrix-assisted laser desorption/ionization−time-of-flight tandem mass spectrometry (MALDI−ToF MS−MS, ultrafleXtreme Bruker, Germany).[17] In brief, protein bands were destained, cleaned, and digested in gel with trypsin (Promega, Madison, WI). The extracted peptide mixtures were analyzed by MALDI−ToF−ToF MS. All peptide spectra were matched with the online MASCOT program (http://www.matrixscience.com) against the Swiss-Prot databases. The data matching was performed with a peptide mass tolerance of 0.12 Da and ToF−ToF fragment ion mass tolerance of 0.6 Da. Carbamidomethyl of Cys was chosen as fixed modification; oxidation of Met and pyro-Glu formation of N-terminal Gln were chosen as dynamic modifications; and one missing tryptic cleavage was allowed. Hits were applied only if their MASCOT probability were less than 0.05.

Characterization of the Digested Products. *MALDI−ToF MS Analysis.* The ethanol-soluble fractions from the pepsin-treated and the pepsin/trypsin-treated samples were characterized by MALDI−ToF MS in duplicate. An aliquot (1 μL) of each sample was spotted on the target plate with an equal volume of matrix solution [α-cyano-4-hydroxycinnamic acid (CHCA), 0.005 g/mL prepared in 50% acetonitrile (ACN)/0.1% trifluoroacetic acid (TFA)]. The mixture was dried before analysis. Positive-ion (MH^+) spectra were acquired in the linear MALDI−ToF MS mode (ultrafleXtreme Bruker, Germany). The *m*/*z* signals were recorded between 200 and 1500 for peptide identification.

The peak data of the MS spectra were subjected to hierarchical clustering using the ClinProTools 2.2 software (Bruker Daltonics, Germany). Principal component analysis (PCA) was performed using the unsupervised clustering mode.

Liquid Chromatography−Mass Spectrometry (LC−MS) Analysis. The ethanol-soluble fractions from the pepsin-treated and pepsin/trypsin-treated samples were also analyzed with hybrid quadrupole orbitrap mass spectrometer equipped with a nanoelectrospray ionization source with an online nano-LC system (Nano LC-Q-Exactive-MS-MS, Thermo Fisher Scientific, Waltham, MA). The ethanol-soluble fractions were filtered through ultra-0.5 mL centrifugal filter units with ultracel-3 membrane (Amicon Ultra, Millipore, Ireland) under centrifugation at 15000*g* for 15 min. Peptide mixtures were then fractionated on an online nano-LC system (EASY-nLC 1000, Thermo Scientific, Waltham, MA). Samples were loaded onto a C_{18} column (2 cm long, 100 μm inner diameter, and 5 μm particle size) at a maximum pressure of 500 bar.

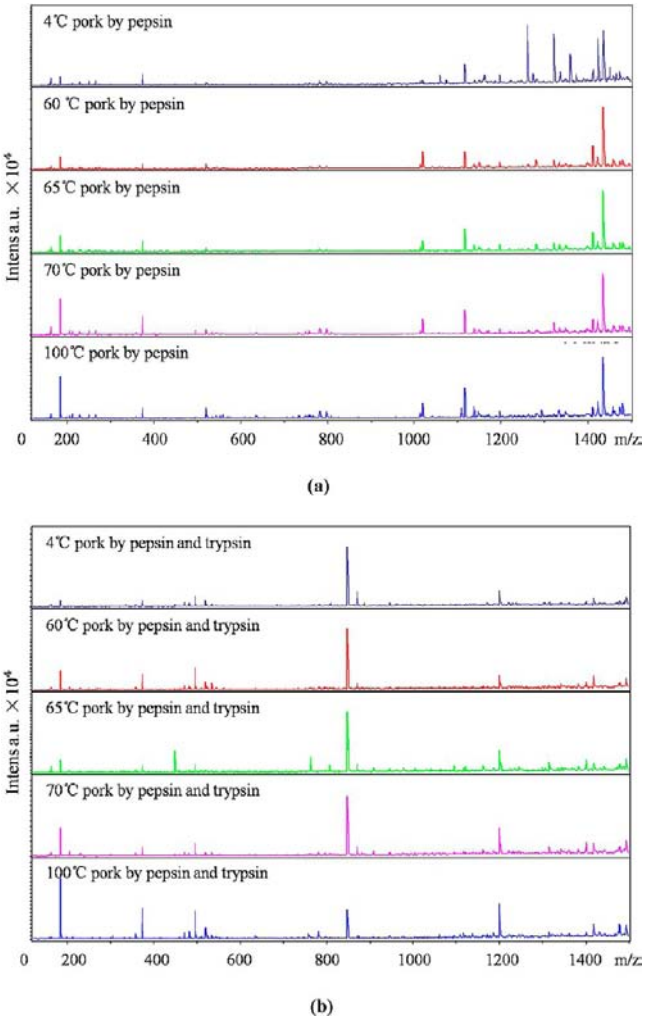

Figure 3. MALDI−ToF MS spectra of ethanol-soluble fragments from pork under different cooking temperatures. Each panel includes five spectra from 4, 60, 65, 70, and 100 °C samples: (a) pepsin treated and (b) pepsin and trypsin treated.

Peptides were separated using a mobile phase changing from 0.1% formic acid (FA) in water (buffer A) to 0.1% FA in ACN (buffer B). A step-gradient elution at a flow rate of 350 nL/min was applied with an increasing concentration of buffer B: (1) 10 min from 0 to 8%, (2) 25 min from 8 to 20%, (3) 15 min from 20 to 30%, (4) 5 min from 30 to 90%, and finally kept at 90% until the procedure completed. The hybrid quadrupole orbitrap mass spectrometer was operated in a data-dependent mode, and a scan cycle was initiated with a full-scan MS spectrum (from *m*/*z* 100 to 1500). The top 20 abundant ions were selected for collision-induced dissociation (CID) fragmentation in the linear ion trap, and the exclusion time was set as 60 s.

MS/MS spectra of peptides were matched using Proteome Discoverer (Thermo Fisher Scientific, Waltham, MA) against the Swiss-Prot *Sus scrofa* database (http://www.uniprot.org/taxonomy/complete-proteomes). Data matching was performed with a fragment ion mass tolerance of 0.8 Da and a parent ion tolerance of 10 ppm. Oxidation of Met and pyro-Glu formation of N-terminal Gln were chosen as dynamic modifications, and two missing cleavages were allowed. Unspecific enzyme was used in the peptic peptide database search, while both unspecific enzyme and trypsin were used in the peptide search for pepsin/trypsin-treated samples. Peptide identification was accepted if they could be established at a PeptideProphet probability of greater than 95%. Protein matching was accepted if they could be established at the probability of greater than 95% and contained at least two identified spectra.

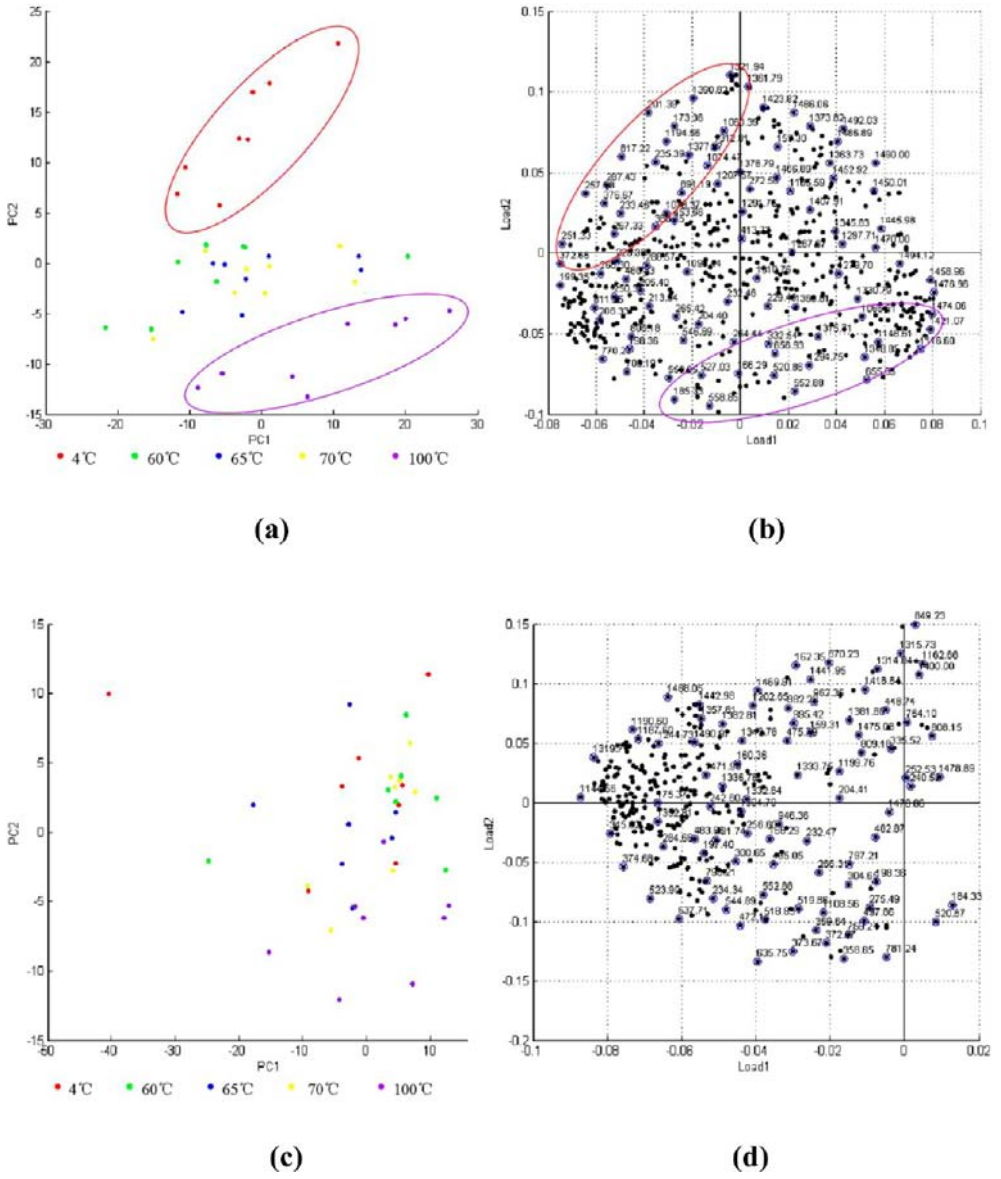

Figure 4. PCA plots of the peptides from cooked pork treated with pepsin and trypsin: (a and c) scores plot, treated with pepsin and pepsin/trypsin, respectively (red, green, blue, yellow, and purple plots represent 4, 60, 65, 70, and 100 °C treatment samples) and (b) and (d) loadings plot, treated with pepsin and pepsin/trypsin, respectively.

Statistical Analysis. The effects of cooking on *in vitro* digestibility and SDS−PAGE band intensities were evaluated by one-way analysis of variance and the Duncan's multiple-range test using the SAS program (SAS Institute, Inc., Cary, NC). PCA on spectral data was described in the MALDI−ToF MS Analysis section.

RESULTS AND DISCUSSION

Effect of Cooking on Pork Protein Profiling and *In Vitro* Digestibility. Generally, band intensities on SDS−PAGE gels decreased as the center temperature increased, especially for 100 °C samples (Figure 1). A possible explanation for the decrease in band intensities is the aggregation of meat proteins. Previous studies indicated that a high cooking temperature led to increased oxidation and protein surface hydrophobicity of myofibrillar proteins[8,9] and, as a result, increased protein aggregation. Sarcoplasmic proteins, which contain various types of enzymes, pigments, and regulatory proteins, may aggregate between 40 and 60 °C.[18] The heat-induced protein aggregation normally appeared with the decreased equivalent circle diameter and number of particles.[11,19]

In details, muscle proteins showed different responses to cooking ($p < 0.05$) in terms of band intensities on SDS−PAGE gels (Figure 1 and Table 1). Myosin heavy chain (224 kDa), α-actinin (104 kDa), β-enolase (48 kDa), and myoglobin (18 kDa) showed a distinct intolerance to heating in that their band intensities dropped at 60 °C ($p < 0.05$). Myosin-binding protein C (128 kDa), glycogen phosphorylase (98 kDa), and actin/creatine kinase (42 kDa) had a bit stronger heat tolerance, and the band intensities decreased significantly at 70 °C ($p < 0.05$). A previous study has confirmed that myosin has endothermic transitions at 54 °C, with a transition temperature of 77 °C for actin.[20] However, triosephosphate isomerase and myosin light chain 3 (22 kDa) were more tolerant to high-temperature cooking (100 °C). Kajak-Siemaszko et al. showed a similar SDS−PAGE pattern of meat proteins during cooking, but they did not show qualitative and quantitative data.[21] Our data suggest that the

dx.doi.org/10.1021/jf505323g | J. Agric. Food Chem. 2015, 63, 250−261

different responses of meat proteins to cooking could be indicative of different digestibilities.

Cooking had a significant effect ($p < 0.05$; Figure 2) on *in vitro* digestibility of pork treated with pepsin and trypsin. When pork was treated only with pepsin, cooking led to a distinct decrease ($p < 0.05$) in digestibility between 60 °C and raw meat and between 70 and 100 °C but there was no significant difference ($p > 0.05$) between 60 and 70 °C. For pork treated with pepsin followed by trypsin, only a high temperature (100 °C) resulted in a significant decrease in digestibility. These results are in accordance with previous studies in which the digestion rate was applied to evaluate *in vitro* digestibility.[11,19] In those studies, the decrease in protein digestibility was associated with protein aggregation. It is notable that the values of digestibility are quite different from those by Santé-Lhoutellier et al.[8] mainly because of the different methodologies in which the OD_{280} value was applied to quantify peptides in that previous study, while we calculated it on a dry weight basis.

Effect of Cooking on Peptide Profiling after Digestion. As described above, cooking affected the extent of *in vitro* digestion. However, to our knowledge, peptides in the digested products under different cooking temperatures have never been characterized. Therefore, two types of high-throughput methods, including MALDI−ToF MS and nano-LC−MS−MS, were applied to characterize the composition of digested products.

MALDI−ToF MS analysis revealed different peptide profiles for the ethanol-soluble fractions from the samples with different degrees of cooking (Figure 3). Meat cooked at higher temperatures had relatively less abundant peptides with a m/z range between 200 and 1200 after pepsin treatment (Figure 3a), but the difference became weak after pepsin/trypsin treatment (Figure 3b). This is in accordance with the changes of *in vitro* digestibility.

PCA revealed significant differences in peptide composition and abundance under different cooking temperatures. Again, peptides from raw (4 °C) and very well done (100 °C) pork were well-separated from the other three groups after pepsin digestion (Figure 4a; scores plot) in that fragments from raw meat had relatively smaller mass than the other groups (Figure 4b; loadings plot). Peptides from 60, 65, and 70 °C samples could not be well separated (Figure 4b). However, peptides from all of the groups could not be separated at all after pepsin/trysin digestion (panels c and d of Figure 4). It is notable that the sensitivity of MALDI−ToF MS seems not good enough to characterize low-abundance peptides.

LC−MS analysis was performed to characterize peptides more sensitively. According to a previous study, the size of peptides from pepsin/pancratin-digested pork ranges from 6 to 16 amino acids,[14] and in the present study, the m/z search range was set between 800 and 2000. A total of 1000 peptides were identified from the pepsin-treated samples, and 1203 peptides were identified from the pepsin/trypsin-treated samples. Of these peptides, 554, 466, 484, 329, and 376 peptides were sequenced from pepsin-digested samples for 4, 60, 65, 70, and 100 °C groups, individually, and 662, 549, 520, 431, and 549 peptides were sequenced from pepsin/trypsin-digested samples (Figure 5a) from 4, 60, 65, 70, and 100 °C groups, respectively. When peptides were categorized by m/z into three groups, 800−1000, 1000−1500 and 1500−2000, the majority of peptides have a m/z of 1000−1500 or 1500−2000. The 70 °C samples had the least peptides across three mass to charge ranges whether the samples were treated with pepsin alone or followed by trypsin (panels b and c of Figure 5). This could be due to the protein

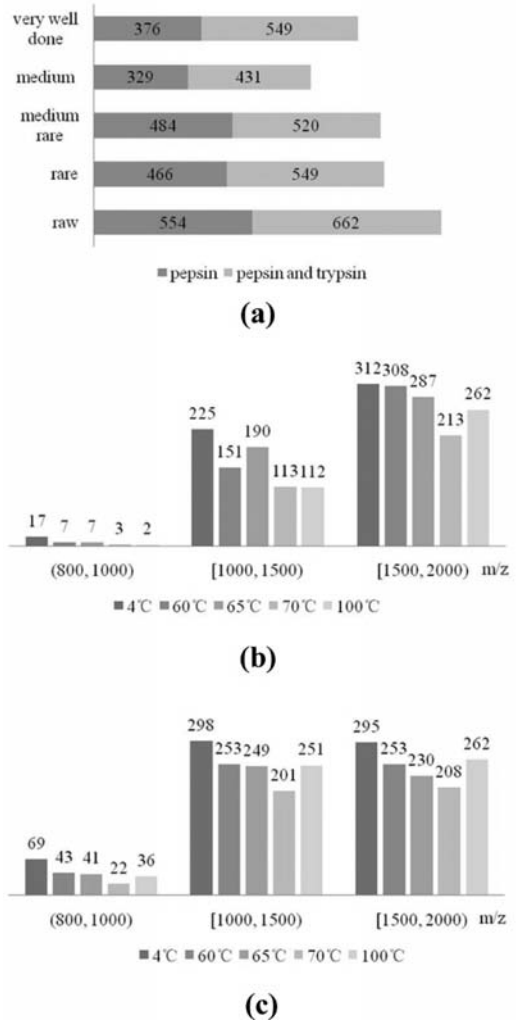

Figure 5. Number of identified peptides from cooked pork treated with pepsin and trypsin: (a) total number of identified peptides between 800 to 2000 Da, (b) number of the peptides from pepsin-digested samples categorized by size, and (c) number of the peptides from pepsin/trypsin-digested samples categorized by size.

aggregation associated with the resistance to the proteolysis of digestive enzymes.[9,11,19] We also found that peptide sequences from pepsin-treated samples were different from those from pepsin/trypsin-treated samples (see the Supporting Information), which could be attributed to the stochasticity of active sites of pepsin.[22]

Peptides were matched with porcine muscle proteins against the Swiss-Prot *S. scrofa* database. High-abundance peptides were mainly from several myofibrillar proteins (myosin, actin, tropomyosin, and titin) and sarcoplasmic proteins (phosphorylase, glyceraldehyde-3-phosphate dehydrogenase, creatine kinase, 6-phosphofructokinase, etc.). Notably, 16−21% of identified peptides came from myosin heavy chain. This gives a good explanation for the decrease in band intensities on SDS−PAGE gels (Figure 1). To explore the effect of cooking on the digestion pattern of these proteins, we localized identified sequences to the intact protein sequence chains. Figure 6 is an example of myosin heavy chain (myosin-4). Generally, peptides identified from pepsin-digested samples under lower temperature disappeared as the temperature increased. Meanwhile, in comparison to the pepsin cleavages (a1−a3 of Figure 6), the pepsin/trypsin cleavages appeared more consistent among samples under

Figure 6. Localization of peptides from myosin-4 in response to cooking: (a1) peptides from pepsin-digested samples located at myosin head-like domain (positions 1−781), (a2) peptides from pepsin-digested samples located at myosin coiled tail domain (positions 812−1250), (a3) peptides from pepsin-digested samples located at myosin coiled tail domain (positions 1251−1937), (b1) peptides from pepsin/trypsin-digested samples located at myosin head-like domain (positions 1−781), (b2) peptides from pepsin/trypsin-digested samples located at myosin coiled tail domain (positions 812−1250), and (b3) peptides from pepsin/trypsin-digested samples located at myosin coiled tail domain (positions 1251−1937). Different colors of highlights were used to distinguish the peptides just next to each other.

different cooking temperatures (b1−b3 of Figure 6). For pepsin-digested samples, 10 peptides appeared in all five groups, while 33 peptides appeared in trypsin digestion with the carbon-terminal cleavage sites as Lys and Arg. Although it could be due to the trypsin peptides better identified in the database search than pepsin, this indicates that cooking may

dx.doi.org/10.1021/jf505323g | J. Agric. Food Chem. 2015, 63, 250−261

change the conformation of proteins but the cleavage sites of digestive enzymes change little.

In summary, cooking had a significant effect on *in vitro* digestibility and pepsin digestion but not for pepsin/trypsin digestion. Characterized peptides showed the stochasticity of pepsin cleavage and the stability of trypsin cleavage. Although there was no significant difference in peptide profiles after two-step digestion, it could be significant for absorption and bioavailability in the live body, and additionally, some of the peptides could have bioactive functions.

ABSTRACT: Chlorogenic acid and its derivatives (CADs) are valuable bioactive plant secondary metabolites with many health benefits. In the present study, *Stevia rebaudiana* hairy root cultures were established, and the culture conditions for the production of CADs were optimized. The hairy roots were induced by coculture of *S. rebaudiana* leaves and *Agrobacterium rhizogenes* (C58C1) after infection, which were further verified by PCR detection of *rol*B and *rol*C genes. HPLC-MS and HPLC analysis showed that chlorogenic acid (3-caffeoylquinic acid, 3-CQA), 3,5-dicaffeoylquinic acid (3,5-CQA), and 4,5-dicaffeoylquinic acid (4,5-CQA) were the major CADs in the hairy roots. Eight single roots with rapid growth rate were selected. Among them, T3 had the highest yield of CADs. B5 medium supplemented with 40 g/L sucrose was more suitable for the production of CADs than others. Under optimal culture conditions, the total content of these three compounds reached 105.58 mg/g and total yield was 234.40 mg/100 mL.

KEYWORDS: *Stevia rebaudiana, hairy root, Agrobacterium rhizogenes, chlorogenic acid, phenylpropanoid*

INTRODUCTION

Stevia rebaudiana is a perennial herbaceous plant first found in South America.[1] The leaves of *S. rebaudiana* contain large amounts of sweet diterpenoid secondary metabolites, named steviol glycosides. Stevioside and rebaudioside A are the main sweet components of *S. rebaudiana* leaf.[2,3] With the increase of public concern with diabetes and obesity, *S. rebaudiana* has gradually become a main resource of commercial natural zero-calorie sweetener and is cultivated in many countries such as China, Korea, Brazil, the United States, Indonesia, and Canada.[4,5] Besides steviol glycosides, secondary metabolites such as polyphenols,[6,7] alkaloids,[8] sterols,[9] flavonoids,[10] triterpenoids,[9] and cardiac glycosides[11] are also found in *S. rebaudiana*. Compared with the high content of steviol glycosides, the amount of these bioactive components is much lower. Karaköse et al. identified 24 hydroxycinnamic acid derivatives of quinic and shikimic acid in *S. rebaudiana* leaves by LC-MS^n, and the contents of 3-caffeoylquinic acid (3-CQA), 3,5-dicaffeoylquinic acid (3,5-CQA), and 4,5-dicaffeoylquinic acid (4,5-CQA) were 35.5, 145.6, and 37.2 μg/g, respectively.[6]

Compared to conventional plant cultivation, which suffers from the limitation of cultivated land and climate, tissue culture (e.g., hairy root and cell suspension culture) is a promising approach to produce high-value plant secondary metabolites.[12] Hairy root cultures are genetically and biologically stable compared with cell suspension cultures and, furthermore, show vigorous growth in phytohormone-free medium.[13−15] Moreover, hairy root cultures often have greater capacity to produce secondary metabolites compared to their parent plants.[16] According to the research of Liu et al., *Echinacea purpurea* hairy root cultures were a possible way to produce caffeic acid derivatives, and the contents of cichoric acid, caftaric acid, and chlorogenic acid in these hairy roots were 19.21, 3.56, and 0.93 mg/g dry biomass, respectively.[17] It has been reported that overexpression of the AtPAP1 gene in *Platycodon grandiflorum* hairy roots caused significant increase of chlorogenic acid accumulation; the chlorogenic acid content was 421.31 μg/100 mg dry weight, which was 9.89 times higher than that of the control hairy root (42.60 μg/100 mg).[18]

In the present work, we establish *S. rebaudiana* hairy root cultures. HPLC-MS analysis of hairy root extracts was carried out, and three compounds, namely, 3-CQA, 3,5-CQA, and 4,5-CQA, were detected (Table 1). It was reported that these compounds have various bioactivities. Shin et al. examined the in vivo anti-inflammatory effects of 3-CQA using dextran sulfate sodium induced colitis in mice and found that 3-CQA dramatically improved colitis histological scores and thus might be used in the diet to prevent intestinal inflammation.[19] Cho et al. showed that 3-CQA was a potential bioactive compound for body weight reduction and lipid metabolism regulation in vivo.[20] Watanabe et al. investigated the blood pressure-lowering effect and safety of CADs through a randomized clinical trial, and their results suggested that these compounds were effective in decreasing blood pressure and safe for patients with mild hypertension.[21] According to Robinson et al., dicaffeoylquinic acids inhibited HIV-1 replication by inhibiting the integrase activity.[22] Xiong et al. reported that 3-CQA, 3,5-CQA. and 4,5-CQA all significantly suppressed the growth of *Staphylococcus aureus* and *Escherichia coli*.[23] To the best of our knowledge, there is no literature on the production of CADs by *S. rebaudiana* hairy root cultures.

Table 1. Linear Relationships of HPLC Analysis of Chlorogenic Acids and Its Derivatives

compound	regression eq	linearity range (μg/mL)	correlation factor (R^2)
3-caffeoylquinic acid	$Y = 28.052X - 121.540$	9.50−285.00	0.9997
3,5-dicaffeoylquinic acid	$Y = 24.989X - 82.588$	9.25−277.50	0.9995
4,5-dicaffeoylquinic acid	$Y = 27.167X - 162.680$	9.75−292.50	0.9992

Our results indicated that hairy root cultures of *S. rebaudiana* would be a promising approach to produce these bioactive compounds.

MATERIALS AND METHODS

Chemicals and Reagents. 3-CQA (HPLC grade, ≥98%), 3,5-CQA (HPLC grade, ≥97%), and 4,5-CQA (HPLC grade, ≥97%) were purchased from Tautobiotech (Shanghai, China). An *EasyPure* Plant Genomic DNA Kit, an *EasyPure* Plasmid MiniPrep Kit, and 2× TransTaq High Fidelity PCR SuperMix were purchased from TransGen Biotech (Beijing, China). The HPLC grade methanol (MeOH) was purchased from TEDIA (Fairfield, OH, USA).

***Stevia rebaudiana*.** The seeds of *S. rebaudiana* var. FengNong 3 were purchased from Suzhou, Anhui, China. The seeds were successively surface-sterilized with 70% ethanol for 30 s and 0.1% (w/v) mercuric chloride for 20 min. The sterile seeds were placed on 1/2MS medium (with 3% sucrose and 0.6% agar, pH 5.8 ± 0.2) and incubated under a 12/12 h (light/dark) photoperiod at 25 ± 1 °C. After 2−3 weeks of incubation, the aseptic seedlings were obtained.

***Agrobacterium rhizogenes*.** *A. rhizogenes* strain C58C1 was kindly provided by Prof. Guo-Yin Kai of Shanghai Normal University. *A. rhizogenes* was inoculated on solid YEB medium, which contained 50 mg/L of kanamycin (Kan) and incubated at 28 °C. Single colonies were picked up and transplanted into YEB liquid medium (supplemented with 50 mg/L of Kan) and then cultured in a shaker (Sukun, Shanghai, China) at 180 rpm and 28 °C for 24 h. *A. rhizogenes* culture was transferred into fresh medium and recultured for another 10 h. The cultured *A. rhizogenes* was collected by centrifugation at 5000 rpm for 10 min and then resuspended in 1/2MS liquid medium. The *A. rhizogenes* was precultured under the above-mentioned conditions for 30 min before use.

Induction of *Stevia rebaudiana* Hairy Root Cultures. The young leaves of aseptic *Stevia* seedlings were collected and precultured on the surface of 1/2MS solid medium containing 100 μmol/L acetosyringone (AS) for 2 days. These precultured explants were immersed in the culture medium of *A. rhizogenes* for 20 min, and then the surface bacteria and moisture were removed with sterile filter paper. The infected explants were placed on the surface of 1/2MS solid medium containing 100 μmol/L AS and cultured at 28 °C in the dark. After 2 days of cocultivation, the explants were transferred to 1/2MS solid medium supplemented with 500 mg/L cefotaxime sodium (Cef) to eliminate the residual bacteria. Adventitious roots appeared in the wound sites of explants in 3 weeks after infection. A single root was excised and cultured on the 1/2MS solid medium containing Cef (500 mg/L). After bacteria were eliminated, hairy roots were transferred into 1/2MS liquid medium for subculture.

Screening of Hairy Roots. Hairy roots with high growth rate were selected for further studies. Half a gram of hairy roots was inoculated in a 250 mL Erlenmeyer flask containing 100 mL of 1/2MS liquid medium (with 3% sucrose, pH 5.8 ± 0.2) and then cultured in a shaker at 115 rpm and 28 ± 2 °C in the dark for 24 days. The hairy roots were collected after 24 days of culture, and the fresh weight (FW) was determined after the hairy roots were rinsed with tap water and the excessive water was removed with filter paper. The hairy roots were dried at 60 °C until a constant dry weight (DW) was obtained. CAD content was determined by HPLC. Hairy root lines that contained more TP-CADs (total production of chlorgenic acid and its derivatives in 100 mL of medium, which was calculated by multiplying the content sum of 3-CQA, 3,5-CQA, and 4,5-CQA with the dry biomass weight) were selected for further experiments.

Confirmation of Hairy Roots. Plasmid DNA of *A. rhizogenes*, total DNA of hairy roots, and total DNA of untransformed roots were extracted with SDS reagent by following the manufacturer's instructions (TransGen Biotech, Beijing, China). PCR amplification was performed in a 50 μL reaction mixture containing 50 ng of templates DNA, 0.4 μM of each primer, and 25 μL of 2× *EasyTaq* PCR SuperMix (containing Taq DNA polymerase, $MgCl_2$, and dNTP). The forward and reverse primer sequences for *rol*B gene amplification were 5′-GCTCTTGCAGTGCTAGATTT-3′ and 5′-GAAGGTGCAAGCTACCTCTC-3′, and those for *rol*C gene amplification were 5′-CTCCTGACATCAAACTCGTC-3′ and 5′-TGCTTCGAGTTATGGGTACA-3′, respectively. The procedure of PCR was as follows: the first cycle was performed at 94 °C for 5 min, followed by 35 cycles of 94 °C for 45 s, 60 °C for 45 s, 72 °C for 60 s, and the final extension was 10 min at 72 °C. PCR products were analyzed by electrophoresis separation.

Extraction of CADs. Hairy roots were ground into fine powder after drying. Two hundred milligrams of hairy root powder was extracted by ultrasonic method in 4 mL of 70% ethanol twice. The supernatant was collected and combined after centrifugation for 10 min at 5000 rpm. Its volume was accurately adjusted to 10 mL with distilled water. After filtering through 0.22 mm pore size filter, the sample solution was used for HPLC and HPLC-ESI-MS analysis.

Qualitative and Quantitative Analysis of CADs. CADs in the hairy roots were identified by HPLC-ESI-MS (6430 HPLC-MS system; Aglient Technologies, Santa Clara, CA, USA) and quantified by HPLC (1260 HPLC system; Aglient Technologies). The HPLC parameters were as follows: chromatographic column, Waters Symmetry C_{18} column (4.6 mm × 250 mm, 5 μm; Waters, Milford, MA, USA); mobile phase, 0.2% acetic acid (A) and methanol (B); flow rate, 1 mL/min; elution procedure, 0−10 min, 70% A; 10−15 min, 70−45% A; 15−25 min, 45% A; 25−26 min, 45−70% A; 26−30 min, 70% A; detection wavelength, 327 nm; column temperature, 40 °C; volume of sample injection, 10 μL. Authentic compounds (3-CQA, 3,5-CQA, and 4,5-CQA) were dissolved in MeOH; the concentrations were adjusted to 9.50−285.00, 9.25−277.50, and 9.75−292.50 μg/mL, respectively, and the calibration curves were established under the same determination conditions. HPLC-ESI-MS analysis was performed in negative mode according to the method of Sun et al.[24]

Optimization of Culture Conditions. Half a gram of T3 hairy roots was inoculated into 250 mL Erlenmeyer flasks that contained 100 mL of 1/2MS liquid medium supplemented with 30 g/L of different sugars (maltose, glucose, sucrose, or fructose) or 100 mL of different media (MS 1/2MS, B5, 1/2B5, WPM, or 1/2WPM) supplemented with 30 g/L of sucrose, or 100 mL of B5 liquid medium supplemented with different concentrations of sucrose (10, 20, 30, 40, 50, or 60 g/L), respectively. All of the hairy roots were cultured under the same conditions described above, and FW, DW, and CAD content were determined.

Dynamic Characteristics of Hairy Root Growth and CAD Accumulation. The growth curve and CAD accumulation curve of T3 hairy root were established according to the change of FW, DW, and CAD content during a growth cycle. Half a gram of T3 hairy roots was inoculated in a 250 mL Erlenmeyer flask that contained 100 mL of B5 liquid medium supplemented with 40 g/L sucrose and then cultured for 36 days under the aforementioned conditions. FW, DW, and CAD content were determined every 3 days during the growth cycle.

Data Statistics and Analysis. The results were given as mean values ± standard deviations (SD). Data were analyzed by the DPS 6.55 statistical software, and statistical analysis was performed using the ANOVA followed by Tukey's test (at $P \leq 0.01$).

Establishment of *Stevia rebaudiana* hairy root cultures: (a) preculture of *S. rebaudiana* leaves on 1/2MS medium supplemented with 100 μmol/L of AS; (b) hairy roots grew from infected explants (1/2MS medium supplemented with 100 mg/L of Cef); (c) hairy roots cultured on 1/2MS solid medium; (d) hairy roots cultured in 1/2MS liquid medium.

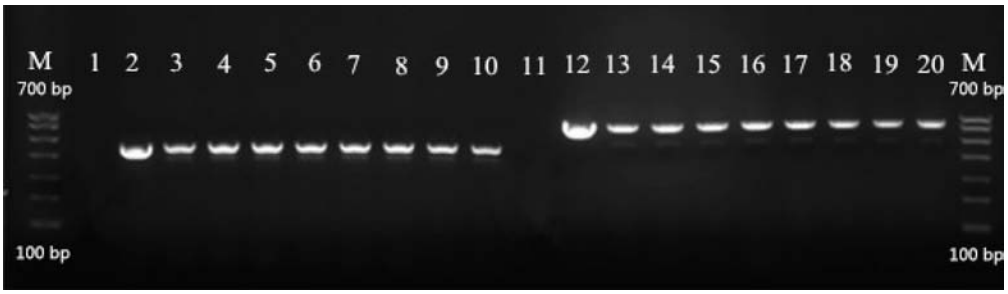

Figure 2. PCR analysis of the *rol*B and *rol*C genes in the hairy root lines of *Stevia rebaudiana*. Lanes: M, marker (from 100 to 700 bp); 1 and 11, DNA from nontransformed roots (negative control); 2 and 12, Ri plasmid DNA (positive control); 3−10 and 13−20, DNA from T1, T3, T4, T5, T9, T14, T16, and T17 strains induced by *Agrobacterium rhizogenes*. *RolB* genes are shown in lanes 1−10, and *rolC* genes are shown in lanes 11−20.

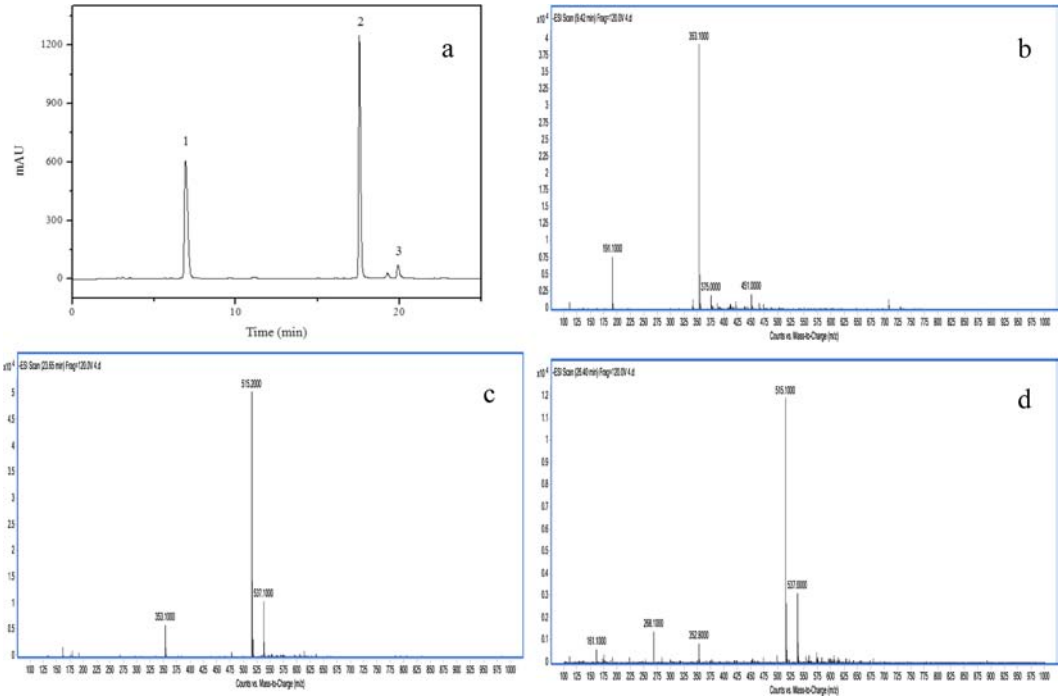

Figure 3. HPLC chromatograms and mass spectra of hairy root extracts: (a) HPLC chromatogram of hairy root extracts; (b) mass spectrum of peak 1 shown in the HPLC chromatogram; (c) mass spectum of peak 2 shown in the HPLC picture; (d) mass spectrum of peak 3 shown in the HPLC picture. Peaks 1 (6.877 min, *m*/*z* 353.1) was identified as 3-CQA ($C_{16}H_{18}O_9$), peak 2 (17.553 min, *m*/*z* 515.2) was identified as 3,5-CQA ($C_{25}H_{24}O_{12}$), and peak 3 (19.908 min, *m*/*z* 515.1) was identified as 4,5-CQA ($C_{25}H_{24}O_{12}$). HPLC chromatogram was obtained at 327 nm.

RESULTS AND DISCUSSION

Establishment of Transgenic Hairy Root Lines. Coculture is a method commonly used to induce hairy roots, by which hairy roots are induced from wounded explants when they were cocultured with *A. rhizogenes*. The sterilized *S. rebaudiana* explants (young leaves) were infected by *A. rhizogenes* C58C1 after 2 days of preculture. Hairy root cultures were generated from the wounds of infected explants in the third week after infection, which showed high branching and no geotropism (Figure 1b). No similar root was observed in the

DOI: 10.1021/jf504176r
J. Agric. Food Chem. 2015, 63, 262−268

control. Sujatha et al. reported that *Artemisia vulgaris* hairy roots were generated in 2 weeks after cocultivation, and no hairy roots appeared in the control group.[25] According to Kúzma's investigation, hairy roots grew from the wounded and infected sites of *Salvia austriaca* explants in 2 weeks after infection and continued to grow to the fourth week.[26] Single root tips (2−3 cm long) were excised and cultured on 1/2MS hormone-free solid medium. The root tips grew rapidly (as shown in Figure 1c). After several successive subcultures, there was no visible bacterium on the surface of medium, indicating that the residual bacteria had been clearly removed. The bacterium-free root tips were transferred into 1/2MS liquid medium for suspension culture (Figure 1d).

Confirmation of Hairy Roots by PCR. *Rol* genes are the important Ri plasmid genes of *A. rhizogenes* and play a vital role in hairy root induction. Therefore, *rol* genes are commonly used as reference genes to confirm the hairy roots. In the present paper, eight hairy root samples, Ri plasmid (positive control), and uninduced root (negative control, from germ-free *S. rebaudiana* seedling) were analyzed by PCR. The results (Figure 2) showed that *rol*B (lanes 3−10 in Figure 2) and *rol*C (lanes 13−20) were present in all eight hairy root samples, as well as in the positive control (lanes 2 and 12). However, these genes were absent in the roots excised from nontransformed plants (lanes 1 and 11). The results indicated that the *rol* genes were successfully inserted into the genome of *S. rebaudiana*.

Qualitative Analysis of CADs. The extracts of *S. rebaudiana* hairy roots were analyzed by HPLC-ESI-MS and HPLC. The results indicated that there were three major compounds in the extracts (Figure 3a). These compounds were identified as chlorgenic acid (peak 1) and dicaffeoylquinic acid (peaks 2 and 3) by their pseudomolecular ions at m/z 353 $[M - H]^-$, 515 $[M - H]^-$, and 515 $[M - H]^-$, respectively. We further confirmed that the three compounds were 3-CQA (peak 1), 3,5-CQA (peak 2), and 4,5-CQA (peak 3), respectively, by standard addition of authentic standards.

It has been reported that the biosynthesis of steviol glycosides is limited to green tissues in *S. rebaudiana*. Steviol is produced in the plastids and endoplasmic reticulum and glycosylated by UDP-glucosyltransferases in the cytoplasm; the steviol glycosides are then stored in vacuoles.[27] It is not surprising that no steviol glycoside was detected in the hairy root cultures because the biosynthetic genes were probably not expressed in roots. To overcome such problems, we will need to overexpress key genes of the biosynthetic pathway in the hairy roots. Certainly other parameters may also play roles for producing secondary metabolites, such as the available oxygen, nutrients, light, water, and pH. These growth conditions in the shake flask culture of hairy roots were dramatically different from those of field growth, and the notable difference may cause the silence of the critical genes of steviol glycoside synthesis. The insert of exogenous gene(s) from *A. rhizogenes* may also result in the change of gene expressing and thus lead to the absence of steviol glycoside.

Screening of High-Producing Hairy Root Lines. Eight hairy root lines with typical phenotype and high growth rate were selected from the induced hairy roots at the beginning. These hairy root lines were further confirmed by PCR detection of *rol*B and *rol*C genes. To get the lines with high production of CADs, the eight roots were further screened by the determination of FW, DW, and CAD content after 24 days of culture (Figure4). Among the eight roots, T3 exhibited the highest growth rate, followed by T17. The FW and DW of T3

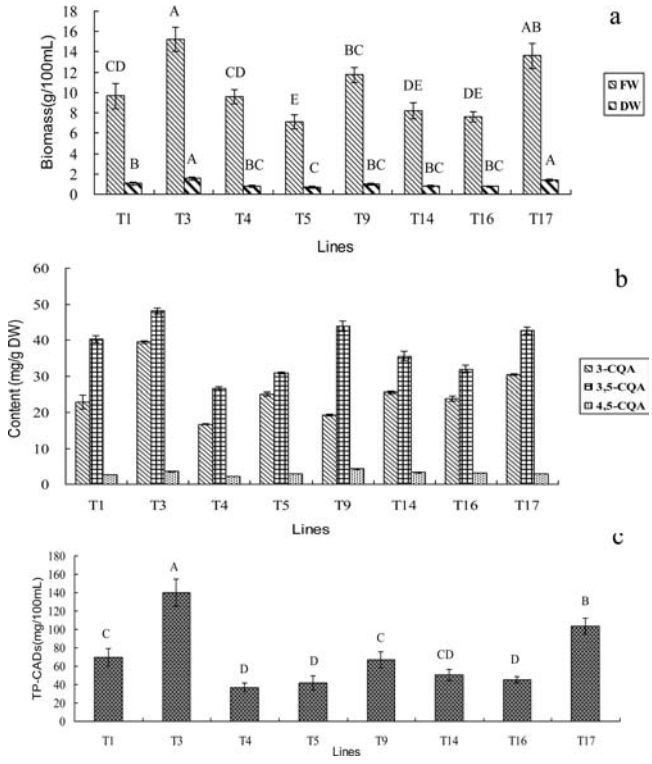

Figure 4. Biomass accumulation and CAD production of eight hairy root lines: (a) biomass accumulation of eight hairy root strains; (b) content of 3-CQA, 3,5-CQA, and 4,5-CQA in eight hairy root strains; (c) TP-CADs of eight hairy root strains. Half a gram of hairy roots was inoculated in 250 mL Erlenmeyer flasks containing 100 mL of 1/2MS liquid medium supplemented with 30 g/L sucrose. Each experiment was repeated five times. TP-CADs is the summation production of 3-CQA, 3,5-CQA, and 4,5-CQA.

were 15.23 and 1.54 g/100 mL, respectively, which increased over 30 times after 24 days of culture. According to the results of HPLC analysis, T3 hairy roots had the highest contents of 3-CQA (39.41 mg/g) and 3,5-CQA (48.10 mg/g), whereas T9 contained more 4,5-CQA (4.29 mg/g). For each line, 3,5-CQA was the most abundant compound, followed by 3-CQA. The content of 4,5-CQA was much lower than those of 3,5-CQA and 3-CQA. In terms of TP-CADs, T3 was the optimal line. Its TP-CADs (140.36 mg/100 mL) is significantly higher than that of other lines. Therefore, T3 was selected as the optimal one for further experiments.

Optimization of Culture Conditions on Biomass Accumulation and TP-CADs. It is widely believed that sucrose is a suitable carbon source for the biosynthesis of secondary metabolites in the cultivation of plant in vitro systems.[28] In the present paper, the effects of maltose, glucose, sucrose, and fructose on biomass accumulation and TP-CADs of T3 hairy root were compared. Our results confirmed that sucrose was the most suitable carbon source.

Furthermore, the effect of sucrose concentration (10−60 g/L) on biomass accumulation and TP-CADs of T3 hairy roots was also investigated. The highest biomass accumulation was achieved in 40 g/L of sucrose, and the FW and DW were 17.93 and 2.34 g/100 mL, respectively (Figure 5a). The slow growth of hairy roots in the medium with sucrose lower than 40 g/L might be caused by the lack of energy substance. However, the inhibition of growth in higher concentration of sucrose might result from the high osmotic stress. Similar to our study, the

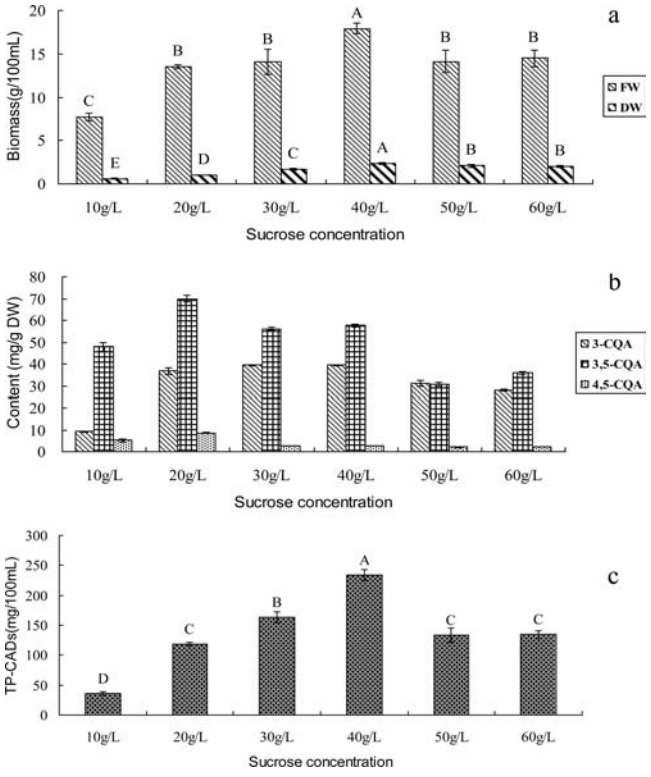

Figure 5. Effect of sucrose concentrations on biomass and CAD accumulation of T3: (a) biomass accumulation of T3 cultured in medium supplemented with 10, 20, 30, 40, 50, or 60 g/L sucrose, respectively; (b) content of 3-CQA, 3,5-CQA, and 4,5-CQA of T3 cultured in medium supplemented with 10, 20, 30, 40, 50, or 60 g/L sucrose, respectively; (c) TP-CADs of T3 cultured in medium supplemented with 10, 20, 30, 40, 50, or 60 g/L sucrose, respectively. Half a gram of hairy roots was inoculated in 250 mL Erlenmeyer flasks containing 100 mL of B5 liquid medium, which were supplemented with 10, 20, 30, 40, 50, or 60 g/L sucrose, respectively. Each experiment was repeated five times.

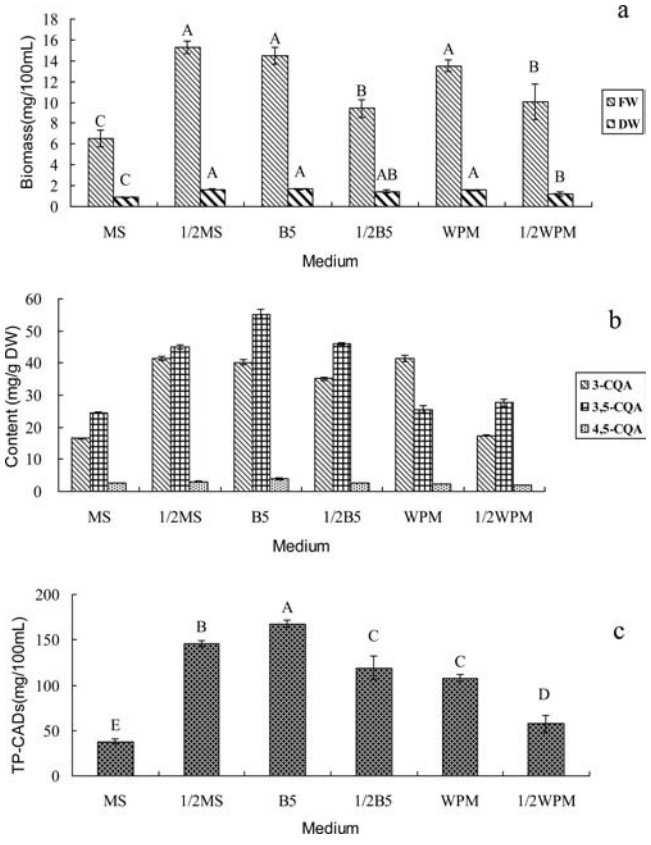

Figure 6. Effect of medium on biomass and CAD accumulation of T3: (a) biomass accumulation of T3 cultured in different media; (b) content of 3-CQA, 3,5-CQA, and 4,5-CQA of T3 cultured in different media; (c) TP-CADs of T3 cultured in different media. Half a gram of hairy roots was inoculated in 250 mL Erlenmeyer flasks containing 100 mL of MS, 1/2MS, B5, 1/2B5, WPM, or 1/2WPM liquid medium, respectively. All of the media were supplemented with 30 g/L sucrose. Each experiment was repeated five times.

highest biomass accumulation of *A. vulgaris* hairy roots was obtained in 1/2MS medium supplemented with 40 g/L sucrose.[25] The highest content of 3-CQA (39.45 mg/g) was achieved in B5 medium with 30 g/L sucrose. However, for 3,5-CQA and 4,5-CQA, the highest contents were obtained with 20 g/L sucrose, which were 69.45 and 8.63 mg/g, respectively (Figure 5b). In consideration of both biomass and metabolite content, the highest TP-CADs (233.54 mg/100 mL) were achieved in 40 g/L sucrose (Figure 5c). The results indicated that 40 g/L sucrose was the optimal concentration for both growth and TP-CADs of *S. rebaudiana* hairy roots. It has been reported that high content of caffeic acid derivatives was obtained in MS medium supplemented with 30 g/L sucrose by *E. purpurea* hairy root cultures.[17] Wu et al. used 1/2MS medium with 50 g/L sucrose to cultivate adventitious roots of *E. purpurea* in a 1000 L airlift bioreactor and obtained 5 mg of chlorogenic acid, 22 mg of chichoric acid, and 4 mg of caftaric acids per gram of roots (DW).[29]

Culture medium was one of the most important factors in the accumulation of secondary metabolites of in vitro cultures.[28,30] In the present study, the effects of three commonly used media with two different concentrations on the production of CADs were compared (Figure 6). The results showed that 1/2MS, B_5, and WPM were all suitable for T3 hairy root growth; although the highest DW (1.69 g/100 mL) was obtained in B5 medium, no significant difference was observed among these three media (Figure 6a). The highest contents of 3-CQA, 3,5-CQA, and 4,5-CQA were obtained in 1/2MS (41.33 mg/g), B5 (55.24 mg/g), and B5 medium (3.88 mg/g), respectively (Figure 6b). For TP-CADs, B5 was the most suitable culture medium with production of 167.78 mg/100 mL (Figure 6c). Therefore, B5 was selected as the optimal culture medium for *S. rebaudiana* hairy root growth and CAD production. Similar to our study, B5 medium was found to be fit for *Scutellaria baicalensis* hairy root growth, and the baicalin content of dry root cultured in this medium was 14.1−30.0%, which was significantly higher than that of the control (field-grown roots).[31]

Growth Kinetics of Hairy Root Cultures and TP-CADs. The time course of *S. rebaudiana* hairy root growth in B5 liquid medium is shown in Figure 7a. The whole growth cycle could be divided into four stages: adaptive phase (0−6th day), exponential phase (6−24th day), stationary phase (24−30th day), and decline phase (after the 30th day). The highest biomass accumulation appeared in the 24−27th days, and the DW reached 2.22 g/100 mL, which was over 48 times that in inoculation. The hairy roots changed to brown, and the liquid culture medium gradually darkened after 30 days. Similar results were reported by Cesar et al., and they obtained the highest DW of muscadine grape hairy roots at the 21st day with

DOI: 10.1021/jf504176r
J. Agric. Food Chem. 2015, 63, 262−268

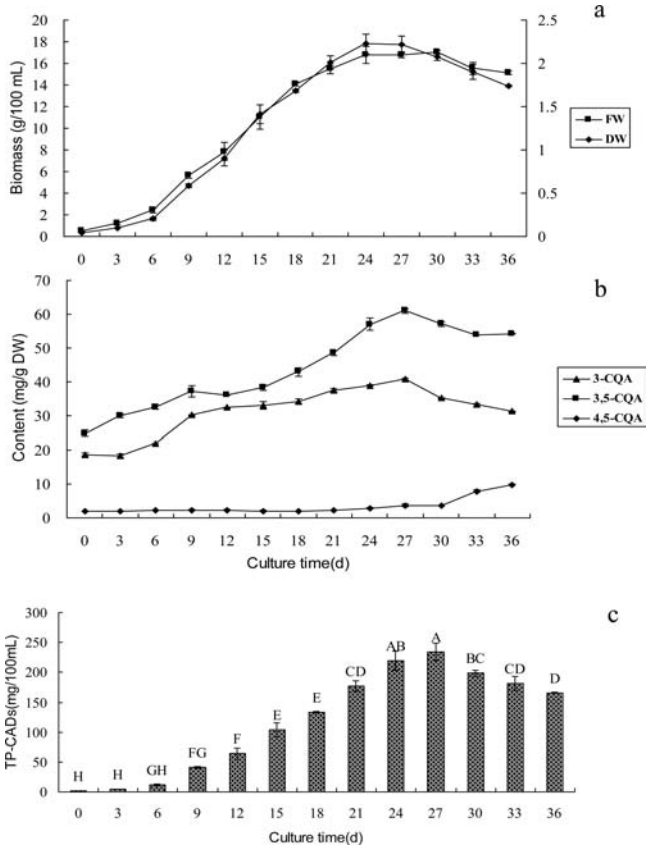

Figure 7. Time course of growth and CAD production of *Stevia rebaudiana* hairy roots: (a) time course of growth of hairy roots; (b) time course of the contents of 3-CQA, 3,5-CQA, and 4,5-CQA of hairy roots; (c) time course of TP-CADs of hairy roots. Half a gram of hairy roots was inoculated in 250 mL Erlenmeyer flasks containing 100 mL of B5 liquid medium supplemented with 40 g/L sucrose. Hairy roots were collected every 3 days. Each experiment was repeated three times.

BDS medium and at the 27th day with BDS+GR medium.[32] The highest contents of 3-CQA (40.85 mg/g) and 3,5-CQA (61.03 mg/g) were achieved at the 27th day after inoculation. However, the highest 4,5-CQA content (9.81 mg/g) was achieved at the 36th day (Figure 7b). We obtained the highest TP-CADs at the 27th day after inoculation (Figure 7c), which was 234.40 mg/100 mL. Therefore, hairy root cultures of *S. rebaudiana* provide an attractive alternative and sustainable approach to produce CADs.

In conclusion, the hairy root cultures of *S. rebaudiana* for the production of CADs were first reported. Three secondary metabolites, 3-CQA, 3,5-CQA, and 4,5-CQA, were identified and quantified in the hairy roots. B5 medium supplemented with 40 g/L sucrose was the best culture condition for CAD production, and the best harvest date of hairy root was the 27th day after inoculation. Our results suggest that the hairy root cultures of *S. rebaudiana* are promising for the large-scale production of CADs.

Supporting Information

ABSTRACT: A total of 95 yeast strains were isolated from the microbiota of different grapes collected at vineyards in southern Brazil. The yeasts were screened for β-(1 → 3)-glucanases using a newly developed zymogram method that relies upon the appearance of clearance zones around growing colonies cultured on agar−botryosphaeran medium and also by submerged fermentation on nutrient medium containing botryosphaeran, a (1 → 3),(1 → 6)-β-D-glucan. Among 14 β-(1 → 3)-glucanase-positive yeasts identified, four strains produced the highest β-glucanolytic activities and were evaluated for enzyme production on cellobiose, botryosphaeran, and mycelial biomass from *Botryosphaeria rhodina* (MAMB-05). Yeast strain 1WA1 produced the highest β-(1 → 3)-glucanase and β-glucosidase activities and was identified by molecular characterization as *Aureobasidium pullulans*. The physicochemical properties of the crude β-glucanolytic enzyme preparation were characterized, and the preparation was used to hydrolyze several β-D-glucans (laminarin, botryosphaeran, lasiodiplodan, pustulan, and curdlan). The production and physicochemical properties of the β-glucanolytic preparation enable its potential applications in wine enology and production of prebiotics through hydrolysis of β-D-glucans.

KEYWORDS: *grape microbiota yeasts, Aureobasidium pullulans, Botryosphaeria rhodina, β-D-glucans, β-(1 → 3)-glucanases, β-glucosidases, botryosphaeran*

INTRODUCTION

The fruiting body of grapes constitutes a biôme (phytophyllosphere) of complex microbiota colonizing the skin of the grape berry that includes bacteria and filamentous fungi, among which are yeasts. Their presence in grape must used to make wine can exert sensorial features on the wines produced.[1] These microbial consortia may constitute an important source of enzymes that can be applied to wine oenology and food and beverage processing. In this special category are the β-glucosidases that have been demonstrated in playing a role in releasing flavors and aromas in wines through their cleavage of monoterpene glucosides into monoterpenes.[2] Wines left to age on the lees (*sur lie*) result in autolysis of the sedimented yeast cells as a consequence of enzymatic hydrolysis of the cell wall (1 → 3),(1 → 6)-β-D-glucans by yeast β-(1 → 3)-glucanases that release mannoproteins, which impart organoleptic characteristics to the wine and improve its quality.[3] Some of the enzymes produced by yeasts of grape biota have distinct benefits of operating at low acid pH values and can tolerate high alcohol levels, conditions that occur during vinification.[4]

The enzymes capable of hydrolyzing the (1 → 3)-β-D-glucans that may carry (1 → 6)-β-linked D-glucosyl appendages are active on substrates, such as (1 → 3),(1 → 6)-β-D-glucans found in yeast and fungal cell walls, fungal exopolysaccharides (EPS), e.g., botryosphaeran and scleroglucan, laminarin [a low branched algal (1 → 3)-β-D-glucan], paramylon [an unbranched algal (1 → 3)-β-D-glucan], and curdlan [an insoluble, unbranched bacterial (1 → 3)-β-D-glucan],[5] include β-(1 → 3)-glucanases of the *exo* and *endo* types and unspecific β-glucosidases, and have been found in yeasts as well as bacteria, fungi, algae, and higher plants.[6]

Botryosphaeria rhodina MAMB-05 secretes an EPS of the (1 → 3),(1 → 6)-β-D-glucan type named botryosphaeran by submerged fermentation (SmF) when cultivated on glucose or sucrose, concomitantly producing large amounts of mycelial biomass.[7] Three types of D-glucans [(1 → 3),(1 → 6)-β-D-glucan, a (1 → 4),(1 → 6)-α-D-glucan, and a (1 → 6)-β-D-glucan] are present in the mycelium from *B. rhodina* MAMB-05.[8] This material constitutes a rich source of β-D-glucans and can serve as a suitable and cheap fermentation substrate to induce specific β-(1 → 3)- and β-(1 → 6)-glucanases rather than using more expensive isolated (1 → 3)-β-D-glucans for this purpose.[9]

In this paper, we describe the isolation of yeasts from different cultivars of grapes and wine musts collected in vineyards within the southern states of Brazil. The yeast isolates were screened for β-(1 → 3)-glucanase activities using a newly developed zymogram method and also by SmF when grown on botryosphaeran and mycelial biomass obtained from *B. rhodina* (MAMB-05). The best enzyme-producing yeast strain (1WA1) was identified by molecular characterization as *Aureobasidium pullulans*. Production of β-(1 → 3)-glucanases and β-glucosidases by *A. pullulans* 1WA1 on mycelial biomass was examined, and the crude β-glucanolytic enzyme preparation characterized and used in the hydrolysis of several β-D-glucans.

MATERIALS AND METHODS

Materials. Botryosphaeran was produced by *B. rhodina* MAMB-05 [Microbiological Culture Collection at Universidade Estadual de Londrina (UEL), Brazil] grown on glucose.[10] Fungal mycelium was collected by centrifugation (1500*g* for 15 min at 4 °C) and freeze-dried without prewashing the mycelium. The lyophilized fungal mycelium (LFM) was pulverized to a powder, stored dry in sealed plastic bags at −20 °C, and referred to as LFM *in natura*. A portion of the fungal mycelium collected was also sterilized in an autoclave (121 °C for 20 min), followed by lyophilization, and used for comparative purposes. Lasiodiplodan [an exocellular soluble (1 → 6)-β-D-glucan] was produced by *Lasiodiplodia theobromae* MMPI grown on glucose.[11] Curdlan [a (1 → 3)-β-D-glucan from *Alcaligenes faecalis*] was purchased from Megazyme International (Bray, Ireland). Pustulan [a (1 → 6)-β-D-glucan isolated from the lichen *Actinogyra muehlenbergii*] was a kind gift from Dr. Philip A. J. Gorin (Universidade Federal do Paraná, Curitiba, Paraná, Brazil). Laminarin [a (1 → 3),(1 → 6)-β-D-glucan from the alga *Laminaria digitata*], laminaribiose, laminaritriose, gentiobiose, and *p*-nitrophenyl-β-D-glucopyranoside (*p*-NPG) were purchased from Sigma-Aldrich (St. Louis, MO).

Isolation of Yeast Species from Grape Microbiota. Nine different table/wine grape varieties common to southern Brazil (Isabel, Bordô, Rubi, Vênus, Itália, Benitaka, Takasumi, Brasil, and Moscato-Bailey) and the must from Isabel and Bordô grapes were collected from vineyards in the states of Paraná and Rio Grande do Sul. The grape berries were collected in the field and placed in sterile cotton sacks. Three whole, undamaged berries from each grape variety were aseptically transferred to flasks containing 25 mL of 0.9% (w/v) NaCl and left stationary at room temperature (28 ± 2 °C). After 48 h, aliquots were transferred to YEPD solid medium [1% (w/v) yeast extract, 2% (w/v) peptone, 2% (w/v) glucose, and 2% (w/v) agar, containing 0.05% (w/v) amoxicillin] and left at 28 °C for 3 days. A total of 95 yeast strains were isolated and purified by the streak-plate method. Yeast colonies were replated repeatedly on YEPD plates until pure. The purified yeast isolates were maintained in YEPD tubes at 4 °C and subcultured at 3 monthly intervals.

Screening Yeast Isolates for β-(1 → 3)-Glucanases. In the screening program, two methods were employed; the isolated yeast strains were grown in SmF on botryosphaeran and on agar medium (zymogram; see below). From this combinatory approach, yeasts were identified that were β-glucanolytic through the observation that botryosphaeran was hydrolyzed and supported cell growth. Yeast isolates were cultivated in 50 mL Erlenmeyer flasks containing 10 mL of nutrient medium comprising Vogel minimum salts medium (VMSM)[12] and botryosphaeran (0.6 g/L) at 28 °C under shaking conditions (180 rpm) for 96 h. β-(1 → 3)-Glucanase activity was assayed against laminarin; see below. The extracellular fluid (ECF) was recovered by centrifugation (3000*g* for 15 min at 4 °C) and used as the source of enzyme.

Zymogram Method for Detecting β-(1 → 3)-Glucanase Activity. The yeast isolates were cultured on agar media in Petri dishes containing agar (2%, w/v), VMSM, and 0.8 g/L botryosphaeran as the sole carbon (C) source. Cultures were incubated at 28 °C for up to 120 h. β-(1 → 3)-Glucanase activity was visualized on the agar plates as a transparent halo around the yeast colonies, following the flooding of the plates with absolute ethanol (~15 mL). The intensity of transparency of the developed halo observed after 1 h (Figure 1) indicated the presence of strong β-(1 → 3)-glucanase activity as a consequence of the yeasts producing enzymes capable of hydrolyzing botryosphaeran.

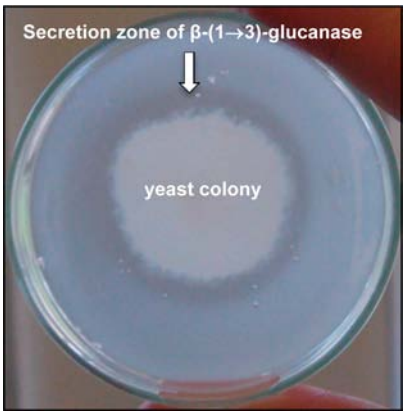

Figure 1. Zymogram showing a halo displaying β-(1 → 3)-glucanase activity around a growing colony of *A. pullulans* 1WA1. Cells were grown on agar−botryosphaeran media in Petri dishes for up to 120 h, and then the plates were flooded with absolute ethanol and left for 1 h to develop the clearance zone.

Molecular Identification of Yeast Strain 1WA1 from Grape Microbiota. Of the 14 β-(1 → 3)-glucanase-positive yeast strains isolated in the screening program, strain 1WA1 produced the highest enzyme activity and was selected for identification and phylogenetic positioning by sequencing of the internal transcribed spacer (ITS) ITS1−5.8S−ITS2 region of the nuclear ribosomal gene complex. Strain 1WA1 was grown in liquid YEPD medium for 48 h, and total DNA was extracted.[13] Polymerase chain reaction (PCR) amplification reactions were carried out,[14] and the amplification products were purified using PureLink Quick Gel Extraction and PCR Purification Combo Kit (Life Technologies, Carlsbad, CA). Sequencing reactions were performed on an ABI 3500 automated sequencer (Applied Biosystems, Germany) using a BigDye Terminator v3.1 Cycle Sequencing Kit (Life Technologies, Carlsbad, CA) with the same primers used for PCR amplifications. The new 5.8S-ITS sequence of strain 1WA1 was deposited in GenBank (accession number HM855956). The identity of the sequenced strain was determined by BLASTN comparison using the National Center for Biotechnology Information (NCBI) database, assuming the best hit to confirm the identity of the selected strain at the species level when sequences showed at least 98% identity to the best hit, a procedure considered robust for fungal species identification. The identity of the sequenced strain 1WA1 was further confirmed through the Fungal Barcoding Pairwise Sequence Alignment tool using the default parameters (http://www.fungalbarcoding.org/BioloMICSSequences.aspx?file=all) and submitted to multiple alignment with 25 closely related taxa retrieved from GenBank. The multiple alignment was accomplished using the ClustalX2 program,[15] with the resulting multiple sequence alignment manually adjusted using BioEdit software.[16] Phylogenetic inference was conducted using MEGA6;[17] the evolutionary history was inferred using the neighbor-joining method; and the evolutionary distances were computed using the Jukes−Cantor method. The strength of internal branches of the final phylogenetic tree was tested with bootstrap (BS) analysis with 1000 replications, and the sequences were employed in the molecular data sets that ranged from 470 to 575 base pairs (bp) in length prior to the elimination of ambiguous or unalignable data, with a total of 430 positions in the final data set. BS values of 50% or higher are shown at the tree branches. The ITS region of *Dothichiza pithyophila* (FJ150969) was used as an outgroup.

Cultivation of *A. pullulans* 1WA1 and Production of β-Glucanolytic Enzymes. Cells of *A. pullulans* 1WA1 (deposited at

DOI: 10.1021/jf504333h
J. Agric. Food Chem. 2015, 63, 269−278

the Microbiological Culture Collection at UEL) were grown on YEPD plates for 96 h. Inoculum was prepared by taking a loopful of yeast cells and added to isotonic saline to a final concentration of 1×10^7 cells. A total of 1 mL was used to inoculate 25 mL of nutrient medium (VMSM and 0.6 g/L botryosphaeran at pH 6.0) in 125 mL Erlenmeyer flasks. Enzyme production was also examined using cellobiose (10 g/L) as the sole C source and in separate experiments, sterilized (autoclaved) and unsterilized (*in natura*) LFM (10 g/L). The effect of the concentration of *in natura* LFM (0.5−3.0%, w/v) on the production of β-(1 → 3)-glucanase and β-glucosidase was performed in Erlenmeyer flasks (125 mL) comprising VMSM. Cultures were incubated at 28 °C (180 rpm) for 96 h. The profiles of growth and β-glucanolytic enzyme production of *A. pullulans* 1WA1 were examined by cultivating the yeast strain on *in natura* LFM (10 g/L) for 168 h. At the following time intervals: 0, 6, 12, 24, 36, 48, 60, 72, 96, 120, 144, and 168 h, three Erlenmeyer flasks were removed for analyses. All experiments were carried out in triplicate, and the results represent the means ± standard deviation (SD).

Analytical Methods. *Enzyme Assays.* The ECF obtained after centrifuging the yeast-grown cultures was used as the source of enzyme. β-(1 → 3)-Glucanase activity was measured against laminarin,[18] followed by measuring the reducing sugars produced by the cuproarsenate method.[19] β-Glucosidase activity was measured against *p*-NPG.[18] β-Glucosidase activity was determined by measuring the amount of *p*-nitrophenol (*p*-NP) liberated (A_{410}; extinction coefficient, 18 300 M^{-1} cm^{-1}). Units of enzyme activity were defined as the number of micromoles of product per minute per milliliter under the standard assay conditions.

Sugars. Total sugars were determined by the phenol−sulfuric acid method,[20] and reducing sugars were determined by the cuproarsenate method.[19] D-Glucose was used as the standard.

Proteins. Soluble proteins were determined by a modified Lowry method[21] using bovine serum albumin as the standard.

Physicochemical Properties of the Crude β-Glucanolytic Enzyme Preparation. To evaluate the effect of pH and temperature on enzyme activity, the ECF was incubated with substrate (laminarin or *p*-NPG) at 35 °C in buffers of different pH (pH 2.5−3.5, 0.2 M glycine/HCl; pH 4−5.5.0, 0.2 M sodium acetate; pH 3.5−6.0, 0.2 M sodium citrate; and pH 3.0−6.5, 0.2 M sodium citrate−sodium phosphate) and at various temperatures (30−90 °C) at the optimum pH for 20 min. Temperature stability of β-(1 → 3)-glucanase activity was determined by incubating the enzyme solution without substrate at 30−60 °C for times ranging from 10 min to 24 h and then adding substrate and assaying for enzyme activity. Kinetic parameters were determined by incubating the ECF at different concentrations of laminarin (0.02−1.20 mg/mL) in 0.2 M citrate−phosphate buffer (pH 4.5) for 20 min at 60 °C for β-(1 → 3)-glucanase and, for β-glucosidase, *p*-NPG (0.016−0.48 mg/mL) in 0.2 M sodium acetate buffer (pH 4.0) and incubated for 20 min at 75 °C. K_m and V_{max} values were determined from Lineweaver−Burk plots.

Enzymatic Hydrolysis of β-D-Glucans by the Crude β-Glucanolytic Enzyme Preparation. Enzymatic hydrolysis of the β-D-glucans, botryosphaeran, laminarin, lasiodiplodan, pustulan, and curdlan (1 g/L), was conducted in 50 mL volumes in 0.025 M sodium acetate buffer (pH 4.5) using 0.5 units of β-(1 → 3)-glucanase (activity assayed against laminarin) in the crude enzyme preparation and incubated at 40 °C. Aliquot samples (1.0 mL) were withdrawn at various intervals (0 min, 5 min, 10 min, 15 min, 30 min, 45 min, 60 min, 120 min, and 24 h) and heated for 10 min at 100 °C to inactivate enzyme activity. The degree of β-D-glucan hydrolysis was measured by the reducing sugar method.[19] Glucose in the hydrolyzates was measured by the glucose oxidase method (Glucose Assay Kit, Sigma). Enzymatic hydrolysis products were analyzed by high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC/PAD; see below).

Enzymatic hydrolysis of cellobiose, gentiobiose, and laminariobiose (1 g/L) was conducted in a final volume of 0.5 mL consisting of 0.025 M sodium acetate buffer (pH 4.5) using 0.1 units of β-glucosidase (activity assayed against *p*-NPG) in the crude enzyme preparations from *A. pullulans* 1WA1, *Trichoderma harzianum* Rifai, and *B. rhodina* MAMB-05. The latter two enzyme preparations were produced according to Giese et al.[18] The reactions were performed at 50 °C for 20 min and then heated for 10 min at 100 °C to arrest enzyme activity. The hydrolysis products were measured as glucose by the glucose oxidase method.

HPAEC/PAD Analysis of β-D-Glucan Enzymatic Hydrolyzates. Unhydrolyzed polymeric material in the enzymatic digests was precipitated with ethanol (3 vol) and removed by centrifugation (7000*g* for 15 min). The supernatant was evaporated under reduced pressure, and the resulting syrup was redissolved in 0.4 mL of deionized water. Samples of 0.025 mL were used for sugar analysis by HPAEC/PAD on a Dionex ICS 3000 instrument (Dionex, Sunnyvale, CA). Mono- and oligosaccharides were separated on a CarboPac PA200 (Dionex) column (4 × 250 mm) at a flow rate of 1.0 mL/min. The column was equilibrated in 0.10 M NaOH (97%) and 0.50 M sodium acetate (3%). After 15 min, a linear 0−0.25 M concentration gradient of sodium acetate was applied over a 70 min interval, while the concentration of NaOH remained at 0.10 M. Sugar quantification was carried out from peak area measurements using response factors obtained from standard sugars.

RESULTS AND DISCUSSION

Screening Grape Yeasts for β-(1 → 3)-Glucanase and β-Glucosidase Activities. The microbial biodiversity of grape berries are complex, and their population varies according to environmental conditions.[1] Among the filamentous fungi dominating grape microflora is the yeast-like fungus, *A. pullulans*.[22] A strain of *A. pullulans* isolated from Brazilian grape ecosystems was reported to produce β-glucosidases.[23] Non-*Saccharomyces* β-glucosidases have been applied commercially in wine oenology to augment aroma and taste of wines, and β-(1 → 3)-glucanases too have found applications in vinification.[24]

The streak-plate method was used to isolate yeasts from the microbiota of nine grape varieties from vineyards in the southern states of Brazil and some grape musts. The grape berries were left in contact with isotonic saline solution to facilitate detachment of the microbial species from the grape skin, which comprises a waxy, cuticular layer that affects the adherence of microbial cells colonizing the surface.[25] The dislodgement of microbes from the grape berry appears to depend upon the extraction methods employed.[26] Saline water extracts of the grape berries were plated onto agar medium containing amoxicillin (antibiotic) and left to grow, resulting in a mixture of different filamentous fungi, including yeasts colonizing the surface of the agar. The microorganisms growing on the agar plates displayed various morphological characteristics: color (white, yellow, pink, but not black), superficial colony features, such as smooth or rough surfaces, and brightness or opaqueness of the colony. A total of 95 yeasts were isolated: 85 yeast strains from grapes taken from vineyards in the state of Paraná located at Marialva (designated by the letter M) and Warta (W) and 10 yeasts from the Isabel grape variety (*Vitisla brusca*) taken from a vineyard in the southern state of Rio Grande do Sul in Brazil.

The isolated yeast colonies were screened for β-glucanolytic activity [β-(1 → 3)-glucanase and β-glucosidase] by growing them on agar medium containing botryosphaeran and employing a specific zymogram procedure developed in this work (see below). The yeasts were evaluated according to their ability to produce exocellular enzymes that formed a transparent halo around the growing colony when plated on agar. To determine quantitative enzyme activities of each of the isolated yeasts, it was necessary to cultivate the yeast strains on liquid nutrient medium containing botryosphaeran and evaluate the

[a]Grown for 96 h. [b]Specific activity (units/mg of protein). [c]Assayed against laminarin as the substrate. [d]Molecularly characterized as *A. pullulans*. [e]Assayed using *p*-NPG.

β-(1 → 3)-glucanase and β-glucosidase activities produced through specific assays against the substrates, laminarin and *p*-NPG, respectively.

The developed zymograms allowed for rapid screening of large numbers of yeast strains for β-glucanolytic activity, which, in turn, were used for further study by SmF on nutrient medium containing botryosphaeran as the sole C source under shaking conditions. Through this combined approach (zymogram and SmF), 14 yeast strains were identified as showing β-glucanolytic activity. Yeasts that could grow on botryosphaeran included strains 4MA3 and 4MA5 (isolated from Takassumi grapes) and 6MS1 and 6MA2 (Benitaka grapes) taken from grapes in a vineyard at Marialva (Paraná) and 1WA1, 1WA2, and 2WS2 (Moscato-Bailey grapes) and 3WS2, 3WS3, 3WS5, 3WS6, 3WS10, 3WS13, and 3WA10 (Isabel grapes) from a vineyard in Warta (Paraná).

Among the Marialva yeasts isolated, strains 4MA3, 4MA5, 6MS1, and 6MA2 produced low enzyme titers that ranged from 1 to 6 milliunits/mL for β-(1 → 3)-glucanase and from 0 to 4.3 milliunits/mL for β-glucosidase when grown by SmF on nutrient media containing botryosphaeran. Yeasts isolated from grapes collected in Warta, in contrast, produced higher enzyme titers that ranged from 1.5 to 113 milliunits/mL for β-(1 → 3)-glucanase and from 2.7 to 12.6 milliunits/mL for β-glucosidase.

Among the yeast strains examined by SmF when grown on botryosphaeran, the best four producers of β-(1 → 3)-glucanases were strains 1WA1, 1WA2 and 2WS2 (Moscato-Bailey grapes) and 3WS5 (Isabel grapes), all isolated from grapes collected at the Warta vineyard and evaluated for enzyme production by SmF when grown on different substrates.

Zymogram for Screening β-(1 → 3)-Glucanase Activity. Screening by SmF was slow and costly on the use of media, including botryosphaeran, and could not conveniently process large numbers of yeasts for screening. A more rapid screening method was sought that was cheaper on polysaccharide use, and a new zymogram procedure was developed. The two methods, nevertheless, demonstrated that the same yeast strains showed β-glucanolytic activities. The zymogram method allowed for a specific assay procedure to rapidly detect β-(1 → 3)-glucanase activity for screening large numbers of yeasts on agar plates. The zymogram procedure was fine-tuned using the yeast strain 1WA1 (molecularly characterized as *A. pullulans*; see below), which was found to be the best producer of β-(1 → 3)-glucanases through SmF (Table 1). The yeasts were grown on agar medium containing botryosphaeran, and afterward, the plates were irrigated with absolute ethanol, which after 1 h, developed clear halos (transparent zones) around the yeast colony (Figure 1). The halo diameters were greater than the diameters of the yeast colony, indicating that β-(1 → 3)-glucanase was secreted exocellularly and diffused through the agar medium to hydrolyze the substrate. Botryosphaeran was hydrolyzed to degraded products (mixed linked gluco-oligosaccharides) that resulted in a clear zone on the agar plates, because these sugars were soluble in alcohol. The unhydrolyzed areas of botryosphaeran on the agar plates remained opaque because of the β-D-glucan not being soluble in ethanol. The novelty of this method was that alcohol was used to distinguish areas between hydrolyzed and unhydrolyzed botryosphaeran on the agar plates, which allowed for rapid detection of yeast β-(1 → 3)-glucanase activities. A bacterial β-(1 → 3)-glucanase has been detected by a zymogram method employing laminarin and using calcofluor white to detect the hydrolysis zones when visualized under ultraviolet (UV) light.[24]

Production of β-Glucanolytic Enzymes by Selected Yeast Strains Grown on Different Substrates. Commercially available laminarin has commonly been used to induce the microbial synthesis of β-(1 → 3)-glucanases by SmF[6] but is an expensive substrate for this purpose. Botryosphaeran, as used in this work, is also considered expensive to produce, but in producing botryosphaeran by *B. rhodina* MAMB-05, large amounts of mycelial biomass are produced.[7] Studies from our laboratory have shown[8] that the mycelium is a rich source of β-D-glucans and a more convenient and less expensive substrate for the microbial production of β-(1 → 3)-glucanases by SmF.[9]

Table 1 shows the production of β-(1 → 3)-glucanases and β-glucosidases by four selected yeast strains (1WA1, 1WA2, 2WS2, and 3WS5) grown on different substrates: cellobiose, botryosphaeran, and LFM (*B. rhodina* MAMB-05 cultivated on glucose and prepared and treated as described under the

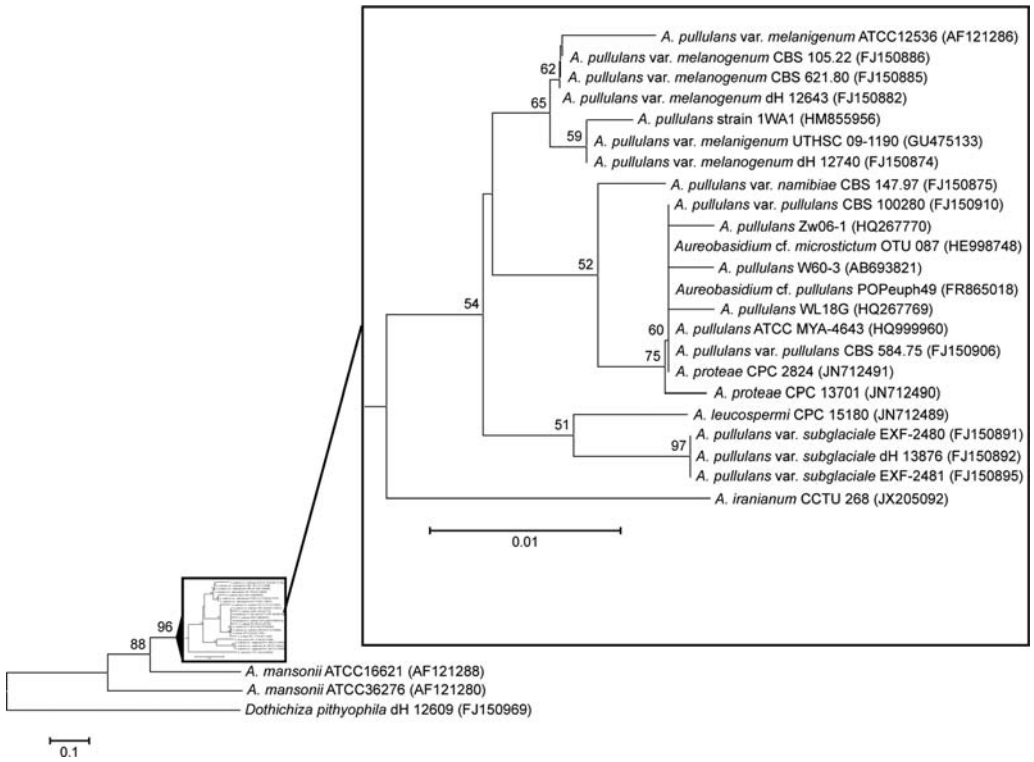

Figure 2. Phylogenetic tree of *A. pullulans* strain 1WA1. The evolutionary history was inferred using the neighbor-joining method. The percentage of replicate trees in which the associated taxa clustered together in the BS test (1000 replicates) is shown above the branches when higher than 50%. The evolutionary distances were computed using the Kimura two-parameter method and are in the units of the number of base substitutions per site. All positions with less than 95% site coverage were eliminated; that is, fewer than 5% alignment gaps, missing data, and ambiguous bases were allowed at any position. There were a total of 430 positions in the final data set. Evolutionary analyses were conducted using MEGA6.

Materials and Methods). The highest activity for both enzymes occurred with strain 1WA1. Cellobiose resulted in the highest β-(1 → 3)-glucanase titers (1.047 units/mL) for 1WA1, while the other yeast strains exhibited lower enzyme activities. *Candida wickerhamii*, a yeast fermenting cellobiose into ethanol, was reported to produce high intracellular β-glucosidase activity (13.7 units/mg) when grown on cellobiose[27] but has not been described as an inducer of β-(1 → 3)-glucanases. Botryosphaeran proved to be a poor substrate for the production of both enzymes compared to the fungal mycelium. The two LFM preparations (*in natura* and autoclaved) did not produce significant differences between them in terms of enzyme titers (units/mL) and specific activities (units/mg of protein), but the β-(1 → 3)-glucanase and β-glucosidase activities produced on both substrates were higher compared to the other substrates tested (Table 1). *B. rhodina* MAMB-05 mycelium contains both (1 → 3),(1 → 6)- and (1 → 6)-linked β-D-glucans,[8] and these components were possibly responsible for inducing the higher β-(1 → 3)-glucanase activities obtained. *T. harzianum*, has also been reported to produce β-(1 → 3)-glucanases when cultivated on the mycelium of *Botrytis cinerea* (1.04 units/mg) and *Saccharomyces cerevisiae* (1.0 units/mg) cells.[28] β-(1 → 3)-Glucanase production by *T. harzianum* Rifai and *B. rhodina* MAMB-05 cultivated on mycelium from *B. rhodina* MAMB-05 resulted in enzyme titers of 0.80 and 0.67 units/mL obtained over 5 and 10 days growth for the respective fungi.[18] Yeasts, in contrast, produce these enzymes in lesser times than the fungi, e.g., in 3 days for *Pichia anomala* YF07b,[29] while our yeast strain 1WA1 reached maximal β-(1 → 3)-glucanase activity after 2−3 days of growth on LFM (*in natura*; see below). Of the four yeast strains evaluated, strain 1WA1 resulted in the highest β-(1 → 3)-glucanase activity and was selected for molecular identification, with a further study on β-glucanolytic enzyme production.

Molecular Identification of Yeast Strain 1WA1. The identification of fungal isolates is largely facilitated by the sequencing of the ITS region of the nuclear ribosomal operon and is supported by the large data set available in public databanks and recently proposed for use as a primary barcode marker for fungi phylogeny.[30] The sequence analysis of yeast strain 1WA1 isolated from the grape berries led to the identification at the species level as being *A. pullulans*, through the use of both the BlastN and the Fungal Barcoding tools. The fungus-like yeast *A. pullulans* and filamentous fungi dominate the microflora of grape berries.[22] The phylogenetic analysis of yeast strain 1WA1 plus 25 of the closest relative *Aureobasidium* species and *A. pullulans* varieties confirmed their close phylogenetic relatedness with *A. pullulans* with BS of 96% and clustering close to *A. pullulans* var. *melanogenum* with BS of 59%, as presented in Figure 2. Cultures of *A. pullulans* var. *melanogenum* form characteristically melanized, dark-colored colonies and are found colonizing environments with nutritional limitations.[31] This contrasts with the characteristically white colonies formed by strain 1WA1 described here. Although the use of ITS sequences to identify new fungal isolates is supported by the literature and widely used as a phylogenetic marker, the unequivocal attributes of a species must be supported by different sets of gene sequences. In addition, as observed in Figure 2, the variability of the *Aureobasidium* ITS sequences observed by most of the data available is narrow and the possible occurrence of a new species is not discarded.

[a]Measured by the phenol−sulfuric acid method.[20] [b]Measured by the cuproarsenate method.[19] [c]LFM = lyophilized fungal mycelium (*in natura*). [d]Soluble protein concentration (measured by the Hartree[21] method) in the culture medium after 96 h of growth. [e]Specific activity (units/mg of protein). The initial soluble protein concentrations were 0.58, 1.01, 1.35, 1.85, and 1.92 mg/mL for the respective LFM concentrations.

Production of β-Glucanolytic Enzymes by *A. pullulans* 1WA1 Cultivated on Mycelial Biomass. The effect of the concentration of mycelial biomass (LFM, *in natura*) on the production of β-(1 → 3)-glucanases and β-glucosidases by *A. pullulans* 1WA1 is shown in Table 2. β-(1 → 3)-Glucanase titers (units/mL) increased, while the specific activity (units/mg of protein) inversely decreased as the concentration of LFM in the nutrient medium increased. The amount of soluble protein in the culture fluid was high at 96 h of cultivation and increased as the LFM concentration in the nutrient medium increased (Table 2), despite no exogenous protein being added to the nutrient formulation. The protein arises through its solubilization by autoclaving of the LFM as well as from the disruption of the fungal mycelium during SmF through the action of the cell-wall-degrading enzymes, resulting in the release of soluble proteins (measured by a modified Lowry method[21]) into the culture medium, hence, the decrease in the specific activity as the amount of LFM increased. β-Glucosidase titers similarly increased but did not appear to significantly affect the specific activity of this enzyme (Table 2).

The initial sugars content (total and reducing sugars) in the nutrient media following autoclaving and prior to inoculation was rather high for each of the amounts of LFM added (Table 2). LFM was isolated following the harvesting of the fungal mycelium and was deliberately not prewashed. This procedure allowed for the LFM preparation to retain residual botryosphaeran in the mycelial fraction that could, in turn, induce β-glucanolytic enzymes. EPS retained and polysaccharides from fragmented cell wall material released to the medium upon autoclaving will present high initial total sugars content as measured by the phenol−sulfuric acid method.[20] The initial reducing sugars content too was high and may arise from the action of β-glucanases present in the LFM preparation during time of harvesting and lyophilization. Cell-wall-bound β-glucanases have been observed in the mycelium from another *B. rhodina* strain, DABAC-P82.[32]

The residual reducing sugars (RRS) content in the medium decreased at all of the concentrations of LFM examined, indicating that the yeast totally consumed these sugars (Table 2). The RRS concentration decreased during growth of the yeast at each of the levels of LFM added. However, in contrast to the RRS, only between 41 and 48% of the total soluble sugars were consumed by the yeast at 96 h within the range of LFM added to the nutrient medium. The remaining total sugars content (52−59%) may have been attributable to the presence of EPS produced by *A. pullulans* 1WA1 (see also the profile of sugar use in Figure 3B), because *A. pullulans* is well-known to produce exocellular pullulan[33] and, recently, a (1 → 3),(1 → 6)-β-D-glucan.[34] The presence of EPS in the culture medium would contribute to the total sugars concentration as measured by the phenol−sulfuric acid method.

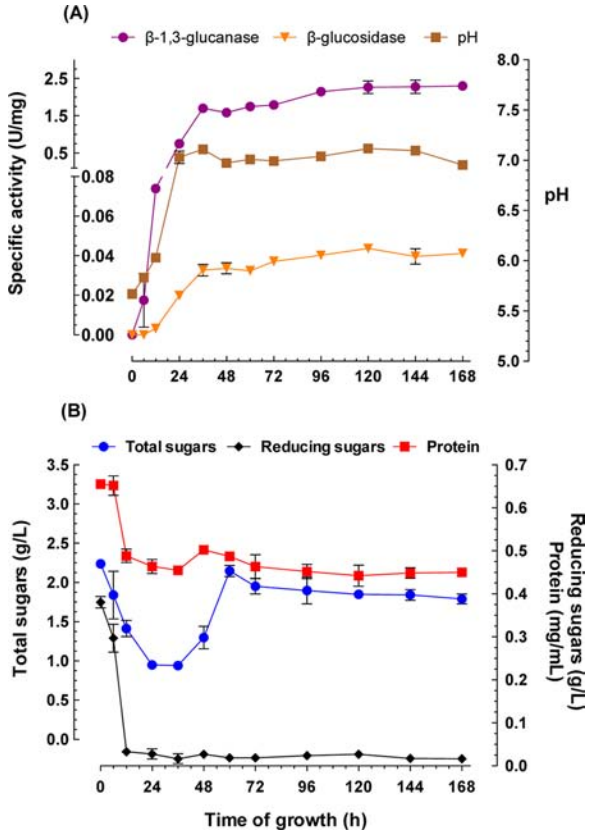

Figure 3. Profile for the production of β-(1 → 3)-glucanases and β-glucosidases by *A. pullulans* 1WA1 cultivated on the mycelium of *B. rhodina* MAMB-05. β-(1 → 3)-Glucanase activity was measured against laminarin as a substrate. Yeast biomass could not be determined during the fermentation run, because undegraded fungal mycelium (LFM) still remained in the culture fluid, and this interfered with yeast biomass determination by the gravimetric procedure.

The profile for enzyme production is shown in Figure 3 when the yeast strain was grown on nutrient medium containing LFM (*in natura*) over a period of 168 h. A substrate loading of 1% (w/v) of LFM was chosen as at higher loadings, SmF on this substrate becomes impractical because of the high solids consistency of the culture medium. β-(1 → 3)-Glucanase production plateaued after 48 h (1.10−1.20 units/mg), while β-

DOI: 10.1021/jf504333h
J. Agric. Food Chem. 2015, 63, 269−278

glucosidase also leveled-off after 48 h (0.03−0.04 units/mg). About 31% of the soluble protein liberated from the LFM was consumed by the yeast over the time course of fermentation, with most of this occurring within the first 36 h of growth. The total sugars concentration in the culture medium decreased for the first 36 h (from an initial 2.238 g/L), as the yeast consumed the LFM. Thereafter, the total sugars concentration commenced to increase until 60 h and then leveled-off to a final concentration of 1.791 g/L at 168 h (Figure 3). The reason for the increase was most likely due to the secretion of EPS, as discussed above. During the 168 h period, there was no increase in the RRS level, indicating that the yeast consumed all RRS. Both yeast enzymes, however, remained remarkably stable over the 168 h fermentation period. Optimization of both enzymes by statistical design when *A. pullulans* 1WA1 was cultivated on fungal mycelium has resulted in specific activities of 5.96 units/mg [β-(1 → 3)-glucanase] and 1.77 units/mg (β-glucosidase) (unpublished results).

Physicochemical Properties of the Crude β-Glucanolytic Enzyme Preparation. Considering that *A. pullulans* 1WA1 produced β-glucanolytic enzymes, it may find application to aid wine maturation to improve the sensorial characteristics of wines. It was therefore of interest to assess whether the β-(1 → 3)-glucanases and β-glucosidases could tolerate and survive under the conditions of winemaking: low pH (3.3−3.7 for table wines) and high ethanol content (9−15% by volume). The crude β-glucanolytic enzyme preparation from *A. pullulans* 1WA1 grown on LFM was examined for its stability at pH 3.5 (0.20 M citrate−phosphate buffer; control) in the presence of 15% (v/v) ethanol at this pH when exposed at ambient temperature for 72 h. The yeast crude enzyme preparation was found to be remarkably stable under this condition. β-(1 → 3)-Glucanase retained ∼80% of its original activity in the presence of 15% ethanol, while β-glucosidase retained full activity under the same conditions. A bacterial β-(1 → 3)-glucanase grown on yeast cell walls as the C source has been found to be stable to 17.5% (v/v) ethanol and was used in vinification.[24] Both β-(1 → 3)-glucanases and β-glucosidases in the crude enzyme preparation from *A. pullulans* 1WA1 were remarkably stable at low pH, high ethanol content, and 30−40 °C, a requirement for functioning during vinification.

The physicochemical properties of the crude β-glucanolytic preparation from *A. pullulans* 1WA1 are summarized in Table 3. The optimum pH and temperature of β-(1 → 3)-glucanase and β-glucosidase was 4.5 and 60 °C and 4.0 and 75 °C, respectively, which agreed with the literature for yeast species.[29,35] High-temperature optima were also reported for the β-glucosidases from a commercial preparation from *Aspergillus niger* (62 °C),[36] and the wine yeast *Debaryomyces vanrijiae* (40 °C).[37] β-(1 → 3)-Glucanase from *A. pullulans* 1WA1 was stable at 30−40 °C for up to 24 h. The apparent K_m of β-(1 → 3)-glucanase and β-glucosidase was evaluated using laminarin and *p*-NPG, respectively, as substrates. The respective apparent K_m values were 0.09 and 0.04 mg/mL, with V_{max} of 1.07 and 0.011 μmol min^{-1} mg^{-1}. The apparent K_m values were relatively low and show that these enzymes have high affinities for their substrates, laminarin and *p*-NPG, respectively. The apparent K_m of a β-(1 → 3)-glucanase from *Pichia pastoris* was reported to be 3.5 mg/mL,[38] while that for β-glucosidase from *P. anomala* was 0.47 mM.[36]

Enzymatic Hydrolysis of β-D-Glucans and β-Glucodisaccharides by the Crude β-Glucanolytic Enzyme Preparation. β-(1 → 3)-Glucanases have been used to obtain laminari-oligosaccharides through the enzymatic hydrolysis of various (1 → 3)-β-D-glucans.[39,40] Gluco-oligosaccharides find commercial applications as prebiotics in formulating physiological functional foods because of their health benefits, including immunostimulation.[41]

Laminarin [algal (1 → 3),(1 → 6)-β-D-glucan], botryosphaeran [fungal (1 → 3),(1 → 6)-β-D-glucan], lasiodiplodan [fungal (1 → 6)-β-D-glucan], pustulan [lichen (1 → 6)-β-D-glucan], and curdlan [bacterial (1 → 3)-β-D-glucan] were hydrolyzed using the crude β-glucanolytic enzyme preparation of *A. pullulans* 1WA1 grown on LFM.

Although laminarin[42] and botryosphaeran[10] are both (1 → 3),(1 → 6)-β-glucans, they possess different degrees of branching, 10 and 22%, respectively, and the nature of the appendages at C-6 along the (1 → 3)-β-D-glucan chain also differs: glucose as compared to glucose and gentiobiose, respectively. Both (1 → 3)-β-D-glucans exist in solution in a triple helix conformation.[43] The crude β-glucanolytic enzyme preparation hydrolyzed the two polysaccharides differently and reflects a difference in the molecular structure between these (1 → 3)-β-D-glucan types (see Supplementary Table 1 of the Supporting Information). At 24 h, laminarin was almost totally hydrolyzed (∼95%), while botryosphaeran was hydrolyzed to the extent of ∼7.6%. HPAEC/PAD analysis of the enzymatic hydrolyzates of the two β-D-glucans revealed an array of gluco-oligosaccharides of the (1 → 3)-β-D-linked kind [degree of polymerization (DP) of 2−4] as well as gentiobiose. Products of DP > 4 were also observed but could not be resolved during the chromatographic run in all of the enzymatic hydrolyzates of the β-glucans examined. At 120 min, laminarin was hydrolyzed to the extent of ∼66% and the enzymatic hydrolyzates contained the following products as percent relative amounts: glucose as the chief product (71%), with lesser amounts of gentiobiose (18.5%), laminaribiose (8.3%), laminaritriose (1.4%), and laminaritetraose (1%). During the same time (120 min), botryosphaeran was poorly hydrolyzed (5.4%) and the product array was somewhat similar to glucose (74.1%), the major hydrolysis product, but gentiobiose was present in lower amounts (7.9%) compared to laminaribiose (15.6%). Laminaritetraose was not detected. The presence of large amounts of

glucose in both hydrolyzates was a consequence of the action of β-glucosidases, which act as accessory enzymes in synergy with the β-(1 → 3)-glucanases in degrading the (1 → 3),(1 → 6)-β-D-glucans into glucose. Similar profiles of hydrolysis products have been observed when crude β-(1 → 3)-glucanase preparations from *T. harzianum* Rifai and *B. rhodina* MAMB-05 degraded laminarin.[41] In contrast, the crude β-(1 → 3)-glucanase preparations of *T. harzianum* Rifai and *B. rhodina* MAMB-05 were reported to degrade botryosphaeran more extensively, ∼100 and ∼50%, respectively, within 24 h.[40]

Lasiodiplodan consists of a non-ramified chain of β-(1 → 6)-linked D-glucose units.[44] Pustulan from lichen is also a linear (1 → 6)-β-D-glucan but contains an *O*-acetyl group at every 8−9 glucose units along the chain.[45] The hydrolysis of the two (1 → 6)-β-D-glucans by the crude β-glucanolytic enzyme preparation from *A. pullulans* 1WA1 resulted in different degrees of hydrolysis. Lasiodiplodan was hydrolyzed to the extent of 20% over 24 h, while that of pustulan resulted in 4.4% hydrolysis within the same time interval (see Supplementary Table 1 of the Supporting Information). Hydrolysis of the (1 → 6)-β-D-glucan chain is only possible through the action of the β-(1 → 6)-glucanases, which were present in the crude enzyme preparation. HPAEC/PAD analysis of 120 min hydrolyzates of lasiodiplodan and pustulan showed that glucose represented 85.6 and 91.8%, respectively, of the total hydrolysis sugars released. Both enzymatic hydrolyzates also revealed the presence of gentiobiose (14.4% from lasiodiplodan and 8.2% from pustulan) as well as gentio-oligosaccharides of DP > 4. The reason why the two (1 → 6)-β-D-glucan preparations from different genetic sources were hydrolyzed differently is not known, but the presence of *O*-acetyl groups along the (1 → 6)-β-D-glucan chain of pustulan may have influenced the mode of enzymatic attack. The crude β-glucanolytic enzyme preparation from *Acremonium persicinum* was also reported to degrade pustulan to very small extents.[46]

Curdlan, an unbranched, linear bacterial (1 → 3)-linked β-D-glucan,[47] was hydrolyzed by the crude β-glucanolytic enzyme preparation to the extent of ∼40% within 24 h (see Supplementary Table 1 of the Supporting Information). HPAEC/PAD analysis of 120 min hydrolyzates of curdlan revealed that 68% of the liberated products were glucose, together with laminaribiose (20%) and laminaritriose (11.6%). Laminaritetraose was not detected. A crude β-(1 → 3)-glucanase preparation from *T. harzianum* was reported to hydrolyze curdlan and resulted in 80% saccharification,[48] while β-(1 → 3)-glucanases from *Streptomyces* sp. selectively hydrolyzed curdlan to laminaribiose.[49]

Table 4 shows that non-specific β-glucosidase activity was observed in the crude β-glucanolytic enzyme preparation from *A. pullulans* 1WA1, with preference for the disaccharides, cellobiose and laminaribiose. The specificities of the β-glucosidases present in the crude β-glucanolytic enzyme preparations from the three microorganisms examined varied considerably (Table 4). The β-glucosidases from *B. rhodina* MAMB-05 showed the highest preference toward laminaribiose and lower preferences for cellobiose and gentiobiose, whereas the crude enzyme showed equal preference for (1 → 4)- and (1 → 3)-β-D-glucosidic linkages. In contrast, the β-glucosidase from *T. harzianum* Rifai showed low preference for all three D-glucosidic linkages (Table 4). The crude β-glucanolytic enzyme preparations from *B. rhodina* MAMB-05 and *T. harzianum* Rifai grown on botryosphaeran were reported to have similar preferences for cellobiose and gentiobiose.[18]

Table 4. Comparison of the Specificities of β-Glucosidases from the Crude β-Glucanolytic Enzyme Preparations of *A. pullulans* 1WA1, *T. harzianum* Rifai, and *B. rhodina* MAMB-05 toward Different Gluco-disaccharides

[b]Cellobiose, β-D-glucopyranosyl-(1 → 4)-β-D-glucopyranose; gentiobiose, β-D-glucopyranosyl-(1 → 6)-β-D-glucopyranose; and laminaribiose, β-D-glucopyranosyl-(1 → 3)-β-D-glucopyranose. [c]*B. rhodina* MAMB-05 and *T. harzianum* Rifai were grown on nutrient medium containing botryosphaeran as the sole C source.[18]

In summary, 95 yeast strains were isolated from the microbiota of nine grape varieties taken from vineyards in Brazil. The yeast isolates were screened for β-(1 → 3)-glucanase activity by SmF and a novel zymogram procedure when cultivated on botryosphaeran. Among the 14 β-(1 → 3)-glucanase-positive yeasts isolated, yeast strain 1WA1 (identified as *A. pullulans*) produced the highest β-glucanolytic activities. The crude enzyme preparation was used to hydrolyze several β-D-glucans. These enzymes find application in wine oenology, food and beverage processing, and the production of (1 → 3)- and (1 → 6)-linked β-gluco-oligosaccharides for use as prebiotics.

Supporting Information

ABSTRACT: This study describes the approach of amino acid and monosaccharide combined with Hotelling T2 range plot to identify edible bird nests (EBN) and non-EBN. Prior to the approach, an analytical method was developed and validated to quantify monosaccharides in EBN. Hotelling T2 range plots of both compounds were successful in predicting the different types of EBN and differentiating EBN and non-EBN. This outcome suggests EBN contains a group of glycoproteins which is not affected by the EBN's coloration, country of origin, and/or the processing method of the food item. In addition, the glycoproteins were shown to be unique to EBN. EBN were revealed to be rich in protein and essential amino acids as well as contain a wider variety of monosaccharides than most food items. The overall findings suggest that amino acid and monosaccharide provide information not only on the detected compounds and also insights into the glycoproteins of EBN.

KEYWORDS: *edible bird's nest, amino acid, monosaccharide, Hotelling T2 range plot*

INTRODUCTION

Edible bird's nests (EBN) are known to be a invaluable food made from the salivary secretion of the *Aerodramus* genus (commonly known as swiftlets) located mainly in the South East Asian countries or regions within this geographical range.[1] It is a highly esteemed food item, especially among the Chinese, as it has been shown to have an inhibitory effect toward the flu virus and helps maintain a youthful, radiant complexion.[3] These therapeutic effects are due to the sialyl-sugar chains and epidermal growth factor in EBN, respectively.[5,6] In spite of the long history of EBN consumption dating back to 618 AD, the first scientific study on EBN was conducted only in the early 20th century to determine the proximate protein and carbohydrate content.[7] It was revealed that the largest compositional fraction of EBN is protein followed by carbohydrate. As such, many new analytical methods have been developed, especially in the past decade, to understand the characteristic structure of the protein and carbohydrate in EBN. These analytical methods can be divided into 2 categories: molecular biological methods and chemical methods.

Molecular biological based methods, such as electrophoresis, are some of the earliest methods used to study the major biological macromolecule in EBN, protein. In the study by Roussel et al., it was demonstrated that electrophoresis was capable of isolating the proteins in EBN.[7] In addition, the authors further deduced that the proteins were rich in serine, threonine, and proline. This study laid the foundation for future work on EBN's protein. Recently, Yang et al. demonstrated the use of SDS-PAGE to isolate two major protein molecules in EBN (106 kDa and 128 kDa).[11] They also performed a detailed analysis on the proteomic profile of EBN using two-dimensional electrophoresis.[2] Though the use of molecular biology based methods in isolating distinguishing and quantifying protein molecules in EBN is achievable, the protein molecules must still be intact, which is often not feasible in the case of a heavily processed food item like EBN.

Chemical methods used for characterization of EBN are generally based on chromatographic techniques such as gas chromatography (GC) and liquid chromatography (LC) coupled to different types of detectors. The applications of the GC and LC based analytical platforms have been reported in several research studies to be able to determine structure of the glycans and also a diverse class of compounds such as amino acids, monosaccharides, fatty acids, and hormones in EBN.[8−13] While the use of chemical analytical methods is a useful tool in identifying EBN, the major problem of employing these methods lies in the inadequate number of samples to represent the entire spectrum of EBN. In view of the limitations and drawbacks on current studies, it is important to develop a new approach to identify EBN and non-EBN.

Amino acid and monosaccharide are promising candidates for the identification of EBN as they are the monomeric constituents of protein and carbohydrate in EBN.[18,19] Although determination of both amino acids and monosaccharides is a relatively complex process, amino acids and monosaccharides are preferred over their polymers.[23] This is because EBN is a food item that is cleaned by soaking it in water and drying under high temperature for a long period of time.[8] These cleaning processes are likely to trigger the denaturation and breakdown of the polymers, protein and carbohydrate, which would cause inaccuracy in quantification of the polymers. On

the other hand, amino acid and monosaccharide are relatively stable even when the samples are soaked in water and/or subjected to heat.[24,25] Additional information on the type of protein and carbohydrate could also be provided by the analysis of amino acid and monosaccharide. Hence, amino acid and monosaccharide analysis are selected for this study.

The aim of this study is to demonstrate the potential of amino acid and monosaccharide analysis, combined with Hotelling T2 range plot, to identify EBN and non-EBN. Hotelling T2 range plot is a chemometrics plot which reduces the amino acids and monosaccharides into a T2 value. This plot simplifies the data analysis process and, more importantly, combines multiple variables to create a unique fingerprint for the sample. Its application is often found in quality control of products.[20−22] In this study, Hotelling T2 range plot is used to determine whether the sample is an EBN by comparing the T2 value against the T2 critical value, corresponding to 95% confidence interval. The practical applicability of the plot was evaluated with different types of EBN and samples suspected to possess a similar matrix to EBN (non-EBN). Furthermore, EBN will be compared with other food items rich in protein and/carbohydrate to assess the nutrition value of the former. This comprehensive study will, we hope, be able to not only create a new approach in identifying EBN, but also offer insightful information on the monomers (amino acid and monosaccharide) and polymers (protein and carbohydrate) of EBN.

MATERIALS AND METHODS

Information on the Samples and Chemical Reagents. All EBNs used in this Article had been processed by soaking, physical removal of birds' feathers and drying prior to the analysis. The EBN samples are labeled by a number to represent the biological replicate followed by a letter to indicate the different technical replicate in Supporting Information Table 1 (e.g., EBN 1A). The non-EBN samples, cow's milk, chicken egg yolk, chicken egg white, quail egg yolk, and quail egg white, were obtained from the local retailers. The rest of the non-EBN samples (fetuin, infant formula, and human saliva) were obtained from various sources. Fetuin from fetal bovine serum was purchased from Sigma-Aldrich (St Louis, MO) while the standard reference material infant formula, T2562, was purchased from FAPAS. The human saliva was obtained from a male human volunteer. Amino acid standards and the amino acid derivatization kit (EZ: faast GC-FID amino acid analysis kit) were purchased from Phenomenex. The standard used consists of the following 17 amino acids: alanine (1), glycine (2), valine (3), leucine (4), isoleucine (5), threonine (6), serine (7), proline (8), aspartic acid (9), methionine (10), 4-hydroxyproline (11), glutamic acid (12), phenylalanine (13), lysine (14), hydroxylysine (15), tyrosine (16), and cystine (17). The internal standard for amino acid analysis is norvaline. The chemicals 1-phenyl-3-methyl-5-pyrazolone (PMP) and trifluoroacetic acid were obtained from Aldrich (St. Louis, MO). The 7 monosaccharides, mannose (1), glucose (2), galactose (3), rhamnose (4), fucose (5), ribose (6), and xylose (7), used in the standards were purchased from Sigma-Aldrich (St. Louis, MO). The internal standard (D-glucose-$^{13}C_6$) was purchased from Cambridge Isotope Laboratories. All the other reagents utilized were of analytical grade.

Amino Acid Analysis. EBN (0.2 g) was hydrolyzed with concentrated HCl (6 N) for 24 h. The hydrolyzed sample was filtered and dried using a rotary evaporator. The dried extract was reconstituted with 10 mL of hydrochloric acid (0.1 N) The reconstituted sample was further diluted 20 times prior to mixing 100 μL of the diluted solution with 100 μL of internal standard. A 1.5 mL syringe with a sorbent tip was then immersed into the mixture solution, and the mixture solution was drawn up the sorbent tip. Next, 200 μL of deionized water was added and was drawn up the sorbent tip. Subsequently, the 1.5 mL syringe was replaced with a 0.6 mL syringe. A mixture solution of sodium hydroxide and n-propanol, consisting of 1 portion of n-propanol to 1.5 portion of sodium hydroxide, was prepared. A 200 μL portion of the mixture solution of sodium hydroxide and n-propanol was pipetted into the sample preparation vial. The mixture solution was drawn up the 0.6 mL syringe, and all the liquid and sorbent particles were ejected into the sample preparation vial. Next, 50 μL of the derivatizing agent was added to the mixture followed by 100 μL of iso-octane and then 100 μL of hydrochloric acid solution. The mixture was vortexed for 0.5 min after each chemical reagent was added into the preparation vial. The emulsion was allowed to stand for 1 min so that two distinct layers would appear. The upper layer is then transfer into a 1 mL vial for the analysis with a Hewlett-Packard 6890 Series GC system coupled to an Aligent Technologies 7683 series injector and flame ionization detector (FID). The Zebron ZBAAA (10 m × 0.25 mm capillary GC column) was used for the GC separation. The carrier gas (helium) had a flow rate of 1.5 mL/min. The column oven temperature was programmed to start at 110 °C and to increase at 32 °C per min to 320 °C. The FID detector temperature was set at 320 °C. A 2 μL portion was injected by an autosampler at an injection temperature of 250 °C and a split level of 1:2. The software Chemstation was used to analyze the results.

Monosaccharides Analysis. A 2 μg portion of EBN was hydrolyzed in 2.0 mL of trifluoroacetic acid (2 M) at 120 °C for 4 h. After that, the hydrolyzed solution was cooled to room temperature prior to filtration into a round-bottom flask with a 0.45 μm PTFE filter. Next, the hydrolyzed solution was evaporated to dryness, and the dried extract was reconstituted with 3 mL of water. Two solutions, 0.75 M of PMP dissolved in methanol and 50:50, v/v ammonium hydroxide/deionized water, were prepared for the derivatization reaction. A 750 μL portion of PMP solution, 450 μL of ammonia hydroxide, and 10 μL of the internal standard (100 mg/L) were added to 150 μL of the reconstituted monosaccharide solution. The mixture solution was then vortexed and incubated in a heating block at 70 °C for 2 h to permit derivatization to occur. Then, the mixture solution was evaporated to dryness using a gentle stream of nitrogen gas. Finally, the mixture solution was reconstituted with 150 μL of ACN and 850 μL of water prior to sending it to an Agilent 1100 LC system coupled to an API 3000 Q-Trap liquid chromatography tandem mass spectrometer (LC/MSMS) with Turbolon Spray source (Applied Biosystems, Foster City, CA) for analysis. The analytical column Inertsil HPLC column (ODS-3, 3 μm particle size, 3 mm i.d. × 100 mm) produced by G.L. Sciences, Tokyo, Japan, was used for the separation of the monosaccharides. The injection volume was 10 μL. Elution was carried out with a flow rate of 0.35 mL/min at 25 °C. The mobile phase consisted of 100 mM ammonia acetate (pH 6.9) with (A) 0% of acetonitrile and (B) 60% acetonitrile. The condition of the mobile phase is follows: 30−35% B (0.0−25.0 min), isocratic at 35% B (25.0−30.0 min), 35−55% B (30.0−50.0 min), 55−30% B (50.0−50.1 min), isocratic at 30% B (50.1−55.0 min). The mass spectrometer (MS) was equipped with an electrospray ionization interface operating in the positive mode. The MS parameters are stated in Supporting Information Table 2. The software Analyst Software 1.4.2 was utilized to analyze the results obtained from the samples.

Statistical Analysis. The normalized data from both analyses were exported to SIMCAP+ software package version 13 (Umetrics, Umea, Sweden) for chemometrics analysis. Significance calculation was based on a two-tailed Student's t test performed with Microsoft Excel software (Microsoft Corporation). Compounds with $p > 0.05$ are considered to have no significant difference. The data was divided into model set and prediction set. The model set comprises genuine EBNs, and it is used to establish the Hotelling T2 range plot. EBN for the model set were collected at random by the authors from an EBN farm located in Johor Bahru, Malaysia, to ensure the integrity and quality of the food item from farm to fork. In the model set, each EBN has three technical replicates to factor in the variation of the analytical method. The prediction set consists of EBNs to account for variation in color and country origin of the food item. Each EBN is also analyzed three times in the prediction set. The prediction set is utilized to determine

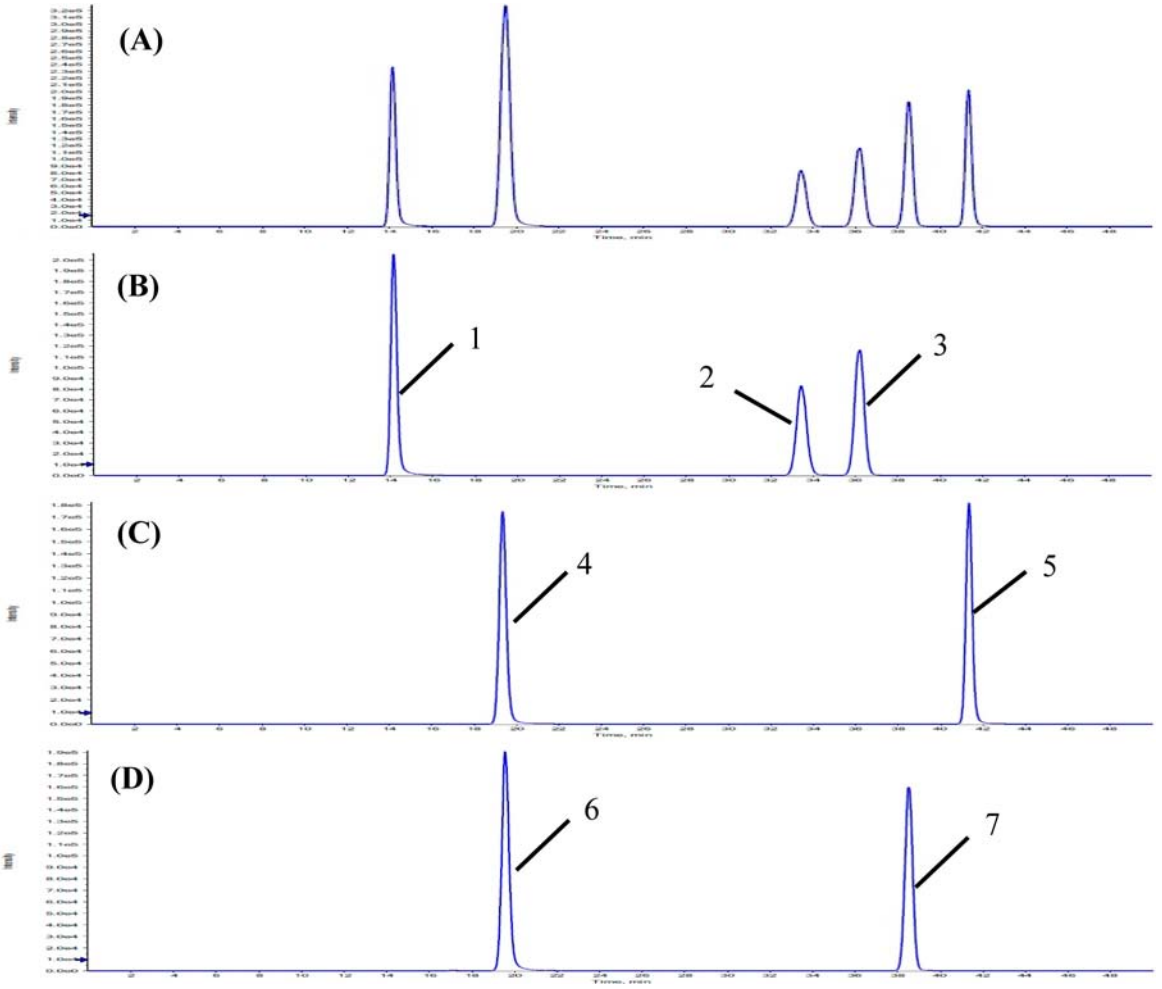

Figure 1. Chromatograms of a 10 000 ppm monosaccharide standard. (A) Total ion chromatogram. (B) Extracted ion chromatogram for mannose, glucose, and galactose (m/z 511.4 → 175.1). the optimal scaling method and to serve as an independent group of EBN for validation.

RESULTS AND DISCUSSION

Development and Validation of an Analytical Method for the Monosaccharide Analysis of EBNs. In this study, the amino acid and monosaccharide content of EBN was analyzed. The analytical method used to determine amino acids is a well-established one. It has been demonstrated by Ruiz et al. that the accurate quantification of amino acids could be performed within a short analysis time of 10 min with GC-FID.[29] Hence, this analytical method was employed in the study for the quantification of the amino acid content in EBN. On the other hand, the analysis of monosaccharides is not as straightforward. Studies have revealed that the monosaccharides originated mainly from the glycans of EBNs.[12,30] As such, it is expected that the monosaccharides' concentration may differ by a few orders of magnitude due to the minute presence of some monosaccharides in the glycans.[31] Thus, the analytical method employed to analyze the monosaccharides requires a large dynamic range to take into account this fact. However, at the moment, most analytical methods do not possess the required dynamic range to quantify the monosaccharides in EBN.[32] In addition, low resolution and long analysis time often hinder the accuracy and efficiency of the available analytical methods.[33] Hence, a new analytical method would have to be developed and validated.

Acid hydrolysis is performed to release the monosaccharides in this study. This is an indiscriminating method which implies that monosaccharides would be released from all the oligosaccharides and/or polysaccharides in EBN.[34] Hence, besides the quantification of common neutral monosaccharides in glycans, mannose, glucose, galactose, fucose, and xylose, it is also important to include monosaccharides like rhamnose and ribose as they exhibit a high possibility to be in polysaccharide.[35] After the liberation of monosaccharides, LC/MSMS in MRM mode was utilized to analyze the monosaccharides. This is because the analytical platform is able to make use of the advantages provided by both the gradient flow of the mobile phase and the MRM mode to improve the resolution and sensitivity of the analysis.

However, it has reported that MS detection would not be able to achieve the dynamic range for monosaccharide analysis as monosaccharides have poor MS/MS fragmentation.[36] Thus, a derivatization step is incorporated into the analytical method. The derivatizing agent chosen was PMP because the monosaccharide PMP derivative possesses excellent fragmentation efficiency for MS detection.[37] In addition, the derivatiza-

dx.doi.org/10.1021/jf503157n | J. Agric. Food Chem. 2015, 63, 279−289

tion reaction could be conducted under mild conditions, and no isomerization of the derivatized monosaccharides would occur.[38] Referring to Figure 1, it is observed that chromatographic separation of mannose, glucose and galactose, rhamnose and fucose, ribose and xylose was achieved with the gradient flow of the mobile phase while coeluting monosaccharides are differentiated with the MRM mode.

The optimized analytical method was also applied onto monosaccharide standards with concentration range 50−10 000 ppb. The linearity of all 7 monosaccharides was evaluated by inspecting the peak area as a function of concentration. Excellent correlation coefficients (>0.99) were obtained from the calibration curves of the monosaccharaides. The retention time, limits of detection (LODs), and limits of quantification (LOQs) were tabulated in Table 1. The LODs and LOQs are observed to be lower than the reported literature values.[37] Moreover, the small fluctuation in retention times and high correlation coefficient provided confidence for the quantification of the 7 monosaccharides using the developed analytical method.

Table 1. Retention Time, Linearity, LOQ, and LOD for Seven Monosaccharides (n = 6)

compd name	equation	linearity	LOQ (ppb)	LOD (ppb)
mannose	$y = 2.30x - 0.0634$	1.000	10	5
glucose	$y = 1.35x + 0.0033$	0.990	20	10
galactose	$y = 0.25x + 0.0011$	1.000	20	10
rhamnose	$y = 2.19x - 0.0696$	0.990	10	5
fucose	$y = 2.07x + 0.0180$	1.000	10	5
ribose	$y = 2.47x - 0.0474$	1.000	10	5
xylose	$y = 2.20x + 0.015$	1.000	10	5

The reference material, fetuin, was used to validate the monosaccharide analysis. Fetuin was utilized because similarly to EBN, it is a matrix rich in glycoproteins.[39] Besides, fetuin is a well-established glycoprotein that has been used in the validation of analytical methods involved in the quantification of monosaccharides from carbohydrate.[33] An intra- and interday study was conducted on the reference material. Results of the validation were in good agreement with the stated literature range of the reference material (Table 2).[25,33,40,41] Excellent RSDs for the monosaccharides were achieved utilizing the analytical method (RSD < 5%). Interestingly, several monosaccharides like glucose, rhamnose, and xylose were noted to be present in the fetuin even though they are not part of the glycoprotein in fetuin. This is possibly due to monosaccharides attaching to the glycoprotein through glycation.[40]

Although the amino acid analysis has been established, an intra- and interday study was conducted with infant formula to verify the accuracy and precision of the analytical method. The results were in agreement with the state values of the reference material and the RSDs were below 6% (Supporting Information Table 3).

Establishing the Hotelling T2 Range Plot To Identify EBN. The amino acid and monosaccharide chromatograms representing the EBN were illustrated in Figure 2. Visual inspection of the amino acid chromatograms reveals that 17 amino acids were detected in the EBN. It was noted that several amino acids such as tryptophan, asparagine, and glutamine are not detected in EBN. This is due to the utilization of acid hydrolysis to liberate the amino acids before the chromatographic analysis. This approach would result in the hydrolysis of tryptophan and the deamidation of asparagine and glutamine into aspartic acid and glutamic acid, respectively.[42] It was also observed from the amino acid chromatogram that there are no obvious differences between the EBNs from the model and prediction set. On the other hand, 7 monosaccharides were detected in EBN, and there was no clear distinction between the EBNs from the model and prediction set. This provides the confidence that it is viable to establish a Hotelling T2 range plot with both types of analysis to identify EBN.

Amino acids and monosaccharides have been used in the past to differentiate food items that are suspected to have a similar matrix.[43,44] Such studies rely on the fact that the polymers of amino acids and monosaccharides, protein and carbohydrate, would exhibit variation if they are produced from different species. However, in this study, the authors utilized a different approach: the homogeneity of amino acids and monosaccharides. EBN is a food item that is known to be produced by *Aerodramus* genus. Thus, EBNs are expected to exhibit a homogeneous amino acid and monosaccharide signature as they originate from the same species.

In this study, the data from amino acid and monosaccharide analysis was combined with PCA to identify the EBN. PCA is known to be capable of reducing the complex data from individual amino acid and monosaccharide chromatogram into a single score on the score plot. The scores are then utilized to deduce the confidence region known as Hotelling T2 ellipse. Studies have shown that the scaling method has a direct impact on the prediction ability of the score plot as it changes the weights of the variables. As such, three different scaling methods, uv scaling, par scaling, and no scaling, were performed to determine the ideal scaling method to be employed to identify EBN. The PCA score plots for the different scaling methods are displayed in Supporting Information Figures 1 and 2. It was observed that no score was found located beyond the

Hotelling T2 ellipse, at 95% confidence level. In addition, the PCA score plots exhibited satisfactory goodness of fit (R^2) and goodness of prediction (Q^2) that were generally greater than the level of 0.5 (Table 3).

The Hotelling T2 range plots of the respective PCA score plots were plotted to visualize the graphical display in their numerical form. It was evident from the T2 range plots that none of samples from the model set has a T2 range value greater than the T2 critical value (Table 3). Thus, the prediction set would be used to evaluate the different scaled score plots. The result from the amino acid data shows that application of uv scaling (Figure 3A) would result in a Hotelling T2 range plot that could accurately predict all the EBN while par and no scaling would create score plots with low prediction ability (Table 3). Similarly, the score plots based on the monosaccharide data also demonstrated that uv scaling is the ideal scaling method (Figure 3B). Uv scaling involves the division of each variable by its standard deviation. Upon scaling, the variables would have the same weight, thus preventing the dominance of variables with high fluctuations.[47] This indicates that the Hotelling T2 range plots from both data sets have to be unbiased to all the input variables to be able to predict EBN.

The amino acid and monosaccharide content of EBN could be significantly affected by the difference in EBN: coloration, country of origin, and/or type of cleaning method applied to the EBN.[48] Thus, the optimized Hotelling T2 range plots from both data sets were used to perform a study on the different types of EBN. The prediction ability results in Table 3 show that different types of EBN could be accurately predicted by the plots from both data sets, thereby pointing out the feasibility of identifying EBN with amino acid and monosaccharide combined with Hotelling T2 range plot. The success of predicting the different types of EBN also demonstrated that amino acid and monosaccharide content is not significantly

affected by variation in the coloration, country of origin, and/or type of cleaning method applied to the food item.

Recently, several research studies have demonstrated the existence of common glycoproteins among the EBN with different coloration or country of origin.[3,2] Thus, since the amino acid and monosaccharide originated mainly from the protein and carbohydrate portion of EBN, the similarity in amino acid and monosaccharide could be attributed to the glycoproteins in EBN. In addition, it is suggested the quantity of these glycoproteins is not significantly affected by factors such as coloration, country of origin, and/or type of cleaning method applied to the EBN.

Evaluation of Hotelling T2 Range Plot with Non-EBN. The Hotelling T2 range plots from the amino acid and monosaccharide data were established with 17 amino acids and 7 monosaccharides, respectively. These amino acids and monosaccharides are known to be common building blocks for protein and carbohydrate. As such, it is possible that there are samples which contain similar amino acid and monosaccharide content as EBN. Thus, non-EBN samples are utilized to determine the differentiating capabilities of the Hotelling T2 range plots. These samples were selected because they are known to contain a high quantity of amino acid and monosaccharide or they were being produced in a similar manner as EBN.[43,49,50]

From the examination of the Hotelling T2 range plot in Figure 4, it was observed that the T2 range values for all the non-EBN samples were larger than the T2 critical value for both amino acid and monosaccharide data, thereby affirming that the Hotelling T2 range plot from both data sets are objective parameters to identify EBN and non-EBN. Furthermore, the result suggests that the common glycoproteins in EBN do not exist in non-EBN.

Contribution plot is also applied to visualize the variable contribution difference between EBN and non-EBN.[51] On the basis of the contribution plots on both the amino acid and monosaccharide data, it was observed that the non-EBN would contain several variables which were clearly separated from EBN (Supporting Information Figures 3 and 4). Another interesting observation was that samples such as egg yolk and egg white from chicken and quail exhibited a similar variable profile for their respective data sets. This is not unexpected because these samples are similar products, originating from avian (Supporting Information Figures 3 and 4). However, in the case of milk and infant formula, both originating from cows, the contribution plots for the amino acid data illustrated a dissimilar profile while the opposite is exhibited in the plots based on monosaccharides (Figure 5). This could be attributed to the fact that infant formula is often enriched with amino acids to meet the needs of infant development.[4] Hence, the contribution plot reaffirms that only samples with a similar amino acid or monosaccharide content as EBN could be identified with the Hotelling T2 range plots.

Application of monosaccharide analysis to identify EBN has been reported. In these cases, identification of EBN is based on one or two monosaccharides.[9,45] Such an approach may lead to misinterpretation of samples with a similar matrix as EBN, since monosaccharides are commonly found in animals and plants.

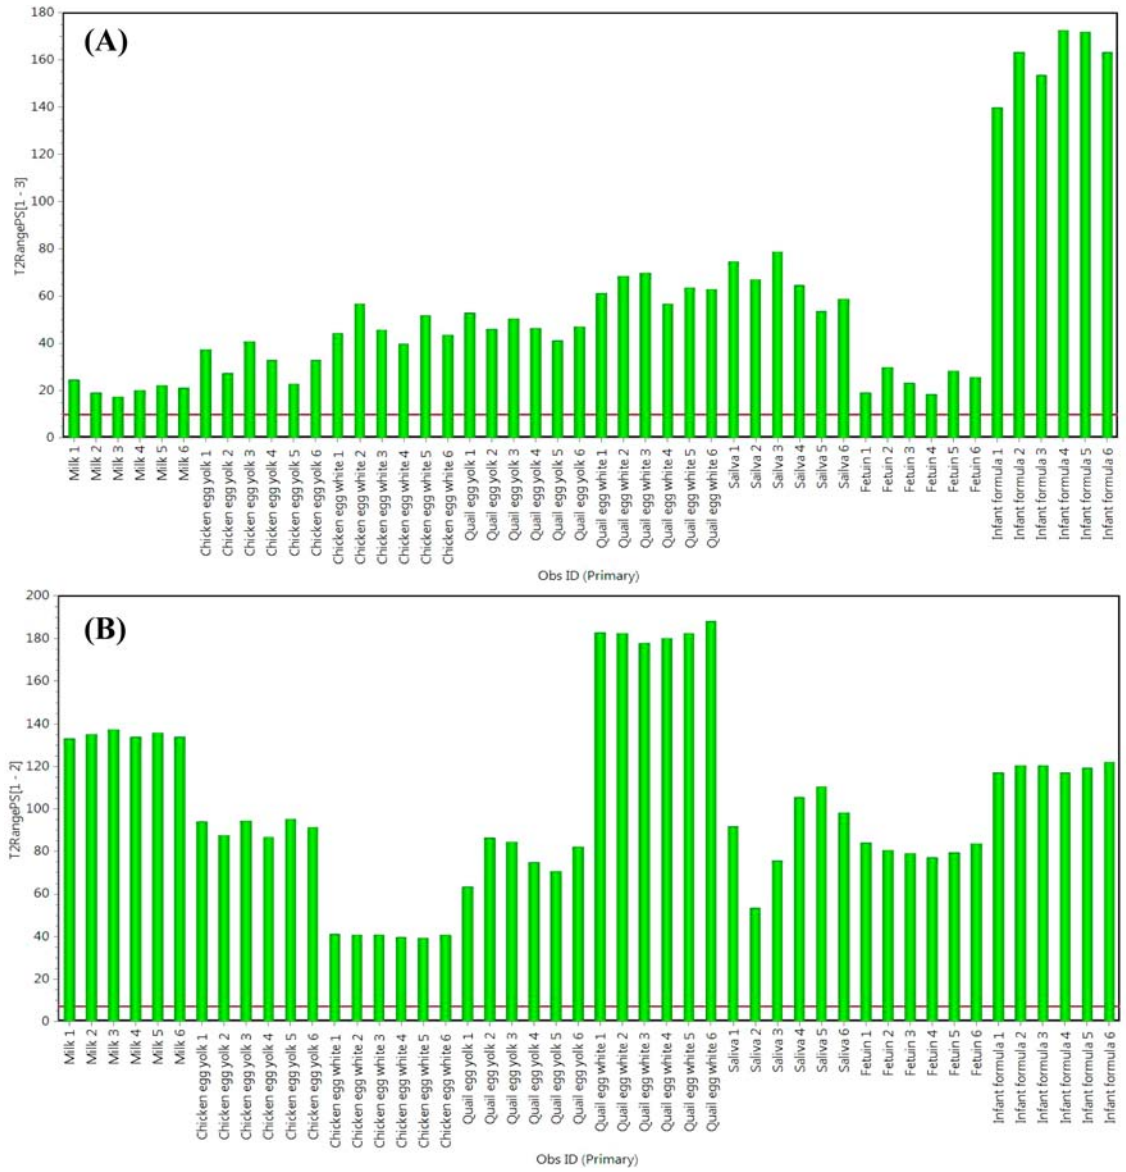

Figure 4. T2 range value of non-EBN from (A) amino acid data and (B) monosaccharide data.

Thus, in this study, identification of EBN is based on T2 range value. This would greatly increase the confidence level of the results as T2 range value is formulated from 7 monosaccharides.

In a comparison of the two types of analyses employed in this study, the amino acid analysis uses GC-FID while the monosaccharide analysis makes use of the LC/MSMS. Despite a difference in the type and monetary value of the analytical instruments utilized, both types of analyses were able to produce reliable results. The sample preparation in the amino acid analysis involves an extraction method taking up to 24 h and a number of steps to derivatize the amino acids. On the other hand, the monosaccharides are liberated using a hydrolysis method within 4 h and then derivatized using a one-step procedure prior to analyzing with LC/MSMS. This greatly reduces the complexity of the monosaccharide analysis. However, the analysis time taken to achieve chromatographic separation in the monosaccharide analysis was much longer than the amino acid analysis, which in turn leads to a lower throughput. As there is no single analysis method deemed to be more favorable than the other, the type of analysis method selected ultimately depends on the availability of the chemicals and machines, as both types of analysis are capable of producing Hotelling T2 range plots that are able to identify EBN and non-EBN.

Assessment of Amino Acid and Monosaccharide Content of EBN. In terms of the amino acid, aspartic acid, proline, and threonine were observed to have the highest concentration in EBN (Table 4). This result is in line with the findings published by Theng et al., and thus increases the reliability of the results on amino acids.[52] Aspartic acid (representing aspartic acid and asparagine) and proline are classified to be nonessential amino acids, implying that they could be synthesized by the human body. On the other hand, threonine is noted to be an essential amino acid (EAA); thus, the only way for humans to obtain this amino acid is through the consumption of food containing the amino acid. EAAs are vital to the well-being of human's health as EAAs are the precursors for protein synthesis and they are required as intermediates in various pathways of metabolism.[53] In fact, due

dx.doi.org/10.1021/jf503157n | J. Agric. Food Chem. 2015, 63, 279−289

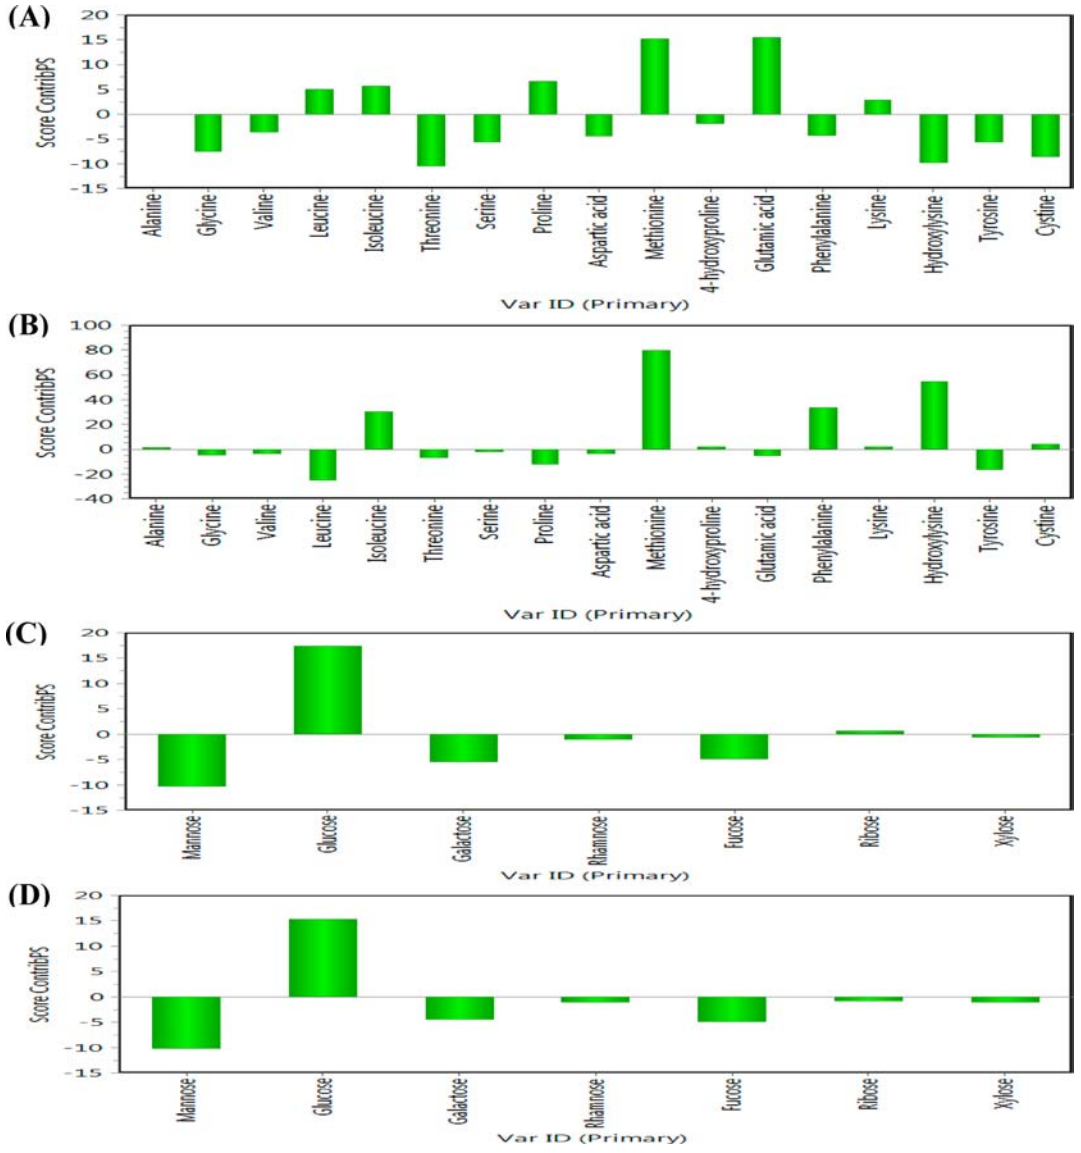

Figure 5. Contribution plots of milk and infant formula: (A) milk and (B) infant formula from amino acid data; (C) milk and (D) infant formula from monosaccharide data.

to the importance of EAA, the World Health Organization, Food and Agriculture Organization of the United Nations, and the United Nations University have set a recommended daily amount for EAAs.[15] The tabulation of amino acids also indicated the presence of two nonproteinogenic amino acids, namely, 4-hydroxyproline and hydroxylsine in EBN. These two amino acids are often used as indicators for the existence of collagen. Thus, it is proposed that the EBN contains collagen.[54,55]

The nutritional value of EBN was also assessed by comparing EBN with protein- and/or carbohydrate-rich food items such as milk, chicken egg yolk, chicken egg white, quail's egg yolk, quail's egg white, and infant formula (Table 4). Generally, the amino acid contents of all the amino acids are higher concentration in EBN than the rest of the food items with the exception of methionine in infant formula, thus illustrating that EBN is a better provider of amino acids than the protein rich food items. The total amino acid content was found to be larger in EBN. This indicates that protein constitutes a larger compositional fraction in the EBN matrix relative to the protein rich food items. EBN is also more enriched in EAAs than the protein and/or carbohydrate rich food items. Studies have shown that a higher EAA content would provide more building blocks for protein synthesis as well as increase the rate of the protein synthetic pathway.[51] As such, apart from the epidermal growth factor in EBN, the high EAA content is suggested to support the growth effects caused by the consumption of EBN.[6]

In the case for the monosaccharide data, the most prominent monosaccharide in EBN is galactose (111.85 μg/g of sample), which is likely to be derived from the glycans in EBN (Table 5). This deduction was made as several studies pointed out that galactose is the major neutral monosaccharide in the glycans of EBN.[13,9] Besides galactose, mannose, glucose, rhamnose fucose, and xylose were suggested to be derived from glycans as well. Ribose is the only monosaccharide that has not been demonstrated to be present in the glycans of EBN.[52] Its presence is most probably due to the DNA in EBN. It was noted from Table 4 that the monosaccharides have a much larger variation as compared to the amino acids; RSD of monosaccharide ranges from about 50% to 90% while it is less

than 20% in amino acids (Table 5). As mentioned earlier, monosaccharides are derived generally from the glycans. Glycans are linear or branched monosaccharide structures protruding out from the protein molecule. Thus, glycans might have been lost due to degradation during the cleaning process of EBN. In addition, Li et al. has demonstrated that proteoglycans of EBN could be extracted with water.[31] This implies that the loss of proteoglycans during the cleaning process of EBN could also have contributed to the larger RSD values in the monosaccharides.

Comparing the monosaccharides of EBN and the different types of food items, all 7 monosaccharides were detected in EBN while only certain monosaccharides were present in the rest of the food items (Table 5). This diversified monosaccharide profile in EBN could be attributed to the glycans detected in the food item mentioned previously. EBN has a significantly lower concentration of glucose than milk and infant formula. This is because both milk and infant formula contain a large amount of lactose.[49] This reasoning is further supported by the ratio of glucose and galactose in milk and infant formula, approximately 1:1 which coincides with lactose. Besides milk and infant formula, the glucose concentration in EBN is also found to be significantly lower than in chicken and quail egg white. Egg white of chicken and quail are known to be the source of energy for the avian embryonic growth.[53] As such, it was not surprising that the concentration of glucose is elevated in the chicken and quail egg white. Although the concentration of individual monosaccharide varies between the different types of samples, EBN generally has a higher overall monosaccharide content, with the exception of infant formula. This could be due to the presence of a rich lactose content in infant formula to satisfy the nutritional and energy requirements for infant growth.[54,55]

Influence of Geosmin-Producing *Streptomyces* on the Growth and Volatile Metabolites of Yeasts during Chinese Liquor Fermentation

Hai Du, Hu Lu, and Yan Xu*

Synergetic Innovation Center of Food Safety and Nutrition, State Key Laboratory of Food Science and Technology, Key Laboratory of Industrial Biotechnology of Ministry of Education, School of Biotechnology, Jiangnan University, 1800 Lihu Avenue, Wuxi, Jiangsu 214122, People's Republic of China

ABSTRACT: Diverse *Streptomyces* species act as geosmin producers in the Chinese liquor-making process, causing an earthy, off-odor containment. Through microbiological and metabolite analyses, this paper investigates the influence of several geosmin-producing *Streptomyces* on the microbial community of a brewing system. The antifungal activity against functional liquor-brewing microbes was assayed by an agar diffusion method. Several *Streptomyces*, most notably *Streptomyces sampsonii* QC-2, inhibited the growth of the brewing functional yeasts and molds in pure culture. In a simulated coculture, *Streptomyces* spp. reduced the flavor compounds (alcohols and esters) contributed by yeasts. Nine components in *Streptomyces sampsonii* QC-2 broth were detected by ultraperformance liquid chromatography coupled with photo diode array (UPLC−PDA), with characteristic ultraviolet absorptions at 360, 380, and 400 nm. The main products of *Streptomyces sampsonii* QC-2 were identified by ultraperformance liquid chromatography−quadrupole time-of-flight mass spectrometry (UPLC/Q-TOF−MS/MS), and confirmed by standard mass spectrometry. The antifungal active components were revealed as a series of heptaene macrolide antibiotics.

KEYWORDS: *Streptomyces, geosmin, antifungal activity, heptaene macrolide antibiotics, Chinese liquor*

INTRODUCTION

Chinese liquor is fermented from grains (rice, sticky rice, sorghum, wheat, and corn) in multistrain solid-state culture. Liquor fermentation spontaneously occurs in pottery vats or mud pits over several months. The microbial counts and metabolite concentrations in heterogeneous natural liquor fermentations are widely variable, affecting the flavor and composition of Chinese liquor.[1] Successful Chinese liquor fermentation requires a succession of particular microbial activities. The main microbial source in Chinese liquor making is the fermentation starter *Daqu*, which provides nutrients for microbes that produce an array of enzymes with various biochemical properties. Therefore, the fermentation activities of yeasts, bacteria and filamentous fungi in *Daqu* largely determine the typical characteristics of the resulting fermented brans and fresh liquor.[2−5]

The *Daqu* fungi, including molds and yeasts, play an important role in the saccharification and alcoholic fermentation of Chinese liquor. Molds appear to influence the evolution of flavors and the activities of enzymes such as amylases and proteinases,[5,6] which are required for alcoholic fermentation of cooked sorghum. The predominant *Daqu* yeasts have been reported as *Saccharomyces cerevisiae*, *Pichia anomala*, and *Saccharomycopsis fibuligera*, which constitute the functional microbes in other fermented alcoholic beverages. *S. cerevisiae* and *P. anomala* mainly contribute flower-like and fruit-like volatile compounds, such as alcohols and esters, to the liquor flavor.[1,7] *S. fibuligera* secretes high-activity α-amylase and glucoamylase that can degrade raw starch.[8] Culture-independent methods have also identified non-*Saccharomyces* species (*Issatchenkia orientalis*, *Hanseniaspora guilliermondii*, and *Debaryomyces hansenii*),[5] which may potentially improve flavor diversity and reduce the alcohol content.[9,10]

When the fermented grains are removed from the opened fermenter, they become contaminated by a variety of microorganisms derived from the surrounding environment, many of which contribute to subsequent fermentation. In our previous studies, we found that if *Streptomyces*-sourced geosmin is introduced to the fermentation process, it becomes concentrated in the liquor after distillation.[2,11,12] Geosmin presence usually indicates that off-flavor producers have become well-established in the Chinese liquor-making process. Geosmin-producing *Streptomyces* have been identified in certain high- and low-temperature *Daqu*.[2]

Streptomyces spp. are ubiquitous soil bacteria noted for their ability to produce a vast array of antibiotics.[13] Indeed, 90% of *Streptomyces* produce antibiotics that inhibit the growth of other microbes.[13−15] Antibiotic-mediated species interactions are believed to enhance *Streptomyces* fitness and have been exploited as a plant disease biocontrol in soil.[16]

The present study investigates the extent to which introducing geosmin-producing *Streptomyces* affects the microbial community and flavor development in the fermentation processes of Chinese liquor. Adopting an analytical chemistry approach, it also proposes a mechanism by which geosmin-producing *Streptomyces* influences the brewing-functional microbes in the Chinese liquor-making process.

MATERIALS AND METHODS

Strains and Assays of Antifungal Activity. All strains in this study were isolated from the making process of *Daqu*-based Chinese light aromatic liquor. The isolated strains were identified by molecular taxonology based on their conservative rDNA sequences. Four geosmin-producing *Streptomyces* strains (*Streptomyces albus* FXJ, *Streptomyces fradiae* HX, *Streptomyces radiopugnans*QC-1, and *Streptomyces sampsonii* QC-2) were isolated from *Daqu*, and geosmin production was confirmed by gas chromatography−mass spectrometry (GC−MS). Antifungal activity was determined by the modified agar diffusion assay described in Coda et al.[17] Petri plates (90 mm diameter) containing 10 mL of potato dextrose agar (PDA) medium were inoculated with geosmin-producing strains. The plates were incubated at 30 °C for 72 h. Once the colony had developed, it was excised from the plate as an agar cylinder (9 mm diameter) and placed on a plate spread with functional liquor-brewing microbes at an appropriate concentration of cell suspension. The spread plates were then incubated at 30 °C for 72 h. All experiments were run in triplicate. The inhibitory activity of geosmin-producing strains was quantified as the diameter ratio of inhibition zone to agar cylinder ($R_{\text{inhibition zone}}/R_{\text{colony}}$).

The inhibitory effect of QC-2 broth sterilized by filtration was also assayed by modified agar diffusion assay. Strain QC-2 was inoculated in potato dextrose medium at 30 °C with shaking (250 rpm). At different incubation times, the QC-2 broths were filtered through a 0.22 μm membrane filter (Millipore Corporation, Bedford, MA). A plate inoculated with the test fungus (*S. fibuligera* FJ-4) at an optimal cell concentration was then dotted with 5 μL of the sterilized broth. All assays were performed in triplicate. The plate was incubated at 30 °C for 72 h, and the diameter (in mm) of the inhibition zone was measured.

Co-cultivation and Fermentation Experiments. The fermentation system of Chinese liquor was simulated as a cocultured system of the main brewing microorganisms. The solid-state fermentation medium was prepared as follows: 250 g sorghum was added to 350 mL hot water (70−80 °C), soaked for 24 h, and sterilized at 121 °C for 20 min. *Rhizopus oryzae* G4 (*R. oryzae* G4) was introduced to the simulated fermentation system at 10^4 CFU/g spore suspension, and incubated at 30 °C for 1 day to allow saccharification. The saccharified cultures were then inoculated with 10^5 CFU/g each of four yeast species (*S. cerevisiae* FJ-7, *P. anomala* FJ-3, *I. orientalis* FJ-2, and *S. fibuligera* FJ-4). Following 2-days of incubation at 30 °C, the spore or cell concentrations of the yeasts were adjusted to match the results of plate counts on PDA medium. *Streptomyces sampsonii* QC-2 (spore suspension 10^4 CFU/g) was inoculated into potato dextrose broth, and shaken at 250 rpm. The broths at different growth stages (lag phase (I), exponential phase (II), and stationary phase (III)) were sterilized by filtering through a 0.22 μm nylon membrane. Five-milliliters of the filtered QC-2 broths were added to the yeast cocultures. Medium without broth addition was prepared as a control reference sample.

Analysis of Yeast Growth. Yeast growth was measured by spread-plating onto Wallerstein Laboratory Nutrient (WLN) medium. Yeast cells from the simulation fermentation system were collected, 10-fold serially diluted in saline (0.85%, wt/vol, NaCl), and spread on triplicate WLN medium plates. Following incubation for 3 days at 30 °C, the yeast colony-forming units (CFUs) were identified by their morphological characteristics and counted.

Purifying Antifungal Active Compounds. The culture broth of strain QC-2 was prepared under the conditions of the cocultivation and fermentation experiments. The broth was incubated for 5 days, then centrifuged at 10 000 rpm for 15 min at 4 °C. The supernatant (approximately 40 mL) was purified and concentrated by a solid phase extraction (SPE) column (Welchrom C18E, Welch materials, Inc., MD, U.S.A.), and then successively eluted by 10 mL water, 50% acetonitrile/water, and 100% acetonitrile. The three eluents were separately collected and concentrated to 2 mL under a jet of nitrogen gas. After filtration through 0.22 μm membrane filters, 5 μL of each eluted fraction was retained for agar diffusion assay. Fractions showing antifungal activity were subjected to UPLC−PDA and ultra-performance liquid chromatography−quadrupole time-of-flight mass spectrometry (UPLC/Q-TOF−MS/MS) for compound identification.

Identifying Antifungal Active Substances. The active antifungal substances were identified by UPLC/Q-TOF−MS/MS. UPLC was performed in a Waters Acquity UPLC system (Milford, MA, U.S.A.) equipped with a binary solvent delivery system and an auto sampler. Chromatography was performed on a Waters Acquity C18 column (5 cm × 2.1 mm, 1.7-μm particles). The mobile phase was a gradient prepared from 0.1% formic acid (component A) and 100% acetonitrile (component B). Elution started with 5% B for 0.5 min; the proportion of A was then linearly increased to 100% over 10 min, reduced to 95% in the next 1 min and maintained isocratic for 2 min. Total run time, including conditioning of the column to the initial conditions, was 12 min. The flow rate of the eluting solvent was 0.3 mL/min. During the analyses, the column was maintained at 30 °C. The injection volume was 5 μL. Mass spectrometry was performed with a Waters Synapt Q-TOF system in positive and negative ion modes according to the manufacturer's instructions. The masses and compositions of the precursor and fragment ions were accurately calculated by the MassLynx 4.1 software supplied with the instrument, which calculates all possible elemental compositions consistent with the accurate mass. The relative concentrations of antifungal compounds to the external standard (amphotericin B 200 μg/L) were semiquantified on the basis of comparing their peak areas to that of the external standard on UPLC-PDA chromatograms at 380 nm.

Analysis of Volatile Metabolites. Analytes were extracted by solid-phase microextraction (SPME), using an automatic headspace sampling system (Multi Purpose Sample MPS 2 with an SPME adapter (GERSTEL Inc., Baltimore, MD, U.S.A.) equipped with a 50/30 μm DVB/CAR/PDMS fiber (2 cm, Supelco Inc., Bellefonte, PA, U.S.A.). Prior to analysis, the fiber was conditioned by insertion into the GC injector at 250 °C for 2 h to prevent contamination. A solid-state sample (3 g) was transferred to a screw-capped, straight-sided headspace vial (volume = 15 mL) and spiked with 10 μL of L-(−)-menthol (internal standard, IS), 4 mg/L in ethanol. After saturating the diluted solution with NaCl, the vial was tightly capped with a Teflon-faced silicone septum. The samples were equilibrated at 60 °C for 5 min and extracted for 45 min at the same temperature with stirring (250 rpm). Following extraction, the fiber was inserted into the injection port of the GC (250 °C) for 5 min to desorb the analytes.

The GC−MS analysis was performed in an Agilent 6890N GC coupled to an Agilent 5975 mass selective detector (MSD). The capillary column was a CP-Wax column (length = 60 m, i.d. = 0.25 mm, film thickness = 0.25 μm; Varian Inc., Palo Alto, CA, U.S.A.). The injector temperature was 250 °C, and the analysis was conducted in splitless mode. The operating conditions were as follows: temperature was started at 80 °C (holding for 2 min), then raised to 230 °C at 8 °C/min, and held at 230 °C for 10 min. The column carrier gas was helium (99.9995% purity) supplied at a constant flow rate of 2 mL/min. The electron impact energy was 70 eV, and the ion source temperature was set to 230 °C. The compounds were characterized by full-scan acquisition over an appropriate mass range (30−350 amu). The compounds were clearly identified by comparison to reference spectra (NIST05a.L, Agilent Technologies, Inc.) and pure standards.

The compounds were quantified by their main mass fragments. A calibration curve was derived by plotting the peak area ratios against the concentration ratios of main mass fragments to IS (m/z 81) as described in our previously published paper.[12] Each compound concentration in the sample was quantified by comparing the ratios of the peak areas with the calibration curve. Each determination was triplicated.

Statistical Analysis. To determine the effect of geosmin-producing strains on the flavors produced by the functional liquor-brewing fungus, the volatile metabolites were quantified. The obtained results were visualized on a heat map computed by R (version 3.0.2), in which cells were colored according to their Z scores (where Z = [observed value − mean]/standard deviation).

[a]Inhibition results are expressed as the mean diameter ratio of inhibition zone to agar cylinder in triplicate experiments. [b]R denotes the diameter of an inhibition zone or colony. [c]— indicates no inhibition zone.

RESULTS AND DISCUSSION

Influence of Geosmin-Producing *Streptomyces* On The Growth Of Microbes And Dynamics Of Yeast Populations Involved In Chinese Liquor Fermentation. Four *Streptomyces* strains (*Streptomyces albus* FXJ, *Streptomyces fradiae* HX, *Streptomyces radiopugnans* QC-1, and *Streptomyces sampsonii* QC-2) were identified as geosmin producers in our previous studies.[11] Communities of geosmin-producing *Streptomyces* have been studied by denaturing gradient gel electrophoresis (DGGE) and quantitative PCR.[2] In the present study, the antibacterial activity of geosmin-producing *Streptomyces* was determined by the agar diffusion method. Single-colony agar cylinders of the four geosmin-producing strains were placed on agar previously spread with functional brewing strains isolated from the liquor-making process, which provide flavor and enzymes. The inhibitions of geosmin-producing *Streptomyces* on the main functional strains were determined from the inhibition zones. As shown in Table 1, strain FXJ exerted a very weak antifungal activity, whereas strain HX inhibited only a portion of the fungus. Strain QC-1 inhibited a fraction of the bacteria, yeasts and molds. The strongest effect was exhibited by strain QC-2, which inhibited not only yeasts, molds and other fungi, but also (to some extent) bacteria under the same conditions. Importantly, the transparent inhibition zones around *S. fibuligera* FJ-4 and Y4 show that QC-2 strongly inhibits both of these strains. *S. fibuligera*, also known as *Endomycopsis fibuligera*, expresses liquefied raw starch enzyme and saccharifying enzyme. *S. fibuligera* ranks among the best yeast producers of starch decomposition enzymes.[21,22]

The sterilized potato dextrose broths, in which *S. sampsonii* QC-2 had been incubated up to different stages (QC-2 I (lag phase); QC-2 II (exponential phase), and QC-2 III (stationary phase)), were introduced to mixed cultures of the four yeasts, *S. cerevisiae* FJ-7, *P. anomala* FJ-3, *I. orientalis* FJ-2, and *S. fibuligera* FJ-4. According to Figure 1, the populations of the four yeasts were reduced by different degrees, reflecting their different inhibitions by strain QC-2. The QC-2 III results conspicuously differed from those of the controlled experiment, implying that *Streptomyces* can unbalance the microbial community of the brewing system. In contrast, the QC-2 I results varied only slightly from those of the control.

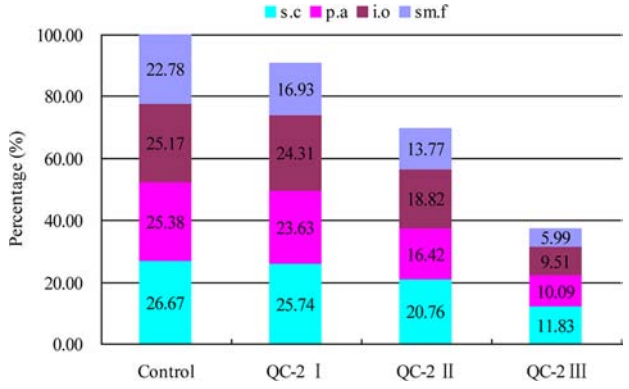

Figure 1. Populations of four brewing functional yeasts in a mixed-culture fermentation (s.c, *Saccharomyces cerevisiae* FJ-7; p.a, *Pichia anomala* FJ-3; i.o, *Issatchenkia orientalis* FJ-2; and sm.f, *Saccharomycopsis fibuligera* FJ-4) exposed to *Streptomyces sampsonii* QC-2 at different incubation stages (I, lag phase; II, exponential phase; and III, stationary phase). Numbers show the percentage of the yeast populations.

Kinetics of Biomass, Geosmin and Antifungal Activity during Strain QC-2 Fermentation. During fermentation in potato dextrose medium, strain QC-2 reached a maximum dry cell weight of 3.75 g/L after 5 days (stage II). The dry cell weight slightly decreased at later times, stabilizing at 2.65−3.68 g/L after prolonged fermentation (7−8 days; stage III). The concentration of the geosmin produced by strain QC-2 followed similar trends to the biomass (Figure 2). The activities of the sterile QC-2 broths were assayed against *S. fibuligera* FJ-4 from *Daqu*. Sterile broths of strain QC-2 incubated at different stages were pipetted onto PDA spread with *S. fibuligera* FJ-4, and the inhibition zone was measured after 3 days at 30 °C. As shown in Figure 3, the QC-2 broth of cells incubated for 2 days exerted no obvious antifungal effect. After 3−9 days, the inhibition zones became obvious and enlarged at later fermentation times.

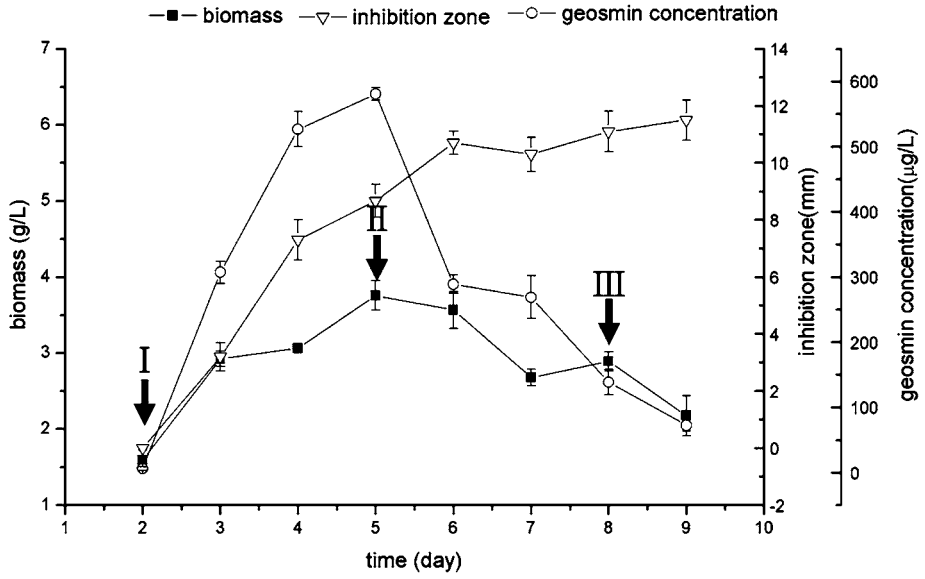

Figure 2. Biomasses, geosmin contents and antifungal activities of broths exposed to QC-2 at different fermentation stages. The test fungus is *Saccharomycopsis fibuligera* FJ-4.

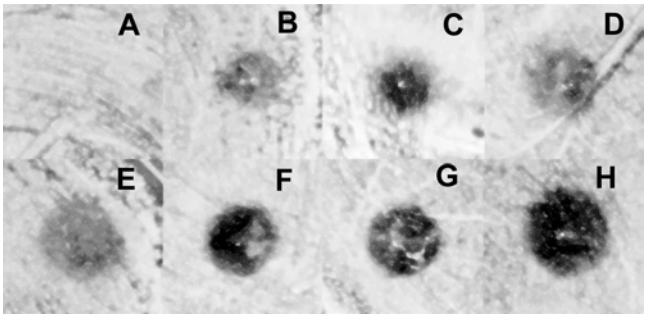

Figure 3. Antifungal activities of filter-sterilized broths of *Streptomyces sampsonii*QC-2 fermented for different periods. Shown are the inhibition zones against *Saccharomycopsis fibuligera* FJ-4 after 3 days of incubation at 30 °C. A, 2 days; B, 3 days; C, 4 days; D, 5 days; E, 6 days; F, 7 days; G, 8 days; and H, 9 days.

Influence of Strain QC-2 on the Volatile Metabolites in Mixed-Culture System. The mixed-culture system contained four brewing functional yeasts (*S. cerevisiae* FJ-7, *P. anomala* FJ-3, *I. orientalis* FJ-2, and *S. fibuligera* FJ-4) isolated from a Chinese liquor-making environment. The sterilized broths of geosmin-producing strain QC-2 at different incubation stages were introduced to the system. The volatile compounds in these experimental batches were quantified by HS−SPME−GC−MS, and a heat map of their Z scores was prepared. As shown in Figure 4, the main products of the mixed-yeast culture were esters, alcohols and acids. The geosmin concentration increased as the QC-2 incubation period lengthened before spiking into the mixed-culture system. The flavor of the mixed-culture brewing system was most obviously decreased by the QC-2 broth of cells incubated for 5 days (stage III). This decline was chiefly due to degradation of Group I and II alcohols and esters, such as 3-octanol, 3-methyl butanol, ethyl octanoate, and ethyl decanote. Meanwhile, the geosmin produced by *Streptomyces* has been recognized as an off-flavor volatile.[23,24] The results imply that geosmin-producing *Streptomyces* secretes antifungal compounds against the functional yeasts.

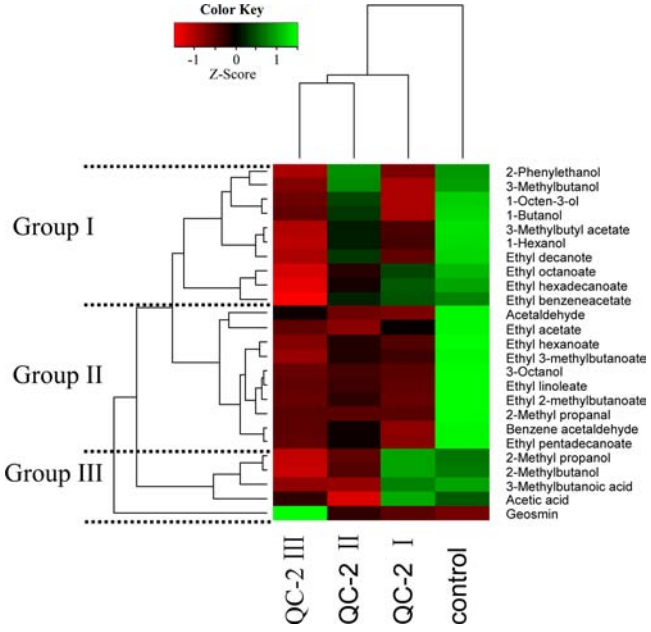

Figure 4. Volatile metabolites of four brewing functional yeasts in a mixed-culture fermentation (s.c, *Saccharomyces cerevisiae* FJ-7; p.a, *Pichia anomala* FJ-3; i.o, *Issatchenkia orientalis* FJ-2; sm.f, *Saccharomycopsis fibuligera* FJ-4) exposed to *Streptomyces sampsonii* QC-2 at different incubation stages (I, lag phase; II, exponential phase; and III, stationary phase).

Identifying the Antifungal Active Substances Produced by Strain QC-2. The QC-2 broth was purified and concentrated in a solid phase extraction (SPE) column. Three fractions were collected from three different eluents (see Materials and Methods). The ultraviolet absorption spectrum of the 50% acetonitrile/water fraction exhibited three characteristic peaks at 360, 380, and 400 nm. These peaks, detected by a photodiode array (PDA) detector at 6.5−7.6 min retention time (Figure 5B), characterize the chromophores of conjugate heptaene macrolides.[18,19] Nine peaks appeared in the spectrum of potato dextrose broth incubated with strain QC-2. However,

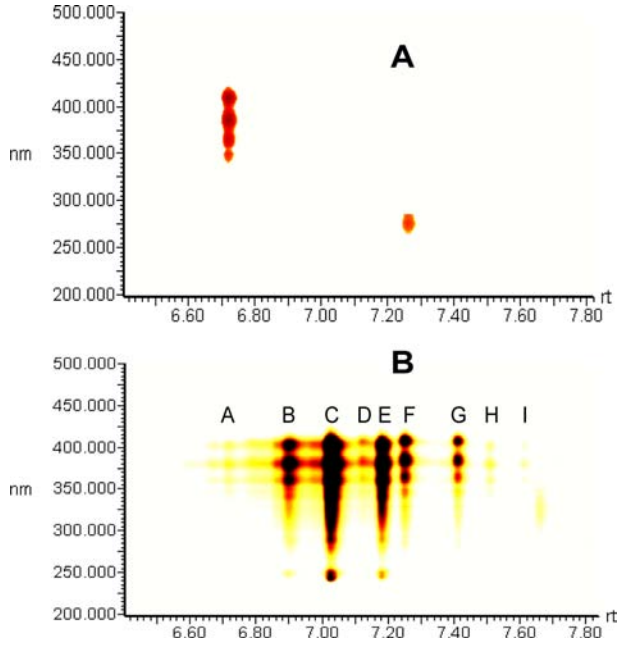

Figure 5. Photodiode array UV spectra of (A) standard sample amphotericin B and (B) peak A-I extracted from *Streptomyces sampsonii* QC-2 fermentation broth, precipitated on a C18 UPLC column (5 cm × 2.1 mm, 1.7-μm particles).

comparison with the retention time of amphotericin B in the PDA chromatogram reveals no amphotericin B production by strain QC-2 (Figure 5A).

The main components produced by strain QC-2 were identified and confirmed by UPLC−Q-TOF−MS/MS, standard spiking and mass spectrometry. The masses of these components were accurately determined by TOF−MS using negative electron spray ionization,[20] and the molecular ions are listed in Table 2. The approximate molecular weights of the main components in QC-2 broth were 1110.4, 1108.4, 1092.4, and 1176.4. This method also determines the abundances of the ion fragments. The molecular structures, derived from the mass spectrogram and compared with the PDA chromatogram, confirm the compounds as heptaene macrolide antibiotics. The number of double-bond equivalents (DBE) reported by the elemental composition tool were also consistent with the heptaene basic skeleton structure of the macrolide antibiotic class: C: 45, N: 1, O: 16, and DBE: 12. Error 0.1 Da. The ranges of possible elements and atomic numbers were as follows: C: 45−100, H: 0−100, N: 1−3, O: 16−20, and DBE: 16−25. The most likely formula was identified by analyzing the chemical element composition, based on the $[M - H]^-$ peak in negative ion mode. This analysis was performed by MassLynx application management software. The molecular formulas of the nine target compounds are listed in Table 2.

To confirm the structural formulas of these separate products, we directly imported the parent fragment ions from the raw data file, along with their structural formulas, into the Massfragment software, thus providing the fragment "soft spots". Finally, the proposed structural formulas were elucidated by Massfragment to assess their match to the corresponding fragment information. The formulas input to Massfragment were obtained from the accurate masses, which deviated from the theoretical values by 1.5 ppm at most. When the candicidin mixture standard was spiked into the broth of strain QC-2, the peaks of components B, C, E, and I were enhanced (see Figure 6A). The retention time of component C in QC-2 broth was similar to that of candicidin D, a heptaene macrolide of known chemical structure.[19] The contents of different components produced during fermentation were also quantified. Antifungal compound production in the QC-2 broth was maximized aat the seventh day of fermentation (Figure 6B), and was dominated by component C (whose concentration reached 504.83 μg/L). The changing trends of the antibiotics in the fermenting broth were consistent with those of the antifungal effect (inhibition zone diameter; see Figure 3). These results further confirm the active antifungal materials as heptaene macrolide antibiotics. Jørgensen and colleagues reported that most of their *Streptomyces* isolates produced candicidin, while all of them contained the *can* gene cluster responsible for candicidin biosynthesis.[19] The plasmid containing the genes can be conjugatively transferred to other streptomycetes.[19] Linear plasmids have also been identified as temperature-sensitive and easily lost,[25] and are commonly transferred to other species.[26] Although the *can* plasmid is not transferable to other *Streptomyces* strains in the laboratory, it may be responsible for spreading the candicidin biosynthesis gene cluster to other strains in natural environments such as Chinese liquor-making plants.

In conclusion, there were significant influences of diverse *Streptomyces* spp. acting as geosmin producers on the brewing functional microbials in a Chinese liquor making system. Some geosmin-producing *Streptomyces* could secrete antifungal compounds, heptaene macrolide antibiotics, against the normal fungi microbiota. In view of our results, the presence of *Streptomyces* may cause the imbalance of the microbial community of a brewing system. Accordingly, the contribution

ABSTRACT: Beta-lactoglobulin (BLG)−catechin conjugates were prepared by a free radical method and investigated with sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), electrospray ionization−mass spectrometry (ESI-MS), and far-UV circular dichroism (CD). Covalent binding between BLG and catechin were confirmed with SDS-PAGE and ESI-MS. About 93% of beta-lactoglobulin was conjugated with catechin or catecin fragments according to the gel intensity analysis software. Far-UV CD results showed that the content of β-sheet decreased with a corresponding increase in unordered structures after grafting. Both nanoemulsions with mean particle size between 160 and 170 nm were prepared. Both the rate of particle growth and the total beta-carotene (BC) loss at 50 °C were significantly greater than at 4 and 25 °C. The retention rates of BC in nanoemulsions were 27.8% and 48.6% for BLG and BLG−catechin conjugates, respectively, after 30 days of storage at 50 °C. The BC retention encapsulated in nanoemulsion was significantly improved using BLG−catechin conjugates, compared with BLG alone. The increase of BC retention in nanoemulsions encapsulated with BLG−catechin conjugates was due to the significant improvement of antioxidative properties (reducing power, free radical scavenging activity, and hydroxyl radical scavenging activity) of BLG after covalent binding with catechin. The results indicated that the proteins modified with polyphenols can be widely used in a labile bioactive compounds encapsulation delivery system.

KEYWORDS: *beta-lactoglobulin, beta-carotene, catechin, antioxidant activities, ESI-MS, nanoemulsion*

INTRODUCTION

High previtamin A activity and strong antioxidant activity make beta-carotene (BC) an important carotenoid for human nutrition.[1,2] BC is, however, highly susceptible to isomerization, oxidation, and degradation due to the polyunsaturated structure (11 double bonds),[3] and its application in food systems was strictly limited. Oil-in-water nanoemulsion delivery systems encapsulated by biomacromolecules have been developed recently to encapsulate and protect BC from oxidation. The advantages of such a system include high stability against flocculation or aggregation, high optical clarity, and increased bioavailability of lipophilic bioactive molecules.[4−6]

Compared to conventional emulsions (1−10 μm), the nanoemulsion delivery systems loaded with lipophilic bioactives (BC) may have much higher bioavailability (bioaccessibility). However, due to the small droplet diameter (D < 200 nm) and the high surface area-to-volume ratio, protection of BC with nanoemulsions may be less effective compared with conventional emulsion.[6] We recently reported that there is an inverse relationship between the chemical stability of incorporated BC and the particle diameter.[6] Tan and Nakajima also reported that small particle size with large interfacial surface led to more loss of BC.[7] To increase the stability of BC in nanoemulsions without decreasing bioavailability, new emulsifiers with strong antioxidant activity are needed.

It was reported that a free radical grafting approach, which employed a hydrogen peroxide−ascorbic acid pair as the radical initiator system, may be used to prepare biopolymer−polyphenol conjugates.[8,9] Compared with biopolymers alone, biopolymer−polyphenol conjugates may provide better protection of easily oxidized lipophilic bioactive compounds used in food delivery systems. However, the binding mechanism and the effects of polyphenol on biomacromolecules structure have not been clearly explained.

Generally, proteins exhibit lower toxicity and were more biocompatible compared with small surfactants and synthesized polymers.[10] Bovine beta-lactoglobulin (BLG), the major component of whey protein, is a common food addictive, used especially as an emulsifier due to the excellent emulsification properties. What's more, compared to surfactants (Tween), BLG showed protective activity of encapsulated bioactive compounds against degradation, as well as controlled release capacity for the resistance digestion properties against pepsin but not trypsin.[11,12]

Catechin is one of the natural polyphenols found in tea and fruits with strong antioxidant activities.[13−15] Noncovalent

interactions between proteins and catechins have been documented,[16,17] and covalent conjugation between biopolymers and catechin has been proposed to enhance their antioxidant activities.[8,18,19] The objective of this study was to obtain covalent BLG−catechin conjugates with improved antioxidant activities, which were characterized by SDS-PAGE, ESI-MS, and far-UV CD. Also, the potential applications in oil-in-water nanoemulsion delivery systems as emulsifier were analyzed.

MATERIALS AND METHODS

Materials. Beta-lactoglobulin (≥90%), beta-carotene (≥97%, UV), (+)-catechin (≥98% high-performance liquid chromatography (HPLC)-grade), L-ascorbic acid, hydrogen peroxide (30%, w/w), 2,2-diphenyl-1-picrylhydrazil (DPPH), potassium ferricyanide, and 1,10-phenanthroline were obtained from Sigma-Aldrich (St. Louis, MO). Corn oil was purchased from a local market (Albany, CA, U.S.A.). All solvents used for ESI-MS were Optima liquid chromatography/mass spectrometry (LC/MS)-grade (Fisher Scientific, PA). All other chemicals and reagents used were HPLC-grade and obtained from Sigma-Aldrich (St. Louis, MO). Ultrapure water (18.2 MΩ) was supplied by a Milli-Q apparatus (Millipore Corporation).

Conjugation of BLG with Catechin. The conjugation of BLG−catechin was prepared with a method similar to that reported in the literature.[9] Briefly, 0.5 g of BLG was dissolved in 50 mL of ultrapure water in a 125 mL glass flask, then 0.5 mL of 10.0 M H_2O_2 and 0.25 g of L-ascorbic acid were added and incubated for 2 h at room temperature with stirring. After that, 0.35 mmol of catechin was added and the reaction was allowed to proceed for 24 h at room temperature. Unreacted catechin was removed by dialysis against ultrapure water to 30 times the volume of the reaction solution using Slide-A-Lyzer Dialysis Cassettes, 2K MWCO (Thermo-Scientific, Waltham, MA, U.S.A.) for 48 h at 4 °C. The water was changed 10 times at approximately equal intervals. No free catechin was detectable in the dialyzed conjugates solution by HPLC analysis. The resulting BLG−catechin solution was lyophilized for further use. Blank BLG (control) was prepared with the same method without catechin.

Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis. A 4−20% gradient polyacrylamide gel prepared in-house was used for SDS-PAGE analysis. Five μL of BLG and BLG−catechin conjugates (protein content was ∼5 mg/mL) were mixed with 5 μL of ultrapure water and 10 μL of 2X SDS sample buffer (100 mM Tris-HCl, pH 6.8, 4% SDS, 0.2% bromophenol blue, 20% glycerol, and 200 mM 2-mercaptoethanol) and then heated for 5 min at 95 °C. Fifteen μL of each sample was loaded to a designated well for electrophoresis at 120 V with a Tris-HEPES-SDS running buffer (100 mM Tris, 100 mM (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) (HEPES), 3 mM sodium dodecyl sulfate (SDS), pH 8.0). The gel was stained using the Colloidal Coomassie G-250 Staining protocols.[20] The stained gel was scanned with an ImageQuant LAS 4000 digital imaging system (GE Healthcare, Piscataway, NJ, U.S.A.).

Circular Dichroism. A J-815 circular dichroism (CD) spectrometer (Jasco, Tokyo, Japan) was used to analyze the conformational changes of the protein after grafting in the wavelength range of 195−260 nm using a cell with a 2.0 mm path length as described previously.[21] Samples were prepared with 10 mM phosphate buffer (PB) (pH 7.0) at a protein concentration of 0.2 mg/mL. Scanning was performed at 50 nm/min at 20 °C. CD spectra were collected 10 times for each sample and displayed as mean residue ellipicity (degrees × cm^2/dmol) using 113 for the average number of amino acid residues per molecule of BLG.

Electrospray Ionization−Mass Spectrometry. A Thermo Easy Nano-II (Thermo Fisher Scientific, Waltham, MA, U.S.A.) HPLC was used to inject samples in the LC-MS system. After filtered with a 0.22 μm filter, 1 mg/mL blank BLG or BLG−catechin conjugates dissolved in ultrapure water were diluted 1:10 with 0.1% formic acid in water. Solvent A was 0.1% formic acid in water. Solvent B was 0.1% formic acid in acetonitrile. For each injection, 2 μL of the sample was applied at 100 bar backed with 8 μL of solvent A onto a reverse-phase trap cartridge (100 μm i.d. with 3 cm of Vydac Everest C18 5 μM/200 Å) (Precision Capillary Columns, CA, U.S.A.). Gradient elution of the sample was accomplished at 200 nL/min with the gradient 2−16% B for 7 min, 16−35% B for 20 min, and 35−80% B for 4 min. The analytical column was a New Objectives PicoChip column with 10 cm Reprosil-PUR C18-AQ, 3 μm, 120 Å packing (New Objectives Inc., MA, U.S.A.). Electrospray ionization−mass spectrometry (ESI-MS) data were collected on a Thermo Orbitrap Elite. Heated capillary was set to 250 °C. ESI voltage was 2.7 KV. Full scans (300−2000 Da) were collected in the Orbitrap with resolution set to 30 000. MS−MS scans were collected, but only full scan data were used for deconvolution and calculation of molecular mass of BLG and the conjugates. The program MagTran was used to deconvolute the electrospray data to determine the molecular masses for the samples.[22] Positive-ion mode was used in this study.

Preparation of Beta-Carotene Emulsions. Blank BLG or BLG−catechin conjugates were dissolved in ultrapure water and stirred for 3 h to form a 1% (w/w) solution. Beta-carotene (BC, 0.1%) was dissolved in carrier oils (corn oil) by stirring for 5 min at 50 °C, and stirring continued for 1 h at room temperature to ensure complete solubilization under nitrogen. A crude emulsion of 10% (wt) of the BC corn oil solution in the 1% protein solution at a mass ratio of 1:9 (oil phase/aqueous phase) was formed by high-speed homogenization for 2 min (PT10/35, Kinematica GmbH, Eschbach, Germany). The crude emulsion was then further homogenized through a high-pressure microfluidizer (M-110L, Microfluidics, MA, U.S.A.) seven times at 15 000 psi (103.4 MPa) at 25 °C. The homogenized samples were stored at 4 °C for further use.

Particle Diameter and Zeta-Potential Analysis. The mean particle diameter, particle size distribution (PDI), and zeta-potential of BC nanoparticles were determined by dynamic light scattering technique using a Malvern Zetasizer (Nano-ZS; Malvern Instruments, Worcestershire, U.K.). Refractive indices of 1.45 for BC oil droplet and 1.33 for ultrapure water were used. To reduce multiple scattering effects, the nanoparticles were diluted 100 times prior to the measurements. The tests were performed in triplicate.

Storage Stability of BC Emulsions. The nanoemulsion samples prepared freshly were transferred into screw-capped glass vials immediately after preparation. The samples were stored at 4, 25, and 50 °C in the dark for 30 days, and the same aliquots were removed at day 0, 2, 4, 6, 9, 16, 23, and 30 for particle size and BC content analysis. The BC was extracted from the nanoemulsions with 3 mL of ethanol/*n*-hexane (1:2, v:v) three times. The hexane fractions were combined and brought up to 10 mL for HPLC analysis to assay the stabilization of BC by BLG and BLG−catechin conjugates in the BC-loaded nanoemulsions.[6]

HPLC quantification of BC was performed using an Agilent 1100 HPLC system with diode array UV−vis absorption detector (DAD; Agilent, Santa Clara, CA, U.S.A.) as previously described,[23] and the BC quantitation range (0.1−100 μg mL^{-1}) was established for HPLC analysis of BC in nanoemulsions. A polymeric C_{30} reverse-phase analytical column (250 × 4.6 mm i.d., 5 μm, YMC, Inc., Wilmington, NC, U.S.A.) was used to separate BC with a flow rate of 1 mL min^{-1} at room temperature. The guard column was a reverse-phase C_{18} column (50 × 3.0 mm i.d., 5 μm, YMC, Inc.). The injection volume was 20 μL, and the detection wavelength was 450 nm. The chromatography conditions were as follows: solvent A, methanol/acetonitrile/water (84:14:2, v/v/v); solvent B, dichloromethane. The solvent gradient program was 80% A/20% B at 0 min and was changed linearly to 45% A/55% B in 15 min, maintained for 5 min, and followed by a linear return to 80% A/20% B at 25 min.

Chemical Antioxidant Activities. *Ferric Reducing Power.* The reducing power of blank BLG, BLG−catechin conjugates, and catechin was measured as described by Siddhuraju and Becker[24] with slight modifications. One mL of the blank BLG, BLG−catechin, and free catechin as a control at 1 mg/mL (w/v) was diluted in phosphate buffer (PB) (0.2 M, pH 7.0), mixed with 1 mL potassium ferricyanide (1% w/v) and incubated at 50 °C for 20 min. Next, 1 mL of trichloroacetic acid (TCA) (10% w/v) was added, and the mixture was centrifuged at 4000 rpm for 10 min (Beckman Coulter, Pasadena, CA,

DOI: 10.1021/jf5056024
J. Agric. Food Chem. 2015, 63, 297−303

U.S.A.). One mL of distilled water and 0.5 mL of ferric chloride (0.1% w/v) was added to the supernatant and blended for 10 s. The absorbance was detected at 700 nm by Nanodrop 2000c (Thermo Scientific, Wilmington, DE, U.S.A.) after 10 min. The antioxidant activity of free catechin was measured and used as a control.

DPPH Radical Scavenging Activity. The 2,2-diphenyl-1-picrylhydrazil (DPPH) radical scavenging activity was determined according to the method of Gülçin et al.[25] Two mL of the sample (blank BLG, BLG−catechin conjugate, or catechin) at 1 mg/mL (w/v) was added to 2 mL of 0.1 mM DPPH dissolved in ethanol and was agitated for 10 s, and then kept for 30 min at room temperature. The absorbance was read at 517 nm. The radical scavenging activity (AA_D) was calculated according to the following equation,

$$AA_D(\%) = 100 \times (A_C - (A_S - A_B))/A_C$$

where A_C represents the absorbance of control, A_S represents the absorbance of the solution after the sample solution was added, and A_B represents the absorbance of the sample solution alone.

Hydroxyl Radical Scavenging Activity. With slight modification, the method described by Li et al.[26] was used to measure the hydroxyl radical scavenging activity of blank BLG, BLG−catechin conjugate, and catechin at 1 mg/mL (w/v). 1,10-Phenanthroline (5 mM) was dissolved in PB (0.2 M, pH 7.4) and was mixed with $FeSO_4$ (5 mM) solution. 0.1% H_2O_2 was added, and the mixture was incubated at 37 °C for 60 min. The absorbance at 536 nm was recorded with a Nanodrop 2000c (Thermo Scientific, U.S.A.). The hydroxyl radical scavenging activity of the sample was calculated using the following equation,

$$AA_H(\%) = 100 \times (A_S - A_C)/(A_B - A_C)$$

where A_S is the absorbance of the sample, A_C is the absorbance of control solution that sample solution was replaced with the same amount of distilled water, and A_B is the absorbance of solution without the samples or H_2O_2.

Statistics. All experiments were performed at least three times and were reported as mean ± standard deviation. The data were analyzed by the analysis of variance (ANOVA) using the SPSS 17.0 package (IBM, New York, U.S.A.). Duncan's multiple range test was used to determine the significant differences of the mean values ($P < 0.05$).

RESULTS AND DISCUSSION

BLG−Catechin Conjugation. The molecular weight of native BLG, blank BLG, and BLG−catechin conjugates was determined by SDS-PAGE. The bands corresponding to native BLG, blank BLG, and BLG conjugation with catechin under reducing conditions are shown in Figure 1. Different isoforms of BLG were found at ~18 kDa. Small amounts of BLG dimers are observed at ~40 kDa. Almost no changes occurred after beta-lactoglobulin reacted with L-ascorbic acid (free radical method without catechin), indicating no L-ascorbic acid was conjugated on BLG. The slight decrease of the mobility of BLG after grafting with catechin in SDS gel indicated the increase of molecular weight of BLG. The SDS-PAGE results showed that catechin was covalently binding to BLG. This is consistent with the apparent increase in the molecular weight of other proteins after covalent grafting. The molecular weight of bovine milk proteins was also increased after covalent grafting with flavonoid by laccase-catalyzed method,[19] and You et al. reported that the molecular weight of ovotransferrin was increased after covalent binding with catechin.[27] According to the SDS-PAGE results and the gel intensity analysis software, about 93% of beta-lactoglobulin was conjugated with catechin or catecin fragments.

The molecular weight changes after conjugation were further investigated with ESI-MS (Figure 2). Two main peaks, 18 361.5 and 18 277.6 Da, were found in the BLG purchased from Sigma, corresponding to BLG A and BLG B, respectively. After conjugation, the BLG−catechin conjugates were found to contain mainly two components with molecular weights of 18 474.4 and 18 390.6 Da, respectively. The differences in the molecular mass of the components in blank and catechin-conjugated BLG (increase by 113 Da) were consistent with the successful covalent attachment of possible parts of catechin molecules, which gave several fragments peaks when analyzed with ESI-MS. The ESI-MS results further confirmed the conjugation of catechin with BLG.

Catechin Conjugation Effect on BLG Secondary Structure. After covalent conjugation with catechins, changes in the secondary structure of BLG were determined by far-UV CD spectroscopy (Figure 3). The negative peak at 216 nm indicates that BLG is rich in β-sheet secondary structure. However, the catechin-grafting reaction resulted in marked shifts in wavelength of negative peak from 216 to 206 nm, indicating changes occurred in BLG's secondary structure. The secondary structure compositions of BLG and BLG−catechin conjugates were calculated with DichroWeb online (Table 1). The composition of blank BLG in this study was as follows: α-helix, 12.8%; β-sheet, 38.8%; turn, 21.7%; and unordered, 25.5%, similar to the result reported in a recent publication.[21] After conjugation, the β-sheet structure decreased from 38.8% to 30.0%, while the unordered structure increased from 25.5% to 31.9%, indicating that BLG became more unordered, which was consistent with the results reported by Ali et al.[28] Rawel et al.[29] also found that covalent attachment of chlorogenic acid to bovine serum albumin led to the decrease of ordered structure with a parallel increase in unordered structures. The increase of unordered secondary structure of BLG may lead to the exposure of an interior hydrophobic amino acid, such as tryptophan and tyrosine, which is mainly responsible for the antioxidant activities of proteins, resulting in improvement of antioxidant activities. The exposure of the hydrophobic amino acid may also lead to the increase of emulsifying activities.

Physical Stability of BC Nanoemulsions. The particle diameters of BC nanoemulsions prepared with BLG and BLG−catechin are shown in Table 2. No significant differences in

Table 1. Secondary Structure Composition of Blank BLG and BLG−Catechin Conjugates[a]

samples	α-helix (%)	β-sheet (%)	turns (%)	unordered (%)
blank BLG	12.8	38.8	21.7	25.5
BLG−catechin	15.2	30.0	21.6	31.9

[a]The secondary structure composition was calculated from far-UV CD spectra data using DichroWeb online (http://dichroweb.cryst.bbk.ac.uk/html/home.shtml).

particles size were found, indicating the emulsifying properties of BLG were not affected by grafting catechin.

Particle diameter profiles were used to evaluate the physical stability of BC-loaded nanoemulsions over 30 days at 4, 25, and 50 °C (Figure 4). Heat treatment is inevitable in the food industry. To simulate food process parameters and to show the great ability of BLG−catechin conjugates in improving BC's storage stability, 4, 25, and 50 °C were chosen as storage temperature. The initial mean particle diameters were 161.7 and 167.6 nm for BLG and BLG−catechin conjugates, respectively. However, due to the large difference in density between the oil-emulsified droplet and the aqueous continuous phase, gravitational forces may cause the emulsion particles to rise and concentrate at the surface. The reduction in the interparticle distances may result in flocculation or aggregation. During the 30-day testing period at 4 °C, both BC nanoemulsions were kept relatively stable and the diameters showed <5 nm increase. At 25 °C, the diameters of the particles in both samples showed a slight increase (~5−15 nm). In contrast, the particle diameters of emulsions at 50 °C showed a higher increment of 25−35 nm for high-motion velocity and the particle size distribution was broadened, compared to the initial droplet diameters. The exposure of the nonpolar amino acid group of BLG increased the hydrophobic attraction between droplets, and this may lead to the increase in the particle size and particle aggregation.[30] Even though a larger particle size increase occurred at high temperature, no phase separation or creaming were observed during the 30-day period at the three temperatures for the samples, suggesting both BLG and BLG−catechin conjugate-stabilized nanoemulsions possessed high kinetic stability.

Table 2. Mean Particle Diameter (Z-average, nm), Polydispersity Index (PDI), and Zeta-Potential of BC Nanoemulsions Encapsulated with Blank BLG and BLG−Catechin Conjugates

characteristics	blank BLG	BLG−catechin conjugates
Z-average (nm)	161.7 ± 1.7	167.6 ± 1.3
PDI	0.101 ± 0.021	0.104 ± 0.018
zeta-potential	−57.2 ± 1.3	−62.9 ± 1.5

Retention of BC in Nanoemulsions. BC retention in both samples decreased with the increase of storage time in the dark at three different incubation temperatures. At 4 °C, after 30 days, the BC retentions were 89.8% and 94.0% for BLG- and BLG−catechin-stabilized BC nanoemulsions, respectively.

J. Agric. Food Chem. 2015, 63, 297−303

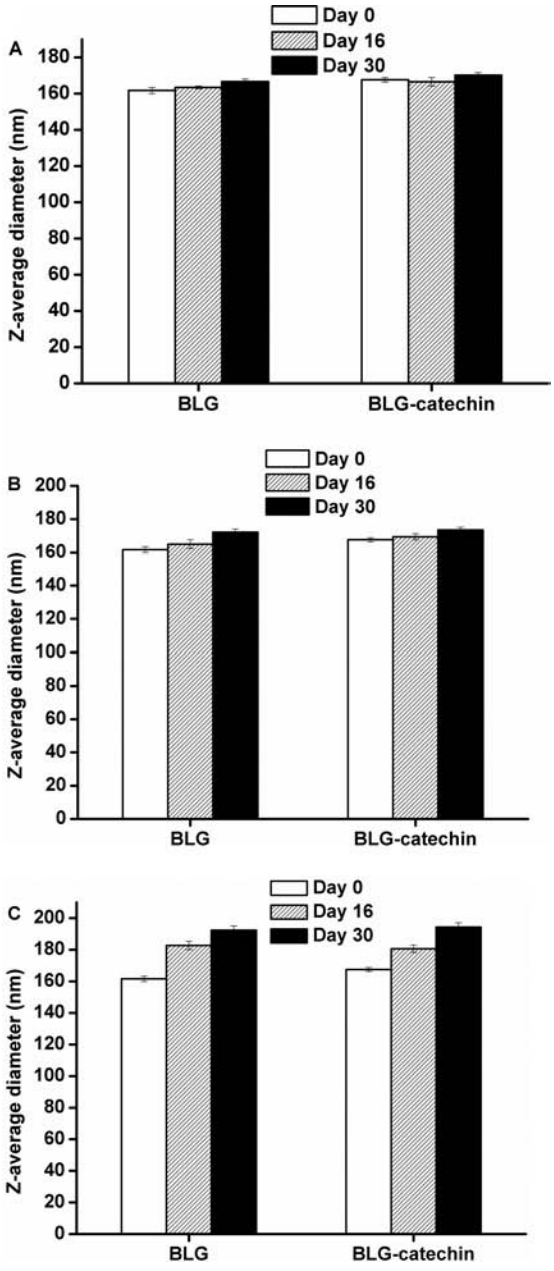

Figure 4. Change of Z-average diameters of blank BLG and BLG−catechin conjugate-stabilized BC nanoemulsions over time (30 days) at 4 (A), 25 (B), and 50 °C (C). Data are represented as the mean ± standard deviation (n = 3).

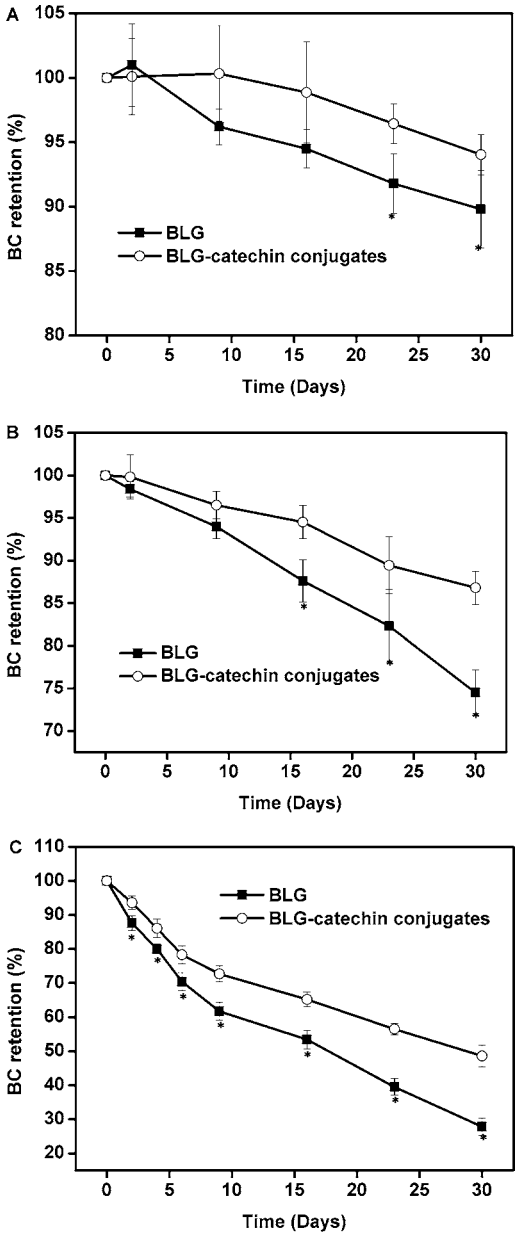

Figure 5. Retention of BC in blank BLG and BLG−catechin conjugate-stabilized nanoemulsions over time (30 days) at 4 (A), 25 (B), and 50 °C (C). Data are represented as the mean ± standard deviation (n = 3). *Significant (P < 0.05) difference.

Stored at 25 °C for 30 days, 74.5% and 86.8% of BC was retained in the emulsions when stabilized with BLG and BLG−catechin conjugates, respectively; BC retention decreased to 27.8% and 48.6% for BLG and BLG−catechin conjugate nanoemulsions, respectively, at 50 °C after 30 days (Figure 5). Similar to particle diameter growth, the total BC loss was greater at 50 °C than at 4 and 25 °C (Figure 5), demonstrating that temperature is an important factor in impacting the stability of encapsulated bioactive compounds. Compared to blank BLG, BC stabilized with BLG−catechin conjugate nanoemulsions exhibited significantly improved chemical stability and higher retentions (Figure 5), indicating the great capability of BLG−catechin conjugates in enhancing the chemical stability of encapsulated lipophilic molecules. Ali et al.[28] also reported that, compared with the unmodified protein, whey protein modified by coffee-specific phenolics showed an increase in lutein ester remaining in conventional emulsions when exposed to UV light. BC oxidation and degradation were mostly likely due to the dissolved oxygen, transition metal (Fe^{3+}) in aqueous phase, and free radicals in oil phase.[3,31] The improvement of reducing power, DPPH radical scavenging activity, and hydroxyl radical scavenging activity (Table 3) may be among the factors that led to the increase of BC chemical stability encapsulated by BLG−catechin conjugates.

Chemical Antioxidant Activities. The effects of catechin conjugation on BLG antioxidant activities were analyzed. The reducing power, DPPH radical scavenging activity, and hydroxyl radical scavenging activity (OH·) at 1 mg/mL of protein concentration are shown in Table 3. The reducing

Table 3. Reducing Power, AA_D Free Radical Scavenging Activities, and AA_H Free Radical Scavenging Activities of Blank BLG, BLG−Catechin Conjugates, and Catechin[a,b]

antioxidant activities	blank BLG	BLG−catechin conjugates	catechin
reducing power (Abs)	0.008 ± 0.002 a	0.032 ± 0.003 b	0.222 ± 0.026 c
DPPH AA_D scavenging activity (%)	7.6 ± 0.4 a	87.4 ± 2.6b	85.9 ± 2.9 b
hydroxyl AA_H scavenging activity (%)	7.3 ± 0.8 a	66.5 ± 2.0 c	21.9 ± 1.5 b

[a]BLG, BLG−catechin conjugates, and catechin concentrations were 1 mg/mL (w/v). [b]Different letters in the same row indicate significant difference ($P < 0.05$) (Duncan analysis).

power measurement was quantified by calculating the inhibition of the conversion of Fe^{3+} to Fe^{2+} by the samples. Compared to the reducing power of BLG (0.008), that of BLG−catechin conjugate quadrupled to 0.032. Compared to control BLG, the DPPH radical and hydroxyl radical scavenging activities of BLG after catechin conjugation were markedly improved 11.5 and 9.1 times (to 87.4% and 66.5%), respectively. These results indicated BLG's chemical antioxidant activities were sharply improved after grafting with catechin. It is worth noting that the hydroxyl radical scavenging activity of BLG−catechin conjugates was greater than those of both free BLG and catechin, indicating strong synergistic antioxidant effects existed between BLG and catechin.

The antioxidant activities of other proteins were also reported to have significant improvement, e.g., in gallic acid or catechin−gelatin conjugates and catechin−ovotransferrin conjugates.[9,27] The outstanding antioxidant activity of polyphenols has been attributed to the higher number of hydroxyl group substituents.[32−34] The hydroxyl groups of catechin added to BLG may lead to improved antioxidant activities of BLG−catechin conjugates.

In summary, BLG−catechin conjugates were obtained using hydrogen peroxide−ascorbic acid pair by radical method. The covalent binding of catechin to BLG was confirmed by SDS-PAGE and ESI-MS and the impact of the conjugation on BLG secondary structure was analyzed by far-UV CD. BC retention in nanoemulsions encapsulated by conjugates was higher than that in BLG alone. Chemical antioxidant activities of conjugates were appreciably improved, compared to BLG alone. High antioxidant activities suggested that BLG−catechin conjugates can be used in functional food and delivery food systems.

ABSTRACT: Yeast lees influence the organoleptic properties of wines by increasing their sweet taste. This effect is in part due to the protein Hsp12p, which is regulated by different stress response pathways in *Saccharomyces cerevisiae*. This work investigated the genetics and environmental factors influencing the expression level of the *HSP12* gene in an enological context. RT-qPCR confirmed that the *HSP12* expression level is regulated by temperature change and ethanol content during the alcoholic fermentation but not by the sugar content. Moreover, this gene shows an important variation according to the yeast strain used. For the first time yeast strain is demonstrated to play an important role in the perception of sweetness in red wine due to post-fermentation lees autolysis. Interestingly, a correlation between the expression level of *HSP12* and the sweetness perception was found using yeast strains of different origins. All of the findings provide new insights on the contribution of yeast to wine taste.

KEYWORDS: *HSP12, wine sweetness, expression level, protein, strain, Saccharomyces cerevisiae, taste*

INTRODUCTION

Wine quality depends on both its complexity of odors and its harmony of flavors. This taste balance is mainly due to interactions between sweet, sour, and bitter tastes. In particular, sweetness plays a decisive role in wine perception and is likely to contribute to the pleasure of the tasters.[1] Dry wines containing <2 g/L (below the perception threshold) of residual sugar exhibit paradoxically a subtle sweet taste.[2] Previous works have established that ethanol, glycerol,[3−5] polysaccharides,[4] and nucleotides[6] have no direct influence on sweetness perception in the concentration ranges at which they are found in dry wines. However, sensory studies have shown that wine sweetness increases during yeast lees autolysis[5] and oak wood aging;[7] therefore, the molecular determinants explaining these phenomena have been, at least in part, elucidated.[5,8]

In particular, we demonstrated in a previous work that *HSP12* has a direct or an indirect role in the increase of wine sweetness observed during yeast lees autolysis.[5] Biochemical and sensory experiments suggested that a peptide fraction of Hsp12p causes the sweet perception. We also demonstrated that sweetness intensity was linked to the amount of yeast lees in contact with wine during autolysis. All of these findings suggest that Hsp12p is involved in the gain of sweetness conferred by yeast lees.

The *HSP12* gene encodes a small heat-shock protein described as a LEA-like protein in *Saccharomyces cerevisiae*.[9] This protein is crucial for the survival of a variety of stress conditions including heat shock,[10] osmotic[11] and oxidative stresses,[10] freezing,[12] or desiccation.[13] Hsp12p protein is also implied in the extension of lifespan in dietary restriction[14] as well as in biofilm formation.[15] Despite numerous studies, the molecular function of this protein was not completely elucidated. Unlike other small heat shock proteins, *HSP12* displays a negligible molecular chaperone activity regarding protein aggregation.[14] In contrast, structural and biochemical studies suggested that *HSP12* interacts with lipid molecules and has a membrane-stabilizing role acting as a "lipid chaperone".[10,14,16] The expression level of this gene has been widely investigated due to its important response to a wide set of environmental stresses.[17] Many studies reported an induction of *HSP12* expression related to stress in both laboratory[18] and biotechnological contexts.[12,19] In the wine alcoholic fermentation context, *HSP12* appears to be highly expressed[20] despite the high sugar concentration found in wine, which is supposed to down-regulate its expression.[21,22] The high expression level of *HSP12* in the enological context is likely due to high ethanol concentration[23] and the stationary growth phase of fermenting yeast. Moreover, important physicochemical parameters in wine fermentation can modulate the expression level of this gene, including low and high temperatures,[24,25] nitrogen content,[26] and lipid concentration.[27] Besides the impact of environmental conditions, an important variability in global gene expression can be found within yeast strains[28,29] and species.[30] For *HSP12*, this general trend is verified both for the mRNA expression[31,32] and for the protein production level.[30]

These previous works emphasize that the great range of *HSP12* expression variation and the subsequent amount of protein may be linked to the resulting sweetness perception in wine.[5] However, these experiments were carried out in many

different conditions (media, strain), impairing the elucidation of the main factors modulating the *Hsp12p* expression in wine context. This study proposes to investigate the effect of some genetic and environmental factors affecting *HSP12* expression.

MATERIALS AND METHODS

Yeast Strains and Growth Media Used. The *S. cerevisiae* strains used are listed in Table 1. The construction of the strain Δ°*hsp12* was described in Marchal et al.[5] This strain is isogenic to the commercial starter Zymaflore Fx10 (Laffort, France) referenced as H4-1D in a previous work.[33] The other strains are commercial starters form Laffort or homothallic monosporic clones previously referenced by Blein-Nicolas et al.[30] Yeast strains were propagated at 28 °C on YPD medium (1% yeast extract, 2% peptone, dextrose 2%) containing 2% agar to prepare a solid medium.

Fermentation on KP Medium. Fermentations were carried out using the model synthetic medium (KP medium) buffered at pH 3.30 and containing 190 mg(N)/L of assimilable nitrogen.[34] Fermenting sugars are constituted by an equimolar mix of glucose and fructose and were set to 240 g/L. Other concentrations of sugars were used (120, 160, or 300 g/L) for one experiment as specified in the text. Precultures were run for 24 h at 24 °C under orbital agitation (150 rpm) in the fermentation media filtered through a 0.45 μm nitrate cellulose membrane (Millipore, Molsheim, France) and diluted 1:1 with Milli-Q water. The inoculum concentration was 10^6 viable cells/mL. Fermentations were run in closed 350 mL glass reactors, locked to maintain anaerobiosis, with permanent stirring (300 rpm). Fermentations were carried out at 26 °C, but other temperatures (12, 18, 22, or 31 °C) were used for an experiment as specified in the text.

The amount of CO_2 released (g/L) was monitored daily by the weight loss of the bioreactors. The raw fermentation kinetics data were smoothed by a Loess function and plotted using the R program as previously described.[35] All fermentations were done in triplicate.

Yeast Cell Collection and Quantification. Cells were collected from fermenting KP medium at nearly 46 g/L of CO_2 produced for analyzed cell expression. In the expression monitoring experiment, samples were collected at different fermentation points (30, 46, 55, 66, or 76 g/L of CO_2 produced). The cell concentration was quantified using a flow cytometer (QuantaSC MPL, Beckman Coulter, Fullerton, CA, USA), equipped with a 488 nm laser (22 mW) and a 670 nm long-pass filter. Samples were diluted in McIlvaine buffer, pH 4.0 (0.1 M citric acid, 0.2 M sodium phosphate dibasic), and propidium iodide was added (0.3% v/v) to stain dead cells (FL3 channel).

Quantification of *HSP12* Expression Level. Extractions of mRNA and cDNA synthesis were carried out as previously described (Thibon et al. 2008).[36] Briefly, 1×10^7 cells were harvested, washed, and lysed using a Fastprep FP120 apparatus (MP Biomedicals, Solon, OH, USA). RNA was extracted using Tri reagent (Sigma, L'Isle d'Abeau Chesnes, France), and DNA contamination was treated using a DNA-free Kit (Ambion Inc., Austin, TX, USA); RNAs were retrotranscribed into cDNAs using the iScriptTM cDNA Synthesis Kit (Bio-Rad, Hercules, CA, USA). The extracted RNA was quantified using the ND-1000 UV−visible light spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA). The absence of contaminant genomic DNA in RNA preparations was verified using RNA as a template in real-time PCR assays. Each cDNA sample was analyzed two times independently by quantitative real-time PCR using iCycler iQ (Bio-Rad). Gene transcripts were amplified by using the following primers: *HSP12* p321, GGGTGTCTTCCAAGGTGTC; p322, TTGGCGGCTCCCATGTAATC (151 bp); *ALG9* p605, CACGGATAGTGGCTTTGGTGAACAATTAC; p606, TATGATTATCTGGCAGCAGGAAAGAACTTGGG (163 bp); *ACT1* p323, TACCGGCCAAATCGATTCTC; p904, TACTGGTATTGTTTTGGATTCC (123 bp). The *ALG9* gene was used as a second reference gene as proposed previously.[37] Real-time quantitative PCRs (qPCRs) were carried out using the iQ SYBR Green Super Mix (Bio-Rad). Primers were added at a concentration of 0.3 mM each. The PCR program used was as follows: 3 min at 95 °C for initial denaturation, then 40 cycles of 10 s at 95 °C, 30 s at TM, and 30 s at 72 °C. A final melt curve was carried out for control specific amplification by 36 cycles of 10 s starting at 65 °C, with increasing steps of 0.5 °C at each cycle. The PCR efficiencies were 80.2, 89.7, and 88.7% for *HSP12*, *ACT1*, and *ALG9*, respectively. A standard curve was determined for each gene using genomic DNA as template, where x is the threshold cycle and y is the log value of the starting quantity (ng): *HSP12* ($y = -3.90x + 21.44$, adjusted $R^2 = 0.995$); *ACT1* ($y = -3.62x + 22.44$, adjusted $R_2 = 0.985$); *ALG9* ($y = -3.65x + 23.81$, adjusted $R_2 = 0.994$). Standard curves were obtained from eight points in triplicate, and linearity was observed from 0.0366 to 183 ng of DNA. A threshold value for the fluorescence of all samples was set manually to adjust the Ct value of standard samples in each experiment. The relative amounts of *HSP12* with respect to each reference gene were calculated from the standard curve. Expression levels obtained from both reference genes were highly correlated (Pearson correlation test $r = 0.99$, $p_{val} = 1 \times 10^{-8}$); consequently, only the *HSP12/ACT1* ratios are graphically presented.

Production of Wine without *Hsp12p*. A red grape juice of Merlot (Bordeaux) harvested in 2011 was used for this study. This grape must obtained by thermoextraction was supplemented with ammonium sulfate and glucose plus fructose to obtain a final concentration of 210 mg(N)/L of assimilable nitrogen and 210 g/L of sugar. A batch of 6 L of this grape must was fermented with the strain Δ°hsp12 at 24 °C until completion of the fermentation. The final amount of residual sugar at the end of alcoholic fermentation was <2 g/L. This wine was then dispatched in 1 L glass vessel and supplemented with the biomass of different strains freshly harvested by centrifugation (5 min, 8000*g*) and washed two times with sterile water (4 °C). The concentration of the added biomass in wine was adjusted to 2×10^8 cells/mL to remain close to the yeast concentration usually found in enology.[35] After 24 h, the viability of the cell was controlled by platting 1 mL of wine on YPD. Fewer than 10^3 viable cells/mL were recovered.

Yeast Autolysis. Yeast autolysis of the different strains (Fx10, Δ°hsp12, D2, W1, B1, VL3, F33, and XMC30) took place at 32 °C during 10 days without light or stirring. At the end of this period, the wines were centrifuged (4000 rpm, 15 min) to eliminate yeast lees and kept at 4 °C for 24 h in sterilized glass bottles inerted with CO_2 until tasting.

Wine Tasting. All of the tasting sessions took place in a specific room equipped with individual booths and air-conditioned at 20 °C. The samples (20 mL) were presented at 18 °C in normalized dark glasses coded with random numbers. All of the panelists (17 tasters aged from 21 to 64 years) were wine-tasting specialists or winemakers and had been previously informed of the nature and risks associated

J. Agric. Food Chem. 2015, 63, 304−311

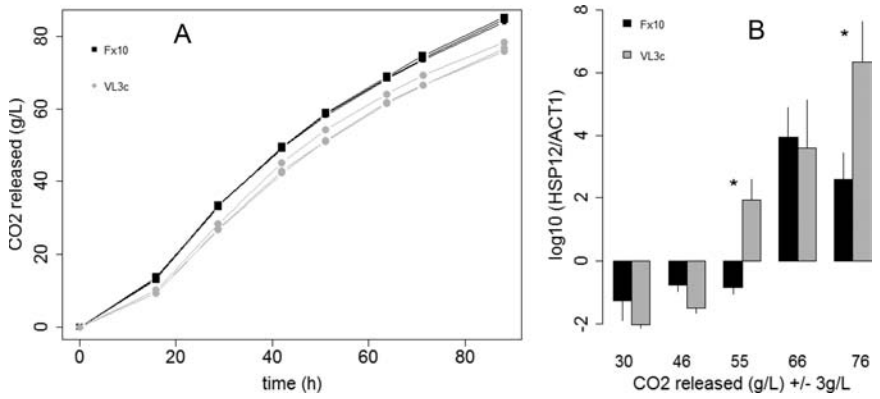

Figure 1. *HSP12* expression monitoring during alcoholic fermentation at 26 °C. (A) Yeast strains were cultivated in a synthetic medium containing 240 g/L sugar and fermented at 26 °C. The time course of CO_2 production is shown for each strain replicate. The black squares and gray circles represent the strains Fx10 and VL3, respectively. (B) Cell samples were collected at different fermentation points when the CO_2 produced reached 30, 46, 55, 66, and 76 g/L. The average of the *HSP12* expression at each time point is shown on the bar plot (expressed as the logarithm of *HSP12*/*ACT1* ratio). Bar errors indicate the standard error of the three replicates. Statistically relevant differences between strains were indicated for each collecting point by a (∗) Wilcoxon test ($\alpha = 0.05$).

with the investigation. The presentation order of the glasses was randomly changed between each taster.

Prior to the formal evaluation of wines, the panelists performed training sessions. In a first session, a hydroethanolic solution (12% alcohol by vol, 3 g/L of tartaric acid, pH adjusted to 3.5) with sucrose adjusted at different concentrations (0, 3, 6, and 12 g/L) was presented to the tasters. In a second session, a red wine (Bordeaux 2011, 12.9% alcohol by vol, 0.3 g/L glucose + fructose) was used for a similar test. For both sessions, tasters were asked to classify the wines following the intensity of sweetness. A Page test was used to interpret these results.[38]

For the formal evaluation of the yeast strain impact on sweetness, the wines were tasted the day after centrifugation. The tasters were asked to rate the wines on a scale from 0 to 7. The statistical interpretation was based on an analysis of variance (ANOVA) according to the recommendations of the International Organization for Standardization.[39]

Statistical and Graphical Analyses. All of the statistical and graphical analyses were carried out using the R program version 2.15.1.[40] The variation of each trait analyzed was estimated by an analysis of variance (ANOVA) according to the model in figure captions. For each variable, the homogeneity of the variance was assessed using a Levene test by means of R's car package, as well as the normality of residues distribution using a Shapiro test. Duncan's multiple comparison was used to determine which means differ significantly (Duncan's multiple comparison, $\alpha = 0.05$) using the *agricolae* package. When required, a Wilcoxon test was used with at least three independent repetitions.

RESULTS AND DISCUSSION

***HSP12* Expression Correlates with the Progression of Alcoholic Fermentation.** Our study investigated the genetic and environmental factors affecting the expression level of *HSP12* during the alcoholic fermentation. First, we monitored by quantitative PCR the *HSP12* mRNA level of two commercial starters (Zymaflore VL3 and Fx10) during the alcoholic fermentation carried out at 26 °C in a synthetic grape juice containing 240 g/L of sugar. The expression level of both strains was compared nearly at the same fermentation advancement (30, 46, 55, 66, and 76 g/L of CO_2 produced) to compare the strains at the same physiological stage (Figure 1A). As shown in panel B, the expression level of *HSP12* steadily increased during the fermentation process. For both strains, significant changes were observed between the earliest and latest stages (Table 2). At 55 and 76 g/L of CO_2 produced,

Table 2. Multiple Test Comparison of the *HSP12* Expression during Alcoholic Fermentation[a]

	CO_2 produced in				
strain	30 g/L	46 g/L	55 g/L	66 g/L	76 g/L
Fx10	−1.25 cd	−0.75 bcd	−0.84 bcd	3.93 ab	2.58 bcd
VL3	−2.02 c	−1.50 bc	1.92 abc	3.59 ab	6.34 a

[a]Data presented are the mean of *HSP12* expression levels expressed in log 10(*HSP12*/*ACT1*) at different moments of alcoholic fermentation (CO_2 produced). For each strain, a one-way analysis of variance was carried out to estimate the sampling point effect ($Y = \mu + CO_2 i + \varepsilon(i)$). The letters beside each strain value indicate groups with a statistical difference according to the linear model used (Duncan test, $\alpha = 0.05$).

the *HSP12* expression level differs between VL3 and Fx10 (pairwise Wilcoxon test, $\alpha = 0.05$), indicating that the strains do not respond at the same time to their changing environment (pairwise Wilcoxon test $\alpha = 0.05$).

This first experiment confirms previous studies showing the steady increase of *HSP12* expression during the alcoholic fermentation.[20] Indeed, a linear correlation between CO_2 produced and *HSP12* expression was found (Spearman $\rho = 0.71$, $p_{val} = 2.89 \times 10^{-6}$), suggesting that ethanol concentration and fermentation progression might trigger in part *HSP12* expression. The strain VL3 seems to be generally more stressed than Fx10 with an earlier induction of *HSP12* expression. Accordingly, the strain VL3 showed a longer CO_2 production kinetics, finishing 3 days after Fx10 (data not shown). This first experiment suggested that the expression level of *HSP12* is concomitant with the increasing level of ethanol in wine, corroborating the results obtained in previous studies.[23]

In aqueous solution, ethanol exhibits a sweet taste but also an antagonist bitterness.[41,42] Previous works have showed that this compound has no significant effect on wine sweetness.[3,4] In accordance with these results, we have recently demonstrated that the addition of 1.5% v/v ethanol to a wine does not increase its sweet taste.[5] These data suggest that ethanol has no direct impact on wine sweet taste. Nevertheless, some tasters frequently point out that wines with high levels of alcohol often exhibit an intense sweet taste.[2] Consequently, this empirical relationship between ethanol level and sweetness intensity could be indirect and interpreted through the effect of Hsp12p. Indeed, a higher level of ethanol could lead to an increased

J. Agric. Food Chem. 2015, 63, 304−311

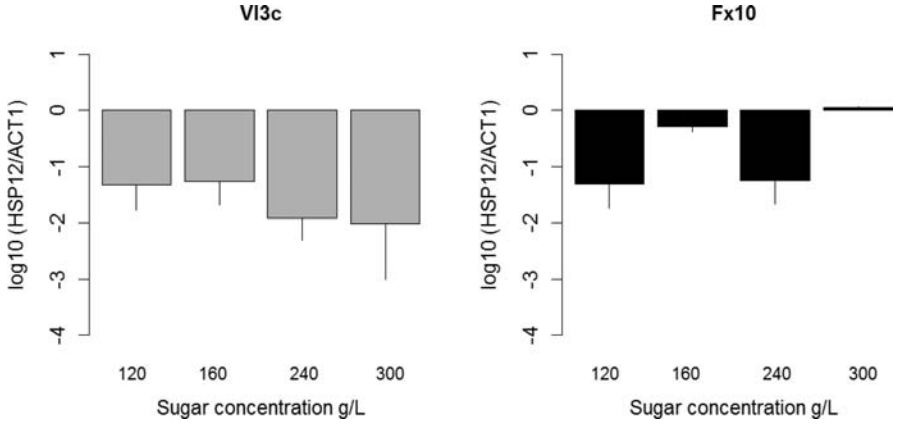

Figure 2. Sugar concentration does not affect the *HSP12* expression level at 26 °C. Fermenting biomass samples were collected at mid fermentation (46 g/L of CO_2 produced) from different synthetic musts containing 120, 160, 240 and 300 g/L initial sugar and fermented at 26 °C. The average of the *HSP12* expression is shown on the bar plot (expressed as the logarithm of *HSP12/ACT1* ratio). Bar errors indicate the standard error of the three replicates.

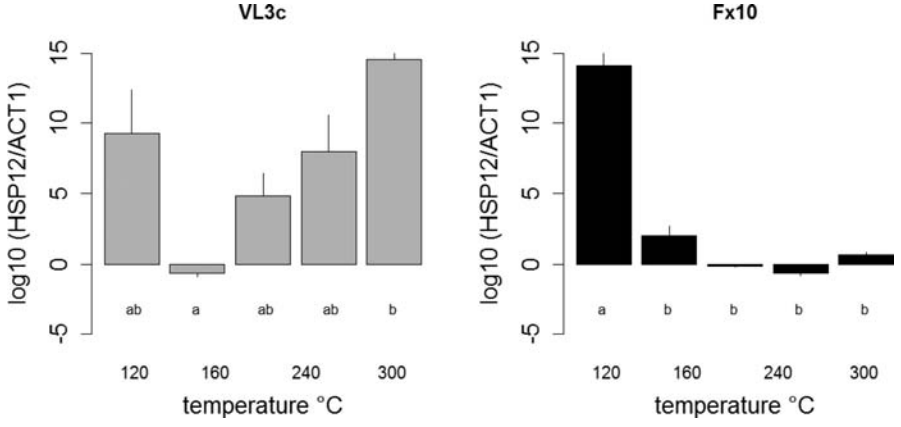

Figure 3. Temperature has a strong effect on *HSP12* expression level. Fermenting biomass samples was collected at mid fermentation (46 g/L of CO_2 produced) from a synthetic must containing 240 g/L initial sugar and fermented at different temperatures of 12, 18, 22, 26, and 31 °C. The average of the *HSP12* expression is shown on the bar plot (expressed as the logarithm of *HSP12/ACT1* ratio). Bar errors indicate the standard error of the three replicates. A two-way analysis of variance was carried out to estimate the strain and temperature and their interaction ($Y = \mu + \text{strain}^{i} + \text{temperature}^{j} + \varepsilon^{ij}$). A significant effect was found for yeast strains and temperature × strain interaction. The letters below the bar plot indicate groups with a statistical difference according to the linear model used (Duncan test, $\alpha = 0.05$).

expression of this protein at the end of alcoholic fermentation, thus increasing the sweet taste of wine.

Temperature and Sugar Concentration Differentially Influenced *HSP12* Expression. In this section, the transcriptional response of the *HSP12* gene for osmotic pressure and temperature was investigated using the same two yeast starters (VL3 and Fx10) in a synthetic grape must. For the osmotic stress response, fermentations were carried out at 26 °C with initial sugar amount varying from 120 to 300 g/L. Fermenting yeast was sampled when the CO_2 produced reached 46 g/L. In fact, at this fermentation point, both strains showed a similar expression level (Figure 1), allowing comparison of other factors. Therefore, this point was chosen to measure the specific effect of sugar concentration by dissociating it from ethanol impact. As expected, sugar content has a strong impact on the successful completion of fermentation. Strains Fx10 and VL3 left, respectively, 9 and 43 g/L of residual sugars in the highest sugar conditions (data not shown). In contrast, we did not detect any significant changes between *HSP12* expression fold for both strains. This result suggested that sugar content in must did not affect per se the expression of this gene (Figure 2). Although the *HSP12* gene is activated by the HOG pathway,[43] this lack of expression induction due to high sugar concentration has been previously described in industrial conditions.[21]

To analyze the *HSP12* response to temperature, isothermal fermentations (12, 18, 22, 26, or 31 °C) were carried out in a synthetic must containing 240 g/L sugars. Samples of both Fx10 and VL3 were taken when the CO_2 produced reached 46 g/L. Contrary to sugar content, the temperature drastically modified the expression level of *HSP12* (Figure 3). For both strains, high *HSP12* expression values were found at low temperature (12 °C), confirming the strong induction of this gene in cold conditions.[24] With warmer temperatures, strains responded in a different manner. At 18 °C, VL3 and Fx10 showed similar expression profiles. However, when fermentation temperature was higher, the *HSP12* expression level strongly increased for VL3 (>10-fold). These findings confirmed that the white wine starter VL3 is quite sensitive to temperature as previously shown for heat shock resistance.[31] In contrast, Fx10 showed a steady expression level of *HSP12* between 18 and 31 °C, which corroborates the good adaptation of this strain to high temperatures and its use for red grape fermentation.[33] The strong strain × temperature effect found

DOI: 10.1021/jf504408t
J. Agric. Food Chem. 2015, 63, 304−311

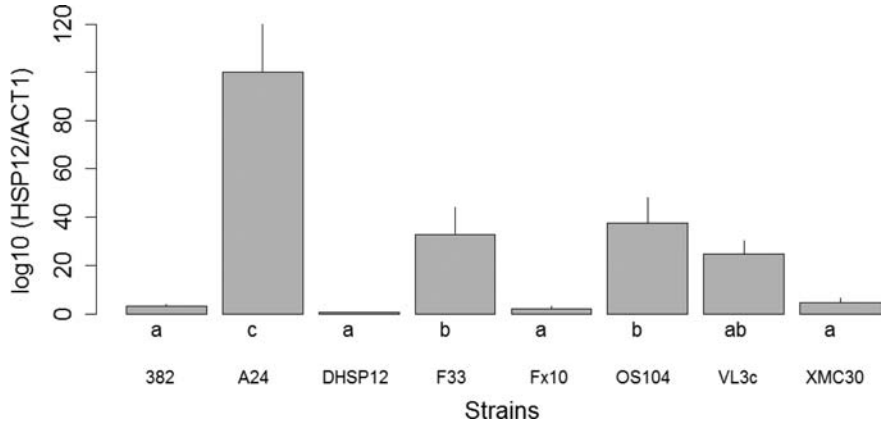

Figure 4. The *HSP12* expression level differs according to the strains at mid fermentation. Fermenting biomass of eight yeast strains was collected at mid fermentation (46 g/L of CO_2 produced) from a synthetic must containing 240 g/L initial sugar and fermented at 26 °C. The average of the *HSP12* expression is shown on the bar plot (expressed as the logarithm of *HSP12/ACT1* ratio). Bar errors indicate the standard error of three replicates. A one-way analysis of variance was carried out to estimate the strain effect ($Y = \mu + \text{gene}^i + \varepsilon^i$). The letters below the bar plot indicate groups with a statistical difference according to the linear model used (Duncan test, $\alpha = 0.05$).

(24% of total variance explained) by analysis of variance highlighted that yeast strains and fermentation temperature might affect drastically both the expression level of *HSP12* mRNA and its related protein amount.

Even if fermentation temperature significantly influences the *HSP12* expression, this parameter does not appear to be really relevant as a possible tool to modulate the sweetness intensity in enological conditions. In fact, fermentation temperature deeply affects the overall organoleptic profile,[44,45] and high temperatures (>30 °C) are detrimental to completion of fermentation.[33] In white winemaking, the temperature must be controlled when fermentation is run in high-capacity fermenting tanks to avoid these risks. Furthermore, low temperatures (<18 °C) drastically affect the aromatic expression of wine due to the increase of ester synthesis by yeast.[44] Thus, low temperatures are not recommended for the elaboration of complex white wines.[46] In the case of white winemaking in oak barrels, the fermentation temperatures remain close to the cellar temperature and are most of the time not controlled. Therefore, they are often higher than in stainless steel tank fermentation (from 22 to 25 °C).[46] Such a winemaking process could therefore result in higher *HSP12* expression and, combined with the release of sweet compounds from oak wood,[8] may produce a more intense sweetness in the final product.

In red winemaking, whereas the wine temperature should be maintained at 26−28 °C to avoid stuck fermentation, post-fermentation maceration is sometimes achieved at higher temperatures (30−32 °C).[46] During this period, part of the yeast biomass is still metabolically active and may have a *HSP12* expression shift that could increase the concentration of the related protein.

Yeast Strain Background Affects *HSP12* Expression during Alcoholic Fermentation. The impact of yeast strains on the expression of *HSP12* was then assayed during alcoholic fermentation. For these studies we used four commercial starters (VL3, Fx10, XMC30, and F33), the Δ°hsp12 strains (isogenic to Fx10), and three yeast strains from other biotopes (brewery = B1, distillery = D2, and oak exudate = W1). These three last strains showed sluggish CO_2 kinetics and were unable to ferment the totality of the synthetic must (data not shown). As *HSP12* expression is linked to the relative amount of produced ethanol, all of the fermenting yeasts were sampled when the accumulative produced CO_2 was close to 46 g/L. At this sampling point, all of the strains showed a high viability (>85%) and were fermenting actively. As shown in Figure 4, the *HSP12* expression ranged about 34-fold between extreme individuals. Four distinct groups were statistically determined (Duncan test, $\alpha = 0.05$). The nonenological strains D2 and W1 expressed the highest quantity of *HSP12* mRNA, whereas some wine starters F10, Fx10, and XMC30 showed the lowest values. Nevertheless, no significant correlations were found between fermentation phenotypes and *HSP12* expression level (data not shown), which was likely due to the small set of strains studied in this work. To our knowledge, few studies investigated the expression level of several strains during the wine alcoholic fermentation. In previous studies, similar variations were found between unrelated strains.[31] However, the *HSP12* expression level was estimated after the application of a heat shock situation not frequently found in controlled enological conditions. Our results confirmed that the mRNA expression level of *HSP12* is strongly affected by the strain used.

Impact of the Yeast Strain on the Sweetness Perception after Lees Aging. Our data confirmed a strong variability for *HSP12* gene expression within yeast strains. The role of this gene product on sweetness perception suggested that yeast strain may affect the sweetness of wine during lees aging. Because yeast strains affected wine taste for many factors (i.e., acetic acid, residual sugars, esters...[47]), the direct comparison of wines fermented with different strains does not allow verifying rigorously this hypothesis. To overcome this problem, we fermented a Merlot grape juice with the strain Δ°hsp12 to obtain a red wine exempted of Hsp12p protein and related peptides. Yeast biomass of eight different strains was added to this wine, and a post-fermentative maceration was carried out for 10 days as described under Materials and Methods. The biomass was harvested at the mRNA quantification point (46 g/L CO_2) from the eight strains previously described. Because of the small quantities of residual sugars (<2 g/L), yeasts were not able to develop and were degraded following autolysis mechanisms.

The application of Page methodology (Table 3) showed that the sensory training tests were significant at 1% in both matrices. The implementation of this methodology resulted in

Table 3. Results of the Panel Training to Sweetness Perception[a]

matrix	R_1	R_2	R_3	R_4	L	L'[b]
model solution	30	36	47	57	471	3.86**
red wine	26	34	46	64	488	5.29**

[a] R_1, R_2, R_3, and R_4 are the sums of ranks for addition of, respectively, 0, 3, 6, and 12 g/L of sucrose. L and L′ were calculated as described in ISO 8587:2006[38] for the Page test: $L = \sum_{i=1}^{p} iR_i$ and $L' = (12L - 3np(p+1)^2)/(p(p+1)(n(p-1))^{1/2})$ (n is the number of panelists and p the number of modalities/treatments). [b] Significance: ns, nonsignificant ($L' < 1.645$); *, significant at 5% ($L' \geq 1.645$); **, significant at 1% ($L' \geq 2.326$)

the successful creation of a panel trained to perceive differences of sweetness intensity in both a model solution and a red wine. The results demonstrate their ability to classify wines following sweet intensity even in a matrix such as red wine containing numerous sapid compounds that are likely to interact with sweetness perception.

The eight resulting wines obtained after the post-fermentation maceration were submitted to sensory analysis to assay their sweetness intensity. Panelists were asked to rate sweetness on a scale from 0 to 7. A two-way analysis of variance was used (Figure 5) and demonstrated that there was no "panelist effect". In contrast, the results showed a strong "yeast strain effect", allowing the discrimination of five distinct groups of sweetness intensity among the eight modalities (Duncan's test, $\alpha = 0.05$). The base wine was the same for all of these modalities, and the only difference was the yeast strain used for lees aging. Consequently, this sensory study clearly establishes that yeast strain influences the sweet taste of wine. Previous works showed that yeast strain has a strong influence on white wine aroma,[48,49] and a recent study suggests a similar effect for fruity red wine aroma revelation.[50] Here, we demonstrated for the first time that the taste of wine was also affected by the yeast strain during autolysis. This parameter appears as an effective factor to modulate wine sweetness and such sweetening effect could therefore be taken into consideration as an additional relevant criterion to select industrial yeast strains.

Moreover, the wine aged with the strain Δ°hsp12 received the lowest rate (Figure 5), whereas the one aged with W1 was perceived as the sweetest. Among the commercial starters used for red winemaking, Fx10 and XMC30 provided more sweetness to wine than F33. More generally, we observed a weak correlation between *HSP12* expression and sweetness intensity (Kendall correlation test, $T = 22$, p value = 0.0601), suggesting that Hsp12p might contribute to the sweetness modulation consecutive to yeast autolysis. The imperfect correlation observed can be due to different causes. First, the correlation was established with yeast samples collected at mid fermentation, which does not reflect exactly the final expression level of this gene. In fact, as shown in Figure 1, the *HSP12* expression level can vary drastically during the alcoholic fermentation. However, we chose this sampling point to compare strains with an active fermentation and showing the same viability level (>85%). As some strains (W1, D2) used were unable to finish the alcoholic fermentation, a sampling point at mid fermentation was the most relevant choice. This correlation should be also much clearer using more strains or by measuring directly the expression level of Hsp12p protein instead of quantifying the mRNA level. However, independent

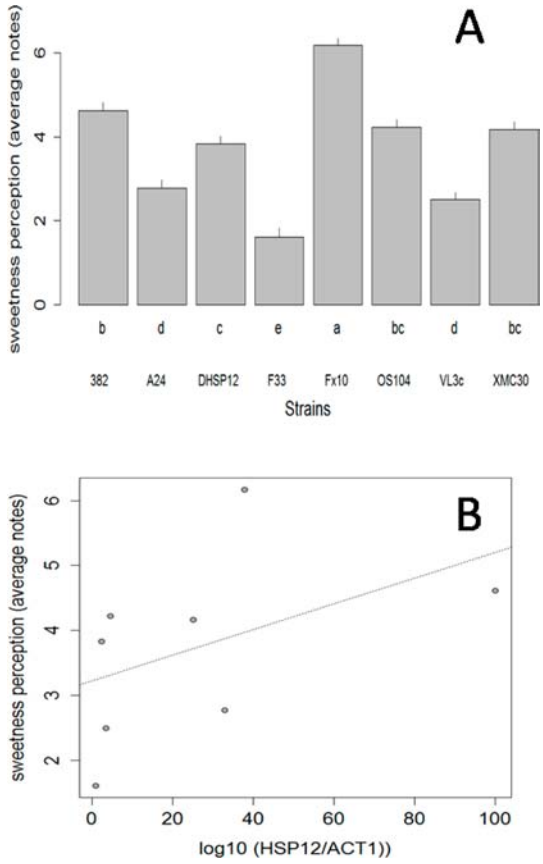

Figure 5. Wine in contact with lees obtained from different yeast strains showed marked differences in sweetness perception. (A) A wine without Hsp12p was obtained by fermenting a Merlot juice with Δ°hsp12. Yeast biomass of eight different strains was added to this wine, and aging on lees was carried out at 32 °C for 10 days. This biomass was collected from fermenting cells at 46 g/L of CO_2 produced. After wine centrifugation, a panel tasted the modalities, and the sweetness intensity was rated on a scale from 0 to 7. Bar errors indicate the standard error of 17 notes. A two-way analysis of variance was used to estimate the strain effect ($Y = \mu + \text{strain}^i + \text{panel}^j + \varepsilon^{ij}$). The letters below the bar plot indicate groups with a statistical difference according to the linear model used (Duncan test, $\alpha = 0.05$). (B) Relationship between sweetness perception and expression level of *HSP12* (Kendall correlation test, $T = 22$, p value = 0.0601).

experimental data suggest that in the case of the *HSP12* gene, the mRNA and protein expression are well correlated.[51] Moreover, in a previous work we quantified by shotgun proteomics the relative abundance of Hsp12p for some strains used in this study.[30] For example, strains W1 and D2 exhibited a high expression level of Hsp12p, whereas strain B1 showed a much lower expression; these results sustain the results found in the present study.

This work provides new insights concerning the fermentative parameters modulating wine sweetness by means of *HSP12* expression. The exact implication of the Hsp12p protein and the factors influencing its release in wine need further investigations to better control and rationalize the post-fermentative processes.

Contribution of Phenolic Compounds to Food Flavors: Strecker-Type Degradation of Amines and Amino Acids Produced by *o*- and *p*-Diphenols

Rosa M. Delgado, Rosario Zamora, and Francisco J. Hidalgo*

Instituto de la Grasa, Consejo Superior de Investigaciones Científicas, Avenida Padre García Tejero 4, 41012 Seville, Spain

ABSTRACT: The ability of 20 phenolic derivatives to produce the Strecker-type degradation of phenylalanine and phenylglycine methyl ester was studied to investigate both the direct degradation of amino acids and amines by phenolic compounds in the absence of added oxidants and the effect of the number and positions of hydroxyl groups in the aromatic ring of the phenolic compound in relation to its ability to produce carbonyl derivatives from amino compounds. The obtained results showed that polyphenols can produce the Strecker degradation of amino acids and amines in the absence of added oxidants. The only requisite for producing the reaction is the presence of two hydroxyl groups in ortho or para positions. However, the presence of two hydroxyl groups in meta position in an additional aromatic ring can inhibit the Strecker-degrading ability of the hydroxyl groups in ortho or para positions. A reaction pathway that explains all of these findings is proposed. In addition, the effect of reaction conditions on the obtained reaction yields was studied. Activation energies (E_a) for phenylacetaldehyde formation from phenylalanine in the presence of hydroquinone, 1,2,4-trihydroxybenzene, and benzoquinone were 32.9, 31.5, and 28.8 kJ/mol, respectively.

KEYWORDS: *amine degradation, amino acid degradation, phenols, quinones, Strecker-type degradation*

INTRODUCTION

Phenolic compounds contribute to food flavors in multiple ways. Thus, and because of their bitterness or astringency, phenolic compounds have a significant role in the flavor of foods and drinks such as beer, wine, tree nuts, chocolate, coffee, tea, fruit-based products, and soy products.[1−3] In addition, and because of their antioxidant properties, they participate in the lipid oxidation process that takes place in many foods upon processing. In these foods they play a major role in the inhibition of the production of lipid-derived off-flavors.[4−6] Furthermore, because some phenols are able to react with carbonyl compounds, they are able to modify the flavor-generating reactions in which these carbonyl compounds are involved. This occurs, for example, in the flavor and off-flavor development via Maillard chemistry.[7−9] Moreover, phenolic compounds are able to scavenge lipid-derived carbonyl compounds that play a significant role in the flavor of foods.[10]

In addition to all of these roles, phenolic compounds can also be transformed either enzymatically or nonenzymatically into quinones, and quinones are able to degrade amino acids with major consequences in the flavor of foods.[11,12] Thus, for example, Rizzi[13] converted catechol moieties into *o*-quinones by using ferricyanide ion as the oxidant at 22 °C in pH 7.17 phosphate buffer, and these quinones were able to convert amino acids into their corresponding Strecker aldehydes.

Although different studies have shown that amino acids can be degraded by quinones, to the best of our knowledge the direct degradation of amino acids by phenolic compounds in the absence of added oxidants has not been described. Furthermore, the effect of the number and positions of hydroxyl groups in the aromatic ring of the phenolic compound in relation to its potential for degrading amino acids is not known.

In an attempt to understand the structural characteristics of phenolic compounds that favor their ability to degrade amino acids, this study analyzes the role of 20 phenolic compounds on phenylalanine degradation in a buffered model system analogous to that employed previously in the study of amino acid degradation by lipid oxidation products.[14] Phenylalanine was selected as model amino acid because its Strecker aldehyde phenylacetaldehyde has a high boiling point (195 °C), can be easily determined by gas chromatography−mass spectrometry (GC-MS), and is a very powerful odorant.[15]

MATERIALS AND METHODS

Chemicals. Twenty phenolic compounds were employed in this study. They were simple phenolic compounds having two or three hydroxyl groups, phenolic derivatives having also alkyl, methoxy, or carboxylic groups, and complex phenolic compounds having more than one aromatic ring (Figure 1). To facilitate their study, they were classified into five groups: *o*-diphenols, *m*-diphenols, *p*-diphenols, trihydroxy derivatives, and complex phenols. These groups also included some analogues for comparison purposes. All of these phenolic compounds as well as the other employed chemicals were purchased from Aldrich (Milwaukee, WI, USA), Sigma (St. Louis, MO, USA), Fluka (Buchs, Switzerland), or Merck (Darmstadt, Germany) and were of analytical grade.

Formation of Phenylacetaldehyde in Phenylalanine/Phenol Reaction Mixtures. Mixtures of phenylalanine (25 μmol) and the phenolic compound (0−30 μmol) in 500 μL of 0.3 M buffer were introduced in closed test tubes and heated in a heater block at 120−180 °C for 0−1 h. The following buffers were employed: sodium

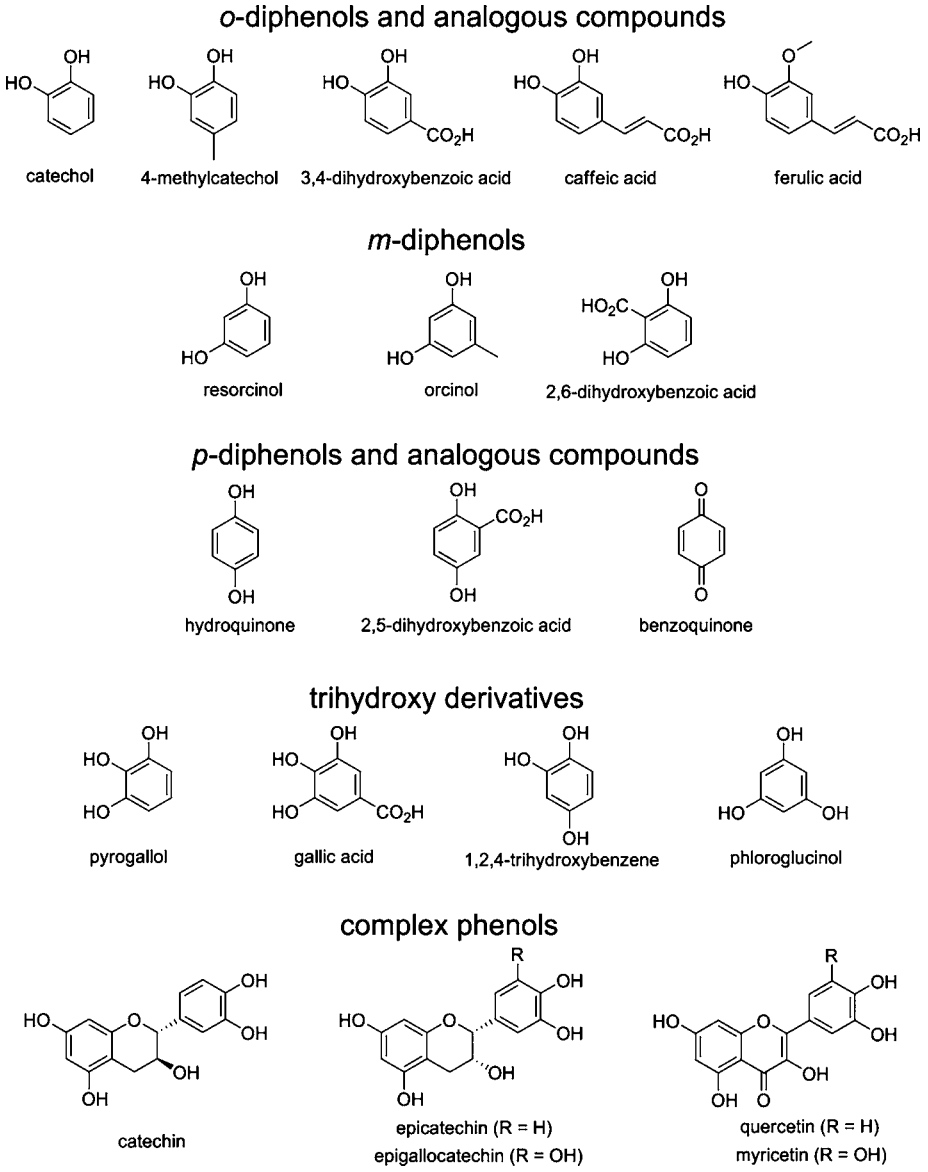

Figure 1. Phenolic compounds employed in this study.

citrate for pH 3−6 and sodium phosphate for pH 6−8. After cooling (10 min at room temperature), reaction mixtures were diluted with 1 mL of acetonitrile and 50 μL of internal standard solution (54.8 mg of methyl heptanoate in 25 mL of ethanol). Phenylacetaldehyde was determined by GC-MS.

Formation of Methyl 2-Oxo-2-phenylacetate, Benzaldehyde, Benzoic Acid, and Methyl Benzoate in Phenylglycine Methyl Ester/Phenol Reaction Mixtures. Equimolecular mixtures of phenylglycine methyl ester and either hydroquinone or benzoquinone (10 μmol of each) in 500 μL of 0.3 M sodium citrate buffer, pH 3, were introduced in closed test tubes and heated at 180 °C for 1 h. After cooling (10 min at room temperature), reaction mixtures were studied by GC-MS to determine the formed reaction products.

GC-MS Analyses. GC-MS analyses were conducted with a Hewlett-Packard 6890 GC Plus coupled with an Agilent 5973 MSD (mass selective detector, quadrupole type). A fused-silica HP5-MS capillary column (30 m × 0.25 i.d.; coating thickness, 0.25 μm) was used, and 1 μL of sample was injected in the pulsed splitless mode. Working conditions were as follows: carrier gas, helium (1 mL/min at constant flow); injector, 250 °C; oven temperature programmed from 40 °C (1 min) to 240 °C at 5 °C/min and then to 300 °C at 10 °C/min; transfer line to MSD, 280 °C; ionization EI, 70 eV; ion source temperature, 230 °C; mass range, 28−550 amu.

Determination of Phenylacetaldehyde Content. Quantification of phenylacetaldehyde was carried out as described previously[14] by preparing standard curves of phenylacetaldehyde in the 1.55 mL of solution prepared for GC-MS injection. Ten different concentration levels of phenylacetaldehyde were used. Phenylacetaldehyde content was directly proportional to the aldehyde/internal standard area ratio (r = 0.999, p < 0.0001). The coefficients of variation were <10%.

Statistical Analysis. All data given are mean ± SD values of, at least, three independent experiments. Statistical comparisons among different groups were made using analysis of variance. When significant F values were obtained, group differences were evaluated by the Tukey test.[16] Statistical comparisons were carried out using Origin v. 7.0 (OriginLab Corp., Northampton, MA, USA). The significance level is p < 0.05 unless otherwise indicated.

RESULTS

Formation of Phenylcetaldehyde in Phenylalanine/Phenol Reaction Mixtures. The ability of 20 phenolic compounds to convert phenylalanine into phenylacetaldehyde was investigated by heating 10 μmol of the phenol and 25 μmol

DOI: 10.1021/jf5047317
J. Agric. Food Chem. 2015, 63, 312−318

of the amino acid in sodium citrate buffer, pH 3, for 1 h at 180 °C. The obtained results (Table 1) showed that there was a relationship between the structure of the assayed phenol and its ability to produce phenylacetaldehyde.

Table 1. Formation of Phenylacetaldehyde in Mixtures of Phenylalanine and Phenols[a]

phenol tested	phenylacetaldehyde formed (μmol/mmol of phenylalanine)
none	10.7 ± 2.2 a
catechol	30.3 ± 2.4 b,c
4-methylcatechol	36.7 ± 4.2 b,d
3,4-dihydroxybenzoic acid	19.2 ± 5.5 e,f
caffeic acid	22.0 ± 1.7 e,g
ferulic acid	8.5 ± 0.8 a
resorcinol	11.1 ± 1.0 a
orcinol	11.5 ± 1.1 a
2,6-dihydroxybenzoic acid	10.6 ± 2.1 a
hydroquinone	29.5 ± 1.9 b,c
2,5-dihydroxybenzoic acid	24.9 ± 5.7 c,e,g
benzoquinone	66.1 ± 2.0 h
pyrogallol	43.2 ± 4.5 d,i
gallic acid	27.5 ± 1.5 c,g
1,2,4-trihydroxybenzene	46.0 ± 1.5 i
phloroglucinol	9.2 ± 1.5 a
catechin	10.9 ± 1.8 a
epicatechin	11.2 ± 1.8 a
epigallocatechin	11.9 ± 2.4 a,f
quercetin	11.9 ± 0.4 a
myricetin	12.9 ± 1.9 a,f

[a]Values with the same letter in the same column are not significantly different ($p < 0.05$).

For polyphenols having two hydroxyl groups at the aromatic ring, only those having these groups in ortho or para positions were able to produce the Strecker degradation of the amino acid to a higher extent than the control phenylalanine. For that reason, neither resorcinol, orcinol, nor 2,6-dihydroxybenzoic acid produced more phenylacetaldehyde than the control (Table 1). In addition, the presence of the two hydroxyl groups is needed, and one hydroxyl group cannot be replaced by a methoxy group. For that reason, ferulic acid did not produce more phenylacetaldehyde than the control. On the contrary, caffeic acid was able to increase phenylacetaldehyde formation by 106%.

There was not any difference between the Strecker degradation ability of *o*- and *p*-diphenols. Thus, catechol and hydroquinone increased the phenylacetaldehyde produced by the control by about 180%. However, the presence of other groups in the ring and the relative positions of all groups determined either an increase or a decrease in the phenylacetaldehyde produced. Thus, a methyl group at position 4 (4-methylcatechol) increased the formation of phenylacetaldehyde by 33% with respect to that formed by catechol. On the contrary, the presence of a carboxylic group at the same position (3,4-dihydroxybenzoic acid) reduced the formation of phenylacetaldehyde by 57% with respect to that formed by catechol. Curiously, the same carboxylic group only reduced by 24% the formation of phenylacetaldehyde with respect to that formed by hydroquinone in 2,5-dihydroxybenzoic acid. Finally, the presence of a conjugated carbon−carbon double bond at position 4 (such in caffeic acid) also reduced the phenylacetaldehyde formed by catechol by 42%.

When three hydroxyl groups were present, the relative positions of the hydroxyl groups determined the activity. Thus, the presence of two hydroxyl groups at ortho or para positions was required to observe an increased phenylacetaldehyde formation. For that reason, phloroglucinol did not increase phenylacetaldehyde formation in comparison to the control. On the contrary, both pyrogallol and 1,2,4-trihydroxybenzene increased phenylacetaldehyde formation. This increase was higher than that exhibited by catechol and hydroquinone, more likely because the number of hydroxyl groups in ortho or para positions was higher in these trihydroxy derivatives than in the dihydroxy derivatives. The increases in phenylacetaldehyde formation with respect to control were 304 and 330% for pyrogallol and 1,2,4-trihydroxybenzene, respectively. The introduction of a carboxylic group in the ring, such as in gallic acid, decreased the amount of phenylacetaldehyde formed by 48% with respect to that produced by pyrogallol.

Complex phenols, such as those shown in Figure 1, usually have several aromatic rings with different substitutions. Thus, they may have two hydroxyl groups in meta position at the A-ring, which according to the above results did not seem to contribute to phenylacetaldehyde formation. In addition, they may have several hydroxyl groups, usually in ortho positions at the B-ring, which should be contributing to phenylacetaldehyde formation, also according to the above results. Despite these hydroxyl groups in ortho positions at the B-ring, the assayed complex phenols did not increase phenylacetaldehyde formation (Table 1).

When benzoquinone was tested in place of a phenolic derivative, this compound produced more phenylacetaldehyde than any of the assayed phenolic compounds (Table 1). In fact, it produced 195% more phenylacetaldehyde than its phenol analogue hydroquinone.

1,2,4-Trihydroxybenzene and hydroquinone, as models of tri- and dihydroxy derivatives, respectively, were selected for the rest of this study because of their ability to degrade phenylalanine to a high extent. In addition, parallel studies were also carried out with benzoquinone for comparison purposes.

Effect of Reaction Conditions (pH, Concentration of the Phenolic Compound, Time, and Temperature) on the Phenylacetaldehyde Produced in Phenylalanine/Phenol Reaction Mixtures. The formation of phenylacetaldehyde depended on the pH of the reaction (Figure 2), although this dependence was smaller than that observed in the Strecker-type degradation of amino acids produced by lipid oxidation products.[14] Thus, the formation of phenylacetaldehyde was more or less constant at pH values ≤5 and decreased at higher pH values. Because previous studies involving the Strecker degradation of amino acids were carried out at pH 3,[14] this pH was also selected for this study.

Phenylacetaldehyde formation also depended on the amount of phenol added (Figure 3). In fact, there was a linear correlation ($r > 0.99$, $p < 0.01$) between the amount of phenol added and the phenylacetaldehyde produced at low concentrations of phenol. The maximum concentrations of phenylacetaldehyde were achieved when 25 μmol of phenylalanine was treated with either 10 μmol of hydroquinone, 7.5 μmol of benzoquinone, or 5 μmol of 1,2,4-trihydroxybenzene. Addition

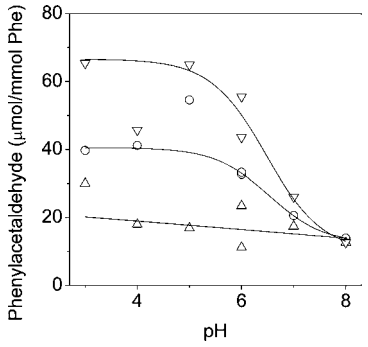

Figure 2. Effect of reaction pH on the phenylacetaldehyde produced in the reaction of phenylalanine with hydroquinone (△), 1,2,4-trihydroxybenzene (○), and benzoquinone (▽). Equimolecular mixtures of the amino acid and the phenol were heated at 180 °C for 1 h.

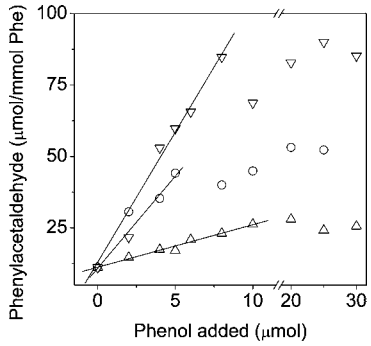

Figure 3. Effect of the concentration of the phenol on the phenylacetaldehyde produced in the reaction of phenylalanine with hydroquinone (△), 1,2,4-trihydroxybenzene (○), and benzoquinone (▽). Mixtures of the phenylalanine (25 μmol) and the phenol in 0.3 M sodium citrate buffer were heated at 180 °C for 1 h.

of higher amounts of phenolic compound did not produce significant increases in the phenylacetaldehyde produced.

Phenylacetaldehyde formation also depended on the incubation time and temperature (Figure 4). Thus, the amount of phenylacetaldehyde produced increased linearly ($r > 0.93$, $p < 0.02$) as a function of time at the different assayed temperatures when phenylalanine was heated in the presence of hydroquinone (Figure 4A). Similar behavior was observed in the case of the other two derivatives assayed: 1,2,4-trihydroxybenzene ($r > 0.97$, $p < 0.03$; Figure 4B) and benzoquinone ($r > 0.97$, $p < 0.002$; Figure 4C).

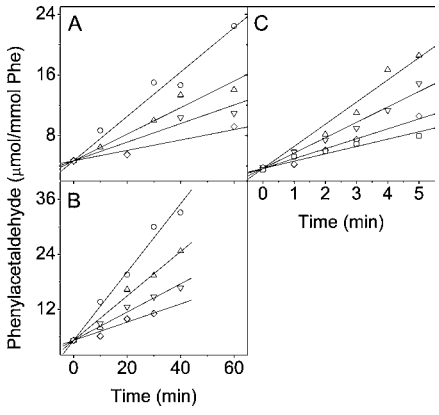

Figure 4. Time course of phenylacetaldehyde produced in the reaction of phenylalanine with (A) hydroquinone, (B) 1,2,4-trihydroxybenzene, and (C) benzoquinone. Equimolecular mixtures of phenylalanine and the phenol in 0.3 M sodium citrate buffer were heated at the indicated times and temperatures. The temperatures assayed were 180 (○), 160 (△), 140 (▽), 120 (◇), and 100 °C (□).

Reaction rates at the different assayed temperatures were calculated using the equation

$$[\text{phenylacetaldehyde}] = [\text{phenylacetaldehyde}]_0 + kt$$

where $[\text{phenylacetaldehyde}]_0$ represents the intercept, k is the rate constant, and t is the time. These rate constants were used in an Arrhenius plot (Figure 5) for calculation of the activation

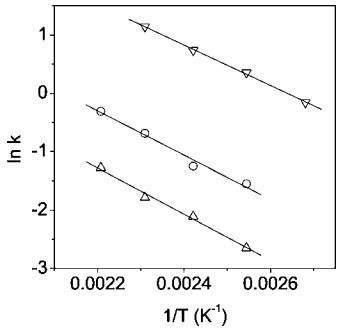

Figure 5. Arrhenius plot for phenylacetaldehyde production in the reaction of phenylalanine with hydroquinone (△), 1,2,4-trihydroxybenzene (○), and benzoquinone (▽).

energy (E_a) of phenylacetaldehyde formation from phenylalanine in the presence of phenolic compounds. The values obtained for E_a were 32.9 kJ/mol for hydroquinone, 31.5 kJ/mol for 1,2,4-trihydroxybenzene, and 28.8 kJ/mol for benzoquinone.

Strecker-Type Degradation of Phenylglycine Methyl Ester. In an attempt to clarify the mechanism of the reaction and to investigate if amines were also able to suffer Strecker-type degradation, the reaction of phenylglycine methyl ester with both hydroquinone and benzoquinone was studied under the same reaction conditions above-described for phenylalanine. Phenylglycine methyl ester was selected for this study because it has several substituents at the α-carbon that can favor the exit of the proton at this carbon.

Figure 6A shows the chromatogram obtained after 1 h of heating at 180 °C of an equimolecular mixture of hydroquinone and phenylglycine methyl ester. As observed in the figure, the initial phenylglycine methyl ester was absent after 1 h of heating, but a significant amount of hydroquinone was still present. The main reaction product was benzaldehyde, although other degradation products of phenylglycine methyl ester could be easily identified. These were the Strecker-type degradation products methyl 2-oxo-2-phenylacetate, benzoic acid, benzoic acid methyl ester, and benzaldehyde dimethyl acetal. Products derived from hydroquinone were 4-methoxyphenol and trace amounts of benzoquinone, which was unambiguously identified. 4-Aminophenol could also be present in trace amounts, but it appeared under the hydroquinone peak and could not be unambiguously identified.

When the reaction was carried out between benzoquinone and phenylglycine methyl ester, the same products as in the reaction with hydroquinone were identified in the reaction mixture, although proportions among them were slightly

J. Agric. Food Chem. 2015, 63, 312−318

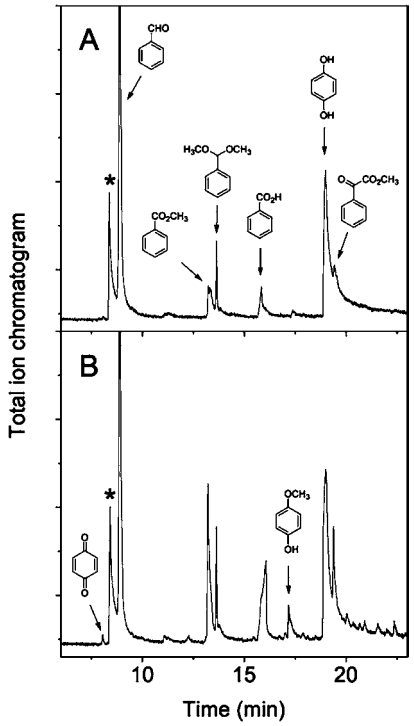

Figure 6. Total ion chromatograms obtained for reaction mixtures of phenylglycine methyl ester with (A) hydroquinone and (B) benzoquinone. Samples were heated for 1 h at 180 °C in sodium citrate buffer, pH 3. Identified compounds are indicated in the figure. Peaks marked with ∗ corresponded to the buffer.

different (Figure 6B). Thus, phenylglycine methyl ester disappeared completely after 1 h of heating at 180 °C in the presence of benzoquinone, and a part of benzoquinone was converted into hydroquinone. In addition, the residual presence of benzoquinone was detected to a higher extent than when hydroquinone was the reactant (see Figure 6A). Analogously to the hydroquinone/phenylglycine methyl ester reaction mixture, the main reaction product was benzaldehyde. Other reaction products were methyl 2-oxo-2-phenylacetate, benzoic acid, benzoic acid methyl ester, and benzaldehyde dimethyl acetal. Analogously to hydroquinone/phenylglycine reaction mixtures, the products derived from benzoquinone were 4-methoxyphenol and hydroquinone. 4-Aminophenol could also be present in trace amounts, but it appeared under the hydroquinone peak and could not be unambiguously identified.

DISCUSSION

Since its discovery more than 150 years ago,[17] the Strecker degradation of amino acids has emerged as an almost endless source of flavor-significant compounds.[12,18] Although it was considered for many years as a part of Maillard chemistry produced by carbohydrates, nowadays Strecker-type reactions are known to be also produced in the course of nonenzymatic browning reactions by other food components such as lipid oxidation products,[19,20] amines,[21] and polyphenol-derived quinones,[13] among others. The results obtained in the present study extend the number of food components able to produce the Strecker degradation of amino acids also to polyphenols in the absence of added oxidants. Nevertheless, not all polyphenols were able to produce the Strecker degradation of amino acids. Only polyphenols having some structural characteristics produced this reaction. Thus, only polyphenols having at least two hydroxyl groups in ortho or para positions were able to degrade phenylalanine. However, the presence in the same molecule of other aromatic ring with two hydroxyl groups in meta position canceled the ability of these complex phenols to degrade phenylalanine.

This behavior should be a consequence of the mechanism of the reaction. Thus, the fact that two hydroxyl groups in ortho or para positions are needed suggests that the polyphenol has to be converted into the corresponding quinone to produce the reaction. This was observed when the reaction between hydroquinone and phenylglycine methyl ester was studied by GC-MS (Figure 6A). The presence of trace amounts of benzoquinone was observed in the chromatogram, although no oxidant was added. These oxidations of *o*- and *p*-dihydroxy derivatives to the corresponding quinones have been described by different authors.[22,23] According to these findings, the reaction pathway shown in Figure 7 is proposed for the

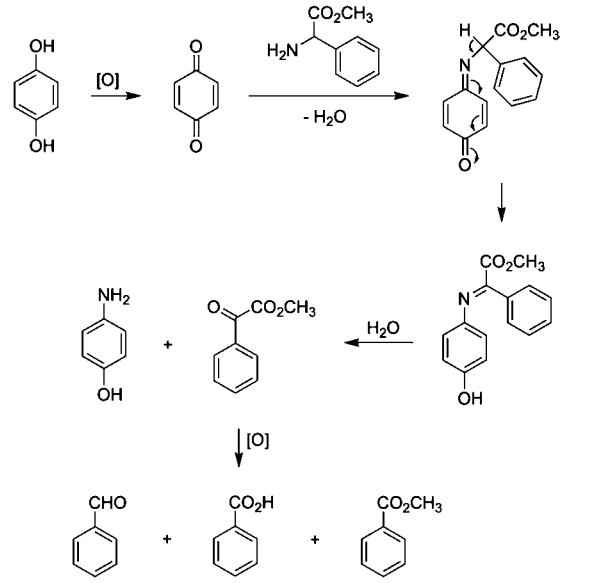

Figure 7. Proposed pathway for the reaction of phenylglycine methyl ester with hydroquinone and benzoquinone.

phenylglycine methyl ester degradation in the presence of hydroquinone. In the presence of amino compounds and air, *o*- and *p*-diphenols are able to produce the corresponding quinones to some extent. These quinones form then the corresponding imines with the amino group of the amino compound. Finally, tautomerism converts the ketoimine into the corresponding α-imino ester, the driving force being conjugation. The hydrolysis of the α-ketoimine is the origin of the Strecker-type carbonyl compound (methyl 2-oxo-2-phenylacetate) detected in the reaction and of 4-aminophenol, which was not unambiguously identified. This 4-aminophenol might be the origin of the detected 4-methoxyphenol. Methyl 2-oxo-2-phenylacetate was not stable under the employed reaction conditions as it degraded to benzaldehyde, which was the major reaction product. Benzaldehyde oxidation is likely the origin of benzoic acid and its methyl ester, although benzoic acid can also be produced directly in the cleavage of methyl 2-oxo-2-phenylacetate.

A similar pathway is likely taking place with phenylalanine (Figure 8). In this case, the produced α-iminocarboxylic acid intermediate decarboxylates to the corresponding *N*-(4-

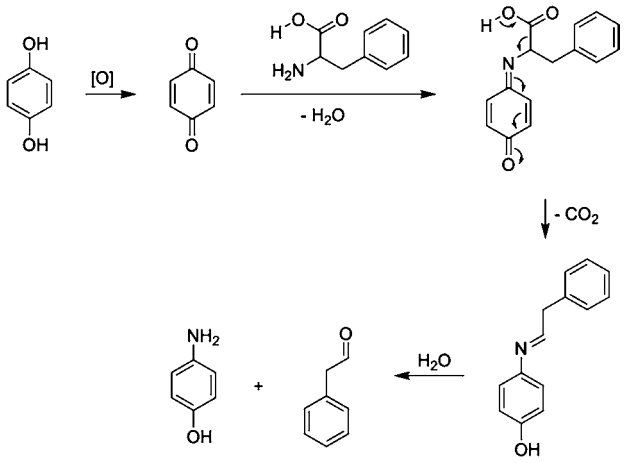

Figure 8. Proposed pathway for the reaction of phenylalanine with hydroquinone and benzoquinone.

hydroxyphenyl)aldimine. After hydrolysis of the latter aldimine, phenylacetaldehyde is produced.

These pathways explain the relative activities of simple di- and trihydroxy derivatives, which are related to their relative facility to be converted into quinones. In addition, the electronic effects of other substituents in the ring will also play a role in the overall reaction yield. On the contrary, it does not explain the low yields of phenylacetaldehyde obtained with complex phenols. These last results are likely a consequence of two opposite effects. On the one hand, the above results demonstrate that *o*- and *p*-diphenols are easily transformed into quinones, and these derivatives are able to convert amino acids and amines into their corresponding carbonyl derivatives. On the other, *m*-diphenols have been shown to be very efficient carbonyl scavengers.[10,24,25] The obtained results seem to suggest that the carbonyl-scavenging ability of the A-ring is higher than the Strecker-inducer capacity of the B-ring. Only myricetin, which has a pyrogallol moiety in the B-ring, seemed to increase slightly the phenylacetaldehyde produced in comparison to control, although this increase was not significant.

A further proof of this pathway was obtained when the reaction between benzoquinone and phenylglycine methyl ester was studied. The reaction not only produced compounds identical to those of the hydroquinone/phenylglycine methyl ester reaction mixtures but significant amounts of hydroquinone were found, therefore confirming the existence of redox processes in these mixtures that would facilitate the conversion of benzoquinone into hydroquinone and vice versa. For the same reason, the appearance of benzoic acid as an oxidation product of benzaldehyde is not surprising. The only differences between benzoquinone and hydroquinone for these reactions are the reaction yield, which was higher for benzoquinone (Table 1 and Figure 3), and the lower reaction time needed for benzoquinone to produce phenylacetaldehyde (Figure 4). Both results are in agreement with the conversion of hydroquinone into benzoquinone as a previous step for the Strecker degradation. Nevertheless, E_a for phenylacetaldehyde formation in benzoquinone/phenylalanine reaction mixtures was only slightly lower than E_a for phenylacetaldehyde formation in hydroquinone/phenylalanine reaction mixtures, therefore indicating that conversion of hydroquinone into benzoquinone is not an energetically difficult process, although it does not seem to be very favored kinetically.

All of these results confirm that polyphenols can produce the Strecker degradation of amino acids in the absence of added oxidants. In addition, analogous reactions can also be produced in amines, therefore demonstrating that the presence of the carboxylic group might be desirable but not essential. The only requisite for polyphenols to produce Strecker-type degradations is the presence of two hydroxyl groups in ortho or para positions. On the other hand, the presence of two hydroxyl groups in meta position in another part of the molecule can inhibit the Strecker-degrading ability of the hydroxyl groups in ortho or para positions.

Application of High-Intensity Ultrasound to Palm Oil in a Continuous System

Yubin Ye and Silvana Martini*

Department of Nutrition, Dietetics, and Food Sciences, Utah State University, 8700 Old Main Hill, Logan, Utah 84322-8700, United States

Supporting Information

ABSTRACT: High-intensity ultrasound (HIU) was used in a continuous system to change the crystallization behavior of palm oil. Different power levels (75, 110, and 180 W) and pulse durations (continuous application and 5, 10, and 15 s pulses) were used to optimize sonication conditions. Results showed that HIU applied at low power level (75 W) was the most efficient condition in inducing palm oil crystallization at 35 °C, generating a crystalline network with higher solid fat content (SFC), higher elasticity, and sharper melting profile after 60 min of crystallization. Changes in elasticity observed as a consequence of sonication were maintained after tempering the samples at 25 °C for 24 h, but were lost after tempering at 5 °C. No significant differences (α = 0.05) were observed in SFC values of the sonicated and nonsonicated samples after tempering, whereas the sharper melting behavior observed in the sonicated sample was maintained after tempering.

KEYWORDS: *high-intensity ultrasound, flow cell, power level, crystallization, palm oil, polymorphism*

INTRODUCTION

Power ultrasound, or high-intensity ultrasound (HIU), is an invasive technique that uses acoustic waves operating at low frequency (20−100 kHz) and high power (10−10000 W cm^{-2}) levels. These acoustic waves travel through the material and induce the formation of cavities.[1] Cavitation is associated with high localized temperatures, high shear forces, and high pressures that lead to several physicochemical changes in the material.[2] Some of these changes include the generation of chemical reactions (sonochemistry),[3,4] changes in crystallization behavior (sonocrystallization),[5,6] and changes in physical properties of materials.[7−9] In particular, sonocrystallization is defined as the phenomenon associated with the induction or modification of the crystallization behavior of different materials without generating any chemical changes.[10] Sonocrystallization techniques have been used in food applications since the early 2000s. Chow et al. used HIU to modify the primary and secondary nucleation of ice and sucrose,[11,12] whereas Patel et al. showed that power ultrasound can be used to control the crystallization process of lactose during the nucleation phase.[13] Early studies in lipid systems were performed by Patrick et al., who evaluated the effect of ultrasonic intensity on palm oil crystalline structures.[14] Sato and co-workers used HIU in cocoa butter and pure triacylglycerols[15,16] and showed that HIU induces lipid crystallization as evidenced by shorter induction times in sonicated samples. In addition, these authors showed that HIU promotes the formation of a stable polymorphic form, especially at high crystallization temperatures.

Previous work in our laboratory[17−20] and by other research groups[21] indicates that HIU can be used as a novel processing tool to modify the functional properties of lipids. HIU has the ability to change the crystallization behavior of lipids and therefore their functional properties such as texture, thermal behavior, solid/liquid ratio, and crystal size.

All previous studies about lipid sonocrystallization have been performed in a batch with volumes between 5 and 100 mL.[16−21] The effect of HIU on the crystallization of lipids in a continuous system has never been investigated.

The purpose of this research is to evaluate the use of HIU in a continuous system, which is a more realistic representation of an industrial setting. The overall objective of this research is to optimize the processing conditions (power level and irradiation pulse) needed to use HIU in a continuous system to modify the physical properties (microstructure, melting profiles, polymorphism, and viscoelasticity) of palm oil.

MATERIALS AND METHODS

Materials. Refined, bleached, and deodorized palm oil provided by Archer Daniels Midland (ADM Oils, Oils Division, Chicago, IL, USA) was used in this experiment. The melting point of the palm oil is 37.2 ± 0.4 °C (AOCS Official Method Cc 1-25). The chemical composition of the sample consisted of 48% of saturated fatty acids, 40% of monounsaturated fatty acids, 10% of polyunsaturated fatty acids, and 2% of *trans*-fatty acids according to the product data sheet provided by ADM.

Sample Preparation and Continuous System. The continuous system consisted of a flow cell connected to a sonicator and an external water bath (Figure 1). Five liters of palm oil was placed in a 6 L Erlenmeyer flask and melted in a 70 °C water bath to completely erase crystal memory. The flask was then placed in a 40 °C water bath to allow for temperature stabilization. Once the sample reached approximately 42 °C, it was pumped into the flow cell at 7.3 mL/s using a peristaltic pump (261 mL; the retention of the sample in the cell is around 36 s) and collected in NMR tubes and beakers. The flow cell was connected to a water bath filled with an ethylene glycol water mixture (3:1 v/v) and set at −18 °C. This low temperature in the

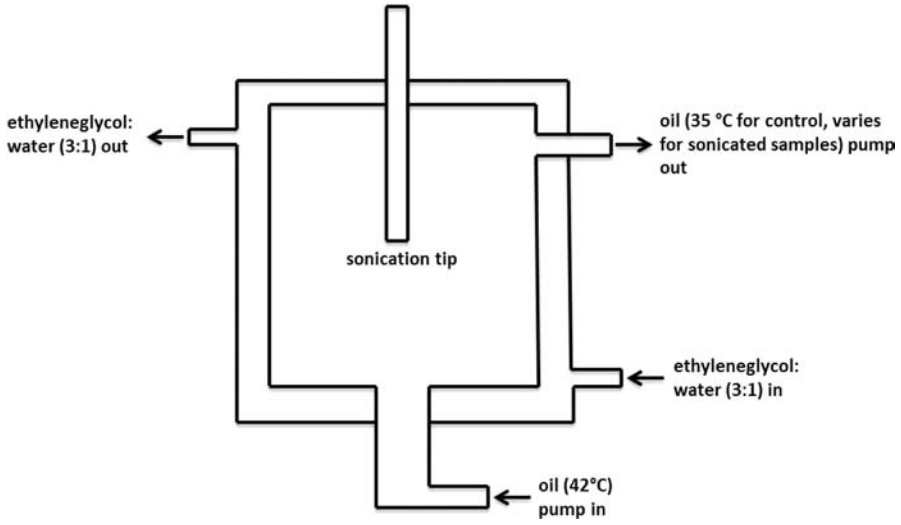

Figure 1. Flow cell system used to evaluate the effect of HIU on the crystallization behavior of palm oil.

water bath was necessary to cool the sample in the flow cell from 42 to 35 °C. A diagram of the flow cell used is shown in Figure 1.

Ultrasound Application. HIU (20 ± 1 kHz operation frequency) was generated using UIP1500hd equipment (Hielscher Ultrasound Technology, Ringwood, NJ, USA) with a 3.8 cm^2 frontal area sonication tip. HIU was applied 1 min after pumping of the sample had been started to ensure that the cell was completely filled with the sample and to stabilize the temperature of the sample. Previous research in our laboratory[17,19] and by other research groups[21] showed that the effect of HIU is more significant when samples are crystallized at low supercoolings. Because the melting point of our sample is 37.2 ± 0.4 °C, a crystallization temperature of 35 °C was chosen for our experiments. The effects of ultrasound using different power levels were evaluated in this study using 75 W (the lowest power setting that can be achieved by our ultrasound generator), 110 W (middle setting), and 180 W (safety maximum power setting recommended by the manufacturer of the sonicator). Sonication was applied in a continuous manner and using 5, 10, and 15 s pulse durations. A continuous duration indicates sonication continuously for 5 min, whereas sonication using an X s pulse duration means that HIU was applied every X s for a duration of X s. For example, a 5 s pulse duration means HIU was applied every 5 s with the duration of 5 s. Sample was pumped into the system for 5 min from the start of the sonication. Control samples (samples crystallized without the use of HIU) were collected at the beginning of the experiment before the application of HIU. Samples were collected every minute during the crystallization process in different tubes (one tube per minute). The first tube always consisted of nonsonicated sample (control). Solid fat content and crystal morphology were monitored in these samples as a function of storage time at 35 °C. Samples were kept at 35 °C in an incubator for 60 min to allow complete crystallization and then rapidly cooled to 25 and 5 °C and tempered for 24 h at these temperatures. The objective of this step is to evaluate if the effect of sonication is maintained through the tempering process.

Solid Fat Content (SFC). SFC values of palm oil during and after crystallization at 35 °C were measured using a NMR 120 minispec NMR analyzer (Bruker, Germany) following AOCS direct method Cd 16b-93. Samples were collected at the exit of the flow cell and loaded into the NMR tube every minute and kept at 35 °C to allow complete crystallization. SFC was measured as soon as the sample was taken out of the flow cell (time zero) and every 5 min for 30 min and every 10 min until the end of crystallization (60 min). The crystallization curves were fitted to the Avrami equation (eq 1) by least-squares nonlinear regression.[22]

$$SFC_{(t)}/SFC_{(\infty)} = 1 - \exp(-kt^n) \quad (1)$$

$SFC(t)$ and SFC_∞ are the SFC (%) at time t and the maximum SFC after crystallization is completed, respectively. The SFC data fitted to this model were used to determine the rate constant of crystallization (k) at a particular temperature and the mechanism of nucleation and crystal growth through the exponent, n.[23]

Microstructure. Crystal morphology was recorded during crystallization using a polarized light microscope (PLM-Olympus BX 41 America Inc., Melville, NY, USA) with a digital camera (Lumenera Scientific, Infinity 2, Ottawa, Ontario, Canada) attached and a thermostated stage to allow for temperature control during the measurement. The pipet, slides, and slide covers were tempered at 35 °C in the incubator. A 20× magnification objective was used.

Crystal Polymorphism by X-ray Diffraction (XRD). After 60 min of crystallization, samples were filtered under vacuum for 2 min, and crystals were collected to perform XRD measurement. The same filtration treatment was performed in samples tempered at 25 and 5 °C for 24 h. Samples were filtered to separate as many crystals as possible from the liquid phase, minimize the signal of the liquid fat in the XRD, and therefore obtain a better resolution. The polymorphic forms of fat crystals were determined by using a Philips Analytical X'Pert Pro X-ray Diffraction system (PW 3040/60 Console). The X-ray generator used a high-power ceramic diffraction X-ray tube with copper anode (PW 3373/00 ceramic tube Cu LFF), with voltage at 45 kV and current at 40 mA. Samples were scanned from 3° to 30° (2θ scale) at a rate of 1°/min at ambient temperature. The data were collected using X'Pert Data Collector and analyzed by X'Pert HighScore PANalytical software.

Melting Profile. The thermal behavior of the crystallized material was evaluated using a differential scanning calorimeter (DSC-TA Instruments Q20). The crystallized material (5−15 mg) was placed in a hermetic aluminum pan and heated from T_c (35, 25, or 5 °C) to 80 °C at 5 °C/min to evaluate its melting behavior. Melting parameters such as onset temperature (T_{on}; temperature at which the sample starts melting), peak temperature (T_p; temperature at which the melting peak reaches its maximum), and melting enthalpy (energy required for melting) were recorded. The melting enthalpy was used to evaluate the amount of crystallized material and the solid/liquid ratio in the lipid network. These analyses provided information about (a) the amount of solids generated as a consequence of HIU (induction or delay of the crystallization) through the melting enthalpy values, (b) the solid/liquid ratio of the crystal network formed as a function of temperature during melting, and (c) the melting range of the lipid network (through T_p and T_{on}).

Viscoelastic Properties. A TA Instruments AR-G2 magnetic bearing rheometer was used to evaluate the viscoelastic properties of the material. Oscillatory tests were performed by strain sweep step to obtain viscoelastic parameters such as the storage modulus (G'). The

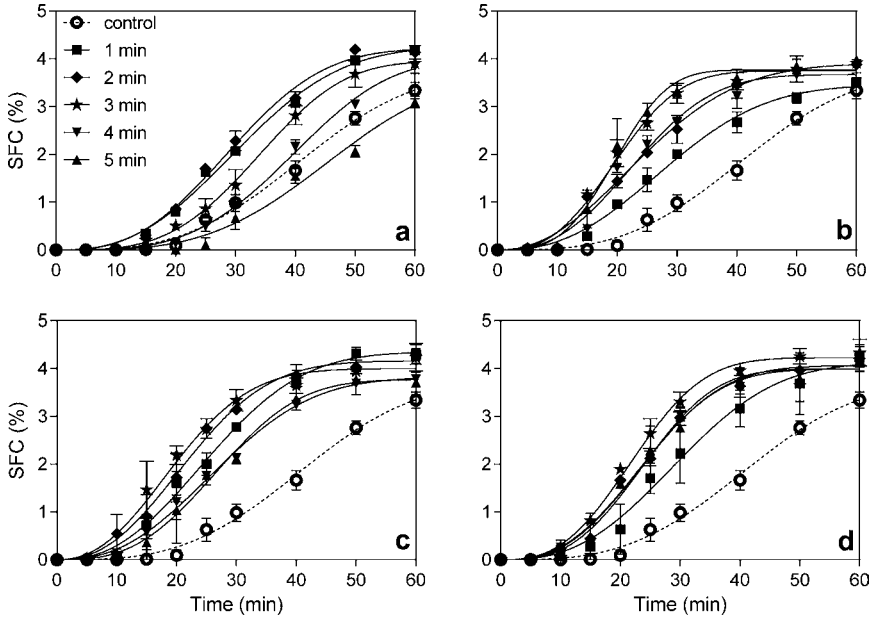

Figure 3. SFC of palm oil without (control, open circles) and with (solid symbols) HIU during the first 60 min of the crystallization process at 35 °C. A 110 W power level was used in a continuous manner (a) and using pulses of different durations (5, 10, and 15 s; b, c, and d, respectively).

experiments were carried out using a parallel plate geometry (40 mm diameter) with a temperature-controlled Peltier plate. The temperature of the plate was set at 35, 25, or 5 °C. For the strain sweep step, a constant frequency of 1 Hz (6.28 rad/s) was used, and strain values were set from 0.0008 to 10%.

Statistical Analysis. Crystallization experiments were performed in duplicate, and physical properties were measured in duplicate. Significant differences (α = 0.05) were evaluated using two-way ANOVA using GraphPad Prism software, version 6.00 for Windows (GraphPad Software, San Diego, CA, USA).

RESULTS AND DISCUSSION

Optimizing the Process Condition. Figures 2−4 show the crystallization behavior of palm oil measured by SFC as a function of time when different power levels of ultrasound were applied using different pulse types. Figure 2 shows SFC changes when samples were sonicated using 75 W power using a continuous sonication (Figure 2a), a 5 s pulse (Figure 2b), a 10 s pulse (Figure 2c), and a 15 s pulse (Figure 2d). When HIU is applied in a continuous manner, SFC values increased rapidly after 10 min, whereas SFC values increased after 20 min in the control samples (Figure 2a). Panels a−d of Figure 2 show no difference in crystallization between the modes of sonication (continuous vs pulses) with onset of crystallization observed at 20 min for the nonsonicated samples and at 10 min for the sonicated ones and final SFC values of 3.3 and 4.3% on average, respectively. Avrami analysis (R^2 values between 0.96 and 0.99)

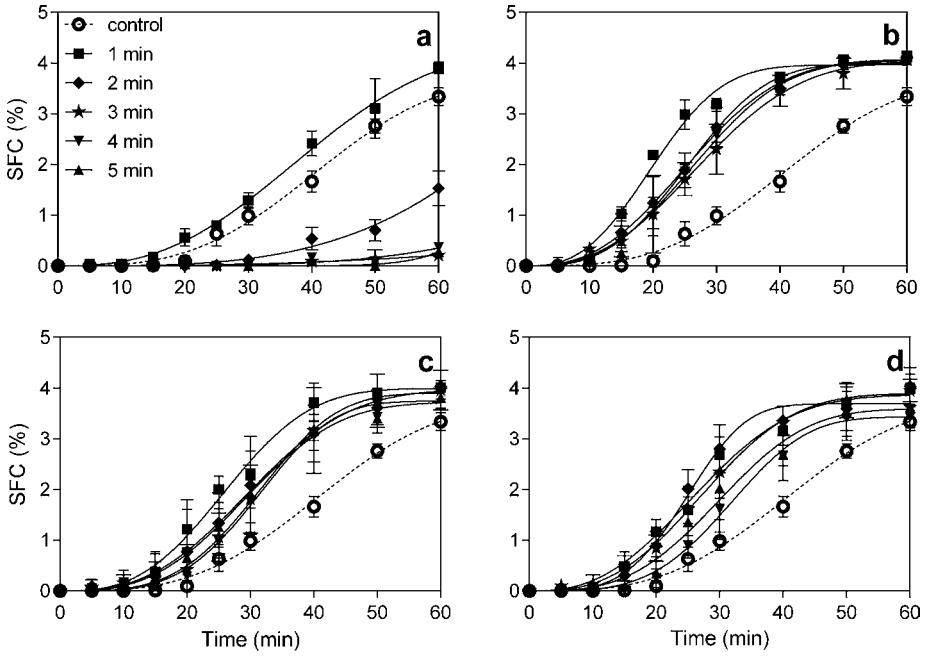

Figure 4. SFC of palm oil without (control, open circles) and with (solid symbols) HIU during the first 60 min of the crystallization process at 35 °C. A 180 W power level was used in a continuous manner (a) and using pulses of different durations (5, 10, and 15 s; b, c, and d, respectively).

showed 2 orders of magnitude higher k values for the sonicated samples compared to the nonsonicated ones with very little change in n values (Table 1). These data show that sonication indeed increased the crystallization rate of palm oil. Figure 3a shows SFC values obtained when samples were sonicated at 110 W in a continuous manner. This sonication condition did not induce lipid crystallization as shown by the similar SFC obtained between tubes at 1−5 min and the control tube and the similar values of k (Table 1). However, when sonication was applied using 5, 10, and 15 s pulses, sonication seems to be somehow efficient at inducing crystallization (Figure 3b−d) and k values were 1 or 2 orders of magnitude higher in the sonicated samples compared to the nonsonicated ones. R^2 values obtained from the Avrami fitting for these samples ranged between 0.96 and 0.99. When samples were sonicated using 180 W of power in a continuous manner (Figure 4a), HIU delayed crystallization after 2 min of sonication (see data in Figure 4a, tube 2 to 5 min). This delay in crystallization was so significant that data obtained for tubes 2−5 did not converge to the Avrami equation. Similar to the data discussed in Figure 3, HIU was able to induce crystallization when applied at 180 W using 5, 10, and 15 s pulses (Figure 4b−d), but higher k values were consistently obtained only for samples sonicated using 5 s pulses (Table 1). Avrami R^2 values ranged from 0.93 and 0.99.

Data obtained from the Avrami analysis show some variation in n values between the sonicated and nonsonicated samples (Table 1). n reflects details regarding nucleation and crystal growth mechanisms. Many studies discussed the values of n for various types of nucleation and growth of crystals.[24,25] For example, an n value of 3 indicates plate-like growth from sporadic nuclei or spherulitic growth from instantaneous nuclei, whereas an n of 2 corresponds to needle-like growth from sporadic nuclei or plate-like growth from instantaneous nuclei. For the control samples, n values were close to 3, whereas after sonication, the n values decreased to close to 2. This suggests a change in the type of nucleation and growth of crystals after HIU was applied. As discussed by Meng et al., lower values of n and higher values of k are associated with an increased rate of crystallization and a more instantaneous nucleation process with a shorter induction time.[25] Table 1 also shows the SFC_∞ calculated using the Avrami fit with significantly ($P > 0.05$) higher SFC_∞ values obtained for the samples sonicated using 75 W of power.

It is very likely that the lower efficiency of HIU observed at higher power levels is due to temperature increases obtained during sonication. When samples were sonicated in a continuous manner, a linear temperature increase was observed as a function of time with values of 0.6491 °C/min (R^2 = 0.8879) for 75 W, 1.463 °C/min (R^2 = 0.9671) for 110 W, and 1.847 °C/min (R^2 = 0.9869) for 180 W. The total temperature increases after 5 min of sonication are 3.2, 7.3, and 9.2 °C for 75, 110, and 180 W, respectively. The above results indicate that even though higher power levels of ultrasound can generate more cavitation in the system and therefore more positive effects on crystallization as described in previous research,[19−21] they can also generate higher temperatures, which contrast the cavitation events by melting the crystals that are being formed. In this experimental setup, the thermal effect of higher power levels of HIU played an important role in delaying lipid crystallization (Figures 3a and 4a). In addition, greater temperature increases were obtained for the continuous application compared to the pulsed ones for samples sonicated at higher power levels (110 and 180 W). Temperature increases observed over the 5 min sonication using 110 W for 5, 10, and 15 s were 6.1, 4.9, and 6.2 °C, respectively, whereas temperature increases observed for the 180 W sonication condition were 5.8, 6.1, and 4.9 °C for the 5, 10, and 15 s pulses, respectively. The lower temperature increase for pulse irradiation types with higher power levels explains the induction in crystallization when pulse sonication was applied in Figures 3b−d and 4b−d. In summary, higher power levels of HIU generate more heat, and when the temperature is high enough, a delay in crystallization might occur. To overcome this

[a]Subscript "c" indicates the control sample, subscripts "1−5" indicate the samples collected at each minute during sonication. R^2 values for Avrami fitting were all above 0.96, except for the samples collected from 2 to 5 min under 180 W sonication in a continuous manner, where data did not fit the Avrami model, [b]SFC_∞ values are significantly different ($P < 0.05$) from the control sample.

disadvantage, pulse irradiation of sonication can be applied to induce crystallization by generating less heat. Temperature increases as a function of time can be found in Figure 1 of the Supporting Information.

Physical Properties of Sonicated Samples (75 W Continuous). Results described in the previous section demonstrate the sonication using 75 W is the most efficient at inducing crystallization and at generating more solids in the crystalline network formed. Becausee no differences were found in SFC values as a function of sonication mode (continuous vs pulse), the continuous mode was chosen to continue our experiments of physical characterization of the sonicated samples. The continuous condition was chosen over the pulse ones because it would be an easier method to implement in a processing plant. To perform the physical characterization, samples were collected at the exit of the flow cell as described before and mixed together as the "sample with HIU". A control sample was always taken before the sonication. Physical properties such as crystal microstructure, viscoelasticity, melting profile, and polymorphism were evaluated on these samples.

Microstructure of the Crystals. Figure 5 shows the microstructure of the palm oil samples crystallized in the flow

J. Agric. Food Chem. 2015, 63, 319−327

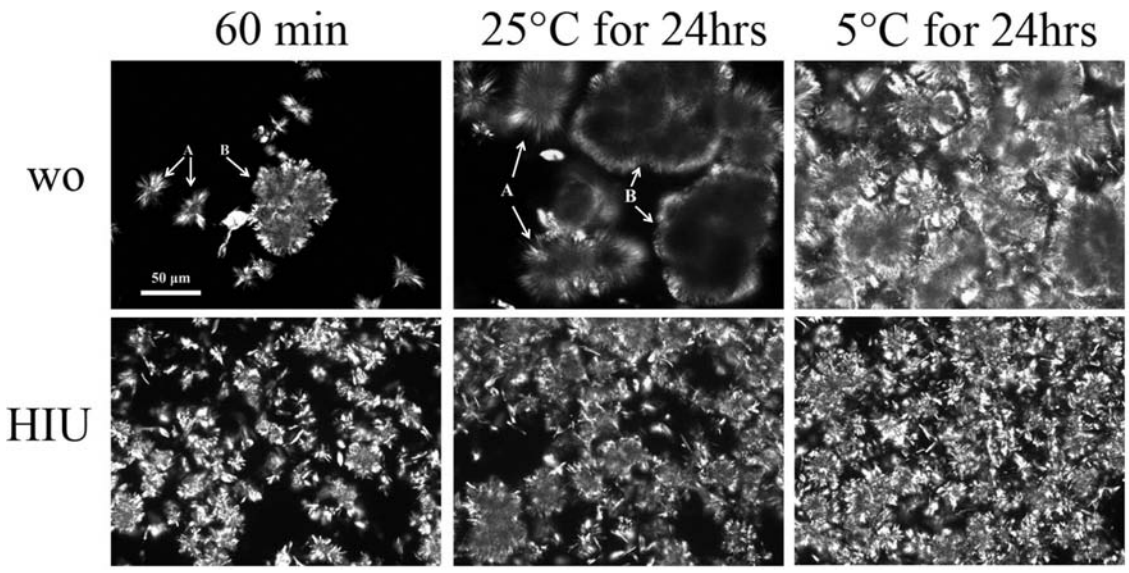

Figure 5. Microstructure of palm oil crystallized without and with HIU at 35 °C for 60 min and tempered at 25 °C for 24 h and at 5 °C for 24 h. In the pictures for samples without HIU for 60 min and at 25 °C for 24 h, two different morphologies are indicated (A and B).

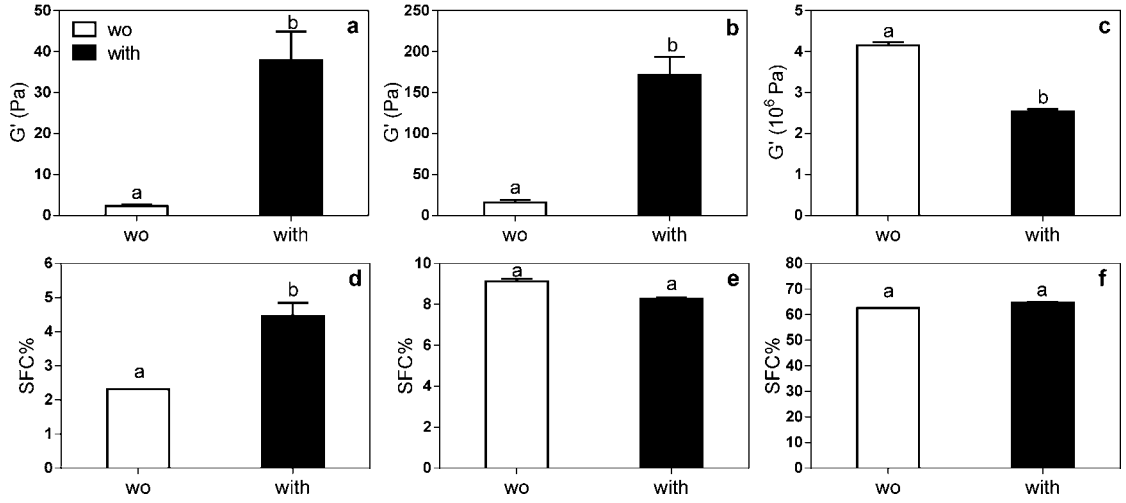

Figure 6. Storage modulus (G') and corresponding SFC values of palm oil crystallized without and with HIU at 35 °C for 60 min (a, d) and after tempering at 25 °C for 24 h (b, e) and 5 °C for 24 h (c, f).

cell with and without HIU using 75 W of power in a continuous manner. After crystallization had been induced in the flow cell, samples were kept at 35 °C in an incubator for 60 min to allow for complete crystallization and tempered for 24 h at 25 and 5 °C. PLM pictures shown in Figure 5 demonstrate that HIU significantly affects the formation of crystals in different sizes and shapes compared to the nonsonicated samples. Big round crystals (indicated with arrow B in the picture wo_60 min) were observed after 60 min at 35 °C in samples crystallized without HIU. A continuous growth of size for this big round crystal was observed after 24 h of tempering at 25 °C (approximately 80 μm in diameter). Arrow A in the picture shows an example of a crystal with a different morphology characterized by needle-like spherulites, which are usually associated with β' crystals.[26] Crystals continued to grow and formed an interconnected crystalline network of big spherulites after tempering at 5 °C for 24 h, which makes the identification of individual crystals or clusters very difficult. When HIU was applied to the samples, the amount of crystal clusters increased and the crystal aggregates generated a more uniform size distribution with smaller crystals, especially after 24 h of tempering. Similar results were found in the research on palm oil by Chen et al.,[21] who showed different crystal morphologies of palm oil crystallized with and without sonication. It is also interesting to observe that crystal size and morphology did not change substantially in the sonicated samples as a function of tempering. There might be several reasons that can cause this phenomenon: (a) the greater number of crystals generated after HIU application act as nuclei for the secondary crystallization to occur, and therefore the solid mass deposited over each crystal is lower compared to the nonsonicated samples were fewer crystals are present and therefore more solid mass is deposited in each crystal, resulting in crystal growth; (b) the solid/liquid ratio for sonicated samples is higher than that of nonsonicated samples, which means less liquid oil could be used to crystallize in sonicated samples during tempering; and (c) high pressures and high shear forces generated during sonication destroyed the regular shape of the crystal clusters and irregular or rough cluster shape might prevent the orderly arrangement of TAG molecules into the crystalline lattice.

DOI: 10.1021/jf505041s
J. Agric. Food Chem. 2015, 63, 319−327

Changes observed in crystal morphology as a consequence of sonication can be attributed to the formation of different molecular compounds or to the presence of different polymorphic forms. Therefore, XRD measurements were performed to evaluate the polymorphic forms generated during sonication and tempering.

Crystal Polymorphism. The polymorphism of crystals obtained after crystallization of the samples with and without HIU at 35 °C for 60 min was determined with X-ray. This measurement was also performed in the same samples tempered for 24 h at 25 and 5 °C. Signals at short spacings of 3.7, 3.8, 3.9, 4.45, and 4.6 Å were identified. All conditions tested showed a strong signal at 4.6 Å, indicating the presence of β crystals. No strong peaks were observed at 4.2 Å, indicating that β' crystals were not present in these samples[27−30] (X-ray diffractograms can be found in Figure 2 of the Supporting Information).

Viscoelastic Properties. Figure 6 shows the comparison of the storage modulus (G') and the corresponding SFC measurements between samples crystallized with and without HIU application. Samples were taken after 60 min of crystallization at 35 °C and after 24 h of tempering at 25 and 5 °C. As expected, sonicated samples crystallized for 60 min at 35 °C had significantly ($P < 0.05$) higher G' and SFC values than those of nonsonicated ones. After 24 h of tempering at 25 °C, G' values for both samples (sonicated and nonsonicated ones) increased as a result of ongoing crystallization during tempering (Figure 5) due to the exposure to a higher supercooling. Sonicated samples maintained a higher G' after tempering ($P < 0.05$), whereas SFC values showed no statistical difference ($P > 0.05$). Changes observed in G' and SFC values after tempering at 25 °C might be due to different phenomena: (a) increased interaction between crystal clusters in smaller crystals (Figure 5), leading to a higher G'; (b) SFC of the nonsonicated samples increased from 2.4 to 9.1% on average during tempering, whereas SFC of the sonicated samples increased only from 4.5 to 8.3%; this means that HIU induced the crystallization during the first 60 min and therefore there is not much left to crystallize during the tempering as the sample reached the thermodynamic equilibrium. When samples were tempered at 5 °C for 24 h, SFC values for both samples increased dramatically to the same level, and it is very interesting to observe that the G' values obtained for samples without HIU application are significantly higher than the ones obtained for the sonicated samples. The difference in crystal size and shape (Figure 5) and cluster interconnections might contribute to the different G' values observed after tempering at 5 °C for 24 h.

Melting Profile. The melting profiles of palm oil crystallized with and without HIU at 35 °C and stored at different tempering conditions (25 and 5 °C for 24 h) are shown in Figure 7. Only one melting peak was observed for both samples (with and without HIU) crystallized at 35 °C for 60 min (Figure 7a). Samples crystallized with HIU showed a sharper and deeper but narrower melting curve as compared to the nonsonicated sample. The peak temperature of the sample decreased from 48.4 ± 3.1 to 41.2 ± 0.1 °C when HIU was applied (Table 2). As expected, after tempering at 25 °C for 24 h (Figure 7b), two melting peaks were observed for both samples (with and without HIU). The melting peak observed at lower temperatures can be attributed to the secondary crystallization that occurred during tempering. Three peaks were observed for samples tempered at 5 °C for 24 h (Figure 7c), of which the two lower melting peaks can be attributed to the secondary crystallization that occurs during the tempering at 5 °C. Table 2 shows the melting parameters of palm oil crystallized with and without HIU application. Melting parameters reported for the tempered samples correspond to the highest melting peak because this peak represents the crystals formed during the sonication experiment. The peak temperature (T_p) for the nonsonicated samples crystallized for 60 min at 35 °C was significantly ($P < 0.05$) higher than the sonicated samples. The same results were maintained after tempering at 25 and 5 °C for 24 h. The reason for the shift to lower peak temperature after sonication might be due to the different crystal microstructure and to different particle size distribution of the crystals. Enthalpy (ΔH) values of samples crystallized with HIU and kept for 60 min at 35 °C were significantly ($P < 0.05$) higher than the ones obtained in the nonsonicated samples. After tempering at 25 and 5 °C, no difference was found for the enthalpy between HIU samples with and without HIU for the highest melting fraction. These results are in accordance with previously discussed data related to SFC values (Figure 6).

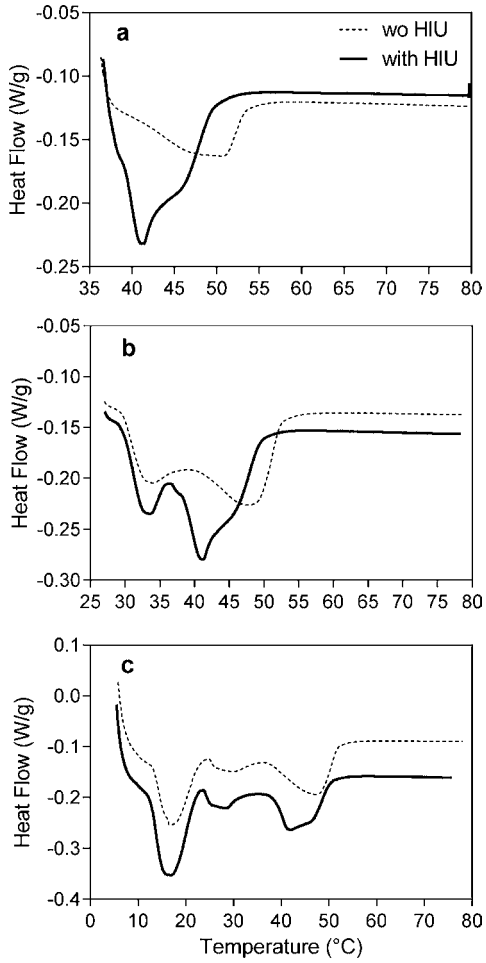

Figure 7. Melting profile of palm oil crystalline network obtained after crystallization without (dotted line) and with (solid line) HIU at 35 °C for 60 min (a) and after tempering at 25 °C (b) and 5 °C (c) for 24 h.

Figure 8 shows the melting profile of the crystalline networks generated in this study. The melting profile is reported as the amount of solids remaining at a specific temperature (% solid) as the sample is being heated in the DSC. Only the highest

Table 2. Melting Parameters of Palm Oil Crystallized with and without Sonication[a]

	60 min		25 °C, 24 h		5 °C, 24 h	
melting parameter	without HIU	with HIU	without HIU	with HIU	without HIU	with HIU
T_{on} (°C)	N/A	N/A	39.4 ± 0.9A	38.3 ± 0.5A	39.0 ± 1.6A	38.4 ± 0.0A
T_p (°C)	48.4 ± 3.1A	41.2 ± 0.1B	47.6 ± 1.5A	41.4 ± 0.1B	48.5 ± 1.1A	42.5 ± 0.3B
ΔH (J/g)	4.8 ± 0.4A	11.1 ± 0.6B	5.8 ± 0.3AC	6.8 ± 0.9AC	7.2 ± 1.9AC	9.4 ± 1.1BC

[a]The data were collected at 60 min and after tempering for 24 h at 25 and 5 °C. Data reported are mean values and standard deviations of two independent runs. The same upper case letters in a row indicate that values are not significantly different (α = 0.05). N/A indicates that the value could not be calculated because it fell outside the temperature range of the DSC run.

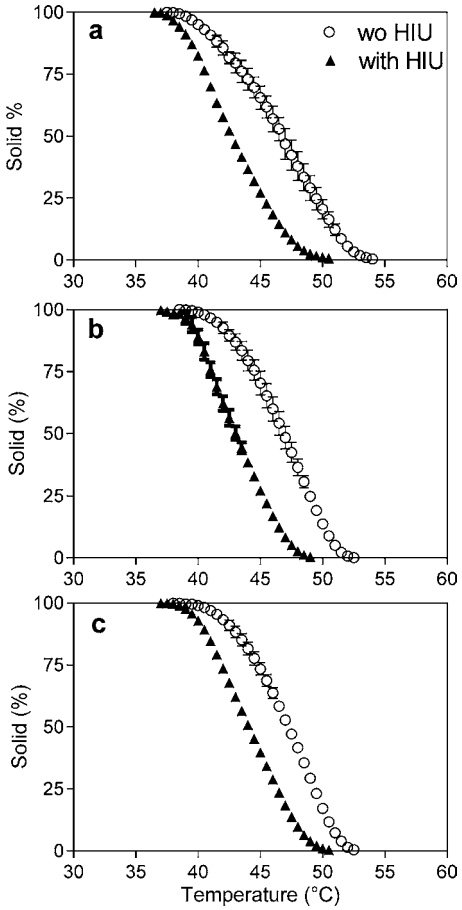

Figure 8. Melting profile of palm oil samples expressed as the percentage of solids remaining at a specific temperature during DSC melting. Melting profiles of sonicated and nonsonicated samples are indicated with solid and open symbols, respectively. Samples were crystallized at (a) 35 °C for 60 min and tempered at (b) 25 °C for 24 h and (c) 5 °C for 24 h.

melting fractionation was studied. Palm oil crystallized with HIU showed a lower percentage of solid at any given temperature when crystallized at 35 °C. The same results were maintained after tempering at 25 and 5 °C. The sonicated sample showed a steeper and sharper melting profile, which can be explained by the smaller size of crystals generated by HIU and as a consequence of a faster melting rate. Similar results were reported by Suzuki et al.[18] and Ye et al.[19] in other lipid systems such as anhydrous milk fat and interesterified soybean oil.

This study showed that HIU can be used in a continuous system to promote the crystallization of palm oil and to change its functional properties. Results obtained in this study provide scientific support to implement HIU as an additional processing tool in the edible oil industry. The importance of optimizing the sonication conditions is highlighted in this research noting that the amount of heat generated during sonication can contrast the effect of cavitation. Future work in this area to support the hypothesis that HIU can be used as an additional processing tool to modify the functional properties of edible lipids in industrial settings could include changing the flow rate of the pumped oil and the crystallization temperature in the system. The goal of implementing this additional tool in the edible oil industry is not only to change the physical properties of the lipid but also to induce lipid crystallization, reduce processing times, and ultimately reducing processing costs.

De Novo Synthesis of Amino Acids during the Maillard Reaction: qTOF/ESI Mass Spectrometric Evidence for the Mechanism of Akabori Transformation

Ossanna Nashalian and Varoujan A. Yaylayan*

Department of Food Science and Agricultural Chemistry, McGill University, 21,111 Lakeshore, Ste. Anne de Bellevue, Quebec, Canada H9X 3V9

ABSTRACT: The transformation of α-amino acids into their hydroxymethyl derivatives during the Maillard reaction is an intriguing possibility for catalysis by metal salts in the presence of Strecker aldehydes; the process is commonly known as the Akabori reaction. The mechanism of this reaction was studied in the presence of glucose, using glycine copper complex and paraformaldehyde as Akabori model system in aqueous mixtures heated at 110 °C for 2 h and subsequently analyzed by qTOF/ESI/MS. Isotope-labeling studies of the various products identified have provided for the first time mass spectrometric evidence for the detailed mechanism of Akabori transformation, particularly the formation of Schiff base adducts prior to the final conversion into serine and hydroxymethyl-serine. Furthermore, the results have indicated that sugars do not interfere with such transformations and, on the contrary, the presence of glycine−copper complexes in the Maillard model systems can enhance the production of Maillard reaction intermediates.

KEYWORDS: *mechanism of Akabori reaction, glycine−copper complexes, Maillard reaction, serine, hydroxymethyl-serine*

INTRODUCTION

Contrary to the reaction of α-amino groups of amino acids with carbonyl moieties, which has been studied for over a century, the interaction of α-carbons of α-amino acids with aldehydes such as Strecker aldehyde has not been examined in detail in the context of the Maillard reaction. Akabori et al. first reported the chemical synthesis of serine or threonine from glycine in the presence of two common Strecker aldehydes, formaldehyde and acetaldehyde.[1] This transformation of one amino acid into another was catalyzed by metal salts such as copper and iron and is commonly referred to as the Akabori reaction.[2] The generality of this reaction was later extended to different amino acids (serine, glycine, and alanine) and different metal complexes (Ni, Co, and Cu) and using various aldehydes (acetaldehyde, formaldehyde, pyruvic acid, and benzaldehyde).[3,4] The transformation of the α-amino acids into their corresponding β-hydroxy amino acids required relatively mild conditions; heating at 100 °C for 1 h in water generated both serine and threonine with average yields of 30%[1] and 32−80%,[3−5] respectively. The initial mechanism proposed by Akabori et al.[1] attributed the activation of the α-carbon to the formation of the amino acid metal complexes. William and Busch[6] demonstrated through NMR studies the enhanced acidity and lability of α-methylene hydrogens in such complexes due to the electron-withdrawing action of the metal ions. Under alkaline conditions, the formed carbanion would serve as a nucleophile that can condense with a carbonyl moiety such as formaldehyde or acetaldehyde.[1,4] However, it was later proposed that the amino acid metal complexes first undergo Schiff base formation with the aldehyde followed by the subsequent activation of the α-carbon to generate carbanion.[3,7] The formation of the Schiff base adducts was assumed to enhance even more the acidity of the α-carbon, allowing the reaction to proceed at milder pH conditions and with higher yields.[3] The formation of Schiff base intermediates was further confirmed in polarimetric studies involving serine−copper complexes and formaldehyde[8] and glycine−copper complex and acetaldehyde through observation of their subsequent intramolecular cyclization products initiated by the newly formed serine hydroxyl groups to generate 1,3-oxazolidine moieties as reported by the two research groups of Aune et al.[9] and Teo and O'Connor.[8]

Although the Akabori reaction was initially intended for chemical synthesis to generate β-hydroxy amino acids, the conditions needed for its formation are readily available in food. Many foods are heated under conditions similar to those of the Akabori reaction, and the needed precursors the amino acids, Strecker aldehydes, and metals are either present or generated during processing. In fact, a variant of this reaction has been observed under pyrolytic conditions,[10] where the α-carbons of amino acids were activated toward nucleophilic addition with aldehydes. However, such activation was initiated through decarboxylation (Figure 1, pathway A) rather than through metal catalysis as in the case of the Akabori reaction, and consequently the resulting adduct after deamination step constituted a chain elongation process of the aldehyde rather than the formation of a new amino acid as in the case of Akabori reaction (Figure 1, pathway B). If Akabori transformation can be demonstrated to be a feasible pathway in the Maillard reaction, it can generate hitherto unknown amino acid structures or enhance the concentration of serine and threonine levels that are known to generate sugar-like reactive intermediates upon thermal degradation.[11] Considering the fact that the occurrence of this reaction could influence the aroma profile and may even generate potentially unknown amino acid structures, we have studied its

role in Maillard model systems using glucose, glycine, and paraformaldehyde aqueous mixtures heated at 110 °C for 2 h and subsequently analyzed by qTOF/ESI/MS.

MATERIALS AND METHODS

Materials and Reagents. L-Glycine (98%), L-alanine (99%), L-serine (99%), D-glucose, paraformaldehyde, potassium hydroxide (KOH), and copper(II) chloride ($CuCl_2$) (99.9%) were purchased from Sigma-Aldrich Chemical Co. (Oakville, ON, Canada). [^{13}C-1,^{13}C-2,^{15}N]glycine (98%) and [U_6-^{13}C]glucose (99%) were purchased from Cambridge Isotope Laboratories (Andover, MA, USA). LC-MS grade water and methanol (OmniSolv, >99%) were obtained from VWR International (Mississauga, ON, Canada).

Synthesis of Amino Acid–Metal Complexes. $(Ala)_2Cu$, $(Gly)_2Cu$, and $(Ser)_2Cu$ complexes were prepared by dissolving alanine (0.89 g), glycine (0.75 g), and serine (1.05 g) in methanol (10 mL) in the presence of KOH (0.05 g) followed by the addition of 0.5 mol of

DOI: 10.1021/jf5051975
J. Agric. Food Chem. 2015, 63, 328−334

$CuCl_2$. The dark blue precipitates were washed with methanol, filtered, and dried. The amino acid adducts were confirmed by obtaining their elemental composition from their accurate masses determined by qTOF/ESI/MS analysis (alanine−copper complex at m/z 261.9985 $[M + Na]^+$ (calculated for $C_6H_{12}CuN_2NaO_4$ with an error of −1.4 ppm, glycine−copper complex at m/z 233.9665 $[M + Na]^+$ (calculated for $C_4H_8CuN_2NaO_4$ with an error of 5.4 ppm), and serine−copper complex at m/z 272.0059 $[M + H]^+$ (calculated for $C_6H_{13}CuN_2O_6$ with an error of 3.9 ppm). Isotope-labeled precursors were prepared similarly.

Sample Preparation. Model systems (6.0 mg) consisting of amino acid metal complexes were mixed with glucose (equimolar amounts) and excess paraformaldehyde (20 mg), dissolved in water (2 mL), and heated on a sand bath in an open vial (5 mL capacity) at 110 °C for 2 h until dry. Controls such as serine and $(Ser)_2Cu$ were also similarly heated and analyzed generating ions at m/z 106.0492 and 272.0059, respectively. To generate some of the observed intermediates, mixtures comprising $(Ser)_2Cu$/glycine and $(Gly)_2Cu$/excess serine were similarly heated and analyzed, generating the ions at m/z 241.9956 and 272.0045, respectively (see Figure 2). In addition, $(Ser)_2Cu$ was heated in the presence of excess paraformaldehyde and analyzed as control (see Table 1). Selected dry residues were then analyzed for their volatile components using pyrolysis gas chromatography−mass spectrometry (Py-GC/MS), and for their nonvolatile components using electrospray ionization mass spectrometry (qTOF/ESI/MS). All samples were analyzed in duplicates.

[a]Heated (110 °C for 2 h in water) and dried model systems were first analyzed by qTOF/ESI/MS for nonvolatiles, and some model systems (indicated by asterix) were also thermally desorbed by Py-GC/MS for volatile analysis.

Quadrupole Time of Flight/Electrospray Ionization/Mass Spectrometric (qTOF/ESI/MS) Analysis. The dry reaction residues or synthetic samples were dissolved in water to a concentration of 1 mL/mg. The sample was then diluted 10-fold in 10% methanol prior to analysis by qTOF/ESI/MS. The qTOF/ESI/MS system was composed of a Bruker Maxis Impact quadrupole time-of-flight mass spectrometer (Bruker Daltonics, Bremen, Germany) operated in positive ion mode. Samples (1 μL) were injected directly into the LC-MS. Instrument calibration was done using sodium formate clusters. The electrospray interface settings were the following: nebulizer pressure, 1.0 bar; drying gas, 8 L/min, 200 °C; capillary voltage, 4500 V. Scan range was from m/z 100 to 1000. The data were analyzed using Bruker Compass Data Analysis software version 4.1. Tandem mass spectrometry (MS/MS) was carried out in MRM mode using 20.0 eV collision energy for the ion at m/z 272.

Thermal Desorption by Pyrolysis Gas Chromatography−Mass Spectrometry (Py-GC-MS). A Varian CP-3800 gas chromatograph coupled to a Saturn 2000 ion trap detector interfaced to a CDS Pyroprobe 2000 unit through a valved interface (CDS 1500) was used for the desorption of the volatiles from the dried residues. The residues from selected dry and heated model systems shown in Table 1 were weighed (0.5 mg) into quartz tubes (0.3 mm thickness), plugged at both ends with glass wool (Supelco, Bellefonte, PA, USA) inserted inside a coil probe and pyrolyzed at 250 °C for 20 s under a helium atmosphere (Table 1).The separation was performed using a fused silica DB-5MS column (50 m length × 0.2 mm i.d. × 33 μm film thickness). The GC method used for the analysis of the volatiles was as follows: GC column flow rate was regulated by an electronic flow controller (EFC) and set at a pressure pulse of 55 psi for first 3 min and then decreased to 32 psi at the rate of 300 psi/min and finally increased to 70 psi at a rate of 1.23 psi/min for the rest of the run. The GC oven temperature was set at −5 °C for the first 5 min using CO_2 as the cryogenic cooling source and then increased to 50 °C at a rate of 50 °C/min. Then, the oven temperature was again increased to 270 °C at a rate of 8 °C/min and kept at 270 °C for 5 min. The samples were detected by using an ion trap mass spectrometer. The MS transfer line temperature was set at 250 °C, manifold temperature was set at 50 °C, and ion trap temperature was set at 175 °C. The ionization voltage of 70 eV was used, and EMV was set at 1600 V. The generated data were analyzed using the AMDIS_32 version 2.69 computer software, and peak identification was done using the NIST version 2.0 mass spectral research program.

Structural Identification. Evidence for the proposed structures of nonvolatile reaction intermediates were provided through qTOF/ESI MS analysis of their elemental composition and isotope-labeling studies or by the use of synthetic intermediates or standards. Furthermore, the incorporation of copper in the identified complexes was confirmed by the isotopic signature of copper through detection of M + 2 peaks at 30% relative intensity. Volatile reaction products were identified by comparison of their retention times and mass spectra with commercial or in situ generated standards in addition to NIST library matches and stable isotope labeling data.

RESULTS AND DISCUSSION

Amino acids are one of the primary reactants required for the Maillard reaction. The type and distribution of various amino acids contribute significantly to the nutritive value and aroma profile of foods.[12,13] Although free amino acids are usually formed in processed food through hydrolysis of proteins, the notion that some amino acids may be also generated de novo during processing from already existing precursors has not been explored in the context of the Maillard reaction. The chemical transformation known as the Akabori reaction provides this opportunity because it requires precursors that are generally found in food and reaction parameters encountered under food-processing conditions. As detailed above, the Akabori reaction transforms existing amino acids into their β-hydroxyl counterparts (Figure 1, pathway B), of which only two amino acids, serine and threonine, are naturally found in food proteins. The Akabori modification of amino acids has not been explored within the context of the Maillard reaction or in the presence of

reducing sugars. Detailed understanding of the role of Akabori transformation within the Maillard reaction system can reveal not only the possible formation of new amino acid structures but also its possible influence on the mechanism and the general outcome of the Maillard reaction itself. Isotope-labeling studies were performed to confirm the formation of serine, the Akabori amino acid in heated (110 °C) aqueous model systems of glucose, glycine–copper complex [$(Gly)_2Cu$], and formaldehyde, and to investigate the role of glycine copper complex in modifying the Maillard reaction profile.

The various model systems listed in Table 1 were heated at 110 °C for 2 h, and the resulting dry residues were analyzed by qTOF/ESI/MS for nonvolatiles, and selected model systems were also analyzed by Py-GC/MS to thermally desorb and characterize the volatile reaction products already formed under aqueous heating conditions. Heating $(Gly)_2Cu$ alone mainly causes oxidative decarboxylation of glycine and formation of its corresponding Strecker aldehyde;[14,15] however, when heated in the presence of excess formaldehyde with or without glucose, the reaction mixtures generated many products and intermediates that supported the proposed formation of serine, the Akabori

amino acid of glycine observed at *m/z* 106.0500 (see Table 2 and Figure 2) and α-hydroxymethyl-serine at *m/z* 136.0603, which was predicted to be formed through two consecutive Akarbori transformations of glycine[16] and can be considered as the Akabori amino acid of serine under the Maillard reaction conditions. Furthermore, as shown in Figures 2 and 3 and Tables 2 and 3, many of the copper-containing intermediate complexes identified in the reaction medium provided, for the first time, high-resolution mass spectral evidence (qTOF/ESI/MS) for their formation supported by the presence of isotopic peaks of copper and the isotopic incorporation patterns from the specifically labeled precursors, thus further confirming the mechanistic details of Akabori transformation of glycine. Furthermore, the model system that included glucose also showed, in addition to the above-mentioned ions, additional major ions at *m/z* 238.0930, 325.1369, and 342.1392, which were absent when the glycine−copper complex was replaced with glycine. The first two ions incorporated 6 carbon atoms from U_6-^{13}C-glucose, and their elemental compositions indicated sugar amino acid(s) adducts, whereas the third ion incorporated 12 carbon atoms from U_6-^{13}C-glucose that can be assigned to a diglycosylated ammonia. (The details of the role of glucose during the Akabori reaction will be published elsewhere.)

Mass Spectrometric and Isotope-Labeling Evidence for the Formation of Schiff Bases of Amino Acid−Metal Complexes with Aldehydes Prior to Akabori Transformation. The Akabori modification of amino acids is a stepwise transformation involving several consecutive reactions. Much like the Maillard reaction, a key initial step proposed in the Akabori reaction is the formation of imine between the amino groups of the metal complex and the excess aldehyde in the reaction mixture.[2] This step is considered critical for the activation of the α-carbon. Although there is indirect evidence for the formation of this intermediate, no mass spectrometric evidence is presented so far. Analysis of the heated reaction mixture of $(Gly)_2Cu$ and formaldehyde indicated the formation of several copper complexes and the free serine as shown in Figure 2 and listed in Table 2. According to the intermediates identified in Figure 2, the glycine−copper complex undergoes double Schiff base formation with formaldehyde to generate the ion at *m/z* 235.9840. The activated complex then can react with two formaldehyde molecules to generate the ion at *m/z* 296.0054 followed by hydrolysis of the Schiff bases resulting in the formation of a $(Ser)_2Cu$ complex at *m/z* 272.0044. Depending on the pH, the amino acid−metal complexes can either undergo ligand exchange[17] in the presence of free amino acids to generate the mixed complex (Gly)Cu(Ser) at *m/z* 241.9943 or decompose at lower pH values to release free amino acid serine at *m/z* 106.0500. As shown in Table 4, all of the listed intermediates display the expected isotope label incorporation patterns from C-1, C-2, and the nitrogen atom of glycine. Furthermore, each of the intermediate copper complexes also exhibited the isotopic signature of copper through detection of its M + 2 peaks at 30% relative intensity (Table 2). To confirm the formation of serine complex at *m/z* 272.0044 in the reaction

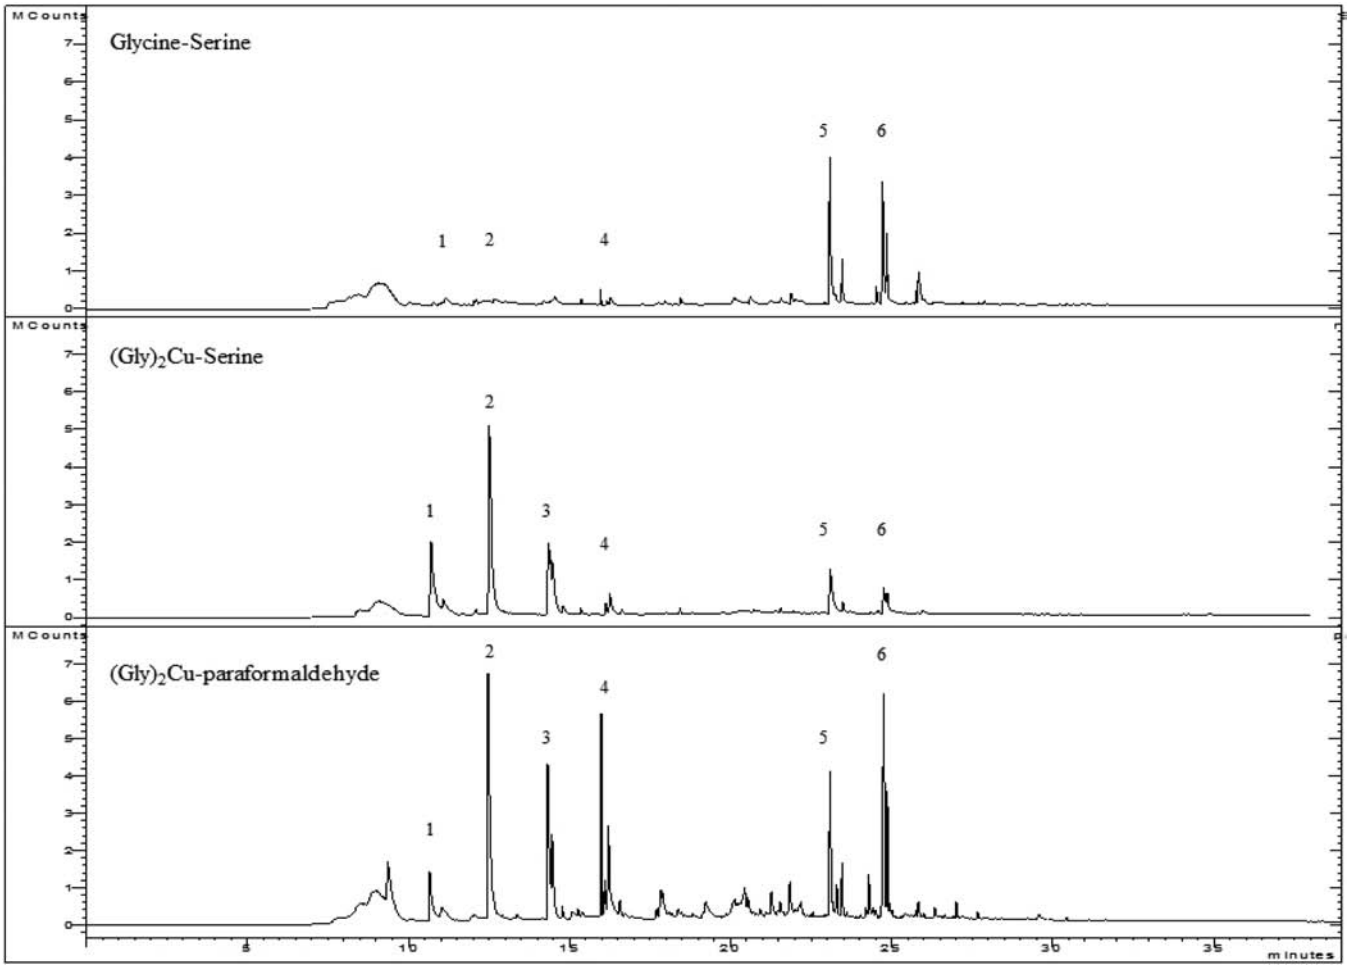

Figure 5. Comparison of the major volatile compounds thermally desorbed from the heated (in water at 110 °C) residues of glycine/serine, $(Gly)_2Cu$/serine, and $(Gly)_2Cu$/paraformaldehyde model systems: (1) 2-methyl-(1*H*)-pyrrole; (2) 2-methylpyrazine; (3) 2,6-dimethylpyrazine; (4) 1,3,5-trimethylhexahydrotriazine; (5) 1,5-dimethyl-2(1*H*)-pyrazinone; (6) 1,5,6-trimethyl-2(1*H*)-pyrazinone.

mixture of $(Gly)_2Cu$ and formaldehyde, MS/MS analysis of synthetic $(Ser)_2Cu$ was performed and the product ions were compared with the daughter ions of m/z 272.0044 detected in the reaction mixture. The MS/MS fragments of this adduct matched exactly that of the synthetic standard (see Table 5). Furthermore, the synthetic $(Ser)_2Cu$ complex was reacted with formaldehyde to identify many of the other copper-containing complexes observed in the original reaction mixture of $(Gly)_2Cu$ and formaldehyde, which were thought to arise from the in situ formed $(Ser)_2Cu$ complex and the already present formaldehyde. Table 3 and Figure 3 show the observed and predicted complexes of copper that could be formed by the interaction of formaldehyde with serine−copper complex. These ions were also detected in the original reaction mixture of $(Gly)_2Cu$ and formaldehyde. The serine−copper complex, similar to the glycine−copper complex, can undergo Akabori transformation as shown in Figure 3 through Schiff base formation and similarly generate its corresponding Akabori amino acid hydroxymethyl-serine observed at m/z 136.0603, which was originally identified by Akabori et al.[1] as an unknown compound but later characterized as α-hydroxymethyl-serine by Otani and Winitz.[16] The two key intermediates identified at m/z 314.0143 and 302.0151 (Figure 3) not only support the formation of α-hydroxymethyl-serine but provide further evidence for the importance of formation of Schiff base−metal complexes in the Akabori reaction. None of the above products were detected in the absence of copper complex of glycine or when free glycine was reacted with formaldehyde. The formation of α-hydroxymethyl-serine in this model system is noteworthy because it indicates the possibility of formation of unusual amino acids during the Maillard reaction. In addition, the reaction of alanine−copper complex with formaldehyde similarly generated the Schiff base adduct observed at m/z 264.0144, further supporting the importance and generality of Schiff base formation in the mechanism of Akabori reaction (see Figure 4; Table 6). These observations are not surprising and are consistent with the theoretical considerations regarding the ease of Schiff base formation on the amino groups of metal complexes due to the extra stabilization gained through hyperconjugation of its π-system with the metal[7] and, consequently, further enhancing the acidity of the α-carbon due to additional delocalization of the negative charge over the newly formed imminium moiety,[18] giving rise to a more reactive α-carbanion intermediate capable of being alkylated more readily by formaldehyde.

Implications of the Akabori Transformation to the Volatile Profile of the Maillard Reaction. Considering that $(Gly)_2Cu$ when heated will generate serine in the presence of formaldehyde, it was expected that volatiles generated in this model system should resemble the volatiles generated in a glycine/serine system. Indeed, when the dried residues of the

J. Agric. Food Chem. 2015, 63, 328−334

above heated model systems (unheated samples when pyrolyzed did not generate any volatiles) were thermally desorbed, five of the six major peaks shown in Figure 5 were found to be in common. Similarly, the $(Gly)_2Cu$/serine model system also shared these common peaks as shown in Figure 5. More importantly, the intensities of these peaks in the Akabori model system of $(Gly)_2Cu$/formaldehyde were significantly enhanced, indicating the ability of $(Gly)_2Cu$ to sustain the transformation of glycine into serine through stabilization of the important precursors shown in Figures 2 and 3 that can act as a reservoir for the continuous generation of volatiles.

Supporting Information

ABSTRACT: Furanoterpenoid accumulation in response to microbial attack in rotting sweetpotatoes has long been linked to deaths and lung edema of cattle in the world. However, it is not known whether furanoterpenoid ipomeamarone accumulates in the healthy-looking parts of infected sweetpotato storage roots. This is critical for effective utilization as animal feed and assessment of the potential negative impact on human health. Therefore, we first identified the fungus from infected sweetpotatoes as a *Rhizopus stolonifer* strain and then used it to infect healthy sweetpotato storage roots for characterization of furanoterpenoid content. Ipomeamarone and its precursor, dehydroipomeamarone, were identified through spectroscopic analyses, and detected in all samples and controls at varying concentrations. Ipomeamarone concentration was at toxic levels in healthy-looking parts of some samples. Our study provides fundamental information on furanoterpenoids in relation to high levels reported that could subsequently affect cattle on consumption and high ipomeamarone levels in healthy-looking parts.

KEYWORDS: *sweetpotato, furanoterpenoids, ipomeamarone, animal and human health safety, Rhizopus stolonifer*

INTRODUCTION

Despite the prevalence of respiratory infections and deaths relating to furanoterpenoids on global health of cattle and possibly humans, the concentration levels of these compounds in diseased and healthy-looking parts of infected sweetpotatoes is poorly understood and insufficiently documented. Phytoalexins are inducible metabolites elicited by biotic and abiotic factors. Sweetpotato contains several phytoalexins, collectively known as furanoterpenoids, including ipomeamarone, **1**; dehydroipomeamarone, **2**; 4-ipomeanol, **3**; and 1,4-ipomeadiol, **4** (Figure 1).[1,2] Biotic factors such as fungi are reported to elicit varying levels of furanoterpenoids,[2] which cause hepatoxicity, pneumonia, lung edema,[3−5] and cattle deaths.[6] Although information on furanoterpenoids is available concerning isolation methods[7] and presence in sweetpotatoes,[2,8] there is no documented or accessible information on variation of the concentrations from inoculation point on toward healthy-looking parts of an infected sample. This is important because in sub-Saharan Africa (SSA), sweetpotato is a food crop for many rural poor families whereby both healthy and infected sweetpotato storage roots are harvested together. The infected parts are usually removed and fed to farm animals, while the remaining apparently healthy parts are consumed by the farm households, typically in western Kenya (Dr. Robert Mwanga, sweetpotato breeder, personal communication).

Sweetpotato is ranked the third most important root and tuber crop after potato and cassava in SSA. As a food crop, sweetpotato is used by many poor families because of the higher yield in dry matter content per unit area compared to cereal cultivation on an equivalent piece of land.[9] In addition, sweetpotatoes are particularly important during dry periods of the year when cereal crops are unavailable.[9] Unfortunately, it is during the same dry period that the crop is attacked by insects and microbes.[10,11] It is also known that farmers in SSA practice piece-meal harvesting, which exposes the storage roots left in the soil during dry seasons to insects and microbes.[12] Farmers who harvest sweetpotato storage roots for sale are faced with postharvest infection because microbes attack the storage roots owing to the favorable warm conditions and bruising caused by handling.[13] Storage roots respond to attack by eliciting production of furanoterpenoids to fight off the infection within the sweetpotato tissues. The total furanoterpenoid level of three compounds was documented between 25 and 67,000 mg/kg in harvested storage root samples irrespective of the microbe that elicited their accumulation.[1,2] The use of radioactivity to analyze ipomeamarone levels has been done, but more sensitive

techniques, such as coupled liquid chromatography-quadruple time-of-flight mass spectrometry (LC−QToF−MS) and coupled gas chromatography−mass spectrometry (GC−MS), are needed.[14]

It is not known how far into the healthy-looking storage root samples that these furanoterpenoids are found and at what levels. Since this could potentially expose both humans and farm animals to either chronic or acute toxicity, we (i) isolated and identified a fungus from field samples that elicited furanoterpenoid production; (ii) characterized the furanoterpenoids using GC−MS and LC−QToF−MS; (iii) evaluated the furanoterpenoid concentration levels produced for different sweetpotato cultivars after infection by the isolated fungus; and (iv) determined the furanoterpenoid levels within the apparently healthy part of infected storage roots.

MATERIALS AND METHODS

Plant Materials. Two types of sweetpotato (*Ipomoea batatas* L. Lam) samples were used to analyze for ipomeamarone concentrations: weevil-infected sweetpotatoes for fungal isolation and healthy sweetpotatoes for inoculation experiments with the isolated fungus. Healthy sweetpotatoes were purchased from markets in Nairobi, Kenya and were classified by the vendors as Kemb, Naspot, Bungoma, and Nyawo cultivars. Weevil-infested sweetpotato storage roots were sampled from a farm at the Kenya Agricultural Research Institute (KARI), Marigat, Kenya during the dry season when infestation was high. Sampled storage roots were carefully placed in covered but aerated plastic jars (20.5 cm × 10.5 cm) immediately after harvest and then incubated at 25−28 °C for 5 days to promote growth of microbes.

Isolation and Identification of Fungus from Weevil-Infested Sweetpotatoes. Isolation was carried out from fully infected storage roots in jars by using a pin and plated on potato dextrose agar (PDA) (Oxoid, Hampshire, England) media supplemented with 50 μg/mL streptomycin sulfate (Sigma, St. Louis, MO) and chloramphenicol (25 μg/mL) (Sigma, St. Louis, MO) to inhibit bacterial growth. Plates were incubated overnight at 25 °C during which several colonies emerged. Single colonies were isolated and subcultured on PDA without antibiotics. There was a colony that was consistently found on all the PDA plates, and then named Marigat isolate-1 (MI-1). It was identified using both morphological and molecular characterization. For morphological identification, a fungal isolation technique previously described was used.[15] The PDA plate was inoculated using a sterile needle. A sterile glass coverslip was placed in an oblique position on the culture, and plates were incubated at 25 °C for 4−6 days. From day two onward, coverslips were removed daily and mounted on a slide stained with lactophenol aniline blue (Sigma-Aldrich, St. Louis, MO). The coverslips were examined using a light microscope (Leica, Wetzlar, Germany) at the magnifications ×8 and ×40.

Molecular characterization of MI-1 was initiated by isolation of genomic DNA using CTAB method from mycelia grown on PDA plates.[16] Polymerase chain reaction (PCR) was conducted using internal transcribed spacers (ITS) primer pairs.[17] Nonspecific PCR products generated were further eliminated by band-stab PCR.[18] The PCR comprised a 25 μL reaction that consisted of PCR buffer (1*x*), ITS1 primer (0.2 μM), ITS4 primer (0.2 μM), dNTPs (0.06 mM), $MgCl_2$ (2 mM), and Taq polymerase (0.5 unit) (Thermo Scientific, Wyman, MA). The primer sequences for ITS1 and ITS4 were 5′ TCCGTAGGTGAACCTGCGG 3′ and 5′ TCCTCCGCTTATTGATATGC 3′, respectively.[17] This reaction mix was subjected to the following PCR program: initial denaturation 94 °C for 5 min, followed by 40 cycles of denaturation 94 °C for 45 s, annealing temperature 60 °C for 30 s, elongation 72 °C for 90 s, and a final elongation 72 °C for 6 min. PCR was conducted on several other microbes to verify that the amplicon generated from MI-1 was not present in other microbes or if present, it was not of a similar size. The microbes included were as follows: MI-1; *Metarhizium anisopliae* IC30 from ICIPE; *Ceratocystis fimbriata* f. sp. *platani* (CBS 127659); *Clavibacter michiganensis* ssp. *michiganensis*; *Catharanthus roseus* containing Udinese-Stolbur phytoplasma from CBS-KNAW Fungal Biodiversity Centre (Utrecht, The Netherlands); and an unknown fungus culture collected from potato fields and were grown on PDA media containing streptomycin sulfate. PCR products were resolved on 1% agarose gel in TBE for 1 h at 100 V. PCR products were purified using QIAquick PCR Purification kit (Qiagen, Hilden, Germany) and Gel Extraction kit (Qiagen, Hilden, Germany). Purified PCR products were sequenced using GS-FLX 454 platform (454 Life Sciences/Roche, Bradford, CT).

Extraction and Identification of Furanoterpenoids from Fungal-Infected Sweetpotatoes. The storage root samples were prepared using a previously described method[2] with few modifications. Healthy storage roots from sweetpotato cultivars namely Kemb, Naspot, Nyawo, and Bungoma were washed, surface sterilized for 5 min using 0.5% sodium hypochlorite, and rinsed three times in sterile distilled water in a laminar flow hood. In the first experiment, the storage root samples were cut into halves and placed in clean sterile plastic containers and then inoculated with actively growing fungal isolate (MI-1) from agar plugs, while the controls were not inoculated. The sweetpotato samples (both inoculated and noninoculated) were replicated three times for each cultivar. The second experiment consisted of inoculating Kemb and Naspot cultivars using MI-1, and storage roots tied with polythene and elastic bags to restrict growth of the fungus. The storage roots were incubated at 25 °C for 7−14 days for infection. This second experiment consisted of two cultivars, Kemb and Naspot, with seven samples. Each sample was chopped into 1 cm slices to analyze furanoterpenoid levels from infection point to the healthy-looking tissue. Differences between means were estimated using a Student−Newman−Keuls test.

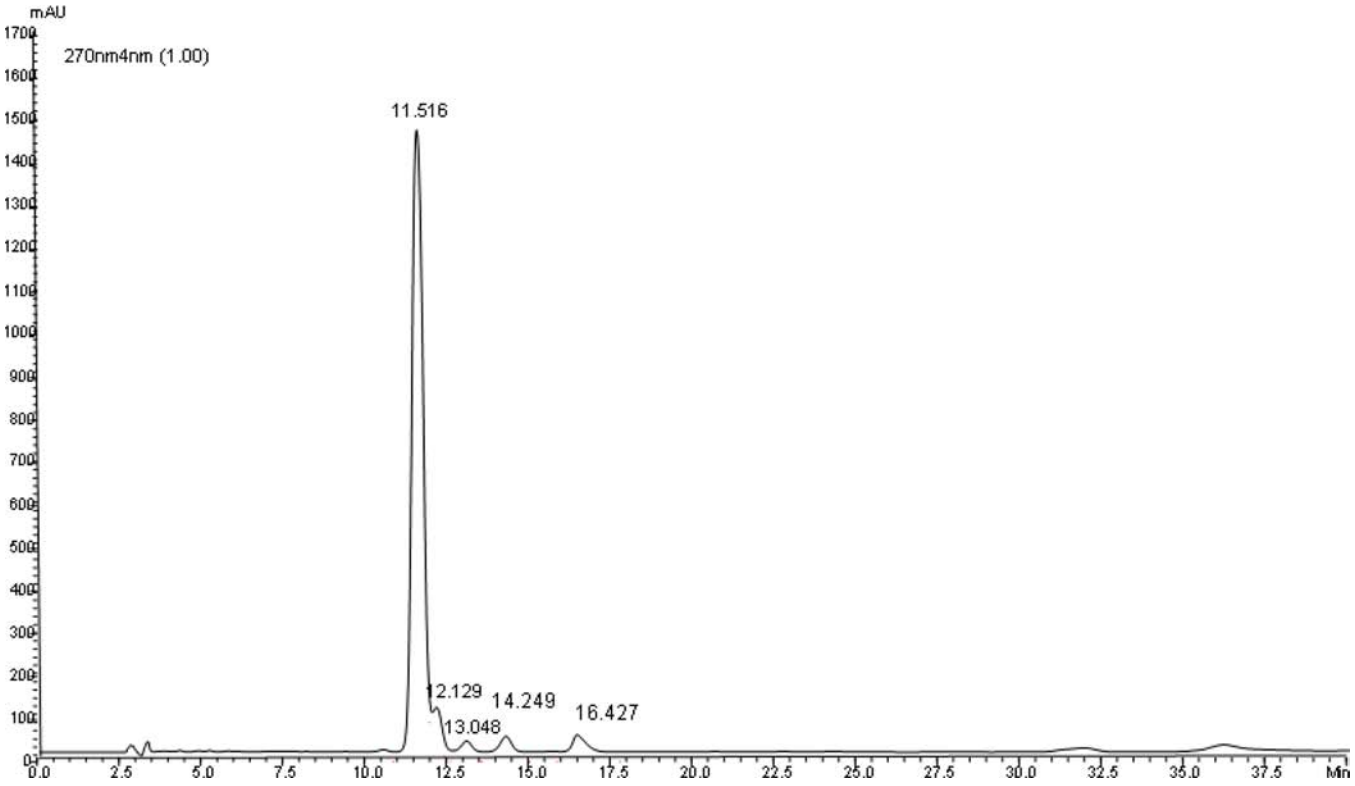

Figure 2. HPLC profile of the furanoterpenoid mix isolated from column chromatography with ipomeamarone and dehydroipomeamarone indicated as 16.43 min and 11.52 min, respectively.

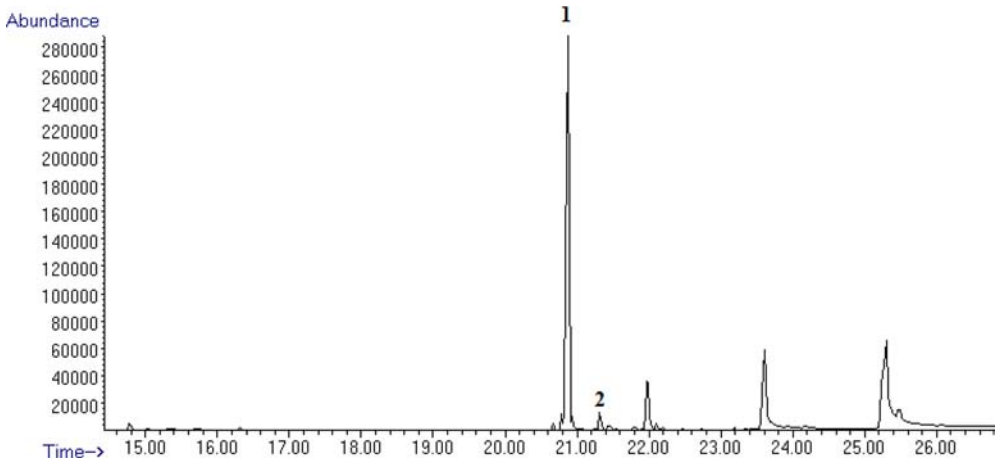

Figure 3. Representative GC−MS total ion chromatogram of purified furanoterpenoids: ipomeamarone, **1**; and dehydroipomeamarone, **2**.

The fungus covering the sweetpotato was scraped off. The storage roots were then weighed and blended in 100 mL of methanol and 3 g of NaCl for 3 min. For isolation and purification of dehydroipomeamarone and ipomeamarone, 268 g of infected sweetpotato was extracted with 550 mL of methanol. The extracts were filtered using Whatman filter paper No. 4, poured in conical flasks, and then concentrated in a rotary evaporator to remove methanol and water. The volume of concentrated crude extract was estimated as 10 mL, and the same volume of 10 mL of dichloromethane (Sigma, St. Louis, MO) was added to effectively double the volume of the extract for each flask. The organic phases were combined, concentrated to dryness in a rotary evaporator to remove any remaining solvents from the crude extract, weighed, and then purified by chromatography.

Fifteen grams of the extracted materials was chromatographed on 32−63 μm silica gel (Riedel-de Haen, Seelze, Germany) using a hexane−ethyl acetate gradient. The furanoterpenoids fraction was eluted with 90% hexane:ethyl acetate, which was further cleaned by column chromatography using a hexane−acetone gradient to yield ipomeamarone mix (1 g). Further purification of the eluent was carried out on a Shimadzu VP series using a 205 mm × 10 mm i.d., 5 μM ACE Q C-18 column (ACE, Aberdeen, Scotland). The mobile phase used an isocratic program (A:B), 60:40 with a flow rate of 1 mL/min, and run time was 20 min. Detection was by UV absorption at 270 nm to obtain 18 mg of ipomeamarone and 15 mg of dehydroipomeamarone with percentage yield being 0.12% and 0.10%, respectively (Figure 2). Structures of the isolated furanoterpenoids were determined by means of chromatographic and spectroscopic techniques (LC−QToF−MS, GC−MS, and 1- and 2-D NMR) and by comparison with spectroscopic literature data.[1,19]

For GC−MS analyses, the furanoterpenoids fractions was analyzed by split/splitless injection using a model 7890 gas chromatograph coupled to a 5975C inert XL EI/CI mass spectrometer (Agilent

dx.doi.org/10.1021/jf504702z | J. Agric. Food Chem. 2015, 63, 335−342

Technologies, Palo Alto, CA) (GC−MS) equipped with a 30 m × 0.25 mm i.d. × 0.25 μm film thickness HP-5 column (El 70 eV) (Agilent Technologies, Palo Alto, CA). Helium was used as the carrier gas at a flow rate of 1.2 mL/min. The oven temperature was held at 35 °C for 3 min and then programmed to increase at 10 °C/min to 280 °C and maintain this temperature for 10 min. The target peaks were identified through comparison of their mass spectra with Adams2.L, Chemecol.L, and NIST05a.L library data (Figure 3).

For LC−QToF−MS analyses, the crude extract was concentrated in vacuo to dryness, redissolved in 3 mL of LC−MS grade CHROMASOLV methanol (Sigma-Aldrich, St. Louis, MO), and centrifuged at 14,000 rpm for 5 min, after which 0.5 μL was automatically injected into LC−QToF−MS. The chromatographic separation was achieved on a Waters ACQUITY UPLC (ultra-performance liquid chromatography) I-class system (Waters Corporation, Maple Street, MA) fitted with a 2.1 mm × 100 mm, 1.7-μm particle size Waters ACQUITY UPLC BEH C18 column (Waters Corporation, Dublin, Ireland) heated to 40 °C and an autosampler tray cooled to 15 °C. Mobile phases of water (A) and acetonitrile (B), each with 0.01% formic acid were employed. The following gradient was used: 0−1.5 min, 10% B; 1.5−2 min, 10−50% B; 2−6 min, 50−100% B; 6−9 min, 100% B; 9−10 min, 90−10% B; 10−12 min, 10% B. The flow rate was held constant at 0.4 mL/min. The UPLC system was interfaced by electrospray ionization (ESI) to a Waters Xevo QToF−MS operated in full scan MS^E in positive mode. Data were acquired in resolution mode over the m/z range of 100−1200 with a scan time of 1 s using a capillary voltage of 0.5 kV, sampling cone voltage of 40 V, source temperature of 100 °C, and desolvation temperature of 350 °C. The nitrogen desolvation flow rate was 500 L/h. For the high-energy scan function, a collision energy ramp of 25−45 eV was applied in the T-wave collision cell using ultrahigh purity argon (≥99.999%) as the collision gas. A continuous lock spray reference compound (leucine enkephalin; $[M + H]^+ = 556.2766$) was sampled at 10 s intervals for centroid data mass correction. The mass spectrometer was calibrated across the 50−1200 Da mass range using a 0.5 mM sodium formate solution prepared in 90:10 2-propanol/water (v/v). MassLynx version 4.1 SCN 712 (Waters Corporation, Maple Street, MA) was used for data acquisition and processing. The elemental composition was generated for every analyte. Potential assignments were calculated using monoisotopic masses with specifications of a tolerance of 10 ppm deviation and both odd- and even-electron states possible. The number and types of expected atoms were set as follows: carbon, ≤100; hydrogen, ≤100; oxygen, ≤50; nitrogen, ≤6; sulfur, ≤6. The LC−QToF−MS data acquisition and analysis were based on the following defined parameters: mass accuracy (ppm) = 1,000,000 × (calculated mass − accurate mass)/calculated mass; fit conf % is the confidence with which accurate mass (measured data) matches the theoretical isotope models of the elemental composition in the list; elemental composition is a suggested formula for the specified mass. This is a summation of the quantities of elements, isotopes, or superatoms that can compose the measured data, calculated using the following atomic masses of the most abundant isotope of the elements: C = 12.0000000, H = 1.0078250, N = 14.0030740, O = 15.9949146, and S = 31.9720718. The empirical formula generated was used to predict structures that were proposed based on the online database, fragmentation pattern, and literature.

To verify the identity of these peaks, nuclear magnetic resonance (NMR) was done. The isolated and purified ipomeamarone and dehydroipomeamarone samples (5 mg each) were each dissolved in $CDCl_3$ (Cambridge Isotope Laboratories, Tewksbury, MA) and placed in 2.5 mm × 100 mm MATCH NMR tubes (Norell, Landisville, NJ). 1D and 2D ^1H and ^{13}C NMR spectroscopy, including correlation spectroscopy (COSY), heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC) spectroscopy, were used for verification. For the dehydroipomeamarone, 2D nuclear Overhauser effect spectroscopy (NOESY) data were collected and analyzed for additional structural verification (see Supporting Information). All NMR spectra were acquired at 22 °C using a 5 mm TXI CryoProbe (Bruker Corporation, Billerica, MA) and a Bruker Avance II 600 console (600 MHz for ^1H and 151 MHz for ^{13}C) except for 2D NOESY data, which was collected at 25 °C. Residual $CHCl_3$ was used to reference chemical shifts to δ 7.26 ppm for ^1H, and δ C1 of ipomeamarone is referenced to 72.6 ppm for ^{13}C in the HSQC spectrum by a previous report for consistency with the literature.[20] We also checked the residual $CHCl_3$ in $CDCl_3$ for ^{13}C in the HSQC spectra to confirm that it was properly referenced according to a previous study.[21] NMR spectra were processed using Bruker Topspin 2.0 and MestReNova (Mestrelab Research) software packages.

Quantitation of Furanoterpenoids in Sweetpotato Samples. LC−QToF−MS in full scan MS^E in positive mode was used to detect furanoterpenoids in extracts based on accurate mass measurement, retention time, fragmentation pattern, and reference spectra database published online of isolated dehydroipomeamarone and ipomeamarone (standards).[22] Dehydroipomeamarone and ipomeamarone were quantitated using generated standard calibration curves prepared from the isolated compounds. Serially diluted solutions of isolated standards (0.01−200 μg/μL) were analyzed by LC−QToF−MS to generate linear calibration curves (peak area vs concentration) for ipomeamarone [$y = 583{,}064x + 642{,}221$ ($R^2 = 0.9991$)] and dehydroipomeamarone [$y = 324{,}980x + 177{,}617$ ($R^2 = 0.9995$)], which served as the bases for external quantitation.

RESULTS AND DISCUSSION

Identification of MI-1 as *Rhizopus stolonifer*. Identification of MI-1 fungus isolated from the field-collected sweetpotato storage roots was conducted because different microbes elicit varying furanoterpenoid responses.[2] On the basis of morphological features (sporangia, sporangiophores, spores, collumella, rhizoids, and stolons); sporangiophores that arise from intersections with rhizoids and stolons; the dome-shaped columella; and not falling off when the sporangium dried out, MI-1 was identified as belonging to the genus *Rhizopus*. Morphological features of MI-1 had similarities to previously reported *R. stolonifer*.[23,24] The major finding was the collumella being dome-shaped, which differed from other *Rhizopus* species as previously reported as follows: *R. oryzae* has an ellipsoidal collumella; *R. sexualis*, a conical-cylindrical shape; and *R. microspores*, a subglobose to conical shape.[25] From these observations, it was appropriate to suggest that MI-1 fungus was *R. stolonifer*.

The morphological features of *Rhizopus* further confirmed by molecular evidence enabled us identify the species. The ITS primer pair generated an amplicon of 950 bp for MI-1 fungus; none of the other species in this study had a similar band size to MI-1. *Metarhizium anisopliae* IC30 had a band of 600 bp. Sequencing generated a number of reads, but searches were conducted using sequences longer than 200 bp, based on nonredundant database of NCBI, and produced 100 hits. These hits were mainly ITS1, ITS2, 5.8S, 18S, and 28S fragments with partial or complete length sequences; the top 19 hits based on *e*-value were *Rhizopus stolonifer*. Sequence similarity was of 91−99% with *e*-values between 0 and 9×10^{-162}. The best alignment to MI-1 was isolate AM933546.1, which had a sequence identity of 98% and an *e*-level of 0. The *R. stolonifer* isolate had a partial sequence of 18S rRNA gene, ITS1; 5.8S rRNA gene, ITS2; and partial sequence of 28S rRNA gene. Molecular characterization using ITS primers confirmed that MI-1 fungus was *R. stolonifer*; such primers have previously been used in *R. stolonifer* identification.[16]

Chromatographic and Spectroscopic Techniques Confirmed Presence of Furanoterpenoids. The furanoterpenoids ipomeamarone and dehydroipomeamarone were successfully identified using HPLC, GC−MS, LC−QToF−MS,

Table 1. Furanoterpenoids-Present and Concentrations in Sweetpotato Extracts from Four Cultivars for Both Inoculated Samples and Their Respective Controls[a]

cultivar samples inoculated with MI-1 and respective controls with no inoculation	phytolaexin present	mean concentration levels (μg/g) ± s.e.

[a]Means with the same letter are not significantly different from each other.

and 1D and 2D NMR techniques by comparing their resonances to published data.[20,21,26,27] The HPLC analysis (Figure 2) showed six peaks with ipomeamarone and dehydroipomeamarone eluting at 16.4 and 11.6 min, respectively. GC−MS analysis also revealed six peaks and tentatively identified two of these peaks as ipomeamarone, **1**, at a retention time (R_t) of 20.8 min and dehydroipomeamarone, **2**, at an R_t of 21.4 min (Figure 3). LC−QToF−MS analysis also identified the two peaks as ipomeamarone (with elemental composition, $C_{15}H_{23}O_3$; m/z 251.1647, 0.0 ppm error to theoretical value; and a fit conf % of 99.96) at a R_t of 2.87 min and dehydroipomeamarone (with elemental composition, $C_{15}H_{21}O_3$; m/z 249.1491, 2.0 ppm error to theoretical value; and a fit conf % of 98.78) at a R_t of 3.04 min. These results were consistent with the GC−MS analysis.

The HPLC purified peaks analyzed by NMR confirmed the presence of ipomeamarone and dehydroipomeamarone. ^{1}H chemical shifts of ipomeamarone were in agreement with literature, while dehydroipomeamarone was a mixture based on LC−QToF−MS and NMR data.[20,27] For dehydroipomeamarone, we observed the ^{1}H chemical shifts at positions C-7 as 6.15 ppm (1H), C-9 as 2.13 ppm (3H), and C-10 as 1.85 ppm (3H), which were the only ^{1}H chemical shifts as provided by previous workers.[27] These workers reported the ^{1}H chemical shifts for positions C-7 as 6.11 ppm (1H), C-9 as 2.09 ppm (3H), C-10 as 1.81 ppm (3H), and all of the other ^{1}H chemical shifts were similar to those of ipomeamarone.[27] Unfortunately, these three ^{1}H chemical shifts differed 0.04 ppm between our spectrum and previously reported data.[27] Since the dehydroipomeamarone sample was a mixture, having just ^{1}H 1D NMR was not satisfactory to confirm the presence of dehydroipomeamarone. Unfortunately, previous workers did not provide any information about NMR solvent or ^{13}C chemical shift data for the synthetic dehydroipomeamarone.[27] Therefore, we acquired a 2D NMR (COSY, HSQC, HMBC, NOESY) spectrum for dehydroipomeamarone and ipomeamarone samples to compare the ^{13}C chemical shifts, since dehydroipomeamarone is a derivative of ipomeamarone, which we confirmed using ^{1}H NMR. Ipomeamarone 2D NMR data was used for comparison. Both ^{1}H and ^{13}C chemical shifts of dehydroipomeamarone were similar to ipomeamarone for carbon positions from 1′−4′ and from 1−6, but differed at positions 7, 8, 9, and 10: consistent with the structure. NOESY data for dehydroipomeamarone provided us additional evidence to confirm its correct identification.

Variations in Ipomeamarone Concentrations between and within Cultivars. The main furanoterpenoids produced were ipomeamarone, **1**, and dehydroipomeamarone, **2**, found in all samples and noninoculated controls. The concentration of furanoterpenoid ranged between 50.6 and 2,330 mg/kg for inoculated samples and 12.4−144.5 mg/kg for the controls. These high levels exceeded those reported previously for *R. stolonifer* of 200−1,100 mg/kg but were comparable to high ipomeamarone elicitors such as *C. fimbriata* and *Fusarium solani* with levels from 1,100−9,300 mg/kg.[2] Similar results have been reported on noninfected sweetpotatoes with low ipomeamarone concentrations between 40 and 325 mg/kg for cultivars in the United Kingdom.[8] Generally, mechanical injury or damaged but noninfected sweetpotato is reported to elicit low furanoterpenoid levels, while infected samples have high levels due to the increase in enzyme activity, which correlates to furanoterpenoid production.[28,29] The low ipomeamarone levels in storage roots of negative control samples from this study confirm that injury or bruising of sweetpotato roots occurs, but the ipomeamarone levels are low.

Concentration levels for ipomeamarone ranged between 50.6 and 2,126.7 mg/kg, while they ranged from 39.3−2,230.4 mg/kg for dehydroipomeamarone. The higher dehydroipomeamarone levels could possibly be because it is a precursor of ipomeamarone, which means that it was yet to be enzymatically converted to ipomeamarone, or dehydroipomeamarone might have inhibited production of ipomeamarone to some extent as reported previously.[1] In preliminary experiments (not shown), ipomeamarone levels were high in inoculated samples, probably due to long incubation time of 28 days compared to the current study where inoculation ranged between 7 and 14 days. More research needs to be conducted to verify this.

Variations in mean ipomeamarone levels by cultivar were as follows: Kemb had the highest mean of 1,476.2 mg/kg, followed by Nyawo with 1,089.9 mg/kg; Naspot had a mean of 833.7 mg/kg, while Bungoma had a mean of 676.5 mg/kg (Table 1). High concentrations of dehydroipomeamarone were

dx.doi.org/10.1021/jf504702z | J. Agric. Food Chem. 2015, 63, 335−342

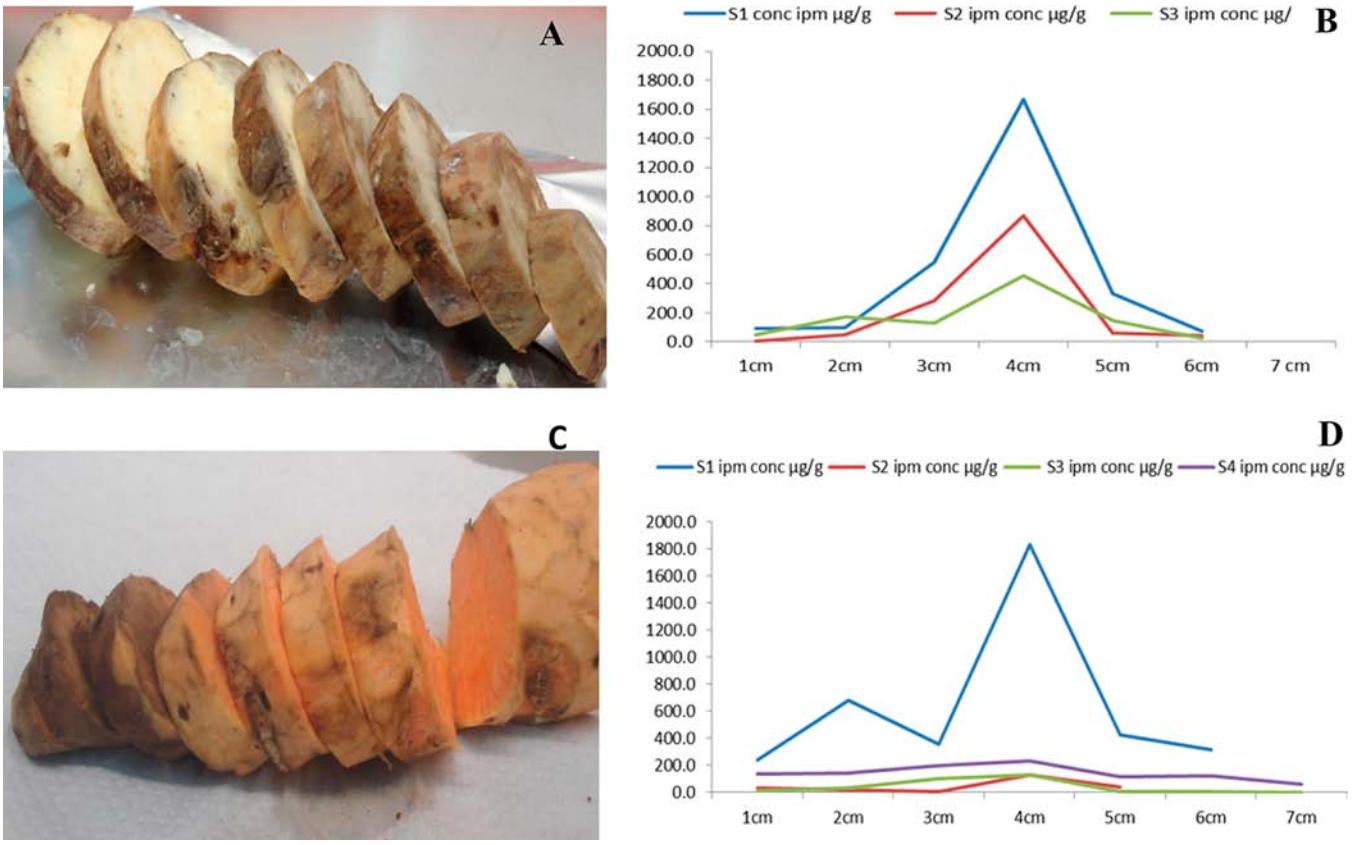

Figure 4. Controlled infection of sweetpotato samples by *Rhizopus stolonifer* that enabled ipomeamarone analysis of 1 cm slices for Kemb (A, B) and Naspot (C, D) cultivar samples.

also observed in almost all samples in this study: Kemb had the highest with 1,462.6 mg/kg, Nyawo had 1,459.7 mg/kg, Naspot had 1,153.2 mg/kg, and Bungoma had 910 mg/kg (Table 1). There were significant ($p < 0.05$) differences between cultivars. In addition, there were differences in ipomeamarone levels within the same cultivar, for example, Nyawo had 602 mg/kg in one sample, while the other had 2,126 mg/kg. Similar variations were observed for different cultivars for ipomeamarone in other studies ranging from 11−2,000 mg/kg.[2,8] Such variations have been speculated to be associated with moisture loss, root maturity, and susceptibility or resistance to fungal infection.[30] Other causes of variation include environmental factors such as postharvest practices by different farmers before arrival at the markets. These variations could have affected the concentrations in the current study. Differences in concentrations for these cultivars also suggest that they vary in resistance to *R. stolonifer* attack with Kemb being the most resistant, followed by Nyawo, Naspot, and Bungoma. These results concur with reports from other studies where the differences in ipomeamarone levels were attributed to *Rhizopus* soft rot resistance.[31]

Higher Ipomeamarone Concentrations in Healthy Parts Away from the Infection Site. We were successful in confining MI-1 fungus in the controlled infection experiment of Naspot and Kemb cultivars. We observed visually the infection to be high at the inoculation place while decreasing progressively with increased distance from the inoculation site (Figure 4). By contrast, evaluation of the 1 cm slices recorded high ipomeamarone levels for regions with visibly low infection, while low levels were observed for regions with visibly high infection (Figure 4). This trend was observed for all samples evaluated, which showed high ipomeamarone levels at the border between the visibly infected and the healthy-looking site. Similar results have been reported that phytoalexins are produced in healthy tissues surrounding wounded parts but terminate in the necrotic tissue.[32] The highest levels of ipomeamarone were observed in both Kemb and Naspot samples of 1,671.2 and 1,708.4 mg/kg, respectively, at the border between the visible infection and healthy-looking tissues (Figure 4). We also observed differences in ipomeamarone levels in some samples, which could have been due to variations in infection on the fungus along the storage root (Figure 4). There were significant ($p < 0.05$) differences between the samples. In another study, it was reported that elimination of 3−10 mm of disease portions beyond infected regions and also cooking removes most ipomeamarone.[33] This could be true for root samples with high levels only at the border, but in the current study, some samples had high levels even in subsequent layers. This suggests that removal of 1 cm from the infection area will still leave behind most of ipomeamarone depending on how much the subsequent layers had accumulated. In other studies, cooking was reported to destroy about 80% of ipomeamarone, but this depends on the initial concentration level found in the storage root before cooking.[34,35]

Since rural poor farmers in SSA keep 1−2 cows, and these farm animals contribute 30−80% of farm income,[36] if they feed them with diseased sweetpotatoes with exceeding toxicity, their fragile revenues will be at threatened by high costs of treatment or even total low of the intoxicated cow. This information is important for farmers' knowledge since they harvest infected roots, cut off the infected part to feed the farm animals, and then consume the healthy-looking parts (Dr. Robert Mwanga,

dx.doi.org/10.1021/jf504702z | J. Agric. Food Chem. 2015, 63, 335−342

sweetpotato breeder, personal communication). Although there are no reports on how far into the visibly healthy-looking part the farmers cut off these storage roots, either the farmers' household consume the parts with high ipomeamarone concentration, or the animals are fed with it. Results drawn from this study suggest that at least 2−3 cm away from the border between the healthy-looking and the infected part of the damaged sweetpotato storage root should be cut off and disposed of, and the infected part should not be fed to the farm animals because of the presence of toxic phytoalexins.

In conclusion, ipomeamarone accumulation in the apparently healthy parts of damaged sweetpotato storage roots should be considered as a potential economic problem and health threat to both the rural poor farm families and large-scale farmers worldwide. Our results reveal the importance of this problem, but more research should be directed to obtaining information on (i) furanoterpenoids present in infested and infected sweetpotatoes harvested from the sweetpotato fields; (ii) furanoterpenoid levels in sweetpotatoes from farmers' households; (iii) varietal response to fungal infection resulting in ipomeamarone accumulation; (iv) degradation of ipomeamarone after processing infested roots and accumulation in metabolism in animal and human organisms; and (v) management of the problem by the rural poor.

Supporting Information

ABSTRACT: A total of 70 tomato-based and 86 citrus-based products collected in China were analyzed for alternariol, alternariol monomethyl ether, tentoxin, and tenuazonic acid by ultraperformance liquid chromatography−electrospray ionization−tandem mass spectrometry. No toxins were found in any fresh tomato or citrus fruit samples. Tenuazonic acid was the predominant toxin detected in all tomato ketchup (10.2−1787 μg/kg) and tomato juice samples (7.4−278 μg/kg). Alternariol was quantitated at higher level than alternariol monomethyl ether with the ratio of alternariol/alternariol monomethyl ether ranging from 0.37 to 104 in 14 alternariol-positive tomato ketchup samples. Tentoxin was detected at much lower levels in all samples analyzed. Some citrus juice samples were positive for tenuazonic acid and alternariol monomethyl ether. It is necessary to conduct a systemic surveillance of *Alternaria* toxins in raw and processed foods to provide the scientific basis for risk assessment of dietary exposure to these toxins in Chinese populations.

KEYWORDS: *Alternaria toxins, tomato-based products, citrus-based products, China, UPLC-MS/MS*

INTRODUCTION

Alternaria toxins are produced by *Alternaria* species that are saprophytic and pathogenic on many plants. These species of fungi produce more than 70 secondary metabolites, but a small proportion of these toxins have been chemically characterized and documented to act as mycotoxins to humans and animals.[1,2] The most important *Alternaria* toxins with toxicological significance reported to occur in cereals, oilseeds,[3] vegetables (especially tomato),[4,5] and fruits (apples,[6] citrus fruits[7] etc.) are alternariol, **1**; alternariol monomethyl ether, **2**; tentoxin, **3**; and tenuazonic acid, **4** (Figure 1).

Limited in vivo study showed that alternariol monomethyl ether poses fetotoxicity and teratogenicity to hamsters.[8] Moreover, alternariol and alternariol monomethyl ether are mutagenic and genotoxic in various in vitro systems, and there is also some evidence for carcinogenic properties in unconventional assays.[9,10] In addition, it has been suggested that the contamination of *Alternaria* toxins in small grains, especially in wheat grains, is much heavier in the high-incidence areas for human esophageal cancer than in the low-incidence areas.[11] The production of these toxins is affected by interactions among the *Alternaria* strain, the growing substrate, and the environmental conditions.[2] Fresh plant products affected by *Alternaria* regularly present visible rotten areas, and the *Alternaria* toxins can be transferred from the rotten part to the surrounding tissues.[6] Hence, *Alternaria* toxins are also present in processed plant products due to the limitations of the current industrial procedures to eliminate the rotting tissues completely.[12] The occurrence of *Alternaria* mycotoxins in processed foodstuffs is becoming an increasing concern for public health. The analytical methods for the analysis of these toxins have focused on liquid chromatography coupled to single mass spectrometry (MS) or tandem MS.[7,10,13−17] Stable isotope dilution assays have been employed in the determination of *Alternaria* toxins, in which labeled internal standards were used to compensate for analyte losses during sample preparation and ion suppression in the ESI interface in current methodology.[16,18,19]

Tomatoes and citrus fruits can easily be infected by fungi of *Alternaria*, and their products such as tomato ketchups and citrus juice are frequently contaminated with *Alternaria* mycotoxins.[7] Although only a limited number of papers describe the contamination of *Alternaria* toxins in local agricultural crops in China, the natural occurrence of these mycotoxins in tomato and tomato products, citrus, and citrus products have not been reported so far. On the other hand, risk assessments relating to food safety in China are frequently hampered by the lack of quantitative data. According to the European Food Safety Authority (EFSA),[10] the contribution to dietary exposure to *Alternaria* toxins is mainly made by grain and grain-based products, vegetables and vegetable products, and fruits and fruit products, depending on the toxin and the food consumption pattern in different countries. To the present

time, however, no study has been carried out for *Alternaria* toxin contamination in tomato and citrus products at the national level in China. Therefore, no data on risk assessment of dietary exposure to *Alternaria* toxins in the Chinese population is available so far. To provide the scientific data for assessing the impact of *Alternaria* toxins on Chinese public health, the purpose of this study was to evaluate the natural occurrence of associated *Alternaria* mycotoxins in Chinese fresh tomato, tomato ketchup, and fresh citrus, and citrus juice. The results obtained will be expected to contribute to either the development of strategies to reduce risk from these contaminants or the ongoing research on the relationship between the consumption of tomato and citrus products contaminated with *Alternaria* toxins and human disease.

MATERIALS AND METHODS

Reagents and Chemicals. Methanol and acetonitrile used for sample extraction and toxin separation were of HPLC grade (Dikma Pure, Richmond Hill, GA, USA). Both ammonium bicarbonate (Sigma-Aldrich, St. Louis, MO, USA) and formic acid (≥95% purity) (Fluka, Steinheim, Germany) were of analytical grade. Pure water was obtained from a Millipore Milli-Q System (Millipore, Bedford, MA, USA). Standards for alternariol (purity > 98%), alternariol monomethyl ether (purity > 98%), tentoxin (purity > 99%), and tenuazonic acid (purity > 99%) were purchased from Fermenteck Ltd. (Jerusalem, Israel). All experimental practice followed Environmental Health Safety Guidelines for the use of chemicals authorized by China National Center for Food Safety Risk Assessment. In addition, sample collection and solvent extracts should be handled with care.

Samples. A total of 30 fresh tomato and 40 tomato-based products including tomato ketchup (n = 31) and tomato juice (n = 9) samples as well as 50 fresh citrus and 36 citrus juice samples were randomly collected from supermarkets and agricultural trade markets in Beijing. The fresh tomatoes covered the main cultivars in China such as common tomato and cherry tomato that came from the main vegetable-producing regions including Beijing, Shandong, Hebei, Jiangsu, Tianjin, Fujian, Zhejiang, and Guangdong provinces. Tomato ketchup and tomato juice samples covered the main brands available in markets in China; the nine tomato ketchup samples were imported from Bulgaria (two samples), Italy (two samples), Japan, Turkey, Australia, the United States, and Spain, respectively. All samples were stored at 4 °C until analysis.

Toxin Extraction. The extraction of *Alternaria* toxins from samples was modified on the basis of the methods described by Kocher[20] and Rheinhold et al.[21] with a minor modification. In brief, both fresh tomatoes and citrus fruits were fully ground, whereas tomato- and citrus-based products were blended or shaken thoroughly. A test portion of 5 g of sample was homogenized with 20 mL of acetonitrile/water/methanol (45:45:10, v/v/v) and sonicated in an ultrasonic cleaner for 30 min, followed by centrifuging for 10 min at 7000 rpm. A portion of 5 mL of supernatant was diluted 5 times with distilled water, adjusted to pH 3−4 with formic acid, and passed through a HLB solid phase extraction (SPE) cartridge (Waters, Rupperswil, Switzerland) preconditioned with 5 mL of methanol followed by 5 mL of water. The cartridge was washed with 5 mL of water followed by 5 mL of methanol−water (20:80, v/v). *Alternaria* toxins were eluted with 5 mL of methanol and 5 mL of acetonitrile sequentially. The organic phase elutes were combined, evaporated to dryness, and dissolved in 1 mL of methanol/water (10:90, v/v) containing 0.5 mmol/L ammonium bicarbonate and centrifuged for 5 min at 10000 rpm. An aliquot of 10 μL of the extract was injected for *Alternaria* toxins analysis by UPLC-MS/MS.

UPLC Conditions. Detection and quantitation of the four target mycotoxins were performed on a Micromass Quattro Premier XE ultra performance liquid chromatography−tandem mass spectrometry (UPLC-MS/MS) system (Waters, Milford, MA, USA). The column used was a 100 mm × 2.1 mm i.d., 1.7 μm, BEH C_{18} (Waters) thermostated at 40 °C. The mobile phase included 0.5 mmol/L ammonium bicarbonate solution (solvent A) and methanol (solvent B). A binary gradient at a flow rate of 0.3 mL/min was programmed starting at 90% A, reached 100% B in 5 min, and was maintained there for 2 min. Afterward, B was linearly decreased to 10% B within 0.1 min and maintained at this composition of mobile phase for 2 min. The retention times of the four toxins were 1.69 min for tenuazonic acid, 3.79 min for alternariol, 4.38 min for tentoxin, and 4.94 min for alternariol monomethyl ether.

Preparation of Standard Solutions. Stock *Alternaria* toxin standard solutions at the concentration of 100 mg/L were prepared by dissolving appropriate amounts of alternariol, alternariol monomethyl ether, tentoxin, and tenuazonic acid standard powder in methanol, respectively, and stored in amber vessels at −18 °C for up to 1 year. Working standard solutions were made by diluting the stock standard solutions with *Alternaria* toxin-free sample extract prepared following the toxin extraction procedure.

MS/MS Conditions. MS/MS was performed on a Waters Aquity Quattro Premier XE triple-quadrupole mass spectrometer equipped with electrospray ionization (ESI) source. The source block temperature was 100 °C, and desolvation temperature was 350 °C. Nitrogen (purity = 99.9%) was used as both the cone gas and desolvation gas at flow rates of 1 and 552 L/h, respectively, whereas high-purity argon was used as the collision gas at a flow rate of 0.2 mL/min. The mass spectrometer was operated in negative electrospray ionization (ESI^-) mode for quantitation of the four toxins. Data acquisition and evaluation were performed by Masslynx software (Micromass, Manchester, UK).

Method Validation. To evaluate the performance of UPLC-MS/MS conditions for analysis of the four mycotoxins, the matrix-matched calibration curve was made to compensate for matrix effect. Standard solutions of the four mycotoxins at concentrations ranging from 5 to 100 μg/L for tenuazonic acid, from 20 to 400 μg/L for alternariol, from 2 to 40 μg/L for tentoxin, and from 0.4 to 8 μg/L for alternariol monomethyl ether were added to the final extract solution of mycotoxin-free fresh tomato, tomato ketchup, fresh citrus, and citrus juice and processed for analysis by LC-MS/MS. To determine the method recoveries and the relative standard deviation (RSD), analyses of the spiked four matrix samples at spiking levels between 5 and 50 μg/kg (six repetitions for each) for the four mycotoxins were carried out. The limit of detection (LOD) and the limit of quantification (LOQ) for these four mycotoxins were determined with signal-to-noise ratios of 3:1 and 10:1, respectively. Reproducibility was evaluated over five consecutive days at three nominal tenuazonic acid concentrations (50, 500, and 5000 μg/kg) by spiking the

DOI: 10.1021/jf5052738
J. Agric. Food Chem. 2015, 63, 343−348

uncontaminated matrix. For each concentration and day, the standard addition scheme described above was conducted. For determination of intralaboratory reproducibility, two tomato ketchup samples naturally contaminated with tenuazonic acid, alternariol, tentoxin, and alternariol monomethyl ether at levels of 370, 37, 3.3, and 10 μg/kg and two citrus juice samples naturally contaminated with tenuazonic acid, alternariol, tentoxin, and alternariol monomethyl ether at concentrations of 370, 37, 3.3, and 10 μg/kg, respectively, were analyzed three times within 2 weeks, and duplicate analyses were conducted for each sample each time.

RESULTS AND DISCUSSION

Method Optimization. For the four toxins cleanup from a HLB SPE cartridge, methanol/water in different ratios (20:80, 30:70, and 40:60, v/v) and acetonitrile/water/methanol (45:45:10, v/v/v), respectively, were studied. Better cleanup efficiency of the analytes was obtained when methanol/water (20:80, v/v) was selected. Additionally, the choice of mobile phase should be based on the consideration of ionization efficiency before the analytes enter the MS/MS system to obtain good resolution and high sensitivity. In terms of additives in the mobile phase, aqueous ammonia, ammonium formate, and ammonium bicarbonate were studied. Responses and peak shape were greatly improved when 0.5 mmol/L of aqueous solution of bicarbonate was used as solvent A. Results indicated that when acetonitrile was chosen as the mobile phase, the ionization of all the selected analytes was significantly suppressed, and the abundance and sensitivity were thus reduced. Conversely, very positive results were observed when methanol was used as the mobile phase. Therefore, methanol was selected as the strong elution mobile phase in the present study.

Method Validation. Matrix-matched standards were used for calibration to compensate for the matrix effect. The concentrations used for making calibration curves ranged from 5 to 100 μg/L for **1**, from 20 to 400 μg/L for **2**, from 2 to 40 μg/L for **3**, and from 0.4 to 8 μg/L for **4** with linear coefficients better than 0.999. The method showed an excellent linearity over the ranges of 16−320 μg/kg for **1**, 0.3−6 μg/kg for **2**, 1.6−32 μg/kg for **3**, and 4−80 μg/kg for **4** expressed by the coefficients (r^2) of >0.99 for all curves. The validation results demonstrated high sensitivity, repeatability, and linearity of the method. The LODs of tenuazonic acid, alternariol, tentoxin, and alternariol monomethyl ether were 1, 5, 0.5, and 0.1 μg/kg in tomato-based products and 1, 6, 0.7, and 0.1 μg/kg in citrus-based samples, respectively, which were the same as or lower than those reported by Noser et al.[5] but higher than those obtained with the stable isotope method.[14,16,19]

To extract the four mycotoxins rapidly from the tested matrix and to eliminate coextraction of potentially interfering matrix components as much as possible, absolute recoveries of the four toxins from four matrices were assessed. The recovery of tenuazonic acid from tomato ketchup was performed with a naturally tenuazonic acid-contaminated sample because no tenuazonic acid-free tomato ketchup samples were found in this study. For each analyte/matrix combination, the recoveries at three spiking levels ranged from 73.4 to 111.2% for all four toxins in tomato- and citrus-based product samples; values fall within the range of 70−120% as recommended by the European Commission.[22] On the other hand, RSDs for all four toxins were <20% with the range 2.5−20.0%, which was compatible with the general requirement of the analytical method. With regard to intralaboratory repeatability, the coefficients of variation (CV) were 4.2% for tenuazonic acid in tomato ketchup and 4.2% in citrus juice, 14.6% for alternariol in tomato ketchup and 14.6% in citrus juice, 12.3% for tentoxin in tomato ketchup and 12.3% in citrus juice, and 9.8% for alternariol monomethyl ether in tomato ketchup and 9.8% in citrus juice. On the basis of these results, we conclude that the extraction efficiencies achieved by the method used in the present study were high and consistent. Under LC-MS/MS conditions, very good resolution for the four mycotoxins in tomato samples was observed and their spectra were similar to those of the corresponding standards.

Natural Occurrence of the Four *Alternaria* Toxins in Fresh Tomato and Tomato-Based Products. Contamination levels of the four *Alternaria* toxins in Chinese tomato and tomato-based product samples are given in Table 1. No toxins were detected in all of the fresh tomato samples. In terms of tomato ketchup, alternariol and alternariol monomethyl ether were detected in 14 (45.2%) samples at levels ranging from 2.5 to 300 μg/kg (mean = 80 μg/kg) and in 28 (90.3%) samples within a range of 0.32−38 μg/kg (mean = 8.0 μg/kg), respectively. Alternariol was quantitated at higher levels than alternariol monomethyl ether with the ratio of alternariol/alternariol monomethyl ether ranging from 0.37 to 104 (average = 17) in 14 alternariol positive samples, among which 21.4% (3/14) were <1. Thus, the concentration of alternariol was higher than that of alternariol monomethyl ether in these alternariol-positive samples. All tomato juice samples were negative for alternariol but 7 (7/9, 77.8%) were positive for alternariol monomethyl ether with the level up to 5.8 μg/kg (average = 1.4 μg/kg). Tentoxin was less frequently detected than alternariol monomethyl ether and tenuazonic acid. Alternariol was negative in tomato juice samples.

Table 1. Concentrations of the Four *Alternaria* Toxins in Tomato and Tomato-Based Products

			toxin concn (μg/kg)		
sample	toxin	positive (%)	range	mean	median
fresh tomato (n = 30)	**1**	0			
	2	0			
	3	0			
	4	0			
tomato ketchup (n = 31)	**1**	31 (100)	10.2−1787	338	186
	2	14 (45.2)	2.5−300	80	29
	3	26 (83.9)	1.53−15.8	4.9	5.0
	4	28 (90.3)	0.32−38	8.0	6.6
tomato juice (n = 9)	**1**	9 (100)	7.4−278	87	72
	2	0			
	3	3 (33.3)	1.85−5.7	3.7	3.6
	4	7 (77.8)	0.20−5.8	1.42	0.62

Tenuazonic acid was the predominant toxin quantitatively as shown in Table 1. It was detected at average concentrations of 338 μg/kg in tomato ketchup and 87 μg/kg in tomato juice samples. A total of 2 (6.4%) tomato ketchup samples were contaminated with tenuazonic acid at >1000 μg/kg with a maximum of 1786 μg/kg, 4 samples (12.9%) between 500 and 1000 μg/kg, 15 samples (48.4%) between 100 and 500 μg/kg, and 18 samples below 100 μg/kg. The maximum concentration of tenuazonic acid was higher than the result reported by Noser,[5] but lower than that reported by Terminiello et al.[4]

DOI: 10.1021/jf5052738
J. Agric. Food Chem. 2015, 63, 343−348

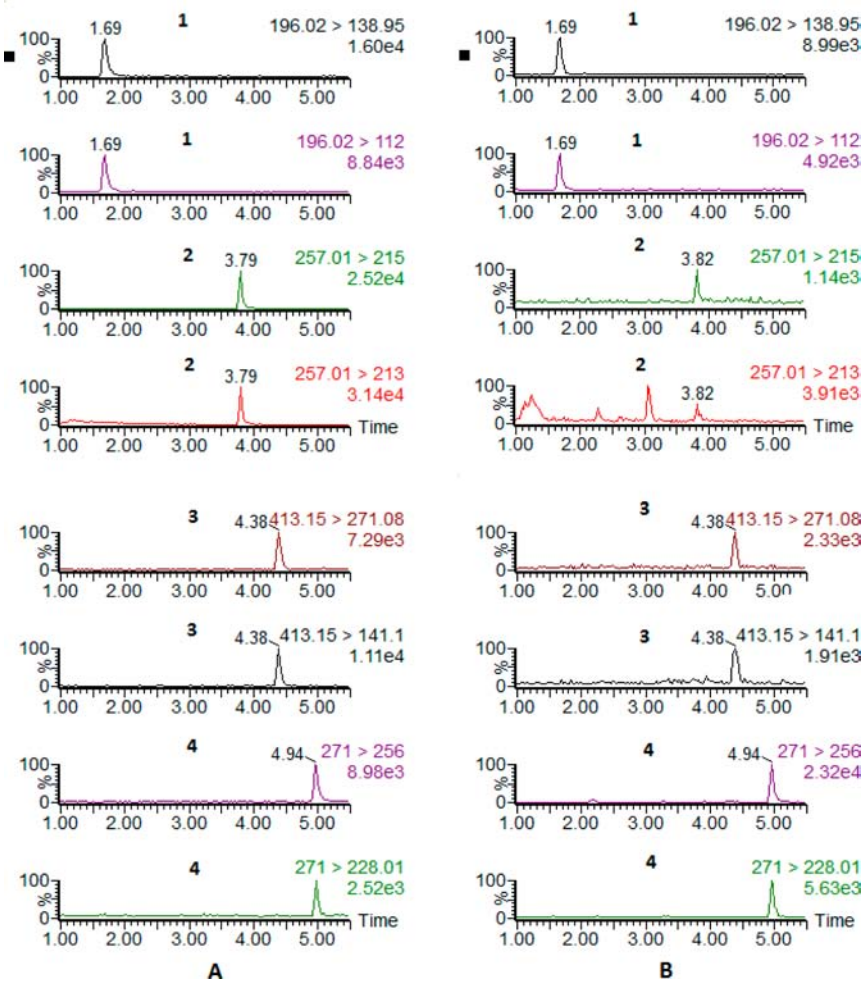

Figure 2. MRM chromatograms of (A) tenuazonic acid, **1**; alternariol, **2**; tentoxin, **3**; and alternariol monomethyl ether, **4** standards in 25, 100, 5, and 1.2 μg/kg; and (B) a naturally contaminated tomato ketchup sample in 89 μg/kg for tenuazonic acid, **1**; 11 μg/kg for alternariol, **2**; 6.2 μg/kg for tentoxin, **3**; and 12 μg/kg for alternariol monomethyl ether, **4**, respectively.

With regard to tenuazonic acid concentration in tomato juice, six samples were contaminated with tenuazonic acid at a level of <100 μg/kg and three samples with tenuazonic acid at >100 μg/kg. It should be pointed out that 10 imported tomato ketchup samples were heavily contaminated by tenuazonic acid with the average concentration of 558 μg/kg, much higher than those of domestic origin (Mann−Whitney U test, $Z = -2.155$, $P < 0.05$). Among these, the top three concentrations of tenuazonic acid (1787, 1464, and 939 μg/kg) were found in samples imported from Italy, Spain, and Australia, respectively. Tentoxin was found in 26 (26/31, 83.9%) tomato ketchup and 3 (3/9, 33.3%) tomato juice samples up to 15.8 and 5.7 μg/kg, respectively. Therefore, tentoxin was the toxin with the lowest contamination level in tomato products. With regard to the co-occurrence of four *Alternaria* toxins in tomato ketchup, all of the toxins were simultaneously detected in 14 alternariol-positive samples (45.2%), whereas alternariol monomethyl ether, tentoxin, and tenuazonic acid were in 28 alternariol monomethyl ether-positive samples (90.3%). The MRM chromatograms of a naturally contaminated ketchup sample as well as the corresponding standards are given in Figure 2.

Natural Occurrence of the Four *Alternaria* Toxins in Citrus Fruit and Citrus Juice. None of the four *Alternaria* toxins were detected in 50 fresh citrus samples without any spoilage (shown as Table 2). Tenuazonic acid was also the main *Alternaria* toxin detected in 9 of 36 (25.0%) citrus juice samples at a level between 1.21 and 4.3 μg/kg (mean = 1.80 μg/kg and median of 1.28 μg/kg), whereas alternariol monomethyl ether was found in 4 of 36 samples (11.1%) at levels up to 0.2 μg/kg. However, neither alternariol nor tentoxin was detected in citrus juice samples. Tenuazonic acid and alternariol monomethyl ether were simultaneously detected in only one citrus juice. These results were consistent with those reported by Asam et al.[14]

Table 2. Concentrations of the Four *Alternaria* Toxins in Fresh Citrus Fruit and Citrus Juice

			toxin concn (μg/kg)		
sample	toxins	positive (%)	range	mean	median
fresh citrus fruit (n = 50)	**1**	0			
	2	0			
	3	0			
	4	0			
citrus juice (n = 36)	**1**	9 (25.0)	1.21−4.3	1.80	1.28
	2	0			
	3	0			
	4	4 (11.1)	0.11−0.20	0.14	0.12

DOI: 10.1021/jf5052738
J. Agric. Food Chem. 2015, 63, 343−348

To the best of our knowledge, this is the first report on the natural co-occurrence of alternariol, alternariol monomethyl ether, tentoxin, and tenuazonic acid in Chinese retail fresh tomato, tomato ketchup, fresh citrus, and citrus juice. The levels of four *Alternaria* toxins in citrus and citrus juice were quite low and might not be of any health risk for human beings. In terms of each toxin that occurred and the level in tomato ketchup samples, our findings correspond with those of Swiss samples: tenuazonic acid > alternariol > alternariol monomethyl ether > tentoxin.[7] In particular, alternariol was quantitated at higher levels than alternariol monomethyl ether with the ratio of alternariol/alternariol monomethyl ether up to 104 (average = 17) in 14 alternariol-positive samples. These results tended to be different from those in wheat reported previously in China.[23] Additionally, a positive correlation between alternariol and alternariol monomethyl ether (r^2 = 0.850, $P < 0.001$) and also the total dibenzopyrone derivatives (alternariol + alternariol monomethyl ether) and tenuazonic acid (r^2 = 0.796, $P < 0.001$) in wheat samples has been demonstrated by Li et al.,[23] indicating the coproduction of these toxins on wheat grains by *Alternaria* species in fields. However, no significant correlations were found in concentrations between alternariol and alternariol monomethyl ether (r^2 = 0.070) and total dibenzopyrone derivatives and tenuazonic acid (r^2 = 0.035) in tomato ketchup samples. Invasion of tomato and wheat by different species of *Alternaria* may mainly contribute to the difference in toxin levels in the same area.

In contrast, alternariol was found at levels of 1 and 13 μg/kg with high frequency in apple (67% of 44 samples) and tomato (93% of 44 samples) products, respectively, reported by Ackermann et al.[24] A survey conducted in Brazil revealed that neither alternariol monomethyl ether nor alternariol was detected in 80 samples, but tenuazonic acid was found in 7 tomato pulp (39−111 μg/kg) and 4 tomato puree (29−76 ng/g) samples.[25] Low mean levels of alternariol (up to 25 μg/kg) and alternariol monomethyl ether (up to 0.7 μg/kg) were measured in vegetables, mainly tomato paste.[16] Tenuazonic acid at levels between 15 and 195 μg/kg, between 363 and 909 μg/kg, and between 8 and 242 μg/kg were found in commercial tomato ketchup, tomato paste, and pureed tomato samples analyzed by stable isotope dilution assays, respectively.[16] All results mentioned above are much lower than ours. However, about 60% of Argentinian tomato pulp samples were contaminated with tenuazonic acid, alternariol monomethyl ether, and alternariol at levels up to 4021 μg/kg (29% of 80 samples), 1734 μg/kg (26% of 80 samples), and 8756 μg/kg (6% of 80 samples),[4] respectively, with the maximum levels of tenuazonic acid, alternariol, and alternariol monomethyl ether higher than those obtained in the present study.

Alternaria mycotoxins in tomato and citrus products are most likely to come from the contaminated raw material. Tomato ketchup was made from tomatoes through a series of steps including washing, heating, pulping, condensing, etc. It is well-known that *Alternaria* rapidly colonizes tomatoes and produces mycotoxins under favorable conditions. It was speculated that *Alternaria* mycotoxins in tomato ketchup probably came from decayed tomatoes or from the steps contaminated with *Alternaria* species during the production line.[4] *Alternaria* mycotoxins detected at higher concentrations in tomato ketchup than in fresh tomatoes were partly due to the former being concentrated after production.

EFSA has given a scientific opinion on the risks for animal and public health related to dietary exposure to seven *Alternaria* mycotoxins.[10] The estimated chronic dietary exposures for the four toxins were much lower than the corresponding threshold of toxicological concern (TTC), indicating no human health concern according to the in vitro model for intestinal absorption and consumption data in China (data not shown).[26,27] However, alternariol and alternariol monomethyl ether were genotoxic and bound to the DNA of esophageal epithelium of the human fetus, activated oncogenes in the human fetal epithelium, and induced epithelial proliferation of human fetal esophagus in vitro.[28] Although *Alternaria* spp. are the most frequent fungal species invading tomatoes,[2,12] there are no specific regulations for any of the *Alternaria* toxins in foods in China so far. Therefore, systemic long-term surveillance of *Alternaria* toxins in raw and processed foods all over China, especially in the area with high incidence of esophageal cancer, as well as a thorough assessment of dietary exposure to these toxins in Chinese populations should be intensified to evaluate consumers' health risk.

ABSTRACT: Obesity is considered to be a metaflammatory condition. *Ecklonia cava*, brown algae rich in polyphenols, has shown strong antioxidant activity in vitro. This study investigated the effect of *E. cava* polyphenol extract (ECPE) on the regulation of fat metabolism, inflammation, and the antioxidant defense system in high fat diet-induced obese mice. After obesity was induced by a high-fat diet (HFD), the mice were administered ECPE by gavage for 5 days/12 weeks. ECPE supplementation reduced body weight gain, adipose tissue mass, plasma lipid profiles, hepatic fat deposition, insulin resistance, and the plasma leptin/adiponectin ratio derived from HFD-induced obesity. Moreover, ECPE supplementation selectively ameliorated hepatic protein levels associated with lipogenesis, inflammation, and the antioxidant defense system as well as activation of AMPK and SIRT1. Collectively, ECPE supplement might have potential antiobesity effects via regulation of AMPK and SIRT1 in HFD-induced obesity.

KEYWORDS: *Ecklonia cava polyphenol extract, obesity, AMPK, SIRT1, hepatic lipid metabolism, inflammation*

INTRODUCTION

Recently, obesity has been recognized as a chronic metabolic disorder.[1] Under an obese condition, there are several abnormalities in lipid metabolism, the antioxidant defense system, and inflammatory responses. As the storage of triglyceride (TG) in adipose tissue exceeds its limit, it is likely to encourage the release of free fatty acids (FFA) into circulation, and released FFA could be brought into nonadipose tissues such as the liver.[2] Obese subjects might undergo nonalcoholic fatty liver disease (NAFLD) characterized by an increase in fat accumulation in the liver caused by abnormalities, including reduced fatty acid (FA) oxidation or TG secretion and increased FA uptake or de novo lipogenesis.[3] Moreover, the TG overload in liver could cause hepatic damage and increase reactive oxygen species (ROS), which induce lipid peroxidation and inflammation.[4]

At the molecular level, AMP-activated protein kinase (AMPK) and Sirtuin 1 (SIRT1) are regarded as key fuel sensors or metabolic modulators. It is well-documented in detail that AMPK plays a key role in hepatic lipid metabolism, through inactivation of several metabolic enzymes, in switching on catabolic pathways such as β-oxidation as well as switching off anabolic pathways involving lipid metabolism in the liver.[5,6] SIRT1, an NAD^+-dependent protein deacetylase, is involved in several metabolic pathways in various tissues.[7] Especially, SIRT1 is involved in lipid and glucose metabolism, inflammatory response, and oxidative stress in hepatic tissue.[8] Furthermore, it has been reported that SIRT1 modulates fatty acid β-oxidation and cholesterol/bile homeostasis through the peroxisome proliferator-activated receptor alpha (PPARα)/peroxisome proliferator-activated receptor gamma coactivator 1 (PGC1) pathway and liver X receptor (LXR)/farnesoid X receptor (FXR) signaling, respectively.[9,10] SIRT1 might also regulate lipid metabolism by deacetylation of sterol regulatory element binding proteins (SREBPs), which are pivotal modulators of lipogenesis and cholesterolgenesis[11,12] and inflammatory responses such as tumor necrosis factor alpha (TNFα) and interleukin 1 beta (IL-1β).[9] Thereby, inactive or reduced levels of SIRT1 increased susceptibility to dyslipidemia, hepatic steatosis, inflammation, and endoplasmic reticulum stress.[7,9] Recently, a partnership between AMPK and SIRT1 has been well-documented in a previous study.[13] Briefly, when SIRT1 is stimulated by certain activators such as NAD^+, SIRT1 regulates AMPK by deacetylation of liver kinase B1 (LKB1). According to previous studies, the mechanism provides a comprehensive explanation in hepatic lipid metabolism and NAFLD by suggesting an SIRT1/AMPK cycle.[14] Therefore, partnership between AMPK and SIRT1 could be considered as a crucial target to regulate hepatic lipid metabolism related to NAFLD in obesity.

Brown alga *Ecklonia cava* is produced in bountiful amounts on the coast of Jeju Island, Korea. *E. cava* contains copious polysaccharides such as fucoidans as well as polyphenols including dieckol, eckol, phloroglucinol, 6,6′-bieckol, and eckstolonol.[15] In the previous study, *E. cava* ethanolic extracts suppressed the lipopolysaccharide (LPS)-induced cytokines such as TNFα and IL-1β and reduced the inducible nitric oxide

synthase (iNOS) and the cyclooxygenase-2 (COX-2) expression by blocking transcription factors of the nuclear factor kappa B (NFκB) and the mitogen-activated protein kinase (MAPK) activation in BV2 microglia.[16] Among the polyphenols of *E. cava*, dieckol is the most ample compound in *E. cava*, and it has been reported for having some beneficial potential such as antioxidative effects and antithrombotic activity.[17,18] A recent study reported that dieckol, which was isolated from *E. cava*, inhibited adipogenesis by activating AMPK and suppressing adipocyte differentiation in 3T3-L1 preadipocytes.[19] However, little research has focused on the molecular mechanisms by which *E. cava* polyphenol extract (ECPE) regulates hepatic lipid metabolism in an obese animal model.

We investigated how ECPE ameliorates hepatic lipid metabolism, oxidative stress, and inflammation through modulation of AMPK and SIRT-1 in high-fat diet (HFD)-induced obese mice.

MATERIALS AND METHODS

Preparation of ECPE. ECPE used in this study was provided from Aqua Green Tech., Jeju, Korea. The preparation of dieckol-rich polyphenols from *E. cava* was described previously.[20] In brief, the *E. cava* was collected from the coast of Jeju Island, Korea. The powdery *E. cava* (500 g) was suspended in 10 L of 70% ethanol and stirred for 24 h at room temperature. The solution was filtered and then concentrated under reduced pressure to give the oily extract. Then, the organic soluble fraction was taken by treatment with ethyl acetate (47.85 g), and the extract was evaporated under vacuum.

Quantification of Total Phenol and Major Compounds in ECPE. The total phenol content in the polyphenol extract was measured by using the protocol described by Kim et al.[21] The quantitative analysis in the major compounds in the polyphenol extract from *E. cava* was performed by their HPLC analysis and quantitative standard curve. The quantitative standard curves of the main compounds were calculated by their area (%) in high-performance liquid chromatography (HPLC) under concentrations between 25 and 400 μg/mL.

Identification of Major Compounds in ECPE and Chemical Structure of Dieckol. The structural identification of the major compounds in the polyphenol extract from *E. cava* was performed by using the method described in a previous paper.[22] The major compounds in the extract were confirmed by LC-DAD-ESI/MS and 1D NMR spectrum. To operate LC-DAD-ESI/MS, 10 μL of 5 mg/mL sample solution was directly injected on an Atlantis T3 column (3 μm 3.0 × 150 mm column) (Waters, Milford, MA, USA). The mobile phase comprised acetonitrile/water in gradient mode as follows: acetonitrile with 0.1% formic acid/water with 0.1% formic acid (0−40 min, 10:90−40:60 v/v; 40−50 min, ∼50:50 v/v; and 50−60 min, ∼100:0 v/v). The flow rate was 0.2 mL/min, and the UV absorbance was detected at 290 nm. The source voltage was set to 4.5 kV and the capillary temperature to 250 °C. The other conditions were as follows: capillary voltage, −36.5 V; interoctapole lens voltage, 10 V; sheath gas, 80 psi (551.6 kPa); auxiliary gas, 20 psi (137.9 kPa). The major compounds were confirmed as dieckol, 2,7″-phloroglucinol-6,6′-bieckol, pyrogallol-phloroglucinol-6,6′-bieckol, and phlorofucofuroeckol-A, respectively. After purification of the compounds from the *E. cava* extract, their ^{1}H NMR and ^{13}C NMR spectra were measured with a JEOL JNM-LA 300 spectrometer (JEOL Ltd., Tokyo, Japan), and the mass spectra (FAB-MS and EIMS) were recorded on a JEOL JMS 700 spectrometer.

Dieckol: amorphous powder; ^{1}H NMR (400 MHz, methanol-d_4) δ 6.15 (1H, s), 6.13 (1H, s), 6.09 (1H, δ, 2.9 Hz), 6.06 (1H, δ, 2.9 Hz), 6.05 (1H, δ, 2.9 Hz), 5.98 (1H, δ, 2.8 Hz), 5.95 (1H, δ, 2.8 Hz), 5.92 (3H, m); ^{13}C NMR (100 MHz, methanol-d_4) δ 161.8, 160.1, 157.8, 155.9, 154.5, 152.4, 147.3, 147.2, 147.1, 146.9, 144.3, 144.1, 143.4, 143.3, 138.6, 138.5, 126.5, 126.2, 125.6, 125.5, 124.9, 124.6, 124.5, 99.9, 99.7, 99.5, 99.4, 97.6, 96.2, 95.8, 95.7, 95.3; ESI-MS $[M - H]^-$ at m/z 741.11.

2,7″-Phloroglucinol-6,6′-bieckol: amorphous powder; ^{1}H NMR (400 MHz, methanol-d_4) δ 5.57 (1H, s), 5.89 (1H, s), 5.74 (1H, m), 5.84 (1H, m), 5.74 (1H, m), 6.25 (1H, s), 6.14 (1H, s), 5.84 (1H, m), 5.89 (1H, m), 5.84 (1H, m), 6.52 (1H, s), 6.14 (1H, m), 6.44 (1H, m), 6.77 (1H, s), 6.72 (1H, s), 8.93 (1H, s), 8.93 (1H, s), 9.19 (1H, s), 9.19 (1H, s), 9.19 (1H, s), 9.04 (1H, s), 8.26 (1H, s), 9.94 (1H, s), 8.59 (1H, s), 9.88 (1H, s), 9.86 (1H, s), 9.25 (1H, s), 9.75 (1H, s), 9.21 (1H, s); ^{13}C NMR (100 MHz, methanol-d_6) δ 127.6, 143.0, 93.0, 137.1, 125.6, 147.2, 106.5, 152.2, 95.5, 152.4, 127.6, 137.1, 162.0, 98.7, 160.3, 95.5, 160.3, 98.8, 124.3, 147.2, 94.5, 144.1, 124.3, 147.2, 110.0, 144.1, 101.5, 151.8, 137.2, 144.1, 159.7, 96.7, 157.1, 95.5, 157.1, 96.7, 159.8, 97.8, 159.3, 95.2, 159.2, 97.9, 122.5, 153.9, 99.8, 156.8, 99.9, 152.8; ESI-MS $[M - H]^-$ at m/z 973.37.

Pyrogallol-phloroglucinol-6,6′-bieckol: amorphous powder; ^{1}H NMR (400 MHz, methanol-d_4) δ 6.10 (1H, s), 5.99 (1H, s), 5.72 (1H, m), 5.75 (1H, m), 5.72 (1H, m), 6.25 (1H, s), 6.14 (1H, s), 5.88 (1H, δ, 2.21 Hz), 5.88 (1H, δ, 2.21 Hz), 5.85 (1H, δ, 2.21 Hz), 6.72 (1H, δ, 2.2 Hz), 6.08 (1H, δ, 2.2 Hz), 5.89 (1H, δ, 2.01 Hz), 5.54 (1H, δ, 2.01 Hz), 5.89 (1H, δ, 2.01 Hz), 9.116 (1H, s), 9.03 (1H, s), 8.92 (1H, s), 9.27 (1H, s), 9.20 (1H, s), 9.20 (1H, s), 9.18 (1H, s), 9.03 (1H, s), 8.92 (1H, s), 8.25 (1H, s), 9.94 (1H, s), 9.87 (1H, s), 9.87 (1H, s), 9.20 (1H, s), 9.20 (1H, s); ^{13}C NMR (100 MHz, methanol-d_4) δ 125.2, 145.9, 95.5, 145.9, 125.1, 147.9, 105.5, 148.4, 95.4, 151.9, 127.8, 135.3, 161.9, 97.9, 160.3, 95.5, 160.3, 97.8, 124.4, 144.4, 94.4, 144.4, 124.5, 147.9, 105.4, 148.4, 95.5, 151.4, 127.8, 138.3, 159.2, 100.2, 156.9, 99.5, 159.3, 96.3, 154.0, 96.6, 152.1, 122.5, 153.5, 96.6, 159.9, 99.0, 159.8, 94.6, 159.8, 98.6; ESI-MS $[M - H]^-$ at m/z 973.03.

Phlorofucofuroeckol-A: amorphous powder; ^{1}H NMR (400 MHz, methanol-d_4) δ 6.63 (1H, s, H-7), 6.40 (1H, s, H-11), 6.26 (1H, s, H-2), 5.97 (2H, δ, J = 2.1 Hz, H-200, 600), 5.94 (1H, t, J = 1.9 Hz, H-40), 5.92 (1H, t, J = 2.0 Hz, H-400), 5.88 (2H, δ, J = 2.1 Hz, H-20, 60); ^{13}C NMR (100 MHz, CD_3OD) δ 162.7, 162.6, 161.0, 161.0, 154.0, 152.5, 152.0, 149.1, 149.0, 146.7, 144.7, 139.2, 136.2, 128.9, 125.9, 125.6, 123.2, 106.2, 106.1, 100.8, 100.2, 98.6, 98.5, 97.0, 96.2, 96.2; ESI-MS $[M - H]^-$ at m/z 601.36.

Animals and Experimental Design. Male C57BL/6 mice (n = 40; 4 weeks old) were obtained from Orient Bio (Gyeonggi-do, South Korea) and were housed two or three per cage in a room (temperature, 21−23 °C; relative humidity, 45−55%; 12 h dark/light cycle). After acclimation for 1 week, mice were then randomly divided into two groups: the normal control diet group (CD; n = 10) and the high-fat diet group (HFD; n = 30). CD was provided with regular diet (D12450B, 10% kcal fat, Research Diets, New Brunswick, NJ, USA), whereas HFD was provided with high-fat diet (D12451, 45% kcal fat, Research Diets) for 10 weeks. Food and distilled water were supplied ad libitum.

After obesity was induced by the high-fat diet, the animals were divided into four groups, 10 mice in each group and supplemented as follows: CON, nonobese control group mice fed CD were gavaged with distilled water; HF, obese mice fed HFD were gavaged with distilled water; LE, obese mice fed HFD were gavaged ECPE at a (low) dose of 100 mg/kg/day; HE, obese mice fed HFD were gavaged with ECPE at a (high) dose of 500 mg/kg/day. The identical volume of gavage with either distilled water or ECPE was administrated by oral gavage 5 times a week for 12 weeks. ECPE was freshly suspended in distilled water. The body weight and food intake were measured twice a week.

Mice were fasted for 15 h after the last treatment and then euthanized by inhalation with isoflurane (Baxter, Deerfield, IL, USA). Blood was collected by cardiac puncture using a heparin (Sigma-Aldrich, St. Louis, MO, USA) coated syringe. Plasma was obtained by centrifugation at 3000 rpm for 15 min. Tissues such as the liver and adipose pads were removed after cardiac puncture, washed of blood or foreign materials by saline, weighed, and immediately frozen in liquid nitrogen. All of the samples were stored at −80 °C until they were used for experiments. Experimental protocol was approved by the Institutional Animal Care and Use Committee of the Kyung Hee University.

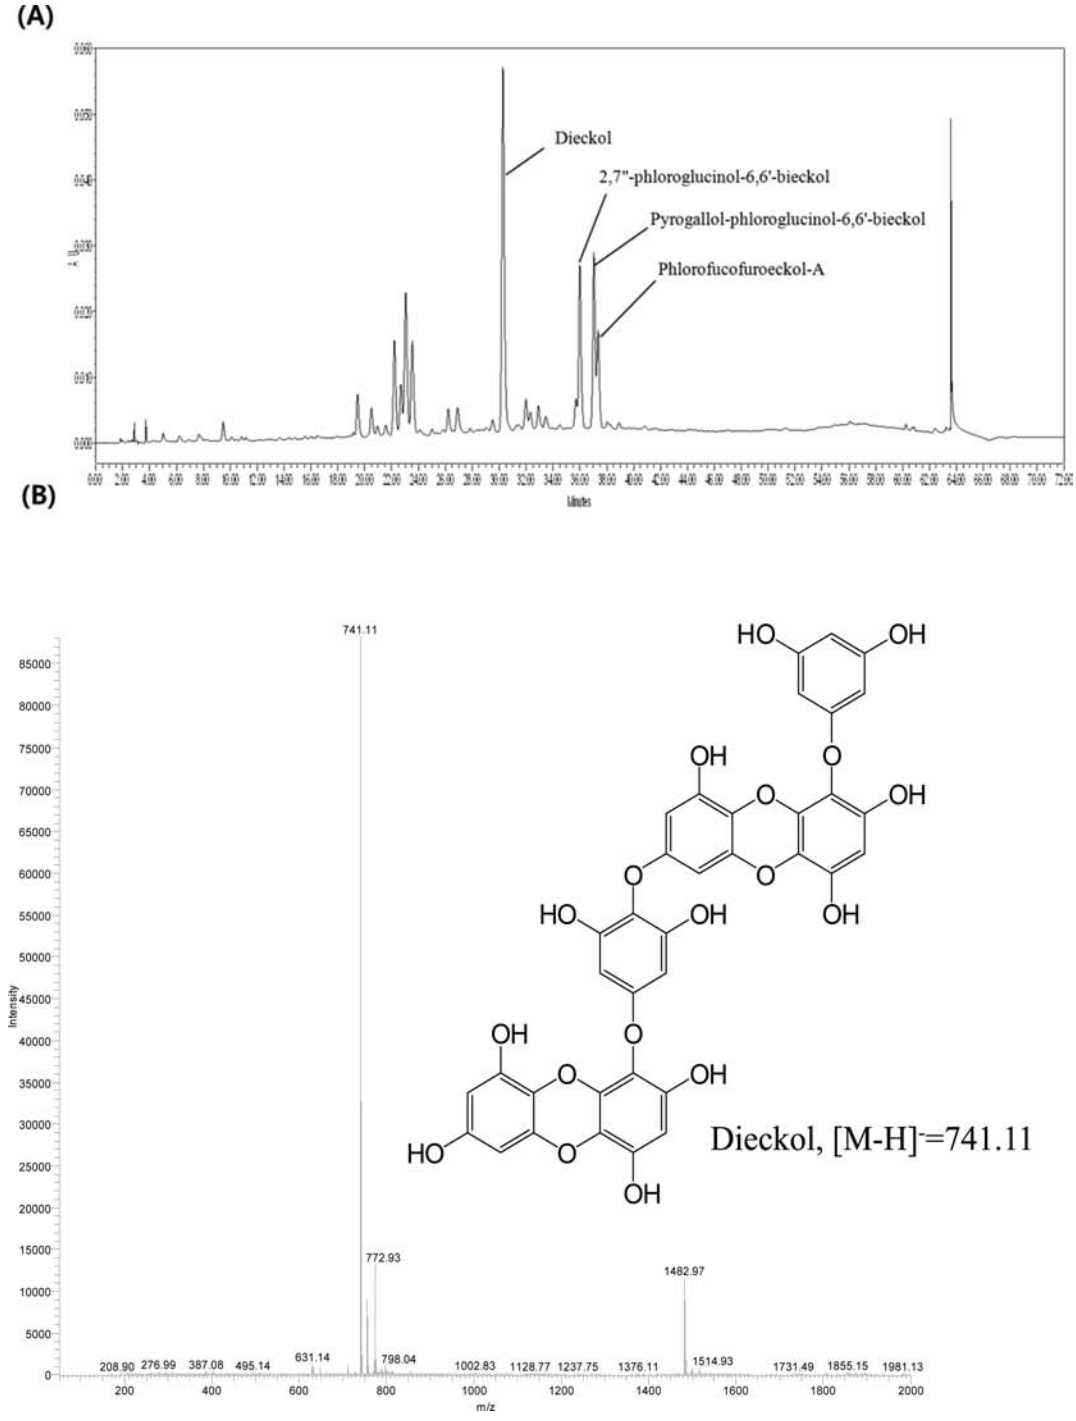

Figure 1. Quantification and identification of *E. cava* polyphenol extract (ECPE): (A) polyphenol contents in ECPE quantified by HPLC analysis; (B) electrospray ionization mass spectrometry (ESI/MS) of ECPE and chemical structure of dieckol.

Intraperitoneal Glucose Tolerance Test (IPGTT). A week before the end point, the animals were fasted overnight for 16 h prior to the IPGTT test. The 50% glucose solution (2 g/kg) was injected intraperitoneally. Blood glucose level was measured with a glucometer (NOCODING1, Seoul, Korea) at 0 (as basal fasting blood glucose level, FBG), 15, 30, 60, 90, and 120 min after injection of glucose solution. The area under the curve (AUC) was calculated using the trapezoidal rule as follows: $AUC_i = [(\text{blood glucose})_i + (\text{blood glucose})_{i-1}] \times [(\text{time})_i - (\text{time})_{i-1}]/2$.

Plasma Biomarker Analysis. The contents of plasma triglyceride (TG), total cholesterol (TC), and high-density lipoprotein cholesterol (HDL-C) were determined using commercial kits (Bio-Clinical System, Gyeonggi-do, South Korea). The atherogenic index (AI) was estimated as follows: AI = ([TC] − [HDL-C])/[HDL-C]. Plasma glutamic oxaloacetic transaminase (GOT) and glutamic pyruvic transaminase (GPT) were determined by enzymatic assays with commercial kits (Bio-Clinical System). The plasma concentrations of leptin, adiponectin, and insulin were determined using enzyme-linked immuosorbent assay (ELISA) commercial kits (RayBiotech, Inc., Norcross, GA, USA). The homeostasis model assessment of insulin resistance (HOMA-IR) was calculated as follows: fasting insulin (μU/mL) × fasting glucose (mmol/L)/22.5. All of the commercial kits were performed according to the manufacturer's instructions, respectively.

[a]Values are means ± SEM. Mean values with unlike letters are significantly different ($p < 0.05$). [b]CON, mice fed the control diet (negative control); HF, mice fed the high-fat diet (positive control); LE, mice supplemented with low dose (100 mg/kg/day) of ECPE; HE, mice supplemented with high dose (500 mg/kg/day) of ECPE.

Histological Observation of Hepatic Tissue. Liver tissue was isolated and immediately fixed in 10% neutral buffered formalin. The tissues were dehydrated and then embedded in paraffin wax. Histological sections (5 μm thickness) of the tissues were cut, deparaffinized in xylene, rehydrated in alcohol gradients, and then stained with hematoxylin and eosin (H&E). The stained sections were mounted with histological mounting medium (Histomount, GA, USA) after drying. All images were observed using an optical microscope (Olympus BX51; Olympus Optical, Tokyo, Japan).

Western Blot Analysis. Liver was homogenized at 4 °C in the lysis buffer (20 mM Tri-HCl, 150 mM $NaCl_2$, pH 7.5, 1% NP40, 0.5% sodium deoxycholate stock, 1 mM EDTA, 0.1% sodium dodecyl sulfate (SDS)) and then centrifuged at 14000 rpm at 4 °C for 30 min. The supernatants were used for Western blot analysis. The total protein concentrations of the fraction were measured by Bio-Rad protein assay (Bio-Rad, Hercules, CA, USA). A total of 40 g of protein samples was separated with SDS-PAGE and then transferred onto polyvinylidene fluoride (PVDF) membranes (Millipore, Marlborough, MA, USA). The membranes were blocked with 3% bovine serum albumin in phosphate-buffered saline−0.1% Tween 20 (PBS-T) and incubated overnight with primary antibodies at 4 °C. The primary antibodies were directed against AMPK, phosphorylated AMPK (p-AMPK; Thr172), acetyl CoA carboxylase (ACC), phosphorylated ACC (p-ACC; Ser79), monocyte chemoattractant protein-1 (MCP-1), catalase, and nuclear factor kappa B (NFκB) (Cell Signaling Technology, Inc., Danvers, MA, USA); carnitine palmitoyltransferase I A (CPT1A), SIRT1, C-reactive protein (CRP), glutathione peroxidases (GPx), and Lamin B1 (Abcam, Cambridge, MA, USA); SREBP1c, PPARα, fatty acid synthase (FAS), lipoprotein lipase (LPL), PPARγ coactivator 1 (PGC1), interleukin 6 (IL-6), IL-1β, TNFα, COX-2, and copper−zinc superoxide dismutase (CuZnSOD) (Santa Cruz Biotechnology, Inc., Santa Cruz, CA, USA); hemeoxygenase 1 (HO-1) and manganese superoxide dismutase (MnSOD) (Stressgen, Victoria, Canada); and α-tubulin (Sigma-Aldrich, St. Louis, MO, USA). Then, the blots were washed four times for 10 min with PBS-T. Thereafter, the membranes were incubated with respective secondary antibodies for 1 h and washed with PBS-T again. Signals were then developed using the ECL luminol reagent (Santa Cruz Biotechnology, Inc.) and then recorded and quantified with the Syngene G box (Syngene, Cambridge, UK, USA).

Measurement of Lipid Peroxidation. As a marker of lipid peroxidation, levels of malondialdehyde (MDA) were measured by using the thiobarbituric acid (TBA) method.[23] Mixtures of 10% (w/v) tissue homogenate with 0.15 M KCl, 8.1% SDS, and a 20% acetic acid−0.8% TBA mixture were heated in a water bath at 95 °C for 60 min. After cooling with tap water, distilled water and a mixture of *n*-butanol and pyridine (15:1 v/v) were added and then centrifuged at 4000 rpm for 10 min to obtain a clear supernatant. The absorbance of the supernatant was measured at 532 nm.

Statistical Analysis. The results are expressed as means ± standard error of mean (SEM). Significant differences among the groups were determined by one-way ANOVA using SPSS (version 20.0 for Windows, SPSS Inc., Chicago, IL, USA). Duncan's multiple-range tests was followed when differences were identified among the groups at p values of <0.05.

RESULTS

Quantification and Identification of Major Polyphenol Compounds in ECPE. Total phenol content exhibited 28.20 ± 0.58% in the extract; therefore, we named it the polyphenol extract for this study. The contents of the main compounds shown, respectively, in 5 mg of ECPE were as follows: dieckol, 235.54 μg (4.70%); 2,7″-phloroglucinol-6,6′-bieckol, 125.7 μg (2.51%); pyrogallol-phloroglucinol-6,6′-bieckol, 42.12 μg (0.84%); and phlorofucofuroeckol-A, 48.22 μg (0.96%) (Figure 1A).

In addition, identification of major polyphenol compounds in ECPE was performed by LC-MS, and the chemical structure of dieckol, which was at the highest peak of Figure 1A, is also indicated in Figure 1B.

Effect of ECPE on Food Intake and Body Weights. The mice fed HFD gained more weight compared to the mice fed CD during the obesity induction period. For the 12 weeks of supplementation, the HF group still gained more weight (9.96 ± 0.79) compared to CON (6.95 ± 0.44 g) (Table 1). At the same time, the mice supplemented with ECPE were affected in body weight, and especially a high dose of ECPE significantly lowered body weight gain (6.94 ± 0.62 g). Body weight gain in HE was similar to that of CON. In addition, the food intake of the HFD-fed groups was lower than CON regardless of ECPE supplementation. Accordingly, the food efficiency ratio (FER) of ECPE supplementation was lower than that of HF dose-dependently (Table 1).

[e]FBG, fasting blood glucose level; HOMA-IR, homeostasis model assessment of insulin resistance.

Effect of ECPE on Liver and Adipose Tissue Weights. The liver weight was not significantly different among HFD-fed groups or between CON and HF as shown in Table 1.

To demonstrate the effect of ECPE on body fat accumulation, we measured adipose pad weight of five sites (epididymal, mesenteric, retroperitoneal, inguinal, and brown adipose tissue) and total body fat mass. The weights of adipose tissues in HF were higher than those in CON. However, the weight of visceral adipose tissues (VAT), except epididymal fat, in HE was slightly decreased compared to the HF group. In addition, the weight of brown adipose fat in HE was significantly lower than that in HF. Thus, the body weight and the gross weight of adipose tissue were decreased in HE compared to HF (Table 1).

Effect of ECPE on Plasma Biomarkers. Plasma lipid profiles are shown in Table 2. The concentrations of the plasma TG and total cholesterol were significantly increased in HF compared to CON. However, TG and TC levels of the ECPE-supplemented group regardless of dose showed significant decreases compared to those of HF. The AI related to cardiovascular disease in LE and HE was lower than that in HF, whereas there were no significant differences in high-density lipoprotein cholesterol (HDL-C) among all groups.

To verify the potential toxic effects of ECPE supplementation, plasma GOT and GPT levels were measured as markers of hepatic function and liver injury (Table 2). Both GOT and GPT in HF levels were higher than those of CON, whereas LE and HE showed lower levels of GOT and GPT compared to HF.

As shown in Table 2, there was an increase in plasma leptin in HF compared to CON and there was a slight decrease in plasma leptin in HG compared to HF. There were no significant differences among all groups in plasma adiponectin levels. As a useful inflammatory and obesity biomarker, we calculated the leptin and adiponectin ratio (LAR). LAR in HF was significantly higher than that in CON, but HE showed a significant decrease in LAR compared to HF.

Effect of ECPE on Glucose Tolerance and Insulin Resistance. An IPGTT was performed to evaluate glucose tolerance and insulin resistance (Figure 2A). The data showed that HFD induced glucose tolerance compared to CD. On the other hand, the levels of blood glucose in ECPE-supplemented groups were lower than those of HF an hour after injection. To quantify the effectiveness of supplementation, we also calculated the area under the curve (AUC) of the IPGTT (Figure 2B). FBG in HF were higher than those of CON, but the IPGTT levels between the HF group and ECPE-supplemented groups were not significantly different. However, AUC was significantly reduced in both LE and HE compared to HF (Figure 2B).

To examine insulin resistance, FBG and plasma insulin levels were measured and HOMA-IR values were calculated (Table 2). There was an increase in FBG level in HF contrary to CON, but *E. cava* supplementation regardless of dose did not show any beneficial effect on FBG level. However, plasma insulin levels in HE were significantly lower than those in HF. HOMA-IR in HF was higher than that in CON, but HE showed a significant decrease in HOMA-IR compared to HF.

Histological Analysis of Liver. The fat deposition in the liver was increased in HF contrary to CON. However, the ECPE-supplemented group showed dose-dependently decreased fat accumulation in hepatic tissue compared to HF (Figure 3).

Effect of ECPE on Protein Levels of Hepatic AMPK and Its Downstream Genes in the HFD-Induced Obese Mice. To investigate whether ECPE supplementation activates AMPK and its downstream genes, we measured protein levels of AMPK and phosphorylated AMPK (p-AMPK) in the liver (Figure 4A). The protein levels of AMPK were not different among the groups. However, protein levels of the phosphorylation of AMPK in HE were significantly increased compared to other groups.

Effect of ECPE on Protein Levels of Hepatic Lipogenesis and Energy Metabolism Related Genes in the

dx.doi.org/10.1021/jf502830b | J. Agric. Food Chem. 2015, 63, 349−359

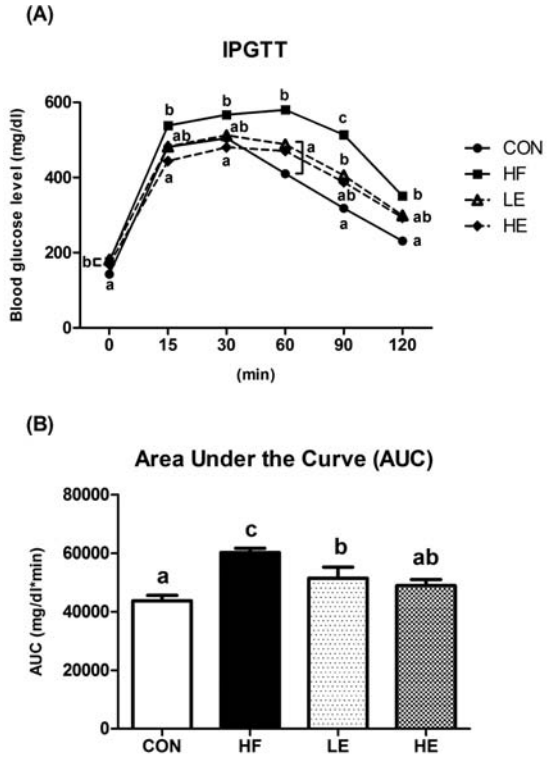

Figure 2. Effect of ECPE on (A) glucose tolerance and (B) glucose area under the curve (AUC) in high-fat diet induced obese mice. Values are means ± SEM. Mean values with unlike letters are significantly different ($p < 0.05$). CON, mice fed the control diet (negative control); HF, mice fed the high-fat diet (positive control); LE, mice supplemented with low dose (100 mg/kg/day) of ECPE; HE, mice supplemented with high dose (500 mg/kg/day) of ECPE.

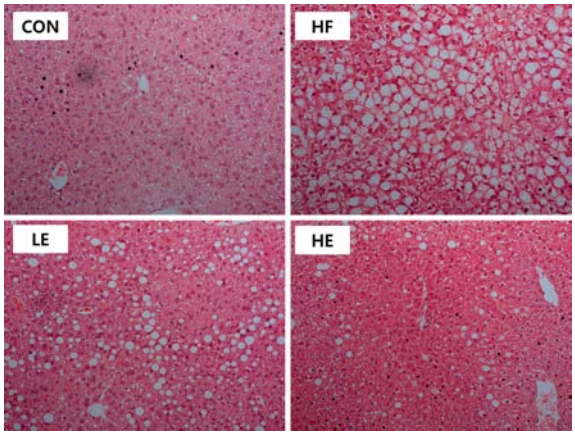

Figure 3. Effect of ECPE on liver morphology (magnification ×100) in high-fat diet induced obese mice. CON, mice fed the control diet (negative control); HF, mice fed the high-fat diet (positive control); LE, mice supplemented with low dose (100 mg/kg/day) of ECPE; HE, mice supplemented with high dose (500 mg/kg/day) of ECPE.

HFD-Induced Obese Mice. We examined protein levels of hepatic lipogenesis (Figure 4B) and fatty acid β-oxidation (Figure 4C). HF group was characterized by increased levels of SREBP1c and decreased levels of PPARα compared to CON, but ECPE-supplemented groups showed a reversed tendency. The FAS and LPL levels were increased in HF compared to CON. On the other hand, ECPE supplementation reduced the protein levels of FAS and LPL regardless of dose (Figure 4B). At the same time, the protein levels of fatty acid β-oxidation, including p-ACC and CPT1A, were decreased in HF compared to those of CON, but ECPE supplementation regardless of dose increased the protein levels of those markers (Figure 4C).

Effect of ECPE on Protein Levels of Hepatic SIRT1 and PGC1α in the HFD-Induced Obese Mice. The protein levels of SIRT1 and PGC1α were measured in the liver. SIRT1 was decreased under the obese condition. However, the ECPE-supplemented groups showed an increased pattern of SIRT1 levels compared to HF dose-dependently. In addition, the protein level of PGC1α in cytosol was not significantly different among all groups. Although the protein level of PGC1α in the nucleus was significantly decreased in HF compared to those of CON, LE and HE presented increased levels of PGC1α in the nucleus (Figure 5A).

Effect of ECPE on Protein Levels of Hepatic Inflammatory Response Related Genes in the HFD-Induced Obese Mice. The protein levels of inflammatory markers, including MCP1, TNFα, IL-1β, and IL-6, were increased under the obese condition. However, the protein levels of those markers were significantly decreased in HE, except IL-6. In addition, the protein levels of nuclear factor kappa B (NFκB) were increased in HF compared to CON. On the other hand, the levels of nuclear NFκB were significantly decreased in both LE and HE compared to HF. The protein levels of COX-2 were increased in HF compared to CON, but the levels were slightly decreased in both LE and HE (Figure 5B).

Effect of ECPE on Hepatic Lipid Peroxidation and Hepatic Antioxidant Defense System Related Proteins in the HFD-Induced Obese Mice. The level of MDA was checked for explaining lipid peroxidation as an indicator of hepatic oxidative stress (Figure 6A). HFD has an adverse effect on the liver through oxidative stress compared to CD. Despite the high oxidative stress in HF, the MDA level of ECPE-supplemented groups was decreased. In addition, we measured the protein involved in the antioxidant defense system at the molecular level. The protein levels of CuZnSOD were not significantly different among the groups. However, the protein levels of GPx and catalase were significantly increased in HE among the groups. At the same time, the protein levels of HO-1 were significantly increased in HF compared to CON, but the levels in LE and HE were not changed compared to HF (Figure 6B).

DISCUSSION

In this study, we investigated whether ECPE could have antiobesity and anti-inflammatory effects and mechanisms in which regulate hepatic lipid metabolism in HFD-induced obese mice for the first time. Our results demonstrated that supplementation of ECPE regardless of dose reduced further weight gain, improved glucose tolerance and dyslipidemia, attenuated TG accumulation, and stimulated hepatic β-oxidation in hepatic tissue. Furthermore, our data showed that supplementation of ECPE is beneficial in regulation of the antioxidant defense system and in improvement of the inflammatory status of HFD-induced obesity. ECPE used in the study contains various polyphenols including diekol, 2,7″-phloroglucinol-6,6′-bieckol, pyrogallol-phloroglucinol-6,6′-bieckol, and phlorofucofuroeckol-A. Although dieckol is the major bioactive component in ECPE, the beneficial effect of ECPE might be derived from combination of dieckol and/or other polyphenol components in ECPE.

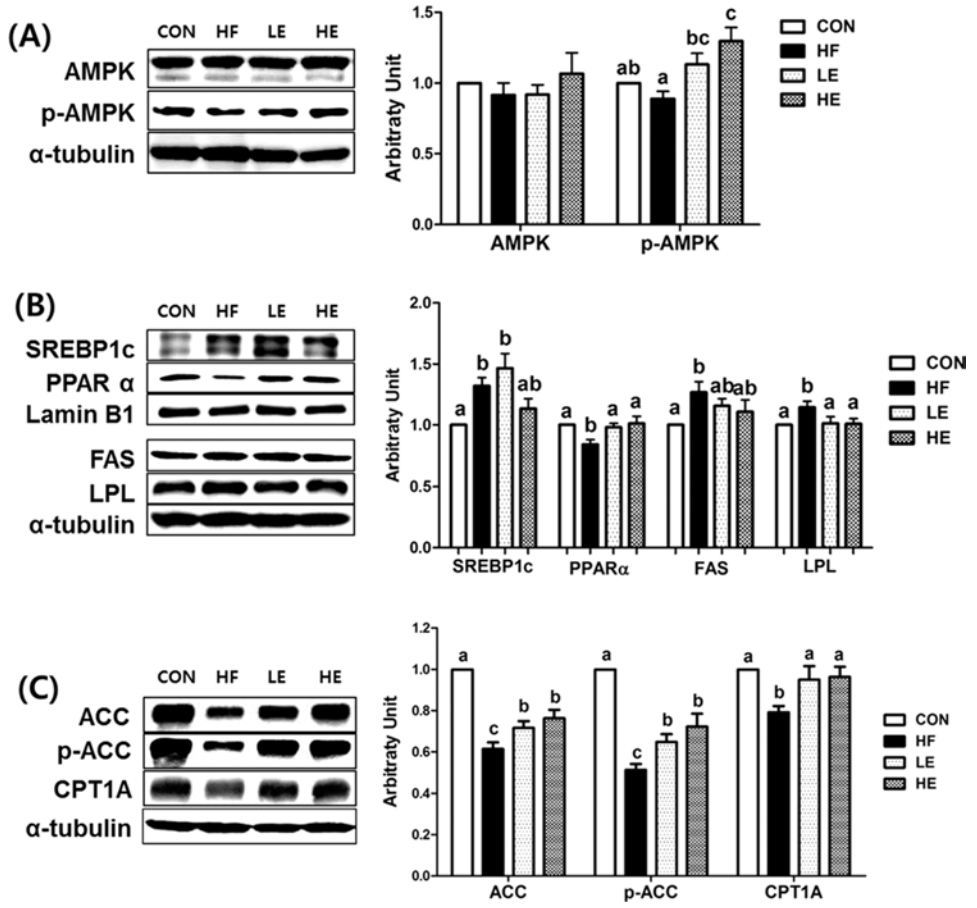

Figure 4. Effect of ECPE on expression of (A) AMPK (AMPK and p-AMPK), (B) lipogenesis (SREBP1c, PPARα, FAS, and LPL), and (C) fatty acid β-oxidation (ACC, p-ACC, and CPT1A). The protein samples measured by Western blot were pooled from six mice per group. A representative image of repeated experiments is shown in the left panel. The bands show the intensity of the bands that were densitometrically measured and normalized to the band levels of α-tubulin (cytosol) or Lamin B1 (nucleus). Values are means ± SEM (n = 6). Mean values with unlike letters are significantly different ($p < 0.05$). CON, mice fed the control diet (negative control); HF, mice fed the high-fat diet (positive control); LE, mice supplemented with low dose (100 mg/kg/day) of ECPE; HE, mice supplemented with high dose (500 mg/kg/day) of ECPE.

The body weight gain at the end-point of this study was significantly lower in HE than that of HF without food intake change. In addition, the visceral fat weights, particularly in mesenteric and retroperitoneal fat pads, were decreased in HE, which led to a reduction of total adipose tissue weight (Table 1). However, the epididymal fat weight did not show a significant difference between CON and HF regardless of ECPE supplementation.

It is also well-known that obesity, particularly increased visceral adipose tissue mass, is one of the major risk factors in developing type 2 diabetes.[24] In other words, individuals with obesity show increased FBG levels or insulin resistances. Our current study showed the beneficial effect of ECPE, especially at high dose, on impaired glucose metabolism demonstrated by AUC levels for glucose tolerance and HOMA-IR for insulin resistance. HE, high dose of ECPE supplementation (500 mg/kg), reduced plasma insulin levels but did not lower the fasting blood glucose level under obese condition. Thus, it can be inferred that HE improves glucose tolerance and insulin resistance, represented by HOMA-IR, under obese condition.

Furthermore, plasma levels of adipokines are distinguished biomarkers for insulin resistance as well as adiposity. Al-Hamodi et al. reported that alterations in plasma adiponectin or leptin might be associated with adiposity and insulin resistance and suggested that the leptin/adiponectin ratio would be a better indicator of insulin resistance as well as adiposity than the singular level of leptin or adiponectin.[24] In addition, plasma leptin has a stronger correlation with obese parameters such as body mass index (BMI) and lipid profiles than plasma adiponectin.[24] In the current study, we observed that plasma leptin in HF was increased compared to CON and HF showed a higher leptin/adiponectin ratio than CON. At the same time, we found that the high-dose ECPE supplementation reduced the leptin/adiponectin ratio compared to HF. This tendency was comparable with the plasma insulin and HOMA-IR data that we presented above. The results suggest that *E. cava* might have a beneficial effect on impaired glucose metabolism by ameliorating glucose intolerance and insulin resistance in HFD-induced obesity, especially with respect to type 2 diabetes.

Dyslipidemia is another well-known complication of obesity. The archetypal dyslipidemia in obesity includes increases in TG and free fatty acids (FFA) as well as an imbalance between HDL-C and LDL-C.[25] In a previous study, extract of *E. cava* reduced levels of plasma TG and total cholesterol and increased levels of HDL-C in db/db mice.[26] Our results similarly showed that ECPE supplementation significantly reduced the plasma TG levels in HFD-fed mice regardless of dose. Moreover, ECPE supplementation regardless of dose group showed decreases in TC levels, whereas there were no significant differences in HDL-C levels among the groups. Eventually, all

dx.doi.org/10.1021/jf502830b | J. Agric. Food Chem. 2015, 63, 349−359

ECPE supplemented groups showed an improvement in the A) compared to HF. These results suggest that ECPE supplementation might have a beneficial effect on improving circulating TG and TC levels and thus have potential in the prevention of dyslipidemia-induced atherogenesis in obese mice.

We examined how ECPE influences the HFD-induced abnormal hepatic lipid metabolism as well. Previous studies showed that fatty liver disease was caused by an increased fatty acid influx into the liver, which leads to ectopic fat accumulation in hepatocytes in obese subjects.[27,28] Furthermore, recent studies reported that HFD-fed animals showed a higher hepatic expression of genes related to lipogenesis, whereas they showed lower levels of hepatic proteins related to fatty acid β-oxidation.[29,30] At the molecular level, our results showed that ECPE supplementation regulated hepatic lipid metabolism by stimulating phosphorylation of AMPK. Previous studies reported that activated AMPK negatively regulates SREBP, a major transcription factor of fatty acid synthesis. Particularly, the level of SREBP is higher in subjects with NAFLD.[31,32] An overexpression of SREBP1c, one of SREBP isoforms, allows expression of lipogenic enzymes, including acetyl-CoA carboxylase 1 (ACC1) and FAS.[33,34] The primary downstream targets for AMPK are 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMG-CoA reductase) and ACC, which are rate-controlling enzymes of cholesterol and malonyl-CoA synthesis, respectively. Because malonyl-CoA is a material of fatty acid synthesis and an allosteric regulator of carnitine palmitoyltracsferase-1 (CPT1), which takes up long-chain fatty acyl-CoA into mitochondria, inactivation of ACC leads to reducing lipogenesis as well as fatty acid β-oxidation.[35] A previous study showed that dieckol isolated from *E. cava* activated AMPK and inhibited adipogenesis in 3T3-L1 preadipocytes.[19] Similarly, this study demonstrated that ECPE supplementation in HFD-induced obese mice had higher levels of proteins involving β-oxidation and lower levels of proteins associated with lipogenesis than the HF group, as shown in Figure 4B. In detail, a high dose of ECPE supplementation decreased the protein level of SREBP1c in the nucleus, and this led to a decreased protein level of FAS. At the same time, both a low and a high dose of ECPE supplementation increased the protein level of PPARα, and this increase resulted in decreased LPL production. In addition, ECPE supplementation inactivated ACC and thus increased the protein level of CPT1A, which is a rate-limiting enzyme of lipid oxidation.[36] Taken together, we suggest that ECPE supplementation suppressed hepatic lipid accumulation by reducing lipogenesis and stimulating fatty acid β-oxidation. The results are well in accordance with our histological observation of hepatic tissue, as shown in Figure 3. HF had a large amount of fat droplets in liver compared to CON. However, ECPE supplementation ameliorated hepatic lipid accumulation, particularly in the high dose ECPE-supplemented group.

A previous study reported that the increase in fatty acid β-oxidation through AMPK activation changed the NAD^+/NADH ratio and consequently stimulated SIRT1 expression in hepatocytes.[37] SIRT1 plays crucial roles in glucose homeostasis, lipid metabolism, oxidative stress, and inflammation.[8] In particular, SIRT1 activation results in an increase in fatty acid β-oxidation via PPARα and peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC1α)[8] as well as an improvement of inflammatory response via NFκB activation.[38] In a previous study, rats with NAFLD showed significantly low levels of hepatic SIRT1, but caloric restriction restored hepatic SIRT1 levels to that in nonobese subjects.[39] In addition, Puigserver mentioned that PGC1α in hepatocytes interacts with liver-enriched transcription factors, including hepatocyte nuclear factor 4 alpha (HNF4α), forkhead box protein O1 (FOXO1), and PPARα, and these factors are associated with gluconeogenesis.[40] Taken together, activation of AMPK by decreased cells' energy status, accompanied by exercise or caloric restriction, stimulates SIRT1 in response to NAD^+ ratio, subsequently increases PGC1α and consequently enhances mitochondrial biogenesis and its function.[13] The present study showed that the protein levels of cytosolic SIRT1, as well as the nuclear levels of both PGC1α and PPARα, were increased in the ECPE-supplemented groups, whereas those were decreased in obese control group (HF). In addition, the nuclear protein levels of both PGC1α and PPARα are in accordance with insulin resistance demonstrated by AUC levels, as mentioned earlier. These results suggest that activated AMPK by ECPE supplementation might consequently increase NAD^+ by fatty acid β-oxidation and lead to activated hepatic SIRT1 in HFD-induced obese mice. Thus, increased SIRT1 by ECPE supplementation might ameliorate impaired glucose metabolism as well as up-regulate lipolysis through increased fatty acid β-oxidation, as demonstrated by PGC1α and PPARα in HFD-induced obesity.

As stated above, obesity is also recognized as a systemic low-grade chronic inflammation, which is induced by inflammatory mediators such as TNFα, IL-6, and CRP secreted from excessive adipose tissue and some improperly activated immune cells.[41] Our results similarly showed that HFD increased pro-inflammatory cytokines, such as TNFα, IL-1β, and IL-6, and the increases in those markers activated NFκB, which produced much more TNFα and IL-1β and also resulted in the production of other inflammatory mediators, such as COX-2, in the liver. At the same time, our data showed that a particularly high dose of ECPE supplementation reduced the levels of pro-inflammatory markers, including TNFα and IL-1β. In addition, whereas NFκB translocation into the nucleus was increased in the HF group compared to CON, ECPE supplementation at both low and high doses decreased the NFκB translocation into the nucleus (Figure 5B). Consequently, the increase in COX-2 resulting from NFκB activation was decreased in the ECPE-supplemented groups. Previous studies had demonstrated a similar tendency that *E. cava* inhibited lipopolysaccharide-induced COX-2, TNFα, and IL-1β via the NFκB pathway in BV2 microglia.[16]

Elevated oxidative stress is another factor for obesity-linked inflammation.[42] In this study, we measured lipid peroxidation, as demonstrated by MDA, one of the valid biomarkers of oxidative stress[43,44] in the liver. Our data showed that the MDA level was significantly increased in the HF group compared to CON, whereas the level was decreased in all ECPE-supplemented groups regardless of its dose. The results suggest that ECPE suppresses overproduction of ROS induced by obesity. In addition, the current study demonstrated that antioxidant defense enzymes, including GPx and catalase in the liver, were significantly increased in HE compared to the other groups. Both GPx and catalase are involved in the conversion of H_2O_2 into H_2O and molecular O_2. Increased levels of GPx and catalase may be associated with decreased lipid peroxidation demonstrated by MDA levels. Therefore, it is fairly easy to understand why ECPE supplementation significantly reduced the plasma levels of GOT and GPT compared to nontreated

HF groups. As plasma activities of GOT and GPT are sensitive clinical markers of hepatic damage including NAFLD,[45] our data suggest that ECPE supplementation, especially at high dose, plays a beneficial role in protection against liver damage via regulation of oxidative stress under an obese condition. However, some previous studies had documented that *E. cava* increased the hepatic activity of SOD against ethanol-induced liver damaged mice[20] and phlorotannins isolated from *E. cava* have neuro-protective effects by regulating ROS scavenging activity in HT22 cells.[46] Several studies have tried to establish the mechanisms of the antioxidant defense enzymes such as SODs, GPx, catalase, and HO-1 but, unfortunately, the patterns in expression of endogenous antioxidants between healthy normal status and disease state have not shown consistency so far.[47] Therefore, further experiments are required for examination of the activation of key markers such as the nuclear factor (erythroid-derived 2)-like 2 (Nrf2) and the activities of antioxidant enzymes in other tissues.

Collectively, ECPE has beneficial effects on hepatic lipid metabolism, inflammation, and oxidative stress through activation of AMPK and regulation of its downstream genes in HFD-induced obese mice. In other words, ECPE might be involved in a partnership between AMPK and SIRT1, which reduces hepatic lipogenesis in HFD-induced obesity. Moreover, ECPE reduced the protein levels that are related to inflammatory response such as TNFα, IL-1β, and NFκB. Furthermore, ECPE activated GPx and catalase and consequently reduced hepatic lipid peroxidation. These results suggest that *E. cava* might be a potential nutraceutical to treat not only impaired hepatic lipid metabolism but also inflammation and oxidative stress via regulation of AMPK and SIRT1 in obesity.

Supporting Information

ABSTRACT: Elevating the yield and altering the composition of seed tocopherols (Toc's) are important to rapeseed breeding and production. However, little is known about the biosynthesis of Toc's in response to environmental signals. In this study, we investigated the effects of exogenous gibberellin (GA_3) and paclobutrazol (PAC) on Toc biosynthesis. We also explored the interactive effects between the two plant growth regulators (PGRs) and other factors, such as PGR treatment duration, genotype, and growing location on the total Toc yield and composition in oilseed rape seed. GA_3 significantly enhanced the production of Toc's and elevated the α-/γ-Toc ratio in a time- and genotype-dependent manner. By contrast, PAC significantly reduced Toc yield. Genotypic differences were observed in the effects of GA_3 on Toc yield and composition in the seeds. GA_3 significantly increased the Toc yield and α-/γ-Toc ratio in Zheyou-50, a genotype with a low proportion of very long chain fatty acids (VLCFAs). However, GA_3 did not significantly influence these parameters in Jiu-Er-13Xi, a genotype with a high VLCFA proportion. The increased Toc yield induced by GA_3 was mediated by the upregulation of genes (*BnPDS1* and *BnVTE1*) that catalyze the production of Toc precursors. Therefore, applying GA_3 can improve rapeseed quality by increasing Toc yield and improving Toc composition.

KEYWORDS: *Brassica, Arabidopsis, gibberellin (GA_3), paclobutrazol (PAC), tocopherol content, tocopherol composition, gene expression*

INTRODUCTION

Oilseed rape (*Brassica napus* L., AACC, $2n$ = 38) in the Brassicaceae family has a high economic importance worldwide.[1,2] Oilseed rape oil is a vital dietary source of vitamin E in China, particularly in the Yangtze River valley region.[3,4] Tocopherols (Toc's) constitute a family of vital lipid-soluble antioxidants with several health benefits.[5−8] Protection of the photosynthetic apparatus from oxygen toxicity and lipid peroxidation in plants is attributed to α-tocopherol (α-Toc) enrichment in the chloroplast membrane,[9] whereas the prevention of polyunsaturated fatty acids from oxidation in seeds is enhanced by γ-tocopherol (γ-Toc).[10] The biological activities of the vitamin E components α-Toc, β-tocopherol (β-Toc), γ-tocopherol (γ-Toc), and δ-tocopherol (δ-Toc) are 100%, 30%, 15%, and 5%, respectively.[11] Canola oil, on the average, contains a high amount of vitamin E, with ∼64% γ-Toc, ∼35% α-Toc, and <1% δ-Toc.[1,12,13]

Plant growth regulators (PGRs) play important roles in various aspects of plant growth and development, including seed maturation and the accumulation of seed storage reserves.[14] Gibberellins (GAs) constitute a large group of tetracyclic diterpenoids that regulate seed germination, leaf expansion, stem and root extension, flower induction and development, and fruit expansion.[15−18] GA signals are received and transduced via the GID1 GA receptor/DELLA repressor pathway. *Arabidopsis* has five functionally overlapping DELLA proteins,[19−22] namely, GAI, RGA, RGL1, RGL2, and RGL3, that are nuclear negative regulators in the GA signaling pathway.[20,23,24] Paclobutrazol (PAC) or (2*RS*,3*RS*)-1-(4-chlorophenyl)-4,4-dimethyl-2-(1*H*-1,2,4-triazol-1-yl)pentan-3-ol interacts antagonistically with GA by inhibiting its synthesis by blocking conversion of *ent*-kaurene to *ent*-kaurenoic acid. Exogenous PAC suppresses shoot growth, leading to reduced plant height, internode elongation, and leaf area as well as to increased lodging resistance, branch number, and seed yield in oilseed rape.[25,26]

Increasing the total Toc and/or altering the Toc composition (α-/γ-Toc ratio) are important to rapeseed breeding and commercial production. Previous studies on vegetable and maize seeds revealed interactive effects between genotypes and environmental factors on seed Toc's.[27−31] However, little is known about the response of seed Toc's to exogenous PGRs. Therefore, we conducted a field experiment to investigate the effects of gibberellic acid (GA_3) and its synthesis inhibitor PAC on seed Toc's. We also analyzed the expression levels of the

	S3									

[a]S1 = PGRs spray from bud formation to seed maturity; S2 = from flowering initiation to seed maturity; S3 = from flowering completion to seed maturity stage. Shaded boxes show the timings of PGRs spray.

PDS1, *VTE1*, and *VTE4* genes to monitor the synthesis of Toc precursors. *PDS1* plays a critical role in the conversion of *p*-hydroxyphenylpyruvate (HPP) to homogentisic acid (HGA). *VTE1* encodes a Toc cyclase that directly converts 2-methyl-6-phytyl-1,4-benzoquinol (MPBQ) into δ-Toc or 2,3-dimethyl-5-phytyl-1,4-benzoquinol (DMPBQ) into γ-Toc.[32] *VTE4* is a transmethylase that catalyzes the production of α-Toc from γ-Toc and β-Toc from δ-Toc [33] (Figure 1). We also aim to understand the interactive effects between the PGRs and other factors, such as PGR treatment duration, genotype, and growing location.

MATERIALS AND METHODS

Plant Materials and Growth Conditions of *Arabidopsis*. The *Arabidopsis thaliana* ecotype Langdsberg *erecta* (L*er*) (wild-type (WT)), the quadruple mutant (*gai-t6 rga-t2 rgl1-1 rgl2-1*) of wild-type background (*q-della/WT*), and the penta mutant (*ga1-3 gai-t6 rga-t2 rgl1-1 rgl2-1*) of *ga1-3* background (*p-della*), were used to evaluate the effects of GA_3 application on Toc's in *Arabidopsis* seeds.[24] The *q-della/WT* mutant was donated by Prof. Fu Xiangdong of the Institute of Genetics and Developmental Biology, Chinese Academy of Sciences. The *p-della* mutant was provided by Prof. Jinrong Peng of the College of Life Science, Zhejiang University. All plants were grown under the same conditions (16 h light/8 h darkness) and harvested almost simultaneously. Seeds were stored in a dry cabinet (15% moisture level) until used.

Plant Material and Growth Conditions of Rapeseed. Field experiments were conducted during the winter canola growing season (2012−2013) at Hangzhou (location 1, L1) and Jinhua (L2). Both cities are in Eastern China, and are ∼250 km apart. Zheyou-50 (genotype 1, G1), a canola type with a high seed oil content of ∼50%, and Jiu-Er-13Xi (G2), a high erucic acid type with a low seed oil content of only 40%, were used. Pesticides and herbicides were applied following local cultivation management. One-month-old seedlings of uniform height were selected and transplanted from the nursery to the respective fields. The soil type of the fields at both locations was loamy clay. Before transplanting from nursery to field, urea at a rate of 150 kg ha^{-1} was applied as a basal dose fertilizer. At the end of January 2013, a second dose of urea was applied as topdressing at a rate of 75 kg ha^{-1}.

DOI: 10.1021/jf505312c
J. Agric. Food Chem. 2015, 63, 360−369

The fields at both sites were not irrigated because rainfall was sufficient in Hangzhou (738.4 mm) and Jinhua (868.5 mm) during the rapeseed growth season. Plants were spaced 0.35 m apart between rows and 0.30 m within rows. The field experiment at both locations was performed following a randomized complete block design with three replications (blocks).

Application of PGRs to the Plants. GA_3 (plant growth regulator 1, P1) at 150 μmol L^{-1} and PAC (P3) at 150 mg L^{-1} were applied to rapeseed plants. Both PGRs were purchased from Sangon Company (Shanghai, China). Water was used as a control (P2). All PGRs were sprayed at 7−9 day intervals (no spraying on raining days) during one of the following stages: S1 (from bud formation to seed maturity), S2 (from flowering initiation to seed maturity), or S3 (from flowering completion to seed maturity). Timing and duration of PGR applications are listed in Table 1. S1, S2, and S3 included 9, 7, and 5 PGR spray events, respectively. Colored threads were tied to the main branch of rapeseed plants to tag the flowering initiation dates.

Analysis of Tocopherols. Toc's were extracted and analyzed as previously described with slight modifications.[2,34] In brief, ~75 mg of seeds were weighed and transferred into a 2 mL skirted screw-cap microtube containing 1.3 mL of *n*-hexane. The seeds were pulverized with a bead mill homogenizer (Bead Ruptor-24, Omni, Kennesaw, Georgia, U.S.A.) at 8 m s^{-1} for 30 s. The samples were stored in the dark for 15 h to extract Toc's. A 20 μL aliquot of the supernatant was analyzed on a normal-phase high-performance liquid chromatography (HPLC) apparatus (model 600, Waters, Milford, Massachusetts, U.S.A.) equipped with a Zorbax Rx-SIL column (4.6 mm × 250 mm × 5 μm; Agilent, Englewood, Colorado, U.S.A.) and a fluorescence detector (λ_{ex} = 295 nm; λ_{em} = 330 nm). The mobile phase of hexane/*tert*-butyl methyl ether (94:6, v/v) was delivered isocratically at 1 mL min^{-1}. Calibration curves of pure standards were used to quantify the Toc isoforms. References for α- (purity 99.90%, cat. no. 47783), β- (purity 99.00%, cat. no. 46401), γ- (purity 99.10%, cat. no. 47785), and δ-Toc (purity 95.50%, cat. no. 47784) were analytical standards and were obtained from Supelco (Bellefonte, Pennsylvania, U.S.A.). Liquid chromatography-grade hexane (Sigma−Aldrich, Shanghai, China) was used as the solvent. The peaks of the Toc standards (α-, β, γ-, and δ-Toc) were distinguished by their retention times. The standard curve for the quantification of the experimental samples was calibrated according to the corresponding peaks of individual Toc derivatives. The contents of Toc's were expressed in mg per kg of seed, and the total amount of Toc's was calculated as the sum of α- and γ-Toc.

Analysis of Gene Expression by Reverse Transcription Quantitative Polymerase Chain Reaction. Flowers were tagged with different colored threads to indicate days after pollination (DAP). Only seeds from the siliques on main inflorescences were harvested for RNA extraction. The RNA samples were isolated with the Invisorb Spin Plant RNA Mini Kit (Invitek, Berlin, Germany) following the manufacturer's instructions. Reverse transcription quantitative polymerase chain reaction (RT-qPCR) amplification was performed as previously described.[35] All primer pairs used in the RT-qPCR analyses of *Arabidopsis* and rapeseed are listed in Supporting Information, Tables S1 and S2, respectively.

Statistical Analysis. For the analysis of gene expression, baseline and threshold cycles (CT value) were determined automatically by using Bio-Rad iQ Software (version 3.0; Hercules, California, U.S.A.). Relative amounts of RNA transcripts were calculated as previously described.[36] Field experimental data were classified with Win-Excel and subjected to ANOVA with the MStatc statistical package (version 7.05). Treatment means were compared for least significant differences at $P \leq 0.05$ or $P \leq 0.01$ (Table 2).

RESULTS

Response of Total Toc and Its Components to Exogenous PGRs and the Interactions between PGRs and Other Factors. ANOVA reveals that genotype (G), PGR (P), and number of PGR applications (S) significantly affected the total Toc and its composition. Growth location (L) only significantly affected α-Toc and the α-/γ-Toc ratio. Most of the interactions among these factors significantly affected the variation in total Toc and its components. However, the interaction between L × S and L × P × G exerted no significant effects on the α-Toc content, and the interaction between P × G exhibited no significant effect on the γ-Toc content (Table 2).

[a]P, plant growth regulators (PGRs); G, genotype; L, location; S, duration of PGR effect (or total spray times); details are available in the Materials and Methods section. *Indicates significance at $P \leq 0.05$; **indicates significance at $P \leq 0.01$; ns = nonsignificant.

Effect of PGRs on Toc Content and Composition. Compared with the water control, GA_3 significantly increased the total Toc, α-Toc, and γ-Toc contents as well as the α-/γ-Toc ratio ($P \leq 0.01$). Meanwhile, PAC significantly reduced the total Toc but did not significantly influence the α-Toc and γ-Toc contents or the α-/γ-Toc ratio (Table 3).

Effect of the Interaction between PGR and Genotype on Seed Toc's. Highly significant variations in the seed total Toc, α-Toc, and α-/γ-Toc ratio ($P \leq 0.01$) were observed in response to the interaction between PGR and genotype (G), whereas no significant differences were observed in the seed γ-Toc (Table 3). Zheyou-50 plants treated with GA_3 produced higher total Toc (667.22 mg kg^{-1} seeds) and α-Toc (282.54 mg kg^{-1} seeds) than those treated with PAC or water. The lowest total Toc (380.74 mg kg^{-1} seeds) and α-Toc contents (160.00 mg kg^{-1} seeds) were observed in the Jiu-Er-13Xi plants untreated with PGR (Table 3). The Jiu-Er-13Xi plants treated with GA_3 had the highest α-/γ-Toc ratio (0.80), whereas the Zheyou-50 plants treated with PAC had the lowest α-/γ-Toc ratio (0.66) (Table 3).

Effect of the Interactions between PGR and Location on Seed Toc's. The interaction between PGR and location caused highly significant variations in the total Toc, α-Toc, and γ-Toc contents as well as in the α-/γ-Toc ratio ($P \leq 0.01$) (Table 2). The highest total Toc (538.35 mg kg^{-1} seed) and γ-Toc (315.32 mg kg^{-1} seed) contents were obtained after applying GA_3 at the Hangzhou site (L1). Conversely, the highest α-Toc content (238.38 mg kg^{-1} seed) and α-/γ-Toc ratio (0.82) were

	Sig. Level	**	**	**	**	Sig. Level	**	**	**	**

[a]Sig. level shows the level of significance. The values of Toc yield and composition are the means of three replications. P, plant growth regulators (PGRs); G, genotype; L, location; S, duration of PGR effect (or total spray times); details are available in the Materials and Methods section. Different letters to the figures in the same column following each category indicate significant differences at $P \leq 0.01$ (**) or 0.05 (*) as per ANOVA results.

Effect of the Interaction between PGR and PGR Treatment Duration on Seed Toc's. The interaction between PGR and PGR treatment duration led to significant variations in the total Toc, α-Toc, and γ-Toc contents and in the α-/γ-Toc ratio ($P \leq 0.01$) (Table 2). The application of GA_3 (P1) from the green floral bud stage to seed maturity (S1) resulted in the highest total Toc (625.50 mg kg^{-1} seed), α-Toc (263.62 mg kg^{-1} seed), and γ-Toc (361.88 mg kg^{-1} seed) contents, whereas the application of GA_3 from flowering completion to seed maturity (S3) produced the highest α-/γ-Toc ratio (0.81). The application of PAC from flowering completion to seed maturity caused the lowest total Toc (458.44 mg kg^{-1} seed), α-Toc (187.45 mg kg^{-1} seed), and γ-Toc (270.99 mg kg^{-1} seed) contents and the α-/γ-Toc ratio (0.69) made statistic sense (Table 3).

Effect of the Interaction among PGR, Location, and PGR Treatment Duration on Seed Toc's. The interaction among PGR, location, and PGR treatment duration caused significant variations in the total Toc, α-Toc, and γ-Toc contents ($P \leq 0.01$) and a significant variation in the α-/γ-Toc ratio ($P \leq 0.05$) (Table 2). Among the 18 treatment combinations, the application of GA_3 from the green floral bud stage to seed maturity at the Hangzhou site (P1L1S1) resulted in the highest total Toc (673.90 mg kg^{-1} seed), α-Toc (269.79 mg kg^{-1} seed), and γ-Toc (404.12 mg kg^{-1} seed) contents. Conversely, the application of PAC from flowering initiation to seed maturity at the Hangzhou site (P3L1S2) led to the lowest total Toc (449.73 mg kg^{-1} seed) and γ-Toc (261.28 mg kg^{-1} seed) contents. The lowest α-Toc content (185.14 mg kg^{-1} seed) appeared following the P3L1S3 treatment combination. The highest α-/γ-Toc (0.88) was achieved by the P1L2S3 treatment combination, whereas the lowest α-/γ-Toc value (0.64) was obtained by the P3L1S1 treatment combination (Table 4).

Effect of the Interaction among PGR, PGR Treatment Duration, And Genotype on Seed Toc's. The interaction among PGR, genotype, and PGR treatment duration (PGS) gave rise to significant variations in the total Toc, α-Toc, and γ-Toc contents and the α-/γ-Toc ratio ($P \leq 0.01$) (Table 2). Among the 18 treatment combinations, GA_3 treatment from flowering initiation to seed maturity (P1S1G1) produced the highest total Toc (832.14 mg kg^{-1} seed), α-Toc (345.46 mg kg^{-1} seed), and γ-Toc (486.67 mg kg^{-1} seed) contents in the Zheyou-50 plants. The Jiu-Er-13Xi plants treated with PAC from flowering completion to seed maturity (P3S3G2) had the lowest total Toc (345.99 mg kg^{-1} seed), α-Toc (140.20 mg kg^{-1} seed), and γ-Toc (205.79 mg kg^{-1} seed) contents. The highest (0.83) and lowest (0.63) α-/γ-Toc ratios were produced by the P3S2G2 and P3S1G1 treatment combinations, respectively (Table 4).

Effect of the Interaction among PGR, Genotype, And Location on Seed Toc's. The interaction among the PGR, genotype, and location (PGL) caused a significant variation in the total Toc yield ($P \leq 0.05$) as well as significant variations in the γ-Toc content and α-/γ-Toc ratio ($P \leq 0.01$). However, the interaction did not produce a significant variation in the α-Toc content (Table 2). Among the 12 treatment combinations, GA_3 treatment at the Jinhua site (P1G1L2) produced the highest total Toc (698.67 mg kg^{-1} seed) and γ-Toc (393.24 mg kg^{-1} seed) yields in the Zheyou-50 plants. Conversely, the Jiu-Er-13Xi plants treated with PAC at Hangzhou (P3G2L1) resulted in the lowest total Toc (381.29 mg kg^{-1} seed) and γ-Toc (217.39 mg kg^{-1} seed) yields. The highest (0.87) and lowest (0.62) values of α-/γ-Toc were caused by the P1G2L2 and P3G1L1 treatment combinations, respectively (Table 4).

Effect of the Interactions among PGR, Location, PGR Treatment Duration, And Genotype on Seed Toc's. The interaction among all the four factors significantly influenced amount of Toc and composition ($P \leq 0.01$, Table 2). Among the 36 treatment combinations, GA_3 treatment from bud formation to seed maturity at the Hangzhou site (P1G1L1S1) produced the highest total Toc (875.01 mg kg^{-1} seed), α-Toc (334.73 mg kg^{-1} seed), and γ-Toc (540.28 mg kg^{-1} seed)

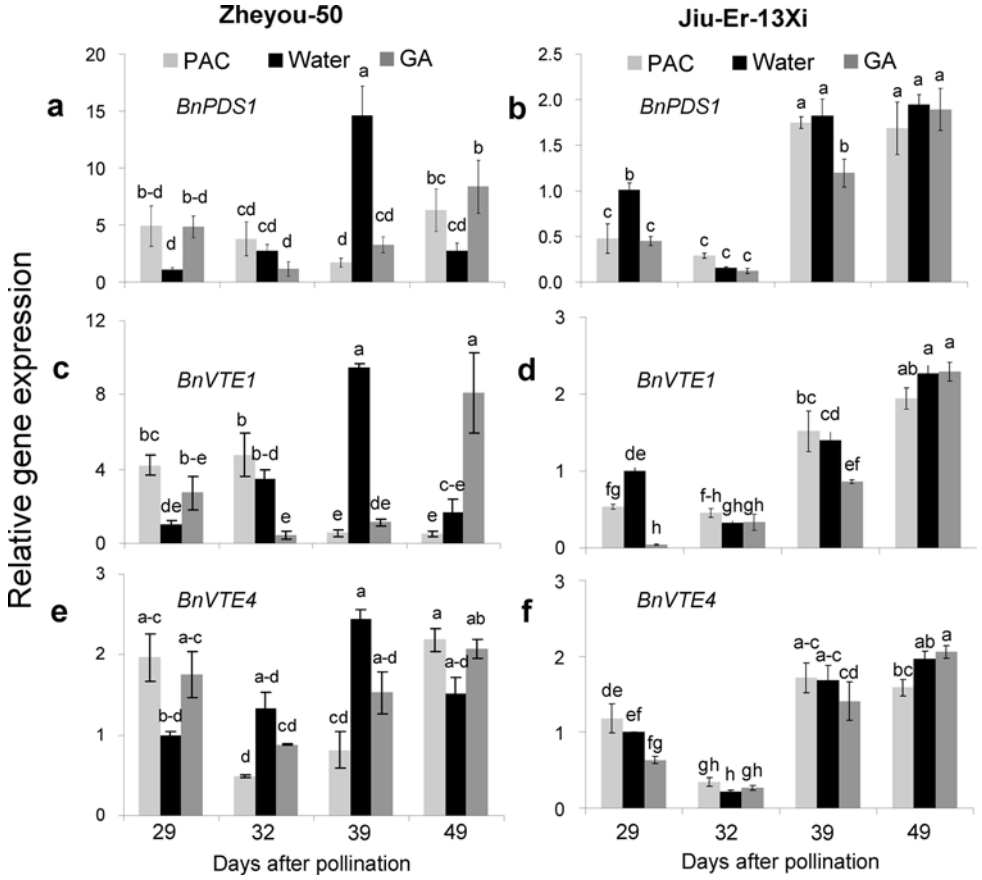

Figure 2. Relative transcription levels of tocopherol biosynthesis genes in GA_3, PAC, and water treated (control) plants of oilseed rape genotypes treated for different durations of GA_3 (or total spray times). Water, untreated/control plants; PAC, paclobutrazol. Bars on graphs show ±standard error.

contents in the Zheyou-50 plants. The Jiu-Er-13Xi plants untreated with PGR from flowering completion to seed maturity at the Jinhua site (P2G2L2S1) produced the lowest total Toc (324.64 mg kg^{-1} seed), and α-Toc (137.20 mg kg^{-1} seed) that was statistically at par to α-Toc content obtained with P3G2L2S3 treatment combination. The lowest γ-Toc (170.52 mg kg^{-1} seed) contents were produced by P1G2L2S3 treatment combination. The highest (0.96) and lowest (0.52) α-/γ-Toc ratios were obtained from the P1G2L2S3 and P3G1L1S1 treatment combinations, respectively (Table 5).

Transcriptional Changes in the Genes Regulating Toc Biosynthesis in Response to PGR Application. We investigated the effects of exogenous GA_3 and PAC on the expression levels of *BnPDS1*, *BnVTE1*, and *BnVTE4*, which are important in the Toc biosynthetic pathway (Figures 1 and 2). The RNA samples were harvested at 29, 32, 39, and 49 DAP, 7, 3, 4, and 1 day(s) after the sixth, seven, eighth, and ninth PGR applications, respectively. The result of RT-qPCR based on the RNA samples collected at 49 DAP, 1 day after the ninth application, indicated that GA_3 significantly upregulated the expression of *BnPDS1* and *BnVTE1* in Zheyou-50 (Figure 2a and c). No significant differences in gene expression were observed between the plants treated with GA_3 and water at 49 DAP in Jiu-Er-13Xi (Figure 2b, d, and f). The RT-qPCR results based on the RNAs collected at other time points (29, 32, and 39 DAP) from both genotypes did not show that GA_3 significantly upregulated the expression levels of *BnPDS1*, *BnVTE1*, and *BnVTE4*. Moreover, at 39 DAP striking inhibitory responses were observed in the expression of all three genes to PGRs in Zheyou-50 and to GA_3 in Jiu-Er-13Xi (Figure 2a–f).

Response of Toc Synthesis to GA Enhancement in *Arabidopsis*. To confirm whether or not GA enhancement can increase *PDS1*, *VTE1*, and *VTE4* expression and seed Toc content, we compared the expression levels of *VTE1*, *VTE4*, and *PDS1* between the WT (L*er*) and *q-della/WT* mutant (Figure 3d–f) as well as the seed Toc yield among the WT (L*er*), *q-della*, *p-della*, and wild-type plants treated with GA_3 (WT + GA_3) in *Arabidopsis* (Figure 3a–c).

The enhanced GA signaling in the *q-della/WT* mutant induced the upregulation of *VTE1*, *VTE4*, and *PDS1* at 4, 8, 12, and 16 DAP (Figure 3d–f). The expression levels of all three genes peaked at 12 DAP. *PDS1* expression showed the greatest difference between WT and the mutant. The transcript level of *PDS1* was 2-fold higher in the *q-della/WT* mutant than in the WT (Figure 3d).

The *q-della/WT* mutant, *p-della* mutant, and WT + GA_3 plants had considerably higher seed Toc yields than the WT plants (Figures 3a). Each 1 kg of *q-della/WT*, *p-della*, and WT + GA_3 seeds contained 412, 413, and 402 mg of Toc's, respectively, which were 11.9%, 12.2%, and 9.2% higher than the Toc in WT. The differences in the total Toc content between the genotypes were derived from the differences in γ-Toc content. No significant differences in seed α-Toc content were observed among the WT, *q-della/WT*, *p-della*, and WT + GA_3 plants, but the γ-Toc content was significantly higher in the *q-della*, *p-della*, and WT + GA_3 plants than in the WT plants (Figure 3a–c).

J. Agric. Food Chem. 2015, 63, 360–369

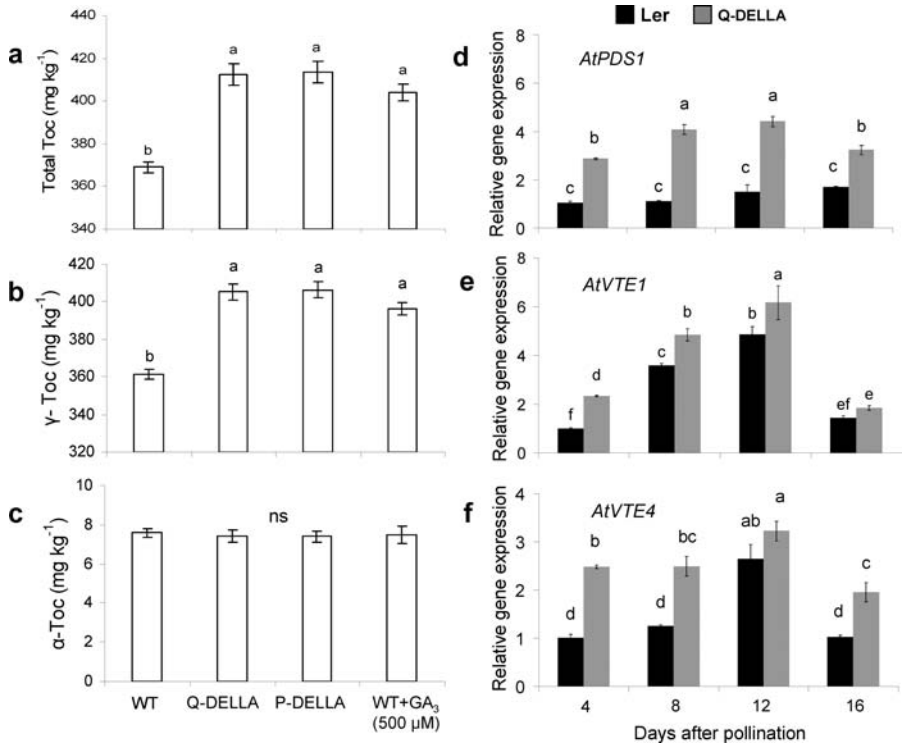

Figure 3. Comparison of α-Toc (a), γ-Toc (b), and total Toc (c) content among *Arabidopsis thaliana* WT, *q-della/WT*, *p-della* mutants and WT + GA_3 plants. Letters on the bars shows the comparison among treatment being significant at $P \leq 0.01$; ns = nonsignificant. Comparison of relative transcription levels of tocopherol biosynthesis genes (*AtVTE1*, *AtVTE4*, and *AtPDS1*) among *Arabidopsis* ecotype Langdsberg *erecta* [WT(*Ler*)] and *q-della/WT* mutant are shown in (d), (e), and (f), respectively, at different seed developmental stages. Bars on graphs show ±standard error.

DISCUSSION

GA signaling regulates a number of genes that are important for plant development processes, including seed germination, stem elongation, trichome, flower and fruit formation, and seed maturation.[15−18,37,38] We have reported recently that GA signaling promotes the expression of a group of GDSL-type genes that hydrolyze lipids.[24] We also observed that GA affects total Toc yield and the major Toc components in *Arabidopsis*. We postulated that a similar mechanism might exist in rapeseed, a major source of edible oil worldwide. Given that PAC is an inhibitor of GA synthesis and functionally antagonistic to GA,[39,40] we assumed that exogenous GA_3 and PAC may reversely affect seed Toc's in rapeseed. To test this hypothesis, we designed a field experiment and analyzed the PGR effects as well as any interactive effects between the PGR and factors such as genotype, PGR treatment duration, and planting location. Regardless of other factors, GA_3 increased total Toc yield 5.6% compared with the control. By contrast, the GA inhibitor PAC reduced the total Toc yield 3.3% compared with the control. Although the α-Toc and γ-Toc contents were both increased by exogenous GA_3, the increased α-Toc content (11.24%) was much higher than that for γ-Toc content (1.7%). Consequently, the value of α-/γ-Toc was significantly increased following GA_3 treatment (Table 3). In general, α-Toc is the predominant form of Toc in photosynthetic tissues, whereas γ-Toc is predominant in most plant seeds. A high α-/γ-Toc ratio is desired by rapeseed breeders because α-Toc has the highest vitamin E activity (100%), whereas γ-Toc has merely 8−19% relative activity.[41,42]

PGR treatment duration affected Toc production. The seed Toc yield increased as the PGR treatment duration was prolonged. The longest duration (S1) of GA_3 application (P1S1) caused the highest total Toc yield (625.5 mg kg^{-1} seed), whereas the shortest PAC duration (P3S3) led to the lowest total Toc yield (458.44 mg kg^{-1} seed) (Table 3, section P × S interaction). GA_3 signaling affects various processes of plant growth.[25,26] In the present study, early application of GA_3 (S1) caused undesirable changes in various agronomic traits, including increased plant height, reduced numbers of branches and pods per plant, and reduced seed yield (data not shown). However, late application of GA_3 (P1S3) did not significantly influence Toc yield compared with the control (P2S3). This dilemma can be overcome under some circumstances through particular genotype and location combinations. For example, the effect of GA_3 in elevating Toc yield was significantly greater than that for the control (P2G2L1S3) when GA_3 was applied during S3 to Jiu-Er-13Xi plants at the Hangzhou site (P1G2L1S3) (Table 5, section P × G × L × S interaction).

Genotype and PGR interaction significantly influenced the total Toc and Toc composition of the seeds. In general, the application of GA_3 to Zheyou-50 plants (P1G1) significantly increased Toc yield compared with the control (P2G1). However, the application of GA_3 to Jiu-Er-13Xi plants (P1G2 combination) did not significantly increase the total Toc yield as compared with the control (P2G2 combination) (Table 3, section P × G interaction). These results indicate the presence of genotypic differences in the response to exogenous GA_3. Zheyou-50 is a canola-type winter cultivar with a low content of erucic acid (<1%) but a high proportion of C_{18} fatty acids in seeds. By contrast, Jiu-Er-13Xi is a traditional Chinese "double high" cultivar with a high content of erucic acid (>40%) in seeds. Erucic acid (C22:1) is a very long chain fatty acid (VLCFA). In our previous study, we concluded that the amount of Toc, in particular α-Toc, significantly and negatively

DOI: 10.1021/jf505312c
J. Agric. Food Chem. 2015, 63, 360−369

correlates with VLCFA in seeds.[2] Given such a correlation, we speculate that the increase in the Toc content of Jiu-Er-13Xi seeds as promoted by GA signaling enhancement is considerably limited.

The mechanism by which GA increases seed Toc yield can be partially explained by analyzing the transcriptional levels of the genes that are important to the Toc biosynthetic pathway (Figure 1). At the first day after the ninth application, the expression levels of *BnPDS1* and *BnVTE1* were 3-fold and 4-fold upregulated, respectively, by exogenous GA_3, which may account for the increased total Toc yield. *PDS1* is responsible for the synthesis of HGA, an upstream precursor of Toc, from HPP, whereas *VTE1* participates in the synthesis of γ-Toc from DMPBQ.[43−48] However, the upregulation of these two genes was observed only in Zheyou-50, which coincided with the finding that the Zheyou-50 plants treated with GA_3 exhibited increased total Toc (Table 3, section P × G interaction). Moreover, the genes were only upregulated at day one after the ninth application of GA_3 (Figure 2). The upregulation of genes in response to PGRs was not detected by RT-qPCR at other time points (29, 32, and 39 DAP). This might be due to (i) the long interval between PGR applications in terms of DAP and (ii) the delayed harvesting of seed samples for RNA extraction after PGR applications. To demonstrate the effect of endogenous GA_3 enhancement, we used the *Arabidopsis q-della/WT* mutant, in which most DELLA genes have lost their function and GA signaling is genetically enhanced. Under the given conditions, *AtPDS1* and *AtVTE4* were upregulated at all time points, whereas *AtVTE1* was upregulated at all time points except at 16 DAP. The upregulation of these genes increased the total Toc and γ-Toc contents but not the α-Toc content in the *Arabidopsis* mutants and WT + GA_3 plants (Figure 3a and b). This result was partially contradictory to that of rapeseed, where the upregulation of *BnPDS1* and *BnVTE1* was also associated with a greater amount of total Toc but was mainly due to the increase in α-Toc content (Table 3, section P sole effect and P × G interaction). Normally, in *Arabidopsis* seed, Toc composition predominately consists of γ-Toc (≥95%), δ-Toc (≤5%), and very small amounts of α-Toc (≤1%).[49−51] On the other hand, the most abundant types of seed Toc's on average in rapeseed are γ-Toc (46%) and α-Toc (35%), with a small proportion of δ-Toc (1%).[52,53,2,4,34] The difference between the α-Toc contents in both the species could be explained in terms of lower γ-tocopherol methyltransferase (γ-TMT) activity in *Arabidopsis*. Previously, Shintani and DellaPenna made an attempt to overexpress the γ-TMT in *Arabidopsis* seeds that led to the conversion of more than 95% of the γ-Toc to α-Toc, showing that the activity of γ-TMT could be the possible rate-limiting factor in the conversion of γ-Toc to α-Toc in *Arabidopsis*.[49]

In conclusion, exogenous GA_3 elevated total Toc yield, particularly the α-Toc content, in seeds of oilseed rape. However, the increased total Toc was dependent on the duration of GA_3 treatment, genotype, and planting location. Rapeseed plants responded to longer durations of GA_3 treatment with higher Toc yield. The genotype with a low VLCFA proportion responded to GA_3 with significantly higher Toc yield and α-/γ-Toc ratio, whereas the genotype with a high VLCFA proportion did not show a significant response to GA_3 in terms of the overall Toc yield or Toc composition. However, the molecular mechanisms by which GA signaling increases α-Toc content in rapeseed but increases γ-Toc content in *Arabidopsis* have yet to be elucidated.

ABSTRACT: The endogenous occurrence of natural hormones obstructs the application of classical targeted methods as confirmatory options. In the case of estradiol, the ultimate confirmation of its exogenous administration relies on gas chromatography coupled to combustion/isotope ratio mass spectrometry (GC-C/IRMS). A serum dipeptide composed of pyroglutamic acid and phenylalanine was identified as a potential biomarker of estradiol treatments in adult cows. To evaluate its potential to pinpoint suspicious samples, samples from prepubertal females under different estrogenic treatments have been analyzed. The results confirmed the up-regulation of the dipeptide in adult bovines. The 2-week-old females exhibited short-lasting responses only in a few animals. The 6-month-old female showed a delayed but clear increase on the biomarker level. The composition of the anabolic preparations, the dose, and/or the administration route are possible additional reasons for the reduced response in young animals. A comparison to previous results reported by various researchers is included.

KEYWORDS: *biomarker, estradiol, serum, cattle, age*

INTRODUCTION

Natural hormones and compounds with hormonal activities are widely applied in veterinary medicine. Anabolic steroids have been effective in increasing feed conversion and promoting growth in farm animals.[1] On the other hand, some steroids and hormones influencing sexual functions have been administered to females to induce and/or synchronize estrus. The low cost and high effectiveness of protocols based on a combination of estradiol with progestagens have led to the widespread application of hormones in reproductive control programs for timed artificial insemination in cattle.[2,3] Despite all these prima facie benefits, the administration of hormones and substances having a hormonal action in livestock farming has been forbidden in the European Union (EU) since the 1980s,[4−7] aiming at protecting consumers. This ban has resulted in controversial disputes among different countries.[8] With respect to the use of estradiol-17β with the aim of promoting animal growth, the Scientific Committee on Veterinary Measures relating to Public Health evaluated recent evidence suggesting that it had to be considered as a complete carcinogen (http://ec.europa.eu/food/fs/sc/scv/out50_en.pdf), and its opinion was accordingly reflected in a European Directive.[9] As other options for estrus synchronization exist and are already implemented in the European market,[10] estradiol and its ester-like derivatives were also forbidden as reproductive tools in the EU with the Directive 2003/74/EC.[9] The use of estradiol in farm animals has been limited to strict veterinary prescription and always for non-growth-promoting purposes (treatment of fetus maceration or mummification or treatment of pyometra in cattle). However, the large profit obtained with anabolic and hormonal preparations through both kinds of applications may cause, illegal, continued use by some veterinary practitioners and farmers.

The administration of anabolic xenobiotic compounds can be relatively easily detected using targeted methods.[11] However, the administration of synthetic natural hormones such as estradiol or testosterone largely remains an unsolved issue for European authorities. These compounds are endogenous to the animal, and the establishment of acceptable threshold levels to detect an exogenous administration is a quite limited approach.[12,13] The hormone levels for a population cannot be easily defined due to the wide animal diversity and the great influence of many physiological and environmental factors. In addition, natural hormones such as estradiol and/or testosterone are frequently administered as esterified forms to obtain a slow release of the hormones. Even though steroid esters have been detected in hair,[14−16] their detection and quantification are not always possible in every treated animal.[15,17] The confirmation of intact steroid esters in body fluids or tissue would provide unequivocal evidence of an illegal administration of an endogenous compound. However, their detection presents a number of analytical challenges such as a rapid metabolism to nature-identical steroids and their low concentration in the animal body.[15,18,19] As a result of all these facts, a deeper insight and additional research on natural hormones administration in farm animals are relevant and necessary.

Innovative in vivo methods that may be useful in the future control of the abuse or misuse of natural hormones in cattle include targeted and untargeted profiling methods, metabolic pathways analyses, the "omics" technologies, and gas chromatography coupled to combustion/isotope ratio mass

spectrometry (GC-C/IRMS). In the past few years, the pattern recognition of steroid profiles, including phase II metabolites, has emerged as a promising approach for tracing the abuse of natural hormones.[20,21] Researchers have suggested the study of untreated and/or control animals to provide a reference threshold value on hormone levels.[13] However, the levels of these natural compounds are highly variable among animals, and it is hard to confidently define the endogenous levels of a specific population.[22,23] In these cases, the inspection of the overall steroid profile is also required as an additional check, as well as further confirmation with alternative methods. On the other hand, a few "omic" studies have been reported as promising strategies to detect the administration of exogenous estradiol in cattle[24−29] and also for other anabolic compounds in different species.[30−32] These methods based on high-dimensional data sets are very useful tools to find candidate biomarkers for a specific biological situation. Biomarkers in general, and in particular blood biomarkers, have found several applications in the veterinary analytical field.[33] The potential of biomarker profiling to screen for the use of steroids administration, including estradiol, has been already highlighted. Specific combinations of plasma proteins were studied and their profiles proposed as future screening methods of steroids administration in cattle, mainly in calves.[34,35] However, additional validation studies covering both treated and untreated animals are required to confidently apply these approaches in monitoring strategies. Basically, all of the previously mentioned methods can be used to pinpoint suspect samples that should be confirmed with, preferably, GC-C/IRMS. This technique has offered a unique method for the unambiguous differentiation between natural hormones and homologous synthetic compounds in cattle.[36] However, the costly instrumentation and the time-consuming and complex sample preparation reduce the applicability of this method to only a few laboratories. Besides, no criterion devoted to the interpretation of GC-C/IRMS analytical data are available in any official analytical document such as the 2002/657/EC decision. Recently, Janssens et al. applied a threshold value of $|\Delta\ ^{13}C| > 3‰$, used by the World Anti-Doping Agency for doping control purposes, illustrating the capability of the method and the validity of the threshold for food safety as well.[37] The selection of suspicious samples through the application of more accessible methods would limit the number of samples that would require further GC-C/IRMS.

Most likely in the near future the detection of the administration of a natural hormone, more precisely estradiol-17β, in cattle will be based on the measurement and profiling of other compounds, directly or indirectly related with this estrogen. In this regard, the investigation and study of novel biomarkers that could be applied alone or combined with other similar ones is necessary. In a previous metabolomics study performed on serum from estradiol-treated female animals, a dipeptide, composed by pyroglutamic acid and phenylalanine, that is, L-Pyr-L-Phe, was highlighted as a potential biomarker candidate for these hormonal treatments. This compound is up-regulated in cows treated with estradiol-17β or estradiol benzoate. The usefulness of this biomarker was tested and confirmed in several serum samples from adult (2−5 years) female animals, using a targeted HPLC-MS/MS method.[38] The biomarker proved to be useful for a specific population composed of adult female Holstein-Friesian bovine animals, from a certain geographical area (northwestern Spain). However, for the validation of these promising candidates, the evaluation of their performance using more animal trials and applying different estradiol preparations is mandatory. In this research, plasma samples from prepubertal females (2−24 weeks) treated with estradiol-based preparations and under different conditions have been analyzed.

MATERIALS AND METHODS

Chemicals. Estradiol benzoate, testosterone decanoate, and testosterone cypionate were obtained from Sigma-Aldrich (Zwijndrecht, The Netherlands). Ivomec, dimethyl sulfoxide (DMSO), Mygliol 840, diethylene glycol monobutyl ether (DEGMBE), and arachide oil were purchased at Spruyt Hillen (IJsselstein, The Netherlands). Estradiol benzoate, methyl prednisone acetate, dromostanolone (5α-androstane-2α-methyl-17β-ol-3-one), and 1-dehydroandrostanolone (1,(5α)-androstene-17β-ol-3-one) for the treatment of the 6-month-old animal were obtained from Steraloids Inc. Ltd. (London, UK). L-Pyroglutamyl-L-phenylalanine (L-Pyr-L-Phe) was purchased from Bachem Distribution Services GmbH (Weil am Rhein, Germany). LC-MS grade acetonitrile, water, and methanol were obtained from Biosolve (Valkenswaard, The Netherlands). Formic acid was obtained from Merck (Darmstadt, Germany). All other chemicals used were of analytical reagent grade.

Experimental Animals. The serum and plasma samples used in this study were selected from previous animal experiments, collected at different times, but analyzed now during the same time frame.

The serum samples were obtained from 13 Holstein-Friesian cows aged between 24 months and 5 years, from different dairy farms in Galicia (Spain). Animals were fed a diet usually employed in the animal husbandry practice and had ad libitum access to water. Blood samples were collected from (a) three cows treated with an intramuscular injection of a veterinary drug containing 5 mg of estradiol benzoate (EB) and 1.250 IU of chorionic gonadotropin; (b) one animal treated with an intramuscular injection of a veterinary drug consisting of 2 mg of estradiol-17β (E_2) and 8 mg of vitamin E; and (c) three cows treated with an intravaginal device composed of a progesterone-releasing spiral (1.55 g) plus a capsule containing 10 mg of EB. Samples were collected (a and b) 3 days and (c) 6 days after administration. The day of sample collection was based on the veterinary purpose of these drugs (estrus control). Four nontreated cows were used as control animals. In addition, two samples from bovine females treated with an intravaginal progesterone-releasing spiral (not containing estradiol) were analyzed and expected to behave as control samples. Samples from progesterone-treated animals were collected 8 days after administration. Immediately after blood clotting and 10 min of centrifugation at 1300*g*, serum samples were frozen at −20 °C. The veterinary treatments took place under a veterinary reproductive control program before October 2006.

Some of the plasma samples were obtained from a previous animal trial conducted at the Physiology Weihenstephan, Technical University of Münich (Germany).[39] The protocol was approved by the ethical committee of the "Regierung von Oberbayern". Twenty prepubertal female Holstein-Friesian calves were obtained from identified sources at an age of 2 weeks, and the four different groups (control, control carrier-only, treated once, treated three times) were housed in separate pens. The animals were fed according to veal calf practice, using milk replacer and roughage, and had drinking water ad libitum. Five animals were not treated and were used as reference group. Pour-on experiments were carried out using hormone cocktails containing three steroid esters: 25 mg of estradiol benzoate (EB), 60 mg of testosterone decanoate (TD), and 60 mg of testosterone cypionate (TC). Prior to the application, the animals were shaved on the back from neck to tail. There, they were treated with 10 mL of pour-on cocktail, using four different carrier solvents (ivermectin 1% pour-on preparation Ivomec; DMSO; propylenglycol dicaprylate Miglyol 840; and DEGMBE). Four animals were treated only once, at day 1, with 10 mL of hormone cocktail, but each animal was treated with a different carrier solvent. Four animals were treated three times, on days 1, 7, and 14 (repeated treatment), with 10 mL of hormone cocktail and also different carrier. Four animals were treated three times, on days 1, 7, and 14 (repeated treatment), with 10 mL of a different carrier solvent for each animal.

dx.doi.org/10.1021/jf503773u | J. Agric. Food Chem. 2015, 63, 370−378

Additionally, one animal was injected intramuscularly in the neck on day 1 with a cocktail of 35 mg of EB, 60 mg of TD, and 60 mg of TC, and one animal was injected on days 1, 7, and 14 with the hormone cocktail. For the injection, arachide oil was used as the carrier. One animal was injected three times (days 1, 7, and 14) only with arachide oil. Samples of blood were collected at different points after the first treatment (considered as day 1), up to 70 days after. Samples were collected in EDTA blood collection tubes and centrifuged, and the plasma was stored at −20 °C and used for the analysis.

Lastly, plasma samples from a Holstein-Friesian female treated by intramuscular injection with four substances suspended in vegetable oil were also analyzed. The experiment was performed at the facilities of ASG (Animal Sciences Group of Wageningen UR), Lelystad, The Netherlands, starting at 6 months of age. The animal was treated weekly, twice with each steroid, in the following order: 1-dehydroandrostanolone, methyl prednisone acetate, estradiol benzoate, and dromostanolone, 25 mL per injection (12.5 mL in each side of the neck). The total dose of each steroid was 250 mg per 50 mL of solution in vegetable-based oil. Pretreatment control samples were collected 29, 30, 31, and 32 days before the first EB administration (considered as day 1). The injections of 1-dehydroandrostanolone were administered 28 and 21 days before the first EB dose and those of medroxy prednisone acetate 14 and 7 days before. Then, estradiol benzoate was administered at days 1 and 8 (repeated treatment). Afterward, dromostanolone was injected at days 14 and 21. Blood samples were collected daily (except 2 days every 5 days) starting at day 1, up to day 25. Samples were collected in EDTA blood collection tubes and centrifuged, and the plasma was stored at −20 °C and used for the analysis.

Table 1 presents a summary of all samples analyzed during this study. All of the samples were stored at −20 °C until analysis.

Sample Preparation. All serum and plasma samples were prepared using a very simple and straightforward protocol. Briefly, samples were defrosted at room temperature and homogenized. An amount of 100 μL of serum/plasma was filtered on centrifugal devices (cutoff at 10 kDa, 8600*g*, 4 °C, 30 min) to remove high molecular weight proteins. After transferring the filtrates to injection vials, 5 μL of each sample was injected into the chromatographic system.
