Figure 1. 3T3-L1 cell differentiation detected by Oil Red O staining. Panels A and B show pre-Oil Red O staining, and panels C and D show post-Oil Red O staining. Panels A and C represent undifferentiated cells, and panels B and D represent differentiated cells (magnification, 100×; bar, 200 μm).

Anti-TLR4 and anti-GLUT4 were from Abcam Biochemicals (Hong Kong). Anti-PI-3K and p-NF-κB were obtained from Cell Signaling Technology (Shanghai, China). Anti-TNF-α and anti-β-actin were obtained from Santa Cruz Technology (Carlsbad, CA). Fluorescein (FITC)-AffiniPure donkey anti-rabbit immunoglobulin G (IgG) was from Jackson ImmunoResearch (West Grove, PA). The monoclonal antibody against mouse TLR4/MD-2 (Affymetrix) was obtained from Affymetrix eBioscience (Carlsbad, CA). Mouse IL-6 enzyme-linked immunosorbent assay (ELISA) kits were obtained from Dakewe (Dakewe Biotech Co., Ltd., Beijing, China). Insulin (from bovine pancreas), 3-isobutyl-1-methylxanthine (BioUltra, ≥99%), dexamethasone (purity of ≥97%), lipopolysaccharides from *Escherichia coli* 055:B5, EGCG (purity of ≥95%, from green tea), and routine chemicals were all purchased from Sigma Chemical (Sigma-Aldrich, St. Louis, MO).

Cell Culture and Differentiation. 3T3-L1 fibroblasts were obtained from the American Type Culture Collection (Manassas, VA) and cultured at a 37 °C, 5% CO_2, and 95% humidity. Preadipocytes were induced to differentiate as follows.[22] Cells were maintained in DMEM plus 10% heat-inactivated FCS and 0.5% penicillin−streptomycin (Invitrogen). After 2 days in culture when the cells reached confluence (day 0), they were induced to differentiate by adding medium containing 10% FBS, 1 μM dexamethasone, 0.5 mM 3-isobutyl-1-methylxanthine, and 5 μg/mL insulin for 48 h. Fresh media containing only 5 μg/mL insulin and 10% FBS was added for an additional 48 h. Media was subsequently changed every 48 h. More than 90% of cells expressed the adipocyte phenotype between days 8 and 10 post-differentiation, and they were used for experiments.

Oil Red O Staining of 3T3-L1 Adipocytes. Conversion of 3T3-Ll fibroblasts to adipocytes was monitored by measurement of intracellular lipid accumulation using Oil Red O staining. A 0.5% (w/v) solution of Oil Red O was prepared in 60% isopropanol. After day 8, differentiated 3T3-L1 preadipocytes were washed twice with phosphate-buffered saline (PBS), fixed in 4% paraformaldehyde, then incubated with Oil Red O working solution for 2 h at room temperature, and rinsed to remove unbound dye. Staining was visualized with an Olympus DP70 camera (Olympus, Japan). As shown in Figure 1, differentiated 3T3-L1 cells were positive for fat droplets and lipid storage by Oil Red O. We used the cells for further experiments when more than 90% expressed the adipocyte phenotype between 8 and 10 days post-differentiation.

LPS and EGCG Treatment of Differentiated 3T3-L1 Adipocytes. Fully differentiated adipocytes incubated in serum-free medium and stimulated by adding different concentrations of LPS from *E. coli* for 48 h to elicit an immune response in the absence or presence of 3 h of pretreatment with EGCG. Cells were divided into eight groups, including one control group (blank), while the remaining seven groups were treated with 0.1−1 μg/mL LPS or 1 μg/mL LPS + 10−100 μM EGCG. After treatment, supernatants were collected for ELISA and the adipocytes were collected for detection of inflammation-related proteins (p-NF-κB, IKKβ, and TNF-α) and key insulin signaling protein (PI-3K and GLUT4) levels.

Anti-67LR Treatment. To evaluate the effect of EGCG on TLR4 signaling, we performed blocking experiments in adipocytes. Fully differentiated adipocytes were pretreated with 67LR antibody[35] (10 μg/mL, MLuC5) for 30 min, followed by EGCG (100 μM) for 3 h, and subsequent incubation with LPS (1 μg/mL) for 48 h. IL-6 levels in supernatants of treated and control cells were detected by ELISA, and inflammatory mediators and cytokines, such as TLR4, p-NF-κB p65, and TNF-α, and the key insulin signaling protein GLUT4 were examined by western blotting.

Anti-TLR4 Treatment. Cells were treated with a TLR4-specific antibody (anti-mouse TLR4/MD-2 complex functional-grade purified antibodies, MTS510)[43] to inhibit their response to LPS. Fully differentiated adipocytes were pretreated with MTS510 (5 μg/mL) or PBS for 30 min at 37 °C and subsequently treated with LPS (1 μg/mL) for 48 h. IL-6 levels in supernatants and intracellular p-NF-κB p65, TNF-α, and GLUT4 protein levels were determined by western blotting.

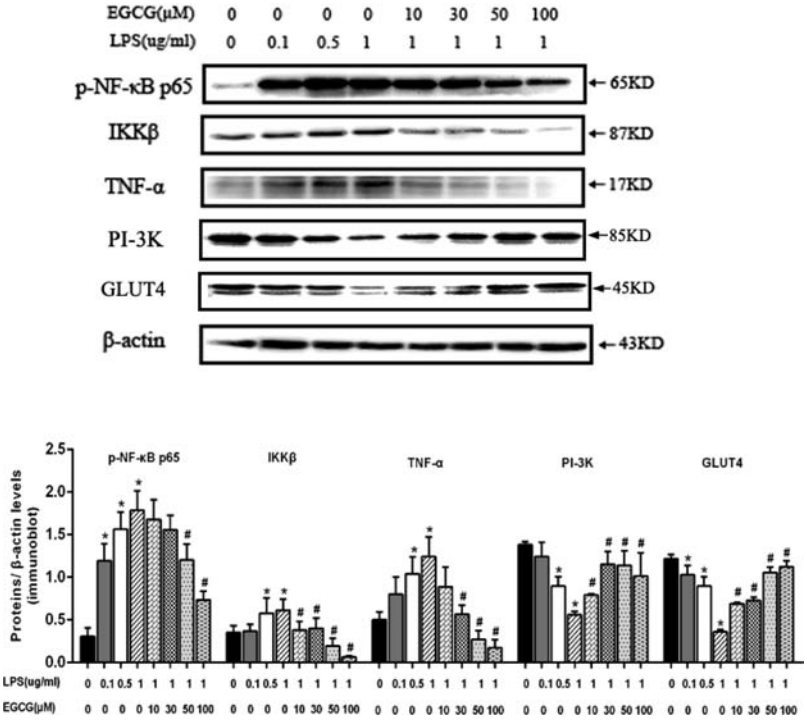

Figure 2. EGCG decreases inflammation-related protein levels and increases the expression of key insulin signaling proteins in adipocytes. Various doses of LPS (0.1, 0.5, and 1 μg/mL) stimulated inflammatory cytokine expression in mature 3T3-L1 adipocytes. Mature 3T3-L1 adipocytes pretreated with EGCG (10, 30, 50, and 100 μM) decreased LPS-stimulated inflammatory-related factor expression (IKKβ, p-NF-κB, and TNF-α) to different degrees. EGCG (10, 30, 50, and 100 μM) increased key insulin signaling protein expression (PI-3K and GLUT4). Results are expressed as the mean ± SD (n = 6). (*) $p < 0.05$ versus the 0 ng/mL LPS + 0 μM EGCG group. (#) $p < 0.05$ versus the 1 μg/mL LPS group.

Cellular ^{3}H-2-Deoxy-D-glucose Uptake Measurements. 3T3-L1 cells were seeded in 24-well plates (1×10^5 cells/well) and induced to differentiate, as described above. On day 9, adipocytes were incubated for 2 h at 37 °C in serum-free medium, and cells were washed twice with 37 °C Krebs Ringer phosphate (KRP) buffer (pH 7.4) and placed in KRP buffer containing insulin (100 nM) for 30 min, followed by the addition of ^{3}H-2-deoxy-D-glucose (2 μCi/mL, Beijing Yuan Zi Gao Ke Corporation, China) for an additional 10 min at 37 °C. Cells were then immediately washed 3 times in ice-cold PBS to terminate the reaction. Lastly, cells were solubilized in 0.5 M NaOH (0.4 mL/well) for 2 h and subjected to scintillation counting for ^{3}H radioactivity as disintegrations per minute. The radioactivity of each sample was normalized to the protein concentration. Counts per minute and per milligram of protein were measured to analyze experimental glucose uptake.

IL-6 Measurements. IL-6 levels in culture supernatants were measured in duplicate by the ELISA (Dakewe Biotech) kit according to the instructions of the manufacturer. The minimum detectable level of each kit was 15.6 pg/mL; the sensitivity was 8 pg/mL; and the coefficient of variation between the plates was <10%.

GLUT4 Immunofluorescence. 3T3-L1 cells were grown and induced to differentiate on glass coverslips, incubated for 2 h in serum-free culture medium, and then stimulated with insulin (100 nM) before EGCG or LPS treatment. Cells were rinsed with PBS, fixed in 4% paraformaldehyde and 0.05% glutaraldehyde for 30 min at room temperature, then blocked in bovine serum albumin, permeabilized with 0.3% Triton X-100 for 1 h, and then incubated with GLUT4 antibody (5 μg/mL) overnight. Primary antibodies were detected with fluorescent secondary antibodies (FITC-AffiniPure donkey anti-rabbit IgG, 1:200) and imaged with a Leica TCS SP5 X camera (Germany).

Immunoblotting Analyses. Mature 3T3-L1 adipocytes were washed 3 times in PBS and lysed (KGP 250 kit, Keygen Biotech, Nanjing, China) on ice. All steps were carried out according to the instructions of the manufacturers. Bound antibodies were detected with horseradish-peroxidase-conjugated anti-IgG with an enhanced chemiluminescence kit (Pierce) protocol and visualized with the Chem Doc XRS with Quantity One software (Bio-Rad). Blots were repeated at least 6 times. The band intensities were quantified using ImageJ analysis software (National Institutes of Health, Bethesda, MD).

Statistical Analyses. All values were expressed as the mean ± standard deviation (SD). Differences between groups were tested for statistical significance using one-way analysis of variance (ANOVA), and when the F value indicated significance, least significant difference (LSD) was used to correct for multiple comparisons. All analyses were performed using SPSS statistics software, version 17.0 (SPSS, Inc., Chicago, IL) on a computer with a Windows operating system. A p value less than 0.05 was considered statistically significant.

RESULTS

EGCG Decreases Inflammation-Related Protein Levels and Increases Insulin Signaling Protein Expression in Adipocytes. We treated mature 3T3-L1 adipocytes with various doses of LPS (0.1, 0.5, and 1 μg/mL) for 48 h to induce inflammation. In comparison to the control group, LPS treatment increased inflammation-related protein levels to different degrees. IKKβ (approximately 1.1-, 1.6-, and 1.7-fold, respectively), p-NF-κB (approximately 3.9-, 5.0-, and 5.8-fold, respectively), and TNF-α (approximately 1.5-, 2.0-, and 2.5-fold, respectively) protein levels significantly increased ($p < 0.05$ versus baseline), while the expression of insulin signaling proteins, such as PI-3K (approximately 89.9, 64.9, and 40.5%, respectively) and GLUT4 (approximately 84.7, 73.7, and 29.6%, respectively), decreased ($p < 0.05$; Figure 2).

Various doses of EGCG (10, 30, 50, and 100 μM) decreased LPS-induced IKKβ, p-NF-κB, and TNF-α expression. EGCG reduced IKKβ (approximately 64.5, 66.8, 31.9, and 10.4%, respectively), p-NF-κB (approximately 89.5, 85.8, 67.5, and 41.2%, respectively), and TNF-α (approximately 71.6, 45.7,

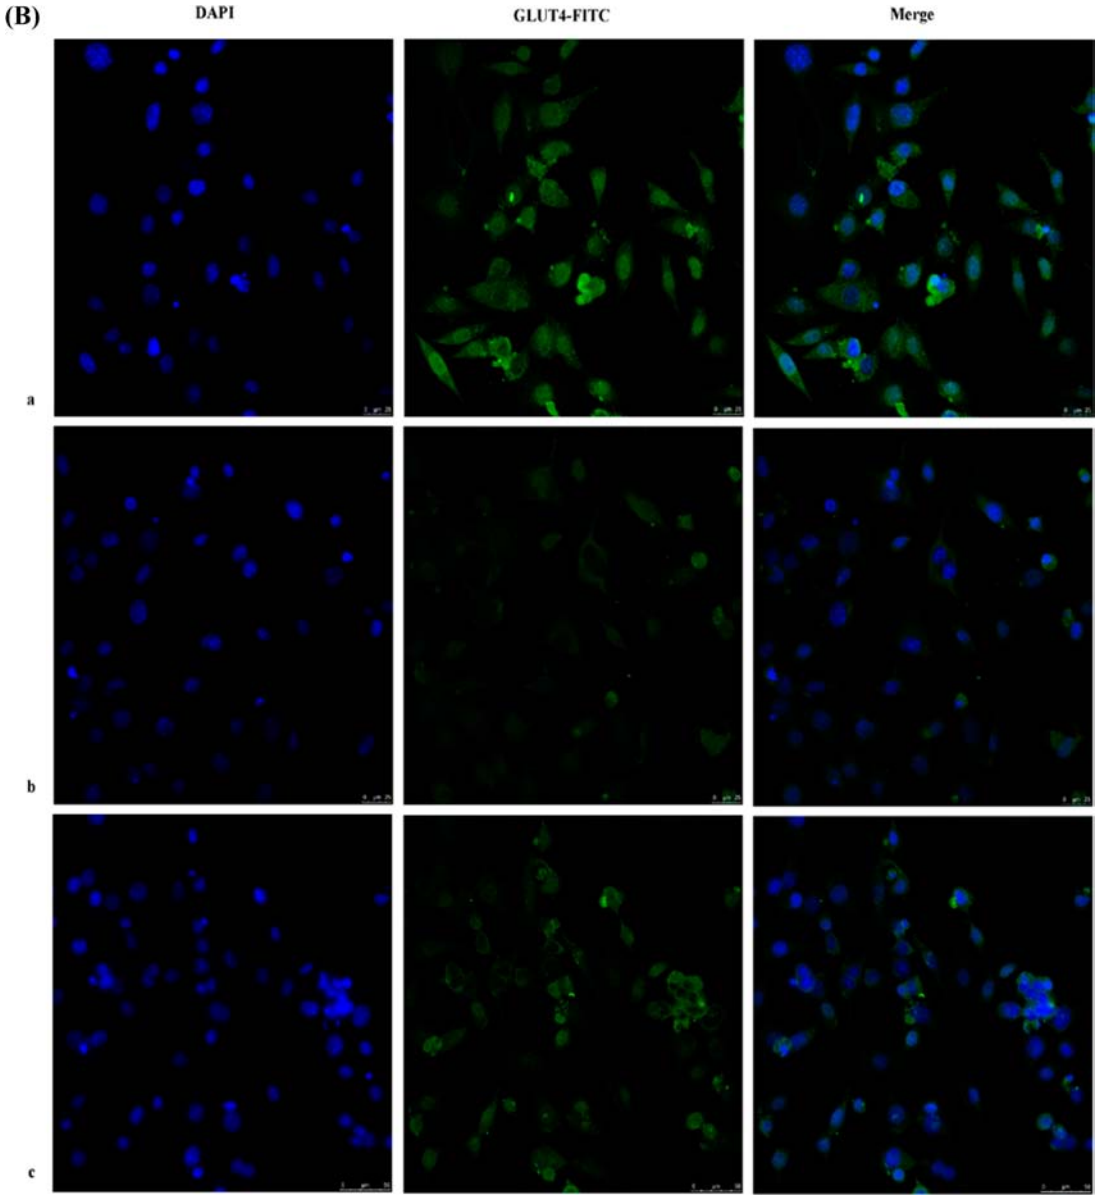

Figure 3. EGCG reversed intracellular GLUT4 expression in LPS-stimulated adipocytes: GLUT4 (FITC, green) and nuclear (DAPI, blue) immunofluorescence, for (A-a) control group, (A-b) 0.1 μg/mL LPS group, (A-c) 0.5 μg/mL LPS group, and (A-d) 1 μg/mL LPS group and (B-a) control group, (B-b) 1 μg/mL LPS group, and (B-c) 100 μM EGCG + 1 μg/mL LPS group (magnification = 400×).

21.9, and 14.0%, respectively) expression and increased PI-3K (approximately by 1.4-, 2.0-, 2.0-, and 1.8-fold, respectively) and GLUT4 (approximately by 1.9-, 2.1-, 2.9-, and 3.1-fold, respectively) levels compared to treatment with 1 μg/mL LPS alone (Figure 2; $p < 0.05$ for each). These data suggest that EGCG decreases LPS-stimulated inflammatory cytokine and insulin signaling protein expression in adipocytes.

EGCG Reverses Intracellular GLUT4 Expression in LPS-Stimulated Adipocytes. We used immunofluorescence labeling to investigate cellular GLUT4 expression. GLUT4 fluorescence intensity demonstrated that LPS treatment decreased GLUT4 levels. As shown in Figures 2 and 3A, various doses of LPS (0.1, 0.5, and 1 μg/mL) dramatically decreased the GLUT4 signal. In contrast, EGCG treatment (100 μM) increased GLUT4 expression compared to LPS (1 μg/mL) treatment alone (Figures 2 and 3B).

67LR Antibody Blocks the Effect of EGCG on LPS-Induced TLR4 Signaling. Upon treatment with the 67LR antibody (10 μg/mL), TLR4 protein levels increased by more than 1.2-fold compared to the EGCG group (Figure 4B; $p < 0.05$). As expected, NF-κB p65 phosphorylation significantly increased (1.4-fold; Figure 4C; $p < 0.05$), as did the downstream protein TNF-α (1.6-fold; Figure 4D; $p < 0.05$). The level of IL-6 increased in the supernatant upon 67LR antibody treatment compared to the EGCG group (1.8-fold; Figure 6A; $p < 0.05$), and there was no difference between the ±EGCG treatment groups in the presence of the 67LR antibody ($p > 0.05$). Furthermore, GLUT4 levels were reduced by approximately 72.4% in the 67LR antibody group compared to the EGCG group (Figure 4E; $p < 0.05$). These data suggest that 67LR antibody blocks the effect of EGCG on LPS-induced TLR4 signaling, resulting in a subsequent series of changes, such as increased inflammatory cytokine expression and decreased GLUT4 levels. However, we did not detect any obvious differences in 67LR expression among the control (blank), EGCG (100 μM EGCG plus 1 μg/mL LPS), and LPS

J. Agric. Food Chem. 2015, 63, 2811–2819

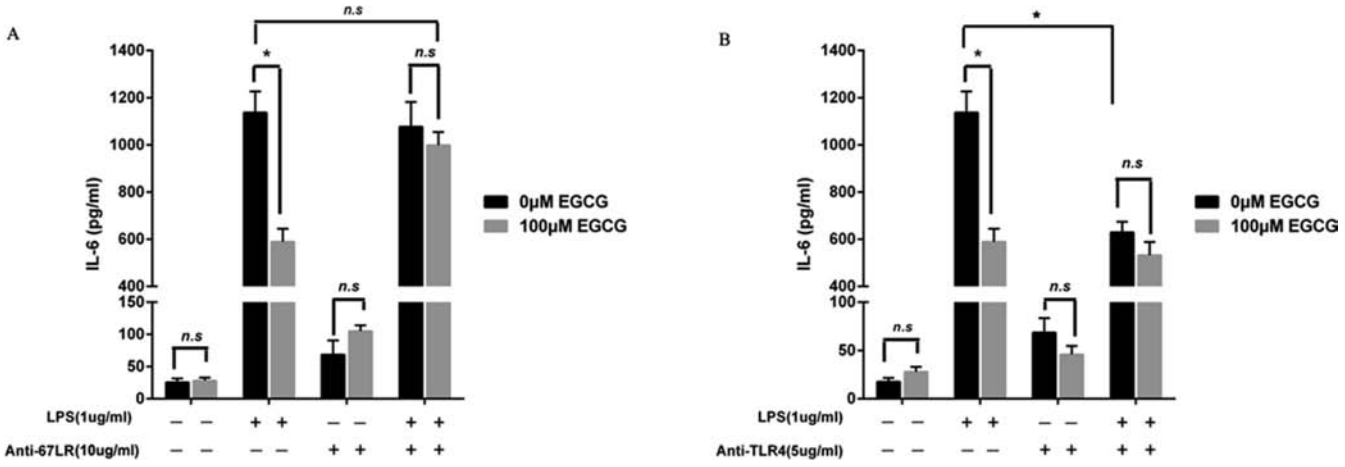

Figure 6. EGCG and the anti-TLR4 antibody inhibit IL-6 production, and an inhibitor of 67LR blocks EGCG effects. IL-6 levels in culture supernatants measured by ELISA. (A and B) IL-6 levels in cell culture supernatants were measured in duplicate. (*) $p < 0.05$. ns = not significant between the two groups. Panel A showed that EGCG inhibits IL-6 production in the context of LPS and does not work effectively with an inhibitor of 67LR. Panel B showed that IL-6 production was blocked with the anti-TLR4 antibody and has similar effect to EGCG.

groups (1 μg/mL LPS) (Figure 4F; $p > 0.05$). We hypothesize that EGCG performs its anti-inflammatory role by regulating 67LR activity or translocation.

TLR4 Mediates LPS-Induced Inflammatory Activation and Insulin Resistance. As shown in Figure 5, the specific TLR4/MD2 inhibitor MTS510 (5 μg/mL) treatment significantly reduced p-NF-κB (67.9% decrease; $p < 0.05$; Figure 5B), TNF-α (21.5% decrease; $p < 0.05$; Figure 5C), and IL-6 (45.5% decrease; $p < 0.05$; Figure 6B) levels after LPS stimulation, although IL-6 levels were still higher than the blank group, perhaps because of the effects of LPS. Meanwhile, MTS510 treatment increased GLUT4 expression by 1.3-fold ($p < 0.05$; Figure 5D) compared to LPS-induced control cells. The above data suggest that TLR4/MD2 inhibition decreased NF-κB activation and upregulated GLUT4 expression and EGCG had similar effects to the anti-TLR4 antibody.

EGCG Upregulates Cellular ^{3}H-2-Deoxy-D-glucose Uptake by Decreasing TLR4 Expression. To determine the effects of TLR4 on glucose transport in inflammation, cellular ^{3}H-2-deoxy-D-glucose uptake contents were measured (Figure 7). We found that insulin-stimulated glucose influxes were significantly greater than untreated control cells ($p < 0.05$). Pretreatment with EGCG (100 μM) for 3 h before 48 h of LPS exposure (1 μg/mL) significantly increased glucose uptake compared to LPS stimulation alone (~1.2-fold; $p < 0.05$), while anti-67LR Ab reversed the trend (about 84.4% of the EGCG group; $p < 0.05$). Anti-TLR4 Ab increased glucose uptake even in the absence of EGCG (about 1.2-fold higher than the LPS group; $p < 0.05$). Our data suggest that TLR4 attenuates insulin-stimulated glucose uptake and EGCG blocks these changes by decreasing TLR4 signaling.

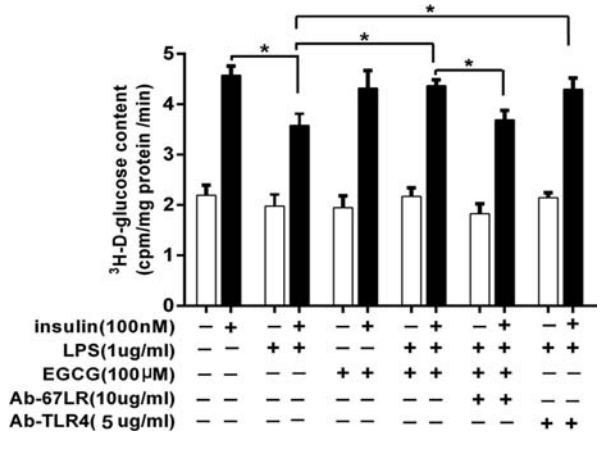

Figure 7. Cellular ^{3}H-2-deoxy-D-glucose uptake. (*) $p < 0.05$.

DISCUSSION

Here, we showed that EGCG suppresses the TLR4 signaling pathway in adipocytes via 67LR. Upon 67LR inhibition, The suppressive effect of EGCG on TLR4 activity was blocked; inflammatory cytokine levels, such as TNF-α and IL-6, increased; and GLUT4 expression decreased. These effects led to attenuated insulin signal transduction and decreased glucose uptake. In contrast, TLR4 inhibition inactivated the inflammation pathway, phenocopying the effect of EGCG and increasing expression of the key insulin signaling protein GLUT4 in LPS-stimulated adipocytes, thus promoting insulin-stimulated glucose uptake. These results suggest that EGCG improves insulin signaling by suppressing TLR4 activity in adipocytes.

Type 2 diabetes and obesity are characterized by low-grade inflammation with increased inflammatory cytokine levels and changes in the gut microbiota.[23] As an important pathogen recognition receptor, high TLR4 levels impair insulin action and negatively regulate insulin signaling.[36,37] Increased TLR4 levels underlie non-infectious chronic inflammation and dysfunction of adipose tissue in obesity.[5,24,25] In our previous study, we found that a high-fat diet increases the TLR4-mediated inflammatory response in the adipose tissue of obese rats.[8] TLR4-deficient mice are partially protected from inflammation and insulin resistance,[26] and inhibition of TLR4 signaling protects against type 2 diabetes in mice.[27,38,39] Studies have shown that the TLR4 ligand LPS activates NF-κB and increases inflammatory biomediator release in 3T3-L1 adipocytes, a process which may be blocked by a TLR4 inhibitor.[12] Importantly, these biomediators also work on insulin target cells and insulin-producing cells, such as adipocytes, pancreatic islet cells, and the hypothalamus, further impairing insulin sensitivity and secretion.[25,28−30] Consistently, our work suggests that LPS activates the TLR4 signaling

DOI: 10.1021/jf505531w
J. Agric. Food Chem. 2015, 63, 2811−2819

pathway, a specific TLR4/MD2 inhibitor partially weakens inflammatory cytokines, such as TNF-α and IL-6, and upregulates insulin signaling protein GLUT4 expression, and TLR4 inhibition has similar effects to EGCG treatment in 3T3-L1 adipocytes.

EGCG is the most abundant polyphenol in tea and has many biological properties.[13−15,17−19] Its metabolites can exist in methylated, glucuronide, and sulfate forms, and the phenolic hydroxyls in their structure determine their antibacterial, anticardiovascular disease, and antitumor activities.[31] Studies have shown that EGCG exclusively binds to 67LR and influences downstream insulin signaling,[17,32,33] and treatment with 67LR antiserum blocks extracellular signal regulated kinase 1/2 (ERK1/2) phosphorylation while increasing insulin receptor-β and insulin receptor substrates 1 and 2 (IRS1 and IRS2) phosphorylation in preadipocytes.[17,32] Our work demonstrated that pretreatment of adipocytes with a 67LR blocking antibody blocked the suppression of the TLR4 signaling pathway of EGCG, activated the NF-κB signal pathway, induced inflammatory cytokine transcription, and decreased GLUT4 expression, leading to a further decrease in cellular ^{3}H-2-deoxy-D-glucose uptake, which is associated with insulin signaling transduction.

Our work demonstrated that 67LR expression did not change upon EGCG treatment. It has yet to be determined whether 67LR membrane localization changes upon EGCG treatment. However, previous research[33] stated that EGCG increases 67LR efficiency by inducing its translocation from the cytoplasm to the membrane. EGCG downregulation of inflammatory signals may be induced by Tollip, which is associated with decreased TLR signaling-mediated NF-κB activation.[34,35] Therefore, it is crucial to further delineate the mechanisms involved to support our findings.

Additionally, TLRs and nucleotide-binding and oligomerization domain (NOD)-like receptors (NLRs) are very remarkable pathogen recognition receptors in obesity and type 2 diabetes characterized by low-grade inflammation.[23,40,41] Both TLRs and NLRs mediate NF-κB activation, leading to inflammatory cytokine production and insulin resistance.[40−42] Therefore, we speculate that EGCG may simultaneously decrease inflammation through the NLR signaling pathway. Therefore, further studies are necessary to target TLR- or NLR-regulated pathways in obesity-related metabolic complications.

Taken together, these data suggest that EGCG affects the TLR4 signaling pathway, reduces chronic low-grade inflammation, and further influences insulin signaling protein expression, while the entire process is blunted by 67LR inhibition, which further strengthens the link between the TLR4-induced inflammatory response and insulin resistance in adipocytes. Our work also provides insight into better prevention of insulin resistance by revealing the possible molecular mechanism and developing targeted therapies to protect against it.

integrity of tea catechins, such as encapsulation with liposome[30] or formulation with sucrose or ascorbic acid,[31] is necessary for their bioactivities.

Literature studies have shown that OSA-starch, as an emulsifier, has been used as a carrier material for the controlled release of bioactive compounds with formed micelles in an aqueous environment.[16,17] Therefore, OSA-starch might be prepared as a carrier to protect the structural integrity of tea catechins to improve their bioactivity, and the presence of tea catechins may further improve the slow digestion property of OSA-starch on the basis of a literature report.[23] Thus, the in vivo slow digestion property of OSA-starch in the presence of TPLs, as a novel approach to produce functional carbohydrate materials capable of sustaining glucose release and reducing oxidative stress, was studied in the current investigation to improve the knowledge of functional carbohydrates for improved health.

MATERIALS AND METHODS

Materials. TPLs were obtained from Hetian Biotechnology (Zhejiang, China) with a total tea catechin content of ∼99%, and its composition (EGCG, 66.90%; EGC, 5.88%; ECG, 10.62%; EC, 15.70%) was analyzed using a common HPLC method.[32] Waxy maize starch was obtained from National Starch and Chemical Co. (Bridgewater, NJ, USA). The preparation of OSA-starch and measurement of degree of substitution (DS) were based on a literature report,[13] and the final DS was estimated to be 0.0194. Octenyl succinic anhydride, glucuronidase (G-7896, EC 3.2.1.31, from *Escherichia coli* with 9×10^6U/g solid), and sulfatase (S-9754, EC 3.1.6.1, from abalone entrails with 2.3×10^5U/g solid) were purchased from Sigma Chemical (St. Louis, MO, USA). Diphenyl-(2,4,6-trinitrophenyl)iminoazanium (DPPH) was purchased from Wolsen Bio. Co. (Shanxi, China).

Animals and Treatment. Four-week-old male Kunming mice were purchased from Slac Co. (Shanghai, China) and kept on a 12 h light/dark schedule (lights on from 8:30 a.m. to 8:30 p.m.) in a constant condition (22 ± 1 °C and 60% humidity) with standard chow (Slac Co.) and drinking water provided ad libitum. Experiments were performed 1 week later after overnight fasting. Starch samples (10% w/v in distilled water) with and without TPLs (5%, w/w starch based) were cooked in a boiling water bath for 20 min to gelatinize the starches. After the samples were cooled to room temperature, mice were divided into three groups (20 mice per group) and gavaged with OSA-starch (1000 mg/kg bw, ig) alone or in combination with TPLs (OSAT), and TPLs alone were used as the control (50 mg/kg bw, ig). No chow was provided to mice during the experiment.

Mice were sacrificed at time 0 (as the control without feeding) and 30, 60, and 120 min after gavaging. Blood samples were collected into heparin-containing tubes by eyeball extirpating before cervical dislocation and then centrifuged at 3000*g* for 10 min at 4 °C for plasma insulin analysis. In the meantime, the small intestine tissue (ST) was removed immediately, and luminal contents (LC) was expelled into microcentrifuge tubes with cold saline. ST and LC were snap-frozen and kept at −80 °C for later analysis. All animal experiments were approved by the Institutional Animal Care and Use Committee at Jiangnan University under protocol 20131024-0107.

The samples of ST and LC for the measurement of enzyme activity, TPLs' content, malondialdehyde content, and DPPH scavenging activity were prepared through homogenization of ST and LC by adding ice-cold saline (1:9 (w/v)), which was carried out in a ice bath for a total time period of 30 s (5 s per operation) using a homogenizer (Ultra-Turrax T25, IKA Works Inc., China) at 24000 rpm. The homogenates were centrifuged at 3000*g* for 10 min at 4 °C, and the supernatant was used as the sample for analysis.

Postprandial Glycemic Response Measurement. The postprandial glycemic response was measured by feeding different test diets (TPLs, 50 mg/kg bw; OSA-starch, 1000 mg/kg bw; OSA-starch + 5% TPLs, 1000 mg/kg bw) via gavage. Blood samples were taken from the lateral tail vein at 0 (as the control before gavage), 15, 30, 45, 60, 90, and 120 min after gavage. The blood glucose concentration was measured using a glucose analyzer (Johnson & Johnson, China) and expressed as the mean ± standard error (SE).

α-Amylase and α-Glucosidase Activity Assays. The activity of small intestine α-amylase was examined using the chromogenic GalG2CNP kit according to the specified instruction (Leadman, Bejing, China). Briefly, the supernatants (40 μL) from the homogenates of ST and LC were combined with 200 μL of GalG2CNP (3 mmol/L) suspended in (2-(*N*-morpholino)-ethanesulfonic acid (MES) buffer (100 mmol/L MES in distilled water, pH 6.0), and after incubation at 37 °C for 60 s, the changing rate of OD_{405} monitored within 2 min at 37 °C was used to calculate the activity of α-amylase. For α-glucosidase, 20 mg/mL maltose (1.0 mL) was hydrolyzed by supernatants (0.1 mL) from homogenates of ST and LC in a sodium phosphate buffer (100 mmol/L, $CaCl_2$ 1.0 mmol/L, pH 6.9) at 37 °C for 10 min, and the concentration of glucose was measured using a hexokinase kit (Leadman). The enzyme activities were expressed as percentages compared to the initial values measured before gavaging.

An in vitro experiment was also carried out to test the effect of TPLs on the activity of mucosal α-glucosidase of the small intestine. First, the dose−response effect of TPLs (0−10 μg/mL) on the enzyme activity in the supernatant (0.1 mL) of ST homogenate from fasted mice was studied at 37 °C for 10 min in a sodium phosphate buffer (100 mmol/L, $CaCl_2$ 1.0 mmol/L, pH 6.9) containing 20 mg/mL maltose with a final reaction volume of 2.1 mL. Second, the Michaelis−Menten kinetic model was used to evaluate the kinetic parameters in hydrolysis by measuring the amount of liberated glucose under different substrate (maltose) concentrations (0.02−0.50 mg/mL) in the presence of TPLs (10 μg/mL). A Lineweaver−Burk plot between 1/[substrate] (mg/mL) and 1/[V] (reaction rate, mmol/L/min) was used to determine the action type of TPLs on α-glucosidase.

TPL Concentration Measurement. The content of TPLs in LC and ST was analyzed by HPLC.[33] Briefly, the supernatant from LC or ST homogenate was mixed with 2.5 volumes of sodium phosphate buffer (0.4 mol/L, pH 6.8), hydrolyzed by glucuronidase (250 U/sample) and sulfatase (1 U/sample) at 37 °C for 45 min.[23,34,35] After hydrolysis, the sample was extracted twice with ethyl acetate. The organic phase was dried under vacuum, resuspended in 50% methyl alcohol, and analyzed using an Agilent HPLC 1200 instrument coupled with a GraceSmart reverse-phase C18 column (4.6 × 250 mm, particle size = 5 μm) (Deerfield, IL, USA) and a UV detector (280 nm) at a flow rate of 0.8 mL/min at 30 °C. Solvent A composed of acetonitrile, distilled water, and trifluoroacetic acid (TFA) in a ratio of 10:90:0.05 and solvent B in a ratio of 30:70:0.05 were used as the mobile phase. Beginning with 100% solvent A, a linear gradient mobile phase (decreasing polarity) with solvent B was used until 20 min approaching 100% solvent B. After running for 5 min, the mobile phase was returned to 100% solvent A until 30 min to finish the analysis. The measured result represented the content of total catechins, and samples prepared without glucuronidase/sulfatase were used to quantify the unconjugated fractions of catechins.

Determination of Malondialdehyde (MDA) and DPPH Scavenging Activities. MDA content in the supernatant of ST homogenate was analyzed using the diagnostic kit (Nanjing Jiancheng Bioengineering Institute, Nanjing, China) according to the instruction of the manufacturer, and the results were expressed as nanomoles per milligram of protein. Total protein contents were determined by Coomassie brilliant blue method using bovine serum albumin as the standard. DPPH free radical scavenging activities of ST homogenate was measured as described by Zhong et al. with slight modification.[36,37] DPPH solution in ethanol (0.1 mmol/L) was prepared and used fresh for each test. The DPPH free radical scavenging activities were measured by mixing supernatant from ST homogenate and DPPH solution, and the absorbance at 517 nm was recorded after incubation at room temperature for 30 min. The scavenging rate (%) was calculated with the equation $[1 - (A_1 - A_2)/A_0] \times 100\%$, where A_0 is the absorbance of the control (2 mL of DPPH solution + 1 mL of NaCl (0.9%)), A_1 is the absorbance of the sample (2 mL of DPPH

DOI: 10.1021/jf5059705
J. Agric. Food Chem. 2015, 63, 2820−2829

solution + 1 mL of sample supernatant), and A_2 is the absorbance of blank (1 mL of tissue supernatant + 2 mL of ethanol).

Emulsifying Activity Measurement. The emulsion preparation and emulsifying activity of OSA-starch was measured according to the method proposed by Miao et al. and Meng et al.[7,38] with slight modifications. Starch solutions (1.0% w/w) were prepared by dispersing the samples with/without 5% (w/w, based on starch) TPLs in deionized water at room temperature and heating in a boiling water bath with stirring for 20 min to completely dissolve the samples. Oil-in-water (O/W) emulsions with 5% Arawana soybean salad oil (Yihai Kerry, China) were prepared using a high-speed homogenizer (Ultra-Turrax T25, IKA Works Inc., China) at 24000 rpm for 5 min at room temperature to produce a fine emulsion. For the emulsifying activity, 50 μL of each emulsion was pipetted into 5 mL of 0.1% sodium dodecyl sulfate. After emulsion formation, the absorbance (emulsifying activity, EA) was measured at 500 nm. The emulsion stability (ES) of samples was measured after storage at room temperature for 24 h and calculated as follows:

$$\mathrm{ES} = (\text{height of remaining emulsion layer/total height}) \times 100\%$$

Fourier Transform Infrared Spectral (FT-IR) Analysis. OSA-starch (1.0 g) with or without TPLs (5% w/w based on starch) was mixed in 20 mL of distilled water and cooked in a boiling water bath for 20 min with continuous stirring to completely gelatinize the starch. The samples were freeze-dried after the cooked samples were cooled to room temperature. A Nicolet Nexus 470 Fourier transform infrared spectrometer (Thermo Electron Corp.) equipped with an ATR cell and EZ Omnic software (version 7.0) was used to obtain the spectrograms of the OSA-starch. Accurately weighed samples and KBr (100 times the weight of each sample) were fully milled together to get the infrared information from 4000 to 600 cm^{-1} by accumulating 32 scans per spectra at a resolution of 4 cm^{-1}.

Differential Scanning Calorimetry (DSC). DSC measurements were carried out with a Q20 thermal analyzer (TA Instruments, New Castle, DE, USA). OSA-starch (2 mg) and OSA-starch−TPLs mixture (OSA-starch/TPLs = 20:1) were placed in an aluminum pan with water (2:1, v/w) and held for at least 8 h before analysis. The samples were heated from 30 to 120 °C at a heating rate of 10 °C/min in a nitrogen atmosphere. Thermal transitions for gelatinization were characterized by T_o (onset temperature), T_p (peak temperature), T_c (conclusion temperature), and ΔH (enthalpy of gelatinization).

Scanning Electron Microscopy (SEM) Analysis. To analyze the difference of the microstructure of OSA-starch affected by TPLs, freeze-dried OSA-starch with/without 5% TPLs after gelatinization was used as sample for SEM analysis. Scanning electron micrographs were then obtained with a Quanta 200 scanning electron microscope (FEI Co., Eindhoven, The Netherlands) under a vacuum of 13.33 Pa and an operating voltage of 20 kV.

Dynamic Laser Scattering (DLS) Analysis. A commercial laser light scattering spectrometer (ALV/DLS/SLS-5022F, ALV Co., Langen, Germany) equipped with an ALV-5000/EPP multi-τ digital time correlator covering 125 ns−37 h in delay time and a He−Ne laser (Uniphase, output power ≈ 20 mW at λ = 632.8 nm) was used to measure the hydrodynamic radius of OSA-starch molecules. An OSA-starch solution (0.1 mg/mL) with or without TPLs (5%, OSA-starch weight base) was mixed and used as the sample for analysis. Each sample solution was first passed through a 0.45 μm Millipore syringe filter into a dust-free cell. The dynamic light scattering measurements were obtained at 90°, and CONTIN FIT (ALV Co.) was performed to obtain the hydrodynamic radius distribution of starch molecules.

Viscosity Measurement. OSA-starch (5%) with or without TPLs (5% based on dry weight of starch) was first cocooked at 100 °C for 20 min to completely gelatinize the starch, and then the apparent viscosity (Pa.s) of the samples was measured at 25 °C along the shear rate from 0.1 to 100 s^{-1} using an AR-G2 rheometer (TA Instruments-Waters LLC, Shanghai, China) with a 40 mm diameter steel plate gapped by 1 mm.

Statistical Analysis. Experimental data of in vivo glycemic response, insulin level, and enzyme activity were expressed as means ± SEM, and standard deviation of the mean was used for other experimental results. Statistical analysis was carried out using the one-way analysis of variance (one-way ANOVA) to determine the statistical significance at $p < 0.05$ by Tukey's honest significant difference (HSD) test.

RESULTS AND DISCUSSION

TPLs Modulate the Postprandial Glycemic Response of OSA-Starch. Chemically modified starch has long been used in food applications with different purposes, and nutritionally, most of the chemically modified starches belong to the category of resistant starch. OSA-starch, to our knowledge, is the only one with a substantial fraction of SDS after heat−moisture treatment.[13] However, a human study of its effect on postprandial glycemia showed the glycemic profile is still not good enough to provide a sustained glucose release.[13] Thus, tea polyphenols, which have been shown to inhibit the activity of α-amylase[39,40] and glucose transport of SGLT1,[22] were chosen to further improve the slow digestion property of OSA-starch. The dose of TPLs used in the current study was determined to be 5% (w/w, based on dry weight of OSA-starch) because the lowest digestion rate of OSA-starch was observed at this dosage (data not shown). The OSA-starch was produced according to a literature report,[13] and the degree of substitution of the final OSA-starch was determined to be 0.0194. The successful esterification of waxy corn starch was proved by FTIR analysis (Figure 1) with two new absorption

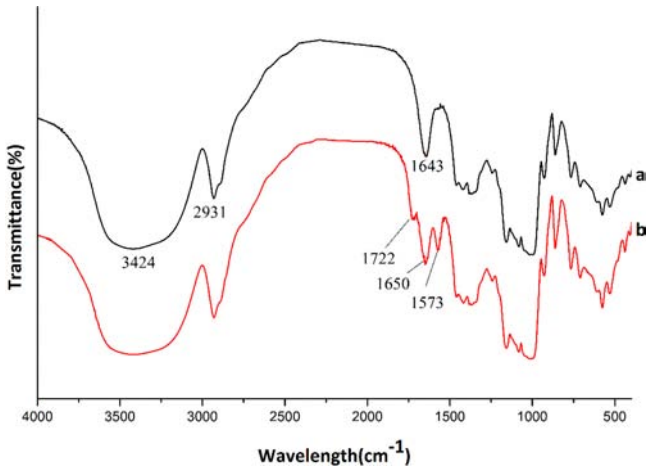

Figure 1. Fourier transform infrared spectrometry of native and OSA starches: (a) waxy starch; (b) OSA-starch. The DS is 0.0194.

bands at 1722 and 1573 cm^{-1} corresponding to the C=O stretching vibration of the ester group and the asymmetric stretching vibration of carboxyl group, respectively.[12]

The postprandial glycemic response to starch reflects the rate of glucose release from starch digestion and glucose absorption in the small intestine. The triggered secretion of insulin also contributes to a reduced blood glucose level by promoting glucose absorption. The addition of TPLs to OSA-starch significantly improved the postprandial glycemic response using Kunming mouse as the animal model. For OSA-starch, the postprandial blood glucose concentration reached a peak value of 4.9 mmol/L above the baseline after gavaging for 15 min. When OSA-starch was cocooked with TPLs (5%, based on starch dry weight, termed OSAT), a significant decrease of postprandial glycemia (from 4.9 to 3.0 mmol/L at the peak from baseline) with a delayed blood glucose peak (from 15 to 30 min) was observed (Figure 2A), although no significant

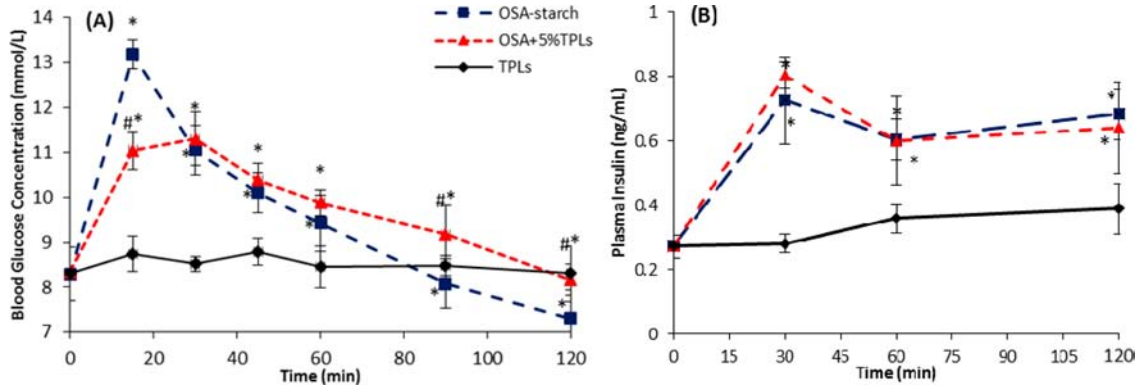

Figure 2. Postprandial glycemic response to OSA-starch affected by the addition of TPLs (A) and insulin levels (B) in mice. Results are shown as means ± SEM (n = 6); (#) $p < 0.05$ compared to OSA starch; (∗) $p < 0.05$ compared to TPLs.

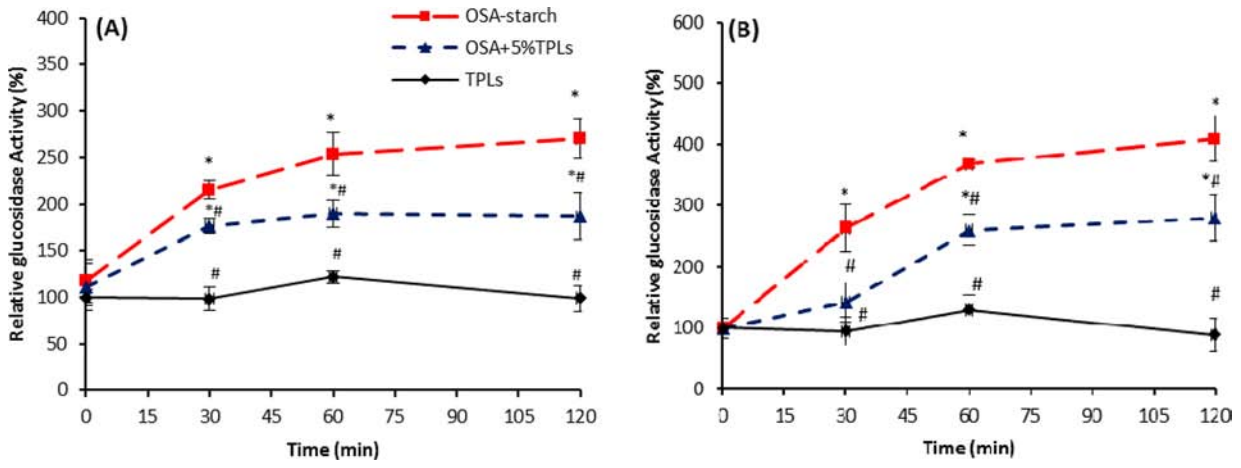

Figure 3. Activities of α-glucosidase in the small intestine tissue (A) and luminal contents (B) of mice after feeding different diets. Results are shown as means ± SEM (n = 6); (#) $p < 0.05$ compared to OSA starch; (∗) $p < 0.05$ compared to TPLs.

difference of the area under the glycemic curves (AUC) was found (1140.8 ± 39.2 for OSA-starch, 1173.2 ± 65.9 min·mmoL/L for OSAT). Compared to regular waxy corn starch with a peak glycemia of ∼7.5 mmol/L from baseline in the same mouse model,[41] the OSA-starch itself is of slow digestion property, and the addition of TPLs to OSA-starch further significantly decreased its postprandial glycemia. However, the addition of TPLs did not significantly affect the secretion of insulin following oral administration of OSA-starch or OSAT (Figure 2B), indicating insulin is not likely responsible for the decreased glycemia. Additionally, our previous study showed an identical postprandial glycemic response profile to glucose whether in the presence or absence of TPLs, indicating that TPLs have a negligible effect on glucose absorption in the small intestine,[22] which is also supported by a study showing that acute administration of EGCG did not inhibit glucose transport across the intestinal wall.[23] Therefore, the decreased postprandial glycemia of OSA-starch in the presence of TPLs is likely due to the reduced digestibility of OSA-starch.

Effect of TPLs on the Activity of α-Glucosidase. Starch is primarily digested by α-amylase and mucosal α-glucosidase in the small intestine. α-Amylase is responsible for cleaving the large strach molecules into maltooligosaccharides and α-limit dextrins, and α-glucosidase is a group of enzymes anchored on the cell membrane to generate monosaccharides for absorption. As shown above, starch digestion is likely the main reason for decreased postprandial glycemia, so the enzyme activities of α-amylase and α-glucosidase in the small intestine were first examined. Because the secretion of digestive enzymes needs the stimuli of food materials, TPLs alone did not show any changes of enzyme activity and can only act as the baseline.

Regarding the influence of TPLs on α-amylase activity, it has been well documented in the literature that TPLs mainly inhibit the activity of α-amylase for carbohydrate digestion based on in vitro studies under the optimum condition of enzyme activity.[39,40,42−44] Indeed, there was a literature report[23] that decreased α-amylase activity was concluded as the reason for decreased postprandial glycemia in a mouse model study using normal corn starch. However, the in vivo activity of α-amylase was not studied, and the conclusion was solely based on an in vitro measurement using commercially sourced α-amylase.[23] In the current study, we did not find significant changes of α-amylase activities in the small intestine (data not shown).

α-Glucosidase inhibitors are commonly prescribed to diabetics to reduce postprandial hyperglycemia induced by the digestion of starchy foods in the small intestine,[45] and TPLs are potent α-glucosidase inhibitors from a literature study on Caco-2 cell cultures.[46] Thus, the activity of small intestine α-glucosidase was examined in both luminal content (LC) and the tissue (ST) of the small intestine. The activities of α-glucosidase in LC and ST were significantly decreased in the OSAT-treated mice compared to that in OSA-starch-treated mice (Figure 3). Considering the regulatory effct of starch molecules on the gene expression of starch-hydrolyzing

enzymes,[47] the decreased activity of α-glucosidase might be due to a decreased gene expression. However, at least 6 h is required for carbohydrate to affect the expression and post-translation modification of mucosal sucrase-isomaltase (one type of α-glucosidase) in a Caco-2 cell model study.[48] Thus, the duration of our in vivo experiment (2 h) is not likely long enough for OSA-starch to affect the expression of small intestine mucosal α-glucosidase, so the decreased activities of α-glucosidase in LC and ST were most likely caused by the inhibiton effect of tea catechins in OSAT during digesiton. Indeed, the in vitro study of the effect of TPLs on the activity α-glucosidase in small intestine homogenate (Figure 4A) showed that its activity was inhibited by TPLs in a dose-dependent manner. Kinetic analysis on homogenate α-glucosidase showed a decreased reaction velocity (from 1.21 to 0.83 mmol/L/min) without affecting the enzyme's affinity for substrate, indicating a noncompetitive inhibition function of TPLs (Figure 4B). Therefore, the decreased activity of α-glucosidase in the presence of TPLs might be the main reason for the reduced and prolonged postprandial glycemia, which is characteristic of slowly digestible starch.[49] A higher enzyme activity of α-glucosidase after feeding OSA-starch alone also

supports the inhibition effect of TPLs on the activity of mucosal α-glucosidase.

Catechin Release from OSAT Sample. Although TPLs can inhibit the activities of digestive enzymes and alleviate postprandial hyperglycemia, their sensitivity to environmental conditions might affect their bioactivity. In the environment of the small intestine, the alkaline pH makes TPLs more susceptible to degradation, leading to a rapid clearance and a loss of bioactivities.[31] The levels of four major catechins in LC after mice were administered OSAT (1000 mg/kg bw, ig) and control of TPLs (50 mg/kg bw, ig) were first analyzed. The results (Figure 5) showed that the concentration of catechins (total and unconjugated) decreased rapidly in LC following administration of the control sample of TPLs and almost undetectable after 120 min, whereas concentration of catechins in the small intestine (ST + LC) of OSAT-treated mice remained relatively stable along the digestion of starch. A lower content of catechins (total and unconjugated forms) was also detected in LC at the early stage of digestion from the OSAT-treated mice. All of these results indicate a sustained release of TPLs from OSAT along the digestion process.

Conjugated forms of tea catechins are formed during the in vivo elimination process through the action of phase II enzymes. Literature reports showed that glucuronidated EGCG is the major conjugated form when EGCG is orally administered to mice,[35] and sulfated and methylated forms are also widely present in the conjugated catechins.[27] The biotransformation of TPLs after absorption is intimately associated with the bioactivities of tea cateahins. A literature report showed methylated EGCGs such as 4″-MeEGCG are much less effective than EGCG to induce the apoptosis of prostate cancer cells of LNCaP,[50] and some glucuronidated forms of EGCG and EGC are less effective in free radical scavenge activity than their unconjugated forms.[51] Thus, we also measured the content of tea catechins in the small intestine tissues, and the results (Figure 5C,D) showed that catechins and EGCG after OSAT treatment were mostly present as the unconjugated forms rather than the conjugated types, indicating the OSAT sample might also have the function to improve the bioactivity of TPLs. However, comparison of the amount of total catechins and unconjugated TPLs showed that the content of total catechins is less than the unconjugated forms, which has also been observed in the literature.[23] The reason is likely due to the complex of biotransformation that makes the used method less effective in detecting all of the conjugated catechins, but the actual reason needs further clarification through a systematic study, which is beyond the scope of this paper.

Complexation between TPLs and OSA-Starch. Decreased postprandial glycemic response in the presence of TPLs has been shown to be associated with the inhibitory funciton of TPLs on small intestinal α-glucosidase in the current study. However, our previous study of the effect of TPLs on the glycemic responses of normal corn and waxy corn starch did not show significant changes.[24] Therefore, it is necessary to understand how TPLs in OSAT sample inhibit α-glucosidase and decrease the postprandial glycemia.

Differential scanning calorimetry records the amount of heat involved in the starch gelatinization. TPLs considerably affected the gelatinization properties of OSA-starch (Figure 6A), and there was a clear shift in the endothermic peak toward a lower temperature with significantly decreased enthalpy (from 11.05 ± 0.25 to 9.32 ± 0.12 J/g). The reason for the decreased gelatinization temperature in the presence of TPLs might be due to a rapid hydration of OSA-starch when its hydrophobicity is decreased through a possible hydrophobic interaction with TPLs. Specifically, the interaction between the aromatic rings of TPLs and hydrocarbon chains of OSA groups[51] that are mostly present in the amorphous regions of starch granules because the crystalline regions in the granules are difficult for chemical regents to penetrate. In the meantime, the H-bond interactions between the hydrophilic group of TPLs with linear segment[33] of amylopectin located in the amorphous region of starch granules might weaken the coupling forces between the crystallites and the amorphous matrix,[52] leading to a lower energy required to gelatinize the starch granules.

OSA-starch, as an amphiphilic derivative of starch, is an effective stabilizer in water in oil emulsions and some oil-in-water systems.[12] As shown in Figure 6B, the emulsifiability of OSA-starch and its stability were decreased significantly after cocooking with TPLs (25.5 and 23.2% declines, respectively), which directly indicates the presence of a hydrophobic interaction between TPLs and OSA-starch leading to a decrease of the hydrophobic property of OSA-starch, and so to a decreased emulsifiability. The above conclusion is supported by a literature report showing that TPLs, especially EGCG, can interact with the lipid layer of emulsions and increase emulsion drop size,[53] and this might reflect the same phenomenon of an

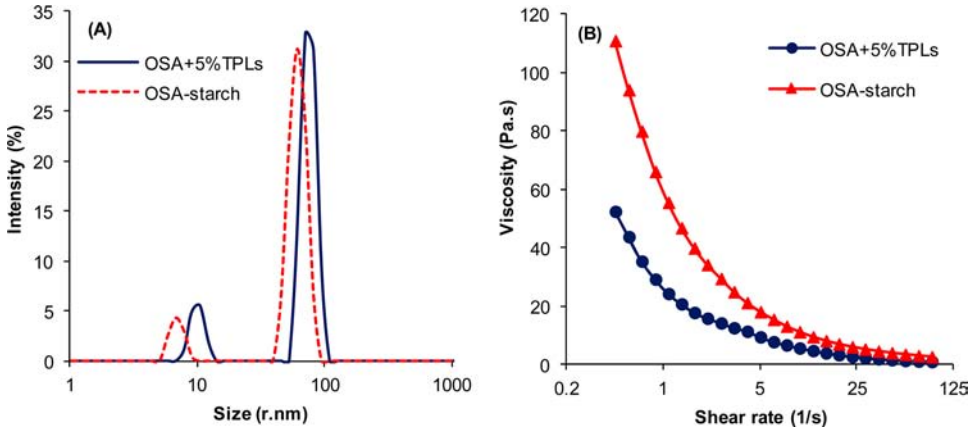

Figure 7. Effect of TPLs on the molecular size distribution (A) and the viscosity of OSA-starch (B).

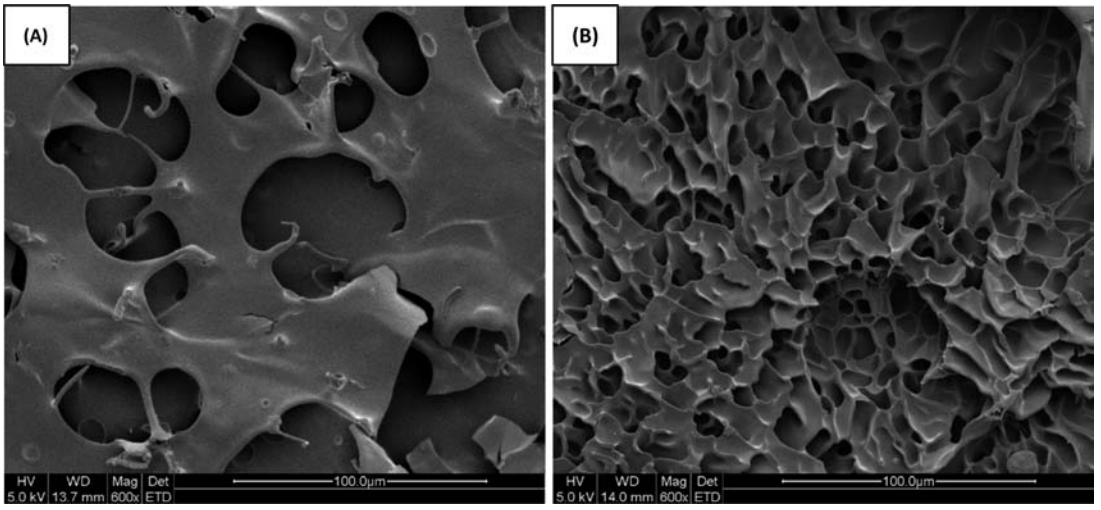

Figure 8. SEM analysis of freeze-dried OSA-starch (A) and OSAT (B). Scale bar = 100 μm.

increase of particle size of OSA-starch molecules (Figure 7A) in which TPLs might bridge more OSA-starch molecules together through hydrophobic interaction. In the meantime, this bridge also changes the conformation or shape of the OSA-starch molecules with a more spherical nature that is less viscous and less shear-thinning (Figure 7B) because shear-thinning behavior is characteristic of linear macromolecules. The influence of TPLs on OSA-starch structure due to hydrophobic interaction was also supported by SEM observation of the freeze-dried samples of OSA-starch and OSAT sample with dramatic difference of macroscopic structures (Figure 8).

All of the above experimental results showed the interaciton between OSA-starch and TPLs, and considering the molecular structure of OSA-starch and the TPLs, there might exist a spherical-like OSA-starch−TPL (OSAT) complex in which the hydrophobic interaction between the OSA group of OSA-starch and aromatic hydrocarbons of TPLs is the major force for their complexation.[54] When the hydrophobic complexation occurs, they might pull the amylopectin molecules together to shorten the distance between these molecules, facilitating the interaction between linear segments of amylopectin through TPLs' bridge function as shown in our previous study,[33] which further tightens the aggregation of OSA-starch molecules in the OSAT complex. When the complex was digested by α-amylase, the TPLs embedded in the complex might not be accessible to α-amylase, so that the activity of α-amylase in the small intestine is not likely affected even though TPLs do have the capability of inhibiting the activity of α-amylase. However, the complex structure might be a barrier to α-amylase, making it less efficient to hydrolyze starch, which also contributes to a reduction of postprandial glycemia. After TPL-containing (through interaction with OSA group) malto-oligosaccharides or α-limited dextrin (substrate of α-glucosidase) are slowly produced by α-amylase, their accessibility to mucosal α-glucosidase might also be affected. A gradual release of TPLs after digestion by α-amylase and α-glucosidase might lead to a high association between TPLs and α-glucosidase due to their closeness in distance, which facilitates the binding of TPLs by α-glucosidase, resulting in activity inhibition. Thus, the OSAT complex causes not only a decreased digestion efficiency by α-amylase and a slow production of substrate for mucosal α-glucosidase but also an inhibition of α-glucosidase activity by a sustained release of tea catechins from the complex, which all together result in a lower and prolonged postprandial glycemia.

Health Implication. Epidemiological studies have associated tea consumption with prevention of chronic and degenerative diseases including cancer,[55] cardiovascular disorder,[56] obesity, and diabetes.[57] However, low bioavailability limits the bioactivities of catechins.[31] In our study, a sustained release of unconjugated catechins from OSAT after acute administration was observed (Figure 5). Catechins, mainly EGCG, were present mostly as the more active unconjugated

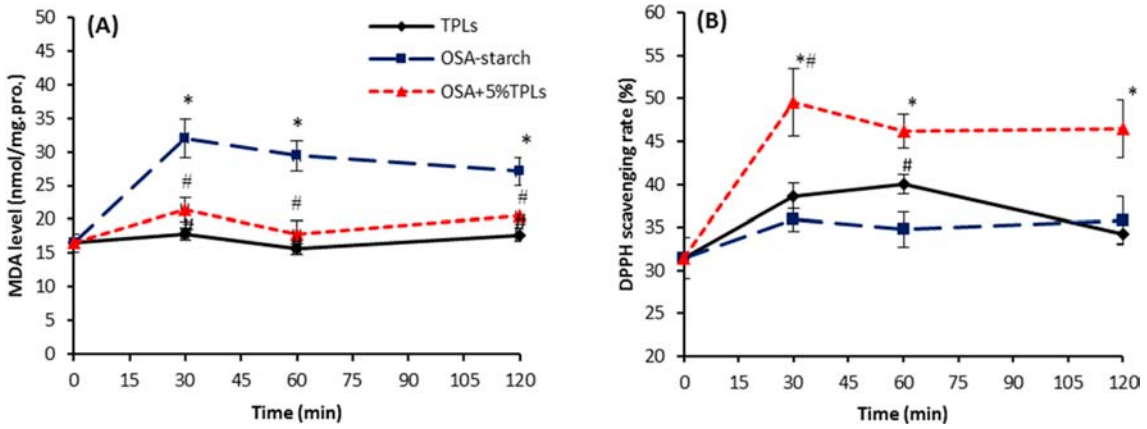

Figure 9. Level of MDA (A) and DPPH radical scavenging activity (B) in the small intestine tissue of mice. Results are shown as means ± SEM (n = 6); (#) $p < 0.05$ compared to OSA starch; (∗) $p < 0.05$ compared to TPLs.

form in ST rather than the conjugated form. In the meantime, the uptake of unconjugated TPLs might also be increased due to a high concentration of unconjugated TPLs in the luminal side of the small intestine and closeness to the absorptive enterocytes.

MDA is a major reactive aldehyde that appears during the peroxidation of fatty acid. Therefore, the content of MDA is widely used as a biomarker of oxidative stress and indicator of tissue damage involving a series of chain reactions.[58] We observed a significant increase of MDA level in intestinal tissue of mice due to the fluctuation of plasma glucose caused by OSA starch (Figure 9A). It has been demonstrated that glucose fluctuation is more deleterious to endothelial function through excessive generation of reactive oxygen species (ROS), resulting in oxidative stress.[59] Our study showed that the content of MDA decreased significantly in mice dosing OSAT (Figure 9A). Additionally, OSAT feeding also showed stronger DPPH scavenging activity than both OSA-starch and TPLs alone in the ST of mice (Figure 9B; $p < 0.05$). Thus, the OSAT complex also has an antioxidative bioactivity.

In conclusion, experimental results on the physicochemical properties of OSAT sample demonstrate the presence of a hydrophobic interaction-induced complexation between OSA-starch and TPLs. This complex not only changes the digestion property of OSA-starch, leading to a slow elevation of postprandial glycemia and possibly a sustained glucose release, but also has the capability to reduce the oxidative stress, which is likely the first study on functional or bioactive starch material to improve health. Although OSA-starch is not a common food ingredient that is generally consumed in large quantity, the complex formed between OSA-starch and TPLs, as the structural basis for TPLs' function, indicates some carbohydrate-coupled delivery systems of TPLs might be developed to efficiently decrease the postprandial glycemia for improved health.

Nuclear magnetic resonance (NMR) spectroscopy holds many advantages, such as high reproducibility, fast analysis, minimal preparation, and available databases, which make it useful as a metabolic profiling technique in metabolomics. Therefore, using urine and fecal samples from the study by Soerensen et al.,[10] the aims of the present study were (i) to investigate possible metabolic mechanisms associated with cheese and milk intake by employing untargeted NMR-based metabolomics and (ii) to identify potential metabolites that may explain how the intake of cheese and milk affects blood cholesterol level as reported by Soerensen et al.[10]

MATERIALS AND METHODS

Subjects and Study Design. A total of 15 healthy young men (ages, 18−50 years; body mass index, 20−28 kg/m^2) participated in a crossover intervention study during which they randomly consumed three isocaloric diets, which were either high in semiskimmed milk (1.5% fat) or high in semihard cow's cheese with equal amounts of dairy calcium (1.7 g/day) or a control diet containing butter but no other dairy products for 14 days. Nutrient compositions of the three diets are listed in Table S1 of the Supporting Information. Exclusion criteria of subjects were as follows: chronic illnesses, supplements or medications, excessive physical activity (>10 h/week), milk allergy, lactose intolerance, participation in other studies, or inability to follow the intervention. The intervention periods were separated by a washout period of at least 14 days. During each intervention, 5 days of feces samples (days 10−14) and 24 h urine samples (day 14) were collected and frozen at −80 °C. The detailed study design has previously been described.[10] The trial was approved by the Municipal Ethical Committee of Copenhagen (H-1-2011-004) and registered in the database (NCT01317251, http://www.clinicaltrial.gov).

NMR Measurements. NMR spectra were recorded on a Bruker Avance 600 spectrometer equipped with a 5 mm TXI probe (Bruker BioSpin, Rheinstetten, Germany) operating at a frequency of 600.13 MHz. The main acquisition parameters included 32K data points, a relaxation delay of 2 s, a spectral width of 7288.63 Hz, and an acquisition time per scan of 2.25 s. For urine, samples were thawed, vortexed, and centrifuged at 10000*g* for 5 min, and 500 μL of supernatant was transferred to a 5 mm NMR tube and mixed with 100 μL of a 0.75 M phosphate buffer solution containing 0.5% sodium trimethlysilyl propionate-d_4 (TSP) in D_2O. A standard Bruker "zgpr" pulse program with water presaturation was used to acquire ^{1}H NMR spectra at 25 °C. For fecal extracts, approximately 40 mg of lyophilized fecal powder was weighed into a 1.5 mL Eppendorf tube, and then 300 μL of ice-cold methanol was first added and then mixture vortexed thoroughly and placed on ice for 10 min. Then, ice-cold chloroform and water were consecutively used for extraction acording to the same procedure with methanol. The mixture last was put in a 4 °C refrigerator overnight for separation. On the next day, the mixture was centrifuged at 1400*g* for 30 min at 4 °C, and the upper methanol−water layer as water-soluble extract (WSE) and the lower chloroform layer as lipid extract (LE) were transferred to fresh 1.5 mL Eppendorf tubes, respectively, and then dried by using vacuum centrifugation for around 3 h. The dried sample was stored at −80 °C until NMR analysis. The dried WSE was redissolved in 550 μL of D_2O, 25 μL of H_2O, and 25 μL of D_2O containing 0.05% TSP, and the dried LE was redissolved in 575 μL of $CHCl_3$-*d* and 25 μL of $CHCl_3$-*d* containing 0.05% tetramethylsilane (TMS). Then, the mixture was vortexed thoroughly and transferred to a 5 mm NMR tube immediately. Both the water-soluble and lipid samples were analyzed by using a standard "zgpr" pulse program at 25 °C.

NMR Data Preprocessing. NMR data were processed in the Topspin 3.0 software (Bruker BioSpin) as described in our previous paper.[12] The ^{1}H spectra of urine and feces were referenced to TSP and TMS signals at 0 ppm, respectively. The "icoshift" procedure was applied to align NMR spectra in MATLAB (R2012a, The Mathworks Inc., Natick, MA, USA).[19] The spectral region from 0.0 to 10.0 ppm without the residual water signals from 4.7 to 5.0 ppm for urine, the region between 0.6 and 9.4 ppm excluding the water signals from 4.7 to 5.0 ppm for fecal WSE sample, and the region between 0.4 and 8.1 ppm excluding the chloroform signals from 7.1 to 7.3 ppm for fecal LE sample were subdivided into 0.01 ppm spectral regions (bins) and integrated. Finally, the binned data were normalized to the total signal amplitude of each NMR spectrum to minimize the dilution effect for urine but not for feces.

Multivariate Data and Statistical Analyses. Principal component analysis (PCA) is an unsupervised model that provides visualization of a multivariate data set and thereby enables identification of clusters of different diet groups in the present study. In addition, orthogonal partial least-squares discriminant analysis (OPLS-DA) as a supervised model was used to compare the difference between any two diet groups. The advantage of OPLS-DA is to separate the classification property in the predictive component P[1] and the within-class variation in the orthogonal component O[1], which can achieve better separations and thereby make data interpretation easier.[20] PCA and OPLS-DA were carried out on Pareto-scaled data by using SIMCA 13.0 software (Umetrics, Umeå, Sweden). Pareto scaling keeps the structure of the original spectra and thereby reduces the impact of low-intensity, noisy signals. For OPLS-DA, a leave-one-out cross-validation (LOOCV) method was performed, where R^2Y and Q^2 were calculated as the explained variance in the Y matrix and the predictive capability of the model, respectively. Values of these two parameters close to 1.0 represent an excellent model. Furthermore, the significance of the models was tested by CV-ANOVA in the SIMCA software.[21] The significance of variables for the separation between two groups in OPLS-DA was assessed by the variable importance in the projection (VIP) method, and those variables with VIP scores above 2.0 are considered important and used for further analysis.

The NMR signals (VIP > 2.0) were carefully inspected for the quality of spectral alignment and assigned on the basis of our previous paper for urine[12] and reported data for feces[22] as well as HMDB,[23] as shown in Table S2 in the Supporting Information. In addition, 2D ^{1}H−^{1}H total correlation (TOCSY) and 2D ^{13}C−^{1}H heteronuclear single-quantum coherence (HSQC) experiments were performed on representative samples of urine and feces. All NMR spectra were processed by the Processor module in Chenomx NMR Suite software (version 7.7, Edmonton, Canada) including phase, baseline, and shim correction and saved as the CNX file format. The identified metabolite peak was integrated and quantified using the Profiler module in the software. Each metabolite peak was checked manually to ensure a good fitting, and the data were then output to an Excel file for univariate analysis.

Prior to univariate analysis, all data were evaluated for normal distribution based on the Anderson−Darling test (P value < 0.05) in SAS software (PROC UNIVARIATE procedure, SAS 9.2, SAS Institute Inc., Cary, NC, USA). When non-normality was observed, data were log-transformed and assessed for normal distribution once again. Analysis of variance (ANOVA) was carried out by using a linear mixed effects model (PROC MIXED procedure, SAS 9.2)[12] to evaluate the effect of diet, period, and their interaction for each quantified metabolite. The mixed model included the fixed effects of diet, period, and their interaction, whereas the intercept of model and individuals was used as random effect. Least-squares mean procedure was performed to calculate means and standard errors. Statistical significance was assessed using Student's t test with Bonferroni correction for multiple comparisons, and a Bonferroni-adjusted P value <0.05 was considered statistically significant. In the present study, we analyzed the metabolite profiles in urine and feces samples from the study of Soerensen et al.,[10] wherein they found that total and LDL cholesterol levels in blood were increased with all three diets during intervention. The cholesterol levels increased significantly less in the cheese and milk groups relative to the control group.[10] Dietary effects on cholesterol levels are likely to correlate with changes in the metabolome, and thus a correlation analysis between changes in cholesterol levels and metabolites that were significantly affected by the dietary intervention may help elucidate the underlying metabolic mechanism regulating cholesterol metabolism. Pearson correlation

DOI: 10.1021/jf505878a
J. Agric. Food Chem. 2015, 63, 2830−2839

coefficients (R) were calculated to explore the relationship between each metabolite and total or LDL cholesterol in SAS 9.2 (PROC CORR procedure, SAS 9.2) and considered statistically significant when a P value was <0.05.

RESULTS

Multivariate Analysis of Data from the Intervention with Cheese and Milk. High-resolution ^{1}H NMR spectra were obtained on the urine and fecal samples (Figure 1) that

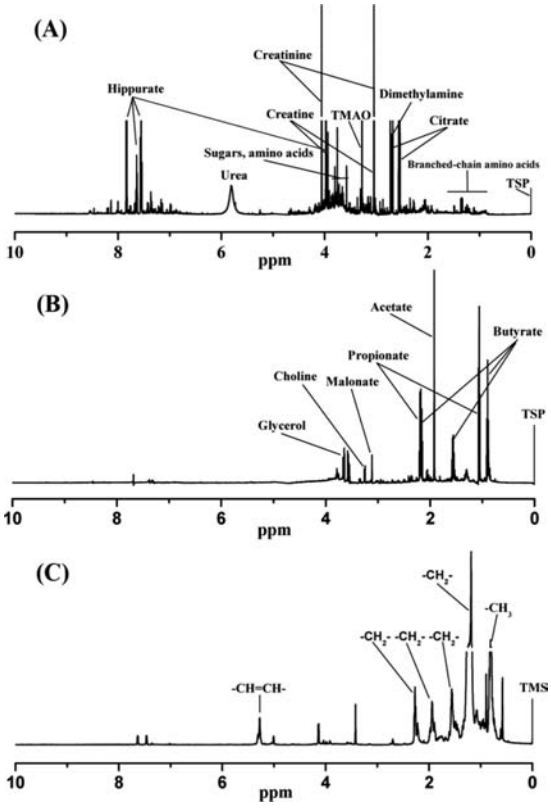

Figure 1. Representative 600 MHz ^{1}H NMR spectra of (A) urine, (B) feces water-soluble extract, and (C) feces lipid extract from a healthy young man.

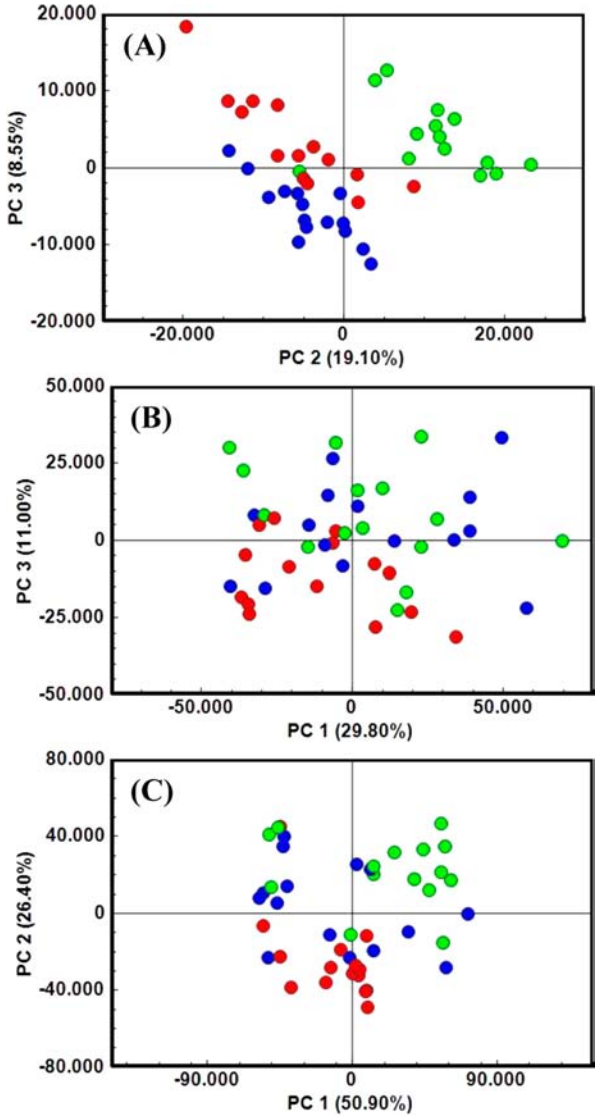

Figure 2. PCA scores plots from NMR-based metabolomics of (A) urine, (B) feces water-soluble extract (WSE), and (C) feces lipid extract (LE) during the human intervention study with cheese (blue), milk (green), and a control diet (red).

enabled the detection and assignment of a number of metabolites including a range of amino acids, organic acids, and fatty acids. Figure 2 illustrates PCA scores plots based on metabolite profiles of urine and feces samples collected after the interventions with cheese, milk, and control. A clear separation among groups can be observed from the urinary (Figure 2A) and fecal LE (Figure 2C) metabolomes. In addition, from the fecal WSE metabolome (Figure 2B), a slight separation between the control group and the dairy groups is evident along PC3.

OPLS-DA models resulted in satisfactory model performances using one predictive component and one orthogonal component (components = 1 + 1; A, milk versus control, R^2Y = 0.95, Q^2 = 0.86, CV-ANOVA = 6.02e−010; B, cheese versus control, R^2Y = 0.91, Q^2 = 0.78, CV-ANOVA = 1.14e−007; C, cheese versus milk, R^2Y = 0.96, Q^2 = 0.90, CV-ANOVA = 1.12e−011), achieving clear separations between any dietary groups based on the urinary metabolome (Figure 3). The corresponding loading in Figure 3A shows that milk intake increased urinary excretion of citrate, creatine, creatinine, and urea, but decreased prolinebetaine, TMAO, and hippurate levels in urine, when compared with the control diet. Figure 3B reveals that the differentiation of cheese intake from the control group could be ascribed to an increase in urinary prolinebetaine and urea excretion and a decrease in the levels of creatine, creatinine, choline, TMAO, and tyrosine. In addition, inspection of the loading plot from Figure 3C revealed that cheese consumption increased prolinebetaine and hippurate levels in urine and reduced urinary citrate, creatine, creatinine, and urea relative to milk intake.

Figure 4 shows that OPLS-DA model parameters based on the fecal WSE metabolome between the milk and control groups (components = 1 + 1, R^2Y = 0.87, Q^2 = 0.79, CV-ANOVA = 2.89e−008) were higher than for the other two models (cheese versus control, components = 1 + 2, R^2Y = 0.72, Q^2 = 0.36, CV-ANOVA = 0.04; cheese versus milk, components = 1 + 1, R^2Y = 0.73, Q^2 = 0.50, CV-ANOVA = 0.001). The corresponding loadings reveal that both cheese and milk groups had an increased level of fecal short-chain fatty acids (SCFAs), acetate, butyrate, and propionate, and a

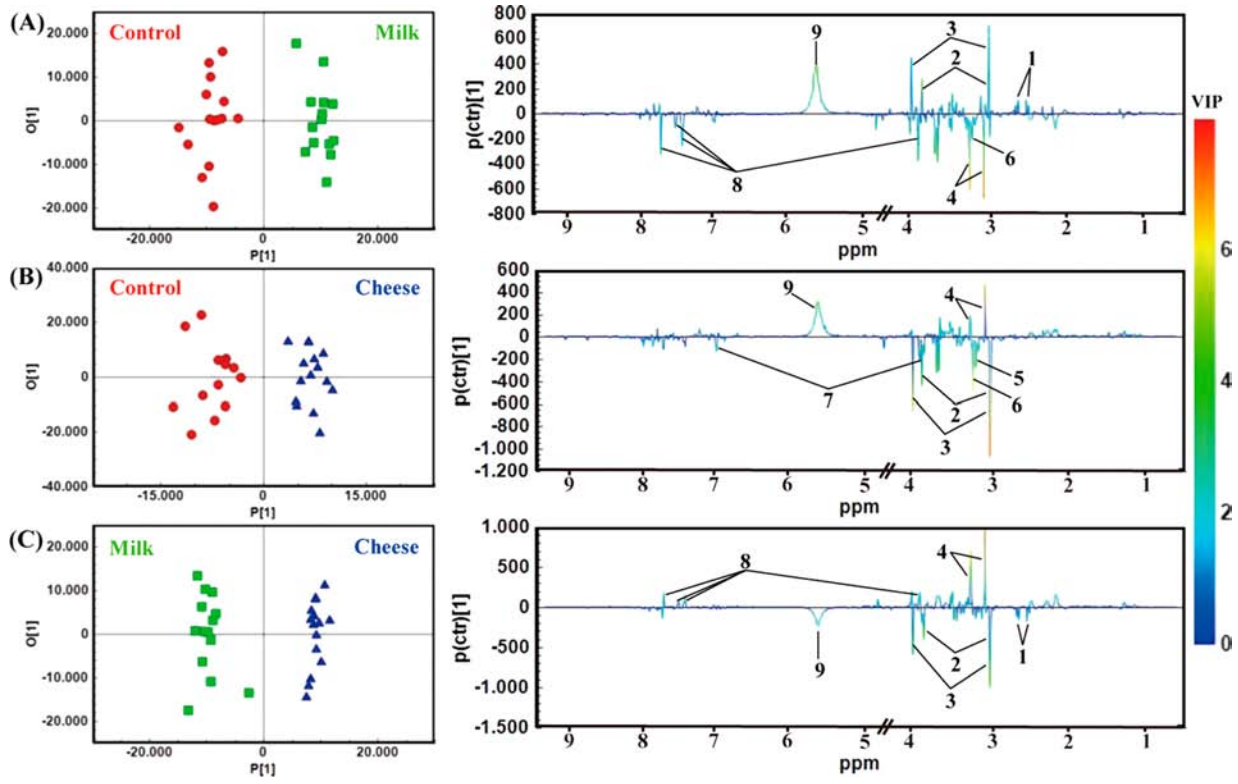

Figure 3. OPLS-DA scores and loadings plots obtained from NMR-based urine metabolomics during the human intervention study with cheese, milk, and a control diet: (A) milk versus control, components = 1 + 1, R^2Y = 0.95, Q^2 = 0.86, CV-ANOVA = 6.02e−010; (B) cheese versus control, components = 1 + 1, R^2Y = 0.91, Q^2 = 0.78, CV-ANOVA = 1.14e−007; (C) cheese versus milk, components = 1 + 1, R^2Y = 0.96, Q^2 = 0.90, CV-ANOVA = 1.12e−011. The loadings are colored according to VIP values. The numbers represent the assignment of metabolites: 1, citrate (2.54 and 2.68 ppm); 2, creatine (3.04 and 3.92 ppm); 3, creatinine (3.05 and 4.06 ppm); 4, prolinebetaine (3.11 and 3.30 ppm); 5, choline (3.23 ppm); 6, trimethylamine *N*-oxide (3.27 ppm); 7, tyrosine (3.94 and 6.68 ppm); 8, hippurate (3.97, 7.55, 7.64, and 7.84 ppm); 9, urea (5.80 ppm).

reduction in the levels of malonate and choline compared with the control group. In addition, milk intake was associated with a higher fecal excretion of glycerol than the control group (Figure 4A). Compared with the milk group, cheese intake increased fecal butyrate, propionate, and malonate concentrations and decreased fecal acetate and glycerol (Figure 4C).

For the lipophilic fecal metabolites, according to OPLS-DA results in Figure 5, a separation of all intervention groups could be obtained; however, the differentiation between the milk and control groups (components = 1 + 1, R^2Y = 0.82, Q^2 = 0.78, CV-ANOVA = 1.34e−007) was stronger as compared with the differentiation between the cheese and control groups (components = 1 + 2, R^2Y = 0.76, Q^2 = 0.45, CV-ANOVA = 0.03) and between the cheese and milk groups (components = 1 + 1, R^2Y = 0.44, Q^2 = 0.31, CV-ANOVA = 0.05). Inspection of the loadings from Figure 5A,B shows that cheese and milk intake in general increased fecal lipid excretion relative to the control diet as all lipid signals was positively associated with the dairy diets compared with control. The OPLS-DA loadings also show that the methylene ($-CH_2-$) peak at 1.22 ppm had the highest contribution to the discrimination between interventions. The OPLS-DA model between milk and cheese indicated also a higher lipid excretion for the milk group than for the cheese group (Figure 5C).

Mixed Linear Model Analysis of Identified Metabolite. Metabolites identified to be important in the discrimination of the dietary interventions from multivariate data analysis were quantified, and Table 1 lists the change of metabolites between different dietary interventions and Bonferroni-adjusted *P* values based on a linear mixed-effects model. Urinary prolinebetaine and tyrosine levels were significantly higher in the cheese group relative to the other two groups, whereas a significant reduction was obtained in urinary creatine and creatinine excretion. Compared with the control group, cheese intake significantly decreased urinary choline level. Fecal butyrate level tended to be increased significantly after cheese consumption relative to intake of the other two diets (Bonferroni-adjusted *P* value = 0.06). In the milk group, urinary citrate and fecal glycerol were significantly increased as compared with the other two groups, whereas a significant reduction was observed in the level of hippurate in urine and malonate in feces (Table 1). Relative to the control group, milk intake increased urinary urea excretion significantly, whereas no significant difference was observed after cheese intake. Fecal acetate and choline levels tended to be significantly increased and decreased in the milk group compared with the control group (Bonferroni-adjusted *P* value = 0.06), respectively. Furthermore, compared with the control group, both cheese and milk consumptions had significantly lower levels of urinary TMAO, but significantly higher fecal lipid excretion.

Correlation Analysis between Identified Metabolite and Cholesterol. Figure 6 shows the correlation coefficients obtained between the 10 significant metabolites in urine or feces and diet-induced increases in total and LDL cholesterol levels. The corresponding biplots based on correlation analyses are illustrated in Figure S1 in the Supporting Information. Weak but significant negative correlations between fecal butyrate, propionate, and lipid levels and the increase in total

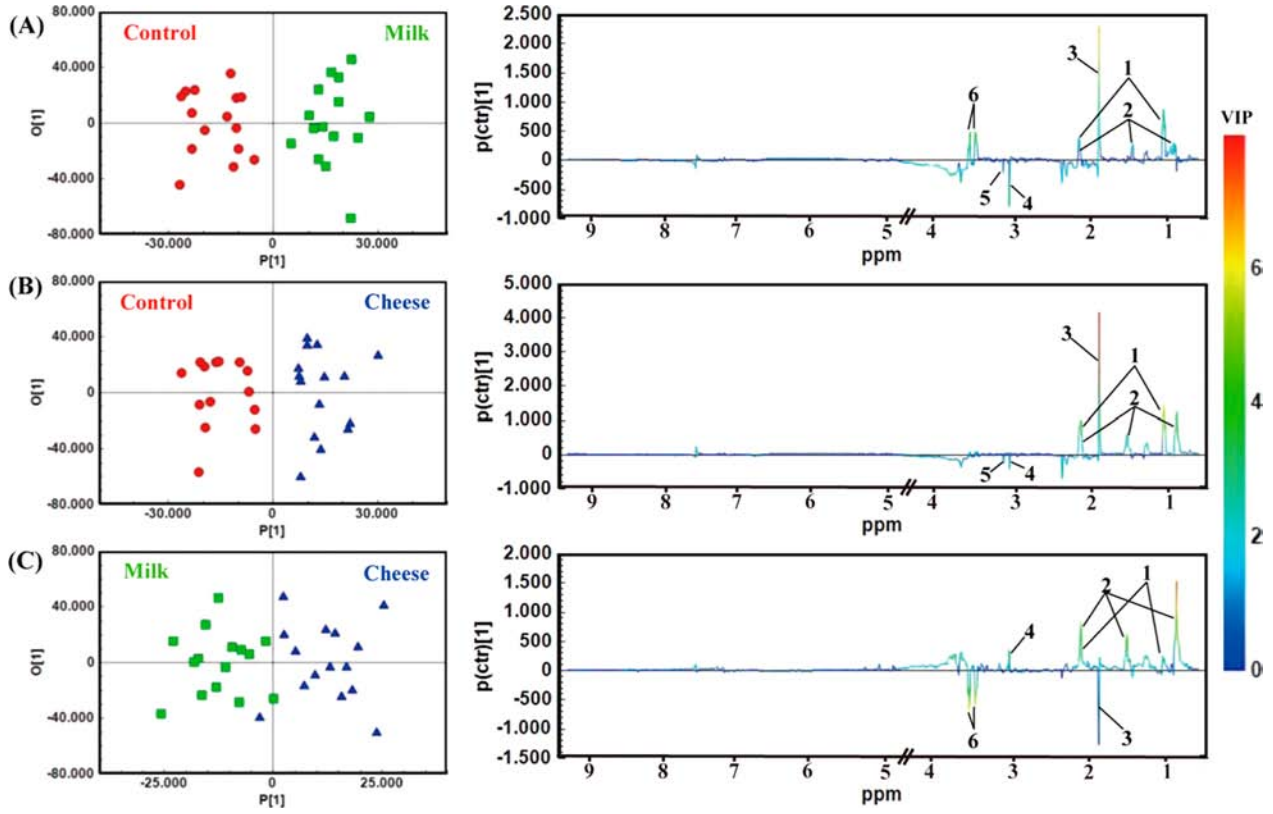

Figure 4. OPLS-DA scores and loadings plots obtained from NMR-based metabolomics of feces water-soluble extract (WSE) during the human intervention study with cheese, milk, and a control diet: (A) milk versus control, components = 1 + 1, $R^2Y = 0.87$, $Q^2 = 0.79$, CV-ANOVA = 2.89e−008; (B) cheese versus control, components = 1 + 2, $R^2Y = 0.72$, $Q^2 = 0.36$, CV-ANOVA = 0.04; (C) cheese versus milk, components = 1 + 1, $R^2Y = 0.73$, $Q^2 = 0.50$, CV-ANOVA = 0.001. The loadings are colored according to VIP values. The numbers represent the assignment of metabolites: 1, propionate (1.05 and 2.16 ppm); 2, butyrate (0.90, 1.56, and 2.20 ppm); 3, acetate (1.92 ppm); 4, malonate (3.11 ppm); 5, choline (3.20 ppm); 6, glycerol (3.56, 3.65, and 3.77 ppm).

cholesterol were identified (Figure 6). A similar result was observed for LDL cholesterol (Figure 6). In addition, urinary citrate concentration was weakly, but significantly, positively correlated with the increase in LDL cholesterol. The results of the correlation analyses could suggest that microbial and lipid metabolism may play a role in the effect of cheese and milk consumption on cholesterol level as shown in Figure 7.

DISCUSSION

In the present study, we found that the urine metabolome could clearly discriminate between intake of cheese and milk, and metabolites responsible for the discrimination could easily be identified by NMR-based metabolomics. Relative to the milk group, a significantly lower urinary excretion of citrate, creatine, and creatinine in the cheese group suggests that cheese consumption affects TCA and urea cycles (Figure 7). In fact, a cheese-induced lowering of urinary citrate is consistent with previous findings showing a lower urinary excretion of TCA intermediates after casein intake (the main protein fraction in cheese) than after whey intake in a murine model.[17] Lillefosse et al.[17] speculated that a lower metabolic acidosis and higher levels of organic acids (citrate, cisaconitic acid, and citramalic acid) and amino acids (alanine, aspartate/aspargine, threonine, and trytophane) after whey intake might be responsible for an enhanced urinary TCA intermediate excretion compared with casein intake. Compared with the control, we found that intake of milk but not cheese significantly increased urinary excretion of urea, which is the major outcome of protein catabolism.[12] Because cheese mainly consists of casein and milk contains approximately 80% casein and 20% whey, this finding might be attributed to the fact that whey and casein have been characterized as "fast" and "slow" proteins, respectively, on the basis of their digestion and absorption rates.[24] Moreover, the urea cycle is an energy-consuming pathway. A cheese-induced change in these metabolites could imply an effect on energy utilization. However, additional metabolites need to be identified for the detailed metabolic pathway analysis of metabolic effects associated with cheese intake.

Furthermore, it is worth noting that urinary prolinebetaine and tyrosine excretions were significantly increased in the cheese group compared with the other two groups. A high prolinebetaine content has been reported in some types of cheese, such as brie (≈185 μg/g) and blue (≈48 μg/g) cheeses.[25] The level of free tyrosine in cheese is significantly increased during cheese ripening.[26] Thus, urinary prolinebetaine and tyrosine may possibly be assigned as exposure markers of cheese consumption. This would have an interesting potential because identification of dietary biomarkers receives a lot of attention in relation to compliance in both intervention and large cohort studies. However, it remains to be further explored if they are sufficiently specific for cheese intake to be useful markers.

In addition, the microbiota-related metabolite hippurate was significantly higher in the cheese group than in the milk group, suggesting that a stimulation of gut bacteria activity after intake of cheese was different from the stimulation achieved with milk

intake.[4] Another interesting finding is that urinary TMAO excretion was significantly reduced after cheese and milk consumption. TMAO is a well-known metabolite produced from the metabolization of choline. Many animal-based foods, such as egg, milk, red meat, poultry, and fish, are principal dietary sources of choline, which thereby increases TMAO production and excretion. In this study, relative to the control group, a decrease in choline was also found in urine samples in the cheese and milk groups, which resulted in a concomitant lowering of the TMAO level (Figure 7). Yet, the formation of

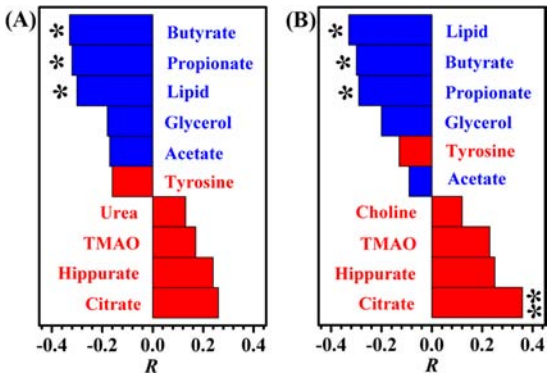

Figure 6. Top 10 metabolites correlated with the diet-induced increases in (A) total and (B) LDL cholesterol based on Pearson correlation coefficients. Red and blue bars represent urinary and fecal metabolites, respectively. (∗) $P < 0.05$; (∗∗) $P < 0.01$.

TMAO is dependent on the metabolism of specific gut microbiota.[27] Thus, our results may suggest that cheese and milk can beneficially modify the gut microbiota to decrease TMAO production; however, this hypothesis needs to be further tested in future studies. Wang et al.[28] identified TMAO as a possible marker of CVD in serum samples from human CVD patients. Consequently, a lowering of TMAO may also be involved in the mechanisms contributing to a beneficial effect of dairy products in relation to the risk of CVD and CHD.

On the fecal metabolome, diet-induced differences were also evident. SCFAs including acetate, butyrate, and propionate were identified as potential contributors to the diet-induced differences. SCFAs are reported to be present in milk[29] and, particularly, in cheese,[30] and therefore the fecal SCFAs could be a direct effect of differences in the intake of SCFAs. However, it is also likely that the change of fecal SCFAs was ascribed to a diet-induced effect on the gut microbiota. Many studies have reported the impact of diet on the gut microbiota.[31,32] In fact, the present results indicate that dairy consumption, especially cheese, can beneficially modify the gut microbiota to increase SCFA levels. This finding is consistent with the result of St-Onge et al.,[4] in which they reported that fermented dairy products cause an increase in the content of gut microbiota that ferment indigestible carbohydrates to produce SCFAs. The C_3 dicarboxylic acid, malonate, is also produced by the gut bacteria at lower concentration. Thus, cheese intake significantly increased fecal malonate level relative to milk intake but significantly reduced it as compared with intake of the control

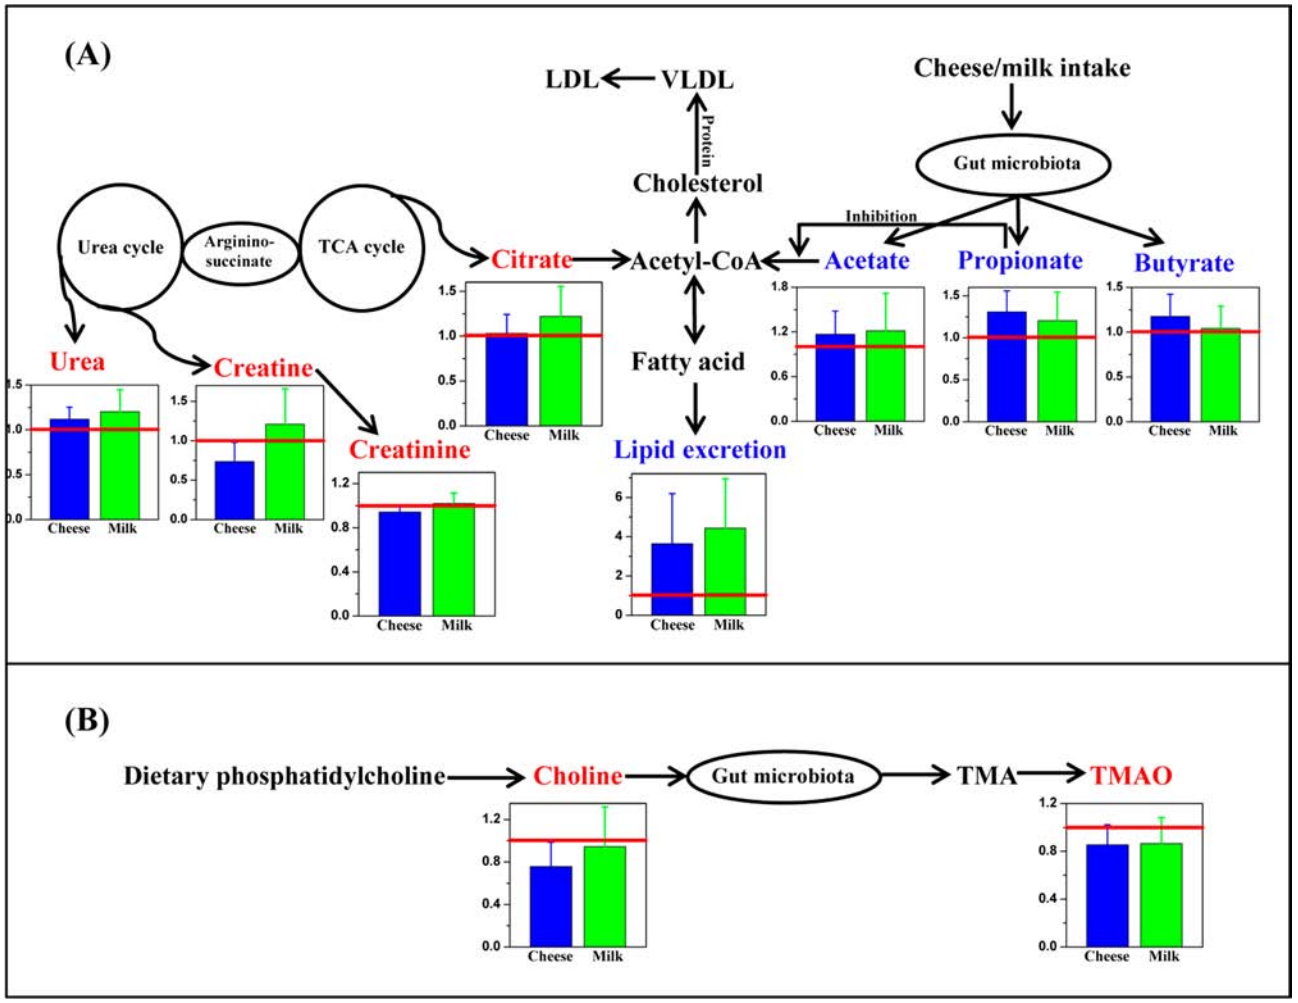

Figure 7. Schematic metabolic pathways explaining the effects of cheese and milk on microbial and lipid metabolism: (A) lipid metabolism and SCFAs; (B) TMAO production. diet, suggesting a distinct stimulation of gut bacteria activity after the intake of cheese.[4]

Metabolomics analysis of the lipophilic extracts showed a higher lipid excretion for the dairy diets compared with control, which is probably attributed to a higher content of calcium in dairy products.[33,34] A meta-analysis also revealed that increasing dairy calcium intake by 1241 (800−1600) mg/day resulted in an increase in fecal fat excretion of approximately 5.2 (1.6−8.8) g/day.[35] The lipid excretion was higher for milk than for cheese. A higher fecal glycerol excretion in the milk group was also identified from the fecal water extracts, likewise revealing higher lipid excretion after milk intake compared with cheese intake. The results are consistent with the findings of Soerensen et al.[10]

^{1}H NMR spectroscopy enables detection of saturated and unsaturated fat and has even been applied for the determination of specific fatty acids in cheese.[36] In the present study, OPLS-DA models showed a contribution from all lipid signals to the discriminations of the groups, whereas the contribution from the methylene signal was dominating. This could possibly be a result of longer fatty acid chains giving rise to a stronger methylene signal, which would imply an effect of the intervention on both the amount and composition of the lipids excreted in the feces. However, the fact that the contribution from the methylene signal was dominating in the loading should most likely be ascribed to the fact that this signal has the highest signal intensity.

Overall, the present results clearly document that metabolomics as a postgenomic technique has great promise in the exploration of the metabolic effects associated with specific diets.[37] Recently Hjerpsted et al.[38] used an untargeted LC-MS metabolomics approach to investigate differences between cheese and butter intake in a comparable crossover design. Even though the untargeted LC-MS metabolomics approach identified a substantially higher number of metabolites than the NMR-based methodology applied here, a much stronger separation and thus diet-induced effect was demonstrated in the present study. This should most likely be ascribed to the fact that the study by Hjerpsted et al.[38] included subjects in an age range between 22 and 70 years and both genders were represented, whereas all of the subjects in the present study were young men. We have previously demonstrated a strong gender and age effect on the metabolome,[39] which likely will mask a diet effect in an intervention study. In addition, sample collection,[40] storage,[41] preparation,[41] and analysis[42] may also affect metabolomics results.

Soerensen et al.[10] previously reported that all three diets in the current intervention study resulted in an increase in total and LDL cholesterol. However, the increases were lower for the cheese and milk intake compared with the control group. Here we employed correlation analyses to elucidate the associations between perturbations identified in the urinary and fecal metabolome and the concomitant changes observed in total and LDL cholesterol. The correlation analyses revealed that citrate in urine and butyrate, propionate, and total lipid in feces were weakly but significantly correlated to the increases in total and LDL cholesterol. Even though no causal relationship could be proved, these findings imply that microbial and lipid metabolism may be involved in diet-induced effects on cholesterol metabolism (Figure 7). SCFAs have been reported to play a key role in the regulation of lipid metabolism.[43] Acetate is a precursor of cholesterol synthesis, whereas propionate may decrease cholesterol by inhibiting the formation of acetyl-CoA from acetate.[44] We also found that there was a significant negative relationship between fecal butyrate excretion and the diet-induced increase in cholesterol level including total and LDL cholesterol. A possible reason for this is that butyrate, like propionate, can inhibit cholesterol synthesis and in turn reduce intestinal fat absorption and circulating lipoprotein levels as demonstrated in Caco-2 cells.[45] In addition, a significant negative relationship between fecal lipid excretion and the increases in total and LDL cholesterol, which is in accordance with the findings of Soerensen et al.,[10] suggests that the increase in fecal lipid excretion reduced available substrates for cholesterol formation and in turn decreased blood cholesterol level (Figure 7). Citrate is an intermediate in the TCA cycle and is converted to acetyl-CoA for cholesterol synthesis through ATP-citrate lyase.[46] Therefore, a decrease in citrate after cheese intake may also be responsible for reducing the increases in total and LDL cholesterol.

Niemann−Pick C2 (NPC-2) protein as a cholesterol-binding protein plays an important role in regulating intracellular transport and homeostasis of cholesterol.[47] Nielsen et al.[48] reported that NPC-2-deficient mice increased visceral cholesterol level compared with wild-type mice, whereas a lowering effect was found after NPC-2 protein treatment. However, no difference was observed in blood cholesterol.[48] Interestingly, NPC-2 protein, also called EPV20, was obtained at approximately 2.5 mg/L in bovine milk.[49] Thus, it could be of great interest to investigate the effect of NPC-2 protein in dairy products on the regulation of cholesterol metabolism.

In conclusion, using an NMR-based metabolomics approach in a human intervention study, the present study demonstrated strong effects of dairy product intake on the urine and fecal metabolome. Furthermore, it was demonstrated that cheese consumption was associated with a different metabolic response compared with milk consumption. Our results lead us to suggest that cheese consumption is associated with an increased level of SCFAs in the gut, possibly induced by stimulation of beneficial gut microbiota, as well as an increased extent of lipid excretion with resultant beneficial effects on cholesterol metabolism. In addition, a reduced TMAO production may also contribute to potential beneficial effects of cheese intake on the risk of CVD. Overall, this metabolomics study suggests that cheese could be an important piece in the French paradox puzzle. However, further studies are needed to explore the exact metabolic mechanisms linking cheese consumption, stimulation of the gut microflora, and cholesterol metabolism.

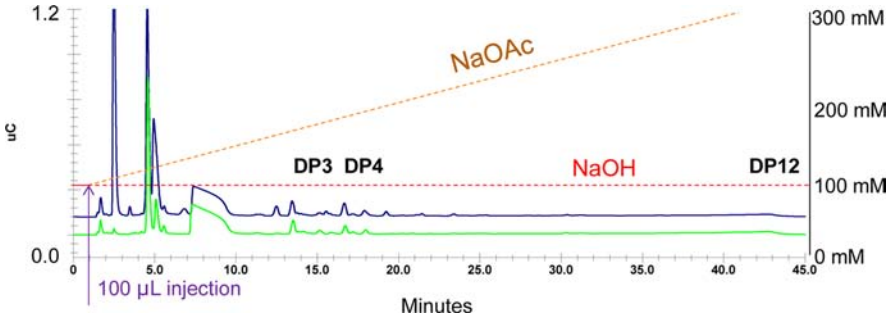

Figure 1. Gradient separation on a Thermo Scientific (previously Dionex) CarboPac PA1 column of oligosaccharides in fresh (green line) and deteriorated (blue line) sugar cane juice (samples were standardized to the same Brix value). DP, degree of polymerization. See the text for full IC-IPAD method conditions.

strong alkaline mobile phase also catalyzes the mutarotation of reducing sugars such as glucose and fructose very efficiently, and at room temperature the α- and β-anomers elute together in one sharp peak.[3] This is an added advantage of IC-IPAD over both gas and liquid cation-exchange chromatography with RI detection, with which double peaks of the reducing sugars are often obtained.[3]

The high-resolving power of IC-IPAD and its ability to determine oligosaccharides of higher degrees of polymerization has allowed the "fingerprinting" of numerous products manufactured from sugar crops. This includes sugar cane and sugar beet used in the global manufacture of sugar, as well as sweet sorghum, which is increasingly being used as a sugar feedstock for the manufacture of biofuels and bioproducts. The fingerprinting capability of a NaOH/NaOAc gradient IC method utilizing a Thermo Scientific (previously Dionex) CarboPac PA1 strong anion-exchange column, combined with the sensitivity of the IPAD has allowed its application to numerous industrial problems associated with these sugar crops, which are discussed herein.

MATERIALS AND METHODS

Chemicals and Reagents. HPLC grade sodium hydroxide and sodium acetate were obtained from Thermo Scientific Dionex (Sunnyvale, CA, USA). Deionized water (with resistivity of 18 MΩ) was used to prepare eluents and samples. Standard sugars, oligosaccharides, and mannitol were of analytical grade. 1-Kestose, 1,1-nystose, and 1,1,1-fructofuranosylnystose were from Meiji Seika Kaisha, Ltd. (Tokyo, Japan). Theanderose (6-*O*-α-D-glucosylsucrose) was from Wako Chemicals (Richmond, VA, USA) and kindly purified by Dr. Greg Cote of USDA-ARS-NCAUR. Dextran was T2000 (2,000,000 Da) from Amersham Biosciences AB (Uppsala, Sweden). Dextranase was obtained from BioCat, Inc. (Troy, VA, USA), and pullanase (Promozyme D2 manufactured by Novozymes (Franklinton, NC, USA)) was obtained from Brenntag Southwest (Houston, TX, USA). Distiller's yeast in dried form (*Saccharomyces cerevisiae*; Crosby & Baker Ltd., Westport, MA, USA) was donated by Delta BioRenewables LLC (Memphis, TN, USA). Absolute ethanol was from Aaper (USA).

IC-IPAD Oligosaccharide Chromatograms. Carbohydrates (mainly oligosaccharides up to 12 dp), including sugar alcohols and ethanol, were separated on a Dionex (now Thermo Scientific, Sunnyvale, CA, USA) BioLC or Dx500 instrument, using a strong NaOH/NaOAc gradient over 40 min.[14] The compounds were separated on Thermo Scientific CarboPac PA1 analytical anion-exchange (250 × 4 mm) and guard columns (50 × 4 mm) at 30 °C or, unless otherwise stated, using a Dionex LC25 Chromatography Oven. The CarboPac PA1 column was designed for the rapid analysis of mono- and oligosaccharides, in particular, linear homopolymers.[13] The CarboPac PA1 column contains 10 μm substrate of polystyrene (2% cross-linked with divinylbenzene) agglomerated with MicroBead quaternary ammonium fuctionalized latex (5% cross-linked). Flow rate = 1.0 mL/min. Injection volume = 25 μL. Eluent conditions were as follows: carbonate-free 100 mM NaOH (isocratic (0.0−1.1 min; inject 1.0 min), a gradient of 0−300 mM NaOAc in 100 mM NaOH (1.1−40.0 min), and return to 100 mM NaOH (40.1−45.0 min) to re-equilibrate the column to the starting conditions prior to injection). The re-equilibration is needed for good retention time reproducibility. The eluents were prepared by diluting a 50% w/w NaOH solution with 18 MΩ deionized water and then degassing them with ultrahigh-purity helium for 20 min. Once the eluents were prepared, they were kept blanketed under helium (20 kPa) at all times. The samples were diluted 1 g/25 mL in deionized water, unless otherwise stated, and filtered through a 0.45 μm PVDF filter to remove particulates. IPAD detection was with either a Dionex PED-2 or Dionex ED50 detector; both detectors were equipped with Au working and Ag/AgCl reference electrodes. The PED-2 detector operated with the following working electrode pulse potentials and durations: E_1 = +0.05 V (t_0 = 0.00 s), E_2 = 0.05 V (t_1 = 0.42 s), E_3 = +0.75 V (t_3 = 0.43 s), E_4 = +0.75 V (t_4 = 0.60 s), E_5 = −0.60 V (t_5 = 0.61 s), and E_6 = −0.60 V (t_6 = 0.96 s). The ED50 detector operated as follows: E_1 = +0.10 V (t_0 = 0.00 s), E_2 = 0.10 V (t_1 = 0.20 s), E_3 = +0.10 V (t_3 = 0.40 s), E_4 = +2.00 V (t_4 = 0.41 s), E_5 = −2.00 V (t_5 = 0.42 s), E_6 = +0.60 V (t_6 = 0.43 s), E_7 = −0.10 V (t_7 = 0.44 s), and E_8 = −0.10 V (t_8 = 0.50 s). A refrigerated Spectra-Physics SP8880 or Dionex AS refrigerated autoinjector/autosampler was used to prevent degradation of sugars in samples while waiting for injection onto the column. Dionex Peaknet or Chromeleon chromatography software was used to accumulate multiple samples and check standards.[15] Oligosaccharides, mannitol, and ethanol were identified by comparing retention times with standards and by spiking with standards.

A representative chromatogram with the gradient method conditions overlaid is shown in Figure 1. To maintain baseline stability, the sodium hydroxide was kept constant during the sodium acetate gradient, because acetate has no buffering capacity at high pH.[11]

Brix (Percent Refractometric Dry Substance). Brix value was measured using an Index Instruments (Kissimmee, FL, USA) TCR 15-30 temperature-controlled refractometer accurate to ±0.01 Brix, and results were expressed as an average of triplicates.

RESULTS AND DISCUSSION

Deterioration of Juices from Sugar Crops. IC oligosaccharide fingerprint profiles have been used to investigate the deterioration of juices extracted from sugar cane (*Saccharum officinarum*) and sweet sorghum (*Sorghum bicolor*) during storage, as well as from freeze-deteriorated sugar cane.[16−18] The typical progression of deterioration in sugar cane juice during storage at ∼25 °C is illustrated in Figure 2. By overloading the column with high concentrations of glucose, fructose, and sucrose present in the juice, the presence of oligosaccharides and other related deterioration compounds

was detectable (Figure 2). This highlights another marked advantage of this IC-IPAD method in that the anion-exchange CarboPac PA1 column can tolerate high concentrations of samples (up to 20 °Brix[15]), yet still detect low levels of oligosaccharides and other compounds of interest. The very large sucrose peak is not quantitated at this high concentration but is completely separated from these other low-level oligosaccharides, permitting their quantitation. Moreover, extensive column washings between runs are not required.[15]

Oligosaccharides form on the deterioration of sugar crops, with the main oligosaccharides produced being glycosyl acceptor (secondary) products produced from the action of dextransucrase by *Leuconostoc mesenteroides* bacteria.[16,19] Examples of *Leuconostoc* oligosaccharides are leucrose, isomaltose, and isomaltotriose (Figure 2). Other oligosaccharides formed on sugar cane deterioration include kestoses (GF_2 trisaccharides), which can form from invertase activity. However, kestoses are also primary oligosaccharides that occur naturally in the sugar cane plant, particularly in the leaves and top part of the stalk.[14] Early in our sugar crop deterioration research, we discovered that mannitol was a major degradation marker of sugar cane deterioration[16] and later found it in sweet sorghum deterioration.[20] Mannitol is also formed by *Leuconostoc* lactic acid bacteria via a metabolic pathway separate from that for dextran biosynthesis. Fructose is reduced to mannitol by the enzyme mannitol dehydrogenase in that pathway.[21] As illustrated in Figure 2, mannitol is a very sensitive indicator of sugar cane deterioration and is even more sensitive than dextran as a deterioration marker.[22] Steinmetz et al.[23] had also reported that mannitol was even a better marker of sugar beet deterioration than dextran. Mannitol (a sugar alcohol) is a reduced carbohydrate that is a weaker acid than its nonreduced counterpart mannose and, therefore, it is poorly retained on the CarboPac PA1 column, which explains its early elution (Figure 2). Ethanol is also formed during the

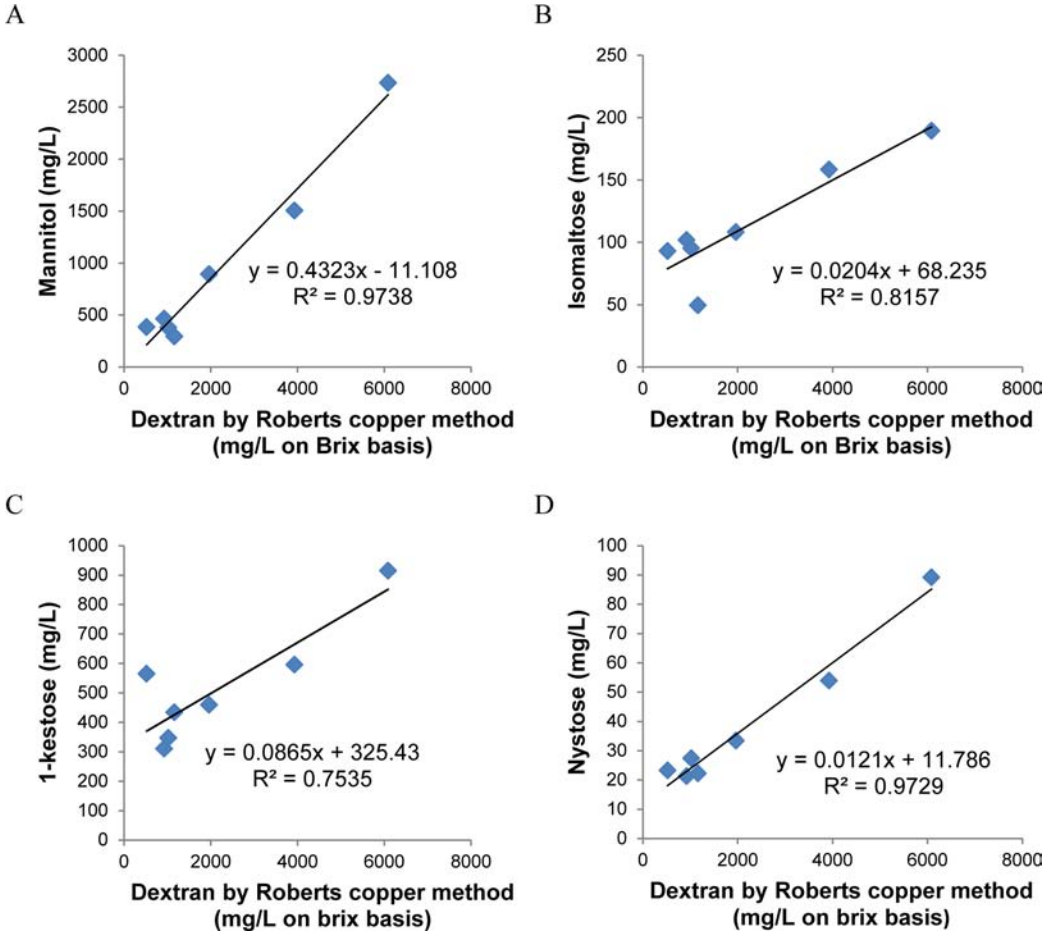

Figure 3. Dextran concentration correlations with (A) mannitol, (B) isomaltose, (C) 1-kestose, and (D) nystose determined in sugar cane juice.

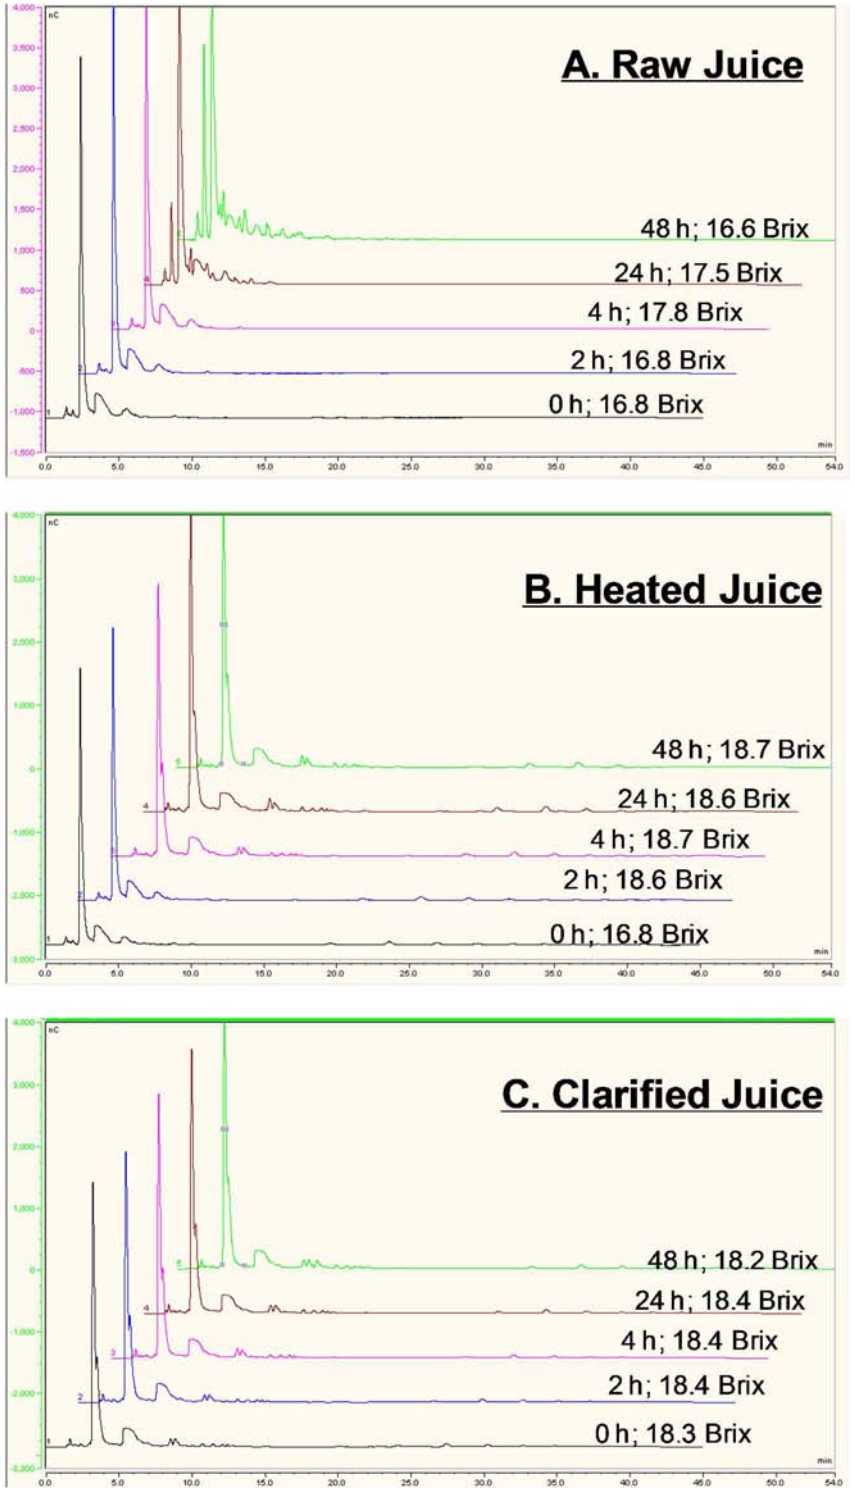

Figure 4. IC-IPAD fingerprint oligosaccharide chromatograms of stored juice extracted from KN Morris sweet sorghum cultivar (November 2013): (A) raw juice; (B) heated juice; (C) clarified juice. Times of storage and Brix values of the juices are denoted on the overlaid chromatograms. Reprinted with permission from ref 20. Copyright 2014 Elsevier.

Leuconostoc deterioration of sugar cane but is only a minor metabolite of *Leuconostoc* compared to dextran and mannitol.[16] Similarly to mannitol, ethanol elutes very early due to its weak interaction with the stationary phase in the column. Detection of ethanol by PAD using a gold working electrode is also less sensitive than for mannitol.[16]

In sugar cane juice collected from a Brazilian factory, there was a strong correlation between the mannitol concentration and the dextran concentration when the latter was measured accurately by the Roberts copper method[24] (Figure 3A). Other microorganism and plant metabolites, including isomaltose, 1-kestose, and nystose, were also shown to strongly correlate with the dextran concentration (Figure 3B–D). However, as concluded in previous research,[16,22] mannitol was shown to be the most sensitive deterioration indicator (Figure 3A).

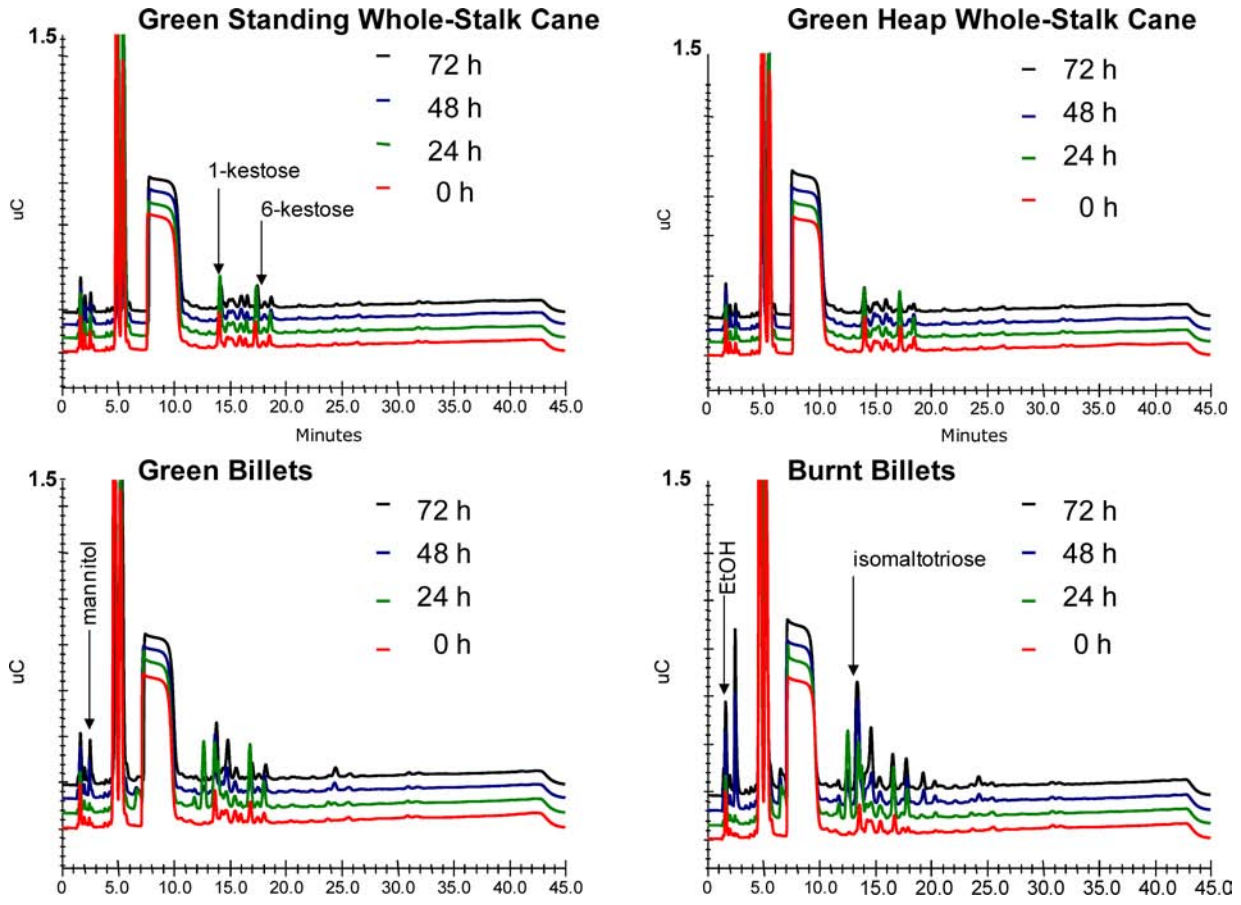

Figure 5. Example IC-IPAD oligosaccharide fingerprint profiles to illustrate the effect of sugar cane harvest method and cut-to-crush delays on deterioration (Brix value was standardized in the samples). The chromatograms were obtained on a Dionex BioLC system with a PED-2 detector at ~25 °C. Adapted from ref 14.

More recently, the IC-IPAD has been used to successfully confirm bacterial count results in a study to stabilize and preserve sweet sorghum juices.[20] Sweet sorghum is similar to sugar cane in that it has a juicy stalk that is rich in sugars. The effects of heat pasteurization (80 °C; 30 min) and clarification (80 °C; limed to pH 6.5; addition of 5 ppm of polyanionic flocculant; settling for 30 min) to juice from sweet sorghum cultivar KN Morris, which was then stored for up to 48 h at 25 °C, are illustrated in Figure 4 oligosaccharide fingerprint profiles. Treated juices were compared to the susceptible raw juice (not treated) (Figure 4). No formation of deterioration products was detected in KN Morris clarified juices stored from 0 to 48 h, although a slight amount of oligosaccharides after the sucrose peak was detected in the 24 and 48 h heated juice samples (Figure 4). This agreed with the lactic acid microbial data, with no detectable growth in the amount of total and lactic acid bacteria in the clarified juice across the 48 h storage period.[20] In comparison, deterioration products were found in the 24 h stored raw juice, which was worse after 48 h of storage (Figure 4). This was no surprise, as before storage the raw juice contained 2.8×10^8 total bacteria/mL, which increased ~5-fold during the 48 h storage period.[20] In contrast, total bacteria in the 0 h heated and clarified juices were approximately 4-log less than in the 0 h raw juice, and no lactic acid bacteria were detected in the clarified juice at 0 h.[20] Lactic acid formation was slightly worse in KN Morris heated than in clarified juice, but this was still considerably lower than in the raw juice.[20] Thus, the IC fingerprint profiles confirmed the bacterial growth results as well as the fact that the clarification process destroyed or removed all lactic acid bacteria, although other bacteria remained at $\sim 10^3$ cfu/mL levels.

Overall, it was shown that the IC-IPAD fingerprint profiles are extremely sensitive, being able to detect as low as 10^2 cfu/mL lactic acid bacterial growth.[20] Additionally, the effect of heat pasteurization was very similar to the whole clarification process, which confirmed that heat was the major contributor to juice stabilization.

Optimization of Sugar Cane Harvesting Methods and Cut-to-Crush Times. The IC-IPAD profile method has also been used to determine the formation of oligosaccharides and other deterioration products caused by various sugar cane harvest and storage treatments, and example chromatograms are illustrated in Figure 5. The changing oligosaccharide profiles allowed for a much more sensitive elucidation of the different deterioration reactions contributing to overall sugar cane deterioration than typical deterioration analyses, those being pH and titratable acidity.[14] Using the IC-IPAD method it was possible to show that at 0 h there were no marked differences in oligosaccharide profiles for harvest treatments, which reflected the freshness of all of the samples and indicated that, initially, when the field cane is cut, freshness is more important than harvest method.[25] This result had considerable consequences for the factory in that as long as billeted cane is transported to the factory quickly on the day it is harvested, deterioration problems should be no worse than encountered in fresh-cut whole stalks (soldier harvested). There were, however, marked

differences in the formation of oligosaccharides and other deterioration products on cut-to-crush/delay time (Figure 5). For the whole-stalk treatments shown in Figure 5, no significant formation of either *Leuconostoc* oligosaccharides and mannitol or kestose oligosaccharides occurred during storage. 1-Kestose (1^F-*O*-*β*-fructofuranosylsucrose) was the most abundant isomer, followed by 6-kestose (6^F-*O*-*β*-fructofuranosylsucrose) and neo-kestose (1^G-*O*-*β*-fructofuranosylsucrose), and separate peaks for 1- and 6-kestose isomers are shown in Figure 5. In strong contrast, deterioration products formed within 24 h during the storage of both green and burnt billeted cane, with greater deterioration occurring in burnt than green billets (Figure 5).

Figure 6 illustrates a correlation between the sum of oligosaccharide concentrations related to sugar cane deterioration (isomaltose, palatinose, isomaltotriose, 1-kestose, nystose, and 1^F-fructofuranosylnystose) and cut-to-crush time in a Brazilian sugar factory that had problems with delivered sugar cane from two different fields. The results were compared with relatively fresh sugar cane delivered to the factory with a cut-to-crush time of <24 h. As the problem sugar cane loads were extremely deteriorated, it was possible to observe (Figure 6) that the longer the cut-to-crush time, the higher the oligosaccharide concentrations. As expected, the mannitol concentration was also higher as the cut-to-crush time increased (results not shown).

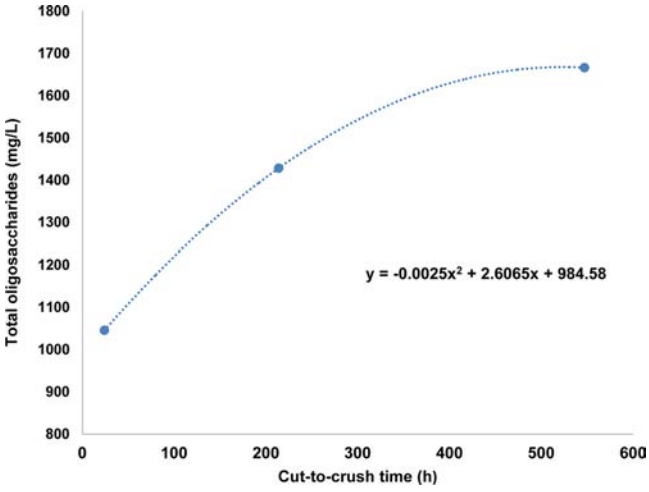

Figure 6. Correlation between sum of oligosaccharides concentration (isomaltose + palatinose + isomaltotriose + 1-kestose + nystose + 1^F-fructofuranosylnystose) with sugar cane cut-to-crush time.

Differentiation between White Refined Sugar from Sugar Cane and Sugar Beets. Approximately 11 years ago, there were reports of illegal trading in Serbia and Montenegro, whereby the origin of white refined sugar could not be certified[26,27] Other countries have also most likely suffered from illegal intermixing of (less expensive to produce) cane white sugar (CWS) with beet white sugar (BWS). For the purpose of international sugar trade, we were requested by industry to develop a new analytical screening method that (1) was capable of distinguishing between CWS and BWS and (2) could measure the percentage of CWS in a CWS/BWS mixture. Moreover, if methods are readily available to differentiate CWS/BWS mixtures, then illegal traders may reconsider their practices. In addition, from an economic standpoint, detection of adulteration is essential to avoid unfair competition that can create a destabilized market and disrupt the regional economy. The detection of adulteration of refined sugars is also of interest to sugar and food manufacturers, consumers, and regulators because of issues of legal compliance. Manufacturers need to ensure that correctly labeled refined sugar is available to the consumer and/or buyer. Consumers also have an interest in ensuring the food they purchase is authentic.

Although raffinose (*O*-*α*-D-Gal*p*-(1→6)-*O*-*α*-D-Glu*p*-(1→2)-*β*-D-Fru*f*) and theanderose (*O*-*α*-D-Glc*p*-(1→6)-*O*-*α*-D-Glu*p*-(1→2)-*β*-D-Fru*f*) had both been advocated as differential markers, raffinose is present in both BWS and CWS (although to a much lesser extent in CWS) and pure theanderose was not commercially available; also, small IC peaks had been found in BWS samples with the same retention time as theanderose. Although some highly sophisticated methods exist to differentiate the source of white sugar, such as isotope ratio mass spectrometry (IRMS) and deuterium NMR, these were considered only to be reference techniques[28] because the equipment is expensive and not readily available. A general analytical screening method was needed to detect a wide range of compounds in the same run. Suspect samples could then be detected and evaluated by more sophisticated techniques as just described.

Because IC-IPAD had (i) become a preferred technique for the routine monitoring of sugars in sugar industry products, (ii) been used to detect simple types of adulteration such as the addition of sucrose to honey,[29] and (iii) a very high sensitivity that offered the great advantage of detecting very low levels of adulterant compounds, we investigated its use to differentiate between beet (BWS) and cane white (CWS) refined sugar.[30] By overloading the CarboPac PA1 column with ∼7.0 Brix blind BWS/CWS samples and running the IC-IPAD NaOH/NaOAc 45 min gradient method, low raffinose combined with numerous characteristic cane marker peaks was successfully used to detect 20% CWS adulteration, which is illustrated in Figure 7. In general, IC profiles of CWS samples had more peaks of 2−12 dp than BWS samples. Increasing the Brix levels to 10.0 allowed detection of 10% CWS adulteration.[30]

Chromatography libraries of CWS, BWS, and BWS/CWS samples for direct comparisons would aid adulterant detection, as would pattern recognition chemometric techniques.[31] The use of an internal standard would greatly help in the standardization of chromatographic patterns and be necessary for chemometric analysis. The use of column ovens and refrigerated autosamplers also aids in the stabilization of retention times. Overall, at the least, the use of IC profiles can be used as a screening method before the further verification and quantitation with more sophisticated techniques.

Verification of the Activities of Carbohydrate Enzymes. Dextran (*α*-1→6-*α*-D-glucan) is a detrimental glucose polysaccharide that is found in deteriorated sugar cane, sugar beet, and sweet sorghum products. In the sugar industry, dextranase (EC 3.2.1.11; *α*-D-1,6-glucan-6-glucanohydrolase) is applied to hydrolyze high molecular weight (HMW) dextran into more manageable lower MW poly- and oligosaccharides. The goal is to improve viscosity and throughput rates in sugar cane and sugar beet factories (in sugar cane factories crystal elongation is also reduced). Most dextranases currently available are manufactured from *Chaetomium gracile* or *erraticum* fungi[32] and are generally recognized as safe (GRAS). One of the greatest sources of confusion for factory or refinery personnel is that it is not possible to compare the activities of commercial dextranases because suppliers/vendors

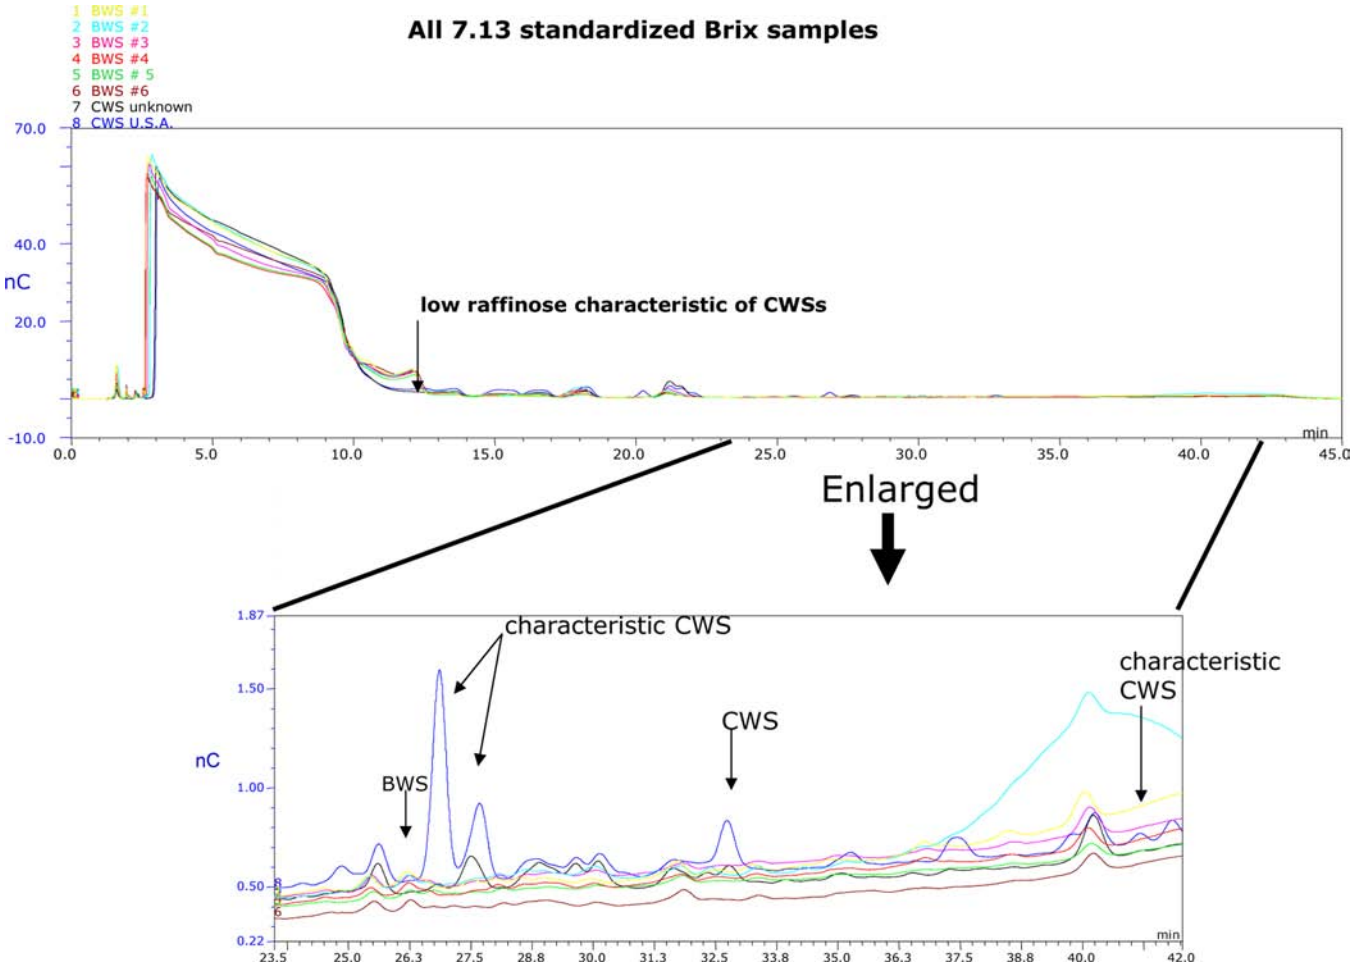

Figure 7. Comparison of six beet white sugars (BWS) of European origin to two cane white sugars (CWS) using IC-IPAD profiles. All samples were adjusted to 7.13 Brix. The chromatograms were obtained on a Dionex BioLC system with a PED-2 detector at ~25 °C. Reprinted with permission from ref 30. Copyright 2005 Verlag Dr. Albert Bartens.

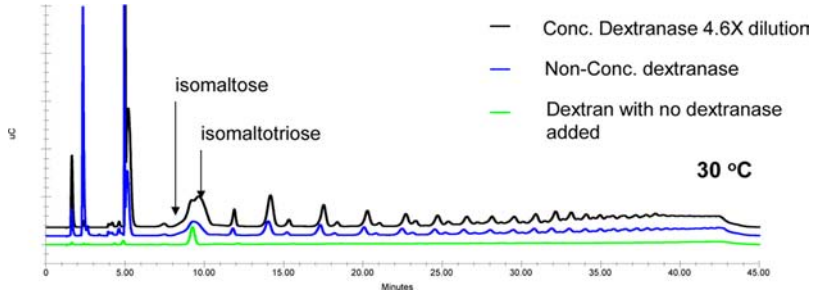

Figure 8. IC-IPAD oligosaccharides profiles used to accurately verify the relative activities of different commercial dextranases used in the sugar industry to hydrolyze dextran. The nonconcentrated dextranase had an activity of ~5500 DU/mL. The initial activity of the concentrated dextranase was 52000 DU/mL but was diluted 4.6-fold to make the dextranases equal in price based on DU/mL/$US. Reprinted with permission from ref 32. Copyright 2005 Elsevier.

use different methods, and activities are quoted in different units. This problem is exacerbated by the dextranase market being very dynamic with activities and prices changing regularly.[32] For these reasons, an easy, inexpensive method based on ferricyanide reduction of free sugars and simple thiosulfate titration of a starch−iodine complex was developed by Eggleston and Monge[32] to measure dextranase activities at the industrial site. Even more importantly, it allowed the calculation of activities per unit cost. The developed industrial method was confirmed as accurate by using IC-IPAD profiles of dextran/dextranase mixtures, which are illustrated in Figure 8. Dextranase hydrolyzed HMW dextran into a series of isomaltogoligosaccharides, with isomaltose, isomaltotriose, and glucose being the major breakdown products. The IC-IPAD method was even able to detect isomaltooligosaccharide isomers (Figure 8). The greater the activity of the dextranase, the greater the number and heights of the oligosaccharide peaks that occurred on the fingerprint chromatograms (Figure 8). The concentrated dextranase (52000 DU/mL) had approximately 8−10-fold differences in activity relative to non-

DOI: 10.1021/jf506370s
J. Agric. Food Chem. 2015, 63, 2841−2851

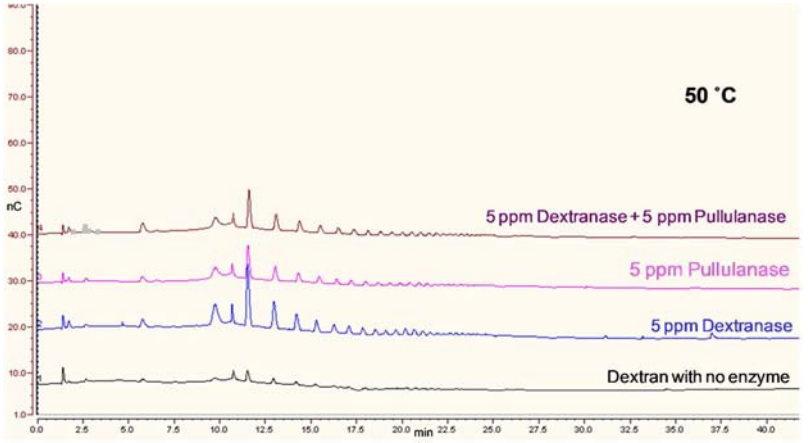

Figure 9. IC-IPAD oligosaccharide profiles used to demonstrate that pullulanase hydrolyzes HMW dextran (2000 ppm) very similarly to dextranase, after 3 min at 50 °C. The concentrated dextranase was 52000 DU/mL.[33] The pullulanase (Promozyme D2) was 1350 NPUN/g activity.[34] The enzymes (5 ppm), individually or combined, were added to the dextran solution (200 mL) in an Erhlenmeyer flask placed in a 50 °C water bath with slight shaking. Samples were removed after 3 min and then boiled immediately for 2.5 min to denature the enzyme(s). The resulting sample was diluted 1 g/25 mL deionized water, filtered through a 0.45 μm filter, and injected onto the CarboPac PA1 column. ED50 detector settings and Chromeleon software were utilized (see Materials and Methods).

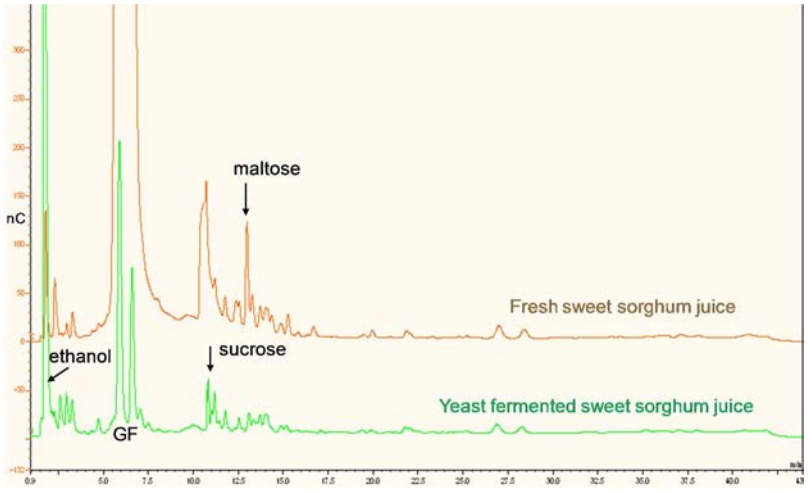

Figure 10. IC-IPAD oligosaccharide profiles used to demonstrate the use of distiller's yeast (*S. cerevisiae*) to metabolize glucose, fructose, sucrose, and maltose in juice from sweet sorghum cultivar Top 76-6 (1:10 w/w) for the production of bioethanol. Fermentations were undertaken at 35 °C with no shaking for 14 h.

concentrated dextranases, but only ~4.6-fold difference in price per pound. IC-IPAD profiles were successfully used to show that, even when the concentrated dextranase was diluted to the economical equivalent to the nonconcentrated dextranase, it still produced a greater number and height of breakdown peak products (Figure 8). As for the sugar cane harvest method research (see previous section), when trying to persuade industrial customers to adopt or change a technology, the visual chromatograms containing numerous peaks often proved more effective as evidence than numerical data results alone.

We also used the IC profiles to show that pullulanase (EC 3.2.1.41; pullulan-6-glucan hydrolase) debranching enzyme can also break down HMW dextran (Figure 9). Although pullulanase is available as an industrial enzyme (it is often used as a processing aid in the production of ethanol and sweeteners from starch in grains, because it specifically hydrolyzes glucose molecules linked by $\alpha 1 \rightarrow 6$ bonds), it may be more expensive than dextranase. Sometimes, however, dextranase has not always been easily or readily available, because the market for this enzyme is very small.[33] When there is an emergency with regard to dextran at a sugar factory, for example, after a sugar cane or sugar beet freeze, and dextranase is not readily available, then more readily available pullulanase may be useful. The optimum pH and temperature conditions for the pullanase, pH 4.5−5.4 and 60 °C,[34] roughly coincide with the recommended best practice for dextranase in juices (pH 5.4 and 50 °C[33]). Pullanase may also be useful to break down sarkaran polysaccharide (pullulan), which has been reported in dry areas of the world where sugar cane is vulnerable to fungal deterioration.[35] Brunt[3] reported the use of a NaOH (100 mM)/NaOAc (500 mM) CarboPac PA1 gradient method over 90 min to characterize the side-chain length binomial distribution of amylopectins after enzymatic debranching. Torto et al.[36] used an online microdialysis system coupled with IC-IPAD to characterize the enzymatic mannanase hydrolysates of ivory nut mannan.

Selection of Yeasts for Bioethanol Fermentations. Most conventional fermentation processes of sugar cane juices

DOI: 10.1021/jf506370s
J. Agric. Food Chem. 2015, 63, 2841−2851

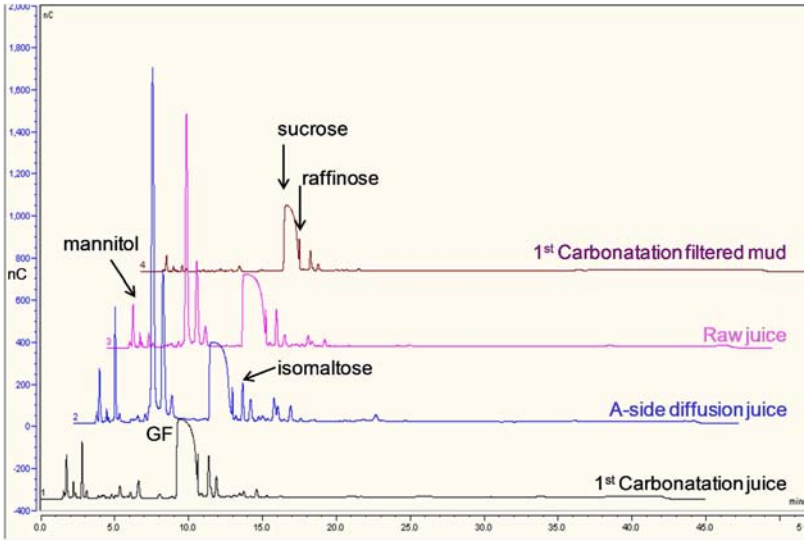

Figure 11. IC-IPAD oligosaccharide profiles of various products from a U.S. sugar beet factory (February 2014) to diagnose processing problems. The factory had been suffering from multiple sugar beet processing problems including freeze−thaw cycles of the sugar beets on storage and low-purity sugar beets.

have used yeasts such as *S. cerevisiae* and its derived mutants. Basso et al.[37] reported results from a yeast selection program consisting of 12 years of cumulative research data aimed at selecting *S. cerevisiae* strains suitable for fermenting sugar cane substrates (juice or molasses) into fuel ethanol in Brazil. A great yeast diversity exists with respect to fermentation characteristics, those being high yield, reduced glycerol and foam formation, maintenance of high viability during recycling, high transfer ability into industrial fermenters, and tolerance to inhibitor compounds and high concentrations of end-product.[37,38] Another important and associated issue for industrial fermentations includes the control of contaminating microorganisms,[39] for example, by the application of sulfuric acid or antibiotics, to maximize fermentation yields. Amorim et al.[40] of Fermentec Ltda., Piracicaba, Brazil, have selected yeast strains particularly for Brazilian bioethanol processing needs and have evaluated different yeasts for sweet sorghum and corn fermentations (H. Amorim, Fermentec Ltda., personal communication). With increased interest in the production of fuel ethanol and other biofuels and bioproducts from sweet sorghum and other biomass crops, there is now a need to select yeasts that can utilize maltose and other maltooligosaccharides from starch to augment fermentation yields.[41] This is because starch occurs in much greater amounts in sweet sorghum than in sugar cane, being particularly rich in the seed heads but also found in relatively large amounts in other tissues.[41]

Figure 10 displays how we have used IC-IPAD fingerprint profiles to simultaneously (i) screen yeast for their ability to utilize maltose in a sweet sorghum juice, (ii) check that bacterial contamination has not occurred in the fermentation broth, particularly from *Leuconostoc* and *Lactobacillus* bacteria, and (iii) qualitatively monitor the production of ethanol and consumption of glucose, fructose, and sucrose. Hanko and Rohrer[42] previously reported the use of IC-IPAD to determine carbohydrates, sugar alcohols, and glycols in cell cultures and fermentation broths. By using IC-IPAD profiles, it was found that baker's yeast was not able to utilize maltose, but distiller's yeast could (results not shown).

Isolation of Microbial Infections and Processing Problems at Sugar Beet Factories. We are frequently asked to solve acute processing problems in a multiple array of factories, refineries, and distilleries that are part of the sugar industry or connected to it. The IC-IPAD profile method is always the first diagnostic tool we apply to "problem" samples, because of the breadth of visual data gained from one chromatogram and the method's high sensitivity and selectivity. Examples of the use of IC-IPAD profiles as a diagnostic tool applied on problem sugar beet factory samples are illustrated in Figure 11. This factory had been suffering from multiple sugar beet processing problems including (i) freeze−thaw cycles of the stored sugar beets, (ii) low purity and relatively high fiber sugar beets, and (iii) bacterial infections causing substandard lime mud filtration during the carbonatation clarification process (Greg Golovanoff, Amalgamated Sugar, Boise, ID, USA, personal communication). Sugar beet juices, in comparison to sugar cane and sweet sorghum juices, contain very little glucose and fructose, which is illustrated in the first carbonatation juice and filtered mud. By using the IC-IPAD method we were able to isolate a lactic acid bacterial infection in the A-side of a tower diffuser (method used to extract juice from sugar beet juice) as compared to none in the B-side (results not shown). The high amounts of glucose and fructose in the raw juice sample also suggested that unwanted inversion reactions had occurred in the stored beet or in production of cossettes (Figure 11). Using this data, the factory personnel were able to mitigate this problem in the future by reconfiguring steam lines to the diffusers to allow the use of heat cycling for the practical reduction of reduce bacterial infections (Greg Golovanoff, personal communication).

It must be noted that anion-exchange columns other than the CarboPac PA1 have been developed that have greater resolution and require a lower sodium acetate concentration to elute the higher dp oligosaccharides as well as lower volume of eluent.[14] Also, Clarke et al.,[43] by utilizing a PAD waveform with six potentials, have allowed the detection of amino acids and amino sugars, which may be particularly more abundant in sugar beets.

were rarely studied in cultivation experiments. One study analyzing the influence of fertilization on the leaf glucosinolates of *Tropaeolum majus* L. showed that sulfur fertilization increased benzyl glucosinolate content, whereas nitrogen fertilization had no significant influence.[17] *M. oleifera* contained in all plant parts (below- and above-ground) very high levels of aromatic glucosinolates, which is a characteristic that makes this plant unique. In addition to some other trees in the families of Akaniaceae, Bretschneideraceae, or Gyrostemonaceae,[18] *M. oleifera* has in all plant parts considerable quantities of glucosinolates. Our knowledge of the glucosinolate content in tree species is only rudimentary compared to the numerous studies that have been conducted on the influence of nitrogen and/or sulfur fertilization on brassicaceous leafy plants.

Several studies have been undertaken about nitrogen and sulfur fertilization and their influence on phenolics in Brassicaceae.[19−22] Li and colleagues[20] as well as other authors[21,22] found an improving influence of sulfur fertilization on phenolic compounds in different *Brassica* species. Based on the findings of the aforementioned studies, the influence of sulfur fertilization on the content and composition of phenolic acids and flavonoids was analyzed using *M. oleifera* ecotypes.

Because of the fact that one characteristic of *M. oleifera* is drought tolerance and that harvest takes place all year round, the influence of water deficiency on the polyglycosylated aromatic glucosinolates was also analyzed. Because *M. oleifera* is not an annual plant like other herbaceous species containing glucosinolate, results are difficult to predict. Analysis of other studies showed enhancing or decreasing effects depending on the extent of water stress (e.g., refs 23 and 24) and plant species (e.g., refs 25 and 26). On the basis of different previous studies, which show increasing phenolic content after drought stress,[27,28] a change in the content and composition of phenolics in *M. oleifera* leaves is conceivable. Therefore, the corresponding analyses were included in the present study.

Because studies on accumulation of secondary metabolites under varying conditions are rare or nonexistent for *M. oleifera*, effects of sulfur fertilization and drought stress on plant growth and levels of secondary metabolites in the leaves of different *M. oleifera* ecotypes were investigated. The results will generate information providing insights into the optimal cultivation conditions for *M. oleifera* ecotypes. The overarching aim of the study was to find differences in *M. oleifera* ecotypes in growth and secondary metabolite content to determine the most suitable ecotype for leaf and secondary metabolite production. The goal was to identify an optimal cultivation variant with the best plant-growth performance and the highest secondary metabolite content. The results provided information about how to achieve a high yield in biomass as well as potentially health-promoting ingredients in the cultivation of *M. oleifera*.

MATERIALS AND METHODS

Cultivation Experiments in Großbeeren. After a prescreening using 13 different ecotypes of *Moringa oleifera* Lam., seeds of the six best-germinating and -growing ecotypes were selected for the experiments. The *M. oleifera* ecotypes were precultivated in a greenhouse at the Leibniz-Institute of Vegetable and Ornamental Crops in Großbeeren (Germany). Seeds from four ecotypes adapted to different climatic conditions were obtained from AVRDC - The World Vegetable Center (Taiwan): TOT4880 (origin USA, ecotype 1); TOT5028 and TOT7277 (origin Thailand, ecotypes 2 and 3); TOT7267 (origin India, ecotype 4). Seeds from the other two ecotypes were collected in the Philippines and Taiwan (ecotypes 5 and 6). Seedlings (8 weeks old) were planted in grid patterns at 0.5 m apart in a 1 m deep enclosed greenhouse bed. Drip irrigation and a nebulization system were used to humidify soil and air. In 2010, the mean temperature during the vegetation period (from June to October) in the greenhouse was 19.5 °C (2011: 18.6 °C and 2012: 19.5 °C) and varied during this period between a maximum temperature of 23.5 °C in July and a minimum temperature of 16.3 °C in October (2011: 20.5 °C in August and 14.6 °C in October; 2012: 22.3 °C in July and 15.7 °C in October). The ventilation temperature was set to 19 °C. Biomass production, height, and total glucosinolate content were determined to analyze ecotype differences. Plant samples were taken in August 2010 (first harvest, H1), November 2010 (second harvest, H2), July 2011 (third harvest, H3), October 2011 (fourth harvest, H4), and August 2012 (fifth harvest, H5). The leaf/stem ratio of well-established plants was analyzed from plant material at the second harvest, November 2010. By this time, the plants had grown into completely developed trees.

Furthermore, the influence of different growing variants on the growth and secondary metabolite content (glucosinolates, phenolic acids, and flavonoids) of the six *M. oleifera* ecotypes was analyzed in November 2010 (second harvest) and in July 2011 (third harvest) (normal variant, sulfur variant, water-deficiency variant; Supporting Information, Table 1). Per variant and ecotype 5 plants were cultivated. Each growing variant was located in a closed bed surrounded with concrete, separating the variants from one another. All beds were fertilized (basic fertilization) with 7.04 g/m^2 nitrogen (372 g of calcium ammonium nitrate per parcel, twice a year), 2.56 g/m^2 phosphorus (Superphospate, 465 g of phosphorus pentoxide per parcel), and 5.76 g/m^2 potassium (Patentkali, 330 g of potassium oxide per parcel) once a year at the end of April/beginning of May. The plants of the sulfur variant received an additional 0.704 g/m^2 sulfur annually (56 g of potassium sulfate per parcel). To reach low to moderate water deficiency in one bed, the irrigation and the nebulization system for the whole cabin was switched off in defined periods (August−November 2010 and June−September 2011). In the cultivation beds containing the normal and sulfur variant, a continuous soil water tension of approximately 50−100 hPa was maintained. In the bed with the water-deficiency variant, a higher soil water tension was determined (second harvest: 380 hPa, third harvest: 175 hPa; Supporting Information, Figure 1). At the second harvest, the upper limit of the field capacity (FC) was exceeded (FC ranged between 63−316 hPa, therefore pF 1.8−2.5). The water content of the sandy soil was at this time <2%. At the third point of harvest, the soil water tension was in the range of field capacity. Tensiometers used had a measurement range between 0 and 1.000 hPa. A rewetting of the dry bed from December 2010 to May 2011 was necessary to prevent plants from death. Wilting and chlorosis of leaves have been recognized.

Leaves from the top of the plants (upper 20 cm, youngest leaves) were used for the analysis of glucosinolates, flavonoids, and phenolic acids (secondary metabolites). In this way, it was possible to guarantee that leaf material of the same age was used for analysis. The glucosinolate content of older and middle-aged leaves was determined additionally to get an idea of the allocation of the glucosinolate over the whole plant. After each sampling, the whole plantation was pruned back to a height of 60−70 cm. Because of space limitations in the

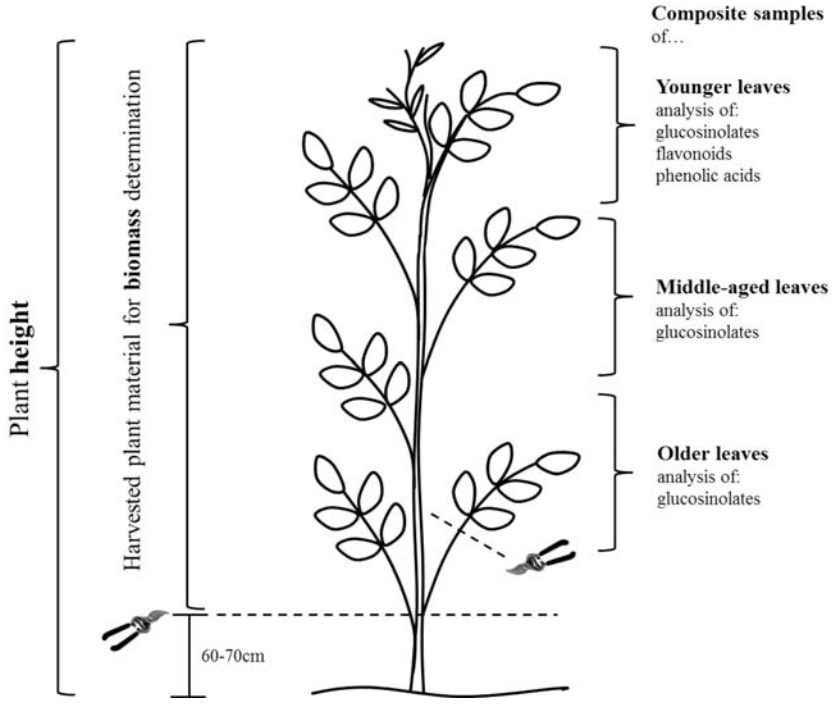

Figure 1. Sampling of plant material of *Moringa oleifera*.

greenhouse, a doubled pruning of the plants was required. The biomass was determined at each harvest by weighing the freshly cut plant material (leaves and stem of each plant, which exceeded the 60−70 cm). As an example, for the first harvest, the glucosinolate profit per plant was calculated to show ecotype variability (Supporting Information, Table 2).

For all cultivation variants, samples from five different plants per ecotype were taken according to Figure 1. Therefore, the analysis was performed in five replications.

Determination of Glucosinolates. Leaf material for glucosinolate analysis was shock-frozen in liquid nitrogen and kept at −20 °C until freeze-drying. The content and composition of *M. oleifera* glucosinolates were determined using a method for extraction of intact glucosinolates described in detail by Förster et al.[29] Briefly, a methanolic extraction (70%) was performed in three steps with 20 mg of pulverized leaf material (Retsch Mixer Mill MM 301, fineness about 5 μm, manufacturer specifications). The combined supernatant was concentrated (vacuum concentrator, Thermo Scientific Savent SPD111 V Concentrator; vacuum pump, Vacuumbrand PC 3000 series, SVC3000) and precipitated with barium acetate (0.4 M). After precipitation (30 min), samples were centrifuged (16 000 g, Thermo Scientific, Heraeus Megafuge 11R Centrifuge for 10 min), decanted, and filled up to 2 mL with ultrapure water. In each HPLC vial, 1 mL of filtered sample (Costar SpinX tubes) was transferred. The remaining amount of each sample was incubated with 0.05 U myrosinase (thioglucosidase, Sigma-Aldrich) for 8 h at 37 °C to hydrolyze glucosinolates to their corresponding breakdown products. Hydrolyzed samples were filtered (Costar SpinX tube) and transferred to HPLC sample vials for analysis. The internal standard, 2-propenyl glucosinolate, was added at the first extraction step.

Extracts were qualitatively and quantitatively analyzed on a Merck Hitachi HPLC system. A volume of 10 μL of sample was injected (LaChrom L-7200 auto sampler) and separated on a 4.6 × 250 mm SB-C18 column (Zorbax 5 μm, Agilent) using a gradient program described by Förster et al.[29] Two solvents were used for the HPLC analysis: solvent A, 100% 0.1 M ammonium acetate, and solvent B, 40% acetonitrile/0.1 M ammonium acetate. Detection was performed at 229 nm using a photodiode array detector (LaChrom L-7455), and components were identified from the retention time and quantified against internal standard. The peak area remaining after myrosinase treatment of the intact glucosinolate extract was subtracted from the peak area of the glucosinolate of the intact glucosinolate extract without myrosinase treatment. Interfering/coeluting ballast compounds were excluded from the calculation by using myrosinase (described in detail by Förster et al.).[29] Relative response factors (RF) were used according to Förster et al.[29] and were therefore generated from fractionated standards.

Determination of Flavonoids and Phenolic Acids. Flavonoids and phenolic acids in *M. oleifera* leaves were analyzed using a slightly modified HPLC method described by Mewis et al.[30] A total of 20 of mg lyophilized, powdered leaf material was extracted in 300 μL of 70% methanol (pH 4, acetic acid) for 15 min in ice water using sonification (Bandelin Sonorex Super AG 102H). The pellet was re-extracted twice with 300 μL of the extraction solvent for 10 min. After each extraction step, the samples were centrifuged for 5 min at 16 000 g (Thermo Scientific, Heraeus Megafuge 11R Centrifuge), and the supernatants were combined. Supernatants were concentrated (vacuum concentrator, Thermo Scientific Savent SPD111 V Concentrator; vacuum pump, Vacuumbrand PC 3000 series, SVC3000) to near dryness, dissolved in 50% methanol, and filled up to 1 mL. The samples were centrifuged for 2 min, filtered (Costar SpinX tubes), and transferred to HPLC vials. 4-Methoxycinnamic acid (1 mmol/L, Sigma-Aldrich) was used as internal standard.

Extracts were qualitatively and quantitatively analyzed on a HPLC−MS/MS system (Agilent 1100 Series, Waldbronn,

[a]Significant differences were determined using Tukey's HSD test, $p < 0.05$ (capital letters: significant differences between the harvests; lower case letters: significant differences between the ecotypes); z = glucosinolate content.

Germany). A volume of 10 μL of extract was injected and separated using a 150 × 2.1 mm C16 column (AcclaimPA, 3 μm, Dionex) with the following gradient program: 0−1 min, 0.5% B; 1−10 min, 0.5−40% B; 10−12 min, 40% B; 12−18 min, 40−80% B; 18−20 min, 80% B; 20−24 min, 80−100% B; 24−30 min, 100% B; 30−34 min, 100−0.5% B; and 34−39 min, 0.5% B at a flow rate of 0.4 mL/min. Two solvents were used for analysis: solvent A, H_2O (0.5% formic acid), and solvent B, 40% acetonitrile. The oven temperature was 35 °C. Detection was carried out at 290, 320, and 370 nm on a photodiode array detector. Because all components showed a good signal at 290 nm, the compounds were quantified against internal standard 4-methoxycinnamic acid detected at this wavelength. Compounds were identified as deprotonated molecular ions and characteristic mass fragment ions by HPLC-DAD-ESI-MS.[2] Commercially available standards of single compounds were used as references. Relative response factors (RF) were used to correct for absorbance differences between the reference standard 4-methoxycinnamic acid (RF = 1): RF = 1.16 for chlorogenic acid (Sigma-Aldrich) and an isomer of chlorogenic acid, RF = 1.06 for neochlorogenic acid (Sigma-Aldrich), RF = 1 for the two isomers of *p*-coumaroyl quinic acid and an isomer of feruloyl quinic acid (commercial standard not available), RF = 1.51 for vitexin (Fluka) and isovitexin, RF = 1.53 for quercetin 3-*O*-glucoside (Carl Roth GmbH), RF = 1.4 for kaempferol 3-*O*-glucoside (Carl Roth GmbH), RF = 1.84 for quercetin 3-*O*-(6″-malonylglucoside) (Sigma-Aldrich) and kaempferol 3-*O*-(6″-malonylglucoside) (commercial standard not available).

Statistical Analysis. Data were analyzed for significant differences using analysis of variance (ANOVA) following the mean comparison test, Tukey's HSD, with SigmaPlot 12.0. Cross dependence was analyzed by using the two-way ANOVA. The p-value was fixed at $p < 0.05$; any exceptions are mentioned in the text.

RESULTS

Ecotype Differences. *Biomass, Height, and Glucosinolate Content.* In addition to the growth parameters, ecotype differences in secondary metabolites were analyzed by focusing on the glucosinolates that were considered to have health-promoting effects. The data were collected at five different harvest points (Table 1). A very high variability among ecotype replicates in biomass production, height, and glucosinolate content can be noticed. Significant differences were hard to identify. When considering all points of harvest, ecotypes 1, 2, and 4 had the highest biomass. Ecotypes 2, 3, 5, and 6 were significantly smaller than ecotype 4 (Table 1). On average across all ecotypes at each point of harvest, the biomass production and plant height were significantly higher at the third and fifth points of harvest in comparison to the other points of harvest. Considering the glucosinolate levels, ecotype 3 contained significantly lower glucosinolate content than the other ecotypes (Table 1). Ecotype 1 showed the highest glucosinolate content overall. The mean glucosinolate content of all analyzed ecotypes was significantly lower at the first point of harvest. At the second and fifth points of harvest, the ecotypes showed a significantly higher glucosinolate content in comparison to the other points of harvest. No significant interaction between the point of harvest and the ecotype was found for the biomass production, plant height, and glucosinolate content (two-way ANOVA, $p < 0.05$). Taking height, biomass, and glucosinolate content of the five harvest points into consideration, ecotypes 1 and 4 were found to be the best performers in terms of biomass production and glucosinolate amounts in leaves. Not surprisingly, we detected a correlation between height and biomass. With an elimination of extreme values, a polynomial dependency ($y = 0.0153x^2 - 0.7184x$, $R^2 = 0.80$) was found. In contrast, no correlation was found between biomass/height and glucosinolate content. Also,

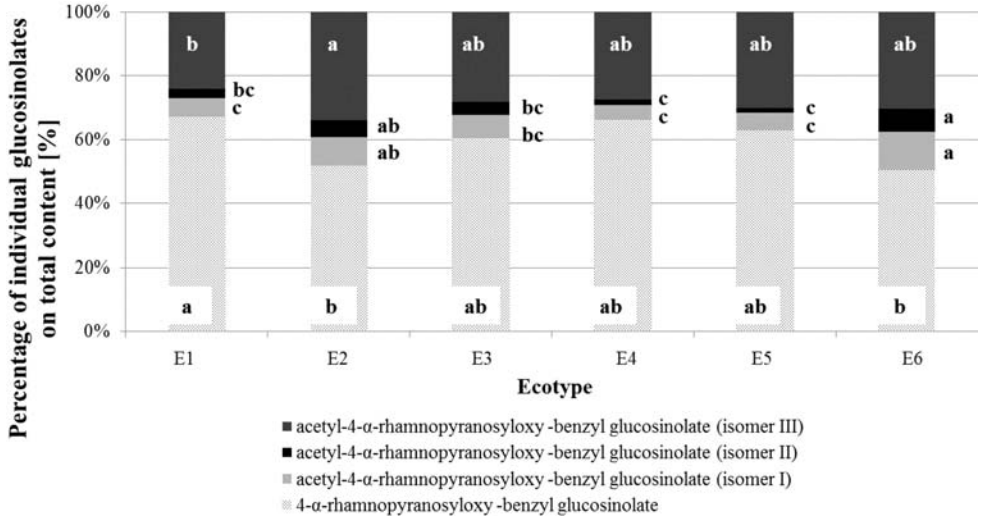

Figure 3. Percentage of single *Moringa oleifera* glucosinolates on the total glucosinolate content in leaves at the third point of harvest (different letters indicate significant differences between the different ecotypes within each glucosinolate, Tukey's HSD test, $p < 0.05$).

the leaf−stem ratio did not differ between the six *M. oleifera* ecotypes. A total of 60% of the tree biomass harvested was formed by the leaves (Supporting Information, Table 2).

Glucosinolate Profile. *M. oleifera* ecotypes differed in their total glucosinolate content depending on the date of harvest. In all six ecotypes, four *Moringa* glucosinolates were identified: 4-α-rhamnopyranosyloxy-benzyl glucosinolate (Rhamno-Benzyl-GS) and three isomeric acetyl-4-α-rhamnopyranosyloxy-benzyl glucosinolates (Ac-Isomer-GSs I−III, Figure 2). As an exception in individual plants of ecotypes 5 and 6, only one glucosinolate, Rhamno-Benzyl-GS, was found. Furthermore, the six *M. oleifera* ecotypes exhibited differences in their glucosinolate composition. The percentage of individual glucosinolates relative to the total glucosinolate content was determined (Figure 3, exemplary presentation based on data from the third harvest, plants from ecotypes 5 and 6 with only Rhamno-Benzyl-GS were excluded from the calculation). Ecotype 1 displayed a consistently higher percentage of Rhamno-Benzyl-GS and a lower percentage of Ac-Isomer-GS III. A low percentage of Rhamno-Benzyl-GS and a high

[a]Significant differences within each phenolic acid or flavonoid between the ecotypes, Tukey's-HSD-test, $p < 0.05$.

percentage of the three Ac-Isomer-GSs were found for ecotypes 2 and 6. Ac-Isomer-GS I was found at consistently low content levels in ecotypes 4 and 5, likewise Ac-Isomer-GS II in ecotypes 1, 4, and 5. Furthermore, the glucosinolate composition of younger and older leaves of the different *M. oleifera* ecotypes was compared, but no significant differences were observed (detailed data not shown).

Phenolic Acid and Flavonoid Profile. In *M. oleifera* leaves, the following phenolic compounds were identified: an isomer of chlorogenic acid, neochlorogenic acid, two isomers of *p*-coumaroyl quinic acid, an isomer of feruloyl quinic acid, chlorogenic acid, vitexin, isovitexin, quercetin 3-*O*-glucoside, kaempferol 3-*O*-glucoside, quercetin 3-*O*-(6″-malonylglucoside), and kaempferol 3-*O*-(6″-malonylglucoside) (Figure 2). The main phenolic acid was identified as neochlorogenic acid, and the main flavonoid was quercetin 3-*O*-(6″-malonylglucoside). The total phenolic acid content in the leaves differed significantly between the six *M. oleifera* ecotypes (Table 2). Ecotype 5 had a significantly higher phenolic acid content than ecotype 3 (one-way ANOVA, Tukey's HSD test, $p < 0.05$). The phenolic acid content ranged between 9.86 and 17.08 μmol/g dry weights (dw), and the flavonoid content ranged between 4.47 and 10.73 μmol/g dw. Significant differences between single phenolic acids and flavonoids were identified (Table 2). Vitexin and isovitexin were found in all plants of the *M. oleifera* ecotype 5, whereas these secondary metabolites were not present in detectable levels in the plants of ecotypes 2 and 3. No correlation was found between plant height and the phenolic acid/flavonoid content ($R^2 < 0.06$). In summary, ecotypes 4 and 5 had the highest contents of flavonoids and phenolic acids.

Influence of Water Deficiency and Sulfur Fertilization on Biomass, Height, and Secondary Metabolite Content of *M. oleifera* Ecotypes. The influence of water deficiency and sulfur fertilization on biomass accumulation, plant height, and the secondary metabolite profile (glucosinolate, phenolic acids, and flavonoids) was analyzed in six *M. oleifera* ecotypes. Contrary to the results of the second point of harvest (plants were exposed to drought stress, Supporting Information, Figure 2), plants showed stronger reactions at the beginning of a repeated water limitation (third point of harvest, Figure 4). Therefore, the results of the third point of harvest are presented in more detail in the present work. At the third point of harvest, the plants in the normal cultivation variant were significantly taller and had a higher biomass than plants grown under water limitation (Figure 4, Tukey's HSD test, $p < 0.05$). The glucosinolate content was overall significantly higher in the water-deficiency variant in comparison to the normal variant (Tukey's HSD test, $p < 0.05$). Cultivation conditions had different impacts on biomass accumulation, plant height, and glucosinolate content of the six ecotypes (Figure 4). No statistically significant correlation between the cultivation variant and the ecotype was found for the glucosinolate content, biomass, and plant height (two-way ANOVA, $p < 0.05$). Although no influence of the cultivation variant on the flavonoid content was identified for the single ecotypes, statistical differences in the phenolic acid content were found (Figure 5, ecotypes 1 and 4). With regard to the sum of phenolic acids and flavonoids, ecotypes 1 and 2 had significantly higher levels in the sulfur variant in comparison to the normal variant. Ecotypes 3 and 4 had significant higher levels in the drought variant in comparison to the normal variant (Tukey's HSD test, $p < 0.05$). A statistically significant interaction between the cultivation variant and ecotype was identified (two-way ANOVA, $p < 0.01$). In general, the effect of the cultivation variant on the plant biomass and content of glucosinolates, phenolic acids, and flavonoids strongly depended on the ecotype.

DISCUSSION

M. oleifera ecotypes are characterized by phenotypic differences, such as the shape of leaves, the production of leaf biomass, the plant height, and the secondary metabolite profile, as reported in other studies.[3,12,31] Therefore, the intensive cultivation of *M. oleifera* ecotypes should be associated with a high yield of leaf biomass and secondary metabolites. Differences in the secondary metabolite content and composition have not been the basis for selecting ecotypes for intensive cultivation until today, although the health-promoting effects of chemical compounds of *M. oleifera* are commonly described next to its nutritional value.[2,9] The six different *M. oleifera* ecotypes used in this study showed morphological (height and biomass) and chemical (glucosinolates, phenolic acids, and flavonoids)

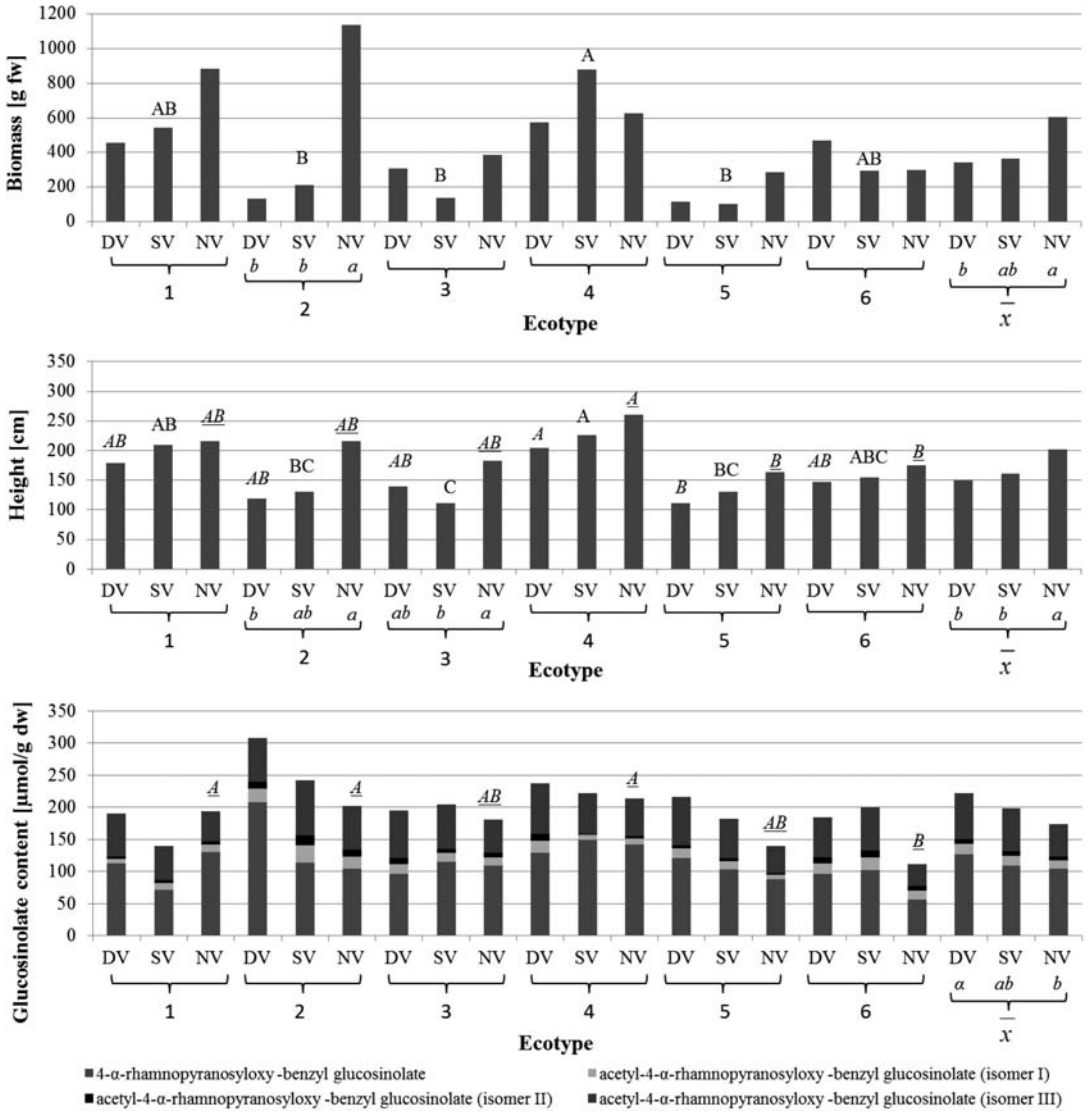

Figure 4. Influence of cultivation variants on biomass, height, and glucosinolate content of six *Moringa oleifera* ecotypes at the third point of harvest (lower case letters = significant differences between the cultivation variants within each ecotype; capital letters = significant differences between the different ecotypes within one cultivation variant; Tukey's HSD test, $p < 0.05$; DV = water-deficiency variant; SV = sulfur variant; NV = normal variant).

phenotypic differences under similar cultivation conditions. Ecotypes 1 and 4 were identified as having the highest yields of biomass and glucosinolate content (Table 1), and ecotypes 4 and 5 were identified as having the highest yields of phenolic acids and flavonoids, followed by ecotypes 1 and 6 (Table 2). It is most likely that the diverse characteristics in the phenotype (growth characteristics and chemical profile) found in our analysis are fixed genetically because the ecotypes arise from germplasm collection and were cultivated and analyzed in a similar manner. To exclude the effects of the environment on the analyzed parameter, seeds were sown and planted at the same time so that each plant was of the same age and at the same developmental stage. Interestingly, most trees of ecotypes 5 and 6 in the present study contained only one glucosinolate, Rhamno-Benzyl-GS, with none of the three Ac-Isomer GSs. This observation was not described by other authors. Shockey et al.[32] reported that acyl-activating enzymes are present in all living organisms. According to these authors, *Arabidopsis thaliana* L. possesses an acyl-activating enzyme superfamily containing 63 different genes. It is conceivable that different enzyme activity in the plants could lead to a lack of acetylated glucosinolates in some plants of the *M. oleifera* ecotypes.

As described by Brown et al.[33] for *A. thaliana*, we found higher glucosinolate contents in the younger leaves of *M. oleifera* than in the older leaves, whereas no differences in glucosinolate composition were determined (Supporting Information, Table 2). This could be explained by glucosinolate concentration dropping and stabilizing during leaf expansion.[33]

Consistent with findings of several authors in different glucosinolate containing plant species,[31,34] the glucosinolate content of the *M. oleifera* plants tended to increase as the plant matured. Although the glucosinolate content increased for all ecotypes at approximately 50−100%, the biomass accumulation increased at different degrees depending on the ecotype. Analysis using different *Salix* clones, a tree species that is very similar in its growth characteristics and high content of secondary metabolites (salicylates) to *M. oleifera*, showed that the amount of shoots and the biomass increased in trees of three different species from the first to the second year after planting.[35] On the one hand, this increase can be attributed to

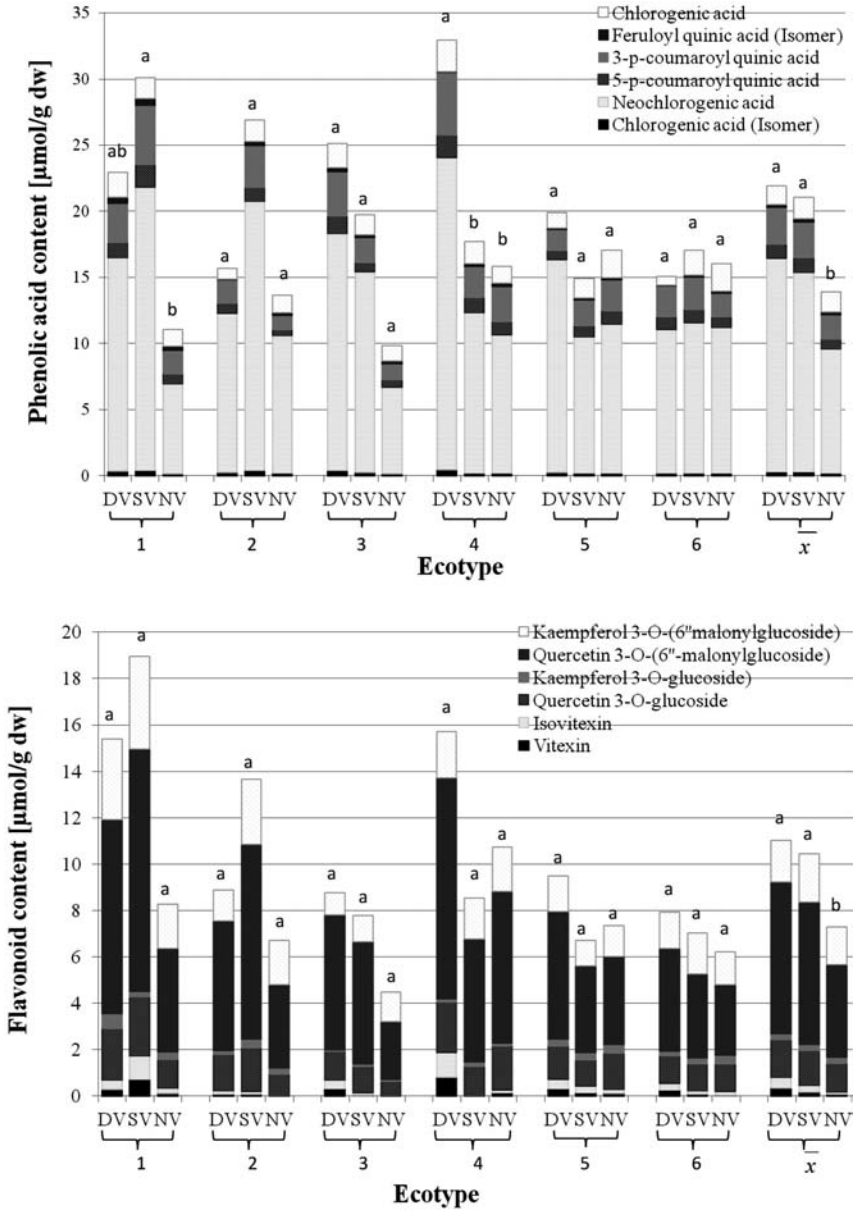

Figure 5. Phenolic acid and flavonoid content of six *Moringa oleifera* ecotypes in different cultivation variants at the third point of harvest (lower case letters = significant differences in total contents between the cultivation variants within each ecotype; Tukey's HSD test, $p < 0.05$; DV = water deficiency variant; SV = sulfur variant; NV = normal variant).

different environmental conditions at the harvests (temperature, day length, and solar radiation). On the other hand, the plant became better adapted over time (root penetration in the rhizosphere and access to existing water and nutrition sources). The ecotypes seem to be able to adapt to the set environmental conditions at a different speed and degree because of a variable increase in biomass accumulation over the five harvest points. A possible influence of plant age on phenolic acids and flavonoids will not be discussed at this point because these secondary metabolites were only determined at the second and third point of harvest.

Different authors have described the influence of nitrogen and sulfur fertilization[15,16,36] and different water regimes[23] on the glucosinolate content and growth of plants. Our analysis did not show a consistent result of either sulfur fertilization or water deficiency on growth and secondary metabolite accumulation in *M. oleifera*. Under water limitation (second point of harvest) ecotypes showed no differences in biomass accumulation and glucosinolate content (Supporting Information, Figure 2). With repeated moderate water limitation (third point of harvest, soil water tension did not exceed the range of the field capacity; Supporting Information, Table 3), biomass and plant height were reduced; on average across all ecotypes, the glucosinolate content increased in comparison to the normal variant (Figure 4). The content of phenolic acids (more so than flavonoids) at the third point of harvest was significant lower in the normal cultivation variant in comparison to the sulfur variant and under water limitation (Figure 5). Growth and glucosinolate content were not significantly influenced by sulfur fertilization. Additional sulfur input could not be identified in soil analyses two months after fertilization, indicating a complete sulfur uptake of plants. For further studies, more frequent and higher sulfur fertilization is recommended. Clearly, all effects are strongly ecotype-depend-

ent. To our knowledge, there are no studies available about the influence of sulfur and water deficiency on the growth and secondary metabolite content of *M. oleifera*. *M. oleifera* seems to be an intermediate between annual brassicaceous plants that contain glucosinolate and fast-growing tree species; this makes a comparison of the growth as well as secondary metabolite development of *M. oleifera* with other plants described in the literature very difficult. Furthermore, this rapidly growing tree is cut back several times a year,[1] which makes it even more difficult to compare growth parameters with other trees. Regular pruning, as also performed with the trees in the present study, promotes a compact and dense habitus, and the trees were much more strongly branched, resulting in an increased biomass accumulation. Clearly, the results of the present study showed that different cultivation variants influenced the morphological and chemical phenotype of single *M. oleifera* ecotypes differently.

A trade-off between biomass accumulation and secondary metabolite production, for example, as observed in the fast-growing tree species *Salix sericea* Marsh by Nichols-Orians et al.,[37] was not generally the case for the *M. oleifera* ecotypes investigated here. Ecotypes 1, 2, and 4 each had a biomass twice as high as those of ecotypes 5 and 6. At the same time, the glucosinolate content of ecotypes 1, 2, and 4−6 was not significantly different (Table 1). These findings are not in agreement with the trade-off between growth and defense over a resource-availability gradient, as stated in the growth-differentiation-balance hypothesis. However, on average across all ecotypes, the biomass accumulation was significantly higher in the normal cultivation variant in comparison to plants grown under drought stress at the third point of harvest. We found the opposite pattern for the glucosinolate content. These findings confirm results from Zhang et al.[24] or Schreiner et al.[38] that determined increased glucosinolate contents under moderate drought stress in *Brassica carinata* A. Braun and *Brassica rapa* L. ssp. *rapa*, whereas other authors found contradictory results (e.g., ref 39). The content of phenolic acids and flavonoids was not dependent on the biomass and plant height of *M. oleifera*.

Observed phenotypic differences under the same environmental conditions as in the present study can be attributed to plant genetics. The effects of sulfur and water deficiency (different cultivation variants) on six *M. oleifera* ecotypes, as a tree containing glucosinolate, had not previously been the subject of investigation. The phenotype of *M. oleifera* plants depended on the analyzed environmental factors (water deficiency and sulfur supply). This demonstrates that the plant genetics determine biomass production, growth, and content of phytochemicals, although environmental factors can modulate these parameters.[31] The presented results showed that no general cultivation recommendations can be made. The optimal cultivation of *M. oleifera* seems to be highly dependent on the ecotype. Nevertheless, potential suitable ecotypes, meeting the criteria of an optimal leaf yield (high biomass) with high levels of nutritional and health-promoting properties (glucosinolate, phenolic acid, and flavonoid content) in addition to a capability to withstand water limitation could be identified within the present study: Ecotypes 1 (TOT4880, origin USA) and 4 (TOT7267, origin India). Because of an enormous suggestibility of growth and secondary metabolites by the environment, findings should be proved in field trials in *M. oleifera* cultivation areas.

amino acids. In addition to the most abundant 7S β-conglycinin and the 11S glycinin, soybeans also accumulate a few other proteins that contain higher concentrations of methionine and cysteine. Earlier studies have demonstrated low-level accumulation of a methionine-rich protein in soybean seeds.[7,8] This 2S albumin protein contains 8.6% methionine and has been proposed as a candidate protein for overexpression in transgenic soybean seeds to elevate the methionine content.[9] Other potential proteins for overexpression in soybean include the Bowman−Birk inhibitor (BBI) and the BBI-related family of isoinhibitors. These protease inhibitors are rich in cysteine and are mainly responsible for the overall sulfur-containing amino acids of soybean seed.[10−12]

Leginsulin, a peptide consisting of 37 amino acids, belongs to the cysteine-knot family[13] and is homologous to pea (*Pisum sativum* L.) albumin (PA1b).[14] Soybean leginsulin is synthesized as a precursor polypeptide that is subjected to post-translational processing to give rise to 6 and 4 kDa peptides.[15−17] The 4 kDa peptide that is rich in cysteine residues is coined "leginsulin". We have previously shown that this peptide is preferentially soluble in 50% isopropanol and that the accumulation of this cysteine-rich peptide is drastically higher in Asian than in North American soybean accessions.[18] Furthermore, it was demonstrated that the soybean genome contains two leginsulin genes, which are differentially expressed in the embryonic axis and the cotyledons.[18] Because North American soybean cultivars accumulate low levels of leginsulin, we hypothesized that overexpression of this cysteine-rich peptide in North American soybean cultivars would improve their overall cysteine content. In this study, we crossed PI 427138, an Asian soybean accession, with an experimental North American line, resulting in lines that exhibited significantly higher protein content with improved protein quality. However, the amount of sulfur-containing amino acids was not increased.

MATERIALS AND METHODS

Reagents. Acrylamide, bis-acrylamide, ammonium persulfate, *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED), and Coomassie Brilliant Blue G-250 and R-250 were obtained from BioRad Laboratories, Inc. (Hercules, CA, USA). Protease inhibitor cocktail (Plant ProteaseArrest) was obtained from G-Biosciences (St. Louis, MO, USA). IPG strips were obtained from GE Healthcare (Piscataway, NJ, USA). Urea, thiourea, and β-mercaptoethanol were obtained from Fisher Scientific (Pittsburgh, PA, USA). Dithiothreitol (DTT), iodoacetamide, EDTA, and 2-hydroxyethyl disulfide (2-HED) were obtained from Sigma-Aldrich (St. Louis, MO, USA).

Plant Material. During the course of identification of soybean lines exhibiting high BBI activity, we serendipitously identified PI 427138 as a soybean line accumulating high amounts of leginsulin. In 2007, LD00-3309 was crossed with PI 427138 in Urbana, IL, USA. LD00-3309 is an early-maturity group IV cultivar developed at the University of Illinois and was selected because it was one of the highest yielding, publicly developed cultivars available at the time.[19] In 2008, two F1 plants were grown, and the seeds from each plant were harvested separately. In 2009, approximately 500 seeds were planted from each F1 plant. The F2 populations confirmed that each putative F1 plant was the product of cross-pollination with segregation for flower and pubescence color as expected, and 285 plants were harvested and threshed individually. In 2010, seeds from each harvested F2 plant were planted in rows 1.2 m long. Between 1 and 5 single plants were harvested from 66 rows selected for agronomic appearance for a total of 172 plants. In 2011, 27 of the F4 plant rows had a homogeneous appearance and acceptable agronomic characteristics and were bulk harvested.

Seeds from 40 F4 lines with acceptable agronomic characteristics were selected for characterization. Fifty percent isopropanol soluble proteins were isolated from these 40 F4 plants and examined for the accumulation of leginsulin. Examination of Coomassie-stained gels revealed that 15 plants accumulated high amounts of leginsulin (Supplemental Figure 1). We also measured the sulfur content of the soybean seeds from 40 plants by inductively coupled plasma−mass spectrometry. The sulfur content of these plants ranged from 3000 to 4000 ppm (Supplemental Figure 2). Seeds from the 40 plants were advanced another generation, and seeds from lines having a homogeneous appearance and acceptable agronomic characteristics were bulk harvested. From these F5 plants, we selected two lines (Leg-3 and Leg-7) that accumulated high amounts of leginsulin and high sulfur content for further characterization. Another line (Leg-8) that had high sulfur content but failed to accumulate leginsulin was also selected for further analysis.

Small plots of the three experimental lines plus the two parents were planted in two replications at Bellflower, Ivesdale, and Urbana, IL, USA, and Bradford, MO, USA, and on two soil types at Portageville, MO, USA. Seeds were harvested from all plots for analysis.

Nitrogen Content. Fifteen seeds per line from each field plot were ground to a fine powder and used for total nitrogen/protein analysis. Nitrogen content was measured using a LECO truSpec model FP-428 nitrogen analyzer (St. Joseph, MI, USA). A 200 mg sample of seed powder was combusted at 900 °C in a chamber in the presence of oxygen, leading to the release of carbon dioxide, water, and nitrogen. The gases were then passed over a potassium hydroxide aqueous solution, eliminating carbon dioxide and water. A column containing a thermal conductivity detector was then used to separate the nitrogen from any residual carbon dioxide and water, and the remaining nitrogen content was measured. The instrument was calibrated using ultrapure EDTA of known nitrogen content. The protein content of the seeds was inferred from its nitrogen content using a protein correction factor of 6.25. Three separate biological replicates were evaluated per line, and results were compared using standard deviation of the mean.[20]

Oil Content. The oil content of 10−15 seeds per line was determined using an Oxford Instruments America MQC Oilseeds Analyzer with a 26 mm probe (Concord, MA, USA). A 15-point calibration curve was built using data obtained from both pure soybean oil and soybean seeds of known oil contents (11−21%) as determined by the University of Missouri Experiment Station Chemical Laboratories (AOCS Official Method Ca 5b-71). Three separate biological replicates were evaluated per line, and results were compared using standard deviation of the mean. JMP version 9 software (SAS Institute Inc., Cary, NC, USA) was used to perform one-way analysis of variance (ANOVA) tests.[20]

Sulfur Content. Inductively coupled plasma−mass spectrometry was performed as previously described.[21] Individually weighed dry seeds were digested overnight with 2.5 mL of concentrated HNO_3 at room temperature before the samples were heated to 105 °C over 2 h and then cooled to room temperature over 2 h. Following this step, the samples were diluted with ultrapure water and transferred to 96-well autosampler plates. A PerkinElmer Elan DRC-e inductively coupled plasma mass spectrometer (Waltham, MA, USA) with an Apex Desolvation Nebulizer, a FAST sampling valve, and an Elemental Scientific SC4 DX autosampler (Omaha, NE, USA) was used for the analysis of sulfur. A liquid reference material composed of pooled samples of soybean digests was run every ninth sample to correct for ICP-MS run-to-run variation and within-run drift. All samples were normalized to the recorded dry weights.

Amino Acid Analysis. Amino acid analysis was performed at the Donald Danforth Plant Science Center Proteomics and Mass Spectrometry Facility. For the determination of the total amino acid content, the seed powder was first subjected to hydrolysis with 6 N HCl. For the quantification of methionine and cysteine, duplicate samples were first subjected to an initial oxidation step using performic acid prior to acid hydrolysis. Amino acids were quantified using the manufacturer's instructions for sample preparation in the Waters AccQ-Tag Ultra Kit and quantified on a Waters Acquity UPLC system

DOI: 10.1021/jf505202z
J. Agric. Food Chem. 2015, 63, 2862−2869

(Milford, MA, USA). Samples were run in quadruplicate and subjected to appropriate statistical analysis. Cysteine and methionine quantities are reported as cysteic acid and methionine sulfone.

1-D Electrophoresis. For 1-D electrophoretic analysis, dried mature seeds were ground into a fine powder, and 10 mg was placed into a tube for extraction using 1 mL of sodium dodecyl sulfate (SDS) sample buffer (60 mM Tris-HCl, pH 6.8, 2% SDS (w/v), 10% glycerol (v/v), and 5% 2-mercaptoethanol (v/v)) followed by boiling for 5 min. The clarified supernatant was resolved with 15% gels run using a Hoeffer SE 250 mini-Vertical electrophoresis apparatus (GE Healthcare). Separation was achieved with a constant 20 mA/gel and a typical run time of 1.2 h. Gels were removed from the cassette and placed immediately in Coomassie Blue R-250 solution.

Western Blot Analysis. Western blot analysis was performed as described earlier.[18] Briefly, total seed proteins or 50% isopropanol extracted proteins were first resolved on a 15% SDS-PAGE gels. Subsequently, the proteins were transferred to a 0.45 μm nitrocellulose membrane. After blocking with TBS (10 mM Tris-HCl, pH 7.5, 500 mM NaCl) containing 5% nonfat dry milk, the nitrocellulose membranes were incubated overnight with either lunasin or synthesized BBi peptide (N-CVDITDFCYEPCKPSEDDK) antibodies that had been diluted 1:5000 in TBST (TBS with 3% nonfat dry milk containing 0.2% Tween 20). Following three washings with TBST, the membranes were incubated with goat anti-rabbit IgG–horseradish peroxidase conjugate. Proteins reacting specifically with the antibodies were detected using the Pierce SuperSignal West Pico kit's instruction (Rockford, IL, USA).

2-D Electrophoresis. Sample preparation for 2-D electrophoretic analysis was carried out as previously described.[22] For isoelectric focusing, 300 μg of protein sample was loaded per strip using overnight in-gel rehydration. Linear gradient, 13 cm IPG strips (GE Healthcare) were brought to a rehydration volume of 250 μL with 7 M urea, 2 M thiourea, 1% CHAPS, 2% C7BzO, 5% glycerol, and 2.2% 2-HED. Strips were then passively rehydrated with the entire rehydration solution containing protein sample at 23 °C for 15 h prior to focusing. Prior to the second dimension, IEF strips were equilibrated with 5% SDS in a urea-based solution (0.05 M Tris-Cl, pH 8.8, 6 M urea, 30% glycerol, and 0.1% bromophenol blue) containing 2% DTT for 20 min and again but with 2.5% iodoacetamide for 20 min. IEF strips were placed carefully onto a Hoeffer SE600 (GE Healthcare) 16%T vertical second-dimension and secured into place with a warm 1% agarose SDS-PAGE running buffer solution (0.2% SDS). Gels were run at an initial 10 mA/gel for 1 h followed by 5 W/gel for the remainder of the run (elimination of dye front; approximately 4 h). After electrophoresis, the gels were immediately removed and fixed in 5:4:1 methanol/water/acetic acid for 30 min, followed by two brief rinses in water, and stained in a Coomassie G-250 solution overnight.

Image Acquisition and Analysis. 2-D Coomassie-stained gels were destained with multiple changes of ultrapure H_2O to remove background. Individual gels of PI 427138 and LD00-3309 were scanned separately using an Epson V700 Perfection scanner controlled through Adobe Photoshop. Images were analyzed using Decodon Delta2D v3.6 (Greifswald, Germany) to provide normalized percent spot volume data using a technique known as differential gel imaging. Essentially, each gel image was imported into Delta2D individually and overlaid to provide a combined fusion image in gray scale, whereas the individual images of each were assigned either a blue (PI 427138) or an orange (LD00-3309) color. Differences in color between the two samples indicate a higher or lower amount of that particular protein in that sample. Delta2D parameters were set to maximize spot detection (using *global* image warping and *exact* spot matching) and minimize background detection.

RESULTS

PI 427138 Accumulates High Amounts of Leginsulin. BBI and the BBI-related family of isoinhibitors are rich in cysteine and are mainly responsible for the overall sulfur-containing amino acids of soybean seed.[10−12] During the course of screening a diverse array of soybean accessions from the USDA Soybean Germplasm Collection for the identification of soybean lines with high and low contents of Bowman–Birk protease inhibitor, we serendipitously observed that soybean PI 427138 accumulated high amounts of a 4 kDa protein. We have previously shown that Asian soybean accessions accumulate higher amounts of a 4 kDa protein than the genetic base of U.S. cultivars.[18] On the basis of Western blot analysis and mass spectrometry, this protein was identified as leginsulin.[18] Even though this protein accumulates in higher amounts in Asian soybean accessions, its contribution to overall protein content of the seed is only minimal. To confirm the identity of the 4 kDa protein that is enriched in PI 427138, we performed Western blot analysis using antibodies raised against the leginsulin peptide. The antibodies reacted strongly against the 4 kDa peptide, indicating that this protein is leginsulin (Figure 1).

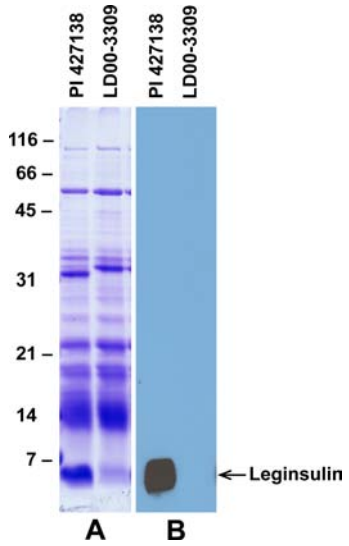

Figure 1. Accumulation of leginsulin in soybean seeds. Isopropanol (50%) soluble proteins were extracted from PI 427138 (lane 1) and LD00-3309 (lane 2), a high-yielding North American soybean cultivar, and analyzed by SDS-PAGE. Separated proteins were detected by staining the gel with Coomassie Blue (panel A) or electrophoretically transferred to a nitrocellulose membrane and reacted with leginsulin specific antibodies that were diluted 1:5000 in TBS containing 3% dry milk powder. Immunoreactive proteins were identified using anti-rabbit IgG–horseradish peroxidase conjugate followed by chemiluminescent detection (panel B). The arrow points to the 4 kDa immunoreactive peptide preferentially accumulating in PI 427138. The 4 kDa protein band in the stained gel is a mixture of the proteins, whereas the immunoreactive band shown in panel B is a single protein. The positions and sizes of the molecular weight markers in kilodaltons are shown on the left side of the figure. The same amount of protein used in panel A was used for the Western blot analysis (panel B). Also, note the size polymorphism of a prominent polypeptide (32–33 kDa) between PI 427138 and LD00-3309; however, the basis of this polymorphism is unknown (panel A).

Information on the country of origin, phenotypic data, and seed composition of PI 427138 was obtained from the USDA Germplasm Resources Information Network (GRIN) database (http://www.ars-grin.gov/cgi-bin/npgs/acc/search.pl?accid=PI+427138+). PI 427138 originated from South Korea, belongs to maturity group 0, and accumulates 48% protein and 14% oil. Earlier we reported the biochemical characterization of several high-protein soybean accessions.[23] By high-resolution two-

DOI: 10.1021/jf505202z
J. Agric. Food Chem. 2015, 63, 2862−2869

dimensional gel electrophoretic analysis, it was demonstrated that the 11S globulins (glycinin) were mainly responsible for the increased protein content of these high-protein soybean accessions. Because PI 427138 is also a high-protein accession, we wanted to examine its protein composition. For this purpose we performed high-resolution two-dimensional gel electrophoretic analysis of seed proteins of PI 427138 and compared it with LD00-3309, a high-yielding, publicly developed cultivar that contains 38% protein.[19] To monitor proteome differences between PI 427138 and LD00-3309, total seed proteins resolved by 2-DE were analyzed using Delta2D image analysis software (Figure 2). Delta2D parameters were set to maximize

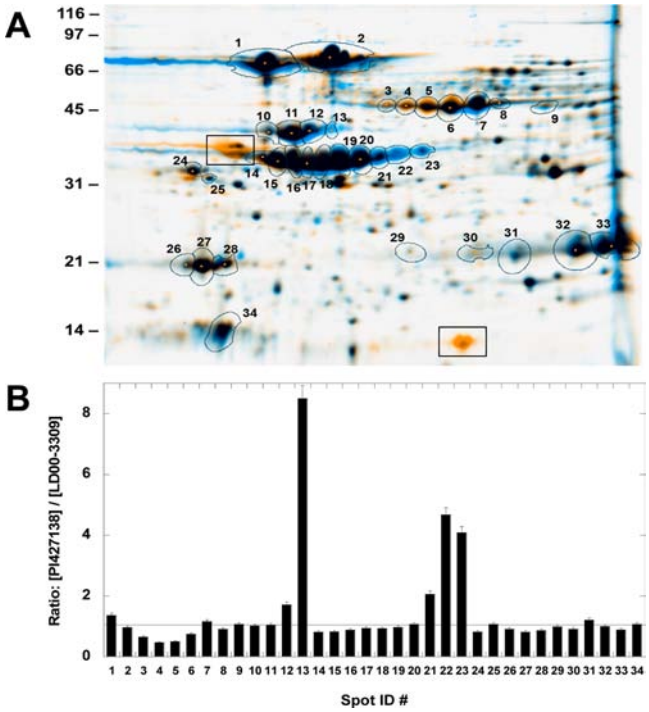

Figure 2. 2-DE comparison of total seed proteins extracted from PI 427138 and LD00-3309. Equal volumes of identically extracted seed proteins were separated using 2-DE. The Coomassie-stained gel images were analyzed using Delta2D software. Panel A shows the fusion of the two independently derived images. Gel images of PI 427138 and LD00-3309 were imported separately into Delta2D and overlaid to provide a combined fusion image. The blue color denotes those protein spots that were found to be higher in percent spot volume in PI 427138 compared with LD00-3309, whereas the orange color denotes those proteins that were found to be lower in percent spot volume. IEF separation was from pH 4 to 7, and molecular weight markers are designated in kDa. Panel B shows the ratios of percent volume [PI 427138]/[LD00-3309] of 34 spots generated from percent spot volume data collected using Delta2D image analysis software. The identities of the 34 proteins spots are shown in Supplemental Table 1. Leginsulin is not detected in these gels due to their low abundance in the total seed protein fraction.

spot detection (using global image warping and exact spot matching). A total of 34 protein spots identified previously by matrix-assisted laser desorption time of flight (MALDI-TOF) mass spectrometry as the major seed storage proteins of soybean were compared (Supplemental Table 1).[23] A comparison of the spot percent volume ratio differences clearly indicated that spots 12 (glycinin A3B4), 13 (glycinin A3B4), 21 (glycinin A1aBx precursor), 22 (proglycinin A1ab1b), and 23 (proglycinin A1ab1b) accumulated at higher amounts in PI 427138 (Figure 2). The preferential accumulation of the 11S globulins appears to the major contributing factor for the higher protein content of PI 427138.

Characterization Soybean Lines Derived from PI 427138 × LD00-3309 Crosses. The influence of environment on the seed composition traits of soybean LD00-3309, PI 427138, Leg-3, Leg-7, and Leg-8 were evaluated by growing these soybean lines at six locations, three in Illinois and three in Missouri. Total seed protein and oil content were determined with a LECO truSpec model FP-428 nitrogen analyzer and near-infrared (NIR) spectroscopy, respectively. The protein content of LD00-3309 seeds obtained from the six locations ranged from 36 to 39% (Figure 3A), whereas their oil content ranged from 19 to 21% (Figure 3B). In contrast, the protein content of PI 427138 seeds ranged from 45 to 51% (Figure 3A) and their oil content ranged from 11 to 13% (Figure 3B). The protein content of Leg-3, Leg-7, and Leg-8 ranged from 42 to 47%, which was significantly higher than that of LD00-3309, indicating the high-protein trait from PI 427138 had been successfully introgressed into these three lines (Figure 3A). The seed oil content of these soybean lines, which ranged from 14 to 17%, was intermediate when compared with the values obtained for the parents (Figure 3B). In general, soybeans grown in Columbia, MO, USA, had the highest protein content, whereas plants grown in Portageville, MO, USA, had the highest seed oil content.

The protein composition of leginsulin introgressed lines (Leg-3 and Leg-7) was also examined by 2-D gel electrophoresis (Figure 4). An examination of the Coomassie Blue stained gel revealed that PI 427138 accumulated higher amounts of 11S globulins when compared to LD00-3309. PI 427138 also failed to accumulate the Gy4 subunits. Interestingly, no substantial difference in the β-conglycinin content was observed between these two lines (Figure 4). The leginsulin introgressed lines (Leg-3 and Leg-7) also exhibited higher 11S glycinin content and, like PI 427138, lacked the Gy4 subunits (Figure 4).

Leginsulin Introgressed Lines Accumulate Lower Amounts of Bowman–Birk Protease Inhibitor. We also investigated the effect of growing location on the accumulation of leginsulin in soybean seeds. Isopropanol (50%) soluble proteins isolated from seeds grown at six locations were analyzed by SDS-PAGE (Figure 5A). A prominent 4 kDa protein was detected readily in leginsulin introgressed lines from all six locations. Western blot analysis using leginsulin antibodies confirmed the identity of this 4 kDa protein as leginsulin (Figure 5B). Previous studies have shown that the introduction of sulfur-rich proteins in soybean is often accomplished at the expense of native sulfur-rich proteins.[24] Bowman–Birk protease inhibitors are rich in cysteine and are the major contributors to the overall sulfur amino acid content of the seed. To investigate the effect of introgression of leginsulin on the accumulation of BBI, we performed Western blot analysis using antibodies raised against BBI. This analysis revealed a reduction in the accumulation of BBI in the leginsulin introgressed lines (Figure 5C). LD00-3309, which does not accumulate leginsulin, contained relatively high amounts of BBI (Figure 5C). These results suggest that accumulation of leginsulin in Leg-3 and Leg-7 occurs at the expense of BBI.

Leginsulin Introgressed Lines Contain Relatively Higher Amounts of Elemental Sulfur but the Concen-

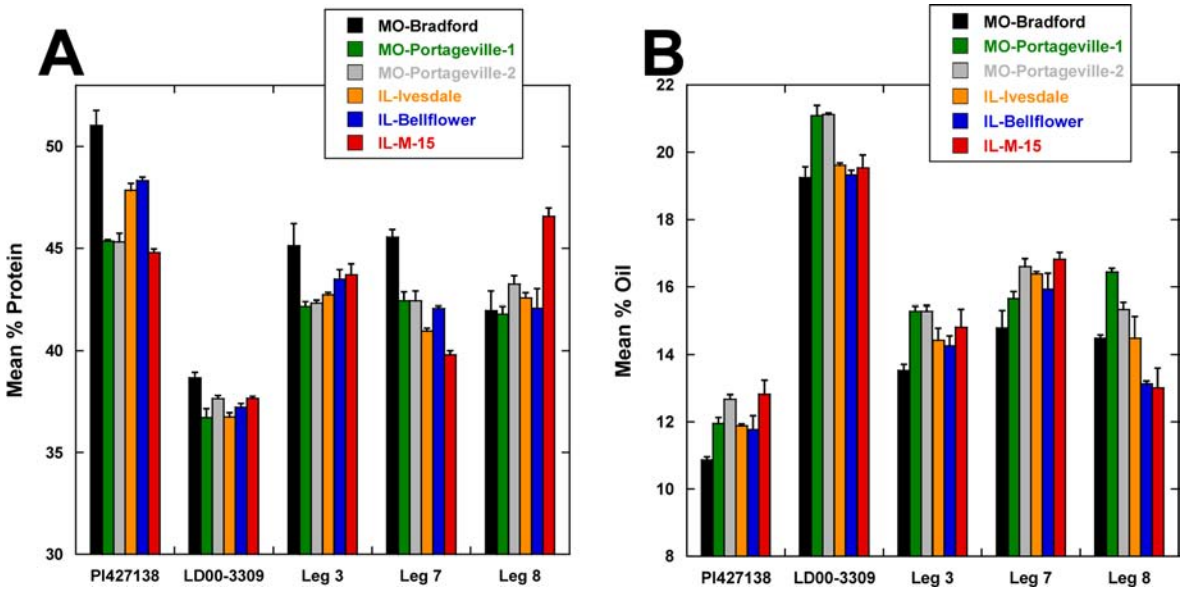

Figure 3. Mean protein and oil concentrations of soybean seeds grown in six different locations. Soybeans LD00-3309, PI 427138, Leg-3, Leg-7, and Leg-8 were grown at six locations (three in Illinois and three in Missouri). Seed protein and oil contents were determined with a LECO truSpec model FP-428 nitrogen analyzer and near-infrared (NIR) spectroscopy, respectively. Three separate biological replicates were evaluated per line. Error bars indicate the standard deviation of the mean.

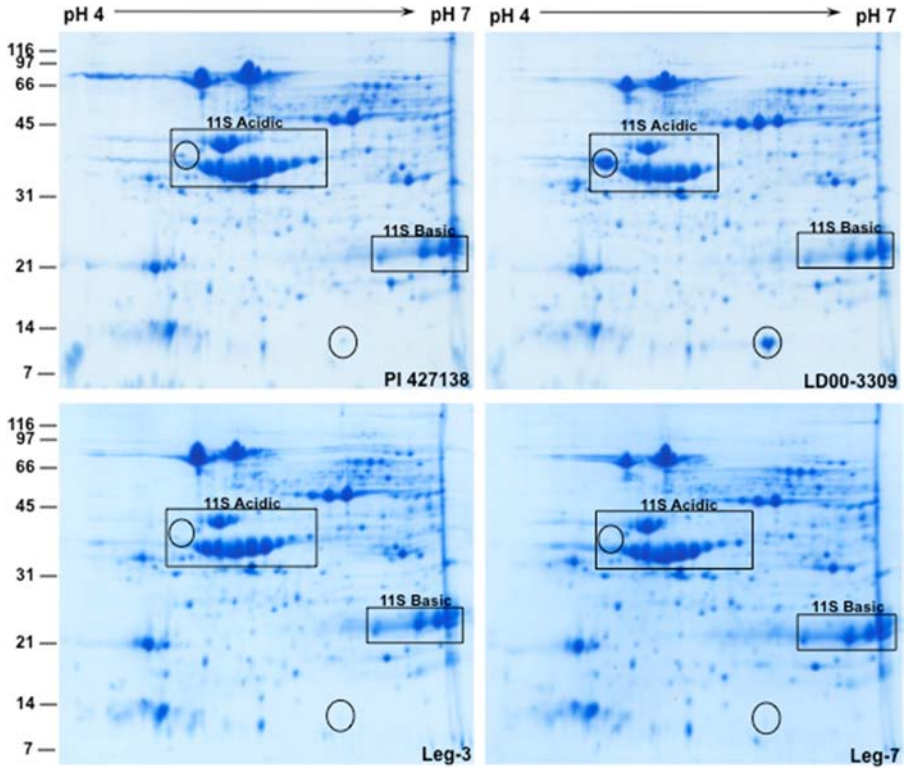

Figure 4. Comparison of the storage proteins of leginsulin introgressed soybean lines by 2-D gel electrophoresis. Total seed proteins isolated from the parents (PI 427138 and LD00-3309) and leginsulin introgressed lines (Leg-3 and Leg-7) were first separated by isoelectric focusing using a pH gradient from 4 to 7 and then by SDS-PAGE on a 13% gel. The rectangles in each panel represent the acidic and basic subunits of glycinin. The circles represent the Gy4 subunits, which are missing in PI 427138, Leg-3, and Leg-7. The gels were stained with Colloidal Coomassie Blue G-250. The positions and sizes of the molecular weight markers in kilodaltons are shown on the left side of the figure. Leginsulin is not detected in these gels due to their low abundance in the total seed protein fraction.

tration of Sulfur-Containing Amino Acids Remains Unchanged. The sulfur content of soybean seeds grown at six different locations was determined by inductively coupled plasma− mass spectrometry (Figure 6). Regardless of the location, LD00-3309 had the lowest amount of sulfur, which ranged from 3000 to 3600 ppm, whereas PI 427138 had the highest amount in most locations, ranging from 4000 to 4780 ppm (Figure 6). The sulfur content averaged from the six

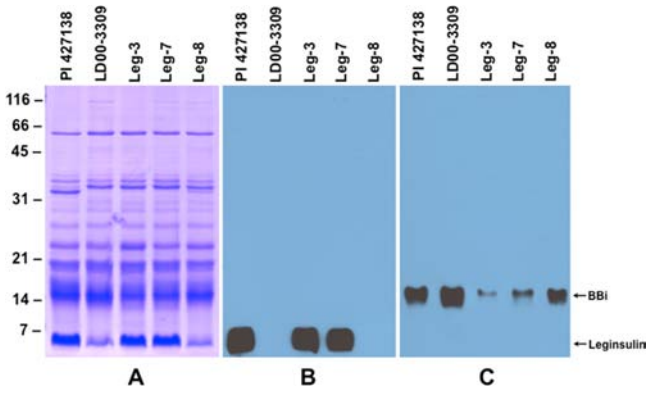

Figure 5. Leginsulin and Bowman–Birk protease inhibitor accumulation in soybean seeds. Fifty percent isopropanol soluble proteins isolated from the parents (PI 427138 and LD00-3309) and the resulting offspring (Leg-3, Leg-7, and Leg-8) were separated by SDS-PAGE on a 15% gel. Resolved proteins were detected by staining the gel with Coomassie Blue (panel A) or electrophoretically transferred to a nitrocellulose membrane and probed with leginsulin (panel B) or Bowman–Birk protease inhibitor (panel C) specific antibodies that were diluted 1:5000 in TBS containing 3% dry milk powder. Immunoreactive proteins were identified using anti-rabbit IgG–horseradish peroxidase conjugate followed by chemiluminescent detection.

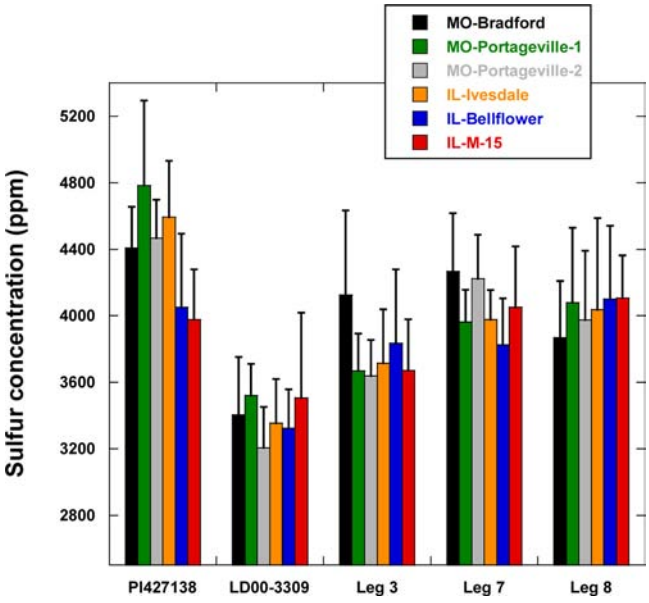

Figure 6. Elemental sulfur content of soybean seeds grown at six different locations. Soybeans LD00-3309, PI 427138, Leg-3, Leg-7, and Leg-8 were grown at six locations (three in Illinois and three in Missouri). Sulfur was determined by inductively coupled plasma–mass spectrometry. The error bars indicate the standard deviation of the mean.

locations for Leg-3, Leg-7, and Leg-8 were 3774, 4057, and 4027 ppm, respectively. These values are significantly higher than values obtained for LD00-3309. These results indicate that the high-sulfur trait from PI 427138 has been partially transferred to Leg-3, Leg-7, and Leg-8. It is also evident that growing location had only a minimal effect on sulfur accumulation in the seeds with a similar trend observed at all six locations (Figure 6).

The two soybean lines used as parents in this study, LD00-3309 and PI 427138, differ significantly in their sulfur contents. LD00-3309 averaged from the six locations had 3380 ± 264 ppm of sulfur, whereas PI 427138 had 4499 ± 113 ppm of sulfur. We were interested to examine if the differences seen in the sulfur content are also reflected in the concentration of sulfur-containing amino acids, cysteine and methionine. For this purpose we determined the amino acid content of soybean seeds of LD00-3309, PI 42713, Leg-3, Leg-7, and Leg-8. Interestingly the overall concentrations of cysteine and methionine were equivalent in all of these soybean lines (Table 1).

DISCUSSION

In this study we have successfully introgressed leginsulin from PI 427138 into a North American experimental line. Previously we have shown that leginsulin is encoded by two closely related genes (Gm13 g26330 (leginsulin 1) and Gm13 g26340 (leginsulin 2)). These two genes are located on chromosome 13 and are 5.9 kB apart.[18] Accumulation of leginsulin is drastically lower in most North American soybean cultivars than in Asian accessions.[18] Northern blot analysis has revealed that leginsulin accumulates only in the cotyledons but not in the embryonic axis in the North American soybean cultivars. In contrast, leginsulin mRNA was abundantly expressed in both the cotyledons and the embryonic axis of Asian soybean accessions. Thus, it appears the expression of leginsulin in both cotyledons and the embryonic axis may be responsible for the higher accumulation of leginsulin in Asian soybean accessions.[18]

Leginsulin, a peptide composed of 37 amino acids, is rich in cysteine residues. Our objective was to improve the overall sulfur amino acid content into adapted experimental lines by introgression of leginsulin. However, this goal was elusive because amino acid analysis revealed that the overall sulfur amino acid content (cysteine + methionine) remained unchanged (Table 1). Accumulation of Bowman–Birk protease inhibitor, another cysteine-rich protein, is reduced in leginsulin introgressed soybean lines Leg-3 and Leg-8, indicating that there is a limitation in the availability of cysteine in developing soybean seeds. Introgression of sulfur-rich proteins results in siphoning the limited cysteine pool from native sulfur-rich proteins such as Bowman–Birk protease inhibitor. Previous studies have shown the expression of Brazil nut 2S albumin, a methionine-rich protein, in transgenic soybean resulted in the reduction of Kunitz trypsin inhibitor.[24] Thus, it appears that introduction of sulfur-rich proteins into soybean alone will not be sufficient for improving the sulfur amino acid content. Metabolic engineering of sulfur assimilatory pathway will be critical for improving the availability of cysteine and methionine in developing soybean seeds.[25] Recent studies have demonstrated that such an approach can be used successfully to elevate the sulfur amino acid content of soybean seeds.[26,27]

Numerous high-protein plant introductions exist in the USDA Germplasm Collection. These plant introductions are currently being exploited as a source of high-protein alleles. The USDA ARS Soybean Genetics and Genomics Database (SoyBase) lists several potential protein QTLs located in different genomic regions. In addition, recent studies have identified new QTLs that could be used by breeders to develop high-protein lines.[28−30] We have transferred the high-protein trait of PI 427138 into Leg-3, Leg-7, and Leg-8, resulting in a substantial increase in the overall protein content. The increase

[a]Dry seed powder from triplicate samples was analyzed by HPLC to measure the total hydrolyzed amino acids from the parents (PI 427138 and LD00-3309) and the resulting offspring (Leg-3, Leg-7, and Leg-8). Cysteine is reported as cysteic acid (CyA), and methionine is reported as methionine sulfone (MetS). Results are the mean of three samples (n = 3), reported along with standard error (SE) of the mean.

in the protein content is, however, accompanied by a reduction in the oil content. It is well established that there is a negative correlation between seed protein and oil content.[31−35] Typically an increase of 2% protein results in a 1% decrease in oil content.[36] It has been proposed that this inverse correlation is associated with either a pair of tightly linked QTLs for protein and oil or by one pleiotropic QTL, the two alleles of which have inverse effects on both oil and protein contents.[28] Recent studies have identified new oil QTLs that have no major impact on seed protein content.[28−30] These oil-related QTLs could be exploited to increase the oil content of Leg-3, Leg-7, and Leg-8 without lowering the protein content.

Our study has identified PI 427138 as a *Gy*4 mutant. 2-D gel electrophoresis analysis of the total seed proteins from PI 427138 reveals the absence of the A5, A4, and B3 glycinin subunits, the product of the Gy4 gene. Leg-3, Leg-7, and Leg-8 generated in this study were also found to lack A5, A4, and B3 glycinin subunits (Figure 4). Tofu, a food product made of soy milk, is widely consumed in Asian countries. It is well-known that the tofu firmness, texture, and volume can be influenced by the absence of specific glycinin polypeptides.[37−39] For this reason *Gy*4 null lines such as 'Enrei' and 'Raiden' are commonly utilized in breeding programs to develop high-quality tofu cultivars. Thus, the soybean experimental lines Leg-3, Leg-7, and Leg-8 could be valuable breeding material for the production of high-quality tofu. It is not known if there is any correlation between the concentration of sulfur-containing amino acids and tofu quality. The 7S β-conglycinin is relatively low in sulfur amino acids, and its absence has been shown to alter tofu quality.[37] Additional studies are required to establish a correlation or lack thereof between the sulfur amino acid content of soybean seed proteins and tofu quality.

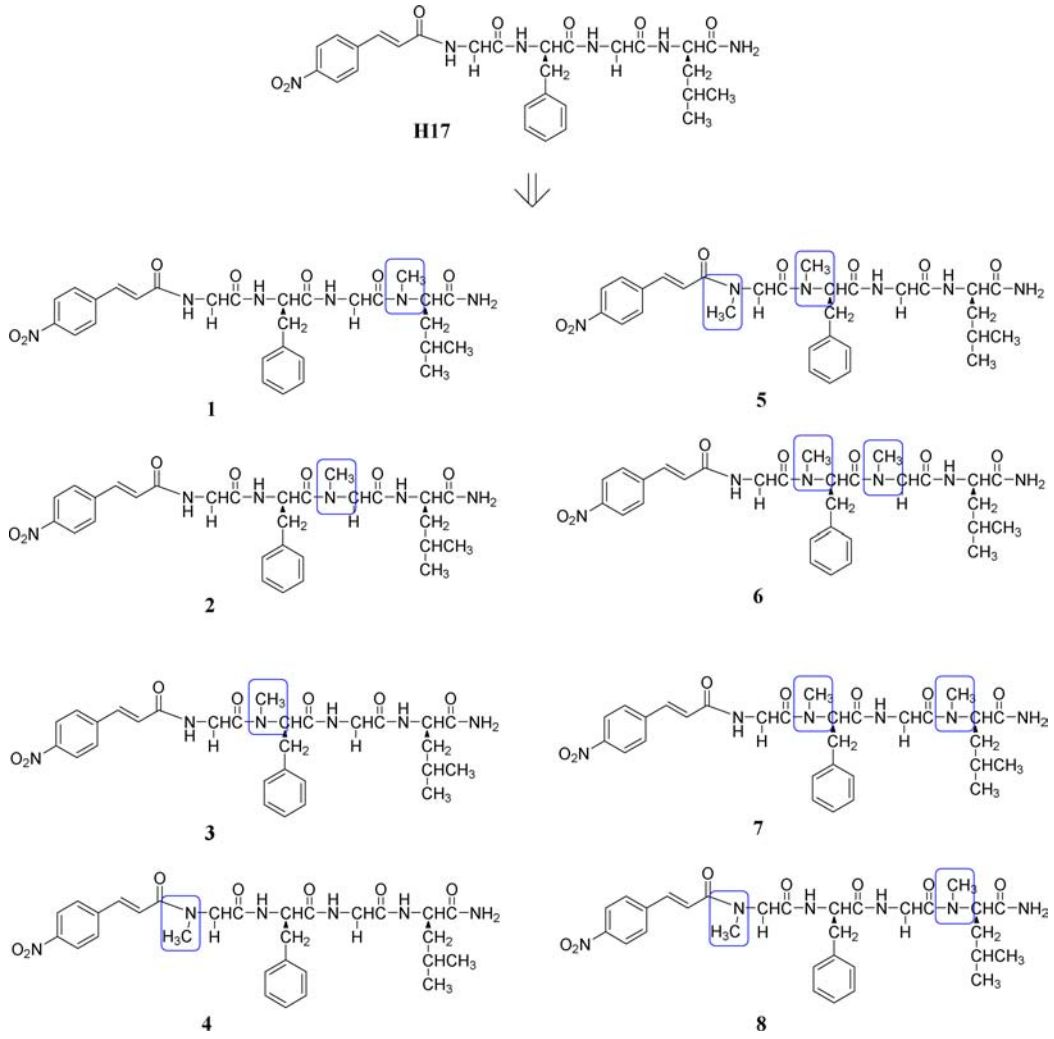

Figure 1. Structures of N-methylated AST analogues **1**−**8**.

MATERIALS AND METHODS

Chemistry. Protected N^{α}-Fmoc-amino acids, N^{α}-Fmoc-[*N*-Me]-amino acids, Rink amide-AM resin (0.68 mmol/g), 1-hydrozybenzotriazole anhydrous (HBTU), *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyluroniumhexafluorophosphate (HOBt), *N*,*N*-diisopropylethylamine (DIEA), trifluoroacetic acid (TFA), and *N*,*N*′-diisoprophlcarbodiimide (Dic) were purchased from GL Biochem, Ltd. (Shanghai, China). *N*,*N*-Dimethylformanide (DMF), dichloromethane (CH_2Cl_2), and acetonitrile were purchased from DIMA Technology, Inc. (Beijing, China) and were of high-performance liquid chromatography (HPLC)-grade or better. (*E*)-3-(4-nitrophenyl)-acrylic acid (NAA) and other reagents for chemical synthesis were purchased from Alfa Aesar (Shanghai, China).

All N-methylated analogues were synthesized by solid-phase peptide synthetic techniques.[21−23] The analogues were prepared using a N^{α}-Fmoc-protection scheme with Rink amide-AM resin. Individual N^{α}-Fmoc-amino acids were coupled via HBTU, HOBt, and DIEA in DMF for 3 h. Removal of the N^{α}-Fmoc group was accomplished with 20% piperidine in CH_2Cl_2 for 20 min. The resin was then washed in turn with DMF, MeOH, and CH_2Cl_2 (2× each) and dried under reduced pressure. The peptides were then cleaved from the resin using TFA containing 5% phenol, 2.5% thioanisole, and 5% water for 2.5 h. The peptides were then washed with anhydrous ethyl ether and lyophilized.

Crude peptides were dissolved in a mixture of aqueous 0.1% TFA and acetonitrile (exact ratio depending upon the solubility of the peptide) and then purified by preparative reversed-phase HPLC with a flow rate of 10 mL/min using acetonitrile/water (50:50, v/v). Ultraviolet (UV) detection was at 225 nM. Peptide fractions determined to be pure by analytical HPLC were combined, concentrated under reduced pressure, and lyophilized.

Preparation of Analogue 1. N^{α}-Me-Leu-Rink amide-AM resin (0.5 mmol) was prepared as described in the general procedure. N^{α}-Fmoc-Gly (3 mmol, 6 equiv) and Dic (1.5 mmol, 3 equiv) were mixed in CH_2Cl_2 (5 mL) for 30 min at 0 °C, and then N^{α}-Me-Leu-Rink amide-AM resin and DIEA (3 mmol, 6 equiv) were added. The reaction mixture was shaken for 2 h, and the procedure was repeated. After removal of the N^{α}-Fmoc group, N^{α}-Fmoc-Phe, N^{α}-Fmoc-Gly, and (*E*)-3-(4-nitrophenyl)-acrylic acid were coupled to the resin with HBTU, HOBt, and DIEA in DMF. The crude analogue **1** was purified by reversed-phase HPLC with a flow rate of 10 mL/min using acetonitrile/water (50:50, v/v) to yield 100 mg of peptide; HPLC t_R, 10.5 min; HRMS, *m*/*z* 603.2537 $[M + Na]^+$ (calcd $[M + Na]^+$, 603.2538).

Preparation of Analogue 2. N^{α}-Me-Gly-Leu-Rink amide-AM resin (0.5 mmol) was prepared as described in the general procedure. N^{α}-Fmoc-Phe (3 mmol, 6 equiv) and Dic (1.5 mmol, 3 equiv) were mixed in CH_2Cl_2 (5 mL) for 30 min at 0 °C, and then N^{α}-Me-Gly-Leu-Rink amide-AM resin and DIEA (3 mmol, 6 equiv) were added. The reaction mixture was shaken for 2 h. After removal of the N^{α}-Fmoc group, N^{α}-Fmoc-Gly and (*E*)-3-(4-nitrophenyl)-acrylic acid were coupled to the resin with HBTU, HOBt, and DIEA in DMF. The crude analogue **2** was purified by reversed-phase HPLC with a flow rate of 10 mL/min using acetonitrile/water (50:50, v/v) to yield 97 mg of peptide; HPLC t_R, 8.7 min; HRMS, *m*/*z* 603.2541 $[M + Na]^+$ (calcd $[M + Na]^+$, 603.2538).

Preparation of Analogue 3. N^{α}-Me-Phe-Gly-Leu-Rink amide-AM resin (0.5 mmol) was prepared as described in the general procedure. N^{α}-Fmoc-Gly (3 mmol, 6 equiv) and Dic (1.5 mmol, 3 equiv) were mixed in CH_2Cl_2 (5 mL) for 30 min at 0 °C, and then N^{α}-Me-Phe-Gly-Leu-Rink amide-AM resin and DIEA (3 mmol, 6 equiv) were added. The reaction mixture was shaken for 2 h. After removal of the N^{α}-Fmoc group, (*E*)-3-(4-nitrophenyl)-acrylic acid was coupled to the resin with HBTU, HOBt, and DIEA in DMF. The crude analogue **2** was purified by reversed-phase HPLC with a flow rate of 10 mL/min using acetonitrile/water (50:50, v/v) to yield 104 mg of peptide; HPLC t_R, 11.2 min; HRMS, *m/z* 581.2715 $[M + H]^+$ (calcd $[M + H]^+$, 581.2718).

Preparation of Analogue 4. N^{α}-Me-Gly-Phe-Gly-Leu-Rink amide-AM resin (0.5 mmol) was prepared as described in the general procedure. (*E*)-3-(4-Nitrophenyl)-acrylic acid (3 mmol, 6 equiv) and Dic (1.5 mmol, 3 equiv) were mixed in CH_2Cl_2 (5 mL) for 30 min at 0 °C, and then N^{a}-Me-Gly-Phe-Gly-Leu-Rink amide-AM resin and DIEA (3 mmol, 6 equiv) were added. The reaction mixture was shaken for 2 h. The crude analogue **2** was purified by reversed-phase HPLC with a flow rate of 10 mL/min using acetonitrile/water (50:50, v/v) to yield 89 mg of peptide; HPLC t_R, 8.8 min; HRMS, *m/z* 603.2540 $[M + Na]^+$ (calcd $[M + Na]^+$, 603.2538).

Preparation of Analogue 5. N^{α}-Me-Phe-Gly-Leu-Rink amide-AM resin (0.5 mmol) was prepared as described in the general procedure. N^{α}-Fmoc-*N*-Me-Gly (3 mmol, 6 equiv) and Dic (1.5 mmol, 3 equiv) were mixed in CH_2Cl_2 (5 mL) for 30 min at 0 °C, and then N^{α}-Me-Phe-Gly-Leu-Rink amide-AM resin and DIEA (3 mmol, 6 equiv) were added. The reaction mixture was shaken for 2 h. After removal of the N^{a}-Fmoc group, (*E*)-3-(4-nitrophenyl)-acrylic acid (3 mmol, 6 equiv) and Dic (1.5 mmol, 3 equiv) were mixed in CH_2Cl_2 (5 mL) for 30 min at 0 °C and then N^{α}-Me-Gly-*N*-Me-Phe-Gly-Leu-Rink amide-AM resin and DIEA (3 mmol, 6 equiv) were added. The reaction mixture was shaken for 2 h, and the procedure was repeated. The crude analogue **5** was purified by reversed-phase HPLC with a flow rate of 10 mL/min using acetonitrile/water (50:50, v/v) to yield 85 mg; HPLC t_R, 8.7 min; HRMS, *m/z* 595.2874 $[M + H]^+$ (calcd $[M + H]^+$, 595.2875).

Preparation of Analogue 6. N^{α}-Me-Gly-Leu-Rink amide-AM resin (0.5 mmol) was prepared as described in the general procedure. N^{α}-Fmoc-*N*-Me-Phe (3 mmol, 6 equiv) and Dic (1.5 mmol, 3 equiv) were mixed in CH_2Cl_2 (5 mL) for 30 min at 0 °C, and then N^{α}-Me-Gly-Leu-Rink amide-AM resin and DIEA (3 mmol, 6 equiv) were added. The reaction mixture was shaken for 2 h. After removal of the N^{α}-Fmoc group, N^{α}-Fmoc-Gly was coupled to the resin using the same method as N^{α}-Fmoc-*N*-Me-Phe. (*E*)-3-(4-Nitrophenyl)-acrylic acid was coupled to the resin with HBTU, HOBt, and DIEA in DMF. The crude analogue **6** was purified by reversed-phase HPLC with a flow rate of 10 mL/min using acetonitrile/water (50:50, v/v) to yield 58 mg of peptide; HPLC t_R, 10.9 min; HRMS, *m/z* 617.2694 $[M + Na]^+$ (calcd $[M + Na]^+$, 617.2694).

Preparation of Analogue 7. N^{α}-Me-Leu-Rink amide-AM resin (0.5 mmol) was prepared as described in the general procedure. N^{α}-Fmoc-Gly (3 mmol, 6 equiv) and Dic (1.5 mmol, 3 equiv) were mixed in CH_2Cl_2 (5 mL) for 30 min at 0 °C, and then N^{α}-Me-Leu-Rink amide-AM resin and DIEA (3 mmol, 6 equiv) were added. The reaction mixture was shaken for 2 h. After removal of the N^{α}-Fmoc group, N^{α}-Fmoc-*N*-Me-Phe, N^{α}-Fmoc-Gly, and (*E*)-3-(4-nitrophenyl)-acrylic acid were coupled to the resin with HBTU, HOBt, and DIEA in DMF. The crude analogue **7** was purified by reversed-phase HPLC with a flow rate of 10 mL/min using acetonitrile/water (50:50, v/v) to yield 67 mg of peptide; HPLC t_R, 12.3 min; HRMS, *m/z* 617.2698 $[M + Na]^+$ (calcd $[M + Na]^+$, 617.2694).

Preparation of Analogue 8. N^{α}-Me-Leu-Rink amide-AM resin (0.5 mmol) was prepared as described in the general procedure. N^{α}-Fmoc-Gly (3 mmol, 6 equiv) and Dic (1.5 mmol, 3 equiv) were mixed in CH_2Cl_2 (5 mL) for 30 min at 0 °C, and then N^{a}-Me-Leu-Rink amide-AM resin and DIEA (3 mmol, 6 equiv) were added. The reaction mixture was shaken for 2 h. After removal of the N^{α}-Fmoc group, N^{α}-Fmoc-Phe and N^{α}-Fmoc-*N*-Me-Gly were coupled to the resin with HBTU, HOBt, and DIEA in DMF. (*E*)-3-(4-Nitrophenyl)-acrylic acid was coupled to the resin using Dic. The crude analogue **8** was purified by reversed-phase HPLC with a flow rate of 10 mL/min using acetonitrile/water (50:50, v/v) to afford 63 mg of peptide; HPLC t_R, 7.9 min; HRMS, *m/z* 617.2692 $[M + Na]^+$ (calcd $[M + Na]^+$, 617.2694).

Biological Assay *in Vitro*. All radiochemical assays for JH biosynthesis were performed using individual CA from day 7 mated females. Compounds were dissolved in medium 199 with Hank's salts, without L-methionine (custom formulation) (GIBCO, Grand Island, NY) for assay as described previously.[24−26] Compounds were used in the bioassay on the same day of sample preparation. The solutions were discarded at the end of each day. Rates of JH release were determined using the modified *in vitro* radiochemical assay.[26] This assay measures the incorporation of radiolabeled methionine into JH III in the final step of biosynthesis by CA maintained *in vitro*. CA were incubated for 3 h in 100 μL of medium 199 (GIBCO, 1.3 mM Ca^{2+}, 2% Ficoll, methionine-free) containing [^{14}C-*S*-methyl]-L-methionine (40 μM, specific radioactivity of 1.48−2.03 GBq/mmol) (Amersham Pharmacia Biotech, Inc., Piscataway, NJ). Samples were extracted, and JH release was determined. Each data point on the dose−response figures represents replicate incubations of 10−17 experimental CA compared to control CA (i.e., no analogue added).

NMR Experiments. All spectra of analogues **1**−**4** were obtained using a Bruker AMX 400 spectrometer (Bruker, Beijing, China) located at Beijing Nuclear Magnetic Resonance Center, Peking University, with tetramethylsilane (TMS) as the internal standard. The probe temperature was 298 K. The analogues were dissolved in 6 mM DMSO-d_6 in a standard 5 mm NMR tube. Peaks were assigned using total correlation spectroscopy (TOCSY) spectra. TOCSY spectra were recorded with 640 points in F2 and 256 points in F1. Proton distances were calculated using the two-spin approximation from nuclear Overhauser enhancement spectroscopy (NOESY). The mixing times in TOCSY and NOESY spectra were 50 and 500 ms, respectively.[13,27,28]

Molecular Modeling. All molecular modeling calculations were performed using Sybyl 7.3 (Tripos, Inc., St. Louis, MO) running on a Silicon Graphics Fuel Visual workstation (Silicon Graphics, Inc., Milpitas, CA). Distance ranges of 1.8−2.7, 1.8−3.3, and 1.8−5.0 Å were assigned for strong, medium, and weak nuclear Overhauser enhancement (NOE) interactions, respectively. The dihedral angles of θ (H−N−C_α−H_α) and θ (H_α−C_α−C_β−H_β) were calculated according the value of $^3J_{N\alpha}$ and $^3J_{\alpha\beta}$.[29,30] The energy minimization of four analogues (analogues **1**−**4**) used the minimized module of Sybyl. The force field was Merck Molecular Force Field 94 (MMFF94) with an 8.0 Å cutoff for non-bonded interactions, and the atomic point charges were also calculated by MMFF94. The minimizations were implemented with the descent method for the first 100 steps, followed by the Broyden Fletcher Goldfarb Shanno (BFGS) method until the root mean square (RMS) of the gradient was less than 0.005 kcal mol^{-1} $Å^{-1}$.[28] Then, these sample minimization procedures were selected to study their conformations using the method of the rotating-frame Overhauser enhancement (ROE)-restrained simulated annealing (SA) calculations. The ROE-derived distance constraints were applied as a biharmonic constraining function, and force constants for upper and lower boundaries were initially set to 20 kcal mol^{-1} $Å^{-2}$. The atomic velocities were applied following a Boltzmann distribution about the center of mass to obtain a starting temperature of 100 K.

RESULTS AND DISCUSSION

Chemistry. Several methods for N-methylation of amino acids are known in the literature.[23,31−33] Following the Fmoc strategy in peptide synthesis, methods of symmetrical anhydrides and esterification are favorable because it results in N-methylated Fmoc-protected amino acids in good overall yields without racemization.

To permit N-protected amino acids and (*E*)-3-(4-nitrophenyl)-acrylic acid coupling to HBTU, their symmetrical anhydrides were used if amino acids or (*E*)-3-(4-nitrophenyl)-

	Leu[5]	4.21	1.47	8.01	1.55 Hγ, 0.85 Hδ, 7.01, 7.31 NH_2

[a]NAA = (*E*)-3-(4-nitrophenyl)-acrylic acyl group.

acrylic acid were coupled to the N^{α}-Me-amino acid-Rink amide-AM resin. If incomplete incorporation of the acylating agent was indicated, the amino acid was recoupled until a negative Kaiser test[30,34] was obtained. After coupling of (*E*)-3-(4-nitrophenyl)-acrylic acid, the peptide mimics were cleaved from the resin and then the crude peptide mimics were extracted into aqueous solution, concentrated under reduced pressure, and lyophilized. Purification by reversed-phase high-performance liquid chromatography (RP-HPLC) yielded peptides that were >98% pure.

Biological Data *in Vitro*. The ability of N-methylated AST analogues to inhibit biosynthesis of JH by the CA of *D. punctata* was evaluated by measuring the incorporation of radiolabeled methionine into JH III. As shown in Figure 2, analogues **1** and

DOI: 10.1021/acs.jafc.5b00882
J. Agric. Food Chem. 2015, 63, 2870−2876

4 in which C-terminal Leu^5 and Gly^2 were modified into N-methylated Leu and N-methylated Gly, respectively, exhibited activity similar to H17 ($IC_{50} = 6.15 \times 10^{-8}$ M *in vitro* and $IC_{50} = 1.2 \times 10^{-8}$ M *in vitro*[19]). These results demonstrated that analogues **1** and **4** have a significant effect *in vitro* when compared to the pentapeptide ($IC_{50} = 1.3 \times 10^{-7}$ M).[18] Single N-methylation of Phe^3 and Gly^4 produced about 2- and 4-fold lower activity than H17 but still showed significant potency with IC_{50} values of 1.03×10^{-7} and 2.97×10^{-7} M, respectively. A comparison of the activities elicited by single N-methylation mimics with double N-methylation mimics (to give analogues **5**−**8**) suggested that the introduction of a double N-methylation could decrease activity. Analogue **5**, containing both N-methylated Gly^2 and N-methylated Phe, was less active, with an IC_{50} value of 4.98×10^{-7} M. Analogue **6**, containing both N-methylated Phe and N-methylated Gly^4, was less active than analogue **2** but still showed activity, with an IC_{50} of 1.84×10^{-7} M. Analogue **7**, which contains N-methylated Phe and N-methylated Leu, and Analogue **8**, which contains N-methylated Gly^2 and N-methylated Leu, were found to have the lowest activity, with IC_{50} values of 3.37×10^{-6} and 2.11×10^{-6} M, respectively.

NMR Studies. Conformational investigations of analogues **1**−**4** were performed using standard one-dimensional (1D) and two-dimensional (2D) NMR spectroscopy in DMSO-d_6 at 298 K. A complete assignment of the protons was obtained (Table 1). The aliphatic spin systems and amide protons, besides the amide protons of the first residues, were observed using TOCSY experiments. The protons of Phe and (*E*)-3-(4-nitrophenyl)-acrylic acid as well as the prochiral methylene protons of Gly^2 and Gly^4 were identified by corresponding $^3J_{\alpha\beta}$ coupling constants and NOE correlations to their respective aromatic protons. Hα of the (*E*)-3-(4-nitrophenyl)-acrylic acyl group in analogues **1**−**3** appeared near 7 ppm, and in analogue **4**, it appeared as 7.4 ppm. For analogue **1**, *N*-CH_3 appeared as a singlet at 2.84 ppm and Hα of *N*-Me-Leu^5 appeared near 4.98 ppm. For analogue **2**, *N*-CH_3 appeared as a singlet at 2.76 ppm and Hα of *N*-Me-Gly^4 appeared near 3.87 ppm. For analogue **3**, *N*-CH_3 appeared as a singlet at 2.78 ppm and Hα of *N*-Me-Gly^4 appeared near 4.85 ppm. For analogue **4**, *N*-CH_3 appeared as a singlet at 2.70 ppm and Hα of *N*-Me-Gly^4 appeared near 4.11 ppm.

Important NOE correlations for analogue **1** included strong interactions between Gly^4 Hα and Leu^5 Hα and (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hγ and Phe^3 N−H, a medium interaction between (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hβ and Phe^3 Hγ, and a weak interaction between (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hα and Gly^2 N−H. For analogue **2**, strong interactions were observed for (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hδ and Leu^5 N−H and (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hα and Leu^5 CO−NH_2, a medium interaction was observed for (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hβ and Leu^5 N−H, and a weak interaction was observed for (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hγ and Leu^5 CO−NH_2. For analogue **3**, an interaction was observed for (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hβ and Leu^5 CO−NH_2, a medium interaction was observed for (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hγ and Gly^4 N−H, and a weak interaction was observed for (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hγ and Leu^5 N−H. Finally, for analogue **4**, a medium interaction occurred between (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hδ and Leu^5 N−H, and a weak interaction occurred between (*E*)-3-(4-nitrophenyl)-acrylic acyl group Hα and Phe^3 Hδ.

Molecular Modeling. Because of conformational flexibility, restrained molecular dynamics was applied, to determine conformation in the case of peptides. The 10 lowest energy structures found for the four analogues are shown in Figure 3.

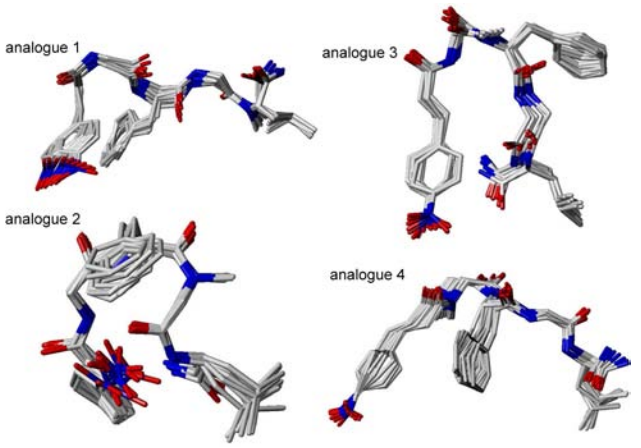

Figure 3. Backbone atom superposition of the low-energy structures obtained for analogues **1**−**4** by simulated annealing. Only backbone atoms are shown for clarity.

Torsion angles and distance between Cα of different residues of the lowest energy structure are summarized in Tables 2 and 3, respectively. The different turn conformations were assigned by comparing the average Φ (i + 1), Ψ (i + 1), Φ (i + 2), and Ψ (i + 2) values with standard values, allowing for a ±30° deviation from standard values.[35] Analogue **2** showed a type IV β-turn around Gly^2-Phe^3-Gly^4-Leu^5, and analogue **3** formed a type IV β-turn around NAA^1-Gly^2-Phe^3-Gly^4. As shown in Table 3, the distances of Cα(NAA^1)−Cα(Leu^5) of analogues **1** and **4** were 9.17 and 11.39 Å, respectively, and the distances of Cα(NAA^1)−Cα(Leu^5) for analogues **2** and **3** were 5.00 and 4.56 Å, respectively. Analogues **1** and **4** did not form a classic turn because the Cα(NAA^1)−Cα(Gly^4) and Cα(Gly^2)−Cα(Leu^5) distances were larger than 7.0 Å, the upper limit for turns.[35] It seems that the conformation of analogues **1** and **4** was flexible and linear.[36,37]

In previous studies, the β-turn at the end of the C terminus was predicted in ASTs and AST mimics.[11,13,28,38−40] We also found that analogues **2** and **3**, which demonstrated significant activity, formed a type IV β-turn. However, analogues **1** and **4**, which exhibited more activity, showed a flexible linear conformation. Banerjee et al.[15] observed that Dippu-AST 5 did not form a β-turn at the end of its C-terminal motif, using sodium dodecyl sulfate and water as solvent, but rather showed a γ-turn.[15] Therefore, we suggest that this kind of flexible linear conformation is a very important and indispensable structural element in AST mimics, and it may be directly involved in the recognition of the AST receptors. However, these ASTs and AST mimics are flexible, which are free to form any number of conformations under different conditions, such as β-turns, helical turns, or other conformations. Particularly, the flexible conformation does not eliminate the fact that the actual active conformation may be a β-turn, so that more data are required to confirm this hypothesis.

In summary, eight AST analogues were synthesized using N-methylation scanning, in an effort to understand the

conformation of novel AST analogues and their ability to inhibit JH biosynthesis. The activity of analogues **1** and **4** proved roughly equivalent to that of the lead H17, with IC_{50} values of 5.17×10^{-8} and 6.44×10^{-8} M, respectively. Single N-methylation mimics (analogues **1**−**4**) showed higher activity than double N-methylation mimics (analogues **5**−**8**). We further investigated the conformational properties of single N-methylation mimics (analogues **1**−**4**) by 1D and 2D ^{1}H NMR and molecular modeling. Evaluating the torsion angles and distances between Cα of different residues, we found that analogues **1** and **4**, which formed a flexible linear conformation, exhibited more activity than analogues **2** and **3** containing a type IV β-turn. On the basis of our present study, these results provide evidence that the flexible linear conformation may be an indispensable structural element in AST mimics and may be involved in the interaction with the AST receptors.

limits of quantitation well below the reported sensory threshold for these compounds. However, when multiple analyte responses require optimization, the most favorable handling conditions for individual analytes becomes increasingly convoluted. This method has also allowed for the first reported investigation of compounds that contribute to the off-flavors found in wines made from ripe rot (*Colletotrichum acutatum*)-affected grapes.

MATERIALS AND METHODS

Chemicals. Analytical-grade chemicals and reagents for the preparation of standard solutions for GC−MS analysis were used without further purification. 2-Isobutyl-3-methoxypyrazine, 2-isopropyl-3-methoxypyrazine, 3-octanone, 1-octen-3-one, *trans*-2-octen-1-ol, 1-octen-3-ol, 2-methylisoborneol, 2,4,6-trichoroanisole, geosmin, 2,4,6-tribromoanisole, methyl isobutyl ketone, 2-octanol, and geosmin-d_3 were obtained from Sigma-Aldrich (St. Louis, MO). Fenchone and fenchol were obtained from Fulka (Buchs, Switzerland). 2-Methyl-d_3-isoborneol, 2,4,6-trichloroanisole-d_5, 2,4,6-tribromoanisole-d_5, and pentachloroanisole-d_3 were obtained from CDN Isotopes (Pointe-Claire, Quebec, Canada). Ethanol (VWR Prolabo, Fontenay Sous Bois, France), L-(+) tartaric acid (Sigma, Steinheim, Germany), and potassium hydrogen tartrate (BHD Chemicals, Ltd., Poole, U.K.) were used for preparation of model wine base solutions. Deionized water was obtained from a Milli-Q mixed bed resin system (18 MΩ/cm, 25 °C).

Instrumentation. An Agilent 7890A gas chromatograph, equipped with a Gerstel multipurpose sampler with automated SPME capability and Peltier cooled sample tray, interfaced to an Agilent 5975C triple axis mass detector, was used for confirmation of compound identity, method development, and final sample analysis. MSD Chemstation E.02.00.493 (Agilent Technologies, Ltd.) and NIST MS Search 2.0, version 2008, were used to control the instrument and for mass spectra assessment. Prepared samples were placed into the Peltier cooler tray set at 8 °C until analysis, whereupon vials were transferred to a heater block with a 2 min pre-incubation time before insertion of the SPME fiber. A fused silica capillary column (DB-Waxetr, 60 m × 0.25 mm inner diameter, 0.25 μm film thickness, Agilent Technologies, Santa Clara, CA) was used for compound separation by GC. The injector block was fitted with a 2 mm internal diameter borosilicate liner (SGE), and the injector temperature set to 260 °C in splitless mode. Fibers were inserted into the injector for 1 min, withdrawn, and injected into a second injector set at 270 °C with a 50:1 split for 10 min with a 15 mL/min purge flow to clean the fiber, prior to the next sample analysis. The oven temperature program commenced at 40 °C for 3 min, increased to 115 °C at a rate of 5 °C/min, increased to 166 °C at a rate of 3 °C/min, a final increase to 210 °C at a rate of 10 °C/min, and held for 12 min. The total run time was 51.4 min. The flow rate of ultra-high-purity helium gas was constant at 3 mL/min. The MS source, quadrupole, and transfer line temperatures were set to 230, 150, and 275 °C, respectively.

Compound Identification and Elution Profiles. Solutions of all listed compounds were prepared at the approximate midpoint of the calibration range, in a model wine consisting of tartaric acid (0.008 M), potassium hydrogen tartrate (0.011 M), and ethanol (3.0%, v/v). These solutions were used to confirm compound elution times and ion profiles. Samples (10 mL) were transferred to the heater block set at 50 °C with an agitation rate of 250 revolutions per minute (rpm) and equilibrated for 1 min. A divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) SPME fiber, which is reported to possess a high level of sensitivity for the compounds of interest,[15] had been preconditioned according to the instructions of the manufacturers and was then inserted into the headspace for 20 min at 50 °C, before the insertion into the GC injector. Mass spectral data was collected in both selective ion monitoring (SIM) at ionization voltage of 70 eV and scan mode (m/z 35−350). Final elution profiles were confirmed by matching mass spectral data with the National Institute of Standards and Technology (NIST) mass spectral search program (version 2.0) MS library (version 8.0) and the determination of Kovat's retention indices (RIs). RIs were checked for each compound using a commercial mixture of *n*-alkanes (Sigma, Steinheim, Germany), an identical oven ramp profile, and gas flow rates as used for the final analyses.

Preparation of Wine Base (WB) and Grape Base (GB) Solutions. A WB solution was prepared by diluting commercial Chardonnay wine (Charles Sturt University Winery 2009) with ultrapure water 1:4 to achieve an ethanol concentration of 3% (v/v) and adjusting the pH to 7.0 by the addition of sodium hydroxide (1 M). A GB solution was prepared by homogenizing Thompson seedless grapes (approximately 2 kg) with an ultra-Turax T25 (Jane & Kunkel Ika-labtechnik) for 2 min. This was diluted 1:5 with ultrapure water to achieve a carbohydrate concentration of 2.5% (w/v), and pH was adjusted to 7.0. Prior to the use of WB and GB for further method development, the absence of the compounds of interest was confirmed by HS-SPME−GC−MS using SIM mode, with all conditions as previously mentioned.

Optimization of Sample Extraction Conditions. Optimization of extraction time and temperature was determined using a Box−Behnken experiment designed with a three-level factorial design as previously described.[13,16] Compounds were tested in WB or GB with salt at approximately the one-tenth point of the calibration curve. SPME extraction was performed using a DVB/CAR/PDMS fiber. Temperature conditions of 30, 50, and 70 °C with extraction times of 30, 50, and 70 min were examined in a randomized order, with the central condition

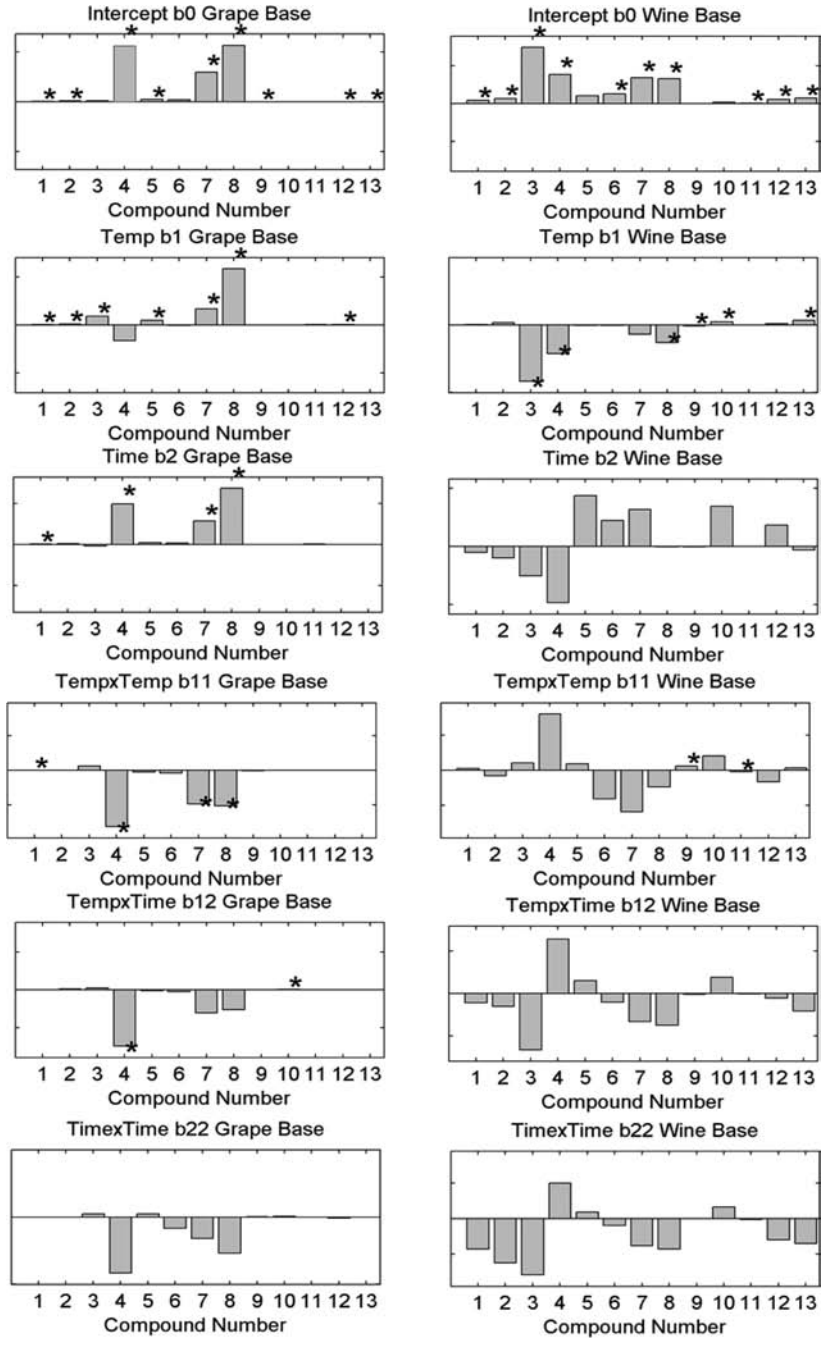

Figure 1. Response surface modeling of quantification ion counts to determine the optimized experimental conditions was undertaken in accordance with eq 1 for each analyte of interest. An asterisk above the coefficient indicates a significant term in the regression model ($p < 0.05$). Compound numbers: (**1**) 2-isopropyl-3-methoxypyrazine, (**2**) 2-isobutyl-3-methoxypyrazine, (**3**) 3-octanone, (**4**) fenchone, (**5**) 1-octen-3-one, (**6**) *trans*-2-octen-1-ol, (**7**) fenchol, (**8**) 1-octen-3-ol, (**9**) methylisoborneol, (**10**) 2,4,6-trichloroanisole, (**11**) geosmin, (**12**) 2,4,6-tribromoanisole, and (**13**) pentachloroanisole.

repeated 3 times to determine the extraction repeatability. Thus, the experimental design was constructed with independent variables at levels (−1, 0, and 1) for temperature (30, 50, and 70 °C) and time (30, 50, and 70 min). Compound quantitation ion results for each compound were exported to MATLAB R2007a (The Mathworks, Natick, MA), and extraction conditions were modeled using response surface methodology. The predicted maximum quantitation ion response at optimized conditions for each compound was determined from the response surface model using a full quadratic model to account for constant, linear, and squared terms[17]

$$Y = b_0 + b_1X_1 + b_2X_2 + b_{12}X_1X_2 + b_{11}X_1^2 + b_{22}X_2^2 + \varepsilon \qquad (1)$$

where Y is the predicted response for each compound, X_1 is the extraction temperature, X_2 is the extraction time, b_0 is the constant term, b_1 and b_2 are the coefficients for the linear terms, b_{12} is the coefficient for the interactions, b_{11} and b_{22} are the coefficients for the squared terms or variables (time and temperature) for each compound model, and ε is the residual. The coefficients were calculated using regression analysis, and the significance of each variable was determined using a two-tailed t test. The coefficients b_n and indication of their significance are shown in Figure 1.

The response surface curve of geosmin for the extraction conditions is shown in Figure 2. A modified desirability method for the optimization of multiple response variables was used, in which the importance of

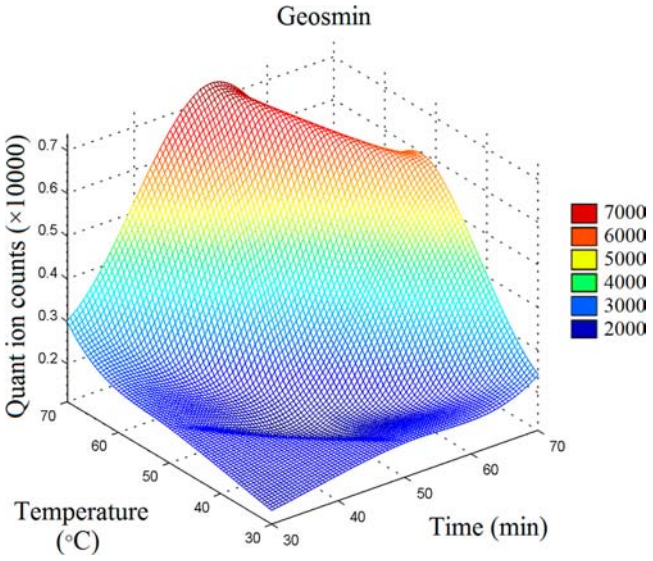

Figure 2. Response surface curve in WB for geosmin of varying sample incubation temperatures and fiber exposure time.

specific responses were down-weighted.[14] Briefly, relative peak size (RPS) coefficients for each compound were calculated from the inverse of the largest predicted maximum quantitation ion peak divided by each target compound peak area in the compound list (Tables 1 and 2). Weighted mean extraction times and temperatures were then calculated from the product of inverse RPS and optimized time or optimized temperature for the compounds. This enabled a comparison of the relative extraction and detection efficiencies for all compounds and assisted in minimizing the loss of analytical sensitivity for specific compounds that give low peak areas compared to compounds with large peak areas.

Effect of Salting on Extraction Efficiency. Duplicate samples were prepared in either a WB or GB with or without salt. Samples were spiked with compounds to produce a concentration of one-tenth of the maximum calibration point. The effects of salting on the ionic strength were determined by placing 3.0 g of NaCl into each 20 mL sample vial prior to introducing 10 mL of sample. SPME extraction was conducted at final SPME optimized extraction conditions [for GB, 65 °C for 67 min (Table 1) and, for WB, 44 °C for 65 min (Table 2)] using a DVB/CAR/PDMS fiber with quantitation ions counted in SIM mode. Quantitation ion counts for target compounds in WB or GB solution with or without the salt are presented in Figure 3.

Calibration Curves. Calibration solutions were prepared in either WB or GB by diluting a mix of the pure compounds to seven concentrations over the analytical range (Table 3) and internal standard (IS), as designated in Table 4, and saturated with NaCl (30%). Triplicate analysis was conducted for each calibration level in both WB and GB, and SPME extraction was conducted as previously mentioned.

Limit of Detection (LOD) and Limit of Quantitation (LOQ). WB and GB spiked with low levels of target compounds were used to establish the LOD and LOQ of the overall method. The LOD (concentration for signal/noise = 3) and the LOQ (concentration for signal/noise = 10) were manually calculated from the ratio of the peak heights to the average noise before and after each peak. These data are listed in Table 3.

Recovery Experiments in Red and White Wine and Grapes. Recovery experiments were conducted in triplicate in wines (diluted 1:4) and grape homogenates (diluted 1:5) adjusted to a pH of 7.0 using 1 M NaOH. Compounds were spiked in these solutions at approximately one-fifth and one-tenth of the calibration curve. NaCl (3.0 g) was placed into each 20 mL sample vial prior to introducing 10 mL of sample. Compound recoveries are reported as a percentage of the spiked quantity determined from the calibration curves for each analyte.[18]

Repeatability and Reproducibility. To evaluate repeatability, five white wines (Chardonnay) and five homogenate Thompson seedless grape samples were spiked with a concentrated mix of target compounds, as described above. To evaluate reproducibility spiked, samples were prepared and analyzed over a period of 5 days with results expressed as the coefficient of variation (% CV).[18]

Analysis of Healthy and Infected Grape and Wine Samples. *Healthy and Infected Grape Samples.* Bunches of Shiraz grapes were collected from a vineyard in the Riverina, New South Wales, Australia, during the 2012 vintage. Fruit was handpicked and sorted into two separate batches according to a visual assessment for the presence of obvious fungal bunch rots. On the basis of a visual examination, gray mold or *B. cinerea*[19] was the predominant bunch rot disease in these grapes. Cabernet Sauvignon bunches were similarly collected from a commercial vineyard located in the Hunter Valley, New South Wales, Australia, during the 2013 vintage and sorted into two batches according to the presence or absence of obvious mold growth. On the basis of a visual examination, ripe rot or *C. acutatum*[20] was the predominant bunch rot disease in these grapes. Triplicate samples from each batch of grapes were prepared the same as GB samples.

Wine Made from Grapes Affected with Bunch Rot Molds. Grapes were obtained from a single block of Semillon vines located in the Riverina, New South Wales, Australia, during the 2011 vintage.

[a]As a proportion of the quantitation ion. [b]WB, wine base; GB, grape base.

Whole bunches were randomly selected along vine rows from both sides of the vine and sorted into two groups based on the visible level of infection. The control group had no perceived infection (i.e., clean fruit or 0% bunch infected), while the second treatment had high level infection (up to 45−50% of the bunch infected). These treatments were juiced and fermented separately to finished wine.[21] A further experimental wine made from Cabernet Sauvignon grapes that investigated the effect of ripe rot in an earlier study[22] was also used in this investigation.

Three commercially made wines were selected for analysis. These wines were a 2003 Semillon wine from the Hunter Valley, New South Wales, Australia, a 1978 Cabernet Sauvignon wine, and a 1987 vintage

wine made from *Botrytis* Muscat of Alexandria grapes from the Riverina, New South Wales, Australia. Triplicate samples from each batch of wine were prepared the same as WB samples for the quantitation of the compounds of interest.

RESULTS AND DISCUSSION

Optimization. Optimization of sample treatment parameters is arguably the most important aspect of method development for sensitive, accurate, and precise quantitation of volatile compounds.[23,24] Optimized sample handling parameters were determined using response surface modeling and a desirability function, in which the importance of sample conditions for compounds with a high signal response relative to those with a low signal, is down-weighted by the calculation of a relative response factor.[14] Weighted mean extraction times and temperatures were calculated from the product of inverse RPS and optimized time or optimized temperature for the compounds of interest (Tables 1 and 2 for WB and GB, respectively). This approach for HS-SPME optimization enabled lower limits of quantitation to be achieved than previously reported for the compounds of interest.[25]

Response surface modeling to determine the optimized experimental conditions was undertaken in accordance with eq 1 for each analyte of interest. Consequently, for each analyte and solvent system (WB or GB), there exists six b coefficients that correspond to the fitted response when linear, squared, and interaction terms are modeled for a two-factor (time and temperature) model. The magnitude of each b coefficient is dependent upon the analyte signal, and the significance for each coefficient can be determined using a t test. Inspection of the t test values for the b coefficients for each compound in WB infers that an optimized sample incubation temperature is a more important factor than fiber exposure time to achieve maximum analytical sensitivity (Figure 1). In GB, fiber exposure time and sample incubation temperature are both important factors to optimize for the analysis of some compounds. The diminished importance of fiber exposure time for optimizing WB analysis may reflect a modified polarity of the solvent base because of the presence of ethanol, which has increased the volatility of the analytes and, hence, headspace concentration. Consequently, equilibrium between the WB headspace concentration and binding of these compounds onto the fiber, once exposed to the sample, occurs more rapidly than in GB. The analysis of alcoholic beverages can be challenging for HS-SPME analysis because the competitive adsorption between ethanol and other interesting volatile compounds onto the SPME fiber may cause loss of analytical sensitivity. This is due to the relative concentration of ethanol far exceeding that of other compounds leading to fiber saturation.[26] Dilution of samples to a lower ethanol concentration limits competitive binding of ethanol to the fiber, allowing for a lower detection limit for interesting compounds to be achieved.[27]

[a]NR = not reported.

The incorporation of high ionic strength solutes into the sample matrix is frequently employed for the analysis of volatile compounds with HS-SPME methods,[28,23] with sodium chloride or sodium sulfate most commonly used. An increased ionic strength sample matrix often results in higher analyte signal responses with HS-SPME methods. This is because an increased volatility of specific compounds arises from the altered solubility of polar compounds.[29] Partition coefficients for the gaseous phase are therefore improved, and consequently, greater analyte quantities are absorbed by the SPME fiber. This phenomenon was observed for all compounds of interest in the present investigation (Figure 3).

Calibration Curves and Method Evaluation. Calibration curves prepared in a diluted wine or grape homogenate matrix were constructed from the mean quantitation ion count of three replicate analyses, using a mix of naturally occurring and deuterated analogues as ISs. Good correlation coefficients (r^2 > 0.981) for all compounds (Table 3) and recovery experiments (Table 5) indicate that matrix interferences were relatively minor. Recovery values expressed as the coefficient of variation ranged from 83 to 131 in WB and from 89 to 121 in GB and indicate that the wine matrix had a greater impact upon the analysis than the grape base. This is not unexpected because, even with dilution, the ethanol concentration in wine was still relatively high compared to the analyte concentration. Additionally, the wine matrix is comprised of a significantly greater number of volatile compounds arising from yeast metabolism, which may lead to competitive interactions on the fiber surface and contribute to the matrix effect. Recovery values for spiked red wine also indicate possible interactions of the matrix with analytes to a greater extent than in the white wine (Table 5). It is possible that the greater concentration of phenolic compounds in red wine may have caused interference with recovery. However, values from two spiked additions were acceptable for analytical use (Table 5).

The limits of detection and quantitation for all analytes (Table 3) are lower than levels previously reported for wine and grape samples.[30] These values for are remarkably lower than those found in the literature (Table 6) and, in any case, are well below the reported sensory threshold of these components in wine. To the authors knowledge, no prior single GC−MS method has been developed that enable rapid and sensitive analysis of the diverse compounds elicited from mold growth that impart earthy taint aromas in one single GC−MS run. Our approach demonstrates the value of using optimization of multiple response factors by weighting specific variables according to a global desirability function.

Analysis of Healthy and Infected Grape and Wine Samples. The method has been applied to the analysis of infected grapes and wines. The growth of *C. acutatum* and *B. cinerea* on grapes is clearly associated with elevated levels of 2-methylisoborneol, geosmin, and 1-octen-3-one (Table 7). These compounds are also present in wine made from grapes infected with these fungal pathogens and are reported above in sensory thresholds. Previously reported levels of geosmin in grapes infected with *B. cinerea* support our findings for the production of these compounds in grapes infected with this mold.[5−8]

As shown in Table 7, geosmin was measured at levels higher than the reported sensory perception threshold in Semillon wine made from grapes infected with *B. cinerea*. Similarly, in Cabernet Sauvignon wines made from grapes infected with *C. acutatum*, 2-methylisoborneol levels were higher than the sensory perception threshold. It appears that 2-methylisoborneol contributes to the off-flavors found in wines made from ripe-rot-affected grapes, while geosmin has a greater role in contributing to the off-flavors found in wines made from gray-mold-affected grapes. While previous studies have examined off-flavors found in wine made from grape infected with gray mold (*B. cinerea*) and *Penicillium* rots[8] and sour rot,[11] as far as we are aware, this is the first study that has attempted to identify the chemical nature of the off-flavors found in wine made from grapes affected with ripe rot (*C. acutatum*).

Dilution of wines to an approximate ethanol concentration of 3% (v/v), increasing ionic strength in SPME fiber exposure, and sample extraction conditions have enabled a sensitive HS-SPME method to be devised. This method is also suitable for grape samples and has excellent analytical reproducibility and repeatability for volatile fungal metabolites. It has been validated across a large range of analytical levels and has a higher sensitivity than previously reported. The methods described enabled the determination of off-flavors in wine and grapes at nanograms per liter levels and achieve a linear, specific, accurate, and repeatable method in a single run. The levels of detection are below the reported olfactory thresholds of perception.[25] The method had good recoveries (83−131%), with acceptable repeatability and reproducibility. The developed method requires little or no sample preparation, is easily automated and reliable, and has no requirement for solvent extraction. Because of its simplicity, the method is suitable for the analysis of fungal off-flavor

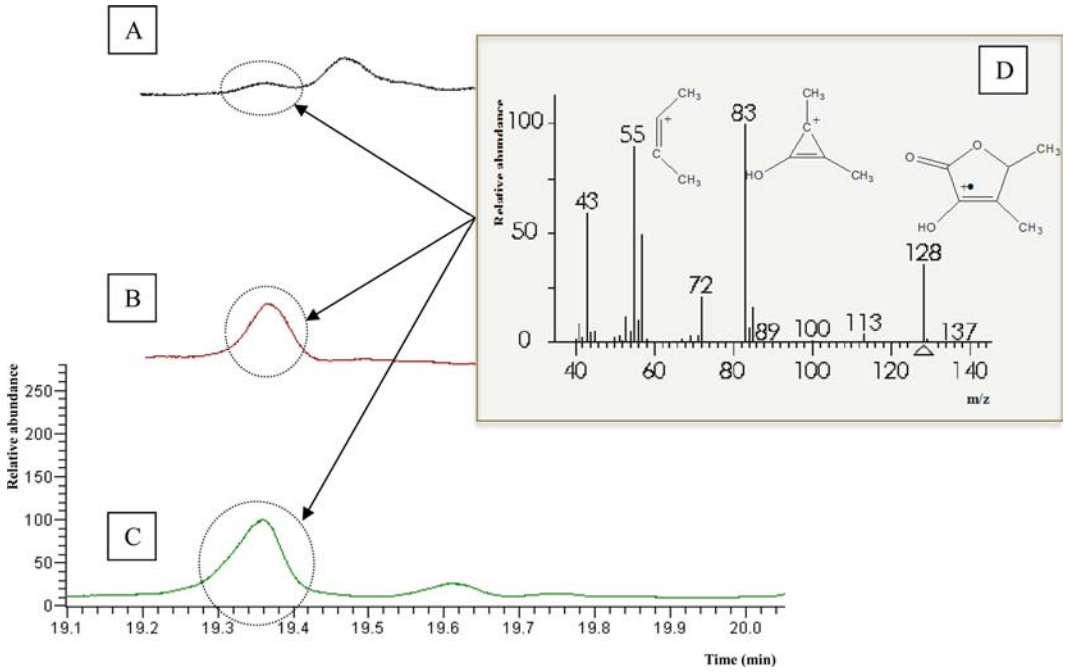

Figure 2. MS (SIM) chromatogram of fresh (A), 18-month-aged (B), and 24-month-aged (C) BL3 beer, and TIC mass spectrum of sotolon after 24 months (D).

No scientific paper describes how sotolon might be involved in the Madeira off-flavor found in aged beers, especially when strongly oxidized. Callemien et al.[6] detected the presence of sotolon in an aged lager beer. The aim of the present work was to compare the concentration of sotolon in fresh and aged samples of different commercial specialty beers. A specific lactone extraction procedure was applied, and the extracts were analyzed by GC-MS (gas chromatography-mass spectrometry). Beers or model media spiked with different hypothetical precursors and subjected to different beer storage conditions were compared in order to evidence which key factors should be controlled by brewers.

MATERIALS AND METHODS

Chemicals. Diethyl ether (99.9%), nonadecane (99.9%), hydrogen peroxide (30%), iron(II) chloride (98%), sotolon (99%), L-ascorbic acid (>99%), acetoin (>96%), diacetyl (97%), acetaldehyde (≥98%), and glycolaldehyde (hydroxyacetaldehyde dimer) were purchased from Sigma-Aldrich (Bornem, Belgium). Methanol (99.9%), acetone, and absolute ethanol were obtained from Analar Normapur (Fontenay-sous-bois, France). Anhydrous sodium sulfate (99%) was obtained from Merck (Darmstadt, Germany). Hydrochloric acid (36%) was purchased from Fisher Scientific (Tournai, Belgium). Sodium hydroxide was purchased from VWR international (Radnor, PA). Dichloromethane (99.9%) from Romil (Cambridge, U.K.) was distilled before use. Milli-Q water was used (Millipore, Bedford, MA). Amberlite XAD 2 resin (Supelco, Bellefonte, PA) (with a pore size of 9 nm and a specific area of 330 m^2/g) was sequentially washed with methanol and diethyl ether (each for 4 h) in a Soxhlet and stored in methanol at 4 °C.

Beer Samples. Seven commercial top-fermented beers (BL1, BL2, BL3, BL4, AM1, BR1, and TR1) were kindly supplied by Belgian brewers and stored in the dark at 20 °C for 2 years (Table 1) for natural aging. An analog of BL3 without ascorbic acid (BL5) was produced by a brewer for some spiking and accelerated aging experiments.

XAD 2 Procedure for Sotolon Extraction.[14] Amberlite XAD 2 resin (2 g) was thoroughly rinsed with Milli-Q water (approximately 400 mL), and the mixture was poured into a 250 mL Schott flask containing 50 mL of degassed beer adjusted at pH 11.5 by addition of 4 M NaOH. Beer alkalinization was done to increase lactone polarity, thus avoiding its adsorption onto the resin. Samples were shaken in the dark for 2 h and then poured onto a glass XAD column for separation. Beer percolating from the XAD 2 resin was recovered. Then, resin was washed with 50 mL of water, which was collected and mixed to the first eluate. This mixture was extracted three times with 40 mL of dichloromethane (10 min, 1000 rpm) after adjusting the pH to 3 to allow lactone cyclization. The organic phases were finally pooled and dried with anhydrous sodium sulfate. Then 0.5 mL of nonadecane stock solution (20 mg/L) was added as EST (external standard) before concentration to 0.5 mL in a Kuderna–Danish apparatus at 45 °C (total concentration factor = 100, final EST concentration = 20 mg/L). The final extract was stored at −80 °C for further analysis. A recovery factor of 89% was calculated for sotolon by the standard addition method in BL3.

Gas Chromatography Connected to Mass Spectrometry (GC-MS). Electronic impact mass spectra were recorded at 70 eV on a ThermoFinnigan (Waltham, MA) Trace MS simple quadrupole mass spectrometer connected to a ThermoFinnigan Trace GC 2000 gas chromatograph equipped with a split/splitless injector (splitless time = 0.5 min) and a polar FFAP-CB column (Varian, CP7485, 25 m × 0.32 mm i.d., 0.3 μm film thickness). The carrier gas was helium, and the pressure was set at 50 kPa (100 kPa were applied on the CP-Sil5-CB MS column, 50 m × 0.32 mm, 1.2 μm film thickness, that we used for RI (retention index) checking on a second chromatographic phase). The injection volume was 1 μL. The oven temperature was programmed to rise from 36 to 85 °C at 20 °C/min, then to 145 °C at 1 °C/min, and finally to 250 °C at 3 °C/min. Sotolon was quantified by standard addition with an EST (spiking to beer of 0.5, 1, 7, 15, and 20 μg/L), as recently described by Collin et al.[23] The SIM mode (single-ion monitoring mode) was used with m/z = 83 and 128. Spectral recording was automatic throughout separation (Xcalibur software, NIST database).

Gas Chromatography Connected to Olfactometric Detection (GC-O). A 1 μL amount of each extract was analyzed with a Chrompack CP9001 (Santa Clara, CA) gas chromatograph equipped with a split/splitless injector maintained at 250 °C (the split vent was opened 0.5 min postinjection) and connected to a GC-O port (Chrompack), also at 250 °C. The sotolon odor was checked with a polar FFAP-CB capillary column (Varian, CP7485, 25 m × 0.32 mm

DOI: 10.1021/jf505953u
J. Agric. Food Chem. 2015, 63, 2886−2892

i.d., 0.3 μm film thickness) and the CP-Sil5-CB MS column (50 m × 0.32 mm, 1.2 μm film thickness). The carrier gas was nitrogen, and the pressure was set at 30 (FFAP-CB) or 60 kPa (CP-Sil5-CB). The oven temperature program was the same as that described for GC-MS. The effluent was diluted with a large volume of air (20 mL/min) prehumidified with an aqueous copper(II) sulfate solution.

Beer Standard Analysis. Alcohol and extract determination were done with an Anton Paar (Graz, Austria) density meter DMA 4500M. Color, pH, and bitterness analyses were performed according to EBC analytical procedures.[24]

Sensory Analyses. Ten trained panelists scored 6 aging attributes on a scale of 1−5: cardboard, Madeira, nutty, bread, cooked fruit, and honey. A score of 0 meant the panelist did not detect the aroma, whereas a score of 5 meant the aroma was strongly perceived.

Determination of Sotolon Flavor Threshold in Beer. Determination of the flavor threshold of sotolon was performed with the ASTM method (Ascending Concentration Series Method of Limits), as recommended by the European Brewery Convention (method 13.9).[24] Sotolon was added to fresh beer (reference beer = fresh BL3) at six different levels of concentrations (from 0.5 to 20 μg/L). The panel was composed of 10 nontrained university students and 10 trained experts. Each assessor received 6 sequences of 3-Alternate Forced Choice (3-AFC) tests. For each sequence, sotolon was spiked into one test sample, the other two containing reference beer without any addition. The "best estimated threshold" (BET) of a panelist corresponds to the geometric mean of the highest concentration missed and the next highest adjacent concentration tested. The group best estimated threshold (group BET) was calculated as the geometric mean of the individual best estimated thresholds.

Investigation of Sotolon Pathways. *Pathway A.* BL3 bottles were spiked with 100 mg/L acetaldehyde and aged in the dark at 40 °C for 10 or 30 days. Pathways E/F: diacetyl 40 μg/L, acetoin 400 μg/L, serine 10 mg/L, and/or glycolaldehyde 40 μg/L were added to a sterilized phosphate buffer (pH = 4.5) containing 5% v/v ethanol. Samples were stored in the dark at 40 or 60 °C for 30 days. Pathways B/C/D: Oxygenated and control samples consisted in fresh BL5 exposed or not to sterile oxygen (final concentration = 6 mg/L in the "oxygen" sample) without any other spiking. Ascorbic acid was added at 880 mg/L final concentration, with or without 555 mg/L SO_2, to 200 mL of fresh BL5 in a glass flask exposed to oxygen by bubbling 6 mg/L sterile oxygen. A combination of iron at 1 mg/L and hydrogen peroxide at 1 g/L was also spiked as pro-oxidants to a BL5 sample exposed in the same way to 6 mg/L oxygen. Samples were stored for 30 days in the dark at 40 °C.

Statistical Analyses. Analyses were carried out in duplicate, and comparisons of means were performed with the Student−Newman−Keuls test with SAS software version 9.2 (SAS Institute, Inc., Carry, NC). Values sharing no common letter are significantly different ($p < 0.05$).

RESULTS AND DISCUSSION

Identification and Quantitation of Sotolon in Aged Beers. As depicted in Figure 2 and Table 2, only traces of sotolon (<1 μg/L) were found in fresh beer samples. In contrast, the lactone-specific extraction enabled us to quantify it in all special beers after 6, 12, 18, and 24 months of natural aging, whatever the type of beer (blond, amber, trappist, or brown, with or without bottle refermentation or ascorbic acid addition; Table 1). Identification was confirmed by mass spectrometry (coincidence of the main m/z with the commercial reference and the NIST library entry), the retention indices on two capillary columns (RI = 2213 on FFAP-CB and 1068 on CP-Sil5-CB), and odors (curry, walnut). For the 7 beers analyzed, the amount of sotolon already reached 4.6−14.2 μg/L after 6 months and continued to increase thereafter up to 42.1 μg/L in the ascorbic-acid-protected beer BL3 after 2 years. These values are well above the 2 μg/L sensory threshold previously assessed in hydro-alcoholic solution.[15] They also exceed after 12 months the 8 μg/L sensory threshold that a jury of 20 panelists here determined in BL3 (already after 6 months for BL2, BL3, and BL4). The Madeira attribute was also scored (together with five other aging descriptors) in all beers over the first year of storage by a jury of trained panelists (data given for BL3 in Figure 3). The Madeira character was set above 2 in all 6- and 12-months-aged beers and under 1 in fresh beers.

Table 2. Sotolon Concentration (μg/L) in Top-Fermentation Beers Stored at 20 °C[a]

	BL1	BL2	BL3	BL4	TR1	AM1	BR1
fresh	nq	nq	nq	nq	nq	nq	nq

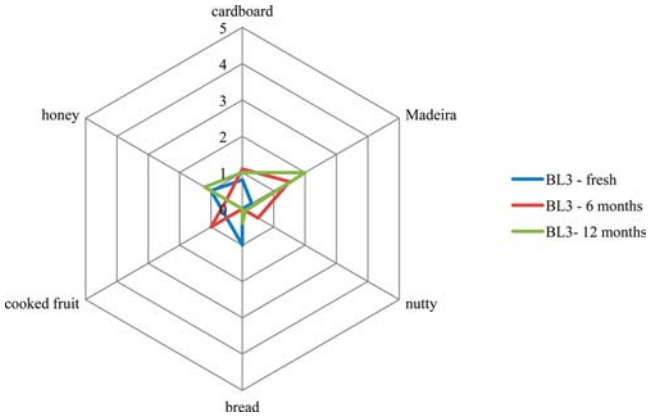

Figure 3. Aging off-flavors in BL3 through natural aging.

As depicted in Figure 4 for BL3, 30 days at 40 °C treatment revealed to produce sotolon (9 μg/L) in a range close to what we observed after 6 months of natural aging. Such accelerated aging was therefore applied to assess in a short time which synthesis pathways could occur in beer. As BL3 contained

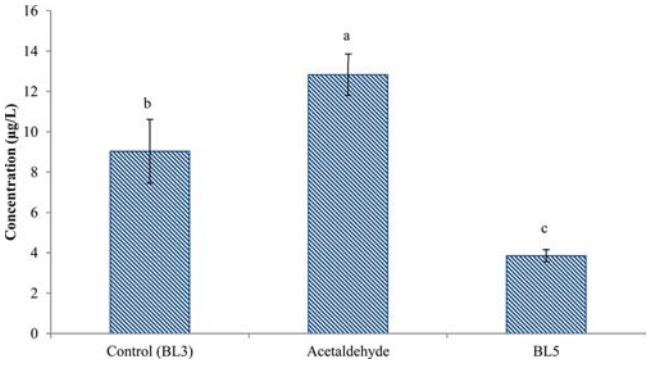

Figure 4. Sotolon concentration (μg/L) in a control beer (BL3, containing ascorbic acid), in the same beer spiked with 100 mg/L acetaldehyde, and in BL5 (devoided of ascorbic acid) after 30 days at 40 °C. Values sharing no common letters are significantly different ($p < 0.05$).

DOI: 10.1021/jf505953u
J. Agric. Food Chem. 2015, 63, 2886−2892

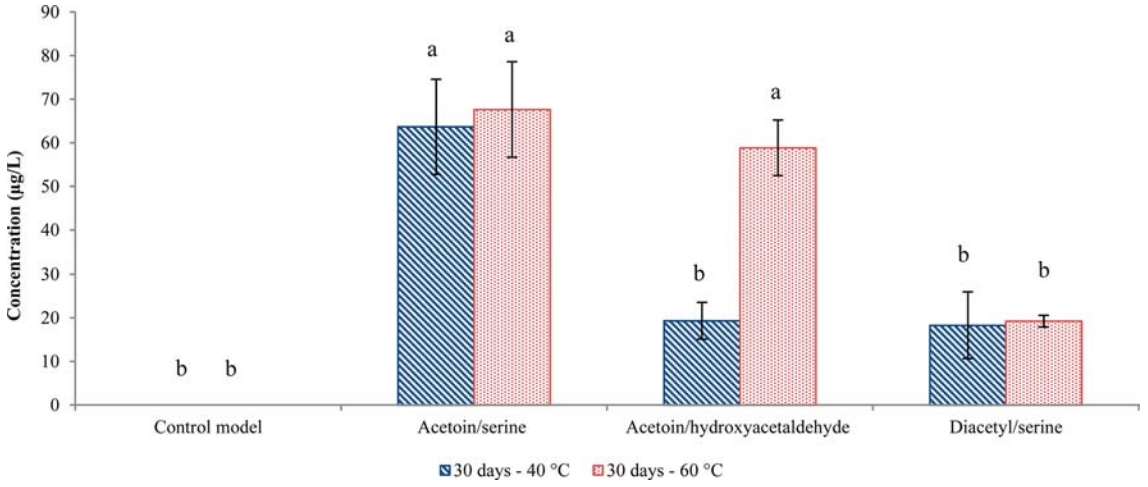

Figure 5. Sotolon concentration (μg/L) in a model beer medium (control model), and the same solution spiked with acetoin, serine, diacetyl, and/or hydroxyacetaldehyde after 30 days at 40 or 60 °C. Values sharing no common letters are significantly different ($p < 0.05$).

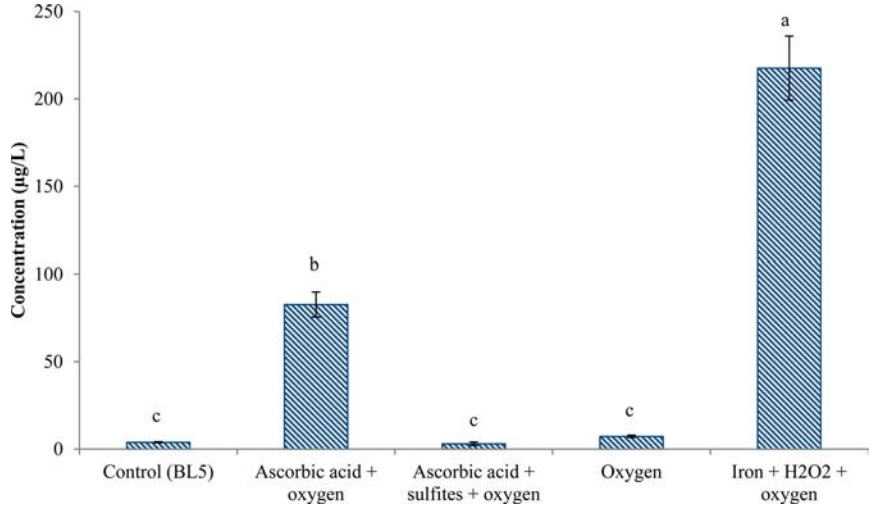

Figure 6. Sotolon concentration (μg/L) in a control beer (BL5, devoided of ascorbic acid) and the same BL5 beer spiked with 8 mg/L oxygen, with 880 mg/L ascorbic acid and 8 mg/L oxygen, a combination of 880 mg/L ascorbic acid, 6 mg/L oxygen, and 555 mg/L sulfites, or pro-oxidant species (Fe^{2+} (1 mg/L) + H_2O_2 (1 g/L)) after 30 days at 40 °C. Values sharing no common letters are significantly different ($p < 0.05$).

ascorbic acid, a pilot version without ascorbic acid addition at bottling (BL5) was requested of the manufacturer. This beer was used for all experiments where oxidation could play a key role. As shown by its accelerated aging (30 days at 40 °C), the absence of ascorbic acid already allowed minimizing the content of sotolon (4 μg/L in BL5 instead of 9 in BL3).

Potential Pathways for Sotolon Formation in Beer. *Pathway A.* Many researchers have demonstrated the key role of acetaldehyde in the appearance of sotolon in beverages.[19−25] Therefore, fresh BL3 was spiked with 100 mg/L acetaldehyde (usual concentration in fresh ales = 3.8−33.8 mg/L[26]) in the absence of oxygen, and samples were aged for 30 days at 40 °C. As depicted in Figure 4, sotolon was found to be significantly produced from added acetaldehyde (12.8 μg/L versus 8 in the control).

Pathways E/F. Diacetyl has been mentioned in the literature as a possible precursor of sotolon when combined with hydroxyacetaldehyde under quite harsh conditions[22] (usual diacetyl concentration in ale = 60−300 mg/L[27]). Its reduced form, acetoin, is another well-known constituent of beer (usual acetoin concentration in ale = 10−200 mg/L[27]) which could react with serine-derived compounds such as hydroxyacetic acid by aldol condensation (usual serine concentration in beer = 2−12 mg/L[28]). The compounds diacetyl, acetoin, glycolaldehyde (the commercial dimer of hydroxyacetaldehyde), and serine were mixed in different combinations in a beer model solution before aging for 30 days at 40 or 60 °C. As depicted in Figure 5, only acetoin proved able to generate large amounts of sotolon. The highest concentrations (63−67 μg/L) were obtained after addition of acetoin in the presence of serine. Hydroxyacetaldehyde together with acetoin led to lower amounts of sotolon at 40 °C (19.3 μg/L after 30 days) but reached 59 μg/L at 60 °C, probably because glycolaldehyde must dissociate to hydroxyacetaldehyde before it can react. In the case of diacetyl together with serine, both temperatures led to only 12−14 μg/L, suggesting that it is probably a minor pathway in natural beer aging. Transferred to beer, these results could mean that the efficiency of the reduction of diacetyl to acetoin by yeast could impact the Madeira off-flavor.

Pathways B/C/D. In the brewing industry, ascorbic acid is sometimes used as antioxidant at the bottling step in association (e.g., AM1) or not (e.g., BL3) with sulfites. As

DOI: 10.1021/jf505953u
J. Agric. Food Chem. 2015, 63, 2886−2892

illustrated in Figure 1 from the literature (pathways B–D), degradation of ascorbic acid can generate different species, possibly involved in sotolon synthesis. Ascorbic acid can also act as a pro-oxidant in beer.[28] Spiking of BL5 with 880 mg/L ascorbic acid (much higher amount than the industrial spiking of BL3 = 30 mg/L) and 6 mg/L oxygen led to sotolon concentrations up to 82.7 μg/L after 30 days at 40 °C, whereas the same beer, when untreated (control = no ascorbic acid and <0.05 mg/L oxygen), did not even reach the 8 μg/L flavor threshold of the lactone in beer (Figure 6). As expected, mixing 555 mg/L sulfites with ascorbic acid annihilated the latter's negative effect. In beer, sulfites arise either through the action of yeast or through exogenous addition at the bottling step.

BL5 was also aged for 30 days at 40 °C in absence of ascorbic acid, under a bottleneck saturated with 6 mg/L oxygen. Only 7.3 μg/L sotolon was measured here, suggesting that beer polyphenols are able to minimize its effect. In comparison, spiking of hydrogen peroxide and iron (well known for the Fenton reaction) dramatically increased sotolon concentration (up to 217 μg/L). Ethanol most probably acts as a quencher of hydroxyl radicals, as mentioned by Andersen et al.,[29] leading to the formation of acetaldehyde involved himself in sotolon synthesis (Pathway A).

In conclusion, prevention of oxidation is required to decrease the Madeira off-flavor brought to the beer by sotolon. Yet addition of ascorbic acid at bottling should be avoided, at least if not combined with sulfites, because of the role of ascorbic acid either as a reagent (precursor of α-ketobutyric acid, α-hydroxy-β-ketobutyric acid, or hydroxyacetic acid) or as a pro-oxidant (for acetaldehyde production). Despite a very low oxygen content in such beers, refermented beers seem not to be fully protected against the Madeira off-flavor, probably because of additional pathways, including the biochemical deamination of threonine and serine by yeast, followed by combination with either acetaldehyde or acetoin.

be the most effective glycerophospholipid with regard to the reduction of viscosity while having less of an effect on reducing the chocolate yield value. PE, on the other hand, is said to be more effective in reducing the chocolate yield value than the viscosity.[17−19] Therefore, when sunflower lecithin is replaced with soybean lecithin, it is important to keep in mind that sunflower lecithin has slightly more PC and less PE.

With regard to the analysis of lecithin's glycerophospholipids, various methods have been used such as thin layer chromatography (TLC), high-performance thin-layer chromatography (HPTLC), gas chromatography (GC), and high-performance liquid chromatography (HPLC).[1,20] GC was usually used for the identification of the individual fatty acids,[1] wheras TLC, HPTLC, and HPLC methods were applied to separate and identify glycerophospholipid classes (assignment of headgroups by normal phase chromatography) or the fatty acid species (reversed phase (RP) chromatography, silver ion chromatography).[6,21] HPLC was the most applied method because of its speed, resolution, high sensitivity, and specificity[22,23] as well as hyphenation with MS. For the MS analysis soft ionization methods such as fast atom bombardment (FAB), nowadays rarely used, or electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) were preferred because they allowed a direct analysis of the glycerophospholipid species.[24] In recent studies, HPTLC separation was combined with MALDI−time of flight mass spectrometry (TOFMS).[25−28] Recently, sialylated and sulfated glycosphingolipids as well as a total lipid extract of bovine brain were investigated by HPTLC-MS.[29] Two different direct elution techniques (contactless surface sampling versus the elution head-based approach) were compared. Although it was mentioned that in the bovine brain glycerophospholipids such as PE, PI, and phosphotidylserine (PS) were detected, no further details were given.

Hence, the aim of this study was to investigate the interchangeability of soybean and sunflower lecithin with regard to changes in the rheology of different chocolate masses. Occurring changes in rheology were compared with glycerophospholipid differences of the lecithin samples. The glycerophospholipid pattern and content of the different lecithin samples used in chocolate production were analyzed by HPTLC-FLD and further characterized by HPTLC-ESI$^+$-MS and HPTLC-FLD-ESI$^+$-MS. LODs and LOQs were determined for seven glycerophospholipids by the three analytical techniques for the first time. HPTLC-MALDI-TOFMS was employed for confirmation.

MATERIALS AND METHODS

Materials and Reagents. Two sunflower lecithin samples from different suppliers (SN1 and SN2) and one soybean lecithin sample (SJ) were obtained from Stollwerck (Cologne, Germany). The standards PE 34:1, PC 34:1, lyso-phosphatidylcholine (LPC 18:0), lyso-phosphatidylethanolamine (LPE 18:0), phosphatidylserine (PS 36:4), and phosphatidic acid (PA 36:4) were all purchased from Avanti Polar Lipids (Alabasta, AL, USA), except PE 32:0, which was bought from Sigma-Aldrich (Steinheim, Germany). For HPTLC-FLD and HPTLC-ESI$^+$-MS as well as HPTLC-FLD-ESI$^+$-MS, HPTLC plates silica gel 60 F_{254} (20 × 10 cm), and for HPTLC-MALDI-TOFMS, HPTLC foils silica gel 60 F_{254} (20 × 20 cm) were used (all Merck, Darmstadt, Germany). 2,5-Dihydroxybenzoic acid (DHB) was also provided by Merck. Chloroform (>99.5%, stabilized with 1% ethanol), isopropyl acetate (>99.0%), acetonitrile (≥99.9%), trifluoroacetic acid (≥98.0%), ammonium phosphate (≥99.0%), and primuline (≥50%, as sodium salt) were purchased from Sigma-Aldrich (Steinheim, Germany). Ammonia (25%, w/w) and methanol (gradient grade) were obtained from VWR (Darmstadt, Germany) and acetone (HPLC grade) from Carl Roth (Karlsruhe, Germany). Chocolate masses and lecithin samples were obtained from Stollwerck.

Standard Solutions. The solvent used for the preparation of standard solutions was a mixture of chloroform and methanol (1:1, v/v). About 0.5−1.0 mg of each glycerophospholipid standard was dissolved in 10 mL of solvent mixture (50−100 ng/μL). The standard solutions were stored in the dark at −20 °C. For limit of detection (LOD)/limit of quantification (LOQ) studies, the standard solutions were diluted 1:10 (5−10 ng/μL). Standard mixtures were generated via overspraying of the individual solutions onto the same starting zone.

Lecithin Sample Preparation. About 50 mg of the different lecithin samples were extracted with a mixture of methanol and isopropyl acetate (2:3, v/v). After centrifugation at 2300*g* for 10 min, the supernatant was removed and stored in the dark at −20 °C.

Sample Application. For quantitation, the solutions were sprayed with the Automatic TLC Sampler 4 (ATS4, CAMAG, Muttenz, Switzerland) as 8 mm bands allowing up to 20 tracks to be applied on one HPTLC plate of 20 × 10 cm (distance from lower edge 8 mm, distance from left edge 15 mm, automatic distance between bands). For calibration, 3.0−12.0 μL of the standard solutions was sprayed on the HPTLC plate (140−1200 ng/band), and sample volumes ranged between 4.0 and 12.0 μL. For LOD/LOQ determinations by HPTLC-ESI$^+$-MS and HPTLC-FLD-ESI$^+$-MS, 4 mm bands were applied to fit the dimensions of the oval elution head (4 × 2 mm). To determine the maximum sample application volume possible, volumes of the lecithin sample SN2 ranging between 60.0 and 320.0 μL were applied as rectangles (8 × 3 mm) on a cut HPTLC plate (smartCUT Plate Cutter, CAMAG). For HPTLC-MALDI-TOFMS, bands of 4 mm length were applied on HPTLC foils, later cut to the size of 5 × 7.5 cm (distances from lower and side edge as before, distance between bands 8 mm). The sample extracts (10 μL) and standard solutions of PC 34:1 and PE 34:1 (1 μg/band) were applied.

Chromatography. Development was performed on HPTLC plates or foils silica gel 60 F_{254} with a mixture of chloroform/methanol/water/ammonia (25%) (30:17:2:1, v/v/v/v)[20] in the Automatic Developing Chamber (ADC2, CAMAG). Before development, the chamber was saturated for 20 min and the relative humidity was adjusted to 33% by a saturated magnesium chloride-6-hydrate solution for 3 min. The migration distance was 65 mm (from the lower edge of the plate). After application of the starting zones and after development, the plate was automatically dried for 0.5 and 2 min, respectively.

Derivatization. For visualization of the glycerophospholipids, the developed plates were dipped into a primuline solution (100 mg of primuline in 200 mL of acetone/water 4:1, v/v) at a speed of 3 cm/s and an immersion time of 1 s using a TLC Chromatogram Immersion Device (CAMAG). The plate was dried in a stream of warm air (hair dryer at 30 cm distance from the plate) for 2 min.

Densitometry and Documentation. The densitometric evaluation via fluorescence measurement at UV 366/>400 nm (mercury lamp, measurement slit size 6.0 mm × 0.2 mm, scanning speed 20 mm/s, K400 optical filter) was performed using a TLC Scanner 4 (CAMAG). Plate images were documented at 366 nm by a TLC Visualizer (CAMAG). All CAMAG instrumentation used so far as well as data obtained was processed with winCATS, version 1.4.6.2002 (CAMAG).

Mass Spectrometry. The derivatized, at 366 nm, blue fluorescent glycerophospholipid bands (4 mm band length applied) were marked at UV 366 nm illumination with a soft pencil and directly eluted via the oval elution head (4 × 2 mm) of the TLC-MS Interface (CAMAG) using 100% methanol at a flow rate of 0.1 mL/min (pump of the HP 1100 ChemStation, Agilent, Waldbronn, Germany). In the tubing to the MS a C18 guard cartridge (SecurityGuard cartridge, Phenomex, Torrance, CA, USA) was integrated. A single-quadrupole MS (mass resolution of 1 unit) equipped with an ESI ion source was employed (ExpressIon CMS, Advion, Ithaca, NY, USA). For positive ionization, the capillary voltage was set to 170 V, the ESI voltage to

J. Agric. Food Chem. 2015, 63, 2893−2901

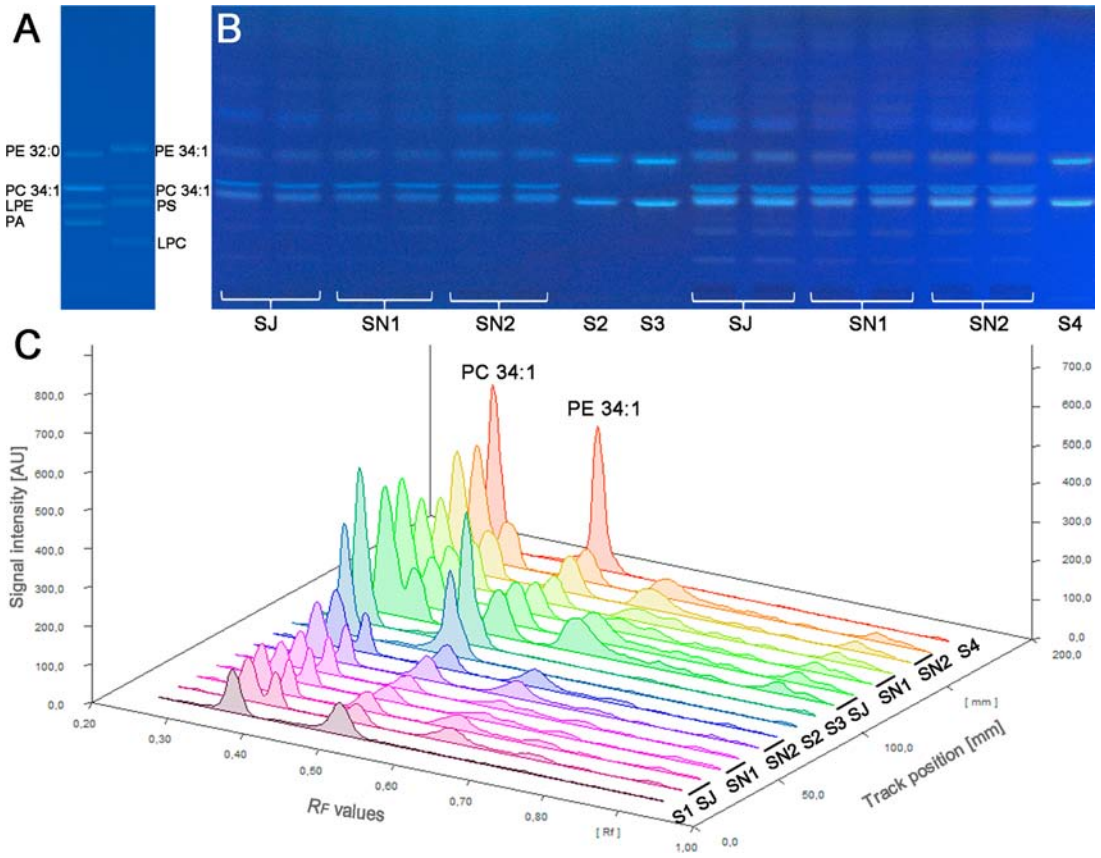

Figure 1. HPTLC chromatograms of (A) all glycerophospholipid standards available (tracks 1 and 2) and (B) PC 34:1 and PE 34:1 with different volumes applied (S2−S4) beside samples of soy lecithin (SJ) and sunflower lecithins (SN1 and SN2) as well as (C) an HPTLC 3 D densitogram.

3500 V, and the source voltage to 25 V. The nebulizer gas pressure was 60 psi, the temperatures of the capillary and the source gas were set to 250 °C, and the dissolvation gas flow rate was 4 L/min. The mass spectra were recorded in the full scan mode (total ion current (TIC) chronogram) m/z 100−1000 using a detection gain of 1100. Data processing for MS measurement was carried out with Mass Express 1.1.22.15, and evaluation was done with Data Express 1.1.22.15 (both Advion). A plate background at a migration distance comparable to the analyte zone was subtracted from the analyte spectrum. For LOD/LOQ determination by HPTLC-FLD-ESI$^+$-MS, the x,y-coordinate for elution was obtained after fluorescence measurement at UV 366/>400 nm, as such a low substance amount was not visible in the UV 366 nm image. For HPTLC-ESI$^+$-MS of nonderivatized zones, the x,y-coordinate for elution was received by extrapolation from the respective derivatized band on a cut plate strip (y-coordinate) and from the respective starting zone (x-coordinate).

For HPTLC-MALDI-TOFMS,[28,30] the HPTLC foil was homogeneously coated with a DHB solution (8 g in 40 mL of a mixture of acetonitrile and 10 mM aqueous ammonium phosphate solution with 0.1% trifluoroacetic acid 9:1, v/v). Therefore, the foil was dipped into the DHB solution at a speed of 4.5 cm/s and an immersion time of 1 s using the TLC Chromatogram Immersion Device (CAMAG). For the first 90 s the solvent was allowed to evaporate in the air, followed by 90 s of drying with a hair dryer. All steps were repeated, but the last drying step was extended to 4 min. The foil's reverse side was cleaned with a tissue, and the foil was cut to a size of 5 × 7.5 cm using a scissors. The cut foil part was mounted into a TLC-MALDI adapter target (Bruker Daltonics, Bremen, Germany). The HPTLC-MALDI-TOF mass spectra were acquired in the positive mode on an Ultraflex 1 TOF/TOFMS (Bruker Daltonics), which had a mass accuracy of about 75 ppm.

Rheological Measurements of the Chocolate Masses. Three different chocolate masses (dark, milk, and white) were manufactured without emulsifiers. Of the regular soybean lecithin sample SJ the original concentration according to the recipe (original-%) was added, whereas for the sunflower samples SN1 and SN2 three different concentrations (original-% as well as ±0.1%) were added to each of the three base chocolates by a defined manual mixing process.[31] The rheology of the chocolate samples was measured at 40 °C with a RheolabQC viscosimeter (Anton Paar, Graz, Austria) using a DIN cup and bob geometry. After a defined conditioning step including 30 s of preshearing at 5 s^{-1}, the viscosity measurements were carried out with increasing shear rates from 2 to 100 s^{-1} and recording of 29 data points. The rheological parameters viscosity and yield value were taken by fitting the Casson equation to the data.[32,33] Each analysis was executed in triplicate (n = 3).

Statistical Analysis. Statistical analysis was done with Microsoft Excel, version Office Standard 2010. The respective means, standard deviations, and relative standard deviations were calculated. The two-sample t test (independent, two-sided, P = 95, 99, 99.9%) was applied to test the different lecithins for significant differences in the PC and PE contents.

RESULTS AND DISCUSSION

The HPTLC-FLD method allowed a satisfying separation of seven glycerophospholipid standard substances (available in our institute), which were divided in two mixtures (Figure 1A). The standard compound PC 34:1 showed a hR_F value of 30, whereas both of the PE standards (PE 32:0 and PE 34:1) had higher hR_F values (hR_F = 41 and 43).

Comparison of the Lecithin Fingerprints. The separation of the lecithin samples' glycerophospholipids showed equally good results (Figure 1B). The brilliance of the blue fluorescence increased with the concentration. The lecithins from both plants had a comparable glycerophospholipid pattern, with PC (hR_F = 31) and PE (hR_F = 43) as the main

DOI: 10.1021/jf506332f
J. Agric. Food Chem. 2015, 63, 2893−2901

glycerophospholipids. Other glycerophospholipid bands visible in the samples (hR_F = 12, 21, 36, 54, and 84) could not definitively be assigned to any standard compound available in our institute. Thus, the glycerophospholipid zones found were subjected to a subsequent characterization by MS (see Characterization by HPTLC-FLD-ESI+-MS). As PC and PE were identified to have the highest influence on rheology,[17−19] quantitation was focused on these two compounds.

Quantitation of PC and PE in the Lecithin Samples. With regard to the quantitative analysis of PC and PE in soybean and sunflower lecithins, the calibration was performed in the ranges of 140−550 ng/band for PC 34:1 and 300−900 ng/band for PE 34:1 (Figure 1C). If required, the working ranges can be expanded; however, they were sufficiently wide for the given analysis. The mean repeatabilities (%RSD, n = 2, instant repetition within a laboratory) for both compounds in the lecithin matrix were mostly ≤5.0%, whereas the intermediate precisions (%RSD, n = 2, repetitions within a laboratory over several weeks) were mostly ≤10.0% (Supporting Information Table S1). After statistical analysis, the mean PC and PE contents were found to be different in soybean and sunflower lecithins (Figure 2). Both sunflower lecithin samples

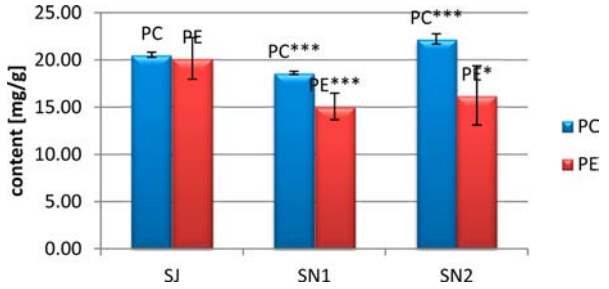

Figure 2. PC 34:1 and PE 34:1 contents (mean ± standard deviation) of one soybean (SJ) and two sunflower (SN1 and SN2) lecithin samples. (*) Statistically, (**) significantly, and (***) highly significantly different compared to SJ (P = 95, 99, 99.9%).

showed significantly lower values for PE than the soybean lecithin, currently used for chocolate production. For both soybean and sunflower lecithin samples, the mean PC content was about 20 ± 2 mg/g (2.0%), whereas the results for PE showed a wider content range between 14 and 22 mg/g (1.4−2.2%). This was reflected in the ratios PC/PE. The soybean lecithin sample (SJ) had a PC/PE ratio of 1.0. In contrast, the two sunflower samples (SN1 and SN2) showed higher ratios of 1.2 and 1.3, respectively (Table S1). According to the independent, two-sided t test, there were differences in the glycerophospholipid content between SJ and either SN1 (calculated t value t_1 = 10.36 for PC and t_1 = 4.76 for PE) or SN2 (calculated t value t_2 = 5.55 for PC and t_2 = 2.52 for PE) (Figure 2).

Selection of the Ionization Mode of HPTLC-FLD-ESI-MS. For HPTLC-FLD-ESI-MS, the derivatized, blue fluorescent zones of interest were eluted via the TLC-MS Interface as described.[30] The derivatization reaction with the primuline reagent was based on a physisorption (only interaction with the analyte due to van der Waals forces), and during the MS measurement the primuline molecule was separated from the glycerophospholipid molecule. The primuline was observed in the negative ionization mode as a desodiated molecule at m/z 452 $[M-Na]^-$ (S/N 24 in the extracted ion current (EIC) chronogram). As the primuline substance bought was only 50% pure, an additional ion at m/z 319 was observed as base peak (S/N 50 in EIC chronogram). This ion was assumedly assigned as the desodiated fragment of primuline, named 2-(4-aminophenyl)-6-methyl-1,3-benzothiazole-7-sulfonate $[M-C_7H_3NS-Na]^-$). Because the primuline forms negative ions, the phospholipid measurement was performed in the positive ionization mode. Thus, the derivatization reagent did not impair the glycerophospholipid mass signal and eased its interpretation. Using a single-quadrupole MS, the glycerophospholipid bands in the standard mixture were clearly detected at 400 ng/band (S/N 110 and S/N 310 for the base peaks $[M+Na]^+$ of PE 34:1/32:0 and PC 34:1, respectively). Thus, the positive ionization mode was found to be a good compromise, although the negative ionization might be more sensitive for some glycerophospholipids.

Characterization by HPTLC-FLD-ESI$^+$-MS. The preliminary assignment of the head groups (PC and PE) of the unknown glycerophospholipid bands in the lecithin samples was based on the hR_F values. For characterization of their fatty acyl residues, the ESI^+ mass spectra of the glycerophospholipid bands found were recorded. For comparison, the mass spectra of the PC and PE standards were recorded, too. The identities of the standards PE 32:0 and PE 34:1 as well as PC 34:1 were confirmed due to their characteristic sodium adducts $[M+Na]^+$ and $[M+2Na-H]^+$(Supporting Information Figure S1).

The mass spectra of the respective glycerophospholipid bands preliminarily assigned as PC in the lecithin samples SJ, SN1, and SN2 (12.0 μL applied, Figure 3) showed a mass signal pattern comparable to the PC standard. Two molecular species with mass signals at m/z 782 $[PC1]^+$ and m/z 758 $[PC2]^+$ were evident. This suggested the presence of PC 36:4 (PC1) and PC 34:2 (PC2). These results corresponded with the literature, in which *sn*-1,2-dilinoleoyl-PC and *sn*-1-palmitoyl-2-linoleoyl-PC were reported in soybean lecithin.[27] The respective sodium adducts were observed at m/z 804 $[PC1+Na]^+$ and m/z 780 $[PC2+Na]^+$. Furthermore, the mass signal at m/z 564 was explained by fragmentation (fatty acid elimination), that is, elimination, of linoleic acid $[PC1-C18:2]^+$ and palmitic acid $[PC2-C16:0]^+$, respectively.

With regard to the PE preliminarily assigned bands in the lecithin samples, all mass spectra showed a mass signal pattern (Figure 4) comparable to that of the PE standard. According to Stübinger et al.,[27] the mass signals were assigned as PE 36:4 (PE1) and PE 34:2 (PE2). The obtained mass signals showed predominantly adducts, that is, the respective sodium adducts at m/z 762 $[PC1+Na]^+$ and m/z 738 $[PC2+Na]^+$ as well as the disodium adducts at m/z 784 $[PC1+2Na-H]^+$ and m/z 760 $[PC2+2Na - H]^+$.

It can be concluded that the PE and PC present in the lecithin samples were most likely esterified with palmitic and linoleic acid. The latter is the main fatty acid in soybean and sunflower oil.[13,38] In oils derived from plants, the unsaturated fatty acid (here, linoleic acid) is predominately located at the *sn*-2-position of the glycerophospholipid.[3,27] For an unequivocal identification of the fatty acyl residues, additional MS/MS measurements and also measurements in the negative mode could be helpful, especially for samples in which the glycerophopholids and their fatty acyl pattern are not yet described in such detail. For the purpose of the current study, however, the simple identification in the positive ionization mode with a single-quadrupole MS and comparison with data from the literature were sufficient.

J. Agric. Food Chem. 2015, 63, 2893−2901

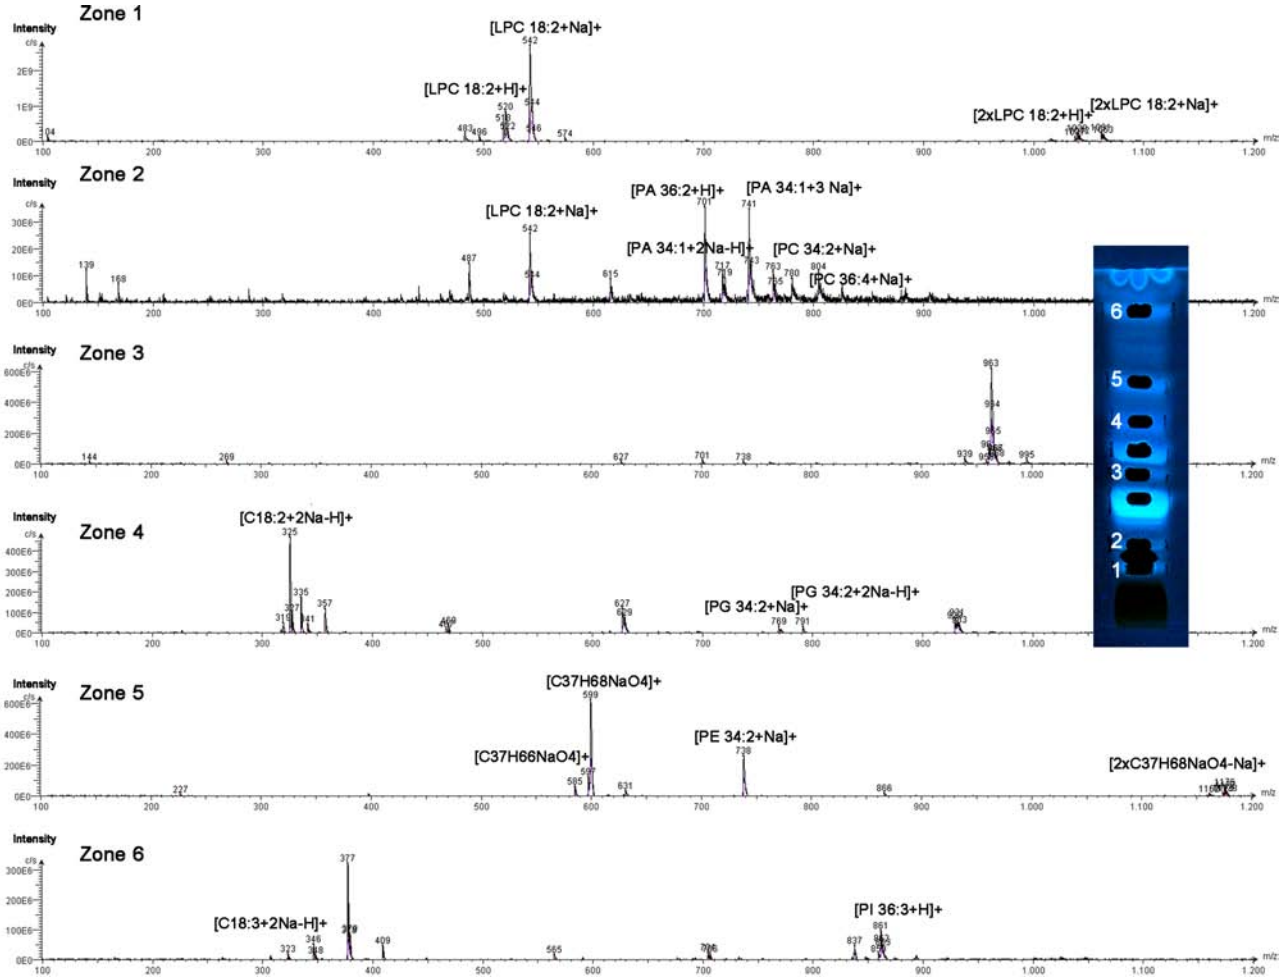

Figure 5. HPTLC-FLD-ESI$^+$-MS of six lower concentrated glycerophospholipid zones of the sunflower sample SN2 (zones 1−6, application volume 60 μL).

Additionally, mass spectra were recorded from the SN2 sample's lower concentrated fluorescent zones, clearly visible on the plate at higher application volumes (Supporting Information Figure S2). Several unknown minor glycerophospholipid zones were tentatively assigned, for example, LPC 18:2, PA 34:1, and 36:2, phosphatidylglycerol (PG) 34:2, and PI 36:3 (Figure 5).[39] However, the zone 3 (hR_F 36) just above PC could not be assigned unambiguously. Although the signal at m/z 963 would be consistent with both a triacylglycerol ($C_{63}H_{110}O_6$) and PI (43:1) or PI (44:8), the zone's position on the plate seemed to be implausible for a triacylglycerol, and the fatty acyl pattern of PI fits to neither soybean nor sunflower lecithins. Whereas for a final identification high-resolution MS would be the logical next step, this still demonstrated that mass spectra were obtainable also from minor glycerophospholipids and that it is a matter of the application volume in HPTLC to obtain clear mass signals (here, 60 μL applied).

Mean LODs and LOQs of Seven Glycerophospholipids via HPTLC-FLD, HPTLC-ESI$^+$-MS, and HPTLC-FLD-ESI$^+$-MS. So far, no literature has reported LOD and LOQ values for glycerophospholipids via HPTLC-FLD, HPTLC-ESI$^+$-MS, and HPTLC-FLD-ESI$^+$-MS, so it was unclear how sensitive potential phospholipids in samples could be detected. Thus, LOD and LOQ values[34] were studied for three modes of detection, that is, via HPTLC-FLD, HPTLC-ESI$^+$-MS, and HPTLC-FLD-ESI$^+$-MS. In HPTLC, the application volume applied influences the calculation of the LOD/LOQ. As the spray-on application (as aerosol) includes a concentration step, the selected application volume determines the LOD/LOQ obtained. The rule is the higher the application volume, the lower the LOD. Thus, for the calculation of the LOD and LOQ, increased sample volumes (between 60 and 320 μL) were applied to get an impression of how the matrix influences the separation and how high a maximal application volume can be. Even at the highest investigated sample volume of 320 μL, the phospholipid zones were still clearly distinguishable (Supporting Information Figure S2). Therefore, it was possible to apply at least 320 μL to achieve low LODs. Thus, the highest experimentally proven sample volume (320 μL) was taken into account for the calculation of the LOD and LOQ values. However, it is important to keep in mind that for the LOD and LOQ analyses by HPTLC-ESI$^+$-MS and HPTLC-FLD-ESI$^+$-MS, 4 mm instead of 8 mm bands were applied to ensure that the glycerophospholipid zones were eluted as completely as possible. Therefore, by halving the application band, the maximum application volume that was experimentally proven (320 μL) was also halved to be 160 μL. The mean LODs (S/N 3) of HPTLC-FLD-ESI$^+$-MS were 60 and 45 mg/kg for PE 34:1 and PE 32:0, respectively. For PC 34:1, the mean LOD was 15 mg/kg. Mean LODs and LOQs of the seven glycerophospholipids investigated were mostly comparable, although slightly higher for most of the nonderivatized bands

[a]Calculated according to ICH using S/N 3 and 10. [b]Only a 50% aliquot of the 8 mm band was covered by the TLC-MS Interface elution head of 4 × 2 mm.

Table 2. Mean Rheological Values (n = 3) of Dark, Milk, and White Chocolates Using Soybean (SJ) and Sunflower Lecithins (SN1, SN2)

		lecithin samples in chocolate mass		
type of chocolate	Casson parameter	SJ	SN1	SN2
dark (0.54%)[a]	yield value (Pa)	19.40 ± 0.67	19.09 ± 1.27	19.89 ± 0.41
	viscosity (Pa·s)	4.28 ± 0.05	4.46 ± 0.04[b]	4.24 ± 0.07
milk (0.58%)[a]	yield value (Pa)	9.25 ± 0.36	9.63 ± 0.10	10.35 ± 0.28[b]
	viscosity (Pa·s)	1.87 ± 0.02	1.87 ± 0.02	1.87 ± 0.02
white (0.50%)[a]	yield value (Pa)	6.18 ± 0.24	6.33 ± 0.33	5.75 ± 0.17
	viscosity (Pa·s)	1.68 ± 0.02	1.71 ± 0.01	1.64 ± 0.03

[a]Lecithin content that is added according to the recipe (original-%). [b]Statistically different compared to SJ (p < 0.05).

(Table 1). Reasons for this could be that properly targeting the nonderivatized zones was more difficult or that the derivatization reagent helped to promote the ionization of some glycerophospholipids. Also, to achieve better LOD and LOQ values, especially for PS 36:4 and LPE 18:0, optimizing the ionization parameters for these substances would be an important next step. LOD and LOQ (experimentally obtained in ng/band as listed in Table S2 in the Supporting Information) were calculated as milligrams per kilogram on the basis of the experimentally proven application volume (160 μL applied as 4 mm bands); if necessary, lower LOD and LOQ values could also be achieved by a more complex sample preparation to reduce the matrix influence and allow the application of even higher application volumes.

Comparison with HPTLC-MALDI-TOFMS. The manually cut foil was fixed in the TLC-MALDI adapter target (Supporting Information Figure S3A). The mass signals obtained by HPTLC-FLD-ESI$^+$-MS were confirmed by HPTLC-MALDI-TOFMS, exemplarily shown for PC 34:1 (Figure S3B). However, in some HPTLC-MALDI-TOFMS spectra the signals were shifted by about $\Delta m/z$ = 1 if compared to those obtained by HPTLC-FLD-ESI$^+$-MS. In this case, the shift was also evident for the mass signals of the DHB matrix, resulting in mass signals at m/z 552 and 728 instead of m/z 551 $[3DHB - 3H + 4Na]^+$ and m/z 727 $[4DHB - 4H + 5Na]^+$. This shift may have been caused by irregularities of the HPTLC surface after repeated immersion in the DHB matrix solution, but more likely by an uneven aluminum foil carrier, due to the necessity of cutting the 20 × 20 cm plate to fit the dimensions of the TLC-MALDI adapter target.[40] In a further study, precut HPTLC foils, silica gel 60 F_{254} MS-grade, for MALDI (5 × 7.5 cm) solved this problem. This demonstrated how important it is to fix an even foil with a plane and smooth rear in the TLC-MALDI adapter target.

Comparison with Other Methods and Benefit of the HPTLC Method. For the HPLC-MS/MS method published by Lee et al.[35] (phospholipids in soybean cultivars) and for the SPE-HPLC-ELSD method published by Narváez et al.[36] (phospholipids in the subcutaneous fat of Iberian pig) the glycerophospholipid LOD/LOQ values were in the low micrograms per kilogram range. For a recently published RP-HPLC-UV method[37] (fatty acid composition of soybean PC), the values were in the low milligrams per liter range. Although some of these methods may be more sensitive, one has to keep in mind that the sample preparation was more complex and time-consuming (e.g., additional SPE step) or more powerful MS analyzers (e.g., MS/MS) were used. Thus, a direct method comparison is often not feasible or leads to wrong conclusions.

HPTLC-FLD-ESI$^+$-MS proved to be well suited for the investigation of glycerophospholipids in crude lecithin extracts from soybean and sunflower seeds. The lecithin sample preparation was kept simple (only dissolving the sample). The method allowed the visual comparison of the phospholipid patterns of different samples separated next to each other on one plate. Although it is fast and cost-effective and has a high matrix tolerance, the separation on silica gel layers also allowed the separation according to the headgroup, making this method complementary to RP18-HPLC methods. Additionally, the

DOI: 10.1021/jf506332f
J. Agric. Food Chem. 2015, 63, 2893−2901

hyphenation with MS allowed the investigation of the glycerophospholipids' fatty acyl pattern. It was proven that the derivatization reagent did not impair the detectability by MS (only slight differences), and quantitation by fluorescence measurement as well as documentation can be performed before the mass spectra are recorded. In favor of this method are also relatively low LOD and LOQ values. The present study clearly demonstrated that the hyphenated HPTLC-FLD-ESI$^+$-MS method is highly suited for the analysis of incoming lecithin samples and their quality control with regard to the lecithin pattern and content.

Rheology of Respective Chocolate Samples Prepared. The interchangeability of soybean and sunflower lecithins in chocolate masses was investigated next. Two sunflower lecithin samples (SN1 and SN2) were compared to soybean lecithins (SJ) in three different chocolate masses (dark, milk, and white) regarding a potential diverse influence on the rheology of the chocolate. The rheology of the respective chocolates (lecithin samples added according to the original recipe) showed overall comparable results using sunflower or soybean lecithins (Table 2). Similar flow parameters were detected by using SN1 or SJ in milk and white chocolate. However, SN1 led to slightly higher values in the viscosity of dark chocolate than SJ. The sunflower lecithin SN2 showed similar functionality as SJ regarding the rheology of dark and white chocolates. Nevertheless, the yield value of milk chocolate using SN2 was slightly increased compared to the use of SJ (Table 2). In white chocolate, no significant differences in the flow parameters could be detected. It was found that the differences between the flow parameters of chocolates containing sunflower lecithin instead of soybean lecithin were marginal. To a certain extent, there were slight differences in the rheological characteristics of dark and milk chocolates. A reduction or increase of the sunflower lecithin content (original content (%) ± 0.1%) led to significant and sometimes highly significant differences compared to the original content of SJ.[41]

Comparison of the Glycerophospholipid Content with the Rheological Result. Additionally, the differences in the PC and PE contents of sunflower and soybean lecithins were studied regarding a potential causal correlation to the measured rheological parameters. Previous studies using enriched lecithin samples revealed PC as the most effective glycerophospholipid in reducing chocolate viscosity and PE in decreasing the yield value.[17−19] Thus, a regression analysis was done for the respective glycerophospholipid content of the lecithin sample and the rheological result of the prepared chocolate mass (original concentration). Nevertheless, a correlation between the PE content of the lecithins and the yield value could not be found for any of the chocolates prepared in this study. In addition, neither the 10% lower (SN1) nor the 10% higher (SN2) PC content with regard to SJ (Table S1 in the Supporting Information) had a divergent effect on the viscosity of dark or milk chocolate. However, a negative correlation (r = −0.99) between the PC content and the viscosity of white chocolate was found for the studied samples. Further investigations with a higher number of samples and different concentrations of lecithin have to verify this initial result. In summary, the content differences for PC (18.4−22.2 mg/g) or PE (13.8−22.3 mg/g) in the lecithin samples seem to be too marginal to be the reason for the slight differences in the rheology of milk or dark chocolate by using sunflower or soybean lecithin. Nevertheless, a correlation between viscosity and PC content was indicated for white chocolate. It can be concluded, on the basis of these initial results, that the soybean lecithin can be substituted by one of the sunflower lecithins investigated. However, this conclusion might not be generalized due to potential natural variances in the single glycerophospholipid contents of the lecithins.

Author Contributions

S.K. wrote the initial manuscript, but some parts were contributed by L.B., and all were revised by G.E.M. L.B. performed the PE and PC quantitation in the lecithin samples as well as the rheological tests of the produced chocolate masses. S.K. performed all of the mass spectrometric investigations and evaluations. The statistical tests were calculated by both. All experiments were supervised by G.E.M.

Notes

The authors declare no competing financial interest.

■ ACKNOWLEDGMENTS

We thank Stollwerck, Cologne, Germany, for providing the lecithin samples, chocolate masses, and instrumental equipment for the rheological analysis; Prof. Dr. Lochnit, Department of Biochemistry, Justus Liebig University Giessen, Germany, for recording the HPTLC-MALDI-TOFMS spectra; and Bruker Daltonics, Bremen, Germany, for the TLC-MALDI adapter target.

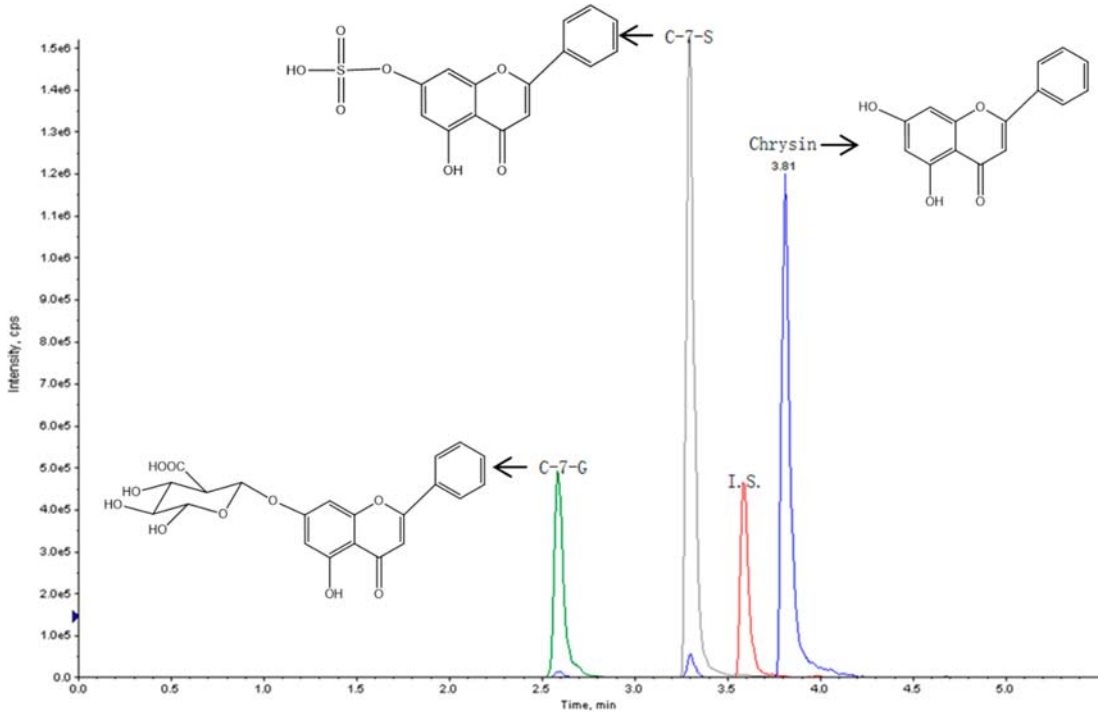

Figure 1. MS/MS chromatograms for chrysin, C-7-O-glucuronide (C-7- G), C-7-O-sulfate (C-7-S), and formononetin (I.S.) in a blood sample.

exposure level of chrysin and its metabolites in Bcrp1 (−/−) mice would be observed. Finally, human Caco-2 cells were used as in vitro tool to explore the disposition mechanisms of chrysin phase II conjugates in intestinal epithelial cells.

MATERIALS AND METHODS

Chemicals. Chrysin was purchased from INDOFINE Chemical Company (Hillsborough, NJ). Formononetin was purchased from LC Laboratory (Woburn, MA). Solid phase extraction (C18) columns were purchased from J.T. Baker (Phillipsburg, NJ). Ora-Plus oral suspending vehicle was obtained from Paddock Laboratories Inc. (Minneapolis, MN). Ko143 was purchased from Cayman Chemical (Ann Arbor, MI). Hanks' balanced salt solution (powder form) was purchased from Sigma−Aldrich (St. Louis, MO). All other materials (typically analytical grade or better) were used as received.

Biosynthesis of Chrysin Glucuronide and Sulfate. Chrysin glucuronide/sulfate was obtained from FVB mouse intestine perfusate samples and used for method development and validation. The intestinal surgical procedures, approved by the University of Houston's Institutional Animal Care and Use Committee, were described in previous publications.[18,19] Briefly, the mouse intestine was perfused with 20 μM of chrysin at the flow rate of 0.191 mL/min, and the perfusate sample was applied to a C18 solid phase extraction column. After washing out the salt, acetonitrile was used to elute chrysin and its conjugates, and the concentrations of these conjugates were determined using UPLC. This solution was then used as the stock solutions of chrysin and its metabolites, and it was stored in acetonitrile at −80 °C.

Instruments and Conditions. *UPLC.* A UPLC system, Waters AcQuity with diode-arrayed detector (DAD) was performed to determine the concentrations of stock solution of chrysin conjugates. The UPLC conditions for analyzing chrysin, its conjugates, and formononetin (I.S.) in aqueous samples were the following: column, AcQuity UPLC BEH C18 column (50 mm × 2.1 mm I.D., 1.7 μm, Waters, Milford, MA, U.S.A.); mobile phase A, 100% aqueous buffer (2.5 mM ammonium acetate, pH7.4); mobile phase B, 100% acetonitrile; gradient: 0−0.5 min, 5% B, 0.5−1 min, 15% B, 1−2 min, 15−25% B, 2−3 min, 25−50% B, 3−3.5 min, 50−85% B, 3.5−4 min, 85−95%, 4−4.3 min, 95% B, 4.3−4.5 min, 95−5% B, 4.5−5.5 min, 95% B; flow rate, 0.45 mL/min; column temperature, 45 °C; sample temperature, 20 °C; and injection volume, 10 μL.

LC-MS/MS. A Waters Ultra Performance Liquid Chromatography (UPLC) system coupled with an ESI-triple quadrupole mass spectrometer (QTRAP5500; AB Sciex, Foster City, California) was used for the analysis in plasma medium by MRM (Multiple Reaction Monitoring) method in the negative ion mode. The instrument dependent parameters for mass spectrum were set as follows: ionspray voltage, −4.5 kV; ion source temperature, 600 °C; gas1, 20 psi; gas2, 30 psi; curtain gas, 10 psi. Unit mass resolution was set in both mass-resolving quadruples Q1 and Q3. Compound-dependent parameters were summarized in Table 1.

Table 1. Compound-Dependent Parameters in UPLC-MS Analysis

analyte	Q1 (m/z)	Q3 (m/z)	DP (V)	CE (V)	CXP (V)	dwell time (ms)
chrysin	252.9	142.9	−160	−36	−11	100
C-7-G	428.9	252.9	−160	−36	−11	100
G-7-S	332.9	252.9	−100	−36	−11	100
formononetin	267.0	252.0	−235	−29	−15	100

Determination of Concentrations of Chrysin Conjugates. The concentrations for conjugated metabolites were determined by using a chrysin standard curve and conversion factors of molar extinction coefficients. Conversion factor (K) was determined using a previously published method.[20] Briefly, it was determined by comparing the UV absorption peak area change of chrysin after glucuronide and sulfate was hydrolyzed by β-glucuronidases or sulfatase with the corresponding peak area change in glucuronide or sulfate. Concentrations of metabolites were calculated using the following equations:

$$K = \Delta PA_{metabolites}/\Delta PA_{chrysin} \quad \text{(eq 1)}$$

$$C_G = C/K_G \quad \text{(eq 2)}$$

$$C_S = C/K_S \quad \text{(eq 3)}$$

DOI: 10.1021/jf5056979
J. Agric. Food Chem. 2015, 63, 2902−2910

where K is the coefficient factor, $\Delta PA_{metabolites}$ is the change in peak area of conjugated metabolites (glucuronide or sulfate), and $\Delta PA_{chrysin}$ is the change in peak area of parent chrysin. C, C_G, and C_S are concentrations of chrysin, chrysin glucuronide, and chrysin sulfate, respectively, and K_G and K_S were conversion factors for glucuronide and sulfate, respectively.

Method Validation. *Calibration Curve, LLOQ, and LOD.* Calibration curve was prepared in the same way as described in Pharmacokinetic Studies. The linearity of each calibration curve was determined by plotting the peak area ratio of chrysin, chrysin glucuronide, and chrysin sulfate to I.S. Weighted least-squares linear regression method ($1/x^2$) was applied to determine the slope and correlation coefficient of linear regression equation. The lower limit of quantitation (LLOQ) was determined on the basis of a signal-to-noise ratio of 10:1. The limit of detection (LOD) was determined on the basis of a signal-to-noise ratio of 3:1.

Precision and Accuracy. The "intraday" and "interday" precision and accuracy of the method were determined with three different concentrations of QC samples on the same day or on three different days.

$$\text{Precision} = \frac{\text{standard deviation of measured concentration}}{\text{mean of measured concentration}} \times 100\% \quad \text{(eq 4)}$$

$$\text{Accuracy} = \frac{\text{mean of measured concentration}}{\text{nominated concentration}} \times 100\% \quad \text{(eq 5)}$$

Extraction Recovery and Matrix Effect. The extraction recovery of chrysin and its metabolites were determined by comparing the peak areas obtained from blank blood spiked with analytes before the extraction with those from samples to which analytes were added after the extraction. The matrix effect was assayed to compare the peak areas of blank blood extracts spikes with analytes with those of the standard solutions dried and reconstituted.

$$\text{Extraction recovery} = \frac{\text{pre-extraction spike}}{\text{post-extraction spike}} \times 100\% \quad \text{(eq 6)}$$

$$\text{Matrix effect} = \frac{\text{post-extraction spike}}{\text{matrix-free spike}} \times 100\% \quad \text{(eq 7)}$$

Stability. Short-term (25 °C for 4 h), long-term (−80 °C for 3 days), and three freeze−thaw cycle stabilities were determined.

Pharmacokinetic Studies. *Animals.* Male FVB wild-type mice (25−30 g, 10−12 weeks old) were from Harlan Laboratory (Indianapolis, IN). Male FVB Bcrp knockout mice (25−30 g, 10−12 weeks old) were purchased from Taconic Farm, Inc. (Hudson, NY). All the animals were kept in an environmentally controlled room (temperature: 25 ± 2 °C, humidity: 50 ± 5%, 12 h dark−light cycle) for at least 1 week before any experiments.

Experimental Design. The animal protocols used in this paper were approved by the University of Houston's Institutional Animal Care and Use Committee. Animals were fasted overnight with free access to water before the day of experiment. An oral gavage of chrysin dispersed in oral suspension vehicle was given to mice at a dose of 20 mg/kg. After a mouse was anesthetized with isoflurane gas, its tail was snipped near the tip of the tail to allow the collection of blood samples. Blood samples (about 10 μL) were collected in heparinized tubes at 15, 30, 60, 120, 240, 360, 480, and 1440 min. The blood samples were stored at −80 °C until analysis.

Blood Sample Preparation. The blood sample (10 μL) was spiked with 10 μL of HBSS buffer and 100 μL of I.S. (formononetin in acetonitrile, 4 nM). The mixture was vortexed for 1 min. After centrifugation at 15 000 rpm for 15 min, the supernatant was transferred to a new tube and evaporated to dryness under air. The residue was reconstituted in 50 μL of 30% acetonitrile aqueous solution and centrifuged at 15 000 rpm for 15 min. Ten microliters of supernatant were injected into the UPLC-MS/MS system for quantitative analysis.

Preparation of Standard and Quality Control Samples. Calibration standard samples were prepared in HBSS buffer by diluting the perfusate stock solution prepared in previous section to the following analyte concentrations: 0.78, 1.56, 3.13, 6.25, 12.5, 25, 50, 100, 200, 400, 800, 1600, 3200 nM for chrysin; 0.85, 1.70, 3.41, 6.82, 13.63, 27.27, 54.53, 109.06, 218.13, 436.25, 872.5, 1745, 3490 nM for chrysin glucuronide; 0.50, 1.01, 2.01, 4.02, 8.05, 16.09, 32.19, 64.38, 128.75, 257.50, 515, 1030, 2060 nM for chrysin sulfate. The quality control samples for each compound were prepared at three different concentrations in the same way as the blood samples for calibration, and QC samples were stored at −80 °C until analysis.

Cell Culture and Transcellular Transport Study. Caco-2 cells have been routinely cultured in our laboratory. The culture conditions were the same as those described previously.[21,22] Briefly, porous polycarbonate cell culture inserts (3 μm) from Corning Life Sciences (Lowell, MA) were used to seed the cells at a seeding density of 60 000 cells/cm^2. Cell monolayers were ready for experiments from 19 to 22 days after seeding. Transepithelial electrical resistance values of the cell monolayers were measured before experiments. The protocol for performing transport experiments was the same as described previously.[23] Loading solution (2.5 mL) containing 5 μM of chrysin with or without 5 μM of Ko143 in HBSS was added to the apical side of the cell monolayers for BCRP inhibition studies. Blank HBSS (2.5 mL) was loaded onto the basolateral side. Samples (0.4 mL) were taken at different times (0, 1, 2, 3, and 4 h) from both sides. The same volume of loading solution was added immediately to replace the volume lost.

Chrysin and its metabolites were determined in both apical and basolateral side by UPLC-MS/MS. Rate of transport was calculated as described before.[23] The following equation (eq 8) was used to obtain both apical and basolateral excretion rates.

$$\text{Rate of transport} = \frac{dC}{dt} \times V \quad \text{(eq 8)}$$

dC/dt: rates of change in concentration of transported chrysin/metabolites as a function of time. V: volume of the chamber.

The percentage of basolateral excretion was calculated by the following equation:

$$\%\ \text{basolateral excretion} = \frac{\text{basolateral excretion rate}}{\text{basolateral excretion rate} + \text{apical excretion rate}} \times 100\% \quad \text{(eq 9)}$$

Intracellular concentrations of chrysin and its conjugates were also determined at the end of experiment using the same protocol as described in a previous study.[23] The fraction of dose metabolized (f_{met}) was calculated using the following equation (eq 10).

$$f_{met} = \frac{\sum \text{metabolites}}{\sum \text{metabolites} + \sum \text{parent compound}} \quad \text{(eq 10)}$$

Data Analysis. Chrysin and its metabolites' pharmacokinetic parameters were calculated by the noncompartmental method, using Win-Nonlin 3.3 (Pharsight Corporation, Mountain View, California). Data were presented as means ± S.D., if not specified otherwise. Student's t test was used to analyze data. The level of significance was set at $p < 0.05$.

RESULTS

Conversion Factors of Chrysin Metabolites. We performed the hydrolysis studies at three different concentrations to calculate average K values. The conversion factor K is 1.6 for chrysin glucuronide and 0.91 for chrysin sulfate. These conversion factors were used to calculate the concentration of chrysin glucuronide/sulfate in the perfusate stock solution.

Identification of Chrysin Metabolites. In previous studies,[7] UV spectroscopy coupled with moderate alkalization, which was reported to be a sensitive diagnostic approach to identify the site of substitutions for flavonoid molecules,[24] had been used to determine the molecular position of the conjugation for chrysin, and it had been demonstrated that the

DOI: 10.1021/jf5056979
J. Agric. Food Chem. 2015, 63, 2902−2910

site of conjugation was the 7-position for both glucuronide and sulfate (Figure 1).

UPLC Analysis. Two metabolite peaks that have UV absorbance profile similar to parent chrysin were detected in mouse perfusate (Supplemental Figure S1). After incubating perfusate sample with β-glucuronidases (without sulfatase) or sulfatase (without glucuronidase), the peaks corresponding to chrysin glucuronide or chrysin sulfate disappeared, whereas the peak for parent chrysin increased (data not shown).

Chromatography and Mass Spectrometry. A sensitive and reliable method to quantify chrysin and its two metabolites' concentrations was established in this study. This method enabled us to determine the plasma concentration of chrysin and its metabolites in mouse after oral administration. Because of the fact that the blood volume we can take from a mouse is very limited and at the same time mice are often used as animal model in different studies, this method will be very useful in these situations. Typical chromatograms of spiked chrysin and its two metabolites in blank blood sample are shown in Figure 1. The retention time of C-7-G, C-7-S, chrysin, and formononetin (I.S.) were 2.60, 3.32, 3.84, 3.59 min, respectively.

Chrysin and its two metabolites were further confirmed by mass spectrometer. The MS2 full scan mass chromatograms are shown in Figure 2a–c. Chrysin glucuronide has ion $[M - H]^-$ at m/z 429, which is consistent with a glucuronic acid moiety (176 amu) added to the molecular ion of chrysin of m/z 253. Chrysin sulfate has an $[M - H]^-$ ion of m/z 333, which is 80 Da higher (addition of one sulfuric acid) than that of parent chrysin (m/z 253). In addition, the MS2 full scan showed that the ion $[M - H]^-$ of m/z 429 and 333 can produce fragment ion m/z 253, which also confirmed the presence of glucuronide and sulfate.

Method Validation. *Linearity and Sensitivity.* The method validation was conducted in blank mouse blood. The standard curves were linear in the concentration range of 3.13–3200 nM for chrysin, 3.41–3490 nM for chrysin glucuronide (C-7-G), 0.5–2060 nM for chrysin sulfate (C-7-S). The lower limit of quantitation (LLOQ) was 1.48 nM for chrysin, 1.70 nM for C-7-G, and 0.5 nM for C-7-S. The limit of detection (LOD) was 1.25, 0.68, and 0.05 nM for chrysin, C-7-G, and C-7-S respectively.

Accuracy and Precision. Accuracy, intraday, and interday precision were determined by measuring six replicates of QC samples at three concentration levels in mouse blood. The precision and accuracy are shown in Table 2. These results demonstrated that the precision and accuracy values were in the acceptance range (<15%).

Recovery, Matrix Effect, and Stability. The mean extraction recoveries determined using three replicates of QC samples at three concentration levels in mouse blood are shown in Table 2. Acetonitrile was used to extract chrysin and its metabolites. The recoveries were not less than 85.3% for all the analytes at three different concentrations.

The results showed that the relative peak areas of the analytes after spiking blood samples at three concentration levels were similar to aqueous standard solutions, indicating that there was no measurable matrix effect or recovery problem that interfered with the quantification of all analytes in blood. The results were also reported in Table 2.

Stabilities of chrysin and its metabolites in blood were evaluated by analyzing triplicates of QC samples at three different concentrations following storage at 25 °C for 4 h, at −80 °C for 3 days, and after going through three freeze–thaw cycles (−80 and 25 °C). All the samples showed 85–115% recoveries after various stability tests.

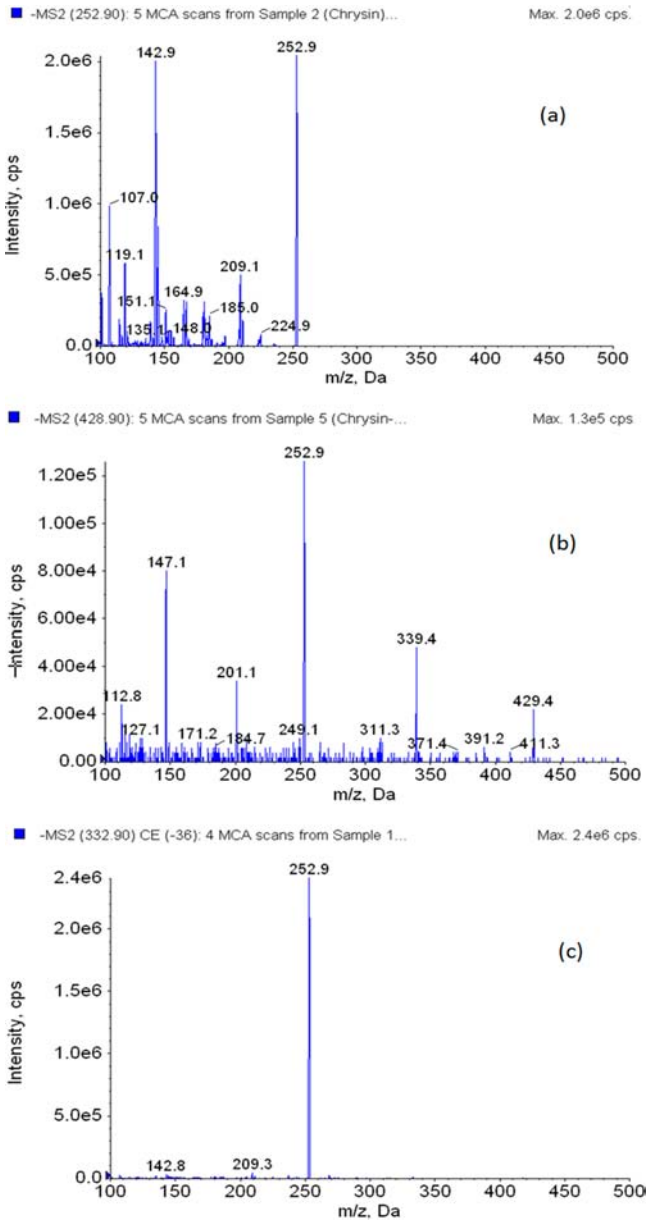

Figure 2. MS2 full scan for chrysin (a), C-7-G (b), and C-7-S (c). The results showed the molecular ion 429 $[M - H]^-$ and its MS2 fragment 253 $[M - H]^-$ for C-7-G and molecular ion 333 $[M - H]^-$ and its MS2 fragment at m/z 253$[M - H]^-$ for C-7-S.

Pharmacokinetic Studies of Chrysin in Wild-Type and Bcrp1 (−/−) Mice. The validated analytical method was employed to study the pharmacokinetic behaviors of chrysin in FVB wild-type and Bcrp1 (−/−) mice. The mean plasma concentration–time curves of chrysin and its two metabolites after p.o. administration (20 mg/kg dose) in FVB wild-type and Bcrp1 (−/−) mice are shown in Figure 3.

Chrysin and its metabolites' pharmacokinetic parameters were calculated by the noncompartmental method, using Win-Nonlin 3.3. The results are shown in Table 3. After 20 mg/kg oral administration, chrysin reached a maximum concentration (C_{max}) of 0.01 ± 0.01 μM at approximately 4 h in wild-type mice and 0.02 ± 0.01 μM at 3.31 h in Bcrp1 (−/−) mice. C-7-G and C-7-S were detected as major metabolites. In wild-type mice, the T_{max} of glucuronide and sulfate were 7.0 and 6.5 h, and the C_{max} of these two metabolites were 0.16 and 0.13 μM,

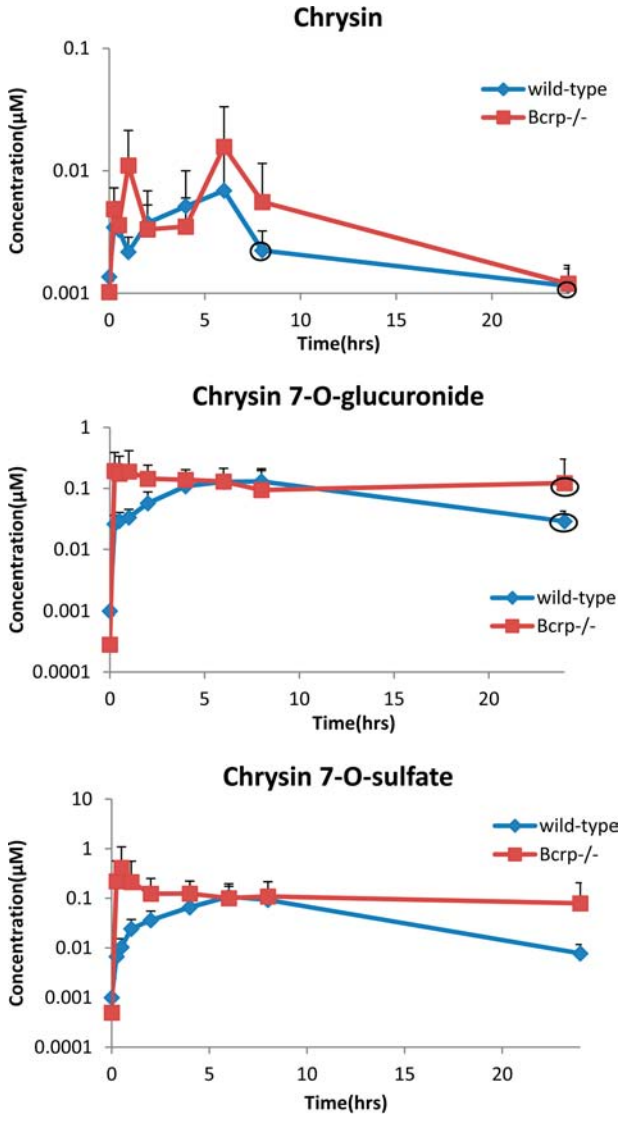

Figure 3. Blood concentrations of chrysin, C-7-G, and C-7-S after oral administration of 20 mg/kg chrysin in FVB wild-type and Bcrp−/− mice. Each point is the average of four determinations, and the bars are standard deviations of the mean. The circled points represented data points where concentrations for some mouse blood samples fell below the quantitation limit.

Table 3. Pharmacokinetics Parameters of Chrysin, Chrysin-7-O-G, and Chrysin-7−O-S after Oral Administration of 20 mg/kg Chrysin in Mice (n = 4)

	parameters	T_{max} (h)	C_{max} (μm)	AUC_{0-t} (h μM)
chrysin	wild-type mouse	4.00 ± 1.36	0.01 ± 0.01	0.06 ± 0.03
	Bcrp −/− mouse	3.31 ± 3.12	0.02 ± 0.01	0.11 ± 0.08
C-7-G	wild-type mouse	7.00 ± 1.15	0.16 ± 0.04	2.00 ± 0.82
	Bcrp −/− mouse	1.81 ± 1.63 **	0.22 ± 0.21	2.83 ± 3.03
G-7-S	wild-type mouse	6.50 ± 1.00	0.13 ± 0.04	1.32 ± 0.42
	Bcrp −/− mouse	3.25 ± 3.57	0.43 ± 0.67	2.62 ± 3.13

respectively. In Bcrp1 (−/−) mice, C_{max} was slightly higher for both metabolites and was reached at shorter T_{max}. For chrysin glucuronide, T_{max} was significantly shorter (p < 0.01) in Bcrp1 (−/−) mice, whereas the difference in T_{max} of chrysin sulfate in two species was not statistically significant because of large variations among mice. The AUC_{0-24h} of chrysin, chrysin glucuronide, and chrysin sulfate were summarized in Figure 4. In Bcrp-deficient mice, the AUC values of parent compound and its metabolites were higher (~2 folds) than the AUC values in wild-type mice. However, the differences were not statistically significant because of high standard deviation.

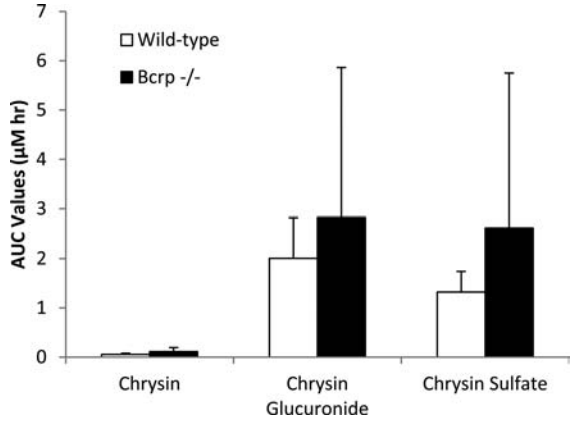

Figure 4. AUC values of chrysin and its conjugates in wild-type and Bcrp (−/−) mice (n = 4) after oral administration of chrysin at 20 mg/kg.

DOI: 10.1021/jf5056979
J. Agric. Food Chem. 2015, 63, 2902−2910

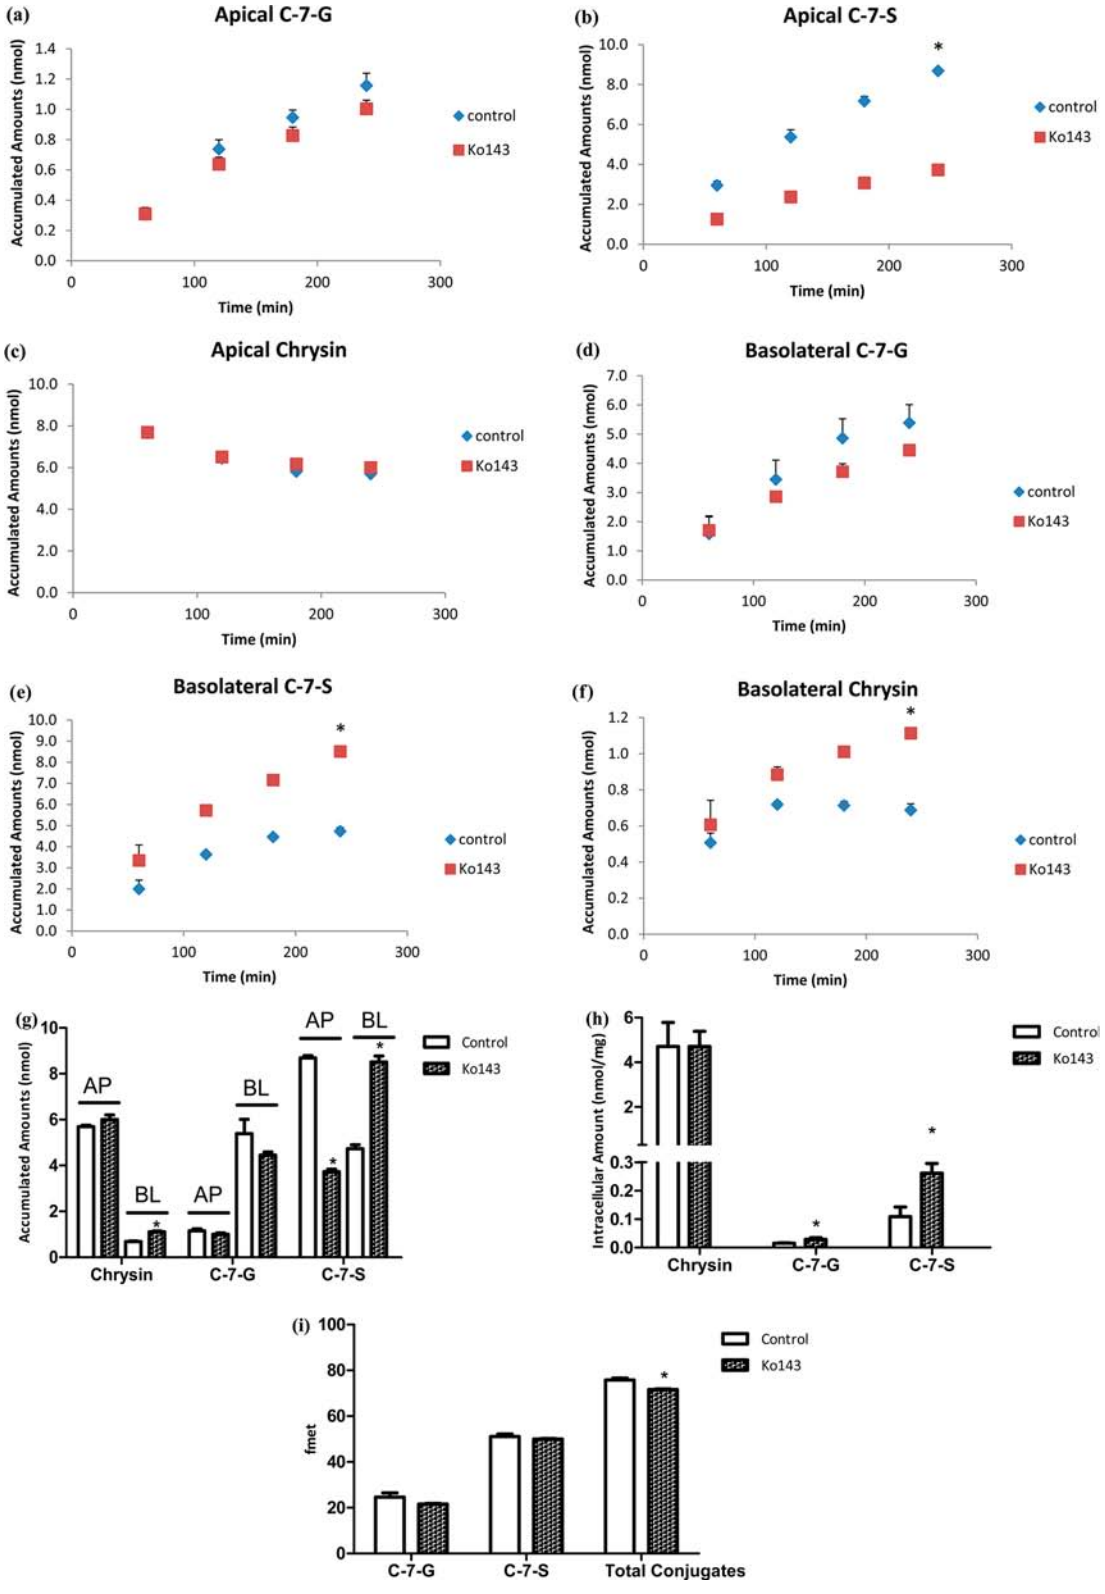

Figure 5. Excretion of chrysin and its conjugates in Caco-2 cells. The apical (a–c) and basolateral (d–f) excretion of chrysin, chrysin glucuronide (C-7-G), and sulfate (C-7-S) was shown at different time points. The accumulated amounts of compounds at the end of experiment (4 h) with or without treatment were summarized (g). The intracellular amount of chrysin and its metabolites were determined and normalized with total protein amount in each well (h). f_{met} of chrysin glucuronide, chrysin sulfate, and total conjugates in Caco-2 cells was also calculated (i).

Role of BCRP in the Excretion of Chrysin Glucuronides and Sulfates in Caco-2 Cells. To show how BCRP inhibition by Ko143 affected polarized excretion of chrysin conjugates in enterocytes, studies using 5 μM of chrysin in the presence or absence of 5 μM of Ko143 were conducted using the Caco-2 cell membrane. With Ko143 treatment, there was no significant alteration in the apical excretion of chrysin glucuronide. However, the apical excretion of chrysin sulfate decreased

DOI: 10.1021/jf5056979
J. Agric. Food Chem. 2015, 63, 2902–2910

significantly (>2-fold) in the presence of Ko143 treatment. Meanwhile, a similar amount of chrysin aglycone was found in apical side with or without the inhibitor (Figure 5a−c, g).

With respect to basolateral excretion, no significant change was found for chrysin glucuronide in the presence of Ko143. As for chrysin sulfate, a significant increase in basolateral excretion of chrysin sulfate was observed. It was found that the percentage of basolateral excretion of chrysin sulfate increased from 35% (control) to 70% (Ko143 treatment), whereas the percentage of basolateral excretion of chrysin glucuronide remained about the same (80%) (Figure 5d−f, g; Supplemental Figure S2). Our results suggested that the excretion pathway of chrysin sulfate was substantially changed when BCRP was inhibited, resulting in more basolateral excretion. It was also found that with Ko143 treatment, the transport of chrysin from apical to basolateral side significantly increased after 1 h (Figure 5).

Intracellular concentrations of chrysin and its conjugates were also determined at the end of experiments and normalized with total protein amount in each well (Figure 5h). Our data showed that the intracellular amount of chrysin glucuronide and sulfate increased significantly (~2-fold) in the presence of Ko143, whereas the amount of chrysin inside cells remained the same.

To determine if Ko143 had any impact on phase II metabolism of chrysin in Caco-2 cells, f_{met} values of glucuronide and sulfate were calculated as a measurement of phase II enzyme activities in cells. It was found that f_{met} of glucuronide and sulfate did not change much after Ko143 treatment, and the decrease in f_{met} of total conjugates (glucuronide plus sulfate) was statistically significant, although the extent of difference was small due to extensive phase II chrysin metabolism (Figure 5i).

DISCUSSION

BCRP was initially discovered in multidrug resistant breast cancer cell lines and recognized as an efflux pump which renders cancer cells resistant to diverse chemotherapeutic agents. Besides chemotherapeutic drugs, more and more drugs from other therapeutic classes and other compounds (e.g., dietary flavonoids and their conjugated metabolites) are recognized as BCRP substrates.[17] BCRP is also expressed in normal human tissues including the small intestine, liver, placenta, and brain endothelium. In recent studies, it has been shown that BCRP in small intestine can efflux glucuronide and sulfate conjugates into intestinal lumen. For example, Adachi et al. (2004) have demonstrated that BCRP plays an important role in extruding conjugates of 4-methylumbelliferone and E3040 back into the lumen in rat and mouse.[13] In another study, experiments in ABCG2-expressing membrane vesicles showed that BCRP transports estrone 3-sulfate.[16] In our previous studies, the bioavailability of genistein (an isoflavone) was found to increase moderately in Bcrp knockout mice, but the disposition of genistein conjugates was also altered substantially (often AUC changes more than 10−20-fold) in the Bcrp1 knockout mice.[23] In other published studies, it has been demonstrated that genistein's phase II metabolites (glucuronides and sulfates) can serve as the reservoir for parent compound in vivo because of enteric/enterohepatic recycling and enzymatic hydrolysis.[25,26] Therefore, we thought it would be of great value to reveal the mechanism for the distribution of phase II conjugates of another flavonoid, and in this study, we investigated the impact of BCRP on phase II disposition of chrysin.

As expected, we also observed that the pharmacokinetic profile of chrysin was different in Bcrp1 (−/−) mice when compared to the control FVB mice. For example, in the knockout mice, blood concentrations of chrysin and its metabolites were higher than concentrations in wild-type mice, and the peak blood concentrations of metabolites were achieved sooner. For chrysin glucuronide, a significantly shorter T_{max} (Figure 3, Table 3) was observed in the knockout mice. We also observed a different apparent slope of terminal phase for the metabolites in Bcrp1 (−/−) mice. Blood concentrations of chrysin metabolites decreased at a slower rate after 8 h in Bcrp-deficient mice. Because the fitting goodness (R^2) in the terminal phase was less than 0.8 using noncompartmental model method, the elimination rate constant (k) values could not be reliably determined and therefore were not reported. However, the AUC values of chrysin and its metabolites in Bcrp1 (−/−) mice were not significantly different ($P > 0.05$) from the AUC values observed in wild-type mice, which indicated BCRP might not be a critical efflux transporter for phase II disposition of chrysin in vivo, or other transporters such as MRP2 were overexpressed as a compensation for the knockout of BCRP. To determine if MRP2 is overexpressed in Bcrp1 (−/−) mice, protein quantification or PCR assays need to be performed for intestine and liver in WT and Bcrp1 (−/−) mice.

Moreover, we performed in vitro studies in Caco-2 cells to further investigate the role of BCRP in the intestine. Cells were treated in the presence or absence of Ko143 as a specific BCRP inhibitor. Because about 70% of chrysin was metabolized into conjugates by the end of experiment (Figure 5i), the accumulated amount excreted in apical or basolateral side versus time was not linear at the later sampling time as shown in Figure 5. In the presence of Ko143, the basolateral excretion of chrysin sulfate significantly increased (Figure 5), indicating that BCRP was an important transporter to efflux chrysin sulfate into the lumen. However, significant impact of BCRP on systemic exposure of chrysin conjugates was not observed in our in vivo studies (Figure 4). The discrepancy could be explained by the possibility that certain amount of chrysin conjugates can be excreted into the bile instead of entering the systemic circulation. Furthermore, this explanation is supported by the fact that chrysin metabolites were found at high concentrations in bile when chrysin was dosed in rat.[10] Inhibition of BCRP did not change the amount of chrysin aglycone in apical side but slightly increased (<2-fold) the accumulated amount in basolateral side (Figure 5g). There could be two explanations for this observation: 1. Chrysin itself is a substrate for BCRP, and the inhibition of BCRP can affect the distribution of chrysin. However, we also noticed that the intracellular amount of chrysin did not change with Ko143 treatment (Figure 5h). Therefore, we believe that this should not be the major reason. 2. The metabolism of chrysin was inhibited in the presence of Ko143, more chrysin left enterocytes intact as a result, and this explanation is in agreement with our observations in f_{met} (Figure 5i). Zhang et al. reported that chrysin was an inhibitor of BCRP in BCRP-overexpressing human breast cancer cells (MCF-7) and large cell lung carcinoma cells (NCI-H460)[27] and Ebert et al. showed that chrysin could induce the expression of BCRP in Caco-2 cells and enhance the transport of benzo[a]pyrene-3-sulfate,[15] there was no report to show that this compound is a good substrate of BCRP. Hence, we believe that BCRP plays a more important role in the disposition of chrysin phase II conjugates (i.e., glucuronides and sulfates).

Besides BCRP, other ABC transporters can also be involved in the transport of chrysin conjugates. Walle et al. (1999) have shown that the treatment of anion transport inhibitor MK-571 can reduce the apical excretion of chrysin glucuronide and sulfate in Caco-2 cells, suggesting chrysin conjugates can be effluxed by

DOI: 10.1021/jf5056979
J. Agric. Food Chem. 2015, 63, 2902−2910

MRP2.[11] They found that the inhibition of MRP2 could result in 71% and 20% inhibition of the efflux of chrysin glucuronide and chrysin sulfate, respectively. However, MK-571 is known to inhibit activities of UGT but not SULT enzymes.[22] In contrast, our studies in Caco-2 cells showed that the efflux of chrysin sulfate could be inhibited more efficiently by BCRP inhibitor. Therefore, it is reasonable to conclude that BCRP has more impact on the transport of chrysin sulfate whereas transport of chrysin glucuronide may be more influenced by other efflux transporters such as MRP2. To our knowledge, the role of other transporters in disposition of chrysin conjugates is still not clear. MRP1 and MRP3 may also be involved. As a dietary supplement in humans, the recommended dose of chrysin supplements is 500−2000 mg/day.[28] Therefore, high concentrations of chrysin could be found in the intestine and large amount of conjugates could interact with transporters on the cell membrane, which could result in chrysin-drug interactions in vivo.

Taken together, our studies have shown that although there was an alteration in the pharmacokinetic profile (with shorter T_{max}) of chrysin conjugate, the in vivo disposition of chrysin (a flavone) was not as sensitive to Bcrp1 knockout as we had expected and very different from our earlier study using genistein in the same animal model. In our in vitro studies, inhibition of BCRP showed greater inhibitory effect on the efflux of chrysin sulfate than that of chrysin glucuronide. The use of a sensitive and reliable UPLC-MS/MS method for the simultaneous determination of chrysin, chrysin 7-O-glucuronide, and chrysin-7-O-sulfate in mice was the enabling factor for us to determine their pharmacokinetics in expensive knockout mice. This is because only 10 μL of blood is required for each time point, which means that the animals did not have to be sacrificed for the study. Hence, it is highly significant that we were able to develop and validate the LC-MS/MS method for analyzing chrysin and its conjugates.

In conclusion, a sensitive and reliable UPLC-MS/MS method for determination of chrysin and its phase II metabolites in blood was developed and validated. This method was successfully applied for pharmacokinetic studies in mice. The impact of BCRP on phase II disposition of chrysin and its metabolites in Bcrp-deficient mice was different from those observed using genistein, and our in vitro data showed inhibition of BCRP reduced the efflux of chrysin sulfate significantly. Our data suggested that impact of efflux transporters on phase II disposition may be dependent on the structure of aglycone and/or its conjugates, and deserve further investigation.

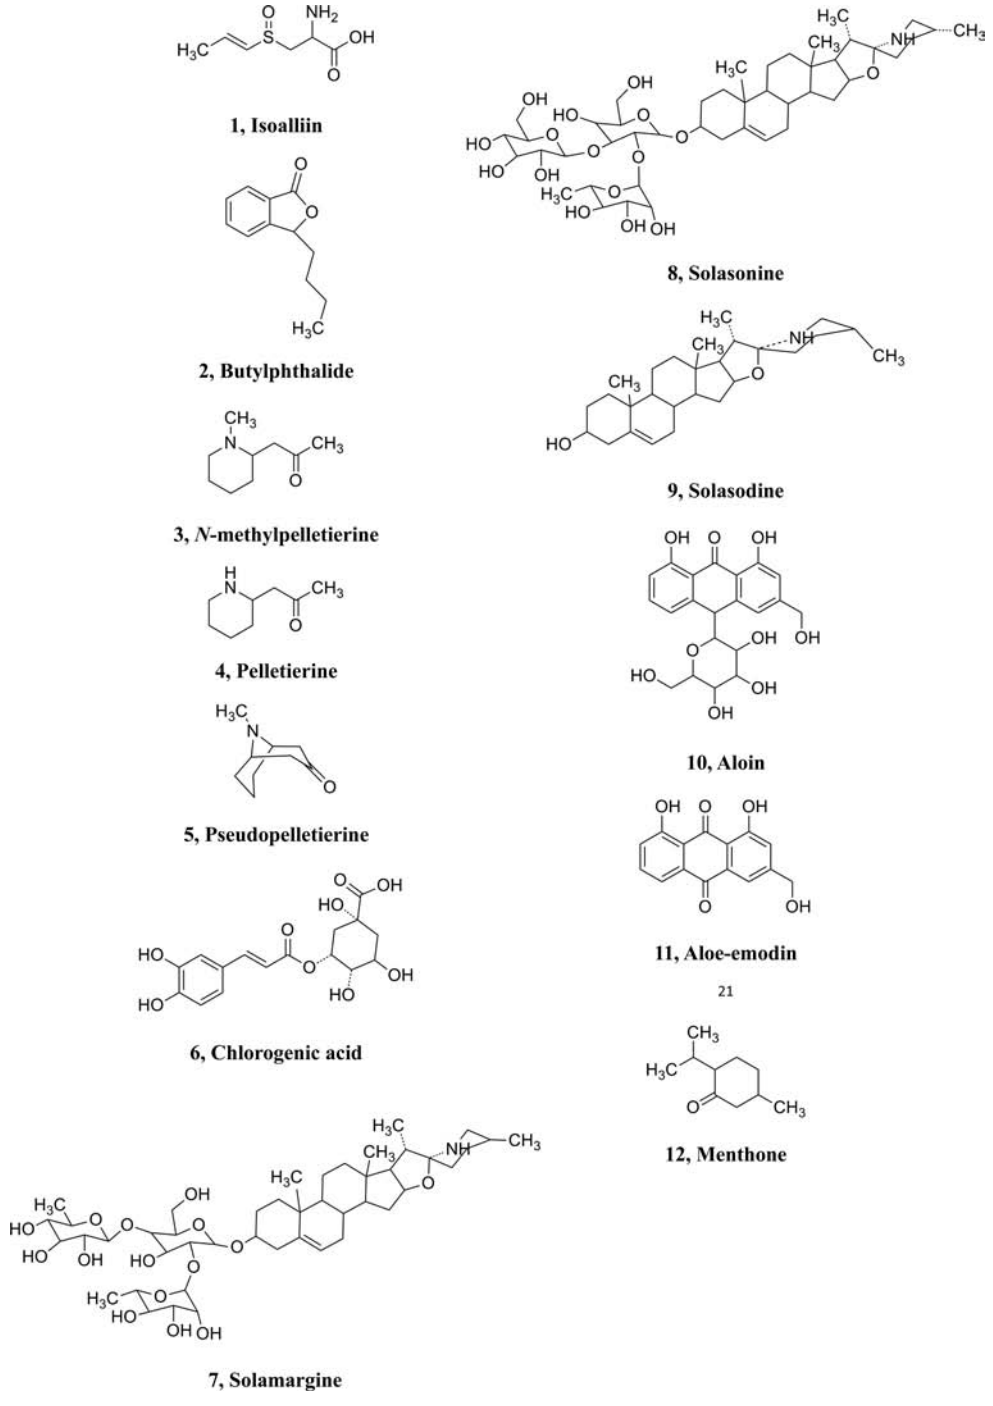

Figure 2. Chemical structures of compounds **1**−**12**.

Fabrication of in Vivo Nanospray Ion Source. The in vivo nanospray device was similar to that used in our previous study.[17] A quartz capillary (50 μm i.d., 148 μm o.d.) of 20 mm length was partially inserted into a specific region of the plant selected for sampling. A high dc voltage (3.5 kV, positive or negative) was applied to the plant via a needle close to the capillary to generate a spray of charged droplets carrying bioactive molecules toward the inlet of the mass spectrometer (Figure 1). The formation of charged droplets relies on the tissue fluid of fresh plants and eliminates the need for any auxiliary solvent. The sample was placed on an electrically insulated platform, in front of the MS inlet. The length of capillary outside the plant was 10 mm, and the distance between the end of the capillary and the MS inlet was 30 mm, to prevent electrical discharge.

HR-MS Analyses. Full-scan, selected ion monitoring (SIM) and MS/MS experiments were performed using a Q Exactive mass spectrometer (Thermo Scientific, Bremen, Germany). Mass spectra were processed using the instrument software Xcalibur 2.1 (Thermo Scientific), and both positive and negative ion spectra were recorded. Software Mass Frontier 7.0 SR1 was used to offer theoretical fragments and fragmentation mechanisms of compounds for the prediction of fragmentation patterns. The system was operated with a capillary temperature of 320 °C, an S-lens RF level of 50%, and a mass resolution of 70000.

In this work, the accurate mass measurements of precursor ions and fragment ions were accomplished by HR-MS. Full-scan/SIM was used to provide an accurate mass and possible elemental composition of the target ions. Further fragmentation and structural elucidation of the

DOI: 10.1021/jf505749n
J. Agric. Food Chem. 2015, 63, 2911−2918

selected precursor ions was performed by MS/MS. The mass tolerances of the parent and fragment ions were below 3 and 5 ppm, respectively.

RESULTS AND DISCUSSION

Vegetables. Isoalliin, **1**, in onion and butylphthalide, **2**, in celery were identified and confirmed. Onion has long been cultivated for its flavor and health benefits, which are both due to the unique sulfur chemistry and biochemistry of members of this genus.[18,19] Isoalliin, the main alkylated cysteine sulfoxide in onion, is the main source of its bioactive compounds.[20] Upon mechanical damage, isoalliin degrades into *trans*-1-allyl-methyl thiosulfate ($C_4H_8OS_2$), the main pharmacologically bioactive component in onion.[19] The chemical structures of all the identified bioactive ingredients may be found in Figure 2.

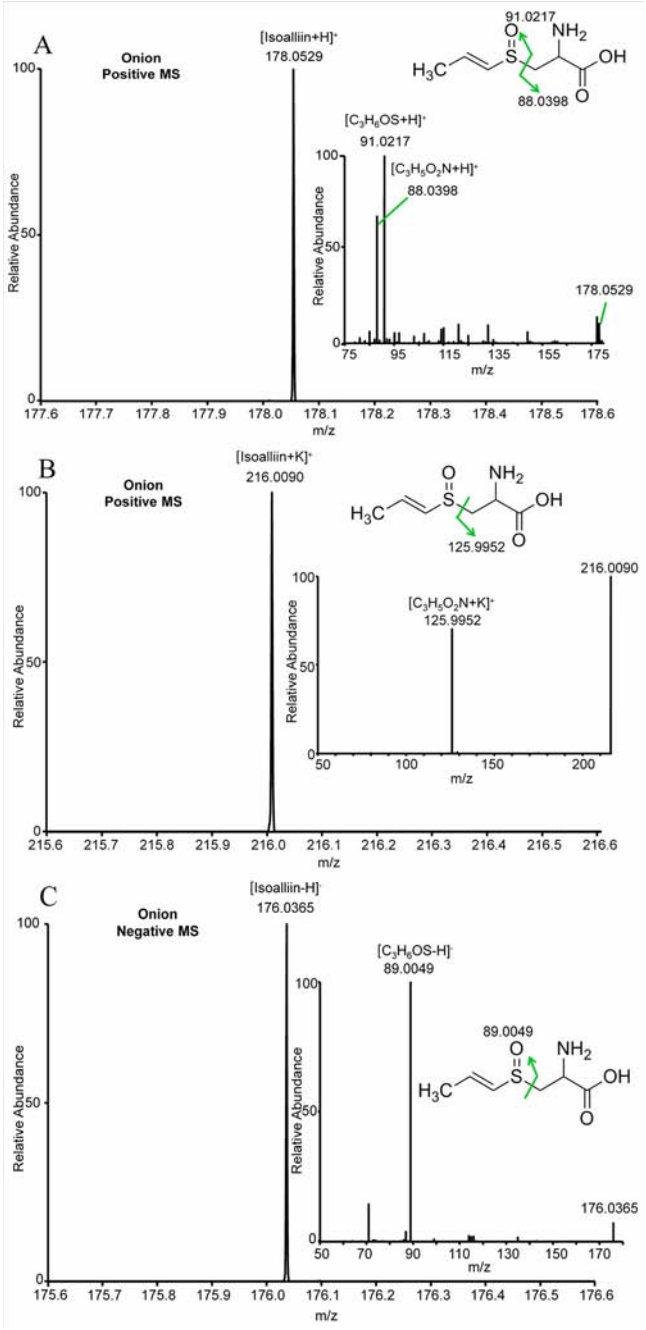

Figure 3. Mass spectra of isoalliin in onion: (A) protonated isoalliin and its fragment ions (inset); (B) potassium adducts of isoalliin and its fragment ions (inset); (C) deprotonated isoalliin and its fragment ions (inset).

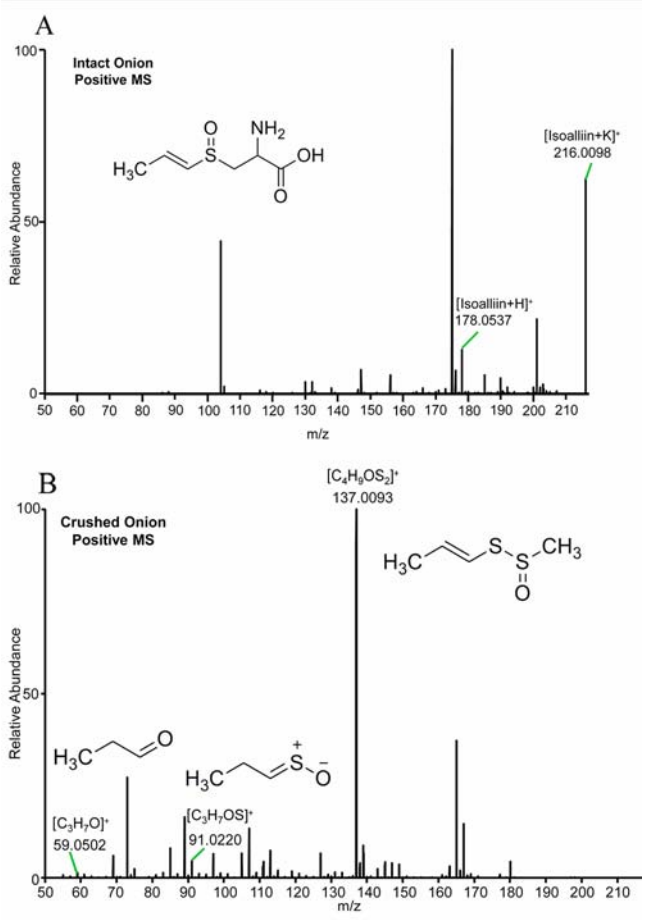

Figure 4. Mass spectra of isoalliin in different conditions: (A) intact onion observed by in vivo nanospray; (B) crushed onion observed in conventional nanospray.

Full-scan/SIM and MS/MS were performed in both positive and negative ion modes. In the positive ion mode, protonated isoalliin, m/z 178.0529 (Figure 3A) and the potassium adduct of isoalliin, m/z 216.0090 $[\text{isoalliin} + K]^+$ (Figure 3B), are observed in SIM mode. In the MS/MS spectrum of $[\text{isoalliin} + H]^+$, the two highest abundance ions are m/z 91.0217 $[C_3H_6OS + H]^+$ and m/z 88.0398 $[C_3H_5O_2N + H]^+$ (Figure 3A inset). The same fragmentation is observed in the MS/MS spectrum of $[\text{isoalliin} + K]^+$, which shows a base peak with m/z 125.9952 $[C_3H_5O_2N + K]^+$ (Figure 3B inset). In the negative ion mode, deprotonated isoalliin, m/z 176.0365 $[\text{isoalliin} - H]^-$ (Figure 3C) in SIM mode, and a product ion with m/z 89.0049 $[C_3H_6OS - H]^-$ in MS/MS (Figure 3C inset) are detected. All MS/MS fragmentation patterns are identical to those reported in the literature.[21−23]

Isoalliin, the major bioactive ingredient in onion, is also a labile compound. We studied the full-scan spectra of intact onion recorded by our in vivo nanospray and compared the results to those obtained from crushed onion using conventional nanospray. The results are shown in Figure 4. Only the protonated product and the potassium adduct of isoalliin were detected using in vivo nanospray ionization, and no degradation products were detected (Figure 4A). In contrast, in conven-

J. Agric. Food Chem. 2015, 63, 2911−2918

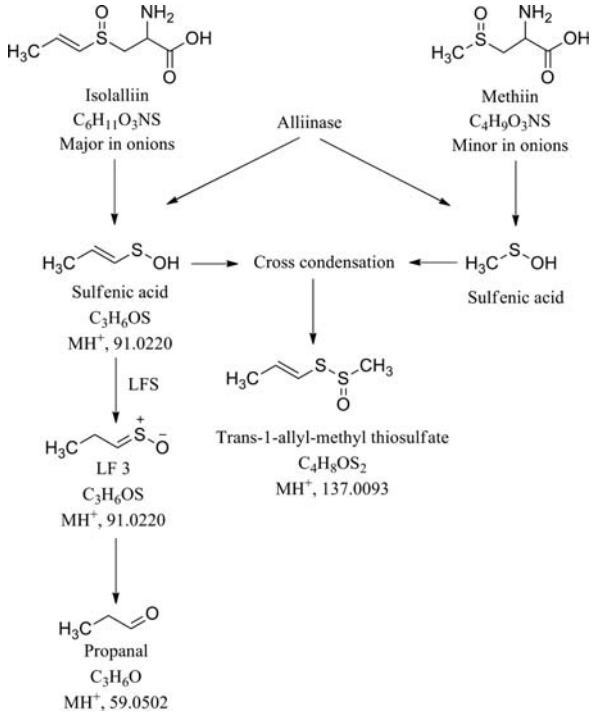

Figure 5. Biochemical degradation process of isoalliin in crushed onion.[19−23]

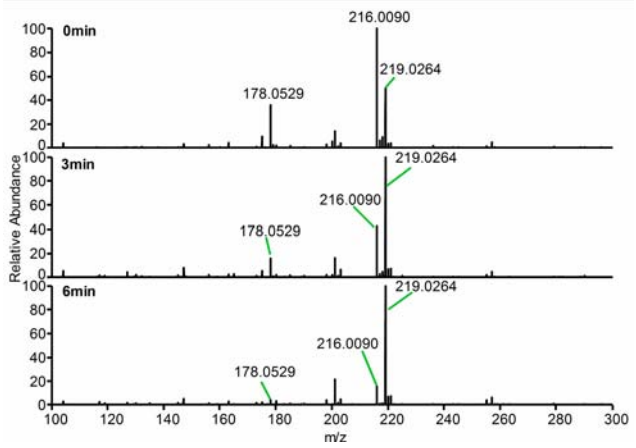

Figure 6. MS spectra of isoalliin in injured onion at multiple sampling time points.

tional nanospray ionization, only degradation products of isoalliin, including protonated *trans*-1-allyl-methyl thiosulfate, lachrymatory constituent LF3, and propanal, were observed (Figure 4B). These results indicate that in vivo nanospray HR-MS is suitable for the rapid in situ detection of labile ingredients in plants.

Isoalliin and methiin are the major and minor bioactive ingredients, respectively, in onion.[20] When onion tissue is damaged, isoalliin is released from the cells, and the exposed isoalliin will rapidly degrade to lachrymatory constituent LF3 (C_3H_6OS) and further to propanal (C_3H_6O) by the catalytic action of alliinase and lachrymatory factor synthase (LFS).[19] By the catalysis of alliinase, isoalliin and methiin are also transformed into sulfenic acids, which further cross-condense into *trans*-1-allyl-methyl thiosulfate ($C_4H_8OS_2$).[20] This degradation process of isoalliin in crushed onion is shown in Figure 5.

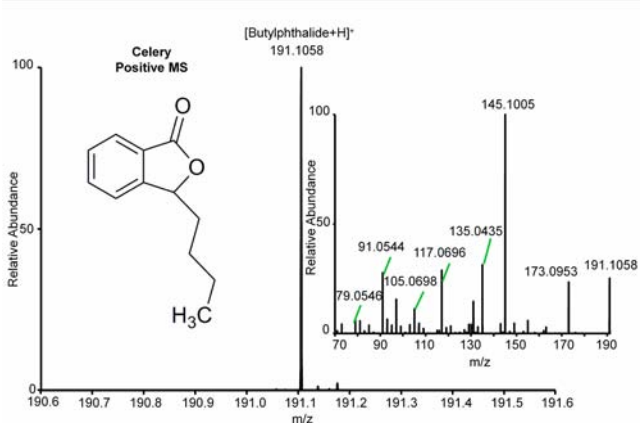

Figure 7. Mass spectra of butylphthalide and its fragment ions (inset) in celery.

The in vivo nanospray method was also used to track the changes of isoalliin concentration in onion at multiple sampling time points after punching, and the MS spectra are shown in Figure 6. The potassium adduct of glucose (m/z 219.0264 [glucose + K]$^+$) was used as a reference. The relative abundance of [isoalliin + H]$^+$ and [isoalliin + K]$^+$ reduced gradually over time, and the results show that the method is also suitable for continuously monitoring the change in concentration of labile ingredients in injured plant tissue.

The outer diameter of the capillary is about 148 μm; therefore, it could be used to analyze biomolecules in a microregion of the plant. We used in vivo nanospray to detect compounds located in three different microregions of the onion (top, middle, and bottom) using a scan region of m/z 150−250. Three main compounds were detected: protonated arginine (m/z 175.1191), potassium adducts of isoalliin, and glucose (m/z 216.0090 and 219.0264, respectively). However, there was a big difference in the relative abundance of these three ions in the different parts of the onion. In the top regions of the onion, glucose (relative abundance 100%) was the most abundant, followed by isoalliin (26%), and finally arginine (12%). In the middle region, too, glucose (100%) exhibited the highest signal intensity, followed by arginine (58%) and then by isoalliin (1%). In the bottom region of the onion, arginine (100%) was the most abundant, followed by glucose (32%) and finally by isoalliin (16%).

Celery is rich in volatile oils. Butylphthalide, **2**, is a typical volatile oil and shows antitumor, antioxidant, anti-inflammatory, and sedative properties.[24,25] In the positive ion mode mass spectrum of celery, protonated butylphthalide, m/z 191.1058 (Figure 7), was detected. The MS/MS experiment was performed on the [M + H]$^+$ ion of butylphthalide, and the spectrum exhibited peaks mainly at m/z 173.0953, 145.1005, 135.0435, 117.0696, 105.0698, 91.0544, and 79.0546 (Figure 7 inset). The m/z values of the fragment ions are in agreement with those reported in the literature.[26,27] This fragmentation can be partly explained by the loss of various neutral species. It is proposed that the peaks at m/z 173.0953, 145.1005, 135.0435, and 117.0696 can be attributed to the loss of 18 (− H_2O), 46 (− H_2O, − CO), 56 (− C_4H_8), and 74 (− H_2O, − C_4H_8) Da, respectively.

Fruits. The identification and structural elucidation of bioactive ingredients in fresh fruits were also accomplished,

DOI: 10.1021/jf505749n
J. Agric. Food Chem. 2015, 63, 2911−2918

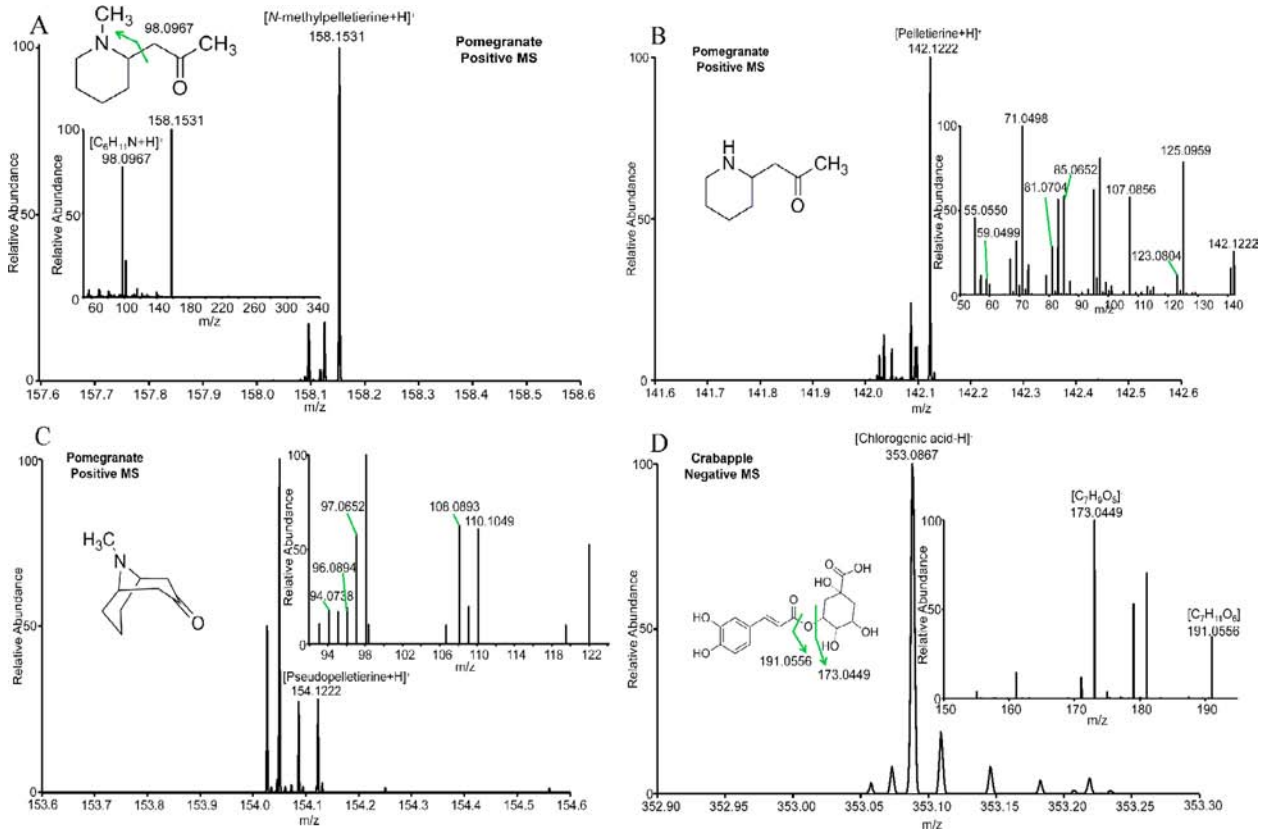

Figure 8. Mass spectra of bioactive ingredients in fruits: (A) protonated *N*-methylpelletierine and MS/MS (inset) in pomegranate; (B) protonated pelletierine and its fragment ions (inset) in pomegranate; (C) protonated pseudopelletierine and its fragment ions (inset) in pomegranate; (D) deprotonated chlorogenic acid and its fragment ions (inset) in crabapple.

including the piperidine alkaloids *N*-methylpelletierine, **3**, pelletierine, **4**, and pseudopelletierine, **5**, in pomegranate, and chlorogenic acid, **6**, in crabapple (Figure 2).

Pomegranate has medicinal and nutritional value due to various bioactive ingredients, such as piperidine alkaloids, which have antibacterial and anti-inflammatory effects.[28,29] In the positive ion mode mass spectra of pomegranate berry, protonated *N*-methylpelletierine, m/z 158.1531 (Figure 8A), pelletierine, m/z 142.1222 (Figure 8B), and pseudopelletierine, m/z 154.1222 (Figure 8C), were detected. Structural confirmation of the three ions was conducted in the MS/MS mode. In the MS/MS spectrum of *N*-methylpelletierine, we observed a prominent product ion at m/z 98.0967 ($[C_6H_{11}N + H]^+$). The fragmentation pattern and MS/MS spectrum have been labeled (Figure 8A inset). The result is in agreement with previously published research.[30] The MS/MS spectra of protonated pelletierine and pseudopelletierine are also shown in the insets in panels B and C, respectively, of Figure 8. The product ions indicated by the green line in the spectra are consistent with theoretical fragmentation patterns of protonated pelletierine and pseudopelletierine obtained by Mass Frontier. The results confirmed the presence of pelletierine and pseudopelletierine.

Phenolic acids are known to play an important role in plants' resistance to pathogens and herbivores, allelopathy, oxidative stress, and plant growth regulation.[31] Furthermore, they have been shown to have beneficial effects on human health.[32] Chlorogenic acid has antioxidant and antineoplastic properties and is found in a wide range of fruits.[33,34] Here, negative ion mode was selected for the analysis of chlorogenic acid in crabapple, and the mass spectrum of deprotonated chlorogenic acid (m/z 353.0867 [chlorogenic acid − H]$^-$) was obtained (Figure 8D). The MS/MS experiment was performed on deprotonated chlorogenic acid for structural elucidation (Figure 8D inset). The two product ions (m/z 173.0449 and 191.0556) were produced by cleavage at two different locations across the ester bond and are indicated by the green arrows in Figure 8D. The fragmentation patterns are in agreement with those reported in the literature.[35,36]

Medicinal Plants. Medicinal plants, including nightshade, aloe, and mint, have also been analyzed by our in vivo nanospray HR-MS technique. We have detected solamargine, **7**, solasonine, **8**, and solasodine, **9**, in berry of nightshade; aloin, **10**, and aloe-emodin, **11**, in aloe; and menthone, **12**, in mint (Figure 2).

The unripe berry of nightshade has both neural and cardiovascular pharmacological effects, and glycosides, including solasodine, solasonine, and solamargine, are the major contributors to this effect.[37,38] In the positive ion mode mass spectrum of unripe nightshade berry, protonated solasonine and solamargine, m/z 884.4965 and 868.5025, respectively (Figure 9A), and solasodine, m/z 414.3353 (Figure 9D), were detected. The MS/MS experiment was performed on the [M + H]$^+$ of these three ions. The fragmentation of the [M + H]$^+$ of solamargine is illustrated in Figure 9B. The initial loss from the precursor ion (from m/z 868.5025 to 850.4911) corresponds to M + H -18 (loss of water). The subsequent fragmentations yielding the product ions m/z 722.4431 (M + H − 146), m/z 704.4341 (M + H − 18 − 146), and m/z 558.3768 (M + H − 18 − 146 − 146) correspond to the consecutive loss of

DOI: 10.1021/jf505749n
J. Agric. Food Chem. 2015, 63, 2911−2918

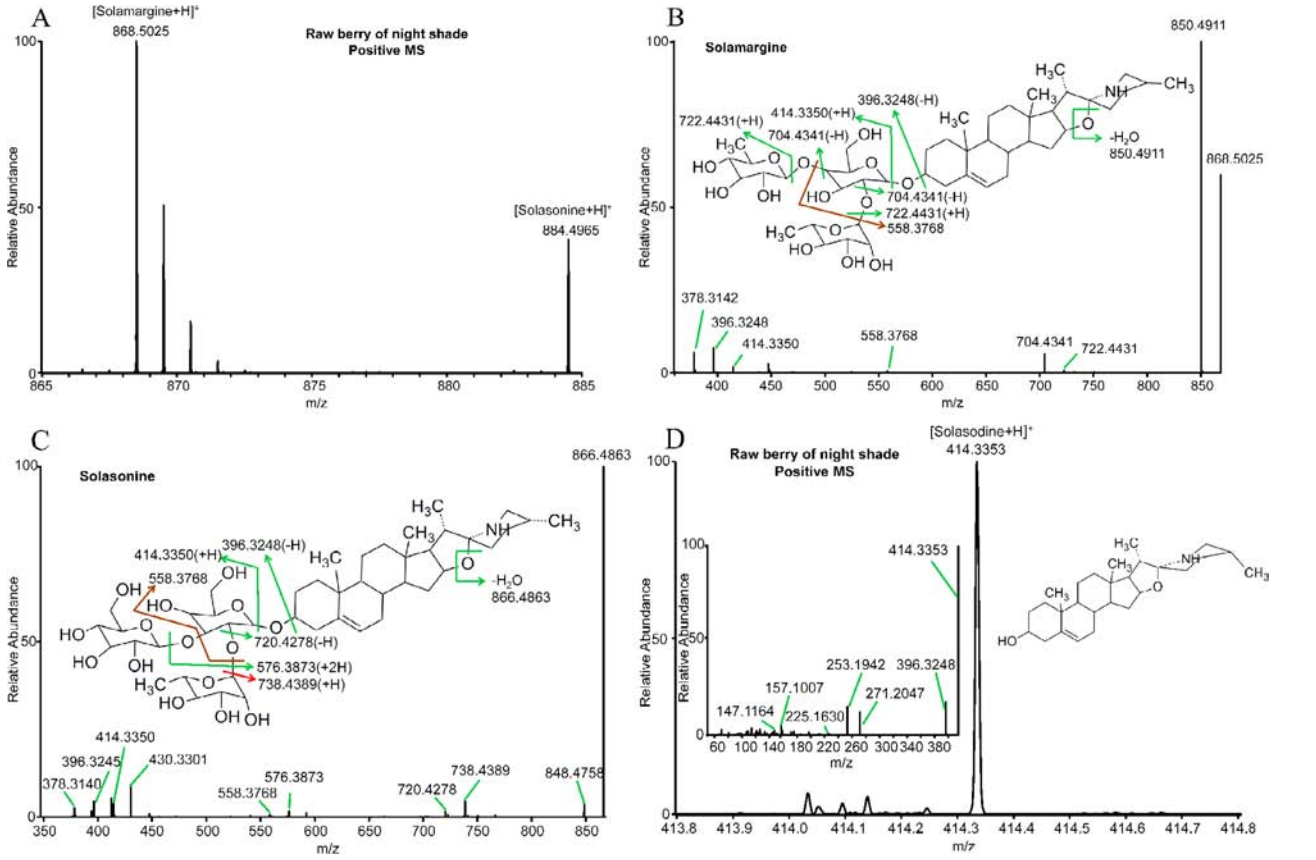

Figure 9. Positive mode mass spectra of alkaloids in raw unripe nightshade berry: (A) protonated solasonine and solamargine; (B) MS/MS of solamargine; (C) MS/MS spectrum of solasonine; (D) protonated solasodine and its MS/MS spectrum (inset).

rhamnosyl groups (164 − 18 → 146). The subsequent fragmentation to m/z 396.3248 (M + H − 18 − 146 − 146 − 162) corresponds to the loss of a glucosyl group (180 − 18 → 162). The final fragmentation to m/z 378.3142 (M + H − 18 − 146 − 146 − 162 − 18) corresponds to the loss of water. The detailed fragmentation process is shown in Figure 9B. This spectrum is identical to spectra reported in the literature.[39,40] Almost the same fragmentation pattern is observed with solasonine, as shown in Figure 9C. The inset in Figure 9D illustrates the MS/MS and fragmentation pattern of $[\text{solasodine} + \text{H}]^+$ in the positive ion mode and shows a rapid loss of water (M + H − 18) from the structure to yield the 396.3248 product ion. This spectrum is in accordance with other reports in the literature.[41] There is a huge difference in the content of bioactive compounds between raw unripe nightshade berry and raw ripe nightshade berry. In raw unripe nightshade berry, protonated solamargine, solasonine, and solasodine were all detected. However, in ripe berry, solasodine was not detected, and the signal of protonated solamargine decreased substantially, whereas only a small change in signal occurred for protonated solasonine.

Aloin and aloe-emodin, the two main bioactive components in aloe, have the strongest antibacterial activity of the anthraquinones.[42] The negative ion mode was selected for the detection of aloin and aloe-emodin (Figure 10A,B), because it resulted in the best sensitivity. The corresponding $[\text{M} - \text{H}]^-$ ion was selected as the precursor ion for each analyte. The most abundant product ion observed for aloin was at m/z 297.0768, which corresponds to the loss of $[\text{C}_4\text{H}_8\text{O}_4]^-$ from the precursor ion (Figure 10A inset). The main product ion observed for aloe-emodin was m/z 240.0425, which corresponds to the loss of $[\text{CHO}]^-$ from the precursor ion (Figure 10B inset). The above results are in accordance with those reported in the literature.[43,44]

Mint is one of the main raw materials for the production of toothpaste and chewing gum,and is also a medicinal plant. Menthone is the major bioactive ingredient in mint, giving it its intense flavor and strong analgesic effect.[45] Protonated menthone, m/z 155.1425 (Figure 10C), was observed in the positive ion mode spectra. The product ions in the MS/MS spectrum (Figure 10C inset) are consistent with the theoretical fragmentation pattern derived from Mass Frontier.

The above results demonstrate that in vivo nanospray HR-MS is a good method for the rapid detection and identification of bioactive compounds in microregions of plants. Because many of the bioactive molecules in plants are labile, this method has great potential for obtaining information on labile compounds and their biochemical reaction intermediates, so as to elucidate the degradation principle. In the future, we plan to apply this method for the study of easily degradable chemicals in plants. However, it is important to note that because the in vivo nanospray uses tissue fluid in plants to generate charged droplets during electrospray ionization, the method is viable for detecting polar molecules in fresh plants rich in water. Although the inner diameter of the capillary tip used in this study is 50 um, a capillary with a much smaller inner diameter can be used to enhance the signal intensity. In addition, the device, which is small and convenient to carry, can be combined with a portable mass spectrometer for rapid field analysis and will be beneficial for the full application of the methodology.

disease diagnosis, drug discovery, and the evaluation of drug efficacy and toxicity.[19−23] Such an approach may shed new light on the holistic therapeutic efficacies and synergistic effects of traditional herbal medicines.[24,25] NMR- and MS-based metabolomics have been employed to measure variations in the properties of ginseng in the context of plant age, cultivation conditions, origin, and processing[26−30] and to evaluate the effects of ginseng on diabetes, excessive fatigue, and myocardial infarction in animal models.[31−33]

As both hyperlipidemia and obesity are disorders of lipid metabolism, characterized by abnormal lipid levels, more attention must be paid to the effects of ginseng on lipid metabolism. However, only very limited data on lipidomic biomarkers reflecting the pharmacological effects of ginseng are available.[34] In the present study, we used mass spectrometry (MS)-based serum lipid profiling and conventional serum chemical analysis to explore the biochemical abnormalities in obese mice fed HFD and determined the pharmacological effects of compound K-reinforced ginsenosides (CK) in such mice. MS-based lipidomics yielded global profiles of endogenous lipids including lysophopholipids, phospholipids, and triacylglycerols, all of which are metabolites closely associated with metabolic diseases. We subjected the data to multivariate statistical analysis to define lipid metabolites contributing to discrimination among mice fed a normal diet (ND), an HFD, and an HFD plus CK.

MATERIALS AND METHODS

Chemicals and Reagents. Methanol and water were purchased from Merck (LC-MS grade, Darmstadt, Germany). Ammonium acetate, chloroform, methyl-*tert*-butyl ether (MTBE), and triglycerides (TG) mixture standard (8:0/8:0/8:0, 10:0/10:0/10:0, and 12:0/12:0/12:0) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Phosphatidylcholine (PC 18:2/16:0 and PC 18:2/18:2), phosphatidylethanolamine (PE 16:0/18:1), phosphatidylglycerol (PG 16:0/18:1), phosphatidylinositol (PI 16:0/18:1), lysophosphatidylcholine (LPC 16:0 and LPC 18:0), lysophosphatidylethanolamine (LPE 16:0), lysophosphatidylglycerol (LPG 16:0), and lysophosphatidylinositol (LPI 18:1) were purchased from Avanti Polar Lipids (Alabaster, AL, USA).

Preparation of Compound K-Reinforced Ginsenosides. Four-year-old Korean ginseng (*P. ginseng* C.A. Meyer) roots were cultivated in and collected from farms in Geumsan, Chungcheongnam-do, Korea. The CK fraction was prepared via enzymatic conversion and column fractionation as described in our patent application (WO 2013/109062 A1). Briefly, dried roots of ginseng were extracted three times with boiling water at 80 °C for 4 h and the extracts filtered and concentrated to obtain a crude extract (60 °Brix). The extract was next diluted with water (to 7 °Brix) and adjusted to pH 4.3 with citric acid; an enzyme powder containing pectinase (Cytolase PCL5; DSM Food Specialties, Servian, France) was next added to 2% (w/v) to bioconvert the ginsenosides at 56 °C for 72 h. The reaction mixture was then heat-treated at 95 °C for 30 min to eliminate enzyme activity and the ginsenoside fraction next isolated via adsorption column chromatography using Diaion HP-20 resin (Samyang, Seoul, Korea). The loaded column was washed with water to remove non-ginsenosides and the ginsenosides fraction eluted with 90% (v/v) ethanol. The eluted sample was evaporated under vacuum and freeze-dried to obtain the CK powder. HPLC revealed that compound K constituted ∼12% of total ginsenosides of the CK fraction, but compound K was not detectable in the crude extract.

Animal Study. Five-week-old male C57BL/6J mice purchased from Central Laboratory Animal Inc. (Seoul, Korea) were housed in standard plastic cages with free access to water and food in a room under constant temperature (21 ± 2.0 °C) and relative humidity (50 ± 5%) with a 12 h light/12 h dark cycle. The mice were acclimatized to the laboratory environment for 1 week and were next randomly divided into three groups (eight mice per group): (1) ND; (2) HFD; (3) HFC plus CK at 400 mg/kg (HFD+CK). The ND (3.1 kcal/g; 18% of calories from fat) was the "2018S Teklad Global 18% Protein Rodent Diet" and the HFD (5.1 kcal/g; 60% of calories from fat) the "TD.06414 Teklad Adjusted Calories Diet"; both chows were purchased from Harlan Laboratories (Madison, WI, USA). The mice were allowed free access to either diet for a total of 16 weeks. CK was given orally six times per week for the last 8 weeks. Body weights were measured once weekly.

Histological Examination and Triglycerides in Liver Tissue. Slices of liver tissue were frozen immediately in OCT compound (Fisher Scientific, Waltham, MA, USA) and subjected to Oil Red O staining. For the triglyceride assay, total lipids were extracted according to the Folch method from liver tissue.[35] Briefly, frozen liver (50-mg amounts) was weighed and homogenized in 1 mL of chloroform/methanol (2:1, v/v). The homogenate was centrifuged at 12000 rpm to recover the liquid phase. Water (0.2 mL) was added and the mixture centrifuged at 4000 rpm; the lower lipid-containing phase was retained. Triglycerides content was measured via a colorimetric assay, using a kit from Asian Biochemicals.

Serum Assay. Mouse blood extracted via cardiac puncture was allowed to clot for 30 min at room temperature and then centrifuged for 10 min at 12000 rpm at 4 °C to collect serum. Serum total cholesterol, low-density lipoprotein cholesterol (LDL-c), and triglycerides (TG) were analyzed using BS-400, an automatic blood chemistry analyzer (Mindray, Shenzhen, China).

Sample Preparation. Serum lipids were extracted using the Matyash method with some modifications.[16,36] In brief, 225 μL of ice-cold methanol was added to 10 μL of serum, and the mixture vortexed for 10 s. Next, 750 μL of ice-cold MTBE was added, and phase separation was induced by the addition of 187.5 μL of distilled water. After centrifugation (14000*g*, 4 °C), the supernatant was collected and completely dried prior to lipid profiling. Dried samples were stored at −70 °C prior to analysis.

Direct Infusion MS Analysis. Each dried lipid extract was reconstituted in 100 μL of chloroform/methanol (1:9, v/v) and diluted 5-fold with chloroform/methanol (1:9, v/v) containing 7.5 mM ammonium acetate. The lipid solution was infused into a Thermo LTQ XL ion trap mass spectrometer (Thermo Fisher Scientific, West Palm Beach, FL, USA) using a chip-based nanoelectrospray infusion system (TriVersa NanoMate, Advion Biosciences, Ithaca, NY). The ion source was controlled with the aid of Chipsoft software (version 8.3.1, Advion Biosciences, Ithaca, NY, USA). The ionization voltage was 1.4 kV in the positive mode and the backpressure, 0.4 psi. The temperature of the ion transfer capillary was 200 °C and the tube voltage, 100 V. For lipid profiling, 5 μL of each sample was randomly loaded onto a 96-well plate of the TriVersa Nanomate ion source, to avoid analytical bias. A standard mixture of TG, PC, and LPC and a quality control (QC) sample (a pooled sample) were loaded at the beginning, middle, and end of each batch. Each 96-well plate was sealed with Thermowell aluminum sealing tape (Corning, Corning, NY, USA) and next placed on a Nanomate cooling plate (4 °C) to prevent evaporation of the solvent. The mass spectrum of each sample was acquired in the profile mode over 2 min. Data collection featured a full scan (scan range m/z 400−1000) and a data-dependent MS/MS scan of abundant ions. Standard spectra were obtained in low-resolution mode using a 30 eV collision-induced dissociation (CID) voltage to achieve specific MS/MS fragmentation. All spectra were recorded with the aid of the Thermo Xcalibur software (version 2.1, Thermo Fisher Scientific, Waltham, MA, USA).

Data Processing. Nominal ion mass spectra data files from the ion trap mass spectrometer (".raw" files) were directly loaded into the Genedata Expressionist MSX module (Genedata AG, Basel, Switzerland). The default processing parameters were applied unless otherwise specified. The spectral data were first averaged between 0.5 and 1.0 min and simplified by subtracting background noise. After subtraction, all data points below a threshold intensity of 300 were clipped to zero. The spectral set was next aligned in the m/z direction via nonlinear transformation, mapping the original m/z data set onto a common universal data set. Next, spectrum peak detection was used to

J. Agric. Food Chem. 2015, 63, 2919−2929

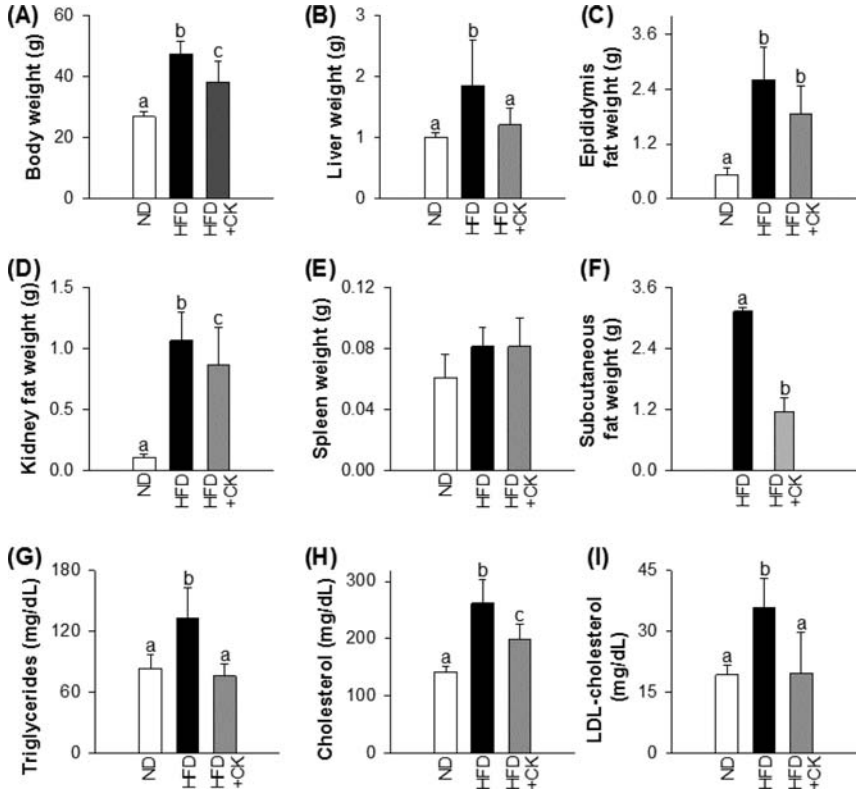

Figure 1. Characteristics of mice fed a normal diet (ND, n = 7), a high-fat diet (HFD, n = 7), or a high-fat diet + compound K-reinforced ginsenosides (HFD+CK, n = 7): (A) body weight; (B) liver weight; (C) epididymis fat weight; (D) kidney fat weight; (E) spleen fat weight; (F) subcutaneous fat weight; (G) triglycerides level; (H) cholesterol level; (I) LDL-cholesterol level. Different letters indicate significant differences by analysis of variance (ANOVA; $p < 0.05$).

define peaks on the temporarily averaged spectrum; the following parameters were used: smoothing window, three points; method, curvature-based peak detection; peak refinement threshold, 5%; consistency filter threshold, 0.8; and signal/noise threshold, 1. Peaks thus detected were grouped into isotopic clusters of individual peaks via spectrum isotope clustering activity, using the following parameters: minimum charge, 1; maximum charge, 2; maximum missing peaks, 1; first allowed gap position, 3; ionization, protonation; and m/z tolerance, 0.1 Da. Data on all detected peaks, including m/z and intensity values, were exported as Excel files. To normalize spectral data, the average of the sum of intensities of QC samples was divided by the sum of the intensities of each sample spectrum, and next each value (-fold) was multiplied by the peak intensity of each lipid species in that sample. The resulting Excel data were exported to SMICA P+ software (version 13.0, Umetrics, Umea, Sweden). In addition, serum lipids were identified by comparison with the MS/MS fragmentation patterns of commercially available standards or using the LIPID MAPS Lipidomics Gateway (http://www.lipidmaps.org), the Human Metabolome Database (HMDB; http://www.hmdb.com), and/or our in-house lipid library (LipidBlast).[37]

Statistical Analysis. Principal component analysis (PCA) was performed, featuring mean centering and Pareto scaling, to explore the extent of differences among the three groups (ND, HFD, and HFD +CK). Hotelling's$T2$ test was used to exclude outliers from the 95% confidence region.[34] Partial least-squares discriminant analysis (PLS-DA) and orthogonal partial least-squares discriminant analysis (OPLS-DA, which affords clearer separations than does PCA, by considering the nature of each group) were performed using the same scaling mode that was used in PCA. The level of fitness and predictability were next examined by determining R^2Y and Q^2Y values, respectively. Generally, R^2Y varies between 0 and 1, where 1 indicates a model with a perfect fit, whereas a Q^2Y value >0.5 is considered to reflect good predictive capability.[38] The reliability of PLS-DA modeling was rigorously validated via permutation testing (n = 999). All of the variables in the model were selected by the value of variable importance in the projection (VIP) value (>0.7) and p value (<0.05) using SIMCA-P+ software and Stastistica 7 (StatSoft Inc., Tulsa, OK, USA). An S-plot showing the combined covariance $p(1)$ and correlation $p(\mathrm{corr})$ values from the OPLS-DA model was created to allow us to identify metabolites contributing to discrimination.[34] In addition, statistical comparisons of body weights, liver weights, epididymis fat weights, kidney fat weights, spleen weights, subcutaneous fat weights, triglyceride levels, and cholesterol levels were performed using Duncan's multiple-range test.

RESULTS AND DISCUSSION

Animal Characteristics. The characteristics of mice fed a normal diet, a high-fat diet, and a high-fat diet plus compound K-reinforced ginsenosides are shown in Figure 1. The body weight (47.3 ± 4.2 g), liver weight (1.84 ± 0.74 g), and subcutaneous fat weight (3.12 ± 0.08 g) of mice fed an HFD were significantly greater than those of mice fed ND, but the weight gains were ameliorated in mice fed an HFD+CK (Figure 1A–F). These results show that an HFD triggered obesity in

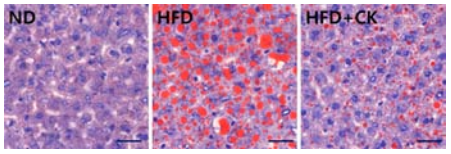

Figure 2. Histology of fatty liver sections. Liver tissues were stained with Oil-Red O [normal diet (ND), high-fat diet (HFD), and high-fat diet + compound K-reinforced ginsenosides (HFD+CK)]. The bar represents 30 μm.

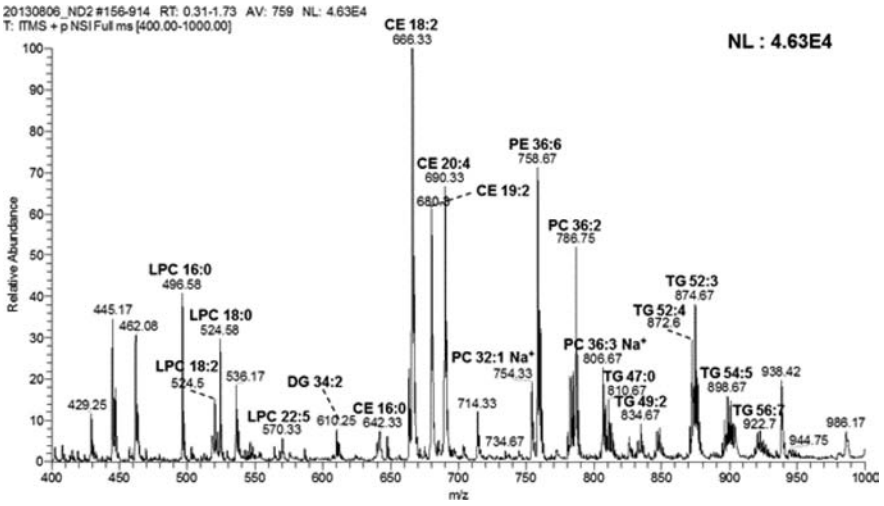

Figure 3. Analysis of phospholipids and triacylglycerols in mouse serum by direct infusion into a nanoelectrospray ionization−tandem mass spectrometry (ESI-MS/MS) operating in the positive mode. LPC, lysophosphatidylcholine; DG, diacylglycerol; CE, cholesteryl ester; PE, phosphatidylethanolamine; PC, phosphatidylcholine; TG, triacylglycerol; *m/z*, mass-to-charge ratio; NL, normalized intensity level.

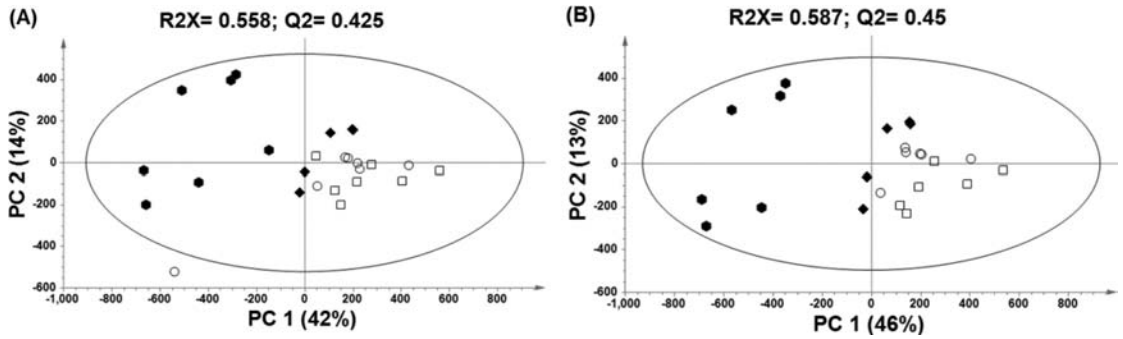

Figure 4. (A) Principal component analysis (PCA) score plots (PC1 vs PC2) based on direct infusion nanoelectrospray−mass spectrometry data of mice serum samples from three groups [normal diet (ND, ●), high-fat diet (HFD, □), high-fat diet + compound K-reinforced ginsenosides(HFD +CK, ○), and quality control (QC, ◆)]. On the score plot, each point represents an individual sample. The center and margin of the eclipse indicate the mean and standard deviation, respectively. (B) The PCA score plot (R^2X, 0.587; Q^2, 0.45) of serum samples obtained from the three groups without outliers.

Table 1. Validation Parameters of the Partial Least-Squares Discrimination Analysis (PLS-DA) Models That Were We Developed, Using "Variable Importance in the Projection" (VIP) Cutoff Values, Employing 999 Permutations

VIP cutoff value	total no. of compounds	R^2Y	Q^2Y	R^2Y intercept	Q^2Y intercept
none	250	0.94369	0.88459	0.425	−0.342
0.7	65	0.94125	0.88907	0.338	−0.348
0.8	54	0.93837	0.88345	0.327	−0.35
0.9	47	0.94008	0.88236	0.325	−0.361

mice and that CK exerted an antiobesity effect. In line with this observation, when CK was fed to obese mice that consumed an HFD, serum levels of triglycerides ($p < 0.01$), cholesterols ($p < 0.01$), and LDL-cholesterols ($p < 0.01$) returned to the levels seen in ND-fed mice (Figure 1G−I). The sterol regulatory element-binding proteins-1c gene (*SREBP-1c*) plays a major role in regulating cholesterol and fatty acid synthesis.[39] Kim et al. reported that compound K attenuated expression of *SREBP-1c* as well as genes encoding fatty acid synthase and stearoyl-CoA desaturase (SCD1), well-known targets of SREBP-1c.[16] RT-PCR (data not shown here) also revealed that *SREBP-1c* expression was significantly suppressed in mice given HFD +CK. Thus, compound K-reinforced ginsenosides restored normal clinical biochemistry in our obesity model. Fatty livers were histologically apparent in mice fed a HFD, whereas in the CK group, fat droplet numbers were significantly reduced in liver tissues, as revealed by Oil Red O staining (Figure 2). In line with these observations, the liver triglyceride contents (ND, HFD, and HFD+CK) were 28.3 ± 5.0, 75.6 ± 12.8, and 34.3 ± 4.6 mg/g, respectively. These results suggest that compound K-reinforced ginsenosides could decrease the extent of fatty liver.

Lipid Identification. Representative pooled samples of mouse sera were used to identify lipids therein. In the positive ion mode, 132 lipids [11 cholesteryl esters (CE), 6 diacylglycerols (DG), 24 LPC, 19 PC, 6 PE, and 66 TG] were detected (Figure 3). LPC, LPE, PC, and PE were present as $[M + H]^+$ or $[M + Na]^+$ adducts, whereas DG and TG were detected as $[M + NH_4]^+$. Serum lipids were identified on the basis of pseudomolecular ion masses ($[M + H]^+$, $[M + Na]^+$, or $[M + NH_4]^+$); MS/MS product ion analysis; and/or comparison with authentic standards or information in databases including the LIPID MAPS Lipidomics Gateway (http://www.lipidmaps.org), the Human Metabolome Database (HMDB; http://www.hmdb.com), and our in-house lipid library (LipidBlast).[37] Specific diagnostic ions were also used to

[a]Variables were selected on the basis of VIP (variable importance in the projection) value (>0.7) and p value (<0.05) upon PLS-DA modeling. [b]LPC, lysophosphatidylcholine; PC, phosphatidylcholine; CE, cholesteryl ester; TG, triacylglycerol. [c]p values were analyzed by ANOVA.

identify each lipid class. For example, LPC and CE species were identified by ion fragments at m/z 184 and 369, corresponding to phosphocholine (Figure S1) and [cholesterol − H_2O] (Figure S2), respectively. In addition, PC species were identified via the loss of choline (−59) and phosphocholine (−184) from protonated pseudomolecular ions of their MS/MS spectra (Figure S3), whereas CE species were identified by the loss of a C_4H_8 (56 amu) and a C_8H_{16} (112 amu) moiety from the side chain of cholesterol (Figure S2); this is a characteristic CE fragment pattern.[40] In addition, acyl chain information on LPC, PC, and TG species was obtained via the loss of fatty acyl chains from pseudomolecular ions. Ions of m/z 524.6, 786.6, and 900.8 in the positive ion mode serve as examples illustrating the identification process for LPC, PC, and TG species, respectively. The product ion mass spectrum of m/z 524.6 (Figure S1) revealed a major fragment ion at m/z 506 attributable to loss of a water molecule from the protonated molecular ion and two minor peaks at m/z 258 and 240 attributable to loss of the stearoyl group (C18:0) and the stearoyl group and a water molecule, respectively. The peak at m/z524.6 was identified as LPC 18:0. The MS/MS spectrum of m/z 786.6 (Figure S3) yielded characteristic fragment ions at

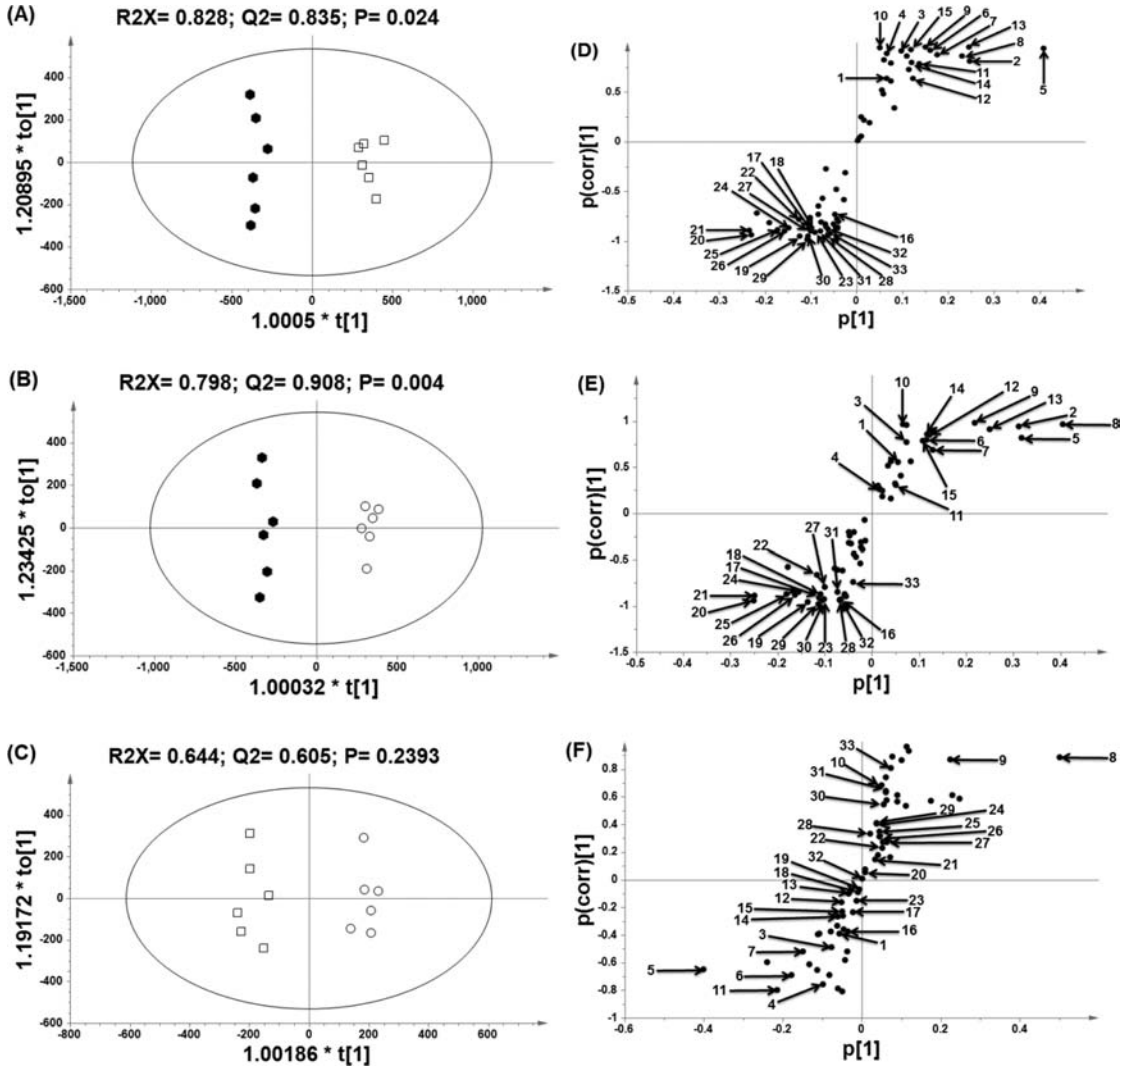

Figure 6. OPLS-DA scores plots of serum lipids of mice fed (A) a normal diet (●) and a high-fat diet (□), (B) a normal diet and a high-fat diet + compound K-reinforced ginsenosides (○), or (C) a high-fat diet and a high-fat diet + compound K-reinforced ginsenosides, and the S-plots associated with the OPLS-DA score plots (D−F) of serum metabolite profiles derived via direct infusion nanoelectrospray−mass spectrometry. The numbers for the metabolites are as given in Table 2.

m/*z* 524 and 520 caused by loss of a linoleoyl group (C18:2) and a stearoyl group (C18:0), respectively. The spectrum also yielded fragment ions at *m*/*z* 506 and 502 caused by loss of water molecules from ions of *m*/*z* 514 and 520, respectively. On the basis of these findings, the peak at 786.6 was identified as PC 36:2 (18:0/18:2). The MS/MS spectrum of *m*/*z* 900.8 (Figure S4) contained a major fragment ion at *m*/*z* 883.7 caused by loss of an ammonia molecule from the ammonium adduct ion and three peaks at *m*/*z* 627.5, 601.5, and 577.5 caused by loss of the pamitoyl (C16:0), oleoyl (C18:1), and meadoyl (C20:3) moieties, respectively. The peak at *m*/*z* 900.8 was identified as TG 54:4 (16:0/18:1/20:3).

Multivariate Statistical Analysis of Serum Metabolite Levels. To validate our model, a QC sample was prepared by mixing equal volumes of serum from all samples studied. System stability was evaluated by analyzing fresh QC samples after groups of eight serum samples were run. Of the 250 ions detected, the number of ions with CV values <30% was >95%, suggesting that the analytical system was stable.[41] These results indicate the excellent stability and reproducibility of the mass spectrometric analysis. To normalize the spectra, the average of the sum of QC sample intensities was divided by the sum of sample spectrum intensities, and, next, each value (fold) was multiplied by the intensity of each lipid species in that sample. After normalization, outliers were selected with the aid of Hotelling's *T*2 test (Figure 4A).[34] If outliers were present outside the ellipse, representing the 95% confidence region of the PCA score plot (these were thus strong outliers), the analysis was repeated after deleting such outliers (Figure 4B) to remove factors irrelevant in the identification of metabolites.[42] PLS-DA is a form of PLS regression employing categorical response variables and is a powerful tool enabling predictions to be made with a minimum probability of error when many variables are in play.[43] In a PLS-DA model, VIP reflects the influence of every *X* variable on *Y*, and, generally, a cutoff VIP value of about 0.7−0.8 is considered significant when *Y* is to be explained.[44] To select metabolites playing key roles in the differentiation of each group, we ran PLS-DA models built using variables chosen by reference to various VIP cutoff values with the aid of permutation test parameters. Such parameters, in the context of the various VIP cutoff values, are listed in Table 1. The highest R^2Y and Q^2Y values were observed when

[a]Different letters indicate significant differences by analysis of variance [ANOVA; (*) $p < 0.05$, (**)$p < 0.01$, and (***) $p < 0.001$].

The metabolite profiles of the sera of mice fed ND, HFD, and HFD+CK, as determined via direct infusion nano-electrospray−ion trap mass spectrometry, were statistically evaluated using a PLS-DA. Figure 5A shows typical direct infusion mass spectra of sera from the ND, HFD, and HFD +CK groups. The HFD-fed groups (HFD and HFD+CK) could be clearly distinguished from the ND group on the first two-component PLS-DA scores plot generated using Pareto scaling (Figure 5B). The metabolite profile of the HFD+CK-fed group differed from that of the HFD group, indicating that CK rectified disturbances in metabolism induced by HFD. The significant differences evident between the two groups ($p < 0.001$) indicated that the metabolic patterns were distinct. We obtained good-quality parameters using the PLS-DA model, which were validated by 7-fold cross-validation ($p < 0.001$) [fitness (R^2X) = 0.686 and R^2Y = 0.869]; predictability (Q^2 = 0.799); and permutation values (the R^2 and Q^2 intercepts = 0.338 and −0.348, respectively), indicating that the PLS-DA model was not overfitted and could be regarded as a predictable model (Figure 5B,D). A PLS-DA loadings plot for all groups was generated using Pareto scaling to identify metabolites contributing to the observed discrimination (Figure 5C). This plot revealed that metabolites located distant from the intersection of $w*c[1]$ and $w*c[2]$ principally explained the observed discrimination. Metabolites in the positive $w*c[1]$ increased in level in mice on the HFD, whereas the opposite was true for those in the negative $w*c[1]$. Major metabolites were identified on the basis of p values and VIP values (Table 2) and numbered on the loadings plot (Figure 5C).

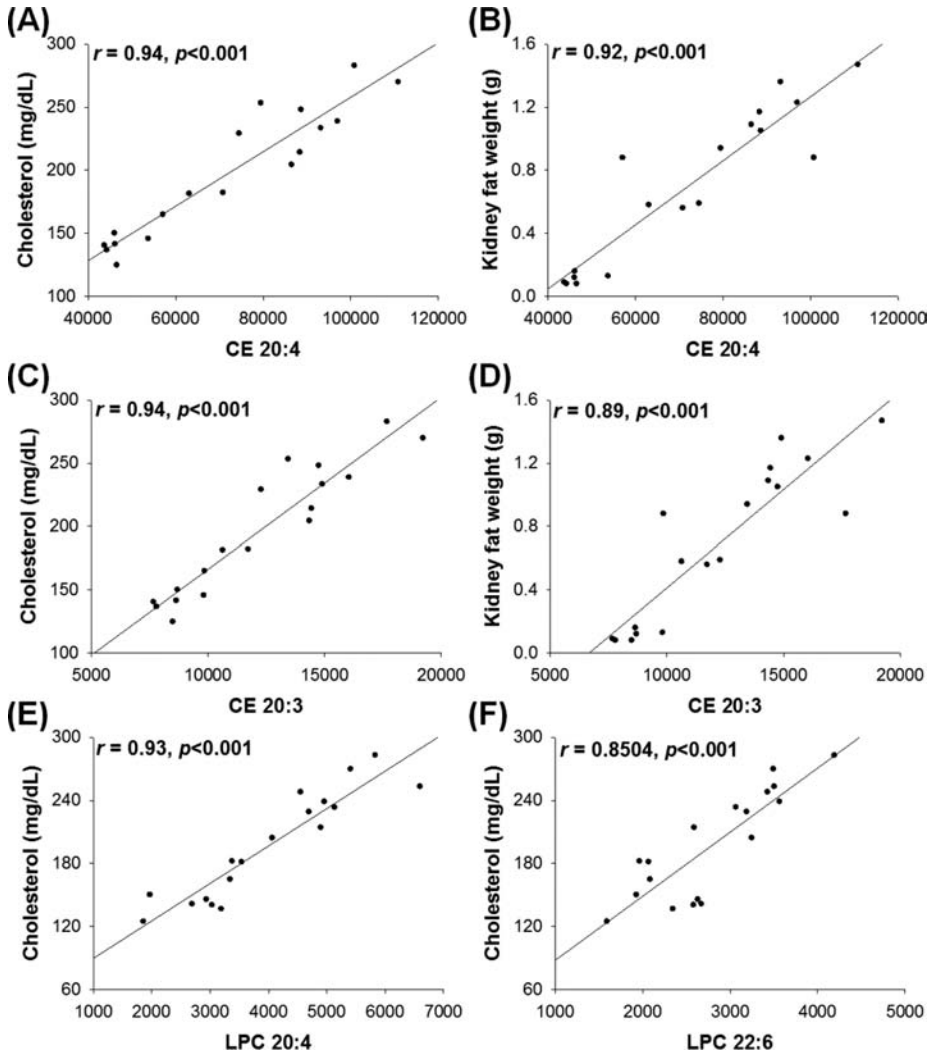

Figure 9. Correlation analysis between serum lipid biomarker candidates and animal characteristic data (kidney fat weight or serum cholesterol level): (A) CE 20:4 versus serum cholesterol; (B) CE 20:4 versus kidney fat weight; (C) CE 20:3 versus serum cholesterol; (D) CE 20:3 versus kidney fat weight; (E) LPC 20:4 versus serum cholesterol; (F) LPC 22:6 versus serum cholesterol.

To explore the differences between pairs of groups by treatment, discriminations afforded by the models between the ND and HFD groups, the ND and HFD+CK groups, and the HFD and HFD+CK groups were visualized on OPLS-DA scores plots (Figure 6A−C). All groups of samples were significantly separated from each other. To identify metabolites contributing to such discrimination, S-plots of all models were generated using Pareto scaling (Figure 6D−F); this revealed the metabolites responsible for separations between groups. Numbered metabolites in the plots were identified (Table 2). The farther the distance of a metabolite from the origin, the greater the potential thereof as a biomarker candidate;[41] these metabolites were responsible for the observed differences in ND versus HFD, ND versus HFD+CK, and HFD versus HFD +CK.

Effect of a High-Fat Diet on Mice. Of the 250 metabolites detected by direct infusion mass spectrometry, the levels of 65 exhibiting "variable importance in the projection" (VIP) values of >0.7 and that were very relevant in explaining the differences between the three groups were statistically analyzed using a nonparametric *t* test. Of the 65 metabolites, 33 (all LPC, CE, PC, and TG) exhibited statistically significant differences ($p < 0.05$) between the HFD and HFD+CK groups (Table 2). Of these, LPC 18:0, CE 20:3, CE 20:4, PC 34:1, PC 36:1, PC 36:2, PC 36:3, TG 47:0, TG 52:3, TG 52:4, and TG 54:5 had VIP values >2.0 and were the principal metabolites contributing to discrimination among the three groups (Table 2). The levels of TGs of higher carbon number (>50) were significantly decreased by the HFD group, whereas the levels of TGs of lower carbon number (<50) and CEs (CE 20:3 and CE20:4) were increased (Figure 7A). Similar observations were reported by Rhee et al.[45] The cited authors also found that triacylglycerols of lower carbon number and reduced double bond content (TG 44:1, TG 46:1, TG 48:0, and TG 50:0) were associated with an increased risk of diabetes, whereas TGs of higher carbon number and greater double-bond content (TG 56:9, TG 58:10, and TG 60:12) were associated with a decreased risk of the disease.[45] DeMarco et al. also reported recently that triacylglycerol composition changed to feature more saturated fatty acyl chains of lower carbon number in obese male *db*/*db* mice 15 weeks of age.[46]

In our present study, the TG 47:0 content increased with a VIP value of 2.726, whereas those of TG52:3, 52:4, 52:5, 54:4, 54:5, and 54:6 decreased with VIP values of 2.712, 2.736, 1.489, 1.792, 2.002, and 1.726, respectively (Table 2). It has been reported that diabetes- and obesity-induced changes in hepatic lipid compositions correlated with changes in the levels of fatty acid elongase and desaturase.[47−49] For example, insulin is known to increase the expression levels of various fatty acid desaturases in animals.[47] In addition, HFD significantly suppressed expression of fatty acid elongase-5 (Elovl-5) (a key enzyme of polyunsaturated fatty acid synthesis) by inhibiting the expression of nuclear sterol-regulatory element binding protein-1 (SREBP-1).[48] In addition, deletion of Elovl-5 triggered fatty liver development in mice by activating SREBP-1c.[50] On the basis of these findings, we suggest that the carbon number and double-bond values of TGs may serve as very useful markers of metabolic diseases including obesity and diabetes mellitus. However, further study is needed.

Of the PCs and LPCs, four PCs (PC 34:1, PC 36:1, PC 36:2, and PC 36:3) and four LPCs (LPC 18:0, LPC 18:1, LPC 20:4, and LPC 22:6) were significantly increased in level in the HFD group (Figure 7B). Changes in LPC levels caused by HFD have been reported. For example, the levels of LPC 18:0,[18,51] 20:4,[51,52] and 22:6[51] in serum and LPC 20:4[18] in the liver were significantly higher in mice fed HFD, similar to our findings. In addition, overweight/obese males also had higher levels of LPC 14:0 and LPC 18:0 than did lean subjects.[38] Obese cotwins had higher concentrations of LPC 18:0, LPC 18:1, and LPC 20:4 than did nonobese cotwins.[53]

Effect of Compound K-Reinforced Ginsenosides in Mice. In the present study, we identified four biomarker candidates that might explain the effects of compound K-reinforced ginsenosides on mice fed an HFD. The compounds are shown in Figure 8 (box-and-whisker plots). As shown in Figure 8, the levels of four compounds (LPC 20:4, LPC 22:6, CE 20:3, and CE 20:4) were significantly increased in mice fed an HFD. Of these compounds, the levels of the cholesterol esters (CE 20:3 and CE 20:4) were lower in the HFD+CK group than in the HFD group (Figure 8). The biosynthesis of cholesteryl esters is regulated by stearoyl-CoA desaturase (SCD1), which increases lipogenesis and the synthesis of such esters.[54,55] SCD-1-deficient mice had reduced levels of cholesteryl esters despite high activity of acyl-CoA:cholesterol acyltransferase (ACAT), which catalyzes the synthesis of such esters.[54] Compound K attenuated expression of the gene encoding the sterol regulatory element-binding protein 1c (SREBP-1c), thus indirectly suppressing the SCD1 gene, the well-known target of SREBP-1c in insulin-resistant HepG2 human hepatoma cells.[16] Therefore, the fall in cholesteryl ester levels in the HFD+CK group (compared to the HFD group) may be attributable to down-regulation of *SREBP-1c* by compound K.

LPCs are major components of "atherogenic factor" and important biomarkers of the effects of HFD.[51] LPCs, major lipid constituents of oxidized LDL, are generated via hydrolysis of the lipid components of oxidized LDL by lipoprotein-associated phospholipase A2.[51,56] The levels of LPCs, including LPC 20:4 and LPC 22:6, increased on ingestion of an HFD but were significantly reduced in mouse serum if the diet contained compound K. Especially, the LPC 22:6 level did not differ significantly from normal controls under such circumstances (Figure 8). Earlier studies found that LDL oxidation was inhibited by ginsenosides Rb1 and Rg1.[57] Therefore, our work highlights the fact that the reduced LPC 20:4 and LPC 22:6 levels in the HFD+CK group may be attributable to an effect of compound K, a metabolite of ginsenoside Rb1.

These biomarker candidates were significantly correlated with the animal characteristic data ($p < 0.05$, Table 3). Especially, the levels of CE 20:3 and CE 20:4 were highly correlated with kidney fat weight ($r > 0.89$, $p < 0.001$), and those of CE 20:3, CE 20:4, LPC 20:4, and LPC 22:6 were significantly correlated with serum cholesterol levels ($r > 0.85$, $p < 0.001$) (Figure 9). Therefore, these metabolites may serve as valuable "biomarker candidates" indicating consumption of an HFD and can be used to measure the efficacy of a compound K-containing diet or medication used to treat obesity. Together, our findings suggest that diets containing compound K might help to control lipid metabolism when such diets are basically HFD.

DOI: 10.1021/jf506216p
J. Agric. Food Chem. 2015, 63, 2919−2929

to a classic luminol−H_2O_2 system, the Lum-AgNP−H_2O_2 CL system is a relatively slow process and dynamically tunable according to adjusting various reaction conditions, such as pH and the H_2O_2 concentration.[14] A single experimental operation can obtain triple-channel information containing CL intensity, the time for CL emissions to appear (T_a), and the time to reach the CL peak value (T_p).[14]

It has been demonstrated that various pesticides can influence the luminol CL system with different degrees.[15] Additionally, some pesticides have a strong affinity for AgNPs.[16] Thus, the addition of different pesticides will cause distinct CL responses. On these bases, we develop a simple and sensitive CL sensor array based on the utilization of triple-channel properties of the Lum-AgNP−H_2O_2 CL system for the discrimination of organophosphate and carbamate pesticides for the first time. The developed sensor array allows for the differentiation of five organophosphate and carbamate pesticides (Figure 1) with detection limits of 24 μg/mL.

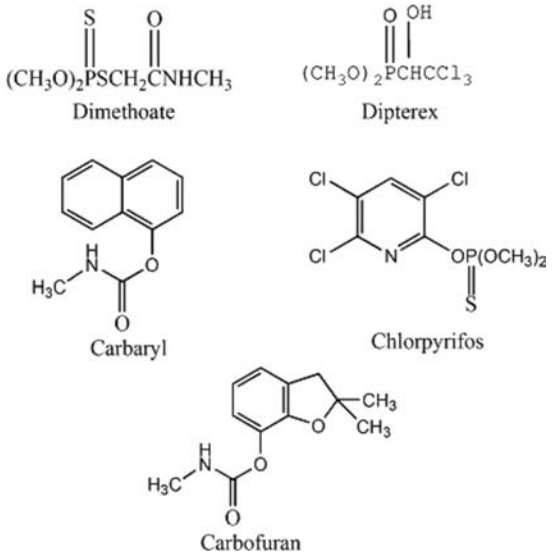

Figure 1. Chemical structures of five selected pesticides.

Moreover, the triple-channel properties are easily simultaneously detected via a single experiment, thereby greatly simplifying the operation procedure.

EXPERIMENTAL SECTION

Chemicals and Materials. Silver nitrate, absolute ethanol, sodium hydroxide, and hydrogen peroxide were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Luminol was obtained from Sigma-Aldrich. Dimethoate, dipterex, carbaryl, chlorpyrifos, and carbofuran (Figure 1) were supplied by J&K Scientific, Ltd. (Shanghai, China). All of the reagents are used as received without further purification. Ultrapure water (18.2 MΩ cm^{-1}) was produced from a Millipore Milli-Q system and used throughout the experiment.

Instrumentations. All of the CL measurements were carried out on an ultraweak luminescence analyzer (BPCL, China) with a fixed voltage of −700 V. The morphology of the as-prepared Lum-AgNPs was investigated using JEM-2100F field emission transmission electron microscopy (TEM) operating at 200 kV.

Synthesis of Lum-AgNPs. Lum-AgNPs were synthesized by the published protocol.[14] Typically, a mixture solution of $AgNO_3$ aqueous solution (4 mL, 5 mM) and absolute ethanol (10 mL) was heated to 60 °C under vigorous stirring and a luminol solution (0.5 mL, 10 mM) dissolved in 0.1 M NaOH aqueous solution was rapidly added. The solution was heated at 60 °C with vigorous stirring for another 2 h. Then, the mixture solution was allowed to cool to room temperature. The Lum-AgNPs were separated from the mixture via centrifugation and washed with ultrapure water. The collected Lum-AgNPs were dispersed into 30 mL of ultrapure water and stored at 4 °C before use.

Analyte Pesticide Response. The stock solutions of five organophosphate and carbamate pesticides were prepared in toluene. For each pesticide detection, the as-prepared Lum-AgNPs (100 μL) were added to pesticide solutions (10 μL) with a final concentration of 24 μg/mL and incubated for 10 min at room temperature, followed by successive injection of H_2O_2 solution (300 μL, 10 mM), and the CL emission was simultaneously measured. Five replicates were tested for each pesticide to give a 3 channel (T_a, T_p, and CL intensity) × 5 pesticide × 5 replicate data matrix. To identify randomly selected pesticide samples, similar procedures were also carried out.

Data Analysis. The CL patterns were processed using a classical principal component analysis (PCA) in MATLAB (version 7.0). After the analysis, three principal components were generated, which represented linear combinations of the response matrices obtained from the raw data matrix [3 channels (T_a, T_p, and CL intensity) × 5 pesticides × 5 replicates]. The first two most significant principal components were employed to produce a two-dimensional plot. The identification of unknown samples, which were randomly prepared by three separate researchers, was made by estimating Mahalanobis distance close to known group centroids from the training matrix.

RESULTS AND DISCUSSION

Principle of the CL Sensor Array Based on the Lum-AgNP−H_2O_2 System. The CL sensor array is based on the triple-channel properties (T_a, T_p, and CL intensity) of the Lum-AgNP−H_2O_2 CL system (Figure 2). Lum-AgNPs were prepared via a previously reported method,[14] which were characterized by TEM, as shown in Figure S1 of the Supporting Information.

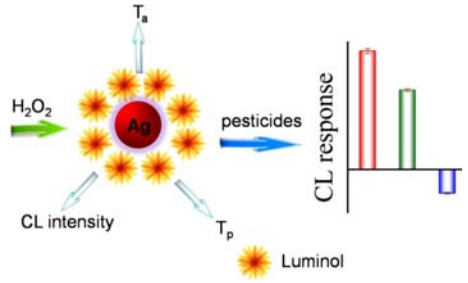

Figure 2. Schematic diagram of the principle of the CL sensor array based on the triple-channel properties of the Lum-AgNP−H_2O_2 CL system.

As expected, the Lum-AgNPs can react with H_2O_2, producing a slow CL kinetic process, as shown in Figure 3. When 0.3 mL of 10 mM H_2O_2 was injected into 0.1 mL of Lum-AgNP solution, the CL emission did not emerge immediately, which was completely different from the traditional luminol-based CL systems. After 9 s, CL emission gradually appeared and the corresponding intensity increased with the increase of time and reached its maximum at 276 s. Thus, a single experiment could obtain triple-channel properties (T_a, T_p, and CL intensity) from this CL system.

The mechanism of this CL system contains the following three processes:[14] (1) Lum-AgNPs were partially dissolved by H_2O_2 to form Ag^+ ions, producing $HO^•$ radicals, which were adsorbed on the surface of AgNPs. (2) The formed $HO^•$ radicals reacted with H_2O_2 and luminol, generating superoxide anion and luminol radical, respectively. (3) Further reaction between the superoxide anion radical and luminol radical

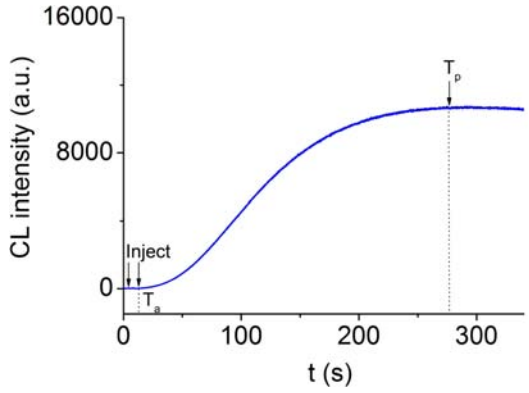

Figure 3. CL kinetic curve of the Lum-AgNP–H_2O_2 system. Reaction conditions: 0.1 mL of Lum-AgNP solution and 0.3 mL of 10 mM H_2O_2 aqueous solution.

generated excited-state 3-aminophthalate anions, resulting in a CL emission. The concentration of H_2O_2 and luminol on the surface of AgNPs was low. Moreover, the CL reaction occurred under static conditions rather than stirring (see the Experimental Section). Therefore, the CL emission was controlled by the diffusion process of H_2O_2. On the initial stage, no CL emission was observed because of the lack of adequate H_2O_2 around the Lum-AgNPs. With the reaction proceeding, the amount of H_2O_2 around the Lum-AgNPs increased, leading to the increase of $HO^•$ radicals and appearance of CL emission (T_a). When the consumption and diffusion of H_2O_2 reached a state of equilibrium around the Lum-AgNPs, the CL intensity attained its maximum, corresponding to T_p. The diffusion process of H_2O_2 was demonstrated by investigating the effect of the H_2O_2 concentration on T_a and T_p. As shown in Figure S2 of the Supporting Information, with the decrease of the H_2O_2 concentration, T_a and T_p became longer. Besides, with the decrease of the AgNP concentration, T_a and T_p also became longer, which further confirmed the presence of the diffusion process (see Figure S3 of the Supporting Information). The dissolution of AgNPs to form Ag^+ ions was confirmed by inductively coupled plasma–atomic emission spectroscopy. The supernatant prepared by centrifugation of the CL reaction solution was found to possess Ag element, whose content was 13.05 μg/mL, which was evidently over that of the control sample (2.03 μg/mL). Furthermore, the effect of various radical scavengers on the CL system was investigated (see Table S1 of the Supporting Information), which demonstrated the presence of various radicals in the CL emission process.

On the other hand, as seen from Figure 1, the structures of organophosphate and carbamate pesticides contain sulfur, phosphorus, or nitrogen groups, which are easy to adsorb on the surface of AgNPs via covalent interaction.[16] Additionally, the reducing group of −OH or −NH− in pesticides reacted readily with the oxygen-containing intermediate radicals.[17] The differential interactions between the Lum-AgNP–H_2O_2 CL system and various pesticides generate distinct CL responses related to each specific pesticide.

Fingerprints of Pesticides Generated via the Triple-Channel Properties (T_a, T_p, and CL Intensity) of the Lum-AgNP–H_2O_2 System. As a proof-of-concept system, five organophosphate and carbamate pesticides with different molecular structures, including dimethoate (Dim), dipterex (Dip), carbaryl (Car), chlorpyrifos (Chl), and carbofuran (Cbf), were chosen as the sensing targets, as shown in Figure 1. As illustrated in Figure S4 of the Supporting Information, the presence of analyte pesticides (24 μg/mL) caused a variety of CL responses. This result confirmed that different pesticides would influence the CL kinetic process of the Lum-AgNP–H_2O_2 system with different degrees, leading to distinct response patterns. To better investigate the effect of various analyte pesticides on the CL sensor array, the signal change rate ($\Delta I/I_0$) for each pesticide as the fingerprint was calculated, as shown in Figure 4. Car and Chr are observed to significantly increase

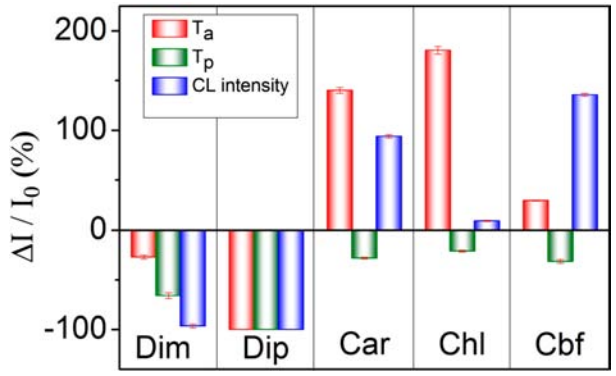

Figure 4. Fingerprints of five selected pesticides based on the CL response patterns ($\Delta I/I_0$) at 24 μg/mL analyte concentration. $\Delta I = I - I_0$, where I and I_0 are the values of T_a, T_p, or CL intensity in the presence and absence of various pesticides, respectively.

T_a by 140.2 and 180.5%, respectively, while Dim and Dip decreased T_a by 27 and 100%, respectively. Cbf made a mild impact on T_a, and the signal was increased by 29.9%.

The effect of analyte pesticides on T_p of the sensor array was also studied (olive-colored column diagram in Figure 4). All of the pesticides decreased T_p with different degrees. Car, Chl, and Cbf decreased T_p by 28.1, 21.1, and 32%, respectively. However, Dim and Dip decreased T_p more effectively, because they decreased the signal by 65.9 and 100%. The influence of various pesticides on CL intensity was further investigated (blue-colored column diagram in Figure 4). Dim and Dip were found to apparently decrease the CL intensity by 96.5 and 100%, while Chl slightly enhanced the CL intensity by 9.4%. Besides, Cbf and Car evidently enhanced the CL intensity by 135.7 and 93.9%.

The distinct CL responses after adding different pesticides could be explained as follows. The presence of a reductive hydroxyl group (−OH) and amino group (−NH−) for Dip and Dim could consume the oxidants in the CL system, such as H_2O_2, $HO^•$ radicals,[17] and superoxide anion radical, leading to the decrease of the CL intensity and increase of T_a and T_p. It was reported that Chl, Car, and Cbf could react with oxidants, such as H_2O_2, to form unstable intermediates, which accelerated the oxidation of luminol,[18−20] leading to the increase of the CL intensity and T_a and decrease of T_p. Owing to the difference of molecular structures for Chl, Car, and Cbf, the corresponding triple-channel information (T_a, T_p, and CL intensity) was not all exactly the same.

CL Sensor Array for Discrimination of Pesticides. These differential CL responses, like "fingerprints", were further subjected to PCA; PCA converts the patterns of the training matrix (3 channels × 5 pesticides × 5 replicates) to canonical scores, as shown in Figure 5. The first two most significant principal components contain 87.5 and 9.8% of the variation,

DOI: 10.1021/acs.jafc.5b00671
J. Agric. Food Chem. 2015, 63, 2930−2934

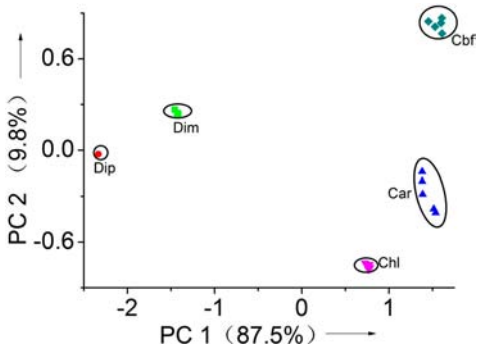

Figure 5. Canonical score plot of the two primary principle components for the discrimination of five selected pesticides (24 μg/mL).

respectively, which occupies 97.3% of total variation. At a pesticide concentration of 24 μg/mL, PCA verifies that the canonical response patterns of the pesticides to the triple-channel properties of the Lum-AgNP−H_2O_2 CL system were classified into five separate groups that corresponded to each pesticide. Moreover, the five repeated measurements of each pesticide were in a narrow distribution in the PCA plots. These results indicated that the five organophosphate and carbamate pesticides at concentrations of no less than 24 μg/mL could be effectively distinguished.

The performance of the CL sensor array was further tested by the discrimination of unknown samples. The identification accuracy of 20 unknown samples at the 24 μg/mL level was found to be 95% (see Table S3 of the Supporting Information). It meant that the CL sensor array could identify pesticides as low as 24 μg/mL.

For a sensor array, another challenge is to discriminate different pesticides at different concentration levels. To elucidate the application potential of the CL sensor array, we performed experiments with Chl, Car, and Cbf at three different concentrations (1, 5, and 10 μg/mL). As shown in Figure 6, various concentrations of three pesticides were able to

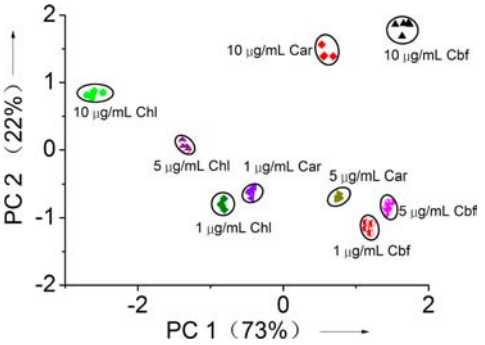

Figure 6. PCA score plot for the discrimination of Chl, Car, and Cbf at three different concentrations (1, 5, and 10 μg/mL).

be discriminated from each other in the PCA score plot. In addition, the CL responses from different concentrations of one pesticide produced patterns around a center; thus, each pesticide could be differentiated.

In summary, we have demonstrated that various analyte pesticides could influence T_a, T_p, and light intensity of the Lum-AgNP−H_2O_2 CL system simultaneously. The signal changes in such triple-channel properties of this CL system resulted in distinct patterns related to each pesticide, which were able to be incorporated into a novel pesticide sensor array with a single sensing unit. Benefiting from the high sensitivity and simple operation of CL technology, several organophosphate and carbamate pesticides, such as dimethoate, dipterex, carbaryl, chlorpyrifos, and carbofuran, have been recognized and discriminate with a high sensitivity.

To the best of our knowledge, this work is the first case of recognition and discrimination of organophosphate and carbamate pesticides in aqueous solution by virtue of a nanoparticle-based CL sensor array that is fabricated by a simple Lum-AgNP−H_2O_2 CL system with triple-channel information. In view of the simple preparation method and available surface modification technique of Lum-AgNPs as well as ready dynamically tunable CL process of this system, we believe that the present study opens a new avenue for the development of simple and facile high-throughput assays for the identification of organophosphate and carbamate pesticides, which may hold great potential application in environmental protection and food safety. In our future work, we will further improve the discrimination ability of the nanoparticle-based CL sensor array to extend its application for recognition of other pesticides.

J. Agric. Food Chem. 2015, 63, 2930−2934

polyphenols extracted from frozen and freeze-dried blueberry powder. We have also evaluated the ability of these polyphenols to inhibit α-glucosidase, a key enzyme in the human stomach responsible for catabolizing maltose, a disaccharide, that contributes to postprandial increase in blood glucose.

MATERIALS AND METHODS

Blueberries. Frozen wild blueberries (low-bush) obtained from the local supermarket were divided in two batches: (1) kept as frozen blueberries and (2) used for making blueberry freeze-dried powder. Blueberries were freeze-dried (at −45 ± 5 °C and 100 Pa/1 mbar) in a freeze-dryer (Thermo Savant, USA) for 72 h (2% moisture content on dry basis), milled with a blender, and stored in airtight containers at −20 °C until further analysis. Blueberries from the same lot were used for all experiments.

Chemicals and Reagents. All chemicals and solvents were purchased from Fisher Scientific (Ottawa, ON, Canada) or Sigma-Aldrich (Oakville, ON, Canada). Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS), L-glutamine, trypsin−EDTA, sulforhodamine B (SRB), acetic acid, and Tris base were purchased from Sigma-Aldrich (Oakville, ON, Canada). Cyanidin- and delphinidin-3-glucosides were purchased from Chromadex (Irvine, CA) and malvidin-3-glucoside from extrasynthese (Genay, Cedex, France). Human epithelial colorectal adenocarcinoma cell line HT-29 and human normal epithelial colon cell line CRL-1790 were obtained from the American Type Culture Collection (Rockville, MD). Minimal Essential Medium Eagle (MEME) was purchased from Hyclone (Thermoscientific, Canada). Phosphate-buffered saline (PBS) 10x, penicillin−streptomycin solution, and trypan blue were from Gibco (Bethesda, MD).

Polyphenol Extraction. Methanol and water were used as extraction solvents. Methanolic extraction enabled a more efficient way of extracting phenolic components, and water, on the other hand, simulated the state where anthocyanins are extracted and liberated after consumption as food. One part of frozen blueberries was homogenized with two parts of solvent (50 g of blueberries in 100 mL of solvent) using a shear homogenizer (Brinkman Instruments, Westbury, NY) fitted with a Polytron PTA 10 probe for 5 min. The homogenates were centrifuged (Beckman J2-21, Missisauga, ON) at 27 000*g* for 20 min; the supernatants were collected and stored in amber tubes at −20 °C for further analysis.

Separation of Free and Bound Polyphenols. Blueberry extracts from the aqueous and methanolic crude extracts (10 mL) were transferred into a dialysis membrane reservoir (6−8 kDa cutoff, Spectrapor, Spectrum Laboratories, Houston, TX) previously soaked and rinsed with distilled water. Dialysis was carried out in 500 mL of distilled water at 4 °C for 24 h. The dialyzed (complexed polyphenols) and the dialyzate (free polyphenols) were collected and used for various analyzes.[12]

Total Polyphenol Content. Total polyphenol contents of the samples were estimated according to the Folin−Ciocalteau method.[13] An aliquot of extract was mixed with 50% (v/v) of ethanol in water, to a final volume of 100 μL. Reaction mixture was prepared by adding 500 μL of distilled water, 50 μL of Folin Ciocalteau reagent (2 N), and 100 μL of 5% (w/v) sodium carbonate solution to the sample, vortexed, and incubated in the dark for 1 h. Samples were mixed thoroughly after incubation, and the absorbance was measured at λ_{max} = 725 nm using a Beckman Coulter DU 800 spectrophotometer (Beckman Coulter Inc., IN). A standard curve was generated using gallic acid with concentrations ranging from 0 to 200 μg/mL. Polyphenol concentrations were expressed as weight of gallic acid equivalent per gram fresh weight of fruit. Dry weight of a known amount of polyphenols was determined after freeze-drying. While expressing polyphenol content of blueberries from dry powder, the value was expressed as fresh weight equivalent.

Solid-Phase Extraction. Solid-phase extraction (SPE) with Sep-Pak C18 (Waters Corporation, MA) cartridge was used to purify polyphenols.[14] The columns were washed with water and polyphenols eluted with 100% methanol. All samples were adjusted to 1 mg/mL of polyphenols with methanol, filtered with 0.45 μm nylon filters, and subjected to LC-MS analyses.

Identification of Individual Polyphenols by LC- ESI- MS. Chromatographic analysis of anthocyanins isolated from the crude extracts, the dialyzed extracts, and the dialyzate fractions was performed on an Agilent 1100 series LC-MS. Separation was carried out using an X-Terra MS C-18 (5 μm, 150 × 3.0 mm, Waters Corporation, MA). Anthocyanins were eluted with a gradient of mobile phases formed by mixing methanol (phase A) and 2.0% (v/v) formic acid (phase B) at a flow rate of 0.8 mL/min. The gradient used was as follows: 0−2 min, 93% B; 2−30 min, 80% B; 30−45 min, 70% B; 45−50 min; 65% B, 50−60 min, 50% B; 60−65 min, 20% B; 65−70 min, 93% B. Detection was carried out both at 520 and 260 nm. Electrospray ionization (ESI) was performed with an API-ES mass spectrometer. Nitrogen was used as the nebulizing and drying gas, 12 L/min at 350 °C, ion spray voltage, 4000 V, and fragmentor voltage, 80 V. Electrospray ionization mass spectra were scanned from m/z 100 to 1000. Spectra were acquired in the positive ion mode for anthocyanins and negative ion mode for phenolics and flavonoids. A sample injection volume of 20 μL (20 μg) was used for all samples. Chemical identification of the compounds was achieved by matching the molecular ions (m/z) and daughter ions obtained by LC-ESI-MS with spectral data (www.metabolomics.jp).

Relative amounts of individual phenolic components were calculated as follows. The sum of all peak areas was taken as 100% resulting from the separation of 20 μg of phenolics sample. Individual peak areas corresponding to specific components were also calculated. From these values, (individual peak area/total peak area) × 20, the relative content of specific peaks in micrograms was obtained. From these values, mg phenolics content per gram fresh weight of fruit could be calculated knowing the fresh weight of the sample and its polyphenol content.

Antioxidant Assays. Total antioxidant activity of blueberry crude extracts and dialyzed fractions was measured by using 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical (Molyneux),[16] superoxide scavenging,[17] and hydroxyl radical scavenging[18] assays according to standard methods.

α-Glucosidase Inhibition. α-Glucosidase inhibitory activity was measured as described.[19] Blueberry polyphenol samples were diluted with water to a sample volume of 50 μL to obtain concentrations of 10, 25, 50, and 100 μg/mL of polyphenols, and water of equal volume was used as a control. Reaction was initiated by the addition of 100 μL of 0.1 M sodium phosphate buffer (pH 6.9) containing α-glucosidase solution (1.0 U/mL) to the samples followed by incubation at 25 °C for 10 min. After the reaction, 50 μL of 5 mM *p*-nitrophenyl-α-D-glucopyranoside solution [prepared in 0.1 M sodium phosphate buffer (pH 6.9)] was added to the reaction mixture (final volume = 200 μL) and incubated at 25 °C for 5 min. After incubation, distilled water (800 μL) was added to the reaction mixture and the absorbance was recorded at λ_{max} = 405 nm (A). Inhibition of the enzyme activity was expressed as percentage inhibition and calculated as α-glucosidase inhibition (%) = (A control − A sample)/(A control) × 100.

Fruit Matrix Isolation and Estimation of Pectin Content. Polyphenols were removed from whole blueberries (50 g) by soaking (5×) in 50% v/v ethanol (100 mL) and (2×) in distilled water (100 mL) for 1 h each. The fruits were homogenized in water as described in Polyphenol Extraction. To verify the absence of polyphenols, samples were dialyzed overnight, and Folin−Ciocalteau assay was performed on the extracts. Samples containing the fruit matrix were stored at −20 °C until further analysis. Pectin content in the fruit matrix and crude extracts was estimated according to Taylor.[15] Briefly, 200 μL of samples, 3 mL of concentrated sulfuric acid, and 100 μL of 0.1% (w/v) carbazole reagent (made up in 100% ethanol) were mixed, incubated in a water bath at 60 °C for 1 h, and cooled to room temperature, and absorbance was measured at 530 nm against a water blank. A stock solution of pectin from apples was used at concentrations in the range of 0−200 μg/mL to generate a standard curve.

Cell Proliferation Assay. HT-29 cells were cultured in 25 cm^2 flasks with Dulbecco's Modified Eagle's (DMEM) medium supple-

Table 1. Total Polyphenol and Anthocyanin Content of Different Blueberry Extracts

sample	solvent	polyphenol (mg GAE/g fruit fresh weight)[a]		
		crude extract	dialyzed extract	dialyzate
frozen blueberries	water	1.66 ± 0.03[a]	0.57 ± 0.02[a]	0.79 ± 0.02[a]
frozen blueberries	methanol	3.20 ± 0.07[b]	0.97 ± 0.01[b]	2.21 ± 0.09[b]
blueberry freeze-dried powder	water	2.00 ± 0.15[a]	0.72 ± 0.01[a]	1.21 ± 0.01[a]
blueberry freeze-dried powder	methanol	3.63 ± 0.19[b]	0.80 ± 0.02[b]	2.82 ± 0.04[b]

[a]The data represent the mean ± SEM from three independent analyses. Means with different superscript letters are statistically significant ($p < 0.05$).

mented with 10% (v/v) FBS, 200 mM L-glutamine, and 1% (v/v) penicillin−streptomycin. CRL-1790 cells were cultured in Eagle's minimal essential medium (EMEM) contained in 25 cm^2 flasks and supplemented with FBS, penicillin−streptomycin, and L-glutamine as described above. Both cell lines were incubated at 37 °C in a humidified chamber including 5% CO_2. Cells were incubated with blueberry extracts for 24 and 48 h. HT-29 cells seeded at 2.0×10^3 cells/well and CRL-1790 seeded at 1.0×10^3 cells/well in 96-well plates were incubated for 24 h to attach to the surface and achieve log phase growth at the time of treatment (time 0). Stock solutions were prepared containing 1 mg/mL of polyphenols dissolved in water and diluted in growth media to obtain concentrations of 10, 25, 50, 75, and 100 μg/mL of media for each sample and immediately tested for antiproliferative activity. Negative control cells were supplied with growth media, and blank wells contained growth media only. The medium was changed every 24 h. Cell proliferation assay was carried out according to a modification of procedure used by Vichai and Kirtikara.[20] After 24 and 48 h of treatment, cells were stained with sulforhodamine dye (0.4% dissolved in 1% acetic acid, 50 μL per well), and the optical density of each well was measured at 570 nm using a Synergy HT Multi Detection Microplate Reader (Bio-Tek Instruments, Winooski, VT), and KC4 version 3.03 Power Report Bio-Tek software was used to analyze the data.

Statistical Analysis. Statistical analyses were conducted by using Graph Pad Prism software, version 4. Results with multiple means were compared by using one-way analyses of variance (ANOVA), which was followed by Tukey's test to evaluate the level of significance. Significantly different means ($p < 0.05$) are denoted by different letters.

RESULTS

Polyphenol Composition of Blueberry Extracts. Total polyphenol content from different preparations of blueberries ranged from 1.6 to 3.6 mg GAE/g frozen fruit (Table 1). Polyphenol content of methanol extracts of frozen blueberries and freeze-dried blueberries were much higher than that obtained after water extraction, suggesting the presence of significant amounts of bound polyphenols that are not extractable with water. Dialyzed fraction and dialyzate of methanol extracts also possessed increased levels of polyphenols as compared to those from water extracts. Further experiments were largely carried out using polyphenols obtained after water extraction of frozen blueberries, as this was also similar to the levels obtained after water extraction of freeze-dried blueberries. Occasional comparisons have also been made with polyphenols obtained from methanol extracts.

Identification and Quantification of Phenolic Compounds. Polyphenols from the original extract (crude extract), dialyzed extract, and dialyzate of blueberry homogenates were analyzed to compare their composition. Major phenolic components identified in the water extracts from frozen blueberries are given in Table 2. These components were also isolated after methanol extraction and dialysis of the extracts which were similar as in water extract but generally higher in amounts (data not shown). Chlorogenic acid was the major phenolic acid in blueberry extracts. Glucosides, galactosides, and arabinosides of major aglycones including delphinidin, cyanidin, petunidin, peonidin, and malvidin were observed. Glycosylated flavonoids such as quercetin arabinoside (xyloside) and syringetin galactoside (glucoside) were also identified. Acetoylated anthocyanins of delphinidin, and malvidin glucosides, were major components among anthocyanins.

Table 2. Major Polyphenols Identified in Blueberry Extracts by HPLC-MS-ESI

peak[a]	t_R[b] (min)	major ions[c]	compound[d]
1	15.75	353, 336, 288, 180	chlorogenic acid
2	22.00	465, 302, 148	delphinidin 3-*O*-galactoside
3	24.91	465, 302, 148	delphinidin 3-*O*-glucoside
4	26.91	435, 302, 132	delphinidin 3-*O*-arabinoside
5	28.70	449, 287,148	cyanidin 3-*O*-glucoside
6	30.27	479, 316, 148	petunidin 3-*O*-galactoside
7	33.30	463, 301, 148	peonidin 3-*O*-galactoside
8	35.05	449, 316, 132	petunidin 3-*O*-arabinoside
9	36.77	493, 331, 148	malvidin 3-*O*- galactoside
10	39.03	433, 301, 132	peonidin 3-*O*-arabinoside
11	40.56	493, 331, 148	malvidin 3-*O*-glucoside
12	45.15	463, 331, 132	malvidin 3-*O*-arabinoside
13	47.44	507, 367, 302, 204, 148	delphinidin 6-acetoyl,3-*O*-glucoside
14	49.06	535, 367, 302, 204, 148	malvidin 6-acetoyl,3-*O*-glucoside
15	52.98	435, 303, 229, 153	quercetin 3-*O*-arabinoside/xyloside
16	55.54	507, 347, 331, 315, 287, 153	syringetin 3-*O*-galactoside/glucoside

[a]Peaks were recorded at 260 nm, the absorbance maximum of phenolic moiety in polyphenols. [b]Retention time for individual component is denoted as t_R. [c]Mass spectra for anthocyanins were obtained in the positive ion mode, and those for phenolics and flavonoids in the negative ion mode. [d]Compounds were identified by comparing the mass spectra to authentic standards that are available at www.metabolomics.jp.

HPLC profiles of polyphenols purified from water extracts, dialyzed extract, and the dialyzate of frozen blueberries revealed the presence of 16 major phenolic compounds (Figure 1). The content of individual phenolic/flavonoid components and anthocyanins in these samples is shown in Table 3 and Table 4, respectively. Chlorogenic acid was the major phenolic acid component in blueberries, approaching nearly 50% of the total phenolic components in the aqueous crude extract and the dialyzate. Quercetin arabinoside (xyloside) was the major flavonoid glucoside, present in both crude extract and dialyzate. In addition, flavonoids such as myricetin, quercetin arabinoside, and syringetin galactoside (glucoside) were also present in aqueous crude extracts. Several other phenolic components such as isorhamnetin, 4-*O*-feruloylquinic acid, and myricetin

Table 3. Flavonoid and Phenolic Acid Composition (mg/g Fresh Weight) of Crude Extract, Dialyzed Extract, and Dialyzate Fraction Obtained from Frozen Blueberries Extracted with Water[a]

phenolic component	crude extract	dialyzed extract	dialyzate
isorhamnetin	0.028 ± 0.003[a]	Tr[b]	Tr
myricetin	0.024 ± 0.001[a]	0.009 ± 0.000[b]	0.010 ± 0.002[b]
chlorogenic acid	0.216 ± 0.010[a]	0.031 ± 0.014[b]	0.190 ± 0.026[a]
4-*O*-feruloylquinic acid	0.041 ± 0.008[a]	0.062 ± 0.006[b]	Tr
quercetin- 3-*O*-arabinoside/ xyloside	0.091 ± 0.021[a]	0.036 ± 0.006[b,c]	0.054 ± 0.005[c]
syringetin 3-*O*-galactoside/ glucoside	0.020 ± 0.006[a]	Tr	0.050 ± 0.004[b]
total	0.420 ± 0.040[a]	0.128 ± 0.015[b]	0.304 ± 0.037[c]

[a]The values given are mean ± SEM from three independent analyzes. Means with different superscript letters in the same row are statistically significant ($p < 0.05$). [b]Tr = traces.

were detected in very low amounts (mass spectral identification). Aqueous dialyzed fraction contained less than 10% of the polyphenols present in the original crude extract, having most of the components typically present in the crude extract and the dialyzate.

Antioxidant Activity. Antioxidant activities of free and complexed blueberry polyphenols isolated from frozen- and freeze-dried blueberries were evaluated to observe if freeze-drying affected complex formation with the food matrix, and this in turn affected the antioxidant activity of polyphenols. The specific quenching values per 10 μg polyphenols were calculated from the linear phase of the activity curve (Table 5). Maximal levels of DPPH radical scavenging and hydroxyl radical scavenging were observed in the free polyphenol fraction obtained after dialysis of frozen blueberry extracts, and these values were nearly twice as high as in the crude extract. The highest level of superoxide scavenging was observed in the dialyzed fraction (polyphenols bound to the matrix) of frozen blueberry extracts. Dialyzate of the frozen blueberry extract was as efficient as the standards in DPPH scavenging and far reduced in hydroxyl radical scavenging. For freeze-dried blueberries, dialyzed extract showed the highest DPPH scavenging and superoxide scavenging activities. But the dialyzate of the freeze-dried berries showed the maximum level of hydroxyl radical activity (Table 5).

α-Glucosidase Inhibition. Polyphenols isolated from water and methanol extracts of blueberries (crude extracts, dialyzed extract, and dialyzate) from both frozen fruits and freeze-dried powder were evaluated for their potential to inhibit α-glucosidase, a key sugar catabolizing enzyme in the stomach responsible for the liberation of sugars from disaccharides such as maltose, produced during the digestion of starch. As shown in Figure 2, the specific inhibition of α-glucosidase by the crude extract, the dialyzed extract, and dialyzate was highly variable, with the dialyzed extracts showing the most efficient inhibition and the dialyzate showing the least inhibition. The crude extracts of polyphenols in methanol showed levels of glucosidase inhibition higher than those of water extracts from both frozen and freeze-dried blueberries. A similar pattern was observed while using the dialyzed extract, but with effectiveness nearly twice as high as that observed in the crude extracts with maximal inhibition observed between 80% and 100%. Interestingly, the dialyzed methanol extract was

twice as effective as the dialyzed water extract from frozen blueberries at 20 μg/mL level. The dialyzate from extracts of both frozen and freeze-dried blueberries comprising free polyphenols showed the least amount of α-glucosidase inhibition (<10%; Figure 2). Neither gallic acid (data not shown) nor catechin inhibited α-glucosidase activity more than 20% at 100 μg/mL.

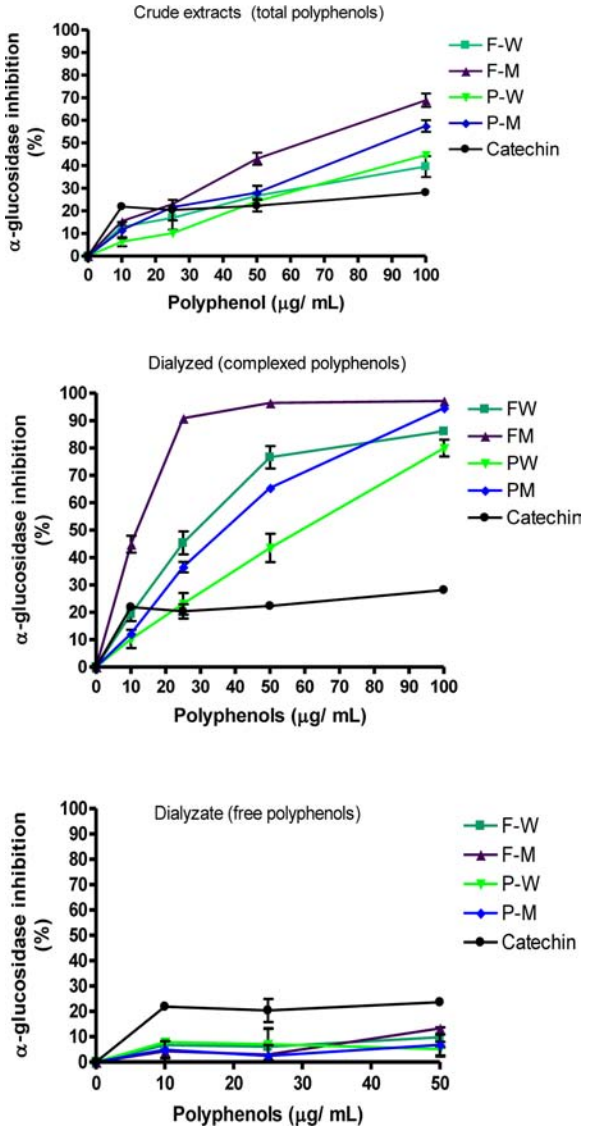

Figure 2. Percent inhibition of α-glucosidase activity of polyphenols isolated from blueberry extract, dialyzed extract, and dialyzate fractions. Frozen blueberries and freeze-dried blueberries were extracted with water or methanol, and the polyphenols were subjected to dialysis against water and purified using sep-pak C_{18} columns. Inhibition of α-glucosidase activity was performed in the presence of increasing levels of polyphenols. The activity curves are denoted as follows: dark green square, frozen blueberries extracted with water; purple triangle, frozen blueberries extracted with methanol; light green triangle, freeze-dried powder extracted with water; blue diamond, freeze-dried powder extracted with methanol. Catechin was used as a standard: black circle. The results shown are mean ± SEM from three independent experiments.

Antiproliferative Activity. Colon cancer (HT-29) and normal colon (CRL-1790) cells were incubated in the presence or absence of free and complexed blueberry polyphenols (dialyzed and dialyzate fractions) at concentrations ranging from 0 to 100 μg total polyphenols/mL medium, and proliferation was evaluated using the SRB binding assay relative to an untreated control (only medium without polyphenols) (Figure 3). Results clearly indicated that all samples exhibited significant inhibitory activities on the growth of both HT-29

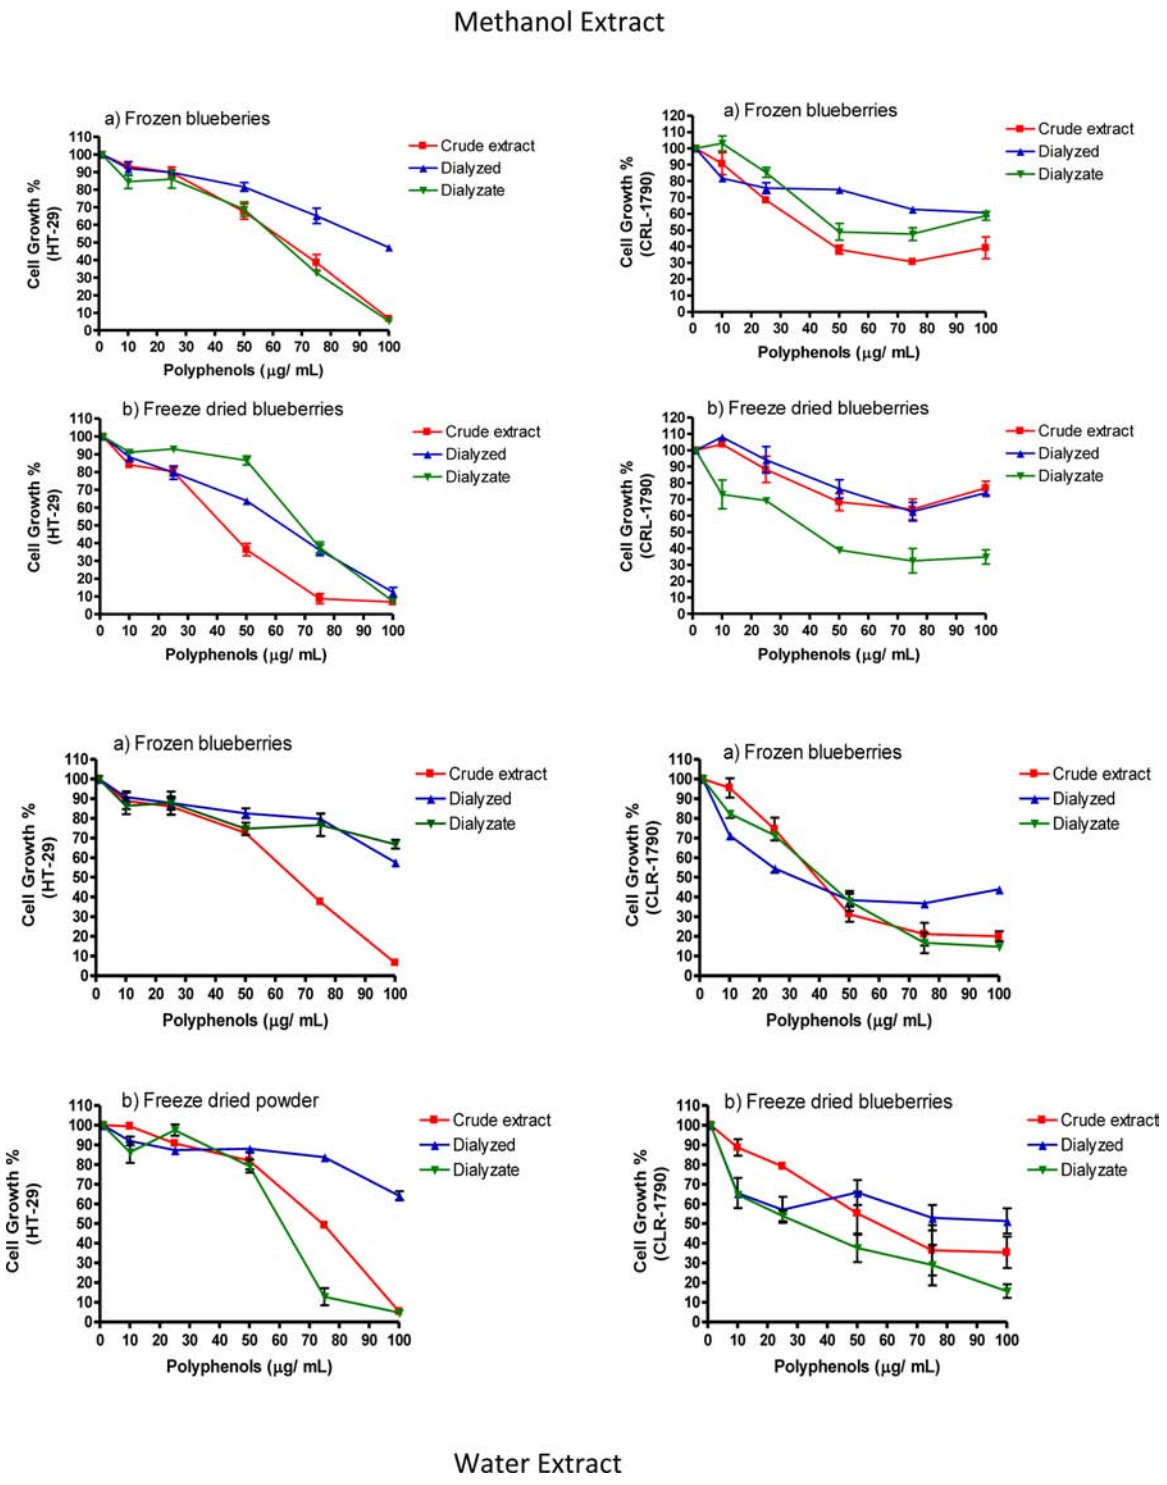

Figure 3. Antiproliferative activity of various fractions isolated from blueberries. Frozen blueberries and freeze-dried blueberries were extracted with methanol (top four panels) or water (bottom four panels). Activities of polyphenols isolated from crude extract, dialyzed extract, and dialyzate were evaluated using a colorectal cancer cell line HT 29 and a normal colon cell line CRL 1790. The data represent the mean ± SEM of results from four independent experiments.

and CRL-1790 cells in a dose-dependent manner but generally at relatively high concentrations (>50 μg/mL). Methanol-extracted and purified polyphenols, dialyzed extract, and dialyzate from frozen blueberries showed a similar degree of antiproliferative action on HT-29 cells as compared to similar extracts from freeze-dried blueberries (Figure 3). Inhibitory properties of these extracts were slightly reduced in CRL 1790 cells. Antiproliferative activity of polyphenols obtained after water extraction and purification of frozen blueberries and freeze-dried blueberries was much higher against HT 29 cells, while that of the dialyzed extract was marginal (~30% inhibition). Dialyzate from freeze-dried blueberries showed much higher antiproliferative activity against HT-29 cells. Polyphenols isolated from the aqueous extracts of frozen

J. Agric. Food Chem. 2015, 63, 2935−2946

blueberries and freeze-dried blueberries, as well as their dialyzed extracts and dialyzates, showed a relatively higher antiproliferative activity against CRL 1790 cells at concentration ranges lower than 50 μg/mL.

Pectin Content of Blueberry Extracts. To further understand the potential nature of polyphenol food matrix interactions, levels of pectin, the major cell wall component in ripe fruit, were analyzed in different berry fractions (Figure 4).

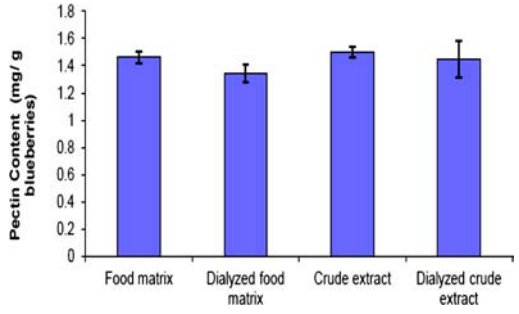

Figure 4. Pectin contents of different blueberry food matrixes. A set of blueberry fruit (50 g) was bleached with ethanol to remove the polyphenols completely, and the resulting fruit were subjected to homogenization in water, removal of debris by centrifugation, and dialysis. These fractions are denoted as food matrix and dialyzed food matrix. A separate set (50 g) was subjected to water extraction, removal of debris, centrifugation, and dialysis. Pectin content was estimated by a colorimetric method. The data are from three separate analyses and expressed as mean ± SEM.

There were no significant differences in pectin content between crude extracts and dialyzed extracts of decolorized fruits and the original blueberry extracts and dialyzed extracts. The average pectin content in all samples was approximately 1.5 mg/g frozen weight of blueberries.

To evaluate the ability of purified carbohydrate-rich matrixes to complex with polyphenols, varying concentrations of pectin and cellulose were mixed with 1 mg gallic acid equivalent of free polyphenols. To confirm that these polyphenols could form complexes with pectin and cellulose after mixing, the mixtures were dialyzed overnight. Table 6 shows the proportion of polyphenols complexed with pectin−cellulose and those that are free and recovered in the dialyzate fraction after dialysis. A fixed amount of polyphenols (1.3 mg) was mixed with different solutions: 0.5% w/v pectin, 0.5% w/v cellulose, and 0.5% w/v pectin−cellulose, and total polyphenols were quantified. During dialysis, over 90% of the polyphenols leaked out of the bag when polyphenols were alone or mixed with cellulose. When mixed with pectin or pectin and cellulose, there was some retention of the polyphenols within the dialysis bag, indicating a weak binding between pectin and polyphenols, but this was far lower than what was observed in the dialyzed extract of blueberries (Table 1).

Antioxidant Activity in Mixed Complexes. The ability of fruit matrix (i.e., pectin, cellulose, and pectin + cellulose) to scavenge DPPH radicals was assessed in comparison to the dialyzed and dialyzate fractions obtained from blueberry homogenate. Fruit matrix alone (obtained after the extraction of the polyphenols) was tested after mixing with equivalent levels of polyphenols that were present in the original blueberry homogenate. Blueberry dialyzed extract containing polyphenols showed a dose-dependent increase in DPPH scavenging ability (Figure 5). Dialyzate from blueberry extract containing free polyphenols showed almost 90% scavenging of DPPH radicals at the highest concentration tested, followed by complexed polyphenols obtained from dialyzed extract of blueberries. Natural food matrix isolated from ethanol-bleached blueberries before and after dialysis showed a very low scavenging ability of DPPH at ∼10%. Different solutions containing food matrixes made of pectin or cellulose showed ∼5% inhibition. When complexed as in the dialyzed extract, the matrix tends to reduce the antioxidant capacity of polyphenols in the range of 10−20% (Figure 5).

Antiproliferative Activity in Mixed Complexes. Antiproliferative activities of blueberry polyphenols and different food matrixes were evaluated using colon cancer cell line HT-29. As shown in Figure 6, free polyphenols at the highest concentration (100 μg/mL) inhibited approximately 80% of the growth of HT-29 cells. By contrast, when the same amount of polyphenols was naturally complexed with the blueberry fruit matrix, there was only 50% inhibition. Samples containing 100 μg/mL of the fruit matrix, or the dialyzed food matrix, showed only 10% and 30% inhibition of cell growth after 24 and 48 h incubation periods, respectively. In another experiment, when the dialyzate containing free polyphenols or purified polyphenols was mixed with pectin, cellulose, or a mixture of pectin and cellulose and incubated with HT 29 cells, antiproliferative action was nearly similar for 24 h incubation, but during prolonged incubation for 48 h, polyphenol−pectin mixture tended to show a higher degree of antiproliferative activity, suggesting that during long-term incubation in media, pectin may complex with proteins, resulting in enhanced bioavailability of polyphenols and an increase in antiproliferative activity (Figure 7). These aspects need further investigation.

DISCUSSION

Public interest in blueberries as a functional food has increased in recent years because of its health benefits. Blueberry is commonly consumed fresh, frozen, and as a powder. Simple and acylated anthocyanins have been found in some low bush cultivars.[21,22] Overall, the profile of polyphenols in this study is consistent with those reported previously in the literatur-

Table 6. Effect of Dialysis on the Retention of Polyphenols by Pectin (0.5%), Cellulose (0.5%), and a Mixture of Pectin and Cellulose (0.25% each)[a]

	original extract		dialyzed extract		dialyzate	
sample	phenolic content (mg)	recovery (%)	phenolic content (mg)	recovery (%)	phenolic content (mg)	recovery (%)
polyphenols alone	1.3 ± 0.05	100	0.10 ± 0.003	7.7	1.20 ± 0.02	92
pectin−polyphenol	1.3 ± 0.03	100	0.10 ± 0.002	7.7	1.13 ± 0.09	86
cellulose−polyphenol	1.3 ± 0.06	100	0.10 ± 0.006	7.7	1.18 ± 0.18	91

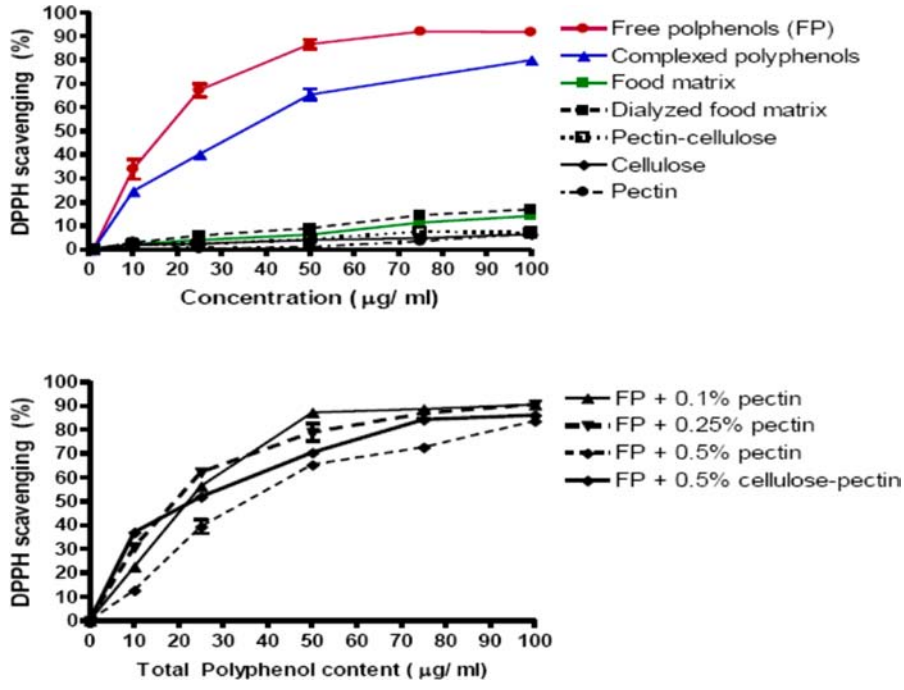

Figure 5. A comparison of DPPH radical scavenging activities of isolated bleached blueberry fruit matrix, pectin, and cellulose (each at 100 μg/mL) alone, with the dialyzed extract (complexed polyphenols) and with the dialyzate (free polyphenols) of water extracted blueberries (top panel). The concentrations indicated (x-axis) are for both polyphenols (as estimated by Folin's reagent) and the matrix (weight). The bottom panel shows the effect of pectin and a combination of cellulose and pectin (100 μg/mL) on the DPPH-radical scavenging activity of free polyphenols isolated from blueberries. The data represent mean ± SEM from three separate experiments.

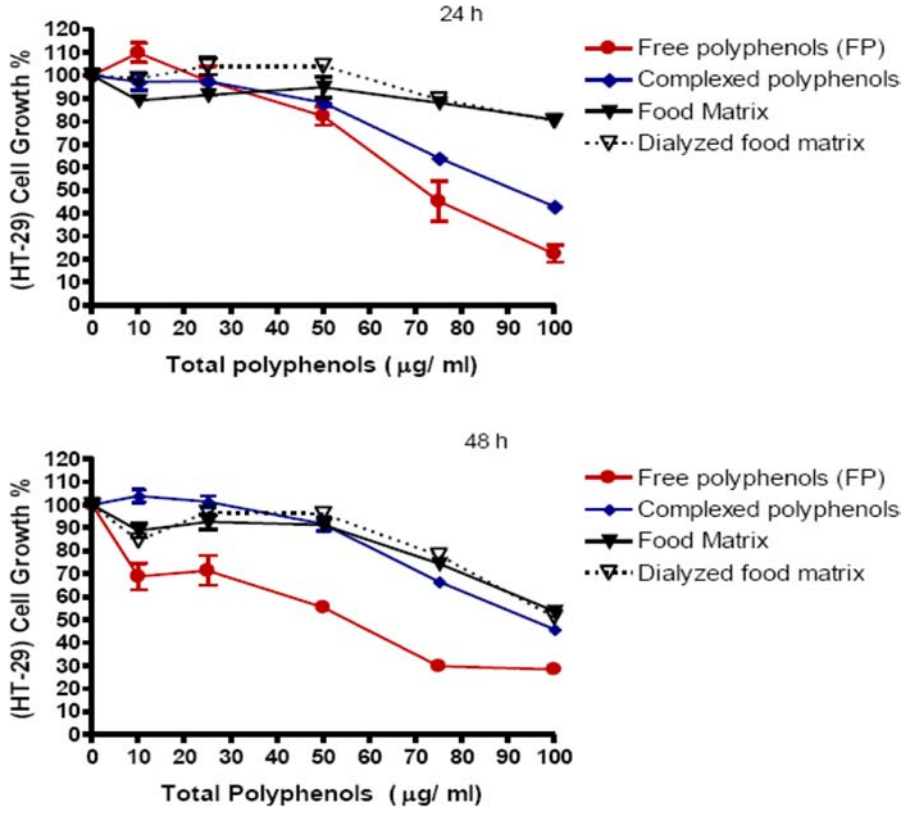

Figure 6. Effect of food matrix (100 μg/mL) isolated from blueberries on antiproliferative activity of free polyphenols (dialyzate) and complexed polyphenols (dialyzed extract) monitored at 24 h after treatment (top panel) and 48 h after treatment (bottom panel) using HT 29 colorectal cancer cells. The data are mean ± SEM from three independent experiments.

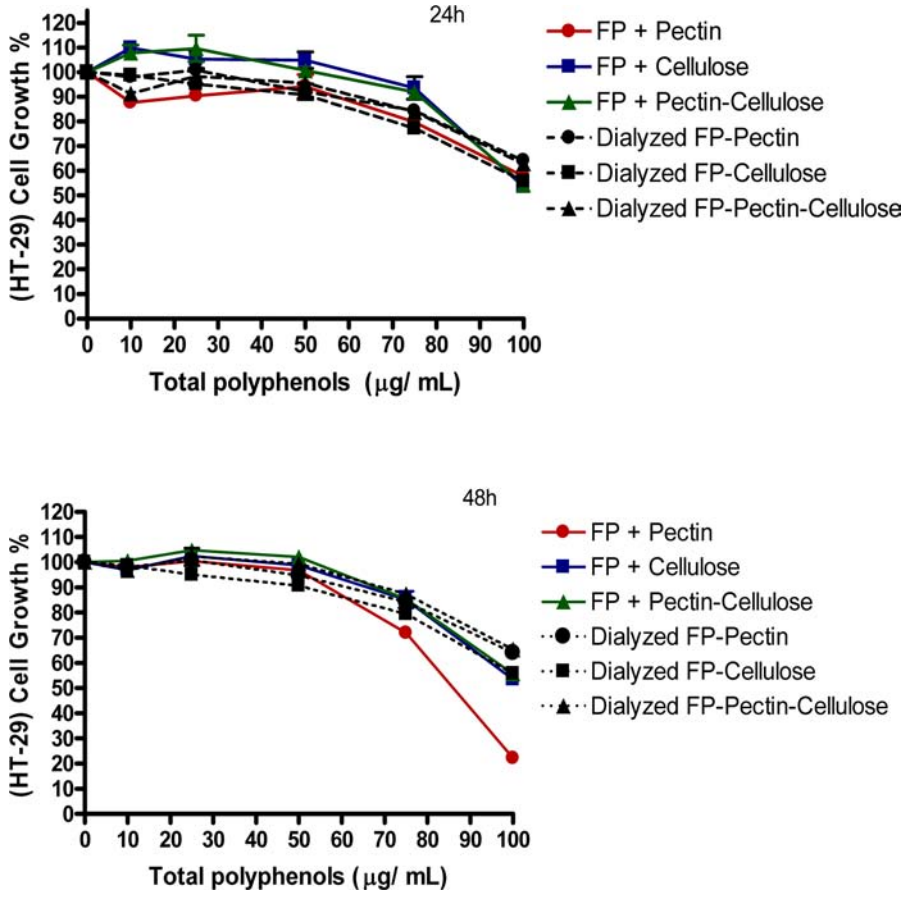

Figure 7. Antiproliferative activity of free polyphenols (dialyzate) in combination with various mixtures of polyphenols, pectin, and cellulose (100 μg/mL) evaluated using HT 29 cells. Antiproliferative activity was monitored at 24 h (top panel) and 48 h (bottom panel). The data are mean ± SEM from three independent experiments.

e.[23−26]Organic acids are also helpful in the stabilization of ascorbic acid and anthocyanins in frozen and processed berries.[27]

Blueberries are rich in phenolic acids such as benzoic acid and cinnamic acid derivatives. Benzoic acid derivatives include vanillic acid, syringic acid, gallic acid, protocatechuic acid, *m*-hydroxybenzoic acid, *p*-hydroxybenzoic acid and ellagic acid. Major cinnamic acid derivatives include chlorogenic acid, caffeic acid, ferulic acid, quinic acid and coumaric acid.[23] Polyphenols in blueberries are naturally esterified with other phenolic acids or sugars, suggesting that they are frequently found as glucosides such as quercetin glucoside, myricetin glucoside, and kaempferol glucoside.[28] In our study, chlorogenic acid was the major component identified, and other phenolic acids were nondetectable or occurred as minor components eluting before chlorogenic acid.[10] Flavonoid derivatives of quercetin, rhamnetin, syringetin, and myricetin were also identified.

In blueberry skin and flesh, delphinidin, cyanidin, petunidin, peonidin, and malvidin monoglycosides (glycosides, galactosides and arabinosides) are the main anthocyanins. Because of the diversity in the glycosylation and acylation pattern, more than 25 anthocyanins have been identified in blueberries. The distribution of anthocyanins in five different blueberry genotypes have been reported,[29] where delphinidin was the most abundant anthocyanin (27−40%), followed by malvidin (22−33%), petunidin (19−26%), cyanidin (6−14%), and peonidin (1−5%). Nearly equal distribution of anthocyanins was observed in blueberry fruits analyzed in this study.

Anthocyanins are rarely ingested on their own but as a component of fruits or vegetables or in meals containing other simple and macromolecular food components. Studies carried out by Mazza and co-workers[30] have shown that there are significant differences in the absorption rates of anthocyanins when consumed either alone or with high fat meals.[30,31] In a study[32] on red grape juice, a synergistic enhancement in intestinal anthocyanin absorption by glucose was observed, as compared to that from red wine. It has also been shown that isolated polyphenols from grape juice are more effective in arresting the growth of tumor in mice than those isolated from red wine, when provided through gavage.[33] Although it is generally believed that the food matrix may not affect the functionality of polyphenols, molecular interactions between polyphenols and other components present in the food matrix ultimately may alter their antioxidant function and bioefficacy.[12,34,35] For instance, 34−40% of polyphenols in red wine seem to be complexed to dietary fiber.[35] In another study, nearly 25% of polyphenols present in grape juice concentrate were found to be complexed with carbohydrates.[12] Thus, food-matrix interactions may play a major role in the functionality of polyphenols.

In this study, we analyzed the potential modulatory role of food matrix in polyphenol function. During ripening, the structural matrixes such as cellulose and pectin undergo degradation. As the compartmentalization of ripening tissue decreases, the polyphenols that are normally confined to vacuoles may leak out and form complexes with cellular

DOI: 10.1021/acs.jafc.5b00016
J. Agric. Food Chem. 2015, 63, 2935−2946

macromolecules. Thus, it was interesting to see if food matrix isolated from ripe fruits or those reconstituted by components such as cellulose and pectin had any influence in polyphenol functionality, such as its antioxidant function or anticancer properties. These interactions may have an impact on the delivery and absorption of polyphenols in vivo. Our results show that nearly 28% of the polyphenols in blueberry crude extracts are naturally complexed with the food matrix. These results are in agreement with previous studies[12] demonstrating that approximately 25% of nondialyzable polyphenols in grapes were bound to carbohydrates and lipids.

The present study suggests that food matrix alone, as well as the synthesized food matrixes used in the experiments, did not have a considerable antioxidant activity. When free polyphenols were mixed with different concentrations of pectin or/and cellulose, their scavenging capacity of the DPPH radical was similar to that of free polyphenols. As well, isolated matrix devoid of polyphenols by itself showed minimal antioxidant or antiproliferative activity. When polyphenols are mixed with high amounts of pectin or cellulose, antioxidant activity of polyphenols does not decrease. However, when the dialyzed extract containing naturally complexed polyphenols was mixed with food matrix, it showed a lower antioxidant activity and antiproliferative activity as compared to that of free polyphenols. This may be due to complex formations involving key hydroxyl groups of the polyphenols with polygalacturonic acid moieties of pectin that make polyphenols less amenable to scavenge free radicals.

Despite the fact that there are numerous reports of inhibition of cancer cell growth and proliferation in vitro by purified anthocyanin-rich extracts or crude extracts, very few studies have been conducted to delineate potential influences of food matrix on the biological activity of components studied. In this study, the antiproliferative action of free polyphenols, complexed polyphenols, and food matrix was compared separately.[36,37] It is of great interest to understand the effect of the food matrix on the biological activity of polyphenols to develop processing techniques that take advantage of such interactions and lead to the production of high quality and value-added products. Although, blueberry food matrix did not show a considerable effect on antiproliferative activity, there was a significant decrease in the inhibitory activity when polyphenols were naturally complexed with the blueberry food matrix. By contrast, various mixtures containing free polyphenols and the synthetic food matrixes did not have the same effect as polyphenols complexed with matrix during extraction. These results suggest that strong interactions between polyphenols and fruit matrixes may affect the bioavailability and efficacy of polyphenols in several ways.

Besides having high in vitro antioxidant activity, different fruit extracts have been studied for their ability to inhibit α-glucosidase, a key enzyme involved in the digestion of starch into sugars. Inhibition of the activity of carbohydrate-hydrolyzing enzymes has the potential to lower sugar absorption and consequently may provide an additional tool for the management of blood sugar levels by preventing postprandial hyperglycemia, thus controlling the onset of type II diabetes.[38,39] Efficacy of the polyphenols in binding with proteins and subsequent enzymatic inhibition could be attributed to the fact that polyphenols are multidentate ligands, capable of binding simultaneously (via different hydroxyl groups) to more than one site of the protein (enzyme).[40] In contrast to the reduction observed in antioxidant and antiproliferative activities, the dialyzed extract containing complexed polyphenols showed the highest inhibitory activity toward α-glucosidase. It has been previously hypothesized[41] that the inhibitory effectiveness of berry fruit extracts against α-glucosidase was related to their anthocyanin content. The results from this study suggest that the complexed polyphenols or their interactions with other components of the food matrix enhance their ability to inhibit α-glucosidase activity. In vivo studies with healthy human volunteers demonstrated that freeze-dried wild blueberry powder increased the serum antioxidant status.[42] Whole blueberry freeze-dried powder also reduced the insulin resistance in adipose tissue and increased the function of β cells in male C57BL mice fed high fat diets, suggesting that processed fruits are equally effective in providing health benefits.[42,43] Thus, polyphenols, whether free or complexed with fruit matrixes, can thus provide multiple protective roles in the human body.

Apart from the phenolic components, flavonoids, and anthocyanins, blueberries are a rich source of procyanidins which are dimers, trimers, and polymers of flavan-3-ols, catechin, and epicatechin.[44] These components have not been analyzed in the present study. Because of their complex structure, procyanidins are ideally suited to form molecular complexes with pectin and other cell wall polymers. It is also highly likely that the health benefits observed in blueberries may in part be due to their procyanidin content.[44]

In conclusion, interactions between polyphenols and food matrix can play an important role in the bioactivity of blueberries. Although complex formation did not reduce the antioxidant and α-glucosidase activities of blueberry polyphenols, it slightly reduced the antiproliferative activity. These results suggest that different fractions of polyphenols obtained in frozen or freeze-dried blueberry products may provide multiple effects such as antioxidant activity, regulation of glucose homeostasis, and antiproliferative functions to different extents depending on their complexed or free state. The presence of a food matrix may positively affect the stability of polyphenols in the gastrointestinal tract, as well as the extent of absorption and their metabolism in vivo. A better understanding of which compounds form complexes with the polyphenols is needed, as well as their stability in the gastrointestinal tract to obtain relevant information about the bioavailability and metabolism of phenolic compounds in blueberries.

Excess production of free radicals is associated with oxidative damage to biomolecules, including lipids, proteins, and DNA, eventually leading to many chronic diseases, such as atherosclerosis, cancer, and other degenerative diseases in humans.[15] Plant-based dietary polyphenols and flavonoids have been used to estimate antioxidant activity in vitro, and have been associated with the prevention of cancer, type 2 diabetes, and cardiovascular diseases.[16−18] However, there is little information on the polyphenol and flavonoid levels or the potential cancer-prevention activity of horseradish roots. Because these phytochemicals and bioactivities have been associated with reduced disease incidence, quantitation of horseradish root polyphenol and antioxidant activity will be useful information.

The objectives of this study were to determine the variation of AITC formation and corresponding nitrile formation from several horseradish accessions, including accessions from the Li and Kushad study.[2] Another objective of this study was to evaluate the potential cancer-prevention properties of horseradish roots by assessing QR-inducing bioactivity, as well as antioxidant activity, using two different commercial grades (U.S. Fancy vs U.S. No. 1) in four different genotypes of horseradish. As a result, significant variation of AITC and CETP formation was observed among genotypes and grades. To our knowledge, this is the first detection and measurement of CETP from horseradish. There were significant correlations between sinigrin and AITC as well as AITC and QR bioactivity that can be useful information for horseradish quality. U.S. Fancy grade showed significantly higher sinigrin and AITC concentrations than U.S. No. 1, whereas U.S. No. 1 showed significantly higher CETP and total phenolic concentrations than U.S. Fancy.

MATERIALS AND METHODS

Chemicals. Benzyl GS was purchased from POS Pilot Plant Corp (Saskatoon, SK, Canada). DEAE Sephadex A-25 resin was purchased from GE Healthcare (Piscataway, NJ, USA). Lead acetate, barium acetate, AITC, benzyl isothiocyanate (BITC), 2-penethyl isothiocyanate (PEITC), 2-phenylpropionitrile (PPNT), benzyl cyanide, alpha-minimum essential medium (α-MEM) high-performance liquid chromatography (HPLC)-grade acetonitrile, ACS-grade hexane, 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid (ABTS), Folin-Ciocalteu, potassium persulfate, 2,4,6-tripyridyl-s-triazine, $FeCl_3 \cdot 6H_2O$, and Trolox were purchased from Sigma (St. Louis, MO, USA).

Cultivation of Horseradish. Six accessions of horseradish were selected for this study: IL196, IL706, IL785, IL813, IL1091, and IL1573. Horseradish accessions IL813 and IL196 previously showed high sinigrin content, whereas IL1573 showed comparatively low levels.[2] In addition, IL785 and IL1091 accessions were selected as new high root sinigrin-containing horseradish accessions as well as IL706 with low levels. These accessions are part of a germplasm collection housed at the Vegetable Research Farm, University of Illinois, Urbana−Champaign, IL. Vegetative propagation of two plants in three replications of each accession were established in a completely randomized block design on the Vegetable Research Farm on April 4, 2012 from root cuttings (sets) approximately 35−40 cm long and 1.0−1.5 cm in diameter. Sets were hand-planted in rows, spaced at 90 cm between rows and 56 cm within each row. The ends of the sets that would send up a shoot were planted facing the same direction (for ease of harvest) in furrows, then hilled-over into ridges approximately 18 cm high and 30 cm wide. According to the U.S. Department of Agriculture standard, horseradish roots are classified U.S. Fancy, U.S. No. 1, and U.S. No. 2 on the basis of diameter of horseradish and length of root.[19] Specifically, in order to meet U.S. Fancy grade, the roots "shall be not less than 20.32 cm in length when the diameter is 3.81 cm or more". For U.S. No. 1 grade, the roots "shall be not less than 15.24 cm in length when the diameter is 3.18 cm or more". For U.S. No. 2 grade, the roots "shall be not less than 10.16 cm in length and not less than 1.27 cm in diameter". The two primary horseradish roots harvested from each three field replications of each accession (n = 6) that met the U.S. Fancy grade standard,[19] were cleaned with tap water, and dried with paper towels. Two primary main roots from U.S. Fancy grade plants were pooled for each three field replications for four accessions, and an additional two root samples from the same plants that met the U.S. No. 1 requirements were collected in this manner. Because U.S. No. 2 grade root is not commercially preferred, replicated samples were collected from only one accession that has low sinigrin concentration for better correlation analysis. Harvest was done on October 20, 2013. Samples were frozen in liquid nitrogen and stored at −20 °C prior to freeze-drying (less than a week). Freeze-dried tissues were ground into a fine powder using a coffee grinder and stored at −20 °C prior to analyses (less than a month).

Determination of GS Concentrations. Extraction and quantitation of GS using HPLC was carried out using a protocol described by Brown et al.[20] with some modifications. Freeze-dried, powdered horseradish (0.2 g) and 2 mL of 70% methanol were placed in 10 mL centrifuge tubes (Nalgene, Rochester, NY) and heated on a heating block at 95 °C for 10 min. After cooling on ice for 5 min, 0.5 mL of benzyl GS (1 mM) was added as internal standard (POS Pilot Plant Corp, Saskatoon, SK, Canada), mixed, and centrifuged at 3000 g for 15 min at 4 °C using a Beckman L7-65 Ultracentrifuge (Beckman Coulter, Brea, CA). The supernatant was saved and the pellet was re-extracted with 2 mL of 70% methanol at 95 °C for 10 min, and the two extracts were combined. A subsample (1 mL) from each pooled extract was transferred into a 2 mL microcentrifuge tube (Fisher Scientific, Waltham, MA). Protein in the extract was precipitated with 0.15 mL of a 1:1 mixture of 1 M lead acetate and 1 M barium acetate. After centrifugation at 12 000 g for 1 min using an Eppendorf 5415 benchtop centrifuge (Hamburg, Germany), each sample was then loaded onto a column containing DEAE Sephadex A-25 resin for desulfation with arylsulfatase (*Helix pomatia* Type-1, Sigma-Aldrich, St. Louis, MO) for 18 h. The desulfated GS samples were eluted off the column using 2 mL of distilled water. A 100 μL sample of each was filtered through a 0.2 μm nylon filter and injected into an HPLC system under the previously reported conditions.[21] For individual GS quantitation (sinigrin, gluconasturtiin, gluconapin glucobrassicin, and 4-methoxy glucobrassicin), relative response factors was used as previously published.[21] The concentration of GS was expressed as micromole per gram dry weight.

Measurement of GS Hydrolysis Products. Freeze-dried horseradish tissue (50 mg) was suspended in 1 mL of distilled water and 1 mL of hexane in a 2 mL microcentrifuge tube (Fisher Scientific, Waltham, MA). Hydrolysis products were generated naturally by endogenous myrosinase in the absence of light at room temperature for 24 h. The samples were then centrifuged at 12 000 g for 2 min using a Eppendorf 5415 benchtop centrifuge (Hamburg, Germany), and the supernatant was collected for analysis using a Hewlett-Packard HP 5890 Series-I gas chromatography (GC) system equipped with a single flame-ionization detector (Agilent Technologies, Santa Clara, CA), an Agilent model 7683B series autosampler, and a 30 m × 0.32 mm J&W HP-5 capillary column (Agilent Technologies). A 1 μL sample of the hexane extract was injected onto the GC. After an initial temperature hold at 40 °C for 2 min, the oven temperature was increased by 10 °C/min to 260 °C and held for 10 min.[8] Injector and detector temperatures were set at 200 and 280 °C, respectively. The flow rate of the helium carrier gas was set at 25 mL/min. Results were quantitated on the basis of external standards of AITC, BITC, PEITC, PPNT, and benzyl cyanide. 1-Cyano 2,3-epithiopropane (CETP) was quantitated on the basis of effective carbon number concept.[22] Each peak from the horseradish sample extracts was further identified using a 6890N GC coupled to an HP-5973N MS Detector, according to a previously published study.[11] The concentration of GS hydrolysis products were expressed as micromole per gram dry weight. Samples were assayed in triplicate.

Quinone Reductase Activity. Freeze-dried powdered horseradish root (75 mg) was suspended in 1.5 mL of water in the dark for 24 h at

[a]Includes gluconapin and 4-methoxyglucobrassicin. [b]Selected U.S. Fancy accession for comparing with corresponding U.S. No. 1. [c]Calculated by paired t test. All data are expressed as mean ± SD, n = 3. [d]For $F_{x,y}$, x and y indicate degree of freedom of numerator and the denominator, respectively, for F test; CV, coefficient of variation (%). [e]Highly significant variance by F test at ≤ 0.01.

room temperature in a sealed 2 mL microcentrifuge tube (Fisher Scientific, Waltham, MA) to allow for GS hydrolysis by endogenous myrosinase. GS hydrolysis extracts were then centrifuged at 12 000 g for 5 min using an Eppendorf 5415 benchtop centrifuge (Hamburg, Germany), and the supernatant was used for the QR assay. Hepa1c1c7 murine hepatoma cells (ATCC, Manassas, VA) were grown in α-MEM, enriched with 10% fetal bovine serum, and maintained at 37 °C in ambient air enriched with 5% CO_2. The cells were divided every 3 days with a split ratio of 7. Cells with 80−90% confluence were plated into 96-well plates (Costar 3595, Corning Inc., Corning, NY), 1×10^4 cells per well, and incubated for 24 h in antibiotic-enriched media (100 units/mL penicillin and 100 μg/mL streptomycin). The QR-induction activities of different samples were determined by means of the protocol described by Prochaska and Santamaria.[23] Samples were assayed in triplicate.

Estimation of Myrosinase Activity Using Glucose Appearance. Total myrosinase activity was measured by using the glucose release assay.[24] Briefly, freeze-dried plant material (50 mg) was weighed in duplicate (for adjusting background glucose) into 2 mL tubes and 1 mL of sinigrin (10 mM) was added to each tube. After 10 s of vigorous vortexing, one of the paired samples was put directly into a heating block (95 °C) for 10 min to inactivate the myrosinase enzyme (zero time blank). The second sample was incubated at 40 °C for 30 min and then inactivated as outlined above. After inactivation, samples were cooled on ice for 5 min and then centrifuged at 16 000 g for 2 min using an Eppendorf 5415 benchtop centrifuge (Hamburg, Germany). The supernatants were diluted 96-fold with water and aliquots of 30 μL were added in a 96 well plate, followed by adding 200 μL of an ABTS-glucose solution (2.7 mM ABTS, 10 000 units peroxidase, and 4000 units glucose oxidase). The mixtures were incubated for 20 min and their absorbances were measured at 630 nm in a μQuant plate reader (Bio-Tek instruments, Winooski, VT). Glucose standards were also prepared similarly, as described above, and their absorbance was used to develop a standard curve (7.8−250 μg/mL). One unit was defined as 1 μmol glucose release per min. Samples were assayed in triplicate.

Determination of Nitrile and Epithionitrile Formation from Different GSs. Freeze-dried horseradish root (75 mg) was suspended in 0.75 mL of 1 mM benzyl GS. After 20 s vigorous vortexing, 0.75 mL of hexane was added and incubated for 20 min in the absence of light. The mixture was vigorously vortexed for 10 s and then centrifuged at 16 000 g for 1 min using an Eppendorf 5415 benchtop centrifuge (Hamburg, Germany). The supernatant was transferred to GC vials and injected onto the GC as described above. Nitrile formation (simple nitrile PPNT from gluconasturtiin and epithionitrile CEPT from sinigrin) is presented as percentage formed relative to total hydrolysis products of individual endogenous and exogenous GS, as previously described.[9] Samples were assayed in triplicate.

Determination of Total Polyphenol Content. Analysis of total polyphenol content (TPC) was conducted as previously described.[25] The extraction procedure was identical to that described above for the QR activity measurement. The assay conditions were as follows: a 10 μL sample was added to 0.2 N Folin-Ciocalteu's phenol reagent (100 μL) in 96 well plates. After 3 min, 90 μL of 7.5% sodium carbonate solution was added to the mixture and subsequently incubated at room temperature for 1 h. The absorbance of the mixture was measured at 630 nm using a BioTek EL 808 microplate reader (Biotek Instruments Inc., Power Wave XS, Winooski, VT). Total polyphenol content was calculated on the basis of a standard curve using gallic acid (concentration range = 31.25−500 μg/mL). Results are expressed in milligram gallic acid equivalents (GAE) per gram of dried horseradish. Samples were assayed in triplicate.

Determination of ABTS Radical Scavenging Activity and Ferric Reducing/Antioxidant Power Activity. The ABTS assay was conducted as previously described.[25] Briefly, 7 mM ABTS ammonium salt was dissolved in a 2.45 mM potassium persulfate solution. The mixture was then allowed to stand at room temperature for 12−16 h for full color development (dark blue). The solution was then diluted with potassium phosphate buffer (pH 7.4) until absorbance reached 1.0 ± 0.02 at 630 nm using a BioTek EL 808 microplate reader (Biotek Instruments Inc., Power Wave XS, Winooski, VT). Subsequently, 190 μL of this solution was mixed with 10 μL of the sample. The absorbance was recorded at room temperature after 6 min. Results are expressed as percent of radical-scavenging activity compared to controls as extraction solvent. Samples were evaluated in triplicate.

The ferric reducing/antioxidant power (FRAP) reagent, freshly prepared and kept at room temperature, contained 2.5 mL of a 10 mM 2,4,6-tripyridyl-s-triazine solution in 40 mM HCl plus 2.5 mL of 20 mM $FeCl_3 \cdot 6H_2O$ and 25 mL of 300 mM acetate buffer (pH 3.6).[25] The FRAP reagent (190 μL) was mixed with 10 μL of sample, and absorbance was measured at 593 nm after 4 min using a BioTek EL 808 microplate reader. The FRAP values were calculated from a standard curve of Trolox concentrations ranging from 62.5 to 500 μmols.

[a]Selected U.S. Fancy accession for comparing corresponding U.S. No. 1. [b]Calculated by paired t test. All data are expressed as mean ± SD, n = 3. [c]For $F_{x,y}$, x and y indicate degree of freedom of numerator and the denominator, respectively, for F test; CV, coefficient of variation (%). Superscripted NS, *, and ** indicate non-significant, significant, and highly significant variance by F test at > 0.05, ≤ 0.05, and ≤ 0.01, respectively.

Statistical Analysis. Horseradish accessions were considered a fixed factor with blocks a random factor. Analysis of variance (ANOVA), Student's t test, paired t test, F test, and Pearson's correlation coefficient analysis were conducted using JMP 10 (SAS institute Inc., Cary, NC). All sample analyses were conducted in triplicate. The results are presented as means ± SD. Coefficients of variation (CV) are presented in the tables.

RESULTS AND DISCUSSION

Concentration of GS in Different Accessions and Grades of Horseradish Root. There is significant variation in sinigrin concentration among the U.S. Fancy horseradish accession extracts ($F_{5,12}$ = 110, P < 0.001); the lowest sinigrin concentration was found in accession IL706 extract (41.0 μmol/g dry weight, DW), whereas the highest was found in IL1091 (80.3 μmol/g DW, Table 1). Among the accessions of U.S. Fancy grade, the maximum to minimum ratio is approximately 2-fold, suggesting that genotype plays a major role in determining sinigrin concentration. Gluconasturtiin concentrations from six U.S. Fancy grade accession root extracts ranged from 3.77 to 10.0 μmol/g DW. Average glucobrassicin concentrations from six U.S. Fancy accession root extracts ranged from 0.16 to 2.07 μmol/g DW, which is a 13-fold difference in minimum to maximum values. Aside from these, the only other GS found was gluconapin in trace amounts (less than 0.05 μmol/g DW). According to a previous study using 168 Nordic horseradish accessions,[26] sinigrin levels varied between 10 and 45 μmol/g DW, gluconasturtiin between 1.3 and 7.4 μmol/g DW, and glucobrassicin between 0.1 and 2.6 μmol/g DW. A recent paper reported that sulfate supply was closely related with GS accumulation in horseradish.[27] The different GS concentration between US Midwest horseradish and Nordic horseradish accessions may be related to different weather and/or soil conditions as well as genetic backgrounds, which require further research. Another study[28] detected 11 different GS levels from horseradish roots using LC electrospray ionization hybrid linear ion trap with Fourier transform ion cyclotron resonance mass spectrometry and infrared multiphoton dissociation, but we only identified five GS by HPLC, as also reported in previous studies.[2,26]

Horseradish root diameter (grades) was another source of variation in sinigrin concentration. Partitioning variance component analysis based on ANOVA estimated that differences among root diameters accounted for 44% of sinigrin variation displayed in Table 1. Selected accessions of horseradish of U.S. Fancy grade (IL196, IL1573, IL813, and IL785) contained an average of 60.9 μmol/g DW of sinigrin, whereas corresponding U.S. No. 1 grade samples contained 38.1 μmol/g DW of sinigrin. Across the four accessions tested, the U.S. Fancy grade root extracts exhibited significantly greater sinigrin concentrations than the U.S. No. 1 grade roots extracts, on the basis of a paired t test (P = 0.003, Table 1). Previous research also reported that the total amount of GS as well as sinigrin was higher in the shoulder zone than in the middle and tip zones of horseradish roots.[26] 4-Methoxyglucobrassicin was not present in the U.S. Fancy grade, whereas the U.S. No. 1 and U.S. No. 2 grade root extracts had measurable concentrations of this compound (0.24−2.21 μmol/g DW; data not shown).

Variation in Content of GS Hydrolysis Products among Horseradish Accessions and Grades. Generation of isothiocyanate (AITC) or epithionitrile (CETP) concentrations from sinigrin varied among the horseradish accessions. The average of AITC concentration from the six U.S. Fancy grade horseradish root extracts was 42.4 μmol/g DW and ranged from 37.4 to 47.1 μmol/g DW. Even though sinigrin showed about a 2-fold ratio between maximum to minimum concentrations, the variation in AITC (CV = 9.2%) was smaller than that of its precursor GS (CV = 23.2%). The reduced variation in AITC may be related its volatility. The average CETP concentration from root extracts of the six U.S. Fancy grade horseradish accessions was 3.73 μmol/g DW and ranged from 0 to 11.4 μmol/g DW. PEITC showed significant variation with a 3.4-fold difference between minimum to maximum values (3.9 and 13.4 μmol/g DW, respectively, $F_{5,12}$

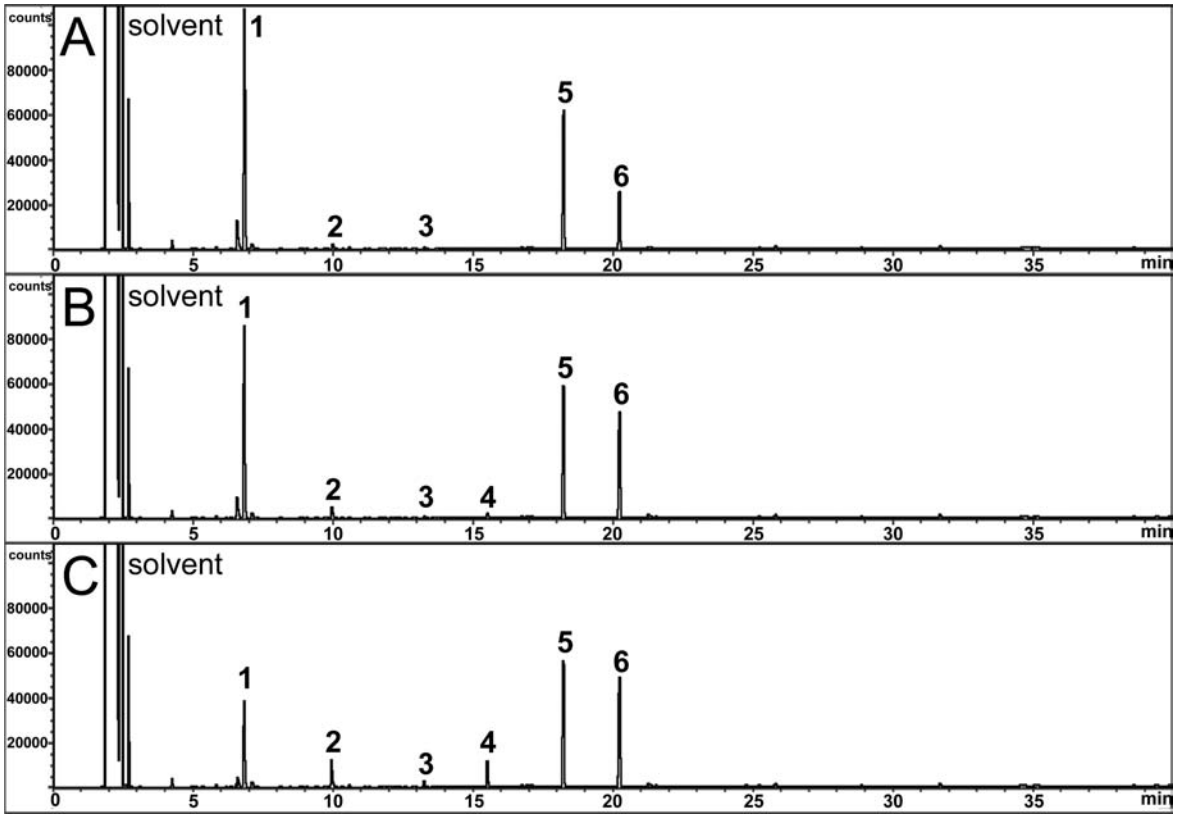

Figure 1. Gas chromatograms of different USDA grades of horseradish accession IL785. (A) U.S. Fancy, (B) U.S. No. 1, and (C) U.S. No. 2. Peaks: 1, AITC; 2, CETP; 3, BZCN; 4, PPNT; 5, BZITC; and 6, PEITC.

= 135, $P < 0.001$). Regardless of genotypes, PPNT concentrations were less than 1.0 μmol/g DW. Allyl cyanide was not detected because of its extreme volatility and loss during sample preparation.[12]

Horseradish root diameter (grade) was another source of variation in AITC and CETP concentrations. Selected horseradish accessions of U.S. Fancy grade (IL196, IL1573, IL813, and IL785) contained 43.0 μmol/g DW of AITC, whereas corresponding U.S. No. 1 grade roots generated only 19.5 μmol/g DW of AITC, which was significantly lower than U.S. Fancy on the basis of a paired t test ($P = 0.013$, Table 2). These same accessions of U.S. Fancy grade contained 2.75 μmol/g DW of CETP, whereas their corresponding U.S. No. 1 grade roots contained significantly greater amounts, averaging 6.95 μmol/g DW ($P = 0.022$, Table 2). In general, AITC levels fell and CETP levels rose in the lower root grades including U.S. No. 1 and U.S. No. 2, compared to the corresponding levels in U.S. Fancy grade roots. PEITC and PPNT concentrations were not significantly different between U.S. Fancy and U.S. No. 1 grades, although PPNT levels rose in the lower grades (Table 2 and Figure 1). Horseradish accession IL785 is good example how phytochemical composition changes depending on the grade. Past reports suggest that horseradish roots contain about 79% AITC and 18% PEITC, whereas wasabi, another GS-rich plant root, contains 95% AITC.[29] Thus, the PEITC in horseradish provides a distinct flavor difference compared to wasabi.[29] Most horseradish roots produced AITC as the major hydrolysis product (Table 2). However, U.S. No. 1 grade roots of accession IL813 produced more CETP and PPNT than AITC and PEITC (Table 2). The U.S. Fancy grade root of accession IL785 produced a greater proportion of AITC than U.S. No. 1 or U.S. No. 2 grades (Table 2 and Figure 1). It has been reported that horseradish produces only AITC and no CETP because of a lack of ESP in horseradish.[11,12] However, this study reports on the presence of CETP (the epithionitrile form of sinigrin) in certain horseradish accessions, suggesting that there may be ESP activity in horseradish or the activity of some other cofactors, including ascorbic acid and metal ions, to form nitriles.[7] Reduction in CETP levels as root grade improves suggests that less ESP or other myrosinase cofactors may be present in larger, more mature roots.

According to previous research, AITC has about a 300-fold stronger odor than CETP.[30] AITC-rich horseradish is therefore suitable material for the food industry, for example, high-quality horseradish sauce. In addition to the flavor of AITC, the compound has potential cancer-prevention bioactivity, which can be quantitated by its capacity for the induction of QR. In contrast, CETP has comparatively reduced QR-inducing activity.[5,31] AITC may be a good dietary anticarcinogen, because bioavailability of AITC is extremely high, with nearly 90% absorption of an oral dose.[14] In addition AITC, even at high doses, exhibits a relatively low degree of cytotoxicity and genotoxicity in animal studies.[14] Significant variation in AITC levels across the accessions was observed within the U.S. No. 1 grade samples ($F_{3,8} = 71.0$, $P < 0.001$; Table 2): U.S. No. 1 grade IL785 accession has about a 9-fold-higher AITC concentration than the IL813 accession. These chemical analyses indicate that the USDA grading system is a good indicator for pungency.

Averaged AITC and PEITC concentrations determined that the genotype and root grade described 66 and 17%,

[a]Sample extract activity divided by the nontreated control cells. [b]Unit defined as 1 μmole glucose release per min. Analysis was done in triplicates. [c]Amount of products are expressed as a percentage of nitrile form over the total amount of hydrolysis products measured [CETP /(AITC+CETP) and PPNT/(PEITC+PPNT) for sinigrin and gluconasturtiin, respectively]. Exogenous benzyl glucosinolate was used for determination of nitrile formation (%) [benzyl cyanide/(benzyl cyanide + benzyl isothiocyanate). [d]Selected U.S. Fancy accession for comparing corresponding U.S. No. 1. [e]Calculated by paired t test. All data are expressed as mean ± SD, n = 3. [f]$F_{x,y}$, where x and y indicate degree of freedom of numerator and the denominator, respectively, for F test; CV, coefficient of variation (%). Superscripted NS, *, and ** indicate non-significant, significant, and highly significant variance by F test at > 0.05, ≤ 0.05, and ≤ 0.01, respectively.

respectively, of the total variation (as calculated from Table 2), which is comparable to a previous study that reported these variables accounted for 64−82% and 4−18% of the variation, respectively.[32] However, this study reported a broader range of AITC and PEITC concentrations.

Quinone Reductase, Myrosinase, and Nitrile/Epithionitrile Formation (%) of Different Accessions and Grades of Horseradish. The QR-inducing activity of the U.S. Fancy grade horseradish did not correlate with the variation in phytochemical concentrations (Table 3). The mean value of QR-inducing activity from extracts of all six of the U.S. Fancy grades evaluated (expressed as induction ratio relative to the control) was 1.33 ± 0.04. QR-inducing activity ranged from 1.29 to 1.37, which was small compared to the variation in sinigrin and AITC. Variation of myrosinase activity in U.S. Fancy horseradish ranged from 0.25 to 1.72 U/g. Nitrile generation from sinigrin (0.0−20.2%) was greater than from gluconasturtiin (1.3−7.3%) and benzyl GS (0.4−0.9%). There was no epithionitrile formation in accessions IL706 and IL1573. These accessions could be good resources for a high-AITC-producing horseradish-breeding program.

QR-inducing activity of horseradish roots varied among grades. In general, QR-inducing activity in the U.S. Fancy grade roots of accessions IL196, IL1573, IL813, and IL785 (mean = 1.34, Table 3) were not significantly higher than those from U.S. No. 1 grade roots of the same accessions (mean = 1.19, P = 0.129, Table 3). However, U.S. Fancy grade roots of accessions IL1573 and IL813 have significantly higher QR-inducing activity than those of U.S. No. 1 grade roots of the same accessions, suggesting more research is needed to confirm the interaction between accessions and grades. QR-inducing activity of U.S. No. 1 grade roots ranged from 1.05 to 1.33. Myrosinase activity in U.S. Fancy and U.S. No. 1 grade roots were similar (0.68 U/g, n = 4 and 0.57 U/g, n = 4, respectively; Table 3) and not significantly different. The average of percent epithionitrile formation (expressed as percent nitriles formed over total hydrolysis products) for endogenous sinigrin from the selected four U.S. Fancy grade accessions was 5.7% (mean of all U.S. Fancy grade roots = 7.1%), whereas the corresponding percent epithionitrile formation across the U.S. No. 1 grade root samples was 32.9%. Thus, U.S. No. 1 grade horseradish roots had about 4.6-fold higher percent epithionitrile formation than the U.S. Fancy grade horseradish.

Average percent nitrile formation relative to endogenous gluconasturtiin from the selected four U.S. Fancy grade horseradish accessions was 2.6% (mean of all U.S. Fancy = 3.2%), whereas the corresponding percent nitrile formation across the U.S. No. 1 grade samples was 19.3% (t-test P = 0.243, Table 3). U.S. No. 1 grade horseradish had about 7-fold higher nitrile formation levels than the U.S. Fancy grade (Table 3). Average percent nitrile formation for exogenous benzylglucosinolate from selected four U.S. Fancy grade horseradish accessions was 0.50% (mean of all U.S. Fancy = 0.55%), which is less than the percent nitrile formation across U.S. No. 1 grade samples (1.60%, t-test P = 0.324; Table 3). Thus, U.S. No. 1 grade horseradish had about a 3-fold greater percent nitrile formation than the U.S. Fancy grade horseradish. The low percent nitrile formation from benzyl GS compared to the two other substrates has previously been reported.[9] This indicates that ESP or another myrosinase cofactor activity may be different for different GS and/or for endogenous and exogenous GS. The variation of nitrile/epithionitrile formation observed here for different accessions and grades of horseradish root could be due to differences in ESP abundance or to

DOI: 10.1021/jf505591z

different levels of cofactors such as ferrous or magnesium metal ions or other protein cofactors.[9]

Total Phenolic Content and Antioxidant Activity in Different Accessions and Grades of Horseradish. Total phenolic content of horseradish roots varied among accessions and grades. Total phenolics present in U.S. Fancy grade horseradish ranged from 2.83 to 5.48 mg/g DW (Table 4).

Table 4. Total Phenolic Content, ABTS, and FRAP Antioxidant Activity from Different Genotype and USDA Grades of Horseradish

[a]Value expressed as gallic acid equivalent concentration. [b]Value expressed as Trolox equivalent concentration. [c]Selected U.S. Fancy accession for comparing corresponding U.S. No. 1. [d]Calculated by paired t test. All data are expressed as mean ± SD, n = 3. [e]$F_{x,y}$, where x and y indicate degree of freedom of numerator and the denominator, respectively, for F test; CV, coefficient of variation (%). ** [f]Highly significant variance by F test at ≤ 0.01.

ABTS and FRAP antioxidant activities showed significant variations in U.S. Fancy grade horseradish, ranging from 19.7 to 31.4 mmol/g DW ($F_{5,12}$ = 145) and from 20.5 to 34.1 mmol/g DW ($F_{5,12}$ = 83.3), respectively (Table 4).

Within the same accession, U.S. No.1 grade horseradish roots have higher concentrations (4.63 mg/g DW) of total phenolics compared to the U.S. Fancy grade roots (3.68 mg/g DW), implying that total phenolic accumulation may be related to diameter and length of horseradish roots. Smaller diameter roots have greater levels of total phenolics (and less sinigrin and total GS, as shown in Table 1) than thicker roots, but the trend was not significant in a paired t test (P = 0.073, Table 4).

Correlations between Phytochemicals and Bioactivities in Different Accession and Grades of Horseradish Roots. As expected, there were significant correlations between sinigrin and AITC (r = 0.834, P = 0.001) and between gluconasturtiin and PEITC (r = 0.830, P = 0.002; Table 5). Similarly, AITC also significantly correlated to QR activity (r = 0.727, P = 0.011; Table 5). It is reported that AITC is relatively volatile and has low solubility in water (1.3 mg/mL) compared to sulforaphane (8.0 mg/mL).[33] Although AITC was successfully extracted by adding hexane to water and measured by GC, there would be some AITC loss after treatments in cell media and incubation at 37 °C for 24 h for the QR assay. This probably attributed to the relatively small QR-inducing difference between U.S. Fancy and U.S. No. 1, even though there was a significant AITC concentration difference between U.S. Fancy and U.S. No. 1 (Tables 2 and 3). AITC has high bioavailability when orally consumed.[14] Considering the significant correlation between AITC and QR activity, the difference in QR activity between U.S. Fancy and U.S. No. 1 maybe underestimated because of the volatility of active compounds and the attributes of the QR assay system. This also indicates that a reliable QR assay system needs to be be established for volatile compounds. Similarly, PEITC has been reported to induce QR activity[34] and was detected in our study when measured immediately after hydrolysis; the lack of correlation between PEITC and QR may also have been due to evaporation of this volatile compound (solubility in water = 0.051 mg/mL)[33] during the 24 h cell treatment. Previous studies have reported that PEITC was not detected following hydrolysis of watercress and broccoli.[34,35] Interestingly, QR activity was negatively correlated with concentrations of two different nitriles (sinigrin-dependent epithionitrile formation, r = −0.682 and P = 0.021; gluconasturtiin-dependent simple nitrile formation, r = −0.742 and P = 0.009). AITC was also significantly negatively correlated with epithionitrile formation

(from sinigrin) and simple nitrile formation (from gluconasturtiin, Table 5). Our data show that higher grades of horseradish accumulate more sinigrin and tend to have lower ESP or other myrosinase cofactor activity than lower grades (Table 1 and 3), which may explain why epithionitrile formation correlates negatively with AITC concentrations.

There were significant and positive correlations between TPC and FRAP (r = 0.750, P = 0.008) as well as between FRAP and ABTS (r = 0.974, P < 0.001). These correlations are explained by the fact that these two different antioxidant assays and TPC measurement are based on the electron-transfer reaction mechanism.[25,36] Thus, three different methods measuring the same event should result in correlations, otherwise one of the methods is not valid. There were significant correlations between TPC and epithionitrile formation (from singirin, r = 0.682, P = 0.021) as well as between TPC and AITC (r = −0.689, P = 0.019). This relationship between TPC and epithionitrile formation requires further investigation to determine if TPC impacts on GS hydrolysis.

In conclusion, this study has examined for the first time the variation in health-promoting properties of different accessions and grades of horseradish roots and measured induction of QR as well as estimates of AITC and nitrile formation. U.S. Fancy showed significantly higher sinigrin and AITC concentrations than U.S. No. 1, whereas U.S. No. 1 showed significantly higher CETP, the epithionitrile hydrolysis product of sinigrin, and significantly higher total phenolic concentrations than U.S. Fancy. The present results suggest that higher grades of horseradish roots display better quality, with higher sinigrin and AITC that is responsible for chemopreventive bioactivity.

[a]Gastric and ileal deliveries are modeled with a power exponential formula: $f = 1 - 2^{-(t/t1/2)\beta}$, where f represents the fraction of meal delivered; t, the time of delivery; $t^{1/2}$, the half-time of delivery; and β, the coefficient describing the shape of the curve. [b]SIES, small intestine electrolyte solution.

digestive stability and bioaccessibility of egg carotenoids is poorly understood. Therefore, the objectives of this study were to determine the effect of cooking and digestion on the stability and bioaccessibility of carotenoids and to characterize the carotenoid profile in digested eggs using TIM-1.

MATERIALS AND METHODS

Chemicals. Pepsin (3200 U/mg, P6887, from porcine gastric mucosa), trypsin (7500 U/mg, T9201, from bovine pancreas), and pancreatin (4xUSP, P1750, from porcine pancreas), lutein (xanthophyll from marigold), zeaxanthin, canthaxanthin, and butylated hydroxytoluene (BHT) were obtained from Sigma-Aldrich (Oakville, ON, Canada). β-Apo-8′-carotenoic acid ethyl ester was obtained from CaroteNature (Lupsingen, Switzerland). (*Z*)-Isomers were obtained by iodine-catalyzed photoisomerization of the (all-*E*)-carotenoids.[24] Lipase (150 units/mg, from *Rhizopus oryzae* DF 15) was obtained from Amano Enzyme USA Co. The electrolyte solutions used for the digestion of proteins were gastric electrolyte solution (GES) containing NaCl (4.8 g/L), KCl (2.2 g/L), $CaCl_2$ (0.3 g/L), and $NaHCO_3$ (1.25 g/L) and small intestinal electrolyte solution (SIES) containing NaCl (5.0 g/L), KCl (0.6 g/L), and $CaCl_2$ (0.3 g/L). Fresh pig bile was collected from Olymel slaughterhouse (Vallée-Jonction, QC, Canada), aliquoted for individual TIM experiments and stored at −20 °C until use. Bile bladder had a minimal size of 8 cm in length. HPLC grade solvents (methanol, ethyl acetate, petroleum ether, and *tert*-butyl methyl ether) were purchased from Fisher Scientific (Ottawa, ON, Canada).

Sample Preparation. Fresh eggs (n = 180) were obtained from the Poultry Research Centre of University of Alberta (Edmonton, AB, Canada). Eggs were divided into three groups of 60 each and subjected to boiling, frying, and scrambling. Boiled and fried eggs were prepared using the same cooking conditions that were reported previously.[24] Briefly, shell eggs were boiled in a boiling water bath for 10 min, cooled under running tap water, and peeled, and the yolks were separated from the whites. A nonstick frying pan (model SK200TY nonstick frying pan, Black & and Decker Canada Inc., Brockville, ON, Canada) preheated to 205 °C was used to prepare fried eggs. Whole eggs were fried for 6 min (3 min each side), and the yolks were separated from the whites. To prepare scrambled eggs, yolks were separated and combined and stirred on a preheated (205 °C) model SK200TY nonstick frying pan (Black & Decker Canada Inc.) by stirring yolks for 1 min. Each sample of cooked egg yolks was divided into two subgroups. Samples were vacuum packed, covered with aluminum foil to protect carotenoids from light exposure, and frozen immediately at −20 °C. The next day, all samples were shipped in a Styrofoam box along with dry ice to the Institute of Nutrition and Functional Foods (INAF) at Laval University (Quebec City, QC, Canada), where they were stored at −80 °C until subjected to digestion.

TIM-1 Dynamic Gastrointestinal Model. TIM-1, which has been previously described in detail[8] and commercialized by TNO Nutrition and Food Research (Zeist, The Netherlands), was used for this study. In brief, the computer-controlled system consists of four compartments made of a glass outer wall and a flexible inner wall to represent the stomach, duodenum, jejunum, and ileum. These compartments are connected by peristaltic valve pumps, which facilitate the passage of a constant volume of chyme during each open-and-close cycle. The space between the two walls is filled with water at 37 °C to mimic body temperature. Changing the water pressure enables peristaltic movements and churning of chyme by alternated compression and relaxation of the inner walls. Previously formulated solutions to mimic salivary, gastric, biliary, and pancreatic secretions are introduced into the system via a computer-controlled pumping system. Two hollow-fiber membranes are connected to the jejunum and ileum to simulate the absorption of nutrients/drug and water from chyme. The volume in each compartment and pH, which is regulated using hydrochloric acid and/or sodium bicarbonate, are continuously monitored and controlled.

Digestion of Samples with TIM-1. Approximately 200 g of cooked egg sample was homogenized with 200 g of distilled water to prepare the "meal" using a hand-held blender model CSB-79C (Cuisinart, Woodbridge, ON, Canadae) for 12 s. A sample of 100 g from the meal was taken out as a control, and the rest (300 g) was immediately fed into the gastric compartment of the TIM-1 system. The digestion was carried out using predetermined parameters of TIM-1 modified from Speranza et al.[25] and adapted to reproduce the digestion of a semisolid meal in a healthy human adult (Table 1). The jejunal and ileal compartments were connected to specific hollow-filter membranes (MiniKros module M80S-300-01P, Spectrum Laboratories Inc., Rancho Dominguez, CA, USA) that separate the micellar phase from the fat phase to determine bioaccessibility of lipophilic products.[26,27] The mixed micelles that contain the bioaccessible lipophilic fraction are able to pass through these membranes, whereas the undigested fat is retained. These bioaccessible fractions are collected in separate pouches kept on ice. After the passage of the chyme throughout the system, the residual digestion mixture is discharged as the effluent, which was kept on ice during the experiment. The digestion was carried out under subdued light to prevent photodegradation of carotenoids. All solutions/secretions used during the digestion were purged with nitrogen, and continuous nitrogen flow to the jejunal, ileal, and effluent compartments was maintained to minimize carotenoid oxidation and to reproduce the in vivo luminal conditions. Duplicated digestions were carried out for each cooked egg sample. A blank digestion was also performed using the same parameters with 200 g of distilled water in place of egg sample to estimate the carotenoids from digestive secretions and bile found in each sample.

Sampling Location and Time. During the total digestion time of 300 min, samples were obtained from different compartments as follows: 8 g of stomach chyme at 120 min and 8 g samples from duodenal, jejunal, and ileal chyme at 150 min were taken out. Jejunal filtrate, ileal filtrate, and effluent were collected from 0 to 150 min and from 150 to 300 min into separate pouches kept on ice. The residual chyme samples in duodenal, jejunal, and ileal compartments at the end of the digestion were also collected. Samples were weighed, aliquoted, and immediately transferred to a −80 °C freezer in airtight containers. All samples were freeze-dried and transported to the University of Alberta (Canada) with ice packs, where they were stored at −20 °C until analysis.

Analysis of Carotenoids in Digested Samples. Carotenoids in each sample were extracted as described previously with modifications.[28] Briefly, 500 mg of sample was accurately weighed into a microcentrifuge tube and extracted twice with 0.5 mL of a ternary solvent mixture consisting of methanol/ethyl acetate/petroleum ether (1:1:1 v/v/v) containing 0.1% BHT. The supernatants were combined in microcentrifuge tubes, evaporated under nitrogen, and reconstituted in 0.5 mL of acetone. The acetone extracts were kept at −80 °C for ∼1 h, and then the samples were vacuum filtered using a sintered glass funnel in a freezer compartment at −20 °C to remove the crystallized lipids.[24,46] The crystallized white color lipids were retained in the funnel; the filtrates containing carotenoids were centrifuged at 16500*g* for 30 s, and the supernatants were immediately transferred to a separate microcentrifuge tube, evaporated under nitrogen, and reconstituted in 200 μL of methanol. The extracts were filtered through a 0.45 μm nylon syringe filter and analyzed by HPLC using a Waters 600 HPLC system (Waters, Millford, MA, USA) equipped with a 2702 thermoautosampler, a binary gradient pump, and a 2998 photodiode array detector. The separation of carotenoids was performed on a C_{30} reversed-phase column (YMC 250 mm × 4.6 mm, i.d. = 5 μm) operated at room temperature (22 °C) using the conditions reported before.[24] Duplicate analyses were performed. To protect carotenoids from light- and oxygen-induced degradation, dim light conditions were used during sample handling, extraction, and analysis, and solvents used were purged with nitrogen. Identification of *trans* and *cis* isomers of lutein and zeaxanthin standards were performed on the basis of our previous study.[24] Carotenoids in the samples were identified on the basis of their UV spectra, retention time, and order of elution compared to the standard compounds and quantified using seven-point standard calibration curves.

Calculations and Statistical Analysis. The recovery of carotenoid compounds (separately for lutein and zeaxanthin) in each cooked egg sample was calculated as a percentage of the total amount of carotenoid compounds in the initial meal fed into the system using following equation:

$$\begin{aligned}&\text{recovery of carotenoids (\%)}\\&= (\text{total amount in jejunal filtrate} + \text{ileal filtrate} + \text{effluent}\\&\quad + \text{chyme residue at 300 min})/(\text{total amount fed into the system}\\&\quad - \text{amount detected during blank digestion}) \times 100\end{aligned}$$

All data were analyzed by analysis of variance (ANOVA) followed by Tukey's multiple-range test using Statistical Analysis System software (SAS version 9.3, SAS Institute Inc., Cary, NC, USA). Significance of differences was defined at the 5% level ($p < 0.05$).

RESULTS AND DISCUSSION

Carotenoid Profile of Eggs. The main carotenoid isomers found in undigested egg yolk were all-*E*-lutein, all-*E*-zeaxanthin, 13′-*Z*-lutein, and 13-*Z*-zeaxanthin. The other carotenoids usually found in eggs, such as all-*E*-canthaxanthin and all-*E*-β-apo-8′ carotenoic acid ethyl ester, were found in only trace amounts (Figure 1). The eggs used in this study did not use synthetic carotenoids as poultry feed additives. This might explain their absence in eggs as the egg carotenoid profile is

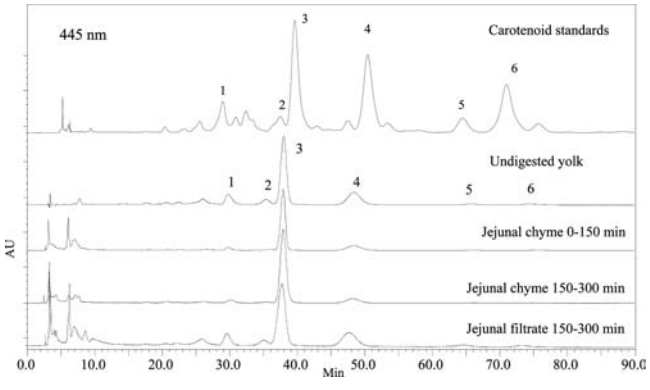

Figure 1. Representative HPLC chromatograms of carotenoid standards, egg yolk carotenoids from meal, and different intestinal compartments during digestion. Peaks: (1) 13′-*Z*-lutein; (2) 13-*Z*-zeaxanthin; (3) all-*E*-lutein; (4) all-*E*-zeaxanthin; (5) all-*E*-cantha-xanthin; (6) all-*E*-β-apo-8′-carotenoic acid ethyl ester.

DOI: 10.1021/jf505615w
J. Agric. Food Chem. 2015, 63, 2956−2962

highly dependent on hens' diet.[28] The qualitative HPLC chromatographic profile of the egg carotenoid isomers remained unchanged during the digestion as no new isomer formation was observed (Figure 1). 13′-*Z*-Lutein and 13-*Z*-zeaxanthin were found in most of the samples, but were below the limit of quantitation in the duodenal, jejunal, and ileal chyme. Thus, the total recovery of these *cis* isomers could not be calculated. Coinciding with previous results,[29,30] no significant *trans*−*cis* isomerization of carotenoids was observed during the digestion due to the high recovery of *trans*-lutein and -zeaxanthin as well as the total quantity of *cis* isomers in filtrates and effluent being much lower than the amounts in the meal. Therefore, in this study we mainly focused on all-*E*-lutein and all-*E*-zeaxanthin levels in the gut during the digestion; unless mentioned otherwise, lutein and zeaxanthin represent the *trans* form of the respective carotenoid.

Digestive Stability of Carotenoids and Distribution in TIM-1 Compartments during Digestion. Only trace amounts of endogenous lutein and zeaxanthin from bile and/or other intestinal secretions were observed in the samples from the blank digestion, which were below the quantitative limits of HPLC. Hence, the distribution and recovery of carotenoids were calculated as a percentage of carotenoid content present in eggs fed into the TIM-1. Overall, both lutein and zeaxanthin were stable at 300 min of the digestion, with average recoveries of 90 and 88% calculated for all-*E*-lutein and all-*E*-zeaxanthin, respectively. At half time of the digestion (150 min), approximately 37% of lutein, irrespective of the type of sample, exited the small intestine (indicated as "effluent") without absorption (Figure 2A). Around 16 and 8% of lutein were passed through the hollow fiber membrane as bioaccessible lutein into the jejunal and ileal filtrates, respectively. Most of the remaining lutein was still in the jejunal and ileal compartments, whereas only about 2% was present in the duodenum. No lutein was detected in the stomach samples even at 120 min through digestion, and by 150 min the stomach was completely free from meal. All-*E*-zeaxanthin had distribution profiles similar to those of lutein at 150 min; however, a comparatively higher proportion (∼50%) in scrambled eggs was found in effluent as nonbioaccessible zeaxanthin (Figure 2). The average recovery of zeaxanthin from fried eggs at 150 min was 69.7%, much lower than those of boiled and scrambled samples (Figure 2B). This is because the zeaxanthin contents in duodenal, jejunal, and ileal chyme samples at 150 min from one of the two fried egg digestions were below the quantifiable limits of HPLC. Consequently, the calculated recovery at 150 min was lower than the true recovery of zeaxanthin. However, this does not influence the digestive stability calculations at 300 min, as we have collected all of the chyme remaining in the intestinal compartments and had enough samples for quantification (see the equation under Materials and Methods). At the end of the digestion (at 300 min), almost 50% of the total lutein was found in effluent followed by 30% in jejunal filtrates. Around 10% of lutein was in ileal filtrate, whereas only a small amount remained in duodenal, jejunal, and ileal compartments. A similar distribution pattern was observed with zeaxanthin except that a higher amount (∼63%) was found in the effluent in scrambled eggs (Figure 2B), apparently the reason for comparatively lower bioaccessibility (Figure 3), which is discussed below. Even

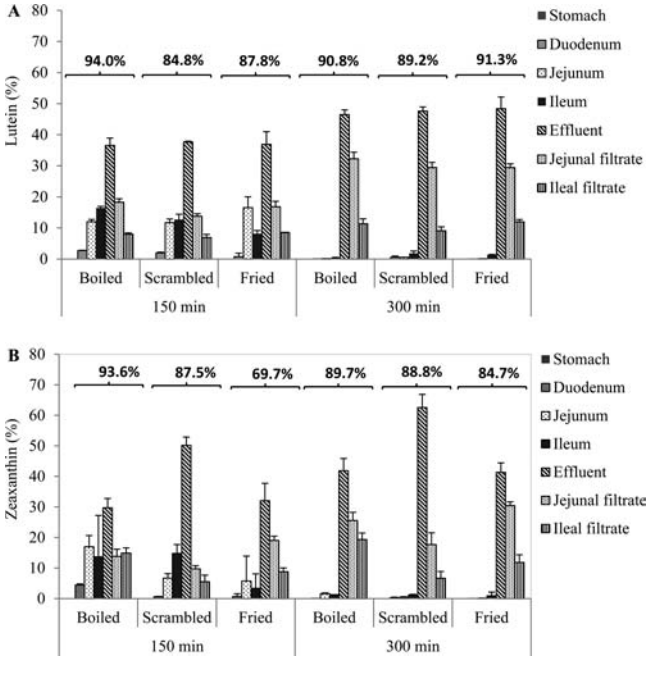

Figure 2. Total recovery (indicated on top of the bars) and distribution of all-*E*-lutein (A) and all-*E*-zeaxanthin (B) in the gut during digestion (as a % of the feeding). Data are the average of two measurements.

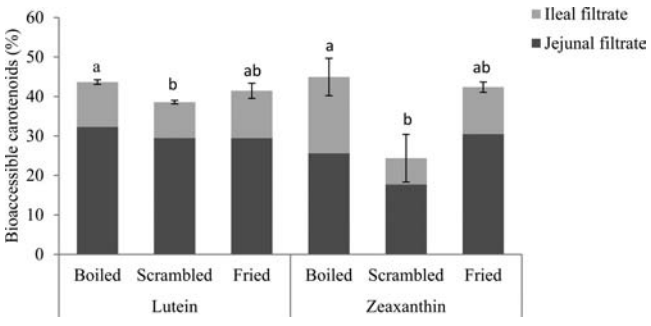

Figure 3. Cumulative carotenoids in jejunal and ileal filtrates (bioaccessible carotenoids) as a percentage of the feeding at the end of the digestion (n = 2; different letters (a, b) denote significant difference (p < 0.05)).

though no studies are available regarding the gut distribution and/or stability of lutein and zeaxanthin from egg yolk, these carotenoids have been reported as highly stable during gastrointestinal digestion regardless of the food source. Blanquet et al.[20] used TIM-1 to compare the digestive stability of xanthophylls and carotenes and found that lutein and zeaxanthin were stable throughout the digestion and the digestive stability of xanthophylls is higher than that of carotenes. Studies that used other in vitro digestion methods also showed a higher digestive stability (>80%) of lutein and zeaxanthin derived from different food sources.[9,10,19,29]

Bioaccessibility of Carotenoids from Cooked Eggs. Bioaccessibility of carotenoids was the total amount of ileal and jejunal filtrates expressed as a percentage of the total carotenoids present in starting meal. According to Etcheverry et al.,[31] there are principally four in vitro methods for measuring bioaccessibility and/or bioavailability: solubility, dialyzability, or a gastrointestinal model (e.g.,TIM) for bioaccessibility and cell culture for bioavailability. There exist no in vitro digestion models that have the capability to mimic

DOI: 10.1021/jf505615w
J. Agric. Food Chem. 2015, 63, 2956−2962

perfectly the complex environment of the GI tract. However, TIM-1 is the only in vitro digestion model with the capacity to simulate the dynamic conditions of the stomach and small intestine during digestion.[32] As shown in Figure 1, the isomeric profiles of carotenoids were similar in both nonbioaccessible (jejunal chyme, 0−150 and 150−300 min) and bioaccessible samples (jejunal filtrate, 150−300 min), indicating both *trans* and *cis* isomers of carotenoids passed through the hollow fiber membranes into the bioaccessible filtrates. In boiled, fried, and scrambled eggs, the bioaccessibility of lutein was 44, 41, and 39%, whereas that of zeaxanthin was 45, 42, and 24%, respectively (Figure 3). Total bioaccessible carotenoids were higher in the jejunal filtrate than in the ileal filtrate. A similar trend was observed in recent studies using TIM-1 to study the effect of fat on blueberry anthocyanins[33] and β-carotene bioaccessibility.[21] Although we did not find any study on lutein bioaccessibility using TIM-1, there are many other papers on lutein bioaccessibility using other in vitro digestion models. Garrett et al.[9] developed an in vitro digestion model and found the lutein bioavailability (solubility assay + cells culture) in a standard baby food to be 25−40%, which is consistent with our results. Using the same model, O'Connell et al. demonstrated that lutein from fruits including orange, kiwi, grapefruit, and honeydew melon (100−109%) is more bioaccessible compared to that from dark green vegetables, spinach (19%), and broccoli (38%).[11] However, Chitchumroonchokchai et al.[10] found a much higher lutein micellarization (53%) in microwave-cooked spinach using solubility assay coupling with Caco-2 cells, presumably due to the disruption of cell walls. Bioaccessibility of lutein from pure durum wheat pasta amounted to 71%, whereas from egg pasta it was 57%,[34] which seems contradictory to the fact of high bioavailability of egg lutein. It was speculated that egg lutein was incorporated into the complex mixture of proteins and starch during pasta processing, leading to low bioaccessibility. Lutein-fortified whole, semiskimmed, and skimmed milk showed bioaccessible levels of 46.5, 45.8, and 19.7%, whereas in whole, semiskimmed, and skimmed yogurts, it was 47.5, 38.3, and 17.8%, respectively;[35] these data are comparable to bioaccessibility levels observed in our study.

The bioaccessibility of both lutein and zeaxanthin was affected by the type of cooking (Figure 3). Lutein and zeaxanthin from scrambled eggs yielded significantly lower bioaccessibility compared to boiled eggs, but were not different from fried eggs. The exact reason for this difference is not clear, but presumably the chemical and structural changes of proteins and lipoproteins in egg yolk occurring during different cooking conditions may have influenced the micellarization efficiency, that is, the transfer of carotenoids to the filtrates. Textural differences between the cooked eggs can be a considerable factor on micellarization as boiled eggs are easily blended with water compared to fried and scrambled eggs. Particle size, food processing, and food preparation[16−19] have been reported as influencing factors on carotenoid bioaccessibility. Panozzo et al.[18] showed bioaccessibility of carotenoids from tomato pulp was affected by homogenization in two main ways: (a) decreased particle size, which enables release of carotenoids; and (b) increased consistency due to the formation of a fiber network, which entraps the carotenoids. Similarly, the industrially extracted orange juice resulted in smaller particle sizes and increased the relative bioaccessibility compared to hand extraction.[16] The composition and degree of saturation of fatty acids are also considered important factors on carotenoid bioaccessibility and bioavailability.[36−38] Gleize et al.[38] observed that saturated and monounsaturated short-chain fatty acids (MUFA) lead to the formation of small micelles and higher bioaccessibility of lutein and zeaxanthin compared to the long-chain polyunsaturated fatty acids (PUFA). The significant inverse relationship between micelle size and bioaccessibility was attributed to increased specific surface area with smaller micelles. They hypothesized that due to the polar nature, xanthophylls located at the micelle surface and, therefore, increased surface area increases amount of xanthophylls that can be incorporated into the micelles. Different cooking methods resulted in diverse fatty acid profiles in egg yolk.[39,43] The amount of PUFA reported in scrambled eggs is significantly higher compared to boiled eggs, which may lead to the formation of larger micelles and lower bioaccessibility. This can also explain our observations on bioaccessibility of carotenoid from eggs after different cooking methods. Lutein and zeaxanthin differ only by the position of one double bond. This minor structural difference may influence how these two compounds incorporated into the micelles and their respective bioaccessibility. It has been shown that the orientations of lutein and zeaxanthin in a phospholipid bilayer are different. Zeaxanthin adopts an orientation spanning the membranes from outer polar headgroup layer to the other polar headgroup layer, whereas lutein can have two different orientations; one way of orientation is similar to that of zeaxanthin, whereas the other is arranged horizontally to the membrane.[48] In a similar way, lutein and zeaxanthin may have different orientation patterns in mixed micelles during digestion, which might contribute to their differences in bioaccessibility.

TIM-1 is so far considered the digestive model simulating the in vivo conditions of human gut and very useful in predicting the fate of nutrients and pharmaceuticals, optimizing the oral formulations for clinical studies and also allowing the simulation of the digestion of infants, young adults, seniors, and patients with impaired gastrointestinal conditions.[40] However, the data obtained through in vitro digestion models on the bioaccessibility of carotenoids may not directly be applied as bioavailability in humans and should be interpreted with caution. On the basis of previously published studies, Reboul et al.[19] made a comparison between the bioaccessibilities of carotenoids obtained using in vitro digestive models and bioavailability values measured in healthy subjects. They found that there is a significant relationship ($r = 0.98$, $p < 0.0001$) between bioaccessibility ratios measured in vitro and the mean bioavailability ratios. In contrast, Granado et al.[41] showed that the bioaccessibility of carotenoids and vitamin E from broccoli under in vitro conditions does not fully explain the changes they observed in healthy individuals. Another paper stated that, although the micellarization efficiencies of lutein from human milk and infant formula were similar, accumulation efficiency of human milk lutein was 4.5 times higher by Caco-2 human intestinal cells.[42]

In summary, we studied the effect of different domestic cooking methods on the stability and bioaccessibility of carotenoids from egg yolk. In alignment with the previous findings, lutein and zeaxanthin were stable during the in vitro digestion. Digestive stability was not affected by the different types of cooking, whereas scrambling resulted in significantly lower bioaccessibility compared to boiled eggs in both lutein and zeaxanthin. To the best of our knowledge, this is the first study to investigate the bioaccessibility of egg yolk carotenoids affected by the cooking methods. The results presented here provide detailed information on digestive stability and

DOI: 10.1021/jf505615w

bioaccessibility of egg carotenoids under various thermal processing conditions and may be useful in estimating the bioavailable carotenoids from eggs and egg-containing foods.

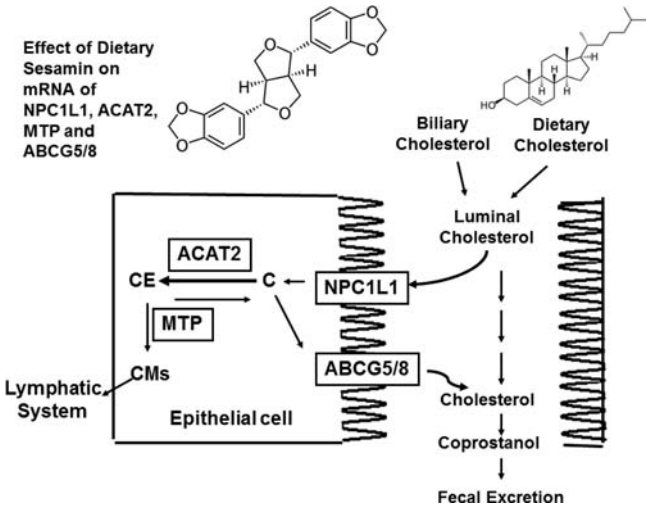

Figure 1. Structure of sesamin and cholesterol absorption pathway. Dietary and biliary cholesterol (C) is transported into enterocytes by Niemann−Pick C1 like 1 transporter (NPC1L1). Acyl-CoA:cholesterol acyltransferase 2 (ACAT2) esterifies cholesterol to form cholesteryl ester (CE), which is then packed into chylomicrons (CMs) by microsomal triacylglycerols transport protein (MTP). CMs containing CE are then transferred into blood through the lymphatic system. ATP binding cassette transporters (ABCG5 and ABCG8) return the unabsorbed cholesterol to the lumen of intestine. Cholesterol in the large intestine is converted to coprostanol and other derivatives by bacteria.

into enterocytes.[16] Second, intestinal acyl-CoA:cholesterol acyltransferase 2 (ACAT2) subsequently converts the free cholesterol to cholesteryl ester (CE) followed by the action of microsomal triacylglycerol transport protein (MTP), which packs CE into chylomicrons (CM).[17] Third, CM are transferred into blood through the lymphatic system. Finally, ATP-binding cassette transporter subfamily G members 5 and 8 (ABCG5 and ABCG8) return the unabsorbed free cholesterol left in the enterocytes to the lumen for excretion.[18,19] Although some research has addressed the effect of sesamin on plasma cholesterol, no study to date has investigated the effect of dietary sesamin on gene expression of intestinal NPC1L1, ACAT2, MTP, ABCG5, and ABCG8 (Figure 1).

A systematic investigation concerning the effect of sesamin on cholesterol metabolism is also lacking. Cholesterol homeostasis is partially regulated by two different transcription factors, namely, sterol regulatory element-binding protein 2 (SREBP-2) and liver X receptor alpha (LXRα).[20,21] SREBP-2 controls the gene expressions of LDL receptor and HMG-CoA reductase. LDL receptor is responsible for the removal of LDL-C from circulation, whereas HMG-CoA reductase is a rate-limiting enzyme in the cholesterol synthesis pathway. LXRα is a sensor of cholesterol concentration in the liver and governs the gene expression of hepatic cholesterol-7α-hydroxylase (CYP7A1), a key enzyme in bile acid synthesis. The excess cholesterol in the liver is partially removed by being converted to bile acids. To date, there is no study that has examined the effect of dietary sesamin on gene expression of these transcript factors, enzymes, or receptor involved in maintaining cholesterol homeostasis.

The present study was therefore designed to (i) investigate if dietary sesamin could reduce plasma TC in a dose-dependent manner and (ii) examine the interaction of dietary sesamin with the gene expressions of hepatic SREBP-2, LXRα, HMG-CoA reductase, LDL receptor, and CYP7A1 as well as intestinal NPC1L1, ACAT2, MTP, and ABCG5 and ABCG8.

MATERIALS AND METHODS

Chemicals and Diet Ingredients. Sesamin with a purity of 93% was purchased from KEB Biotechnology (Beijing, China). Casein, mineral mix, and vitamin mix were purchased from Harlan Teklad (Madison, WI, USA). Cholesterol and DL-methionine were purchased from Sigma-Aldrich (St. Louis, MO, USA). Lard was obtained from Hop Hing Oils & Fats Ltd. (Hong Kong, China).

Preparation of Diets. The three diets were prepared with some modification of AIN-93 Purified Diet for Laboratory Rodents. The control diet (CON) was prepared by mixing the following ingredients (g): cornstarch, 508; casein, 242; lard, 50; sucrose, 119; mineral mix, 40, vitamin mix, 20; DL-methionine, 1; cholesterol, 1. The two experimental diets were formulated by adding 0.2% (SL) or 0.5% (SH) sesamin into the control diet, respectively. The total cholesterol content in the three diets was actually 1.05 mg/kg as lard contained 90 mg cholesterol/100 g. The rationale for adding cholesterol at 0.1% was because such a level could induce a rise in plasma TC to reach >6.2 mM, which is similar to human hypercholesterolemia.[22]

Hamsters. Male Golden Syrian hamsters (n = 30) were divided into three groups (n = 10 each) and fed one of the three diets formulated above. Hamsters were housed in an animal room at 23 °C with 12/12 h light/dark cycles. The fresh diets were given daily, and body weight was recorded twice a week. The hamsters were fed ad libitum. At weeks 0, 3 and 6, about 100 μL of blood from each hamster was taken from the retro-orbital sinus under inhalational anesthesia of isoflurane after overnight fasting. At the end of week 6, all of the hamsters were killed with the liver being removed for the mRNA analyses of SREPB-2, LXRα, LDL receptor, HMG-CoA reductase, and CYP7A1. The first 40 cm of the small intestine was kept for the

mRNA analyses of NPC1L1, ACAT-2, MTP, ABCG5, and ABCG8. All samples were stored in a −80 °C freezer prior to analysis. All of the feces from each hamster at weeks 1, 3, and 6 were pooled, freeze-dried, ground, and saved for neutral and acidic sterol analyses. The whole experimental procedure was approved by the Animal Experimental Ethical Committee, The Chinese University of Hong Kong.

Analysis of Plasma Lipoproteins. Plasma TC, high-density lipoprotein cholesterol (HDL-C), non-HDL-C, and TG were measured using the commercial enzymatic kits from Infinity (Waltham, MA, USA) and Stanbio Laboratories (Boerne, TX, USA), respectively.[23]

Analysis of Cholesterol in the Liver. Cholesterol in the liver was analyzed as previously described.[22,24] In brief, the total lipids were extracted from 300 mg of sample using a solvent of chloroform/methanol (2:1, v/v) with 5α-cholestane being added as an internal standard. The extract was then subjected to cold saponification at room temperature. Nonsaponifiable materials were extracted into hexane followed by TMS derivatization. The cholesterol TMS-ether derivative was analyzed in a SAC-5 column in a Shimadzu GC-14B equipped with a FID detector (Shimadzu, Tokyo, Japan).

Table 2. Food Consumption, Body Weight, and Organ Weights in Male Golden Syrian Hamsters Fed the Control (CON) or One of the Two Experimental Diets Containing 0.2% Sesamin (SL) or 0.5% Sesamin (SH), Respectively[a]

	CON	SL	SH
food intake (g)	9.9 ± 0.7	9.9 ± 1.2	10.0 ± 1.1
body wt (g)			
initial	110 ± 7	109 ± 9	110 ± 9
final	122 ± 8	125 ± 9	122 ± 9
absolute organ wt (g)

perirenal fat pad	1.1 ± 0.2	1.3 ± 0.5	1.1 ± 0.3

[a]Data are expressed as the mean ± SD; n = 10 each group.

Determination of Fecal Cholesterol, Coprostanol, and Other Neutral and Acidic Sterols. Fecal cholesterol, coprostanol, other neutral and acidic sterols were determined as previously described.[22−24] 5α-Cholestane and hyodeoxycholic acid were added into the fecal samples as internal standards to quantify the amount of total neutral and acidic sterols, respectively. In brief, the dried fecal samples were hydrolyzed and extracted with cyclohexane. Neutral sterols in cyclohexane extract were dried and converted into their corresponding TMS derivatives. Acidic sterols in the bottom aqueous layer left after cyclohexane extraction were saponified, extracted, and similarly converted to their corresponding TMS derivatives. Both neutral and acidic sterol TMS derivatives were then subjected to the GC analysis.

Real-Time PCR Analysis of Intestinal NPC1L1, ACAT2, ABCG5, ABCG8, and MTP and Hepatic SREBP-2, LXRα, CYP7A1, HMG-CoA Reductase, and LDL Receptor. mRNA for each target gene was quantified as previously described.[22−25] In brief, the total RNA in the intestine or the liver was extracted followed by transcription to complementary DNA (cDNA) using a high-capacity cDNA reverse transcription kit (Invitrogen, Carlsbad, CA, USA). Reverse transcription was then carried out followed by the real-time PCR analysis on a Fast Real-time PCR System 7500 (Applied Biosystems, Foster City, CA, USA). The expression of NPC1L1, ACAT-2, ABCG5, ABCG8, and MTP was normalized with cyclophilin, whereas that of hepatic SREBP-2, LXRα, CYP7A1, HMG-CoA reductase, and LDL receptor was normalized with GAPDH. Each primer and TaqMan probe (Table 1) was obtained from Applied Biosystems. Real-time PCR was performed using a TaqMan Fast Universal PCR Master Mix. Data were analyzed using Sequence Detection Software version 1.3.1.21.

Statistical Analysis. One-way analysis of variance (ANOVA) followed by post hoc LSD test was used to statistically evaluate differences in lipoproteins, gene expression of transcription factors, sterol transporters, and enzymes involved in the cholesterol metabolism among the three groups. A simple linear regression analysis was carried out to assess the dose-dependent activity of sesamin using SPSS (PASW Statistics for Windows, version 18.0, Chicago, IL, USA).

RESULTS

Food Intake and Body and Organ Weights. No differences in food intake and body weight were seen among the three groups (Table 2). The weights of kidney, heart, and

perirenal and epididymal adipose tissues were similar among the three groups.

Plasma TC, LDL, TG, and Liver Cholesterol. The three groups of hamsters had similar levels of plasma TC, HDL-C, non-HDL-C, and TG at week 0. When the experiment reached the end of weeks 3 and 6, SL and SH hamsters had decreased plasma TC, non-HDL-C, and TG in a dose-dependent manner (Table 3). At week 6, SL and SH groups had plasma TC reduced by 20 and 25%, respectively, compared with the control hamsters at the end of week 6. The amount of cholesterol in the liver decreased significantly in both SL and SH groups (Table 3). Results demonstrated that the control hamsters had liver cholesterol of 128.0 μmol/g, whereas SL and SH hamsters had liver cholesterol of 105.0 and 99.4 μmol/g, equivalent to 16 and 22% reductions, respectively.

Fecal Neutral Sterols. Microbial hydrogenation and bioconversion of cholesterol in the large intestine produce several derivatives, namely, coprostanol, coprostanone, and

DOI: 10.1021/jf5063606
J. Agric. Food Chem. 2015, 63, 2963−2969

dihydrocholesterol, whereas stigmasterol and β-sitosterol are of dietary origin. At week 1, no differences in individual and total fecal neutral sterols were seen among the three groups (Table 4). At week 3, SL and SH groups had increased fecal excretion of cholesterol, dihydrocholesterol, and total neutral sterols in a dose-dependent manner. At week 6, addition of sesamin into the diet dose-dependently increased the fecal excretion of cholesterol, coprostanol, coprostanone, and dihydrocholesterol. Compared with the control hamsters, SL and SH groups had increased excretion of fecal total neutral sterols by 62 and 120%, respectively (Table 4).

Fecal Acidic Sterols. Fecal bile acids are divided into primary and secondary bile acids. The primary bile acids are cholic acid and chenodeoxycholic acids, whereas the secondary bile acids are deoxycholic, lithocholic, and ursocholic acids. In week 1, no differences in the excretion of total bile acids were seen among the three groups. At week 3, the excretion of total bile acids and secondary bile acids lithocholic and deoxycholic acids was significantly increased in SL and SH groups in a dose-dependent manner (Table 4). At week 6, addition of sesamin into the diet dose-dependently increased the excretion of total fecal bile acids by 40 and 49% in the SL and SH groups, respectively.

Real-Time PCR mRNA of Intestinal NPC1L1, ACAT2, MTP, ABCG5, and ABCG8. RT-PCR analysis demonstrated that addition of sesamin into diets had significant effects on gene expression of transporters, enzymes, and protein involved in cholesterol absorption. As shown in Figure 2, dietary sesamin dose-dependently down-regulated the mRNA of intestinal NPC1L1, ACAT2, MTP, ABCG5, and ABCG8. For mRNA NPC1L1, it was down-regulated in SL and SH groups by 22.3 and 51.5%, respectively, compared with the control. Similarly, mRNA ACAT2 was decreased by 24.5 and 53.3%, whereas mRNA MTP was down-regulated by 24.4 and 50.1% in SL and SH groups, respectively, compared with the control. mRNA ABCG5 and ABCG8 were also decreased by 13.1−13.5 and 26.1−49.5%, respectively, compared with the control values.

Real-Time PCR mRNA Analysis of Hepatic SREBP2, LDL Receptor, HMG-CoA Reductase, LXRα, and CYP7A1. RT-PCR analysis found the addition of sesamin in the diet had no effect on mRNA of LDL receptor and SREBP2 (Figure 3). Dietary sesamin at 0.2 and 0.5% significantly up-regulated the mRNA of CYP7A1 by 55.3 and 71.3%, respectively, compared with the control value. In contrast, sesamin at 0.2 and 0.5% in diets significantly down-regulated mRNA HMG-CoA reductase by 46.8−49.4% and mRNA LXRα by 60.1−62.6%, respectively, compared with the control values.

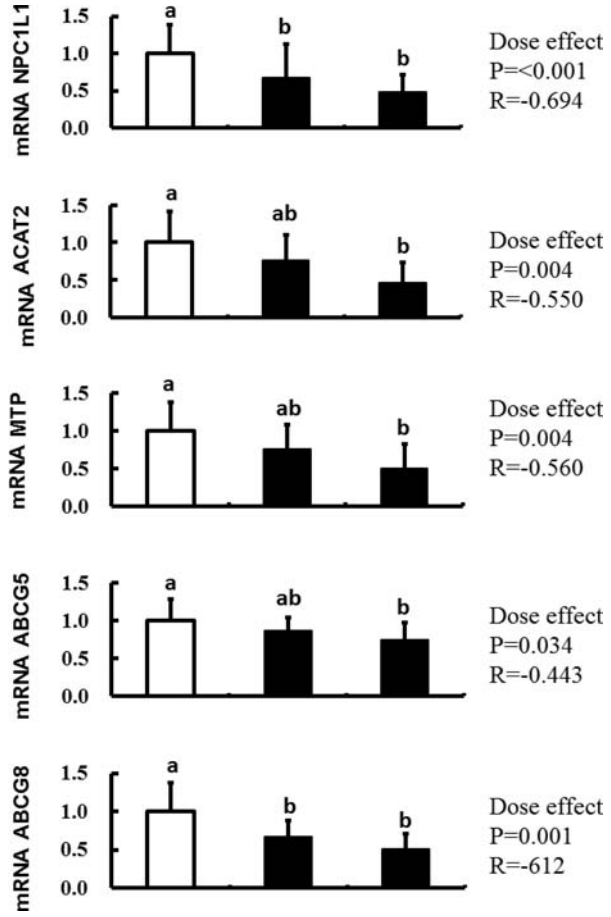

Figure 2. mRNA levels of intestinal Niemann−Pick C1 like 1 protein (NPC1L1), acyl coenzyme A:cholesterol acyltransferase 2 (ACAT2), microsomal triacylglycerol transport protein (MTP), and ATP binding cassette transporters subfamily G members 5 and 8 (ABCG5 and ABCG8) in hamsters fed the control diet (CON) or one of the two experimental diets with the addition of 0.2% sesamin (SL) or 0.5% sesamin (SH). Data were normalized with cyclophilin. Values are expressed as means ± SD (n = 10) with those for the control group being arbitrarily taken as 1. Means with different letters (a, b) differ significantly, $P < 0.05$. R is the coefficient of correlation for the regression analysis on the dose-dependent effect of sesamin on target genes.

DISCUSSION

We chose sesamin as a representative lignan and investigated its effect on plasma TC using hamsters as a hypercholesterolemia model. It was found that dietary sesamin was capable of modulating favorably the plasma lipoprotein profile with the following observations. First, dietary sesamin at 0.2 and 0.5% could decrease plasma TC by 20−25% in a dose-dependent manner (Table 3). Second, dietary sesamin decreased both non-HDL-C and HDL-C; however, it decreased non-HDL-C more than HDL-C, thus favorably reducing the ratio of non-HDL-C to HDL-C. The rationale for adding sesamin into diets at 0.2 and 0.5% was that such doses were comparable to the recommended intake for other cholesterol-lowering nutraceuticals such as plant sterols. It is generally recommended to take 2 g of plant sterols per day to decrease plasma LDL-C by about 10% for humans.[26] This translates to a dose of 1 g plant sterols/1000 kcal in the diet provided that humans daily consume about 2000 kcal energy. In the present study, 0.2−0.5% sesamin added in diets was equivalent to 0.5−1.2 g/1000 kcal, which was close to the recommended intake for plant sterols.

We proposed two underlying mechanisms by which dietary sesamin decreased plasma TC. The first mechanism was that dietary sesamin reduced plasma TC concentration by down-regulating the gene expression of transporters and enzymes involved in cholesterol absorption pathway in the intestine. The proposed mechanism was supported by the results from RT-PCR analysis with the following evidence. First, dietary sesamin dose-dependently down-regulated mRNA of intestinal NPC1L1, ACAT-2, MTP, ABCG5, and ABCG8 (Figure 2), all of which are essential for cholesterol absorption. Second, such down-regulation on these genes was accompanied by 62−120% greater excretion of neutral sterols (Table 4), proving that dietary sesamin inhibited cholesterol absorption. To the best of

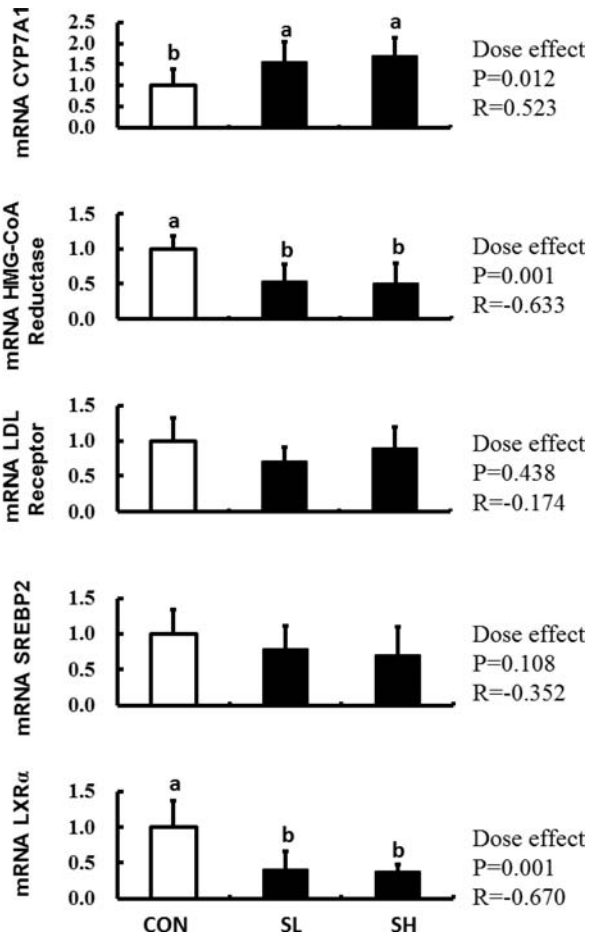

Figure 3. mRNA levels of hepatic sterol regulatory element-binding protein-2 (SREBP-2), liver X receptor-alpha (LXRα), 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase, LDL receptor (LDLR), and cholesterol-7α-hydroxylase (CYP7A1) in hamsters fed the control diet (CON) or one of two experimental diets with the addition of 0.2% sesamin (SL) or 0.5% sesamin (SH). Data were normalized with GAPDH. Values are expressed as means ± SD (n = 10) with those for the control group being arbitrarily taken as 1. Means with different letters (a, b) differ significantly, $P < 0.05$. R is the coefficient of correlation for the regression analysis on the dose-dependent effect of sesamin on target genes.

our knowledge, this is the first study to demonstrate that the cholesterol-lowering activity of dietary sesamin was mediated by down-regulation on the gene expression of intestinal NPC1L1, ACAT2, MTP, ABCG5, and ABCG8.

The second mechanism was that sesamin could modulate the cholesterol homeostasis in a way favoring the reduction of plasma TC. The present study clearly demonstrated that dietary sesamin down-regulated mRNA HMG-CoA reductase in a dose-dependent manner, suggesting dietary sesamin inhibited cholesterol biosynthesis in the liver (Figure 3). The present results also demonstrated that sesamin had a trend of down-regulating mRNA SREBP-2 in the liver, although such an effect was statistically insignificant. It is known that the expression of HMG-CoA reductase is under the control of SREBP-2, which is activated at a lower cholesterol level. Therefore, down-regulation of HMG-CoA reductase was expected in response to reduction of liver cholesterol and mRNA SREBP-2. The most important observation was that dietary sesamin dose-dependently up-regulated the mRNA CYP7A1, indicating dietary sesamin promoted the biosynthesis of bile acids and deceased the liver cholesterol concentration. This was supported by a 40−49% increase in the excretion of fecal bile acids in hamsters given diets with the addition of 0.2 or 0.5% sesamin. It is worth noting that dietary sesamin could down-regulate the mRNA of LXRα by 60.1−62.6% in the liver. It is known that LXRα acts as a cholesterol concentration sensor in the liver. When cellular oxysterols accumulate as a result of increasing concentrations of cholesterol in the liver, LXRα is up-regulated to induce the transcription of genes that protect cells from cholesterol overload and then activate the bile acid synthesis.[27] In the present study, such down-regulation of mRNA LXRα was expected because dietary sesamin decreased the cholesterol concentration in the liver by 16−22%. The discrepancy between down-regulation of mRNA LXRα and up-regulation of mRNA CYP7A1 was probably due to changes in other nuclear receptors such as farnesoid X receptor (FXR), which can also regulate the gene expression of CYP7A1.[27,28] We plan to investigate the issue in our future research.

In summary, dietary sesamin could favorably modulate plasma lipoprotein profile by decreasing plasma TC, non-HDL-C, and the non-HDL-C/HDL-C ratio. Dietary sesamin-induced reduction in plasma TC was accompanied by greater excretion of both total fecal neutral and acidic sterols. It was concluded that the cholesterol-lowering activity of dietary sesamin was mediated by up-regulation of hepatic mRNA CYP7A1 and down-regulation of intestinal mRNA NPC1L1, ACAT2, MTP, ABCG5, and ABCG8 as well as down-regulation of hepatic mRNA HMG-CoA reductase.

isolation and analysis were of analytical grade and used without further purification.

Fractionation and Purification of Hemicellulosic Polysaccharides. The ground powders were suspended in a 95% ethanol solution and heated to 75 °C for 2 h to remove small molecular components. After centrifugation at 4500*g* for 10 min at 4 °C, the obtained residues were suspended in a 15-fold volume of distilled water (DD H_2O, w/v) and kept at 80 °C for 2 h to remove the water-soluble polysaccharides and proteins. Each step was repeated three times. The water-insoluble residue was extracted four times by a 20-fold volume of 1 M NaOH at ambient temperature with continuous stirring for 12 h. The alkali extract was neutralized with HCl solution and precipitated with a 4-fold volume of 95% ethanol (v/v) and washed three times with 75% ethanol, followed by lyophilization to obtain the crude hemicellulosic polysaccharides of alfalfa stem.

The crude polysaccharides were subjected to further fractionation by membrane ultrafiltration (Minimate TFF system, Pall Corp., Port Washington, NY, USA) with a molecular weight (MW) cutoff of 10 kDa to obtain the cold alkali-extractable polysaccharide molecules of alfalfa stem (ACAP) with MW larger than 10 kDa. ACAP was further purified by gel filtration on a Sephacryl S-400 Superfine column (80 × 1.6 cm i.d., Amersham Pharmacia Biotech, Uppsala, Sweden) eluted with DD H_2O at 1.0 mL/min. The collected fraction was freeze-dried prior to further analyses.

Molecular Weight and Size. A particle size analyzer (Zetasizer Nano-ZS90, Malvern Instruments Ltd., Malvern, Worcs, UK) was used to determine the molecular weight and size of ACAP. In brief, the purified ACAP was dissolved in DD H_2O and heated at 80 °C for 2 h to avoid aggregation. The dispersed solution was diluted to 1.00, 0.75, 0.50, 0.25, and 0.10 mg/mL. The laser light scattering was measured for these samples using a static light scattering (SLS) to obtain the Debye plot, which was used to calculate the weight-averaged molecular weight (M_w) according to the Rayleigh equation (eq 1).[15] To avoid the interactions of molecules, 0.05 mol/L NaOH solution was prepared to dissolve ACAP molecules for size determination using the SLS method. The molecular size was obtained at the concentration of 0.25 mg/mL.

$$\frac{KC}{R_\theta} = \left(\frac{1}{M_w} + 2A_2C\right) \times P(\theta) \quad (1)$$

In the equation, K, M_w, A_2, and C represent optical constant, sample molecular weight, second virial coefficient, and sample concentration, respectively. The Rayleigh ratio (R_θ) indicates the ratio of scattered light to incident light of the sample, whereas $P(\theta)$ means the angular dependence of the sample scattering intensity. $P(\theta)$ reduces to 1 when the particles are much smaller than the wavelength of incident light. The M_w (Da or g/mol) was then determined from the intercept at zero concentration ($C \rightarrow 0$) according to $KC/R_\theta = 1/M_w$.

Chemical Composition Analysis. The total carbohydrate and uronic acid contents were determined using the phenol−sulfuric acid[16] and *m*-hydroxydiphenylsulfuric acid methods,[17] respectively. The protein content was analyzed by bicinchoninic acid protein assay (BCA) as described previously.[18]

The compositions of neutral sugars and uronic acids of ACAP were determined by PMP-HPLC method.[19] ACAP (10 mg) was hydrolyzed with 200 μL of 4 M trifluoroacetic acid (TFA) at 110 °C for 2 h. TFA in the reaction mixture was removed under nitrogen stream with the addition of 200 μL of methanol and repeated three times. The hydrolysates were dissolved in 50 μL of 0.3 M NaOH solution and reacted at 70 °C for 100 min with the addition of 50 μL of 0.5 M 1-phenyl-3-methyl-5-pyrazolone (PMP) solution in methanol. After cooling to room temperature, the mixture was neutralized with 0.3 M HCl, followed by the addition of DD H_2O to the final volume of 1 mL. An equal volume of dichloromethane was added, vortex-mixed, and repeated three times to remove the residual PMP. The sugar standard was prepared by mixing a solution of L-rhamnose (Rha), L-fucose (Fuc), L-arabinose (Ara), D-xylose (Xyl), D-mannose (Man), D-galactose (Gal), D-glucose (Glc), D-glucouronic acid (Glc*p*A), and D-galactouronic acid (Gal*p*A). The mixed standard also went through the above procedures except for hyrolyzation with TFA. The obtained upper layer solution was filtered through a 0.45 μm Millipore filter and subjected to HPLC analysis at 250 nm with an Inersil ODS-3 column (100 mm × 2.1 mm i.d., 2 μm, GL Sciences Inc., Tokyo, Japan). The chromatographic separation was carried out at 30 °C under the elution conditions of 0.1 M phosphate buffer (pH 6.7)/acetonitrile at a ratio of 80:20 (v/v).

Linkage Analysis by Methylation. For the existence of uronic acid, ACAP was first reduced using $NaBD_4$[20] and then methylated using methyl iodide (CH_3I) in a NaOH−DMSO dry slurry as reported previously,[21] followed by hydrolysis with 4 M TFA for 2 h at 121 °C. Samples were reduced with 0.1 mL of 10 mg/mL $NaBD_4$ and then acetylated by 100 μL of acetic anhydride. Afterward, the obtained partially methylated alditol acetate (PMAA) mixtures were examined using an Agilent 7890A-5975C GC-MS system (Agilent Technology, Santa Clara, CA, USA) equipped with a HP-5 capillary column (30 m × 0.32 mm i.d., 0.25 μm film). The GC conditions were as follows: initial temperature, 50 °C, increased at 30 °C/min to 150 °C, increased at 3 °C/min to 220 °C, and finally increased to 300 °C at 30 °C/min and held for 10 min; injector temperature, 250 °C; interface temperature, 280 °C. The MS conditions were as follows: ion source temperature, 300 °C; ionization energy, 70 eV; detector voltage, 1.5 kV; mass range, 50−550. Glycosidic linkages of ACAP were determined by comparing the GC-MS results of the PMAAs with mass spectrum patterns from the online database.[22] The molar ratios of individual linkage residues were calculated on the basis of the peak areas and response factors for individual sugars in the TIC as described previously.[23]

Spectroscopic Analysis. The Fourier transform infrared (FT-IR) spectrum of ACAP was recorded using a FT-IR spectrometer (Nicolet 6700, Thermo Fisher, USA) in the range of 4000−400 cm^{-1} using the KBr disk method.

One- and two-dimensional measurements (including ^1H NMR, ^{13}C NMR, DEPT 135, HH COSY, TOCSY, and HSQC) of ACAP were recorded on a 600 MHz NMR spectrometer (Bruker Avance III HD) with a 5 mm TCl CryoProbe ($^{13}C/^1H/^{15}N$) at 25 °C using D_2O as the solvent at a final concentration of 40 mg/mL.

Microscopic Analysis. To observe the microstructure of ACAP, sodium dodecyl sulfate (SDS) was selected as a surfactant to disperse the polysaccharide in aqueous solution as described previously.[24,25] ACAP aqueous solution was prepared at a concentration of 1 mg/mL, followed by the addition of an equal volume of SDS solution (1 mg/mL). The mixture was then heated at 80 °C for 2 h with constant stirring and diluted with DD H_2O to a final concentration of 5 μg/mL. A droplet of ACAP solution was deposited on the carbon film specimen (200 mesh, Beijing Zhongjingkeyi Technology, Beijing, China). Transmission electron microscopy (TEM, Tecnai G2 Spirit BIOTWIN, FEI, USA) with an accelerating voltage of 120 kV was applied to visualize the molecular morphology of the ACAP samples after they were dried at ambient temperature and humidity.

Isoconversional Thermal Characteristics. A simultaneous thermal analyzer (SDT-Q600, TA Instruments, USA) was used to determine the thermodynamic characteristics of the ACAP. ACAP samples (5 mg for each) were treated at three different heating rates (including 5, 10, and 20 °C/min from 50 to 600 °C) under a nitrogen atmosphere at a flow rate of 100 cm^3/ min. The obtained data were then analyzed by the isoconversional Flynn−Wall−Ozawa (FWO) method (eq 2) as previous studies reported.[26,27]

$$\log \beta = \log \frac{AE_a}{Rg(\alpha)} - 2.315 - 0.4567\frac{E_a}{RT} \quad (2)$$

$g(\alpha) = \int_0^\alpha d\alpha/f(\alpha)$; β is the heating rate; R is the general gas constant; A stands for the pre-exponential factor; E_a is the apparent activation energy; and T is the temperature at the conversion α. This model-free approach was applied to obtain a plot of log β versus $1/T$ at different conversion rates for calculation of $-E_a/R$ as the slope.

Following the calculation of an average E_a value, ln$A$ was obtained by the compensation effect relationship as eq 3. The compensation parameters of a and b could be obtained from a plot of ln$A$ versus E_a from a model-fitting approach using Coats−Redfern eq 4 with T' being the average experimental temperature. In addition, the experimental ln A could be calculated according to eq 3.

DOI: 10.1021/acs.jafc.5b00063
J. Agric. Food Chem. 2015, 63, 2970−2978

$$\ln A = aE_a + b \quad (3)$$

$$\ln \frac{g(\alpha)}{T^2} = \ln\left[\left(\frac{AR}{\beta E_a}\right)\left(1 - \frac{2RT'}{E_a}\right)\right] - \frac{E_a}{RT} \quad (4)$$

The thermal analysis data were analyzed using Universal Analysis 2000 software (version 4.5A, TA Instruments, USA) and MS Excel 2013.

Anti-inflammatory Activity Determination. To analyze the anti-inflammatory effect of ACAP, RAW 264.7 mouse macrophage cells were selected to detect the inhibition of IL-1β, IL-6, and COX-2 gene expressions. The aqueous ACAP solution was prepared at two treatment concentrations of 10 and 50 μg/mL. RAW 264.7 cells were cultured in 6-well plates for 24 h to reach an 80% confluence before the addition of ACAP-containing media. After further incubation for 24 h, LPS was pipetted into the medium at a final concentration of 10 ng/mL and incubated for another 4 h at 37 °C under 5% CO_2. The macrophage cells were collected and washed for RNA isolation and real-time PCR analysis according to previously described laboratory procedures.[28,29] In general, total RNA was isolated using the TRIzol reagent, followed by the reverse transcription cDNA using a IScript Advanced cDNA Synthesis kit. Real-time PCR was carried out on an ABI 7900HT Fast Real-Time PCR System (Applied Biosystems, Foster City, CA, USA) using the following PCR conditions: 50 °C for 2 min, 95 °C for 10 min, and 46 cycles of amplification at 95 °C for 15 s and 60 °C for 1 min.

Statistical Analysis. Significant differences between means were evaluated by one-way ANOVA followed by Tukey's multiple-comparison test to identify differences in means using SPSS for Windows (version rel. 18.0, SPSS Inc., Chicago, IL, USA). Statistical significance was declared at $P < 0.05$.

RESULTS AND DISCUSSION

Preparation of ACAP. After successive extractions with 95% ethanol and hot water, the crude cold alkali-soluble fraction was obtained, and the yield was found to be 8.47% on a per alfalfa stem dry weight basis. The composition analysis indicated that ACAP was composed of approximately 95.42% (w/w) of total carbohydrate, which contained about 9.38% uronic acid, whereas no protein was detected in the crude ACAP.

After sequential purification by ultrafiltration and gel permeation chromatography, a single fraction was obtained and designated ACAP (Figure S1 in the Supporting Information). The PMP-HPLC analysis showed that ACAP was composed of xylose, glucouronic acid, and arabinose in a molar ratio of 23:3:1. The M_w of ACAP was calculated to be 7.94×10^3 kDa (or 7.94×10^6 g/mol), whereas A_2 was calculated to be 2.45×10^{-4} from the gradient of the Debye plot (Figure S2 in the Supporting Information). The value of A_2 (>0) indicated that the aqueous solution of ACAP was a stable system. The radius of gyration (R_g) was determined to be 58 ± 6 nm for ACAP. The SLS method was applied to determine the molecular weight of ACAP because the commonly used size exclusion chromatographic analysis is not suitable for weight determination of branched polysaccharides.

Glycosidic Linkages of ACAP. ACAP was composed of a terminal arabinose (T-L-Ara*f*), 1,3,4-D-xylose (Xyl*p*), 1,2,4-D-Xyl*p*, 1,4-D-Xyl*p*, and a terminal glucouronic acid (T-D-Glc*p*A) in a molar ratio of 1:1.1:3.2:20.6:3.1, according to the PMAA analysis (Table 1). The ratio between terminal units (T-L-Ara*f* and T-D-Glc*p*A) and the branching points (1,3,4-D-Xyl*p* and 1,2,4-D-Xyl*p*) was 0.95, indicating that the number of terminal units was approximately equal to the number of branching points in ACAP. These results indicated that ACAP might contain a →1)-D-Xyl*p*-(4→ backbone with T-L-Ara*f* and T-D-Glc*p*A residues at the *O*-2 or *O*-3 site to form the side chains. Additionally, the degree of branching (DB) value of ACAP was calculated as 29% following the equation DB = (NT + NB)/ (NT + NB + NL) as described by Hawker and others,[30] where NT, NB, and NL are the numbers of the terminal residues, branch residues, and linear residues, respectively.

Table 1. Molar Ratio of Glycosidic Linkages in ACAP by Methylation Analysis

retention time (min)	PMAA[a]	mass fragments (*m*/*z*)	linkage type	molar ratio
10.632	1,4-*O*-Ac2-2,3,5-*O*-Me3-D-arabinitol	87, 101, 117, 129, 161	T-L-Ara*f*	1.0
13.015	1,4,5-*O*-Ac3-2,3-*O*-Me2-D-xylitol	87, 101, 117, 129, 189	1,4-L-Xyl*p*	20.6
13.314	1,2,4,5-*O*-Ac4-3-*O*-Me-D-xylitol	87, 129, 189	1,2,4-D-Xyl*p*	3.2
13.637	1,3,4,5-*O*-Ac4-2-*O*-Me-D-xylitol	85, 99, 117, 127, 159, 201, 261	1,3,4-D-Xyl*p*	1.1

[a]Ac, acetyl; Me, methyl.

FT-IR Spectrum. As shown in Figure S3 in the Supporting Information, most of the absorption bands could be assigned according to previous literature.[31,32] The signals at 3431 and 2925 cm^{-1} originated from the stretching vibrations of OH and CH_2, respectively. The strong absorption at 1635 cm^{-1} was attributed to the H−O−H angle vibration of water, because hemicellulosic polymers was usually reported to contain bound water. The absorptions at 1465, 1383, 1248, 1158, 1044, 989, and 897 cm^{-1} were the characteristic peaks of hemicelluloses. Among them, the two weak signals at 1158 cm^{-1} (the C−O−C vibration) and 989 cm^{-1} represented small amounts of arabinosyl side chains, which were only attached at positions of the xylopyranosyl backbone according to a previous study.[33] Moreover, the strong peak at 1044 cm^{-1} (the C−O, C−C stretching, or C−OH bending vibration) was a typical absorbance of xylopyranosyl units in hemicellulose, whereas the signal at 897 cm^{-1} was attributed to β-glycosidic linkages between monosaccharide units.[34−36] In addition, the signal at 1420 cm^{-1} was from the symmetric stretching vibration of glucuronic acid groups in side chains.

Structural Characterization by NMR Analysis. The attributions of structural residues with different substitution patterns in the polysaccharide were determined by quantitative ^{1}H NMR (Figure 1A) and ^{13}C NMR (Figure 1B) spectra, along with HSQC spectrum (Figure 1C) and single-bond (COSY) and multiple-bond (TOCSY) proton−proton correlations and HMBC spectra (Figure S4 in the Supporting Information). In the HSQC spectrum (Figure 1C), the anomeric region of ^{1}H is from 4.3 to 5.5 ppm, whereas the corresponding ^{13}C is in the range of 90−110 ppm. The obtained assignments were confirmed according to the previous reports on hemicellulosic heteroxylan and summarized in Table 2. Consistent with the result of linkage analysis, β-1→4-linked xylopranosyl units were characterized to be dominant in ACAP by five primary peaks at 101.6 (4.38), 72.6 (3.17), 73.6 (3.45), 72.7 (3.68), and 62.9 (4.01 and 3.28) ppm, which were assigned to C1 (H1), C2 (H2), C3 (H3), C4 (H4), and C5 (H5) of the β-D-Xyl*p* units, respectively. In addition, weak signals of α-4-*O*-MeGlc*p*A and T-α-L-Ara*f* were identified to be in the side chains of β-D-Xyl*p* backbone from the present spectra (Table 2). The results of linkage analysis, FT-IR

spectrum, and NMR analysis also indicated that ACAP contained no $-OCH_3$ group, which was different from other hemicellulosic heteroxylans. According to previous studies, hemicellulosic xylan often contains large amounts of $-OCH_3$ groups on the *O*-2 and/or *O*-3 sites of the xylan backbone. This difference might be explained by the fact that the alkali extraction procedure might result in the hydrolysis of potential $-OCH_3$ groups in ACAP. Additionally, the above result indicated that T-D-Glc*p*A existed in the ACAP molecule as the form of *α*-4-*O*-MeGlc*p*A. According to the present results and previous literature on the structure of hemicellulosic xylan,[37−39] the primary structure of ACAP could be deduced as a *β*-1→4-D-Xyl*p* backbone with small amounts of *α*-4-*O*-MeGlc*p*A and T-*α*-L-Ara*f* in the side chains on the *O*-2 and *O*-3 sites, respectively (Figure 2).

Microscopic Morphology of ACAP. Morphological information is important to illustrate the fine structure of macromolecules intuitively. In the present study, TEM analysis was conducted to further observe the microstructure of ACAP. As shown in Figure 3, both single chain and entangled chain were observed in ACAP molecules under the experimental conditions. Similar to the triple-helical conformation of lentinan, ACAP molecules trended to form entangled chains, which contained even more than three single chains as shown in Figure 3A. Moreover, the approximately linear structure with minor branches from Figure 3B was consistent with the above results of methylation and NMR analysis.

Thermal Decomposition Analysis. The applicability of polysaccharide is also largely dependent on its thermal behavior. Thermal degradation characteristics of ACAP were determined from the curves of thermal gravity, differential thermal gravity, and second-time derivatives (TG, DTG, and D^2TG) in the temperature range of 50−600 °C. As shown in Figure 4A, two steps of weight loss occurred in the thermogravimetric analysis. The major decomposition of polysaccharide structure occurred at 200−350 °C, because about 70% of the weight was lost within this temperature range. In addition, minor weight loss (∼7%) occurred in the 50−150 °C range due to the loss of trapped water. Therefore, the weight at 150 °C was defined as 100% dry weight for the next degradation analysis of ACAP.

Three different heating rates were applied to identify the thermal degradation parameters of ACAP in the 150−600 °C range (Figure 4B) and deduced to a β value of 0 for each of the three temperatures (Figure 4C). The degradation characteristics are summarized in Table 3, where the parameters T_o, T_p, and T_s represent the onset, maximum, and shift decomposition temperatures, respectively, whereas WL_o, WL_p, and WL_s indicate the corresponding weight loss percentage parameters. As indicated in Table 3, the maximum degradation rate was observed at 278.6 °C (T_p) with a weight loss of 21.81% on a dry weight basis (WL_p), whereas ACAP experienced a rapid degradation in a narrow temperature range from the transition of T_p to T_s.

The apparent activation energy (E_a) and pre-exponential factor *A* were obtained by the isoconversional FWO method (Figure 5) at a conversion range from 0.3 to 0.7 with a 0.1 increment. The average E_a value was calculated as 220.0 kJ/mol, whereas the experimental ln *A* was obtained by the compensation effect relationship as eq 3 (Table S1 in the Supporting Information). The compensation parameters of *a* and *b* were obtained from a plot of ln *A* versus E_a (Figure S5 in the Supporting Information) using the Coats−Redfern equation (eq 4) (Table S2 in the Supporting Information).

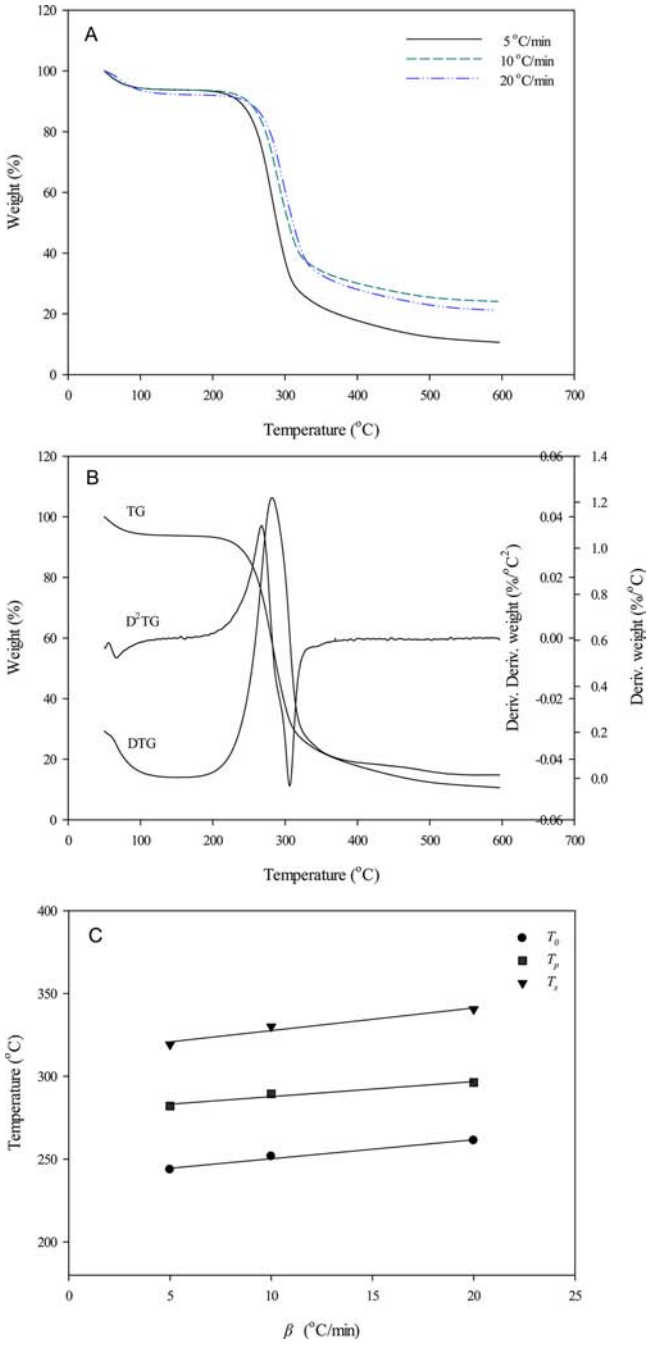

Figure 4. Thermal decomposition analysis of ACAP: (A) TG curves of ACAP at different heating rates; (B) determination of thermal decomposition parameters of ACAP at a heating rate of 5 °C/min; and (C) thermal degradation parameters of ACAP at different heating rates.

Compared with the single-heating rate method, the isoconversional method provides more accurate values of E_a and *A*.[40] Therefore, the obtained thermal kinetic parameters had greater practical value to comprehend and predict the thermal degradation process of ACAP. The thermal analysis has been widely performed on cellulose and hemicellulose to obtain the degradation characteristics.[41,42]

The pyrolysis range of ACAP (238.8−314.0 °C) was found to be consistent with a previous study of several isolated natural polysaccharides, the major weight loss of which occurred in the range of 225−325 °C.[41] In this temperature range (238.8−314.0

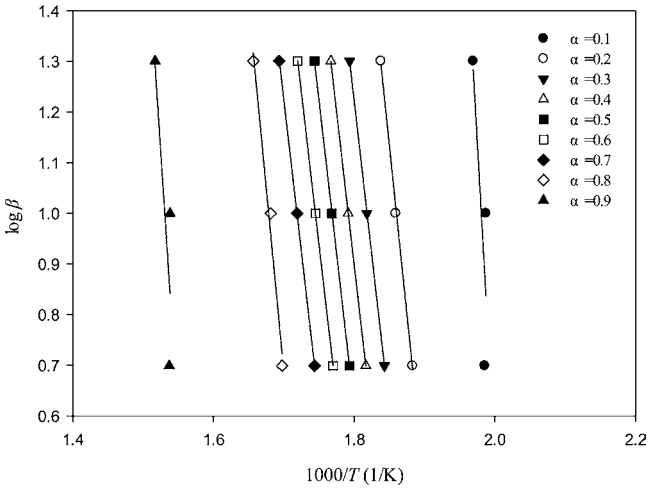

Figure 5. Typical isoconversional plot of Flynn–Wall–Ozawa (FWO) method at different conversion rates.

°C), most of the ACAP (54.37%, Table 3) decomposed to volatiles, including CO, CO_2, CH_4, CH_3COOH, and HCOOH, according to the literature.[31,43] Moreover, the E_a value of ACAP was determined to be 220.0 kJ/mol, which indicated the good thermal stability of this hemicellulosic heteroxylan. Among these thermal parameters, E_a might indicate a minimum energy requirement to initiate the degradation reaction, with a lower E_a value associated with a lower thermal degradation temperature. These thermal kinetic parameters, including the experimental E_a and A, may also be important for thermal stability evaluation and shelf life prediction of the related polysaccharide products. In other words, the thermal kinetic parameters of ACAP might be important for determining its future applications.

Anti-inflammation Effects of ACAP. ACAP was able to suppress the LPS-induced mRNA expressions of IL-1β, IL-6, and COX-2 genes in the cultured RAW 264.7 macrophage cells under the experimental conditions (Figure 6). The suppression was dose-dependent for IL-1β and IL-6 mRNA expressions, but not for COX-2 gene expression. As shown in Figure 6A, 73.98% of IL-1β mRNA expression was suppressed by ACAP at the final treatment concentration of 50 μg/mL, whereas the IL-1β mRNA expression was reduced to 56.80% at 10 μg/mL. ACAP at 10 μg/mL reduced the LPS-induced IL-6 mRNA expressions and showed a stronger inhibition effect by 49.38% compared to that at 50 μg/mL by 31.79% (Figure 6B), suggesting that concentration or dosage may be critical for a desired level of inhibition on IL-6 mRNA expression. Moreover, its inhibitory effects on COX-2 mRNA expression were 20.86 and 26.18% at 50 and 10 μg/mL final treatment concentrations (Figure 6C), respectively. These results suggested that ACAP might be further developed as a potential functional food ingredient to reduce the risk of inflammation related chronic human diseases.

Hemicelluloses have attracted more and more interest for their environmentally friendly and biosafety properties. Nowadays, hemicellulose has been extensively developed as an important

biomass in several important fields, including materials, energy, medical, and food industries.[37,44,45] Alfalfa stem contains

DOI: 10.1021/acs.jafc.5b00063
J. Agric. Food Chem. 2015, 63, 2970–2978

abundant hemicellulosic polysaccharides, but little is known about their chemical structures and functionalities at the molecular level. The structural study of alfalfa polysaccharides remained at the level of the 1960s, which only revealed the monosaccharide composition and partial glycosidic linkages[3,4] without detailed structural features due to the restriction of prevailing technique and equipment. Elucidation of the structure, pyrolysis features, and anti-inflammatory bioactivity will facilitate the further application of hemicellulosic polysaccharides from alfalfa stem.

In summary, a new hemicellulosic polysaccharide (ACAP) was purified from the cold alkali extract of alfalfa stem and characterized as a heteroxylan, with a molecular weight of 7.94 × 10^3 kDa and a radius of 58 nm. ACAP contained a β-1→4-linked D-Xyl*p* backbone with 29% short side chains of 4-*O*-MeGlc*p*A and T-L-Ara*f* units at the *O*-2 and *O*-3 branching points, respectively, and had entangled chains. ACAP showed excellent thermal stability with a key decomposition in 238.8−314.0 °C (the extrapolated temperatures) and apparent activation energy E_a and pre-exponential factor *A* values of 220.0 kJ/mol and 2.81 × 10^{24}/s, respectively. The thermal characteristic parameters provided a simplified approach to evaluate the thermal decomposition behavior of ACAP in food or industrial applications. In addition, ACAP significantly inhibited the mRNA expressions of the pro-inflammatory cytokine genes, especially for IL-1β, suggesting its potential anti-inflammatory effect. These results suggested the potential application of ACAP in functional foods and dietary supplement products.

known as the lipogenic transcription factors.[18] Therefore, we hypothesized that chitosan might inhibit lipogenesis-related protein/gene expressions induced by obesity through an AMPK-regulated signaling pathway. In the present study, high-fat (HF) diet-fed rats were used as an in vivo obesity model to clarify the mode of action and the possible mechanism of chitosan in lipid responses and lipid-related metabolic changes.

MATERIALS AND METHODS

Materials. High molecular weight (HMW) chitosan was purchased from Taiwan Tanabe Seiyaku Co. (Taipei, Taiwan). Chitosan was prepared by processing crab shell, which involves demineralization, deprotienization, and deacetylation. The measurements of average molecular weight (MW) and degree of deacetylation (DD) of chitosan were determined by high-performance liquid chromatography and Fourier transform infrared spectroscopy, respectively. The detection of viscosity was performed on chitosan dissolved in 0.1 N HCl solution by a viscometer (CV20, Haake Mess-Technik GmbH Co., Karlsruhe, Germany). The DD of chitosan was about 89.8%, and the average MW and viscosity of chitosan were about 560 kDa and 33 cP, respectively. Cellulose was obtained from Sigma Chemical Co. (St. Louis, MO, USA).

Animals and Diets. Male, 6-week-old Sprague−Dawley rats were purchased from BioLASCO Taiwan Co., Ltd. (Taipei, Taiwan). Rats were fed a chow diet (Rodent Laboratory Chow, Ralston Purina, St. Louis, MO, USA) for 1 week, and then the animals were randomly divided into two groups: a control group that received standard rodent diet with 5% cellulose (ND) and a HF group that received a HF diet with 5% cellulose. After 4 weeks of acclimation, the rats that received a HF diet were further randomly divided into four groups: (1) HF-diet-fed rats with 5% cellulose, (2) HF-diet-fed rats with 3% HMW chitosan (HF diet+3%CS), (3) HF-diet-fed rats with 5% HMW chitosan (HF+5%CS), and (4) HF-diet-fed rats with 7% HMW chitosan (HF+7%CS). Each group contained eight animals. The compositions of the experimental diets given to test animals are shown in Table 1. Rats were housed in individual stainless steel cages in a room kept at 23 ± 1 °C and 40−60% relative humidity with a 12 h light and dark cycle (lighting from 8:00 a.m. to 8:00 p.m.). The body weight was measured every week. After the 7 week feeding study, the animals were sacrificed. This study was approved by the Animal House Management Committee of the National Taiwan Ocean University (permission no. ACUC98045). The animals were maintained in accordance with the guidelines for the care and use of laboratory animals as issued by the Animal Center of the National Science Council.

Table 1. Composition (Percent) of Experimental Diets[a]

ingredient	ND	HF	HF+3%CS	HF+5%CS	HF+7%CS

cholesterol		0.5	0.5	0.5	0.5
choline chloride	0.2	0.2	0.2	0.2	0.2
cholic acid		0.2	0.2	0.2	0.2
corn starch	65.8	53.1	53.1	53.1	51.1
cellulose	5	5	2		
chitosan[d]			3	5	7

[a]ND, normal control diet; HF, high-fat diet; HF+3%CS, HF + 3% chitosan; HF+5%CS, HF + 5% chitosan; HF+7%CS, HF + 7% chitosan. [b]AIN-93 vitamin mixture. [c]AIN-93 mineral mixture. [d]The average molecular weight and viscosity of chitosan were about 5.6 × 10^5 Da and 33 mPa·s, respectively. The degree of deacetylation was about 89.8%.

Collection of Feces and Tissue Samples. At the end of the experimental period, animals were fasted for 12 h prior to being sacrificed by exsanguination via the abdominal aorta while under carbon dioxide anesthesia. The liver and epididymal and perirenal white adipose tissues from each animal were excised, dried, weighed, flash-frozen, and stored at −80 °C until biopsy. Feces were collected for three consecutive days before euthanasia and stored at −80 °C until lipid content analysis was performed.

Triglyceride (TG) and Total Cholesterol (TC) Determination. The levels of hepatic and fecal TG and TC were measured as described previously by Carlson and Glodfarb.[19] Briefly, 0.2 g of liver or feces was mixed with 4 mL of chloroform/methanol (2:1, v/v). The chloroform layer was collected and concentrated in a Speed Vac Sc 110 rotary evaporator (Savant, Farmingdale, NY, USA). After the addition of Triton X-100, the sample was assayed with TG enzymatic kits (Audit Diagnostics, Cork, Ireland) and TC enzymatic kits (Audit Diagnostics) according to the manufacturer's instructions.

Determination of Hepatic Lipid Metabolism Enzymes. Hepatic fatty acid synthase (FAS) and acetyl-CoA carboxylase (ACC) were assayed as described previously by Nepokroeff et al.[20] and Mohan and Kekwick,[21] respectively. HMGCR reductase was determined as described previously by Edwards et al.[22] The enzyme activities were determined by the rate of nanomoles of NADPH increased.

Lipolysis Rate Measurement. Adipose tissue (0.2 g) was minced into small pieces and placed in 2 mL of 25 mM *N*-tris-(hydroxymethyl)methyl-2-aminoethanesulfonic acid buffer containing 1 μM isoproterenol and incubated at 37 °C. Isoproterenol produced a dose-dependent increase in lipolysis. There was a time-dependent increase in lipolysis. After 1, 2, and 3 h of incubation, 0.2 mL of medium was used to measure the levels of glycerol by a commercial reagent (RANDOX GY105, Amtrim, UK), and then the absorbance at 520 nm was recorded using a spectrophotometer. The lipolysis rate was indicated by micromoles of glycerol released per gram of tissue per hour.

Lipoprotein Lipase (LPL) Activity. LPL activity in adipose tissue was measured as described previously by Kusunoki et al.[23] Adipose tissue (0.1 g) was minced into small pieces and placed in Krebs−Ringer bicarbonate buffer (pH 7.4) in the presence of heparin (10 units/mL) for 60 min at 37 °C. The heparin solution was mixed with an equal volume of 2 mM *p*-nitrophenyl butyrate (pNPB). Absorbance at 400 nm was recorded following a 10 min incubation using a spectrophotometer. LPL activity was recorded as the amount of *p*-nitrophenol product formed over the 10 min incubation.

Histological Examination. Epididymal white adipose tissue was fixed with 10% formalin and paraffin embedded. Standard sections of 5 μm were mounted on glass slides and stained with hematoxylin and eosin (H&E). The sections were observed and photographed with an Olympus BX51 light microscope (Olympus, Tokyo, Japan). Three H&E sections of each group were selected, and three random fields of each section were used to measure adipocyte area by ImageJ software, which is represented as the average adipocyte area.

Western Blot Analysis. Total protein containing 50−100 μg was separated on 10% sodium dodecyl sulfate (SDS)−polyacrylamide minigels and transferred to polyvinylidene difluoride membranes (Millipore, Billerica, MA, USA). After blocking, blots were incubated with antibodies for phosphorylated AMPKα (p-AMPKα), AMPKα (Cell Signaling Technology, Danvers, MA, USA), microsomal triglyceride transfer protein (MTTP), angiopoietin-like 4 (Angptl4), GAPDH, PPAR-γ, β-actin (Santa Cruz Biotechnology, Santa Cruz, CA, USA), apolipoprotein E (ApoE) (Bioss Antibodies, Woburn, MA, USA), and SREBP1c (Proteintech Group, Chicago, IL, USA) in phosphate-buffered saline (PBS)/Tween-20 for 1 h, followed by two washings in PBS/Tween-20, and then incubated with horseradish peroxidase-conjugated goat anti-mouse or anti-rabbit IgG for 30 min. Moreover, GAPDH served as a control for sample loading and integrity. The antibody-reactive bands were revealed by the enhanced

chemiluminescence kit (BioRad Laboratories, Redmond, WA, USA) and were exposed to Kodak radiographic film.

Quantitative Reverse Transcription Polymerase Chain Reaction (qRT-PCR) Analysis. Total RNA was extracted from the liver and epididymal fat tissues using Trizol (Invitrogen, Carslbad, CA, USA) and was reverse-transcribed to cDNA using a MMLV High Performance Reverse Transcriptase kit as recommended by the manufacturer (Epicentre, Madison, WI, USA). The sequences of the designed primers are shown in Table 2. GAPDH was used as an internal control. The resultant cDNA was stored at −20 °C until commencement of the qRT-PCR procedures. For qRT-PCR, the reaction was done on StepOne Real-Time PCR Systems (Applied Biosystems, Life Technologies, Grand Island, NY, USA) to check the expression using Maxima SYBR Green/ROX qPCR Master Mix (Thermo Scientific, Waltham, MA, USA). Relative quantification of gene expression was performed by using the comparative threshold cycle method (ΔΔCT), in which the expression level of each target gene was normalized to the levels of GAPDH. Data output was expressed as fold changes of mRNA expression levels, given by $2^{-\Delta\Delta CT}$.

Statistical Evaluation. Results are given as mean ± standard deviation (SD) values. The significant difference from the respective controls for each experimental test condition was assessed by one-way analysis of variance (ANOVA) and two-tailed Student's *t* test. The statistical software SPSS for Windows version 10.0.7C (SPSS, Chicago, IL, USA) was used.

RESULTS

Effects of Chitosan on Lipid Responses and Lipid-Related Metabolic Changes in HF-Diet-Fed Rats. During the obesity induction period (first 4 weeks), the body weights of HF-diet-fed rats were significantly higher than those of ND-fed rats, and supplementation of 7% chitosan could efficiently decrease the increased body weights in HF-diet-fed rats throughout the rest of the 7 weeks (HF+7%CS vs HF, a decrease of 9.13%, $p < 0.05$) (Figure 1 and Table 3). In addition, rats fed a HF diet supplemented with chitosan (3, 5, and 7%) had lower liver weights, and a significant reduction (HF+7%CS vs HF, a decrease of 18.18%, $p < 0.05$) in adipose tissue weights was exhibited only in the HF diet + 7% chitosan group (Table 3). There were no significant changes in plasma TC levels of all tested groups. The plasma TG of HF-diet-fed rats exhibited a decreased level as compared to the ND group, which could be significantly reversed by chitosan (3, 5, and 7%) supplementation (Table 3).

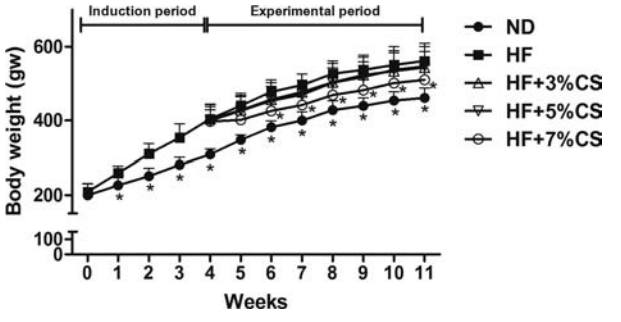

Figure 1. Effects of chitosan on body weights of HF-diet-fed rats. The changes of body weights in rats fed the HF diet in the presence or absence of chitosan (3−7%) during induction period (weeks 0−4) and experimental period (weeks 4−11) are shown. Results are expressed as the mean ± SD for each group ($n = 8$). (*) $p < 0.05$ as compared with the HF-diet group.

The effects of chitosan on adipose tissue characteristics are shown in Figures 2 and 3. Rats fed the HF diet showed a significant increase (29.74%, $p < 0.05$) in cell size of epididymal adipose tissues, and supplementation of 5 and 7% chitosan could significantly suppress hypertrophic adipocyte formation (adipose cell size: HF, 36.45 ± 3.03 μm^2; HF+5%CS, 29.5 ± 2.67 μm^2; HF+7%CS, 21.25 ± 1.85 μm^2) (Figure 2B). Moreover, the TG level (Figure 3A) and the LPL activity (Figure 3B) in epididymal fat of HF-diet-fed rats were elevated, and the rate of lipolysis (Figure 3C) was contrarily diminished. Supplementation of 7% chitosan in the diet significantly raised the lipolysis rate and decreased the accumulation of TG and the LPL activity.

We next tested the levels of TG and TC in the livers and feces. As shown in Figure 4 and Table 4, the livers/feces of the HF-diet-fed rats supplemented with chitosan (3, 5, and 7%) contained significantly less/more TC than the HF-diet-fed control rats. The TG levels were also decreased by 27.68% ($p < 0.05$) in the livers of the HF+7%CS group and increased in the feces of chitosan-supplemented groups (HF+CS7% vs HF, an increase of 46.88%, $p < 0.05$). Furthermore, the increased hepatic enzyme activities of lipid biosynthesis (acetyl-CoA carboxylase, fatty acid synthase, and HMG-CoA reductase) in HF-diet-fed rats could also be efficiently ameliorated by chitosan (7%) supplementation (Figure 4).

We next examined protein expressions of Angptl4, MTTP, and ApoE, which are known to be involved in TG metabolism.[24−26] The inhibitions of Angptl4, MTTP, and ApoE protein expressions were observed in the plasma and liver of HF-diet-fed rats, which could be significantly reversed by chitosan supplementation (Figure 5).

Effects of Chitosan on Lipogenesis-Related Factors in Livers and Adipose Tissues of HF-Diet-Fed Rats. AMPK is known to play an important role in regulating lipid metabolism of the liver and adipose tissue.[15−17] We next investigated the effects of chitosan on AMPK-regulated lipogenesis-associated protein/gene expressions in HF-diet-fed rats. We found that the suppression of AMPK phosphorylation in livers (Figure 6) and adipose tissues (Figure 7) of HF-diet-fed rats could be significantly reversed by chitosan supplementation in a dose-dependent manner (HF+CS3, 5, and 7% vs HF, increases of 3.39-, 3.67-, and 4.98-fold in livers, respectively, $p < 0.05$ for all groups; increases of 0.5-, 1.3-, and 1.5-fold in adipose tissues, respectively, $p < 0.05$ for HF+5%CS and HF+7%CS). Supplementation of 7% chitosan in the diet could also significantly attenuate the HF-diet-increased protein expressions of PPARγ (Figures 6 and 7) and SREBP1c (Figures 6 and 7) in livers (HF+CS7% vs HF, decreases of 80 and 25% in

[a]Results are expressed as the mean ± SD for each group (n = 8). (*) $p < 0.05$ versus HF. [b]The adipose tissue weight is the sum of epididymal and perirenal white adipose tissue weight.

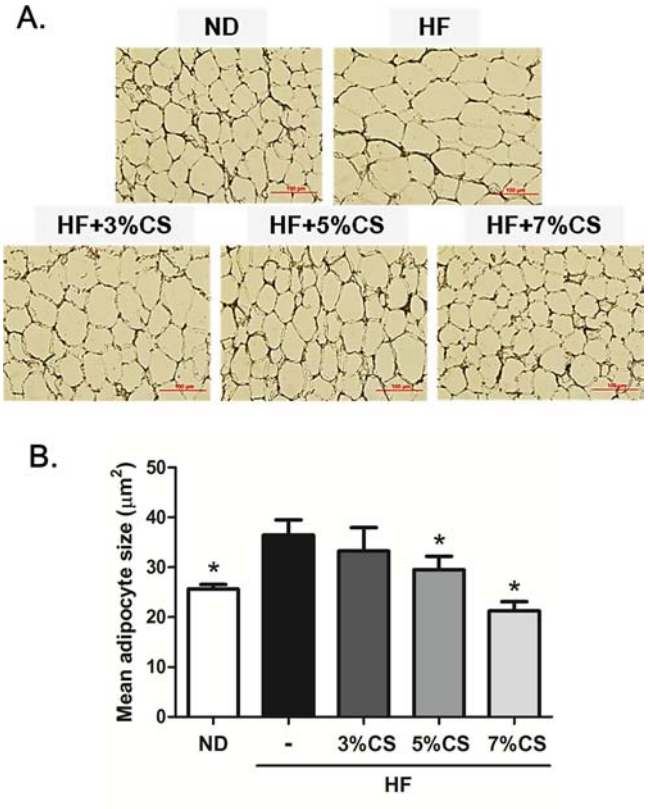

Figure 2. Effects of chitosan on adipocyte morphology of HF-diet-fed rats: (A) histological morphology of adipocytes; (B) mean adipocyte size. Histological analysis of epididymal white adipose tissues isolated from rats fed different experimental diets for 7 weeks is shown. Tissue sections were stained with H&E. Results are expressed as the mean ± SD for each group (n = 3). Scale bar = 100 μm. (*) $p < 0.05$ as compared with HF diet alone group.

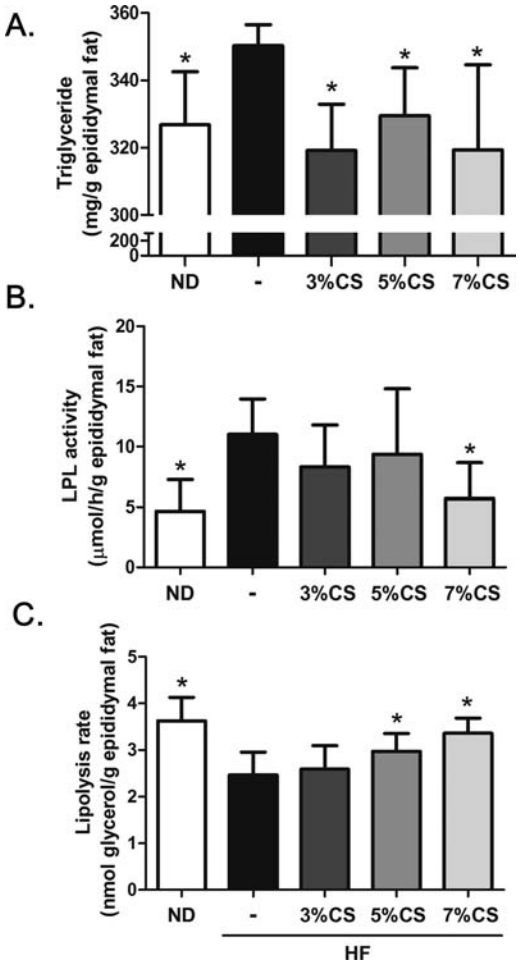

Figure 3. Effects of chitosan on adipose tissue characteristics of HF-diet-fed rats: levels of triglyceride (A), lipoprotein lipase (LPL) activity (B), and lipolysis rate (C) in epididymal white adipose tissues of Sprague−Dawley rats fed different experimental diets for 7 weeks. Results are expressed as the mean ± SD for each group (n = 8). (*) $p < 0.05$ as compared with HF diet alone group.

PPARγ and SREBP1c expressions, respectively, $p < 0.05$) and adipose tissues (HF+CS7% vs HF, decreases of 41 and 74% in PPARγ and SREBP1c expressions, respectively, $p < 0.05$).

Further investigations were carried out to determine the effect of chitosan on lipogenesis-associated gene expressions in livers or epididymal adipose tissues, such as *FAS*, *HMGCR*, *FATP1*, and *FABP4*. As shown in Figure 8, supplementation of 7% chitosan in the diet significantly inhibited the gene expressions in livers (*FAS* and *HMGCR*) (HF+CS7% vs HF, decreases of 67 and 62% in *FAS* and *HMGCR* expressions, respectively, $p < 0.05$; Figure 8A) and in adipose tissues (*FATP1* and *FABP4*) (HF+CS7% vs HF, decreases of 78 and 68% in *FATP1* and *FABP4* expressions, respectively, $p < 0.05$; Figure 8B) of HF diet-fed rats.

DISCUSSION

Chitosan is used as a dietary supplement against obesity because synthetic compounds exhibit some harmful side effects, including dry mouth, constipation, and insomnia.[18,27] Sumiyoshi and Kimura have indicated that low molecular weight chitosan prevents increases in body weights, white adipose tissue weights, and accumulation of liver lipids and enhances the fecal fat excretion in mice fed a HF diet.[28] Liu and colleagues have also shown that chitosan and its two derivatives, *O*-carboxymethyl chitosan and *N*-[(2-hydroxy-3-

Densitometric analysis for protein levels corrected to each internal control is shown. Results are expressed as the mean ± SD for each group (n = 4−6). (∗) $p < 0.05$ as compared with the HF diet alone group.

feces of HF-diet-fed rats. Although the association between chitosan and obesity has been well established, the detailed mechanism that links chitosan to lipid-related metabolic changes remains unclear.

Obesity develops due to an imbalance of lipid metabolism. Lipoprotein lipase and lipolysis rate are known to play important roles in TG metabolism. Lipoprotein lipase is an enzyme that hydrolyzes triglycerides of triglyceride-rich lipoproteins (such as very-low-density lipoprotein, VLDL) into nonesterified fatty acids and glycerol.[30] Lipolysis in the adipose tissue is modulated in a stepwise process by adipose triglyceride lipase (ATGL), hormone-sensitive lipase (HSL), and monoacylglycerol lipase (MAGL). The regulation is that ATGL initiates lipolysis by cleaving the fatty acids (FA) from triacylglycerol and then HSL and MAGL react on diacylglycerol and monoacylglycerol to release two additional FAs and one glycerol.[31] However, previous studies have shown that the HF diet dysregulates lipolysis and lipid metabolism, increasing LPL activities and decreasing lipolysis rates in visceral and subcutaneous adipocytes, which may promote adipocyte enlargement by facilitating TG accumulation in adipocytes.[23,32] The results of the present study were in agreement with those

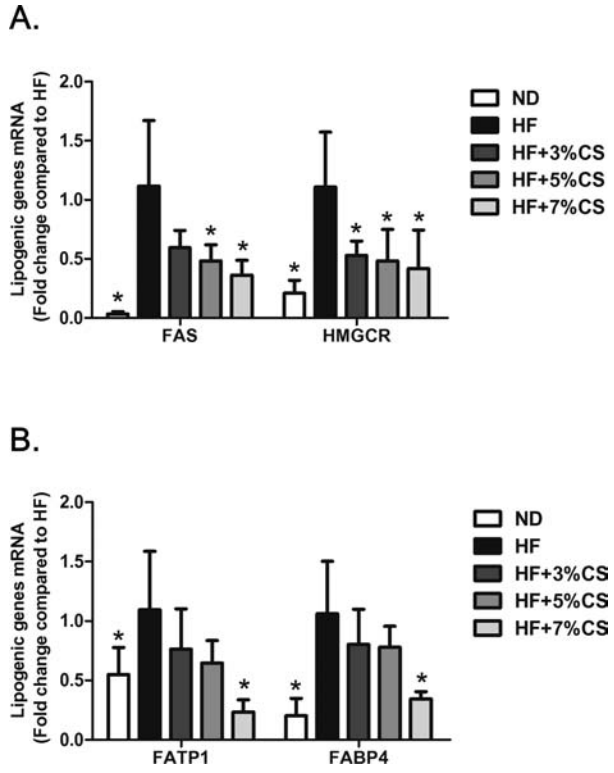

Figure 8. Effects of chitosan on lipogenesis-associated gene expressions in livers and epididymal white adipose tissues of HF-diet-fed rats. Gene expressions of livers (*FAS* and *HMGCR*) (A) and epididymal white adipose tissues (*FATP1* and *FABP4*) (B) were determined by qRT-PCR. Results are expressed as the mean ± SD for each group (n = 6). (*) $p < 0.05$ as compared with the HF diet alone group.

in the foregoing research that HF diet feeding suppressed the rate of lipolysis and elevated LPL activities, which may induce FA entry into adipose tissue, resulting in adipocyte enlargement. In addition, supplementation of 5 and 7% chitosan in the diet significantly reversed the dysregulation of lipid metabolism in HF-diet-fed rats.

In the present study, we found a paradoxically decreased plasma TG in HF-diet-fed rats. A decreased plasma TG has also been reported in HF-diet-fed mice, which may be owing to reduction of dietary carbohydrate.[33,34] Meugnier et al. have also found a significant decreased circulating TG level of lean men with fat overfeeding.[35] We further found that Angptl4, characterized as a suppressor of LPL in the plasma,[36] MTTP, which functioned as a transporter of TG in the liver,[37] and ApoE, acting as a VLDL-TG secretion enhancer in the liver,[38] were down-regulated by HF diet feeding, indicating it might result in TG accumulation in the liver. Administration of chitosan-supplemented diet (5 and 7%) could significantly reverse this phenomenon to the baseline level. These findings suggest that supplementation of chitosan in the diet may improve the altered lipid homeostasis induced by HF diet.

AMPK is a major regulator of cellular energy homeostasis (glucose and lipid metabolism) in the target tissues (liver, adipose tissue, and muscle).[39] AMPK can also phosphorylate and inactivate acetyl-CoA carboxylase (ACC) and HMGCR in the liver, which are the rate-limiting enzymes of fatty acid and sterol synthesis, respectively.[40] Additionally, AMPK is capable of down-regulating lipogenic transcription factor SREBPs, which regulates the lipogenesis-associated genes, including *FATP*, *FABP*, *FAS*, *ACC*, and *HMGCR*.[41,42] Moreover, PPARγ is known to be a key positive regulator of adipogenesis and TG storage in adipocyte. It has been demonstrated that AMPK exerts antiadiposity activity through the suppression of PPARγ in adipose tissue.[43] In the present study, we found that HF diet feeding inactivated the protein expression of AMPK and promoted the protein expressions of PPARγ and SREBP and the lipogenesis-associated gene expressions in the liver and adipose tissue. The significant increase of lipogenic tran-

scription factors and lipogenesis-associated genes results in promoting lipid synthesis in the liver and the abnormal accumulation of fat in the liver, which may refer to the fatty liver. Recent studies have suggested that the derivatives of chitin and chitosan (carboxymethyl chitin and chitosan oligosaccharides) exert the antiobesity effect on blocking lipid accumulation and inhibition of adipocyte differentiation via AMPK activation in 3T3-L1 adipocytes.[44,45] We further found that administration of a chitosan-supplemented diet, especially supplementation of 7% chitosan, was resistant to HF-diet-induced obesity and fat accumulation in the liver accompanying AMPK activation and suppressive expression of lipogenic transcription factors and lipogenesis-associated genes. On the other hand, leptin is an adipocyte-secreted hormone in proportion to white adipose mass. Obesity is known to be characterized by leptin resistance. Leptin is capable of stimulating the fatty acid oxidation via AMPK activation, which prevents lipid accumulation in nonadipose tissues.[43] Our previous study has found that chitosan can induce leptin secretion, which triggers the inhibition of liver gluconeogenesis via AMPK activation in streptozotocin-induced diabetic rats.[14] Therefore, chitosan reversed the inhibition of HF diet on AMPK activity through the induction of leptin secretion. In general, it would be reasonable to assume that AMPK is necessary for inhibition of lipogenic transcription factors and downstream target lipogenic genes in the liver and adipose tissue. Chitosan can serve as an antiobesity functional food for control of lipid accumulation in the liver and the adipose tissue via AMPK activation.

In the present study, we found that the abdominal (epididymal and perinephrial) adipose tissue weights and blood TC levels were not changed, but TG exhibited a decreased level in HF-diet-fed (15% lard + 0.5% cholesterol) rats for 11 weeks as compared to the ND-fed rats. Takeuchi et al. have shown that the weights of abdominal (epididymal, perinephrial, and mesenteric) adipose tissue in rats are not affected by feeding a lard fat-containing (20% lard) diet for 12 weeks as compared with dietary vegetable oils.[46] Bronkowska et al. have found that the blood level of TC, but not TG, in rats fed a lard-containing diet (15% lard + 1% cholesterol) for 28 days is higher than in rats receiving the diet containing vegetable oil.[47] However, Li et al. have shown that the blood TG contents in rats fed a HF diet (10% lard + 1% cholesterol) are higher than those of rats receiving ND on day 6, but the TG contents drop to a statistically significant level lower than ND-fed rats on day 42.[48] Moreover, Águila et al. have found that the serum TC levels are not changed, but serum TG levels are significantly decreased in rats long-term (45 weeks) fed a HF diet (29% lipids—lard + egg yolk) as compared with rats fed a soybean oil-containing diet.[49] These previous and our findings indicate that the different experimental conditions or parameters for HF diet may affect the changes in blood lipid profile in experimental animals.

During obesity, there is an increase in adipocyte size by abnormal TG accumulation, which is not only associated with FA biosynthesis but also with the regulation of FA fluxes, including fatty acid transport proteins (FATPs) and fatty acid binding proteins (FABPs).[3,50] The putative mechanism of lipogenesis in adipocytes during obesity is that excess insulin activated LPL located on the cell surface of vascular endothelium, and activated LPL removes FA from chylomicron and VLDL into adipocytes through fatty acid transporters, such as FABP and FATP. FA is subsequently esterified into triglycerides, leading to adipocyte hypertrophy.[51] FATP1, the first member of FA transport proteins, is mostly expressed in adipose tissue and also present in muscle. It is reported that mice with whole body deletion of FATP1 (*fatp1*−/−) are protected from HF-diet-induced obesity and insulin resistance.[52] Once FAs have crossed the membrane, they are transported by FATPs and bound by cytoplasmic FABPs. FABP4 is highly expressed in adipose tissue and also one of the most abundant proteins in mature adipocytes.[53] Several studies have shown that deficiency of FABP4 expression protects mice from dietary or genetic obesity-induced metabolic syndrome, such as hypercholesterolemia, insulin resistance, and atherosclerosis.[54−56] In the present study, we found that supplementation of chitosan in the diet significantly decreased the mRNA expression of *FATP1* and *FABP4* in epididymal adipose tissues and alleviated the levels of TG in epididymal adipose tissues. It is therefore plausible that chitosan attenuated adipocyte hypertrophy via inhibiting FA synthesis and uptake. On the basis of evidence presented in this study, we conclude that a postulated mechanism for the lipid regulation of chitosan is that chitosan activates AMPK phosphorylation and sequentially suppresses downstream expression of lipogenic transcription factors and lipogenesis-associated genes, which can attenuate TG accumulation and lipid biosynthesis in the liver and adipose tissues.

inflammatory[15,16] and anticarcinogenic properties.[17] In this context, the consumption of fruit pomaces or extracts produced from them ensures exhaustive utilization of the biological potential of the harvested fruits.

The main component of strawberry ellagitannins is dimeric GOG type agrimoniin built of two monomeric units of α-1-*O*-galloyl-2,3:4,6-bis-HHDP-D-glucose that are linked by two residues of gallic acid with a C−O−C bond.[10,18] In turn, raspberries contain sanguiin-H-6 and lambertianin-C,[19] the monomeric units that are linked with a sanguiinsorboyl group.[18] This difference in the structure of ellagitannins may affect the physiological effect of polyphenols of Rosaceae family fruits as well as byproducts of fruit processing and seeds used for oil production. It is a novel product so far little recognized in terms of composition and physiological properties.

In the context of the above overview of the literature, the goal of this study was to enrich knowledge about the chemical composition of interesting and rich in dietary fiber ellagitannins, byproducts of fat carbon dioxide supercritical extraction of strawberry and raspberry seeds, and to identify the local and systemic physiological effects of such products on intestinal functions, blood glucose level, and selected blood markers of lipid metabolism of experimental rats.

MATERIALS AND METHODS

Recovery of Seeds and Their Defatting Using SFE. Strawberry and raspberry seeds after removal of oils by CO_2 supercritical extraction constituted research material. Seeds were separated from industrial residues of juice production. Seeds (300 g) were crushed in a roller crusher in a CO_2 atmosphere to the particle size of 0.4−0.6 mm and immediately placed in a supercritical extractor. The plant (NCSI) was composed of the extractor with 1 dm^3 volume, two separators with separation capacity up to 500 bar (S_1) and up to 100 bar (S_2), circulating pump, condenser, and CO_2 tank. The following conditions were used: extraction pressure, 200, 250 bar; I grade separation level pressure, 53 bar; temperature of the inlet, T_w, 40 °C; mass of raw material, 300 g; flow rate, Q_{CO_2}, 6.0−7.0 kg (one cycle duration = 180−210 min).

Analyses of Preparations. *Basic Composition.* AOAC methods[20] were used: dry matter and ash, 940.26; protein, 920.152; crude fat, 930.09; TDF, 985.29; IDF, 991.42.

Polyphenols. Extraction of polyphenols was carried out according to the method in ref 1 using 70% acetone. To 500 mg of the material was added 4 mL of a solvent, which was mixed, sonified for 15 min, and centrifuged at 800 rad/s, and the solution was decanted. The procedure was repeated twice. The solutions were combined, and the acetone was evaporated by the use of a vacuum rotary evaporator. Residue was dissolved in 2 mL of 70% glycerol and analyzed with HPLC.

Sum of Ellagitannins (ET). The released ellagic acid (EA) was computed from the difference between the contents of total and free EA. The total ET, expressed per monomer α-1-*O*-galloyl-2,3:4,6-bis-HHDP-D-glucose, was calculated by multiplying the content of released EA by a conversion factor of 1.55, which takes into account the molar content of EA in α-1-*O*-galloyl-2,3:4,6-bis-HHDP-D-glucose, a monomer unit of agrimoniin.[1] Half a milliliter of a 70% glycerin solution and 0.075 mL of trifluoroacetic acid (Fluka) were added to 0.15 g of the sample. The components were mixed and kept at a temperature of 95 °C for 18 h. After hydrolysis, the samples were filled to 5 mL with methanol, filtered through syringe Teflon filters with a pore size of 0.45 μm (Millipore, Bedford, MA, USA), and analyzed with HPLC.

Polyphenol HPLC Analysis. A Smartline (Knauer, Berlin, Germany) chromatograph with a PDA detector was used. A Phenomenex Gemini 5u C18 110a (250 × 4.60 mm; 5 μm) column was kept at 35 °C. Eluent A contained 0.05% phosphoric acid in water, and eluent B contained 0.05% phosphoric acid in 80% (v/v) acetonitrile in water. Flow rate was 1.25 mL/min. Gradient was as follows: 0−5 min, 4% B; 5−12.5 min, 4−15% B; 12.5−42.5 min, 15−40% B; 42.5−51.8 min, 40−50% B; 51.8−53.4 min, 50−55% B; and 53.4−55 min, 4% B. The volume of injection was 20 μL. Detection conditions were as follows: 280 nm (agrimoniin, sanguiin-H-6, and lambertianin-C); 360 nm (ellagic acid, quercetin and kaempferol glycosides, quercetin, and kaempferol); 520 nm (anthocyanins). Standards used were ellagic acid, quercetin-3-*O*-glucoside, kaempferol-3-*O*-glucoside, quercetin, kaempferol, pelargonidin-3-*O*-glucoside, cyanidin-3-*O*-glucoside, kaempferol-3-*O*-β-D-(6″-*E*-*p*-coumaroyl)-glucopyranoside (Extrasynthese, Genay, France), agrimoniin, sanguiin-H-6, and lambertianin-C (see below).

Extraction and Purification of Agrimoniin, Sanguiin-H-6, and Lambertianin-C. The extraction of agrimoniin was carried out from strawberry pomace and that of sanguiin-H-6 and lambertianin-C from raspberry pomace before the separation of seeds, with 70% acetone. One hundred grams of pomace was treated with the solvent at a 1:14 weight ratio and left to macerate for 24 h. The solution was filtered through a filter paper, and acetone was evaporated by vacuum. The solution was loaded onto an Amberlite XAD-1600N column (8 cm × 2 cm), which was rinsed with 25 mL of water and eluted with 50 mL of 60% ethanol. Purified 10 mL fractions were collected. Isolation of ETs was carried by the use of a Knauer chromatograph, composed of two pumps (Knauer K-501), a Phenomenex Luna 10u C18 100a (250 × 21, 20 mm; 10 μm) (Torrance, CA, USA) column, a UV−vis detector, and a Foxy R1 Teledyne ISCO (Lincoln, NE, USA) fraction collector.[7] The flow rate was 15 mL/min. Eluent A was 0.1% formic acid in water, and eluent B was 80% methanol. Gradient was as follows: 0−3 min, 20% B; 3−20 min, 20−35% B; 20−45 min, 35−70% B; 45−50 min, 70% B; 50−55 min, 70−20% B; and 55−60 min, 20% B. The volume of injection was 500 μL. Detection parameter was 280 nm. Agrimoniin, sanguiin-H-6, and lambertianin-C peaks were collected from 10 separations, then combined; methanol was removed by distillation, and the preparations were freeze-dried. The purity of agrimoniin at 280 nm was 96%, that of sanguiin-H-6, 92.5%, and that of lambertianin-C, 92.1%.

The molecular masses of agrimoniin, sanguiin-H-6, and lambertianin-C were confirmed by ESI-MS/MS detector. Water solution of the substance was directly injected into the MS detector (lCQ DECa, Thermo-Finnigan). The negative ion mode was used. The source parameters were as follows: ion spray voltage, 3.00 kV; capillary temperature, 325 °C; sheath gas and auxiliary gas, 30 and 10 units/min, respectively. To generate MS/MS data, the precursor ions were fragmented by helium gas collision in the ion trap by optimizing the collision energy to obtain an intensity of the precursor ion close to 10% of the relative scale of the spectrum.[18]

The main pseudomolecular ion [M − H] of agrimoniin H-6 was observed at 1869 (m/z), and the analysis of decomposition showed the presence of 1567, 1265, 935, 633, and 301 (m/z) fragment ions. The main pseudomolecular ion [M − H] of sanguiin-H-6 was observed at 1869 (m/z), and the analysis of decomposition showed the presence of 1235, 935, 933, 633, and 301 (m/z) fragment ions. The main pseudomolecular ion [M − H] of lambertianin-C was observed at 1401 $[M - 2H]^2$ (m/z), and the analysis of decomposition showed the presence of 1869, 1567, 1265, 1103, 933, 631, and 301 (m/z) fragment ions.

Proanthocyanidins and Free Catechins. Proanthocyanidin degradation in an acidic environment with an overdose of phloroglucinol was performed as in ref 21. To 20 mg of a sample was added 800 μL of a methanol solution containing phloroglucinol (75 g/L) and ascorbic acid (15 g/L). Phloroglucinolysis was started by adding 400 μL of 0.2 mol/L hydrochloric acid in methanol and was carried out for 30 min at the temperature of 50 °C and then stopped by adding 600 μL of a 40 mmol/L sodium acetate solution in an ice bath. The samples were centrifuged for 5 min at 500 rad/s and diluted with a 40 mmol/L sodium acetate solution. A Knauer Smartline chromatograph with a fluorescence detector (FD) RF-10AXL (Shimadzu, Tokyo, Japan) and a Phenomenex Gemini 5u C18 110a (250 × 4.60 mm; 5 μm) column was used. The gradient was as follows: 0−10 min, 4−7% B; 10−27 min, 7−30% B; 27−29 min, 30−70% B; 29−34 min, 70% B; 34−35 min, 70−4% B; and 35−40 min, 4% B. Phase A consisted of a 2.5%

DOI: 10.1021/acs.jafc.5b00648
J. Agric. Food Chem. 2015, 63, 2989−2996

water solution (v/v) of acetic acid, and phase B consisted of 80% (v/v) acetonitrile in water. The flow rate was 1 mL/min, and the temperature was 25 °C. The identification was conducted on the basis of the retention times of standards of (−)-epicatechin, (+)-catechin, (−)-epicatechin-phloroglucinol, and (+)-catechin-phloroglucinol. Quantitative analyses of released flavonols, namely, (+)-catechin and (−)-epicatechin, and phloroglucinol adducts were conducted on the basis of chromatograms recorded with the FD set at 278 nm excitation wavelength and 360 nm emission wavelength.

The mean degree of polymerization was determined on the basis of the molar ratio of all flavan-3-ol units, that is, adducts of phloroglucinol and terminal units to the sum of terminal units, which included (+)-catechin and (−)-epicatechin.

All of the analyses were performed in duplicate.

In Vivo Experiments. *Animals and Diets.* Experiments were conducted on 24 Wistar strain rats following the protocol approved by the Local Ethical Commission for Experiments on Animals in Olsztyn (permission no. 71/2012). The animals were maintained under standard conditions: temperature of 21−22 °C, relative air humidity of 50−70%, intensive ventilation of rooms (15×/h), and 12 h lighting. Individual body weights and food intakes were recorded. The experiment, conducted on three experimental groups (eight males each), lasted for 4 weeks from week 4 of age. All animals were housed individually in metabolic cages with free access to water and the experimental diets. Diets contained similar levels of protein, fat, minerals, and vitamins and a similar content of fiber. All of the diets were isocaloric.

Experimental diets were prepared as modified semisynthetic AIN-G93G diet[22] and differed only in the addition of defatted seeds of strawberries (strawberry) or raspberries (raspberry), introduced instead of a respective content of maize starch. The analyzed preparations were introduced into the diet at the same dose of 6%. The preparations introduced dietary fiber (4%), a small quantity of protein (<1%) and polyphenols (0.1%). A 1% addition of cellulose as an additional source of dietary fiber was administered to diets, whereas in the control diet cellulose content was 5%. The compositions of the experimental diets are summarized in Table 1. All diets contained 3% of fructooligosaccharides (FOS) added to reduce the potential negative effect of polyphenols on fermentative functions of the intestines.[23]

Table 1. Composition (Percent) of Diets

maize starch	64.0	61.7	61.5

[a]Experimental diets: strawberry, diet with defatted strawberry seeds; raspberry, diet with defatted raspberry seeds.

Analytical Procedures. Individual feed consumption and body weight gains of rats were determined. After 4 weeks of experiment, animals were weighed and anesthetized with sodium pentobarbitone. Blood samples were taken from the caudal vein. Serum was prepared by centrifugation at 300 rad/s for 15 min at 4 °C and stored at −40 °C. The concentrations of triacylglycerol (TG), total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), and glucose in the serum were determined with commercial diagnostic kits Alpha Diagnostics (Warsaw, Poland) and Pointe Scientific (Warsaw, Poland). The atherogenic index (AI) of a diet was calculated for each animal according to the formula AI = log(TG/HDL). The rats were then sacrificed by cervical dislocation. After laparotomy, the small intestine, cecum, and colon, including the contents, were taken from each rat. As soon as possible the small intestine, cecal, and colonic pH values were directly measured using a microelectrode and pH/ION meter (model 301, Hanna Instruments, Vila do Conde, Portugal). The small intestine was weighed with the contents. Samples of cecal and colonic digesta were then stored at −70 °C. The cecum and the colon were flushed clean with ice-cold saline, blotted on filter paper, and weighed. In cecal digesta samples, ammonia was extracted and trapped in a solution of boric acid in Conway dishes.[12] The activity of bacterial enzymes (α- and β-glucosidase, α- and β-galactosidase, and β-glucuronidase) in the cecum was measured by the rate of *p*- or *o*-nitrophenol release from their nitrophenylglucosides, according to the method described elsewhere.[23] The enzymatic activity was expressed as micromoles of product formed per an hour per gram of digesta. Cecal digesta samples were subjected to SCFA analysis, using GC (Shimadzu GC-2010, Kyoto, Japan). The samples (0.2 g) were mixed with 0.2 mL of formic acid, diluted with deionized water, and centrifuged at 800 rad/s for 10 min. The supernatant was loaded onto a capillary column (SGE BP21, 30 m × 0.53 mm) using an on-column injector. The initial oven temperature was 85 °C and was raised to 180 °C at 8 °C/min and held there for 3 min. The temperatures of flame ionization detector and the injection port were 180 and 85 °C, respectively. The volume of injection was 1 μL.

Dry Matter. The dry matter of small intestinal and cecal digesta was determined at 105 °C for 4 h.

Free Ellagic Acid and Metabolites in Cecal Digesta. Extraction of free ellagic acid and metabolites (urolithin-A and nasutin) was carried by the use of methanol and formic acid 99:1 (v/v) solution. To 500 mg of cecal digesta was added 2 mL of the solvent, which was mixed, sonified for 15 min, and centrifuged (800 rad/s). The procedure was repeated twice with 1.5 mL of the solvent. The extracts were combined and filled to 5 mL. For HPLC parameters, see Polyphenol HPLC Analysis. Detection was performed at 280 nm. Urolithin-A, a standard for the determination of EA metabolites, was used as described in ref 24. Nasutin-A and urolithin-A were the main EA metabolites of cecum digesta.[24]

Ellagic Acid Bound with Cecal Digesta. The content of ellagic acid bound with cecal digesta was determined by direct hydrolysis of ET adducts with proteins of digesta, extraction of released EA with methanol, and its analysis with HPLC. Half a milliliter of a 70% glycerin solution and 0.075 mL of trifluoroacetic acid (Fluka) were added to 0.15 g of cecal digesta. Next, the components were mixed and kept at a temperature of 95 °C for 18 h. After hydrolysis, the samples were filled to 5 mL with 100% methanol. The solution was centrifuged (900 rad/s) and analyzed with HPLC (see Polyphenol HPLC Analysis).

Statistics. Statistics were performed using a one-way ANOVA and Duncan's multiple-range tests at a significance level of $P \leq 0.05$ using STATISTICA 6.0 (StatSoft Corp., Kraków, Poland) software.

RESULTS

Chemical Composition of Strawberry and Raspberry Seeds. The main component of defatted seeds of strawberry and raspberry was the polysaccharide fraction, determined as total dietary fiber (Table 2). Compared to strawberry seeds, raspberry seeds contained less crude protein (10.4 vs 15.6%), less crude ash (1.8 vs 3.6%), more TDF (73.7 vs 68.6%) mainly in the insoluble form; and less total polyphenols (2.41 vs 1.75%).

The main components of the seed polyphenols were ellagitannins (ET), 0.97 and 1.76% in strawberry and raspberry seeds, respectively (Table 2). The contributions of ET in total polyphenols were 55 and 81%, respectively. Seeds were characterized by a significant content of proanthocyanidins, that is, 0.64% in strawberry and 0.37% in raspberry seeds. The

[a]Strawberry, defatted strawberry seeds; raspberry, defatted raspberry seeds. [b]Carbohydrates = dry matter − (ash + protein + fat + polyphenolics). [c]ET as ellagic acid released in hydrolysis × 1.55. [d]ET determined by HPLC. [e]Monomeric ET = ET total − (lambertianin-C + sanguiin-H-6 + agrimoniin). [f]DP, degree of polymerization.

degree of polymerization of these compounds reached 4 and 2, respectively. Contents of the remaining groups of polyphenols, flavonols and anthocyanins, were relatively low. The compared preparations differed in the composition of ellagitannins; in strawberry seeds the only non-monomer was dimeric agrimoniin, whereas in raspberry seeds non-monomers were sanguiin-H6 (dimer) and lambertianin-C (trimer). In addition, the monomeric ellagitannins represented 55% of strawberry seeds ET and barely 18% of raspberry seeds ET.

Diet Intake and Parameters of Rat Growth and Development. Dietary inclusion of seed preparations did not affect the final body weight of rats (Table 3). Diet intake was not affected by dietary treatments (data not shown). Compared to group C, in the animals from the strawberry and raspberry groups, analyses showed a lower mass of the small intestine with digesta ($P = 0.028$), lower mass of cecal digesta ($P = 0.004$), and higher dry matter content of cecal digesta ($P < 0.001$). No significant differences were demonstrated between the analyzed groups in pH value of the intestinal digesta.

Ellagitannin Metabolites in Intestinal Digesta. The cecal digesta of rats from the strawberry and raspberry groups were characterized by various contents of ellagic acid and ellagitannin metabolites (Table 4). In both groups, the main ET metabolite was nasutin (54 and 39 μg/g digesta in, respectively, in the strawberry and raspberry groups), followed by urolithin A (35 and 9 μg/g digesta, respectively). The sum of these ET metabolites in cecal digesta of rats from the strawberry group was almost 2-fold higher than in the raspberry group, but still the contribution of urolithin A in the sum of metabolites in the strawberry group reached 39%, whereas in the raspberry group, 19%. In addition, cecal digesta of rats were found to contain bound ellagic acid, that is, 1.31 and 2.35 mg/g in the strawberry and raspberry groups, respectively.

[a]Experimental diets: strawberry, diet with defatted strawberry seeds; raspberry, diet with defatted raspberry seeds. Values in rows with different letters are different at $\alpha < 0.05$.

Fermentation Processes in the Cecum of Rats. The applied dietary interventions had various effects upon the enzymatic activity of microflora of rat cecum (Table 5). Compared with the control group, a significant increase was determined in the activity of α-glucosidase in cecal digesta of rats from the strawberry and raspberry groups ($P = 0.078$), whereas no difference was demonstrated in the activity of β-glucosidase. Activities of α-galactosidase and β-glucuronidase were significantly higher in the strawberry group (both $P = 0.001$), and β-galactosidase activity was higher in both strawberry and raspberry groups than in the control group (C).

Compared to group C, a higher concentration of acetate was determined in cecal digesta of rats from the raspberry group (P

= 0.001) as well as higher concentrations of propionate and butyrate in the strawberry and raspberry groups (both P = 0.001). In terms of total SCFA concentration in cecal digesta, the order of groups was as follows: raspberry > strawberry > C, P = 0.001. Both groups administered diets with seeds showed decreased percentages of acetate (P = 0.004) and an increased contribution of butyrate (P = 0.008) in total SCFA, compared to group C.

Ammonia content in cecal digesta was significantly lower in the raspberry group than in the strawberry group (P = 0.018) and numerically higher compared to group C.

Biochemical Blood Markers. The study demonstrated various effects of the applied dietary interventions on the levels of the analyzed biochemical blood markers (Table 6). Fruit seeds content in the diet increased blood glucose level; however, a statistically significant (P = 0.005) difference was found only between raspberry and C groups. In the raspberry group lower concentrations of triacylglycerols and total cholesterol (P = 0.001 and P = 0.013, respectively) and a lower value of atherogenic index (P = 0.007) were shown.

DISCUSSION

Results of ample investigations proved that dietary fiber intake from vegetables and fruits is one of the key elements in prophylactics of human health, as implicated in reducing the risk of many diseases such as diarrhea, diabetes, obesity, ischemic heart disease, and colon cancers.[25] It results from a complex chemical structure of dietary fiber, its specific intestinal fermentation, and a wide spectrum of physiological effects.[26] An additional fact is that dietary fiber occurs in complexes with polyphenols, metabolized in the lower section of the gastrointestinal tract by gut microflora.[27] This release of polyphenols in the colon is believed to be a factor determining a lower incidence of chronic diseases in persons preferring consumption of food products made of whole cereal grains.[28] Moreover, the interaction between the gut flora and polyphenols is two-way: on the one hand, the ingested compounds modify the qualitative composition of the flora; on the other hand, 90−95% of the total intake of polyphenols (5−10% in ingested in the small intestine) reaches the colon, where they are metabolized by the colonic microbiota.[5] For

J. Agric. Food Chem. 2015, 63, 2989−2996

these reasons, a key element in the evaluation of the physiological properties of components rich in fiber−polyphenolic complexes is the assessment of the physiological response of the gastrointestinal tract and, most of all, the gut ecosystem.[23]

In the reported experiment, the main component of defatted seeds of strawberry and raspberry was the polysaccharide fraction, determined as total dietary fiber. The total protein content of the seeds was relatively low (10−15%). Compared with raspberry seeds, the strawberry seeds contained more crude protein and crude ash and less total dietary fiber, 15.6 vs 10.4% and 68.6 vs 73.7%, respectively, including soluble fiber (1.4 vs 6.1%). Similar results were obtained in earlier analyses of the chemical composition of strawberry, raspberry, and blackberry.[12,14] The higher crude ash content determined in strawberry seeds could be due to greater contamination of strawberry pomace with sand, as shown in the study.[10]

In the discussed experiment, the content of total polyphenols in raspberry seeds was significantly higher than in strawberry seeds (2.15 vs 1.75%). Compared to raspberry seeds, strawberry ellagitannins were characterized by a high concentration of monomers (56 vs 17% of total polyphenols) and the occurrence of agrimoniin only, whereas in raspberry seeds the ellagitannins were constituted mainly by sanguiin-H6 and lambertianin-C. The differences noted in contents of polyphenols in seeds corresponded to these determined in fresh fruits of raspberry and strawberry.[7,29] Results of earlier investigations have demonstrated that the main components of the polyphenolic fraction of strawberry and raspberry seeds are ellagitannins and proanthocyanidins[1,8,18,30] and that contents of anthocyanins and flavonols are negligible compared to the values assayed in fruits of these species.[6,8,16]

In the presented experiment, the content of strawberry and raspberry seeds in diet had no influence on feed intake and body weight gains of rats, but reduced the bulk of digesta in the small intestine and the cecum. This was, probably, due to the physiological effect of the dietary fiber of the seeds, which substituted for 4% of cellulose in the control diet. Studies of other authors demonstrate that insoluble dietary fiber accelerates gut peristalsis,[26] whereas soluble dietary fiber increases viscosity and delays transit of digesta.[31] One of the effects of increasing dietary fiber content in a diet may be increased hydration of digesta.[32,33] This was, however, not observed in our experiment in digesta with the content of fruit seeds. The concentration of dry matter was even increased; however, dry matter content in cecal digesta of the rats from strawberry and raspberry groups was lower than in the control diet in which cellulose was the component of the dietary fiber fraction.

The use of strawberry and raspberry seeds as substitutes for cellulose and part of the maize starch in the diet evoked tangible enhancement of α-glucosidase activity and a statistically significant increase in the activity of β-galactosidase, as well as, only in the case of strawberry seeds, a significant increase in α-galactosidase and β-glucuronidase activities. Consequently, an increase in SCFA concentration was observed in both experimental groups compared to the control group. Strawberry and raspberry seeds did not increase the concentration of acids with a branched chain (isobutyric and isovaleric). This was consistent with no effect of the content of fruit seeds in the diet on increasing ammonia concentration in cecal digesta. In the raspberry group, the concentration of ammonia in cecal digesta of rats was even lower than in the control group. Results of the presented experiment were in agreement with results obtained in other studies in which rats were administered diets with 10% content of defatted seeds of black currant, which resulted in enhanced glycolytic activity of intestinal microflora confirmed by increased SCFA production in cecal digesta.[13] This indicates that dietary fiber contained in strawberry and raspberry seeds was a distinctly better substrate than cellulose in fermentation processes proceeding in the cecum of rats. This is also confirmed by the reported increased production of propionate and, most of all, a significant increase in the content of butyrate in total SCFAs. It is known that SCFAs are rapidly absorbed and metabolized by various tissues, including liver (propionate and partly acetate), muscle (acetate), and intestinal epithelium (butyrate).[34] In this context, the higher production of butyrate in cecal digesta of experimental rats was a significant outcome of the presented experiment, because butyric acid is more effective in inducing the proliferation of intestinal epithelial cells than acetic acid.[35] Similar concentrations of isobutyric and isovaleric acids in intestinal digesta of the rats indicate that the contribution of strawberry and raspberry seeds in diet does not enhance bacterial proteolytic degradation, which results in the production of acid with a branched chain.[36]

Results of the previous study indicate that dietary polyphenols may reach any segment of the gastrointestinal tract in measurable quantities and modify the functioning of its ecosystem.[37] In the case of ellagitannins only trace amounts of these substances are absorbed in the stomach and small intestine;[38] however, the majority of these substances are metabolized by the intestinal microbiota.[39] According to this, the use of strawberry and raspberry seeds in diets caused the presence of metabolites of ellagic acid and ellagitannin, that is, urolithin and nasutin, in cecal digesta.

In the gastrointestinal tract of humans and some experimental animals, mainly urolithins were metabolites of ellagitannins.[27] In selected animals, such as beavers and pigs, dehydroxyellagic acid derivative, referred to as nasutin, was determined as an ET metabolite.[39] Also in cecal digesta of the rats from our experiment, the main metabolite of ellagitannin was nasutin (respectively 61 and 81% of total ET metabolites in the strawberry and raspberry groups), and urolithin A occurred in a lower quantity. A surprising outcome of the presented experiment was the fact that administration of the raspberry diet with a higher content of ellagitannins than in the strawberry group (1.76 vs 0.97%), resulted in lower concentrations of ET metabolites in cecal digesta (48 vs 89 μg/g). This indicates that strawberry ellagitannins, with a high contribution of monomers and dimer, agrimoniin, were more easily metabolized by cecal microbiota. The ETs contained in raspberry seeds were degraded, to a greater extent, to nasutin; however, the total content of nasutin and urolitin A in intestinal digesta was tangibly lower. A significantly higher ratio of ellagic acid to ET metabolites in cecal digesta was observed in the raspberry group.

In the presented experiment, the above-indicated differences in the content and composition of ET metabolites could differentiate selected parameters of the functioning of cecal ecosystem of rats, including the activity of microflora and SCFA production.

The comparison of results achieved in the strawberry and raspberry groups demonstrated that the increased content of ET metabolites in cecal digesta modified the effect of dietary fiber from fruits on fermentation processes. One of the effects

DOI: 10.1021/acs.jafc.5b00648
J. Agric. Food Chem. 2015, 63, 2989−2996

was both beneficial enhancement of the glycolytic activity of α-galactosidase as well as an unfavorable increase of β-glucuronidase activity. The enhanced activity of β-glucuronidase is claimed to result from the increased count of unfavorable microflora, such as *Escherichia coli* and *Clostridium*, in intestinal digesta.[40] Results of other experiments demonstrate that the increase of β-glucuronidase activity may result from dietary inclusion of pectins, dietary fiber with beneficial physiological properties.[32,41] Some experiments showed that strawberry polyphenols in rats' diet resulted in reduced activity of β-glucuronidase.[21]

The content of strawberry seeds, unlike that of raspberry seeds, did not increase the total SCFA production in the cecum of rats, and even negligibly lowered the SCFA pool, compared to the control diet. Such a result ought to be linked with a higher content of ET metabolites in cecal digesta, thus suppressing the glycolytic activity of microflora. The enhanced enzymatic activity in the cecum of rats fed the diet with raspberry seeds corresponded with a higher blood level of glucose in this group of rats.

In our experiment, raspberry seeds containing 1.8% of ellagitannins affected the blood lipid profile, especially the content of triglycerides, which corresponded with a decreased atherogenicity index in blood (0.49 vs 0.70). This was confirmed in results of other investigations, which demonstrated the positive effect of ellagitannins on the level and composition of blood lipids.[42,43] In the case of strawberry seeds, with a lower content of ellagitannins (1.0%), analyses did not show any statistically significant effect on the lipid profile in blood.

The results of the presented experiment demonstrate that ellagitannins of strawberry seeds are mainly composed of monomers (54% of total ETs) and a dimer, agrimoniin, whereas raspberry seeds characterized by a higher content of ET polymers (83% of total ET) were mainly constituted by a dimer, sanguiin-H6, and a trimer, lambertianin-C. The lower content and less polymerized structure of strawberry ellagitannins, applied in rat diets, resulted in a higher concentration of metabolites in the cecum, which reduced SCFA synthesis but did not affect the blood lipid profile. Raspberry seeds were a better metabolized substrate in fermentation processes in the cecum of rats, resulting in enhanced production of SCFA and a higher content of butyrate as well as promoting reduced serum atherogenic index compared to control dietary treatment. Defatted strawberry and raspberry seeds were found to be an interesting source of dietary fiber and ellagitannins.

Proteolytic and carbohydrate-degrading enzymes have been shown to enhance protein extractability from rapeseed press cake.[21] We have also previously shown that hydrolysis of the embryonic cell walls (consisting of pectin, arabinogalactan, arabinan, xyloglucan, xylan, and cellulose) with a commercial pectinase preparation can increase protein recovery from cold-pressed rapeseed press cake by 73%.[8] However, the effect of solid content on protein recovery during combined enzymatic treatment and aqueous extraction has not been previously reported.

In the current study, we aimed to increase the total solid content during pectinase treatment of cold-pressed, SC-CO_2-defatted rapeseed press cake to limit water consumption in the production of a rapeseed protein concentrate. Another aim was to investigate the impact of extraction pH and isoelectric precipitation on protein recovery as well as on the solution behavior of the protein concentrates.

MATERIALS AND METHODS

Materials and Enzymes. Rapeseed press cake (6.8% moisture) was obtained from Kankaisten Öljykasvit Oy (Turenki, Finland). The press cake had been produced by cold pressing of oil from *Brassica rapa* L. seeds at 50−60 °C, pelletizing, and air-drying. A commercial pectinase preparation, Pectinex Ultra SP-L, was obtained from Novozymes A/S (Bagsvaerd, Denmark). It had a total protein content of 61 mg/mL and contained 2876 nkat of polygalacturonase (pectinase, assayed using polygalacturonic acid as a substrate), 135 nkat of endo-β-glucanase (assayed using β-glucan as a substrate), 22 nkat of endoglucanase (cellulase, assayed using hydroxyethyl cellulose as a substrate), and 7 nkat of endo-1,4-β-xylanase activity (assayed using glucuronoxylan as a substrate) per total protein, as measured at 30 °C and pH 5.5.[8]

Pretreatment. Rapeseed press cake was ground at 1000 rpm using an SM 300 cutting mill (Retsch GmbH, Düsseldorf, Germany) and defatted by SC-CO_2 extraction in a Nova Swiss extraction vessel (Nova Werke Ag, Effretikon, Switzerland) equipped with a Chematur Ecoplanning compressor (Chematur Engineering Ltd., Pori, Finland). The vessel was operated for approximately 5 h under 300 bar of pressure at 40 °C. The defatted press cake was dry-milled twice at 17 800 rpm using a 100 UPZ-II Fine Impact mill (Hosokawa Alpine Ag, Ausburg, Germany). The defatted press cake contained 39% crude protein, 2% crude fat, 24% carbohydrates, and 8% ash on dry matter basis, as measured by using the methods described in Rommi et al.[8]

Enzymatic Treatment, Protein Extraction, and Isoelectric Precipitation. The defatted and milled rapeseed press cake was treated with Pectinex Ultra SP-L at an enzyme dosage of 5 mg total protein/g dry substrate (Figure 1). The treatment was performed at 40 and 20% (w/v) solid content in water without pH adjustment at the natural pH of the substrate (pH 5.8−6.0). Reference treatments were carried out similarly but without enzyme addition. All treatments were performed in duplicate. After 2 h of enzyme or reference treatment at 40 °C in a closed 500 mL stirred tank reactor with 40 rpm mixing, the reaction suspension was thoroughly mixed and aliquoted into 50 mL extraction tubes. Water was added to obtain 10 and 20% (w/v) solid content. The subsequent water or alkaline extraction and precipitation steps were performed in duplicate for each replicate enzyme treatment or reference treatment (N = 4). Water extraction was performed without pH adjustment at pH 5.5−6.0. After agitation at 320 rpm and 30 °C for 1 h, the suspension was centrifuged for 15 min at 3220g and 4 °C. Both the liquid fractions (supernatant) and the residual solids (pellet) were freeze-dried and weighed before further analysis. The lyophilized liquid fraction from water extraction will be referred to as "water extract", "pH6 E" throughout the text.

For alkaline extraction, the pH of the initial aliquoted suspensions (10 or 20% solid content) was adjusted to 10 using 10 M NaOH. The suspensions were stirred at 320 rpm for 1 h at 30 °C and centrifuged for 15 min at 3220g. The residual solids were directly freeze-dried and weighed for further analysis. The liquid fractions (supernatant) from

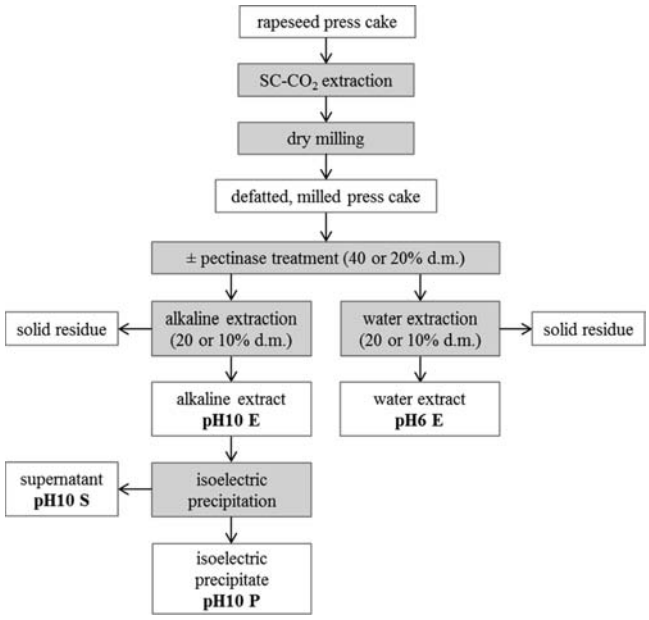

Figure 1. Pretreatment, enzymatic treatment, protein extraction, and protein precipitation schemes performed for rapeseed press cake. Pectinase treatment was performed at 40 or 20% total solid content (dm), and protein extractions were performed at 20 or 10% total solid content. Respective extraction and precipitation steps were performed after reference treatments of the defatted, milled press cake without enzyme addition. The isoelectric precipitates (pH10 P), water extracts (pH6 E), and extraction residues were obtained after centrifugation and freeze-dried before further analysis. Samples of the alkaline (pH10 E) and water extracts (pH6 E) and supernatants after precipitation (pH10 S) were stored at −20 °C.

alkaline extraction (referred to as "pH10 E") were subjected to isoelectric precipitation by adjusting the pH to 4 with 1 M HCl, mixing for 10 min, and centrifugation at 3220g for 20 min. The precipitate was recovered and freeze-dried without washing. The lyophilized precipitate will be referred to as "isoelectric precipitate", "pH10 P", throughout the text. All lyophilized samples as well as samples of unlyophilized water and alkali extracts (pH6 E and pH10 E) and supernatants remaining after isoelectric precipitation (referred to as "pH10 S") were stored at −20 °C until carbohydrate and protein analysis. Protein extraction yield was determined as the percentage of total nitrogen removed from the solids. The yield of protein precipitation was expressed as the percentage of total nitrogen or alkali-extracted nitrogen that was recovered in the precipitate. Extraction and precipitation yields were calculated as the average of four replicate experiments.

Protein Composition. Protein composition of the water and alkali extracts, isoelectric precipitates, and supernatants after isoelectric precipitation was analyzed by SDS-PAGE in reducing conditions using a Criterion TGX, Stain-Free Precast 18% gel (Bio-Rad, Hercules, CA, USA) and Precision Plus Protein standards (Bio-Rad). Water and alkali extracts and supernatants after isoelectric precipitation were diluted in 0.15% NaCl solution, mixed with loading buffer (0.1 M Tris-HCl, pH 6.8, 20% (v/v) glycerol, 4% (w/v) SDS, 10% (v/v) β-mercaptoethanol, 0.02% (w/v) bromophenol blue), and heated at 98 °C for 5 min. Isoelectric precipitates were dissolved in the loading buffer by heating at 98 °C for 10 min. Samples (20−30 μg of protein/lane) were loaded onto the precast gel and subjected to electrophoresis at a constant voltage of 250 V. The gel was imaged using Criterion Stain Free Imager with UV-induced fluorescence detection of tryptophan residues and examined with Image Lab software (Bio-Rad). Cruciferin and napin polypeptides were identified on the basis of correspondence of their known molecular weights with the band molecular weights. Protein concentration in the residual solids, isoelectric precipitates (pH10 P), and lyophilized water extracts

DOI: 10.1021/acs.jafc.5b01077
J. Agric. Food Chem. 2015, 63, 2997−3003

(pH6 E) was determined as the total nitrogen content (N × 6.25) analyzed in duplicate by Kjeldahl, according to the method by Kane.[22]

Carbohydrate Composition. Free monosaccharide and sucrose concentrations in the water and alkali extracts were determined by high-performance anion-exchange chromatography with pulse amperometric detection (HPAEC-PAD) using an ICS-3000 ion chromatography system equipped with a CarboPac PA1 column (Dionex, Sunnyvale, CA, USA) after filtration of the samples through a 0.45 μm syringe filter.[23] Total carbohydrate concentration was determined in duplicate by secondary hydrolysis of the extracts in 4% sulfuric acid for 1 h at 120 °C and analysis of the resulting monosaccharides by HPAEC-PAD after filtration of the hydrolysates through a 0.45 μm syringe filter.[23,24] Polysaccharide concentration was obtained by subtracting the free monosaccharides and sucrose from the total carbohydrates. To determine the total carbohydrate content of the isoelectric precipitates, the precipitates were hydrolyzed in triplicate with 70% sulfuric acid for 1 h at 30 °C followed by hydrolysis with 4% sulfuric acid for 50 min at 120 °C.[24] The released monosaccharides were analyzed by HPAEC-PAD as described above.[23]

Ash Content. The ash content of the lyophilized water extracts and isoelectric precipitates was determined in duplicate by combustion for 23 h at 550 °C in an N 11 muffle furnace (Nabertherm GmbH, Lilienthal, Germany) and weighing of the incombustible residue.

Solubility, Particle Size, and ζ-Potential. The amount of soluble protein in the lyophilized water extracts and isoelectric precipitates was determined at pH 4 and 8. The samples were dispersed in water to 2% (w/w) protein concentration on the basis of their total nitrogen content. The pH was adjusted to 4 and 8 using HCl or NaOH. The dispersions were stirred with a magnetic stirrer at 300 rpm and 40 °C for 2 h, after which they were centrifuged for 15 min at 10000*g*. The protein concentration of the supernatant was measured using a DC Protein Assay Kit (Bio-Rad) to determine the proportion of soluble protein in relation to the total nitrogen content of the dispersion.

Particle size distribution and ζ-potential of the supernatants were analyzed using Zetasizer nano ZS (Malvern Instruments, Malvern, UK). Two replicates with three consecutive measurements at 25 °C were performed. The samples were diluted 1:100 in MQ water and filtered through a 0.2 μm membrane (Millex Syringe Filter Unit, Millipore, Cork, Ireland). Disposable cuvettes and disposable folded capillary cells were used for particle size and ζ-potential measurements, respectively. Before the particle size measurement, the diluted and filtered samples were equilibrated in cuvettes for 2 h at 25 °C. For the intensity-based distribution of the particle sizes, the "general purpose" (non-negative least-squares analysis) algorithm in the Zetasizer Software was used. Volume size distributions were derived from the intensity distributions using the Mie theory by the software (refractive index $(RI)_{protein}$ = 1.450, RI_{water} = 1.330).

Statistical Analysis. Statistical analysis of the yield of extracted and precipitated protein from four replicate experiments was carried out by general linear model multivariate analysis using SPSS Statistics software (version 22, IBM, Armonk, NY, USA). The level of significance was set at $p < 0.05$ and assessed by Tukey's test.

RESULTS AND DISCUSSION

Effect of Total Solid Content, Enzymatic Treatment, and Extraction pH on Protein Extractability. The impact of solid content and pH on enzyme-aided recovery of protein from defatted rapeseed press cake was studied. Pectinase treatment was carried out at 20 and 40% total solid content to understand the influence of substrate concentration on the hydrolysis efficiency and subsequent protein release. As previously reported for nondefatted rapeseed press cake,[8] enzymatic treatment of the defatted press cake improved the protein recovery at pH 6 ($p \leq 0.05$ at 10% solid content, Tukey's test) (Figure 2). However, in alkaline extraction the preceding pectinase treatment did not have a clear benefit. Pectinase treatment at either 20 or 40% solid content resulted in similar protein extraction yields at 10% solid content, pH 6

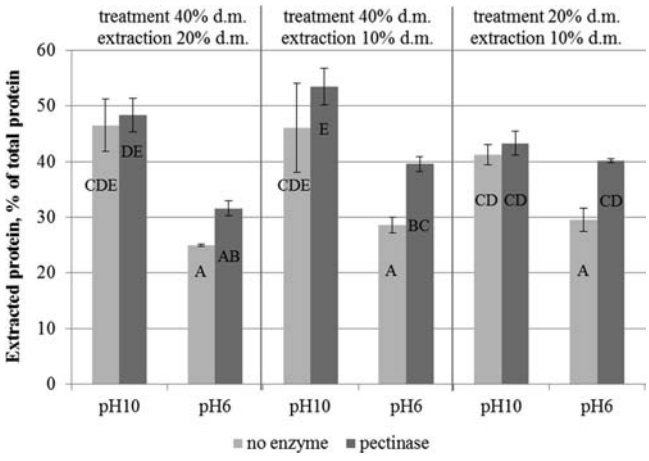

Figure 2. Yield of extracted proteins from defatted rapeseed press cake after pectinase treatment or reference treatment (no enzyme) at 40 and 20% solid content (dm) followed by alkaline (pH 10) or water extraction (pH 6) at 20 and 10% solid content. The yield was calculated on the basis of the loss of total nitrogen from the residual solids after extraction. Error bars represent standard deviations of two parallel extractions performed after each of the two replicate enzyme or reference treatments ($N = 4$). The sample points were categorized into subsets (A–E) on the basis of Tukey's test ($p < 0.05$).

(Figure 2, bars 8 and 12), indicating that the increase of solid content did not affect the hydrolysis efficiency. Interestingly, protein recovery in alkaline conditions seemed to increase when the enzyme or reference treatment was performed at higher solid content. Specifically after pectinase treatment at 40% solid content, alkaline extraction at 10% solid content was significantly improved ($p < 0.05$ Tukey's test) (Figure 2, bars 6 and 10). Although the enzyme itself did not clearly influence alkaline extraction, mixing at high solid content may have facilitated the release of additional protein that was extractable at pH 10.

Solid content of the extraction step (10 or 20%) did not significantly affect the protein yield (Figure 2), although at pH 6, somewhat less protein was extracted at 20% than at 10% solid content. The protein recovery was most probably limited by insufficient phase separation at increased solid content: after centrifugation of the 20% dm suspensions, a larger relative amount of liquid remained associated with the residual solids. Therefore, the residual solids presumably contained solubilized protein, which was not recovered in the extract. Protein recovery at low water content could be facilitated by more effective centrifugation practices that reduce the entrapment of soluble components in the sediment.

Overall, 41–53% of the total protein in the defatted rapeseed press cake was recovered in the alkaline extracts (pH10 E) and 25–40% in the water extracts (pH6 E) (Figure 2). In accordance with previous studies, protein recovery could be improved using either pectinase treatment or alkaline conditions.[8,16] When the extraction step was carried out at 10% solid content, enzyme-aided extraction at pH 6 resulted in the same protein yield as nonenzymatic alkaline extraction (Figure 2). This suggests that by facilitating protein recovery, pectinase treatment could allow protein extraction to be carried out without the use of alkali. However, enzyme-aided extraction at pH 6 was applicable only at relatively low (10%) solid content, whereas at 20% solid content, alkaline conditions

DOI: 10.1021/acs.jafc.5b01077
J. Agric. Food Chem. 2015, 63, 2997–3003

could more effectively improve protein recovery than pectinase treatment.

The highest protein yield (53% of total protein) was obtained by enzymatic treatment of the defatted press cake for 2 h at 40% solid content and subsequent alkaline extraction for 1 h at 10% solid content (Figure 2). A similar amount of protein was previously recovered during 48 h of pectinase treatment of a nondefatted rapeseed press cake at 10% solid content, pH 6.[8] At the highest, >80% of the total protein had been extracted at pH 11−12, ca. 5% solid content[19] and upon enzymatic hydrolysis of the proteins into peptides.[21] The effect of enzymatic hydrolysis was less profound than in the previous study,[8] in which pectinase treatment increased protein extractability by 73% in comparison to the reference treatment. In the present study, the enzymatic hydrolysis may have been less extensive due to reduced enzyme dosage and treatment time. According to protein patterns visualized by reducing SDS-PAGE, no selective extraction of the major rapeseed proteins occurred (Figure 3, lanes 2−5).

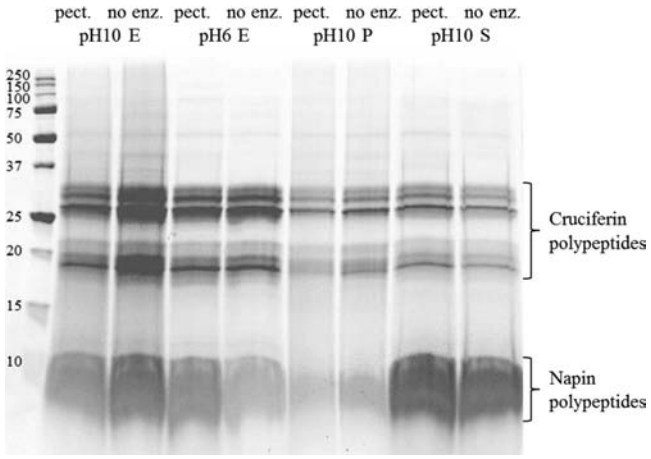

Figure 3. Protein patterns of the alkaline (pH10 E) and water extracts (pH6 E), isoelectric precipitates (pH10 P), and supernatants after isoelectric precipitation (pH10 S), as analyzed by SDS-PAGE in reducing conditions. The fractions were obtained after pectinase or reference (no enzyme) treatment of defatted rapeseed press cake at 40% solid content followed by extraction at 20% solid content and isoelectric precipitation of proteins from the alkaline extracts.

Effect of Enzymatic Treatment and Total Solid Content on Protein Precipitation. Precipitation of alkali-extracted proteins was carried out at pH 4, at which cruciferin (p*I* 4−7) was expected to have very low solubility.[25,26] However, upon acidification to pH 4, only 35−64% of the total extracted protein precipitated (Table 1). An expected factor for the limited precipitation yield was that napin, which constitutes 20% of rapeseed proteins, was positively charged and not prone to precipitation at pH 4. This was also shown in the SDS-PAGE patterns of the precipitates and the supernatants after isoelectric precipitation (Figure 3, lanes 5−8), where the precipitates (pH10 P) contained mainly cruciferin polypeptides and the supernatants (pH10 S) were enriched with napin polypeptides. Interference from nonprotein compounds in the extracts is another factor that probably contributed to the low protein precipitation yield. Anionic carbohydrates and proteins are known to interact through electrostatic interactions, and depending on the charge state of the proteins, either repulsion or formation of soluble or insoluble complexes can occur.[27] Isoelectric precipitation of cruciferin at pH 4 could have therefore been hindered by the formation of soluble complexes between negatively charged pectic carbohydrates and cruciferin, which, on the basis of its p*I* range (4−7), is suggested to have possessed a weak positive charge at pH 4.[5] The proposed cationic state of cruciferin is in accordance with a previous study on the surface charge of cruciferin-rich protein isolates as a function of pH.[28]

Proteins in the alkaline extracts were significantly less prone to precipitation after enzymatic treatment ($p < 0.05$ Tukey's test) (Table 1, precipitated protein/extracted protein). These extracts most probably contained partially hydrolyzed pectin with lower molecular weight, higher surface charge, and lower degree of esterification due to the pectin esterase activity of Pectinex.[29,30] Because the strength of pectin−protein complexes is affected by pectin molecular mass and degree of esterification,[31] the low-molecular-weight hydrolysis products of pectin may have formed stronger interactions with cruciferin at pH 4, limiting its aggregation and precipitation (Table 1).

Composition of Water Extracts and Isoelectric Precipitates. Water extracts and isoelectric precipitates (one representative from each of the four replicate samples) from extraction at 20% total solid content were characterized for chemical composition and solution behavior. In the water extracts (pH6 E), 16−29% of the total dry mass was recovered, comprising 38−47% protein and 48−52% carbohydrates (Table 2). By contrast, only 17−18% of the total dry mass was recovered in the isoelectric precipitates (pH10 P). In comparison to the extracts, the precipitates had a slightly higher protein content of 57−66% and contained 11−13% of carbohydrates and 5−6% of ash on dry matter basis. The composition is similar to that reported by Karaca et al.[18] The presence of carbohydrates and ash most probably results from

Table 1. Protein Yield in the Isoelectric Precipitates (pH10 P) Obtained after Pectinase and Reference (No Enzyme) Treatment of Defatted Rapeseed Press Cake Followed by Alkaline Extraction and Isoelectric Precipitation[a]

sample (pH10 P)	solid content in treatment (%)	solid content in extraction (%)	precipitated protein/total protein (%)	precipitated protein/extracted protein (%)
no enzyme	40	20	29.7 ± 3.2 (C)	63.9 ± 1.4 (E)
pectinase	40	20	25.6 ± 3.0 (BC)	53.1 ± 5.5 (CD)
no enzyme	40	10	28.0 ± 6.7 (BC)	60.3 ± 4.4 (DE)
pectinase	40	10	22.7 ± 2.5 (ABC)	42.4 ± 3.0 (AB)
no enzyme	20	10	20.3 ± 0.6 (AB)	49.4 ± 2.7 (BC)
pectinase	20	10	15.1 ± 1.3 (A)	34.9 ± 4.2 (A)

[a]Yields were calculated as the proportion of total or alkali-extracted nitrogen that was recovered in the precipitates. ± values represent standard deviations of two parallel extractions performed after each of the two replicate enzyme or reference treatments ($N = 4$). Table 2. Protein, Carbohydrate, and Ash Concentrations of Rapeseed Isoelectric Precipitates (pH10 P) and Water Extracts (pH6 E)[a]

sample	protein (% dm)	total carbohydrates (% dm)	ash (% dm)
no enzyme pH10 P	65.6	10.7	10.1
pectinase pH10 P	57.3	13.1	10.1
no enzyme pH6 E	47.3	47.6	6.0
pectinase pH6 E	37.8	51.7	7.7

[a]The precipitates were obtained after pectinase or reference treatment (no enzyme) of rapeseed press cake at 40% solid content, followed by alkaline extraction at 20% solid content and isoelectric precipitation. The water extracts were obtained after extraction of protein from the pectinase and reference-treated samples without pH adjustment. The concentrations represent an average result from two parallel analyses.

the fact that the precipitates were not washed after centrifugation to prevent redissolution of proteins. The undefined 18−24% of dm was expected to include phenolic compounds such as condensed tannins and phenolic acids, which are strongly coextracted with rapeseed proteins in alkaline conditions.[32]

On the basis of the protein patterns visualized by SDS-PAGE, the isoelectric precipitates seemed more enriched in cruciferin, whereas no clear difference was observed in the intensities of the cruciferin and napin bands in the water extracts. After pectinase treatment, the majority of the extracted neutral carbohydrates were in the form of monosaccharides (mainly glucose, fructose, arabinose, and galactose), whereas without enzymatic treatment, mainly polysaccharides were present in the water extracts (data not shown). This is consistent with the results of our earlier study in which the pectinase and glucanase activities in Pectinex Ultra SP-L partially hydrolyzed rapeseed carbohydrates into monosaccharides and uronic acids.[8]

Solution Behavior of Water Extracts and Isoelectric Precipitates. Solubility of proteins in the isoelectric precipitates (pH10 P) and water extracts (pH6 E) was determined at pH 4 and 8. As expected, the solubility was pH-dependent: at pH 4, which is close to the p*I* range of cruciferin, only 6−13% of the protein among different samples was soluble, whereas at pH 8 the protein solubility varied between 20 and 41% (Table 3). The isoelectric precipitates generally contained less soluble protein in comparison to the water extracts. Similar solubility differences between rapeseed protein extracts and isoelectric precipitates were also reported by Karaca et al.[18] and Yoshie-Stark et al.[26] Lower protein solubility in the precipitates at pH 4 can be partially explained by the higher proportion of cruciferin in these samples, because the solubility of cruciferin was expected to be highly reduced at pH 4. In addition, it has been suggested that the lower solubility of oilseed isoelectric precipitates regardless of pH is related to possible partial denaturation of the protein during their production.[33] In the current study, SDS-PAGE analysis in nonreducing conditions (data not shown) revealed faint, smeared bands in the high molecular weight region of the isoelectric precipitates, indicating formation of non-native disulfide bonds as a result of partial polypeptide unfolding. Proteins are known to be prone to partial denaturation in alkaline conditions, and thus partial unfolding may have occurred during the alkaline extraction.[34] Because high protein solubility is usually associated with better technological functionality,[17] minimal processing in mild conditions can be favorable for the production of rapeseed protein ingredients for food and cosmetics applications.

Table 3. Solubility and ζ-Potential of the Supernatants Obtained after Dispersing the Isoelectric Precipitates and Dried Water Extracts in Water at pH 4 and 8[a]

	soluble protein/total protein (%)		zeta potential (mV)	
sample	pH 4	pH 8	pH 4	pH 8
no enzyme pH10 P	6.2 ± 0.1	25.1 ± 0.2	8.7 ± 0.2	−21.9 ± 1.9
pectinase pH10 P	6.4 ± 0.1	19.8 ± 0.1	10.2 ± 0.2	−21.3 ± 2.4
no enzyme pH6 E	13.4 ± 0.0	40.7 ± 0.1	−1.6 ± 0.6	−6.4 ± 0.5
pectinase pH6 E	10.2 ± 0.0	39.1 ± 0.1	−5.7 ± 0.6	−11.4 ± 0.3

[a]The isoelectric precipitates (pH10 P) were obtained after pectinase or reference treatment (no enzyme) of rapeseed press cake at 40% solid content followed by alkaline extraction at 20% solid content and isoelectric precipitation. The water extracts (pH6 E) were obtained after extraction of proteins from the pectinase and reference-treated samples without pH adjustment. ± values represent standard deviations of two parallel analyses for solubility and at least three parallel analyses for zeta potential.

The soluble fractions obtained from the protein dispersions were further characterized by ζ-potential (describing the net charge of the particles in the media) and particle size measurements to obtain insights on their dispersion stability. At acidic pH, ζ-potential values for the water extracts (pH6 E) obtained after pectinase and reference treatment were around −6 and −2 mV, respectively (Table 3). Isoelectric precipitates (pH10 P), on the other hand, attained positive ζ-potential values around +9 mV at pH 4, supporting the fact that cruciferin most probably possessed a weak positive charge at this pH. The proximity of the ζ-potentials to zero was in accordance with the low solubility of both products at pH 4. At pH 8, ζ-potentials of the water extracts were −11 and −6 mV with and without pectinase treatment, respectively, whereas isoelectric precipitates attained a higher negative charge around −21 mV. The net charge of isoelectric precipitates was not influenced by enzymatic treatment, whereas in the water extracts, the more negative charge of the enzymatically treated samples may be related to the de-esterification and depolymeration of pectin by the pectin esterase and polygalacturonase activities of Pectinex[29,30] and the resultant exposure of polar groups.[31]

Higher surface charge of proteins is generally associated with improved solubility.[35] However, the isoelectric precipitates, which attained stronger net charges, showed lower protein solubility than the water extracts, which attained net charges closer to zero (Table 3). This inverse relationship between solubility and net charge was more clearly seen at pH 8. Similar results were obtained by Karaca et al. when comparing rapeseed protein isolates prepared by isoelectric precipitation and salt extraction.[18] The low solubility of isoelectric precipitates may be related to partial denaturation during alkaline extraction, as indicated by the smears in nonreducing SDS-PAGE. Furthermore, soluble carbohydrates (Table 2) most probably contributed to the improved protein solubility of the water extracts. As previously discussed, protein solubility in the water extracts may have been increased by the formation of soluble complexes between oppositely charged proteins and pectic carbohydrates.[36] Similar mechanisms are well documented in

DOI: 10.1021/acs.jafc.5b01077
J. Agric. Food Chem. 2015, 63, 2997−3003

milk[37] and soy protein systems,[38] where attachment of pectin on protein particles rendered electrostatic and steric stabilization against sedimentation.

Particle size distribution in the supernatants of the protein dispersions was determined at pH 8, at which at least 20% of the protein was soluble. The water extract (pH6 E) samples contained mainly particles of 10 nm in diameter (constituting 15−20% of the sample volume), whereas the dominant particle size in the isoelectric precipitate (pH10 P) samples was remarkably higher and closer to 50 nm (Figure 4). Changes in

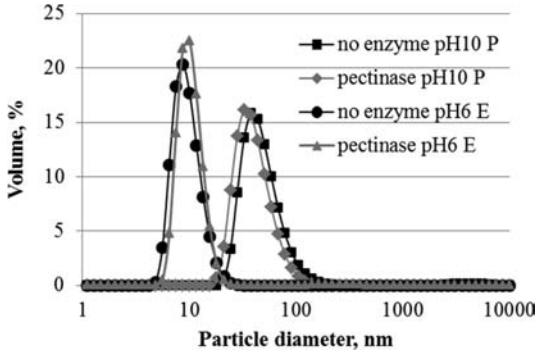

Figure 4. Volume-based particle size distribution in the supernatants obtained after dispersing the isoelectric precipitates and dried water extracts in water at pH 8. The isoelectric precipitates (pH10 P) were obtained after pectinase or reference (no enzyme) treatment of defatted rapeseed press cake at 40% solid content followed by alkaline extraction at 20% solid content and isoelectric precipitation. The water extracts (pH6 E) were obtained after extraction of proteins from the pectinase and reference-treated samples without pH adjustment.

particle size during storage were also monitored by carrying out measurements for the diluted, filtered samples, which were stored in the cuvettes at 25 °C for 24 h. A gradual increase in particle size of the isoelectric precipitate samples was observed, whereas absolutely no change occurred in the particle size distribution of the water extract samples (data not shown). The results support the proposed electrostatic and steric stabilization of protein particles by anionic carbohydrates in the water extracts.

The volume-based mean diameter of the protein particles in the water extract samples was around 10 nm, which corresponds to the reported size of rapeseed globulins measured by small-angle X-ray scattering.[39] By contrast, larger mean diameter in the isoelectric precipitate samples suggests that the precipitates contained aggregates of several monomers formed either via physical or chemical interactions. The formation of disulfide-linked soluble aggregates in the isoelectric precipitates was likewise observed by nonreducing SDS-PAGE (data not shown). Limited dispersion stability in the precipitate samples may have resulted from both partial protein denaturation and reduced concentration of stabilizing pectic carbohydrates. Additionally, it should be noted that apart from charged carbohydrates, other components in the water extracts and isoelectric precipitates may also have influenced the dispersion stability. Although not analyzed in this study, the aqueous extracts from rapeseed press cake commonly contain phytates and phenolics, which interact and form insoluble complexes with proteins.[18,32] Pectin has been reported to solubilize protein−phenolic aggregates, which may have further contributed to the better dispersion stability of the crude water extracts in comparison to the isoelectric precipitates.[31]

Our results suggest that alkaline extraction and isoelectric precipitation, which are commonly used to recover protein from rapeseed press cake, could be replaced by enzyme-aided aqueous extraction without pH adjustment in dilute conditions. Enzymatic hydrolysis of carbohydrates improved the recovery of protein extracts at pH 6 but did not introduce improvements in alkaline extraction. By contrast, enzyme treatment hindered the recovery of protein from alkaline extracts by isoelectric precipitation. Pectinase treatment was feasible also at high (40%) total solid content, which could open up possibilities for water-lean fractionation technologies. However, extraction of rapeseed protein at increased solid content is suggested to require the use of alkali due to the limited efficiency of water extraction in these conditions. Crude water extracts from pH 6 extraction had better protein solubility and dispersion stability than isoelectric precipitates from alkaline extraction. Different solution properties of these fractions are proposed to be caused by stabilizing electrostatic interactions of proteins and anionic pectic carbohydrates in the water extracts and partial denaturation of proteins in the isoelectric precipitates.

Funding

The research leading to these results has received funding from the European Community's Seventh Framework Programme FP7/2007-2013 under Grant Agreement 289170-APROPOS. In addition, we gratefully acknowledge funding from the Academy of Finland to Kaisa Poutanen.

Notes

The authors declare no competing financial interest.

ACKNOWLEDGMENTS

We thank Kankaisten Öljykasvit Oy for the rapeseed press cake, Tuija Kössö for the mechanical pretreatment and supercritical carbon dioxide extraction, and Atte Mikkelson for the carbohydrate analyses. We asknowledge with gratitude the experimental work performed by Mariitta Svanberg, Nina Vihersola, and Heljä Heikkinen at VTT Technical Research Centre of Finland.

J. Agric. Food Chem. 2015, 63, 2997−3003

In general, studies are focused on the effect of bentonite fining on fermentative and varietal aroma compounds in finished wines.[15,18] Moreover, very few works have studied the effects on aroma compounds of the use of bentonite in musts,[19,20] and only two previous works have considered bentonite addition during fermentation for a Macabeo wine.[20,21] In this way, bentonite fining may affect both the production and the loss of fermentative compounds. The relationship between grape varieties, protein content, and protein stability has been briefly described up to now. The relationship of varieties such as Sauvignon Blanc[22] and Macabeo[23] and protein stability has been largely described, but for other varieties like Albariño, there is no information available.

To avoid the risk of haze in bottled wine, bentonite treatment is often done to remove unstable proteins and protect the wine. However, this is a nonselective treatment, with the result that some of the proteins associated with the good characteristics of the wine are removed as well. This fact makes oenologists especially concerned when applying bentonite for protein stability.

The main objective of this work was to determine the best time for treatment with bentonite in a white wine of the Albariño variety both from the standpoint of protein stability and the preservation of aromas, minimizing the bentonite dose.

MATERIALS AND METHODS

Fermentation Process. The winemaking of Albariño wines was performed on a pilot scale in the "Estación Experimental de Viticultura y Enoloxía de Ribadumia EGEVA—INGACAL" (Pontevedra, SPAIN) between September and October of 2012. Grapes berries used came from the same vineyard (Ribadumia, Pontevedra; D.O. Rías Baixas, Subzone Salnés, Spain), the soil of which has a granitic rock origin, and vines were planted on 2001 on a V trellis conduction system, at a density of 4.000 pl/Ha, over 196−17 Castel rootstock. Albariño grapes were hand harvested in plastic trails of 20 kg, received 8 g/hL of potassium metabisulphite and 6.67 g/hL of ascorbic acid before the pressing of whole clusters in a pneumatic press (Bucher, Vaslin X pro), and then distributed to the different tanks according to each treatment.

Each tank contained the free run juice or juice obtained at low pressures ($\leq$1.0 kg/cm^2) and treated with 5 g/100 kg of grapes of pectolytic extractive enzymes (Lafazym press, Laffort, Bordeaux, France). Juice clarification was done at low temperatures (18 °C for 48 h), except for the tank clarified also with bentonite as part of the treatments in the study.

The volume of the fermentation stainless steel tanks was 30 L, filled up to the recommended height (85% of the tank volume), and the process was carried out in triplicate. Temperature and density controls were carried out on a daily basis according to the center protocols for this variety in the same way as every addition or treatment was usually made. Fermentation was carried out with the commercial yeast IOC-18-2007 (Institut Oenologique de Champagne, Reims, France) in a dose of 30 g/hL. In addition, during fermentation, two different nutrients were used: 15 g/hL of Nutriferm (Enartis, Vilafranca del Penedès, Spain) and 10 g/hL Helper (Oenofrance, Bordeaux, France). Fermentation was carried out around 18 °C until dry wines were obtained.

Once alcoholic fermentation finished, 6.5 g/hL of potassium metabisulphite was added in order to keep 3.5 g/hL of free sulfur dioxide and the wines were kept at 12 °C the first 2 days and later at 8 °C until tartaric and protein stabilization treatments were applied. Tartaric stabilization treatment was done during 9 days at −6 °C in a cold chamber. Before bottling, wines were filtered with a cellulose plates filter AF-110, checking before that free sulfur dioxide was between 3.0−3.5 g/hL.

Bentonite Treatments. A dose of 40 g/hL bentonite was decided together with the oenological center, considering the stabilizing treatment done in previous years. The bentonite used was natural sodium granular bentonite (Microcol-Alpha, Laffort; Bordeaux, France). The bentonite treatments were performed to grape juice before alcoholic fermentation and removing this bentonite by settling before starting fermentation, at the beginning of alcoholic fermentation, in the middle of alcoholic fermentation, and at the end of alcoholic fermentation. An untreated fermentation without application of bentonite was used as a control.

Protein Analysis by Bradford's Method. Total protein concentration was measured by Bradford's method using Coomassie brilliant blue reagent. Under acidic conditions, the red form of the dye is converted into its bluer form upon binding to protein. This change was assayed at 595 nm on a spectrophotometer (Cecil CE2021, Cambridge, England) after 5 min of incubation.[24] The anionic (bound) form of the dye has a maximum absorption spectrum historically held to be at 595 nm. The cationic (unbound) forms are green or red. Binding of the dye to the protein stabilizes the blue anionic form. The increase of absorbance at 595 nm is proportional to the amount of bound dye and thus to the concentration of protein present in the sample. The protein content was expressed as mg/L of bovine serum albumin (BSA; Sigma, cat. no. A-3803, Madrid, Spain). Unlike other protein assays, the Bradford protein assay is less susceptible to interference by various chemicals that may be present in protein samples. All analyses were done in triplicate.

Fast Protein Liquid Chromatography (FPLC). Samples of 200 mL of each must, wine, or sample obtained during fermentation were centrifuged at 4000*g* for 5 min at 4 °C. Aliquots of 45 mL of the supernatant were immediately dialyzed for 72 h in three dialysis tubes (SIGMA, dialysis tubing−cellulose membrane, D-9652, Madrid, Spain) to remove salts and other low molecular weight compounds. The dialyzed samples were lyophilized and kept at −20 °C. The lyophilized samples were resuspended in freshly obtained pure deionized water (15 × 106 W/cm) until the protein concentration was about 0.5 mg/mL, expressed as BSA. The samples were centrifuged 12000*g* for 2 min at 4 °C and frozen again. On the day of the analysis, they were lyophilized again and resuspended in 0.6 mL of 0.3 M ammonium acetate solution (pH 6.80) to obtain a protein concentration of 0.25 μg/μL. The samples were centrifuged (5 min at 12000*g*, 4 °C), and the supernatants were used directly for FPLC analysis.[25] Analyses were carried out with a Superdex 75 PC 3.2/30 column on an FPLC system (Smart System, Pharmacia, Uppsala, Sweden). The samples (50 μL) were injected and eluted with a 0.3 M ammonium acetate solution (pH 6.80) at a flow rate of 40 μL/min. The column eluents were continuously monitored at 280 nm using a μPeak Monitor (Pharmacia, Uppsala, Sweden).

Determination of Bentonite Dose. The treatment with bentonite included a preliminary test that use a variety of different dose (5−100 g/hL) so that the most appropriate dose could be determined. For every treatment a heat stability test was applied.

Heat Stability Test. A wine sample of 20 mL was filtered through a cellulose nitrate membrane with a pore size of 0.45 μm (Whatman, catalogue no. 7184009, England) and heated for 2 h at 80 °C in a bath equipped with a digital control immersion thermostat (Digiterm 100 model). It was then incubated for 2 h at 4 °C. Finally, the turbidity was measured by nephelometry (Turbiquant 1000 IR turbidimeter) and expressed in nephelometric turbidity units (NTU). The difference in turbidity between the initial wine and the wine after the thermal test was proportional to protein instability. The wines were considered stable if this difference did not exceed 2 NTU.[4] All analyses were carried out in triplicate.

Chemical Analysis of Musts and Wines. Basic parameters of wines (alcohol content, residual sugars, pH, titratable and volatile acidity, tartaric, malic, and lactic acids) were determined by Fourier transform infrared spectrometry (FTIR) using a Bacchus II analyzer (TDI, Barcelona, Spain) calibrated according to the official methods for wine analysis (EC Regulation 479/2008). The spectra were obtained in triplicate and averaged for each sample. In addition, density, total dry matter, and free and total sulfur dioxide were determined using methods of the OIV (June 2012).

[a]Protein fractions: F1 (>100 kDa), F2 (60−40 kDa, invertase and β-glucanases), and F3 (20−30 kDa, chitinases and thaumatin like protein TLP).

Wine Sensory Analysis. A test of preference was performed with a panel of 24 untrained tasters (14 male, 10 female). Fourteen tasters had some previous tasting experience against 10 that did not have any, but none of them were professional tasters. They were asked to choose between the five different wines obtained from the four treatments and the control and to sort from the highest to the lowest preference at nose and palate. The objective was to select the best samples to contrast it with their analytical information.

Wines were tasted by the panel 5 months after being bottled. The tasting was done in the tasting laboratory of the Enology Faculty of Rovira i Virgili University (Tarragona, Spain), which has the right conditions for the wine service and tasting. Before the sensorial analysis, wine panelists tasted different wines to make sure that they understood the purpose of the tasting.

The results were analyzed using the test of Friedman, performing a global comparison of each series and then a comparison of pairs to determine the differences found by the tasters.

Aroma Profile. Because of the wide range of contents that present the volatile compounds of wines, the approach for the aroma compounds analysis was based according to groups of compounds with contents in similar order of magnitude. Thus, three analytical methodologies were used. Major volatile compounds (methanol, higher alcohols, acetaldehyde, ethyl acetate, ethyl lactate, 1-hexanol, γ-butyrolactone, and 2-phenylethanol) were determined by gas chromatography−flame ionization detection (GC−FID) using a

DOI: 10.1021/acs.jafc.5b00993
J. Agric. Food Chem. 2015, 63, 3004−3011

method of direct injection described in Blanco et al.[26] The quantification was carried out by interpolation into calibration curves obtained with model wines spiked at different levels with the pure commercial aroma compounds. For determination of minor alcohols, volatile fatty acids, ethyl esters of fatty acids, and acetates of higher alcohols, a liquid−liquid extraction (with diethyl ether−hexane (1:1 v/v)) was carried out previous to the injection in a GC−FID system according with the method described in Blanco et al.[26] For the quantification, model wines spiked at different levels with the pure commercial aroma compounds were extracted to build the calibration graphs.

For the analysis of terpenols, a solid phase extraction (SPE) was carried out according with the method described in López-Vázquez et al. with some modifications.[27] A sample of 50 mL of wine diluted with 50 mL of distilled water (spiked with 0.132 mg/L of 4-decanol as internal standard) was percolated through an Isolute ENV+ SPE cartridge (1 g). The free aroma components were eluted with 30 mL of dichloromethane; the eluate was dried with sodium sulfate and concentrated to 1.5 mL on a Vigreux column, stored at −10 °C, and immediately prior to GC analysis, further concentrated to 100 μL under a gentle nitrogen stream. The chromatographic analysis were conducted using Agilent 6890 gas chromatograph with a mass spectrometric detector (MSD) model 5973N (Agilent Technologies). The capillary column was a HP-Innowax (Agilent) (30 m × 0.25 mm i.d. and 0.25 μm of phase thickness) and the column oven program was 35 °C (2 min), at 30 °C/min to 60 °C (0.5 min), at 2 °C/min to 160 °C (10 min), and at 3 °C/min to 230 °C (10 min). Injector temperature was 250 °C, and the injection (2 μL) was in split mode 1:5. The carrier gas was helium at 1 mL/min. The mass spectrometer was operated in the electron ionization mode at a voltage of 70 eV. The temperatures of source, quadrupole, and transfer-line were 230, 150, and 220 °C, respectively. The acquisition mass range was 30−300 amu. The identification was carried out by comparison with the spectra of Nist Mass Library (rev 05) and with those obtained from the injection of the pure commercial compounds (when available). The quantification were carried out by the internal standard method, so the concentrations was expressed in μg/L equivalent of 4-decanol. Quantification ions (m/z) were the following: terpinene (105), linalool (71), hotrienol (71), α-terpineol (59), citronellol (69), nerol (69), geraniol (69), 3,7-dimethyl-1-octen-3,7-diol (71), *E*-3,7-dimethyl-1,5-octadien-3,7-diol (82), *E*-3,7-dimethyl-1,5-octadien-3,6-diol (71), and 4-decanol (55). Linear retention indexes were calculated by injection of the standards of aliphatic alkanes for each analytical method.

For theoretical estimation of the sensory importance of each compound, the odor activity values (OAV) were calculated using the formula OAV = (concentration of compound)/(odor threshold) (expressed in units of aroma [ua]) and odor thresholds published in the literature.[28−35]

Statistical Analysis. All the statistical analyses were performed with the SPSS statistical package (version 17.0, SPSS Inc., Chicago, IL, USA). One-way analysis of variance (ANOVA) was applied to the data for scale and treatment effect and Principal component analysis (PCA) was applied to compounds with odor activity value higher than 1 ua.

RESULTS AND DISCUSSION

Fermentation Kinetics and Chemical Analysis of Wines. The main characteristics of initial must used for all the experiments were: density of 1101 ± 11 kg/m^3, total acidity of 8.63 ± 0.09 g tartaric acid/L, potential alcoholic degree of 14.08 ± 0.14% v/v, and pH of 3.30 ± 0.03. Alcoholic fermentation followed a similar tendency in all fermentations, except for the must clarified with bentonite that had a faster evolution in the first 2−5 days, favored by the presence of bentonite not removed by racking.[36,37] Fermentations lasted 14 ± 2 days within a temperature range of 17 ± 2 °C.

In Table 1 are shown the main analytical parameters for each wine once stabilized and bottled. Differences in analytical values were due to the time of sampling and the analytical methods used for each case but did not represent a significant difference among the final wines from a practical point of view.

Table 3. Statistical Analysis of Preference Tests (Nose and Palate)[a]

samples compared	nose Ra − Rb[b]	palate Ra − Rb[b]
must/beginning	2.0 ns	4.0 ns
must/middle	35.0 s	4.0 ns
must/end	15.0 ns	26.0 s
must/control	3.0 ns	4.0 ns
beginning/middle	33.0 s	8.0 ns
beginning/end	13.0 ns	30.0 s
beginning/control	1.0 ns	8.0 ns
middle/end	20.0 ns	22.0 s
middle/control	32.0 s	0.0 ns
end/control	12.0 ns	22.0 s

[a]ns, not significant difference; s,: significant difference. [b]Ra − Rb: difference between ranges. Critical value Ra − Rb = 21.5 (p = 0.05).

Protein Content Evolution and Stability. The protein content, stability, bentonite stabilizing dose, bentonite total dose, and protein profile of samples obtained from the initial grape juice until the finished wine in the whole process is presented in Table 2 for each treatment and the control. Of the five wines obtained, the two treated at the end of fermentation were stable, while the other three were unstable. Unstable wines needed an additional bentonite dose of 40 and 10 g/hL for the wine obtained with the must clarified with bentonite and the wine treated at the beginning of fermentation, respectively. The control wine needed a dose of 70 g/hL for its stabilization. From these data, it can be concluded that wines treated during fermentation need less bentonite for their stabilization. Similar results were obtained by Lira et al.[20,21] and Pocock et al.,[10] for Macabeo and Sauvignon Blanc wines, respectively.

Analysis of the protein profile (Table 2) showed the presence of three fractions: F1 (>100 kDa), F2 (60−40 kDa, invertase and β-glucanases), and F3 (20−30 kDa, chitinases and thaumatin like protein TLP).[7,25,38] Fractions F1 and F2 had a lower protein concentration than F3. Fraction F1 showed a high sensitivity to bentonite treatment, as independently of the dosage during fermentation, its diminution was almost complete.

The concentration of fraction F2 in free run juice and initial musts clarified with enzymes was in the range of 5.4−5.8 mg BSA/L. Must clarified with bentonite showed a 60% decrease in fraction F2, which remained stable until the end of the fermentation and was further diminished with the additional treatment of bentonite. In wines treated at the beginning and in the middle of fermentation, there was an increase of the concentration of F2 before the treatment, probably due to yeast action, up to values between 8−9 mg BSA/L.[39] In the wine treated at the end of fermentation, there was a decrease in F2 compared with the initial content, similar to the control dry wine. The fermentation had a longer action time and followed the normal evolution with an increase of the protein content due to yeast lysis and the later diminution as an effect of the hydrolysis.[38] The final effect of bentonite dosage during fermentation led to a decrease of F2 fraction of around 50−60%, and as bentonite remained in the medium, the F2 fraction continued to decrease, as observed in dry wines.

The main fraction was F3, with an initial content in the free run juice of 23.3 ± 0.3 mg BSA/L and a content of 26.3 ± 0.4

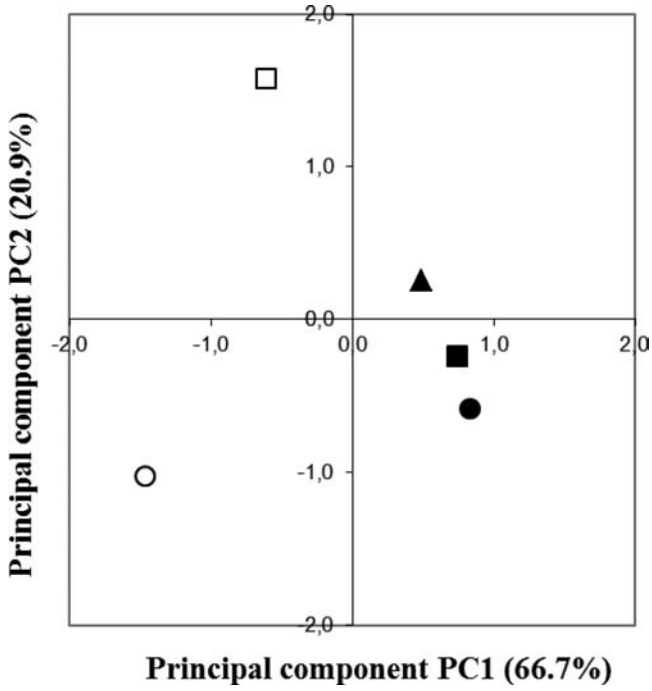

Figure 1. Principal component analysis of musts and wines treated with bentonite at different vinification stages, for Albariño wines. (○) Must clarification, (■) beginning fermentation, (●) middle fermentation, (▲) end fermentation, (□) control. Numbers in figure indicate the order in the sensory preference test.

mg BSA/L in musts clarified with enzymes. The diminution of this fraction in the must clarified with bentonite was until 14.2 ± 1.4 mg BSA/L 24 h after applying the treatment. At the end of fermentation, the content of the F3 fraction was 11.1 ± 0.3 mg BSA/L, representing unstable wines. The additional stabilizing treatment with bentonite reduced this concentration to 3.0 ± 0.0 mg BSA/L. The wines treated with bentonite during fermentation showed a diminution of the F3 fraction of 30−40% after 24 h of treatment, similar to the F2 fraction that decreased after the addition of bentonite, by around 50%. In these wines, the content of fraction F3 decreased until the end of fermentation to values in a range of 4.9−6.1 mg BSA/L, representing stable wines, except the wine treated at the beginning of fermentation, which needed an additional dose of 10 g/hL of bentonite. In the control wine, the content of the F3 fraction in dry wine was 17.0 ± 1.5 mg BSA/L, which decreased to 5.7 ± 0.7 mg BSA/L after the stabilizing treatment with bentonite. The results obtained suggest that the F3 fraction would be involved in protein stability.[3,7]

Sensory Evaluation. The tasting panel evaluated the Albariño wines obtained from the four treatments and the control in nose and palate, ranking them according to their preferences in nose and palate separately. Statistical analysis of results between pairs of wines (for $p < 0.05$) are presented in Table 3. As can be seen, in the case of nose sensory data, a clear preference of tasters for the wine treated in the middle of fermentation were observed, with a significant difference versus each of the other wines except with the wine treated at the end of fermentation, which was ranked in second place. The other three wines had similar values and, according to the tasters, there was no difference. On palate, the comparative analysis of the wines resulted in a clear preference for the wine treated at the end of fermentation over the other four wines, which did not have significant differences for the panel.

Aroma Compounds. The results of the volatile composition analysis of wines are presented in Table 4. In addition, in order to estimate the sensory importance of each compound and the differences between treatments, the odor activity values (OAVs) are also presented in Table 4 (in brackets) for compounds with OAV > 1 ua. As can be seen, treatments with bentonite at different stages of fermentation, in general, affected the production of volatile fermentative compounds. The effect of the treatments on the contents of esters and acids was remarkable and probably affected the wine aroma because most

DOI: 10.1021/acs.jafc.5b00993
J. Agric. Food Chem. 2015, 63, 3004−3011

of them are in contents higher than their odor thresholds. In addition to the possible loss of volatile compounds due to adsorption on bentonite, the effects on the production of fermentative compounds could be related to the variation in nitrogen composition and other nutrients[3,40] of musts and wines removed by the bentonite. In the case of varietal compounds, is it remarkable that the total terpenes amounts were highest in control and wines treated at the end of fermentation, while the lowest content was observed for clarified must. These effects could be related to the adsorption on bentonite of bound terpenes (glycoside forms). In addition, the release of free terpenes from the glycoside forms during fermentation could be influenced by the bentonite treatments affecting the interaction of yeast and the specific glycosides.[16] Among all terpenes analyzed, it can be observed that studied wines contain high amounts of hotrienol and *E*-3,7-dimethyl-1,5-octadien-3,7-diol, characteristic of this variety, with respect to other Galician varieties[41] and that only hotrienol showed contents higher than its odor thresholds, however, some less aromatic terpenes, such as *E*-3,7-dimethyl-1,5-octadien-3,7-diol, could transform into other more aromatic terpenes during wine aging.[42]

To obtain more information on the volatile composition analysis and with the aim of focus the discussion on the compounds with sensory importance, a principal component analysis (PCA) was carried out considering only the compounds with odor activity value higher than 1 ua. PCA selected three principal components with eigenvalue higher than 1. Table 5 shows the loading of each variable for the three PC, as well as the eigenvalue for each factor.

It was observed that more than 87% of the variation of the values could be explained by the two first principal components. The plot of the different wine samples in the plane defined by the first two PCs is shown in Figure 1. As can be seen, the PC1 (66.7%) showed a clear separation of the treated wines during fermentation (with positive PC1 values) of the control (negative values of PC1 over −0.6) and of the wine obtained from clarified musts (PC1 values over −1.5). On the other hand, the PC2 (20.9%) also allow separation of the samples treated during fermentation (situated between −06 and 0.25 values for PC2) and the control (values of PC2 of 1.6) and musts clarified wines (values of PC2 over −1). As can be seen in Table 5, the PC1 is mainly associated and positively correlated with seven compounds: two acids (octanoic and decanoic acids), five esters (ethyl esters of decanoic, octanoic, and hexanoic acids, and ethyl and isoamyl acetates), and the γ-butyrolactone. According with the results of sensory preference test (Wine Sensory Analysis section) and the position of the treated samples during fermentation (preferred by tasters) and the wine worst ranked (must clarified) in the plot (Figure 1), it could be concluded that the sensory quality of these wines is related, at least in part, with the concentration of these seven compounds. On the basis on the bibliography, acids, ethyl esters, and acetates have an important influence on the fruity and freshness character of wine aroma.[28] On the other hand, PC2 is mainly positively associate with two acids (isovaleric and hexanoic acids), ethyl butyrate, and isoamyl alcohols and negatively correlated with ethanal. In this case, probably the influence of these compounds on the "preference test" was less important, and it did not show a clear separation of the better and worst wines ranked.

In summary, the addition of bentonite during alcoholic fermentation, and especially in the middle or at the end, reduced the total dose required for protein stabilization of Albariño wines and maintained the sensory characteristics of this variety. For practical purposes, the oenological parameters of the fermentations were not affected by any of the treatments. With regard to the sensory quality of wine, the results obtained from aroma analysis allow us to conclude that the wines with higher aroma intensity and quality will be the ones treated with bentonite in the middle or at the end of fermentation. These results were corroborated by the sensory analysis in which the wines treated in the middle and at the end of fermentation were preferred by tasters. In addition, both wines were stable and did not need any extra dose of bentonite, so they were the wines with a less aggressive stabilizing treatment. Nevertheless, further work must be carried out in the future with other varieties and on an industrial winemaking scale to adjust, improve, and adapt this technique.

[a]Abbreviations: t_R, retention time; Ac, acetyl; caff, caffeoyl; diox, dioxallyl; EA, ellagic acid; gall, galloyl; glc, glucose; glcA, glucuronic acid; he, hexoside; HHDP, hexahydroxydiphenic acid; Me, methyl; meth, methoxy; mal, malonyl; pent, pentoside; rha, rhamnoside; xyl, xyloside. [b]Experimental data. [c]Chemicals identified for the first time in *Rubus fruticosus* L. [d]Identification confirmed by commercial standards.

were purchased from Extrasynthese (Lyon, France). Formic acid and methanol were purchased from Sigma-Aldrich (Steinheim, Germany). Acetonitrile was from Merck (Darmstadt, Germany).

Plant Material. Blackberry fruits (*Rubus fruticosus* L.) of five thorny cultivars ('Darrow', 'Gazda', 'Leśniczanka', 'Early Wilson', and 'Zagroda') and nine thornless cultivars ('Black Beauty', 'Black Satin', 'Chester Thornless', 'Hull Thornless', 'Loch Ness', 'Orkan', 'Smoothstern', 'Tayberry', and 'Thornfree') were used for this study. Fruits were collected from the Research Station for Cultivar Testing in Masłowice and hand-harvested at the stage of consumption (full color) during the growing season of July−August 2012. Before analysis, fruits were cleaned, frozen with liquid nitrogen, and stored overnight at −20 °C.

Extraction of Polyphenols for Quantitative and Qualitative Analysis. Frozen fruits of blackberries were homogenized. A 5 g portion of homogenate was extracted twice with 80% aqueous methanol (v/v) acidified with 1% HCl (ultrasound bath, 10 min). Combined solution was then filtered through a Schott funnel with Whatman no. 1 filter paper, and filtrates were collected into 50 mL flasks. Each sample was prepared three times in order to have three technical replicates. For HPLC/UPLC-MS analysis, portions of extracts (2 mL) were centrifuged at 19000*g* for 15 min at 4 °C, and the supernatant was filtered through a Hydrophilic PTFE 0.22 μm membrane (Millex Samplicity Filter, Merck) and used for analysis.

UPLC-MS/MS Analysis of Polyphenols. Identification of blackberry polyphenols was carried out by using an ACQUITY Ultra Performance LC system (UPLC) with binary solvent manager (Waters Corp., Milford, MA, USA) and a Micromass Q-Tof Micro mass spectrometer (Waters, Manchester, UK) equipped with an electrospray ionization (ESI) source operating in negative and positive modes. Separations of individual polyphenols were carried out using a UPLC BEH C18 column (1.7 mm, 2.1 mm × 50 mm, Waters Corp., Milford, MA, USA) at 30 °C. The elution solvents were aqueous 0.1% formic acid (A) and 100% acetonitrile (B). Samples (10 μL) were eluted according to the linear gradient described previously by Kolniak-Ostek et al.[16] Analysis was carried out using full scan, data-dependent MS scanning from m/z 100 to 2500. The effluent was led directly to an electrospray source with a source block temperature of 130 °C, desolvation temperature of 350 °C, capillary voltage of 2.5 kV, and cone voltage of 30 V. Nitrogen was used as desolvation gas at a flow rate of 300 L/h.

HPLC-PDA Analysis of Polyphenol. The contents of anthocyanins, flavonols, ellagitannins, and phenolic acids were calculated on the basis of assays by HPLC-PDA described previously by Sokół-Łętowska et al.[17] The compounds were monitored at 254 nm (ellagitannins and ellagic acid derivatives), 320 nm (hydroxycinnamic acids), 360 nm (flavonols), and 520 nm (anthocyanins). The amounts of anthocyanins, flavonols, ellagitannins, including ellagic acid derivatives, and hydroxycinnamic acids were calculated as an external standard of regression equations, determined experimentally and converted into cyanidin 3-*O*-glucoside (anthocyanins), quercetin (flavonols), chlorogenic acid (hydroxycinnamic acids), and ellagic acid (ellagitannins and ellagic acid derivatives).

Statistical Analysis. Results were presented as the mean ± standard deviation of three technical replications. All statistical analyses were performed with Statistica version 10.0 (StatSoft, Tulsa, OK, USA). One-way analysis of variance (ANOVA) by Duncan's test was used to compare the mean values. Differences were considered to be significant at $p < 0.05$. Principal component analysis (PCA) was performed using XLSTAT on mean values of 14 samples (thorny and thornless blackberries) and 5 variables (anthocyanins, ellagic acid derivatives, ellagitannins, flavonols and hydroxycinnamic acids).

RESULTS AND DISCUSSION

Qualitative Analysis of Polyphenols. *General.* Table 1 lists the 35 compounds identified through UPLC-MS/MS (with PDA and Q/TOF detectors) experiments along with their retention times (t_R), UV−vis spectral profiles at 200−600 nm, and comparison with standard reference compounds, when available. Molecules that were certainly or putatively identified in negative ion mode belong to the compound groups of flavonols,

DOI: 10.1021/jf5039794
J. Agric. Food Chem. 2015, 63, 3012−3021

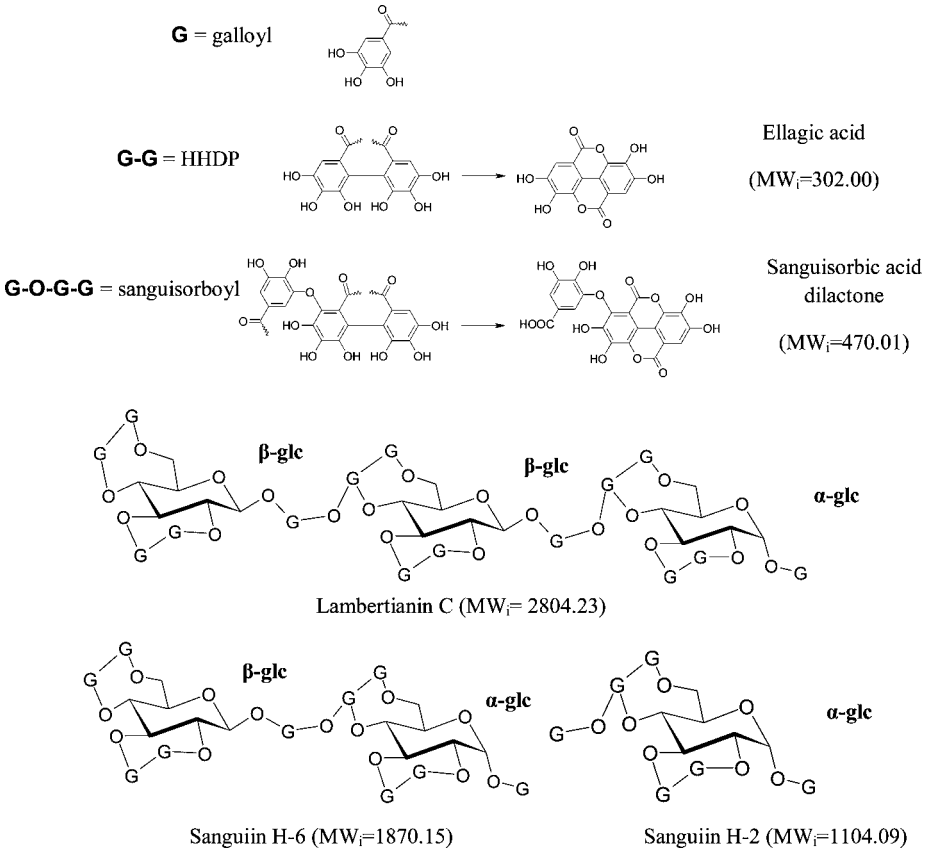

Figure 1. Structures of identified ellagitannins.

ellagitannins, ellagic acid derivatives, and hydroxycinnamic acids. Positive ionization was used for the identifiction of anthocyanins.

Seven anthocyanins (peaks 3, 4, 6, 8, 11, 14, and 18), seven flavonols (17, 19, 20, 21, 23, 26, and 35), three ellagitannins (5, 9, and 10), six ellagic acid derivatives (12, 13, 16, 25, 27, and 28), and one hydroxycinnamic acid (peak 2) were reported previously in blackberry fruits.[13,18−20] The following compounds, one phenolic acid (peak 1), one anthocyanin (peak 7), six flavonols (22, 24, 29, 31, 32, and 33), and three ellagic acid derivatives (15, 30, and 34) were identified for the first time in blackberries.

Anthocyanins. The analysis in the TOF-MS revealed the presence of eight anthocyanins in the investigated cultivars of blackberries, using positive ionization mode (Table 1). As previously stated, the identification of anthocyanins was performed by using the complementary information on chromatographic behavior and mass fragmentation, together with UV−vis profile and retention time. The MS/MS fragmentation demonstrated that the pseudomolecular cations of identified anthocyanins (peaks 3, 4, 6, 7, 8, 11, 14, and 18) were the precursors of cyanidin ($[M + H]^+$ at m/z 287.0557), indicative of cyanidin -glycosides. Peaks 3 and 4, with identical pseudomolecular cation (m/z 449.1183) and mass spectrometric fragmentation patterns, were identified as cyanidin 3-*O*-galactoside and cyanidin 3-*O*-glucoside on the basis of their retention times and UV−vis absorption spectra, compared with those of corresponding authentic standards. According to Long-Ze and Harnly,[21] the elution order of phenolic compounds for C18 columns is invariant. Glycosylated flavonoids with a monosaccharide at the same position elute in the order galactoside, glucoside, xyloside, arabinopyranoside, arabinofuranoside, rhamnoside, and then glucuronide. Peak 8, with m/z at 595.1713, was identified as cyanidin 3-*O*-rutinoside and peak 7, with m/z at 494.8155, as cyanidin dimethoxyrhamnoside. Peaks 6 and 11, with identical psudomolecular cation (m/z 419.0987) and mass spectrometric fragmentation patterns, were identified as cyanidin 3-*O*-arabinoside and cyanidin 3-*O*-xyloside on the basis of their retention times and UV−vis absorption spectra, compared with those of corresponding authentic standards. Peak 14, with $[M + H]^+$ at m/z at 535.1084, was identified as cyanidin 3-*O*-(6-*O*-malonyl-*β*-D)-glucoside, whereas peak 18, with $[M + H]^+$ at m/z at 593.1520, was identified as cyanidin 3-*O*-dioxalylglucoside.

Flavonols. The examination of the chromatograms in TOF-MS mode revealed the presence of quercetin (peak 35, m/z 301.0354). The MS/MS fragmentation showed further dissociation of the main fragment and produced the typical ion cluster of quercetin with large abundance of m/z 178.9938 and 151.0042.[22] Examination of the chromatograms in TOF-MS mode of thorny and thornless blackberries also revealed the presence of 10 quercetin glycosides (peaks 17, 19−24, 29, and 32).

Peak 17 had a pseudomolecular ion at m/z 609.1483 that fragmented in m/z 301.0354, owing to the loss of rhamnose (146 Da) and glucose (162 Da) residues. This compound was therefore tentatively identified as quercetin 3-*O*-rutinoside (rutin) on the basis of its retention time and UV−vis spectra, compared with those of corresponding authentic standards. Peaks 19 and 21, with identical pseudomolecular anions at m/z 463.0879 that fragmented in m/z 301.0359 owing to the loss of a hexose residue (162 Da), were identified as quercetin 3-*O*-galactoside (hyperoside) and quercetin 3-*O*-glucoside (isoquercitrin) on the basis of their retention times, UV−vis spectral profiles, and accurate standards. Peak 20 showed an $[M - H]^-$ at m/z 477.0665, which produced fragments at m/z 301.0354,

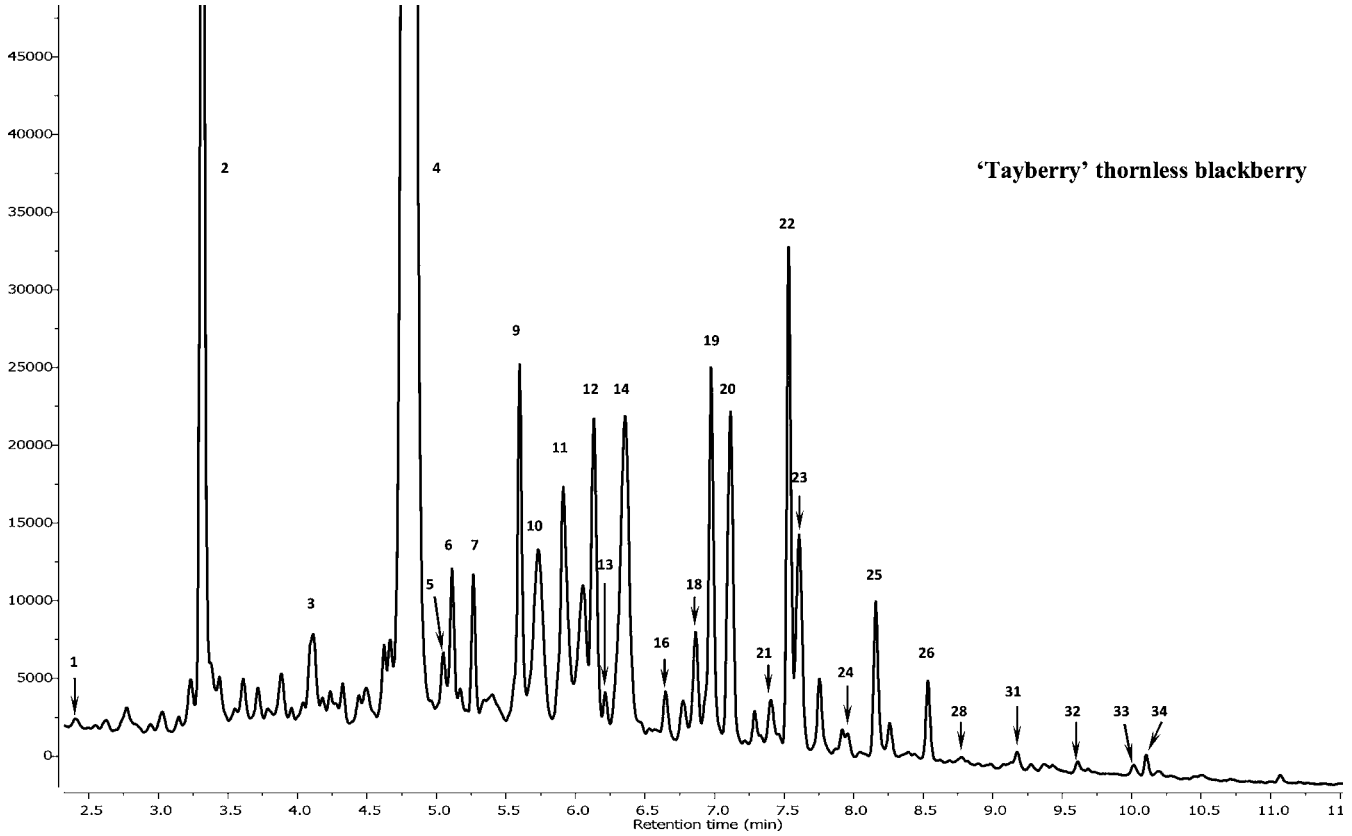

Figure 2. Segment from 2.25 to 11.25 min of LC-DAD chromatogram at 280 nm of 'Tayberry' thornless blackberry. Peak number identities are displayed in Table 1.

corresponding to the loss of a glucuronic acid residue (176 Da), and at 178.9938 and 151.0042, which are characteristic for quercetin. This pattern of fragmentation is in agreement with quercetin glucuronide, which was previously reported in *Rubus* species.[22] Peaks 23 (m/z 433.0735) and 32 (m/z 507.2253) were characterized as quercetin pentoside and quercetin dimethoxyrhamnoside, on the basis of their fragmentation pattern, with a loss of pentose (132 Da) and rhamnose (146 Da), respectively. Peaks 22, 24, and 29, with an identical pseudomolecular anion (m/z 505.0979) and mass spectrometric fragmentation patterns, were identified as quercetin acetylhexosides.

Peak 26 had a pseudomolecular ion at m/z 447.0959, which fragmented to m/z 285.0394, owing to the sugar moiety (162 Da) and corresponding formation of the aglycone.[23] This fragmentation was in agreement with those elsewhere and was attributed to kaempferol glucoside.[24] Peaks 31 and 33 have pseudomolecular ions at m/z 489.1059 and are fragmented at 285.0394, owing to the loss of the acetylhexose unit (204 Da). These compounds may be identified as kaempferol acetylgalactoside and acetylglucoside.

Ellagitannins. High MW ellagitannins based on galloyl-bis-HHDP-glucose units, such as sanguiins and lambetianins, have been commonly found in different kinds of berries, including blackberries.[18,19] The structures of identified ellagitannin are shown in Figure 1. The analysis in the TOF-MS revealed the presence of sanguiin H-6, a dimeric ellagitannin (peak 9, m/z 1869.1028). The MS/MS fragmentation gave an ion with $[M - H]^-$ at m/z at 935.0878, owing to the loss of galloyl-bis-HHDP-glucose (935 Da), a fragment with m/z at 633.0853, corresponding to the galloyl-HHDP-glucose structure, a fragment with m/z at 469.0005, corresponding to sanguisorbic acid dilactone, which is formed from the liberated sanguisorboyl group (Figure 1), and a fragment with m/z at 300.9999, corresponding to ellagic acid. Peak 5 had an $[M - 2H]^{-2}$ at m/z 1401.0981 and was identified as trimer lambertianin C. The MS/MS fragmentation gave an ion with $[M - H]^-$ at m/z at 935.0669, owing the loss of galloyl-HHDP-glucose (466 Da), and fragments with m/z at 633.0727, 469.0005, and 300.9999, corresponding to galloyl-HHDP-glucose, sanguisorbic acid dilactone, and ellagic acid, respectively. Peak 10 had a $[M - H]^-$ ion at m/z 1103.0897 and a principal MS/MS fragment at m/z 934.5746 derived from the loss of a gallic acid unit (169 Da) and was identified as monomeric sanguiin H-2. The MS/MS fragmentation also gave fragments with m/z at 633.1234, 469.0005, and 300.9999, as described above.

Ellagic Acid and Its Derivatives. The examination of the UPLC chromatograms in TOF-MS mode of thorny and thornless blackberries revealed the presence of free ellagic acid (peak 16, m/z 300.9999), MS/MS fragments at m/z 285.0425, 257.0208, and 229.0137, which are characteristic for ellagic acid,[25] and eight ellagic acid derivatives (peaks 12, 13, 15, 25, 27, 28, 30, and 34). Peak 12 has a pseudomolecular ion at m/z 433.0415 and MS/MS fragments at m/z 300.9999 and 229.0137; this dissociation pattern was previously observed by Simirgiotis and Schmeda-Hirschann[26] in *Fragaria chiloensis* berries and attributed to an ellagic acid pentoside. The TOF-MS analysis revealed the presence of ellagic acid acetylmethylpentoside (peak 15, m/z 489.1042). The MS/MS mass spectrum showed peaks at m/z 300.9999, corresponding to the loss of acetyl (42 Da) and methylpentoside (146 Da); 257.0208, corresponding to the loss of carbon oxide (28 Da); and 229.0137, corresponding to the loss of the second carbon

DOI: 10.1021/jf5039794
J. Agric. Food Chem. 2015, 63, 3012−3021

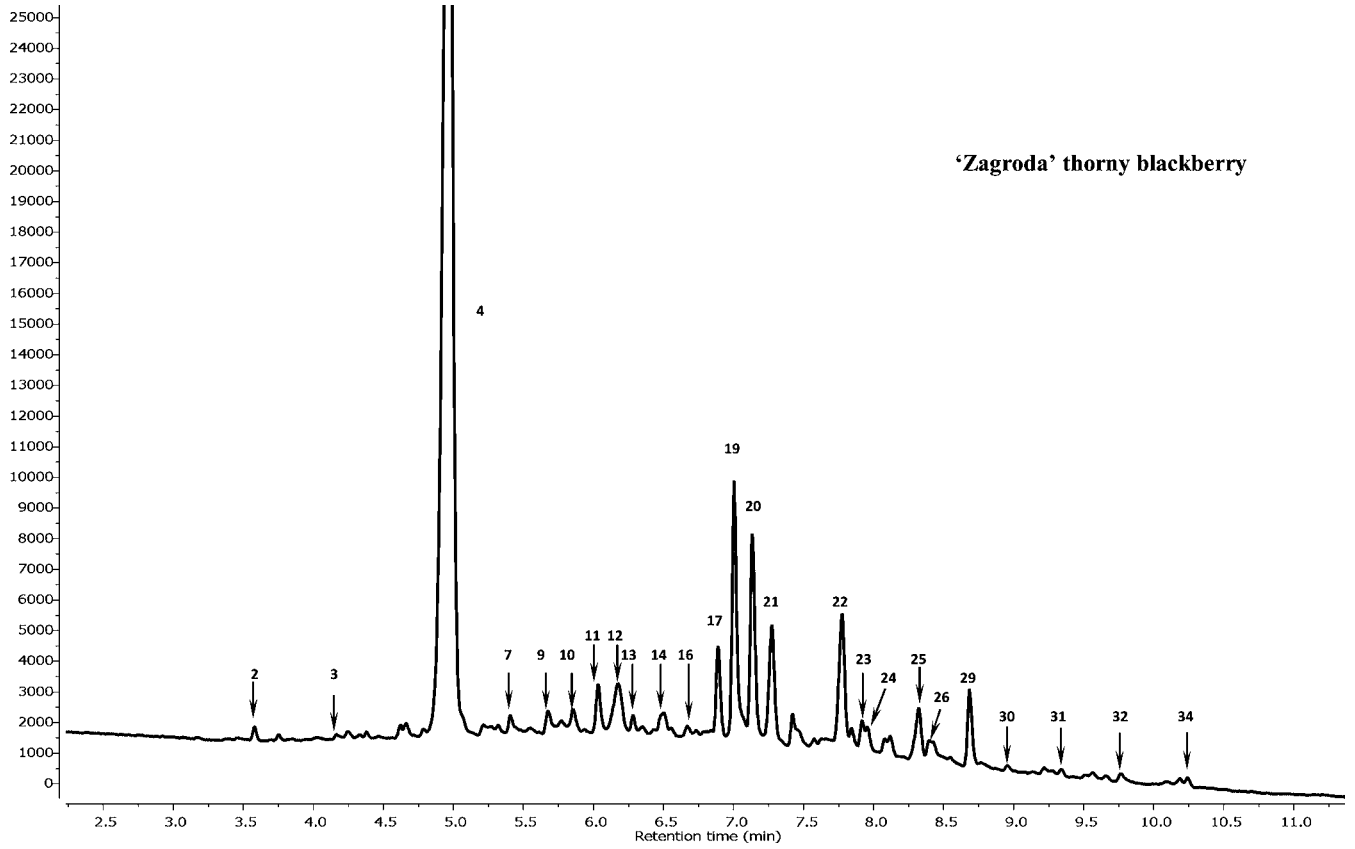

Figure 3. Segment from 2.25 to 11.25 min of LC-DAD chromatogram at 280 nm of 'Zagroda' thorny blackberry. Peak number identities are displayed in Table 1.

monoxide (28 Da). Peak 25, which showed $[M - H]^-$ at m/z 447.0570 and fragmentation with MS/MS ions at m/z 315.0113, owing to the loss of a pentose residue (132 Da) and m/z 300.9999 (further loss of methyl), can be attributed to methylellagic acid pentoside. Peak 27 had an $[M - H]^-$ at m/z 447.0570 that fragmented in the MS/MS at m/z 300.9999, corresponding to the loss of rhamnose residue (146 Da); 257.0208, owing to the loss of carbon oxide (28 Da); and 229.0137, corresponding to the loss of the second carbon monoxide (28 Da). This compound was identified as ellagic acid methylpentoside.[19] The analysis in the TOF-MS revealed the presence of two methylellagic acid glucuronide isomers (peak 13 with m/z at 491.0434 and peak 28 with m/z at 491.1976). The MS/MS mass spectrum showed peaks at m/z 315.0113 and 300.9999, corresponding to the loss of glucuronide (176 Da) and methyl (15 Da). Peaks 30 and 34 were identified as methylellagic acid acetylpentosides.[19] They had a pseudomolecular ion at m/z 489.1042 and produced MS/MS fragments at m/z 447.0959, corresponding to the loss of acetyl (42 Da); 315.0149, owing to the loss of pentose (132 Da); and 300.9999, corresponding to the loss of methyl (15 Da).

Hydroxycinnamic Acids and Others. Two hydroxycinnamic acids were identified by monitoring precursor and product ion scans and their retention times and UV−vis absorption spectra, by comparing them with those of corresponding authentic standards. Hydroxycinnamic acid (peak 1) yielded $[M - H]^-$ at m/z 353.0880, which was fragmented to generate m/z at 191.0552 (quinate ion). This component was identified as neochlorogenic acid by comparing it with the retention times and UV−vis profile of authentic standards of chlorogenic, cryptochlorogenic, and neochlorogenic acids. Hydroxycinnamic acid (peak 2) was identified as the *p*-coumaric acid hexoside by comparing it with the retention times and UV−vis profile of authentic standards of *p*-coumaric acid. Its MS/MS produced an $[M - H]^-$ of m/z 325.0949, which fragmented to 163.2778, corresponding to the loss of hexose residue (162 Da).

Quantitative Analysis of Polyphenols. *General.* Figures 2 and 3 show the LC-DAD chromatograms of thornless blackberries 'Tayberry' and thorny blackberries 'Zagroda'. Tables 2 and 3 show the contents of individual phenolic compounds of thorny and thornless blackberries. The amounts of anthocyanins, flavonols, ellagitannins, ellagic acid derivatives, and hydroxycinnamic acids were converted into cyanidin 3-*O*-glucoside (anthocyanins), quercetin (flavonols), chlorogenic acid (hydroxycinnamic acids), and ellagic acid (ellagitannins and ellagic acid derivatives). The qualitative compositions were similar for all cultivars but were quantitatively very different (Tables 2 and 3).

Anthocyanins. In thorny blackberries, the dominant compound among anthocyanins was cyanidin 3-*O*-glucoside (mean = 73.85 mg/100 g fresh weight). The highest amount of this compound (122.54 mg/100 g FW) has been found in 'Zagroda', whereas the lowest (25.15 mg/100 g FW) was reported in the 'Gazda' variety. The 'Zagroda' variety was also characterized by the highest contents of cyanidin methylpentoside, 3-*O*-arabinoside, 3-*O*-xyloside, and 3-*O*-(6-*O*-malonyl-*β*-D)-glucoside (11.00, 0.41, 6.37, and 3.34 mg/100 g FW, respectively). Cyanidin 3-*O*-rutinoside has been found only in 'Early Wilson' blackberries (4.66 mg/100 g FW) and cyanidin 3-*O*-dioxalylglucoside only in the 'Leśniczanka' variety.

[b]Values are means ± standard deviation, $n = 3$. Mean values within a row with different letters are significantly different at $p < 0.05$. [c]Amounts of anthocyanins, flavonols, ellagitannins, including ellagic acid derivatives, and hydroxycinnamic acids were converted into cyanidin 3-*O*-glucoside (anthocyanins), quercetin (flavonols), chlorogenic acid (hydroxycinnamic acids), and ellagic acid (ellagitannins and ellagic acid derivatives).

The dominant compound among anthocyanins in thornless blackberries was cyanidin 3-*O*-glucoside (mean = 134.77 mg/100 g FW). The highest amount of this compound (188.77 mg/100 g FW) was found in 'Loch Ness' fruits, whereas the lowest (80.76 mg/100 g FW) was in 'Hull Thornless'. Simultaneously, cyanidin 3-*O*-rutinoside (11.14 mg/100 g FW) has been found only in 'Hull Thornless' blackberries.

The analysis revealed statistically significant differences in the anthocyanin concentrations of thorny and thornless blackberries. The sum of those compounds of individual thornless varieties was higher by 47% in comparison to thorny ones.

Flavonols. In thorny blackberries, the dominant compound among flavonols was quercetin 3-*O*-galactoside (mean = 1.64 mg/100 g FW). The highest amount of this compound was found in 'Gazda' fruits (2.56 mg/100 g FW), whereas the lowest (0.72 mg/100 g FW) was reported in the 'Early Wilson' variety. The 'Zagroda' variety was characterized by the highest contents of quercetin 3-*O*-rutinoside and glucuronide (0.59 and 1.79 mg/100 g FW) simultaneously; quercetin 3-*O*-pentoside was not found in those fruits.

In thornless fruits, the dominant compound among flavonols was quercetin 3-*O*-acetyl-hexoside (1.13 mg/100 g FW). The highest concentration of this compound has been determined in the 'Chester Thornless' variety (1.60 mg/100 g FW), whereas the lowest (0.66 mg/100 g FW) was in 'Hull Thornless' blackberries. Quercetin 3-*O*-rutinoside has been found only in 'Smoothstern' and 'Orkan' fruits (0.14 and 0.18 mg/100 g FW, respectively). The analysis shows that the concentrations of flavonols in thorny and thornless blackberries were significantly different. In thornless blackberries the sum of flavonols of individual varieties was lower by 86% in comparison to thorny ones.

Ellagitannins. In thorny blackberries, the dominant compound was lambertianin C (mean = 3.47 mg/100 g FW). The highest amount of this compound (4.56 mg/100 g FW) has been found in 'Zagroda', whereas the lowest (2.37 mg/100 g FW) is in 'Gazda' blackberries. The 'Zagroda' variety was characterized by the highest content of all ellagitannins. The amounts of sangiuiins H-6 and H-2 in those fruits were 4.82 and 0.29 mg/100 g FW, respectively. The lowest concentration of ellagitannins has been found in 'Early Wilson' blackberries. The amounts of sanguiins H-6 and H-2 in those varieties were 1.00 and 0.03 mg/100 g FW, respectively.

In thornless blackberries, similar to in thorny ones, lambertianin C was dominant (mean = 6.30 mg/100 g FW). The highest amount of this compound (8.65 mg/100 g FW) was found in 'Thornfree', whereas the lowest (3.95 mg/100 g FW) was in 'Hull Thornless' blackberries. The 'Thornfree' variety was also characterized by the highest concentration of other ellagitannins. The amounts of sanguiins H-6 and H-2 in those fruits were 7.58 and 0.47 mg/100 g FW, respectively. The lowest amounts of sanguiin H-6 (2.48 mg/100 FW) and

DOI: 10.1021/jf5039794

sanguiin H-2 (0.12 mg/100 g FW) were found in 'Chester Thornless' variety. The analysis revealed statistically significant differences in the total ellagitannins concentration of thorny and thornless blackberries. The sum of those compounds of individual thornless varieties was higher by 44% in comparison to thorny ones.

Ellagic Acid and Its Derivatives. In thorny blackberries, the dominant compound among ellagic acid derivatives was ellagic acid (mean = 1.69 mg/100 g FW). The highest amount of ellagic acid (2.71 mg/100 g FW) was determined in 'Leśniczanka', whereas the lowest (0.66 mg/100 g FW) was in 'Zagroda' variety. 'Early Wilson' variety was characterized by the greatest diversity of ellagic acid derivatives. Ellagic acid acetyl methylpentoside (0.10 mg/100 g FW) was found in only those fruits. Ellagic acid pentoside was found only in 'Zagroda' and 'Early Wilson' varieties (0.76 and 0.19 mg/100 g FW, respectively).

In thornless blackberries, ellagic acid was also the dominant compound (mean = 2.60 mg/100 g FW). The highest content of this compound (4.02 mg/100 g FW) was found in 'Hull Thornless' blackberries, whereas the lowest (1.18 mg/100 g FW) was in the 'Tayberry' variety. Ellagic acid pentoside was found only in 'Loch Ness' variety (0.45 mg/100 g FW), whereas methylellagic acid acetylpentoside 2 was found only in 'Hull Thornless' (0.23 mg/100 g FW). The analysis revealed statistically significant differences in the sum of ellagic acid derivatives of thorny and thornless blackberries. The sum of those compounds of individual thornless varieties was higher by 27% in comparison to thorny ones.

Hydroxycinnamic Acids. In thorny blackberries, hydroxycinnamic acids were found only in the 'Zagroda' variety. The amount of neochlorogenic acid was 0.95 mg/100 g FW, and that of *p*-coumaric acid hexoside acid was 0.47 mg/100 g FW.

In thornless blackberries, the highest amount of neochlorogenic acid has been determined in 'Black Beauty' fruits (1.55 mg/100 g FW). The highest amount of *p*-coumaric acid hexoside (0.38 mg/100 g FW) was found in the 'Thornfree' variety. In 'Hull Thornless', 'Smoothstern', and 'Orcan' blackberries, no hydroxycinnamic acids were found. The analysis shows that the concentrations of the sum of hydroxycinnamic acids in thorny and thornless blackberries were significantly different. In thornless blackberries, the sum of hydroxycinnamic acids of individual varieties was lower by 21% in comparison to thorny ones.

The concentrations of ellagic acid derivatives (mean = 2.92 mg/100 g FW in thorny and 2.49 mg/100 g FW in thornless blackberries) were quite similar to those reported by other authors. Siriwoharn and Wrolstad[9] reported that blackberries had ellagic acid derivative contents varying from 1.64 to 3.62 mg/100 g FW, whereas Gancel et al.[27] reported 7.57 mg of ellagic acid in 100 g FW of highland blackberry. Hager et al.[5] reported that ellagitannins content in blackberries varied from 2.06 to 9.78 mg/100 g FW, whereas Siriwohran et al.[7] reported anthocyanins content varying from 131 to 256 mg/100 g FW, which was higher than our research (mean = 86.47 mg/100 g FW in thorny and 171.23 mg/100 g FW in thornless blackberries) and similar to values of Gancel et al.,[27] who reported 126.3 mg/100 g FW for cyanidin 3-*O*-glucoside and 11.73 mg/100 g FW for cyanidin 3-*O*-malonylglucoside in highland blackberry. Bilyk and Sapers[28] reported a mean of 1.55 mg/100 g FW of flavonols, which was lower than in our research (5.70 mg/100 g FW in thorny and 2.09 mg/100 g FW in thornless blackberries), whereas Heinonen et al.[29] and Siriwoharn and Wrolstad[9] described higher concentrations of these compounds: 8.3 mg/100 g FW and 11.6−17.8 mg/100 g, respectively. Sellappan et al.[12] reported that blackberries and blueberries had hydroxycinnamic acid contents varying from 0.40 to 2.08 mg/100 g FW, which was quite similar to our results (1.42 mg/100 g FW in thorny and 0.7 mg/100 g FW in thornless blackberries).

According to Wang and Lin[30] and Jiao and Wang,[31] the levels of phenolics are influenced by maturity and there is pronounced variation among cultivars. The results of the present study demonstrate that the proportion and content of anthocyanins, flavonols, ellagitannins, and phenolic acids varied greatly among cultivars and types of blackberries. The large standard deviation in some of the results underscores the difficulty in obtaining evenly matured fruit samples for analysis. Thornlessness has long been a priority in almost all blackberry breeding programs and remains a major goal today; the second one is pest and disease resistance.[32]

In plants, flavonoids play an important role in biological processes. Polyphenols, which can be acquired in tissues under stress, are key components of active and potent defense mechanisms against pests and pathogens.[33] In many works[34−36] there is a strong correlation between a high phenolic concentration and resistance against herbivores including insect pests.

The higher concentration of polyphenols in thornless blackberries may be the result of development of cultivars resistant to pests and diseases. At the same time, thornless blackberries could develop new strategies of physiological defense by the production of larger amounts of flavonoids, including tannins. Tannins are derivatives with a bitter taste and toxic properties that can discourage or deter animals from feeding. The incorporation of novel resistance to pests and diseases is regarded as essential for the development of cultivars suitable for processing.

In conclusion, total phenolic and total anthocyanin contents varied greatly among cultivars. The 'Loch Ness' and 'Chester Thornless' cultivars contained the highest total anthocyanin and total phenolic contents among the 14 cultivars studied. 'Gazda' berries had the highest flavonol concentrations, whereas 'Thornfree' and 'Hull Thornless' selections were highest in ellagitannins and ellagic acid derivatives, respectively. Thorny and thornless blackberries are a good source of antioxidants that can be used in foods and nutritional supplement formulations.

corresponding volatiles, can be further transformed in the mouth. This leads to a long-lasting hoppy aroma.[21] This source of hoppy note must be viewed as part of the hop flavoring potential.

Besides free and bound terpenoids, polyfunctional thiols have recently been referred to as important hop-derived flavoring compounds in beer, especially when dual-purpose hop varieties are used. Forty-one volatile polyfunctional thiols have been reported in hop, most of them having a 3-carbon distance between the thiol and the oxygenated functions.[8] Rhubarb/grapefruit-like 3-sulfanyl-4-methylpentan-1-ol (3S4MPol) and blackcurrant-like 4-sulfanyl-4-methylpentan-2-one (4S4M2Pone) constitute key compounds of the "Sauvignon-like" notes imparted to beer by Nelson Sauvin hop.[14] Floral-like 3-sulfanyl-2-ethylpropyl acetate (3S2EPrA) and citrus/peach-like 3-sulfanyloctanal (3SOal) distinguish Tomahawk from all other thiol-rich varieties. Most low-bitter varieties, including Saaz, appear to be greatly lacking in polyfunctional thiols. Yet blackcurrant-like 4S4M2Pone and grapefruit-like 3-sulfanylhexan-1-ol (3SHol) have been described as key aroma compounds participating in the Muscat-like flavor perceived in Cascade (4.5−8% α-acids) hopped beer.[8,13,15,22]

Whatever the cultivar, the thiol content of the final beer reaches much higher values than expected from the hop content. S-cysteine conjugates, recently evidenced for the first time in hop,[23,24] are partly responsible for the increases in thiol content from hop to wort and beer. The β-lyase activity of yeast, causing specific cleavage of the thiol from its conjugate, converts nonvolatile precursors to odorant thiols. The commercial apotryptophanase from *Escherichia coli* has been widely used to investigate cysteine- and cysteinylglycine adducts in plants[24−27] (free amine required for the enzyme activity-glutathione adducts not quantified by this assay[27]). Depending on the hop variety, the S-cysteine conjugate fraction represents a bound potential 23−126 times as high as the fraction of corresponding volatiles.[24] The rate of conversion by the action of yeast remains low during the main fermentation.[28−30] The late stage of bottle refermentation[20] and dry hopping during maturation constitute additional chances for yeast to convert these intact S-conjugates.[19] The nutrient-depleted conditions encountered after fermentation are thought to favor this yeast activity.[19,30,31]

Chemical information concerning the aromatic potential of other new dual-purpose varieties remains scarce. The aim of the present work was therefore to quantify free terpenoids and both free and bound polyfunctional thiols in five selected cultivars: Amarillo, Citra, Hallertau Blanc, Mosaic, and Sorachi Ace. The aromatic profiles of these cultivars were compared with those previously obtained for the dual-purpose varieties Tomahawk and Nelson Sauvin and for the low-bitter aromatic reference Saaz.[8,24]

EXPERIMENTAL PROCEDURES

Chemicals. Ammonia (28%) was from VWR (Leuven, Belgium). *p*-Hydroxymercuribenzoic acid (*p*HMB), 37% HCl, S-benzyl-L-cysteine (IST for apotryptophanase assays), apotryptophanase, pyridoxal-5-phosphate, ethylenediaminetetraacetic acid, the Amberlite IR-120 resin, carvone (IST for Likens Nikerson extractions), myrcene, linalool, geraniol, β-caryophyllene, α-humulene, β-farnesene, undecan-2-one, 3-sulfanylpropyl acetate (**1**)*, 3-sulfanylpropan-1-ol (**14**)*, 3-sulfanyl-3-methylbutan-1-ol (**17**)*, 2-sulfanylethan-1-ol (**36**)*, 2-sulfanylethyl acetate (**38**)*, and 2-acetylthiophene (EST for free thiol extractions) were purchased from Sigma-Aldrich (Bornem, Belgium). An asterisk means that numbering of compounds is conserved from refs 8 and 24. 4-Methoxy-2-methylbutan-2-thiol (IST for free thiol extractions), 3-sulfanylhexyl acetate (**11**)*, 3-sulfanylhexan-1-ol (**23**)*, and 3-methyl-2-buten-1-thiol (**37**)* were obtained from Oxford Chemicals (Oxford, U.K.). 4-Sulfanyl-4-methylpentan-2-one (**29**)* was from Frutarom (Hartlepool, U.K.). Dichloromethane (99.9%) obtained from VWR (Leuven, Belgium) was distilled before use. Milli-Q water was used (Millipore, Bedford, MA, U.S.A.). NaOH and sodium sulfate (99%) were supplied by Janssen (Geel, Belgium). A strongly basic Dowex resin 1 × 2, Cl^- form (Sigma-Aldrich, Bornem, Belgium) was stored in hydrogen chloride (0.1 M). Anhydrous sodium sulfate was obtained from Merck (Darmstadt, Germany), and tris(hydroxymethyl)-aminomethane (Tris) was obtained from USB (Cleveland, Ohio, U.S.A.). Formic acid was provided by Fischer (Loughborough, U.K.). Polyvinylpyrrolidone was supplied by Spindal (Gretz-Armainvilliers, France).

Reference Compounds Synthesized in Our Laboratory. 3-Sulfanyl-2-ethylpropyl acetate (**10**)* was synthesized prior to this work (reagents and complete procedure described in ref 32). 1-Sulfanylpentan-3-ol (**19**)* and 3-sulfanylpentan-1-ol (**21**)* were obtained with the reagents and procedure disclosed in ref 33. 3-Sulfanylheptanal (**33**) and 3-sulfanyloctanal (**35**)* were obtained according to the procedure described in ref 34. 3-Sulfanyl-4-methylpentan-1-ol (**26**)* was synthesized according to ref 35.

Hop Samples. Amarillo, Citra, Mosaic, and Sorachi Ace bred in the U.S.A. were provided by Yakima Chief (Louvain-la-Neuve, Belgium). Hallertau Blanc hop came from Hopsteiner (Germany). Their α-acid contents were given by the suppliers.

Extraction of Terpenoids and Other Non-Sulfur Hop Oils by the Likens Nickerson Method. Steam distillation−solvent extraction was carried out in a microextractor (Alltech 8910) according to ref 36. Hop pellets (0.5 g) were milled and mixed with 50 mL of deoxygenated ultrapure water and 1.5 mL of a carvone solution at 20 mg/L (internal standard) in flask A. Dichloromethane and ultrapure, deoxygenated water (1.5 mL each) were introduced into the liquid/liquid extraction area. Dichloromethane (1.5 mL) was introduced into the organic-phase vessel (B). A few clean grains of carborundum were added into flasks A and B. Prior to the procedure, the entire system was purged with nitrogen (2−3 mL/min) for 5 min. Flask A was then heated in a 140 °C oil bath, and flask B was heated in a 70 °C water bath. The vapors were condensed by means of a coldfinger maintained at −10 °C by a cryostat. The entire steam distillation−solvent extraction procedure was carried out under a 2 mL/min nitrogen flow. The steam distillation was stopped after 45 min. The dichloromethane extract was then concentrated to 0.5 mL at 45 °C with a Kuderna−Danish concentrator. The method allows most of the terpenic compounds to be recovered with factors >92% and variation coefficients <6%.[36]

Extraction of Free Polyfunctional Thiols by *p*HMB. Polyfunctional thiols were extracted from hop according to ref 8, adapted from ref 37 (dichloromethane liquid/solid extraction of 15 g of hop, extraction of the resulting organic phase with a *p*HMB solution, loading of bound thiols onto a strong anion-exchange resin, release of free thiols by exchange with washed cysteine [4 × 50 mL of dichloromethane for washing 640 mg of cysteine], final extraction with dichloromethane, and concentration to 250 μL in a Kuderna−Danish apparatus and to 70 μL in a Dufton column). 4-Methoxy-2-methylbutane-2-thiol was added as internal standard (IST, at 33.5 μg/kg), and 2-acetylthiophene was added as external standard (EST, 1 mL at 200 μg/L added before concentration).

Extraction of Cysteine-S-conjugates from Hop and Release of the Corresponding Free Thiols by the Apotryptophanase Assay. The extraction was conducted on the hop according to the procedure of ref 24 adapted from ref 27. Milled pellets (100 g) spiked with 1 mL of 1600 mg/L S-benzyl-L-cysteine were extracted with 1 L of hydroalcoholic solution ($EtOH/H_2O/HCOOH$ = 49.5:49.5:1, v/v/v) for 2 h. After centrifugation for 30 min at 1200*g*, the polyphenols present in the supernatant were partially removed by addition of 30 g of polyvinylpyrrolidone and stirring for 30 min. After a second centrifugation, the extract was purified on the IR-120 (H+) cation-exchange resin (100 g) conditioned with 100 mL of 6% HCl followed by 1 L of ultrapure water. After washing with 500 mL of water, sequential fractions were recovered by eluting with aqueous ammonia solutions (100 mL each) at the following concentrations: 0.3, 0.6, 0.9, 1.2, 1.5, 1.8,

[a]Data issued from ref 8; letters after T, NS, or S indicate the statistical group for the reported concentrations in Tomahawk, Nelson Sauvin, and Saaz. I^+, compound identified by mass spectrometry (full scan monitoring) and coincidence with the retention index. [b]Compounds previously selected for discriminating Cascade, Challenger, Hallertau Mittelfrueh, Lublin, Mount Hood, Northdown, Northern Brewer, Nugget, Saaz, Styrian Golding, and Target.[5,7]

and 2.1 M. The 1.2 and 1.5 M fractions were pooled, vacuum-evaporated, and lyophilized. The dried 1.2−1.5 M fraction (~100 mg) was suspended in 2 mL of potassium phosphate buffer (100 mM, pH 7.7) containing pyridoxal 5-phosphate (0.1 mM) and ethylenediaminetetraacetic acid (1 mM). Five hundred microliters of a solution containing the commercial apotryptophanase from *Escherichia coli* (75−150 units/mg), freshly prepared (1 mg in 0.5 mL of buffer), were added. The incubation was kept at 28 °C for 30 min. A control without enzyme was conducted in parallel. The mixture was then stirred with 5 mL of bidistilled dichloromethane for 30 min. The organic phase was dried over sodium sulfate prior to concentration to 500 μL in a Kuderna−Danish apparatus and to 70 μL in a Dufton column.

Gas Chromatography Hyphenated to Olfactometric and Flame Ionization Detectors (GC-O and GC-FID). Two μL of extract (Likens Nikerson, *p*HMB free thiols or enzymatically released thiols) was analyzed with a Chrompack CP9001 gas chromatograph equipped with a splitless injector maintained at 250 °C; the split vent was opened 0.5 min postinjection. Compounds were analyzed with a wall-coated open tubular (WCOT) apolar CP-Sil 5 CB (50 m × 0.32 mm i.d., 1.2 μm film thickness) column or a polar FFAP (25 m × 0.32 mm i.d., 0.3 μm film thickness) capillary column. The carrier gas was nitrogen, and the pressure was set at 50 kPa (CP-Sil 5 CB) or 30 kPa (FFAP). The oven temperature was programmed to rise from 36 to 85 °C at 20 °C/min, then to 145 °C at 1 °C/min, and finally to 220 °C at 3 °C/min and held for 30 min. The column was connected to an FID detector (set at 250 °C with inlet of 21 mL/min H_2 and 210 mL/min air) and a GC-O port (Chrompack) maintained at 250 °C. The GC-O effluent was diluted with a large volume of air (20 mL/min) prehumidified with an aqueous copper(II) sulfate solution. All extracts were analyzed immediately after extraction by two trained panelists.

Quantitation of Terpenoids and Other Non-Sulfur Hop Constituents. For commercially available compounds, FID calibration curves (with areas relative to carvone (IST)) were used. For commercially unavailable compounds, quantitations are given in IST equivalents (response coefficient relative to the IST set at 1; values carrying an IST superscript in Table 1).

Gas Chromatography Hyphenated to a Pulsed-Flame Photometric Detector (GC-PFPD) and an Electronic Impact Mass Spectrometer (GC-MS). Two μL of extract (Likens Nikerson, *p*HMB free thiols or enzymatically released thiols) were analyzed with an Agilent 6890N gas chromatograph. The injections were carried out in the splitless mode at 250 °C, the split being turned on after 0.5 min. The oven temperature program and the columns were the same as described for GC-FID and GC-O. The carrier gas was helium, and the pressure was set at 100 kPa (CP-Sil 5 CB) or 45 kPa (FFAP). The column was connected to a mass spectrometer (m/z = 40−380 recorded at 70 eV) and a PFPD port (O.I. Analytical PFPD, model 5380). The following parameters were selected for the PFPD detector: temperature, 220 °C; voltage, 590 V; gate width, 18 ms; gate delay, 6 ms; trigger level, 400 mV; pulse frequency, 3.33 Hz. PFPD and MS chromatograms were simultaneously recorded throughout elution; ChemStation software was used. Identifications were done as previously described in ref 8.

Quantitation of Thiols (A) in *p*HMB Extracts. The following general equation was used for compound A quantitation: concentration of A (in μg/kg) = IST concentration (in μg/kg) × (A molecular weight/IST molecular weight) × (A area/IST area) × (IST molar response coefficient/A molar response coefficient) × (IST recovery factor/A recovery factor).

The IST-relative recovery factor was set at 1 for all compounds (experimental values from 0.8 to 1.2, previously determined by standard addition) except for 2-sulfanylethan-1-ol (bad recovery at the second dichloromethane extraction; approximate concentrations given by applying a ratio of 0.1 assessed by standard addition). For commercially available thiols, complete calibration curves relative to the IST were used (use of the experimental response coefficient ratio in the above equation). For commercially unavailable compounds (values carrying an

DOI: 10.1021/jf505855b

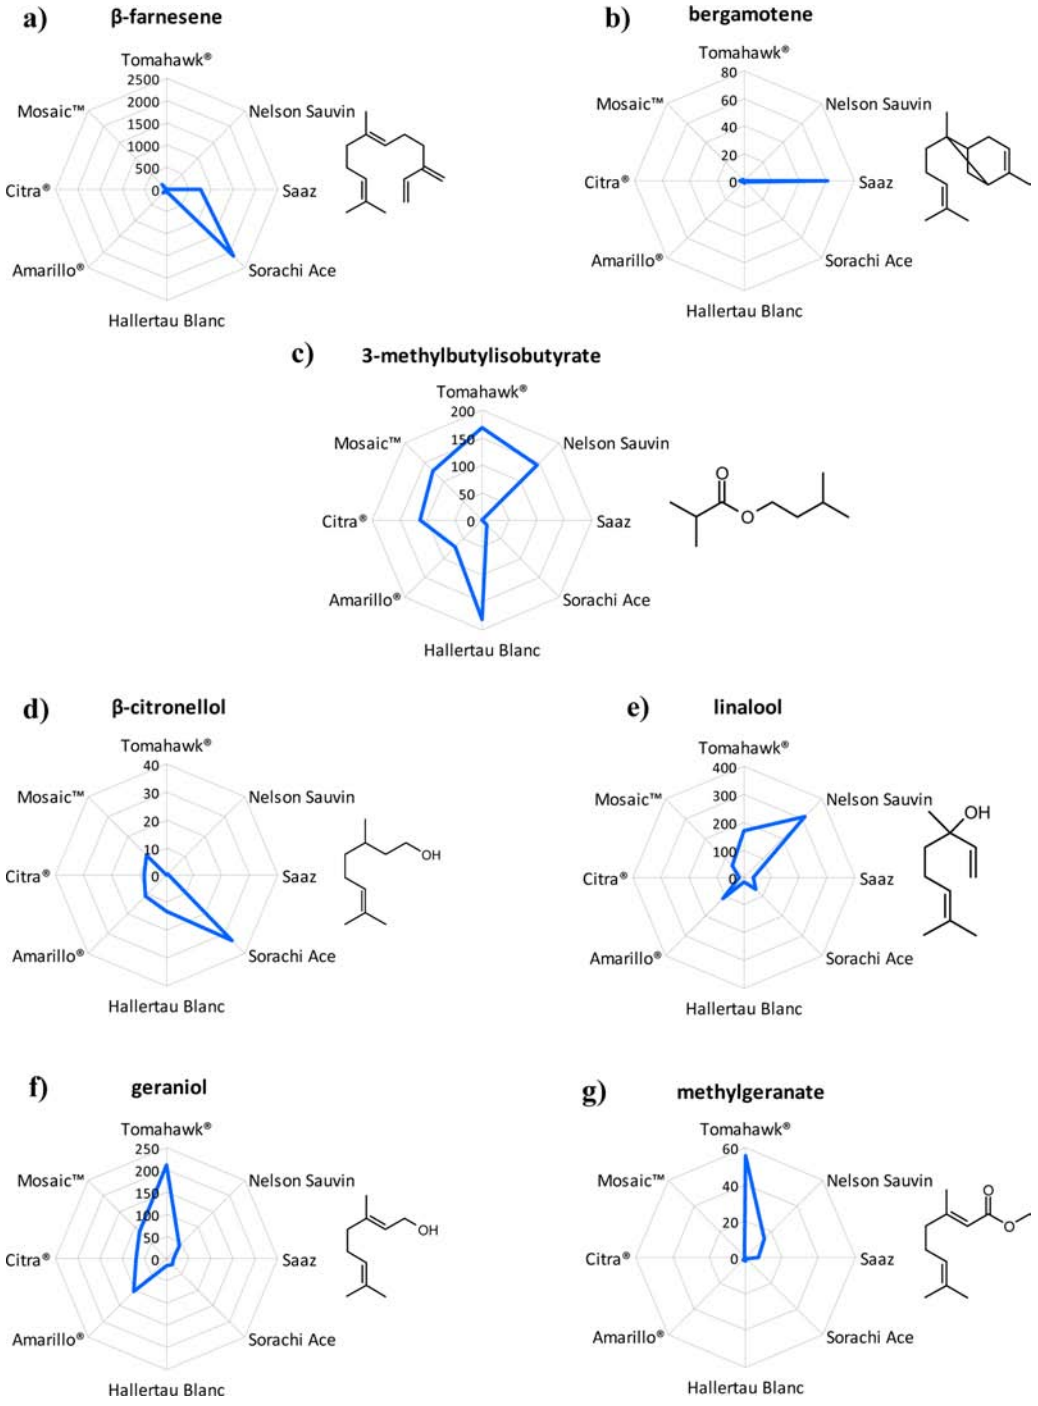

Figure 1. Spider diagrams and corresponding chemical structures of discriminant nonsulfur constituents in seven dual-purpose hop varieties, as compared to Saaz. Concentrations in mg/kg of hop.

IST superscript in Table 2), the good equimolarity of the PFPD detector enabled us to set the IST-relative molar response coefficients at 1. The variation coefficients for thiols (extraction and analysis) were below 15%.

Quantitation of Free Thiols (X) Released by Enzymatic Treatment. For free thiol quantitation, the following equation was used:[24] concentration of X (in μg/kg) = concentration of bound IST (in μg/kg) × (molecular weight of free IST/molecular weight of bound IST) × (peak area of X/peak area of free IST) × (mass response coefficient of free IST/mass response coefficient of X).

The same bound-to-free thiol conversion rates were used for all compounds.[24] For commercially unavailable compounds, the mass response coefficient of X was assessed as the molar response coefficient of free IST × (molecular weight of X/molecular weight of free IST)

Statistical Analyses. All analyses were carried out in duplicate. Multiple comparisons of means were performed by means of Student−Newman−Keuls tests, with SAS software version 9.2 (SAS Institute, Inc., Cary, NC, U.S.A.). Values that do not share a letter indicating significance are significantly different ($p < 0.05$).

RESULTS AND DISCUSSION

To extend the data provided by Gros et al.,[8] the terpenoid profiles of five new dual-purpose hops were determined (Figure 1

DOI: 10.1021/jf5058556
J. Agric. Food Chem. 2015, 63, 3022−3030

and Table 1). GC-MS analyses of hop Likens Nickerson extracts showed much diversity.

The most unexpected result was the concentration of β-farnesene (2101 mg/kg) in the Sorachi Ace variety, despite its high α-acid content (12.3%) (Figure 1a). Amarillo (9.3% α-acids) and Mosaic (11.7% α-acids) also contained concentrations of β-farnesene (152.6 and 102.8 mg/kg, respectively) very close to those usually found in the finest aromatic varieties Lublin, Saaz, and Styrian Golding (discrimination level for these aromatic hop set at 150 mg/kg for fresh samples).[5] On the other hand, bergamotene, claimed to be the second discriminating sesquiterpene of aromatic varieties (>10 mg/kg),[7] was found only at trace levels in all dual-purpose varieties (1.4−3.1 mg/kg).

As expected for bitter varieties, 3-methylbutylisobutyrate derived from α-acid lateral chain degradation was found at much higher levels (69−181 mg/kg) in Amarillo, Citra, Hallertau Blanc, and Mosaic than in Saaz (Figure 1c). Surprisingly, a low concentration was found in Sorachi Ace (13 mg/kg).

The concentration of β-citronellol was above 7 mg/kg in the five dual-purpose hops investigated here, while values under 1.2 mg/kg have been reported for Nelson Sauvin and Tomahawk (Figure 1d). Taking into account a dilution factor of ∼500 between hop and beer (hopping rate generally ∼200 g/hL) and a flavor threshold of 8 μg/L,[14] we can assume an impact of this citrus-like terpenoid in the flavor of derived beers. On the other hand, the two other monoterpenic alcohols linalool (Figure 1e) and geraniol (Figure 1f) remain good discriminating compounds for Nelson Sauvin and Tomahawk, respectively (18−109 mg/kg linalool in the five hops investigated here versus 312 mg/kg in Nelson Sauvin; 16−105 mg/kg geraniol versus 211 mg/kg in Tomahawk, where more methylgeranate was also found, together with α- and β-selinene and α-amorphene). The fruity Mosaic variety was characterized by the presence of 237 mg/kg of undecan-2-one (<113 in all other varieties).

Polyfunctional thiols were selectively extracted from hops with an organomercuric reagent (*p*HMB). Identifications were achieved on two capillary columns (polar FFAP and apolar CP-Sil 5 CB) by the coincidence of retention times at the selective pulsed flame photometric detector (PFPD) and odors at the olfactometric port (GC-O). The selective PFPD enabled us to quantify 9 thiols (some peaks previously found in other hop extracts were here undetected or unsufficiently resolved; see Table 2 and Figure 2). As previously evidenced for Nelson Sauvin and Tomahawk,[8,13,35] each variety investigated here exhibited a unique thiol profile.

2-Sulfanylethyl acetate (no. 38, 2SEA, toasted, Figure 3a), 3-sulfanylpropyl acetate (no. 1, 3SPrA, grilled), and 2-sulfanylethan-1-ol (no. 36, 2SEol, grilled, Figure 3b) were found in the Citra variety at levels never encountered in other hops (see also Figure 2b and Table 2). 2SEA and 2SEol explain 95% of the exceptionally high total amount of polyfunctional thiols found in Citra (1296 μg/kg). Also worth stressing is the presence in the Citra variety of a very pleasant discriminating compound, 3-sulfanylhexyl acetate (no. 11, 3SHA, passionfruit, grapefruit, 27 μg/kg, Figure 3c). By comparison with its threshold of 0.005 μg/L in beer[38] and taking into account a dilution ratio of ∼500 from hop to beer, 3SHA should have an impact in the flavor of Citra-hopped beers. This is probably not the case for the empyreumatic odorants discussed earlier (867 μg/kg / 500 L/kg = 1.7 μg/L of 2SEA for a threshold of 40 μg/L).[39]

Although relatively poor in other polyfunctional thiols (total = 122 μg/kg), the Hallertau Blanc cultivar proved much richer in 3-sulfanyl-4-methylpentan-1-ol (no. 26, 3S4MPol, grapefruit, rhubarb, Figure 3d), although 3S4MPol was previously claimed to be specific to the Nelson Sauvin. Here we found it at

[a]Concentration determined by GC-PFPD. Mean of duplicates. Values within a row with different letters are significantly different ($p < 0.05$) according to the Student−Newman−Keuls test. [b]nd, not detected (<8 μg/kg). d, detected but unresolved. [c]Data issued from ref 24; letters after T, NS, or S indicate statistical group for the reported concentrations in Tomahawk, Nelson Sauvin, and Saaz.

concentrations up to 109 μg/kg (IST equivalents), compared to 25−46 μg/kg in Mosaic, Nelson Sauvin, and Amarillo and 10−13 μg/kg in Citra and Tomahawk. This compound was not detected at all in the Sorachi Ace variety.

J. Agric. Food Chem. 2015, 63, 3022−3030

4-Sulfanyl-4-methylpentan-2-one (no. 29, 4S4M2Pone, catty, Figure 3e), another proposed marker of the Nelson Sauvin cultivar (7 μg/kg), was found at amounts 4-fold higher (30 μg/kg) in Mosaic and 11-fold higher (83 μg/kg) in Sorachi Ace. 1-Sulfanylpentan-3-ol (no. 19, 1S3Pol, nettle, Figure 3f) was found at the highest level in Mosaic (30 μg/kg, IST equivalents).

3-Sulfanyl-2-ethylpropyl acetate (no. 10, 3S2EPrA, floral, vinegar) and 3-sulfanyloctanal (no. 35, 3SOal, citrus, peach) remained undetected in all five new dual-purpose varieties investigated here, whereas they were previously identified as markers of Tomahawk and Nelson Sauvin.

S-cysteine conjugates of our five varieties were purified and subjected to apotryptophanase treatment (Table 3). Quantitations were done in IST equivalents, assuming that benzylthiol was released from its S-cysteine conjugate in the same way as all free amine hidden hop thiols.[24] Eight different adducts were identified, including two never before reported (2SEol and 3S4MPol).

The Sorachi Ace, Citra, and Amarillo varieties contained 1158, 616, and 413 μg/kg of hidden 3SHol, respectively. These values should be compared to the 1641 μg/kg previously found by Gros et al. in Cascade,[24] the hop variety where they identified the first S-cysteine conjugate by high-performance liquid chromatography (HPLC)/MS/MS. No obvious relation seems to exist between free and bound 3SHol. The following ratios of free to bound 3SHol were calculated: 1.9% for Citra, 4.3% for Tomahawk, and 7.1% for Cascade. For the Sorachi Ace variety, the free thiol was undetectable.

3-Sulfanyl-3-methylbutan-1-ol (3S3MBol) was also found to be released (127 μg/kg from Amarillo and 109 μg/kg from Mosaic). The thiol S-cysteine conjugate of 3S3MBol, known as felinine, has never been evidenced before in hop but was recently identified in cat urine.[40]

Never reported before, the 3-sulfanyl-4-methylpentan-1-ol S-conjugate was found in the Hallertau Blanc cultivar. Unlike the others, it occurred at lower concentration than the corresponding free thiol (39 and 109 μg/kg, respectively).

Already discriminant in its free form for the Citra variety, 2-sulfanylethan-1-ol also proved to be enzymatically released in a high amount (2.5 mg/kg) from the Citra bound extract (free/bound ratio = 14%). A strong impact of the hop variety on the amount of 2SEol generated during beer fermentation has recently been reported.[23] From this first evidence of the presence of 2SEol S-conjugate, we can suspect that its cleavage might be an additional 2SEol synthesis pathway occurring during beer fermentation, together with Ehrlich degradation of cysteine.[39,41]

In conclusion, although much diversity was found among the investigated dual-purpose hops, all proved to contain an exceptional citrus-like potential. In Sorachi Ace, β-citronellol is probably the main compound responsible for such notes, while in others, polyfunctional thiols such as 3SHA (Citra) or 3S4MPol (Hallertau Blanc, Mosaic) could play a key role. Complementary investigations are now needed to assess which molecules involved in the citrus note must be preferred in beer, especially for increasing its flavor stability. The free/bound ratio of discriminating polyfunctional thiols also should be determined for successive harvest years.

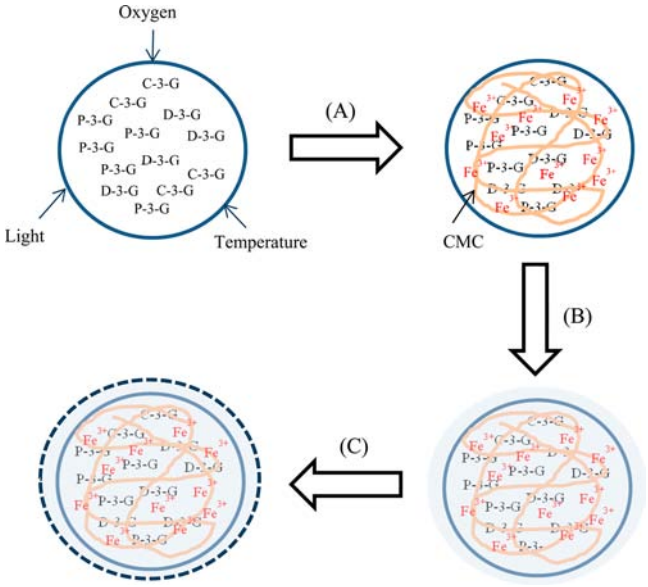

Figure 1. Diagram of the research hypothesis: (A) polysaccharide (CMC)−metal ($FeCl_3$)−anthocyanin complex, (B) CNF coating containing $CaCl_2$ and/or MC, and (C) SA treatment to form a second layer coating (LBL coating system).

than 50. The aqueous suspensions/slurries of the fibrous nanocellulose are capable of forming highly water-resistant and thermomechanical coatings/films because of the strong and percolated inter-/intrafibrillar networks through hydrogen bonds.[16] However, CNF coating/film can be disintegrated in aqueous media because of the competitive interaction with water through hydrogen bonds,[17] which would displace CNF coatings from the surface of fruits in the aqueous system. To enhance the attachment of CNF coating onto the fruit surface and hydrophobicity against water, CNF was modified by calcium chloride ($CaCl_2$) and/or methyl cellulose (MC). Fruits coated by CNF containing $CaCl_2$ and then subjected to SA solution can form Ca^{2+} cross-linked alginic acid hydrogel onto the CNF layer because Ca^{2+} is gradually released from CNF structures, thus generating a water-insoluble semi-permeable LBL coating on the fruit surface. It was also expected that, by incorporating MC into CNF, CNF coating can be less impacted by water because of less hydrophilic blocks of the methoxyl groups.[18] Therefore, the LBL coating system established with CNF as the first layer and SA-based hydrogel as the second layer would not only provide close adhesion between CNF and the fruit surface but also improve the protection of fruit anthocyanins from leaching and coating swelling when subjected to heating in aqueous media.

Therefore, the specific objective of this study was to investigate the retention mechanisms of combined MA or PMA complexation and CNF/SA LBL coating on anthocyanin pigments and the developed technologies on the physicochemical properties of the fruits using blueberries as a model system. To investigate the efficiency and stability of MA and PMA complexation, percent polymeric color (PPC) and monomeric anthocyanin content were evaluated for fresh sample, complexed sample, and complexed sample subjected to the thermal process at 93 °C for 7 min (simulated canning conditions for acidified food). The microstructure of coated fruits and the simulated LBL coating system were also investigated using a stereoscope microscope and/or a scanning electron microscope (SEM) to demonstrate protection mechanisms. Results from this study would provide a new understanding on the anthocyanin retention mechanism in thermally processed whole fruits for improving the existing technologies and developing new value-added colorful fruit products.

MATERIALS AND METHODS

Materials. CNF was obtained from University of Maine Process Development Center (Orono, ME) and prepared from bleached pulp. The following chemical reagents were used for the experiments: Folin−Ciocalteu's (FC) phenol reagent (MP Biomedicals, LLC, Santa Ana, CA), gallic acid (Sigma-Aldrich Co., LLC, St. Louis, MO), acetic acid (Avantor Performance Materials International, Inc., Center Valley, PA), L-ascorbic acid (Avantor Performance Materials International, Inc., Center Valley, PA), 2,2-diphenyl-1-picrylhydrazyl (DPPH) (95%) (Alfa Aesar, Ward Hill, MA), hydrochloric acid (HCl) (EMD Chemicals, Inc., Gibbstown, NJ), sodium acetate (EMD Chemicals, Inc. Gibbstown, NJ), potassium chloride (KCl) (EMD Chemicals, Inc., Gibbstown, NJ), sodium carbonate (EMD Chemicals, Inc., Gibbstown, NJ), and trifluoroacetic acid (EMD Chemicals, Inc., Gibbstown, NJ). Analytical-grade methanol, ethanol, and acetone were used for the extraction of anthocyanins. CMC, MC, and SA were obtained from Sigma-Aldrich (St. Louis, MO), Hercules, Inc. (Wilmington, DE), and TIC Gums, Inc. (White Marsh, MD), respectively.

Sample Preparation. The sample preparation procedures from complexation to LBL coating are illustrated in Figure 1.[15] Fresh blueberries (California Giant, Inc., Watsonville, CA, and Hurst Berry Farm, McMinnville, OR) were soaked in Environne (Consumer Health Research, Inc., Roseburg, OR) for 10 min to wash out the remaining substances (pesticides and waxes) on fruit surfaces and dried at ambient temperature. Two different complexations were applied at ambient conditions: (1) Fe^{3+}−anthocyanin and (2) CMC−Fe^{3+}−anthocyanin. For Fe^{3+}−anthocyanin complexation,[6] blueberries were soaked in 1% $FeCl_3$ solution for 30 min and then dried under an air-flow fan. For CMC−Fe^{3+}−anthocyanin complexation, fruits were soaked in 1% $FeCl_3$ solution for 30 min, followed by soaking in 0.1% CMC at pH 6.5 phosphate buffer for another 30 min, and then dried under an air-flow fan.

Two different CNF coating formulations were prepared: (1) 0.75% CNF containing 0.5% $CaCl_2$ and (2) 0.75% CNF containing 0.5% $CaCl_2$ and 0.5% MC in distilled water (w/w). Coating formulations were sprayed onto fruit surfaces using an air-spray gun (25−30 psi) and dried at ambient temperature under an air-flow fan. To apply SA-based hydrogel coating onto the CNF coating layer further, coated fruits were put into 0.5% SA bath for 5 min and then transferred to a 3% $CaCl_2$ bath for 5 min to form reverse and basic spherifications, respectively. After the prepared fruit samples were washed by distilled water to remove the residual $CaCl_2$ compounds, they were put into glass jars containing 15% sucrose solution with pH 4.0 (adjusted by 1% formic acid) and then thermally processed at a 93 °C water bath (Precision, Winchester, VA) for 7 min to stimulate canning process conditions for berry fruits. The hot jars were cooled in a cold-water bath to reach ambient temperature and stored at the ambient conditions for 2 days before analysis. Anthocyanins, total phenolic content (TPC), PPC, color, total soluble solid, pH, texture property of fruits, and total monomeric anthocyanin (TMA), PPC, and TPC of the packing solutions were all analyzed.

Extraction of Phenolic Compounds from Fruits. Samples were extracted using 60% methanol at a 1:10 (sample/methanol) ratio for 20 min using a sonication unit (B-200H, Branson, Danbury, CT) in 50 mL centrifuge tubes (VWR International, LLC, Radnor, PA) based on the optimized extraction conditions developed from our laboratory (data not shown). The obtained extracts were centrifuged (International Equipment Co., Boston, MA) at 10000*g* at 4 °C for 10 min and filtrated through the Whatman No. 1 filter paper. Methanol was evaporated with a vacuum rotary evaporator (Brinkmann Instruments, Westbury, NY) at 40 °C, and resulting extracts were redissolved in citric buffer (pH 3.5) in a 25 mL volumetric flask. The extracts were

DOI: 10.1021/acs.jafc.5b00616
J. Agric. Food Chem. 2015, 63, 3031−3038

stored in a −80 °C freezer (VWR International LLC, Radnor, PA) until further analysis on TPC, TMA, and PPC.

Analysis of Monomeric Anthocyanins, TPC, and PPC of Fruit and Packing Solution. The TMA content was determined using the pH-differential method[19] and expressed as milligrams of Cy-3-glu per 100 g of fresh fruits with a molecular weight of 449.2 g/mol and a molar absorptivity of 26 900. TPC was measured using the FC-reagent-based colorimetric assay as described by Singleton and Rossi.[20] The phenolic content was calculated as gallic acid equivalent (GAE) and reported as milligrams per 100 g of fresh fruits.

PPC of the fruits was determined using the method by Cao et al.[21] Briefly, 0.2 mL of 0.2 g/mL potassium metabisulfite was added to 2.8 mL of diluted sample (bleached sample), whereas 0.2 mL of distilled water was also added to 2.8 mL of diluted sample (control sample). After equilibration for 30 min at ambient conditions, the absorbance of the bleached and control sample was evaluated at a wavelength of 420 nm, $\lambda_{vis\text{-}max}$, and 700 nm, respectively, using an ultraviolet/visible (UV/vis) spectrophotometer (Shimadzu, Japan). The color density of the control sample and the polymeric color of the thermally processed sample were calculated using the following equation:

$$\text{color density or polymeric color} = [(A_{420\ nm} - A_{700\ nm}) + (A_{\lambda_{vis\text{-}max}} - A_{700\ nm})] \times \text{dilution factor}$$

PPC was further calculated as (polymeric color/color density) × 100%.

With consideration of the possible leaching of anthocyanin pigments from fruits into packing solution during thermal process and storage, TPC, TMA, and PPC of packing solutions were also analyzed using the same methods described above.

Physicochemical Properties of Blueberries. Color and total soluble solid content (TSS, °Brix) of fruits were measured using a colorimeter (HunterLab LabScan XE spectrophotometer, Reston, VA) and a refractometer (Brix RA-250 HE, Kyoto Electronics Manufacturing Co., Ltd., Kyoto, Japan), respectively.[22] Fruit pH and titratable acidity (TA) were determined using the methods from Fisk et al.[22] Briefly, five berries were randomly collected, weighed, mixed with distilled water at 1:9 (w/w) ratio, and blended for 1 min using a homogenizer (Osterizer, Jarden Corp., Mexico). The mixture was filtered through qualitative filter paper to remove insoluble materials. The filtrate was titrated with a standardized 0.1 N aqueous NaOH solution up to an end point of pH 8.2 using a pH meter (Corning 125, Corning Science Products, Tewksbury, MA). TA values were calculated on the basis of the assumption that citric acid was the predominant acid in blueberries. Firmness was measured using a texture analyzer (TA.XT2, Stable Micro Systems, Inc., U.K.),[23,24] where individual fruit was compressed for a total deformation of 3 mm between two parallel plates at a speed of 0.5 mm/s. The stem−calyx axis of blueberries was placed in parallel onto the compression plates. The firmness index was calculated as the slope of force/deformation curves between 0.5 and 2.5 mm of displacements and represented as N/mm. Three berries were randomly chosen from the processed fruits for texture analysis.

To investigate the effect of complexation and coating on fruit weight after thermal treatment and storage, the weight change (%) of fruits was calculated as the weight of processed fruits subtracted from the initial weight of fresh fruits divided by the initial fruit weight and multiplied by 100.

Microscopic Analysis. To evaluate adhesion of coatings onto the fruit surface, images on the cross-sections of non-coated and coated fruits (CNF/$CaCl_2$ and CNF/$CaCl_2$/MC coatings) before the thermal process were taken using a stereomicroscope (Leica Microsystems AG, Heerbrugg, Switzerland) equipped with an extended digital camera (QImaging, Surrey, British Columbia, Canada).

The morphology of CNF film incorporated with $CaCl_2$ and/or MC was analyzed using the AmRay 3300 field emission (FE)-SEM (AmRay, Bedford, MA). To investigate the LBL coating system, CNF/$CaCl_2$ and CNF/$CaCl_2$/MC films were treated at 0.5% SA bath for 10 min, dried at 50 °C for 24 h, and then stored in a desiccator for 1 day. Prepared film pieces were mounted on aluminum stubs with the cross-section oriented up and coated by a gold−palladium alloy sputter coater (Edwards model S150B sputter coater, BOC Edwards Vacuum, Ltd., West Sussex, U.K.) to improve the interface conductivity. Digital images were collected at an accelerating voltage of 5 kV.

To quantify the amount of $CaCl_2$ released from the CNF/$CaCl_2$ and CNF/$CaCl_2$/MC films, Ca and Cl contents in the films before and after the films were soaked in water were measured using energy-dispersive X-ray analysis (EDXA). The result would show the reactions of $CaCl_2$ released from CNF with SA to help interpret the adhesion of a SA-based second layer of hydrogel coating on the CNF coating based on the cross-linking between Ca^{2+} and alginic acid within the short reaction time.

Experimental Design and Statistical Analysis. A randomized factorial design with two treatment factors was applied in this study. Factor A [complexation type (CT)] had three levels: non-complexation, Fe^{3+}−anthocyanin complexation, and CMC−Fe^{3+}−anthocyanin complexation. Factor B [coating formulation (CF)] included three types: non-coated, coated by 0.75% CNF containing 0.5% $CaCl_2$, and coated by 0.75% CNF containing 0.5% $CaCl_2$ and 0.5% MC. Replication was also considered as the main effect because of the large variations among individual fruits. Non-complexed and non-coated blueberries subjected to the same thermal process and fresh blueberries without any treatment were considered as controls. About 25−30 individual fruits were treated for each replication, and all experiments were performed in duplicate. The results were analyzed for statistical significance via multi-way analysis of variance (ANOVA), with post-hoc testing using least significant difference (LSD) by means of statistical software (SAS, version 9.2, SAS Institute, Cary, NC). Results were considered to be significantly different at $p < 0.05$.

RESULTS AND DISCUSSION

Effect of Complexation and CNF/SA LBL Coatings. Fruit samples subjected to different complexation and/or CNF/SA LBL coating, followed by thermal process and storage at the ambient conditions for 2 days, are illustrated in Figure 2.

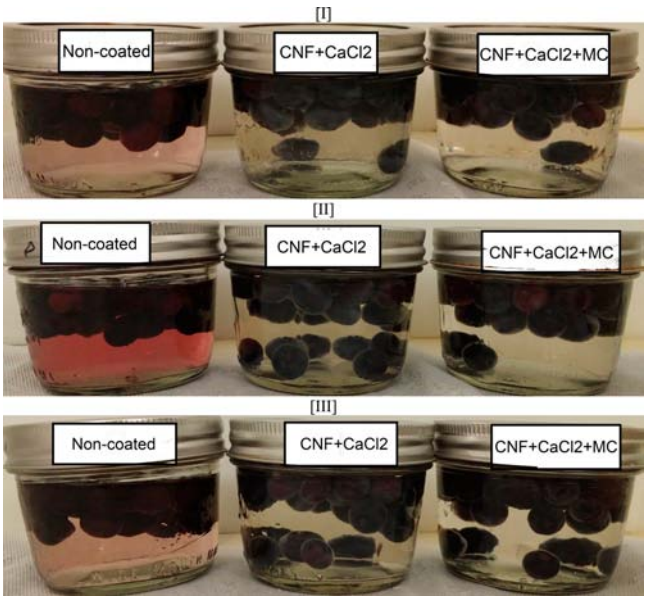

Figure 2. Illustration of pretreated samples after subjected to the thermal process at 93 °C for 7 min and stored at the ambient conditions for 2 days. Second layer coating with SA was applied on all samples with CNF coating. (I) Non-complexation, (II) Fe^{3+}−anthocyanin complexation, and (III) CMC−Fe^{3+}−anthocyanin complexation. The label on the jar indicates different types of coating treatment. MC is methyl cellulose.

[a]Means followed by the same letter in a column were not significantly different (p > 0.05). [b]All coated fruits were also subjected to SA second layer coatings. [c]Weight change (%) was calculated as the weight of processed fruits subtracted with the initial weight of fresh fruits divided by the initial fruit weight and multiplied by 100. [d]MC = methyl cellulose.

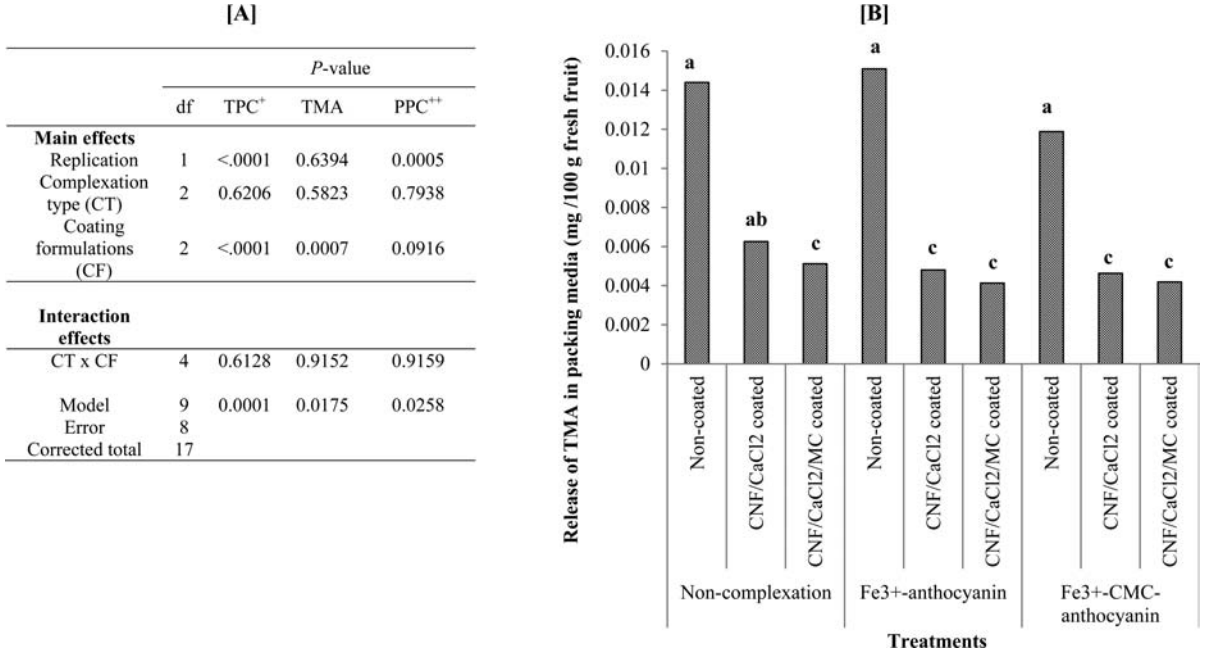

Figure 3. ANOVA results (p = 0.05) for analyzing (A) independence or interactions among treatment factors and (B) amount of released TMA (milligrams of Cy-3-glu/100 g of fresh fruit) in the packing media from thermally processed blueberries subjected to different treatments and stored at the ambient conditions for 2 days. Second layer SA coating was applied on all samples coated by CNF. TPC, total phenolic content; PPC, percent polymeric color.

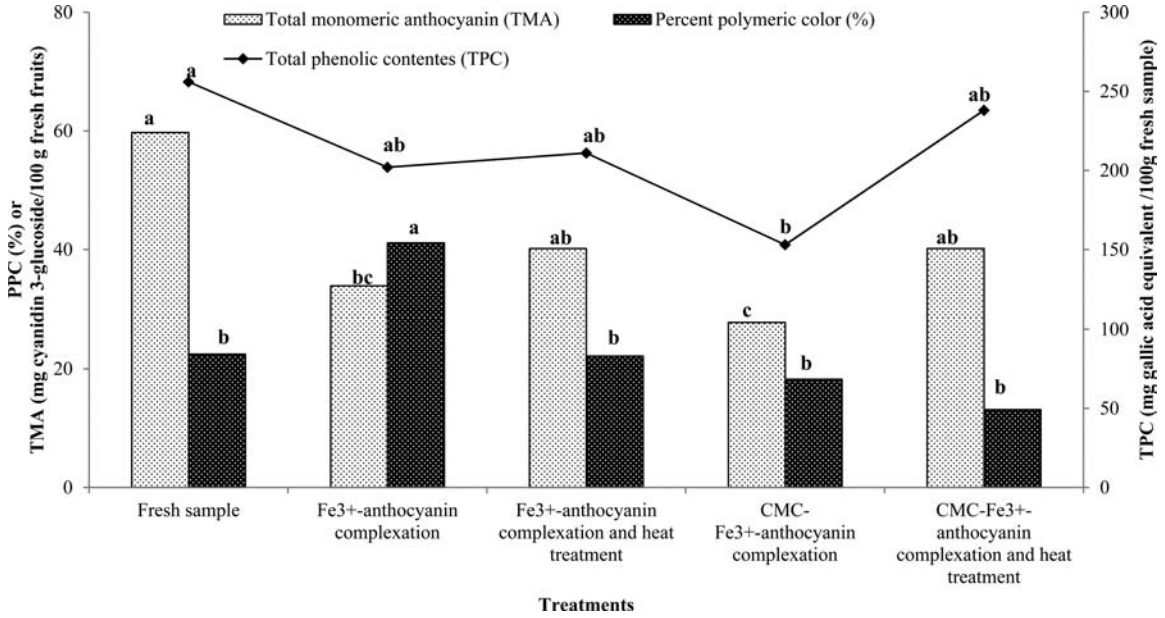

Figure 4. TMA (milligrams of Cy-3-glu/100 g of fresh fruits), TPC (milligrams of GAE/100 g of fresh sample), and PPC (polymeric color/color density × 100) of fresh fruits, fruit subjected to complexation, and complexation and then heat treatment at 93 °C for 7 min. The same letter placed above each column and line within the measurement were not significantly different ($p > 0.05$).

For non-coated fruits, it was observed that anthocyanin pigments were leached from fruits into the packing media, regardless of complexation types (non-coated of I, II, and III in Figure 2). Moreover, Fe^{3+}−anthocyanin complexation (II in Figure 2) resulted in more pigment leaching than both non-complexation (I) and Fe^{3+}−CMC−anthocyanin complexation (III). It was previously reported that heating causes dissociation of the co-pigmented anthocyanins,[25] and Fe^{3+}−anthocyanin complex is dissociated in acidic media.[26] Hence, thermally processed fruit packing in the acidic media (pH of 4.0 in this study) could exert the dissociation of the Fe^{3+}−anthocyanin complex, leading to pigment loss with a similar rate to that of the control (non-complexation) or even worse. It was found that fruits subjected to CMC−Fe^{3+}−anthocyanin complexation had less pigment leach than fruits subjected to Fe^{3+}−anthocyanin complexation (III in Figure 2), which was similar to the previous study that anthocyanin−metal chelates interacting with polysaccharides enhanced the anthocyanin stability in comparison to anthocyanin−metal chelates.[27] Nonetheless, both Fe^{3+}−anthocyanin and CMC−Fe^{3+}−anthocyanin complexation did not prevent leaching of anthocyanin pigments into the aqueous media because both were dissociated and/or degraded by heat and acid.

The effect of each treatment factor and their interactions on the anthocyanin retention and physicochemical properties of fruits are reported in Table 1. Color, TA, TMA, and PPC of processed fruits were significantly ($p < 0.05$) affected by the replication factor because of large variations among individual fruits. Weight change (%), firmness index (N/mm), and TTS of fruits were significantly affected by CF. For these three measurements, post-hoc testing using LSD was conducted and is reported in Table 2. The weight of CNF/SA LBL coated fruits were significantly ($p < 0.05$) increased (10.7−14.0% increase) after thermal treatment and storage, whereas those of non-coated fruits lost weight (0.5−2.7% decrease). The weight loss in non-coated fruits could be due to the hydrolyzation of pectin in fruit skin and soluble solids and pigment leaching into packing solution during thermal treatment and storage. The weight gain in CNF/SA LBL coated fruits might be contributed by the weight of both hydrogel type of SA coating and CNF coating. This CNF/SA LBL coating system also significantly ($p < 0.05$) improved the firmness index and TSS of fruits in comparison to those of non-coated fruits.

ANOVA of TPC, TMA, and PPC of the packing solution along with post-hoc testing results of TMA are presented in Figure 3. CF showed a significant ($p < 0.05$) effect on TPC and TMA. Because of the significant ($p < 0.05$) effect of the replication factor on TPC, post-hoc testing was only conducted for TMA (Figure 3B). CNF/SA LBL coatings significantly ($p < 0.05$) prevented TMA leaching from fruits into the packing media in comparison to non-coated fruits. These results demonstrated that the CNF/SA LBL coating system was successful in retaining anthocyanin pigments in thermally processed fruits packing in aqueous media.

Stability of Fe^{3+}−Anthocyanin and Fe^{3+}−CMC−Anthocyanin Complexes. To investigate the stability of complexation (Fe^{3+}−anthocyanin and Fe^{3+}−CMC−anthocyanin) on the thermally processed blueberries packed in aqueous media, TMA, TPC, and PPC of fresh fruits, fruit subjected to complexation, and complexation plus heat treatment at 93 °C for 7 min were quantified (Figure 4). Fe^{3+}−anthocyanin complexation induced the polymerization of anthocyanin compounds, leading to a significantly increase in PPC (41.13%) compared to that of the fresh sample (22.49%). This might be explained as a metal-chelation-formed ligand (Fe^{3+}−anthocyanin), which binds with other anthocyanins, resulting in polymerization of anthocyanins. Consistently, Fe^{3+}−anthocyanin complexation resulted in significantly lower TMA (38.89 mg of Cy-3-glu/100 g of fresh fruits) of fruit in comparison to that of the fresh sample (59.73 mg of Cy-3-glu/100 g of fresh fruits). After the thermal process, however, PPC of fruits subjected to Fe^{3+}−anthocyanin complexation was significantly reduced (22.15%), reaching a similar level to that of the fresh sample (22.49%). These results indicated that the thermal process dissociated the polymerized Fe^{3+}−anthocyanin complex in fruits packing in the aqueous media, consistent with

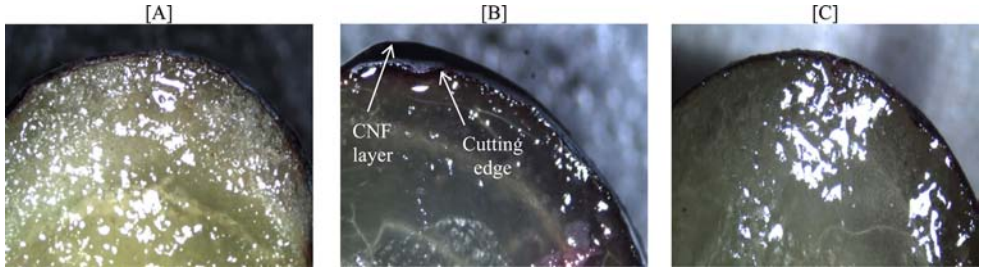

Figure 5. Stereomicroscopic images on the cross-sections of fresh or coated blueberries before the thermal process to illustrate the effect of MC-modified CNF on adhesion properties between CNF and the fruit surface: (A) fresh fruit, (B) CNF coating containing $CaCl_2$, and (C) MC-modified CNF containing $CaCl_2$.

the previous report that the metal−anthocyanin complex was dissociated by the heating process.[25] CMC−Fe^{3+}−anthocyanin complexation was not able to induce further polymerization (PPC of 18.26%) in comparison to Fe^{3+}−anthocyanin complexation (PPC of 41.13%), even without the thermal treatment. This result might be related to the stability of Fe^{3+}−anthocyanin complexation in aqueous media. While the fruits subjected to Fe^{3+}−anthocyanin complexation were soaked in CMC solution, the complex was dissociated before associating with CMC. This result was inconsistent with previous studies reporting the stabilization effect of PMA complexation.[27,28] However, the pigment leaching of fruits treated by CMC−Fe^{3+}−anthocyanin complexation was less than that from Fe^{3+}−anthocyanin complexation treatment (Figure 2), which might be more related to the cation (Fe^{3+}) bridges between fruit pectin and anionic CMC. Hence, the complexation was not successful to achieve the objective of enhancing anthocyanin stability in thermally treated blueberries because of the lack of stability under heat and during storage in aqueous media. Therefore, more studies to improve the heat stability of polysaccharide−metal ion−anthocyanin complexation in aqueous media are necessary.

Pigment Retention Mechanisms of CNF/SA LBL Coatings. From ANOVA results for fruits and packing media (Table 1 and Figure 3), CF only showed the significant effect on weight change (%), firmness index (N/mm), and TTS of fruits and TPC and TMA of packing media. To investigate retention mechanisms of different types of CNF-based coatings and to demonstrate the principal of the CNF/SA based LBL coating system, a stereomicroscope and SEM were illustrated in Figures 5 and 6, respectively. Stereomicroscopic images on the cross-sections of non-coated, CNF/$CaCl_2$-coated, and MC-modified CNF/$CaCl_2$-coated fruits without the thermal process are illustrated to demonstrate the adhesion of CNF coating onto the hydrophobic fruit surface as the first layer of the LBL system (Figure 5). Blueberries have a visible, white- or bluish-colored epicuticular wax layer on the surface, which limits the diffusion of hydrophilic coating materials.[29] Although the washing process was applied to remove the wax layer on the fruit surface in this study, some white substances still visibly remained after washing (data not shown). It was observed that MC-modified CNF/$CaCl_2$ coating improved the adhesion of the coating onto the fruit surface (Figure 5C) because of the modified CNF surface by less hydrophilic methoxyl groups of MC.[30] Two strategies have been commonly applied for enhancing adhesion of coating solutions onto the fruit surface.[31] One was to apply surface-active agents, such as emulsifiers and other amphiphilic chemicals, to reduce the surface tension of the coating solution and decrease the solid

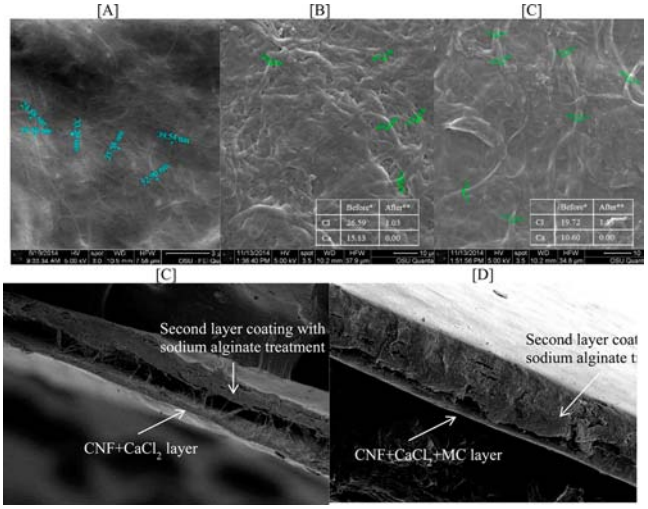

Figure 6. SEM images of different types of CNF films and LBL coating system. Panels A, B, and C illustrate the morphology of CNF, CNF/$CaCl_2$, or CNF/$CaCl_2$/MC films, respectively. Tables in panels B and C show the change of calcium contents in films before and after soaking in water for 10 min at the ambient temperature using EDXA. Panels C and D are the simulated LBL coating system after SA treatment for CNF/$CaCl_2$ and CNF/$CaCl_2$/MC coating, respectively.

surface energy.[32] Another approach was by means of chemical modifications of biopolymers, introducing hydrophobic groups into their structures.[31] MC-modified surface characteristics of CNF coating became more hydrophobic, thus enhancing the adhesion between CNF coating and the hydrophobic fruit surface. A previous study demonstrated that hydrophobization of chitosan successfully enhanced compatibility with the strawberry surface.[33]

SEM analysis illustrated the CNF morphology incorporating with $CaCl_2$ and/or MC to demonstrate anthocyanin-retaining mechanisms of the simulated CNF/SA LBL coating system (Figure 6). EDXA evaluated released $CaCl_2$ contents of CNF films after soaking in water and supported the principal of forming a hydrogel SA layer with released Ca^{2+} as the cross-linking agent onto the CNF layer. The cross-sectioned sample of the simulated CNF/SA LBL film was prepared to demonstrate the development of the hydrogel SA layer onto CNF and the effect of MC-modified CNF on the interaction with the fruit surface and SA layer. It was confirmed that $CaCl_2$ crystals were assimilated on the CNF film matrix (Figure 6B) and MC-modified CNF/$CaCl_2$ film made the surface more homogeneous (Figure 6C) in comparison to CNF and CNF/$CaCl_2$ films (panels A and B of Figure 6). CNF/$CaCl_2$ coating subjected to SA was able to form an impermeable layer of Ca^{2+}

DOI: 10.1021/acs.jafc.5b00616
J. Agric. Food Chem. 2015, 63, 3031−3038

cross-linked alginic acid onto CNF because Ca^{2+} was rapidly released from the CNF structure. MC-modified CNF/$CaCl_2$ induced closer attachment with SA hydrogel than CNF/$CaCl_2$ (panels C and D of Figure 6) because of the presence of Ca^{2+} as a cross-linking agent between MC and SA. A previous study also showed the cross-linking between SA and MC through Ca^{2+}, which was successfully applied in the microencapsulation technology.[34] Hence, $CaCl_2$- and MC-incorporated CNF was able to develop a versatile CNF/SA LBL system and to improve the association with both the fruit surface and SA hydrogel layer, thus preventing leaching of anthocyanin pigments and fruit damage from thermally processed fruit.

This study was the first demonstrating the efficacy of CNF/SA LBL coating for preventing leaching of heat-sensitive and water-soluble anthocyanin pigments from thermally processed whole fruits. The developed coating technology can be used for protecting overall quality and bioactive compounds in various types of anthocyanin-rich fruits while processing and storing in the aqueous system. More studies on the potential structure changes of anthocyanins when subjected to developed treatments, long-term stability of the pigments at ambient storage conditions in aqueous media, sensory attributes through both trained and consumer sensory panels, and evaluations on other types of anthocyanin-rich fruits, such as cherries, plumbs, and red-colored pears, are under way.

FED 53 ripening cabinet (Binder, Tuttlingen, Germany) for a period of 9 days. During the first 24 h the units were kept at 22 °C and the relative humidity of 95%. Within 48 h, storage conditions were gradually reduced to 89% humidity and 17 °C. Models were stored at 12 °C the remaining days. Sampling was carried out at different ripening days: 0 (24 h after batter meat preparation and just before stuffing into casings), 1, 3, 5, 7, and 9 days. A total of three units of each batch were collected for each of the studied times. Physicochemical analyses were performed at each sampling time and, in any case, before freezing. Then sausages were vacuum packaged and stored at −20 °C until further analyses.

Physicochemical Analysis. Water activity (a_w), pH, and dry matter (DM) were determined in triplicate samples of each of the considered products and ripening times. Water activity (a_w) was measured using a Decagon CX1 hygrometer (Decagon Devices Inc., Pullman, WA, USA) at 25 °C. The pH was determined in a homogenate of the sample with distilled water (1:10 w/v). DM was determined by drying the sample at 110 °C to constant weight, and the results were expressed as a percentage.[18]

NMR Analyses. Sausage models were thawed prior to NMR analysis. To carry out thawing, samples were kept at room temperature for approximately 6 h. Sausage behavior was similar in both SMS and SMS+P, and syneresis or exudate loss was never observed. Samples (approximately 4 cm long and 1 cm in diameter, weight approximately 5 g) were placed in a cylindrical glass tube (5 cm long by 14 mm diameter). Before measurement, the sausage samples were thermostated to 25 °C in a water bath for 15−20 min. Proton NMR T_2 relaxation measurements were performed on a Maran Benchtop Pulsed NMR Analyzer (Resonance Instruments, Witney, UK) operating at 23.2 MHz and equipped with an 18 mm variable-temperature probe where the cylindrical glass tubes were placed. A total of six replicates of each product and ripening time were analyzed at 25 °C. Transverse relaxation time, T_2, was measured using the Carr−Purcell−Meiboom−Gill sequence (CPMG)[19,20] with a τ value (time between 90 °C pulse and 180 °C pulse) of 150 μs. Data from 4096 echoes were acquired as 16 scan repetitions. The repetition time between two succeeding scans was 2 s. The obtained T_2 data were analyzed using algorithm[21] and carried out in MatLab (The Mathworks Inc., Natick, MA, USA) using in-house scripts. Distributed exponential fittings are shown in a plot of relaxation amplitude versus relaxation time, over a predefined range of characteristic relaxation times.

Measurement of Proteolysis. Degree of proteolysis was estimated by measurement of free amino terminal groups using the fluorescamine assay described earlier.[22] One hundred milligrams of each sample was solubilized in 1 mL of phosphate-buffered saline (0.05 M phosphate buffer, 0.14 M NaCl, pH 6.7). To 500 μL of 1.67 M (24%) trichloroacetic acid in water was added an equal volume of solubilized sample, and the mixture was held for 20 min on ice to allow precipitation of intact proteins. The precipitated mixture was centrifuged (17000*g* for 20 min) and then filtered through a no. 41 filter paper (Whatman PLC, Brentford, UK). A 12.5 μL aliquot of this filtrate was mixed with 1 mL of 100 mM borate buffer and 500 μL of 719 μM fluorescamine in acetone, and 250 μL was then transferred to each well in a microtiter plate. Fluorescence of the samples was measured, 18 min after the addition of the fluorescamine, at an excitation wavelength of 390 nm and an emission wavelength of 480 nm using a model Synergy 2 Multi-Mode microplate reader (Holm & Halby, Brøndby, Denmark). Quantitation was achieved by calculating leucine equivalents using an external leucine standard curve prepared as follows: a 0.1 M leucine stock solution was made (327.5 mg of leucine in 25 mL of 1 mM HCl), and from the stock solution six different concentrations were made (0.00050−0.0030 M leucine) and mixed with 10 mL of 1 mM HCl and analyzed as the sausage samples.

SDS-PAGE. Myofibrillar proteins were extracted by homogenization of 1 g of sausage in 5 mL of a solution containing 7 M urea, 2 M thiourea, and 400 mM Tris-base. The homogenate was centrifuged for 20 min at 10000*g* at 4 °C, and the supernatant containing myofibrillar proteins was separated. The protein concentration of the myofibrillar protein extracts were determined by using the Bradford assay.[23] The protein concentration was adjusted with water to give a final concentration of 2 mg/mL and diluted 1:1 with SDS-PAGE sample buffer [2% SDS, 20% glycerol, 20 mM Tris-Cl, pH 6.8, 2 mM ethylenediaminetetraacetic acid (EDTA), 160 mM dithiothreitol (DTT), and 0.1 mg/mL bromphenol blue] to give a final concentration of 1 mg/mL. The samples were heated at 100 °C for 5 min prior to electrophoresis. SDS-PAGE was carried out under reducing conditions,[24] using Criterion TGX (any kDa) precast ready-made gels (Bio-Rad Laboratories, Hercules, CA, USA). The amount of protein solution injected into the electrophoresis gels was 20 μL in each lane. After electrophoresis, the gels were covered with fixative solution (40% methanol, 10% acetic acid) and then stained using Coomassie Brilliant Blue R-250. The molecular weights of the products of proteolysis were estimated by reference to the relative motilities of standard proteins.

Statistical Analysis. Statistical analysis was carried out using Statgraphics, ver. 5.1. Plus. The analyses were conducted across the two manufactured batches (SMS and SMS+P) and six different ripening times (0, 1, 3, 5, 7, and 9 days), so 18 individual units per treatment were analyzed. Data are presented as mean and standard deviation (SD). One-way ANOVA was performed. Bartlett's test was used to test the null hypothesis that the standard deviations of data (within each of the model systems) were the same. Duncan's test for multiple mean comparisons procedure was used to determine which means are significantly different from others (at 95% of confidence level).

RESULTS AND DISCUSSION

Physicochemical Parameters. DM, pH, and a_w mean values and standard deviations for SMS and SMS+P are shown in Figure 1. The products showed significant differences ($P < 0.05$) for the three physicochemical parameters studied throughout all stages of the manufacturing process. As expected, results showed that the lowest DM content ($P < 0.05$) could be attributed to the samples collected on day 0 (28.11 ± 0.31% for SMS and 27.16 ± 0.30% for SMS+P). As ripening progressed, a steady and considerable increase in DM was observed, and the highest value was reached at day 9 (56.12 ± 0.98% for SMS and 51.66 ± 0.62% for SMS+P). There were also significant differences ($P < 0.05$) in pH, so the highest value was detected at day 0 (5.64 ± 0.04 for SMS and 5.84 ± 0.03 for SMS+P). Lactic acid production due to the fermentation of sugars by lactic acid bacteria led to the lowest pH values at day 3 (around 5.00). From day 5, a slight increase in pH was observed in both batches. This may be due to production of free amino acids and ammonia as a result of enzymatic activity.[2,25] With the increase in DM, previously mentioned, a_w decreased constantly (from 0.960 ± 0.001 in SMS and 0.953 ± 0.001 in SMS+P to 0.911 ± 0.001 and 0.903 ± 0.001, respectively), which results in a microbial stabilization of the transformed product. The measured parameters are within the normal range previously described for dry fermented sausages,[26,27] taking into account that the products manufactured for this study had a shorter ripening time (9 days) compared to commercial brands (around 20−28 days), which explains that higher DM values have not been reached at the end of the process.

NMR Studies on Sausage Model Systems. *Water Mobility and Distribution throughout Sausage Model Manufacturing.* Distributed exponential analysis of the NMR T_2 relaxation data revealed the presence of three different water populations in SMS (Figure 2A): a minor component, with relaxation times around 1−10 ms (T_{2b}), a major component around 30−70 ms (T_{21}), and a slower relaxing component (T_{22}) around 100−300 ms. Chopping results in disintegration

of the overall structure with maintenance of intact myofilaments. It has been previously proved[12] that disruption of the macroscopic structure of fresh meat did not change the relaxation pattern in meat, so water assignments for minced meat are comparable to those obtained in fresh meat. It has been suggested that T_{2b} represents water closely associated with macromolecules and/or protons in plasticized macromolecular structures; T_{21} reflects water located within highly organized protein structures, and T_{22} represents more mobile water located in extramyofibrillar spaces.[12,28,29] The T_{22} population was not present at day 0, but it was detected on all of the consecutive ripening days analyzed, which suggests that it may be related to protein aggregation. Intensive chopping and a high concentration of NaCl result in the swelling of myofibrils and the dissolving process of proteins, so water is mainly associated with myofibrillar proteins. After a certain period of adaptation, the growth of lactic acid bacteria results in the formation of lactic acid,[2] and the pH decrease brings the myofibrillar proteins gradually closer to their isoelectric point and their water-binding capacity decreases.[30] Consequently, the amount of immobilized water entrapped by myofibrillar proteins is reduced; meanwhile, protein chains are approaching each other, creating aggregates. Once inside the ripening cabinet, water release from the interior of the sausage takes place partially by diffusion, due to the moisture difference between the sausages and the environment,[31] which leads to the appearance of the T_{22} population, related to this mobile extramyofibrillar water fraction. The drying process of meat resulted in a shift toward faster relaxation times for both populations, T_{21} and T_{22}. This shift may be explained, mainly, by the fact that the viscous protein system is transformed from the "sol-state" into the colloidal viscous "gel-state"[31] that leads to the constitution of an irreversible protein network that holds water in a less mobile state.[32] The existence of different water fractions and their changes during the drying process in sausage models found in the present work is in good agreement with data obtained in a previous study on fermented meat[14] except for the absence of the T_{22} component at day 0. This difference could be due to the existence of a resting period at cooling temperature (4 °C, approximately) before stuffing into casings and the absence of starter added culture in the present work, which may have a significant effect on preserving protein structure from coagulation or aggregation, because, as

mentioned above, the temperature and the pH descent are key factors in promoting the structural changes in the protein matrix.

Effect of Proteases on Sausage Models Structure. Figure 2B shows distributed T_2 relaxation times obtained on SMS+P. T_{2b1}, T_{2b2}, and T_{21} populations were identified for all ripening times. Previous studies[14,33] have related the addition of salt to the appearance of a T_{2b2} population (5–10 ms), absent in fresh meat, and also identified in this batch throughout the entire manufacturing process. The presence of this new population could be associated with a different distribution of salt in both batches. For the SMS batch, it was possible to distinguish the T_{2b2} component only on days 0, 1, and 3 of production, although it was not a clear peak and appeared almost merged with T_{2b1}. In this batch, ripening took place on a conventional basis, which means that the myofibrils were able to swell and retain water, and the added salt was easily absorbed or incorporated into protein structure as ripening progressed. The proteins dissolved as a result of the mincing and the addition of salt produce filament-shaped aggregates that interact and contribute to the stability of the gel.[2] However, in SMS+P models, protein breakdown prevented an efficient absorption of salt by myofibrils in such a way that it together with water constituted an independent compartment with faster relaxation time, different from the major myofibrillar protein component (T_{21}) that could be clearly identified during the entire process. The presence of the T_{2b2} population suggests that the protein matrix did not present a strong and well-organized structure. The T_{22} component was not present in SMS+P samples until day 9, which constitutes an important difference compared to T_2 distributions in SMS. The absence of the T_{22} component suggests a nonaggregation behavior of the proteins. Partial denaturation of protein is required as an initial step to achieve the ordered protein–protein interaction and aggregation;[34] however, the hydrolysis induced by proteases prevents the proper establishment of the protein network and severely affects final texture resulting in a softening of the product, as previously reported.[4,5] Consequently, T_{2b2} and T_{22} populations are both related to the absence of a strong and firm protein matrix. Proteolysis can also produce an extensive unfolding of the protein inducing the formation of a network with large cavities where the T_{22} can be related to the mobile water in the cavities. Distributed T_2 relaxation times in SMS+P compared to that obtained for SMS showed how the structural integrity was changed by the introduction of proteases. In fact, the ripening-induced shift of T_{21} and T_{22} populations in SMS+P is not as noticeable as it is in SMS, suggesting that water immobilization is not taking place until day 7, as affected by protein degradation.

Time constants and relative areas (corresponding to the proportion of protons represented by the specific T_2 population) of the two main components (T_{21} and T_{22}) for SMS and SMS+P are shown in Table 1. Significant differences were detected by comparison between T_{21} relaxation times corresponding to SMS and SMS+P throughout ripening time, so that SMS+P consistently maintained higher T_{21} values over time. These findings can be related to the fact that the water content was also higher in SMS+P than SMS for the same studied stage, ranging from 71.9 ± 0.3 to 43.9 ± 0.9 g of water/100 g of sample in SMS and from 72.8 ± 0.3 to 48.3 ± 0.6 g of water/100 g sample in SMS+P. The drying process resulted in a decrease of the relative areas of both populations, although the decrease was more progressive in SMS and values were higher in SMS+P, especially from day 3 on.

Proteolysis in Model Samples As Measured by Increase in Free Amino Groups. Proteolysis was quantified by assaying for protein breakdown products through determination of free amino terminals (N-terminal + lysine side chains, as well as other amines that may be present). Although the concentration of free amino groups increased for both batches over time (Figure 3), higher values were found for SMS+P (concentration varied from 657.83 ± 1.54 to 1487.09 ± 5.06 mg Leu equiv/DM at days 0 and 9, respectively) than for SMS (values from 290.35 ± 3.71 to 487.78 ± 0.93 mg Leu equiv/DM, respectively), showing that the proteolysis was more prominent in the protease-added batch, SMS+P. This finding is in agreement with previous works[4,5] in which the nitrogen fractions achieved higher values in protease-added batches than those of the control. Significant differences were found over time for both batches regarding free amino group concentration, although the lower increase occurred toward the end of the process for SMS+P, during days 7 and 9 (5.5%),

suggesting a trend to stabilization, because the protease activity was higher between days 0 and 3 of production. During the fermentation and ripening of dry fermented sausages, a large number of biochemical reactions associated with the degradation of myofibrillar and sarcoplasmic proteins take place.[4,5] These biochemical reactions are promoted by muscle endopeptidases (calpains I and II and cathepsins B, D, H, and L).[35] For batch SMS, therefore, the increase of free amino groups corresponds to a natural proteolysis process conducted by endogenous enzymes, so the protein degradation was lower during the whole process and, finally, the proteolysis rate increased during days 7 and 9, when the greatest increase in the concentration was found (53.5%). SMS+P samples experienced a substantial degradation from the moment of the addition of the enzymes (day 0), resulting in low-molecular-weight compounds. Meanwhile, SMS samples experienced a lower extent of proteolysis, and it was possible to distinguish high-molecular-weight compounds, almost during the whole process. The considerably lower degree of protein degradation in SMS samples could explain why different free amino group concentrations were obtained. On the other hand, as proteolysis contributes to a weakening of the myofibrillar network and the subsequent generation of peptides and free amino acids that contribute to flavor development,[36] the formation of a large amount of free amino groups is inconsistent with the emergence of the T_{22} component, because this fact is opposed to the establishment of an organized and compact meat matrix. However, a moderate production of amino groups combined with appropriate dehydration conditions allow the development of a high structured meat gel in which T_2 distributed data could be characterized by the presence of the T_{22} population during almost the whole process.

SDS-PAGE. As the contribution from myofibrillar proteins is the most important parameter for the development of desirable gel characteristics in processed meat products,[3,37] SDS-PAGE of myofibrillar proteins was performed to elucidate the differences in protein degradation pattern between SMS and SMS+P. Some bands were identified on the basis of their molecular weights, determined by comparison with standards in the stained gel (Figure 4). Heavy myosin chain (MHC) (220 kDa), α-actinin (94 kDa), actin (45 kDa), troponin-T (37 kDa), tropomyosin (35 kDa), myosin light chains (MLC) 1, 2, and 3 (25, 18, and 15 kDa, respectively), troponin I (24 kDa), and troponin C (20 kDa) were present in all SMS samples.[38] As ripening progressed, a degradation of myofibrillar proteins was evident. The intensity of MHC and actin bands decreased over time; troponin T and tropomyosin degradation was also noticeable. MLC 1 and troponin I bands were not so intense from day 3 on, and MLC 2 and 3 were especially affected by proteolysis because they disappeared completely after 3 days of ripening. New polypeptides of smaller size (≈12 kDa) also accumulated from day 1 on. These findings are in agreement with previous studies on fermented sausages,[15,16,39] although in the present study the pattern of proteolysis was not that intense due to the fact that sausages were ripened for a shorter period

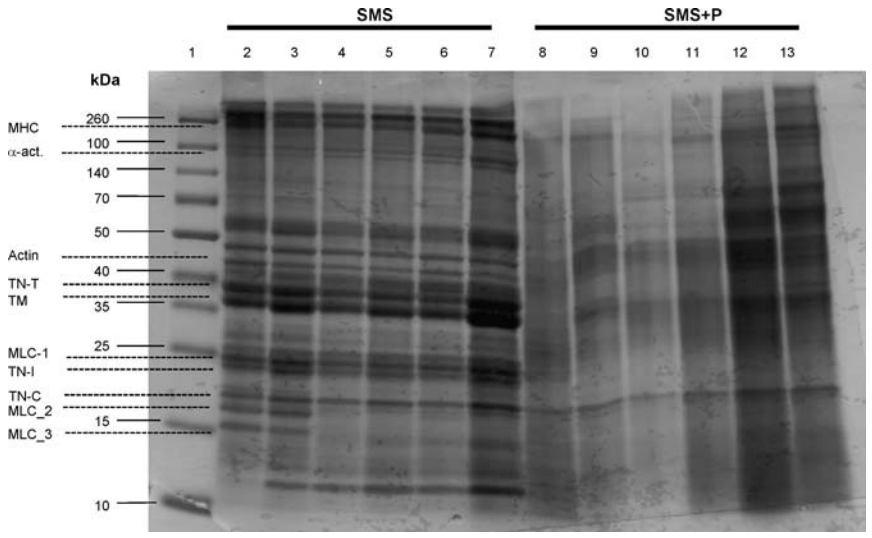

Figure 4. SDS-PAGE electrophoretograms of myofibrilar proteins throughout the ripening of sausages. Lanes: 1, protein standards; 2−7, sausage model systems (SMS), days 0, 1, 3, 5, 7, and 9; 8−13, models with proteases (SMS+P), days 0, 1, 3, 5, 7, and 9. of time. Throughout fermentation, the combination of salt, temperature (20−26 °C), and the decline in pH provokes insolubilization of sarcoplasmic and myofibrillar proteins. Insolubilization progresses during ripening due to advanced dehydration.[2,41] A decrease in the solubility of myofibrillar proteins was observed, because the bands were much more intensely stained at the end of ripening than at day 0. The loss in myofibrillar protein solubility has been previously described by other researchers.[15,40] A dramatically different protein band pattern was observed for SMS+P, where high-molecular-weight compounds cannot be distinguished as a result of the proteolysis to which samples have been subjected. However, protein insolubilization during drying was clearly evident. These results, together with proteolysis measurements (Figure 3), prove that protein denaturation on SMS+P was very intense from day 0; consequently, the molecular weight of the protein chains is too low, and they solubilize completely before aggregating. The solubility of myofibrillar proteins in SMS+P decreased with ripening time due to the dehydration process and the increase in salt concentration, which leads to the aggregation of protein chains and the formation of higher molecular weight compounds, so the bands on days 7 and 9 were more intensely stained than on previous days. With regard to T_2 distributions, the stronger protein chain association at day 9 compared with earlier stages by reducing the pore size of the matrix due to the water loss, together with the extensive unfolding suffered by proteins, could be associated with the appearance of T_{22} population, suggesting that some degree of aggregation is needed for the presence of the water population T_{22} in dried sausages. The fact that the T_{2b2} population was also present in the final stages supports the hypothesis that a true coagulation is not taking place and the structural modification is not complete and, further, related to the dehydration taking place during ripening.

In conclusion, the present study revealed that (i) changes in water mobility and distribution during the manufacture of sausage model systems were detectable by means of LF-NMR relaxation, where ripening produced a shift toward faster relaxation times related to the reduction of the intrinsic pore size of the meat matrix; and (ii) the distribution of water in sausage models was significantly affected by the addition of proteases to the meat batter, supporting the role of myofibrillar proteins in meat coagulation and suggesting that some aggregation degree is needed for the presence of a T_{22} population in fermented sausages. Finally, the extinction of the T_{22} population in meat systems could be associated with a high enzymatic proteolysis degree and, consequently, the presence of great amounts of free amino groups.

Diabrotica sp.), as well as the 5-enolpyruvylshikimate-3-phosphate synthase protein from *Agrobacterium* sp. strain CP4 (CP4 EPSPS) that confers tolerance to glyphosate. MON 89034 expresses the *Bt* Cry1A.105 and Cry2Ab2 proteins that protect against feeding damage caused by the European corn borer (*Ostrinia nubilalis*) and other select lepidopteran insect pests.

MON 88017 and MON 89034 traits were introgressed into the conventional sweet corn variety Temptation, which served as the control in this study. Harvested fresh sweet corn kernels were collected from MON 88017, MON 89034, the conventional control, and reference sweet corn hybrids grown in a 2010 U.S. field production. The field trials were conducted at five replicated sites representative of major commercial sweet corn production areas. These sites were Jefferson County, Iowa; Clinton County, Indiana; Ottawa County, Michigan; Freeborn County, Minnesota; and Miami County, Ohio.

At each site, starting seeds were planted in a randomized complete block design with four blocks each for MON 88017, MON 89034, the conventional control, and reference sweet corn hybrids. A total of 17 reference hybrids were included in the study and distributed across the five sites (see the Supporting Information for details of site distribution of reference hybrids). Normal agronomic practices were followed for each growing region, including the application of registered non-glyphosate-containing maintenance pesticides. Glyphosate was applied to MON 88017 sweet corn. Fresh ear samples were collected at the R3 growth stage from approximately 20 plants from each plot by removing pollination bags from collected ears and placing all nonshucked ears into an appropriately labeled sample container. Samples were then transferred to dry ice within 30 min after collection and shipped to Monsanto in St. Louis on the day of harvest. Fresh sweet corn kernels were removed from husked, desilked whole ears, and after samples were processed, stored in a −80 °C freezer prior to compositional analysis.

Compositional Analyses. Compositional analyses included proximates (ash, carbohydrates by calculation, moisture, protein, and fat), acid detergent fiber (ADF), neutral detergent fiber (NDF), total dietary fiber (TDF), 18 amino acids, fatty acids (C8−C22), sugars (raffinose, glucose, fructose, sucrose, and maltose), vitamins [β-carotene (referred to as vitamin A), B_1 (thiamin), B_2 (riboflavin), B_3 (niacin), B_6 (pyridoxine), B_9 (folic acid), C, and E (α- and γ-tocopherol)], other carotenoids (lutein and zeaxanthin), and minerals (calcium, copper, iron, magnesium, manganese, phosphorus, potassium, sodium, and zinc). The antinutrient phytic acid was also measured, as well as the secondary metabolites furfural (2-furaldehyde), ferulic acid, and *p*-coumaric acid. Compositional analyses were conducted by Covance Laboratories Inc. in Madison, WI, USA. Samples were analyzed in a randomized order to minimize assay bias. Methods for all components, with the exception of vitamin C and carotenoids, have been previously described.[10] Measurement of vitamin C followed AOAC International Method 967.22.[11] Briefly, vitamin C in each sample was extracted, oxidized, and mixed with *o*-phenylenediamine to produce a fluorophor having an activation maximum at approximately 350 nm and a fluorescence maximum at 430 nm. Fluorescence was proportional to concentration. Development of the fluorescence compound with the vitamin was prevented by forming a boric acid−dehydroascorbic acid complex prior to addition of the *o*-phenylenediamine solution. Any remaining fluorescence was due to extraneous material and served as the blank. The limit of quantitation for the vitamin C method was 1.00 mg/100 g. Carotenoid measurements followed AOAC International Method 967.22[12] (for β-carotene) and AOAC International Method 2005.07[13] (for lutein and zeaxanthin). Briefly, samples were blended with alcohol, filtered, and extracted with hexane. The extracts were evaporated, reconstituted with mobile phase, and analyzed on a reverse-phase HPLC system equipped with UV detection. Individual carotenoids were determined by comparison to known standards. The limit of quantitation for the carotenoid method was 0.0200 mg/100 g. Measurement of the sugars followed the same methodology used in raffinose determinations described previously.[10] Samples for sugar analysis were extracted with deionized water, and the extract was treated with hydroxylamine hydrochloride solution in pyridine, containing phenyl-β-D-glucoside as an internal standard. The resulting oximes were converted to silyl derivatives by treatment with hexamethyldisilazane and trifluoroacetic acid and analyzed by gas chromatography using a flame ionization detector. The limit of quantitation for the sugar method was 0.0500%.

Prior to the compositional study, the stabilities of vitamin C, sugars, and carotenoids after sweet corn harvest were evaluated in the conventional sweet corn (Temptation) stored at three storage conditions: at 5 °C and −20 °C for up to 45 days and at −70 °C for up to 200 days. On the basis of these results, it was determined that the best storage condition for the samples was in freezers set to maintain at least −70 °C (see the Supporting Information).

Statistical Analysis of Composition Data. In all, 77 different analytical components were measured. Across all samples, components with >50% of observations below the assay's limit of quantitation (LOQ) were excluded from summaries and statistical analysis. The following 22 components were excluded: caprylic acid, capric acid, lauric acid, myristic acid, myristoleic acid, pentadecanoic acid, pentadecenoic acid, palmitoleic acid, heptadecanoic acid, heptadecenoic acid, γ-linolenic acid, eicosadienoic acid, eicosatrienoic acid,

arachidonic acid, sodium, β-carotene (referred to as vitamin A), furfural (2-furaldehyde), phytic acid, *p*-coumaric acid, raffinose, α-tocopherol, and γ-tocopherol. For components with individual measurements below the assay's LOQ, where fewer than 50% of the values were below the LOQ, a value equal to half the quantitation limit was assigned prior to statistical analyses. Outliers were investigated using PRESS residuals. Analytical components with values outside the ±6 studentized PRESS residual range were considered for removal as outliers. A single copper value was outside the ±6 studentized PRESS residual range and was removed. The outlier test procedure was reapplied to all remaining copper values; no additional result had a PRESS residual value outside the ±6 range.

The data analysis and output for this compositional assessment were generated using SAS software, versions 9.2 and 9.3 of the SAS System for Windows (SAS, 2002−2010). The replicated sites were assessed as a combination of all sites (the combined-site analysis). All component levels were statistically modeled using a mixed model analysis of variance. In particular, data were analyzed using the model

$$Y_{ijk} = U + T_i + S_j + B(S)_{jk} + ST_{ij} + e_{ijk}$$

where Y_{ijk} = unique individual observation, U = overall mean, T_i = fixed effect of material i, S_j = random effect of site j, $B(S)_{jk}$ = random effect of block k within site j, ST_{ij} = random effect of the interaction between site i and material j, and e_{ijk} = residual error. For each analytical component, the mean of MON 88017 and MON 89034 sweet corns was compared with the conventional control. Significant differences were determined at the 5% level.

A variance components analysis was also conducted by fitting the above model with a single modification; to compare the sources of variability, T_i was modeled as a random effect. The restricted maximum likelihood (REML) method was used to calculate covariance parameter estimates from the MIXED procedure in SAS. Bar charts and box plots were generated.

RESULTS AND DISCUSSION

Means and ranges of observed values for MON 88017, MON 89034, control, and reference sweet corn hybrids are presented in Tables 1−4 and Supplementary Tables 1 and 2 in the Supporting Information. Results of the combined-site analysis included 21 significant differences ($p < 0.05$) between the test materials and the conventional control. These encompassed 11 analytes in the assessment of MON 88017 sweet corn (ADF, NDF, TDF, carbohydrates by calculation, total fat, stearic acid, calcium, copper, iron, manganese, and zinc) and 10 analytes in the assessment of MON 89034 sweet corn (ADF, ash, carbohydrates by calculation, total fat, maltose, vitamin B_1, vitamin C, zeaxanthin, stearic acid, and arachidic acid). None of these 21 significant differences were considered compositionally meaningful as they were characterized by small magnitudes of difference and were much smaller than natural variation known to be associated with crop composition.[14−16] Graphical options to display the compositional data in this assessment were also pursued.[17] This is shown as box plots of selected analytes including maltose and sucrose (Figure 1), lutein and zeaxanthin (Figure 2), and vitamin C (Figure 3) and bar graphs of the fatty acid composition data (Figure 4). Results of variance components analysis on selected analytes are also shown graphically: sucrose and maltose (Figure 1), lutein and zeaxanthin (Supplementary Figure 2), vitamin C (Figure 3), and fructose and glucose (Supplementary Figure 1).

Proximate and Fiber Composition. There were a total of five significant differences ($p < 0.05$) between mean values of MON 88017 sweet corn and control components and four differences between MON 89034 sweet corn and the control (Table 1). In general, fat and fiber levels were higher in both MON 88017 and MON 89034 sweet corn hybrids when

[a]Vitamins in mg/kg dry weight; Carotenoids in mg/100 g dry weight. [b]Least-squares mean and range (minimum and maximum replicate values) across all sites. [c]Statistically different ($p < 0.05$) from control. [d]Reference 22. [e]Reference 21

compared to the sweet corn control. The increase in fiber was somewhat more pronounced in MON 88017 sweet corn, for which the TDF value was 8.88% dwt, whereas corresponding values for MON 89034 sweet corn and the control were 7.89 and 7.56% dwt, respectively. Fat values for MON 88017 and MON 89034 were 3.52 and 3.49% dwt, respectively, whereas the corresponding control value was 3.00% dwt. These differences were considerably less than the range of variation associated with the in-study reference sweet corn hybrids (Table 2).

Sugar Composition. Table 2 summarizes data from the analysis of sugar (fructose, glucose, maltose, and sucrose) levels in MON 88017 and MON 89034 sweet corns. No differences were observed between MON 88017 sweet corn and the conventional sweet corn control, and only one significant difference (maltose, $p < 0.05$) was observed between MON 89034 sweet corn and the control. The mean maltose value for MON 89034 sweet corn was 1.54% dwt, and the corresponding value for the conventional sweet corn control was 1.99% dwt, a difference of 0.45% dwt. This difference was considerably less than the range of variation (2.59% dwt) associated with the reference sweet corn hybrids (0.57–3.16% dwt, Table 2). Box plots for sucrose and maltose (Figure 1) highlighted the lack of significant impact on sugar composition. Consistent with these findings, variance components analysis showed that for maltose the MON 88017 and MON 89034 sweet corn materials contributed in part to the small amount of variation observed between the biotech and control comparator, and that for sucrose (Figure 1) and fructose and glucose (Supplementary Figure 1) variation is predominately due to location with negligible contribution from the biotech materials.

Characteristics of high-quality sweet corn are tenderness and sweetness,[18] and cultivars with greater sugar concentrations at harvest maturity have been shown to improve eating quality and consumer acceptance.[19,20] The data from this compositional assessment of MON 88017 and MON 89034 sweet corns have demonstrated sugar values consistent with the values reported in the literature[21,22] and that the biotech traits do not meaningfully affect sugar composition.

[a]Percent total fatty acid. [b]Least-squares mean and range (minimum and maximum replicate values) across all sites. [c]Statistically different ($p < 0.05$) from control.

Vitamin and Carotenoid Composition. Vitamin (B_1, B_2, B_3, B_6, B_9, and C) and carotenoid (lutein and zeaxanthin) compositional analysis results are presented in Table 3. One significant difference ($p < 0.05$) was found for MON 88017 sweet corn in vitamin or carotenoid composition when compared with conventional control; the combined site mean value of vitamin B_1 (thiamine) in MON 88017 sweet corn was 2.91 mg/kg dwt and the corresponding value for the conventional sweet corn control was 3.51 mg/kg dwt, a difference of 0.6 mg/kg. This difference was considerably less than the range of variation (3.79 mg/kg) associated with the reference sweet corn hybrids (1.38–5.17 mg/kg dwt; Table 3). Two significant differences were observed between MON 89034 sweet corn and the conventional sweet corn control (vitamin C and zeaxanthin). Mean values for vitamin C and zeaxanthin in MON 89034 sweet corn were 368.4 mg/kg dwt

DOI: 10.1021/jf505687s
J. Agric. Food Chem. 2015, 63, 3046–3052

and 0.55 mg/100 g dwt, respectively. Corresponding values for vitamin C and zeaxanthin in the conventional sweet corn control were 331.88 mg/kg dwt and 0.46 mg/100 g dwt, respectively. Again, mean differences between the biotech and conventional comparators are of small magnitude and considerably less than the range of variation associated with the reference sweet corn hybrids (Table 3). Similar to the sugars, box plots for the carotenoids, lutein and zeaxanthin (Figure 2) highlight the lack of impact the biotech traits have on key sweet corn components. Results from variance components analysis of the carotenoids are presented in Supplementary Figure 2. The data presented in the supplementary figure demonstrate that MON 88017 and MON 89034 sweet corns have carotenoid values consistent with those reported in the literature[23,24] and that the biotech traits do not significantly affect carotenoid composition. This conclusion extends to the B and C vitamins[25] and is exemplified for vitamin C in Figure 3.

Fatty Acid Composition. Table 4 summarizes fatty acid composition data for MON 89034 and MON 88017 sweet corns. With the exception of stearic acid and arachidic acid, there were no differences ($p > 0.05$) in the mean levels of fatty acid components in MON 89034 sweet corn and the conventional sweet corn control and, with the exception of stearic acid, no significant differences were observed between MON 88017 sweet corn and its control. In those three instances when a significant difference was observed, the relative magnitude difference, with respect to the control, was small (<10%), and overall there was no change in the fatty acid profile. This is demonstrated in graphical form in Figure 4.

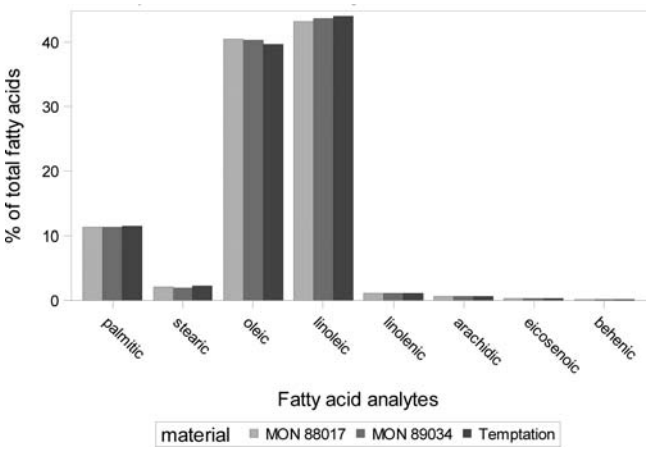

Figure 4. Clustered bar chart of fatty acids (expressed as perecentage of total fatty acids) for MON 88017, MON 89034, and control sweet corns.

Amino Acid Composition. Results from the amino acid analysis are presented in Supplementary Table 1. Consistent with the lack of differences ($p < 0.05$) observed in mean protein levels (Table 1) between both MON 89034 and MON 88017 sweet corns and the conventional sweet corn control, no significant differences were observed in amino acid levels.

Mineral Composition. The results for minerals (calcium, copper, iron, magnesium, manganese, phosphorus, potassium, and zinc) are presented in Supplementary Table 2. There were no significant differences ($p > 0.05$) between MON 89034 sweet corn and the sweet corn control, whereas for MON 88017 sweet corn, five differences ($p < 0.05$) were observed. In those latter instances, magnitudes of differences, with respect to the control, were small, particularly in the context of the extensive variability in mineral composition associated with maize.[14−16] These results established that the biotech traits have no meaningful impact on mineral composition.

Conclusion. Farmers in the United States have benefited from advancements in breeding and biotechnology for over a decade. Studies have consistently shown that these benefits have been accompanied by no loss in nutritional quality.[14−16] In the case of sweet corn, the benefits conferred by biotech traits include reductions in pesticide applications and fuel use.[3] As would be expected from results on field corn, levels of key nutritional components in MON 89034 and MON 88017 sweet corns were equivalent to those of a near-isogenic conventional sweet corn comparator. This conclusion especially extended to components such as sugars that are important determinants of sweet corn quality. Overall, the results of this study were consistent with a 20 year history of observed equivalence between GM and non-GM crops[15] and increasing understanding at the molecular level as to why such equivalence is expected.[26] In fact, it could be noted that the few statistically significant differences observed in this study are most likely due not to the GM traits but are associated with the effects of residual genetic variation between any near-isogenic comparators.[14] In summary, the benefits from biotech traits experienced in corn developed for feed use can also be incorporated into sweet corn while maintaining the high nutritional quality expected in sweet corn for food use.

to characterize the antimicrobial components of commercial *Leuconostoc*/radish root filtrates.

MATERIALS AND METHODS

Materials. *Leuconostoc*/radish root ferment filtrate (LRRFF) was obtained from retail stores in Lincolnton, NC and Olga, WA, via their Web sites. The samples were produced by Active Micro Technologies (Lincolnton, NC), and were marketed as Leucidal Liquid. Lot numbers were given as FSS130415, FSS111019-1, and 29283P-5139. *Raphanus sativus* (daikon/winter radish) was purchased at Planet Organic Market (Edmonton, Canada). Strong anion exchange resin AG 1-X8 (chloride form, 50−100 mesh) was purchased from Bio-Rad (Hercules, CA). Before use, the resin was pretreated with 6 M HCl for 20 min then washed with deionized water until pH 7.

Chemicals. Salicylic acid was purchased from Sigma-Aldrich (St. Louis, MO). Didecyldimethylammonium chloride was purchased from Lonza Inc. (Basel, Switzerland). High-performance liquid chromatography (HPLC)-grade methanol and acetonitrile were purchased from Caledon Laboratory Chemicals (Georgetown, Canada) and filtered through a 0.22 μm membrane before use. All other solvents were of American Chemical Society (ACS) grade and purchased from Fisher Scientific (Hampton, NH). Deionized water was obtained from a Milli-Q reagent water system (Millipore Co., Milford, MA). Protease XIV was obtained from Sigma-Aldrich (St. Louis, MO) and used according to the manufacturer's instructions.

Instrumental Analysis. Analytical high-performance liquid chromatography was done on a Varian ProStar equipped with model 210 pump heads, a model 325 dual wavelength detector, and a 1 mL Rheodyne 7725i manual injector. The analytical column was a 5 μm, 4.6 × 250 mm Vydac C18 (Torrance, CA). The HPLC mobile phase consisted of (A) methanol and (B) water, each containing 0.1% trifluorocetic acid (TFA). A gradient HPLC method was used, consisting of 5 min hold at 5% A; 50 min increase of A from 5 to 90%; 4 min hold at 90% A; 3 min decrease from 90 to 5% A; and 3 min hold at 5% A, with a flow rate of 1 mL/min and ultraviolet (UV) detection at 220 nm.

Nuclear magnetic resonance (NMR) spectra were recorded from samples in $CDCl_3$ on a Varian Unity 500 MHz or Varian Inova 600 MHz spectrometer at ambient temperature. Chemical shifts (δ) are reported in parts per million (ppm) relative to tetramethylsilane and are corrected to the solvent residue peak (7.26 ppm).

High-resolution electrospray ionization (ESI) mass spectra were acquired by flow injection analysis using an Agilent 6220 oaTOF instrument (Santa Clara, CA) equipped with a dual sprayer electrospray ionization source (the second sprayer providing a reference mass solution) and an Agilent 1200 Series isocratic pump, or by direct insertion probe electron impact (EI) ionization using a Kratos MS-50G instrument (Manchester, UK). The carrier solvent for flow injection analysis and mass spectral conditions was methanol. Mass correction of spectra was performed for every individual spectrum, using peaks at m/z 121.0509 and 922.0098 in the positive mode and m/z 226.9785 and 1033.9881 in the negative mode. Data analysis was performed using the Agilent Mass Hunter Qualitative Anaslysis software version B.03.01.

Radiocarbon dating was performed by the Research Laboratory for Archaeology and the History of Art at University of Oxford, England, U.K.[31]

Antimicrobial Activity by Spot-on-Lawn Assay. The assay was performed in a laminar flow hood. Soft agar (0.75% w/v agar) (10 mL) was inoculated with an overnight culture of the desired indicator strain (100 μL, 1% inoculation) and poured over a hard agar (1.5% w/v agar) plate of the same medium. Once the agar solidified, an aliquot of the sample (10 μL) was spotted on the plate and allowed to dry. The plate was incubated overnight at a temperature suitable for the growth of the indicator strain (30 or 37 °C). A clear zone in the bacterial lawn at the site of sample addition indicated antimicrobial activity. Indicator strains were *Escherichia coli* DH5α, *E. coli* ATCC 25922, *Lactococcus lactis* subsp. *cremonis* HP, and *Staphylococcus aureus* ATCC 6538.

Fractionation of *Leuconostoc*/Radish Root Ferment Filtrate by Hydrophobic Interaction Resin. Amberlite XAD-16 resin (40 g) was swelled by gentle stirring in isopropanol (IPA) for 30 min, followed by three rinses with deionized H_2O. To this resin was added a 1:1 mixture of LRRFF (100 mL from the 1100 mL bottle purchased from Formulator Sample Shop) and deionized H_2O (100 mL). The resulting slurry was gently shaken for 20 min then loaded into a 2.5 × 50 cm fritted column. The flow through was collected, and the column was washed with three bed-volumes of deionized H_2O, then two bed-volumes each of 20% IPA, 40% IPA, 60% IPA, 80% IPA, and finally 80% IPA containing 0.1% TFA. All solutions were collected, concentrated to remove isopropanol, and evaluated for biological activity using a spot-on-lawn assay.

Extractive Analysis of LRRFF. A 50 mL portion of *Leuconostoc*/radish root ferment filtrate was mixed with 40 mL of deionized water and extracted with 4 × 70 mL of ethyl acetate (EtOAc). The organic extracts were combined and dried over Na_2SO_4 and then concentrated in vacuo. The resulting white residue was analyzed by NMR spectrometry, HPLC, and elemental analysis. This residue could be further purified by dissolving in approximately 20 mL of EtOAc and extracting into water with 5% NaOH (3 × 70 mL). After the aqueous layers were combined and acidified with 6 M HCl to pH 2, a white solid (salicylic acid) crystallized from the solution. This solid was recrystallized from water, then dissolved in a 1:1 mixture of methanol (MeOH) and water for the spot-on-lawn activity assay.

A second compound (didecyldimethylammonium salt) was isolated as follows: LRRFF (50 mL) was mixed with 5% NaOH (20 mL) to a pH of 9−10 and then extracted with dichloromethane (4 × 70 mL). The organic extracts were pooled, dried with Na_2SO_4, and the solvent was removed in vacuo. The resulting residue was resuspended in a 1:1 mixture of MeOH:H_2O (2 mL) and then combined with a slurry of AG 1-X8 anion exchange resin (2 g, Cl^- form). This mixture was incubated at room temperature for 20 min with occasional swirling, followed by gravity filtration to remove the resin. The flow-through was collected, concentrated to dryness in vacuo, and subjected to NMR analysis.

Characterization Data. *Salicylic Acid.* FTIR (neat, cm^{-1}, ν): 3236, 3004, 2858, 2598, 1669, 1612, 1444. ^{1}H NMR (600 MHz, $CDCl_3$, δ): 7.94 (m, 1H, Ph-H), 7.56 (m, 1H, Ph-H), 7.03 (m, 1H, Ph-H), 6.95 (m, 1H, Ph-H). ^{13}C NMR (125.7 MHz, $CDCl_3$, δ): 174.7, 162.2, 137.0, 130.9, 119.6, 117.9, 111.3. Anal. Calcd. for $C_7H_6O_3$: C, 60.99; H, 4.45, Found: C, 60.87; H, 4.39; EI-HRMS m/z calcd for $C_7H_6O_3$: 138.03169 [M^+]. Found: 138.03116.

Didecyldimethylammonium Chloride. ^{1}H NMR (600 MHz, $CDCl_3$, δ): 3.51 (m, 4H, $(C\underline{H}_2)_2$-N), 3.40 (s, 6H, $(C\underline{H}_3)_2$-N), 1.70 (br. s, 4H, $(C\underline{H}_2CH_2)_2$-N), 1.35 (m, 28H, $(CH_3(C\underline{H}_2)_7$-$CH_2CH_2)_2$-N), 0.88 (t, 6H, $C\underline{H}_3CH_2$. ^{13}C NMR (125.7 MHz, $CDCl_3$, δ): 63.9, 51.6, 31.8, 29.7, 29.4, 29.4, 29.2, 26.4, 22.9, 22.7, 14.1. ESI-HRMS m/z calcd. for $C_{22}H_{48}N$: 326.3781 [$M + H^+$]. Found: 326.3784.

RESULTS AND DISCUSSION

In a spot-on-lawn assay, the commercial LRRFF inhibited the growth of *E. coli* DH5α, *E. coli* 25922, and *L. lactis* subsp. *cremonis* HP (Table 1). Antimicrobial activity was retained following treatment with Protease Type XIV or exposure to 100 °C for 60 min, conditions under which peptides typically degrade. Fractionating the liquid with Amberlite XAD-16 localized activity against both *E. coli* and *L. lactis* strains to the 60% isopropanol and 80% isopropanol, 0.1% TFA fractions. Trifluoroacetic acid was included in the final wash to protonate any potential amines which might otherwise be too hydrophobic to elute from the XAD-16 resin.

When the XAD-16 fractions were left at room temperature overnight, a white needle-like solid precipitated from the 60% IPA and 80% IPA with 0.1% TFA fractions. This solid was collected and characterized by Fourier transform infrared (FTIR), NMR, elemental analysis, and mass spectrometry (EI) analysis. The solid was found to have a mass of 138 g/mol,

consistent with a molecular formula of $C_7H_6O_3$. The mass, FTIR, ^{1}H NMR, and ^{13}C NMR data and chromatographic behavior were in accord with that of salicylic acid, with a minor alkyl impurity visible by ^{1}H NMR (Figure 1).

Salicylic acid is a natural product, produced by both lactic acid bacteria and plants, and is present in fermented radish brine.[21,32,33] It inhibits the growth of some Gram-negative bacteria and fungi but is not generally active against Gram-positive bacteria.[33−38] This was confirmed with a spot-on-lawn assay using commercial salicylic acid, dissolved in 1:1 MeOH:H_2O, which inhibited the growth of *E. coli* DH5α and not *L. lactis* subsp. *cremonis* HP. The solid which was isolated from LRRFF following XAD-16 fractionation was active against both organisms (Figure 2). High-resolution ESI-MS analysis of the solid showed only one signal in the positive mode, with a m/z value of 326.3776. This corresponded to a chemical formula of $C_{22}H_{48}N^+$, suggesting that at least part of the salicylate had a saturated alkyl amine counterion. This was verified via direct extraction of LRRFF with ethyl acetate, followed by washing with sodium hydroxide and acidification with hydrochloric acid. Upon acidification, salicylic acid precipitated out of solution and was collected via filtration. This sample was identical to a commercial sample by HPLC and did not inhibit the growth of *L. lactis* subsp. *cremonis* HP (Figures 2 and 3, Table 2). MS analysis no longer showed a peak at 326.3776 in the positive mode.

To determine the structure of the substance responsible for the activity against *L. lactis*, we concentrated the base-washed ethyl acetate layer and examined the resulting solid by ^{1}H NMR. While generally consistent with didecyldimethylammonium bromide, the spectra contained a small salicylate impurity. To remove this, the mixture was dissolved in water and passed through a column of anion exchange resin AG 1-X8 (Cl^-). Once the sample was concentrated to dryness and reconstituted in $CDCl_3$, NMR analysis showed no trace of salicylate (Figure 4), and all of the ^{1}H and ^{13}C NMR spectra were identical to that of didecyldimethylammonium bromide.[39] In mass spectral analyses, the molecular formula of the positive ion obtained from didecyldimethylammonium bromide matched that obtained by high-resolution mass spectrometry (HRMS), and tandem mass spectrometry analysis of our sample showed only one fragmentation peak, with a molecular formula of $C_{12}H_{28}N^+$. This corresponds to loss of $C_{10}H_{20}$, one of the two decyl chains.

Didecyldimethylammonium chloride is known to inhibit the growth of several Gram-positive bacteria, including *Staphylococcus aureus*.[40,41] Both the isolated salt and a commercial

sample strongly inhibited the growth of *S. aureus* ATCC 6538 and *L. lactis* subsp. *cremonis* HP at 8 μg/mL in our spot-on-lawn assay.

To estimate the amount of salicylic and didecyldimethylammonium salt in commercial LRRFF, 50 mL aliquots were drawn from three different samples obtained from two different suppliers. The results were performed without duplication, and are summarized in Table 3. We also blended a 150 g sample of daikon/winter radish (*Raphanus sativus*), and extracted the resulting aqueous mixture with EtOAc, but were unable to detect salicylic acid or didecyldimethylammonium salts by mass spectrometry. While salicylic acid is one of the organic acids produced by lactic acid bacteria and is known to occur in fermented radish brine,[2,33] to date didecyldimethylammonium salts have been produced only through anthropogenic chemical synthesis.[42]

To determine the origin of the salicylic acid and didecyldimethylammonium salts we isolated from LRRFF, samples were submitted for carbon dating. On the basis of the amount of ^{14}C present, these compounds were dated to 52 000 ± 2 900 and 21 140 ± 100 years old, respectively. This clearly indicates that the salicylic acid and the didecyldimethylammonium chloride are largely derived from petroleum-based precursors and that neither is the product of a recent fermentation of plant material. The didecyldimethylammonium salts, which are used as detergent biocides and wood preservatives, have toxicity to aquatic organisms and can also affect human health.[40,42,43] They are known to enhance permeability of salicylic acid through

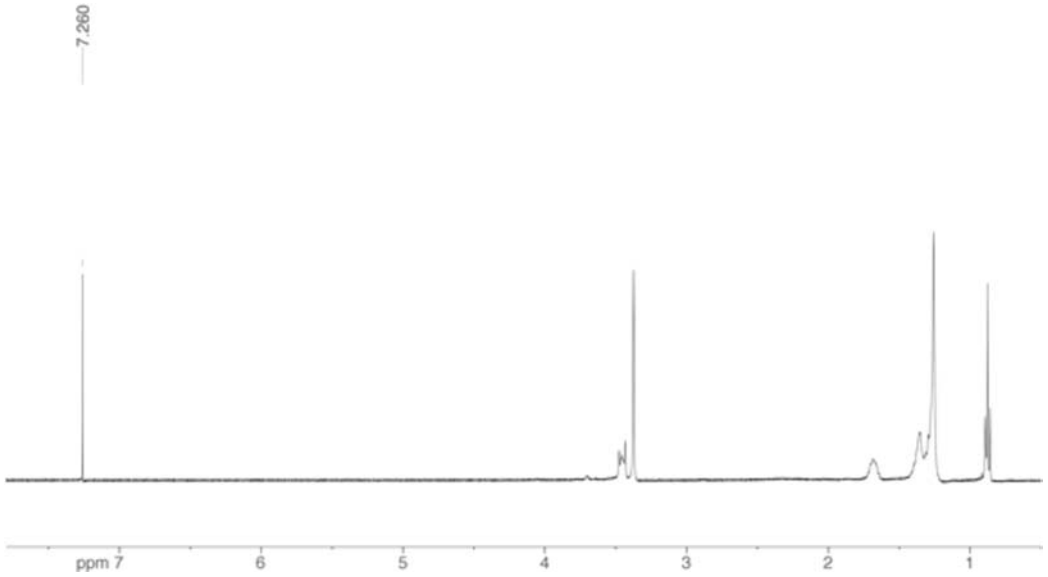

Figure 4. ^{1}H NMR spectrum of didecyl dimethyl chloride obtained after ion-exchange chromatography. The residual solvent peak of deuterated chloroform appears at 7.26 ppm.

Table 3. Amount of Purified Salicylic Acid and Didecyldimethylammonium Salts Obtained from *Leuconostoc*/Radish Root Ferment Filtrate Purchased from Two Companies

sample	1		2
batch	batch 1 (8 oz)	batch 2 (1 kg)	batch 3 (8 oz)
isolated and purified salicylic acid (g/50 mL)	0.31	0.12	0.19
didecyldimethylammonium salts as chloride (mg/50 mL)	8	16	10

animal skin,[44] and can cause skin allergenic effects, asthma, and lung problems, as well as eye irritation.[45−48] In Europe, the acceptable daily intake of didecyldimethylammonium chloride has been set to 0.1 mg/kg body weight per day.[49] As indicated in Table 3, a 50 mL batch of LRRFF would exceed this level for an adult human male.

In summary, the antimicrobial activity of commercial *Leuconostoc*/radish root ferment filtrates (LRRFF) are attributed to salicylic acid and didecyldimethylammonium salts. Moreover, these two compounds are too deficient in ^{14}C to be the product of recent fermentation, suggesting that they are derived from petroleum feedstock. We were unable to detect antimicrobial peptides in any sample of fermented radish root filtrate.

and in turn, to identify these metabolites by the synthesis standard as well as to assess safety of forchlorfenuron and its metabolites.

MATERIAL AND METHODS

General. Forchlorfenuron (purity >99%), high performance liquid chromatography (HPLC) grade methanol, and acetonitrile were provided by Sigma-Aldrich (St Louis, Missouri). Formic acid and ethyl acetate used were of analytical grade (Sigma-Aldrich, St Louis, Missouri). HPLC-grade water was obtained by Milli-Q-Plus ultrapure water system from Millipore (Milford, MA). Nuclear magnetic resonance spectra were recorded on an AVANCE III, 500 MHz spectrometer (Bruker, Fällanden, Switzerland). Melting points were recorded on an MP420 automelting-point system (Jinan Hai-neng Co., China). Optical density (OD) was read on iMark microplate reader (Bio-Rad, Richmond, CA). Commercial solvents and reagents were of analytical grade (Sigma-Aldrich, St Louis, Missouri).

Plant Material. The trial was carried out between 2012 and 2013, in Xi'an city, Shaanxi province, China, in a 7-year-old Hayward kiwifruit orchard. The vines were spaced 5 m × 4 m and trained to the T-bar trellis system. These experiments were designed according to the standard operating procedures on pesticide registration residue field trials, issued by the Institute for the Control of Agrochemicals, Ministry of Agriculture, China.[27] Twenty kiwifruit vines were selected, with uniform vegetative and reproductive characteristics. Fifteen days after full bloom, all initial fruits of 15 vines were dipped for 5 s in aqueous forchlorfenuron solution (50 mg/kg), while the fruit of the other five vines were dipped in water only as a control set. After 90 days, representative forchlorfenuron-treated samples and the control samples were randomly collected.

Sample Preparation. A brief description of the extraction procedure used is as follows: forchlorfenuron-treated samples were processed in a blender. A 300 g, thoroughly homogenized sample was placed in a 1000 mL glass beaker then mixed thoroughly with 300 mL of ethyl acetate, 120 g of anhydrous magnesium sulfate, and 30 g of anhydrous sodium acetate, using ultrasonic-assisted extraction for 40 min. The homogenate was allowed to settle, and the supernatant was paper-filtered into a 1000 mL rotary evaporation flask. The solid residue was washed twice with 60 mL of ethyl acetate. A rotary evaporator, set at 40 °C and 250 mbar, was used to evaporate the extract to less than 5 mL. Once reduced, extract was transferred to a graduated conical tube (15 mL) and evaporated at 50 °C. The sample was reconstituted in 2 mL of methanol and filtered through a 0.22 μm microporous membrane and stored at −20 °C until used.[28−30]

Chromatographic Conditions. Liquid chromatography experiments were conducted on a HPLC system, consisting of an LC-20AD binary pump, DGU-14A degasser, SIL-20AD autosampler, and CTO-20AC column oven (Shimadzu, Kyoto, Japan). Chromatographic separation was achieved in a Shim-pack XR ODS column (75 mm × 3.0 mm i.d, 2.2 μm Shimadzu). The mobile phase (delivered at 0.2 mL/min) consisted of solvent A (acetonitrile) and B (0.1% formic acid in water). Elutions were performed with under the following conditions: linear gradient 95−30% B from 0 to 5 min, 30−0% B from 5 to10 min, retained for 1 min, then quickly returned to initial 95% B and maintained for 20 min for column equilibration.

MS^n analyses were conducted on an LC-IT-TOF-MS (Shimadzu, Kyoto, Japan) equipped with an electrospray ionization (ESI) source, under the following optimized operating conditions: positive ion mode, detector voltage at 1.6 kV, curved desolvation line (CDL) temperature at 200 °C, heat block temperature at 200 °C, nebulizing gas flow of 1.5 L/min, drying gas (N_2) pressure of 100 kPa, and scan

DOI: 10.1021/acs.jafc.5b01100
J. Agric. Food Chem. 2015, 63, 3059−3066

ranges of m/z 100−1000 for MS^1, m/z 100−800 for MS^2, and m/z 100−800 for MS^3. Metabolite analyses were performed by MetID solution, version 1.1. Finally, the Composition Formula Predictor software (Shimadzu) was used to provide chemical formulas for forchlorfenuron and its metabolites.

Assay for Cytotoxicity. Forchlorfenuron and three metabolites were evaluated for reproductive cytotoxicity by sulforhodamine B (SRB) assay, using Chinese hamster ovary (CHO) cells.[31,32] CHO cells were provided by the College of Life Sciences, Northwest A&F University. CHO cells were cultured in high-glucose DMEM medium, containing 10% (v/v) fetal bovine serum (FBS), penicillin (100 KU/L), and streptomycin (100 μg/mL), at 37 °C, in a 5% CO_2 atmosphere with 95% (v/v) humidity. Forchlorfenuron and its kiwifruit metabolites were dissolved in DMSO then diluted in culture media to the required concentration. The DMSO content of the final concentration was below 0.1%(v/v).[33]

Exponentially growing cells (2.5×10^4) were seeded in a 96-well flat microtiter plate for 24 h, at a volume of 100 μL per well. After 24 h, cells were then incubated for an additional 48 h with various concentrations of the compounds under the same conditions. Next, cells were fixed with 10% trichloroacetic acid and incubated for 60 min at 4 °C. The supernatant was discarded, then the plates were washed 5 times with distilled water and air-dried. Using 0.4% SRB solution dissolved in 1% acetic acid, the cell layer was strained, then the plates were incubated for 20 min at room temperature. After staining, unbound dye was recovered and residual dye was removed by washing 5 times with 1% acetic acid before allowing plates to air-dry. The stained cells was solubilized in 10 mM unbuffered Tris base and optical density (OD) was measured at 560 nm.[33]

Synthesis of the Reference Standards. The general synthetic routes of the reference standards are outlined in Figure 2. The compounds **10**,[34] **11**,[35] and **13**[36,37] have been previously mentioned in research literature.

Synthesis of 1-(2-chloropyridin-4-pyridinyl)-3-(4-methoxyphenyl)-urea (**10**). To a solution of 4-amino-2-chloropyridine (2.38 g, 18.52 mmol) in toluene (103 mL) was added 4-methoxyphenyl isocyanate (2.30 g, 15.43 mmol) at room temperature. The reaction mixture was stirred at 80 °C for 8 h. To prevent reaction between 4-methoxyphenyl isocyanate and water, the synthesis of **10** was conducted under anhydrous conditions. The resulting precipitate was collected by filtration, washed with toluene, and dried in vacuo to yield the title compound as a colorless solid (3.70 g, 13.33 mmol, 86% yield in this step);[38] mp 166−168 °C. ^{1}H NMR (500 MHz, acetone-d_6) δ 8.62 (s, 1H, NH), 8.16 (s, 1H, NH), 8.13 (d, J = 5.6 Hz, 1H, −HC═N−), 7.71 (d, J = 1.7 Hz, 1H, HC═CCl), 7.41 (d, J = 9.0 Hz, 2H, Ar−H), 7.35 (dd, J = 5.6, 1.8 Hz, 1H, −HC-C═N−), 6.87 (d, J = 9.0 Hz, 2H, Ar−H), 3.76 (s, 3H, $-CH_3$). ^{13}C NMR (125 MHz, acetone-d_6) δ, 157.0, (CH_3O−C), 153.0 (−C-C═CCl), 152.6 (−C═O), 150.7 (C═N), 150.4 (−CCl), 132.7 (Ar−C), 122.2 (Ar−C), 114.9 (Ar−C), 112.7 (−C═CCl), 112.6 (−C-C═N), 55.7 ($-CH_3$).

Synthesis of 1-(2-chloropyridin-4-pyridinyl)-3-(3-methoxyphenyl) urea (**11**). The synthesis of procedure of **11** was similar to that of **10**, with the exception that 3-methoxyphenyl isocyanate was used as the starting material instead of 4-methoxyphenyl isocyanate, a colorless solid, yield 85%, mp 160−162 °C. ^{1}H NMR (500 MHz, acetone-d_6) δ 8.66 (s, 1H, NH), 8.34 (s, 1H, NH), 8.16 (d, J = 5.6 Hz, 1H, −HC═N−), 7.73 (s, 1H, HC═CCl), 7.37 (d, J = 4.3 Hz, 1H, −HC-C═N−), 7.27 (s, 1H, Ar−H), 7.19 (t, J = 8.1 Hz, 1H, Ar−H), 7.01 (d, J = 7.9 Hz, 1H, Ar−H), 6.62 (dd, J = 8.2, 1.6 Hz, 1H, Ar−H), 3.78 (s, 3H, −CH3). ^{13}C NMR (125 MHz, acetone-d_6) δ, 161.3 (CH_3O−C), 152.7 (−C-C═CCl), 152.6 (−C═O), 150.8 (−C═N), 150.2 (C−Cl), 141.2 (Ar−C), 130.5 (Ar−C), 112.8 (Ar−C), 112.7 (Ar−C), 112.2 (C═CCl), 109.3 (−C-C═N), 106.0 (Ar−C), 55.6 ($-CH_3$).

Synthesis of 4-hydroxyphenyl-forchlorfenuron (**12**). BBr_3 (6.76 g, 27.01 mmol) was dropwise added to a solution of **10** (3.00 g, 10.80 mmol) in dry CH_2Cl_2 (50 mL) at −30 °C. The reaction mixture was gradually warmed to room temperature and stirred for 24 h, when reaction was terminated by the dropwise addition of methanol, with further stirring for 20 min. The solvent was then concentrated until dry.[39−41] Two pre-experiment demethylations with HBr, BBr_3 were performed, where we found the reaction of HBr demethylation has disadvantages such as many impurities and low productivity. We therefore chose the BBr_3 demethylation reaction. The reaction mixture was evaporated to dryness. The crude product was purified by silica gel column chromatography (chloroform:methanol, 9:1), to obtain **12** (2.17g, 76%) as a colorless solid; mp 214−216 °C. ^{1}H NMR (500 MHz, MeOD) δ, 8.04 (d, J = 5.8 Hz, 1H, −HC═N−), 7.58 (d, J = 1.9 Hz, 1H, HC═CCl), 7.24 (dd, J = 5.8, 2.0 Hz, 1H, −HC-C═N−), 7.20−7.05 (m, 2H, Ar−H), 6.89−6.63 (m, 2H, Ar−H). ^{13}C NMR (125 MHz, MeOD) δ, 153.5 (−C-C═CCl), 152.9 (HO-C), 151.5 (−C═O), 149.5 (−C═N), 148.9 (−CCl), 129.4 (−Ar-C), 122.2 (−Ar-C), 115.3 (−Ar-C), 112.0 (−C═CCl), 111.5 (−C-C═N).

Synthesis of 3-hydroxyphenyl-forchlorfenuron (**13**). The synthesis procedure of **13** was similar to that of **12**, with the exception that **11** was used as the starting material instead of **10**. **13** was a colorless solid, yield 73%, mp 213−215 °C. ^{1}H NMR (500 MHz, MeOD) δ, 8.03 (d, J = 5.8 Hz, 1H, −HC═N−), 7.59 (d, J = 1.8 Hz, 1H, HC═CCl), 7.24 (dd, J = 5.8, 1.9 Hz, 1H, −HC-C═N−), 7.01 (t, J = 8.1 Hz, 1H, Ar−H), 6.96 (t, J = 2.1 Hz, 1H, Ar−H), 6.78−6.68 (m, 1H, Ar−H), 6.45−6.35 (m, 1H, Ar−H). ^{13}C NMR (125 MHz, MeOD) δ, 159.3 (HO-C), 154.0 (−C-C═CCl), 153.0 (−C═O), 151.3 (−C═N), 151.0 (C−Cl), 141.0 (Ar−C), 131.0 (Ar−C), 113.3(Ar−C), 113.1 (Ar−C), 111.8 (C═CCl), 111.7 (−C-C═N), 108.0 (Ar−C).

Synthesis of forchlorfenuron-4-*O*-β-D-acetylglucoside (**14**). A mixture of **12** (1.00 g, 3.79 mmol), tetrabutylammonium bromide (0.20 g, 0.63 mmol), and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (2.34 g, 5.7 mmol) in $CHCl_3$(80 mL) was added to 0.25 mol/L K_2CO_3 (15 mL, 2.5 mmol), the mixture was stirred for 12 h at 50 °C, the organic phase was separated, and the aqueous phase was extracted with $CHCl_3$.[42] The organic extracts were combined, washed with brine, and dried over anhydrous $MgSO_4$. The residue obtained was purified by silica gel column chromatography (chloroform/methanol, 5:1) and dried in vacuo to give the title compound as a yellow solid 0.86 g, yield 38%.

Synthesis of forchlorfenuron-3-*O*-β-D-acetylglucoside (**15**). The synthesis procedure of **15** was similar to that of **14**, with the exception that **13** was used as the starting material instead of **12**. The resulting **15** compound was a yellow solid, with a yield of 30%.

Synthesis of forchlorfenuron-4-*O*-β-D-glucoside (**16**). **14** (0.30 g, 0.5 mmol) was added to a solution of 30% $NH_3 \cdot H_2O$ (10 mL) in CH_3OH (40 mL) with stirring for 12 h at room temperature, after which the solvent was removed under reduced pressure. Using ethyl acetate/methanol (3:1) as eluent, chromatography of the residue was performed on silica gel, providing 0.15 g of colorless solid, a yield of 71%,[42] mp 207−209 °C. ^{1}H NMR (500 MHz, MeOD) δ, 8.12 (d, J = 5.8 Hz, 1H, −HC═N−), 7.70 (d, J = 1.8 Hz, 1H, HC═CCl), 7.39−7.36 (m, 2H, Ar−H), 7.35 (dd, J = 5.8, 1.9 Hz, 1H, −HC-C═N−), 7.12−7.07 (m, 2H, Ar−H), 4.88 (d, J = 7.4 Hz, 1H, O−CH-O), 3.93 (dd, J = 12.0, 1.9 Hz, 1H, $-CH_2OH$), 3.73 (dd, J = 12.0, 5.3 Hz, 1H, $-CH_2OH$), 3.52−347 (m, 2H, $-CH_2C\underline{H}OH-$, $-CH_2CHC\underline{H}OH$), 3.45 (m, 1H, $-CH_2CHCHC\underline{H}OH$), 3.44−3.39 (m, 1H, −OOHC-C<u>H</u>OH). ^{13}C NMR (125 MHz, MeOD) δ, 155.6 (−C-C═CCl), 154.3 (HO-C), 152.9 (−C═O), 151.4 (−C═N), 150.9 (−CCl), 134.3 (Ar−C), 122.5 (Ar−C), 118.5 (Ar−C), 113.3 (−C═CCl), 113.2 (−C-C═N), 102.9 (O−C−O), 78.3 ($-CH_2\underline{C}HOH-$), 78.1 ($-CH_2CH\underline{C}HOH$), 75.1 ($-CH_2CHCH\underline{C}HOH$), 71.5 (−OOHC-<u>C</u>HOH), 62.7 (CH_2).

Synthesis of forchlorfenuron-3-*O*-β-D-glucoside (**17**) was performed similar to the procedure for **16**, and synthesis of **17** proceeded, with the exception that **15** was used as the starting material instead of **14**. Although the yields for steps (c) and (d) were lower than that reported previously,[42,43] we obtain our target products, **16** and **17**. Compound **17** was a colorless solid, yield 69%; mp 210−211 °C. ^{1}H NMR (500 MHz, DMSO) δ, 9.54 (s, 1H, −NH), 9.15 (s, 1H, −NH), 8.17 (d, J = 5.6 Hz, 1H, −HC═N−), 7.64 (s, 1H, HC═CCl), 7.33 (d, J = 5.4 Hz, 1H, −HC-C═N−), 7.23 (s, 1H, Ar−H), 7.20 (t, J = 8.2 Hz, 1H, Ar−H), 7.06 (d, J = 8.0 Hz, 1H, Ar−H), 6.72 (d, J = 8.2 Hz, 1H, Ar−H), 5.34 (s, 1H, −OH), 5.09 (S, 1H, −OH), 5.02 (S, 1H, −OH), 4.82 (d, J = 7.4 Hz, 1H, O-CH-O), 4.55 (s, 1H, −OH), 3.69 (d, J = 11.4 Hz, 1H, $-CH_2OH$), 3.53−3.43 (m, 1H, $-CH_2OH$),

3.16−3.30 (m, 4H, $-CH_2CHOH-$, $-CH_2CHCHOH$, $-CH_2CHCHCHOH$, $-OOHCCHOH$). ^{13}C NMR (125 MHz, DMSO) δ, 157.9 (HO-C), 151.9 (−C-C═CCl), 150.9 (−C═O), 150.0 (−C═N), 149.2 (C−Cl), 139.9 (Ar−C), 129.5 (Ar−C), 112.3 (Ar−C), 111.9 (Ar−C), 111.3 (C═CCl), 110.2 (−C-C═N), 107.1 (Ar−C), 100.5 (O−C−O), 77.05 ($-CH_2CHOH-$), 76.61 ($-CH_2CHCHOH$), 73.22 ($-CH_2CHCHCHOH$), 69.59 (−OOHC-CHOH), 60.60 (CH_2).

RESULTS AND DISCUSSION

On the basis of the published findings,[23−26] the proposed strategy for identifying and assessing the safety of forchlorfenuron metabolites involves four procedural steps: Forchlorfenuron metabolites detected by total ion current (TIC) were recorded, searching for evident differences between peaks of the blanks and those of treated samples by MetID solution software. Obtained MS^1 and MS^n spectra of differences in peaks were used to deduce forchlorfenuron metabolites. The standard substances were synthesized, and comparison between synthetic standard substances and forchlorfenuron metabolites was performed. Safety of forchlorfenuron and its metabolites were assessed.

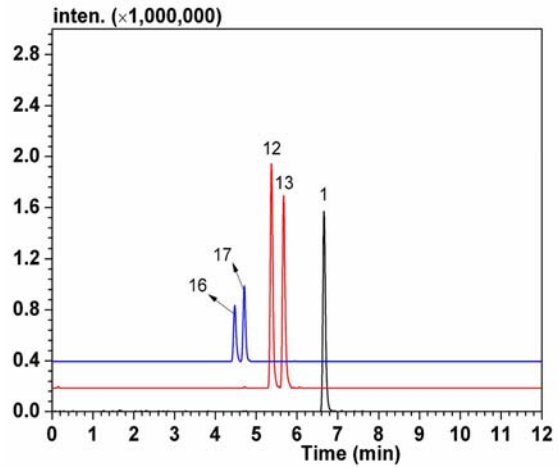

Figure 3. Extracted ion chromatograms of the synthetic standards.

Fragmentations of Forchlorfenuron. For the fragmentation pattern study, 200 μg/mL forchlorfenuron and four synthetic standard substances of its metabolites (**12**, **13**, **16**, **17**), prepared in methanol, were used. Extraction chromatograms of 20 μg/mL forchlorfenuron and four synthetic standard substances (**12**, **13**, **16**, **17**) appear in Figure 3. The proposed fragmentation patterns are illustrated in Figure 4. Figure 5 presents accurate mass measurements of the protonated molecules and fragment ions of forchlorfenuron and four synthetic metabolites. Table 1 shows data for forchlorfenuron and synthetic metabolites by LC-ESI-IT/TOF-MS analysis in positive ion mode.

Analysis of Metabolites. The treated sample and the control sample were analyzed by LC-ESI-IT-TOF/MS. In a search of possible metabolites, targeted data analysis was carried out with the aid of MetID solution software. The biotransformation reactions of forchlorfenuron follow typical patterns of hydroxylation and glycosylation. Aside from the parent compound, there are six peaks which can be found as potential metabolites derived from oxidation and glycosylation. Extraction chromatograms of the treated sample and the control sample are depicted in Figure 6, while Figure 7 shows mass spectra of **2**−**7** in positive ion mode. MS^n of metabolite data from forchlorfenuron in positive ion mode, by LC-ESI-IT-TOF/MS analysis, are presented in Table 2.

Metabolite 2 (Figure 7, Table 2), eluting at 5.193 min, shows the predominant protonated molecule ion $[M + H]^+$ at m/z

1	6.66	248.0585	$C_{12}H_{10}ClN_3O$	**1**- MS^1	248.0557	−11.29
				1-MS^2	155.0008, 129.0201, 93.0443	

[a]SS = synthetic standards. RT = retention time.

264.0552, with a ^{37}Cl isotope signal at m/z 266.0581. **2** yields two main MS^2 ions at m/z 155.0009 (error, 1.29 ppm) and 129.0230 (error, 12.40 ppm). The fragment ion at m/z 129.0230 yields an MS^3 ion at m/z 93.0430 (error, −18.27 ppm). **2** calculates as $C_{12}H_{10}ClN_3O_2$ according to the accurate mass by Formula Predictor software. The protonated molecule at m/z 264.0552 is 15.9967 Da higher than the protonated molecule of forchlorfenuron (m/z 248.0585), corresponding to addition of oxygen. To deduce the site of hydroxylation on **2** (m/z 264.0552), we compared the MS^n data of **2** with the corresponding data for forchlorfenuron. The MS^2 ions of **2** at m/z 155.0007 and 129.0230 form through neutral loss of

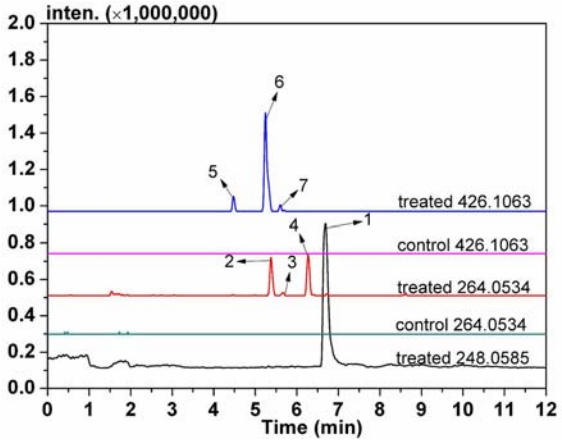

Figure 6. Extracted ion chromatograms of the treated and control samples.

C_6H_7NO and $C_7H_5NO_2$; therefore, the most likely hydroxylation position is located on the benzene ring. On the basis of the results of the above analysis, standards (**12**, **13**) of possible metabolites were synthesized. As can be seen in Figure 4 (Figure 7, Table 1), **2** shares with **12** the common MS^1 ion at m/z 264.0534, MS^2 ions at m/z 155.0007/129.0214 and the MS^3 ions at m/z 93.0447. We conclude that **2** and **12** share the same fragment pathway. The retention time for **2** and **10** corresponded. Therefore, **2** is identified as **12**.

Metabolite 3, (Figure 7, Table 2), eluting at 5.667 min, shows the predominant protonated quasimolecular ion [M +

Table 2. MS^n Data of CPPU Metabolites in Positive Ion Mode[a]

SS	RT (min)	elemental compositions	MS^n	$[M + H]^+$ (m/z)	error (ppm)
2	5.37	$C_{12}H_{10}ClN_3O_2$	**2**-MS^1	264.0552	6.82

J. Agric. Food Chem. 2015, 63, 3059−3066

$H]^+$ at m/z 264.0528, with a ^{37}Cl isotope signal at m/z 266.0653. According to the accurate mass by the Formula Predictor software, **3** calculates as $C_{12}H_{10}ClN_3O_2$. Thus, **3** is identified as **13**.

Metabolite 4 (Figure 7, Table 2), eluting at 6.240 min, shows the predominant protonated molecule ion $[M + H]^+$ at m/z 264.0513, with a ^{37}Cl isotope signal at m/z 266.0508. **4** yields two main MS^2 ions at m/z 155.0002 (error, −3.23 ppm) and 129.0213 (error, −0.78 ppm). Using the accurate mass by the Formula Predictor software, **4** calculates as $C_{12}H_{10}ClN_3O_2$. The protonated molecule at m/z 264.0513 is 15.9928 Da higher than the protonated molecule of forchlorfenuron (m/z 248.0585). On the basis of the analysis result for **2**, the most likely hydroxylation position for **4** is at the benzene ring. Because **2** and **3** are respectively 4-hydroxyphenyl-forchlorfenuron and 3-hydroxyphenyl-forchlorfenuron, **4** is therefore identified as 2-hydroxyphenyl-forchlorfenuron (Figure 5B).

Metabolite **5** (Figure 7, Table 2) shows the protonated molecular ion $[M + H]^+$ at m/z 426.1065, with a ^{37}Cl isotope signal at m/z 428.0974, retention time 4.468 min. In comparison with the protonated molecule of **2** (**3**, **4**), **5** represents an increase of 162.0531 Da ($C_6H_{10}O_5$). **5** calculates as $C_{18}H_{20}ClN_3O_{7,}$ according to the accurate mass by Formula Predictor software. Thus, we deduce that **5** is a glycosylated metabolite of **2**, **3**, or **4**. Comparing the data of **5** and the standard substances (**16**, **17**), the retention time difference for **5** and **16** is 0.002 min, while the retention error for **5** and **17** is 0.242 min. Therefore, **5** is identified as **16**.

Metabolite **6** (Figure 7, Table 2), shows the protonated molecular ion $[M + H]^+$ at m/z 426.1063 (a ^{37}Cl isotope signal at m/z 428.1026) with mass error of 0 ppm and representing an increase of 162.0529 Da ($C_6H_{10}O_5$), compared to the spectra of MS^2 at m/z 264.0535. The fragment ion at m/z 264.0535 (error, −0.38 ppm) leads to two MS^3 product ions at m/z 154.9978 (error, −18.71 ppm) and 129.0227 (error, 10.08 ppm). in MS^1, a fragment ion at m/z 110.0606 (error, 5.45 ppm) was generated. **6** calculates to be $C_{18}H_{20}ClN_3O_7$, and thus the glycosylated metabolite of **2**, **3**, or **4**. As can be seen in Table 1, Table 2, the retention time error is 0.507 min between **6** and **17**. From the above, we may deduce that **6** is an isomer of **16** or **17**, which are respectively forchlorfenuron-4-*O*-*β*-D-glucoside and forchlorfenuron-3-*O*-*β*-D-glucoside. Therefore, **6** is identified as forchlorfenuron-2-*O*-*β*-D-glucoside (Figure 5C).

Eluted at 5.62 min, a possible metabolite (Figure 7, Table 2) at m/z 426.0971 (error, −21.59 ppm) and a ^{37}Cl isotope signal at m/z 428.0933, exhibits the protonated molecular ion $[M + H]^+$. MS^1 for **7** reveals the protonated fragment ions at m/z 248.0565 (error, −8.06 ppm) and 129.0212 (error, −1.55 ppm). Our observations included only the MS^1 data for **7**, however, and lack MS^n for **7**. Thus, **7** is not presumed to be a metabolite of forchlorfenuron.

Cytotoxicity. Cytotoxic action is expressed as the value of 50% inhibition concentration. Results of the in vitro studies demonstrate IC_{50} values of **1** and **2** are, respectively, 12.1 ± 2.1 and 36.2 ± 1.6 μM. Cytotoxicity of **1** is higher than **2**, while **3** and **5** exhibit no activity in CHO. Hydroxylation reduced cytotoxicity of forchlorfenuron, whereas glycosylation resulted in loss of cytotoxicity. Therefore, for increasing yield and quality of kiwifruit, we ought to use modern biological techniques to breed new varieties instead of dipping in solution of plant growth regulator.

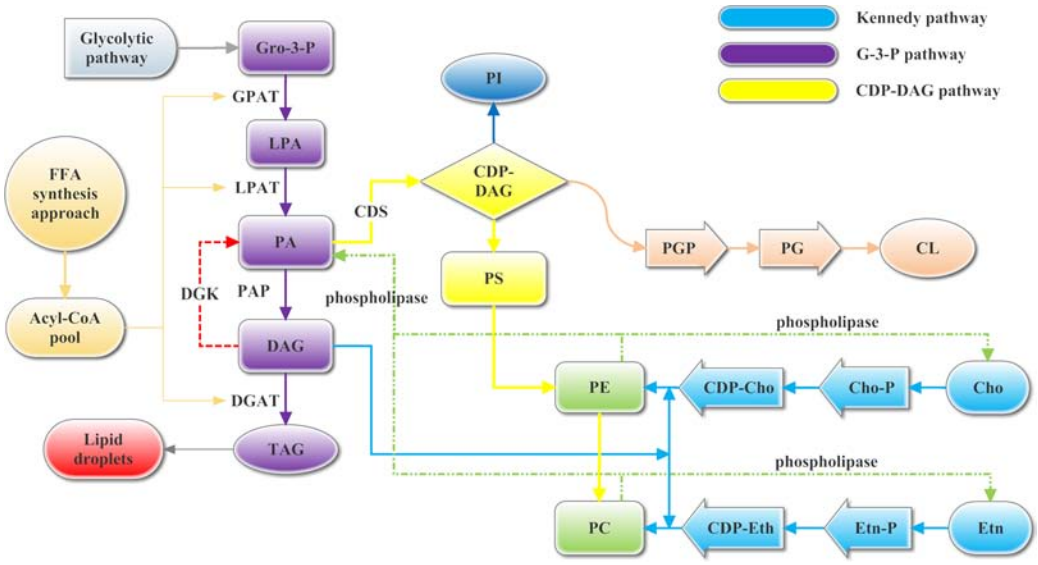

Figure 1. Lipid metabolism includes the TAG and phospholipid assembly process in the microorganism. Pink represents de novo synthesis of free fatty acids, which provides acyl-CoA for three times acylation reaction in TAG synthesis; purple represents the G3P pathway; the red imaginary line represents the reverse reaction of DAG formation; yellow represents the CDP-DAG pathway; blue represents the Kennedy pathway; the green imaginary line represents the degradation of PE and PC catalyzed by phospholipase. See text for additional details.

However, before we begin rational genetic manipulation of genes in TAG formation pathway or competing pathways, we need to have a better comprehensive understanding of how TAG biosynthesis is regulated in different oleaginous microorganisms. This review primarily focuses on PAP, DGAT, and a reverse reaction enzyme (diacylglycerol kinase) involved in the G3P pathway for TAG accumulation and other related pathways that also have an influence on TAG formation.

OLEAGINOUS MICROORGANISMS

Numerous studies have looked at the process of lipid anabolism and catabolism in yeast or microalgae.[6−9] It was speculated that, among the oleaginous microbial species, microalgae and yeast maybe the most promising ones for biodiesel production. Microalgae are considered to be among the best oleaginous organisms to displace fossil diesel.[10] However, the identification and cultivation of ideal algal strains that are excellent in high levels of both biomass productivity and TAG content is still an ongoing and laborious process.[1] Common oleaginous microalgae include green algae (*Chlorophyceae*) and diatoms (*Bacillariophyceae*), such as *Chlorella*, *Dunaliella*, and *Cylindrotheca*.[10−12] Researchers also show great interest in oleaginous yeast, their genes, regulatory factors, and enzyme and functional motifs in lipid synthesis or degradation. Budding yeast *Saccharomyces cerevisiae*, fission yeast *Schizosaccharomyces pombe*, and an unconventional yeast *Yarrowia lipolytica* are the species that have been widely studied among yeast. Actinomycete is one of the few oleaginous groups in bacteria that are suitable for volume production of biofuel. Common oleaginous actinomycetes include *Mycobacterium*, *Nocardia*, *Rhodococcus*, and *Streptomyces*.[13]

TAG BIOSYNTHESIS

Triglyceride (TAG, triacylglycerol, or triacylglyceride) consists of glycerol and fatty acids. In TAG formation, the upstream part that mainly focuses on generating acyl-CoA is the fatty acid synthesis approach, and the downstream is the G3P pathway.

In fact, the processes of TAG synthesis in higher plants and microalgae are very similar. Glyceraldehyde-3-phosphate (GAP) is catalyzed by glyceraldehyde-3-phosphate dehydrogenase (GAPDH, EC 1.2.1.12) to form 1,3-diphosphoglycerate; GAPDH is a highly conserved enzyme across the phylogenetic scale but also plays a multifunctional role in critical cell activities, and it uses NADH or NADPH or both as its cofactors.[14] Finally, through the remaining steps in the glycolytic pathway, pyruvate is formed. Afterward, with the help of the citrate−pyruvate cycle, citrate (an intermediate product of TCA cycle) eventually splits into oxaloacetic acid (OOA) and acetyl-CoA. The next step is the formation of malonyl-CoA, catalyzed by acetyl-CoA carboxylic enzyme (ACC, EC 6.4.1.2), whose substrate is acetyl-CoA. Then, malonyl-CoA:ACP transacylase (MAT) catalyzes the newly produced malonyl-CoA to form malonyl-acyl-carrier protein (malonyl-ACP); the malonyl part will participate in the elongation of long chain fatty acids with the help of β-ketoacyl-ACP synthase (KAS, EC 2.3.1.41), and, after several times of C2 (malonyl) addition, long chain fatty acids are formed. This is the simplified description about the process of fatty acid synthesis.

The TAG synthesis approach mainly takes place in endoplasmic reticulum (ER). As can be seen in Figure 1, in this approach, acyl-CoAs are sequentially added onto the sn-1, sn-2, and sn-3 positions of a G3P molecule. G3P is derived from dihydroxyacetone phosphate (DHAP), and this dehydrogenation reaction is catalyzed by glycerol-3-phosphate dehydrogenase (G3PDH, EC 1.1.1.8), a key enzyme in the pathway of glycerol synthesis,[15,16] which is encoded by *GPD1* and necessary for the process of growth under osmotic stress in *Saccharomyces cerevisiae*.[17] In *Dunaliella*, long-term osmotic response (starts under the osmotic stress within 12−24 h) is involved in related gene expression and protein generation,[18,19] indicating that *GPD1* expression and G3DPH accumulation may be influence by long-term response.

The enzyme catalyzing the first acylation step is acyl-CoA:glycerol-*sn*-3-phosphate acyltransferase (GPAT, EC

2.3.1.15); it consumes an acyl-CoA and a G3P molecule to form lysophosphatidate (LPA). Once LPA has formed, lysophosphatidate acyltransferase (LPAT, EC 2.3.1.51) expends another acyl-CoA to form phosphatidate (PA). Then, phosphatidic acid phosphatase (PAP) releases the phosphate from PA to produce diacylglycerol (DAG), the immediate precursor of TAG. Finally, diacylglycerol acyltransferase (DGAT), an important determinant in the accumulation of TAGs, employs a third acyl-CoA as acyl donor, and utilizes DAG to form TAG. It is generally accepted that DAGs, zymolyte of the last step of the G3P pathway, are produced by endoplasmic reticulum (ER)-specific acyltransferases, but a recent study has suggested that the *Chlamydomonas reinhardtii*, a unicellular microalga, employs diacylglycerol (DAG) only from the chloroplast for the accumulation of TAGs.[20]

G3P PATHWAY

Reports about genetic engineering aimed at GPAT, LPAT, PAP, DGAT, or multiple gene transformation are quite few, but in terms of contemporary research, most of them are involved in plants (oil seeds). However, as stated above, oleaginous microorganisms have shown their huge advantages (compared to oil seeds) such as less necessity for a good environment (wasted water), short life cycle, high percentage of oil, and convenience for scaling up. Obviously, oleaginous microorganisms have a promising future for biodiesel production. Hence, it makes sense to introduce recent research about enzymes in the G3P pathway in an oleaginous microbial cell.

G3P produced by the glycolytic pathway is the origin and source of the G3P pathway. LPA is mainly derived from its precursor G3P via acylation reaction with the help of GPAT. However, in yeast, the DHAP pathway can generate LPA as well. Then LPA is engaged to the synthesis of PA, a crucial crossroad in lipid metabolism; this step is catalyzed by LPAT and needs acyl-CoA provided by the FA synthesis pathway to cooperate with this acyltransferase. Among the three acyltransferase in the TAG synthesis approach, LPAT was the first one to be cloned from plants (in *Limnanthes douglasii* and *Cocos nucifera*, both 1995).[21,22]

The PA substrate pool is utilized by two competing pathways (Figure 1) in addition to the G3P pathway, and the metabolic flux of PA into these three pathways has a huge influence on TAG biosynthesis. One is the CDP-DAG pathway, an important phospholipid biosynthesis approach based on glycerophosphate and involved in regulating the nuclear membrane biogenesis;[23] the other is the Kennedy pathway for the de novo biosynthesis of phosphatidylethanolamine (PE) and phosphatidylcholine (PC).[24]

Compared to PAP and DGAT, GPAT and LPAT are not good candidates for metabolic engineering. Comparatively less work has been done on the role of GPATs and LPATs in lipid biosynthesis. This review focuses on PAP and DGAT, two key rate-limiting enzymes in the G3P pathway, to introduce the progresses of their genetic and metabolic engineering for TAG accumulation in oleaginous microorganisms.

PAP in Microorganisms. Phosphatidate (PA) is an intermediate product of the G3P pathway; it is employed by phosphatidic acid phosphatase (PAP) to form DAG and P_i. In essence, the process is a step of dephosphorylation. The function studies of PAP in the accumulation of TAGs are mainly involved in yeast and bacteria. It has been proved that PAP plays a major role in lipid metabolism regulation.[13,25]

Yeast Pah1p. *PAH1* (alias: *SMP2*[26,27]) gene (Table 2), first named by Gil-Soo Han et al.,[28] encoded Pah1p in yeast *Saccharomyces cerevisiae*. *PAH1*-encoded Mg^{2+}-dependent phosphatidate phosphatase (PAP1, Pah1p, specific for PA), containing the DXDX (T/V) catalytic motif in the haloacid dehalogenase (HAD)-like structural domain, is an enzyme

DOI: 10.1021/jf505975k
J. Agric. Food Chem. 2015, 63, 3067−3077

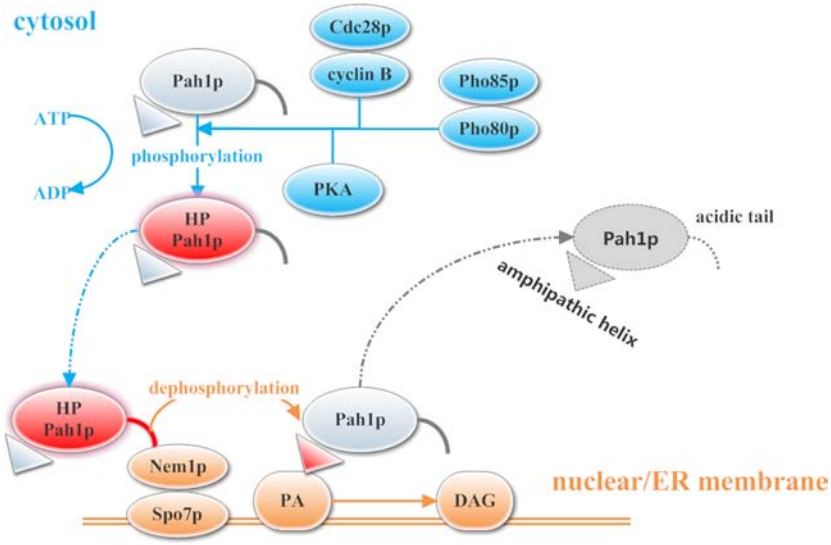

Figure 2. Action mechanism of DAG formation catalyzed by Pah1p.[30] Red represents one of the key components of the Pah1p (amphipathic helix or acidic tail) that is functioning in a specific time. Pho85p-Pho80p,[28] Cdc28p-cyclin B,[29] and protein kinase A (PKA)[27] are involved in the phosphorylation process of Pah1p in cytosol. Then highly phosphorylated Pah1p experiences a series of dephosphorylation by Nem1p-Spo7p in the surface nuclear/ER membrane surface, and a C-terminal acidic tail contributes to the combination of Pah1p and Nem1p-Spo7p.[31,34] Subsequently, Pah1p tethered onto the nuclear/endoplasmic reticulum (ER) membrane and touched PA with the help of a functional amino-terminal amphipathic helix.[35] HP Pah1p: highly phosphorylated Pah1p. For more details, see text.

located in cytoplasm and ER, and its enzyme cofactor is Mg^{2+} ions.[28,29] Within the catalytic motif of DXDX (T/V), there are some conserved Asp residues (398−402) that are found to be essential for the catalytic function of Pah1p. Mutational analysis revealed that the activity of the D398E and D400E mutant enzyme is less than 0.1% compared to wild-type enzyme.[25]

Pah1p serves as a substrate of several protein kinases in phosphorylation reaction; it is an ATP-consuming process.[30,31] Three protein kinases are involved in the process: Pho85p-Pho80p,[32] Cdc28p-cyclin B,[33] and protein kinase A (PKA),[31] and have respectively seven (Ser-110, Ser-114, Ser-168, Ser-602, Thr-723, Ser-744, Ser-748), three (Ser-602, Thr-723, Ser-744), and five (Ser-10, Ser-677, Ser-773, Ser-774, Ser-788) target phosphorylation sites. As shown in Figure 2, highly phosphorylated Pah1p then undergoes multisite dephosphorylation in the nuclear/ER membrane. Nem1p-Spo7p transmembrane phosphatase complex, encoded by *NEM1* and *SPO7* and localized to the nuclear/ER membrane,[32,34] is essential for the dephosphorylation of Smp2p, namely, Pah1p,[27,35] and thus regulates ER membrane flow and nuclear growth.[27,34] A C-terminal acidic tail of the yeast Pah1p has been confirmed to mediate the interaction between Nem1p-Spo7p protein phosphatase complex and Pah1p, and thus affect the membrane recruitment and the expression of *INO1* gene that encodes inositol-1-phosphate synthase (EC 5.5.1.4), which catalyzes glucose-6-phosphate to inositol-1-phosphate and was first purified by Donahue and Henry from *S. cerevisiae*.[36−38] Subsequently, Pah1p tethers onto the nuclear/endoplasmic reticulum (ER) membrane by a functional amino-terminal amphipathic helix, which has been shown to be responsible for the recruitment of dephosphorylated Pah1p and plays an indispensable role in both TAG assembly and phospholipid biosynthesis.[39]

It is suggested that Pah1p is the veritable enzyme that is involved in the process of de novo lipid synthesis in *S. cerevisiae*. App1p, Dpp1p, and Lpp1p (for more details, see Other PAP Enzymes in Yeast and Bacteria) actually have no impact on de novo TAG assembly in ER (Table 1).[28] Inositol is one of the important factors in mediating phospholipid synthesis. It could combine with the phosphatidyl moiety of CDP-DAG to form phosphatidylinositol (PI), as well as affect transcription regulation of the genes in phospholipid biosynthesis.[35] *PAH1* expression is induced throughout its growth cycle, and can be stimulated by inositol supplementation in the stationary phase.

Other PAP Enzymes in Yeast and Bacteria. Three other enzymes (App1p, Dpp1p, Lpp1p, see Table 2) exhibit PAP activity in yeast as well, but the characteristics and function of each are not all the same (Table 1).[29,40] App1p is a cytosolic enzyme that has been well studied by Chae et al.;[29,40] it is a Mg^{2+}-dependent phosphatidate phosphatase. Lysophosphatidate (LPA) and DAG pyrophosphate (DGPP) can also be dephosphorylated by App1p apart from PA. Unlike the sole status of Mg^{2+} in Pah1p, Mn^{2+} can partly substitute the role of Mg^{2+} in App1p. Its PAP activity can be influenced by the DXDXT motif to a large extent, but this conserved domain has low-level similarity to the haloacid dehalogenase (HAD)-like domain.[29,40] A ten times increase in PAP activity has been found in the *pah1*Δ*dpp1*Δ*lpp1*Δ triple mutant by overexpression *APP1* gene.[29] Of the 20 mutants deleting genes that encode potential enzymes involved in the phospholipid formation process, only *app1*Δ manifests a 30% reduction of PAP activity compared to the wild strain of yeast *S. cerevisiae*.[29] A 34-fold disparity of turnover number (k_{cat} = 406 $s^{-1}$for App1p and k_{cat} = 12 s^{-1} for Pah1p) in PAP activity between App1p and Pah1p may explain why App1p exhibits high PAP activity despite its being a low abundant protein in yeast.[28,40]

DPP1 and *LPP1* are the genes that encode diacylglycerol pyrophosphate phosphatase and lipid phosphate phosphatase, respectively. In *S. cerevisiae*, studies about *DPP1* were earlier than *LPP1*, and *DPP1* was first characterized by Wu et al.,[41] whereas *LPP1* was first named, isolated, and characterized by Toke et al.[42,43]

Dpp1p and Lpp1p were identified by Faulkner et al.,[44] and they have some common attributes. For instance, they are

DOI: 10.1021/jf505975k
J. Agric. Food Chem. 2015, 63, 3067−3077

Mg^{2+}-independent enzymes containing six transmembrane regions, their PAP activities are subject to a three-domain catalytic motif (KX_6RP, PSGH, and SRX_5HX_3D), and their substrates are the same.[25,42,43] They also catalyze the dephosphorylation of sphingoid base phosphate and isoprenoid phosphate.[28,29,40] However, positions of the two enzymes are different: Dpp1p is located in the vacuole, and Lpp1p is in Golgi. Studies have shown that, in yeast, *dpp1*Δ *lpp1*Δ mutations exhibit no obvious influence on TAG formation in ER, and App1p also is not involved in de novo lipid synthesis. However, Pah1p indeed participates or even plays a key role in the synthesis of TAG in ER.[28,40,45]

In eukaryotes, genes encoding for the Mg^{2+}-dependent phosphatidate phosphatase are highly conserved, whereas in bacteria, there are no homologues for PAP-encoded genes.[13] In *Streptomyces coelicolor*, *LPPα* and *LPPβ* (Table 2) are decisive PAP enzymes for TAG biosynthesis; they belong to the PAP2 (Mg^{2+}-independent enzymes) family.[13] Overexpression of *LPPα* and *LPPβ* resulted in a rise of cellular TAG (15.7% and 29.9%, respectively). Heterogeneous expression of PAPs derived from *S. coelicolor* in *Escherichia coli* or yeast also aroused a severalfold increase of cellular DAG level.[13]

Summary of PAPs from Horizontal Perspective. The dephosphorylation reaction catalyzed by PAP exists widely in plants and microorganisms. We have listed different enzymes above that exhibit PAP activity; now it will be safe to conclude that in terms of TAG formation, although App1p (or Lpp1p and Dpp1p) and Pah1p have similarity in cofactor, substrate, and catalytic motif, Pah1p is the only one that is involved in de novo synthesis of TAG. But in some bacteria such as *S. coelicolor*, lipid phosphate phosphatase indeed controls the dephosphorylation reaction for DAG formation. The mechanism of DAG formation (Figure 2) may become a new field of improving the efficiency of Pah1p; perhaps further effort should be spent on enhancing the function of highly phosphorylated Pah1p, the functional amino-terminal amphipathic helix, and the C-terminal acidic tail or other keypoints in this complicated process.

Dgk1p: The Counter Reaction Enzyme of DAG Formation. PA is a key regulator of lipid synthesis because it is the intersection of the G3P pathway (for TAG formation), the CDP-DAG pathway (for PS, PE, and PC formation), and the Kennedy pathway (for PC and PE formation). Besides LPAT and phospholipase, diacylglycerol kinase (Dgk1p, EC 2.7.1.107 Table 2), an ER-associated enzyme, also takes part in the mobilization of TAG for membrane phospholipid biosynthesis.[46] In plants, animals, and bacteria, Dgk1p uses ATP as phosphate donor, whereas in yeast, CTP substitutes the place of ATP and forms PA and CDP.[47] Dgk1p catalyzes the reverse reaction of DAG synthesis from PA; it is a crucial step that is necessary for phospholipid synthesis and membrane expansion in yeast.[48] The *DGK1*-encoded CTP-dependent diacylglycerol kinase in budding yeast *Saccharomyces cerevisiae* was characterized by Han et al. for the first time.[47,49] Point mutations of four conserved residues in the CTP transferase domain, a crucial portion in Dgk1p in that it is the actual performer to incorporate CTP when it comes to reactivity, resulted in an inactivation of diacylglycerol kinase activity.[47] In addition, a *dgk1*Δ strain (*DGK1*(D177A)) also lost its Dgk1p activity after undergoing alanine mutation on one of the residues in the CTP transferase domain.[49] Therefore, the CTP transferase domain maybe a good candidate for regulating TAG biosynthesis and membrane expansion. Furthermore, CDP-DAG has been proved to have inhibitory activity for CTP-dependent DAG kinase activity, and this CDP-DAG-caused inhibition is considered to contribute to the accumulation of DAG and TAG.[47] Qiu revealed that the Reb1p-binding site mutations could weaken the conversion from TAG to phospholipids, indicating that the newly discovered transcription factor Reb1p has a certain influence on *DGK1* expression and Dgk1p activity.[46]

Researchers also have revealed that Dgk1p and Pah1p counteract each other to a great degree, which is the reason that DAG and PA are kept balanced, and thus influences the level of TAG and phospholipid. Based on the analysis, we can conclude that yeast *DGK1* expression and DAG kinase activity affect membrane growth, lipid droplet formation, and cellular growth.[46]

DGAT and Other TAG Synthetase in Microorganisms. DGAT is the rate-limiting enzyme that catalyzes the last step of the G3P pathway.[50] At least four classes of DGAT have been identified in plants and microorganisms: they are DGAT1, DGAT2, DGAT3, and wax ester synthase/acyl-CoA:diacylglycerol acyltransferase (WS/DGAT, EC 2.3.1.75). It is worth mentioning that another important TAG synthetase, named phosphatidylcholine:diacylglycerol acyltransferase (PDAT, EC 2.3.1.158), is also responsible for the biosynthesis of TAG. Although these enzymes catalyze the same reaction, they belong to different gene families and have different functions.

DGAT1 and DGAT2. DGAT1 is similar to the acyl-CoA:cholesterol acyltransferase (ACAT, EC 2.3.1.26) family in gene sequence. Both ACAT and DGAT1 are subject to the membrane-bound *O*-acyltransferase (MBOAT) protein superfamily, which contains six or more transmembrane domains, including KSR block, PTR block, QP block, LWLFFEFDRFYWWNWWNPPFSHP block, LQL block, and NGQPY block.[51−54] A mouse DGAT1 gene was cloned by Cases and Zheng for the first time.[55] Soon after, DGAT1 gene was cloned from the model organism *Arabidopsis thaliana*.[56] DGAT2 belongs to the monoacylglycerol transferase (MGAT, EC 2.3.1.22) family (Table 2); it was first found in the oleaginous fungus *Mortierella ramanniana*.[57] Then the acyltransferase was cloned and characterized in other organisms like mouse and yeast.[58,59] There are six conserved motifs in DGAT2: PH block, PR block, GGE block, RGFA block, VPFG block, and G block.[51]

The DGAT1 and DGAT2 gene family consists of members of microorganisms, plants, and animals. They catalyze the same enzymatic reaction, and have similar relatively conserved residues that contribute to TAG synthesis.[51] Both DGAT1 and DGAT2 are ER membrane-bound proteins. However, the two enzymes are situated in different and specific domains of ER. The identity between type 1 and type 2 DGAT gene sequences is low, and they also have substrate discrimination.[60,61] It is suggested that the two types of DGATs play different roles in oleaginous plants or microorganisms in spite of their convergent evolution; discrepant biochemical characteristics may responsible for the divergence of the two types of DGATs.[1]

One or two decades ago, studies on *Arabidopsis thaliana* had shown that DGAT1 plays an extremely important role in TAG biosynthesis via mutation experiment.[62,63] DGAT1 mutants exhibited a 20−40% decrease on oil content in *Arabidopsis* seed.[64] DGAT2 plays a dominant role in TAG accumulation in *Ricinus communis* or yeast.[65−67] In developing castor bean seeds, DGAT2 showed much higher level than that in leaves, whereas

DGAT1 is indifferent to this organ diversity, and the same situation happened in tung tree.[61,65] Sequence analysis of deduced amino acids of DGAT2 has shown that *Mortierella ramanniana*, a fungus, has close homology to DGAT2 in plants or animals.[65] When only expressing DGAT2 encoded by *DGA1* (Table 2) in yeast (open reading frame YOR245c), TAG level in the mutant type reached 87% of the wild type.[66] It is demonstrated that none of the two types of enzymes is redundant in tung tree in that they have no overlap regions in ER. However, DGAT2 often participates in the synthesis of trieleostearin, a kind of unusual fatty acid which is the major ingredient of tung oil.[61] Other studies also support the conclusion that DGAT2 is preferential to take part in the synthesis of unusual fatty acids (UFA).[65,67,68] DGAT2 is in favor of 18:1-OH DAG (DAG which contains hydroxy fatty acids) compared to 18:1- or 18:2-DAG in castor bean or in yeast, and thus improves the content of hydroxy fatty acids (belongs to UFA).[67]

Compared to DGAT1, DGAT2 and PDAT are more likely to assemble epoxy and hydroxy fatty acids onto the sn-3 position in TAG formation.[68] In yeast, the *ARE1* and *ARE2*-encoded acyltransferases (Table 2), which are mainly responsible for sterol biosynthesis (thus contribute to storage lipid synthesis), also exhibit feeble DGAT activity, and influence TAG accumulation to a slight degree.[69] Coexpression of DGAT and *LPPα* or *LPPβ* derived from *Streptomyces coelicolor* in *E. coli* gains the ability to create an entire pathway for de novo TAG biosynthesis.[13]

PDAT. PDAT is an acyltransferase catalyzing the last step in the G3P pathway. It is acyl-CoA-independent, and its activity has been found in both yeast and plant microsomes.[70,71] In the wild type and the mutants of *Streptomyces coelicolor*, PDAT activity has also been reported.[72] As shown in Figure 3, PDAT employs phospholipids as acyl-donor, whereas DGAT utilizes acyl-CoA (Figure 3). PDAT is thought to be related to the accumulation of unusual fatty acids, including hydroxylated fatty acid and epoxidated fatty acid.[50,70] In eukaryotic cells, PDAT influences the ingredients of cell membrane lipid.[73]

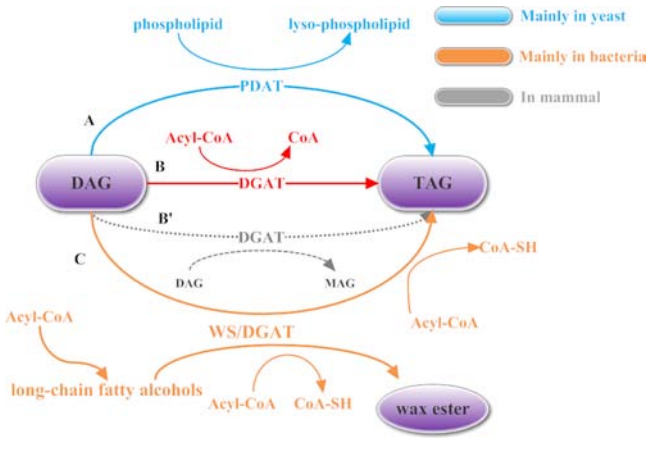

Figure 3. DGATs that are involved in the last step of TAG assembly. (A) PDAT uses phospholipid as acyl-donor to form TAG, meanwhile, PDAT is the only acyl-CoA-independent DGAT enzyme. (B) DGAT employs acyl-CoA as acyl-donor for the accumulation of TAG, and that is the most common way in this acylation reaction. (B′) To our knowledge, it is a special way that only exists in mammals. (C) Bifunctional WS/DGAT consumes acyl-CoA to synthesis wax ester (WE) and TAGs simultaneously.

LRO1, a gene encoding PDAT in yeast,[74] is suggested to incorporate with *DAG1* (encode DGAT2) for the last acylation reaction step in the G3P pathway (Table 2). However, the ways that Lro1p and Dga1p perform their functions are different. The fatty acid that previously belonged to the sn-2 position of PE or PC is utilized by *LRO1* to form TAG, whereas Dga1p uses the fatty acid derived from acyl-CoA.[75] A mutant of *S. cerevisiae* which only induces *LRO1* has nearly 40% of the wild type TAG level, indicating that *LRO1*-encoded PDAT plays the non-negligible role in TAG accumulation.[66] When the carbon source for the oleaginous yeast *Yarrowia lipolytica* is oleic acid, TAG synthesis is much faster in the *DGA1*-defective mutants than in wild type or lro1Δ mutant. Further experiment indicated that two other triacylglycerol synthases (except Dga1p and Lro1p) existing in *Y. lipolytica* play a major role when oleic acid serves as carbon source.[6]

An in vivo experiment in developing *Arabidopsis* pollen and seed revealed that PDAT and DGAT1 have complementary functions.[64] Obvious change did not take place in over-expressing AtPDAT mutants or in T-DNA insertion mutants of PDAT in *Arabidopsis*,[71,76] and the loss of TAG content in null mutants of DGAT1 is 20 to 40% compared to the wild type;[64] the reason is that PDAT partly makes up for the absence of DGAT1. By and large, the simultaneous absence of DGAT1 and PDAT is fatal, but not fatal for budding yeast (e.g., *S. cerevisiae*) in that lipid storage is not imperative for yeast.[66] However, in the fission yeast *Schizosaccharomyces pombe*, the absence of TAG assembly can cause apoptosis when it comes into the stationary phase.[77]

At least three aspects affect the efficiency of PDAT in TAG formation. First, sn-2 acyl group of PC, acyl groups with more double bonds, or more epoxy and hydroxyl groups have higher PDAT activity.[71] Second, it depends on the growth phase. In exponential growth phase PDAT does better for TAG accumulation compared to the late period of logarithmic phase.[65] Finally, PDATs in different species exhibit different activity, although several former examples have demonstrated that the function of PDAT cannot be ignored; some studies in oil palm or olive calli revealed that PDAT may be not that important.[65,71,76,78]

WS/DGAT. WS/DGAT is a membrane-related bifunctional enzyme catalyzing the last acyl transfer reaction of the G3P pathway. In the process, wax ester (WE) and TAGs, both of which are crucial storage lipids and biodiesel in some prokaryotes, are incorporated synchronously (Figure 3).[79] The broad range substrates of WS/DGAT are long-chain fatty alcohols and fatty acid CoA thioesters including linear and cyclic alkyl alcohols, mono- and diacylglycerols, and sterols,[80−82] which indicated that WS/DGAT has a boundless potential in producing fatty acid ethyl esters (FAEEs), fatty acid isoamyl esters, fatty alcohols, and waxes via its prokaryotic or even eukaryotic expression hosts.[83] The *ATFA*-encoded WS/DGAT (Table 2) was found in *Acinetobacter calcoaceticu* (a Gram-negative bacterium) strain ADP1 for the first time, and its function in mediating WE and TAG (to a smaller extent) formation was proved by an experiment on the *ATFA*-knockout mutant which showed an obvious reduction of storage lipids.[81,84] Nearly every member in bacterial WS/DGATs has a highly conserved motif: HHXXXDG motif, which may be responsible for the combination with fatty acyl-CoA or play a catalytic activity role in the acylation reaction.[82]

As mentioned above, in budding yeast *S. cerevisiae*, four genes are responsible for the synthesis of storage lipids: *DGA1*, *LRO1*,

DOI: 10.1021/jf505975k
J. Agric. Food Chem. 2015, 63, 3067−3077

ARE1, and *ARE2*. Heterologous expression of WS/DGAT from *A. calcoaceticus* ADP1 in the quadruple mutant (*DGA1*, *LRO1*, *ARE1*, and *ARE2*) strain *S. cerevisiae* H1246, which is defective in TAG synthesis and steryl ester accumulation, exhibited a restoration of TAG assembly and also produced FAEEs (an advanced biodiesel feedstock)[85] as well as fatty acid isoamyl esters.[81] Through coexpression of the WS/DGAT gene from *Acinetobacter baylyi* strain ADP1with ethanol production genes from *Zymomonas mobilis* in recombinant *E. coli* and fed-batch fermentation, the consistency of FAEE has reached 1.28 g/L.[79] In the engineered *E. coli*, expression of several genes including the gene encoding wax-ester synthase led to a decent production of nearly 400 mg/L of FAEEs in 2 days from the economic raw material glucose.[86] A recently discovered WS2 derived from *Marinobacter hydrocarbonoclasticus* has proved to have greater wax synthase activity for ethanol but does not exhibit DGAT activity.[83] A novel DGAT-like protein which has high similarity with the *Acinetobacter calcoaceticus* WS/DGAT has been cloned by Cui et al. from the diatom *Phaeodactylum tricornutum*.[87] Heterologous expression in strain *S. cerevisiae* H1246, ptDGAT3 exhibited its preference to incorporate C_{18} fatty acids into TAGs.

DGAT3. In peanut, castor bean, and *Arabidopsis thaliana*, another DAG acyltransferase named DGAT3 has been found and soon became a hot research point.[88−90] The third type of DGAT is a cytosolic enzyme without membrane-bound regions. Unlike the conventional DGATs, DGAT3 is a soluble enzyme. It shares more similarity with WS/DGAT (13%) compared to DGAT1 or DGAT2 (10%).[88] Expression of the peanut (*Arachis hypogaea*) *ahDGAT* gene in *E. coli* led to the biosynthesis of TAG.[88] In a recent study, three DGAT genes were identified and isolated from peanut (*Arachis hypogaea*), and their activity was proved by heterologous expression in the quadruple mutant (*DGA1*, *LRO1*, *ARE1*, and *ARE2*) strain *S. cerevisiae* H1246.[91]

In *Arabidopsis thaliana*, the soluble DGAT3 plays an important role in a putative cytosolic pathway for TAG synthsis. In various developmental stages, the *Arabidopsis thaliana* DGAT3, which is encoded by *At1g48300*, always maintains a high expression level. This fact suggests that ahDGAT3 has a management function in mediating the metabolic flux between the cytosolic acyl-CoA pool and TAG.[92] The ahDGAT3 shows a preference for 18:3 and 18:2 (to a lesser degree) other than 20:1 acyl-CoA, while a larger percentage of acyl-CoA pool is 20:1 acyl-CoA.[92] *DCR* (*At5g23940*), the gene in *Arabidopsis thaliana* that encodes a soluble DAG acyltransferase, has a typical HX_4D motif (N-terminal) and the VX_2GF motif binding to the lipid body.[90] Overexpression of *At5g23940* in *S. cerevisiae* H1246 led to the formation of TAG.[90]

Summary of TAG Synthetases from Horizontal Perspective. Although these TAG synthetases catalyze the same acylation reaction, they have different characteristics. DGAT1 widely exists in plants and microorganisms. In various developmental stages or in different organs, DGAT1 always maintains a relatively high expression level, whereas DGAT2, PDAT, and DGAT3 may be more sensitive. In addition, DGAT2 and PDAT preferentially participate in the synthesis of UFA. To be more specific, DGAT2 and PDAT are more likely to incorporate epoxy and hydroxy fatty acids to the sn-3 position. WS/DGAT is the only bifunctional enzyme in these TAG synthetases, found only in microorganisms. In yeast, the *ARE1* and *ARE2*-encoded acyltransferases which exhibit feeble DGAT activity can play an auxiliary role of DGAT and PDAT for the conversion from DAG to TAG.

The CDP-DAG Pathway and the Kennedy Pathway for Phospholipids. The conversion from PA to CDP-DAG is catalyzed by CDP-DAG synthase (EC 2.7.7.41), which is encoded by *CDS1* and utilizes PA as its phospholipid substrate.[23,47,93] Once formed, CDP-DAG divides into three ways, one for PI formation, one for phosphatidylglycerol (PG) and cardiolipin (CL) formation, and the last one being the CDP-DAG pathway for phosphatidylserine (PS), PE, and PC formation (Figure 1.). The CDP-DAG pathway is required in many microorganisms including bacteria, yeast, and microalgae because of its pivotal role in generating phospholipids and interactive function with DAG synthesis. In microalgae, PI and PG can only be derived from the CDP-DAG pathway, whereas both the CDP-DAG pathway and the Kennedy pathway can generate PE and PC.[94]

The CDP-DAG pathway and the TAG synthesis pathway are in metabolic interlock (MI) with each other.[95] More specifically, PA will convert to DAG if excess accumulation of CDP-DAG occurs; the reverse is also true.[95]

The Kennedy pathway is another important metabolic process for PE and PC formation. It shares with the G3P pathway the same way from G3P to DAG, and the two pathways then start to go their separate ways (Figure 1). Obviously, the diversion of DAG inevitably leads to a decrease in TAG concentration. However, like the MI effect between the CDP-DAG pathway and the TAG synthesis approach, there is an intercommunication between the Kennedy pathway and the TAG synthesis approach as well. To be specific, once DAG level is sufficient, the two branches (CDP-choline branch and CDP-ethanolamine branch) then have a chance of synthesizing PE and PC, and the two phospholipids can in turn be catalyzed by phospholipase for the accumulation of PA, choline, and ethanolamine (Figure 1).

In conclusion, the free fatty acid synthesis approach plays a significant role in de novo synthesis of TAG. This approach persistently provides acyl-CoA for the G3P pathway, the latter part of TAG biosynthesis. Of the four enzymes (GPAT, LPAT, PAP, and DGAT) that are involved in the G3P pathway, PAP and DGAT largely affect the accumulation of TAG or other lipids like FAEE and WE. Via genetic engineering and metabolic engineering, the operating force of PAPs and DGATs in ultimate production of TAG has been amplified dramatically.

PA is a crucial intermediate product in the G3P pathway and the CDP-DAG pathway. Naturally, we can promote the TAG synthesis approach and repress the CDP-DAG pathway by regulating genes that encoded diacylglycerol kinase, PAP and CDP-DAG synthase, or even overexpression of more genes (multigene approach). In addition, the degradation of phospholipids is beneficial to the accumulation of PA as well, thus forming more TAGs by the rational use of the metabolic interlock between the CDP-DAG pathway and the TAG synthesis pathway. DAG is another critical point; by mediating diacylglycerol kinase, DGAT, and enzymes involved in the Kennedy pathway, we can also enhance the G3P pathway.

PAP is well studied in yeast. For the aim of improving TAG yield, *PAH1* seems to be the most suitable PAP gene in yeast to be modified. In bacteria, *LPPα* and *LPPβ* may enjoy similar status like *PAH1* in yeast. In bacteria and yeast, the ER-associated diacylglycerol kinase influences the level of PA and

DOI: 10.1021/jf505975k
J. Agric. Food Chem. 2015, 63, 3067−3077

DAG to a large extent, indicating that inhibition of this enzyme may benefit TAG accumulation in bacteria or yeast.

Among the four classes of DGAT, WS/DGAT becomes a new concern. The reason is that, except for TAGs, WS/DGAT can generate another important biodiesel feedstock: FAEEs. Hence, bacteria that contain WS/DGAT will be a hot area of biodiesel production research.

To summarize, PA and DAG are the central hubs of the three pathways in lipid metabolism, therefore, the enzymes that can regulate PAP and DAG (PAP, DGAT, diacylglycerol kinase, CDP-DAG synthase, and phospholipase) are all suitable candidates for mediating the conversion between TAG and phospholipids, and thus affect TAG concentration.

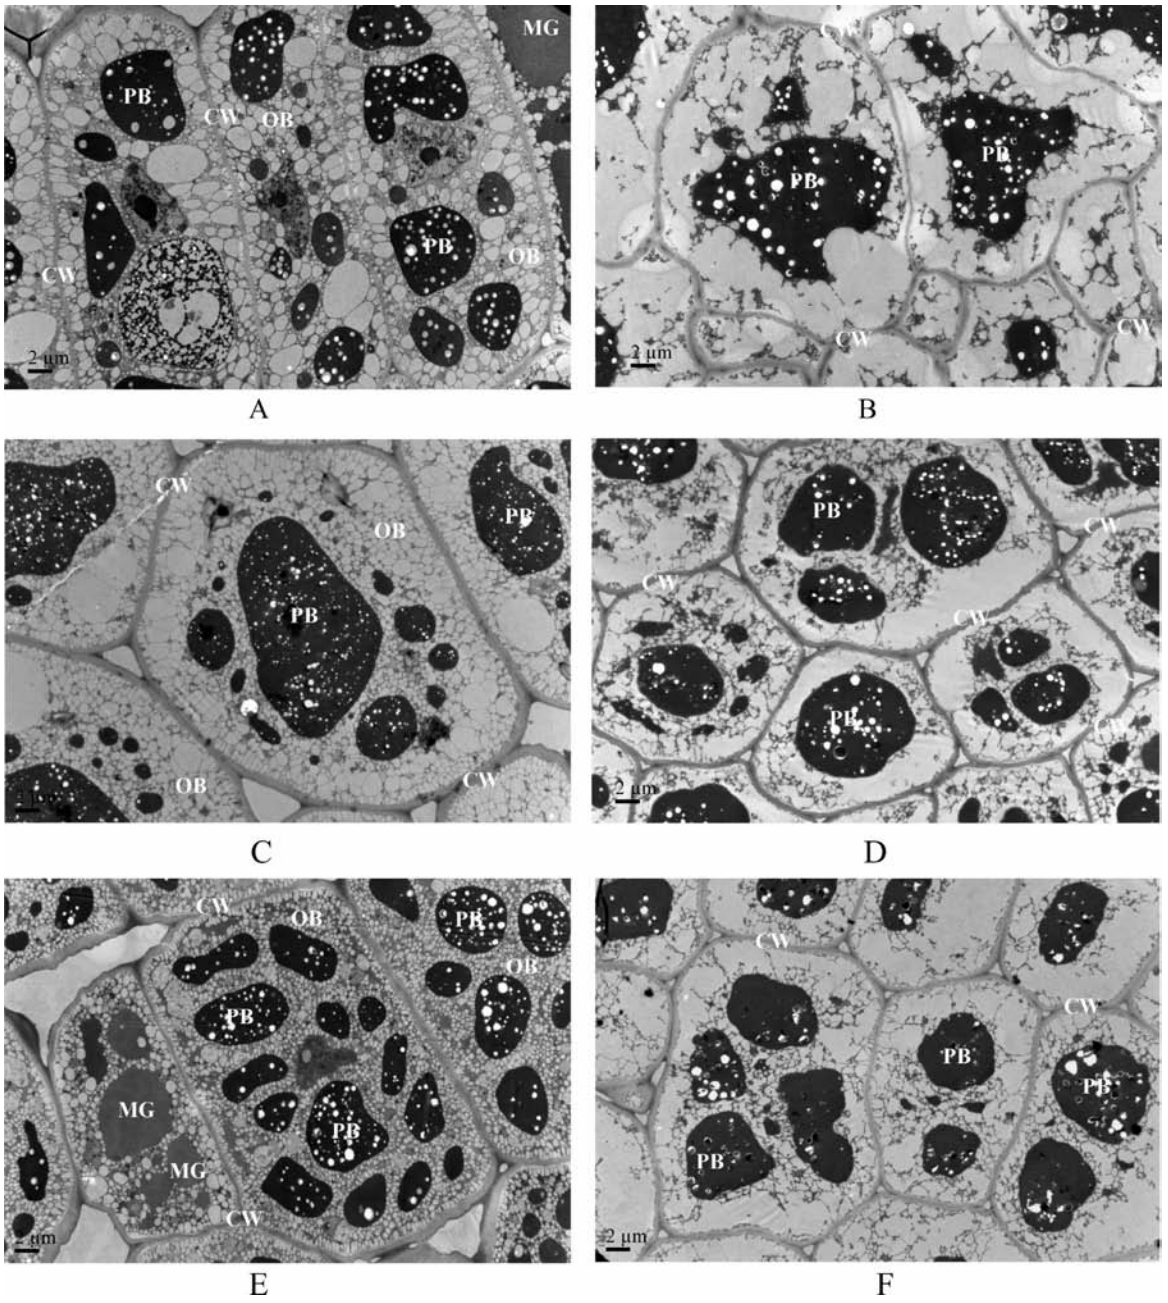

Figure 1. Transmission electron microscopy of two types of *Brassica napus* rapeseed and *Brassica juncea* mustard without or with microwave treatment: (A) *B. napus* rapeseed (intermediate-glucosinolate; as-is); (B) *B. napus* rapeseed (intermediate-glucosinolate) microwaved for 5 min; (C) *B. napus* rapeseed (low-glucosinolate; as-is); (D) *B. napus* rapeseed (low-glucosinolate) microwaved for 5 min; (E) *B. juncea* mustard (high-glucosinolate; as-is); (F) *B. juncea* mustard (high glucosinolate) microwaved for 5 min. CW, cell wall; PB, protein bodies; MG, myrosin cells; OB, oil bodies. Magnification: ×4000.

Crops Research Institute, Chinese Academy of Agricultural Sciences, Hubei Province, People's Republic of China. *Brassica juncea* mustard (high-glucosinolate; ∼130 μmol/g, fat-free basis; moisture content = 11.0%) was provided by the Institute of Economic Crops, Xinjiang Academy of Agricultural Sciences, Xinjiang Province, People's Republic of China. All seeds were produced in 2012.

Sample Preparation and Treatments. The seed samples (400 g each) were subjected to microwave irradiation (MarsX, CEM, Matthews, NC, USA) at a frequency of 2450 MHz at a medium power of 800 W for 1, 2, 3, 4, 5, and 6 min. All microwave-treated samples were allowed to cool to room temperature for 60 min. The samples without or with microwave heating were expeller-pressed using an oil expeller at a feeding rate of 3 kg h^{-1} and barrel temperature of no more than 90 °C (KOMET CA59G, IBG Monforts Oekotec GmbH & Co. KG, Germany).

Microscopy Analysis. The seed samples were fixed with 2.5% glutaraldehyde in phosphate buffer (pH 7.0) for 4 h, washed three times with phosphate buffer, postfixed with 1% of OsO_4 in phosphate buffer (pH 7.0) for 1 h, and washed three times in the phosphate buffer. The samples were then dehydrated in the progressive ethanol solutions of 50, 70, 80, 90, 95, and 100% for about 15−20 min at each solution, embedded in acetone and Spurr resin. Sections 70−90 nm in size were cut from the embedded tissue using a microtome (Ultracut E, Reichert-Jung, Vienna, Austria), double stained with uranyl acetate and lead citrate, and then were examined under a transmission electron microscope (H-7650, Hitachi Instrument, Tokyo, Japan).

DOI: 10.1021/jf504872x
J. Agric. Food Chem. 2015, 63, 3078−3084

Chemical Analyses. The samples were ground and were adjusted to the same moisture content by exposure to room humidity for 7 days at 25 °C.[11] The samples were then defatted with hexane for 6 h and air-dried. Oil content and neutral detergent fiber (NDF) were analyzed according to AOAC (1990) method 920.39 and Van Soest et al.,[12] respectively.

Glucosinolate analysis was performed as described by Slominski and Campbell.[13] Briefly, 100 mg of high-glucosinolate or 300 mg of low-glucosinolate samples was weighed into 15 mL centrifuge tubes. Two milliliters of methanol, 1.0 mL of benzyl glucosinolate (internal standards, 0.5 mM), and 0.1 mL of lead−barium acetate were added to the tubes, extracted for 3 h at room temperature, and then centrifuged. Two milliliters of supernatant was transferred to a DEAE-Sephadex column, which was washed successively with 1 mL each of 67% methanol, water, and pyridine acetate. Purified sulfatase solution was then added to the column, and the contents were incubated at room temperature overnight. The resulting desulfated glucosinolates were eluted with 2 mL of 60% methanol and evaporated under nitrogen. The dry residue was trimethylsilylated by adding 0.2 mL of a mixture of anhydrous acetone/*N*,*O*-bis(trimethylsilyl)acetamide (BSA)/trimethylchlorosilane (TMCS)/1-methylimidazole (2:1:0.1:0.05 v/v) and incubated for 30 min at room temperature. The trimethylsilyl derivatives of desulfoglucosinolates were separated by gas−liquid chromatography using a glass column (1.2 m × 2 mm i.d.) packed with 2% OV-7 on Chromosob W (HP) (100−120 mesh) with helium gas at a flow rate of 40 mL/min. The oven temperature was kept at 200 °C for 4 min and then increased at 5 °C min^{-1} to 275 °C. Injection port and detector temperatures were 280 and 300 °C, respectively.

Myrosinase activity was determined by difference between total sample glucosinolate content and the glucosinolates remaining following incubation of the sample with distilled water (autolysis) at 40 °C for a defined period of time. Glucosinolate analysis was conducted as described above. One unit of myrosinase activity was defined as the amount of enzyme that catalyzes the hydrolysis of 1 μmol of glucosinolate per 1 min.

The analyses of moisture content, oil content, NDF, and glucosinolate content were run in triplicate, wheereas those for myrosinase activity were run in duplicate.

Statistical Analysis. All of the statistical analysis was conducted by the SAS program (version 9.1, SAS Institute Inc., Cary, NC, USA). Means were separated by Tukey's honestly significant difference. All statements of significance were based on $P \leq 0.05$.

RESULTS AND DISCUSSION

Effect of Microwave Treatment on Microstructure of the Seed. The effect of microwave heating (400 g, 800 W) on the microstructure of the seed samples is shown in Figure 1. The microstructure of the intact (unheated) seed revealed well-defined pattern of protein bodies and intact myrosin cells amid oil bodies with smooth cell walls. In high-glucosinolate *B. juncea* (E) and intermediate-glucosinolate *B. napus* (A) myrosin cells were quite visible, whereas there were almost no visible myrosin cells in the seed of low-glucosinolate rapeseed (C). The microstructure of all samples changed significantly after 5 min of microwave heating (see images F, B, and D) with the oil bodies and myrosin cells almost disappearing. The microscopy images clearly demonstrate that microwave treatment disrupts the membranes of oil bodies as well as other intracellular organelles.

Most of the biological membranes of rapeseed are composed of phospholipids and proteins (i.e., oleosins) with the oil bodies covered by a single-layer membrane. Eighty percent of this layer is filled with phospholipids, and the other 20% is occupied by oleosins. Phospholipids constitute a polar headgroup and a nonpolar fatty acid region.[14] It has been reported that the composition of phospholipids in the oil bodies would account for 60% of phosphatidylcholine, 6% of phosphatidylethanolamine, 14% of phosphatidylinositol, and 20% of phosphatidylserine. According to Valentov et al.,[15] microwave treatment could improve the content of phospholipids in the crude oil by more than twice, which would be a consequence of the membrane rupture. A strong relationship between oil bodies' stability and oil extractability has been reported,[16] indicating that the oil from the microwave-treated rapeseed should be easier to extract.

Myrosin cells are the subcellular compartments associated with enzyme myrosinase. Normally, glucosinolates are located in vacuoles and are separated from the myrosin cells.[17] The presence of the glucosinolate−myrosinase system is characteristic of the Brassicaceae family, and it serves as a defense system against biotic and abiotic stressors.[18] Disruption of the tissue induced by mechanical damage, infection, or pest attack brings glucosinolates into contact with myrosinase,[19] resulting in their hydrolysis to biologically active and often toxic breakdown products, including isothiocyanates, goitrin, and nitriles. After microwave treatment, it appeared evident that the structure of myrosin cells was effectively damaged, indicating the potential for myrosinase to come into contact with glucosinolates.

In Figure 1 images A, C, and E, the cells of rapeseed were well coherent, and the shape was smooth, whereas in the microwave-treated samples (i.e., images B, D, and F) the cell walls became folded. This phenomenon may be ascribed to the water loss of the cells, as documented by Niu et al.[20] As illustrated in Figure 2, there was a significant decline in moisture content of *B. napus* rapeseed and *B. juncea* mustard.

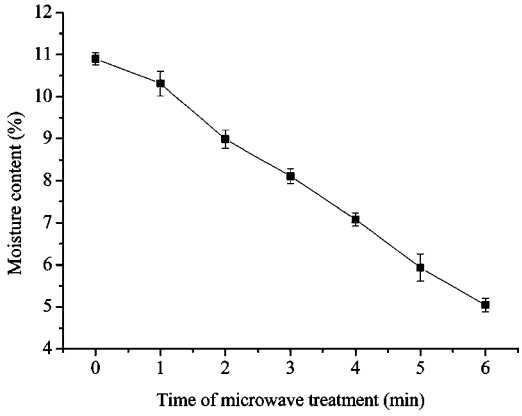

Figure 2. Effect of time of microwave heating on mean moisture content of *B. napus* rapeseed and *B. juncea* mustard.

Effect of Microwave Treatment on Oil Content of Expeller Meal. The effect of time of microwave heating on the oil content of seed and expeller meal of two types of *B. napus* rapeseed and *B. juncea* mustard is shown in Table 1. The oil contents of *B. napus* rapeseed (intermediate- and low-glucosinolate) and *B. juncea* mustard were similar. After expeller-pressing, however, the oil content of expeller meal decreased significantly with increased time of microwave heating. After 6 min of microwave heating, the oil content of intermediate- and low-glucosinolate *B. napus* rapeseed and of *B. juncea* mustard expeller meal decreased from 26.6, 22.6, and 29.8 to 13.5, 11.3, and 14.1%, respectively. Overall, the microwave treatment decreased the oil content of expeller meal by 49−53% with an oil extraction rate of 79−83%.

The oil contents of expeller meals are in agreement with the changes in microstructure of microwave-treated seed showing

the broken membranes of oil bodies, which, in turn, facilitated higher efficacy of oil extraction during expeller-pressing. The oil extraction rate by expeller-pressing after 6 min of microwave heating used in the current study was similar to the conditioning of the seed at 80 °C for 30 min, flaking of the seed, and then expeller-pressing.[21] In another study, similar results were achieved when the seed was subjected to 40 min of heat treatment with the temperature increased to 80 °C and then heat treatment at 80 °C for 30 min followed by 40 min of flaking to 0.3 mm thickness and expeller pressing under a barrel temperature of 105–110 °C.[1] According to Grageola et al.[22] expeller-pressing recovers around 75% of oil from canola seed. This indicates that the microwave treatment could be an effective method of increasing the efficacy of oil extraction by expeller pressing and would facilitate oil extraction down to the industry standards of 8–10% of residual oil. which, in turn, would prevent the need for double pressing.

Effect of Microwave Treatment on NDF Content of Expeller Meal. The effect of time of microwave heating on NDF content of seed and expeller meal is shown in Table 2. The contents of NDF in the seed and expeller meal of two types of *B. napus* rapeseed and *B. juncea* mustard were different, with *B. juncea* showing significantly less fiber than *B. napus*. This is due to the fact that *B. juncea* mustard is yellow-seeded, whereas *B. napus* rapeseed is black-seeded. The yellow seed coat color is a visual marker of lower polyphenol (i.e., proanthocyanidin) content and a thinner seed hull. As a result, black-seeded rapeseed contains more fiber than its yellow-seeded *B. napus* counterparts or *B. juncea* mustard.[23] After microwave heating for 6 min, the NDF contents of all seed samples were similar, so there was no significant effect of heat treatment on fiber content. In the expeller meals, however, the NDF content of intermediate-glucosinolate *B. napus* rapeseed increased from 24.1 to 29.2% after 6 min of microwave heating, whereas in low-glucosinolate *B. napus* rapeseed and *B. juncea* mustard no significant changes were observed. It is well-known that heat treatment of oilseeds during processing may lead to losses of digestible amino acids due to the formation of Maillard reaction products. This highly indigestible fraction, often referred to as a neutral detergent insoluble crude protein

[a]Mean ± SD. Values within rows with the same letter (a–f) are not significantly different ($P \leq 0.05$). [b]Includes gluconapin (3-butenyl), glucobrassicanapin (4-pentenyl), progoitrin (2-hydroxy-3-butenyl), gluconapoleiferin (2-hydroxy-4-pentenyl), glucobrassicin (3-indolylmethyl), and 4-hydroxyglucobrassicin (4-hydroxy-3-indolylmethyl). [c]Includes sinigrin (2-propenyl), gluconapin (3-butenyl), progoitrin (2-hydroxy-3-butenyl), gluconapoleiferin (2-hydroxy-4-pentenyl), and 4-hydroxyglucobrassicin (4-hydroxy-3-indolylmethyl).

(NDICP), would contribute to the increase in the NDF content of heat-treated products and would significantly affect the nutritive value of rapeseed/canola meal.[24] In the current study, expeller pressing of intermediate-glucosinolate *B. napus* rapeseed microwave heated for 6 min resulted in some protein damage as documented by the increase in NDF content which, in turn, could lead to reduced protein and amino acid digestibilities. Therefore, extending the time of microwave treatment could further contribute to protein damage and the increase in NDICP content of expeller meal.

Effect of Microwave Treatment on Myrosinase Activity of the Seed. As illustrated in Table 3, there was a significant decline in myrosinase (thioglucoside glucohydrolase, EC 3.2.3.1) activity with increased time of microwave heating for two types of *B. napus* and *B. juncea* seed. This is in agreement with a study by Verkerk and Dekker,[25] who demonstrated that myrosinase in microwave-treated cabbage almost completely lost its hydrolytic capacity, despite the fact that the stability of myrosinase is strongly dependent on the water content,[26] which was most likely much higher in cabbage than in the seed samples used in the current study (i.e., 10%). When compared with *B. napus* intermediate-glucosinolate rapeseed and *B. juncea* mustard, the myrosinase activity in *B. napus* low-glucosinolate rapeseed was relatively low, although the enzyme per se appeared to be more heat-stable with some activity still being present after 6 min of microwave treatment.

Among other reasons, application of heat treatment in any crushing operation of rapeseed is essential for an effective inactivation of myrosinase enzyme. In the presence of moisture and following rupture of the seed, this enzyme would hydrolyze glucosinolates to unstable aglucones, which would then break down to yield a range of products, including isothiocyanates, goitrin, nitriles, and thiocyanates, that interfere with the function of the thyroid gland and would adversely affect growth performance of monogastric animals.[24] Therefore, it is critical that myrosinase is effectively inactivated by heat treatment prior to seed expelling.

Effect of Microwave Treatment on Glucosinolate Content of Seed and Expeller Meal. The effect of time of microwave heating on total glucosinolate content in seed and expeller meal is shown in Table 4. The total glucosinolate content of *B. napus* seed samples decreased after 4 min of microwave heating. It is of interest to note that in the seed of *B. juncea* mustard the total glucosinolate content did not change during microwave heating. The glucosinolate content of the corresponding expeller meals was much lower and reflected the hydrolysis of glucosinolates by myrosinase during the expelling process. However, their contents increased with increased time of microwave heating and, thus, myrosinase inactivation and then decreased due to excessive time of microwave heating, which coincided with the decrease in glucosinolate content in the seed samples for 5–6 min. More specifically, the glucosinolate content of expeller meal of *B. juncea* mustard and intermediate-glucosinolate *B. napus* rapeseed increased significantly during microwave heating for 4 and 5 min, respectively, and then decreased. Somewhat similar changes, although not significant, were observed for low-glucosinolate *B. napus* rapeseed.

According to their structure, glucosinolates can be divided into aliphatic glucosinolates, including sinigrin, gluconapin, glucobrassicanapin, and progoitrin, and indole glucosinolates, including glucobrassicin and 4-hydroxyglucobrassicin. In different *Brassica* species the compositions of glucosinolates are different. The major glucosinolates of *B. napus* rapeseed are gluconapin, progoitrin, and 4-hydroxyglucobrassicin, whereas sinigrin and gluconapin are the predominant glucosinolates of *B. juncea* mustard.

It is well-known that heat treatment and myrosinase activity are the factors that affect the glucosinolate content during processing.[27] It has also been shown that indole glucosinolates are more susceptible to thermal degradation than aliphatic glucosinolates.[27−30] As a result, the decrease in total glucosinolate content due to microwave heating observed in the current study was more pronounced for two types of *B. napus* rapeseed than for *B. juncea* mustard.

The effect of time of microwave heating on the major glucosinolate contents in the seed and expeller meal samples of two types of *B. napus* rapeseed and *B. juncea* mustard are shown in Figures 3, 4, and 5. When compared to the seed samples, the aliphatic glucosinolates gluconapin and progoitrin contents of the corresponding expeller meal samples of intermediate-glucosinolate *B. napus* rapeseed (Figure 3) increased significantly after 3 min, which was directly related to myrosinase inactivation and thus lack of glucosinolate autolysis. The decrease after 6 min of microwave treatment was a consequence of extended microwave heating. The indole glucosinolate hydroxyglucobrassicin content of expeller meal demonstrated a less clear pattern, probably due to its

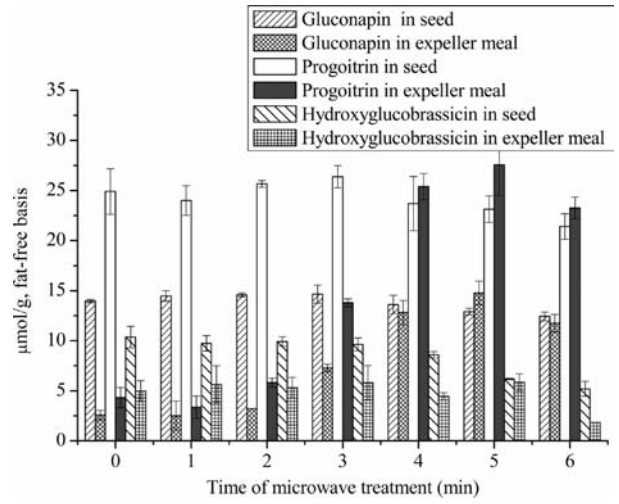

Figure 3. Effect of time of microwave heating on major glucosinolate of *B. napus* intermediate-glucosinolate rapeseed and expeller meal.

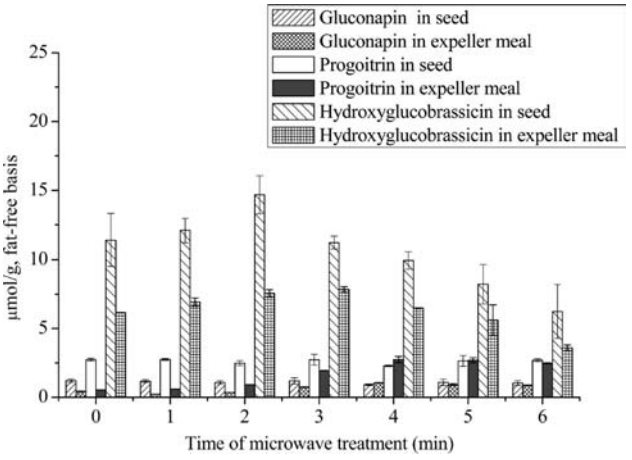

Figure 4. Effect of time of microwave heating on major glucosinolate of *B. napus* low-glucosinolate rapeseed and expeller meal.

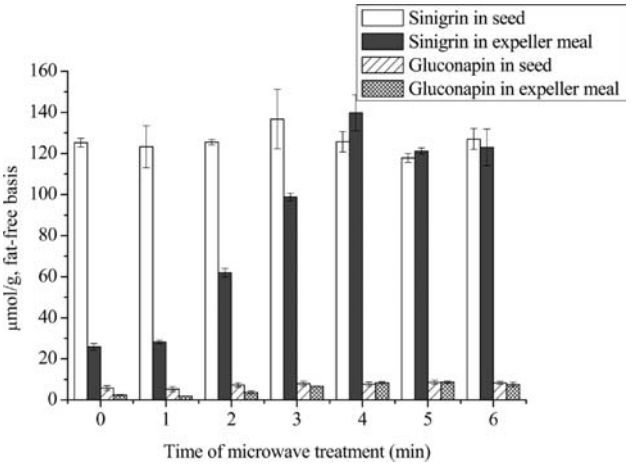

Figure 5. Effect of time of microwave heating on major glucosinolate of *B. juncea* high-glucosinolate mustard seed and expeller meal.

pronounced thermal decomposition in the seed during 5 or 6 min of microwave heating. The glucosinolate content of the seed and expeller meal samples of low-glucosinolate *B. napus* rapeseed (Figure 4) showed a similar pattern with the indole glucosinolate hydroxyglucobrassicin showing a significant thermal decomposition after 4, 5, and 6 min. Overall, the content of hydroxyglucobrassicin in the seed of intermediate- and low-glucosinolate *B. napus* rapeseed decreased by 50 and 53%, respectively, after 6 min of microwave heating. As aliphatic glucosinolates are less sensitive to heat treatment, sinigrin and gluconapin contents of *B. juncea* mustard seed showed no significant differences with increased time of microwave heating (Figure 5). However, their content after 4, 5, and 6 min of microwave treatment reached the level of that of the seed, which was a consequence of complete myrosinase inactivation.

There was a strong negative relationship between myrosinase activity in the seed (Table 3) and the total glucosinalate content in the corresponding expeller meals (Table 4) with intermediate-glucosinolate *B. napus* rapeseed and *B. juncea* mustard showing R^2 values of −0.92 and −0.92, respectively.

In a study on the effect of microwave treatment on the glucosinolate content of canola seed, Ebrahimi et al.[9] reported that the glucosinolate content after 2, 4, and 6 min of microwave heating decreased by 42, 55, and 59%, respectively, which was significantly higher than that observed in the current study. The main reason for the difference could be related to the processing method used. In their study, canola seed was dried at 55 °C for 48 h, after which time water was added to increase the moisture content to 25%. It is very probable that drying of the seed inactivated the myrosinase activity, whereas the heat produced during microwave treatment under high moisture conditions facilitated glucosinalate degradation.

In conclusion, it would appear evident that microwave heating of 2 W kg^{-1} for 6 min could be an effective method of producing expeller meal without toxic glucosinolate breakdown products while at the same time increasing the yield of oil during the expelling process.

[a]Values with the same letter in a column are not significantly different according to a Duncan's multiple-range test ($p < 0.05$).

The 24 h temperature regimens for day/night during the grain-filling period were 22/14, 25/17, 28/20, and 31/23 °C, changed at 1 h intervals. This 8 °C gap between day and night during the grain-filling period was based on the climate data (30 year average) of 1971−2000 from the Korea Meteorological Administration. The relative humidity in the room was maintained at 70 ± 5%.

Rice samples were harvested at an accumulated temperature of 1000 °C from heading, the panicle exsertion. Harvested grain samples were dried to achieve 15% moisture content. The rough rice was dehulled and milled using a rice sheller (Kiya ST-50; Yanmar Co., Ltd., Osaka, Japan) and miller (Pearlest; Kett Electric Laboratory, Tokyo, Japan). Milled rice was kept in sealed bags under refrigeration (4 °C) until analysis.

Ripening and Physicochemical Characteristics. Grain size characteristics (e.g., length, width, and thickness) were measured from 10 head rice kernels using a Mitutoyo Digimatic Caliper (CD-15CP; Mitutoyo Corp., Kawasaki, Japan). A 1000-grain weight from each sample was determined randomly in triplicate and weighed separately. The head rice of the milled rice was assessed by using a standard consisting of a kernel or a piece of kernel with its length equal to or greater than three-fourths of the average length of the unbroken kernel and kernels with half or less opaque like the color of chalk and brittle.

The amylose contents were tested by two methods, iodine and concanavalin A, to confirm the results. The iodine test was performed according to the method of Juliano,[9] and the concanavalin A method was performed by using an amylose/amylopectin assay kit (Megazyme International Ltd. Co., Wicklow, Ireland).[10] Protein content was determined by using the Kjeldahl method with the conversion factor for nitrogen to protein of 5.95.[11] Hardness was determined with 10 head rice kernels using a TA-XT2 texture analyzer (Stable Micro Systems Ltd., Godalming, Surrey, UK) with a 2 mm probe following the method of Song et al.[12]

Amylopectin Fine Structure. The molecular structure of amylopectin were determined by using HPSEC-MALLS-RI (high-performance size-exclusion chromatography on a system equipped with multiangle laser-light scattering and refractive index detectors) following Patindol's method.[13] The weight-average molecular weight (M_w), z-average radius of gyration (R_z), and polydispersity (ratio of weight-average and number-average molar masses: M_w/M_n) were determined using HPSEC-MALLS-RI (Wyatt Technology, Santa Barbara, CA, USA), and the density ($\rho = M_w/R_z^3$) and specific volume for gyration (SVg = 2.522 R_z^3/M_w) were calculated from these values.[13]

Amylopectin chain length distribution was determined by high-performance anion-exchange chromatography (HPAEC) with a pulsed-amperometric detector as performed by Nishi et al. with a slight modification.[14] The milled rice was ground with a mortar and pestle, and then 5−7 mg of the resulting powder was suspended in 5 mL of methanol and allowed to dissolve for 1 day. The homogenate was centrifuged at 2500g for 5 min. The pelleted polyglucan was washed twice with 5 mL of 90% (v/v) methanol, suspended in 5 mL of distilled water, and then boiled for 3 h. Then, 50 μL of 600 mM sodium acetate buffer (pH 4.4) and 10 μL of 2% (w/v) NaN_3 was added to an aliquot (1 mL) of gelatinized polyglucan. Hydrolysis was achieved by the addition of 0.5 μL of isoamylase from *Pseudomonas amyloderamosa* (Sigma I2758, 1,250,000 units) and incubation at 37 °C with shaking at 150 rpm for 24 h. The homogenate was centrifuged at 15000 rpm for 5 min, and then a 1 mL aliquot was filtered through a 0.2 μm syringe filter (PTFE). The HPAEC system (ICS-3000; Dionex Corp., Sunnyvale, CA, USA) components were an ICS 3000 dual pump, an EO1 eluent organizer, a gold electrode with an AgCl reference electrode, and an ED electrochemical detector. Samples were analyzed with a CarboPac PA1 column (2 × 250 mm) with a CarboPac PA1 guard column (2 × 50 mm). Samples (50 μL) were eluted by a 60 min linear gradient from 100 to 475 mM sodium acetate in 150 mM sodium hydroxide at a flow rate of 0.250 mL/min. Peak area ratios (%) were calculated using Dionex Chromeleon (version 6.80).

Gelatinization and Pasting Properties. The gelatinization properties of rice starch were analyzed using a differential scanning calorimeter (DSC) (TA Q1000; TA Instruments, New Castle, DE, USA) following the method of Song et al.[15] Rice starch (20 mg) was weighed into aluminum sample pans (TA Instruments) and mixed with 40 μL of distilled water. The pans were sealed and allowed to reach equilibrium for 1 h. Thermal curves were obtained from 30 to 150 °C with a heating rate of 10 °C/min. All DSC analyses were conducted in triplicate. The pasting properties of rice flour were determined in triplicate with a Rapid Visco Analyzer (RVA; Newport Scientific model 3D, Warriewood, NSW, Australia) following AACC method 61-02.

X-ray Diffraction. The crystallinity of the rice starch was analyzed according to the method of Han et al.[16] Amorphous starch was used to generate a background pattern, as used by Cairns et al.[17] X-ray diffraction patterns were obtained using a Philips PW3710 diffractometer with a step width of 0.010° in the 2θ range of 3−38°. Approximately 0.5−1 g of rice flour was firmly packed into an aluminum sample holder. X-ray data were collected at a rate of 3 s/step, and there were 3501 steps. Cu Kα (λ = 1.5418 Å) radiation was used from a generator operating at 40 kV and 25 mA. Data were analyzed with Philips PC-APD (version 3.6) software.

Cooking Properties. Cooking properties were evaluated according to Chun's method in triplicate.[18] First, 8 g of rice grains in a stainless steel mesh container was washed to eliminate surface residue. The container was fixed in a 300 mL tall beaker with 160 mL of distilled water using a glass rod, and these grains were cooked in an electric rice cooker (CR-3020 V; Cuckoo Electronics Co. Ltd., Yangsan, Republic of Korea). After 20 min for equilibrium, the water absorption ratio (w/w) and expansion volume of the cooked rice were measured. The eluate was filtered and dried at 105 °C, and the soluble solid was weighed from it. The pH and iodine index were also measured from filtrate of eluate with 2% iodine solution and using absorbance at 600 nm, respectively. The shape of cooked rice kernels (length, width, and thickness) was measured 40 times using a Mitutoyo Digimatic Caliper.

Sensory Evaluation. The sensory properties of cooked rice were evaluated by six trained panels in triplicate.[19] A modified preference

test was used involved scoring the cooked rice quality on a 7-point hedonic scales from −3 to +3. The sensory evaluation test provided information on appearance, aroma, taste, hardness, stickiness, and overall quality of cooked rice.[20]

Statistical Analysis. Data were processed with Statistical Analysis System software (version 9.1.; SAS Institute Inc., Cary, NC, USA). The data were statistically analyzed using Duncan's multiple-range test at a probability level of 0.05. Homogeneity of variance was calculated with Levene's test. General linear model analysis and correlation analysis with Pearson's correlation coefficient were also performed. Quantification analysis was conducted to evaluate the relative importance of various factors for the textural properties of the cooked rice by using the SAS PROC REG program, with PCORR2 in the model.[21] The squared partial correlation coefficients of PCORR2 measure the marginal contribution of one explanatory variable when all others are already included in multiple linear regression models.

RESULTS AND DISCUSSION

Grain Characteristics. The weight, shape, appearance, and hardness of the rice grains changed according to the ripening temperature (Table 1). The 1000-grain weight ranged from 20.1 to 21.7 g for Ilpum (IP) and from 18.9 to 19.8 g for Chucheong (CC). Even though the grains of CC weighed less than those of IP in each ripening temperature state, the higher the ripening temperature of the rice, the lower the 1000-grain weight of the rice kernels, with significant differences for both cultivars. These results are consistent with previous studies stating that a high temperature at the grain-filling stage decreases grain weight.[5,22]

The decreased grain weight in response to a higher ripening temperature is caused by various factors. The decrease in weight seemed to be related to the sink size or kernel shape. The grain size of milled rice depended on cultivar and temperature. Grains grown at a high ripening temperature tend to be shorter and thinner.[23] Likewise, the grain shape (i.e., grain length, width, and thickness) of IP was stable until 28/20 °C, but showed a significant reduction in shape at the highest ripening temperature (31/23 °C). On the other hand, the grain size of CC did not noticeably change with ripening temperature, meaning that ripening temperature affected the grain size of IP more than that of CC. Testing the interaction effects (cultivar × ripening temperature) using general linear model analysis revealed a significant interaction effect for length and thickness ($p < 0.001$) and grain width ($p < 0.1$). This result also means that there is an interaction effect of both cultivar and ripening temperature on grain size properties. The grain weight is also positively associated with the grain-filling duration and negatively with the grain-filling rate in rice cultivars during ripening.[24] Thus, a high ripening temperature slightly increases the grain-filling rate and decreases the grain-filling duration, decreasing the grain weight.[22,25]

The head rice yield, considering not only the shape but also the appearance of the grain tissue, was decreased in both cultivars when the grain-filling temperature was higher or lower than 28/20 °C. There is more non-head rice (i.e., chalky, immature, and dead rice) when the grain-filling temperature is higher or lower than the optimum temperature.[25] Low temperature causes spikelet sterility, a delay of grain filling, and reductions in yield.[6,26,27] The head rice percentage were lowest at 22/14 °C, peaked at 28/20 °C, and re-decreased at 31/23 °C in both IP and CC cultivars. Non-head rice is one of the primary issues in the rice market due to its undesirability to consumers. The palatability of cooked rice is decreased by an increased chalky rice proportion in sensory evaluation tests, even at just a 5% blend of non-head to head rice.[28]

A high ripening temperature reduces cereal yield by increasing imperfect or empty grains.[29] Here, head rice percentage decreased at 31/23 °C ripening temperature in both IP and CC cultivars. IP showed a steeper decrease in head rice than CC at 31/23 °C. The optimum temperature for these cultivars for producing head rice during grain filling has previously been reported: IP and CC show the highest yield and grain filling near 28/20 °C, and IP has a slightly lower optimum temperature (0.6 °C lower) than CC.[30]

Starch Compositions, Structures, and Crystallinities. With regard to starch composition, amylose content and short amylopectin chains decreased and intermediate amylopectin chains increased with an increased grain-filling temperature (Table 2; Figure 1). The amylose contents of IP and CC grown at the high ripening temperature were clearly decreased in both analyses. As previously reported, the high-temperature-ripened grain showed decreased levels of amylose,[7,8,31] which might be due to the repressed expression of granule-bound starch synthase I (*GBSSI*) at high temperatures, through which the amylose in endosperm of rice grain is synthesized.[5,32,33]

In the amylopectin chain length profile, the degree of polymerization (DP) for the peak chain length distribution of amylopectin was equal (at 11) in both cultivars. The proportion of short chains clearly reduced as the ripening temperature increased, ranging from DP 5 to 12 for IP and from DP 5 to 13 for CC. On the other hand, the relative amounts of amylopectin intermediate chains, DP 20−30 for IP and DP 18−33 for CC, increased when the ripening temperature increased. However, the longer chains above DP 30 or 33 were unaffected by the maturation temperature in both cultivars. A similar tendency was reported in wheat,[34] in which amylopectin branch chains were classified into three groups as the maturation temperature

increased: amylopectin branch chains with DP 6−12 decreased, the proportion of DP 13−34 increased, and those of DP ≥ 35 showed no significant difference. The high-temperature-ripened rice grain was also reported to contain intermediate and long-chain-enriched amylopectin, which might be due to the repressed expression of branching enzymes, especially the branching enzyme IIb.[5,6]

HPSEC-MALLS-RI analysis of the molecular structure of amylopectin revealed a different tendency in response to ripening temperature (Table 3). Amylopectin showed the highest density (ρ) at the optimal temperature for grain filling, suggesting that amylopectin had the highest compactness. The M_w of amylopectin ranged from 1.64×10^8 to 2.20×10^8 g/mol and from 1.52×10^8 to 2.02×10^8 g/mol for IP and CC, respectively, similar to Patindol's results for rice amylopectin.[13]

The polydispersity (M_w/M_n), an indication of the narrowness of the distribution,[13] of amylopectin grown at higher ripening temperatures (28/20, 31/23 °C) had lower values of 1.15−1.42 and 1.20−1.24 for IP and CC than the polydispersity at a lower ripening temperature (22/14, 25/17 °C; 1.83−1.96 and 1.66−1.99 for IP and CC, respectively). These lower polydispersity values meant that amylopectin molecules of rice ripened at a high temperature had a more homogeneous mass distribution than those of rice ripened at a low temperature. On the other hand, amylopectin molecules had the smallest specific volume for gyration (SVg) value when ripened at 28/20 °C, 0.16 and 0.19 for IP and CC, respectively. The specific volume for gyration, the theoretical gyration volume per unit of molar mass, is significantly reduced by branching.[35] The R_z, the theoretical probability of finding a molecule at a given distance from the center, showed a similar tendency to SVg. These results revealed that the amylopectin molecule was more highly branched at 28/20 °C than at other ripening temperatures. Similarly, the density (ρ) had the largest values at 28/20 °C, 15.4 and 13.0 g/mol/nm^3 for IP and CC, respectively. These results suggest that the appropriate ripening temperature may be around 28/20 °C for amylopectin branches and compactness compared with SVg, R_z, and ρ at lower or higher ripening temperatures.

X-ray powder diffraction pattern analysis of the crystallinity of rice flour also showed that the highest compactness and largest crystalline region were at the optimum temperature (28/20 °C; Table 4). X-ray diffraction provides data on the relative amounts of crystallites and amorphous phases for elucidating the crystal structures of the crystallites of the starch granules. By integrating the X-ray scattering intensity separately over the peak and the background, a number is obtained and interpreted as the "X-ray crystallinity".[36] The crystallinities for

IP and CC ranged from 19.7 to 21.6% and from 20.5 to 25.2%, respectively. In all ripening conditions, CC had a higher degree of crystallinity than IP. The crystallinity, related to the double helices of amylopectin in X-ray diffraction analysis,[37] was greater at high ripening temperatures (28/20, 31/23 °C) than at a low ripening temperature (21/14, 25/17 °C) in both cultivars. The largest crystalline regions were at 28/20 °C, with values of 21.6 and 25.2% for IP and CC, respectively. The crystallinity of rice flour was slightly decreased, by 0.1% for IP and by 0.9% for CC, from 28/20 to 31/23 °C.

In this study, amylopectin intermediate chains, which construct double helices, increased under elevated temperature conditions (Figure 1). In addition, the samples had a higher proportion of crystalline regions when ripened at high temperatures of 28/20 and 31/23 °C in both cultivars. The increase in crystallinity with an increased ripening temperature was likely due to the increased amount of amylopectin intermediate chains. However, this increase could not explain the reduced crystallinity at 31/23 °C. Instead of the amylopectin chain length distribution from a previous study,[38] the crystallinity of rice flour was highly correlated with the head rice percentage, with a correlation coefficient of 0.790 ($p < 0.05$). As stated above, the head rice percentage of both cultivars was highest at 28/20 °C. Therefore, one likely reason for the decreased crystallinity was the increased chalky rice at high ripening temperatures. The amylopectin chain length distribution and DSC properties were determined with only head rice to reduce the error due to the differences between head rice and chalky rice,[39] but the crystallinity was measured using rice flour, which included chalky rice. Chalky rice has less starch accumulation in the tissue. In addition, crystallinity is related to the density of the packing arrangement,[40] as also shown here by the decreased head rice percentage and reduced packing density (based on SVg, R_z, and ρ values) at 31/23 °C in Table 3. These results revealed that the crystallinity of rice flour was related to the head rice percentage, as well as the amylopectin chain length distribution, and confirmed the decreases in head rice yield, the compactness of amylopectin molecular structure, and the crystallinity of rice flour at a high grain-filling temperature above the optimal temperature.

Gelatinization and Pasting Properties. The gelatinization properties of rice are closely related to the eating quality.[41] In this study, the gelatinization properties of starch markedly changed as the ripening temperature changed (Tables 5), supporting our findings that rice starch grown at a high temperature would require a higher cooking temperature and longer cooking time.

The rice starch matured at a high temperature had consistently higher gelatinization temperatures (e.g., T_o, T_p, and T_c) and enthalpies, and the gelatinization temperatures increased with an increased ripening temperature. The gelatinization starting (onset) temperature, T_o, increased by 2.3 °C, from 68.5 to 70.8 °C, for IP and by 3.8 °C, from 67.7 to 71.5 °C, for CC. The peak temperature (T_p), completion temperature (T_c), and gelatinization enthalpy (ΔH) also significantly increased with increases in the ripening temperature in both cultivars, reflecting differences in the amylopectin crystalline order. These findings are consistent with those of a previous study, which suggested that the DSC characteristics of rice correlated with the environmental temperature.[8] Our results confirmed that a higher ripening temperature increased the gelatinization temperatures of rice starch.

Previous reports found that a longer chain length of an individual double helix of amylopectin increases the stability of the amylopectin double helix in gelatinization conditions.[42] In addition, the gelatinization enthalpy mainly reflects a loss of the double-helical order of amylopectin.[38] The formation of the double-helical structure that leads to crystallization requires a chain length of at least 10 for pure malto-oligosaccharides.[42] Therefore, more long amylopectin chains (DP > 10) forming double helices due to a higher ripening temperature would lead to more stable gelatinization.

The temperature range of gelatinization (ΔT) of starch also tended to widen in response to ripening temperature increases. This increased range would mean that the starch of rice grown in a high ripening temperature condition would require more energy in terms of cooking time and temperature than that grown in a low ripening temperature condition. This trend was more obvious for IP starch than for CC starch. In the IP cultivar, the ΔT of the starch showed a significant tendency to increase from 18.1 to 23.6 °C under elevated ripening temperature conditions. On the other hand, the ΔT of CC starch also increased, but the increase was not statistically significant.

The ΔT is a function of both the proportion of amylopectin short chains and their DP.[1] The ΔT of starch was reported to positively correlate with the amount of DP 6−9 in amylopectin due to an increase in the relative crystallinity in comparison with other rice varieties.[43] However, here, the ΔT increased with an increase in the crystallinity at a high ripening temperature, despite a reduction in the amount of DP 6−9 in amylopectin (Tables 4 and 5; Figure 1). The increase in the ΔT was mainly due to an increase in the T_c. Moreover, a negative correlation between the ΔT and short chains of amylopectin was identified ($r = -0.841$; $p < 0.01$). It seems that the ΔT is

related to the packing density, which is related to crystallinity, and not directly with the amount of short chains of amylopectin.

Amylography using the RVA is a commonly used pasting property test that predicts the texture of cooked rice. With regard to the pasting properties of rice flour, the viscosity increased with an increased ripening temperature in both cultivars (Table 6). Peak and trough viscosities were clearly increased and setback was decreased with increasing ripening temperature. The CC cultivar had a higher increase in peak viscosity, with 52.9 RVA units (RVUs) compared with the 33.8 RVUs of IP. The trough viscosity of CC also increased to 48.7 RVUs compared with the 32.7 RVUs of IP. The breakdown displayed maximum values of 49.6 RVUs for IP and 54.0 RVUs for CC at 28/20 °C, with no statistically significant difference of IP. Setback was markedly decreased with an increase in the ripening temperature. However, the decreased amount of the CC cultivar was lower than that of the IP (14.7 vs 22.5 RVUs, respectively), with a different trend from above. These results concur with a report stating that a lower peak viscosity and higher setback are seen in rice with a higher amylose content (from the coldest growing season) than in rice with a lower amylose content.[7]

Pasting properties are affected by amylose content and by the branch chain length distribution of amylopectin.[44] The amylose content is generally thought to be a critical determinant of starch pasting properties because amylose suppresses starch swelling. The amylose helix has an internal hydrophobic tube,[45] providing a space for hydrophobic complexing agents such as lipids.[46] Amylose−lipid complexes restrict granule swelling,[47] which consequently affects pasting.[48] Hence, the apparent amylose content was negatively correlated with flour swelling volume[49] and stickiness[50] and was positively correlated with the hardness[50] of cooked rice. However, the correlation between amylose content and pasting properties is variable,[50] because amylopectin structure also affects pasting properties.[51] The amylopectin fine structure has been reported to be related to the breakdown of swollen granules and viscosity, with a negative correlation with long chains and a positive correlation with short chains.[52]

We confirmed the negative correlation between amylose content and peak ($r = -0.912$, $p < 0.01$) and trough ($r = -0.909$, $p < 0.01$) viscosities (Table 7). Thus, rice flour made from rice ripened at higher temperatures swelled more easily and resisted shear more readily than that of rice grown at low temperatures. On the other hand, the breakdown had a slightly different tendency with maximal values at 28/20 °C in both cultivars, showing that the capacity of starch granules to rupture after cooking was higher near the optimum temperature for grain weight, especially in the CC cultivar. Breakdown has also been reported to be positively correlated with the stickiness of cooked rice.[53] Setback also has a positive correlation with cohesiveness of mass in cooked rice, a sensory textural attribute.[54] Here, the lower amylose content at higher ripening temperatures is related to decreased setback ($r = 0.731$, $p < 0.05$). Those values in the breakdown and setback, together with the lower amylose content mentioned above, showed that cooked rice grown at high ripening temperatures may have lower hardness and cohesiveness and higher stickiness. However, in this study, these results were not confirmed by analysis of the textural properties of the cooked rice using a texture analyzer (data not shown). The higher protein content in rice grown at higher ripening temperatures may explain the texture differences, because protein content correlates with cooked rice texture. Protein is also involved in providing structural support to the rice kernel during cooking, thereby restricting starch granule swelling. Thus, treatment with protease, an enzyme that cleaves protein, significantly decreases cooked rice firmness.[55] In addition, protein influences the stickiness of cooked rice, with increased stickiness after protein disruption.[56] We concluded that these contradictory roles of protein in the texture of cooked rice offset the predicted effects

Table 10. Relative Importance of Starch Properties and Protein Content for the Palatability of Cooked Rice through Quantification Analysis

	amylopectin					
	DP 6−12	DP 13−24	DP 25−36	DP 37−60	amylose	protein
palatability (%)	9.2[a]	6.9	29.4	1.4	27.6	25.6

[a]Squared partial correlation coefficients (%) through quantification analysis.

of a low amylose content on the pasting properties discussed above at high ripening temperatures.

Furthermore, the setback value reflects the degree of retrogradation of starch paste and shows that starch grown at high ripening temperatures had less retrogradation. However, the short amylopectin chain of DP 6−9 has the opposite effect on retrogradation, showing a negative correlation.[57] Thus, the retrogradation did not appear to be affected by an increased ripening temperature, shown by the percentage retrogradation, calculated by the $\Delta H_{\text{retrograded starch}}/\Delta H_{\text{gelatinization}}$ in the rice starch tested (data not shown).[44]

Cooking Properties and Palatability. The cooking properties of the rice were predicted to be best at the optimum temperature according to water absorbability and a low iodine index and soluble solid value (Table 8). The water absorption ratio was significantly higher at 31/23 °C in both cultivars. Water absorbability is highly related to the gelatinization and eating quality of rice.[58] This high water absorption following a high ripening temperature is related to the starch granular structure and low amylose content. The rigidity of the starch granular structure is in proportion to its amylose content and in inverse proportion to the degree of granular swelling.[59] In other words, a high temperature during grain filling caused a loose starch granular structure due to low amylose content, increasing water absorbability.

The starch−iodine blue value of the residual liquid after cooking has been negatively correlated with eating quality.[60] Here, the iodine index was significantly lower at a high ripening temperature than at a low temperature. This low iodine index may be due to the low amylose content of the samples. However, the amylose content did not seem to be affected by the leaching of starch exudates. Despite the low amylose content, the amount of leaching of starch exudates was decreased during the cooking of rice grown at a high ripening temperature, although high levels of amylose reduced the amount of starch exudates leaching into the solution, because amylose suppresses starch swelling.[49] Enriched long amylopectin may be related, because lower levels of soluble solid were seen in both cultivars at 28/20 °C, the optimum temperature for amylopectin density.

Finally, we performed a sensory evaluation of the palatability of the cooked rice. Palatability showed a nonsignificant tendency to decrease in response to an increase in the ripening temperature (Table 9). The relative importance or contribution of starch components and protein content for the palatability of cooked rice was analyzed using the quantification method type I[61] (Table 10). The amylopectin chains of DP 25−36 showed the greatest effect on palatability at 29.4% among the rice samples grown with various ripening temperatures. In addition, the amylopectin chains of DP 25−36 had a high effect on the gelatinization properties of rice starch, as discussed above.

DOI: 10.1021/jf504870p
J. Agric. Food Chem. 2015, 63, 3085−3093

However, the amylose and protein contents also had high relative importances of 27.6 and 25.6%, respectively. Therefore, we could conclude that palatability was mostly related to the following chemical properties: amylopectin, amylose, and protein content. Of amylopectin chains, the DP 25−36 chains had the greatest relative importance on eating quality, because of their effect on starch gelatinization.

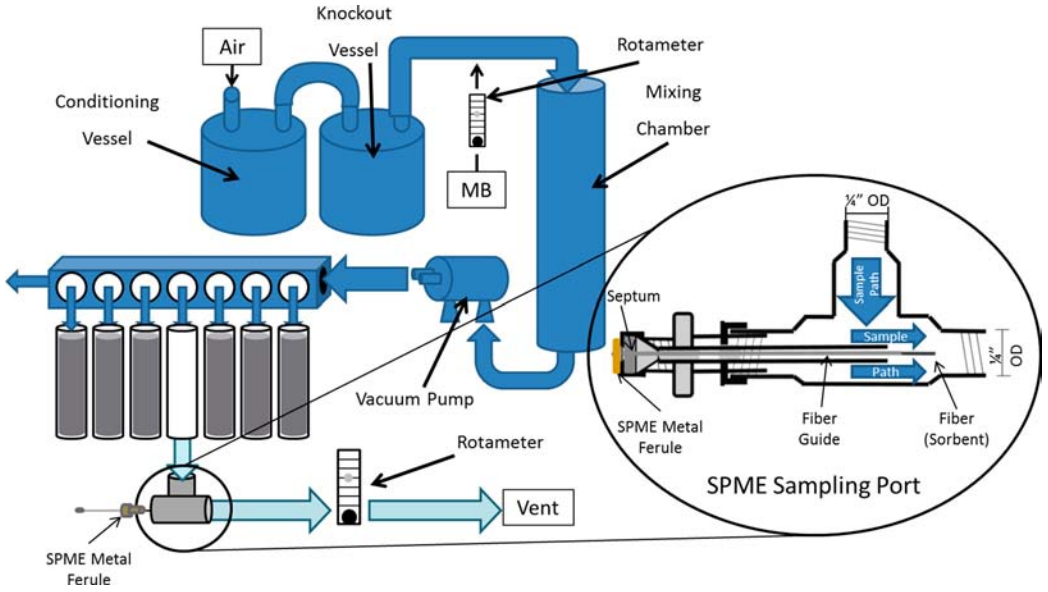
Scheme 1. Parallel Adsorbent Column Tester (PACT)



Results are presented and discussed relative to activated carbon derived from coconut shell, the type of sorbent used in several commercial systems that remove MB from effluent during chamber ventilation.

MATERIALS AND METHODS

Chemicals. A 50-lb (23 kg) cylinder of compressed MB, Meth-o-gas 100 (>99.5% purity), was obtained from Cardinal Professional Products (Woodland, CA, USA). Respective 300-lb (136 kg) cylinders of compressed ultra high purity nitrogen (>99.9% purity) and carbon dioxide (>99.3% purity) gases were used for the carbon preparation and were received from the Fresno, California USA Airgas distributor. When air was used for carbon preparation, it was supplied by a compressor that pushed air (60 psi) serially through an Altech L21 charcoal filter and a Drierite-filled moisture trap. Commercially marketed activated carbon derived from coconut shell source, Westates Vocarb 48C (WEST-AC), was purchased from Siemens Industry, Inc. (Alpharetta, GA, USA) and was stored at ambient conditions in an airtight jar until use. Deionized (DI) water was produced with a Millipore Elix 10/Gradient A10 water purification system to a specification of 18 MΩ resistivity.

SPME Quantification: Modeling TWA versus DFE. The PACT was used to evaluate, in parallel, gram-scale quantities of materials for capture performance as a function of conditions typical of ventilation effluent from chamber fumigations: effluent flows (ca. 0−225 mL min^{-1}), volumes (≥ 6.75 L), durations (≥ 30 min), and [MB]s (ca. 3−16000 ppmv). Over the range of these conditions, solid-phase microextraction (SPME) fibers have the potential to be more effective than established methods for MB quantification (e.g., colorimetric tubes, gas-sampling, IR detection, electrochemical detection). Two passive sampling techniques involving SPME, direct fiber exposure (DFE) "instantaneous grabs" as well as "diffusive" time-weighted averaging (TWA),[16−20] were comparatively evaluated for potential to quantify MB in the flowing air of the PACT system as well as in headspace of a static system for comparison.

With DFE sampling, the SPME fiber was directly exposed to the sample matrix (i.e., air−MB mixtures). When the sample volume is much larger (>10×) than the volume of the SPME fiber and the analyte concentration in the sample is less than that required to saturate the fiber (vide infra), the amount of analyte (e.g., MB) collected on the fiber can be predicted by[16,17]

$$m_{eq} = K_{fs} v_f C_0 \quad (1)$$

where m_{eq} is the mass of MB sorbed onto fiber at equilibrium, v_f is the volume of the fiber, and C_0 is the initial concentration of MB. The distribution of MB between the fiber and sample, K_{fs} (unitless), is expressed as the ratio

$$K_{fs} = [MB]_{fiber}/[MB]_{sample} \quad (2)$$

where $[MB]_{fiber}$ is the concentration of MB in the fiber, and $[MB]_{sample}$ is the concentration of MB in the sample matrix.

At equilibrium, the rate of MB sorption and desorption are equal in magnitude where

$$d[MB]_{fiber}/dt = d[MB]_{sample}/dt = 0 \text{ and } K_{fs} = \text{constant} \quad (3)$$

K_{fs} varies for each type of fiber coating (and anlyte) and as a function of many factors including total concentration of analyte (MB), matrix interferences, thickness of the coating, temperature, humidity, etc.

With TWA sampling, the SPME fiber was exposed to the sample matrix while "retracted" in the fiber guide, which served as a physicomechanical constraint on the diffusive flux of MB from the sample matrix toward the fiber. The use of SPME fibers in concert with TWA sampling to quantify an analyte has been rigorously discussed.[16−22] The translational rate of MB diffusion, *SR*, is approximated by

$$SR = A/z \times D \quad (4)$$

where A is the cross-sectional area of the fiber guide, z is the distance that the fiber is retracted into the fiber guide, and D is the diffusion coefficient for MB. The mass of MB sorbed to the fiber, m, is calculated using

$$m = \bar{C} \times SR \times t \quad (5)$$

where $\bar{C}$ is the time-weighted average concentration of MB over the span of time, t, the fiber assembly is exposed to the sample matrix. Variation in m is only linear (i.e., eq 5 will be valid) for times < $t_{50,v}$ which is the time required for sorption of 0.5 m_{eq} (vide infra).

SPME Quantification: TWA versus DFE Protocols. To sample MB-containing airstreams in the PACT system, each SPME sampling port (vide infra) was outfitted with a Carboxen/PDMS Stable Flex SPME fiber assembly (#57335-U, Sigma-Aldrich (Milwaukee, WI), 23 gauge, $A = 1.464 \times 10^{-3} cm^2$ (eq 4), 85-μm thick coating on a 170-μm OD fiber, length = 10 mm, $v_f = 0.549$ μL (eq 1)). Autosampler SPME fiber assemblies, such as the ones employed in this study, were chosen because one can manually adjust the position of the fiber on the z-axis (z value) without the need for a fiber holder. DFE and TWA sampling was conducted at a temperature in the range of 25−30 °C with t = 5

DOI: 10.1021/jf505193e
J. Agric. Food Chem. 2015, 63, 3094−3103

min and t = 0.5−30 min, respectively, while z was consistent across the respective sampling techniques. For TWA sampling, a fiber holder (#57330-U, Sigma-Aldrich) was used to standardize a fully retracted "zero position" for z, ∼31 mm from metal ferule to the screw hub of the fiber assembly. For DFE sampling, z = 17 mm based on using a piece of plastic (length = 14 mm, diameter = 6.3 mm) to standardize the distance between the metal ferule and the screw hub of the fiber assembly.

To sample MB-containing headspace in static systems, serial dilutions of MB (Meth-o-gas 100, Great Lakes Chemical Corporation, >99.5% purity) in air were prepared in volumetric 1200−1300 mL glass gas flasks (1-L Erlenmeyer flask fitted with two ports). Flasks had ∼200 mL of air withdrawn using a gastight syringe (B-D Yale, # Z 3876), predetermined amounts of MB were introduced (<200 mL), and then normal atmospheric pressure (NAP) was (re)established at a temperature of 25−30 °C. A 10 mL "headspace" vial (#SU860099, Sigma-Aldrich) was fitted with a screw cap (PTFE/silicone septa (#SU860101, Sigma-Aldrich) that was then pierced by two needles with Leur-lock connectors (Ranfac, #6515430440). The inlet needle was positioned in the center of the septum, just above the bottom of the vial, and the vent needle was positioned at the edge of the septum, penetrating just below its inner surface. Headspace was then purged from the vial over the span of ∼10 s with 50 mL of a MB dilution from a gas flask. After the needles were removed, the fiber guide from the fiber assembly described above was inserted through the hole made by the inlet needle. To control the depth of the fiber from the septa following penetration, the fiber guide (and fiber) was inserted concentrically through a 1/4 in. OD tube reducer to 1/8 in. tube fitting (#B-200-R-4, L = 1.42 in, Swagelok, Northern California, Fremont, CA) so that the metal ferule of the fiber assembly was supported by the fitting, which buttressed against the septa of the vial. Values of t and z for DFE and TWA sampling were as described above.

Gas Chromatography. An Agilent 6890 gas chromatograph (GC) was used with a split−splitless inlet at 250 °C, a 100:1 split ratio activated at 0.01 min, and a 0.75 mm ID SPME injection sleeve inlet liner (#2−6375,05, Sigma-Aldrich, Bellefonte, PA). The inlet was also equipped with a 250-μL loop on a gas-sampling valve (GSV) held at 110 °C. The analytical column was a 30 m (L) × 250 μm (ID) DB-5 with 0.25 μm film thickness held isothermally at 150 °C for 3 min and 1.8 mL min^{-1} He carrier flow. The flame ionization (FID) detector was at 275 °C with respective flows of 30 mL min^{-1} H_2, 400 mL min^{-1} air, and 30 mL min^{-1} N_2 makeup. Retention time was used for chemical verification of MB and hexane.

After sampling MB in either the static or flowing systems, the fiber was retracted to "zero position" (if necessary), and the fiber guide was capped by burying it into a septum (#6514, Grace, Deerfield, IL) to prevent the loss of MB (vide infra) until just before GC-FID analysis. The SPME fiber assembly was loaded into a SPME fiber holder (#57330-U, Sigma-Aldrich), the fiber guide was injected 2 in. into the inlet, and the fiber was desorbed for 1 min. Alternatively, GSV injections were conducted for comparison as noted below.

Sorbent Preparation. Pits from two species of tree fruits, *Prunus domestica* (prunes) and Prunus persica (peaches), as well as shells from two species of tree nuts, *Juglans sp.* (walnuts) and *Prunus amygdalus* (almonds), were obtained as end-products of key California USA horticultural production and used as carbon sources. Sorbents from respective carbon sources were prepared, as detailed below, using different methods following the general sequence of pyrolysis, activation, and then quenching. During pyrolysis, the carbon source was heated under an inert gas atmosphere to form char, a carbonaceous derivative material with a "rudimentary porous structure" relatively void of noncarbon heteroatoms.[15] A single type of carbon source served as starting material and was loaded into a 2 in × 2.25 in × 22 in (5.1 cm × 5.7 cm × 55.9 cm, inner diameter (ID) × outer diameter (OD) × length (L)) mullite working tube (Carbolite, MVO66325-N-18) to fill the heated-zone of a 13 in (33.0 cm) tube furnace (Thermolyne, 21100). The mass of the carbon source loaded into the working tube was measured gravimetrically. The contents of the tube were flushed with nitrogen gas at ∼900 mL min^{-1} for 1 h with the temperature controller set to 75 °C. The furnace temperature controller was increased to 700 °C, which resulted in ramp rate of ∼25 °C min^{-1}, and held isothermal for 1 h. The furnace temperature controller was increased to 800 °C, and the char was then "activated" to form a sorbent, as described in detail below, by introducing either carbon dioxide or steam into the tube to remove residual material, such as tars, from the pore spaces. Sorbent was "quenched" using various procedures during the return to temperature <50 °C. When preparation was completed, the mass of the carbon sorbent was measured gravimetrically. Sorbents were ground using a hand mill equipped with tooth auger and fine plates (Lehman Mills, Quaker City Mill #1171295), sized to a 20/40 mesh with brass sieves (McMaster-Carr, 3286K14 and 3286K16), and stored at ambient conditions in an airtight jar until use.

CO_2 Activation with Nitrogen Quenching. To activate the char, carbon dioxide was flushed through the tube furnace at ∼900 mL min^{-1} following pyrolysis and just before the furnace temperature controller was set to 800 °C. After 1 h, the carbon dioxide was replaced with nitrogen, and the temperature controller was turned off to initiate a gradual decrease of the CO_2-activated nitrogen-quenched carbon (CO2A-NQ) to <50 °C.

Steam Activation with Nitrogen Quenching. Steam was directed through high temperature silicone rubber tubing (McMaster-Carr, 5236K871) into the char-containing tube for 1 h following pyrolysis and just before the furnace temperature controller was set to 800 °C. Steam was generated by sparging nitrogen through a 1000 mL round-bottom flask containing ∼800 mL of boiling DI water. The feed rate of steam, 4.73 ± 0.34 g min^{-1}, was determined by measuring the mass of water before and after the 1-h process in triplicate trials. Quenching was as above to yield steam-activated nitrogen-quenched carbon (SA-NQ).

CO_2 Activation with Air Quenching. Following CO_2 activation, the furnace temperature controller was lowered to 300 °C, and air (ca. 20−40 RH) was directed through the furnace tube at ∼900 mL min^{-1} for 1 h. The air was then replaced with nitrogen gas, and the CO_2-activated air-quenched carbon (CO2A-AQ) was allowed to cool to <50 °C before being processed for use as described above.

CO_2 Activation with Water Quenching. Following CO_2 activation, the furnace temperature controller was lowered to 300 °C, and the entire contents was transferred using heat-resistant gloves to a 32 oz (946 mL) Mason jar filled with approximately 1 mL of water for every 2 g of raw material. The carbon−water mixture was allowed to cool to <50 °C, the water was decanted, and the CO_2-activated water-quenched carbon (CO2A-WQ) was dried in an oven at 110 °C overnight before being ground, sized, and stored for use as above.

PACT System and Sorbent Evaluation. The PACT was constructed based on modification to the bench scale adsorbent column apparatus as described by Leesch et al.,[7] which was about a 3,500:1 scaled-down model of a chamber ventilation system (Scheme 1). PACT diverts a single source of flowing air into seven channels. Briefly, air is pulled with an oil-free vacuum pump through 1 in. Tygon tubing connecting two vessels and a mixing chamber in series. The first vessel (conditioning) was filled with either water, to humidify, or silica gel, to dry, the airstream. To increase the humidity from ∼25 to ∼70%, silica gel was removed from the conditioning vessel and replaced with water to a depth of ∼10 cm. The second vessel (knockout) allowed any water droplets to fall out of the airstream and contained a HOBO datalogger (Onset, #U10−003) to monitor temperature and %RH. Next, the airstream was combined with MB (Meth-o-gas 100 Great Lakes Chemical Corporation, >99.5% purity) as metered by a rotameter (Key Instruments, #10410_R5) before entering into a mixing chamber comprised of a 3 in (ID) × 39 in (L) schedule 40 poly(vinyl chloride) pipe. The MB-containing airstream was then routed through the vacuum pump; the pressure of the airstream entering and exiting the pump was monitored with respective Magnehelic gauges (Dwyer Insruments, Cat. No. 2020C). Exhaust from the pump was directed through a stainless-steel manifold with seven channels as well as an outlet that was tuned to balance pressure. Unless otherwise noted, the total flow of MB and air into the manifold was 50 SCFH (∼23,502 mL min^{-1}).

DOI: 10.1021/jf505193e
J. Agric. Food Chem. 2015, 63, 3094−3103

Each channel was outfitted with a quick-connect fitting (McMaster-Carr, #s 51545K23 and 51545K79) to a 1/2 in (OD) × 6 in (L) stainless-steel column with a bed volume (for sorbent materials) of ∼12 mL. Flow from the column exited through 1/4 in. Swagelok tee and was directed to the outlet at 90° (see inlay of Scheme 1). The branch opposite the outlet was fitted with a Teflon 1/8−1/4 in (OD) tube reducer (Swagelok, #T-200-R-4), which was bored so that a 1/8 in (OD) × 56 mm (L) piece of stainless-steel tubing spanned into the central cavity of the tee. The fiber guide was inserted through a septum (Grace-Davison, #6514) and into the stainless-steel tubing (to protect the fiber) so that the tip of the fiber guide was flush with the end of the tubing. This alignment enabled the fiber to access the airstream coaxially within the outlet branch of the tee. The outlet flow from each SPME sampling port was metered to 224 mL min^{-1}, unless otherwise noted, with a rotameter (Lab-crest # FP 1/8−041-G-6/443U381U10).

Prior to each experiment where carbon performance was evaluated, six (of seven) stainless-steel columns were loaded with sorbent material to a 11.4 cm bed depth, the ends of each column were capped with circular 40-mesh stainless steel strainer cloth (1/8 in OD), all columns were placed in the working tube (vide infra), and the furnace temperature controller was set to 300 °C with a nitrogen gas flow of ∼900 mL min^{-1} for 2 h. The seventh column contained no sorbent. After the heating period, all columns were stored in an airtight jar containing ∼5 g of drierite until being fitted onto the seven-channeled manifold of the PACT apparatus. SPME fiber assemblies, with the fibers retracted into the fiber guide for TWA sampling with z = 10 mm,[16] were inserted into the sampling ports, and all airflows were metered as described above.

To simulate chamber effluent consistent with ventilation of a postharvest MB fumigation,[7,8] [MB] in the airstream of the PACT apparatus was temporally modulated from the start of a dose (when t = 0): 16,210 ppmv for 3 min, 4,870 ppmv for 13 min, and 0 ppmv for the remaining 14 min (30 min total). For a single test, dosing was repeated serially ($Dose_n$, where n = 1, 2, 3, etc.) at ∼60 min intervals. After each dose, the mass of the MB cylinder was gravimetrically measured. Additionally, each column was gravimetrically measured, and each Carboxen/PDMS Stable Flex SPME fiber assembly (#57335-U, Sigma-Aldrich (Milwaukee, WI)) was removed from the sampling ports of the PACT apparatus for analysis of MB with GC coupled to FID (vide supra). A "breakthrough" threshold was reached when [MB] exiting a column exceeded 500 ppmv (∼13 mg escaping the column over the 30 min dosing period).[7] If breakthrough (BT) was observed on the same column for two consecutive doses, the column was replaced with an empty column. Dosing continued until all columns containing sorbent were removed from the PACT apparatus.

The capacity of an activated carbon sorbent to sorb MB was calculated as the percentage of the total mass of MB sorbed ($m_{MB,sorbed}$) by the column over consecutive doses, including the first dose where BT was observed ($Dose_n$, where n = 1,2,3,4...first BT), relative to the mass of carbon sorbent measured just before testing, m_{AC}, in the form

$$\%\ \text{Capacity}_{MB} = m_{MB,sorbed}/m_{AC} \times 100 \tag{6}$$

where $m_{MB,sorbed}$ is calculated by

$$m_{MB,sorbed} = m_{entering} - m_{exiting} \tag{7}$$

and $m_{entering}$ is the total mass of MB entering the column containing no carbon sorbent (e.g., column attached to the seventh channel of manifold), and $m_{exiting}$ is the total mass of MB exiting a carbon containing-column as calculated by

$$m_{entering} = \sum_{Dose_1}^{Dose_{BT}} \bar{C} \times 0.224\ \text{LPM} \times 30\ \text{min} \tag{8}$$

or

$$m_{exiting} = \sum_{Dose_1}^{Dose_{BT}} \bar{C} \times 0.224\ \text{LPM} \times 30\ \text{min} \tag{9}$$

where $\bar{C}$ is the time-weighted average [MB] in mg L^{-1} (vide infra), 0.224 LPM (L min^{-1}) is the flow rate through the column, and 30 min is the duration of a dose.

RESULTS AND DISCUSSION

SPME Calibration and Response Factors. Seven individual fibers were each arbitrarily assigned a number, one through seven. For each fiber, a total of 17 analyses were conducted on the PACT system, nine using TWA sampling (n = 9) and eight using DFE sampling (n = 8). A response factor, RF, was calculated for each fiber, with Fiber 7 serving as reference for comparison:

$$RF_{FiberX} = \sum_{i=1}^{n} \left(\frac{Area_{FiberX,i}}{Area_{Fiber7,i}} \right) / n \tag{10}$$

Respective analyses (JMP, Version 9. SAS Institute Inc.) for TWA and DFE sampling indicated that the RFs of individual fibers were significantly different from the grand mean of all RFs (ANOVA: TWA, $F_{5,48}$ = 3.751, p < 0.01; DFE, $F_{5,17.532}$ = 39.764, p < 0.0001). For TWA sampling, the RFs of Fibers 3 and 4 were distinct from that of Fiber 6, while Fibers 1, 2, and 5 did not differ from Fibers 3 and 4, nor Fiber 6 (Tukey-Kramer HSD, α = 0.05). For the DFE sampling, the RFs of Fibers 1 and 4 were each different from the RFs of all other fibers, and the RFs of Fibers 2 and 6 were different from each other (Tukey-Kramer HSD, α = 0.05). t tests of individual fibers indicated that RFs associated with DFE sampling were significantly (P < 0.01) more extreme than respective RFs from TWA sampling ($RF_{DFE} < RF_{TWA} < 1.000$ or $1.000 < RF_{TWA} < RF_{DFE}$). These results support the conclusion that quantitative analyses with SPME using TWA and DFE sampling should differentiate, at least for MB, between each fiber and sampling technique (i.e., each fiber and sampling technique should be considered unique).

Accordingly, the RFs respective to each fiber and sampling technique (DFE and TWA) were used for the quantification of MB. Following each GC analysis, the integral of the MB peak area, *Area*, was adjusted using

$$Area_{Adj} = Area/RF \tag{11}$$

The RF-adjusted areas, $Area_{Adj}$, (i.e., detector response) were then plotted on the y-axis versus an x-axis of m, m_{eq}, [MB], or the concentration−time "CT" product (i.e., [MB] × t). Linear least-squares analyses of the respective correlations were used for calibration and quantification.

The RF of each fiber was tracked chronologically for performance or loss of function. Over the course of this study, only accidents (e.g., nicks, dents, etc.) that physically damaged the fiber changed the RF. Future studies will evaluate the potential "drift" in RF values over relatively long experimental time courses or operational periods.

DFE Sampling. The distribution of MB between the fiber and sample matrix, K_{fs}, reached equilibrium (i.e., K_{fs} was constant, eq 1 is valid) at t < 2 and t < 5 min when airstreams in PACT and static headspace, respectively, were sampled with DFE. The time required for equilibrium (disadvantageously) impacts quantification of MB from static headspace with t < 5 min as well as from flowing systems where concentration changes are occurring when t < 2 and resolution of this change is required, such as when quantifying MB in ventilation effluent from postharvest chamber fumigations. The time required for equilibrium can (advantageously) concentrate MB from flowing

DOI: 10.1021/jf505193e
J. Agric. Food Chem. 2015, 63, 3094−3103

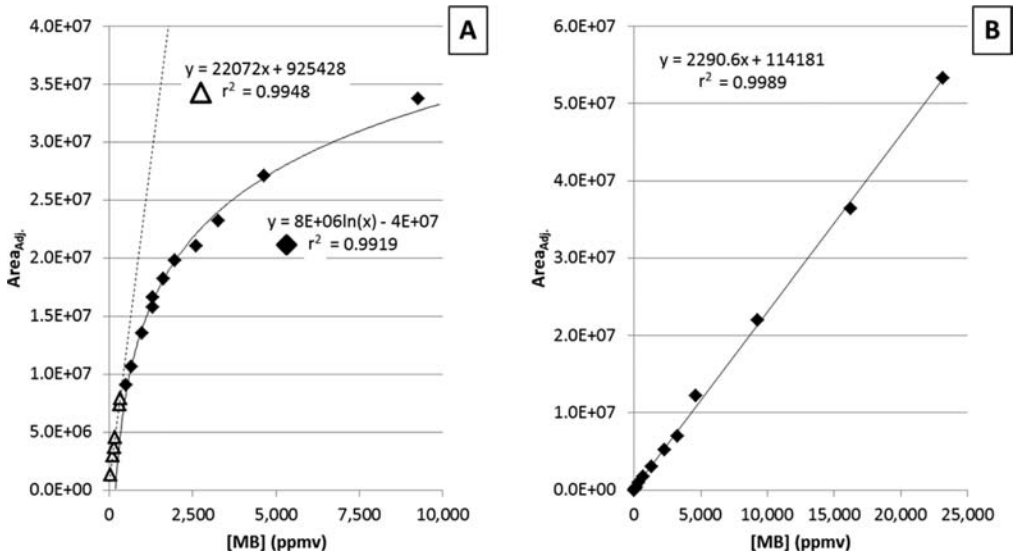


Figure 1. (A) A calibration curve for DFE sampling of methyl bromide concentrations ([MB]) (32−9542 ppmv) in the static headspace of vials with t = 5 min shows a linear response up to ∼300 ppmv (triangles, dashed line) and logarithmic response at higher concentrations (diamonds, solid line). (B) A calibration prepared from GSV injections shows that GC-FID detector response remains linear at [MB]s exceeding 20,000 ppmv.

airstreams or static headspace, which thereby increases the limit or the dynamic range of detection. For example, when [MB] of 504 ppmv in static headspace was sampled with DFE when t = 5 min, nearly 10× more MB was detected (m = ∼4096 ng) in subsequent GC-FID analyses as compared to a 250-μL GSV injection of the same headspace concentration (m = ∼490 ng). The ability of DFE (with t = 5 min) to concentrate MB from static headspace was not linear over [MB]s of 31.8−9542 ppmv (Figure 1A). The detector response (GC-FID) was linear at relatively low concentrations, but above [MB] of ∼300 ppmv, the response was logarithmic possibly due to a lack of, or modification to, sorption sites on the fiber as critically discussed by Ouyang and Pawliszyn.[17] Figure 1, panel B shows a calibration plot made from GSV injections over the same detector response range; the correlation was linear throughout, which indicates that the logarithmic response at higher [MB] with DFE (Figure 1A) was not a detector artifact. It is critical to note the consequence of this nonlinear phenomenon when using DFE sampling to quantify (or predict) K_{fs} for a particular fiber. Figure 2 provides further support for these observations and shows an exponential decrease in K_{fs} (unitless) based on DFE sampling, with $t \geq 5$ min, of the airstream in the PACT system as well as in static headspace of vials. K_{fs} values derived from eq 1 versus eq 2 were consistent (slope = 0.995, r^2 = 1) and ranged from ∼10−8000 over the relevant [MB]s with the ∼300ppmv estimated upper limit of the linear response corresponding to an experimentally measured K_{fs} of 5196 (Figure S1, Supporting Information). Note that much of the robust modeling associated with SPME-based air sampling stems from analyte-fiber pairings exhibiting at least an order of magnitude greater K_{fs}values. As related to this study and the relatively low distribution of MB between the Carboxen/PDMS fiber and sample, the works of Górecki et al.[21] and Koziel et al.[22] offer theoretical insight to possibly explain observations; as K_{fs} for a given analyte and fiber decreases, the overall response across an equivalent (subsaturation) concentration regime shows less curvature (more linearity) (i.e., less pronounced linear-, kinetic-, and equilibrium regimes). Future studies will probe the mechanism and develop novel theories for SPME sampling of fumigants with Carboxen-based fiber types and

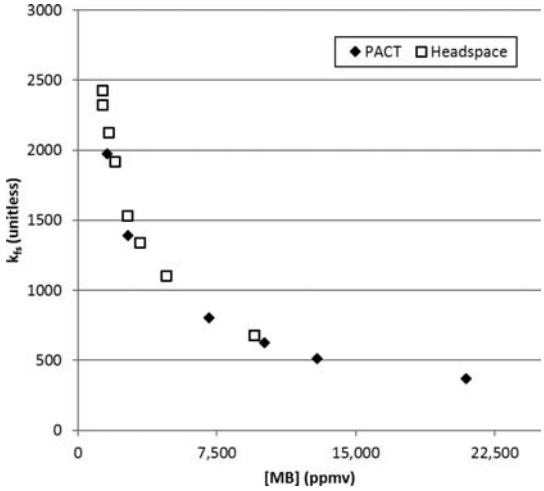

Figure 2. K_{fs} values calculated for DFE sampling of MB concentrations, with $t \geq 5$ min, in flowing (PACT,◆) and static (headspace,□) systems.

specifically address the influences of relatively low K_{fs} values on the maintenance of "zero-sink" conditions; however, such investigations are outside the scope of this manuscript, in which experimental results are described in relation to existing SPME models.

TWA Sampling. With TWA sampling, the time required for equilibrium between MB and the fibers (i.e., K_{fs} is constant, eq 1 is valid) occurs over considerably longer time scales than for DFE. With reference to the example above in static headspace, TWA sampling [MB] of 504 ppmv with t = 30 min yielded a value of m equivalent to that of a 250-μL GSV injection and ∼10-fold less than DFE with t = 5 min. Relative to DFE sampling, the longer amount of time required by TWA sampling for equilibrium can be used (advantageously) to quantify MB in ventilation effluent from postharvest chamber fumigations, as it allows for a linear detector response of [MB] values in the range of ∼20−5000 ppmv when t = 30 min (equivalent to "CT" products in the range of ∼500−150,000 ppmv min).

DOI: 10.1021/jf505193e
J. Agric. Food Chem. 2015, 63, 3094−3103

As noted in the work of Ouyang and Pawliszyn,[17] the temporal interval(s) of TWA sampling should occur when $t < t_{50,x}$, which was calculated and tabulated (Figure 3) for six

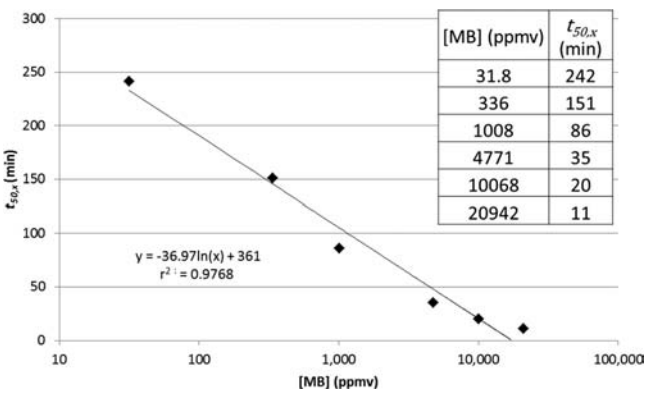

Figure 3. Approximate $t_{50,x}$ values calculated using eq 8 with m_{eq} values determined by DFE sampling of [MB] in static headspace with a t = 5 min.

different fumigation-relevant [MB]s using a modification to eq 5:

$$t_{50,x} = \frac{0.5m_{eq}}{C_x SR} \quad (12)$$

where m_{eq} is measured experimentally by DFE sampling with t = 5 min at a given concentration, C_x. Twenty-two separate measurements using TWA sampling of either static headspace or the PACT system at fixed [MB] were used to calculate SR, (1.416 ± 0.09) × 10^{-4} cm^3/s ($\bar{x}$ ± s), a lower value than calculated by solving eq 4 using D = 0.114 cm^2 s^{-1}.[23] The suggestion that the value of SR be derived from measurement, rather than literature reference, is consistent with the work of Ouyang et al.,[24] which linked this discrepancy, at least in part, to an instrument-specific difference in the amount of analyte entering the GC inlet versus that transferred onto the analytical column.

Calibration from Flowing Systems. Several approaches to detector calibration can be utilized if the temporal interval(s) of TWA sampling occur when $t < t_{50,x}$. Figure S2A of the Supporting Information shows the adjusted GC-FID detector response $Area_{Adj}$ versus "CT" products from TWA sampling of MB flows in the PACT system. Different [MB] values were sampled with t = 10 min (diamonds), and constant [MB] was sampled while varying t (squares) (each point represents the response from one fiber). Note the utility of the later calibration approach for use with TWA sampling of the PACT system at fixed [MB], as the entire range of relevant "CT" products can be obtained by varying the span of time, t, that the fiber assembly is exposed to airstream; as described above, this approach was used to calibrate FID detector response relative to PACT airstreams metered to ∼2500 or 11,000 ppmv over exposure (i.e., sampling) times of 0.75, 1.5, 3.0, 6.0, 10, and 15 min, which encompass $\bar{C}$ values in the range of ∼60−6000 ppmv when t = 30 min (Figure S3, Supporting Information).

Calibration from Static Systems. If SR is known, the relationship between m and $\bar{C}$ can be calculated using eq 5, which thereby allows detector response from TWA sampling to be calibrated based on measurements of MB in static headspace. Calibration in static headspace can accommodate a wider range of [MB]s than what may be achieved in flowing systems, which can be operationally restricted by the physics of mass-flow controllers or rotameter(s). For example, MB flows in the PACT system were metered to either 1562 or 10,068 ppmv (theoretical), and six channels (n = 6) were sampled using the TWA technique with t in the range of 0.5−15 min. Figure S2B of the Supporting Information shows the agreement between theoretical [MB]s and those detected based on calibrations derived from sampling static headspace using either GSV injections of MB dilutions (white) or TWA sampling of different [MB]s with t = 5 min (gray).

Advantage of Using TWA versus DFE Sampling with PACT. The effect of the airstream flow rate on the quantification of MB in the PACT system was evaluated. Airflows of 75 mL min^{-1} or 224 mL min^{-1} were establish as the outlet flow from each channel of the PACT system with [MB]s metered to 5092 ppmv or 548 ppmv for TWA and DFE sampling, respectively. For both sampling approaches, a t test showed no difference at the 99% confidence interval between MB quantification at either flow rate (TWA, t test: t_4 = 0.7436, $P > |t|$ = 0.5023; DFE, t test: t_6 = 0.6214, $P > |t|$ = 0.5680).

However, if the simulated ventilation of a postharvest chamber fumigation (vide supra) is sampled using the TWA technique with a t of 30 min, an average [MB] of 3434 ± 211 ppmv (n = 35, $\bar{x}$ ± s) (5 replicate analyses of 7 samplings) was obtained, which agrees well with a calculated $\bar{C}$ of 3731 ppmv MB. It is interesting to note the accuracy of TWA sampling for MB quantification in the PACT system despite changes in concentration over the sampling interval, a period where no MB is released, and a relatively short exposure to the highest [MB]. This result is in marked contrast to DFE "instantaneous grab" sampling in the PACT system with a single fiber (i.e., without temporally exchanging fiber assemblies) and t = 30 min, where m would be based overwhelmingly on the [MB] in the minutes preceding the conclusion of the simulated ventilation, rather than the total amount of MB in the effluent over that time.

TWA Sampling of PACT: Handling, Parametrics, Interferents, and Limits of Detection. Desorption of MB from the SPME fiber over the time that lapsed between sample acquisition and analyses was evaluated. With respect to TWA sampling of the airstream in the PACT system, the fiber guide was capped by burying it into a septum (to seal the tip of the fiber guide) immediately following acquisition for a "hold" time of 0, 30, 60, or 195 min. Alternatively, the fiber guide was analyzed without being buried in a septum after "hold" times of 0 or 60 min. Figure S4 of the Supporting Information shows a linear least-squares analysis of the data (solid line = with septa: r^2 = 0.2074, $F_{1,46}$ = 12.0366, P = 0.0011; dashed line = without septa: r^2 = 0.8026, $F_{1,26}$ = 105.707, P < 0.0001); burying the fiber into the septum resulted in minimal MB loss over ∼30 min (solid line), with just 0.089% loss per minute. Without burying the fiber into a septum, a statistically significant loss (95% confidence interval) of MB occurred after ∼11 min (solid red vertical line), consistent with a 0.4% loss of MB per minute.

Experiments were conducted to address the possibility that a nontarget compound, or interferent, could compete for sorption sites on the fiber and impact the quantification of MB using TWA sampling. The PACT system was metered to a [MB] of about 725 ± 53.13 ppmv ($\bar{x}$ ± 95% CI) with either ∼25% "dry" or ∼75% RH " wet" airstreams, and six channels (n = 6) were sampled for 15 min using the TWA approach. Three independent replicate analyses were performed for each

DOI: 10.1021/jf505193e
J. Agric. Food Chem. 2015, 63, 3094−3103

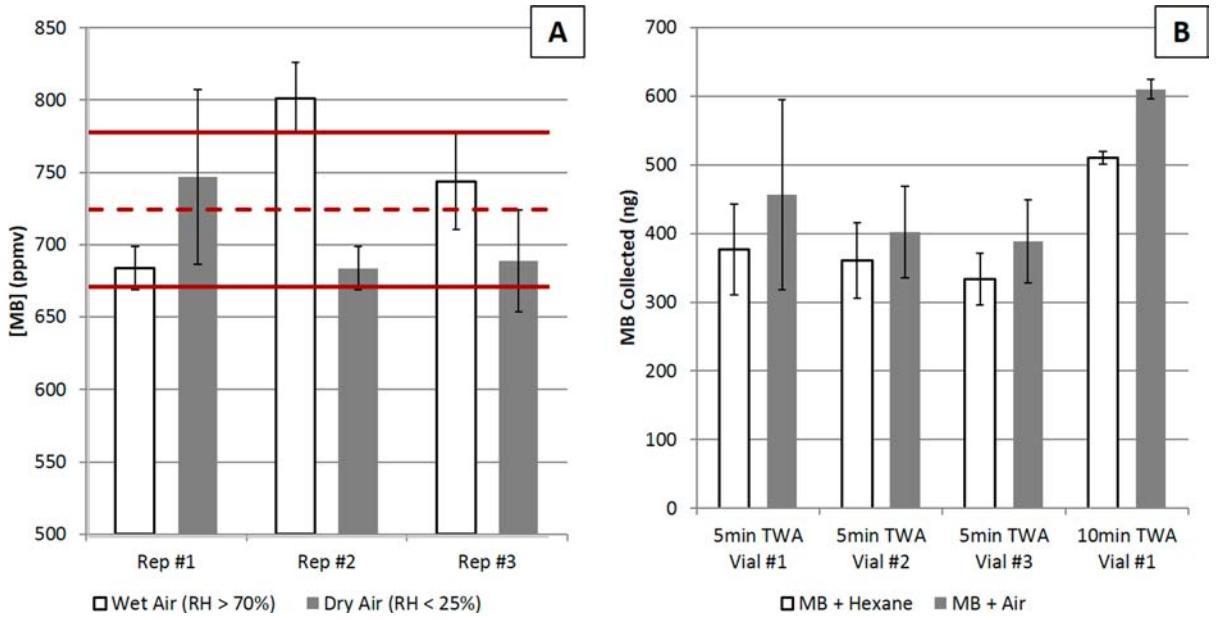

Figure 4. Effects of interferents with values reported as $\bar{x} \pm s$: (A) TWA sampling of [MB] from either humid (≥70% relative humidity (RH)) or dry (≤25% RH) airstreams (dashed red line indicates the theoretical concentration, solid red lines the 95% confidence intervals), (B) mass of MB on fiber (m) via TWA sampling of static headspace with or without hexane.

condition, and the [MB] was calculated from a calibration curve based on response under dry conditions. When mean [MB]s for each of the six analyses were adjusted for model uncertainty, there was no significant difference between wet and dry conditions (Figure 4A).

Hexane, which has a higher vapor pressure relative to H_20,[25] was selected as a surrogate volatile organic carbon (VOC) interferent to MB quantification. A [MB] of about 1040 ppmv was established in the static headspace of eight vials, and then 1 mL aliquots of the headspace were removed. Four of the vials then received 1 mL aliquots of air, while the other four were fortified with 1 mL aliquots of ~170,000 ppmv hexane in air. Three vials, both with and without hexane fortifications, were sampled with t = 5 min using the TWA technique, while the remaining two vials were with t = 10 min (Figure 4B). On the basis of triplicate analyses, a consistently lower (357 ± 22 ng) ($\bar{x} \pm s$), but not statistically distinct, amount of MB was detected in the hexane-fortified vials relative to the control (416 ± 36 ng) with t = 5 min (t test: $t_{16} = -1.7304$, $P < t = 0.0514$). Interference was more pronounced with t = 10 min, as ~20% less MB (510 ± 9 ng) (n = 3, $\bar{x} \pm s$) was detected in the hexane-fortified vial relative to the control (610 ± 14 ng MB) (t test: $t_4 = -10.337$, $P > |t| = 0.0005$). This result suggests that with longer sampling times, compounds with physiochemical properties similar to hexane may affect TWA sampling of MB in the PACT system.

SPME is a sampling technique, not a method of analysis; the ability to resolve the signal for MB from any interferents and background depends on the method of analysis used. As with interference, the limit of detection (LOD)[26] is dependent on the instrument and parameters used for analysis. For TWA sampling of MB in the PACT system, determining a LOD was complicated by physical limitations of the rotameters, which could not be metered below [MB] of ~1100 ppmv. At this lower limit of [MB], the LOD was 14.7 ng MB based on seven replicate (n = 7) TWA samplings with t = 30 s and subsequent GC-FID detection, which corresponds to an average $\bar{C}$ of 14.9 ppmv over the 30 min timespan (t = 30 min) of the simulated ventilation.

Quantifying Sorbed MB on PACT: TWA versus Gravimetric Methodology. In addition to measuring $m_{entering}$ via TWA sampling of a column containing no sorbent, the mass of MB lost from the cylinder was tracked to provide an analogous estimate, $m_{entering-grav}$, in the form

$$m_{entering-grav} = (m_{cyl\text{-}f} - m_{cyl\text{-}i}) \times flow_{PACT}/flow_{column} \quad (6a)$$

where $m_{cyl\text{-}f}$ and $m_{cyl\text{-}i}$ are respectively the final and initial mass of the cylinder and $flow_{PACT}$ and $flow_{column}$ are the total PACT flow into the manifold (~23,502 mL min^{-1}) and an individual column (~224 mL min^{-1}), respectively.

Figure 5 shows the relationship between the quantification of MB across eight serial doses (Dose$_n$, where n = 1, 2, 3, ...8) of the PACT apparatus using gravimetric- versus TWA SPME-based methodologies. Note the agreement between the slope of the line obtained from a least-squares analysis (m = 0.75) and

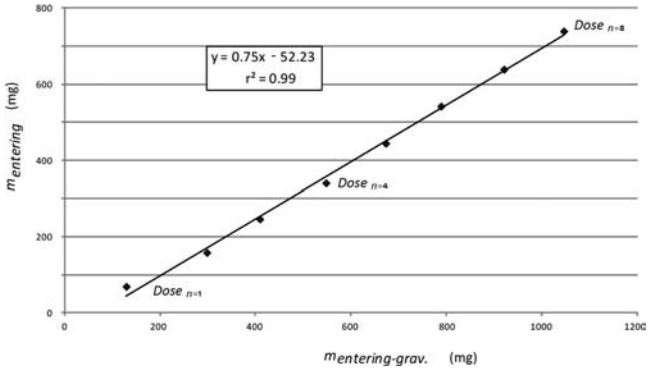

Figure 5. Relationship between the quantification of MB across eight serial doses to the PACT apparatus (Dose$_n$,where n = 1, 2, 3, ...8) using gravimetric measurement ($m_{entering-grav}$)) of MB loss from the source cylinder versus SPME-based TWA sampling of a column containing no sorbent ($m_{entering}$).

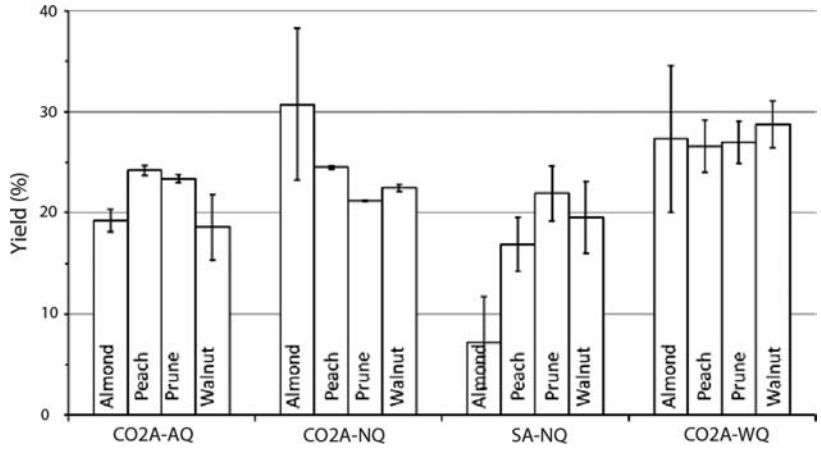

Figure 6. Yields (n = 4, bar height = $\bar{x}$, error bars = ± s) of each type of preparation (CO_2-activated air-quenched (CO2A-AQ), CO_2-activated nitrogen-quenched (CO2A-NQ), steam-activated nitrogen-quenched (SA-NQ), and CO_2-activated water-quenched (CO2A-WQ)) for each source of activated carbon sorbent (almond shell, peach pit, prune pit, and walnut shell) were estimated as a percentage of the mass of material after quenching relative to the mass of starting material loaded into the tube furnace prior to pyrolysis.

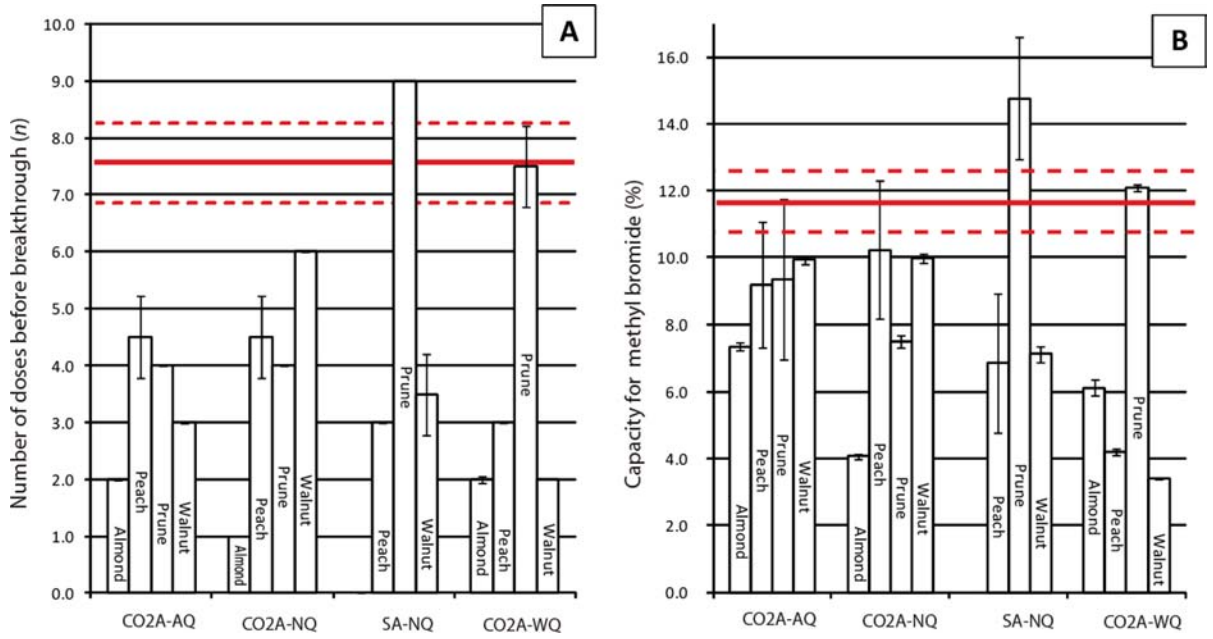

Figure 7. Number of doses needed to first observe breakthrough (A) and the capacity (%) to sorb MB (B) were used as measures of sorbent performance and evaluated for each type of preparation (CO_2-activated air-quenched (CO2A-AQ), CO_2-activated (CO2A-NQ), steam-activated (SA-NQ), and CO_2-activated water-quenched (CO2A-WQ)) and each source of activated carbon (almond shell, peach pit, prune pit, and walnut shell), where bar height = $\bar{x}$, error bars = ± s, and n = 2. Commercially marketed activated carbon, Westates Vocarb 48C (WEST-AC) served as a benchmark of comparison (n = 18) with results shown ±95% confidence intervals (dashed red lines).

the average ratio, 0.737 ± 0.055 (ave. ± stdev., $\bar{x} \pm s$, n = 8), of MB concentrations measured by TWA SPME, $m_{entering}$, relative to gravimetric methodology, $m_{entering-grav}$. We have interpreted this difference to be a result of MB losses to the system forward of the SPME sampling ports. This result identifies that TWA SPME measurements of $m_{entering}$ should be used, whenever possible, to quantify MB in airstreams of the PACT apparatus. Additionally, this result supports the conclusion that MB loss due to system was consistent across trials and that experiments involving the PACT apparatus be conducted in facilities with sufficient ventilation (e.g., fume hoods) to minimize MB inhalation exposure to individuals conducting the tests.

Commercially Sourced Activated Carbon Sorbent "Benchmark". WEST-AC, derived from coconut shell, served as a commercially marketed "benchmark" of comparison for the various preparations of activated carbon sorbents from tree fruit pits and tree nut shells. WEST-AC, randomly selected from one of four different commercial batches, was loaded into two columns of the PACT apparatus, and nine replicate tests were conducted to evaluate, as measures of performance, the capacity for MB (%) and the number of doses needed to first observe BT. One-way ANOVAs were not significant (capacity: $F_{(17, 0.006)}$ = 2.273; P = 0.1215, BT: $F_{(17, 0.004)}$ = 2.531; P = 0.1562), which indicates that the overall average capacity, 10.9 ± 1.8% ($\bar{x} \pm s$), as well as the average number of doses applied before BT, 7 ± 1 ($\bar{x} \pm s$), could be used to estimate the performance of WEST-AC irrespective of the batch.

J. Agric. Food Chem. 2015, 63, 3094−3103

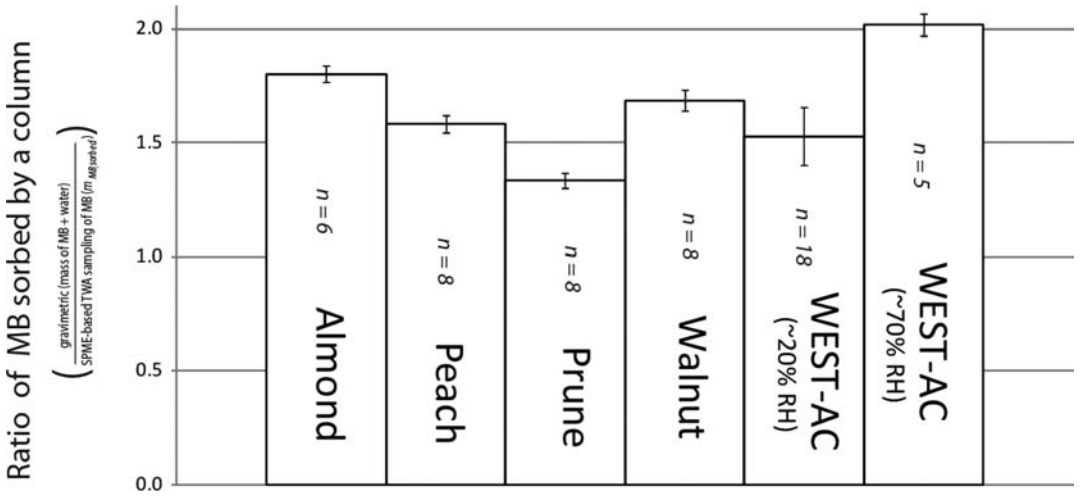

Figure 8. Results from PACT testing of all activated carbon preparations were grouped by type of carbon source. The grand mean of the mass of MB (and water) sorbed by a particular column based on gravimetric measurement was normalized relative to that detected by SPME-based TWA sampling, $m_{MB,sorbed}$. Results suggest the discrepancy between the ability of carbon source types to sorb MB was related to the source-specific competitive sorption of water vapor.

Tree Fruit Pit and Tree Nut Shell Activated Carbon Sorbents. The average yields across all preparations and sources of activated carbon sorbent, ranged from 7−31% (w/w) and were estimated as the fractional percentage of the mass after quenching relative to the mass of starting material loaded into the working tube prior to pyrolysis (Figure 6). A one-way ANOVA was significant ($F_{(15,\ 0.0476)} = 5.262$; $P = 0.015$), which indicated that the overall average yield across all preparations and carbon sources, 22 ± 6% ($\bar{x} \pm rsd$), was not an accurate indicator of all yields. Means comparison testing only showed significant difference between yields for CO2A-WQ and SA-NQ preparations, independent of source carbon type (Tukey-Kramer HSD, $\alpha = 0.05$). The yield of activated carbon sorbent prepared by SA-NQ from almond shells was <10%, far below any other preparations, which suggests an unlikely prospect of its commercial use to remove MB in ventilation effluent from postharvest chamber fumigations.

The performance of each type of preparation and source on the PACT tests, expressed as both the number of doses needed to first observe BT (Figure 7A) as well as the corresponding capacity for MB (%) (Figure 7B), were evaluated relative to results for WEST-AC. Activated carbons from prune pits prepared by CO2A-WQ as well as SA-NQ resulted in the greatest number of doses needed to first observe BT, ∼7.5, and the highest corresponding capacity, ∼12−14%. CO2A-AQ and CO2A-NQ preparations of activated carbon from prune pits as well as all preparations of activated carbons from peach pits and walnut shells reached BT in ∼3−6 doses and had capacities ranging from 4−7%. Regardless of preparation, activated carbons derived from almond shells performed relatively worse, as is clearly demonstrated by fewer number of doses needed to first observe BT.

In an attempt to correlate the performance of activated carbon derived from peach pits, prune pits, almond shells, and walnut shells to the type of carbon source, data were analyzed to indirectly probe the competitive sorption of water vapor and its potential influence on the sorption of MB. Results from PACT testing of preparations were grouped by type of carbon source, and the grand mean of the mass of MB (and water) sorbed by a particular column at BT based on gravimetric measurement was normalized relative to that detected by TWA SPME sampling, $m_{MB,sorbed}$ (Figure 8). Given the finding that TWA-SPME quantification, and thus $m_{MB,sorbed}$, is unaffected across a range of ∼20−80% RH (see Figure 4A), a likely explanation for the discrepancy in performance was the preferential sorption of water vapor by carbon source types. It is critical to note that activated carbons derived from prune pits had the lowest ratio (of water sorbed relative to MB sorbed), and those derived from almond shells had the highest ratio. A one-way ANOVA was significant ($F_{(14,\ 0.835)} = 3.983$; $P = 0.038$), which indicated that the overall average ratio across carbon sources, 1.45 ± 0.2% ($\bar{x} \pm sd$), was not a representative estimate for each carbon source. Subsequent means comparison testing only showed significant difference between prune- and almond-derived activated carbon sorbents (Tukey-Kramer HSD, $\alpha = 0.05$).

The interpretation that the performance of activated carbon derived from almond shells, peach pits, prune pits, and walnut shells was related to the source-specific competitive sorption of water vapor was further supported by an experiment conducted with WEST-AC. The relative humidity in the PACT system was increased from ∼25−70%, WEST-AC was loaded into five columns, and eight tests were conducted that evaluated, as above, the grand mean of the mass of MB sorbed by a particular column based on gravimetric measurement normalized relative to that detected by SPME-based TWA sampling, $m_{MB,sorbed}$ (see Figure 8). The ratio resulting from the PACT testing at ∼70% RH was significantly higher at the 99% confidence interval than that obtained with ∼20% RH (t test: $t_{21} = 2.0796$, $P > |t| = 0.0003$).

It is interesting to note the selectivity of each activated carbon source for water vapor as related to the MB removal from the airstreams of the PACT apparatus. Data suggest that the two preparations of activated carbon from prune pits that used water vapor for either activation, SA-NQ, or quenching, CO2A-WQ, imparted a surface modification that decreased the potential for competitive sorption and ultimately resulted in more MB removal from the airstream per mass of activated carbon sorbent. Future studies will focus on scaling, from gram- to kilogram-scale, the production of prune pit-derived activated carbon prepared by SA-NQ and CO2A-WQ. If the preparations are effectively scaled, as assayed by performance on the PACT

DOI: 10.1021/jf505193e
J. Agric. Food Chem. 2015, 63, 3094−3103

apparatus, the logical extension would be to conduct confirmatory trials in which ventilation effluent following a commercial postharvest chamber fumigation was directed through a columnar bed of the respective prune pit-derived activated carbons, with subsequent evaluation of MB removal performance.

AFG_1, AFG_2), ochratoxin (OTA), fumonisins (FB_1, FB_2) HT-2 and T-2, and their respective stable carbon-labeled isotopes (^{13}C-AFB_1, ^{13}C-AFB_2, ^{13}C-AFG_1, ^{13}C-AFG_2, ^{13}C-OTA, ^{13}C-FB_1, ^{13}C-FB_2, ^{13}C-HT-2 and ^{13}C-T-2). Negative polarity was applied for the analyses of deoxynivalenol (DON) and zearalenone (ZEA), and their stable carbon-labeled isotopes (^{13}C-DON and ^{13}C-ZEA). Electrospray voltages were set to 5.5 kV for positive ionization polarity and −4.5 kV for negative ionization polarity. The source temperature and nitrogen gas flows (GS1 and GS2) were set to 500 °C and 40 psi, respectively. A summary of precursor ions, their respective retention times, and MS conditions is listed in Table 1.

Materials and Reagents. Acetonitrile (MeCN) and MeOH were of HPLC grade from Labscan (a brand from

DOI: 10.1021/acs.jafc.5b00471
J. Agric. Food Chem. 2015, 63, 3104−3113

Sigma-Aldrich). HPLC grade NH_4-formate, acetic acid, and benzene were purchased from Sigma-Aldrich (St. Louis, MO, U.S.A.). Water was purified by passing through a Purelab Option-Q water purification system (a brand from Elga, U.K.). Analytical standards of aflatoxins, OTA, and fumonisins were purchased from Sigma-Aldrich, whereas HT-2, T-2, DON, and ZEA were purchased from Biopure (Tulln, Austria). Stable carbon isotopic standards of all 11 mycotoxins were purchased from Biopure (Tulln, Austria). Purity of the standards and their respective ^{13}C-labeled isotopes is summarized in Table 2. Stock preparation of Aflatoxins and OTA was reproduced from previous work.[10] Briefly, an individual stock solution of aflatoxins was prepared by dissolving in benzene (to extend the shelf life of aflatoxins). For OTA, methanol was selected as solvent of choice. Stock solutions of FB_1 and FB_2 were prepared in 50% MeOH and then diluted using mobile phase B. Next, individual stock solution of HT-2, T-2, DON, and ZEA was prepared in MeCN. From these individual stock solutions, mixed calibrants of all 11 analytes were freshly prepared, by dilution, using mobile phase B at six concentration levels as shown in Table 2. For aflatoxins, an additional drying step (under a gentle stream of nitrogen gas) was required to remove benzene prior to preparation of mixed calibrants. ^{13}C-AFB_1, ^{13}C-AFB_2, ^{13}C-AFG_1, ^{13}C-AFG_2, ^{13}C-OTA, ^{13}C-FB_1, ^{13}C-FB_2, ^{13}C-HT-2, ^{13}C-T-2, ^{13}C-DON, and ^{13}C-ZEA were applied for spiking experiments and commercial sample screening. Concentrations ranged from 1 μg/L for ^{13}C-AFG_2 to 20 μg/L for ^{13}C-FB_2. All chemicals were used without further purification.

Sample Preparation and Extraction. Rice samples from 9 Asian countries were investigated in this work, as follows: P.R. China (6 samples, white rice), India (31 samples, parboiled rice and basmati rice,), Japan (26 samples, white rice and brown rice), Malaysia (6 samples, white rice and brown rice), Myanmar (2 samples, broken rice), Pakistan (15 samples, basmati rice), Taiwan (10 samples, white rice), Thailand (79 samples, white rice, brown rice and red rice) and Vietnam (15 samples, white rice and brown rice) were purchased from a local distributor in Singapore. An aggregate sample of 1 kg (minimum) was required for retail sampling (European Union Commission Regulation 401/2006). White rice, brown rice, red rice, and basmati rice were randomly selected from the pool of 190 rice varieties and tested for mycotoxins before the selected sample was used for the matrix effect assessment, recovery, and individual analyte stability study.

Before performing extraction, an individual rice sample (approximately 1 kg) was milled using Ultra Centrifugal Mill ZM 200 from Retsch (a brand from Haan, Germany), which was fitted with a ring sieve with an aperture size of 0.5 mm. For a sample size of 1 kg, three batches of milling were required because the miller has a capacity limit of 400 g for rice samples. A household blender was then used to blend the milled samples. To ensure minimum carry over between rice samples' preparation, potato starch powder was applied to both the miller and the household blender, and then discarded.

Sample extraction was developed with the intention of ease of execution and low cost of operation for a routine laboratory. Rice extraction was performed by applying a modified sample extraction protocol reported by Sulyok et al.[11] and Varga et al.[12] for maize analysis. A 1 g sample weight was used to determine matrix effects and recovery. Single extraction using an equal volume of MeCN and purified water containing 1% acetic acid was applied. Briefly, 4 mL ($v1$) of extraction solvent was added to a 1 g (w) sample in a 50 mL taper tube and shaken for 30 min. Then, the mixture was centrifuged at 8000 rpm (3226g) for 6 min at room temperature. Next, 1:1 dilution ($v2$) using mobile phase B was performed. Individual isotopic standards were added to the diluted supernatant and shaken vigorously by hand, and the samples were then purified using a 0.2 μm PTFE syringe filter before they were transferred into 1.5 mL HPLC amber vial with deactivated inserts. Finally, 10 μL of purified supernatant was injected into the LC-MS/MS for analysis. By applying this sample purification protocol for method validation and commercial sample screening, a solute to solvent ratio of 1:8 can be achieved. For commercial rice samples screening, a scaled-up extraction protocol was applied to a 25 g sample weight portion.

Data Processing for LC-MS/MS. The data were analyzed using the quantitation wizard built into Analyst software 1.6.0 for windows (AB Sciex, Foster City, CA, U.S.A.). Transition ions representing individual analytes were summarized in Table 1. The most abundant transition ion of each isotope was used to perform quantitative analysis.

Evaluation of Matrix Effect and Detection Limit. The intention of performing matrix effect assessment is to examine ion signal enhancement/suppression due to coextractants originating from the rice matrix over a practicable concentration range. A 1 g rice sample was first extracted, followed by spiking at six concentration levels. Isotopic dilution was not applied. The application of the post-extraction spiking strategy identified ion signal enhancement/suppression due to matrix interference and distinguished them from effects due to recovery. Spiking levels (A, in μg/kg) were determined as

$$A = [(\text{spiking concentration}/w)] \times v1 \times 2 \quad \text{(eq A.1)}$$

Six levels of spiking concentration were generated by applying eq A.1, as summarized in Table 2 (n = 3). Matrix effect (ME) was evaluated as[13]

$$\text{ME} = (\text{peak area of matrix-matched}/\text{peak area of matrix-free}) \times 100 \quad \text{(eq A.2)}$$

Linearity was assessed using a residual plot and statistical test for goodness-of-fit. Limits of detection (LOD) and limits of quantitation (LOQ) were determined as (2.33 × standard deviation)/gradient of slope and LOD + (1.64 × standard deviation)/gradient of slope, respectively.[14]

Recovery, Intraday, Interday Repeatability and Stability Studies. Fumonisins are known to suffer from poor recovery in maize based on reports published previously.[11,12] Losses can occur during sample preparation and during storage. In this study, we examined the fate of all 11 analytes (including fumonisins) in rice through spiking experiments, and by using normal and deactivated glass inserts for storage. Briefly, 1 g aliquots (n = 6) of rice samples were spiked at three concentration levels (standard 2, 3, and 5) and extracted using protocols described in the section Sample Preparation and Extraction. Matrix-free calibration curves at six concentration levels (Table 2) were freshly prepared for recovery study. Isotopic dilution was applied. Recovery (extraction efficiency, R) was assessed as

$$R = [(\text{mean measured concentration}_{\text{standard2,3,5}}) / (\text{spiked concentration}_{\text{standard2,3,5}})] \times 100 \quad \text{(eq A.3)}$$

using the respective calibration curves of individual mycotoxin.

For analyte stability study, two sets of matrix-free calibrants were required. The first set of calibrants was used for recovery

Sweden	rice (basmati, brown, jasmine)	AFB_1, AFB_2, AFG_1, AFG_2, OTA	99	(Fredlund et al., 2009)
Turkey	rice	total aflatoxin, AFB_1, OTA	100	(Aydin et al., 2011)
United Kingdoms	rice and rice products (long grain, easy cook, basmati, specialty, brown, short grain, flaked, ground)	aflatoxins, fumonisins, OTA, sterigmatocystin, tricothecenes, ZEA	100	(FSA, 2002)
Vietnam	rice	AFB_1, citrinin, OTA	100	(Nguyen et al., 2007)

experiments. The same set of sample vials used for recovery experiments were measured 1 month later using freshly prepared calibrants. Sample vials were stored at 4 °C when not in use. This way, information related to individual analyte stability in solution and in matrix can be obtained.

In addition, effects of acetic acid on recovery for all analytes including fumonisins in selected white rice were investigated. This study was motivated by a report on degradation of fumonisins in various samples of Thai white rice.[15] For this purpose, spiking experiments (at standard 2 concentration) were conducted in triplicates for each composition of acetic acid (extraction solvent containing 0.1% and 1% acetic acid, respectively) by applying the protocols described in the section Sample Preparation and Extraction. To distinguish losses due to degradation from losses due to extraction inefficacy, single concentration calibrant (standard 2) was prepared in supernatant. Measurements were performed 12 h later to simulate degradation in matrix reported previously.[15] Isotopic dilution was then applied. Recovery for individual analytes was calculated using eq A.3.

Screening of Commercial Samples. A total of 190 rice samples were screened for aflatoxins, OTA, fumonisins, HT-2 and T-2 toxins, DON, and ZEA. Duplicate testing was performed on suspect samples. An average of the two values was reported. Owing to a lack of reference materials containing all 11 mycotoxins in rice, compensation for recovery for individual analyte was made by spiking.

Statistical Analysis. Two-tailed Student's *t*-test was applied to identify significant differences between two sets of experimental data at 95% confidence level,[16] where applicable. To determine the correlation between mycotoxins contamination and rice species, Pearson Correlation (r) was calculated for results obtained described in the section Screening of Commercial Samples by assigning rice species (count) as (X) and mycotoxins positive samples as (Y).

RESULTS AND DISCUSSION

MS Method, Mobile Phase Selection, and Chromatography. Applying MS for multimyotoxins detection in rice is not new.[17,18] Common to these publications, aflatoxins, fumonisins, deoxynivalenol, zearalenone, ochratoxin A, T-2 and HT-2 toxins in rice were examined using analyte-specific sample purification columns. In this study, we applied a simple dilute-and-shoot workflow to determine aflatoxin B_1 (AFB_1), B_2 (AFB_2), G_1 (AFG_1) and G_2 (AFG_2), deoxynivalenol (DON), fumonisins (FB_1 and FB_2), T-2 and HT-2 toxins, ochratoxin A (OTA), and zearalenone (ZEA) in rice. Our choice of mycotoxins is based on mycotoxins' occurrence reports published previously, as shown in Table 3.[19−33]

For MS method selection, we applied scheduled MRM because only targeted analytes at their respective retention time were monitored. The application of scheduled MRM provided the benefit of decreasing the number of concurrent MRMs monitored at the same time.[34] This way, we were able to achieve reproducible peak symmetry and optimum data quality by adhering to the guideline of 10 to 15 data points per peak even when concurrent polarity switching was applied for the entirety of our experiment.[35] In our work published previously, MS^3 was applied as an accurate tool to identify and quantify aflatoxins and OTA in chilli matrices because it exhibited superior resilience to ion ratio distortion for AFG_2 and OTA.[10] In this study, however, the application of scheduled MRM was fit-for-purpose for quantification of multimycotoxins in rice because ion ratio distortion was absent.

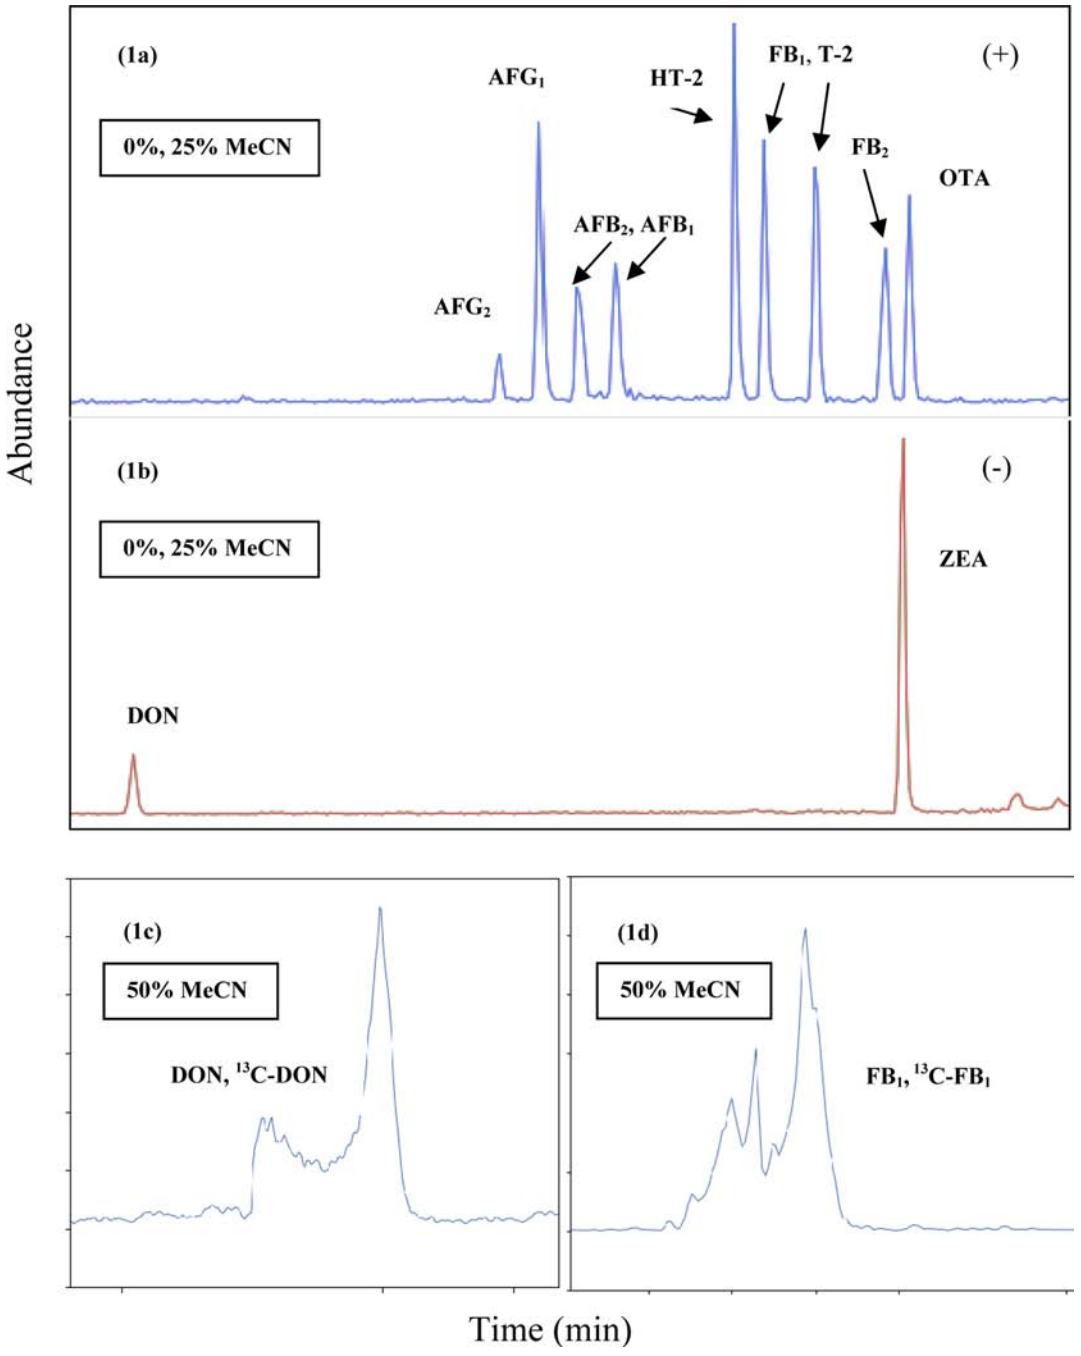

Figure 1. LC-MS/MS separation and detection showing current polarity switching for concentration **S1** (1a) total ion chromatograms of AFG_2, AFG_1, AFB_2, AFB_1, HT-2, FB_1, T-2, FB_2, and OTA. (1b) Total ion chromatograms of DON and ZEA prepared in mobile phase B and 25% MeCN. (1c) and (1d) show distorted ion chromatograms of DON and FB_1 (as well as their respective isotopes) at 50% MeCN strength.

For mobile phases selection, we considered the ionization efficacy of aflatoxins and HT-2 toxin in acetonitrile and methanol individually. For aflatoxins, we reported previously that the addition of 1 mM ammonium formate to both the extraction solvent and mobile phase would yield a combined ion signal improvement of 3 orders of magnitude based on triplicate measurements[10] using triple stage mass spectrometry (MS^3). Under MRM mode, adding 1 mM ammonium formate to the extraction solvent provided insignificant ion signal enhancement for aflatoxins. The addition of ammonium formate to both mobile phases A and B alone enabled measurements for sub μg/L (~0.01 μg/L) concentrations of AFB_1, AFB_2, AFG_1, and AFG_2 to be made. In order to improve the ionization efficiency of NH_4-adduct for HT-2 toxin under positive polarity,[10] we chose methanol over acetonitrile as mobile phase A. Experimentally, LOD for HT-2 from 50 μg/kg to 2.3 μg/kg in white rice. Similarly, the addition of 0.1% acetic acid converted DON into its acetate adduct for MRM quantitation.[36] The transitions monitored for DON in this study is different from those reported previously[12] because the QTRAP 5500 did not generate useful fragmentation pattern for $[DON + H]^+$. We attribute the difference in fragmentation reaction for $[DON + H]^+$ to be collision-cell-specific. Selection of methanol and water as mobile phases of choice (containing 1

[a]Average matrix effect (%) = (peak area of matrix-matched/peak area of matrix-free) × 100.

mM ammonium formate and 0.1% acetic acid) would provide the optimum chemical environment needed to examine individual analyte on our proposed LC column.

There were challenges related to peak shape reproducibility when we performed rice extraction without applying dilution using mobile phase B. Briefly, we found the peak shapes for both DON and FB_1, as well as their respective isotopes were severely distorted. Performing 1:1 dilution (25% MeCN) using mobile phase B preserved peak shape integrity for both DON and FB_1. Figure 1a,b showed the total ion chromatogram representing individual mycotoxins when prepared in water dominant mobile phase B (respective isotopically labeled peaks not shown) and 25% MeCN. Figure 1c,d showed distorted peaks for DON and FB_1 in extraction solvent (50% MeCN) without 1:1 dilution. Although peak shape integrity is easily dismissed by some researchers as cosmetic imperfection due to poor chromatographic skills, we observed significant variation for precision (RSD > 50%) at three spiking concentrations in rice for both DON and FB_1. Clearly, adopting good chromatographic separation practices provided data confidence through repeatability assessment.

Evaluation of Matrix Effect. Matrix effect or the occurrence of ion-suppression or enhancement in quantitative analysis using LC-ESI-MS/MS was reported previously.[37] It has a significant impact on method integrity by giving inaccurate and unreliable results, thereby affecting reproducibility, linearity, and recovery values. Thus, matrix effect was evaluated at six concentration levels using both matrix-free and matrix-matched calibration curves to assess analyte performance without internal standards.

A summary of matrix effect on LC-MS/MS using MRM is tabulated in Table 4. In particular, fumonisins showed severe ion signal enhancement effect in all rice matrices at all six concentration levels, ranging from 100 to 5730%. Ion signal suppression for aflatoxins ranged from 40% to 97%. For OTA, T2 and HT2 toxins, DON, and ZEA, effect of ion signal enhancement or suppression were observed. Mechanisms such as competition for available charges and access to droplet surface for gas phase emission,[37] among others, could explain the wide ranging matrix effect results shown in Table 4. Although matrix effect in some rice was reported previously,[38] there was no mention of significant variation in matrix effect for fumonisins in white rice, brown rice, red rice, and basmati rice. Application of *dilute-and-shoot* strategy alone was insufficient to compensate for matrix effect. Isotopic dilution was therefore applied.

Evaluation of Recovery, Linearity, Intraday, Interday Repeatability and Stability. We investigated the recovery performance of all analytes in white rice, brown rice, red rice, and basmati rice. From Table 5A, we found there is no evidence to show mycotoxins can degrade in white rice extract from Thailand/China. However, we did observe recovery losses for all analytes when 0.1% acetic acid was applied to the initial extraction solvent (Table 5B) for some rice samples from Thailand/China. From Table 5C, the presence of 1% acetic acid in the extraction solvent provided significant recovery improvement ($p < 0.05$) for all analytes (including fumonisins) in white rice samples from China/Thailand. Although the use of 1% acetic acid for extraction of mycotoxins was reported previously,[11,38] the data reveal the reason it is used.

Our recovery study aimed to assess method accuracy, precision, and repeatability by performing spiking using rice blanks ($n = 6$) made at three concentration levels. Recoveries were evaluated using matrix-free calibration curves with internal

[a]Experiments for recovery were performed at S2 spiking concentration in triplicates, with isotopic dilution. [b]Measurements were performed 12 h later to simulate "degradation" in rice extract. [c]Measurements were performed immediately after extraction. *Indicates significantly different from values obtained at 0.1% acetic acid[b] composition, ($p < 0.05$) at 95% confidence interval.

standards added. Mean recoveries, intraday and interday relative standard deviation (RSD) values were calculated and shown in Table 6. RSD values were less than 15% for all analytes.

From Table 6, satisfactory recovery values ranged from 70% to 120% were achieved for all analytes in all rice matrices. The application of single extraction protocol containing 1% acetic acid provided recovery advantage for fumonisins in all rice matrices without the need to apply double extraction protocols to address fumonisins' losses such as in maize.[12] The sample extraction protocol presented in this study is also suitable for maize analysis (based on FAPAS 04223 Proficiency Test) because it produced a satisfactory z-score value of <0.7 for all analytes. Method precision and accuracy fulfils the performance criteria for aflatoxins, OTA, fumonisins, T-2 and HT-2 toxins, DON, and ZEA in foodstuffs.[14]

For the same set of sample vials (1 month old) containing spiked solution of aflatoxins, OTA, fumonisins, T-2 and HT-2 toxins, DON, and ZEA, recovery values were greater than 150% for all analytes except for fumonisins. When the same set of sample vials were determined using a set of freshly prepared calibrants, significant losses of more than 50% was reported for most analytes except fumonisins. Fumonisins did not undergo significant degradation ($p < 0.05$, $n = 3$) when prepared in mobile phase B. Clearly, all analytes except fumonisins underwent significant degradation when prepared in mobile phase B.

For fumonisins, it was necessary to use deactivated inserts because normal glass inserts resulted in significant ($p < 0.05$, $n = 3$) random losses when prepared in mobile phase B. The application of deactivated inserts provided lower uncertainty range for fumonisins. The combined uncertainty in rice using deactivated inserts and normal inserts were 12% and 82%, respectively. The application of deactivated inserts would provide significant improvement for method accuracy for fumonisins, which represented the major contributing factor toward uncertainty calculation. Therefore, we can conclude that deactivated inserts improved measurement uncertainty by providing greater accuracy in the determination of fumonisins in rice.

Hence, we recommend fresh preparation of mycotoxin calibrants and store in deactivated inserts, when prepared in water-enriched solvent system such as mobile phase B. Therefore, for the first time, information related to aflatoxins, OTA, fumonisins, T-2 and HT-2 toxins, DON and ZEA stability in rice matrix and in solution has been made available.

Coefficient of determination values obtained were between 0.9991 and 0.9998 for all analytes examined. LOD and LOQ values for individual mycotoxins are summarized in Table 6. Measurement uncertainty ($k = 2$) values were calculated[39] and reported for rice samples tested positive for mycotoxins.

Screening Commercial Rice Samples for Multimycotoxins. Screening commercial rice samples for multimycotoxins would provide occurrence data in the supply chain to support prospective maximum regulatory limits revision.

A survey involving 190 rice samples from nine countries was conducted of which six rice samples were tested positive for mycotoxins. This constituted a mere 3.2% compared to contamination figures published previously (Table 3). One possible reason for the difference in mycotoxin-contaminated rice values presented in this study and those reported previously in Table 3 could be due to sampling strategy. A summary of samples tested positive for mycotoxins is shown in Table 7. Information related to contamination levels, mycotoxins, source of production, and types of rice were provided. Table 7 provided no evidence for co-occurrence of mycotoxins. The results showed that AFB_1 concentration levels ranged from 1.1 to 3.2 (±0.1 to 0.2) μg/kg, which was below the EU maximum limits of 5 μg/kg[7]. From a wide variety of rice species analyzed, basmati rice samples have the highest risk of contamination from AFB_1 based on occurrence. Basmati rice produced by Pakistan represent four out of six rice samples tested positive for AFB_1, as shown in Table 7. A sample of Indian parboiled rice for use by diabetic patients was positive for AFB_1 at 1.7 ± 0.1 μg/kg. Only one sample of broken rice produced by Myanmar was positive for OTA at 46.6 ± 4.2 μg/kg. All rice samples were negative for AFB_2, AFG_1, FB_1, FB_2, DON, T2, HT-2, and ZEA. Our rice survey identified Pakistan as a major aflatoxin-contaminated rice producer in the supply chain. This observation is consistent with data reported previously by RASFF in 2008, which identified Pakistan as the major aflatoxin-contaminated rice producer.

There are parallels in rice contamination profiles between our report and those published previously.[19,21,30] Common to these survey outcomes, AFB_1 represented the single major contaminant in all basmati rice samples examined. Indeed, Reiter et al.[21] showed that 22 out of 24 basmati varieties which were positive for AFB_1 in Sweden were produced by Pakistan and India. In yet another series of similar rice profiling exercises conducted previously,[30,32] basmati rice samples of localized Pakistan produce represented the host crops for AFB_1 contamination. The prevalence of AFB_1 in rice samples produced by localized Pakistan farmers[10] explained the need for increased level of official controls on imports for basmati rice from Pakistan.[40] Indeed, a study conducted by Asghar et al.[29] over a period of 6 years revealed a persistent AFB_1 fingerprint (1.2 μg/kg) in the supply chain. The level detected

[a]Three independent sets of matrix-matched calibrants prepared at six concentration levels were used to calculate LOD and LOQ values. LOD and LOQ were calculated as (2.33 × standard deviation)/gradient of slope and LOD + (1.64 × standard deviation)/gradient of slope, respectively (EU, 2006a). Values for LOD and LOQ were rounded to one decimal place.

is below the 5.0 ug/kg limit recommended by European Commission.[7] Even though there was only a single OTA positive sample from Myanmar in our survey, this preliminary data may be useful for prospective food safety efforts with focus on multimycotoxins control in Asian rice. To date, no complete information related to mycotoxins in rice is available from Myanmar, albeit Nguyuen et al.[33] presented some preliminary data on Vietnamese rice and reported some values for AFB_1, citrinin, and OTA contamination. The reason for this paucity of data on mycotoxins contamination in rice from Myanmar and Vietnam remains unclear. Based on our study, there is insufficient evidence to show that a correlation exists between mycotoxins contamination and rice species ($r = 0$).

In brief, a comprehensive paper describing analytical method validation, its application as an analytical tool, and its impact on food safety in Asia was presented for regulated mycotoxins in Asian rice. These mycotoxins are, namely, aflatoxins, OTA, fumonisins, T-2 and HT-2 toxins, DON, and ZEA. Method

Table 7. Summary of Rice Samples (n = 190) Tested Positive for Mycotoxins, Including Information Related to Country of Origin, Types of Mycotoxins, and Contamination Levels

sample no.	type of rice	country of origin	concentration (μg/kg)	
			AFB_1	OTA
16	fragrant basmati rice	Pakistan	2.0 ± 0.1	nd
21	broken rice	Myanmar	nd	46.5 ± 4.2
170	basmati rice	Pakistan	3.2 ± 0.2	nd
176	basmati rice	Pakistan	1.1 ± 0.1	nd
182	parboiled rice for diabetics	India	1.7 ± 0.1	nd
188	premium basmati rice	Pakistan	1.7 ± 0.1	nd

nd = not detected.

accuracy, precision, sensitivity, repeatability, robustness, and individual analyte stability were examined and found to be highly satisfactory. Random fumonisins' losses in solution was also identified and suitably counteracted using deactivated inserts. Significant ($p < 0.05$) degradation of all analytes except for fumonisins in mobile phase B was reported for the first time. Spiked recoveries performed at three concentration levels using single extraction (measured over 2 days) provided satisfactory mean recovery range from 70% to 120% for all analytes, including some white rice from Thailand and China. The application of 1% acetic acid (to the extraction solvent) addressed recovery losses for all analytes, including fumonisins in white rice from Thailand/China. Incidence of staple rice crop tested positive for mycotoxins was reported to be 3.2%. Rice from Pakistan represented 67% of naturally AFB_1 contaminated samples. Unlike spices,[10] there is no evidence to suspect regulated mycotoxins can co-occur in Asian rice. Likewise, there is insufficient evidence to show *Fusarium graminearum* can occur in Asian rice.

salts and lecithin) which generate micelles that may enhance the dissolution rate and solubility of lipophilic resveratrol-loaded lipid nanoparticles.[36,37] Hence, a monolithic C18 column, consisting of micro- and mesopores,[38,39] was selected with regard to its suitability for bioanalysis,[40] avoiding further sample treatment.

MATERIALS AND METHODS

Chemicals. *trans*-Resveratrol was purchased from Sigma-Aldrich (St. Louis, MO, USA). Acetonitrile and acetic acid (LiChrosolv HPLC grade) were obtained from Merck (Darmstadt, Germany). Water from an arium water purification system (resistivity > 18 MΩ cm, Sartorius, Goettingen, Germany) was used for the preparation of all solutions. Acetic acid aqueous solution (2% (v/v)) was filtered through a 0.22 μm Millipore-type GVWP filter. Prior to use, the mobile phase was degassed in an ultrasonic bath for 15 min. The transport medium HBSS was purchased from Gibco (Paisley, UK), whereas FaSSIF and FeSSIF were prepared by using SIF instant powder (Phares Drug Delivery AG, Muttenz, Switzerland) according to the instructions of the manufacturer. Table S2 summarizes the compositions of HBSS, FaSSIF, and FeSSIF media.

For the nanoparticle synthesis, cetyl palmitate was kindly supplied by Gattefossé (Nanterre, France), polysorbate 60 (Tween 60) was provided by Merck, and miglyol-812 was from Acofarma (Madrid, Spain). For cell culturing, the Caco-2 cell line purchased from the American Type Culture Collection (ATCC, Wesel, Germany) between passages 35 and 55 was maintained in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal bovine serum, 1% fungizone (amphotericin B, 250 μg mL^{-1}), and 1% Pen Strep (penicillin, streptomycin), all obtained from Gibco.

Equipment and Chromatographic Conditions. The samples were injected (50 μL) into a reversed-phase monolithic column (Chromolith RP-18e, 100 mm × 4.6 mm i.d., Merck), connected to a Jasco (Easton, MD, USA) HPLC system (pump PU-2089, autosampler AS-2057, and LC-Net II/ADC controller) coupled to a fluorometric detector (Jasco FP-2020, λ_{exc} = 330 nm, λ_{em} = 374 nm). Chromatographic separation was achieved by isocratic mode consisting of 80:20 (v/v) aqueous solution (acetic acid 2%, v/v) and acetonitrile at a flow rate of 1.0 mL min^{-1}.

Standard Solutions and Quality Control Samples. Stock solutions of *trans*-resveratrol were daily prepared in mobile phase, HBSS, FaSSIF, and FeSSIF at 10 μmol L^{-1}. Standard solutions were accurately prepared by dilution in the same transport media to final concentrations of 0.020, 0.050, 0.100, 0.150, 0.200, 0.400, 0.700, 1.00, 1.50, and 2.00 μmol L^{-1}. The standard solutions were divided in two calibration curves for each transport media, the low-level calibration curve between 0.020 and 0.200 μmol L^{-1} and the high-level calibration curve between 0.200 and 2.00 μmol L^{-1}.

The quality control (QC) samples at three different levels (low, middle, and high) were prepared at concentrations of 0.020, 0.200, and 1.50 μmol L^{-1} for each transport medium, within three batches of five samples each. The standards containing 0.020 and 0.200 μmol L^{-1} were interpolated in the low-level calibration curve, whereas the 1.50 μmol L^{-1} standard was interpolated in the high-level calibration curve.

Acetonitrile was added to all standard solutions and samples immediately after preparation or collection to attain a 20% (v/v) concentration (100 μL of standard or sample +25 μL of acetonitrile:-acetic acid (92:8, v/v)) to match the mobile phase composition, avoiding peak broadening effects.

Validation of HPLC Method. The chromatographic method developed was validated for selectivity, concentration range, detection and quantification limits, accuracy, precision, and stability according to the ICH guidelines on bioanalytical method validation.[11] Selectivity concerns the ability to differentiate the analyte of interest (*trans*-resveratrol) from endogenous components in the matrix or in the sample and was assessed by analyzing six different samples of blank HBSS, FaSSIF, and FeSSIF, which were evaluated for interference. To evaluate linearity, calibration curves were acquired in triplicate, on three consecutive days, by plotting the integrated peak area of *trans*-resveratrol in all three media against the nominal concentration of six standard solutions, for each low-level and high-level calibration curve. Linear regression analysis was performed using the least-squares method. The detection limit (DL) and the quantification limit (QL) of the developed HPLC method were determined by the signal to-noise ratio. The DL and QL were the concentrations of *trans*-resveratrol generated by a peak 3 times and 10 times, respectively, higher than the baseline noise. Precision and accuracy were estimated by analyzing five replicates of the three different QC levels (0.020, 0.200, and 1.50 μmol L^{-1} of *trans*-resveratrol) for each matrix. Repeatability and reproducibility were assessed by analyzing five replicates of the three QC levels on three different runs within the same day (intraday) and on three different days (interday), respectively. Stability studies were performed by maintaining the samples inside the autosampler of the HPLC instrument at 4 °C for 24 h, at room temperature for 24 h, and after three freeze−thaw cycles, by thawing at room temperature for 2 h and freezing again for 24 h. Five replicates of each QC sample were analyzed for each storage condition in all matrices.

Application to in Vitro Intestinal Permeability Studies. The developed method was targeted to application in studies of intestinal permeability of *trans*-resveratrol carried inside lipid nanoparticles (SLNs and NLCs), after oral administration. Resveratrol-loaded lipid nanoparticles were prepared by a modified hot homogenization technique and characterized as described elsewhere.[10] The results showed spherical and uniform nanoparticles with a smooth surface, a *Z*-average of 150−250 nm, a highly negative zeta potential of −30 mV, and a resveratrol entrapment efficiency of 70%.[10] The recovery of resveratrol from lipid nanoparticles corresponded to 93%, and it was determined using 4.0 mL of a 1.25 mg mL^{-1} suspension of *trans*-resveratrol-loaded nanoparticles, where 1.0 mL of acetonitrile was added to promote the disruption of the lipid matrix and the release of *trans*-resveratrol. Next, *trans*-resveratrol was quantified by direct spectrophotometric detection at 306 nm, using standards prepared in 20% (v/v) acetonitrile/water, after subtraction of signal scattering by blank nanoparticles. In vitro intestinal permeability assays were performed using Caco-2 monolayers in transwell devices that mimic the intestinal barrier.[41] Three different transport media were used to mimic intestinal fluids: HBSS as the control medium, FaSSIF as the fasted state medium, and FeSSIF as the fed state medium. Resveratrol-loaded lipid nanoparticles were incubated during 4 h in the apical side of the intestinal barrier, and aliquots of 100 μL were withdrawn at regular intervals of 30 min from the basolateral side for quantification to determine the intestinal permeability in all three media. Sample treatment was minimal, involving the addition of 25 μL of acetonitrile/acetic acid (92:8, v/v) solution to 100 μL of sample to promote the disruption of the lipid matrix and the release of *trans*-resveratrol to be quantified by HPLC and also to avoid band broadening effects due to differences from mobile phase composition.

Statistical Analysis. Statistical analyses were performed using SPSS software (v 18.0; IBM, Armonk, NY, USA). Permeability measurements were repeated at least six times, and data were expressed as the mean ± SD. Data were analyzed using one-way analysis of variance (one-way ANOVA), followed by Bonferroni, Tukey, and Dunnett post hoc tests. A p value <0.05 was considered statistically significant.

RESULTS AND DISCUSSION

Study of Chromatographic Conditions. Considering the method application to studies of intestinal permeability of *trans*-resveratrol inside lipid nanoparticles, the main goal to be achieved in the development of this chromatographic method was low detection and quantification limits. Furthermore, because there was a constraint in the available sample volume, it was also important to develop a method that needed minimal sample treatment. Therefore, a monolithic column coupled to fluorescence detection was chosen to meet these needs.

In this work, the development of a simplified HPLC method with isocratic elution was aimed for. The choice of the organic

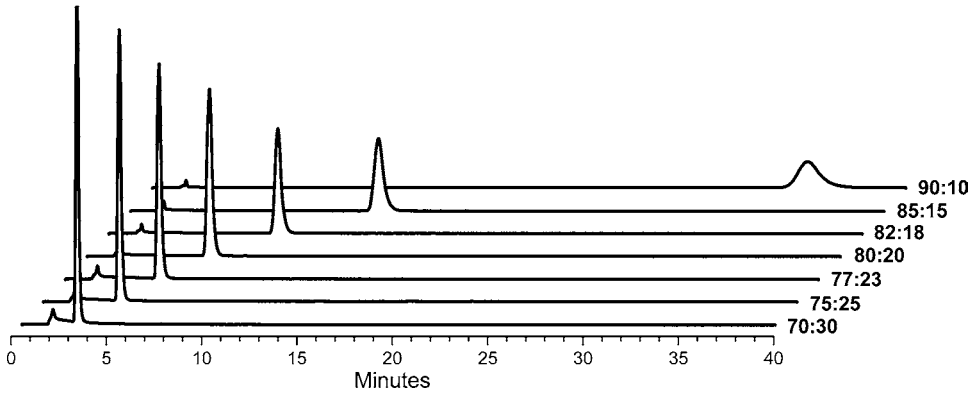

Figure 1. Chromatograms of *trans*-resveratrol (10 μmol L^{-1}) using different mobile phase compositions containing acetic acid (2%, v/v)/acetonitrile.

phase was based on the ability to break nanoparticles for the release of the compound to be quantified. Therefore, acetonitrile was selected as the organic phase once it could destroy the matrix of the nanoparticles. The aqueous phase chosen was acetic acid 2% (v/v) as described elsewhere.[30] Hence, the mobile phase composition was studied to decrease the retention time of *trans*-resveratrol, to provide resolution from sample matrix, and to determine the best acetonitrile concentration that enabled the disruption of the lipid matrix of nanoparticles, releasing the compound to be quantified. Different ratios of organic phase (acetonitrile) and aqueous phase (acetic acid 2%, v/v) were tested as depicted in Figure 1.

Table 1 summarizes the properties of chromatographic peak retention time, area, height, and symmetry of *trans*-resveratrol.

Table 1. Values of Retention Time, Area, Height, and Symmetry Factor for Each Chromatogram of *trans*-Resveratrol (10 μmol L^{-1}) Using Different Mobile Phase Compositions (Acetic Acid (2%)/Acetonitrile)

[a]Calculated as the ratio between W and $2f$, where W is the peak width at 5% of the peak height and f is the distance between the maximum and the leading edge of the peak.

As expected, when the volume of the organic phase decreases, the retention time of the compound increases, and a reduction of the peak area due to peak broadening for longer retention times or possible lack of total nanoparticle disruption is visible. It is also important to note that the mobile phase with only 10% (v/v) of organic phase produced a retention time more than twice higher than that found for 15% (v/v). In addition, from previous experiments with similar types of nanoparticles, at least 20% (v/v) of acetonitrile is required to cause total disruption of the lipid matrix and to promote the release of the compound for correct quantification. In fact, the results obtained are in agreement with this observation as the increase in peak area was 33% when acetonitrile was increased from 18 to 20% (v/v), whereas only a 2% enhancement in peak area was observed when acetonitrile was increased from 20 to 23% (v/v). Therefore, a mobile phase composed of 20% of acetonitrile and 80% of acetic acid (2%, v/v) was selected. This composition permitted the elution of *trans*-resveratrol with a good compromise between the *trans*-resveratrol retention time and the peak symmetry factor, allowing a sharp peak separation. Using this isocratic condition, *trans*-resveratrol was eluted with a retention time of 6.5 min and with the lowest peak symmetry factor of 1.22, which reflects a reduced peak tailing in these conditions (Table 1).

The injection volume was also tested to increase the sensitivity of the developed method. Injection volumes of 50 and 100 μL were tested, providing a signal area enhancement of ca. 2 as expected. The injection volume chosen was 50 μL as the volume collected during the permeability assay should be <100 μL. Hence, improved sensitivity can be attained if required by increasing the sample volume.

Method Validation. The validation of the analytical HPLC method was carried out after evaluation of selectivity, linearity, detection and quantification limits, accuracy, precision, and stability as proposed by ICH guidelines on bioanalytical method validation.[11]

Selectivity is the ability to differentiate the analyte of interest from endogenous components in the matrix or in the sample and was assessed by analyzing six different samples of blank matrices HBSS, FaSSIF, and FeSSIF (Figure S2). No interfering peaks from endogenous substances were observed at the retention time of *trans*-resveratrol. A good separation was obtained under the described conditions, and *trans*-resveratrol was eluted at 6.5 min, with any potentially interfering compound washed from the column together with the solvent. Therefore, the method was shown to be selective for the intended application.

The linearity of response was established by analyzing standard solutions in two ranges of concentrations for mobile phase and for each transport medium (HBSS, FaSSIF, and FeSSIF), the low-level calibration curve (n = 5) between 0.020 and 0.200 μmol L^{-1}, and the high-level calibration curve (n = 6) between 0.200 and 2.00 μmol L^{-1}. Calibration curves were acquired in triplicate, on three consecutive days, with relative standard deviations (RSD) for slope <8.6%. As shown in Table 2, the calibration curves for *trans*-resveratrol indicated good linearity for all matrices in the proposed range, with correlation coefficients for all linear regressions >0.99. When the calibration slopes obtained using each cell culture media were

[a]Quality control concentrations interpolated in low-level calibration curve (n = 5). [b]Quality control concentrations interpolated in high-level calibration curve (n = 5).

compared, values were between 33 and 68% of those found for mobile phase (Table 2). This decrease in sensitivity may account for fluorescence quenching effects reported for complex media, where interactions with solvent molecules (for instance, formation−disruption of hydrogen bonds with solvent molecules)[42] or ions (for instance, quenching of phenolics emission due to the deprotonation of the phenolic group promoted in the excited state by phosphate ions)[43] may occur. The decrease in sensitivity was more pronounced for HBSS media, followed by FaSSIF and FeSSIF. In these last two media, despite the increased amount of salts when compared to HBSS (Table S2), sodium taurocholate and lecithin were also present, promoting hydrophobic interactions with resveratrol and decreasing its exposure to hydrogen bonding with solvent.

Furthermore, the slope values obtained for the low-level calibration curves are lower than those of the high-level calibration curves, and this effect is more pronounced for HBSS and for standards prepared in mobile phase, where the slope values for low-level standards are 60 and 79% of those found for high-level standards prepared in the same solvent, respectively. This decrease in sensitivity is almost absent in FeSSIF medium, where low-level slope value accounts for 96% of the high-level counterpart. These results might be also due to the quenching effects described above for interaction of resveratrol with solvent molecules and ions present in the medium. These effects would be more pronounced for low concentrations of resveratrol (low-level standards), where the protection from hydrophobic interactions with emulsifier agents would also be more pronounced. Considering that FeSSIF has 5 times more sodium taurocholate and lecithin (Table S2) than FaSSIF, this might explain that the slope ratio between low and high levels for FaSSIF (0.855) increased for FeSSIF (0.956). Hence, considering the matrix effects found, further calibrations and quantifications were undertaken using standards containing the target matrix.

Sensitivity was investigated by determining the DL and QL of the developed HPLC method through the signal to-noise ratio. The DL and QL were the concentrations of *trans*-resveratrol generated by peaks 3 times and 10 times higher than the baseline noise, respectively. Because matrix effects were observed and calibration curves were performed for mobile phase and for each transport medium (HBSS, FaSSIF, and FeSSIF), a set of DL and QL values was also determined for each matrix (Table 2). DL and QL values decrease in all matrices when compared to the mobile phase, probably due to the composition of the studied matrices (Table S2). In the case of HBSS, the composition is very rich in salts of chlorides, sulfates, and phosphates that are known to promote the fluorescence quenching phenomenon. FaSSIF and FeSSIF are very rich in bile salts and micelles of phospholipids, which may also promote events of fluorescence quenching, lowering the sensitivity of the method in these media, even though the minimum detectable concentration of *trans*-resveratrol achieved, for a 50 μL injection volume, was 1−3 nmol L^{-1}

[a]Quality control concentrations interpolated in low-level calibration curve (n = 5). [b]Quality control concentrations interpolated in high-level calibration curve (n = 5).

and the limit of quantification was 2−6 nmol L^{-1}. Hence, the proposed method allows the quantification of 23−69 pg of *trans*-resveratrol. Therefore, the sensitivity of the method developed is very high, and the values for DL and QL are substantially lower than those found in previous studies (Table S1), which can be considered an advantage compared with the other methods, being particularly adequate to the measurement of *trans*-resveratrol at very low concentrations, carried inside lipid nanoparticles after intestinal permeability studies.

The accuracy of the analytical method was determined by the percentage of recoveries of five replicates of QC samples, whereas precision was obtained by determination of the RSD. The intraday precision and accuracy were determined on the same day by analyzing QC samples (n = 5) on three different runs for all transport media, and the interday precision and accuracy were assayed on three consecutive days for QC samples (n = 5) in each matrix. The method was shown to be accurate and precise as depicted in Table 3. Intraday and interday precisions of the method were lower than 5.8 and 5.4%, respectively, for all of the matrices studied, which was within the acceptable limits of the guidelines for bioanalytical method validation, considered to be <15%. The accuracy of the method for all of the matrices was also good with the deviation between the nominal concentration and the calculated concentration for *trans*-resveratrol within the limit of 20% for the lowest QC sample and below 15% for all other QC samples. Accordingly, the intraday accuracy was found to be between 85.0 and 120.1% of the nominal *trans*-resveratrol concentrations and the interday accuracy between 88.2 and 120.5% of the nominal values in all matrices. This precision and accuracy evaluation indicates that the HPLC method developed for quantification of *trans*-resveratrol inside lipid nanoparticles from mimetic intestinal fluids is highly reproducible and robust.

Evaluation of stability was carried out in all matrices by analyzing five replicates of each QC sample after three storage conditions: inside the autosampler of the HPLC instrument (at 4 °C) for 24 h; at room temperature for 24 h; and after three freeze−thaw cycles, comprising at least 24 h at −18 °C before defrost. According to ICH guidelines, samples were considered to be stable when the mean concentration of *trans*-resveratrol after the storage period was within ±15% of the initial concentration of freshly prepared samples.

As shown in Table 4, the results suggested that *trans*-resveratrol was stable in all matrices after 24 h in the autosampler at 4 °C with mean recoveries of *trans*-resveratrol >89.3% and precision values <7.8% for all transport media. However, *trans*-resveratrol was not stable after 24 h at room temperature and after three freeze−thaw cycles, mainly in HBSS medium for which recoveries were <58.2% and with poor precision (RSD up to 24.1%). On the other hand, FaSSIF and FeSSIF media seem to protect *trans*-resveratrol against degradation because recoveries were higher (between 71.3 and 108.5%). These media mimic intestinal juices because they contain natural surfactants (bile salts and lecithin) that can also have effects on *trans*-resveratrol protection against oxidation and degradation.[36,37] However, the results for recoveries of *trans*-resveratrol in these two mimetic intestinal fluids are still below acceptable levels for ICH guidelines, at room temperature and at freeze−thaw conditions tested. Therefore, *trans*-resveratrol is only stable after 24 h at 4 °C for all three media, and its storage at room temperature or its utilization after three freeze−thaw cycles is not recommended.

Application to in Vitro Intestinal Permeability Studies. The proposed HPLC method was applied in studies of in vitro intestinal permeability of *trans*-resveratrol inside lipid nanoparticles, by using Caco-2 cell monolayers. The use of these nanodelivery systems can be an important tool to increase the protection, to enhance the absorption, and thereby to improve the bioavailability of *trans*-resveratrol inside the organism, after oral administration as a food additive. The representative intestinal permeability profile for resveratrol-loaded NLCs in HBSS, FaSSIF, and FeSSIF media is illustrated in Figure 2, as a relevant application of this method.

Values between 0.05 ± 0.01 and 1.8 ± 0.3 μmol L^{-1} were found along the experimental time frame, showing the suitability of the proposed method to assess the minimum amount of *trans*-resveratrol assessed, present in the first aliquot, taken after 30 min. These preliminary results suggest that FaSSIF and FeSSIF media increase *trans*-resveratrol permeability inside lipid nanoparticles, after 4 h of incubation, when compared to the control medium HBSS (2-fold higher for FaSSIF and 2.5-fold higher for FeSSIF; $p < 0.05$).

Comparison with Other Methods. The comparison between the developed method and methods described in the literature for *trans*-resveratrol quantification (Table S1)

DOI: 10.1021/acs.jafc.5b00390
J. Agric. Food Chem. 2015, 63, 3114−3120

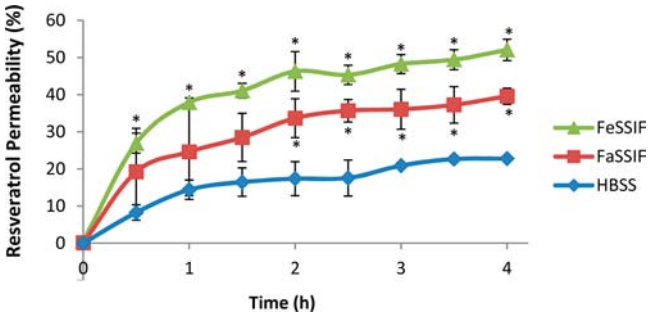

Figure 2. *trans*-Resveratrol permeability (%) across Caco-2 cell monolayers loaded in lipid nanoparticles (NLCs), using different media (HBSS, FaSSIF, and FeSSIF). All data represent the mean ± SD ($n > 6$). (*) Statistically significant differences in relation to HBSS medium ($p < 0.05$).

suggested that the proposed method is suitable for measuring *trans*-resveratrol carried by lipid nanoparticles in intestinal fluid matrices, when generally the other methods are suitable mostly for quantifying *trans*-resveratrol at higher levels, targeted to wines, grapes, and plasma. In fact, the present method revealed an extended range of the linear zone (0.020−2.00 μmol L^{-1}), the lower level of quantification of which was matched only by the method proposed by Das and Ng.[27] Nevertheless, this method presented a higher detection limit and required extensive sample preparation by liquid−liquid extraction. In the proposed method, the only sample treatment necessary is the addition of acetonitrile for nanoparticle disruption and release of *trans*-resveratrol, showing the suitability of monolithic columns for application to complex samples. Moreover, the detection (1−3 nmol L^{-1}) and quantification (2−6 nmol L^{-1}) limits were the lowest obtained so far to the best of our knowledge, as confirmed by the information in Table S1, where the lowest values are 2−10 nmol L^{-1}.[12,25,27]

In general, the proposed method provides a simple chromatographic procedure with minimal sample treatment, good peak resolution, reduced run time, and low cost, allowing the analysis of a large number of samples and avoiding possible degradation of *trans*-resveratrol due to long run times. The isocratic elution also allowed the simplification of the technique. In fact, the estimated cost per run concerning mobile phase consumption is ca. 0.017 euro. These are, undoubtedly, clear advantages of the proposed method, which enables the performance of pharmacokinetic studies concerning *trans*-resveratrol to enhance its bioavailability after oral administration as a nutraceutical.

fragment length polymorphisms (AFLP).[22,23] The above methods are based on the comparison of the patterns of DNA fragments separated by gel electrophoresis or capillary electrophoresis in automated systems. More recently, single-nucleotide polymorphisms (SNPs) have emerged as new genetic markers with unique advantages for varietal discrimination.[24−27] The progress in automated sequencing technology has facilitated greatly the discovery of characteristic SNPs for olive cultivars.[28,29] The main advantages of SNPs over other genetic markers are as follows:[12,29] (a) SNPs enable pinpointing very similar cultivars because the differentiation is based on a single-nucleotide change rather than a whole DNA sequence. (b) SNP genotyping can be accomplished even with short amplified DNA sequences (e.g., 100 bp). This is particularly important in cases when the integrity of the DNA may be affected during the extraction process and storage of olive oil. (c) SNPs constitute the most abundant genetic markers. (d) They are mainly biallelic and stably inherited. Therefore, the trend is that SNP genotyping will replace the classical genetic markers for cultivar identification. The methods reported so far for SNP genotyping of olive oil DNA include capillary electrophoresis of restriction enzyme-digested DNA fragments[25,26] and DNA-microarray analysis of ligation reaction products.[24] It should be noted, however, that microarrays are suitable for parallel genotyping of thousands of SNPs in one sample; that is, the SNP-throughput per sample is high but the sample-throughput is low.

The proposed method for SNP genotyping is based on a suspension of fluorescent microspheres and, in comparison with the above methods, offers the following advantages. (i) It allows for high sample throughput; that is, compared to microarrays, the method is best suited for genotyping of a small number of useful SNPs in a large number of samples. (ii) The suspension of microspheres provides flexibility and convenience in modification and/or expansion of the assay by just replacing sets of microspheres or adding more sets of microspheres in the suspension. (iii) The microspheres offer rapid solution kinetics.

Previous studies have employed suspensions of fluorescent microspheres for the detection and/or quantification of PCR-amplified DNA fragments from food samples.[30,31] However, to our knowledge, this is the first report of SNP genotyping assays for food authenticity testing using this technological platform.

The aim of the present work is the development of a high sample throughput method for the identification of olive

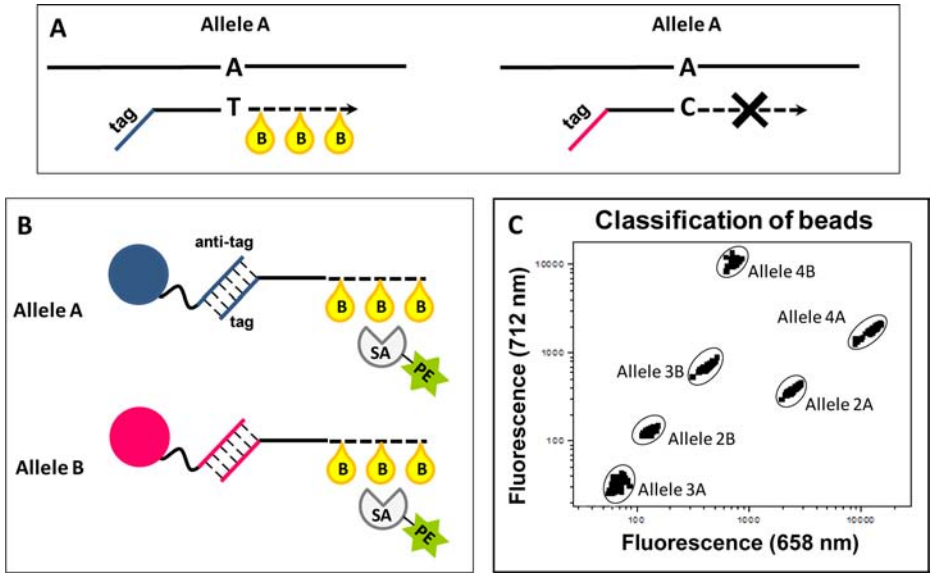

Figure 1. (A) Allele-specific primer extension reaction. Each allele-specific primer consists of a segment complementary to the target sequence, a tag sequence at the 5′ end, and a 12 nt spacer. The two allele-specific primers differ only at the 3′ end nucleotide. Extension by DNA polymerase occurs only when the primer anneals to the corresponding allele. (B) Hybridization assay on spectrally encoded fluorescent microspheres. The extension reaction products are captured on the surface of the microspheres through hybridization with the immobilized antitag sequences. The added streptavidin−phycoerythrin conjugate binds only to the extended primers that contain biotin moieties. The fluorescence of phycoerythrin of each microsphere is measured by flow cytometry. (C) Classification of the fluorescent microspheres by flow cytometry. The classification is based on the fluorescence intensities of the two dyes used for the staining of the microspheres. Each cluster represents a set of microspheres. The dots inside the cluster are data from at least 100 microspheres.

cultivars based on the simultaneous genotyping of single-nucleotide polymorphisms.

MATERIALS AND METHODS

Apparatus and Reagents. PCR and primer extension reactions were performed in the MJ Research PTC-0150 thermal cycler (Watertown, MA, USA). The digital camera, Kodak DC 120, and the Gel Analyzer software for DNA documentation were purchased from Kodak (Rochester, NY). The ultrasonic cleaner from Branson Ultrasonics (Danbury, CT, USA) was used for resuspension of the microspheres. The Luminex 100 IS flow cytometer (Luminex, Austin, TX, USA) was used for the analysis of the microspheres. Fluorescent carboxylated microspheres (5.6 μm) were purchased from Luminex. Amplitaq Gold DNA polymerase was from Applied Biosystems (Foster City, CA, USA), and Vent (exo-) DNA polymerase was from New England Biolabs (Beverly, MA, USA). Ultrapure 2′-deoxyribonucleoside 5′-triphosphates (dNTPs) were purchased from Invitrogen (Carlsbad, CA, USA). KAPA 2G Fast multiplex PCR kit was from Kapa Biosystems (Woburn, MA, USA). Biotin-11-dUTP was from Applichem (Darmstadt, Germany). Streptavidin-R-phycoerythrin conjugate (SA-PE) was purchased from Molecular Probes (Eugene, OR, USA). The primers and probes used in this study were synthesized by VBC-Biotech (Vienna, Austria). The sequences of the oligonucleotides used throughout this work are listed in Table 1. All other common reagents were from Sigma (St. Louis, MO, USA).

Experimental Outline. The method includes the following steps: (i) DNA isolation; (ii) PCR amplification of three DNA segments that contain the three SNPs (SNP2, SNP3, and SNP4); (iii) multiplex genotyping reaction based on the extension of six allele-specific primers; (iv) multiplex hybridization assay of the genotyping reaction products on spectrally encoded fluorescent microspheres (Figure 1).

Samples and DNA Extraction. The Koroneiki and Chondrolia monovarietal extra virgin olive oil samples were provided by Anatoli S.A. Chania, Crete, and Makedoniki Elaiourgia S.A. Kalives, Chalkidiki, respectively. The monovarietal olive oil samples of Adramytini, Valanolia, and Kalamon were extracted from fruits of the respective cultivars in the pilot olive mill of the Institute of Subtropical Plants and Olive, NAGREF, Chania, Crete. The samples were stored in the dark at room temperature for several months before use. Genomic DNA was extracted from young leaves of five Greek olive varieties (Adramytini, Chondrolia Chalkidikis, Kalamon, Koroneiki, and Valanolia) according to the method Saghai-Maroof et al.[32] as modified by Angiolillo et al.[33] Monovarietal olive oil samples (500 μL) were used to extract genomic DNA according to the CTAB/hexane/chloroform protocol.[34]

DNA Amplification Protocol A. DNA isolated from olive leaves and oil was subjected to two consecutive rounds of amplification (PCR I and PCR II). PCR I was carried out in a total volume of 50 μL containing 15 mM Tris-HCl, pH 8.0, 50 mM KCl, 2.5 mM $MgCl_2$, 200 μM of each dNTP, 0.3 μM of each primer, 1.25 U of Amplitaq Gold DNA polymerase, and 2 μL of genomic DNA or PCR I product. The cycling conditions for PCR I and PCR II for SNP2, SNP3, and SNP4[25] were as follows: 10 min at 95 °C followed by 35 cycles (40 cycles for PCR I of olive oil) at 95 °C for 30 s, 50 °C (60 °C for PCR I for SNP2) for 30 s, and 72 °C for 30 s. At the end of the cycling, the mixture was held at 72 °C for 10 min. A 2 μL aliquot from PCR I of olive oil was used directly in PCR II. The products of PCR I from leaves were first diluted 200 times, and a 2 μL aliquot was used as DNA template for PCR II. The PCR II primers (nested primers) were as previously reported.[25] The cycling conditions for PCR II were exactly the same as for PCR I. The PCR II products were confirmed and quantified by 2% agarose gel electrophoresis and ethidium bromide staining. The PCR I products were 501, 224, and 239 bp for SNP2, SNP3, and SNP4, respectively, whereas the PCR II products were 112, 105, and 137 bp for SNP2, SNP3, and SNP4, respectively.

DNA Amplification Protocol B (Multiplex PCR). The multiplex PCR was performed in a final volume of 25 μL containing 12.5 μL of Kapa 2G fast multiplex PCR mix, 0.2 μM of each of the PCR II primers for the three SNPs, and 2 μL of the isolated DNA. The multiplex PCR conditions were as follows: an initial step at 95 °C for 3 min followed by 35 cycles of 95 °C for 15 s, 50 °C for 30 s, and 72 °C for 30 s. A final step at 72 °C for 10 min was included. An aliquot of 5 μL of the PCR products was then subjected to a multiplex primer extension reaction, and an aliquot of 10 μL of the primer extension products was subjected to a multiple hybridization assay (see below).

DOI: 10.1021/jf5054657
J. Agric. Food Chem. 2015, 63, 3121−3128

Allele-Specific Primer Extension Reaction. Each allele-specific primer contained (a) at the 5′ end, a unique 24 bp oligonucleotide sequence (tag) complementary to the antitag sequence that was attached to the surface of a specific set of fluorescent microspheres; (b) a 12 bp common spacer; and (c) an allele-specific sequence 17−24 bp (Figure 1). Extension reactions were performed in the presence of a mixture of six primers specific for the six alleles of all three SNPs (SNP2, SNP3, and SNP4). The extension reaction was carried out in a total volume of 20 μL containing 20 mM Tris-HCl, 10 mM $(NH_4)_2SO_4$, 10 mM KCl, 0.1% Triton X-100, pH 8.8, 1.5 U Vent (exo-) DNA polymerase, 400 fmol of amplified DNA, 2 pmol of each primer, 2 mM $MgSO_4$, 10 μM of each dATP, dCTP, and dGTP, and 10 μM biotin-dUTP. The extension reactions were performed in the thermal cycler as follows: 95 °C for 5 min and 40 cycles of 95 °C for 15 s, 58 °C for 15 s, and 72 °C for 15 s.

Multiplex Hybridization Assay on Spectrally Distinct Microspheres. The extension reaction products (10 μL) were analyzed by a multianalyte hybridization assay, performed in a total volume of 55 μL (Figure 1). A suspension of six sets of spectrally encoded microspheres was prepared for the assay, each set consisting of 5000 identical microspheres. Each microsphere was stained with precise amounts of two fluorescent dyes, thus creating a built-in fluorescent signature. Also, antitag oligonucleotides were attached on the surface of each microsphere for molecular recognition of the allele-specific extension products. All of the microspheres were suspended in the hybridization buffer (100 mM Tris-HCl, pH 8.0, 200 mM NaCl, and 0.8 mL/L Triton X-100) and preheated at 37 °C. The extension reaction products were denatured for 3 min at 95 °C, placed immediately on ice for 2 min, and subsequently added to the above mixture and incubated for 1 h at 37 °C. The microspheres were then pelleted by centrifugation at 10000*g* for 1 min and washed once with 50 μL of hybridization buffer followed by resuspension in 80 μL of hybridization buffer containing 250 ng of streptavidin−phycoerythrin conjugate (SA-PE). The mixture was incubated for 20 min at room temperature, and the microspheres were analyzed by flow cytometry without prior washing. During the flow cytometric detection process, each microsphere was irradiated by two laser beams, 635 and 532 nm. The 635 nm beam was used for the excitation of the two fluorescent dyes within the microsphere and the ratio of the fluorescence intensities at 658 and 712 nm provided the classification of the microsphere. The 532 nm laser beam was used for the excitation of the reporter molecule, phycoerythrin, and the fluorescence intensity was related to the presence of a specific allele in the sample. At least 100 microspheres of each set were analyzed by the flow cytometer, and the median fluorescence value was calculated (Figure 1).

Genotype Assignment. The genotype of a sample, for SNP2, SNP3, and SNP4, was determined as follows: The fluorescence intensity obtained from each set of microspheres was first normalized to scale of 0−100, that is, it was expressed as a percentage of the maximum fluorescence value of the set. Then, for each SNP, the allelic fraction $R = 100F_A/(F_A + F_B)$ was calculated (as a percentage), where F_A and F_B are the normalized fluorescence values for alleles A and B of the SNP, respectively. In the presence of allele A only, the value of R is expected to be close to 100, whereas in the absence of allele A (only allele B present), the value of R would be close to 0. If both alleles, A and B, of the SNP are present, then R is about 50.

RESULTS AND DISCUSSION

The olive oil cultivar identification is based on the genotyping of three SNPs, namely, SNP2, SNP3, and SNP4, that are located in the plant's genome, giving a unique genotype fingerprint for each variety.[25] The SNP database of the five Greek olive cultivars is presented in Table 2.[25] The principle of the method is illustrated in Figure 1. The method is performed on a suspension of spectrally encoded microspheres in a high sample throughput and cost-effective format. We used sets of microspheres stained with precise amounts of two spectrally distinct fluorophores, thus providing unique "fluorescence signatures" for 100 different sets, which in turn permit the rapid simultaneous genotyping of up to 50 SNPs. Allele discrimination was accomplished through primer extension reaction. The extension reaction products were captured from the suspension of the microspheres and reacted with a streptavidin−phycoerythrin conjugate. The microspheres were then analyzed, within seconds, by a flow cytometer. Each microsphere "fluorescence signature" corresponds to a specific allele, whereas the signal of the phycoerythrin reporter denotes the presence of this allele in the sample. The suspension of microspheres allows solution kinetics and great assay flexibility.

Table 2. SNP Database of the Five Greek Olive Cultivars[a]

SNP	Adramytini	Chondrolia	Kalamon	Koroneiki	Valanolia
SNP2	A/A	A/C	A/A	A/C	A/C
SNP3	A/G	A/G	G/G	A/G	G/G
SNP4	C/C	C/C	C/C	C/T	C/C

[a]A, adenine; C, cytosine; G, guanine; T, thymine.

Biotin-dUTP was incorporated during the extension, and hence the reaction products were labeled with biotin. The products were heat-denatured and allowed to hybridize with a mixture of six sets of microspheres, each set carrying a characteristic antitag sequence. The hybrids were detected with a streptavidin−phycoerythrin conjugate. The fluorescence of the microspheres was finally measured by a flow cytometer.

As a model, the proposed method was applied to the authentication of five olive varieties: Adramytini, Chondrolia Chalkidikis, Kalamon, Koroneiki, and Valanolia.

The PCR amplification yielded fragments with sizes of 112, 105, and 137 bp for SNP2, SNP3, and SNP4, respectively. The PCR products were subjected to the extension reaction in the presence of six allele-specific primers (two primers per SNP).

Several parameters were evaluated for the optimization of the allele-specific primer extension reaction. The concentration of primers was tested in the range from 0.05 to 0.1 μM. The concentrations of dATP, dGTP, and dCTP were studied in the range of 2.5−25 μM of each, and the concentration of biotin-dUTP was tested in the range of 1.25−10 μM. The annealing temperature of the reaction was performed at 50−58 °C, and the reaction was carried out for 20−40 cycles. The optimized conditions are reported under Materials and Methods. Finally, the effect of the PCR product purification prior to the PEXT reaction was tested. Several PCR products were treated with exonuclease I and alkaline phosphatase, which hydrolyze the primers and the dNTPs, respectively. The treated PCR products were subjected to extension reaction in parallel with untreated products. The untreated products performed the same with treated ones. Optimization studies for hybridization assays on fluorescent microspheres included the effect of the number of microspheres (500−10000) on the signal of the assay, the hybridization time (30−120 min), the amount of streptavidin−phycoerythrin conjugate (100−500 ng), and the incubation time for the conjugate (10−30 min). Finally, the volume of the extension reaction mixture used for the multiplex hybridization assay was optimized, and 10 μL of the product was sufficient to obtain a high fluorescence signal.

Synthetic DNA Controls for Olive Varieties. The method was initially evaluated by using synthetic DNA controls representative of each variety. A synthetic control was a mixture of single-stranded DNA target sequences (60-mers), each corresponding to an allele (two targets per SNP). The sequences of the synthetic targets are listed in Table 1.

DOI: 10.1021/jf5054657
J. Agric. Food Chem. 2015, 63, 3121−3128

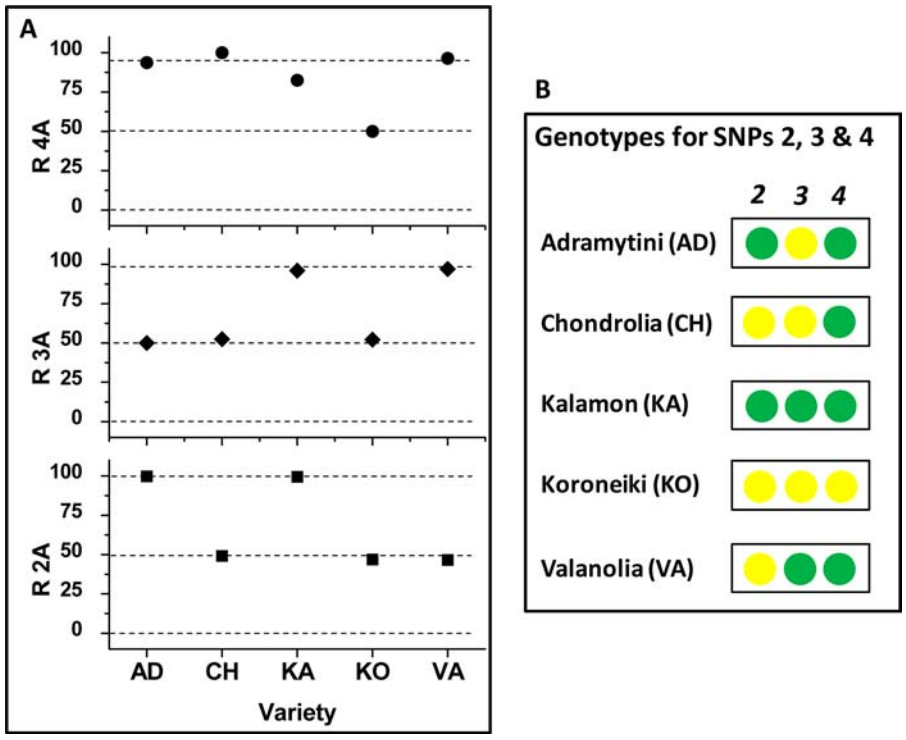

Figure 2. (A) Genotyping results for synthetic controls that represent the five Greek olive varieties, namely, Adramytini (AD), Chondrolia Chalkidikis (CH), Kalamon (KA), Koroneiki (KO), and Valanolia (VA). For each SNP, an allelic fraction *R* (expressed as a percentage) close to 100 corresponds to the presence of the allele A only, whereas an *R* value close to 50 indicates the presence of both alleles A and B. R 2A, allelic fraction (percentage) of allele A of SNP2; R 3A, allelic fraction (percentage) of allele A of SNP3; R 4A, allelic fraction (percentage) of allele A of SNP4. (B) Color code for the genotypes of the five olive varieties as assigned by the combination of the three SNPs. For each SNP, the green circle shows the presence of allele A only, whereas the yellow circle indicates the presence of both alleles (A and B).

Mixtures of the synthetic targets of the three SNPs were prepared, according to the known genotype of each olive variety. Given that the two alleles of each SNP are denoted with the letters A and B, the known genotypes of the five olive varieties for SNP2−SNP3−SNP4 are as follows:[25] Adramytini (AD), AA−AB−AA; Chondrolia Chalkidikis (CH), AB−AB−AA; Kalamon (KA), AA−AA−AA; Koroneiki (KO), AB−AB−AB; Valanolia (VA,: AB−AA−AA. Thus, the combination of the three genotypes provided a unique varietal code.

We produced synthetic controls that represent the five olive varieties: Adramytini, Chondrolia Chalkidikis, Kalamon, Koroneiki, and Valanolia. The synthetic controls contained 200 fmol/μL of each allele in the case of a "homozygote" control of the specific SNP and 100 fmol/μL of each allele in the case of a "heterozygote" control. A 1 μL aliquot of each synthetic control was subjected to a multiple extension reaction using a mixture of six extension primers, specific for the SNP2, SNP3, and SNP4 alleles. The extension products were subjected to a multiplex hybridization assay with the six sets of microspheres. The genotyping results for the synthetic controls are presented as plots of the allelic fraction *R* versus the olive variety that corresponds to each synthetic control (Figure 2). A color-code presentation of the SNP2, SNP3, and SNP4 genotypes for the five olive varieties is shown in Figure 2. It is demonstrated that the combination of the three genotypes gives a unique identification code for each variety.

Genotyping of Olive Leaves and Olive Oil. The proposed method was applied to the genotyping of DNA samples isolated from leaves and oil of the five olive varieties. The olive leaves and fruits used for olive oil production of Adramytini, Valanolia, and Kalamon were collected from the same olive trees. Adramytini and Valanolia samples were harvested from olive groves on the island of Lesvos and Kalamon samples from an olive grove in Chalkidiki. The Koroneiki leaf sample was harvested from the experimental olive grove at MAICh. The Chondrolia leaf and fruit samples were harvested from an olive grove in the Chalkidiki area. The fruits were then transferred for olive oil extraction to the Makedoniki Elaiourgia Co. (Greece). The leaf and olive oil DNA samples of all cultivars were characterized accordingly.[25] Following PCR, an amount of 400 fmol of amplified DNA was subjected to the multiplex primer extension reaction in the presence of the six allele-specific primers. A volume of 10 μL of the extension products, after heat denaturation for 3 min at 95 °C, was hybridized to a mixture of the six sets of microspheres. The results of the genotyping of the leaf samples are presented in Figure 3. Similarly, the proposed method was applied to the genotyping of DNA isolated from various olive oil samples, and the results are presented in Figure 4. We observe that, for each olive variety, the genotypes obtained from the leaf samples and from olive oil samples coincide with those of the synthetic controls.

All-Multiplex Method. An all-multiplex method was developed comprising (a) multiplex PCR amplification, (b) multiplex extension reaction, and (c) multiplex hybridization assay. The multiplex PCR of all three SNP segments in a single round of amplification was accomplished by using the Kapa 2G fast DNA polymerase. The genotyping results, presented in Figure 5, show the agreement of the all-multiplex protocol with the single-PCR approach.

Reproducibility. The reproducibility of the method was assessed by analyzing DNA samples from Valanolia, Kalamon,

DOI: 10.1021/jf5054657
J. Agric. Food Chem. 2015, 63, 3121−3128

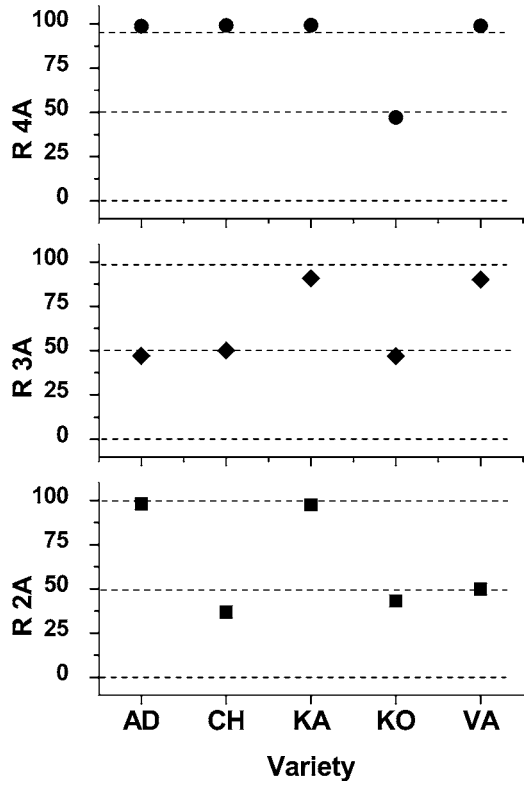

Figure 3. Genotyping results obtained from leaf samples of the five olive varieties, Adramytini (AD), Chondrolia Chalkidikis (CH), Kalamon (KA), Koroneiki (KO), and Valanolia (VA). For each SNP, an allelic fraction *R* close to 100 corresponds to the presence of allele A only, whereas an *R* value close to 50 indicates the presence of both alleles A and B.

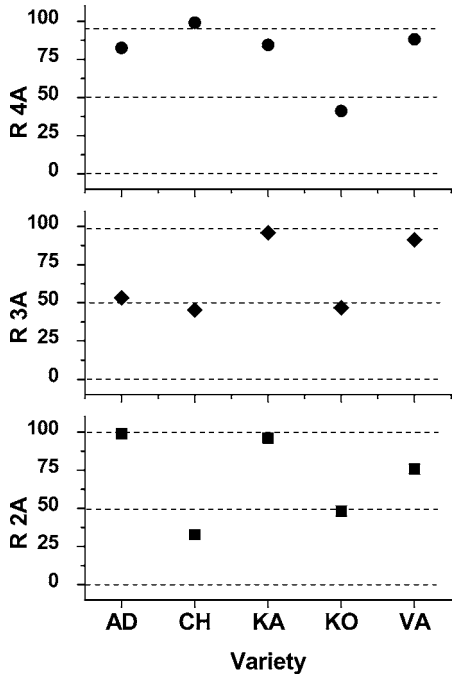

Figure 4. Genotyping results obtained from olive oil samples of the five olive cultivars, Adramytini (AD), Chondrolia Chalkidikis (CH), Kalamon (KA), Koroneiki (KO), and Valanolia (VA). For each SNP, an allelic fraction *R* close to 100 corresponds to the presence of allele A only, whereas an *R* value close to 50 indicates the presence of both alleles A and B.

and Koroneiki. The analyses were performed in triplicate, and the mean allelic fractions along with their coefficient of variation (%CV) were calculated for each SNP. The results are presented in Table 3. In all cases the reproducibility of the allelic fraction was very good for all three SNPs and genotypes.

The proposed method can be easily expanded to include more olive varieties because there are 100 sets of commercially available and spectrally distinguishable fluorescent microspheres carrying antitag sequences. Given that each set corresponds to an allele, the potential of the present method extends to the multiplex genotyping of 50 biallelic SNPs. Furthermore, the flexibility of the proposed method arises from the fact that the suspension of microspheres is not a fixed array (as in the case of planar arrays), but it can be easily adapted to specific laboratory needs because it is convenient to select and mix only those microsphere sets that are relevant to the SNP panel that is used for the interrogation of a particular olive oil sample. Moreover, the PCR products are introduced directly (without prior purification) to a single-tube multiplex primer extension reaction followed by a single-tube multiplex hybridization of all extension products on the microspheres and flow cytometric analysis. The flow cytometric detection is completed within 30 s. The method is accurate because the results obtained from the five olive cultivars are in full agreement with previous studies[25] that established the genotypes of the five olive varieties for SNP 2, SNP3, and SNP4. Moreover, for each cultivar, DNA isolated from leaf samples gave identical genotypes with DNA isolated from olive oil.

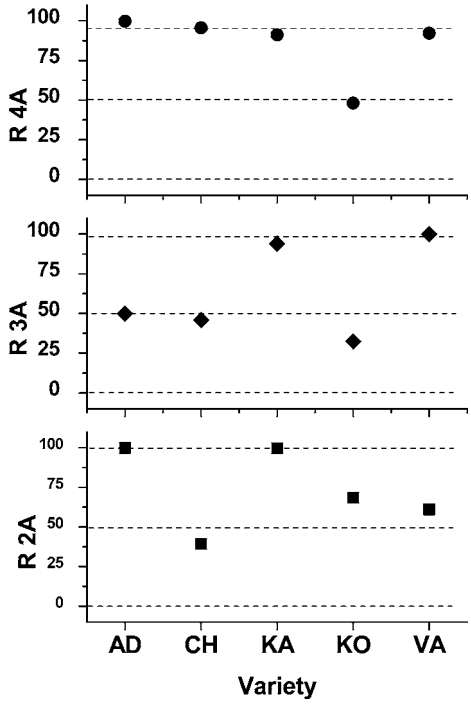

Figure 5. Genotyping results of the all-multiplex method for the five cultivars, Adramytini (AD), Chondrolia Chalkidikis (CH), Kalamon (KA), Koroneiki (KO), and Valanolia (VA). For each SNP, an allelic fraction *R* close to 100 corresponds to the presence of allele A only, whereas an *R* value close to 50 indicates the presence of both alleles A and B.

In our opinion, the proposed high sample throughput assay will contribute significantly to the traceability and authenticity

with advantageous, low-cost ultrahigh performance LC−MS/MS (UPLC−MS/MS). This method combined the advantages of IAC specificity with the speed and sensitivity of UPLC−MS/MS instrumentation. Further, the optimized method was applied to the detection of TTX in real samples.

MATERIALS AND METHODS

Chemicals and Materials. TTX was purchased from Tocris Cookson (Bristol, UK) (purity ≥99.6%). HPLC grade acetonitrile, methanol, formic acid, glacial acetic acid, and ammonium acetate were purchased from Sigma-Aldrich (St. Louis, MO, USA). Ultrapure water was produced by a Millipore Milli-Q system (Millipore, Bedford, MA, USA). All other chemicals and solvents were of analytical grade and were obtained from Shanghai Chemical Reagent Co. (Shanghai, China).

Standard Solutions and Buffers. TTX standard stock solution (100 μg mL^{-1}) was prepared by dissolving TTX (5 mg) in ultrapure water (50 mL) containing formic acid/acetonitrile (0.1%, 5:5, v/v). The working standard solution of TTX was prepared by appropriate dilution of the stock solution using ultrapure water containing 0.1% formic acid/acetonitrile (5:5, v/v) and stored at 4 °C. Phosphate buffered saline (PBS, pH 7.4) was prepared by dissolving $KH_2PO_4 \cdot 2H_2O$ (1.09 g), $Na_2HPO_4 \cdot 12H_2O$ (6.45 g), and NaCl (4.25 g) in ultrapure water (500 mL).

Preparation of Immunoaffinity Column. Cynogen bromide (CNBr)-activated Sepharose 4B powder (0.5 g) was added to hydrochloric acid (HCl, 1 M, 100 mL) and poured into a sintered glass funnel (40−60 mm). The gel was washed with the coupling buffer (0.1 mol L^{-1} NaHCO3, 0.5 mol L^{-1} NaCl, pH 8.3, 100 mL). Subsequently, the gel (1.5 mL) was mixed with TTX monoclonal antibody (mAb, 10 mg mL^{-1}, 1.5 mL); the mixture was transferred into a stoppered flask and incubated on a shaker (120 rpm) at room temperature for 2 h. The resulting solution was collected to calculate the coupling efficiency and determine the antibody amount by Bradford protein assay method. The mixture was then washed with coupling buffer (30 mL) to remove the uncombined MAbs. The unreacted active groups on the sorbents were capped with the blocking buffer (0.1 mol L^{-1} Tris-HCl, pH 8.0) for 2 h at room temperature following which the column was washed with PBS (100 mL, 0.01 mol L^{-1}, pH 7.3) and stored in PBS (0.01 mol L^{-1}, pH 7.3) containing ethylmercurithiosalicylic acid (0.05%, w/v) at 2−8 °C.

Determination of Column Capacity. A relatively large amount (6000 ng) of TTX was dissolved in PBS (25 mL) containing 20% methanol. The solutions were then transferred into the IAC column (preconditioned with 10 mL of PBS) with the flow rate of 1 mL min^{-1}. The saturated column was washed with water (8 mL). Finally, methanol (4 mL) containing 0.1% acetic acid was used to elute the analytes. The eluate was evaporated to dryness under a stream of nitrogen at 60 °C. The so-obtained residue was redissolved in methanol (1 mL). Further, the solution was filtered through a 0.22 μm PTFE filter, and 10 μL of the solution was injected into the UPLC system.

Sample Preparation for IAC. Muscle tissue homogenate (2 g, ± 0.01 g) was weighted into a 50 mL polypropylene centrifuge tube. Acetic acid (0.1%) in methanol (10 mL) was added to the sample and vortexed for 2 min and then ultrasonicated for 15 min. After centrifugation at 6000 × g for 50 min, 5 mL of the supernatant was decanted into a clean tube. The supernatant was diluted with PBS (20 mL, pH 7.4), and the pH was adjusted to 7−8 using 1 M NaOH solution.

The IAC column was preconditioned with PBS (10 mL) prior to the analyte loading. Subsequently, the analyte solution was loaded onto the IAC at a flow rate of about 9 mL/min by gravity. The analyte was washed with water (8 mL) and eluted with 1% acetic acid in methanol (4 mL). The elute was completely dried under a stream of nitrogen at 60 °C. The residue was redissolved in LC mobile phase (1 mL, 95% A mix with 5% B) and filtered through a 0.22 μm PTFE filter into an autosampler vial for analysis. The columns, after elution, were immediately regenerated by PBS (50 mL) and stored in PBS (containing 0.01% sodium azide) at 4 °C for the subsequent use.

LC−MS/MS Equipment and Parameters. The TTX analysis was carried out on an ACQUITY UPLC system (Waters, Milford, MA,USA) coupled with Quattro Premier XE Micromass triple−quadrupole mass spectrometer (Waters, Manchester, UK). The UPLC separation was performed on an ACQUITY UPLC BEH Amide column (50 mm × 2.1 mm I.D., 1.7 mm particle size) at 40 °C. The injection volume was 10 μL. Acetonitrile (A) and 5 mmol L^{-1} ammonium acetate in ultrapure water containing 0.1% formic acid (v/v) (B) were used as the mobile phases, and the flow rate was 0.3 mL min^{-1} throughout the analysis. The solvent gradient was increased linearly from 5−80% B in 1.5 min, kept constant for 1.5 min, and then returned to 5% B after 0.5 min, and held at this level for 1.5 min so that the system could re-equilibrate prior to the next injection.

The mass spectrometer was operated in electrospray positive mode with the capillary voltage set at 3.0 kV. The source temperature was set at 110 °C, desolvation temperature at 350 °C, and cone gas flow at 50 L h^{-1} with desolvation gas flow at 600 L h^{-1}. Data acquisition was in multiple reactions monitoring mode (MRM). The cone voltage and collision energy were optimized for TTX by standard infusion. The precursor/product ions monitored were 320.0 > 302.0 (cone voltage 45 V, collision energy 25 eV) and 320.0 > 161.8 (cone voltage 45 V, collision energy 35 eV). The precursor/product ion m/z 320.0 > 302.0 was used for quantification in MRM mode.

Calculations of Results. Data acquisition was acquired and processed using MassLynx 4.1 and QuanLynx software. The concentrations of TTX in samples (ng g^{-1}) were calculated directly from the area responses using a linear six-point calibration produced from 0.3−20 ng mL^{-1} TTX standard solutions. If the concentration of analyte exceeds the linear range, the sample solution should be diluted with mobile phase appropriately, then injected into the UPLC−MS/MS system.

RESULTS AND DISCUSSION

Preparation of IAC Column. The antibody plays an important role in the potential use of the immunosorbent whether the IAC is used for a single analyte or for class-selective purposes. In this study, TTX−BSA (bovine serum albumin) conjugate was synthesized, and mAb against TTX was successfully produced using the hybridoma method.[30] CNBr-activated Sepharose 4B was employed as a coupling matrix because it is water insoluble; however, it is hydrophilic and could be easily activated. To obtain the best binding capacity, several amounts of antibodies (3−15 mg mL^{-1} gel) were separately conjugated to Sepharose 4B, and the corresponding capacities were measured. Coupling efficiency of different amount of mAb combined with CNBr-activated Sepharose 4B (1 mL) are shown in Figure 2. The result showed that 6 mg of the mAb saturated in 1 mL gel exhibited a good coupling efficiency of about 97.4%. An excessive amount of antibody (>6 mg) might introduce steric hindrance to antigen/antibody recognition and thus lead to the reduction of column capacity.

Optimization of IAC Conditions. Appropriate elution solvents are important not only for the efficient uncoupling of the captured analyte off the IAC, but also in preserving the column reusability.[31] In this study, loading, washing, and elution conditions were developed and optimized. It is universally acknowledged that the bond between the antigen/hapten and the antibody is due to electrostatic forces, Vander Waals forces, hydrogen bonds, and hydrophobic interactions.[32] To elute the antigen from the antibody−antigen complex in the IAC, the column environment was required to be changed. In this study, pure methanol and acetonitrile were tested to elute the analyte; however, the results were not satisfying with the recoveries of only 65.6 and 75.2%, respectively. Moreover, a

DOI: 10.1021/acs.jafc.5b00045
J. Agric. Food Chem. 2015, 63, 3129−3134

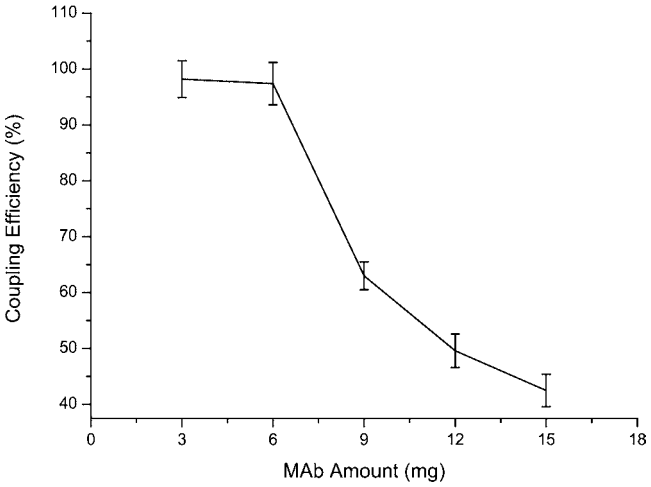

Figure 2. Coupling efficiency of different amount of mAb combined with CNBr-activated Sepharose 4B (1 mL).

large amount of solvent was required for elution, and the process was time-consuming. According to the literature,[29] the acidic solvents could enhance the strength of the eluent solution in IAC elution procedure. Therefore, acidic methanol and acetonitrile were tested to elute the analyte, with the volumes for elution measured to be about 1−5 mL. The recoveries corresponding to different elution conditions are listed in Table 1. The result shows that 5 mL of acidic methanol

Table 1. Recoveries of TTX (400 ng) at Different Elution Conditions

	recovery in various fractions (%)[a]			
elution fraction[a]	methanol	acetonitrile	1% acetic acid in methanol	1% acetic acid in acetonitrile
fraction 1 (1 mL)	34.8	21.5	89.8	68.7
fraction 2 (1 mL)	17.8	13.1	5.3	7.5
fraction 3 (1 mL)	10.0	10.2	2.4	5.4
fraction 4 (1 mL)	7.0	11.4	0.6	2.7
fraction 5 (1 mL)	5.6	9.4	0.3	2.3
total recovery[b]	75.2	65.6	98.4	86.6

[a]New IAC column was preconditioned with PBS (10 mL), the analyte solution containing 400 ng of TTX was loaded, then the column washed with water (8 mL) and eluted with each elution summarized in the table. [b]Total recovery is the sum of fraction 1 to fraction 5.

leads to the best recovery of 98.4% in less time, which thus indicates that organic solvents with low pH could disrupt these bonds and efficiently elute the antigen from the IAC column. Therefore, 5 mL of 1% acetic acid in methanol was selected as the optimized elution condition.

Column Capacity and Reusability. In this study, the capacity was evaluated and presented as nanograms of analyte relative to IAC bed volume (ng mL^{-1}). The column capacity of new IAC column was found to be 1106 ng mL^{-1}, which was sufficient for TTX determination and suitable for marine organisms. The reusability of IAC depended on the concentration and activity of the immobilized antibodies and chemical stability of the support. The reusability of IAC was evaluated in 10 days at 1 day intervals. Each time after using, the IAC was stored in PBS at 4 °C. The column capacity curve is shown in Figure 3. The column capacity decreases with

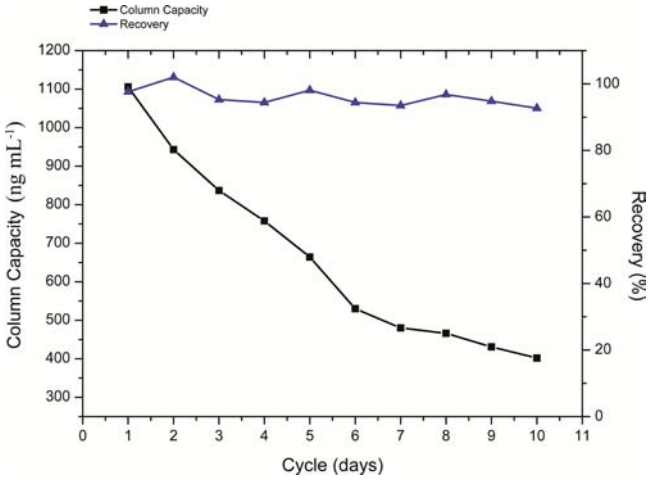

Figure 3. Capacity and recovery variation curves of the IAC column during ten cycles.

increasing cycles of usage, in particular, during the fifth and the sixth runs. In China, the official test method for TTX in aquatic products is HPLC method with a measure range 50−500 ng g^{-1}; and a HPLC−MS/MS confirmation is needed. When the UPLC−MS/MS method described in this paper used for confirming of TTX, the IAC column has the potential to reuse for five times with column capacity above 500 ng mL^{-1} to meet the HPLC method measure range.

Optimization of UPLC−MS/MS Conditions. The optimization of the electrospray ionization (ESI) interface parameters was highly desirable for obtaining the maximum abundance of the molecular ions of the analyte. Acquisition parameters were determined by direct infusion of standard solution (5.0 μg mL^{-1}) into the mass spectrometer at a flow rate of 10 μL min^{-1}. ESI probe temperature was set at the minimum acceptable value (110 °C), and capillary voltage was kept at 3.0 kV. The predominant peak in the primary ESI spectra of TTX corresponded to the $[M + H]^+$ ion at m/z 320.0. Then, dissociation with argon was induced, and different collision energies were tested to find the most abundant product ion. Figure 4 shows the product ion spectra of the [M

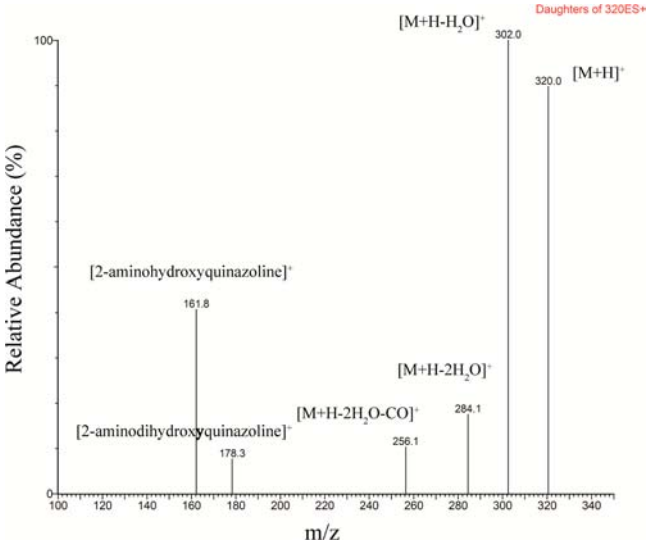

Figure 4. MS/MS fragmentation spectra of TTX.

DOI: 10.1021/acs.jafc.5b00045
J. Agric. Food Chem. 2015, 63, 3129−3134

+ H]$^+$ ion of TTX. The major fragment ions at m/z 302.0, 161.8, 284.1, 256.1, and 178.3 are observed. The daughter ion m/z 302.0 (CE 25 eV), with the highest relative abundance, was selected for quantification in MRM mode. The fragmentation pathways of TTX have been studied and reported in the literature.[8] On the basis of the product ion spectra of TTX (Figure 4), the ions at m/z 302.0, 284.1, and 256.1 are assigned to [M+H−H_2O]$^+$, [M+H−2H_2O]$^+$, and [M +H−2H2O−CO]$^+$, respectively. Notably, the ion at m/z 256.1 fragmentation pathway mentioned previously was different from that reported by Cho et al.[23] The other ions at m/z 178.3 and m/z 161.8 were derived probably from [2-amino-dihydroquinazoline]$^+$ and [2-aminodihydroxyquinazoline]$^+$, respectively, with sequential elimination of water molecules.

Chromatographic conditions were optimized to obtain maximum sensitivity and best peak shape. The Acquity UPLC BEH C18, Acquity UPLC BEH HILIC, and Acquity UPLC BEH Amide columns were tested for the separation of TTX. Lack of retention was observed with reverse-phase chromatography on BEH C18 column. As expected, TTX was not retained on this stationary phase because of its high polarity. Although TTX was retained in BEH HILIC column and the column provided several advantages[24] in chromatographic separation, asymmetric peak was observed in this study. UPLC BEH Amide column enabled the use of a wide range of pH values of the mobile phase, and the presence of amide group also favored both partitioning and hydrogen bonding separation mechanism, which facilitated the separation of high polarity analyte. The results revealed that BEH Amide column provided the best resolution and peak shape for the studied analyte in the shortest time of 5 min. Consequently, following the optimization of the gradient profile, the Acquity UPLC BEH Amide column was selected as the proper column for chromatographic separation. Typical LC−MS/MS chromatograms of blank sample, standard solution, spiked sample, and naturally contaminated TTX sample are shown in Figure 5.

Method Validation. The proposed method was validated by assessment of its specificity, linearity, limit of detection (LOD), limit of quantification (LOQ), recovery, and intra- and inter-day precision. The specificity of the method was determined by comparing the chromatograms of blank sample with standard-spiked sample. The TTX was detected without apparent interference from endogenous components of all marine organisms. Good linearity was obtained at concentrations of standard solutions ranging from 0.3−20 ng mL^{-1} for calibrating TTX in marine organisms, as demonstrated by the high correlation coefficient (r^2) value above 0.9984. The LOD and LOQ for TTX in marine organisms, which were defined as signal/noise ratios of 3:1 and 10:1, respectively, were determined to be 0.1 and 0.3 ng g^{-1}. To date, there are few methods available for the detection of TTX with LOD from 0.32−100 ng g^{-1}.[21−23] However, in this study, the method was found to be more sensitive. Precision and accuracy were assessed from replicated experiments (n = 6) using new IAC columns at three different concentrations, namely, 0.3, 1.5, and 5 ng mL^{-1}. The values corresponding to the results for intra- and inter-day precision and accuracy are listed in Table 2. The recoveries of TTX from fortified samples ranged from 86.5−103.6% with intraday RSDs of 3.40−7.22% and interday RSDs of 4.74−9.88%.

Application to Real Samples. One-hundred marine organisms samples (no. 1−100) including puffer fish, shrimps, crabs, clam, and horseshoe crab collected from Zhoushan local market were analyzed for the presence of TTX. All the samples were processed according to the IAC method described above, and the results are listed in Table 3. Nine samples were found to contain TTX at concentrations ranging from 2.22−590 ng g^{-1}. The result shows that some puffer fish (*Lagocephalus gloveri*) and horseshoe crab (*Carcinoscorpins rotundicauda*) contain a certain amount of TTX; however, it is virtually absent in horseshoe crab (*Tachpleus tridentatus*). These results were consistent with the previously published study.[33] One of the 20 manila clams (*Ruditapes philippinarum*) was found to contain TTX with a low value of 2.22 ng g^{-1}. Although several studies[22] have reported that bivalves such as *Paphies australis* were found to contain TTX, TTX positive *Ruditapes*

Table 2. Recovery, Intra- and Inter-Day Precision of TTX in Marine Organisms[a]

species	added (ng g^{-1})	average recovery (%, n = 6)	intraday RSD (%, n = 6)	interday RSD (%, n = 6)
shrimps (*Penaeus orientalis*)	0.3	101.8	7.22	5.33
	1.5	96.7	5.42	4.74
	5.0	103.6	3.94	6.07
puffer fish (*Lagocephalus gloveri*)	0.3	86.5	6.31	6.74
	1.5	89.1	4.82	9.88
	5.0	94.7	3.40	6.03
horseshoe crab (*Tachpleus tridentatus*)	0.3	92.0	5.36	4.86
	1.5	96.9	5.95	5.15
	5.0	94.4	4.54	6.63

[a]TTX was determined according to section Sample Preparation for IAC using new IAC columns.

Table 3. Presence of TTX in Marine Organisms (Analysis of 100 Samples)

species	sample number	positive sample code	concentration of TTX (ng g^{-1})
puffer fish (*Lagocephalus gloveri*)	1–20	3	128
		4	103
		14	590
		17	146
		18	61.6
shrimps (*Solenocera melantho*, *Penaeus orientalis*)	21–40		ND[a]
crabs (*Portunus trituberculatus*)	41–60		ND
manila clams (*Ruditapes philippinarum*)	61–80	67	2.22
horseshoe crab (*Carcinoscorpins rotundicauda*)	81–90	83	162
		88	101
		90	24.8
horseshoe crab (*Tachpleus tridentatus*)	90–100		ND

[a]ND indicates "not detected".

philippinarum found in this study has never been mentioned before.

[a]Vitamin B2 was not detected due to its low solubility in methanol; vitamin B7 was not quantified due to spectral overlap; vitamins B12, D3, and K were not detected by NMR (below LOD). [b]Not detected by NMR and is not labeled by the manufacturer.

Apart from active ingredients (vitamins), a number of accompanying substances (sweeteners, acidifiers, and antioxidant agents) can be found in multivitamin preparations. The methods for their simultaneous quantification in this matrix were not reported so far. However, the nuclear magnetic resonance (NMR) method exists, for example, for quantification of some sweeteners in carbonated soft drinks or coenzyme Q10 in dietary supplements.[20,21]

Therefore, development of a fast, reliable, and precise analytical method for the determination of the majority of fat- and water-soluble vitamins as well as accompanying substances without a need for time-consuming sample preparation is desirable. In this study, a method based on NMR spectroscopy was proposed, which provides spectral information about all mixture constituents and opportunities to quantitative analysis using an internal standard. Previous studies have shown that NMR can successfully solve the task of multicomponent analysis of food and medicinal products; however, it has never been applied to multivitamin preparations.[22−24]

MATERIALS AND METHODS

Samples and Chemicals. A total of 16 different products were investigated. The samples including effervescent tablets (n = 6), tablets (n = 4), capsules (n = 1), caplets (n = 1), and ampules (n = 1) were randomly selected from local supermarkets in Cologne, Germany. Furthermore, three liquid multivitamin drinks based on orange juice concentrate and multivitamin direct juice were examined. The information about the samples is summarized in Table 1.

The deuterated solvents of 99.8% purity (methanol, chloroform, water, and dimethyl sulfoxide) were purchased from Euriso-top (Saarbrücken, Germany). The certified reference standards of retinol palmitate (vitamin A, >85%), nicotinamide (vitamin B3, >99.5%), and ascorbic acid (vitamin C, 99%) were obtained from Fluka Chemie; cobalamin (vitamin B12, >98%), cholecalciferol (vitamin D3, >98%), and α-tocopherol (vitamin E, >96%) were purchased from Sigma-Aldrich (Steinheim, Germany).

Thymol (99.5%), mannitol (99%), saccharin (>98%), and citric acid (99%) were provided by Sigma-Aldrich; cyclamate (99.8%) and butylhydroxytoluene (>99%) by Supelco (Bellefonte, Pennsylvania, USA); maleic acid and acesulfame K (>99%) by Fluka Chemie (Buchs, Switzerland); and phosphonoacetic acid (98.8%) by Alfa Aesar (Karlsruhe, Germany). The purity of all chemicals is shown in parentheses.

Sample Preparation. The content of investigated tablets and the capsules was first pulverized. For the standard sample preparation, 200 mg of the sample was weighed and mixed with 1 mL of thymol solution (1 mg/mL in MeOD). The resulting solution was centrifuged (2 min at 2000 rpm). The extract was carefully removed and placed in a separate flask. Two additional successive extractions with pure MeOD were conducted, and the liquid phases from each extraction step were combined with the first part. The resulting mixture was centrifuged, and an aliquot was then transferred in the NMR tube for direct measurements.

Stock solutions were prepared by weighing approximately 5 mg of reference compounds and dissolving this amount in 1 mL of MeOD. For spiking experiments, 10−20 μL of each standard solution was separately added to the methanol extract prepared according to the standard scheme.

To investigate the stability of ascorbic acid in solution, the methanol extract of sample S4 was measured 10 times with 5 h intervals while staying in the autosampler. Additionally, reference ascorbic acid solution (30 mg/mL in MeOD) was measured before and after staying in a drying oven at 70 °C for 24 h to accelerate the degradation reaction.

To model the composition of sample S4, the defined amounts of vitamins B3, C, and E were directly weighed and mixed with 200 μL of aliquot of each of the separately prepared stock solutions of vitamins A, B1, B5, B6, B7, B9, B12, D3, E, and K. Afterward, thymol solution in methanol (1 mg/mL) was added to the mixture. The composition of this artificial mixture corresponds to that of sample S4 except for the presence of accompanying compounds.

NMR Measurements. NMR measurements were performed on Bruker Avance III 500/600 MHz spectrometers (Bruker Biospin, Rheinstetten, Germany) with BBO Prodigy cryo/QNP cryo probes equipped with Bruker Automatic Sample Changer (B-ACS 120). ^{1}H NMR spectra were recorded using a standard 1D pulse sequence with 30° flip angle. One hundred twenty-eight scans and 4 prior dummy scans of 131k points were acquired with a spectral width of 24.0258 ppm, a receiver gain of 9, and an acquisition time of 5.4525952 s. The relaxation delay was 1.0 s, which was sufficient for accurate quantification of vitamins. The data were acquired automatically under the control of ICON-NMR (Bruker Biospin, Rheinstetten, Germany). All NMR spectra were phased, baseline-corrected, and manually integrated using Topspin 3.1 (Bruker Biospin, Rheinstetten, Germany).

DOI: 10.1021/acs.jafc.5b00087
J. Agric. Food Chem. 2015, 63, 3135−3143

Quantification and Validation Studies. The NMR signals of vitamins in the samples were assigned using spectra of reference compounds and spiked solutions. Baseline-separated peaks (i.e., peaks not overlapped or interfered with by a matrix) of each substance were selected for integration.

For quantification, the well-known equation was utilized, which includes molar weight, integral, number of protons of reference compound (thymol) and analytes (vitamins), and purity and concentration of the reference compound.[25] The quantity of targeted substances is calculated by integrating a particular signal of interest and signal of thymol at δ 6.57 ppm, which corresponds to two protons.

Validation was performed for vitamins and not for accompanying substances. The limits of detection (LODs) and the limits of quantification (LOQs) were defined as signals with signal-to-noise ratios (SNRs) of 3 and 6, respectively. The average values were calculated using six separately prepared sample extracts (sample S4). SNR of 1D spectra was calculated according to the formula SNR = maxval/(2·noise), where maxval is the highest spectral intensity in the spectral region. The noise is computed from the data points in the defined frequency range. The limits of noise and signal regions were located close to each other and were set manually for each spectrum. The noise regions were approximately 0.2 ppm wide, where no real matrix signal was observable.

To assess repeatability, six separate standard sample preparations were performed for one sample and measured within a short period of time. To estimate linearity, the standard extraction procedure was conducted three times for the sample weight of 140 mg (70%), 200 mg (100%), and 260 mg (130%). The recovery rates were ascertained by adding standard solutions at four different concentrations (0%, 37.5%, 75%, 112.5%, and 150% of the labeled content for each vitamin) to a real sample (S4). The recovery rates were additionally estimated using the artificial mixture of all vitamins, whose concentrations exactly coincide with the labeling information for sample S4.

RESULTS AND DISCUSSION

Rationale of NMR Analysis of Vitamins. To be competitive with existing chromatographic methods, a new NMR method has to be characterized by simple sample preparation and fast acquisition time, and, therefore, be suitable for routine analysis with high throughput. However, as many fat- and water-soluble vitamins as possible should be simultaneously analyzed. For the method development, an effervescent tablet (sample S4) was used, which can be considered as a representative sample for our data set because it contains both fat- and water-soluble vitamins (Table 1).

Table 2. NMR Integration Regions Used for Quantification and Validation Studies (δ, Multiplicity, Number of Protons)[a]

compound	main signal	alternative signal[b]
vitamin A	1.02 (s, 1)	1.90 (s, 3)
vitamin B1	5.50 (s, 3)	8.15 (s, 3)
vitamin B3	8.30 (tt, 1)	
vitamin B5	0.91 (s, 6)	
vitamin B6	4.67 (s, 2)	8.04 (s, 1)
vitamin B7	2.31 (t, 2)	
vitamin B9	6.73 (d, 2)	
vitamin B12	0.45 (s, 3)	
vitamin C	4.79 (s, 1)	
vitamin D3	0.55 (s, 6)	
vitamin E	2.31 (s, 3)	
vitamin K	0.81 (d, 6)	
citric acid	2.80−2.74 (AB, 2)	
mannitol	3.84−3.76 (m, 2)	
saccharin	8.10−7.90 (m, 4)	
sodium cyclamate	1.78−1.68 (m, 2)	
butylhydroxytoluene (BHT)	6.93−6.91 (s, 2)	
steviol glycoside[c]	4.68−4.65 (d, 1)	

[a]Related to the main signal for quantification and standard sample preparation. [b]Used for quantification in the case of overlap of the main signal. [c]The sum of steviol glycosides was calculated.

Selection of Solvent, Internal Standard, and Optimization of the Extraction Procedure. The most important requirement for the solvent utilized in the NMR method is the complete solubility of the investigated analytes in it. In our case, most of vitamins regardless of their physical properties have to be extracted by the optimal solvent without heating of the samples. The NMR signals of extracted compounds selected for quantification should be stable and not overlap with each other.

During the method optimization, different deuterated solvents (pure D_2O, MeOD, $CDCl_3$, and DMSO) and their mixtures (DMSO-$CDCl_3$ (1:4), MeOD/D_2O (1:1), MeOD/D_2O (3:1), MeOD/DMSO (1:1), and D_2O/MeOD/$CDCl_3$ (1:1:2)) were tested. It was observed that the majority of vitamins can be extracted using ternary mixture D_2O/MeOD/$CDCl_3$. The advantage of this solvent mixture is that the signals of water- and fat-soluble vitamins were separately observed in polar and nonpolar phases after centrifugation (except vitamin B3, which was found in both phases). Therefore, the matrix effect can be minimized. However, we decided to utilize MeOD as a solvent for routine analysis due to better phase separation, lower extraction, and acquisition time.

During optimization, the sample weight was varied between 100 mg and 250 mg using methanol as a solvent for extraction. We have found that 200 mg is the optimum value because the smaller initial sample weight did not provide the required sensitivity for quantification, while bigger ones led to the saturation of the sample solutions.

For the development of quantitative procedure, 100% extraction of all compounds has to be ensured. The second methanol extraction resulted in an additional yield of approximately 14% of vitamins compared to that of the first extraction step. Additionally, the precipitation resulted after three successive extractions of sample S4 mixed with MeOD and was analyzed. In this experiment, signals of vitamins had approximately the same height as ^{13}C satellites of niacin after the three-step extraction. It means that the addition uncertainty resulting from the extraction procedure is about 1%. Therefore, three successive extractions were considered to be enough to achieve almost complete extraction of vitamins.

In qNMR, it is important to select an appropriate reference compound (internal standard) for calculating the concentration of all analytes. Among the main requirements for the choice of a particular compound are low costs and high purity, together with its stability and inertness. It should also be nonvolatile, nonhygroscopic, and soluble in the selected NMR solvent. The signal of an ideal internal standard should not overlap with other signals and preferably be a singlet with low relaxation time.[25,26] A number of internal standards were tested during our preliminary experiments. Phosphonoacetic acid was rejected because its signals overlap with those of citric acid present in multivitamin preparations in the δ 2.84−2.79 ppm range. Maleic acid that shows an undisturbed singlet at δ 6.33 ppm was also found unsuitable for quantification purposes because after its addition to an authentic sample, several new signals in the δ 6.45−6.05 ppm range appeared in the spectrum due to an unknown reaction. Thymol was chosen as an

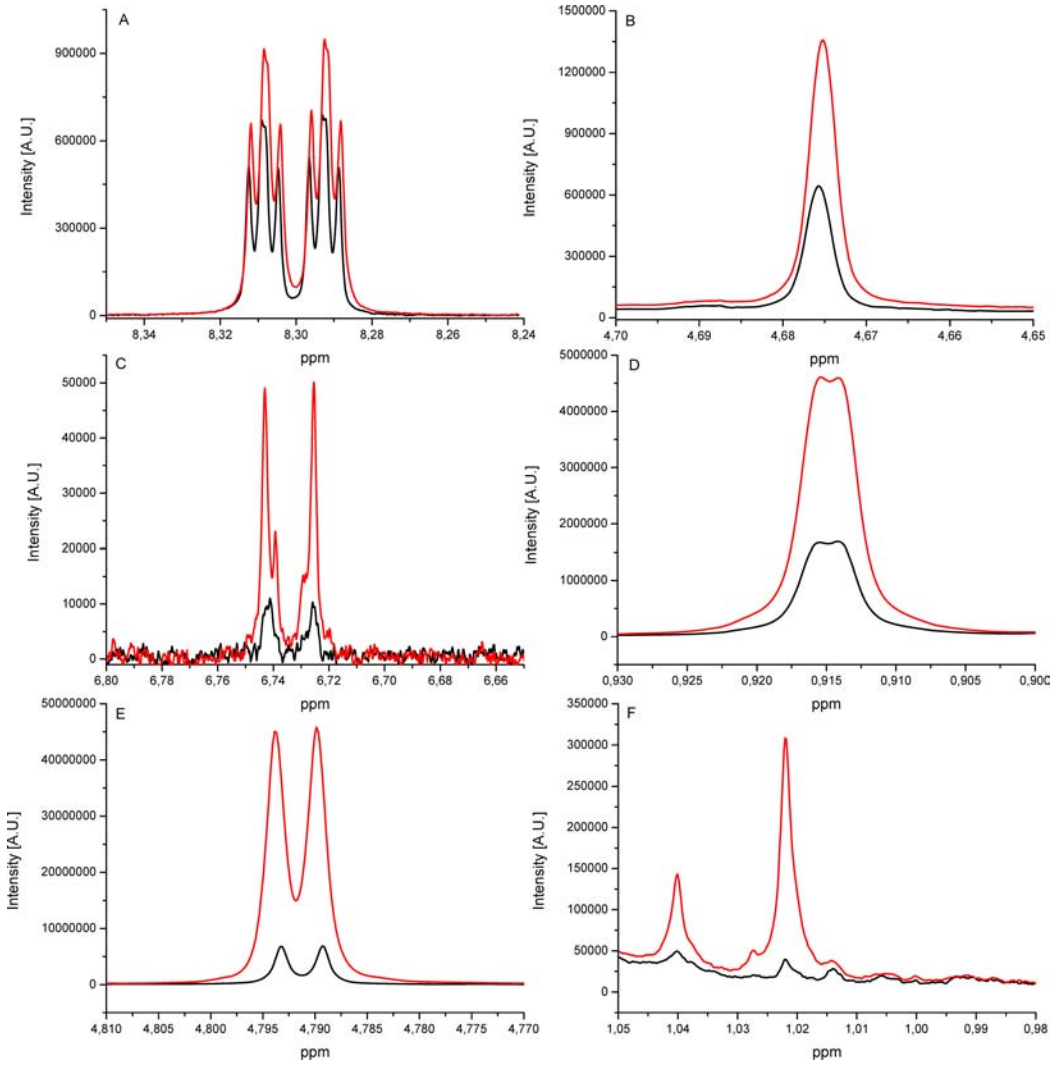

Figure 1. NMR resonances of vitamins B3 (A), B6 (B), B9 (C), B5 (D), C (E), and A (F) in multivitamin preparation (S4) and its spiked solutions. Spiked amounts were 100 μg for all vitamins except vitamin A (50 μg) and vitamin C (undefined amount).

appropriate internal standard for quantification. This compound has a signal at δ 6.57 ppm derived from two protons of the molecule.

NMR Ranges for the Quantification of Vitamins and Accompanying Substances. The NMR peaks together with their multiplicity and the number of protons selected for quantification for each analyte are given in Table 2. For vitamins A, B1, and B6, alternative peaks were defined for their quantification in case of the overlap of the main signal. Figures 1 and 2 showed some examples of the defined NMR regions for vitamins. It can be concluded that vitamins B5, B12, D3, and K1 have signals in the δ 0.81−0.45 ppm region, which is particularly suitable for identification and quantification by NMR spectroscopy due to the absence of other signals. However, the contents of vitamins K1 and D3 were too low in our samples to be detected by NMR (Figure 2). Other substances showed suitable signals in the δ 6.0−1.0 ppm region (A, B1, B6, C, and E). Vitamins B3 and B9 can be differentiated in the low-field NMR region. Unfortunately, it was only possible to provide qualitative analysis of vitamin B7 in multivitamin preparations due to signal overlap (Figure 2). The NMR analysis of only vitamin B2 was impossible because of its insolubility in methanol.

Alternatively to the qNMR approach, multivariate calibration methods, e.g., partial least-squares (PLS) regression could be used to improve quantification results because several peaks of each substance (including those with spectral overlap) can be simultaneously evaluated. However, this will require time-consuming reference analysis of all studied vitamins. In our case, the specific undisturbed signal was identified for each analyte of interest; therefore, direct NMR quantification was preferable in this case (Table 2).

Apart from vitamins, a number of accompanying substances were detected in NMR spectra of multivitamin preparations. The identification of citric acid, mannitol, saccharin, sodium cyclamate, and the sum of steviol glycosides and butylhydroxytoluene was performed using its specific signals (Table 2). As these substances are contained in relatively high concentrations in multivitamin preparations and show undisturbed NMR signals (Figure 3), their quantification was also possible based on the qNMR approach (Table 3).

Validation Studies. Table 4 provides validation results for the investigated vitamins. In particular, the LODs were found between 9.0 mg/kg for vitamin A and 77.0 mg/kg for vitamin B3. LOQ values varied between 18.0 mg/kg and 153.5 mg/kg. Intermediate LOQ values were found for vitamin B6 (34.5 mg/

DOI: 10.1021/acs.jafc.5b00087
J. Agric. Food Chem. 2015, 63, 3135−3143

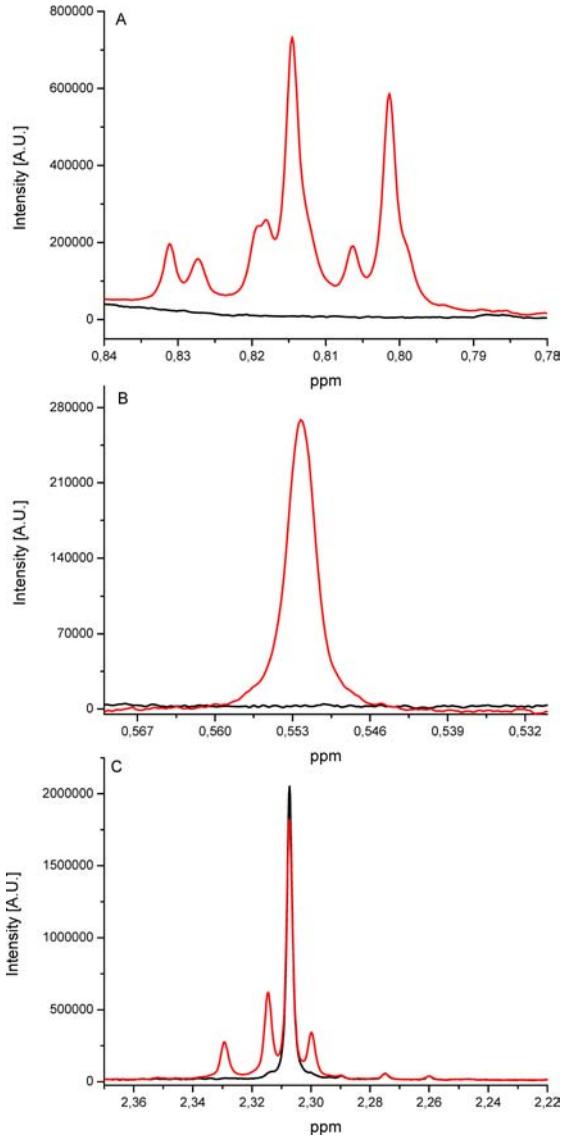

Figure 2. NMR resonances of vitamins K (A), D (B), and B7 (C) in multivitamin preparation (S4) and its spiked solutions. Spiked amounts were 100 μg in all cases.

kg) and vitamin C (93.5 mg/kg). All values were calculated for the 200 mg sample weight. The reference values for the daily vitamin requirement provided by the US Food and Drug Administration are shown in Table 4 for comparison.[27] Taking into account the vitamin contents in multivitamin preparations, we observed that LOD/LOQ values are sufficient to quantify major vitamins by NMR (Table 4).

Validation of the NMR method was further conducted by repeated sample preparation of sample S4 (n = 6, intraday validation). The concentrations obtained by the qNMR method were summarized, and repeatability values expressed as CVs were calculated. Table 4 showed that CVs ranged between 0.9% for vitamin B3 and 12% for vitamin A. The relatively high CV of 12% for vitamin A is due to spectral overlap that leads to impossibility of obtaining a baseline-separated signal. The comparably high CV value for vitamin B9 (6.4%) can be explained by its small concentration in the sample. In other cases (except vitamins A and B9), the repeatability never exceeded 6%, which also showed the reliable quantification of the developed qNMR method (Table 4). The EU legislation allows tolerances for vitamins in foods from minus 50% up to plus 35%; therefore, even the highest errors are acceptable.[28] It should be noted that, in general, better repeatability can be achieved with a concentrated sample solution, where a better SNR can be obtained. However, an authentic sample (S4) was used to estimate practically meaningful validation characteristics.

Furthermore, linear ranges were established for three different sample weights (140 mg, 200 mg, and 260 mg) using in-house calibration curves (concentration versus integral value related to the IS integral) for all investigated substances. The standard deviations for three different sample weights showed that the best repeatability between 1.5% and 5.3% was obtained for the 200 mg sample weight for the majority of vitamins (E, C, B1, and B5). On the contrary, comparable but better values were found for the higher sample weight (260 mg) for vitamins A and B3 and for the smallest sample weight (140 mg) for vitamin B6. These results also confirmed our choice of 200 mg as the optimum sample weight. The ^{1}H NMR spectra showed linearity in the defined concentration ranges (70−140%). The regression coefficients of the calibration curves varied between 0.962 and 0.997 for vitamins B1 and B3, respectively. The worst correlation coefficient (R = 0.918) was obtained for vitamin A due to spectral overlap and the low intensities leading to the big uncertainties in integrals values for this compound. Additionally, spiking solutions at four different concentrations (0%, 37.5%, 75%, 112.5%, and 125% of the labeled amount for each vitamin) were used to ascertain the vitamin content in an authentic sample.

The contents of vitamins B1 and B9 in the spiked sample were found to be 0.83 mg/g and 1.1 mg/g using the standard addition approach, which correspond to the recovery values of 96% and 92%, respectively, with respect to the declared amounts. However, worse recoveries were found for vitamin A (0.06 mg/g was found; 250% recovery), B9 (0.21 mg/g was found; 135% recovery), and B5 (2.73 mg/g was found; 142% recovery) probably due to incomplete solubility of reference compounds in methanol, low SNR, or erroneous labeling information.

Furthermore, qNMR analysis was performed for the artificial vitamin mixture, whose composition coincides with that of sample S4. Acceptable recovery rates were found for vitamins B1 (88%), B3 (100%), B5 (89%), B6 (96%), B9 (86%), and C (93%). The insufficient recoveries for vitamin A (38%), E (61%), and K (32%) can be explained by difficulties in weighing the viscous reference substances.

Stability of Ascorbic Acid in Multivitamin Preparations. It was observed that ascorbic acid was not stable in samples prepared according to our standard procedure. Its main peak at δ 4.76 ppm selected for quantification gradually degrades within 100 h (Figure 4A). The same effect was monitored for the ascorbic acid signals at δ 3.91 ppm, δ 3.67 ppm, and δ 3.32 ppm. At the same time, several multiples appeared in the range of δ 4.5−4.0 ppm (Figure 4B).

It is known that equilibrium exists in solutions between ascorbic acid and its first oxidation product, dehydroascorbic acid (DHAA), which undergoes hydrolysis with the formation of 2,3-diketogulonic acid.[29−31] Some additional products can be formed by further reactions in complex matrixes such as fruit juice or wine.[30,31] In our case, linear dependency was observed between the integral values of the ascorbic acid signal at δ 4.76 ppm and the DHAA peak at δ 4.50 ppm with the correlation coefficient of −0.97. The equilibrium is achieved in solution

[a]Not detected by NMR and is not labeled by the manufacturer. [b]The sum of steviol glycosides was calculated.

after 100 h after sample preparation, and afterward, no changes in integral values were observed. The time course of the degradation reaction can be observed in NMR spectra of an authentic sample. The peak at δ 4.76 ppm belongs to ascorbic acid, whereas the signals in the 4.5−4.0 ppm region can be explained by the presence of different degradation products of ascorbic acid such as DHAA and 2,3-diketogulonic acid (Figure 4B). DHAA has been also previously detected in herbal formulations by ^{1}H NMR.[32] This compound showed resonances at δ 4.58 ppm, δ 4.43 ppm, δ 4.21 ppm, and δ 4.05 ppm in the CD_3CN:D_2O mixture, which is in good agreement with our results (Figure 4B).

The existing equilibrium of ascorbic acid in the multivitamin preparation is complicated due to the presence of other matrix compounds. Indeed, it was shown that the metal ions (e.g., Cu, Fe) present in multivitamin preparations can act as catalysts.[29,31] However, ascorbic acid solution can be stabilized in the presence of citric acid used as an acidifier in our samples.[29] Unambiguous assignment of all substances existing in solution requires the use of 2D NMR experiments, which was not a primary goal of this study.

Clearly, the appearance of degradation products of ascorbic acid influences the accuracy of its quantification. Because of the complexity of the matrix, we did not try to stabilize solutions similar to what has been recently done for acrolein in alcoholic

beverages.[33] The multivitamin preparations have to be measured directly after extraction, where the percentage of degradated ascorbic acid is negligible.

Application to Authentic Samples. The final goal of each method development is its applicability to the broad range of matrixes. Therefore, our data set included different kinds of multivitamin preparations, namely, tablets, capsules, caplets, effervescent tablets, and liquid samples (Table 1). Contrary to tablets and capsules that usually contain high doses of both water- and fat-soluble vitamins, effervescent tablets are characterized by smaller amounts of water-soluble vitamins in the absence of fat-soluble vitamins. These products, however,

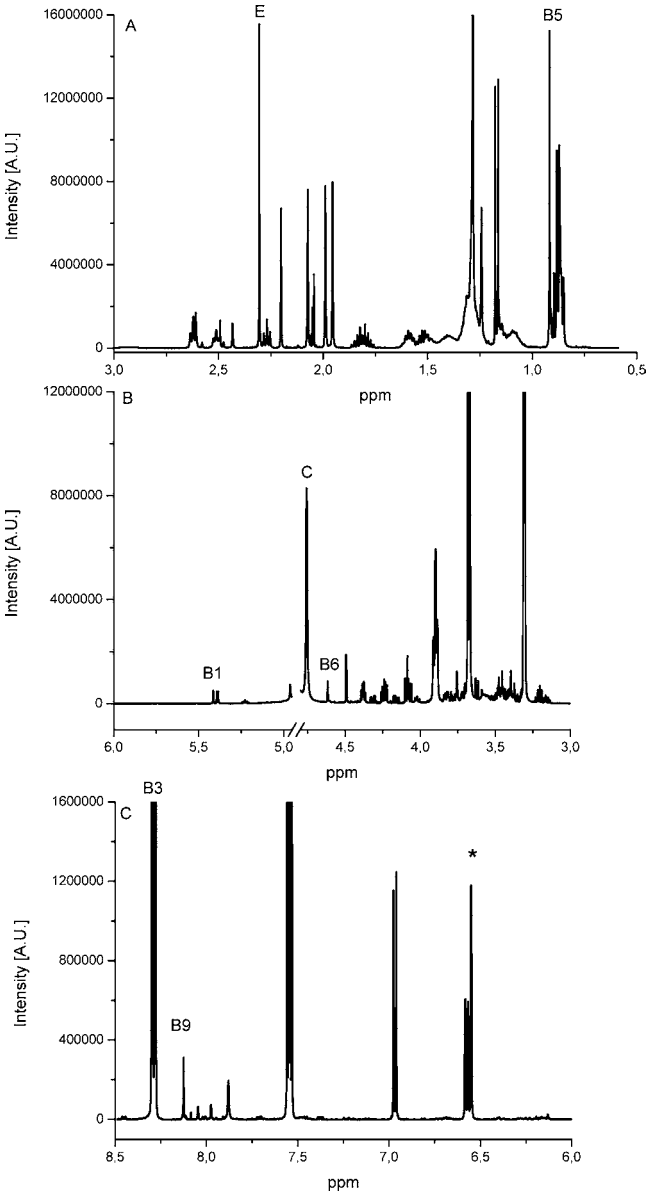

Figure 5. Detailed NMR spectrum of sample S2. The peaks of each individual vitamin and internal standard (*) used for quantification are depicted on the spectrum. The calculated vitamin contents can be found in Table 1

are rich in accompanying substances such as sweeteners. Another matrix studied was liquid samples, e.g., fruit juices enriched with vitamins and syrups containing sweeteners, stabilizers, preservatives, thickening agents, and oils. The method development for these kinds of samples was complicated by their viscosity and high liquid content, which result in difficulties in weighing and in the appearance of a broad water signal in ^{1}H NMR spectra. Actually, another sample preparation procedure has to be developed for this group of matrixes.

The NMR results for 13 investigated samples are summarized in Table 1 for vitamins and in Table 3 accompanying substances. As an example, Figure 5 shows the detailed NMR spectra of an authentic sample (S2). First, it can be seen that NMR provided reliable qualitative analysis of all vitamins. For example, vitamin A was not detected in six samples, which was in agreement with the labeling information.

DOI: 10.1021/acs.jafc.5b00087
J. Agric. Food Chem. 2015, 63, 3135−3143

However, in some samples NMR was not able to detect vitamins A and B9 due to small concentrations of these substance (LOD values are listed in Table 4).

The results of quantitative analysis showed a broad variation of vitamin content in the investigated samples ranging from 0.30 mg/g to 42.5 mg/g on average for vitamins A and C, respectively (Table 1). Furthermore, the NMR concentrations were compared with the information provided on the label by the manufacturer. Good average recovery rates were found for vitamins B1 (101%), B3 (103%), B5 (94%), B6 (90%), C (93%), and E (108%). That means that NMR is a reliable analytical tool for quantification of these compounds in multivitamin preparations. Worse recoveries for vitamins A (85%) and B9 (132%) can be explained by their small concentrations (near the LODs) in the products studied, which result in large uncertainties in integral values. The errors were, however, acceptable in accordance with the official guideline for food products.[28]

Vitamin B12 was found in sample S10 (ampule with vitamin B12), and its concentration was in very good agreement with the labeled content (87.5 mg/kg compared to 100 mg/kg provided on the label), which shows that NMR is suitable for the analysis of B12-rich multivitamin preparations. In other samples, vitamin B12, however, cannot be detected due to its small content in comparison with that of other vitamins.

It should be mentioned that the observed deviations cannot lead to a conclusion of inapplicability of NMR for the analysis of these vitamins. Indeed, the labeling information cannot be considered as real reference data. The deviations between declared and found values can be a result of the sample inhomogeneity or erroneous labeling information. The reference analysis should be conducted to make comprehensive evaluation of the accuracy of the NMR method.

Selected accompanying compounds were also quantified in the multivitamin preparations (Table 3). Citric acid was detected in 7 of 13 samples (the content varied between 70 mg/g and 540 mg/g), saccharin (0.35−1.25 mg/g), sodium cyclamate (2.0−2.80 mg/g), and BHT (0.05−0.20 mg/g) in four samples. Steviol glycosides and mannitol were found only in two investigated multivitamin preparations (Table 3). In all other samples, investigated accompanying compounds were not detected, and this was in accordance with the labeling information (Table 3).

Comparison with Previous Studies and Future Perspective. This study is the first to show the feasibility of qNMR for simultaneous analysis of 12 essential vitamins (except B2) and accompanying substances (citric acid, mannitol, saccharin, cyclamate, steviol glycoside, and BHT) in complex multivitamin preparations. This includes effervescent tablets, coated tablets, caplets, and capsules. Juices and syrups, however, cannot be analyzed by the present method due to their specific physical properties. The total analysis time including sample preparation, measurements, spectra evaluation requires approximately 1 h and, therefore, can be used as an alternative to existing HPLC methods.

Regarding quantification analysis, it is possible to reliably determine 5 of 13 vitamins, namely, B1, B3, B5, B6, and E. Although ascorbic acid is the most abundant compound in the studied products, its determination sometimes leads to incorrect values due to degradation reactions (mainly, oxidation) taking place in solution. Accordingly, for more accurate quantification, NMR measurements have to be conducted directly after sample preparation. Vitamins A, B9, B12, D3, and K are usually present in multivitamin preparations in low quantities; therefore, their quantitative analysis can be accompanied by relatively high uncertainty. A number of accompanying substances can be additionally quantified from the same NMR spectrum.

Previous studies on vitamins using NMR spectroscopy were restricted to qualitative analysis and signal assignments of separate vitamin molecules. For example, 1D and 2D NMR were applied to distinguish among α-, β-, γ-, δ- tocopherols (vitamin E) and to estimate the purity of reference materials using benzoic acid as an internal standard.[34] Multinuclear solid-state NMR methods (^{59}Co, ^{13}C, ^{15}N, and ^{31}P NMR) were applied for structural and dynamic analysis of different polymorphs of cyanocobalamin (vitamin B12).[35] Another solid state NMR study was devoted to the characterization of four vitamin D compounds.[36] Vaysse et al. using ^{1}H NMR have identified different vitamins (B-group, C, and E) as accompanying ingredients in herbal medicines or dietary supplements marketed as natural slimming products.[32] The authors, however, did not perform quantitative analysis of vitamins.[32]

Further research should be conducted toward more precise NMR method validation including comparison with the results of a reference method and additional spiking experiments to establish the correction factors for quantitation of some vitamins. Finally, some efforts can be made to improve the LOD values by using solvent evaporation at low temperatures and dimmed light in order to preserve unstable vitamins.

based safety and efficacy data have not been published, and established methods for the detection and characterization of nanomaterials within these products have not been well documented in the literature.

To date, several detection and separation techniques have been reported by researchers to address these needs, specifically for SiO_2 or TiO_2 nanomaterials in food products.[2,9,31−35] Lozano et al.[34] documented an ion beam technique, particle-induced X-ray emission (PIXE), for the quantification of SiO_2 nanoparticles dispersed in water, coffee, and milk. This technique offers fast measurements, minimal sample preparation, and parts per million (ppm) levels of sensitivity. Dekkers et al.[35] described the presence of nanoscale SiO_2 (known as food additive E551) in several food products (e.g., sugar, noodle, soup, seasoning mix) and discussed the potential risks of the intake of nanoscale SiO_2 through the food chain. Chen et al.[2] applied a centrifugation method to separate TiO_2 nanoparticles in sugar-coated chewing gum and described several characterization techniques for TiO_2 nanostructures. Although centrifugation is a relatively simple and cost-effective method to isolate nanomaterials without altering particle size or shape, the potential for many other interfering compounds and/or particles remaining with the target nanostructures is of concern. Other methods with high efficiency are still needed to separate nanometer particles, especially for nanoscale SiO_2 and TiO_2 in foods, including dietary supplements.

In this study we describe a simple and unique method to separate and characterize SiO_2 and TiO_2 nanomaterials in dietary supplements marketed specifically for women. A total of 12 dietary supplements claiming the inclusion of SiO_2 and TiO_2, but not providing any information related to particle size in their products, were purchased through various retailers. SiO_2 and TiO_2 nanostructures were selectively separated from the products using a simple acid digestion and centrifugation step, in which other metallic particles were dissolved during the process. The resulting nanostructures were characterized using multiple techniques including dynamic light scattering (DLS), field emission scanning electron microscopy (FESEM), transmission electron microscopy (TEM), energy dispersive spectroscopy (EDS), and X-ray diffraction (XRD). Nanometer-sized SiO_2 and TiO_2 particles were detected in 11 products, and many of those particles were aggregated. The methods that were developed can be utilized to detect and characterize the physicochemical properties of these nanoparticles within other consumer products.

EXPERIMENTAL PROCEDURES

Materials and Reagents. SiO_2 (amorphous, 20−60 nm in diameter) and TiO_2 (rutile, 10−30 nm) nanoparticles were purchased from Skyspring Nanomaterials, Inc. (Houston, TX, USA), to use as reference materials. TiO_2 nanopowder (anatase, diameter < 25 nm) was purchased from Sigma-Aldrich (St. Louis, MO, USA). Polystyrene (PS) standard nanoparticles, 50 and 500 nm in diameter, were purchased from Thermo Fisher Scientific Inc. (Waltham, MA, USA). Nitric acid (HNO_3, Optima 67−70%), hydrogen peroxide (H_2O_2, 30%), and ethanol (C_2H_6O) were purchased from Fisher Scientific (Houston, TX, USA). Type I ultrapure water (18 MΩ·cm) was available through a Thermo Scientific Barnstead Nanopure System (Waltham, MA, USA).

Detection and Characterization of SiO_2 and TiO_2 Particles. *Isolation of SiO_2 and TiO_2 Particles.* To separate SiO_2 and TiO_2 particles from complex matrices, a digestion solution consisting of 10 mL of hydrogen peroxide and 0.5 mL of nitric acid was prepared in a 15 mL conical tube. Approximately 100 mg of each dietary supplement and 3 mL of the digestion solution were mixed and heated in a sand bath at 120 °C. When the sample volume was reduced to 2 mL, the solution was allowed to cool to room temperature. The sample was then transferred into a 2 mL centrifuge tube and ultrasonicated for 1 min (Branson 2510, Danbury, CT, USA). The white particles were centrifuged at approximately 10000*g* for 20 min (Eppendorf Centrifuge 5430R, Hauppauge, NY, USA). The supernatant was carefully removed and the precipitate was resuspended in 2 mL of ethanol. The extraction processes were repeated twice with the isolated particles being redispersed in ethanol or ultrapure water.

Dynamic Light Scattering. For particle size and size distribution analysis, DLS measurements were carried out using a ZetaPALS from Brookhaven Instruments Corp. (Holtsville, NY, USA), with particle sizing software version 5.23. All particles were diluted with ultrapure water and ultrasonicated for 3 min. The instrument was operated at a laser wavelength of 658 nm and a temperature of 23 °C. The data collection period was set at 2 min and replicated five times (total elapsed time = 10 min).

Table 1. Dietary Supplements Investigated[a]

sample	formulation	market claim	labeling of SiO_2 or TiO_2 as ingredient
DS-1	solid/tablet	sexual health formula for women	TiO_2
		supports energy production	
DS-2	solid/tablet	support hormonal balance	SiO_2
DS-3	solid/capsule	maximum strength enhancement	SiO_2
DS-4	liquid/soft gel	passion and pleasure boost	TiO_2
DS-5	solid/capsule	menopause support	TiO_2
DS-6	solid/capsule	enhances fertility and desire	SiO_2
DS-7	solid/capsule	female fertility support	SiO_2
DS-8	solid/capsule	balances yeast and bacteria to maintain feminine health	TiO_2
DS-9	solid/tablet	menopause support	SiO_2
DS-10	solid/capsule	urinary tract health	SiO_2, TiO_2
DS-11	solid/capsule	urinary tract support	SiO_2
DS-12	solid/capsule	pleasure enhancer for women	SiO_2, TiO_2

[a]The dietary supplements (DS) were given arbitrary numbers and reviewed for (a) physical condition, (b) intent of use, and (c) indications of contents containing SiO_2 or TiO_2 based on product labeling.

Table 2. Particle Size and Size Distribution Measured by Dynamic Light Scattering (DLS)[a]

	particle size			
sample	number-based mean diameter (nm)	intensity-based mean diameter (nm)	size distribution (nm)	polydispersity index (*P*)
DS-1	308	557	260−1255	0.20
DS-2	282	2146	236−3590	0.38
DS-3	100	4275	87−7288	0.40
DS-4	142	500	121−834	0.30
DS-5	328	542	202−705	0.20
DS-6	344	2701	281−4019	0.43
DS-7	441	2736	237−4617	0.37
DS-8	156	869	136−1418	0.38
DS-9	254	2496	213−3680	0.45
DS-10	146	350	120−416	0.10
DS-11	47	4905	41−6840	0.41
DS-12	57	403	53−533	0.29

[a]The dietary supplements (DS) were given arbitrary numbers. A solution of nitric acid and hydrogen peroxide was used to dissolve the various components of the products at high temperature, leaving only SiO_2 and TiO_2. The particles sizes were characterized by DLS following suspension and ultrasonication in ultrapure water.

J. Agric. Food Chem. 2015, 63, 3144−3152

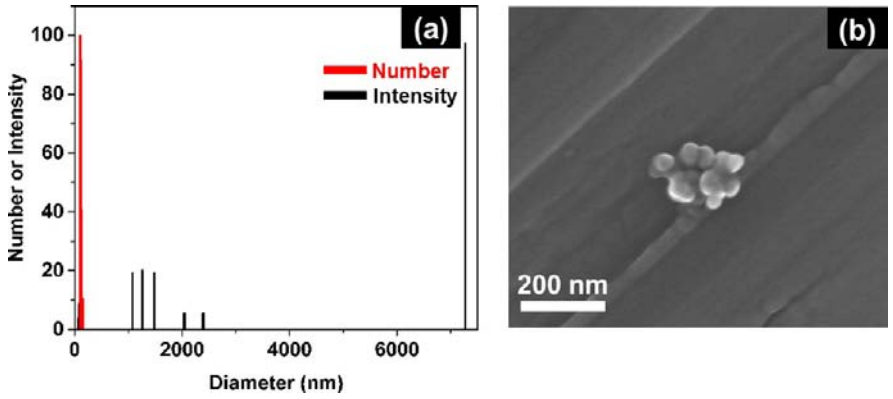

Figure 1. (a) Number- and intensity-based hydrodynamic particle size of sample DS-3 analyzed by DLS and (b) representative FESEM image of sample DS-3.

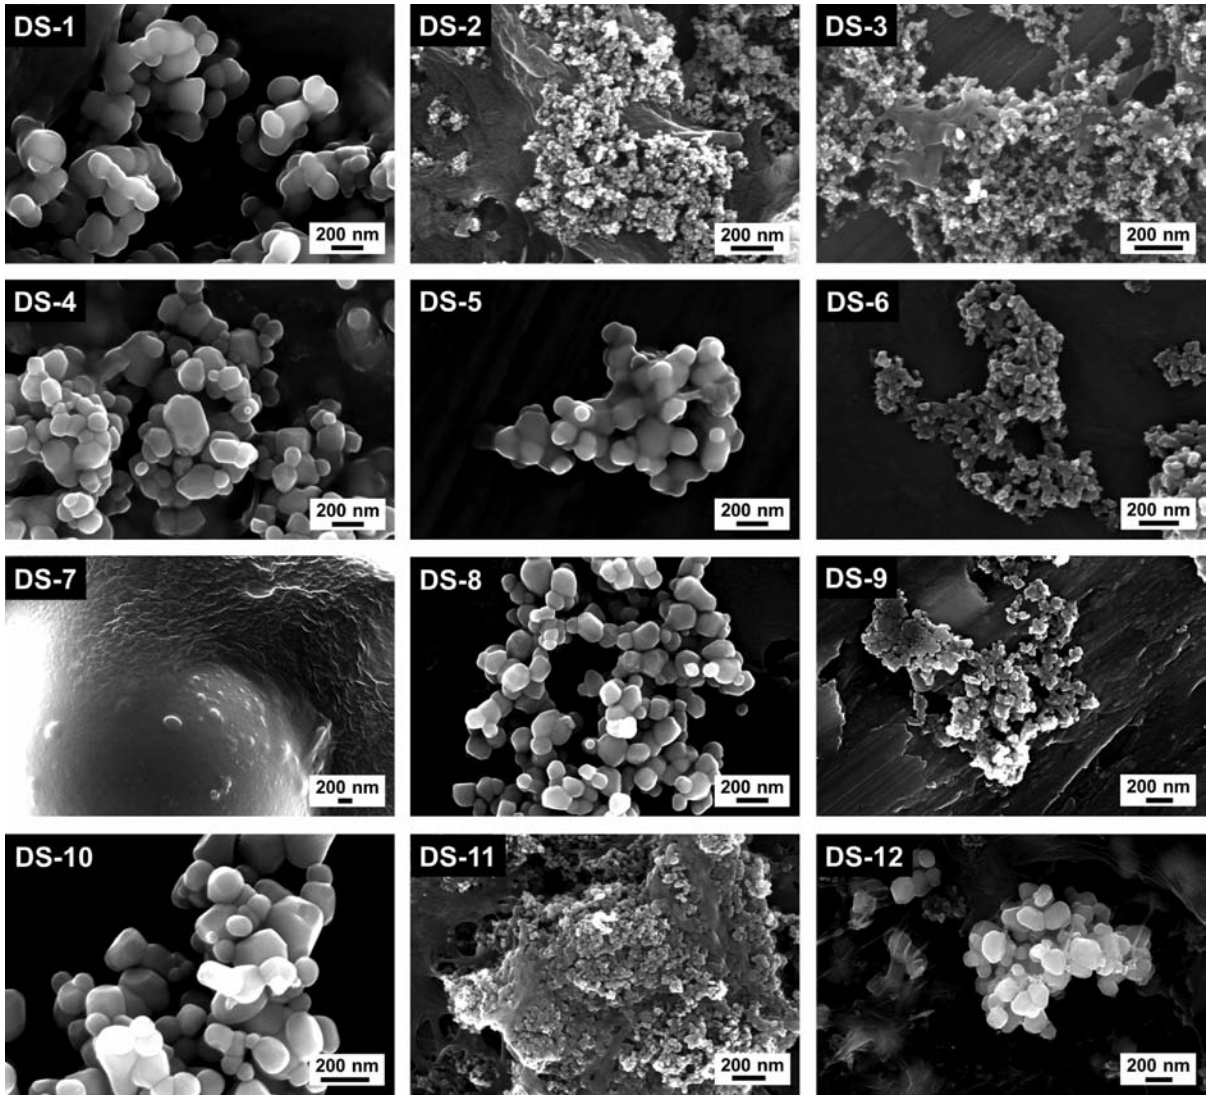

Figure 2. FESEM images of SiO_2 and TiO_2 particles separated from each product labeled DS-1—DS-12. The dietary supplements were digested and SiO_2 and TiO_2 particles isolated, suspended in ethanol, and placed on FESEM platform for analysis.

Field Emission Scanning Electron Microscopy. The shape and morphology of the nanostructures were characterized by a Zeiss-Merlin FESEM (Thornwood, NY, USA) under high-vacuum conditions. Before characterization, the particles were dispersed in ethanol, ultrasonicated for 1 min (Branson 2510), and directly placed on a standard Zeiss sample holder. The dispersion was allowed to evaporate to dryness and a very thin layer (approximately 4 nm) of Au/Pd was sputtered onto the sample using a Denton Vacuum Desk V (Moorestown, NJ, USA). The presence of Si and Ti in the SiO_2 and TiO_2 particles, respectively, was confirmed using an EDAX Apollo XL (EDAX Inc., Mahwah, NJ, USA) energy dispersive X-ray spectroscopy (EDS) while the sample was irradiated in the FESEM.

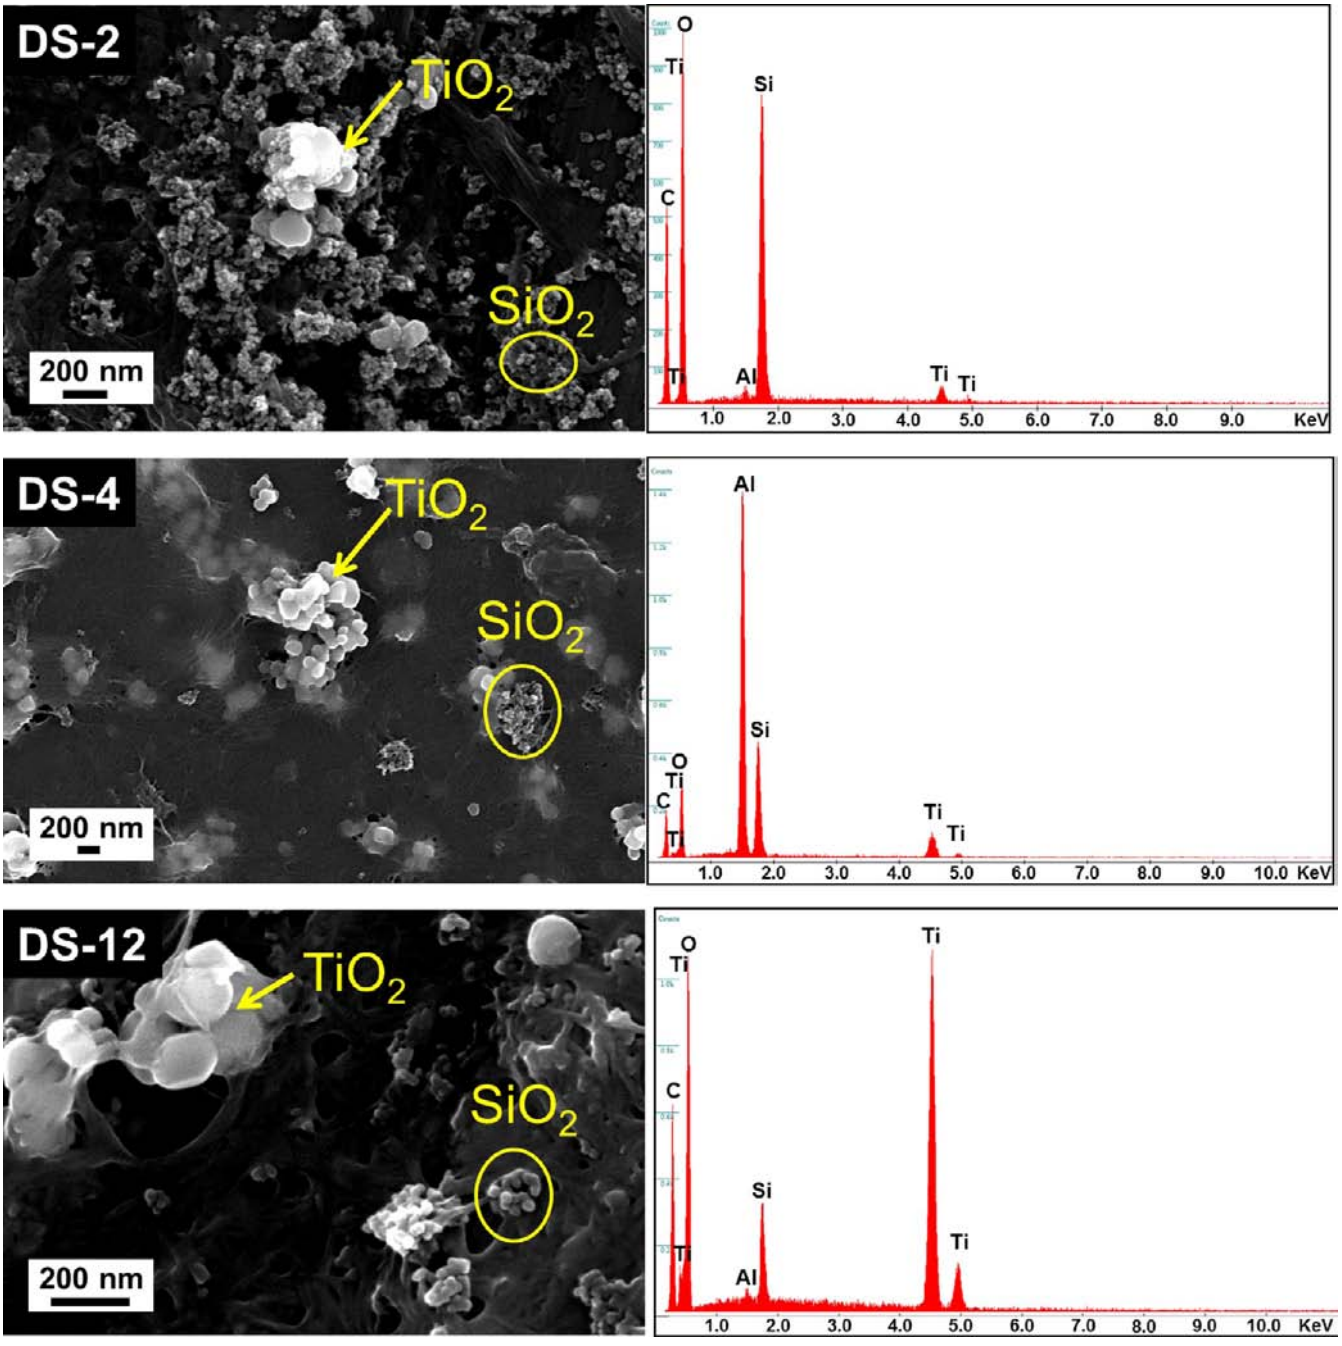

Figure 3. FESEM images and EDS spectra of SiO_2 and TiO_2 nanoparticles in DS-2, DS-4, and DS-12. Al peaks are associated background signal of the sample holder.

Transmission Electron Microscopy. TEM samples were prepared by adding 5−10 μL of the specimen dispersed in ethanol on 300-mesh carbon coated copper grids purchased from Electron Microscopy Sciences (Hatfield, PA, USA), and the samples were allowed to dry at room temperature. TEM images were acquired using a JEOL 2100 TEM (Peabody, MA, USA) operated at an acceleration voltage of 80 kV. Particle shape, size, and size distribution were characterized using multiple images of each sample with the reported statistics based on a minimum of 500 particles. The elemental composition of the nanostructures was determined by an EDS detector (EDAX Genesis 2000).

X-ray Diffraction (XRD). The crystalline structure of the particles, separated from dietary supplements, was determined using a Bruker AXS (Madison, WI, USA) XRD D2 Phaser operated at 30 kV and 10 mA at 24 °C. Samples placed onto the zero diffraction silicon sample holder (MTI Corp., Richmond, CA, USA) were dried overnight at room temperature. XRD patterns were obtained from 20° to 80° (2θ) using a Lynxeye detector and Cu Kα (λ = 1.541 Å) radiation.

RESULTS AND DISCUSSION

Twelve dietary supplements (arbitrarily assigned DS-1−DS-12) were randomly selected and procured from national retailers. A list of the products can be found in Table 1 including the corresponding formulation type, market claim, and labeling information on the inclusion of SiO_2 and/or TiO_2. None of the supplements included in this paper contained labeling that specifically indicated the presence or absence of nanosized materials as dietary ingredients, preservatives, or colorants.

The products selected for analysis contain a variety of active ingredients and excipients (e.g., vitamins, botanicals or herbs,

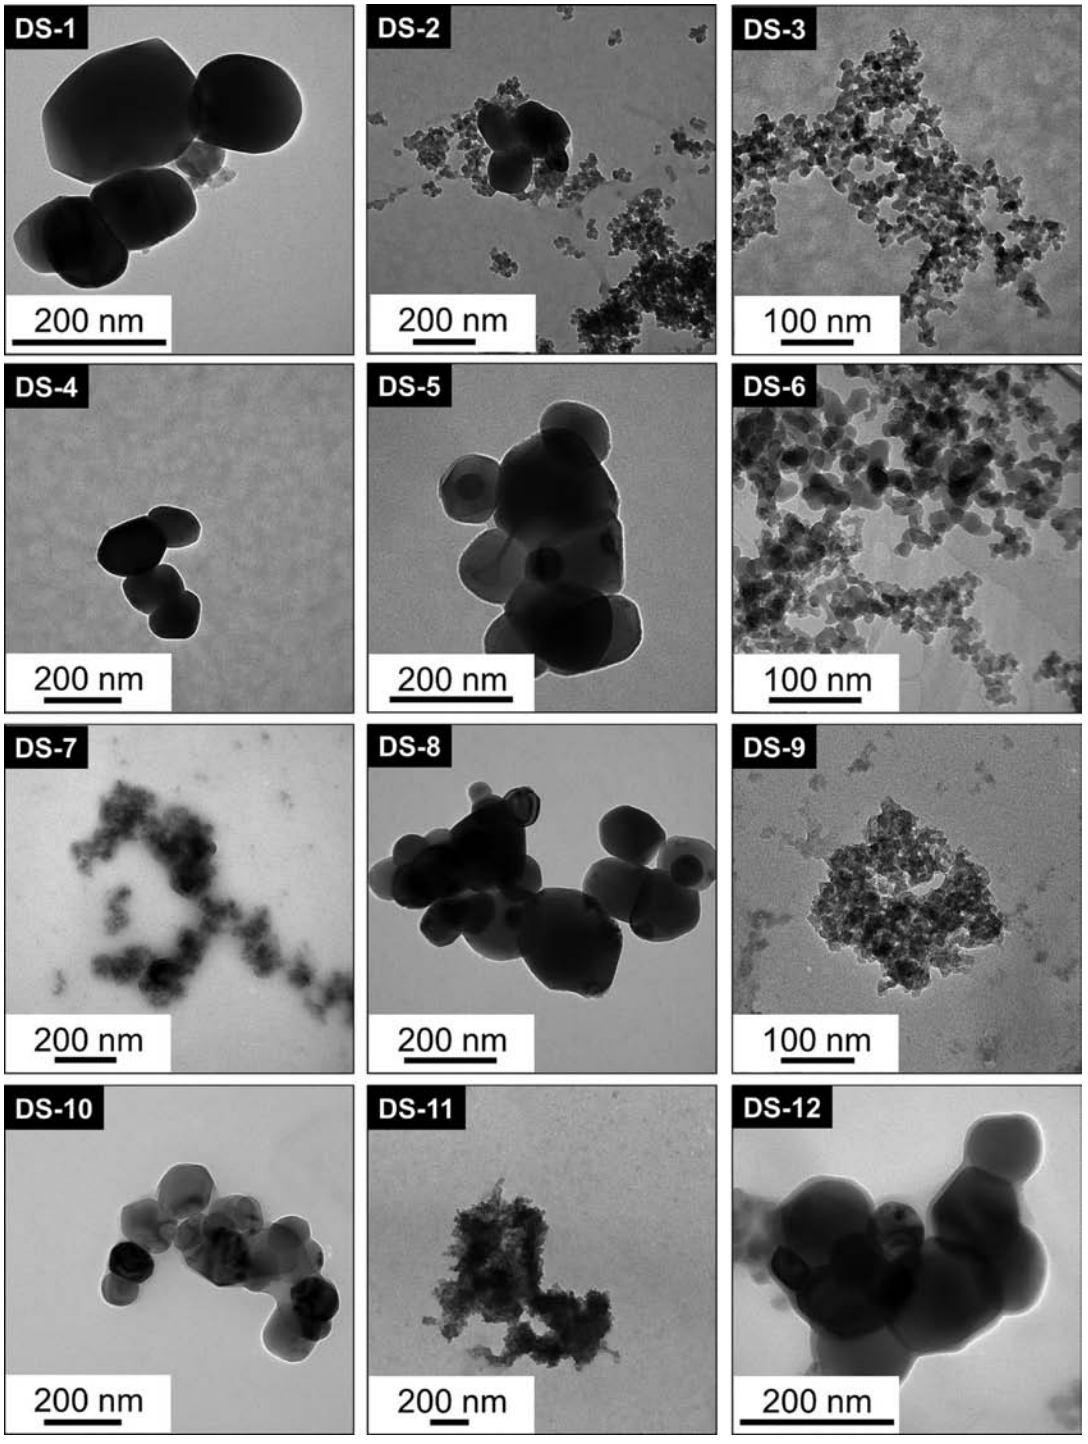

Figure 4. TEM images of SiO_2 and TiO_2 particles in DS-1−DS-12.

amino acids, dietary substances), which are problematic for the isolation of the SiO_2 and TiO_2 nanostructures. To overcome this obstacle, a combination of acid digestion and centrifugation was adopted from Weir et al.[36] and used to isolate SiO_2 and TiO_2 simultaneously. A solution of nitric acid and hydrogen peroxide was used to dissolve or decompose the various components of the products at high temperature, leaving only SiO_2 and TiO_2. It has been well documented that SiO_2 and TiO_2 are not dissolved without the presence of HF.[37] The remaining particles were rinsed three times with ethanol (collection by centrifugation) and suspended in ethanol or ultrapure water. This simple and facile method was able to isolate the metal oxide particles while not altering the particle size and morphology of the separated materials (see Supporting Information Figures SI1 and SI2).[38] The average size, morphology, size distribution, and crystal structure of the isolated particles were further characterized using multiple techniques as described below.

DLS is a technique that is commonly used to measure particle size or particle size distributions due to its rapid and simple operation. The particle size can be analyzed and reported on the basis of the number or intensity average with multimodal size distribution. A summary of the particle size analysis is shown in

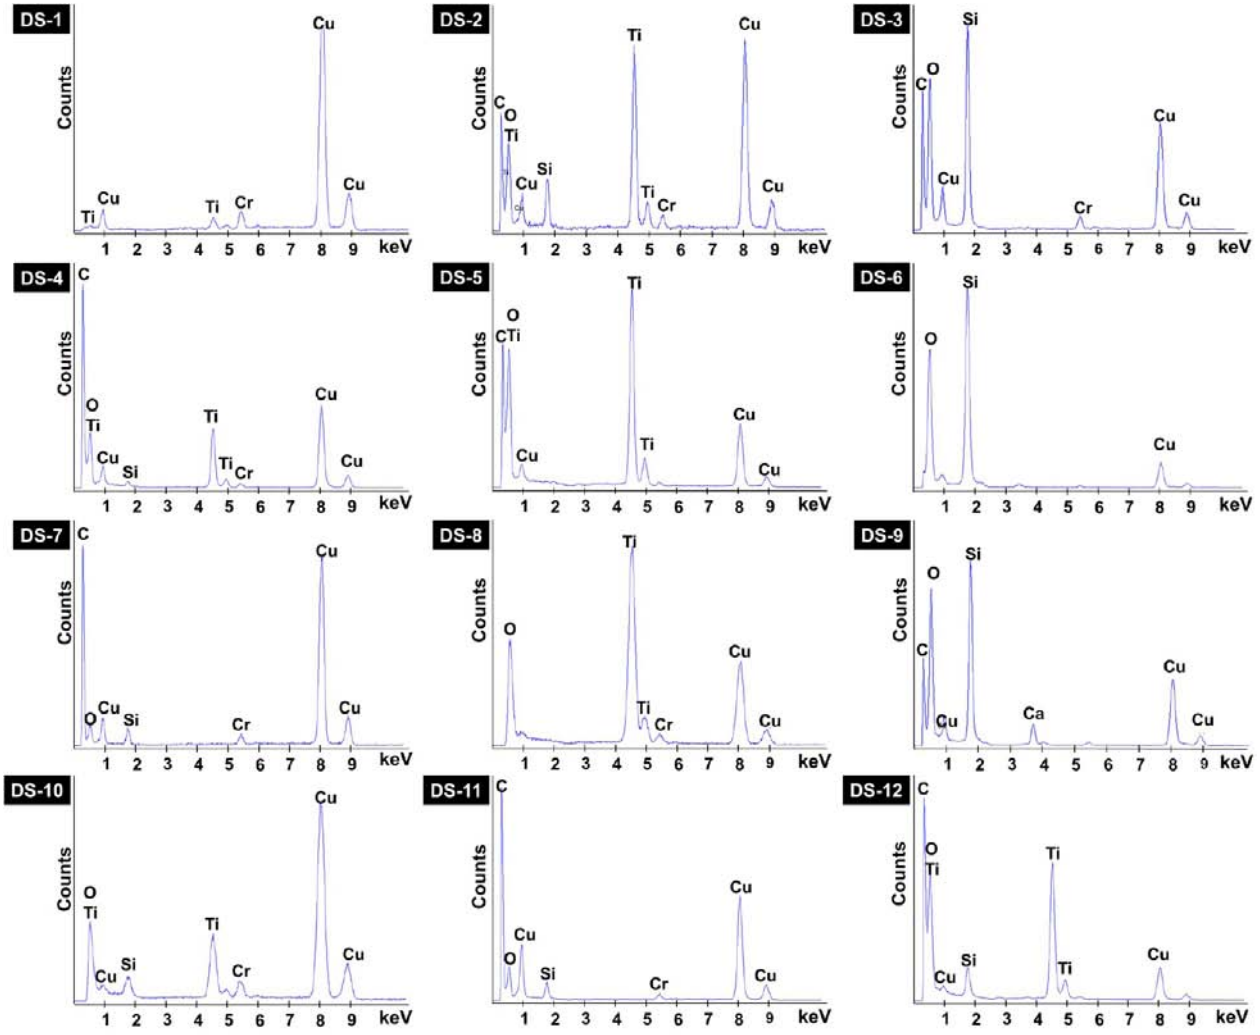

Figure 5. EDS spectra of particles in TEM images (Figure 2). The C, Cr, and Cu peaks are associated with background signal of the sample holder.

Table 2. The size of the nanoparticles isolated from the dietary supplements was very polydisperse. This is indicated by the differences in the modes of analysis of the DLS data (number versus intensity) and a high polydispersity index (P) as shown in Table 2. The smallest particle sizes of three samples including DS-3, DS-11, and DS-12 were below 100 nm. As shown in Figure 1, the actual size of the nanoparticles was closer to the number-based particle size in DLS. In this case, the hydrodynamic particle size calculated by intensity-based mode is highly dependent on the larger particles because the intensity (I) of light scattered is proportional to d^6 and $1/\lambda^4$ from the Rayleigh approximation, where d is a particle diameter and λ is a laser wavelength.[39,40] For instance, as shown in Supporting Information Figure SI3, the particles have a narrow size distribution showing very close numbers in both number- and intensity-based modes. However, when the particles with 50 and 500 nm in diameter were mixed, large different mean diameters were observed in the two modes and the P value was also >0.3. This occurred because the intensity of the 500 nm particles would be 10^6 times higher than that of the 50 nm particles.[40] Larger particles exhibit a greater instrumental response compared to smaller particles, and the signal corresponding to the smaller particles can be masked. It is important to note that when the value of the polydispersity index is >0.3, the size information obtained by DLS calculations is not always accurate.[40,41] In addition, the shape of the particles can also play a role in the experimental determination of the hydrodynamic size, as the principles of DLS are based on the Stokes−Einstein relationship, which has two fundamental assumptions: (1) the particle shape is spherical and (2) the particles are in Brownian motion.[39] As shown in Figures 2−4, the SiO_2 and TiO_2 particles were not spherical, with many single particles being barrel-shaped, and many primary particles aggregated into small clusters.

To characterize the morphology and size of separated particles from each product, microscopic imaging techniques were adopted. Nanometer-scale particles were found in a total of 11 products, with the exception of DS-7. Although DLS data for DS-7 indicated that nanometer-scale materials were present, advanced imaging via FESEM and TEM could not locate particles in this size domain. FESEM images in Figure 2 showed both spherically shaped and irregularly shaped nanoparticles with various particle sizes. By using the X-ray emission spectra from FESEM-EDS, it was determined that the isolated particles were consistent with the presence of Si and Ti. The samples containing TiO_2 (DS-1, DS-2, DS-4, DS-5, DS-8, DS-10, and DS-12) showed 50−200 nm sized individual particles; however, several of those particles were found within aggregates. Unlike TiO_2 particles, the sizes of individual SiO_2 particles in DS-2, DS-3, DS-4, DS-6, DS-9, DS-11, and DS-12 were <100 nm, but they were likewise found in a state of aggregation. Clusters of SiO_2 nanoparticles showed size ranges of several nanometers to micrometers.

DOI: 10.1021/acs.jafc.5b00392
J. Agric. Food Chem. 2015, 63, 3144−3152

FESEM images suggest that individual SiO_2 nanoparticles are much smaller than TiO_2 nanoparticles. The degree of aggregation supports the large polydispersity observed in products containing SiO_2 as compared to other products (Table 2). Figure 3 shows that both SiO_2 and TiO_2 nanoparticles could be found within the same samples, as was the case in DS-2, DS-4, and DS-12. TEM images (Figure 4) were consistent with the morphology and size information obtained using FESEM. The TiO_2 particles separated from products DS-1, DS-2, DS-4, DS-5, DS-8, DS-10, and DS-12 were found to have at least one dimension below 100 nm in size and a round shape. An analysis of the size showed that 94% of the TiO_2 particles showed size ranges between 50 and 200 nm, and 99% of SiO_2 nanoparticles found in DS-2, DS-3, DS-4, DS-6, DS-9, DS-11, and DS-12 were <100 nm in diameter and present in large aggregates. As can be seen in Figures 2 and 4, no nanosized structures were found in DS-7.

In Figure 5, EDS analysis showed the presence of elements (i.e., Si, Ti, and O peaks indicating SiO_2 or TiO_2) in the specific area corresponding to TEM images in Figure 4. The C, Cr, and Cu peaks were from the sample grid and instrument. Taken together, the FESEM, TEM, and EDS data demonstrated that the particles isolated from 11 products consist of nanosized SiO_2 and/or TiO_2.

To assess the crystal structure of the isolated particles, XRD was used in conjunction with the reference data file, Joint Committee on Powder Diffraction Standards (JCPDS) card. XRD data presented in Figure 6 reveal that SiO_2 nanoparticles exhibit a 2θ broad peak from 20° to 25° corresponding to amorphous SiO_2 (broad peaks near 55−70° are from the sample holder). TiO_2 particles show diffraction peaks at 2θ = 25.3°, 36.9°, 37.8°, 38.5°, and 48.1°, which can be indexed to the (101), (103), (004), (112), and (200) planes. The diffraction peak positions are consistent with the standard diffraction pattern of anatase TiO_2 (JCPDS card no. 21-1272).[42] In the cases of DS-2 and DS-4, both SiO_2 and TiO_2 peaks were detected even though the labeling on product DS-2 discloses only SiO_2 and the labeling on product DS-4 discloses only TiO_2. These results suggest that the isolated particles were a mixture of amorphous SiO_2 and anatase TiO_2 particles. Furthermore, DS-12 showed both amorphous SiO_2 and anatase TiO_2 peaks as claimed.

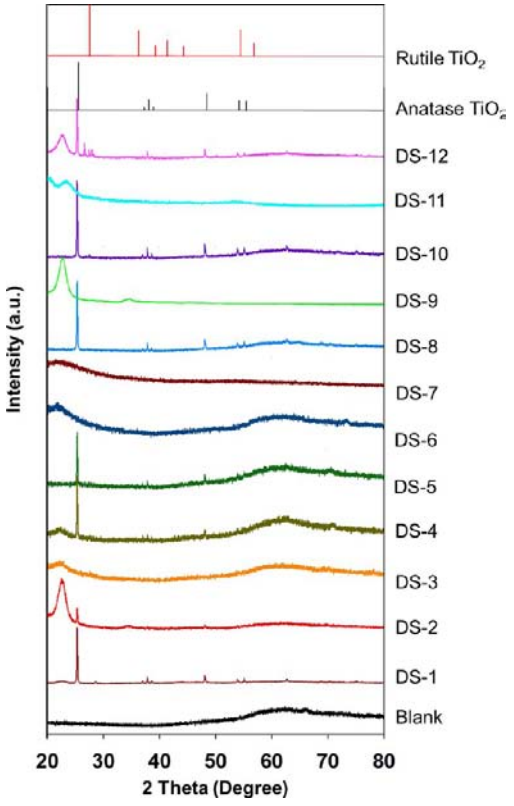

Figure 6. XRD analysis of samples DS-1−DS-12. Reference patterns for anatase (JCPDS no. 21-1272) and rutile (JCPDS no. 21-1276) TiO_2 peaks are provided along with the pattern observed from the zero diffraction silicon XRD sample holder.

A comparison between experimentally determined data and product labeling showed that unexpected TiO_2 and SiO_2 nanoparticles were detected in DS-2 and DS-4, respectively. DS-10 claims the inclusion of both SiO_2 and TiO_2, but only anatase TiO_2 was detected. All TiO_2 nanoparticles detected and characterized in this study were found in the anatase phase, which is reported to be more toxic than the rutile phase.[43,44] The concentrations of Si and Ti in each product were experimentally determined by inductively coupled plasma−mass spectrometry (ICP-MS) and can be seen in Supporting Information Table SI1.

Herein we developed a simple and high-temperature acid digestion method to isolate SiO_2 and TiO_2 nanomaterials in commercially available dietary supplements. The isolated SiO_2 and TiO_2 particles were characterized using several complementary techniques. The analytical data demonstrated that 11 of the 12 dietary supplements contained nanometer-scale SiO_2 and/or TiO_2 particles. Interestingly, the properties of TiO_2 nanomaterials detected in this study are very close to those identified in several different commercial products, for example, foods,[2] cosmetics,[45] textiles,[46] or personal care products[36] recently reported in the literature. It is important to note that all of those products did not indicate the presence of nanomaterials on their labels. A recent survey released by "As you Sow" concluded that most manufacturers are uncertain whether nanomaterials are used within their products.[47] Although this is a small number of studies to represent a global market, it is possible that large amounts of SiO_2 and TiO_2 nanomaterials are included in various commercial products without proper labeling.

We expect that the developed methodologies can be applied to properly isolate and characterize the physicochemical properties of SiO_2 and TiO_2 nanoparticles within consumer products and can assist in the critical assessment of public health risk and science-based regulation of products using nanotechnology-based ingredients.

separation mechanism in CE is different from those in liquid chromatography, it is considered as an orthogonal analysis and provides complementary information.[19]

For online detection of species after separation, the detection method must possess sufficient sensitivity and be able to interface with the separation system. Among all of the techniques that have been applied for elemental analysis, atomic spectrometry has played a crucial role in the determination of the arsenic concentration in a variety of samples.[8−10] Earlier development works involved the use of atomic emission spectrometry (AES) or atomic absorption spectrometry (AAS) coupled with liquid chromatography for arsenic speciation.[20,21] In recent years, with the continuous improvement in sensitivity, inductively coupled plasma mass spectrometry (ICPMS) has become the most popular detector for elemental analysis. It offers several advantages over other atomic spectroscopy techniques, including improved detection limits, minimization of interferences with the application of reaction/collision cell gases, capability to easily interface with other instruments, and the simultaneous monitoring of multiple isotopes. It has been demonstrated to be an essential tool in the routine analysis of arsenic species.[14,15,22,23]

CE interfaced with ICPMS has been widely used in the speciation of elements in various matrices. Although there have been reports about speciation of selenium, arsenic, and other elemental species in wastewater, soil, and seafood matrices using CE,[23−27] quantitation of common arsenic species in rice products using CE still remains relatively unexplored. In this study, we report the development of a hyphenated analytical technique consisting of CE and ICPMS for arsenic speciation in a rice matrix. An enzyme-assisted water-phase microwave digestion procedure was tested and used for the extraction. Multiple conditions that would affect the separation or detection of rice samples were evaluated. The optimized conditions were used for analysis of locally purchased rice samples. The precision and accuracy of this method was validated by analyzing rice standard reference materials and comparing the results to certified values.

EXPERIMENTAL SECTION

Materials and Chemicals. Methylarsonic acid monosodium salt (MMA, 98.5%) was purchased from Crescent Chemicals (Islandia, NY). Dimethylarsinic acid (DMA, 98%) was purchased from Strem Chemicals (Newburyport, MA), and *o*-arsanilic acid (*o*-ASA, 98%) was purchased from Pfaltz & Bauer (Waterbury, CT). National Institute of Standards and Technology (NIST)-traceable arsenite [As(III)] and arsenate [As(V)] stock solutions (1000 mg L^{-1}) were purchased from Spex Certiprep (Metuchen, NJ). All chemicals that were used to prepare calibration standards were assayed using ICPMS to verify the arsenic concentration. The enzyme, α-amylase from *Bacillus subtilis* [165 000 bacterial amylase units (BAU)/g], was purchased from MP Biomedicals (Carlsbad, CA). TraceSELECT sodium carbonate (≥99.9999% metal basis), TraceSELECT sodium hydroxide monohydrate (≥99.9995% metal basis), and TraceSELECT 2-propanol (≥99.9%) were purchased from Sigma-Aldrich (St. Louis, MO). Potassium hydroxide pellets (>85%) and nitric acid (68−70%, OPTIMA ultrapure grade) were purchased from Fisher Scientific (Waltham, MA). All chemicals were used as received without further purification. Deionized water (>18 MΩ cm^{-1}) from a Milli-Q reference system (Millipore, Billerica, MA) was used throughout the experiments. Individual stock solutions (1000 ng g^{-1}) of DMA, MMA, *o*-ASA, As(III), and As(V) were prepared with Milli-Q water and stored at 4 °C in the dark. The As concentrations of the stock solutions were analyzed by ICPMS. Multi-analyte calibration standards were prepared fresh on the day of use by diluting DMA, MMA, *o*-ASA, As(III), and As(V) stock solutions with Milli-Q water. For the rice flour standard reference materials, SRM 1568b was purchased from NIST (Gaithersburg, MD) and CRM 7503-a [prepared by the National Metrology Institute of Japan (NMIJ)] was purchased from Waco Chemicals US (Richmond, VA). Rice (polished long grain rice) and rice cereal (single-grain infant cereal) were acquired from a local market.

Instrumentation. CE was performed on a 7100 CE system (Agilent Technology, Santa Clara, CA). A 60 cm long coated fused-silica capillary (Molex, Phoenix, AZ) with a 100 μm inner diameter and a 360 μm outer diameter was used for sample introduction. The separation of five arsenic species was carried out under basic condition through the use of Na_2CO_3 (8 mM, pH 11) buffer. A new capillary was initialized by flushing 1 M KOH at 950 mbar for 30 min and running buffer (8 mM Na_2CO_3, pH 11) for 30 min, followed by rinsing with water for 5 min. The capillary was conditioned with 0.1 M KOH and running buffer for 15 min prior the analysis. Before each run, the capillary was equilibrated with 0.1 M KOH for 3 min and running buffer for 3 min. After each run, the capillary was rinsed with water for 1 min. Samples were hydrodynamically injected at 15 mbar for 8 s, followed by an injection of running buffer at 15 mbar for 5 s. The temperature of the cartridge was set at 21 °C (ambient temperature), and the applied voltage for the separation was 20 kV. The coupling of CE with ICPMS (Agilent 7700x, Agilent Technology, Santa Clara, CA) was performed by directly connecting the outlet of the capillary to a Mira Mist CE nebulizer (Burgener Research, Inc., Mississauga, Ontario, Canada). A solution containing 1% HNO_3 (v/v) and 10% 2-propanol (v/v) was used as the makeup solution. Alcohol was added to the makeup solution to lower the liquid surface tension and facilitate the formation of an aerosol. Additionally, alcohol was used as a carbon source to enhance the signal intensity and overcome matrix effects.[28] A final concentration of 10% 2-propanol was chosen for the analysis. Although a higher alcohol concentration can be used,[29] carbon deposits on the sampling cone can occur and affect system stability. The peristaltic pump speed was set at 0.06 rpm using a 0.5 mm inner diameter tube. This configuration gives a flow rate of 15 μL min^{-1}, with no visual droplets formulating inside the spay chamber, suggesting an approximate 100% sample delivery efficiency. The pH value of the running buffer was adjusted by adding 0.1 M NaOH or 0.1 M HNO_3 solutions and was measured with an Orion Star A214 pH meter (Thermo Scientific, Waltham, MA). The ICPMS was tuned daily under reaction gas (H_2) mode. The polyatomic interference of $ArCl^+$ is eliminated by hydrogen gas through a proton-transfer process.[30] The mass isotopes of m/z 75 and 77 were monitored for arsenic and the interference. Detailed operation conditions are listed in Table 1. The viscosity of the rice extract was measured on a VISCOlab

5000 viscometer with temperature control (Cambridge Viscosity, Medford, MA). The measurement of viscosity was performed in triplicate.

Sample Preparation. Rice flour of NIST SRM 1568b and CRM 7503-a were received as fine powder and used directly for the extraction. Rice and rice cereal were first ground with an 8000 M mixer/mill (SPEX SamplePrep, Metuchen, NJ) and sieved using 0.1 mm mesh size. Rice powders were oven-dried at 90 °C for 2 h to determine the residual moisture content. An enzyme-assisted water-phase microwave extraction was used for sample extraction. Typically, in a 15 mL glass tube, 0.2 g of rice powder and 0.1 g of 0.5% (w/w) α-amylase solution were diluted with water to a total weight of 2 g, which gave a final enzyme concentration of 0.05% (w/w). The tube was capped and put in a Discover SP microwave digestion system (CEM, Matthews, NC) at 80 °C for 1 h and 90 °C for 2 h with stirring. No pressure was generated inside the tube during the extraction. A method blank, which contains only 0.05% α-amylase, was also included in each extraction batch as a control to verify the absence of arsenic species. The extracted mixture was centrifuged, and any remaining solids were removed. An aliquot of 30 μL of *o*-ASA (50 ng g^{-1}) was added to the 270 μL of rice extract for a final concentration of 5.0 ng g^{-1} of *o*-ASA. Each sample was prepared in triplicate. All of the standards and samples were prepared gravimetrically.

RESULTS AND DISCUSSION

Optimization of the Separation Condition. The target arsenic species in this study are DMA, MMA, As(III), and As(V). In addition, *o*-ASA, which is not present in the rice, was also added for this analysis. It served as an internal standard and mobility marker for the other four analytes of interests. The five arsenic species were separated with the use of CE and then directly delivered to ICPMS for detection.

Several factors that may affect the separation efficiency were evaluated. Separation conditions were first investigated at various buffer concentrations (i.e., 3−10 mM). The results suggested that a buffer solution with a concentration as low as 3 mM can be used to obtain acceptable resolution among the five tested arsenic species. From Figure 1a, baseline separations were achieved in all assayed conditions with enhanced peak resolution as the buffer concentration increased. Higher buffer concentrations led to stronger ionic strengths, which can suppress the electron double layer on the inner surface of the capillary, reducing electroosmotic flow (EOF) and resulting in longer migration times. Furthermore, a concentrated buffer solution largely increases the electric current in the capillary and results in larger variations because of Joule heating.[19] After the resolution and analysis duration of each run were balanced, 8 mM Na_2CO_3 was selected as the running buffer for all of the measurements. Similar to the buffer concentration, the applied voltage had a strong effect on the EOF, which affected the migration speed of all analytes. However, it only exhibited a limited contribution to the peak separation. As shown in Figure 1b, voltages as low as 8 kV could resolve all of the species of interest. Because the magnitude of EOF generated from the low voltage is relatively small, the migration of the analytes is slow, leading to a longer elution time. Increasing the applied voltage was effective in shortening the analysis time without compromising the resolution. A voltage of 20 kV was found to be an optimum value. Although higher voltages can further reduce the analysis time, these voltages caused a significant loss in peak resolution. This is especially true for DMA and As(III). Furthermore, higher voltages also generate strong currents that can lead to an undesired heating effect, especially for capillaries with a large inner diameter. In other buffer systems, similar

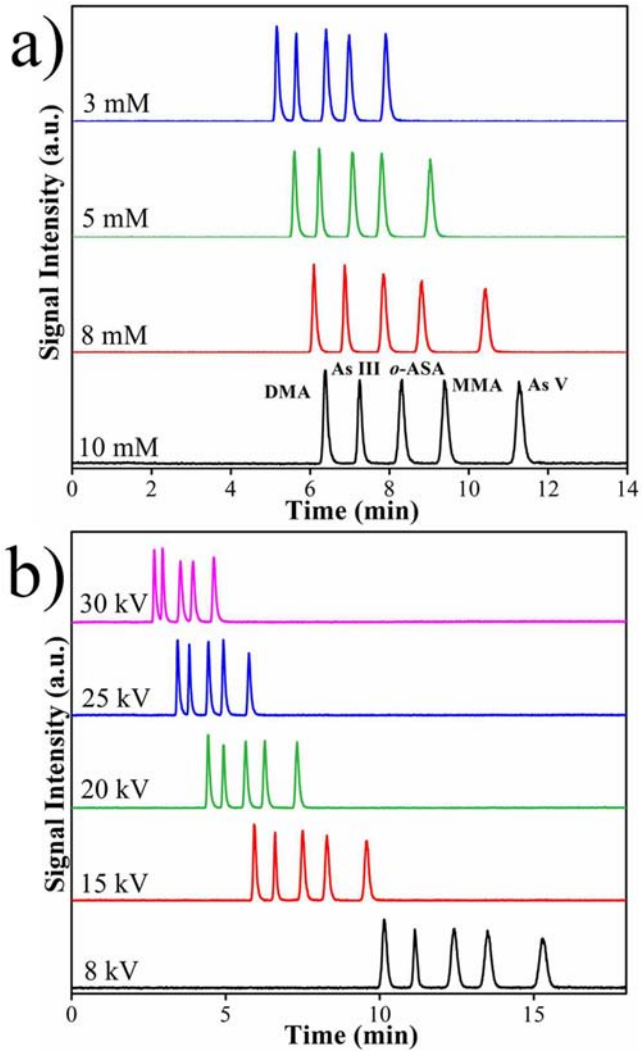

Figure 1. (a) Separation of five arsenic species under different buffer concentrations (voltage, 15 kV), and (b) effect of the applied voltage on the migration of arsenic species (buffer concentration, 5 mM). Other conditions: buffer, Na_2CO_3, pH, 11.

effects of the buffer concentration and voltage on the migration of arsenic species have been observed.[26,27]

The effects of pH on the separation of arsenic species were also evaluated. A basic condition with positive polarity was selected for CE separation to take advantage of the strong EOF toward the cathode. From Table 2, the acid dissociation constants (pK_a) of five As species ranged from 0.7 to 9.2. To maintain the magnitude of the EOF and avoid repeatability problems commonly encountered at weak basic conditions, moderate to strong basic conditions are favorable.[31] Because As(V) is eluted last, its migration ultimately determines the duration of the analysis. It was found that higher pH conditions

Table 2. Acid Dissociation Constants of As Species[31,35]

As species	formula	pK_a
As(V)	$O{=}As(OH)_3$	2.3, 6.8, 11.6
As(III)	$O{=}As(OH)$	9.2
DMA	$(CH_3)_2AsO(OH)$	6.2
MMA	$CH_3AsO(OH)_2$	3.6, 8.2
o-ASA	$H_2NC_6H_4AsO(OH)_2$	0.7, 3.8, 8.9

DOI: 10.1021/acs.jafc.5b00446
J. Agric. Food Chem. 2015, 63, 3153−3160

generated a faster EOF, increasing the migration speed of As(V), therefore reducing its overall retention time. Special attention was paid to DMA and As(III) for the accurate determination of their identities. In an earlier study, Liu and co-workers studied the migration behavior of multiple arsenic species in HBO_3 and NaH_2PO_4 buffers at different pH conditions. They found that, as the pH values of the buffer solution increased from 8.5 to 9.8, the elution time of As(III) also increased, whereas the elution time of DMA was almost unaffected.[26] We have observed a similar trend in our study. Furthermore, we discovered (Figure 2a) that, when the pH

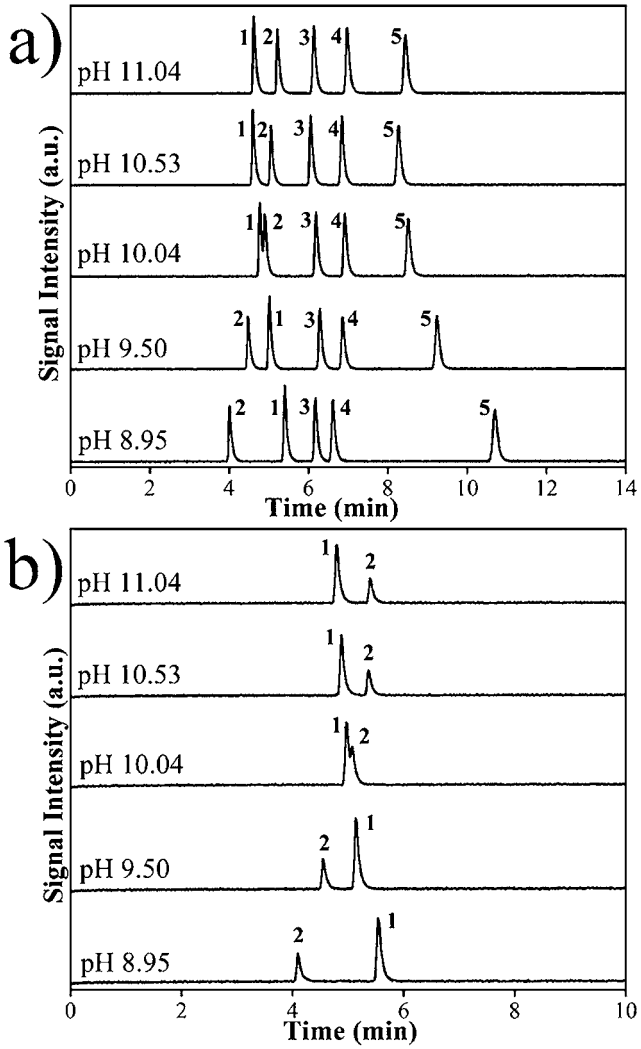

Figure 2. (a) Effect of the pH value on the migration of five arsenic species [1, DMA; 2, As(III); 3, *o*-ASA; 4, MMA; and 5, As(V)] and (b) electropherogram of a mixture containing 10 ng g^{-1} of DMA and 5 ng g^{-1} of As(III).

value of the running buffer increased beyond 10, the elution order of the peaks for DMA and As(III) reversed. The separation between As(III) and DMA first became less resolved at a pH of approximately 10 and then recovered at higher pH conditions. Because As(III) has a pK_a value of 9.2, it gradually acquired a negative charge when the pH was adjusted from 8.9 to 11. However, because DMA remained negatively charged throughout the entire range, its electrophoretic mobility was surpassed by that of As(III) at around pH 10 and the peaks of the two species were resolved at higher pH conditions. To verify the peak position of DMA and As(III), we analyzed a sample containing 10 ng g^{-1} of DMA and 5 ng g^{-1} of As(III) within the same pH range. It is clearly shown in Figure 2b that the elution time of As(III) and DMA continually changed as the pH increased.

Both injection pressure and time are factors that determine the injection plug length, which directly affects the precision of the method. Different combinations of pressure and time were tested to find the optimal conditions (see Table S-1 of the Supporting Information). All of the measurements with injection pressures above 30 mbar resulted in relative standard deviations (RSD %) higher than 10%. It is very clear that high injection pressures combined with relatively short injection times resulted in poor repeatability. A high applied pressure usually requires a much longer injection time to equilibrate the vacuum level change inside the capillary.[32] However, this would increase the plug length and enlarge the variation.[19] When a low pressure with a moderate injection time was applied, the precision was significantly improved. With an injection pressure of 15 mbar, the RSD % was reduced to an average of 5%. After both injection volume and precision of the method were considered, an applied pressure of 15 mbar with 8 s of injection time was chosen for the analysis. Additionally, in our study, the application of an internal standard mixed with sample effectively negated the variance caused by inconsistent injection volumes.

Analytical Performance. Figure 3 is a typical electropherogram of the separation of five arsenic compounds under

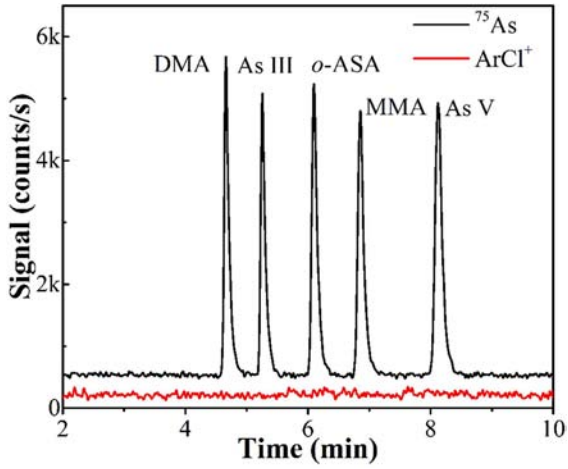

Figure 3. Electropherogram of a standard solution containing 5 ng g^{-1} of five arsenic species. m/z 77 was selected to monitor $ArCl^+$ (^{40}Ar and ^{37}Cl) interference.

optimized conditions (as presented in Table 1) at a level of 5 ng g^{-1}. Baseline separation was achieved for all species in less than 10 min. Hydrogen gas (H_2) was used as the reaction gas to eliminate the polyatomic interference of $ArCl^+$. A baseline was observed for m/z 77 ($^{40}Ar^{37}Cl^+$) during the assay, demonstrating the absence of interference. A calibration range of 0.5−20 ng g^{-1} was analyzed, and a linear relationship between the concentration and peak area was plotted. From previous studies, most of the rice samples surveyed have less than 200 ng g^{-1} of each arsenic species.[6,13,14] Because the extraction procedure usually involves a dilution factor of 10−20, our calibration range is sufficient to analyze most of the rice

DOI: 10.1021/acs.jafc.5b00446
J. Agric. Food Chem. 2015, 63, 3153−3160

products on the market. To further evaluate the method linearity, a standard spike (50 ng g^{-1}) at approximate 2.5 times the highest calibrator was analyzed. The results (see Table S-2 of the Supporting Information) suggested that acceptable recoveries were reached for all analytes. As listed in Table 3, the

Table 3. Analytical Performance of CE−ICPMS

			RSD %[a]			
compound	linear range (ng g^{-1})	R^2	migration time	peak area	LOD (ng g^{-1})[b]	LOQ (ng g^{-1})
DMA	0.5−20	0.998	0.82	2.62	0.27	0.87
MMA	0.5−20	0.999	1.08	2.08	0.16	0.52
As(III)	0.5−20	0.999	0.75	2.62	0.15	0.47

[a]Sample concentration = 5 ng g^{-1} (n = 7). [b]Instrument detection limit.

RSD % (n = 7) for migration time ranged from 0.75 to 1.23% for four arsenic species. After adjustment for the signal variation, the RSD % of the peak area was between 2.08 and 2.91%, demonstrating satisfactory repeatability for this method. The limit of detection (LOD, 3σ criteria) was determined to be 0.27, 0.16, 0.15, and 0.24 ng g^{-1} for DMA, MMA, As(III), and As(V), respectively (Table 3).

Analysis of the Arsenic Concentration in Rice and Rice Cereal. The sample extraction procedure was performed prior to analysis to isolate arsenic species from the matrix. Previous studies have suggested several possible methods to extract common arsenic species from rice and rice products with acceptable confidence. Among these methods, nitric acid-assisted extraction has received a considerable amount of attention and was used in HPLC−ICPMS for arsenic speciation by many groups.[12,13,15] However, because the speciation in CE−ICPMS was carried out under basic pH conditions, injections of sample extracts from acid digestion negatively affect the results. Heat-assisted aqueous extraction is another effective alternative to fully extract arsenic from rice samples.[11] A common problem in this methodology is that large amounts of starch remain in the solution, which cannot be separated by simple centrifugation or filtration. Loss of resolution, peak broadening, and column deterioration because of carbohydrates was observed in previous studies.[11,14] Some methodologies have demonstrated that low-temperature extraction with enzymes or the addition of enzymes post-extraction can be effective in removing biological matrices, such as proteins and starch, in rice.[14,33,34] To simplify the procedure, we focused our efforts on a direct enzyme-assisted microwave digestion for the extraction process. It is known that thermally stable α-amylase is able to catalyze the hydrolysis of starches and break them down to smaller sugar molecules. The addition of this type of enzyme during the extraction should reduce matrix effects. To compare the extraction efficiency, rice samples were microwave-extracted with and without the addition of α-amylase during preparation. The analysis (see Figure S-1 of the Supporting Information) exhibited significantly higher signal responses for all arsenic species when the enzyme was added during the extraction. The migration of arsenic species was faster for samples extracted with the enzyme, which can also be attributed to the lower viscosity. The extracts were also digested with nitric acid and analyzed using ICPMS for total arsenic concentration to compare the results from the two different extraction methods. Upon evaluation of the analytical results, it was concluded that the two different extraction methods provide equivalent results.

We believe that the differences in signal response of samples prepared from two methods were primarily attributed to the viscosity of the extraction solution. In CE, the injection volume (V_{inj}) can be calculated by

$$V_{inj} = \frac{\Delta P d^4 \pi t_{inj}}{128 \eta L} \quad (1)$$

where ΔP is the pressure difference across the capillary, d is the capillary inner diameter, t_{inj} is the injection time, η is the buffer viscosity, and L is the total capillary length. When the viscosity of the sample solution increases, it will result in a decrease in total injection volume and a lower signal response. We have measured the viscosity of sample solutions from the extraction procedures with and without the addition of α-amylase. The results show that the viscosity is 7.5 ± 0.1 mPa s (T = 23.3 °C) in samples (rice 1) extracted with only water. If α-amylase is introduced into the extraction procedure, the viscosity dropped to 1.3 ± 0.1 mPa s (T = 23.3 °C). Additionally, a similar signal loss was also observed for o-ASA in samples extracted without the enzyme, and in both cases, the signal ratios of o-ASA to analytes of interest were the same. Because o-ASA was added as an internal standard post-extraction to both samples, the results support the conclusion that the signal difference is from sample viscosity rather than the extraction efficiency.

Under optimized conditions, common arsenic species in rice were successfully separated and detected by the CE−ICPMS methodology (Figure 4). Increased migration times were observed in the capillary column during analysis. We believe that this can be attributed to the dissolved sugar molecules left in the sample solution, which affected the movement of the analytes in the capillary. In addition to the four analytes of interest in this study, a trace amount of unknown arsenic species produced unidentified peaks. Rice and rice cereal (denoted as rice 1 and rice 2) acquired from a local market were analyzed. The rice powder was divided into two portions. One portion was digested with nitric acid for a total arsenic measurement. The second portion was first treated with the enzyme-assisted microwave digestion, and the supernatant was further analyzed by the CE−ICPMS method. From Table 4, the summation of the four arsenic species in the rice samples generated a quantitative value very close to the total arsenic amount. The recoveries were 96.2 and 92.2% for rice 1 and rice 2, respectively. Previous studies have suggested the possible existence of tetramethylarsonium and other trace amounts of arsenic species in rice grain.[13] These species may contribute up to 10% of the total arsenic amount, but in our case, the intensity of unknown peaks were insignificant. To assess the reliability of this method, two rice standard reference materials (NIST SRM 1568b and NMIJ CRM 7503-a) were assayed. The analytical results were compared to certified values. As summarized in Table 4, the quantitative values of organic arsenic and the sum value of inorganic arsenic were within 5% of the certified values of the two reference materials. Small differences between the quantitative and certified values for As(III) and As(V) were observed in rice flour CRM 7503-a reference materials. We believed that these differences were due to a well-documented interspecies conversion that may occur during the extraction process.[8,11]

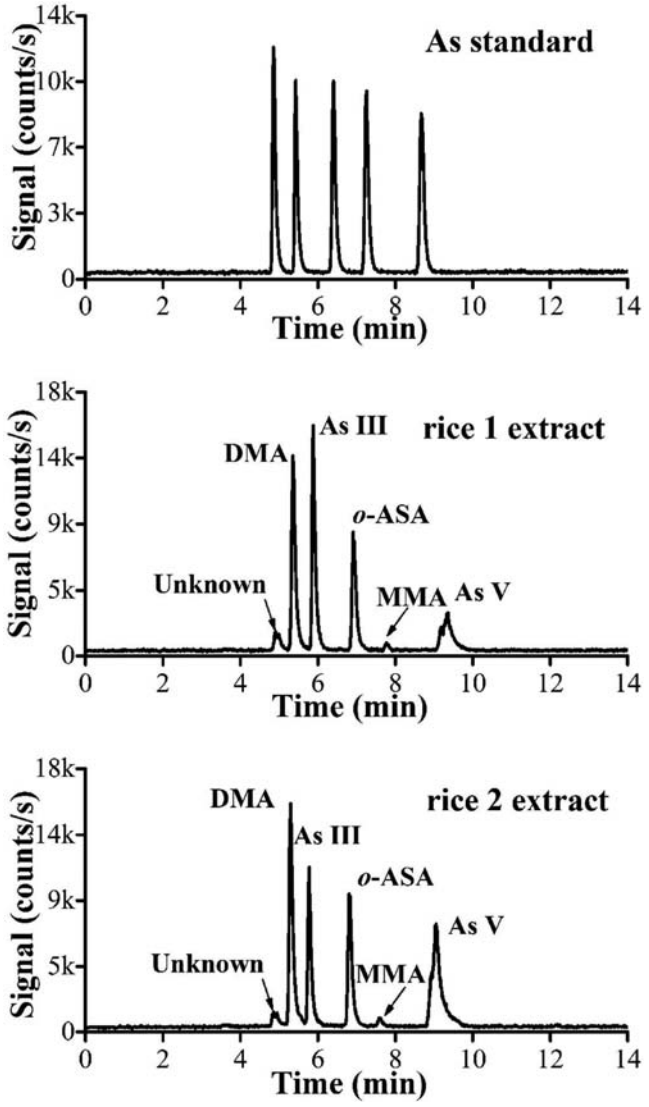

Figure 4. Electropherogram of arsenic standards and rice extracts with post extraction addition of *o*-AsA.

This study demonstrated a robust and reliable analytical method using CE−ICPMS, for the determination of common arsenic species, including DMA, MMA, As(III) and As(V), in rice and rice cereal by providing better separation efficiency over several liquid chromatography methods. An arsenic-containing compound *o*-ASA was used as an internal standard to compensate for signal drift and variance caused by the CE injection. Under a basic buffer condition of moderate concentration with a pH value around 11 and applied voltage of 20 kV, CE−ICPMS analysis can be completed within 10 min with excellent repeatability. The detection limits were determined to be lower than 0.3 ng g^{-1}, with a linear range from 0.5 to 20 ng g^{-1}. The linearity up to 50 ng g^{-1} was also demonstrated. The enzyme α-amylase was deemed necessary to achieve sufficient digestion and signal response. Rice samples purchased from a local market were successfully analyzed by this method, and the summed quantitative value of each arsenic species was consistent with the total arsenic quantitative concentration determined by standard ICPMS measurements. This methodology was further validated through the analysis of two rice standard reference materials. The quantitative results of DMA, MMA, and inorganic arsenic were well-matched with the certified values.

with fluorescence detection (UPLC-FLD) method for the analysis of nitro-PAHs. The method involves Fe/H^+-induced reduction of the nitro-PAHs to amino-PAHs that are intensely fluorescent for the indirect analysis of nitro-PAHs by UPLC-FLD (Figure 1). Derivatization conditions such as the reaction

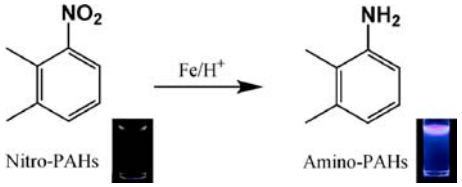

Figure 1. Fe/H^+-induced nitro-reduction of nonfluorescing nitro-PAHs forms fluorescent amino-PAHs for UPLC-FLD analysis.

temperature, reaction time, and amount of acid in the reaction medium were optimized for the highest reaction yield of the amino-PAH derivatives for the sensitive determination of nitro-PAHs by UPLC-FLD. Our developed method offering superior sensitivity was validated and applied in quantifying nitro-PAHs in different foodstuffs.

MATERIALS AND METHODS

Chemicals and Reagents. All chemicals and reagents of the highest purity available were used without further purification unless otherwise stated. 1-Nitronaphthalene (1-NN, 99%), 2-nitrofluorene (2-NF, 98%), and 1-nitropyrene (1-NP, 99%) were obtained from Sigma (St. Louis, MO, USA). Meat products were obtained from local supermarkets. HPLC grade acetonitrile was purchased from Tedia (Fairfield, OH, USA). *n*-Hexane and dichloromethane (DCM) were obtained from Mallinckrodt (St. Louis, MO, USA). Water was produced by a Milli-Q Ultrapure water system with the water outlet operating at 18.2 MΩ (Billerica, MA, USA).

Instrumentation. UPLC-FLD analysis was performed on an Agilent 1260 Infinity LC system (Palo Alto, CA, USA) equipped with a diode array and a FLD detector. High mass accuracy mass spectrometric and collision-induced dissociation (CID) mass spectrometric analyses were performed on a hybrid quadrupole time-of-flight mass spectrometer with a standard electrospray ionization interface (Xevo G2 Q-TOF, Waters, Milford, MA, USA) in positive ionization mode.

Sample Preparation. *Extraction.* Meat products were cut into small slices, lyophilized, and ground using a mortar and pestle. Prior to analysis, approximately 1 g of the powdered meat samples was accurately weighed and extracted with 20 mL of DCM by sonication. After 30 min of ultrasonication at room temperature, the samples were filtered through PTFE filter papers (20 μm, Whatman) to separate the meat powder from the sample extracts. The filtrates after evaporation of DCM were resuspended in 1 mL of *n*-hexane and loaded onto silica SPE columns for sample cleanup.

SPE Purification. The sample extracts were loaded onto Waters silica Sep-Pak SPE cartridges, which were conditioned with 10 mL of DCM followed by 10 mL of *n*-hexane for sample cleanup. After loading the sample, the columns were eluted with 2 mL of *n*-hexane and 6 mL of *n*-hexane/DCM (75:25, v/v). The eluates were collected and evaporated to dryness under nitrogen. The residue was dissolved in 1.5 mL of acetonitrile and centrifuged at 13800 rpm for 5 min prior to Fe/H^+ treatment.

Fe/H^+ Treatment. To 100 μL of the concentrated extracts were added 900 μL of acidified methanol (15% acetic acid, v/v) and 10 mg of iron powder. The sample mixture after vortex mixing was incubated at 60 °C for 40 min with periodic mixing. The Fe/H^+-treated samples after being cooled to room temperature were centrifuged at 13800 rpm for 10 min before the supernatant was transferred to an HPLC vial for UPLC-FLD analysis.

Determination of Derivatization Efficiency. The efficiency of reducing the nitro-PAHs to their corresponding amino-PAHs under the developed condition was evaluated by UPLC-UV analysis (254 nm) of nitro-PAHs under the same LC conditions as described above. Specifically, a standard solution mixture of nitro-PAHs at 40 μg/mL was prepared and analyzed before and after the Fe/H^+ treatment. According to the relative peak areas of nitro-PAHs, reaction efficiency was calculated.

UPLC-FLD Analysis. Ten microliters of the Fe/H^+-treated sample extract was injected on an Agilent Eclipse Plus C18 column (100 mm × 3.0 mm, 1.8 μm) thermostated at 40 °C for chromatographic separation. The column was eluted with a binary solvent system, with solvent A being water and solvent B being acetonitrile. Gradient elution at a constant flow rate of 0.5 mL/min was adopted, with the solvent gradient as follows: 30% B programmed linearly to 100% B in 10 min and held for another 5 min before reconditioning. The UPLC was coupled to a programmable FLD with the FLD time-programmed at excitation/emission wavelengths ($\lambda_{ex}/\lambda_{em}$) as follows: 0−6.3 min, λ_{ex} 240 and λ_{em} 430 nm; 6.3−7.6 min, λ_{ex} 280 and λ_{em} 370 nm; 7.6−15 min, λ_{ex} 240 and λ_{em} 435 nm.

Calibration and Method Validation. A stock solution mixture of 1-NN, 2-NF, and 1-NP at 460, 375, and 412.5 mg/L, respectively, was prepared in methanol and stored at −20 °C until diluted and Fe/H^+ treated for UPLC-FLD analysis. The working standard solutions of 1-NN (0.05−4.6 μg/mL), 2-NF (0.04−3.75 μg/mL), and 1-NP (0.04−4.13 μg/mL) were prepared by diluting the nitro-PAH stock solution mixture with methanol, derivatized, and UPLC-FLD analyzed as described above. Calibration curves were established by plotting the peak areas of the amino-PAHs against the nitro-PAHs concentrations in the calibration standard solutions.

The optimized method was also validated for analytical sensitivity, precision, and accuracy. The limit of detection (LOD) was established as the amount of nitro-PAH that generated a response 3 times the standard deviation of the analytical signal from replicated analyses (n = 7) of 1-NN, 2-NF, and 1-NP at 0.05, 0.04, and 0.04 μg/mL, respectively.[16,20] The method precision was evaluated by analyzing ham extracts spiked with nitro-PAHs at three concentrations (1-NN, 11.5, 115, and 460 μg/L; 2-NF, 9.4, 93.8, and 375 μg/L; 1-NP, 10.3, 103.1, and 412.5 μg/L), on the same day (n = 5) and over five separate days in a month. The method accuracy was determined by spiking nitro-PAHs at the three stated concentrations to ham sample matrix, SPE enriched, reduced by Fe/H^+ treatment, and analyzed using the UPLC-FLD method described above.

RESULTS AND DISCUSSION

Preparation and Characterization of the Nitro-reduction Product of Nitro-PAHs. The analysis of carcinogenic nitro-PAHs is challenging due to their low concentrations and the presence of complex matrices of food and environmental samples. The molecular fluorescence of nitro-PAHs, although rigid polycyclic compounds, is not observed due to the presence of the fluorescence-inhibiting nitro group.[6,16,17] Therefore, the analysis of nitro-PAHs by fluorescence detection, one of the most sensitive analytical methods, is hampered.[6] Few reports on the use of fluorescence in detecting nitro-PAHs in meat samples were reported in the literature. We report in this study the development of a simple and robust method converting nitro-PAHs to amino-PAHs facilitating their analysis by UPLC-FLD (Figure 1).

The commonly identified food- and environment-contaminating nitro-PAHs, namely, 1-NN, 2-NF, and 1-NP, were targeted in this study.[12] Upon treatment with powdered iron in an acidic medium, the nitro-PAHs were reduced to their corresponding amino-PAHs. The reduction products were characterized by fluorescence spectrophotometry. Depicted in Figure 2 are the fluorescence excitation and emission spectra of the amino-PAHs. Due to the very much differentiated

fluorescence excitation (λ_{ex}) and emission maximum (λ_{em}) wavelength of the target analytes, a programmed compound-dependent fluorescence detection method was adopted in this study for the sensitive and selective quantification of nitro-PAHs in food samples (see Materials and Methods).

The resultant amino-PAHs were also analyzed by high mass accuracy mass spectrometry and collision-induced dissociation (CID) mass spectrometry. High mass accuracy mass spectrometric analysis of the HPLC eluate collected at 5.75, 6.97, and 8.38 min showed $[M + H]^+$ ion peaks at 144.0810, 182.0971, and 218.0971, respectively (Supporting Information Figure S1), which correlated closely with that of the theoretical m/z values for 1-aminonaphthalene (144.0808), 2-aminofluorene (182.0964), and 1-aminopyrene (218.0964). Product ion scan MS/MS analyses of the pseudomolecular ions produced a major fragment ion of m/z value 17 Da less than their corresponding parent ions, originating from the neutral loss of the exocyclic amino group. Both findings lead to a common conclusion that the fluorescing products were amino-PAHs.

Optimization of Fe/H$^+$-Induced Nitro-reduction Parameters. The heterogeneous reducing agent of iron powder in an acidic medium was adopted for this study to reduce the nonfluorescent nitro-PAHs to amino-PAHs, which strongly fluoresce for UPLC-FLD analysis (Figure 1). Factors affecting the nitro-reduction process were optimized for the highest yield of the amino-PAHs. Specifically, the concentration of acetic acid, the reaction time, and the reaction temperature were investigated for the highest analytical signal in UPLC-FLD analysis.

With the reduction medium containing a fixed acetic acid content (15%, v/v), the effects of various reaction temperatures (from 25 to 70 °C) and reaction times (from 0 to 120 min) in different reactions were investigated. It was found in UPLC-FLD analyses that 40 min of heating (Figure 3A) at 60 °C (Figure 3B) is the most efficient condition for producing the fluorescing amino-PAHs. Further increases in reaction time and reaction temperature were found to have a negative impact on the analytical signal. We postulated that the predominance of the inadvertent amino-oxidation process over nitro-reduction reaction in the adverse heating condition reduced the population of the fluorescing amino-PAHs, thus their detector response in the UPLC-FLD analyses.

We then investigated the effect of different acetic acid contents (from 1 to 25%, v/v) on the reduction yield. Our results showed that 15% acetic acid in methanol (v/v) gave the best detector response (Figure 3C). Under the above developed nitro-reduction conditions, the reduction yields of amino-PAHs were found to be >97% (Figure 4), indicating the Fe/H$^+$-induced nitro-reduction process is highly efficient. Depicted in Figure 3 are the relative peak areas from analyzing

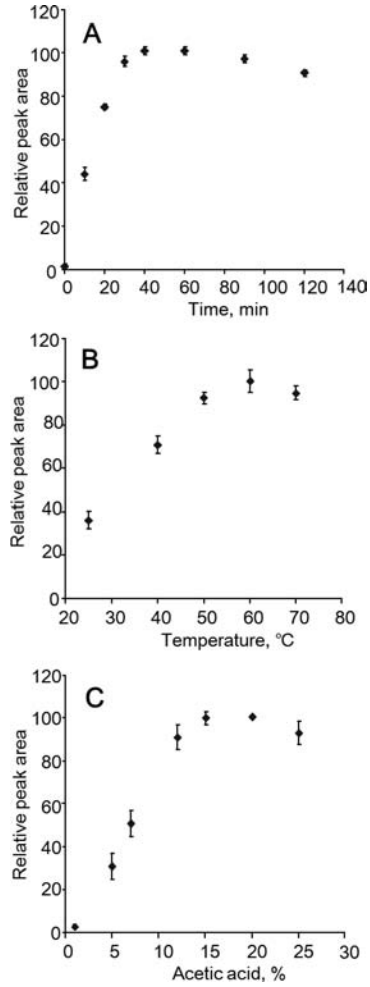

Figure 3. Influence of (A, 60 °C) reaction time, (B, 40 min) reaction temperature, and (C) acetic acid content on the reaction efficiency of the Fe/H$^+$-induced nitro-reduction of nitro-PAHs. The data represent the mean ± SD of three independent experiments with 1-NN at 4.6 μg/mL.

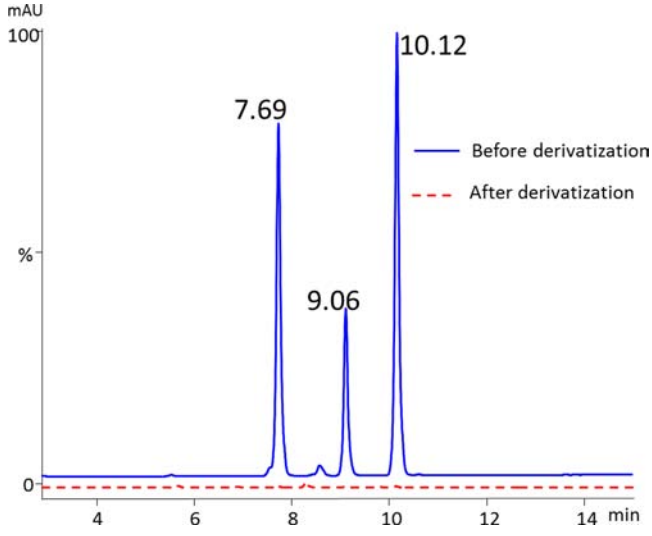

Figure 4. UPLC-UV analysis of underivatized and Fe/H$^+$-treated nitro-PAHs. 1-NN, 2-NF, and 1-NP were eluted at retention times of 7.69, 9.06, and 10.12 min, respectively.

DOI: 10.1021/acs.jafc.5b00523
J. Agric. Food Chem. 2015, 63, 3161−3167

the reaction mixtures in the different derivatization conditions. The optimized derivatization parameters of heating at 60 °C for 40 min in 15% acetic acid (v/v) were selected and used in all subsequent studies quantifying nitro-PAHs in meat products.

Calibration, Recovery, and Method Validation. Calibration curves were established by derivatizing and UPLC-FLD analyzing standard solution mixtures of nitro-PAHs in triplicate reactions using the optimized method described above. The concentrations of individual nitro-PAHs ranged from 0.04 to 4.6 μg/mL. The peak areas of amino-PAHs increased linearly over the tested concentration range, with coefficients of determination (R^2) >0.9994, indicating that the nitro-reduction step is highly quantitative. Table 1 summarizes the calibration slopes, intercepts, and coefficients of determination for the nitro-PAHs. Depicted in Figure 5A is a typical chromatogram obtained from analyzing the standard mixture.

Table 1. Linear Regression Parameters of the Calibration Curves and Limit of Detection (LOD) of the Developed UPLC-FLD Method

	1-NN	2-NF	1-NP
linear range (μg/mL)	0.05−4.60	0.04−3.75	0.04−4.13
slope[a]	1009.6 ± 89.8	1384.5 ± 68.6	1902.9 ± 146.9
intercept[a]	−58.4 ± 5.4	−37.5 ± 4.4	−73.3 ± 8.3
R^2	0.9994	0.9996	0.9997
LOD (μg/L)	5.9	5.1	3.1
LOD[b] (μg/kg)	0.59	0.51	0.31
LOQ[c] (μg/kg)	1.97	1.70	1.03

[a]The data represent the mean ± SD for three independent experiments. [b]The LOD is the sample extract based on 1 g of sample. [c]Limit of quantitation, S/N = 10.

The recovery of the method, as determined by spiking nitro-PAHs at three concentrations (1-NN, 11.5, 115, and 460 μg/L; 2-NF, 9.4, 93.8, and 375 μg/L; 1-NP, 10.3, 103.1, and 412.5 μg/L) to a ham sample matrix, SPE purified, Fe/H^+ treated, and UPLC-analyzed using the method described above were found to be 78.1 ± 4.8, 84.3 ± 2.8, and 78.5 ± 2.2%, respectively. Measurements of 1-NN, 2-NF, and 1-NP were thus corrected by factors of 1.28, 1.19, and 1.27 to achieve their respective concentrations in the meat samples.

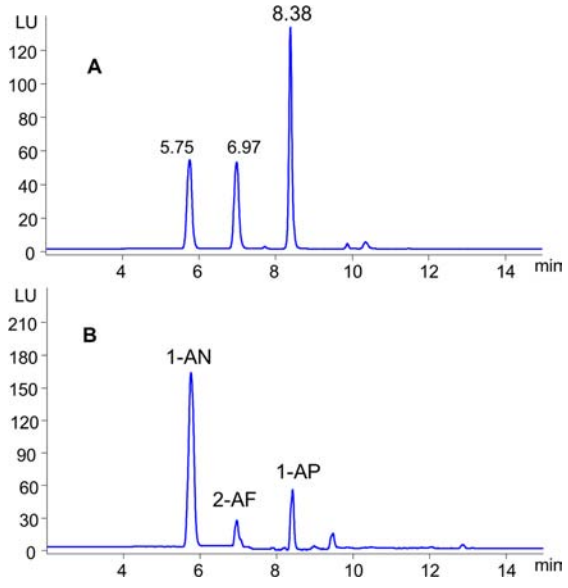

Figure 5. Typical chromatograms obtained from UPLC-FLD analyses of Fe/H^+-treated (A) standard mixture (1-NN, 0.5 μg/mL; 2-NF, 0.4 μg/mL; and 1-NP, 0.4 μg/mL) and (B) fresh chicken sample extract. The chromatographic retention times of 1-AN, 2-AF, and 1-AP were 5.75, 6.97, and 8.38 min, respectively.

The intraday precision of the analytical method for determining nitro-PAHs at low, medium, and high concentrations revealed relative standard deviation (RSD) of <6.4% for within-day analyses (n = 5). Over a period of 1 month, the RSD for individual nitro-PAHs measurements ranged from 7.5 to 12.8% (n = 5). The data of reproducibility and accuracy shown in Table 2 demonstrate good performance of UPLC-FLD method for the quantitative analysis of nitro-PAHs in the complex matrix of food products. The high reproducibility of the method allowed the analysis to be performed without the use of an internal standard.

Table 2. Validation Parameters of the Developed Method for the Determination of 1-NN, 2-NF, and 1-NP in Meat Samples

		accuracy		precision[a]	
	concn spiked (μg/kg)	concn found (μg/kg)	recovery (%)	intraday (% RSD)	interday (% RSD)
1-NN	11.5	8.9 ± 0.9	77.7 ± 7.8	6.3	12.8
	115	87.8 ± 3.7	76.3 ± 3.2	4.7	11.0

Determination of Nitro-PAHs in Meat Products. The developed method combining precolumn nitro-reduction and UPLC-FLD analysis was applied to the quantification of 1-NN, 2-NF, and 1-NP in meat products. Twenty frozen meat samples (Table 3) including chicken, pork, beef, ham, salmon, etc., were randomly selected from supermarkets in Hong Kong. These samples were processed and tested for the presence of nitro-PAHs using the newly developed method. Figure 5B shows a typical chromatogram obtained from UPLC-FLD analysis of fresh chicken sample using the developed method.

Interestingly, our results revealed that 1-NN was the most commonly identified nitro-PAH in the collected meat products (Table 3). Among the tested samples, 1-NN was detected at its highest levels in fresh chicken (158.1 ± 40.5 μg/kg) and smoked salmon (161.7 ± 29.5 μg/kg) samples. On the contrary, 2-NF was reported to be the most commonly identified nitro-PAHs by Schlemitz and Pfannhauser.[12] It is our belief that the choice of samples may explain the bulk of the observed discrepancy. Whereas a combination of fresh and cured meat products was chosen in this study, most of the food commodities chosen by Schlemits and Pfannhauser were heat-treated foods.[12]

Furthermore, our results showed significantly higher levels of nitro-PAHs in most of the food products than those tested by

Schlemitz and Pfannhauser.[12] The difference is partly attributed to the different choices of samples, as described above. Food processing by heat treatment may cause thermal decomposition of nitro-PAHs and therefore lead to lower nitro-PAH content. The other potential cause for the observed discrepancy includes differences in the sample preparation methods that were used. Whereas Schlemitz and Pfannhauser extracted nitro-PAHs from the food sample with acetonitrile at 98 °C,[12] a milder condition of ultrasonication at room temperature was employed in our study. As will be discussed in detail shortly, high-temperature food processing may reduce the nitro-PAH content in fresh meat products.

1-NP, being one of the most mutagenic compounds and marker molecules for diesel exhaust,[21−23] was detected in a few of the tested samples. UPLC-FLD analysis identified 1-NP at concentrations dramatically lower than that of 1-NN. This result is in fairly good agreement with the results of Schlemitz and Pfannhauser, who reported low microgram per kilogram levels of 1-NP in selected meat products.[12] The trend of nitro-PAHs levels is also in line with the reported levels of 1-NN, 2-NF, and 1-NP in the ambient environment in selected locations around the world. It was reported that 1-NN and 2-NF were detected at levels significantly higher than that of 1-NP in both urban and suburban areas.[24] Therefore, results from this study may provide evidence linking environmental pollution to nitro-PAHs in meat products.

Effect of Thermal Processing on Nitro-PAH Contents in Food Products. Our results also revealed high-temperature food processing to have pronounced, but dramatically differentiated, effects on the levels of nitro-PAHs in fresh and cured food commodities. As elucidated from studies in fresh chicken samples (sample 1), heat treatment produced a temperature-dependent decrease in the levels of 1-NN, 2-NF, and 1-NP in the chicken samples. Potential reasons for the observed decline in nitro-PAH levels include dissolvation of nitro-PAHs in the cooking water/oil or thermal decomposition of nitro-PAHs during the cooking process.

On the contrary, ham cooked by boiling in water or stir-frying was observed to have a pronounced effect in elevating the level of 1-NN (sample 4). A temperature-dependent increase in 1-NN concentration was observed in ham cooked in boiling water (100 °C) and in corn oil (250 °C). With ham being a cured meat product containing higher levels of nitrate and nitrite salts (>100 mg/kg) than fresh meats,[25,26] it is possible that nitro-PAHs are formed by reacting nitrate/nitrite with PAHs in the meat and that the nitro-PAH formation outweighed the thermal decomposition/dissolvation. Therefore, elevated nitro-PAH content was observed in the cooked ham samples.

In summary, we have developed a sensitive and selective UPLC-FLD method for the determination of nitro-PAHs in meat products. The combination of precolumn nitro-reduction and UPLC-FLD analysis allows confident determination of 1-NN, 2-NF, and 1-NP at sub parts per billion levels. The method after validating for accuracy and precision was applied for the determination of nitro-PAHs in fresh and cured meat products. High levels of nitro-PAHs were detected in fresh chicken (195.4 μg/kg) and smoked salmon (161.7 μg/kg). For the first time, our study revealed that high-temperature food processing has a pronounced, but differentiated, effect on nitro-PAHs in fresh and cured meats.

by Chung et al.,[8] the mechanism underlying D-psicose's hypolipidemic action is less clear at present.

Commercial production of D-psicose is now available, which makes it feasible to do in vivo research.[24] Because D-psicose does not stay in the body and is excreted in the urine as D-psicose,[9] animals may have a fluctuation of serum D-psicose level throughout a 24 h feeding−fasting cycle. This suggested that timing of collecting serum and tissues from rats fed D-psicose for subsequent analysis would be important observations to find the relationship between D-psicose and lipid metabolism. Thus, rats fed the 3% D-psicose diet for 4 weeks were sacrificed without fasting every 6 h over a period of 24 h, and changes in serum lipid and glucose levels, liver lipid levels, liver enzyme activity, and gene expression of proteins related to lipid and glucose metabolism were quantified in experiment 1. Effects of D-psicose on 24 h energy expenditure were evaluated in experiment 2.

MATERIALS AND METHODS

Chemicals. D-Psicose was provided by Matsutani Chemical Industry Co., Ltd. (Itami, Japan). The purity of D-psicose was 97.5%. Other reagents were of analytical grade and used without further purification.

Experiment 1 (24 h Continuous Measurement of Serum and Liver Lipid Levels). *Animal Experiments.* Four-week-old Sprague−Dawley (SD) rats were purchased from Japan SLC (Shizuoka, Japan) and individually housed in stainless steel cages under controlled atmospheric conditions (temperature, 22 ± 1 °C; humidity, 55 ± 5%; light cycle, 8:00 a.m.−8:00 p.m.), and fed a commercial pellet diet (CE-2, Clea Japan, Tokyo, Japan) for a week. Animal studies were carried out under the Guidelines for Animal Experiments of University of Nagasaki (Nagasaki, Japan), and Law no. 105 and Notification no. 6 of the government of Japan. After a week's acclimation, rats were then assigned to two groups, 24 animals per group. The control group was fed a modified AIN-93G diet with corn starch as a major source of carbohydrate. For the animals fed the D-psicose diet, 3% D-psicose replaced the same amount of corn starch in the control diet (Table 1).

Table 1. Nutrient Composition (Percent) in the Diets

	control	D-psicose
casein[a]	20.0	20.0
α-corn starch	13.2	13.2
soybean oil	7.0	7.0
sucrose	10.0	10.0

total (%)	100.0	100.0

[a]Purchased from Wako Pure Chemical Industries (Osaka, Japan). [b]Purchased from Oriental Yeast (Tokyo, Japan).

Animals were provided diets ad libitum for 4 weeks. Subsequently, five to six animals on each dietary regimen were decapitated every 6 h, beginning at 9:00 a.m. and followed at 3:00 p.m., 9:00 p.m., and 3:00 a.m. without fasting. Blood was collected with decapitation, and serum was obtained after centrifugation at 1500*g* for 15 min. Liver, soleus muscle, and adipose tissue (mesenteric, perirenal, and epididymal) were dissected and stored at −80 °C prior to further analysis for tissue lipid, enzyme activity, or gene expression. Interscapular brown adipose tissue was also removed for the measurement of enzyme activity. The small intestine was collected, flushed with ice-cold saline, and divided into two segments designated jejunum and ileum, respectively. Serum and liver lipid levels were measured. The activity of liver enzymes involved in lipid metabolism was also measured.

Serum and Tissue Biochemical Analyses. Serum glucose and lipid levels were assayed enzymatically using commercial kits (Glu CII-Test, Cholesterol E-Test, Triglyceride E-Test, Phospholipid C-Test, NEFA C-Test; Wako Pure Chemical Industries, Osaka, Japan). Serum insulin and leptin levels were measured by enzyme-linked immunosorbent assay (ELISA) kits (Morinaga Institute of Biological Science, Yokohama, Japan). Liver was weighed and a fraction removed, and lipids were extracted according to the method of Folch et al.[25] Cholesterol, phospholipid, and triglyceride levels in the liver were enzymatically measured with the kits used for serum lipids.

Liver Enzyme Activity. To determine how D-psicose alters lipid metabolism, the activity of lipid metabolism-related enzymes in the liver and brown adipose tissue was measured. A small aliquot of the excised liver was homogenized in 6 volumes of 0.25 M sucrose solution containing 10 mM Tris-HCl and 1 mM EDTA (pH 7.4) to obtain aliquots for isolated liver subcellular fractions. After sedimentation of the nuclei fraction, the supernatant was centrifuged to sediment mitochondria at 12000*g* for 10 min. Then, the supernatant was again centrifuged at 100000*g* for 60 min to precipitate microsomes, and the remaining supernatant was used as cytosol fraction. The mitochondrial and microsomal pellets were resuspended in the same 0.25 M sucrose solution. Activities of cytosol fatty acid synthase (FAS),[26] glucose-6-phosphate dehydrogenase (G6PDH),[27] and malic enzyme (ME)[28] in the liver were measured. Microsomal phosphatidate phosphohydrolase (PAP)[29] and mitochondrial carnitine palmitoyltransferase (CPT)[30] were also determined. Interscapular brown adipose tissue was collected and homogenized as described above, and mitochondrial CPT activity was measured. Protein was assayed according to the method of Lowry et al.[31]

Analysis of Gene Expression by Real-Time Quantitative PCR. To further determine how D-psicose affects lipid metabolism at the molecular level, gene expression of enzymes and proteins involved in lipid metabolism as listed in Table 2 was analyzed. Total RNA was extracted from a subsample of liver, jejunum, soleus muscle, and mesenteric adipose tissue using RNA extraction reagent (RNAiso Plus, Takara Bio, Shiga, Japan) according to the manufacturer's instructions. Total RNA (1 μg) was reverse-transcribed to synthesize cDNA with a reverse-transcription kit (PrimeScript RT Master Mix, Takara Bio). Real-time PCR was performed on a 7300 Real-Time PCR system (Applied Biosystems, Foster City, CA, USA) using the manufacturer's standard protocol. The PCR reaction mixture was prepared using THUNDERBIRD SYBR qPCR Mix (Toyobo, Osaka, Japan). The mRNA (mRNA) levels, measured relative to 36B4 mRNA levels used as an internal control,[32] were determined using the $2^{-\Delta\Delta Ct}$ method. Primers were designed using Primer Express Software for Real-Time PCR (Applied Biosystems), and the forward and reverse primers used are listed in Table 2.

Experiment 2 (Measurement of 24 h Energy Expenditure). *Animals.* Four-week-old male SD rats weighing about 100 g were individually housed and fed the commercial pellet diet. After a week's acclimation period, one group (eight rats) was fed the control diet and the test group (eight rats) was fed the 3% D-psicose diet ad libitum for 4 weeks as in experiment 1.

Measurement of 24 h Energy Expenditure. At 9 weeks of age and with an approximate weight of 400 g, rats fed each diet were individually housed in a metabolic chamber and maintained on the control or D-psicose diet ad libitum through subsequent measurements. Energy expenditure and oxidation of carbohydrate and fat were measured over a 24 h period by a combined gas analyzer and mass spectrometer (model ARCO-200 Series, ArcoSystem, Chiba, Japan). Room air was pumped through the chamber at a rate of 1.0 L/min. Measurement of oxygen and carbon dioxide started at 9:00 a.m. and were continuous at 5 min intervals over 24 h. The oxidation of carbohydrate and fat was calculated with a multiprocess monitor

system (ARCO 2000 MM, ArcoSystem) as described by Ishihara et al.[33]

Statistical Analysis. All of the values are expressed as means ± SE. In experiment 1, two-way ANOVA was used to analyze time course changes (dietary group × time). When a significant effect of dietary groups and interactions was found, an independent t test was carried out at each point. In experiment 2, an independent t test was performed. Values were considered to be significantly different when the p value was <0.05.

RESULTS

Experiment 1 (24 h Continuous Measurement of Serum and Liver Lipid). Body weight, food intake, and organ weights of the rats in experiment 1 are reported in Table 3. Feeding D-psicose significantly decreased body weight, but not food intake. As reported in Figure 2, the D-psicose diet significantly reduced serum total cholesterol level at 3:00 a.m. without significant differences in serum triglyceride and nonesterified fatty acid levels. No difference was observed for serum glucose level between the two diets, whereas serum insulin level was significantly decreased in the D-psicose-fed rats compared to the control-fed animals at 3:00 a.m. and 9:00 a.m. ($p < 0.05$ at both time points). The level of serum leptin was also affected by D-psicose and significantly lowered at 3:00 p.m. ($p < 0.05$). Feeding D-psicose lowered liver triglyceride level and increased liver cholesterol levels as compared to the control-fed animals, but these consistent observations were not significantly different (Figure 3).

Activities of specific liver enzymes involved in lipid homeostasis at 6 h intervals over 24 h are illustrated in Figure 4. The activity of FAS was not modulated by the diets. In contrast, feeding the D-psicose diet constantly reduced activities of G6PDH and ME over a 24 h period compared to the control diet, with a significant difference at 9:00 a.m. ($p < 0.05$). No effect of the diets was seen on PAP activity. The activity of CPT in liver was marginally increased in the D-psicose group compared to the control group at 9:00 p.m. ($p = 0.06$) and at 3:00 a.m. ($p = 0.09$). The activity of the CPT in brown adipose tissue was not modified by dietary treatment. No significant interaction between diet and time to sacrifice was found for any enzyme activities.

To see the effects of D-psicose on lipid homeostasis at the molecular level, gene expression of proteins involved in lipid and glucose metabolism was measured, and results are reported as shown in Figures 5−8. In the liver (Figure 5), mRNA of

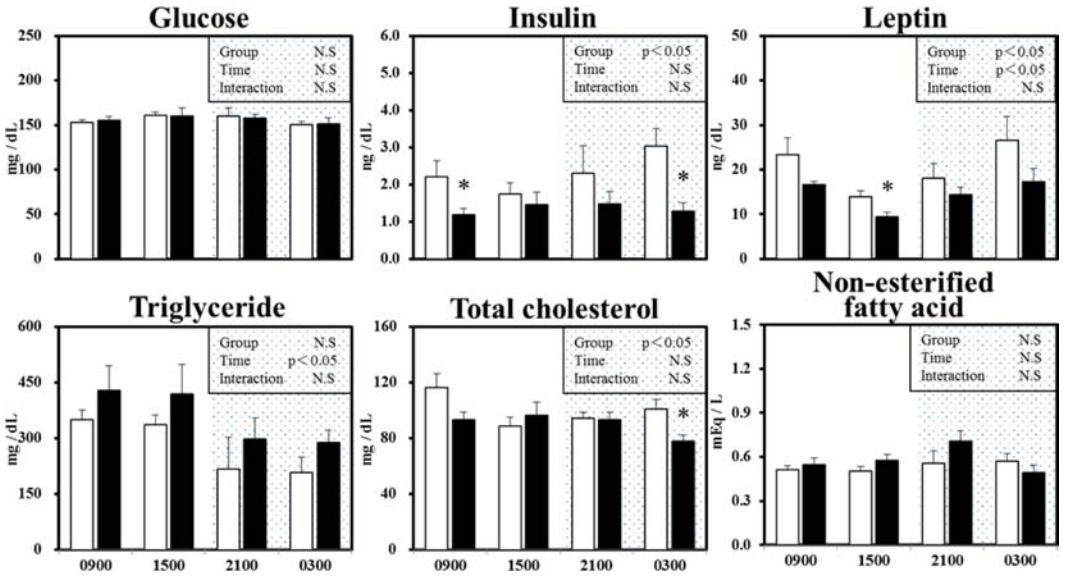

Figure 2. Effect of the 4 week administration of the 3% D-psicose diet on serum levels of lipids, glucose, insulin and leptin in rats: (white bars) control; (black bars) D-psicose. Data are the mean ± SE (n = 5–6). (*) Significant difference at $p < 0.05$, using independent t test.

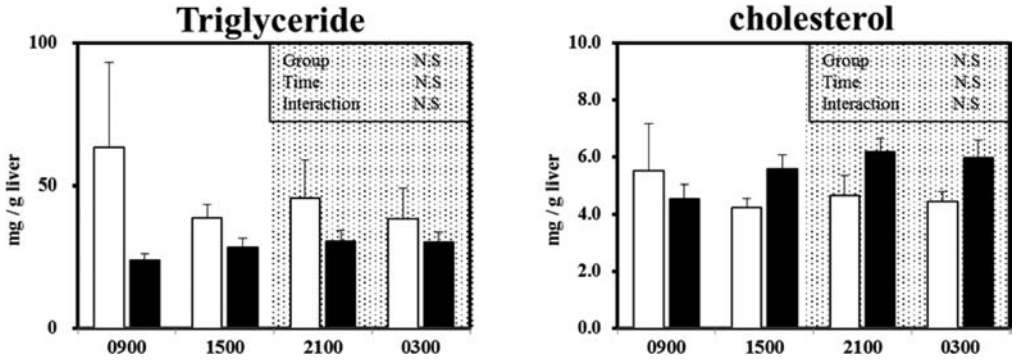

Figure 3. Effect of the 4 week administration of the 3% D-psicose diet on the levels of liver lipids: (white bars) control; (black bars) D-psicose. Data are the mean ± SE (n = 5–6).

peroxisome proliferator-activated receptor α(PPARα), a regulator of fatty acid oxidation,[34] was significantly higher in rats fed the D-psicose diet compared to rats fed the control diet ($p < 0.05$). In soleus muscle (Figure 6) and adipose tissue (Figure 7), gene expression of proteins involved in lipid metabolism was not modified by the diets. From the examination of the tissue from the jejunum, mRNA expression was generally lowered by the D-psicose diet. A significant interaction between type of carbohydrate and time to sacrifice was found for mRNA of fatty acid translocase (CD36) and scavenger receptor B1 (SR-B1) (Figure 8). Gene expression of CD36 was significantly down-regulated by the D-psicose diet compared to the control diet at 9:00 a.m. ($p < 0.05$). mRNA of microsomal triglyceride transfer protein (MTP), essential for the assembly/secretion of chylomicrons,[35] was significantly down-regulated by the D-psicose diet compared to the control diet.

Experiment 2 (Measurement of 24 h Energy Expenditure). Hour-by-hour profiles of 24 h energy expenditure and oxidation of fat and carbohydrate are illustrated in Figure 9. When rats were housed in metabolic cages after feeding diets for 4 weeks, final body weights (426 ± 6 vs 389 ± 3 g, $p < 0.05$) and food intake (25.7 ± 0.4 vs 23.8 ± 0.2 g/day, $p < 0.05$) were significantly lower in the rats fed D-psicose compared to the rats fed the control diet. When expressed per kilogram of body weight, total energy expenditure in rats fed the D-psicose diet was significantly higher during a late light period. Following the consumption of the D-psicose diet for 4 weeks, fat oxidation was significantly enhanced during the dark period. Conversely, carbohydrate oxidation was significantly reduced in rats fed the D-psicose diet during the dark period compared to rats fed the control diet (Figure 9).

DISCUSSION

With the intense interest and study of fructose's lipogenic properties,[5,6] it is of interest and potential benefit to determine how D-psicose, an epimer of D-fructose, affects lipid homeostasis. In the current study, we fed 3% D-psicose in a modified AIN-93G diet to SD rats for 4 weeks and measured lipid levels and related parameters every 6 h over a 24 h period and compared with data obtained from rats fed the control AIN-93G diet.

In agreement with previous studies,[16,18,22,23] body weight and food intake were significantly lower in rats fed the D-psicose diet compared to rats fed the control diet in experiment 2. It therefore appears that although D-psicose provides no calories,[11] rats fed the 3% D-psicose diet did not increase

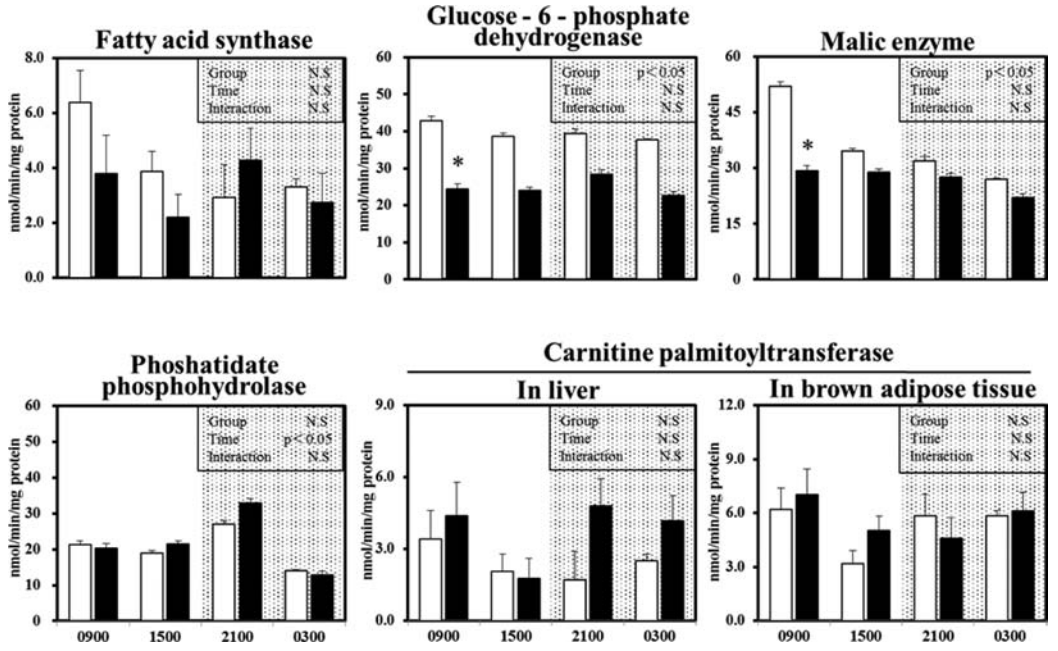

Figure 4. Effect of the 4 week administration of the 3% D-psicose diet on activities of enzymes related to lipid metabolism in liver and brown adipose tissue: (white bars) control; (black bars) D-psicose. Data are the mean ± SE (n = 5−6). (∗) Significant difference at $p < 0.05$, using independent t test.

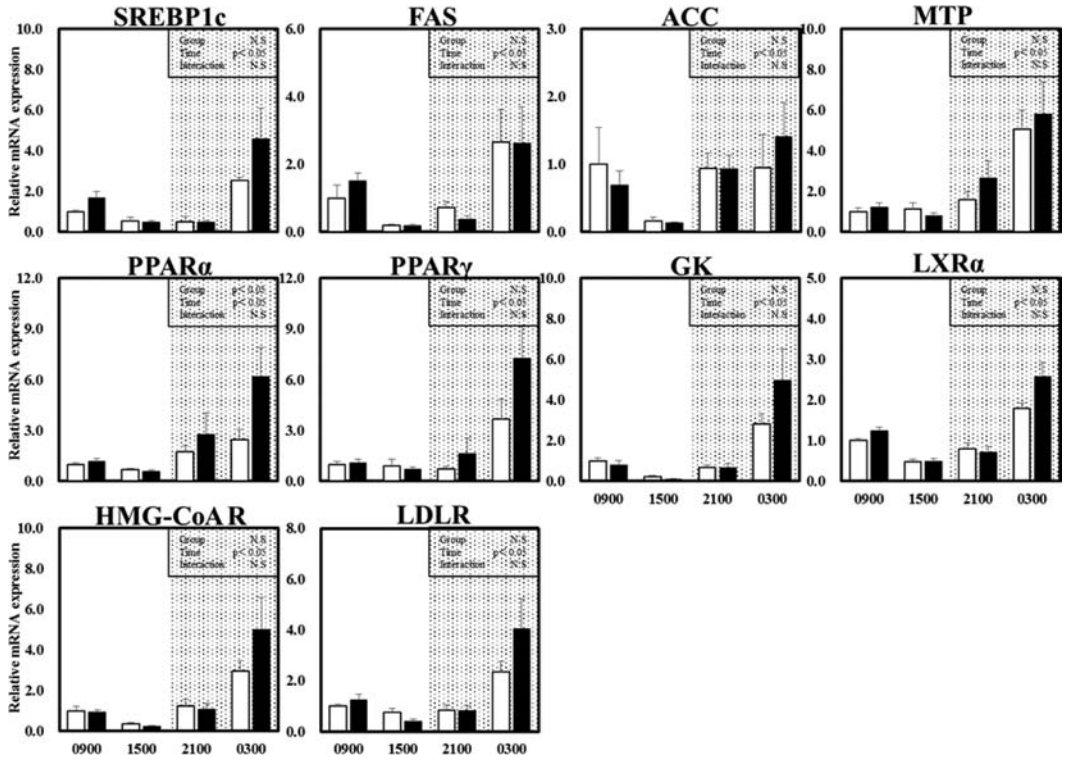

Figure 5. Effect of the 4 week administration of the 3% D-psicose diet on mRNA expression in liver: (white bars) control; (black bars) D-psicose. Data are the mean ± SE (n = 5−6) expressed relative to the control at 9:00 a.m., which was set at 1.0.

food intake to compensate for the displaced energy, resulting in reduced body weight. The level of serum leptin, a modulator of food intake,[36] was significantly decreased by D-psicose, whereas food intake was not elevated. The decreased level of serum leptin was also confirmed in Otsuka Long-Evans Tokushima Fatty (OLETF) rats supplemented with D-psicose in their drinking water and male Wistar rats fed a D-psicose-containing mixture of sugars.[15,21] Because several studies observed D-psicose-induced lower food intake,[21−23] further detailed studies are warranted to clarify the relationship among D-psicose, hormone levels, and food intake. These studies are especially important in the event that D-psicose would be used for foods to treat and help manage weight gain and blood glucose level by providing food with fewer calories. Serum levels of insulin

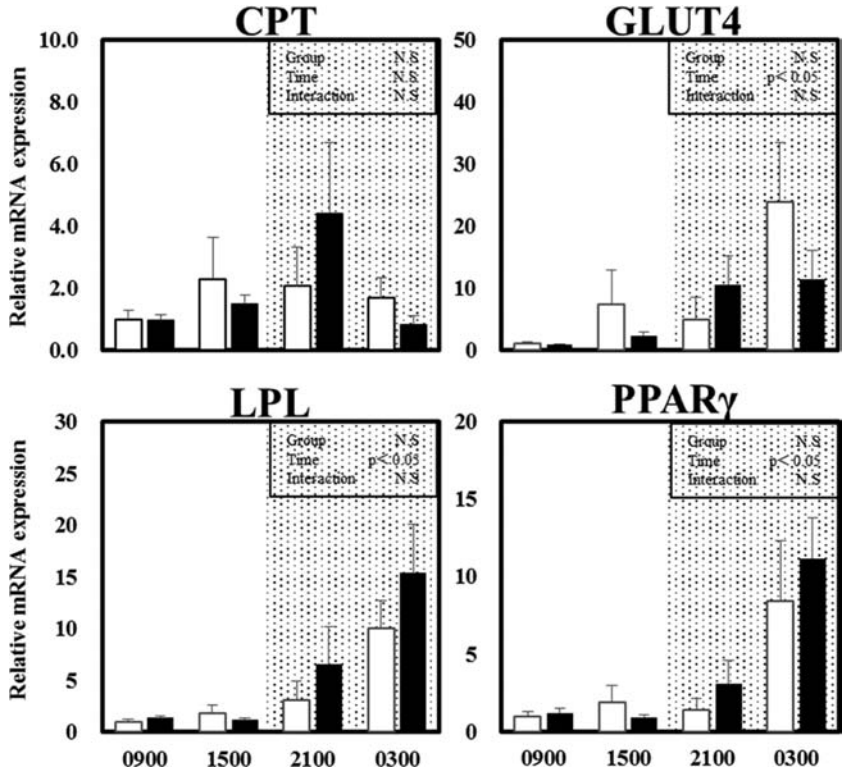

Figure 6. Effect of the 4 week administration of the 3% D-psicose diet on mRNA expression in skeletal muscle: (white bars) control; (black bars) D-psicose. Data are the mean ± SE (n = 5−6) expressed relative to the control at 9:00 a.m., which was set at 1.0.

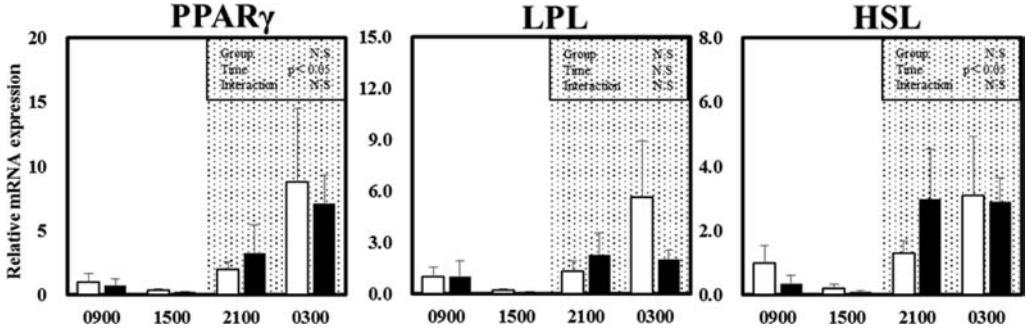

Figure 7. Effect of the 4 week administration of the 3% D-psicose diet on mRNA expression in white adipose tissue: (white bars) control; (black bars) D-psicose. Data are the mean ± SE (n = 5−6) expressed relative to the control at 9:00 a.m., which was set at 1.0.

and leptin were significantly diminished by D-psicose as compared to the control. However, no difference was found in serum glucose levels (Figure 2), which is different from studies showing that D-psicose reduced plasma glucose levels in *db*/*db* mice, rats meal-fed D-psicose, and Wistar rats fed D-psicose and a mixture of other sugars.[13,18,21] This is partly attributed to the fact that the rats used in our study were not fasted upon termination. In addition, it is possible that the level of D-psicose in the 3% D-psicose diet is not high enough to provide an inhibitory action of D-psicose on α-glucosidase, and corn starch as a major carbohydrate in the diet is not a good substrate for α-glucosidase. However, effects of difference in model animals, species, and experimental conditions on serum glucose could not be ruled out. Irrespective of these reported differences, this finding is of interest in terms of managing weight gain with dietary treatment because both insulin and leptin in blood are directly correlated with the degree of adiposity.[37] Furthermore, D-psicose diminished serum leptin and adipose tissue weight in OLETF rats and male Wistar rats.[15,21]

With regard to lipid homeostasis, the activities of lipogenic enzymes such as G6PDH and ME, but not FAS, were significantly and constantly diminished by feeding the D-psicose diet compared to the control diet (Figure 4). These results confirmed the study done by Matsuo et al. in which rats fed D-psicose had decreased activity of lipogenic enzymes compared to rats fed glucose or fructose.[20] Hepatic CPT, an enzyme that catalyzes a rate-limiting step in fatty acid oxidation,[38] was marginally elevated by D-psicose during the dark period (p = 0.06 at 9:00 p.m.) (Figure 4). Given that D-psicose reduces liver levels of triglyceride[13,16] and adipose tissue weight,[15−18,22,23] these results probably imply that the combined effects of lowered fatty acid synthesis and enhanced fatty acid oxidation in the liver at least partly contribute to decreased liver triglyceride and adipose tissue weight in rats fed the D-psicose diet. This hypothesis may also support the results observed in

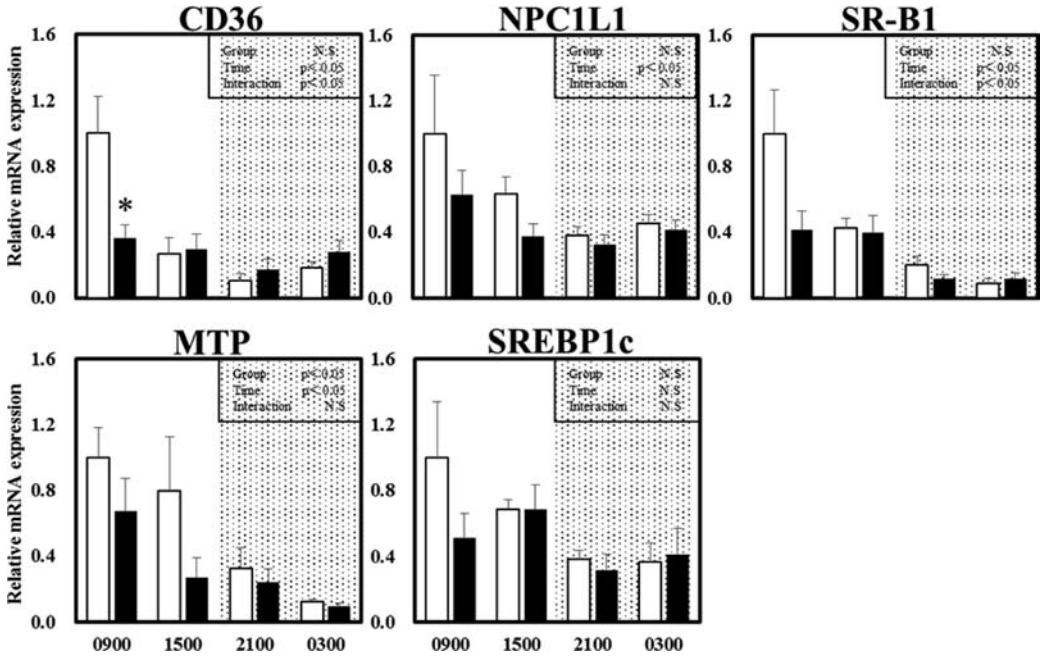

Figure 8. Effect of the 4 week administration of the 3% D-psicose diet on mRNA expression in jejunum: (white bars) control; (black bars) D-psicose. Data are the mean ± SE (n = 5−6) expressed relative to the control at 9:00 a.m., which was set at 1.0. (∗) Significant difference at $p < 0.05$, using independent t test.

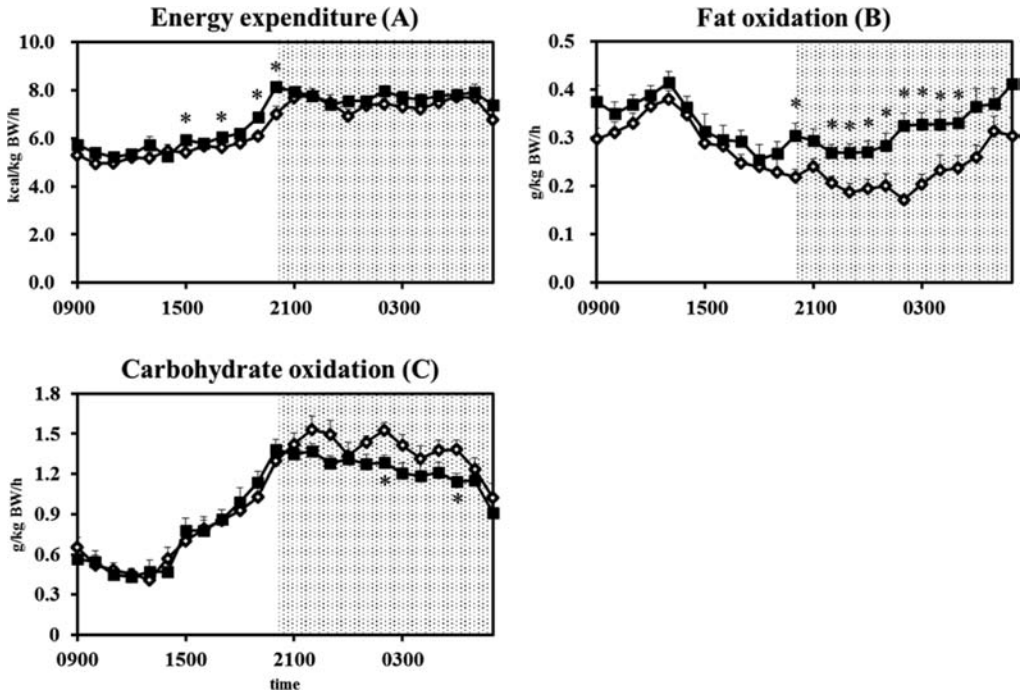

Figure 9. Effect of the 4 week administration of the 3% D-psicose diet on (A) energy expenditure, (B) fat oxidation, and (C) carbohydrate oxidation: (◇) control; (■) D-psicose. Data are the mean ± SE (n = 8). (∗) Significant difference at $p < 0.05$, using independent t test.

24 h energy expenditure; D-psicose enhanced energy expenditure in the light period and fat oxidation during the dark period (Figure 9). Because D-psicose is chemically similar to, but structurally different from, fructose, it is of interest to note that the effect of D-psicose on 24 h energy expenditure and fat oxidation in the present study was totally different from the previous report showing that fructose-sweetened beverages diminished energy expenditure and fat oxidation in overweight and obese subjects.[39] This is probably because D-psicose decreases insulin levels and the resultant lowered insulin levels do not impair lipid homeostasis, given that insulin plays an important role in lipid metabolism in the liver.[40] We observed that D-psicose constantly gave lower liver triglyceride levels over 24 h without a significant difference, whereas Baek et al. showed that D-psicose significantly decreases liver lipids in *db/db* mice.[13] This difference may be due to the type of animals and diet composition. Because our current study demonstrated that a D-psicose diet exhibited lower lipogenic enzyme activities

DOI: 10.1021/jf502535p
J. Agric. Food Chem. 2015, 63, 3168−3176

(Figure 4), further studies to confirm the hypolipidemic action of D-psicose are needed using hyperlipidemic animals and high-fat and/or high-fructose diets.

To gain insight into D-psicose-induced hypolipidemic action at the molecular level, gene expression of proteins and enzymes related to lipid metabolism was analyzed as depicted in Figures 5−8. In the liver, the qualitative response of individual mRNA in response to D-psicose was similar; gene expression was up-regulated at 3:00 a.m. and 9:00 a.m. mRNA expression of PPARα, a key transcriptional modulator of fatty acid oxidation, was up-regulated by D-psicose, probably supporting the observations that liver CPT activity tended to be higher during the dark period. These observations correspond with the observed results that D-psicose significantly increased fat oxidation during the dark period as shown in Figure 9. This substantiates results from the recent study in which the 5% D-psicose diet enhanced energy expenditure during the dark period.[23] However, these authors did not determine if fatty acid oxidation is at least partly responsible for enhanced energy expenditure at enzymatic and molecular levels. Our data on enzyme activity and gene expression of lipid metabolism-related proteins seem to suggest the underlying mechanism of D-psicose-induced hypolipidemic action.

It is of interest to note that D-psicose affects gene expression of intestinal proteins involved in lipid transfer such as CD36, SR-B1, and MTP (Figure 8), all of which are associated with lipid absorption in the small intestine.[35] Although D-psicose inhibits intestinal α-glucosidase in vitro, probably resulting in a decrease in glucose absorption in the small intestine,[12] to our knowledge, no studies have thus far shown an involvement of D-psicose in intestinal events. In addition to altered enzymatic activities in the liver, D-psicose may modulate lipid handling at the small intestinal level, subsequently contributing hypolipidemic action. Given that diabetes patients and genetically diabetic obese rats have increased intestinal lipid transport,[41,42] D-psicose may be a promising food ingredient to maintain and control blood glucose level under conditions where glucose metabolism is compromised. Further studies are warranted to determine how the small intestine has a role in lipid metabolism in D-psicose-fed rats.

Taken together, our results suggest that D-psicose favorably alters lipid metabolism partly through decreased fatty acid synthesis and increased fatty acid oxidation, thereby enhancing energy expenditure. Additional studies are needed to unravel the precise molecular mechanism underlying the effects of D-psicose on antiobesity and antihyperlipidemic actions. In summary, D-psicose appears to be a unique sugar that could offer beneficial effects to help control body weight and maintain healthy blood lipid and glucose level in many individuals and especially in obese people with insulin resistance.

Table 1. Summary of Optimum Hydrolysis Conditions, Characteristics, and Enzyme Sources

enzyme	optimum conditions[a] pH	optimum conditions[a] temperature (°C)	characteristics	brand/source
Alcalase	8.0	50	endopeptidase	Sigma-Aldrich/*Bacillus lichenifarmis*
Flavourzyme	7.0	50	endoprotease and exopeptidase	Sigma-Aldrich/*Aspergillus oryzae*
Cellulase	4.5	50	cellulase	Sigma-Aldrich/*Aspergillus niger*
Viscozyme L	4.5	50	multienzyme complex of carbohydrases: arabanase, cellulase, β-glucanase, hemicellulase, and xylanase	Sigma-Aldrich/*Aspergillus* sp.

[a]Information based on Wang et al.[13] and Heo et al.;[25] pH values of *S. muticum*, *O. pinnatifida*, and *C. tomentosum* water solutions before extraction were 5.6, 4.3, and 6.6, respectively.

assisted extraction (UAE), an alternative energy input-assisted extraction method, is based on sound wave migration, which generates cavitations that grow and collapse, leading to disruption of cells and their walls.[13] UAE and EAE have been reported as alternative approaches with great potential to extract bioactive substances from marine algae.[14]

Considering the limitations of water-based extraction (low selectivity and low extraction yields), yet wishing to target efficient food compatible methods, the main objective of this study was to obtain extracts rich in bioactive compounds using alternative water-based approaches such as EAE and UAE on representative red, brown, and green species of the Central West Portuguese coast, some of which are less studied such as *Osmundea pinnatifida* and *Codium tomentosum*. Hence, this study was based on three steps: (i) performance of different extraction modes and evaluation of respective yield, (ii) chemical characterization of each extract obtained from each of the three different seaweeds, and (iii) evaluation of the biological potential of the extracts in terms of antioxidant, antidiabetic, and prebiotic activities.

Seaweeds such as *Sargassum* species (Phaeophyceae, brown algae) have been found to be good sources of dietary fiber and of phenolic compounds and carotenoids with antioxidant activity, all of which play important roles in the prevention of intestinal and neurodegenerative diseases, respectively.[15−17] Several other compounds able to scavenge and/or neutralize oxidative compounds (antioxidant activity) have been isolated from other seaweeds including phenolic compounds, sulfated polysaccharides, or proteins.[18,19] Prebiotics are defined as nondigestible compounds mainly of carbohydrate nature that selectively enhance the activity and viability of beneficial bacteria in the intestine by providing these with fermentable substrates that lead to the production of short-chain fatty acids.[20] They have been associated with several health benefits in the large intestine such as modulation of beneficial gut bacteria, hypocholesterolemic effect, reduction of cancer and obesity risks, or increase of the bioavailability and uptake of some minerals (Ca and Mg).[20] Inhibitory compounds of α-glucosidase or α-amylase with antidiabetic activity are of much interest because by acting as competitive inhibitors of the enzymes they inhibit the hydrolysis of oligo-, tri-, and disaccharides to glucose and other monosaccharides in the small intestine and thereby delay postprandial glucose absorption, lowering blood glucose.[21] Inhibition of the carbohydrate-hydrolyzing enzymes has been reported for different extracts of red and green seaweeds.[22]

To our knowledge this is the first study applying water-based extraction through combined EAE and UAE technologies in *Sargassum muticum*, *O. pinnatifida*, and *C. tomentosum* seaweeds, and there are no papers regarding the prebiotic and antidiabetic potential of water-based enzyme-assisted extracts for these studied species.

MATERIALS AND METHODS

Chemicals. Ethyl acetate, hydrogen peroxide, boric acid, barium chloride dihydrate, sodium salicylate, sodium carbonate decahydrate, L-(+)-ascorbic acid, potassium peroxodisulfate ($K_2S_2O_8$), Folin−Ciocalteu, and MRS broth were purchased from Scharlau (Sentmenat, Spain). Ethanol, Kjeldahl catalyst, trichloroacetic acid, sodium dihydrogen phosphate 1-hydrate, and ethylenediaminetetraacetic acid disodium salt (EDTA) were purchased from Panreac (Barcelona, Spain). Phenol, 2,2-diphenyl-1-picrylhydrazyl (DPPH), α-glucosidase, Alcalase, Flavourzyme, Cellulase, Viscozyme L, 4-nitrophenyl-α-D-glucopyranoside, acarbose, and catechol were purchased from Sigma-Aldrich (St. Louis, MO, USA), and ferrous sulfate heptahydrate was purchased from Sigma-Aldrich (Sintra, Portugal). Sulfuric acid was purchased from Fisher Chemical (Leicestershire, UK), and hydrogen chloride and sodium sulfate were obtained from Pronalab (Lisbon, Portugal). 2,2′-Azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) was purchased from Fluka (Germany), and L-cysteine hydrochloride monohydrate and MRS agar were obtained from Merck (Gernsheim, Germany). D-(+)-Glucose monohydrate and disodium hydrogen phosphate-7-hydrate were purchased from Riedel-de Häen (Germany) and riboflavin and L-methionine from Acrōs Organics (Geel, Belgium); nitroblue tetrazolium (NBT) was purchased from Fisher Scientific (Erembodegem-Aalst, Belgium).

Specimens of Seaweeds. Specimens of the red alga (Rhodophyta, Florideophyceae) *O. pinnatifida* (Ceramiales) Rhodomelaceae family, the brown alga (Heterokontophyta, Phaeophyceae) *S. muticum* (Fucales) Sargassaceae family, and the green alga (Chlorophyta, Ulvophyceae) *C. tomentosum* (Bryopsidales) Codiaceae family were harvested in April 2012 from Buarcos bay (Figueira da Foz, Portugal). The classification of seaweeds was based on *AlgaeBase*.[23] The seaweeds were first washed with running tap water and then with deionized water and then dried in an oven at 60 °C. The dried samples of seaweeds were milled to <1.0 mm particle size.

Ultrasound- and Enzyme-Assisted Extractions. In this study UAE and EAE as well as hot water extraction (HWE) were performed on the three different seaweeds (*S. muticum*, *O. pinnatifida*, and *C. tomentosum*). Two carbohydrate-degrading enzymes (Viscozyme L, Cellulase) and two proteases (Alcalase, Flavourzyme) were tested for EAE. All extraction procedures were conducted in triplicate.

For HWE, 2 g of dried seaweed was dispersed in 50 mL of deionized water and incubated in an agitated water bath at 50 °C for 24 h in darkness. The aqueous solution (4% dw) was then centrifuged at 5000*g* for 10 min at 4 °C (centrifuge Medifriger BL-S, JP Selecta, Spain), and the supernatant was filtered with a glass filter funnel (porosity 1) and the extract frozen at −80 °C until lyophilization.

UAE and EAE were performed according to the methods of Huang et al.[24] and Wang et al.,[9] respectively, with modifications. The UAE extracts were prepared on the basis of the HWE procedure except that after 24 h at 50 °C, an ultrasound extraction was carried out in a water bath ultrasonicator (Ultrasonik 57H Ney, 400 W, 50/60 Hz) for 60 min (sonicate for 10 min and pause for 2 min) at 50 °C. The resultant

DOI: 10.1021/jf504220e
J. Agric. Food Chem. 2015, 63, 3177−3188

aqueous solution was then centrifuged, filtered, and frozen according to HWE procedures.

For the EAE extracts, the same amount of seaweed (2 g) was dispersed in 50 mL and incubated in an agitated water bath for 10 min. After adjustment of the pH to specific enzyme optimum conditions (Table 1), 100 mg of enzyme was added and incubated for enzymatic hydrolysis for 24 h at 50 °C. The enzymatic reaction was stopped by heating the sample at 90−100 °C for 10 min followed by immediate cooling in an ice bath. The enzymatic aqueous solutions were then centrifuged, filtered, and frozen according to HWE procedures.

The pH of all extracts was adjusted to pH 7.0 with 1 M HCl and/or NaOH before freezing. The frozen extracts were lyophilized, weighed, and stored in desiccators in the dark at room temperature. The extraction yield was calculated as weight percentage of lyophilized extract to the dried seaweed submitted to extraction.

Proximate Characterization of Extracts. The total nitrogen content in the extracts was determined according to the Kjeldahl method adapted from US ISO 5983-1. Total sugars content was determined by the phenol−H_2SO_4 method[25] with modifications using glucose (0−200 μg/mL) as a standard. The content of sulfate groups was determined by turbidity through the barium chloride−gelatin method.[26]

Total phenolic content was determined by the colorimetric method of Folin−Ciocalteu,[27] using catechol (0−75 mg/L) as standard and expressed as micrograms of catechol equivalent per gram of lyophilized seaweed extract. Extraction was carried out with 0.1 g of lyophilized seaweed extract in 10 mL of ethyl acetate after 30 min of sonication. The extract was filtered with anhydrous sodium sulfate and brought to dryness with a rotary evaporator (Laborato 4000, Heidolph). The residue was redissolved in 5 mL of Milli-Q water and the content of total polyphenols of 2 mL was determined by colorimetry at 720 nm.

Determination of Antioxidant Activity of Extracts. Total Antioxidant Capacity. The total antioxidant capacity of extracts' solutions was measured according to method described by Gião et al.[28] This method is able to quantify both water- and lipid-soluble antioxidants, as pure compounds or in crude extracts via direct production of the $ABTS^{\bullet+}$ chromophore (blue/green) by reaction of ABTS and potassium persulfate. To 2 mL of diluted $ABTS^{\bullet+}$ solution was added 120 μL of extract solution (2 mg lyophilized solids/mL), and the absorbance at 734 nm was measured (A_{sample}). Three replicates were performed. Using ascorbic acid as standard (0−100 μg/mL), the results were expressed as equivalent concentration of ascorbic acid ($\mu g_{ascorbic\ acid\ equiv}$/mL). The percentage of scavenging activity was also determined using the following formula:

$$\text{scavenging}\,\% = \left(\frac{A_{ABTS^{\bullet+}} - A_{sample}}{A_{ABTS^{\bullet+}}}\right) \times 100$$

For each sample the initial absorbance of 2 mL of diluted $ABTS^{\bullet+}$ was measured ($A_{ABTS^{\bullet+}}$).

DPPH Free Radical Scavenging Activity. The DPPH free radical scavenging activity was measured according to the method described by Suresh et al.[29] An aliquot (0.1 mL) of each extract (2 mg of lyophilized solids/mL) was added to 3.0 mL of a 0.1 mM ethanolic DPPH solution, and the absorbance was measured at 517 nm after incubation for 30 min at 30 °C in the dark (A_{sample}). Three replicates were performed. Using catechol as standard (0−50 μg/mL), the results were expressed as equivalent concentration of catechol ($\mu g_{catechol\ acid\ equiv}$/mL), whereas the percentage of scavenging activity was also calculated using the following formula:

$$\text{scavenging}\,\% = \left(1 - \frac{A_{sample} - A_{blank}}{A_{control}}\right) \times 100$$

For each sample, the absorbance of 3 mL of DPPH plus 0.1 mL of ethanol was measured as control ($A_{control}$), whereas the absorbance of 3 mL of ethanol plus 0.1 mL of extract was measured as the blank (A_{blank}).

Hydroxyl Radical Scavenging Activity. Hydroxyl radical ($OH^{\bullet}$) scavenging activity was measured according to the method described by Sudha et al.[30] based on that of Smirnoff and Cumbes.[31] An aliquot (1 mL) of each extract (2 mg of lyophilized solids/mL) was added to 2 mL of reaction mixture containing 1 mL of 1.5 mM $FeSO_4$, 0.7 mL of 6 mM hydrogen peroxide, and 0.3 mL of 20 mM sodium salicylate. After incubation for 1 h at 37 °C, the absorbance of the hydroxylated salicylate complex was measured at 562 nm (A_{sample}). Three replicates were performed. Using ascorbic acid as standard (0−100 μg/mL), results were expressed as equivalent concentration of ascorbic acid equivalent ($\mu g_{ascorbic\ acid\ equiv}$/mL) whereas the percentage of scavenging activity of hydroxyl radical was also calculated using the following formula:

$$\text{scavenging}\,\% = \left(1 - \frac{A_{sample} - A_{blank}}{A_{control}}\right) \times 100$$

For each sample, the absorbance of 2 mL of reaction mixture plus 1 mL of deionized water was measured as the control ($A_{control}$), whereas 2 mL of reaction mixture, with sodium salicylate substituted by water plus 1 mL of extract, was measured as blank ($A_{control}$).

Superoxide Radical Scavenging Activity. Superoxide anion radical ($O_2^{\bullet-}$) scavenging activity was based on the capacity of the extract to inhibit the photochemical reduction of NBT in the riboflavin−light−NBT system according to the method described by Fiorentino et al.[32] An aliquot (0.1 mL) of each extract (0.2 mg lyophilized solids/mL) was added to 3 mL of reaction mixture containing 50 mM sodium phosphate buffer (pH 7.8), 13 mM methionine, 2 μM riboflavin, 100 μM EDTA, and 75 μM NBT. After 20 min of illumination (fluorescent lamp), the absorbance was measured at 560 nm (A_{sample}). Three replicates were performed. Using gallic acid as standard (0−15 μg/mL), results were expressed as equivalent concentration of gallic acid equivalent ($\mu g_{gallic\ acid\ equiv}$/mL), whereas the percentage of scavenging activity of hydroxyl radical was also calculated using the following formula:

$$\text{scavenging}\,\% = \left(1 - \frac{A_{sample} - A_{blank}}{A_{control}}\right) \times 100$$

For each sample, the absorbance of 3 mL of reaction mixture plus 0.1 mL of deionized water was measured as control ($A_{control}$), whereas the absorbance of 3 mL of reaction mixture plus 0.1 mL of extract without light incidence throughout the 20 min was measured as the blank (A_{blank}).

Determination of Prebiotic Potential of Seaweed Extracts. The evaluation of potential prebiotic activity of seaweed extracts was performed by enumeration of viable cells of two probiotic strains, namely, *Lactobacillus acidophilus* La-5 and *Bifidobacterium animalis* BB-12, in MRS broth without conventional carbon source and supplemented with seaweed extracts (6%) throughout 48 h at 37 °C. The probiotic cultures of *B. animalis* BB-12 and *L. acidophilus* La-5 were obtained as freeze-dried cultures from CHR-Hansen (Denmark). Growth of both probiotic bacteria were also evaluated in MRS broth with glucose (6%), with fructooligosaccharides (FOS) (6%) as well as without glucose. All media were sterilized at 110 °C for 10 min and, after cooling, were added with filter-sterilized 0.5 g/L L-cysteine-HCl and were inoculated with a 24 h probiotic culture (2%). Two replicates of inoculated media were incubated at 37 °C under agitation and sampled at 0, 4, 8, 12, 24, and 48 h. At each sampling time, decimal dilutions using sterile 0.1% (w/v) peptone water were plated with 20 μL aliquots, in duplicate, on MRS agar containing 0.5 g/L L-cysteine-HCl. The viable cells were enumerated according to the Miles and Mishra method[33] after incubation at 37 °C for 48 h under aerobic conditions for La-5 and under anaerobic conditions for BB-12 with GENbox.

Determination of α-Glucosidase Inhibitory Activity. The α-glucosidase inhibitory activity was determined in 96-well plates according to the method described by Kwon et al.[34] The extracts (50 μL), at the concentration of 10 mg lyophilized solids/mL, were mixed with 100 μL of 0.1 M phosphate buffer (pH 6.9) containing α-glucosidase solution (1.0 U/mL) and pre-incubated at 25 °C for 10 min. Then, 50 μL of 5 mM *p*-nitrophenyl-α-D-glucopyranoside

DOI: 10.1021/jf504220e
J. Agric. Food Chem. 2015, 63, 3177−3188

solution in 0.1 M phosphate buffer (pH 6.9) was added to each well at 5 s intervals. The reaction mixtures were incubated at 25 °C for 5 min, and the absorbance readings were recorded at 405 nm by a multiscan microplate fluorometer (FLUOstar optima, BMG Labtech, Offeuburg, Germany) and compared to a control, which had 50 μL of buffer solution in place of the extract. Acarbose (Sigma) was used as positive control at the concentration of 10 mg/mL. The α-glucosidase inhibitory activity was expressed as inhibition (%) and was calculated as

$$\%\ \text{inhibition} = \left(\frac{\Delta\text{Abs}_{\text{control}} - \Delta\text{Abs}_{\text{sample}}}{\Delta\text{Abs}_{\text{control}}}\right) \times 100$$

where $\Delta\text{Abs}_{\text{control}}$ is the variation of absorbance of the control and $\Delta\text{Abs}_{\text{sample}}$ is the variation of absorbance of the samples.

Statistical Analysis. Data are expressed as the mean plus standard deviation of replicates. Two-way analysis of variance (ANOVA) was performed for each parameter analyzed, except for prebiotic activity, with SigmaStat (Systat Software, Chicago, IL, USA) to assess if seaweed species and extraction method were a significant source of variation, at a significance level of $p = 0.05$. Subsequently, and because significant differences and significant interactions were recorded, one-way (ANOVA) was carried out for each seaweed species to assess whether each extraction method was a significant source of variation for the parameters analyzed, at a significance level of $p = 0.05$. The Holm−Sidak method was used for pairwise comparisons at a significance level of $p = 0.05$.

In terms of prebiotic activity, for each probiotic bacterium, a three-way analysis of variance (ANOVA) was carried out with SigmaStat (Systat Software) to assess whether the seaweed species, extract, and incubation time at 37 °C were significant sources of variation at a significance level of $p = 0.05$. Because significant differences were observed for each factor (seaweed species, extract, and incubation time) as well as significant interactions, one-way ANOVAs were carried out for each seaweed species to observe if the carbon source (glucose, FOS, or extract) was statistically significant for the number of viable cells of *L. acidophilus* La-5 or *B. animalis* BB12, after 24 or 48 h of incubation, respectively. One-way ANOVAS were also performed to evaluate statistical significance of the viable cells after 24 and 48 h, in comparison to values at 0 h.

RESULTS AND DISCUSSION

Extraction Yield. The extraction yields achieved for each of the different aqueous extractions of the three seaweeds are displayed in Figure 1. Both seaweed species and extraction method were shown to have a significant effect on extraction yield ($p < 0.05$). In general, in terms of species, higher extraction yields were observed for *C. tomentosum* (green algae), followed by *O. pinnatifida* (red algae) and *S. muticum* (brown algae) extracts. Interestingly, an inverse correlation between the organic matter of the seaweed and the respective extraction yields was observed; 67, 58, and 55% of organic matter were reported for *S. muticum*, *O. pinnatifida*, and *C. tomentosum*, respectively.[35] According to Wijesinghe and Jeon,[11] the amount, diversity, and complexity of polysaccharides in the seaweeds' cell wall could reduce the extraction efficiency especially with classical extraction methods. In terms of extraction method, EAE extracts were shown to be the most effective. The extraction efficiency of compounds from seaweeds is limited due to the presence of complex cell walls and, therefore, the degradation of their structure is a fundamental step for the release of compounds from seaweeds. Hydrolytic enzymes have been reported to improve the extraction yield in seaweeds,[9] an effect that was corroborated with the results reported herein for all three seaweed types studied.

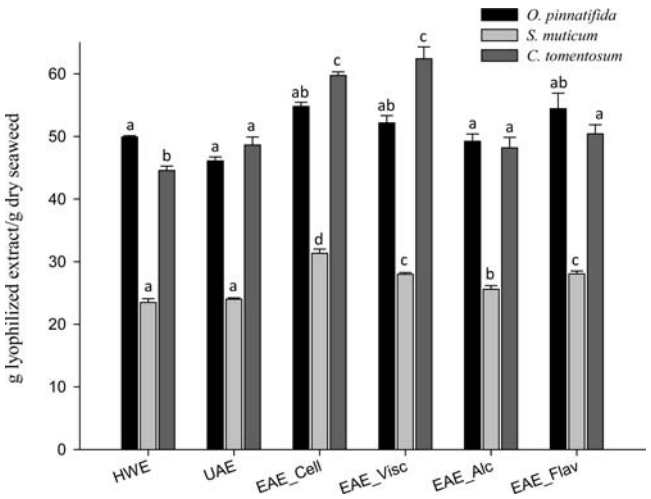

Figure 1. Extraction yields of *O. pinnatifida*, *S. muticum*, and *C. tomentosum* extracts obtained by hot water extraction (HWE), ultrasound-assisted extraction (UAE), and enzyme-assisted extraction (EAE) with Cellulase (Cell), Viscozyme L (Visc), Alcalase (Alc), and Flavourzyme (Flav) at 50 °C. Different letters indicate significant differences ($p < 0.05$) between extracts for each seaweed.

In general, higher extraction yields were observed when assisted by both types of enzymes (carbohydrases and proteases) than in hot water-based extracts or ultrasound-assisted extracts, especially in the case of *S. muticum* and *C. tomentosum*. Higher yields were also reported by Hardouin et al.[12] for *S. muticum* extracts obtained with proteases and carbohydrases than with hot water. To our best of knowledge, there are no studies involving EAE of functional ingredients from *O. pinnatifida* or *C. tomentosum*, which hinders any further comparison besides that achieved within this study. Cellulase and Viscozyme L were responsible for the statistically significant highest extraction yields (60−62%) in *C. tomentosum* (Figure 1, $p < 0.05$), whereas no statistical differences were found in extraction by both proteases (Alcalase and Flavourzyme) or by ultrasound procedures (49−50%, $p > 0.05$) in comparison to HWE. Apparently, cellulase and the multicarbohydrase complex actions of Viscozyme on *C. tomentosum* cell wall polysaccharides were responsible for higher solid content in lyophilized extracts. Extraction yields with Cellulase and Viscozyme L were of similar magnitude to those observed by Wang et al.[9] with red algae *Palmaria palmata*, which were around 60%. Complex polysaccharides such as alginates, agar, carrageenans, and α- and β-D-mannans are practically nondigested by human gastrointestinal enzymes, whereas microorganism-derived enzymes such as some types of carbohydrases are able to degrade complex polysaccharides, converting water-insoluble seaweeds into water-soluble materials collected in water-based extracts.[7]

Similar tendencies such as those for *C. tomentosum* but with lower extraction yield values were observed for *S. muticum* (Figure 1). Cellulase was responsible for the statistically significant highest extraction yield of 31.3% ($p < 0.05$). This value is in the range of extract yield (30−40%) reported by Plaza et al.[36] with subcritical water extraction (SWE) at 100 and 200 °C and by Hardouin et al.[12] with EAE (cellulase) for *S. muticum*, respectively. Although SWE is known for its speed, high yields, and the use of reduced amount of solvents, EAE with Cellulase may also provide several advantages given the enzyme versatility and robustness; furthermore, similar

[a]For each seaweed, different letters indicate significant differences ($p < 0.05$) between methods of extraction.

extraction efficiency of targeted compounds and bioactivity properties is achieved using conventional equipment.

No statistically significant differences ($p > 0.05$) were found between *S. muticum* extracts obtained from Viscozyme (28.0%) and Flavourzyme (28.1%) and between extracts obtained from UAE (24.0%) and HWE (22.5%) methods. Alcalase action resulted in the lowest extraction yield (25.6%) within the EAE methods applied.

In *O. pinnatifida*, Cellulase and Flavourzyme were responsible for the statistically significant highest extraction yields (54−55%, $p < 0.05$), whereas no statistically significant differences ($p > 0.05$) were found between extracts obtained from Alcalase (49.2%), UAE (49.1%), and HWE (49.9%) treatments. The hydrolytic action of the endoprotease and exopeptidase in the Flavourzyme enzymatic complex from *Aspergillus oryzae* (Table 1) on peptide bonds of *O. pinnatifida* proteins could be responsible, at least in part, for the higher extraction yield given its highest protein content (23.8%) in comparison to *S. muticum* and *C. tomentosum* (16.9−18.8%, respectively).[35] According to Cian et al.,[37] proteolysis promoted by Flavourzyme in *Porphyra columbina* (red seaweed) residual cake enhanced extraction of peptides.

UAE is considered an emerging potential technology being considered an efficient alternative to traditional extraction techniques that has been successfully used in the plant extraction field.[38] However, in the present study UAE was not responsible for higher extraction efficiency than HWE for *O. pinnatifida* and *S. muticum*, yet in the case of *C. tomentosum* it enabled a slightly higher, and statistically significant, value (48.6%) than HWE (44.6%). Because UAE was applied to water extracts after 24 h at 50 °C, an improved yield extract was expected, resulting from ultrasound waves due to the implosion of cavitation bubbles. In addition, it has been reported that UAE should be carefully used because unstable compounds such as carotenoids could be degraded.[39] Lee et al.[40] evaluated the potential use of UAE in water and methanolic extracts of *Ecklonia cava* (brown alga) and reported slightly higher extraction yield values after 6 and 12 h at 30 °C in an ultrasonic bath with 200 W (31.3−34.3%) than after 24 h in a shaking incubator at room temperature (28.7%).

Proximate Characterization of the Extracts. In general, and as expected, enzymatic extracts resulting from proteases action presented higher nitrogen content (Table 2); Alcalase and Flavourzyme were responsible for higher content in *S. muticum* (25−30 $mg/g_{lyoph\ extract}$; $p < 0.05$), *O. pinnatifida* (15−19 $mg/g_{lyoph\ extract}$; $p < 0.05$), and *C. tomentosum* (22−24 $mg/g_{lyoph\ extract}$; $p < 0.05$). Indeed, proteases appeared as the most effective enzyme for protein recovery and accessibility.

In terms of sugars, EAE extracts obtained from carbohydrase action presented higher content of sugars; Cellulase was responsible for higher content in *S. muticum* (87 $mg_{glucose\ equiv}/g_{lyoph\ extract}$; $p < 0.05$) and in *O. pinnatifida* (102 $mg_{glucose\ equiv}/g_{lyoph\ extract}$; $p < 0.05$), whereas higher values were obtained by Viscozyme action in *C. tomentosum* (157 $mg_{glucose\ equiv}/g_{lyoph\ extract}$; $p < 0.05$).

The different yields of nitrogen and sugar contents in the extracts for the three species (Table 2) did not correlate with the seaweeds proximate composition in terms of total protein and total sugars content. For both parameters, an inverse correlation between their content in the enzymatic extracts and the seaweed composition was observed: a statistically significant higher value of protein content was observed for *O. pinnatifida* (23.8 $g/100\ g_{dry\ seaweed}$) and the lowest for *S. muticum* (16.9 $g/100\ g_{dry\ seaweed}$); in terms of total sugars *S. muticum* was characterized by a higher content in sugar (49.3 $g/100\ g_{dry\ seaweed}$) than *O. pinnatifida* and *C. tomentosum*, with similar contents of 32−33 $g/100\ g_{dry\ seaweed}$.[35]

No statistically differences were observed for both nitrogen and sugar contents in the extracts obtained with HWE and UAE for the three seaweeds except for *O. pinnatifida*, for which the nitrogen content was higher in the HWE extract than in the UAE counterpart ($p < 0.05$). These results may indicate that

J. Agric. Food Chem. 2015, 63, 3177−3188

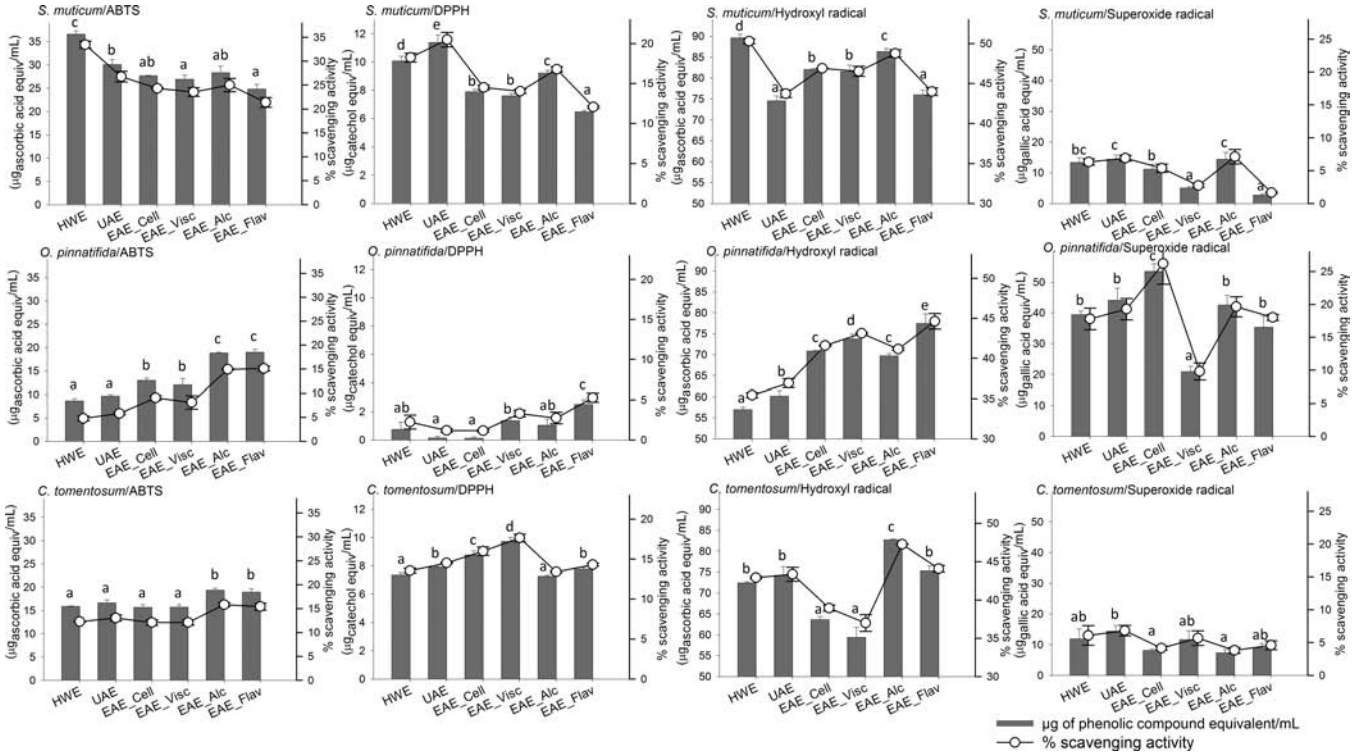

Figure 2. Total antioxidant capacity, DPPH free radical, hydroxyl radical, and superoxide radical scavenging activities of *S. muticum*, *O. pinnatifida*, and *C. tomentosum* extracts obtained by hot water extraction (HWE), ultrasound-assisted extraction (UAE), and enzyme-assisted extraction (EAE) with Cellulase (Cell), Viscozyme L (Visc), Alcalase (Alc), and Flavourzyme (Flav) at 50 °C. Different letters indicate significant differences ($p < 0.05$) between extracts for each seaweed.

the mechanical action resulting from ultrasound waves under the extraction time and temperature conditions used did not promote the release of extra proteins or polysaccharides from the intracellular or wall contents of seaweeds.

Variable content in sulfate groups, which was significantly different for each seaweed species and extraction method ($p < 0.05$), is observable in Table 2. Previous studies with FTIR-ATR analysis showed that in the brown algae *S. muticum*, alginates and fucoidans were the main polysaccharides, whereas *O. pinnatifida* was mostly an agar producer; sulfate esters of sulfated polysaccharides were observed in the spectrum of *C. tomentosum*.[35] Therefore, the sulfated content in each extract was in part related to the nature and amount of sulfated polysaccharide in each seaweed species as well as the extraction efficiency.

High content of sulfate groups was observed in *O. pinnatifida* extracts (39−60 $\mu g_{Na_2SO_4\ acid\ equiv}/g_{lyoph\ extract}$) probably from agar, a less sulfated polysaccharide than carrageenans, also characteristic in some red seaweeds. A significantly higher content was obtained with EAE using Viscozyme. According to Domozych,[10] red algae possess complex composite cell walls, which are made of cellulose, xylan, or mannan fibrils as well as an extensive matrix of polysaccharides such as agar and carrageenan.

For *S. muticum* extracts, enzymatic activity did not result in higher content of sulfate groups except for extraction performed with Flavourzyme, in accordance with data reported by Hardouin et al.[12] for this seaweed. Hot water and UAE extracts were revealed to be more suitable to obtain extracts richer in the sulfate groups. These probably result from fucoidans. The presence of sulfated ester groups (S═O), a characteristic component in fucoidan and other sulfate polysaccharides, was assigned by FTIR-ATR for *S. muticum*.[35] According to Ale and Meyer,[41] fucoidans cover several different structural fucose-containing sulfated polysaccharides, comprising many different types of fucose-rich polysaccharides, including sulfated fucogalacturonans found in *Sargassum* sp., for example. The lower content of sulfated groups in *S. muticum* in comparison to *O. pinnatifida* could be related to the presence of alginates (a nonsulfated polysaccharide), also evidenced by FTIR-ATR analysis. *S. muticum*, an original species from Japan now found in the Atlantic Ocean and in the Mediterranean Sea, has been reported to possess, when dry, 10−18% alginates.[42] A slightly higher content in sulfated groups, in comparison to *S. muticum*, was observed in *C. tomentosum* extracts. These could be related to the presence of sulfated xyloarabinogalactans such as sulfated arabinan and sulfated arabinogalactan, which have been identified in *C. tomentosum*[43] or other sulfated polysaccharides.[35] Extracts that resulted from EAE with Cellulase and Viscozyme, as well as from HWE and UAE, were those with higher content in sulfated groups.

Total phenolic content varied significantly according to extraction mode and seaweed type ($p < 0.05$). Higher values for total phenolic content were found for *S. muticum* extracts, which ranged between 201 and 301 $\mu g_{catechol\ equivalent}/g_{lyoph\ extract}$ (Table 2). Once again, no direct correlation was observed between total phenolic content in each seaweed and those in the respective aqueous extracts. Significant differences in total phenolic content were observed between the three seaweed species, namely, 460, 250, and 169 $\mu g_{catechol\ equivalent}/g_{dry\ seaweed}$ for *C. tomentosum*, *S. muticum*, and *O. pinnatifida*, respectively.[35] This observation might suggest that none of the extraction modes were sufficiently efficient to extract all phenolics in *C. tomentosum* and *O. pinnatifida*. It has been

DOI: 10.1021/jf504220e
J. Agric. Food Chem. 2015, 63, 3177−3188

reported that organic solvents such as ethanol are more efficient for polyphenol extraction than water.[19]

Variable efficiency of phenolic compound extraction was observed by the different extraction modes for each seaweed species. For *S. muticum* statistically higher values were obtained by HWE and by Viscozyme and Alcalase EAE (Table 2). For *C. tomentosum*, UAE and Flavourzyme EAE were responsible for higher efficiency, whereas for *O. pinnatifida* no statistical difference were observed for the different extracts. No information on effects of water-based extraction mode on phenolic compounds was found in the literature. For example, higher content in total phenols values was reported by Plaza et al.[36] in *S. muticum* extracts obtained by SWE water extracts at 100 and 200 °C ranging between 10.7 and 58.67 $mg_{gallic\ acid}/g_{extract}$, respectively, but no explanation is given for the increment in total phenols except that with a higher extraction temperature a higher mass transfer occurs, which increases extraction yield. Water and ethanolic extracts of 16 species collected at the Danish coast were screened for extraction yield and respective total phenolic content by Farvin and Jacobsen.[19] For all species, water extracts showed higher yield, but in terms of phenolic content this was dependent on the species. In general, the ethanolic extracts had higher content of total phenolics except for four species including *S. muticum*.[19] No explanation is yet available for the higher extractability of phenolic compounds by water in some species such as in *S. muticum*. In turn, for *O. pinnatifida*, methanolic extraction rendered a higher extraction yield and higher polyphenol content than by aqueous extraction.[44] According to Budhiyanti et al.[45] phenolic content varied from 0.006 to 0.65 and from 6.72 to 21.99 $g_{phloroglucinol\ equiv}/100\ g_{dried\ extract}$ for cytoplasmic and membrane-bound extracts from *Sargassum* sp., respectively. These data show that the phenolic contents are extremely variable among species of *Sargassum* and cell structure.

Antioxidant Activity. Figure 2 presents data for total antioxidant capacity and for DPPH free radical as well as hydroxyl and superoxide radical scavenging activities of the different extracts for each seaweed, evaluated both as micrograms of phenolic compound equivalent and as percent of scavenging activity. Because the diverse expression of results for the different antioxidant capacity evaluation methodologies found in the literature makes comparison between studies difficult,[46] the authors think that the perception of the relative proportion between phenolic content (μg/mL) of extract and the corresponding value in terms of percentage of scavenging activity makes the interpretation more objective and more valuable (Figure 2). The four different antioxidant evaluations varied significantly among seaweed species and among extraction modes ($p < 0.05$). Maximum total antioxidant capacities as well as DPPH free radical and hydroxyl radical scavenging activities were observed in the extracts of *S. muticum* followed by *C. tomentosum* (Figure 2). In *O. pinnatifida* extracts, lower total antioxidant capacity and DPPH free radical scavenging activity were observed in comparison to any of the two other seaweeds, but higher scavenging capacity for reactive oxygen species such as $HO^{\bullet}$ and in particular of radical $O_2^{\bullet -}$ were achieved. Heo et al.[18] also reported variable scavenging activities in brown seaweed extracts obtained by carbohydrases or proteases in terms of DPPH free, hydroxyl, and superoxide radicals. According to Freitas et al.[46] no single assay seems to be able to accurately reflect the mechanism of action of all radicals and antioxidants, especially in complex systems. For example, some antioxidants may not be efficient quenchers of peroxyl radicals but be only singlet-oxygen scavengers.[47]

The statistically significant difference between the seaweed extracts ($p < 0.05$) could be, at least in part, attributed to the higher amount of total phenolic compounds and proteinaceous compounds found in *S. muticum* (Table 2). The radical scavenging activity of phenolic compounds is, however, dependent on the phenolic structure and number and location of hydroxyl groups,[48] and therefore the radical scavenging potential of the extracts is dependent on qualitative and quantitative phenolic combination. Our results are in accordance with those published by Yangthong et al.,[49] who reported higher phenolic content and antioxidant activity for brown seaweeds than for red and green seaweeds. Polysaccharides in brown algae such as those with high content of uronic acid and alginates with low molecular weight have also been reported as good antioxidant potential.[50]

The antioxidant potential of *S. muticum* water extracts was higher in HWE especially in terms of total antioxidant capacity ($p < 0.05$) with 33.5% scavenging activity (corresponding to 37 $\mu g_{ascorbic\ acid\ equiv}$/mL) and hydroxyl radical scavenging activity ($p < 0.05$) with 50.3% scavenging activity (corresponding to 90 $\mu g_{ascorbic\ acid\ equiv}$/mL), respectively. Maximum DPPH free radical scavenging activity was observed for UAE with 20% scavenging activity (corresponding to 11 $\mu g_{catechol\ equiv}$/mL). In terms of antioxidant activity no increase was observed in the *S. muticum* extracts obtained from EAE. Higher values of free and hydroxyl scavenging activity were reported by Je et al.[16] in EAE extracts with Alcalase and Viscozyme from brown seaweed *Undaria pinnatifida*, but no hydroxyl scavenging activity from EAE extracts with Flavourzyme was reported. Hydroxyl scavenging activity of *S. muticum* extracts produced with Flavourzyme was 42%, one of the lowest values together with those obtained for UAE extracts (Figure 2). In *O. pinnatifida*, EAE extracts had, in general, higher scavenging potential than HWE or UAE. In terms of total antioxidant capacity, protease-assisted extracts with 19% scavenging activity (corresponding to 15−16 $\mu g_{ascorbic\ acid\ equiv}$/mL) presented statistically significant higher values ($p < 0.05$) than the other extraction methods. According to Cian et al.,[37] the low molecular weight peptides and polyphenols released during proteolysis were responsible for the DPPH radical scavenging activity of red seaweed *Porphyra columbina*. No radical scavenging activity toward ABTS was reported by Jiménez-Escrig et al.[44] for aqueous extracts of *O. pinnatifida*. For the hydroxyl radical, EAE extracts were capable of 42−45% scavenging activity (corresponding to 70−79 $\mu g_{ascorbic\ acid\ equiv}$/mL) (Figure 2). *O. pinnatifida* EAE extracts from Cellulase had a statistically significant ($p < 0.05$) higher superoxide scavenger potential with 28% scavenging activity (corresponding to 54 $\mu g_{gallic\ acid\ equiv}$/mL) than the other extracts.

The extraction procedures did not affect the total antioxidant capacity displayed by *C. tomentosum* extracts except for those obtained by protease EAE, where results were higher and statistically different (Figure 2). In terms of superoxide radical scavenging activity only slight differences were observed between the different *C. tomentosum* extracts. However, Cellulase and Viscozyme extracts of *C. tomentosum*, which had higher sugar content, had statistically significant ($p < 0.05$) higher DPPH free radical scavenger activity with 16−18% (corresponding to 9−10 $\mu g_{catechol\ acid\ equiv}$/mL). Valentão et al.[51] also reported a weak concentration-dependent antioxidant capacity for *C. tomentosum* aqueous lyophilized extracts (10% of

DPPH free radical scavenging activity with 794 μg/mL extract). In terms of the hydroxyl radical, Alcalase and Flavourzyme extracts were able to inhibit >44% of scavenging activity corresponding to 76−83 $g_{\text{ascorbic acid equiv}}$/mL, which may indicate that such bioactivity is related not only to total phenolic content but also to proteinaceous compounds (Table 2). Nevertheless, given the statistically significant difference between Alcalase and Flavourzyme scavenging capacities and their respective phenolic and nitrogen contents shown in Table 2, it seems that not only the content but also the nature of the compounds is important to eventually justify the antioxidant properties. For example, Heo et al.[18] reported that enzymatic extracts of brown algae *Ecklonia cava* with Alcalase did not possess DPPH free radical scavenging activity, although they contained as much phenolic compounds as other extracts with free radical scavenging activity. In turn, Farvin and Jacobsen[19] reported some extracts with good antioxidant effects but with low total phenolic content, indicating that other compounds were coextracted in water extracts such as sulfate polysaccharides, proteins, or peptides. However, not much antioxidant potential was observed in crude sulfated polysaccharides from *Sargassum plagiophyllum* (2 mg/mL) for free radical (11.2%), hydroxyl (11.2%), or superoxide (0%) radical scavenging activities.[29]

In summary, the different extracts, with 2 mg lyophilized extract/mL, from *S. muticum*, *O. pinnatifida*, and *C. tomentosum* did not exhibit high total antioxidant capacity or DPPH free radical scavenging activity but more prominent effects on hydroxyl radical scavenging activity (35−50%). Extracts from *O. pinnatifida* with 0.2 mg lyophilized extract/mL, namely, HWE, UAE, and EAE with Cellulase and Alcalase, exhibited moderate effects on superoxide radical scavenging activity (18−26%).

Prebiotic Potential of Seaweed Extracts. Recently, some research has been done in identifying potential prebiotic compounds in marine resources, namely, in seaweeds, given their rich profile in polysaccharides present in the cell walls;[52] nonetheless, to our best of knowledge, no information is available regarding the prebiotic potential of the three seaweed species targeted in our study. Hence, the potential prebiotic effect of seaweed water-based extracts was evaluated by using pure cultures of representative beneficial bacteria including strains of lactobacilli and bifidobacteria (usual target genera for prebiotics) in parallel with well-established prebiotics, such as FOS, for comparison purposes. Both probiotic strains were also grown under the same conditions but in the absence of sugar (negative control) as well as in the presence of glucose or FOS at similar concentrations (positive controls) (Figures 3−5). Seaweed species, extraction mode, and incubation time were revealed to be significant factors for both probiotic strains viability ($p < 0.05$). Because significant differences were observed for each factor as well as significant interactions, one-way ANOVAs were carried out for each seaweed species to observe if the carbon source (glucose, FOS, or extract) was statistically significant for the viable cell numbers of *L. acidophilus* La-5 or *B. animalis* BB12, after 24 or 48 h of incubation, respectively. With regard to *L. acidophilus* La-5, significantly higher values ($p < 0.05$) of viable cell numbers were observed for the majority of culture media enriched with seaweed water-based extracts after 24 h of incubation in comparison to growth in media with glucose or FOS. In addition, some significant increases ($p < 0.05$) in viable cell numbers in comparison to those at 0 h were observed such as

DOI: 10.1021/jf504220e
J. Agric. Food Chem. 2015, 63, 3177−3188

in media containing HWE and EAE with Viscozyme, Cellulase, and Flavorzyme extracts of *S. muticum*, and EAE with Viscozyme and Alcalase extracts of *O. pinnatifida* as well as EAE with Viscozyme and Cellulase extracts of *C. tomentosum* (Figures 3ii,a–c, 4ii,a–c, and 5ii,a–c). Despite the enhanced growth by 24 h of incubation, after 48 h of incubation lower viable cell numbers were observed, in particular for *O. pinnatifida* extracts (Figure 4ii,b–c); end-product formation or substrate depletion could justify this decrease in viable cell numbers.

In terms of seaweed extracts' impact on *B. animalis* BB-12, it was found that, in general, they have a lower prebiotic potential (Figures 3i,a–c, 4i,a–c, and 5i,a–c). Nonetheless viable cell numbers of *B. animalis* BB-12 in all *S. muticum* and *C. tomentosum* extracts after 48 h of incubation were significantly higher than those obtained with prebiotic FOS and glucose ($p < 0.05$) (Figures 3i,a–c and 5i,a–c).

Although of preliminary nature, these results show that the majority of the extracts obtained from the three seaweeds possess carbon sources that can be metabolized by *L. acidophilus* La-5 and *B. animalis* BB-12. A more promising prebiotic potential was observed for *S. muticum* and *C. tomentosum* extracts, especially for those obtained by enzymatic action. Because a lower potential was observed in extracts of *O. pinnatifida*, this could be related to the largest amount of sulfated sugars observed in these extracts. Red seaweed *O. pinnatifida* has been mostly characterized as an agar producer, and it is known that microorganisms are not able to hydrolyze and metabolize this polysaccharide, which is used as a solidifying agent of culture media. On the other hand, it should not be totally overlooked because it was shown recently that some low molecular weight polysaccharide fractions derived from seaweed agar and alginate by acid hydrolysis or degradation with hydrogen peroxide were fermented by gut microbiota, namely, bifidobacterial populations, exhibiting potential to be used as a novel source of prebiotics.[53]

Enzymatic extracts, especially those obtained with carbohydrases (Viscozyme and Cellulase), probably possess polysaccharides and oligosaccharides derived from hydrocolloids present in each type of seaweed that can act as sources of soluble fibers exerting a prebiotic effect. According to Wu et al.[54] *Bifidobacterium longum* BCRC 11847 could utilize polysaccharide extracts of red seaweed *Gracilaria* sp. extracted with Cellulase R-10 and Macerozyme R-10 and display an increase in pH-lowering ability. Zaporozhets et al.[52] recently reviewed the prebiotic potential of polysaccharides and extracts from seaweeds. In that review the authors included their research group studies' results on the prebiotic potential of fucoidan and alginic acid derived from brown seaweed *Fucus evanescens* in vitro and in vivo with mice. These authors confirmed that fucoidan and alginic acid were used instead of lactose with a 3–5.8-fold increase in biomass of *Bifidobacterium* in comparison to the control.

Given the promising reported results obtained in terms of growth promotion of *L. acidophilus* La-5 and *B. animalis* BB-12 and considering the prebiotic potential of polysaccharides and seaweed extracts reported in the literature concerning other seaweed species, further in vitro (nondigestibility and selective fermentation capacity) and in vivo studies must be performed with the enzymatic extracts assisted by Cellulase of *S. muticum* and *C. tomentosum* as well as in UAE extracts of *C. tomentosum*. The identification of polysaccharide (and associated molecular weight) and oligosaccharide fractions in the extracts derived from the enzymatic action will also be determinant to understand and correlate with the prebiotic activity.

α-Glucosidase Inhibitory Activity. The α-glucosidase inhibitory activity, expressed as percent of inhibition, by *S. muticum*, *O. pinnatifida*, and *C. tomentosum* water-based extracts is displayed in Figure 6. Extraction mode and seaweed species

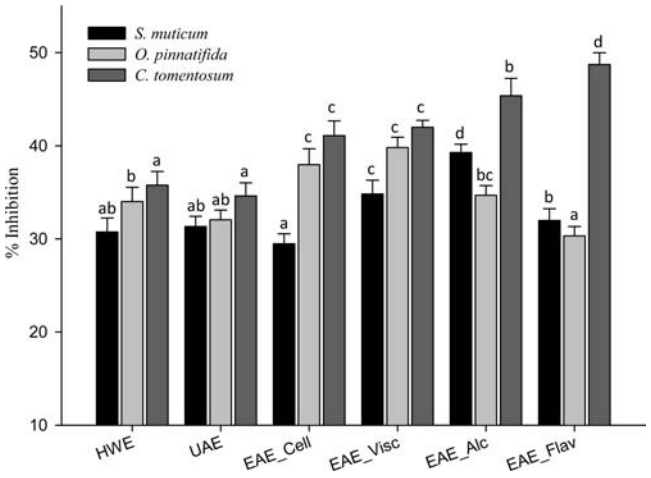

Figure 6. α-Glucosidase inhibitory activity, expressed as percent of inhibition, of *S. muticum*, *O. pinnatifida*, and *C. tomentosum* extracts obtained by hot water extraction (HWE), ultrasound-assisted extraction (UAE), and enzyme-assisted extraction (EAE) with Cellulase (Cell), Viscozyme L (Visc), Alcalase (Alc), and Flavourzyme (Flav) at 50 °C. Different letters indicate significant differences ($p < 0.05$) between extracts for each seaweed.

were both statistically significant factors ($p < 0.05$). Extracts obtained by enzymatic action possess higher inhibition activity especially for *O. pinnatifida*, with 38–40% inhibition in the extracts obtained by Cellullase and Viscozyme, and for *C. tomentosum* with 45–49% inhibition in the extracts obtained by Alcalase and Flavourzyme. To our knowledge there are no reports on potential antidiabetic activity of water-based enzymatic seaweed extracts, in particular for the studied species, and therefore no direct comparisons with other works with only other seaweed species and other extraction modes are possible. For example, Senthil et al.[22] reported that ethyl acetate extracts of red seaweeds of *Chondrococcus harnmanni* and *Padina gymnospora* (81 and 94%, respectively) possesses high levels of α-amylase inhibitory activity. Lower values of α-glucosidase inhibitory activity were observed for *S. muticum* extracts with a maximum of inhibition in the extracts obtained with Alcalase (39%). This is an interesting observation because the *S. muticum* extract showed the highest protein content among all other extracts (Table 2). Other research works have studied the role of seaweed polysaccharides, from other *Sargassum* species, or of phenolic compounds on the inhibition activity of α-amylase and α-glucosidase but less on the role of protein or peptides for the same purpose. For example, Hardoko et al.[55] reported inhibitory activity on α-glucosidase by laminaran and fucoidan fractions from two brown seaweeds (*Sargassum duplicatum* and *Turbinaria decurens*) but not by the alginate fraction. According to Motshakeri et al.,[56] 35–36% blood glucose reduction was observed in type 2 diabetic rats after 22 days of feeding with 300 mg/kg body weight ethanolic or water extracts of *Sargassum polycystum*. In the present study, EAE extracts from *O. pinnatifida* and *C. tomentosum* showed promising inhibitory

DOI: 10.1021/jf504220e
J. Agric. Food Chem. 2015, 63, 3177–3188

potential against α-glucosidase and, although further in vivo studies are required to test for effective hypoglycaemic activity, these may prove to be important strategies in the prevention (functional food) or management (oral therapeutic agent) of blood glucose level in type 2 diabetic and borderline patients.

In conclusion, this study demonstrates once more that edible seaweeds such as *S. muticum* (brown alga), *O. pinnatifida* (red alga), and *C. tomentosum* (green alga) are natural sources of compounds with important biological interest. In the present study, water-based crude extracts were obtained from efficient methods that are also food grade compatible and sustainable. Enzyme-assisted extraction was revealed to be a promising tool to obtain extracts with attractive biological properties. According to the general results achieved, it becomes difficult to pinpoint the most efficient extraction method with the highest biological potential because it depends on several factors: (i) seaweed species; (ii) extraction mode considering the duality extraction yield versus chemical/biological properties; and (iii) the type of analysis made. From this perspective, *S. muticum* EAE presented interesting antioxidant and prebiotic potentials, *O. pinnatifida* enzyme-assisted free radical scavenging activity given its high sulfated sugar content, and *C. tomentosum* EAE a promising α-glucosidase inhibitory activity and consequently attractive antidiabetic potential. In general, it can be pointed out that the enzyme-assisted extraction seems to be one of the best options in terms of food compatible extraction method with higher yield rates, and through the selection of a specific enzyme some biological properties may be favored over other properties. It is our opinion that, for future studies with these seaweeds in terms of functional food development, the selection of the most efficient extraction mode will need to be coupled to the best results in terms of biological properties according to the intended purpose associated with the identification of polysaccharides, peptides, and phenolic compounds.

highly differ in their phenolics profile, 'Amari' and 'Hallawi',[13] in order to obtain fractions of diverse composition. The isolated fractions were analyzed for their composition, ferric-reducing power, free radical scavenging capacity, inhibition of copper ion-induced LDL oxidation, and enhancement of HDL-mediated cholesterol efflux from macrophages. Date fruit phenolics' structure–activity relationships were examined by comparing the nature and magnitude of activities manifested by the two phenolics' subgroups, as well as different compositions within each subgroup.

MATERIALS AND METHODS

Chemicals. Caffeic acid, catechin, catechin gallate, chlorogenic acid, *o*-coumaric acid, *p*-coumaric acid, epicatechin, epicatechin gallate, epigallocatechin, epigallocatechin gallate, ferulic acid, gallic acid, gallocatechin, gallocatechin gallate, hydrocaffeic acid, phenyl acetate, pyrogallol, protocatechuic acid, sinapic acid, syringic acid, vanillic acid, tannic acid, and Folin-Ciocalteau reagent were all purchased from Sigma-Aldrich Co., Israel. Ellagic acid, 2-hydroxybenzoic (salicylic) acid, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid, kaempferol-3-glucoside, procyanidin B2, and quercetin-3-β-glucoside were acquired from Fluka, France. 2.2′-Azobis-2-amidinopropane hydrochloride (AAPH) was from Wako, Japan. Acetonitrile HPLC grade was purchased from Merck, Germany, and phosphoric acid from Frutarum, Israel. [^{3}H]-Labeled cholesterol was acquired from Amersham Biosciences, Inc., USA. Dulbecco's modified Eagle's medium (DMEM) and fetal calf serum (FCS) were purchased from Biological Industries, Beit Haemek, Israel.

Date Fruit. Commercial ready-to-eat tree-ripened semidry fruits ("tamr" stage) of two date varieties, 'Amari' and 'Hallawi', were obtained shortly after harvest from Hadiklaim, Israel Date Growers Cooperative Ltd., and stored at −20 °C until processing.

Date Crude Phenolics Extract Preparation. Pitted 'Amari' or 'Hallawi' fruits were ground with a Kenwood MG600 meat grinder (Kenwood Ariete, Italy) and homogenized in cold 70% acetone solution containing 0.5% acetic acid at a fruit to solvent ratio of 1:3 (w/v) using a mortar and pestle. The homogenate was kept at 4 °C overnight and shaken on ice for an additional 2 h. The procured slurry was centrifuged at 12000*g* for 10 min at 4 °C (Sorvall Instruments RC5C), and the clear supernatant was collected and stored at −20 °C in light-protected vessels.

Date Phenolics Subgroup Fractionation. The crude phenolics extracts were fractionated into phenolic acids and flavonols subgroups by solid-phase extraction (SPE) on a C18 column, following Oszmianski et al.,[24] with some modification. Two extraction columns [Bakerbond spe octadecyl (C18) disposable extraction columns, sorbent weight 1000 mg, column size 6 mL, J.T. Baker] were preconditioned with 5 mL of methanol. One column was equilibrated to neutral pH with 10 mL of double-distilled water (DDW), pH 7.0, and the other, to acidic pH with 10 mL of DDW, pH 2.0. The crude acetone extracts were diluted 20-fold with DDW and adjusted to pH 7.0 with 1 N NaOH. A total of 10 mL of the diluted extract was loaded onto the pH 7.0 column. The effluent containing the ionized phenolic acids and other polar components was saved. The column was then washed with 10 mL of DDW pH 7.0, and the two effluents were combined.

Phenolic Acids' Isolation. The combined effluents were adjusted to pH 2.0 with 1 N HCl and loaded onto the acidified column. The phenolic acids were then eluted with a total of 3 mL methanol; the latter were collected sequentially in aliquots of 0.8, 1.0, and 1.2 mL. The second aliquot of eluent was dried in a miVac Duo concentrator (Genevac Limited, UK) at 45 °C and kept at −20 °C.

Flavonols' Isolation. After the removal of the polar compounds, the pH 7.0 column was adjusted to pH 2.0 by passing 10 mL of DDW at pH 2.0 and washed with 3 mL of 16% acetonitrile at pH 2.0. The flavonols were then eluted with a total of 3 mL methanol; the latter were collected sequentially in aliquots of 0.8, 1.0, and 1.2 mL. The second aliquot of eluent was dried as described before and kept at −20 °C.

Total Phenolics Content. The dried isolated fractions were each dissolved in 1.0 mL of 50% ethanol. The resulting solutions were diluted 5- and 10-fold with DDW and assayed for total phenolics content with Folin-Ciocalteau 2 N phenol reagent, following Singleton and Rossi.[25] Aliquots of 100 μL were added to 900 μL of reaction solution consisting of 200 μL of freshly prepared 10-fold diluted Folin-Ciocalteau reagent, 100 μL of 20% Na_2CO_3, and 600 μL of DDW. Calibration curves were constructed with gallic acid (0–0.8 μmol mL^{-1}). The absorbance at 765 nm was measured after 1 h incubation, and the results are expressed in terms of gallic acid equivalents (GAE). Each measurement was done in triplicate.

RP-HPLC Analysis of Isolated Phenolics Fractions. Phenolics analysis by RP-HPLC was carried out as described earlier.[13] The dissolved isolated fractions were filtered through a 0.45 μm PTFE filter and analyzed with a LaChrom Merck Hitachi HPLC system, consisting of pump L7100, column oven L7350, and mixer-degasser L-7614, coupled with a diode array detector with a 3D feature (multi-wavelength detector, Jasco MD-2010 Plus), interface (Jasco LC-Net II/ADC), and scientific software (EZChrom Elite Client/Server version 3.1.6 build 3.1.6.2433) that provides real-time data acquisition and postrun data manipulation and integration capabilities. Aliquots of 20 μL were injected by a manual injector (Rheodyne, Rohnert Park, CA, USA) and loaded onto a PurospherStar RP-18 end-capped column (250 × 4 mm LichroCART cartridge, 5 μm particle size) with an end-capped Lichrospher100 RP-18 guard column (4 × 4 mm LichroCART cartridge, 5 μm particle size). The binary mobile phase consisted of 0.1% phosphoric acid, pH 2.4 (solution A), and acetonitrile (solution B) and was delivered at a flow rate of 1 mL min^{-1}. Elution was carried out with the following stepwise gradient outline: 1 to 10 min, 5% to 15% solution B; 10 to 30 min, 15% to 30% solution B; 30 to 40 min, 30% to 100% solution B. The column was then washed and equilibrated by 10 min postruns with 100% and 5% B, respectively. The oven temperature was set at 40 °C, and the pressure was 158 atm. Acetonitrile was HPLC grade (LiChrosolv Merck, Germany); column-filtered water was further distilled by a Corning Megapure System, MP-6A, and passed through a 0.20 μm nylon membrane. Phosphoric acid was of analytical grade.

Phenolics classification and tentative identification were performed by the system software on the basis of UV/vis absorbance spectra and the retention times of the chromatograms peaks, and the system phenolics library constructed from authentic standards.

Individual phenolic compounds were quantified from the corresponding chromatogram peak areas calculated by the software in three repetitive runs, and calibration curves constructed with authentic standards of caffeic, coumaric, ferulic, and salicylic acid and kaempferol-3-glucoside. A cutoff area of 100000 mV min was applied to discern between significant and nonsignificant peaks. The concentrations of the various hydroxybenzoic acids, hydroxycinnamic acids, and flavonols were expressed in terms of nmol equivalents of the corresponding standards mL^{-1}.

Ferric-Reducing Antioxidant Power (FRAP). The dissolved isolated fractions were diluted 5- and 10-fold with DDW and assayed for ferric-reducing ability by the colorimetric test originally developed to assess the ferric-reducing antioxidant power of plasma.[26] A 50 μL aliquot was added to 950 μL of reaction solution freshly prepared by mixing 50 mL of 300 mmol L^{-1} acetate buffer, 5 mL of 10 mmol L^{-1} 2,4,6-tripyridyl-*s*-triazine (TPTZ), and 5 mL of 20 mmol L^{-1} ferric chloride. Absorbance at 593 nm was measured after 4 min incubation in a 37 °C water bath. Vitamin C was used for the calibration curve (0–0.6 μmol mL^{-1}), and the results were expressed in terms of vitamin C equivalents (VCE). Each measurement was done in triplicate.

Free Radical Scavenging Capacity. The radical-generating compound 1,1-diphenyl-2-picryl-hydrazyl (DPPH) was employed to assess the capacity of the isolated fractions to scavenge free radicals.[27] Aliquots of 50 μL of the isolated fractions at a concentration of 0.5 mmol L^{-1} GAE in 50% ethanol were mixed with 1 mL of 0.1 mmol L^{-1} DPPH in ethanol, and the optical density (OD) at 517 nm was

'Amari'	phenolic acids	PhA 1	4.27 ± 0.62	0.81 ± 0.02 b	14 ± 1 b
'Hallawi'		PhA 2	0.38 ± 0.09	0.80 ± 0.01 b	22 ± 3 a
'Amari'	flavonols	Fl 1	1.37 ± 0.15	0.88 ± 0.01 a	8 ± 1 c
'Hallawi'		Fl 2	0.43 ± 0.11	0.87 ± 0.03 a	9 ± 2 c

[a]Abbreviations: GAE, gallic acid equivalents; VCE, vitamin C equivalents; $OD_{517\ nm}$, optical density at 517 nm.Values are mean ± SD (n = 3). Values within a column with different letters are significantly different at a 95% confidence interval (Tukey–Kramer *post hoc*).

monitored continuously for 5 min at room temperature. For the control, 50 μL of 50% ethanol was added to the DPPH solution. The free radical scavenging capacity in terms of percentage loss of OD at 517 nm was calculated using the following equation:

$$\text{Free radical scavenging capacity} = \left[1 - \frac{\text{sample OD at 517 nm}}{\text{control OD at 517 nm}}\right] \times 100$$

where the sample and control OD at 517 nm correspond to the measurements after 5 min incubation in the presence and absence of the isolated phenolic fraction, respectively.

LDL and HDL Preparation. Fresh plasma was derived from three healthy normolipidemic volunteers (Rambam Hospital Helsinki Committee number 30572-10-RBM). These volunteers received a Mediterranean diet, but they did not consume any additional antioxidants. The plasma samples were inactivated (30 min at 56 °C) and then pooled together. The LDL and HDL fractions were isolated from the pooled plasma sample by discontinuous density gradient ultracentrifugation.[28] The LDL was separated at d = 1.063 g mL^{-1}, and the HDL at d = 1.210 g mL^{-1}. Both lipoproteins were dialyzed against 150 mmol L^{-1} NaCl and 1 mmol L^{-1} Na_2EDTA (pH 7.4) at 4 °C and then sterilized by filtration (0.45 μm), kept under nitrogen in the dark at 4 °C, and used within 2 weeks. The LDL and HDL protein concentration was determined with the Folin phenol reagent.[29]

Copper Ion-Induced LDL Oxidation. Prior to oxidation, the LDL was dialyzed overnight against EDTA-free, phosphate-buffered saline (PBS) solution, pH 7.4, at 4 °C. LDL (100 μg of protein mL^{-1}) was preincubated for 30 min at room temperature with increasing volume concentrations (0–25 μL mL^{-1}) of the isolated phenolics fractions. Then, 5 μmol L^{-1} of $CuSO_4$ was added and the tubes were incubated for 1.5 h at 37 °C. At the end of the incubation, the extent of LDL oxidation was determined by measuring the generated amount of thiobarbituric acid reactive substances (TBARS) and of lipid peroxides. The TBARS assay was performed at 532 nm, using malondialdehyde (MDA) for the standard curve.[30] The lipid peroxide assay, which analyzes lipid peroxide formation by their capacity to convert iodide to iodine, was measured spectrophotometrically at 365 nm.[31] The measurements were repeated three times.

HDL-Mediated Cholesterol Efflux from Macrophages. J774 A.1 murine macrophage cells were purchased from the American Tissue Culture Collection (ATCC, Rockville, MD, USA). Cells were grown in DMEM containing 5% FCS. The macrophages (1 mL of 10^6 cells mL^{-1}) were preincubated at 37 °C for 20 h with 10 to 170 μM GAE of the isolated phenolics fractions. Control cells were incubated with an equivalent volume of 50% ethanol. The cells were then washed and incubated with [^{3}H]cholesterol (2 μCi mL^{-1}) at 37 °C for 1 h, followed by a cell wash in ice-cold PBS three times, and further incubation in the absence (basal cholesterol efflux rate) or presence of HDL (100 μg protein mL^{-1}) for 3 h at 37 °C. Cellular and medium [^{3}H]-labels were quantified and HDL-mediated cholesterol efflux was calculated as the ratio of [^{3}H]-label in the medium/([^{3}H]-label in the medium + [^{3}H]-label in the cells).[32] HDL-mediated cholesterol efflux data were corrected for the nonspecific loss of cholesterol (basal cholesterol efflux rate). The experiments were repeated three times.

Statistical Analysis. The results are reported as means ± their respective standard deviations (SD) of three measurements (n = 3). Statistical analysis of the data was performed with IBM SPSS Statistics, version 17.0. Conformity of all data sets to a normal distribution and homogeneity of variances was established by the Shapiro–Wilk's and Levene's tests, respectively. One-way ANOVA and Tukey–Kramer *post hoc* means comparison test were employed to verify significant differences (p < 0.05, 0.01, or 0.001) in comparison to the control or among fractions. Correlations between fraction capacities were tested with the correlation analysis tool of Microsoft Excel 2010 and are reported in terms of the correlation coefficient, r.

RESULTS AND DISCUSSION

Composition of Isolated Date Phenolics Subgroup Fractions. To obtain variable compositions of phenolic acid and flavonol fractions, we employed fruits of two date varieties, 'Amari' and 'Hallawi', that largely differ in their phenolics composition.[13] Crude phenolics extracts were prepared with acidified 70% acetone, which was found to be more efficient than 50% ethanol in recovering antiatherogenic capacities from dates.[13]

Fractionation of the crude extracts of 'Amari' and 'Hallawi' fruits, carried out as described under Materials and Methods, yielded two fractions of phenolic acids, PhA 1 and PhA 2, and two of flavonols, Fl 1 and Fl 2. Fractions PhA 1 and Fl 1 were derived from 'Amari', and PhA 2 and Fl 2 from 'Hallawi' fruits. The yields of the isolated fractions are presented in Table 1, in terms of μmol GAE per g fruit. The yield of 'Amari'-derived fractions was considerably larger than that of the fractions isolated from 'Hallawi', by approximately 10- and 3.5-fold for phenolic acids and flavonols, respectively. This is consistent with the higher content of soluble phenolics present in 'Amari' compared to 'Hallawi' dates.[13] By and large, the recovery of the various phenolics through the fractionation process was low. Optimization of the process conditions, e.g., the weight ratio of phenolics to solid phase and the flow rate during phenolics loading onto and elution from the column, is likely to improve the yield.

The isolated phenolics fractions were analyzed by RP-HPLC to classify and tentatively identify, as well as quantify, the phenolic constituents. Figure 1 presents the concentrations of the major phenolic acids in PhA 1 and PhA 2, in order of ascending retention time (t_R). Altogether, eight prominent peaks of phenolic acids were detected in the two fractions. The peaks at t_R values of 9.7, 10.1, 11.4, 11.7, and 12.5 min corresponded to caffeic acid derivatives, and their concentrations are expressed as nmol caffeic acid mL^{-1}. The compounds associated with a t_R 14.9, 16.7, and 27.4 min were coumaric and ferulic acid and a salicylic acid derivative, respectively, and their concentrations are expressed accordingly in nmol mL^{-1} equivalents of coumaric, ferulic, and salicylic acid. Seven and five phenolic acids constituted PhA 1 and PhA 2, respectively. The major hydroxycinnamic acid in both fractions

J. Agric. Food Chem. 2015, 63, 3189–3195

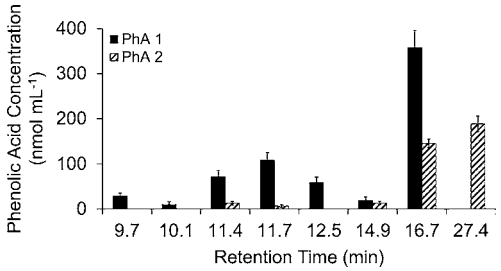

Figure 1. Composition of phenolic acid fractions isolated from date fruits. Fraction composition was analyzed by RP-HPLC. Chromatogram peak concentrations in nmol mL^{-1} are presented in order of ascending retention times. Results are the mean ± SD (n = 3).

was ferulic acid, comprising approximately 55 and 40 mol % of the total phenolic acid concentration in PhA 1 and PhA 2, respectively. This is consistent with our earlier findings on ferulic acid being the most abundant hydroxycinnamic acid in the fruits of nine date varieties, including 'Amari' and 'Hallawi'.[13] The other major phenolic acids in PhA 1 were derivatives of caffeic acid; most prominent were those detected at a t_R of 11.4, 11.7, and 12.5 min, consisting 11, 17, and 9 mol % of the total phenolic acid concentration, respectively. On the other hand, in PhA 2 the most abundant phenolic acid was a salicylic acid derivative that accounted for approximately 51 mol % of the total phenolic acid concentration. Notably, this hydroxybenzoic acid was absent in PhA 1. Small amounts of caffeic acid derivatives at a t_R of 11.4 and 11.7 min were also present in PhA 2. Both fractions contained comparable small amounts of coumaric acid, accounting for merely 3−4 mol % of the total phenolic acid concentration.

In summary, the two isolated fractions of date phenolic acids contained ferulic acid as a major component and comparable small amounts of coumaric acid, but differed considerably in the composition of the complementary set of phenolic acids; that of PhA 1 consisted mostly of caffeic acid derivatives, whereas that of PhA 2 comprised mostly a salicylic acid derivative. In this respect, PhA 1 relates to date varieties such as 'Amari', 'Deglet Noor', and 'Medjool', which are rich in caffeic acid derivatives and poor in salicylic acid derivatives, whereas PhA 2 relates to varieties such as 'Deri', 'Hadrawi', 'Hallawi', and 'Zahidi', which are relatively low in caffeic acid derivatives and have significant amounts of the salicylic acid derivative.[13]

Figure 2 illustrates the concentrations of the major flavonols in Fl 1 and Fl 2, in order of ascending t_R. Altogether, seven prominent peaks of flavonols were evident in the two fractions. On the basis of the authentic standard library all seven flavonols were tentatively classified as kaempferol derivatives; their

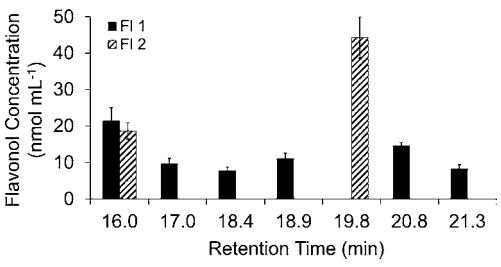

Figure 2. Composition of flavonol fractions isolated from date fruits. Fraction composition was analyzed by RP-HPLC. Chromatogram peak concentrations in nmol mL^{-1} are presented in order of ascending retention times. Results are the mean ± SD (n = 3).

concentrations in the figure are expressed in nmol mL^{-1} kaempferol-3-glucoside equivalents. Six and two peaks constituted Fl 1 and Fl 2, respectively. Both fractions shared a principal component at a t_R of 16.0 min, amounting to approximately 30 mol % of the total flavonol concentration. The other flavonols in Fl 1, corresponding to t_R values of 17.0, 18.4, 18.9, 20.8, and 21.3 min, accounted for approximately 13, 11, 15, 20, and 11 mol % of the total flavonols, respectively. The other flavonol in Fl 2, at a t_R of 19.8 min, was the most abundant in this fraction and was absent in Fl 1.

In summary, the two isolated fractions of date flavonols considerably differed in composition; in addition to one prominent flavonol shared by the two fractions, Fl 1 consisted of significant amounts of five other flavonols, whereas Fl 2 contained a single unique flavonol as the major component.

Antioxidant and Antiatherogenic Properties of Isolated Date Phenolics Subgroup Fractions. *Ferric Ion Reducing Power.* The ferric-reducing activity of the isolated fractions relative to vitamin C is shown in Table 1 in terms of the mole ratio of VCE to GAE. All the fractions exhibited considerable capacities to reduce ferric ions, which on average were 80% to 88% that of vitamin C. Under the FRAP assay conditions, the flavonol fractions were slightly, yet significantly, better reductants, exceeding the reducing power of the phenolic acid fractions by approximately 10%.

Free Radical Scavenging Capacity. The capacity of the isolated fractions to scavenge free radicals is presented in Table 1. All the fractions demonstrated the ability to neutralize free radicals, however, with different potencies. At an equivalent concentration of phenolic hydroxyls (24 μmol GAE L^{-1} in the final reaction mixture) and after 5 min exposure, the phenolic acid fractions exhibited significantly higher efficiencies compared to the flavonol fractions. PhA 2 was significantly the most potent fraction, decreasing DPPH concentration by 22%; PhA 1 followed, with a radical scavenging capacity of 14%. The two flavonol fractions had comparable lower potencies, measuring approximately 39% and 61% of the radical scavenging capacities exhibited by PhA 1 and PhA 2, respectively.

The antioxidant and antiradical capacity of phenolic molecules relate to their molecular structure, most significantly, the number and position of hydroxyl groups, extent of double-bond conjugation, and the nature and position of substituents.[21,22] Negative correlation was obtained between the FRAP and DPPH assays (r = −0.906). It should be noted, however, that the equivalent mole concentration of phenolic hydroxyls of the various fractions employed in our DPPH assay did not correspond to an equivalent mole concentration of phenolic compounds, due to the variable number of hydroxyls per molecule among the phenolics composing the fractions. This may have influenced the order of radical scavenging potencies of the phenolics fractions as presented in Table 1, since the reaction rate is affected by reactant mole concentration.

Date Phenolics' Effect on LDL Oxidation. LDL oxidation is an important process in the initiation of atherosclerosis development. We therefore studied the effect of the isolated date phenolics fractions on the susceptibility of LDL to oxidation. The extent of copper ion-induced LDL oxidation was measured in the presence of increasing concentrations of the isolated fractions. All the fractions considerably and dose-dependently inhibited LDL oxidation, as determined by the TBARS and lipid peroxide assays (Figure 3). By both assays, the potency to protect LDL from oxidation significantly

DOI: 10.1021/jf506094r
J. Agric. Food Chem. 2015, 63, 3189−3195

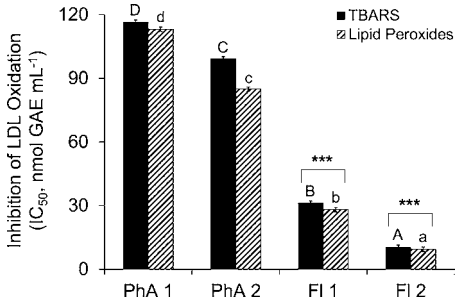

Figure 3. Effect of phenolic acid and flavonol fractions isolated from date fruits on copper ion-induced LDL oxidation. LDL (100 μg protein mL^{-1}) was incubated with increasing concentrations (0–25 μL mL^{-1}) of the isolated date phenolics fractions in the presence of 5 μmol L^{-1} $CuSO_4$. The extent of LDL oxidation was determined by the TBARS and lipid peroxides assays. The phenolics concentrations needed to achieve 50% inhibition (IC_{50}) are shown in terms of nmol GAE mL^{-1}. Results are the mean ± SD (n = 3). Bars labeled with different uppercase (TBARS assay) or lowercase (lipid peroxide assay) letters are significantly different at $p < 0.01$; *** indicates significant differences at $p < 0.001$ compared to PhA 1 and PhA 2 (Tukey–Kramer *post hoc*).

differed ($p < 0.01$) among the four fractions. Moreover, the data sets obtained by the two assays exhibited a strong positive correlation (r = 0.995), strengthening the validity of the assay. The flavonol fractions were significantly more potent than the phenolic acid fractions ($p < 0.001$), requiring considerably lower phenolics concentrations to obtain 50% inhibition (IC_{50}). Fl 2 was the most efficient inhibitor of LDL oxidation, followed by Fl 1, with IC_{50} values of 10 and 31 nmol GAE mL^{-1} by the TBARS assay and 9 and 28 nmol GAE mL^{-1} by the lipid peroxides assay, respectively. PhA 1 was the least effective inhibitor, while PhA 2 was somewhat better, as implied by their IC_{50} values of 116 and 99 nmol GAE mL^{-1} by the TBARS assay and 113 and 85 nmol GAE mL^{-1} by the lipid peroxides assay, respectively.

The competence of phenolic compounds to inhibit copper ion-mediated LDL oxidation depends on their abilities to chelate or oxidize copper ions, act as hydrogen-donating antioxidants, delocalize electrons, and partition between the aqueous medium and the lipophilic microenvironment within the LDL particle, all of which are governed by their molecular structure.[21,22,33−35] Flavonols were found to be especially effective inhibitors of LDL oxidation compared to other flavonoids.[36] Flavonols are superior to simple phenolic acids in electron delocalization capability due to the large number of conjugated double bonds. A quantum-mechanical investigation of the quercetin radical has revealed extended electronic delocalization between adjacent rings, as well as cross-conjugation occurring at the C ring.[37] Moreover, the amphipathic nature of flavonols is more pronounced, especially in that phenolic acids are completely ionized at the physiological pH of 7.4. Consistent with all the above, our study demonstrated that the isolated date flavonol fractions were better inhibitors of LDL oxidation by 3- to 10-fold over the phenolic acid fractions.

Date Phenolics' Effect on HDL-Mediated Cholesterol Efflux. Reverse cholesterol transport (RCT) is a major mechanism for the attenuation of atherosclerosis development. Macrophage cholesterol efflux is the first and potentially most critical step in macrophage RCT. We therefore explored the effect of the isolated date phenolic acid and flavonol fractions on cholesterol removal from J774A.1 macrophage cells. The extent of HDL-mediated cholesterol efflux from macrophages that were preincubated with the date phenolics fractions was compared to that measured in control cells that were pretreated with an equivalent volume of 50% ethanol. The results are shown in Figure 4, in terms of percent change over control cells

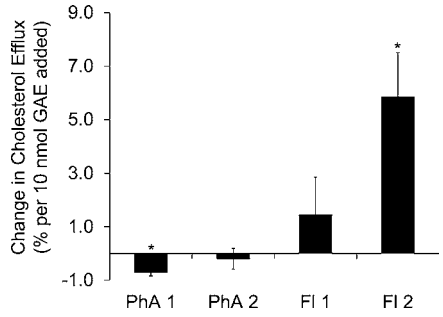

Figure 4. Effect of phenolic acid and flavonol fractions isolated from date fruits on HDL-mediated cholesterol efflux from macrophages. J774A.1 macrophages (1 mL of 10^6 cells mL^{-1}) were preincubated at 37 °C for 20 h with 20 to 170 μM GAE of the isolated phenolics fractions. After a cell wash the cells were labeled with [^{3}H]-cholesterol and the extent of HDL (100 μg protein mL^{-1})-mediated cholesterol efflux from the cells was determined. Phenolics fraction effect is presented in terms of percent change over the control in cholesterol efflux per 10 nmol of GAE added. Results are the mean ± SD (n = 3). * denotes significant difference at $p < 0.05$ (one-way ANOVA) between fraction-treated and control cells.

in the extent of cholesterol efflux per 10 nmol of GAE added. The two subgroups of date phenolics demonstrated markedly different effects on cholesterol removal from the macrophages. Pretreatment of the cells with PhA 1 slightly, yet significantly, inhibited the efflux by approximately 1%; PhA 2 had practically no effect. On the other hand, preincubation with the flavonol fractions increased the magnitude of cholesterol efflux from the cells, especially with Fl 2, which significantly enhanced cholesterol removal by approximately 6%.

A major factor in phenolics' effect on cellular processes is their mode of interaction with the membrane bilayer, i.e., the partition of less polar compounds in the hydrophobic interior of the membrane and the formation of hydrogen bonds between phospholipid polar head groups and the more hydrophilic phenolics at the membrane/water interface.[38] The relatively polar phenolic acids (ionized at a slightly alkaline pH) may cause cell membrane depolarization; a greater depolarization was reported to be induced by hydroxycinnamic acids than the corresponding hydroxybenzoic acids.[39] PhA 1 consists of mostly hydroxycinnamates, whereas PhA 2 accommodates equal proportions of hydroxycinnamates and hydroxybenzoates. PhA 1 is therefore likely to cause a more extensive membrane depolarization (i.e., increased membrane ion permeability) than PhA 2. Such a disturbance in membrane integrity may interfere with the macrophage cellular functions, leading eventually to the adverse effect of PhA 1 on cholesterol efflux. The positive effect exhibited by the flavonol fractions on cholesterol removal from macrophages may pertain to their more profound amphipathic nature that enables protection of the cell membrane from oxidation by free radicals generated both extra- and intracellularly. In this context, it is noteworthy that Fl 1, the less potent enhancer of cholesterol efflux, had a higher proportion of components with shorter t_R (≤18.9 min) compared to Fl 2 and is therefore likely to consist of somewhat

DOI: 10.1021/jf506094r
J. Agric. Food Chem. 2015, 63, 3189−3195

more polar flavonols. The date flavonols may interact with the macrophage plasma membrane and modify it in ways that consequently augment HDL binding to and cholesterol removal from the cells. Moreover, their interaction with the membrane and/or internalization may initiate signaling pathways implicated in the expression of transporters involved in serum-mediated cholesterol efflux from macrophage foam cells. Under a similar experimental setup, pretreatment of macrophages with 20 μM quercetin increased HDL binding to and cholesterol efflux from the cells by 27% and 50%, respectively, compared to control cells.[40] Moreover, the cellular levels of mRNA for the ATP-binding cassette A1 (ABCA1) transporter, a mediator of macrophage cholesterol efflux, and the nuclear factor PPARα, which induces ABCA1 expression in macrophages, increased by 42% and 77%, respectively.[40]

Taken together, our current study demonstrates that both phenolic acids and flavonols of date fruits have activities that affect processes pertinent to atherosclerosis development. However, the nature and potencies of the activities exhibited by the two phenolics subgroups varied considerably. The date phenolic acids were efficient reductants and free radical scavengers, whereas the flavonols were superior inhibitors of LDL oxidation and, in addition, stimulated cholesterol efflux from macrophages. Furthermore, different phenolics' compositions of the same subgroup, i.e., more subtle molecular structure differences, displayed variable levels of activities, as is evident from the performance disparities comparing PhA 1 to PhA 2, and Fl 1 to Fl 2. All in all, the results are consistent with the strong structure−function relationships established for phenolic compounds[21,22,33−36] and support our interpretation that the large differences in the antiatherogenic potency of phenolics extracts from a diverse collection of date varieties were inflicted by the substantial varietal divergence in phenolics composition.[13]

We have recently shown that regular consumption of 'Medjool' and 'Hallawi' dates by healthy human subjects had beneficial antiatherogenic effects.[9] The two date varieties differed in both the range and magnitude of the favorable effects and the fruit phenolics' composition, suggesting a possible role for phenolic compounds in the fruit's health traits. Identifying the antiatherogenic bioactives in dates is necessary to establish the fruit's health value and to utilize dates in nutritional approaches directed at cardiovascular heath preservation. Our present study identifies date flavonols as potentially efficient antiatherogenic biochemicals. The *in vitro* biological assays employed nano- to low micromolar concentrations of the isolated date flavonols, well in the range of blood phenolic concentrations.[41] Thus, the present findings may be relevant to the *in vivo* antiatherogenic capacities of date fruits; the latter may comprise flavonol action in concert and/or synergy with other fruit components, e.g., other phenolics and nutritional fibers. In this context, we have recently demonstrated that consumption of the combination of pomegranate together with date fruit and date seed polyphenols had the most beneficial anti-atherogenic effects, as shown in mice serum, macrophages, and aortas.[42] We are currently exploring the identity and *in vitro* activities of flavonol constituents from a diverse collection of date varieties. However, to establish causal relationships between date fruit flavonol composition and antiatherogenic benefits, *in vivo* studies with the purified flavonols are needed.

other triterpenic acids such as AA and GA might benefit survival and function of human bronchial epithelial cells.

Both 16HBE and BEAS-2B cells are normal human bronchial epithelial cell lines, and have been widely used in bronchial disease related research.[3,18] Hydrogen peroxide, an oxidant in cigarette smoke extract, could cause apoptotic and oxidative injury in those bronchial epithelial cells.[19,20] Thus, 16HBE and BEAS-2B cells were used in this present study to investigate the protective activities of AA, GA, and OA at two doses, 4 and 8 μmol/L, against hydrogen peroxide induced apoptotic, oxidative, and inflammatory stress. The impact of these triterpenic acids upon the activity and protein expression of associated factors including COX-2, NADPH oxidase, MAPK, and NF-κB was evaluated.

MATERIALS AND METHODS

Materials. AA, GA, and OA (95%) and rhodamine123 (Rh123) were bought commercially (Sigma-Aldrich Chemical Co., Milwaukee, WI, USA). 16HBE and BEAS-2B cells were purchased from American Type Culture Collection (Rockville, MD, USA). Medium, antibiotics, chemicals, and plates used for cell culture were obtained from Difco Laboratory (Detroit, MI, USA).

Experimental Design and Cell Culture. Our preliminary data indicated that 12, 24, 36, and 48 h of incubation resulted in approximately 21.7, 48.6, 72.9, and 96.3% incorporation of test compound into test cells. Thus, 48 h of incubation was used for the present study. In addition, the improvement upon cell viability of test compounds at 0.5, 1, 2, 4, and 8 μmol/L against H_2O_2 was also examined in a preliminary test, and results showed that these compounds at 0.5, 1, or 2 μmol/L did not significantly improve cell viability. Thus, these compounds at 4 and 8 μmol/L were further used. Dimethyl sulfoxide (DMSO) was used to prepare stock solution for three triterpenic acids, and stock solution was further diluted by bronchial epithelial growth medium (BEGM). The final concentration of DMSO in cell culture was lower than 0.5%, which did not impact any measurements. 16HBE and BEAS-2B cells were routinely cultured in BEGM containing 2.5 mM L-glutamine, 10% fetal calf serum, 100 units/mL streptomycin, and 100 units/mL penicillin (pH 7.4) under 5% CO_2 and 95% air at 37 °C. Culture medium was renewed every 72 h, and cells were subcultured every 7 days. Cell number (10^5/mL) was adjusted by a phosphate buffer saline (PBS) with pH at 7.2 for experiments and measurements. After aspiration, cells were pretreated by test compound at 4 or 8 μmol/L at 37 °C for 48 h, followed by washing twice with PBS. The concentration of test compound in PBS was measured using a HPLC method described by Yin et al.[12] The compound left in cells was considered as incorporated. Results showed that 48 h of incubation resulted in 97.1 ± 1.3 and 95.8 ± 0.9% incorporation into 16HBE and BEAS-2B cells, respectively. Cells were then treated with 100 μM H_2O_2 for 4 h at 37 °C. Control groups had no test compound and were without H_2O_2 treatment.

Cell Viability Assay. Cell viabiliaty was examined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT).[21] Cells (10^5/mL) were treated by test compound for 48 h and then H_2O_2 treatment for 4 h. MTT at 0.25 mg of MTT/mL was added into the medium, followed by incubating at 37 °C for 3 h. MTT formazan product was quantified by a Bio-Rad microplate reader (Hercules, CA, USA) to measure the absorbance at 570 nm, with a reference wavelength at 630 nm. Cell viability was shown as a percent of control groups.

Determination of DNA Fragmentation. DNA fragmentation was determined by using a cell death detection kit purchased from Roche Molecular Biochemicals (Mannheim, Germany). Cells were mixed with 5 mL of lysis buffer containing HEPES (10 mM, pH 7.9), KCl (10 mM), $MgCl_2$ (1.5 mM), EDTA (0.1 mM), PMSF (1 mM), DTT (1 mM), and Nonidet P-40 (0.6%) for 30 min, followed by centrifugation for 10 min at 200×*g*. Supernatant at 20 μL was added on a plate precoated with streptavidin, followed by adding 80 μL of immunoreagent and incubating at 25 °C for 2 h. PBS was used to wash twice. After adding substrate solution, the mixture was incubated for a further 15 min. The absorbance at 405 nm, with 490 nm as a reference wavelength, was measured by a microplate reader. DNA fragmentation was determined as the enrichment factor by using the following equation: absorbance of sample (cells with test compound and/or H_2O_2) ÷ absorbance of control (cells without H_2O_2 and test compound).

Mitochondrial Membrane Potential (MMP) Assay. MMP was assayed by a Beckman-FC500 flow cytometer (Beckman Coulter, Fullerton, CA, USA) and Rh123, a fluorescent dye.[22] After centrifugation for 5 min at 1200×*g*, cells were resuspended in BEGM medium, and further mixed with Rh123 at 100 μg/L. After incubating at 37 °C for 45 min, the collected cells were washed twice by PBS. Mean fluorescence intensity (MFI) was then analyzed by flow cytometry.

Preparation of Mitochondrial Fractions. Cells were lysed first, followed by centrifugation at 4 °C and 200×*g* for 10 min. The supernatant was collected for further centrifugation at 4 °C and 10 000×*g* for 20 min to get a mitochondrial pellet. PBS was used to resuspend this mitochondrial pellet, and the protein concentration of this fraction was measured by a kit purchased from Pierce Biotechnology Inc. (Rockford, IL, USA). Bovine serum albumin was used as a standard.

Assay of Na^+-K^+-ATPase Activity. Na^+-K^+-ATPase activity was assayed by monitoring the released inorganic phosphate (Pi) from ATP.[23] The cell mitochondrial fraction was mixed with 30 mM Tris−HCl buffer (pH 7.4) containing 100 mM NaCl and 20 mM KCl. ATP at 2 mM was added to initiate this assay. After 15 min of incubation at 37 °C, the assay was stopped by adding 15% trichloroacetic acid. The absorbance at 640 nm was measured to determine the Pi level. The value of a sample was shown as a percent of that of the control groups.

Measurement of Caspase Activity. Fluorometric assay kits (Upstate, Lake Placid, NY, USA) were obtained to meaure caspase-3 or -8 activity according to the manufacturer instructions. The interassay CV was 4.5−6.1%, and the intra-assay CV was 4.2−4.9%. Cells were first lysed in 25 mL of lysis buffer, followed by incubating on ice for 10 min. Cell lysates at 50 μL were then added into 25 mL of reaction buffer and further mixed with 5 mL of fluorogenic substrates which were specific for either caspase-3 or -8. After incubating at 37 °C for 60 min, a Hitachi F-4500 fluorophotometer (Tokyo, Japan) was applied to determine fluorescence, in which excitation and emission were set at 400 and 505 nm, respectively. The value was expressed as a percent of the control groups.

Analyses for ROS, 8-Hydroxydeoxyguanosine (8-OHdG), and Glutathione (GSH) Levels. ROS level was measured by $DCFH_2$-DA, a dye. After they were washed and resuspended in medium, cells were mixed with $DCFH_2$-DA at 50 μmol/L for 30 min. PBS was used to wash and suspend cells, followed by centrifugation at 4 °C and 412×*g* for 10 min. Collected cells were dissolved by adding 1% Triton X-100. A fluorescence microplate reader was used to measure the fluorescence change, in which excitation and emission were set at 485 and 530 nm, respectively. The result was shown as relative fluorescence unit (RFU)/mg of protein, in which RFU was the change in fluorescence between 5 min and time 0. A DNA Extractor WB kit purchased from Wako Pure Chemical Industries Ltd. (Tokyo, Japan) was used to extract the DNA fraction. The obtained DNA at 1 mg/mL was dissolved in water. An ELISA assay kit for 8-OHdG bought from OXIS Health Products Inc. (Portland, OR, USA) was used to determine the oxidative injury of DNA. The detection limit of 8-OHdG was 10 pg/mg of protein. A colorimetric GSH kit purchased from OxisResearch (Portland, OR, USA) was used to measure GSH concentration (ng/mg of protein), and its detection limit was 10 ng/mg of protein.

Measurements for Tumor Necrosis Factor (TNF)-α, Interleukin (IL)-6, and PGE_2. After cells were homogenized and centrifuged, the TNF-α or IL-6 level (pg/mg of protein) in supernatant was assayed by cytoscreen immunoassay kits obtained from BioSource International (Camarillo, CA, USA). The detection limit of TNF-α and IL-6 was 10 and 5 pg/mg of protein, respectively. The PGE_2 level (pg/mg of protein) was measured by a PGE_2 EIA kit

DOI: 10.1021/acs.jafc.5b00102
J. Agric. Food Chem. 2015, 63, 3196−3204

purchased from Cayman Chemical Co. (Ann Arbor, MI, USA), and its detection limit was 10 pg/mg of protein.

Cytosolic or Nuclear Fraction Preparation. Cells were treated with cold buffer containing 1.5 mM $MgCl_2$, 10 mM KCl, 10 mM HEPES (pH 7.9), 0.5 mM DTT, 0.5 mM PMSF, 1 mg/mL aprotinin, and 1 mg/mL leupeptin for 15 min. After centrifugation for 1 min at 4 °C and 14 000×*g*, the cytosolic fraction was obtained. The nuclear pellet was then resuspended in buffer containing 1.5 mM $MgCl_2$, 450 mM NaCl, 20 mM HEPES (pH 7.9), 25% glycerol, 0.5 mM DTT, 0.5 mM PMSF, 0.2 mM EDTA, 1 mg/mL aprotinin, and 1 mg/mL leupeptin for 30 min. After centrifugation for 15 min at 4 °C and 14 000×*g*, the nuclear fraction was obtained.

Western Blot Analyses. PBS was used to wash the plate twice. Cells were then scraped and suspended in lysis buffer. Reagents purchased from Bio-Rad Laboratories Inc. (Hercules, CA, USA) were used to assay protein content. A 40 μg protein sample was used for gel electrophoresis containing 10% SDS−polyacrylamide, followed by applying to a Millipore nitrocellulose membrane (Bedford, MA, USA) for 60 min. After being treated by a solution of 5% nonfat milk for 60 min to block binding from nonspecific antibody, the membrane was then reacted with monoclonal antibodies against Bcl-2, cleaved caspase-3, or Bax (1:2000); $p47^{phox}$, $gp91^{phox}$, or COX-2 (1:1000); NF-κB p65, NF-κB p50, or MAPK (1:500) at 4 °C overnight. These antibodies were bought from Boehringer-Mannheim (Indianapolis, IN, USA). The sample was further treated with horseradish peroxidase conjugated antibody at 25 °C for 3.5 h. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was a control for loading, and the obtained bands were processed by an ATTO image analyzer (Tokyo, Japan). Densitometric analysis was processed to quantify the blot, and data were normalized against GAPDH.

Statistical Analysis. A Shapiro−Wilk test was used to assess normality of data. Nine preparations were used to examine the effects of treatments (n = 9). Statistical analysis was undertaken by one-way ANOVA. Post-hoc comparisons were processed by Dunnett's t test. A difference of $P < 0.05$ was considered to be significant.

RESULTS

Effects of AA, GA, or OA upon Cell Viability. Without H_2O_2 treatment, three triterpenic acids at two doses did not change 16HBE and BEAS-2B cell viability (Figure 1, $P > 0.05$).

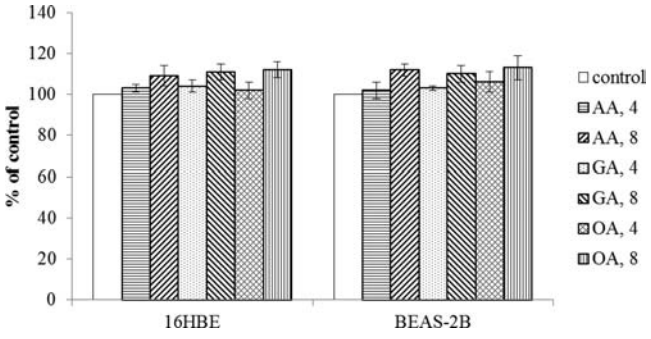

Figure 1. Effects of AA, GA, and OA upon the growth of 16HBE and BEAS-2B cells, without H_2O_2 treatment. Cells were pretreated with test compound at 4 or 8 μmol/L for 48 h. Control groups were cells that contained no test compound. Data are mean ± SD (n = 9).

H_2O_2 treatment decreased survival and raised DNA fragmentation of test cells (Figure 2, $P < 0.05$). AA, GA, or OA pretreatments enhanced cell survival and lowered fragmentation of DNA in those cells ($P < 0.05$). H_2O_2 treatment downregulated Bcl-2 expression and enhanced Bax and cleaved caspase-3 expression in test cells (Figure 3, $P < 0.05$). AA treatments retained Bcl-2 expression, but GA and OA only at high dose preserved protein expression of Bcl-2 ($P < 0.05$). Three triterpenic acids lowered cleaved caspase-3 expression

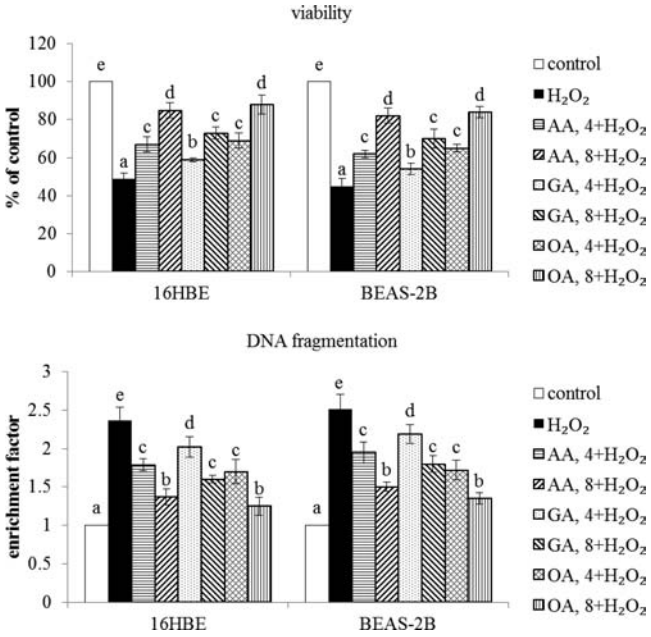

Figure 2. Effects of AA, GA, and OA upon viability and DNA fragmentation determined as the enrichment factor in 16HBE and BEAS-2B cells. Cells were pretreated with test compound at 4 or 8 μmol/L for 48 h and followed by adding 100 μM H_2O_2 to induce cell damage. Control groups were cells that contained no test compound, and without H_2O_2 treatment. Data are mean ± SD (n = 9). a−e: Mean values among bars without a common letter differ, $P < 0.05$.

dose-dependently. Three test compounds did not change the protein expression of Bax in test cells ($P > 0.05$).

Influence of AA, GA, or OA on Mitochondrial Stability. H_2O_2 treatment lowered Na^+-K^+-ATPase activity or MMP in two cell lines (Table 1, $P < 0.05$). AA, GA, or OA maintained Na^+-K^+-ATPase activity or MMP dose-dependently ($P < 0.05$). H_2O_2 treatment raised the activity of caspase-3 and caspase-8 in 16HBE and BEAS-2B cells (Figure 4, $P < 0.05$). AA, GA, or OA decreased caspase-3 activity in both cell lines dose-dependently but only at high dose significantly reduced caspase-8 activity in test cells ($P < 0.05$).

Impact of AA, GA, or OA upon Oxidative and Inflammatory Factors. H_2O_2 treatment significantly increased ROS and 8-OHdG production, and reduced the GSH level in 16HBE and BEAS-2B cells (Table 2). AA, GA, or OA treatments dose-dependently lowered the ROS and 8-OHdG levels; also reserved GSH level of test cells ($P < 0.05$). H_2O_2 treatment significantly increased TNF-α, IL-6, or PGE_2 levels (Table 3). AA, GA, or OA treatments decreased TNF-α, IL-6, and PGE_2 generation dose-dependently ($P < 0.05$).

Effects of AA, GA, or OA on NADPH Oxidase, COX-2, NF-κB, and MAPK Expression. H_2O_2 treatment promoted protein expression of $p47^{phox}$, $gp91^{phox}$, and COX-2 as well as cytosolic and nuclear NF-κB of 16HBE and BEAS-2B cells (Figure 5, $P < 0.05$). AA, GA, or OA treatments downregulated protein expression of $p47^{phox}$, COX-2, and cytosolic or nuclear NF-κB p65 ($P < 0.05$), but these agents decreased $gp91^{phox}$ expression only at high dose ($P < 0.05$). Three triterpenic acids failed to affect NF-κB p50 expression of test cells ($P > 0.05$). H_2O_2 treatment upregulated MAPK expression in 16HBE and BEAS-2B cells (Figure 6, $P < 0.05$). AA, GA, or OA treatments significantly downregulated p-p38 expression and decreased

protein expression of p-JNK only at high dose in test cells ($P < 0.05$).

DISCUSSION

Cigarette smoke or particulate matter could stimulate the release of hydrogen peroxide in airway epithelial cells, which contributes to apoptotic, oxidative, and inflammatory stress in those cells.[24,25] In our present study, pretreatments from three triterpenic acids, AA, GA, and OA, markedly protected two human bronchial epithelial cell lines (16HBE and BEAS-2B cells) against hydrogen peroxide induced oxidative and inflammatory injury, which in turn enhanced cell survival. In addition, we found that these compounds were able to mediate protein expression of NADPH oxidase, COX-2, NF-κB, and MAPK in these bronchial epithelial cells. Furthermore, these triterpenic acid treatments alone, without hydrogen peroxide, did not affect the growth of these test cells. These findings implied that these triterpenic acids might be safe and benefit respiratory epithelium stability and functions.

Bcl-2, Bax, and cleaved caspase-3 are involved in mitochondrial apoptotic regulation. Bcl-2 is an antiapoptotic factor; Bax and cleaved caspase-3 are proapoptotic factors. Hydrogen peroxide triggered a mitochondria-mediated apoptotic pathway via decreasing Bcl-2 expression, and enhancing the expression of cleaved caspase-3 and Bax. However, triterpenic acid pretreatments effectively downregulated protein expression of cleaved caspase-3 and also mildly retained the expression of Bcl-2 of two cell lines, which consequently mitigated hydrogen

peroxide elicited mitochondria-mediated apoptotic stress. Na^+-K^+-ATPase plays a critical role in maintaining ion homeostasis of mitochondrial membrane. Abnormality of this enzyme disturbs ion homeostasis and causes mitochondrial malfunctions.[26] Thus, the reduction in Na^+-K^+-ATPase activity or mitochondrial membrane potential in cells from hydrogen peroxide treatment indicated that mitochondrial structure and functions in those cells had been impaired, which in turn contributed to apoptotic insult. However, three triterpenic acid pretreatments markedly maintained the activity of Na^+-K^+-ATPase and the potential of the mitochondrial membrane in

bronchial epithelial cells to protect DNA, and counteract apoptotic stress from hydrogen peroxide. On the other hand, loss in the membrane potential of mitochondria activates caspase-3 and caspase-8.[27] Both caspase-3 and caspase-8 are apoptotic executors because they could cause cell morphological changes and/or nuclear protein cleavage.[21] Thus, the increased activity of caspase-3 or caspase-8 in 16HBE and BEAS-2B cells from hydrogen peroxide treatment was partially due to mitochondrial membrane potential change. Since test triterpenic acids already maintained the membrane potential of mitochondria in those cells, it was reasonable to observe the lower caspase activities. These results support that these compounds could protect 16HBE and BEAS-2B cells against apoptosis by stabilizing the mitochondrial membrane and caspases.

Hydrogen peroxide evoked oxidative and inflammatory stress in two cell lines in our present study, which was evidenced by overproduction of ROS, 8-OHdG, IL-6, and TNF-α. It is documented that three triterpenic acids could exhibit antioxidative and antiinflammatory activities.[28−30] Thus, the observed less generation of oxidative and inflammatory factors in triterpenic acid-treated cells seems acceptable. NADPH oxidase is an important regulator responsible for ROS generation within the progression of respiratory system disorders.[31,32] Our data indicated that these triterpenic acids substantially suppressed protein expression of $p47^{phox}$ and $gp91^{phox}$, a cytosolic and a membrane component of NADPH oxidase, which subsequently decreased ROS production in hydrogen peroxide treated cells. Apparently, these triterpenic acids could execute their antioxidative action through mediating NADPH oxidase. It is known that ROS could activate NF-κB and MAPK signaling pathways, which further exacerbates the formation of proinflammatory mediators.[33,34] In this present study, triterpenic acid pretreatments at two doses markedly downregulated protein expression of NF-κB p65 and p-p38 and limited JNK phosphorylation at high dose. These results could

DOI: 10.1021/acs.jafc.5b00102
J. Agric. Food Chem. 2015, 63, 3196−3204

be explained as being due to the fact that these agents already reduced ROS production. The other possibility was that these triterpenic acids directly regulated NF-κB and/or MAPK expression. Thus, the lower release of inflammatory cytokines, IL-6 and TNF-α, in triterpenic acid treated cells could be explained, since these two pathways were already declined. In addition, COX-2 is responsible for PGE_2 synthesis and PGE_2 is another key proinflammatory mediator. It has been indicated that COX-2 and its derived prostanoids such as PGE_2 are involved in cigarette smoking associated lung cancer progression.[35] We found that three triterpenic acids markedly suppressed COX-2 protein expression, which in turn decreased PGE_2 formation, and finally diminished inflammatory stress in those cells. These findings revealed that these compounds could protect 16HBE and BEAS-2B cells against hydrogen peroxide induced oxidative and inflammatory injury via declining NF-κB, MAPK, and COX-2 pathways.

It is interesting to find that OA was greater than other test compounds in suppressing NF-κB p65 expression in 16HBE cells but AA was more effective than others in lowering cleaved caspase-3 expression in BEAS-2B cells. Although AA, GA, and OA have similar structures, their protective effects for these two bronchial epithelial cell lines were not identical. These three triterpenic acids are compounds naturally present in herbs, vegetables, and fruits.[12] They are also used as food supplement ingredients.[36] Humans could obtain these natural triterpenic acids through consuming certain edible plants. Thus, these agents seem safe for application. Our previous animal study indicated that dietary AA and OA could be absorbed and accumulated in organs such as liver.[12] The bioavailability of these agents certainly benefits their application. Thus, using these compounds for respiratory protection might be feasible; even so, further in vivo study is needed in order to prove the safety and efficiency of these compounds for airway disease prevention or alleviation.

In conclusion, asiatic acid, glycyrrhizic acid, or oleanolic acid at 4 or 8 μmol/L protected human bronchial 16HBE and BEAS-2B cells against hydrogen peroxide induced oxidative and inflammatory injury via enhancing mitochondrial stability, decreasing ROS and PGE_2 production, and suppressing protein expression of NAPDH oxidase, COX-2, NF-κB p65, and p-p38. These results support that these triterpenic acids or foods rich in these agents could benefit bronchial epithelial cells, and might prevent the development of airway disorders.

[a]Extraction was performed using different ethanol concentrations ranging from 0 to 25%, at 4, 22, and 40 °C and liquid solid ratio of 30:1, 40:1, and 50:1 mL/g DDGS. Anthocyanin concentration was measured using the pH differential method. Optimum anthocyanin concentration recorded at 12.5% ethanol, 40:1 liquid-to-solid ratio, and 22 °C extraction. Means followed by different letters are significantly different from each other. DDGS, dried distillers grains with solubles; C-PC, conventional-purple corn; GC-PC, granular starch hydrolysis-purple corn; GC-DC, granular starch hydrolysis-dark corn.

ingredient, DDGS from colored corn can be used as a starting material for anthocyanin pigment extraction.

To our knowledge, extraction of anthocyanins from DDGS generated by ethanol fermentation from colored corn cultivars has not been previously reported. For this purpose, the use of an effective tool such as response surface methodology (RSM) is valuable in the extraction of bioactive compounds when responses are influenced by many factors and their interactions. RSM is a group of mathematical and statistical techniques used in the development of a functional relationship between a response of interest (also known as dependent variable) and a number of associated control variables (also known as independent or input variables).[19] RSM has been successfully used in the extraction of flavonoids in medicinal plants and mangiferin from mango leaves.[20,21] Therefore, the objectives of this study were to determine optimum parameters for the extraction of anthocyanins from purple and dark corn DDGS and determine the effect of DDGS processing methods and corn cultivars on anthocyanin and polyphenol concentrations and their identification in extracts from DDGS.

MATERIALS AND METHODS

Materials. Proprietary purple (PC) and dark corn (DC) varieties in development were obtained from a private company. Chemicals used for extraction were all ACS grade and purchased from Sigma-Aldrich (St. Louis, MO) and Fisher Scientific (Pittsburgh, PA). All solvents for chromatographic techniques were of high-performance liquid chromatography (HPLC)-grade or better.

Preparation of DDGS. DDGS was prepared using two different processes, conventional (C) and granular starch hydrolysis (GC), as previously reported.[22] Briefly, in the conventional process, cleaned corn samples (50 g, dry basis) were ground in a hammer mill (model MHM4, Glen Mills, Clifton, NJ) at 500 rpm using a 0.5 mm sieve. Ground corn acclimated at room temperature was mixed with deionized water to obtain a mash of 30% dry solids content. The pH was adjusted to 5.7 using 10 N sulfuric acid. Liquefaction was conducted by adding 0.013 mL of α-amylase (Spezyme CL, Dupont Industrial Biosciences, Palo Alto, CA) and agitating the mash for 1.5 h at 85 °C. The slurry was cooled to 32 °C, and pH was adjusted to 4.0. Simultaneous saccharification and fermentation was conducted for 72 h with addition of 0.025 mL of glucoamylase (Distillase SSF, Dupont Industrial Biosciences, Palo Alto, CA), 1 mL of yeast inoculum, and 0.5 mL of 50% urea. For the conventional process, purple corn (C-PC) was used to generate the DDGS. In the GC process, 0.15 mL of granular starch hydrolyzing enzyme (Stargen 001, Dupont Industrial Biosciences, Palo Alto, CA) containing α-amylase from *Aspergillus kawachi* and a glucoamylase from *Aspergillus niger* was added to the mash (30% dry solids content) along with 0.02 mL of protease (GC212, Dupont Industrial Biosciences). For the GC process, both purple (GC-PC) and dark (GC-DC) corns were used to produce DDGS. After fermentation, the mash from both processes was heated at 90 °C for 3 h to evaporate ethanol. DDGS was recovered by drying in a convection oven at 49 °C for 72 h.

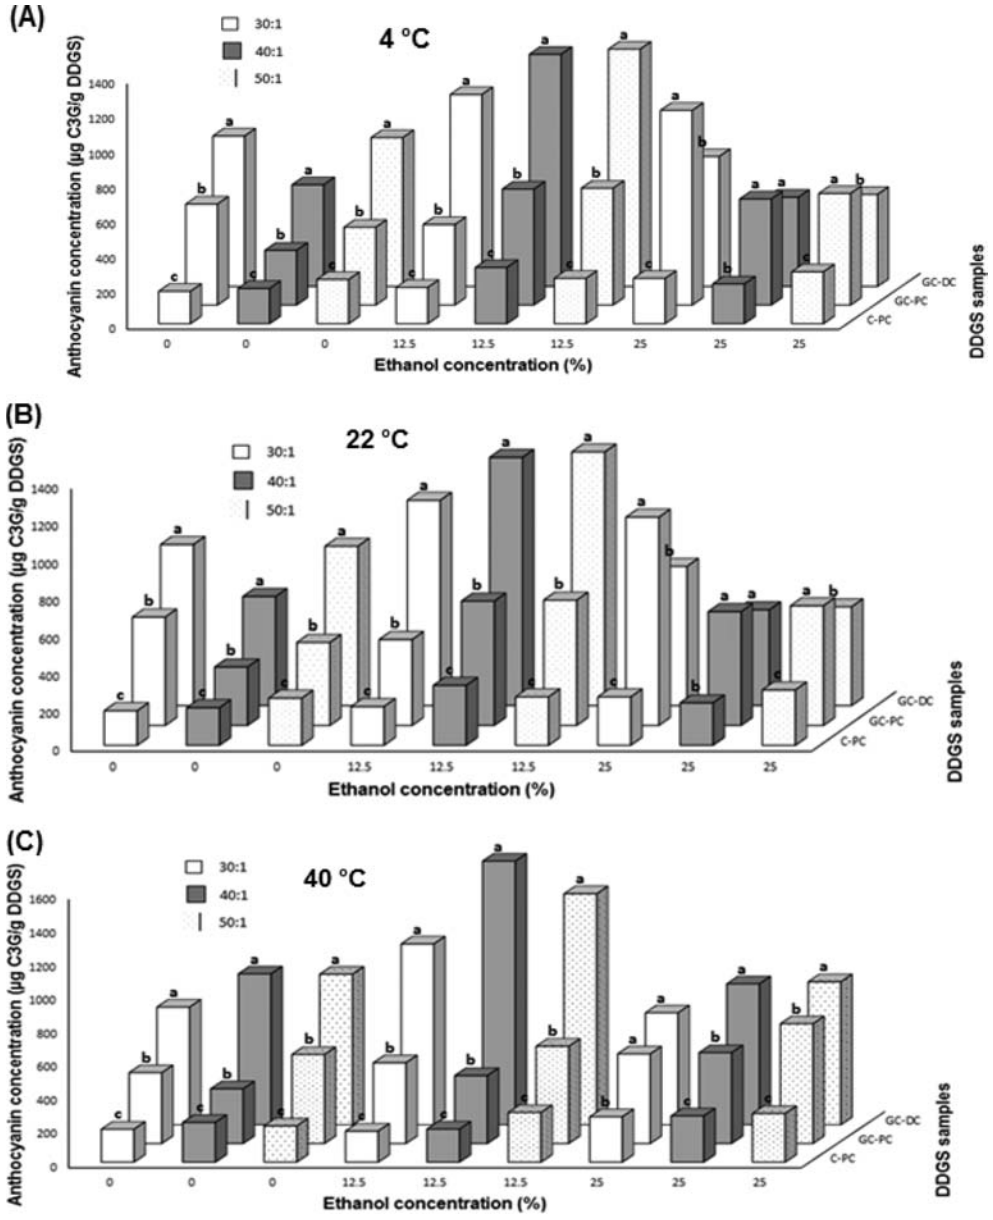

Figure 1. Anthocyanin concentrations of DDGS extracts derived from different corn cultivars and processing methods. In general, dark corn DDGS (GC-DC) had anthocyanin concentration higher than that of purple corn (GC-PC) and DDGS obtained by granular starch hydrolysis process (GC-PC) had anthocyanin concentration higher than that of DDGS obtained by conventional method (C-PC). Bars followed by different letters within the same ethanol concentration and liquid-to-solid ratio were statistically different from each other ($P < 0.05$). (A) 4 °C, (B) 22 °C, and (C) 40 °C extraction ($N = 3$).

Extraction of Anthocyanin from DDGS Samples. Anthocyanins were extracted from DDGS samples using 2% formic acid in water (pH 2.0) with different concentrations of ethanol ranging from 0 to 25%. Extraction was performed by stirring (600 rpm) at room temperature for 2 h, 40 °C for 2 h, and at 4 °C for 24 h. Liquid−solid ratios of 30:1, 40:1 and, 50:1 were used for the extraction of anthocyanin from DDGS. After extraction, the mixture was filtered using Whatman no. 4 filter paper. All extracts were immediately analyzed for total monomeric anthocyanin, total polyphenol, and total flavonoid concentrations.

Measurement of Total Monomeric Anthocyanin Concentration. Total monomeric anthocyanin was determined by a pH differential method as previously reported.[23] Samples were diluted to a factor of 1:20 using two buffers (pH 1.0, 0.25 M KCl buffer and pH 4.5, 0.40 M sodium acetate buffer). Samples of 200 μL of diluted solutions at each pH were transferred to a 96-well plate, and the absorbance was read at 520 and 700 nm using a Synergy 2 multiwell plate reader (Biotek, Winooski, VT). The total monomeric anthocyanin concentration was calculated as cyanidin-3-glucoside (C3G) equivalents per liter as below:

$$\text{total monomeric anthocyanins (mg/L)} = \frac{A \cdot \text{MW} \cdot D \cdot 1000}{\varepsilon \cdot \text{PL} \cdot 0.45}$$

Where $A = (A_{520} - A_{700})$ at $\text{pH}_{1.0} - (A_{520} - A_{700})$ at $\text{pH}_{4.5}$; MW = 449.2 g/mol for C3G; D, dilution factor; PL, constant path length (1 cm); $\varepsilon = 26\,900$ L/(mol cm), which is the molar extinction coefficient for C3G, 1000 conversion factor from grams to milligrams, and 0.45 as the conversion factor from the established method[23] to the plate reader method. Milligrams per liter of extract was then expressed as micrograms of C3G equivalents per gram of DDGS.

Measurement of Total Polyphenol Concentration. Total polyphenol was measured using the Folin−Ciocalteu method adapted to a microassay.[24] Samples were diluted to a factor of 1:10 and 1:20 with deionized water. To a 96-well plate were added 50 μL of diluted samples, standard or blank (deionized water); 50 μL of 1N Folin−Ciocalteu's phenol reagent was added. After 5 min, 100 μL of 20% Na_2CO_3 was added, and the mixture was allowed to stand for another 10 min. The absorbance was read at 690 nm using a Synergy multiwall plate reader

DOI: 10.1021/acs.jafc.5b00128
J. Agric. Food Chem. 2015, 63, 3205−3218

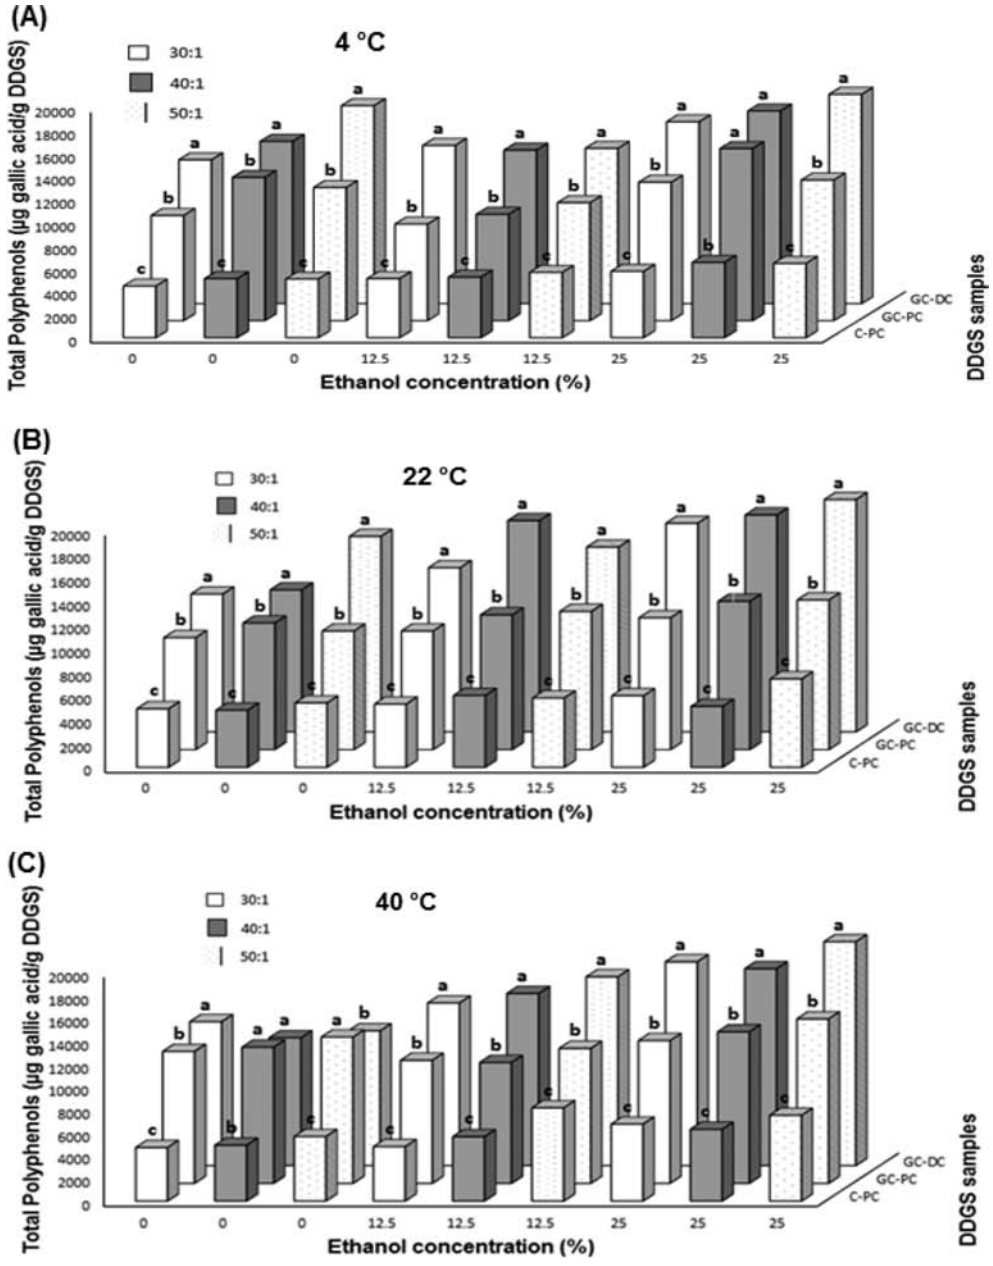

Figure 2. Polyphenol concentrations of DDGS extracts derived from different corn cultivars and processing methods. In general, dark corn DDGS (GC-DC) had polyphenol concentration higher than that of purple corn (GC-PC) and DDGS obtained by granular starch hydrolysis (GC-PC) had polyphenol concentration higher than that of DDGS obtained by conventional method (C-PC). Bars followed by different letters within the same ethanol concentration and liquid-to-solid ratio were statistically different from each other ($P < 0.05$). (A) 4 °C, (B) 22 °C, and (C) 40 °C extraction ($N = 3$).

(Biotek, Winooski, VT), and the results were expressed as micrograms of gallic acid per gram of DDGS.

Measurement of Total Flavonoid Concentration. Total flavonoid concentration was measured using the absorbance at 400 nm method as reported previously.[25] Briefly, 50 μL of diluted samples (1:20), standards, and blank (methanol) were added to a 96-well plate. After which, 180 μL of methanol and 20 μL of 1% aminoethylborinate in methanol were added. After the samples were shaken gently, the absorbance was read at 400 nm using an ELX 808 microplate reader (Biotek, Winooski, VT). Results were expressed as micrograms of rutin per gram of DDGS.

HPLC/MS-MS Analysis. DDGS extract from GC-PC was concentrated 10× by evaporation using a Centrivap Concentrator (Labconco, Kansas City, MO) at 45 °C for 6−8 h. Concentrated samples were analyzed by an HPLC system (Waters, Milford, MA) equipped with a photodiode array detector, MassLynx software, and a C18 3 μ analytical column, 250 mm × 4.6 mm, at 30 °C using previously reported conditions.[26] The mobile phase was a linear gradient of 2% formic acid (v/v) in water and methanol starting at 0% methanol, increasing to 25% methanol in 10 min, and to 50% methanol in 30 min; flow rate was 0.5 mL/min, and the injection volume was 20 μL. Chromatograms were generated at 280, 320, 360, and 520 nm wavelengths. For MS/MS analysis, an electrospray ionization-time-of-flight system (Bruker Daltoniks, Billerica, MA) was used with the following conditions: Survey ion mode, ES mode; polarity, positive; scan range, 50−950 m/z; source temperature, 114 °C; desolvation temperature, 248 °C; cone gas flow, 964 L/h; and desolvation gas flow, 1175 L/h.

Colorimetric Measurements. Color was measured using a Lovibond Tintometer PFX990 (The Tintometer Limited, England) instrument. The instrument was calibrated, and the following parameters were used: L^*, a^*, and b^*; observer/illuminant, 10° and D65 and path length, 1 cm. Briefly, 2−3 mL of extracts acclimated at room

DOI: 10.1021/acs.jafc.5b00128
J. Agric. Food Chem. 2015, 63, 3205−3218

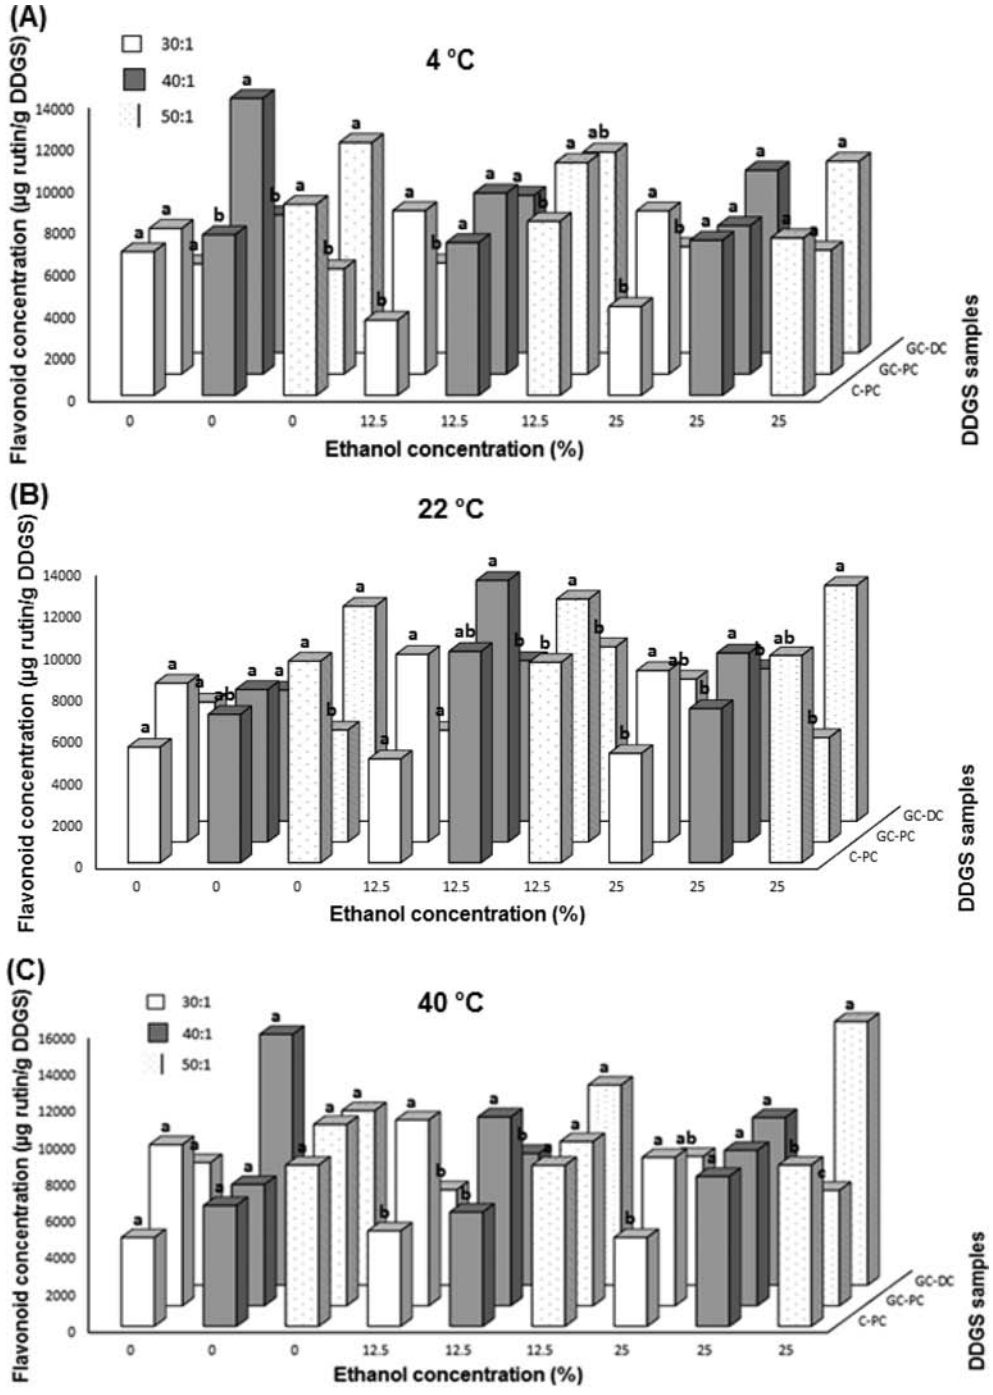

Figure 3. Flavonoid concentrations of DDGS extracts derived from different corn cultivars and processing methods. In general, no effect of corn cultivar and DDGS processing method on flavonoid concentrations of DDGS extracts was detected. Bars followed by different letters within the same ethanol concentration and liquid-to-solid ratio were statistically different from each other ($P < 0.05$). (A) 4 °C, (B) 22 °C, and (C) 40 °C extraction ($N = 3$).

temperature was placed in a disposable ultraviolet−visible cuvette, and the color parameters L^*, a^*, and b^* were measured and recorded. Color squares were generated by converting L^*, a^*, and b^* values to R, G, and B values using http://colormine.org/convert/rgb-to-lab and Microsoft Power Point Software.[26]

Response Surface Methodology. RSM was used to optimize the extraction of anthocyanin from DDGS using functional relationships between the dependent variable and the independent variables as previously reported.[19] Ethanol concentration (x_1), liquid-to-solid ratio (x_2), and extraction temperature (x_3) were chosen for independent variables. The range and center point values with actual and coded values of variables used for the optimization of anthocyanin extraction from purple corn DDGS were for coded levels −1, 0, +1, for ethanol concentration (x_1, %), 0, 12.5, and 25; for liquid-to-solid ratio (x_2, mL/g), 30:1, 40:1 and 50:1; and for extraction temperature (x_3, °C), 4, 22 and 40.

Anthocyanin concentration and a^*-value (measure of redness) were selected as the responses for the combination of the independent variables, as presented in Table 1. The variables were coded according to the following equation:

$$x = (x_i - x_0)/\Delta x$$

where x is the coded value, x_i the corresponding actual value, x_0 the actual value at the center of the domain, and Δx the increment of x_i

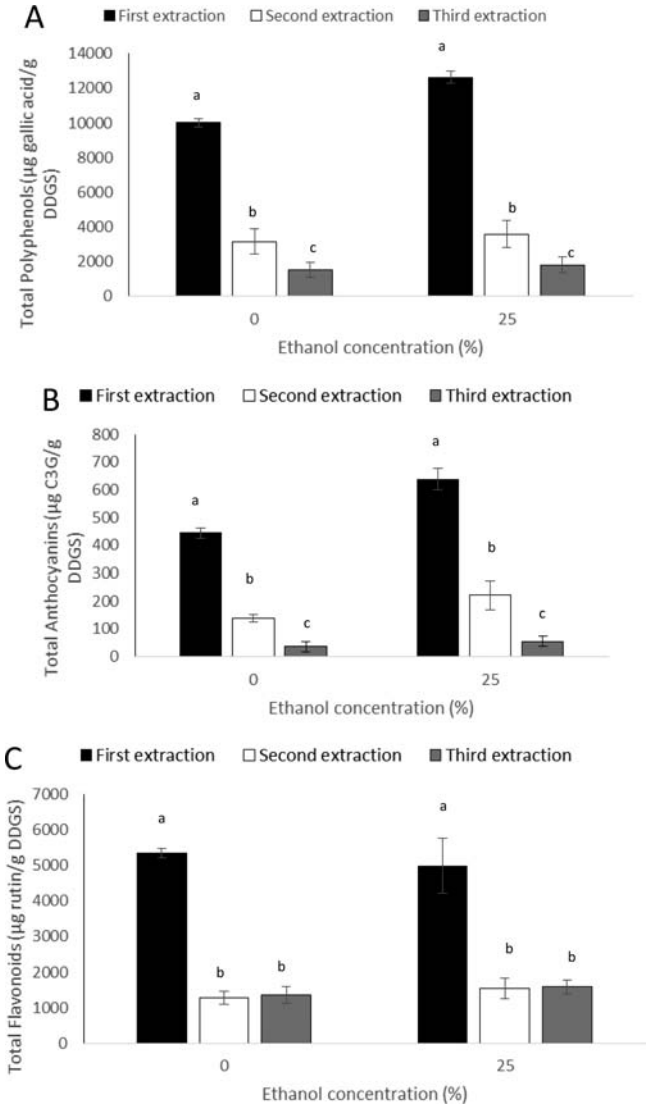

Figure 4. Effect of multiple extractions on total polyphenols (A), total anthocyanins (B), and total flavonoids (C) of purple corn DDGS extracts using 2% formic acid acidified 0% ethanol and 25% ethanol. Bars with different letters within ethanol concentration were significantly different from each other ($N = 3$).

corresponding to a variation of 1 unit of x. The polynomial second degree equation is described by the following equation:

$$y = b_0 + \sum_{i=1}^{3} b_i x_i + \sum_{i=1}^{3} b_{ii} x_i^2 + \sum_{i=1}^{2} \sum_{j=i+1}^{3} b_{ij} x_i x_j$$

Statistical Analysis. All analyses were done in 2−3 independent replicates. The data obtained were analyzed using one-way ANOVA to compare experimental to control values using SAS version 9.4 (Cary, NC); statistical differences among independent variables were determined using the Proc GLM procedure and Tukey posthoc test ($P < 0.05$). RSM analysis was performed using the Proc Rsreg procedure. Correlation among parameters measured was performed using the GraphPad Prism software (Version 5.02; GraphPad Software, Inc.; San Diego, CA).

RESULTS

Total Anthocyanin Concentrations of Corn DDGS Extracts. Figure 1 shows the concentrations of total monomeric anthocyanin in corn DDGS extracts. In the C-PC samples, anthocyanin concentration ranged from 174.3 μg C3G equivalents/g DDGS (for 0% ethanol extract, 30:1 liquid-to-solid ratio, 4 °C) to 321.0 μg C3G equivalents/g DDGS (for 12.5% ethanol extract, 40:1 liquid-to-solid ratio, and 22 °C extraction conditions). In the GC-PC samples, the highest anthocyanin concentration of 714.3 μg C3G equivalent/g DDGS was observed when extracted with 25% ethanol extract, 50:1 liquid-to-solid ratio, and 40 °C. The lowest anthocyanin concentration of 312.9 μg C3G equivalent/g DDGS was attained at 0% ethanol, 40:1 liquid-to-solid ratio, and 4 °C. In the GC-DC samples, the total anthocyanin concentration ranged from 509.6 μg C3G equivalent/g DDGS (25% ethanol, 40:1 liquid-to-solid ratio, and 22 °C) to 1573.4 μg C3G equivalent/g DDGS (12.5% ethanol, 40:1 liquid-to-solid ratio, and 40 °C). As shown in Figure 1, considering the effect of corn cultivar (GC-PC vs GC-DC), dark corn DDGS gave anthocyanin concentrations higher than that of purple corn DDGS. On the other hand, the GC process of obtaining DDGS from corn showed total anthocyanin concentrations higher than that of the conventional method of DDGS production (C-PC vs GC-PC).

Table 3. Identification of Anthocyanins and Condensed Forms in 2% Formic Acid Water Extract of DDGS from Purple Corn Cultivars Obtained by Granular Starch Hydrolysis Processing Method

	GC-PC			
peak	Rt (min)	M^+	MS/MS fragments	possible identity[a]
1	17.87	823	605, 274, 214	catechin-(4,8)-cyanidin-3-malonylglucoside
2	18.42	899	575, 737, 423, 329, 287	catechin-(4,8)-cyanidin-3,5-diglucoside
3	21.42	317	229	isorhamnetin (presumed)
4	28.03	449	287, 288	cyanidin-3-glucoside

9	41.12	641	449	cyanidin-disuccinylglucoside (presumed)

[a]Identification of the major peaks was done using the database service massbank.jp.

Total Polyphenol Concentrations of Corn DDGS Extracts. The total polyphenol concentrations of different DDGS extracts are shown in Figure 2. In C-PC samples, the highest polyphenol concentration (8154.1 μg gallic acid equivalent/g DDGS) was obtained at extraction conditions of 25% ethanol, 50:1 liquid-to solid ratio, and 40 °C, while the lowest polyphenol concentrations (4489.6 μg gallic acid equivalent/g DDGS) was attained at 0% ethanol, 30:1 liquid-to-solid ratio, and 4 °C extraction conditions. The total polyphenol concentrations for GC-PC samples ranged from 8405.3 to 14975.7 μg gallic acid equivalent/g DDGS for extraction conditions of 12.5% ethanol, 30:1 liquid-to-solid ratio, 4 °C, and 25% ethanol, 40:1 liquid-to-solid ratio, and 4 °C, respectively. GC-DC sample had a total polyphenol concentration from 11178.8 μg gallic acid equivalent/g DDGS (0 ethanol, 40:1 liquid-to-solid ratio, and 40 °C) to 19603.7 μg gallic acid equivalent/g DDGS (25% ethanol, 50:1 liquid-to-solid ratio, and 40 °C). As can be observed in Figure 2, polyphenol concentrations were higher in DDGS extracts obtained from dark corn cultivar than from purple corn cultivar (GC-DC vs GC-PC) while DDGS obtained by GC process had

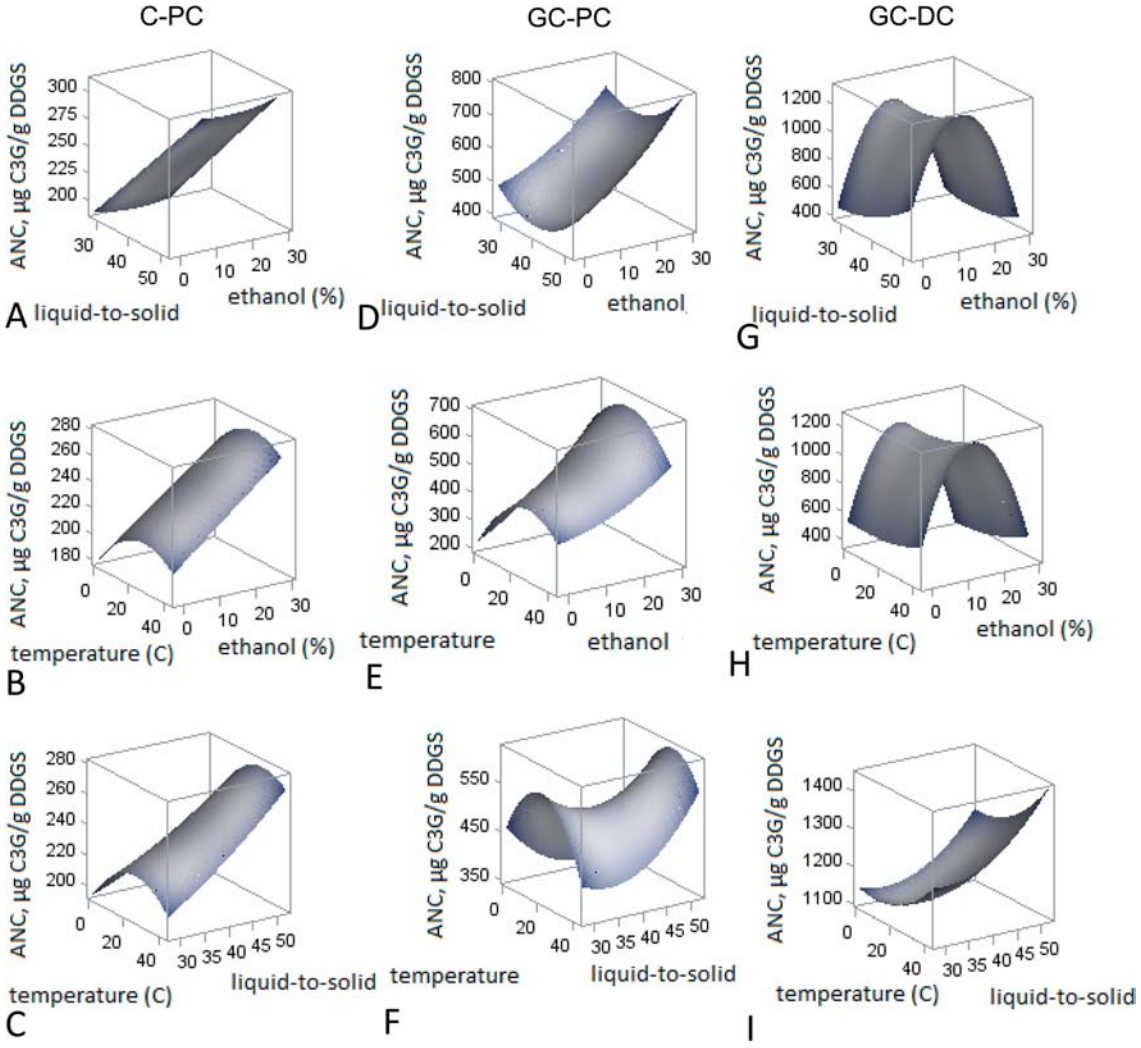

Figure 5. Response surface methodology for the extraction of anthocyanin of DDGS obtained from different cultivars of corn and different processing methods of DDGS as affected by ethanol concentration, liquid-to-solid ratio, and extraction temperature.

polyphenol concentration higher than that of DDGS obtained by the conventional method (GC-PC vs C-PC).

Total Flavonoid Concentrations of Corn DDGS Extracts. The total flavonoid concentrations from DDGS extracts are presented in Figure 3. The highest flavonoid concentrations for C-PC, GC-PC, and GC-DC samples were 10098.7, 13158.8, and 14348.0 μg rutin/g DDGS, respectively. These concentrations were obtained at extraction conditions of 12.5% ethanol, 40:1 liquid-to-solid ratio, and 22 °C for C-PC; 0% ethanol, 40:1 liquid-to-solid ratio, and 4 °C for GC-PC; and 25% ethanol, 50:1 liquid-to-solid ratio, and 40 °C for GC-DC. Unlike total anthocyanin and total polyphenol concentrations, there was no distinct effect of corn cultivar and DDGS processing method on total flavonoid concentrations of DDGS samples.

Effect of Multiple Extractions on Total Anthocyanin, Total Polyphenol, and Total Flavonoid Concentrations of DDGS Extracts from GC-PC. Panels A, B, and C of Figure 4 show the total polyphenol, total anthocyanins, and total flavonoid concentrations, respectively, after a three-step sequential extraction using 2% formic acid acidified 0% ethanol and 25% ethanol extracting solvents. All first extracts generated statistically higher concentrations of anthocyanin, polyphenols, and flavonoids as compared to those of the second and third extracts. In addition, the first extract accounted for 63.6, 63.8, and 66.9% of the cumulated polyphenols, anthocyanins, and flavonoid concentrations for 0% ethanol extracts, respectively. For 25% ethanol extracts, the first extract accounted for 70.1, 69.7, and 61.4% of the cumulated polyphenols, anthocyanins, and flavonoid concentrations, respectively.

Optimization of Anthocyanin Concentration and *a-Value of DDGS Extracts.** The concentration of anthocyanins and *a*-value from DDGS extracts were further optimized using the RSM approach. The coded and actual values of the three variables, namely, ethanol concentration, liquid-to-solid ratio, and extraction temperature, were selected to optimize the yield. In Table 1, the treatments together with coded and actual values are presented. The actual anthocyanin concentration for DDGS samples was recorded in the dependent yield variable as measured in the procedures described in Materials and Methods. A total of 27 treatments were recorded and used to model the equation using the RSM method. Multiple regression analysis of anthocyanin concentration from C-PC sample showed that the test variables were related to anthocyanin concentration by the following second-degree polynomial equation:

$$Y = 162 + 1.75x_1 - 0.54x_2 + 1.51x_3 + 0.01x_1x_2 + 0.005x_1x_3 + 0.02x_2x_3 + 0.0001{x_1}^2 + 0.03{x_2}^2 - 0.04{x_3}^2$$

DOI: 10.1021/acs.jafc.5b00128
J. Agric. Food Chem. 2015, 63, 3205−3218

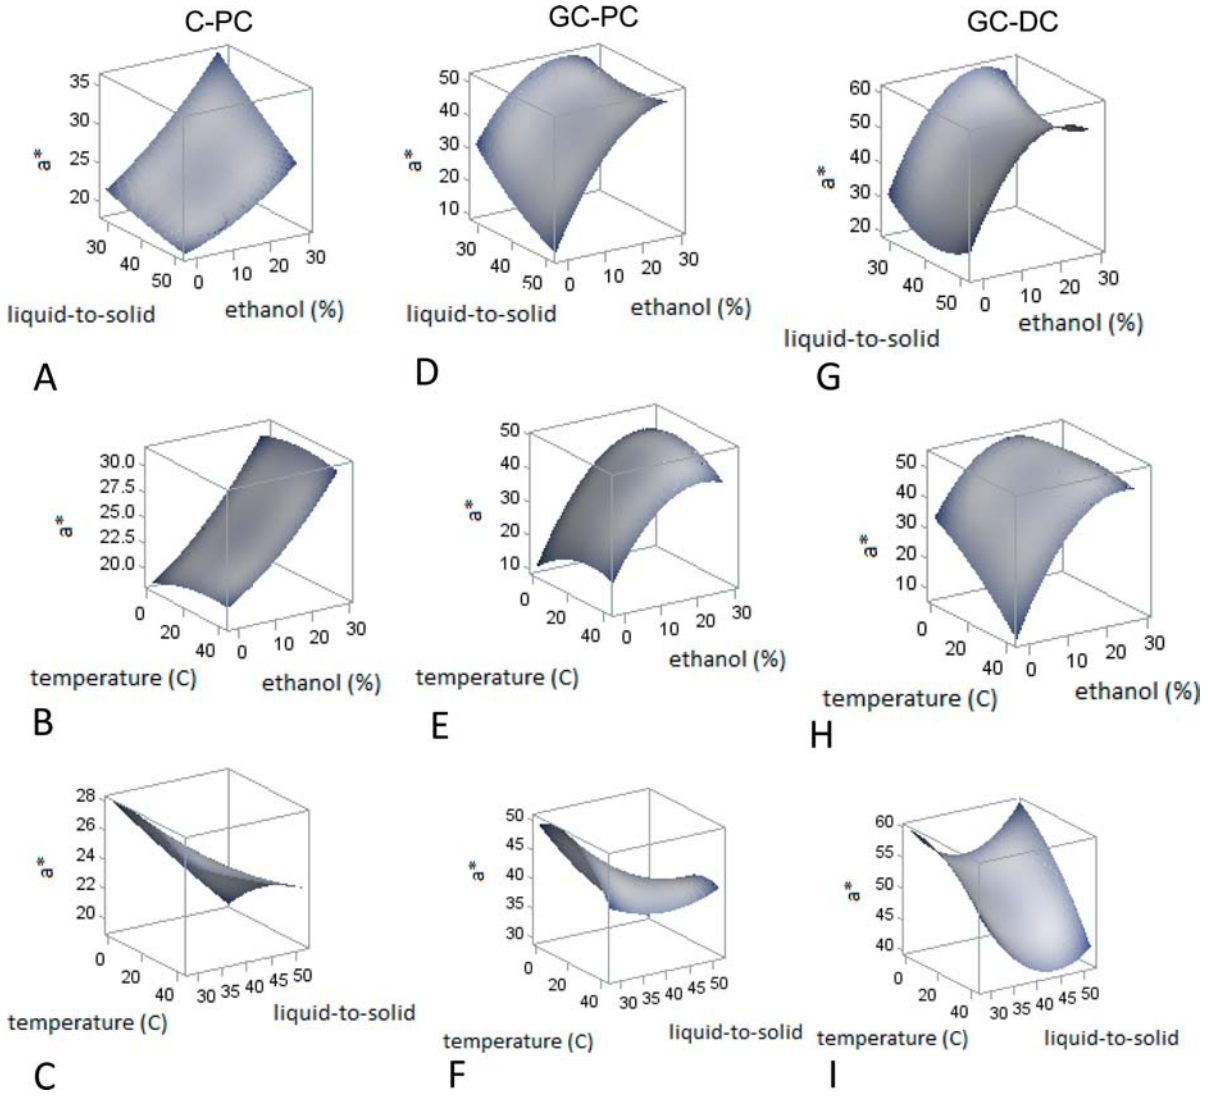

Figure 6. Response surface methodology for a^* color parameter from DDGS extracts from different cultivars of corn and different processing methods of DDGS as affected by ethanol concentration, liquid-to-solid ratio, and extraction temperature.

When multiple regression analysis was applied, anthocyanin concentration and the test variables were related by the following second-degree polynomial equation for GC-PC:

$$Y = 1175 + 2.14x_1 - 43.17x_2 + 7.72x_3 + 0.14x_1x_2 - 0.12x_1x_3 + 0.19x_2x_3 + 0.16{x_1}^2 + 0.49{x_2}^2 - 0.28{x_3}^2$$

For GC-DC, anthocyanin concentration was related by the following second-degree polynomial equation:

$$Y = 1046 + 83.77x_1 - 25.03x_2 - 4.30x_3 - 0.27x_1x_2 + 0.06x_1x_3 + 0.06x_2x_3 - 3.14{x_1}^2 + 0.43{x_2}^2 - 0.10{x_3}^2$$

In the preceding equations, Y pertains to anthocyanin concentration, x_1 to ethanol concentration, and x_2 to liquid-to-solid ratio; x_3 is the extraction temperature. The total model was highly significant ($P < 0.0001$) for all 3 DDGS samples. For the C-PC sample, ethanol concentration and liquid-to-solid ratio were highly significant with P-values of <0.0001 and 0.0002, respectively. All test variables were significant for the GC-PC sample, indicating that ethanol concentration ($P < 0.0001$), liquid-to-solid ratio ($P < 0.0089$), and temperature of extraction ($P < 0.0001$) affected anthocyanin concentrations of GC-PC extracts. On the other hand, only ethanol concentration and liquid-to-solid ratio affected anthocyanin concentrations of GC-DC extracts with P-values of <0.0001 and 0.0041, respectively. Figure 5 shows the three-dimensional response surface plots. As shown in Figure 5, an increase in ethanol concentration (x_1) led to an increase in the concentration of anthocyanin extracted for C-PC (Figure 5A,B) and GC-PC (Figure 5D,E) samples. On the other hand, an initial increase in ethanol concentration to 12.5% led to a peak anthocyanin concentration for the GC-DC sample, and a reduction of anthocyanin concentration was observed with an additional increase in ethanol concentration (Figure 5G,H). In the case of liquid-to-solid ratio (x_2) and extraction temperature (x_3), there was an initial increase in anthocyanin concentration which then decreased with an increase in liquid-to-solid ratio and extraction temperature (Figure 5C,F,I). The optimal conditions when fixed as given by the SAS Rsreg procedure were 12.5% ethanol, 40:1 liquid-to-solid ratio, and 22 °C for C-PC; 12.3% ethanol, 39.9:1 liquid-to-solid ratio, and 22 °C for GC-PC; and 12.5% ethanol, 40:1 liquid-to-solid ratio, and 22 °C for the GC-DC sample.

Figure 7. Color squares of DDGS extracts from different corn cultivars obtained by different processing methods. The conditions for each treatment were x_1, ethanol concentration (%); x_2, liquid-to-solid ratio (mL/g); x_3, extraction temperature (°C).

Regarding a^*-value, a measure of the redness of the DDGS extract, multiple regression analysis showed that the a^*-value was related with the test variables for C-PC as follows:

$$Y = 32 + 0.62x_1 - 0.37x_2 - 0.11x_3 - 0.01x_1x_2 - 0.001x_1x_3 + 0.01x_2x_3 + 0.01{x_1}^2 + 0.001{x_2}^2 - 0.001{x_3}^2$$

For GC-PC, the relationship was as follows:

$$Y = 90 + 1.07x_1 - 2.52x_2 - 0.18x_3 + 0.03x_1x_2 - 0.01x_1x_3 + 0.01x_2x_3 - 0.04{x_1}^2 + 0.02{x_2}^2 - 0.01{x_3}^2$$

Finally, for GC-DC, the analysis revealed

$$Y = 105 + 1.93x_1 - 3.34x_2 + 0.02x_3 - 0.0002x_1x_2 - 0.02x_1x_3 - 0.01x_2x_3 - 0.06{x_1}^2 + 0.04{x_2}^2 - 0.005{x_3}^2$$

Figure 6 presents the surface response for a^*-value parameter as affected by ethanol concentration, liquid-to-solid ratio, and temperature of extraction. Ethanol concentration significantly affected a^*-value for 3 DDGS samples, and surface response showed that an increase in ethanol concentration led to an increase in a^*-value of the extract. Liquid-to-solid ratio also significantly affected a^*-value for 3 DDGS, and surface response showed that increase in liquid-to-solid ratio resulted in reduction in a^*-value parameter (Figure 5A,B,D,E,G,H). Temperature of extraction significantly affected a^*-value for GC-PC and GC-DC samples, with an initial increase leading to an increased a^*-value and further decrease leading to a reduction in a^*-value, as shown in the surface response (Figure 6F,I).

Table 2 and Figure 7 show the color measurements and color squares of the extracts, respectively, from 3 DDGS samples with 27 treatments. In general, GC-DC extracts show higher red intensity in the color squares as compared to that of GC-PC and C-PC extracts (Figure 7), which is further validated by higher a^*-value color parameters (Table 2).

HPLC/MS-MS Analysis of Purple Corn Anthocyanin Extracts. Figure 8 presents the HPLC chromatograms at 520 nm, total ion chromatogram, and representative time-of-flight MS/MS ions for the 2% formic acid aqueous extract (0% ethanol)

J. Agric. Food Chem. 2015, 63, 3205−3218

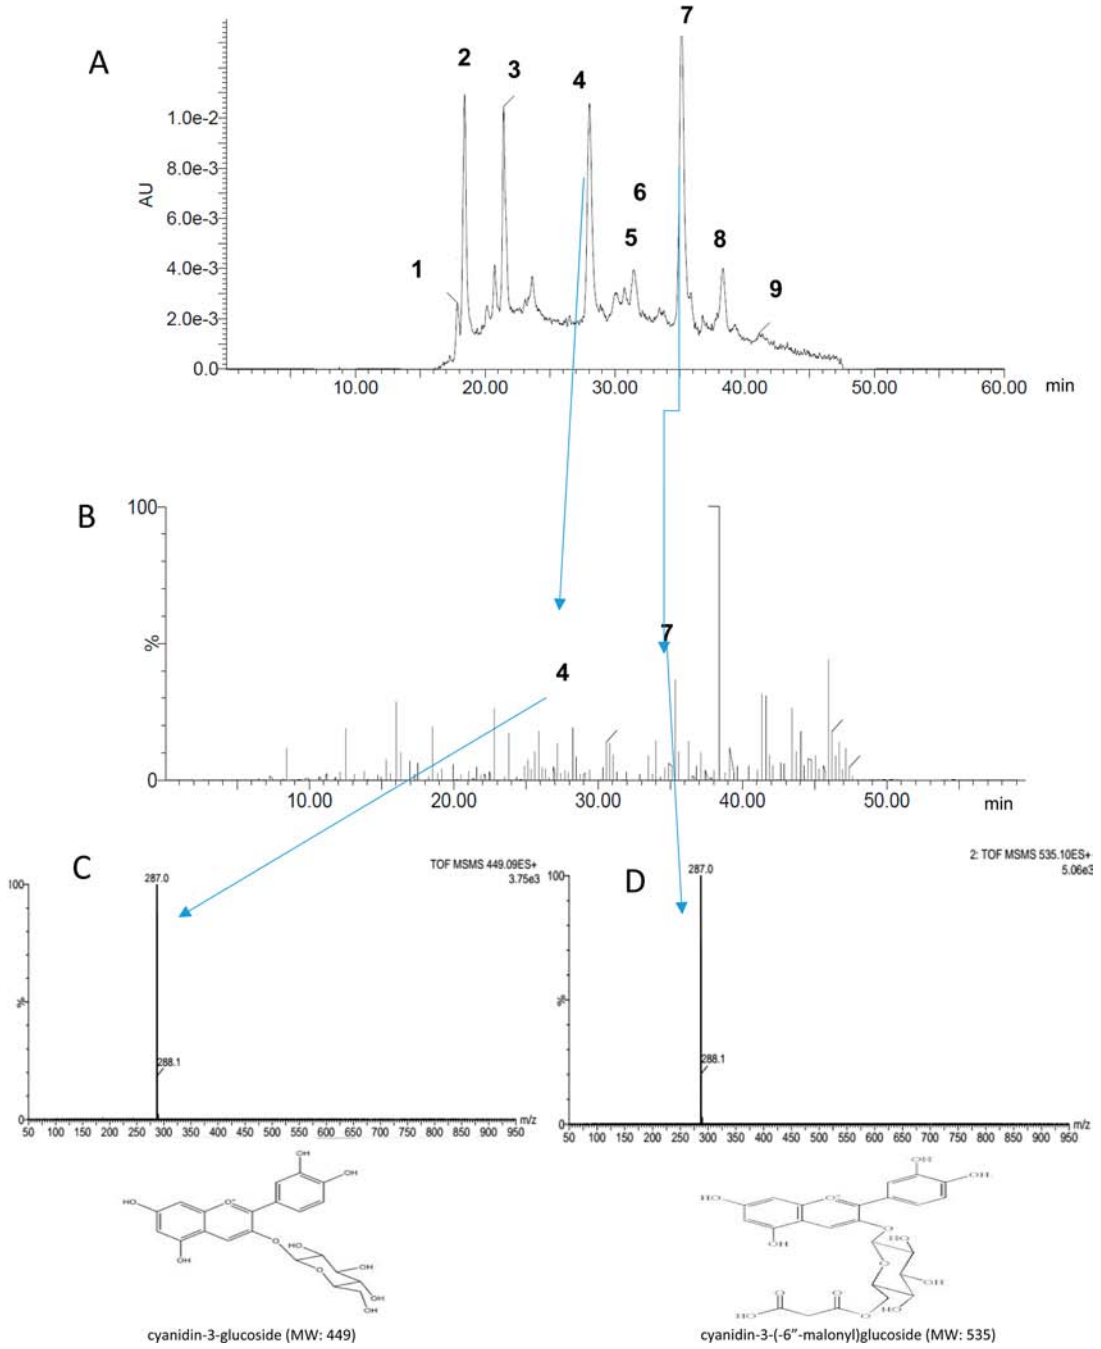

Figure 8. Anthocyanin profile of DDGS purple corn extract prepared by granular starch hydrolysis process (GC-PC).

from purple corn DDGS. The HPLC chromatogram of the extract shows major peaks at 28.03 and 35.13 min retention times with AU values of 0.010 and 0.014, respectively (Figure 8A). MS/MS analysis of these peaks showed that they are cyanidin-3-glucoside and cyanidin-3-(6″-malonyl)glucoside, respectively (Figure 8B,C,D). Another major anthocyanin found was at retention time 38.35 min, corresponding to peonidin-3-(6″-malonyl)glucoside. Identification of peaks from the MS/MS total ion chromatogram of the two extracts is summarized in Table 3. Condensed flavanol−anthocyanin derivatives were also identified in the extracts at an earlier retention time between 17 and 19 min corresponding to catechin-(4,8)-cyanidin-3-malonylglucoside and catechin-(4,8)-cyanidin-3,5-diglucoside. Supporting Information provides the HPLC chromatograms at 520 nm from water extracts of different DDGS.

DISCUSSION

In the United States alone, 316 million metric tons of corn valued at US $66 billion were produced in 2010.[13] To date, very few studies have been reported on the extraction of natural compounds from DDGS.[27] In this study, we optimized the extraction of anthocyanin from DDGS as coproduct of biofuel production from two colored corn varieties and two DDGS processing methods. The total polyphenol concentration ranged from 4489.6 to 19 603.7 μg gallic acid equivalent/g DDGS. Previous study on the total polyphenol concentrations of DDGS extracted with or without microwave irradiation showed that the highest concentration of polyphenols was 12.0 mg gallic acid/g DDGS achieved by 50% aqueous ethanol at 150 °C with microwave irradiation for 15 min.[28] Our results cover this previously

Figure 9. Correlations among parameters measured in DDGS extracts between total anthocyanins and total polyphenols (A), total anthocyanins and total flavonoids (B), total anthocyanins and *a**-value (C), total polyphenols and total flavonoids (D), total polyphenols and *a**-value (E), and total flavonoids and *a**-value (F). An insert table is presented to summarize the statistical parameters of correlation (G).

reported polyphenol concentration from DDGS extract; the slight difference can be explained by the use of different extraction conditions. To our knowledge, this is the first report that quantifies the amount of total monomeric anthocyanins and total flavonoid concentrations of different extracts from colored corn DDGS. Previous studies on the total anthocyanin concentrations of purple corn showed that the concentration of anthocyanin varied depending on which material was analyzed. Purple corncob gave the highest anthocyanin concentration of 1333 mg/100 g;[29] ground purple corn had a concentration of 6.02 mg/g[30] and 1277 μg/g,[31] while purple waxy corn kernel and cob had a concentration of 754 μg/g DW and 2534.1 μg/g DW, respectively.[32] Anthocyanin content of colored corn DDGS extracts ranged from 174.3 to 1573.4 μg C3G equivalent/g DDGS, which are comparable to what were previously reported on the anthocyanin level in purple corn kernel, indicating that the process of biofuel production did not affect the level of anthocyanin in DDGS. Dark corn cultivar had an anthocyanin concentration higher than that of purple corn cultivar, indicating the effect of cultivar in anthocyanin concentration, hence affecting the *a**-color parameters of the extracts, which was further supported by the generated color squares. In addition, DDGS obtained by the GC method yielded anthocyanin and polyphenol concentrations higher than those of the conventionally obtained DDGS, indicating the effect of DDGS processing methods on these compounds. The effect might be attributed to the temperature used during the liquefaction process.

Previous studies have shown that the major flavonoids found in purple corn were quercetin and hesperitin derivatives.[33] In addition, the concentration of flavonoids from purple corn was reported to be in the range of 1.18 to 2.66 g rutin equivalent/kg,[34] higher than what we found in this study. The difference could be attributed to the method of measuring flavonoid concentration as well as the solvent used in the extraction. We first reported here that extracts from colored corn DDGS are a potential source of different bioactive compounds. This result is economically important as it showed DDGS is a potential inexpensive source of these health-promoting compounds, and the left-over residue after bioactive extraction could still be used as an ingredient for animal diets.

Aside from the reported health benefits of anthocyanin, one of its major potential uses is as food colorant in the food industry. There is an increasing push in the food industry to replace the use of artificial food colorants with plant pigments. The maximum anthocyanin concentration was recorded after using 12.5% ethanol, 40:1 liquid-to-solid ratio, and 22 °C for C-PC; for GC-PC, 25% ethanol, 30:1 liquid-to-solid ratio, and 22 °C; and for GC-DC, 12.5% ethanol, 40:1 liquid-to-solid ratio, and 40 °C as extraction conditions. RSM analysis indicated that the optimum values for anthocyanin extraction were 12.5% ethanol, 40:1 liquid-to-solid ratio, and 22 °C. Analysis of variance of the regression equation for anthocyanin concentration as the dependent variable showed that a linear model ($P < 0.0001$) was significant for the C-PC sample; both linear and quadratic models were highly significant ($P < 0.0001$) for GC-PC and GC-DC samples. The R^2 for each model was 0.509 for C-PC, 0.640 for GC-PC, and 0.773 for GC-DC. Eigenvalues for the total experimental values were a mixture of positive and negative values for anthocyanin concentration, indicating that the stationary point is a saddle point.

Statistical analysis of the correlations among parameters measured in the DDGS extract showed that total anthocyanins and total polyphenols, total anthocyanins and *a**-value, total polyphenols and total flavonoids, and total polyphenols and *a**-value correlated (Figure 9) with each other with P-values of <0.0001, < 0.0001, 0.0138, and <0.0001, respectively. On the other hand, flavonoids did not correlate with anthocyanins and *a**-value of the extracts with P-values of >0.05. These results indicated that anthocyanins and polyphenols might have direct impact on the color of the extract while total flavonoids will have no impact on the color of the extract. These results further supported our observation of the effect of corn cultivars and DDGS processing methods on the total anthocyanins and total polyphenols of the extracts and the observation that total flavonoids were not affected.

A vast collection of color corn, as part of the maize germplasm bank collection at the University of Illinois, has shown that color corn stores well, maintains viability, and it is not more susceptible to degradation than white or yellow corn. However, more post-harvest studies are needed to measure and compare food grain quality— quantitative, qualitative, nutritive, and economic—of color corn versus white or yellow corn. Significant amounts of purple corn are processed for making cereals, tortillas, meal, chips, and other products.[13] Handling of purple corn (harvesting and drying) may be different from yellow dent corn because of its soft endosperm, but it is practiced commercially. Breeding efforts will be required to develop robust purple corn hybrids with good ethanol yields before they can be used by the biofuels industry; such efforts are underway at our institution.

In conclusion, the results suggested that anthocyanin extraction from colored corn DDGS can be optimized using 40:1 mL/g DDGS liquid-to-solid ratio, 22 °C extraction temperature, and 12.5% ethanol concentration. DDGS processing methods and corn cultivar affected total anthocyanins and polyphenols of the obtained extracts.

MATERIALS AND METHODS

Materials. The alfalfa sample was harvested in the time period between the bud and initial flowering stage (10% bloom) from Gansu province of China and dried at environmental conditions. TRIzol reagent was purchased from Invitrogen (Carlsbad, CA, USA), whereas an IScript Advanced cDNA Synthesis kit was purchased from Bio-Rad (Hercules, CA, USA). RAW 264.7 mouse macrophage cells were obtained from the Chinese Academy of Sciences (Shanghai, China). Lipopolysaccharide (LPS) from *Escherichia coli* O111:B4 was obtained from Millipore (Bedford, MA, USA). Other reagents for isolation were of analytical grade without further purification.

Fractionation and Purification of Pectic Polysaccharide. After removal of the leaves, the dried alfalfa stem was milled into powders through a 200-mesh screen using an IKA mill (IKA, A11, Germany). Small molecules were removed from alfalfa stem powders by three 95% ethanol extractions at 75 °C for 2 h. Afterward, hot water (DD H_2O, 80 °C, 2 h; three times) and cold alkali (1 M NaOH, room temperature, 12 h; four times) were successively used to extract the water-soluble substances and hemicellulosic polysaccharides (Figure S1). The pectins were then extracted four times using a 20-fold volume of 1 M NaOH (w/v) at 80 °C with continuous stirring for 2 h. After neutralization with HCl solution, the extract was precipitated by using a 4-fold volume of 95% ethanol (v/v) and washed three times with 75% ethanol, followed by lyophilization to afford the crude pectic polysaccharides of alfalfa stem.

Further purification was carried out by membrane ultrafiltration (Minimate TFF system, Pall Corp., Port Washington, NY, USA) with defined exclusion limits of 10000 Da to obtain the pectic polysaccharide molecules of alfalfa stem (APPS) with MW >10000 Da. The cutoff polysaccharide was then purified by gel filtration chromatography on a Sephacryl S-400 Superfine column (80 × 1.6 cm i.d., Amersham Pharmacia Biotech, Uppsala, Sweden) eluted with DD H_2O at 1.0 mL/min. The collected eluates were combined and freeze-dried prior to further analysis (Figure S1).

Molecular Weight and Size Determination. The molecular weight and size of APPS were determined using a particle size analyzer (Zetasizer Nano-ZS90, Malvern Instruments Ltd., Malvern, Worcs, UK). In general, the well-dispersed APPS stock aqueous solution (2 mg/mL) was diluted to 1.00, 0.75, 0.50, 0.25, and 0.10 mg/mL. The Debye plot from static light scattering (SLS) was obtained to calculate the weight-averaged molecular weight (M_w) of APPS based on the Rayleigh equation (eq 1).[25]

$$\frac{KC}{R_\theta} = \left(\frac{1}{M_w} + 2A_2C\right) \times P(\theta) \tag{1}$$

In eq 1, K, M_w, A_2, C, and R_θ represent optical constant, sample molecular weight, second virial coefficient, concentration, and Rayleigh ratio, respectively. Representing the angular dependence of the sample scattering intensity, the value of $P(\theta)$ would reduce to 1 when the particles are much smaller than the wavelength of the incident light. The M_w (Da or g/mol) was determined from the intercept at zero concentration ($C \rightarrow 0$) according to $KC/R_\theta = 1/M_w$. The molecular size was simultaneously obtained along with the molecular weight determination at the concentration of 0.25 mg/mL.

Chemical Composition Analysis. APPS was analyzed for contents of total protein, carbohydrate, and uronic acid using bicinchoninic acid (BCA),[26] phenol–sulfuric acid,[27] and *m*-hydroxydiphenylsulfuric acid[28] methods, respectively.

The PMP derivation method was used to determine the monosaccharide and uronic acid compositions of APPS as described previously.[29] The obtained sugar derivatives were then determined by HPLC analysis at 250 nm with an Inertsil ODS-3 column (100 mm × 2.1 mm i.d., 2 μm, GL Sciences Inc., Tokyo, Japan) under the following chromatographic conditions: 30 °C, 0.1 M phosphate buffer (pH 6.7)/acetonitrile at a ratio of 80:20 (v/v), 0.3 mL/min.

Linkage Analysis by Methylation. APPS was first reacted with $NaBD_4$ to reduce the uronic acid residues according to a previously reported protocol.[30] The partially methylated alditol acetates (PMAAs) of APPS was prepared according to a modified Needs method[31] for the following determination using GC-MS (Agilent 7890A-5975C, Agilent Technology, Santa Clara, CA, USA), equipped with a HP-5 capillary column (30 m × 0.32 mm i.d., 0.25 μm film). The temperature of GC was increased from 50 to 150 °C at 30 °C/min, then to 220 °C at 3 °C/min, and finally to 300 °C at 30 °C/min and held for 10 min. The injector temperature was set at 250 °C, whereas the interface temperature was 280 °C. The MS parameters were set as ion source temperature at 300 °C, ionization energy at 70 eV, detector voltage at 1.5 kV, and mass range from 50 to 550. Glycosidic linkages of APPS were identified by comparing the mass spectrum patterns of PMAAs with the database of CCRC.[32] The molar ratios of individual linkage residues were calculated on the basis of peak areas and response factors for each sugar in the TIC as described previously.[33]

Spectroscopic Analysis. The infrared spectrum of APPS was measured on a FT-IR spectrometer (Nicolet 6700, Thermo Fisher, Waltham, MA, USA) using KBr pellets in the infrared region of 4000–400 cm^{-1} at a resolution of 4 cm^{-1}. One- and two-dimensional NMR analyses of APPS were carried out on an Avance Bruker III HD 600 MHz NMR spectrometer equipped with a 5 mm TCI CryoProbe at 25 °C using D_2O as the solvent to a final sample concentration of 40 mg/mL.

Transmission Electron Microscopy (TEM). In brief, a well-dispersed polysaccharide solution was first prepared using sodium dodecyl sulfate (SDS, 5 μg/mL) to a final concentration of 5 μg/mL. SDS aqueous solution was applied to dissolve APPS as the SDS solution could reduce the molecular aggregation.[34] A droplet of APPS solution (5 μL) was deposited on a carbon film specimen (200 mesh, Beijing Zhongjingkeyi Technology, Beijing, China) and dried at ambient temperature and humidity. The specimen was examined using TEM (Tecnai G2 Spirit BIOTWIN, FEI, Hillsboro, OR, USA) at an accelerating voltage of 120 kV to observe the morphology of APPS molecular assembly or the microstructures of APPS.

Isoconversional Thermal Characteristics. Pyrolysis characteristics of APPS were determined on a simultaneous thermal analyzer (SDT-Q600, TA Instruments, New Castle, DE, USA). In general, three different heating rates (including 5, 10, and 20 °C/min) were used to decompose the APPS sample from 50 to 600 °C under N_2 protection at a flow rate of 100 cm^3/min. The decomposition results were analyzed using the Flynn–Wall–Ozawa (FWO) method (eq 2) to obtain the experimental apparent activation energy (E_a)[35−37]

$$\log \beta = \log \frac{AE_a}{Rg(\alpha)} - 2.315 - 0.4567\frac{E_a}{RT} \tag{2}$$

where $g(\alpha) = \int_0^\alpha (d\alpha)/(f(\alpha))$, β is the heating rate, R is the general gas constant, A stands for the pre-exponential factor, E_a is the apparent activation energy, and T is the temperature at the conversion α. The experimental value of ln A was obtained by the compensation effect relationship (eq 3), the compensation parameters (a and b) of which could be deduced by a plot of ln A versus E_a from a model-fitting approach using the Coats–Redfern equation (eq 4) with T' being the average experimental temperature.

$$\ln A = aE_a + b \tag{3}$$

$$\ln \frac{g(\alpha)}{T^2} = \ln\left[\left(\frac{AR}{\beta E_a}\right)\left(1 - \frac{2RT'}{E_a}\right)\right] - \frac{E_a}{RT} \tag{4}$$

Both the FWO and Coats–Redfern methods were classified to model-free methods. By using these methods, the process is detectable in the form of a dependence of the activation energy E_a on the conversion rate α. The thermal analysis data were analyzed using the Universal Analysis 2000 software (version 4.5A, TA Instruments) and MS Excel 2013.

Anti-inflammatory Bioactivity Determination. The potential anti-inflammatory effect of APPS was evaluated by determining its potential inhibition of IL-1β, IL-6, and COX-2 gene expressions in the cultured RAW 264.7 mouse macrophage cells. Briefly, the aqueous solution of APPS was first prepared at two different treatment concentrations (10 and 50 μg/mL). RAW 264.7 cells were cultured in

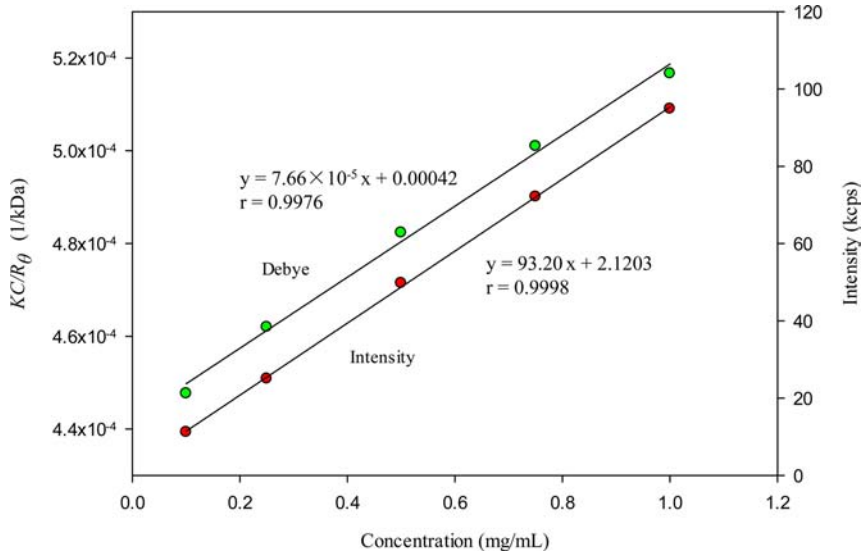

Figure 1. Debye plot of APPS for its molecular weight determination: angular dependences of KC/R_θ with K being the optical constant, C being the concentration, R_θ being the Rayleigh ratio, and θ being the scattering angle.

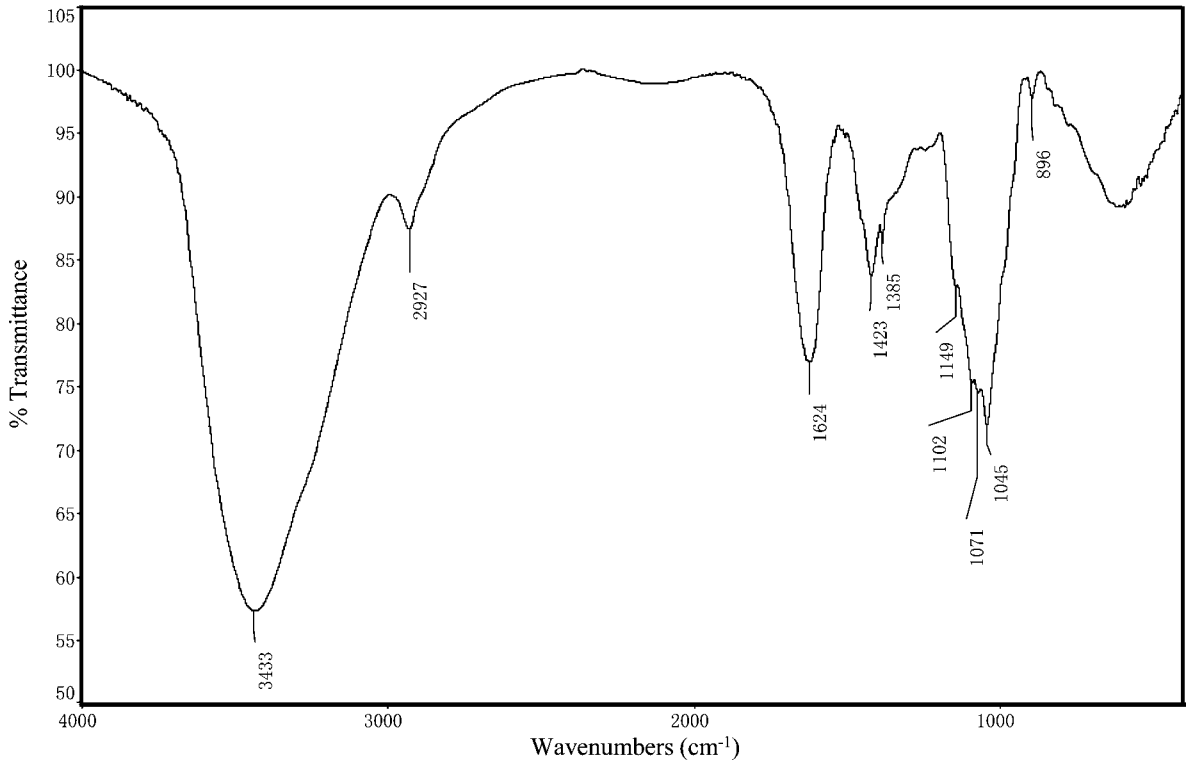

Figure 2. FT-IR spectrum of APPS.

6-well plates for 24 h to reach an 80% confluence before the treatment. After further incubation for 24 h, LPS was pipetted into the medium at a final concentration of 10 ng/mL and incubated for another 4 h at 37 °C under 5% CO_2.[38,39] Total RNA was isolated from the mouse peritoneal macrophages using a TRIzol reagent (Invitrogen) for further reverse transcription of cDNA and real-time PCR analysis using the IScript Advanced cDNA Synthesis kit on an ABI 7900HT Fast Real-Time PCR System (Applied Biosystems) with the following PCR conditions: 50 °C for 2 min, 95 °C for 10 min, and 46 cycles of amplification at 95 °C for 15 s and 60 °C for 1 min.

Statistical Analysis. Data were recorded as the mean ± SD for triplicate determination. The significance of differences between means were evaluated by one-way analysis of variance (ANOVA) and Tukey's test using SPSS for Windows (version rel. 18.0, SPSS Inc., Chicago, IL, USA) with statistical significance assigned at $P < 0.05$.

RESULTS AND DISCUSSION

Preparation of APPS. The crude hot alkali extractable fraction was about 3.31% dry weight of the alfalfa stem and contained 96.79% (w/w) of total carbohydrate including 10.03% uronic acid, whereas no protein was detected. A homogeneous polysaccharide fraction was purified from the crude extract by ultrafiltration and size exclusion chromatography (SEC) and designated APPS (Figure S2). APPS

[a]Residues A, B, C...H are designated according to the decreasing order of proton peak intensity.

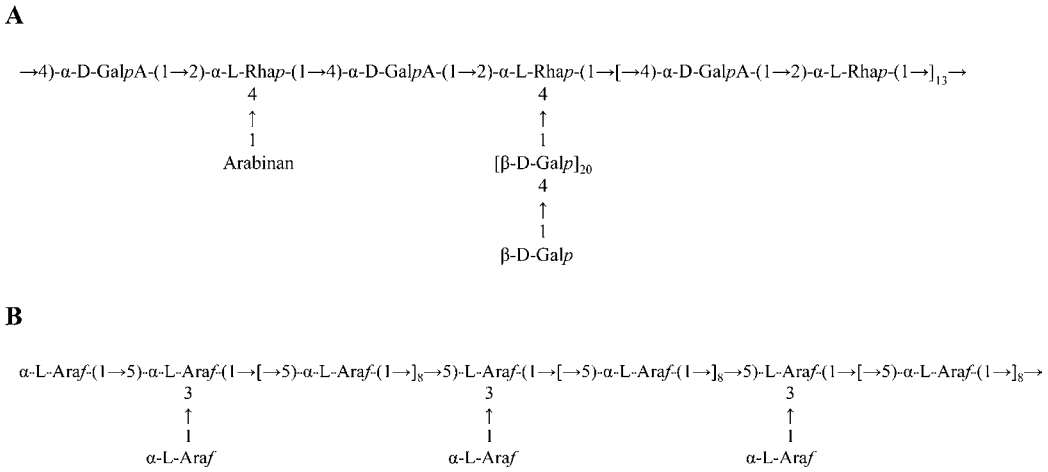

Figure 4. Proposed repeating units of APPS molecular structure: (A) schematic structure of APPS; (B) schematic structure of arabinan side chains in APPS.

consisted of rhamnose, galactose, galactouronic acid, and arabinose in a molar ratio of 2.4:1.4:1.0:3.4 (data not shown).

The M_w of APPS was calculated to be 2.38×10^3 kDa (or 2.38×10^6 g/mol) (Figure 1), whereas A_2 was calculated to be 7.66×10^{-5} from the gradient of the Debye plot, which indicated the aqueous solution of APPS was a stable system for the sake of A_2 over zero.[40] In addition, the average radius of APPS was simultaneously determined to be 123 nm.

Glycosidic Linkages of APPS. The result of PMAA analysis demonstrated that APPS was composed of eight different linkage residues including nonreducing terminals of arabinose (T-L-Ara*f*) and galactose (T-D-Gal*p*), the molar ratios of which are listed in Table S1 in the Supporting Information. The arabinose residues were primarily 1,5-L-Ara*f*, whereas the rhamnose residues were mainly 1,2-L-rhamnose (Rha*p*). Large percentages of 1,4-D-Gal*p* and 1,4-D-glactouronic acid (Gal*p*A) were also determined as the intrachain residues. The main branching points were at 1,3,5-L-Ara*f* and 1,2,4-L-Rha*p*. The ratio between terminal units and branching points was 0.97, indicating that the number of terminal units was approximately equal to the number of branching points in the polysaccharide. Additionally, the degree of branching (DB) value was 12% for APPS according to the equation DB = (NT + NB)/(NT + NB + NL),[41] where NT, NB, and NL are the numbers of the terminal residues, branch residues, and linear residues, respectively.

FT-IR Spectrum. Figure 2 shows the primary maxima of absorption bands in IR spectra of APPS. The strong absorption at 3433 cm^{-1} was dominated by the stretching vibrations of OH, whereas the band at 2927 cm^{-1} was attributed to stretching vibrations of CH_3. The signal at 1624 cm^{-1} was originated from the blending of water $\delta(H_2O)$, indicating H−O−H angle vibration. The bands at 1423 and 1385 cm^{-1} were assigned to be carboxylate groups of APPS.[42] Among them, the absorptions at 1624 and 1423 cm^{-1} were the characteristic peaks of pectin material, whereas no peak was detected at ~1750 cm^{-1}, indicating the absence of carboxyl ester groups.[43] In the region of 1200−950 cm^{-1}, several intense signals at 1149, 1102, 1071, and 1045 cm^{-1} contributed by the vibrations of glycosidic bonds and pyranoid rings.[43] Moreover, the band maximum at 1045 cm^{-1} was usually found in arabinogalacto-

DOI: 10.1021/acs.jafc.5b00494
J. Agric. Food Chem. 2015, 63, 3219−3228

rhamnoglycan, containing the dominant arabinose and rhamnose over the galactose units.[44]

Structural Characterization by NMR Analysis. Linkages between glycosyl residues in APPS were further investigated by NMR analyses, including ^{1}H NMR, ^{13}C NMR, and HSQC spectra (Figure 3), with the assistance of single-bond (COSY) and multiple-bond (TOCSY) proton−proton correlations (Figure S3). As shown in Figure 3C, eight cross peaks were presented in the anomeric region (^{1}H is from 4.3 to 5.5 ppm, whereas ^{13}C is in the range of 90−120 ppm) of the HSQC spectrum. The chemical shift assignments of ^{1}H and their corresponding ^{13}C were identified and are summarized in Table 1 from the above spectra according to the literature data for arabinofuranosides, arabinans, and pectins.[45−47] The backbone was indicated by the presence of the characteristic C-1 signals (Figure 3B) of α-(1→4)-Gal*p*A and α-(1→2)-Rha*p* at 99.17 and 98.56 ppm, respectively. According to the results of linkage analysis and the literature,[48,49] the intense peaks at 106.81, 81.75, 79.01, 83.11, and 67.62 ppm were assigned to C1, C2, C3, C4, and C5 of α-(1→5)-Ara*f*, respectively, which confirmed the prominence of an arabinan-like structure as a side chain. The pectic polysaccharides of the rhamnogalacturonan I class were reported to consist of repeating units →2)-α-L-Rha*p*-(1→4)-α-D-Gal*p*A-(1→ as backbone with side chains of either arabinan (average of 25−30 arabinose units) or galacto-oliosaccharides (average of 3−4 galactose units) attached to the *O*-4 position of →2)-α-L-Rha*p*-(1→ residues in the backbone.[50] On the basis of previous literature on the structure of pectic polysaccharides,[11,51,52] the results of methylation and NMR analysis indicated the proposed partial structure of APPS (Figure 4), which was mainly consistent with previous partial characterization of alfalfa pectic polysaccharide indicating large amounts of D-galacturonic acid and 2-*O*-(α-D-galactopyranosyluronic acid)-L-rhamnose based on partial acid hydrolysis and/or partial acetolysis analysis.[5] The primary difference between APPS and the previous arabinogalactorhamnoglycan type pectin was the degree of polymerization of the side chains.

Microscopic Morphology of APPS. TEM analysis was performed to observe the microstructure of APPS intuitively. As demonstrated in Figure 5, linear chains with minor branched structures were observed in APPS molecules under the experimental condition. The result was in agreement with that of methylation and NMR analyses that branching structure existed in APPS molecules.

Thermal Decomposition Analysis. Along with the structural properties, thermal decomposition characteristics also play an important role in the evaluation of polysaccharide applicability. In the present study, the thermal properties of APPS were assessed by thermogravimetry (TG), derivative thermogravimetry (DTG), and D^{2}TG (second-time derivatives). From the TG curves, two steps of weight loss were observed during three different heating rates (Figure 6A). In the first step, a small amount of weight loss (∼8%) occurred in the temperature range of 50−150 °C due to the loss of trapped water.[53] However, the structure of APPS was mainly pyrolyzed at the heating process of 200−400 °C, which resulted in ∼55% weight loss. Thereby, the weight at 150 °C was designated 100% dry weight of APPS for the degradation analysis.

The curves of TG, DTG, and D^{2}TG among three heating rates (β) were employed to calculate the thermal decomposition parameters of APPS in the 150−600 °C range (Figure 6B). Afterward, the pyrolysis properties of APPS were obtained from the β value of 0, which was deduced from each of the three temperatures (Figure 6C). Table 2 indicates the temperature of onset, maximum, and shift decomposition (T_o, T_p, and T_s) of APPS and their corresponding weight loss percentages (WL_o, WL_p, and WL_s). The decomposition of APPS was primarily started at 215.6 °C (T_o) and reached the maximum rate at 256.7 °C (T_p) with a loss of 12.80% dry weight (WL_p), whereas APPS experienced a rapid degradation in a narrow temperature range from the transition of 256.7 °C (T_p) to 328.0 °C (T_s). The major dry weight (51.12%) of APPS was lost in a 112.4 °C range of the heating process.

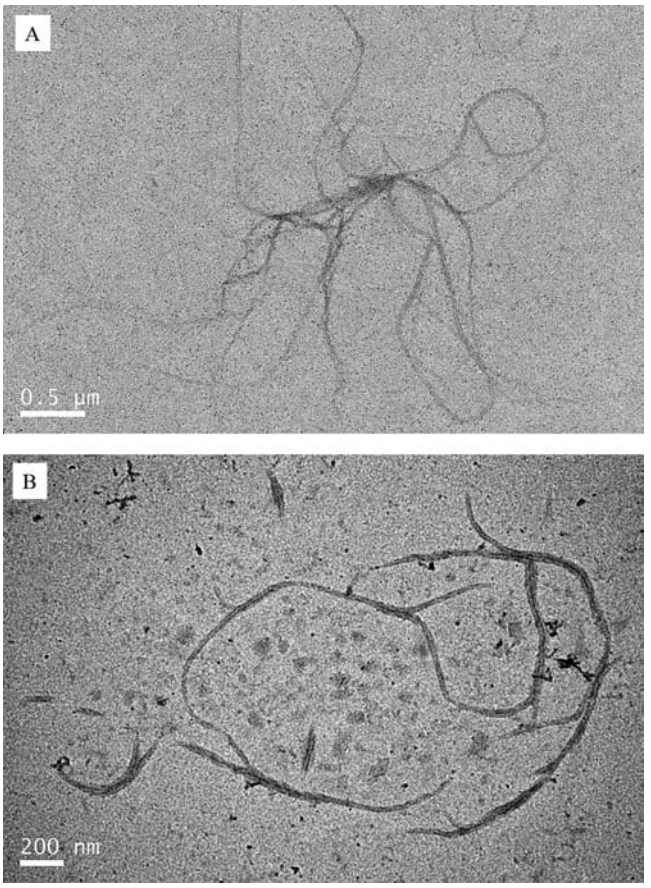

Figure 5. TEM images of APPS in sodium dodecyl sulfate (SDS) solution.

As shown in Figure 6D, the linear relationship and the fitted lines are nearly parallel in the conversion rate range of 0.3−0.7, which indicates approximate activation energies at different conversions and consequently implies the possibility of a single-reaction mechanism (or the unification of multiple-reaction mechanisms). However, the reaction mechanism could be different in the ranges of lower and higher conversion periods due to unsatisfied parallel lines at $\alpha < 0.3$ and $\alpha > 0.7$. The apparent activation energy (E_a) was thereby calculated to be 226.5 kJ/mol as listed in Table S2 in the Supporting Information, which was based on the FWO method at a conversion range from 0.3 to 0.7 with 0.1 increment (Figure 6D). The experimental pre-exponential factor (A) was obtained by the compensation effect relationship as eq 3 (Table S3). The compensation parameters of a and b were obtained from a plot of ln$A$ versus E_a using the Coats−Redfern equation (eq 4) (Figure S4).

The major decomposition occurred in temperature range of 215.6−328.0 °C (Figure 6A), which could be caused by the

Table 2. Thermal Degradation Characteristics of APPS[a]

sample	$T_{o\,\beta\to0}$ (°C)	WL_o (%)	$T_{p\,\beta\to0}$ (°C)	WL_p (%)	$T_{s\,\beta\to0}$ (°C)	WL_s (%)	$T_s - T_o$ (°C)	$WL_s - WL_o$ (%)
APPS	215.6	1.43	256.7	12.80	328.0	52.55	112.4	51.12

[a]Data are the mean temperatures from three different heating rates. T = temperature, WL = weight loss, subscript: o = onset, p = DTG peak, s = shift, $\beta\to0$ = extrapolated values to the heating rate of 0 °C/min.

degradation of polysaccharide structure.[20] Moreover, the E_a value of APPS was determined to be 226.5 kJ/mol, which revealed the good thermal stability of this pectic polysaccharide. The apparent activation energy (E_a) and pre-exponential factor (A) are the important parameters of the Arrhenius equation, where E_a might indicate a minimum energy requirement to initiate the decomposition reaction. These thermal decomposition characteristics are very important for the evaluation of the thermal stability of polysaccharides in their further application.

Anti-Inflammation Effects of APPS. The anti-inflammatory bioactivity of APPS was evaluated by determining its suppression effect of the IL-1β, IL-6, and COX-2 mRNA expressions in RAW 264.7 macrophage cells stimulated by LPS. As shown in Figure 7, the greater concentration of APPS was associated with a stronger suppression for IL-1β and IL-6 mRNA expressions, whereas increasing APPS concentration from 10 to 50 μg/mL increased the COX-2 mRNA expression. The results indicated the potential application of APPS in food and medicine fields to reduce the risk of chronic inflammatory diseases.

In summary, a pectic polysaccharide (APPS) was purified from the hot alkali extract of alfalfa stems and characterized for its chemical and molecular structures. APPS was composed of repeating units of →2)-α-L-Rha*p*-(1→4)-α-D-Gal*p*A-(1→ as the backbone and substituted at C-4 of Rha*p* with L-arabinosyl and D-galactosyl side chains, with a degree of branching value of 12%. The thermal stability and decomposition properties of APPS revealed the primary decomposition temperature range of 215.6−328.0 °C with an apparent activation energy (E_a) and a pre-exponential factor (A) of 226.5 kJ/mol and 2.10×10^{25}/s, respectively. APPS also showed a significant anti-inflammatory effect on LPS-stimulated RAW 264.7 mouse macrophage cells for suppression of IL-1β, IL-6, and COX-2 gene expressions. Compared with previous studies of alfalfa pectin,[5] the molecular structure of APPS was identified in combination with chemical characterization and morphological observation for the first time. The anti-inflammatory effect was also performed on a purified alfalfa pectic polysaccharide using an in vitro model. In addition, APPS showed a stronger potential anti-inflammatory effect compared with the pectic polysaccharide isolated from celery stalks.[54] Moreover, thermal degradation

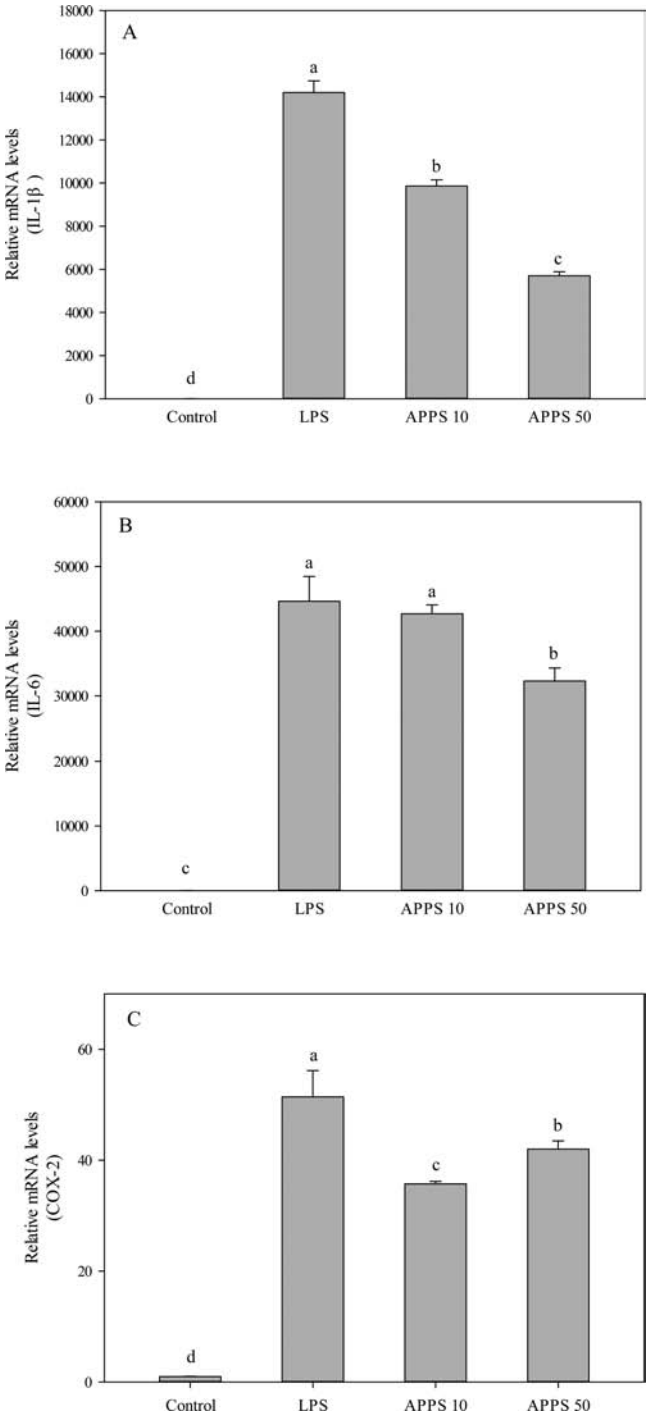

Figure 7. Effects of APPS on (A) IL-1β, (B) IL-6, and (C) COX-2 mRNA expressions in LPS -stimulated RAW 264.7 mouse macrophage cells. LPS represents cells treated with LPS at a final concentration of 10 ng/mL; APPS 10 and APPS 50 stand for the final treatment concentrations of APPS at 10 and 50 μg/mL followed by LPS inducement, respectively. The vertical bars represent the standard deviation (n = 3) of each data point. Different letters (a–d) represent significant differences (P < 0.05).

behavior was estimated to illustrate the stability for pectic polysaccharides from alfalfa for the first time. These results indicated the potential application of APPS in functional foods and dietary supplement products.

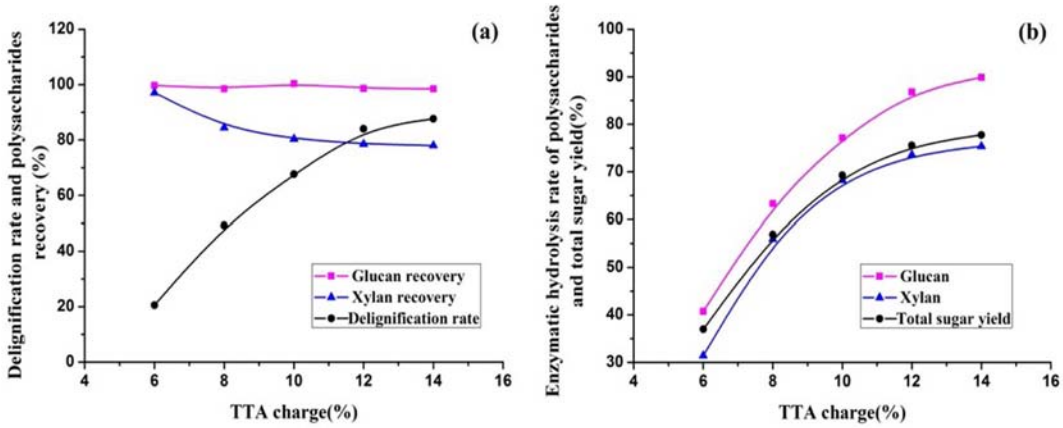

Figure 1. Effect of TTA charge on delignification rate, polysaccharide recovery, enzymatic hydrolysis rate of polysaccharides, and total sugar yield.

MATERIALS AND METHODS

Materials. The corn stover used in the present study was obtained from Qingdao, Shandong Province, China. Air-dried corn stover was milled using a plant grinder, and the particles between the sizes of 5 and 40 mesh were collected. The screened corn stover was stored in sealed plastic bags at room temperature.

Sodium hydroxide and sodium sulfite were purchased from Sinopharm Chemical Reagent Co. Ltd. The enzymes used for the enzymatic hydrolysis were Celluclast 1.5L (cellulase, enzyme activity 192 FPU/mL) and Novozyme 188 (β-glucosidase, enzyme activity 741 IU/mL) provided by Sigma-Aldrich China Inc. The enzymes activities were determined according to the method reported by Ghose.[22] All chemicals and enzymes were used as received.

Pretreatment of Corn Stover. The pretreatment of corn stover (50 g oven-dried) was carried out in a pot with a total volume of 1.5 L. Corn stover was subjected to pretreatment using sodium hydroxide (NaOH)−sodium sulfite (Na_2SO_3) with total titratable alkali charge of 6%, 8%, 10%, 12%, and 14%. The molar ratio of NaOH−Na_2SO_3 was 1:1. The ratio of pretreatment liquor to corn stover (oven-dried) charge was 4:1, 6:1, 8:1, 10:1, and 12:1, respectively. Both solution and corn stover were heated to the desired temperature in 20 min from 30 °C. The pretreatments were done at five levels in the range of 120−160 °C at holding time ranging from 10 to 50 min. After pretreatment, the bombs were cooled in water to room temperature. The solids were collected and washed with deionized water to remove residual chemicals and dissolved compounds and then used for determination of total solid, lignin, and polysaccharides prior to enzymatic hydrolysis.

PFI Refining. The pulp pretreated with alkali was beaten in a PFI mill. Beating conditions were as follows: pulp consistency 10%, beating gap 0.3 mm, revolutions in the range 1500−6000 rpm and increments of 1500 revolutions. The refined pulp was collected and stored in the refrigerator.

Enzymatic Hydrolysis. Enzymatic hydrolysis of the substrates was conducted on a 0.4 g (oven-dried) basis in a serum bottle with substrate consistency of 2% (W/V) at 50 °C using an incubator shaker at 95 rpm for 48 h. Sodium citrate buffer (pH = 4.8) was added to maintain the pH at 4.8, while 0.02% sodium azide was used in the mixture to inhibit the microbial infections. An enzyme cocktail of cellulase (20 PFU/g of dry biomass) and β-glucosidase (10 IU/g of dry biomass) was used for enzymatic hydrolysis.

Analysis Methods. *Chemical Component Analysis.* Cellulose, hemicellulose, and lignin contents of corn stover were determined according to the procedures described by National Renewable Energy Laboratory (NREL).[23] Acid and enzymatic hydrolysates were examined by high performance liquid chromatography (HPLC; model 1200, Agilent, USA). The HPLC system was equipped with a Bio-Rad Aminex HPX-87H column (300 mm × 7.8 mm) and refractive index detector. The column was run at 55 °C with sulfuric acid (0.005 M) as a mobile phase (0.5 mL/min), and the quantitative analysis was carried out using external standard calibration. Duplicate experiments were conducted, and the mean values were reported.

FTIR Analysis. The FTIR spectra of the untreated and pretreated corn stover were determined on a FTIR spectrometer (Nicolet 6700, Thermo Fisher Scientific Inc.). The samples were prepared by KBr pellet (the ratio of the samples to the KBr was 1:100). The resolution of the spectra was 4 cm^{-1} in the range of 400−4000 cm^{-1}, and 32 scans were taken for per sample.

SEM Analysis. The SEM analyses of the samples were conducted by scanning electron microscopy (S-4800, Hitachi, Japan) at different magnifications. The oven-dried dried samples were coated with platinum and treated with accelerating voltage of 3.0 kV.

RESULTS AND DISCUSSION

Optimization of the Alkali Dosage. The rates of delignification and polysaccharide retention after different pretreatments are presented in Figure 1a. Lignin is one of the major barriers for the enzymatic hydrolysis of lignocellulosic biomass. The efficiency of enzymatic hydrolysis was usually improved by the lignin removal.[24−26] The removal of lignin not only exposes more accessible cellulose but also reduces the strong surface interaction between lignin and enzyme. Figure 1a shows that the removal of lignin was improved by increasing the total titratable alkali (TTA) charge. When TTA charge was 14%, the removal of lignin was as high as 87.66%. Sodium hydrate has a certain effect on delignification. Sulfite also plays an important role in alkaline sulfite pretreatment process. The nucleophilic sulfite (SO_3^{2-}) in the pretreatment liquor lead to the sulfonation of lignin, as well as the break of α-benzyl ether linkages, α-alkyl ether linkages, and β-benzyl ether linkages on phenolic lignin units.[18] One can also observe that glucan and xylan decrease with the increase of TTA charge, and the degradation of glucan is less than that of xylan. One can infer that cellulose is more stable than hemicellulose under the alkaline sulfite pretreatment condition because of its high degree of polymerization and crystalline nature.[27] This is the main disadvantage of alkali-based pretreatment at present. So how to promote the deprivation of lignin and maximum preservation of hemicellulose will be an important research topic.

The enzymatic hydrolysis rates of polysaccharides and total sugar yield at different chemical charge are illustrated in Figure 1b. Undoubtedly, higher chemical charge will enhance the enzymatic hydrolysis rates of polysaccharides. When the TTA charge increased from 6% to 14%, the enzymatic hydrolysis rates of glucan and xylan increased more than one times. This

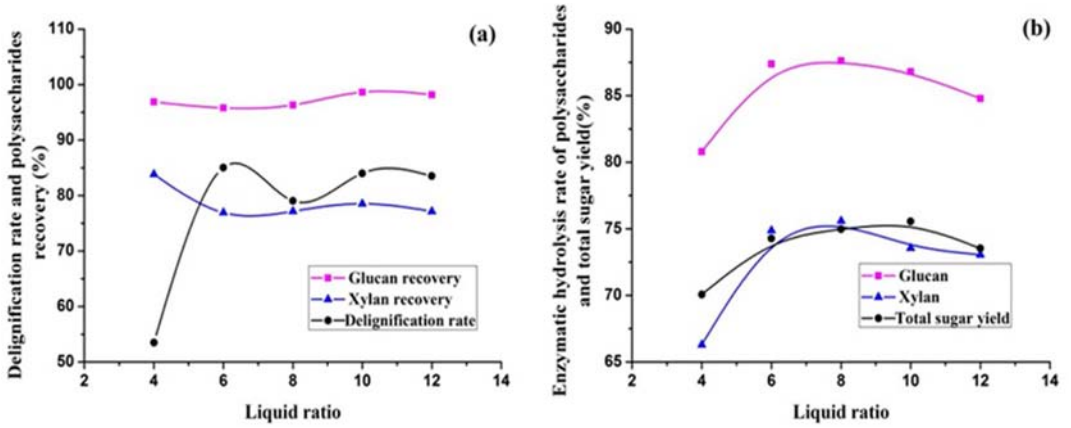

Figure 2. Effect of liquid/solid ratio on delignification rate, polysaccharide recovery, enzymatic hydrolysis rate of polysaccharides, and total sugar yield.

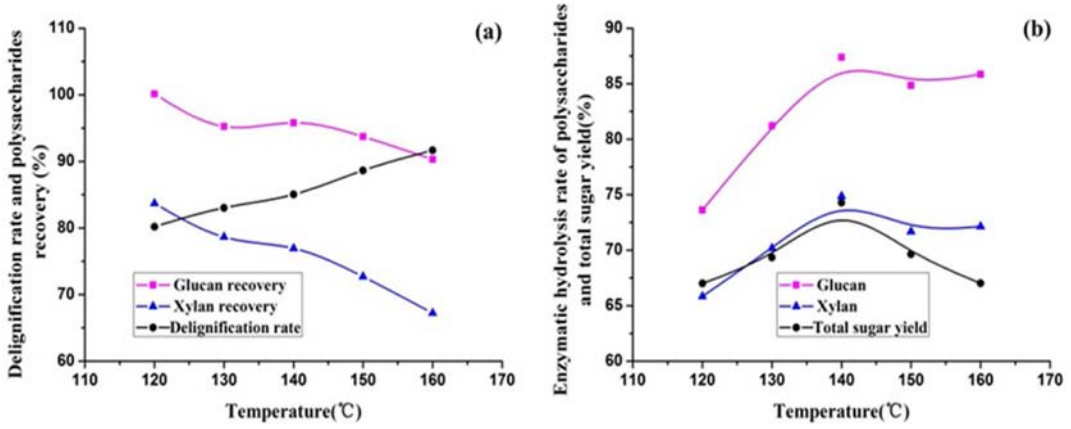

Figure 3. Effect of temperature on delignification rate, polysaccharide recovery, enzymatic hydrolysis rate of polysaccharides, and total sugar yield.

results from the destruction of cell walls and the dissolution of hemicellulose and lignin. It is obvious that the total sugar yield showed a rapid increase trend with the increase of alkali dosage and reached the maximum value when the TTA charge was 12%. However, the total sugar yield did not increase when we continued to increase the TTA charge to 14%. This was because the retention rate of glucan and xylan decreased in different degrees though the enzymatic hydrolysis rates of glucan and xylan increased 3.52% and 2.45%, respectively, when we continued to increase the TTA charge. Based on the data from Figure 1, one can conclude that 12% is the optimal dosage of chemicals for alkaline sulfite pretreatment.

Optimization of the Liquid/Solid Ratio. Figure 2a shows the impacts of liquid/solid ratio on the delignification rates and polysaccharide retention when TTA charge is 12%. About 85% of the lignin in the raw material was removed when the liquid/solid ratio was 6:1. However, when liquid/solid ratio was 4:1, the removal of lignin was only 53.48%. A high concentration of lignin in the pretreatment liquid can inhibit the dissolution of lignin in the raw material. But if the liquid/solid ratio is too high, the high liquid/solid ratio will reduce the concentration of chemicals and increase the difficulty of subsequent processing. In addition, the data showed that the role of liquid/solid ratio on polysaccharide retention is not significant.

According to the curves of enzymatic hydrolysis rates of polysaccharides and total sugar yield in Figure 2b, some details can be seen. With the increase of liquid/solid ratio, enzymatic hydrolysis rates of polysaccharides increased first and then decreased, and there was little difference when liquid/solid ratio ranged from 6 to 10. Total sugar yield showed the same trends. For example, the total sugar yields were 70.07% and 73.53%, respectively, when liquid/solid ratio was 4:1 and 6:1. In addition, the total sugar yield was only 74.28−75.56% when liquid/solid ratio ranged from 6 to 10. Therefore, the liquid/solid ratio of 6:1 was optimal.

Optimization of Temperature. Figure 3a shows the effect of temperature on the delignification rates and polysaccharide retention under the conditions of TTA charge at 12% and liquid/solid ratio of 6:1. The data show that lignin removal increased with the pretreatment temperature. For example, the removal of lignin increased from 80.19% to 91.66% when the temperature rose from 120 to 160 °C. This indicates that pretreatment temperature plays an important role in delignification. However, the retention of polysaccharides reduced with increasing pretreatment temperature. The degradation of xylan is higher than that of glucan in the same pretreatment conditions. This demonstrates that hemicellulose in corn stover is easier to degrade than cellulose in alkaline sulfite pretreatment.

The enzymatic hydrolysis rates of polysaccharides, increased first and then decreased, can be seen from Figure 3b. It is obvious that the enzymatic hydrolysis rate at 140 °C is much higher than that at 120 °C. This is mainly caused by the limited removal of hemicellulose and lignin at relatively low temper-

J. Agric. Food Chem. 2015, 63, 3229−3234

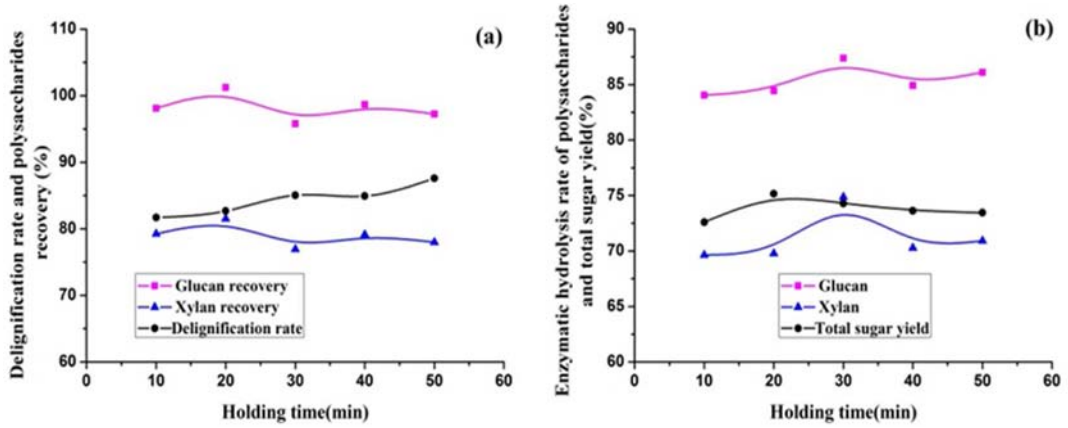

Figure 4. Effect of holding time on delignification rate, polysaccharide recovery, enzymatic hydrolysis rate of polysaccharides, and total sugar yield.

ature, which does not provide a loose enough structure of corn stover.[28] According to the curve of total sugar yield of pretreated corn stover in Figure 3, the highest sugar yield is obtained at 140 °C, which is 74.28%. Furthermore, temperature higher than 140 °C was not necessary nor recommended because higher temperature consumes more energy. Hence, 140 °C was recommended as the optimum pretreatment temperature.

Optimization of the Holding Time. In order to investigate the effect of holding time on delignification rates, polysaccharide retention, enzymatic hydrolysis rates, and total sugar yield, the pretreatments were done at holding time ranging from 10 to 50 min. Figure 4a shows the effect of holding time on and polysaccharide retention. One can observe that the delignification rates were increased with the increase of the holding time while the polysaccharides retention decreased. As seen in Figure 4b, increasing the holding time from 10 to 50 min only led to 2% increase in the enzymatic hydrolysis rates of glucan. When holding time was more than 20 min, the total sugar yield decreased because of the reduction in polysaccharide retention. The holding time of 20 min can obtain a better effect.

Comparison of Pretreatment between Alkaline Sulfite and Sodium Hydroxide. Optimum pretreatment conditions were obtained through the above optimization experiments: total titratable alkali of 12%, liquid/solid ratio of 6:1, temperature of 140 °C, and holding time of 20 min. Figure 5 shows the comparison between alkaline sulfite pretreatment and sodium hydroxide pretreatment under the optimum conditions. Delignification rates and polysaccharide retention rates of corn stover pretreated with alkaline sulfite are higher than those when we used sodium hydroxide alone. This is because the nucleophilic sulfite (SO_3^{2-}) and bisulfite (HSO_3^-) lead to the sulfonation of lignin. Sulfonation makes the lignin more hydrophilic. In addition, a lower sodium hydroxide charge reduces the degradation of cellulose and hemicellulose, which enhances the retention of carbohydrate. For example, compared with sodium hydroxide pretreatment, the retention of xylan is improved by more than 10%.

Figure 6 shows the enzymatic hydrolysis rates and total sugar yield of the corn stover pretreated by two different methods and then beaten with a PFI mill. One can observe that both the enzymatic hydrolysis rate of polysaccharides and total sugar yield are improved with the increase of revolutions. The shearing action in mechanical refining results in more internal delamination and surface fibrillation, which will disrupt the

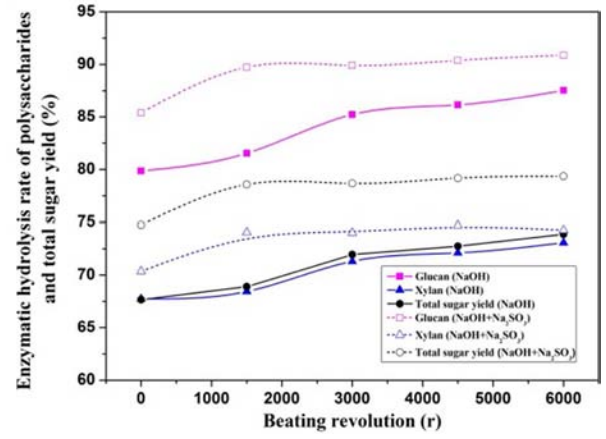

Figure 6. Effect of refining on enzymatic hydrolysis of polysaccharides and total sugar yield.

crystalline structure of the cellulose microfibrils, increase the accessible specific areas, and lead to a more efficient biomass digestibility.[29] Xu et al. found that beating degree of PFI refined substrates was strongly linear with final total sugar yields for the given pretreated corn stover.[30] Furthermore, it can achieve a relatively high enzymatic hydrolysis rate of polysaccharides with PFI refining at 1500 revolutions, and the total sugar yield was 78.58%. Compared with the sodium hydroxide pretreatment, the total sugar yield was increased by about 9.68%.

Mechanism Analysis for the Improvement of Corn Stover Enzymatic Hydrolysis Rate. *FTIR Analysis.* FTIR spectra of untreated and pretreated corn stover are shown in Figure 7. In particular, all the spectra are dominant by signals at

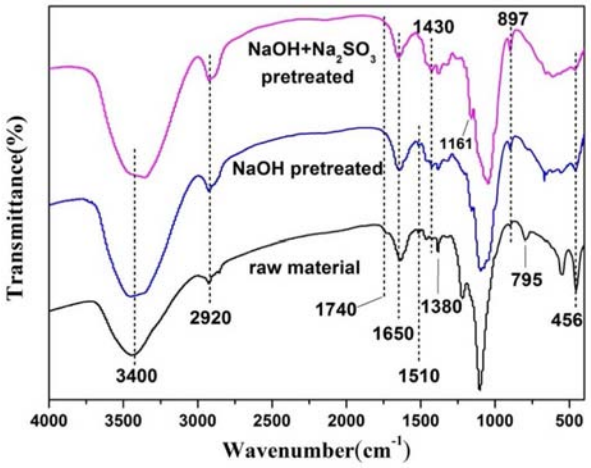

Figure 7. FTIR spectra of untreated and pretreated corn stover.

3400 and 2920 cm^{-1} due to the stretching vibrations of O−H and C−H corresponding to the aliphatic moieties in lignin and polysaccharides.[31] A shoulder at 1740 cm^{-1} is attributed to the acetyl and uronic ester groups on hemicellulose or linkages in lignin and ester hemicellulose feurilic and p-coumaric acid carboxylic groups.[32] The band at 1740 cm^{-1} being almost absent indicated that the pretreatment nearly cleaved this ester band from the hemicellulose and lignin. The lignin-associated peaks at 1510 and 795 cm^{-1} that were assigned to aromatic ring stretch vibrations in lignin were decreased, indicating the removal of the lignin after pretreatment. Furthermore, the band at 1510 cm^{-1} after alkaline sulfite pretreatment almost vanishes, which also indicates that the alkaline sulfite pretreatment is more efficient than sodium hydroxide on delignification. The carbohydrate-related peaks at 1380 and 1161 cm^{-1} were assigned to the C−H deformation in carbohydrate and C−O−C vibration in cellulose and hemicellulose.[33] After pretreatment, the intensity of these bands was decreased due to the degradation of cellulose and hemicellulose, and after sodium hydroxide pretreatment, the intensity decreased more severely than after alkaline sulfite pretreatment, which corresponded to the results obtained by sugar analysis. In addition, the peak at 897 cm^{-1} was associated with the β-glucosidic bonds of cellulose, and its increase after pretreatment was also because of the removal of lignin and hemicelluloses.[34] As can be seen from Figure 7, the band at 897 cm^{-1} after alkaline sulfite pretreatment is stronger than that after sodium hydroxide pretreatment, which indicated that the degradation of lignin and hemicellulose were relatively stronger in alkaline sulfite pretreatment. The decrease of the peak at 465 cm^{-1} (Si−O) was due to the removal of ash.

SEM Analysis. Pretreatment affects not only the chemical composition of the corn stover but also the physical appearance of the corn stover at the microscopic level. The scanning electron micrograph (SEM) images of untreated and pretreated corn stover are shown in Figure 8 at different magnifications. The surface of the corn stover that is untreated shown in Figure 8a,b is smooth and contiguous without pores. The tissue surface and cell wall were altered after pretreatment. Figure 8c,d

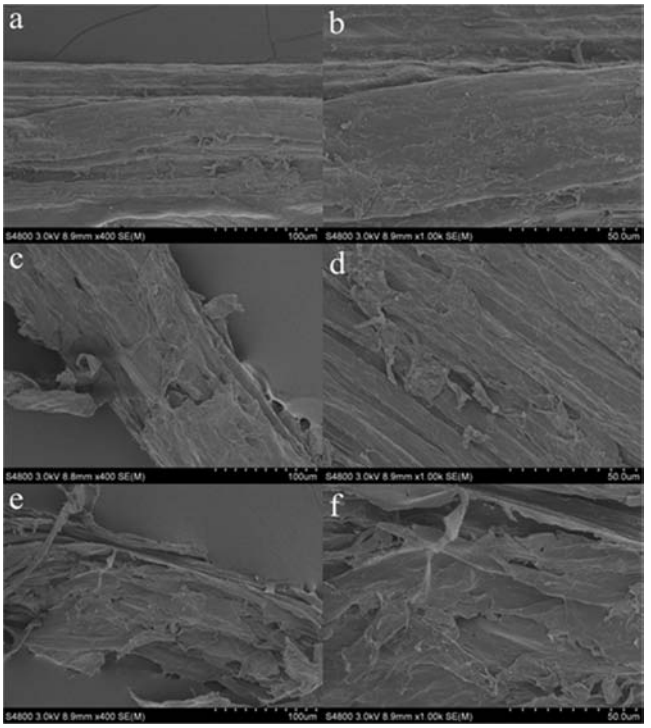

Figure 8. SEM of untreated and pretreated corn stover: (a, b) raw corn stover without pretreatment; (c, d) samples pretreated with NaOH pretreatment; (e, f) samples pretreated with alkali sulfite pretreatment. Pretreatment was performed at 140 °C with the liquid/solid ratio of 6 and 12% alkali.

shows images of corn stover after NaOH pretreatment. The smooth, contiguous surface of untreated stover has been perforated by the pretreatment processes. Alkaline pretreatments disrupt the lignocellulosic structure by dissolving lignin and hemicellulose. Treatment with Na_2SO_3 significantly alters the fibrillar structure. Coarse surfaces and porous areas are very evident. The microfibrils are separated from the initial connected structure and fully exposed. This would increase the external surface area and the porosity of the biomass.[35] These pores may increase the enzyme accessible surface area, which increases the enzyme digestibility of the corn stover.[36]

Conclusion. The optimum conditions of alkaline sulfite pretreatment for corn stover were as follows: total titratable alkali of 12%, liquid/solid ratio of 6:1, temperature of 140 °C, and holding time of 20 min. The delignification rate and the total sugar yield at the optimal condition were 82.45% and 74.73%, respectively, which was higher than those under only NaOH pretreatment, 79.20% and 67.67%. The corn stover pretreated under the optimum pretreatment conditions was beaten by PFI for 1500 rotations. After beating, the total sugar yield was 78.58%. Compared with 1500 rotations of PFI beating after sodium hydroxide pretreatment at the same amount of total titratable alkali, the total sugar yield improvement rate was 14.05%. Furthermore, lignin dissolved in the alkaline sulfite pretreatment exists in the form of lignosulfonate, which is a potential high-value coproduct. Thus, alkaline sulfite pretreatment is a suitable process for corn stover conversion to fermentable sugars.

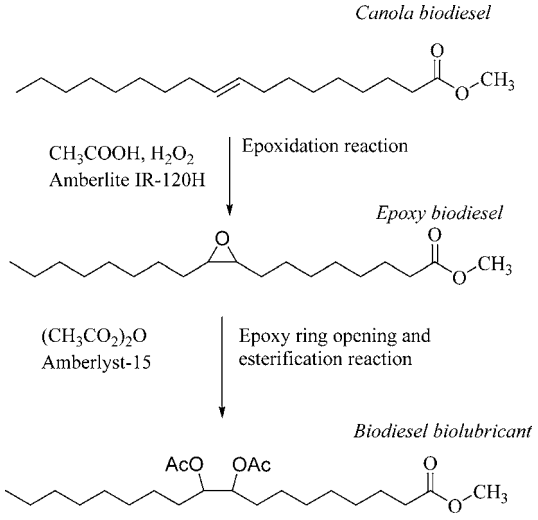

Figure 2. Reaction scheme for the synthesis of biodiesel derived biolubricant.

out using Amberlite IR-122 resin as catalyst.[18] Also, Amberlite IR-120H resin was found to be active catalyst for the epoxidation of polyunsaturated canola triglycerides.[12]

A few studies have been reported on the vicinal diacylation of epoxidized vegetable oils to obtain the product biolubricant. Hwang and Erhan[19] studied epoxy ring-opening by various linear and branched alcohols. Adhvaryu et al.[20] synthesized acylated soybean oil derivatives (biolubricants) using different carboxylic anhydrides and pyridine as catalysts. The synthesis method reported by Salimon et al.[21] for the acylation of ricinoleic acid includes sulfuric acid as a catalyst. Limited literature reports are available on the application of heterogeneous catalysts for the simultaneous oxirane ring-opening and diacylation of epoxidized triglycerides in vegetable oils to obtain biolubricant (i.e., esterified product). Application of solid metal oxide catalysts for the preparation of biolubricants from vegetable oils not only promote green technology but also minimize workup procedures to separate the product and the catalyst can be reused several times.[22,23]

The present investigation deals with the synthesis of biolubricants from canola oil and canola biodiesel by using heterogeneous catalysts (Figures 1 and 2). As per our knowledge, this report finds novelty with the preparation of

new value-added product biolubricant from canola biodiesel and the characteristic lubricity properties associated with it in comparison to canola oil biolubricant.

EXPERIMENTAL SECTION

Chemicals and Reagents. Edible grade canola oil (Loblaws Inc. Montreal, Canada), canola biodiesel (Milligan Biofuels Inc., Saskatoon, Canada), glacial acetic acid (reagent grade), 30 wt % hydrogen peroxide (GR grade) (EMD Chemicals Inc., Darmstadt, Germany), Amberlite IR-120H (Sigma-Aldrich, St. Louis, MO), Amberlyst-15 (Sigma-Aldrich, St. Louis, MO), Wijs' solution (VWR, San Diego, CA), ethyl acetate, and 33 wt % hydrobromic acid in acetic acid (EMD Chemicals Inc., Montreal, Canada) were purchased.

Analytical Methods. The iodine value (% unsaturation) analysis was carried out as per the AOCS Cd 1−25 standard method. The amount of epoxy content (oxirane oxygen) in the oil was calculated using AOCS Cd 9-57 volumetric titration method. Each experiment was repeated thrice and found to have ±3% error in the conversion. Equations 1 and 2 give the appropriate formulas employed for determining the change in the percentage unsaturation and the epoxy content in the oils during the course of the reaction.

$$\text{oxirane oxygen content} = \frac{\text{mL of HBr consumed} \times N \times 1.60}{\text{mass of sample, g}} \quad (1)$$

Where, N stands for HBr solution normality.

$$\text{epoxy conversion (\%)} = \frac{\text{oxirane value at O h} - \text{oxirane value at time } (t)}{\text{oxirane value at O h}} \times 100 \quad (2)$$

Kinematic viscosity, cloud point, and pour point were measured as per the ASTM methods. The oxidative stability measurements were carried out by AOCS methods. Lubricity of the products was performed according to ASTM methods. Thermogravimetric analysis was carried to determine the weight loss of materials. The details of the analysis procedure and equipment used for the determination of tribological properties of biolubricants are described in the literature.[6,23]

EXPERIMENTAL SETUP AND PROCEDURE

Epoxidation. The unsaturated fatty acids present in the feed stocks such as canola oil and canola biodiesel were epoxidized by using hydrogen peroxide and acetic acid.[6] A sample of 22.6 g of canola oil/biodiesel, acetic acid, and Amberlite IR −120H (22 wt % w.r.t to g of feed stock taken) were placed in a three neck round-bottom flask and maintained at 65 ± 2 °C. Then, aqueous hydrogen peroxide (30 wt %) was added with a molar ratio of 1.5:1 (unsaturation in canola oil/canola biodiesel: H_2O_2). The reaction was continued at 65 ± 2 °C for 8 h with rapid stirring. The oil phase was extracted using ethyl acetate as solvent and was separated by evaporation. The conversion was assessed by the iodine value (7.5 and 7.6 g of I_2/100 g for canola oil and biodiesel, respectively), oxirane content (5.6 and 5.8%), and glycol

content (0.08 and 0.06 mol/100 g) of canola oil and canola biodiesel, respectively. Further, the product formation was also confirmed by spectroscopic techniques such as ^{1}H NMR, ^{13}C NMR, and FT-IR.

Epoxy Ring-Opening of Epoxidized Canola Oil/Epoxidized Biodiesel. The oxirane ring-opening and diacylation reactions were performed in a single pot. Typically, 30.0 g of epoxidized canola oil/epoxidized biodiesel, 45 g of acetic anhydride, and Amberlyst-15 (10 wt % of epoxidized product) were mixed in the three neck round-bottom flask and stirred for 15 h at 130 °C. The percentage epoxy conversion was measured periodically by the oxirane content method (eq 1), and the product formation was also identified with FTIR, ^{1}H NMR, and ^{13}C NMR analysis.

RESULTS AND DISCUSSION

Characterization of Products. *NMR Spectroscopy.* Figure 3 represents ^{1}H NMR spectra of starting materials and products. The olefinic hydrogens (H−C═C−H) of canola oil and canola biodiesel showed a chemical shift between 5.2 and 5.4 ppm. These proton shifts were found to be absent in the epoxidized canola oil and epoxidized canola biodiesel, indicating that all olefinic groups are converted to the epoxy group. ^{1}H NMR spectra of epoxidized canola oil and epoxidized canola biodiesel showed a chemical shift between 2.7 and 3.1 ppm due to the vicinity of epoxy oxygen.[12] The CH_2 proton α-to epoxy group showed a chemical shift at 1.9 ppm, while the β-CH_2 proton has a chemical shift at 1.6 ppm. The terminal $-CH_3$ proton indicates the chemical shift at 0.8−1.0 ppm. ^{1}H NMR spectra of canola oil biolubricant and biolubricant from canola biodiesel show a chemical shift at 5.0 ppm, which represents both CH− protons associated with the carbonyl group. The D_2O exchanged ^{1}H NMR spectrum of canola oil biolubricant, and biolubricant from canola biodiesel confirmed the absence of hydroxyl proton in the molecule which indicates the formation of diacylated product after the epoxy ring-opening step. Figure 3 confirmed the presence of methine proton of glycerol backbone by the signal appearing between 5.2 and 5.4 ppm and also the presence of $-COOCH_3$ proton that appeared at 3.7 ppm, which is characteristic of canola biodiesel.

Figure 4 represents ^{13}C NMR spectra of starting materials and products. Canola oil and canola biodiesel showed the signal appearing between 120 and 140 ppm due to the existence of olefinic carbon atoms. Epoxidized canola oil and epoxidized canola biodiesel exhibited no signal between 120 and 140 ppm, indicating the conversion of the olefinic carbon (−C═C−) to epoxy linkage, given by the signal appearing between 53 and 58 ppm. Biolubricant from canola oil and biolubricant from canola biodiesel showed no signal between 53 and 58 ppm, which indicates the conversion of epoxy linkage to ester linkage. This is indicated by a new signal at 170 ppm, which is attributed to carbonyl carbon. The presence of glycerol backbone in canola oil biolubricant is indicated by the shift at 62 and 68 ppm for α and β carbon atoms of the glycerol backbone, respectively. Figure 4 also confirmed the presence of $-CH_3$ carbon of $-COOCH_3$ that appeared at 51 ppm, which is characteristic of canola biodiesel. Therefore, the formation of canola oil biolubricant and canola biodiesel-derived biolubricant is confirmed by the NMR spectra.

FT-IR Spectroscopy. FT-IR transmittance spectra of the products and reactants were recorded to confirm the formation of biolubricant on the basis of functional groups present. FT-IR spectra are shown in Figure 5. Canola oil and canola biodiesel show the bands at 3007 and 738 cm^{-1}, which are due to the bending and stretching vibrations of H−C═C−H. No bands appeared at 3007 and 738 cm^{-1} indicating that −C═C− bonds in the oil are converted into epoxide. Epoxy band was found to appear at 831 cm^{-1}.[24] The FT-IR spectra of biolubricant from canola oil and biolubricant from canola biodiesel have no band at 831 cm^{-1}, indicating the absence of the epoxy group. However, two new bands appeared at 725 and 604 cm^{-1}, with also a corresponding increased intensity of the band at 1750 cm^{-1}. This confirmed the ester structure present in the products. Hence, FT-IR analysis indicated the formation of biolubricant from canola oil and canola biodiesel which was also confirmed by NMR results.

Low Temperature Properties. The cold flow temperature properties of the biolubricants from canola oil and canola biodiesel were represented by the cloud point and pour point. These properties of lubricants derived from vegetable oil are poor, hence, making it difficult to use in cold countries. It can be improved by reducing the aliphatic carbon chain length. Table 1 represents the low-temperature properties of epoxidized canola oil, epoxidized biodiesel, biolubricant from canola oil, and biolubricant from canola biodiesel. The epoxidized canola oil and epoxidized canola biodiesel have

Table 1. Tribological Properties of Products

entry	product	low temperature property: cloud point (°C)	low temperature property: pour point (°C)	kinematic viscosity (cSt): 40 °C	kinematic viscosity (cSt): 100 °C	oxidative stability (OIT) h
1	epoxidized canola oil	15	9	–	–	–
2	epoxidized canola biodiesel	6	0	–	–	–
3	biolubricant from canola oil	−3	−9	0	670	56.1
4	biolubricant from canola biodiesel	−12	−18	116	19	76.3

the cloud points of 15 and 6 °C and the pour points of 9 and 0 °C, respectively. It was found that cloud and pour point of epoxidized biodiesel are low as compared with epoxidized canola oil, which can be due to the presence of less number of aliphatic carbon atoms present in epoxidized biodiesel. Hence, an increase in the aliphatic carbon chain length reduced the low-temperature properties. Also, these low-temperature properties can be improved by adding the ester linkage in the epoxidized molecules, which promote steric hindrance. The cloud points of biolubricant from canola oil and biolubricant from canola biodiesel were found to be −3 and −12 °C, while pour points were −9 and −18 °C, respectively. Hence, it elucidates that biolubricant obtained from biodiesel has better low-temperature properties as compared to biolubricant obtained from canola oil, which can be due to the less steric hindrance. Hence, biolubricant from canola biodiesel is superior for low-temperature applications and has better future prospects for the automotive industry as compared to biolubricant from canola oil.

Viscosity. The viscosity of the fluid defines the effectiveness of the lubricant to lubricate the contact surface of the metals. The kinematic viscosity of canola biolubricant and biodiesel biolubricant were measured at 40 °C and found to be 0 and 116 cSt, whereas at 100 °C, it was found to be 670 and 19 cSt (Table 1). The viscosity index for biolubricant from canola biodiesel was found to be 185. High viscous nature of canola oil biolubricant is because of the addition of ester linkage in the oil at the unsaturation. The increase in the viscosity is also attributed to the intramolecular hydrogen bonding of the ester linkages.[25] Canola oil biolubricant is highly viscous and can be used as a lubricant for high temperature, high load, and high-speed operations like heavy machinery. However, biolubricant from canola biodiesel is less viscous as compared with biolubricant from canola oil. It might be because of less number of aliphatic carbon present in the biolubricant derived from canola biodiesel, which creates less steric hindrance and fewer hydrogen bondings as compared with the biolubricant derived from canola oil (Figure 2). Therefore, biolubricant derived from biodiesel can be used as lubricant for automobiles at low temperature. Hence, it can be anticipated that the biolubricant from biodiesel has a better future prospect for automobile sector.

Friction and Anti-Wear Properties. Lubricity testing was performed according to the report by Sripada et al.[26] All the samples were tested twice, and the average value is reported. The wear scar diameter of standard diesel sample was found to be 600 μm. With the addition of 1% of canola oil biolubricant to the standard diesel sample, the diameter of the wear scar was found to reduce to 130 μm, while 1% of biolubricant derived from canola biodiesel integrated in the standard diesel sample showed a wear scar diameter of 95 μm. It was noticed that canola oil biolubricant resulted in more wear scar on the steel test ball as compared with biolubricant from canola biodiesel (Figure 6). This can be due to the presence of more steric hindrance and intramolecular hydrogen bonding present in canola biolubricant, which increases the viscosity and hence decreases the solubility in the standard diesel sample and resulted in more wear scar diameter (130 μm). Furthermore, a lower number of aliphatic carbon atoms is present in biodiesel biolubricant as compared with canola biolubricant, which makes it less viscous and less nonpolar and, hence, increases the solubility in diesel fuel and results in less wear scar (95 μm). The better lubricity property of biodiesel biolubricant can also be explained by the presence of ester oxygen moieties in 1, 9, and 10 positions, which are free of hydrogen bonding and help to reduce the friction by developing the antifrictional film on metal surfaces.[27] Table 2 indicates that with the increase in lubricant content in pure diesel fuel, the wear scar on the steel test ball is decreased.

Table 2. Wear Scar Diameter of Bio-lubricants Diluted in Low Lubricity Diesel

biolubricant added in pure diesel (%)	wear scar diameter (μm): biolubricant from canola oil	wear scar diameter (μm): biolubricant from biodiesel
1	130	95
2	125	90

epoxidized biodiesel, and biodiesel biolubricant was studied by thermo gravimetric differential thermal analyzer (TG/DTA). The detailed analysis procedure is described in the literature.[26] The graphs of weight loss against temperature are shown in Figure 7. It is clear from the graph that canola oil, epoxidized canola oil, and canola biolubricant are thermally stable below 305 °C. Maximum weight loss (90−95% wt) was observed in all these three materials at the temperatures 460, 461, and 530 °C, respectively. However, canola biodiesel, epoxidized canola biodiesel, and biodiesel biolubricant are found to be thermally stable below the temperatures 305, 160, and 194 °C, respectively, and about 90−95% weight loss was found for each sample at the temperatures 462, 251, 370 °C, respectively (Table 3). Hence, it is conclusive that canola biolubricant is thermally more stable as compared to biolubricant from canola biodiesel, which can be due to the presence of intra molecular hydrogen bonding. Thermogravimetric analysis (TGA) also confirms that canola biolubricant can be more useful for high-temperature applications, whereas biodiesel biolubricant is useful for low-temperature applications.

Table 3. Thermal Stability Data of Feed and the Products

	temperature (°C)		
product	stability	15−20 wt % loss	90−95 wt % loss
Canola oil	333	375	460
epoxidized canola oil	319	370	461
Canola biolubricant	309	364	530
biodiesel	309	360	462
epoxidized biodiesel	160	204	251
biodiesel biolubricant	194	247	370

Differential Scanning Calorimetry (DSC) Analysis. Figure 8 represents a DSC thermogram of epoxidized canola oil, epoxidized canola biodiesel, canola biolubricant, and biodiesel biolubricant. The exothermic crystallization peaks of epoxy canola oil and epoxy canola biodiesel appeared at −7 and −12 °C, respectively, because epoxy canola oil is well-stacked due to intramolecular forces.[25] Epoxy canola biodiesel crystallizes at lower temperature because of the presence of the *cis* epoxy linkage.[26] Biolubricant from canola oil shows the peak at −118 °C, and the biolubricant from biodiesel showed no peak for exothermic crystallization up to −140 °C, which can be due to the arrangement of the saturated molecules that influence the crystallization of the compound. Hence, biolubricant from biodiesel has better low-temperature properties.

Oxidation Stability Study. The oxidation stability of biolubricants depends on the degree of unsaturation present in the molecules which are very prone to oxidation. These oxidation processes of lubricants take place during the combustion process of the fuel inside the engine, hence it is a critical parameter.[28] Canola biolubricant showed a lower value of 56.1 h, whereas biodiesel biolubricant gave 76.3 h of oxidative induction time (Table 1). This increase in the oxidative stability is because of the existence of short chain ester linkage in canola biodiesel biolubricant as compared with canola biolubricant.[27] Hence, biodiesel biolubricant is close to 1.5 times more stable when compared with canola biolubricant, under similar oxidative conditions, which makes it more suitable for automotive applications.

Catalyst Reusability. In the present study, the two-step process was demonstrated for preparation of biolubricant, hence two different heterogeneous catalysts were used (i.e., Amberlite IR-120H and Amberlyst-15). The reusability of the catalysts was tested up to the third run. The reusability procedure was followed as in the literature.[6] The conversion decreased marginally in both the steps, and both the catalysts were used successfully up to three times.
