Caspase-3, -8, and -9 Activity Assay. Caspase activities were measured using the caspase-3, -8, and -9 activity kits purchased from Millipore (Billerica, MA, USA) according to the manufacturer's instructions. Briefly, α-tomatine-treated cells (1×10^6 cells) or tumor tissues were extracted in an ice-cold lysis buffer (50 mM Tris, 150 mM NaCl, 1 mM EGTA, 1 mM EDTA, 1% NP-40, 1 mM sodium orthovanadate, 1 mM NaF, 1 mM PMSF, 10 μg/mL aprotinin, 10 μg/mL leupeptin) for 30 min, and pulverization of tumor tissues using a homogenizer was conducted for effective protein extraction in a lysis buffer. Lysates were clarified by microcentrifugation at 14000*g* for 10 min. Supernatants (cytosolic extract) containing proteins (50 μg) were incubated in an assay buffer (100 μL) containing colorimetric substances, Ac-Asp-Glu-Val-Asp (DEVD)-*p*-nitroaniline (*p*NA), Ac-Ile-Glu-Thr-Asp (IETD)-*p*-NA), and Ac-Leu-Glu-His-Asp (LEHD)-

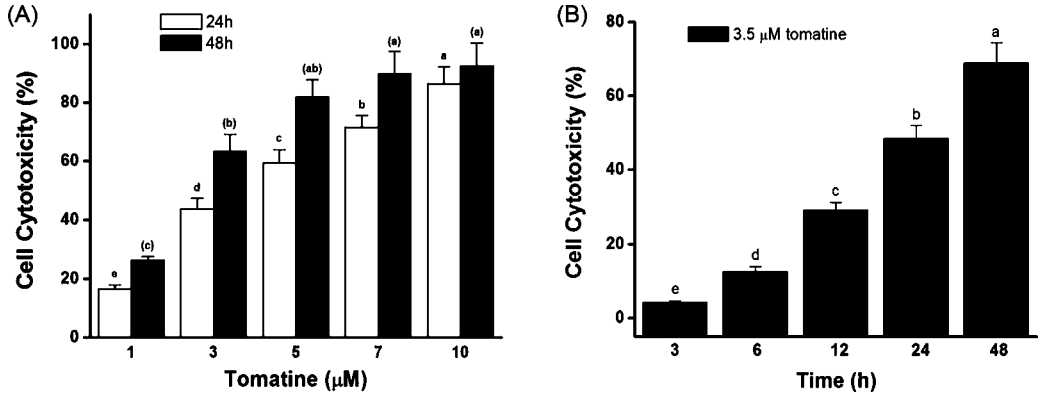

Figure 2. Cytotoxic effect of α-tomatine on CT-26 mouse colon cancer cells. (A) The cells were plated at a density of 1×10^5 cells/well in a 96-well microplate and then treated with the indicated concentrations of α-tomatine for 24 or 48 h at 37 °C, followed by measurement of cell death by LDH activity. (B) The cytotoxicity of α-tomatine was measured for the indicated time periods at a concentration of 3.5 μM. Plotted values are the mean ± SD (n = 3).

Table 1. Changes in Caspase-Independent CT-26 Mouse Colon Cancer Cell Death According to α-Tomatine Incubation Times[a]

	cell viability (%)			
sample	3 h	6 h	12 h	24 h
vehicle	100.0 ± 3.4	100.0 ± 4.7ab	100.0 ± 2.7b	100.0 ± 5.6b
z-VAD-fmk[b]	102.6 ± 6.5	105.7 ± 5.1a	108.4 ± 5.8a	115.3 ± 7.7a
tomatine[c]	98.7 ± 5.3	92.5 ± 3.3b	71.6 ± 3.6c	59.3 ± 3.1c
tomatine + z-VAD-fmk	99.8 ± 4.5	93.1 ± 5.2b	74.0 ± 4.0c	61.9 ± 4.2c

[a]Values are expressed as the mean ± SD of triplicate experiments. Values not sharing the same letter in the column are significantly different at $p < 0.05$. [b]100 μM z-VAD-fmk used as a pan-caspase inhibitor indicates z-Val-Ala-Asp-fluoromethyl ketone. [c]3.5 μM α-tomatine in 200 μL of DMSO was administered once a day. 100 μM z-VAD-fmk used as a pan-caspase inhibitor indicates z-Val-Ala-Asp-fluoromethyl ketone. Vehicle indicates 0.1% DMSO. MTT assay was employed to assess cytotoxicity. Cytotoxicity (%) = 100 × (1 − absorbance of α-tomatine-treated cells/absorbance of vehicle-treated cells).

*p*NA for caspase-3, -8, and -9 activity assays, respectively, at 37 °C for 2 h. Absorbance at 405 nm was quantified in a microplate reader.

Western Blot Analysis of Cell Proteins. α-Tomatine-treated CT-26 cancer cells (10^6 cells/mL) were harvested and then lysed in radioimmunoprecipitation assay (RIPA) buffer (50 mM Tris Cl, 150 mM NaCl, 1% NP-40, 0.5% sodium deoxycholate, 0.1% SDS, and 1 mM EDTA, pH 7.4) to prepare whole cell proteins. For the preparation of nuclear protein fraction, the cells were suspended in hypotonic buffer A (10 mM HEPES, 10 mM KCl, 0.1 mM EDTA, 0.1 mM EGTA, 1 mM DTT, 0.5 mM PMSF, pH7.9) and were allowed to swell on ice. After the addition of NP-40 (final 0.6%), the cells were subjected to vigorous vortexing and centrifugation at 12000*g*. The resultant nuclear pellet was further extracted with hypertonic buffer (20 mM HEPES, 0.4 M NaCl, 1 mM EDTA, 1 mM EGTA, 1 mM DTT, 1 mM PMSF, pH7.9). The extract was centrifuged at 12000*g* to recover the supernatant termed nuclear fraction. Protein concentrations were determined according to the Bradford method using a Bio-Rad Protein kit. Bovine serum albumin (BSA) was used as standard. The cell extract containing proteins (30 μg) was separated on 12% SDS−polyacrylamide gels and electrophoretically transferred onto nitrocellulose membrane (Millipore). The membrane was blocked in 5% skim milk at 4 °C overnight and probed with the primary antibodies as follows: anti-p65 nuclear factor kappa B (NF-κB) monoclonal antibody (catalog no. 6956S, Cell Signaling Technology, Inc., Danvers, MA, USA), anti-β-actin monoclonal antibody (catalog no. 04-1116, Millipore), rabbit anti-mouse apoptosis-inducing factor (AIF) polyclonal antibody (catalog no. 4642S, Cell Signaling Technology, Inc.), anti-survivin monoclonal antibody (catalog no. 2808S, Cell Signaling Technology), 21 monoclonal antibody (catalog no. MAB10072, Millipore), and anti-caspase-3 (catalog no. 9664S), anti-caspase-8 (catalog no. 9429S), and anti-caspase-9 polyclonal antibodies (catalog no. 9509S, Cell Signaling Technology). After allowing the primary antibody reaction for at least 3 h, the secondary antibody reaction with horseradish peroxidase (HRP)-conjugated anti-IgG antibody was performed under the same conditions. Blots were developed using the ECL detection kit (Pierce, Rockford, IL, USA). The intensity of separated protein bands was quantified using a gel documentation system (model LAS-1000CH, Fuji Photo Film Co., Tokyo, Japan). At least three separate replicates were determined for each experiment.

Statistical Analysis. Results are expressed as the mean ± SD of three independent experiments. Significant differences between means were determined by ANOVA test using the Statistical Analysis Software package SAS (Cary, NC, USA). $p < 0.05$ is regarded as significant.

RESULTS

Growth Inhibition of CT-26 Cells. Figure 2 shows the cytotoxicity of α-tomatine on CT-26 mouse colon cancer cells. Treatment with α-tomatine decreased cell viability in a concentration- and time-dependent manner. The maximum inhibitions with α-tomatine at 10 μM were about 86.4 and 92.63% at the end of the 24 and 48 h treatments, respectively. The calculated concentration that results in ∼50% cell death after 24 h was 3.5 μM.

Death Pattern of CT-26 Cells. Next, experiments were carried out to answer the question of whether or not the growth inhibition by α-tomatine resulted from apoptotic cell death. The 3.5 μM α-tomatine treatment for 24 h that induced 48% cell death was used to further treat CT-26 cancer cells. At this concentration, we examined whether the pan-caspase inhibitor,[18] z-VAD-fmk, blocks α-tomatine-induced cell death. The results of the MTT assay (Table 1) show that cell death

DOI: 10.1021/jf5040288
J. Agric. Food Chem. 2015, 63, 1142−1150

was 71.6 and 59.3% at 12 and 24 h of incubation, respectively. z-VAD-fmk (100 μM) failed to reverse α-tomatine-induced cell death; cell viability was not significantly different at $p < 0.05$ between tomatine-treated and tomatine plus the caspase inhibitor-treated groups.

The results of the apoptotic cell death process on α-tomatine-treated CT-26 cancer cells were confirmed by flow cytometric analysis using double staining with annexin V-FITC and PI. This method detects apoptosis by monitoring translocation from the inner membrane to outer cell surface.[19] Indeed, FITC-labeled annexin V can bind to PS to detect apoptotic cells. Figure 3 shows that ~32% of CT-26 cancer cells

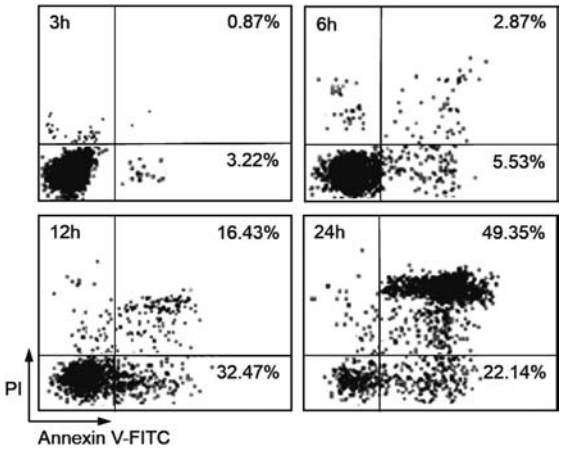

Figure 3. Contour diagram of annexin V-FITC/PI flow cytometry of CT-26 cells after being treated with α-tomatine for the indicated incubation periods. After being treated with 3.5 μM α-tomatine, cells were treated with 1 μg each of annexin V-FITC and PI, respectively, for 15 min. The lower left quadrants of each panel show the viable cells, which exclude PI and are negative for annexin V-FITC binding. The lower right quadrants contain the early apoptotic cells, positive for annexin V-FITC binding and negative for PI uptake, whereas the upper right quadrants contain the later apoptotic/necrotic cells, positive for annexin V-FITC binding and for PI uptake. The figure represents three independent experiments.

treated with α-tomatine for 12 h were stained by annexin V-FITC, which represented the early stage of apoptotic cells, and 16% of the cells were stained by both annexin V and PI, which indicated late-phase apoptosis/necrosis. After treatment for 24 h, 22% of the cells were in the early phase of apoptosis and 49% in the late phase.

CT-26 Cell Death Is Independent of Caspase Activation. Caspase activation is known to play an important role in both intrinsic and extrinsic apoptotic pathways.[20] Among caspases, activation of caspase-3, -8, and -9 is thought to be an important mechanism in the apoptosis pathway (caspase-3 effector caspase, caspase-8 and -9 initiator caspases). Figure 4A shows that the α-tomatine (3.5 μM) treatment failed to increase the initiator caspase activities of caspase-8 and -9 to statistically significant levels. In contrast, the effector caspase-3 activities were significantly induced by α-tomatine treatment during the 12 and 24 h incubations (about 3.2- and 5.0-fold increases during 12 and 24 h incubations, respectively). However, the extent of activity increase was much less than that observed in 50 μM etoposide-treated positive control (18.8- vs 3.2-fold increase during the 12 h incubation).

Etoposide used in the assay is a compound that induces cell apoptosis through the caspase-dependent signal transduction

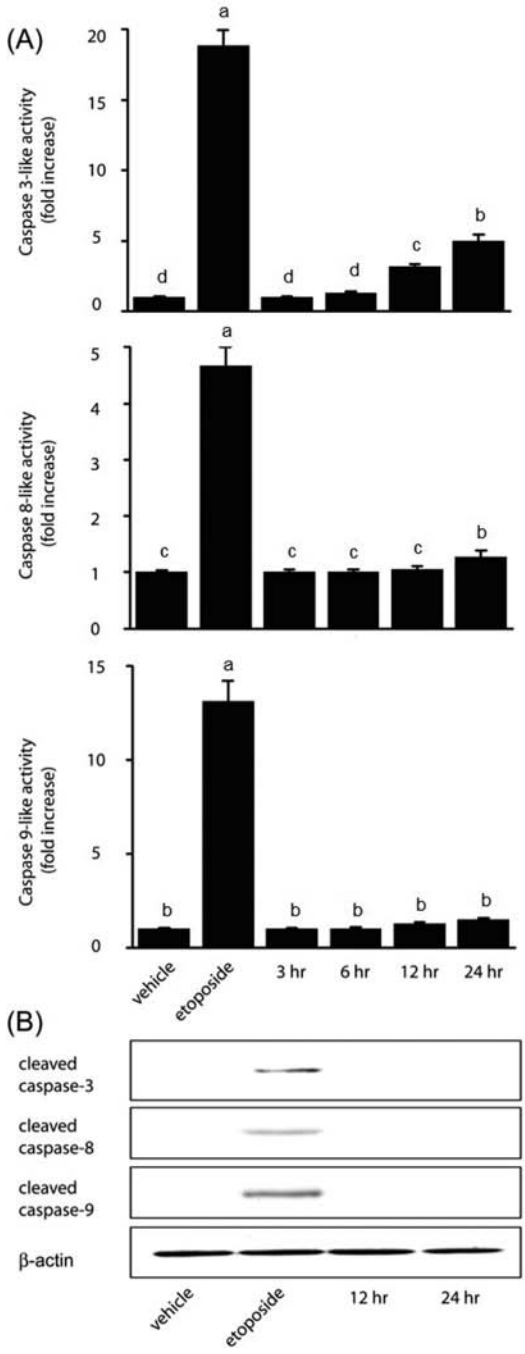

Figure 4. Changes in caspase-3, -8, and -9 activities by treatment with α-tomatine for the indicated incubation times in CT-26 cells. (A) The enzymatic activities of caspase-3, -8, and -9 in the cell lysates were determined by incubation with caspase-specific colorigenic substrates DEVD-*p*NA, IETD-*p*NA and LEHD-*p*NA, respectively. (B) Active forms of caspases produced from pro-forms by proteolytic cleavage. Total cell lysate from α-tomatine-treated cells was subjected to Western blot analysis using caspase-3, -8, and -9 specific antibodies. β-Actin was used as an internal control. Etoposide-treated controls (50 μM) were subjected to incubation for 12 h. Bars not sharing a common letter are significantly different between groups at $p < 0.05$. The figures are representative of three independent experiments.

pathway. It is generally used as a positive control to determine whether cell apoptosis occurs by triggering of caspases. Because etoposide exerts its apoptogenic effect via a caspase-dependent pathway, these findings on α-tomatine-triggered caspase-3-, -8,

DOI: 10.1021/jf5040288
J. Agric. Food Chem. 2015, 63, 1142−1150

and -9 activation modes suggested that CT-26 cell death by α-tomatine largely occurs through a caspase-independent pathway.

Western blot analysis was employed to further examine whether active forms of caspases were produced by proteolytic cleavage from pro-forms in α-tomatine-treated cells due to caspase-dependent apoptosis. Because no detectable protein bands of active forms of caspases were present in Figure 4B, this method confirms that α-tomatine-induced cell death most probably occurred through caspase-independent pathways.

Inhibition of Survivin and NF-κB/p65 Expressions and Induction of AIF Nuclear Translocation. α-Tomatine-induced cell death independent of caspase activation was also supported by the following data (not shown). First, no 4′,6′-diamidino-2-phenylindole (DAPI)-stained chromosomal condensation and apoptotic body appeared during the test conditions. Second, digestion of genomic DNA into a ladder of internucleosomal fragmentation was not observed. Third, there was no evidence that α-tomatine induced release of cytochrome *c* from mitochondria into cytosol.

It has been reported that the permeability of the mitochondrial membrane is regulated by AIF and that AIF-induced cell death bypasses caspase activation.[21] It has also been reported that survivin inhibition promotes cell death independently of cell cycle progression in many types of leukemia cell lines.[22] In addition, survivin has been shown to suppress intracellular translocation of AIF to the nucleus from mitochondria that could induce the caspase-independent apoptotic pathway. We therefore examined the possibility of whether α-tomatine could directly down-regulate the survivin protein level that leads to cell death. The results show that the expression of survivin was down-regulated in CT-26 cancer cells treated with α-tomatine for 24 h (88% reduction compared to control), where marked cell death was observed (Figure 5A and Table 1). Similar results were obtained with NF-κB/p65, in which α-tomatine suppressed nuclear translocation of the p65 subunit from the cytosol, resulting in growth inhibition of the α-tomatine-treated cells.[23] Figure 5B shows that in normal cells, survivin expression blocks nuclear translocation of AIF from mitochondria, suggesting that AIF intracellular translocation and survivin inhibition were strongly involved in α-tomatine-mediated caspase-independent cell death. We examined the translocation of NF-κB because the survivin gene is known to be a target gene regulated by NF-κB.[24]

Antitumor Effects of α-Tomatine in Vivo. To extract the total cell protein, equal amounts of tissue samples were collected and mixed. Relative expression (R.E.) in the figures is an arbitrary value that shows the expression ratio of target protein compared to expressed β-actin as the control protein. Standard deviation does not have statistical significance for R.E. Mean ± SD values were calculated from the average for 10 mice in each group. These values were derived by calculating means ± SD from three independent (separate) experiments.

To examine the antitumor efficacy of α-tomatine in vivo, CT-26 cancer cells were transplanted intracutaneously onto the backs of the mice. The mice were divided into two groups: a vehicle (control) and α-tomatine treatment group (5 mg/kg, ip injection per day). Figure 6 and Table 2 show that compared to the control, α-tomatine inhibited tumor growth by about 38%. Tumor inhibition was not associated with changes in body, heart, lung, stomach, or liver weight. However, there was a significant 29% increase in spleen weight. In addition, there

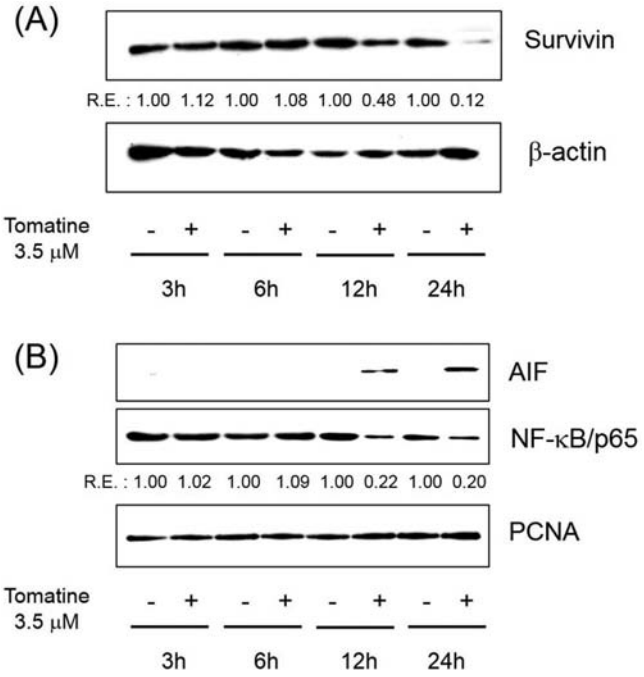

Figure 5. Down-regulation of survivin expression and inhibition of AIF nuclear translocation by α-tomatine treatment on CT-26 mouse colon cancer cells. (A) Total cell lysate from α-tomatine-treated cells was subjected to Western blot analysis using survivin-specific antibodies. β-Actin was used as an internal control for quantifying the modulation rate of survivin expression. (B) Translocation of AIF and NF-κB/p65 to nuclei was assessed by Western blot analysis on nuclear fraction prepared from α-tomatine-treated cells. Each protein expression level was expressed relative expression (R.E.) value calculated from target protein/β-actin or PCNA protein level. The figures represent three independent experiments.

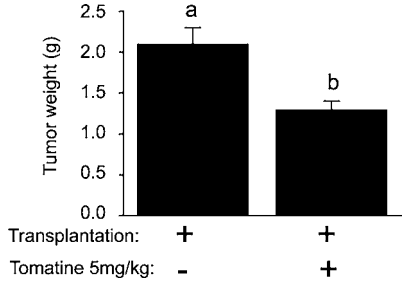

Figure 6. Effects of α-tomatine on tumor growth in vivo. BALB/c mice were intracutaneously transplanted with CT-26 mouse colon cancer cells (1×10^6 cells, 200 μL) and then subjected to intraperitoneal administration of α-tomatine (5 mg/kg body weight in 200 μL of 0.1% DMSO). After 2 weeks, mice were sacrificed and tumors excised to compare tumor growth patterns between experimental and vehicle-treated control group. Tumor weights are expressed as the mean ± SD ($n = 10$). Bars not sharing the same letters are significantly different between groups at $p < 0.05$.

were no associations between tumor regression and caspase-8 and -9 activity increases. However, caspase-3 activity increased in response to α-tomatine administration (Figure 7).

Western blot analysis was used to measure the expression of AIF and survivin (Figure 8). Consistent with the observed effects of α-tomatine in the vitro system, the α-tomatine increased the nuclear-localized AIF protein level and decreased the survivin level. These findings indicate that α-tomatine induced cell death in vitro and inhibited the transplanted tumor

Table 2. Body and Organ Weights of Mice Intraperitoneally Administered α-Tomatine[a]

sample	final body wt (g)	organ wt (g/20 g body wt)				
		heart	lung	stomach	liver	spleen
vehicle	35.7 ± 2.1	0.18 ± 0.01	0.29 ± 0.02	0.28 ± 0.01	1.10 ± 0.12	0.15 ± 0.01b
tomatine 5 mg/kg	35.5 ± 2.3	0.17 ± 0.01	0.28 ± 0.03	0.26 ± 0.02	1.05 ± 0.19	0.21 ± 0.02a

[a]Values are expressed as the mean ± SD of each mouse group (n = 10). Values not sharing the same letters in a column are significantly different at $p < 0.05$. Vehicle indicates 0.1% DMSO treatment only.

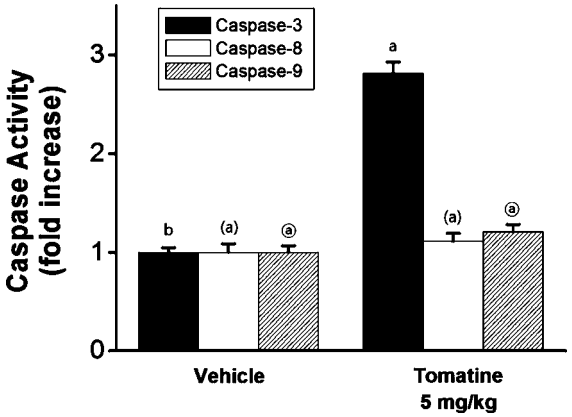

Figure 7. Effects of α-tomatine on caspase-3, -8, and -9 activities on tumor tissues from mice intracutaneously transplanted with CT-26 mouse colon cancer cells. α-Tomatine (5 mg/kg body weight) or vehicle was administered via peritoneal route into mice. The enzymatic activities of caspase-3, -8, and -9 in the tumor tissue lysates were determined by incubation with specific colorigenic substrates DEVD-*p*NA, IETD-*p*NA, and LEHD-*p*NA, respectively. Enzyme activities are expressed as the mean ± SD (n = 10). Bars not sharing a common letter are significantly different between groups at $p < 0.05$. The figures represent three independent experiments.

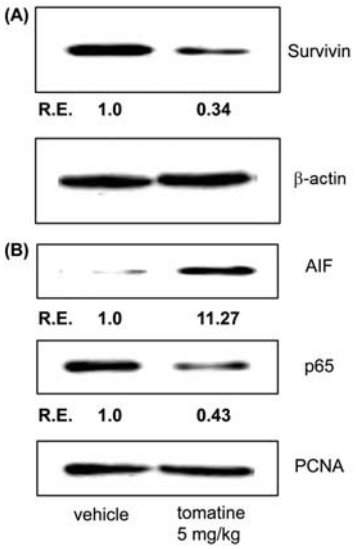

Figure 8. Down-regulation of survivin expression and inhibition of AIF nuclear translocation by α-tomatine treatment on mouse tumors transplanted with CT-26 mouse colon cancer cells. (A) Total tumor tissue lysate from the mice ip administered α-tomatine was subjected to Western blot analysis using survivin-specific antibodies. β-Actin was used as an internal control for quantifying modulation rate of survivin expression. (B) Nuclear translocations of NF-κB/p65 from cytosol and AIF from mitochondria were assessed by Western blot analysis on nuclear fraction prepared from the tumor from the mice administered α-tomatine via peritoneal route. Each protein level was expressed as the R.E. value calculated from target protein/ β-actin or PCNA protein level. The figures represent three independent experiments.

growth in vivo by survivin inhibition and AIF induction, indicating that anticancer effects of α-tomatine might be exerted through caspase-independent pathway in both CT-26 cultured cancer cells and the mice tumor transplanted with the colon cancer cells.

DISCUSSION

Anticarcinogenic Effects of α-Tomatine against CT-26 Cells in Vitro and in Vivo. The cited data imply that α-tomatine induced apoptosis of CT-26 cells and that cell death occurred through caspase-independent pathways. This suggestion is reinforced by the observed failure of a pan-caspase inhibitor, z-VAD-fmk, to block cell death.

A journal reviewer suggested we validate the concentration of z-VA-fmk used in the present study. Table 1 gives the concentration of z-VAD-fmk used. However, we believe that it is not necessary to validate the concentration of z-VAD fmk because this concentration (50−100 μM) was widely used in related earlier studies. We therefore used 100 μM as the working concentration above the saturation point. In addition, increases in the cell viability observed in the control group treated only with z-VAD-fmk might have resulted from suppression of initiation of spontaneous apoptosis.

The cited results show that nuclear localization of AIF and inhibition of survivin expression were strongly involved in the α-tomatine-mediated, caspase-independent cell death and that the tumor-growth-inhibiting effect of α-tomatine was not accompanied by adverse effects such as changes in organ weights, with the possible exception of an increase in spleen weight. In addition, there was no apparent association between tumor regression and increases in caspase-8 and -9 but not caspase-3 activities. We have no obvious explanation for this difference.

Western blot analysis used to measure the in vivo expression of AIF and survivin paralleled the observed effects induced by α-tomatine in vitro; α-tomatine increased the AIF level and decreased the survivin level. Taken together, the described findings indicate that α-tomatine inhibited the cancer cells in vitro and tumor growth in vivo by inhibition of survivin and induction of AIF. It seems that these anticarcinogenic effects of α-tomatine appear to be exerted largely through a caspase-independent pathway in both the CT-26 cultured cancer cells and in the transplanted mouse colon tumor cells.

End Points of Cytotoxicity and FACS Assays. These two assays measure different end points. The two cytotoxicity assays used in this study measure cellular dehydrogenase activities as an indicator of cell viability. The FACS analysis measures the incorporation of PI into nuclei through the gap generated by the collapse of the cell membrane together with staining of phosphatidylserine that is localized on the inner side of the lipid bilayer that flipped over to the outer side. The FACS analysis

DOI: 10.1021/jf5040288
J. Agric. Food Chem. 2015, 63, 1142−1150

data show only the population of cells that are susceptible to apoptosis and not directly associated with cell death. By contrast, the MTT assays measure cell death.

Reported Anticarcinogenic Activities and Mechanisms of α-Tomatine. To place the findings of the present study in proper perspective, we will briefly mention results of reported studies on the anticarcinogenic potential of α-tomatine in vitro and in vivo.

- Using a microculture tetrazolium (MTT) in vitro assay, we previously reported that tomatine is a strong inhibitor of growth for both human colon and liver cancer cell lines, as evidenced by the dose-dependent (0.1−100 μg/mL) inhibition of HT29 colon cancer cells at levels ranging from 38.0 to 81.5% and of human HepG2 cancer cells, from 46.3 to 89.2%.[25] The anticarcinogenic activity against human liver cancer cells at a tomatine concentration of 1 μg/mL was higher than the corresponding activity observed with the commercial anticancer drug doxorubicin.
- We also investigated six green and three red tomato extracts for their ability to induce cell death in human cancer and normal cells using a microculture MTT assay.[26] Compared to untreated controls, the high-tomatine green tomato extracts strongly inhibited the following human cancer cell lines: breast (MCF-7), colon (HT-29), gastric (AGS), and hepatoma (liver) (HepG2), as well as normal human liver cells (Chang).
- α-Tomatine (a) inhibited cell invasion and migration and phosphorylation of Akt and extracellular signal-regulated kinases 1 and 2 (ERK1/2) in human lung adenocarcinoma A549 cells; (b) did not affect phosphorylation of c-Jun N-terminal kinase (JNK) and the p38 gene; (c) decreased nuclear levels of NF-κB, c-Fos, and C-Jun; and (d) inhibited binding abilities of NF-κB and activator protein-1 (AP-1).[27] Inhibition of metastasis occurs by reducing MMP-2, MMP-9, and urokinase-type-plasminogen activator (uPA) activities through the phosphoinositide 3-kinase/Akt (PI3K/Akt or ERK1/2) signaling pathway and inhibition of NF-κB or AP-1 binding activities.
- Another study confirmed that α-tomatine suppressed invasion and migration of human non-small lung cancer NCI-H460 cells through inactivation of the FAK/PI3K/Akt signaling pathway and lowering binding activity of NF-κB.[28] Cytotoxicity occurred through inactivation of the signaling pathway and enhancement of IκBα protein expressions to reduce NF-κB DNA binding activity, resulting in down-regulation of MMP-7 expression, inhibition of cell migration and invasion, and interference with the rearrangement of the actin cytoskeleton by decreasing the expression of the pFAK protein.
- α-Tomatine inhibited PC-3 prostate cancer cells with an IC_{50} value of 1.67 μM.[29,30] Cytotoxicity occurred after an hour of treatment and was mainly due to induction of apoptosis as evidenced by decreased mitochondrial membrane potential and increased nuclear condensation, polarization of F-actin potential, cell membrane permeability, cytochrome *c* expression, induction of activation of caspase-3, -8, and -9, inhibition of NF-κB nuclear translocation, and a decrease in NF-κB/p50 and NF-κBp65 in the nuclear fraction.
- α-Tomatine inhibited human leukemia MOLT-4 cells by activating cell cycle checkpoints without damaging single or double DNA strands in the cells.[31] The slowing of the cell cycle seems to involve caspase-independent cell death associated with an increase in the tumor suppressor protein p53, and the pro-apoptotic protein PUMA (p53 up-regulated modulator of apoptosis), as well as other protein biomarkers associated with cell cycle regulation.
- α-Tomatine-mediated anticancer activity against human chronic myeloid leukemia cells in vitro and in a transplanted mouse tumor operated through cell-cycle and caspase-independent pathways.[32] The mechanism against the leukemia cells seems consistent with that described in the present study for the colon cancer cells.
- We found that feeding 2000 ppm of tomatine and 224 ppm of the multiorgan carcinogen dibenzo[*a*,*l*]pyrene (DBP) to rainbow trout for 9 months resulted in a reduced incidence of liver and stomach tumors by 41.3 and 36.3%, respectively, as compared to the incidence of tumors observed with DBP alone.[33]
- Ip-administered α-tomatine (5−10 mg/kg) significantly attenuated the growth of androgen-independent PC-3 prostate cancer cells in mice.[34] Tumor-suppression was associated with increased apoptosis and by reduced nuclear translocation of the p50 and p65 gene components of the NF-κB signaling pathway. This study seems to provide evidence that α-tomatine can inhibit the growth of prostate cancer tumors in vivo without inducing overt toxicity.
- The activity of α-tomatine generally decreases upon removal of one or more of the four carbohydrate groups of the lycotetraose side chain.[35] For example, the activity of α-tomatine against the PC-3 prostate cancer cells was about 200 times greater than that of the aglycone tomatidine. By contrast, tomatidine was highly active against the foodborne pathogen *Staphylococcus aureus*,[36] suggesting that the two bioactivities are governed by different mechanisms.
- Ip-injected α-tomatine at 1 mg/kg slowed the growth of Ehlich tumor in mice; the combination of α-tomatine (1 mg/kg) and the cancer drug doxorubicin (2 mg/kg) acted synergistically and extended survival of the mice with the Ehrlich tumors.[37] The activity against the tumors, which are derived from adenocarcinoma of the mammary gland, seems to involve the immune system in the inhibition of tumor progression. This suggestion seems plausible on the basis of reports by other investigators that tomatine contributes to the protective immunity of rodents.[38,39]

The results of the present study on the inhibition of tumor growth in mice with implanted colon cancer complement and extend the cited in vitro and in vivo studies by other investigators. It seems that the mechanistic molecular, signaling, biomarker, and immunomodulating events associated with apoptosis and cell migration might not be the same for the different cancer cell lines. Overall, the cited observations imply that both intrinsic and extrinsic pro-apoptosis pathways are involved and that α-tomatine may protect against development and progression of several cancers (multiorgan protection). This is not surprising because carcinogenesis is a sequential multistage cellular process consisting of tumor initiation, tumor

DOI: 10.1021/jf5040288
J. Agric. Food Chem. 2015, 63, 1142−1150

promotion, and tumor progression characterized by dysregulation of multiple genes resulting in multiple adverse symptoms. Each stage involves signaling pathways and associated biomarkers.

Safety of Tomatine. The following reported observations indicate that tomatine does not appear to be toxic to animals or humans.

(a) The following LD_{50} value have been reported for tomatine in mice (in mg/kg body weight): ip, 25–33.5; iv, 18; oral, 500; subcutaneous, >1000.[15,40]

(b) As part of the anticarcinogenic study of feeding tomatine to rainbow trout for 9 months, we found that tomatine did not induce changes in mortality, fish weights, liver weights, or tissue morphology.[33] We also observed a lack of toxicity in hamsters orally fed tomatine.[41]

(c) The apparent nontoxicity of tomatine in animal models is reinforced by the fact that Peruvians consume without deleterious effects high-tomatine red tomatoes grown in the Andes mountains[8] and that high-tomatine "pickled green" and "green-fried" tomatoes are part of the human diet.

(d) The present study shows that except for the spleen, the body and organ weights of the mice were not affected by their exposure to tomatine. Pancreas weights were not determined.

Outlook. Because our previous studies found that dietary tomatine and high-tomatine green tomatoes decreased plasma low-density (bad) cholesterol and plasma triglyceride in hamsters fed a diet high in saturated fat and cholesterol by 41 and 47%,[41,42] chemopreventive effects of α-tomatine and high-tomatine tomatoes against both cancers and cardiovascular disease in humans merit further study. Such studies should evaluate pure tomatine and high-tomatine green tomato diets. A key consideration in cancer prevention and treatment should be the ratio of effective preventive or therapeutic to toxic dose. Combinations of low doses of tomatine with cancer drugs that might act synergistically with reduced side effects also merit study.

There is also a need to develop high-tomatine red tomatoes by suppressing the genes in the tomato plant that govern the biosynthesis of enzymes that degrade most of the tomatine during ripening of tomatoes.[43−46] Such new red tomatoes will contain two highly bioactive health-promoting molecules, α-tomatine and the red pigment lycopene.[40,47,48]

2. MATERIALS AND METHODS

2.1. Isolation of the Compound of Interest. *2.1.1. Materials.* Fresh alperujo samples (not stored) were obtained after virgin oil extraction from Picual olive fruits in an experimental mill at the Instituto de la Grasa, Seville, Spain. Samples of wet alperujo were taken from the output of the horizontal centrifuge of the two-phase process. The alperujo (a semi-solid residue composed of olive peels, pulp, seeds, and ground stones) was processed without removal of the stones.

2.1.2. Standard Compounds. Hydroxymethylfurfural, protocatechuic acid, *p*-hydroxybenzoic acid, vanillic acid, 4-methylcatechol, catechol, 3,4-dihydroxyhydrocinnamic acid, and 3,4-dihydroxyphenylglycol were obtained from Sigma-Aldrich (Deisenhofer, Germany). Tyrosol was obtained from Fluka (Buchs, Switzerland). Oleuropein was obtained from Extrasynthese (Lyon Nord, Geney, France). Hydroxytyrosol was obtained by the method described by Fernández-Bolaños et al.[13] Hydroxytyrosol acetate was isolated following the process described by Fernández-Bolaños et al.[14]

2.1.3. Thermal Treatment. The hydrothermal treatment used has been patented[5] and was performed using a prototype designed by our research group at the Instituto de la Grasa (Seville, Spain). The reactor has a stainless-steel reservoir (100 L capacity) that can operate at temperatures between 50 and 190 °C and at a maximum pressure of 1.2 MPa. A total of 20 kg of fresh alperujo was loaded into the reactor and treated for 60 min at 140 and 170 °C, increasing the liquid by steam condensation. The wet material was centrifuged at 4700 *g* (Comteifa, SL, Barcelona, Spain) to separate the solids and liquids. After centrifugation, 10 L of the liquid phase was concentrated to 1 L by rotary evaporation under vacuum at 30 °C.

2.1.4. Phenol Extraction with Refluxing Ethyl Acetate. The liquid portions obtained after treatment were washed with hexane to remove the lipid fraction. A total of 1 L of liquid was mixed with 500 mL of hexane; the mixture was shaken vigorously; and then the phases were separated by decantation and washed twice. Extraction of phenolic compounds was carried out with ethyl acetate. A total of 200 mL of aqueous sample was extracted with 500 mL of ethyl acetate. The liquid−liquid extraction was performed with ethyl acetate (refluxed at 77 °C) in a continuous extractor of a heavier liquid (water) by lighter liquid (ethyl acetate) for 8 h.

2.1.5. Chromatographic Fractionation of the Ethyl Acetate Extract. Approximately 12 g of extract was dissolved in 60 mL of H_2O/MeOH (80:20). The extracts were passed through a column 3.5 cm in diameter and 40 cm in height filled with Amberlite XAD16. The elution was performed with 1 L of H_2O, 30% EtOH (v/v), 50% EtOH (v/v), and 95% EtOH (v/v). A total of 10 fractions of 100 mL each were collected. Fractions were analyzed by high-performance liquid chromatography (HPLC), and those containing the derivative of elenolic acid of interest were mixed and concentrated to 50 mL. The fractions 1 and 2 used in the antimicrobial test were obtained in this step.

2.1.6. HPLC−Diode Array Detector (DAD). The compounds were identified using a Hewlett-Packard 1100 liquid chromatography system with a C_{18} column (Teknokroma Tracer Extrasil ODS-2, 250 × 4.6 mm inner diameter, 5 μm particle size). The system was equipped with a DAD (the wavelengths used for quantification were 254, 280, and 340 nm) and Rheodyne injection valves (20 μL loop). The method used for quantification was described by Rubio-Senent et al.[6] Quantification was performed in triplicate using external standards; standard curves were linear in all cases ($R^2 > 0.99$).

2.1.7. Isolation. The compound of interest was isolated using a semi-preparative system. A HPLC method similar to that described for HPLD−DAD analysis was used. Jasco HPLC (LC-Net II ADC, Kyoto, Japan) equipped with a DAD and a semi-preparative Synergi 4 μm Hydro-RP80A reverse-phase column (25 cm × 21.20 mm inner diameter, 4 μm particle size, Phenomenex, Macclesfield, Cheshire, U.K.) was used. The flow rate was maintained at 12 mL/min, and the injection volume was 600 μL. Before the DAD, the flow was divided with a T connection (0.25 mL/min to the DAD and 11.75 mL/min to the collection port).

2.2. Structural Analysis. *2.2.1. ^1H and ^{13}C NMR, Correlation Spectroscopy (COSY), Heteronuclear Single-Quantum Coherence (HSQC), Nuclear Overhauser Effect Spectrometry (NOESY), and Heteronuclear Multiple-Bond Correlation (HMBC) Experiments.* ^1H (300.1 and 700.2 MHz) and ^{13}C (75.5 and 176.1 MHz) NMR spectra were recorded on Bruker Avance-300 III and Avance-700 III spectrometers using CD_3OD as the solvent. The latter spectrometer was equipped with a cryogenically cooled 5 mm QCI gradient probe. Chemical shifts are reported in δ units (ppm) relative to the solvent peak (3.31 and 49.0 ppm for ^1H and ^{13}C NMR, respectively). The ^{13}C NMR spectrum registered at 75.5 MHz was acquired with the following acquisition parameters: acquisition time, 0.9 s; relaxation delay, 1.5 s; spectral width, 239 ppm; data points, 32 000; number of scans, 1434; and line broadening, 1.0 Hz. The ^{13}C spectrum registered at 176.1 MHz was acquired with the following acquisition parameters: acquisition time, 0.8 s; relaxation delay, 3.0 s; spectral width, 220 ppm; data points, 64 000; number of scans, 14 336; and line broadening, 1.0 Hz. The enhanced sensitivity of NMR at 176.1 MHz with the cryoprobe for the ^{13}C NMR spectrum allowed the signal for the carboxyl groups to be clearly observable, whereas that signal was missing at 75.5 MHz and a shorter relaxation delay (1.5 s).

The assignments of ^1H and ^{13}C signals were confirmed by homonuclear COSY and heteronuclear HSQC spectra (Avance-300 III), respectively. The configuration of the double bond was confirmed by a two-dimensional (2D) NOESY experiment (Avance-300 III). The HMBC (Avance-700 III) experiment confirmed the connection of glutaric acid with the crotonaldehyde moiety through C-3 of the dicarboxylic acid.

2.2.2. Mass Spectrometry (MS). Mass spectra [chemical ionization (CI) and high-resolution chemical ionization (HR-CI)] were recorded on a Micromass AutoSpec-Q mass spectrometer with a resolution of 1000 or 10 000 (10% valley definition).

2.2.3. Infrared (IR) Spectra. IR spectra were recorded on Jasco FT/IR 4100 equipped with an attenuated total reflection (ATR) accessory.

2.3. (*E*)-3-(1-Oxobut-2-en-2-yl)glutaric Acid. IR ν_{max}: 3300−2400, 2727, 1684, 1440, 1405, 1310, 1234, 1160, 982, 932 (br), 844, 801 cm^{-1}. ^1H NMR (700.2 MHz, CD_3OD) δ: 9.28 (d, 1H, $J_{1',3}$ = 2.0 Hz, H-1′), 6.79 (q, 1H, $J_{3',4'}$ = 7.0 Hz, H-3′), 3.59 (m, 1H, H-3), 2.68 (dd, 2H, $J_{2a,2b}$ = 15.5 Hz, $J_{2a,3}$ = 9.1 Hz, H-2a, H-4a), 2.61 (dd, 2H, $J_{2b,3}$ = 6.2 Hz, H-2b, H-4b), 2.08 (d, 3H, $J_{4',3'}$ = 7.0 Hz, H-4′). ^{13}C NMR (176.1 MHz, CD_3OD) δ: 197.0 (C-1′), 176.3 (C-1, C-5), 155.9 (C-3′), 145.3 (C-2′), 38.4 (C-2, C-4), 31.9 (C-3), 15.4 (C-4′). CIMS *m*/*z*: 201 ($[M + H]^+$, 22%), 183 ($[M - H_2O + H]^+$, 66%), 165 ($[M - 2H_2O + H]^+$, 100%). HR-CIMS *m*/*z* calcd for $C_9H_{13}O_5$ ($[M + H]^+$): 201.0763, found: 201.0769.

2.4. Assay of Extraction. Fresh alperujo was submitted to extractions with water, methanol−water, and two hydrothermal treatments. Further phenol extractions from the aqueous fractions were performed with ethyl acetate at 77 °C (hot) and room temperature (cold), to evaluate the optimal conditions for extraction of a high concentration of glutaric acid derivative.

2.4.1. Extraction with Water at Room Temperature. A total of 500 g of fresh alperujo was mixed with 500 mL of water at room temperature for 1 h with stirring. The mixture was filtered, and the liquid was extracted with cold and hot ethyl acetate.

2.4.2. Extraction with Aqueous Methanol at Room Temperature. We used the method reported by Obied et al.[15] for the extraction from 300 g of fresh alperujo with aqueous methanol (80%, v/v; 15 mL/10 g of alperujo) at room temperature for 30 min. The extraction was repeated twice more using 10 mL/10 g of alperujo. The combined organic fractions were filtered, evaporated to dryness in a rotary evaporator (Buchi, Milan, Italy) at 40 °C, and then redissolved in water. The phenols were extracted with cold and hot ethyl acetate.

2.4.3. Thermal Treatment at 140 °C/60 min. A total of 20 kg of fresh alperujo sample was hydrothermally treated at 140 °C for 60 min with saturated steam, obtaining 35 L of aqueous fraction by steam condensation, which was filtered and extracted with cold and hot ethyl acetate.

2.4.4. Thermal Treatment at 170 °C/60 min. A total of 20 kg of fresh alperujo sample was hydrothermally treated at 170 °C for 60 min

DOI: 10.1021/jf5057716
J. Agric. Food Chem. 2015, 63, 1151−1159

with saturated steam, obtaining 41 L of aqueous fraction by steam condensation, which was filtered and extracted with cold and hot ethyl acetate.

2.4.5. Liquid–Liquid Extraction with Ethyl Acetate at 77 °C (Hot). We used the procedure as described in section 2.1.4.

2.4.6. Liquid–Liquid Extraction with Ethyl Acetate at Room Temperature (Cold). The aqueous portions (200 mL) obtained after treatment were mixed with ethyl acetate (250 mL) in a separating funnel, vigorously shaken for 10 min at room temperature, and then allowed to settle for 20 min. The phases were separated, and the extraction was repeated twice. The combined organic phases were evaporated to dryness at a reduced pressure.

2.5. Bactericidal Activity. *P. syringae* CECT 4429T and *A. tumefaciens* CECT 4119T bacterial strains were purchased from the Spanish Type Culture Collection (CECT) at Burjasot, Valencia, Spain. Bactericidal activity of the samples (extracts and pure compound) was tested using 150 μL of the sample inoculated with 10 μL of an overnight broth culture of each microorganism, diluted with saline to obtain an initial population between 5×10^5 and 5.7×10^5 colony-forming units (CFU)/mL. The inoculated samples were incubated at room temperature for 5 min with occasional shaking and plated onto nutrient agar to count the number of survivors after incubation. Experiments were performed in duplicate.[16]

The pH of the extracts (2.8–2.6) and the pure compound (3.1) were adjusted to 5.6 with dilute NaOH and filtered through 0.20 μm pore size cellulose membranes before inoculation. Controls were run with saline.

3. RESULTS AND DISCUSSION

3.1. Isolation and Structural Analysis of Compound 1. The phenolic extract obtained from hydrothermally treated alperujo was characterized as containing different phenolic compounds and various elenolic acid derivatives.[6] In a previous work,[6] these derivatives were called compounds A, B, and C, with derivative A present in the highest proportions and one of the most abundant constituents in ethyl acetate extract after hydroxytyrosol. This compound was purified by HPLC using a C_{18} semi-preparative column (as described in the Materials and Methods). HPLC–DAD analysis revealed the presence of a pure compound at 11 min with an ultraviolet (UV) absorption maximum at 230 nm (Figure 1).

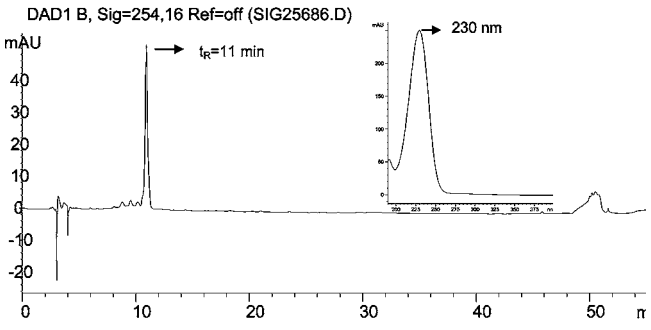

Figure 1. HPLC chromatogram and UV spectrum of compound **1**.

The structure of the compound was elucidated using one-dimensional (1D) ^{1}H and ^{13}C NMR experiments (panels A and B of Figure 2). Structural analysis was completed by using DEPT-45 (see Figure S1 of the Supporting Information) and homonuclear and heteronuclear 2D NMR techniques, such as COSY (see Figure S2 of the Supporting Information), HSQC (see Figure S3 of the Supporting Information), and NOESY and HMBC experiments (panels A and B of Figure 3, respectively). In addition, IR analysis and MS (low-resolution and HR-CI) were also used.

The ^{1}H NMR data showed a doublet at δ 9.28 ppm (J = 2.0 Hz), corresponding to an aldehyde group (H-1′) coupled with H-3 (^4J) of a glutaric acid moiety, as deduced from the COSY experiment. It is remarkable that the aldehyde proton of 2-alkylalk-2-enals, with either *E* or *Z* configuration, do not show any H,H coupling.[17] Furthermore, a quartet at δ 6.79 ppm (J = 7.0 Hz) indicated the presence of an olefinic proton (H-3′) coupled (^3J) to a methyl (H-4′) at δ 2.08 ppm; these data suggest that the compound contains a crotonaldehyde moiety substituted at the α carbon. The ^{1}H NMR spectrum also showed two symmetrical pairs of geminal protons as a doublet of doublets at δ 2.61 ppm (H-2a and H-4a) and δ 2.68 ppm (H-2b and H-4b) (2H each, $^2J_{2a,2b}$ = 15.5 Hz) and a multiplet at δ 3.59 ppm (1H) for protons of the CH_2CHCH_2 fragment, as confirmed by a COSY spectrum (see Figure S2 on the Supporting Information). Furthermore, the HSQC experiment allowed for complete assignments of the carbon signals in the spectrum corresponding to a symmetrical glutaric acid derivative, C-2/C-4 and C-3, for signals at 38.4 and 31.9 ppm, respectively, whereas the crotonaldehyde moiety had carbon signals at 197.0, 155.9, and 15.4 ppm for C-1′, C-3′, and C-4′, respectively (Figure 2). The signals observed at 176.3 and 145.3 ppm in ^{13}C NMR corresponded with the carboxylic carbons (C-1 and C-5) and a quaternary olefinic carbon (C-2′), respectively; this information was corroborated by DEPT-45 experiment, in which quaternary carbon atoms do not appear (see Figure S1 on the Supporting Information).

E configuration of the C=C double bond of compound **1** and the *s-trans* conformation for the C-1′–C-2′ bond were confirmed by a 2D NOESY experiment (Figure 3A), where the off-diagonal cross-peaks, H-1′/H-3′ and H-3/H-4′, indicate through-space interaction, therefore suggesting close proximity of the involved hydrogen atoms (Figure 4A). The planar W pathway between formyl and H-3 protons, depicted in Figure 4A, also explains the long-range coupling (^4J = 2.0 Hz) observed in the ^{1}H NMR spectrum, and it is in agreement with a planar conformation of the crotonaldehyde moiety included in the plane of the C-3–H-3 bond of glutaric acid. No nuclear Overhauser effect (NOE) interactions were observed between H-2/H-4 and crotonadehyde protons, also in agreement with the suggested conformation for compound **1**.

The centrality of C3 was confirmed by the HMBC spectrum (Figure 3B), because it showed correlations between C-3 of glutaric acid with protons H-1′ and H-3′ of the crotonaldehyde moiety and strong correlation with H-2 and H-4 of glutaric acid. Three bond couplings were also observed between aldehydic carbon (C-1′) and both H-3′ of the crotonaldehyde moiety and H-3 of glutaric acid. Furthermore, the carboxylic carbons (C-1) were strongly coupled to H-2/H-4 and weakly coupled to H-3.

Next, we analyzed the CI-MS and IR spectra (see Figures S4 and S5 of the Supporting Information, respectively) to complete the structural deductions for the isolated compound. The pseudo-molecular ion $[M + H]^+$ obtained by HR-CI-MS was in accordance with the assigned molecular formula $C_9H_{13}O_5$ (m/z 201). Additionally, the fragment obtained for the loss of two water molecules successively, $[M + H - H_2O]^+$ and $[M + H - 2H_2O]^+$ with m/z 183 and 165, respectively, was identified. The IR spectrum of the compound revealed an absorption band at 3300–2400 cm^{-1} (vbr), which was attributed to the O–H stretch of hydrogen-bonded carboxylic acids and a band at 930 cm^{-1} associated with the O–H bend. Absorption bands at 2727 and 1684 cm^{-1} can be attributed to

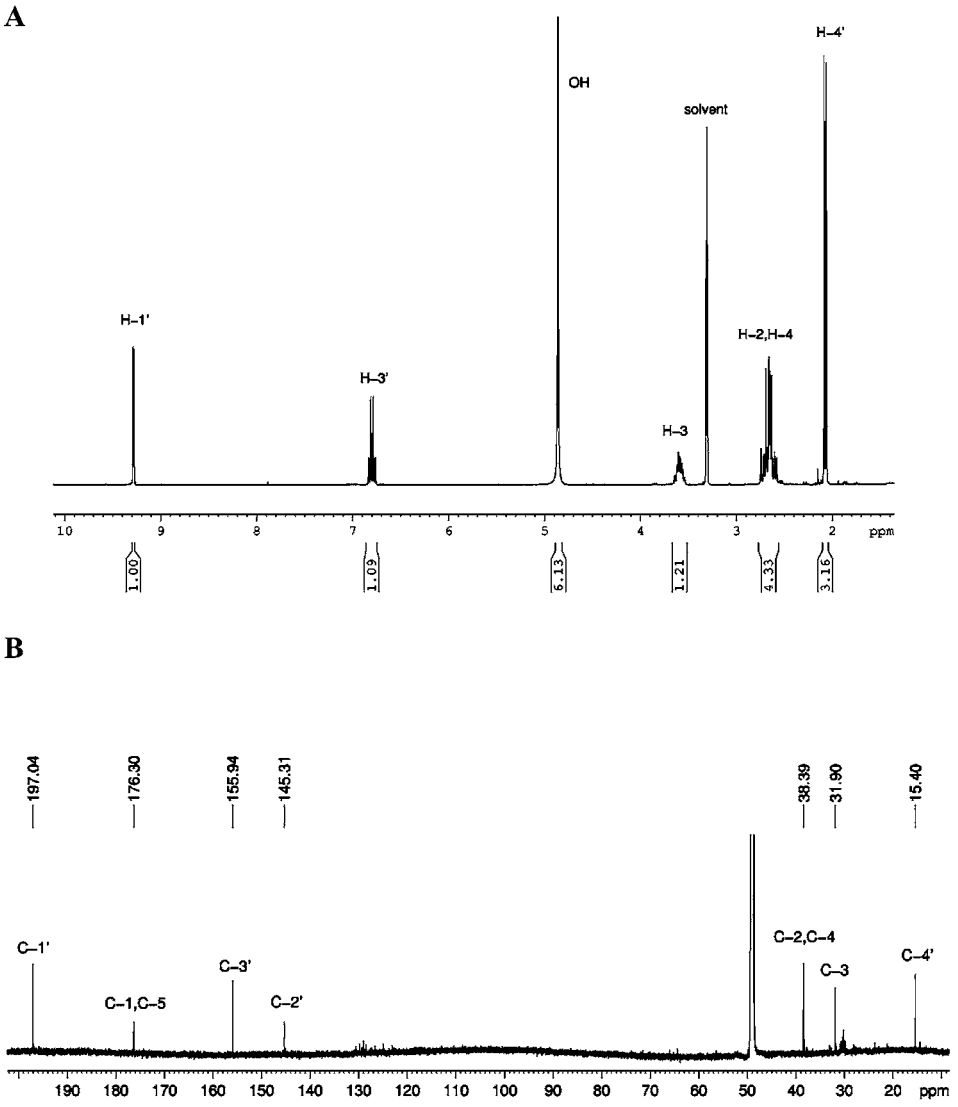

Figure 2. (A) ^{1}H spectrum at 300.1 MHz and (B) ^{13}C NMR spectra at 176.1 MHz, for compound **1** in MeOH-d_4. The signals at 4.85 and 3.31 ppm in panel A and at 49.0 ppm in panel B correspond to the solvent.

C−H(O) and C═O of the conjugated aldehydic group, respectively. Finally, a signal at 1440 cm^{-1} was associated with the asymmetric bending vibrations of the methyl group.

Taking into account the structural descriptions as detailed above, the compound was identified as (*E*)-3-(1-oxobut-2-en-2-yl)glutaric acid (**1**). A similar compound has been described by Gil et al.[18] from olive oil residue, although, in this case, the compound was isolated in its methylated form in the previous treatment of the extract with diazomethane and characterized as its dimethyl ester derivative. Also, Fotinos et al.[19] claimed to have isolated the same compound from oil-press waste of a Greek olive crop variety, the Koroneiki olives, although, in this case, no structural chemical data were reported.

The configuration of this compound was reported to be *Z* (Figure 4B) by the Chemical Abstracts Service (CAS registry number 220007-88-5), the opposite to the configuration described herein, as noted above. Curiously enough, Gil et al.[18] and Fotinos et al.[19] named their isolated compound as the *E* estereoisomer, although they both formulated the compound as *Z*.

3.2. Assay of Extraction. The molecule identified in this paper was obtained and quantified from the ethyl acetate extract, resulting from the hydrothermal treatment of olive oil waste in a previous work.[6] To identify the origin of this molecule, four solid−liquid extractions were realized for fresh alperujo from an olive mill plant. The first was realized with water at room temperature; the second was realized with methanol/water (80:20), followed by methanol elimination; and the other two extractions were performed using a hydrothermal treatment. Subsequent extractions with ethyl acetate were realized in cold and hot conditions for the four aqueous fractions obtained.

The amount of compound **1** measured in the four initial aqueous samples from alperujo and in each of the eight organic fractions is shown in Table 1. To our surprise, the data show that, in the aqueous initial samples obtained after solid−liquid extraction, prior to extraction with ethyl acetate, compound **1** was not detected. However, the compound was identified after extraction with ethyl acetate (in hot and cold), following extractions with H_2O, MeOH:H_2O (80:20), and hydrothermal treatment of 140 °C/60 min. Higher values were obtained in extractions with refluxing ethyl acetate in all cases. These data are in agreement with those obtained by Gil et al.[18] and Fotinos et al.,[19] who, in both cases, isolated their glutaric acid derivative

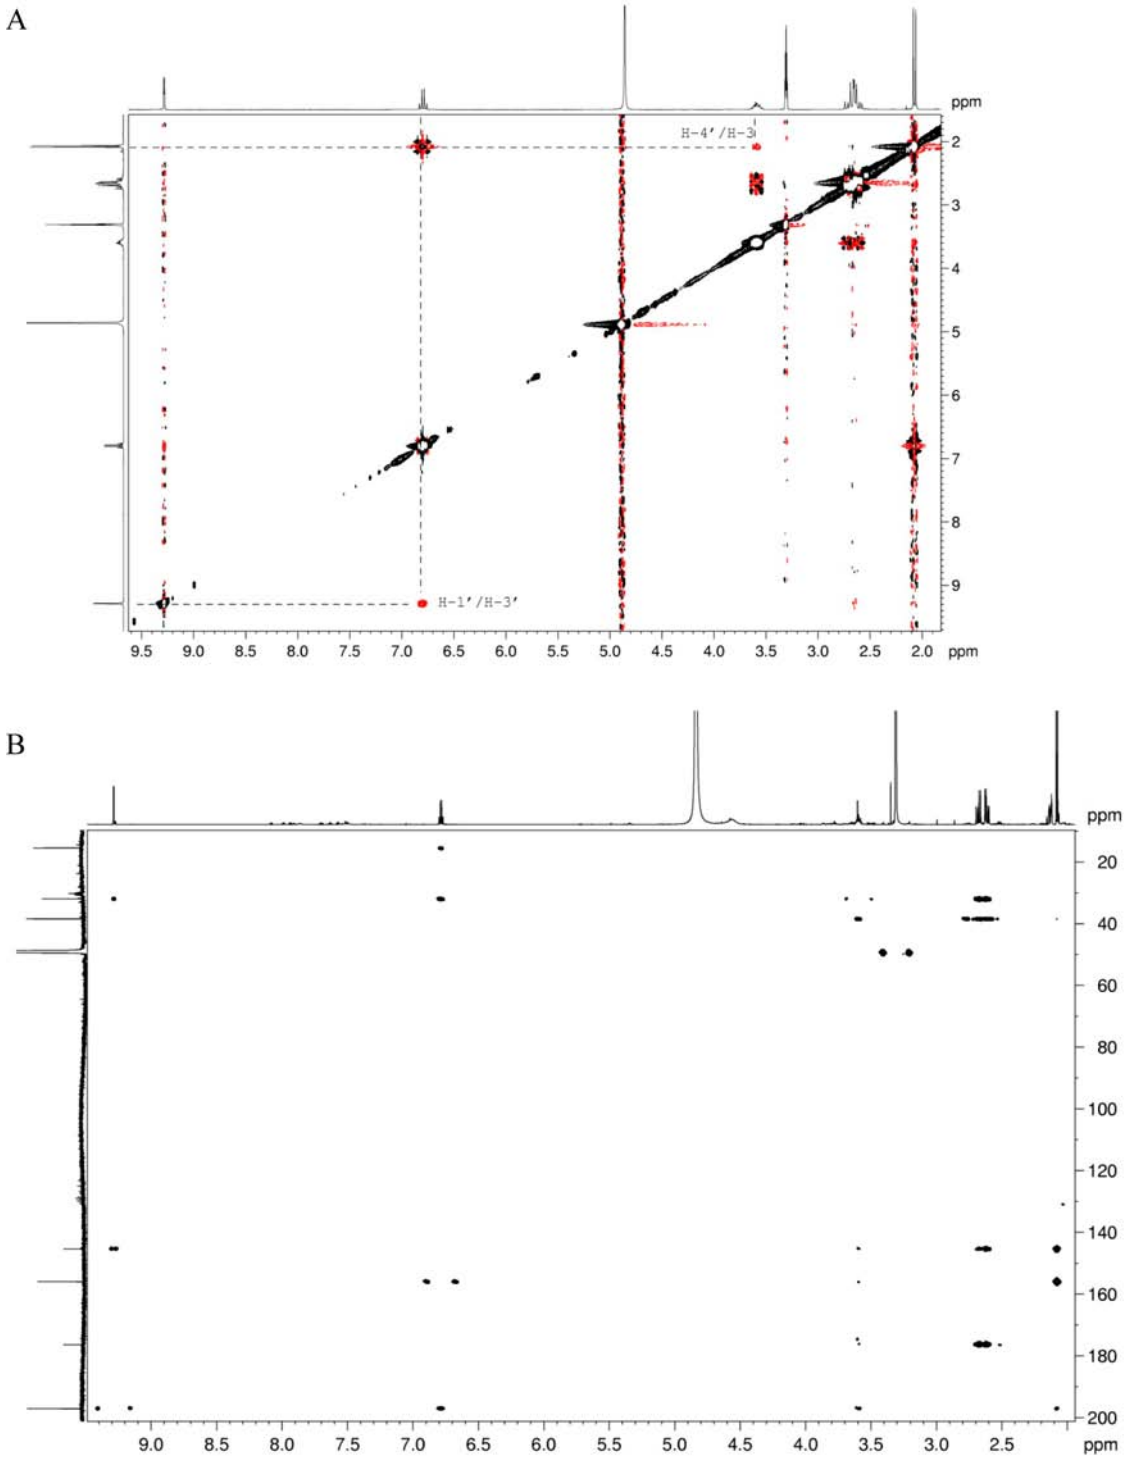

Figure 3. (A) NOESY spectrum for compound **1** in MeOH-d_4 recorded at 300 MHz and (B) HMBC spectrum for compound **1** in MeOH-d_4 recorded at 700 MHz.

from olive products after extraction with ethyl acetate. The fact that, before the extraction with ethyl acetate, compound **1** was not identified and, after extraction, is identified in high concentrations makes us think that the compound **1** is formed during the extraction process, favoring its formation when the process is performed at a temperature of 77 °C. However, in samples of the wastewater from stored alperujo (not ethyl acetate extracted) from a pomace processing mill, a compound named decarboxymethyl elenolic acid (EDA)-like derivative, with a maximum absorbance at 230 nm and MS spectrum with a signal at m/z 199 in the negative mode, was identified,[10] which is present in significant amounts (0.9−1.6 g/kg of alperujo) and matches the compound that we have isolated and identified, although, in this case, after the extraction with ethyl acetate in higher amounts. Thus, these results suggest that the compound could be produced chemically by a hypothetical hydrolytic reaction during the storage and/or processing of the alperujo, in similar conditions that occur when dealing with

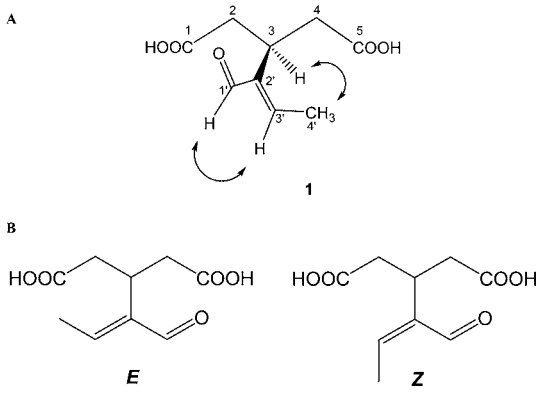

Figure 4. (A) Significant NOE correlations for (*E*)-3-(1-oxobut-2-en-2-yl)glutaric acid (**1**) observed in MeOH-d_4 and (B) possible *E* and *Z* configurations for the cronotonadehyde moiety of compound **1**.

fresh alperujo and ethyl acetate extraction, as described herein. In both cases, the compound likely originates from elenolic acid, the terpenoid skeleton of oleuropein (or ligstroside). Three alternative routes (Figure 5) can be devised for the formation of compound **1** from elenolic acid (**3**), involving ester hydrolysis of compounds **3** or **6**, decarboxylation of β-ketoacid (**4**) or malonic acid derivative (**7**), and oxidation of the formyl group of compounds **3**, **4**, or **5**. Significatively, glutaraldehyde (**5**) is the only intermediate that has been previously described, for example, in stored alperujo[10] and in extra virgin olive oil.[20] Therefore, the pathway through compounds **4** and **5** is the most likely. Nevertheless, two compounds named as "oxidized 3,4-DHPEA-EDA" (oxidized dialdehydic form of decarboxymethyl elenolic acid linked to hydroxytyrosol) with *m*/*z* 335 and 393 (by MS in negative mode) have been recently detected among oxidation products in stored virgin olive oil,[21] which might, in fact, be hydroxytyrosyl esters of compounds **1** and **6**, respectively. These authors have also detected peaks with *m*/*z* 183 and 199, which match with compounds **5** and **1**, respectively.[21]

Table 1 also shows that the highest yield of the compound is obtained by extraction with MeOH:H_2O (80:20), followed by extraction with water, with the yield decreasing with the increasing severity of the solid−liquid extraction process, such that the molecule was not identified in the process of 170 °C/1 h. These results are consistent with the results previously obtained,[6] in which the concentration of the compound herein described as compound **1** decreases at 160 °C with increasing treatment time.

A logical explanation for the absence of compound **1** in aqueous extractions of fresh alperujo and the detection of important amounts of it after extraction with ethyl acetate might be that one or several enzymatic processes (methyl ester hydrolysis, oxidation, or decarboxylation) take place in a faster fashion in ethyl acetate than in aqueous media. Enzymatic oxidation of virgin olive oil (VOO) secoiridoids by enzymes, such as polyphenol oxidase (PPO) and peroxidase (PPP), activated during the oil mechanical extraction process, has been previously described.[22] Furthermore, no detection of compound **1** after the thermal treatment under harsh conditions (170 °C/60 min) might be related to enzyme denaturalization. These results showed that the formation of compound **1** can take place over long storage processes or be accelerated by the extraction with ethyl acetate. In future studies, we will address the origin of compound **1** and will study whether the activity of PPO and PPP is improved in ethyl acetate.

3.3. Antimicrobial Activity. The phenolic ethyl acetate extract obtained from hydrothermally treated alperujo (160 °C/60 min) was fractionated using Amberlite XAD16. This method led to the isolation of two fractions (fractions 1 and 2) that contain the glutaric acid derivative (**1**), together with other phenolic compounds in different ratios (Table 2). Antimicrobial activity against *P. syringae* and *A. tumefaciens* of fractions 1 and 2 and the purified compound were screened. In this work, the antimicrobial ability was determined after only 5 min of contact,[10] because such a bactericidal effect would be of more interest for the application of active compounds for field trials on plants than other methods. The method evaluates the antimicrobial activity considering that the application is performed on the plant and there may be external agents (rain and/or wind) that delimit the most prolonged time of contact. This method is employed by numerous authors to evaluate the antimicrobial activity of different compounds in plants.[10,23]

The bactericidal effect of fraction 1 (Figure 6A) was assessed at concentrations of 50 mg/mL for *P. syringae*, reducing the initial population by 4 log CFU/mL (10 000-fold), and for *A. tumefaciens*, reduced by only 2 log units (100-fold). Fraction 2 (Figure 6B) had the same bactericidal effect on *P. syringae* as fraction 1 at 50 mg/mL; however, 75 mg/mL of this fraction was required to elicit a bactericidal effect against *A. tumefaciens*. The purified glutaric derivative, (*E*)-3-(1-oxobut-2-en-2-yl)-glutaric acid, dramatically decreased the *P. syringae* population by more than 4 log units at the concentration of 18 mg/mL; however, no bactericidal effect was observed at the same concentration for *A. tumefaciens* (Figure 6C).

The concentrations of phenolic compounds in the fractions 1 and 2 are shown in Table 2. After observation of the results obtained for fraction 1, the bactericidal effect on *P. syringae* at 50 mg/mL could be attributed to its high glutaric derivative content (38.9%), corresponding to 19 mg/mL, a concentration that coincides with 18 mg/mL of the purified compound that showed a strong bactericidal effect. Nevertheless, fraction 1 also contained other known antimicrobial compounds, such as hydroxytyrosol (33.7%), representing 16.8 mg/mL of 50 mg/

Table 1. Amount of Compounds Measured in the Initial Aqueous or Hydromethanolic Samples and in Each of the Organic Fractions Isolated after Extraction with Hot and Cold Ethyl Acetate

[a]nd = not detected.

mL that provoked inhibition of microbial growth. We determined that the hydroxytyrosol concentration required to cause an antimicrobial effect on *P. syringae* and *A. tumefaciens* was less than 16.8 mg/mL (data not shown). The effect of purified hydroxytyrosol from aqueous alperujo solution was higher than in the presence of the other substances comprising fraction 1, which would suggest an antagonistic interaction.

Fraction 2 exerted bactericidal activity against *P. syringae* at a concentration of 50 mg/mL, containing 8% of glutaric acid derivative (4 mg/mL) and 4.5% of hydroxytyrosol (2.2 mg/mL), while 75 mg/mL of this fraction were needed to act on *A. tumefaciens*, representing 6 mg/mL of glutaric acid derivatives and 3.3 mg/mL of hydroxytyrosol. In this case, the bactericidal effect of fraction 2 can be explained by the concentration of only hydroxytyrosol, because the effect of purified hydroxytyrosol was detected at a similar concentration (data not shown). However, it could also be explained by the combined effects of hydroxytyrosol, oleuropein, and 4-methylcathecol, with the last compound being the most toxic.[24]

These preliminary studies of antimicrobial activity of compound **1** show that the isolated compound has good antimicrobial activity when compared to hydroxytyrosol. Hydroxytyrosol is a polyphenol found in high concentrations in the alperujo, which present an important antimicrobial activity; its activity has been studied against many bacterial and fungi; and many studies have been realized evaluating this compound.[23,25] Particularly, hydroxytyrosol at 1 mg/mL has bactericidal effect for the two microorganisms evaluated in this paper.[25] Therefore, this first screening opens a new way to study the bactericidal effect of this compound on other pathogens for plants and humans. Furthermore, compound **1** could be used as not only an antimicrobial agent but also a key source of a lactone with significant cytoprotective properties against DNA damage induced by oxidative stress.[19]

Generals Comments. In the present investigation, chemical studies of a phenolic extract obtained from aqueous, methanolic aqueous, or hydrothermically treated fresh alperujo led to the isolation and identification of an elenolic acid derivative, (*E*)-3-(1-oxobut-2-en-2-yl)glutaric acid (**1**). To the best of our knowledge, this is the first time that the structure has been well-established with the spectroscopy data shown. The *s-trans* conformation for the Cα−CHO bond is in agreement with the NOESY experiment. The compound was quantified in large amounts, and synthetic routes to explain its formation involving ester hydrolysis, decarboxylation, and oxidation have been suggested. The role of ethyl acetate as an extracting solvent seems to be key in the process. From a practical point of view, (*E*)-3-(1-oxobut-2-en-2-yl)glutaric acid could be used as an important source of a lactone with significant cytoprotective properties[19] and as an antimicrobial agent against bacteria responsible for plant diseases.

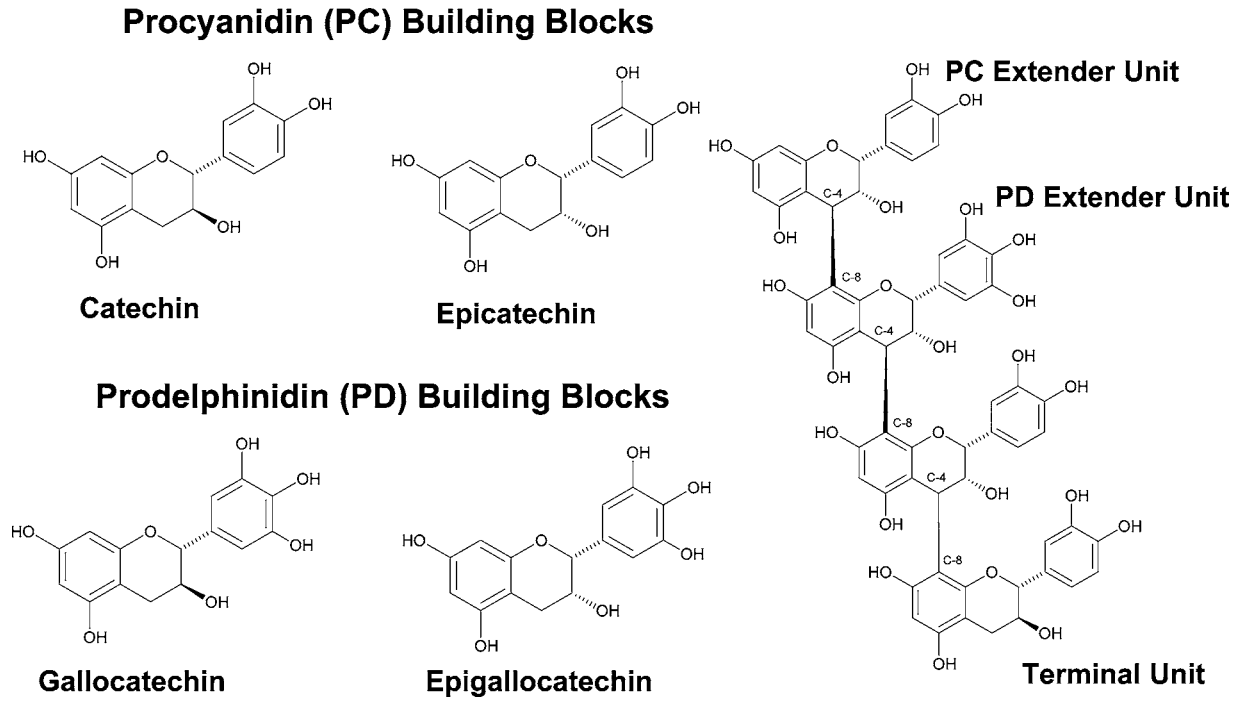

Figure 1. Structures of major flavanol subunits that occur in condensed tannins (left). A condensed tannin tetramer (right) shows a terminal unit with different extender units connected by C4−C8 (B-type) linkages.

tetramer series and beyond. Additional studies leading to the same conclusion include inhibition of methane production parallel with molecular weight increases of CT fractions from *Leucaena* in in vitro rumen fermentation studies[30] and binding to bovine serum albumin (BSA),[31] although in these cases molecular weight did not appear to be the sole factor in determining protein binding affinity.[31,32] To add to the confusion, mixed results of CT size versus protein precipitation capability were seen even across *Leucaena* genotypes.[33] Others have reported conflicting results for protein precipitation. For example, Naumann et al.[34] reported that mDP was not a factor in methane production from in vitro fermentation studies or in protein precipitation studies.[35] Thus, it is clear that the question of the correlation of CT mDP on the formation of CT−protein complexes and precipitates and their ramifications on biological activities remains unresolved.

Progress in this area has been hampered by the difficulty in obtaining sufficient quantities of highly pure and well-characterized CT fractions. Researchers are now starting to perform the necessary purification and characterization of isolated CTs to aid in the unraveling of the intricacies of CT−protein interactions. Noteworthy in this regard is a recent report by Harbertson et al.,[36] which utilized HPLC-purified cocoa CT, consisting entirely of epicatechin (PC) subunits, into singular DP fractions of trimer to octamer oligomers. These authors reported that each individual CT fraction exhibited a linear response in the precipitation of BSA with increasing CT concentration and protein precipitation increased with DP of the CT fractions. In addition, mixtures of the trimer with pentamer through octamer oligomers generally showed an additive effect on precipitation of BSA from solution. However, the authors noted that, in some cases, a synergistic effect was observed for precipitation of BSA when a nonprecipitating level of trimer was added.

Whereas HPLC purification can provide pure CTs or mixtures of CTs sharing the same degree of polymerization up to DP 9,[36−38] and provides insightful information on structure−activity relationships of CT−protein precipitation, the purification process is costly, labor intensive, and quantity limiting. These limitations hamper scale-up preparation of CTs for executing important, next-level in vitro studies, such as rumen and ensiling protein degradation studies and the investigation of ammonia and methane abatement by CTs. Larger quantities of CT are required to execute these studies. At this time and at the current level of purification technology, these limitations force the use of CT mixtures isolated from plant sources containing a range of DP in each fraction to perform these in vitro studies.

When larger quantities of CT fractions have been obtained, the purities of the CT fractions were generally not determined and impurity profiles are often not known. The fact that other plant components can interfere with CT−protein complex formation, especially carbohydrates,[4] incorporates a realm of uncertainty in studies using fractions of unknown purities and may have led to confounding results. McNabb et al.[24] pointed this out, noting that their preparations should be referred to as simply "CT extracts" due to the lack of any purity assessment and their unknown impurity profile. Thus, alternative purification protocols for producing sufficient quantities of well-characterized CTs of high purity are essential for laboratory and in vitro experimentation to obtain unambiguous results.

We have initiated a program directed toward the isolation of highly pure and well-characterized CT fractions with the goal of utilizing information gained in laboratory and in vitro investigations to further our understanding of CT−protein interactions. Here we describe the protein precipitation profiles of two paired sets of purified CT fractions of similar composition against three different protein types. The CT fractions isolated from *Lotus pedunculatus* (big trefoil) leaves and *Trifolium repens* (white clover) flowers possess similar compositions (PC/PD and *cis*/*trans* ratios) but differ 2-fold in

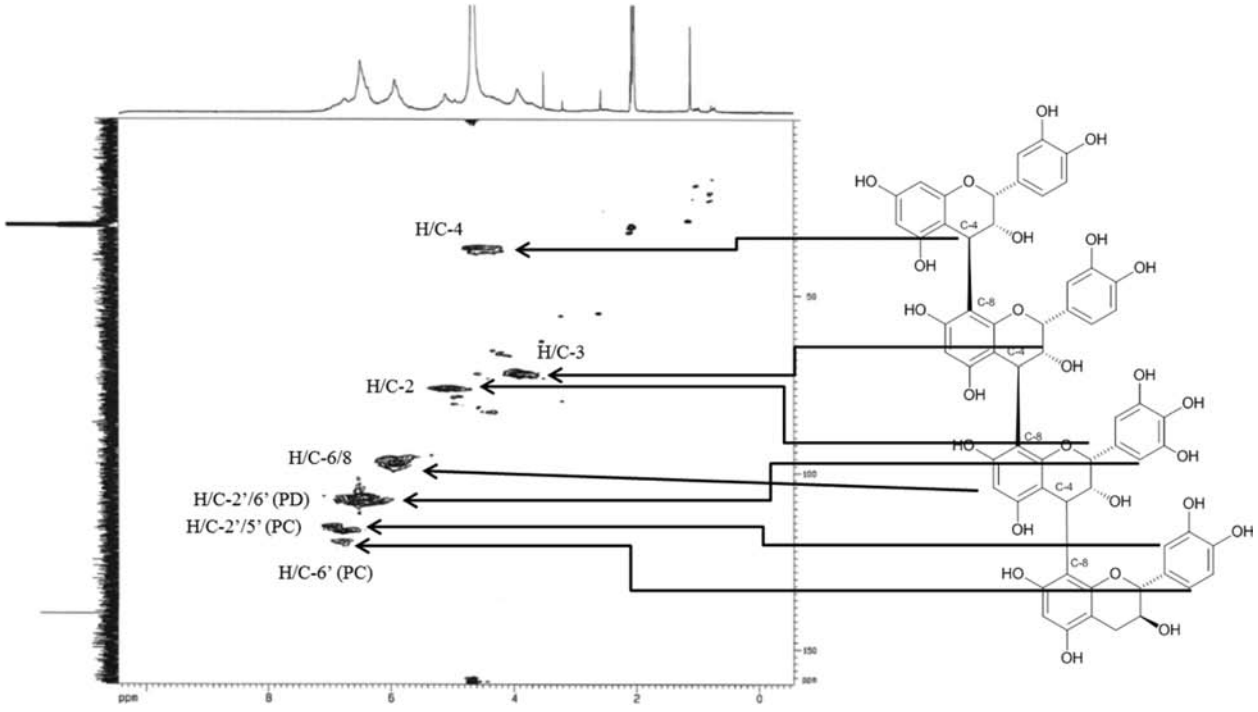

Figure 2. Signal assignments for the $^{1}H-^{13}C$ HSQC NMR spectrum (360/90 MHz, D_2O/acetone-d_6, 4:1) of a large-sized condensed tannin fraction purified from big trefoil (BT-Large). The purity of the fraction was 91.3% by thiolysis.

their mean degrees of polymerization (mDP ~9 versus mDP ~ 18). We selected two commercially available proteins with different p*I* values, BSA and lysozyme (LYS), as test proteins. To provide protein material relevant to ruminant animal production systems, we selected alfalfa leaf protein extract (ALF), the main protein of which is Rubisco.[39]

MATERIALS AND METHODS

Reagents. Lysozyme and bovine serum albumin were purchased from Sigma (St. Louis, MO, USA) and the Pierce 660 nm Protein Assay Reagent from Thermo Scientific (Rockford, IL, USA). Sephadex LH-20 and G-25 were purchased from GE Healthcare Biosciences (Piscataway, NJ, USA).

Plant Materials. In 2013, flowers from naturalized populations of white clover were harvested from lawns in Viroqua, WI, USA, and in Reading, UK, frozen at −20 °C, and subsequently freeze-dried, ground in a cyclone mill (1 mm screen), and stored frozen until used. In 2009, herbage of 45-day-old summer regrowth of big trefoil was harvested from established stands near Prairie du Sac, WI, USA, and frozen at −20 °C. After freeze-drying, herbage was shaken to recover leaves, which were ground with a cyclone mill (0.5 mm screen) and stored frozen until used.

General Procedure for Purification and Analysis of Condensed Tannins. The isolation and purification of condensed tannin fractions BT-Medium and WC-Medium were accomplished by using the previously published procedures.[40,41] Briefly, the ground plant material was extracted with acetone/water (7:3) three times and filtered. The combined filtrates were concentrated on a rotary evaporator (<40 °C) and extracted with dichloromethane to remove nonpolar components, and the resulting aqueous solution was freeze-dried. The freeze-dried extracts were dissolved in water and applied to a Sephadex LH-20 column, and the column was rinsed with water to remove carbohydrates. Then CTs were eluted with acetone/water (3:7, v/v; fraction 1) and acetone/water (1:1; fraction 2), with fraction 2 providing CTs of high purity for the BT-Medium and WC-Medium preparations, from ground big trefoil leaves and white clover flowers, respectively, used in this study. For the isolation of CT fractions BT-Large and WC-Large, the freeze-dried acetone/water (7:3) extracts were obtained in a similar manner, but a different elution scheme was used. This scheme consisted of adsorbing the 7:3 acetone/water extraction residue onto Sephadex LH-20 in methanol/water (1:1) and then eluting the resin with the following series of solvents, first with methanol/water (1:1) and then with a series of acetone/water mixtures (1:1, 7:3, 9:1). As a representative example, details of the purification of CT from big trefoil leaves (BT-Large) are given here. Dried and ground big trefoil leaves (70.2 g) were transferred to a 1 L Erlenmeyer flask, equipped with a large magnetic stir bar. The mixture was rapidly stirred with 7:3 (v/v) acetone/water for 30 min (3 × 700 mL) and filtered through a Buchner funnel. Combined extracts were concentrated on a rotary evaporator at 35 °C to remove acetone and then washed with dichloromethane (2 × 500 mL). Traces of dichloromethane were removed by rotary evaporation, and the material was freeze-dried to yield 19.2 g of solids. The solids were transferred to an 800 mL beaker and dissolved in 1:1 methanol/water (200 mL), and then Sephadex LH-20 (60 g) was added in small portions with stirring until a slurry was formed with the consistency of wet sand. The slurry was transferred to a 600 mL sintered-glass funnel equipped with a filter paper. The Sephadex LH-20 bed was sequentially suspended in the washing solvent, allowed to stand for 5−10 min, and vacuum filtered with the following series of solvents. Solvent washings were pooled into fractions as follows: fraction 1 (BTF1), with methanol/water (1:1; 4 × 250 mL); fraction 2 (BTF2), with methanol/water (1:1; 2 × 250 mL); fraction 3 (BTF3), with methanol/water (1:1; 2 × 250 mL); fraction 4 (BTF4), with acetone/water (1:1; 4 × 250 mL); fraction 5 (BTF5), with acetone/water (7:3; 4 × 250 mL); fraction 6 (BTF6), with acetone/water (9:1; 4 × 250 mL). After removal of volatile organics by rotary evaporation, small aliquots of all of the fractions were freeze-dried and subjected to ^{1}H NMR analysis. Fractions deemed reasonably pure from this analysis (little or no evidence of carbohydrate signals) were forwarded to $^{1}H-^{13}C$ HSQC NMR analysis. Inspection of the $^{1}H-^{13}C$ HSQC NMR spectra of each fraction allowed a qualitative assessment of purity based on the absence of significant non-CT cross-peak signals. On the basis of these evaluations, fraction BTF1 was discarded, fractions BTF2 and BTF3 were set aside pending further purification, and fractions BTF4, BTF5, and BTF6 were freeze-dried. Yields of solids from fractions BTF4, BTF5, and BTF6 were 1.51, 0.809, and

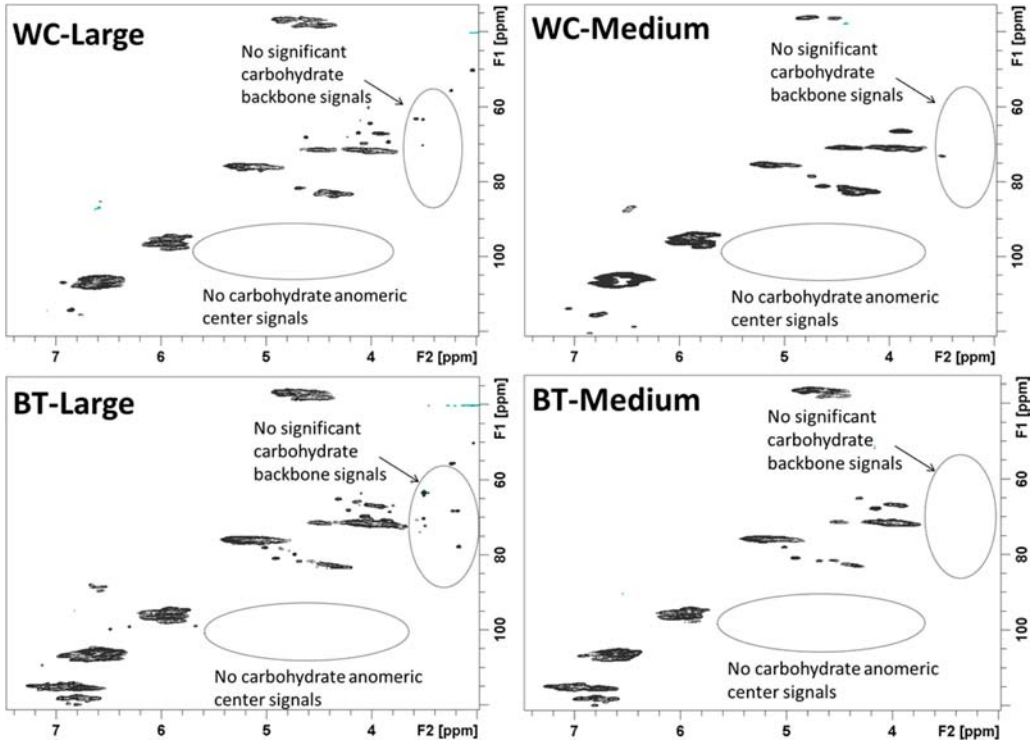

Figure 3. $^{1}H-^{13}C$ HSQC NMR spectra (500/125 MHz, DMSO-d_6/pyridine-d_5, 4:1) of large- and medium-sized condensed tannin fractions purified from white clover (WC) and big trefoil (BT).

0.020 g, respectively. Fractions BTF4 and BTF5 were forwarded to thiolysis[3,40] for purity and compositional analysis. Herewith, fraction BTF5 is referred to as BT-Large (Tables 1 and 2 and Figures 2–4).

NMR Spectroscopy. ^{1}H, ^{13}C, and $^{1}H-^{13}C$ HSQC NMR spectra used for screening of CT fractions were obtained on a Bruker Avance 360 instrument (Bruker Corp., Billerica, MA, USA) operating at 360 MHz (^{1}H) and 90 MHz (^{13}C). Spectra obtained were referenced to the center residual signals of acetone-d_6 contained within the 4:1 D_2O/acetone-d_6 mixture, at 2.04 and 29.8 ppm for ^{1}H and ^{13}C, respectively. Spectra were obtained using standard Bruker pulse programs (programs zg30, zgpg30, and invietgpsi for ^{1}H, ^{13}C, and $^{1}H-^{13}C$ HSQC NMR spectra, respectively). ^{1}H, ^{13}C, and $^{1}H-^{13}C$ HSQC NMR spectra for the CT fractions used in the precipitation studies were recorded at 27 °C on a BrukerBiospin DMX-500 (^{1}H 500.13 MHz, ^{13}C 125.76 MHz) instrument equipped with TopSpin 2.1 software and a cryogenically cooled 5 mm TXI $^{1}H/^{13}C/^{15}N$ gradient probe in inverse geometry. Spectra were recorded in DMSO-d_6/pyridine-d_5 (4:1) mixtures and were referenced to the residual signals of DMSO-d_6 (2.49 ppm for ^{1}H and 39.5 ppm for ^{13}C spectra). ^{13}C NMR spectra were obtained using 5K scans (acquisition time = 4 h and 30 min each). For $^{1}H-^{13}C$ HSQC experiments, spectra were obtained using 128 scans (acquisition time = 18 h and 30 min each) obtained using the standard Bruker pulse program (programs zg30, zgpg30, and hsqcegtpsi for ^{1}H, ^{13}C, and $^{1}H-^{13}C$ HSQC NMR spectra, respectively).

Thiolysis Determination of CT Fraction Composition and Percent Purity. Thiolysis was conducted as previously described.[3,40] Briefly, approximately 8 mg of purified CT fractions was subjected to thiolysis with concentrated HCl in methanol in the presence of benzyl mercaptan providing the extender units of the CT as their benzyl mercaptan adducts and terminal units as underivatized flavan-3-ols. The resulting mixture was then analyzed by LC-MS on an HPLC Agilent 1100 series system and an API-ES instrument Hewlett-Packard 1100 MSD series (Agilent Technologies, Waldbronn, Germany). Separation of mixture components was accomplished on an ACE C_{18} column (3 μm; 250 × 4.6 mm; Hichrom Ltd., Theale, UK) fitted with a guard column at room temperature using a flow rate of 0.75 mL/min. The HPLC eluent consisted of mixtures of 1% acetic acid in water (solvent A) and HPLC grade methanol (solvent B) utilizing the following gradient program: 0–52 min, 36% B; 52–60 min, 36–50% B linear; 60–65 min, 50–100% B linear; 65–73 min, 100–0% B; 73–80 min, 0% B. Chromatograms were recorded at 280 nm, and mass spectra were recorded in the negative ionization scan mode. The percent of each benzyl mercaptan adduct was calculated on the basis of molar response factors determined relative to the internal standard taxifolin. Percent purity was calculated through summation of the total mass of all terminal and extension flavan-3-ol units divided by the initial mass of the analyzed material (g total flavan-3-ols/100 g CT fraction × 100).

Protein Precipitation Assay. BSA and chicken egg white LYS were dissolved in 50 mM 2-[*N*-morpholino]ethanesulfonic acid (MES), pH 6.5 (with NaOH), to a concentration of 10 mg/mL. Alfalfa leaf protein extract was prepared and desalted using Sephadex G-25 spin columns as described previously[42] except that the buffer used for extraction and spin column equilibration was 50 mM MES, pH 6.5. Protein concentration of the desalted alfalfa leaf extract was determined using the Pierce 660 nm Protein Assay Reagent with BSA as the standard and varied from 2.2 to 3.0 mg/mL. Small aliquots of the protein solutions (500 and 1700 μL for the pure proteins and the alfalfa extract, respectively) were flash frozen in liquid nitrogen and stored at −80 °C until needed.

A master stock solution of each CT fraction was prepared by weighing out approximately 20 mg of purified CT and dissolving to a final concentration of 10 mg/mL in ethanol. Further working stock solutions were prepared in ethanol from the master stock to give 5.00, 3.75, 2.50, 1.88, 1.25, 0.95, and 0.62 mg/mL solutions. For each protein tested, 20 μL of each CT working stock solution (or buffer control for no CT) was pipetted into 1.7 mL microfuge tubes in duplicate. A no-protein control series was also carried out for each CT fraction. The CT samples were dried down in a centrifugal vacuum concentrator (Eppendorf Concentrator 5301) and redissolved in 50 mM MES, pH 6.5 (80 μL for BSA and LYS precipitation assays, 10–20 μL for ALF assays depending on the protein concentration of the extract). Previously frozen protein stock solutions were thawed and added to the CT in each tube to give a final reaction volume of 100 μL and a final protein concentration of 2 mg/mL (20 μL for BSA or LYS,

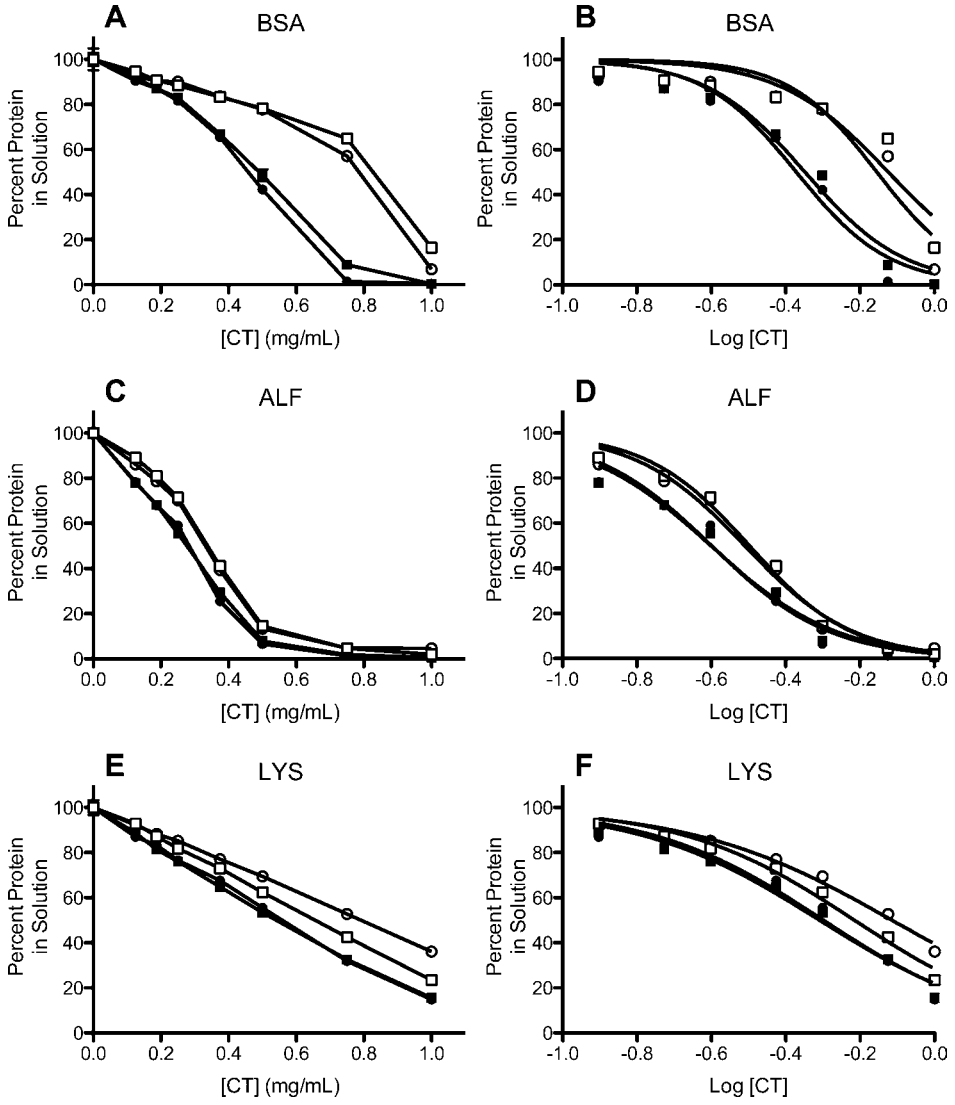

Figure 4. Precipitation of bovine serum albumin (BSA), alfalfa leaf protein extract (ALF), or lysozyme (LYS) by two large- and two medium-sized condensed tannins (CT) isolated from big trefoil and white clover: big trefoil, medium (□); big trefoil, large (BT-Large) (■); white clover, medium (○); white clover, large (●). The concentrations of CT are expressed on a milligram per milliliter basis (left) and a log[CT] basis (right). Graphs depict data from one of two experimental replicates.

80−90 μL for ALF, depending on the protein concentration of the extract). The precipitation reactions were incubated for 10 min on ice and then centrifuged for 5 min at 20000*g*. A sample of each resulting supernatant (20 μL) was added to 30 μL of 50 mM MES (pH 6.5). Protein present in the supernatant samples was determined by adding 750 μL of Pierce 660 nM Protein Assay Reagent and measuring the absorbance at 660 nm using a Beckman DU800 spectrophotometer (Beckman-Coulter, Brea, CA, USA). In pilot experiments we found that the Pierce 660 Protein Assay Reagent was linear over the range of protein concentrations being examined and showed virtually no reactivity with the tannin preparations tested. The duplicate data points were averaged, and data for each tannin/protein combination were analyzed by fitting a curve to the data using Prism (GraphPad Software, La Jolla, CA, USA). Because in pilot experiments protein could be quantitatively precipitated by tannins, an inhibitor dose−response curve (log[tannin concentration] versus normalized response with variable slope) was the nonlinear regression curve-fitting model selected. Fitted curves had *r*-squared values of >0.95, except for BSA with medium mDP CT, which had *r*-squared values of >0.87 and >0.89 for big trefoil and white clover tannins, respectively. This approach allowed determination of an IC_{50} (in this case the tannin concentration at which half the protein was precipitated, hereafter referred to as PP_{50}). The entire experiment was replicated (for $N = 2$) using independently prepared master stock solutions of each tannin.

Statistical Analysis. The replicated PP_{50} values were subjected to a mixed model analysis in a randomized complete block design by running PROC MIXED (SAS, 2014). Protein, CT, and their two-way interactions were considered fixed effects, whereas replicates ($N = 2$) from two independent experiments and their interactions with fixed effects were considered random effects. If *F* tests were significant ($P \leq 0.01$), then least-squares means of fixed effects were compared at $P = 0.01$ using a *t* test performed by a SAS pdmix800 macro.[43] Unless noted otherwise, treatment differences described in the text were significant at $P = 0.01$.

RESULTS AND DISCUSSION

Determinination of Purity and Composition of CT Fractions by NMR and Thiolysis. In previous studies, CTs bound to Sephadex LH-20 or other resins were typically washed with selected polar protic solvent mixtures, eluted with acetone−water, and apparently used in protein precipitation studies without any assessment of purity. Unknown variations in CT purity may therefore account for the conflicting results

from previous studies examining the effects of CT structure on protein precipitation. When using such isolation procedures, we have found that acetone−water fractions contain between 30 and 80% CTs (unpublished data) with the balance composed mainly of carbohydrate impurities. As carbohydrates do not possess chromophoric entities, they would not be observed if commonly employed UV detectors were used to track CT elution from chromatography columns. In addition to introducing errors through hitherto unaccounted for variations in CT purity, carbohydrates and carbohydrate derivatives can also bias CT−protein precipitation results by competing with proteins during CT complexation.[44−46] Thus, the need for highly pure CT fractions, free of significant carbohydrate impurities, seems a prerequisite for obtaining meaningful results from CT−protein precipitation studies. Hence, for our protein precipitation studies, we opted to use only CT fractions with purities exceeding 90% as determined by thiolysis. The results of thiolysis analysis for PC/PD and *cis*/*trans* ratios and mDP of the four CT fractions used in the protein precipitation studies are presented in Table 1. The percent purities provided by thiolysis for the CT fractions were BT-Medium, 91.3 ± 0.4; BT-Large, BTF5, 108.0 ± 0.1; WC-Medium,(106.6 ± 5.1; and WC-Large, 120.6 ± 0.9. Occasionally, the purity determined by the thiolysis method exceeds 100%, especially when samples of very high purity are analyzed. This is one identifiable flaw in the method and may be due to the cumulative errors in the summation of multiple HPLC peaks. The presence of coeluting, undetected compounds is unlikely as NMR analysis confirmed the high purity of all fractions. Figure 3 provides the $^{1}H-^{13}C$ HSQC NMR spectra for the CT fractions used in the precipitation studies. The absence of any significant non-CT related cross-peak signals implies high purity of these samples. Cross-peak signals (see Figure 2 for assignments) for H/C-4, H/C-6,8, H/C-2′,6′ (PD), H/C-2′,5′ (PC), and H/C-6′ (PC) appear as compact contours. Clusters of cross-peaks are seen for C-2 and C-3 signals and are not the result of impurities present. These clusters arise from different H/C-2 and H/C-3 chemical shifts for *cis*/*trans* isomers, interflavan (C4−6 vs C4−8) bond isomers, and terminal flavanol subunits. A comprehensive analysis of these spectra is currently underway in an effort to assign specific structural features to these cross-peak signals. On the basis of thiolysis, both plant species yielded a medium-sized CT (mDP ∼9) and a large-sized CT (mDP ∼18). Overall, the compositionally matched pairs of PD-based CTs with mDPs of ∼9 and ∼18 appear ideal for testing whether medium- and large-sized CTs differ in their capacity to precipitate protein.

Protein Precipitation Studies. The three protein preparations used in our precipitation studies were selected because their interaction with CT has direct relevance to protein utilization by ruminants or because they represent proteins with contrasting chemical and structural properties. Alfalfa leaf protein extract (ALF) represents the main group of soluble proteins that react with CT in forage crops consumed by ruminants. The proteins of ALF are composed of approximately 70% Rubisco,[39] which is a large, loose globular protein with an acidic p*I* ∼4.6.[47] The reaction of soluble proteins such as those in ALF with CT limits their degradation by plant proteases and by proteases produced by rumen microflora, and this potentially increases the amount of forage protein digested in the gastrointestinal tract for use in animal growth and production.[48,49] Like Rubisco, BSA is a large, loose globular protein with an acidic p*I* ∼4.7[50] that is commonly used in CT precipitation assays, in part because it is readily available from commercial sources. In contrast to ALF and BSA, LYS is a small basic protein with a p*I* 11.35[51] and has a compact, globular topology. We included LYS in the study to gain some insight into whether the relative reactivity of medium- versus large-sized CTs is markedly affected by the charge, size, and structure of protein.

Precipitation studies were carried out in aqueous buffered solutions at pH 6.5, a value that approximates the pH of freshly chopped or macerated alfalfa[52] and of rumen contents where excessive proteolysis of alfalfa protein commonly occurs. In the assay, proteins were incubated with various quantities of CT, and protein precipitation was estimated by analyzing the supernatants with a protein assay reagent that does not react with CTs. The overall ability of CT to precipitate protein was determined by fitting the data to a dose−response curve to estimate PP_{50} (similar to previously described *b* values),[31,33] which we defined as the amount of CT required to precipitate 50% of the protein from a 2 mg/mL solution.

Overall, PP_{50} values suggested protein precipitation was significantly more effective with large CTs (mDP ∼18) than with medium CTs (mDP ∼9) and with ALF than with BSA or lysozyme (Table 2). The quantity of CT required to precipitate protein was, however, influenced by a highly significant ($P < 0.001$) protein × CT interaction. Within each protein type, large CTs prepared from white clover or big trefoil had similar capacities to precipitate protein, but responses to medium CT from these plant sources differed with protein type. Medium CTs from both plant sources had a similar capacity to precipitate ALF or BSA, but medium CTs from big trefoil were more effective than those from WC for precipitating LYS. The mechanism responsible for these differing protein precipitation responses to medium CT is currently unknown.

All CTs precipitated ALF much more effectively than BSA or LYS, and among the proteins examined, ALF exhibited a smaller, albeit significant, difference in PP_{50} for medium versus large CTs (Table 2). It has been previously shown that leaf protein extracts from white clover precipitate at lower CT concentrations than BSA.[24] The precipitation profiles of ALF in response to increasing CT concentrations were somewhat sigmoidal (Figure 4), suggesting that aggregation of CT−

SE	0.0046	0.0145	0.0022	0.0138	

[a]PP_{50} values are defined as the amount of CT required to precipitate 50% of the protein from a 2 mg/mL solution. [b]Within rows, means with unlike letters (a–c) differ at $P = 0.01$. Within columns, means with unlike letters (x–z) differ at $P = 0.01$. [c]SE, standard error of the mean.

protein complexes may have slightly accelerated the precipitation process. This aggregation effect on CT–protein precipitation has been noted in previous studies.[53,54] Compared to BSA and LYS, Rubisco, the major component of ALF, is relatively unstable, and disruption of its quaternary structure can cause its large subunit to precipitate out of solution even in the absence of tannins.[55] Thus, precipitation of ALF proteins by CT may be facilitated by the disruption of the quaternary structure of Rubisco, as was recently observed with the gallotannin pentagalloylglucose.[56] Although confirmation is needed, the results with ALF might also suggest that CTs aggregate and precipitate a mixed population of proteins more readily than individual proteins.

Differences in the PP_{50} values of BSA and LYS were quite modest considering the greatly differing p*I* and structural characteristics of these proteins. These two proteins, however, had markedly different precipitation profiles in response to increasing CT concentrations (Figure 4). The precipitation profiles of BSA were strongly biphasic or sigmoidal, suggesting that aggregation of CT–protein complexes accelerated the precipitation process. The precipitation profile of LYS, however, exhibited a linear response ($R^2 = 0.99$) to increasing CT concentrations.

Examination of the amino acid sequences for existing lysozyme crystal structures from the Protein Data Bank[57] shows a high ratio of basic/acidic (>2) amino acid residues, translating to a high positive charge density of the resulting CT–lysozyme complex, which is bound to inhibit aggregation. Thus, using lysozyme in protein precipitation studies at pH 6.5 may remove complications in analysis due to aggregation. We did not pursue precipitation studies at higher pH ranges because CT fractions tend to oxidize at pH >8 in aqueous solutions.[58] Because LYS–CT complexes do not appear to undergo accelerated precipitation due to aggregation, CT precipitation studies with LYS might provide a way to more clearly distinguish how CT structural features such as PC/PD ratios, *cis*/*trans* ratios, and different interflavanol linkage types affect the formation of CT–protein complexes. For this reason, additional studies with LYS along with those of ALF and BSA are underway to further investigate how structural features of CT affect protein precipitation.

Coupled with results from Harbertson et al.,[36] these studies clearly show that CT with higher mDP more readily precipitates soluble proteins. The synergy described for protein precipitation using well-defined mixtures of cocoa CTs[36] may indicate that a combination of CTs of various lengths, as present in all CT-containing forages, facilitates precipitation through cooperative complexation and more readily promotes aggregation with the soluble forage proteins. This phenomenon was clearly observed in the current study as nonlinear precipitation profiles for BSA and ALF and is in contrast to the lower DP cocoa CTs' linear precipitation profiles. These results may explain, to some extent, that having mixtures of large and small CTs provides a more powerful combination for generating insoluble protein complexes.

In conclusion, we have demonstrated that BSA, ALF, and LYS proteins are more readily precipitated at pH 6.5 by larger-sized CTs (mDP of ∼18) than by medium-sized CTs (mDP of ∼9) prepared from white clover and big trefoil. The confounding effects of other CT properties on protein precipitation were largely eliminated by using CT pairs that had comparable PD/PC and *cis*/*trans* ratios of subunits and high purity as determined by $^1H–^{13}C$ HSQC NMR and thiolytic degradation with benzyl mercaptan. On the basis of PP_{50} values, all CTs were very efficient at precipitating ALF proteins, possibly because the large subunit of Rubisco has a propensity to dissociate and self-aggregate. Such a dissociation could be facilitated by interactions with CT. The presence of other types of proteins in ALF might further promote aggregation and precipitation by CT. Compared to ALF, the precipitations of BSA and LYS were affected to a larger extent by the mDP of CTs, and both proteins had relatively high PP_{50} values. On the basis of the biphasic or sigmoidal response to increasing CT concentrations, the precipitation of ALF and BSA was likely accelerated by aggregation of CT–protein complexes. By contrast, the linear response of LYS to increasing CT concentration suggests that aggregation was inhibited by the positive charge of this protein at pH 6.5. Studies with high-purity CTs exhibiting a wider range of mDP, PD/PC ratios, and *cis*/*trans* ratios will be pursued to more thoroughly define how compositional and structural features of CTs affect their ability to precipitate various types of proteins under differing pH conditions.

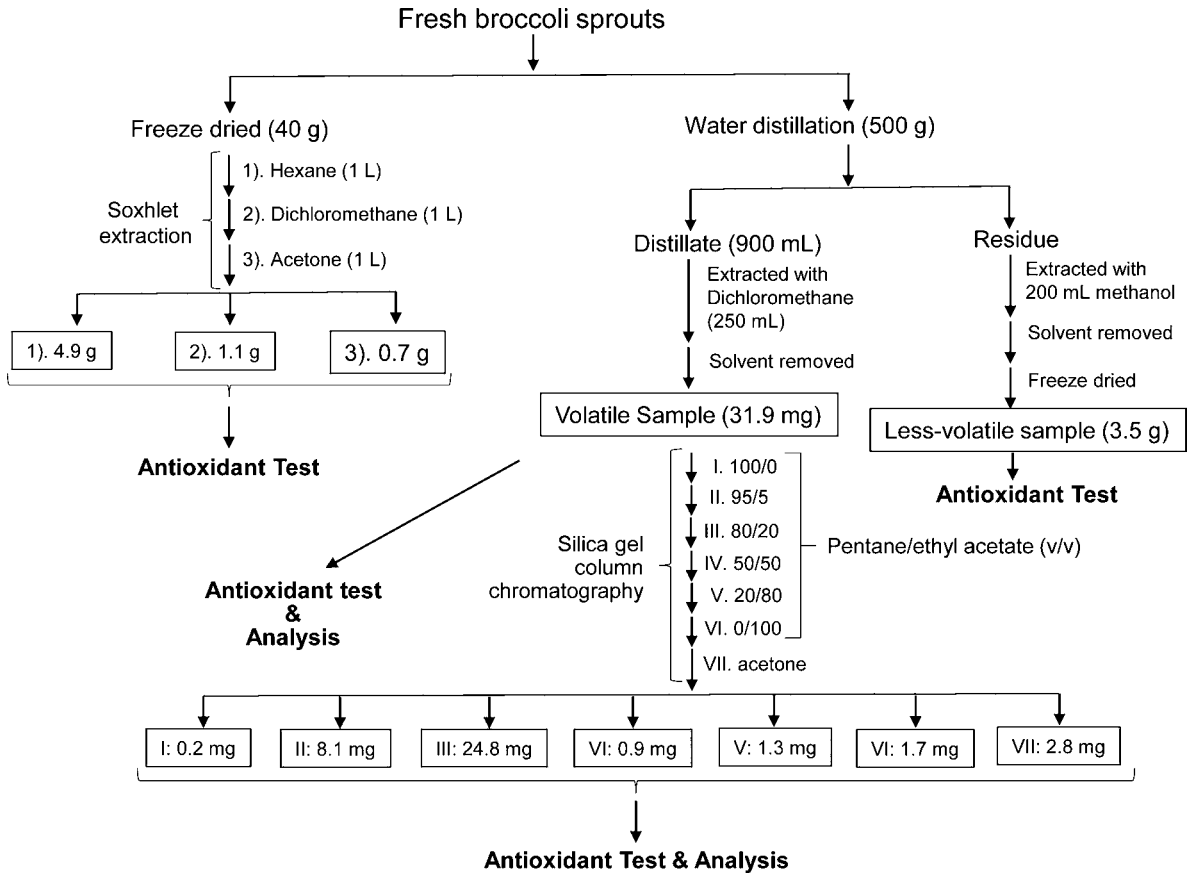

Figure 1. Experimental scheme of sample preparations.

Sample Preparations for Analysis and Antioxidant Assays. The entire scheme of the experimental procedures in the present study is shown in Figure 1.

Water Distillation Samples. Fresh broccoli sprouts (500 g) were placed in a 3 L round-bottom flask with 1 L of deionized water. The aqueous solution was water-distilled at 50 °C for 5 h under reduced pressure (95 mmHg). The distillate (900 mL) was extracted with 250 mL dichloromethane using a liquid–liquid continuous extractor for 6 h. After the extract was dried over anhydrous sodium sulfate, the solvent was removed by a rotary flash evaporator and then placed under a purified nitrogen stream to yield brown viscous material (31.9 mg). This material, labeled the volatile sample, was set aside to be used further for the antioxidant tests and GC-MS analysis.

The residual broccoli sprouts in the distillation flask were mixed with 200 mL of methanol by stirring for 2 h and then filtered. The solvent of the filtrate was removed by rotary flash evaporator, and residual materials were freeze-dried (as the less-volatile sample) and stored at 4 °C until used in the antioxidant tests.

Fractionation of the Volatile Sample. The volatile sample was placed in a glass column (15 cm × 1 cm i.d.) packed with 5 g of silica gel (100–200 mesh, Avantor Performance Materials, Inc., Philipsburg, NJ, USA) and eluted sequentially with the following 100 mL pentane/ethyl acetate solvent fractions: 100/0 (fraction I), 95/5 (fraction II), 80/20 (fraction III), 50/50 (fraction IV), 20/80 (fraction V), 0/100 (fraction VI); finally, elution with 200 mL of acetone yielded fraction VII. The solvent of each fraction was removed by a rotary flash evaporator and then by a purified nitrogen stream to 1 mL in volume. The seven fractions prepared were stored at 4 °C until used for the antioxidant tests and GC-MS analysis.

Freeze-Dried Sample. Fresh broccoli sprouts were freeze-dried at −48 °C for 48 h (FreezOne, Labconco, MO, USA). The freeze-dried broccoli sprouts (40 g) were extracted sequentially with 1 L each of hexane, dichloromethane, and acetone using a Soxhlet extractor. The extracts were dried over anhydrous sodium sulfate. After the solvent of each extract was removed by rotary flash evaporator, they were stored at −5 °C until used for the antioxidant tests.

Analysis of Components in the Volatile Sample. Components in the volatile sample were isolated and identified by GC and GC-MS. Identification was conducted by comparing the Kovats index[20] and MS fragmentation pattern of a GC component with those of an authentic chemical.

The concentration of each compound in broccoli sprouts was calculated according to a previously reported method.[15]

Antioxidant Assays. Three assays were used to examine the antioxidant activity of the samples. Details of the assays used in the present study were described in a previous paper.[21] A standard antioxidant, BHT, was used to validate the assays used.

Malonaldehyde/Gas Chromatography (MA/GC) Assay. This assay is useful for examining the last stage of lipid oxidation.[21]

An aqueous assay solution (5 mL) containing 30 μL of cod liver oil, 0.25 mmol of trizma buffer (pH 7.4), 1 μmol of ferrous chloride, 2 μmol of hydrogen peroxide, 0.75 mmol of potassium chloride, and 1% surfactant sodium dodecyl sulfate was prepared. Various amounts of broccoli sprout samples were added to this assay solution and incubated for 17 h at 37 °C in a 20 mL test tube. After incubation, 50 μL of 4% BHT solution was added to terminate the oxidation of the samples. After MA formed from cod liver oil in the test tube, it was derivatized to 1-methylpyrazole with *N*-methylhydrazine (30 μL). The 1-methylpyrazole formed was eluted with 10 mL of ethyl acetate through an SPE cartridge (MEGA BE-C_{18}, 1 g, 6 mL, Varian, USA). After 20 μL of GC internal standard was added, 2-methylpyrazine was added to the eluate, and the volume of the eluate was adjusted to exactly 10 mL with ethyl acetate. The eluate solution was analyzed for 1-methylpyrazole by GC. All experiments were carried out in triplicate.

2,2-Diphenyl-1-picrylhydrazyl (DPPH) Assay. The DPPH solution (1.52×10^{-4} M) was prepared in ethanol. DPPH solution (4.5 mL) and 0.5 mL of test sample were mixed using a vortex and stored in the dark for 20 min. After the reaction ran to completion, the absorption

DOI: 10.1021/jf504929m
J. Agric. Food Chem. 2015, 63, 1169–1174

activity was measured at 517 nm using a UV−visible spectrophotometer. A solution without the testing sample was used as the control. All experiments were conducted in triplicate.

Aldehyde/Carboxylic Acid Assay. This method is useful to test the long-term antioxidant activity, which is important for determining the shelf life of a product.[21]

Various amounts of the volatile sample (refer to Figure 1) were added to a 2 mL dichloromethane solution of hexanal (3 mg/mL) containing 0.2 mg/mL undecane as a GC internal standard. Standard antioxidant BHT was used to validate the method. Oxidation of the sample solution was initiated by heating at 60 °C for 10 min in a sealed vial and then stored at room temperature. The oxidation of hexanal to hexanoic acid was monitored at 5 day intervals by measuring the amount of hexanal using GC. All experiments were performed in triplicate.

Instruments. An Agilent model 6890 GC equipped with a 60 m × 0.32 mm i.d. (d_f = 0.25 μm) DB-WAX bonded-phase fused-silica capillary column (Agilent, Folsom, CA, USA) and an FID were used for obtaining a Kovats index of components in the volatile sample and its fractions (refer to Figure 1). The linear velocity of the helium carrier gas was 28 cm/s at a split ratio of 10:1. The injector and detector temperatures were 260 and 300 °C, respectively. The oven temperature was programmed to increase from 50 to 210 °C at 2 °C/min and held for 30 min. An Agilent model 6890 GC interfaced to a 5973 mass selective detector (GC-MS) was used for mass spectral identification of the GC components at an MS ionization voltage of 70 eV. GC column conditions were exactly the same as the ones used for GC-FID.

The quantitative analysis of 1-methylpyrazole for the MA/GC assay was performed using an Agilent model 6890 GC equipped with a 30 m × 0.32 mm i.d. (d_f = 0.25 μm) DB-WAX bonded-phase fused silica capillary column (Agilent) and an NPD. The injector and detector temperatures were 250 °C. The oven temperature was programmed to increase from 60 to 160 °C at 4 °C/min and held for 2 min. The linear velocity of the helium carrier gas was 28 cm/s at a split ratio of 20:1.

The quantitative analysis of hexanal for the aldehyde/carboxylic acid assay was conducted by using an Agilent model 6890 GC equipped with a 30 m × 0.25 mm i.d. (d_f = 0.25 μm) DB-1 bonded-phase fused-silica capillary column (Agilent) and a FID. The linear velocity of the helium carrier gas was 30 cm/s at a split ratio of 20:1. The injector and detector temperatures were 300 and 280 °C, respectively. The oven temperature was programmed to rise from 40 to 180 °C at 5 °C/min and then held for 10 min.

Statistical Analyses. The data obtained from the present study were treated with an ANOVA analysis based on the SAS system, and the level of significance was determined using Duncan's multiple-range test at α = 0.05.

RESULTS AND DISCUSSION

Antioxidant Activities of Samples Prepared by Freeze-Drying and Water Distillation. Whereas spectrophotometric methods, such as DPPH assay, cause some difficulties because the absorption of color materials overlaps with that of the target chemical, the MA/GC assay can be applied to samples with dark colors because it measures MA specifically by GC. Therefore, the MA/GC method was used for the preliminary examination of the samples prepared from broccoli sprouts (refer to Figure 1).

Figure 2 shows the antioxidant activity of the samples examined by the MA/GC assay. The values are the mean ± SD (n = 3). BHT showed antioxidant activities of 95.3 ± 0.2% at the level of 500 μg/mL, 92.2 ± 0.4% at the level of 100 μg/mL, and 87.2 ± 3.1% at the level of 20 μg/mL, confirming that the method used was valid. All samples exhibited dose-dependent antioxidant activity. The antioxidant activity ranged from 74.48 ± 0.46% (less volatile sample) to 93.2 ± 0.2% (dichloromethane extract sample) at the level of 500 μg/mL, indicating

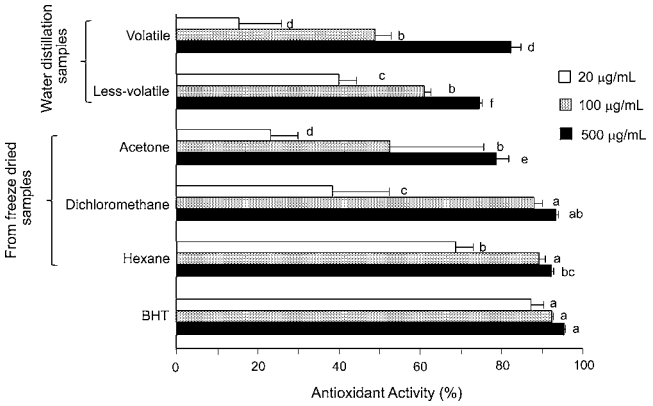

Figure 2. Results of MA/GC assay on the samples prepared from broccoli sprouts by freeze-drying and water distillation.

that all samples contain strong antioxidants. The volatile sample showed 82.1 ± 2.4% at the level of 500 μg/mL. Among the samples tested in this experiment, the sample prepared by Soxhlet extraction with dichloromethane solvent from the freeze-dried sample (refer to Figure 1) exhibited the most potent antioxidant activity. Its antioxidant activities (87.9 ± 1.9% at 100 μg/mL and 93.2 ± 0.6% at 500 μg/mL) were comparable to that of BHT.

Figure 3 shows the results of the DPPH assay. Values are the mean ± SD (n = 3). The results are consistent with those of the

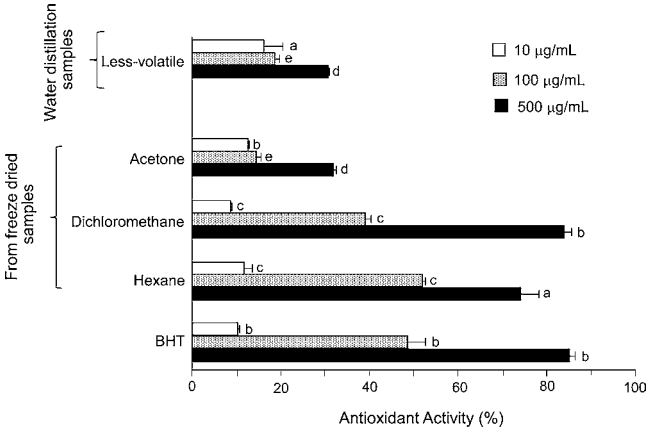

Figure 3. Results of DPPH assay on the samples prepared from broccoli sprouts by freeze-drying and water distillation.

MA/GC assay. The volatile sample was not tested in this experiment because it was tested by the aldehyde/carboxylic acid assay. BHT exhibited clear antioxidant activities with dose response effects: 85.0 ± 1.0% at the level of 500 μg/mL, 47.3 ± 3.9% at the level of 100 μg/mL, and 10.8 ± 0.2% at the level of 20 μg/mL, confirming that this assay is valid. Less volatile samples and acetone samples showed slight dose-dependent antioxidant activities: 30.42 ± 0.17 and 31.7 ± 0.8% at the level of 500 mg/mL, respectively. Dichloromethane samples showed the most potent antioxidant activity among the samples tested in this experiment, which was the same as the results obtained by the MA/GC assay. The antioxidant activity of a dichloromethane sample (83.3 ± 1.7%) was comparable to that of BHT (85.0 ± 1.0%) at the level of 500 μg/mL. Also, dichloromethane and hexane samples exhibited moderate antioxidant activities at the level of 100 μg/mL, which were 39.1 ± 1.2 and

DOI: 10.1021/jf504929m
J. Agric. Food Chem. 2015, 63, 1169−1174

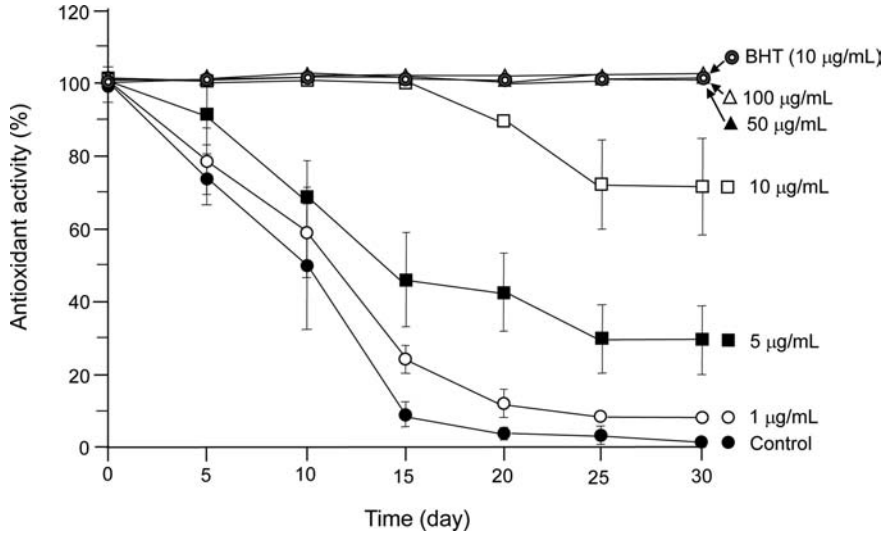

Figure 4. Results of aldehyde/carboxylic acid assay on the volatile sample.

51.8 ± 0.6%, respectively. The less volatile and acetone samples showed only slight antioxidant activities (30.42 ± 0.17 and 31.7 ± 0.8% at the level of 500 mg/mL).

These results from two antioxidant assays suggest that potent antioxidants are present in the dichloromethane and hexane samples and that the amounts of water-soluble antioxidants are less than those of organic solvent extractable (volatile) antioxidants in broccoli sprouts.

Figure 4 shows the antioxidant activity of the volatile sample examined by the aldehyde/carboxylic acid assay over 30 days. This assay is useful in discovering the long-term antioxidant activities of a chemical or a group of chemicals.[21] The values are the mean ± standard deviation (SD) (n = 3). SD ranged from 0.88 (500 μg/mL sample at 10 days) to 34.64 (control sample at 10 days). SDs lower than 1.0 do not appear in the figure. BHT showed >99% antioxidant activity throughout the experiment. The volatile sample exhibited dose-dependent antioxidant activity. The control sample was completely oxidized after 30 days. By the 30th day, the antioxidant activity of the samples was 8% by 1 μg/mL, 29% by 5 μg/mL, 70% by 10 μg/mL, 98% by 50 μg/mL, and 99% by 100 and 500 μg/mL. The 50 and 100 μg/mL samples exhibited antioxidant activity comparable to that of BHT. The results suggest that broccoli sprouts contain antioxidants, the activity of which is maintained for prolonged periods.

Figure 5 shows the antioxidant activity of the fractions obtained from the volatile sample tested by the aldehyde/carboxylic acid assay after 30 days. Values are the mean ± SD (n = 3). BHT exhibited 99.84 ± 2.49% at the level of 10 μg/mL. Fractions I, II, and III exhibited potent dose-dependent antioxidant activity. In particular, fraction II showed activity (95.56 ± 0.22%) comparable with that of BHT at the level of 10 μg/mL. On the other hand, fractions IV, V, VI, and VII exhibited only slight antioxidant activities at the levels tested in this experiment. These results suggest the presence of volatile nonpolar antioxidants in broccoli sprouts.

According to the results obtained in the present study, samples prepared with dichloromethane seem to contain potent antioxidants. Therefore, the volatile sample was analyzed to determine the principal antioxidants in the sprouts.

Compounds Identified in the Volatile Sample. Table 1 shows the compounds identified in the volatile sample from broccoli sprouts, along with their calculated concentrations (μg/g of broccoli sprouts) and Kovats index. Among the over 88 GC peaks observed in the gas chromatogram, 43 compounds were positively identified. The major compounds are 4-methylpentylisothiocyanate (2.48 μg/g), 4-(methylthio)-butylnitrile (10.63 μg/g), 5-(methylthio)pentylnitrile (31.64 μg/g), 3-(methylthio)propylisothiocyanate (3.00 μg/g), and 4-(methylthio)butylisothiocyanate (14.55 μg/g). One recent study reported that these compounds possess strong anti-*Helicobacter* activity.[18]

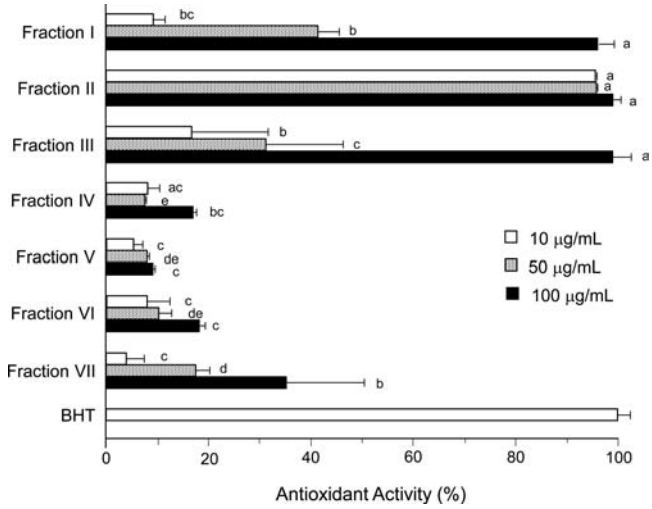

Figure 5. Results of aldehyde/carboxylic acid assay after 30 days on fractions obtained from the volatile sample.

Dimethyl disulfide, 1-penten-3-ol, 2,4,5-trimethylthiazole, 3-(methylthio)propanal, allylisothiocyanate, 2-ethyl-1-hexanol, phenylethyl alcohol, 2-methoxy-4-vinylphenol, and 2-isothiocyanatoethylbenzene have also been reported as volatile components in various vegetables and fruits, including soybeans, mung beans, onions/sprouts, horseradish, cumin, kale sprouts, and persimmon, and some organic solvent extracts of these plants showed certain antioxidant activities.[22−24] When a headspace of raw and cooked broccoli was analyzed, dimethyl sulfide, dimethyl trisulfide, hexanal, and nonanal, which contribute to the characteristic aroma of broccoli, were

identified.[25] 4-(Methylthio)butylisothiocyanate, 2-phenylethylisothiocyanate, 5-(methylthio)pentylnitrile, and 1,2-dimethoxybenzene were also reported in raw broccoli in a previous study.[26] In broccoli stored under low-oxygen conditions, 3-hydroxybutan-2-one, 2-pentenol, hexanal, hexanol, (*E*,*E*)-2,4-heptadienal, and phenylpropanenitrile were identified.[27]

In this study, 4-methylpentylisothiocyanate, 3-(methylthio)-propylisothiocyanate, and 4-(methylthio)butylnitrile were found as the major compounds found in broccoli sprouts but not in mature broccoli. The functional group −N═C═S in isothiocyanate compounds has been known to possess antioxidant activity, which induces phase II enzymes associated with detoxification of chemical carcinogens.[28]

It is well-known that phenolic compounds found in plants possess antioxidant activity.[29] Possible phenolic antioxidants found in the present study are 4-(1-methylpropyl)phenol, 4-methylphenol, and 2-methoxy-4-vinylphenol. A potent antioxidant activity of 2-methoxy-4-vinylphenol isolated and identified from a persimmon peel was previously reported.[30] Moreover, 2-methoxy-4-vinylphenol found in brewed coffee possessed potent antioxidant activity (>90%) at the level of 200 μg/mL tested by MA/GC assay.[31]

Fraction I (refer to Figure 1) contained isobutylisothiocyanate (0.03 μg/g), allylisothiocyanate (0.02 μg/g), and 2-phenylethylisothiocyanate (0.73 μg/g). A previous study has demonstrated that allylisothiocyanate was found as a volatile compound in Emeraude cauliflower and possessed strong antioxidant activity.[32] Fraction II contained 4-methylpentylisothiocyanate (0.31 μg/g), 4-(methylthio)butylnitrile (3.70 μg/g), 5-(methylthio)pentylnitrile (7.15 μg/g), 3-(methylthio)-propylisothiocyanate (3.20 μg/g), and 4-(methylthio)-butylisothiocyanate (9.98 μg/g). 4-(Methylthio)-butylisothiocyanate has direct antioxidant activity in addition to inducing phase II enzymes. It also oxidizes to sulforaphane, which has anticancer, anti-*Helicobacter*, and antioxidant activities.[18,33] 4-Methylpentylisothiocyanate found in *Raphanus sativus* root induced apoptotic cell death in human cancer cell lines.[34] 4-(Methylthio)butylnitrile, 5-(methylthio)pentylnitrile, and 3-(methylthio)propylisothiocyanate were also reported in Emeraude and Magnifico cauliflower as major volatile compounds.[32] Fraction III also contained high levels of 4-(methylthio)butylnitrile (8.26 μg/g) and 5-(methylthio)-pentylnitrile (24.98 μg/g), which may have contributed to the antioxidant activity of this fraction. These nitrogen/sulfur-containing compounds comprised >90% of the volatile sample and may significantly contribute to the antioxidant activity of broccoli sprouts.

The less volatile sample (refer to Figure 1) also showed relatively moderate antioxidant activity with dose response effects as shown in Figures 2 and 3, suggesting the presence of water-soluble antioxidants. Therefore, the total antioxidant activity of the samples prepared from broccoli sprouts may be comparable to those of known antioxidants such as α-tocopherol and BHT. The present study demonstrated that broccoli sprouts have a strong potential to be a valuable source of antioxidants. Moreover, broccoli sprouts have a short harvest time (2 weeks) and are relatively easy to produce. Therefore, broccoli sprouts could be a good source for natural antioxidants.

olives harvested in 2011 and fresh with lyophilized fruits from the 2012 season. This research also sheds further light on some biosynthetic aspects of secoiridoids during ripening of the three Tuscan cultivars: Frantoio, Moraiolo, and Leccino. These findings provide a better evaluation of possible applications of the olive flours obtained from unripe freeze-dried fruits for nutraceutical uses.

MATERIALS AND METHODS

Chemicals. All chemicals for the analyses were of analytical reagent grade. The Milli-Q-system (Millipore SA, Molsheim, France) was used to produce deionized water. *n*-Hexane and methanol of HPLC grade were from J.T. Baker (Phillipsburg, NJ), and ethanol and acetonitrile of HPLC grade were purchased from Panreac (Barcelona, Spain). Phosphoric acid was from Merck (Darmstadt, Germany). Tyrosol, syringic acid, verbascoside, and luteolin 7-*O*-*β*-D-glucoside from Sigma-Aldrich (Steinheim, Germany) and oleuropein from Extrasynthese (Genay, France) were used as standard compounds. All the stock solutions containing the standards were prepared in methanol.

Samples. During the 2011 crop season, 10 olive plants of each of the typical Tuscan cultivars Frantoio, Moraiolo, and Leccino were selected from the farm Azienda Agricola Torre Bianca at San Casciano Val di Pesa (Florence). The olive samples were picked from the selected olive plants on a weekly basis, starting from the 109th day after full blooming (DAFB), corresponding to the last week in August. Picking was carried out every Monday morning for 13 weeks until the 193rd DAFB, corresponding to the third week in November. For each of the 13 dates, approximately 500 g of olive fruit of each cultivar was picked from 10 olive plants along their circumference at a height close to 170 cm. As soon as they arrived in the laboratory, some of the olives were used for the fresh fruit analyses while the rest were deep-frozen in liquid nitrogen and stored in a freezer at approximately −20 °C.

During the 2012 crop season, 10 plants of each of the same cultivars were selected from the farm Azienda Agricola Buonamici, Fiesole (Florence). The olive samples were collected on a weekly basis, from the 80th DAFB, corresponding to the first week in September, until the 171th DAFB, corresponding to the first week in December. The conditions of picking were the same as for the 2011 season. As soon as the olives arrived in the laboratory, all samples were analyzed as fresh fruits. On a biweekly basis, part of the sample was freeze-dried.

Freeze-Drying Process. The freeze-drying process was conducted on whole fruits. The olives were deep-frozen in liquid nitrogen, and immediately after, they were subdivided into smaller lots of 125 g and placed in the freeze-dryer at 0.3 atm and −20 °C until they reached a constant weight (5−7 days).

Water Content. The cake/powder obtained by crushing a homogeneous batch of whole olives using a laboratory crusher was used to determine the water content. The procedure consists of placing 60 g of the sample in an oven at 105 °C until it reaches constant weight.

Total Oil Content. The total oil content was determined on fresh olive paste, previously dehydrated in an oven at 103 °C until constant weight, and on freeze-dried olive pastes. In the case of fresh olive paste, the samples were extracted with hexane in an automatic Randall extractor (model 148, VELP Scientifica, Milan, Italy), as previously described.[23] When using lyophilized olive paste, approximately 3 g of sample was weighed in a beaker, and 50 mL of hexane was added. The mixture was stirred at room temperature for 6 h. The results are expressed as grams per kilogram of dry matter (dm).

Extraction of Phenolic Compounds from the Fresh Fruits. Approximately 100 g of fresh olives was crushed with a small laboratory crusher (Zeutec, Germany) to obtain an olive cake as homogeneous as possible within a few hours after collection by applying the extraction method previously described.[18] Briefly, immediately after crushing, 8 g of cake was extracted twice with 30 mL of the EtOH/H_2O (80:20) solution in the presence of 0.5 mL of the internal standard (syringic acid close to 1.5 mg/mL) using a cold ice bath. The obtained solution was concentrated under reduced pressure at 35−40 °C, washed twice with hexane, centrifuged at 7000 rpm and 10 °C, and filtered in a 10 mL flask by a cellulose acetate membrane of 0.45 μm; 5 mL of methanol was

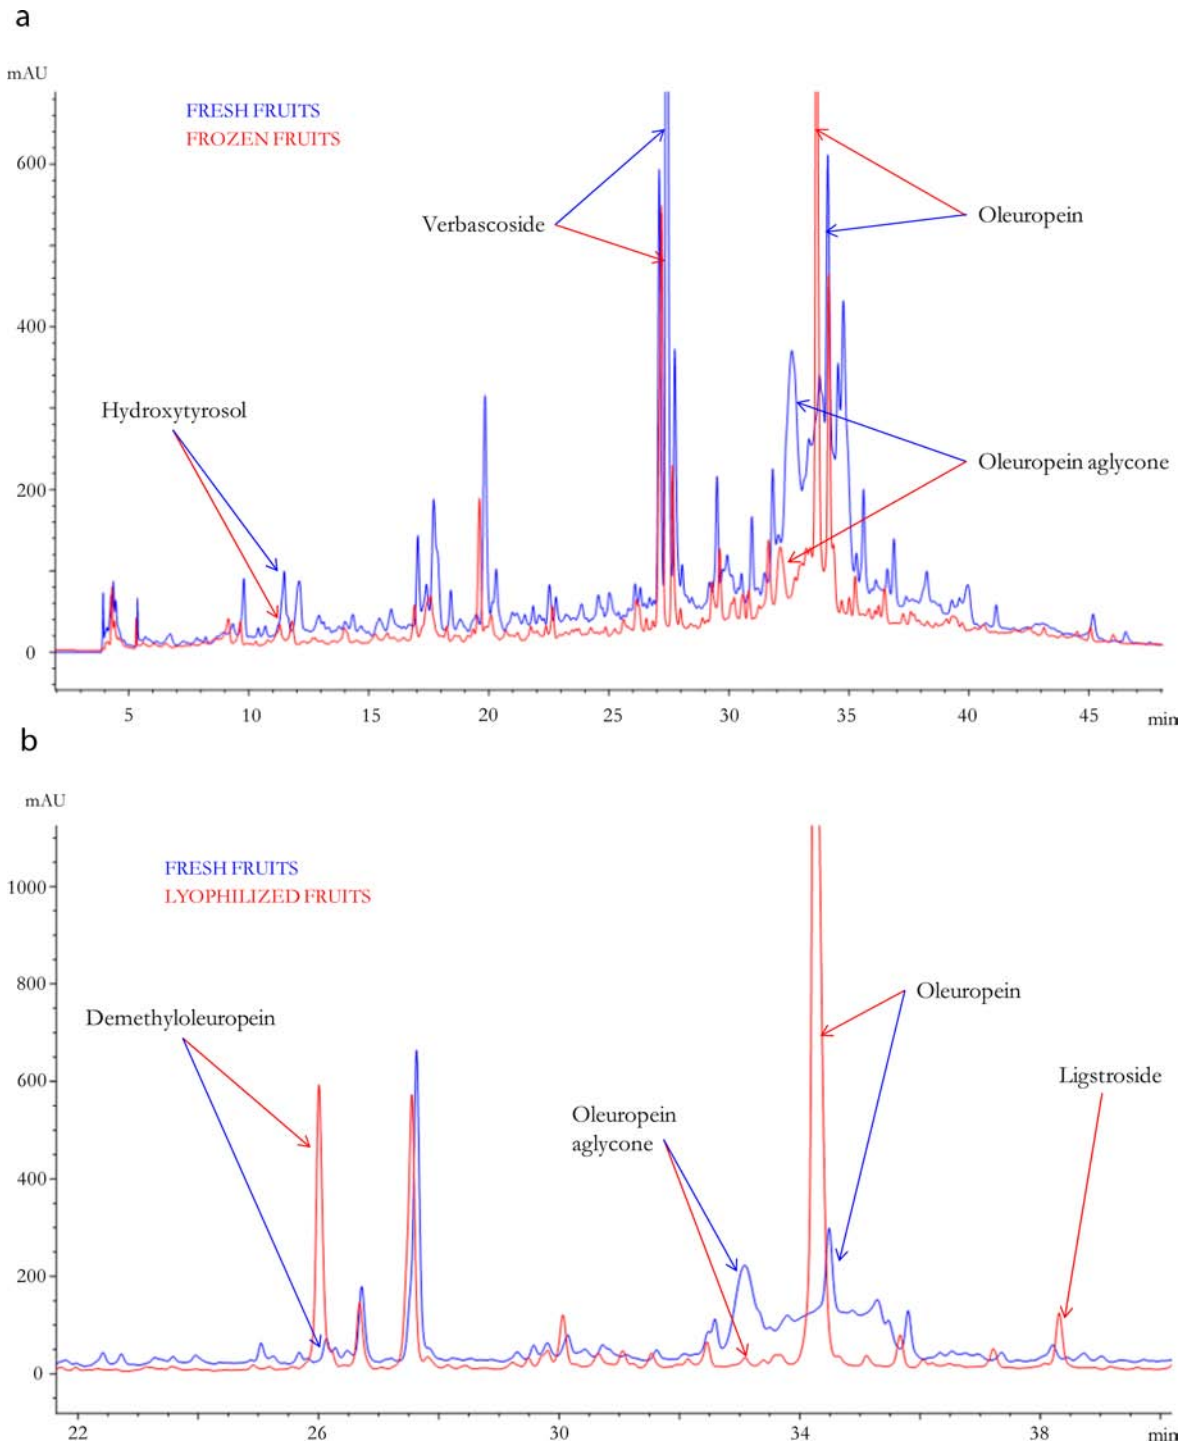

Figure 1. Overlapping of the HPLC profiles at 280 nm of (a) fresh (light blue) and frozen (red) Moraiolo olives at 151 DAFB and (b) fresh (light blue) and freeze-dried (red) Frantoio olives at 150 DAFB.

added, and the final volume was reached with Milli-Q water. The obtained solution was immediately used for chromatographic analysis.

Extraction of Phenolic Compounds from the Frozen Fruits. Five months after collection and freezing, the frozen samples from the 2011 season were used for extraction of the phenolic compounds. The frozen fruits were crushed immediately after they were removed from the freezer (temperature close to −20 °C), and the extraction method used was the same as for the fresh samples. The samples before the addition of the hydroalcoholic solution were kept close to 0 °C.

Extraction of Phenolic Compounds from the Freeze-Dried Fruits. The whole olives were freeze-dried within 6 h after harvest. Five months after collection and freeze-drying, the dried samples of the 2012 season were treated by applying the same extraction method used for the fresh samples, but the weight of each sample was 4 g.

Storage Conditions for the Ground Freeze-Dried Fruits. The olive pastes/powders obtained from milling the whole freeze-dried fruits were stored in conditions of oxidative stress: natural light exposure, temperature higher than 23 °C, and air exposure. Four months after milling, phenolic compounds were extracted again from these olive pastes.

HPLC−DAD−ESI-MS Analysis. Analyses were performed using an HP1100 liquid chromatograph, coupled with DAD and MS detectors, with the HP1100 MSD API-electrospray as the interface (all from

Elution was performed using H_2O at pH 3.2 by formic acid (A), acetonitrile (B), and methanol (C), with a flow rate of 0.8 mL/min with a multistep linear gradient. Both the organic solvents B and C changed as follows: from 2.5% to 27.5% in 45 min and then to 50% in 10 min, with a final plateau of 5 min, with 60 min as the total time of analysis. The following wavelengths were simultaneously selected: 240, 280, and 330 nm.

Quantification of Phenolic Compounds. To quantify each compound, syringic acid was chosen as the internal standard. To evaluate the relative response factor (RRF), the following standards were used: oleuropein for the quantification of oleuropein, oleuropein aglycon, ligstroside, nuzhenide, demethyloleuropein, hydroxytyrosyl acyclodihydroelenolate, comselogoside, caffeoyl 6′-secologanoside, oleoside, oleoside 11-methyl ester, and nuzhenide oleoside (whose values are expressed in milligrams of oleuropein per kilogram of dm); luteolin 7-*O*-glucoside for the quantification of luteolin, rutin, and luteolin 7-*O*-glucoside (whose values are expressed in milligrams of luteolin 7-*O*-glucoside per kilogram of dm); verbascoside for the quantification of chlorogenic acid, verbascoside, and isoverbascoside (whose values are expressed in milligrams of verbascoside per kilogram of dm); tyrosol for the quantification of hydroxytyrosol and tyrosol (whose values are expressed in milligrams of tyrosol per kilogram of dm).

With the aim of also evaluating the minor compounds, the total phenolic content was calculated using only one reference standard and is expressed in milligrams of oleuropein per kilogram of dm. All these molecules were evaluated at 280 nm with the exception of the following secoiridoids: nuzhenide oleoside, oleoside, and oleoside-11-methyl ester. Since these latter molecules do not have the phenol moiety in their molecular structure, their determination was done working at 240 nm.

Precision Parameters. The procedure precision was evaluated only for the lyophilized samples from 2012 because these parameters for fresh and frozen olives had been previously reported.[18] The extraction was repeated five times starting from different shares of olives from the same batch collected at 122 DAFB (about 400 g of fresh olives), and the obtained findings are expressed in terms of the coefficient of variation (CV; %) (Table 1).

RESULTS AND DISCUSSION

Phenolic Profiles of Fresh and Frozen Olives. The phenolic profile of the fresh fruits from the 2011 crop season were compared with that of the corresponding frozen fruits. These two kinds of samples are characterized by similar amounts of water (close to 50% of the total weight), but different temperatures at the moment of milling (room temperature for the fresh fruits, close to 0 °C for the frozen fruits). The overlay of the phenolic profile from fresh and frozen fruits of a sample of Moraiolo shown in Figure 1a highlights some relevant differences. Analyzing the quantitative data of all the fresh and frozen fruits (Supporting Information, Table a), the main differences were related to the secoiridoidic phenols. First, the ligstroside was undetectable, while oleuropein, as expected, was often one of the main compounds.

Oleuropein. In unripe fruits, the oleuropein content was similar in fresh and frozen olives of the Frantoio and Moraiolo cultivars, while it was more abundant in fresh olives of Leccino (Figure 2). During ripening, a strong decrease of oleuropein in all the fresh olives was observed. On the other hand, the content in the corresponding frozen olives increased up to 7-fold in the Frantoio cultivar, 10-fold in Moraiolo, and 5-fold in Leccino. Moraiolo olives were richer in oleuropein (from 1061 to 2758 mg/kg in fresh olives, from 2267 to 13656 mg/kg in frozen olives) than Frantoio (from 113 to 1825 mg/kg in fresh fruit, from 762 to 6677 mg/kg in frozen fruit) or Leccino (from 297 to 1892 mg/kg in fresh fruit, from 501 to 2804 mg/kg in frozen fruit) at all the DAFB.

Demethyloleuropein. This compound, when detectable, was more abundant in frozen olives compared to fresh ones. Low amounts only in the last 3 weeks of sampling (from 55 to 101 mg/kg) were detected in the fresh olives from Frantoio. Increased amounts (from 198 to 4452 mg/kg) were detected in the frozen olives harvested from the middle of the ripening period. Analogous behavior was observed for the fresh Leccino olives with low quantities (from 51 to 258 mg/kg) only in the last 4 weeks of ripening and again higher concentrations (from 487 to 1892 mg/kg) in the frozen fruits harvested in the last 5 weeks of ripening. This molecule was never detectable in the fresh Moraiolo olives, and low content was found in the frozen olives (from 231 to 355 mg/kg) only at the end of the ripening season.

Oleuropein Aglycon. This secoiridoid was more abundant in the fresh olives of the three cultivars at all the DAFB if compared with the corresponding frozen fruits. In particular, Moraiolo was the richest cultivar with values ranging from 4854 to 12386 mg/kg in fresh fruits and less (from 1493 to 10117 mg/kg) in frozen ones. The same behavior but with lower content was true for Frantoio (from 871 to 8553 mg/kg in fresh fruits, from 581 to 4147 mg/kg in frozen fruits) and Leccino (from 1756 to 9164 mg/kg in fresh fruits; from 737 to 7045 mg/kg in frozen fruits).

Nuzhenide. The ratio between nuzhenide levels in frozen olives and that in fresh olives increased during ripening in all three cultivars.

The minor secoiridoids, oleoside, oleoside 11-methyl ester, and nuzhenide oleoside, were greatly increased in frozen olives as shown in the Supporting Information (Table a).

Overall, the main differences between the treatment of the fresh and frozen fruits can be related to the temperature of milling, which is close to 25 °C for fresh fruit and close to 0 °C for frozen fruits. The β-glucosidase hydrolyzes the substrates even when a very short time of milling (30 s) is applied and the time between milling and the addition of the hydroalcoholic mixture (less than 2 min) is strongly reduced. By observing the data related to oleuropein and oleuropein aglycon, it emerges that the low temperature of milling for frozen fruit partially inhibits the enzyme, as confirmed by the lower amounts of the corresponding aglycon (Supporting Information, Table a).

Anyway, the presence of the water's fruit allows a certain activity of this enzyme to also be maintained in the frozen olives. To quantify this effect, we analyzed the phenolic compounds in the freeze-dried fruits of the same cultivar in the 2012 crop season.

Phenolic Profiles in Fresh and Whole Freeze-Dried Olives. In light of the data collected from the 2011 samples, our aim was to use the 2012 crop season to better investigate the role played by the water of the fruits to affect the final phenolic content. Therefore, each sample was divided into two aliquots: one analyzed as fresh and the other as freeze-dried (Supporting Information, Table b). As expected, the choice to lyophilize the olives as whole fruit without any preliminary breaking was crucial. Each pair of samples had different amounts of water during the crushing, close to 50% of the total weight for the fresh olives and a negligible amount in the freeze-dried fruits (Supporting Information, Table c). Unlike the 2011 fruits, the same temperature (close to room temperature) during the milling process was guaranteed for all the 2012 samples.

The overlay of the chromatograms at 280 nm for the phenolic profiles of fresh and freeze-dried fruits (Figure 1b) highlights strong differences. According to the quantitative results (Supporting Information, Table b), the freeze-drying process protects the phenolic compounds against enzymatic degradation

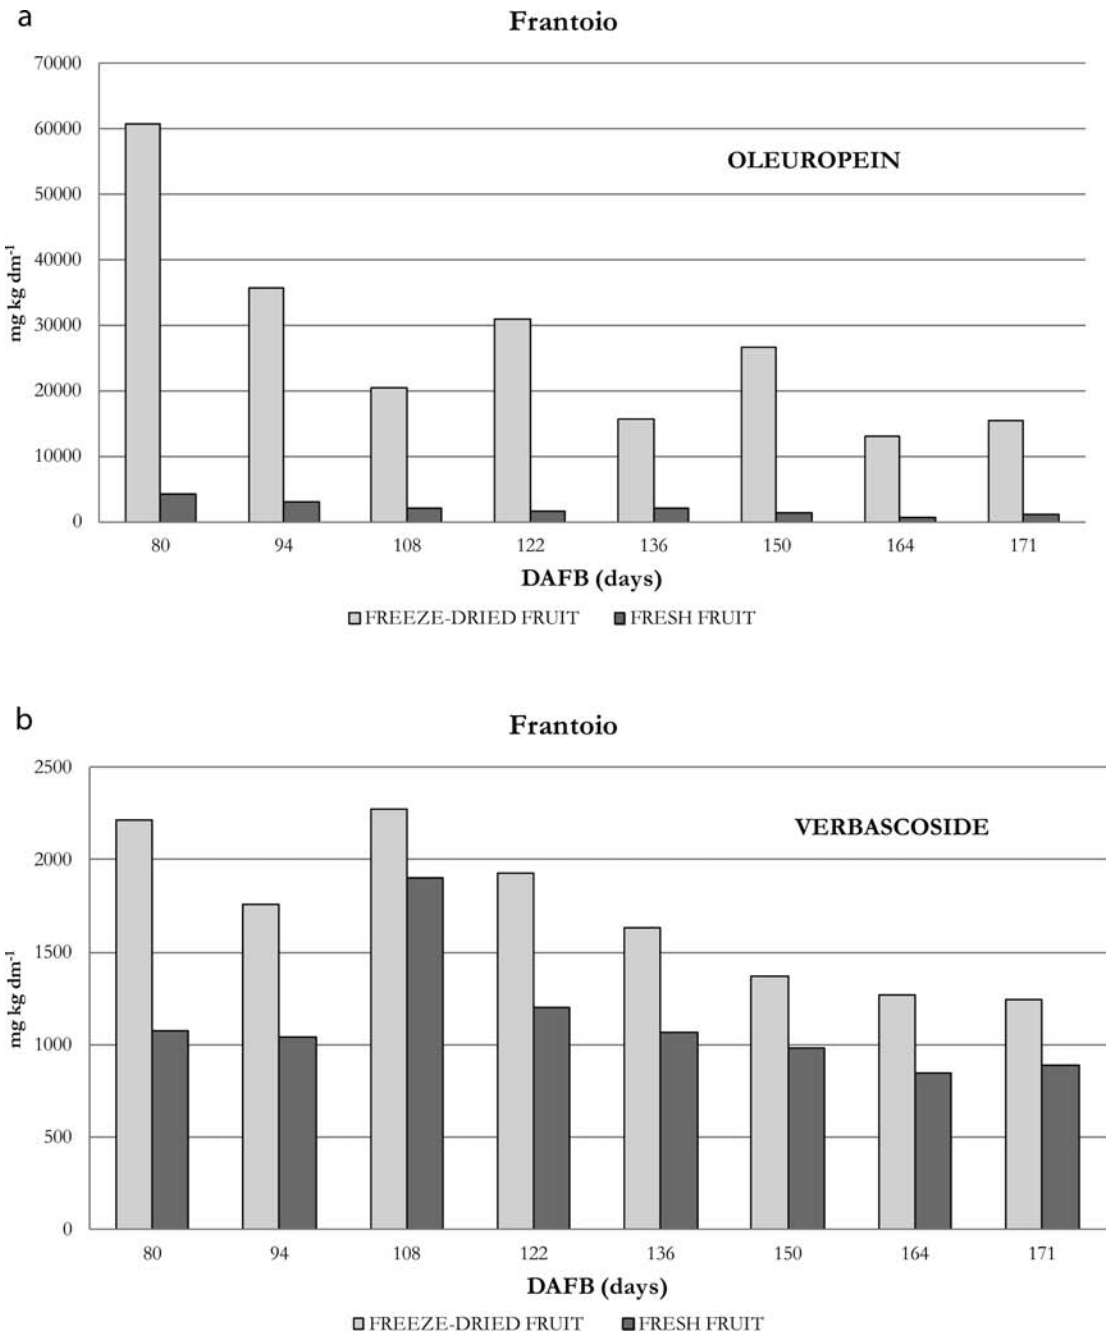

Figure 3. Changes over time for oleuropein and verbascoside in fresh and freeze-dried Frantoio olives.

that occurs during the milling process and/or during the short time before the addition of the hydroalcoholic mixture. The almost complete elimination of the water does prevent endogenous enzyme activity, mainly of the phenol oxidases,[14−17] which during extra virgin olive oil production rapidly induces a decrease in the secoiridoid content.

The novelty of our research is that we have shown that there are huge differences in the contents of the secoiridoids in fresh and whole lyophilized olives. The values of some key molecules such as oleuropein in the dried fruits were several times higher compared with those in the corresponding fresh sample. On the other hand, these differences were consistently lower for other compounds, such as verbascoside (Figure 3). The same results obtained for all the coupled samples harvested during the ripening period confirm that the secoiridoidic compounds are always the main target of enzymatic activity (see also the section "Biosynthetic Considerations Regarding the Secoiridoids").

Oleuropein. This molecule was in very high concentration in freeze-dried olives of the three cultivars at all the DAFB. The values ranged from 12993 to 60679 mg/kg for Frantoio, from 17113 to 80276 mg/kg for Moraiolo, and from 7515 to 79812 mg/kg for Leccino. In the corresponding fresh olives the oleuropein content was up to 30 times lower (from 588 to 4092 mg/kg for Frantoio, from 1001 to 3097 mg/kg for Moraiolo, from 379 to 5745 mg/kg for Leccino).

Oleuropein Aglycon. Although it is shown that the freeze-drying process preserves phenolic compounds, a contrary trend compared to oleuropein was observed for oleuropein aglycon: indeed, in fresh olives, the quantities of this molecule were greater that in freeze-dried olives. In particular, we observed a

DOI: 10.1021/jf5051359
J. Agric. Food Chem. 2015, 63, 1175−1185

decrease (from 3107 mg/kg at 80 DAFB to 740 mg/kg at 122 DAFB) for Frantoio olives followed by an increase in fresh fruits (up to 6278 mg/kg), while in freeze-dried fruits it was initially not detectable and then present but in quantities not over 1379 mg/kg. The amounts of this molecule were higher in Moraiolo than in Frantoio olives with a decrease during ripening in both fresh (from 10139 mg/kg at 80 DAFB to 2787 mg/kg at 171 DAFB) and freeze-dried olives (from 14393 mg/kg at 80 DAFB to 1342 mg/kg at 171 DAFB). Analogously, higher quantities were revealed in fresh Leccino olives and a decrease in lyophilized fruits (Supporting Information, Table b). The very low content of the aglycon in the dried fruit is due to the complete inhibition of the enzyme's activity in the absence of water.

Demethyloleuropein. This secoiridoid was detectable in freeze-dried olives from half of the study period (122 DAFB), with a strong increment over time (up to 8700 mg/kg in Frantoio, 1468 mg/kg in Moraiolo, and 24535 mg/kg in Leccino). In fresh olives, demethyloleuropein was undetectable in Moraiolo at all the DAFB and only in low amounts in Frantoio and Leccino olives (Supporting Information, Table b).

Ligstroside. This precursor of a well-known biologically active compound, namely, oleocanthal,[5] was undetectable in fresh olives of the three cultivars at all the DAFB (Table 2). On the other hand, the freeze-dried fruits had slight amounts of this secoiridoid, with the highest values at the start of sampling. At the 80th DAFB, ligstroside was 3889 mg/kg in Frantoio, 4586 mg/kg in Moraiolo, and 3082 mg/kg in Leccino olives. The concentrations of ligstroside in freeze-dried olives were 20−30 times lower than those of its analogous oleuropein (Figure 4; Supporting Information, Table b).

[a]The molecule was not revealed in fresh and frozen olives from 2011. nd = not detected.

Other minor secoiridoids such as nuzhenide, hydroxytyrosyl acyclodihydroelenolate, oleoside, oleoside 11-methyl ester, and nuzhenide oleoside had significantly different quantities in fresh and lyophilized fruits, with a great increment in the latter ones (Supporting Information, Table b).

Biosynthetic Considerations Regarding the Secoiridoids. The results of this research allow us to clarify some biosynthetic aspects of olive phenolic compounds. In a previous work,[24] the researchers hypothesized that demethyloleuropein is both an intermediate in the oleuropein biosynthesis and a degradation product of the oleuropein. In another paper,[20] it was suggested that demethyloleuropein is cultivar-dependent. Our previous data from frozen olives[18] allowed us to hypothesize the existence of two independent biosynthetic pathways for oleuropein and demethyloleuropein.

Our present research sheds light on biosynthetic aspects of the secoiridoidic compounds. In the unripe freeze-dried 2012 olives, demethyloleuropein was undetectable, and then its content consistently increased during ripening while oleuropein decreased in Moraiolo, as shown in Figure 4 (see also the Supporting Information, Table b). This behavior, confirmed for all three cultivars, was in contrast with the hypothesis that this molecule could be an intermediary of oleuropein biosynthesis. On the other hand, demethyloleuropein seems to be a degradation product obtained from the action of an endogenous esterase on oleuropein.

The results relating to ligstroside in the freeze-dried fruits are similar to those observed for oleuropein; the former molecule was undetectable in fresh or frozen fruits (sample of 2011; Supporting Information, Table a) because it was quickly hydrolyzed by enzymes in the presence of the olive's water. This phenomenon had already been described for the secoiridoids by other authors[15,16] and was in agreement with a previous study on these cultivars.[18] As shown in Figure 4, a similar trend was seen for oleuropein and ligstroside over time in freeze-dried Moraiolo olives. The whole lyophilized samples from Frantoio and Leccino confirmed these results. In light of our data, the use of dried fruit can be suggested as a model to study some biosynthetic pathways, taking into account that overall enzymatic degradation is prevented by the lack of water.

Defatting and Stability over Time of Cake/Powder from Whole Dried Fruit. To evaluate the potential use of this matrix in the field of food, several aspects need to be evaluated regarding treatment of higher quantities for industrial purposes. To this aim, the method of production needs to be as easy as possible, the stability over time needs to be controlled, and the final aspect of the material needs to be homogeneous and manageable.

The product obtained by crushing freeze-dried olives has varying consistency: a green homogeneous powder was derived from unripe olives, and a violet-brown cake with muddy consistency due to the increasing oil content was obtained from ripe olives. As discussed above, the phenolic content of lyophilized olives is considerably greater than that obtained from fresh olives, and the greatest differences occur at the beginning of ripening. These latter samples could be particularly useful for preparation of nutraceuticals. To evaluate the feasibility of such an idea, the stability of the cake/powder of three samples of Moraiolo at different ripening stages was controlled after 4 months (Table 3). The storage conditions were under strong oxidative stress: light exposure, room temperature close to 23−28 °C, and free air exposure. After this storage period, the initial green color of the cakes/powder was maintained, confirming the absence of the rapid enzymatic browning typical of fresh fruit.[14] Moreover, we proved that a cold extraction by using *n*-hexane, a widely applied food-grade solvent, compared with the exhaustive Soxhlet extraction, was sufficient to completely remove the fat from the olive cake/powder. In fact, the oil content of the samples reported in Table 3, obtained via Soxhlet and *n*-hexane extraction, were 16.9% and 13.9% for the sample at 80 DAFB, 33.1% and 34.0% for the sample at 122 DAFB, and 45.7% and 44.8% for the sample at 164 DAFB.

Regarding the phenolic content obtained from lyophilized olives at time 0 and after 4 months of storage, Table 3 shows the observed percentage variations for the three selected samples. It is noticeable that the total phenolic amounts were only slightly

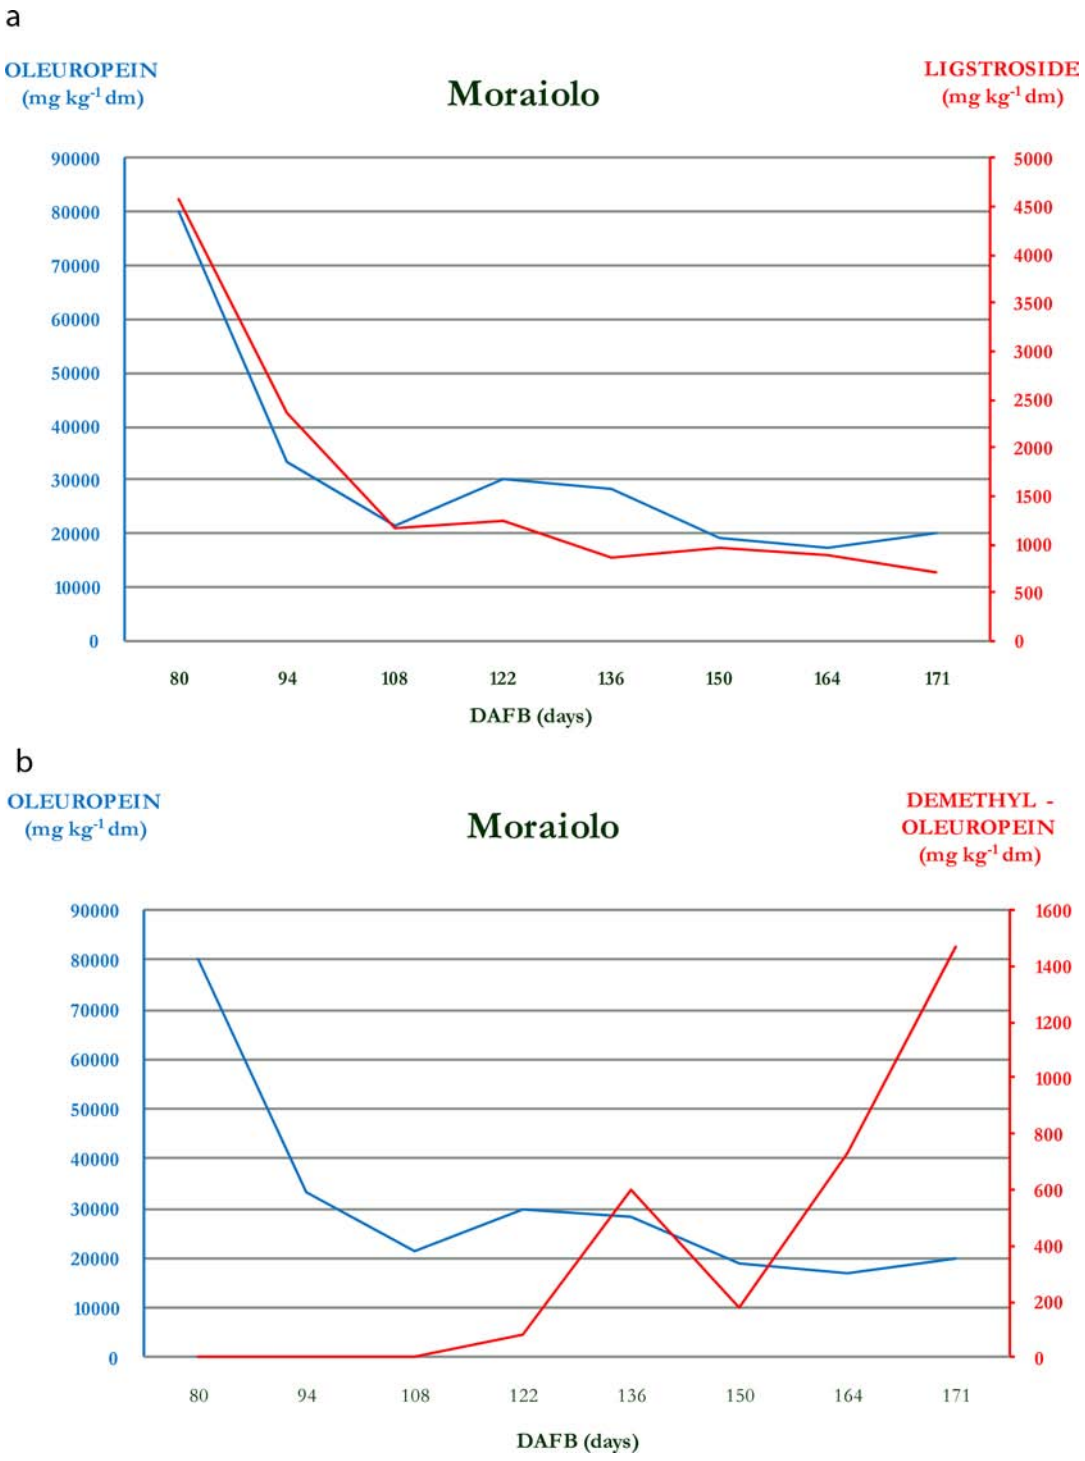

Figure 4. Concentrations of ligstroside and demethyloleuropein in Moraiolo olives during ripening in 2012. To better highlight the relation between each secoiridoid and the oleuropein, the figure shows two different scales (mg/kg of dm).

decreased, even in these stressed storage conditions; the decrease was close to 10% in the unripe sample and was even below 5% in the others.

The main decrease involved oleuropein and oleuropein aglycon. This latter molecule had close to 44% reduction in all studied samples. Oleuropein slightly decreased only in unripe olives (−11.7%), and in correspondence with this change, strong increments of hydroxytyrosol and oleoside 11-methyl ester were observed. It can be hypothesized that the decrease of oleuropein is due to the rupture of the ester bond (Figure 5) mediated by the esterase enzyme, with hydroxytyrosol and oleoside 11-methyl ester formed by this rupture.[15] The results from the other two samples confirmed this hypothesis, because the low variations of oleuropein were related to a nonsimultaneous increase in hydroxytyrosol and oleoside 11-methyl ester.

In light of the recognized benefits of secoiridoid compounds from olive oils in cardiovascular health,[13] the olive powder/cake from dried fruits could be proposed as a new source of these important phenolic compounds.

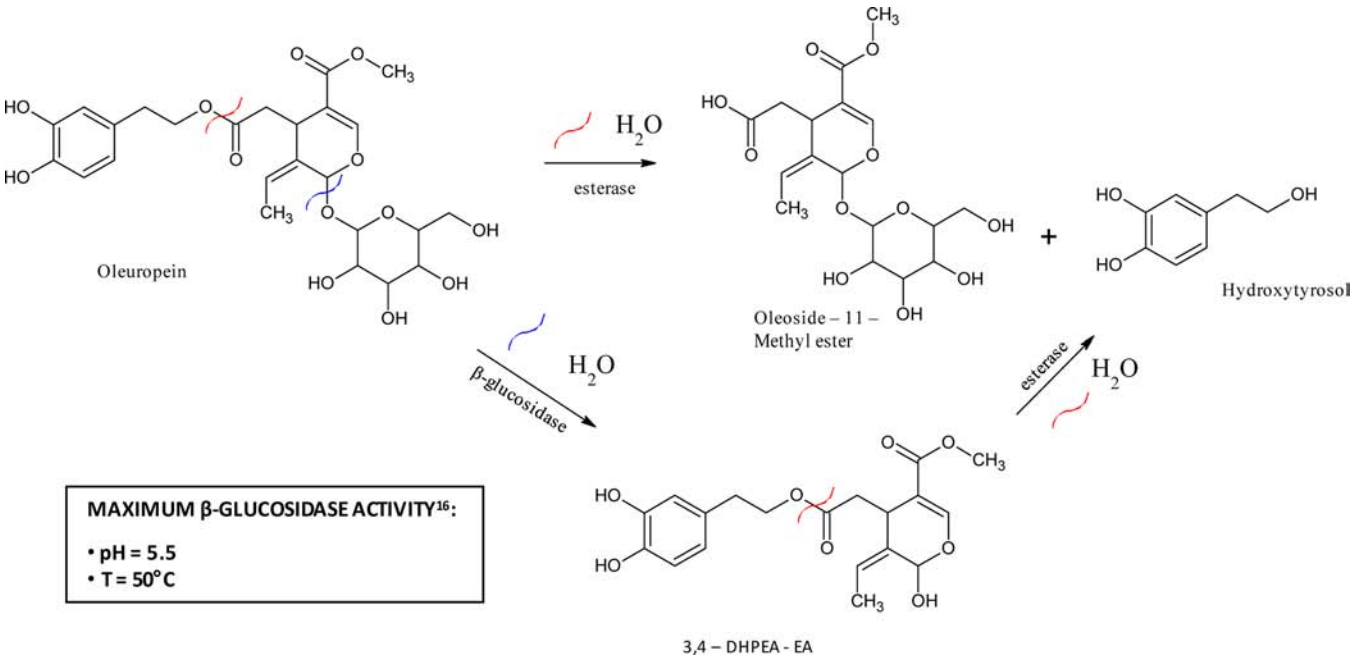

Figure 5. Oleuropein and its relationship with the other main secoiridoids.

In conclusion, the principal novelty of this research is the study of whole freeze-dried olives which turn out to have unexpectedly high concentrations of the secoiridoidic compounds (from 10 to 20 times higher than those in fresh fruits), an observation which has not been previously reported in the literature. The removal of water without previous crushing prevents the rapid enzymatic degradation of this fraction, allowing us to better investigate the real phenolic content in the fruit and providing useful information on some biosynthetic aspects of these secoiridoidic molecules. To the best of our knowledge, this approach has never been applied to whole dried olives to date. Another novelty of this work is the strong stability of the dried cake/powder obtained from whole olives maintained in stress conditions for up to 4 months. In light of these results, it can be hypothesized that unripe olives are a potential source of secoiridoids in the form of a homogeneous powder which is very low in fat and suitable for human consumption. To date, those secoiridoids typical of the olive but also of extra virgin olive oils are not widely present in common foods, as happens for many other phenolic and flavonoid compounds. Several commercial products rich in phenolic compounds derived from different parts (leaves, fruit) of *Olea europaea* or from milling wastes have been marketed, confirming the great interest in these compounds. The freeze-drying process is an expensive method not suitable for work on a

DOI: 10.1021/jf5051359
J. Agric. Food Chem. 2015, 63, 1175−1185

large scale, but the obtained data can be useful to suggest further investigation on most convenient methods to remove the water and/or inhibit the endogenous enzymes in olives. Moreover, this approach can be the best way to exploit this fruit not only as a source of olive oil.

■ ACKNOWLEDGMENTS

Our deepest gratitude goes to the Azienda Agricola Buonamici and to the Azienda Agricola Torre Bianca for providing the olives and to Dr. Marco Mugelli, who recently passed away, for his great contribution to research in the field. We also thank Dr. Aleandro Ottanelli and Prof. Edgardo Giordani for freeze-drying the fruits and Dr. Mary Forrest for final English editing of the manuscript.

which then reacts with several enzymes in the mevalonate pathway to yield cholesterol.[15] It is well established that HMGCR activity was 3-fold higher in mononuclear blood cells from patients with leukemia, compared with cells from healthy subjects.[16]

We here provide a detailed mechanistic investigation of the apoptotic effect of monacolin K and how it is related to the inhibition of GLO1. In the present study, we hypothesize that monacolin K showed its apoptotic activity through the inhibition of HMGCR, inactivation of Ras translocation, and down-regulation of PI3K/Akt and Raf/ERK1/2 signal pathways, leading to suppression of GLO1 and HMGCR in U937 cells.

MATERIALS AND METHODS

Chemicals and Antibodies. Monacolin K, perchloric acid, 2-methylquinoxaline (2-MQ), *o*-phenylenediamine, 3-(4,5-dimethylthiazol-2-y-l)-2,5-diphenyltetrazolium bromide (MTT), dimethyl sulfoxide (DMSO), and 4,6-diamidino-2-phenylindole (DAPI) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Cell culture media were purchased from Invitrogen (Carlsbad, CA, USA). Antibodies against phospho-p44/42 MAPK (Thr202/Tyr204), phospho-Akt (Ser473), ERK1/2, Akt1/PKBα, and actin, were obtained from Millipore (Billerica, MA, USA). Antibodies against GLO-1, NF-κB (p65), H-Ras, Raf-1, and lamin A were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Antibodies against K-Ras and N-Ras were obtained from GeneTex (San Antonio, TX, USA). Alexa Fluor 594 goat anti-mouse IgG (H+L) was purchased from Invitrogen. U0126 (MEK1/2 inhibitor), LY294002 (PI3K inhibitor), JSH-23 (NF-κB inhibitor), IgG HRP-conjugated goat anti-mouse and IgG HRP-conjugated goat anti-rabbit were obtained from Chemicon (Temecula, CA, USA).

Cell Culture. U937 cells were purchased from the American Type Culture Collection (Rockville, MD, USA). The cells were cultured in RPMI 1640 medium with 10% fetal bovine serum (GibcoBRL, Grand Island, NY, USA), 5 mM L-glutamine (GibcoBRL), and 1% penicillin/streptomycin (10000 units of penicillin/mL and 10 mg/mL streptomycin) at 37 °C in a humidified 5% CO_2 incubator.

Cell Viability Assay. Cell viability was assessed by MTT assay.[17] Briefly, cells at 1×10^5/mL were treated with various concentrations of monacolin K in 96-well plates for 48 h, followed by treatment with MTT for 4 h at 37 °C. The medium was removed, DMSO was added to dissolve the blue formazan residue, and color intensity was measured using an ELISA reader at 570 nm.

Morphological Assay. After treatment with various concentrations of monacolin K for 48 h, cells were harvested and fixed with 4% paraformaldehyde in PBS for 20 min at room temperature and stained with 2.5 mg/mL DAPI solution for 30 min at room temperature. The cells were washed two more times with PBS and analyzed via a confocal microscope (CARV II Confocal Imager; BD Biosciences).

DNA Fragmentation Assay. After treatment with various concentrations of monacolin K for 48 h and washing with ice-cold PBS, the cells were resuspended in 180 μL of DNA lysis buffer (0.5% lauroylsarcosine, 10 mM EDTA, 0.5 mg/mL proteinase K, and 50 mM Tris-HCl at pH 8.0) overnight at 56 °C and treated with RNaseA (0.5 μg/mL) for 1 h at 37 °C. Total DNA was extracted from the cells with an equal volume of phenol/chloroform/isoamyl alcohol (Sigma-Aldrich). Ten microliters of DNA was analyzed on 1.8% agarose gel.

Image Cytometry Analysis. Cell sub-G1 phase was analyzed by the DNA content using the DAPI staining method. After treatment with various concentrations of monacolin K for 48 h, U937 cells were centrifuged at 1500 rpm for 5 min, and the cell pellets were fixed in 70% ice-cold ethanol overnight at 4 °C. Fixed cells were washed with PBS, incubated with 0.5 mL of hypotonic buffer containing 0.5% Triton X-100 and 0.5 mg/mL RNase A for 30 min at 37 °C, and then stained with 50 μg/mL DAPI, and the sub-G1 phase content was determined on a NucleoCounter NC-3000 cytometer (ChemoMetec, Allerod, Denmark).

RNA Isolation and Reverse Transcription-PCR Amplification (RT-PCR). Total RNA was extracted from U937 cells using a commercially available RNA extraction kit (Favorgen, Pingtung, Taiwan) and following the manufacturer's instruction. First-stranded cDNA was synthesized using 1 μg of total RNA by RT-PCR kit (Roche, Indianapolis). The relative expressions of GLO1 and HMGCR were analyzed using RT-PCR with GAPDH as an internal control. The primers used were GLO1, sense 5′-ATGGCAGAACCGCAGCCCCCGT-3′ and antisense 5′-CTACATTAAGGTTGCCATTTTGTTAG-3′, yielding a product of length 564 bp; HMGCR, sense 5′-TACCATGTCAGGGGTACGTC-3′ and antisense 5′-CAAGCCTAGAGACATAATCATC-3′, yielding a product of length 252 bp; GAPDH, sense 5′-TACCATGTCAGGGGTACGTC-3′ and antisense 5′-CAAGCCTAGAGACATAATCATC-3′, yielding a product of length 248 bp. A 10 μL volume reaction for PCR included 2 μL of cDNA, 1 μL each of sense and antisense primers, and 5 μL of PCR master mix. The conditions were 94 °C for 5 min, 94 °C for 40 s, 60 °C for 35 s (GLO1), 58 °C for 30 s (HMGCR), and 64 °C for 30 s (GAPDH), 72 °C for 40 s, and 72 °C for 7 min, for 26 cycles. The PCR products were separated by electrophoresis on 1.5% agarose gels, and the results were analyzed using a Kodak Gel logic imaging system (Hyland Scientific, Stanwood, WA, USA).

Western Blot Analysis. The whole cell protein was extracted via the addition of 100 μL of gold lysis buffer (50 mM Tris-HCl, 150 mM NaCl, 1 mM EDTA, 1% Triton X-100, and 1% protease inhibitor cocktail at pH 7.4), followed by incubation at 4 °C for 1 h, centrifugation, and collection of cell lysate. A Subcellular Protein Fractionation Kit was used to determine the levels of protein expression in cytosol, nucleus, and membrane. Extract preparation followed instruction of the manufacturer's published protocol (Thermo, Rockford, IL, USA). Protein concentrations were measured with a Bio-Rad protein assay reagent (Bio-Rad Laboratories, Munich, Germany). Equal amounts of lysate protein (30 μg/lane) were subjected to sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE). After electrophoresis, the proteins were electrotransferred to polyvinylidene difluoride (PVDF) membranes (Millipore, Billerica, MA, USA), blocked at 37 °C for 1 h with 1% BSA in TBST (20 mM/L Tris-base; 125 mM/L NaCl; 0.2% Tween 20; 0.1% sodium azide), then immunoblotted with primary antibodies overnight at 4 °C, and washed with TBST solution (0.05% Tween 20 in TBS). After six washings with TBST buffer, the blot was washed and exposed to horseradish peroxidase conjugated secondary antibodies for 1 h, and immunoreactive proteins were visualized with an enhanced chemiluminescence (ECL) detection system (GE Healthcare, Little Chalfont, UK).

Total Cholesterol Quantitation. The total cholesterol concentration was measured using a Cholesterol/Cholesterol Ester Quantitation Kit (Calbiochem, Novabiochem, Boston, MA, USA). After treatment with monacolin K for 48 h, cells were washed with cold PBS and centrifuged. The pellet was resuspended in 0.2 mL of chloroform/isopropanol/NP-40, homogenized for 3 min, and cleared by centrifugation at 14000 rpm for 10 min. Supernatants were decanted, air-dried at 50 °C, and vacuum-dried for 30 min to remove residual solvents. The dried lipids were dissolved in 0.2 mL of the reaction buffer, and the absorbance was measured at 570 nm for total cholesterol detection.

Methylglyoxal Measurement. MG was measured by using an *o*-phenylenediamine method.[18] MG was derivatized with *o*-phenylenediamine to form the quinoxaline product 2-MQ, which is very specific for MG. Briefly, the supernatant of the cell was incubated with 100 mM *o*-phenylenediamine for 3 h at room temperature. The quantity of the quinoxaline derivative of MG (2-MQ) was measured using a Hitachi L-6200 HPLC system (Hitachi, Ltd., Mississauga, ON, Canada). The mobile phase was generally 68 vol % of 10 mM KH_2PO_4 (pH 2.5) and 32 vol % of HPLC grade acetonitrile. The analysis conditions were as follows: detector wavelength, 315 nm; mobile phase flow rate, 1.0 mL/min; and column temperature, 20 °C. The whole series of samples in a single experiment was run in duplicate.

Immunofluorescence Microscopy. To detect the localization of NF-κB in monacolin K treated U937 cells, the U937 cells were first seeded in a 12-well dish. The cells were fixed with 4% paraformaldehyde

J. Agric. Food Chem. 2015, 63, 1186−1195

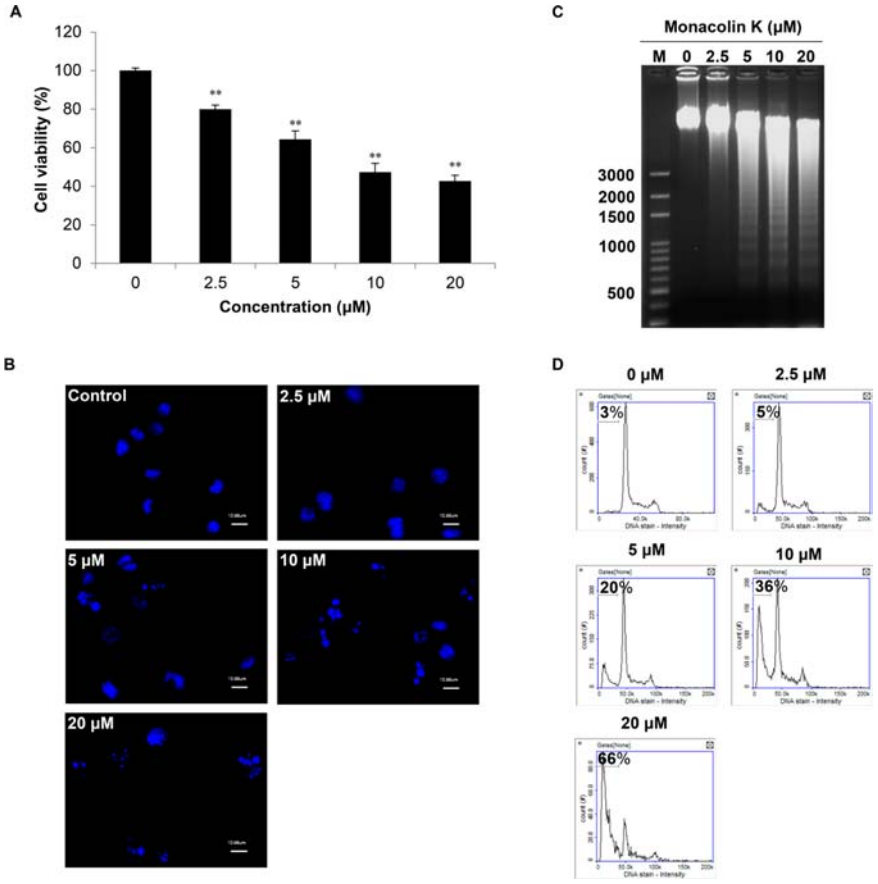

Figure 1. Inhibition of cell viability and apoptosis-inducing effects of monacolin K on U937 cells. (A) U937 cells were seeded (1×10^5 cells/well) in a 96-well plate, the cells were treated with variable concentrations of monacolin K for 48 h, and cell viability was measured by MTT assay. (B) Nuclear condensation in apoptotic cells detected by DAPI staining. U937 cells were treated with various concentrations of monaclin K for 48 h. (C) DNA fragmentation was detected by gel electrophoresis following stimulation with 2.5−20 μM monacolin K for 48 h. (D) Image cytometry analysis shows the percentage of sub-G1 phase in U937 cells treated with monacolin K for 48 h. All data represent means ± SD of triplicates ($n = 3$). In panel A, ** $p < 0.01$, compared with untreated cells (control groups).

for 30 min and permeabilized with PBS containing 0.1% Triton X-100 for 5 min at room temperature. After specimens were blocked with 5% BSA for 1 h at room temperature, they were further incubated with NF-κB (p65) antibody for 2 h. After three washings in TPBS, specimens were then stained with Alexa Fluor 594 goat anti-mouse IgG for 1 h at room temperature. After three washings with TPBS, cells were stained with 0.5 mg/mL of DAPI for 10 min to counterstain the nucleus and then washed three times for 5 min with TPBS. Images were collected by confocal microscope.

Statistical Analysis. The data were analyzed using the SAS program (SAS Institute, Cary, NC, USA). The significance of the difference among mean values was determined by one-way analysis of variance followed by the t test; (*) $p < 0.05$ and (**) $p < 0.01$ were considered statistically significant. Values are the mean ± SD of three independent experiments.

RESULTS

Monacolin K Induced Apoptosis in U937 Cells. MTT assays were performed to evaluate the potential cytotoxic effects of monacolin K. As shown in Figure 1A, U937 cells were incubated with increased concentrations of monacolin K for 48 h. Exposure of monacolin K to U937 cells resulted in a significant decrease in viable cells in a dose-dependent fashion. Treatment with 20 μM monacolin K achieved 57% inhibition ($p < 0.01$). To determine whether an increase in apoptosis was associated with the observed decrease in cell number after monacolin K treatment, the cells were stained with DAPI and analyzed by using a confocal microscope. As shown in Figure 1B, the nuclei of U937 cells exposed to monacolin K exhibited nuclear condensation and fragmented chromatin of typical apoptosis in a dose-dependent manner. Apoptosis was also detected by DNA fragmentation assay. DNA fragmentation was significantly increased after treatment with monacolin K in a dose-dependent manner (Figure 1C). Furthermore, the degree of apoptosis was quantified by analyzing the amount of sub-G1 DNA content in the U937 cells treated with monacolin K using an image cytometer. As shown in Figure 1D, in untreated control, the percentage of untreated control cells with fragmented DNA (sub-G1) was only 3%. Treatment with 20 μM monacolin K increased the percentage of cells with fragmented DNA (sub-G1) to 66%. Taken together, these findings indicated that exposure to monacolin K resulted in the inhibition of cell proliferation and a striking induction of apoptosis in U937 cells.

Monacolin K Down-regulated HMGCR Expression and Reduced Cholesterol Generation. To elucidate the effects of monacolin K on HMGCR production on the transcriptional level, cells were treated with various concentrations of monacolin K for 24 h. The cDNA was amplified by PCR with primers specific for HMGCR or GAPDH (as a control gene), and the results indicated that HMGCR mRNA expression was suppressed in the presence of monacolin K as shown in Figure 2A. The suppression of HMGCR mRNA expression correlated to Western blot analysis. Treatment of U937 cells with monacolin K

DOI: 10.1021/jf505275s
J. Agric. Food Chem. 2015, 63, 1186−1195

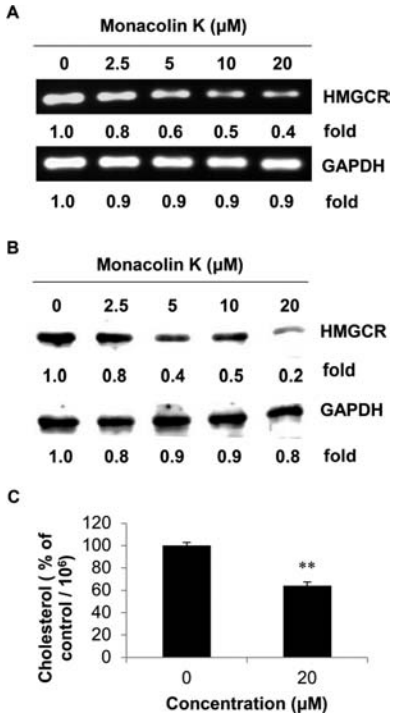

Figure 2. Monacolin K specifically suppresses HMGCR expression and cholesterol level in U937 cells. (A) Cells were incubated with various concentrations of monacolin K for 24 h, and HMGCR and GAPDH mRNA levels were analyzed by RT-PCR. (B) Immunoblots of whole cell lysates were probed with antibodies specific to HMGCR and actin. (C) U937 cells were treated with 20 μM monacolin K for 48 h, and the intracellular total cholesterol content was measured. All data represent means ± SD of triplicates (n = 3). In panel C, ** $p < 0.01$, compared with untreated cells (control groups).

inhibited HMGCR protein expression also in a dose-dependent manner (Figure 2B). After incubation with 20 μM monacolin K, we measured the intracellular total cholesterol content. As shown in Figure 2C, monacolin K showed significant inhibitory effect on cholesterol level at approximately 36% ($p < 0.01$), as compared with control cells.

Monacolin K Down-regulated GLO1 Expression and Increase MG Levels. To understand the critical roles of GLO1 in apoptosis, expression of GLO1 in U937 cells was monitored following treatment with monacolin K. U937 cells were treated with various concentrations of monacolin K for 48 h or 20 μM monacolin K for various times. The cDNA was amplified by PCR with primers specific for GLO1 or GAPDH (as a control gene). As shown in Figure 3A, monacolin K induced time- and dose-dependent down-regulation of GLO1 mRNA levels. Additionally, monacolin K administration resulted in a marked decrease in the GLO1 protein level as compared with control (Figure 3B). To investigate the effect of GLO1 expression blockage on MG level, U937 cells were treated with monacolin K at a concentration of 20 μM for 48 h. A significant increase in MG level was observed in comparison to levels produced by untreated cells (Figure 3C). Monacolin K caused an increase in MG accumulation by 2.7-fold as compared with that of control ($p < 0.05$).

Effects of Monacolin K on Ras Protein Expression and Downstream Signaling Pathways Regulation. Ras is considered a key protein for proliferative, survival, and oncogenic signals. We examined the regulatory effect of monacolin K on membrane protein Ras and its downstream signaling proteins, those being, Raf-1, Akt, and ERK. As shown in Figure 4A, after incubation with 20 μM monacolin K for 24 h, monacolin K significantly decreased the levels of H-Ras, K-Ras, N-Ras, and Raf-1 in cell membrane. In contrast, the H-Ras, K-Ras, N-Ras, and Raf-1 levels in cytosolic fraction were significantly higher in the monacolin K treatments. To assess whether monacolin K mediated and/or inhibited the phosphorylation of Akt and ERK, U937 cells were treated with various concentrations of monacolin K for 24 h. Figure 4B shows that monacolin K significantly inhibited the activation of Akt and ERK as shown by the decrease in the phosphorylation of Akt and ERK.

Monacolin K Abrogated NF-κB Signaling by Blocking the Nuclear Translocation of NF-κB (p65). To explore the underlying mechanism of NF-κB inactivation by monacolin K, we analyzed the protein expression of p65 by immunoblotting. As shown in Figure 5A, treatment of the U937 cells with 20 μM monacolin K for 24 h resulted in a significantly decreased level of p65 in the cell nucleus. In contrast, the p65 levels in cytosolic fraction were significantly increased. Confocal microscope analysis revealed that monacolin K inhibited p65 translocation from cytosol to nucleus (Figure 5B). Therefore, it was possible that the inhibitory effect of monacolin K on the NF-κB translocation was due to inactivation of Akt and ERK pathways, leading to a reduction in GLO1 expression.

Inhibitory Effects of Several Specific Inhibitors on Expression of Akt, ERK, and GLO1 and on Cell Viability in U937 Cells. Several specific inhibitors were used to assess whether a specific signaling pathway was involved in inhibition of monacolin K on GLO1 and other protein expressions. LY294002, U0126, and JSH-23 were used in the treatment of U937 cells. After treatment, cell extracts were prepared to determine the levels of GLO1. As shown in Figure 6A, three LY294002, U0126, and JSH-23 inhibitors could effectively suppress the GLO1 protein expressions. In addition, Figure 6B showed that Akt and ERK phosphorylation decreased after LY294002 and U0126 treatment for 24 h, and JSH-23 had little effect on the phosphorylation of Akt and ERK (Figure 6B). Next, we administered these inhibitors to U937 cells to determine whether suppression of the Ras/PI3K/Akt/NF-κB and Ras/Raf/ERK/NF-κB signaling pathways would inhibit cell viability. As shown in Figure 6C, these inhibitors had a strong inhibitory effect on U937 cell growth ($p < 0.01$). These results confirmed that the apoptotic effect of monacolin K followed the Ras/Akt/NF-κB/GLO-1 and Ras/Raf/ERK/NF-κB/GLO-1 signaling pathways.

Mevalonate Attenuated Monacolin K Induced Apoptosis and Protein Expression in U937 Cells. Accumulation of mevalonate, a precursor of cholesterol, has been reported to be associated with cell survival and proliferation of cancer cells. In the study, the treatment of mevalonate with monacolin K fully reversed its induced apoptosis in U937 cells as evidenced by DNA fragmentation and cell viability analysis ($p < 0.01$) (Figure 7A,B). Next, co-incubation of mevalonate with monacolin K for 24 h reversed monacolin K triggered loss of Akt and ERK phosphorylation (Figure 7C). We further investigated whether mevalonate blocked monacolin K suppresses GLO1 expression. After cells had been pre-incubated with mevalonate for 1 h and then treated with monacolin K for 48 h, as shown in Figure 7D,E, mevalonate prevented the decrease in GLO1 mRNA and protein by monacolin K. These results indicated that down-regulation of the mevalonate pathway is highly associated with monacolin K inhibition on GLO1 as well as the induction of apoptosis in U937 cells.

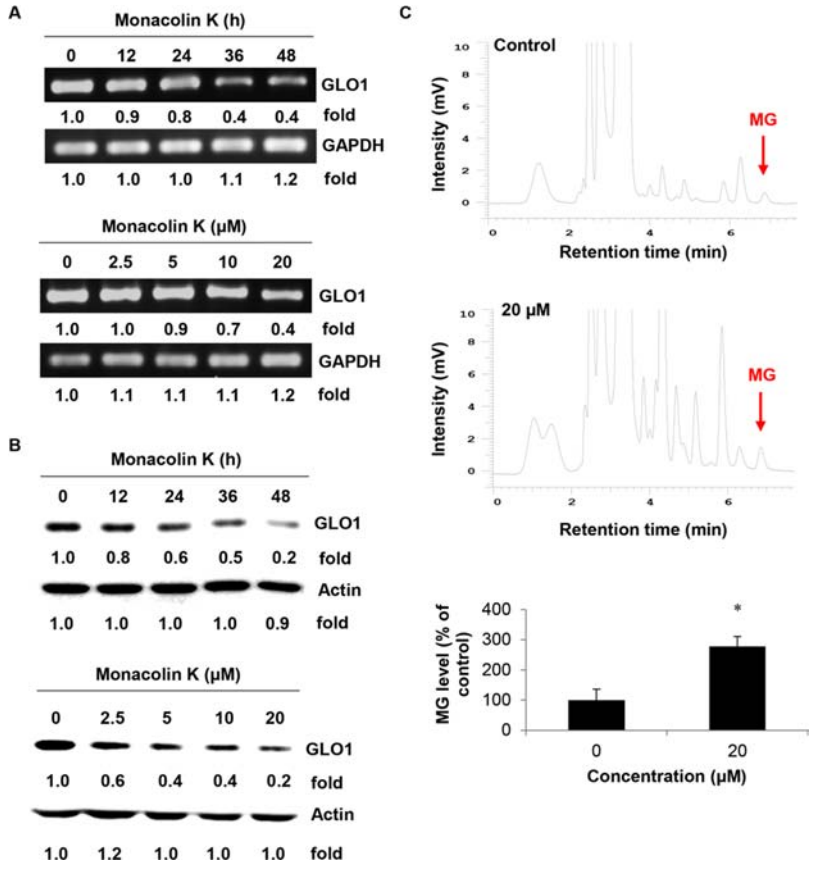

Figure 3. Down-regulation of GLO1 and increase MG levels by monacolin K in U937 cells. U937 cells were incubated with various concentrations of monacolin K for 48 h or with monacolin K (20 μM) for the indicated periods. (A) GLO1 and GAPDH mRNA levels were analyzed by RT-PCR. (B) Immunoblots of whole cell lysates were probed with antibodies specific to GLO1 and actin. (C) MG levels were estimated by HPLC as described under Materials and Methods. Monacolin K caused an increase in MG accumulation by 2.7-fold as compared with that of control (panel C). All data represent means ± SD of triplicates (n = 3). In panel C, ** $p < 0.05$, compared with untreated cells (control groups).

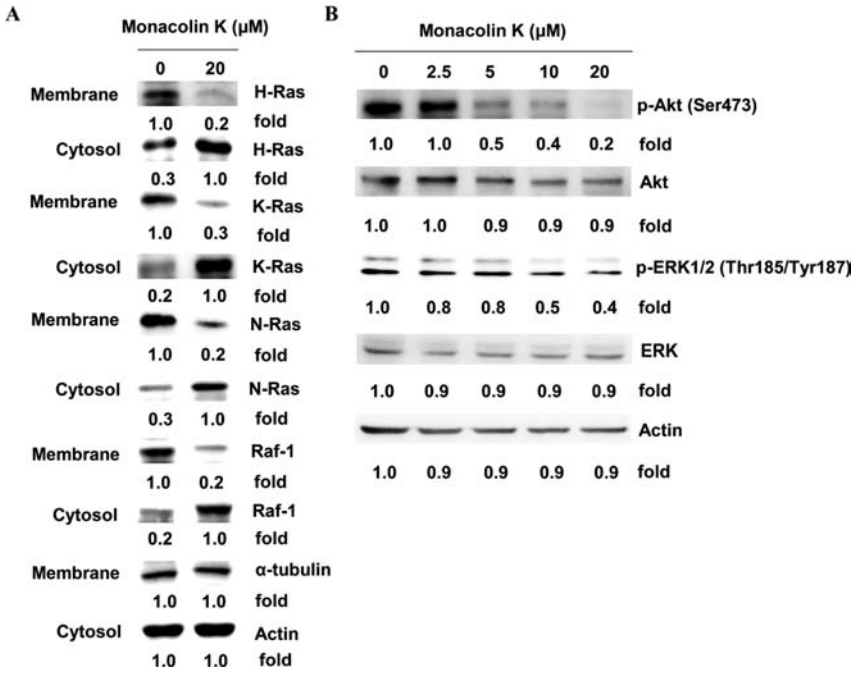

Figure 4. Down-regulation of Ras and its downstream signaling molecules by monacolin K in U937 cells. (A) After treatment with monacolin K for 24 h, membrane and cytosol proteins were extracted and used for immunoblotting of Ras (H, K, and N) and Raf-1. (B) Cells were lysed, and the total protein (30 mg) was submitted to SDS-PAGE and immunodetected with antiphospho- or anti-(ERK or Akt) antibodies. Tests were performed in triplicate and all experiments repeated three times (n = 3).

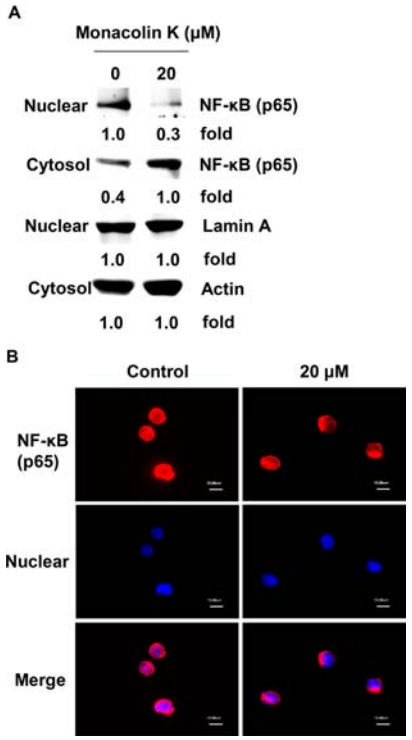

Figure 5. Monacolin K inhibits the translocation of NF-κB (p65) to the nucleus. (A) U937 cells were incubated for 24 h with indicated concentrations of monacolin K, and nuclear extracts were immunoblotted for p65 and the loading control lamin A. (B) After treatment for 24 h, cells were fixed, stained with p65 antibody and Alexa Fluor 594 goat anti-mouse (red), and counterstained with DAPI (blue). Tests were performed in triplicate and all experiments repeated three times (n = 3).

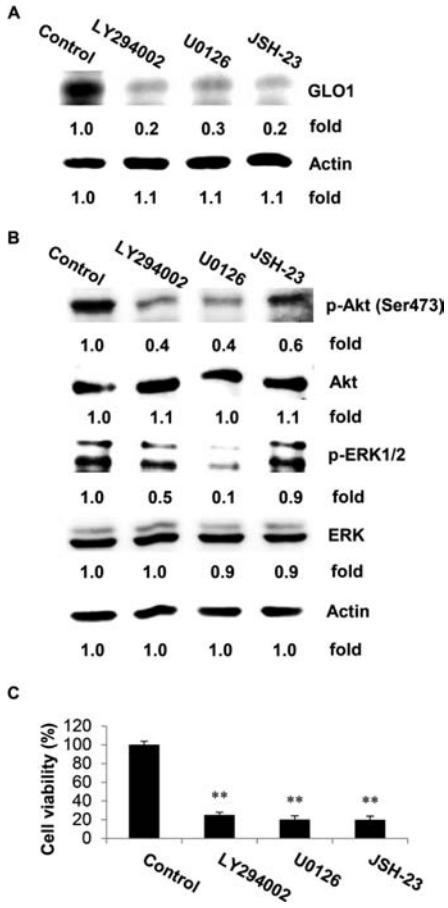

Figure 6. Down-regulation of Ras downstream signaling molecules and cell viability by various inhibitors in U937 cells. (A) U937 cells were treated with 20 μM of various inhibitors for 48 h. Total cell extracts were generated and immunoblotted with antibodies against GLO1. (B) U937 cells were treated with 20 μM of various inhibitors and incubated for 24 h; immunoblots of whole cell lysates were probed with antibodies specific to p-Akt and p-ERK. (C) The cell viabilities of U937 cells treated with 20 μM various inhibitors for 48 h were measured by MTT assay. All data represent means ± SD of triplicates (n = 3). In panel C, ** p < 0.01, compared with untreated cells (control groups).

DISCUSSION

The anticancer effect of monacolin K was demonstrated by its growth inhibitory activity on various cancer cell lines including human acute myeloid leukemia,[19] breast cancer,[20] and pancreatic cancer.[21] A structure−activity relationship analysis showed the alkyl functional group increased the lipophilicity of monacolin K, leading to a direct diffusion through the cell membrane, and affected cell proliferation, survival, and motility.[4] We hypothesize that monacolin K may induce apoptosis in U937 cells by inhibiting the mevalonate pathway and impairing Ras localization to the plasma membrane. It interrupted downstream Akt and ERK pathways, leading to the decreased HMGCR and GLO1 protein expressions.

Tumors, including leukemia, transformed from normal cells alter metabolism. Mutations of oncogenes and tumor-suppressor genes are believed to switch the glucose metabolism from oxidative phosphorylation to glycolysis in cancer cells.[22] Previous papers showed that cancer cells tend to use the glycolysis pathway to metabolize glucose due to lacking or mutated p53 gene.[23] Positron emission tomography (PET) data demonstrated that tumor cells accumulated extraordinary amounts of glucose. Elevated glucose metabolism is seen in activated lymphocytes in the draining lymph nodes of Moloney Murine Sarcoma and Leukemia Virus Complex-challenged mice using a ^{18}F-FDG probe.[24]

MG can be derived nonenzymatically from phosphorylated glycolytic intermediates dihydroxyacetone phosphate and glyceraldehyde-3-phosphate. MG causes DNA fragmentation at physiological concentrations in U937 cells[25] and HL-60 cell lines.[26] Recent studies have shown that MG specifically inhibits mitochondrial respiration in human leukemic leucocytes, leading to a tumoricidal effect.[27] We postulate that U937 cancer cell may use glycolysis to get the required energy and increase the GLO1 expression to eliminate excess MG for surviving and proliferation.

Detoxification of MG is mainly activated via the glyoxalase pathway present in the cytosol of all mammalian cells that use GSH as a cofactor.[28] The apoptotic effects of MG were found in high-glucose-treated VL-17A cells[29] and brain microvascular endothelial cells.[30] It has been shown that GLO1 expression was significantly up-regulated in prostate cancer LNCaP,[31] hepatocellular carcinoma,[32] and human gastric cancer,[33] when compared with adjacent nontumorous tissue. Recently, a novel mechanism of MG cytotoxicity in prostate cancer cells was proposed.[31] The silenced GLO1 in prostate LNCaP and PC3 cancer cells was found to be responsible for the accumulation of excess MG that led to the apoptosis via the cell survival NF-κB signaling pathway.

All data represent means ± SD of triplicates (n = 3). In panel C, ** $p < 0.01$, compared with untreated cells (control groups).

Ras has been reported to be frequently mutated in patients with AML. *Ras* gene mutation leads to the expression of activated Ras proteins and triggers constitutively overactive signaling inside the cell.[34] A previous study found N-Ras mutations (11%) and K-Ras mutations (5%) in AML patients.[35] Among the Ras isoforms, only H-Ras is palmitoylated and integrated into lipid rafts.[36] Activated Ras recruits Raf family proteins to the lipid raft and activates the subsequent ERK pathway. The constitutively activated Raf/MEK/ERK pathway has been characterized in both AML and acute lymphocytic leukemia (ALL).[37] Down-regulation of activated Raf proteins is closely related to cell cycle arrest in human promyelocytic leukemia and some hematopoietic cells. It is well established that the cross-talk between Ras/Raf/MEK/ERK and Ras/PI3K/PTEN/Akt pathways regulates cell growth and tumorigenesis in many leukemia samples.[38] Both pathways may trigger the phosphorylation of downstream targets and regulate cell survival and proliferation.

PI3K activity is another predominant growth factor activated pathway in varieties of human tumors including leukemia.[39] Accumulated evidence shows that PI3K is heavily involved in the malignant transformation of cells through the activation of the downstream Akt.[40] Blalock et al.[41] reported that MEK-mediated transformation of certain hematopoietic cells requires the activation of the PI3K pathway. Combined treatment with the Chk1 inhibitor 7-hydroxystaurosporine (UCN-01) and lovastatin was found to synergistically disrupt Ras prenylation and its translocation to membrane leading to the inhibition of the phosphorylation of both ERK 1/2 and Akt and enhanced apoptosis in U937 cells.[42] Using immunoprecipitation analysis, Chiu et al.[43] showed that Raf-1, Akt, and Ras can accumulate in the membrane to increase cell migration/invasion through PI3K/Akt and Raf-1/ERK activation. A redox modulated up-regulation of survival signaling, involving the ERK and PI3K/Akt phosphorylation pathways, has been reported in U937 cells.[44] Recent studies demonstrated that monacolin K can inhibit the Akt and ERK pathways leading to the decreased Bcl-2, whereas increased Bax expression in human colon carcinoma HCT-116 cell line.[45]

The expression and activity of the transcription factor NF-κB have been shown to be regulated by the Ras/PI3K/AKT and RAS/MAPK pathways.[46] The transcription factor NF-κB promotes cell proliferation and prevents apoptosis through its regulation of various gene products. Monacolin K and other natural statins were found to reduce NF-κB DNA-binding activity in tumor necrosis factor-α (TNF-α)-stimulated human myeloid leukemia KBM-5 cells.[47]

She et al.[48] reported that farnesyltransferase inhibitor manumycin A (manumycin) induced nitric oxide production and apoptosis in two myeloid leukemia cell lines (U937 and HL-60). Manumycin reduced the amount of functional Ras localized at the cytoplasmic membrane, thus blocking Raf-1 association with Ras. Manumycin inhibits the phosphorylation of both ERK1/2 and Akt and interferes with the association of PI3K and Ras in HepG2 cells.[49]

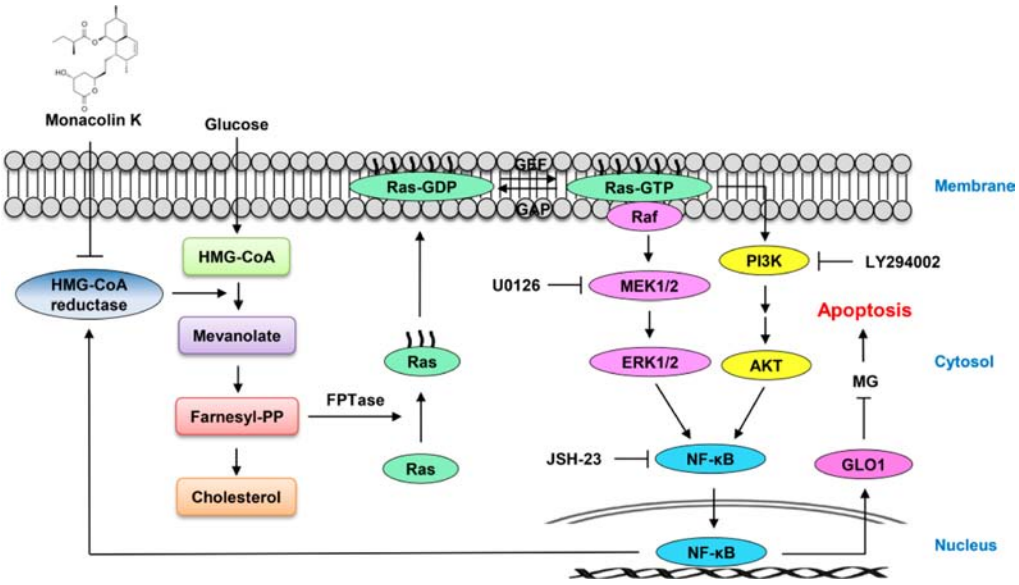

Figure 8. Diagram depicting the hypothesis of signaling regulation on GLO1 expression through both Ras/Raf/ERKNF-κB and Ras/PI3K/Akt/NF-κB pathways following monacolin K exposure in U937 cells. Farnesyl-PP, farnesyl pyrophosphate; FPTase, farnesyl prenyl transferase; GEF, guanine nucleotide exchange factor; GAP, GTPase-activating protein.

Monacolin K and other statins stimulate cell death, which was accompanied by the collapse of the mitochondrial membrane potential (MMP) in isolated Sprague–Dawley rat hepatocytes.[18] This observation indicates that cholesterol levels play a major role in the integrity of cell membranes, and the inactivation of HMGCR activity by monacolin K may be responsible for the apoptotic effect.

Our results reveal that the translocation of both Ras and Raf-1 to membrane and the levels of p-Akt in the PI3K/AKT/mTOR signaling pathway as well as p-ERK in the MAPK signal pathway were down-regulated by monacolin K in the U937 cell line. We postulate that monacolin K, a HMGCR inhibitor, blocks the biosynthesis of mevalonate and the subsequent farnesyl pyrophosphate through the inactivation of HMGCR. Lack of farnesyl pyrophosphate results in the inhibition of the isoprenylation of Ras protein and leads to the repression of accumulation of putative lipid raft-associated proteins. The subsequent phosphorylation of both Akt and ERK pathways will be thus abrogated. Overall, these results provided evidence of the specific molecular pathways by which monacolin K induces apoptosis: it decreases the activation of GLO1 and lowers cholesterol levels through the inhibition of Ras/Raf/ERK/NF-κB and Ras/Akt/NF-κB pathways (Figure 8). These findings provide evidence that it will be worthwhile to investigate the potential of monacolin K for the treatment of leukemia and potentially other types of human cancers.

[a]The chemical shifts are in δ values (ppm) from TMS. [b]2D ^{1}H, ^{1}H (COSY) and 2D ^{13}C, ^{1}H (HSQC) NMR experiments delineated the correlations of all of the protons and the corresponding carbons. [c]Multiplicities were assigned by DEPT spectrum. [d]Signals overlapped.

metabolites, which by preliminary spectroscopic investigation appeared to be closely related to alternethanoxins A and B. This study was designed to establish the chemical and biological characterization of these three new metabolites, named alternethanoxins C–E.

MATERIALS AND METHODS

General Experimental Procedures. UV spectra were taken in MeCN solution on a Beckman Coulter DU800 spectrophotometer (Fullerton, California, USA); ^{1}H and ^{13}C NMR spectra were recorded at 400 and at 100 MHz, respectively, in CD_3COCD_3 on a Bruker AVANCE III 400 MHz spectrometer (Karlsruhe, Germany). The same solvent was used as internal standard. Carbon multiplicities were determined by distortionless enhancement by polarization transfer (DEPT) spectra.[8] DEPT, correlation spectroscopy (COSY)-45, heteronuclear multiple-quantum coherence (HMQC), heteronuclear multiple-bond correlation (HMBC), and nuclear Overhauser enhancement spectroscopy (NOESY) experiments[8] were performed using standard Bruker microprograms. HRESI MS spectra were recorded on an Agilent 6530 Q-TOF LC/MC (ESI-HRMS) spectrometer (Santa Clara, California , USA). Analytical and preparative TLC was performed on silica gel and reverse phase (Kieselgel 60 F_{254} plates, 0.25 and 0.5 mm, and Kieselgel 60 RP-18 F_{254} plates, 0.20 mm, respectively) (Merck, Darmstadt, Germany). The spots were visualized by exposure to UV radiation (254 nm) and/or by spraying first with 10% H_2SO_4 in MeOH and then with 5% phosphomolybdic acid in EtOH, followed by heating at 110 °C for 10 min. Column chromatography was performed on a silica gel column (Kieselgel 60, 0.063–0.200 mm) (Merck, Darmstadt, Germany). Medium-pressure chromatography was performed with Puriflash (Interchim, France, Montluçon, Fr) prepacked normal-phase (Silica HP 30 μm 40G and Silica HP 15 μm 12G) and reverse-phase (C18 HP 15 μm 20G) columns (Interchim, Montluçon, France).

Fungal Strains and Toxins Production and Purification. The strain (S-102) of *A. sonchi* used in this study was deposited in the collection of All-Russian Research Institute of Plant Protection (Pushkin, Saint Petersburg, Russia). The fungus was grown on autoclaved pearl barley, and the solid culture (1.3 kg) was extracted with Me_2CO–H_2O (50:50) according to the procedure previously reported.[7] After evaporation of the Me_2CO, H_2O phase was passed through a column containing 20 g of Diaion HP-20, and then was washed with water, MeOH, EtOAc, and CH_2Cl_2. The dry residue (5.2 g) of the MeOH extract demonstrated phytotoxic activity. It was then subjected to bioassay-guided fractionation through column chromatography (750 mm × 30 mm) on silica gel, eluted with CH_2Cl_2/MeOH (100:0 (800 mL), 95:5 (800 mL), 90:10 (800 mL), and 80:20 (800 mL), v/v) affording four homogeneous fractions. The residue of the second fraction (3.3 g) showing both phytotoxic and antimicrobial activity was further purified by CC on silica gel eluted with $CHCl_3$/*i*-PrOH (90:10, v/v) giving five homogeneous fractions. The residue of the fourth fraction (244 mg) was further purified by MPLC on silica gel, eluted with *n*-hexane/Me_2CO (100:0 to 50:50, v/v), yielding alternethanoxin B, **2** (R_f 0.37, toluene/EtOAc/glacial CH_3COOH (70:30:0.1, v/v/v), R_f 0.35, H_2O/MeOH (20:80, v/v), 8.5 mg), and alternethanoxin E, **5** (R_f 0.45 toluene/EtOAc/glacial CH_3COOH (70:30:0.1, v/v/v), R_f 0.24, H_2O/MeOH (20:80, v/v), 5.0 mg) as a pale yellow homogeneous amorphous solid. The residue of the fifth fraction (470 mg) was further purified by reverse-phase MPLC eluted with MeOH/H_2O (20:80 to 100:0, v/v) and finally by PTLC on silica gel (eluent toluene/EtOAc/glacial CH_3COOH 70:30:0.1) affording alternethanoxin A, **1** (R_f 0.39, toluene/EtOAc/glacial CH_3COOH (70:30:0.1, v/v/v), R_f 0.72, H_2O/MeOH (20:80, v/v) 25.0 mg), alternethanoxin C, **3** (R_f 0.59, toluene/EtOAc/glacial CH_3COOH (70:30:0.1, v/v/v), R_f 0.65, H_2O/MeOH (20:80, v/v), 16.0 mg) as a pale rose homogeneous amorphous solid, and alternethanoxin D, **4** (R_f 0.39, toluene/EtOAc/glacial CH_3COOH (70:30:0.1, v/v/v), R_f 0.36 H_2O/MeOH (20:80, v/v), 7.0 mg), as a pale yellow homogeneous amorphous solid.

Alternethanoxin C (3). Pale rose amorphous solid, UV λ_{max} nm (log ε) 345 (0.1), 280 (0.65), 250 (0.40), 210 (1.75); ^{1}H and ^{13}C NMR, see Table 1; HRESI MS (+) spectrum *m/z*: 695 $[2M + Na]^+$; 375 $[M + K]^+$, 359.0845 $[C_{16}H_{16}NaO_8$ calcd 359.0743, M + Na$]^+$.

Alternethanoxin D (4). Pale yellow amorphous solid, UV λ_{max} nm (log ε) 365 (0.17), 300 (0.50), 243 (1.00); ^{1}H and ^{13}C NMR, see Table 1; HRESI MS (+) spectrum *m/z*: 691 $[2M + Na]^+$; 373 $[M + K]^+$, 357.0574 $[C_{16}H_{14}NaO_8$ calcd 357.0586, M + Na$]^+$.

Alternethanoxin E (5). Pale yellow amorphous solid, UV λ_{max} nm (log ε) 352 (0.16), 305 (0.60) 252 (0.75); 235 (1.14); ^{1}H and ^{13}C NMR, see Table 1; HRESI MS (+) spectrum *m/z*: 623 $[2M + Na]^+$; 339 $[M + K]^+$, 323.0521 $[C_{16}H_{12}NaO_6$ calcd 323.0532, M + Na$]^+$.

Bioassay. *Phytotoxic Activity.* Leaf segments of *Elytrigia repens* (couch-grass) 2 cm length and leaf discs of *Sonchus arvense* (perennial sowthistle) 1 cm in diameter were punctured with a sharp needle in the center and were treated with solutions of isolated compounds in 5% EtOH at the concentration of 2 mg/mL as described previously.[11]

DOI: 10.1021/jf5054595
J. Agric. Food Chem. 2015, 63, 1196–1199

Typically, for this bioassay samples of isolated compounds (400 μg) were dissolved in EtOH (10 μL) ultrasonically, and then water (190 μL) was added and the samples were vortexed. At least 10 replicate leaf segments or discs were used for each treatment.

Antimicrobial Activity. The antimicrobial activity of the isolated compounds was tested against a Gram positive bacterium (*Bacillus subtilis*) and a yeast fungus (*Candida tropicalis*) by using an agar diffusion assay according to the protocol previously reported.[12] Both microorganisms were grown on potato-dextrose agar. Up to 100 μg of each metabolite was applied per disc (6 mm diam) (Macherey-Nagel, Düren, Germany). The cultures were incubated at 30 °C for 24 h before activity was determined by minimum inhibitory concentration (MIC) defined as the lowest concentration of antibiotic that inhibited visible growth.[13]

Statistical Analysis. All bioassays were performed twice with at least three replicates. When appropriate, standard deviation was determined.

RESULTS AND DISCUSSION

The organic extract of the *A. sonchi* solid culture was purified by a combination of column and TLC chromatography, yielding three homogeneous amorphous solids that were closely related to alternethanoxins A and B, as deduced by preliminary investigation of the ^{1}H and ^{13}C NMR spectra, and were named alternethanoxins C−E (**3**−**5**, Figure 1).

Alternethanoxin C, **3** has a molecular formula of $C_{16}H_{16}O_8$ as deduced from its HRESI MS spectrum, which is associated with ten hydrogen deficiencies. In particular, its ^{1}H NMR spectrum (Table 1) differed from that of **1** in the presence of two aromatic protons (H-8 and H-9), which were *ortho*-coupled in the COSY spectrum[8] instead of the typical systems of a 1,2,3-substituted benzene ring.[9] H-8 and H-9 resonated as two doublets (J = 7.3 Hz) at δ 7.51 and 7.45 together with the singlet of H-3 and H-6, which appeared as an overlapped signal as in **1**, the methoxy and the methylcarbonyl at δ 6.21, 3.70, and 2.20. Probably the phenolic hydroxy group at C-1 was hydrogen bonded with the acetyl group at C-2 generating a stable six-membered ring as shown by the singlet observed at the typical chemical shift value of δ 12.19 as in **1**.[6,9] The couplings observed in the HMQC spectrum[8] allowed assignment of the signals of the protonated carbons in the ^{13}C NMR spectrum (Table 1) at δ 129.4, 122.1, 110.1 (an overlapped signal), 53.8, and 21.9 to C-8, C-9, C-3, and C-6, OMe and MeCO. The signals observed in the ^{13}C NMR spectrum at δ 166.2, 162.8 (an overlapped signal), 149.8, 136.3, and 127.7 were assigned to C-7, C-4 and C-5, C-10, and C-10a[10] also on the basis of the couplings observed in the HMBC spectrum[8] between the C-4 and C-5, which gave an overlapped signal, with H-3, C-6a with H-8, C-7 with H-9, H-8 and OMe, and C-10 and C-10a with H-9 and H-8. The signals at δ 148.9, 126.2, and 110.0 were assigned to C-1, C-2, and C-10b by comparison with the values reported for the same carbons in **1**.[6] Finally, the carbonyl group appeared at the typical chemical shift value of δ 199.2.[10] The chemical shifts of all protons and corresponding carbons of **3** were assigned and reported in Table 1.

On the basis of these results, alternethanoxin C appeared to be close to **1**, differing in the hydrolytic opening of the hemiacetal bond between C-6 and C-5 and the hydroxylation of C-10. The structure assigned to **3** was confirmed from the other couplings observed in the HMBC spectrum and from the data of its HRESI MS spectrum. This latter spectrum showed the sodiated dimeric form $[2M + Na]^+$ and the potassium and sodium clusters $[M + K]^+$ and $[M + Na]^+$, at m/z 695, 375, and 359.0845, respectively. Furthermore, a correlation was observed in the NOESY spectrum between H-3 and MeCO.

Therefore, **3** was formulated as 2′-dihydroxymethyl-2,5,6,6′-tetrahydroxy-3′-methoxy-biphenyl-3-carboxylic acid methyl ester.

Alternethanoxin D, **4**, has a molecular formula of $C_{16}H_{14}O_8$ as deduced from its HRESI MS spectrum consistent with nine hydrogen deficiencies. The investigation of its ^{1}H and ^{13}C NMR spectra (Table 1) showed that **4** was also very closely related to **1**. In fact, the ^{1}H NMR spectrum differed from that of **1** in the presence of a proton (H-8) of a pentasubstituted benzene ring appearing as a singlet at δ 7.06; the two adjacent carbons to C-8 (C-10 and C-9) were hydroxylated and resonated in the ^{13}C NMR spectrum at the typical chemical shifts values of δ 165.0 and 156.9.[10] The singlets of H-3, H-6, MeO, and MeCO resonated at the expected δ values of 6.66, 6.93, 3.90, and 2.50. Furthermore, the singlet at δ 12.19 was due to the phenolic hydroxy group at C-6 hydrogen bonded with the methoxy group at C-7 as in **2**, indicating for C-6 the same relative stereochemistry assigned to alternethanoxin B. The couplings observed in the HMQC spectrum allowed assignment of the chemical shifts to the hydrogenated carbons and the signals at δ 112.4, 111.6, 106.3, 53.3, and 22.6 to C-8, C-6, C-3, OMe, and MeCO. In addition, the couplings observed in the HMBC spectrum (Table 1) between C-1 and MeCO, C-2 and C-4 with H-3, C-3 with H-6 and MeCO, C-5 with H-6, and C-7 with H-9 and OMe allowed assignment of the chemical shifts at δ 149.3, 128.9, 153.0, 161.4, and 168.6 to C-1, C-2, C-4, C-5, and C-7. The signals at δ 155.3, 133.2, and 112.7 were assigned to C-6a, C-10a and C-10b by comparison with the values reported for the same carbons in **1**.[6] Finally, the acetyl group appeared at the typical chemical shift value of δ 179.8.[10]

The chemical shifts were attributed to all of the protons and the corresponding carbons as reported in Table 1, and alternethanoxin D, **4** was formulated as 1,4,6,9,10-pentahydroxy-7-methoxy-6*H*-benzo[*c*]chromene-2-carboxylic acid methyl ester. This structure was confirmed by the other long-range couplings observed in the HMBC spectrum (Table 1) and from the data of its HRESI MS spectrum. This latter spectrum showed the sodiated dimeric form $[2M + Na]^+$, and potassium and sodium clusters $[M + K]^+$ and $[M + Na]^+$ at m/z 691, 373, and 357.0574, respectively. Furthermore, a correlation was observed in the NOESY spectrum between H-3 and MeCO.

The absolute configuration at C-6 as depicted in Figure 1, established by comparing the chemical shifts of H-6 and H-3, was different in **2** with respect to **1**, as in the latter they gave an overlapped signal. This was confirmed by the signal at δ 12.10 due to the hemiacetalic hydroxy group at C-6, which was probably hydrogen bonded with the methoxy at C-7 generating a stable six-membered cycle.

Alternethanoxin E, **5**, showed the molecular formula of $C_{16}H_{12}O_6$ deduced from its HRESI MS and consistent with 11 hydrogen deficiencies. The preliminary investigation of ^{1}H and ^{13}C NMR spectra showed that **5** is closely related to **2**. In fact, its ^{1}H NMR spectrum (Table 1) differed from that of **2** only in the location of the methoxy group that was attached to C-8 instead of C-7. This generated the typical system of two *meta*-coupled aromatic protons (H-7 and H-9), resonating as two doublets (J = 2.2 Hz) at δ 6.99 and 6.91.[9] Their carbons resonated in the ^{13}C NMR spectrum (Table 1) at the typical chemical shift values of δ 168.4, 112.6, and 103.3 for C-8, C-9, and C-7. As expected, H-3, H-6, MeO, and MeCO were all observed as singlets at δ 6.84, 6.64, 3.92, and 2.45, respectively.[9] The couplings observed in the HMQC spectrum allowed

DOI: 10.1021/jf5054595
J. Agric. Food Chem. 2015, 63, 1196−1199

assignment of the chemical shifts to the other protonated carbons at δ 111.2, 107.2, 52.0, and 21.5 to C-6, C-3, OMe, and MeCO. The couplings observed in the HMBC (Table 1) between C-1 and C-2 with H-3, C-4 with MeCO, C-5 and C-6a with H-6, C-8 with OMe, and C-10 with H-9 allowed assignment of the signals at δ 155.9, 106.2, 148.9, 158.2, 161.2, 168.4, and 168.8 to C-1, C-2, C-4, C-5, C-6a, C-8, and C-10. The signals at δ 135.9 and 110.1 were assigned to C-10a and C-10b by comparison with the values reported for the same carbons in **1**.[6] Finally, the acetyl group appeared at the typical chemical shift value of δ 179.6.[10]

The chemical shifts were attributed to all of the protons and the corresponding carbons as reported in Table 1, and alternethanoxin E, **5** was formulated as 7,9-dihydroxy-2-methoxy-9*H*-4,8-dioxa-cyclopenta[*def*]phenanthrene-5-carboxylic acid methyl ester. This structure was confirmed by the other long-range couplings observed in the HMBC spectrum and from the data of its HRESI MS spectrum. This latter spectrum showed the sodiated dimeric form $[2M + Na]^+$ and the potassium and sodium clusters $[M + K]^+$ and $[M + Na]^+$ at m/z 623, 339, and 323.0521, respectively. Furthermore, a correlation was observed in the NOESY spectrum between H-3 and MeCO.

The absolute stereochemistry at C-6 of alternethanoxin E as depicted in Figure 1 should be the same as **2** considering the chemical shift values of H3/C3 and H6/C6.

The three new alternethanoxins C−E were assayed together with alternethanoxins A and B for their phytotoxic and antimicrobial activity (Table 2). Among the five compounds tested, only alternethanoxins A and C were toxic to the host plant of the fungus, *S. arvensis*. Alternethanoxin C was more active than alternethanoxin A. Couch-grass was sensitive to 4 of 5 compounds. Alternethanoxins A and C caused significantly stronger necrotic reaction than alternethanoxins B and D. Alternethanoxin E was nontoxic to both plants (Table 2).

Table 2. Biological Activity of Althernethanoxins A−E

	phytotoxic activity[a]		antimicrobial activity[b]	
compound	*Sonchus arvensis*	*Elytrigia repens*	*Bacillus subtilis*	*Candida tropicalis*
1	1.7 ± 0.11	1.2 ± 0.40	100	na
2	0	0.5 ± 0	>100	na
3	2.4 ± 0.23	1.1 ± 0.29	10	25
4	0	0.5 ± 0	10	25
5	0	0	na	na

[a]Necrosis, mm ± std deviation. [b]Minimal inhibitory concentration, μg/disc; na, no activity.

Alternethanoxins A and B showed low antibiotic activity against *B. subtilis*. The yeast fungus was insensitive to them. In the previous study,[6] the absence of this kind activity was reported for these two compounds. As compared to them, alternethanoxins C and D had notable antimicrobial activity against both *B. subtilis* and *C. tropicalis*. Alternethanoxin E was not active at all (Table 2).

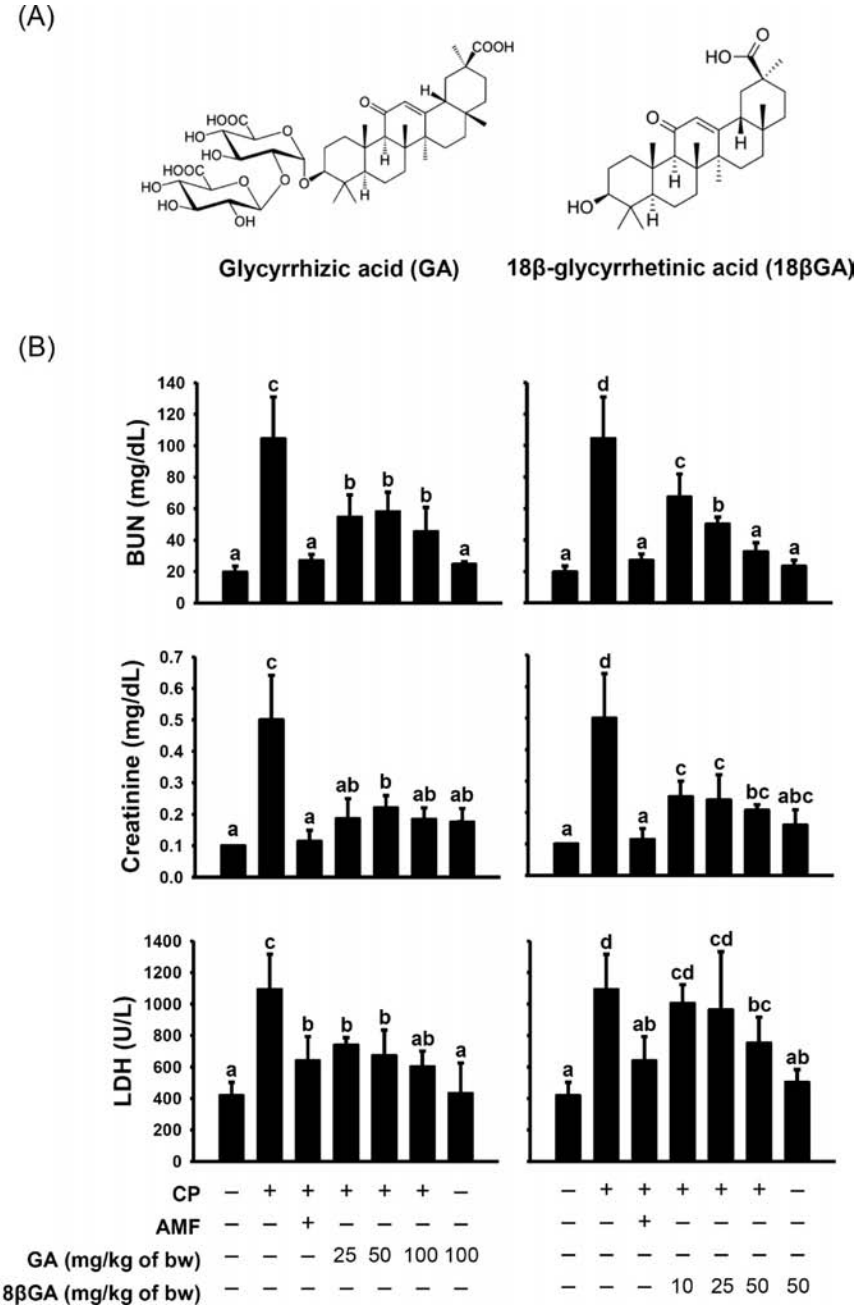

Figure 1. Elevated levels of serum BUN, creatinine, and LDH were reduced by GA and 18βGA in BALB/c mice with CP-induced renal injury. (A) Chemical structures of GA and 18βGA. (B) Mice were gavaged daily with GA (25−100 mg/kg of BW) or 18βGA (10−50 mg/kg of BW) for 8 consecutive days, and a single IP injection of CP (30 mg/kg of BW) was applied on day 6. The positive control group was given a single IP injection of AMF (200 mg/kg of BW) at 0.5 h before the CP challenge. Mice were sacrificed on day 9. Data are presented as the mean ± SD ($n = 8$), and letters (a−c) indicate statistically significant differences in each group ($p < 0.05$). One-way ANOVA tests were used for the statistical analyses.

antioxidant enzyme activities, and reducing inflammatory responses.[1,19] Because oxidative stress and inflammatory responses play key roles in CP-induced nephrotoxicity, this study employed an animal model of CP-induced renal injury to verify the protective effects of GA and 18βGA against chemically induced renal injury and the possible underlying mechanisms of such protective effects.

MATERIALS AND METHODS

Chemicals. CP, GA, 18βGA, Kollisolv PEG E 400, AMF, 1-chloro-2,4-dinitro-benzene (CDNB), glutathione (GSH), glutathione reductase (GSH-Rd), β-nicotinamide adenine dinucleotide phosphate (β-NADPH), sodium azide (NaN_3), and ethanol were obtained from Sigma-Aldrich (St. Louis, MO). The superoxide dismutase (SOD) assay kit was purchased from Faith Technology (Taichung, Taiwan); the GSH assay kit was purchased from Cayman Chemicals (Ann Arbor, MI); the protein assay kit was purchased from Bio-Rad (Hercules, CA); and the anti-nuclear factor E2-related protein (Nrf2), anti-heme oxygenase-1 (HO-1), anti-high-mobility group protein B1 (HMGB1), anti-nuclear factor-κ-light-chain-enhancer of activated B cells (NF-κB), anti-tumor necrosis factor (TNF)-α, anti-interleukin (IL)-1β, and anti-IL-6 antibodies were purchased from Cell Signaling Technology (Beverly, MA).

Experimental Animals and Procedures. The 6-week-old male BALB/c mice were purchased from the National Laboratory Animal

DOI: 10.1021/jf505471a
J. Agric. Food Chem. 2015, 63, 1200−1209

Center (Taipei, Taiwan). The animal experiments in this study were approved by the Institutional Animal Care and Use Committee of the National Chung Hsing University (IACUC approval number 98-76) and followed related regulations of the Animal Care and Use Committee. Animals were housed in animal rooms at the Department of Food Science and Biotechnology of National Chung Hsing University. The temperature and relative humidity (RH) of the animal rooms were maintained at constant levels (22 ± 2 °C and RH of 65 ± 5%). A 12 h light/dark cycle was maintained, and the light cycle was controlled by an automatic timer; the light period was at 06:00−18:00, and the dark period was at 18:00−06:00. After arrival, the experimental mice were immediately weighed, and after a statistical analysis, they were distributed to feeding cages according to a normal distribution. Animals were allowed *ad libitum* access to water and food (laboratory rodent diet 5001, Purina, St. Louis, MO).

The animal groupings and treatments were modified from the methods by Mitazaki et al.[20] and Arjumand et al.[14] After adaptive feeding for 1 week, the 6-week-old male BALB/c mice were continuously fed the sample diets for 8 days (GA at 25, 50, or 100 mg/kg of BW or 18βGA at 10, 25, or 50 mg/kg of BW). After 30 min of sample administration on day 6, an intraperitoneal (IP) injection of CP (30 mg/kg of BW) was given to induce damage, and 30 min prior to the injection of CP on day 6, the positive control group was IP-injected with the chemotherapy protectant, AMF (200 mg/kg of BW). The mice were sacrificed on day 9 to collect samples.

Analysis of Serum Biochemical Values. Serum biochemical values, including BUN, creatinine, and lactate dehydrogenase (LDH), were analyzed using the ADVIA Chemistry Urea Nitrogen Reagent, ADVIA Chemistry Enzymatic Creatinine-2 Reagent, and ADVIA Lactate Dehydrogenase L-P Reagent, respectively (Siemens, NY). The analyses were performed according to protocols in the manuals of the manufacturer.

Histopathological Studies. Renal tissues of BALB/c mice were fixed in 10% formaldehyde immediately following sacrifice, processed for histological examination according to a conventional method, and stained with hematoxylin and eosin (H&E). The morphology of any observed lesions was classified and recorded according to the classification criteria by Shackelford et al.[21]

Analysis of the Activities of Antioxidant Enzymes. Catalase, SOD, glutathione peroxidase (GPx), and glutathione reductase (GRd) activities were measured using an assay kit (Cayman, Ann Arbor, MI) according to the instruction of the manufacturer. The GSH/oxidized glutathione (GSSG) ratio was analyzed using a GSH assay kit purchased from Cayman (Ann Arbor, MI).

Measurement of Malondialdehyde (MDA). The MDA levels in kidney samples of experimental rats were determined using the thiobarbituric acid (TBA) method, with modifications.[22] Briefly, following a preincubation, 0.5 mL of tissue homogenate was mixed with 1 mL of 15% trichloroacetic acid, 0.375% thiobarbituric acid reactive substances (TBARS), and 0.25 mM HCl and then heated in boiling water for 45 min. After centrifugation (2000*g* for 15 min), the absorbance of the butanol phase was read at 535 and 520 nm. The difference between the two values was used to calculate the MDA concentration. An MDA standard was prepared from 1,1,3,3,-tetraethoxypropane. Total protein concentrations were determined by Lowry's method using bovine serum albumin as the standard. The MDA concentration was normalized against the total protein concentration and is expressed in micromoles per milligram of protein.

Immunohistochemical (IHC) Staining. Paraffin blocks of kidney tissues were cut using a microtome into 2 μm thick sections. Sections were floated on water to allow for the tissues to unfold and extend. Tissue sections were placed on 2-aminopropyltriethoxysilane-coated slides, dried at 37 °C, and deparaffinized using xylene. Deparaffinized slides were treated with 3% H_2O_2 and proteinase K (0.5 mg/mL) for 10 min, washed with distilled water 3 times, and incubated in blocking buffer (StartingBlock, Pierce, Rockford, IL) for 5 min. When the slides had slightly dried, they were stained with primary antibodies for 30 min at 40 °C (anti-Nrf2, anti-HO-1, anti-HMGB1, anti-NF-κB, anti-TNF-α, anti-IL-1β, and anti-IL-6 antibodies were used in this study). After the slides were washed with phosphate-buffered saline (PBS) 3 times, they were incubated in EnVision-labeled polymer peroxidase-conjugated anti-immunoglobulin G (IgG, Dako, Glostrup, Denmark) at room temperature for 30 min. Slides were again washed with PBS 3 times and then incubated in diluted 3,3-diaminobenzidine tetrahydrochloride (DAB-4HCl, Dako) for color development. After development, slides were washed with PBS 3 times and counterstained with hematoxylin. Slides were then washed with distilled water 3 times, dehydrated, dried, and mounted. The intensity of antigen expression after staining was quantified using Image-Pro Plus 6.3 image analysis software (Media Cybernetics, Rockville, MD). Results are presented as the positively stained area (%).

Statistical Analysis. All data are expressed as the mean ± standard deviation (SD). An analysis of variance (ANOVA) was used to evaluate differences among multiple groups. Significant differences were subjected to Duncan's test to compare the means of two specific groups. A p value of <0.05 was considered significant.

RESULTS

Evaluation of Renal Function Parameters To Determine the Effects of GA and 18βGA on CP-Induced Renal Injury in BALB/c Mice. The chemical structures of GA and 18βGA are shown in Figure 1A. As shown in Figure 1B, an IP injection of CP (30 mg/kg of BW) induced significant increases in serum BUN, creatinine, and LDH in BALB/c mice. Administration of GA (25, 50, and 100 mg/kg of BW) and 18βGA (10, 25, and 50 mg/kg of BW) significantly reduced CP-induced BUN, creatinine, and LDH levels. The positive control of AMF (200 mg/kg of BW) also showed a protective effect on kidneys exposed to CP-induced acute renal injury. In addition, administration of a high dose of GA or 18βGA alone did not affect levels of BUN, creatinine, or LDH in the kidneys (p < 0.05).

Tissue Pathological Analysis of the Effects of GA and 18βGA on CP-Induced Renal Injury in BALB/c Mice. Acute renal tubular necrosis is an important pathological feature of CP-induced renal injury,[23] and this study used morphological changes in the appearance of the kidneys and renal tubular lesions as indicators to evaluate renal injury. Results showed that CP induced significant lesions that produced whitening of the kidneys in mice. The macroscopic appearances were similar among the GA-, 18βGA-, and AMF-treated sample groups and CP-untreated control group and exhibited a hyperemic dark-maroon color (left panel of Figure 2). The right panel of Figure 2 shows pathological tissue sections with H&E staining (400×) in the GA and 18βGA experimental groups. Changes in tissue morphology indicated that the control group presented a healthy normal morphology of renal glomeruli and tubules, whereas the CP group presented severe renal tubular injury, while the GA and 18βGA groups presented different degrees of protective effects. Further pathological interpretation and classification of the above sections based on the four pathological features of renal tubules, including tubular necrosis, tubular degeneration, hyaline cast, and dilation, were performed according to the classification criteria by Shackelford et al.[21] (Table 1). A statistical analysis of injury scores for the GA and 18βGA experimental groups showed that both compounds significantly protected renal tubules from CP-induced injury (p < 0.05) in dose-dependent manners. In addition, renal tubular injury was found to interfere with the reabsorption of renal filtrate, which might affect BW changes. Administration of a high dose of GA (100 mg/kg of BW) or 18βGA (50 mg/kg of BW) alone did not the affect BW changes in experimental animals (data not shown).

Effects of GA and 18βGA on CP-Induced Lipid Peroxide Accumulation and Alterations of Antioxidant Enzyme

DOI: 10.1021/jf505471a
J. Agric. Food Chem. 2015, 63, 1200−1209

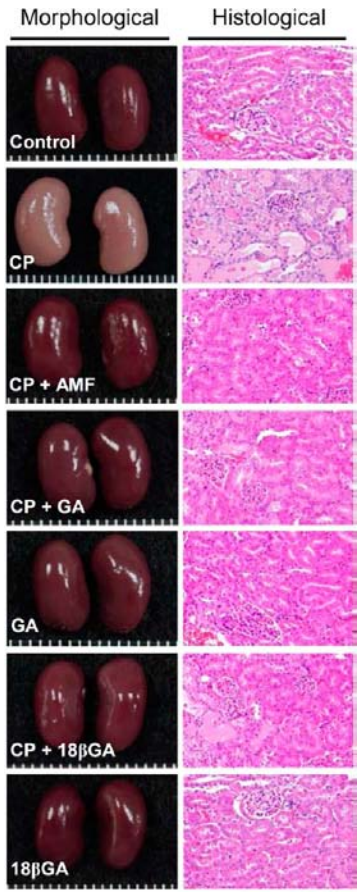

Figure 2. Effects of GA and 18βGA on the kidney morphology and histology in BALB/c mice with CP-induced renal injury. Groups of mice were treated as described in Figure 1, and the data shown are from a representative experiment. Representative macroscopic appearances of the kidneys (left panel) and H&E-stained kidneys (right panel, 400×) were used to assess the renoprotective effects of GA (100 mg/kg of BW) and 18βGA (50 mg/kg of BW) against CP-induced nephrotoxicity in experimental mice.

Activities in the Kidneys of BALB/c Mice. During the pathological process of CP-induced acute renal injury, accumulation of lipid peroxides and reductions in antioxidant enzyme activities in the kidneys play important roles;[24] however, supplementation with antioxidants or activation of the antioxidant defense system can provide a certain degree of protection.[25,26] This study also confirmed that CP promoted formation of MDA and reduced activities of antioxidant enzymes, such as catalase, SOD, and GPx, and the GSH/GSSG ratio in the kidneys. Except for the low dose of GA (25 mg/kg of BW) or 18βGA (10 mg/kg of BW), which showed no effect on GPx activity ($p < 0.05$), AMF and other doses of GA and 18βGA inhibited lipid peroxidation and restored the protective features of the above antioxidant enzymes and GSH/GSSG ratio (Figure 3).

Effects of GA and 18βGA on CP-Induced Antioxidant Protein Expressions in Kidneys of BALB/c Mice. This study used an IHC method to show for the first time that, in a CP-induced renal injury mouse model, the antioxidant transcription factor, Nrf2 (Figure 4A), and its downstream, HO-1 (Figure 4B), were significantly activated in the kidneys. However, GA (50 mg/kg of BW) and 18βGA (25 mg/kg of BW) stimulated antioxidant transcription factor Nrf2 and further stimulated the expression of the above antioxidant proteins in the kidney after CP-induced injury (Figure 4 and Supplementary Figure 1 of the Supporting Information). This result might explain the increased activity of antioxidant enzymes in the kidneys after administration of GA and 18βGA.

Effects of GA and 18βGA on Kidney Inflammation-Related Indicators in BALB/c Mice with CP-Induced Renal Injury. This study also performed IHC analyses and directly used the staining intensity of the detected target molecules in tissues to evaluate alterations in inflammation-related factors in kidney tissues. CP stimulated expression of the NF-κB transcription factor in the kidneys (Figure 5A); however, administration of GA, 18βGA, and AMF all showed a protective effect and significantly inhibited NF-κB (panels A and B of Figure 5). They also had significant inhibitory effects on proinflamma-

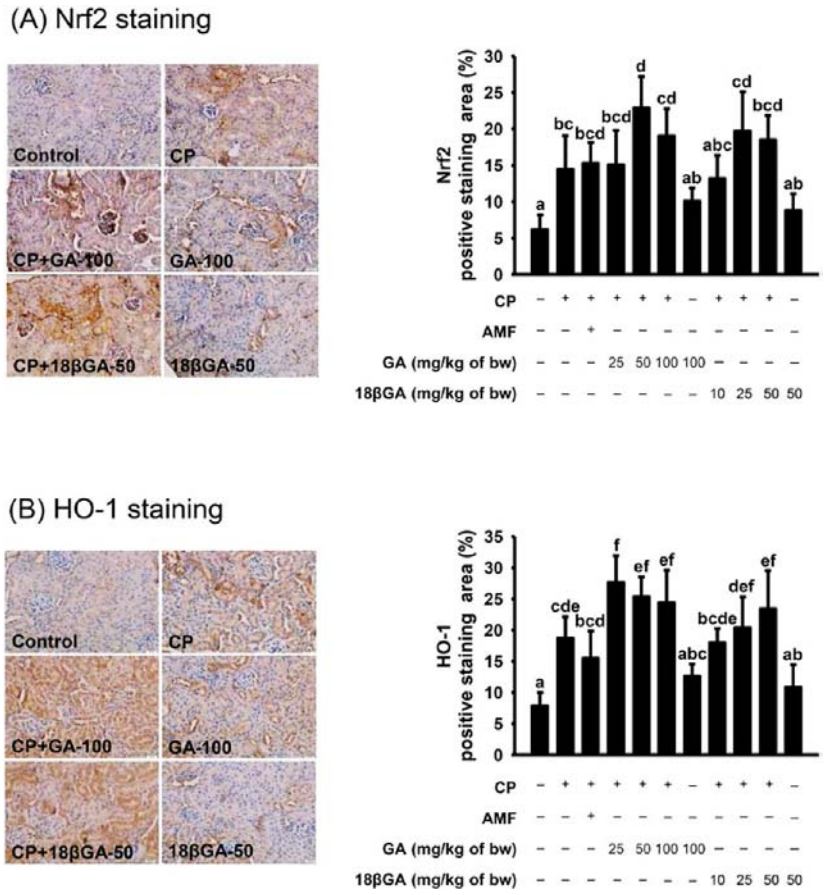

Figure 4. Effects of GA and 18βGA on the IHC expressions of Nrf2 and HO-1 in experimental mice. Groups of mice were treated as described in Figure 1. Renal tissues were analyzed by IHC staining for Nrf2 (A, left panel) and HO-1 (B, left panel). Nrf2- (A, right panel) and HO-1- (B, right panel) stained areas were quantified, and numbers of positively stained areas (%) per 400× field were averaged across eight fields for each section. Each value is expressed as the mean ± SD ($n = 8$), and letters (a−d) indicate statistically significant differences in each group ($p < 0.05$). One-way ANOVA tests were used for the statistical analyses.

indicated that, after CP-induced tissue injury to kidneys of BALB/c mice, HMBG1 showed a typical staining result, indicating diffuse release from nuclei. GA and 18βGA each significantly inhibited the accumulation of HMGB1 in the cytoplasm in a dose-dependent manner, and their inhibitory effects were greater than that of AMF, a known protectant (right panel of Figure 6). In summary, GA and 18βGA were able to decrease expressions of NF-κB, TNF-α, IL-1β, and IL-6 and release of HMGB1; in addition, they provided a protective function by increasing Nrf2 and HO-1 levels.

DISCUSSION

Since approval of CP by the U.S. Food and Drug Administration (FDA) in 1978 as a chemodrug, it has provided great therapeutic contributions to treating solid tumors, such as testicular cancer. Chemotherapy usually causes strong side effects in patients, including serious damage to normal organs, often leading to cessation of treatment; therefore, chemotherapy causes a bottleneck in current cancer treatment. The major clinical side effect of CP is nephrotoxicity, and patients usually show increased serum BUN and creatinine levels in 10 days after an injection.[4] Oxidative stress is the major cause of nephrotoxicity, and CP induces the production of a large amount of ROS in renal tubular cells. Although mitochondria in cells continue to clear ROS by activating antioxidant enzymes (such as catalase, SOD, GPx, and GST), eventually, antioxidant enzyme activities decrease, intracellular GSH is depleted, and mitochondrial dysfunction is induced, which causes cell necrosis and impaired renal function.[28] CP also directly stimulates renal tubular cells to secret TNF-α, which causes severe inflammatory responses, aggravates renal tubular cell damage, directly causes blood vessel injury, reduces blood flow in the kidneys, induces ischemic necrosis of cells, and eventually results in renal failure.[2]

Studies on applying phytochemicals to ameliorate drug side effects are still emerging. The literature shows that quercetin may decrease CP-induced NF-κB and TNF-α expressions and reduce kidney inflammation.[19,29] Lycopene may restore CP-depleted antioxidant enzyme activities through activating the Nrf2/HO-1 signaling pathway.[24] Hesperidin has antioxidant and anti-inflammatory effects and might also decrease CP-induced renal tubular necrosis and high levels of serum BUN and creatinine.[30] Those results show that, during the process of CP-induced renal injury, effective control of excess inflammatory responses and oxidative damage had definite positive effects on renal function maintenance and disease prevention. Previous studies showed that GA and 18βGA have multiple biological activities, such as antioxidant and anti-inflammatory effects,[17,18,31] and are closely associated with the mechanism underlying the aforementioned CP-induced renal injury. Therefore, we speculated that GA and 18βGA might have protective potentials to relieve the nephrotoxicity caused by CP. AMF is a drug currently approved to relieve nephrotoxicity caused by CP treatment. Clinical studies

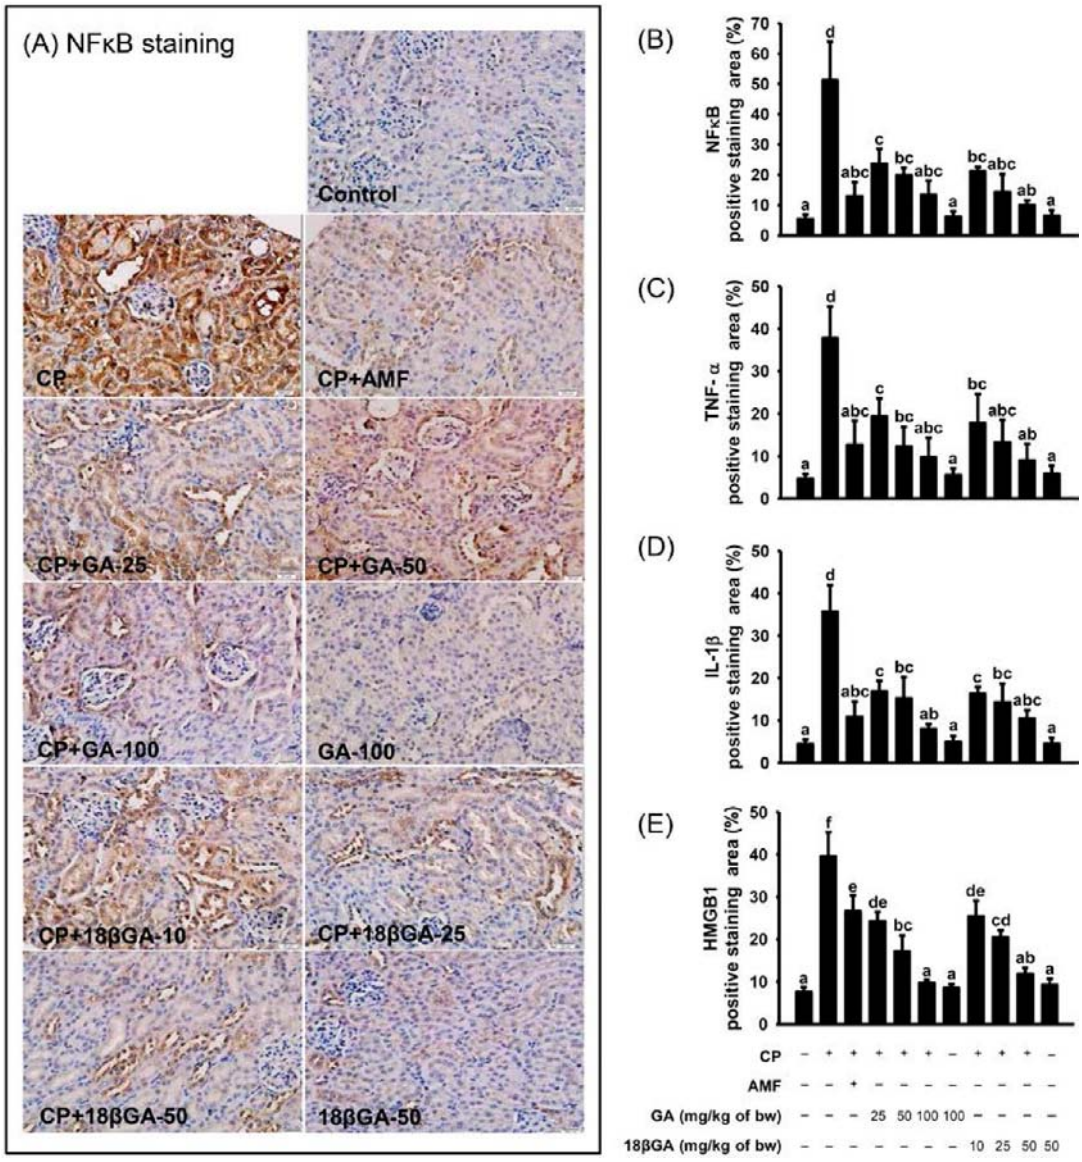

Figure 5. Effects of GA and 18βGA on CP-induced proinflammatory mediator expressions in renal tissues. Groups of mice were treated as described in Figure 1. (A) Renal tissues were analyzed by IHC staining for NF-κB. (B) NF-κB-, (C) TNF-α-, (D) IL-1β-, and (E) IL-6-stained areas were quantified, and numbers of positively stained areas (%) per 400× field were averaged across eight fields for each section. Each value is expressed as the mean ± SD (n = 8), and letters (a–f) indicate statistically significant differences in each group ($p < 0.05$). One-way ANOVA tests were used for the statistical analysis. CP, 30 mg/kg of BW; AMF, 200 mg/kg of BW; GA-25, 25 mg/kg of BW; GA-50, 50 mg/kg of BW; GA-100, 100 mg/kg of BW; 18βGA-10, 10 mg/kg of BW; 18βGA-25, 25 mg/kg of BW; and 18βGA-50, 50 mg/kg of BW.

have confirmed that AMF has inhibitory effects on the accumulation of nephrotoxicity in lung adenocarcinoma patients.[5,6] Therefore, this study selected AMF as the drug in the control group for use as a baseline control of all injury indicators in mice with CP-induced renal injury.

Activation of the Nrf2 is a defense mechanism after toxic insult. In response to CP, the current work also confirmed that expressions of Nrf2 protein were increased (Figure 4A) and the activities of antioxidant enzymes as well as the GSH/GSSG ratio were declined (Figure 3), reflective of more oxidative stress. Instead, not only GA but also 18βGA supplementation was found to significantly improve the changes associated with CP nephrotoxicity, as also evident by the increased level of antioxidant enzymes. A previous study showed that HO-1 expression was upregulated by these two phytochemicals to eliminate ROS formation.[31] Therefore, the expected induction of antioxidant enzymes by GA or 18βGA in CP-treated mice may be at least partly attributed to the functional activation of Nrf2/HO-1 signaling. However, the free radical scavenging ability of GA and 18βGA cannot be ruled out as a mechanism underlying the antioxidant enzyme-inducing effect in response to CP. The protective effects of GA and 18βGA may also be attributable to their ability to scavenge ROS and subsequently ameliorate CP-mediated oxidative stress and appear to be linked to the differential levels of antioxidant enzymes in CP-treated mice.

Previous studies showed that licorice plant extracts can inhibit ochratoxin-A-induced renal injury.[32] GA also showed protective effects against gentamicin-induced acute renal injury in rats.[33] In an ischemic model, GA also decreased neuronal cell apoptosis[17] and acute renal failure in animals.[11] Results of this study also confirmed that GA and 18βGA effectively inhibited CP-induced expressions of proinflammatory agents (NF-κB, TNF-α, IL-1β,

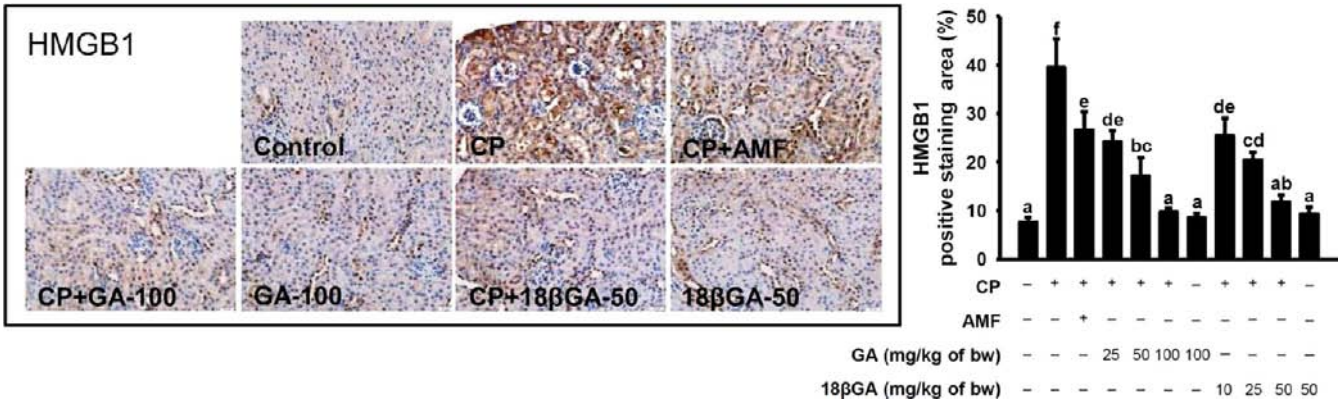

Figure 6. Effects of GA and 18βGA on CP-induced HMGB1 release from nuclei to the cytoplasm in renal tissues. Groups of mice were treated as described in Figure 1. Renal tissues were analyzed by IHC staining for HMGB1 (left panel); HMGB1-stained areas were quantified; and numbers of positively stained areas (%) per 400× field were averaged across eight fields for each section (right panel). Each value is expressed as the mean ± SD (n = 8), and letters (a–f) indicate statistically significant differences in each group ($p < 0.05$). One-way ANOVA tests were used for the statistical analyses. CP, 30 mg/kg of BW; AMF, 200 mg/kg of BW; GA-100, 100 mg/kg of BW; and 18βGA-50, 50 mg/kg of BW.

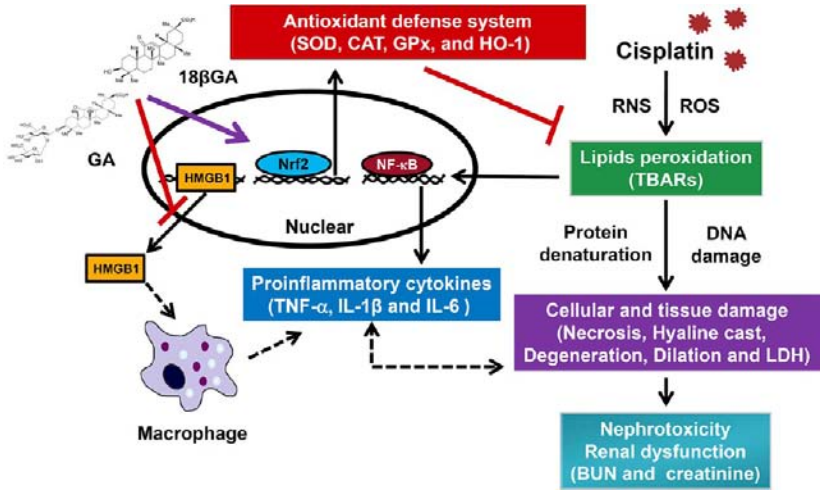

Figure 7. Proposed mechanisms of GA and 18βGA on CP-induced nephrotoxicity in BALB/c mice.

IL-6, and HMGB1) in kidney tissues of BALB/c mice, restored the activities of antioxidant enzymes and the GSH/GSSG ratio, and suppressed CP-induced oxidative stress in the kidneys. Therefore, the conclusion of this study is that GA and 18βGA can be used to relieve CP-induced chemical renal injury because of their antioxidant and anti-inflammatory features.

It is known that HMBG1 is a chaperone protein of nuclear DNA and a secreted protein. HMBG1 can be passively released from necrotic cells or actively released from inflammatory cells, act as an extracellular damage-associated molecular pattern (DAMP) molecule, and is an important mediator of inflammatory responses.[27] Although the association between CP and HMGB1 in cancer treatment is not clear, studies indicated that CP promoted HMGB1 expression in human myeloma cells[34] to produce drug resistance. Sitia et al.[35] suggested that GA interfered with the aggregation of chemotactic neutrophils and other inflammatory cells caused by HMGB1 in hepatitis B virus transgenic mice and relieved hepatic lesions. In addition, GA directly interacts with HMGB1 to inhibit the chemoattractant activity of HMGB1 on inflammatory cells and reduce HMGB1-induced inflammatory responses.[36] The results of this study also found that GA and 18βGA reduced the release of HMGB1 from cell nuclei during CP-induced injury. This result suggests a possible cause of the inhibitory effects of GA and 18βGA on many proinflammatory cytokines during renal injury.

The doses employed in the current work (25–100 mg/kg of BW for GA and 10–50 mg/kg of BW for 18βGA) were based on previous animal studies showing the effectiveness of GA or 18βGA to treat hyperglycemia[16] and chemical-induced hepatotoxicity.[37,38] 18βGA is a metabolic product of GA by way of intestinal bacterial enzymes. Our pilot experiment showed that 100 mg of 18βGA/kg of BW had an unexpected effect of causing a decrease in mice activities and yellowish skin (data not shown). Therefore, this study selected 50 mg of 18βGA/kg of BW, because that dose caused no abnormal conditions in mice. A comparison of the protective effects against renal injury between GA and 18βGA at 50 mg/kg of BW each showed that the biological activity of 18βGA was better than that of GA. This result indicates that 18βGA can possibly be used as an adjuvant factor that has the potential to delay side effects during chemotherapy. Kao et al.[31] indicated that 18βGA had a better anti-inflammatory effect in a cell culture model than GA. GA and 18βGA have different anti-inflammatory mechanisms, with GA mainly activating the PI3K/Akt/GSK3β pathway and 18βGA mainly activating the glucocorticoid receptor. This difference might be explained by the structure of 18βGA, which is much closer to that of steroids; therefore, 18βGA may be able to

DOI: 10.1021/jf505471a
J. Agric. Food Chem. 2015, 63, 1200–1209

activate glucocorticoid receptors to exhibit an improved anti-inflammatory effect.[39]

In addition to GA and 18βGA, there are some constitutes in licorice, such as chalconoids (liquiritin, isoliquiritin, liquiritigenin, and isoliquiritigenin), isoflavonoids (dehydroglyasperin C, dehydroglyasperin D, and glabridin), 18βGA derivative (carbenoxolone), and some unique compounds (licoricidin, licorisoflavan A, and licochalcone A) that have been well-studied and biologically characterized.[10] These effects have been associated with the anti-inflammatory, antioxidative, antimicrobial, antivirus, cell protective, and chemopreventive properties of the compounds, which may also have potential to be developed into a natural chemoprotectant, and they should be analyzed through further investigations in the future.

In summary, CP-induced nephrotoxicity is produced by a combination of interactions among many pathways. GA and 18βGA are phytochemicals in licorice with multiple physiological activities, and a possible mechanism underlying their ability to delay CP-induced physiological renal injury is shown in Figure 7. Our results indicate that GA and 18βGA have the potential to be developed into natural adjuvants to relieve CP side effects in patients undergoing chemotherapy, and they should be analyzed through further clinical validations and investigations in the future.

monnieri. PXT showed anti-inflammatory activity, but the immune modulation properties of PXT and osthole were found to be different, despite their similar chemical structures. The anti-inflammatory activity of PXT was associated with the unique peroxide group, as the anti-inflammatory activity was reduced when this group was replaced by a hydroxyl group.

MATERIALS AND METHODS

Materials. LPS (from *Escherichia coli* 0111:B4), ATP, and mouse antibodies against mouse phospho-ERK1/2, phospho-JNK1/2, phospho-p38, and actin were purchased from Sigma (St. Louis, MO, USA). Rabbit antibodies against mouse phospho-PKC-α/δ, IL-1β, caspase-1, iNOS, and COX-2 and secondary antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Mouse IL-1β, IL-6, and TNF-α ELISA kits were purchased from R&D Systems (Minneapolis, MN, USA). Mouse anti-mouse NLRP3 antibody was purchased from Enzo Life Sciences Inc. (Farmingdale, NY, USA). The AlamarBlue assay kit was purchased from AbD Serotec Ltd. (Oxford, UK). All of the inflammasome inducers and the QUANTI-Blue reagent were purchased from InvivoGen (San Diego, CA, USA).

Compound Extraction and Purification. *C. monnieri* seeds (600 g) were purchased from a traditional Chinese medicine dispensary in Taiwan. The seeds were extracted with 15 L of ethanol (95% v/v) at room temperature for 10 days, and the supernatants were then concentrated to produce an alcoholic extract. PXT and auraptenol were purified by semipreparative high-performance liquid chromatography (HPLC) (D-Star DLC-20 Instruments with a UV−vis detector) with a Phenomenex Luna Silica (2) column (250 mm length, 10 mm i.d., particle shape/size = 5.0 μm) (Figure 1A). The separation conditions were as follows: 500 μL was injected for each separation; flow rate, 4 mL/min; mobile phase, acetone/hexane = 1:6. The structures of PXT and auraptenol were identified by physical and spectral data (mp, EIMS, ^{1}H NMR, UV, IR) compared with previous research values.[4,21]

Cell Cultures. The murine macrophage cell lines RAW 264.7 and J774A.1 were obtained from American Type Culture Collection (Rockville, MD, USA). RAW 264.7 macrophages stably transfected with the NF-κB reporter gene (RAW-Blue cells) were purchased from InvivoGen. Mouse peritoneal macrophages were elicited by intraperitoneal injection of 4% sterile thioglycollate medium (2 mL). After 3 days, the mice were sacrificed by cervical dislocation, and the macrophages were harvested.

AlamarBlue Assay for Cell Viability. RAW 264.7 cells were incubated with or without PXT for 24 h. The AlamarBlue assay was used to determine the cytotoxicity of PXT according to the protocol described in the manufacturer's instructions (AbD Serotec, Oxford, UK).[4]

Detection of Pro-inflammatory Mediators and Protein Phosphorylation. The levels of NO and cytokines (IL-1β, IL-6, and TNF-α) in the culture medium were measured by the Griess reaction and ELISA, respectively. The levels of iNOS, COX-2, and caspase-1 and the phosphorylation levels of ERK1/2, JNK1/2, p38, and PKC-α/δ in cells were measured by Western blotting. The detailed procedures were described in our previous study.[4] The density of the bands of the Western blotting was analyzed by ImageJ software. We selected an identical rectangular area around each lane of the Western blot even there was no band of control lane. The density of the selected area was analyzed by ImageJ, and the relative band density was normalized to actin before fold change was calculated. The densitometry fold change of each group was calculated by comparison to the control group, as the control group had a fold change of 1. The bars accompanying blots are the means of three separate experiments.

Detection of ROS. General ROS production was measured by detecting the fluorescence intensity of 2′,7′-dichlorofluorescein, the oxidation product of 2′,7′-dichlorofluorescein diacetate (Molecular Probes, Eugene, OR USA), at an excitation wavelength of 485 nm and an emission wavelength of 530 nm using a microplate absorbance reader (Bio-Rad Laboratories, Inc.). Mitochondrial ROS generation was measured by detecting the fluorescence intensity of MitoSOX

(Invitrogen, Carlsbad, CA, USA) at an excitation wavelength of 514 nm and an emission wavelength of 585 nm using a microplate absorbance reader.

Detection of Mitochondrial DNA Release. The detection of mitochondrial DNA (mt-DNA) in the cytosol was performed as described.[22] Briefly, after treatment, cells were homogenized in a protease inhibitor-containing buffer (100 mM, pH 7.4, Tricine−NaOH, 0.25 M sucrose, 1 mM EDTA) and then centrifuged for 10 min at 700*g* and 4 °C. The protein concentration and volume of the supernatant were normalized, and the sample was then centrifuged for 30 min at 10000*g* and 4 °C. The resulting pellets were identified as the mitochondrial fraction, and the supernatants were identified as the cytosolic fraction. DNA was isolated from 200 μL of the cytosolic fraction. The mt-DNA copy number was measured by quantitative PCR and normalized to nuclear DNA (encoding 18S rRNA) levels using a ratio of cytochrome *c* oxidase I DNA to nuclear DNA. The results are expressed as fold changes between the sample and control groups. The quality of the mitochondrial and cytosolic fractions was monitored by detecting the protein expression level of voltage-dependent anion channel (VDAC, a marker protein for mitochondria). We found that VDAC can be detected only in the mitochondrial fraction and is not present in the cytosolic fraction (data not shown), indicating that the cytosolic fraction is free of mitochondria. The primers used were as follows: mouse 18S, forward, 5′-TAGAGG-GACAAGTGGCGTTC-3′, reverse, 5′-CGCTGAGCCAGTCAG-TGT-3′; mouse cytochrome *c* oxidase I, forward, 5′-GCCCCAGAT-ATAGCATTCCC-3′, reverse, 5′-GTTCATCCTGTTCCTGCTCC-3′.

NF-κB Reporter Assay. The medium (20 μL) from treated RAW-Blue cells was mixed with 200 μL of QUANTI-Blue medium (Invitrogen) in 96-well plates and incubated at 37 °C for 15 min. The secreted embryonic alkaline phosphatase activity was assessed by measuring the optical density at 655 nm using a microplate absorbance reader.[4]

Phagocytosis Assay. J774A.1 macrophages were seeded in 96-well flat-bottom plates at a density of 5×10^3 cells in 100 μL of RPMI 1640 medium containing 10% FBS per well and incubated with 1 μg/mL LPS for 6 h. The cells were incubated with or without 40 μM PXT or 10 μM colchicine for 30 min and then incubated for 1 h with or without 100 μg of fluorescence-conjugated *Escherichia coli*. The fluorescence intensity was measured at an excitation wavelength of 509 nm and an emission wavelength of 533 nm. Net phagocytosis was calculated by subtracting the average fluorescence intensity of the no-cell negative-control wells from all of the experimental wells. The percent of phagocytosis was then calculated as a fraction of the net positive control phagocytosis, as follows:

$$\%\ \text{of phagocytosis} = \frac{\text{net experimental phagocytosis} \times 100\%}{\text{net positive control phagocytosis}}$$

Bacterial Infection. J774A.1 macrophages were infected with *Klebsiella pneumoniae* (NTUH K-2044) at a multiplicity of infection (MOI) of 100. The number of viable bacteria used in each experiment was carefully determined by plate counting. One hour after infection, the cells were incubated with penicillin (250 IU/mL)/streptomycin (250 μg/mL) to limit the growth of residual extracellular bacteria. The culture medium was collected at 24 h after infection, and the levels of IL-1β in the medium were measured by ELISA.

Statistical Analysis. All values are the mean ± SD. The data analysis involved one-way ANOVA with a subsequent Scheffé test.

RESULTS

PXT Reduces NO Generation, Inducible NO Synthase Expression, and IL-6 Secretion. The anti-inflammatory activity of PXT was investigated using LPS-activated RAW 264.7 macrophages. We found that NO generation (Figure 1B) and IL-6 secretion (Figure 1C) were inhibited by PXT in a

dose-dependent manner, whereas TNF-α secretion was not reduced significantly (Figure 1D). PXT also reduced iNOS expression in a dose-dependent manner, whereas COX-2 expression was not affected (Figure 1E). To examine whether the reduction in pro-inflammatory mediators resulted from reduced cell viability, the toxicity of PXT toward RAW 264.7 cells was examined, and we found that PXT had no significant effect on cell survival at a concentration of 40 μM (Figure 1F).

PXT Reduces the Phosphorylation Levels of Mitogen-Activated Protein Kinases (MAPKs) and PKC-α/δ. MAPKs, including ERK1/2, JNK1/2, and p38, are activated by LPS and regulate inflammatory mediator expression in macrophages.[2−4,23] In the present study, we found that LPS induced an increase in the phosphorylation levels of ERK1/2, JNK1/2, and p38 and that these effects, except ERK1/2, were reduced by PXT (Figure 2). In addition, PKC, a component of the TLR4 signaling pathway, regulates macrophage activation in response to LPS.[2−4,23] As shown in Figure 3, LPS induced increases in the phosphorylation levels of PKC-α and PKC-δ, and these effects were reduced by PXT. Interestingly, PXT alone increased the phosphorylation levels of PKC-α and PKC-δ; however, the detailed mechanism is unclear.

PXT Reduces NLRP3 Inflammasome Activation by Reducing Mitochondrial Damage. We examined whether PXT is able to inhibit the IL-1β secretion induced by NLRP3 inflammasome activators such as monosodium urate (MSU) crystals, calcium pyrophosphate dihydrate (CPPD), SiO_2 nanoparticles, alum crystals, nigericin, and ATP. We found that IL-1β secretion after treatment with MSU, CPPD, SiO_2 nanoparticles, and alum crystals was significantly reduced by PXT, whereas PXT was not able to inhibit IL-1β secretion induced by nigericin and ATP (Figure 4A). The generation of ROS is a crucial element for NLRP3 activation.[24,25] To determine whether the inhibition of IL-1β secretion by PXT occurs via the inhibition of ROS generation, LPS-primed J774A.1 macrophages were incubated with PXT or the antioxidant *N*-acetylcysteine (NAC) for 30 min before the addition of CPPD, MSU, and ATP. We found that PXT reduced CPPD- and MSU-induced ROS generation; however, PXT was not able to reduce ATP-induced ROS generation (Figure 4B). As damaged and ROS-generating mitochondria activate the NLRP3 inflammasome,[22,26,27] to determine whether PXT inhibits the NLRP3 inflammasome by preventing mitochondrial damage, we used the fluorescent probe MitoSOX to detect ROS released from damaged mitochondria. Mitochondrial ROS (mt-ROS) levels were increased by MSU and CPPD treatments, and PXT reduced the mt-ROS levels in these cells (Figure 4C). The overgeneration of mt-ROS induces the translocation of mitochondrial DNA (mt-DNA) into the cytosol, and this cytosolic mt-DNA is a coactivator of the NLRP3 inflammasome.[27] Thus, we examined whether the translocation of mt-DNA into the cytosol is decreased by PXT and found that the levels of mt-DNA released into the cytosol were increased in MSU- and CPPD-activated macrophages but were significantly reduced by PXT (Figure 4D). These results indicate that PXT protects mitochondria from damage in macrophages. In addition, caspase-11 has been demonstrated to be required to activate caspase-1 in response to bacteria;[28] however, PXT did not affect the expression levels of caspase-11 induced by LPS and interferon-γ (Figure 4E).

PXT Reduces IL-1β Precursor Expression. NLRP3 induction is a critical checkpoint for the priming step of NLRP3 inflammasome activation and is regulated by NF-κB.[29] Therefore, we investigated whether PXT inhibits the LPS-mediated priming step for the NLRP3 inflammasome. We incubated cells with PXT for 30 min before treatment with LPS for 6 h and found that PXT did not inhibit the expression level of NLRP3, although it did reduce the expression level of the IL-

J. Agric. Food Chem. 2015, 63, 1210−1219

1β precursor proIL-1β (Figure 5A). Using NF-κB-dependent alkaline phosphatase reporter cells (RAW-Blue cells), we then examined whether PXT is able to inhibit NF-κB activation. As shown in Figure 5B, we found that NF-κB transcriptional activity in LPS-stimulated macrophages was not affected by PXT but was markedly inhibited by NAC, which was used as a positive control. These results indicated that PXT does not inhibit the priming signal of the NLRP3 inflammasome. In addition, we investigated the effect of PXT on ROS generation, which plays important roles in the LPS-induced expression of proIL-1β,[30] and found that LPS-induced ROS generation was reduced by PXT and NAC (Figure 5C). Although PXT was not able to reduce the ATP-induced expression of IL-1β in LPS-primed macrophages (Figure 4A), we assessed whether the secretion levels of IL-1β are reduced by PXT if it is added before LPS priming because we observed decreased expression levels of LPS-induced proIL-1β in PXT-treated cells (Figure 5A). We found that ATP-induced IL-1β secretion was significantly inhibited by PXT when it was added before LPS priming (Figure 5D, left); notably, the activation levels of caspase-1 were also inhibited by PXT under the same condition (Figure 5D, right). PXT also inhibited IL-1β secretion in primary peritoneal macrophages under the same condition (Figure 5E). Furthermore, PXT was not selective for NLRP3-dependent inflammasome stimuli, as PXT reduced the IL-1β secretion triggered by FLA-ST (flagellin from *S. typhimurium*) or muramyl dipeptide, which are dependent on the NLRP1 and NLRC4 inflammasomes,[31,32] respectively, and independent of NLRP3 (Figure 5F).

PXT Reduces the Phagocytic Efficiency of Macrophages and Decreases the Expression Levels of IL-1β in Bacteria-Infected Macrophages. PXT reduced the IL-1β secretion induced by crystal NLRP3 inflammasome inducers, including alum crystals, CPPD, and SiO_2 nanoparticles (Figure 4A). As the activation of the NLRP3 inflammasome by these inducers is dependent on their uptake by phagocytosis, we investigated the hypothesis that PXT inhibits crystal-mediated activation of the NLRP3 inflammasome by inhibiting phagocytic activity. To examine whether PXT affects the phagocytic activity of macrophages, LPS-primed J774A.1 macrophages were treated with PXT or colchicine (a microtubule polymerization inhibitor) for 30 min, and the phagocytosis activity was then assessed by measuring the uptake of fluorescence-conjugated *E. coli*. We found that both PXT and colchicine decreased the uptake of fluorescence-conjugated *E. coli* by macrophages (Figure 6A). In addition, we tested whether PXT affects IL-1β secretion by macrophages infected with live *K. pneumoniae* and found that PXT reduced the secretion level (Figure 6B). These results suggest that PXT may modulate macrophage function at *K. pneumoniae*-infected sites by impairing phagocytosis and reducing cytokine production.

The Peroxide Group of PXT Is Important for Its Anti-inflammatory Activity. Because PXT contains a unique peroxide group (−OOH) on its carbon chain, we investigated the hypothesis that this unique group is important for the molecule's anti-inflammatory activity. To this end, we isolated a PXT analogue, auraptenol, which contains a hydroxyl group (−OH) at the corresponding peroxide group position of PXT (Figure 1A), from the ethanol extract of *C. monnieri* fruits. We then compared the anti-inflammatory activities of PXT and auraptenol in LPS-activated macrophages and found that auraptenol reduced LPS-induced IL-6 secretion (23.5 ± 1.5 ng/mL) to 17.5 ± 0.9 ng/mL at 100 μM, whereas 10 μM PXT reduced it to 7.2 ± 1.0 ng/mL (Figure 7A). In addition, 100 μM auraptenol reduced LPS-induced NO production (39 ± 5 μM) to 25 ± 3 μM, although 10 μM PXT reduced it to 5 ± 2 μM (Figure 7B). Furthermore, whereas auraptenol only slightly inhibited the expression levels of iNOS and proIL-1β in LPS-

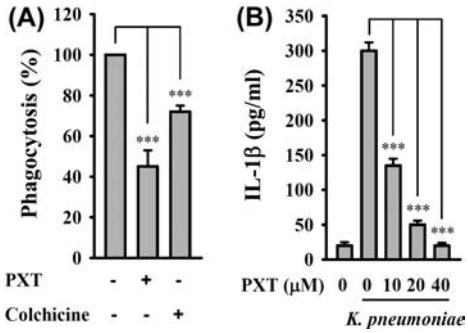

Figure 6. PXT reduces the phagocytic efficiency of macrophages and decreases the expression levels of IL-1β in bacteria-infected macrophages. (A) J774A.1 macrophages were incubated with LPS for 6 h and then for 30 min with or without PXT or colchicine. The cells were incubated with fluorescence-conjugated *E. coli* for 1 h. The phagocytic efficiency was determined by measuring the fluorescence intensity. (B) J774A.1 macrophages were infected with *K. pneumoniae* for 24 h at 100 MOI. The levels of IL-1β in the culture medium were measured by ELISA. The data are expressed as the means ± SD for three separate experiments. *** indicates a significant difference at the level of $p < 0.001$.

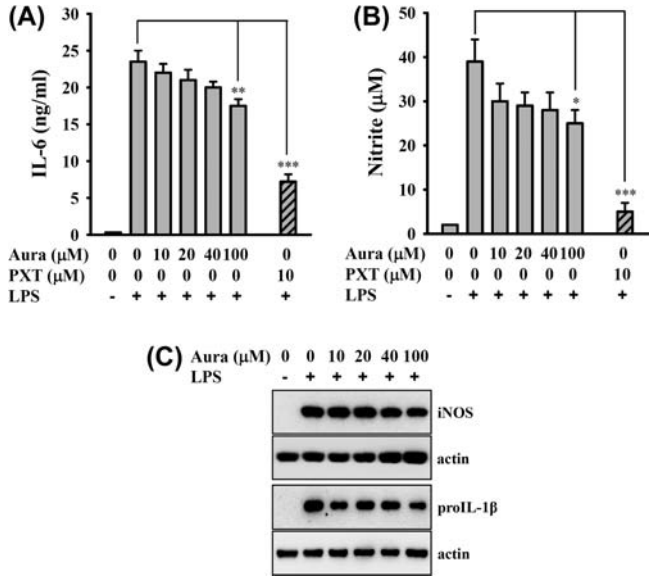

Figure 7. The peroxide group of PXT is important for its anti-inflammatory activity. J. Agric. Food Chem. 2015, 63, 1210−1219

activated macrophages (Figure 7C), PXT significantly inhibited expression, as shown in Figures 1E and 5A, respectively. These results indicated that the anti-inflammatory activity of auraptenol is lower than that of PXT and suggested that the unique peroxide group is important for the anti-inflammatory activity of PXT.

DISCUSSION

PXT was purified along with osthole from the ethanol extract of *C. monnieri* seeds. The structure of PXT is similar to that of osthole; however, their immune modulation properties in LPS-activated macrophages are quite different.[4] The different biological outcomes between PXT and osthole are as follows: (1) PXT reduces the levels of IL-6, but osthole increases them. (2) PXT does not affect the levels of TNF-α and COX-2, whereas osthole reduces them. (3) PXT does not affect the phosphorylation levels of ERK1/2, yet osthole increases them. (4) PXT does not affect the activation levels of NF-κB, whereas osthole reduces them. (5) PXT reduces the phosphorylation levels of PKC-δ phosphorylation, but osthole does not.

The priming step of the NLRP3 inflammasome is regulated by ROS, which are required for NLRP3 expression.[25] PXT did not affect the priming step of the NLRP3 inflammasome, although PXT did reduce the levels of ROS in LPS-activated macrophages (Figure 5C). ROS is involved in both the priming and activation steps of the NLRP3 inflammasome,[24] and the up-regulation of ROS levels in macrophages results in the activation of PI3K, promoting caspase-1 activation and IL-1β secretion.[33] The inhibition of MSU- and CPPD-induced ROS generation may be responsible for the reduced NLRP3 inflammasome-derived IL-1β secretion caused by PXT. Furthermore, we found that PXT reduced mitochondrial ROS generation, which plays an important role in NLRP3 inflammasome activation.[26,27] The overproduction of mitochondrial ROS promotes a mitochondrial permeability transition that facilitates the cytosolic release of mitochondrial DNA, which stimulates the activation of the NLRP3 inflammasome.[26,27] PXT also reduced the cytosolic release of mitochondrial DNA, indicating that mitochondrial stabilization may be responsible for the reduced activation of the NLRP3 inflammasome mediated by PXT.

PXT did not inhibit either ATP-induced IL-1β secretion (Figure 4A) or ROS generation (Figure 4B) in LPS-primed macrophages; PXT also had no effect on LPS-induced NLRP3 expression (Figure 5A). These results indicated that PXT did not affect the priming or activation signal of the NLRP3 inflammasome due to LPS or ATP, respectively. Notably, however, PXT did reduce ATP-induced caspase-1 activation when it was added before LPS or ATP (Figure 5D). One possible mechanism is that PXT might increase the cellular levels of cAMP, which has been demonstrated to inhibit inflammasome assembly by binding to NLRP3 directly.[34] Osthole was reported to increase the tissue cAMP content by inhibiting the activity of cAMP phosphodiesterase in guinea pig trachea.[35] Another possible mechanism is that PXT might increase autophagy, which limits NLRP3 inflammasome activation by targeting inflammasome components for degradation[36,37] and by inhibiting the release of mitochondrial DNA from damaged mitochondria.[22] Furthermore, caspase-11 induction by LPS or interferon-γ synergizes with the assembled NLRP3 inflammasome to regulate caspase-1 activation;[8] however, PXT did not affect the expression levels of caspase-11 induced by LPS and interferon-γ.

K^+ efflux has a role in the regulation of the NLRP3 inflammasome and can be achieved either directly by nigericin or indirectly by the purinergic receptor for ATP.[38,39] It has been reported that crystal-induced NALP3 inflammasome activation is inhibited by phagocytosis inhibitors.[15] These results indicate that crystal uptake by phagocytosis is a prerequisite for activation of the NARP3 inflammasome. In this study, we demonstrated that PXT reduced phagocytosis, which partially explains why PXT inhibited the NLRP3 inflammasome-mediated IL-1β secretion induced by MSU, CPPD, SiO_2 nanoparticles, and alum crystals. In contrast, PXT did not affect IL-1β secretion induced by nigericin and ATP in LPS-primed macrophages, suggesting that PXT might not affect K^+ efflux induced by these molecules.

PXT is a peroxide (−OOH)-containing coumarin compound. When subjected to acid, base, or temperature increases in the environment, the −OOH group on the compound is likely to degrade into hydroxyl radical ($^{\bullet}$OH), a most destructive free radical that reacts readily with the metallic core atoms of intracellular enzymes and in turn modulates the secretion of certain cytokines. However, when the concentrations of these free radicals are sufficient, they may partake in important intracellular metabolism processes and become a line of defense in preventing or fighting disease. In this study, we found that freshly extracted ethanolic PXT tended to decrease in concentration during storage, which became notable with more than 6 months at room temperature; the situation was much improved by storage at −20 °C. However, storing the ethanolic solution of auraptenol at room temperature for more than 6 months resulted in an unchanged concentration based on HPLC and NMR analyses, indicating that the compound is highly stable.

Although PXT exhibited anti-inflammatory activities in LPS-activated macrophages, it did not cause a general unresponsiveness to LPS, as the expressions of COX-2 and TNF-α were not reduced by PXT. These findings indicate that the administration of PXT might prevent excessive inflammatory response but does not cause immunodeficiency. *C. monnieri* fruits have been used to treat gout in traditional medicine, although there is no scientific evidence supporting this. Here, we demonstrate that PXT reduces MSU-induced activation of the NLRP3 inflammasome by inhibiting ROS generation and mitochondrial DNA release, explaining why *C. monnieri* fruits are able to ameliorate gout.[17] In summary, we demonstrate that PXT possesses anti-inflammatory activity by reducing the expression levels of NO and IL-6, as well as by reducing the activation of the NLRP3 inflammasome. These results suggest that PXT may have a potential use as a natural anti-inflammation agent or nutraceutical for preventing and ameliorating inflammation- and NLRP3 inflammasome-related diseases.

Figure 1. Alignment of the internal transcribed spacer (ITS) of the rDNA from several *Delphinium* and *Aconitum* species. Oligonucleotide primers Delph1F and Delph1R are shown.

(AF258718), *D. nuttallianum* (AF258688), *D. ramosum* (AF258687), *D. scaposum* (AF258732), *A. columbianum* (AF258683), and *A. delphiniifolium* (AF258681). An oligonucleotide forward primer Delph1F (5′ GTGAAAAYAAACCGRGACGG 3′) and reverse primer Delph1R (5′ GGGGATGATGAGCACACAACCA 3′) were synthesized by Integrated DNA Technologies, Inc. (Coralville, IA).

Ruminally Cannulated Animals. Three ruminally cannulated Angus cows (510 kg) were maintained on a diet of alfalfa hay at maintenance levels (ca. 10 kg/day). The diet was offered twice daily at 8:30 and 16:00 h. All procedures were approved by the Utah State University IACUC committee and were conducted under veterinary supervision.

Plant Material. Plant material from previous collections representing the following species were used to validate the specificity of the primers: *D. occidentale* (Logan, UT), *D. nuttallianum* (Colbrun, CO), *D. andersonii* (Garrison, UT), *D. glaucesens* (Dillon, MT), *D. scaposum* (Tuweep, AZ), *D. ramosum* (Cuchara, CO), *D. barbeyi* (Crested Butte, CO), *D. occidentale* (Wilsal, MT), *A. columbianum* (Elko, NV), and *Medicago sativa* (Logan, UT). *Delphinium* species were the target species while *A. columbianum* and *M. sativa* were used as negative controls to validate that the primers were specific. Samples when initially collected were placed on dry ice at the time of collection, frozen and freeze-dried upon return to the laboratory, and ground for subsequent DNA extraction.

In Vivo Rumen Digestion. *Delphinium occidentale* leaves collected from Logan, UT, previously frozen, then thawed, were manually cut into pieces with a diameter ranging from 0.5 to 1.5 cm^2. Five grams of cut leaves were placed in each of 27 nylon bags (10 cm × 20 cm and 50 μm pore size) (Ankom Technology, Macedon, NY), respectively.[19] Three bags of material were freeze-dried as control samples. Eight bags each were incubated in the rumen of three ruminally cannulated cows. All eight bags were placed in a larger nylon bag of the same porosity with an inert weight enclosed so the samples would be continually submersed in rumen fluid in the ventral sac, and a 50 cm nylon string attached to allow movement within the rumen yet facilitate the retrieval of the bags. One bag was removed from each animal (n = 3) at the following time points: 4 h, 8 h, 12 h, 16 h, 20 h, 24 h, 36 h, and 48 h. Samples were immediately placed in a −20 °C freezer upon removal and subsequently freeze-dried and ground (1 mm screen).

In Vitro Rumen Digestion. *Delphinium occidentale* leaves, previously frozen, then thawed, from Logan, UT, were cut into pieces with a diameter ranging from 0.5 to 1.5 cm^2. Five grams of cut leaves were placed in each of 21 nylon bags (5 cm × 5 cm, 25 μm pore size, Ankom Technology). Three nylon bags were freeze-dried as control samples. Six bags were placed in each of three nonrotating digestion vessels containing freshly collected and anaerobic rumen inoculum (Daisy II incubator, Ankom Technology) at 39 °C representing a composite rumen fluid sample from the three cannulated cows. One bag was removed from each digestion vessel (n = 3) at the following time points: 8 h, 16 h, 24 h, 32 h, 40 h, and 48 h. Samples were immediately placed in a −20 °C freezer upon removal and subsequently freeze-dried and ground (1 mm screen).

In Vivo and In Vitro Rumen Digestion. *Delphinium occidentale* leaves, previously frozen, then thawed, from Logan, UT, were cut into pieces with a diameter ranging from 0.5 to 1.5 cm^2. Five grams of cut leaves were placed in each of 21 nylon bags as noted above. Three nylon bags were freeze-dried as control samples. Eighteen bags were placed in the rumen of a canulated cow. All 18 bags were placed in a larger bag with the same porosity and an inert weight enclosed so the samples would be continually submersed in rumen fluid in the ventral sac, and a 50 cm string attached to allow movement and to facilitate the retrieval of the bags. All the bags were retrieved at 8 h, and three were immediately frozen. The remaining 15 bags were immediately placed into three nonrotating digestion vessels (Daisy II Incubator, Ankom Technology) containing freshly collected and anaerobic rumen fluid maintained at 39 °C representing a composite sample obtained from the three cannulated cows. One bag was removed from each digestion vessel (n = 3) at the following time points: 16 h (24 h total; 8 h in vivo + 16 h in vitro), 24 h (32 h total), 40 h (48 h total), 48 h (56 h total), and 64 h (72 h total). Samples were immediately placed in a −20 °C freezer upon removal and subsequently freeze-dried and ground.

In Vivo Rumen Digestion Sensitivity. Different ratios of *D. occidentale* leaves from Logan, UT, previously frozen, then thawed, and an alfalfa hay mixture were prepared. Four replicate nylon bags of the following ratios were prepared (g of larkspur:g of alfalfa): 5:0, 1:2.13, 1:5.25, 1:11.5, 1:24, 1:49. One bag of each ratio was freeze-dried as a control sample. One sample of each ratio was placed in the rumen of each of the three cannulated cows. All bags were placed in a larger nylon bag of the same porosity with an inert weight so the samples would be submersed in rumen fluid, and a 50 cm string attached to allow movement within the ventral sac and to facilitate the retrieval of the bags. After 8 h all the samples were retrieved from the cannulated cows. In addition, 3 other ratios were prepared representing the control sample only, namely, 1:99, 1:199, and 1:399. Samples were immediately placed in a −20 °C freezer upon removal and subsequently freeze-dried and ground.

DNA Extraction. DNA was extracted from ∼150 mg of freeze-dried ground tissue using the ZR plant/seed DNA MiniPrep kit (Zymo Research Corp., Irvine, CA). Extractions were performed according to the manufacturer's instructions with one exception: the volume of lysis solution used was increased to 1.2 mL. DNA was quantitated with the ND-1000 spectrophotometer (Nanodrop Technologies, Wilmington, DE).

Polymerase Chain Reaction (PCR). All PCR was performed with a Bio-Rad Dyad PCR detector (Bio-Rad Laboratories Inc., Hercules, CA). Thermal cycling conditions for all material were as follows: (a) an initial denaturation step for 3 min at 94 °C, (b) followed by 10 cycles of 30 s at 94 °C, 45 s at 60 °C, and 30 s at 72 °C, (c) followed by 25 cycles of 30 s at 94 °C, 45 s at 54 °C, and 30 s at 72 °C, and (d) a final extension of 5 min at 72 °C. Each reaction had a total volume of 50 μL containing 500 ng of DNA. GoTaq DNA polymerase (Promega Corporation, Madison, WI) was used following the reaction conditions recommended by the manufacturer. PCR products were resolved on a 1% agarose gel containing ethidium bromide at 118 V for 20 min and visualized under UV illumination. Agarose gels were visualized and analyzed with a Kodak Image Station 2000RT imager and its software (Eastman Kodak, Rochester, NY).

Norditerpene Alkaloid Analysis. Prepared mixtures of plant material were analyzed for larkspur alkaloids by LC−MS.[20] An aliquot

DOI: 10.1021/jf5053496
J. Agric. Food Chem. 2015, 63, 1220−1225

of plant material (100 mg) was extracted with 4.0 mL of methanol for 2 h by mechanical rotation in a sealed (screw cap) test tube. The sample was filtered, and a 0.500 mL aliquot of the extract was diluted with 0.500 mL of 20 mM ammonium acetate in a 1.5 mL autosample vial. LC−ESI-MS analyses was completed using a Thermo Scientific LCQ Advantage system with Surveyor HPLC and autosampler (Thermo Scientific, San Jose, CA). An injection volume of 10 μL was used on a 100 × 2.1 mm i.d., 5 μm, BetaSil C18 column (Thermo Scientific, San Jose, CA) eluted with a mixture of acetonitrile (A) and 0.5% acetic acid/0.05% trifluoroacetic acid (B) at a flow rate of 0.400 mL/min and the following linear gradient: 5−15% A from 0 to 1 min; 15−75% A from 1 to 8 min; 75% A from 8 to 10 min; 75−5% A from 10 to 11 min; and 5% A from 11 to 16 min. The flow from the column was connected directly to the ESI source. The major alkaloid in the *D. occidentale* plant material is deltaline and under the chromatographic conditions eluted with retention time of 4.1 min and gives a strong MH^+ ion (m/z 508). Detection of the alkaloid was targeted by reconstructed ion chromatograms for this select ion.

RESULTS AND DISCUSSION

Primer Specificity. Candidate specific oligonucleotide DNA primers were developed by aligning and comparing the ITS sequence from several *Delphinium* spp. as well as representative *Aconitum* spp. (Figure 1). Oligonucleotide DNA primers were tested to determine if they were specific to representative *Delphinium* taxa of the Western United States. Preliminary experiments were performed to optimize the annealing temperature and reaction conditions that would ensure they were specific to *Delphinium* and not other taxa. The optimal reaction conditions were an annealing temperature of 60 °C for 10 cycles followed by 25 cycles at an annealing temperature of 54 °C. The annealing temperature is critical as lower temperatures will result in amplification of a product from *Aconitum*. A 500 base pair (bp) product was amplified from the seven *Delphinium* species but not from the *Aconitum* or alfalfa sample (Figure 2). The results show that the primers

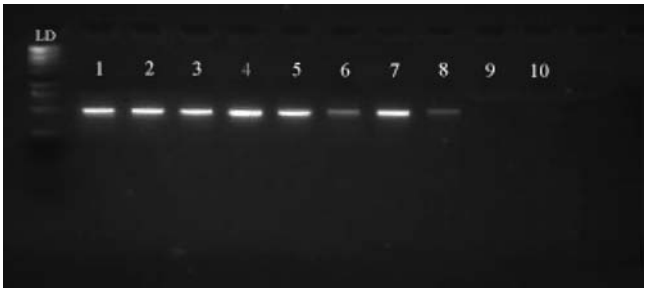

Figure 2. Agarose gel electrophoresis showing specificity of DNA primers. 1000bp marker (LD) shown as a reference. Lanes: 1, *D. occidentale* (Logan, UT); 2, *D. nuttallianum*; 3, *D. andersonii*; 4, *D. glaucescens*; 5, *D. scaposum*; 6, *D. ramosum*; 7, *D. barbeyi*; 8, *D. occidentale*; 9, *A. columbianum*; and 10, *M. sativa*.

amplified a product with all of the *Delphinium* species tested including five of the more important *Delphinium* species in the Western United States in terms of cattle losses. DNA was extracted from all the plant material a second time and PCR performed, and the same results were obtained (data not shown). The alignment of the ITS from the *Delphinium* species (Figure 1) suggests that the primers would also amplify other species including *D. geyeri* and *D. glaucum*. To further demonstrate that the primers amplified a *Delphinium* species, the PCR product could be verified by restriction enzyme digestion or sequencing.

In Vivo Rumen Digestion. An in vivo rumen digestion was performed to determine the length of time one may expect to detect larkspur in a living bovine after the animal ate the plant. A PCR product was amplified from *D. occidentale* samples that had been incubated in the rumen of the three cannulated cows after 4 h, 8 h, 12 h, and 16 h (Figure 3). At the 20 h and 24 h

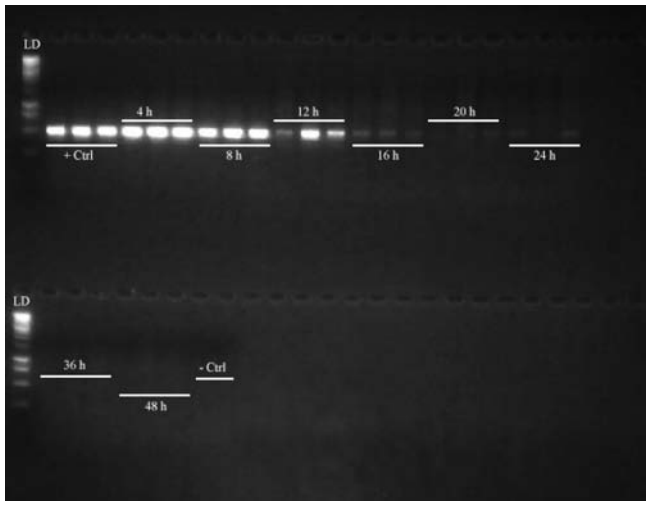

Figure 3. Agarose gel electrophoresis showing amplification of PCR products from the in vivo rumen digestion. 1000bp marker (LD) shown as a reference. Triplicates of undigested positive control (+ctrl) and digested (4−48 h) *D. occidentale*. Negative control (−ctrl) representing *A. columbianum* and *M. sativa*.

time points, a PCR product was detected from 1 or 2 of the replicate samples (Figure 3). No PCR product was amplified from the samples after 36 h and 48 h. As expected, a PCR product was detected from the three control samples but not from the *Aconitum* or alfalfa sample (Figure 3). DNA was extracted from all the plant material a second time and PCR performed, and the same results were obtained (data not shown). These results suggest that the DNA representing *D. occidentale* is degraded over time and that by 36 h post incubation a PCR product is no longer detectable. Studies have shown that plant DNA, particularly naked DNA, may be rapidly degraded by the microbial activity in rumen fluid.[21] Using real-time PCR, Alexander et al.[22] found that digestion of DNA in canola was highly correlated with the digestive activity of intestinal microorganisms. However, DNA from maize has been shown to survive for up to 24 h in the rumen of sheep.[23] Further, Wiedemann et al.[24] reported that survival of corn DNA in the bovine rumen depended on fragment length, previous processing, and the length of time incubated in the rumen.

The in vivo digestion and DNA degradation observed here may have occurred faster than would be expected in a natural grazing scenario, as the starting plant material was initially cut into smaller fragments compared to the large bites consumed by a grazing ruminant.[25] However, biting, mastication, and comminution by a grazing animal may rapidly render grazed larkspur somewhat similar to the chopped material used in this study. Delphinium plants are nutritious and highly digestible;[25,26] as such much of the ingested larkspur probably ends up in the upper layer in the ruminal dorsal sac, part of the raft or mat that is composed primarily of rapidly fermenting, buoyant particles. Digestion and retention time in the rumen

DOI: 10.1021/jf5053496
J. Agric. Food Chem. 2015, 63, 1220−1225

will depend on many complex, interrelated factors, however for comparison ingested larkspur plants are likely to be very similar in retention time to high quality alfalfa hay.[26] Effects of long form (i.e., intact) or chopped alfalfa hay on ruminal retention time were small when high quality alfalfa was used.[27] The retention time in the rumen of high quality alfalfa hay is 18−21 h,[27,28] and larkspur is probably similar.

In Vitro Rumen Digestion. An in vitro rumen digestion was performed to determine the length of time one may expect to detect larkspur in a bovine rumen after a fatal poisoning episode, as the digestion vessels in the Daisy II digestion apparatus were not rotating as is typically done during in vitro experiments (i.e., mimicking a static rumen). A PCR product was detected from *D. occidentale* samples that had been incubated in digestion vessels of rumen fluid in each of the three replicates up to 40 h (Figure 4). At the 48 h time point, a

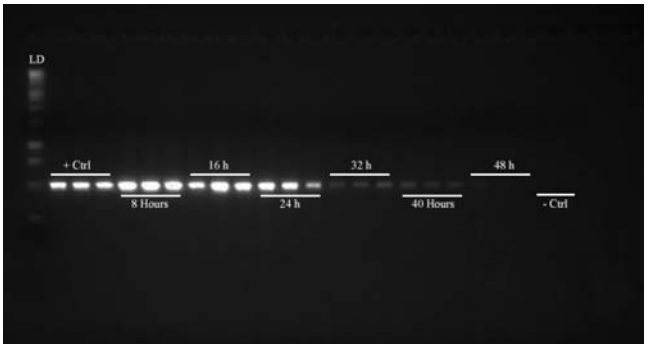

Figure 4. Agarose gel electrophoresis showing amplification of PCR products from the in vitro rumen digestion. 1000bp marker (LD) shown as a reference. Triplicates of undigested positive control (+ctrl) and digested (8−48 h) *D. occidentale*. Negative control (−ctrl) representing *A. columbianum* and *M. sativa*.

PCR product was amplified from one of the replicate samples (Figure 4). As expected a PCR product was detected from the three control samples but not from the *Aconitum* or alfalfa sample (Figure 4). DNA was extracted from all the plant material a second time and PCR performed, and the same results were obtained (data not shown).

Differences were observed in the length of time a PCR product was detected between the in vivo and in vitro rumen digestion of *D. occidentale*. This was evident by the quality and quantity of DNA extracted from the starting material (data not shown). This may be due to the viability of the microflora in the in vitro rumen compared to the in vivo rumen. Further, it may be related to the total ruminal conditions during the in vivo process, including microbial numbers and activity, and rumen fermentation and motility resulting in faster degradation of the target DNA. In the in vitro digestion the rumen fluid was not moving nor was the plant material continually bathed in rumen fluid. The plant material in the nylon bags was buoyant, and moved to the top of the digestion vessel with the other plant material equivalent to the rumen mat. However, there still was evidence of digestion as the nylon bag expanded over time due to the production of gases as the result of fermentation.

In Vivo and In Vitro Rumen Digestion. An in vivo digestion was coupled with an in vitro digestion to determine the length of time one may expect to detect larkspur in a bovine that consumed larkspur and died 8 h later. A PCR product was detected from *D. occidentale* samples that had been incubated in vivo and in vitro from 8 h to 72 h in all three replicates (Figure 5). As expected, a PCR product was detected from the three control samples but not from the *Aconitum* or alfalfa sample

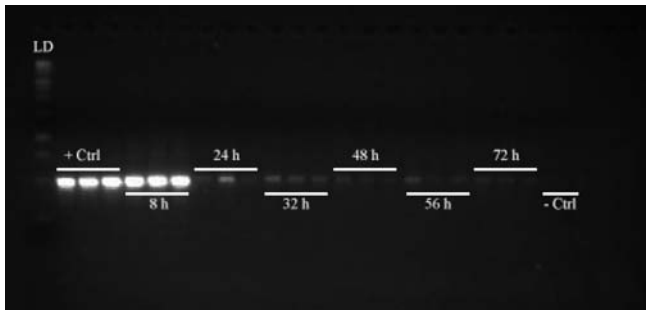

Figure 5. Agarose gel electrophoresis showing amplification of PCR products from the in vivo and in vitro coupled rumen digestion. 1000bp marker (LD) shown as a reference. (Figure 5). DNA was extracted from all the plant material a second time and PCR performed, and the same results were obtained (data not shown). The results from this experiment were similar to the in vitro digestion alone.

In Vivo Rumen Digestion Sensitivity. When collecting rumen samples from poisoned animals, it is not possible to sample the entire rumen. Thus, a rumen from a dead animal has to be randomly sampled with the assumption that the distribution of the plant material is fairly uniform throughout the rumen. Based on research at this Laboratory, we calculate that a minimum of 5−10% of a cow's daily diet needs to be ingested larkspur for the cow to become poisoned.[29−31] Consequently, in the best case scenario, a random sample of rumen contents will contain 5−10% (1:20−1:10) of larkspur plant material. Therefore, different ratios of alfalfa to *D. occidentale* were prepared to determine if it was feasible to detect 5% larkspur, or lower, in the rumen. A PCR product was detected from each undigested control ratio ranging from the *D. occidentale* only sample to 1 g of *D. occidentale* to 399 g of alfalfa (Figure 6). For comparison, the 1:399 sample was analyzed by LC−MS (Figure 7). The norditerpene alkaloids were detected in it and all other ratios. A PCR product was detected from each of the triplicate digested ratios ranging from the *D. occidentale* only sample to 1 g of *D. occidentale* to 49 g of

alfalfa (Figure 8). As expected, a PCR product was not detected from the *Aconitum* or alfalfa sample (Figure 8). DNA was

Figure 8. extracted from a subset of the plant material a second time and PCR performed, and the same results were obtained (data not shown). These results suggest that, if a rumen from a poisoned animal were sampled from several spots at random, there would likely be sufficient larkspur to detect a PCR product based upon the amount of larkspur one would expect to find in a poisoned animal.

Two principal limitations exist with using PCR as a diagnostic tool. The first is a matter of sampling the rumen from the poisoned animal. How much material would need to be sampled to provide confidence that the sample is representative of the overall rumen contents? The data reported here are promising, as a PCR product was detected at a ratio of 1:399, while larkspur is likely to comprise 5–10% (1:20–1:10) or higher of the rumen contents of a poisoned animal.[2,29,31] However, in the cases of plants that are more acutely toxic such as water hemlock (*Cicuta* spp.), this may not be feasible as there could be much less plant material. The second limiting factor is the integrity of the template DNA. Often there is a lapse in time between the death of an animal and its discovery and the subsequent sampling of rumen contents. The data reported here suggests that up to 48 h after the death of the animal, as mimicked by the coupled in vivo and in vitro samples, larkspur can still be detected by PCR, thus supporting the idea that PCR could be used as a diagnostic tool if the dead animals are found and samples collected within 2 days.

In summary, we developed a pair of oligonucleotide primers specific to *Delphinium* spp. Using these primers, a PCR product was detected in samples from an in vivo, in vitro, and in vivo/in vitro coupled digestion of *D. occidentale*. Lastly, using this method, we were able to detect larkspur in a matrix where the amount of larkspur was far less than what one would expect to find in the rumen contents of a poisoned animal. These data demonstrate that this method and the primers are both specific and sensitive, a characteristic of a good diagnostic tool. This research offers a proof of principle that PCR-based methods could be used as a diagnostic tool to detect a plant of interest in the rumen contents of a poisoned animal. However, further research is needed to validate this method. For example, rumen samples need to be collected and analyzed from actual field cases of poisoned cattle. Also additional research needs to be performed to compare the sensitivity and robustness of this PCR-based method to chemical methods where the norditerpene alkaloids are detected. Finally, hypothetically, a PCR-based method could be developed for diagnosis of poisoning by any other plant species that is acutely toxic such as water hemlock, death camas (*Zigadenus* spp.), and oleander (*Nerium oleander*).

(Tokyo, Japan). *Pfu* DNA polymerase was obtained from Promega (Madison, MI), and T4 DNA ligase was obtained from Biolabs (New England Biolabs, Ipswich, MA). A multifunctional DNA purification kit was purchased from BioTeke (Beijing, China). Chelating Sepharose [nickel−iminodiacetic acid (Ni−IDA)] resin matrix was from GE Life Sciences (Pittsburgh, PA). Q Sepharose Fast Flow was purchased from Pharmacia (Uppsala, Sweden). Debranched arabinan, sugar beet arabinan, arabinoxylan, and arabino-oligosaccharides were purchased from Megazyme (Bray, Wicklow, Ireland). The *p*-nitrophenol (*p*NP) substrates were purchased from Biosynth (Staad, Switzerland). Birchwood xylan, *p*NP-α-L-arabinofuranoside, *p*NP-α-L-arabinopyranoside, and *p*NP-β-D-xylopyranoside were purchased from Sigma (St. Louis, MO). The commercial pectinase was obtained from Sinopharm (Beijing, China). All other chemicals were of analytical grade, unless stated otherwise.

Cloning of an Endo-α-1,5-L-arabinanase Gene and Its Nucleotide Sequence Analysis. Recombinant DNA techniques as described by Sambrook and Russell[22] were employed to perform DNA manipulations. The fungus *R. miehei* CAU 432 used in this study was deposited at the China General Microbiological Culture Collection Center (CGMCC) under number 4967. The strain was grown at 50 °C in the media as described by Tang et al.[20] Genomic DNA was isolated from *R. miehei* CAU432 using the CTAB method.[23] The first and second strands of cDNA were synthesized with PrimeScript RT-PCR kit (TaKaRa, Tokyo, Japan). The specific primers AraDNAF (5′-ATGAAACTATCTTTTGCATTGGCG-3′) and AraDNAR (5′-TTAGTAAGTTGGCCAGCCGTTG-3′) were designed on the basis of the genome sequence of *R. miehei* CAU432[21] to amplify the coding region of endo-α-1,5-L-arabinanase. The polymerase chain reaction (PCR) conditions were as follows: a hot start at 94 °C for 5 min, 30 cycles of denaturation for 30 s at 94 °C, annealing for 30 s at 52 °C, extension for 1 min at 72 °C, and a final extension step for 10 min at 72 °C with LA Taq DNA polymerase (TaKaRa, Tokyo, Japan). After amplification, PCR products were purified, ligated to pMD18-T vector, transformed into *E. coli* DH5α competent cells, and sequenced.

BLAST analysis was performed at National Center for Biotechnology Information (NCBI) server (http://blast.ncbi.nlm.nih.gov/Blast.cgi). Multiple alignment analysis was performed by Clustal W2.0 (http://www.ebi.ac.uk/Tools/clustalw2/index.html), and the alignment figure was produced with ESPript (http://espript.ibcp.fr).[24] Signal peptide was analyzed by SignalP 3.0 server (http://www.cbs.dtu.dk/services/SignalP/). Putative catalytic residues were predicted using Motif Scan (http://myhits.isb-sib.ch/cgi-bin/motif_scan) and CAZY (http://www.cazy.org/).

Expression of the Endo-α-1,5-L-arabinanase Gene in *E. coli*. To express the endo-α-1,5-L-arabinanase gene (*RmArase*) in *E. coli*, the open reading frame (ORF) region of the cDNA gene was amplified by PCR with the primers of RmAraF (5′-ATCATGCCATGGCTTGGGAACTCACAGGTGACATT-3′) and RmAraR (5′-ATTCCGCTCGAGTTAGTAAGTTGGCCAGCCGTTG-3′). *Nco*I and *Xho*I sites (underlined) were added to the forward and reverse primers, respectively, so that the expressed protein carries a N-terminal His tag encoded by the vector. PCR conditions were as follows: 94 °C for 5 min, 30 cycles of 94 °C for 30 s, 58 °C for 30 s, and 72 °C for 1 min, followed by 1 cycle of 72 °C for 10 min. The PCR product was cloned into the *Nco*I/*Xho*I sites of pET30a (+) vector (Novagen) and transformed into *E. coli* BL21 (DE3) for protein expression. A single colony of *E. coli* BL21 (DE3) harboring *RmArase* in pET30a (+) was inoculated into Luria−Bertani broth (LB) medium containing kanamycin (50 μg/mL) and incubated on a rotary shaker (200 rpm at 37 °C) until the optical density OD_{600} reached about 0.8−1.0. Isopropyl-β-D-1-thiogalactopyranoside (IPTG) was added to a final concentration of 1 mM to induce expression, and the culture was further grown at 25 °C for 12 h.

Purification of Recombinant Endo-α-1,5-L-arabinanase. Recombinant cells were harvested from culture broth by centrifugation at 10000*g* for 10 min at 4 °C, resuspended in lysis buffer A (50 mM sodium phosphate at pH 8 containing 500 mM NaCl), and disrupted by sonication. The cell debris was removed by centrifugation at 10000*g* for 10 min at 4 °C, and the supernatant was loaded onto a Ni−IDA column (0.8 × 10 cm) equilibrated with buffer B (buffer A containing 20 mM imidazole). After binding, the column was washed with buffer B followed by buffer C (buffer A containing 50 mM imidazole) at a flow rate of 1.0 mL/min. The bound enzyme was eluted with buffer D (buffer A containing 200 mM imidazole). The protein eluted as a single peak, was pooled, and was further fractionated on a Q-Sepharose column (10 × 1 cm) pre-equilibrated with buffer E (50 mM sodium phosphate at pH 8.0). The column was washed with buffer E at a flow rate of 1 mL/min, and the bound protein was then eluted with a linear gradient from 0 to 500 mM NaCl in buffer E. The elution fractions showing endo-α-1,5-L-arabinanase activity were pooled and dialyzed against 50 mM sodium acetate buffer (pH 5.5). The homogeneity of the purified enzyme was monitored by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE).

Enzyme Assay and Protein Determination. The mixture consisting of 10 μL of enzyme and 90 μL of debranched arabinan (10 mg/mL) in 50 mM sodium acetate buffer (pH 5.5) was incubated at 45 °C for 30 min. Activity was assayed by measuring the release of reducing groups according to the method of dinitrosalicylic acid (DNS).[25] The amount of reducing sugars was calculated from a standard plot of L-arabinose. One unit of enzyme activity is defined as the amount of enzyme liberating 1 μmol of reducing sugars per minute under the conditions described. Protein concentrations were measured by the Lowry method[26] using bovine serum albumin (BSA) as a standard.

SDS−PAGE and Size-Exclusion Chromatography. The proteins during the purification process were analyzed on 12.5% SDS−PAGE.[27] The protein bands were stained with Coomassie Brilliant Blue R-250. The molecular mass of the enzyme subunit was determined using a low molecular mass standard (Amersham, London, U.K.) containing phosphorylase B (97.0 kDa), albumin (66.0 kDa), ovalbumin (45.0 kDa), carbonic anhydrase (30.0 kDa), trypsin inhibitor (20.1 kDa), and α-lactalbumin (14.4 kDa).

The native molecular mass of RmArase was determined by size-exclusion chromatography using a Superdex-75 gel filtration column (1 × 40 cm) equilibrated with 50 mM sodium phosphate buffer (pH 8.0) containing 150 mM NaCl at a flow rate of 0.33 mL/min. The molecular mass standards used were phosphorylase B rabbit muscle (97.2 kDa), BSA (66.0 kDa), chicken egg white albumin (45.0 kDa), α-chymotrypsinogen A from bovine pancreas (25.7 kDa), and cytochrome *c* (13.0 kDa).

pH and Temperature Profiles. The optimal pH for endo-α-1,5-L-arabinanase activity was determined in 50 mM different buffers, viz., sodium citrate (pH 3.0−6.0), sodium acetate (pH 4.5−6.0), 2-(*N*-morpholino)ethanesulfonic acid (MES) (pH 5.0−6.5), 4-(*N*-morpholino)propanesulfonic acid (MOPS) (pH 6.5−8.0) and glycine−NaOH (pH 8.5−10.5). pH stability of the enzyme was determined by incubating the enzyme at 45 °C for 30 min in various buffers, as mentioned above, followed by rapid cooling on ice. The residual activity was determined by a standard assay method.

The optimal temperature was determined by the standard assay at temperatures ranging from 30 to 60 °C in 50 mM sodium acetate buffer (pH 5.5). Thermstability was measured by the standard assay after incubating the enzyme in 50 mM sodium acetate buffer (pH 5.5) at different temperatures for 30 min.

Influence of Metal Ions and Other Reagents. The influence of different modulators, such as metal ions and reducing and chelating agents, on enzyme activity was tested. The enzyme was incubated with 1 mM various metal ions and other chemicals [ethylenediaminetetraacetic acid (EDTA), dithiothreitol (DTT), β-mercaptoethanol, SDS] at 45 °C in 50 mM sodium acetate buffer (pH 5.5) for 30 min. The residual activity of the enzyme and the control (without reagents) was determined by the standard assay.

Substrate Specificity and Kinetic Parameters. The substrate specificity of RmArase was determined using different substrates. The enzyme activity toward polysaccharides, including debranched arabinan, sugar beet arabinan, arabinoxylan, and birchwood xylan, was assayed in the presence of 10 mg/mL at 55 °C in 50 mM sodium acetate buffer (pH 5.5) by the DNS method. Activity toward *p*NP derivatives, such as *p*NP-α-L-arabinofuranoside, *p*NP-α-L-arabinopyr-

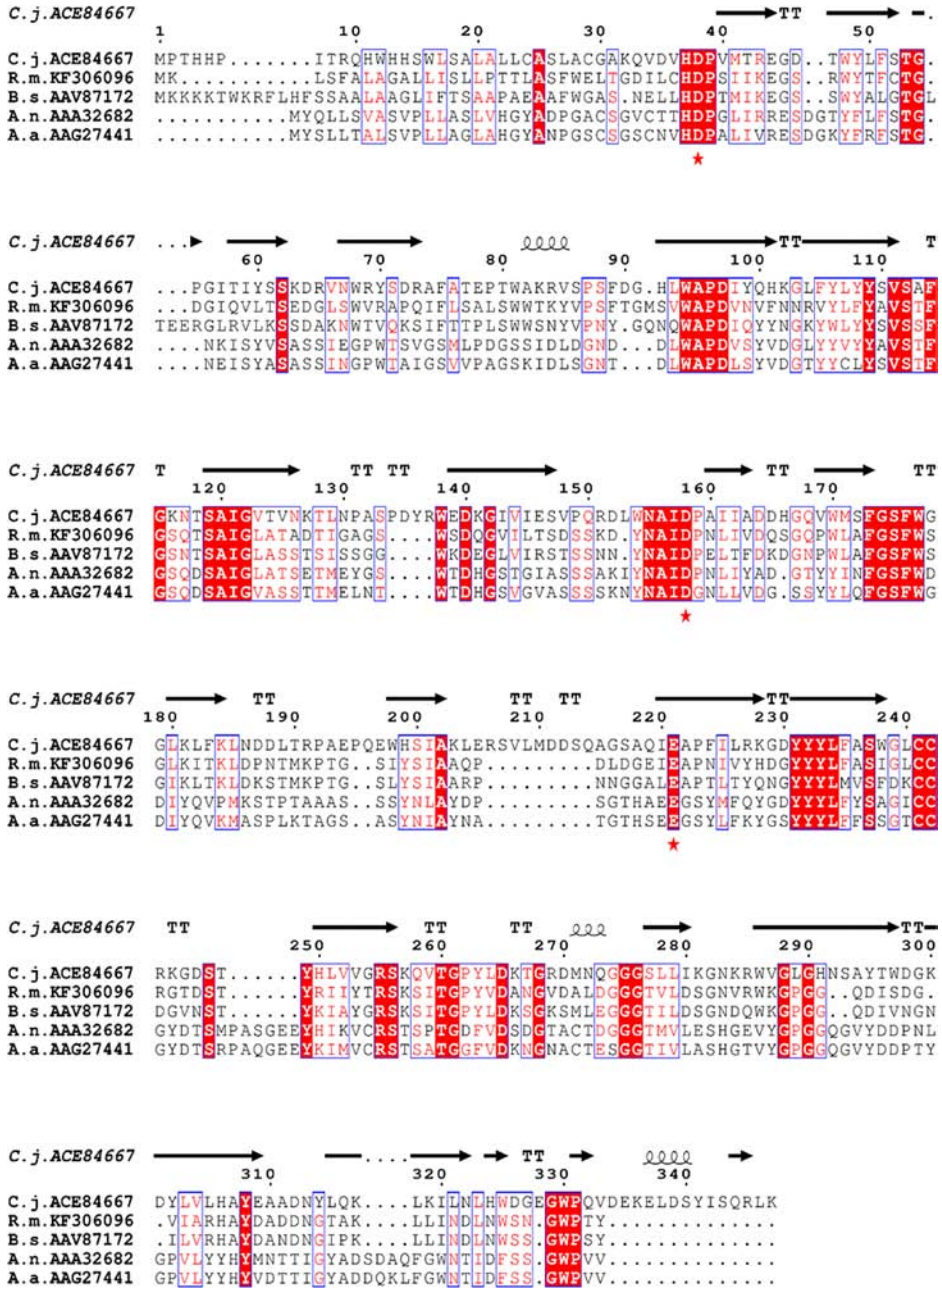

Figure 1. Alignment of homologous endo-α-1,5-L-arabinanases with RmArase sequence. Species for the sequences, with the species abbreviations and GenBank accession numbers in parentheses, are shown as follows: *C. japonicas* (C.j. ACE84667), *R. miehei* (R.m. KF306096), *B. subtilis* (B.s. AAV87172), *A. niger* (A.n. AAA32682), and *A. aculeatus* (A.a. AAG27441). Sequence regions with high similarity are written in red letters and boxed in blue. The secondary structure displayed above the alignment is derived from the three-dimensional structure (PDB code 1GYD) of endo-α-1,5-L-arabinanases (ACE84667) from *C. japonicas* Ueda107. α-Helices are rendered as squiggles, and β-strands are displayed as arrows. The catalytic base (Asp 34), catalytic acid (Glu 202), and another important residue (Asp 150) for enzymatic reaction are denoted by a red star below the residue.

anoside, and *p*NP-β-D-xylopyranoside, was measured by the rate of *p*NP released from 5 mM of the substrate in 50 mM sodium acetate buffer (pH 5.5) at 55 °C after 10 min and detected by spectrophotometry at 410 nm.

For determination of the kinetic parameters for debranched arabinan and sugar beet arabinan, enzyme activities were performed using each substrate with different concentrations at 55 °C in 50 mM sodium acetate buffer (pH 5.5) for 5 min. K_m and V_{max} of the endo-α-1,5-L-arabinanase were calculated using "GraFit" software.

Hydrolysis of Arabinans and Arabino-oligosaccharides. The potential of RmArase in degrading arabinans was analyzed as given below. A total of 1 unit of purified endo-α-1,5-L-arabinanase was incubated in a reaction volume of 1 mL with 10 mg/mL debranched arabinan or sugar beet arabinan at 45 °C in 50 mM sodium acetate buffer (pH 5.5) for 8 h. Samples were withdrawn at various time intervals and boiled for 5 min to terminated the reaction. The hydrolysis products were analyzed by thin-layer chromatography (TLC). The reaction mixtures were spotted on a silica gel plate (Merck Silica Gel 60F254, Darmstadt, Germany) and developed twice in a solvent system containing chloroform/acetic acid/water at 1:1.5:0.1 (v/v/v). Saccharides were detected by heating in an oven after spraying the plates with a mixture of methanol and sulfuric acid (95:5, v/v).

Further, the pattern of RmArase hydrolyzing various arabino-oligosaccharides was assessed. The reaction mixture consisting of 1 unit/mL enzyme and 10 mg/mL different arabino-oligosaccharides

Table 1. Purification Summary of the Recombinant Endo-α-1,5-L-arabinanase (RmArase) Expressed in *E. coli*

purification step	total activity (units)[a]	protein (mg)[b]	specific activity (units/mg)	purification factor (fold)	recovery (%)
crude supernatant	1432	127	11.3	1.0	100.0
Ni–IDA	891	9	100.0	9	62
Q-Sepharose	812	7.5	109	9.7	57

[a]Activity was measured in 50 mM sodium acetate buffer (pH 5.5) at 55 °C using 10 mg/mL debranched arabinan. [b]The protein was measured by the Lowry method,[26] using BSA as the standard.

(arabinobiose, arabinotriose, arabinotetraose, and arabinopentaose) in 50 mM sodium acetate buffer was incubated at 45 °C for 1 h. The hydrolysis products were analyzed by TLC, as described above.

Synergistic Action of RmArase and the Pectinase. Sugar beet pulp (100 g) was soaked in 1 L of water overnight and autoclaved at 121 °C for 60 min. The suspension was filtered and centrifuged. The supernatant pH was adjusted to 5.5 by the addition of $CaCO_3$. The supernatant was treated with 10 units/mL of a single enzyme (RmArase or pectinase) or a combination of enzymes. The reaction mixtures were incubated at 45 °C for 24 h. Reducing sugars released were determined by the DNS method using arabinose as the standard. The arabinose was determined by high-performance liquid chromatography (HPLC) equipped with a BP-800 Pb++ column (Benson Polymeric, Reno, NV). Ultrapure water (Milli-Q, Millipore, Billerica, MA) was used as the mobile phase. Operation conditions for HPLC were 80 °C at a flow rate of 0.6 mL/min. The injection volume was 20 μL, and the elution time was 40 min.

RESULTS AND DISCUSSION

Cloning and Sequence Analysis of an Endo-α-1,5-L-arabinanase Gene from *R. miehei*. The complete coding region of the endo-α-1,5-L-arabinanase gene (*RmArase*) was amplified from cDNA of *R. miehei* CAU432 using the primers AraDNAF and AraDNAR. The nucleotide sequence reported here has been submitted to the GenBank and has been allocated the accession number (KF306096). No intron was found in the coding region when compared to the genomic sequence. The mature protein has 309 amino acids with a predicted molecular mass of 33.5 kDa and a deduced pI value of 4.27. According to the homology search of the deduced amino acid sequences by BLAST (Figure 1), the amino acid sequence of RmArase shared identities of 34, 56, 35, and 35% with the characterized GH family 43 endo-α-1,5-L-arabinanases from *Cellvibrio japonicus* Ueda107 (ACE84667), *B. subtilis* (AAV87172), *A. niger* (AAA32682), and *A. aculeatus* (AAG27441), respectively. Thus, RmArase may be a novel member of GH family 43 endo-α-1,5-L-arabinanases.

To elucidate the secondary structure and catalytic residues of RmArase, the endo-α-1,5-L-arabinanase sequence from *C. japonicus* Ueda107 was added to the alignment because its three-dimensional structure [Protein Data Bank (PDB) code 1GYD] is available. Most of the β-strands are located in the conserved region. Furthermore, Asp 34, Asp 150, and Glu 202 in RmArase match with Asp 38, Asp 158, and Glu 221 in the *C. japonicus* Ueda107 endo-α-1,5-L-arabinanase, which composes the catalytic center.[28] These results suggest that the RmArase should have similar overall molecular folding and catalytic mechanism with the GH family 43 endo-α-1,5-L-arabinanase from *C. japonicus* Ueda107.

Purification of the Recombinant Endo-α-1,5-L-arabinanase (RmArase). The recombinant endo-α-1,5-L-arabinanase (RmArase) expressed in *E. coli* was a soluble, intracellular histidine-tagged protein. The enzyme activity of RmArase was 2.1 units/mL in crude lysate, which is higher than that of *Bacillus licheniformis* (0.25 unit/mL)[31] and *Phanerochaete chrysosporium* (1.66 units/L).[33] The purification summary of RmArase is presented in Table 1. RmArase was purified to homogeneity with an overall yield of 56.7% using affinity chromatography and ion-exchange chromatography. The specific activity of the endo-α-1,5-L-arabinanase increased from 11.3 to 109 units/mg.

It is noted that the purified RmArase exhibited high specific activity against debranched arabinan of 109 units/mg. The high specific activity of RmArase may enhance the degrading ability toward arabinans. The purified enzyme showed a single, homogeneous protein band on SDS–PAGE corresponding to 40.6 kDa (Figure 2), which matches with its native molecular

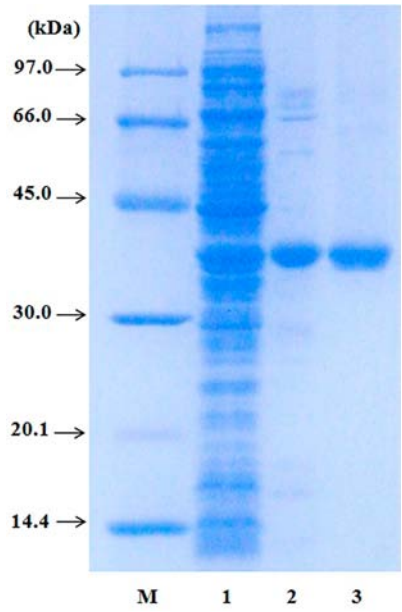

Figure 2. SDS–PAGE analysis of purified RmArase: lane M, low-molecular-weight standard protein markers; lane 1, crude lysate; lane 2, after Ni–IDA; and lane 3, after Q-Sepharose.

mass of RmArase of 38.2 kDa as determined by gel filtration, indicating that the enzyme is a monomer. The molecular mass of RmArase is similar to those of most endo-α-1,5-L-arabinanases from GH family 43. All fungal endo-α-1,5-L-arabinanases are monomeric enzymes with molecular masses in the range of 30–40 kDa.[8,10,16,17,31]

Biochemical Characterization of RmArase. The biochemical properties of the purified RmArase were further determined. RmArase exhibited a maximal activity at pH 5.5 (Figure 3a). The enzyme was stable within pH 5.0–8.5 because it retained more than 90% of its initial activity (Figure 3b). The enzyme showed an optimum temperature at 55 °C (Figure 3c). It was stable up to 45 °C (Figure 3d).

Generally, endo-α-1,5-L-arabinanases from fungi are characterized by their acidic pH optima (pH 5.0–7.0),[5,11,12,19,29] which makes them valuable in application in fruit juice clarification at acidic pH.[12] The optimal pH 5.5 of RmArase

J. Agric. Food Chem. 2015, 63, 1226–1233

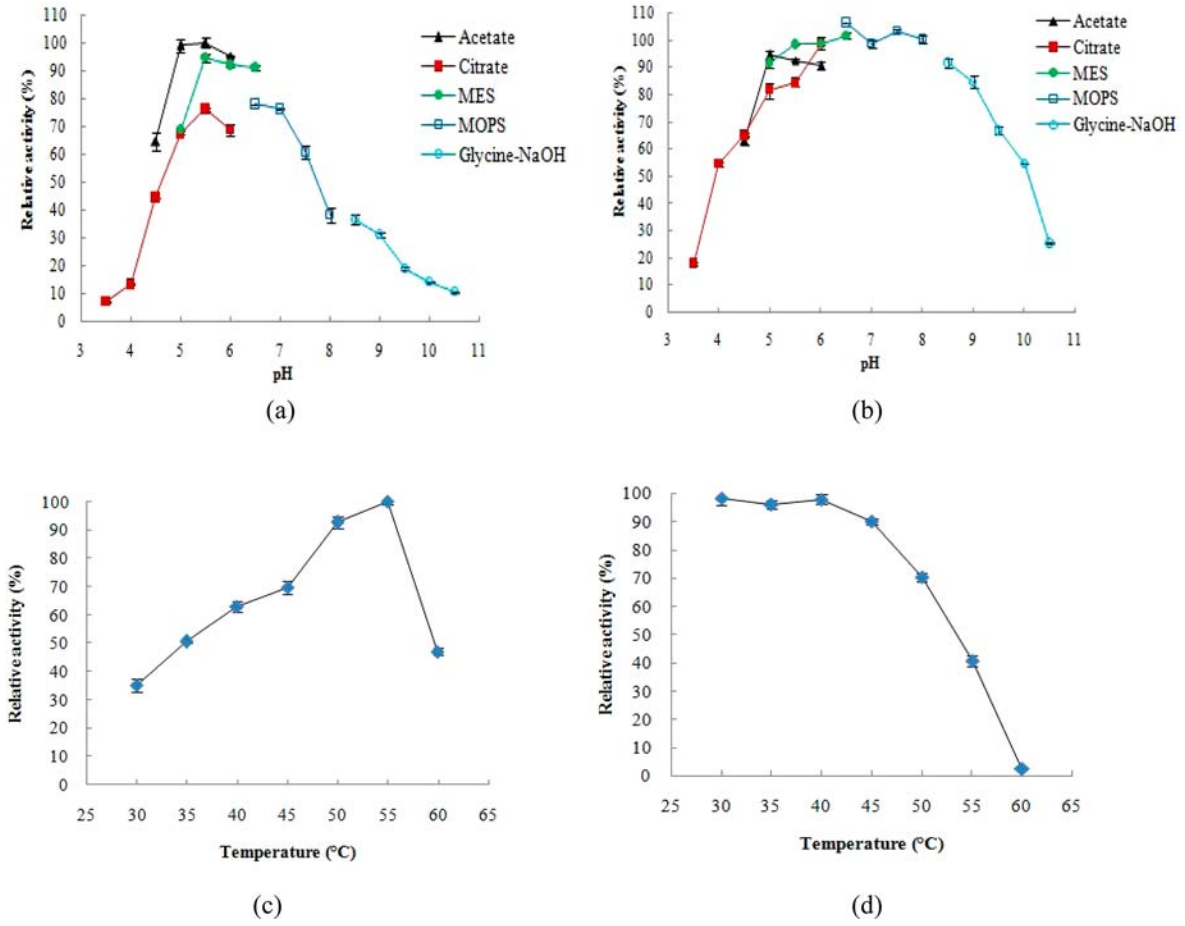

Figure 3. pH and temperature profiles of the purified recombinant endo-α-1,5-L-arabinanase (RmArase). Effect of pH on the (a) activity and (b) stability was performed at 45 °C in 50 mM different buffers. The residual activities were measured after incubation at 45 °C for 30 min over various pH ranges. Effect of the temperature on the (c) activity and (d) thermostability of RmArase were determined at temperatures ranging from 30 to 60 °C in 50 mM sodium acetate buffer (pH 5.5).

is lower than that of two other fungal endo-α-1,5-L-arabinanases from *P. chrysogenum* (pH 6−7).[5,12] Despite its acid pH optimum, RmArase showed good pH stability. RmArase is stable within pH 5.0−9.0, where it retained more than 80% of its activity. In general, fungal endo-α-1,5-L-arabinanases are stable in the acidic to neutral pH range. Thus far, only the endo-α-1,5-L-arabinanase from *P. chrysogenum* is stable up to pH 9.0.[12] The optimal temperature and thermostability of RmArase are comparable to that of the reported recombinant endo-α-1,5-L-arabinanases. RmArase display an optimal temperature of 55 °C, which is higher than that reported from the fungi, such as *A. aculeatus*,[19] and bacteria, such as *B. subtilis*[30] and *B. licheniformis*.[18] RmArase retained about 70% of its activity at 50 °C for 30 min, which is higher than the recombinant endo-α-1,5-L-arabinanase from *B. licheniformis*.[18]

The effects of various metal ions and other reagents on enzyme activity were studied. Among the metal ions tested, Na^+ (113 ± 4.7%), Co^{2+} (108 ± 3.4%), Mg^{2+} (105 ± 2.9%), and K^+ (104 ± 2.0%) slightly activated the enzyme. The activity of RmArase was strongly inhibited by Hg^{2+} (9 ± 2.0%), Cr^{2+} (12 ± 1.0%), Fe^{3+} (18 ± 0.3%), Sn^{2+} (30 ± 2.0%), Ag^+ (34 ± 0.4%), and Zn^{2+} (34 ± 1.3%) and moderately inhibited by Cu^{2+} (65 ± 1.0%), Mn^{2+} (49 ± 1.8%), and Fe^{2+} (46 ± 0.9%). It was slightly affected by DTT (102.5 ± 1.9%), Ca^{2+} (99 ± 1.2%), Ni^{2+} (94 ± 1.6%), and Ba^{2+} (94 ± 4.4%). Additionally, SDS and β-mercaptoethanol enhanced the enzyme activity to 112 and 110%, but the activity was significantly inhibited by EDTA (61.7 ± 3.8%).

The enzyme activity was stimulated by Co^{2+} and Mg^{2+} and inactivated by Fe^{3+}, Sn^{2+}, Zn^{2+}, and Fe^{2+}, similar to endo-α-1,5-L-arabinanases from *Caldicellulorsiruptor saccharolyticus*[15] and *B. licheniformis*.[18] Like most other endo-α-1,5-L-arabinanases, RmArase was inhibited by Hg^{2+} (9%), indicating the presence of free cysteines in the active site.[9,12] Mn^{2+} inhibited the enzyme by 50%, enhanced the enzyme from *C. saccharolyticus*,[15] and slightly affected the enzyme from *P. chrysogenum* 31B.[12] EDTA inhibited the activity of RmArase (60%), suggesting that the recombinant endo-α-1,5-L-arabinanase was a metal-dependent enzyme.

Substrate Specificity and Kinetic Parameters. The substrate specificity of RmArase was determined using various substrates. The enzyme showed highest specific activity toward debranched arabinan (100%), followed by sugar beet arabinan (48.4%). The enzyme, however, did not show any detectable activity toward birchwood xylan, *p*NP-α-L-arabinofuranoside, *p*NP-α-L-arabinopyranoside, and *p*NP-β-D-xylopyranoside.

Most of the GH family 43 endo-α-1,5-L-arabinanases show high activity toward the arabinans, no activity toward arabinoxylan, and no activity toward *p*NP-α-L-arabinofuranoside.[9,11,12,15,18,30−32] In contrast to other endo-α-1,5-L-arabinanases, RmArase exhibits the highest relative specific activity

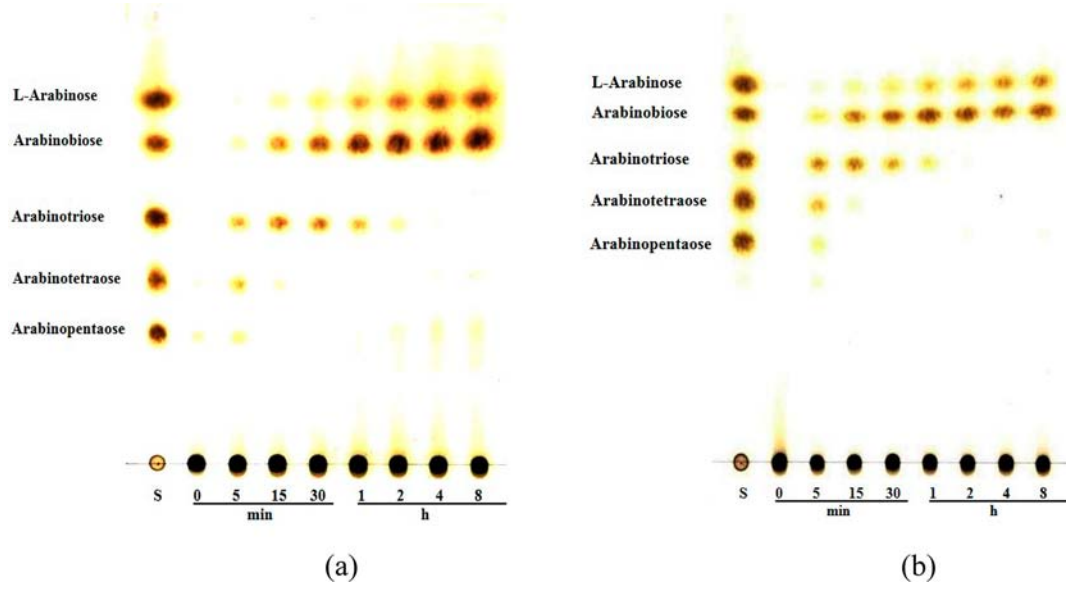

Figure 4. Hydrolysis of (a) debranched arabinan and (b) sugar beet arabinan by RmArase. The reaction mixture containing 10 mg/mL arabinans in 50 mM sodium acetate buffer (pH 5.5) and RmArase (1 unit/ml) was incubated at 45 °C for 8 h. Samples were subjected to TLC. Lane S, a mixture of L-arabinose, arabinobiose, arabinotriose, arabinotetraose, and arabinopentaose.

toward sugar beet arabinan (48.4%) when compared to debranched arabinan (100%).[9,17,31]

The Michaelis−Menten constants were determined for debranched arabinan and sugar beet arabinan (data not shown). The results revealed that RmArase had a higher affinity toward debranched arabinan (K_m = 5.8 mg/mL) than sugar beet arabinan (K_m = 27.5 mg/mL). RmArase shows higher binding affinity for debranched arabinan than that of most reported endo-α-1,5-L-arabinanases.[1,10,15,18,29] However, K_m values of endo-α-1,5-L-arabinanases from *P. chrysosporium* (K_m = 4.3 mg/mL),[33] *B. subtilis* (K_m = 2.0 mg/mL),[29] and *A. nidulans* (K_m = 4.9 mg/mL)[11] are a little lower than that of RmArase.

Hydrolysis of Arabinans and Arabino-oligosacchharides by RmArase. The hydrolysis of arabinans and various α-(1,5)-L-linked arabino-oligosaccharides by the purified RmArase was performed. The degradation of arabinans produced a mixture of arabiose-linked saccharides during the initial hydrolysis, with arabinobiose and arabinose as the end products (Figure 4). Further, degradation of various arabino-oligosaccharides was assessed by TLC (Figure 5). Arabinotetraose was slowly hydrolyzed to produce mainly arabinobiose in 1 h (Figure 5c), whereas arabinopentaose was completely hydrolyzed to yield mainly arabinobiose and arabinotriose in 5 min (Figure 5d). RmArase could slightly hydrolyze arabinotriose to produce arabinobiose and arabinose. However, the recombinant enzyme hardly hydrolyzed arabinobiose. The results revealed that RmArase displayed an endotype mode of action.

RmArase was active on sugar beet arabinan, which is composed of 50% 1,2-α- and 1,3-α-L-arabinofuranosyl side chains linked to a 1,5-α-L-arabinofuranosyl backbone, but the activity was much lower than on debranched arabinan, which is prepared by treatment of sugar beet arabinan with α-L-arabinofuranosidase to remove all 1,2- and 1,3-α-L-arabinofuranosyl branch units. It indicates that RmArase displays internal cleavage of α-1−5-linked L-arabinofuranose residues in the polysaccharide chain.[1] The hydrolysis time-course profiles of two arabinan hydrolysis were detected by TLC (Figure 4). At the beginning of the hydrolysis, RmArase mainly produced a series of arabino-oligosaccharides, a typic feature of endotype enzyme. As time progressed, arabino-oligosaccharides with higher units were hydrolyzed and converted into more arabinobiose and arabinose as the end products. In contrast, the end products produced by other endo-α-1,5-L-arabinanases were arabinobiose and arabinotriose[1,9,11,19] or only arabinotriose.[12,17] The monomeric arabinose was not produced from debranched arabinan by the action of fungal endoarabinanases.[9] RmArase degraded arabinans to produce more arabinose. The property should expand its ability to produce arabinose from arabinans, which is the second most abundant pentose in nature.[34] To understand the details of the hydrolysis mechanism, hydrolysis patterns of linear arabino-oligosaccharides were further investigated by TLC (Figure 5). The enzyme hardly hydrolyzed arabinobiose. However, it could hydrolyze arabinotriose, arabinotetraose, and arabinopentaose to mainly produce arabinotriose and arabinobiose. The hydrolytic properties of the RmArase are similar to the arabinanase from *Pseudomonas fluorescens* subspecies *cellulosa*.[17]

Degradation of Sugar Beet Pulp by RmArase and the Pectinase. The synergistic action of RmArase and pectinase on the degradation of sugar beet pulp was investigated (data not shown). RmArase alone hydrolyzed sugar beet pulp to produce 1.89 g of reducing sugar and 0.43 g of arabinose, respectively. The amounts of reducing sugar and arabinose produced by the pectinase alone were 7.92 and 0.76 g, respectively. Further, RmArase together with the pectinase enhanced the hydrolysis of sugar beet pulp, and the reducing sugar and arabinose were improved up to 9.52 and 1.38 g, respectively. In the previous studies, the sugar beet pulp could be degraded by an enzyme cocktail containing endo-1,5-α-L-arabinanase and α-L-arabinofuranosidase, but no report on the synergistic action of arabinanase and pectinase is available.[10] Sugar beet pulp is a byproduct of sucrose refining, which is mainly used as feed for ruminants, but its biotechnological conversion to value-added products, such as arabinose and arabino-oligosaccharides, is desirable.[5] The RmArase cooper-

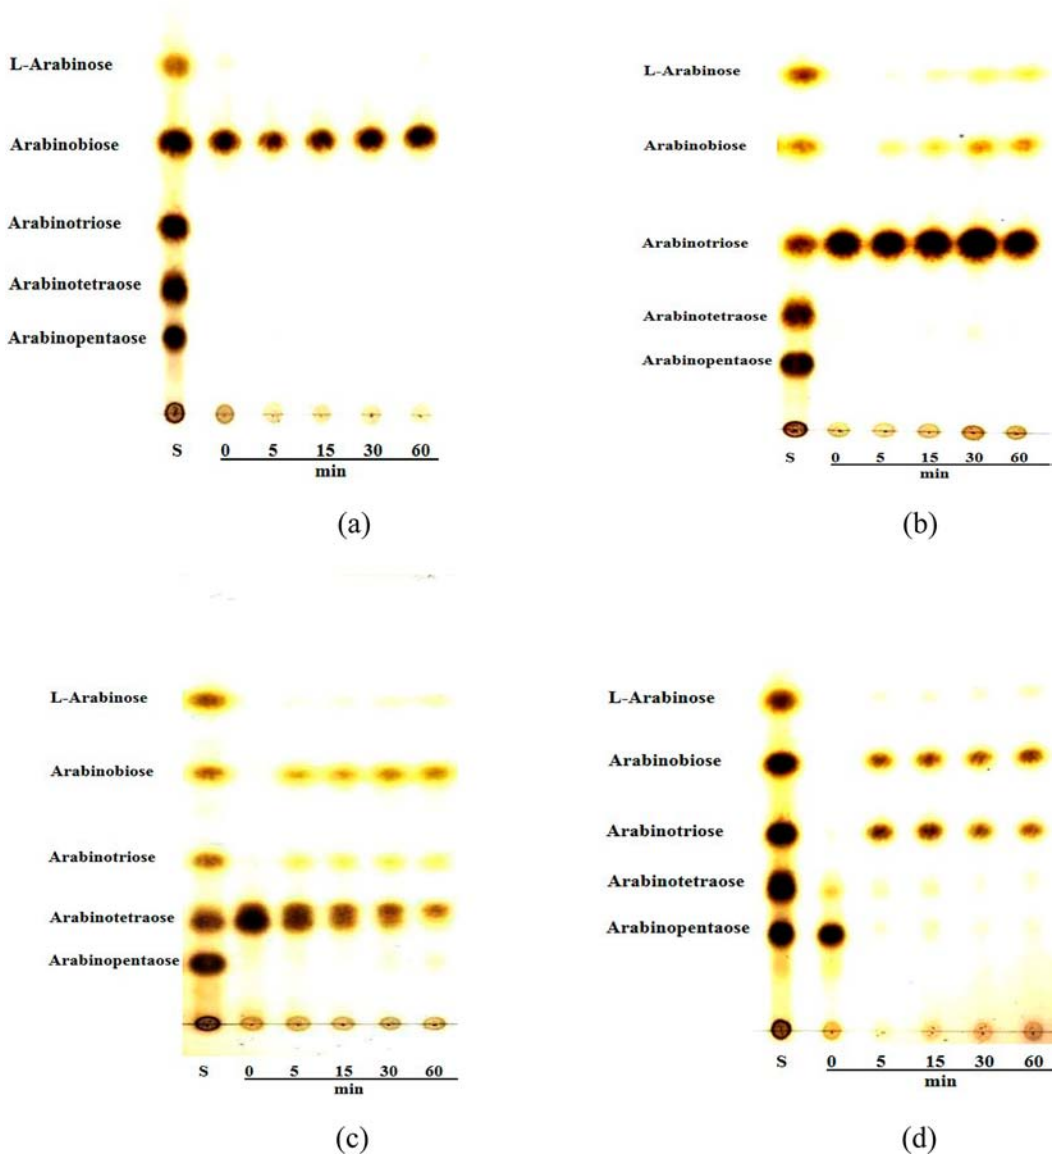

Figure 5. Hydrolysis of (a) arabinobiose, (b) arabinotriose, (c) arabinotetraose, and (d) arabinopentaose by RmArase. The reaction mixture containing 10 mg/mL arabino-oligosaccharides in 50 mM sodium acetate buffer (pH 5.5) and RmArase (1 unit/mL) was incubated at 45 °C for 1 h. Samples were subjected to TLC. Lane S, a mixture of L-arabinose, arabinobiose, arabinotriose, arabinotetraose, and arabinopentaose.

ated with the pectinase can significantly improve the use of sugar beet pulp.

In conclusion, this study reported that the first endo-α-1,5-L-arabinanase gene (*RmArase*) from the thermophilic fungus, *R. miehei*, was expressed in *E. coli*. The recombinant endo-α-1,5-L-arabinanase (RmArase) belonging to GH family 43 was further purified and characterized. RmArase exhibited high specific activity and good pH and thermal stabilities. It exhibited high specificity toward debranched arabinan followed by sugar beet arabinan and hydrolyzed arabinans to mainly produce arabinobiose and arabinose. These results suggest that RmArase has great potential in several industries. Especially, RmArase cooperated with the commercial pectinase may be suitable for arabinose production from sugar beet pulp.

for various foods and condiments.[20] Wheat flour tortillas are also a relatively simple food matrix with a short processing time, which thus presents an ideal model for investigating potential impact of gluten-containing food matrix on PA−starch interactions.

In this work, we use a tannin sorghum bran to investigate how the presence of PA influences in vitro starch digestibility in a food matrix containing wheat proteins by using wheat flour tortillas as a model. Nontannin sorghum brans with different phenolic profiles and wheat bran were also used to control for effect of other phenolic components in the bran. Interaction of the polyphenols with proteins and the fate of the PA during processing were also investigated.

MATERIALS AND METHODS

Materials. Three different types of sorghum bran were chosen for their diversity in polyphenolic content and composition. White sorghum (ATxArg-1/*RT*x436, TAMU, College Station, TX, 2008) was decorticated in a PRL mini-dehuller (Nutama Machine Company, Saskatoon, Canada) and separated (Model 6DT4−1, KICE Industries Inc., Wichita, KS) to yield 12% bran. Brown (high tannin) and black sorghum brans were commercial samples (Nu Life Market, Scott City, KS); these two samples were from similar cultivars we previously used.[13] The white sorghum was chosen for its low flavonoid and extractable phenol content; the black sorghum is high in monomeric flavonoids, especially 3-deoxyanthocyanins, and the brown sorghum has PA as the dominant polyphenols. Wheat bran (ADM, Decatur, IL) was also used for comparison. The wheat and white sorghum brans were ground using a WonderMill (The WonderMill Company, Pocatello, ID) to reduce the particle size to closely match to the brown and black sorghum brans.

Catechin and procyanidin B1 were purchased from Sigma (St Louis, MO); procyanidin B1 and C1 were from Extrasynthese (Genay, France).

Tortilla Formulation and Processing. Base wheat flour was substituted with the brans at 10, 15, and 25% (Baker's, i.e., based on flour weight). The base tortilla flour was made from a 1:1 mixture of high gluten bread flour (C. H. Guenther and Son, Inc., San Antonio, TX) and pastry flour (Cargill Inc., Minneapolis, MN). Control tortillas were made with no bran added. Each batch of tortillas was prepared using 1000 g of flour−bran mixture. To compensate for diluting effect of brans on gluten, 12.0, 19.0, and 31.0 g of vital wheat gluten (Cargill Inc., Minneapolis, MN) were added to the 10, 15, and 25% bran substitution levels, respectively. These values were calculated based on the gluten content of the refined flour blend, which was determined by AACC International method 38−10.01.[21] The rest of the tortilla formulation was described previously.[22,23] Briefly, the tortilla formulation included 15.0 g of table salt, 5.0 g of sodium stearoyl lactylate, 4.0 g of potassium sorbate (Caravan Ingredients, Inc., Lenexa, KS), 6.0 g of sodium propionate (Niacet Corporation, Niagara Falls, NY), 6.0 g of baking soda (Church and Dwight Co., Inc., Ewing, NJ), 5.8 g of sodium aluminum sulfate (Budenheim USA, Columbus, OH), 3.3 g of encapsulated fumaric acid (Balchem Inc., New Hampton, NY), 60.0 g of all-purpose shortening (Cargill Inc., Minneapolis, MN), and distilled water.

Dough moisture content was adjusted to account for increased water absorption of the brans as previously described.[20] After mixing, the dough was allowed to rest for 5 min in a proofing chamber (National Manufacturing Co., Lincoln, NE) at 32 °C and 60−70% relative humidity. The dough was then divided and rounded (Duchess Divider and Rounder, Bakery Equipment and Service Co., San Antonio, TX) into 36 pieces, approximately 30 g each. The dough balls were allowed to rest for another 10 min in the proofing chamber under the conditions listed above. Dough balls were hot-pressed (204 °C, 1150 psi, 1.4 s) and baked in a three-tier gas oven (Lawrence Equipment, El Monte, CA) for approximately 40 s at 193−204 °C. Tortillas were cooled to room temperature and packaged in moisture-proof bags for storage.

Sampling. Samples were retained from four different processing stages: dough, hot-pressed but not baked, immediately after baking (day 0), and after 14 days storage at room temperature. Dough, pressed, and day 0 samples were flash frozen in liquid nitrogen and stored at −20 °C until use. Day 14 samples were frozen at −20 °C after 14 days of room temperature storage. Frozen samples (immediately out of the freezer) were ground in a coffee grinder to reduce the particle size, then dried for 2 h in a hot air oven at 45 °C and further ground with a UDY cyclone sample mill (UDY Corp., Fort Collins, CO) to pass through 0.1 mm screen. For phenolic composition analysis (described below), dried, ground samples were defatted by extracting in hexanes (3:1 hexanes:sample, v/w) for 2 h with shaking at room temperature. Samples were centrifuged, the supernatant was discarded, and the extraction repeated. Defatted samples were air-dried in a fume hood until all remaining hexanes had evaporated. The dried, ground, defatted samples were then stored at −20 °C until analysis. Residual moisture content of the dried samples was determined by a moisture analyzer (Model HB43-S, Mettler-Toledo, Columbus, OH).

Phenolic Composition. *Total Phenolic Content.* Total phenols were measured according to the Folin−Ciocalteu method.[24] Samples were extracted in 1% HCl in methanol with shaking for 2 h. Aliquots were diluted with distilled water and reacted with Folin−Ciocalteu reagent (0.4 mL) and ethanolamine (0.9 mL) for 20 min at room temperature. Absorbance at 600 nm was read on a UV−vis spectrophotometer (Shimadzu Scientific Instruments, Columbia, MD). Results were expressed as mg of gallic acid equivalents (GAE)/g based on a standard curve prepared with serial dilutions of gallic acid in methanol.

High-Performance Liquid Chromatography (HPLC) Analysis. Phenolics were profiled using an Agilent 1200 HPLC system (Agilent Technologies, Santa Clara, CA). Phenolic acids and 3-deoxyanthocyanins were analyzed following the method described by Awika et al.[5] at wavelengths of 280, 330, 360, and 480 nm using a diode array detector. A reverse-phase Luna 5u C18[2] column (150 mm × 4.6 mm, 5 μm, Phenomenex, Torrence, CA) was used. Samples were extracted in 1% HCl in methanol (0.5 g in 5 mL) for 2 h and filtered (0.45 μm, nylon) before injection (10 μL). The mobile phase was composed of 1% formic acid in water (A) and 1% formic acid in acetonitrile (B). The elution gradient (B) over the 40 min run time was: 0−3 min, 10% isocratic; 3−5 min, 10−18%; 5−10 min, 18−20%; 10−23 min, 20−26%; 23−25 min, 26−18%; 25−28 min, 28−40%; 28−30 min, 40−60%; 30−32 min, 60% isocratic; 32−34 min, 60−10%; 34−40 min, 10% isocratic. Flow rate was 1 mL/min.

PA were analyzed and separated based on degree of polymerization according to Langer et al.[25] A fluorescence detector with excitation and emission wavelengths of 230 and 321 nm, respectively, and a normal phase Develosil Diol column (250 mm × 4.6 mm, 5 μm particle size, Phenomenex, Torrence, CA) were used. Samples were extracted in 2% acetic acid in 70% aqueous acetone (1 g in 5 mL) for 2 h and filtered (0.45 μm, nylon) before injection (10 μL). The elution gradient (B) over the 83 min run time was: 0−3 min, 7% isocratic; 3−57 min, 7−37.6%; 57−60 min, 37.6−100%; 60−67 min, 100% isocratic; 67−73 min, 100−7%; 73−83 min, 7% isocratic. Flow rate was 0.6 mL/min. Authentic standards (catechin, procyanidins B1 and C1) were used to quantify PA with a degree of polymerization (DP) of 1−3. Quantitative data for PA with a DP greater than or equal to four were based on procyanidin C1 (DP 3) peak response. Results were corrected for molecular weight according to the DP.

Starch Analysis. In vitro starch digestibility was determined on fully baked tortilla samples. The dried, ground samples were removed from the freezer and allowed to equilibrate at room temperature for 1 h before starch analysis.

Total Starch (TS). The K-TSTA assay kit (determination of total starch content of samples containing resistant starch, but no D-glucose or maltodextrins) from Megazyme (Megazyme International, Wicklow, Ireland) was used to determine TS (AACC International method 76−13.01). The sample (~100 mg) and 80% (v/v) ethanol (0.2 mL) were added to a glass test tube and mixed on a vortex mixer. A magnetic stirring rod was added to each tube, and the tubes were

DOI: 10.1021/jf504112z
J. Agric. Food Chem. 2015, 63, 1234−1241

placed in an ice water bath before 2 M KOH (2 mL) was added to each tube with stirring. The tubes were removed after 20 min, and 1.2 M sodium acetate buffer (8 mL) was added to each tube with stirring. Thermostable α-amylase (0.1 mL; 3,000 U/mL) and amyloglucosidase (0.1 mL; 3,300 U/mL) (Megazyme) were added to each tube. The tubes were incubated in a 50 °C water bath for 30 min with intermittent stirring on a vortex mixer. Samples were diluted to 100 mL with distilled water, centrifuged, and the supernatant was retained for analysis. The K-GLUC (GOPOD format) assay kit from Megazyme was used for the determination of D-glucose using glucose oxidase based on absorbance at 510 nm as read on the UV−vis spectrophotometer.

Rapidly Digestible Starch (RDS), Slowly Digestible Starch (SDS), and Resistant Starch (RS). RDS and SDS were determined using the colorimetric version of the procedure described by Englyst et al.[26] as modified by Barros et al.[13] Dried, ground sample (0.20 g) was used for the analysis. The enzyme mixture was prepared from α-amylase (A3176, Sigma-Aldrich, St. Louis, MO) and purified amyloglucosidase (Cat. No. E-AMGDF, Megazyme International) at concentrations of ~300 U/mL and ~95 U/mL, respectively. The K-GLUC (GOPOD format) assay kit from Megazyme was used for the determination of D-glucose using glucose oxidase based on absorbance at 510 nm as read on a UV−vis spectrophotometer (Shimadzu Scientific Instruments). RDS was determined by stopping digestion after 20 min, whereas SDS was based on 120 min of digestion. The K-RSTAR assay kit from Megazyme was used to determine RS (AACC Int. Method 32−40.01,[21]). Results were expressed on a TS basis.

Protein Analysis. *Total Protein Determination.* Nitrogen content of dried samples was determined by combustion using a LECO instrument (LECO Corporation, St. Joseph, MI) and converted to total protein by a factor of 5.7.

Insoluble Protein (IP) Determination. The soluble protein fraction was extracted as described by Schober et al.[27] Samples (100 mg) were extracted three times in 1 mL of 50% 1-propanol for 5 min. This solvent systems was selected because it is known to preserve PA−protein complexes.[28,29] The samples were centrifuged after each extraction. The supernatant from each extraction was discarded. The sample remaining after extraction contained the IP fraction. The pellet was freeze-dried, and its protein content was determined by combustion as mentioned previously.

In Vitro Protein Digestibility. Protein digestibility was measured using the in vitro pepsin digestibility assay of Mertz et al.[30] except that protein was quantified using nitrogen combustion analysis as described above.

Statistical Analysis. All procedures were performed in duplicate. Means and standard deviations were determined using Microsoft Office Excel 2010 (Microsoft Corporation, Redmond, WA). Statistical Analysis Software (SAS) version 9.3 (SAS Institute, Cary, NC) was used for data analysis. Differences in treatments were determined at the 5% significance level (α = 0.05) using the general linear model (GLM) and least significant difference (LSD) for mean separation.

RESULTS AND DISCUSSION

Effect of Processing on Total (Folin) Phenolic Content. The content of phenols present in the dry ingredient mix (dry mix) was determined in a mixture of all dry ingredients without the shortening, and final values were calculated to account for the shortening used in the formulations. As expected, the samples with brown and black sorghum brans had much higher phenols in the dry mix than those made with wheat and white sorghum brans (Figure 1). In the treatments with wheat and white sorghum bran, extractable phenol content initially increased upon dough formation and then decreased with processing and storage ($p < 0.05$) (Figure 1). This may be attributed to increased extractability of phenols from the dough as compared to the bran and flour in the dry mix. Phenolic acids are the predominant phenolic compounds in wheat and white sorghum but are commonly bound to the cell wall.[31,32]

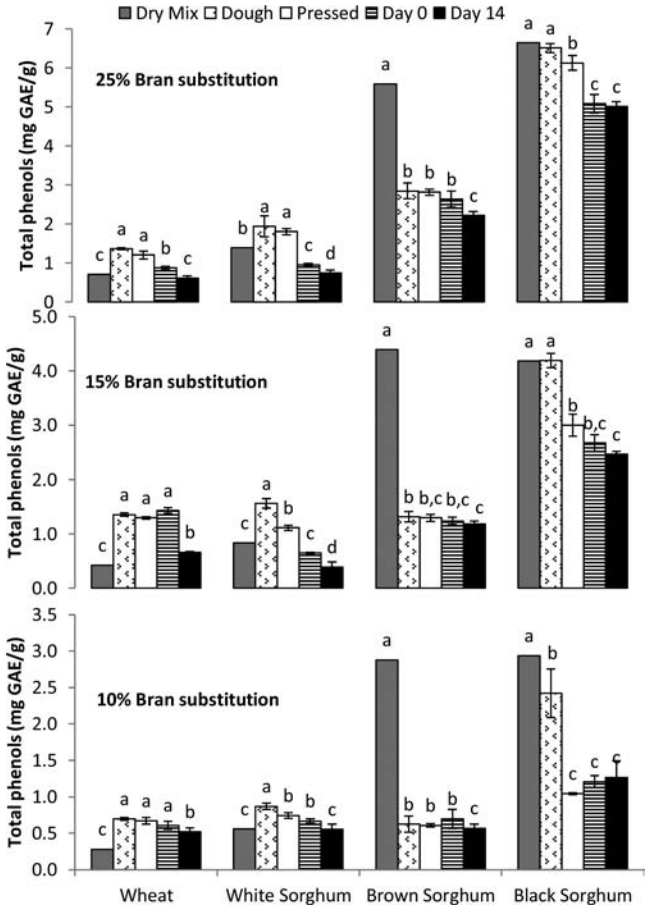

Figure 1. Effect of processing step and bran source on extractable phenols (mg GAE/g) in wheat flour tortillas processing and storage. Bars with the same letter within the same bran treatment category are not statistically different ($p < 0.05$, LSD).

Abdel-Aal and Rabalski[33] observed an increase in free phenolic acids in flat bread dough when prepared with whole grain einkorn wheat flour.

For black sorghum bran treatment, dough formation did not affect extractable phenol content except at 10% bran substitution, where the net change was modest (Figure 1). In general, it appears that the monomeric 3-deoxyanthocyanidins, which are the dominant extractable phenolics in the black sorghum bran, did not significantly interact with dough components. On the other hand, dough formation dramatically decreased the total phenol content in brown sorghum bran treatments (Figure 1). The brown sorghum bran treatments exhibited 58, 69, and 78% decrease in extractable phenols at 25, 15, and 10% substitutions, respectively, in the dough compared to the dry mix.

The large decrease in extractable phenols in dough prepared with brown sorghum bran compared to the other bran treatments suggests that the phenols present in the brown sorghum bran interacted with proteins or starch upon dough formation in a fundamentally different way than the phenols in the other bran treatments. As previously stated, the brown sorghum bran contained the polymeric PA as the dominant polyphenols, which likely accounts for its different behavior. The PA likely formed insoluble complexes with gluten during dough formation.

Interestingly, the changes in extractable phenols in the brown sorghum bran treatments were minimal in subsequent steps

DOI: 10.1021/jf504112z
J. Agric. Food Chem. 2015, 63, 1234−1241

after dough formation (Figure 1). This indicates that the most important chemical interactions that impact the phenolics in the brown sorghum largely occur in the dough. By contrast, significant decreases in extractable phenols were observed in the black sorghum bran treatments postdough formation stage.

Effect of Tortilla Processing on Bran Polyphenol Profile. In general, the phenolic profiles of the black and white sorghum brans were as previously reported,[34] with phenolic acid derivatives dominant in the white sorghum bran treatments and 3-deoxyanthocyanins dominant in the black sorghum bran treatments. The profiles generally did not change during processing, and individual phenolic contents were predictable based on the Folin phenol content trends. An example of 3-deoxyanthocyanin HPLC profile of black sorghum bran treatments is shown in Figure 2. The overall conclusion is

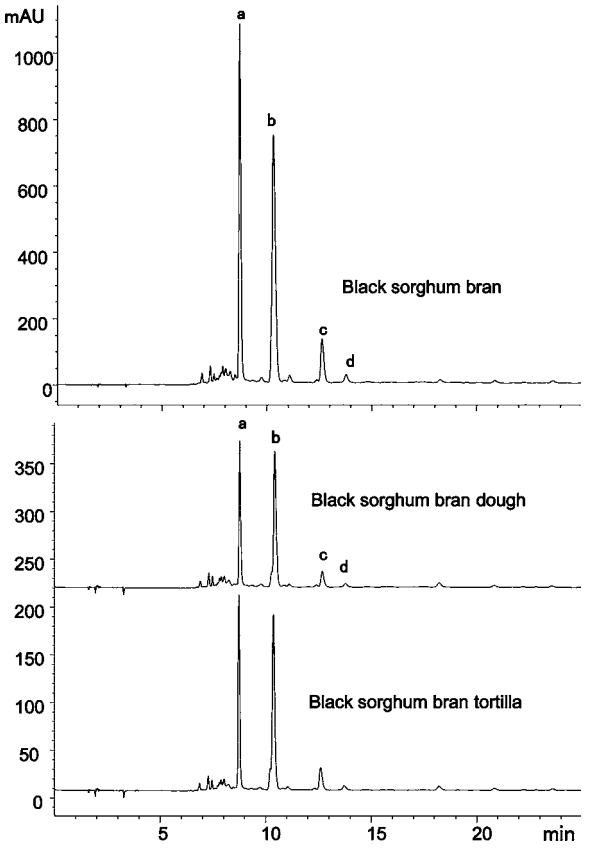

Figure 2. HPLC profile of 3-deoxyanthocyanins in black sorghum bran and dough and tortilla (day 0) made with 25% (baker's) black sorghum bran recorded at 480 nm. The dough and tortilla chromatograms are offset by 100%. Compounds: a = luteolinidin, b = 7-O-methyl luteolinidin, c = 7-O-methyl apigeninidin, d = 5,7-O-dimethyl luteolinidin.

that nonspecific changes in extractability of the monomeric sorghum phenolics are what is impacting the Folin phenols data for white and black sorghum bran treatments and not structural changes (e.g., via thermal degradation) or specific interactions of some of the phenolics in these brans with other ingredients.

The brown sorghum bran treatments, however, presented interesting observations during processing. The brown sorghum bran had a PA profile largely dominated by the high molecular weight polymers (Figure 3), which confirms previous reports.[13] The PA contents of the dry mixes were 0.76, 1.13, and 1.87 mg/g for the 10, 15, and 25% bran substitutions, respectively. In agreement with the Folin phenolic data (Figure 1), the PA, which are the dominant polyphenols in the brown sorghum bran, dramatically declined during dough mixing as determined by normal-phase HPLC (Table 1). The decline in extractable PA in the dough was in the range of 61−72% compared to dry mixes, for the various brown bran substitutions, with the highest decline observed at the lowest bran substitution level. This suggests that the PA in the brown sorghum bran interacted with gluten during dough mixing and thus became less extractable.

We were unable to find any literature reports on interactions of PA with gluten. However, Zhang et al.[35] recently reported that a tannic acid of unspecified source and structure reduced free amino groups in dough when added to flour at 10−30 μg/g. This suggests that the tannic acid participated in cross-linking of the gluten network. It is possible that the PA would participate in similar interactions. Interestingly, after dough mixing, further changes in extractable PA content were relatively small (Table 1), which suggests that most of the "available" or reactive PA constituents in the bran interacted with dough components during mixing. We had previously demonstrated that the PA are relatively stable to thermal processing conditions similar to those used in this study;[13,14] thus, changes during tortilla processing are largely attributable to chemical interactions with other components and not thermal degradation.

Analysis of the PA MW profile during tortilla processing also demonstrated that the most dramatic changes occurred at the dough mixing stage (Figure 3). The higher MW PA decreased the most during dough mixing, which significantly altered the extractable PA MW profile. This suggests specific PA−protein interactions during dough mixing; high MW PA are known to interact more readily with proteins to form insoluble complexes.[10,15] Furthermore, even though the PA can adhere to raw starch and become unextractable,[36] such interaction is limited, nonspecific, and does not affect the MW distribution of the PA.[13] The fact that extractable PA profile remained relatively similar after dough formation (Figure 3) suggests that the protein preferentially bound the high MW PA in the dough, which limited opportunities for PA to interact further during the baking process.

Because the brown sorghum bran itself contained significant amount of proteins, it was important to determine the potential contribution of inherent interactions of the bran PA with the sorghum bran proteins during the dough mixing step to the observed changes in PA profile. The sorghum bran was thoroughly mixed with water (1:0.6, bran:water) and allowed to rest for 2 h at room temperature. The mixture was dried in a convection oven at 45 °C and subjected to PA profiling as described in the Materials and Methods. The PA profile of the wet-mixed sorghum bran was virtually identical to the dry extracted bran (Figures 3 and 4). This suggests that the sorghum bran proteins were not responsible for the dramatic changes in MW profile of the brown sorghum bran dough (Figure 3). More importantly, this provides indirect evidence that the wheat proteins (specifically gluten) are the ones interacting with the PA in the dough. Impact of the above observations on starch and protein properties may provide additional insight.

In Vitro Starch Digestibility. Starch digestibility information is most relevant in final product, thus was only measured in tortillas. None of the bran treatments increased resistant starch content in tortillas relative to refined wheat flour control, and

[a]Values are summation of various MW substituents (see Figure 3 for profile), expressed as mean ± standard deviation, μg/g (db), as determined by normal-phase HPLC. Same letter within row not statistically different ($p < 0.05$, LSD).

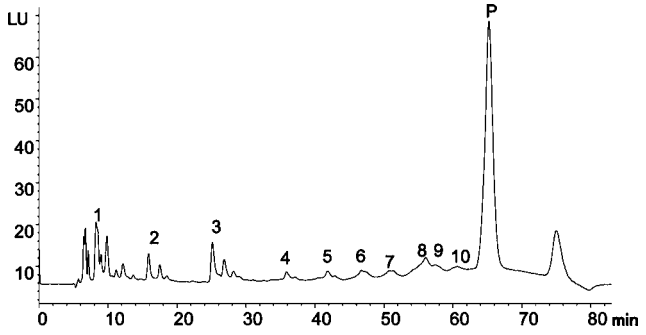

Figure 4. PA profile of brown sorghum bran after mixing with water to imitate dough mixing. Bran was blended with water (0.6 g H_2O/g) and allowed to rest for 2 h before drying in the oven at 45 °C; this was to determine if the PA interaction with the sorghum proteins in the bran contributed to the altered profile observed in the dough (Figure 3). Extraction and analysis followed as described in the Materials and Methods.

all values were below 1% (data not shown). This was contrary to our previous observations using PA and starch in pure systems, where, depending on thermal treatment and starch composition, RS was increased by up to 50% due to interactions with sorghum PA.[14] Thus, the extensive interaction or "binding" of PA observed in the dough (Table 1; Figure 3) likely precluded starch−PA interactions during baking. This further supports the idea that the gluten proteins are the likely components interacting with the PA in the dough.

Contrary to the resistant starch data, significant differences were observed for RDS and the SDS in the tortillas with different bran treatments at 25% substitution level (Table 2). The brown sorghum bran treatment had (as percentage of total starch) the lowest RDS (81.2%) and highest SDS (20.9%) ($p < 0.05$) among all treatments. The rest of the bran treatments were not significantly different from each other or control for RDS (86.1−89.0%) and SDS content (12.2−15.5%) (Table 2). This observation is interesting and somewhat unexpected. We can only hypothesize that the PA likely formed cross-linked networks with gluten during mixing in a way that interferes with amylase enzyme access to starch, likely by physically shielding and slowing, but not blocking, enzyme degradation of starch. Even though the PA can also interfere with starch digestion via enzyme inhibition, the levels used in this study were too low to produce such effect.[17]

The rate and extent of digestion of starch in the small intestine has important implications on glycemic response and calorie impact of starch. RDS causes a rapid peak in blood glucose level as compared to SDS, which takes longer to digest and releases glucose over a prolonged amount of time.[37] Foods that create a moderate glucose response have been shown to

[a]Data reported for day 0 tortillas, all values reported on db. RDS and SDS reported on TS basis. TS and RS were determined independently of RDS and SDS; thus, values may not add up to 100%. All RS values were less than 1% and thus are not reported. Same letter within column not statistically different ($p < 0.05$, LSD).

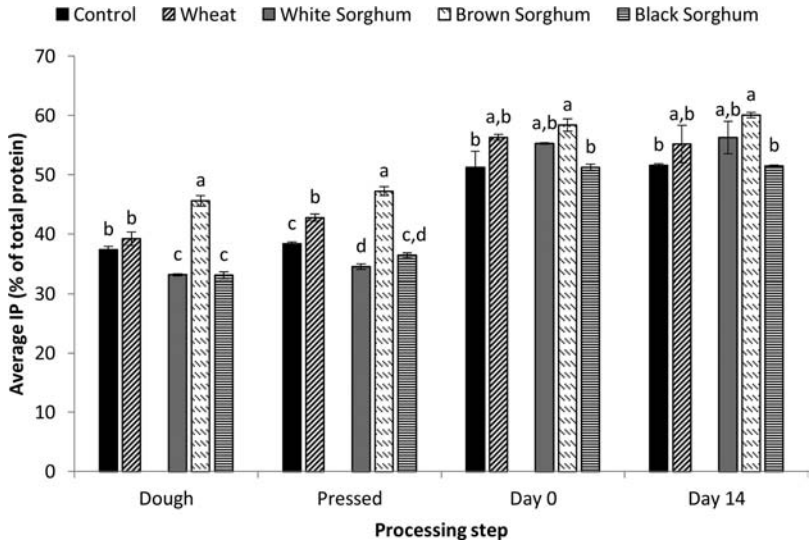

Figure 5. Effect of bran source on IP (% of total protein) content of dough, pressed, day 0, and day 14 tortillas substituted at 25%. Bars with the same letter within the processing step are not statistically different ($p < 0.05$, LSD).

help manage blood glucose levels[38] and may contribute to satiety.[39,40] Thus, the data suggest that sorghum PA may provide a mechanism to modify enzyme degradation kinetics of starch in wheat-based products. However, the PA content of the brown sorghum bran used in this study was relatively low (8.5 mg/g); this may have partly accounted for the less than "dramatic" effect of sorghum PA on starch digestibility in the tortilla matrix. The tannin content is known to affect the feed efficiency of sorghum in vivo, with a minimum tannin threshold needed to produce an effect.[41] In fact, we did not observe any significant difference in starch digestibility among bran substitutions at 15% and 10% levels (data not shown). Thus, it is likely that with a higher level of available PA in the dough formulation, the effect of sorghum PA on starch digestibility would be more significant. Additional work will use purified PA fractions to uncover specific types of interactions of the PA with wheat proteins and how starch digestibility is impacted.

Protein Extractability and in Vitro Digestibility. On the basis of observations for starch digestibility, for protein extractability (in 50% 1-propanol) and digestibility (based on in vitro pepsin assay[30]), only the 25% bran treatments were compared. Protein content of all sorghum bran treatments were similar (Table 2). IP content (as a percent of total proteins) of wheat bran dough was similar to the control but different ($p < 0.05$) from all the sorghum bran treatments (Figure 5).[42] The IP contents of black and white sorghum bran doughs were significantly lower (average 330 mg/g protein) than the wheat bran treatment and control (average 390 mg/g protein) (Figure 5). This may have been due to inherent differences in IP composition of sorghum and wheat brans. Interestingly, the brown sorghum bran dough had significantly higher IP content (456 mg/g protein) than all other treatments. This further suggests that the PA in brown sorghum bran bound to the wheat proteins during dough mixing and formed insoluble complexes, which thus agrees with our hypothesis that the drop in higher MW PA extractability was due to PA–protein complexation.

The fact that the brown sorghum bran dough had proportionately almost 40% higher IP than the other sorghum bran doughs is particularly revealing given that only 1.87 mg extractable PA/g was present in the brown sorghum bran dry formulation at 25% substitution (Table 1). This suggests a rather significant binding capacity of the sorghum PA with the wheat proteins. On the basis of the fact that approximately 1.15 mg PA/g became unextractable at the dough mixing stage (Table 1), we assume this is the amount of PA that complexed with the proteins. If we further assume that the brown sorghum bran dough had similar protein composition as the other sorghum bran treatments, we can estimate that 1.15 mg of PA resulted in the formation of 126 mg of insoluble protein complexes. Furthermore, it is safe to assume that a portion of the PA complexed with native wheat IP; thus, the amount of PA that produced the 126 mg of "new" IP is likely less than 1.15 mg. This suggests a relatively high binding ratio of sorghum PA with the wheat proteins compared to those reported for other protein sources.[3,28]

J. Agric. Food Chem. 2015, 63, 1234–1241

The large differences in IP between the brown sorghum bran treatment and the other sorghum bran treatments indicate that the PA in the brown sorghum bran were involved in cross-linking with the gluten proteins to form insoluble complexes quantified as IP at the dough mixing stage. This is consistent with the dramatic decline in PA in the brown bran dough previously discussed (Table 1). The fact that the black bran treatment, which had higher Folin phenol content than all other brans and did not differ from white sorghum bran treatment, indicates that the monomeric polyphenols are not involved in protein cross-linking in the dough. Thus, it is apparent that the proline-rich gluten proteins have high affinity for, and readily interact with, the sorghum PA to form insoluble complexes.

For all treatments, IP increased with thermal processing (pressing and baking), with the largest increase observed after baking (Figure 5). The changes in IP during 14 day storage was minimal. Increase in IP after baking was expected; heat is known to reduce solubility of wheat gluten proteins, especially glutenins.[43] Tortillas prepared with brown sorghum bran also had the highest amount of IP after baking (58.4%) and storage for 14 days (60.1%), but were statistically similar to wheat and white sorghum bran treatments ($p < 0.05$) (Figure 5). The day 0 and 14 tortilla samples prepared with white and black sorghum bran were statistically similar to the wheat bran and control ($p < 0.05$). Sorghum proteins, specifically kafirins, have been shown to cross-link upon heat treatment and become insoluble.[44,45] This may have contributed to the larger increase in IP of white and black sorghum bran treatments (23 and 19%, respectively) after baking as compared to the control and wheat bran treatment (14 and 16%, respectively). The increase in IP of brown sorghum bran after baking (14%) was not as large as for the other sorghum bran treatments. Some of the proteins that would contribute to this effect due to cross-linking upon heat treatment were likely already interacted with the PA and became insoluble in the dough formation step.

In vitro protein digestibility of tortillas was lowest for the brown sorghum bran treatment but not significantly different from the black sorghum treatment (Table 2). The control proteins had the highest ($p < 0.05$) digestibility, followed by wheat and white sorghum bran treatments. The evidence points to a potential impact of the PA on protein digestibility in the tortillas, but this is not conclusive based on the data. In general, sorghum tannins are known to reduce protein digestibility, but as previously stated, evidence indicates that a minimum amount of the tannins in a matrix is required to produce this effect.[12,41,46] In this study, only 2.1 mg/g PA was present in the 25% brown sorghum bran dry formulation; this may have been too low to produce a practically significant effect.

The overall data suggest that the interaction of sorghum PA with wheat dough proteins is significant and results in the formation of insoluble complexes. The monomeric polyphenols present in the black and white sorghums do not appear to interact much with gluten. Even more important was the fact that SDS was significantly increased, and RDS decreased, in tortillas made with the sorghum bran with the PA. This suggests that the sorghum PA have a potential as ingredients that can be used to beneficially modify starch digestibility in wheat-based baked foods for populations where excess calorie intake is a problem. We suspect that higher levels or more pure PA inclusion in dough formulation will have a more dramatic effect on starch digestibility profile.

the tissues of the peduncles and rachises from veraison to harvest for *Vitis vinifera*, coupled with the fact that we have shown peduncle color evolution parallels with the berry ripening process, we wished to further examine the link between grape stem (peduncle and rachis) color change and their associated chemical evolution. Consequently, the aims of this study were 3-fold: (1) to investigate the change in the chemical composition of five key parameters of the peduncles and rachises separately from veraison to harvest over two vintages: these being moisture content, total chlorophylls (including chlorophyll *a* and *b* levels), total carotenoids, total phenolics, and their antioxidant capacity (DPPH) levels; (2) to statistically model the relationships between peduncle chemical compositional change and peduncle color evolution; and (3) to examine the potential codevelopment between peduncle and rachis chemical composition and the corresponding traditional berry ripeness parameters (°Brix, pH, TA, total anthocyanins, and phenolics) from veraison to harvest. Such comparisons between berry ripeness development and grape stem color and associated chemical changes from veraison to harvest may provide for a new opportunity to assess grape quality and maturity over time in a nondestructive manner and consequently assist in the harvest decision making within a certain vineyard.

MATERIALS AND METHODS

Chemicals and Reagents. Methanol and sodium carbonate were purchased from Chem Supply (Australia). 1,1-Diphenyl-2-picrylhydrazyl (DPPH), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), ascorbic acid and magnesium oxide (MgO) were obtained from Sigma-Aldrich (Australia). Hydrochloric acid (HCl) was supplied by VWR (Australia). Folin-Ciocalteau reagent was from Merck (Germany).

Peduncle and Rachis Samples. All 8 patches were coded as Shiraz (SH) followed by position within vineyard with the key viticultural details of each patch such as row orientation, year of planting etc being reported previously.[1] Grape bunches (48) were sampled from each of the 8 Shiraz patches predominantly on a weekly basis from veraison to harvest during the 2011/2012 and 2012/2013 seasons at Longview vineyard (GPS position: 138°49′54″E, 35°11′25″S). Veraison was determined to be on Jan, 24th (DAF 64) in 2012 and Jan, 29th (DAF 67) in 2013 when 50% of the berries showed purple colorization. The samples were transported to the laboratory immediately under a blanket of dry ice. During the 2012 vintage, 24 bunches were randomly selected to obtain 24 peduncles and 24 rachises from the 48 sampled bunches from each patch on each sampling day. The peduncles and rachises were immediately scanned into JPEG images. During the 2013 vintage, 24 peduncles were obtained from each of the 8 patches of Shiraz and scanned for image analysis. Since preliminary data analysis of the 2012 data indicated that the change in color or chemical traits of the rachises showed no significant correlations with berry ripeness parameters and given the logistics of collecting such data, rachis samples were only analyzed from two representative patches (SH 2N and SH 15) in 2013, the results of which would be comparable to all eight patches in 2012. Images containing peduncles and/or rachises were analyzed semi-automatically using a customized code employing Matlab together with its Image Analysis Toolbox (Mathworks Inc., Natick, MA, USA). For each peduncle or rachis, the code extracts the average color values in both RGB (red, blue and green) and CIE$L^*a^*b^*$ color systems. The code for image analysis is available upon request.

Determination of Moisture Content. The fresh weight of the scanned samples was measured in bulk (in 2012, total weights of 24 samples per patch; in 2013, the 24 peduncles from each patch were divided into four groups according to their four sampling row numbers, and the weight of each group of 6 samples was measured at each sampling). After storing the samples at −20 °C overnight, all samples were freeze-dried completely for 24 to 48 h depending on the sample amount utilizing a freeze drier (FreeZone 6, Labconco, USA). The freeze-dried peduncles and rachises were weighed to calculate their moisture levels. Approximately 2 g of each dried sample were ground into a very fine powder employing a Retsch mill at 30 Hz, 2 min for peduncles and 1 min for rachises, with the remaining of the samples sealed and stored at −20 °C for additional analyses.

Determination of Chlorophyll and Carotenoid Contents. Ground samples of peduncle or rachis (100 mg) were mixed with 100 mg of MgO to neutralize plant acids and prevent pheophytin *a* formation.[26] The chlorophylls and carotenoids were extracted in 5 mL of methanol in a glass vial. After mixing rigorously, the samples were shaken at 100 rpm in the dark at 4 °C for 2 h, employing a nitrogen blanket in the vials. The samples were then transferred into 2 mL microtubes for centrifugation (15 min at 14,000 rpm, 15339*g*, 4 °C). Triplicate sample extractions were conducted for each patch on each sampling day. The supernatants were scanned at 750, 665, 652, 520, and 470 nm absorbance (A) using quartz microcuvettes with methanol as blank. The concentrations of chlorophyll *a* (Ca), chlorophyll *b* (Cb), total chlorophylls ($Ca+b$), and total carotenoids ($Cx+c$) in the samples were calculated utilizing the following equations for methanol extracts as detailed elsewhere,[26−28] and the results recorded as microgram/gram sample dry weight.

$$Ca = 16.72A_{665} - 9.16A_{652}$$

$$Cb = 34.09A_{652} - 15.28A_{665}$$

$$Ca + b = 1.44A_{665} + 24.93A_{652}$$

$$Cx + c = (1000A_{470} - 1.63Ca - 104.96Cb)/221$$

Total Phenolics Analysis. A mixture of 10 mL of 80% aqueous methanol with 0.1% HCl was added to 100 mg of either the dried peduncle or dried rachis samples, and the extracts were shaken at 150 rpm at ambient temperature for 2 h under a blanket of nitrogen. They were then transferred into 10 mL centrifuge tubes for centrifugation at 5000 rpm (2370*g*), 4 °C for 15 min. The supernatants were stored at −20 °C before analysis. Triplicate sample extractions were conducted for each patch at each maturation stage, and all samples were prepared in duplicate for the phenolics assay of each of the phenolic extracts. The total phenolics content of the extracts was measured utilizing the Folin-Ciocalteu method in 96 well plates employing a liquid handling robot for sample loading (Corbett Robotics, Australia). In brief, the Folin-Ciocalteu reagent was first diluted by 25:240 with water. To each microplate well, 255 μL of the diluted Folin-Ciocalteu reagent and 4 μL of the phenolic extract were added and mixed well. After 6 min, 45 μL of 200 g/L Na_2CO_3 was added and the solution was mixed thoroughly. After leaving in the dark for 2 h at room temperature, the plates were read at 765 nm using a microplate reader (Tecan infinite M200 Pro, Australia).[29] Gallic acid was employed as a standard, and all standard curves displayed $R^2 > 0.99$ with the results being recorded as mg gallic acid equivalence per gram sample dry weight.

Determination of Antioxidant Capacity—DPPH Assays. The extracted phenolic samples and Trolox standard solutions were diluted 10-fold using 80% aqueous methanol by the liquid handling robot (Corbett Robotics, Australia), and their antioxidant capacity was measured utilizing a microplate DPPH assay, in a similar fashion to that reported previously with some modification.[30] A 180 μM DPPH solution was prepared in 80% aqueous methanol. To each well in the 96-well plate, 200 μL of the DPPH solution was added followed by 22 μL of the diluted phenolic extracts of ground peduncle or rachis or standard solutions of Trolox before mixing thoroughly. All samples were prepared in duplicate for the DPPH assay of each of the phenolic extracts. The plates were placed in the dark at ambient temperature for 6 h and then read at 520 nm absorbance (Tecan infinite M200 Pro). Trolox was used as a standard, and all standard curves displayed $R^2 > 0.99$ with the results being recorded as μM Trolox equivalence per gram sample dry weight. Ascorbic acid solution (80 mg/L) was used as a reference in each plate.

[a]DAF: days after flowering. All chemical data are predicted means ± standard errors (estimated with REML, GenStat) [sample size: n = 24 for peduncles, measured for 8 patches on each sampling day; n = 6 for rachises, measured for 2 patches on each sampling day]. [b]Sample: P represents peduncles for 8 Shiraz patches, R represents rachises for 2 patches (SH 2N and SH 15). [c]All weight and moisture data are predicted means ± standard errors [sample size: n = 32 for peduncles, n = 8 for rachises on each sampling day].

Statistics. Univariate repeated measurement analyses with heterogeneous variance over time were conducted for the 2012 and 2013 seasons separately employing the REML procedure in GenStat (GenStat for Windows 16th edition. VSN International, Hemel Hempstead, UK). In the REML mixed models, time (DAF) was the fixed effect factor, and the random effects were patch and patch by time. Predicted means and their standard errors (reported in the tables herein) were calculated for each parameter separately. For the analysis and estimation of nonlinear models the FITCURVE directive in GenStat was employed.

RESULTS AND DISCUSSION

Peduncle and Rachis Chemical Compositional Change during Ripening. The changes in moisture content (fresh and dried weight), total chlorophylls (including chlorophyll *a* and *b* levels), total carotenoids, total phenolics, and their antioxidant capacity (DPPH) levels occurring in the tissues of the peduncles and rachises from veraison to harvest are summarized in Tables 1 and 2 for the 2012 and 2013 seasons, respectively.

DOI: 10.1021/jf504215e
J. Agric. Food Chem. 2015, 63, 1242−1250

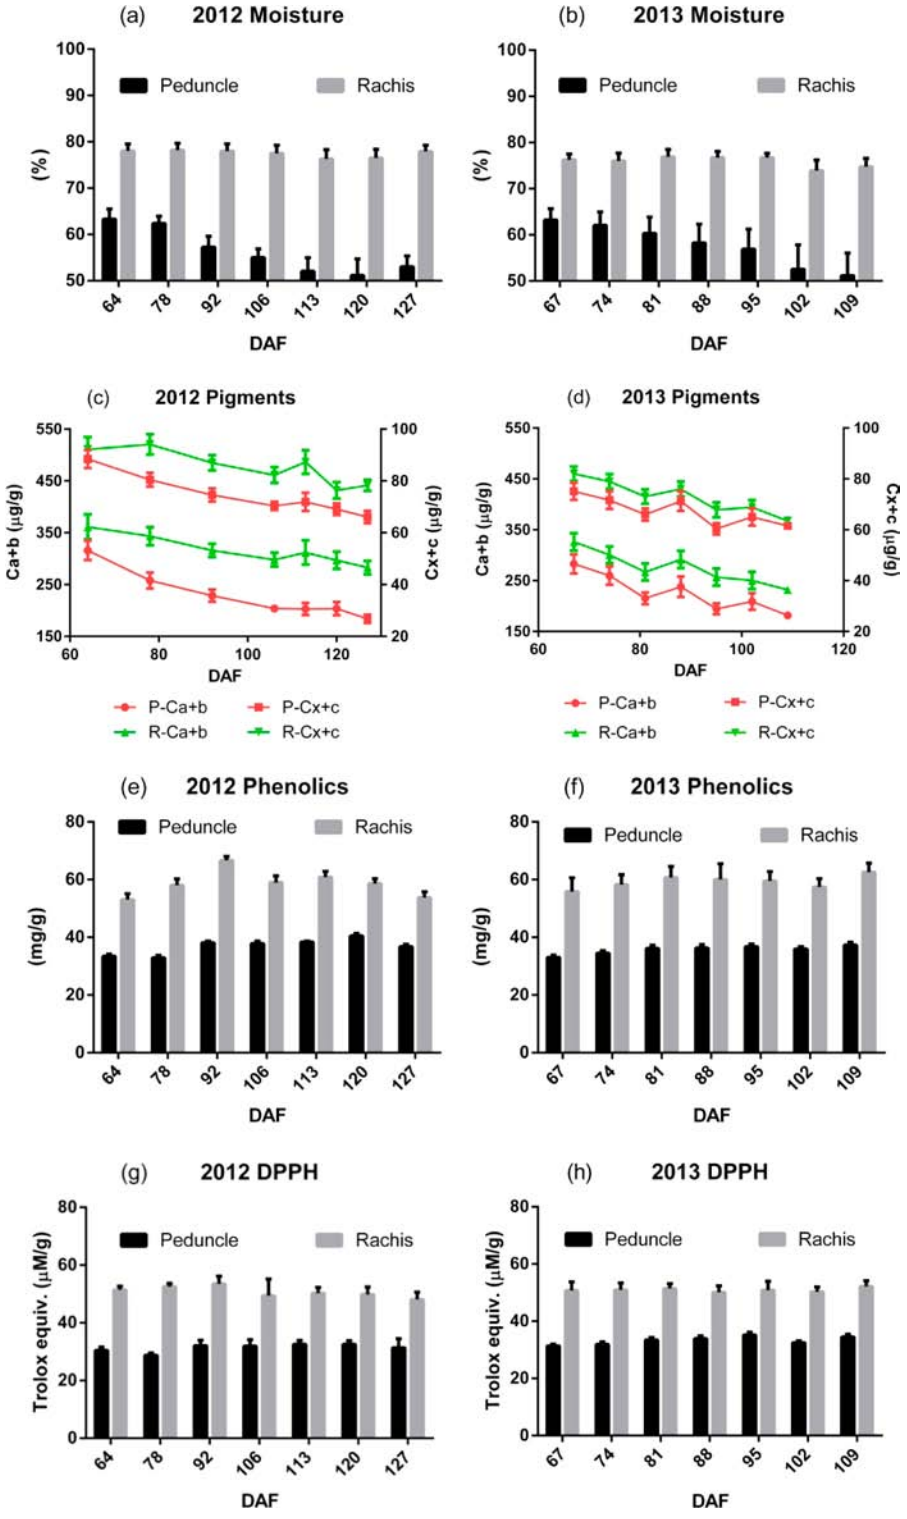

Figure 1. Moisture content, total chlorophylls (*Ca+b*), total carotenoids (*Cx+c*), total phenolics, and antioxidant capacity (DPPH) levels of the peduncles and rachises as a function of time (DAF) from veraison to harvest during the 2012 and 2013 seasons.

Figure 1a displays the change in the average moisture content of the peduncles and rachises over time (DAF). Rachises always contained higher moisture content when compared to the peduncles. Furthermore, it was found that rachis moisture levels remain steady at around 78% from veraison to harvest while the moisture levels of the peduncles decrease by some 10% ± 1.4% from veraison (63%) to harvest. Moisture contents were again measured during the 2013 season (Table 2, Figure 1b), and again the moisture levels of the rachises remained steady from veraison to harvest at around 76% while the peduncles displayed a decrease in moisture content of 12% ± 1.4% over the course of berry ripening. While there are no direct reports in the literature that may be used for comparison, it has been reported on numerous occasions that grape stems (combined peduncle, rachis, and pedicels) from winery waste contain an average of 60−70% moisture.[6,10,31]

DOI: 10.1021/jf504215e
J. Agric. Food Chem. 2015, 63, 1242−1250

From our data, the overall stem moisture content calculated from the combined peduncle and rachis moisture levels fluctuates between 66 and 78% throughout the ripening season and at harvest it can be estimated to be 73% ± 1% in 2012 and 71% ± 2% in 2013, levels which compliment those cited above for winery stem waste. While not directly related to this study, the fresh weight of Shiraz seeds has also been reported to decrease after veraison, with water loss declining until 91−92 DAF before reaching a plateau, a finding also reported by others for Tempranillo seeds.[32,33] Thus, the observed drying out of the peduncles from veraison to harvest may be somewhat related to seed desiccation over time, although further studies would be needed to ascertain this relationship.

Overall, the amount of chlorophyll *a* was found to be some 2.7 times greater in magnitude when compared to that of chlorophyll *b* along the entire veraison to harvest timeline for both seasons (Tables 1 and 2). Consequently and as expected, chlorophyll *a* is the primary pigment and chlorophyll *b* is an accessory pigment in both the peduncles and rachises.[27] Figure 1c and d display the change in total chlorophyll (*Ca*+*b*) and carotenoid levels (*Cx*+*c*) for the 2012 and 2013 seasons, respectively. Overall, the rachises have higher total chlorophyll and carotenoid contents when compared to the peduncles over the entire veraison to harvest ripening period. In terms of total chlorophyll levels, it was observed that the peduncles lost approximately 40% of total chlorophyll from veraison to harvest for both seasons while the rachises lost approximately 25% over the same time frame. Irrespective of whether one is examining total chlorophyll loss for the peduncles or the rachises, there appears to be a concomitant reduction in both the chlorophyll *a* and *b* levels at the same time, as the overall level in total chlorophylls (*Ca*+*b*) over time declines in a steady linear fashion (p-value < 0.01). After the second sampling from veraison (DAF 78 in 2012 and DAF 74 in 2013), the rachises had higher total carotenoid (*Cx*+*c*) levels on average when compared to the peduncles; approximately 14% in the 2012 season (82.2 ± 2.7 in comparison to 70.4 ± 1.9) and 11% in the 2013 season (70.0 ± 2.6 in comparison to 64.6 ± 2.5). Moreover, there is an observed decrease in total carotenoid levels from veraison to harvest for both the peduncles and rachises (p-value < 0.05). Overall, the peduncles lost some 20−25% total carotenoids from veraison to harvest over the two seasons while the rachises display a reduction of some 15−20% total carotenoids over the same time period.

Palliotti and Cartechini measured the pigments within young and old rachises and found that the chlorophyll *a*, chlorophyll *b*, and carotenoid contents were higher in young rachis than old rachis, a finding that correlates with our findings (Tables 1 and 2).[24] On the other hand there are a number of other studies that have examined the total chlorophyll and carotenoid contents of grapes and grapevine leaves over the maturation period. For example, Giovanelli and Brenna observed a decrease in total chlorophylls from fruit-set to harvest for one white and two red Italian grape varieties.[34] Furthermore, Kamffer et al. measured the pigments level in Merlot berries during ripening over two seasons, and they found a decrease in berry chlorophyll and carotenoid levels from veraison to harvest.[35] A number of other studies have reported similar decreasing trends in total chlorophyll and carotenoid levels during the maturation of grape berries.[24,36] Finally, given that leaves are the primary photosynthetic organs of plants, it is not surprising that researchers have investigated the changes in chlorophyll and carotenoid content in leaves during vine growth. For example, Lashbrooke et al. found that the chlorophyll *a* and *b* levels were higher in mature vine leaves when compared to young leaves and their levels dropped post-anthesis.[37] Again, it is too early to determine if our observed changes in total chlorophyll and carotenoid contents of peduncles and rachises are related in any way to those found for grape berries and vine leaves.

Finally, we examined the total phenolics levels and the associated antioxidant capacity (DPPH) of the peduncles and rachises for each patch of Shiraz over the two seasons (Tables 1 and 2). Overall, there was no significant difference (p-value > 0.10) between the amount of total phenolics within the rachises found over the first two sampling time points when compared to the last 5 samplings over both seasons of examination (Figure 1 and f). However, the total amount of phenolics within the peduncles slightly increased after the second sampling date (DAF 78 in 2012 and DAF 74 in 2013, p-value < 0.05) and then remained stable toward harvest in both seasons. The amount of total phenolics was always higher in the rachises (35% in 2012 and 40% in 2013) when compared to the peduncles. Given that the phenolics are the major contributors to the potential antioxidant capacity of the plant tissues, it was not surprising to find that the observed trends in antioxidant capacities of the peduncles and the rachises correlated extremely well with the observed phenolic levels, compare Figure 1g and h with Figure 1e and f. Again, the antioxidant capacity of the rachises was approximately 35% higher after the second sampling (DAF 78 in 2012 and DAF 74 in 2013) when compared to the peduncles over both seasons of examination. For comparison, it has previously been found that the total phenolics levels and overall antioxidant capacity in the stems of Kishmish Chornyi (seedless variety) also remained constant from veraison up until harvest and that the amounts within the stems were greater than those found in the berries or leaves.[23]

Peduncle and Rachis Color and Their Correlations with Moisture and Pigments Levels. Considering that the peduncle and rachis samples in 2012 came from the same bunch stems, it is quite intriguing to see such a significant difference between them in terms of their moisture, total chlorophyll, and carotenoid levels, and total phenolics and antioxidant capacity (DPPH) levels. The rachis tissues displayed higher levels of moisture, total phenolics, and antioxidant capacity (DPPH) throughout the entire maturation process, while the total chlorophyll and carotenoid levels of the peduncles were clearly lower in magnitude after the second sampling, DAF 78 in 2012 and DAF 74 in 2013. Furthermore, our findings above for changes in peduncle and rachis moisture and pigments (total chlorophylls and carotenoids) levels appear to correlate well with our recent findings on the observed color changes of the peduncles and rachises from veraison to harvest for Shiraz. We previously observed that the rachises remain essentially green from veraison to harvest while the overall peduncle color changes from a green soft-unripe state to brittle and brown.[1] We have found herein that the rachis moisture content remains constant while the peduncle moisture content drops during grape maturation. Coupling this observation with the fact that the levels of the pigments (total chlorophylls and carotenoids) of the peduncles dropped to a much greater extent when compared to the rachises, it therefore appears that the observed color change of peduncles from green to brown is primarily driven by a loss of total chlorophyll and carotenoid content coupled with significant dehydration of the peduncle tissue.

[a]All data are predicted means ± standard errors (estimated with REML, GenStat). [Sample size: n = 192, except at DAF 78 in 2012 (n = 96)]. [b]chroma, $C = (a^{*2} + b^{*2})^{0.5}$. [c]hue, $h = arctan2\ (b^*, a^*)$, in this study, $0 < h < \pi$, and when $a^* = 0$, $h = \pi/2$ (1.57).

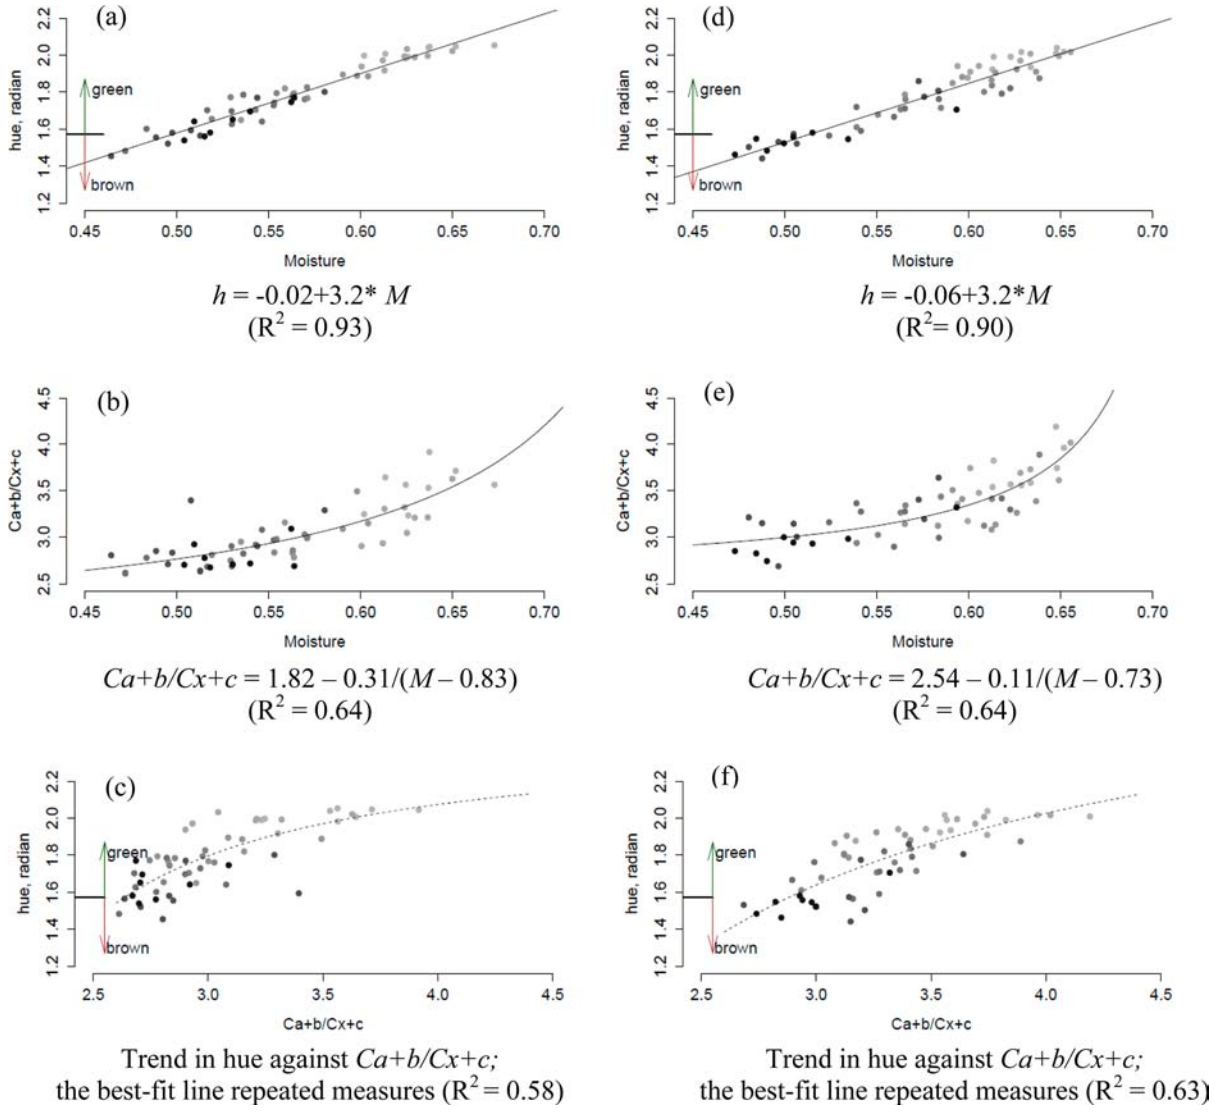

Figure 2. Peduncle chemical and color correlation models with equations for the 2012 and 2013 seasons. (a–c) 2012 data; (d–f) 2013 data. h: hue, $0 < h < \pi$; M: Moisture, $0 < M < 1$; $Ca+b/Cx+c$: weight ratio of pigments, calculated by total chlorophylls/total carotenoids.

Carotenoids serve as an accessory to the light harvesting chlorophylls and aid as photoprotectants during high light conditions or as scavanges during conditions of excessive ROS.[36] The loss or degradation of chlorophylls and carotenoids has been studied and has been shown to increase under conditions of excessive light and oxygen.[38] Consequently, the observed color change of the peduncles from green at veraison to brown at harvest may well be associated with an increase in ROS production which aids pigment destruction in the associated plant tissues. Moreover, lignification of the peduncles may lead to an increase in observed dry weight due to the deposition of starch in the xylem and phloem

J. Agric. Food Chem. 2015, 63, 1242–1250

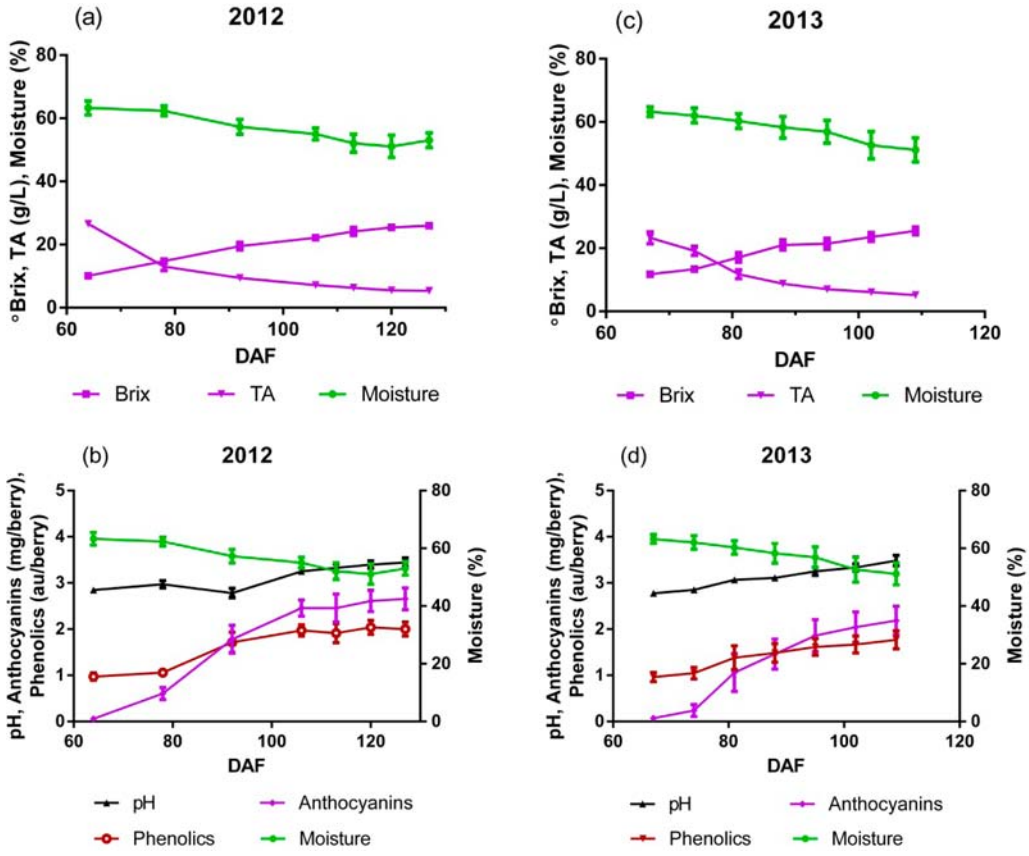

Figure 3. Co-development between peduncle moisture content and prototypical berry ripeness parameters for the 2012 and 2013 seasons.

parenchyma cells as seen in grape stems.[25] Indeed, it appears from the trends in the data that the dry weight of the peduncles increased from veraison toward harvest by more than 10% (17% in 2012 but not significant and 11% in 2013 (p value < 0.01)). When testing this by comparing the first 3 weeks after veraison to the last 3 weeks before harvest, the weight increment was significant (14.0 mg ± 3.8 mg) in 2013 but not significant (25.2 mg ± 26.35 mg) in 2012 (which may be explained by a much larger field variation in the wetter year of 2012 with 100 mm rainfall during vintage compared to 2013 which was considerably drier with 50 mm of rainfall). While at this stage it is clear from these studies that the decrease in moisture content of the peduncles is accompanied by a decrease in total pigments levels, it remains unclear as to why the peduncles indeed initiate such a physiological response in the first place. Several possible hypotheses to explain this observation may include the fact that, as the chlorophyll levels diminish, the requirement for water molecules in the tissues to participate in photosynthesis (i.e., $CO_2 + H_2O +$ photons → sugars + O_2) is lessened; or perhaps it is in some way associated with the known fact that the xylem within the peduncles essentially shuts down after veraison, causing a slowing down of water and solute transport into the berries which may be somehow associated with the dehydration of the peduncle tissues.[39]

With data on the chemical compositional changes for the moisture, total chlorophyll, and carotenoid levels, and total phenolics and antioxidant capacity levels of the peduncles and rachises from veraison to harvest now in hand, we next considered the relationship between these traits and that of the observed color changes seen in the vineyard. In order to do this, we first determined the peduncle and rachis color ($CIEL^*a^*b^*$) change that occurred during ripening in both the 2012 and 2013 seasons. Then the two polar parameters, chroma (C) and hue (h), were calculated from the a^* and b^* color values to quantify the change in peduncle color evolution from veraison to harvest for the 8 Shiraz patches (Table 3).[1]

Independent of which season's data was examined, both the peduncles and rachises had the same green color (same chroma and hue values) at veraison. However, as berry maturation progressed, the peduncles underwent a significant color change, as indicated by a decrease in chroma and hue values (from greenish (over $\pi/2$) to brownish (less than $\pi/2$) based on the color wheel) while the rachises did not change significantly in color intensity and remained essentially green. Statistically, there were no correlations between the color of the rachises over time and the associated moisture and pigments levels and as such the potential use of monitoring rachis color or chemical developmental changes was not considered further herein. However, we found excellent correlations between the change in peduncle color and the associated moisture and pigments levels over time (Figure 2).

Over both seasons of analysis, the average moisture content from a bulk sample of peduncles was predictive ($R^2 > 0.9$) for the average peduncle color hue value with consistent gradient (0.032 rad/(% moisture) in both seasons, Figures 2a, d), and the relationship between peduncle moisture and color existed both between patches and within each patch, suggesting that the relationship was not produced solely from the developmental trends over time. Therefore, if one was to measure the moisture content of a bulk sample of peduncles without knowing their maturation stage, you would still be able to

DOI: 10.1021/jf504215e
J. Agric. Food Chem. 2015, 63, 1242−1250

predict their average color hue value using the equations in Figure 2a and d. Despite the strong correlation between peduncle moisture and color that we have shown herein, there is still a need to further validate this relationship at both overall vineyard level and the individual bunch level.

Moreover, the peduncle moisture level was negatively correlated with peduncle pigments ratio (Figure 2b, e), which could be modeled with a hyperbolic curve but has a weaker prediction power. The relatively low performance of moisture as a predictor for the pigments ratio leads to a loose relationship between peduncle color and the pigments ratio (Figures 2c and f). Even though the peduncle color hue value could also be modeled with a hyperbolic curve against the pigments ratio, the influence of the two parameters on each other was almost at the same extent as the effect of sampling time on peduncle color or pigments ratio. Therefore, although the pigments ratio changed substantially with moisture level and thus affects color, one cannot predict reliably the peduncle color or moisture level from merely the pigments ratio alone; there are obviously other factors influencing peduncle color evolution over time apart from the change in chlorophyll and carotenoid levels. In addition, we also examined the possible relationship between the evolution of peduncle chroma values and moisture content or pigments ratio, but we found that the peduncle chroma values were not as responsive as the hue values to the changes in moisture and were found to be only loosely related to the changes in pigments ratio.

Co-development between Peduncle Moisture Levels and Prototypical Berry Ripeness Parameters. We have previously demonstrated that the change in peduncle color codevelops with the change in berry ripeness parameters, namely °Brix, pH, TA, total anthocyanins, and phenolics from veraison to harvest.[1] Given that peduncle moisture content has a strong linear relationship with peduncle color (Figure 2a and d), it can be speculated that the observed change in peduncle moisture content may also codevelop with berry ripeness parameters. Figure 3 displays an overlay of how peduncle moisture levels and berry °Brix, pH, TA, total anthocyanin, and total phenolics levels changed from veraison to harvest during the 2012 and 2013 seasons. It can clearly be seen that the decrease in peduncle moisture content after veraison parallels with the observed drop in berry TA over both seasons. Furthermore, peduncle moisture content also codeveloped with the observed increase in berry °Brix, pH, total anthocyanin, and total phenolics levels over time. It is also interesting to note that the grapes were determined to be ready for harvest by the viticulturist/winemaker at the time when the peduncle average moisture level dropped to a level close to 50% in both seasons. For example, when the average peduncle moisture level decreased from veraison to harvest to 50%, the berries had an observed 25°Brix, 5.2 g/L of TA, pH 3.49, 2.19 mg of total anthocyanins, and 1.77 au of total phenolics per berry in the 2013 season. In the same way, inspection of the data for the 2012 season also revealed similar codevelopment trends between the changes in peduncle moisture content and the magnitudes of the berry ripeness parameters between veraison and harvest. Given that the grapes were actually defined by the viticulturists and winemakers as ready for harvest, it appears that by utilizing a representative sample of peduncles from an individual patch, one may be able to actually predict the harvest date by just simply measuring their average moisture levels.

Overall we have reported herein the first significant study on how peduncle and rachis moisture content, total chlorophylls (including chlorophyll *a* and *b* levels), total carotenoids, total phenolics, and their antioxidant capacity (DPPH) levels evolve during berry ripening and how this relates to peduncle color change for Shiraz (*Vitis vinifera*). While numerous differences were noted on how the chemical s of the peduncles and rachises change over time, the most significant finding was that there was an excellent linear relationship between the drop in peduncle moisture levels and their associated color hue values. Furthermore, we also found a moderate correlation between peduncle pigment ratio and moisture levels over time. The codevelopment between peduncle moisture level and the corresponding traditional berry ripeness parameters (°Brix, pH, TA, total anthocyanins, and phenolics) from veraison to harvest was also explored, the results of which indicate that monitoring of peduncle moisture levels may be able to be employed to assess grape quality and maturity over time in a nondestructive manner and consequently assist in harvest decision making within a certain vineyard. Since this is the first investigation on how grape peduncle chemistry changes may be linked to berry ripening, further research in the field is needed, with a more extensive sampling procedure that could examine the relationship between berry chemistry and peduncle chemistry at the bunch level.

experiments, they were chosen because of their good combining ability with elite inbred testers. The landraces and introduced populations are further being analyzed for macronutrient content[15] and composition, with the aim to identify accessions with drought tolerance and high oil and/or protein quality. The existence of drought tolerance and grain quality in a single accession should enable more effective improvement of commercial genotypes designed to meet the issues of the ongoing climatic changes and increased food demands because of the population growth.

The objectives of the present study were to (1) explore the variability within the drought-tolerant populations previously identified as potentially high oil accessions by near-infrared spectroscopy (NIR) for (a) oil and protein contents determined by standard laboratory methods, (b) FA composition, and (c) tryptophan content, (2) evaluate kernel physical parameters, (3) determine correlations between the traits, and (4) identify genotypes with nutritional value. Because the drought-tolerant mini core collection was selected in field trials performed in both subtropical and temperate zones, the identified genotypes could be used for breeding value-added maize adapted to both environments.

MATERIALS AND METHODS

Plant Material and Field Trials. A total of 25 accessions from the elite drought-tolerant mini core were increased (via pair crossing, i.e., full-sibbing) in two replications, using a completely randomized block design (RCBD), in Zemun Polje, Serbia, during 2010 and 2011 growing seasons. Walter climate diagrams (Figure 1) illustrate temperature and precipitation conditions during the growing season in these 2 years. Standard agronomic practices were used to provide adequate nutrition and keep the fields disease-free. At least 80 ears per population were collected, dried, and shelled, and samples of kernels from the center of each ear were prepared for the grain quality analysis. NIR analysis (Infratec 1241 grain analyzer, FOSS, Sweden) with artificial neural network (ANN) calibrations was used for oil content determination, on non-destructed kernels (300 g/sample) from each replicate (spectra were collected between 800 and 1100 nm). The analyses were performed at the Faculty of Agronomy, Skopje, Macedonia. A total of 13 potentially high oil accessions, with oil content over 4.5% (average content for maize), were selected for further analysis, with 4 of them from Western Balkan, 2 from Iran, 2 from Italy, and 1 each from Bulgaria, France, Pakistan, and the U.S.A. For one introduced population, there are no available data of origin. Information on the 13 analyzed accessions, including agro-ecological group or country of origin, NIR data, kernel type, and color, are given in Table 1. Kernel types were determined according to the CIMMYT/IBPGR descriptor.[16]

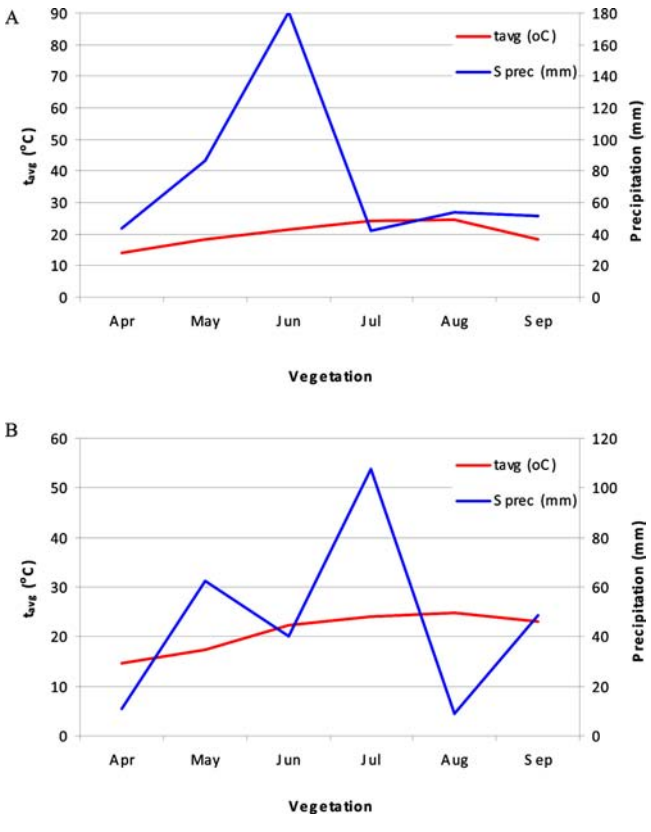

Figure 1. Walter climate diagrams for the years (A) 2010 and (B) 2011 in Belgrade, Serbia. T_{avg}, average temperature (°C); S_{prec}, sum of precipitation (mm).

Determination of the Oil Content and FA Composition. Each accession consisted of 50 g of maize kernels. The oil content was determined by the standard Soxhlet method. Dried kernels were milled in a Cyclotec 1093 lab mill (FOSS Tecator, Sweden) with a particle size of <500 μm, and oil was extracted with hexane in a Soxhlet extractor (INKOLAB, Croatia).

FA composition of the oil samples was determined after transesterification using 0.25 M trimethylsulfonium hydroxide (TMSH, Fluka, Switzerland) in methanol according to EN ISO 5509:2000. Prior to transesterification, 0.05 mL (10 mg mL^{-1}) of the nonadecanoic acid methyl ester (≥99%, Fluka, Switzerland) was added as an internal standard.

The fatty acid methyl esters (FAMEs) were determined by capillary gas chromatography on a GC Shimadzu 2010 (Kyoto, Japan) equipped with a split/splitless injector, fused silica cyanopropyl HP-88 column (length, 100 m; inner diameter, 0.25 mm; film thickness, 0.20 μm; J&W Scientific, Santa Clara, CA), and flame ionization detector. The temperature of the injector was 250 °C, with a split ratio of 1:50, and the detector temperature was 280 °C. Nitrogen was used as the carrier gas at a flow rate of 1.33 mL min^{-1}. The column oven temperature was programmed from 125 to 230 °C. The total analysis time was 50.5 min. FAs were identified by comparing the relative retention time of peaks in the samples to FAME peaks in the Supelco 37 Component FAME mix standard (Supelco, Bellefonte, PA). The chromatographic peak areas were corrected by response factors calculated from the ratios between the peak area of each FA and the internal standard.

Determination of the Protein Content, Tryptophan Content, and Quality Index (QI). Each accession was represented by 60 randomly chosen kernels, divided into two samples of 30 kernels each. Kernels were dried in a controlled oven at 65 °C overnight (16−18 h) and milled in a Cyclotec 1093 lab mill (FOSS Tecator, Sweden) with a particle size of <500 μm. The flour was defatted by hexane treatment for 4 h in a Soxhlet extractor (INKOLAB, Croatia).

The protein content was determined by the standard Kjedahl method using a 2200 Kjeltec auto distillation unit (FOSS, Tecator, Sweden) based on nitrogen determination as explained by Vivek et al.[9] It was estimated from the nitrogen value as percent protein = percent nitrogen × 6.25 (conversion factor for maize).

The tryptophan content was determined using the colorimetric method by Nurit et al.[17] The color was developed in the reaction of flour hydrolysate (obtained by overnight digestion with papain solution at 65 °C) with 2 mL of reagent containing 56 mg of Fe^{3+} dissolved in 1 L of glacial acetic acid and 2 mL of 15 M H_2SO_4. After incubation at 65 °C for 15 min, absorbance was read at 560 nm using an UV-1601 Shimadzu spectrophotometer. The tryptophan content was calculated using a standard calibration curve, developed with known amounts of tryptophan, ranging from 0 to 30 μg mL^{-1}.

QI, defined as the tryptophan/protein ratio in the sample, was calculated as QI = 100(tryptophan content in the sample/protein content in the sample).

Kernel Physical Characteristics. Thousand kernel weight was measured by weighing 5 × 200 unbroken kernels per sample. Flotation

[a]Means followed by the same letter(s) within the same columns are not significantly different ($p < 0.05$). [b]OC = oil content. [c]SFA = saturated fatty acid. [d]MUFA = monounsaturated fatty acid. [e]PUFA = polyunsaturated fatty acid. [f]PC = protein content. [g]TC = tryptophan content. [h]QI = quality index. [i]SD = standard deviation. [j]CV = coefficient of variation. [k]$LSD_{0.05}$ = least significant difference at $p < 0.05$.

index (FI) was measured by soaking 100 randomly selected kernels into an aqueous sodium nitrate solution with a specific weight of 1.25 g cm^{-3} at 35 °C, and values were expressed as a percentage of floating kernels. Kernel dimensions were obtained by measuring thickness, width, and length of a 100 kernels per sample using a digital micrometer. The hull, endosperm, and germ were manually dissected after soaking 50 g of kernels for 2 min in 100 mL of water. After the water was drained, the wet kernels were first manually separated into hull, endosperm, and germ, with the resulting anatomical parts dried in an oven set at 60 °C and weighed to calculate relative percentages. The kernel hardness was measured by a modified Stenvert−Pomeranz method, by milling 20 g of kernels in the micro hammer mill (3600 rpm, 2 mm sieve). Results were expressed as milling response and hard fraction portion (%). The milling response index presents the time (s) necessary for grain grinding until the top level of the material collected in a glass cylinder (125 × 25 mm) reaches the level of 17 mL.

Statistical Methods. All chemical analyses were performed in two replicates, and the results were statistically analyzed. A factorial analysis of variance (ANOVA) for trials was conducted using randomized complete block (RCB) design. Treatment means were tested using Fisher's least significant difference (LSD). All statistical analyses were performed in MSTAT-C software. Pearson's correlation coefficient was used for determining correlations between the estimated traits.

RESULTS AND DISCUSSION

Biochemical Analysis. Laboratory analysis of the oil content in the samples (Table 2) revealed higher values compared to previously performed NIR analysis (Table 1). However, correlation between the two methods was significant at $p < 0.05$ (data not shown). This could be expected, because it was shown that NIR estimation and reference analysis for the oil content in maize kernels were different and that more studies are needed before obtaining accurate measurements using NIR methods.[18] In this context, the oil content determined by the standard Soxhlet method is more accurate.

Populations from the drought-tolerant mini core collection showed significant variability in oil and protein contents as well as in FA composition and tryptophan content (Tables 2 and 3).

However, they can be all considered as high oil and protein genotypes when compared to oil and protein contents of the yellow commodity maize given by Watson;[4] oil content of the analyzed accessions was higher from 35% (IP7001) to 84% (L87), and protein content of the analyzed accessions was higher from 11% (IP7001) to 31% (IP6750). Enhanced nutritional quality of maize with high levels of essential amino acids tryptophan and lysine, such as o2 and QPM, requires tryptophan content and QI (tryptophan/protein ratio) in the whole grain sample to be higher than 0.075 and 0.80%, respectively.[9] Four accessions (L87, IP4842, IP6389, and IP7001) had a low tryptophan content typical for standard maize genotypes. One accession (IP6427) had an elevated tryptophan content of 0.074% (a value close to the threshold of 0.075%) and should be further tested for defining it as a high tryptophan accession. The remaining eight accessions had a tryptophan level over 0.075% and can be considered as high tryptophan genotypes. This also implies that they have high levels of lysine because tryptophan and lysine values are highly correlated and the value of lysine is 3 times that of tryptophan.[9] QI was low in all accessions, with the average value of 0.63.

FA composition for each accession is given in Table 3. Typical dent maize oil has 61.9% linoleic, 24.1% oleic, 11% palmitic, 2% stearic, and 0.7% linolenic acids, while all of the other acids are present only in traces.[12] In our research, palmitoleic (16:1) and heptadecanoic (17:0) acids exhibited less than 0.1% and eicosenoic (20:1), eicosatrieonic (20:3), behenic (22:0), and lignoceric (24:0) acids exhibited less than 0.2% of the total FA content. Arachidic acid (20:0) was the most abundant trace FA, with the average value of 0.49%.

As expected, linoleic (18:2) and oleic (18:1) acids were the most abundant FAs present in the oil samples, accounting for approximately 81−85% of the total FA composition. Their average values were 51.04 and 32.84%, respectively, showing low linoleic acid content and high oleic acid content in comparison to typical dent maize. On average, polyunsaturated linolenic (18:3) and saturated palmitic (16:0) and stearic (18:0) acids were slightly higher than in typical dent maize. Considering saturated fatty acids (SFAs) and unsaturated FAs (Table 2), the most abundant were polyunsaturated fatty acids (PUFAs) with 51.87%, followed by monounsaturated fatty acids (MUFAs) with 33.12% and SFAs with 15.04%. Most of the accessions can be considered high in oleic acid (MUFA) and low in linoleic and linolenic acids (PUFA). Breeding for high oleic acid maize oil can improve the average modern diet rich in saturated fats from animal sources. It was shown that oleic acid has positive effects in reducing serum cholesterol and low-density lipoproteins (LDLs)[7] as well as in preventing degenerative diseases and cancer.[7,19] The same authors found similar positive effects of PUFAs on health, but none of the high oil accessions from the drought-tolerant mini core showed a high content of these FAs. The only exception was accession IP4347, with slightly higher contents of linoleic and linolenic acids than the contents typical for dent maize (62.26 and 0.785% versus 61.9 and 0.70%, respectively). Also, the ω6:3 (linoleic/linolenic) ratios were high, with the average value of 73.15. A significant increase of linolenic acid of over 4% and, thus, a significant decrease in ω6:3 ratio (with values below 10) was achieved in a long-term breeding program through eight cycles of recurrent selection for agronomic traits and high oil content in four subtropical white and yellow maize populations.[20] These changes in linolenic acid content and ω6:3 ratio were achieved from initial populations that had similar contents of linoleic and linolenic acids as our high oil drought-tolerant accessions, suggesting the possibility that they also could be the source for such improvements. This is important because linolenic acid exerts better health benefits but is more prone to oxidation and flavor reversion.

Several accessions can be considered as high SFAs, and some of them had SFAs over 16%. Accession IP6428 proved to be the most prominent high SFA (17.9%), with 13.68% palmitic, 3.20% stearic, and 0.61% arachidic acids. Maize genotypes with high total SFAs can improve manufacturing of margarines and

shortenings without *trans* fats, which raise LDL−cholesterol and lower high-density lipoprotein (HDL)−cholesterol.[12]

Kernel Physical Parameters. Profiles of grain physical parameters are given in Table 4. These parameters are important for dry milling and food processing industries. Because the accessions analyzed in our work are sources of favorable alleles for breeding genotypes with improved nutritional quality, the kernel parameters are to be understood in that context. Kernels with thousand kernel weights greater than 320 g and FI less than 20% are desirable in food processing.[21] In six accessions, thousand kernel weight was over the desirable 320 g, while the remaining seven accessions had lower values from approximately 2% (IP6428 and IP7001) to 15% (IP4353). Great variability was found for FI among the analyzed accessions. It was below 10% in four accessions and below 20% in another two accessions. In the remaining seven accessions, FI was in the range from 20.44% (L87) to 48.2% (L2033). The hardness classification based on FI proposed by Salinas et al.[22] defined that very hard kernels have values between 0 and 12%, hard kernels have values between 13 and 37%, intermediary hard kernels have values between 38 and 62%, and soft kernels have values over 63%. Results showed that none of the accessions had soft kernels, because the highest detected value was 48.20% (L2033).

Kernel dimensions are important for breakfast cereals and oil crushing.[21] The average values of kernel dimensions as well as kernel proportions were compared to average values of these traits given for high oil populations in Preciado-Ortiza et al.[20] Comparisons were performed with data for C7 cycle of selection of four populations, because their oil content (7.5, 7.6, 6, and 6.3%) coincided with the oil content of the accessions. The average kernel dimensions of the accessions were 8.4, 10.1, and 4.4 mm for width, length, and thickness, respectively. Kernel thickness was in good agreement with this trait value found in high oil populations. However, kernel width and length were lower for 5 and 14%, respectively. Considering kernel proportions, the largest part of the kernels was made of endosperm (85.8% on average), followed by the germ (7.6% on average) and the hull (6.6% on average). Endosperm proportions were in good agreement with the same trait by Preciado-Ortiza et al.,[20] but the germ proportions were smaller for most accessions for approximately 28%, except for accessions L244, L632, and L87.

The hardness of the maize kernel is the most important physical characteristic in dry milling and alkaline cooking industries as well as for feed efficiency. Results obtained for milling response showed low variability among the accessions, while higher variability was found for the hard fraction portion. In comparison to 20 commercial hybrids analyzed by Radosavljevic et al.,[23] the average value of milling response was lower (11.84 versus 12.80 s) and that of the hard fraction portion was higher (63.33 versus 58.80%) among the

accessions. The hybrids analyzed by Radosavljevic et al.[23] comprised dent, high oil, waxy, white endosperm, flint, and popcorn hybrids, which showed great variability for hardness. Milling response ranged from 9.4 s (in a dent hybrid) to 19.9 s (in a popcorn hybrid), and the hard fraction portion ranged from 49.6% (in a dent hybrid) to 75.2% (in a popcorn hybrid). The two analyzed oil hybrids showed milling response of 14.1 and 11.6 s, while their hard fraction portion was 63.4 and 58.8%. Because these values coincide with the values obtained for the accessions (Table 4), it can be said that kernel hardness of the high oil accessions is within the range of kernel hardness of the commercial oil hybrids.

Statistical Analysis. Results of the ANOVA for oil content, total FAs, five principal FAs, and protein and tryptophan contents are given in Table 5. Genotype effect was significant for all of the traits analyzed ($p < 0.01$). Year effect was not significant for MUFAs and palmitic, stearic, and oleic acids, while the highest effect was noted for the protein content ($p < 0.01$). Except for stearic acid, all of the other analyzed biochemical components were affected by the genotype × year interaction. Considering trace FAs, the year effect was significant only for eicosenoic ($p < 0.05$) and eicosatrienoic ($p < 0.01$) acids, while genotype and the genotype × year interaction affected all of them (data not shown).

ANOVA for kernel physical characteristics (Table 6) revealed that most of them were not affected by the year, except kernel length, endosperm hardness, and milling response ($p < 0.1$). The genotype effect was significant for all of the traits analyzed at $p < 0.01$, except for hull proportion ($p < 0.05$) and milling response (non-significant). The genotype × year effect was not significant for any of the traits measured. The differences of the values of the traits that were significantly affected by the year are illustrated in Figure 2.

The years differed in total precipitation and number of days, with a maximum temperature over 30 °C during the vegetation period (from April to September), with 2011 having less rainfall and higher temperatures (Figure 1). Biochemical and kernel physical characteristics that were significantly influenced by the year are presented in Figure 2. Although it can be stated that 2010 was optimal and that drought occurred in 2011, oil and protein contents significantly increased in 2011. A significant increase in the same year was also noted for tryptophan, linoleic and linolenic acids, total PUFAs, one monounsaturated trace FA (eicosenoic acid), and two kernel hardness parameters (hard fraction portion and milling response). On the contrary, eicosatrienoic acid, SFAs, and kernel width values were significantly higher in 2010. Most of these results were not expected. It has been shown that drought significantly reduces oil and linoleic acid contents and increases oleic acid content in maize.[24] Similar results were obtained for sunflower[25,26] and in *Moringa oliefera*.[27] However, Petcu et al.[28] found different trends under drought stress, such as an increase in linoleic acid and a decrease in oleic acid of sunflower. This is in accordance with our results, because oleic acid decreased but not significantly (data not shown). Different data on the protein content change under drought stress can be found in the literature. A significant decrease was obtained by Ali et al.,[24] and a significant increase was obtained by Zaidi et al.[29] In the later paper, a significant increase for tryptophan and lysine contents under drought was also recorded. Our results could possibly be explained by rainfall distribution throughout the vegetation period, because total precipitation was not substantially different during the pollination and grain filling period (from July to September) in 2010 and 2011 growing seasons (147 versus 164 mm, respectively). Also, the genotypes analyzed were selected as highly drought tolerant in both subtropical and temperate regions.[14] To precisely determine the effects of drought on the examined kernel traits, an experiment under controlled temperature and water regimes should be performed.

Correlations between biochemical components as well as between biochemical and physical components are given in Table 7. Significant positive correlations were found between oil and protein contents as well as oil and tryptophan contents ($p < 0.01$). Several other studies have shown positive correlations between oil and protein contents in maize kernels.[30−32] Song and Chen[32] reported high positive correlation between lysine and oil, which is in accordance with our results, because lysine and tryptophan values are highly correlated and their ratio is normally 3:1.[9] These positive relationships are important for simultaneous improvement of different nutritional quality traits, because maize is widely used in both human and animal nourishment.

All correlations between oil and principal FA contents were non-significant ($p < 0.05$), but significance was noted with all trace FAs (data not shown). Non-significant correlations between oil and saturated palmitic and stearic acids are in accordance with the results presented in other papers.[33,34] However, in the analysis of elite maize breeding material, Dunlap et al.[35] found small but significant positive correlations between the oil content and levels of stearic and oleic acids. Several other studies representing different genetic backgrounds showed significant positive correlations between oil and oleic acid contents as well as significant negative correlations between oil and PUFA (linoleic and linolenic acids) contents.[33,34,36] In our study, non-significant correlations had the same trend; oleic acid was positively correlated ($r = 0.017$) while linoleic and linolenic acids were negatively correlated ($r = -0.016$ and -0.1363, respectively) with the oil content (data not shown). The lack of significant positive correlations between oil and FAs disables simultaneous selection for increased oil content and FAs, but instead, the

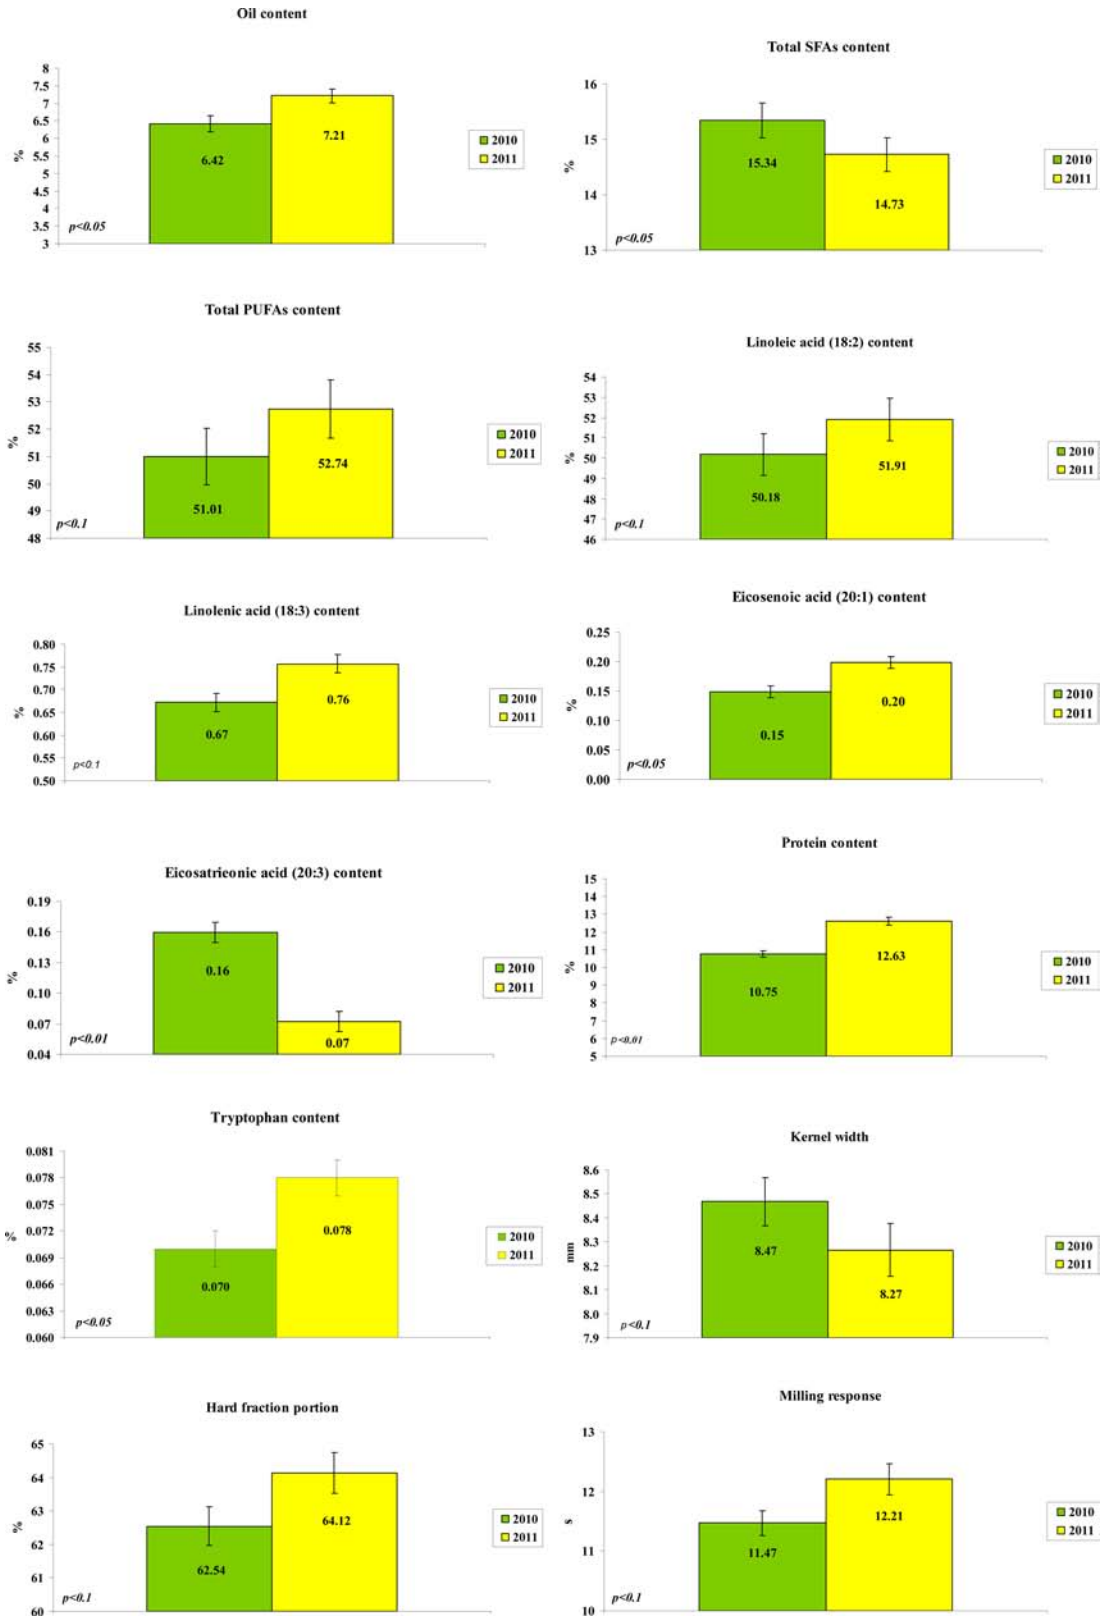

Figure 2. Biochemical and kernel physical characteristics that were significantly influenced by the year. Green bar, optimal temperature and precipitation conditions (2010); yellow bar, drought (2011).

oil content could be increased independently, along with altering FA composition into a desired profile.

Considering correlations between principal FAs, palmitic acid was positively correlated with oleic acid ($p < 0.01$) and negatively correlated with linoleic acid ($p < 0.05$). Correlations between 18-carbon FAs were either non-significant (stearic and oleic, oleic and linolenic, and linoleic and linolenic acids) or significantly negative at $p < 0.01$ (stearic and linoleic, stearic

and linolenic, and oleic and linoleic acids). These results are only partially in accordance with literature data. Wassom et al.[36] found non-significant or weak correlations between palmitic acid and 18-carbon FAs, while all 18-carbon FAs were significantly mutually correlated. On the other hand, Orhun and Korkut[34] reported significant correlations between palmitic acid and 18-carbon FAs and non-significant correlations among 18-carbon FAs. However, a near 1:1 negative correlation between oleic and linoleic acids found within the analyzed accessions was also reported in other studies.[34,36−39] The genetic correlation between oleic and linoleic acids, which is near unity, indicates that most or all of the genes responsible for variation in the accumulation of these two acids are closely linked or pleiotropic.[36]

Correlations between kernel biochemical and physical characteristics revealed, as expected, that the germ proportion was positively correlated with the oil content ($p < 0.01$). This kernel characteristic has been recognized as the most relevant characteristic in high oil breeding programs.[40−43] Among principal FAs, only stearic acid was significantly correlated with germ percent (negatively; $p < 0.01$). This differs from the results presented by Preciado-Ortiza et al.,[20] where all FAs were significantly correlated with germ proportion. In our work, significant correlations with germ were found for all trace FAs (data not presented).

Thousand kernel weight was positively correlated with stearic and oleic acids but negatively correlated with linoleic and linolenic acids. No significant correlation was found between this trait and the oil content, while in the study by Dorsey-Redding et al.,[44] these two traits were correlated at $p < 0.001$. They also noted that the correlation between the protein content and thousand kernel weight was not significant, and this is in accordance with our results for the accessions. Considering other biochemical components analyzed, tryptophan was not significantly correlated with this kernel parameter, while significant positive correlation was found for MUFAs and PUFAs.

The SFA content was significantly correlated with all kernel dimensions and kernel proportions, positively with kernel width, kernel thickness, and endosperm proportion ($p < 0.01$), while negatively with kernel length and hull and germ proportions ($p < 0.01$, $p < 0.01$, and $p < 0.05$, respectively). The hard fraction portion was in positive correlation with palmitic acid and protein content ($p < 0.05$), while milling response was positively correlated with oil, linoleic acid, total PUFAs, and protein content ($p < 0.01$, $p < 0.05$, $p < 0.05$, and $p < 0.01$, respectively) and negatively correlated with oleic acid and total MUFAs ($p < 0.05$ and $p < 0.01$, respectively). These two hardness parameters were also positively correlated with oil and protein contents by Dorsey-Redding et al.[44]

Oil composition and FA concentrations are regulated by more than 40 QTL.[38,45] It is possible that discrepancies in the statistical results of different experiments are due to different genetic backgrounds of the analyzed genotypes and different environmental effects. Differences between our results and results obtained in other studies could also be due to differences in materials analyzed (non-selected populations, versus elite, commercial material). These accessions could harbor alleles not present in commercial germplasm, leading to gene actions involved in oil, FA, and protein metabolic pathways different from the pathways present in elite germplasm.

It was shown that maize kernel nutritional value can be improved by introducing landraces into breeding programs. Genes from exotic germplasm were used for developing maize lines with high total SFAs,[12] and a single cross hybrid was developed from an Italian landrace with high carotenoid content that is being used by an Italian beer industry.[3] The results of biochemical analysis presented in this report indicate considerable potential of the drought-tolerant accessions for improving value-added traits of the commercial genotypes. Moreover, several accessions with multiple nutritional advantages were identified. For example, L632 had high oil and oleic acid contents as well as high tryptophan content, while IP6428 besides high oil and tryptophan contents was also abundant in SFA. On the other hand, positive correlation between palmitic and oleic acids enables the use of IP6428 for improving lines for high contents of these two FAs. Because the drought-tolerant accessions were selected in field trials performed in both subtropical and temperate zones, the identified genotypes could be used for breeding maize with value-added traits adapted to both environments.

bicarbonate supplementation represents a promising strategy to stimulate growth and trigger omega-3-enriched oil production in this species.

Several metabolic studies using lipid and fatty acid analysis[14,21,24−26] or radiolabeled fatty acids,[22,27,28] as well as molecular studies,[29−31] have already been performed to investigate the effect of growth conditions on lipid and fatty acid composition in microalgae, as well as to measure at a transcriptional level the expression of different desaturases and elongases involved in n-3 LC-PUFA biosynthesis.[29,32,33] As an example, it has been demonstrated that the expression of the LC-PUFA front-end desaturase from *P. lutheri* (PlDES1, Δ4-desaturase), which converts 22:5 n-3 and 22:4 n-6 into DHA and 22:5 n-6, respectively, was 4-fold higher during the midexponential growth phase compared to late exponential and stationary phases.[29] However, no metabolic study attempted to measure directly in vivo the effects of environmental factors on desaturase and elongase activities in microalgae. Previous work has provided a method for studying microalgal LC-PUFA biosynthesis pathways and desaturase and elongase activities in vivo using externally supplied radiolabeled fatty acids as direct substrates.[28] Using ^{14}C-labeled dihomo-γ-linolenic (DGLA, [1-^{14}C] 20:3 n-6) and arachidonic (ARA, [1-^{14}C] 20:4 n-6) acids as precursors of EPA and DHA, the metabolic relationship between the n-6 and n-3 fatty acid series have been demonstrated in *P. lutheri* by Δ17-desaturation of DGLA and ARA into 20:4 n-3 and EPA.

Herein, using this method, ^{14}C-labeled ARA (^{14}C-ARA) was also used to assess the effect of light intensity on the incorporation of LC-PUFA into total lipids and the regulation of the final metabolic steps involved in EPA and DHA synthesis in *P. lutheri*. Activities of conversion of ARA into EPA (Δ17-desaturation) and of EPA into DHA (Δ5-elongation + Δ4-desaturation) were estimated under three different light intensities through the distribution of radioactivity into longer and more unsaturated fatty acids using short incubation times (1 and 3 h). The results of this study represented the first data investigating the influence of abiotic factors (i.e., light intensity) on desaturase and elongase activities measured on intact microalgal cells "in vivo" using ^{14}C-radiolabeled fatty acids.

MATERIALS AND METHODS

Chemicals and Radiolabeled Fatty Acids. Radiolabeled [1-^{14}C]-eicosa-5,8,11,14-tetraenoic acid ([1-^{14}C] 20:4 n-6; ^{14}C-ARA), specific activity = 2.07 GBq mmol^{-1}, 99.3% radiochemical purity, was purchased from the Radiochemical Center (GE Healthcare, Amersham, Buckinghamshire, UK). All other chemicals were of analytical and HPLC grades and purchased from Fisher Scientific Bioblock (Illkirch-Graffenstaden, Bas-Rhin, France).

Culture and Radiolabeling Conditions. *P. lutheri* (CCAP 931/6) was batch cultivated on artificial seawater as previously described in 500 mL Erlenmeyer flasks using a working volume of 300 mL under controlled temperature (15 ± 1 °C) and a light−dark cycle of 14 h light using three different light intensities (20, 100, or 340 μmol photons m^{-2} s^{-1}).[28] Cultures in midexponential growth phase (day 14) and midlight period were incubated with 0.3 μM ^{14}C-ARA ammonium salt during 1 and 3 h. The availability and/or accessibility of the ^{14}C-radiolabeled fatty acid substrates have been shown to be nonlimiting under such incubation times for *P. lutheri* grown under intermediate conditions (15 ± 1 °C, 100 μmol photons m^{-2} s^{-1}).[28] To avoid any changes of growth conditions (i.e., decrease in light availability per cell), no concentration of the cells has been performed prior to incubation with ^{14}C-ARA. The final cell density on day 14 was determined with a Malassez improved bright-line hemocytometer, after immobilizing the cells with Lugol 5%. The cell density was estimated to be 2.3, 3.1, and 4.4 × 10^6 cells mL^{-1} at the incubation time, for the three light intensities (20, 100, or 340 μmol photons m^{-2} s^{-1}, respectively). After incubation, algal cells were gently harvested by centrifuging at low speed (1200*g*, 10 min), resuspended, and washed three times with fresh medium. The pellets obtained were then frozen and stored at −70 °C prior to lipid extraction and analysis. Three replicate cultures were grown for each incubation time.

Lipid Radiolabeling Determination. The total lipids were extracted using a modified version as previously described,[14,34] and fatty acid methyl esters (FAMEs) were obtained as described[35] for gas chromatography analysis. The distribution of radioactivity between the different labeled fatty acids was determined by the reversed-phase HPLC method,[36] using a P1500 high-pressure pump (Thermo Separation Products, Les Ulis, Essonne, France), equipped with a 410 differential refractometer (Waters, Milford, MA, USA) and a Lichrocart column (Lichrospher 100 RP-18, 5 mm, 250 mm × 4 mm internal diameter; Merck, Darmstadt, Germany). The samples were eluted using acetonitrile/water solvent system (95:5 v/v) with a flow rate of 1 mL min^{-1}, and the FAMEs were collected at the detector outlet. Figure 1 displays a chromatogram of a mixture of FAMEs

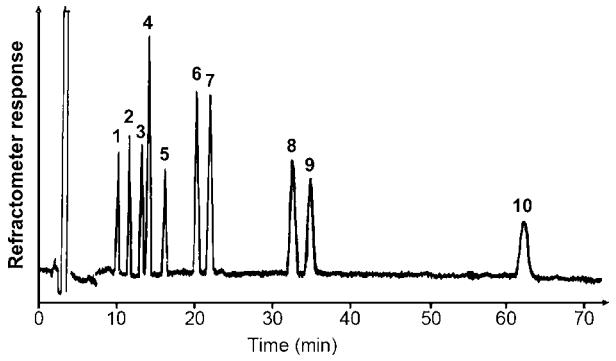

Figure 1. Chromatogram of Mix FAME standards separated using the reversed-phase HPLC method. Peaks: 1, 18:4 n-3; 2, 20:5 n-3 (EPA); 3, 22:6 n-3 (DHA); 4, 18:3 n-3; 5, 20:4 n-6 (ARA); 6, 18:2 n-6; 7, 20:3 n-6; 8, 18:1 n-9; 9, 16:0; 10, 18:0.

separated using the reversed-phase HPLC method described. ^{14}C-Radioactivity incorporated in the total lipid fraction was highly recovered into the FAMEs (percentage of ^{14}C recovered into the FAMEs > 95%). Each individual peak was identified using pure standards (Sigma-Aldrich, St. Quentin Fallavier, Isère, France). The radioactivity levels measured in the total lipid fraction and each individual FAME were expressed in disintegrations per minute (DPM) after correction of the quenching by external standard ratios (ESR) method using a Wallac 1410 liquid scintillation counter (LSC, ECG Instrument, PerkinElmer, Waltham, MA, USA) and liquid scintillation cocktail (ACS, GE Healthcare, Amersham, Buckinghamshire, UK).

Fatty Acid Analysis by GC-FID. Before incubation with ^{14}C-ARA, cultures grown under similar conditions were used to assess the effect of light intensity on *P. lutheri* fatty acid composition. The total lipids were extracted, and FAMEs were prepared as previously described and analyzed with a FOCUS gas chromatography apparatus (Thermo Electron Corp., Les Ulis, Essonne, France) equipped with a flame ionization detector (GC-FID), and a fused-silica capillary column (CP Sil-88, 25 m × 0.25 mm i.d. capillary column, Varian, Les Ulis, Essonne, France). The GC-FID conditions were similar to those used previously.[28] Pure standards (Sigma-Aldrich, St. Quentin Fallavier, Isère, France) were used to identify the fatty acids by comparing the peak retention times of the samples and standards.

Parameters Calculation and Expression. All results and parameters were determined after counting of the radioactivity in DPM. Radioactivity incorporated into the total lipids (Table 1) was expressed in percentage of the radioactivity incorporated into the total lipids in relation to the total radioactivity added in the medium (calculated and expressed in DPM per million cells). According to the

moles of ^{14}C-ARA available per million cells in the medium and the percentage of radioactivity incorporated into the total lipids, results were expressed in picomoles per million cells and in femtomoles per minute and per million cells. Distribution of the radioactivity in each FAME (Figure 4) was expressed in percentage of the total DPM radioactivity incorporated into labeled FAMEs. Enzymatic conversion rates (Table 2) were expressed in percentage of conversion of substrate into longer chain and more unsaturated fatty acids as described by the following eqs 1 and 2:

$$\Delta 17\text{des} = [\Sigma(\text{DPM}_{\text{EPA+DHA}})/\Sigma(\text{DPM}_{\text{ARA+EPA+DHA}})] \times 100 \quad (1)$$

$$\Delta 5\text{elo} + \Delta 4\text{des} = [\text{DPM}_{\text{DHA}}/\Sigma(\text{DPM}_{\text{EPA+DHA}})] \times 100 \quad (2)$$

Enzymatic conversion rates expressed in femtomoles of substrate converted per minute and per million cells were determined using the percentage of conversion (Δ17des or Δ5elo + Δ4des) previously calculated and the radioactivity incorporated into the total lipids and expressed in the same units.

Statistical Analyses. One-way analysis of variance (ANOVA) was used to examine the effect of light intensity (n = 3). The Student−Newman−Keuls (SNK) multiple-comparison test was used to test the differences between groups. Differences were considered significant at a probability level of 0.05. All statistics were performed with Statgraphics (version Centurion XV) software (StatPoint Technologies, Warrenton, VA, USA).

RESULTS AND DISCUSSION

Effect of Light Intensity on Total Fatty Acid Composition. Among the abiotic parameters (e.g., light, temperature, CO_2 disponibility, pH, and nutrients), light stands out as a key environmental factor controlling growth and chemical composition of photosynthetic cells. In microalgae, variations in light regimen impose numerous adaptation mechanisms involving changes in pigment content, biochemical composition, and the capacities of the photosynthetic apparatus.[37−39] In particular, changes in lipid content and fatty acid profile are observed in response to changes in the light intensity.[14,40,41] In our work, *P. lutheri* showed a decrease in the proportions of LC-PUFA, in particular stearidonic acid (18:4 n-3) and EPA, associated with an increase in SFA, especially palmitic acid (16:0), with increasing light intensity (Figure 2). These results are similar to those published for *P. lutheri* grown under identical conditions.[14] This previous study showed that the highest PUFA levels, such as those of EPA, were predominantly found in the galactolipid fraction when the cells were grown under low light, and it has been suggested that accumulation of LC-PUFA in the galactolipids may facilitate

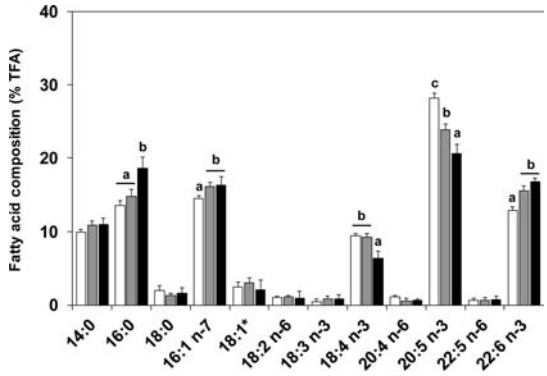

Figure 2. Total lipid fatty acid composition (% TFA) of *P. lutheri* grown under 20, 100, and 340 μmol photons m^{-2} s^{-1} (white, gray, and black bars, respectively), a temperature of 15 °C, and a light−dark cycle of 14 h light and harvested in midexponential growth phase (day 14) and midlight period. Results are expressed as the mean ± SD (n = 3). Means assigned different letters are statistically different (p < 0.05), and results are reported in ascending order: a < b < c.

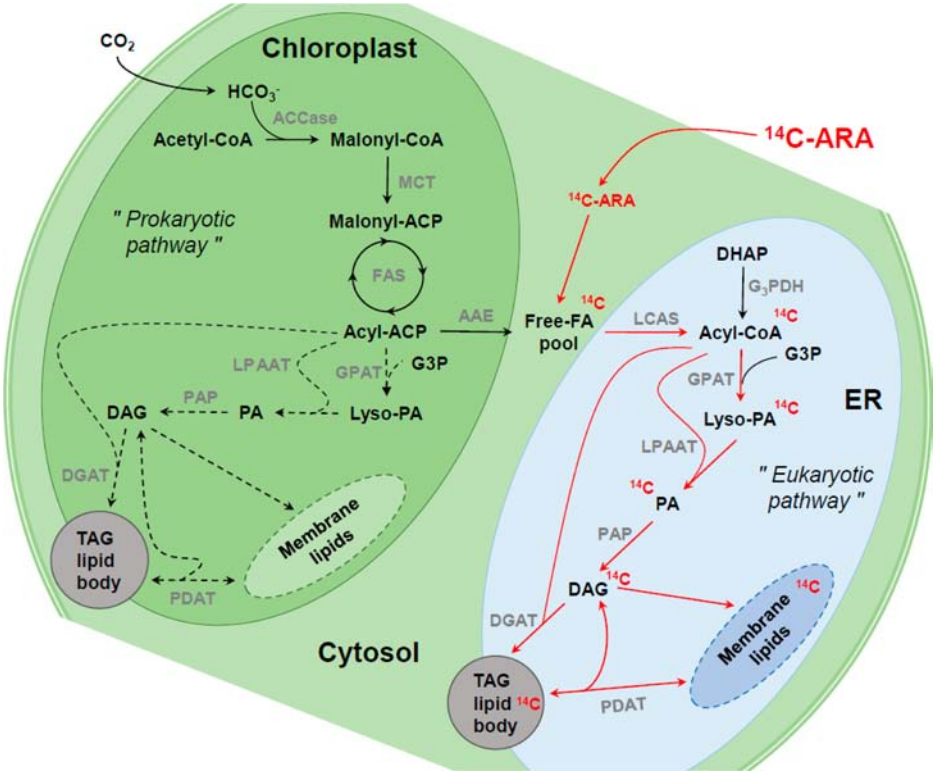

Figure 3. Schematic representation of lipid biosynthesis in microalgae and suggested ways (in red) of incorporation of ^{14}C-ARA into complex lipids of *P. lutheri*. Modified and adapted from previous studies.[42]

thylakoid membrane fluidity and, therefore, the velocity of electron flow involved in photosynthesis during light acclimatization. It is also important to note that ARA accounted for <2% of TFA in *P. lutheri*, suggesting its intermediate metabolic function for longer and more unsaturated LC-PUFA synthesis, whereas EPA and DHA accumulate and reach up to 29% under low light and 18% under high light of TFA, respectively.

Incorporation of ^{14}C-ARA through a Potential Light-Dependent Lipid Biosynthesis Pathway. According to the results reported in Table 1, the incorporation of ^{14}C radioactivity issued from ^{14}C-ARA into total lipids is dependent on the light intensity and the time of incubation. The percentage of ^{14}C incorporated in the total lipid fraction reaches 52% of the radioactivity initially present in the culture medium. After 1 h of incubation and under low light intensity (20 μmol photons m^{-2} s^{-1}), the percentage of ^{14}C incorporated into the total lipid fraction is 2.5 times higher (50% of the radioactivity initially present in the culture medium) than the percentage obtained at 100 and 340 μmol photons m^{-2} s^{-1} (19 and 22%, respectively). Similarly, the amount of ^{14}C incorporated and expressed in picomoles per million cells is highest when the cells are incubated under low light. The average of substrate incorporated per minute and per million cells decreased with increasing light intensity. After 3 h of incubation, the percentages of ^{14}C incorporated were highest at 20 and 100 μmol photons m^{-2} s^{-1} (approximately 52% of the radioactivity initially present in the culture medium), and the amount of ^{14}C incorporated per minute decreased with increasing light intensity. It has been previously demonstrated using [1-^{14}C] 16:0 and [1-^{14}C] 20:3n-6 as radiolabeled fatty acid substrates that 70−80% of the radioactivity incorporated into the cells was recovered in the total lipids of *P. lutheri* whatever the incubation time applied (3, 10, and 24 h).[28] We may assume similar results with ^{14}C-ARA in this study and suggest that the difference may be due to incomplete extraction of the total lipids or losses during this process. The ^{14}C-ARA not incorporated in *P. lutheri* cells was left in the medium, suggesting its nonlimitation over 1 or 3 h of incubation as previously shown.[28]

According to these results, Figure 3 illustrates a suggested way of incorporation of ^{14}C-ARA into complex lipids of *P. lutheri* using a schematic representation of lipid biosynthesis in microalgae. Currently, two locations for de novo lipid biosynthesis have been suggested in microalgae and, more specifically, in *Chlamydomonas reinhardtii*, being the plastid prokaryotic pathway and the endoplasmic reticulum (ER) eukaryotic pathways.[42] The radiolabeled ^{14}C-ARA used in this study may be incorporated into *P. lutheri* cells by diffusion, esterified to CoA by the long chain acyl-CoA synthases (LACS), and therefore associated into the acyl-CoA pool. The LACS gene may be light-dependent and could therefore explained the fast and strong ^{14}C-ARA incorporation into total lipids observed in *P. lutheri* grown under low light. TAG and polar lipids are then assembled using a complex process involving diverse enzymatic activities as presented in Figure 3. As a consequence, ^{14}C-ARA or longer and more unsaturated ^{14}C-radiolabeled fatty acids subsequently synthesized (see the section on LC-PUFA biosynthesis by alternative desaturation and elongation steps), such ^{14}C-EPA and ^{14}C-DHA, may be incorporated into TAG or complex lipids throughout successive acylation steps of the Kennedy pathway.[43,44] Alternatively, fatty acyl donors for production of TAG may also derive from membrane lipids in the acyl-CoA-independent pathway using transacylases or by means of specific lipase activity on membrane lipids, which liberates fatty acyl groups for TAG

DOI: 10.1021/jf504863u
J. Agric. Food Chem. 2015, 63, 1261−1267

synthesis.[42] A similar process using similar enzymes could also be involved in the formation of complex lipids and in the remodeling of fatty acids between membranes. After incubation with ^{14}C-ARA, the high percentage of ^{14}C radioactivity incorporated into total lipids of *P. lutheri* grown under low light could therefore also be explained by an overexpression of all or certain genes encoding acyltransferases or other proteins involved in the process, especially enzymes with strong substrate specificities for lipid membranes containing LC-PUFA such as EPA and DHA. The ability of *P. lutheri* to partition both DHA and EPA to TAG, compared to other microalgal species, raises the question of how this process is regulated.[24] It may involve acyltransferases with different substrate specificities. This could also partially explain the strong ^{14}C-ARA (or other synthesized ^{14}C-LC-PUFA) incorporation into lipids under low light and potentially partitioned to TAGs or complex lipids. Therefore, a high level of expression of specific enzymes, such as acyltransferases, especially under low light conditions, could promote the partitioning of LC-PUFA into complex lipids and could explain the high level of LC-PUFA (e.g., EPA) observed in *P. lutheri* grown under low light intensity and, more specifically, linked to polar lipids (i.e., glycolipids and phospholipids) constituting the membranes.[14,26]

Finally, a strong Δ17-desaturation activity under low light could also explain the high percentage of ^{14}C-ARA incorporated and needed as substrate for the synthesis of longer and more unsaturated fatty acids such as EPA and DHA as described in the following section.

Effect of Light Intensity on the Final Desaturase and Elongase Steps Involved in n-3 LC-PUFA Biosynthesis. In *P. lutheri*, the major radiolabeled fatty acids obtained from ^{14}C-ARA were ^{14}C-EPA and ^{14}C-DHA (Figure 4). After 1 h of incubation, no changes in the percentage of ^{14}C-radioactivity incorporated into EPA and DHA (respectively 38−40 and 2−3% of the total fatty acids labeled) were observed with the level of light. However, after 3 h of incubation, significant variations in the distribution of ^{14}C radioactivity incorporated into the fatty acids were observed with changes in light intensity. The percentage of ^{14}C-EPA was significantly higher when the cells were incubated under 100 μmol photons m^{-2} s^{-1} (61% of the total fatty acids labeled), and the percentage of ^{14}C-DHA decreased under high light (340 μmol photons m^{-2} s^{-1}). Therefore, in addition to the high percentage of ^{14}C-ARA incorporated in the total lipids, the light intensity seems to affect the last desaturation and elongation activities involved in EPA and DHA synthesis in *P. lutheri*. These results are in accordance with several those of other authors and can contribute to the explanation of how the levels of EPA and DHA may vary with light intensity in microalgae.[14,40,45] Whatever the light intensity, the results also show that the proportion of ^{14}C-ARA decreased while those of ^{14}C-EPA and ^{14}C-DHA increased with the time of incubation (data not shown).[28]

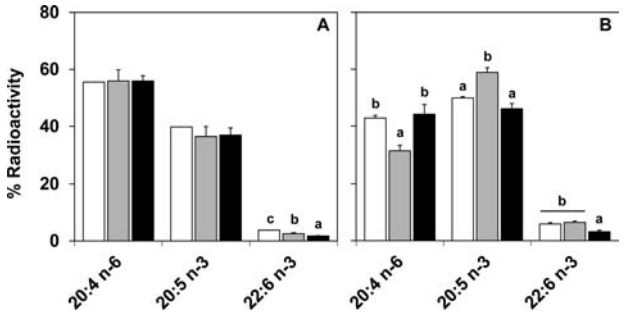

Figure 4. Effect of light intensity on the distribution of radioactivity in the main individual fatty acid fractions of *P. lutheri* grown under 20, 100, and 340 μmol photons m^{-2} s^{-1} (white, gray, and black bars, respectively) and a temperature of 15 °C after incubation with ^{14}C-ARA during 1 h (A) or 3 h (B). Results are expressed as percentage of total radiolabeled fatty acids, mean ± SD (n = 3). Means assigned different letters are statistically different (p < 0.05), and results are reported in ascending order: a < b < c.

The effect of light intensity on the percentage of conversion of ARA into longer and more unsaturated fatty acids and the related conversion rates (expressed in femtomoles of substrate converted per minute and per million cells) are reported in Table 2. The highest percentage of conversion of ARA to EPA was obtained under 100 μmol photons m^{-2} s^{-1} after 3 h of incubation. Under these conditions, 68% of ^{14}C-ARA incorporated in the total lipids was converted to EPA and DHA. The results also show that the highest percentages of conversion of EPA to DHA (Δ5-elongation + Δ4-desaturation) are obtained under 20 and 100 μmol photons m^{-2} s^{-1} after 3 h of incubation (10−11% of the ^{14}C radioactivity were converted to DHA). Meanwhile, whatever the incubation time, the desaturation and elongation conversion rates measured, especially for the Δ17-desaturase, were highest under low light. These rates were also higher after 1 h of incubation compared to those obtained after 3 h of incubation except under 100 μmol photons m^{-2} s^{-1}. The highest conversion rates were consequently obtained under low light (20 μmol photons m^{-2} s^{-1}) after 1 h of incubation (Δ-17 desaturation, 486 fmol min^{-1} 10^6 cell^{-1}; Δ5-elongation + Δ4-desaturation, 96 fmol min^{-1} 10^6 cell^{-1}). Similar to the results obtained during incubation of *P. lutheri* with [1-^{14}C] 16:0 or [1-^{14}C] 20:3 n-6,[28] conversion rates are closely linked to the amount of substrate incorporated. Through photosynthetic mechanisms, the regulatory role played by light regarding gene expression coding for desaturases and elongases could explain the variations of the enzymatic conversion rates observed. Previous study showed that the levels of mRNA transcripts coding for Δ12-, Δ15-, and Δ6-desaturases (*Des*A, *Des*B, and *Des*D, respectively) of the cyanobacteria *Synechocystis* PCC6803 were 10 times higher for cells grown under light conditions compared to those grown in the dark.[46] The desaturation of fatty acids as an adaptive response to shifts in light intensity in five microalga species was also proposed.[37] In that study, the authors suggested that the optimization of photosynthetic process resulted in some increase of the relative content of the most unsaturated fatty acids such as EPA in various unicellular microalgae, which exhibited some similarity in their mechanisms of response to changes in light conditions. Moreover, in their study, the fatty acid desaturation was shown to correlate with the photosynthetic activity, in particular the activity of photosystem (PSI).[37]

In this work, as previously described,[28] the Δ17-desaturation activity involved in the conversion of ARA to EPA was confirmed, as well as the metabolic relationship between the n-6 and n-3 fatty acid series (Figure 5). In addition, microalgal desaturases and elongases are either acyl-CoA dependent or glycerolipid-linked (e.g., phospho-linked) dependent. As examples, acyl-CoA Δ6-desaturases were isolated from microalgae *Ostreococcus tauri* and *Micromonas pusilla*,[47,48] whereas

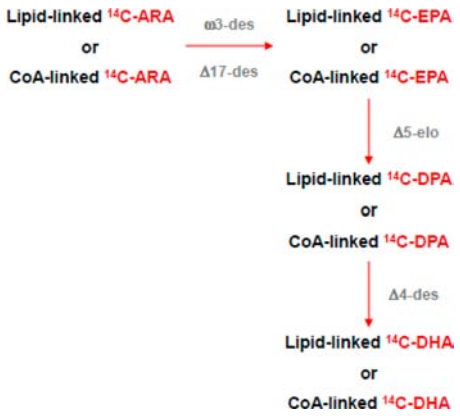

Figure 5. Proposed final steps involved in n-3 LC-PUFA synthesis in *P. lutheri*. Radiolabeled ^{14}C-EPA and ^{14}C-DHA formed by successive desaturation and elongation steps after incubation with ^{14}C-ARA.

two membrane-bound desaturases with Δ6- and Δ5-desaturase activities were isolated from the freshwater microalga *Parietochloris incisa*.[33] As highlighted in Figure 5, the radiolabeled ^{14}C-ARA incorporated in the total lipids of *P. lutheri* may therefore have been converted to ^{14}C-EPA and ^{14}C-DHA before or after esterification to complex lipids by the acyl-CoA dependent or the glycerolipid-linked dependent LC-PUFA biosynthesis pathways, respectively. The strong incorporation of ^{14}C-ARA into total lipids under low light and the strong related Δ17-desaturation activity measured enable us to assume it to be an adaptive response, which provides alterations to lipid−protein interactions in the membrane that may be important for the self-assembly of active chlorophyll−protein complexes for the photosynthetic apparatus. The consequent accumulation of n-3 LC-PUFA such as EPA in *P. lutheri* under low light condition could therefore facilitate thylakoid membrane fluidity and the velocity of electron flow involved in photosynthesis during low light.[14,49]

In conclusion, the present results have confirmed the metabolic relationship between n-6 and n-3 fatty acid series and measured the effect of light intensity on the Δ17-desaturation activity. Our findings also suggested a light-dependent incorporation of LC-PUFA into structured lipids through different enzymes (i.e., acyltransferases) involved in the biosynthesis of lipids (TAGs and membrane lipids), as well as highlight the light-dependent activities of the final desaturation and elongation steps required for n-3 C20/C22 LC-PUFA formation in *P. lutheri*. Therefore, the strong incorporation of ^{14}C-ARA under low light in association with the strong Δ17-desaturation activity could facilitate thylakoid membrane fluidity by LC-PUFA accumulation in the structural lipids (i.e., glycolipids and phospholipids) and, therefore, provide better lipid−protein interactions in the membrane, enhancing the velocity of electron flow involved in photosynthesis during light adaptation.

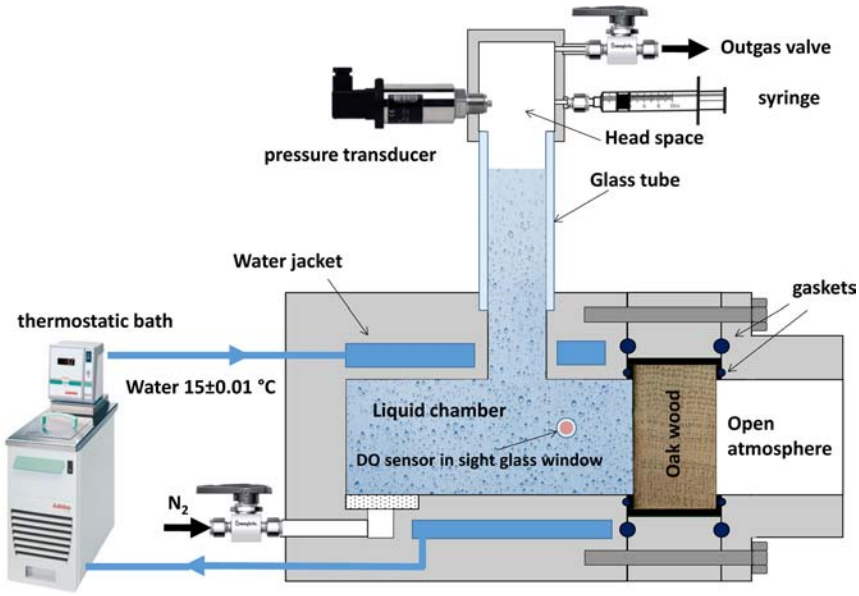

Figure 1. Porous material OTR measuring device.

enological field assessing the measurement of the OTR of oak wood used to build barrels. The limitations of the measurement equipment and those of the gas−wood−gas approach prevented these authors from determining the OTR in oak wood with the same thickness and similar conditions as those found when the wood is part of a barrel containing wine. This work places special importance on the role of moisture content (MC) in the loss of OTR in different wood samples. Other studies have measured oxygen permeability in completely flooded wood in a liquid−wood−liquid setting.[18] In such studies, it was evident that there is oxygen permeation in saturated wood, and the importance of the difference between early wood and late-wood density was highlighted as well as the direction of the diffusion. Likewise, Sorz and Hietz[19] highlight the importance of the MC in oxygen permeation by diffusion in different staves and in different directions. In a previous study,[20] the relationship between oxygen entry through the wood and the increase in its moisture content was demonstrated. For this, the visualization of oxygen diffusion was performed through a French oak stave during moistening in conditions similar to those in a barrel. It was confirmed that the oxygen transmission rate decreases as MC increases with the liquid−wood contact time and that after 40 days, there is still oxygen permeation. This process of progressive moistening of the wood is also reflected in the OTR descending kinetic in new barrels, and this process results in a reduction of up to 40% 2.5 months after being filled.[7]

The aim of this work was to develop a routine method for the classification of rough staves according to their OTR in working conditions similar to those in a barrel, considering the variation in the diffusion coefficient that wood undergoes during aging.

MATERIALS AND METHODS

This study is organized into three phases. The first stage validates the device built for measuring the wood's OTR through the evaluation of the device's airtightness (OTR_{zero}) and the measurement of a material acting as an oxygen barrier with known permeability. In the second phase, rough staves were classified according to their oxygen transmission rates, and from this classification, staves were made from the high- and low-OTR rough stave groups to build two barrels. In the third phase, barrels were built and tested to assess the total OTR of the barrel. Different routes for oxygen entry were also analyzed, hence differentiating between the OTR of the staves after their coopering process and the OTR due to oxygen entry through the joint of the different barrel wood pieces (usually known as gaps).

Measurement Device. A device was developed for the quick measurement of the OTR of porous materials in contact with gas or liquids (Figure 1), including wood for enology applications.[21] The device's dimensions were designed to maintain the same liquid volume/wood surface relationship as in a Bordeaux 225 L barrel. Additionally, the hydrostatic pressure of the liquid in contact with the stave was established to be similar to the pressure of a stave at a barrel's half-height thanks to the glass tube at the top of the device (Figure 1), so the column of liquid was similar to that in a barrel. The study of the diffusion of a gas through a membrane to assess the membrane's permeability to such gas and the gas's diffusivity in said membrane is performed using a classic assay following Crank's diffusion equations.[22] This method, the time lag permeation technique, allows the effective determination of the OTR of different materials in a steady state, under specific circumstances,[23] and in the case of wood, which is considered a porous solid.[19] The method is based on continuous monitoring of the amount of a penetrant diffusing through a solid membrane into a device chamber.[24] The amount of gas recovered in the device chamber as a result of permeation through the membrane is plotted as a function of time. The steady state permeation of gases through a material with thickness d (m) is calculated using the simple equation

$$J = P \times \frac{\Delta p_{O2}}{d} \quad (1)$$

where J (m^3) is the volumetric flow of gas transported per unit of time (s) through a surface area (m^2), which, according to eq 1, is proportional to the constant partial pressure difference Δp_{O2} (Pa) of oxygen between both sides of the solid membrane. The proportionality constant P is called the permeability coefficient ($m^3 \cdot m/m^2 \cdot s \cdot Pa$). The method relies on the measure of the increase in oxygen partial pressure (p_2) over time in an initially oxygen-depleted chamber. Of note, even upon reaching steady state permeation, the partial pressure p_2 of the permeated gas, oxygen, remains negligibly small compared to the partial pressure of the gas at the other side of the membrane, the atmospheric air ($p_2 \ll p_1$). A steady state is reached when the increase in p_2 with time is linear, indicating a constant oxygen entry through the membrane.

J. Agric. Food Chem. 2015, 63, 1268−1275

OTR_{zero}. The device chamber was tested six times to ensure airtightness before the experiments were conducted by fixing a metal piece to the device in place of the membrane. The device's chamber was filled with N_2, and the dissolved oxygen (DO) entry was monitored for 24 h. Then, the OTR_{zero} was established. Once the device tightness was confirmed and prior to each experiment, the accuracy of the oxygen sensor in the liquid chamber under the measurement conditions was verified with the device's chamber full of nitrogen.

Membrane with Known Permeability. To assess the device's capacity, the oxygen permeability was assessed for a membrane with a known permeability when used as a barrier for oxygen. Repeated measurements were performed using a membrane composed of three layers, polyethylene/polyethylene terephthalate metallized/polyethylene (PE/PETmet/PE) with 50/12/50 μm thicknesses and oxygen permeability ≤ 1 $cm^3/m^2 \cdot 24$ h tested by Smurfit Kappa (Spain) according to ASTM F 1927-07 at 23 °C and 75% relative humidity.[13]

Wood Measurements. The evaluation of rough staves requires the emulation of the conditions of a stave in a full barrel. Therefore, the device was used in a liquid−stave−air configuration. The same relationship between the wood surface and liquid volume was maintained, and the system was given the capacity to control the necessary head space and its pressure according to the operation of a barrel.[25,26]

When a barrel is filled, the wood starts a moistening process, and the MC in the stave is not in a steady state. The variation of the MC in the wood of a 27 mm thick stave maintains a transition state for 82 days, which is the time necessary for the MC in the exterior part of the stave to increase after it contacts the liquid in the interior face.[27] This fact is reflected in the OTR decrease in barrels, which reaches an almost steady point at 2.5 months.[7] For this nonsteady state, the equation proposed by Crank[22] allows the use of the time lag permeation technique, as long as two initial conditions are met by the study. The first condition demands that the membrane be at zero concentration of the gas to be measured, and the second is that the face through which the diffusing substance emerges is effectively maintained at zero concentration. If both conditions are met, the steady state is reached after a specific time (lag). This is the time at which the system reaches the steady state or a constant flow state and can be used to determine the diffusion coefficient of the permeated gas for the material[28] and the OTR. Therefore, to measure a constant OTR, it would be necessary to moisten the wood for 82 days, which is when it reaches the steady state. This length of time would not allow the establishment of a routine method for the measurement of the OTR in wood. Moreover, in the first 2.5 months of aging, the barrel doses close to 40% of all the oxygen that will be incorporated in the barrel contents in a year.[7] Therefore, if the wood was to be tested after the moisture stabilization period, the OTR obtained would not consider almost half of the total annual oxygen input. Bearing this in mind, we decided to condition the rough staves prior to the assay.

Wood Conditioning. In this study, the wood was kept in contact with liquid for a week, which was considered to be the necessary moistening time for its conditioning. Additionally, to accelerate the equilibration transition process of p_{O2} inside the wood and reach a steady state, the device's chamber was completely depleted of oxygen before every assay for at least 2 h to gradually remove any gas from the inner to the outer side of the oak wood sample. With this procedure, desorption phenomenon interference, a process described by other authors in porous materials, was avoided.[29,30] Moreover, we were able to reach the partial pressure gradient of the oxygen inside the wood earlier, similar to that produced in the barrel aging conditions, as reported previously.[20] We decided to work under these conditions to develop a quick routine method, without the requirements of the time lag permeation technique; this method demands great technical complexity and high stabilization times to achieve a stabilized MC and a p_{O2} equal to zero on the inside of a porous material such as wood, with a thickness of a barrel stave (27 mm).

Wood Measuring Conditions. Once depleted of gas, the device's chamber was filled with a previously oxygen-free model wine propelled with nitrogen (99.9992% Carburos Metálicos, Barcelona, Spain). Model wine was used instead of wine because the oxygen-consuming compounds of the wine would not allow the measurement of oxygen delivered to the wine. Wood compounds capable of consuming oxygen are considered to closely reproduce conditions similar to those in an operating barrel; otherwise, the amount of oxygen reaching the wine through wood could be overestimated. To reproduce the conditions under which increased oxygen transmission occurs in a barrel,[26,31] the pressure inside the chamber filled with liquid was adjusted to −100 hPa, using a syringe in the system's head space, controlled with a pressure transducer (Transmitter S-10, Wika, Lawrenceville, GA, USA) in the upper part of the tube (Figure 1).

All of the assays were performed in a climate-controlled barrel room, and the holding temperature was kept constant (15 ± 0.01 °C) using a Julabo FP40-ME thermostatic bath (Seelbach, Germany).

OTR Measurement. The oxygen permeation of wood pieces is performed measuring the increase in the oxygen partial pressure with time (hPa/day), which allows the determination of the OTR using the law of ideal gases[32,33]

$$\mathrm{OTR} = \frac{\Delta n \times V_m}{\Delta t} = \frac{\Delta p_{O2} \times V}{R \times T} \times \frac{V_m}{\Delta t} = \frac{\Delta p_{O2} \times V}{\Delta t \times P_{atm}} \quad (2)$$

where n is the amount of a substance in moles, V_m is the molar volume of oxygen, T is the absolute temperature in K, $((\Delta p_{O2})/(\Delta t))$ is the slope in the linear part of hPa/day, V is the device's chamber volume, and P_{atm} is the atmospheric pressure in hPa during the assay. Henry's law was applied to evaluate the oxygen concentration (mg/L), and the Bunsen absorption coefficient $(cm^3(O_2)/cm^3)$ of oxygen in hydroalcoholic mixtures[34] was used to avoid subestimation measurements when oxygen solubility in water was used.[35]

Rough Staves. For the second part of this study, we worked with Radoux Cooperage personnel (Jonzac, France), who selected 69 French oak rough staves (*Quercus petraea*) of the Allier forest with a greater length (120 cm) than is typical (90 cm). Wood pieces (pieces A and B) were extracted from both ends of the rough stave. A total of 138 pieces were sent to our Center for analysis using the same methodology previously described. The remaining parts of each rough stave, now with the typical dimensions, were stored in the cooperage for the production of staves and further construction of the barrels according to the classification delivered by our Center. The tested wood pieces had effective dimensions of a 40 mm diameter and a thickness of approximately 27 mm. The effective surface area for oxygen transmission was 12.57×10^{-4} m^2. All of the samples were stored under environmental conditions of 15 °C and 75% relative humidity, maintaining the MC of the pieces between 14 and 15%.

Measurement in Barrels. Two barrels of 225 L were built using 25 staves selected from the high- or low-OTR groups. The OTRs of the barrels were measured following the protocol described previously[7] and barrel total OTR (wood + gaps) was obtained. After these tests, the oxygen transmission rate of the barrel wood was also evaluated (wood OTR). For this, all joints and gaps were sealed with epoxy, and before the tests, all barrels were conditioned to ensure that the wood had recovered its initial moisture (14% MC).

All tests were performed following the protocol of the cumulative measurement of dissolved oxygen inside the barrel. Barrels were filled with model wine that was previously deoxygenated according to a previous paper.[7] When the measurements showed the constant absence of dissolved oxygen, the barrels were topped with this solution and were sealed with an expandable modified silicon bung, which ensured airtightness. This bung had a feedthrough for both optical fibers of the submergible oxygen probes introduced in each barrel.

The OTR in barrels is typically expressed in mg/L·year.[17,36] To express the OTR in mL/L·year, we used the parameters of 225 L and 2.01 m^2 of internal wood surface. Bearing in mind the importance of the time of the experiments in the annual OTR measurement, this work expresses the measurement as μg/L·day.

During all tests, the barrels were stored in a climate-controlled cellar, where the room temperature was 15 °C and humidity was 75%, to maintain the typical air physical properties in a real cellar situation, regarding diffusion and permeability.

Table 1. Results of the Tests Performed with the Device for the Evaluation of the Zero Oxygen Transfer Rate (OTR_{zero}) and the Permeability (P) of a Known Membrane (PE/PETmet/PE)

	test							
	1	2	3	4	5	6	mean	SD
$OTR_{zero} \times 10^9$	1.778	1.575	1.755	1.733	1.969	1.477	1.714	0.171
P (cm^3 m^{-2} day^{-1})	0.7227	0.7601	0.7310	0.7393	0.7393	0.6895	0.7303	0.0235

Oxygen Partial Pressure Measurement. The measurement of dissolved oxygen in the device[13] was performed using an Oxytrace device (PreSens GmbH, Germany) equipped with a PSt6 oxygen sensor (measurement range, 0−41.4 hPa; detection limit, 0.002% O_2). This sensor was placed inside the device in direct contact with the fluid of the chamber that, according to the test, was nitrogen or synthetic wine. Luminescent measurements were performed using an optical fiber through a transparent surface where the sensor was attached. For the measurement of the dissolved oxygen levels inside the barrels, we used two submergible oxygen probes in each barrel. The probes were equipped with a PSt6 sensor with a four-channel OXY-4 trace transmitter (PreSens GmbH, Germany) connected to a computer. To determine the representative mean value of the dissolved oxygen concentration in the fluid of each barrel, the arithmetic mean of every barrel was calculated.[7]

Calibration of the oxygen systems in the tonometer[37] was performed using a conventional two-point calibration in the model wine saturated with nitrogen (cal 0) and a second value in the range between 5 and 10% air saturation. A calibration gas mixture with 2.001% (±0.5% rel) pure oxygen gas and nitrogen (9.55% air-sat) was used as a second calibration standard (Carburos Metálicos, Spain). Both gases were pumped into the tonometer for 10 min at a constant 15 °C until stable conditions were achieved. All measurements performed for p_{O2} were corrected to compensate for the interferences introduced by ethanol, according to the model developed in previous studies.[38]

Statistical Analysis. Data were collected using Microsoft Excel 2013 software (Redmond, WA, USA).

RESULTS AND DISCUSSION

Zeros. Initially, six measurements of the oxygen entry rate were performed in the device when it had been hermetically closed with a stainless steel piece. These measurements, called zeros, allowed us to assess the hermeticity of the device, and the mean result was subtracted from the measurements performed. The results are shown in Table 1 and indicate that the device has a mean zero of 0.1714×10^{-9} cm^3/m^2·day. This value was low enough to ensure the airtightness of the device.

Measurement Repeatability. Six assays were performed in the same membrane sample previously described to determine the repeatability. The measurements were performed following the time lag permeation technique[33] to check the accurate performance of the newly designed system, indicated by the zero value and the correct measurement of the reference film.

The results obtained correspond to the manufacturer's indications (<1 cm^3/m^2·day) because the OTR measured in the material varies from 0.689 to 0.760 cm^3/m^2·day. This represents an average permeability (P) of 0.730 cm^3/m^2·day and a repeatability of r = 0.023 cm^3/m^2·day. Therefore, the device meets all of the necessary requirements to evaluate the OTR of materials (Table 1).

Oak Wood OTR. The construction of barrels with different oxygenation levels demands the determination of the OTR of the rough staves. For this, the OTR of 138 wood pieces was evaluated following the protocol of dissolved oxygen cumulative measurement in the device, as described under Materials and Methods.[13] Figure 2 shows the increase in oxygen concentration in the device chamber according to the measurement time in the evaluation of some pieces.

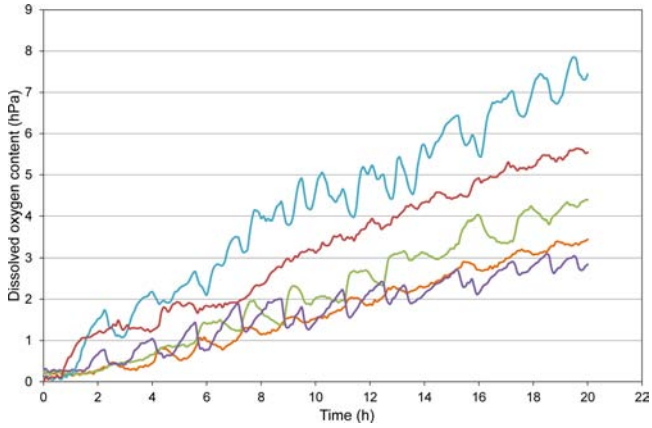

Figure 2. Comparative measurements of the evolution of the dissolved oxygen content (hPa) of five different wood pieces.

Table 2 shows the results obtained expressed as micrograms of oxygen transferred by the wood to each liter of wine during a day (μg/L·day), accumulating the mean of the data obtained from the pieces extracted from each rough stave (piece A, top end; piece B, lower end). These results indicate that in some rough staves, the difference between the pieces of both ends is small, as was the case for rough stave 1 (piece A = 196.41 μg/L·day and piece B = 198.31 μg/L·day) and rough stave 29 (piece A = 113.20 μg/L·day and piece B = 117.11 μg/L·day). However, in other cases, the difference is quite large, such as in the case of rough stave 31 (piece A = 209.86 μg/L·day and piece B = 413.97 μg/L·day) and rough stave 49 (piece A = 150.71 μg/L·day and piece B = 266.23 μg/L·day). This result reflects the wood's natural structural variability throughout the stave, which also affects its physical properties and hence most likely alters its capacity for transmitting oxygen.

The result of the average OTR measured from both ends was considered representative of all of the rough staves and allowed the establishment of the stave classification in two groups. This classification excluded 19 rough staves with values between 180 and 211 μg L·day, which did not clearly belong to either of the two groups. The group of rough staves with a low OTR included staves with an average OTR between 48 and 177 μg/L·day, which represents the group mean OTR of 140 μg/L·day. In contrast, the group of rough staves with a high OTR included staves with an average OTR between 213 and 379 μg/L·day, for a total group mean of 265 μg/L·day (Table 2).

Once a barrel is built, the potential oxygen contribution from the wood must also include the contribution from the gaps. This outcome depends on the assemblage process of each cooperage and on the wood type. Moreover, it is important to bear in mind that the OTR of a rough stave will be modified in the bending and toasting processes performed in the cooperage

[a]Grain value measuring the number of rings in 5 cm of a stave. [b]Grain according to Vivas's classification (1, <1 mm; 2, between 1 and 2 mm; 3, between 2 and 4 mm; 4, between 4 and 5 mm; and 5, >5 mm).

because they modify the shape and maybe also slightly the structure of the wood and therefore most likely affect its OTR.

OTR–Grain Relationship. To assess the relationship between the OTR and the real grain of rough staves, the number of rings present in 5 cm of wood in the transversal section of the rough staves was measured following the medullary rays, yielding the mean width of a growth ring. The results found for the 138 analyzed pieces are shown in Table 2. The classification was also performed according to the method of Vivas,[4] as described previously.

The correlation analysis between the oxygen transmission rate and the measured grain indicates that this relationship is very low (correlation = −0.0216, p = 0.8014). This same result was obtained when the OTR was analyzed with the grain classified according to the method of Vivas (correlation = −0.1172, p = 0.1712).

Barrel Construction. Finally, the barrels were built using 25 staves of each group for each barrel, discarding the staves with an intermediate OTR between the two groups. The barrels were manufactured in the Radoux Cooperage (Jonzac, France), using the regular process with a medium toast.

The results obtained from the assessment of the oxygen entry into the barrels is shown in Figure 3, which displays the

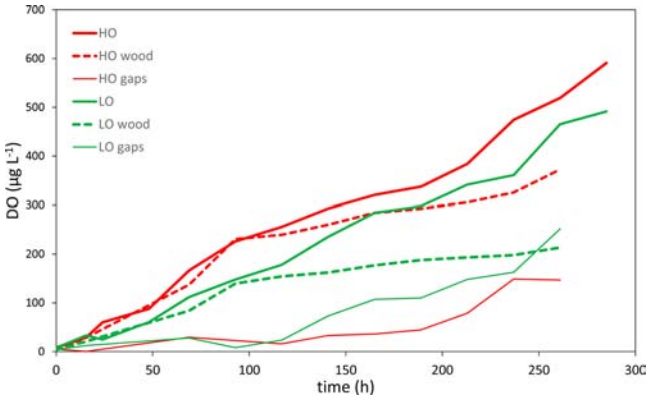

Figure 3. Cumulative measurements of the dissolved oxygen content (μg L^{-1}) inside barrels with a high (HO, in red) and low (LO, in green) OTR, with sealed (dashed) and nonsealed gaps (solid).

increase in dissolved oxygen content in both barrels during 11 days of testing. As expected, the global entrance of oxygen was higher in the barrels that were constructed with rough staves classified with a high OTR than in the barrels constructed with rough staves classified with a low OTR. This experiment was used to assess the aim that was initially proposed. Specifically, it has been found that the high-OTR barrel would supply the aging wine with a total of 116 mg of oxygen (225 L × 519.02 μg/L) in 11 days on average, whereas the low-OTR barrel would supply only 105 mg of oxygen (225 L × 471 μg/L) in 11 days. These global results indicate that the barrel with a high OTR would transfer only 10% more oxygen to the wine than the low-OTR barrel, a result that is not satisfactory in regard to our aim. To perform a comparison of the OTR that is dependent only on the classified staves, it is necessary to analyze in detail the different ways oxygen enters the barrel.

To evaluate the potential of the classification system proposed for the rough staves, the rate of oxygen entry due exclusively to the oxygen transmission process of the wood from the staves of the barrels was evaluated. Figure 3 also shows the oxygen that exclusively enters through the wood, measured in the epoxy-sealed barrels. This procedure allowed us to directly calculate the OTR corresponding to the wood (Table 3). It also permitted us to calculate the oxygen that

Table 3. Cumulative Dissolved Oxygen Content in Barrels with a High or Low OTR, Penetrated by Different Entry Routes after 11 Days

	μg L^{-1}	mg per barrel	%
Low OTR Barrel			
total	465.18	104.7	100
wood	213.31	48.0	46
gaps	251.87	56.7	54
High OTR Barrel			
total	519.02	116.8	100
wood	372.27	83.8	72
gaps	146.75	33.0	28

enters through the gaps as the difference of OTR between the unsealed and the sealed barrel. It was observed that in the case of the barrel with a high OTR, the contribution was 83.8 mg (225 L × 372.27 μg/L) of the 116.8 mg of total oxygen in 11 days. This result indicates that 72% of the oxygen that the aging wine would receive in the high-OTR barrel would enter through the wood, whereas the 33 mg of oxygen (225 L × 146.75 μg/L) that would enter the barrels through the stave gaps would comprise 28% of the total.

In the case of the barrel with a low OTR, it was found that the 48 mg of oxygen (225 L × 213.31 μg/L) that entered the barrel through the wood in 11 days represents 46% of the total oxygen that enters to the barrel, with 54% entering through the gaps. According to the results obtained, the treatment and manufacturing process of the staves from the rough staves classified as having high and low permeability considerably

DOI: 10.1021/jf505360r
J. Agric. Food Chem. 2015, 63, 1268−1275

affected the properties of the wood, as expected. Definitively, the high-OTR staves allowed 1.74 times more oxygen to enter the barrel (372 mg/L) than the low-OTR staves (213 mg/L).

To compare the previously obtained results from the evaluation of the built barrel staves (evaluated for 11 days) with those obtained for rough staves (evaluated for 1 day using the proposed method), an extrapolation was performed to determine the rough stave OTR of 11 days. For this, we included the results of our group's previous studies that were published recently,[7] in which it was demonstrated that the entrance of oxygen to the barrels does not follow a linear variation with time but a potential evolution, such as $y = at^{0.7789}$ in the case of French barrels.[39] Therefore, from the contribution of the first 24 h and considering this model as an approximation of the behavior of French oak barrels, we calculated the constant a for the high- and low-OTR barrels, extrapolating it to 11 days. We found that the high-OTR rough staves would allow 1682.92 μg/L oxygen in and that the low-OTR rough staves would allow 642.23 μg/L oxygen in. These data indicate that the high-OTR rough staves would permit 2.6 times as much oxygen to enter the barrel as the low-OTR rough staves in 11 days.

Analyzing the effect that the bending and toasting processes have on the OTR of rough staves, we found that wood's oxygen permeation decreases between 3 and 4.5 times after these processes. Specifically, after the 11 day evaluation, we found that in the case of high-OTR wood, these changed from dosing 1.68 mg/L in rough staves to 0.37 mg/L in toasted staves, which represents a 4.5-fold decrease in the OTR. In the case of low-OTR wood, they went from 0.64 mg/L in rough staves to 0.21 mg/L in toasted staves. Therefore, wood loses up to 3 times its oxygen transfer rate during the toasting process. This result agrees with previously reported studies,[5,39] which demonstrate the loss of the gas permeability of oak wood after the bending and toasting processes.

From the detailed analysis of the oxygen entrance through the gaps, the results show that the oxygen that enters into the wine in this way greatly varies from one barrel to another. In this case, we found that 56.7 mg (225 L × 251.87 μg/L) of oxygen entered through the gaps of the low-OTR barrels, almost 1.7 times the 33 mg of oxygen entering the high-OTR barrel (225 L × 146.75 μg/L). Bearing in mind that the cooperage is the same (and, therefore, so is the manufacturing system of both barrels), it is possible to conclude that the assembly system makes an important contribution for the variability between barrels.

In conclusion, this study proposes a device and a procedure for the routine measurement of the OTR of oak wood. It is important to highlight that the device has the capacity to reproduce working conditions that are similar to those of the barrel, which allows its use in the classification of rough staves for the manufacturing of barrels. In this way, after the classification of rough staves, two barrels with different oxygen transfer rates were built. Specifically, it was demonstrated that the high-OTR barrel allows almost twice as much oxygen to be transferred throughout the oak wood into the wine as the low-OTR barrel. The results show that the classification of rough stave wood has indeed allowed the construction of barrels with high and low oxygen permeability, accomplishing our aim. The importance of the assembly of staves in the global OTR during barrel construction has been confirmed, a result that requires a deeper study on the factors determining the OTR in this process. Moreover, it was confirmed that the toasting and bending processes are important in the oxygen permeability decrease in oak wood used for barrel making.

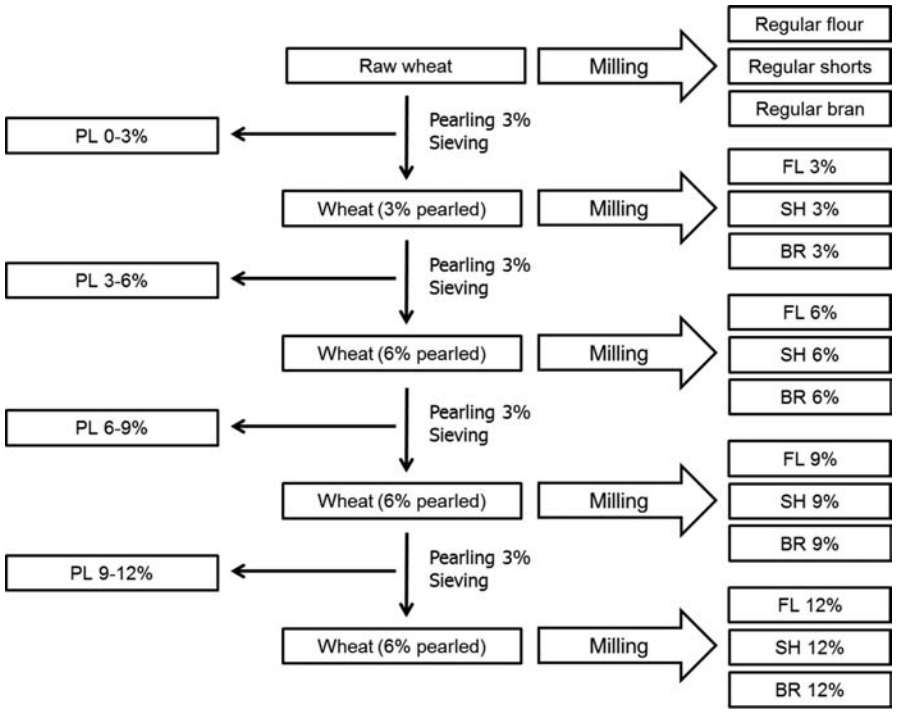

Figure 1. Overview of the production of pearlings, obtained by pearling wheat kernels to 3%, 6%, 9%, and 12%, and flour, shorts, and bran samples, obtained by pearling wheat kernels followed by milling. The pearlings from the sequential pearling process are referred to as PL 0−3%, PL 3−6%, PL 6−9%, and PL 9−12% while flour, shorts, and bran samples produced by (subsequent) roller milling are further referred to as regular flour or flour (FL) *x*%, regular shorts or shorts (SH) *x*%, and regular bran or bran (BR) *x*% respectively, with *x* being the percentage of wheat removed by pearling prior to producing the flour, shorts, and bran samples.

kernels prior to roller milling affects the mineral content of the resulting wheat products. Against this background, this study set out to investigate the distribution of minerals in common wheat and the effect of pearling on the mineral composition of the milled fractions. The resulting knowledge can be used to optimize wheat grain processing methodologies.

MATERIALS AND METHODS

Materials. Wheat grains (cv. Akteur, harvest 2012, moisture content 14.8%) were pearled at Satake Europe (Bredbury, United Kingdom) using PeriTec debranning technology which is based on friction (grain to grain contact) and abrasion (grain to rough surface contact).[19] Wheat was pearled in different successive steps to remove a total of 3.0, 6.0, 9.1, and 11.9% of the grain weight, and pearlings were collected after every pearling step. Broken wheat grains were removed after each pearling step by sieving through a 2.38 mm sieve. The pearlings obtained from this process are referred to as pearlings (PL) 0−3%, PL 3−6%, PL 6−9%, and PL 9−12%, respectively, throughout the remainder of this article. Figure 1 schematically represents pearling and milling fractions. Nonpearled and pearled wheat grains were roller milled with a Bühler (Uzwil, Switzerland) MLU-202 laboratory mill using the diagram described in Delcour et al.[20] Flour, bran, and shorts were produced. The shorts were separated at the end of the milling system using a 150 μm sieve[20] and are essentially bran tissue to which some starchy endosperm is still attached. Flour samples produced by roller milling are further referred to as regular flour or flour (FL) *x*%; where *x* is the percentage of wheat removed by pearling prior to producing the flour under consideration by roller milling. A similar terminology was used for the regular shorts or shorts (SH) *x*%, and regular bran or bran (BR) *x*%, obtained when roller milling wheat from which *x*% had been removed by pearling (Figure 1). Pearling and milling yields of these fractions have been described in De Brier et al.[21]

Sample Digestion and Multielement Analysis. Samples (0.05 g, three analytical replicates) were weighed into glass tubes and digested with 1.00 mL of ultrapure HNO_3 for 4 h followed by dilution to 10.0 mL with Milli-Q water (18.2 U; Milli-Q Plus, Merck Millipore, Darmstadt, Germany) and analysis by ICP-MS (Agilent 7700x, Santa Clara, CA). A reference wheat flour sample with certified mineral composition was included: NIST1567 Wheat (National Institute of Standards and Technology, Gaithersburg, MD). All elements reported were recovered to within 10% of certified values (Supporting Information). For each element, the difference between the concentration in intact (non)pearled wheat kernels and in the weighted average concentration of all corresponding (pearling and) milling fractions did not vary by more than 10% (nonpearled, 3% and 6% pearled) or 20% (9% and 12% pearled). This larger difference is due to the larger number of analyzed pearling fractions needed for the calculations. There was no indication of trace metal contamination (Fe, Cr, Ni, Mo, V) due to kernel pearling or milling from contact with metal parts in the pearling or milling tools (details not shown).

Imaging of Element Distribution. Elemental micro X-ray fluorescence microscopy (μ-XRF) maps were collected at the X-ray fluorescence microscopy beamline (XFM) at the Australian Synchrotron (Melbourne, Victoria, Australia). Thin (80 μm thick) cross-sections of the middle part of the (pearled) wheat grains were made following the method described by Lombi et al.[17] In this way, cross-sections were directly obtained on the Kapton tape without the need for embedding. Two cross-sections from different (pearled) wheat grains were analyzed. The use of thin sections was necessary in order to reduce the distortion of the elemental maps caused by the penetrating nature of the X-rays, as the output is translated into a 2D compression of the illuminated sample volume.[22]

The laterally resolved element maps were collected using the XFM undulator beamline equipped with a Si(111) monochromator and Kirkpatricke−Baez mirrors focusing the beam to a spot size of approximately 3 × 2 μm^2 (horizontal × vertical). An incident beam energy of 10 keV was used, and the fluorescence signal was collected using a 384-element Maia detector system. The detector was placed perpendicularly to the incident beam path and used to collect the full spectra fluorescence signal from the sample. The samples were analyzed continuously in the horizontal direction with steps of 4 μm in

J. Agric. Food Chem. 2015, 63, 1276−1285

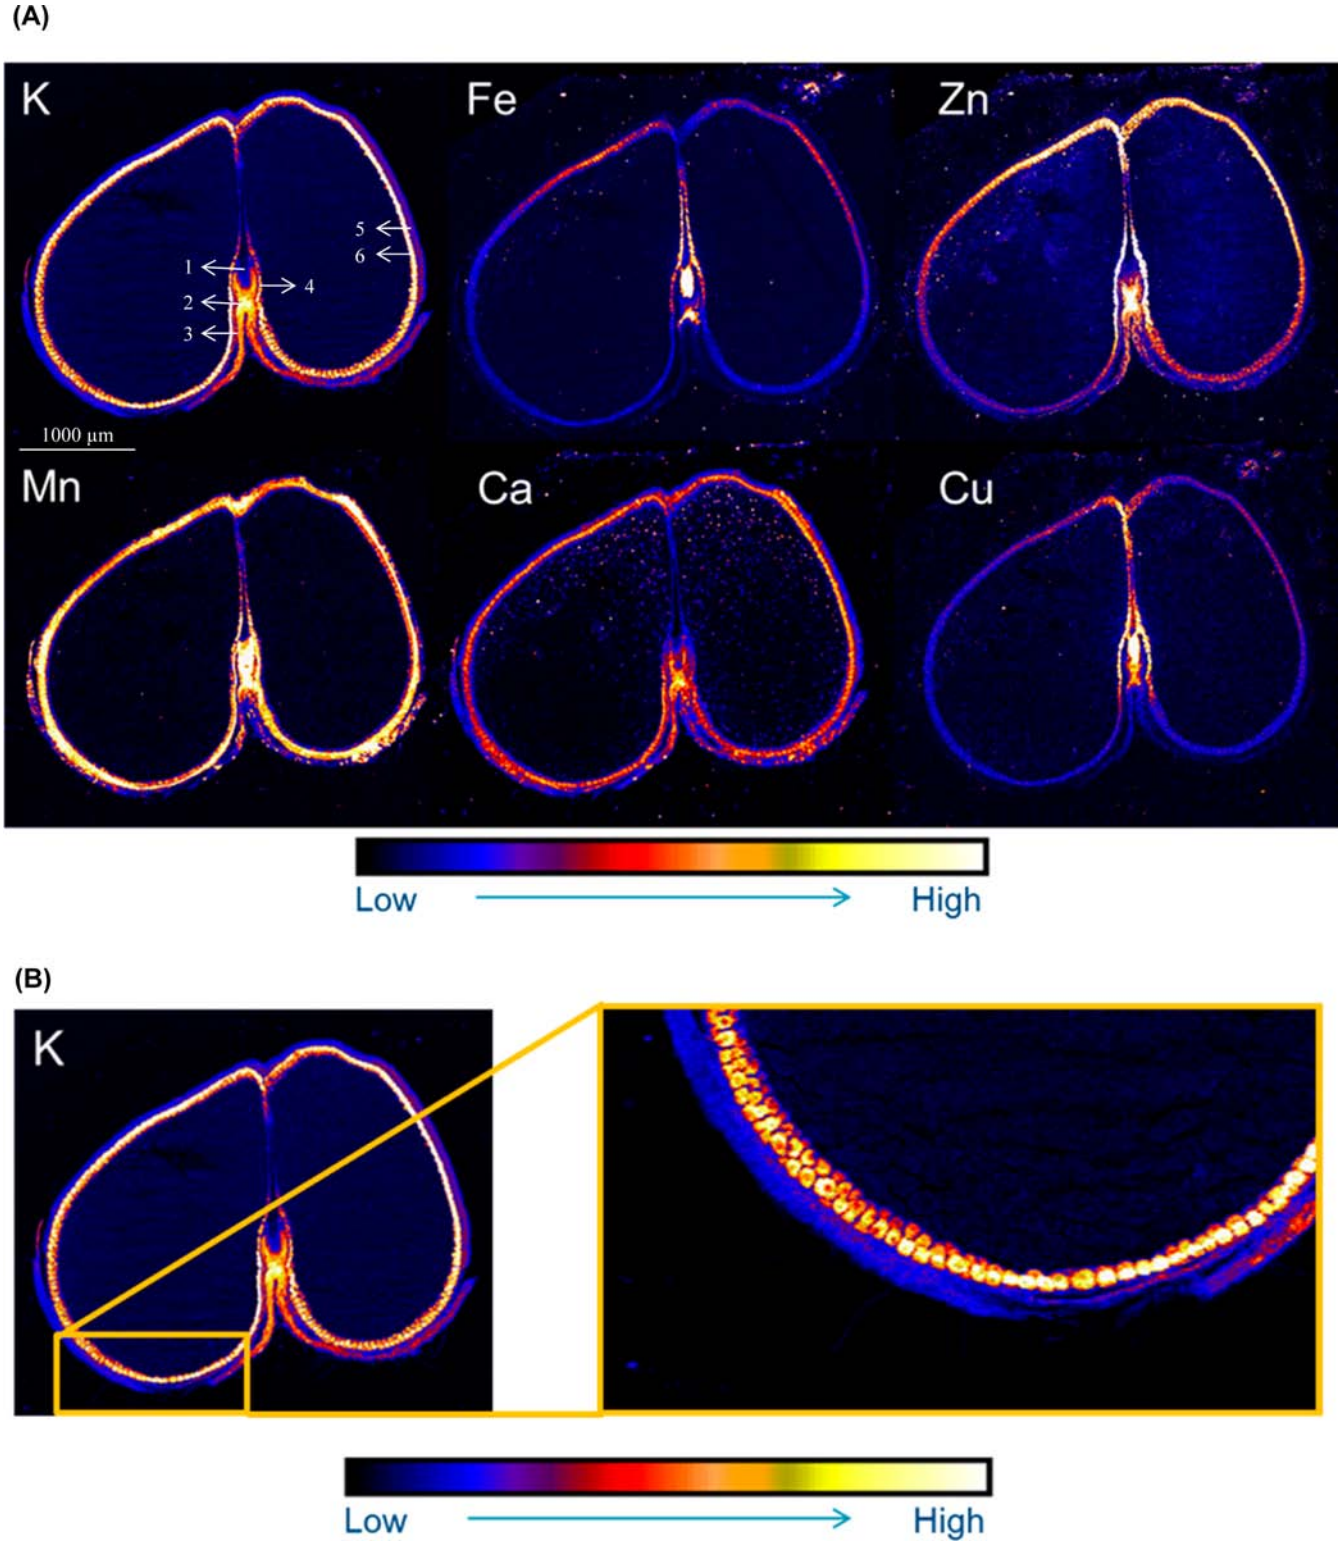

Figure 2. μ-XRF elemental maps of (A) a cross-section of a wheat sample and (B) a detailed picture of individual aleurone cells. The color scale represents different concentrations, with black and white corresponding to the lowest and highest concentration, respectively. The arrows indicate: 1, nucellar projection; 2, transfer cells (vascular bundle); 3, crease pericarp; 4, modified aleurone cells; 5, pericarp; 6, aleurone cells.

the vertical direction. The pixel (4 μm) transit time was approximately 5.2 ms. The full μ-XRF spectra were then analyzed using GeoPIXE.[23] This software uses dynamic analysis to subtract the background and resolves overlapping peaks to generate maps of element concentrations. Using this technique, the distributions of K, Ca, Fe, Zn, Cu, and Mn were imaged (the fluorescence signal for lighter elements cannot be collected using the current version of the Maia detector).

Statistical Analyses. Data was statistically processed using the JMP Pro 11 software (SAS Institute, Cary, NC). One-way analysis of variance (ANOVA) was performed to verify significant differences ($p < 0.05$) between mean values of the analyzed variables. A Dunnett's comparison procedure was used ($p < 0.05$) to test differences in composition, using the milled fractions of nonpearled wheat grains as a control.

J. Agric. Food Chem. 2015, 63, 1276−1285

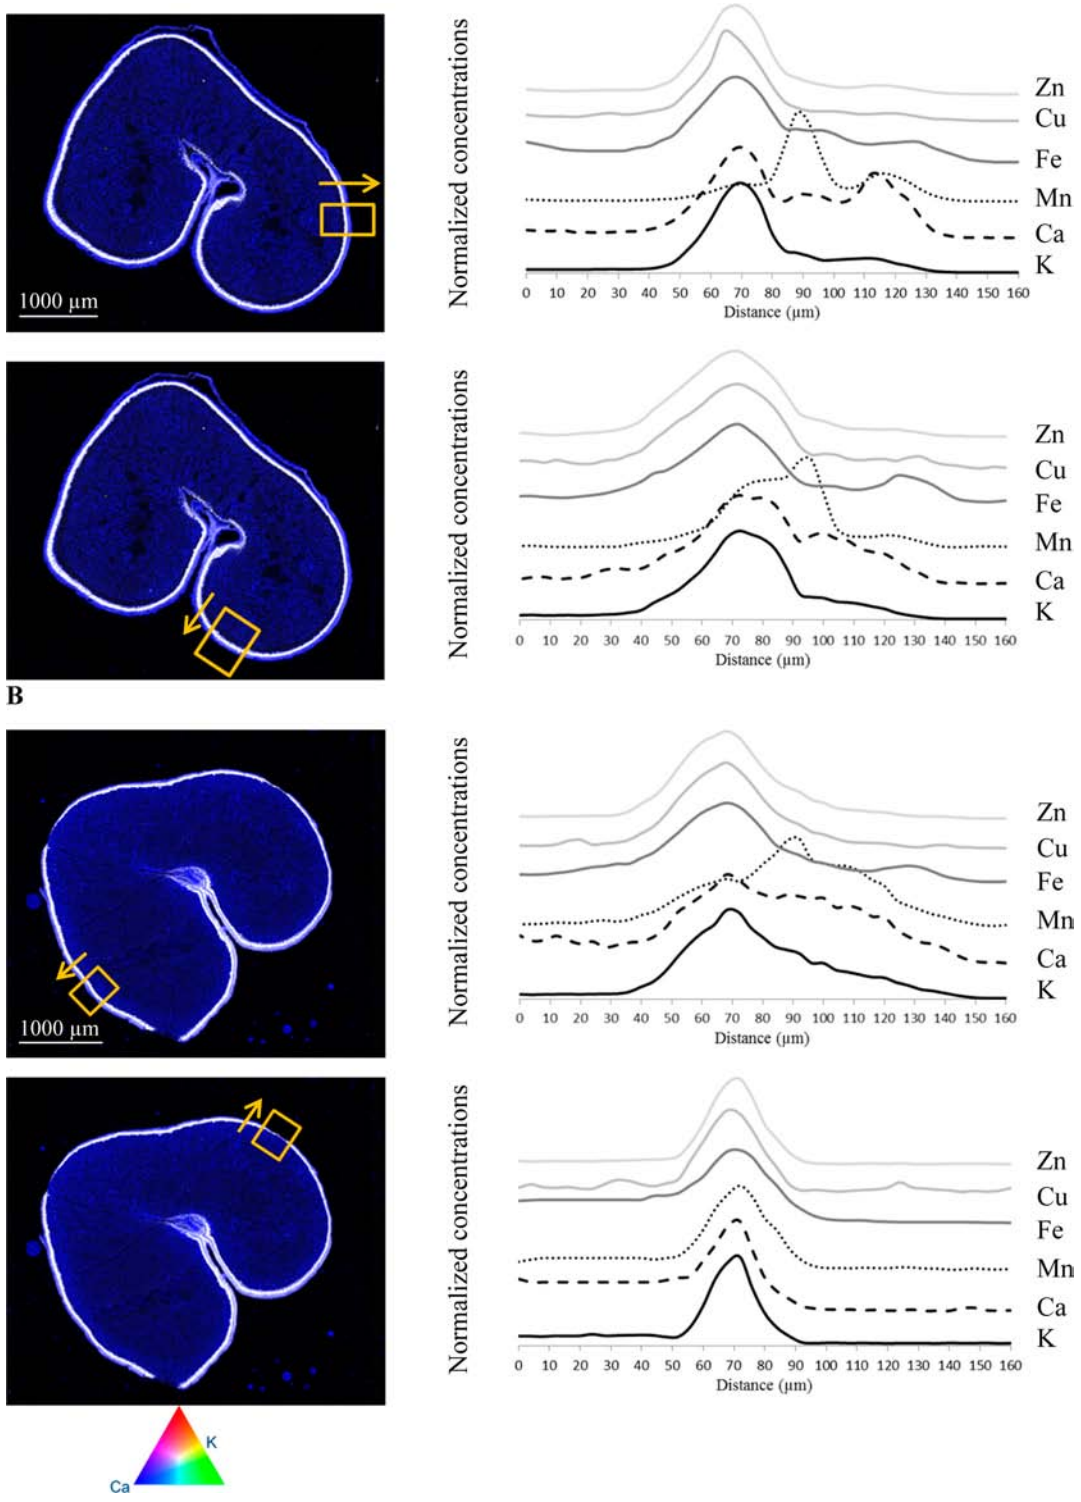

Figure 3. Line scans (from the starchy endosperm to the external surface of the wheat grain) for K, Ca, Mn, Fe, Cu, and Zn for the areas shown in the microphotographs with (A) a map of Ca and K present in a cross-section of nonpearled wheat and (B) 9% pearled wheat. The concentrations in the line scans were normalized against the maximum concentration. Ca is in blue and K in yellow, and the areas where they overlap are given in white.

RESULTS AND DISCUSSION

X-ray Fluorescence Microscopy Mapping of Mineral Distributions in Wheat Grains. Synchrotron μ-XRF is a powerful tool for visualizing the distribution of elements in seeds.[18] Figure 2A shows the distributions of Ca, Cu, K, Fe, Mn, and Zn in a nonpearled wheat kernel cross-section obtained using this technique. Individual cells of the aleurone are distinguishable in the elemental maps (Figure 2A and 2B). Concentrations of Ca and Mn were highest in the outermost bran layers, while the Cu, K, Fe, and Zn concentrations were highest in the aleurone layer. Although K was also mainly confined to the aleurone, a significant proportion was detected

[a]Values with an asterix (*) in one row are significantly different ($p < 0.05$, Dunnett's test) from the control sample (regular flour). Flour samples produced by roller milling are further referred to as regular flour or flour (FL) x%, where x is the percentage of wheat removed by pearling prior to producing the flour under consideration by roller milling. Means and standard deviations (in brackets) of three analytical replicates are presented.

in the pericarp. Calcium and, to a lesser extent, Zn were detected in the endosperm, whereas other element concentrations were very low in the endosperm, especially for Mn and Fe (Figures 2A and 3). Low concentrations of Cu were detected in the endosperm parts close to the aleurone and crease. Similar observations have been made for rice (*Oryza sativa* L.) and barley (*Hordeum vulgare* L.) where Fe and Mn mainly occur in bran tissues, while Zn is more evenly distributed in the grain.[16,18]

Although Cu, Fe, and Zn accumulated in the aleurone, their concentrations were highest in the crease region (Figure 2A). The modified aleurone cells surrounding the crease are very rich in these minerals, and Cu, Fe, and Mn are most abundant in the nucellar projection while Zn, K, and Ca mainly occur in the vascular bundle (transfer cells). Manganese, Ca, and K are also present in the crease pericarp. Potassium is more uniformly distributed over the bran tissues than Cu and Zn.

Figure 3A shows line scans, representing the average of the vertical areas indicated by the boxes in the elemental maps, across the bran tissues for intact (nonpearled) wheat grains. Of all the elements investigated, Mn was the one most strongly distributed in the outside parts of the grain. Manganese was highest in the 90−100 μm region. This result is in agreement with Lombi et al.,[18] who found that the highest level of Mn in barley grains was in the testa. Copper, Fe, and Zn were mainly localized within the same band (about 40 to 90 μm) which most probably corresponds to the aleurone layer [as individual cells of this tissue are visible in the elemental maps (Figure 2A and 2B)]. Moreover, the distributions of Ca and, to a lesser degree, those of K were extended over a wider distance (40 to 140 μm), suggesting that these elements may not be limited to the aleurone layer but also extend into the outermost bran layers. In conclusion, these findings show that the different minerals are distributed in different ways across the wheat grain. In plants, the long-distance transport of mineral elements occurs in the vascular system of phloem and xylem. During wheat grain maturation, most mineral elements are transported from the parent plant mainly via the phloem, and they pass into the grain through specialized cells in the crease region.[24,25] Minerals such as Ca and Mn have low mobility in the phloem. They may enter the grain through the vascular system of the pericarp which may have a xylem supply.[25,26]

Investigation of the pearled grains demonstrated that some wheat grain regions are more accessible for abrasion than others, resulting in an inhomogeneous removal of the tissues.[21] In fact, Figure 3B shows that the distribution remained unchanged in the nonabraded regions, whereas, once the outermost bran layers were abraded, all minerals were localized within the same narrow band (50 to 90 μm), i.e., the aleurone. The mineral distribution after pearling depended on the region of the grain. Semiquantification of the minerals by μ-XRF in the grain cross-sections showed that removing the outermost 3% of the wheat grain tissues increased the concentrations of K, Cu, and Zn and decreased those of Fe, Ca, and Mn (results not shown).

Mineral Concentration in Wheat Flour and Shorts As Affected by Pearling. Potassium, P, Mg, and Ca are the most abundant minerals in wheat flour (Table 1). The mineral levels of regular flour are in line with results of Piironen et al.[27] Removing up to 9% of the wheat by pearling prior to milling increased ($p < 0.05$) the K, P, Mg, Ca (only for 3% pearling), Zn, Mn, Cu, and Sr concentrations in flour produced by subsequent roller milling (Table 1). Their concentrations were highest when 3% of the outer layers was abraded prior to milling, and this relative increase in concentration varied from 5% for Ca to about 30% for Mn. This increase is likely due to an increased incorporation of the mineral rich aleurone tissue in the flour milling fractions since the outermost bran layers (the pericarp tissues) were largely removed by pearling prior to milling. We also noted that the levels of some minerals, e.g., Si and Fe, decreased when the peripheral layers were removed prior to milling while the concentrations of some other minerals (e.g., Mo, Se, and Cd) in the flour were rather unaffected by pearling prior to roller milling. Liu et al.[12] also observed a decrease in Fe concentration and an increase in Zn concentration of flour as the pearling degree increased from 5% to 15%. The Cd concentration of wheat flour could not be reduced by pearling prior to milling, which is in line with observations of Cheli et al.[10] for wheat semolina. In conclusion, including pearling in the milling process enriches most minerals in wheat flour on account of loss of the outer tissues (bran).

As for wheat flour, the main minerals present in the shorts are K, P, Mg, and Ca. The effect of pearling on the mineral composition of shorts differs from the effect on flour (Table 2).

[a]Values with an asterix (*) in one row are significantly different ($p < 0.05$, Dunnett's test) from the control sample (regular shorts). Short samples produced by roller milling are further referred to as regular shorts or shorts (SH) x%, where x is the percentage of wheat removed by pearling prior to producing the shorts under consideration by roller milling. Means and standard deviations (in brackets) of 3 analytical replicates are presented.

The P and Mg concentrations in the shorts increased when the outer pericarp layers were removed prior to milling, especially at higher pearling degrees. In contrast, the concentrations of Ca, Sr, and, to a lesser extent, those of Mn and Si decreased at higher degrees of pearling, which points to their presence mainly in the outermost wheat bran layers. Once pearling had removed the peripheral bran layers, mainly aleurone-enriched bran fractions were present in the shorts. Selenium, Mo, Cu, Zn, and Cd concentrations in the shorts were not influenced ($p > 0.05$) by the degree of pearling.

Mineral Concentration of Wheat Bran As Affected by Pearling. Abrading the peripheral bran layers prior to milling enriches the bran fractions with aleurone. The aleurone is a mineral-rich tissue as reflected by the increase in the K, P, Mg, Zn, and Cu concentrations of the bran fractions when the degree of pearling prior to milling was increased (Table 3). Highly (K, P, and Mg) and intermediately (Zn and Cu) phloem mobile minerals mainly occur in the aleurone.

The distribution of minerals in the grain depends on their uptake by the roots during grain development and the mineral redistribution to the grain from vegetative tissues via the phloem. Remobilization via the phloem depends greatly on the phloem mobility of each element.[25] The enrichment of minerals in aleurone-dense tissues was reflected by the higher K, P, Mg, Zn, and Cu concentrations in the regular bran than in the PL 0−3%. Such pearlings mainly contain the peripheral bran layers. The P, Mg, Zn, and Cu concentrations in the bran increased with the degree of pearling, as their concentration is higher in the aleurone than in the outer tissues (Table 3). However, the mineral concentration of the pearlings was never as high as that of the bran fractions since significant parts of the less mineral-rich endosperm were removed along with the bran tissues during pearling. Pearlings are increasingly enriched with endosperm as the degree of pearling is increased.[21]

Minerals like Ca, Si, Sr, and (to a lesser extent) Mn are mainly situated in the pericarp as shown for PL 0−3% (Table 3). Such pearlings had higher Ca, Si, and Sr concentrations than did regular bran. These results confirm the μ-XRF data. In contrast to most minerals, Ca and Mn are transported almost exclusively in the xylem.[25] The accumulation of Sr results from its ability to replace Ca to a certain extent. In terms of plant transport mechanisms, Sr and Ca probably have similar properties.[28] Epicarp hairs are the main tissue in wheat for Si deposition,[29] and it is hence logical that the outer peripheral layers are enriched in Si. While the mechanisms of Si uptake and deposition in wheat are largely unknown,[30] Si probably mainly accumulates in older tissues because it is not mobile within higher plants.[30] In rice, Si concentrations are higher than in wheat and the majority of Si is situated in the external parts of the rice husk.[17] Taken together, Ca, Mn, Si, and Sr have low mobility in the phloem which causes them to mainly occur in the dead cells of the pericarp.

The Cd concentration in bran was higher than that in flour. Cheli et al.[10] found for durum wheat (*Triticum turgidum* L. ssp. *durum*) that Cd concentration in bran products was higher than in the grain and its semolina. Its levels in bran were not affected ($p > 0.05$) by pearling although they tended to increase slightly once the peripheral bran layers had been removed prior to milling (Table 3). Moreover, the relatively low Cd level in PL 0−3% when compared to the levels in the (residual) bran fractions shows that Cd is not mainly accumulated in the pericarp and that it may be slightly enriched in the aleurone tissue. This is in contrast to results by Sovrani et al.[31] They only detected Cd in the peripheral bran layers. Cd is similar to Zn in that it can be transported in plants via similar pathways. However, Zn has greater mobility in phloem and can be transported in larger amounts than Cd.[32,33] The Mo concentration of bran was also not affected ($p > 0.05$) by pearling prior to milling (Table 3). Nevertheless, a slight increase in Mo concentration was observed when the bran fractions were more enriched in aleurone, which was also reflected in the lower Mo level of PL 0−3%.

Selenium was the only mineral that was almost homogeneously distributed throughout the whole grain (Table 3). Its concentration in wheat flour was only slightly lower than that in bran. It has been reported[34] that Se is located relatively uniformly throughout the aleurone and the protein matrix surrounding the starch granules in the starchy wheat endosperm. The similar distribution patterns of Se and S in the grain suggest that the two elements are transported to and deposited in the grain via the same pathway.[34] Sulfur and Se have high phloem mobility,[25] and most likely Se metabolism is dominated by the substitution of this element for S in methionine, as reported for rice by Li et al.[35]

[a]Values with an asterix (*) in one row are significantly different ($p < 0.05$, Dunnett's test) from the control sample (regular bran). Bran samples produced by roller milling are further referred to as regular bran or bran (BR) x%, where x is the percentage of wheat removed by pearling prior to producing the bran under consideration by roller milling. The pearlings obtained by the sequential pearling process are referred to as PL 0-3%, PL 3-6%, PL 6-9%, and PL 9-12%. Means and standard deviations (in brackets) of three analytical replicates are presented.

Taken together, pearling hardly affected the Mo, Se, and Cd concentrations of flour. In rice, S, Mo, Cd, and especially Se are almost evenly distributed without a clear transition point between bran layers and endosperm, and their concentrations are only slightly affected by pearling.[16,36]

Mineral Distribution throughout the Different Wheat Milling Fractions. The mineral concentrations in different milling fractions were combined with the milling weight fractions to calculate the mineral distribution as a fraction of total mineral content (Table 4). In contrast to what was noted for the other minerals, about equal portions of the Ca in wheat grains occurs in flour (42%) and bran (40%), while 18% occurs in the shorts (Table 4). This finding is in line with the more homogeneous mineral distribution of Ca in the wheat grain as shown by μ-XRF (Figures 2 and 3). The concentrations of Mg and Mn and to a lesser extent those of P and Fe in regular flour were much lower than their concentrations in regular bran. Only 10% of the total Mg and Mn ended up in flour, whereas 70% and 50% was present in regular bran, respectively (Table 4). For P and Fe, 18−20% occurs in flour and about 60% in bran. Similar observations have been made for rice[16] and barley,[18] with a relatively large proportion of Fe, P, Mg, K, and Mn associated with the outer grain layers which are rapidly lost during pearling. However, the data further show that wheat and rice grains do not have completely the same mineral distribution patterns. In rice grains, a major part of the total amount of Zn is situated in the (outer) endosperm.[17,36] Lombi et al. (2009) found that Zn and S are colocated in the endosperm which suggests that Zn could be complexed by thiol groups like in phytochelatins and metallothionein. Our results for wheat show that 50% of the total Zn is present in wheat bran and 22% in flour. Moreover, wheat bran contains 42% of the total Ca present in wheat (cf. supra) while rice bran contains about 55% of total Ca.[36] The majority (44%) of Cu was present in bran, while 28% ended up in the flour.

Table 4. Fractions of the Total Quantity of Different Minerals in Nonpearled Wheat Grain Present in Its Milling Fractions Bran, Flour, And Shorts

	bran (%)	flour (%)	shorts (%)
K	57	24	19
P	60	20	20
Mg	67	12	21
Ca	40	42	18
Fe	57	19	24
Zn	50	22	28
Mn	55	10	35
Cu	44	28	28

The concentrations of Zn, Cu, and Mn in regular shorts were quite similar to those in regular bran although the shorts contain substantially more endosperm. Taking the milling yields into account,[21] 28%, 28%, and 35% of the total Cu, Zn, and Mn levels were present in the shorts, respectively (which makes up only 8.5% of the total mass) while about 18−20% of the total amount of Fe, Ca, K, Mg, P ended up in the shorts (Table 4). The enrichment of Cu, Zn, and Mn in the shorts indicates that the embryo ends up in the shorts, since the embryo contains the highest concentrations of Zn, Cu, and Mn as has also been shown for barley[22] and wheat.[37] More than 30% of the total Mn in barley grains occurs in the embryo, which represents only 3% of the grain.[18]

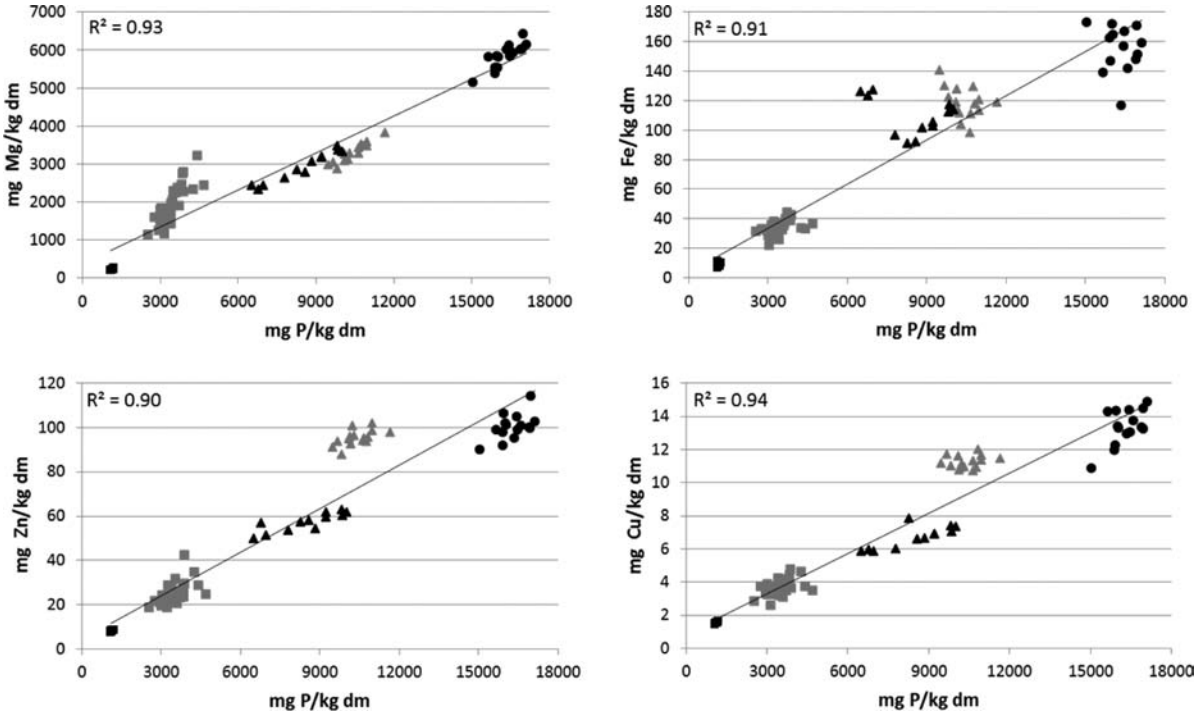

Figure 4. Correlation between P and Mg, Fe, Zn, and Cu in wheat grains (grey square) and its milling [flour (■), shorts (grey triangle), bran (●)] and pearling (▲) fractions.

Taken together, there is good agreement between the quantitative data of the pearling and milling fractions obtained by ICP-MS analysis and the synchrotron μ-XRF images. Both techniques show that Mn is rather confined to the outermost bran layers of the grain while Ca is more homogeneously distributed throughout the wheat grains. Potassium, Fe, Cu, and Zn accumulate mostly in the aleurone.

Correlations between Mineral Element Concentrations in Whole Grains and the Different Pearling and Milling Fractions. The correlation between P and other minerals was investigated across the pearling and milling fraction as P is typically stored as phytate which has a high affinity for minerals such as Mg, Zn, Fe, and Cu and greatly influence their bioavailability. Losses of these minerals during pearling are suggested to be linked to removal of P-containing tissues.[36] A strong positive correlation was observed between P and Mg, Fe, Zn, and Cu (Figure 4). However, not all fractions showed the same behavior when plotting P concentrations as a function of the different mineral concentrations. Zn and Cu concentrations were comparable in shorts and bran and relatively less P ended up in the shorts. This resulted in a higher ratio of Zn/P and Cu/P in the shorts than in the bran fractions. Tang et al.[2] found that shorts contain four times less phytate than bran. The levels of minerals enriched in the peripheral bran layers (Si, Sr, Ca, and Mn in the PL 0−3%) only have a weak correlation with the concentration of P (results not shown).

Furthermore, very good correlations were observed between Cu and Zn concentrations, as they are probably distributed in the same way throughout the wheat grain. As expected (cf. supra), Ca and Sr concentrations and the levels of Cd and Zn also correlated very well with each other (Supporting Information).

In conclusion, this study shows that pearling prior to milling is able to enhance mineral concentrations in pearling and milling products. Pearling increases the mineral concentration of the flour milling products because the bran fractions reaching the flour are probably enriched in aleurone. The highest concentrations of Mn, Si, Ca, and Sr occur in the outer bran layers. In contrast, Mg, Fe, Zn, and Cu accumulate in the aleurone and are probably chelated to phytate, as P is also mostly present in the aleurone-enriched fractions. Removal of the outermost bran layers effectively enriched the residual fractions of most of the essential minerals such as Zn, Cu, P, and Mg but did not change the Fe concentration and did not remove undesired elements such as Cd. The apparent difference in Fe and P may be related to their relative distribution in the scutellum, as this is also known to accumulate these elements. Cadmium, Mo, and especially Se are more uniformly distributed within the wheat grains than the other elements. The μ-XRF images show that Ca and, to lesser extent, Zn are also present in (the outer parts of) the wheat endosperm, while Mn and, to a lesser extent, Fe are more confined to the outer grain parts. This detailed knowledge about mineral distributions in wheat grains may contribute to thorough understanding of the physiological processes responsible for element accumulation. It may also underpin the further development of technologies that preserve or improve the nutritional value contained in wheat grain. Therefore, it would be useful to gain further insights into the mineral distribution in relatively mineral-rich regions such as wheat germ, and the aleurone layer and crease regions.

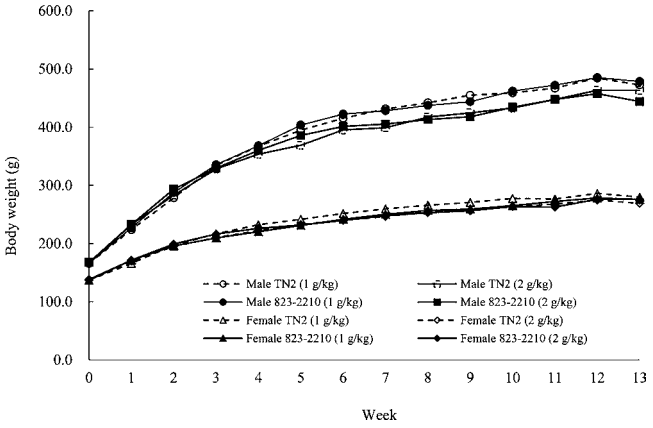

Figure 1. Weekly body weight changes of rats fed with nongenetically modified and genetically modified papaya fruits in the 90 days feeding toxicity trial. TN-2: non-GM papaya of Tainung No. 2. 823-2210: GM papaya fruits. Data expressed as the mean (male and female rats, $n = 10$; except male rats, $n = 9$, and female rats, $n = 11$ in the 2 g/kg 823-2210 groups).

MATERIALS AND METHODS

Samples and Chemicals. The coat protein (CP) gene of *Papaya ringspot virus* (PRSV) was transferred to *Agrobacterium tumefaciens*. Transformation of embryogenic papaya was conducted by liquid-phase wounding with *Agrobacterium tumefaciens*, which contained the CP gene of PRSV.[17] The hybrid line (823-2210) generated by crossing 2210 with 823 was used in this study. Line 2210 was obtained by backcrossing the monoresistant transgenic papaya line 18-2-4 with the non-GM Sunrise. When 18-2-4 was backcrossed with the non-GM Thailand variety, line 823 was obtained. The non-GM control in this study was Tainung No. 2 (TN-2). They were cultivated in a screen house in a certified isolated test field at the Taiwan Agricultural Research Institute. Fresh papaya fruit pulp was harvested and lyophilized (Gold Chia Fong Biotech Co., Wufeng, Taiwan). The ratio of fresh to lyophilized papaya fruit was approximately 8:1. The lyophilized papaya fruits were ground into powder and stored at −20 °C before use. The molecular markers for the characterization of these two GM papaya lines (which were resistant to PRSV) and nontransgenic TN-2 were confirmed in our previous report.[16,17] Isoflurane was obtained from Halocarbon Laboratories (SC, USA), anticoagulative tubes of Vacutainer K3 EDTA syringes were purchased from BD Co. (NJ, USA), and Weigert's iron hematoxylin stain kit was purchased from A.J.P. Scientific (NJ, USA).

Animals. The SPF 5-week-old male and female (nulliparous and nonpregnant) Sprague−Dawley albino rats were obtained from Biolasco Taiwan Co., Ltd. (I-Lan, Taiwan). The same strain of rats was used in the 90-day study as had been used in the previous 28-day and acute toxicity studies.[16] The housing facility was maintained under appropriate environmental conditions at 21 ± 2 °C with 50−70% humidity under a 12-h light/12-h dark cycle. Autoclaved Rat Chow (Purina 5010, MO, USA) and reverse-osmosis water were available ad libitum. This study was approved by the Institutional Animal Care and Use Committee (IACUC) of National Chung Hsing University (IACUC 101-04).

Experimental Design. The 90-day feeding study for the non-GM and GM papaya fruits was performed according to the experimental guidance of EFSA[1] with modification. Tested samples of non-GM TN-2 and GM 823-2210 papaya fruit were prepared in autoclaved reverse-osmosis water. Rats were tagged by picric acid staining on dorsal back with individual cage card as well, randomly assigned and divided into groups that included the low dose of 1 g/kg body weight and high dose of 2 g/kg body weight of non-GM TN-2 and GM 823-2210 papaya fruit lyophilized powder, and gavaged daily for 90 days. For the 10 male and 10 female rats in each group, the body weight did not exceed 20% of the mean weight of each sex in groups at the beginning of the test. However, one female rat was mismatched at day 0 during grouping to make 9 male and 11 female rats in the GM 823-2210 papaya fruit 2 g/kg body weight group.

[a]Data expressed as the mean ± SD. [b]TN-2: Tainung No. 2. 823-2210: GM papaya fruits. [c]Feed consumption (g/day) = [total feed intake (g)/test period (90 days]. [d]Feed efficiency (%) = [daily body weight gain (g)/daily food intake (g)] × 100. [e]Significant difference between the non-GM (TN-2) and GM papaya-treated groups (823-2210) at $p < 0.05$.

Clinical Observations. The health of the animals was observed daily before being gavaged. For the feed consumption record, rats were individually housed in a suspended steel cage with a feeding box. The weekly body weight and feed consumption were recorded. At the end of treatment (day 91), all animals were fasted overnight and sacrificed under 2% isoflurane (Halocarbon Laboratories, USA) anesthesia in an inhalation chamber (MSS 003, Benchtop Small Animal Anesthesia Unit, England).

Hematology and Coagulation. A 0.5 mL amount of whole blood of rats was collected from the abdominal aorta and put it into anticoagulative tubes (K3 EDTA syringes) (Vacutainer, NJ, USA). The red blood cell count (RBC), hemoglobin (HGB), hematocrit (HCT), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), platelet (PLT), and white blood cell count (WBC) were evaluated with a hematology analyzer (Sysmex K-4500, Toa Medical Electronics, Kobe, Japan). Blood smears were stained by Weigert's iron hematoxylin stain kit (A.J.P. Scientific, NJ, USA), and the differential white blood cell counts (neutrophils, lymphocytes, monocytes, eosinophils, and basophils) were observed by a microscope (Olympus BX50F4Micro-scope, Tokyo, Japan). Prothrombin time (PT), fibrinogen (Fbg), and

[a]TN-2: Tainung No. 2; 823-2210: GM papaya fruits. [b]Data expressed as the mean ± SD. [c]Significant difference between the non- GM (TN-2) and GM papaya-treated groups at $p < 0.05$.

activated partial thromboplastin time (APTT) were evaluated with a coagulation analyzer (AMAX 200, Trinity Biotec, Ireland).

Serum Chemistry. Serum albumin, globulin, A/G, alkaline phosphatase (ALKP), amylase, aspartate aminotransferase (AST), alanine aminotransferase (ALT), blood urea nitrogen (BUN), creatinine, creatine kinase (CK), lactate dehydrogenase (LDH), high-density lipoprotein C (HDL-C), total bilirubin (TB), cholesterol, triglycerides (TG), total protein (TP), γ-glutamyltranspeptidase (GGT), glucose, and ions of calcium (Ca^{2+}), sodium (Na^{+}), potassium (K^{+}), chloride (Cl^{+}), magnesium (Mg^{2+}), and inorganic phosphorus (P^{3-}) were evaluated using a Clinical Chemistry Analyzer (Chiron Diagnostics Corp., Oberlin, OH, USA).

Urinalysis. Urinalysis was performed on the day before sacrifice. Urine volume, specific gravity, pH, bilirubin, urobilinogen, protein, glucose, ketones, nitrite, and occult blood (Oc. blood) were evaluated using a Clinitex 100 Urine Chemistry Analyzer (Miles Inc. Diagnostic Division Ellchart, IN, USA). Urinary sediments of leukocytes, red blood cells (RBC), epithelial cells (epithelia), casts, and crystals were evaluated using optical microscopy (Olympus BX50F4 Microscope, Tokyo, Japan).

Gross and Histopathological Examination. A thorough necropsy was performed on all animals, and organs [brain, heart, thymus, liver, spleen, kidneys, adrenal glands, testes (males), and ovaries (females)] were examined grossly, removed, weighed, and fixed in 10% buffered formalin. The organs of the high-dose (2 g/kg) non-GM and GM groups, including the digestive system (liver, esophagus, stomach, duodenum, jejunum, ileum, cecum, colon, rectum, including Peyer's patches, salivary glands, and pancreas), urinary system (kidneys and urinary bladder), respiratory system (lungs, trachea, larynx, and pharynx), cardiovascular system (heart and aorta), hematopoietic system (spleen, thymus, mandibular lymph node, mesenteric lymph node, and bone marrow), endocrine system (pituitary gland, thyroid gland, parathyroid glands, and adrenal glands), nervous system [brain (including cerebrum and cerebellum), spinal cord (cervical, thoracic, and lumbar) and sciatic nerve], musculoskeletal system (skeletal muscle, femur/knee joint, and sternum), reproductive system of males (testes, epididymis, prostate, and seminal vesicles) and females (ovaries, uterus, mammary glands, and vagina), skin, and eyes (including retina and optic nerve) were trimmed based on the revised guidelines for organ sampling and trimming in rats and mice for histopathological examination.[18,19] For semiquantitative grading, lesion severity was graded using the criteria developed by Shackelford et al.[20] Lesion severity was graded as follows: 1 = minimal (<10%); 2 = slight (11−25%); 3 = moderate (26−50%); 4 = moderate/severe (51−75%); and 5 = severe/high (76−100%). The incidence of lesions was expressed as the number of rats affected out of the total number of rats examined.

Statistical Analysis. Data are expressed as mean ± standard deviation. The comparisons were designed to determine whether differences were attributable to the non-GM TN-2 and GM 823-2210 treated groups at the same dosage. All statistical analyses were conducted using Excel software (MicroSoft, WA, USA), and statistical significance levels ($p < 0.05$) were determined by 2-tailed tests with paired comparison in 1 g/kg groups ($n = 10$) and unpaired comparison in 2 g/kg groups for the misidentification of gender ($n = 9$ and 11), respectively.

[a]TN-2: Tainung No. 2. 823-2210: GM papaya fruits. [b]A/G: albumin/globulin. AST: aspartate aminotransferase. ALT: alanine aminotransferase. BUN: blood urea nitrogen. CK: creatine kinase. LDH: lactate dehydrogenase. GGT: gamma glutamyltransferase. HDL-C: high-density lipoprotein C. TP: total protein. [c]Data expressed as the mean ± SD. [d]Significant difference between the non-GM (TN-2) and GM papaya-treated groups at $p < 0.05$.

RESULTS

In Life Observation. No deaths or abnormalities occurred in the non-GM TN-2 or GM papaya 823-2210 fruit treatment groups during the test period. No difference in body weight was observed between the groups of non-GM TN-2 and GM papaya 823-2210 groups (Figure 1). Food consumption (g/day) was lower in male rats at weeks 12 and 13 and female rats at weeks 3, 4, and 6 of the GM papaya 823-2210 (1 g/kg) group and female rats at weeks 7 and 10 of the GM papaya 823-2210 (2 g/kg) group when compared with the non-GM TN-2 group ($p < 0.05$), but no significant difference of feed efficacy (%) was observed at the end of treatment (Table 1).

Blood coagulation exhibited lower APTT in male rats and higher PT in female rats of the GM papaya 823-2210 (1 g/kg) group ($p < 0.05$) but no significant difference in the high dose 2 g/kg treated male and female rats (Table 2). A higher count number of WBCs, white blood cell differentiation of segmented neutrophils (%), and decreases of lymphocytes (%) were found in male rats in the GM papaya 823-2210 (2 g/kg) group when compared with the non-GM papaya TN-2 (2 g/kg) group ($p < 0.05$) (Table 3).

Clinical Biochemistry and Urinalysis. For clinical biochemistry, some of the parameters between the non-GM papaya TN-2 and the GM papaya 823-2210 treated groups expressed statistically significant changes, such as a higher number of triglycerides and lower K^+ in the GM papaya 823-2210 (1 g/kg) male rats ($p < 0.05$), lower albumin, ALP, ALT, AST, amylase, creatinine, glucose, TB, and TP levels in the GM papaya 823-2210 (2 g/kg) treated male rats ($p < 0.05$), lower cholesterol, glucose, triglycerides, and HDL-C in the GM papaya 823-2210 (1 g/kg) treated female rats, and GGT and P^{3-} in the GM papaya 823-2210 (2 g/kg) female rats when compared with the non-GM papaya TN-2 2 g/kg female rats. However, these statistical differences have no dose-dependent relationship and ranged within age-matched (17 weeks of age or greater) historical control values.[21] They were not considered biologically significant in male and female rats (Tables 4 and 5).

Parameters in the urinalysis revealed no statistical difference between the GM papaya 823-2210 and the non-GM papaya TN-2 groups (data not shown).

Organ Weight and Pathological Examination. No significant differences of organ weights in male and female rats were observed between the non-GM and the GM papaya treated groups (Table 6). Furthermore, no gross or histopathological lesions were noted in the high-dose (2 g/kg) groups of non-GM and GM papaya 823-2210. Some of the nonspecific lesions that were observed during pathological examination included minimal to slight degrees of mononuclear cell infiltration of the Hadrian gland, heart, kidney, pancreas, prostate gland, and thyroid gland; tubular regeneration, polycystic kidneys, gastric erosion, epithelioid keratinization of the thyroid gland, and minimal to slight foreign body granulomas of the lung that may have been due to accidental inhalation during gavage of the papaya. These lesions were randomly found in both the non-GM TN-2 and the GM papaya fruit treated rats. Finally, there were no significant gross or microscopic lesions in male or female rats attributable to the non-GM and GM papaya 823-2210 fruit treatment.

DISCUSSION

The aim of the 90-day feeding study of whole foods from GM crops is to assess the potential for unintended effects in terms of toxicological and/or nutritional relevance and to help establish whether GM food is as safe and nutritious as its traditional counterpart. A 90-day animal feeding trial has a large capacity, in terms of sensitivity and specificity, to detect potential toxicological effects of single, well-defined compounds. This conclusion is based on data from studies investigating whether toxicological effects are adequately identified in 3-month subchronic studies in rodents by comparing findings at 3 and 24 months for a range of different chemicals.[10]

The difference between testing chemicals and whole food/feed is that chemicals can be administered to the test animals at dose levels which are much higher than the human exposure levels; however, such a testing approach is not always possible with whole food or feed as they are bulky. In fact, administering high dose levels of whole food/feed is likely to result in unbalanced diets. In some cases, the administered dose level can be equivalent to a high level of human consumption.[1,10] The daily intake of papaya fruit was investigated to be 0.218 g/kg from 2007 to 2011 in Taiwan. In the present study, we selected the low dose of 1 g/kg and high dose of 2 g/kg of lyophilized papaya fruit to evaluate the food safety in rats. The safety factor of these dosages in rats is higher than that of human consumption in Taiwan.[22]

Following allergenicity assessments, the potential human intake of transgene-derived PRSV coat protein (PRSVCP) was assessed by measuring PRSV-CP levels in Rainbow and SunUp varieties, along with estimating the fruit consumption rates, compared to potential intake estimating PRSV-CP from naturally infected nontransgenic papaya. Results showed that

DOI: 10.1021/jf5048404
J. Agric. Food Chem. 2015, 63, 1286−1292

the transgene-derived PRSV-CP did not pose a risk of food allergy,[23] although the transgenic papaya TPY10-4 did not increase the allergenic potential in ovalbumin-sensitized mice.[5] Whether this would be the same for transgenic papaya line 823-2210 is still not known. For food safety, *C. papaya* leaf extract at a dose of 2 g/kg was investigated for subacute oral toxicity in Sprague−Dawley rats with doses at the levels employed in practical use in traditional medicine in Malaysia that could be considered safe as a agent.[24]

For food safety concerns, regarding the potential for altered nutritional composition and altered expression of inherent allergens and toxic proteins. One of the important safety assessments of GM crops is comparison of the composition with the composition of the appropriate non-GM comparator.[10] A previous study showed that the contents of nutrients benzyl isothiocyanate (BITC) and papain of GM Rainbow papaya are within the range of those of non-GM papaya and concluded that the Rainbow cultivar is substantially similar to the non-GM cultivar.[3] The substantial equivalent rates for both unripe and ripe 823 and 2210 GM papaya fruits including the proximate constituents, microconstituents, antinutrients, toxicants, and other constituents were also evaluated. Results revealed that the substantial equivalent rates for unripe and ripe 823 samples were 82% and 91%, respectively, as well as 100% for both unripe and ripe 2210 samples. There is a little difference between GM to control papaya fruits.[25]

Furthermore, in our previous study, in vitro and in vivo genotoxicity tests and the repeated dose 28-day feeding toxicity test revealed that GM papaya 823-2210 could be considered as an equivalent and safe substitute for conventional non-GM papaya fruit.[16] In the current study of the midterm safety of GM papaya 823-2210, the 90-day feeding toxicity test did not reveal any evidence of adverse health effects in male or female rats following 90 consecutive days of oral exposure to GM papaya fruits. Although some parameters revealed statistically observed differences in feed consumption, hematology, and serum chemistry examinations between the non-GM papaya and the GM papaya 823-2210 fruits groups, no biologically significant differences were considered, although the 90-day feeding test is not long enough to conclude that there were no negative effects from feeding the rats with GM papaya. However, this repeated dose 90-day feeding toxicity test of GM papaya fruit demonstrated that there are no adverse effects in rats. These results provide that midterm (90 days) daily intake of GM papaya fruits can be recognized as an equivalent and safe substitute for conventional non-GM papaya fruit.

level (asl)], close to Gmünd. The climate is rather rough, with mean annual temperatures of 6.8 °C and mean annual precipitation of 660 mm. The soil type is acidic pseudogley developed from granite substrate. The experimental site is located in a flat, frequently waterlogged meadow affiliated to the community type Lychnido floris cuculi-Festucetum rubrae Subass. Juncetosum filiformis, typical for this region.[25] Before the experiment was established in 2007, the meadow was mowed once or twice a year after June 15th, without application of fertilizer. A voucher specimen from the toxic plant was deposited in the Herbarium of the University of Vienna (WU) with the accession number WU0079259.[26]

Study Design. A total of 25 permanent plots of 1 m^2 were arranged as a randomized complete block design to apply the five different cutting regimes (treatments) in five pseudo-replicates. The distance from one plot to another was 1 m.

In treatment 1 (standard), cutting was carried out once in early October (Table 1).

Treatment 2 is the common cutting regime for extensive meadows in the Waldviertel. Plots were cut first in early June when all plants were still in the rosette stage, and the second cut took place in early September when the seed set was nearly finished. This treatment allows for full flowering and seed production.

Treatment 3 corresponds to treatment 2, with an additional cut in late July [July (b)], when adult plants are flowering again.

The first cut of treatment 4 took place in early July [July (a)] when marsh ragwort flowered but the seeds were not yet ripened, and the second cut was set in early October.

The plots of treatment 5 were mowed 3 times at full flowering in early July [July (a)], in early August, and in early October. Because the cuttings in July and August took place before the seed set, the seed production is suppressed.

The plots of 1 m^2 were mowed manually to a residual height of 5−10 cm with a scythe from 2007 to 2010. The forage was put into bags; later on, *J. aquatica* was separated. Both *J. aquatica* and the remaining plant material were dried at 50 °C before weighing.

Alkaloid Extraction. A measured aliquot of about 200 mg of the finely powdered plant material of *J. aquatica* was extracted with 25 mL of methanol/0.1 N HCl (30:70, v/v) for 1 h in an ultrasonic bath at room temperature. Exactly 8.0 mL of the filtered resulting extract were reduced under continuous stirring overnight with Zn dust (p.A.). Then, 1.6 mL of 12.5% NH_4OH (diluted from 25% commercially available NH_4OH) and 3 mL (3.96 g) of CH_2Cl_2 were added and vigorously shaken for 5 min. After the separation of the two phases, a measured aliquot (2−3 g) of the CH_2Cl_2 layer was taken and reduced to dryness. Finally, this fraction was made up in 200 μL of methanol containing caffeine (0.25 mg/mL) as an internal standard and subjected to the gas chromatography/mass spectometry (GC/MS) analysis.

GC/MS. The analysis was carried out using a HP 6890 gas chromatograph equipped with a 5972 quadrupole mass selective detector (MSD, Agilent Technologies, Wilmington, DE) and a 30 m × 0.25 mm fused silica column coated with 0.25 μm HP5-MS. The analytical conditions were He carrier gas at 1.3 mL/min constant flow, split ratio of 8:1, and temperature program of heating from 80 to 180 °C at 8 °C/min, then at 4 °C/min up to 280 °C, and held for 10 min at 280 °C. The injector temperature was 275 °C, and the injection volume was 1 μL. The transfer line to the mass spectometer was set at 280 °C, with the detector at 170 °C. The masses were scanned from m/z 40 to 450. The identity of the alkaloids was established according to their mass spectra and retention indices.[27−29]

Quantitative Analysis. For the quantitative analysis, the MSD was operated in the single ion monitoring (SIM) mode recording the mass fragments 109 and 194 for caffeine and 93, 120, and 136 for the alkaloids. Because the macrocyclic pyrrolizidine alkaloids present in *J. aquatica* show similar mass spectra, the calibration graph constructed with senecionine was taken to calculate the concentrations of all alkaloids using the total ion current from the monitored mass fragments.

To construct a calibration graph, seven concentration steps (0.023−0.45 mg/mL) were prepared from a stock solution of 0.45 mg/mL senecionine (Roth, Karlsruhe, Germany) in methanol containing the internal standard caffeine and were each injected 3 times into the GC/MS system. The linear calibration was forced through zero. Repeated injections afforded at most concentrations a coefficient of variation less than 10%. Taking into account the sample preparation, a limit of detection (LOD) of 2 μg/g in the plant material could be calculated.

Statistical Analyses. The SPSS 17.0 software (IBM, Somers, NY) was used to perform the statistical analyses. The data are given as the mean ± standard deviation (SD) for the alkaloid contents and as the mean with the standard error of the mean (SEM) for the growth

parameters. Significance of treatment effects was tested with an analysis of variation (ANOVA), and Bonferroni post-hoc test was used to determine significant differences between individual means. Pearson correlation coefficients were calculated to test for relations between plant production and alkaloid content data.

RESULTS AND DISCUSSION

The *J. aquatica* population in the meadow near Kleedorf looked well-established and very dense. The growth of forage and ragwort and the alkaloid content of toxic plants were measured for 4 years (2007−2010) at the cutting date of the respective treatments with the exception of the last cutting in October 2010 (Tables 1 and 2). Cutting time and sampling year had a significant influence on plant dry matter production and alkaloid content ($p < 0.01$), and there were interactions between these factors. The productivity of the study site was generally very low, with 4.6 t of dry matter (DM)/ha on average.

The forage of the June cuts of treatments 2 and 3 was less infested with *J. aquatica* (Table 2); *J. aquatica* accounted only for 2% of the DM. If the first cut took place in early July (treatments 4 and 5), the average percentage of *J. aquatica* was 5.3%. We measured the highest proportions of *J. aquatica* in the second cut of treatment 3 (mean = 11.2%) in late July and treatment 5 in early August (mean = 8.6%). The amount of *J. aquatica* in the yield of the second cut of treatment 2 in early September (7.0%) was also quite high. In October, the percentage of *J. aquatica* was low in all treatments. Lowest annual percentages of *J. aquatica* (mean = 1.8% over years 2007−2010) were found in treatment 1. This was significantly lower than in the other treatments (2−5), where annual *J. aquatica* percentages did not differ significantly.

The percentage of *J. aquatica* in the forage was highest in 2007 and 2008, when many individuals flowered (6−7%) and lowest (about 2.5%) in the following years.

Six pyrrolizidine alkaloids could be evaluated in *J. aquatica* (Figure 1). The most abundant alkaloids were *Z*-erucifoline (**1**)

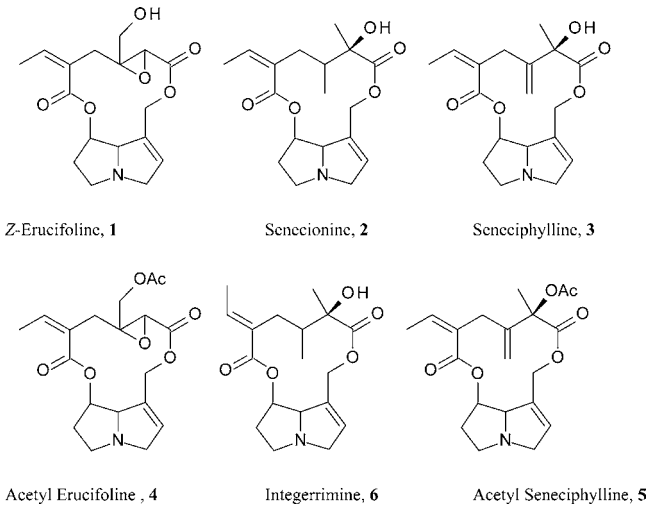

Figure 1. Pyrrolizidine alkaloids from *J. aquatica*.

and senecionine (**2**), followed by seneciphylline (**3**), acetyl-erucifoline (**4**), acetyl-seneciphylline (**5**), and integerrimine (**6**). Table 3 gives the statistical parameters describing the variability in alkaloid concentrations measured in *J. aquatica* plants at the different cutting dates over the 4 years of measurement. The total alkaloid content, as a mean of five plots, varied between 213 and 1979 mg/kg of DM, with *Z*-erucifoline (**1**) and senecionine (**2**) as the main alkaloids. The highest total PA content occurred in August 2010 in treatment 5, and the lowest total PA content occurred in June 2009 in treatment 2.

At certain harvests, some of the alkaloids were below the detection limit of 2 μg/g in the plant material. This was the case

for acetyl-erucifoline (**4**), acetyl-seneciphylline (**5**), and integerrimine (**6**).

Cutting time (from June to October) and year (2007−2010) had a significant influence on the alkaloid production ($p < 0.001$), and all alkaloids were affected (Figures 2 and 3). In the early summer (cutting dates from June to early July), the total alkaloid concentration was higher than later in the summer and autumn (cutting dates from late July to October). The differences in alkaloid accumulation were remarkable (Figure 2); between the years, the highest total alkaloid concentrations were reached in 2010 in July [July (b)], whereas the year 2009 was a period with generally low alkaloid levels ($p < 0.001$). Even in this year, the highest alkaloid contents were obtained in July (cutting dates of early July and late July).

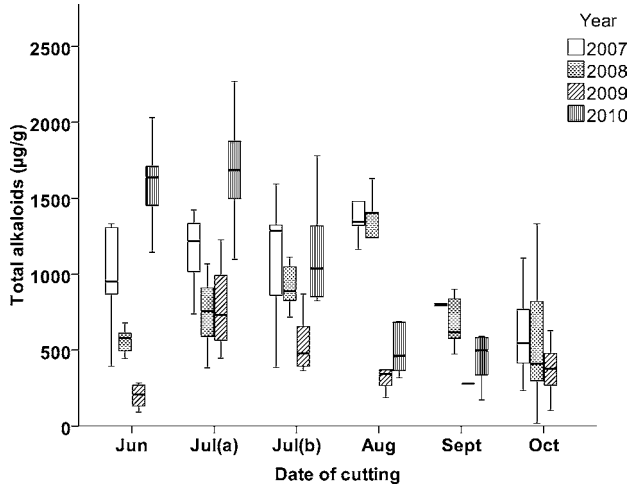

Figure 2. Variability in total alkaloids of *J. aquatica* (box plot, μg/g of DM) at the different cutting dates during the years 2007−2010.

In addition, the different PAs showed a characteristic variation during the vegetation period (panels A−C of Figure 3). The main alkaloid Z-erucifoline (**1**) was higher at the earlier cutting dates, especially in 2010 (Figure 3A; $p < 0.001$), while senecionine (**2**) had its peak instead in midsummer (cutting dates from late July to August) (Figure 3B; $p < 0.001$). Correspondingly, the ratio Z-erucifoline (**1**) to senecionine (**2**) was high at the beginning of the season, and then it decreased and finally increased again slowly. In July and August, there were samples that contained more senecionine (**2**) than Z-erucifoline (**1**). During the year, seneciphylline (**3**) (Figure 3C) followed roughly the distribution of senecionine (**2**), but in July and August, the senecionine (**2**) contents were about 2 times higher; only in June and toward the end of the year, the samples contained more seneciphylline (**3**) than senecionine (**2**).

When the data of the alkaloid concentration, *J. aquatica* growth, and forage production were combined, the alkaloid concentration in the resulting hay was calculated. The variability over the years and the growing season of total alkaloids present in the hay are displayed in Figure 3D. The highest load of alkaloids in the forage could be obtained during midsummer (from late July to August; $p < 0.01$), while the early cutting in early June and the late cuttings in September and October afforded relatively low alkaloid levels in the forage.

Figure 4A compares the alkaloid production in treatments 2 and 5. Treatment 2 representing an early first cutting and a later second cutting is often applied in this region in practice, whereas treatment 5 with two cuttings in July and August is suitable to suppress seed production.[30] Differences between the years became apparent, with the highest alkaloid contents in June and in early July 2010. The July and August cuttings from treatment 5 displayed usually higher alkaloid concentrations than the two cuttings from treatment 2 ($p = 0.027$).

When the alkaloid content is calculated on the basis of fodder (Figure 4B), again the highest contents were obtained in treatment 5 during July and August. At that time, the alkaloid load of the forage was considerably higher during 2007−2008 than during 2009−2010. This was due to the generally lower alkaloid content of *J. aquatica* in 2009 and the lower percentage of this plant in the forage during the last 2 years (Table 2). Finally, for a practical evaluation, the dry matter percentage of *J. aquatica* was correlated with the calculated total alkaloid concentration in the fodder ($R^2 = 0.87$; $p < 0.01$; $N = 28$), while the production of fodder was not correlated with the growth of *J. aquatica*.

Considering the presence of *J. aquatica* on the differently managed meadow plots, this toxic plant was obviously growing vigorously during the summer. Peak flowering took place from July to August, with seed set about 3 weeks later from August to September. The percentage of *J. aquatica* in the forage results from the plants and forage growth, dependent upon the cutting date. The seasonal influence was very high; it is obvious that the percentage of *J. aquatica* DM was lowest in the forage cut in early June, before flowering stems are elongated. The highest percentages were reached in cuts just a few weeks after the previous cut. *J. aquatica* plants regenerate faster than most other plants, and mowed individuals may produce more secondary flower stems and, consequently, more capitulae than undisturbed individuals.[30] Consequently, a few weeks after the last cut, the total forage yield is low and the infestation rate of *J. aquatica* is high. When the meadows are mowed first in autumn (treatment 1), most flowering plants of *J. aquatica* will already have died off. Consequently, the percentage of *J. aquatica* DM in the forage is low, but this cutting regime is not applicable in agricultural practice because of the low quality of hay.

Reports describing the PAs of *J. aquatica* are scarce. Winter et al.[31] reported a *J. aquatica* population with senecionine (**2**) as the main PA, followed by seneciphylline (**3**), integerrimine (**6**),

DOI: 10.1021/jf5047927
J. Agric. Food Chem. 2015, 63, 1293−1299

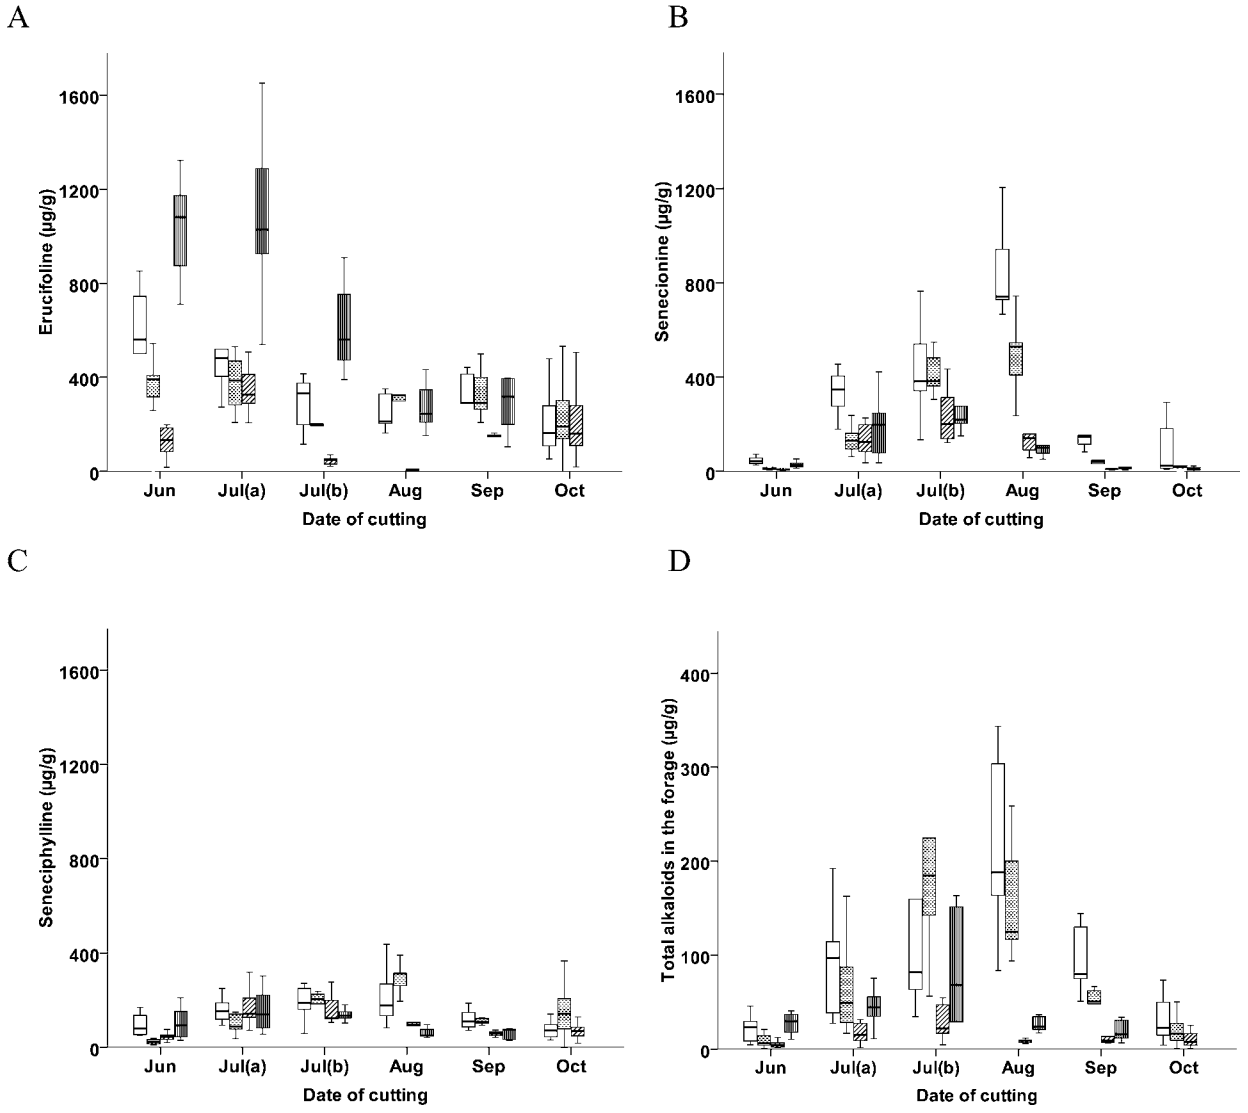

Figure 3. Variability in the content (box plot, µg/g of DM) of (A) *Z*-erucifoline (**1**), (B) senecionine (**2**), and (C) seneciphylline (**3**) of *J. aquatica* and (D) total alkaloid content of forage, at different cutting dates during the years 2007−2010. The legend is the same as in Figure 2.

and *Z*-erucifoline (**1**), from the same Waldviertel region. Erucifoline (**1**) and 9-angeloyl-hastanecine were isolated from *J. aquatica* ssp. *barbareifolius* plants collected in southeast Bulgaria.[22] Senecionine (**2**), integerrimine (**6**), seneciphylline (**3**), *Z*-erucifoline (**1**), and acetyl-erucifoline (**4**) were also found in *J. aquatica* plants in the Netherlands.[3] Additionally, these plants contained jacobine and traces of jacozine, which were not detected in the present study. Further reports from Dutch plants confirmed that these alkaloids for *J. aquatica* as 185 µg/g of senecionine (**2**), 326 µg/g of seneciphylline (**3**), 349 µg/g of integerrimine (**6**), and 29 µg/g of *Z*-erucifoline (**1**) could be measured in the shoots of these plants.[4] In plants, PAs occur as free bases and as *N*-oxides;[24,27,32] for the analysis by GC, the latter must be reduced during clean up.

A systematic analysis of the distribution of the alkaloids within the plant was not carried out in this study. However, in various *Senecio*/*Jacobaea* species, it has been shown that the PAs mostly accumulate in the inflorescences.[32−34] Furthermore, young leaves contain higher alkaloid levels than older leaves.[35] Such a distribution is explained as protecting the plant parts important for further growth.

With regard to the influence of the cutting regime on alkaloid production, we have to take into account different cutting dates. Three treatments were cut in early October. The alkaloid load at that time in the year was generally lower than in earlier cuttings. In comparison to the first year (2007), during 2 years (2008 and 2009), the alkaloid content in the plants from treatment 1, representing a very late first cutting, was lower than in the plants from the other cutting regimes, representing second or third cuttings (data not shown).

The alkaloid accumulation in *J. aquatica* appears to be influenced by several factors, including nutrient supply,[36] water supply,[4] and ontogenetic development.[9,32] Sometimes changes in the PA concentration may be explained by changes in the biomass production rather than true alkaloid production.[36] All of these factors influence the alkaloid levels differently in the various cutting regimes (treatments) tested. Additionally, differences between the years arise from the varying weather conditions. Plants harvested very late in the season (October) were senescent, with their seed production almost completed and the capitulae starting to decay. Thus, they bear lower alkaloid contents in all treatments. Plants cut in late July and August established from individuals that were cut 4−6 weeks

DOI: 10.1021/jf5047927
J. Agric. Food Chem. 2015, 63, 1293−1299

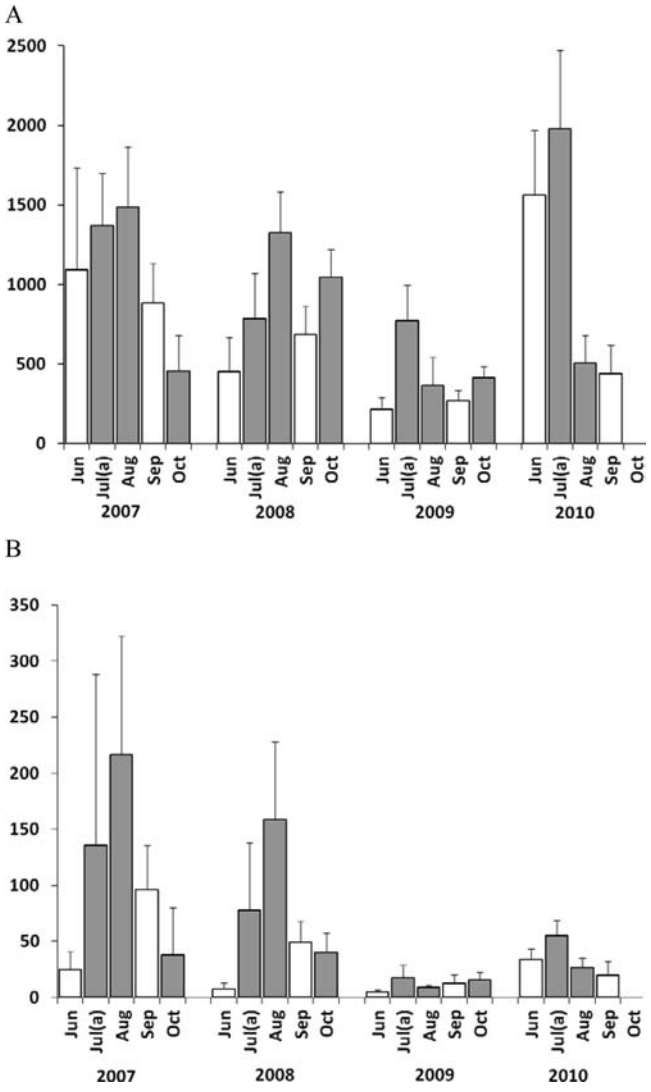

Figure 4. Comparison of the total alkaloid content (μg/g of DM) in (A) *J. aquatica* and (B) fodder, in treatments 2 (white bars) and 5 (gray bars). Mean values with standard deviation (n = 5).

earlier and showed only younger but, nevertheless, flowering shoots with relatively higher alkaloid contents. The samples from treatment 2 cut in September developed from plants that benefited from a longer period for regrowth and, therefore, were already subject to senescence, leading to lower alkaloid contents.

All six monitored PAs are toxic, bearing the structural prerequisites needed to be converted into toxins by cellular cytochrome P450 enzymes. These are (i) a 1,2 double bond, (ii) an esterified allylic hydroxyl group at C-9, and (iii) a second esterified alcoholic hydroxyl group at C-7.[6] During the past few decades, various intoxications of livestock with *Senecio* species have been reported and also feeding experiments with these toxic plants have been carried out to study the toxicity. However, it is difficult to establish toxicity levels because the alkaloid contents of the plants and dosage and duration of toxic plant intake are too variable.[7] Selective food intake may occur because a higher percentage of *J. aquatica* in the remaining material in the manger was left than in the hay. Such a selection was almost impossible in the case of silage.[37] Horses are the most sensitive grazing animals. Among the ruminants, the susceptibility decreases from cattle to goats and to sheep. Levels of 100 μg/g (mg/kg) total alkaloids are easily reached in the fodder cut during July and August (Figures 3D and 4B) when the forage contains more than 5% ragwort. Using this as fodder may provide more than 1−3 mg/kg of body weight PA per day to the animals, a dosage that is considered to induce intoxications,[10] especially when fed during a longer period of time. Therefore, at least the fodder from the July and August cuttings should not be fed to domestic animals.

Great variations occurred in the alkaloid contents of marsh ragwort between the years and the cutting dates. A late cut fodder, which is low in alkaloids, is not useful for agricultural purposes. During the summer, the plants were able to grow quickly, so that they produced flowering stalks 4−5 weeks after a cutting. During this time, marsh ragwort infestation can be high, and therefore, the resulting contamination of forage with toxic PAs may present a health risk for livestock. A long-term management must avoid the seed production of this toxic plant. The following management regime can be a compromise: The forage of a cutting before flowering is best suited for feeding. If it is carried out in early June, it also does not negatively affect biodiversity goals. Further cuttings should be carried out at peak flowering at about 5−7 weeks later. The fodder of these cuttings can be used for non-feeding purposes, such as composting or supply of a biogas plant.

J. Agric. Food Chem. 2015, 63, 1293−1299

The behavior of pesticides in green tea shoots and the effects of manufacturing on residues in made tea, as well as their transfer rates during tea brewing, have been extensively reported.[17−19] However, few studies have reported on the enantioselective dissipation behavior of chiral pesticides in tea matrix, except for indoxacarb and *cis*-epoxiconazole.[20] In this study, a rapid method has been developed for the separation and determination of acephate and methamidophos enantiomers using gas chromatography with a QuEChERS sample preparation technique. Enantioseletive dissipation of acephate and methamidophos in tea was investigated during cultivation, manufacturing, and infusion.

MATERIALS AND METHODS

Field Trial. The field trial was conducted in a tea plantation (variety, Longjing 43; area, 666.7 m^2; location, Tea Research Institute, Chinese Academy of Agricultural Sciences, Hangzhou, China) from June 9 to July 14, 2014. The plantation was divided equally into six plots for treatment or control, leaving one row of bushes to separate each plot. After being diluted by a factor of 1:400, acephate (30% EC) was sprayed on tea leaf surfaces in five replications with a hand-operated knapsack sprayer. The control was sprayed with a similar amount of water. Before application, fresh tea leaves collected in this plantation were analyzed, and no acephate or methamidophos was found.

Sampling and Sample Preparation. The fresh tea leaves (one bud with two leaves) were collected randomly from tea trees in each plot on 0 (2 h), 1, 3, 5, 7, 10, 14, 21, 28, and 35 days after application to investigate the enantioselective dissipation of acephate and its metabolite during cultivation. Meanwhile, to determine the effects of tea manufacturing on the enantioselective dissipation of acephate and its metabolite, fresh tea leaves were picked from both treatment and control on days 1 and 3 and then made into green and black tea immediately. Samples collected at each stage of manufacturing were analyzed on the day of collection prior to storage.

The tea manufacturing steps were as follows. For green tea manufacturing: (a) spreading, that is, the plucked leaves were spread on a bamboo mat for 5 h at room temperature (23−25 °C) with good ventilation; (b) fixing, that is, the spread leaves were fried in a caldron-type water-removing machine at 220−230 °C to inactivate various enzymes; and (c) drying, that is, fixed leaves were dried by hot air at 110 °C to a final moisture concentration of approximately 3%. For black tea manufacturing: (a) withering, that is, the plucked leaves were spread on withering troughs for approximately 15 h at room temperature (23−25 °C); (b) rolling, that is, withered leaves were rolled by hand for 30−40 min at different pressures; (c) fermentation, that is, rolled leaves were stacked together and covered with a wet nylon net to maintain high relative humidity (about 95%) for 5−6 h to facilitate enzymatic oxidation; and (d) drying, a process similar to that in green tea manufacturing.

A total of 3 g of made tea was brewed with 150 mL of boiling water for 5 min. The infusion was then filtered out, and spent leaves were left. Both infusion and spent leaves were cooled for further analysis in the laboratory.

Chemicals and Reagents. Racemate standards of acephate and methamidophos were obtained from Agro-Environment Protection Institute (1000 mg/L, Tianjin, China). Organic solvents were of analytical grade and purchased from Merk (Darmstadt, Germany). The sorbents of primary−secondary amine (PSA), graphitized carbon black (GCB), and octadecylsilane (C_{18}) were purchased from Agela (Tianjin, China). Analytical grade sodium chloride (NaCl) and anhydrous magnesium sulfate ($MgSO_4$) (Zhejiang, China) were baked for 3 h at 650 °C prior to use. Ultrapure water was made from a Milli-Q water purification system (Bedford, MA, USA) in the laboratory.

Sample Pretreatment. For made tea, samples (2 g) were weighed into a 50 mL centrifuge tube and presoaked with 1 mL of boiled ultrapure water for 15 min. Target pesticides were extracted with 10 mL of acetonitrile by homogenization at 12000 rpm for 2 min. Afterward, 5 g of NaCl and 1 g of $MgSO_4$ were added in the centrifuge tube. The sample was mixed on a vortex mixer immediately for 30 s, followed by a centrifugation at 5000 rpm for 10 min. An aliquot of 2 mL was transferred from the supernatant to a 5 mL centrifuge tube, which contains 200 mg of PSA, 200 mg of C_{18}, 50 mg of GCB, and 100 mg of $MgSO_4$. Then the whole centrifuge tube was vortexed for 30 s before centrifugation (4000 rpm, 10 min). An aliquot of 1 mL was transferred and evaporated to dryness using a nitrogen flow controller. Residues were dissolved in 1 mL of acetone and filtered through a 0.22 μm membrane for final determination by GC-FPD.

For the fresh tea leaves collected within 7 days after acephate application, preparation was similar to the made tea samples mentioned above in addition to presoaking. To reduce the limits of quantification (LOQs) and meet the demand of detection, an additional concentration step was used prior to QuEChERS cleanup for the fresh tea leaves collected on days 10−35. The fresh tea leaves (4 g) were homogenized with 20 mL of acetonitrile in a centrifuge tube at 12000 rpm for 2 min. Then 5 g of NaCl and 2 g of $MgSO_4$ were added. Vortexing was performed for 30 s followed by centrifugation for 10 min at 4000 rpm. An aliquot of 10 mL was transferred and evaporated to 2 mL for further cleanup. Subsequent cleanup steps were similar to those for made tea samples, except the dissolved volume used was 0.5 mL of acetone.

For tea soup, liquid−liquid extraction was used to extract target pesticides from 50 mL of tea soup (dissolved with 10% NaCl) with 50 mL of dichloromethane. The organic phase was evaporated to dryness and dissolved in 2 mL of acetone for final determination.

For spent tea leaves, residues after tea brewing were sheared into pieces and transferred into a centrifuge tube, before the addition of acetonitrile (10 mL). The subsequent steps were similar to those for made tea sample.

Instrumentation. Acephate and methamidophos enantiomers were determined by gas chromatography (Agilent 7890 A, Wilmington, DE, USA) coupled with FPD. Enantiomeric separation was performed by a BGB-176 capillary column (30 m × 0.25 mm × 0.25 μm, BGB, Adiswil, Switzerland), having 20% 2,3-dimethyl-6-*tert*-butyldimethylsilyl-β-cyclodextrin dissolved in BGB-15 (15% phenyl-, 85% methylpolysiloxane). Carrier gas was high-purity nitrogen with a constant flow of 1.2 mL/min, and injection volume was 1 μL. The temperatures of the injector and detector were 230 and 245 °C, respectively. Oven temperature was maintained at 80 °C for 1 min, then increased to 220 °C at 10 °C/min, and held for 5 min.

Data Analysis. To evaluate chromatographic peaks of chiral acephate and methamidophos, the resolution (R) was calculated on the basis of the following equation: $R = 1.18 \times [t_{R(2)} - t_{R(1)}]/[W_{1/2(1)} + W_{1/2(2)}]$. $t_{R(1)}$ and $t_{R(2)}$ here stand for the retention times of the first and second enantiomers eluted from the column, respectively. $W_{1/2(1)}$ and $W_{1/2(2)}$ represent the half-peak width of the first and second enantiomers eluted from the column.

Generally, the dissipation of chiral pesticides hypothetically follows first-order kinetics.[21] In this study, this kinetic was calculated by Sigmaplot 12.5. Enantiomeric fractions (EF), as given by Harner et al.,[22] were used to express the differences between enantiomers, that is, $EF = E_1/(E_1 + E_2)$, where E_1 and E_2 represent the concentrations of the first and second enantiomers eluted from the column, respectively. In this study, E_1 stands for (+)-acephate or (+)-methamidophos. The values of EF ranged from 0.000 to 1.000, wherein EF = 0.500 referred to the racemic mixture.

Transfer rates of acephate or methamidophos enantiomers from made tea to infusion were calculated using eq 1

$$\text{transfer}\,(\%) = (m_1 - m_2)/m_1 \times 100 \quad (1)$$

where m_1 and m_2 stand for the concentrations of the target compounds (mg/kg) in made tea and spent tea leaves, respectively.

Validation Study. This method was validated by analyzing its performance characteristics, such as linearity, recovery, limit of detection (LOD), LOQ, and matrix effect (ME).

For sensitivity evaluation, the linearity was determined using mixed standard solutions at five concentration levels, ranging from 0.08 to 1.6

J. Agric. Food Chem. 2015, 63, 1300−1308

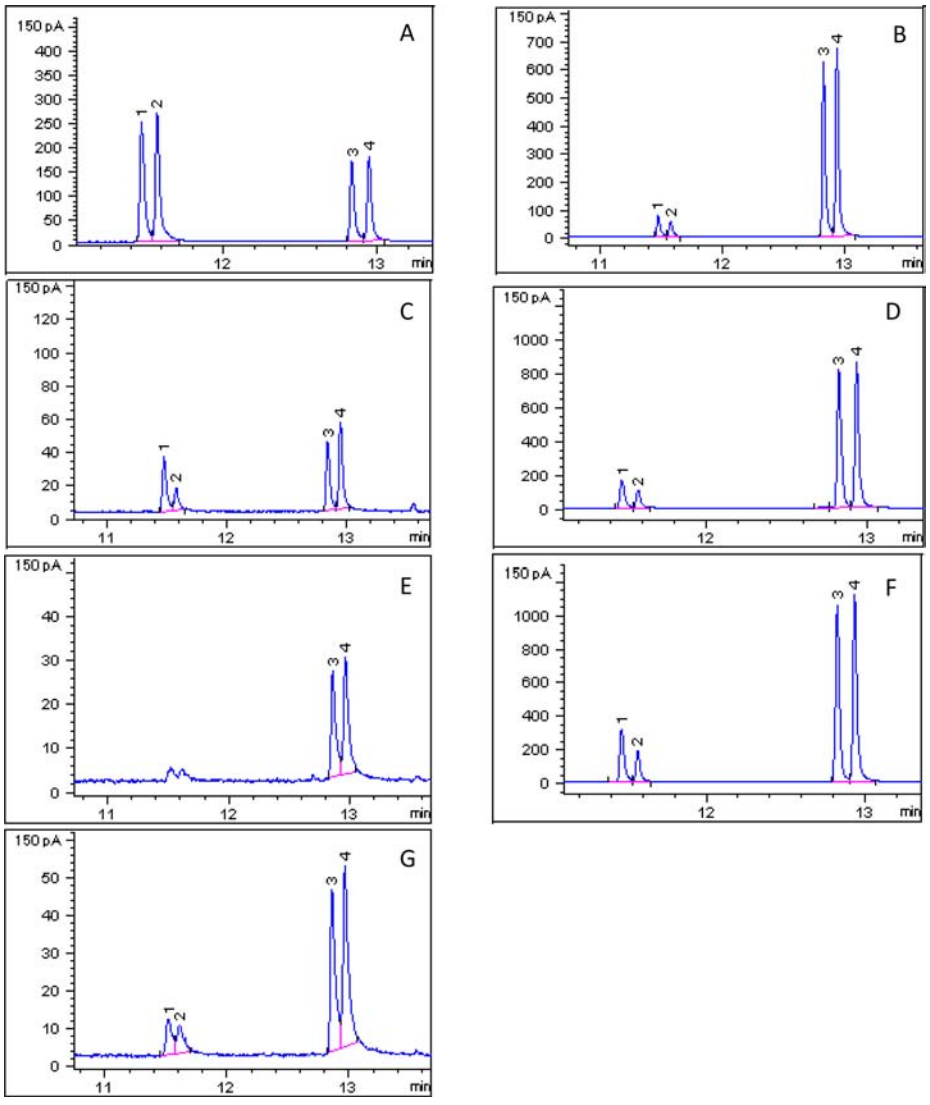

Figure 2. Typical chromatograms of acephate and methamidophos enantiomers in matrix standard solution (fresh tea leaves, 0.8 mg/kg) (A), fresh tea leaves on day 3 (B), fresh tea leaves on day 14 (C), green tea on day 3 (D), spent leaves of green tea on day 3 (E), black tea on day 3 (F), and spent leaves of black tea on day 3 (G). Peaks: 1, (+)-methamidophos; 2, (−)-methamidophos; 3, (+)-acephate; 4, (−)-acephate.

mg/kg for each enantiomer in multiple matrices. The LODs and LOQs for each enantiomer were confirmed on the basis of signal-to-noise (S/N) ratios of 3 and 10, respectively. The matrix effect was calculated by the ratio of the slopes for corresponding matrix-matched and solvent standards. Matrix-matched standard solutions were prepared with blank samples and used for quantification by external standard method.

To evaluate the accuracy and precision of this method, recovery was evaluated by spiking blank materials at two different levels (0.04 and 0.4 mg/kg for fresh tea leaves, whereas 0.4 and 1.6 mg/kg for other matrices).

RESULTS AND DISCUSSION

Method Optimization and Validation. A commercial BGB-176 column was chosen for chiral separation and determination of acephate and methemidophos enantiomers by GC-FPD. Gas chromatographic conditions, such as oven temperature program and flow rate of carrier gas, were optimized step by step for quicker analysis (Supporting Information Tables 1−3). Ultimately, satisfactory capacity ($R_{acephate}$ = 1.37 and $R_{methamidophos}$ = 1.97) was obtained for the whole analysis of each enantiomer within 25 min as described above. According to the previous study by Wang,[23] the (+)-form would be eluted from the column first, followed by the (−)-form for both acephate and methamidophos (Figure 2A).

Addition of water to the tea matrix can significantly improve the extraction efficiency.[24,25] In this study, the effects of adding different levels of water (0, 1, 5 mL) on extraction efficiency were investigated in both spiked made tea and positive made tea. The average recoveries of presoaking with 0, 1, and 5 mL of water were 61.3, 52.5, and 38.2% for acephate and 68.6, 60.0, and 42.5% for methamidophos, respectively. The results indicated that addition of water would reduce the recoveries of both pesticides, which is explained by the pesticides going into the water due to their high polarity.[26] However, extraction yield of acephate in positive samples by presoaking was 11.3−13.9 times that without presoaking. Methamidophos was determined with 0.8−1.0 mg/kg by presoaking, whereas it was not detected without presoaking (Supporting Information Table 4). This indicated that presoaking was necessary to facilitate polar pesticide separation from the matrix. However, it is hard to overcome the great loss of acephate and

[a]ME. matrix effect. It was calculated by the ratio of slope of matrix and solvent, where matrix suppression takes place with ME <1.00 and enhancement occurs with ME >1.00. [b]Values are presented as the mean ± SD (n = 5).

methamidophos that occurred during extraction from the dried matrix by water presoaking.[27,28] We also investigated ethyl acetate, dichloromethane, and acetone as extraction solvent, and recoveries of acephate and methamidophos enantiomers ranged from 36.1 to 58.9% (Supporting Information Table 5). This result indicated that acetonitrile was the best choice for sample extraction among these solvents, which was in agreement with Kanrar et al.[29] Thus, 1 mL of water was selected to be the addition volume before extraction by acetonitrile. For other tea matrices with certain amounts of water, there is no need of presoaking, and recoveries are similar to made tea samples.

To overcome the interference of coextraction, a mixture of adsorbents (200 mg of PSA, 200 mg of C_{18}, 50 mg of GCB, and 100 mg of $MgSO_4$) was used as a QuEChERS technique to clean up the tea matrix. We investigated the effect of the

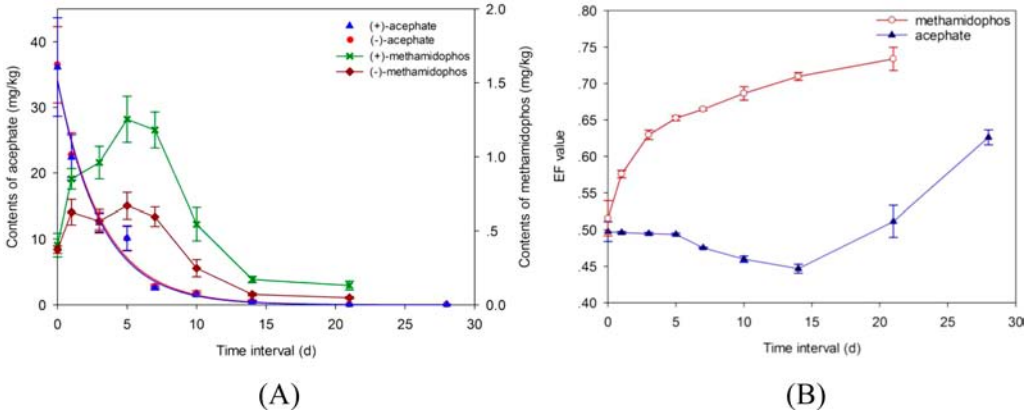

Figure 3. Dissipation of *rac*-acephate in fresh tea leaves (A) and EF value versus time curves of acephate and its metabolite (B). Residues have been corrected with the mean recovery (54% for acephate enantiomers and 62% for methamidophos enantiomers).

proposed adsorbents on the recoveries of acephate and methamidophos enantiomers. Satisfactory recoveries for both pesticides' enantiomers were obtained with the range of 95−98% during cleanup.

The method was validated for fresh tea leaves, made tea, and spent leaves, and the results are presented in Table 1. Recoveries were assessed by spiking the blank samples at two different levels for accuracy evaluation. The recoveries of methamidophos enantiomers spiked in all matrices, which ranged from 58.4 to 65.3%, were higher than those of acephate (50.8−57.5%) ($P < 0.0001$). Low recoveries of acephate (60 ± 10%)[29,30] and methamidophos (26 ± 16%)[30] were also observed in previous studies. All of these studies and our investigation demonstrated that the loss of acephate and methamidophos occurred during extraction, rather than cleanup. The precision was evaluated by the relative standard deviation (RSD) of recoveries for five replications. Acceptable precision for all enantiomers was obtained with RSDs <7%, indicating that this method is consistent. According to European Council No. SANCO 12495-2011,[31] these recoveries could also be acceptable for its consistency. Meanwhile, it is justifiable to correct the results using appropriate recovery factors during quantitation.[32,33] To reflect the actual levels of the residue, data in this study were corrected by the mean recovery of acephate (54%) or methamidophos (62%), respectively, because there is no significant difference of their recoveries among various tea matrices ($P \geq 0.6321$).

Good linearity for each enantiomer was achieved with determination coefficients ≥0.9968. Matrix effects were dependent on enantiomers and tea matrices. Little enhancement or suppression occurred in green tea and its spent leaves for (−)-form enantiomers or in fresh tea leaves for methamidophos enantiomers. Significant matrix enhancement was observed from enantiomers in other matrices. LOQs of enantiomers varied from matrix to matrix. In made tea and spent leaves, although the LOQs (0.1−0.3 mg/kg) were relatively slightly higher, the values have reached the analytical sensitivity in this study because the residues in these samples remained at relatively high levels. Doubled sample amount and lower dissolved volume used in the fresh leaves preparation effectively expanded determination range, resulting in lower LOQs (0.015 mg/kg for acephate enantiomers and 0.01 mg/kg for methamidophos enantiomers). Thus, the proposed method meets the requirements of enantiomer analysis in this study.

Enantioselective Dissipation of Residues in Fresh Tea Leaves. Enantioselective dissipation of acephate and its metabolite, methamidophos, in the tea plantation was investigated, and the results are shown in Figure 3.

Dissipation kinetics of (+)-acephate and (−)-acephate were fitted in a first-order kinetic model with correlation coefficients of 0.9880 and 0.9899, respectively. Half-lives of (+)-acephate and (−)-acephate were about 1.8 and 1.9 days, respectively. The initial deposits of (+)-acephate and (−)-acephate were 36.14 and 36.49 mg/kg, respectively. Then these deposits decreased to 12.50 and 12.76 mg/kg correspondingly 3 days after their field application, which showed a great reduction of approximately 65%. The concentrations of each acephate enantiomer were <10% of initial deposits on day 7, due to the degradation and growth dilution of tea shoots.[34−36]

EF values of acephate decreased from 0.498 to 0.447 in the first 14 days, followed by a significant increase to 0.626 on day 28 ($P < 0.0001$). This phenomenon indicated that faster dissipation of (+)-acephate resulted in a relative enrichment of (−)-acephate in fresh tea leaves within 14 days after application. Acephate would disappear immediately from the surface of the leaves after application and permeated into tissues in 24 h.[37] The enzymatic system was reported to be the most important factor in enantioselective dissipation.[38,39] Therefore, the reduction in the EF curve could be attributed to the effects of various enzymes in the fresh tea leaves. However, it could not be the reason for the increase of EF after day 14, because the enzymatic system in tea fresh leaves should have the same effect on preferential dissipation. Acephate, as a systemic pesticide, can translocate within a tree when it is adsorbed by leaves.[40] Thus, we inferred that enantiotranslocation of acephate was likely to exist and (+)-acephate may prefer to translocate into new leaves during tea growth because new buds have sprouted and grown during this period.

Methamidophos was reported to be one of the most important degradation products of acephate in crops and environments.[37,41] Methamidophos (<1%) is permitted to exist in acephate formulation due to its degradation during storage.[42] Nevertheless, approximately 0.5% of methamidophos was found in acephate formulation (30% EC), from the results obtained from its dilution. Therefore, although 0.40 mg/kg (+)-methamidophos and 0.37 mg/kg (−)-methamidophos in fresh leaves were detected respectively on day 0 (2 h), these compounds most likely originated from the pesticide formulation itself. Subsequently, both (+)-methamidophos

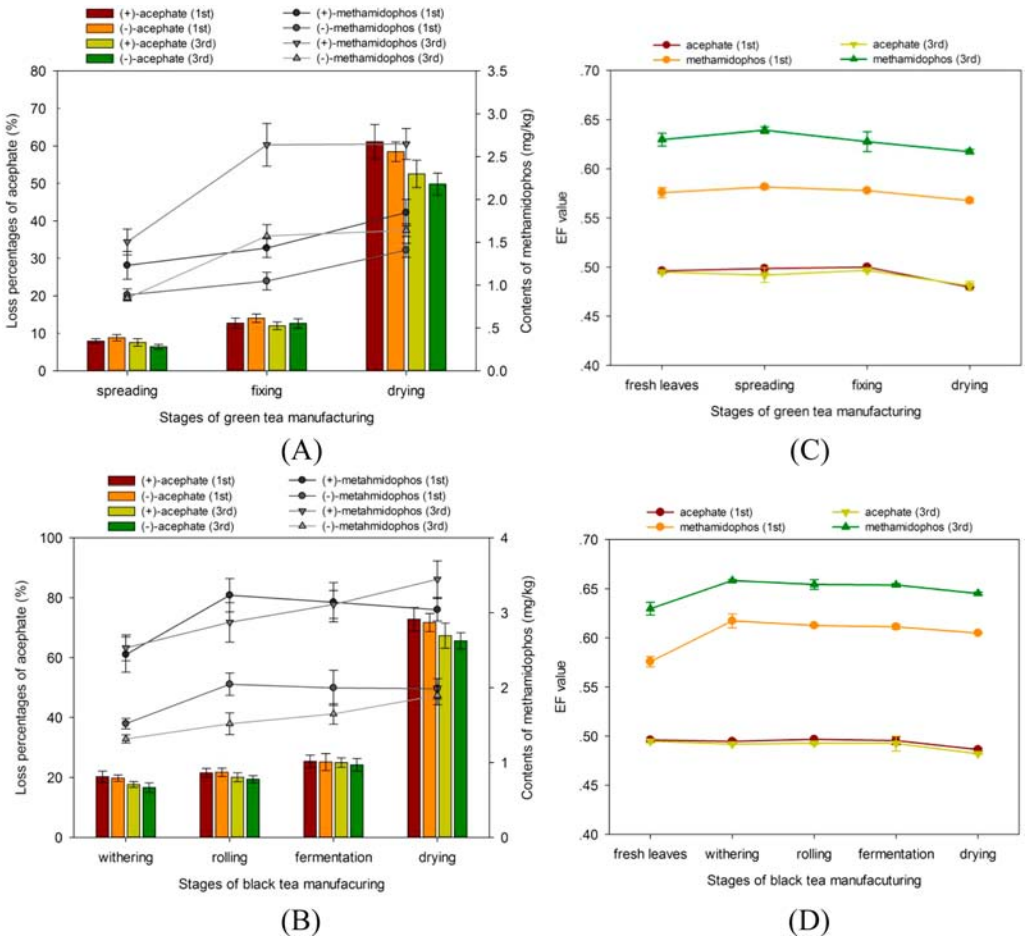

Figure 4. Changes of acephate and its metabolite enantiomers and EF value curves during green tea (A, C) and black tea (B, D) manufacturing. (1) Residues have been corrected with the mean recovery (54% for acephate enantiomers and 62% for methamidophos enantiomers). (2) Moisture content has been taken into account in the loss percentages of acephate enantiomers. (3) First and third stands for the tea manufacturing were conducted on days 1 and 3, respectively.

and (−)-methamidophos reached their highest concentrations (1.25 and 0.67 mg/kg, respectively) on day 5, followed by a gradual dissipation to 0.13 and 0.05 mg/kg on day 21 after application. The increase of methamidophos enantiomers indicated that acephate was degraded into methamidophos in tea cultivation indeed.

The EF value of methamidophos increased with time after application. Wang et al. have reported that there is no interconversion of the (+)-form to the (−)-form or vice versa in soil.[16] In this study, no significant enantioselective dissipation of acephate enantiomers ($P \geq 0.2142$) was found in the first 5 days after application. Thus, compared with its antipode, the higher concentration of (+)-methamidophos during degradation revealed that (−)-methamidophos was preferentially dissipated mainly due to enzyme action.

Effects of Tea Manufacturing on Enantioselective Dissipation. In this study, fresh tea leaves with different deposited pesticides were submitted to green tea and black tea manufacturing. Residues of acephate and methamidophos enantiomer were monitored at each stage of tea manufacturing, and the results are presented in Figure 4. Generally, water evaporation would cause an increase in weight concentration of dry matters, so that residues of pesticides should increase by a similar factor. Thus, the whole amount of residues decreased, although the concentration of the acephate enantiomers showed a slight fluctuation during tea manufacturing. The total loss of acephate enantiomers in black tea was much higher [67.4−72.8 and 65.6−71.8% for (+)-acephate and (−)-acephate, respectively] than green tea [52.6−61.1 and 49.8−58.4% for (+)-acephate and (−)-acephate, respectively]. In addition, fresh leaves collected on day 1 showed a larger loss of enantiomers [61.1−72.8 and 58.4−71.8% for (+)-acephate and (−)-acephate, respectively] than those collected on day 3 [52.6−67.4 and 49.8−65.6% for (+)-acephate and (−)-acephate, respectively].

Among various manufacturing processes, drying made the most important contributions to the dissipation of (+)-acephate and (−)-acephate, leading to a considerable losses of 37.2−48.3%. The loss of acephate enantiomers was much higher than those of carbofuran and carbaryl, which were degraded by 27.0 and 29.0%, respectively, during drying.[43] Drying might facilitate chemical distillation when the water in tea leaves evaporated,[44] wherein the possibility of codistillation depends on the water solubility of the chemicals.[45] Acephate, with extremely high water solubility, is easily absorbed by the water, whether it is inside the leaf tissues or on the surface of tea leaves. Thus, water covolatilization resulted in an impressive reduction of acephate enantiomers. During drying, the EF values of acephate decreased from 0.497−0.500 to 0.479−0.481 when submitted to green tea manufacturing, whereas these values decreased from 0.493−0.495 to 0.482−0.486 in black tea manufacturing. This finding suggested that (+)-acephate was more prone to

[a]First and third in matrix stand for tea manufacturing conducted on days 1 and 3, respectively. [b]These concentrations were corrected by the mean recovery (54% for acephate enantiomers and 62% for methamidophos enantiomers). [c]Enantiometic fractions (EF) = concentration of the (+)-enantiomer/[sum concentrations of the (+)-enantiomer and (−)-enantiomer]. It ranges from 0.000 to 1.000, with EF = 0.500 representing the racemic mixture.

dissipate than its antipode, causing a relative enrichment of (−)-acephate. Such a change in the EF value is similar to that for indoxacarb reported by Zhang et al.,[20] who found that the EF value is much lower in made tea than that in fresh tea leaves collected at the same time. Enantiomers of acephate may demonstrate different distributions inside tea leaves or combinations with compounds of tea leaves. The one close to the surface of leaves or combined lightly would undergo distillation much more easily during water evaporation. However, the reason for the preferential dissipation needs further investigation.

Moreover, compared with spreading in green tea manufacturing, the reduction of (+)-acephate and (−)-acephate during withering in black tea manufacturing (17.6−20.3%) is more than doubled. This finding is in agreement with Hou's suggestion[46] that withering may be the key factor of much lower residues in black tea than in green tea. These two stages resulted in the dissipation of acephate enantiomers because of the physicochemical properties of acephate, such as volatility and water solubility,[19] and residues decreased with increasing time. However, fixing in green tea manufacturing as well as rolling and fermentation in black tea manufacturing did not show much impact on residue concentrations. Little enantioselectivity ($P \geq 0.0619$) was found in all of the stages described above.

By contrast, the concentration of methamidophos enantiomers decreased by 36.4−52.2 and 10.2−30.3% in green tea and black tea, respectively, although an increase in concentration was present during the manufacturing. EF curves of methamidophos demonstrated an increase to 0.582−0.658 during spreading of green tea manufacturing or withering of black tea manufacturing, followed by a slight decrease to 0.568−0.645 during the stages of tea manufacturing. The increase of EF value suggested that (−)-methamidophos was preferentially degraded or dissipated because no enantioselectivity of acephate occurred during withering and spreading. Similar to that on fresh tea leaves, the enantioselectivity of methamidophos was mainly attributed to the effects of enzymes, which had been mentioned above. After spreading, enzymatic activities were inhibited by high temperature of 220−230 °C during fixing, so the key factor of enantioselective dissipation was absent. During rolling, the tea leaf cells were disrupted and chemical compounds, such as polyphenols, started to undergo oxidation, and some competitive effects probably existed among the degradation of methamidophos and other chemical compounds.[47] Thus, methamidophos presented little enantioselectivity ($P \geq 0.0584$) after spreading in green tea manufacturing or withering in black tea manufacturing.

Transfer Rates of Each Enantiomer during Tea Infusion. Residues in made tea would be left in spent leaves during brewing, if they were not transferred into tea infusion, because few of these residues would undergo thermal hydrolysis or escape into atmosphere.[48] In this study, recoveries of acephate and methamidophos enantiomers in tea infusion were too low (<10%; Supporting Information Table 6) for accurate quantification. Therefore, residues in spent tea leaves were analyzed to express the transfer rate indirectly and roughly because satisfactory recoveries of acephate and methamidophos in spent tea leaves were obtained with the range from 51.2 to 64.1% (RSD < 7%). Concentrations and EF values of each enantiomer maintained in made tea and spent leaves are presented in Table 2.

There is a significant difference of EF values for both acephate and methamidiohos between made tea and spent tea leaves ($P \leq 0.0042$). This suggested that significant enantioselectivity of acephate and methamidophos probably occurred during tea infusion. However, the reason for this

DOI: 10.1021/jf504916b
J. Agric. Food Chem. 2015, 63, 1300−1308

change may due to hydrolyzation,[49] which needs further investigation.

Transfer rates of acephate and methamidophos enantiomers were higher than 80.5% and 89.1%, respectively. Theoretically, chemical properties, such as water solubility (W_s) and partition coefficient (K_{ow}), were the key factors of transfer rates of pesticides during tea brewing.[50−52] Therefore, enantiomers of acephate and methamidophos with comparatively high W_s [$W_{s(acephate)}$ = 790 g/L; $W_{s(methamidophos)}$ = 200 g/L] and low K_{ow} [$K_{ow(acephate)}$ = 0.14; $K_{ow(methamidophos)}$ = 0.16] led to a large proportion of 80−90% transferring from made tea to tea infusion.

Interestingly, acephate and methamidophos enantiomers with higher concentration showed lower transfer percentages. Contrary to the present study, Tewary[53] reported that the transfer rate of bifenthrin increased with the residue concentration of made tea, and Chen[54] showed that GA_3 with higher concentration was much more easily extracted during infusion. Such a consequence may be attributed to the high transfer rate, which reached up to approximately 90%. The transfer percentage would no longer be sensitive to W_s when the rate reaches a certain degree.[48] In addition, abundant organic substances, such as polyphenols and caffeine, may promote the saturation of acephate and methamidophos enantiomers in tea infusion, resulting in relatively lower transfer rates.

A metabolomic study can contribute significantly to our understanding of stress in plants and other organisms by identifying various stress-related compounds, such as by-products of stress metabolism, stress signal transducers, and molecules that comprise the acclimation response of plants.[4] This study describes a method that makes use of metabolic profiling and metabolic fingerprinting to obtain a holistic view of stress in plants. This study also includes a detailed pathway analysis. Even with the highest-quality soil and agricultural practices, the impact of stress on a crop can reduce productivity significantly. Thus, diminishing farm land and the potential effects of global climate change on environmental and pathogen or insect-induced stresses provide an increased impetus to understand stress resistance in crop plants.[13] Although much concerning the participation of flavonoids in plant stress is known, the exact function of flavonoid metabolites in a plant's reaction to toxic heavy metals remains a topic of debate.[14] However, it is important to note that not all plants respond to heavy metals in the same manner.[14] This report describes a metabolomic study of burdock roots in response to copper stress.

MATERIALS AND METHODS

Chemicals. Methanol-d_4 (99.8% v/v) and deuterium oxide (99.9% v/v) were obtained from Cambridge Isotope Laboratories, Inc. (Andover, MA). Acetic acid, methylnonadecanoic acid, and 3-(trimethylsilyl)-1-propanesulfonic acid sodium salt were purchased from Sigma–Aldrich (St. Louis, MO). HPLC-grade methanol, water, and methylene chloride were purchased from Burdick & Jackson (Muskegon, MI).

Plant Materials. Burdock plants were cultivated from March to July 2011 in bare ground after seeding. Stress experiments were performed in pots. Eighty plants were transplanted into four pots and allowed to acclimate for 4 weeks. To elicit stress, two pots were spiked with 100 μM $CuCl_2$, while another two pots received a spike of deionized water (DW; control group). Each of the pots received 500 mL of copper solution every 2 days. Plants were harvested after 1 and 6 days, rinsed immediately with water, and divided into groups of eight plants each. Photographs of burdock roots are provided in Supporting Information, Figure S1. Roots cut from the plants were rapidly frozen in liquid nitrogen, chopped into small pieces, freeze-dried, and ground into a fine powder in liquid nitrogen by use of a pestle and mortar. The resulting tissue powder was stored at −80 °C until required for analysis.

Sample Preparation. To obtain a copper-stress-induced metabolic profile, nonpolar and polar metabolites were sequentially extracted from the same sample. This strategy provides a convenient means of replicating the results and performing multivariate data analysis by accounting for the inherent biological variation of independent samples.

For the extraction of nonpolar metabolites, 4 mL of methylene chloride (MC) and 10 μL of 1 mg/mL methylnonadecanoic acid (internal standard) were added to 100 mg of dry, powdered plant material. The mixture was thoroughly mixed at room temperature (RT) for 1 h. The mixtures were centrifuged at 3000 rpm for 10 min at 4 °C. The resulting supernatants were passed through a 0.2-μm poly(tetrafluoroethylene) syringe filter (Merck Millipore, Billerica, MA). The extracts were dried with N_2 gas and dissolved in 200 μL of chloroform for GC–MS analysis. The remaining tissue pellets were extracted with 4 mL of MeOH containing 15 μL of 2 mg/mL sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) in order to profile the polar metabolites. The MeOH extracts were prepared in the same way as the MC phase. Aliquots (500 μL) of the MeOH extracts were transferred to a separate vial for additional analyses. The remaining MeOH extracts were dried with N_2 gas. For NMR analyses, the resulting residue was dissolved in a mixture of 300 μL of methanol-d_4 and 300 μL of 0.2 M sodium phosphate buffer (pH 7) in D_2O. D_2O and DSS provided a field frequency lock and a chemical shift reference (^{1}H, δ 0.00), respectively.

GC–MS Analysis and Data Preprocessing. GC–MS analyses were performed on a 6890 Plus gas chromatograph equipped with a 5973N quadrupole mass spectrometer system (Agilent, Palo Alto, CA). A DB-5 MS capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness, 5% diphenyl–95% dimethylsiloxane phase) was obtained from J&W Scientific (Folsom, CA). The GC oven temperature was maintained at 60 °C for 2 min, then ramped to 320 °C at 10 °C/min and maintained for 10 min. The sample was injected with a splitting ratio of 1:10. The temperatures of the GC injection port and MS interface were 250 and 280 °C, respectively. Helium was used as the carrier gas at a constant flow rate of 1 mL/min. The mass spectrometer was run in electron impact (EI) mode, with an electron energy of 70 eV. Mass spectra were acquired at 1 scan/s with a full scan range of 50–800 atomic mass units (amu). A freely available mass spectral deconvolution algorithm (automated mass spectral deconvolution and identification system, AMDIS) was used to analyze the data in combination with a filtering algorithm (SpectConnect) for processing of multiple data sets. All GC–MS data were normalized by use of methylnonadecanoic acid as an internal standard.

NMR Analysis and Data Preprocessing. ^{1}H NMR spectra were acquired on a VNMRS 600-MHz NMR spectrometer using a triple-resonance HCN salt-tolerant cold probe (Agilent Technologies Inc., Santa Clara, CA). A NOESYPRESAT pulse sequence was applied to suppress the signals from residual water. For each sample, 64 transients were collected into 67 568 data points with spectral width of 8445.9 Hz, relaxation delay of 2.0 s, acquisition time of 4.00 s, and mixing time of 100 ms. A 0.5-Hz line-broadening function was applied to all spectra prior to Fourier transform (FT). The assignments of NMR signals were based on total correlation spectroscopy (2D ^{1}H–^{1}H TOCSY), heteronuclear single quantum correlations (2D ^{1}H–^{13}C HSQC), and spiking experiments.

All NMR spectra were phased and baseline-corrected by use of Chenomx NMR suite version 7.1 (Chenomx Inc., Edmonton, Alberta, Canada). The regions corresponding to water, methanol, and DSS (4.78–4.85, 3.29–3.37, and 0.00–0.70 ppm, respectively) were excluded, and the remaining spectral regions were divided into 0.005 ppm bins. The spectra were then normalized to the total spectral area and converted to ASCII format. The ASCII files were imported into MATLAB (R2006a; Mathworks, Inc., Natick, MA) and all spectra were aligned by use of the correlation optimized warping method.[15]

NMR Data Processing. The resultant NMR data sets were imported into SIMCA-P version 12.0 (Umetrics, Umeå, Sweden) for chemometric analyses. All imported data were Pareto-scaled for multivariate analyses. Pareto scaling, in which each variable is divided by the square root of the standard deviation, gives greater weight to the variables with larger intensity but gives results that are not as extreme as those obtained with unscaled data. Pareto scaling is typically used when a very large dynamic range exists in the data set.[16,17] Principal component analyses (PCA) were performed to examine the intrinsic variation in the data set and to obtain an overview of the variation among the groups. The quality of the models was described by R^2 and Q^2 values. R^2 is defined as the proportion of variance in the data explained by the models and indicates the goodness of fit. Q^2 is defined as the proportion of variance in the data predictable by the model and indicates predictability.[18]

Metabolites were identified by use of Chenomx Profiler, a module of Chenomx NMR Suite version 7.1, and by analysis of the 2D NMR experimental data. The identities of those metabolites deemed important on the basis of chemometric analyses were confirmed by use of spiking experiments and other references. The quantification of primary metabolites was achieved by use of the 600-MHz library from Chenomx NMR Suite version 7.1, which uses the concentration of a known reference signal (in this case DSS) to determine the concentration of individual compounds. The library is based on a database of 260 individual metabolite spectra acquired with the NOESYPRESAT sequence. Because the secondary metabolites were not contained in this library, their intensities were subjected to two-way analysis of variance (ANOVA).

Targeted Analysis by UPLC/QTRAP-MS. Two plant hormones (jasmonic acid and salicylic acid) and seven fatty acids (myristic acid, palmitic acid, stearic acid, palmitoleic acid, oleic acid, linoleic acid, and linolenic acid) of burdock extracts were analyzed by ultraperformance liquid chromatography (UPLC)/QTRAP-MS. Nine targeted metabolites were prepared by dilution of MC and MeOH fractions of the burdock extracts. Separation of these analytes was performed with an Ekspert ultraLC 100-XL system (Eksigent, Dublin, CA) equipped with a high-strength silica (HSS) T3 C18 column that was 50 × 2.1 mm with a 1.8 μm particle size (Waters, Milford, MA). The column temperature was 40 °C and the autosampler was maintained at 4 °C. Aliquots (5 μL) of sample were injected via the partial loop method. The mobile phase consisted of (A) HPLC-grade water with 0.1% acetic acid and (B) methanol with 0.1% acetic acid. The column was eluted at a flow rate of 0.45 mL/min. For separating plant hormones, the mobile phase was changed from 70% A/30% B at time zero to 1% A/99% B over 3.5 min. To separate the fatty acids, the initial composition of the mobile phase was 15% A/85% B, changing to 1% A/99% B over 3.5 min. In both cases the end gradients remained constant for 0.5 min and then returned to the initial composition over 0.1 min and maintained that mixture for an additional 0.9 min.

This UPLC system was connected to a QTRAP 6500 MS/MS (AB Sciex, Framingham, MA) equipped with an IonDrive Turbo V source operating in negative-ion mode. Two plant hormones and seven fatty acids were detected individually by LC−MS/MS using multiple reaction monitoring (MRM) for the transition of the parent ion to the product ion. The concentration of each compound was then calculated according to calibration curves. The MRM transitions were acquired with the following operational parameters: capillary voltage of −4500 V, nebulizer pressure of 60 psi, drying gas pressure of 60 psi, curtain gas pressure of 30 psi, source temperature of 500 °C, entrance potential (EP) of −10 eV, and dwell time of 20 ms for the monitored transition. To obtain reliable results, specific values of collision energy (CE), declustering potential (DP), and collision cell exit potential (CXP) were used for each targeted metabolite. Data acquisition and processing were performed with Analyst version 1.6 software and MultiQuant version 2.1 software (AB SCIEX, Framingham, MA).

Statistical Methods. Two-way ANOVA was performed with GraphPad Prism version 5.0 (GraphPad Software, Inc., La Jolla, CA) to test the significance of differences in metabolite levels among the control and copper-exposed groups on day 1 versus day 6. Bonferroni's test was performed to determine differences between specific groups. Differences were tested at the 95% probability level ($p < 0.05$).

RESULTS

Polar Metabolite Profiling by Use of NMR. Representative one-dimensional ^{1}H NMR spectra of aqueous burdock extracts are shown in Figure 1. Signals in the sugar region of the NMR spectra were higher than those in the aliphatic and aromatic regions. The majority of the detected metabolites were amino acids and sugars, although some organic acids and phenols were also assigned. The following assignments are based on comparisons with the chemical shifts of standard compounds by use of NMR Suite software (version 7.1; Chenomx) and were confirmed by 2D NMR analyses and spiking experiments: alanine at δ = 1.48 and 3.78; arginine at δ = 1.71, 1.93, 3.22, and 3.76; asparagine at δ = 2.81, 2.94, and 4.02; fructose at δ = 3.48−4.11; glucose at δ = 3.20−3.91, 4.58, and 5.19; isoleucine at δ = 0.95 and 1.02; leucine at δ = 0.97; phenylalanine at δ = 7.33 and 7.38; proline at δ = 2.03, 2.34, 3.32, 3.41, and 4.07; succinate at δ = 2.40; sucrose at δ = 3.41−4.18 and 5.40; threonine at δ = 1.33; tyrosine at δ = 6.79 and 7.12; and valine at δ = 1.00 and 1.05. The characteristic signals in the aromatic region of the spectrum were attributed, by 2D

NMR, to phenols having structures similar to that of caffeic acid (Figure 2).

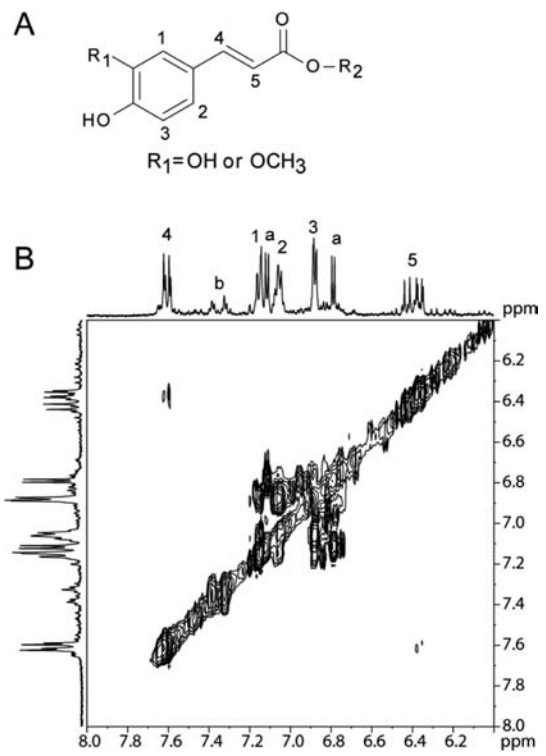

Figure 2. (A) Structure of phenols; (B) expanded TOCSY spectrum. a and b indicate tyrosine and phenylalanine, respectively.

To provide comparative interpretations and a means of visualizing the intrinsic variations and metabolic differences in the burdock root extracts that had been exposed to copper stress, PCA was applied to the ^{1}H NMR data set. The PCA score plot shows significant separation between control and copper-treated groups at different exposure times (Figure 3). The PCA model was established with five components and yielded R^2 and Q^2 values of 0.778 and 0.558, respectively. In this score plot, control groups of burdock root extracts showed no differences between day 1 and day 6. However, groups that had been exposed for 6 days are separated from the other groups by the first component.

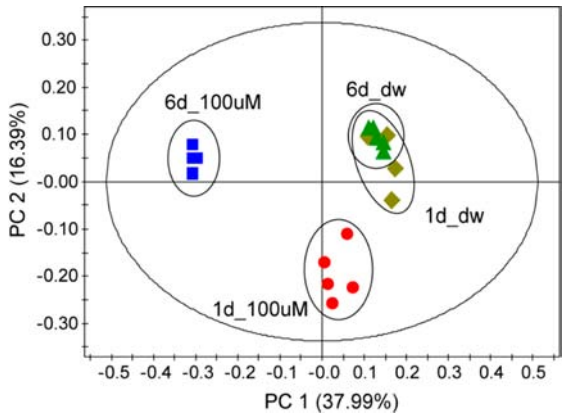

Figure 3. PCA score plot derived from NMR spectra of burdock extracts (R^2 = 0.778, Q^2 = 0.558). The ellipse represents the 95% confidence region for Hotelling's T^2.

To identify the differences in metabolic levels, the aqueous metabolite concentrations were determined by use of the 600-MHz library from Chenomx 7.1. This method compares the integrated intensity of a known reference signal (DSS) with signals derived from a library of compounds containing chemical shifts and peak multiplicities for all of the resonances of that known reference. However, since phenol concentrations could not be determined with Chenomx, peak areas were used instead of compound concentrations.

PCA analyses were performed with quantified metabolites of burdock extracts. The resulting score plot also showed significant separation between control and copper-treated groups (Figure 4). The PCA model was established with three components and yielded R^2 and Q^2 values of 0.926 and 0.803, respectively. In the score plot, control groups of burdock root extracts are separated from copper-treated groups by the first component. Groups with different exposure times (1 or 6 days) are separated by the second component. The loading plot of PCA, in which each data point represents a component (variable), reveals that metabolites that significantly contributed to the intergroup differences were those farthest from the main cluster of metabolites (Figure 4B). Exposure groups were characterized by a lower concentration of all metabolites, except phenols.

Two-way ANOVA was used to assess the significance of observed differences in metabolite levels among the groups. Concentrations of the quantified metabolites and ANOVA results are presented in Table 1. ANOVA showed that, between control and copper-treated groups, all metabolites—with the exception of arginine, proline, and sucrose—were present at significantly different levels.

Nonpolar Metabolite Profiling by Gas Chromatography–Mass Spectrometry. A GC–MS method was used in metabolite profiling of nonpolar extracts. A typical total ion chromatogram of the nonpolar fraction of burdock root extract is shown in Figure 5. Based on spectral similarities and corrections for shifts in retention time, integrated signals of the base peak ions of six major peaks, including the internal standard (IS; methylnonadecanoic acid), were generated by SpectConnect. Identification of the five sample peaks was achieved by searching the NIST05 mass spectral library for compounds matching the experimental fragmented ion to base peak (bp) abundance ratio and retention time. Library matches were validated with standard materials. Thus, the five major peaks were attributed to linoleic acid (9,12-octadecadienoic acid), linolenic acid (9,12,15-octadecatrienoic acid), sitosterol, stigmasterol, and campesterol. The sterol group of the latter three compounds was evidenced by a high-intensity molecular ion. Instead of a molecular ion, compounds containing a fatty acid group yielded an $[M - 15]^+$ ion through the loss of a methyl group.

All mass spectral peaks were normalized by use of methylnonadecanoic acid as an internal standard. Two-way ANOVA was performed to determine the significance of differences in normalized peak intensities. Note that the peak areas used in the ANOVA represented the relative concentration of each metabolite, not the absolute concentration. Nevertheless, relative values can be used to compare among samples. The differences between the copper-treated groups and the controls, determined by Bonferroni post hoc tests, are shown in Figure 6. All five of the metabolites displayed a

[a]Identification and quantification of metabolites were performed with the Chenomx software. Concentrations are indicated as mean ± standard deviation. [b]DW, deionized water (control treatment). [c]P values are the result of two-way ANOVA using GraphPad Prism 5.0. [d]Phenols were assigned by use of standard compounds and 2D NMR data with peak intensities instead of actual concentrations.

significance of $p < 0.05$. Levels of fatty acids, including both linoleic acid and linolenic acid, were significantly higher in extracts of burdock roots that had been exposed to copper for 6 days, while levels of sterols such as sitosterol, stigmasterol, and campesterol were significantly lower than those of the control group.

Targeted Analysis by UPLC/QTRAP-MS. Various primary metabolites—including amino acids, organic acids, and sugars—were detected in NMR analyses of methanolic burdock extracts. However, plant hormones that are known to protect plants from oxidative damage associated with a variety of stresses were not evident in the NMR data. Therefore, targeted analyses of jasmonic acid and salicylic acid were conducted by use of UPLC/QTRAP-MS. In addition, among the various fatty acids in the extracts, only linoleic acid and linolenic acid were detected in the GC–MS analyses. To identify not only unsaturated fatty acids but also saturated fatty acids, targeted analyses of myristic acid, palmitic acid, stearic acid, palmitoleic acid, oleic acid, linoleic acid, and linolenic acid were also performed.

MS/MS analyses of standard compounds were first conducted with the QTRAP system with flow injection via syringe pump. The selected fragment ions (Table 2) allowed for selective detection of two plant hormones and seven fatty acids by LC-MS/MS with MRM. MRM transitions were primarily optimized for deprotonated molecular ions $[M - H]^-$. All resulting calibration curves showed high linearity (R^2 > 0.993). The concentrations of metabolites calculated from the calibration curves are presented in Figure 7. A two-way ANOVA test was performed using Prism version 5.0 (GraphPad Software, Inc.) to determine the significance of differences in metabolite levels among the groups. Of the plant hormones, the concentrations of jasmonic acid were lower than the limit of quantitation in all groups and would therefore be less than 5 μg/mL in the original methanolic extract. The concentration of salicylic acid in the copper-treated groups was significantly higher than that of the control groups after the 6-day exposure period. Levels of saturated fatty acids (myristic acid and stearic acid) did not differ significantly between copper-treated and control groups. Only palmitic acid exhibited an increase in

concentration following copper exposure. Conversely, concentrations of all unsaturated fatty acids (palmitoleic acid, oleic acid, linoleic acid, and linolenic acid) were significantly higher in the copper-treated groups.

DISCUSSION

Generally, the average copper concentration in the dry mass of untreated plant tissue is 10 mg/kg.[19,20] Halasz et al.[21] reported a copper concentration of 21 mg/kg in burdock roots from an uncontaminated site in Hungary. Copper levels above 20−30 mg/kg can be toxic in plants.[20] Roots of *Typha latifolia* contained copper concentrations of 8 and 450−580 mg/kg before and after incubation in a solution of 100 μM copper, respectively.[20] Even though the amount of copper in root extracts was not measured directly, levels of copper concentrations of burdock roots used in this study were expected to be higher than the 20−30 mg/kg toxic level in plants. High copper concentration of 100 μM $CuCl_2$ was selected to induce the metabolic changes in burdock roots under copper stress. It was previously reported that copper concentration of 100 μM or higher was used to identify the effect of copper stress in other plants such as *Vicia faba* L.,[22] *Typha latifolia*,[23] maize,[24] and so on. Growth was significantly inhibited and important cellular processes were impaired in plants containing high copper concentrations. The goals of this study were to examine the metabolic changes in burdock roots in response to copper stress and to understand the metabolic pathway associated with copper stress in burdock roots through polar and nonpolar metabolite profiling.

NMR data acquired on the polar extract showed clear differences between control and exposed groups. In a PCA score plot derived from ^{1}H NMR spectra, the controls were grouped together and the copper-treated groups (6-day exposure) were clearly separated. Conversely, a PCA score

plot derived from specific, targeted profiles showed slight differences in the patterns of control groups. On the basis of NMR spectra, sugars accounted for the majority of polar compounds in the burdock extracts. However, only free sugars, such as sucrose, glucose, and fructose, were identified from the Chenomx library. Thus, it is likely that other bound sugars and polyols were detected in the polar extracts but did not affect the separation between control groups.

The levels of most primary metabolites identified in the NMR data decreased after exposure to copper stress. Generally, heavy metals such as Cu are essential for normal plant growth and development.[25] However, excessive concentrations of heavy metals in the soil can lead to toxicity symptoms, inhibit growth, and induce metabolic disorders.[26] High concentrations of heavy metals in plant tissues can disrupt nutrient metabolism, resulting in abnormal growth.[27] The inhibition of growth may result in the observed decrease in the levels of primary metabolites (free sugars, amino acids, and organic acids) in the copper-treated burdock roots. A plant's response to metal toxicity can be expressed in a variety of ways, such as metal ion chelation. Chelation of metals in the cytosol by high-affinity ligands is a potentially important mechanism of heavy-metal detoxification and tolerance.[25] Histidine is particularly important in the chelation of metal.[26]

Phenolic metabolites were detected in polar metabolite profiling based on NMR. The observed phenolic compounds were found to be similar to the structure of caffeic acid through 2D NMR analysis. Caffeic acid derivatives are typically included in phenylpropanoids, which have important functions in stress defense mechanism, and the levels of caffeic acid derivatives in burdock root increased following copper exposure. Increased production of ROS, followed by primary defense reactions, is associated with production of phytoalexin, activation of the general phenylpropanoid pathway, and induction of lignin biosynthesis.[4,26] Phenylpropanoids are precursors of lignins, which are an integral part of the stress defense mechanism, especially at the root level, where such materials can affect cell wall composition and stiffness.[12] Caffeic acid derivatives of phenylpropanoids would be expected to increase as a part of the burdock's defense response. In addition, salicylic acid, methyl salicylate, jasmonic acid, methyl jasmonate, and other small molecules produced as a result of stress can also serve as signaling molecules that activate systemic defense mechanisms and acclimation responses.[4] These plant hormones were not detected in the above NMR analyses because of the low sensitivity of the technique. However, targeted UPLC/QTRAP-MS data showed that levels of jasmonic acid and salicylic acid in the copper-treated groups were twice those of controls.

Nonpolar metabolite profiling of the MC phase of burdock extracts by use of GC−MS showed high levels of two unsaturated fatty acids (linoleic acid and linolenic acid) and three sterols (campesterol, sitosterol, and stigmasterol). Fatty acids and sterols with phospholipids are primary components of the plasma membrane. Because the cell comes into contact with its environment via the plasma membrane, the adaptability and flexibility of the membrane is vital for cell survival.[28] Therefore,

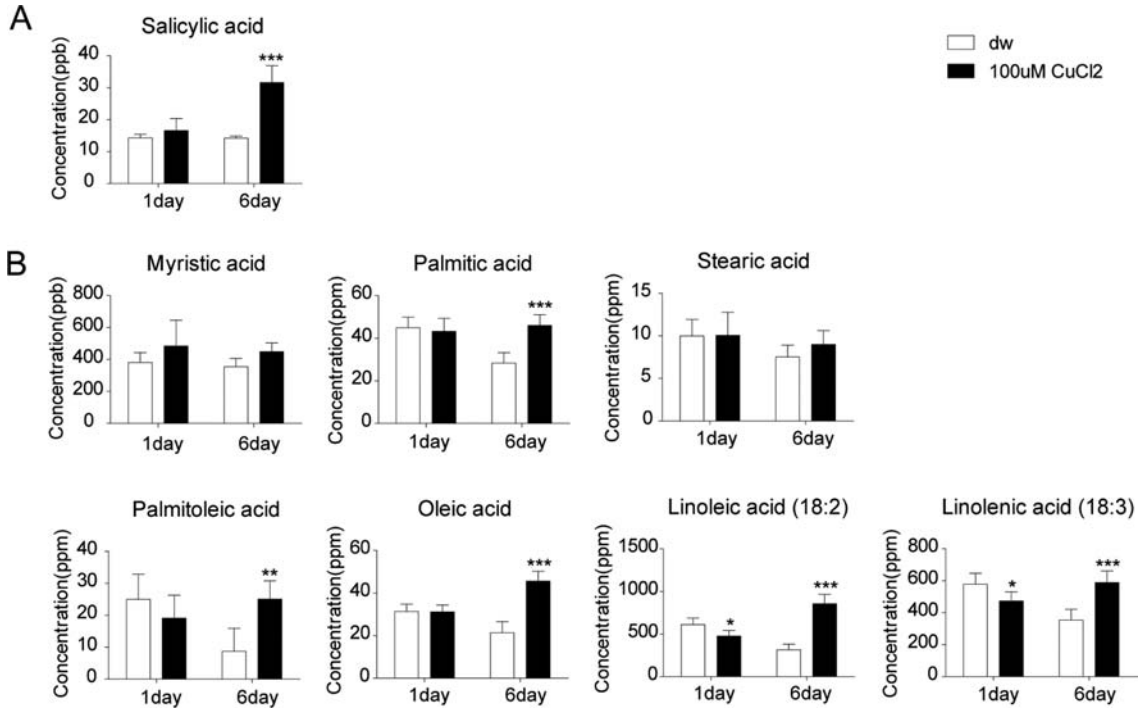

Figure 7. Quantification of identified metabolites by two-way ANOVA on Qtrap-MS data of burdock extracts. Error bars indicate means ± standard deviation. (A) Two-way ANOVA (copper treatment × time) yielded a significant difference in the level of salicylic acid ($P = 0.0001$). (B) Two-way ANOVA revealed significant differences in the levels of five fatty acids ($P \leq 0.0029$). ***$p < 0.001$ as determined by Bonferroni post hoc tests using GraphPad Prism 5.0.

the plant plasma membrane may be regarded as the first "living" structure that is exposed to heavy metal toxicity.[25] The function of the plasma membrane can be rapidly affected by heavy metals, as evidenced by increased cell leakage in the presence of high concentrations of metals, particularly copper.[25] Changes in the composition of the plasma membrane, such as relative levels of sterols and fatty acids, may contribute to changes in membrane fluidity and permeability and can be used as a mechanism of stress adaptation.[28,29]

In the above results, the levels of linoleic acid, linolenic acid, and other unsaturated fatty acids increased following copper exposure, although the presence of other fatty acids was not evident in the GC−MS data. However, targeted UPLC/QTRAP-MS analyses revealed significant changes in the concentrations of various fatty acids as a result of copper exposure. Although the level of palmitic acid increased significantly with copper exposure, the levels of myristic acid and stearic acid were unchanged. However, the levels of all unsaturated fatty acids (palmitoleic acid, oleic acid, linoleic acid, and linolenic acid) increased significantly with copper treatment. This high level of membrane lipid unsaturation is thought to help maintain the fluidity necessary for proper membrane function, which in turn can contribute to cell expansion and plant growth.[29] The ability to adjust membrane lipid fluidity by changing levels of unsaturated fatty acids is a mechanism for stress acclimation in plants. These adjustments are facilitated by the regulated activity of fatty acid desaturases.[13]

Sterol levels (campesterol, sitosterol, and stigmasterol) also decreased following the exposure of burdock roots to copper ion. Sterols are synthesized via the mevalonate pathway of isoprenoid metabolism.[30] The relative levels of stigmasterol, sitosterol, and campesterol have been proposed to influence the properties of cell membranes, particularly in relation to various stresses.[30,31] However, there were no obvious differences in the ratios of these three sterols between the copper-treated and control groups. Although membrane permeability increases according to the relative levels of the three sterols by campesterol < sitosterol < stigmasterol,[30] the observed decrease in concentrations of these three sterols was uniform across all three sterols at approximately 1.5-fold. Therefore, in the copper stress response of burdock roots, sterols may influence the properties of the plasma membrane through changes in their overall levels, not their relative ratios.

In this study, extracts from burdock roots exposed to copper for 1 or 6 days were compared and characterized by metabolite profiling with complementary analyses of ^{1}H NMR, GC−MS, and UPLC/QTRAP-MS data. Changes in primary metabolite and phenol concentrations may result from heavy-metal stress-induced growth inhibition and activation of the phenylpropanoid pathway, respectively. Conversely, changes in levels of salicylic acid and unsaturated fatty acids may result from damage to the cell membrane and/or loss of membrane integrity. This study demonstrates that metabolomic profiling is an effective analytical approach to understand the metabolic pathway(s) associated with copper stress in burdock roots.

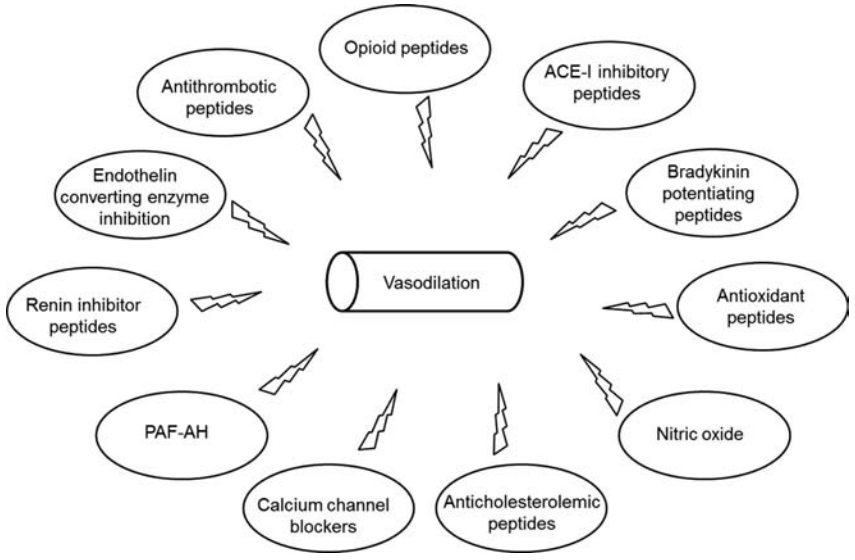

Figure 2. Peptides that can influence blood pressure regulation and vasodilation derived from food protein sources.

economical ACE inhibitors as alternatives to these synthetic drugs. During recent decades, a number of studies have looked at food therapy and dietary approaches for the prevention of chronic, lifestyle-related diseases, including hypertension.[14] Antihypertensive peptides with ACE or renin inhibitory activities are cheaper to produce with less stated side effects.[15] Fish meat consumption is often discussed as a factor in the prevention of heart disease as it is correlated with an increased dietary intake of omega-3 fatty acids.[16] However, fish protein is also a potential source of cardioprotective cryptides with ACE, renin, and phospholipase A_2 (PAF-AH) inhibitory and other activities. This review discusses the different pathways for blood pressure regulation in the circulation system and describes cardioprotective peptide generation from fish proteins. It also discusses the markets and future potential of muscle-derived heart health peptides, and the latest regulations regarding their use and generation.

BLOOD PRESSURE REGULATING ENZYMES AND THE RAAS

The RAAS and the SNS play major roles in the control of blood pressure.[17] In addition, a number of other factors may affect blood pressure due to the action of regulatory peptides including opioid, bradykinin potentiating, calcium channel blockers, and endothelial converting peptides (see Figure 2). Not all opioid or antioxidant peptides affect blood pressure. However, the opioid peptides endomorphin 1 and 2 were found to decrease systemic arterial pressure previously,

J. Agric. Food Chem. 2015, 63, 1319−1331

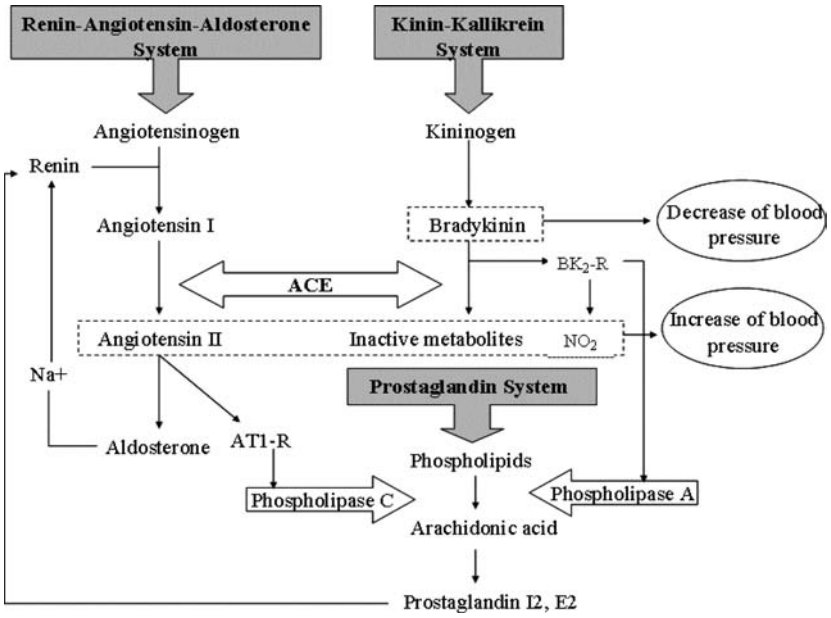

Figure 3. Classical renin–angiotensin aldosterone system (RAAS) and its relationship with the kinin–kallikrein and prostaglandin system. RAAS represents a cascade of enzymatic reactions. The huge precursor molecule of angiotensin II (Ang-II), angiotensinogen, is cleaved by renin, resulting in the still inactive decapeptide angiotensin I (Ang-I), which is then further cleaved by the membrane-bound metalloproteinase angiotensin-converting enzyme (ACE) to give the main effector hormone of the RAAS, the octapeptide Ang-II. In 2000, the first known homologue of ACE, ACE2, was identified. ACE2 catalyzes the generation of Ang-1–9 from An- I and of Ang-7 from An- II. It is not inhibited by ACE inhibitors. ACE2 metabolizes Ang-II to give the vasodilator Ang-1–7, which has been interpreted to mean that ACE2 provides a counterbalance, preventing overactivity of the classic RAAS.

although the mechanism of action is unknown.[18] Furthermore, it is hypothesized that low antioxidant levels may increase coronary heart disease. More research is needed to elucidate the role of antioxidative peptides and their protective functions in humans.[19] The classical RAAS (Figure 3) is a hormonal cascade that functions in the homeostatic control of arterial blood pressure. It was thought to be a straightforward cascade containing one substrate (angiotensinogen), two enzymes (ACE and renin), two peptides, angiotensin I (Ang-I) and angiotensin II (Ang-II), and one receptor (AT1). In reality, RAAS is a multiple effector system that consists of more than two dozen peptidases, a dozen Ang fragments, and at least six receptors.[20] The substrate angiotensinogen is released into the circulation from adipose tissue, and the liver and is degraded by the enzyme renin, which originates in the kidney. This action generates the inactive decapeptide angiotensin I, which is converted at the endothelial surface of blood vessels by the enzyme ACE into angiotensin II, the primary effector molecule of the RAAS.[20] Furthermore, evidence is now available that several RAAS components are expressed in cells from different organs of the body including the kidney.[21] In 2000, a homologue of ACE was discovered and called ACE2. Evidence indicates that ACE2 negatively regulates the activated RAAS by degrading angiotensin II to the heptapeptide Ang-(1–7). The enzymes ACE, renin, and ACE2 are key enzymes in the RAAS and therefore in the control of arterial blood pressure. Furthermore, the peptide Ang-A with the amino acid sequence Ala-Arg-Val-Tyr-Ile-His-Pro-Phe metabolizes Ang-II to Ang-III and causes a vasoconstrictive effect dependent on AT_1 receptors. Furthermore, Ang-M metabolizes Ang-III to Ang-IV and aspartyl aminopeptidase, which metabolizes Ang-I to Ang-2–10. They are suitable targets for functional food therapeutics for potential cardiovascular disease prevention.

ACE (EC 3.4.15.1). ACE, which is also known as kinase II, was first isolated in 1956 and termed the hypertension-converting enzyme.[22] It is a zinc metallopeptidase that requires chlorine for activation.[23] In the RAAS, ACE cleaves the decapeptide angiotensin I (Ang-I) into the octapeptide angiotensin II (Ang-II) by removal of the C-terminal dipeptide His-Leu. Ang-II is a potent vasoconstrictor and stimulates the release of aldosterone and antidiuretic hormone or vasopressin and increases retention of salt and water.[20] These activities raise blood pressure. ACE also inactivates the vasodilatory protein bradykinin and kallidin in the kallikrein–kinin system. ACE cleaves bradykinin (1–7) into the shorter fragment bradykinin (1–5).[24] ACE is also involved in the impairment of nitric oxide bioavailability.[20] Furthermore, ACE is thought to be involved in the functioning of the brain and nervous system as it can hydrolyze neuropeptides including encephalin, substrate P, luteinizing release hormone, and neurotensin.[25] ACE may also play a role in the gastrointestinal system as it hydrolyzes the hormones cholecystokinin and gastrin.[26] Furthermore, the ACE inhibitor perindopril ameliorates cognitive impairment and may have beneficial effects on Alzheimer's disease,[27] although ACE itself is thought to prevent the formation of Alzheimer amyloid β-peptide.[20]

There are over 10 synthetic ACE inhibitors available commercially including Captopril.[20] Drug development of ACE inhibitors is based on the knowledge that somatic ACE has two active sites and that these are not identical. However, ACE inhibitors developed to date show little discrimination between the active sites.[23] A number of studies have looked at isolation of ACE inhibitory peptides from food sources. ACE inhibitory peptides usually have large, bulky side chains, aromatic amino acids at the C-terminal end of the peptide, and nonpolar or positively charged amino acids at the N-terminus.[28] In tripeptides, aromatic amino acids are preferred at

the C-terminus of the peptide, positively charged amino acids for the central position, and hydrophobic amino acids at the N-terminus for bioactivity. The IC_{50} values obtained for food-derived ACE inhibitors are usually a thousand-fold higher than synthetic Captopril.[29]

ACE2 (EC 3.4.17.23). ACE2 belongs to the metalloproteinase family of enzymes but has a single active site and was discovered in 2000 by two research groups.[30] It has a substrate preference for hydrolysis between proline and a basic or hydrophobic C-terminal residue.[30] It functions to counterbalance ACE and increases Ang-(1−7) formation. ACE2 may regulate blood pressure through bradykinin and apelin, and it is known that ACE2 deficiency accentuates vascular atherosclerosis and inflammation.[31] Compared with ACE inhibitor use, ACE2 is an endogenous regulator of RAAS, and activation of ACE2 would produce Ang-(1−7). ACE2 activity is commonly measured by hydrolysis of quenched fluorescent substrates in the absence or presence of an ACE2-specific inhibitor, such as the commercially available inhibitor DX600.[32] Screening marine and food protein sources for ACE2 activators is a potential option for identification of blood pressure and hypertension regulators.

Renin (EC 3.4.23.15). Renin secretion control is a key and rate-limiting step within the RAAS. Renin cleaves angiotensinogen to form the inert decapeptide Ang-I. Angiotensinogen is produced mainly from the liver but is also found in the brain, heart, adrenal, ovary, and adipose tissue.[33] In 2010 meta-analysis of randomized controlled trials with AT1 receptor blockers found that their use led to an increase in new cancer diagnosis. Direct renin inhibition may be an alternative pharmacological approach to RAAS inhibition. The renin inhibitor Aliskiren has been approved for use in Europe and the United States from 2007.[34] A number of dipeptides with renin inhibitory activities have been isolated previously from pea[35] and seaweed.[54] Their bioactivities were observed in vitro and in animal models. Saponins from soybean have also been documented as having renin inhibitory activities in vitro.[36]

COMMERCIALLY AVAILABLE MARINE PROTEIN HYDROLYSATES WITH HEALTH BENEFITS

Commercialization of cardioprotective food products is dependent on the availability of scientific data from in vivo animals and human models that positively demonstrate their contribution to blood pressure control. In Europe, the European Food Safety Authority (EFSA) governs the use of novel food and health claims made on food products and ingredients. Regulation 1924/2006/EC of December 20, 2006, on nutrition and health claims made on foods is a claim to protect consumers by prohibiting the use of misleading information on packaging. Therefore, food producers have to justify the use of a health claim and need to fully substantiate the claim scientifically. To address this, the bioactivity of functional ingredients needs to be characterized as fully as possible.

Guerard and colleagues[37] provide an overview of commercially available fish protein hydrolysates. Commercially available functional food products for human use developed from fish protein include Stabilium 200, an Atlantic fish autolysate (www.yalacta.com), and PROTIZEN, a white fish hydrolysate (www.copalis.fr), both carrying a relaxing effect. Other products include Nutripeptin, a cod hydrolysate, for lowering glycemic index (www.copalis.fr), Seacure, a fish fillet hydrolysate obtained by fermentation using a marine microorganism for improving gastrointestinal health (www.propernutrition.com (USA)), and Fortidium LIQUAMEN, a fish autolysate of white fish (*Molva molva*) (www.biothalassol.com), which claims to reduce oxidative stress and lower glycemic index. Other fish protein hydrolysates with health benefits include a hydrolyzed sardine protein, VALTYRON, manufactured using enzymatic hydrolysis (a protease) of sardine muscle and subsequent water and ethanol extraction of peptides. The Japanese company Senmi Ekisu Co., Ltd., obtained GRAS status for its hydrolyzed sardine protein from the FDA recently. This hydrolysate contains a dipeptide (Val-Tyr) with known ACE inhibitory and antihypertensive benefits. Furthermore, EFSA issued a positive opinion regarding the safety of the hydrolyzed Californian sardine protein hydrolysate product VALTYRON. EFSA concluded that VALTYRON produced by the Japanese company Senmi Ekisu Co., Ltd., was safe for use as a food ingredient at use levels of up to 0.6 g/serving. Significant reductions in blood pressure were observed following administration of single doses of up to 6 g of a sardine peptide hydrolysate product in subjects that exhibited higher than normal blood pressure at the start of the study and not in normotensive individuals. Indeed, EFSA issued a positive opinion regarding the safety of hydrolyzed sardine protein for use in cereal and other food products in 2010.[71]

Peptide sequences obtained from fish sources, muscle tissue, dairy and eggs, and plants are shown in Table 1.[38−70]

MARINE PROTEIN DERIVED CARDIOPROTECTIVE PEPTIDES

ACE Inhibitory Peptides. ACE inhibitory peptides are extensively used in therapy against hypertension.[72] Many ACE inhibitors have been isolated as enzymatic digestion products from food sources such as milk,[72] wheat,[73] soybean,[74] and maize.[75] Several studies have identified ACE inhibitory peptides from fish muscle proteins including salmon and chum salmon,[76] yellowfin sole,[44] sardine,[46] bonito,[78] tuna,[80] and shrimp.[80] Indeed, the most documented fish product with ACE inhibitory effects is dried bonito bowel, a seasoning used in Japan made from thin slices of boiled, dried bonito.[81,82] The pentapeptide corresponding to the amino acid sequence Leu-Lys-Pro-Asn-Met is responsible for the ACE inhibitory activity, and this peptide demonstrates a prolonged blood pressure lowering effect following oral administration.[82] This peptide is also found in traditional Japanese food known as katsuobushi. Katsuobushi is fermented, smoked skipjack tuna (*Katsuwonus pelamis*).[82] Sardine protein hydrolysate is widely documented as a source of ACE inhibitory peptides. The most active ACE inhibitory sardine peptide is the dipeptide VY. This peptide demonstrated a significant antihypertensive effect on mildly hypertensive patients as well as in spontaneously hypertensive (SPH) rats, previously.[84] Indeed, a thermolysin digest of katsuobushi was approved as a food for special health use (FOSHU) in Japan.[85]

The ACE inhibitory effects of fish sauces developed from salmon, sardine, and/or anchovy have also been reported. For example, Bordenave et al.[76] reported that 50 μg of powder consisting of autohydrolyzed protein of sardine and cod head wastes inhibited ACE by 30%. Shrimp autohydrolyzed waste in a similar quantity inhibited ACE by 57%. Furthermore, a study carried out by Fahmi and colleagues[47] showed that a sea bream hydrolysate showed excellent ACE inhibitory activity, and the peptides responsible for this action were determined as Gly-Tyr, Val-Tyr, Gly-Phe, and Val-Ile-Tyr. Freshwater fish muscle

J. Agric. Food Chem. 2015, 63, 1319−1331

proteins and their hydrolysates offer huge potential as novel sources of natural bioactive peptides with ACE inhibitory activity.[83] Recently, two ACE inhibitory peptides were isolated from snakehead fish sarcoplasmic protein hydrolysates.[86] Enzymatic hydrolysis of sarcoplasmic protein was performed using commercial enzymes including Alcalase. The peptides had the amino acid sequences Leu-Tyr-Pro-Pro-Pro and Tyr-Ser-Met-Tyr-Pro-Pro with ACE inhibitory IC_{50} values of 1.3 and 2.8 μM, respectively. These peptides showed no cytotoxicity when tested using human embryonic fibroblast cell line (MRC-5) and human hepatocarcinoma cell line (HepG2).[86] ACE inhibitory peptides have also been isolated from fish skin proteins previously. For example, the ACE inhibitory peptide GPL was isolated from Alaska pollock skin gelatin hydrolysate.[49]

Fish-Derived Antioxidant Peptides. The increased production of reactive oxygen species (ROS), reactive nitrogen species (RNS), and free radicals in combination with the outstripping of endogenous antioxidant defense mechanisms is thought to be an important cause of disease development including cancer, gastric ulcers, Alzheimer's, and arthritis. Oxidation of foods is one of the major causes of food deterioration, especially of lipids and proteins. In the food and pharmaceutical industries, many synthetic antioxidants such as butylated hydroxytoluene, butylated hydroxyanisole, *tert*-butylhydroquinone, and propyl gallate are used to retard peroxidation processes. However, the use of these synthetic antioxidants is strictly controlled due to potential health hazards caused by such compounds. This fact has caused an increase in the interest afforded to the isolation and characterization of natural antioxidants.

In relation to heart health, antioxidant peptides may play a positive role as oxidation by ROS and RNS is also thought to play an important role in the initiation or progression of several vascular diseases such as ischemic reperfusion, which is a common occurrence in cardiovascular surgery patients. It results in inflammation and oxidative damage of tissue due to the return of blood supply after a period of ischemia.[58] Several bioactive peptides including carnosine, anserine, L-carnitine, and the lipid conjugated linoleic acid (CLA) were identified as possessing antioxidant regulating properties.[59] Furthermore, commercial enzyme cocktails can be used to generate hydrolysates containing antioxidant peptides from different fish muscle protein sources.[60] These antioxidant peptides can act at different levels in the oxidative sequence, preventing the formation of free radicals or introducing substances that compete for the existing radicals. The antioxidant properties of peptides derived from different proteins are mainly influenced by the antioxidant properties of the amino acids contained in the peptidic sequence, including histidine, tyrosine, methionine, lysine, and tryptophan.

Protein hydrolysates from muscles of several fish species including tuna dark muscle (*Thunnus tonggol*),[61] round scad (*Decapterus maruadsi*),[62] yellow stripe trevally (*Selaroides leptolepis*),[63] Pacific hake (*Merluccius productus*),[64] tilapia (*Oreochromis niloticus*),[65] silver carp (*Hypophthalmichthys molitrix*),[66] grass carp (*Ctenopharyngodon idellus*),[66] houndshark (*Mustelus mustelus*),[67] mackerel (*Scomber austriasicus*),[68] Alaska pollock (*Theregara chalcogramma*),[41] and brown-tripe red snapper (*Lutjanus vitta*),[69] all have reported antioxidant activities. A report comparing the antioxidant activity of Atlantic salmon, Coho salmon, Alaska pollock, and southern blue whiting hydrolysates, generated using pepsin, pancreatin, and thermolysin enzymes, demonstrated antioxidant activities when hydrolysates were assessed using the 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging activity assay. Alaska pollock pancreatin hydrolysate showed the lowest antioxidant values, whereas all other hydrolysates demonstrated similar antioxidant activities when assayed.[70]

Recently, a peptide identified from a croaker (*Otolithes ruber*) muscle protein hydrolysate with pepsin, trypsin, and α-chymotrypsin, found to contain the bioactive peptide sequence KTFCGRH, exhibited antioxidant activity in vitro against the radical scavenging efficiency of DPPH and hydroxyl radicals.[87] The identified peptide also proved effective when tested in vivo and neutralized ethanol-induced oxidative stress in rats.[87] Peptides VCSV and CAAP were purified and identified from α-chymotrypsin hydrolysate of flounder fish muscle, which showed radical scavenging activity against the DPPH free radical (IC_{50} values of 111.32 and 26.89 μM, respectively) and high cytoprotective activities against 2,2-azobis(2-amidinopropane) dihydrochloride (AAPH) in Vero cells.[88] Recently, Udenigwe and Aluko used partial least-squares (PLS) models to elucidate specific positive and negative contributions of individual amino acid residues and groups to antioxidant activities of proteins. They found that the effects depend on the oxidative assay system used, but on the basis of the results they found that previously reported antioxidant amino acid residues, especially histidine, had a negative effect on the antioxidant properties in the DPPH and H_2O_2 assays.[89]

Opioid Peptides. Opioid peptides bind to opioid receptors to produce morphine-like effects. Opioid receptors exist in the central and peripheral nervous systems, in the endocrine system, and in the immune system of mammals, as well as the intestinal tract. Natural opioid peptides include endorphins, enkephalins, and dynorphins.[90,91]

They are known to regulate various endocrine systems, including the hypothalamic−pituitary−adrenocortical (HPA) axis, and opioid peptides are thought to be responsible for the phenomenon of stress-induced analgesia.[92] Activation of opioid receptors results in adenylate cyclase inhibition, potassium channel activation, and calcium channel inactivation.[93] These receptors are also involved in the regulation of circulation, which can affect blood pressure.[94,95]

The first opioid peptides were identified in the late 1970s and were called "exorphins" due to their structural similarity to the endogenous ligands (endorphins and enkephalins) that interact with the opioid receptors found in the human body (μ-, κ-, and δ-).[96] Individual opioid receptors are responsible for specific bioactivities. For example, the μ-receptor is responsible for emotional behavior and suppression of intestinal motility,[97] the κ-receptor for satiety and food intake, and the δ-receptor for emotional behavior.[97] Opioid peptides derived from foods are of considerable interest as they are considered stable compared to endogenous opioid peptides, which are easily degraded by enzymes. Furthermore, food-derived opioid peptides have weaker bioactivities and therefore fewer side effects than those associated with endogenous opioid peptides, which include addiction and high dependency.[98−101]

The first opioid peptides derived from food proteins were of milk protein origin. The tetrapeptide β-lactorphin (YGLF) was originally released from the milk protein α-lactalbumin by enzymatic hydrolysis and showed an antihypertensive effect after oral administration to spontaneously hypertensive rats (SHR), with maximum reductions of blood pressure (BP) of 23 ± 4 mmHg in systolic BP. The vascular effects of another

DOI: 10.1021/jf505019z
J. Agric. Food Chem. 2015, 63, 1319−1331

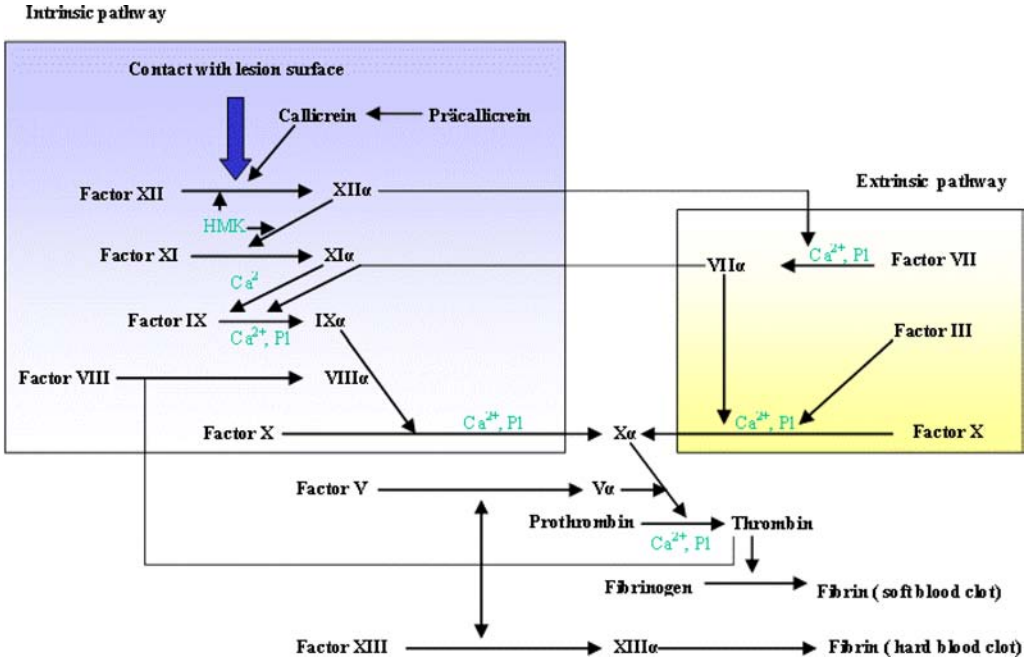

Figure 4. Coagulation cascade. In the intrinsic and extrinsic pathway model, initiation of coagulation is divided into two parts, the extrinsic pathway, which is thought to be responsible for the initial generation of activated factor X (factor Xa), and the intrinsic pathway, which leads to amplification of factor Xa generation. Factor Xa occupies a point where the intrinsic and extrinsic pathways converge and is central to the coagulation cascade.

structurally related tetrapeptide, α-lactorphin (Tyr-Leu-Leu-Phe), which originates from milk protein α-lactoglobulin, were also studied together with α-lactorphin (Tyr-Gly-Leu-Phe) effects. α-Lactorphin produced an endothelium-dependent vasorelaxation effect with nitric oxide synthase (NOS) inhibition. The α-lactorphin peptide also enhanced endothelium-independent vasorelaxation. This study concluded that α-lactorphin may stimulate the opioid receptors, which in turn release NO, causing the vasorelaxative effect.[100,101]

β-Casomorphins are well characterized in the literature.[101] Casomorphins are involved in regulation functions of the gut.[79] They enhance water and electrolyte absorption and act as antidiarrheal agents.[101] The casein-derived peptide casoxin D (Tyr-Val-Pro-Phe-Pro-Pro-Phe) has also been reported to have a hypotensive effect via opioid receptors, causing a vasodilatory relaxing effect in canine mesenteric artery strips.[101] Fish protein hydrolysates are known to accelerate calcium absorption[77] and provide satiety. They include the fish-derived peptide calcitonin/calcitonin gene related peptide (CGRP) and cholecystokinin-like peptides.[102] CGRP is a neuropeptide that acts as a potent arterial and venous vasodilator in humans.[102] Its capacity to increase heart rate as well as its ability to decrease food intake is well documented.[101,102] Guerard and colleagues generated CGRP molecules from a *Pollachius virens* byproduct hydrolyzed with Alcalase and treated with the microbe *Saccharomyces cerevisiae*.[103,104] Indeed, two commercially available products exist that carry relaxing effect claims.[37]

Antithrombotic Effect. An important complication that frequently occurs in patients with heart disease is the predisposition to develop thrombosis. Thrombosis is linked to platelet aggregation and small levels of fibrinolysis. Peptides that inhibit blood platelet aggregation and enhance fibrinolysis are strongly recommended to prevent thrombosis.

Blood coagulation is important in the cessation of blood loss from a damaged blood vessel (also known as hemostasis). A number of factors are involved in blood coagulation. The coagulation cascade consists of two pathways that are interconnected (Figure 4). These include the intrinsic pathway, which is also known as the contact activation pathway, and the extrinsic pathway or tissue factor pathway that leads to fibrin formation. When damaged, a platelet and fibrin-containing clot to prevent further bleeding covers the blood vessel. Both the intrinsic and extrinsic pathways activate the "final common pathway" of factor X, thrombin, and fibrin. Coagulation factors are generally serine proteases, transglutaminases (factor XIII), or glycoproteins (FVIII and FV), helping factors include calcium ions (Ca^{2+}), and phospholipid membranes. Heparin is an important anticlotting agent, which is often isolated from the small intestine of pigs or bovine lung tissue.

Food-derived peptides that inhibit blood platelet aggregation can be useful natural ingredients for the prevention of thrombosis. Thus, the search for new antithrombotic agents has mainly been focused on fruits and vegetables and marine carbohydrates including fucoidans and carrageenan.[105−110] Recently, collagen and its component proteins gelatin, collagen, and gelatin hydrolysates have been examined as potential natural antithrombotic ingredients. Indeed, a tetrapeptide, Asp-Gly-Glu-Ala (D-G-E-A), derived from type I collagen was found to inhibit collagen-induced platelet aggregation.[111] Khiari et al. studied the structure of antithrombotic peptides isolated from mackerel skin gelatin hydrolysates generated with pepsin, and observed antithrombotic activity due to the presence of the tripeptide FGN with a molecular weight of 337 Da.[112]

With regard to muscle sources, a recent study compared the effect of long-term intake of purified vegetable and animal proteins (casein, pork, egg white, chicken, white and red fish, soybean, and potato) and powders from whole vegetable and animal meats (soybean, pork, chicken, and horse mackerel) on thrombotic tendency and found that there was no difference in thrombotic tendency between the vegetable and animal protein diets with the exception of pork protein, which showed a prothrombotic effect.[113] In contrast, soybean powder showed an

DOI: 10.1021/jf505019z
J. Agric. Food Chem. 2015, 63, 1319−1331

antithrombotic effect, which was mainly due to inhibition of atherogenesis rather than to platelet inhibition.[113] More recently, it was published that papain-hydrolyzed pork peptides showed antithrombotic activity using the shear-induced thrombosis test in vivo and a laser-induced thrombosis test in the muscle carotid artery in vivo.[114] However, the amino acid sequence of papain-hydrolyzed peptide responsible for the observed bioactivity was not determined.

Anticholesterolemic Effect. Elevated blood pressure, hypertriglyceridemia, hyperglycemia, and obesity are main factors of metabolic syndrome. These risk factors have a correlation with cardiovascular diseases and are also associated with an increased tendency to develop type 2 diabetes mellitus.[115] Hypercholesterolemia and low levels of high-density lipoprotein cholesterol are strongly associated with increases in blood pressure, which is known to promote atherosclerosis. This process leads to cardiovascular diseases and can cause myocardial infarction, stroke, and peripheral vascular disease. Thus, hypercholesterolemia is usually associated with high levels of low-density lipoprotein (LDL) and lower concentrations of functional, high-density lipoprotein (HDL). These balances are mostly genetically determined but can also be influenced by body build, medications, and food.

The hydrolysis of meat and fish proteins generates peptides that could alter the free and total amount of cholesterol in plasma and, thus, influence blood pressure values and development of cardiovascular diseases. Fish protein hydrolysates have been reported to reduce plasma total cholesterol, increasing the proportion of HDL cholesterol and decreasing the activity of the coenzyme group acetyl coenzyme A (acyl-CoA) in the liver of Zucker rats.[116] Acyl CoA is a group of essential coenzymes in the balance between carbohydrate and fat metabolism. Two acyl CoA molecules can be condensed to create acetoacetyl CoA, which participates in the pathway of cholesterol synthesis. More recently, a combination of fish oil and fish protein hydrolysates in the diet was reported to reduce the plasma cholesterol level and increase the hepatic total cholesterol concentration. This is probably due to the action of the acyl-CoA coenzyme, which increases cholesterol esterification.[117] The hydrolysis of marine waste/byproducts such as freshwater clam residual meat together with insoluble dietary fiber separated from whole *Gracilaria* showed a bile acid-binding capacity and inhibited the micellar solubility of cholesterol in vitro.[118] This study was subsequently conducted in vivo, and results suggested that a combination of the freshwater clam hydrolysate and the insoluble dietary fiber from *Gracilaria* could be used to develop new functional foods for the prevention of hypercholesterolemia.[119]

Calcium Channel Blocking Effects. Calcium channel blockers interact with voltage-gated calcium channels in cardiac muscle and blood vessel walls, reducing intracellular calcium and consequently lowering vasoconstriction. In fact, it has been reported that peptides that bind and solubilize calcium can be considered to be beneficial in the prevention of dental caries, osteoporosis, hypertension, and anemia. During the past decade, some peptides derived from hoki and Alaska pollock frame were reported as calcium channel blockers,[120] and their bioactivities were demonstrated in rat models.[120−122]

Endothelin-1 (ET-1) and Endothelin Converting Enzyme (ECE) Inhibitory Effect. The endothelin system also has an increasingly recognized role in blood pressure regulation. The vasoconstriction peptide ET-1 is released from endothelin-1 by the activation of endothelin converting enzyme. The hyperactivation of the endothelin system has been implicated in the pathogenesis of several cardiovascular disorders such as pulmonary and arterial hypertension, heart failure, myocardial infarction, restenosis, and Chagas cardiopathy.[123]

Indeed, the more potent vasoconstrictive effect of ET-1 over angiotensin II was previously reported. However, only a few studies have focused on the potential effect of food-derived peptides on the endothelin system. Okitsu and colleagues[124] found ECE inhibitory peptides in pepsin digests of bonito pyrolic appendix and beef. Later, the influence of ACE inhibitory peptide Ala-Leu-Pro-Met-His-Ile-Arg, generated through tryptic digestion of bovine β-lactoglobulin, on the release of ET-1 by endothelial cells was investigated,[125] and basal ET-1 release from these cells was reduced by 29% in the presence of 1 mM of the peptide, compared to 42% for 0.1 mM Captopril. More recently, the potential of bovine lactoferrin hydrolysates generated by trypsin and proteinase K digestions as a source of ECE inhibitors was studied.[125,126] The peptides Gly-Ile-Leu-Arg-Pro-Tyr and Arg-Glu-Pro-Tyr-Phe-Gly-Tyr exerted in vitro inhibitory effects on ECE activity.

Useful Computational Methods in the Study of Cryptides. *In Silico Analysis.* Bioinformatics is a useful tool in the study of proteins. Bioinformatics is the computational analysis, modeling, and prediction of biological data. In silico analysis is the use of computational tools and databases to predict the release of bioactive peptides from parent proteins and the prediction of suitable enzymes for the release of bioactive peptides. It is also useful for predicting bioactivities associated with a given peptide sequence. Previously, Vermeirssen and colleagues[127] quantitatively evaluated pea and whey proteins as precursors for ACE inhibitory peptides. This was achieved by means of establishing an ACE inhibitory peptide database, containing about 500 reported sequences and their IC_{50} values. More recently, Iwaniak and Dziuba developed BIOPEP and Pôle Bioinformatique Lyonnais analysis tools.[128,129] These provide valuable data on food protein precursors as sources of bioactive peptides combined with the structural aspects of bioactivities encrypted in proteins. In silico analysis has been used in a number of studies to date to predict the release of bioactive peptides from protein sources including milk[129] cereals,[130] meat,[131] endogenous human proteins,[132] and other food proteins.[133] Bioinformatics and in silico analysis of fish proteins coupled with mass spectrometry technologies could prove useful in the future identification of useful fish-protein derived bioactive peptides.

Computational prediction of peptide bioactivity is also a useful tool for streamlining the search for active peptide sequences. PLS modeling is a widely used descriptive and predictive chemometrics approach for quantitative structure−activity relationship (QSAR) studies. It assists the user in elucidating how variation of molecular structures affects bioactivity of therapeutic agents, especially when working with high numbers of descriptor variables compared to the number of observations. This technique was used in QSAR studies of food-derived peptides and helped to identify bitter peptides[133] and ACE inhibiting peptides[134] previously. The bioactive peptide predictor PeptideRanker can prove useful in identifying among a set of peptides those that are more likely to be bioactive. This allows the focus of experimental screening on this subset.[135]

Technologies for the Identification of Bioactive Peptides. Technologies including mass spectrometry (MS) coupled to

DOI: 10.1021/jf505019z

liquid chromatography (LC) are some of the commonly applied technologies for bioactive peptide analysis. Many bioactive peptides contain two or three amino acid residues. These di- and tripeptides are usually identified using de novo sequencing or by matching the accurate mass and retention time to standards. Commonly used database search strategies using MS/MS spectra of peptide ions include SEQUEST and MASCOT, which are designed for proteomics applications. Other commercial databases used include the NIST 12 MS/MS library, the Wiley MS/MS library, and online spectral databases including METLIN (http://metlin.scripps.edu) and MassBank (http://www.massbank.jp/?lang=en). These libraries are suitable for the identification of oligopeptides greater than four amino acids in length. Recently, Tang and colleagues developed a new library suitable for the identification of di- and tripeptides from complex mixtures and untargeted analysis.[135] This method involved the separation of peptides using hydrophilic interaction (HILIC) liquid chromatography. To facilitate di- and tripeptide identification, a database consisting of all the predicted MS/MS spectra from 400 dipeptides and 8000 tripeptides was created, and a search tool, PEP search, was developed and housed at the MyCompoundID Web site (www.mycompoundid.or/PEP).[136] PEP Search in MyCompoundID searches an MS/MS spectrum against a database of di/tripeptides. This database consists of 400 dipeptides and 8000 tripeptides and their theoretical MS/MS fragments. PEP Search also provides an option to use dimethyl labeling confirmation. This option enables the search against the 8400 di/tripeptide database plus a library that consists of 8400 dimethyl-labeled di/tripeptides and their theoretical MS/MS fragments.[136] Peptide databases including BIOPEP are useful for peptide search operations also.

Bioavailability and Safety of Bioactive Peptides. For a bioactive peptide to be delivered to its active site, it is necessary to fully understand the barriers of the GI tract and the blood−brain barrier (BBB). The GI tract has site-specific absorption based on the peptide consumed and regional differences in pH, residence time, surface area, and enzyme activities.[137,138] For cardioprotective peptides to be active and to give a positive effect in the human body, they must be able to cross the intestinal mucosa and reach the systemic circulation. The most well-known antihypertensive and ACE inhibitory peptides, Ile-Pro-Pro and Val-Pro-Pro, contain a double proline at their C-terminal end and can therefore survive GI transit intact and brush border peptidase bioactivities. Transport across the intestinal epithelium may be either active or passive, and the mechanism of transport depends on the physicochemical properties of the peptide and the length of the peptide.[138] Furthermore, the RAAS has been described in the brain, and an interconnection between neurotransmitters and the brain RAS affects behavior and neurological diseases, for example, Parkinson's and Alzheimer's diseases. For a bioactive peptide with cardioprotective capabilities to exert beneficial effects within the brain RAAS, it would need to cross the BBB. The BBB prevents entry into the brain of many substances.[139] This is due to the epithelial-like tight junctions within the brain capillary endothelium.[139] The BBB is anatomically and functionally distinct from the blood−cerebrospinal fluid barrier.[140] However, it is documented that lipid mediated the free diffusion of substances with a molecular mass under 400 Da, which form less than eight hydrogen bonds and may cross the BBB.[139,140]

Protein is an essential part of the human diet. Bioactive peptides encrypted within native fish muscle proteins and released using food-processing methods including fermentation are an attractive option for use in food therapy for the treatment of high blood pressure. Despite their decreased potency, cardioprotective marine-derived peptides offer a suitable alternative to synthetic drugs for the prevention of high blood pressure and the maintenance of normotensive BP. However, further detailed mechanistic studies on how these antihypertensive peptides interact in humans must be carried out to elucidate the blood pressure lowering mechanisms of action involved. Safety issues including potential toxicity also warrant further research. It is important also that complete physicochemical, technofunctional, and bioactive properties, including potential allergic reactions, are considered prior to production of new fish muscle derived antihypertensive food products.

performed. In this paper, in vitro and in vivo methods for predicting the oral bioavailability of bioactive components will be summarized and compared in relation to their relevance to the living system. Later, a discussion of the potential of using in vitro and in vivo methods for the rapid bioavailability screening of future bioactive ingredients and their related oral formulations will also be included.

■ ORAL BIOAVAILABILITY

A sufficient dosage at the target site of action is critical for nutraceuticals to generate the desirable biological activities. That is, until the compound concentration becomes greater than the threshold dose, there could be no desirable health-promoting effect found. To obtain the appropriate concentration at the target site, it is important to determine the bioavailability of the bioactive compounds. Bioavailability is a principal pharmacokinetic term describing the fraction of the administered dose that reaches the system circulation without being altered. As system concentration obtained from intravenous injection was defined as 100% bioavailability, nutraceuticals administered through other delivery routes generally present lower bioavailability with incomplete absorption due to physiological or physiochemical barriers.

In particular, for the system concentration obtained after oral administration, oral bioavailability is greatly dependent on the ability of nutraceuticals to survive structural alteration from preabsorption degradation and postabsorption metabolism. Preabsorption events such as pH instability, ionic interaction, enzymatic degradation, and rapid GI elimination rate could significantly decrease the amount of ingested compound available for gut wall absorption. Once taken up by the intestinal enterocytes, the bioactive compound is then subjected to extensive structural transformation first by intestinal and then by hepatic metabolism. Taking into the account all of the events occurring after oral administration (Figure 1), oral bioavailability (F_{oral}) can be summarized and defined by the following equation:[5,6]

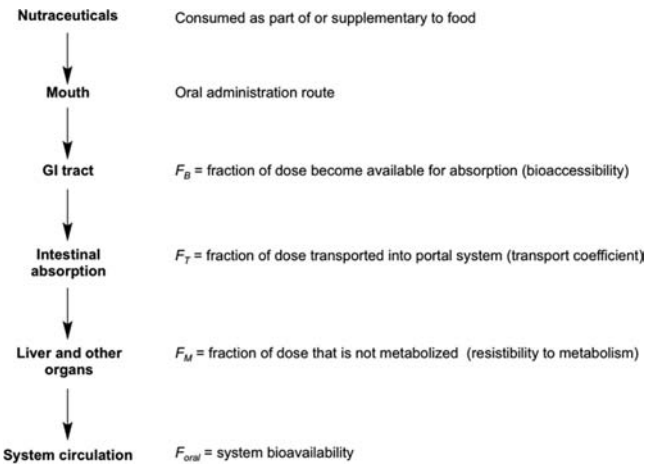

Figure 1. Process of orally ingested compound becoming bioavailable and factors that influence the oral bioavailability.

$$F_{oral} = F_B \times F_T \times F_M \quad (1)$$

In this mathematical expression, F_B is defined as the fraction of ingested dose that becomes accessible for intestinal absorption. The second component of the equation, F_T, describes the fraction of unchanged compound being transported into the portal system. The third component determining the oral bioavailability, F_M, outlines the fraction of ingested dose that survives metabolic activities as it travels to various systemic organs, such as the liver, heart, and lung. Hence, unlike intravenous injection, by which all of the applied dose reaches the system circulation, the system bioavailability of orally ingested nutraceuticals may be reduced to various degrees depending on their specific chemical structure, which influences the above-mentioned physiochemical parameters.

■ IN VITRO MODELS FOR PREDICTING ORAL BIOAVAILABILITY

Oral bioavailability is positively correlated with the bioaccessibility for GI absorption (F_B), the gut wall transport coefficient (F_T), and the resistibility to systemic metabolism (F_M). On the basis of the aforementioned theory, in vitro and in vivo models developed for predicting the oral bioavailability of nutraceuticals generally focus on evaluating one or more of the factors.

Bioaccessibility. Once ingested by mouth, dietary components enter the GI tract, which is essentially a compartment separated from other interior organs and the circulation system with a semipermeable barrier. To get to the inner system, nutraceuticals must be first absorbed by enterocytes. Thus, it is most critical that these bioactives are available at the absorption contact area. The bioaccessibility of a nutraceuitcal is then determined by quantifying the amount of ingested dose reaching the absorption site with its structure intact. The GI tract, specialized for digestion, consists of several sections each having a distinct physical and physiochemical environment responsible for the breakdown of diverse dietary components.

Nutraceuticals, just as all other dietary ingredients, go through the entire GI transition process, during which they may be chemically degraded and/or enzymatically metabolized to a product structure with totally different chemical properties. In other words, nutraceuticals must survive all of the degradation activities within the GI tract while being solubilized, or at least dispersed, in the aqueous lumen to become bioaccessible for absorption. To determine the bioaccessibility of a bioactive component, numbers of in vitro models, from simple to complex, are designed on the basis of the separable nature of the GI tract. Namely, the effect of pH, ionic interaction, enzyme activities, temperature, and luminal solubility on the compound bioaccessibility can be studied individually or systematically using suitable tests.

Chemical tests evaluating the stability of nutraceuticals at physiologically relevant ranges of temperature (37 °C), pH (2−7.5), and ionic composition are commonly performed methodologies to initially assess oral dosage efficiency.[7−14] However, the events occurring in the actual human GI tract comprise a rather complex biochemical process rather than just a few simple chemical reactions. Enzyme activities not only directly cause the structural change, such as bond cleavage and sugar moiety substitution, but also interfere with the absorption kinetics when other dietary components, such as lipids, proteins, and starches, are present.[10,15−18]

As an example, the absorption of hydrophobic compounds is significantly enhanced when lipid is present due to the improved aqueous solubility after being incorporated into the mixed micelle, which is the vehicle-like structure formed after lipid digestion.[5,19−21] An in vitro pH-stat model simulating the digestion environment in the small intestine, the major site for lipid digestion, is an especially suitable analytical tool to evaluate

DOI: 10.1021/jf5047464
J. Agric. Food Chem. 2015, 63, 1332−1338

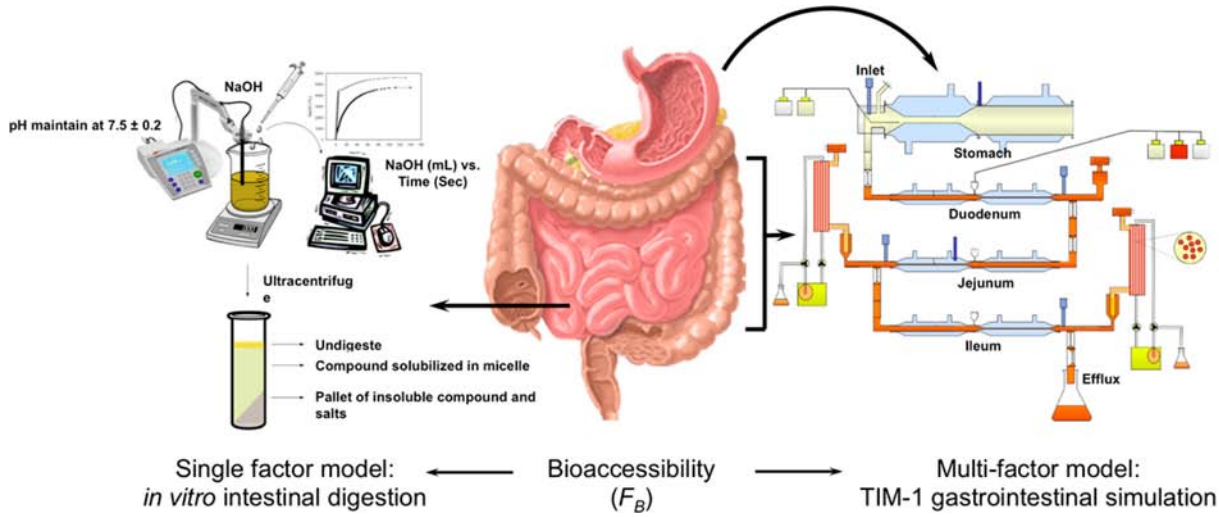

Figure 2. Common in vitro methods to evaluate the bioaccessibility of orally ingested nutraceuticals. The single-factor model simulates only the digestion activity with the small intestine. The multifactor model simulates the dynamic GI digestion events in both the stomach and small intestine.

the change in bioaccessibility for hydrophobic compounds when lipid is ingested either as part of the food matrix or oral formulations.[22,23] The single-factored in vitro chemical model is preferred by many investigators for initial screening of dosing efficiency because it is relatively simple to perform, cost-effective, and rapid and allows large sample throughput.

In addition to methodologies that contain only a single factor, multifactored models that combine two or more bioaccessibility-influential factors are also available (Figure 2). For example, the in vitro digestion model may simulate the physiochemical condition first in the stomach and then in the small intestine.[24] However, the in vitro models discussed above, regardless of number of factors addressed, are considered as static models due to their inability to reproduce the dynamic in vivo physical conditions including the peristalsis motion of the GI tract, integration of all of the influential physiological factors, transitional change in the physiological environment, and elimination from the absorption site. Consequently, the bioaccessibility predicted by static models usually overestimates the oral efficiency.[25]

To take the dynamic factor into account, a sophisticated instrument, a TIM-1 gastrointestinal simulation system, featuring a continuous in vitro digestion process, was developed by TNO Quality of Life, The Netherlands. Physiological and physiochemical factors, such as body temperature, peristalsis movement, gastric and intestinal residence time, pH, luminal composition, and elimination, are closely approximated by an automated computer system.[26] The bioaccessible fraction is determined by continuous sampling from jejunum and ileum sections over a predetermined time period.[25,27] Another advantage of using an open-compartment system, in which the unabsorbed portion is eliminated and collected as efflux, allows estimation of loss due to degradation because it can be quantified by subtracting the total recovered portion from the original input dosage. The TIM system, by far, is the most sophisticated and precise instrument for bioaccessibility estimation of dietary components.

Transport Coefficient. To travel across the intestinal lining, nutraceuticals may undertake either the transcellular or paracellur route. When the transcellular route is assumed, nutraceuticals from the gastric lumen are first absorbed into the enterocytes through either passive diffusion, which is driven by concentration gradient, or active transportation through the transcellular protein channels. During the in-and-out passage through the enterocytes, cellular metabolism significantly reduces the fraction of intact compound being released into the portal circulation.[28] Apart from the transcellular route, small molecules (M_w < 200) permeate through the membrane paracellularly through tight junction and do not go through the enterocytes. Nutraceuticals utilizing the paracellular route escape from the intestinal metabolism and retain the aglycone structure when streaming into the portal blood.[28,29]

Hence, the rate of compound transported from the GI tract into the portal system is dependent on its permeability to the cellular membrane and resistibility to intestinal metabolism. Unlike bioaccessibility, which is determined majorly by the physiochemical events in the GI lumen and can be easily simulated using in vitro chemical studies, the transport coefficient cannot be characterized using only the chemical experiment. A gastrointestinal model that includes a dialysis step after the in vitro digestion is the most simplified in vitro experiment for measuring the membrane transport rate of a dissolved compound.[30] Because no biological system was involved, the dialysis method that allows permeation of small molecules over a concentration gradient can be used only for estimating the fraction of compound that is transported through the paracellualr route.

The intestinal walls composed of a single layer of epithelial cells form the rate-limiting barrier to the transport of bioactive compounds. Cell culture model (Figure 3) of properly differentiated Caco-2 human colon carcinoma cells into phenotype with the characteristic physiochemical functions of the enterocytes is the commonly used in vitro method for elucidating the transport mechanism of nutraceuticals.[31−35] The Caco-2 monolayer allows effective in vitro prediction of compound permeability and absorption while taking into account all of the profound physical, chemical, and biological events during intestinal transportation.[36] Moreover, the Caco-2 monolayer model is also a well-developed model to effectively evaluate lymphatic transport (alterative transport route into the system circulation) of lipid-soluble compounds when included in lipid-based oral formulations.[37−39] However, the transport studies with the Caco-2 monolayer still have a number of disadvantages because the consistency of this study is highly

DOI: 10.1021/jf5047464
J. Agric. Food Chem. 2015, 63, 1332−1338

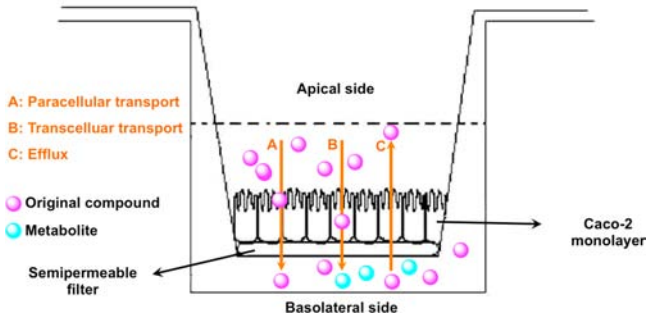

Figure 3. Transport coefficient evaluated using the Caco-2 monolayer model. The Caco-2 monolayer simulated the transport activity of intestinal epithelium utilizing both paracellular and transcellular transport routes.

dependent on the quality of the monolayer. Factors such as cell condition, passage number, length of cultivation, circumstance under which the study is performed, and the transport unit vary among laboratories.[40] Thus, the absolute transport coefficient values generated by different laboratories deviate accordingly and could not be compared directly. Moreover, the fact that Caco-2 human colon carcinoma cells have different physiological characteristics from the normal intestinal cell, such as lacking mucin, biofilm, and other epithelial cell types, can also cause unrealistic prediction of transport coefficient values in humans.[24]

In addition to the cell culture model, single-pass intestinal perfusion (SPIP) is an in situ animal model that provides enhanced approximation of intestinal physiology and allows the study of difference in the absorption behavior at various intestinal regions.[41] The experimental parameters, such as the compound concentration and the flow rate through the perfused section, are closely controlled to ensure the intra- and interexperimental comparabilities. In this model, the compound permeation efficiency is quantified as the concentration difference between the inlet and outlet of perfusate normalized by volume decrease due to water absorption.[42] However, the permeation rate quantified by the loss of compound in the perfusate retains a shortcoming of being unable to differentiate between the metabolized compound and the unchanged fraction, which is the main parameter for calculating the transport coefficient.

Resistibility to Systemic Metabolism. Once transported into the portal system, the absorbed component is then conveyed to the liver, where it will face rigorous first-pass metabolic activities. Due to the high density of the metabolic related cytochromes and enzymes, the liver is the principal facility for biotransformation of xenobiotics and is thought to be one of the major rate-limiting factors that reduce the system bioavailability of orally ingested nutraceuticals.[43] Cytochrome P-450 (CYPs) represents a family of membrane-associated proteins that is variably expressed in different organ tissues[44,45] and is responsible for the metabolism of >75% of endogenous compounds.[46] The major biotransformation of nutraceuticals by CYP450 monooxygenase includes oxidation, hydroxylation, and demethylation.[47,48] The isozymes mainly involved in the metabolism of bioactive compounds are CYP1A1, CYP2B, and CYP3A.[43,49,50]

As CYPs are most abundantly expressed in the liver, isolated liver microsomes are usually employed in the in vitro metabolic model that characterizes the biotransformation of nutraceuticals. During the metabolic test, compounds are incubated with liver microsomes, and the resulting product composition is usually identified by selected analytical instruments. The in vitro metabolism model is an effective method to evaluate the metabolic stability of nutraceuticals as it allows rapid, low-cost, and large throughput sampling. However, the use of animal liver microsomes to predict human metabolite composition is somewhat unreliable because the expression of CYPs is variable among animal species and is also highly dependent on the incubation and sampling interval.

IN VIVO PHARMACOKINETIC MODEL AND CORRELATION TO HUMAN ORAL BIOAVAILABILITY

The bioavailability of orally ingested compounds is the product of a complex process that integrates series of physiological or physiochemical reactions. In vitro methods designed to simulate an aspect of physiochemical process are useful tools for characterization and prediction of the in vivo pharmacokinetics in early screening of bioactive components. Because the bioavailability is affected by multiple factors, in vitro tests conducted in isolation usually present inadequate in vitro−in vivo correlations (IVIVC). Using the combinations of two or more in vitro models, the precision of estimating the oral bioavailability will increase because more influential factors are addressed. However, even the TIM-1 system being the most complex and closest simulation of preabsorption events in the human GI tract still cannot perfectly predict the oral bioavailability due to lack of biological factors, such as enterocyte absorption, systemic metabolism, and volume of body distribution. Thus, even though in vivo pharmacokinetic study is time-consuming, costly, and sometimes inhumane, it is still considered as the best described technique to predict human oral bioavailability. Because completely reproducing the pharmacokinetic process using in vitro models is overly complicated and unrealistic, in vivo animal models offer a living system imitating the full dynamic physiological and physiochemical events during the absorption, distribution, metabo-

lism, and elimination of orally ingested nutraceuticals. Even though the mechanism that underlies the pharmacokinetic process cannot be fully explained, analyzing the timed serum profile from the in vivo studies provides useful information on the oral bioavailability of ingested compounds as well as the metabolite profile.

Although animal data, especially pharmacokinetic profiles of rodents, have been widely used to predict oral bioavailability in humans, the correlation in the absorption of bioactive compounds between animals and humans has not been extensively studied. Variations in body weight, organ size, hepatic and renal blood flow, metabolism, distribution, and elimination rate result in significantly different pharmacokinetic profiles among different animal species. As an example, pharmacokinetic parameters, such as peak concentration time (t_{max}), peak serum concentration (C_{max}), total area under curve (AUC), and urinary excretion, of quercetin deviated accordingly when different in vivo models were used (Table 1). Developed according to the body weight and physiological parameters, allometric scaling was applied to in vivo animal data to better reflect the actual pharmacokinetic process in humans.[51,52] However, due to the complexity of physiological events in living systems, methods of scaling to 100% correlating the in vivo data to human oral bioavailability are still not available.[53]

Besides physiological factors of modeling systems, the pharmacokinetic profile is also significantly affected when different experimental designs were applied. For oral ingestion, the parameter having the most influence on the bioavailability is the physical and chemical characteristic of dosing formulation. By using different dosing media, the absorption of nutraceuticals can deviate appreciably due to changes in the bioaccessibility, a positively correlated parameter to system bioavailability. In particular, for a hydrophobic compound, oral absorption is improved when its solubility, the important factor for the compound to be available for gut wall absorption, becomes higher in the dosing medium.[54−56] In support of this idea, Piskula et al. found the oral bioavailability of quercetin was highest when solubilized in 100% propylene glycol, followed by 25% propylene glycol solution, and then water.[55] Inspired by the finding that better bioaccessibility leads to higher absorption rate, various oral delivery systems were designed to improve the pharmacokinetic profile of nutraceuticals with diverse chemical properties.[5,6] As an example, the oral bioavailability of a hydrophobic compound, such as curcumin (Table 2), is improved by the oral delivery system that enhances its aqueous solubility. On the other hand, delivery systems that could enhance the luminal stability and membrane permeability will lead to better oral bioavailability of EGCG, a hydrophilic compound that could be rapidly degraded in the GI tract (Table 3).

Table 2. Effect of Oral Formulation on the Oral Bioavailability of Curcumin

chitosan−nanoparticle	↑ permeability ↑ stability ↑ paracellular transport	↑ bioavailability	71

Due to the lack of consensus in the selection of animal models, dosing formulation, and delivery system, the in vivo pharmacokinetic data published by different investigators are rarely comparable. Thus, the prediction of human oral bioavailability is difficult without systematic collation of available pharmacokinetic data. Despite being the best preclinical model to evaluate the oral bioavailability of bioactive compounds, pharmacokinetic study itself does not provide enough mechanistic information to allow efficient data organization. In this sense, in vitro tests should be collectively conducted to study the pharmacokinetic behavior of nutraceuticals.

PREDICTION OF HUMAN ORAL BIOAVAILABILITY

To prevent the development of degenerative diseases, it is desirable for nutraceuticals to have good oral dosage efficiency because they are usually consumed either as part of a functional food or as a supplement (dietary supplement) to the diet. Oral bioavailability of bioactive compounds, as discussed in earlier sections, is majorly influenced by their bioaccessibility in the GI lumen, transport rate across the gut wall, and resistibility to the systemic metabolism. To better understand their contribution to the oral bioavailability individually and conjointly, these parameters could be evaluated by using proper in vitro and in vivo modeling systems because evaluating the pharmacokinetic profile using human subjects is expensive and may involve ethical issues. Thus, it is further desirable that these modeling systems could eventually allow accurate prediction of pharmacokinetic events in human body. Even though in vitro studies conveniently examine the factors that contribute to oral bioavailability, they cannot accurately predict human pharmacokinetic profiles without proper correlation to the in vivo system and the application of allometric scaling, which is calculated with regard to the interspecies difference. To take full advantage of the preclinical modeling system to realistically predict human oral bioavailability of nutraceuticals, the mathematical expression of oral bioavailability could be rewritten as follows:

$$F_{oral} = F_B \times F_T \times F_M \times C_A \times C_S \quad (2)$$

The mathematical equation reveals a future perspective, in which the evaluation of human oral bioavailability can be projected using only the in vitro modeling systems. In this equation, the bioaccessibility (F_B), transport rate (F_T), and resistibility to systemic metabolism (F_M) can all be determined with appropriate in vitro studies. The other two components represent the correlation factors of in vitro and in vivo modeling system (C_A) and interspecies scaling (C_S). To determine C_A and

DOI: 10.1021/jf5047464
J. Agric. Food Chem. 2015, 63, 1332−1338

C_S, a consistent experimental procedure is required when pharmacokinetic study using both animal and human subjects is carried out. The in vivo animal models serve as an important bridging factor that links the in vitro data to the actual events occurring in the human body.

To accurately calculate C_A and C_S, much more work needs to be done and problems must be solved. However, the benefits from successfully developing such a mathematical relationship between in vitro measurement and the human pharmacokinetic process are numerous. First, the cost and disadvantages of using models involving living creatures could be minimized. Second, factors that change the pharmacokinetic process can be easily taken into account by conducting in vitro testing of affected parameters. Third, rapid estimation of the required dosage for disease prevention is much more reliable and realistic with regard to the actual value in human subjects. Fourth, the effectiveness of oral formulation to enhance bioavailability can be efficiently determined without going through complicated evaluations. Overall, integration of modeling systems covering all aspects of physiological and physiochemical reactions that contribute to the oral bioavailability of nutraceticals offers the possibility to further elucidate the human pharmacokinetic process via a much more simplified and efficient procedure.

farms is very unlikely.[15−17] To explain this widely occurring phenomenon, thiouracil was no longer accepted to originate solely from synthetic products. In contrast, the semiendogenous status of thiouracil had to be unraveled.

Pinel et al.[18] performed a first study suggesting species belonging to the family Brassicaceae, commonly used as substantial feed ingredients, as a source of thiouracil. Together with the studies of Vanden Bussche et al.[19,20] and Kiebooms et al.,[21] evidence was gathered on the feed-derived origin of thiouracil. Species in the family Brassicaceae are known to contain glucosinolates, which may be metabolized to thiouracil by the enzymatic interaction with myrosinase at the time of chewing, ingestion, and digestion. A correlation between this particular diet and thiouracil in the urine of livestock was indeed definitely demonstrated.[19−21] However, a relevant concentration of thiouracil was not found in the unprocessed feed itself.[18,19] Additionally, the same correlation could not be demonstrated in a small sample study with humans, despite elevated thiouracil levels in their urine samples, suggesting the existence of additional natural thiouracil sources.[19] Because of these new insights and because of the increasing performance of the newly developed analytical techniques, the zero-tolerance approach of the EU for thiouracil needed revision. As a first step, a guidance paper was published in 2007 by the European Union of Reference Laboratories (EURLs),[22] suggesting a recommended concentration (RC) of 10 μg/L for thiouracil in urine. This RC has no legal value, but it is agreed to be a generally accepted target limit, which should be implemented, wherever possible, by any EU laboratory performing analysis in the light of the thiouracil monitoring programs.

More recently, two member states (France and Poland) suggested new thresholds based on their National Residue Monitoring Plan.[15,17] These studies were performed independently but reported similar outcomes for both countries, suggesting the current RC might be deficient, particularly for certain subgroups of cattle.

To encourage a revision of the existing European guidelines, including the definition of a consensual European threshold for endogenous thiouracil, in this study, a large-scale retrospective epidemiologic study (six member states, 2010−2012) was performed on naturally occurring thiouracil detected by LC-MS/MS in urine samples of bovines, small livestock, and porcines.

Epidemiologic Study Approach: Data Generation, Collection, and Analysis. Retrospective data on urinary thiouracil levels from bovines, small livestock (e.g., sheep, goat), with inclusion of reindeer and porcines, sampled between January 2010 and December 2012, were collected.

Qualified laboratories supplied data from six European countries (i.e., The Netherlands, France, United Kingdom (Great-Britain and Northern-Ireland), Norway, Poland, and Belgium). The contributions of each member state to the total data set of 3894 bovine, 85 small livestock, and 654 porcine records are listed in Table 1. A total of eight laboratories were

Table 1. Overview of Urinary Thiouracil Data Collection

	bovines	small livestock	porcines
The Netherlands	273	0	139
Belgium	244	0	4
France	1718	0	0
United Kingdom	871	5	2
Norway	432	79	124
Poland	356	1	385
total	3894	85	654

involved in the chemical analysis (two laboratories for Belgium and the United Kingdom; the Norwegian samples were outsourced to a third Belgian laboratory). These laboratories participated successfully in the 2013 proficiency test for the detection and quantification of thiouracil in bovine urine organized by the EURL (RIKILT, Wageningen).[23] Equal performances in urinary samples of other species, particularly small livestock and porcines, are assumed.

As previously mentioned, the urine samples arrived at the respective laboratories between January 2010 and December 2012 and were each briefly stored at −20 °C prior to analysis. In one laboratory, urine samples were stabilized by adding HCl (37%) and ethylenediaminetetraacetic acid (EDTA) (0.25 M) to prevent degrading of the compounds while extracting at room temperature. At the start of the extraction protocol, an internal standard was added to 1 mL urine. In most cases (7/8 laboratories), the thyrostatic compounds were derivatized with either 3-iodobenzyl bromide, **2** (5 laboratories), 2,3,4,5,6-pentafluorobenzyl bromide, **3** (1 laboratory), or 4-chloro-7-nitrobenzofurazan, **4** (1 laboratory) (Figure 1), followed by solid phase extraction (SPE), (multiple) liquid liquid extraction

[a]RC = recommended concentration. [b]CI = confidence interval.

(LLE), a combination of LLE and SPE, or of LLE with duplicate SPE, adapted from previous reports.[12,14] One participating laboratory did not perform any derivatization but added 1% dithiothreitol (DTT; 1,4-bis(sulfanyl)butane-2,3-diol) to the urine aliquot prior to LLE.[13] Thiouracil (and other thyrostats) was finally detected and identified by triple quadrupole (QqQ-MS/MS) mass analyzers after chromatographic separation on a reversed-phase C18 U(H)PLC column.

For each species (cattle, small livestock, and pigs), statistical analysis was performed on the respective data set. Subpopulations (within one species) were created and compared based on gender (male versus female), age (<6 months, 6−12 months, 12−24 months, and >24 months), the combination of gender and age, or the geographical region (member state). Since these subpopulations clearly deviate from a normal distribution, statistical differences between groups were assessed by either Kruskal−Wallis (multiple comparisons) with a posthoc Dunn's test or by the Mann−Whitney rank sum test (comparison of 2 groups), which is significant if $p < 0.05$. The descriptive statistics (mean, median, standard deviation (SD), minimum, maximum, and percentiles) of each subpopulation were acquired, with special interests for specific population parameters such as the 95 and 99% percentiles. For the latter parameters, a 95% confidence interval (CI) was calculated by nonparametric bootstrapping.[24,25] This confidence interval estimates the uncertainty associated with the population's percentile estimates.

Concentration values below the CCα (decision limit) of the respective (sub)populations were set equal to zero. If analysis was performed on a combination of subpopulations with different CCα values, the CCα of the subpopulation with the highest CCα was used for the entire batch. Clearly, this

approach does not influence the percentiles, but particularly, parametric values such as "mean" and "standard deviation" may be slightly influenced. Statistical analysis was performed with SPSS version 22.0 (IBM, Brussels, Belgium).

Occurrence and Evaluation of Thiouracil in Urine. *Total Bovine Data Set.* A detailed overview of the most important population parameters can be seen in Table 2. Considering the highest CCα (3.9 μg/L) throughout the participating laboratories as a cutoff, the presence of thiouracil was identified in 12.4% (n = 483) of the samples (>CCα = 3.9 μg/L), with 3.6% of the data set (n = 140) containing higher thiouracil levels than the RC (=10 μg/L). Consequently, the 95% percentile is characterized by a concentration below the RC (8.1 [7.2−8.9] μg/L) while the 99% percentile is substantially higher (18.2 [15.5−20] μg/L). A maximum value of 145 μg/L (from Belgium), which could not be explained, was observed within this population (Figure 1).

The animals' gender was known in 72.4% of the sample pool, while their age was defined in 61.1% of the samples. Higher thiouracil concentrations were observed for male bovines compared to female bovines, with significantly higher 95% (12.3 [11.1−14.4] μg/L versus 6.5 [5.1−7.3] μg/L, respectively) and 99% (25.0 [18.4−32.7] μg/L versus 15.1 [13.0−20.0] μg/L, respectively) percentiles, both exceeding the RC (p < 0.01).

Young animals ≤12 months were revealed to be another subpopulation with increased urinary thiouracil levels and 95 and 99% percentiles above the RC (Table 2) (p < 0.001). However, if solely female animals were observed, the definition of "young animals" needed to be adapted to "not older than 6 months", while in male animals both the young (≤12 months) and the older (>24 months) bulls had significantly higher thiouracil levels (p < 0.01).

Member State Specific Bovine Data Set. The descriptive statistics of the six participating member states are presented in Table 3. Frequency plots of these member states are illustrated in Figure 2, and more specific population numbers are added in Table 4.

Overall, the data sets of the two smallest member states, Belgium and The Netherlands, were evaluated as statistically different compared to the remaining four data sets (p < 0.01). Both the 95% (14.8 [7.6−29.7] μg/L and 15.5 [13.5−18.3] μg/L, respectively) and 99% (26.4 [18.8−36.4] μg/L and 67.5 [29.0−145.0] μg/L, respectively) percentiles exceeded the RC

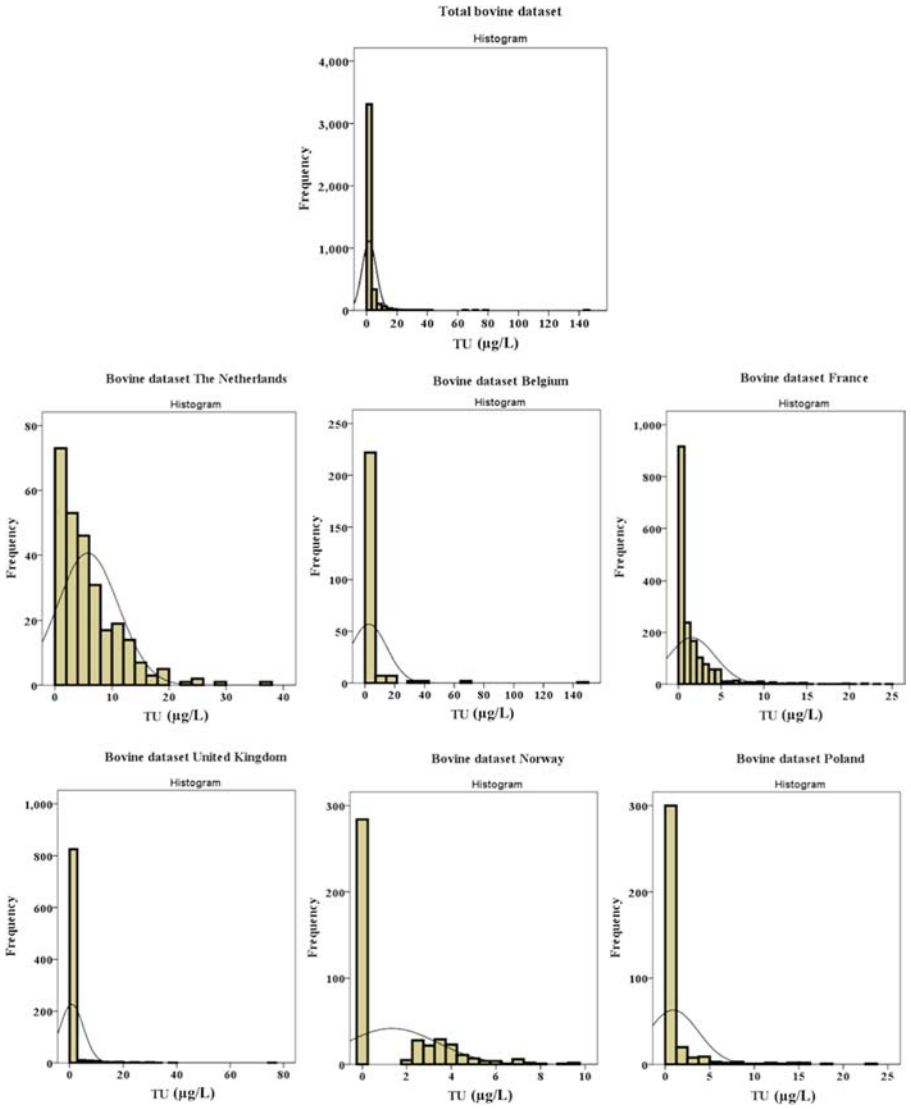

Figure 2. Frequency histograms of the total bovine and member state specific data set indicating the number of samples between given concentrations of urinary thiouracil (μg/L).

Table 4. Member State (Bovine) Population Distributions Based on Age and Gender

	age					gender		
	<6 months	6–12 months	12–24 months	>24 months	unknown	male	female	unknown
The Netherlands	130	143	0	0	0	218	19	36
Belgium	1	1	5	8	229	15	11	218
France	282	121	299	700	316	625	1015	78
United Kingdom	0	0	3	12	856	22	159	690
Norway	4	15	134	178	101	166	218	48
Poland	9	21	134	181	11	122	231	3

substantially, which was not the case for the 95% percentiles of any other member state (max 6.2 μg/L) (nor for the Norwegian 99% percentile (9.2 [6.9–9.4] μg/L)). The Dutch and Belgian data sets are indeed defined by a large sample fraction containing more than 10 μg/L thiouracil (up to 18.7%), while this fraction was limited to 2.8% for the remaining four member states. Due to limited numbers (in one or more subpopulation) and/or lack in detailed information, influences of gender (France, Norway and Poland) and age (France) could only be statistically evaluated in three member states (Table 3). Males and young animals (<6 months) were confirmed to be responsible for higher urinary thiouracil levels, but this could only be statistically confirmed from the largest (French) data set ($p < 0.01$ and $p < 0.01$).

Small Livestock Data Set. Samples ($n = 85$) collected from 63 sheep, 16 goats, and 6 reindeer originating from Norway ($n = 79$), United Kingdom ($n = 5$), and Poland ($n = 1$) were included in this data set (Figure 2). Due to the limited sample group ($n = 85$) with only two samples (2.4%) above the RC, only the 95% percentile (7.3 [4.3–17.0] μg/L) could be defined (Table 5).

[a]CI = confidence interval.

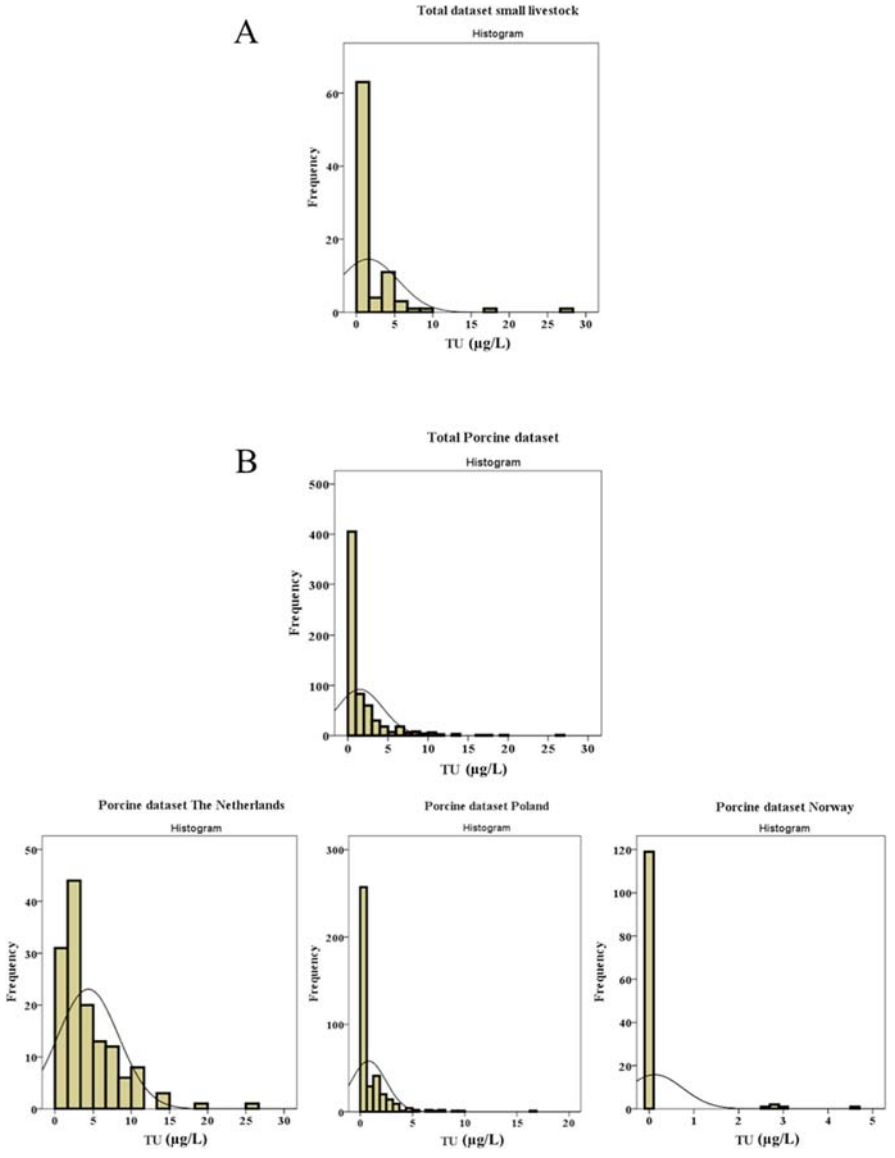

Figure 3. Frequency histograms of (A) the total small livestock population and (B) the total porcine and member state specific data set, indicating the number of samples between given concentrations of urinary thiouracil (μg/L).

Porcine Data Set. The majority of thiouracil data in porcine urine samples was provided by Poland (n = 385), The Netherlands (n = 139), and Norway (n = 124). Limited contributions from Belgium (n = 4) and United Kingdom (n = 2) were included as well.

In 97.7% of the samples, the urinary thiouracil level was below the RC of 10 μg/L, while in 77.1% of the samples,

J. Agric. Food Chem. 2015, 63, 1339−1346

thiouracil could not be detected (<CC_α). The 95% and 99% percentiles for this database were at 7.4 [6.4−8.4] μg/L and 13.5 [10.5−17.0] μg/L, respectively. These thresholds were not influenced by gender or age. However, data sets differed geographically (exclusion of Belgian and British data set), with significantly higher percentiles for The Netherlands (11.3 [10.1−14.0] μg/L and 23.8 [13.4−26.4] μg/L, for the 95% and 99% percentiles, respectively) compared to Norway (<CC_α [0.0−2.8] μg/L and 4.1 [2.2−4.5] μg/L for the 95% and 99% percentiles, respectively) (Table 5; Figure 3).

DISCUSSION

With this retrospective study, we aimed to evaluate the applicability of the recommended concentration (RC) for monitoring thiouracil in urine samples of bovines, small livestock, and pigs, advised by the EURL,[22] by statistically approaching sample outcomes gained in several European member states from January 2010 to December 2012. A similar epidemiologic threshold-definition has been previously performed on the national level by two participating member states.[15,17] However, combining up to six member states with a rather scattered distribution throughout Europe allows assessing a broader and larger (thus statistically more powerful) sample size and may identify geographical peculiarities.

Due to the obvious lack of homoscedasticity of the data set, analysis was performed integrally by nonparametric analysis. The population "extremes" were hereby described by 95% and 99% percentiles, covered by their bootstrapped 95% confidence intervals (CI), which give an estimation of the uncertainty of the numeric concentration value associated with the percentiles.[24,25] The inclusion of the CI in this study allows comparing results of similar studies, such as the earlier mentioned French and Polish study. The (bovine and porcine) percentiles reported in these studies fit the respective national CI values of the current study, with one exception for the 99% percentiles for French male bovines and the 95% percentiles for Polish porcines, both below their respective CI. The results of these and the current study are therefore (largely) in agreement, leading toward similar reflections.

It depends on the kind of threshold and its application-scope whether the 95% or 99% percentile, or its upper CI limits, should be taken into account for decision-making.[26,27] Although recommendations on this final choice are out of the scope of this study, the current obtained results, and earlier reports, strongly indicate the need to increase (if 99% percentiles are taken into consideration), or at least refine (if 95% percentiles are considered), the RC that is currently suggested.

Indeed, when selecting the 95% percentiles (with CI) as most stringent thresholds, the present RC is inadequate in very young and/or male bovines. The latter might explain the highest percentiles for the Dutch data set, since 80% of the data involved male animals younger than 1 year (no population details are available on the Belgian data set with similar percentiles). However, high thiouracil levels were also observed in urine samples of Dutch pigs with no statistical interference of age and gender. Another feature, unrelated with any population characteristic, might explain these high thiouracil levels in both bovine and porcine urine. The Dutch protocol seems to contrast with the seven other laboratory protocols by an additional thyrostat-stabilizing step. The stability of thyrostatic drugs in bovine and porcine urine has been extensively studied.[28] Urinary thiouracil concentrations were found to decrease rather drastically if inappropriately stored (e.g., short time at room temperature or prolonged at −70 °C), if the pH exceeded a value greater than 3 and if copper was present. Vanden Bussche et al.[28] suggested therefore a successful pretreatment by which the pH was adapted to 1 and EDTA was added to chelated copper. This treatment turned out to delay thyrostat-decay for 24 h at room temperature, in effect controlling degradation while performing the extraction and at least for three months at −70 °C. This is likely to be responsible for the more elevated thiouracil levels in the Dutch data set. Similarly, lower thiouracil levels (with low percentiles) in Norwegian bovine and porcine urine samples may be due to the applied protocol, which discriminates itself by the lack of derivatization. However, this protocol[13] was successfully validated in accordance with Commission Decision 2002/657/EC and fulfilled the performance criteria of the 2013 proficiency test.[23,29] It is therefore more likely that other factors, related to the Norwegian farming style (e.g., feed, pasture type, housing, etc.), have been influencing the data.

The definition of a European threshold for urinary thiouracil to distinct endogenous from administered thiouracil is not straightforward. Two independent national surveys have previously expressed their concerns and have suggested a revision of the existent RC. Considering these and current study results, the urge for a revision of the recommended concentration and/or the definition of the reference points for action for thiouracil residues in urine is obviously demonstrated, with special emphasis on the identified influencing factors, for example, the applied laboratory protocol (all species), gender (cattle), and age (cattle). Consequently, our findings are in agreement with the latest reflection paper of the EURL in which an increase of the RC from 10 to 30 μg/L is suggested.[30]

However, since the endogenous thiouracil levels are clearly multifactorially influenced and the uncertainty related to the threshold approach may still result in incorrect decision-making with major impact on the farmers' activities, future research should not only aim to identify other endogenous sources of thiouracil and related pathways but also investigate potential biomarkers specific for exogenous thiouracil administration or endogenous thiouracil formation. The discovery of a discriminating biomarker might unequivocally alleviate any shortcomings related to the threshold-approach.

nm and recording the emission signals at 485 nm over 120 s using a Cary Eclipse fluorescence spectrophotometer (Varian, USA).

ANS Binding Assay. A 0.4 mM stock solution of ANS was prepared by dissolving ANS in PBS (pH 7.0). The ANS stock solution was stored at 4 °C. Aliquots of cC I66Q solution with or without EGCG taken at different times were mixed with an aliquot of ANS solution, followed by the addition of PBS (pH 7.0) to a final volume of 3 mL. After incubation at room temperature in the dark for 30 min, the samples were subjected to fluorescence assay using an excitation wavelength of 380 nm and an emission wavelength between 400 and 600 nm. Both the ANS fluorescence intensity and the average emission wavelength were recorded to account for the changes in intensity and spectrum.

Transmission Electron Microscopy. Cystatin samples with or without EGCG were diluted 5-fold, and 10 μL of each sample was dispensed onto a coated copper-mesh grid. The grids were negatively stained with 1% (w/v) phosphotungstic acid and then observed under a Hitachi H-7650 transmission electron microscope (Techcomp Ltd., Tokyo, Japan) with an accelerating voltage of 80 kV.

MTT Assay. PC12 cells were purchased from American Type Culture Collection. PC12 cells were maintained in DMEM with 10% horse serum, 5% fetal bovine serum, and 1% penicillin/streptomycin antibiotics. Cells were cultured in a 5% CO_2 atmosphere at 37 °C and then harvested and plated in 96-well plates (Beijing Dingguo Changsheng Biotechnology Co., Ltd.) at a density of 10^4 cells/well. The plates were incubated at 37 °C for 24 h. Subsequently, cC I66Q with and without EGCG was incubated at 65 °C for 35 days, and aliquots of the samples were collected after centrifugation at 6000*g* for 1 h. The concentrated cC I66Q samples were dissolved in PBS buffer (pH 7.0, 50 mM), and the protein concentration in each sample was determined by BCA (a kit bought from Beijing Dingguo Changsheng Biotechnology Co., Ltd.) assay. The cC 166Q samples, with and without ECGC, were separately added to the cells to give a final concentration of cC 166Q in the cells ranging from 0 to 500 ng/mL. The final concentrations of cC I66Q samples (both with and without EGCG) in each well were 0, 1, 5, 50, and 500 ng/mL. The plates were then incubated with the protein samples for 48 h at 37 °C, and cell viability was determined using MTT toxicity assay by adding 10 μL of 5 mg/mL MTT (Beijing Dingguo Changsheng Biotechnology Co., Ltd.) reagent to each well, followed by further incubation for 3 h. After that, the medium was removed and replaced with 100 μL of DMSO. After 10 min of shaking at room temperature, the absorbance of the plate was measured at 490 nm using an iMarkMicroplate Reader (Bio-RAD).

Molecular Dynamic Simulations (MD) and Docking Studies. MD simulations were carried out using the GROMACS 4.0.7 software package.[21] The crystal structure of chicken cystatin (PDB entry 1CEW) was downloaded from the Protein Data Bank.[22] The model of I66Q monomer was constructed using the Swiss-Pdb Viewer software package. Before the docking, MD simulations of cC I66Q monomer at 338 K (65 °C) and pH 2.0 (amyloid fibril forming conditions) were carried out for 20 ns to equilibrate (data not shown).

Docking studies on the interaction between EGCG and cC I66Q were carried out using AutoDock 4.2.5.1 (Molecular Graphics Laboratory, The Scripps Research Institute). The 3D structure of EGCG was downloaded from Chem Spider database (http://www.chemspider.com/). Both cC I66Q and EGCG molecules were prepared using AutoDockTools 1.5.6 (1999–2011 Molecular Graphics Laboratory, The Scripps Research Institute) before docking, The docking was carried out with 60 × 60 × 60 0.375 Å spacing grids covering the entire surface of cC I66Q. The Lamarckian genetic algorithm, which is considered one of the most appropriate docking methods available in AutoDock, was used in the docking analysis.

RESULTS AND DISCUSSION

Analysis of Cystatin Fibril Formation Using ThT Fluorescence. The recombinant variant cC I66Q has been reported to form amyloid fibrils following incubation with continuous agitation at high temperature and low pH.[23] After incubation of cC I66Q with and without EGCG at pH 2.0 and 65 °C, inhibition of cC I66Q fibril formation by EGCG was determined using the ThT-binding fluorescence assay. A consistent increase in the ThT fluorescence intensity occurred when cC I66Q was incubated alone, indicating that the

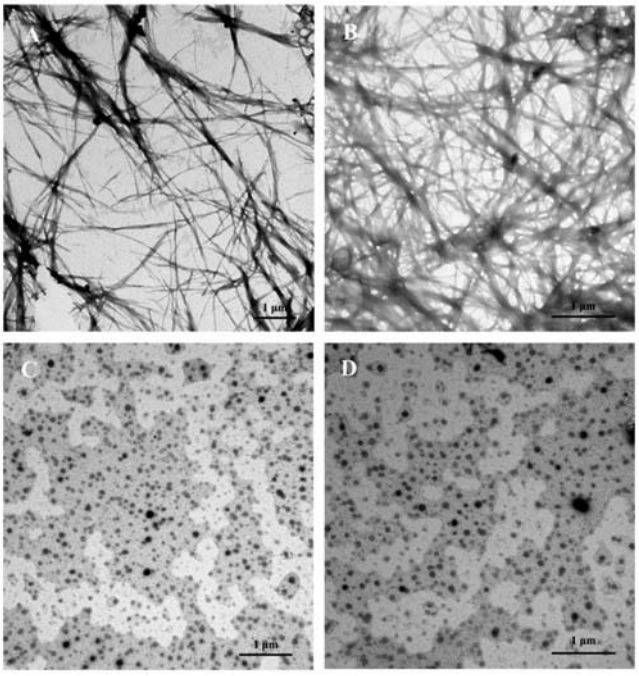

Figure 3. Transmission electron microscopic images of cC I66Q fibrils formed in the absence (A, B) or presence (C, D) of 1 mM EGCG. Data from two independent experiments for each are shown.

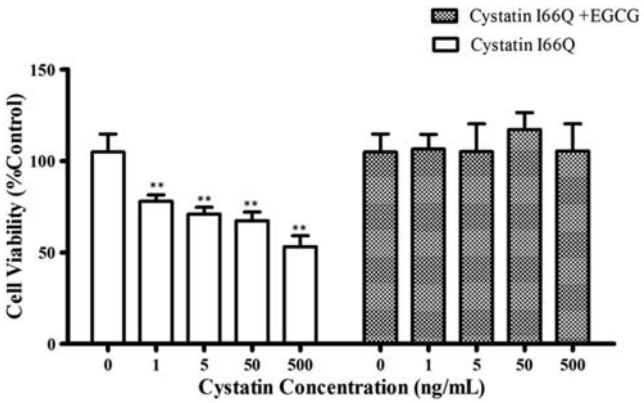

Figure 4. Effect of various concentrations of cC I66Q amyloid fibrils on the viability of PC 12 cells as determined by MTT assay. The concentration of EGCG is 1 mM.

formation of amyloid fibrils proceeded rapidly and without a lag phase (Figure 1A). However, cC I66Q co-incubated with 1 mM EGCG showed a significant decrease in ThT fluorescence across the whole time frame of the experiment. The ThT fluorescence intensity of cC I66Q with EGCG reached a maximum (25.7 au) on the sixth day, indicating that the inhibitory effect exerted by EGCG on the formation of cystatin fibril started from the very beginning of the log phase and continued to the end of the log phase.

To determine the effective concentrations of EGCG for inhibiting cC I66Q fibril formation, the reaction was allowed to occur in the presence of different concentrations (1, 10, 100, and 1000 μM) of EGCG (Figure 1B). Reduction in ThT fluorescence was dependent on EGCG concentration, with significant reduction of fluorescence at 10 μM ($P < 0.05$).

Structural Changes of cC I66Q during Fibril Formation. ANS is a fluorescent dye that probes exposed

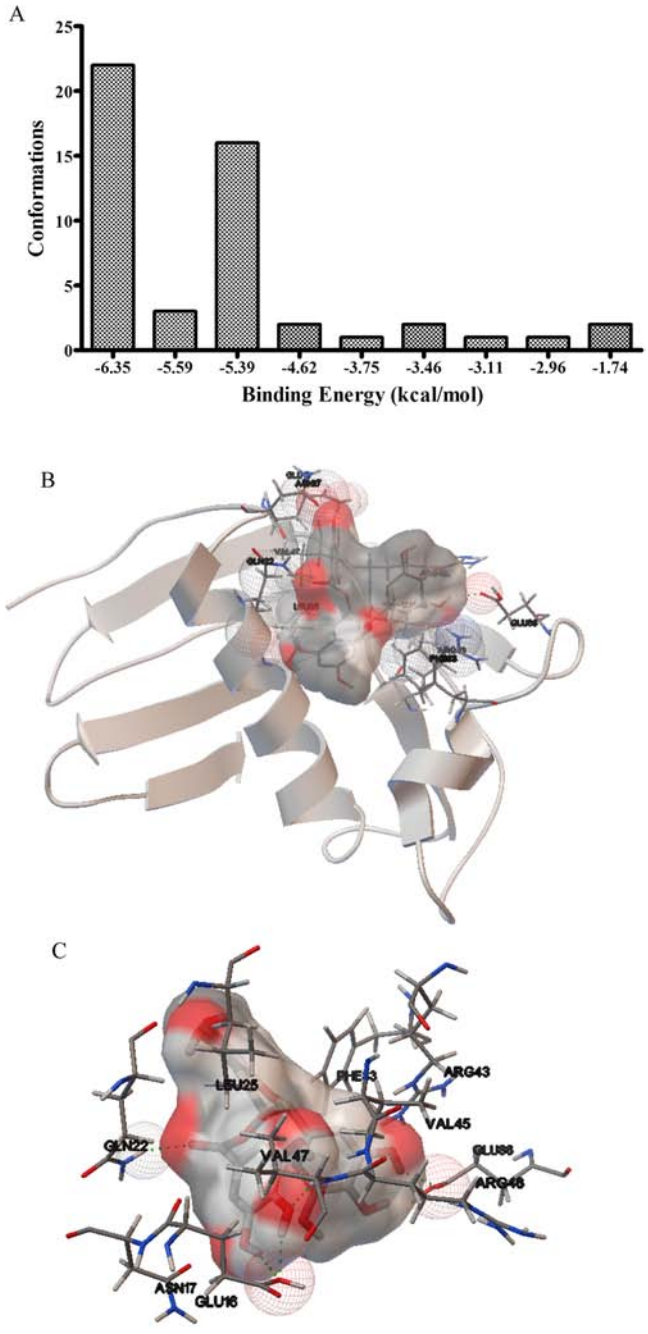

Figure 5. (A) Binding energy of 50 docking models. (B) Panoramic view showing the binding mode between EGCG and cC I66Q at the lowest binding energy of −6.35. (C) Residues of interaction between EGCG and cC I66Q at binding energy of −6.35 (green dots, H-bonds).

hydrophobic surfaces of proteins. Upon binding to the aromatic hydrophobic amino acids of cC, the chemical change of ANS would cause an increase in the intensity of the light to be emitted, with the emission maximum showing a blue shift.[19,24] As shown in Figure 2, the intensity of ANS fluorescence exhibited by cC I66Q fibrils showed a prominent increase in blue shift from 500 to 480 nm. In contrast, the addition of EGCG to cC I66Q resulted in a large reduction in ANS fluorescence intensity and almost no blue shift. This result indicates that the addition of EGCG prevented the accessible exposure hydrophobic regions of cC I66Q. In addition, this

result indicated that binding of EGCG to cC probably occurred at the monomeric level.

Physical Analysis of cC I66Q Fibril Formation and Antifibrillogenic Activity of EGCG. TEM was used to observe the inhibitory effect of EGCG on cC I66Q fibril formation. After incubation at 65 °C and in glycine−hydrochloric acid buffer (pH 2.0) for 35 days, cC I66Q formed long and regular mature amyloid fibrils in the absence of EGCG (Figure 3A,B). The width of the detected fibroid material was calculated to be in the range from 50 to 100 Å, which closely matched the widths of the fibers observed for many amyloidogenic proteins, including those of human cystatins.[17] In the presence of EGCG, cC I66Q formed oligomeric aggregates instead of amyloid fibrils, indicating that EGCG either redirected the amyloidogenic cC mutant I66Q toward unstructured off-pathway oligomers or maintained the proteins in the prefibrillar state without redirecting them toward the aggregation pathway, thus inhibiting the process of fibrillation (Figure 3C,D).[23]

MTT Analysis of the Cellular Toxicity of cC I66Q Amyloid Fibril and Oligomers. The mutation of hCC L68Q is associated with massive amyloid deposition within small arteries and arterioles of the leptomeninges, cerebral cortex, basal ganglia, brainstem, and cerebellum, resulting in severe cellular toxicity within the brain.[25] Therefore, after observing the morphology of the cC I66Q amyloid fibril and oligomer formations in the presence of EGCG, we assessed the cellular toxicity of cC I66Q on PC12 cells (neuronal cell model) using the MTT assay. After 48 h of incubation, cell viability decreased significantly ($P < 0.01$) in the presence of increasing concentrations of cC I66Q (Figure 4). However, the complete abrogation of the toxicity of cC I66Q by EGCG indicated that the cC I66Q oligomers formed in the presence of EGCG were nontoxic.

Computational Analysis of the Binding between EGCG and cC I66Q. Both fluorescence and electron microscopy data showed that EGCG could inhibit the formation of amyloid fibrils by cC I66Q, and this occurred at a very early stage in the process. These results suggested that there could be some kind of interaction between EGCG and cC I66Q at the atomic level and at a stage prior to fibril initiation. To investigate this hypothesis, we carried out in silico studies using molecular dynamics (MD) simulations and docking analysis.

MD simulation of cC I66Q was carried out at 338 K and pH 2.0 for 20 ns (data not shown), and we carried out docking simulations to investigate the possible EGCG-binding site on cC I66Q. The binding energy of 50 models in docking is shown in Figure 5A. On the basis of Figure 5A, the interacting residues of the two most possible binding patterns and properties resulting from the binding are listed in Table 1. Compared with the two binding patterns, EGCG probably bound to cC I66Q and was located in a region between the α-domain and the β-domain, as depicted in Figure 5B,C. The possible site on cC I66Q to which EGCG may bind included the appendant structure. The appendant structure of cC I66Q has been demonstrated to play an important role in amyloidogenic cystatin dimerization prior to domain swapping.[26] Consequently, the stabilizing effect contributed by EGCG on the appendant structure of cC I66Q may prevent the occurrence of domain swapping, so as to redirect cC I66Q away from the fibril-forming pathway and into forming nontoxic, unstructured, and off-pathway aggregates.

In this study we show that EGCG can significantly inhibit the fibrillation of amyloidogenic cystatin mutant I66Q (cC I66Q) and that the inhibitory effect is dose-dependent and extremely potent. This observation is of particular significance as there is minimal research available demonstrating the action of small molecule polyphenols (such as EGCG) against proteins that utilize a domain swapping mechanism to initiate amyloid formation.

protein content. This is most likely due to presence of multiple, seed-expressed BBI genes[17,18] and a pronounced environmental effect on BBI protein accumulation.[19] An alternate, successful approach to reduce BBI protein levels was the overexpression of a mutated, inactive BBI transgene, which was able to outcompete endogenous BBI transcripts and significantly reduced BBI protein levels.[20]

By far the largest success in reducing trypsin inhibitor activity in soybean is due to the identification of a soybean accession (PI 157740) with dramatically reduced (~40%) trypsin inhibitor activity.[21] The molecular genetic cause is a frameshift mutation (termed *KTi3*−) that affects one of three seed-expressed *KTi* genes.[22] This accession has been used in extensive backcrossing and feeding trials,[3,23−25] and raw extruded protein meal lacking KTi3 protein is superior for animal weight gain as compared to raw soybeans.[3,23,24] However, weight gain for young animals fed non-heat-treated soybean materials (including *KTi3*−) is inferior to those fed conventional heat-treated soybeans, although soybean seed lacking KTi3 protein has been shown to require less heat processing in comparison to conventional soybeans.[3,23,24]

In this study, we report identification of a *G. max* line with reduced Kunitz trypsin inhibitor protein and decreased trypsin inhibition, which is not due to mutations affecting the previously identified *KTi3* gene. The objectives of this work were (1) to identify the specific genetic cause for this reduction in trypsin inhibition, (2) to evaluate if this reduction was synergistic with the previously identified *KTi3*− mutation, and (3) to ascertain what effect these mutations had on seed proteome and BBI protein accumulation in mature seed.

MATERIALS AND METHODS

Plant Materials. Seed for soybean lines examined was obtained from the USDA-ARS GRIN collection. Out of 520 lines examined, two were Kunitz trypsin inhibitor (KTi) mutants (PI 68679, *KTi1*−, and PI 542044, Kunitz, *KTi3*−). A wild-type line, Williams 82 (PI 518671, *KTi1*, *KTi3*)[26] was used as a control line. The Kunitz trypsin inhibitor 3 (*KTi3*−) mutation in this line is derived from a landrace identified by Theodore Hymowitz (PI 157740) backcrossed to Williams 82 for five generations.[21]

Population Development. PI 68679 (*KTi1*−) and PI 542044 (*KTi3*−) were crossed in the summer of 2012 at the Southfarm experimental research station, and F_1 seed was advanced in greenhouses to produce F_2 seed. Seed chips from individual F_2 seed were examined via SDS−PAGE analysis and two lines were selected for absence of both KTi1 and KTi3 proteins.

***KTi3*− SimpleProbe Assay.** A SimpleProbe assay was developed to track the *KTi3*− allele,[22] designed by use of Lightcycler probe design software, version 1 (Roche Applied Sciences, Indianapolis, IN). Genotyping PCR reactions were performed with a 5:1 asymmetric mix of primers (5′-TTGCAGTTATAATGCTGTGTGTTG-3′, 5′-AA-TACTAATCCCAATATCCCCACA-3′) in the presence of a non-extensible fluorescently labeled SimpleProbe (5′-fluorescein-SPC-TGAATTCATCATCAGAAACTCTCTCAAGTC-phosphate-3′) using Titanium Taq polymerase (Clonetech, Mountain View, CA) and 5−50 ng of genomic DNA in a Lightcycler 480 II instrument (Roche) under the following conditions: 95 °C for 5 min, followed by 45 cycles of 95 °C for 30 s, 60 °C for 30 s, and 72 °C for 30 s. Following amplification (and a 1 min denaturation step at 95 °C and 2 min at 55 °C), melting curve analysis of 20 reads/deg from 50 to 70 °C was performed. For *KTi3*− homozygote samples, a single melting peak was observed at ~56−57 °C, whereas wild-type lines show a single peak at ~64 °C and heterozygotes showed both peaks (Figure S1, Supporting Information).

SDS−PAGE and Immunoblot Analysis of Extracted Soybean Seed Proteins. Protein extraction and SDS−PAGE analysis was performed as previously described.[19] Briefly, mature soybean seed samples were ground with a mortar and pestle, and proteins were extracted from a 10 mg portion (for analysis of F_2 lines, a 10 mg chip from each seed was used instead) in SDS buffer [125 mM Tris-HCl, pH 6.8, 20% glycerol (v/v), 5% (v/v) 2-mercaptoethanol, 4% SDS (w/v), and 0.03 mM bromophenol blue], boiled for 5 min, and centrifuged to remove insoluble material. Protein extract supernatant was separated by SDS−PAGE with 15% (w/v) total acrylamide monomer in the resolving gel for 1 h at 20 mA on a Hoefer SE 260 minigel apparatus. Protein bands were visualized with Coomassie blue R-250. Immunoblots were performed as previously described with a 1:5000 dilution of an anti-BBI antibody[19] or 1:10 000 anti-KTi (non-isoform-specific) antibody[27] in Tris-buffered saline (TBS; 50 mM Tris-HCl, pH 7.5, and 150 mM NaCl). After being washed with TBST buffer (Tris-buffered saline with 0.3% Tween-20), membranes were incubated with goat anti-rabbit IgG−horseradish peroxidase conjugate for 1 h and detected with enhanced chemiluminescent substrate according to manufacturer's recommendations (Pierce, Rockford, IL).

Two-Dimensional Protein Electrophoresis. Two-dimensional electrophoresis was carried out essentially as previously described.[28] Protein samples (300 μg) were initially separated by use of isoelectric focusing IPG strips (pH 3−10, 13 cm in length) in an IPGPhor system (GE Healthcare, Little Chalfont, U.K.). Following electrophoresis, the protein in the IPG strips was resolved in the second dimension with a Hoefer SE 600 Ruby electrophoresis unit according to the manufacturer's specifications (GE Healthcare). After completion of electrophoresis, the gels were removed from the cassette and stained with Coomassie blue R-250. Coomassie-stained gels were scanned on a UMAX PowerLook 2100XL scanner running Adobe Photoshop version 7.0 (Adobe Systems, San Jose, CA), and image files were analyzed via Phoretix 2-D Advanced software, version 6.01 (Nonliner Dynamics Ltd., Newcastle-upon-Tyne, U.K.).

DEAE Anion-Exchange Chromatographic Separation of Extracted Soybean Seed Proteins. Mature soybean seed was ground into a fine powder with a mortar and pestle. To 20 g of seed powder was added 200 mL of 20 mM Tris-HCl/0.1 mM EDTA buffer, pH 6.8, and the mixture was placed in an orbital shaker (150 rpm, 30 °C) for 15 min. The slurry was clarified by centrifugation at 13320*g* for 20 min. To the clear supernatant was added 100 mM $CaCl_2$ stock solution, to a final concentration of 10 mM of calcium chloride. After incubation at room temperature for 10 min, the solution was clarified by centrifugation as stated above. Protein from the supernatant was precipitated by addition of solid $(NH_4)_2SO_4$ to 70%. The resulting protein was recovered by centrifugation, resuspended in 20 mL of 10 mM sodium phosphate/0.1 mM EDTA buffer, pH 6.5, and dialyzed overnight against the same buffer. The concentrated protein solution was loaded onto a column of DEAE-cellulose (2.5 × 20 cm) previously equilibrated with the dialysis buffer. The column was washed with 2 volumes of buffer and then subjected to a step gradient of 50, 100, 200, 300, 400, and 500 mM NaCl, prepared in dialysis buffer. Fractions of 6 mL were collected, and alternate fractions were examined by SDS−PAGE.

Trypsin and Chymotrypsin Inhibitor Assays. Trypsin and chymotrypsin inhibitor assays were done in duplicate as previously described.[29] Briefly, 10−50 μg of seed protein were used in inhibitor assays, using *N*-benzoyl-L-arginine ethyl ester (BAEE) and *N*-benzoyl-L-tyrosine ethyl ester (BTEE; obtained from Sigma) as trypsin and chymotrypsin reaction substrates, respectively. Absorbance at 256 nm was monitored for ~3 min, and trypsin and chymotrypsin inhibitor activities were calculated as the difference between absorbance change in control and samples containing seed protein.

RNA Extraction and qRT-PCR Analysis. F_3 lines were also grown in a growth chamber in a random complete block design with four biological replicates for each genotype. Immature seed was collected and separated into size categories based on fresh weight. Two seed stages representing midmaturation (200−300 mg/seed fresh weight) and late maturation (400−500 mg/seed fresh weight) were selected for mRNA extraction and qRT-PCR analysis.

Each genotype was evaluated with four biological replicates consisting of three pooled immature seeds. RNA isolation, cDNA

production and qRT-PCR were carried out as previously described[28] with 1 μg of DNase-treated total seed RNA. A subsample of $^1/_{20}$ of the total RT reaction was used for qRT-PCR reaction. Samples were compared by the ΔΔ*CT* method,[26] with the *cons6* gene as a reference gene.[31]

Statistical Analyses. JMP version 9 software (SAS Institute Inc., Cary, NC) was used to perform one-way analysis of variance (ANOVA) tests to compare the effect of genotype on gene expression or trypsin/chymotrypsin inhibition activity of seed extracts. For ANOVA tests that displayed significant differences at the $p < 0.05$ level, Tukey's honest significant differences (HSD) ad hoc test was performed ($\alpha = 0.05$ significance level cutoff).

RESULTS AND DISCUSSION

Identification of a Germplasm Line with Reduced Kunitz Trypsin Inhibitor Content. To identify soybean lines with reduced trypsin and chymotrypsin inhibitor content, we screened a total of 520 soybean accessions, obtained from the USDA Soybean Germplasm Collection, Urbana, IL, by SDS–PAGE and Western blot analysis with antibodies raised against purified soybean KTi protein.[27] Among these soybean accessions, one germplasm line, PI 68679, was identified that had reduced KTi protein levels (Figure 1).

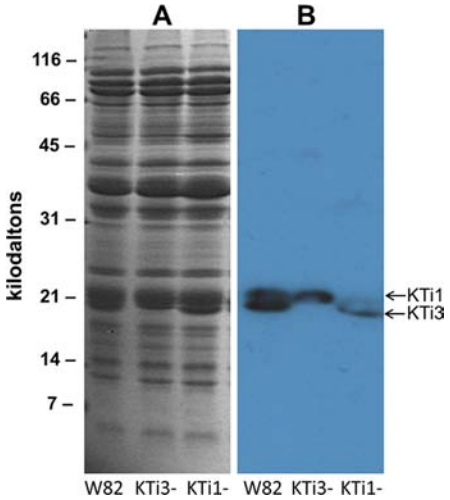

Figure 1. SDS–PAGE protein fractionation of mature soybean seed. Equivalent amounts of protein (50 μg) of clarified seed protein were separated on polyacrylamide gels. (A) Coomassie brilliant blue-stained polyacrylamide gel; (B) Western blot probed with anti-Kunitz trypsin inhibitor antibody (non-isoform-specific). Genotypes are indicated below chart: W82 = Williams 82 (PI 518671, wild type); KTi3– = Kunitz (PI 542044, *KTi3*– mutant); KTi1– = PI 68679 (*KTi1*– mutant). The bands corresponding to KTi1 and KTi3 proteins are indicated by arrows.

Determination of Molecular Genetic Basis for Reduced KTi Levels in PI 68679. In soybean, three *KTi* isoforms (*KTi1*, *KTi2*, and *KTi3*) have been reported to be expressed at the mRNA level in developing seed.[22,32] Cloning of the *KTi3* gene from PI 68679 revealed no mutations that could affect the coding region (Figure 2A). *KTi1/2* were annotated as tightly linked and highly similar (>90%), and were suggested to lack trypsin inhibitor activity based on sequence analysis alone,[32] but this assertion was not experimentally validated. The Williams 82 reference sequence (http://www.phytozome.net/search.php?method=Org_Gmax) does not contain a second locus linked to *KTi1*, which displays high (>90%) similarity reported for *KTi2* in the initial characterization.[22,32] BLAST searches with the *KTi1/KTi2* gene fragment (NCBI accession no. S45035.1), revealed only a single gene (Glyma01g10900/Glyma01G095000) on chromosome 1. Sanger sequencing with cloned *KTi1* PCR products revealed a single-base deletion (GGG356 → 358GG, relative to start codon, NCBI accession no. KC460320), which introduces a frameshift mutation at position 119 (Figure 2B). In concordance with the previously named *KTi3*– allele (Figure 2A), we have termed this new mutant allele *KTi1*–.

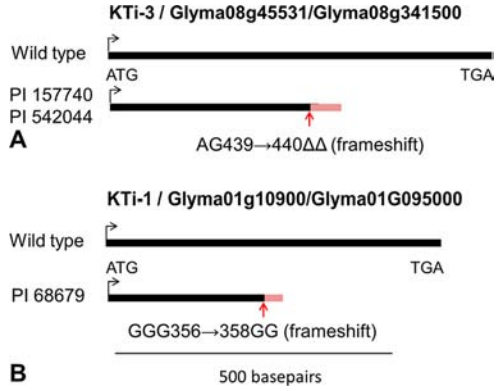

Figure 2. Cartoon depiction of Kunitz trypsin inhibitor genes and the impact of loss-of-function mutations. (A) *KTi3*; (B) *KTi1*.

Development of Lines Containing Two Genetically Distinct Mutations Affecting KTi Encoding Genes. Using traditional hybridization methods, we crossed the line bearing a *KTi1*– mutation (PI 68679) to a line bearing the previously identified *KTi3*– mutation (PI 542044). A SimpleProbe-based genotyping assay for the *KTi3*– mutation was developed (Figure S1, Supporting Information) and this assay was completely predictive for absence/accumulation of KTi3 protein (data not shown). However, attempts to develop a routine molecular marker assay for the novel *KTi1*– mutation were not successful. The mutation is a deletion of one guanine residue within a string of three guanines (GGG > GG), which is extremely difficult to detect by hybridization-based genotyping. We explored other genotyping methods that rely on size polymorphism (e.g., CAPS, dCAPS[33,34]) but no suitable restriction enzymes were identified.

A single F_1 line was advanced and F_2 seed was examined for accumulation of KTi (Figure 3), via SDS–PAGE with seed produced in a greenhouse. Homozygosity for both *KTi1*– and *KTi3*– mutations was completely correlated with absence of both KTi protein bands (Figure 3, lane 8). PCR and sequencing verified that all lines with absent KTi1 and KTi3 protein were homozygous for both *KTi*– mutations and this trait was consistent for at least two generations.

Proteomic Investigations of Mutant Lines Bearing *KTi*– Mutations. Seed of the line homozygous for both the *KTi1*– and *KTi3*– mutations (E16) lacked any KTi protein, as detectable by anti-KTi antibodies. (Figure 4A,B). These results were also concordant with results for F_2 seed chips (Figure 3). However, BBI proteins accumulate to a much greater degree (≥10-fold higher) in mature seed bearing either or both *KTi* mutations, relative to Williams 82 (Figure 4C). Similar seed proteome rebalancing has been documented in previous studies. For example, the silencing of β-conglycinin, 7S seed storage protein, resulted in higher accumulation of the 11S glycinin.[35] Similarly, a soybean β-conglycinin mutant also

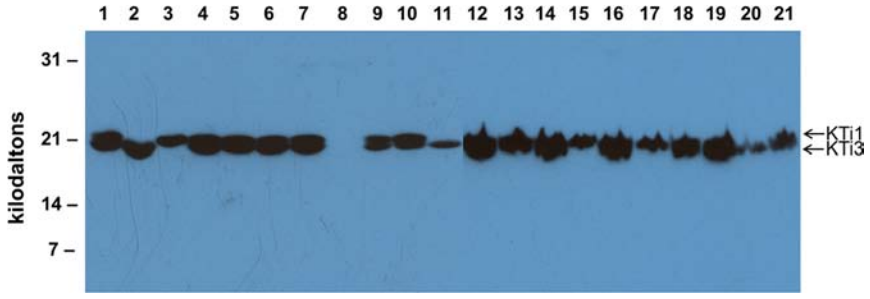

Figure 3. Immunoblot analysis of clarified protein from F_2 seed chips, produced from a single F_1 plant heterozygous for *KTi1*− and *KTi3*−. Immunoblots were probed with a non-isoform-specific anti-Kunitz trypsin inhibitor antibody. Numbers above lanes indicate individual F_2 seed from which seed chips were taken. The bands corresponding to KTi1 and KTi3 proteins are indicated by arrows.

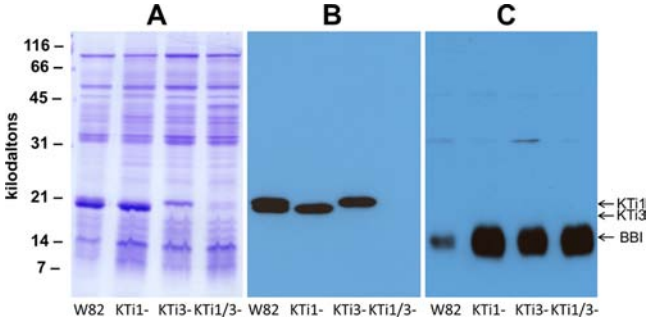

Figure 4. Western blot analysis of Kunitz and Bowman−Birk trypsin inhibitors in soybean seed of selected genotypes. (A) Coomassie brilliant blue R-250-stained PAGE gel. Seed proteins remaining in the supernatant after fractionation with 10 mM calcium were resolved by SDS−15% PAGE and stained with Coomassie brilliant blue. Protein for this analysis was obtained from equal amounts (20 mg) of dry seed powder. (B) Western blot probed with anti-Kunitz trypsin inhibitor antibodies (non-isoform-specific). (C) Western blot probed with anti-Bowman−Birk inhibitor antibody (non-isoform-specific). Bands corresponding to KTi1, KTi3, and BBI proteins are indicated by arrows. Genotypes are indicated below images: W82 = Williams 82 (PI 518671, wild type); KTi3− = Kunitz (PI 542044, *KTi3*− mutant); KTi1− = PI 68679 (*KTi1*− mutant); and KTi1/3− = E16 F_3 progeny of line homozygous for *KTi1*−, *KTi3*− mutant alleles.

exhibited proteome rebalancing by accumulating higher amounts of glycinin.[36]

Proteins extracted from mature seed of Williams 82 or *KTi* mutant lines were separated by DEAE-cellulose chromatography. The elution profile of soybean KTi protein is shown in Figure 5. When DEAE-cellulose-eluted fractions from Williams 82 and *KTi1*− were resolved by SDS−PAGE, an abundant 21 kDa protein was observed in fractions eluted with approximately 250 mM NaCl (Figure 5). Western blot analysis with KTi antibodies reacted strongly with the 21 kDa protein(s), confirming it as KTi (Figure S2, Supporting Information). This abundant protein was drastically reduced in the protein extracts from *KTi3*− and *KTi1/3*− mutant lines (Figure 5). We also fractionated total seed proteins from Williams 82 and *KTi* mutant lines by two-dimensional PAGE (Figure 6). We have previously identified soybean seed proteins resolved by 2D gels by MALDI-TOF-MS.[37] These analyses have demonstrated that the KTi proteins in Williams 82 seed resolves into at least three spots, KTi1/KTi2 and KTi3 (Figure 6, arrows and box indicate KTi protein spots). The protein spot corresponding to KTi3 is much greater in abundance as compared with the KTi1 spots. The *KTi1*− mutant accumulates abundant KTi3 but lacks the KTi1 spot, while the *KTi3*− mutant lacks the abundant KTi3 spot (Figure 6). The homozygote double-mutant line E16 has no detectable KTi protein in mature seed (Figure 6). Although there are at least four *KTi* genes in the soybean genome, the combination of two point mutations (*KTi1*− and *KTi3*−) resulted in complete absence of KTi protein (at a minimum below the threshold level of detection by immunoblot analysis).

Trypsin and Chymotrypsin Activities in Seed of Mutant Lines. The canonical KTi3 protein has been conclusively demonstrated to have trypsin inhibitor activity, and the *KTi3*− nonsense mutation reduces trypsin inhibitory activity by ∼40%.[32] In contrast, the relative contribution of the *KTi1* gene to overall trypsin inhibition activity was unclear.[32] We performed trypsin and chymotrypsin inhibitor assays, and significant genotypic differences were noted by one-way ANOVA (F = 16.8616 and p = 0.0098 for trypsin; F = 7.2156 and p = 0.0432 for chymotrypsin). Seed of all *KTi*− genotypes showed significantly (α = 0.05) decreased trypsin inhibitor activity relative to wild-type seed, and the combination of both mutations in line E16 had the lowest trypsin inhibitor activity (Figure 7A), although the mean trypsin inhibition among *KTi*− genotypes was not significantly different. Soybean genotype E16 revealed only about 50% trypsin inhibitor activity relative to the wild-type Williams 82 (Figure 7A). This observation is consistent with our proteomics data, which show no detectable KTi proteins in E16 (Figure 6). In spite of the complete absence of KTi in E16 genotype, the overall decrease in trypsin inhibitor activity is not significantly different from that of KTi3− mutant. This may be due to E16 seeds compensating for the mutation by overproducing BBI protein (Figures 4C and 8). Mean chymotrypsin activity was lower in all lines bearing *KTi1*− or *KTi3*− mutations, but these differences were significant (α = 0.05) only for the E16 genotype (Figure 7B) as compared to wild-type seed. A previous study has shown that a soybean line lacking KTi3 was nutritionally superior to unheated raw soybean but was inferior to processed soybean meal.[38]Heat treatment reduced trypsin and chymotrypsin inhibitor activities of the KTi3-free soybeans by approximately half and three-fourths in comparison with commercial untoasted soy flour.[38] It will be interesting to compare the effect of heat treatment on trypsin and chymotrypsin inhibitor activities of the E16 genotype created in the current study with those reported for the KTi3− mutant.

qRT-PCR Analysis of Developing Seed of *KTi* Mutant Lines. We examined gene expression in immature seed for all four lines (*KTi1*−, *KTi3*−, *KTi1/3*−, and Williams 82) by qRT-PCR with mRNA isolated from growth-chamber-produced seed at two seed development stages: (1) 200−300 mg/seed fresh weight and (2) 400−500 mg/seed fresh weight. Four of the

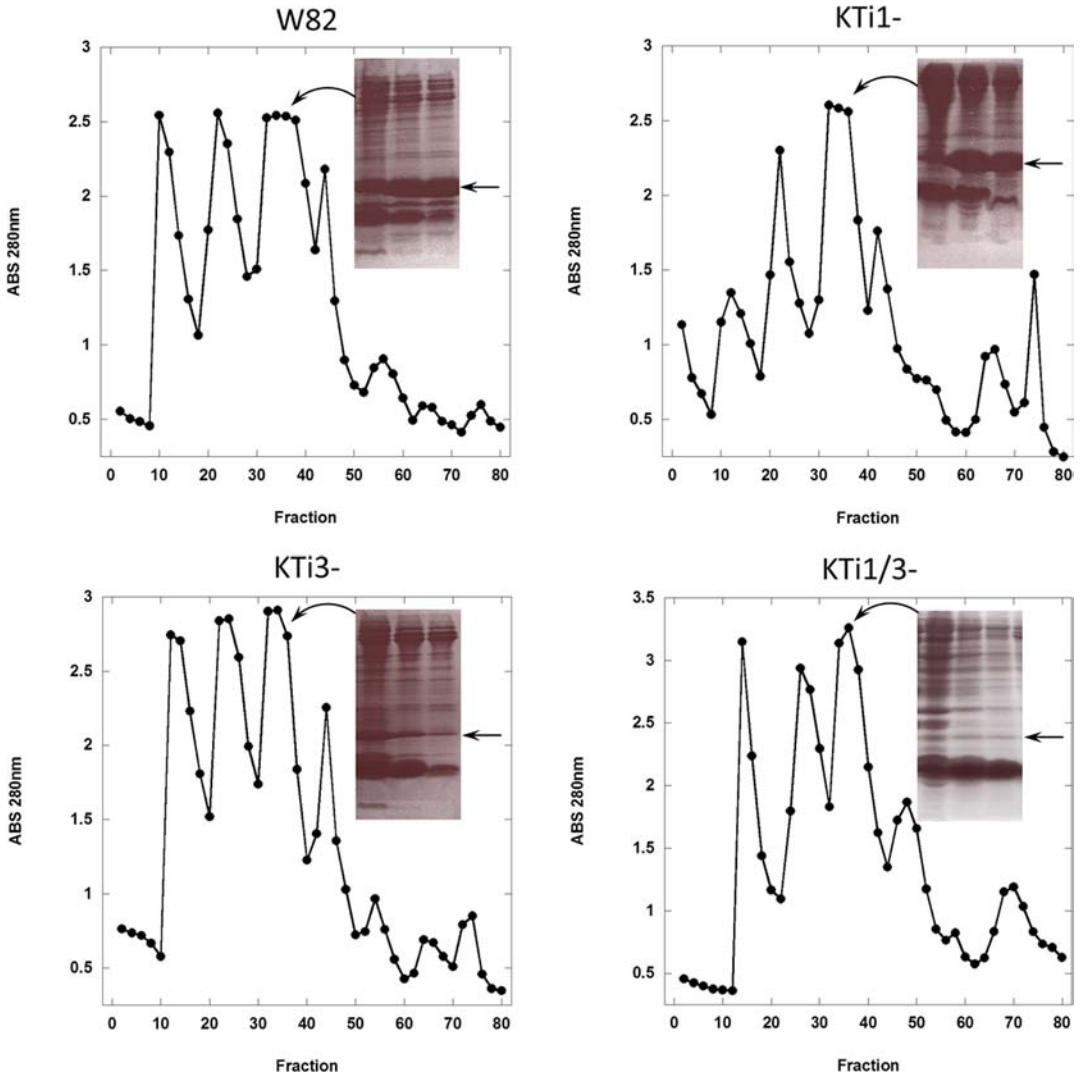

Figure 5. Elution profile of KTi fractionated by DEAE-cellulose chromatography. Soybean KTi was eluted from the column by use of a NaCl step gradient of 50 mM (fractions 1−10), 100 mM (fractions 11−21), 200 mM (fractions 22−31), 250 mM (fractions 32−41), 300 mM (fractions 42−51), 400 mM (fractions 52−61), and 500 mM (fractions 62−82). (Insets) SDS−PAGE images of fractions enriched in KTi. Arrows point to the abundant 21 kDa protein. Genotypes are indicated above each panel as described in the caption for Figure 4.

major seed storage protein-encoding genes present in soybean seed were selected for qRT-PCR analysis: glycinin 4 (*Gy4*), *KTi1*, *KTi3*, and a non-gene-specific primer pair that amplified several BBI genes (full details in Materials and Methods). One-way ANOVA was performed to compare the effect of genotype on each gene's expression level.

We observed no significant differences in *Gy4* mRNA levels between any genotypes at either seed developmental stage (Figure 8A, $F = 0.4091$ and $p = 0.7496$; Figure 8B, $F = 1.0407$ and $p = 0.4127$). No significant differences were noted for *KTi1* at the early developmental stage for any of the genotypes (Figure 8A, $F = 1.5404$ and $p = 0.2591$), and differences at the late developmental stage were not significant (Figure 8B, $F = 2.7633$ and $p = 0.0922$). Significant differences were noted for *KTi3* gene expression at both early and late developmental stages (Figure 8A, $F = 234.9889$ and $p < 0.001$; Figure 8B, $F = 56.8767$ and $p < 0.0001$). We observed significant differences in accumulation of BBI gene transcripts at the early seed developmental stage (Figure 8A, $F = 5.994$ and $p = 0.0113$).

Post hoc analyses were done with the Tukey HSD test ($\alpha = 0.05$) to compare genotype means (Figure 8) for *KTi3* and *BBI*. We noted significant near-absence of *KTi3* gene transcripts in lines bearing the *KTi3*− mutation at both early (Figure 8A) and late (Figure 8B) seed development stages, which is consistent with previous reports.[22] *KTi3* gene expression was similar between Williams 82 and *KTi1*− genotypes and between *KTi3*− and *KTi1/3*− genotypes. BBI gene expression was higher for both the *KTi1*− mutant (~2.75-fold higher) and the *KTi1/3*− mutant (~3.75-fold higher) as compared to Williams 82 at the early seed developmental stage, although only the *KTi1/3*− mutant was significantly different from Williams 82. *BBI* gene expression for Williams 82 and *KTi3*− genotypes were insignificantly different (Figure 8), and no significant differences were found at the later developmental stage for *BBI* gene expression (Figure 8B).

At least 10 BBI isoforms exist in soybean seed, which have been shown to have different specific inhibitory activities on trypsin, chymotrypsin, and/or elastase.[39,40] Some BBI isoforms inhibit only trypsin, or inhibit elastase and trypsin but not chymotrypsin. The specific proportion of these isoforms has been shown to vary from cultivar to cultivar.[41] Enhancement of BBI isoforms that inhibit only trypsin or inhibit elastase and

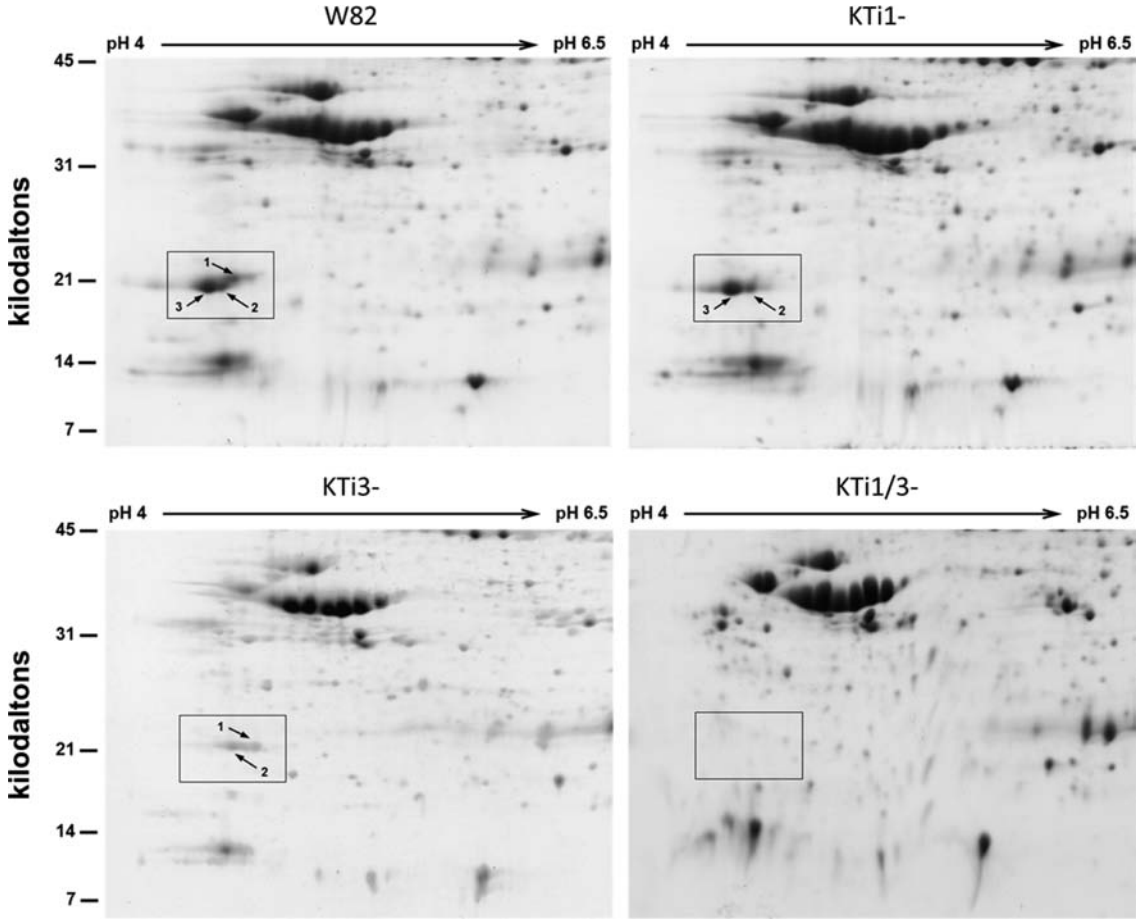

Figure 6. Two-dimensional gel electrophoresis of soybean total seed protein stained with Coomassie brilliant blue. Equivalent amounts of protein (300 μg) were separated on the basis of isoelectric point (p*I*) and then by SDS−PAGE. Genotype is indicated above each image, as described in the caption for Figure 4. The position of KTi proteins is indicated by numbered arrows and box.

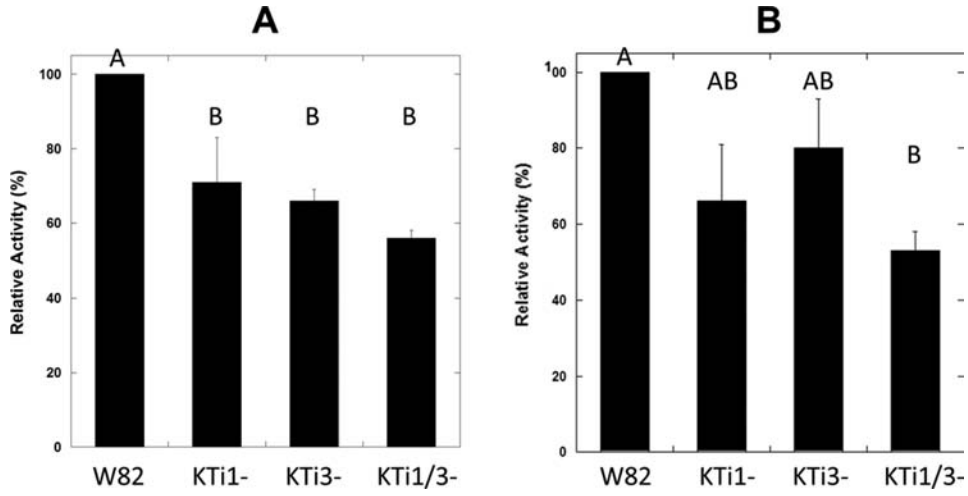

Figure 7. (A) Trypsin and (B) chymotrypsin inhibitor activity levels present in seed of selected genotypes. Letters above columns indicate result of one-way ANOVA ($p < 0.05$) and Tukey's HSD test ($\alpha = 0.05$); common letters indicate insignificant differences between means. Trypsin and chymotrypsin inhibitor activity were measured under standard conditions containing 10−50 μg of soybean seed protein with *N*-benzoyl-L-arginine ethyl ester and *N*-benzoyl-L-tyrosine ester as substrates, respectively. Genotypes are indicated below bars, as described in the caption for Figure 4.

chymotrypsin would compensate for the loss of trypsin inhibitor activity due to the KTi mutations without affecting chymotrypsin inhibitor activity. We observed no change in mRNA abundance of total BBI transcripts in seed of the *KTi3*− mutant (Figure 8A), which suggests that increased BBI protein is not likely due to increased transcription and/or enhanced mRNA stability in *KTi3*− lines. In contrast, we observed significantly higher levels of BBI transcripts in *KTi1*− lines. These results suggest that developing seed responds to *KTi*− lesions to maintain protein homeostasis through two different

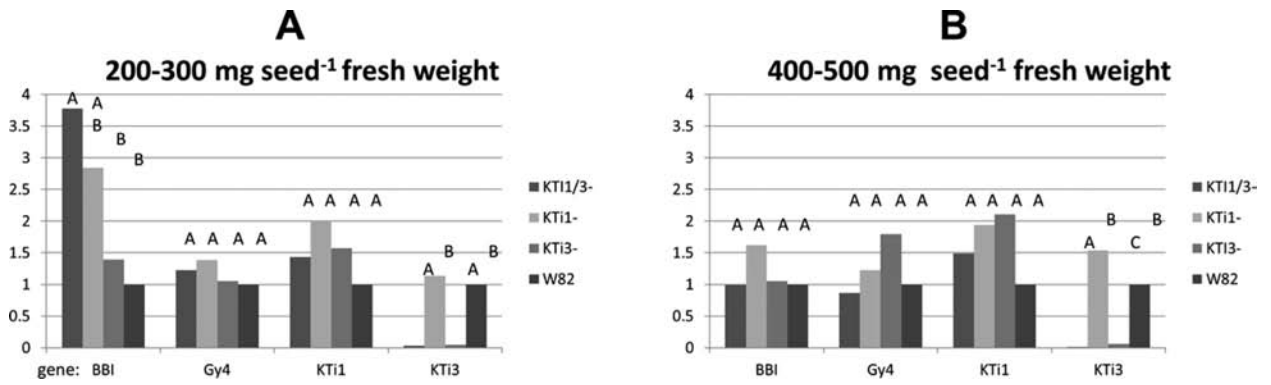

Figure 8. qRT-PCR analysis of mRNA from immature seed of two developmental stages examined with seed storage protein-specific primers: (A) early stage, isolated from immature seed between 200 and 300 mg/seed, and (B) late stage, isolated from immature seed between 400 and 500 mg/seed. Genes examined are *BBI* (non-isoform-specific), *KTi1*, *KTi3*, and glycinin subunit 4 (*Gy4*), and results were normalized to Williams 82 gene expression. Letters above columns indicates result of one-way ANOVA and Tukey's HSD test (α = 0.05); common letters indicate insignificant differences between means.

methods: elevated BBI mRNA levels (*KTi1*−) or proteome rebalancing (*KTi3*−), though the exact mechanisms are still incompletely understood. Enhanced accumulation of BBI proteins, however, does not translate to increased chymotrypsin inhibitor activity, which suggests that only a subset of BBI proteins are upregulated, in contrast to the major BBI isoform, which has functional chymotrypsin inhibition domains.[5] Similar results were obtained by transgenic overexpression of a mutated, nonfunctional BBI transgene, where the nonfunctional version effectively outcompetes translation of an endogenous, chymotrypsin-inhibitory BBI protein.[2016] In this study we have observed a reduction in chymotrypsin inhibitor activity in the KTi mutants (Figure 7B). It has been reported that soybean KTi can inhibit bovine chymotrypsin.[39] The loss of both KTi1 and KTi3 in the E16 genotype could result in greater inhibition of chymotrypsin inhibitor activity.

If substantial reduction in trypsin/chymotrypsin inhibitors can be achieved, beyond that currently possible with the *KTi1*− and/or *KTi3*− mutations, it may be possible to utilize raw soybean derivatives without the pancreatic complications or impaired weight gain issues of conventional soybean seed. This aim is particularly relevant for certain fish species (e.g., salmonoids), which are extremely sensitive to trypsin proteinase inhibitors, as compared to poultry and swine.[12] Even conventional heat-treated soybean meal bears residual trypsin/chymotrypsin inhibitor activity, which has limited inclusion of soybean meal in salmonoid diet mixtures.[42] As the current use of fishmeal is unsustainable in the long term,[43] reducing antinutritional trypsin inhibitory content of soybean seed may facilitate a more sustainable source of protein meal for fish production.

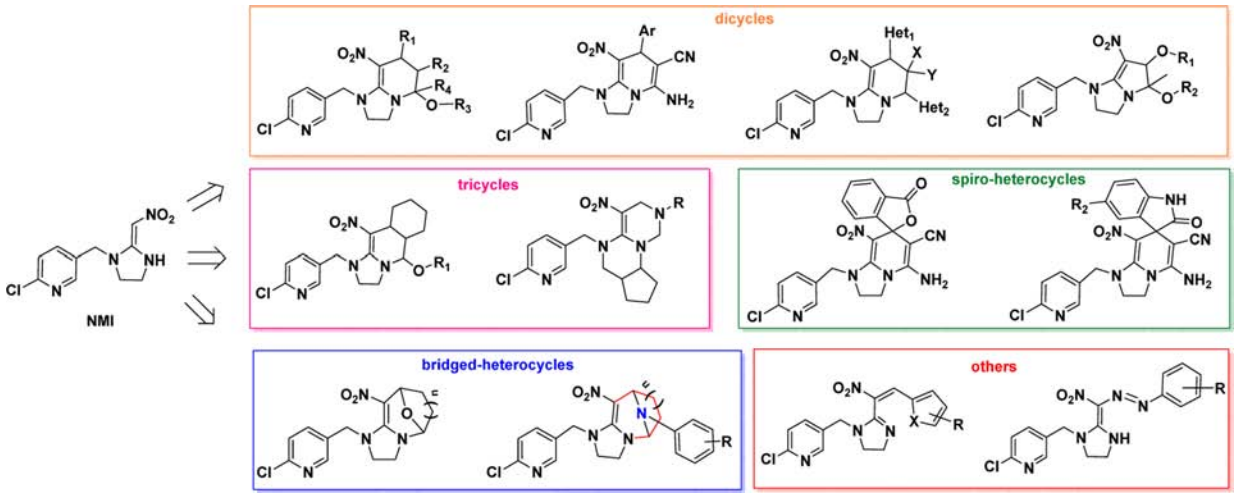

Figure 1. Synthetic variants of neonicotinoids based on NMI.

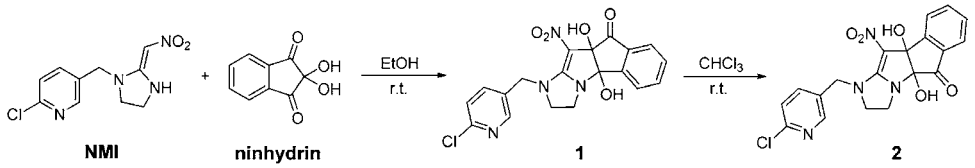

Figure 2. Synthesis and isomerization of NMI-ninhydrin adduct.

General Procedure for the Preparation of 1, 8a, 9a, and 10a. NMI and its analogues were prepared according to our previously reported procedures. To a suspension of NMI or its corresponding analogues (5 mmol) in ethanol (30 mL) was added the solution of ninhydrin (5 mmol) in ethanol (20 mL), and the mixture was stirred at room temperature for 24 h.[35] Then filtration was performed to afford the solid product, which was used directly without further purification.

General Procedure for the Preparation of 2, 8b, 9b, and 10b. Compound **1** or its corresponding analogues (1 mmol) in chloroform (or DMF, 5 mL) were stirred at room temperature for 3 days. Then, the solvent was removed by vacuum, and the solid was further purified by silica gel column chromatography (EtOAc) affording the pure product.[35]

General Procedure for the Preparation of Etherification Products 3a–5d. **3a–3g**: A mixture of **2** (1 mmol) and corresponding alcoholic solvents (10 mL) was stirred at room temperature. Then, TsOH (0.1 mmol) was added to the solution, and the process was monitored by TLC. After completion, the solvent was removed by vacuum, and the solid was further purified by silica gel column chromatography (EtOAc) affording the pure products.

4a–4b: A mixture of **2** (1 mmol) and dry tetrahydrofuran (10 mL) was stirred at room temperature. NaH (1.5 mmol) was added to the solution until no bubbles were produced, then the corresponding alkyl iodide (5 mmol) was added. The process was monitored by TLC. After completion, the solvent was removed by vacuum, and the solid was further purified by silica gel column chromatography (EtOAc) affording the pure products.

5a–5d: A mixture of **2** (1 mmol) and the corresponding alcoholic solvents (10 mL) was stirred at room temperature. Then, TsOH (0.1 mmol) was added to the solution, and the process was monitored by TLC. After completion, the solvent was removed by vacuum, and dry tetrahydrofuran (10 mL) was added. Then, NaH (1.5 mmol) was added to the solution until no bubbles were produced, then the corresponding alkyl iodide (5 mmol) was added. The process was monitored by TLC. After completion, the solvent was removed by vacuum, and the solid was further purified by silica gel column chromatography (EtOAc) affording the pure products.

General Procedure for the Preparation of Chlorine-Substituted Products 6a–6c. A mixture of **2** (1 mmol) and dry chloroform (10 mL) was stirred at reflux. Then $SOCl_2$ (5 mmol) was added to the solution, and the process was monitored by TLC. After completion, to the solution was added the corresponding alcoholic solvents (1 mL), then the solvent was removed by vacuum, and the solid was further purified by silica gel column chromatography (EtOAc) affording the pure products.

General Procedure for the Preparation of Esterification Products 7a–7d. A mixture of **2** (1 mmol), diisopropylethylamine (2.2 mmol), and dry CH_2Cl_2 (10 mL) was stirred at room temperature. Then, the corresponding acyl chloride (2.2 mmol) was added to the solution dropwise, and the process was monitored by TLC. After completion, the solvent was removed by vacuum, and the solid was further purified by silica gel column chromatography (EtOAc) affording the pure products.

Biological Assay. Bioassays were performed on representative test organisms grown in the laboratory. The bioassay was repeated at (25 ± 1) °C according to statistical requirements. All compounds were dissolved in *N*,*N*-dimethylformamide (DMF) (AP, Shanghai Chemical Reagent Co., Ltd., Shanghai, China) and diluted with distilled water containing Triton X-100 (0.1 mg L^{-1}) to obtain a series of concentrations of 500.0, 100.0, 20.0, 4.0 mg L^{-1} and others for bioassays. The results of the bioassay are depicted in Table 1.

Insecticidal Test for Cowpea Aphids (Aphis craccivora). The activities of insecticidal compounds against cowpea aphids were tested by the leaf-dip method. The leaves of the horsebean plant with 40−60 apterous adults were dipped in diluted solutions of the chemicals containing Triton X-100 (0.1 mg L^{-1}) for 5 s, and the excess solution was sucked out with filter paper. The burgeoning shoots were placed in a conditioned room ((25 ± 1) °C, 50% RH). Water containing Triton X-100 (0.1 mg L^{-1}) was used as a control. The mortality rates were evaluated 24 h after treatment. Each treatment had three repetitions, and the data were adjusted and subjected to probit analysis as before.

Insecticidal Test for Armyworms (Mythimna separate). The insecticidal activity against armyworms was tested by foliar application. Individual corn (*Zea mays*) leaves were placed on moistened pieces of filter paper in Petri dishes. The leaves were then sprayed with the sample solutions and exposed to dry. The dishes were infested with 10 second-instar larvae and placed in a conditioned room. The mortality rates were evaluated 48 h after treatment. Each treatment had three repetitions, and the data were adjusted and subjected to probit analysis as before.

Insecticidal Test for Brown Planthoppers (Nilaparvata lugens). The activities of insecticidal compounds against *Nilaparvata lugens* were tested using the dipping method. Rice plants at tillering to booting stages were pulled out, and the rice stems (about 10 cm lengths) with roots were cut and air-dried to remove excess water. Three rice stems were dipped in appropriate solutions of tested compound for 30 s. After rice stems had been air-dried, the rice roots was wrapped with moistened cotton and then placed into a tumbler. Thirty *Nilaparvata lugens* were introduced into the tumbler with the treated insects maintained at a temperature of (27 ± 1) °C. Only distilled water only was used as control for each tested chemical. Each process was repeated 3 times, and the mortality rates were evaluated 48 h after treatment. The data were adjusted and subjected to probit analysis as before.

Molecular Docking. The crystal structure of the *Aplysia californica* acetylcholine binding protein (*Ac*-AChBP) complexed with IMI (PDB code: 2WNJ) was selected to construct the binding models,[4] which showed high affinity with neonicotinoids and was a good prototype for investigating the binding mode of neonicotinoids. Compounds were docked into the ligand binding pocket of *Ac*-AChBP by the "Induced Fit Docking" approach, of which the IFDScore scoring function was selected to evaluate the docking results. All atoms within 20 Å around IMI in the 3C79 structure were selected as the binding pocket and considered in the docking study. All computational studies were performed using Maestro 9.0 (Schrödinger, LLC, 2013).

RESULTS AND DISCUSSION

Synthesis. Our recent reported HKA-ninhydrin reactions allowed for the facile access to novel tetraheterocyclic indeno[2,1-*b*]pyrrol-8(1*H*)-one derivatives. NMI, as a cyclic HKA, reacted with ninhydrin affording two tetracyclic isomers **1** and **2** based on solvent-controlled selectivity (Figure 2). Both isomers have two active hydroxyl groups for further structural derivatizations. Attempts to modify **1** failed due to its easy isomerization to the more thermal stable form **2**. The selective etherification, esterification, and chlorination were explored. Under acidic circumstances, the etherification occurred at the 9b-hydroxyl giving 9b-alkoxy substituted products **3a−g**. While being catalyzed by the base NaH, the etherified products were 4a-alkoxyl substituted compounds **4a−b** (Figure 3B).

This position selectivity upon acid and base can be rationalized by their different catalytic mechanisms. In acid, the stability of the 9b-carbocation is higher than its 4a-counterpart due to the inductive effect of nitro groups and hyperconjugation of the adjacent benzene. While in base, the formed anion at the 9b-oxygen is less stable than that formed at the 4a-position, which preferentially reacts with alkyl iodide.

According to the same or different substituent features, the dietherized compounds **5a−b** were prepared by two methodologies (Figure 3B and D). To introduce the two same alkoxy substituents, **2** was subjected to NaH conditions by adding excess alkyl iodide. In the case of analogues **5c−d** with different alkoxy side chains, a two-step pathway was employed catalyzed by base or acid sequentially. Esterifications of **2** were readily accomplished with acyl chloride in CH_2Cl_2 using DIPEA as the acid capture (Figure 3E). The preparation of mono-ester analogues was unsuccessful due to the high reactivity of acyl chloride. The selectivity mechanism of chlorination is similar to that of etherification in acid conditions. Chlorination by thionyl chloride in $CHCl_3$ was through an S_Ni reaction mechanism in which the carbocation at the 9b-position is more stable (Figure 3C).

Further etherifications of chloride compound **6a** gave **6b−c** with chlorine and alkoxy substituents. All of the compounds were well characterized by ^{1}HNMR, ^{13}CNMR, and HRMS. Furthermore, the structures of **1**, **2**, and **3a** were unambiguously confirmed by X-ray diffraction studies.

Insecticidal Activity. Structure-based design of analogues based on NMI yielded a focused library of compounds leading to clear SAR.[20] Chloropyridinyl, the nitro group, and imidazoline are proved to be the best variations, thus, the modifications of the present study mainly focused on the two hydroxyl groups of compound **2**. To investigate the influence of substituents at the 4a- and 9b-position on activity, commonly

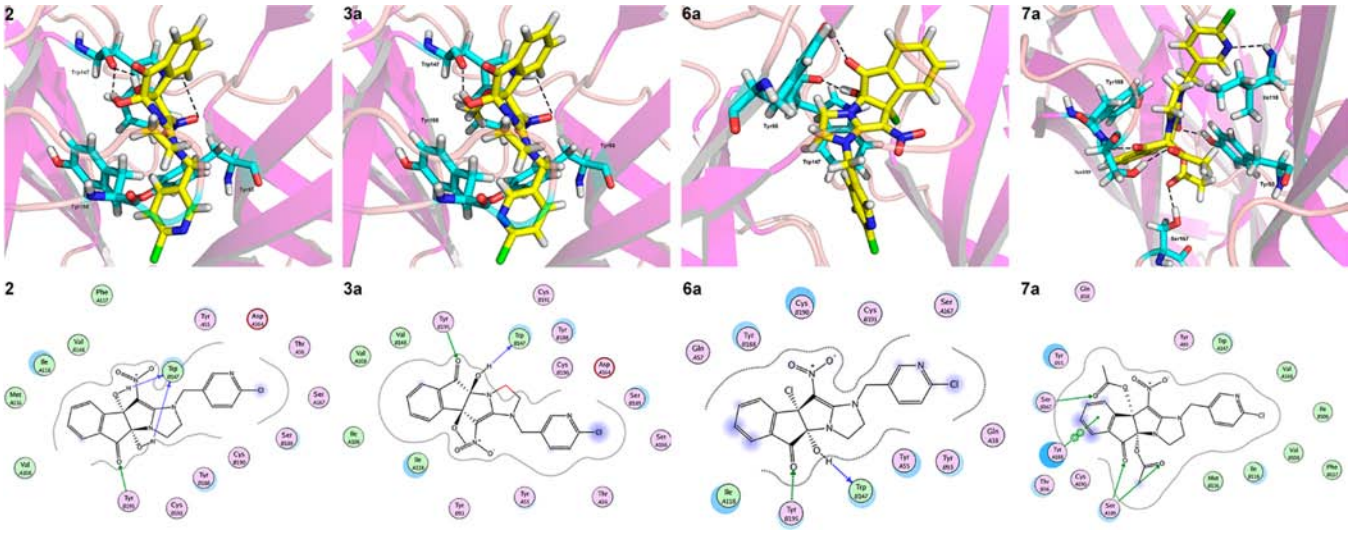

Figure 6. Molecular docking of **2**, **3a**, **6a**, and **7a** with the *Aplysia* acetylcholine binding protein (AChBP).

used derivatization methods such as etherification, chlorination, and esterification were used here to append chemical fragments to this novel chemotype.

Dihydroxy compounds **1** and **2** showed excellent activity against sucking insects, cowpea aphids and brown planthoppers, but very low potency to chewing pests armyworms (Table 1). Compound **1** had slightly higher activity than **2**. Introduction of alkoxy substituents at the 9b-position was unfavorable resulting in a slight decrease of activity. From this set of monoalkoxy substituted compounds, a trend emerged indicating reduced activity with increasing size and hydrophobicity of substituents. Consistent with 9b-alkoxy compounds, insertion of the alkoxy component at the 4a-position also leads to a decrease of the activity. As was expected, dialkoxy compounds **5a**−**d** showed a significant drop in potency compared to that of the corresponding mono- or nonalkoxy substituted analogues, supporting the unfavorable effects of alkoxy substituents at both positions. Chloride compound **6a** maintained high activity but showed much improvement in activity against armyworms. However, etherification of **6a** had a detrimental effect on activity, which agreed with the trend observed above. Encouraged by the interesting results above, we synthesized analogues **7a**−**d** with two ester side chains to increase the activity against the chewing pest armyworm. Satisfyingly, this series had excellent activity against all of the three test insects with the exception of **7c**. Analogues **7a**, **7b**, and **7d** had superior activity even at the concentration of 4 mg L^{-1}.

As a comparison, compounds **8a**−**b**, **9a**−**b**, and **10a**−**b** were prepared with variation at the chloropyridinyl of **2** (Figure 4). Removal of the chloropyridinyl or its replacement with phenyl substantially affected the activity with almost a loss of activity. Bioisoteric replacement of the chloropyridinyl with the chlorothiazolyl group in **1** and **2** maintained the high performance in comparison with that of parent congeners.

Selected compounds were then further evaluated to compare their toxic ratio (Table 2). Imidacloprid and cycloxaprid (CYC), an oxabridged neonicotinoid with outstanding activity discovered in our lab, were used here as a comparison. Against brown planthopper, the activity of **1** (LC_{50} = 0.132 mg L^{-1}) was comparable to that of cycloxaprid (LC_{50} = 0.152 mg L^{-1}), while **2** showed a 7-fold lower activity than CYC. Against cowpea aphids, the activity of **6a**, **7a**, and CYC was almost at the same level. Improvement of activity against armyworms was achieved by attaching an ester or chlorine side chain. Encouragingly, **7d** exhibited a 20-fold enhancement in activity compared to that of CYC, becoming the most potent analogue in this series.

Crystal Structure Analysis. To elucidate the precise three-dimensional structural information for further investigation, crystals of **1**, **2**, and **3a** suitable for X-ray diffraction were obtained by slow evaporation (Figure 5).[35] All of the three compounds showed the common features of our previously reported *cis*-neonicotinoids, such as the delocalization of the electrons in NO_2−C═C−N systems, coplanar olefin-amine network, and fixed *cis*-nitro configuration. The tetracyclic section showed the V-shape feature instead of the planar one with a torsion angle of about 110° between indenone and pyrrolo[1,2-*a*]imidazole. In dihydroxyl compounds **1** or **2**, the indenone part and the pyridine motif were oriented on the same side of the pyrrolo[1,2-*a*]imidazole plane, forming a concave shape, while in monoether analogue **3a**, they pointed in a different direction. This difference in molecular geometry might be one of the causes for the variation in activity.

Molecular Docking. The substituent types at the 4a- or 9b-position showed significant influence on insecticidal potency. In order to understand the activity difference in the target level, the interactions between the tetracyclic derivatives **2**, **3a**, **6a**, and **7a** with the receptor were achieved by a molecular docking study using insect surrogate *Aplysia* AChBP (protein data bank code 2WNJ).[36−38] The most likely binding conformations were selected based on the score and the binding mode (Figure 6). Compounds **2**, **3a**, and **6a** gave the same orientations in the pocket, while **7a** was oriented in a different way. The hydrogen bonds and van der Waals forces are the main features of the interactions of all of the compounds. According to the docking simulations, it appears evident that the chloropyrindyl part is pointing toward a deep hydrophobic hole made by residues Tyr188 and Tyr55 for **2**, **3a**, and **6a**. H-bond formation was found to occur between the nitro oxygen of **2** and **3a** with the hydrogen of H−N of the Trp147 residue (d = 1.76 and 1.90 Å, respectively), indicating a strong interaction of **2** than **3a** in this position. The oxygen of the 4a-hydroxyl in **2** and **3a** participates in a hydrogen-bond interaction with the backbone O−H of Trp147 (d = 1.52 and 2.03 Å, respectively). Meanwhile, the 9b-

DOI: 10.1021/jf505281p
J. Agric. Food Chem. 2015, 63, 1360−1369

hydroxyl in **2** further anchors the ligand by forming a hydrogen bond with the Trp147, which further consolidates the binding. Thus, the comparison between docking **2** and **3a** suggests that the lack of H-bond formation at the 9b-substitutent and the weaker H-bond interaction of the nitro subunit of **3a** attenuate its insecticidal activity. Although the formation of the H-bond between the nitro oxygen with the residue was lacking, an extra H-bond was produced between the carbonyl with Tyr195 (d = 2.0 Å), which contributes to its high activity. The maximum number of H-bond interactions was detected in **7a**-receptor binding, such as the nitro oxygen with Tyr55 (d = 1.90 Å), the pyridyl nitrogen with Ile188 (d = 2.70 Å), carbonyl oxygen of indenone, and in the 4a-ester substituent with Ser189 (d = 1.90 and 2.20 Å, respectively) and carbonyl oxygen in the 9b-ester substituent with Ser167 (d = 1.90 Å). Furthermore, the phenyl ring of **7a** formed the weak $\pi-\pi$ stacking interaction with the Tyr188 residue. All of these interactions made the analogues with two ester side chains the most potent compounds.

In conclusion, the series of tetraheterocyclic tetrahydroindeno[1′,2′:4,5]pyrrolo[1,2-*a*]imidazol-5(1*H*)-one derivatives were synthesized from NMI via cyclization by ninhydrin and etherification, chlorination, or esterification. The etherification showed strong position selectivity upon acid or base catalyzing. Most of the compounds had excellent insecticidal activity against cowpea aphids, brown planthoppers, and armyworms. Crystal structure analysis verified the three-dimensional structural difference in the compounds with different activities. The molecular docking studies indicated that the substituent patterns at the 4a-position play a significant role in the activity. Field trials for high active compounds are in progress.

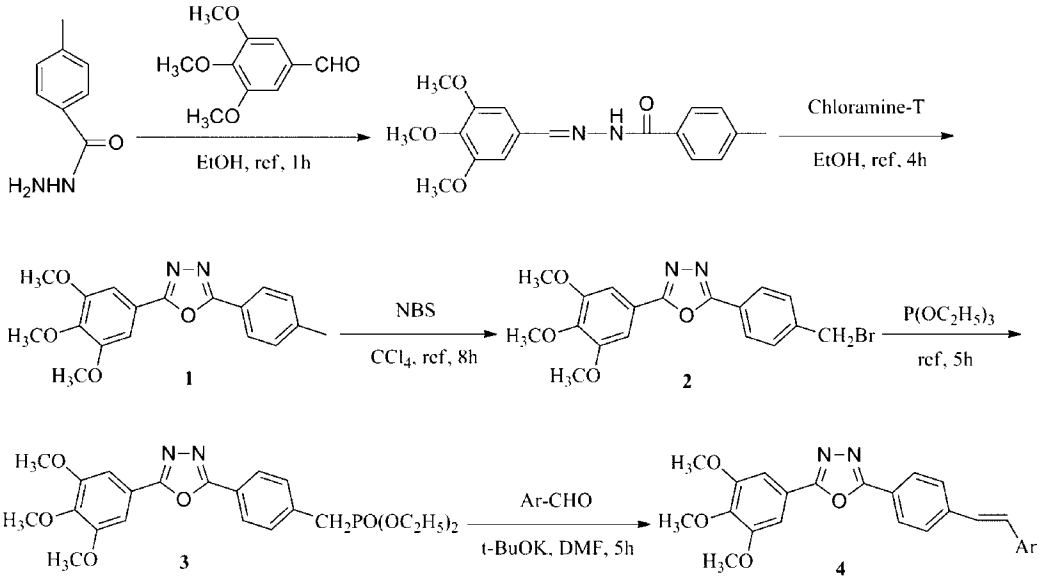

Figure 1. General synthetic route for target compounds: **4a**, Ar = phenyl; **4b**, Ar = 4-F phenyl; **4c**, Ar = 2-Cl phenyl; **4d**, Ar = 3-Cl phenyl; **4e**, Ar = 4-Cl phenyl; **4f**, Ar = 2,4-di-Cl phenyl; **4g**, Ar = 3,4-di-Cl phenyl; **4h**, Ar = 2-Br phenyl; **4i**, Ar = 4-Br phenyl; **4j**, Ar = 2-NO_2 phenyl; **4k**, Ar = 3-NO_2 phenyl; **4l**, Ar = 4-NO_2 phenyl; **4m**, Ar = 2-methoxy phenyl; **4n**, Ar = 3-methoxy phenyl; **4o**, Ar = 4-methoxy phenyl; **4p**, Ar = 3,4,5-trimethoxy phenyl; **4q**, Ar = 1-naphthyl; **4r**, Ar = 9-anthryl; **4s**, Ar = 4-*N*,*N*-dimethylaniline; **4t**, Ar = 2-pyridyl; **4u**, Ar = 3-pyridyl; and **4v**, Ar = 4-pyridyl.

(FTIR) spectra were measured as KBr pellets on a Bruker Vector 33. ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded in $CDCl_3$ on a Bruker AVANCE-400 MHz NMR spectrometer using tetramethylsilane (TMS) as an internal standard. Mass spectra were obtained with a Bruker Esquire HCTplus spectrometer [atmospheric pressure chemical ionization/electrospray ionization (APCI/ESI)]. The purity of the compounds was confirmed by thin-layer chromatography (TLC) on silica gel "G"-coated glass plates, and spots were visualized under ultraviolet (UV) irradiation.

General Synthetic Procedures for Title Compounds 4a−4v. The title compounds were synthesized according to our previously reported procedure.[25] The desired starting materials were prepared by esterification of 4-methylbenzoic acid, followed by treatment with hydrazine hydrate in absolute ethanol. The data for target compounds **4a−4v** are shown below, and the detailed procedures for intermediates **1−3** and target compounds are available in the Supporting Information.

Data for compound **4a**: light yellow solid; yield, 62.5%; melting point (mp), 156−157 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ, 8.13 (d, J = 8.3 Hz, 2H, C_6H_4 2,6-H), 7.67 (d, J = 8.3 Hz, 2H, C_6H_4 3,5-H), 7.56 (d, J = 7.5 Hz, 2H, C_6H_5 2,6-H), 7.45−7.36 (m, 4H, C_6H_5 3,5-H C_6H_2 2,6-H), 7.32 (t, J = 7.3 Hz, 1H, C_6H_5 4-H), 7.25 (d, J = 16.3 Hz, 1H, CH═CH), 7.15 (d, J = 16.3 Hz, 1H, CH═CH), 4.00 (s, 6H, OCH_3), 3.96 (s, 3H, OCH_3); ^{13}C NMR (101 MHz, $CDCl_3$) δ, 164.42, 153.73, 141.28, 140.76, 136.71, 131.07, 128.81, 128.29, 127.39, 127.28, 127.00, 126.80, 122.56, 119.00, 104.31, 61.04, 56.45; high-resolution mass spectrometry (HRMS) (ESI), m/z calcd for $C_{25}H_{23}N_2O_4$ (M + H)$^+$ 415.1652; found, 415.1650.

Data for compound **4b**: yellow solid; yield, 76.9%; mp, 180−181 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ, 8.11 (d, J = 8.3 Hz, 2H, C_6H_4 2,6-H), 7.63 (d, J = 8.3 Hz, 2H, C_6H_4 3,5-H), 7.51 (m, 2H, C_6H_4 2,6-H), 7.36 (s, 2H, C_6H_2 2,6-H), 7.18 (d, J = 16.3 Hz, 1H, CH═CH), 7.13−6.97 (3H, C_6H_4 3,5-H, CH═CH), 3.99 (s, 6H, OCH_3), 3.95 (s, 3H, OCH_3); ^{13}C NMR (101 MHz, $CDCl_3$) δ, 164.41, 164.35, 163.92, 153.72, 141.30, 140.57, 132.91, 129.78, 128.34, 127.27, 127.16, 126.91, 122.56, 118.93, 115.79, 115.68, 104.31, 61.02, 56.44; HRMS (ESI), m/z calcd for $C_{25}H_{22}FN_2O_4$ (M + H)$^+$ 433.1558; found, 433.1556.

Data for compound **4c**: light yellow solid; yield, 69.6%; mp, 178−179 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ, 8.14 (d, J = 8.2 Hz, 2H, C_6H_4 2,6-H), 7.70 (t, 3H, C_6H_4 3,5-H, C_6H_4 5-H), 7.64 (d, J = 16.3 Hz, 1H, CH═CH), 7.42 (d, J = 7.8 Hz, 1H, C_6H_4 2-H), 7.37 (s, 2H, C_6H_2 2,6-H), 7.32−7.21 (m, 2H, C_6H_4 3,4-H), 7.12 (d, J = 16.3 Hz, 1H, CH═CH), 3.98 (s, 6H, OCH_3), 3.96 (s, 3H, OCH_3); ^{13}C NMR (101 MHz, $CDCl_3$) δ, 164.46, 164.33, 153.72, 141.29, 140.40, 134.80, 133.74, 129.95, 129.89, 129.14, 127.32, 127.29, 127.02, 126.99, 126.58, 122.98, 118.96, 104.30, 61.03, 56.44; HRMS (ESI), m/z calcd for $C_{25}H_{22}ClN_2O_4$ (M + H)$^+$ 449.1263; found, 449.1257.

Data for compound **4d**: light yellow solid; yield, 80.6%; mp, 176−177 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ, 8.11 (d, J = 8.4 Hz, 2H, C_6H_4 2,6-H), 7.64 (d, J = 8.4 Hz, 2H, C_6H_4 3,5-H), 7.52 (s, 1H, C_6H_4 5-H), 7.38 (d, J = 7.5 Hz, 1H, C_6H_4 2-H), 7.35 (s, 2H, C_6H_2 2,6-H), 7.29 (t, J = 7.7 Hz, 1H, C_6H_4 3-H), 7.26 (s, 1H, C_6H_4 4-H), 7.13 (s, 2H, CH═CH), 3.96 (s, 6H, OCH_3), 3.92 (s, 3H, OCH_3); ^{13}C NMR (101 MHz, $CDCl_3$) δ, 164.45, 164.28, 153.71, 141.29, 140.12, 138.58, 134.77, 129.99, 129.45, 128.76, 128.11, 127.28, 127.13, 126.53, 125.01, 122.95, 118.94, 104.29, 61.02, 56.43; HRMS (ESI), m/z calcd for $C_{25}H_{22}ClN_2O_4$ (M + H)$^+$ 449.1263; found, 449.1257.

***In Vivo* Bioassays.** The pot culture test method was adopted to evaluate fungicidal activities of the title compounds against *P. cubensis*, *C. lagenarium*, and *S. cucurbitacearum in vivo* at 600 μg/mL according to the references, with slight modifications.[26,27] Two commercial fungicides, 80% Mancozeb WP and 80% Carbendazim WP, were evaluated as controls against the above-mentioned fungi at the same condition. All compounds were dissolved in dimethylformamide (DMF), and then distilled water (containing 0.1% Tween 80) was added to the solution to generate a tested concentration of 600 μg/mL, in each of which the final concentration of DMF was <1% (v/v). *P. cubensis* sporangia were obtained by washing off the leaves of highly infected cucumber plants that were kept overnight (above 80% relative humidity). *C. lagenarium* and *S. cucurbitacearum* were cultured on the potato dextrose agar (PDA). Spores of those two fungal pathogens were removed from the PDA plates. All of the spore suspensions were adjusted to the desired concentrations prior to use. Germination was conducted by soaking cucurbit seeds in water for 2 h at 50 °C and then keeping the seeds moist for 24 h at 28 °C in an incubator.

When the cucurbit plants used for inoculations were at the stage of two seed leaves, tested compounds and commercial fungicides were sprayed with a hand sprayer on the upper leaf surface of seed leaves at the standard concentration of 600 μg/mL. Distilled water without compounds or commercial fungicide treatments was set as a blank control. After the solution on leaves was air-dried, inoculations of *P. cubensis*, *C. lagenarium*, and *S. cucurbitacearum* were carried out by spraying a spore suspension with the concentrations of 1×10^5, 1×10^6, and 1×10^6 spores/mL of water, respectively. Then, the plants were maintained at 24 ± 1 °C and above 80% relative humidity. Three replicates were used per treatment, and the experiment was repeated 3 times.

The fungicidal activity was evaluated visually when the non-treated cucurbit plant (blank control) fully developed symptoms. The percentage of the diseased area on inoculated treated leaves was assessed and compared to that of non-treated leaves to determine the average disease index. The relative control efficacy of compounds compared to the blank assay was calculated via the following equation:

$$I\ (\%) = [(CK - PT)/CK] \times 100\%$$

where I is the relative control efficacy, CK is the average disease index during the blank assay, and PT is the average disease index after treatment during testing.

Three-Dimensional Quantitative Structure−Activity Relationship (3D-QSAR) Analysis. All molecular modeling studies were performed using the Tripos SYBYL 7.3.5 software package.[28] The CoMFA model was derived from the antifungal activity of 22 compounds (17 compounds for training sets and 5 compounds for test sets) against *C. lagenarium* at 600 μg/mL. The fungicidal activity was converted into D values by the formula $D = \log\{[I/(100 - I)] - MW\}$,[29] where I is the percent control efficacy and MW is the molecular weight of the tested compounds. Compound **4k** was chosen as a template for superimposition because of the highest control efficacy. Each structure was built using the SKETCH option and fully geometry-optimized using a conjugate gradient procedure based on the TRIPOS force field and Gasteiger and Hückel charges.

The steric and electrostatic interaction fields for CoMFA were calculated using the SYBYL default parameters: 2.0 Å grid points spacing, a sp^3 carbon probe atom with a charge of +1.0, and a van der Waals radius of 1.52 Å. Steric and electrostatic fields were scaled by the CoMFA−STD method in SYBYL with a default cutoff energy of 30 kcal/mol. A partial least-squares (PLS) approach was used to derive the 3D-QSAR model, in which the CoMFA descriptors were used as independent variables and the experimental D values were used as dependent variables. The cross-validation with the leave-one-out (LOO) option and the SAMPLS program was carried out to obtain the optimal number of components (N) and cross-validated coefficient (q^2). After the optimal number of components was determined, a non-cross-validated analysis was performed without column filtering to obtain regression coefficients (r^2) and its standard error (S) and F-test value (F) for the model evaluation.

RESULTS AND DISCUSSION

Synthesis. The synthetic route of the title compounds is outlined in Figure 1. A series of novel stilbene derivatives containing a 1,3,4-oxadiazole moiety was synthesized in good yields by bromination of *N*-bromosuccinimide (NBS), Arbuzov reaction, and Wittig−Horner reaction. The key step involved the formation of the stilbenes, which were efficiently generated by the reaction of phosphonate **3** with various aldehydes via Wittig−Horner reaction under mild reaction conditions. The chemical structures of the target compounds were confirmed by FTIR, ^{1}H and ^{13}C NMR, and HRMS. Notably, the ^{1}H NMR spectra of target compounds show two fine doublets as well as a coupling constant (16.7−16.0 Hz) corresponding to the olefinic protons (CH═CH) from *trans*-stilbene, which are further confirmed by the FTIR spectra.[30] All spectral and analytical data are consistent with the assigned structures.

Fungicidal Activity. The *in vivo* fungicidal activities of compounds **4a**−**4v** against *P. cubensis*, *C. lagenarium*, and *S. cucurbitacearum* at a concentration of 600 μg/mL are listed in Table 1. The results of bioassays are compared to those obtained from two commercial fungicides. It was worth noting that all of the tested compounds were found safe for the cucurbit plants. As indicated in Table 1, some of the title compounds showed a broad spectrum and comparable fungicidal activities against the tested fungi. Four main conclusions were drawn from the comparison of the fungicidal activities of title compounds against test fungi to those of commercial fungicides: (a) Compounds **4s** exhibited a significant inhibition effect against cucumber *P. cubensis* with a control efficacy of 71.38 ± 1.47%, which was comparable to that of 80% Mancozeb WP (70.13 ± 3.25%), while compounds **4d**, **4l**, and **4v** showed relatively high antifungal activities against cucumber *P. cubensis* (65.01 ± 1.81 and 63.42 ± 4.60%, respectively) compared to the fungicide 80% Mancozeb WP. (b) Compounds **4b**, **4d**, **4f**, **4i**, **4k**, and **4l** showed prominent activities against *C. lagenarium* compared to the control 80% Carbendazim WP. In particular, the activities of compounds **4d** and **4k** were 82.43 ± 4.66 and 83.82 ± 2.69%, respectively, which were similar to that of 80% Carbendazim WP (81.57 ± 2.19%). (c) Most of the compounds exhibited fair to moderate control efficacy against *S. cucurbitacearum*. Notably, compounds **4b**, **4h**, and **4i**, whose efficacy rates were 72.05 ± 0.96, 69.34 ± 0.93, and 67.68 ± 1.43%, respectively, were found to be almost the same activity level as that of 80% Carbendazim WP (69.02 ± 0.47%). (d) Some compounds showed significant bioactivity variances against the different fungi. For example, compound **4g** exhibited moderate activity (44.81 ± 3.85%) against *C. lagenarium*, whereas the control efficacy of compound **4g** against *S. cucurbitacearum* was only 8.03 ± 2.78% and even showed a negative effect on *P. cubensis*. These results indicated that compounds **4b**, **4d**, **4i**, **4k**, and **4l** were the most promising candidates for crop protection because of their broad spectrum and remarkably high activities against all tested fungi.

Table 2. Statistical Parameters of the CoMFA Model

					contribution (%)	
	q^2	r^2	S	F	steric	electrostatic
CoMFA	0.516	0.920	0.114	25.186	56.2	43.8

CoMFA Analysis. The statistical results of the CoMFA model are summarized in Table 2. The internal validation of LOO cross-validated q^2 and non-cross-validated coefficient r^2 are commonly applied as the criterion of robustness and predictive ability of a QSAR model. The statistically recommendatory values for a satisfactory QSAR model are $q^2 > 0.5$ and $r^2 > 0.8$.[31] As listed in Table 2, a good predictive CoMFA model with the LOO cross-validated coefficient $q^2 = 0.516$ and the correlation coefficient $r^2 = 0.920$ was established. The predicted D values are generally in good agreement with the experimental data, as shown in Figure 2. The standard error ($S = 0.114$) and F-test value ($F = 25.186$) further validate the developed model.

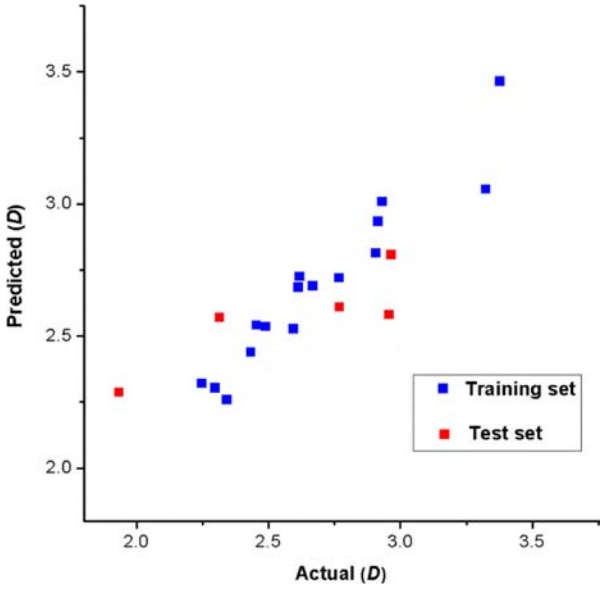

Figure 2. Plot of experimental values versus predicted values for training and test sets based on the CoMFA model.

The contribution steric and electrostatic fields are 56.2 and 43.8% for the QSAR model, respectively. CoMFA contour maps are displayed in Figure 3 to visualize how steric and electrostatic fields contribute to the bioactivity of test compounds.

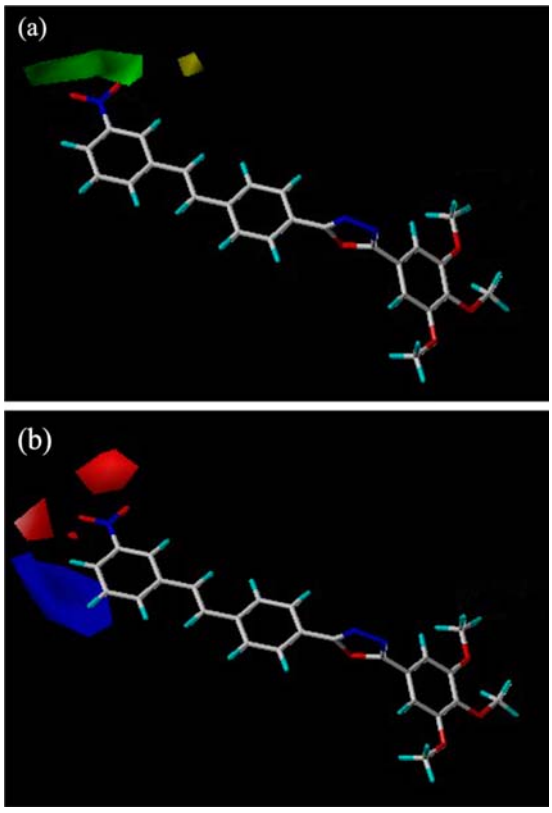

Figure 3. Graphical representation of CoMFA analysis for compound **4k**. (a) Steric contour plots: sterically favored areas are represented by green polyhedra, and sterically disfavored areas are represented by yellow polyhedra. (b) Electrostatic contour plots: positive charge favored areas are represented by red polyhedra, and positive charge disfavored areas are represented by blue polyhedra.

As shown in the steric field contour map (Figure 3a), the green contour surrounding the *meta* position of the benzene ring indicates that a bulky group would be favorable for higher fungicidal activity, while the yellow contour represents the region of unfavorable steric effect. For example, compounds **4k** and **4d** bearing bulkier substituents at the *meta* position displayed higher fungicidal activity. For the electrostatic contour map (Figure 3b), the negatively charged favorable red regions are observed at the *meta* position of the benzene ring, indicating that electron-withdrawing substituents enhance the bioactivity, whereas a positively charged blue region around the *para* position is favored. Compound **4o** (*para* position)

DOI: 10.1021/jf5052893
J. Agric. Food Chem. 2015, 63, 1370−1377

displayed higher activity than those of compounds **4m** (*ortho* position) and **4n** (*meta* position). Analysis of CoMFA contour plots revealed that substitutions at the *meta* position, the bulky groups, and electron-withdrawing groups (e.g., $-NO_2$ and $-Cl$) are favorable to increase the bioactivity.

The results obtained from 3D-QSAR provided reliable clues for mechanistic study and designing of optimized stilbene derivatives. On the basis of the *in vivo* bioassay and 3D-QSAR analysis, it can be concluded that the variances (substituted positions, electronic properties, and steric effects) among substituents (Ar) on stilbenes showed a significant relationship with fungicidal activity against the three fungi. Furthermore, considering that the bioassay of title compounds was evaluated *in vivo*, effects of metabolism and/or biotransformation within the plants or fungi may contribute to the significant variations in fungicidal potency. It is reported that the electron-withdrawing substituents of the phenyl moiety seem to enhance the potency, which may be related to the fact that they tend to retard mechanisms of oxidative metabolism occurring on (or close to) the benzene ring.[32] This assumption is consistent with the higher bioactivity of the title compounds with electron-withdrawing substituents at the *meta* position proposed by the 3D-QSAR analysis.

Discovery of phytopathogenic fungicidal agents with new modes of action and eco-friendly properties is of great importance for crop protection.[33] In the present study, 22 novel stilbene derivatives containing the 1,3,4-oxadiazole moiety and trimethoxybenzene were designed and synthesized. The approach was proven to be an efficient method to implement structural modification by combination of several functional fragments. Bioassay results indicated that compounds **4b**, **4d**, **4i**, **4k**, and **4l** exhibited broad spectrum fungicidal activities *in vivo* against all tested fungi, some of which were comparable to the commercial fungicides. Further field evaluations on their biological efficacies as well as crop toxicities and safety are necessary before they can be developed as fungicide candidates.

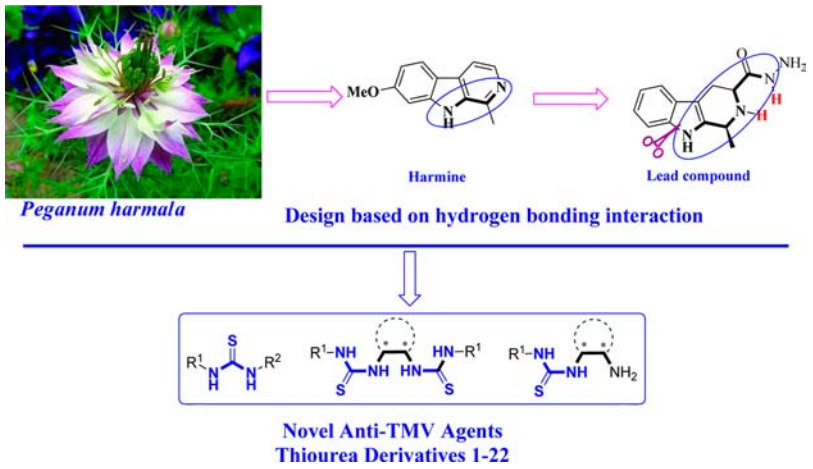

Figure 1. Design of Thiourea Derivatives.

confirmed and assessment for their anti-TMV was systematically evaluated.

MATERIALS AND METHODS

Instruments. The melting points of the products were determined on an X-4 binocular microscope (Gongyi Yuhua Instrument Co., China), and the thermometer was not corrected. NMR spectra were acquired with a Bruker 400 MHz (100 MHz for ^{13}C) instrument at room temperature. Chemical shifts were measured relative to residual solvent peaks of $CDCl_3$ (^1H, δ = 7.26 ppm; ^{13}C, δ = 77.0 ppm) or DMSO-d_6 (^1H, δ = 2.50 ppm; ^{13}C, δ = 39.5 ppm) with tetramethylsilane as internal standards. The following abbreviations were used to designate chemical shift multiplicities: s = singlet, d = doublet, t = triplet, m = multiplet, and bs = broad singlet. All first-order splitting patterns were assigned on the basis of multiplet appearance. Splitting patterns that could not be easily interpreted were designated multiplet (m) or broad (br). HRMS data were obtained with an FT-ICR MS spectrometer (Ionspec, 7.0 T). Analytical TLC was performed on silica gel GF 254. Column chromatographic purification was performed using silica gel. All reagents were of analytical reagent grade or chemically pure and purified prior to use when necessary. Compounds **18**–**22** (Figure 2) were prepared according to our previously reported procedure.[15] The isothiocyanates were prepared according to the literature (±) represented trans-mixture.[16]

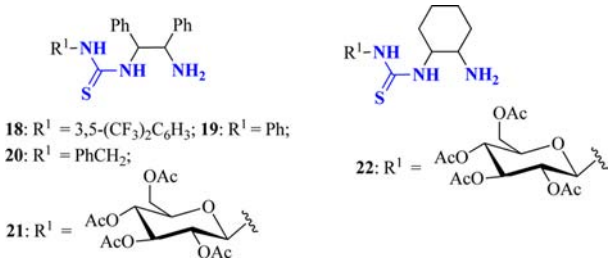

Figure 2. Chemical Structures of **18**–**22**.

General Experimental Procedures. *General Procedures for the Preparation of Compounds **1**–**8**, **13**–**17**, and **20**.*[17] To a mixture of CH_2Cl_2 (10 mL) and amines (5.0 mmol) was added the corresponding isothiocyanate (5.0 or 10 mmol), and the resulting mixture was stirred at room temperature until TLC indicated the reaction was complete. The reaction mixture was evaporated in vacuum. The pure products **1**–**8** and **13**–**17** were obtained by recrystallization from petroleum ether and ether. Compounds **20** were purified by chromatography on a column of silica gel with PE–EtOAc (v/v = 1:1).

*1,3-Diphenylthiourea (**1**).* White solid; yield, 99%; mp 144–145 °C (lit.[18] 140–142 °C). ^1H NMR (400 MHz, $CDCl_3$) δ 8.10 (s, 2H), 7.35–7.40 (m, 10H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 179.8, 137.2, 129.6, 127.1, 125.3. HRMS (ESI) calcd for $C_{13}H_{12}N_2S$ $(M + H)^+$ 229.0794, found 229.0791.

*1,3-Dibenzylthiourea (**2**).* White solid; yield, 98%; mp 142–144 °C (lit.[19] 145–146 °C). ^1H NMR (400 MHz, $CDCl_3$) δ 7.28–7.34 (m, 6H), 7.02 (d, J = 6.8 Hz, 4H), 6.13 (br s, 2H), 4.61 (s, 4H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 181.9, 136.6, 129.0, 128.0, 127.5, 48.6. HRMS (ESI) calcd for $C_{15}H_{16}N_2S$ $(M + H)^+$ 257.1107, found 257.1101.

*1,3-Dicyclohexylthiourea (**3**).* White solid; yield, 99%; mp 176–177 °C (lit.[18] 174–176 °C). ^1H NMR (400 MHz, $CDCl_3$) δ 5.64 (br s, 2H), 3.84 (s, 2H), 1.99–2.02 (m, 4H), 1.60–1.73 (m, 6H), 1.32–1.41 (m, 4H), 1.13–1.24 (m, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 179.0, 52.9, 32.9, 25.4, 24.7. HRMS (ESI) calcd for $C_{13}H_{24}N_2S$ $(M + H)^+$ 241.1733, found 241.1738.

*1-(3,5-Bis(trifluoromethyl)phenyl)-3-phenylthiourea (**4**).* White solid; yield, 99%; mp 135–136 °C (lit.[17] 141–143 °C). ^1H NMR (400 MHz, $CDCl_3$) δ 8.44 (s, 1H), 7.97 (s, 1H), 7.35 (s, 1H), 7.68 (s, 1H), 7.51 (t, J = 6.4 Hz, 2H), 7.40–7.42 (m, 1H), 7.32–7.34 (d, J = 6.8 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 179.8, 139.5, 135.5, 132.1 (J_{C-F} = 33.6 Hz), 130.6, 128.4, 125.6, 124.7 (J_{C-F} = 2.5 Hz), 124.3, and 121.6 (J_{C-F} = 271.1 Hz), 119.82 (m). HRMS (ESI) calcd for $C_{15}H_{10}F_6N_2S$ $(M + H)^+$ 365.0542, found 365.0546.

*1-(3,5-Bis(trifluoromethyl)phenyl)-3-cyclohexylthiourea (**5**).* White solid; yield, 100%; mp 159–160 °C (lit.[17] 164–165 °C). ^1H NMR (400 MHz, $CDCl_3$) δ 8.39 (s, 1H), 7.76 (s, 2H), 6.13 (s, 1H), 4.20 (s, 1H), 2.04–2.08 (m, 2H), 1.61–1.72 (m, 3H), 1.36–1.45 (m, 2H), 1.17–1.22 (m, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 178.9, 139.1, 132.7 (J_{C-F} = 34.7 Hz), 126.8, 124.1, and 121.4 (J_{C-F} = 271.4 Hz), 118.7, 53.9, 32.3, 25.2, 24.5. HRMS (ESI) calcd for $C_{15}H_{16}F_6N_2S$ $(M + H)^+$ 371.1011, found 371.1017.

*1-(3,5-Bis(trifluoromethyl)phenyl)-3-butylthiourea (**6**).* White solid; yield, 98%; mp 94–97 °C. ^1H NMR (400 MHz, $CDCl_3$) δ 7.76 (s, 2H), 7.70 (s, 1H), 7.60 (s, 1H), 6.13 (br s, 1H), 3.62 (s, 2H), 1.58–1.65 (m, 2H), 1.34 (m, 2H), 0.95 (t, J = 7.6 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 180.3, 139.1, 132.8 (J_{C-F} = 33.6 Hz), 126.8, 124.1, and 121.4 (J_{C-F} = 271.3 Hz), 118.7, 45.1, 30.7, 20.1, 13.6. HRMS (ESI) calcd for $C_{13}H_{14}F_6N_2S$ $(M + H)^+$ 345.0855, found 345.0852.

*1-(3,5-Bis(trifluoromethyl)phenyl)-3-(tert-butyl)thiourea (**7**).* White solid; yield, 98%; mp 160 °C (dec.). ^1H NMR (400 MHz, $CDCl_3$) δ 8.44 (br s, 1H), 7.77 (s, 2H), 7.72 (s, 1H), 6.13 (s, 1H), 1.55 (s, 9H). ^{13}C NMR (100 MHz, DMSO-d_6) δ 179.7, 142.4, 130.5 (J_{C-F} = 32.4 Hz), 127.8, 125.1, and 122.4 (J_{C-F} = 271.1 Hz), 119.7, 53.6, 28.7. HRMS (ESI) calcd for $C_{13}H_{14}F_6N_2S$ $(M + H)^+$ 345.0855, found 345.0853.

*1,3-Bis(3,5-bis(trifluoromethyl)phenyl)thiourea (**8**).* White solid; yield, 99%; mp 174–176 °C (lit.[20] 170–172 °C). ^1H NMR (400

Antiviral Biological Assay. The procedure of purifying TMV and the method to test the anti-TMV activity of the thiourea derivatives were the same with those reported previously in the literature.[26]

Purification of Tobacco Mosaic Virus. The upper leaves of *Nicotiana tabacum* L. inoculated with TMV were selected and ground in phosphate buffer and then filtered through a double-layer pledget. The filtrate was centrifuged at 10000*g*, treated with PEG twice, and centrifuged again. The whole experiment was processed at 4 °C. Absorbance value was estimated at 260 nm by ultraviolet spectrophotometer.

$$\text{virus concn} = (A_{260} \times \text{dilution ratio}) E^{0.1\%,260\text{nm}}_{1\text{cm}}$$

Antiviral Activity of Compounds against TMV in Vitro. Fresh leaf of the 5−6 growth stage of tobacco inoculated by the juice-leaf rubbing method (concentration of TMV is 5.88 × 10^{-2} μg/mL) was cut into halves along the main vein. The halves were immersed into the solution of different concentrations (see Table 1) of the compounds and double distilled water for 20 min, respectively, and then cultured at 25 °C for 72 h. Every concentration for each compound was replicated at least three times.

Protective Effect of Compounds against TMV in Vivo. The compound solution was smeared on the left side and the solvent serving as control on the right side of growing *N. tabacum* L. leaves of the same ages. The leaves were then inoculated with the virus after 12 h. A brush was dipped in TMV of 6 × 10^{-3} mg/mL to inoculate the leaves, which were previously scattered with silicon carbide. The leaves were then washed with water and rubbed softly along the nervature once or twice. The local lesion numbers appearing 3−4 days after inoculation were counted. There are three replicates for each compound.

Inactivation Effect of Compounds against TMV in Vivo. The virus was inhibited by mixing with the compound solution at the same volume for 30 min. The mixture was then inoculated on the left side of the leaves of *N. tabacum* L., whereas the right side of the leaves was inoculated with the mixture of solvent and the virus for control. The local lesion numbers were recorded 3−4 days after inoculation. There are three replicates for each compound.

Curative Effect of Compounds against TMV in Vivo. Growing leaves of *N. tabacum* L. of the same ages were selected. TMV (concentration of 6.0 × 10^{-3} mg/mL) was dipped and inoculated on the whole leaves. Then the leaves were washed with water and dried. The compound solution was smeared on the left side, and the solvent was smeared on the right side for control. The local lesion numbers were then counted and recorded 3−4 days after inoculation. There are three replicates for each compound. The in vitro and in vivo inhibition rates of the compound were then calculated according to the following formula ("av" means average, and controls were not treated with

compound). Inhibition rate (%) = [(av local lesion no. of control − av local lesion no. of drug-treated)/av local lesion no. of control] × 100%.

RESULTS AND DISCUSSION

Chemistry. *Synthesis of the Compounds 1−17.* Compounds **1**−**17** were synthesized according to procedures in Figure 3. Amines were reacted with corresponding isothiocyanate to give thioureas **1**−**8** and **13**−**17** in almost quantitatively yields. Compounds **9**−**12** were obtained from isothiocyanatobenzene and amino acids or their derivatives in the presence of NaOH in good yields.

Phytotoxic Activity. Compounds **1**−**22** were first tested for their phytotoxic activity against the test plant.[27] The results indicated that compounds **1**−**22** showed no phytotoxic activity at 500 μg/mL.

Antiviral Activity. The anti-TMV activity of compounds **1**−**22** was tested. The commercial plant virucide Ningnanmycin, perhaps the most successful registered antiplant viral agent, ribavirin, natural product harmine, and lead compound were used as the controls.

In Vitro Anti-TMV Activity. The in vitro antiviral assay results of the synthesized compounds are listed in Table 1. As the control, ribavirin exhibited a 41% inhibitory effect at 500 μg/mL, whereas most of the synthesized compounds **1**−**22** exhibited higher antiviral activity than ribavirin even at the concentration of 100 μg/mL. The optimal compound (*R*,*R*)-**20** exhibited significantly higher inhibitory effect than Ningnanmycin, harmine, and lead compound, emerging as a new lead compound for anti-TMV research. To investigate the influence of the hydrogen bond strength on the anti-TMV activity, compounds **1**, **4**, and **8** were tested. Thiourea **8** with the stronger hydrogen bond did show the best inhibitory effect (inhibitory effect: **8** > **1** ≈ **4**). For studying the influence of the steric effect, thioureas **4**−**7** were synthesized. Compounds **4**−**7** exhibited 45%, 56%, 32%, and 45% inhibitory effect at 500 μg/mL, respectively. Comparing the results of **4**−**7**, the anti-TMV activity was improved by increasing steric hindrance of the thiourea.

Compounds **9**−**12** were prepared from isothiocyanatobenzene and natural amino acids or their derivatives. Compound **11** showed the best in vitro anti-TMV activity among them with 44% inhibitory effect.

Bis-thiourea-type derivatives **13**−**17** displayed in vitro activity ranging from 37% to 56% against TMV at 500 μg/mL. Among them, (*R*,*R*)-**16**, bearing 1,2-diphenylethylenediamine skeleton showed higher activity than (*R*,*R*)-**17** containing 1,2-cyclohexanediamine (46% and 42%, respectively). Compound **13** afforded a good result with an inhibitory rate of 56%. All of primary amine thioureas **18**−**22** exhibited

DOI: 10.1021/jf505355r
J. Agric. Food Chem. 2015, 63, 1378−1384

much higher activity than ribavirin, harmine, and lead compound. Compounds **20** exhibited the best result with an inhibitory rate of >70%. The optical pure compounds **16**, **18**, and **20** were prepared to investigate the effect of configuration on antiviral activity. (*R*,*R*)-Configuration is confirmed to be the optimal in vitro antiviral configuration (inhibitory effect: (*R*,*R*)-**16** > (±)-**16** > (*S*,*S*)-**16**; (*R*,*R*)-**18** > (±)-**18** > (*S*,*S*)-**18**; (*R*,*R*)-**20** > (±)-**20** > (*S*,*S*)-**20**).

As shown in Table 1, most of the compounds **1**−**22** displayed good in vitro activity against TMV. Therefore, these compounds were bioassayed further to investigate their antiviral activity in vivo.

In Vivo Anti-TMV Activity. As shown in Table 2, most of the compounds also displayed higher in vivo activity than that of the Ribavirin. (*R*,*R*)-**20** showed the best result in vivo anti-TMV activity (inactivation activity, 71%/500 μg/mL and 35%/100 μg/mL; curative activity, 73%/500 μg/mL and 37%/100 μg/mL; protection activity, 69%/500 μg/mL and 33%/100 μg/mL), which is significantly higher than that of ribavirin (inactivation activity, 31%/500 μg/mL and 12%/100 μg/mL; curative activity, 39%/500 μg/mL and 18%/100 μg/mL; protection activity, 47%/500 μg/mL and 17%/100 μg/mL) and Ningnanmycin (inactivation activity, 63%/500 μg/mL and 28%/100 μg/mL; curative activity, 54%/500 μg/mL and 22%/100 μg/mL; protection activity, 64%/500 μg/mL and 26%/100 μg/mL).

Just as with the antiviral activity in vitro, compounds **1**−**8** displayed moderate to good in vivo activity, and the results disclosed that the anti-TMV activity related to the hydrogen bond strength and steric effect in molecules. Thiourea **8**, bearing bis-3,5-Bis(trifluoromethyl)phenyl, gave relatively higher activity (60%, 56%, and 58% at 500 μg/mL) than that of **1**−**7**.

Chiral thiourea derivatives **9**−**12** showed moderate antiviral activity ranging from 34%−49% against TMV at 500 μg/mL, and different activity patterns displayed different activity rule (inactivation activity, **9** > **11** > **10** > **12**; curative activity, **11** > **10**> **9** > **12**; protection activity, **11** > **10** > **12** > **9**).

The bis-thiourea derivatives showed relatively lower activity than corresponding single thiourea derivatives (in vivo activity, **19** > **13**; **20** > **14**; **18** > **16**), which indicated that the hydrogen bond is important but not the more the better. All of primary amine thioureas **18**−**22** exhibited much higher in vivo activity than ribavirin, harmine, and lead compound, especially for compounds **20**.

In summary, on the basis of the structures of natural product harmine and lead compound, a series of simple thiourea derivatives were designed and synthesized from amines in one step. The antiviral activity of these compounds were evaluated in vitro and in vivo. Most of them exhibited significantly higher antiviral activity against TMV than commercial plant virucide ribavirin. The optimal compound (*R*,*R*)-**20** showed excellent anti-TMV activity in vitro and in vivo (in vitro activity, 75%/500 μg/mL and 39%/100 μg/mL; inactivation activity, 71%/500 μg/mL and 35%/100 μg/mL; curative activity, 73%/500 μg/mL and 37%/100 μg/mL; protection activity, 69%/500 μg/mL and 33%/100 μg/mL), which is significantly higher than that of ribavirin, Ningnanmycin, harmine, and lead compound. The hydrogen bond is favorable for antiviral activity within a certain range but not the more the better. Present study provides fundamental support for development and optimization of these simple thiourea derivatives as potential inhibitors of plant virus. Further studies on structural optimization and mode of action are currently underway in our laboratories.

popular vegetable in most parts of the world, and it enjoys considerable commercial interest.[30] The prevention or delay of postharvest degreening of broccoli has been addressed in various studies.[18,26] Surprisingly, the nature of the breakdown products of Chl in such a common vegetable is unknown. Identification of Chl-breakdown products may thus be of specific interest from a nutritional point of view, as some Chl-catabolites are suspected to possibly provide health benefits.[9] Earlier work from this group on naturally degreening leaves of spinach (*Spinacia oleracea*) has already addressed the question of the nature of Chl-catabolites in another vegetable.[31,32] As now reported here, we have analyzed degreened florets of broccoli and have identified three main Chl-catabolites in this vegetable, whose structures were elucidated.

MATERIALS AND METHODS

Chemicals and Plant Materials. *Chemicals.* Acetone and methylene chloride (CH_2Cl_2, reagent-grade, commercial) were distilled before use for extractions. HPLC grade HiPerSolv CHROMANORM methanol (MeOH) was from VWR PROLABO. Potassium dihydrogen phosphate and potassium phosphate dibasic anhydrous were from Sigma-Aldrich. Sep-Pak-C18 Cartridges were from Waters Associates. The pH values were measured with a WTW Sentix21 electrode connected to a WTW pH535 digital pH meter.

Plant Material. Fresh, green broccoli (*Brassica oleracea* var. *italica*), produced by Conzorzio APO-FOGGIA S.C., Italy, was typically harvested 5 days before it was sold at the store (Spar Supermarket) in Innsbruck.

Spectroscopy. UV/vis: Hitachi U3000 spectrophotometer, λ_{max} [nm] (relative ε), in H_2O. CD: Jasco J715 spectropolarimeter, λ_{max} and λ_{min} [nm] (Θ), in H_2O. ^1H nuclear magnetic resonance (NMR): Bruker UltraShield 600 MHz or Varian Unity Inova 500 MHz spectrometers, δ[ppm] with δ(HDO) = 4.79 ppm, in D_2O. Electrospray ionization mass spectrometry (ESI-MS): Finnigan MAT 95S, m/z (rel. intensity), positive-ion mode, 1.4 kV spray voltage; signals with >5% rel. intensity are listed.

High Performance Liquid Chromatography (HPLC). Dionex P680 HPLC pump, online UV/vis-spectra: Dionex UVD340U. Column: Phenomenex HyperClone 5 μ ODS 250 mm × 4.6 mm i.d., column at 20 °C, protected with a Phenomenex ODS 4 mm × 3.0 mm i.d. precolumn was used with a flow rate 0.5 mL·min^{-1}. Solvent A: 50 mM aqueous potassium phosphate buffer (pH 7). Solvent B: MeOH, HPLC grade; solvent composition 1:0−5 min, A/B = 80/20; 5−55 min, A/B = 80/20 to 30/70, constant gradient; 55−60 min, 30/70 to 0/100, constant gradient; 60−70 min, A/B = 0/100; 70−75 min:, A/B = 0/100 to 80/20, constant gradient. Analytical HPLC: sample size 50 μL. Semipreparative HPLC: sample size 2 mL.

Preparation and Storage of the Plant Material. Using freshly bought broccoli, green broccoli florets were separated from the stem, their weight was determined, and they were stored up to 6 days at room temperature (about 22 °C), either in the dark or in diffuse day light. On the day of the purchase and on the subsequent 6 days of storage, photographs of the broccoli florets documented their degreening (Figure 2). About 3−6% weight loss was determined at day 1 or day 6, respectively, presumably largely due to loss of water.

Analysis of Chlorophylls and Chlorophyll Catabolites in Senescent Broccoli. The content of Chl in extracts of broccoli florets was determined by an established UV/vis-analytical method.[33] The content of the Chl-catabolites was estimated by quantitative HPLC analysis of the extracts.

Analysis of Chlorophylls. The upper parts of broccoli florets (0.5−1.0 cm; i.e., typically 5−8 g, wet weight) were cut off and were stored for up to 6 days, either in darkness or exposed to diffuse day light. The fresh samples were collected in a mortar then suspended in 10 mL of acetone and ground at room temperature (reduced room light). The suspensions were filtered, and the remaining residues were extracted again with 10 mL of acetone. This procedure was repeated five times until the remaining plant material was practically colorless. Solvents were removed from the collected green filtrates using a rotary evaporator, and green residues were obtained. These were dissolved in 50 mL of a mixture of 80% acetone and 20% 10 mM aqueous ammonium acetate buffer (pH 7); Chl was determined by UV/vis spectroscopy.[33]

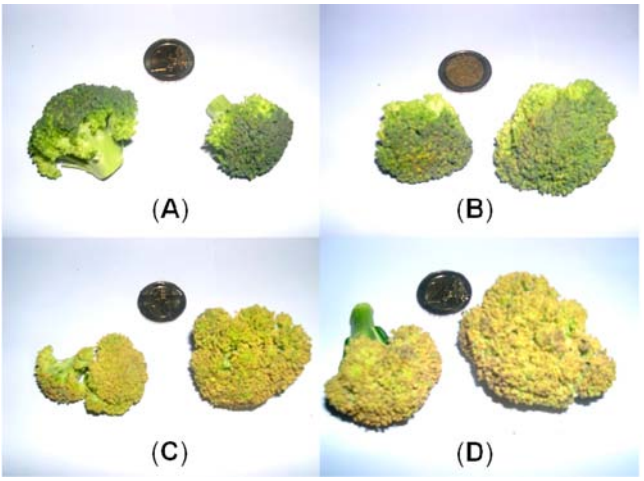

Figure 2. Photographic pictures of broccoli florets at various stages of degreening. (A) On day 1, (B) on day 3, (C) on day 5, and (D) on day 6 of the degreening experiment in the dark.

Analysis of Chlorophyll Catabolites. For analysis of Chl-catabolites, samples of the upper 0.5−1 cm of broccoli florets roughly weighing 3.3 g were likewise collected in a mortar, frozen with liquid nitrogen, crushed, and extracted three times with 3 mL (each) of MeOH. The combined methanolic extracts were mixed 1/1 (v/v) with 50 mM aqueous potassium phosphate buffer (pH 7) and then subjected to analytical HPLC. The catabolites were characterized spectroscopically as described below.

Isolation and Structure Elucidation of Colorless Chlorophyll Catabolites. For structure elucidation, Chl-catabolites were obtained from broccoli florets that were stored for 5 days at room temperature in the dark. The upper 0.5−1 cm of the yellow florets (76.72 g, total wet weight) were cut, frozen with liquid nitrogen, and crushed in a mortar. The cold samples were extracted three times with 100 mL each of MeOH. The combined methanolic extract was analyzed by HPLC (Figure 3) and was concentrated to near dryness under reduced pressure. The residue was taken up in 50 mL of aqueous potassium phosphate buffer (50 mM, pH = 5.1), and the solution was centrifuged (3000 rpm 5 min); a dark-green residue separated, which was extracted two times with 5 mL (each) of aqueous potassium phosphate buffer. The greenish aqueous phases were combined and extracted eight times with 50 mL (each) of CH_2Cl_2. Analyses of the now roughly 50 mL of slightly yellow aqueous phase by HPLC indicated the presence of two Chl-catabolites, of *Bo*-NCC-1 (**1**) and *Bo*-DNCC (**3**). The greenish organic phase contained the less polar *Bo*-NCC-2 (**2**) predominantly.

The greenish CH_2Cl_2 phase was evaporated under reduced pressure, and the remaining residue was resuspended in 25 mL of potassium phosphate buffer (50 mM, pH = 7.0). From the supernatant, *Bo*-NCC-2 (**2**) was isolated by semipreparative HPLC. The fractions containing raw **2** were combined and purified by a second round of semipreparative HPLC. The combined fractions containing pure **2** were desalted by filtration through Sep-Pak-C18 cartridges. Removal of the solvents under reduced pressure gave a sample of *Bo*-NCC-2 (**2**) as an off-white residue that was dried under high vacuum. The sample of pure NCC **2** was dissolved in 0.5 mL of H_2O, and its amount was determined as 0.32 μmol (194 μg) by UV analysis (log $\varepsilon_{(315\ nm)}$ = 3.93).[32]

The yellow aqueous phase that contained *Bo*-NCC-1 (**1**) and *Bo*-DNCC (**3**) was concentrated to about 10 mL using a rotatory evaporator. The now yellow−brownish solution was subjected to semipreparative HPLC in order to isolate raw *Bo*-NCC-1 (**1**) and *Bo*-

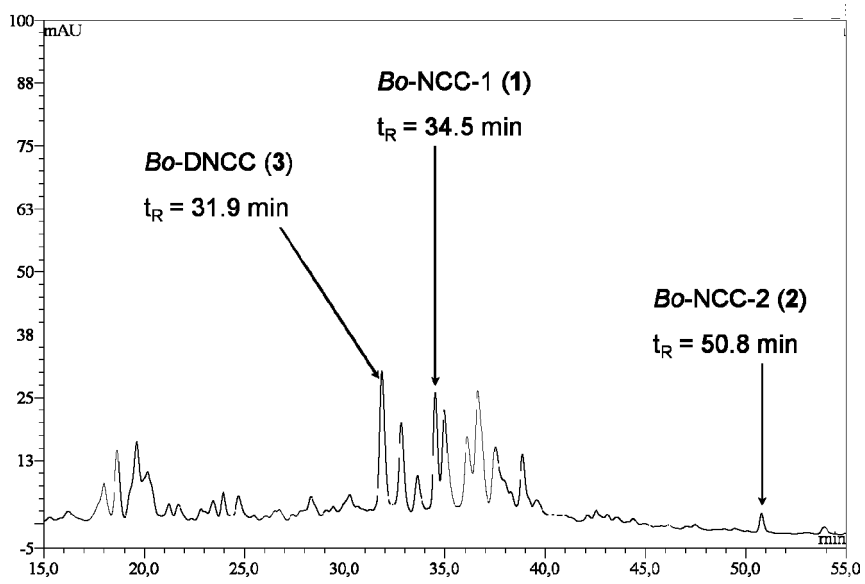

Figure 3. HPLC analysis of a methanolic extract of senescent broccoli florets (online detection at 250 nm). Fractions identified as Chl-catabolites by their UV/vis spectra, are labeled correspondingly as *Bo*-NCC-1 (**1**), *Bo*-NCC-2 (**2**), and *Bo*-DNCC (**3**).

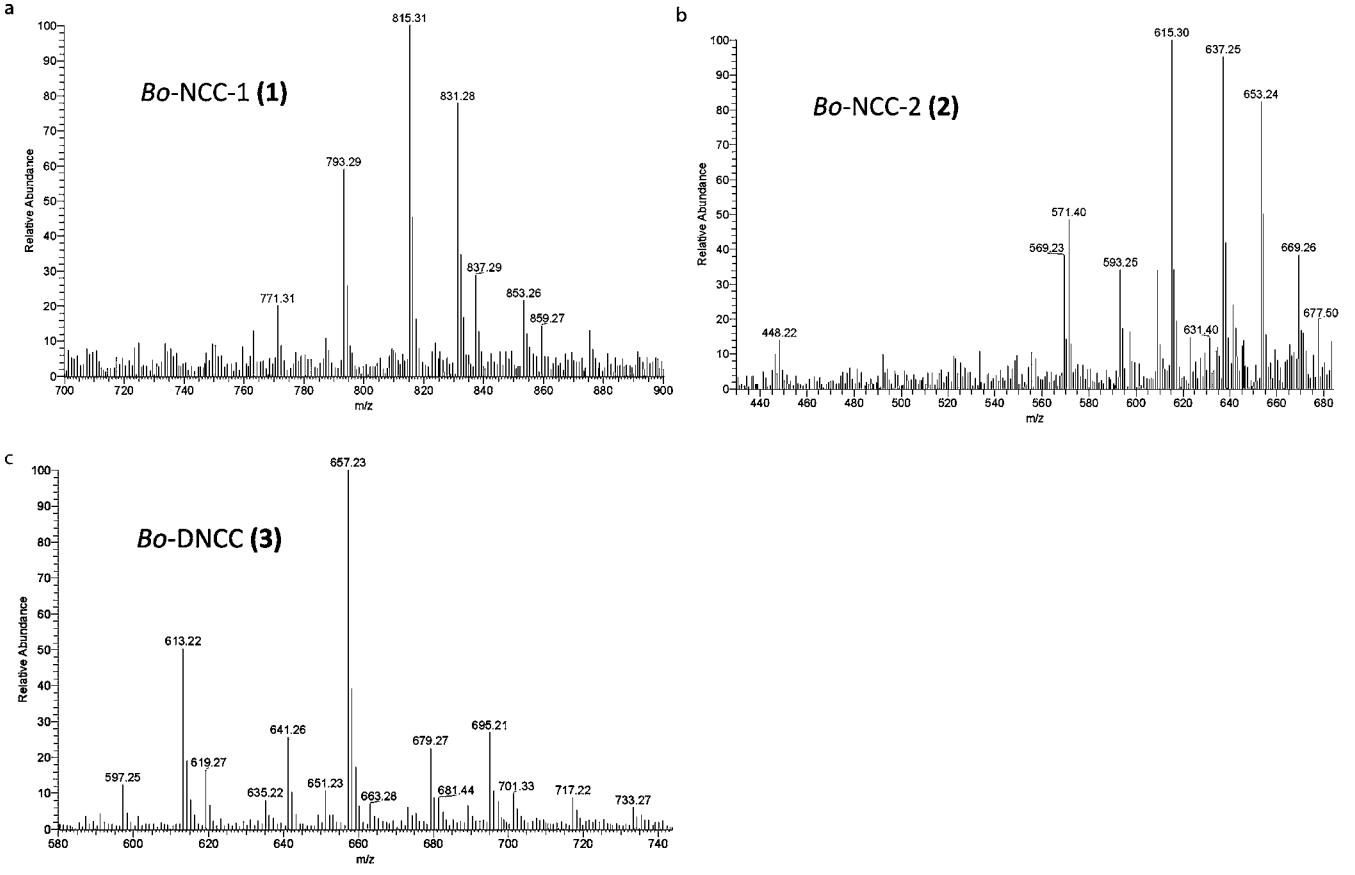

Figure 4. ESI-MS-spectra of *Bo*-NCC-1 (**1**), *Bo*-NCC-2 (**2**), and of *Bo*-DNCC (**3**).

DNCC (**3**). The isolated product fractions were purified by a second round of semipreparative HPLC. Fractions containing **1** or **3** were combined and desalted by filtration through Sep-Pak-C18 cartridges. Solvents were evaporated using a rotatory evaporator, furnishing off-white residues, which were dried at high vacuum, for further analysis. About 0.31 μmol (244 μg) of NCC **1** were obtained (UV-analysis in H_2O[32]). The sample of the DNCC **3** was also analyzed by UV-spectroscopy (log $\varepsilon_{(237\ nm)}$ = 4.49)[16] and was estimated to contain an amount of 0.25 μmol (188 μg).

Identification of *Bo*-NCC-1, *Bo*-NCC-2, and *Bo*-DNCC with Known Chlorophyll Catabolites. According to their spectroscopic data, *Bo*-NCC-1 (**1**), *Bo*-NCC-2 (**2**), and *Bo*-DNCC (**3**) had the same molecular constitutions as *Bn*-NCC-2 and *Bn*-NCC-4, two NCCs from oil seed rape (*Brassica napus*).[34] For the purpose of their further identification, the HPL-chromatographic behavior of *Bo*-NCC-1 (**1**) and of *Bn*-NCC-2 was compared, as well as that of *Bo*-NCC-2 (**2**) and of *Bn*-NCC-4. The samples from the two plant sources showed (pairwise) identical chromatographic properties. In a third coinjection experiment, *Bo*-DNCC (**3**) and a DNCC from *A. thaliana*, provisionally named *At*-DNCC-1,[17] also showed the same chromatographic behavior.

RESULTS

Fresh green florets of broccoli (*Brassica oleracea* var. *italica*), which were bought in a super market, were stored in a dry place at ambient temperature for up to 6 days, either in the dark or being exposed to diffuse day light. In both cases, the broccoli florets degreened and developed a faint yellow color (Figure 2). At regular time intervals, a broccoli floret was selected and its upper part (about 3 g wet weight) was then analyzed. In the extracts obtained, residual Chl *a* and Chl *b* were analyzed by UV/vis-spectroscopy, and three colorless Chl-catabolites were tentatively identified by HPLC analysis (Figure 3). In the green, commercially available broccoli florets, the here characterized three colorless Chl-catabolites were already present in small amounts. During storage (in darkness or diffuse day light), the Chl-content in broccoli was seen to decrease to about 50% within roughly 2 days. After 6 days, less than 10% of the original Chl was still present. In the broccoli florets, two NCC fractions were typified, and a DNCC, based on their characteristic UV absorbance properties. In both cases of storage, in the dark and in diffuse daylight, the amount of the most polar NCC, named *Bo*-NCC-1 (**1**), increased strongly until day 3 and decreased upon further storage. The lesser abundant and less polar NCC, *Bo*-DNCC (**3**) displayed a similar profile of its presence in the florets. A small amount of *Bo*-NCC-2 (**2**) was present from the first day onward with a trend to decrease during storage. Other relevant fractions with UV/vis spectral signatures of colorless Chl-catabolites were not found. During the first 2 days of storage, the observed accumulation of Chl-catabolites was estimated to come up for about 30−35%, overall, of the Chls lost due to the degreening process. As was noted elsewhere with respect to the content of Chl-catabolites,[6] storage of broccoli beyond the early stages of degreening and senescence also showed significantly decreased amounts of the recovered Chl-catabolites. Indeed, degradation of organic micronutrients (vitamins and secondary plant metabolites) during storage is a widely observed phenomenon.

For the purpose of isolation and structure analysis of Chl-catabolites, yellow broccoli florets were selected at day 5 of their storage in the dark, and the upper 0.5−1 cm was severed from the stalk, giving a sample of 76.7 g (wet weight), which was crushed and extracted with MeOH (as described in detail in the Materials and Methods section). After a two-stage isolation and purification procedure by HPLC, 0.32 μmol (194 μg) of *Bo*-NCC-2 (**2**), 0.31 μmol (244 μg) *Bo*-NCC-1 (**1**), and 0.25 μmol (188 μg) *Bo*-DNCC (**3**) were obtained.

The samples of the isolated three Chl-catabolites were used for structure determination. UV spectra allowed the classification of two NCCs[4,6] (**1** and **2**) and of a DNCC (**3**).[13,16] The UV-spectra of the NCC fractions **1** and **2** showed absorption maxima at 319 and at 322 nm, respectively, characteristic for the α-formyl-pyrrole moiety (ring A) of NCCs.[6,35] The UV-spectrum of the *Bo*-DNCC (**3**) showed no maxima, but absorption bands near 250 and 290 nm, as is typical for 1,19-dioxobilane-type NCCs (DNCCs).[13,16] CD-spectra of the purified NCCs showed positive and negative extrema at 321 and at 282 nm, respectively, as is characteristic of natural NCCs.[15,36] The CD spectrum of *Bo*-DNCC (**3**) exhibited a very weak maximum at 310 nm, and a pronounced negative extremum at 282 nm, as was described similarly for *At*-DNCC-1,[17] suggesting the configuration at C15 to be the same as in the DNCC from *A. thaliana*.[17]

The molecular formula of *Bo*-NCC-1 (**1**) was deduced as $C_{40}H_{48}N_4O_{13}$ from its electrospray ionization (ESI) mass spectrum (Figure 4), in which the pseudomolecular ions $[M + H]^+$ and $[M + Na]^+$ were found at m/z = 793.29 and at m/z = 815.31, respectively. A signal at m/z = 771.31 $[M\text{-}CO_2 + Na]^+$ indicated loss of CO_2. A 500 MHz ^{1}H NMR spectrum of **1** in D_2O and at 293 K showed signals of 38 H atoms, i.e., of all carbon-bound protons. On the basis of ^{1}H,^{1}H-COSY and ^{1}H,^{1}H-ROESY spectra, the chemical constitution of *Bo*-NCC-1 (**1**) was deduced. At low field, a singlet was present at 9.15 ppm of the α-formyl group (H−C(20) at ring A) and the set of

DOI: 10.1021/jf5055326
J. Agric. Food Chem. 2015, 63, 1385−1392

signals between 5 and 6.5 ppm of the vinyl group at C18. Singlets at 1.35, 2.19, 2.22, and at 1.87 ppm were assigned to the methyl groups at C17, C2, C7, and C13, respectively. The methylene protons at $C12^1$ and $C12^2$ of the propanoic acid group gave rise to multiplets at 2.26 ppm (H_2C12^2) and at 2.64 ppm (H_2C12^1). The methylene protons at $C3^1$ and $C3^2$ gave multiplets at 2.72 ppm ($H_2{-}C3^1$), 3.57 ppm, and at 3.72 ppm ($H_2{-}C3^2$) and coupled with each other. The protons of $H_2{-}$C15 were assigned to the multiplets at 2.74 and 2.86 ppm, both of which coupled with H−C16 at 3.97 ppm. A β-glycopyranosyl unit was identified by ^{1}H,^{1}H-COSY and ^{1}H,^{1}H-ROESY spectra. On the basis of these data, the constitution of *Bo*-NCC-1 (**1**) was deduced as that of a 1-formyl-19-oxo-3^2-(1-ß-glucopyranosyl)-$O8^4$-desmethyl-16,19-dihydrophyllobilane, a Chl-derived 1-formyl-19-oxobilane (Figure 6).

An ESI mass spectrum of *Bo*-NCC-2 (**2**) (Figure 4) indicated the molecular formula $C_{34}H_{38}N_4O_7$ with pseudomolecular ions at m/z = 615.30 $[M + H]^+$, at m/z = 637.25 $[M + Na]^+$ and at m/z = 653.24 $[M + K]^+$. Fragment ions at m/z = 571.40 $[M - CO_2 + H]^+$ and m/z = 593.25 $[M - CO_2 + Na]^+$, corresponding to loss of CO_2, and at m/z = 448.22 $[M - CO_2$-ring D + $H]^+$, were also observed. In the 600 MHz ^{1}H NMR spectrum of **2** in D_2O at 283 K, signals of 32 of the 38 H atoms could be assigned (i.e., of all carbon-bound H atoms). ^{1}H,^{1}H-COSY and ^{1}H,^{1}H-ROESY spectra were used to derive the chemical constitution of the *Bo*-NCC-2 (**2**) (Figure 5). The

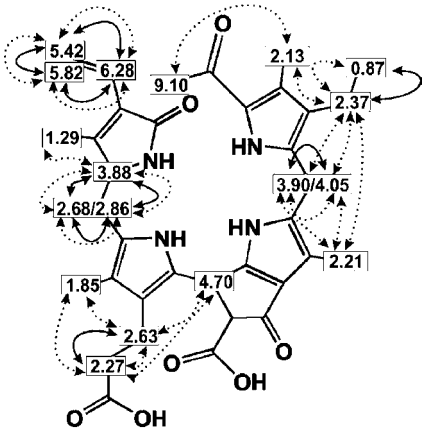

Figure 5. Graphical representation of ^{1}H NMR chemical-shift assignments of signals of carbon-bound H atoms of *Bo*-NCC-2 (**2**) in D_2O (solid arrows represent COSY correlations, dashed arrows represent ROESY correlations).

characteristic singlet of the aldehyde proton H−C20 appeared at 9.10 ppm. In a 600 MHz NMR spectrum of **2** in H_2O/D_2O = 9:1 at 283 K, three additional broad singlets were observed at 7.81, 8.80, and 10.33 ppm of protons bound to pyrrole N-atoms. The signals at 6.28 ppm (dd), at 5.82 ppm (d), and at 5.42 ppm (d) were characteristic of the vinyl group at C18, singlets at 1.29, 1.85, 2.13, and at 2.21 ppm indicated four methyl groups at C17, C13, C2, and C7, respectively. An ethyl group at C3 gave rise to a doublet at 2.37 ppm that coupled with triplet at 0.87 ppm. Multiplets at 2.27 ppm (H_2C12^2) and at 2.63 ppm (H_2C12^1) characterized the propanoic acid group at ring C. H_2C15 gave rise to two multiplets at 2.68 and 2.86 ppm, both showing coupling with a multiplet at 3.88 ppm (HC16). HC10 was seen as a signal at 4.70 ppm. On the basis of mass spectrometric and NMR spectroscopic data, *Bo*-NCC-2 (**2**) was deduced to be a 1-formyl-19-oxo-$O8^4$-desmethyl-16,19-dihydrophyllobilane (Figure 6).

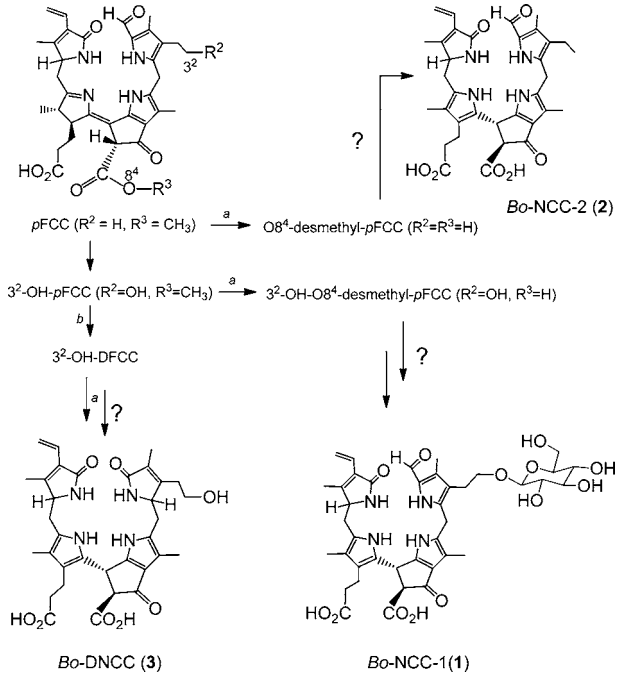

Figure 6. Structures of *Bo*-NCC-1 (**1**), *Bo*-NCC-2 (**2**), and *Bo*-DNCC (**3**), the major Chl-catabolites in senescent broccoli, and possible pathways of their formation from *p*FCC (*a*, methylesterase; *b*, deformylating cytochrome). The hypothetical nonenzymatic isomerization of FCCs and of DFCC to NCCs and to DNCC, respectively, is presumed to take place in the vacuole (see Figure 7).

The colorless catabolite *Bo*-DNCC (**3**) was similarly analyzed by an ESI mass spectrum (Figure 4), which showed pseudo molecular ions at m/z = 619.27 $[M + H]^+$, at m/z = 641.26 $[M + Na]^+$, and at m/z = 657.23 $[M + K]^+$, indicating a molecular formula of $C_{33}H_{38}N_4O_8$. Decarboxylations led to signals at m/z = 651.23 $[M - H\text{-}CO_2 + 2K]^+$, 635.22 $[M - H\text{-}CO_2 + Na + K]^+$, 613.22 $[M - CO_2 + K]^+$, and at m/z = 597.25 $[M - CO_2 + Na]^+$. In the 600 MHz ^{1}H NMR spectrum of **3** in D_2O and at 283 K, signals of 31 C-bound H atoms could be assigned with the help of ^{1}H,^{1}H-COSY and ^{1}H,^{1}H-ROESY spectra. Signals were not found in the low field, consistent with the absence of a formyl group. A vinyl group at C18 gave rise to a characteristic set of signals between 6.5 and 5 ppm. Four singlets of methyl groups (H_3C2^1, H_3C13^1, H_3C17^1, and H_3C7^1 appeared at high field. The methylene protons at $C12^1$ and $C12^2$ of the propanoic acid group gave multiplets at 2.13 ppm (H_2C12^1) and at 2.45 ppm (H_2C12^2). Protons H_2C3^1 coupled with H_2C3^2 and H_AC5 and H_BC5 coupled with HC4. Similarly, an AB system, due to H_AC15 and H_BC15, coupled with HC16. HC10 showed a signal at 4.60 ppm. The mass spectrometric and NMR spectroscopic data established the constitution of the Chl-derived 1,19-dioxobilane **3** as that of a 1,19-dioxo-3^2-hydroxy-$O8^4$-desmethyl-1,4,16,19-tetrahydro-phyllobilane (Figure 6).

The configuration at C10 of the two *Bo*-NCCs **1** and **2** was deduced from the CD spectra to be the same as that of the known natural NCCs, which was tentatively deduced to be (*R*).[36] The absolute configuration of some other stereocenters could not be independently elucidated. However, **1** and **2** were

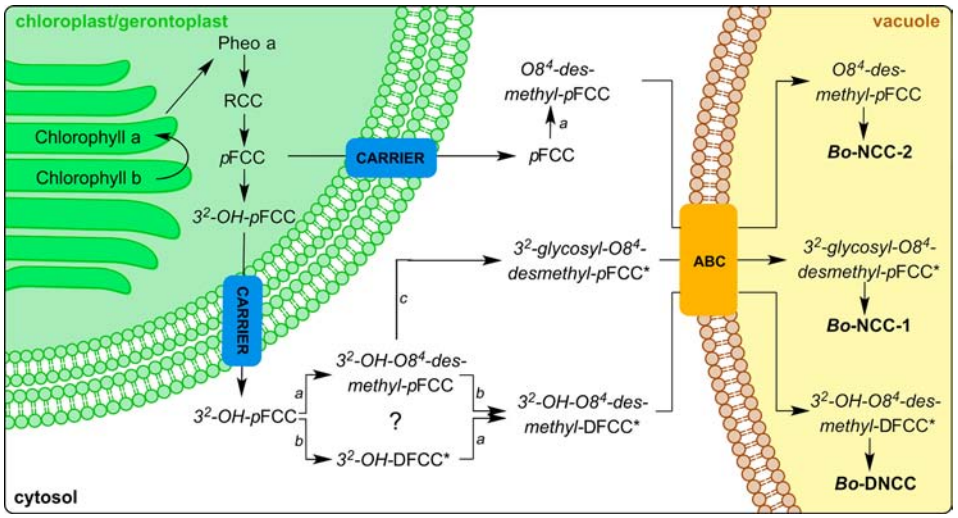

Figure 7. Topographical model of Chl-breakdown in senescent leaves of broccoli, according to the "PAO/phyllobilin-pathway".[7,8] The early steps of this pathway take place in the chloroplast/gerontoplast.[7] The model is based on the current tentative view of the subcellular localization of Chl-catabolites,[41] and Chl-catabolic enzymes of the further pathway are specified, based on presumed modifications of breakdown intermediates, as deduced from the structures of colorless Chl-catabolites identified in the present work. Putative catabolites are labeled with asterisk (*), putative enzyme catalyzed steps are specified by a general label for the enzyme class of a methylesterase (*a*), for a deformylating cytochrome (*b*) and of a glycosidase (*c*) (see Figure 6 for chemical formulas of the suggested intermediate FCCs and of the nonfluorescent catabolites *Bo*-NCC-1 (**1**), *Bo*-NCC-2 (**2**), and *Bo*-DNCC (**3**)).

indicated to have the same constitution as two NCCs from oilseed rape (*Brassica napus*), and named *Bn*-NCC-2[34,37] and *Bn*-NCC-4.[38] The structural identity of **1** and **2**, on one side, and of *Bn*-NCC-2 and Bn-NCC-4, on the other,[34] was established by HPL chromatographic comparison ("coinjection" experiments) of these NCCs. As *Bn*-NCCs were shown earlier to be derived from the "primary" fluorescent Chl-catabolite, *p*FCC[10] (and not from the C1-epimer, *epi*-*p*FCC[11]), the two *Bo*-NCCs **1** and **2** are also indicated to be derived from *p*FCC. In a corresponding experiment, *Bo*-DNCC was identified with *At*-DNCC-1, a prominent Chl-derived dioxobilane from *A. thaliana*.[17] Consistent with these data, the colorless Chl-catabolites of broccoli are all derived from *p*FCC.

DISCUSSION

Degreening is a characteristic sign of breakdown of chlorophyll (Chl) in higher plants, often associated with senescence.[7,39] In this study, the presence of (colorless) Chl-catabolites was investigated in senescent florets of broccoli (*Brassica oleracea* var. *italica*). Two NCCs (1-formyl-19-oxophyllobilanes) and a DNCC (1,19-dioxophyllobilane) could be identified and were structurally characterized. In the early phase of visual degreening of the broccoli florets (days one and two of storage), the amounts of the three colorless Chl-catabolites recovered roughly comes up for about 30−35% of the Chls that disappear during this time. At later stages (days 5 and 6 of storage), not only the green Chls continue to disappear but Chl-catabolites also fade away (by still unknown processes). So far, nongreen Chl-catabolites have been identified only in one other genuine vegetable, in naturally senescing leaves of spinach (*Spinaccia oleracea*).[31,32] A common stereochemical lineage of the catabolites from broccoli with those from oilseed rape (*Brassica napus*)[34] and from *Arabidopsis thaliana*[17] was established, which is consistent with the close phylogenic relationship of the involved *Brassicacea*.

Similar to observations with wild type *A. thaliana*,[17,38] all three catabolites from broccoli carry a free acid function at C8^2, instead of the methyl ester group that is (still) present in their derived common precursor, the "primary" FCC (*p*FCC).[10] An efficient enzyme catalyzed methyl ester hydrolysis is indicated in broccoli. This finding is in line with the recent discovery of the cytosolic methyl esterase Mes16 in *A. thaliana*,[40] which was shown to be crucial in Chl-breakdown path in this plant. Presumably, in broccoli an analogous methyl esterase exists in the cytosol. The occurrence of the now well characterized less polar *Bo*-NCC-2 (**2**) is notable, which was previously identified provisionally in senescent leaves of *A. thaliana*[38] and of spinach.[31] This observation (in broccoli, *A.thaliana*, etc.) suggests export of the "primary" FCC (*p*FCC) into the cytosol, where it is a substrate of the methyl esterase that produces *O*8^4-desmethyl-*p*FCC efficiently (the hypothetical precursor of *Bo*-NCC-2 (**2**), Figures 6 and 7).

Identification of *Bo*-DNCC (**3**), a prominent dioxobilin-type Chl-catabolite in degreened broccoli florets, suggests FCC-deformylation (at C1) to be an important degradation step in broccoli, as was observed in senescent leaves of *A. thaliana*.[17] Thus, similar to the situation in *A. thaliana*, where DNCCs and NCCs were identified,[17] both catabolite lineages occur in broccoli as well. Furthermore, because both hydroxylated DNCC **3** and further glucosylated NCC **1** were found in the extracts of senescent broccoli florets, the enigmatic hydroxylation at the saturated C3^2 position is also indicated to be efficient and to be relevant for both branches of Chl-breakdown. Possibly, this hydroxylation reaction already occurs in the chloroplast, i.e., before export into the cytosol.[7] In contrast, the glycosylation at the OH group at C3^2, observed in the structure of the polar *Bo*-NCC-1 (**1**), would be considered to occur in the cytosol and at the level of the still elusive hypothetical FCCs (Figures 6 and 7). Chl-breakdown in broccoli thus shows the hallmarks of the PaO/phyllobilin pathway,[7,41] and a tentative outline of the Chl-breakdown path in broccoli could be deduced from the structures of the Chl-catabolites found in the degreening florets (see Figures 6 and 7).

In the context of the typical nutritional use of broccoli as a green vegetable, the presence of sizable amounts of colorless Chl-catabolites in the early phase of visual degreening is remarkable. We recently showed NCCs to be excellent antioxidants, such as the ones from apples and pears.[9] Indeed, at present, the physiological effects of the ubiquitous phyllobilanes (NCCs, DNCCs) are unknown that are present in some of our plant-derived nutrition as degradation products of Chl *a*. However, the result with degreening broccoli florets indicates accumulation of such linear tetrapyrroles in this common vegetable, which are also exceptional antioxidants. It will clearly be interesting to learn more about the possible health effects of such colorless Chl-catabolites, as of those that are now known to occur in degreening broccoli florets.

Cooking Process. Three pressure cooker pots of 8 L capacity were purchased from Seb (France) and modified in the following way: for an improved process control, temperature and pressure sensors were integrated into the lid. A temperature sensor was additionally added on the bottom of the pots for an ideal control of internal temperature, achieved via autoregulation of the heating system.

Vegetable broths were prepared from boiling 380 g of carrot, 380 g of leek, 300 g of celeriac, and 250 g of turnip in 3275 mL of water. To avoid uneven cooking and obtain ideal heat transfer, all ingredients were maintained entirely immersed during cooking by two grids, one above and one below the vegetable pieces. The lower grid allowed an improved liquid circulation and eliminated nonhomogenous cooking by preventing direct contact between the solid ingredients and the bottom of the pot.

Experimental Considerations. To compare broths prepared from different processes (pressure and boiling temperature), the concept of cooking value (CV) was used to determine the cooking time that should be applied to achieve the identical cooking degree of ingredients or "cookedness" when working at different pressures.[9−11] The formula describing the CV is the following,

$$\mathrm{CV} = 10^{\theta_i - \theta_{ref}/z} \times t_i$$

with θ_i = boiling temperature at pressure P_i, θ_{ref} = reference temperature (100 °C), z = kinetic constant (14−44 °C depending on the food), and t_i = cooking time at boiling point θ_i.

In the current study, the impact of cooking methods (pressure and heating time) was investigated at similar degree of cookedness achieved after boiling ingredients for 1 h at ambient atmosphere, meaning that $\mathrm{CV_{AP1}} = \mathrm{CV_{HP}} = \mathrm{CV_{LP}}$ (AP1 meaning atmospheric pressure (AP) for 1 h; HP and LP are for high- or low-pressure conditions, respectively). This results in the following formula,

$$10^{\theta_{AP1} - \theta_{ref}/z} \times t_{AP1} = 10^{\theta_{LP} - \theta_{ref}/z} \times t_{LP}$$

$$\Leftrightarrow \frac{\theta_{AP1}}{z} + \ln t_{AP1} = \frac{\theta_{LP}}{z} + \ln t_{LP}$$

$$\Leftrightarrow \frac{t_{LP}}{t_{AP1}} = 10^{\theta_{AP1} - \theta_{LP}/z}$$

with θ_{AP1} = 95 °C, t_{AP1} = 1 h, and θ_{LP} = 80 °C.

Using the same formula for determining t_{HP} (θ_{LP} = 110 °C), this leads to

$$\frac{t_{HP}}{t_{AP1}} = 10^{\theta_{AP1} - \theta_{HP}/z}$$

The z-value is generally given between 14 and 44 °C depending on the nature of the food.[10] Because the vegetable soups were prepared from four vegetables of different intrinsic compositions, the exact z-value of our food preparations in the working conditions was not known. To define the z-value (and then the cooking time to be applied at high and low pressures), preliminary kitchen trials were performed. During these trials, sensory assessment on texture showed that high-pressure boiling for 10 min and low-pressure boiling (cook-vide) for 8 h led to a similar degree of cookedness as the reference sample AP1 (the z-value was found to be ∼16.5 °C).

Atmospheric Cooking. Atmospheric cooking was carried out using a thermostatically controlled hot plate to maintain the set boiling temperature at 95 °C. Vegetables were boiled for 1 h at atmospheric pressure to give the broth AP1 (reference broth).

High-Pressure Cooking. High-pressure cooking was carried out using the modified pressure cooker and a thermostatically controlled hot plate to maintain the set boiling temperature at 110 °C. Vegetables were boiled at 1.5 bar for 10 min and 1 h to give broths HP0.6 and HP1, respectively.

Low-Pressure Cooking. Low-pressure boiling was performed using the vacuum system from Gastrovac (International Cooking Concepts, J.P. Selecta S.A., 08630 Abrera, Spain) and the modified pressure cooker. Vegetables were boiled at 480 mbar for 1, 5, and 8 h (LP1, LP5, and LP8, respectively).

Summary of Experimental Plan. Table 1 summarizes the preparation parameters used to produce vegetable broths in this study.

Table 1. Boiling Conditions for the Preparation of Vegetable Broths

name of vegetable broth	pressure (mbar)	cooking time (h)
AP1	926	1
HP0.6	1500	0.6
HP1	1500	1
LP1	480	1
LP5	480	5
LP8	480	8

This experimental plan allowed for assessing the influence of the pressure (HP1 vs AP1 vs LP1), the cooking method at similar CV (HP0.6 vs AP1 vs LP8), and the cooking time when working under reduced pressure (LP1 vs LP5 vs LP8)

Sample Preparation after Cooking. After cooking, the broths were cooled down. Large vegetable chunks were then removed and squeezed manually to extract as much liquid as possible. The liquid was filtered on SEFAR PETEX, 45 μm. Solid and liquid parts were weighed separately, and the pH of the resulting liquids was determined.

Vegetable and Water Weight Loss after Heating (L_{veg} and L_{water}, Respectively). Solid and liquid losses after cooking were calculated according to the following formula,

$$L = \frac{W_{initial} - W_{final}}{W_{initial}} \times 100$$

with L = loss (%) and W = weight (g).

Volatile Analysis. Preparations (4 mL) were introduced in 20 mL solid-phase microextraction (SPME) vials and saturated with NaCl. One-half μL of methyl caprylate solution (5 ppm, in Millipore water) was added to the vials before analysis as the internal standard. The SPME fiber polydimethylsiloxane/divinylbenzene (PDMS-DVB) (65 μm 23-gauge needle, Supelco no. 57345-U), chosen for its good compromise between sensitivity and response linearity, was exposed for 10 min at 40 °C to the headspace above the sample. After sampling, desorption was performed in splitless mode at 250 °C for 10 min to desorb and transfer volatile compounds. The injector was equipped with a 0.75 mm i.d. liner (Supelco). GC separation was performed on a DB-WAX column (Agilent, 30 m length, 0.25 mm internal diameter, and 0.25 μm film thickness). The GC oven temperature program (Agilent Technologies 6890 GC oven) started at 20 °C for 3 min, then heated at 6 °C/min until 240 °C, and held this temperature for 10 min. The GC was coupled to a mass selective (MS) detector (Agilent Technologies 5973) operating in electron ionization/total ion chromatogram (EI/TIC) (70 eV) mode. Peak identification was tentatively done by comparison with theoretical MS spectra and Kovats indices. Experimental retention indices were obtained by the injection of an alkane solution (C_5−C_{18} fraction). The relative quantitation was carried out by calculating the following ratio:

$$R = \frac{\mathrm{Area_{compound}}}{\mathrm{Area_{methylcaprylate}}}$$

Quantitation of Basic Tastants. Broths were freeze-dried using a Lyolab G freeze-drier (LSL Secfroid, 1111 Aclens, CH). The resulting powders were stored in a plastic box at −20 °C until analysis. The samples were diluted in deionized water for quantitation of carbohydrates (1 mg/L), organic acids (0.5 and 0.1 mg/L), and free amino acids (0.5 mg/L).

Organic acids (quinic, pyroglutamic, lactic, formic, acetic, citric, oxalic, butyric, and propionic acids) were quantitated by high-performance ion-exchange chromatography using an ICS-2000 ion chromatography system from Dionex (Thermo Fisher Scientific,

DOI: 10.1021/jf506173m
J. Agric. Food Chem. 2015, 63, 1393−1400

Waltham, MA, U.S.A.) equipped with an autosampler, a OH^- eluent generator, a suppressor, a column oven, and a conductivity detector. The column was an IonPac (AS11-HC, 4 × 250 mm) coupled with a guard column (4 × 50 mm), both from Dionex. The eluent used was deionized water, and the hydroxide (OH^-) was produced by an eluent generator (KOH cartridge EGCII). The following gradient of OH^- was applied: 0.8 mM [OH^-] from 0 to 12.5 min, 0.8−5 mM [OH^-] from 12.5 to 16 min, 5−38.3 mM [OH^-] from 16 to 28 min, 38.3−60 mM [OH^-] from 28 to 30 min, 60 mM [OH^-] from 30 to 33 min, 60−0.8 mM [OH^-] from 33 to 35 min, and 0.8 mM [OH^-] from 35 to 40 min. Each compound was identified by comparing retention times with a corresponding organic acid standard and quantitated using a calibration curve.

Carbohydrates (mannitol, fucose, arabinose, galactose, glucose, sucrose, xylose, mannose, fructose, and lactose) were quantitated by high-performance ion-exchange chromatography using an ICS-5000 ion chromatography system from Dionex (Thermo Fisher Scientific, Waltham, MA, U.S.A.) equipped with an AS-50 autosampler, a OH^- eluent generator, a suppressor, a column oven, and a conductivity detector. The column was a Carbopac (PA1, 2 × 250 mm) coupled with a guard column (2 × 50 mm), both from Dionex. The eluent was deionized water, and the hydroxide (OH^-) gradient was produced by an eluent generator (KOH cartridge EGCIII) (0.4 mL/min). Elution was isocratic, fixed at 20 mM [OH^-] from 0 to 49 min. Each compound was identified by comparing retention times with a corresponding reference standard and quantitated using a calibration curve.

Free amino acids were quantitated by stable isotopic dilution analysis. The freeze-dried broths were dissolved in Millipore water (0.5 mg/mL), filtered (0.45 μm, disposable syringe filter for aqueous sample), and then spiked with the isotope-labeled internal standard (IS) (500 μL of sample + 500 μL of IS) composed of L-alanine-2-d_1, glycine-2,2-d_2, L-phenyl-d_5-alanine, L-proline-2,5,5-d_3, L-serine-2,3,3-d_3, L-threonine-2,3-d_2, and L-valine-d_8 (100 μM). Determination of response factors was done with a standard solution of the amino acids (Pierce NCI0180) diluted in a range from 5 to 50 μM and spiked with the IS (50:50) to create a 10-point calibration curve. Quantitation was performed using an HPLC 1290 Infinity system (Agilent Technologies) consisting of a binary pump (G4202A), a thermostated autosampler (G4226A + G1330B), a column oven (G1316C), and a Triple Quadrupole MS (G6460A). The column was an EC 250/4 Nucleodur 100-3 HILIC from Macherey-Nagel (760530.40), and the guard column a CC 8/4 Nucleodur 100-3 HILIC from the same supplier (761580.40). The column temperature was maintained at 35 °C. Eluent A was a mixture of acetonitrile/water/formic acid f 100:900:5, and eluent B was a mixture of the same solvents of 900:100:5. The injection volume was 1 μL. The flow rate was 0.8 mL/min. The solvent gradient started at 75% B from 0 to 5 min then 75−50% B from 5 to 6 min, 50% B for 4 min, 50−75% for 1 min, and 75% B for 4 min. In the source (ESI) the gas temperature and flow, respectively, were 300 °C and 5.1 L/min; the nebulizer was set at 45 psi. The sheath gas temperature and the gas flow were 255 °C and 11 L/min, respectively. The capillary voltage was set at 3000 V (+) and 2000 V (−), and the nozzle voltage was 500 V for both the positive and negative modes. Table 2 summarizes mass transitions of quantitated amino acids.

Sensory Evaluation. The panel (12 people) had previous experience in the sensory assessment of vegetable broths, and they were trained during 10 sessions on the relevant sensory attributes. The samples were heated before each session and maintained at ∼65 °C in thermostated flasks.

The samples were served warm and directly before evaluation following a balanced and randomized presentation plan. The panelists evaluated the overall intensity, saltiness, umaminess, sweetness, and carrot, leek, and celery notes of each sample on a 10-point sensory scale. They had a 4 min break between samples and were provided with freshly opened Vittel water and white bread as palate cleansers.

Statistical Analyses. *Instrumental Variables.* A one-way analysis of variance (ANOVA), with product as the fixed factor, was performed to detect significant differences between products. For each discriminant variable, the ANOVA was followed by a Fisher's least significant difference (LSD) procedure to identify all pairs of products that were significantly different.

Sensory Data. A two-way ANOVA with the taster as the random factor and the sample as the fixed factor with interaction taster−product was performed to detect significant differences between samples. Then, for each discriminant sensory attribute, the ANOVA was followed by a Fisher's LSD procedure to identify all pairs of products that were significantly different.

RESULTS AND DISCUSSION

General Characteristics of Vegetable Broths. The pH, solid ingredient/water mass ratios before and after cooking, and the losses in vegetable and water mass (L_{veg} and L_{water}, respectively) are shown in Table 3. The loss of water was dependent on the cooking process. Because low-pressure boiling was carried out in a closed system to maintain a pressure of 480 mbar during boiling, the final water content remained close to the initial one. On the contrary, atmospheric and especially high-pressure cooking allowed water to exit from the system during heating, leading to a higher loss of water. The vegetable mass after cooking decreased by 27.7, 13.1 and 0.3%

Table 3. General Characteristics of Vegetables Broths

for HP1, AP1, and LP1, respectively. Thus, low-pressure boiling implied a reduction in weight loss and therefore increased the yield of vegetables. When boiling at high pressure, the cellular structure of the vegetables might be quickly degraded, leading to the release of water and components of vegetables in the broth. Indeed, after 10 min of boiling at 110 °C under 1.5 bar, a 16% decrease of vegetable mass was observed. At similar CV, the loss of vegetable mass was similar regardless of the pressure (13% for AP1, 15% for HP0.6, and 19% for LP8). Finally, the pH of the vegetable broths ranged from 5.6 to 7.3 and decreased with cooking time (HP0.6 > HP1 and LP1> LP5 > LP8).

Quantitation of Nonvolatile Compounds. During the cooking process, hydrophilic, nonvolatile compounds from the vegetable matter are released into the water. These compounds contribute to the overall flavor of the vegetable broth because they possess their own inherent and specific taste properties. Moreover, they can react with each other to generate new taste-active molecules. Table 4 summarizes the content of organic acids, carbohydrates, and free amino acids in the respective vegetable broths. All carbohydrates and amino acids have been previously detected in leek, carrot, turnip, or celeriac. Sucrose, glucose, and fructose are the most abundant carbohydrates in fresh carrots, celeriac, and leek.[12−15] Mannitol is also present in a relatively high amount in leek and celeriac.[14,15] The main amino acids detected in carrots were aspartic acid and alanine,[12,13] while aspartic and glutamic acids were the most abundant amino acids in leek and celeriac.[15] The occurrence of organic acids in these vegetables is less documented. Phan et al. found that isocitric, citric, malic, and oxalic acids are the most abundant in fresh carrots.[16]

As shown in Table 4, six organic acids were detected and quantitated in vegetable broths (pyroglutamic, acetic, malic, oxalic, citric, and formic acids). Malic acid was the major one with concentrations ranging from 766 to 1393 mg/L. Acetic, formic, and pyroglutamic acids were present at lower concentrations (117−514 mg/L), while the levels of citric and oxalic acids were below 130 mg/L. Malic and acetic acids were present above their respective taste recognition threshold in water, 495 and 120 mg/L,[17] respectively, meaning they contribute to the sourness of the vegetable broths. Significant differences were found for all organic acids except formic and oxalic acids for which the concentrations were similar in all vegetable broths. The highest contents of organic acids were found when the high-pressure cooking process was applied (HP1). On the contrary, the lowest concentrations were found under low-pressure cooking in LP1.

Concentrations of sucrose, glucose, and fructose ranged from 2430 to 3530 mg/L. Mannitol was detected to a smaller extent (963 and 1694 mg/L). Significant differences in their concentrations were found for all carbohydrates except sucrose. However, these sugars were present below their respective taste recognition threshold in water; therefore, they are minor contributors to the taste of broths. The highest levels of carbohydrates were obtained in LP8 cooking, and the lowest ones were obtained in LP1.

Fifteen amino acids were quantitated in the vegetable broths: although significant differences between individual preparations

[a]Results are expressed as means (n = 3). a, b, c, and d represent the statistical groups ($p < 0.05$). [b]Tentatively identified by comparison with theorical MS spectra and Kovats indices. [b]StD means standard deviation; [NS] means nonsignificant statistical difference ($p > 0.05$).

were found (except for alanine), those might not have an impact on the overall taste as their respective concentration was lower than 50 mg/L, far below their taste recognition threshold. Glutamic and aspartic acids followed by valine and alanine were the amino acids found in the highest concentrations. This is in agreement with the literature data.[12,13,15]

When cooking at different pressures for 1 h (HP1 vs AP1 vs LP1), high-pressure boiling generally led to significantly higher concentrations of carbohydrates (glucose and fructose), amino acids (arginine, histidine, tyrosine, methionine, glycine, and threonine) and organic acids, whereas low-pressure and ambient boiling gave similar results except for malic and citric acids, methionine, and threonine, for which concentrations were higher in broth AP1. However, the differences, even when statistically significant, are too small to modify the taste profile of broth.

When comparing preparations with similar CVs (HP0.6 vs AP1 vs LP8), high-pressure and ambient boiled ones had similar concentrations of nonvolatile compounds. Differences were only observed for citric, aspartic, and glutamic acids (47.4 vs 63.2 mg/L, 19.5 mg/L vs 24.4 g/L, and 32.5 vs 41.5 mg/L, respectively, for AP1 and HP0.6). However, those differences observed should be too minor to influence the taste profile. Generally, significantly higher concentrations of amino acids, carbohydrates, and organic acids were found in LP8, likely due to the longer cooking time required to obtain a comparable CV that allowed nonvolatile molecules to be more greatly extracted from the vegetables.

Cooking time generally had an impact on the release of nonvolatile compounds in broth during boiling: the longer the cooking duration, the higher was the concentration. However, broths LP5 and LP8 led to similar compositions of water-soluble, nonvolatile molecules except for leucine, phenylalanine, valine, tyrosine, and threonine, which were slightly more present in broth LP8. This suggests that the maximum release might be reached after 5 h of cooking.

Semiquantitation of Volatile Compounds. Cooking at different temperatures, under different pressures, and for variable durations can impact release, oxidation, and degradation of aroma compounds and thus influence the aroma profile of the final product. The volatile profile of vegetable broths was investigated by headspace SPME-GC/MS. The relative quantitation of 39 molecules was performed using methyl caprylate as internal standard. Table 5 shows peak area ratios for each tentatively identified volatile compound and vegetable broth. These volatiles mainly belong to the chemical classes of terpenoids, aldehydes, alcohols, and sulfuric compounds. Terpenoids and sesquiterpenes such as β-myrcene, α-terpinolene, limonene, caryophyllene, α-pinene, γ-terpinene, and α-humulene are volatile compounds responsible for the typical aroma of raw carrots.[18,19] Limonene, ocimene, myrcene, γ-terpinene, and pinene have also been found as contributors to the celeriac aroma.[20] Sulfur-derived compounds such as methyl propyl disulfide and dimethyl sulfide have been previously identified as key odorants in leek, while isothiocyanates provide the major part of volatiles in turnip *Brassica rapa* var. *rapa* L.[21−23] Statistical analyses showed significant differences in the relative content of volatile compounds in vegetable broths prepared according to different cooking protocols. Sulfur compounds, aldehydes, and alcohols were the chemical classes most affected by the cooking process. Except the 4-terpineol, no significant difference between vegetable broths was found in other terpernoids concentrations.

When comparing AP1, HP1, and LP1, only a few significant differences in the relative content of volatile compounds were observed. On the one hand, aldehydes tended to be lower in abundance when high pressure was applied. Thus, short-chain aldehydes such as propanal, 2-pentenal, and 2-methyl-2-pentenal were not detected in HP1. On the other hand, boiling under low pressure (LP1) tended to increase the relative content of some aroma molecules: 2-phenylethyl isothiocyanate was present in significantly higher concentration in LP1, as well as pentenal, 2-methyl-2-pentenal, and 1-nonanol. Larger differences were observed when working at similar CVs. In that case, the volatile profiles of HP0.6 and AP1 were comparable, while 13 volatiles out of 39 were detected in higher concentrations in the low-pressure preparation LP8. Interestingly, the content of all sulfide compounds identified and quantitated by HS-SPME GC/MS (HS = headspace) was higher in LP8, namely, dimethyl sulfide (cooked cabbage odor), dimethyl disulfide (cabbage, onion-like odor), methyl propyl sulfide (roasted garlic odor), and dimethyl trisulfide (cabbage-like odor). As previously mentioned, these aroma compounds are known to be key aroma contributors of leek and possess a low odor threshold in water (e.g., 0.3−1 ppb for dimethyl sulfide and 0.005−0.01 ppb for dimethyl trisulfide).[24,25] Moreover, low-pressure boiling increased the content of some aldehydes (e.g., hexanal, pentenal, and propanal) and alcohols (e.g., 2-ethyl-1-hexanol and 1-nonanol).

Increasing the cooking time when boiling under low pressure led to higher concentrations of sulfur compounds (e.g., dimethl sulfide, dimethyl sulfide, methyl propyl sulfide, and dimethyl trisulfide). Other chemical classes of volatiles were not affected by the cooking time.

Sensory Analysis. During the preliminary sensory session, the panel described the broths as sweet, salty with leek/onion, carrots, and celery/savory aroma. An evaluation of the overall flavor intensity of broths was included in the study as well. Results of the sensory analysis are shown in Figures 1, 2, and 3.

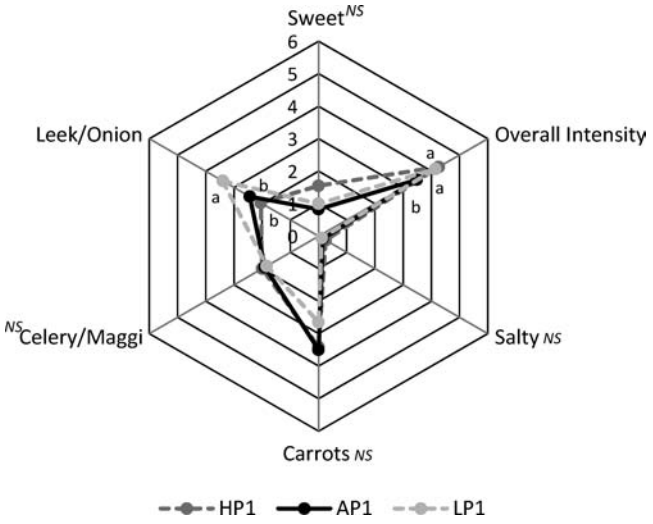

Figure 1. Sensory profile of broths cooked for 1 h. The statistical groups ($p < 0.05$) are represented by [a,b]; [NS] means nonsignificant statistical difference ($p > 0.05$).

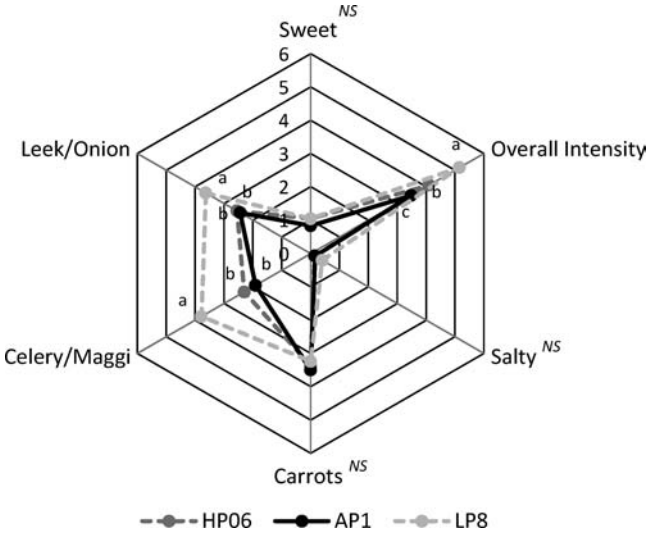

Figure 2. Sensory profile of broths cooked at similar cooking value. The statistical groups ($p < 0.05$) are represented by [a,b]; [NS] means nonsignificant statistical difference ($p > 0.05$).

Sweetness and saltiness were perceived as low with sensory scores below 2 on the 10-point sensory scale, which is explained by the low concentration of sugars as well as the fact that no salt is added to the water. No significant difference for both of these attributes was observed between broths.

As shown in Figure 1, when applying different pressures for an identical cooking time, high and ambient boiling led to broths (AP1 and HP1) with similar sensory profiles. They differed only by the overall flavor intensity, which was greater in HP1. Interestingly, low-pressure cooking for 1 h (LP1) enhanced significantly the overall intensity (compared to AP1) and the leek/onion aroma. Comparing similar CVs (Figure 2), high pressure and ambient boiling (AP1 and HP0.6) consistently gave similar flavor profiles while the greater sensory differences were generated in terms of celery/savory and leek aroma notes when heating under low pressure. Sweet, carrot aroma and saltiness of HP0.6, AP1, and LP8 were found to be similar.

DOI: 10.1021/jf506173m
J. Agric. Food Chem. 2015, 63, 1393−1400

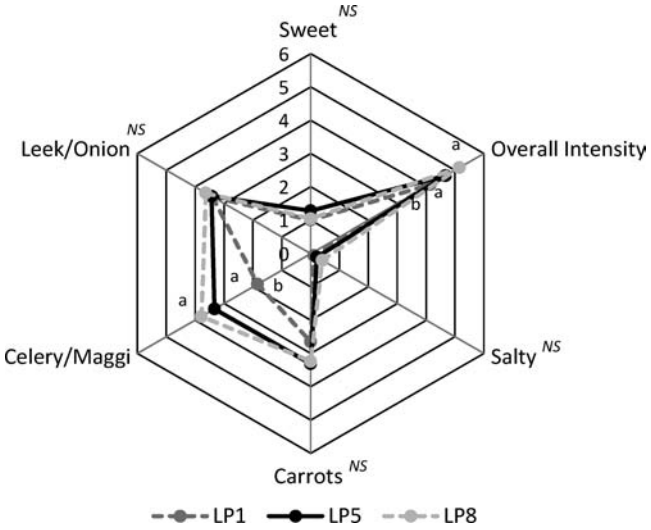

Figure 3. Sensory profile of broths cooked under reduced pressure. The statistical groups ($p < 0.05$) are represented by ^{a,b}; ^{NS} means nonsignificant statistical difference ($p > 0.05$).

Considering the effect of duration when cooking under low pressure, sensory results showed that the maximum intensity of leek/onion aroma was already achieved after 1 h of boiling while celery/savory aroma increased along time and reached a plateau after 5 h, leading to similar flavor profiles of broths LP5 and LP8 (Figure 3).

When assessing the impact of pressure during cooking for 1 h, concentrations of organic acids, amino acids, and sugars were lower when boiling at low pressure; however, no impact on the sweetness or saltiness was observed. Interestingly, the leek/onion note was significantly higher in broth LP1, meaning that some specific aroma might be enhanced by low-pressure cooking. Additionally, the process was found to strongly impact the sensory and chemical profiles of the vegetable broths. Thus, ambient boiling for 1 h or high-pressure cooking for 10 min led to likewise sensory and molecular profiles while low-pressure cooking could be advantageously used to improve the nonvolatile and volatile composition as well as the sensory profiles of broths (especially regarding the overall intensity, leek/onion, and celery/savory notes). Enhancement of sulfur volatiles in the headspace of broths when prepared at low pressure could be correlated to the stronger leek/onion and celery/savory aroma, because those volatiles are known to be the key odorants of leek. The sulfides are known to be highly volatile molecules with low odor thresholds that are sensitive to heat and oxidation. Low-pressure cooking would consequently allow preserving the fragile volatiles even after a long heating time, likely due to the lower boiling point (80 °C in this study) and the reduced level of oxygen. Furthermore, the sensory and chemical profiles of LP vegetable broths seemed to reach a plateau after 5 h, suggesting that cooking time might be reduced to 5 h instead of 8 h while maintaining the same flavor profile of vegetable broths.

Thus, low-pressure boiling might apply to enhance the flavor profiles of culinary preparations and therefore could help to increase consumer preference. The preservative effect of low-pressure boiling might not be restricted to aroma compounds and can be extended to all thermally sensitive compounds like vitamins and coloring molecules. Further work on other culinary preparations and complex dishes is currently being carried out in the laboratory to assess sensorial and nutritional impact of low-pressure cooking.

the composition of volatiles in food has been investigated relative to several factors, including various microorganisms, raw materials, and fermenting and ripening conditions.[5] Moreover, some studies have used fingerprinting analysis or metabolic profiling to obtain the profiles of volatiles of various foods such as tomatoes,[12] green tea,[13] beer,[14] *doenjang*,[4] and pine mushrooms.[15] The application of nontargeted approach has also revealed a correlation between volatile components and sensory attributes in coffee.[16]

The profiles of volatiles of rice-*koji doenjang* inoculated with one or other of three types of *Aspergillus* species (*A. oryzae*, *A. sojae*, and *A. kawachii*) and over a range of fermentation periods were investigated in this study. In addition, the activities of various enzymes were examined to clarify their effects on volatile-compound formation in rice-*koji doenjang*.

MATERIALS AND METHODS

Solvents and Chemicals. The following chemicals were obtained commercially: HPLC grade water (J. T. Baker, Phillipsburg, NJ), methyl cinnamate (Fluka, Buchs, Switzerland), acetonitrile (Merck, Darmstadt, Germany), starch (Samchun, Pyeongtaek Si, Republic of Korea), I_2 (Duksan, Ansan Si, Republic of Korea), and casein (SHOWA, Okayama, Japan). Na_2HPO_4, KH_2PO_4, and Na_2CO_3 were obtained from Daejung (Siheung Si, Republic of Korea). *n*-Paraffins, iodine, KI trichloroacetic acid, Folin and Ciocalteu's phenol, *p*-nitrophenylbutyrate, *p*-nitrophenol, *p*-nitrophenyl palmitate, sodium dodecyl sulfate, Triton X-100, and Tris-HCl buffer were purchased from Sigma-Aldrich (St. Louis, MO).

Preparation of Rice-*koji doenjang*. Polished rice (*Oryza sativa* L., Incheon, Republic of Korea) was steeped in water at 25 °C for 10 h, steamed at 121 °C for 40 min, and then inoculated with three different *Aspergillus* species, including *A. oryzae* (AO), *A. sojae* (AS), and *A. kawachii* (AK), respectively. After that, they were fermented at 30 °C for 40 h to make rice-*koji*. Soybeans (*Glycine max* L.) were soaked in water at 25 °C, cooked at 121 °C for 5 min, and mixed with three different rice-*koji* at the ratio of 4:6 (soybeans:*koji*). Proper amounts of salt and water were added, to the final contents of 17% and 10%, respectively, and then fermented at 30 °C for 8 weeks after yeast strain (*Z. rouxii*) was inoculated at the level of 10^6 CFU/g.

The fermented samples (AO, AS, and AK) were obtained at 0, 1, 2, 4, 5, 7, and 8 weeks, respectively (Table 1), and kept in a deep freezer (below −70 °C) before analysis.

Volatile Components Analysis of Rice-*koji doenjang*. *Extraction of Volatile Components.* Volatile flavor components in rice-*koji doenjang* samples were extracted using the solid-phase microextraction (SPME) method. Each sample (10 g) was mixed with 8 mL of HPLC grade water and 100 μL of methyl cinnamate [200 ppm (w/v) in ethanol] as an internal standard in 60 mL amber SPME vials with a silicon/teflon septum (Supelco, Bellefonte, PA). After that, the mixtures were agitated using a Vortex-Genie 2 (Scientific Industries Inc., Bohemia, NY) at speed 7 for 1 min and maintained at 60 °C, 400 rpm for 30 min with a magnetic stirrer to reach an equilibrium state. The volatiles released into the headspace of the SPME vial were absorbed onto the 75 μm carboxen/polydimethylsiloxane (CAR/PDMS)-coated SPME fiber (Supelco, Bellefonte, PA) that was inserted by 40 mm into the sealed vial for 30 min at the same conditions of equilibrium state. All of the extractions were conducted in triplicate.

GC–MS Analysis. Volatile components extracted were analyzed using a gas chromatograph (6890N) equipped with a mass selective detector (5975) (Agilent Technologies, Palo Alto, CA). The adsorbed volatile compounds onto SPME fiber were desorbed in a GC injector at 230 °C for 5 min, using splitless injection mode with a purge-off time of 5 min and then separated on a DB-FFAP fused silica column (30 m length × 0.25 mm i.d. × 0.25 μm film thickness, J&W Scientific, Folsom, CA).

The oven temperature was maintained at 40 °C for 6 min, increased to 90 °C at a rate of 3 °C/min, raised to 200 °C at 9 °C/min, and then held at 200 °C for 8 min. The temperatures of the transfer line and MS source were 250 and 230 °C, respectively. The other MSD conditions were electronic ionization (EI) mode at 70 eV and scanning range 40–550 amu. Carrier gas was helium at a constant flow rate of 0.8 mL/min.

Identification and Quantification of Volatile Components. The amounts of each volatile component in rice-*koji doenjang* samples were quantified by comparing their peak areas to that of the internal standard compound, 100 μL of methyl cinnamate (200 ppm), on the GC–MS total ion chromatograms. All of the semiquantitative data obtained were mean values of triplicate measurements.

For the identification, each compound was positively confirmed by matching its mass spectral data and retention time to that of an authentic standard chemical. When standards were not available, each volatile compound was tentatively identified by comparing with the Wiley 7n mass spectral data (Agilent Technologies) and Kovats retention index (RI) values in previous literature.[4,17−26] The RI values were calculated with *n*-paraffins from C7 (*n*-heptane) to C22 (*n*-docosane) as external standards.

Enzymatic Activity Assays of Rice-*koji doenjang* during Fermentation. Enzyme activity assays for α-amylase, protease, esterase, and lipase were determined. All experiments were conducted in triplicate.

Preparation of Crude Enzyme Solution from Rice-koji doenjang. Crude enzyme solution from rice-*koji doenjang* was prepared according to the method of Lee et al. with slight modifications.[27] Briefly, 10 g of *doenjang* sample was suspended in 90 mL of distilled water and incubated with gentle shaking for 1 h at 30 °C (JSSI-300C, JSR, Gongju Si, Republic of Korea). After filtration through filter paper (Whatman No. 2), crude enzymes in the filitrate were fractionated with ammonium sulfate ranging from 20% to 80% saturation. The precifitate was centrifuged at 10 000*g* for 15 min, and then the pellet was dissolved in distilled water, followed by dialysis and lyophilization. The resulting crude enzymes were redissolved in the appropriate buffers prior to further analysis of enzyme activities.

Determination of Enzyme Activities. *α-Amylase (EC 3.2.1.1) Assay.* α-Amylase assay was performed with starch solution as substrate. A diluted crude enzyme solution was added to the reaction mixture, which consisted of 2.0 mL of soluble starch substrate solution (1% in the warm water) and 2.0 mL of pH 5.2 buffer (0.1 M citric acid plus 0.2 M Na_2HPO_4), and then at 40 °C for 30 min. After 10 mL of reaction, stopping reagent (1 M CH_3COOH) was added, and 1.0 mL of the mixture was reacted with 10 mL of 0.005% iodine solution,

which was made by mixing KI and I_2 solution, and then measured at 660 nm using a spectrophotometer (Minolta CR-400, Konica Minolta Sensing, Inc., Osaka, Japan).

One unit (U) of α-amylase activity was referred to the quantity of α-amylase that catalyzed the conversion of 1% soluble starch solution to 1.0 mg equivalent of maltose per min under the corresponding conditions.

Protease (EC 3.4.21.19) Assay. To assess protease activity, 2 mL of 2% casein was added to 2 mL of pH 7.0 buffer solution (0.1 M Na_2HPO_4 plus 0.1 M KH_2PO_4) to make substrate solution. One milliliters of crude enzyme solution was mixed, and reacted at 30 °C for 20 min before the reaction was stopped by adding 5 mL of 0.4 M trichloroacetic acid solution for 20 min. The reaction mixture was transferred over filter paper, and then 1 mL of supernatant was mixed with 5 mL of 0.4 M Na_2CO_3 solution and 0.5 M Folin and Ciocalteu's phenol reagent. After reaction ceased, the color change was measured at 660 nm using a spectrophotometer. One unit (U) of protease activity was defined as the quantity of protease inducing a change of 1 μg of tyrosine from 2% casein solution in a minute.

Esterase (EC 3.1.1.1) Assay. The carboxyl ester hydrolase (esterase) activity was determined using a modified spectrometric method,[28] following the hydrolysis of *p*-nitrophenylbutyrate (*p*-NPB) to *p*-nitrophenol at 37 °C for every 5 min. The reaction mixture contained 10 mM *p*-NPB dissolved in acetonitrile and appropriately diluted crude enzyme solution. The instrument was set to zero with Tris-HCl buffer (0.1 M, pH 7.5). The amount of *p*-nitrophenol liberated was measured by a *p*-nitrophenol standard curve at 410 nm (absorbance versus mM of *p*-nitrophenol).

One unit (U) of esterase activity was defined as the amount of esterase needed to liberate 1 μmol of *p*-nitrophenol per minute from *p*-NPB under the specified conditions.

Lipase (EC 3.1.1.3) Assay. A spectrometric method was also performed for the measurement of lipase activity using *p*-nitrophenyl palmitate (*p*-NPP) as a substrate.[29] The substrate solution was prepared by adding 0.0159 g of *p*-NPP, 0.017 g of sodium dodecyl sulfate, and 1.00 g of Triton X-100 into a 100 mL volumetric flask and bringing to volume with distilled water. The assay mixture consisted of 2.5 mL of substrate solution, 2.5 mL of 0.1 M Tris-HCl buffer (pH 7.5), and 1 mL of suitably diluted crude enzyme solution. The release of *p*-nitrophenol from *p*-NPP at 37 °C was continuously monitored at 400 nm using a spectrophotometer every 5 min. The instrument was set to zero with 0.1 M Tris-HCl buffer. To convert absorbance to concentration of substrate hydrolyzed, a *p*-nitrophenol standard curve was used.

One unit (U) of lipase activity was defined as the amount of lipase required to release 1 μmol of *p*-nitrophenol from *p*-NPP in 1 min under the corresponding conditions.

Statistical Analysis. Multivariate analysis of variance (MANOVA) was accomplished using the general linear model procedure in SPSS (version 12.0, Chicago, IL) to assess differences in the volatile components of rice-*koji doenjang*. Duncan's multiple range tests were used when the samples demonstrated significantly different relative peak areas of volatiles according to their fermentation time and fungal

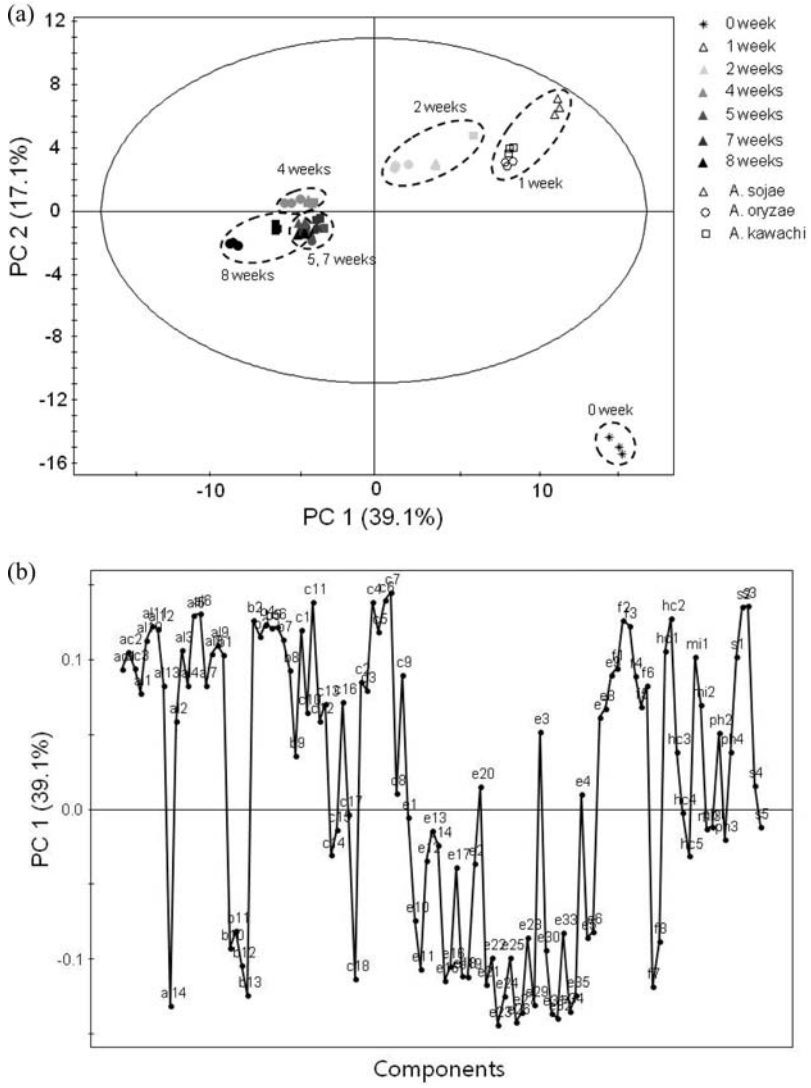

Figure 2. Principal component analysis (PCA) plots for the volatile components isolated from rice-*koji doenjang* according to *Aspergillus* species inoculated and fermentation time: (a) score plot, (b) loading plot.

species inoculated, with the level of significance set at $p < 0.05$ (Table 2). Principal component analysis (PCA) and partial least-squares regression (PLSR) analysis were performed with the aid of SIMCA-P (version 11.0, Umetrics, Umeå, Sweden) software to discriminate different rice-*koji doenjang* samples on the basis of their volatile profiles according to fermentation periods and also clarify the effects of the enzymatic activities originated from *Aspergillus* species inoculated on volatile components formation.

To determine the enzymatic effects on volatiles formation, a bivariate correlation was used, with Pearson's correlation coefficients (r) calculated by SPSS. Also, heatmap was performed using Multiexperiment Viewer (MeV, version 4.8.1, Boston, MA) software to visualize these relationships.

RESULTS AND DISCUSSION

GC−MS Analysis and Assignment of Volatile Components in the Three Sample Types. The 108 volatile components found in the three rice-*koji doenjang* samples during 8 weeks of fermentation are listed in Table 2, with their mean values of relative peak areas and RIs on the DB-FFAP column. These compounds comprised the following 10 classes of compounds: acids (n = 3), alcohols (n = 14), benzene derivatives (n = 13), carbonyls (n = 18), esters (n = 35), furan derivatives (n = 8), hydrocarbons (n = 5), phenols (n = 4), sulfur-containing compounds (n = 5), and miscellaneous compounds (n = 3). Figure 1 shows the GC−MS total ion chromatograms for the volatile compounds of a representative AO sample during 8 weeks of fermentation. The contents of some volatile compounds tended to increase with the fermentation time: most of these compounds were long-chain fatty acid ethyl esters (e22−e35: ethyl dodecanoate, ethyl tetradecanoate, ethyl pentadecanoate, methyl hexadecanoate, ethyl hexadecanoate, ethyl hexadecanoate, ethyl hexadec-9-enoate, ethyl heptadecanoate, butyl hexadecanoate, ethyl octadecanoate, ethyl octadec-9-enoate, ethyl octadeca-9,12-dienoate, ethyl octadeca-9,12,15-trienoate, methyl octadeca-9,12-dienoate), which are considered to be formed via the interaction of acids and ethanol through fermentation, and they affect the quality of fermented rice-*koji doenjang*. In particular, the contents of ethyl tetradecanoate (e23, 33.6 min), ethyl hexadecanoate (e26, 36 min), ethyl octadec-9-enoate (e32, 39.4 min), and ethyl octadeca-9,12,15-trienoate (e34, 40.5 min), which give fatty and oily odor notes, changed considerably with fermentation time.[30] This result indicates that these high-molecular-weight ethyl esters, which are generally related to

[a]EC: Enzyme Commission number is a numerical classification scheme for enzymes based on the chemical reactions they catalyze. [b]Average of specific activities (n = 3) ± standard deviation. [c]Different letters mean significant differences ($p < 0.05$) between the *doenjang* samples varying with fermentation period by Duncan's multi range test. [d]Different letters mean significant differences ($p < 0.05$) between the *doenjang* samples varying with *Aspergillus* species inoculated by Duncan's multi range test.

fatty and oily odor notes, influence mainly the latter fermentation stage of rice-*koji doenjang* inoculated with *Aspergillus* species. These compounds could be produced by the actions of enzymes such as lipase and esterase that were excreted by the inoculated *Aspergillus* species.[31]

However, some low molecular weight acids such as acetic acid, butanoic acid, and propanoic acid could not be found in our study, although they had been detected in previous studies on *doenjang* volatiles.[1,2,4−6] We expected those acids could be converted to the corresponding esters in our study.

Principal Component Analysis of Three Types of Rice-*koji doenjang* According to the Inoculated *Aspergillus* Species and Fermentation Time. PCA is an unsupervised method that enables recognition of any inherent sample clustering. It does not require any information on the data sets and represents a multivariate data table as a low-dimensional plane.[32]

PCA was thus used to analyze the data sets of relative peak areas of volatile components to determine whether their fermentation time could be used to differentiate between the three types of rice-*koji doenjang* samples (Figure 2). A total variance of 56.3% was observed, comprising 39.1% from the first principal component (PC1) and 17.2% from the second principal component. Classification of the plots according to fermentation time revealed that the profiles of the volatiles moved from right to left with increasing fermentation period in the PC1 dimension, accounting for the observed steady changes in profiles as fermentation proceeded (Figure 2a).

Overall, rice-*koji doenjang* samples could be differentiated primarily according to their PC1 score with a positioning of the initial stage (0−2 weeks) in the positive dimension, and the middle or latter stages (4−8 weeks) in the negative dimension. As shown in Figure 2b, butan-2-one, hexanal, 4-methyl heptan-2-one, dimethyl disulfide, 2-methyl thiophene, 2-ethyl furan, hexan-1-ol, methylbenzene, and hexanoic acid contributed positively to the PC1 dimension and exhibited marked changes in their contents during the primary stage of fermentation. With the exception of hexanoic acid, the levels of these compounds peaked at 0 weeks of fermentation, and were generally not detected after 4−8 weeks, which would indicate that they originated mainly from the raw materials of the rice-*koji doenjang* and were utilized as precursors for the subsequent fermentation-related reactions. For example, hexanal is a long-chain aldehyde that imparts a green bean note and is known to be derived from long-chain fatty acids as a result of lipoxygenase-catalyzed lipid oxidation in soybeans.[33,34] Volatile sulfur compounds such as dimethyl disulfide and 2-methyl thiophene can affect the flavor of fermented soybean foods because of their low threshold levels and unique aroma notes.[35] Dimethyl disulfide is associated with cooked-cabbage and garlic-like odors,[35] whereas 2-methylthiophene is characterized as a potent cooked odorant. Hexan-1-ol reportedly imparts the green and beany odorant found in raw soybeans,[36] and is formed during the enzymatic oxidation of linoleic acid (C18:2).[37] Hexanoic acid is one of the mid-chain fatty acids related to unpleasant rancid and cheesy odor notes.[38] As with the other acid compounds identified in the present study, hexanoic acid was detected only at 1 and 2 weeks of fermentation.

Conversely, ethyl octanoate and ethyl hexadecanoate contributed to the negative axis of PC1, and their levels tended to increase during fermentation, peaking in 8-week samples. This demonstrates that these ethyl esters, which are generally associated with fatty and oily odor notes, could influence the latter fermentation stage of rice-*koji doenjang*.[31] Furthermore, the PCA score plot in Figure 2a shows the positioning differences among the three species of *Aspergillus* inoculated into the rice-*koji doenjang*. Relatively large differences were observed at 1, 2, and 8 weeks, whereas smaller gaps were found between 5 and 7 weeks. At the early fermentation stage (i.e., 1−2 weeks), there were significant differences in the levels of acids and alcohols, and particularly of hexanoic acid, hexan-1-ol, oct-1-en-3-ol, and heptan-1-ol. The levels of those components were higher in AS than in AO and AK samples.

At 8 weeks of fermentation, there were also noticeable differences in the contents of ethyl octanoate, ethyl decanoate, diethylbutanedioate, ethyl dodecanoate, and ethyl hexadecanoate relative to the microbial species inoculated, with the highest levels being observed in AO. These ethyl ester compounds could be formed by esterification of ethanol and

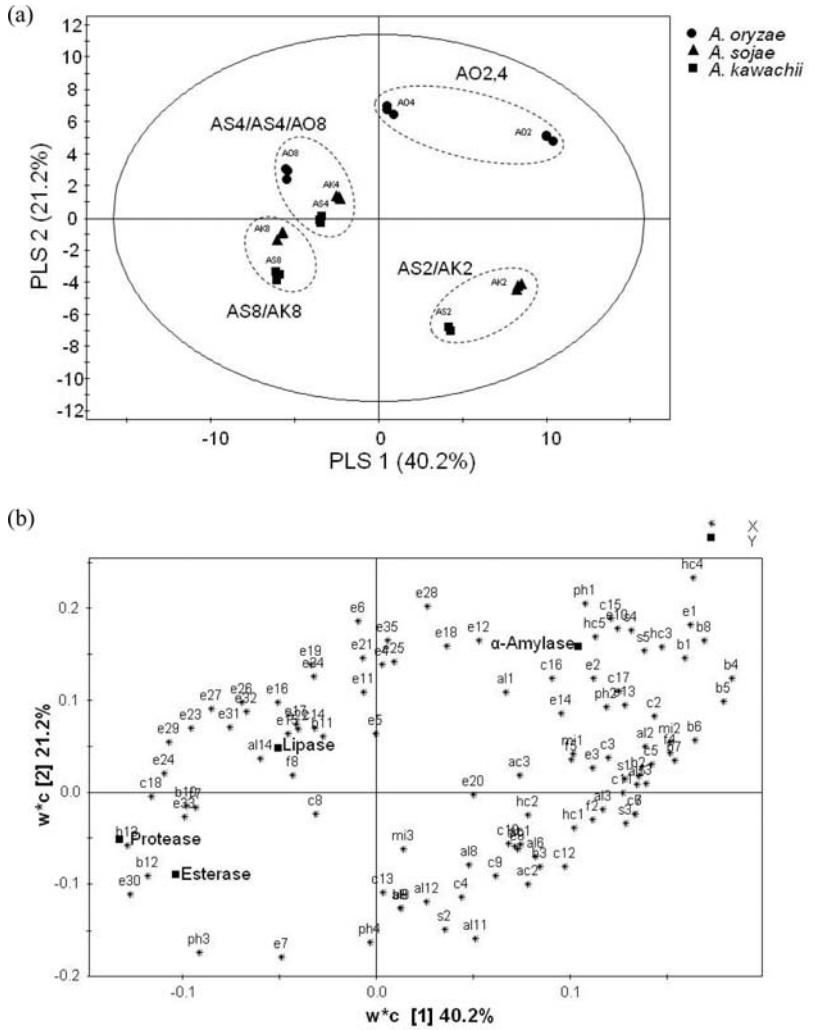

Figure 3. Relationships between the volatile components isolated from rice-*koji doenjang* and enzyme activities (α-amylase, protease, lipase, and esterase) during fermentation using partial least-squares regression (PLSR): score plot (a) and loading plot (b).

fatty acids, which were derived via the Embden−Meyerhof−Parnas pathway by yeast and fungal hydrolysis of soybean lipids, respectively.[38] Lee et al.[25] reported that these high-molecular-weight esters could be detected at much higher levels in *doenjang* samples prepared with *koji* than in traditional *doenjang* samples that were fermented with naturally occurring microorganisms, possibly due to differences in the microbial enzymatic preference for soybean lipid and esterification. These compounds are secondary products formed by reactions after sufficient amounts of ethanol and fatty acids are generated during fermentation, and so differences in enzymatic preferences might be responsible for the differences in the contents of these ester compounds at 8 weeks.

Enzymatic Activities in Three Types of Rice-*koji doenjang* during Fermentation. As described above, rice-*koji doenjang* inoculated with different strains of *Aspergillus* exhibited different volatile-component profiles (Table 2 and Figure 2). This suggests that the *Aspergillus* species exhibit different enzymatic activities, which are in turn directly and/or indirectly related to the formation of volatile components during fermentation.[37] Therefore, the effects of periodic changes in the enzymatic activities of α-amylase, protease, lipase, and esterase on the formation of volatiles of *doenjang* were examined.

Significant differences in the activities of all enzymes according to both fermentation time and microbial species were found (Table 3). α-Amylase activities decreased steadily in all samples over the fermentation period (i.e., at 2, 4, and 8 weeks). The presence of a relatively large amount of carbohydrate, acting as a substrate for α-amylase, in soybean and rice in the early fermentation stage (2 weeks) resulted in the measurement of relatively high levels of enzymatic activity. However, their specific activities gradually declined as the levels of carbohydrate substrate decreased due to its consumption by microorganisms during fermentation. Samples inoculated with *A. oryzae* exhibited the highest α-amylase activity among the samples, ranging from 167.750 to 271.479 units/g of enzyme activity/g protein at 8 to 2 weeks of fermentation, respectively. In contrast, the enzyme activities were lowest in the *A. sojae* samples. α-Amylase catalyzes the breakdown of α-1,4 glucosidic linkages in polysaccharides, such as starches or glycogen, liberating low-molecular-weight sugars.[39] In the present study, it was expected that samples inoculated with *A. oryzae* would exhibit increased formation of mono- or disaccharides and related volatile components in *doenjang* as compared to the other samples.

Conversely, there was a tendency toward a steady increase in protease activities during fermentation. Of particular note was

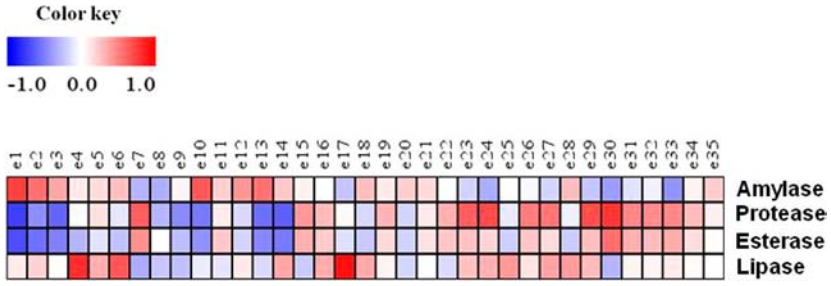

Figure 4. Heatmap representing the relationships between ester compounds identified (e1−e35) and enzymatic activities during rice-*koji doenjang* fermentation: Pearson's correlation coefficients ($-1 \leq r \leq 1$) are shown in each column.

the absence of significant differences in protease activities between samples inoculated with AS and AK (Table 3). It has been shown previously that AS exhibits higher protease activities than AO in solid-state fermentation of soybeans, which are usually used to make soy sauce.[40] In contrast, all AO samples exhibited the lowest protease activity among the samples, the gap between them widening drastically as fermentation proceeded.

Esterase activities increased throughout fermentation, with the highest activities being observed in AS samples. Because esterase catalyzes the formation of ester compounds by condensing alcohols (ethanol) and acids (fatty acids), the increase in esterase activities indicates that there were sufficient amounts of ethanol and fatty acids present in the samples in this study.

All samples exhibited a decreasing tendency of lipase activities after 4 weeks of fermentation in this study, with the greatest change being observed in AK samples. These results concur with those of previous studies.[7,41] Kim et al.[7] reported that lipase activities in soybean pastes prepared with mold-producing protease containing *meju* were increased continuously until 30 days of fermentation, and then decreased gradually thereafter. In addition, Joo et al.[41] demonstrated that soybean/soybean paste fermented with various *Aspergillus* species exhibited a maximum level of lipase activities after 20 days, with the levels increasing dramatically from the beginning of fermentation. The decrease in lipase activities could be attributable to the reduction in triglycerides, which are the substrates of this enzyme, during the fermentation process.

Changes in Enzymatic Activities and Their Effects on the Formation of Volatile Components in Three Types of Rice-*koji doenjang* during Fermentation. The correlations between the formation of volatile components and enzymatic reactions during fermentation were clarified by conducting partial least-squares (PLS) regression analysis. The different enzymatic activities between samples could lead to variance in the profiles of precursors for volatile compounds among them, which may have affected further reactions related to the formation of volatiles throughout the fermentation period.

Figure 3a and b shows the correlations between each of the volatile compounds formed and the activities of each of the associated enzymes (i.e., α-amylase, protease, lipase, and esterase). In terms of microbial types, similar patterns of volatile-components formation were observed for AS and AK, whereas that for AO seemed to differ throughout 8 weeks of fermentation. Figure 3a and b shows that α-amylase was strongly associated with the early stage (2 and 4 weeks) of fermentation in AO, affecting the formation of 2-methylpyrazine, 3-hydroxy-2-methylpyran-4-one, and furan-2-carbaldehyde, which are known to be directly and/or indirectly derived from sugar-degradation products.[4] 2-Methylpyrazine is known to be formed via the Maillard reaction and is found in various foods, such as coffee, cacao bean, and bread, which are manufactured using a heating process.[1,42] It has also been identified in Japanese *natto*,[43] steamed soybeans,[44] and soybean curds,[45] contributing to the nutty and cocoa-like aroma notes.[4] 3-Methyl-2-methyl-4*H*-pyran-4-one is also considered to be formed via the Maillard reaction, and appears to play a role as a sweet enhancer.[46] In *doenjang* production, it is probably formed during the process of steaming the raw materials containing carbohydrates, such as rice and soybeans, which could be exposed to sugar degradation.

There was a close relationship between protease activities and the latter part of the ripening process in AS and AK at 8 weeks. The formation of several compounds, including ethyl 3-phenylpropanoate, 2-phenylethyl acetate, (*E*)-2-phenylbut-2-enal, and 2-phenylethanol, which are known to derive from phenylalanine,[4] could be affected by protease activities. Among these compounds, the formation of two ethyl esters (ethyl 3-phenylpropanoate and 2-phenylethyl acetate) could be influenced by the actions of both protease and esterase, because they were located in the same direction of negative PLS1 and PLS2 (Figure 3b). In the positive dimension of PLS2, most of the ester compounds identified in this study could be more closely related to the activities of lipase and α-amylase than the other enzymes. This indicates that such esters could be more affected by the actions of these enzymes, which involve the hydrolysis of free fatty acids from soybean lipids by fungi and the production of ethanol from sugars by yeasts, respectively. However, because the amount of ethanol in all of the samples increased continuously during fermentation (data not shown), the amount of ethanol was thought to be sufficient to participate in esterification. In other words, lipase activities might have been the rate-limiting step for ethyl ester formation in the present study. Chou et al.[31] also reported that the concentration of ethanol did not affect the fatty-acid profiles in aging Chinese traditional soybean curds, and that ester compound formation was attributed mainly to lipase.

Heatmap of Relationships between the Identified Ester Compounds and Enzymatic Activities during Rice-*koji doenjang* Fermentation. Ester compounds are generally a very important component of many soybean-based fermented foods, mainly due to their characteristic odor notes, including fruity and sweet notes.[30] Given that in the present study, 35 ester compounds (Table 2) were significantly associated with enzyme activities and the levels of some ester compounds quantitatively increased with increasing fermentation time, we focused on the relationship between ester compound formation and enzyme activities.

J. Agric. Food Chem. 2015, 63, 1401−1418

Figure 4 provides the correlation matrix that summarizes the Pearson's correlation coefficients between the contents of the 35 ester compounds and the activities of 4 enzymes. Among 140 possible ester-enzyme pairs, 8 pairs exhibited strong correlations at $p < 0.05$. Pearson's correlation coefficient, r, provides a measure of strength of the linear relationship between the formation of ester compounds and the four enzymatic activities, and can range from −1 to 1, such that $r = 1$ or −1 indicates a perfect positive or negative linear relationship between two variables, respectively, and $r = 0$ means that there is no linear relationship between them.

Clear correlations were found between lipase activities and levels of methyl 2-methylprop-2-enoate ($r = 0.82$) and pentyl propanoate ($r = 0.91$) during fermentation. The former is known to contribute to sweet, fruity, and apple-like odor notes,[47] and the latter imparts sweet and mixed fruit tropical odor notes,[47] which could be formed by esterification of pentanol and propionic acid. In addition, the levels of ethyl butanoate, ethyl heptanoate, 3-methylbutyl hexanoate, ethyl tetradecanoate, methyl hexadecanoate, ethyl hexadecanoate, and ethyl hexadec-9-enoate were positively correlated with lipase activities. Positive correlations were found for α-amylase, ethyl acetate ($r = 0.74$), ethyl propanoate, 3-methylbutyl acetate ($r = 0.65$), and ethyl hexanoate. Protease and esterase had similar correlation tendencies, being negatively correlated with low-molecular-weight esters including ethyl acetate, ethyl propanoate, ethyl 2-methylpropanoate, 3-methylbutyl acetate, ethyl hexanoate, and ethyl heptanoate. Conversely, positive correlations were observed between protease and esterase enzymatic activities and relatively high-molecular-weight esters such as ethyl heptadecanoate, butyl hexadecanoate, ethyl octadecanoate, ethyl octadec-9-enoate, and ethyl octadeca-9,12-dienoate.

This study investigated differences in the volatile components of rice-*koji doenjang* in samples inoculated with various *Aspergillus* species (AO, AS, and AK) and with fermentation for up to 8 weeks, as well as the effects of specific activities of diverse enzymes on the formation of volatiles. Application of PCA to data sets of the volatiles profiles revealed that the different rice-*koji doenjang* samples could be distinguished according to the specific inoculated *Aspergillus* species and fermentation time. 4-Methylheptan-2-one, heptan-2-one, (*E*)-hept-2-enal, and hexanal contributed to the initial stage of fermentation of rice-*koji doenjang*, regardless of the species of *Aspergillus* inoculated. In contrast, the main components related to the latter stage of fermentation were ethyl esters of long-chain fatty acids, including ethyl tetradecanoate, ethyl hexadecanoate, ethyl octadec-9-enoate, ethyl octadecanoate, ethyl hexadec-9-enoate, and ethyl heptadecanoate. In addition, some esters, including methyl 2-methylprop-2-enoate, ethyl 2-methylprop-2-enoate, 3-methylbutyl acetate, ethyl (*Z*)-but-2-enoate, methyl 3-methylbut-2-enoate, 3-methylbutyl hexanoate, pentyl propanoate, 3-methylbutyl octanoate, ethyl hexadecenoate, ethyl hexadec-9-enoate, butyl hexadecanoate, ethyl octadec-9-enoate, ethyl octadeca-9,12,15-trienoate, and methyl octadeca-9,12-dienoate, were found for the first time in rice-*koji doenjang*, possibly due to high esterase activity in this study.[1,2,4,5,48,49]

The effects of enzymatic activities on the formation of volatile compounds during rice-*koji doenjang* fermentation were evaluated using PLS regression analysis and heatmaps of correlation matrixes between enzymes and volatile components. The formation of volatile esters during soybean-paste fermentation appeared to be strongly associated with protease and esterase activities, which increased as fermentation proceeded.

Germany). Dichloromethane, diethyl ether, and pentane were distilled prior to use.

Reference Odorants. Propane-1-thiol, butane-1-thiol, pentane-1-thiol, hexane-1-thiol, heptane-1-thiol, octane-1-thiol, nonane-1-thiol, decane-1-thiol, butane-2-thiol, 2-methylbutane-1-thiol, 3-methylbutane-2-thiol, propane-1,3-dithiol, butane-1,4-dithiol, hexane-1,6-dithiol, octane-1,8-dithiol, and nonane-1,9-dithiol were obtained from Sigma-Aldrich. 2-Methylbutane-2-thiol, decane-1,10-dithiol, 1-(methylthio)-pentane, 1-(methylthio)heptane, 1-(methylthio)-octane, and 1-(methylthio)decane were purchased from TCI Europe Laboratory Chemicals (Eschborn, Germany). Pentane-1,5-dithiol, 1-(methylthio)-butane, and 2-(methylthio)butane were supplied by Alpha-Aesar.

Syntheses. In total 40 sulfur compounds were newly synthesized. All reactions were carried out in oven-dried glassware under argon atmosphere unless otherwise noted.

Primary and Secondary Thiols. The primary and secondary thiols were prepared from the corresponding alcohols in a three-step synthesis following a previously described method[8] with slight modifications. If the respective alcohol was not commercially available (e.g., 2-methylhexan-1-ol and 2-methylheptan-1-ol), these were synthesized from the corresponding carboxylic acid by reduction with $LiAlH_4$.

Tosylation of Primary and Secondary Alcohols. To a solution of the alcohol (30 mmol) in anhydrous pyridine (20 mL) was slowely added *p*-toluenesulfonyl chloride (6.29 g; 33 mmol) at 0 °C. The solution was allowed to reach room temperature, and the mixture was stirred overnight. Hexane (30 mL) was added, the solution was filtered, and the residue was washed with hexane (30 mL). The combined organic layers were washed with aqueous hydrochloric acid (5 mol/L; 2 × 30 mL). After drying over anhydrous sodium sulfate, the solvent was removed by rotary evaporation.

Thioacetylation of the p-Tosylderivates. Potassium thioacetate (5.71 g; 50 mmol) was dissolved in DMF (20 mL). The tosylated alcohol (20 mmol) was added, and the solution was stirred at 80 °C for 2 h. Then, a saturated aqueous sodium chloride solution (100 mL) was added, the aqueous solution was extracted with diethyl ether (3 × 100 mL), and the combined organic layers were washed with a saturated aqueous sodium chloride solution (5 × 50 mL). After drying over anhydrous sodium sulfate, the solvent was removed by rotary evaporation. Purification of the compound was performed by column chromatography on silica gel (silica 60, 0.040−0.063 mm) (Merck, Darmstadt, Germany) using pentane/diethyl ether (99/1; v/v) as the eluent.

Reduction with $LiAlH_4$. The acetylthio derivative (10 mmol) obtained was dissolved in anhydrous diethyl ether (15 mL) and added slowly to a suspension of lithium aluminum hydride (0.76 g; 20 mmol) in anhydrous diethyl ether (20 mL) at 0 °C. The solution was stirred for 2 h at room temperature, and a saturated aqueous ammonium chloride solution (20 mL) was added slowly at 0 °C. Then, aqueous hydrochloric acid (2 mol/L; 50 mL) was added to dissolve the precipitate formed, the ethereal layer was separated, and the aqueous layer was extracted with diethyl ether (3 × 70 mL). The combined organic layers were washed with a saturated aqueous sodium bicarbonate solution (50 mL), followed by water (50 mL). After drying over anhydrous sodium sulfate, the solvent was distilled off by means of a Vigreux column (50 × 1 cm). Purification of the compound was performed by column chromatography on silica gel using pentane as the eluent.

Synthesis of Tertiary Thiols. Tertiary thiols were prepared in a three-step synthesis from the corresponding alcohols by bromination,[9] followed by substitution of the bromine with zinc thioacetate[10] and reduction of the thioacetates with $LiAlH_4$. If the respective alcohol was not commercially available (e.g., 2-methyloctan-2-ol, 2-methylnonan-2-ol, and 2-methyldecan-2-ol), these were synthesized from the respective methyl ketone by a Grignard reaction with methylmagnesium bromide.

Tertiary Alcohols. To a solution of the respective methyl ketone (40 mmol) in diethyl ether (100 mL) was added a methylmagnesium bromide solution (3.0 mol/L in diethyl ether; 19 mL; 56 mmol) at 0 °C, and the mixture was refluxed for 2 h. The mixture was cooled to 0 °C, and water (50 mL) was slowly added, followed by an aqueous saturated ammonium chloride solution (40 mL) to dissolve the precipitate. The organic layer was separated, and the aqueous layer was extracted with diethyl ether (3 × 50 mL). The combined organic layers were washed with saturated aqueous sodium bicarbonate solution (50 mL), followed by water (50 mL). After drying over anhydrous sodium sulfate, the solvent was removed by rotary evaporation.

Bromination of the Tertiary Alcohol. Bromination was done as previously reported.[9] To a mixture of the tertiary alcohol (30 mmol) and lithium bromide (3.91 g; 45 mmol) was slowly added aqueous HBr (10.1 g; 60 mmol; 48%) at room temperature. The organic layer was separated, washed with ethylene glycol (3 × 10 mL), and dried over anhydrous sodium sulfate.

Thioacetylation of the Bromo Derivatives. Following the method by Gurudutt et al.[10] zinc sulfide (1.95 g; 20 mmol) was added to a solution of thioacetic acid (3.04 g; 40 mmol) in dichloromethane (40 mL), and stirred for 2 h at room temperature. The tertiary bromo derivative (20 mmol) was added, and the solution was refluxed for 10 h. The filtrate was washed with dichloromethane (50 mL), and the combined organic solutions were washed with aqueous hydrochloric acid (2 mol/L; 30 mL), followed by a saturated aqueous sodium bicarbonate solution (30 mL). After drying over anhydrous sodium sulfate, the solvent was removed by rotary evaporation. Purification of the compound was performed by column chromatography on silica gel using pentane/diethyl ether (99/1; v/v) as the eluent.

Reduction with $LiAlH_4$. Reduction with $LiAlH_4$ was performed as described above for the primary and secondary thiols.

Synthesis of Alkanedithiols. Alkanedithiols were prepared from the respective dibromoalkanes in a two-step procedure, that is, by thioacetylation with potassium thioacetate, followed by reduction with $LiAlH_4$ as described above.

Preparation of the Methylthioethers. Methylation of the thiols was done as previously reported.[11] To a solution of the thiol (4 mmol) in anhydrous tetrahydrofuran (12 mL) was added *n*-butyllithium (2.5 mol/L in hexane; 2 mL, 5 mmol) at 0 °C. The solution was allowed to warm to room temperature, and the mixture was stirred for 10 min. Then, methyl iodide (568 mg; 4 mmol) was added slowly at 0 °C, and the reaction mixture was stirred for 20 min at room temperature. After the addition of water (20 mL), the mixture was extracted with pentane (3 × 30 mL), and the combined organic layers were washed with water and dried over anhydrous sodium sulfate. The solvent was distilled off by means of a Vigreux column (50 × 1 cm). Purification of the compound was performed by column chromatography on silica gel using pentane as the eluent.

Gas Chromatography−Flame Ionization Detection (GC-FID) and Gas Chromatography−Olfactometry (GC-O). GC-FID and GC-O analyses were performed by means of a gas chromatograph 8160 (Fisons Instruments, Mainz, Germany) using helium as the carrier gas. Samples were applied by the cold-on-column injection technique. Capillaries used were DB-5 and DB-FFAP (each 30 m × 0.32 mm i.d., 0.25 μm film thickness, 70 kPa head pressure) (J&W Scientific, Chromatographie-Handel Mueller, Fridolfing, Germany). The temperature programs were adapted to the respective volatility of each analyte. For GC-O applications, the ends of the capillaries were connected to a deactivated Y-shaped glass splitter (Chromatographie Handel Mueller) dividing the effluent into two equal parts, which were transferred via two deactivated fused silica capillaries (50 cm × 0.25 mm) to a sniffing port and an FID, respectively. The sniffing port consisted of a cylindrically shaped aluminum device (80 mm × 25 mm i.d.) with a beveled top and a central drill hole (2 mm) housing the capillary. It was mounted on a detector base of the GC and heated to 200 °C. The FID was operated at 250 °C with hydrogen (20 mL/min) and air (200 mL/min). Nitrogen (30 mL/min) was used as the makeup gas. The injection volume was 1.0 μL. During a GC-O run, the nose of the panelist was placed closely above the top of the sniffing port, and the odor of the effluent was evaluated. If an odor was recognized, the retention time was marked in the chromatogram, and the odor quality was assigned. The evaluation was performed by three panelists, and the results were averaged. Panelists were trained on a

"flavor language" in weekly training sessions for at least 6 months, in which pure reference odorants were used.[14]

Gas Chromatography–Mass Spectrometry (GC-MS). Mass spectra were recorded after chromatography on a gas chromatograph 5890 series II (Hewlett-Packard, Waldbronn, Germany) connected to a sector field mass spectrometer MAT 95 S (Finnigan, Bremen, Germany). Mass spectra in the electron ionization mode (MS-EI) were recorded at 70 eV ionization energy and mass spectra in the chemical ionization mode (MS-CI) at 115 eV with isobutane as the reactant gas.

Determination of Odor Thresholds and Odor Qualities in Air. Thresholds were determined by aroma extract dilution analysis of a mixture containing known amounts of the target odorant and (*E*)-2-decenal as the internal standard. Thresholds were calculated from the flavor dilution (FD) factors determined by using the method previously described[12] and a threshold of 2.7 ng/L for (*E*)-2-decenal.[13] Odor qualities were assigned during GC-O at the threshold level.

Determination of Odor Thresholds in Water. Odor thresholds were determined following a procedure published previously.[14]

NMR Spectroscopy. The ^{1}H, ^{13}C, and 2D NMR experiments were performed using a Bruker 400 MHz DMX spectrometer (Bruker, Rheinstetten, Germany). Samples were dissolved in $CDCl_3$, and chemical shifts were determined using tetramethylsilane as the internal standard (0.03%) in the proton dimension and from the carbon signal of $CDCl_3$ (77.0 ppm) in the carbon dimension.

Molecular Modeling and Alignment. All molecular modeling studies, CoMFA, and partial least-squares (PLS) approaches were performed using the SYBYL-X 1.2 program package.[15] Initial template structures were built using Sybyl's Concord module. Energy minimizations were carried out using Tripos force field, and Gasteiger–Hückel charges were calculated for all molecules. For molecular alignment, 2-methylpentane-2-thiol, showing the lowest odor thresholds of all investigated sulfur-containing compounds, was used as the reference molecule. Superimposition was performed with the main focus on maximal alignment of the SH group.

Comparative Molecular Field Analysis (CoMFA). For CoMFA, the aligned molecules were positioned inside a three-dimensional grid box with a grid spacing of 2 Å. Steric and electrostatic fields were calculated using an sp^3 carbon probe atom with a van der Waals radius of 1.52 Å and a +1.0 charge. Steric and electrostatic cutoff values were set to 30 kcal/mol.

Partial Least Squares Regression. PLS regression was conducted to establish and validate the 3D-QSAR model. Thereby, the optimal number of principal components was determined using leave-one-out cross-validation.

RESULTS AND DISCUSSION

Syntheses. If not commercially available, primary and secondary thiols were synthesized according to a method described by Simian et al.[8] for the preparation of heptane-2-thiol from the respective primary and secondary alcohols, respectively. If the corresponding alcohols were not available, these were first synthesized by reduction of the corresponding carboxylic acids.

Because of the S_N1 activity of tertiary alcohols, tertiary thiols were prepared according to a different procedure (Figure 1). First, tertiary alcohols were synthesized from the respective methyl ketones by a Grignard reaction with methylmagnesium bromide. After bromination of the tertiary alcohol under S_N1 conditions,[9] followed by an S_N1 substitution of the bromine with zinc thioacetate,[10] the reduction of the thioacetate finally resulted in the targeted thiol in good yields.

Determination of Odor Thresholds. Although several methods for the determination of odor thresholds are available, the results of different methods are not necessarily comparable and may differ by several orders of magnitude.[16,17] Therefore, prior to the study of structure–odor correlations, the selection of an appropriate method for threshold determination was essential. For the following reasons a previously published[12] GC-O method was applied: First, the use of GC before sniffing removes odor-active impurities, which might influence the odor threshold of the target analyte. Second, during elution from the hot column, the compound is completely volatilized and can easily be compared to the threshold of a reference compound. Thus, the influence of different volatilities of the compounds depending on matrices when determined in water or oil, respectively, is negligible.

However, in comparison to a determination of odor thresholds in air, the determination of odor thresholds in water is rather quick and easy. Therefore, most of the odor thresholds published so far were measured in water. To show

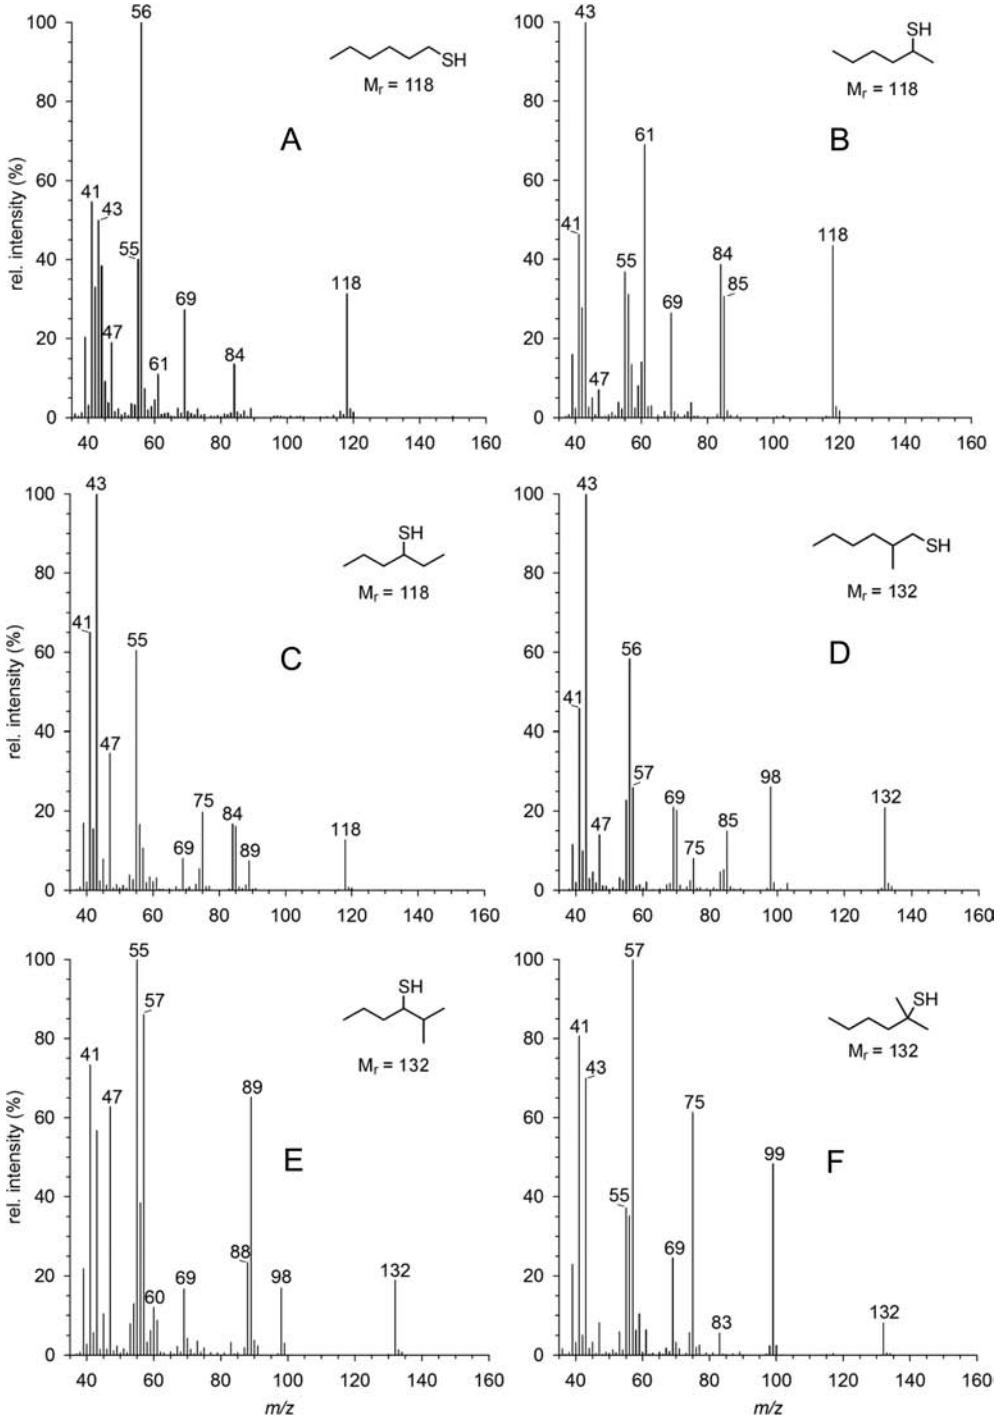

Figure 3. Selected mass spectra (MS-EI) of alkanethiols.

the correlation of odor thresholds in air and in water, thresholds of alkane-1-thiols were determined in both media. For the determination of odor thresholds in water, the thiols had to be purified by column chromatography on silica gel using *n*-pentane as the eluent. In Figure 2, the thresholds of the alkane-1-thiols are plotted versus the number of carbon atoms between 3 and 10. Interestingly, both curves showed a similar shape; however, thresholds in air were by a factor of 1000 lower than those in water. Clearly, in both media, a minimum in odor thresholds was found for hexane-1-thiol, and the highest odor threshold was measured for decane-1-thiol. These results suggest a similar potency of a single thiol independently from the method applied.

Alkane-1-thiols. The mass spectra of the alkane-1-thiols, illustrated by hexane-1-thiol (Figure 3A), revealed strong signals for M^+ (m/z 118). The presence of sulfur in the molecule was clearly indicated by the intensity of $[M + 2]^+$ and by the loss of H_2S (m/z 84). Further significant fragments resulted from an α- (CH_3S^+, m/z 47) and a β-cleavage ($C_2H_5S^+$, m/z 61) as well as from the loss of H_2S and ethylene ($[M - H_2S - C_2H_4]^+$, m/z 56). The fragments at m/z 69 ($C_5H_9^+$), m/z 55 ($C_4H_7^+$), m/z 43 ($C_3H_7^+$), and m/z 41 ($C_3H_5^+$) are formed by fragmentation of the alkyl chain. The

determination of the odor thresholds by GC-O revealed a significant decline from propane-1-thiol to pentane-1-thiol to reach a minimum for hexane-1-thiol (Table 1). With an increasing number of carbon atoms, the thresholds clearly increased with decane-1-thiol, showing a 27,000 fold higher odor threshold than hexane-1-thiol.

[a]For further spectroscopic data (MS-CI, NMR) see the Supporting Information. [b]Odor quality as perceived at the sniffing port during GC-O at threshold level. [c]Odor thresholds in air were determined as previously reported.[12] Data are mean values obtained by three panelists. [d]First report. [e]Correct IUPAC name is 3-methylbutane-2-thiol.

In agreement with the change in odor thresholds, also a change in odor qualities was observed. The short-chain homologues (C_3, C_4) showed garlic-like odors (Table 1). At the minimum level (C_5–C_7) the odor changed to burned, roasty aroma notes, and with increasing number of carbon atoms (C_9, C_{10}) the odor quality changed to fatty, soapy. All alkane-1-thiols except decane-1-thiol have already been reported as food constituents (Table 1).

Alkane-2-thiols. The mass spectra of the alkane-2-thiols, for example, hexane-2-thiol (Figure 3B), also revealed a strong signal for the molecular ion (m/z 118). In addition to the fragment at m/z 84 $[M - H_2S]^+$, also a signal at m/z 85 $[M - SH]^+$ appeared. A further characteristic fragment for the alkane-2-thiols resulted from an α-cleavage at m/z 61 ($C_2H_5S^+$). The odor thresholds of the alkane-2-thiols showed a similar dependency on the chain length as found for the alkane-1-thiols (Table 2). With a minimum at C_5, odor thresholds significantly increased up to 41,000 for C_{10}. As found for the alkane-1-thiols, also for the alkane-2-thiols a change in odor qualities to fatty, soapy odor notes was observed with increasing carbon number (Table 2), and most of these thiols have been reported in foods before. The odor thresholds and odor qualities of the racemic mixtures were determined without differentiation of the single enantiomers.

Alkane-3-thiols. The mass spectra of the alkane-3-thiols, illustrated by hexane-3-thiol (Figure 3C), also showed strong signals for M^+ (m/z 118), $[M - H_2S]^+$ (m/z 84), and $[M - SH]^+$. Characteristic fragments for the alkane-3-thiols at m/z 89 ($C_4H_9S^+$) and m/z 75 ($C_3H_7S^+$) resulted from an α-cleavage. The odor thresholds of the alkane-3-thiols rose exponentially with increasing length of the alkyl chain (Table 3), and the odor threshold of decane-3-thiol was 71,000 times higher than that of pentane-3-thiol.

With the change in odor thresholds, also a change in odor qualities from burned, roasty odors to fatty aroma notes occurred (Table 3). Interestingly, none of these alkane-3-thiols have ever been reported as food constituents.

2-Methylalkane-1-thiols. Mass spectra of the 2-methylalkane-1-thiols, for example, for 2-methylhexane-1-thiol (Figure 3D), again revealed strong signals for M^+ (m/z 132) and $[M - H_2S]^+$ (m/z 98). Typical fragments for primary thiols with a methyl group in the α-position to the thiol function were $C_3H_7S^+$ (β-cleavage, m/z 75) and $C_5H_{10}^+$ (m/z 70). The 2-methylalkane-1-thiols showed rather constant threshold values between C_4 and C_6 (Table 4). However, a further extension of the alkyl chain (2-methylheptane-1-thiol) resulted in a clear increase in odor thresholds by a factor of 75. All homologues exhibited burned, roasty aroma notes (Table 4).

2-Methylalkane-3-thiols. Mass spectra of the 2-methylalkane-3-thiols, represented by 2-methylhexane-3-thiol (Figure 3E), displayed typical signals for the molecular ion M^+ (m/z 132) as well as $[M - H_2S]^+$ (m/z 98). A further characteristic fragment for this homologous series of thiols was $[M - C_3H_7]^+$ (m/z 89). As with the 2-methylalkane-2-thiols, also the 2-methylalkane-3-thiols revealed rather constant threshold values between C_4 and C_6 followed by a significant increase in odor thresholds starting at C_7 (Table 5).

2-Methylalkane-2-thiols. Because of the stability of the tertiary carbenium cation, the 2-methylalkane-2-thiols, in contrast to the primary and secondary thiols, showed considerably higher signals for $[M - SH]^+$ (m/z 99; shown for 2-methylhexane-2-thiol, Figure 3F), whereas the fragment $[M - H_2S]^+$ (m/z 98) showed only a very weak intensity. A

[a]For further spectroscopic data (MS-CI, NMR) see the Supporting Information. [b]Odor quality as perceived at the sniffing port during GC-O at threshold level. [c]Odor thresholds in air were determined as previously reported.[12] Data are mean values obtained by three panelists. [d]First report.

further characteristic fragment for the 2-methylalkane-2-thiols resulted from the α-cleavage at m/z 75 ($C_3H_7S^+$). The odor thresholds of the tertiary 2-methylalkane-2-thiols also revealed a strong dependency on the length of the alkyl chain (Table 6). After a minimum in the odor threshold of 2-methylpentane-2-thiol, threshold values exponentially increased with increasing carbon number by a factor of 290,000 between C_5 and C_{10}. With an extremely low odor threshold and an exceptional black currant-like aroma note, 2-methylpentane-2-thiol and 2-methylhexane-2-thiol were the most remarkable compounds in this homologous series. Neither compound has ever been detected in foods. With increasing chain length ($\geq C_7$), however, again roasty, fatty aroma notes occurred (Table 6).

Alkane-1,ω-dithiols. The presence of two sulfur atoms in the mass spectra of the alkane-1,ω-dithiols, illustrated by hexane-1,6-dithiol (Figure 4A), was indicated by the intensity of $[M + 2]^+$ (m/z 154, 8.5% in comparison to M^+). Further characteristic fragments were $[M - H_2S]^+$ (m/z 116) and the base peak at m/z 87. The odor thresholds of the alkanedithiols were also strongly influenced by the length of the carbon chain (Table 7). Propane-1,3-dithiol, butane-1,4-dithiol, and pentane-1,5-dithiol showed almost identical odor thresholds, but with increasing carbon numbers, the thresholds of the alkanedithiols increased exponentially. Propane-1,3-dithiol showed a garlic-like odor note, whereas the other homologues revealed a cabbage-like aroma quality (Table 7). Compounds with carbon numbers three to six have previously been identified only in beef meat.

To study the influence of an S-alkylation, the thiols reported above were methylated to obtain the respective thioethers.

1-(Methylthio)alkanes. Besides strong signals for the molecular ion, mass spectra of the 1-(methylthio)alkanes, for example, 1-(methylthio)hexane (Figure 4B), revealed characteristic fragments resulting from methyl elimination (m/z 117) and an α-cleavage (m/z 61, $C_2H_5S^+$). The 1-(methylthio)-alkanes showed a minimum in their odor thresholds for 1-(methylthio)heptane (Table 8), but with increasing chain length threshold values increased to 490 ng/L air for C_{10}. The compounds in this homologous series showed predominantly metallic, sweet, and garlic-like aroma qualities, except the long-chain homologues (C_9, C_{10}) exhibiting fatty odor qualities (Table 8).

2-(Methylthio)alkanes. As illustrated for 2-(methylthio)-hexane (Figure 4C), mass spectra of the 2-(methylthio)alkanes showed signals for M^+ (m/z 132) and $[M - CH_3]^+$ (m/z 117). A further characteristic fragment resulted from the β-cleavage yielding m/z 75.

Up to a carbon number of eight, odor thresholds for the 2-(methylthio)alkanes remained relatively constant (Table 9). By contrast, the longer homologues (C_9/C_{10}) showed considerably higher thresholds. For the C_4–C_6 homologues burned, garlic-like aroma qualities were dominant, whereas in C_7–C_{10} compounds mushroom-like odors were detected (Table 9).

3-(Methylthio)alkanes. As for the 2-(methylthio)alkanes, mass spectra of the 3-(methylthio)alkanes revealed a distinct signal for M^+ (Figure 4D), as for 3-(methylthio)hexane, and a weak signal for $[M - CH_3]^+$ (m/z 117). Characteristic signals for the methylthio group in the 3-position, resulting from an α-cleavage, were at m/z 103 ($C_5H_{11}S^+$) and m/z 89 ($C_4H_9S^+$). Odor thresholds of the 3-(methylthio)alkanes increased exponentially with increasing carbon number (Table 10). However, in particular, the thresholds of 3-(methylthio)nonane and 3-(methylthio)decane were too high (>1500 ng/L) to be accurately measured by GC-O. The compounds of this homologous series showed predominantly metallic, sweet aroma qualities (Table 10).

2-Methyl-2-(methylthio)alkanes. In contrast to the primary and secondary methylthioalkanes, the mass spectra of the tertiary 2-methyl-2-(methylthio)alkanes, shown for 2-methyl-2-(methylthio)hexane (Figure 4E), revealed a signal for $[M - SCH_3]^+$ (m/z 99). Further characteristic fragments were M^+ (m/z 146), $[M - CH_3]^+$ (m/z 131), and a fragment ion at m/z 89 resulting from the α-cleavage. As for the 3-(methylthio)alkanes an extension of the alkyl chain resulted in exponentially increasing odor thresholds (Table 11). The thresholds of the C_9 and C_{10} homologues were also too high (>1500 ng/L) to be accurately measured by GC-O. From C_4 to C_6, spicy odor qualities were dominant, which were replaced by mushroom-like odors for compounds with seven to eight carbons (Table 11).

Influence of Thiol Exchange or Modification on Odor Thresholds. *Chain Length.* The biggest effect on odor thresholds of all examined alkanethiols was observed for the length of the alkyl chain. Primary and secondary as well as tertiary thiols showed a very similar dependency on the chain

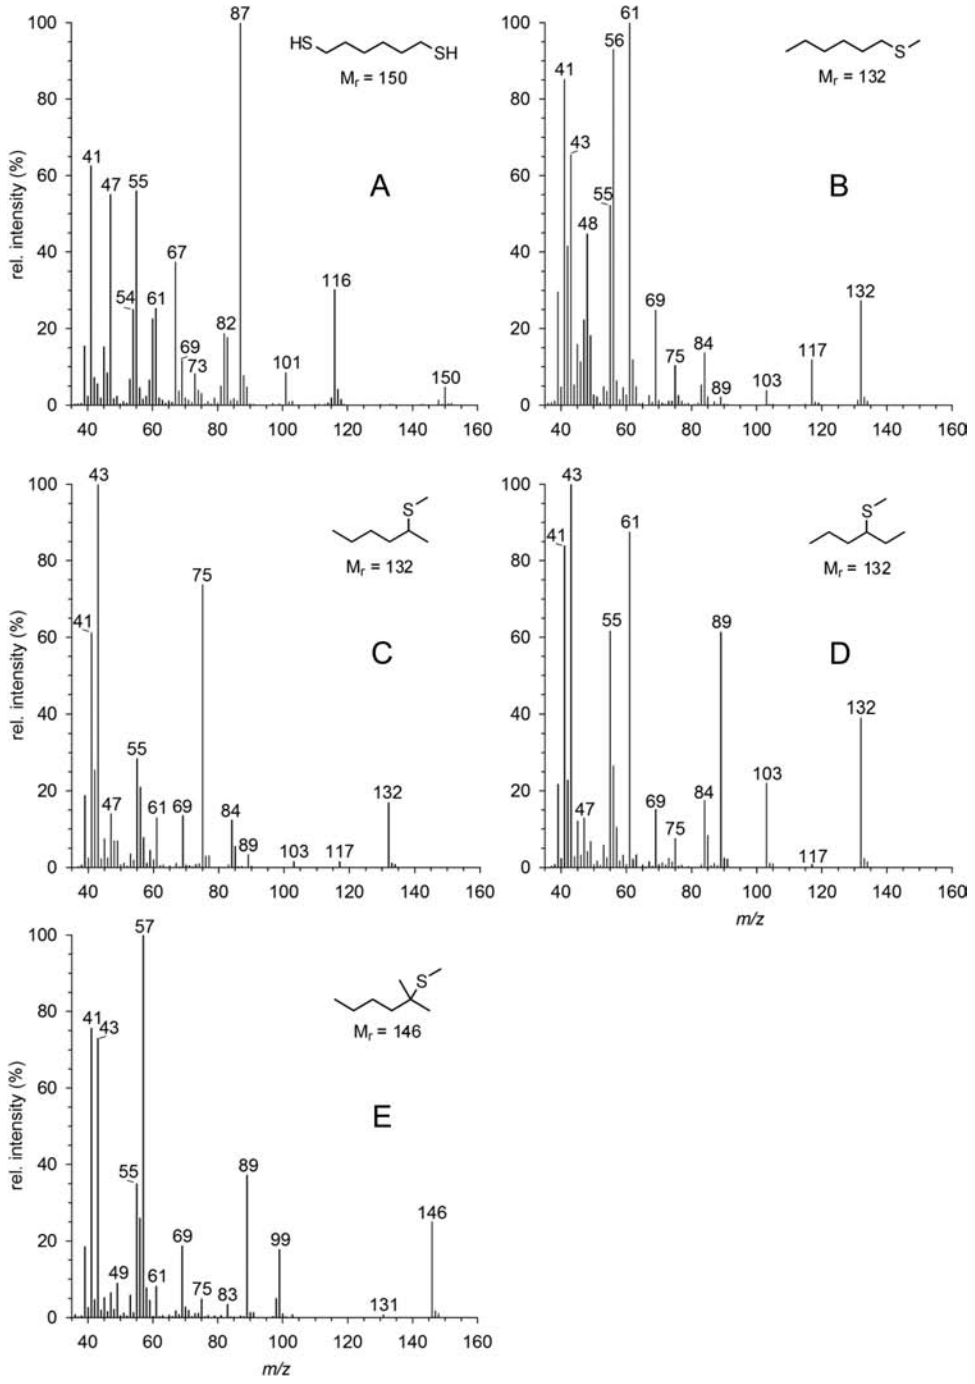

Figure 4. Selected mass spectra (MS-EI) of alkanedithiols and (methylthio)alkanes.

length (Figure 5): After a decline by a factor of ~10 from C_3–C_4 or C_4–C_5, all four homologous series showed a minimum in odor thresholds for thiols with five to seven carbon atoms, but with increasing chain length the thresholds considerably increased. The alkanethiols at minimum level, for example, 2-methylpentane-2-thiol or pentane-3-thiol, with odor thresholds in the range of pico- or femtograms per liter air, belong to the most potent odorants reported so far in the literature. By contrast, the corresponding C_{10} homologues, showing by factors of 27,000 (alkane-1-thiols) or 290,000 (2-methylalkane-2-thiols) higher thresholds than these two thiols, were almost odorless. These results suggest that, besides the importance of the mercapto group on the odor activity of thiols, the odor perception of mercaptans is also strongly influenced by steric effects.

With increasing substitution at the mercapto-containing carbon atom, the thresholds at minimum level decreased. For example, the primary alkane-1-thiols showed by a factor of 20 higher odor thresholds at minimum level than tertiary 2-methylalkane-2-thiols. This is in accordance with the results of Meilgaard,[1] who determined the odor thresholds of, for example, butane-1-thiol, butane-2-thiol, and 2-methylbutane-2-thiol occurring in beer. Furthermore, this is consistent with the theories of Wang et al.[18] and Duan et al.,[19] who found some evidence that metal ions such as zinc(II) or copper(II) may be involved in olfactory perception of thiols at the receptor level.

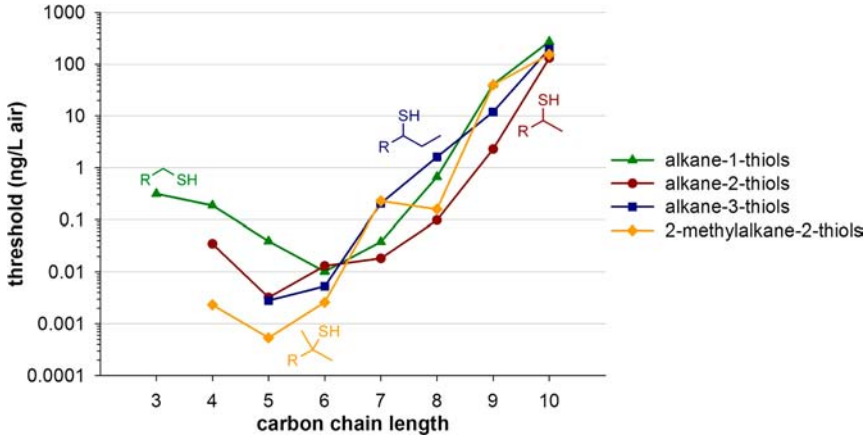

Figure 5. Influence of the chain length on odor thresholds of homologous primary, secondary, and tertiary alkanethiols.

center of a hypothetical olfactory receptor than primary thiols, leading to a more sensitive detection resulting in lower odor thresholds. In agreement with this hypothesis, methyl substitution in the α-position to the SH group, in contrast to a tertiary methyl substitution, did not lower the odor thresholds (Figure 6). The 2-methylalkane-1-thiols as well as 2-methylalkane-3-thiols showed almost the same dependency on the chain length, but exhibited even higher thresholds at minimum level than the respective alkane-1-thiols.

Odor Quality. Because sensory properties of sulfur compounds are often strongly dependent on their concentrations, all odor qualities were determined at threshold level. Nevertheless, with the change in odor thresholds also a change in odor qualities was observed among the members of the

homologous series, whereas compounds with identical chain length of different homologues series often showed similar odor qualities. The C_3 and C_4 homologues of primary and secondary thiols showed garlic-like, burned odor notes. At minimum level, for the C_5 and C_6 homologues, burned, roasty odors were detected, but with increasing carbon numbers (C_9 and C_{10} homologues) the odor changed to fatty, soapy notes. By contrast, short-chain tertiary thiols (C_4–C_7) showed exceptional catty, black currant-like aroma notes. 2-Methylpentane-2-thiol and 2-methylhexane-2-thiol displayed the most attractive odor of all examined mercaptans in this study, and both thiols were previously not identified in foods. With a threshold of 0.00053 ng/L, 2-methylpentane-2-thiol also showed the lowest value of all thiols examined. Surprisingly, with increasing chain length (>C_7) tertiary thiols revealed odor qualities similar to those of the corresponding primary and secondary thiols.

Influence of a Second Mercapto Group. To study the influence of a second thiol group on odor perception, odor thresholds of some alkane-1,ω-dithiols were determined. In contrast to the alkane-1-thiols, the alkanedithiols did not show a clear minimum (Figure 7). Propane-1,3-dithiol, butane-1,4-dithiol, and pentane-1,5-dithiol showed almost identical odor thresholds. With increasing carbon numbers also the thresholds of alkanedithiols increased exponentially as found for the alkane-1-thiols. Altogether, the thresholds of alkane-1-thiols at minimum level were clearly lower than those of the alkane-1,ω-dithiols; for example, hexane-1-thiol had a 35 times lower odor threshold than hexane-1,6-dithiol. Thus, it can be concluded that a second mercapto group in the molecule does not result in an additional activation of SH-specific odorant receptors leading to a lower odor threshold.

Importance of the Mercapto Group. To show the influence of the free mercapto group on odor thresholds, on the one hand the SH group was replaced by the chemically related OH group. On the other hand, the mercapto group was blocked by S-methylation and the thresholds obtained were compared to the thresholds of the alkanethiols.

In comparison to the alkanethiols, the corresponding alcohols showed a completely different dependency of odor thresholds with respect to chain length (Figure 8A). In contrast to the thiols, the odor thresholds of the alcohols clearly decreased with increasing carbon number from C_3 to C_8. The thresholds of some of the short-chain homologues (butan-2-ol, pentan-2-ol, and 2-methylbutan-2-ol) were very high and exceeded the measurement range of GC-O (Table 12). From C_9 to C_{10} the thresholds of the alcohols stayed relatively constant with a weak maximum at C_9 for the secondary and tertiary alcohols. From C_3 to C_8 all alcohols showed much higher odor thresholds than the corresponding thiols. The thresholds of the alcohols were by factors of 16,000 (primary thiols) and 1,200,000 (tertiary thiols), respectively, higher than those of the corresponding thiols at minimum level. With increasing chain length, the odor thresholds of alcohols and thiols were nearly identical, and, finally, for the C_9/C_{10} homologues some alcohols even showed lower thresholds than the corresponding thiols.

This different behaviors of alcohols and thiols indicate that chemoreception of thiols should occur by different mechanisms or at different olfactory receptors than the perception of alcohols, also, because the alcohols showed mainly fruity odors (Table 12). Correlations between the odor qualities of alcohols and thiols, as described by Sakoda and Hayashi[4] for alkane-2-ols and alkane-2-thiols, could not be confirmed.

Table 12. Odor Qualities and Odor Thresholds of Alkanols

compound	odor quality[a]	odor threshold[b] (ng/L in air)
propan-1-ol	pungent, solvent, ethanolic	635
butan-1-ol	pungent, solvent, fruity	336
pentan-1-ol	solvent, fruity, flowery	673
hexan-1-ol	fruity, green	158
heptan-1-ol	fruity, flowery, soapy	81
octan-1-ol	fruity, soapy	42
nonan-1-ol	green, soapy, fatty	21
decan-1-ol	fatty, soapy	21
butan-2-ol		>1500
pentan-2-ol		>1500
hexan-2-ol	fruity, flowery, solvent	317
heptan-2-ol	fruity, flowery	20
octan-2-ol	fruity, soapy	20
nonan-2-ol	fruity, green	87
decan-2-ol	soapy, sour	20
pentan-3-ol	pungent, solvent	1385
hexan-3-ol	fruity, soapy	645
heptan-3-ol	fruity, flowery	169
octan-3-ol	fruity, flowery	39
nonan-3-ol	fruity, fatty	164
decan-3-ol	fatty, soapy	158
2-methylbutan-2-ol		>1500
2-methylpentan-2-ol	fruity, sweet	646
2-methylhexan-2-ol	fruity, flowery, coriander	315
2-methylheptan-2-ol	fruity, flowery, coriander	9.9
2-methyloctan-2-ol	fruity, soapy, mushroom-like	10
2-methylnonan-2-ol	fruity, soapy	186
2-methyldecan-2-ol	soapy, fatty	79

[a]Odor quality as perceived at the sniffing port during GC-O at threshold level. [b]Odor thresholds in air were determined as previously reported.[12] Data are mean values obtained by three panelists.

Methylation of the SH group also resulted in an increase in odor thresholds (Figure 8B). Like the thiols, the (methylthio)-alkanes showed higher odor thresholds with increasing chain length, and the thresholds of 2-methyl-2-(methylthio)nonane and 3-(methylthio)decane were even too high to be accurately measured by GC-O. In contrast to the thiols, the (methylthio)-alkanes did not show clear minima within their homologous series. Apart from the 1-(methylthio)alkanes, all homologous series exhibited their lowest thresholds at C_4. Up to a carbon number of seven, methylation of the thiol group led to a strong increase in odor thresholds, and the thresholds of the corresponding (methylthio)alkanes differed by factors of 180 (primary thiols) to 9000 (tertiary thiols), respectively. Therefore, blocking of the SH group by methylation clearly reduced the olfactory power of the thiols. The data highlight that the free thiol group is an important structural feature for the low odor thresholds of sulfur compounds. Most of the short-chain (methylthio)alkanes showed typical sulfury odors, often with additional metallic or garlic-like odor notes. With increasing chain length (C_7/C_8) odor qualities changed to mushroom-like odors, and finally at C_9/C_{10} also fatty odor notes occurred, as also found for the thiols.

3D-QSAR Studies. To get a first insight into the odotope structure defining the space for a low odor threshold in mercaptans, 3D-QSAR calculations were performed. Using CoMFA, 3D-QSAR models were established to correlate the

threshold data of the 44 thiols analyzed with their molecular structures. The calculation of positive (resulting in lower thresholds) and negative (resulting in higher thresholds) steric and electrostatic fields showed that most of the differences in odor thresholds can be explained by steric effects, whereas electrostatic fields had only little influence on odor thresholds. The thresholds simulated by the theoretical model were in good agreement with the experimentally determined data (Figure 9). Statistical validation showed a reliable model with a

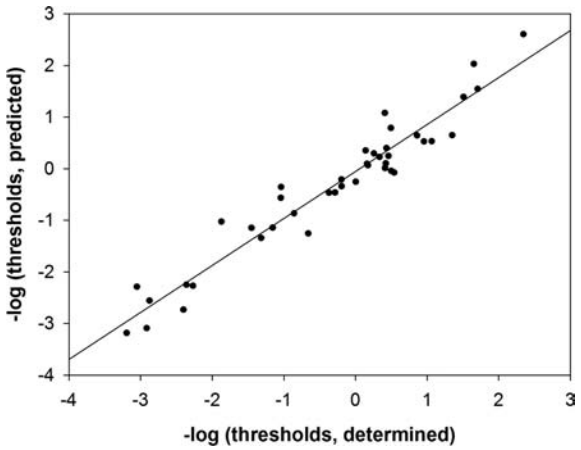

Figure 9. Correlation of determined and predicted odor thresholds of alkanethiols.

coefficient of correlation (r^2) of 0.89 (q^2 = 0.63) at a number of 10 principal components and a standard deviation (s) of 0.52. However, more data are needed to validate this model.

In conclusion, the results have revealed that odor perception of alkanethiols is strongly influenced by steric effects, such as the length of the carbon chain or an additional methyl group in the carbon chain, but in particular only one free SH group is essential for the low odor thresholds of sulfur compounds. Blocking this SH group by alkylation clearly reduced the olfactory power, whereas a second mercapto group in the molecule did not lower the odor thresholds.

scopic characteristics that facilitate collection of information which is complementary to the infrared techniques. These include its relative insensitivity to water and ability to reveal significant information on composition and structure of macromolecules, especially protein, in foods. On the contrary, fluorescence can be a problem, especially with biological materials, and Raman signals are weak. However, fluorescence can be minimized by both appropriate laser wavelength selection and mathematical processing of collected spectra while weak Raman signals are no longer a serious disadvantage due to improved detector sensitivity and the technical feasibility of using longer collection times.

Raman spectroscopy has been reported to predict the sensory quality of beef silverside,[20] to quantify saturated and unsaturated fatty acids in pork adipose tissue,[21] to predict water-holding capacity in meat,[22] to detect protein contents in meat and fish,[23−25] and to predict meat spoilage.[26] Only a small number of studies have reported the use of Raman spectroscopic methods to detect meat adulteration. These have included the use of Raman spectroscopy combined with multivariate analysis to classify adipose tissue in different meat species,[27] to confirm authenticity of poultry species,[28] and to detect and quantify horse meat content in minced beef.[29]

Beefburgers, a classic type of minced beef product, are regularly consumed in the developed world. A typical beefburger is produced as a homogenized item composed of minced beef, water, added fat, certain cereal products (e.g., rusk), and flavoring agents. Some vegetables (spring onion, onion etc.) may be present in greater or lesser amounts in particular formulations. Furthermore, beefburgers may be produced in higher or lower quality variants and sold in either the fresh or frozen state. In this study, an experimental design was undertaken to cover the widest possible range of formulations involving beef offal types (i.e., kidney, liver, heart, and lung) and other ingredients (i.e., water and rusk) in the least number of experiments. Both classification and class-modeling approaches were studied to try to distinguish between the authentic and offal-adulterated beefburgers manufactured. Quantitative models for total offal incorporation and added fat prediction were also developed. The present study investigated detection of beef offal (i.e., kidney, liver, heart, and lung) adulteration in frozen-then-thawed beefburgers using Raman spectroscopy and multivariate data analysis. The main aim of the study was to explore the potential of Raman spectroscopy for addressing authentication issues in processed meat products with complex formulations.

MATERIALS AND METHODS

Beefburger Formulation and Manufacture. *Beefburger Formulation.* Authentic beefburgers comprised two groups, so-called lean burgers and fat burgers, which correspond to higher and lower quality grades. Higher quality burgers contained only lean beef and beef fat; lean meat content was varied between 80 and 100% w/w of burger in 2.5% increments, with fat accounting for the remainder. Lower quality burgers contained rusk (5% w/w) and water (20% w/w) in addition to lean beef (45−65% w/w in 2.5% increments) and beef fat (30−10% w/w in 2.5% increments). These compositional ranges were based on market intelligence concerning those typically used in the butchery trade. Burgers in each of the two groups were made on separate occasions, beginning with the highest lean meat content and moving to the lowest. Depending particularly on the quality of the lean meat purchased, production of either group could require more than 1 day. Each group of beefburgers was produced on two separate occasions; therefore, a total of 36 (18 higher quality and 18 lower quality) authentic beefburgers was prepared.

Adulterated beefburgers were formulated with lean beef, beef fat, water, rusk, and offal (liver, lung, kidney, and heart). Formulations were produced using a D-optimal experimental design (Design Expert v. 7.6.1, Stat-Ease Inc., Minneapolis, MN, USA) with minimum and maximum incorporation levels of meat (0−75% w/w), fat (0−25% w/w), water (0−15% w/w), and rusk (0−5% w/w) set by the operator; each formulation also contained liver, lung, kidney, and heart, each at concentrations between 0 and 20% w/w. A total of 46 different beefburger formulations was generated by the software to efficiently represent the design space for the multitude of possible combinations of ingredients. These beefburgers were produced in random order over a period of several days; because of time constraints, each formulation was produced only once. Variability in this data set was maximized by sourcing meat and offal from several suppliers and on different occasions. Adulterated beefburger formulations are shown in Table 1.

Beefburger Manufacture. Fresh beef (brisket), beef offal (kidney, liver, lungs, and heart), and beef fat were purchased from local stores and stored overnight at 4 °C at Teagasc Food Research Centre Ashtown. Skin, fatty tissue, connective tissue, visible blood vessels, and cartilage were removed to ensure the highest possible quality of the raw materials. Raw materials were cut into cubes, weighed, and mixed according to each formulation before mincing; mixed meat samples were minced twice (Mainca meat mincer, Cheshire, England) through a mesh plate (5 mm diameter holes). In between the two mincing occasions and when required by the formulation, sifted pinhead rusk (Redbrook, Damastown, Dublin) and iced water were blended into the minced meat by hand for 2−3 min. After the second mincing step, the mixture was pressed into a standard beefburger mold. Between each formulation, the meat mincer was washed with warm water and detergent, rinsed with warm water, and then wiped dry with tissue paper. Ten burgers were made for each formulation; two out of the ten were randomly picked and placed in storage at −20 °C.

In total, 82 beefburger samples (36 authentic, 46 adulterated) were prepared. It should be noted that one of the adulterated formulations generated by the experimental design software required the incorporation of no offal, i.e., it was in fact an authentic formulation. To avoid complications in data analysis, it was removed from the data set; therefore, 36 authentic and 45 adulterated samples were studied.

Spectroscopic Measurements. Before spectroscopic analysis, frozen beefburgers were removed from −20 °C storage and allowed to thaw at room temperature for ∼16 h. Each frozen-then-thawed sample was homogenized using a Robot Coupe R301 ultra (Vincennes, France) for 1 min and transferred into a sterile plastic container. The Robot Coupe mincing bowl was washed with detergent, rinsed with tap water, and wiped dry after each sample.

Raman spectra were collected on a DXR SmartRaman spectrometer (ThermoFisher Scientific UK Ltd., Loughborough, UK) equipped with a diode laser operating at 780 nm to minimize sample fluorescence issues and a charge coupled device (CCD) detector operating at −50 °C. For analysis, approximately 10 g of homogenized beefburger was wrapped in PVC clingfilm to form a ball. A smooth side of the wrapped sample was then placed over the aperture of the universal platform sampling (UPS) accessory. All spectra of each sample were accumulated for 3 min (i.e., 15 s exposure time × 20 exposures) using a 100 mW laser power setting. Samples were scanned in random order at ambient temperature (∼20 °C). Raman intensity counts per second (cps) were recorded over the wavelength range 250−3380 cm^{-1} at 2 cm^{-1} intervals). Cosmic spikes were removed automatically by supplied software, while fluorescence correction of spectra was performed using a fifth-order polynomial. Instrument control, spectral acquisition, and file conversion were performed using supplied OMNIC software (v 9.2.98; Thermo Fisher Scientific Inc., USA). Each sample was scanned three times, once each at three different scan sites on the sample ball; the mean of these replicate spectra was used in subsequent chemometric operations.

Chemometric Operations. *Data Pretreatments.* Spectra were exported from OMNIC software as JCAMP.DX files and imported directly into The Unscrambler software (version 9.7; Camo,

Trondheim, Norway), which was used for all preprocessing and chemometric analyses. Spectral data in the fingerprint range 900−1800 cm^{-1} (which is rich in information on water, protein, fat, and glycogen species in meat matrices[22]) were used in all chemometric operations; they were used either without modification (raw) or after preprocessing by normalization to unit vector length (u.v.nor) or Savitzky−Golay derivatisation (note: first derivatives with 5, 9, or 13 points, second derivatives with 5, 9, 13, or 17 points were employed for the trials; eventually first derivatives with 9 points and second derivative with 17 points were selected for use in this study due to their better performances than the others). Additionally, models were developed after both a baseline correction (Savitzky−Golay derivatives) and subsequent normalization step in that order as previously recommended for quantitative Raman applications.[30] These pretreatments have the potential to remove undesirable systematic variation in the data and thus facilitate the development of classification models with best performance; moreover, Savitzky−Golay derivatives can reveal otherwise hidden structure in the spectral data which may make it easier to uncover the chemical basis of the observed signals.

Principal Component Analysis (PCA). Principal component analysis (PCA) of the raw spectral data was used to compress the Raman spectral data via orthogonal constructions. In this study, PCA was used to visually examine the distribution of frozen-then-thawed authentic and offal-adulterated beefburgers in PC space to (i) detect any relevant sample clustering and (ii) identify any unusual or outlying samples.[31]

Partial Least-Squares-Discriminant Analysis (PLS-DA) Models. To discriminate between authentic and offal-adulterated beefburgers, PLS-DA calibration models were developed and evaluated on separate calibration and validation sample sets. Each such set represented approximately 50% of the total sample numbers. In the case of adulterated samples, odd-numbered samples were selected as calibration samples while the remainder were used for validation. In the case of authentic samples, both examples of half of the formulated beefburgers were used for calibration development and the other 50% used in validation. This was to avoid overoptimistic model statistics which would likely arise if one example of each formulation were to be used in calibration and the other in validation. Calibration models were developed using full, i.e., leave-one-out cross-validation; optimum model complexity was determined using the first local minimum in PLS residual variance plots. For PLS-DA models, a dummy *Y*-value was given to each sample, viz. 0 for adulterated samples and 1 for authentic samples. During validation, samples with a predicted value ≥ 0.5 were identified as authentic while those with a value <0.5 were identified as adulterated. Model performance was evaluated on the basis of correct classification rates.

Soft Independent Modeling of Class Analogy (SIMCA) Models. In a class-modeling approach, SIMCA models of authentic beefburgers were developed using 50% of the authentic samples as described above; model performance was estimated using all remaining samples, i.e., the remaining 50% of the authentic samples plus all of the adulterated material. A 5% significance value was utilized for membership determination. The characteristic limitation of SIMCA relates to the fact that principal components are calculated on the basis of variability in spectroscopic measurements alone and individual PCs may not be clearly related to chemical data of specific relevance in any class model. Principal components describe decreasing amounts of variability in spectral data, and the calculated components may not be directly linked to membership of any given class. In contrast, PLS regression involves *Y*-values in the calculation of PLS factors and therefore includes a targeted contribution to PLS scores from *Y*. In an attempt to improve SIMCA modeling, therefore, PLS scores were input to the SIMCA modeling process in a separate exercise. Model performances were evaluated on the basis of sensitivity, specificity, and efficiency. Sensitivity is defined as the fraction of samples belonging to the modeled class which is correctly accepted by the respective model; specificity is that fraction of samples not belonging to the modeled class that is correctly rejected by the model.[32] Efficiency summarizes the sensitivity and specificity of model performance by calculating the geometric mean of their values. Index values of efficiency vary between 0 and 1.[32] In our case, sensitivity was described as the fraction of authentic samples correctly identified by the authentic beefburger model; specificity was the fraction of adulterated samples correctly rejected by the same model; efficiency was calculated as

$$\text{Efficiency} = (\text{Sensitivity} \times \text{Specificity})^{0.5} \quad (1)$$

Partial Least-Squares Regression (PLSR) Models. To quantify offal and added fat adulteration in adulterated beefburgers, PLSR linear models were developed. In the case of offal, *Y*-values were ascribed to each sample according to the total quantity (%w/w) of offal (i.e., heart + liver + kidney + lung) in each formulation. PLS regression models were also developed to quantify added fat in all samples. Half of the

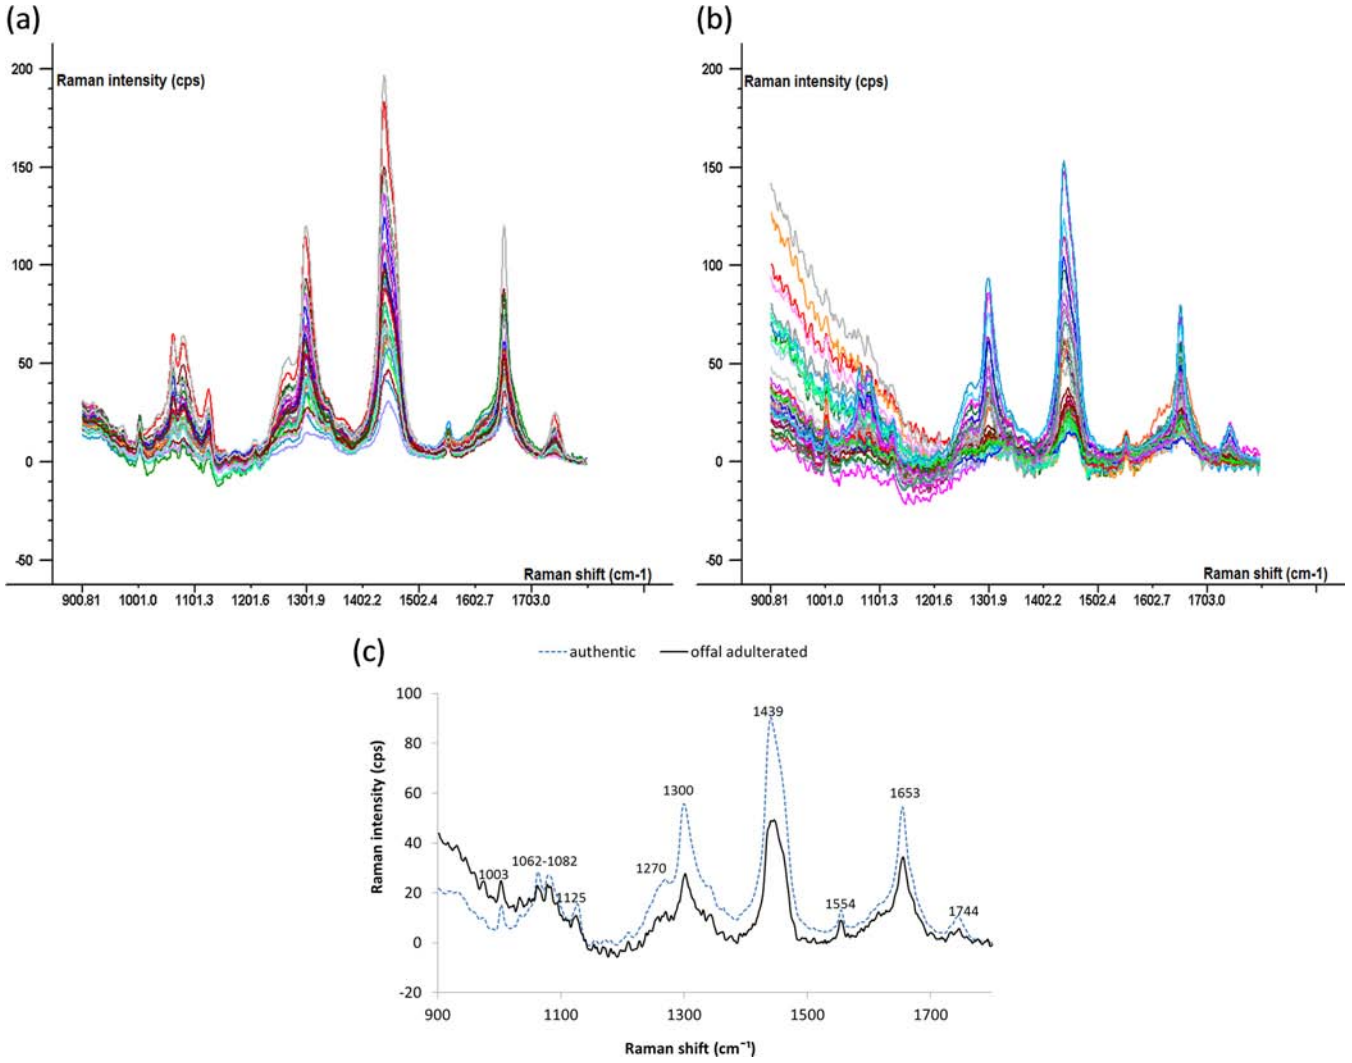

Figure 1. Spectra of (a) authentic beefburgers, (b) adulterated beefburgers, and (c) average spectra of authentic and adulterated beefburgers.

samples were randomly selected as the calibration data set to develop PLS models; the other half was used as the validation data set.

Model performances were evaluated by the correlation coefficients and root-mean-square errors in the calibration (i.e., R^2CV, RMSECV) and the validation (i.e., R^2P, RMSEP) exercises with the bias value calculated. In this case, these values were calculated based on the reference and predicted values of offal or added fat adulteration in beefburger samples. R^2, RMSE, and bias were calculated as follows:

$$R^2 = 1 - \frac{\sum_{i=1}^{n} (\hat{y}_i - y_i)^2}{\sum_{i=1}^{n} (\hat{y}_i - \bar{y})^2} \quad (2)$$

$$\text{RMSE} = \left(\frac{\sum_{i=1}^{n} (y_i - \hat{y}_i)^2}{n} \right)^{0.5} \quad (3)$$

$$\text{Bias} = \frac{\sum_{i=1}^{n} y_i - \hat{y}_i}{n} \quad (4)$$

Where $\hat{y}_i$ and y_i are the predicted and reference values of one sample (i); $\bar{y}$ is the mean of the reference values of all the samples. The value of R^2 is expected to be close to 1 while values of RMSE and bias are expected to be close to 0. A value of R^2 above 0.82 indicates good or excellent performance of a model while a value of R^2 below 0.81 reveals imprecise performance of model.[31]

RESULTS AND DISCUSSION

Raman Spectral Data. Raman spectra (900−1800 cm^{-1}) of frozen-then-thawed authentic and offal-adulterated samples are shown in Figure 1a,b. The major features of these two sets of spectra occur at the same or similar peak positions, although there is an obviously larger and more variable Raman intensity spread over the 900−1231 cm^{-1} range in offal-adulterated samples than is the case for authentic material. Average raw Raman spectra acquired from authentic and offal-adulterated beefburger samples are shown in Figure 1c. Spectra in this wavelength range provide information on some of the main biochemical components of beefburgers; peaks at 1645−1685 and 1200−1350 cm^{-1} have been related to the secondary and tertiary structure of proteins, i.e., amide I and amide III bands, respectively. The peak at 1653 nm is probably due to α-helical structures, while those at 1270 and 1300 cm^{-1} have been attributed to $\alpha_{globular}$- and $\alpha_{fibrous}$-helix formations.[20] Phenylalanine is a strong absorber at 1003 cm^{-1}, tryptophan shows a specific peak at 1554 cm^{-1}, and the peak at 1439 cm^{-1} has been attributed to a CH_2 scissoring vibration in proteins.[20] Bands in the 1062−1082 cm^{-1} region have been reported as originating in the C−O stretching of aspartic and glutamic acids.[25,33] It should be noted, however, that Raman spectral peaks at some of these wavenumbers (i.e., 1744, 1653, 1439, 1300, 1270,

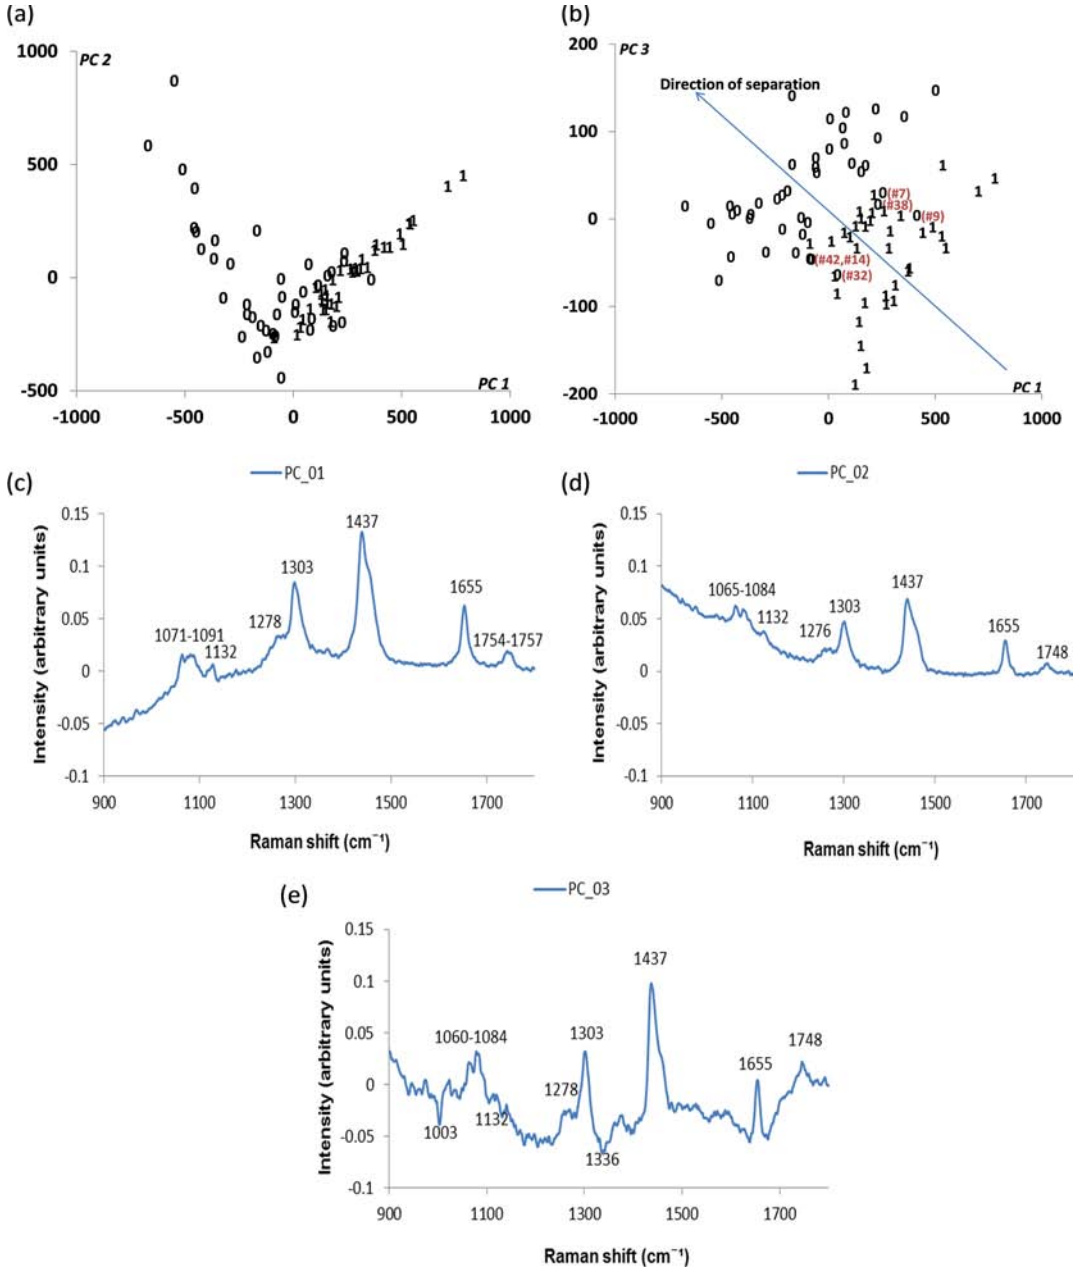

Figure 2. PCA score plots of all beefburger samples (a) PC1 vs PC2, (b) PC1 vs PC3, loading plots of all beefburger samples, (c) PC1, (d) PC2, and (e) PC3 (# = number of adulterated beefburger formulation in Table 1).

1125, and 920 cm^{-1}) have also been assigned to the C═O, C═C stretching bonds, CH_2 scissoring or twisting bonds, and C−H in-plane deformation bonds of aliphatic chains in lipids.[25,34] Thus, the main spectral features can be explained by the major beefburger components, although it is not possible to be prescriptive about actual band assignments given that many species absorb at the same or similar wavenumber locations. Indeed, given the relative range of protein and added fat contents in the formulations used, lipid may arguably be expected to contribute more variation to the spectral collection than protein.

Principal Component Analysis (PCA). Following PCA, three offal-adulterated samples were recognized as potential outliers. Close examination of their spectra revealed them to be faulty; the problem may have arisen from saturation of the CCD detector which occurred during spectral collection but, on the basis of the spectra, their removal was felt justified.

PCs 1−3 described 61%, 34%, and 3%, respectively, of variance in the frozen-then-thawed beefburger spectral data set. PCA score plots (i.e., PC1 vs PC2, PC1 vs PC3) for authentic and offal-adulterated spectra are shown in Figure 2a,b. In these figures, there is no clear separation visible between authentic (labeled as 1) and offal-adulterated (labeled as 0) samples but two discernible although overlapping, extended clusters can be identified. PC1 contributes significantly to the partial separation of the two sample groups which is visible (Figure 2a), while PC2 appears to describe variation within each sample group, especially in the case of the adulterated samples. In Figure 2b, group separation is almost complete along a direction from bottom right to top left of the plot. It is also notable that the samples adulterated at low level were located close to authentic

[a]Unit vector normalization.

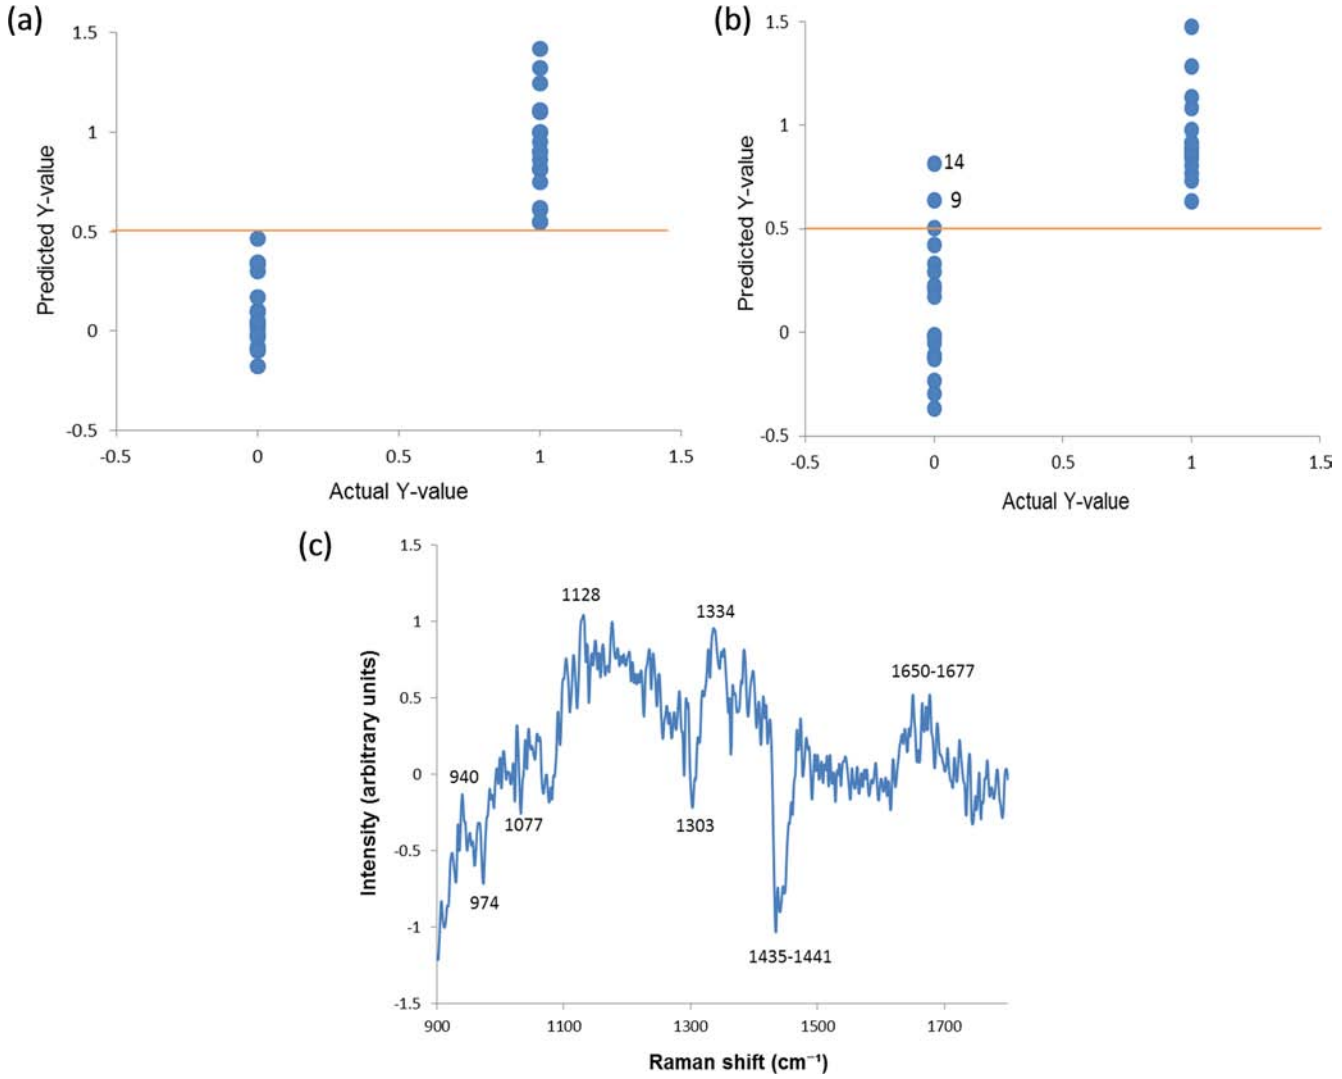

Figure 3. Best PLS-DA model result: (a) predicted *Y*-values in calibration samples, (b) predicted *Y*-values in validation samples, (c) regression vectors for PLS-DA model (3 loadings) (note: all input spectra were normalized on unit vectors).

samples; moreover, six adulterated samples (i.e., nos. 9, 38, 7, 32, 42, and 14) were located at the edge of the adulterated sample (label 0) cluster, merging into the authentic sample (label 1) cluster (Figure 2b). These six adulterated samples all contained a high content of total lean beef and beef fat. Three samples (nos. 9, 38, and 7) individually contained 67.5%, 70%, and 60% total lean beef and beef fat with 20%, 10%, and 40% offal, respectively. The other three samples (nos. 32, 42, and 14) separately contained a high level of lean beef (i.e., 60%, 65%, and 65%) without beef fat but adulterated with 40%, 20%, and 30% offal (Table 1).

Loading plots of PCs 1−3 (Figure 2c−e) show major intensity maxima at similar wavelengths. Maxima at 1303, 1437, 1655, and 1748 cm^{-1} are indicative of lipid contents; other features are located in spectral regions generally related to protein, i.e., 1000−1360 and 1645−1685 cm^{-1}.[25,34] In the plot of PC1 (Figure 2c), the main features mirror those in the mean spectra of beefburgers shown in Figure 1c, although certain features in the original mean spectra are absent, i.e., small peaks at 1554 and 1003 cm^{-1}, and the relative heights of peaks have changed. The plot of PC2 (Figure 2d) shows a general decline in intensity from 900 to 1360 cm^{-1} but reveals maxima at

DOI: 10.1021/jf5041959
J. Agric. Food Chem. 2015, 63, 1433−1441

wavelengths ascribed to lipid structures (1132, 1276, 1303, and 1437 cm^{-1}) with a small contribution from protein at 1655 cm^{-1}. Interestingly, two small maxima at 1065−1084 cm^{-1}, previously noted as originating in aspartic and glutamic acids, are quite obvious. PC 1 and 2 loadings are responsible for locating authentic and adulterated sample clusters in this two-dimensional space; PC2 plays a role in extending the adulterated sample pattern in a different direction from that of the authentic material. Regarding the PC3 loading, some minima appear at 1003, 1336, and 1645−1685 cm^{-1}, which are related to some specific protein structures and separate to some degree the adulterated samples from the authentic. Absorbance by lipid structures is also important in this PC.

PLS Discriminant Analysis (PLS-DA). PLS discriminant models were assessed on the basis of the percentage correct classification of both calibration and validation sample sets; a summary of their performance is shown in Table 2. Results reveal that models required between 3 and 5 loadings; in the calibration sample set, 89−100% of authentic and 90−100% of offal-adulterated beefburgers were correctly classified by the various models. For the validation sample set, the percentage correct classification of authentic samples remained within the range 94−100% but that of adulterated samples decreased to 81−90%. The most accurate classification model was based on data pretreated only by normalization on unit vectors. In this case, all authentic and offal-adulterated samples in the calibration set were predicted correctly; in prediction, all (n = 18) authentic samples and 19 out of 21 (90%) adulterated samples were correctly identified.

PLS scores for this model are shown in Figure 3a,b. In Figure 3b, two adulterated samples (formulations no. 9 and 14 of Table 1) were misclassified. Sample no. 9 contained 42.5% lean beef, 25% beef fat, 7.5% water, 5% rusk, and 20% lung; number 14 contained 65% lean beef, 5% rusk, 10% kidney, and 20% lung. These two samples both contained 20% lung and 65−67.5% beef and beef fat combined. However, these similarities cannot explain the misclassification because other similar formulations have been correctly classified (e.g., no. 42 of Table 1). A regression coefficient plot of the model is shown in Figure 3c. Interpretation of regression plots is difficult and potentially misleading, but it seems that certain features in Figure 3c can be attributed to protein (940, 974, 1077, and 1128 cm^{-1}) and lipid (1303, 1334, 1435−1441, and 1650−1677 cm^{-1}) components.[25,34]

It is interesting that models developed using two pretreatments (baseline correction followed by normalization) were not overall the most accurate; while identification of authentic samples in both calibration and validation had 100% accuracy, classification of the adulterated samples proved more problematic than when a normalization step alone was used. This is despite the fact that one of the most significant sources of systematic error in Raman spectra arises from total intensity variations. In a previous report,[30] the use of such a two-step pretreatment emerged as most successful in the prediction of a specific constituent, i.e., carotenoid in salmon meat. The lack of success of this procedure in our hands may be evidence of the problem specific nature of quantitative solutions using Raman spectra.

SIMCA Modeling. Results of SIMCA modeling (Table 3) based on PCA scores of spectral variables show that models developed using raw and pretreated data exhibited high sensitivity (0.95−1) but lower specificity (0.64−0.89); efficiency values of 0.80−0.94 were recorded. The best model, i.e., that with the highest efficiency value, involved data pretreated by normalization on unit vectors, required five principal components, and produced values of sensitivity, specificity, and efficiency of 1, 0.89, and 0.94, respectively. These results indicated that SIMCA modeling was able to accurately identify authentic beefburgers (i.e., sensitivity value of 1) but did not identify offal-adulterated beefburgers with complete accuracy (i.e., specificity value <1), resulting in some false positive classifications (n = 5).

Table 3. Summary of PCA and PLS Scores-Based SIMCA Model Results (900−1800 cm^{-1}) on Beefburger Validation Sample Set

[a]Principal components or PLS loadings. [b]Unit vector normalization pretreatment.

In an attempt to improve on these results, SIMCA models were also developed using PLS scores extracted from the first 20 PLS loadings of the PLS-DA models derived using the appropriate data pretreatments. SIMCA models based on PLS scores contain information relating to both spectral variables (X-values) and the memberships of specific sample categories (Y-values). Compared to SIMCA models using PCA scores, performance of those based on PLS scores (Table 3) revealed slight improvements regarding specificity (0.81−1.0) and efficiency (0.88−0.97). In the particular case of models using normalization on unit vector pretreated data, specificity values increased from 0.89 to 0.95 although this was accompanied by a drop (from 1 to 0.94) in sensitivity. Efficiency increased marginally from 0.94 to 0.95; 17 of 18 authentic samples and 40 of 42 adulterated samples were identified correctly. The misclassified samples included one sample in the lower quality range of authentic beefburgers and formulations 9, 38, and 44 of the adulterated beefburgers. In Table 3, models based on PCA scores required the involvement of four or five principal components; in the case of models developed using PLS scores, the corresponding number was between 2 and 4 PLS loadings. In general, the use of different data pretreatments or none had only a minor effect on model sensitivity values; in the case of specificity, however, between-model variations were much larger, thus justifying exploration of pretreatment options. SIMCA modeling may therefore play a useful role in quality control of industrial authentic beefburger production based on the formulations used in this work. To improve classification accuracy further, SIMCA models developed using PLS scores could be applied to test samples in parallel to PLS-DA models. Using such an approach, samples identified as adulterated by both types of models may be accepted as offal-adulterated samples with greater confidence than if only one model or the

other was used. However, it should be noted that in this work, formulation no. 9 (Table 1) was incorrectly identified by each model.

PLS Quantitation. Table 4A shows that performance of PLS quantitative calibration models for total offal adulteration was poor; R^2CV values at only 0.27−0.52 were very low, while RMSECV values were relatively high. In prediction, correlations between reference and predicted values were similarly low and accompanied by quite large bias values; therefore, none of these models was suitable for practical application. Possible reasons for modeling failure involve the chemical complexity of the matrix studied, the likely spectral similarity of offal and lean meat, and other effects including structural changes in macromolecular moieties after the freezing and thawing procedure.

A performance summary of PLS models for predicting added fat in all samples is shown in Table 4B. R^2CV values (0.71−0.85) of the calibration data set were generally higher than their validation set counterparts (R^2P; 0.47−0.85); root-mean-square errors of the calibration and validation data sets were 4.2−5.8 (RMSECV) and 3.8−7.2 (RMSEP), respectively. Calibration statistics indicated that the best model was based on data pretreated by a combination of first derivative and subsequent normalization on unit vectors using 2 PLS loadings with values for R^2CV, RMSECV, R^2P, and RMSEP of 0.85, 4.2, 0.85, and 3.8, respectively; however, the model exhibited a bias value of 0.39. Overall prediction accuracy of models for added fat prediction will be compromised by the inclusion of errors arising from the intramuscular fat content of the lean beef that was used in beefburger production because this was a variable and unaccounted for quantity.

In this feasibility study, Raman spectroscopy was studied to (a) discriminate between authentic and offal-adulterated beefburgers in the frozen-then-thawed state and (b) to quantify total offal and added fat contents of these samples. Classification (PLS-DA), class-modeling (SIMCA), and quantitative models (PLS1) have been developed separately on Raman spectra of frozen-then-thawed beefburgers. Results showed that (1) using PLSDA models for offal-adulterated beefburgers, correct predictions of 90−100% of calibration samples and 81−90% of validation samples was achieved; for authentic beefburgers, 94−100% of both calibration and validation samples were predicted correctly; (2) in the case of the SIMCA class-modeling approach, sensitivity values (1.0) of models based on PCA scores were generally slightly higher than those (0.94) of models based on PLS scores; conversely, specificity values (0.81−1.0) for models based on PLS scores were much higher than those (0.64−0.89) of models based on PCA scores; (3) prediction of offal content proved not to be possible, as might be expected given the unlikely possession of a unique spectral signal by this material; (4) performance of quantitative models for added fat prediction was not satisfactory. Compared with previous work of this research team using infrared (i.e., near-infrared (NIR) and Fourier transform mid-infrared (FT-IR)) spectroscopy on frozen-then-thawed offal adulterated beefburgers,[18,19] the correct classification rate of PLS-DA models for adulterated samples (based on the same validation sample group) ranged from 74−91% (NIR), 73−100% (FT-IR), and 81−100% (Raman); the efficiency of SIMCA models varied from 0.62−0.91(NIR), 0.81−0.94 (FT-IR) to 0.88−0.97 (Raman). It therefore seems, on the basis of this specific set of samples at any rate, that Raman spectroscopy may provide higher levels of classification accuracy than either of the two infrared spectral ranges.

In conclusion, the potential of Raman spectroscopy in the analysis of formulated meat products has been examined in this work. Using Raman spectroscopy to study a complex meat formulation has shown some misclassification and quantification errors. One potential strategy to minimize sample misclassification would be the use of multispectroscopic methods (e.g., near-infrared, mid-infrared)[18,19] combined with Raman spectroscopy because these spectra contain complementary information. In future work, the focus will be on such a strategy to improve quantification and qualification outcomes in this adulteration problem.

desirable for the detailed analysis of a complex PL mixture. Off-line NPLC × RPLC/MS was first used for the study of PL molecular species. In general, the PL extract was first separated by NPLC, then each fraction was collected off-line and injected onto a RPLC column separately for further molecular species elucidation.[13,14] In order to solve the possible immiscibility problem between the mobile phases from NPLC and RPLC, a solvent-evaporating interface was used for online NPLC × RPLC/MS analysis.[15] In the lipid profiling of a biological sample, Liu et al. used a vacuum pump at the interface of the NPLC and RPLC; in this way, the mobile phase from the NPLC was evaporated; then the mobile phase from RPLC passed through the interface and transferred the fraction into the second dimension C18 column for further molecular species separation.[16] Later, HILIC was used as the first dimension LC for online 2D-LC separation of PLs.[18,25] HILIC is a versatile tool for the separation of polar compounds; in addition, the aqueous−organic (usually acetonitrile) mobile phase used during HILIC separation is miscible with the second dimension RPLC mobile phase.[17] For the analysis of a milk PL extract, 23 fractions from the first dimension HILIC column were collected and injected onto a C18 column for species separation via a 100 μL sample loop under the stop-flow mode.[18] Further improvement of the stop-flow 2D-LC method was made by using an intermediate column to trap the components eluting from the HILIC column; these components were then eluted from the trap using a makeup flow.[19]

In general, 2D-LC/MS and -MS/MS analyses have revealed a large diversity in both PL classes and molecular species within each class. However, the identification of an specific molecular species may rely on a combination of LC/MS analysis with the separate identification of the overall fatty acid profile, as determined by gas chromatography coupled to a flame ionization detector (GC-FID)[20,21] or from the literature.[18,22,23] A necessary part of the full identification of fatty acids is the specific assignment of double bond positions. In GC-FID, this can often be achieved via the retention times of fatty acid methyl ester (FAME) derivatives. In other cases, the fatty acids from hydrolysis of PLs have been converted into dimethyloxazolines (DMOX) derivatives. Under electron ionization mass spectrometry, DMOX derivatives of fatty acids undergo charge remote fragmentations, and these fragmentation patterns can reveal double bond locations.[11,24] However, in these GC/MS analyses of DMOX or FAME derivatives, the complete PL molecular structure is lost, and the derivatization procedures add additional complexity to the analysis.

Recently, we successfully coupled online 2D-LC with in-line ozonolysis-MS (O_3-MS) to allow the detailed structure determination of PC molecular species, as demonstrated for the identification of PC molecules in the PL extract from rat liver.[25] The fraction containing PC species eluted from the first dimension HILIC column at between 8.2 and 9.0 min was directly injected onto the second dimension C18 column through a 10-port 2-position switching valve. The PC molecular species, eluting from the HILIC × C18 LC separation, then passed through the ozonolysis device that was connected between the C18 column and the ESI source. The ozonolysis device is a length of gas-permeable Teflon tube that passes through a chamber filled with ozone vapor, as described in detail by our previous study.[26] The ozonolysis reaction occurred to all double bonds in the PC molecules, resulting in the formation of diagnostic ozonolysis product aldehydes that were used for the direct assignment of double bond positions in unsaturated PC species.

In this study, the online 2D-LC method is further developed in order to allow for molecular species separation within the PI and PE classes, in addition to that already described for the PC class.[25] In addition, we have also demonstrated for the first time the application of the in-line O_3-MS method to the direct assignment of double bond positions in PI, PE, SM, lyso-PE (LPE), and LPC molecules. Overall, this approach can allow the structural characterization of PL molecules, including the definitive determination of each significant molecular species, as demonstrated here for the PLs extracted from chicken egg yolk.

MATERIALS AND METHODS

Material. HPLC grade water, tetrahydrofuran (THF), chloroform, methanol, acetonitrile (ACN), and isopropanol (IPA) were purchased from Fisher Scientific Company (Ottawa, ON, Canada). HPLC grade ammonium formate and formic acid were obtained from Sigma (St. Louis, MO, USA). All of the standards PI(18:0/20:4 (*n*-6,9,12,15)), PE(18:0/20:4 (*n*-6,9,12,15)), SM(d18:1/18:1(*n*-9)) ("d" means dihydroxy base), LPE(18:1(*n*-9)), and LPC(18:1(*n*-9)) were purchased from Avanti polar lipids, Inc. (Alabaster, AL, USA). Each standard solution was prepared in methanol at a concentration of 200 μg/mL. The Teflon AF-2400 tubing (0.020″ OD, 0.010″ ID) was purchased from Biogeneral Inc. (San Diego, CA, USA).

Nomenclature. We adopted as much as possible the nomenclature and abbreviation conventions from Liebisch et al.[27] In this study, it is advantageous to locate the double bond by counting from the terminal methyl group, thus the "*n*-" terminology is used. For example, 1-octadecanoyl-2-(9*Z*,12*Z*-octadecadienoyl)-*sn*-glycero-3-phosphocholine is expressed as PC(18:0/18:2 (*n*-6,9)). If the *sn*-position of the fatty acids is not known, the separator "_" is used, for example, PC(18:0_18:2 (*n*-6,9)).

Extraction of PLs from Egg Yolk. Fresh eggs were purchased from local markets. The egg yolk was separated from the egg white, and was rolled on the filter membrane in order to completely remove the egg white. Six egg yolks were mixed well together and used for PL extraction according to a modified Bligh and Dyer method.[23] In brief, 100 mg of egg yolk was mixed with 2 mL of extraction solvent (chloroform/methanol/water, 1:2:0.8) and homogenized at 10,000 rpm for 5 min on a Polytron PT1300D homogenizer (Kinematica AG, Switzerland) and then centrifuged at 3000 rpm for 5 min. The extraction procedure was repeated three times, and all of the supernatants were combined and made up to 10 mL using methanol. The extract was further diluted 10-fold with methanol prior to analysis.

LC and MS Instrument. An Agilent 1200 series HPLC system (Agilent Technologies Inc., Palo Alto, CA, USA) coupled to a hybrid quadrupole time-of-flight mass spectrometer (QSTAR Elite, Applied Biosystems/MDS Sciex, Concord, ON, Canada) with ESI source was used for all of the LC-MS analysis. The ion source temperature was kept at 375 °C and the ionspray voltage was at 5500 V for ESI (+) and −4500 V for ESI (−). Source region nitrogen gas flows in arbitrary units assigned by the data system were as follows: curtain gas 25; auxiliary gas 10, and nebulizing gas 50. The declustering potential (DP), focus potential (FP), and DP2 were 40 V, 150 V, 10 V, and −40 V, and −150 V and −10 V for ESI (+) and ESI (−), respectively. Analyst QS 2.0 software was used for data acquisition and analysis.

HILIC × C18 LC/MS Analysis. The 2D-LC configuration was the same as that in our previous study[25] using a 10-port 2-position switching valve (Rheodyne, Rohnert Park, CA) as the interface between the HILIC column and the C18 column (see Figure S1, Supporting Information). Separation conditions were modified for the shorter analysis time. The Ascentis Express HILIC column (2.1 mm i.d. × 150 mm, 2.7 μm particles) (Sigma, St. Louis, MO) was used as the first dimension LC for PL class separation. Mobile phase A was ACN, and B was 10 mM ammonium formate in water at pH 3.0, and the flow rate was at 0.2 mL/min. The gradient was as follows: 0−10 min, from 8% to 30% B; 10.0−10.1 min, from 30% to 95% B; 10.1−

J. Agric. Food Chem. 2015, 63, 1442−1451

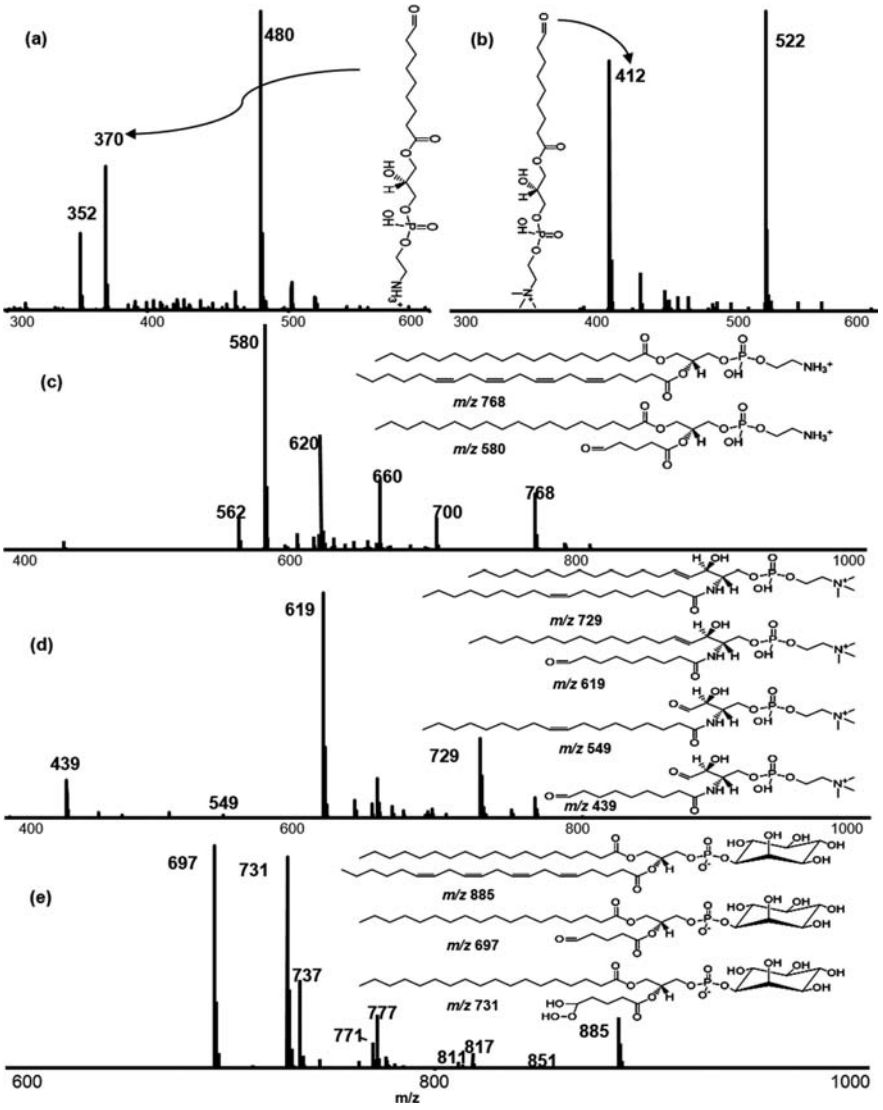

Figure 1. In-line O_3-MS spectrum of PL standard (a) LPE(18:1(*n*-9)) (+ve); (b) LPC(18:1(*n*-9)) (+ve); (c) PE(18:0/20:4 (*n*-6,9,12,15))(+ve); (d) SM(d18:1/18:1(*n*-9)) (+ve); and (e) PI(18:0/20:4 (*n*-6,9,12,15)) (−ve).

15.0 min, held at 95% B; 15.0−15.1 min, from 95% to 8% B; and 15.1−20.0 min, held at 8% B. The Ascentis Express C18 column (2.1 mm i.d. × 75 mm, 2.7 μm particles, Supelco, Bellefonte, PA USA) was used as the second dimension RPLC. The mobile phase at 0.475 mL/min was composed of THF/ACN/IPA/water with 10 mM ammonium formate at pH 3.0 (5:20:16:9, v/v/v) at 45 °C.

The injection of the eluent from the HILIC column to the C18 column was achieved by switching the valve from the A to B position and back to the A position (Figure S1, Supporting Information). For the PI class, the fraction between 4.0 and 4.8 min from the first dimension HILIC column was transferred to the second dimension C18 column and detected under ESI (−). For PE and PC, the fractions between 5.6 and 6.4 min and 8.2−9.0 min were transferred onto the C18 column and analyzed under ESI (+). In this study, LPE, LPC, and SM were analyzed by one dimension HILIC/MS instead of 2D-LC/MS, as described below.

In-line O_3-MS Analysis. The method development of the in-line O_3-MS approach for double bond position determination has been described in detail in our previous study.[26] In this study, a 20 cm length of gas permeable and liquid impermeable Teflon tube passed through a 0.5 L glass chamber filled with oxygen and ozone gas (ozone concentration 56.2 g/m^3) at room temperature. This ozonolysis device was placed in-line between 2D-LC and ESI source of the mass spectrometer for the analysis of PI, PE, and PC molecular species. For the analysis of LPE, LPC, and SM species, the ozonolysis device was coupled in-line with the HILIC column. In this way, each PL species eluting from either the second dimension C18 column or the HILIC column passed through the semipermeable tube, ozone vapor immediately reacted with carbon−carbon double bonds existing in the molecules, and the ozonolysis products would be directly detected by ESI-MS.

RESULTS AND DISCUSSION

In this study, ESI-MS, MS/MS, and in-line O_3-MS analyses were performed on PE, SM, PI, LPE, and LPC standards in order to demonstrate how these can yield similar structural information as was achieved for the analysis of PC in our previous study.[25] Then we further developed the 2D-LC and 2D-LC/O_3-MS methods for the direct identification of the PE, PI, SM, LPC, and LPE molecular species. Finally, these methods were applied to the characterization of the PL extracted from egg yolk.

ESI-MS and MS/MS Analysis of PE, SM, LPE, LPC, and PI Standards. Flow injection analysis (FIA) was performed on PI(18:0/20:4 (*n*-6,9,12,15)), PE(18:0/20:4 (*n*-6,9,12,15)), SM(d18:1/18:1(*n*-9)), LPE(18:1(*n*-9)), and LPC(18:1(*n*-9))

DOI: 10.1021/jf5049595
J. Agric. Food Chem. 2015, 63, 1442−1451

standards in positive ion mode using a mobile phase of ACN/water with 10 mM ammonium formate (85/15, v/v). The PE, SM, LPE, and LPC standards were observed as $[M + H]^+$ ions with high abundance, whereas the PI $[M + H]^+$ ion at m/z 887 appeared at very low intensity, and instead, the ion at m/z 627 generated from the neutral loss of 260 Da was the dominant ion. For PE and SM, mass measurements of the $[M + H]^+$ ions were used to deduce their elemental compositions. However, the ESI (+)-MS/MS analyses of PE and SM $[M + H]^+$ ions failed to provide fragment ions that could be used for the determination of fatty acyl chain composition. The dominant product ions in these MS/MS spectra arise due to the fragmentation of the headgroup, such as phosphocholine ions at m/z 184 for SM or the product ions from neutral loss of phosphoethanolamine (141 Da) from $[M + H]^+$ ions of PE. This has also been observed by other studies.[8,23,28]

ESI(−)/MS analysis of PE(18:0/20:4 (*n*-6,9,12,15)) resulted in $[M - H]^-$ ions at m/z 766. MS/MS analysis of the ion at m/z 766 generated carboxylate anions at m/z 283 and 303 that are characteristic of 18:0 and 20:4 fatty acyl chains (Figure S2a, Supporting Information). For SM(d18:1/18:1(*n*-9)), $[M + HCOO]^-$ ions at m/z 773 were observed, and the following MS/MS analysis of these ions (Figure S2b, Supporting Information) resulted in the demethylated molecular ion $[M - CH_3]^-$ at m/z 713 as the dominant product ions. However, fragment ions directly corresponding to the N-acyl chain did not appear in the MS/MS spectrum. Instead, the ion at m/z 449 was observed, which was formed by the neutral loss of the N-acyl chain (18:1 ketene) from the demethylated molecular ion at m/z 713. Thus, the mass difference between the ion $[M - CH_3 - R_1CO]^-$ (m/z 449 in this case) and the demethylated molecular ion $[M - CH_3]^-$ (m/z 713 in this case) can be used to assign the N-acyl chain. A similar fragmentation pattern to the SM $[M + HCOO]^-$ ion was also observed by another study and used for molecular species assignment of SM.[9]

In contrast to the weak $[M + H]^+$ ions seen under positive ion mode, the PI(18:0/20:4 (*n*-6,9,12,15)) deprotonated molecule $[M - H]^-$ at m/z 885 was seen with high intensity under ESI (−). Thus, with the PI class, mass measurements of $[M - H]^-$ ions can be used for the determination of elemental compositions. The MS/MS spectrum of the ions at m/z 885 is presented in Figure S2c (Supporting Information). The $[RCOO]^-$ ions at m/z 283 and 303 correspond to the 18:0 and 20:4 fatty acyl chains, and in addition, the inositol phosphate ion at m/z 241 is present with high intensity. Other product ions at m/z 599 ([lysostearoyl PI−H]$^-$) and 581 $[\text{lysostearoyl PI} - H - H_2O]^-$) are also observed, probably formed by the loss of the 20:4 acyl chain and the further loss of H_2O. The product ion at m/z 419 is due to the further loss of inositol from the $[\text{lysostearoyl PI} - H]^-$ ion at m/z 599. A similar fragmentation pattern for PI under ESI(−)-MS/MS was also observed by other studies.[10,29]

In-line O_3-MS Analysis of LPE, LPC, PE, SM, and PI Standards. For LPE and LPC, even though the chain length and number of double bonds can already be determined by the mass measurement of $[M + H]^+$ ions, the position of double bonds along the chain cannot be assigned. Hence, in-line O_3-MS analyses of LPE(18:1(*n*-9)) and LPC(18:1(*n*-9)) standards were performed under ESI (+) (Figure 1a and b). The ozonolysis product of LPE(18:1(*n*-9)) was observed at m/z 370 as well as the intact $[M + H]^+$ ion at m/z 480 (Figure 1a). The ion at m/z 370 corresponds to the characteristic ozonolysis product aldehyde that was formed by oxidative cleavage of the *n*-9 double bond in LPE. The mass loss of 110 Da after ozonolysis has also been observed in other lipids with double bonds located at the *n*-9 position such as methyl oleate[26] and PC(16:0/18:1(*n*-9)).[25] The ion at m/z 352 was probably due to the neutral loss of one H_2O molecule from the ion at m/z 370. For the LPC(18:1(*n*-9)) standard, a similar mass loss of 110 Da from the intact molecular ion at m/z 522 was observed resulting in the ion at m/z 412 after in-line ozonolysis (Figure 1b).

In the O_3-MS spectrum of the PE(18:0/20:4 (*n*-6,9,12,15)) standard (Figure 1c), the ozonolysis product aldehyde ions at m/z 700, 68 Da mass lower than that of intact $[M + H]^+$ ion at m/z 768, were generated by the ozonolysis of the double bond at the *n*-6 position. The product ions at m/z 660, 620, and 580 corresponded to the further oxidative cleavage of successive methylene interrupted double bonds. In addition, the neutral loss of one H_2O molecule from the aldehyde ion at m/z 580 was observed at m/z 562.

The O_3-MS spectrum of the SM(d18:1/18:1(*n*-9)) standard (Figure 1d) contained the intact $[M + H]^+$ ions at m/z 729 and the high intensity ozonolysis product ions at m/z 619, which resulted from ozonolysis of the double bond at the *n*-9 position in the N-18:1 chain. The low intensity ions at m/z 549, 180 Da lower mass than that of the $[M + H]^+$ ions at m/z 729, were formed by ozonolysis of the 4,5-*trans* double bond located along the sphingosine (d18:1) chain. The ozonolysis of both double bonds in SM(d18:1/18:1(*n*-9)) resulted in the ions at m/z 439. The ozonolysis product aldehydes formed by oxidative cleavage of double bonds located along the N-acyl chain (m/z 619 in this case) can be used for the direct assignment of the double bond positions within the N-acyl chain.

The in-line ozonolysis products of the PI(18:0/20:4 (*n*-6,9,12,15)) standard were detected in negative ion mode, since the PI can be observed as $[M - H]^-$ ions. In the resulting O_3-MS spectrum (Figure 1e), intact $[M - H]^-$ ions at m/z 885 were still observed along with the ozonolysis product aldehydes ions at m/z 817, 777, 737, and 697, due to the oxidative cleavage of double bonds at the *n*-6,-9,-12,-15 positions. The same group of ozonolysis product aldehyde ions were also reported from the OzID-MS analysis of PI(18:0/20:4 (*n*-6,9,12,15)) under ESI (−).[30] Along with these characteristic ozonolysis aldehyde ions, another set of ions at m/z 851, 811, 771, and 731 were also observed. These ions have 34 Da higher mass than the corresponding deprotonated aldehydes ions at m/z 817, 777, 737, and 697. These ions might be attributed to the further reaction of "Criegee intermediates" that are zwitterions formed during the oxidative cleavage of each double bond. They are probably formed by the addition of a H_2O molecule to the Criegee intermediates, resulting in the formation of hydroperoxide groups. As an example, a possible structure of the product ion at m/z 731 is shown in the inset of Figure 1e. The Criegee intermediates themselves were observed during the OzID-MS analysis of PI under ESI (−) as the carbonyl oxide ions at 16 Da are higher in mass than their corresponding aldehyde ions.[30] Whether the Criegee intermediate adducts observed in the present study were generated during the in-line ozonolysis reaction or during the negative electrospray ionization is not clear, but they do not diminish the use of the ozonolysis product aldehydes for the definitive assignment of double bond positions in PI molecules.

In summary, for LPE, LPC, PE and SM, both the intact molecules and the ozonolysis product aldehydes that are

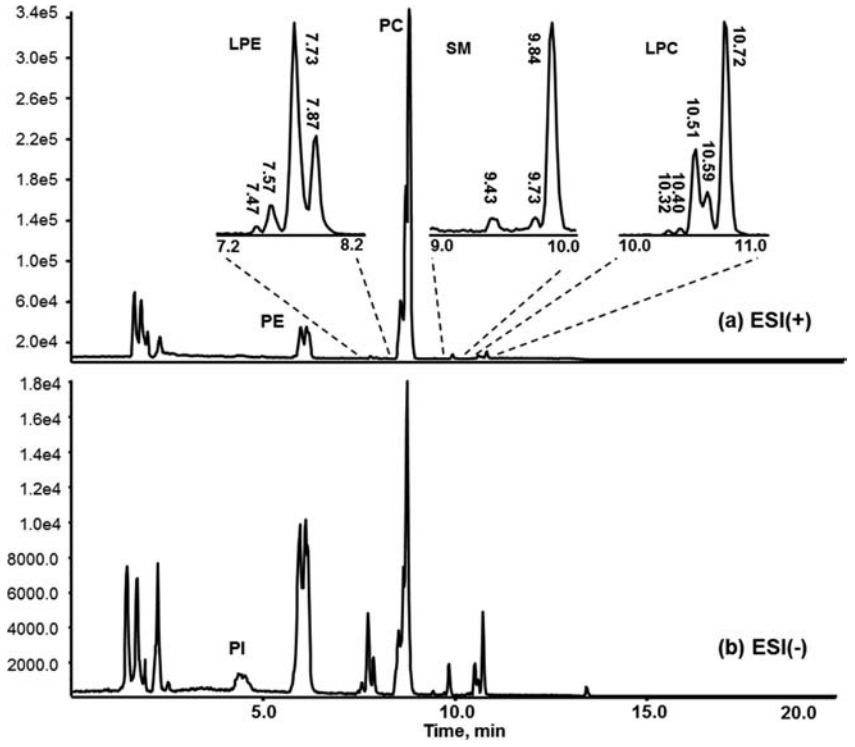

Figure 2. TIC of HILIC/MS analysis of egg yolk PL extract: (a) detected under ESI (+ve); (b) detected under ESI (−ve).

characteristic of double bond positions are detected as $[M + H]^+$ ions during O_3-ESI(+)/MS analysis. For PI, the deprotonated molecule can only be observed as $[M - H]^-$ ions under negative ion mode. The in-line ozonolysis products of PI are also detected under ESI (−) from which the aldehydes can still be used for the unambiguous assignment of double bond locations.

Characterization of Egg Yolk PL Extract. Egg yolk is a good source of dietary PL, and recently, PL extracted from egg yolk has been introduced as a novel food in the EU.[3] In addition, it is known that the egg yolk fatty acid profile can be modified through the hen's diet. For example, the abundance of *n*-3 PUFA in egg yolk can be increased by enriching seal blubber oil in the diet of layers.[10] The main classes of PLs in chicken egg yolk that have been reported include PI, PE, LPE, PC, SM, and LPC.[10,23,31] In the following sections, HILIC/MS and HILIC/MS/MS analyses are used for PL class separation and for the determination of elemental and fatty acyl chain composition. Additionally, online 2D-LC/MS analyses were carried out for the separation of molecular species within each PI, PE, and PC class, and 2D-LC/O_3-MS analysis was also performed to assign the double bond positions directly. Finally, HILIC was coupled to O_3-MS (HILIC/O_3-MS) in order to determine the double bond positions in LPE, LPC, and SM classes since the molecular species within these three classes are relatively simple and can be adequately separated on a HILIC column.

HILIC/MS and HILIC/MS/MS Analysis. We have previously demonstrated the separation of PL classes using a HILIC column with gradient elution.[10,23,31] Here, the egg yolk PL extract was analyzed by HILIC/ESI-MS under both positive and negative ion modes (Figure 2). As can be seen in the total ion current chromatogram (TIC) of HILIC/ESI(+)-MS (Figure 2a), the egg yolk PLs were well separated into PE, LPE, PC, SM, and LPC classes which formed abundant $[M + H]^+$ ions. Under ESI(−) (Figure 2b), the PI class was also observed as $[M - H]^-$ ions at elution times between 4.0 and 5.0 min. The PE, LPE, PC, SM, and LPC classes could still be observed under negative mode but with about half of the intensity of that seen under ESI (+). Hence, the mass measurements of PE, LPE, PC, SM, and LPC $[M + H]^+$ ions and PI $[M - H]^-$ ions were used to determine their elemental compositions. From the mass measurements of LPE and LPC $[M + H]^+$ ions, the fatty acyl chain compositions could be directly assigned.

In order to obtain information on the fatty acyl chain composition for PI, PE, PC, and SM, information dependent acquisition (IDA) mode was used during HILIC/ESI(−) analyses. During IDA, which is used to automatically trigger MS/MS scans, CID with CE of −35 and −42 eV were applied to ions with intensity higher than 10 cps. This results in the formation of fragment ions that are the deprotonated fatty acid residues $[R_1COO]^-$ and $[R_2COO]^-$. Thus, the MS/MS spectra of $[M - H]^-$ ions of PE, PI, and the $[M + HCOO]^-$ ions of PC were used for the determination of their fatty acyl chain compositions. For SM, the mass difference between the fragment ions $[M - CH_3]^-$ and $[M - CH_3 - R_1CO]^-$ in the MS/MS spectrum of $[M + HCOO]^-$ was used to determine the composition of the N-acyl chain. Following this, the composition of the sphingosine group in SM could be deduced.

In this way, the fatty acid residue chain lengths and numbers of double bonds in PI, PE, PC, and SM were assigned even for isomeric species such as PE(18:0_18:3) and PE(18:1_18:2). These are listed in Table 1.

2D-LC/MS and 2D-LC/O_3-MS Analysis of PI, PE, and PC Classes. In our previous study, HILIC × C18 LC, achieved by using a 10-port 2-position switching valve as the interface, was developed for online PC molecular species separation of a rat liver extract. In the present study, a C18 column with the same

[a]The intensity of ozonolysis product aldehyde ions is too low to observe.

DOI: 10.1021/jf5049595
J. Agric. Food Chem. 2015, 63, 1442−1451

stationary phase but only half the length (75 mm) was used along with a modified gradient (see Materials and Methods) in order to shorten the second dimension separation time from 30 to 20 min, with only minor effect on the efficiency of separation. Using this arrangement, 2D-LC/MS analysis was applied to the molecular species separation of PI, PE, and PC classes from egg yolk PL extract. 2D-LC/MS analysis coupled to in-line ozonolysis was also performed for more detailed structural investigation of each eluting molecule within these 3 classes.

In the 2D-LC separation of PI molecular species, the PI fraction eluting from the HILIC column was transferred onto the C18 column by switching the valve to position B at 4.0 min and back to position A at 4.8 min (see Materials and Methods and Figure S1, Supporting Information). Compared to the first dimension HILIC separation (Figure 2b), the molecular species of PI were much better separated on the second dimension C18 column (Figure 3a). The observed molecular species and

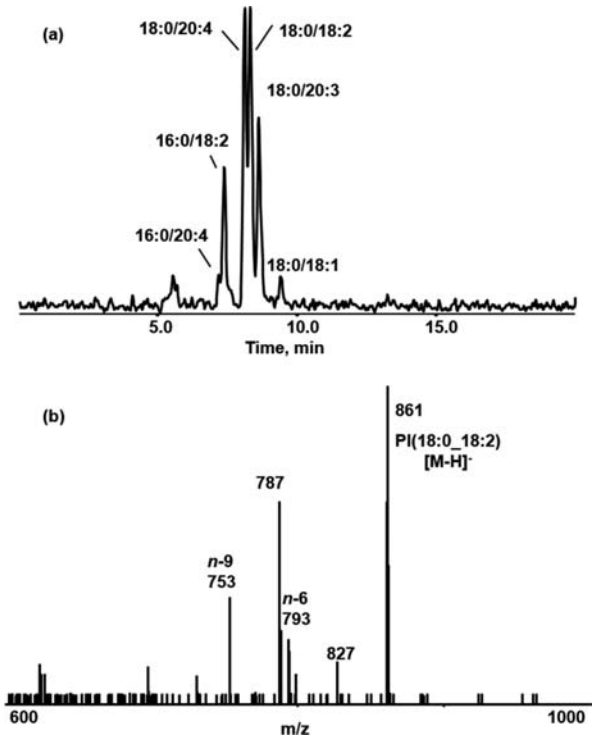

Figure 3. (a) TIC of 2D-LC/MS analysis of the PI class in egg yolk PL extract in negative ion mode; (b) O_3-MS spectrum of PI(18:0_18:2) in the egg yolk sample.

their corresponding t_R are listed in Table 1. The elution order of these PI species was consistent with their equivalent carbon number (ECN), meaning the PI molecules with higher ECN were retained longer on the C18 column. In order to assign the specific fatty acyl chains in these PI species, 2D-LC was coupled to O_3-MS in the negative ion mode. As an example of the results, the O_3-MS spectrum of PI(18:0_18:2) in this egg yolk PL extract is shown in Figure 3b. In addition to the intact $[M - H]^-$ ions at m/z 861, ozonolysis product ions appeared at m/z 753, 787, 793, and 827. The ions at m/z 787 and 827, that are 34 Da higher in mass than the ions at m/z 753 and 793, were generated by H_2O addition to the corresponding Criegee intermediates, consistent with results from the example of in-line ozonolysis of a PI(18:0/20:4) standard (Figure 1e). The ions at m/z 793 and 753 corresponded to ozonolysis product aldehydes from the oxidative cleavage of double bonds at n-6 and −9 positions along the 18:2 acyl chain. For other PI molecular species in this sample, the ozonolysis product aldehydes along with the products at 34 Da or higher are also observed and used for the determination of all double bond positions (Table 1).

For the molecular species separation of the PE class, the fraction eluting at between 5.6 and 6.4 min from the HILIC column (Figure 2a) was transferred onto the C18 column. Although a small degree of PE species separation was achieved on the HILIC column (Figure 2a), the diversity of the PE molecular species was far better resolved after 2D-LC separation (Figure 4a). Since PE $[M + H]^+$ ions under ESI

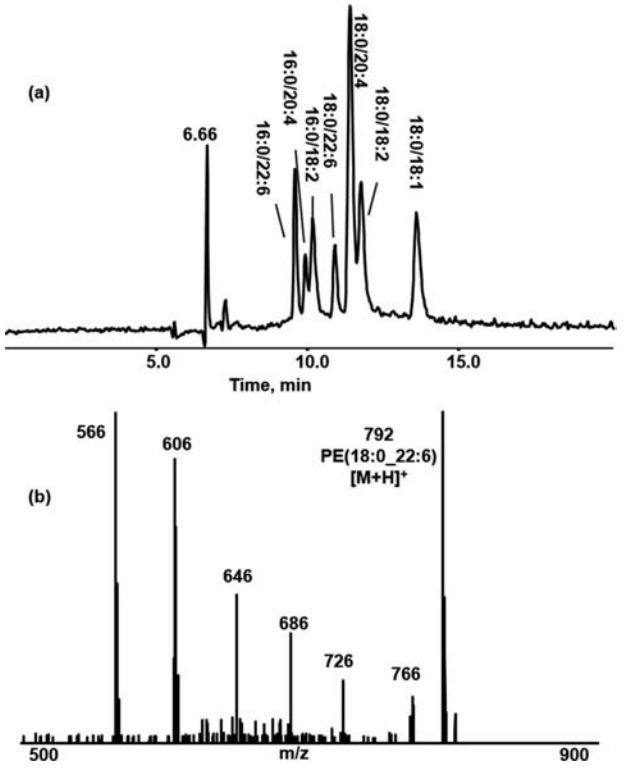

Figure 4. (a) TIC of 2D-LC/MS analysis of the PE class in egg yolk PL extract in positive ion mode; (b) O_3-MS spectrum of PE(18:0_22:6) in the egg yolk sample.

(+) have higher intensity than the $[M - H]^-$ ions seen under ESI (−), 2D-LC/MS analysis was carried out in positive ion mode. The first eluting species was PE(16:0_22:6) (ECN = 26) at 9.56 min, and the rest of the PE molecular species eluted generally according to their ECN, ranging from 26 to 34. However, one exception was observed for PE(18:0_22:6) with an ECN of 28 eluting at 10.89 min, which was retained longer than PE(16:0_18:2) (t_R 10.14 min) with an ECN of 30. Similar retention order exceptions for PLs containing a PUFA chain were also observed during 2D-LC separation of PC in rat liver in our previous study.[25] Even though the PE species containing PUFA such as PE(16:0_22:6), PE(18:0_22:6), PE(16:0_20:4), and PE(18:0_20:4) can be relatively well separated from other species, no more detailed structure information can be derived from just the 2D-LC/MS analysis to identify them as n-3 or n-6 PUFA. Therefore, 2D-LC/O_3-MS analysis was also performed on these PE species. As an example, the O_3-MS spectrum of

DOI: 10.1021/jf5049595
J. Agric. Food Chem. 2015, 63, 1442−1451

PE(18:0_22:6) in the sample is shown in Figure 4b. The mass difference of 26 Da between the intact PE(18:0_22:6) $[M + H]^+$ ion at m/z 792 and the ozonolysis product ion at m/z 766 directly assigns the first double bond at the n-3 position. The successive ozonolysis product ions at m/z 726, 686, 646, 606, and 566, with 40 Da mass differences between each other, demonstrate that as expected, all of the double bonds are separated only by a methylene group. Thus, PE(18:0_22:6) in egg yolk contains the n-3 docosahexaenoic acid chain.

The PC class eluting at between 8.2 and 9.0 min from the HILIC column was also directed onto the C18 column for the further separation of molecular species. The major PC species are indicated in Figure 5a; other minor PC species are listed in Table 1 due to their partial coelution with the major species. Compared to PI and PE, the PC class has an even higher level of species diversity, with ECNs that ranged from 26 to 34. PC molecular species also elute based on their ECN, with the exception of the PC molecule with PUFA such as PC(16:0_22:6) and PC(18:0_22:6), which have greater retention than some PC species with higher ECNs.

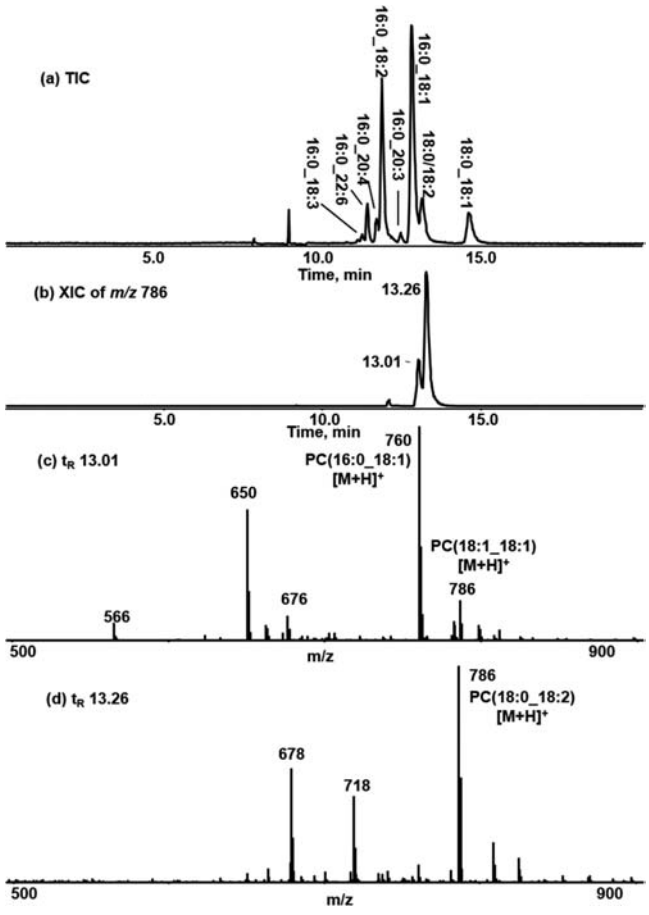

Figure 5. (a) TIC of 2D-LC/MS analysis of PC class in egg yolk PL extract in positive ion mode; (b) XIC of m/z 786 from (a); (c) O_3-MS spectrum of the peak at 13.01 min; (d) O_3-MS spectrum of the peak at 13.26 min.

In-line ozonolysis was also performed on PC species separated by 2D-LC, and the diagnostic ozonolysis product aldehydes were detected as $[M + H]^+$ ions. The isomers of PC 36:2 in the egg yolk is used as an example to illustrate how the double bond positions were assigned using in-line ozonolysis. In the extracted ion chromatogram (XIC) of m/z 786 (Figure 5b), two peaks appear at 13.01 and 13.26 min, indicating that they are PC(18:1_18:1) and PC(18:0_18:2) isomers. In the O_3-MS spectrum of the peak at 13.01 min (Figure 5c), ozonolysis product ions were observed at m/z 676 along with the intact molecular ion at m/z 786, which directly assigned the double bond at n-9 in one of the 18:1 acyl chains. The other ozonolysis product ion at m/z 566 was generated from the further ozonolysis of the double bond in the other chain, and the mass loss of 110 Da from m/z 676 also located the second double bond at the n-9 position in the second 18:1 acyl chain. Also seen in the O_3-MS spectrum of the peak eluting at 13.01 min (Figure 5c) is an abundant $[M + H]^+$ ion at m/z 760 from PC(16:0_18:1), along with its ozonolyis product ion at m/z 650. However, the partial coelution of this species does not affect the assignment of double bond positions in PC(18:1_18:1) at 13.01 min. In Figure 5d, the O_3-MS spectrum of the isomeric species at m/z 786 which elutes at 13.26 min is shown. From this spectrum, the ozonolysis product ions at m/z 718 and 678 allow assignment of the double bond positions at n-6 and 9 in PC(18:0_18:2).

HILIC/MS Analysis of LPE, LPC, and SM Class. Initially, similar to the 2D-LC/MS analysis of PI, PE, and PC classes, LPE eluting between 7.2 and 8.0 min and LPC eluting between 10.2 and 11.0 min from the HILIC column were also switched onto the C18 column and eluted using the same isocratic conditions. However, all of the species in both the LPE and LPC classes had very little retention and almost eluted as one single peak on the C18 column. The low retention of the LPE and LPC classes on the C18 column was also observed in the off-line 2D-LC study, in which LPE and LPC classes from the HILIC column were collected and injected onto a C18 column separately for molecular species separation.[32] However, it can be seen by the insets of Figure 2a that significant molecular species separation of LPE and LPC has already been achieved on the HILIC column. The accurate mass measurement of the ion at m/z 454 identified it as LPE(16:0). In the XIC of the ion at m/z 454 from Figure 2a (not shown), two peaks at 7.73 and 7.87 min are present, representing regio-isomers with the 16:0 acyl chain at either sn-1 or sn-2 position. The regio-isomers of LPE(18:0) at m/z 482 were also observed at 7.57 and 7.73 min. Although unambiguous assignment of regio-isomers cannot be achieved by our study, it was shown earlier that sn-1 LPE and LPC were retained longer than the corresponding sn-2 isomers on a HILIC column.[32] Thus, the assignment of sn-isomers presented is solely based on the retention time on the HILIC column in our study (Table 1). We also observed low intensity ions at m/z 466 from LPE species eluting at a t_R of 7.47 min. The accurate mass measurement at m/z 466.3295 assigned the elemental composition of these LPE molecules as $C_{23}H_{49}NO_6P^+$, which excluded the possibility that this ion represented the isobaric LPE(17:1). Therefore, this LPE species was tentatively identified as either eLPE(18:1) which has the long alkyl chain bound as a 1-O-alkyl ether, or as pLPE(18:0) with the chain bound as 1-O-alk-1′-enyl (note that plasmenyl- or p(18:0) refers to the vinyl ether form, which is derived from the saturated 18:0 but includes a double bond at C-1 and hence is isobaric with eLPE(18:1)). However, the exact structure of this LPE species could not be determined because the MS/MS spectra in both positive and negative ionizations failed to provide product ions that could be used for this specific assignment. In order to differentiate between these two ether lipids, other work has used acidic hydrolysis performed on the ether PL before MS analysis since the double bond in 1-O-

DOI: 10.1021/jf5049595
J. Agric. Food Chem. 2015, 63, 1442−1451

alk-1′-enyl linkage is unstable to acid treatment.[33] It was also previously reported that product ions from the loss of R_1OH can only be observed from the MS/MS analysis of the *p*LPC $[M+Li]^+$ ions and not from the MS/MS analysis of *e*LPC $[M + Li]^+$ ions.[34] For the LPC class, regio-isomers of LPC(16:0), LPC(18:0), and LPC(18:1) were also observed in their XIC traces of *m*/*z* 496, 524, and 522, respectively. As with LPE, the identification of regio-isomers only relied on their retention time on the HILIC column (Table 1).

For the SM class, even though there are two substituents in the molecules besides the polar headgroup, the SM fraction eluting at between 9.2 and 10.0 min from the HILIC column had poor retention and resolution under the current C18 separation. However, the SM molecular species were separated well on the HILIC column (the inset of Figure 2a). SM(d18:1/24:1) eluted at 9.43 min and was separated from SM(d18:1/16:0) (t_R 9.84 min) and SM(d18:1/18:0) (t_R 9.72 min); only SM(d18:0/16:0) coeluted with SM(d18:1/18:0) at 9.73 min.

HILIC/O_3-MS Analysis of LPE, LPC, and SM Class. While molecular species separation of LPE, LPC, and SM classes was achieved on the HILIC column, the double bond positions in unsaturated species such as LPE(18:1), LPC(18:1), and SM(d18:1/24:1) could still not be assigned. Therefore, the in-line ozonolysis device was coupled with the HILIC column (HILIC/O_3-MS). In this way, the ozonolysis products from each eluting LPE, LPC, and SM molecule was detected by ESI (+)-MS. For example, in Figure S3a (Supporting Information) an ion at *m*/*z* 370 appeared in the O_3-MS spectrum of LPE(18:1) along with the intact $[M + H]^+$ ions at *m*/*z* 480. This mass loss of 110 Da allows the assignment of the only double bond in this LPE to the *n*-9 position. Also seen in Figure S3a (Supporting Information) is an ion at *m*/*z* 454, which is due to the coelution of LPE(16:0). However, this does not compromise the value of the diagnostic ozonolysis product ion for the determination of double bond position in LPE(18:1). In the O_3-MS spectrum averaged at between 7.45 and 7.50 min (see Figure 2a and Table 1), the $[M + H]^+$ ion at *m*/*z* 466 was still observed but was accompanied by an ozonolysis product ion at *m*/*z* 356. The latter ion locates the double bond to the *n*-9 position, which in turn confirms that the ion at *m*/*z* 466 corresponds to the $[M + H]^+$ ion of *e*LPE(18:1(*n*-9)) rather than to *p*LPE(18:0). Hence, in this study the differentiation between possible *e*LPE and *p*LPE isomers was achieved using O_3-MS analysis, although further experiments would be needed in order to validate this as a general approach.

Figure S3b (Supporting Information) is the O_3-MS spectrum of the SM (d18:1/24:1) at *m*/*z* 813 from the egg yolk sample. The double bond along the N-24:1 chain was assigned to the *n*-9 position based on the observation of the ozonolysis product ion at *m*/*z* 703, 110 Da below the $[M + H]^+$ ion at *m*/*z* 813. The ion observed at *m*/*z* 523 is the ozonolysis product aldehyde generated by the subsequent oxidative cleavage of the 4,5-*trans* double bond located along the 18:1 sphingosine group. An analogous pattern of ozonolysis product ions was seen in the O_3-MS spectrum of the SM(d18:1/18:1(*n*-9)) standard (Figure 1d).

In the above discussions, it has been demonstrated that for the egg yolk PL extract, all of the molecular species in PI, PE, and PC can be unambiguously identified using HILIC/MS and MS/MS analysis followed by 2D-LC/O_3-MS. It has also been shown that LPE, LPC, and SM molecular species can be accurately assigned using HILIC/MS and HILIC/O_3-MS analyses. Our findings have revealed even more of the diversity of PL species that are present in egg yolk, compared to that in previous reports.[10,23] Furthermore, the methods that we have used have allowed for the definitive identification of each PL species with the position of the double bond directly assigned.

In summary, we have developed a comprehensive PL characterization method which involves using a combination of HILIC/MS, HILIC/MS/MS, 2D-LC/MS, and O_3-MS analyses. The use of in-line ozonolysis coupled with a HILIC column and 2D-LC is necessary for the elucidation of the structure of the chains within the molecules. The experimental setup is very easily adapted to a range of LC and MS configurations, which is especially helpful for the characterization of PL, a group of chemically diverse compounds. While the use of shotgun lipidomics can reveal a great diversity of lipid structures, the minor species and most isomers can only be observed with chromatographic separation prior to MS detection, and other analytical techniques are often required to confirm species identification. The comprehensive method demonstrated here has shown great success, as exemplified by the detailed structure elucidation of egg yolk PL molecules. The additional level of structural detail for lipid analyses that can be generated by this approach will be complementary to other experimental methods used in lipidomics.

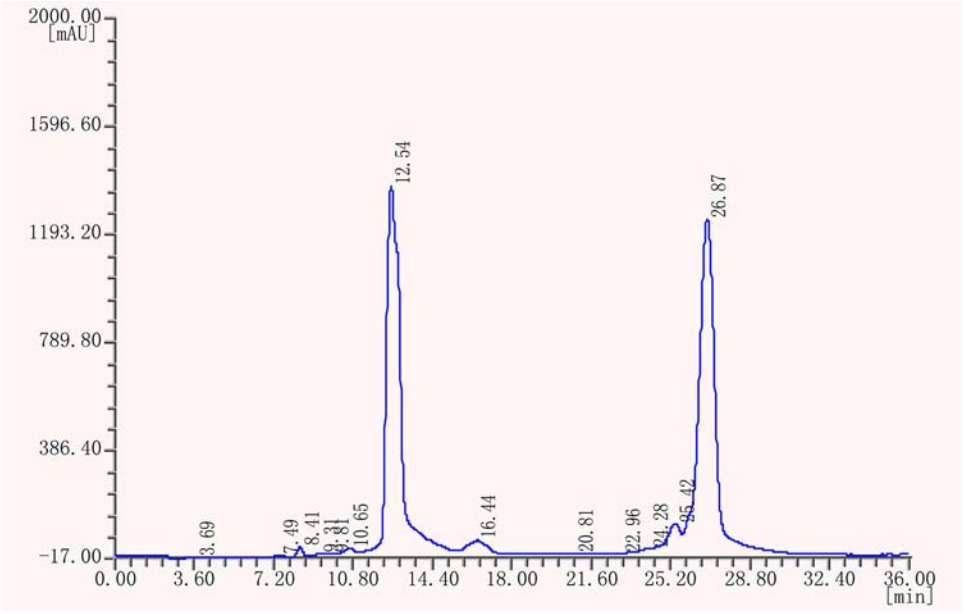

Figure 1. Subfraction $B_{3\text{-}4}$ chromatogram of preparative HPLC. The retention times of kuwanon G (K_1) and kuwanon O (K_2) were 12.5 and 26.9 min, respectively.

a 21.2 × 250 mm XB-C_{18} column (Welch, Ellicott City, MD). Spectra data from ESI−MS were recorded on a 4000 QTRAP liquid chromatography−tandem mass spectrometry (LC−MS/MS) instrument (Allen-Bradley, Milwaukee, WI). Nuclear magnetic resonance (NMR) spectra were obtained from a Bruker Avance III 500 spectrometer (Bruker, Karlsruhe, Germany) operating at 500 MHz for ^{1}H and at 125 MHz for ^{13}C with the samples dissolved in methanol-d_4. An inverted microscope (Nikon, Tokyo, Japan) was used to observe and count the treated theronts.

Plant Material Preparation. *M. alba* was planted by farmers in Guangxi province and identified by a plant taxonomist before the root bark (10 kg) of *M. alba* was purchased from the Chinese medicinal market at Guangzhou, China. The plant was kept in an oven at 55 °C until completely dried before usage.

Extraction, Isolation, and Identification. The dried root bark of *M. alba* was powdered with a pulverizer that contained a 50 mesh strainer. The root bark powder was extracted 3 times with 25 L of 95% ethanol at 78 °C for 2 h each. The ethanol extract was gathered and evaporated in a vacuum rotary evaporator. Subsequently 1.14 kg of the medium dry concentrate was suspended in 1.2 L of water and extracted with petroleum ether, ethyl acetate, and *n*-butanol. Then, the organic solvent extracts were evaporated to dryness by a vacuum rotary evaporator at 40 °C. The water-soluble fraction was freeze-dried. The ethyl acetate extract showed the highest efficacy against *I. multifiliis* theronts among all extracts; therefore, it was used for further separation.

The mixture of 750 g of ethyl acetate extract and 750 g of silica gel (200−300 mesh) was used for column chromatography on a normal-phase silica gel column (7500*g*, 100−200 mesh) and eluted with (A) petroleum ether, (B) petroleum ether/ethyl acetate (1:1, v/v), (C) ethyl acetate, or (D) methanol to obtain four crude fractions. Because fraction B exhibited the strongest anti-Ich activity, the mixture of 350 g of fraction B and 350 g of silica gel (200−300 mesh) was continuously eluted in column chromatography containing silica gel (7000*g*, 100−200 mesh). A polarity gradient of petroleum ether/ethyl acetate (from 10:0 to 0:10, v/v) and ethyl acetate/methanol (1:0, 1:1, and 0:1, v/v) was used in the elution to yield active fraction B_3 on the basis of TLC. A third silica column chromatography (1600*g*, 100−200 mesh) was conducted for the mixture of 80 g of silica gel (200−300 mesh) and 80 g of active fraction B_3 from the elution of 2:1 petroleum ether/ethyl acetate. After repeated column chromatography from 10:0 to 0:10 petroleum ether/ethyl acetate (v/v), fraction B_3 was divided into 10 subfractions ($B_{3\text{-}1}$−$B_{3\text{-}10}$) based on the TLC patterns. $B_{3\text{-}4}$ (18 g) was the most active subfraction against *I. multifiliis* and then used for purification of active compounds with HPLC using a preparative HPLC column. HPLC was performed with a mobile-phase methanol/H_2O (75:25, v/v) at a flow rate of 10 mL/min at room temperature with UV detection at 210 nm. The subfraction $B_{3\text{-}4}$ chromatogram of preparative HPLC is shown in Figure 1. Two active compounds K_1 (3.9 g) and K_2 (4.3 g) were purified. The major purification procedure is shown in Figure 2.

The chemical structures of active compounds were identified on the basis of the physicochemical properties, ESI−MS, ^{1}H NMR spectrum, and ^{13}C NMR spectrum.

Fish and Parasite. Grass carp with an average weight of 22.0 ± 1.3 g were purchased from a commercial fish hatchery at Huadu, Guangzhou, Guangdong, China. All fish were acclimated for 2 weeks in 100 L of aquaria equipped with an aerator and a water suction pump before usage. A light/dark period of 12:12 h was maintained throughout the whole trial. Fish were fed daily at 1% body weight with commercial granule feeds manufactured by Guangdong Haid Group Co., Ltd. One quarter of tank water was exchanged with dechlorinated freshwater every day. The dissolved oxygen, water temperature, and pH were detected with a Professional Plus handheld multiparameter instrument (YSI, Yellow Springs, OH). The water temperature and dissolved oxygen were maintained at 23.0 ± 0.5 °C and 7.1 ± 0.45 mg/L, respectively, and pH was 7.2 ± 0.4 daily.

I. multifiliis was isolated from a goldfish obtained from an ornamental fish market at Guangzhou, China. The parasite was cultured and collected as previously described.[14,23] Theront numbers were enumerated in five 10 μL of 1% formalin-fixed theront suspensions on a glass slide under a microscope (10×) and expressed as the mean number of theronts per milliliter.

Antiparasitic Activity and Toxicity Bioassay. The anti-theront activity was evaluated for two compounds with the methods described by Fu et al.[22] and Buchmann et al.[23] Each purified compound was dissolved in 1 mL of ethanol and adjusted with distilled water to a 100 mg/L stock solution for the bioassay. A 2-fold serial dilution was made from each compound stock solution into working concentrations. There were two negative controls for the trials: one containing only 0.1% ethanol and the other containing only water.

I. multifiliis theronts were considered dead if they were motionless without cilia beating. The lethal exposure duration and mortality were recorded for all theronts in each well of a 96 well plate during 4 h of exposure. The infectivity was evaluated for theronts pretreated with low concentrations of compounds as described by Fu et al.[22] Briefly,

DOI: 10.1021/jf505544e
J. Agric. Food Chem. 2015, 63, 1452−1459

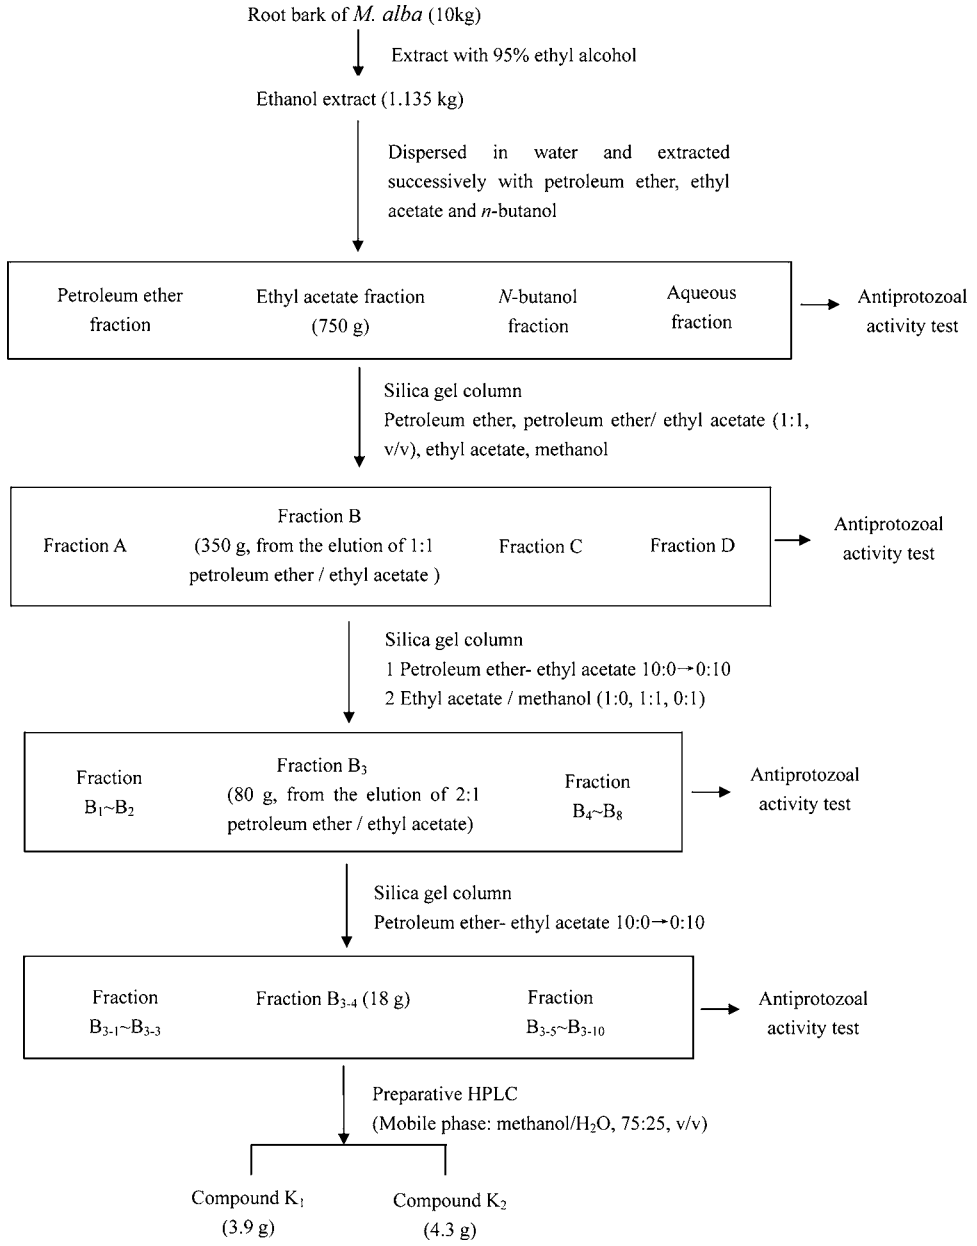

Figure 2. Isolation and purification of parasiticidal compounds.

theronts were treated in 10 mL of kuwanon G or O solution at concentrations of 0 (control), 0.125, 0.25, 0.5, and 1 mg/L for 2 h and then incubated with 10 naive grass carps at 20 000 theronts per fish in 4 L of dechlorinated water for another 2 h. Subsequently, 10 fish were maintained in 10 L of water at 23 ± 0.5 °C for 7 days. Infection prevalence (number of infected fish/total number of fish) and infection intensity (total number of white spots/number of infected fish) were determined 7 days post-exposure in each aquarium after the fish were anesthetized with 150 mg/L tricaine methanesulfonate (MS-222).

In a preliminary acute toxicity trial, kuwanon G or O at 0, 20, 40, 60, and 80 mg/L was used to determine the concentrations, which resulted in 0 or 100% fish mortality. Kuwanon G at 60 mg/L or kuwanon O at 40 mg/L caused 100% fish mortality, but both compounds caused no fish death (0% mortality) at 20 mg/L. On the basis of the result from the preliminary trial, acute toxicity trials were conducted for grass carp with kuwanon G at the concentrations of 0 (control), 20, 25, 30, 40, 50, and 60 mg/L or kuwanon O at the concentrations of 0 (control), 20, 25, 30, and 40 mg/L. Each concentration had three replicated tanks, and each tank contained 10 fish and 5 L of dechlorinated water. Fish were randomly taken from acclimation tank and put into each tank for acute toxicity trial. No feed was given to the fish during the period of acute toxicity trial. Air was provided to each tank by an aerator, and the water temperature was maintained at 23.0 ± 0.5 °C. The compound solution in each tank was replaced daily with fresh solution at the same concentration. Fish behavior and mortality were recorded, and dead fish were removed daily during the 96 h trial. The median lethal concentration (LC_{50}) to fish was determined 96 h post-exposure to each antiparasitic compound.

Statistical Analysis. Data were analyzed with Statistical Product and Service Solutions software (SPSS 17.0) and expressed as the mean ± standard deviation (SD). Mortality, lethal duration, and infectivity of theronts treated at different concentrations of compounds were analyzed by the double-factor variance analysis and Student−Newman−Keuls test. EC_{50} and LC_{50} were calculated by probit analysis.

RESULTS

Structure Identification of Active Compounds. The anti-*I. multifiliis* compounds were isolated from the alcohol extract of *M. alba* root bark by means of bioassay-guided fractionation. A series of fractions were obtained during the isolation and showed various antiparasitic effects (Table 1).

Table 1. Effects of Fractions against *I. multifiliis* Theronts

	anti-theront efficacy (mg/L)			
fraction	0	6.25	12.5	25
petroleum ether fraction	−[a]	−	−	−
ethyl acetate fraction	−	−	−	+[b]
n-butanol fraction	−	−	−	−
aqueous fraction	−	−	−	−
fraction A	−	−	−	−
fraction B	−	−	−	+
fraction C	−	−	−	−
fraction D	−	−	−	−
fraction B_1	−	−	−	−
fraction B_2	−	−	−	+
fraction B_3	−	+	+	+
fraction B_4		−	−	+
fraction B_5−B_8	−	−	−	−
fraction $B_{3\text{-}1}$−$B_{3\text{-}3}$	−	−	−	+
fraction $B_{3\text{-}4}$	−	+	+	+
fraction $B_{3\text{-}5}$− $B_{3\text{-}6}$	−	−	−	+
fraction $B_{3\text{-}7}$−$B_{3\text{-}10}$	−	−	−	+

[a]− = fraction at the listed concentration could not kill 100% theronts by 30 min of exposure. [b]+ = fraction at the listed concentration killed 100% theronts by 30 min of exposure.

The fraction $B_{3\text{-}4}$ demonstrated the best anti-theront effect (Table 1) and was further isolated by preparative HPLC (Figure 1). Finally, two active compounds (K_1 and K_2) were purified and identified according to following data.

Compound K_1 was a yellow brown to reddish brown amorphous powder. ESI−MS *m/z*: 691.5 $[M - H]^-$, 727.5 $[M + Cl]^-$, 693.5 $[M + H]^+$, 715.5 $[M + Na]^+$. ^{1}H NMR (500 MHz, MeOD) *δ*: 7.28 (1H, d, *J* = 8.0 Hz, H-6′), 7.10 (1H, d, *J* = 7.8 Hz, H-14″), 6.70 (1H, d, *J* = 8.1 Hz, H-20″), 6.46 (1H, s, H-3′), 6.43 (1H, d, *J* = 2.0 Hz, H-5′), 6.10 (1H, br s, H-17″), 6.03 (1H, dd, *J* = 8.3 and 2.4 Hz, H-19″), 5.90 (1H, s, H-11″), 5.85 (1H, d, *J* = 8.6 Hz, H-13″), 5.15 (1H, s, H-2″), 5.13 (1H, d, *J* = 7.0 Hz, H-10), 4.54 (1H, s, H-4″), 4.30 (1H, d, *J* = 9.7 Hz, H-3″), 3.17 (1H, br s, H-5″), 3.13 (2H, m, H-9), 1.92 (1H, d, *J* = 14.1 Hz, H-6″), 1.66 (1H, m, H-6″), 1.60 (3H, s, H-12), 1.44 (3H, s, H-7″), 1.42 (3H, s, H-13). ^{1}C NMR (125 MHz, MeOD) *δ*: 210.2 (C-8″), 183.9 (C-4), 165.9 (C1-0″), 165.8 (C1-2″), 163.3 (C-8a), 162.5 (C-4′), 161.9 (C-2), 161.8 (C-7), 161.1 (C-5), 157.8 (C-2′), 157.8 (C-18″), 157.0 (C-16″), 134.4 (C-14″), 134.1 (C-1″), 132.7 (C-11), 132.7 (C-6′), 132.7 (C-20″), 124.7 (C-2″), 123.0 (C-10), 123.0 (C-15″), 121.7 (C-3), 116.0 (C-9″), 113.8 (C-1′), 108.6 (C-5′), 108.2 (C-19″), 108.0 (C-8), 107.9 (C-13″), 105.7 (C-4a), 103.7 (C-3′), 103.6 (C-17″), 102.9 (C-11″), 98.5 (C-6), 49.8 (C-4″), 39.1 (C-3″), 39.1 (C-5″), 39.1 (C-6″), 25.9 (C-12), 24.7 (C-9), 23.2 (C-7″), 17.7 (C-13). The data were identical to those of early studies.[24,25] Compound K_1 was identified as kuwanon G with a molecular formula of $C_{40}H_{36}O_{11}$ and a flavone structure (Figure 3).

Compound K_2 was also a yellow brown to reddish brown amorphous powder. ESI−MS *m/z*: 693.5 $[M - H]^-$, 729.5 $[M + Cl]^-$, 695.5 $[M + H]^+$, 717.5 $[M + Na]^+$. ^{1}H NMR (500 MHz, MeOD) *δ*: 7.60 (1H, d, *J* = 8.8 Hz, H-14″), 7.17 (1H, d, *J* = 8.1 Hz, H-6′), 6.87 (1H, d, *J* = 8.7 Hz, H-20″), 6.36 (3H, m, H-17″, 13′, 5′), 6.06 (1H, d, *J* = 2.4 Hz, H-19″), 6.05 (1H, d, *J* = 2.2 Hz, H-8), 5.97 (1H, d, *J* = 6.7 Hz, H-6), 5.72 (1H, d, *J* = 11.8 Hz, H-2), 5.52 (1H, s, H-2″), 5.21 (1H, m, H-22″), 4.58 (1H, s, H-4″), 4.28 (1H, d, *J* = 8.1 Hz, H-3″), 3.46 (1H, m, H-5″), 3.34 (2H, d, *J* = 8.6 Hz, H-21″), 2.96 (1H, m, H-3), 2.67 (1H, dd, *J* = 16.0 and 2.3 Hz, H-3), 2.15 (1H, m, H-6″), 2.06 (1H, m, H-6″), 1.83 (3H, s, H-7″), 1.70 (3H, s, H-24″), 1.63 (3H, s, H-25″). ^{1}C NMR (125 MHz, MeOD) *δ*: 210.7 (C-8″), 198.6 (C-4), 167.0 (C-7), 165.8 (C-8a), 164.0 (C-5), 163.3 (C-12″), 162.5 (C-10″), 159.6 (C-18″), 157.1 (C-16″), 156.7 (C-2′), 156.6 (C-4′), 134.2 (C-1″), 132.2 (C-20″), 132.1 (C-14″), 131.9 (C-23″), 131.9 (C-6′), 128.8 (C-2″), 125.6 (C-22″), 125.2 (C-15″), 122.8 (C-1′), 117.9 (C-9″), 116.2 (C-11″), 110.6 (C-3′), 110.4 (C-19″), 107.8 (C-13″), 107.3 (C-5′), 103.8 (C-17″), 102.9 (C-4a), 96.1 (C-6), 95.1 (C-8), 76.0 (C-2), 47.4 (C-4″), 43.2 (C-3), 38.8 (C-3″), 38.7 (C-5″), 38.6 (C-6″), 27.5 (C-24″), 26.0 (C-7″), 20.9 (C-21″), 17.8 (C-25″). The data were consistent with those reported previously.[26] Compound K_2 was identified as kuwanon O with a molecular formula of $C_{40}H_{38}O_{11}$ and a flavonone structure (Figure 3).

Anti-*I. multifiliis* Theront Effects of Active Compounds. The anti-theront efficacy of the two compounds was significantly correlated with the tested concentrations (Table 2). The two compounds resulted in 70.1% mortality of theronts by kuwanon O and 59.8% mortality of theronts by kuwanon G at 1 mg/L after 4 h of exposure. Both compounds

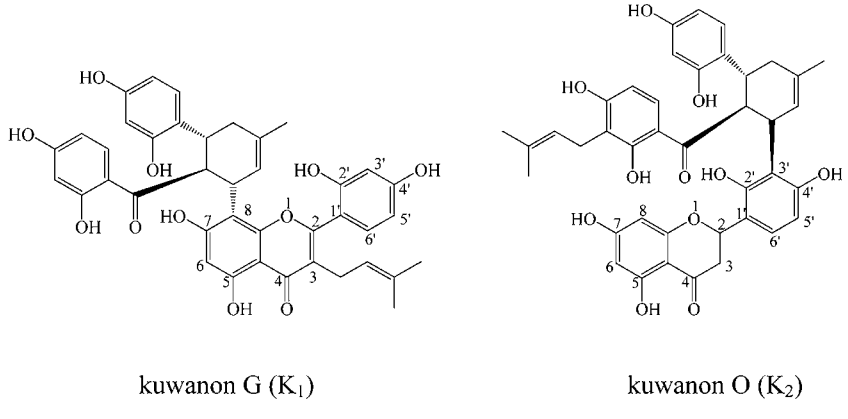

Figure 3. Chemical structures of kuwanon G (K_1) and kuwanon O (K_2).

	40	10	30	0	0	0	100

[a]Each treatment group contained triplicate tanks. [b]Mortality (%) = dead fish number during 96 h/total fish number.

caused 100% mortality of theronts at the concentration of 2 mg/L between 13.2 and 30.7 min of exposure. The lethal duration was significantly shortened to less than 2 min when the concentration of each compound was increased to 4 mg/L.

Infectivity of Theronts Pretreated with Active Compounds. The theront infectivity was significantly reduced after the theronts were exposed to a low concentration of kuwanon G or O for 2 h (Table 3). Kuwanon G or O at 1 and 0.5 mg/L could protect a majority of grass carps from infestation of theronts. The infection prevalences were 3.3 and 13.3% for kuwanon G or 13.3 and 23.3% for kuwanon O at 1 and 0.5 mg/L, respectively. The infection prevalence was 100% in control groups. Meanwhile, fish showed low infection intensities of 0.5 and 8.2 for kuwanon G or 1.3 and 12.4 for kuwanon O after exposure to 1 and 0.5 mg/L for 2 h, respectively. The two compounds at 0.25 or 0.125 mg/L could not prevent infestation of *I. multifiliis* on grass carps but significantly decreased infection intensity compared to those in negative controls (Table 3).

Acute Toxicity to Grass Carp. In the acute toxicity assay, both kuwanons G and O showed external stimulation to the skin and gills of grass carp. Fish increased mucus secretion and respiratory frequency. The fish died at the concentration of ≥30 mg/L kuwanon G or ≥25 mg/L kuwanon O (Table 4). A

J. Agric. Food Chem. 2015, 63, 1452−1459

Table 5. Anti-theront Efficacy and Acute Toxicity of Kuwanons G and O to Grass Carp

	anti-theront efficacy at 4 h		acute toxicity at 96 h	
compound	EC_{50}[a] (mg/L, mean ± SD)	95% CI[b]	LC_{50}[c] (mg/L, mean ± SD)	95% CI[b]
kuwanon G	0.80 ± 0.04	0.59−1.18	38.0 ± 0.82	36.1−40.1
kuwanon O	0.80 ± 0.04	0.65−1.06	26.9 ± 0.51	25.9−28.0

[a]EC_{50} = median effective concentration. [b]95% CI = 95% confidence interval. [c]LC_{50} = median lethal concentration.

100% fish mortality was observed at 50 mg/L kuwanon G or 30 mg/L kuwanon O after 48 h of exposure. There was no fish death in the control groups during the experiments. The 96 h LC_{50} values of kuwanons G and O to grass carp were 38.0 ± 0.82 and 26.9 ± 0.51 mg/L (Table 5).

DISCUSSION

Medical plants contain natural products with a large number of pharmacologically active compounds. In previous studies, crude extracts of some medical plants showed antiprotozoal activity against *I. multifiliis*.[11−13,22,23,27] However, there is an information limit on the purification and identification of the compounds responsible for the antiparasitic activity.[14−17,28] In this study, ethanol extracts of the root bark of *M. alba* were used for bioassay-guided isolation. The ethyl acetate fraction showed strong anti-Ich activity and was used for further separation and purification. Finally, two active flavonoids were identified as kuwanons G and O with similar structural skeletons and owning the same substituent groups. Kuwanon G is a flavone, but kuwanon O is a flavonone, which is from a flavone hydrogenated at the second and third positions of a double carbon−carbon bond. The similar structure and same substituent groups may be responsible for the similar anti-*I. multifiliis* activity of the two compounds. However, the substituent groups are at different positions of the basic structural skeletons. This may be the reason for difference on antiparasitic efficiency between the two compounds. The phenomenon was also found for other compounds in publications.[29−34] The data above suggest that the compound structure may determine its activity against *I. multifiliis*.

Recent studies suggest that flavonoids with phenolic hydroxyl groups or an isopentene group usually show cytotoxicity and antimicrobial activity because they can easily penetrate the cell membrane and result in perforation and leakage.[35−39] Both kuwanons G and O have eight phenolic hydroxyl groups and one isopentene group; therefore, these two compounds might damage the cell membrane of *I. multifiliis* and finally kill the parasite. The exact anti-*I. multifiliis* mechanism of these two flavonoids needs further study.

In previous studies, kuwanon G was reported to possess various biological activities, including antibacterial,[20] hypotensive,[40] and antinociceptive[41] activities. Kuwanon O, another active compound, was found to have antioxidant[42] and tyrosinase inhibitory[43] activities. To the best of our knowledge, this study is the first report to demonstrate the antiparasitic efficacy of kuwanons G and O. The bioassay results showed that kuwanons G and O caused 100% mortality of *I. multifiliis* theronts at 2 mg/L or higher after a short exposure. The lethal exposure time was dramatically reduced with increment of the compound concentrations. However, the 4 h mortality of theronts was significantly reduced with the decrease of treatment concentrations when the dose of the two compounds was less than 2 mg/L. This indicated that 2 mg/L was the lowest lethal dose for kuwanon G or O to kill 100% of *I. multifiliis* theronts. In comparison to the published data, the anti-Ich efficacies of kuwanons G and O were better than those of compounds isolated from *Galla chinensis* and *Cinnamomum cassia*. Pentagalloylglucose killed all theronts at 2.5 mg/L within 228.0 min,[14] and cinnamaldehyde killed all theronts at 8 mg/L within 208.4 min.[28] In addition, the lethal exposure durations and concentrations of kuwanons G and O for killing all theronts were shorter and lower than those of some crude plant extracts and chemicals. Ethyl acetate or acetone extracts from *M. alba* root bark killed all theronts at 8 mg/L within 36.0 or 38.7 min.[22] Garlic (*Allium sativum*) extract killed all theronts at 62.5 mg/L within 15 h.[23] *Psoralea corylifolia* methanol extract killed all theronts at 5 mg/L within 4 h.[27] *Magnolia officinalis* and *Sophora alopecuroides* extracts killed all theronts at 10 mg/L within 3 or 4 h.[12] Potassium ferrate killed all theronts at 24 mg/L within 30 min.[44] Sodium percarbonate killed all theronts at 12.5 mg/L within 3 h.[23] A hydrogen peroxide, peracetic, acetic, and peroctanoic acid-based formulation (HPPAPA) killed all theronts at 8 mg/L within 60 min.[45]

Although kuwanons G and O at the concentrations of 1 mg/L or less for 4 h exposure could not kill all theronts, pretreatment of *I. multifilliis* by exposing theronts at 1, 0.5, 0.25, or 0.125 mg/L for 2 h significantly reduced theront infectivity and partially protected grass carp from infestation. Similar phenomena were observed in several previous studies. When live theronts were pretreated with pentagalloylglucose at low concentrations ranging from 0.5 to 10 mg/L for 1 h, the infectivity of the theronts on catfish was lost or greatly decreased.[14] Bronopol at a concentration of 1 mg/L could not kill 100% theronts within a 12 h exposure but significantly reduced the infection ability of theronts on rainbow trout (*Oncorhynchus mykiss*).[4] Methanol extract from *P. corylifolia* at 2.5 mg/L could not kill all theronts in 4 h but showed an adverse effect on the infectivity of *I. multifiliis*.[27] Kuwanons G and O exhibited the strongest anti-*I. multifiliis* activity compared to the agents mentioned above.

The trial result showed that kuwanons G and O had similar efficacy against *I. multifiliis* theronts. However, the LC_{50} values of the two compounds were different to fish, indicating that kuwanons G and O had various toxicity to fish. These two compounds belong to flavonoids. They are usually absorbed into blood and other tissues and then transferred to the liver for metabolism in humans.[46] Overdose of flavonoids can result in hepatotoxicity and cause liver damage.[47] No information on the metabolism and toxicity of kuwanons G or O has been reported in fish. Kuwanons G and O might have different hepatotoxicity to fish because of their different structure and positions of substituent groups. Different flavonoids have been noted to possess various metabolism ways in liver.[48] However, the toxicity mechanism between kuwanons G and O to grass carp is not clear and needs further study.

The LC_{50} values of kuwanon G (38.0 mg/L) and kuwanon O (26.9 mg/L) to grass carp were higher than those of some reported antiparasitic phytochemicals and chemotherapeutants to fish, such as dihydrochelerythrine (18.2 mg/L), dihydro-

DOI: 10.1021/jf505544e
J. Agric. Food Chem. 2015, 63, 1452−1459

sanguinarine (13.3 mg/L),[16] malachite green (0.05 mg/L),[49] copper sulfate (6.89 mg/L),[50] and potassium permanganate (17.6 mg/L).[51] The LC_{50} values of kuwanons G and O to grass carp were approximately 50−35 times the EC_{50} (0.8 mg/L for both compounds) for killing the theronts. Therefore, kuwanons G and O are safe for fish at an effective treatment concentration.

Because malachite green has been prohibited for use in food fish due to its carcinogenicity,[10,52] extensive research has been conducted to investigate alternatives to control ichthyophthiriasis in recent years.[4,6,11−17,27,28,45] Ideally, the alternative agents are safe to fish and effective to kill the parasite with low environmental impact.[53,54] This study demonstrated that kuwanons G and O from the root bark of *M. alba* possessed good anti-*I. multifiliis* activity and low toxicity to grass carp. In our previous studies, several compounds with anti-Ich activity were obtained by bioassay-guided isolation from *G. chinensis* (pentagalloylglucose),[14] *C. cassia* (cinnamaldehyde),[28] and *Cynanchum atrium* (cynatratoside-C).[17] The antiparasitic efficacy of kuwanons G and O was better than that of pentagalloylglucose or cinnamaldehyde. However, cynatratoside-C was demonstrated to have similar anti-*I. multifiliis* effects as malachite green[17] and show better anti-Ich activity than kuwanons G and O. Approximately 0.039% kuwanon G and 0.043% kuwanon O could be isolated and purified from dried *M. alba* root bark. However, only 0.0031% cynatratoside-C was isolated and purified from dried *C. atrium*. The yield of kuwanons G and O from *M. alba* root bark was 13 and 14 times that of cynatratoside-C from *C. atrium*. The cost would be lower for producing the same amount of kuwanons G and O than that for cynatratoside-C. Moreover, the market price of *M. alba* root bark was about $^1/_3$ of the price for *C. atrium*. The overall costs for producing kuwanons G and O will be cheaper than that for cynatratoside-C. The cheaper product will be easier to be commercialized. Therefore, kuwanons G and O are promising agents to become new, safe, and efficacious anti-Ich drugs. Further evaluation is needed for the effectiveness of kuwanons G and O to control ichthyophthiriasis under fish farm conditions before these two flavonoids become commercial drugs against *I. multifiliis*.

diet did not induce obesity.[17] Germ-free mice on a HF diet did not become obese.

Several lines of research have suggested that the regulation of a host's metabolism by its intestinal microbiota occurs through alteration of the host's nuclear receptor signaling via production of secondary metabolites by bacteria. Intestinal bacteria have been shown to produce short chain fatty acids (SCFAs), which reduce insulin-stimulated fat accumulation via the SCFA receptor GPR43.[18] Trimethylamine-N-oxide (TMAO), another metabolite produced by intestinal bacteria, was associated with cardiovascular risk factors via multiple macrophage scavenger receptors.[19] Reduction of the genus *Lactobacillus* following treatment with the antioxidant, tempol (4-hydroxy-2,2,6,6-tetramethylpiperidin-1-oxyl), caused accumulation of tauro-β-muricholic acid (T-β-MCA) and inactivation of the intestinal farnesoid X (nuclear) receptor (FXR).[20] Gut microbiota modulation of fasting-induced adipocyte factor (Fiaf) gene expression in the intestine and cytochrome P450 7A1 (CYP7A1) gene expression in the liver indicates a role of gut microbiota in host lipid and bile acid metabolism.[21,22] Taken together, these findings suggest that restoration of the healthy phenotypic intestinal microbiota through diet may be a preferred strategy for preventing or treating obesity-related metabolic diseases.

Our previous work[23] has shown that hamsters fed a HF and hypercholesterolemic diet supplemented with white wine grape seed flour (ChrSd diet) exhibited significantly lowered plasma low density lipoprotein (LDL)-, very low density lipoprotein (VLDL)-, total-cholesterol concentrations, abdominal adipose tissue weight, and body weight gain compared to those fed a control diet. To date, the prebiotic effects of whole grape seed itself are largely unknown since most studies have utilized aqueous or alcoholic polyphenolic grape seed extracts. To our knowledge, the effect of wine varietal grape seed flour on intestinal microbiota composition has not been evaluated. In this study, we extended our previous research to evaluate a select number of bacteria from hamster feces by reverse transcription quantitative polymerase chain reaction (RT-qPCR) of 16S rRNA and correlated their relative abundances with physiological changes in order to determine whether metabolic effects were associated with intestinal microbiota in male Syrian Golden hamsters fed HF diets supplemented with grape seed flours from red and white wine production.

MATERIALS AND METHODS

Animals and Diets. Male Syrian Golden hamsters (approximately 80 g, LVG strain, Charles River Laboratories, Wilmington, MA) were randomized into three groups of 10 hamsters each and fed HF diets (37% of energy as fat, 18% as protein, and 45% as carbohydrate) *ad libitum* containing 10% (w/w) grape seed flour (Chardonnay or Cabernet Sauvignon from Sonomaceuticals, LLC/WholeVine Products, Santa Rosa, CA) and a control diet containing 5% microcrystalline cellulose (MCC; Dyets Inc. Bethlehem, PA) for 3 weeks as shown in our previous study.[23] Microcrystalline cellulose (MCC), an insoluble fiber, has little effect on energy or sterol metabolism.[24] Grape pomace was obtained from coastal vineyards in Sonoma County, California. Seeds from the 2010 vintage were screened and dried using heated air (55−70 °C) to be separated from skins and stems. Oil was pressed from the seed, and the residual press cake was then milled to pass through an 85 mesh sieve. Body weights were monitored weekly, and food intake was recorded twice per week. Feces were collected during the last 3 consecutive days of the feeding period and were lyophilized, milled, and stored at −20 °C. Blood was collected by cardiac puncture with syringes previously rinsed with potassium EDTA solution (15 wt %/v) after hamsters were feed-deprived for 12 h and anesthetized with isoflurane (Phoenix

DOI: 10.1021/jf5026373
J. Agric. Food Chem. 2015, 63, 1460−1467

Pharmaceutical, St. Joseph, MO). The plasma was separated after centrifugation at 2000 × *g* for 30 min at 4 °C. Livers, intestines, and adipose tissues (epididymal and perirenal adipose tissues) were collected, weighed, and immediately frozen in liquid nitrogen for later analysis. The protocol, #P-04−02, was reviewed and approved by the Animal Care and Use Committee, Western Regional Research Center, Albany, CA. The male Syrian hamster was used since its hepatic cholesterol and bile acid metabolism is more similar to humans compared to mice and rats.[25,26]

Plasma Lipoproteins and Hepatic and Fecal Lipids Analysis. Cholesterol in plasma lipoproteins was determined by size-exclusion chromatography as previously described.[23,27] Liver and fecal total lipid contents were determined gravimetrically as described before.[23,30]

Fecal Microbiota Analysis. A 200 mg sample of lyophilized fecal samples was added to 10 volumes of RNA later-ICE (Applied Biosystems, Foster City, CA, USA) for 24 h for RNA stabilization. Total RNA from fecal samples was extracted using a Stool Total RNA purification kit (Norgen Biotek Inc., Thorold, ON, Canada), and cDNA was synthesized using a PrimeScript RT reagent kit (TaKaRa Biotechnology, Shiga, Japan) per the manufacturer's protocol. Quantitative PCR was performed on an AB 7500 real-time PCR system (Applied Biosystems) using SYBR Premix Ex Taq (TaKaRa Biotechnology). Individual bacteria strains for generation of standard curve were obtained from Korean Collection for Type Cultures (KCTC), grown in pure culture media, and then isolated cDNA was serially diluted to generate the standard curve. The bacteria number from each sample was calculated by comparing the Ct value derived from the standard curve with the 7500 Software 2.01. Standard curves were generated by a serial 10-fold dilution of DNA from pure cultures, 10^1−10^{12} copies/g feces. The data represented the mean values of duplicate qPCR analysis. Bacterial groups reported to impart health benefits or prevent obesity-related metabolic disorders were selected for this study. The bacterial primer sequences are shown in Table 1. The cycle conditions were as follows: 30 s at 95 °C followed by 40 cycles of incubation at 95 °C for 5 s and 60 °C for 34 s. The experimental data were analyzed with the 7500 Software v2.0.1 (Applied Biosystems).

Hepatic and Intestinal Gene Expression by Real-Time (RT)-PCR. Total RNA from livers and intestines was extracted using a TRIzol plus RNA purification kit (Invitrogen, Life Technologies, Carlsbad, CA), and cDNA was synthesized using a GeneAmpRNA PCR kit (Applied Biosystems, Foster City, CA) per the manufacturer's protocol. One microliter of diluted cDNA (1:10) was used in each real-time RT-PCR using SYBR Green Supermix (Bio-Rad, Hercules, CA) with an Mx3000P instrument (Stratagene, Cedar Creek, TX). The cycle conditions were as follows: 5 min at 95 °C followed by 40 cycles of incubation at 94 °C for 15 s, then 58−60 °C for 1 min and 72 °C for 30 s. The sequences of the primers used for this study are shown in Table 1 and our previous study.[28,29] The primers were validated by size and sequencing of PCR products. No accumulation of nonspecific products and primer dimers was observed in a gel electrophoresis test of the PCR products. The results were analyzed using the software provided with the Stratagene Mx3000P QPCR system. Differences in mRNA expression for intestines and livers were calculated after normalizing to β-Actin or 36B4 mRNA expression.

Statistical Analysis. All data are expressed as means ± SE. One-way analysis of variance (ANOVA) was performed to examine the effect of treatment on plasma biomarkers, lipid levels, and body and tissue weights using the JMP7 statistical program (SAS Institute, Cary, NC). Tukey−Kramer honestly significant difference (HSD) tests were used to determine the significant differences in group means. Pearson correlation coefficients were calculated to investigate relationships between the abundance of intestinal bacteria and plasma cholesterol concentrations as well as liver, adipose tissue, and body weights. Significance was defined at $P < 0.05$.

RESULTS

Metabolic Effects of Grape Seed Flour Supplementation on Hamsters. Plasma VLDL-, LDL-, and total-cholesterol concentrations of hamsters fed the ChrSd diet were 73, 56, and 38%, respectively, lower compared with the control diet ($P < 0.05$) (Table 2). The CabSd diet did not lower plasma cholesterol concentration when compared to the control diet (Table 2). The ChrSd diet also significantly lowered hepatic total lipid concentration by 24% compared to the control diet ($P < 0.05$) (Table 2). Fecal percent total lipid of the grape seed diets did not significantly differ from the control diet (Table 2).

Table 2. Plasma Lipid Concentrations and Hepatic and Fecal Total Lipid Contents in Hamsters Fed HF Control, ChrSd, and CabSd Diets for 3 Weeks[a,b]

	control	ChrSd	CabSd
Plasma Lipid (mg/dL)			
VLDL-cholesterol	23.6 ± 3.5[a]	6.5 ± 1.3[b]	25.6 ± 5.2[a]
LDL-cholesterol	75.2 ± 12.4[a]	33.4 ± 6.6[b]	85.7 ± 7.2[a]
HDL-cholesterol	90.3 ± 4.2[a]	77.6 ± 4.0[ab]	75.4 ± 3.7[b]
total-cholesterol	189.1 ± 14.9[a]	117.6 ± 6.7[b]	186.7 ± 8.9[a]
LDL/HDL	0.8 ± 0.1[a]	0.5 ± 0.1[b]	1.2 ± 0.1[a]
hepatic percent total lipid content (g/100g)	23.9 ± 1.0[a]	18.1 ± 1.0[b]	21.6 ± 1.4[a]
fecal percent total lipid content (g/100g)	2.6 ± 0.5[a]	2.9 ± 0.9[a]	2.3 ± 0.4[a]

[a]ChrSd, Chardonnay seed; CabSd, Cabernet Sauvignon seed. [b]Values are means ± SE, $n = 10$. Different letters indicate significant difference at $P < 0.05$.

The total methanol extractable flavonoid content of the CharSd was 1.4-fold greater than that of CabSd as described in our previous study.[23] The higher levels of flavonoids in red wines and lower levels in seeds are partly due to the ethanol extraction of flavonoids during fermentation. Different processing methods for white and red wine account for some of the differences in flavonoid content; the whole fruit including seed is fermented for the production of red wines; however, only the juice is fermented in typical white wine production.

Fecal Microbiota Profiles by Chardonnay and Cabernet Grape Seed Flour Supplementation. ChrSd supplementation significantly lowered numbers of total bacteria in feces compared to the HF control diet (Figure 1A). Relative abundance of *Bifidobacterium* spp. and *Lactobacillus* spp. in feces was significantly lowered by the ChrSd diet compared to the HF control diet (Figure 1B). In contrast, relative abundance of *Bacteroides fragilis* was significantly greater in feces of the ChrSd diet than the control diet (Figure 1B). The CabSd diet significantly lowered relative abundance of *Enterobacteriaceae* in feces compared to the control diet (Figure 1B). At a phylum level, relative abundance of *Bacteroidetes* tended to be greater, and *Firmicutes* were markedly lower in the ChrSd diet compared to the control diet; this resulted in a significant reduction in the ratio of *Firmicutes*/*Bacteroidetes* (F/B) (Figure 2A,B). Relative abundance of *Proteobacteria* numbers was significantly lower in the CabSd diet than in the control diet (Figure 2A).

Expression of Hepatic and Intestinal Genes following Chardonnay Grape Seed Flour Supplementation. The expression of FGF15/19, a downstream target gene of FXR, in the intestine of hamsters fed the ChrSd diet was one-tenth that of hamsters fed the control diet (Figure 3). The mRNA levels of ZO-1 (zonula occludens 1) and OCLN (occludin), genes that encode intestinal tight junction proteins, were not significantly affected by the ChrSd diet (Figure 3). The

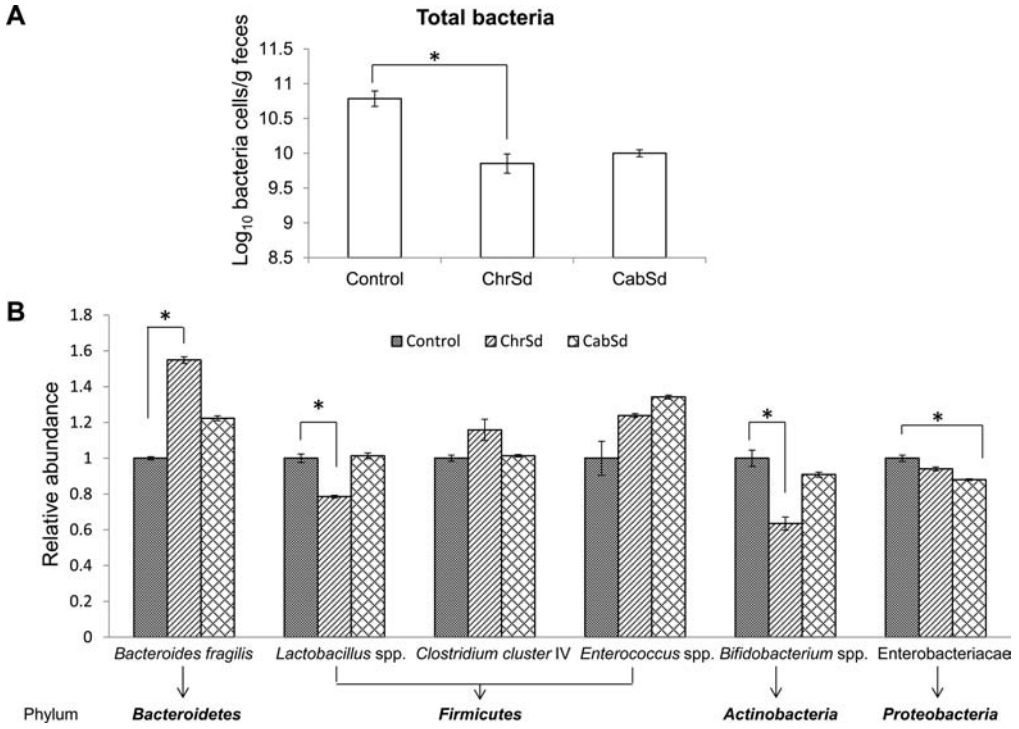

Figure 1. Effect of grape seed flour diets on numbers of total bacteria (A) and relative abundance of specific intestinal bacteria (B). Male Golden Syrian hamsters were fed HF diets containing 10% (w/w) Chardonnay (ChrSd), Cabernet Sauvignon (CabSd) grape seed flours, and 5% MCC (control) for 3 weeks. Data are expressed as means ± SE; n = 4/group. ∗ indicates significant difference at $P < 0.05$.

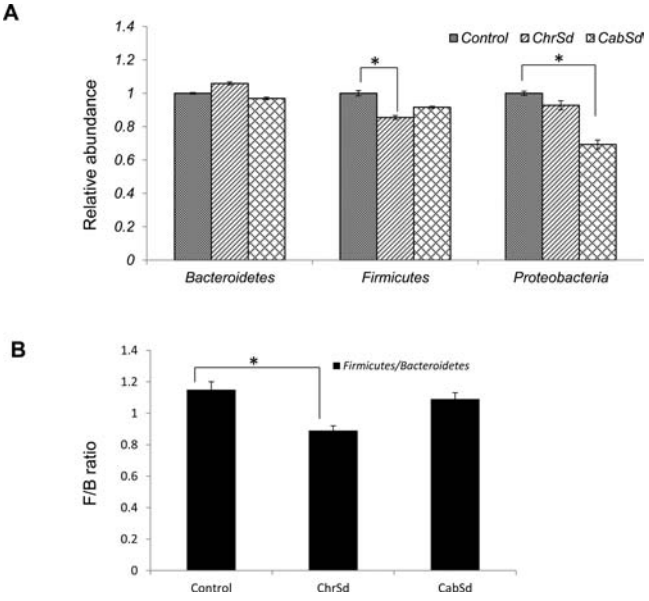

Figure 2. Effect of grape seed flour diets on relative phylum abundance of intestinal bacteria (A) and ratio of *Firmicutes* to *Bacteroidetes* (B). Male Golden Syrian hamsters were fed HF diets containing 10% (w/w) Chardonnay (ChrSd), Cabernet Sauvignon (CabSd) grape seed flours, and 5% MCC (control) for 3 weeks. Data are expressed as means ± SE; n = 4/group. ∗ indicates significant difference at $P < 0.05$.

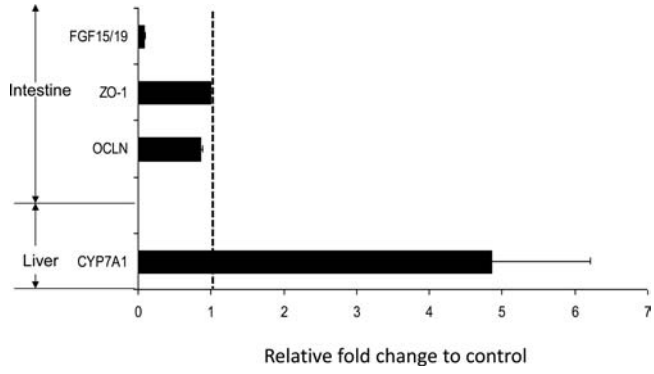

Figure 3. Relative expression of FGF15/19, ZO-1, and OCLN genes in ileum and CYP7A1 in liver of hamsters fed HF diet supplemented with 10% (w/w) Chardonnay (ChrSd) grape seed flours and 5% MCC (control) for 3 weeks. Data are expressed as mean ± SE; n = 5/group.

mRNA level of CYP7A1, the gene that controls the rate-limiting step of bile acid synthesis from cholesterol, was 4.9-fold greater in the livers of hamsters fed the ChrSd diet compared to those fed the control diet (Figure 3).

Correlation of Intestinal Microbiota–Host Metabolic Effects. Correlations of specific genus/species and phylum of intestinal microbiota with plasma cholesterol concentrations, liver, adipose tissue, and body weight were calculated to determine if the changes of the host physiological characteristics were associated with changes in the microbiota after grape seed flavonoid intake (Table 3). Relative abundance of *Lactobacillus* spp. and the F/B ratio showed strong positive correlations to plasma total-, LDL-cholesterol concentrations, and liver weights ($P < 0.05$). Relative abundance of *Bifidobacterium* spp. ($P < 0.01$) and *Firmicutes* ($P < 0.05$) both showed significant positive relationships with liver weights. Relative abundance of *B. fragilis* showed a significant negative relationship with liver weights ($P < 0.01$).

DISCUSSION

The association between the health benefits of grape flavonoids, such as amelioration of cardiovascular and obesity risk factors,

and changes in intestinal microbiota composition has profound implications for the relationship between diet and chronic metabolic disease. The present study provides further indirect evidence for the potential role of the intestinal microbiota in metabolic dyslipidemia. Quantification of selected species/genera and phylum of fecal bacteria from obese and hypercholesterolemic hamsters revealed that supplementation of flavonoid-rich Chardonnay grape seed flour (ChrSd diet) significantly altered intestinal microbiota composition and total number. These modifications were correlated to the prevention of ectopic HF-induced hepatic fat deposition, decreased adipose tissue accumulation and body weight gain, and reduced plasma LDL-, VLDL-, and total-cholesterol concentrations by supplementation of the HF diet with Chardonnay grape seed flour.

The ChrSd diet significantly lowered numbers of total bacteria and relative abundance of *Bifidobacterium* spp. and *Lactobacillus* spp. compared to control. It has been previously shown that there is a positive relationship between total flavonoid content in grape-derived products (pomace or grape seed extract) with selective antimicrobial activity.[30−36] Calculated intakes of flavonoids from our previous study[23] by the hamsters from ChrSd and CabSd diets are about 1000 and 700 mg/kg body wt/d, respectively, and total epicatechin intakes of about 138 and 21 mg/kg body wt/d, respectively. Therefore, lower numbers of total bacteria were associated with higher total catechin content in the grape seed diets, which supports the role of flavonoids as the potential bioactive component responsible for selective antimicrobial effects of Chardonnay grape seed flour on these bacteria. However, other studies reported either no effect or stimulation of growth of *Lactobacillus* spp. or *Bifidobacterium* spp. in the presence of grape or related flavonoids. Tea flavonoids, for example, did not affect growth of these bacteria.[37] Flavonoid intake from red wine or procyanidin-rich grape seed extract was found to stimulate growth of *Bifidobacterium* spp. in human studies.[13,38] Consumption of red wine polyphenols significantly increased numbers of *Bifidobacterium* as well as *Enterococcus*, *Prevotella*, and *Bacteroides*, while it reduced total- and HDL-cholesterol concentrations in a small ($n = 10$) human study.[38] Phenolic extracts from grape pomace increased the growth of *Lactobacillus acidophilus* in an *in vitro* study.[39] Malvidin, an anthocyanidin extracted from grape pomace, and enocianin, an anthocyanin extracted from grape skin, both significantly enhanced the growth of *Bifidobacterium* spp. and *Lactobacillus*−*Enterococcus* spp. in human fecal slurries.[40] At low (150 mg/L) but not high (1000 mg/L) levels, (+)-catechin itself was shown to significantly stimulate growth of *Bifidobacterium* spp. in an *in vitro* study.[11] These discrepancies with our results may be due to *in vivo* versus *in vitro* models, different species (rat, hamster, or human), gut biotype, and dosage threshold. Nonetheless, our observed effect of the ChrSd diet on intestinal bacteria may possibly represent the effects of multiple constituents specific to Chardonnay grape seed flour.

The hypocholesterolemic properties of probiotic bacteria are still unclear.[41] Previously, probiotic *Lactobacillus* and *Bifidobacteria* have been shown to possess bile salt hydrolase (BSH) activity that promotes bile acid excretion by increasing deconjugation of bile acids.[42] Excretion of bile acids leads to a reduction of plasma cholesterol concentration by a compensatory mechanism since cholesterol is the precursor of bile acids in the liver.[43] However, the present study exhibited no significant change in fecal lipid excretion after the ChrSd diet was consumed. Alternatively, studies suggest that intestinal microbiota regulate bile acid metabolism via intestinal FXR signaling and hepatic expression of genes related to bile acid pathway.[22] It has been shown that germ-free mice had lower expression of FGF15 in the intestine, which attenuated FGF15-mediated down-regulation of CYP7A1 in the liver compared to conventional mice.[22] This effect was not observed in FXR-deficient mice. Furthermore, treatment of mice with a strong antioxidant (tempol) inactivated intestinal FXR, which led to a significant reduction in the genus *Lactobacillus* and caused down-regulation of FGF15 expression in the intestine.[20] Our results are similar to these previous reports in that the ChrSd diet lowered the relative abundance of genus *Lactobacillus* in the intestine and that mRNA levels for both FGF15/19 in the intestine and CYP7A1 in the liver were altered compared to the control diet. These findings suggest that a modification of gut microbiota, such as reduction of *Lactobacillus* spp., by the ChrSd diet affects hepatic bile acid metabolism and improved plasma cholesterol concentrations in hypercholesterolemic hamsters possibly by activation of intestinal FXR.

Recent studies have brought light to alterations in gut microbiota that are linked to the development of obesity in both animal models and humans.[44] Our previous study showed that ChrSd supplementation of the HF diet for 3 weeks significantly reduced body weight gain and adipose tissue weights by 31 and 23%, respectively, compared to the control diet.[23] Body weight gains (g) in control, ChrSd, and CabSd

DOI: 10.1021/jf5026373
J. Agric. Food Chem. 2015, 63, 1460−1467

diets were 34.7 ± 1.9, 23.9 ± 1.9, and 38.8 ± 1.9, respectively.[23] Here we observed that reduction of adipose tissue and body weight was accompanied by an increased relative abundance of *B. fragilis* and reduced relative abundance of *Lactobacillus* spp. and *Firmicutes*. The F/B ratio was also lowered by ChrSd supplementation. Consistent to our study, previous studies have shown that *Bacteroidetes* numbers including the *B. fragilis* group were increased with weight loss in obese human subjects undergoing dietary or surgical interventions.[45] Several studies such as a recent report have shown that on HF diets, obese-prone rats had a higher F/B ratio compared to obese-resistant rats.[46] However, other studies, for example, in obese humans, have not shown a causative relationship between the ratio of intestinal F/B and obesity.[47] We have also found similar percentage levels of *Firmicutes* and *Bacteroidetes* compared to total number of bacteria in feces of mice fed ChrSd diets by next generation sequencing (NGS, data not shown). *Lactobacillus* numbers were elevated in obese humans and animals.[48−50] The converse was demonstrated when a reduction of the genus *Lactobacillus* contributed to inactivation of FXR signaling in the intestine via accumulation of intestinal T-β-MCA, a FXR antagonist, and subsequently decreased intestinal FXR-mediated obesity.[20] Interestingly, the present study also correlated a significant reduction of intestinal *Lactobacillus* spp. with the down-regulation of FGF15/19 in the intestine, which supports inactivation of FXR signaling following a ChrSd diet. These data suggest that the antiobesity effect of ChrSd diet may be in part associated with reduced abundance of *Lactobacillus* in the intestine. Other factors in the antiobesity effects of the flavonoid-rich ChrSd diet may be the antioxidant effect of the flavonoids themselves, playing a preventive role in the development of obesity by regulating adipocyte differentiation,[51] or the suppression of PPAR γ2 expression, adipogenesis, and lipid accumulation.[52,53]

Increased abundance of probiotics (*Lactobacillus* spp. and *Bifidobacterium* spp.) may reduce HF-induced plasma lipopolysaccharide (LPS, endotoxin) concentration and inflammatory markers and lead to decreased hepatic steatosis.[54,55] Our previous work showed that ChrSd supplementation of the HF diet for 3 weeks significantly reduced liver weight by 38% compared to the control diet.[23] In the current study, liver weight was positively correlated with relative abundance of *Lactobacillus* spp. and *Bifidobacterium* spp. as well as the F/B ratio. The reduction of liver weight is mainly due to decreased lipid content after ChrSd feeding. Therefore, these results suggest that improvement of hepatic steatosis following ChrSd feeding may be mediated via alteration of the intestinal microbiota independent of the relative abundances of *Lactobacillus* spp. and *Bifidobacterium* spp.

In summary, numbers of total bacteria and relative abundances of *Bifidobacterium* spp., *Lactobacillus* spp., and *Firmicutes* were all lowered in feces from hamsters fed diets supplemented with the ChrSd diet. The ChrSd diet prevented HF and hypercholesterolemic diet-induced increases of plasma LDL-, VLDL-, total-cholesterol concentrations, hepatic steatosis, abdominal adipose tissue weight, and body weight gain. The hypocholesterolemic effect of the ChrSd diet may be mediated, in part, by up-regulation of hepatic CYP7A1 via decreased expression of intestinal FGF15/19 and is associated with lowered relative abundance of *Lactobacillus* spp. There was a significant positive correlation between *Lactobacillus* spp., the F/B ratio, and plasma total- and LDL-cholesterol. Reduction of HF-diet induced adipose tissue and body weight gain was accompanied by an increased relative abundance of *B. fragilis* and other *Bacteroidetes* and by reduced *Lactobacillus* spp. and *Firmicutes*, as represented in the F/B ratio. The antiobesity effect of the ChrSd diet may partially act through a change in the abundance of *Lactobacillus* spp. and subsequent inhibition of intestinal FXR-mediated signaling. In conclusion, although our study did not provide evidence for direct interaction of Chardonnay grape seed flour with intestinal microbiota, these findings suggest that the effect of Chardonnay grape seed flour on ameliorating HF- and high cholesterol-induced metabolic disorders is closely linked to modulation of intestinal microbiota. These data must be considered cautiously because only a few species and genera were quantified. In-depth analysis of intestinal microbiota composition following consumption of Chardonnay grape seed flour warrants further investigation.

is important in the management of chronic respiratory symptoms. Therefore, there is a need to develop new and effective therapies for mucus hypersecretion.

We evaluated the inhibitory effects of CKS or PA on airway inflammation in ovalbumin-induced mice and PMA-exposed A549 cells. Our findings indicated that CKS or PA inhibited the development of airway inflammation, hyperresponsiveness, and remodeling by reducing the allergic responses. This may provide an effective alternative therapy in the treatment of allergy-induced respiratory diseases.

MATERIALS AND METHODS

Chemicals. Chicken egg ovalbumin (OVA) (Grade II), aluminum hydroxide gel, Giemsa solution, and hematoxylin-eosin Y (H&E) staining solution were obtained from Sigma Chemical Co. (St. Louis, MO, USA). Enzyme-linked immunosorbent assay kits were obtained from R&D Systems (Minneapolis, MN, USA) and BD Biosciences (San Diego, CA, USA). Alcian blue periodic acid-Schiff (PAS) staining solution was obtained from Merck KGaA (Darmstadt, Germany).[3] All other chemicals and solvents were of the highest grade available commercially.

Preparation of CKS from the Roots Extract of *Platycodon grandiflorum*. *Platycodon grandiflorum* root (CK) was supplied by Jangsaeng Doraji Co., Ltd. (Jinju, Korea). CK was extracted with MeOH. Concentration of the MeOH solution gave a brown syrupy extract which was suspended in H_2O and then divided successively with ethyl acetate and *n*-butanol. The *n*-butanol layer was suspended in H_2O and put into a Diaion HP20 column. The column was washed with H_2O and then eluted with MeOH. Also, eluted solution was concentrated in reduced pressure to give a crude saponin mixture (CKS).[23]

Preparation of Platycosides by HPLC and NMR Analysis. CKS extracted from the roots of *Platycodon grandiflorum* was analyzed by HPLC. The extracts were dissolved in H_2O and then put into a solid-phase-extraction cartridge (RP-C18, CREEX 600-3506). The cartridge was washed with H_2O and eluted with MeOH. The elution solution was injected into an OptimaPak column (4.6 × 250 mm, 5 μm, 100 Å) maintained at 40 °C on a Futecs NS-3000*i* system equipped with a light scattering detector (ELSD). Platycosides such as deapioplatycoside E, platycoside E, platyconic acid A, platycodin D, 2″-*O*-acetylpolygalacin D_2, and platycodin D_3 were purified from CKS, and then their chemical structures were identified by direct comparison of their physical and spectral data (^{1}H NMR and ^{13}C NMR).[22,23]

Cell Culture. A549 cells were purchased from the American Type Culture Collection (Manassas, VA, USA). A549 cells were cultured in RPMI 1640 supplemented with 10% fetal bovine serum, 100 U/mL penicillin, and 100 μg/mL streptomycin at 37 °C in a humidified chamber with 5% CO_2.[4] PA was dissolved in DMSO and added into the medium.

Animals and Treatment. Six-week-old female ICR mice were obtained from Samtako (Osan, Korea). The animals were allowed free access to Purina rodent chow (Seoul, Korea) and tap water, and were maintained under specific pathogen-free conditions. The animals were acclimated to the temperature (22 ± 2 °C) and humidity (55 ± 5%) of the control rooms with a 12-h light/dark cycle for at least 1 week prior to experimentation.[3] All experimental protocols in the use of the animals were performed according to the rules and regulations of the Animal Ethics Committee, Chungnam National University (Daejeon, Korea).

Immunization and Challenge. Mice were immunized on days 1, 7, and 14 by intraperitoneal (i.p.) injection of 50 μg of chicken OVA emulsified in 1 mg of aluminum hydroxide adjuvant, in a total volume of 100 μL of PBS. The CKS was dissolved in saline. The mice were intragastrically (i.g.) administered 0.5, 1, or 2 mg/kg/day (in 100 μL) CKS each day from days 12 to 16, consecutively. The control and OVA group were administered saline (i.g.). The animals were challenged with OVA on the final day by inhalation of 1 mg/mL OVA in PBS. The control group was immunized and challenged with PBS without CKS administration (Figure 1).[3]

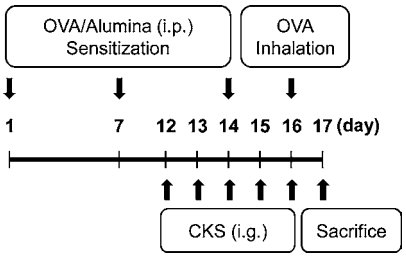

Figure 1. Schematic diagram of the experimental protocol in mice. Mice were divided into five groups. Mice were immunized on days 1, 7, and 14 by intraperitoneal (i.p.) injection of 50 μg of chicken OVA emulsified in 1 mg of aluminum hydroxide adjuvant in a total volume of 100 μL of PBS. CKS was dissolved in saline. Mice were intragastrically (i.g.) administered 0.5, 1, or 2 mg/kg/day (in 100 μL) CKS each day from days 12 to 16, consecutively. The control and OVA group were administered saline (i.g.) without CKS. The animals were challenged with OVA on the final day by inhalation of 1 mg/mL OVA in PBS. The control group was immunized and challenged with PBS without drug administration.

Bronchoalveolar Lavage (BAL) Fluid Collection and Leukocyte Count. Each mouse was anesthetized and the trachea was cannulated by gentle massaging of the throat. BAL fluid was collected by flushing 1 mL of PBS into the lungs via the trachea immediately after sacrifice; approximately 0.8 mL of BAL fluid was recovered after five lavages. The BAL fluid was centrifuged (400*g*, 4 °C, 5 min) and the supernatant was stored at −20 °C until measurement of cytokines. Cells from the BAL fluid were washed three times with PBS, and the pellet was resuspended in 100 μL of PBS. The total cell number was counted by cytospin, and a differential cell count was performed after staining with Giemsa solution.[3]

Enzyme-Linked Immunosorbent Assay (ELISA). The levels of cytokines in the BAL fluid were measured by sandwich ELISA using the OptEIA Set mouse IL-4, IL-5, MCP-1, and IgE kits from BD Biosciences and DuoSet mouse TNF-α, IFN-γ, and IL-13 kits from R&D Systems, according to the manufacturer's instructions. Each concentration was calculated using a linear-regression equation obtained from the standard absorbance values.[3]

Histopathological Studies. Right lung tissues were sliced and fixed in 10% buffered-neutral formalin for 24 h. The fixed lung tissue slices were embedded in paraffin, sectioned, deparaffinized, and rehydrated using standard techniques. Sections 4 μm thick were subjected to H&E staining for general morphological analysis. Airway mucus hypersecretion was evaluated using alcian blue-PAS to stain infiltrated goblet cells. Pulmonary histopathological changes were assessed on a five-point score by three independent examiners. The scores were as follows: 0, no inflammatory cells; 1, minimal accumulation of inflammatory cells; 2, moderate accumulation of inflammatory cells; 3, severe accumulation of inflammatory cells; 4, extreme accumulation of inflammatory cells. Infiltrated goblet cells were also assessed on a five-point score by three independent examiners. The scores were as follows: 0, no goblet cells; 1, minimal infiltration of goblet cells; 2, moderate infiltration of goblet cells; 3, severe infiltration of goblet cells; 4, extreme infiltration of goblet cells.[3,24] All lung tissue was processed according to the histopathological protocols of the pathological laboratory, College of Veterinary Science, Chungnam National University (Daejeon, Korea).

Western Blot Analysis. Western blot analysis was performed as described previously.[3] The intensity of the Western blot bands was measured using the ImageJ software (NIH ImageJ program).

Semiquantitative Reverse Transcription–Polymerase Chain Reaction (RT-PCR) Analysis. Total RNA was extracted from the left lung tissues or A549 cells using RNAiso reagent (Takara, Kyoto, Japan), according to the manufacturer's instructions. RT-PCR analysis was performed as described previously.[3,25] The intensity of the RT-PCR bands was measured using the ImageJ software (NIH ImageJ program). The PCR primer sequences are listed in Table 1.

Quantitative Real-Time RT-PCR (qRT-PCR). Cells were pretreated with PA (0.5, 1, or 2 μM) and then treated with PMA (20 nM). PCR product formation was monitored continuously during amplification using the Sequence Detection System software, version 1.7 (Applied Biosystems, Foster City, CA, USA). The accumulated products were detected directly by monitoring the signal from the SYBR Green reporter dye. MUC5AC mRNA expression was compared between the treated and control cells at each time point using the comparative cycle threshold (Ct) method. The quantity of each transcript was calculated as described in the instrument manual, and normalized to the GAPDH mRNA expression.[34] The PCR primer sequences are listed in Table 1.

Transient Transfection and Luciferase Assays. To determine the promoter activity, a dual-luciferase reporter assay system (Promega, WI, USA) was used. The cells were seeded into 48-well plates and incubated at 37 °C. At 70−80% confluence, the cells were incubated with RPMI1640 without serum or antibiotics for 6 h. The cells were transiently cotransfected with a wild-type MUC5AC promoter luciferase construct, NF-κB reporter vector, and pRL-SV plasmid (Promega, WI, USA) using LipofectAMINE 2000 reagent (Invitrogen, CA, USA), according to the manufacturer's instructions. After 5 h, the medium was replaced with basal medium. The cells were pretreated with PA for 1 h and then treated with PMA for 24 h. After incubation, the cells were lysed and luciferase activity was measured using a luminometer (Luminoscan Ascent, Thermo Electron, Waltham, MA, USA). For each sample, the luciferase signal was normalized to Renilla luciferase activity and expressed relative to the control value.[4]

Statistical Analyses. All experiments were repeated at least three times. Results reported are means ± the standard error of the mean (SEM). Statistical significance was determined using a one-way analysis of variance (ANOVA) followed by the Tukey−Kramer test, with $p < 0.05$ or $p < 0.01$ indicating significance.

RESULTS

CKS Inhibited OVA-induced Leukocyte Recruitment and Histopathological Changes in Mice. Leukocytes play an important role in airway inflammation. To evaluate the effectiveness of CKS in airway inflammation, OVA-induced leukocytes were counted in bronchoalveolar lavage (BAL) fluid. As shown in Table 2, repeated ovalbumin (OVA) application increased the numbers of total and differential leukocytes (i.e., eosinophils, basophils, lymphocytes, and macrophages) in the BAL fluid. The numbers of OVA-induced total and differential leukocytes were reduced by CKS administration in a dose-dependent manner. Continuously, we determined the inhibitory effect of CKS on OVA-induced histopathological changes in the lung tissue. Repeated OVA application increased bronchoconstriction in sensitized mice, with the trachea characterized by goblet cell hyperplasia and mucus hypersecretion from the goblet cells.[26,27] Histopathological analysis by H&E and alcian blue-PAS staining of the lung tissue showed inflammatory cell infiltration and goblet cell hyperplasia in the OVA-treated mice. CKS inhibited these OVA-induced pathological changes in the lung tissue (Figure 2A, B).

CKS Inhibited OVA-Induced IgE, Th1/Th2 Cytokines, and MCP-1 Secretion in Mice. Mast cells are key effector cells in IgE-mediated allergic disorders. IgE-mediated allergic disorders are regulated by mast cells. During mast cells activation, mast cells undergo degranulation and secrete a variety of biologically active substances, which play an important role in the development of airway inflammation.[28,46] We evaluated the effectiveness of CKS against total IgE secretion in BAL fluid. CKS reduced OVA-induced IgE level in a dose-dependent manner (Table 3). Furthermore, airway inflammation is associated with the secretion of Th1/Th2 cytokines and monocyte chemoattractant protein-1 (MCP-1) chemokine.[29] We examined the effectiveness of CKS against OVA-induced TNF-α, IFN-γ, IL-4, -5, -13, and MCP-1 secretion in BAL fluid. Repeated OVA application increased TNF-α, IFN-γ, IL-4, -5, -13, and MCP-1 secretion levels. CKS reduced OVA-elevated Th1/Th2 cytokines and MCP-1 secretion in a dose-dependent manner (Table 3). These results demonstrated that CKS decreased the OVA-induced inflammatory response, affecting leukocyte recruitment and secretion of IgE, Th1 and Th2 cytokines, and MCP-1 chemokine in mice.

CKS Inhibited OVA-Increased MUC5AC and MMP-2/-9 mRNA Expression in Mice. Airway mucus hypersecretion is associated with goblet cell hyperplasia in mice.[30] We determined the inhibitory effects of CKS on OVA-increased MUC5AC

Table 2. Effects of CKS on OVA-Induced Total and Differential Leukocytes in BAL Fluid[a]

	control	OVA	OVA + CKS 0.5	OVA + CKS 1.0	OVA + CKS 2.0
total cells (1×10^4 cells/mL)	14.0 ± 1.00	59.3 ± 6.43[b]	26.0 ± 2.65[c]	21.3 ± 2.31[c]	15.0 ± 2.00[c]
eosinophils (1×10^4 cells/mL)	5.00 ± 1.00	57.0 ± 5.57[b]	27.0 ± 3.61[c]	18.3 ± 2.52[c]	11.7 ± 1.53[c]
basophils (1×10^4 cells/mL)	5.30 ± 1.53	24.0 ± 2.00[b]	16.0 ± 2.00[c]	12.3 ± 2.08[c]	9.70 ± 1.53[c]
lymphocytes (1×10^4 cells/mL)	14.3 ± 1.53	46.0 ± 2.00[b]	35.7 ± 2.52[c]	26.3 ± 3.21[c]	18.7 ± 1.53[c]
macrophages (1×10^4 cells/mL)	11.0 ± 1.00	26.0 ± 2.65[b]	17.7 ± 2.08[c]	14.7 ± 2.08[c]	13.0 ± 1.00[c]

[a]Recovered total cells or differential leukocytes were counted using standard morphological criteria for cytospin (cells number $\times 10^4$). At least 200 cells were examined in each cytospin. PBS-inhaled mice administered saline (control), OVA-inhaled mice administered saline (OVA), OVA-inhaled mice administered CKS 0.5 mg/kg/day (OVA + CKS 0.5), OVA-inhaled mice administered CKS 1.0 mg/kg/day (OVA + CKS 1.0), and OVA-inhaled mice administered CKS 2.0 mg/kg/day (OVA + CKS 2.0). Results represent the means ± SEM of five mice per group. [b]$p < 0.05$, significantly different from the control group. [c]$p < 0.05$, significantly different from the OVA-treated group.

[a]Cytokine levels in the BAL fluid were measured using ELISA kits. PBS-inhaled mice administered saline (control), OVA-inhaled mice administered saline (OVA), OVA-inhaled mice administered CKS 0.5 mg/kg/day (OVA + CKS 0.5), OVA-inhaled mice administered CKS 1.0 mg/kg/day (OVA + CKS 1.0), and OVA-inhaled mice administered CKS 2.0 mg/kg/day (OVA + CKS 2.0). Results represent the means ± SEM of five mice per group. [b]$p < 0.05$, significantly different from the control group. [c]$p < 0.05$, significantly different from the OVA-treated group.

mRNA expression in lung tissues. Repeated OVA application increased MUC5AC mRNA expression, similar to the histopathological changes observed. CKS inhibited OVA-increased MUC5AC mRNA expression in a dose-dependent manner (Figure 3A, B). Airway remodeling is associated with MMPs and TIMPs modulation in mice.[25] We also determined the inhibitory effects of CKS on OVA-mediated MMP-2/9 and TIMP-1/2 mRNA expression in lung tissues. MMP-2/-9 mRNA expression increased with OVA application, but TIMP-1/-2 mRNA expression decreased with OVA application. CKS significantly inhibited OVA-increased MMP-2/-9 mRNA expression and OVA-decreased TIMP-1/-2 mRNA expression (Figure 3A, B). These results demonstrated that CKS inhibited OVA-induced mucus hypersecretion- and airway remodeling-related MUC5AC and MMPs mRNA expression in mice.

CKS Inhibited OVA-Increased NF-κB Activation in Mice. Nuclear factor-kappa B (NF-κB) activation plays an important role in airway inflammation. Various stimuli lead to the phosphorylation, ubiquitination, and proteolytic degradation of IκBα, resulting in the release of NF-κB from its inhibitory protein and its translocation to the nucleus.[31] NF-κB activation has been observed in allergic airway inflammation in human and animal.[33] We determined the inhibitory effect of CKS on NF-κB p65 level during OVA-increased allergic airway inflammation in lung tissues. OVA-sensitized and -challenged mice showed a notably increased NF-κB p65 nuclear protein and a decreased cytoplasmic NF-κB p65 cytosolic protein compared to control mice. CKS treatment inhibited OVA-increased these alterations in a dose dependent manner (Figure 4A, B).

Platyconic Acid A Inhibited PMA-Induced MUC5AC Expression by Inhibiting the Activation of NF-κB in A549 Cells. We determined the inhibitory effects of CKS triterpenoid saponins, platycosides, on PMA-induced MUC5AC expression in A549 cells. First, the cytotoxicity of CKS triterpenoid saponins, platycosides, such as deapioplatycoside E, platycoside E, platyconic acid A (PA), platycodin D, 2″-*O*-acetylpolygalacin D_2, and platycodin D_3 was determined in A549 cells (Supporting Information Supplementary Figure 2). Treatment with each platycoside at concentrations of 0−8 μM for 24 h showed that platycoside concentrations <4 μM did not affect cell viability, and cytotoxicity was determined by MTT reduction and LDH release assays. We further evaluated the inhibitory effects of platycosides on PMA-increased MUC5AC expression in cells. Among the platycosides tested, PA significantly decreased PMA-increased MUC5AC mRNA expression in the cells (Table 4). The chemical structure of platyconic acid A (PA) is shown in Figure 5A. PA is the most potent CKS platycoside, which improves glucose homeostasis by enhancing insulin sensitivity in type 2 diabetic mice.[10] To assess the inhibitory effects of PA on MUC5AC expression, A549 cells were treated with PMA in the presence of PA for 24 h, and MUC5AC mRNA expression was then evaluated by qRT-PCR. PA treatment inhibited PMA-increased MUC5AC mRNA expression in the cells in a concentration-dependent manner (Figure 5B). PA also inhibited PMA-induced MUC5AC luciferase activity by inhibiting the NF-κB promoter-driven luciferase reporter activity (Figure 5C, D). PA inhibited PMA-induced NF-κB p65 phosphorylation, IκBα phosphorylation, and degradation in a concentration-dependent manner (Figure 5E, F). These results demonstrated that PA

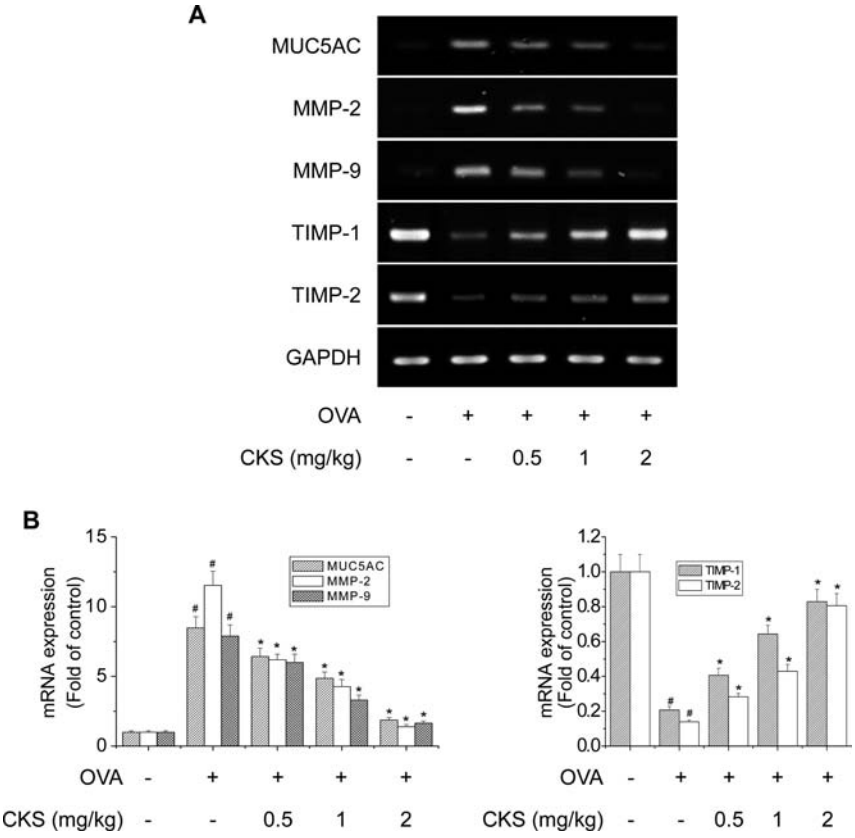

Figure 3. Inhibitory effects of CKS on OVA-induced airway remodeling in mice. (A) Total RNA was extracted from the lung tissue and mRNA expression of MUC5AC, MMP-2, MMP-9, TIMP-1, TIMP-2, and GAPDH were determined by semiquantitative RT-PCR. (B) Intensities of the PCR bands were calculated using the ImageJ software. Results shown are representative of five observations. Results are presented as means ± SEM of three independent experiments. $^{\#}p < 0.05$, significantly different from the control group; $^{*}p < 0.05$, significantly different from the OVA-treated group.

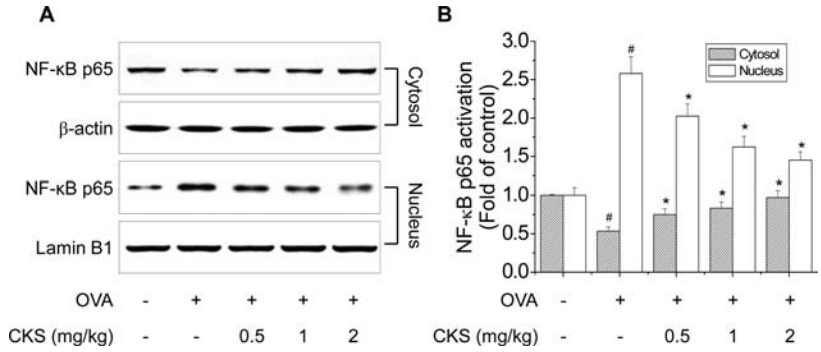

Figure 4. Inhibitory effects of CKS on OVA-induced NF-κB activation in mice. (A) Mice were pretreated with CKS (0.5, 1, or 2 mg/kg) for 1 h and then treated with OVA for 2 h. Cytosolic and nuclear protein was extracted from lung tissue treated with OVA, and NF-κB activation was determined by Western blotting. (B) The intensities of the Western blot bands were calculated using the ImageJ software. Results shown are representative of five observations. Results are presented as means ± SEM of three independent experiments. $^{\#}p < 0.05$, significantly different from the control group; $^{*}p < 0.05$, significantly different from the OVA-treated group.

inhibited PMA-increased MUC5AC expression by suppressing NF-κB activation in cells.

Platyconic Acid A Inhibited PMA-Induced MUC5AC Expression by Inhibiting the Activation of Akt in A549 cells. We demonstrated that PA inhibited NF-κB activity of PMA-treated cells at the transcriptional level (Figure 5). Akt pathway is a well-known upstream regulator of NF-κB signaling in MUC5AC transcription factor.[40] We evaluated the inhibitory effect of PA on PMA-induced Akt phosphorylation in cells. PA inhibited PMA-induced Akt phosphorylation in a concentration-dependent manner (Figure 6A, B).

■ DISCUSSION

There is widespread interest in developing new, and less toxic, anti-inflammatory agents from natural sources. Natural immune modulators from herbal extracts or herbal derivatives have been reported to have inhibitory effects on inflammation.[21,34,41−45] We investigated the inhibitory effects of *Platycodon grandiflorum* root-derived saponins (CKS), especially platyconic acid

Table 4. Effect of Platycosides and CKS on PMA-Induced MUC5AC mRNA Expression in A549 Cells[a]

treatment	relative MUC5AC mRNA to GAPDH (fold of control)
control	1.0 ± 0.11
PMA	2.1 ± 0.22[b]
PMA + deapioplatycoside E	2.0 ± 0.19
PMA + platycoside E	2.0 ± 0.20
PMA + platyconic acid A	1.2 ± 0.11[c]
PMA + platycodin D	1.6 ± 0.17[c]
PMA + 2″-*O*-acetylpolygalacin D_2	1.5 ± 0.16[c]
PMA + platycodin D_3	1.4 ± 0.15[c]
PMA + CKS	1.3 ± 0.14[c]

[a]A549 cells were pretreated with platycosides (1 μM) or CKS (1 μg/mL) and then treated with PMA (each 20 nM). After 24 h, total RNA was extracted from the cells and MUC5AC mRNA levels were determined by qRT-PCR. Results represent the means ± SEM of three independent experiments. [b]$p < 0.01$, significantly different from the control group. [c]$p < 0.01$, significantly different from the PMA-treated group.

A (PA), on airway inflammation in ovalbumin-induced mice and PMA-exposed A549 cells.

Asthma is one of the most common respiratory inflammatory diseases worldwide, and is characterized by airway hyperresponsiveness. Asthma is caused by inappropriate responses to inhaled allergens, and the strength of the hyperresponsiveness correlates with the level of airway inflammation, which is predominated by inflammatory cell infiltration, mucus hypersecretion, allergen-specific IgE, and overproduction of Th1/Th2-mediated cytokines and chemokines.[32]

Allergen exposure in the airway induces a Th2-dominant response by activating inflammatory cells and increasing Th2 cytokines. IL-4, IL-5, and IL-13 play important roles in causing the symptoms, such as airway hyperresponsiveness, airway inflammation, and goblet cell hyperplasia via eosinophil activation and IgE secretion.[33] Th2 cytokines are important therapeutic targets for the inhibition of airway inflammation. We evaluated the inhibitory effects of CKS on the secretion of Th1/Th2 cytokines in OVA-induced mice. OVA-induced

secretion of Th2 cytokines (IL-4, IL-5, and IL-13), as well as secretion of Th1 cytokines (TNF-α and IFN-γ), was reduced by CKS treatment. The Th2 immune response is associated with IgE hypersecretion. In IgE-mediated airway inflammation, IgE released from B cells binds to mast cells, leading to degranulation of the mast cells and the release of various biological mediators.[14] We confirmed that OVA-induced IgE production was reduced by CKS treatment, and we previously reported on the inhibitory effects of CKS on IgE-mediated allergic responses in mast cells.[34] Chemokines play an important role in the development of airway inflammation through their participation in leukocyte recruitment. MCP-1 plays a role in the recruitment and activation of leukocytes in response to various stimuli.[35] We demonstrated that CKS treatment reduced OVA-induced MCP-1 secretion. These results suggest that CKS reduced OVA-induced development of airway inflammation by suppressing IgE-mediated mast cell activation, Th1/Th2 inflammatory cytokines, and MCP-1 chemokine release.

Airway inflammation occurs due to an infiltration of leukocytes into the bronchial and lung tissues. It is associated with the production of Th2 cytokines, which play a critical role in the differentiation, infiltration, and activation of eosinophils.[25] We evaluated the inhibitory effects of CKS on the number of leukocytes in OVA-inhaled mice. We demonstrated that the number of total and differential inflammatory cells was reduced by CKS treatment. Asthma is characterized by the infiltration of inflammatory cells, as well as hyperplasia of goblet cells into the lung tissues. Goblet cell hyperplasia is associated with bronchial inflammation and narrowing of the airways.[36] Pathological changes showed that CKS treatment inhibited OVA-induced inflammatory cell infiltration and goblet cell hyperplasia in the lung tissue.

Airway remodeling often occurs during the initial stages of asthma and may facilitate the continuation of damage to tissues and the inflammatory response. Airway remodeling is characterized by inflammatory cell infiltration, goblet cell hyperplasia, and MMP-2/-9 production.[37] MMPs are proteases that cleave components of the extracellular matrix. MMPs play an important role in tissue remodeling associated with pathological processes such as morphogenesis, angiogenesis, tissue repair, and migration.[37] A recent study reported that MMP-2/-9 overexpression was related to an accumulation of airway inflammatory cells in an animal model.[37] We evaluated OVA-induced MMP-2/9 and MUC5AC mRNA expression associated with airway remodeling in lung tissues. We demonstrated that OVA-induced MMP-2/9 and MUC5AC mRNA expression was reduced by CKS treatment. However, OVA-reduced TIMP-1/-2 mRNA recovered with CKS treatment. Expression of MUC5AC and MMP-2/-9 is controlled by a NF-κB transcription factor. We examined the OVA-induced NF-κB nuclear translocation in lung tissues. OVA-induced NF-κB nuclear translocation was reduced by CKS treatment. We previously reported the inhibitory effects of CKS on cellular MMP-2/-9 and MUC5AC expression via inhibition of NF-κB activity.[4,38] CK inhibited OVA-induced MMP-2/-9 production via inhibition of NF-κB nuclear translocation.[3] Finally, we evaluated the effects of PA, a component of the CKS triterpenoid saponins, on MUC5AC expression via NF-κB activation in the cells. The inhibition of iNOS and COX-2 mRNA expression by PA, through blocking of NF-κB activation, has been reported previously.[39] We showed that PA treatment inhibited PMA-induced MUC5AC expression by suppressing NF-κB activity. These results suggested that CKS reduced OVA-induced airway remodeling by suppression of MMP-2/-9 and MUC5AC expression via inhibition of NF-κB activity. PA potentially inhibited MUC5AC expression through the inactivation of NF-κB.

In conclusion, we demonstrated that CKS and its active component, PA, reduced the severity of airway inflammation in an experimental animal model and in cells. CKS inhibited OVA-induced airway inflammation symptoms, including infiltration of inflammatory cells, hypersecretion of goblet cells, levels of IgE, Th1/Th2, and MCP-1, mRNA expression of MMP-2/-9 and MUC5AC, and NF-κB activation in mice. PA inhibited MUC5AC expression via suppression of NF-κB activation in cells. These results demonstrated that CKS and PA have a potent preventive effect against the progression of airway inflammation related to mucin production.

[a]Peak No. = peak number. [b]t_R = retention time.

primary aim of the present study was the separation, comprehensive identification and quantification of phenolic compounds and antioxidant properties in three different elderflower extracts (methanol and two water extracts prepared as fresh drinks according to local recipes). Moreover, the effect of extraction solution, duration of extraction and method of juice preparation on the content of phenolic compounds has been evaluated. Methanol was used as a standard solvent for phenolic extraction to enable maximum levels of extracted compounds. Additionally, the study aims to underline qualitative and quantitative differences between two types of elderflower beverages: a local drink known as "sabesa" and elderflower syrup. The results are indicative of the potential value of elderflower extracts in the processing industry (juices, syrups, beverages) as well as important for further studies monitoring the effects of plant-based product intake on human health.

MATERIALS AND METHODS

Chemicals. The following standards were used for the quantification of phenolic compounds: neochlorogenic acid (3-caffeoylquinic acid), chlorogenic acid (5-caffeoylquinic acid), naringenin and quercetin-3-rutinoside from Sigma-Aldrich Chemie GmbH (Steinheim, Germany), caffeic and ferulic acid, (−)-epicatechin, quercetin-3-galactoside, quercetin-3-glucoside, *p*-coumaric acid, procyanidin B1 and kaempferol-3-glucoside from Fluka Chemie GmBH (Buchs, Switzerland); isorhamnetin-3-*O*-glucoside from Extrasynthese (Genay Cedex, France) and (+)-catechin from Roth (Karlsruhe, Germany). Methanol for the extraction of phenolics was acquired from Sigma. The chemicals for the mobile phases were HPLC-MS grade acetonitrile and formic acid from Fluka Chemie

DOI: 10.1021/jf506005b
J. Agric. Food Chem. 2015, 63, 1477−1487

GmbH. Water for mobile phase was double distilled and purified with the Milli-Q system (Millipore, Bedford, MA, USA). For the total phenolic content, Folin-Ciocalteu phenol reagent (Fluka Chemie GmBH), sodium carbonate (Merck, Darmstadt, Germany), gallic acid (Sigma) and ethanol (Sigma) were used. For the antioxidant activity 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), 2,2′azinobis(3-ethylbenzthiazoline-6-sulfonic acid ($ABTS^{\bullet+}$); potassium persulfate, acetic acid, 2,4,6-tripyridyl-1,3,5-triazine (TPTZ), $FeCl_3 \cdot 6H_2O$, hydrochloric acid, sodium acetate and methanol were purchased from Sigma-Aldrich.

Plant material. Mature elderberry umbels were hand-picked from wild-growing elderberry shrubs growing near Ljubljana (latitude 46° 08′ 19″ N, longitude 14° 30′ 27″ E) on May 19th 2014. Umbels were picked from the middle and top branches of several elderberry bushes in the morning hours. Approximately 200 umbels were collected and transferred into the laboratory. Stalks were shortened to about 2 cm from the center of the umbel and pedicles and flowers were further processed into different elderflower products.

Processing of elderflower extracts. Three different extracts (in six replications each) were prepared from fresh elderflowers. The first extraction was prepared by extracting 2 g of elderflowers with 15 mL of methanol. Tubes were placed in a cooled ultrasonic bath for 1 h. After extraction, flower extracts were centrifuged for 10 min at 12.857 g. Each supernatant was filtered through a Chromafil AO-20/25 polyamide filter produced by Macherey-Nagel (Düren, Germany), transferred into a vial and stored at −20 °C prior to injection into the HPLC (high performance liquid chromatography) system.

The remaining two extraction procedures utilized tap water for elderflower extraction and were based on traditional recipes for syrup and sabesa beverage preparation. These elderflower beverages are frequently made in Slovenia. The syrup was prepared according to the following procedure: one (1) kg of sugar (sucrose) and 16.7 g of citric acid were dissolved in one (1) L of water. To the sweet liquid 140 g of elderflowers were added to produce syrup. The second type of a local drink, known as sabesa, was prepared by adding 150 g of sucrose, 1 g of citric acid, 50 mL of acetic acid and 14 g of fresh elderflowers to one (1) L of water.

Elderflowers were extracted in a dark cool room (10 °C) for 1, 3, or 7 days and the liquid was stirred several times each day. Original recipe for preparing sabesa is extracting flowers for 3 days and for syrup just 1 day. After the extraction the beverages were filtered through gauze, the extracts were centrifuged for 10 min at 12.857 g and filtered through a polyamide filter (Macherey-Nagel, AO-20/25) into a vial. The samples were stored at −20 °C prior to injection into the HPLC system.

Determination of individual phenolic compounds using HPLC-DAD-MS^n analysis. Phenolic compounds were analyzed on a Thermo Finnigan Surveyor HPLC system (Thermo Scientific, San Jose, USA) with a diode array detector at 280 nm (flavanols, hydroxycinnamic acid derivatives, flavanone) and 350 nm (flavonols). Spectra of the compounds were recorded between 200 and 600 nm. The column was a Gemini C_{18} (150 × 4.6 mm 3 μm; Phenomenex, Torrance, USA) operated at 25 °C. The elution solvents were aqueous 0.1% formic acid in double distilled water (A) and 0.1% formic acid in acetonitrile (B). Samples were eluted according to a linear gradient from 5% to 20% B in the first 15 min, followed by a linear gradient from 20% to 30% B for 5 min, then an isocratic mixture for 5 min, followed by a linear gradient from 30% to 90% B for 5 min, and then an isocratic mixture for 15 min before returning to the initial conditions.[14] The injection amount was 20 μL and flow rate 0.6 mL min^{-1}.

All phenolic compounds were identified using a mass spectrometer (Thermo Scientific, LCQ Deca XP MAX) with electrospray ionization (ESI) operating in negative ion mode. The analyses were carried out using full scan data-dependent MS^n scanning from m/z 115 to 1500 (Table 1). The injection volume was 10 μL and the flow rate maintained at 0.6 mL min^{-1}. The capillary temperature was 250 °C, the sheath gas and auxiliary gas were 60 and 15 units, respectively; the source voltage was 3 kV and normalized collision energy was between 20−35%. Spectral data were elaborated using the Excalibur software (Thermo Scientific).

Contents of phenolic compounds were calculated from peak areas of the sample and the corresponding standards and expressed in mg/L of elderflower extract or in mg/kg elderflowers. For compounds lacking standards, quantification was carried out using similar compounds as standards. Thus, coumaric acid derivatives were quantified in equivalents of *p*-coumaric acid, caffeic acid derivatives in equivalents of caffeic acid, ferulic acid derivatives in equivalents of ferulic acid, procyanidin trimer in equivalents of procyanidin B1, quercetin-glycosides in equivalents of quercetin-3-galactoside, isorhamnetin glycosides in equivalents of isohamnetin-3-glucoside and kaempferol glycosides in equivalents of kaempferol-3-glucoside.

Determination of total phenolic content. Total phenolic content (TPC) of extracts was assessed by the Folin-Ciocalteau phenol reagent method.[15] To 100 μL of the sample extracts (methanolic extracts were diluted 1 to 4 (v/v) with MeOH), 6 mL of double distilled water and 500 μL of Folin-Ciocalteau reagent were added; after resting between 8 s and 8 min at room temperature, 1.5 mL of sodium carbonate (20% w/v) was added. The extracts were mixed and allowed to stand for 30 min at 40 °C before measuring the absorbance on a spectrophotometer (PerkinElmer, UV/vis Lambada Bio 20) at 765 nm. A mixture of water and reagents was used as a blank sample. Total phenolic content was expressed as gallic acid equivalents (GAE) in mg/L of extract or in mg/kg fresh flowers. Absorption was measured in three replications.

Determination of $ABTS^{\bullet+}$ radical cation scavenging activity. The free-radical scavenging activity was determined by ABTS radical cation decolourization assay according to the method of Re et al.[16] ABTS was dissolved in water to a 7-mM concentration. ABTS radical cation ($ABTS^{\bullet+}$) was produced after the reaction of $ABTS^{\bullet+}$ stock solution with 2.45 mM potassium persulfate (final concentration) and the mixture was left in the dark at room temperature for 12−16 h before use. The radical remains stable in this form for more than 2 days. In the following step, $ABTS^{\bullet+}$ solution was diluted with double distilled water to an absorbance of 0.700 (±0.02) measured at 734 nm. Thirty μL of the extract were added to 3.0 mL of diluted $ABTS^{\bullet+}$ solution and the absorbance was assessed exactly 6 min after the initial mixing. All measurements were performed in triplicate. The results of the assay were expressed relative to mM Trolox/L of extract or in mM Trolox per kg of fresh flowers in terms of trolox equivalent antioxidant capacity (TEAC).

Determination of ferric reducing antioxidant power (FRAP) assay. Total antioxidant potential of the extracts was determined using a ferric reducing ability of plasma (FRAP) assay by Benzie and Strain[17] as a measure of antioxidant power. The assay is based on the reducing power of a compound (antioxidant). A potential antioxidant will reduce the ferric ion (Fe^{3+}) to ferrous ion (Fe^{2+}); the latter forms a blue complex (Fe^{2+}/TPTZ), which increases the absorption at 593 nm. Briefly, the FRAP reagent was prepared by mixing acetate buffer (300 μM, pH 3.6), a solution of 10 μM TPTZ in 40 μM HCl, and 20 μM $FeCl_3$ at 10:1:1 (v/v/v). The FRAP reagent (300 μL) and sample solutions (10 μL) were added to each well and mixed thoroughly. The absorbance was measured at 593 nm after 10 min. Standard curve was prepared using different concentrations of Trolox. All solutions were used on the day of preparation. All determinations were performed in triplicate. The results were expressed in mM Trolox/L of extract or in mM Trolox per kg of fresh flowers.

Statistical analysis. The content of individual phenolic in mg/kg of fresh flowers were compared among three treatments (methanol extract, sabesa after 72 h of extraction and syrup after 24 h of extraction) using one-way ANOVA. The effect of extraction time (three levels), type of elderflower beverage (two levels) and their interaction on the content of individual phenolic compound in mg/L was investigated using linear mixed effects model with the extraction vessel as the random factor. The model assumptions tests (variance check, normality check) were performed graphically (plot of residuals vs fitted values and Q-Q plot, respectively). After the overall tests planned contrasts were performed to determine significant differences between extraction times for sabesa and syrup separately. All the analyses were performed in R environment (R Core Team, 2013); for linear mixed models the package nlme was used.

RESULTS AND DISCUSSION

Traditionally beverages (sabesa and syrup) are prepared with different amounts of elderflowers in water. To directly compare the extractability of phenolics between the two beverages and those with standard solvent methanol, results should be express in mg per kg of fresh flowers (Table 2). However, when comparing both traditional drinks, regardless of the quantity of elderberry flowers added, the concentration was expressed in mg per liter (Table 3). Additionally, it should be taken into account that syrup is usually diluted in the ratio 1:5. The traditional extraction time of elderflowers for preparing syrup is 24 h and that for sabesa is 72 h.

Phenolic composition in elderflower extracts. 37 different phenolic compounds have been identified in the methanolic extract of elderflowers with the use of HPLC-MS (Table 1, Figure 1). Four hydroxycinnamic acid derivatives and different flavonol glycosides have been tentatively identified in elderflowers for the first time. Specific information on LC-MS ions and subsequent fragmentation patterns of the dominant ions in MS^2 enabled the identification of compounds based on the molecular masses of conjugates, the masses of the sugars

Table 3. continued

[a]Letters indicate homogeneous groups of extraction durations for each beverage separately at the 0.05 significance level. [b]The content of phenolic compounds was expressed as mean ± SE in mg per kg fresh flowers. [c]Total phenolic content as mean ± SE in mg GAE per kg flowers. [d]Antioxidant activity as mean ± SE in mM trolox per kg flowers.

bonded to the aglycons, and the structures of aglycons (Table 1).

Methanol is widely used to extract phenolics from plant material, as these compounds are often more soluble in organic solvents less polar than water.[18] Alcohols, particularly methanol and ethanol, proved more efficient compared to water in extracting phenolics from different natural sources, such as coffee, onion and grape.[19−21] For this reason, elderflowers were extracted in methanol—a standard solvent for phenolic compounds. In the present study, a second extraction method was employed utilizing water as a solvent because, traditionally, elderflower beverages are prepared at home with tap water. As expected, methanol proved a superior solvent of elderflowers, as higher content levels of phenolic groups have been determined in methanol-extracted samples compared to water-extracted elderflowers (Table 2).

The major group of phenolic compounds in elderflowers comprised hydroxycinnamic acids (HC) representing almost 50% of total analyzed phenolic compounds (TAP) in elderflower syrup. In sabesa, their share accounted for up to 40% TAP and in methanolic extract less than 35% TAP. These results suggest a better extraction of hydroxycinnamic acids in water. Correspondingly, studies report that water is an ideal solvent for extraction of phenolic acids.[22] The main hydroxycinnamic acid detected in elderflower samples was 5-caffeoylquinic acid (chlorogenic acid), representing from 50 to 60% total hydroxycinnamic acids analyzed (TAH). 3-Caffeoylquinic acid (neochlorogenic acid), 3- and 5-feruloylquinic acid and dicaffeoylquinic acid 1, 2, and 3 (diCQA) have also been quantified in elderflower extracts. Three peaks with m/z 515 have been identified as dicaffeoylquinic acids based on the fragment MS^2 ion at m/z 353, and MS^3 ions at m/z 191, 179 (diCQA 1); the second had MS^3 ions at m/z 191, 179, and 173 (diCQA 2); and the last one had MS^3 ions at m/z 173, 179, and 191 (diCQA3). Numbers from 1 to 3 were appointed to these compounds according to their elution or retention time. The fragmentation patterns suggest these dicaffeoylquinic acids to be 1,5-dicaffeoylquinic acid, 3,5-dicaffeoylquinic acid and 4,5-dicaffeoylquinic acid described by Clifford et al.[23] and previously detected in elderflowers.[9]

Fifteen (15) different hydroxycinnamic acid derivatives have been analyzed in elderflower methanolic extracts (Table 1). All except dicaffeoylquinic acid 3 have also been quantified in water-extracted elderflower samples. For nearly all analyzed phenolic compound treatments (sabesa, syrup), the duration of extraction and their interactions were highly significant ($p < 0.001$). TAH increased with the duration of water extraction (Table3; $p < 0.001$). Specifically, a 1.5-fold increase from 24 h (1 day) extraction to 72 h (3 day) extraction time has been determined in sabesa and a 2.3-fold increase in elderflower syrup (Figure 2). An additional 7−20% increase has been measured between the third and seventh days of extraction. Significantly higher levels of individual and total hydroxycinnamic acids have been determined in elderflower syrup compared to sabesa. Despite the fact that the syrup is diluted with water prior to consumption (usually 1:5, v/v), the intake of phenolic acids in the diluted syrup is still much higher compared to sabesa. Some references report a dietary role of hydroxycinnamic acids.[24] Dietary antioxidants may protect the body against oxidative stress-related diseases. Caffeic acid derivatives (e.g., dicaffeoylquinic acid) have been shown to be potent and selective inhibitors of some viruses[25,26] and have antitumor activity.[27] To our knowledge, 3- and 5-feruloylquinic

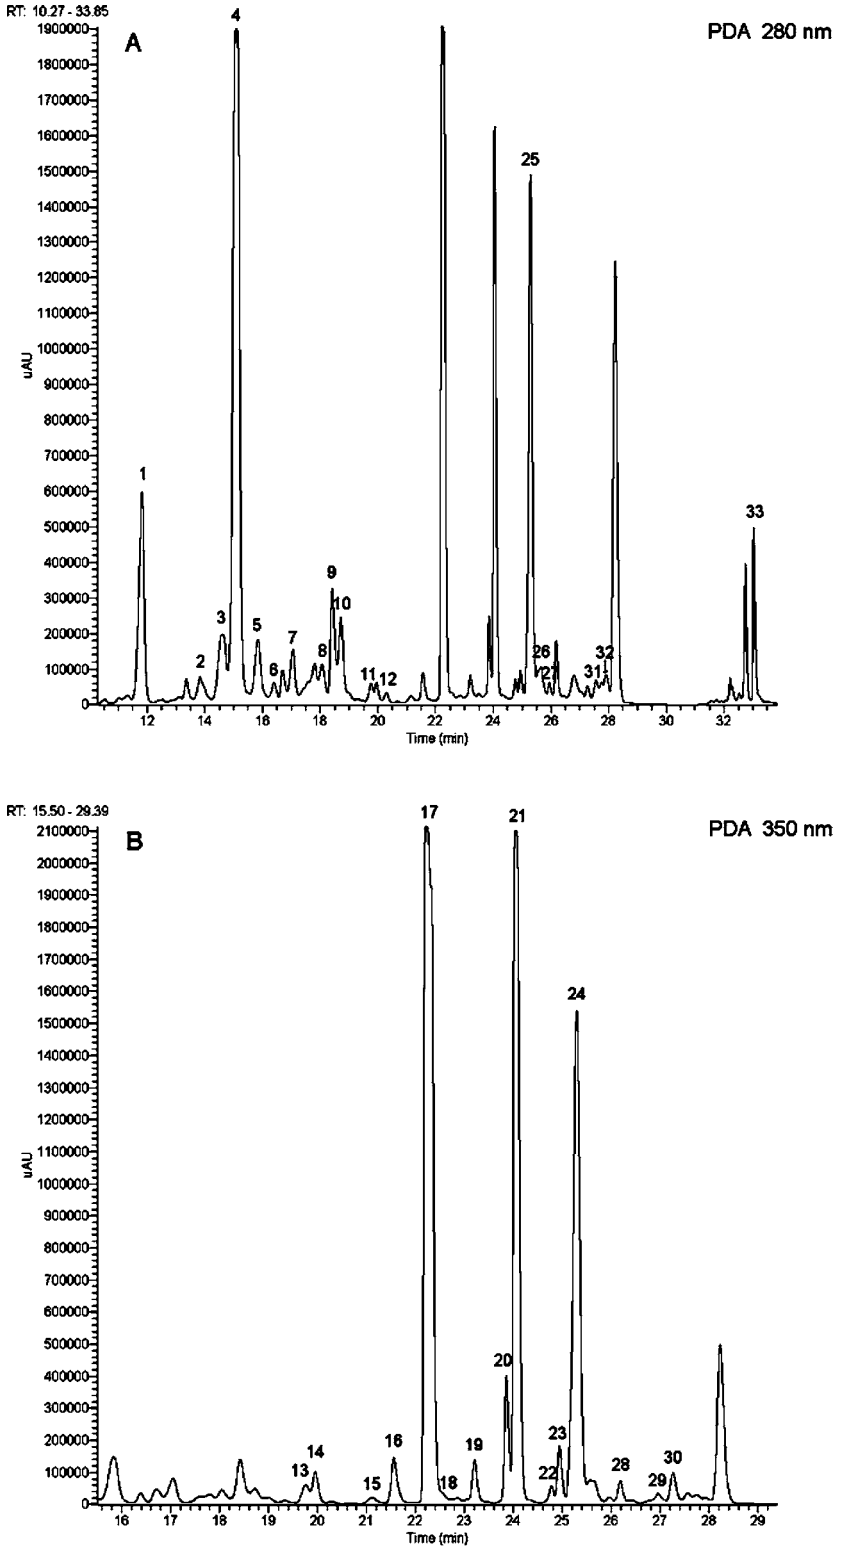

Figure 1. Phenolic chromatogram of elderflower methanolic extract recorded at (A) 280 nm and (B) 350 nm. Peak numbers are described in Table 1

acid and two *p*-coumaroyl-caffeoylquinic acids have not been detected in elderflower extracts prior to the present research.

Flavonols represented the subsequent principal phenolic group and together with hydroxycinnamic acids accounted for up to 98% total analyzed phenolic compounds in water-extracted samples. Eighteen (18) different glycosides of kaempferol, quercetin and isorhamnetin have been identified in elderflower methanolic extract (Table 1). All except kaempferol dihexoside 1, quercetin-3-galactoside and isorhamnetin-pentoside have also been determined in water-extracted samples. Two peaks with $[M - H]^-$ value at m/z 609 have been detected and determined as kaempferol dihexosides based on the MS^3 fragment at m/z 285 obtained after the loss of 2 hexoses. The second unknown peak with $(M - H)^-$ at m/z 447

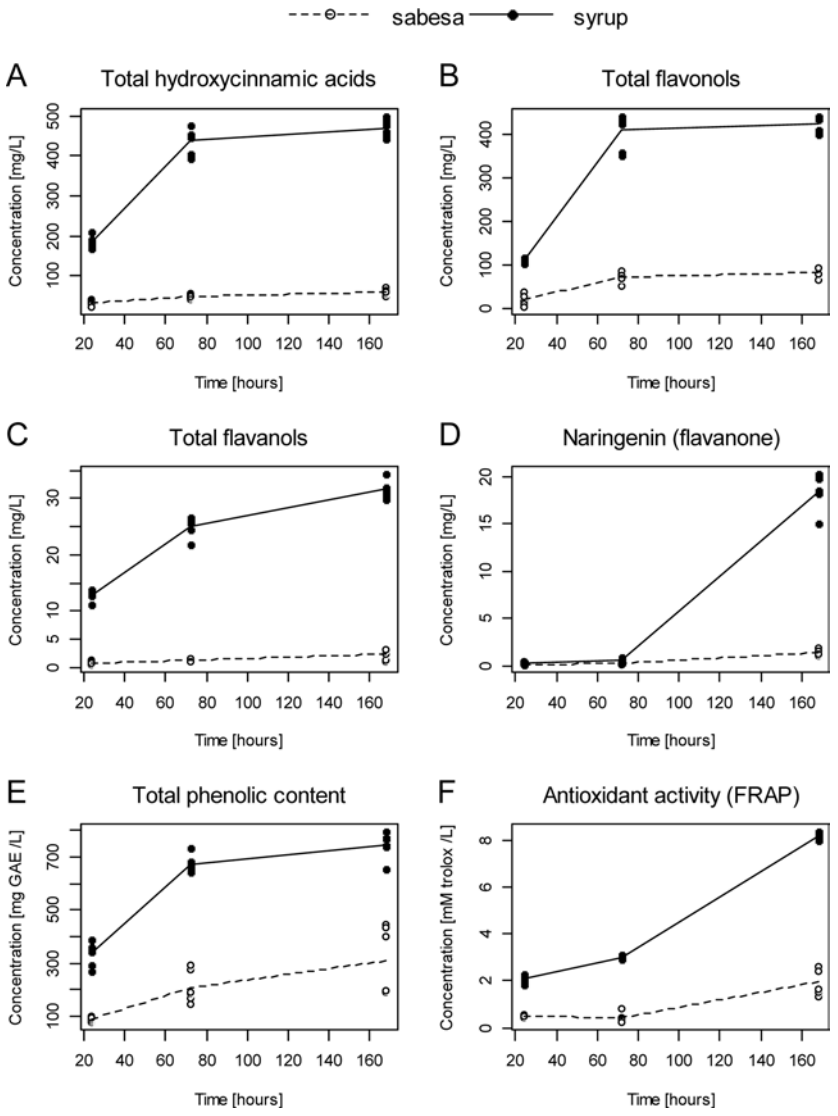

Figure 2. Content of different phenolic groups (mg/L), total phenolic content (mg GAE/L) and antioxidant activity (mM trolox/L) of two elderflower beverages (sabesa and syrup) at different extraction periods.

and MS^2 fragment ion at m/z 315, corresponding to a fragmental loss of a pentose moiety, was identified as isorhamnetin pentoside.

Several glycosides of quercetin and kaempferol have been identified in elderflower extracts representing 5−10% total analyzed flavonols. Additionally, isorhamnetin glycosides accounted for 15−25% total analyzed flavonols. Derivatives of quercetin, kaempferol and isorhamnetin are the most abundant flavonols in plant-based foods.[28] Information on the conjugation of sugar to the polyphenolic section may provide additional knowledge on their nutritional significance, since the sugar moiety is an important determinant of flavonol bioavailability.[29]

In elderflower extracts, quercetin-3-rutinoside (rutin) represented almost 75% of all flavonols. Previous research also reports rutin as the major polyphenol in elderberry.[30,31] Rutin content increased from day 1 to day 3 of water extraction (p < 0,001); in sabesa the increase was 3.8-fold and in syrup 4.4-fold (Table 3). After 7 days of extraction the content of rutin additionally increased for 10%. The results suggest that the majority of rutin is extracted during the first 3 days. This is in accordance with the report of Machavarapu et al.[20] Reis et al.[22] determined that water readily extracts quercetin aglycone but is a poor solvent for quercetin glycosides. Instead, 40% methanol proved to be the best solvent to extract quercetin glycosides. Quercetin-glycosides are probably linked to cell walls with hydrophobic bonds and are therefore difficult to extract from the plant material with water. Similarly, Machavarapu et al.[20] studied the extraction of rutin in onion and reported that methanol was a superior solvent compared to ethanol or water. In our study, better extraction effect of mostly all quercetin glycosides was in beverage sabesa and the lowest in elderflower syrup (Table 2). Statistically the highest content of rutin was analyzed in sabesa after 72 h of extraction (Table 2).

In the present study several flavonol derivatives have been detected, which have not been reported in other studies.[8−10,32,33] Two kaempferol-dihexosides ($[M - H]^-$ at m/z 609), kaempferol triglycoside ($[M - H]^-$ at m/z 755), kaempferol acetylhexoside ($[M - H]^-$ at m/z 489), isorhamnetin-pentoside ($[M - H]^-$ at m/z 447), isorhamentin acetylhexoside ($[M - H]^-$ at m/z 519), isorhamnetin dihexoside ($[M - H]^-$ at m/z 639), quercetin-3-galactoside ($[M - H]^-$ at m/z 463), quercetin dihexoside ($[M - H]^-$ at

J. Agric. Food Chem. 2015, 63, 1477−1487

m/z 625) and two quercetin hexoside-pentosides ($[M - H]^-$ at m/z 595) have been quantified in elderflower extracts.

Elderflower syrup contained up to 5.6-fold levels of total flavonols (110.7−421.65 mg total flavonols per L) compared to sabesa (Table 3, Figure 2). But we must take into account that syrup is diluted with water (1:5, v/v) for consumption, so the differences between both beverages in flavonol levels are not so high. The content levels of individual and total flavonols make these beverages ideal for daily consumption. Several health beneficial activities have namely been attributed to naturally occurring plant flavonols, including antioxidant, anticarcinogenic, anti-inflammatory, neurodegenerative and antidiabetic properties. In recent years, the antioxidant potential of flavonols has become the main topic of investigation, as these compounds exhibited a positive effect on reducing the progression of major diseases. Epidemiological studies indicating that the high dietary intake of flavonols reduces the risk of mortality due to coronary heart disease have provoked interest in the mechanism of their cardioprotective effects.[12,13]

From the group of flavanols, catechin, epicatechin and procyanidin trimer have been identified in elderflower methanolic extract (Table 1). The latter has been detected in sabesa and in elderflower syrup, which also contained epicatechin. Elderflower syrup contained 14- to 21-fold higher levels of total flavanols (12.65 to 31.61 mg/L) compared to sabesa (Table 3, Figure 2). This means that even as the syrup is consumed diluted with water, the prepared beverage still contains significantly higher levels of total flavanols compared to the sabesa beverage. Flavanols can cause astringency (dry and pucker feeling in the mouth) and bitter taste in plant-based foods and drinks. They are mainly the constituents of unripe fruit and have been linked to its bitterness and astringent taste,[34] preventing herbivores consuming and disseminating immature seed. Other researchers reported that adding sugars or other sweeteners reduces bitterness and astringency of plant-based products.[35]

Flavanone naringenin represented as much as 23% total analyzed phenolic compounds (TAP) in methanol-extracted samples. However, water extraction yielded different results. This compound accounted for approximately 0.08% TAP in elderflower syrup and 0.4% TAP in sabesa after 24 h of extraction. The results are indicative of a better solubility of naringenin in methanol, previously stated in several studies. For example, Wilcox et al.[36] report that naringenin is almost insoluble in water and only soluble in organic solvents such as alcohol. Naringenin is the main flavanone naturally occurring in citrus fruits.[11] The role of naringenin in the prevention and treatment of disease has recently received considerable attention, with particular interest as a potential anticancer compound.[11] Therefore, elderflower beverages and extracts can represent important sources of this bioactive compound in the daily diet, but the extraction method must enable naringenin solubility. It has been reported that naringenin enantiomers inhibit several important drug-metabolizing CYP isoforms.[37] Moreover, it has been reported that naringenin present in elderflower extracts is one of the most potent compounds with a major effect on the enhancement of glucose uptake and reduction of fat accumulation.[7] Elderflower extracts have been found to activate peroxisome proliferator-activated receptors and enhance insulin-dependent glucose uptake (GU) in adipocytes.[38] In addition to a decreased blood glucose level, the reduction of body fat is also an important goal for combating obesity and diabetes type 2.[7]

Total phenolic content (TPC) increased in the following order: syrup (water extraction), methanolic extract and sabesa (water extraction) (Table 2). The largest effect of rutin extraction was in sabesa, which was probably the reason for significantly higher TPC in this beverage (Table 2). Contrary to our results, Tai et al.[39] reported that alcoholic extracts of *Sophora viciifolia* flowers had higher TPC in comparison to water extracts. When it comes to duration of total phenolic extraction, the highest total phenolic content (TPC) was measured in elderflower syrup after 7 days and the lowest in sabesa after 1 day of the extraction (Table 3, Figure 2). In water-extracted beverages, TPC significantly increased after 7 days of extraction, 2.2-fold in elderflower syrup and 3.4-fold in sabesa in comparison to the first day (Table 3). Furthermore, water-extracted elderflower beverages had similar TPC as mandarin[40] and orange juice.[41]

Antioxidant activity of elderflower extracts. Two in vitro assays ($ABTS^{\bullet+}$ and FRAP) were used as complementary methods to evaluate the antioxidant activity of the samples. The $ABTS^{\bullet+}$ scavenging activity of various elderflower drinks differed significantly and ranged from 0.36 to 2.34 mM TE (trolox equivalents) per liter. The comparison of the antioxidant activity of elderflower beverages to other juices reveals a high antioxidant activity of the former: 0.206−0.285 mM TE was measured for apple juice[42] and 0.694 to 0.886 mM TE for strawberry juice.[43] The highest antioxidant activity was measured for elderflower syrup after 7 days of water extraction and the lowest for sabesa after 1 day of extraction (Table 3, Figure 2). Prolonged extraction of elderflowers in water solvent caused higher $ABTS^{\bullet+}$ antioxidant activity. The ferric reducing antioxidant power (FRAP) showed a similar pattern. A 4-fold increase of FRAP antioxidant activity has been measured in elderflower syrup and sabesa after 7 days of extraction compared to the first sampling. FRAP antioxidant activity ranged from 0.49 to 1.99 mM TE for sabesa and 2.06 to 8.20 mM TE for elderflower syrup. Both beverages exhibited significantly higher FRAP activity compared to apple juice (0.15−0.21 mM TE) and blackcurrant juice (0.37 mM TE).[42] On the other hand, higher FRAP antioxidant activity has been reported for sweet lemon juice[44] and quince juice.[45]

Total antioxidant activity measured by FRAP and $ABTS^{\bullet+}$ assays was significantly correlated with total phenolic content (r = 0.807 and 0.942). A strong correlation between antioxidant activity and phenolic compounds has been reported in several juices.[46,47] A strong correlation has also been observed between the content of flavonols and total phenolic content (r = 0.954).

The present study focuses on the analysis of a wide spectrum of phenolic compounds in elderflower beverages and compares their contents in three different types of extracts. 37 phenolic compounds have been identified in elderflower methanolic extracts. A smaller diversity of phenolic components has been detected in water-extracted traditional elderflower beverages. Elderflower syrup also contained higher levels of phenolics compared to sabesa. Generally, a longer extraction period caused higher contents of phenolic compounds in traditional beverages. Elderflower beverages were characterized by high total phenolic content (from 91.09 to 746.63 mg GAE/L), which has been linked to high antioxidant activity of the extracts. The $ABTS^{\bullet+}$ antioxidant activity of sabesa ranged from 0.36 to 0.51 mM TE (trolox equivalents), and even higher values have been recorded for elderflower syrup (1.25−2.34 mM TE). Both traditional elderflower drinks should therefore be recommended as a potent source of natural health agents.

J. Agric. Food Chem. 2015, 63, 1477−1487

The consumption of these natural beverages may significantly contribute to the dietary intake of phenolic compounds, which are believed to have a positive effect on human health. The results of the present study can hopefully lead to increased utilization of elderflowers and production of traditional beverages on a larger scale. Not only are the traditional elderflower beverages easy and cheap to make, but they should be promoted due to their pleasing taste characteristics and high levels of health-promoting compounds.

The purified fraction with the highest hemagglutinating activity was Chinese leek seed lectin, designated as CLSL.

Assay of Hemagglutinating Activity. Hemagglutinating activity was performed using the method reported by Silva et al.[22] with modifications. Two-fold serial dilutions of the sample (25 μL) were mixed with erythrocyte buffer solution (25 μL) and 2% (v/v) supernatant of red blood cells (50 μL) at 25 °C in the 96-well microtiter plate. Saline was used as the blank control, and the results were recorded after incubation at 25 °C for 1 h. The maximum number of a serial two-fold dilution of the sample showing hemagglutinating activity was defined as the hemagglutinating titer (U).

Gel Electrophoresis. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) was carried out in a 15.0% separating gel and 5.0% stacking gel under nonreducing and reducing conditions according to the modified method of Zhu et al.[23] The molecular weight of CLSL was determined by the migration rate with reference to the standard molecular weight marker.

Analysis of *N*-Terminal Amino Acid Sequence. The purified CLSL was loaded to SDS-PAGE on 4–12% gradient NuPAGE Bis–Tris gel and then mobilized onto a polyvinylidene difluoride (PVDF) membrane by electroblotting. *N*-Terminal sequencing by Edman degradation was performed by using an Applied Biosystems model 471A protein sequenator (Applied Biosystems, Shanghai, China).

Carbohydrate-Binding Specificity. To confirm the specificity of CLSL for sugars, the inhibition of hemagglutination was performed using a method described by Takahashi et al. with modifications.[24] The 2-fold serial dilution samples (25 μL) were incubated with 25 μL sugar solutions (20 mmol/L) for 30 min at room temperature, and hemagglutination was analyzed as described above. The beginning protein concentration was 0.5 mg/mL, and its hemagglutinating activity was 128 U.

Measurement of Carbohydrate Content. The total sugar content of purified CLSL was measured by the anthrone–sulfuric acid method with reference to glucose, according to the modified method of Alberto Leyva et al.[25]

Effect of pH, Temperature, and Metal Ions. The pH stability of CLSL was measured by incubating 50 μL of CLSL (1.0 mg/mL) in buffers with different pH values (pH 2.0–11.0, 50 μL) for 1 h at room temperature. The temperature stability of CLSL was determined by incubating 50 μL of CLSL at different temperature (20–100 °C) for 60 min. The effect of metallic compounds ($BaCl_2$, $CaCl_2$, LiCl, $CuCl_2$, $FeCl_2$, and $K_2Cr_3O_4$) was measured by incubating 50 μL of CLSL in equivalent volume of metallic compounds buffer.

Circular Dichroism. Circular dichroism (CD) is an effective physical technique for evaluating structures and structural changes of proteins.[26] For the analysis of the secondary structure of purified CLSL, the CD spectra were measured in 2.0 mM acetic acid–sodium acetate buffer (pH 5.0), using a J-810 spectropolarimeter at the room temperature in a wavelength range of 190–260 nm. The spectrum was recorded with the response time of 1 s and scan speed of 100 nm/min. Each data point was an average of three accumulations.

Fluorescence Spectroscopy. The purified CLSL (20 mmol) dissolved in 2.0 mL of deionic water was analyzed using a 970 CRT spectrofluorometer (Shanghai, China) at room temperature, with both the excitation and the emission band-pass filters set at 5 nm. Samples were irradiated at excitation wavelength of 295 nm, and emission spectra were recorded in the range 290–400 nm. Quenching of the protein intrinsic fluorescence was performed by addition of micro-aliquots of the quenchers (10 mmol/L $BaCl_2$ solutions) to the protein.

The synchronous fluorescence spectra, focused on investigating the influence of Ba^{2+} on conformation of CLSL, was carried out at the wavelength interval ($\Delta\lambda$) of 15 and 60 nm between the excitation and emission wavelengths, respectively, with both the excitation and the emission band-pass filters set at 5 nm.

Antiproliferative Activity. The cell lines HepG2, LO2, and Caco-2 were cultivated in 1640 medium supplemented with 10% fetal bovine serum (FBS), 100 mg/L of streptomycin, and 100 U/mL of penicillin at 37 °C in a humidified atmosphere of 5% CO_2. Cells (1.5×10^4/well) were seeded into a 96-well culture plate in their exponential growth phase and added to different concentrations of sample after being maintained for 24 h. Incubation was carried out for another 24 h, and the cell viability of each well was measured by MTT assay.[27]

Statistical Analysis. All experiments were carried out in triplicate ($n = 3$), and all data were expressed as means ± standard deviation. Analysis of variance (ANOVA) was performed using SPSS 19.0 (SPSS, Chicago, IL, USA). The significance in differences was determined by Duncan's multiple range test ($P < 0.05$).

RESULTS

Purification of CLSL. Chinese leek seed extract was purified with two chromatographic steps, namely ion exchange chromatography with a SP Sephadex C-25 column and size exclusion chromatography with a Sephadex G-50 column. As shown in Figure 1A, the extract was resolved into seven peaks after the SP Sephadex C-25 column, but only fraction A7 showed stronger hemagglutinating activity (Table S1, Supporting Information). Purification of fraction A7 was examined with SDS-PAGE, and two bands were observed (Figure 1B). Subsequently, fraction A7 was concentrated and applied onto a Sephadex G-50 column for further purification. As shown in Figure 1C, fraction A7 was resolved into two peaks (G1 and G2),

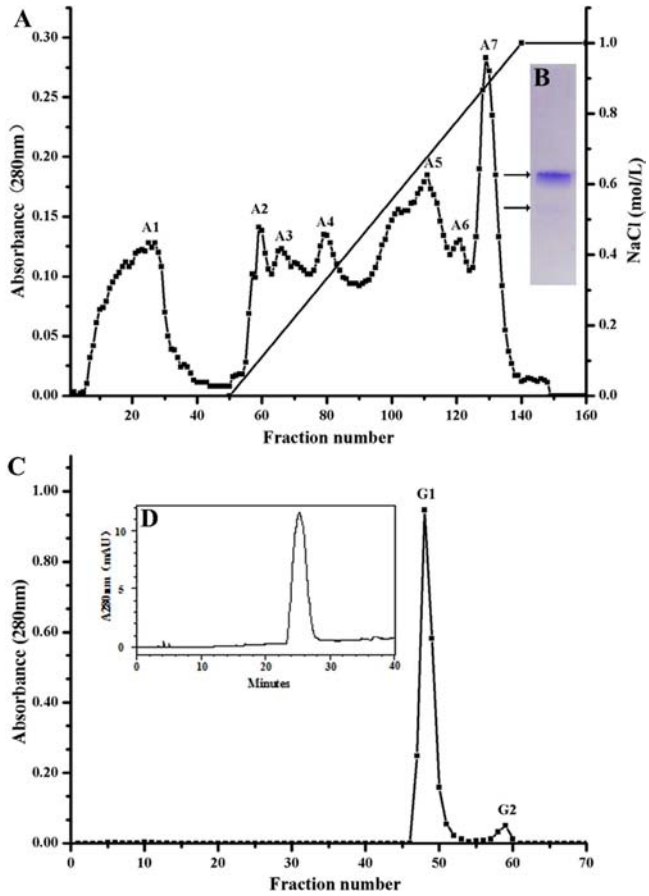

Figure 1. Purification of lectin (CLSL) from Chinese leek seeds. (A) Purification of CLSL using ion exchange chromatography on SP-Sephadex C25 column and fraction A7 showed the higher hemagglutinating activity. (B) Purity of fraction A7 from SP-Sephadex C25 column identified by SDS-PAGE. (C) Further purification of fraction A7 from SP-Sephadex C25 column using gel filtration chromatography on a Sephadex G50 column and fraction G1 exerted the higher agglutinating activity. (D) Purity of fraction G1 from Sephadex G50 column determined by RP-HPLC.

(B) Calculated standard curve of CLSL. The position of CLSL on the regression curve was represented as a red dot.

Table 1. Summary of Purification Process for CLSL and Its Hemagglutinating Activity

fractions	total protein (mg)	extraction yield (%)	HA[a] (U)	purification fold
crude extraction[b]	554.00 ± 0.15	11.08 ± 0.03		
SP Sephadex C-25	215.68 ± 0.35	4.31 ± 0.02	64	1.0
Sephadex G-50	23.04 ± 0.10	0.46 ± 0.02	128	18.7

[a]HA: hemagglutinating activity. The tested concentration of sample was 1.0 mg/mL. [b]Crude extraction was gained from 5.0 g Chinese leek seed powder. SD: standard deviation. All the values were mean ± SD.

and only fraction G1 was identified as the desired fraction. Purification of fraction G1 was confirmed by the elution of single peak from reverse phase-high performance liquid chromatography (RP-HPLC) and a single band on SDS-PAGE (Figures 1D and 2A). The above process resulted in an 18.7-fold purification (Table 1).

Structural Characterization. CLSL appeared as a single band on SDS-PAGE. Molecular weights of the bands under reducing and nonreducing conditions were 11.7 and 23.6 kDa, respectively, suggesting that CLSL was a dimer consisting of two identical subunits connected by disulfide bonds (Figure 2A). A brick-red band was observed after PAS staining, indicating CLSL was a glycoprotein (Figure 2A). The sugar content of CLSL was 3.6 ± 0.25%, measured by anthrone–sulfuric acid method.

The CD spectrum of CLSL was characterized by one positive peak near 195 nm, two negative peaks near 210 and 223 nm, respectively, and a positive to negative crossover at 200 nm (Figure 3), which was characteristic of an α-helical protein. The secondary structure content estimated by Yang's method[28] was 35.8% α-helixes, 8.6% β-sheets, 18.3% β-turns, and 37.3% random coils.

***N*-Terminal Amino Acid Sequences of CLSL.** *N*-Terminal amino acid sequences of CLSL were determined by Edman degradation. The results showed that the seven *N*-terminal residues of CLSL were Cys-Val-Ile-Ala-Pro-Val-Ala (CVIAPVA).

Characterization of Hemagglutinating Activity. The hemagglutinating activity of CLSL was partly inhibited by D-fructose, sorbose, and mannitol at the concentration of 20 mmol/L with the inhibition ratios of 75%, 25%, and 75%,

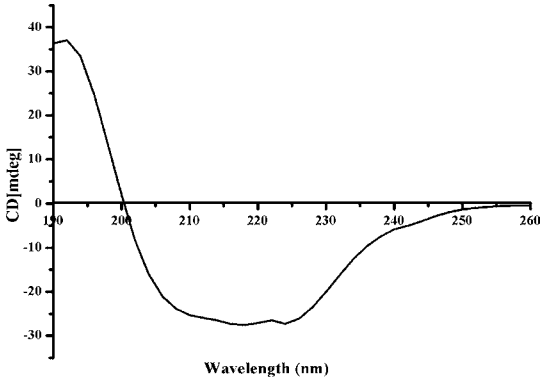

Figure 3. CD spectrum of CLSL in acetate buffer (20 mM, pH 5.0). The concentration of CLSL was 0.4 mg/mL. The positive peak near 195 nm and two negative peaks near 210 and 223 nm, respectively, indicated an α-helical structure of CLSL.

respectively. Other sugars studied did not affect the hemagglutinating activity of CLSL (Table 2), indicating complex sugar specificity of CLSL.[29]

As Table 3 shows, temperatures in the range 20–100 °C did not have significant effects on the hemagglutinating activity of CLSL, implying that CLSL possessed strong thermostability

DOI: 10.1021/jf5046014

Table 5. Effect of Metal Ions on CLSL (Initial Hemagglutination Activity: 128 U)

metal ions (10 mmol/L)	$CuCl_2$	$CaCl_2$	$BaCl_2$	$K_2Cr_3O_4$	LiCl	$FeCl_2$
residual activity (titer/U)	2^{12}	2^{12}	0	8	128	2^{12}

like a lectin from *Moringa oleifera*.[30,31] The hemagglutinating activity was retained at acidic pH values ranging from 2.0 to 6.0. However, the activity began to decrease at neutral pH and was completely lost in the alkaline pH range 8.0−11.0 (Table 4).

The influence of metal ions on the hemagglutinating activity was studied. The hemagglutinating activity of CLSL was completely inhibited by Ba^{2+} but was greatly enhanced in the present of Ca^{2+}, Fe^{2+}, and Cu^{2+} at a concentration of 10 mmol/L (Table 5).

Antiproliferative Activity. Inhibition of proliferations of HepG2 cells was observed in the presence of CLSL, and its IC_{50} value was 30 μM. In contrast, proliferation of Caco-2 cells and the normal cells LO2 were only slightly affected by up to 40 μM CLSL (Figure 4), suggesting that the antiproliferative potential of CLSL was selective.

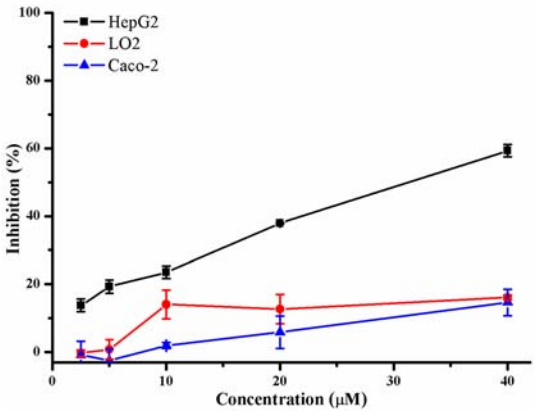

Figure 4. Inhibitory effect of CLSL on proliferation of HepG2, LO2, and Caco-2. Proliferation of HepG2 cells was inhibited with an IC_{50} of 30 μM. Cell proliferation was determined by MTT assay (data represent means ± SD, n = 3).

Effect of Ba^{2+} on the Hemagglutinating Activity of CLSL. To investigate the mechanism of Ba^{2+}-mediated inhibition of hemagglutinating activity, the fluorescence spectra of CLSL quenched by Ba^{2+} at different concentrations were analyzed (Figure 5A). Quenching of the intrinsic fluorescence of CLSL and a slight blue shift of the maximum emission fluorescence peak (about 2 nm) were observed.

The synchronous fluorescence spectra of CLSL in the presence of Ba^{2+} were also shown in Figure 5. The synchronous fluorescence was characteristic of tyrosine residues (Tyr) and tryptophan residues (Trp) at the wavelength interval ($\Delta\lambda$) of 15 and 60 nm between the excitation and emission wavelengths, respectively.[32] It was obvious that the maximum emission peak intensities of both tyrosine and tryptophan decreased with increased Ba^{2+} concentrations. A slight blue shift of the maximum emission wavelength was observed at the wavelength interval of 15 nm, and it did not show significant shift at the wavelength interval of 60 nm (Figure 5B,C).

To further investigate the influence of Ba^{2+} on the CLSL conformation, CD spectroscopy of CLSL was carried out with the addition of Ba^{2+} (Figure 6). A positive peak at 195 nm and two negative peaks near 210 and 225 nm shifted toward the zero graduation with the increase of Ba^{2+} concentrations. Moreover, an apparent change of its ellipticity was observed at the Ba^{2+} concentration of 5.0 μmol/L, and no significant difference was observed at higher Ba^{2+} concentrations, suggesting that the reaction was under saturation conditions.

DISCUSSION

In the present work, a novel lectin (CLSL) was purified from Chinese leek seeds and displayed activity against rat erythrocytes. The purity of CLSL was confirmed by SDS-PAGE and RP-HPLC.

CLSL was a dimeric glycoprotein consisting of two identical subunits linked by disulfide bonds with a molecular weight of 23.6 kDa. It produced a smear on SDS-PAGE, similar to that of some reported lectins.[22,29] The smear was probably because glycoproteins possessed the heterogeneous glycosylation pattern and stronger hydration in water solution due to the presence of carbohydrate units and disulfide bonds.[33,34]

Similar to CLSL, a mannose-binding protein (ATL) from Chinese *Allium tuberosum* was also a dimeric protein.[35,36] ATL had an *N*-terminal sequence of RNVLLNGEGLYAGQS, different from that of CLSL (CVIAPVA). The seven residue sequence of CLSL was submitted to a blast search in the NCBI database. Although some similarities to the sequences of other reported lectins were observed, they were far away from the *N*-terminus (Table 6), which inferred that CLSL was a novel lectin. CLSL was identified to be an α-helix protein with CD spectroscopy. Compared with CLSL, different lectins possessed different contents of secondary structures (Table 7). For example,

Table 6. *N*-Terminal Amino Acid Sequence Alignment of CLSL in NCBI Database

Content	Starting amino acid	Sequences	Ending amino acid	Reference
CLSL	**1**	**C V I A P V A**	**7**	The present
Fucose-specific lectin	9	V I A A V A	14	49

Table 7. Secondary Structure Contents of CLSL Compared with Other Lectins

	secondary structure				
	α-helixes (%)	β-sheets (%)	β-turns (%)	random coils (%)	reference
CLSL	35.8	8.6	18.3	37.3	the present
LAA	6	46	17	31	37
cMoL	46	12	17	25	31
BfL	19	27	22	32	22
MoL	28	23	20	28	41

an α/β lectin contains 46% α-helixes, 12% β-sheets, 17% β-turns, and 25% unordered structures, as reported by Luz et al.[31] A cotyledonary lectin from *Luetzelburgia auriculata* is composed of 6% α-helixes, 46% β-sheets, 17% β-turns, and 31% unordered structures.[37]

CLSL exerted strong thermostability similar to lectins reported by Oliveira et al.,[38] Ngai et al.,[39] and Santos et al.[30] The hemagglutinating activity of CLSL was stable at 100 °C for 60 min. The intramolecular disulfide bonds may be responsible for its thermostability.[40,41] However, CLSL was only active in acidic conditions and rapidly inactivated in neutral and

DOI: 10.1021/jf5046014
J. Agric. Food Chem. 2015, 63, 1488−1495

basic conditions. This might be because the hydroxyl ions increased with pH, induced changes of ionization state on the lectin surface, and affected the interaction between lectin and the cell membrane.[42−44] A similar phenomenon was observed with an *Archidendron jiringa* Nielsen-derived lectin.[6]

Lectins are a class of highly specific carbohydrate-binding proteins. Their multiple function (e.g., recognition and defense against pathogens) is closely related to the types of carbohydrate-binding.[45] The activities of lectins are often inhibited by monosaccharide and oligosaccharides.[46] In the present study, CLSL exhibited complex carbohydrate specificity, and the activity could be inhibited by carbohydrates including D-fructose, sorbitol, and mannitol, the binding of which likely prevented attachment of lectins to cell membranes.[46]

To the best of our knowledge, there has been no evidence demonstrating that hemagglutinating activity is related to antiproliferative activity. Despite that, both hemagglutinating and antiproliferative activities are related to the high binding specificity of lectins to oligosaccharides, and it is well-known that malignant transformation is accompanied by aberrant glycosylation of surface structures that may affect tumor invasion and metastasis.[47] Lectins could recognize the specific conformation of a cell surface due to specific binding of oligosaccharides and affect proliferation of cells. In the present paper, CLSL showed a selective antiproliferation activity against HepG2 cells but not Caco-2 and LO2 cells. The reason for the selectivity might be the discrepant oligosaccharides on HepG2, Caco-2, and LO2 cell surfaces.

Divalent metal compounds (e.g., $CuCl_2$, $CaCl_2$, and $FeCl_2$) could dramatically improve the activity of CLSL, one reason for which might be that some divalent metal ions (e.g., Ca^{2+} and Mn^{2+}) contribute to maintaining the conformation of lectin and stabilize amino acid residues in specific sugar-side-chain-binding sites.[42,43] However, inhibition of the hemagglutinating activity of CLSL by Ba^{2+} was noteworthy. The slight blue shift on fluorescence spectra demonstrated that Ba^{2+} interacted with CLSL and quenched its intrinsic fluorescence.[48] Moreover, synchronous fluorescence spectra also showed that not only was fluorescence intensities of tyrosine and tryptophan residues decreased but there was also a slight blue shift of tyrosine residues, suggesting the increase in hydrophobicity around tyrosine residues.[32,48] The most likely reason for the above changes was that conformation of CLSL had changed.

Notably, we also found that the α-helix content of CLSL gradually increased, accompanied by an equal decrease of its β-fold content when the Ba^{2+} concentration increased (Figure S1, Supporting Information), which hinted that the interaction between CLSL and Ba^{2+} resulted in transformation of its β-fold to α-helical conformations, destroying the conformation of its glycosylation active domains. Therefore, pathways of Ba^{2+}-mediated inactivation of CLSL speculated that the binding of Ba^{2+} changed the conformation of CLSL, leading to conformational changes of glycosylation domains and inhibition of activity. It was also likely that by directly binding to glycosylation domains, Ba^{2+} hindered the recognition and interaction between CLSL and sugar side chains on cell surface (Figure 7).

In conclusion, we reported purification and characterization of a novel lectin, CLSL from Chinese leek seeds, and its interaction with Ba^{2+}. The blood clotting parameters and biological functions of CLSL as a potential anticoagulant and platelet antiaggregation protein were examined in detail. The possible mechanism of interaction between CLSL and Ba^{2+} was deduced.

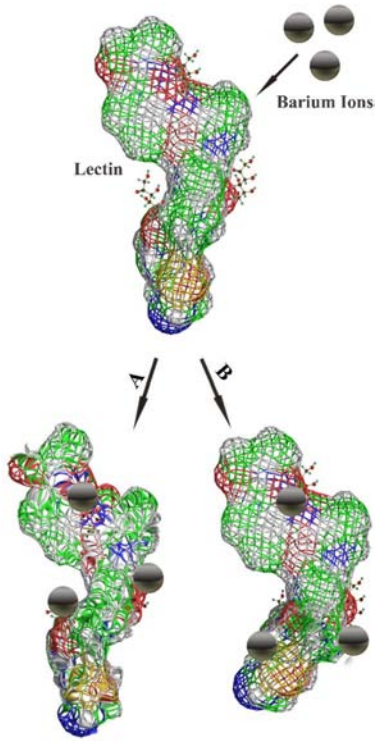

Figure 7. Sketch of the mechanism of interaction between CLSL and barium ions. Pathway A: Barium ions directly bound to carbohydrate-binding sites and caused the overall structural shrinkage of CLSL. Pathway B: The binding of barium ions caused the critical conformation change of CLSL and blocked the active sites. Both of the above pathways could destroy the conformation of its glycosylation domain, leading to the inactivation of CLSL.

Although further experiments should be conducted to elucidate the mechanism of CLSL interaction with sugars and explore its applications in the pharmaceutical industry, the present study provided a valuable basis for future research.

The immune system is a complex biochemical process that enables efficient detection and removal of pathogens that threaten host viability. Immune processes have traditionally been divided into two broad, but interconnected, subsystems on the basis of their functions in host defense: the adaptive immune system and the innate immune system. Innate immunity is composed of those immunological effectors that provide robust, immediate, and nonspecific immune responses. Phagocytosis by neutrophils and complement system are two key factors of the innate immunity.

Neutrophils are the first line of the host defense mechanism against microbial infection. They are recruited to the site of infection and are capable of phagocytosis and killing a wide range of bacteria. Phagocytosis is an actin-dependent mechanism by which cells ingest large particles that are usually >0.5 μm in diameter.[6]

Complement system is a major effector mechanism of the innate immune system. It is a complex network of plasma and membrane-associated serum proteins, which can elicit highly efficient and tightly regulated inflammatory and cytolytic immune responses to infectious organisms, tissue damaged by physical, chemical, or neoplasm insults, and other surfaces identified as "nonself". The complement can be activated by a cascade mechanism of the classical pathway (CP), the alternative pathway (AP), or the mannan binding lectin (MBL) associated serine protease pathway. Inappropriate activation of the system may lead to pathologic reactions in a variety of inflammatory and degenerative diseases such as dermatological diseases, rheumatoid arthritis, and gout.

Although other activities of essential oils have been deeply researched, few studies have examined the influence of essential oils over phagocytosis. From a literature review on the subject, it appears that essential oils of *Houttuynia cordata*, *Allium sativum*, *Cinnamomum zeylanicum*, *Eucalyptus globulus*, and *Rheum palmatum* are capable of stimulating phagocytosis in experiments developed either in vitro or in vivo.[7−11] An inhibitory effect on phagocytosis was found in *Ocimum basilicum* essential oil,[12] whereas those from *Salvia officinalis*, *Lavandula angustifolia*, *Melaleuca alternifolia*, and *Origanum minutiflorum* showed no effect at all.[10,13,14]

Pure compounds have also been examined. 3-Carene was found to be a phagocytosis inhibitor in vitro.[15] On the other hand, limonene, citronellyl acetate, linalyl acetate, and methyl nonyl ketone clearly stimulated phagocytosis,[7,16−18] whereas camphor, menthol, and eucalyptol were found to be rather inactive.[19] The activity of eugenol on phagocytosis has not been tested on untreated cells. Nevertheless, it produced a recovery in the phagocytic function in nicotine-treated mouse peritoneal macrophages.[20] Additionally, mixtures containing eugenol, either in endodontic sealers or mixed with formaldehyde and cresol, showed some phagocytosis inhibitory activity, which cannot be unambiguously assigned to eugenol.[21,22]

Literature on the influence of the essential oils on complement activity is even more scarce. In fact, only one retracted paper[23] has been found on this topic.

The aim of the present study was to investigate the in vitro phagocytic and complement system modulating activities of 15 well-characterized essential oils, 4 essential oil fractions, and 3 pure compounds.

MATERIALS AND METHODS

Chemicals and Reagents. Water was freshly taken daily from a Milli-Q system (Millipore, Bedford, MA, USA). Sodium chloride (NaCl), ethylenediaminetetraacetic acid (EDTA), trypan blue, propidium iodide, Hanks' balanced salt solution (HBSS) with Ca^{2+} and Mg^{2+} or without Ca^{2+} and Mg^{2+}, Alsever's solution, gelatin veronal buffer, ammonium chloride (NH_4Cl), potassium bicarbonate ($KHCO_3$), ethylenediaminetetraacetic acid tetrasodium salt dihydrate (EDTA-Na_4·$2H_2O$), dimethyl sulfoxide (DMSO), paraformaldehyde, quercetin, ethylene glycol bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetra-acetic acid (EGTA), sodium 5,5-diethylbarbiturate, lipopolysaccharides (LPS) from *Escherichia coli* O127:B8, and human sera were obtained from Sigma Chemical Co. (St. Louis, MO, USA). Fluorescent microspheric hydrophilic particles (FluoSpheres) were purchased from Invitrogen, Molecular Probes (Carlsbad, CA, USA). Red blood cell polyclonal antibody anti-sheep were bought at ICN ibérica SA (Barcelona, Spain). Sheep red blood cells in Alsever's solution and rabbit red blood cells in Alsever's solution were obtained from the animal facilities of the Faculty of Veterinary of the Autonomous University of Barcelona and the Faculty of Pharmacy of the University of Barcelona, respectively.

Essential Oils and Compounds Studied. Essential oils from nutmeg (*Myristica fragrans* Houtt.), niaouli (*Melaleuca quinquenervia* (Cav.) S. T. Blake), clove (*Syzygium aromaticum* (L.) Merr. & L. M. Perry), tarragon (*Artemisia dracunculus* L.), coriander (*Coriandrum sativum* L.), juniper (*Juniperus communis* L.), tea tree (*Melaleuca alternifolia* (Maiden & Betche) Cheel), ginger (*Zingiber officinale* Roscoe), rosemary (*Rosmarinus officinalis* L.), bay laurel (*Laurus nobilis* L.), palmarosa (*Cymbopogon martini* (Roxb.) Will. Watson), cajuput (*Melaleuca cajuputi* Powell), lemon (*Citrus limon* (L.) Burm. f.), red thyme (*Thymus zygis* L.), and Spanish oregano (*Coridothymus capitatus* (L.) Rchb. f. = *Thymbra capitata* (L.) Cav.) were tested. The terpenic fractions from nutmeg, clove, and lemon were also included in our research. Finally, the pure compounds eugenol, carvacrol, and thymol, as well as a mixture of bornyl (76.8%) and isobornyl (21.7%) acetates, were also investigated. All samples except eugenol (Sigma-Aldrich) were supplied by Lidervet S.L. (Tarragona, Spain) and obtained from commercial sources (Lluch Essence S.L., Barcelona, Spain, and Ernesto Ventós S.A., Barcelona, Spain). All samples were kept in sealed airtight glass vials, protected from the light, at 4 °C.

Characterization and Analysis of the Essential Oils. The essential oils and fractions were characterized by their composition and some physical constants. The analyses of the composition of the oils were carried out by gas chromatography (GC-FID) and gas chromatography coupled to mass spectrometry (GC-MS), using a fused silica Supelcowax 10 capillary column (60 m × 0.25 mm i.d.; 0.25 μm film thickness). GC-FID analyses were performed on a Hewlett-Packard 6890 instrument, equipped with a HP ChemStation data processor software. Helium was used as carrier gas, and a split ratio of 1:80 was employed. Samples were injected undiluted (0.1 μL). Chromatographic conditions were different depending on the essential oil and, whenever possible, were based on the methods stated in the European Pharmacopeia.[24] Mass spectra were obtained using a Hewlett-Packard GC-MS instrument constituted by a GC HP 6890 coupled to a mass selective detector HP 5973N. The same analytical conditions employed in the GC-FID were applied in the GC-MS. Mass spectra were taken over m/z 35−400, using an ionizing voltage of 70 eV. Identification of the constituents of the oils and fractions was achieved by means of their linear retention indexes calculated in relation to a homologous series of *n*-alkanes (C8−C23) from the GC-FID analysis and by comparison of fragmentation patterns in their mass spectra with those stored in our own library, in the GC-MS database (Wiley 6), and with literature data.[25,26] Percentages of constituents were determined on the basis of their GC-FID peak areas using the normalization procedure without corrections for response factor.

Relative density, optical rotation, and refractive index of the essential oils and fractions were determined according to the European Pharmacopoeia.[24]

Sample Preparation for Biological Testing. Samples of the essential oil, fractions, and pure compounds were prepared at 1.0% (v/v) in HBSS supplemented with 10% (v/v) DMSO and 1.5% (v/v) E-484 (glyceryl polyethylene glycol ricinoleate). All solvents were

DOI: 10.1021/jf504761m
J. Agric. Food Chem. 2015, 63, 1496−1504

previously assayed to rule out any possible intrinsic activity. Samples were emulsified through exhaustive vortexing (10 min) and sonication (5 min, in ice). In the phagocytosis assay, nine dilutions that ranged from 5.0×10^{-3} to 7.8×10^{-7} % (v/v) in HBSS with Ca^{2+} and Mg^{2+} were tested. For the complement system assays, eight successive 2-fold dilutions (ranging from 6.67×10^{-2} to 5.21×10^{-4} % (v/v)) were prepared in barbital gelatin buffer with EGTA (for the AP essay) or barbital gelatin buffer with Ca^{2+} and Mg^{2+} (for the CP essay). Each dilution was thoroughly vortexed (10 min) immediately before use.

Isolation of Human Leukocytes. Leukocytes were isolated through a controlled hemolytic shock with an ammonium chloride solution from buffy coats obtained from blood of healthy donors at the Blood and Tissue Bank of Catalonia. The pellet was suspended in HBSS without Ca^{2+} and Mg^{2+}.

Phagocytosis Evaluation by Flow Cytometry. The phagocytosis assay was carried out following a modification of the method described by Risco et al.[27] A suspension (5.5×10^7 particles/mL) of fluorescent microspheric hydrophilic particles (2 μm in diameter) of modified carboxylate with a yellow-green fluorescence (505/515 nm), and opsonized using human serum (30 min at 37 °C), were used for the phagocytic test.

In a microtiter plate, 200 μL of a suspension of human leukocytes (approximately 10^6 cells) was incubated with 20 μL of different treatments for 10 min at 37 °C. Treatments included a positive control of LPS (1 mg/mL). Fluorescent particles (20 μL) were added to all wells. To manage nonspecific adhesion, 50 μL of paraformaldehyde (1% w/v) was added to wells designated as nonspecific adhesion controls. Microtiter plates were again incubated for 45 min in a stirred thermally controlled chamber at 37 °C. Fifty microliters of stop solution (0.9% w/v NaCl and 0.02% w/v of disodium EDTA) at 0 °C were added to all wells. The EDTA captures cations necessary for the phagocytic process. With the purpose of discriminating viable cells, 2 μL of a propidium iodide solution (10 μg/mL) was added. Finally, 20 μL of quenching solution (trypan blue solution, 2.25 mg/mL) and 50 μL of paraformaldehyde (1% w/v) were added to all wells.

A flow cytometer Cytomics FC 500 MPL system (Beckman Coulter, Inc., Brea, CA, USA) and Summit software v4.2 were employed for the analysis. Cellular viability was well over 95% in all experiments. The gate for neutrophils was established on the basis of the size and granularity. The acquisition process was stopped when 20000 viable neutrophils (negative to propidium iodide) were acquired and the green fluorescence histogram (515−548 nm) was obtained. Activity on phagocytosis (stimulation or inhibition) is calculated as percentage from phagocytic capacity (percentage of cells that ingested one or more particles), which is determined from the fluorescence distributions. Phagocytic capacity was corrected by taking in account the fluorescence due to nonspecific adhesion (particles adhered to the cell surface but not phagocyted). Examples of histograms are given as Supporting Information.

Hemolytic Assay for Human Complement Activity. A hemolytic assay was used to determine the inhibition of the alternative pathway (AP) and classical pathway (CP) of complement activation as described by Klerx et al.,[28] in human pooled serum. Assays were carried out in a microtiter plate, using barbital gelatin buffer with Ca^{2+} and Mg^{2+} (CP) or barbital gelatin buffer with EGTA (AP). Sensitized sheep erythrocytes (CP) or nonsensitized rabbit erythrocytes (AP) were incubated with the test samples for 30 min at 37 °C. Human pooled serum was added and incubated for 30 min (AP) or 60 min (CP) at 37 °C. The reaction was stopped by adding barbital buffer containing 10 mM EDTA. Erythrocytes were removed by centrifugation at 700*g* for 5 min, and the supernatant was transferred to a new flat-bottom microtiter plate. Absorbance was measured at 405 nm using a Benchmark Plus spectrophotometer (Bio-Rad, Hercules, CA, USA). Positive controls used were quercetin (CP) and an aqueous extract from *Azadirachta indica* (AP). Inhibition (%) was calculated from absorbance values of treated samples in relation to untreated controls.

Statistical Analysis. The results were expressed as the mean ± standard deviation (SD) of at least four independent experiments. One-way analysis of variance (ANOVA) followed by a Dunnett's test was used to compare means of untreated controls to each treatment. In all cases, a difference was considered significant when $p < 0.05$. Fifty percent inhibitory concentration (IC_{50}) was calculated by interpolation in a concentration/effect curve when possible. For data analysis, software Graph Pad Prism version 5.0 for Windows (San Diego, CA, USA) was used.

RESULTS AND DISCUSSION

The in vitro activity of 15 essential oils, 4 essential oil fractions, and 3 pure compounds (thymol, carvacrol, and eugenol) on phagocytosis by human neutrophils and complement system was investigated. As will be shown in the present section, tested essential oils were mainly phagocytosis inhibitors, whereas some of them showed a moderate but significant complement inhibitory activity in the classical pathway. Those properties might be related in some measure to the anti-inflammatory activity attributed to essential oils.[29] Because inflammation is a pathogenic factor in the evolution and origin of many diseases, essential oil consumption linked to culinary herbs and spices may prevent or at least alleviate the onset of various pathologies.

Characterization of the Essential Oils and Fractions. The composition of the oils and fractions analyzed is shown in Table 1. Eugenol, carvacrol, and thymol had a purity that was well over 99.0%. The mixture of bornyl acetate and isobornyl acetate contained 76.8% of the former and 21.7% of the latter, together with 1.0% of α-terpineol. The oils were also characterized by physical data, such as relative density, optical rotation, and refractive index (see the Supporting Information).

Activity on Phagocytosis by Human Neutrophils. Results on the activity of essential oils, fractions, and compounds tested on phagocytosis by human neutrophils are shown in Table 2. Most of the volatile oils tested inhibited phagocytosis, although the mixture of bornyl and isobornyl acetates showed a mild stimulating activity (21.3%) at the highest concentration tested (55.90 μg/mL). Some authors have also found stimulatory effects on phagocytosis for a few essential oils, such as those of *Rheum palmatum* L. and *Allium sativum* L., and for some pure constituents, such as citronellyl acetate and linalyl acetate.[8,11,18] Essential oils from cajuput, tarragon, and coriander showed no activity whatsoever on phagocytosis at the concentrations tested.

At the highest concentration tested, essential oils of nutmeg, clove, niaouli, tea tree, bay laurel, lemon, red thyme, and ginger, as well as nutmeg terpenes, eugenol, and thymol, met or exceeded the 25% inhibition of phagocytosis. Thymol was the most active inhibitor of phagocytosis, giving an IC_{50} of 1.5 μg/mL (Figure 1). In an early study, thymol appeared as a moderate promoter of phagocytosis, but results were produced through an in vivo experiment.[30] Red thyme essential oil, with thymol as its main constituent, caused an inhibition of phagocytosis greater than 25% ($p < 0.05$) at the highest evaluated concentration (47.15 μg/mL). Carvacrol and eugenol, the other two phenols tested in the present study, showed weak and mild inhibitory activity (Figure 1). Eugenol inhibited phagocytosis (29% at 57.6 μg/mL, $p < 0.05$) with a concentration−activity profile very similar to that of clove oil (Figure 2), suggesting that it is the major compound responsible for the activity of the oil. Literature reports on this compound have shown dissimilar results. In vitro evaluations of eugenol by different authors resulted in a reduction of phagocytosis.[21,22] In other in vitro experiments, it was found that eugenol was able to recover macrophage

identified (%)	100.0	99.3	99.9	98.4	100.0	95.4	99.7	100.0	99.9	100.0	100.0	97.8	99.5	99.6	100.0	100.0	99.1	99.5

[a]Essential oils and fractions: BL, bay laurel; CA, cajuput; CL, clove; CLT, clove terpenes; CO, coriander; GI, ginger; JU, juniper; LE, lemon; LET, lemon terpenes; NI, niaouli; NU, nutmeg; NUT, nutmeg terpenes; PA, palmarosa; RT, red thyme; RO, rosemary; SO, Spanish oregano; TA, tarragon; TT, tea tree.

phagocytic capacity previously diminished by treatment with nicotine.[20] Other volatile compounds and essential oils, such as 3-carene and basil oil, have been dubbed in the literature as phagocytic inhibitors.[12,15] In in vivo and in vitro experiments, limonene (the main constituent of lemon oil and lemon terpenes) showed a stimulating effect over phagocytosis or the recuperation of the macrophages phagocytic capacity previously reduced.[16−18] Those results differ from ours, although it is important to highlight that employed cells and methodologies were different. Essential oils from juniper, rosemary, palmarosa, and Spanish oregano, lemon terpenes, and carvacrol showed a significant inhibition of phagocytosis, but it was lower than 25% at the highest tested concentration. The measured activity of carvacrol was lower than that of its isomer, thymol (Figure 1).

In some situations, a decreased phagocytic activity caused by essential oils could be a good strategy to reduce viral and bacterial infection. There is evidence that certain microbes subvert neutrophil protective functions and that neutrophils could, in fact, promote susceptibility to infection. This is due to the fact that intracellular invasion achieved with the phagocytic process can allow, in certain infections, pathogen proliferation and protection. This could be the case with leishmania parasites, *Chlamydia pneumoniae* or *Mycobacterium tuberculosi*, Epstein−Barr, and cytomegaloviruses.[31] It has been shown that a selective depletion, in vivo, of neutrophils by monoclonal antibody administration did provide a protective effect against *Chlamydia pneumoniae* in infected mice.[32]

Moreover, antibiotics are also known for their modulating effects on many components of the human immune system, in addition to their direct antimicrobial effects. For example, macrolide antibiotics cause a significant reduction in the chemotactic response of neutrophils to chemokines, resulting in a markedly decreased airway neutrophilia in patients with various inflammatory pulmonary diseases.[33] More than four decades earlier Forsgren and Schmeling[34] had reported a similar inhibition of neutrophil chemotaxis by rifampin, tetracyclines, and chloramphenicol.

Certainly, a body of evidence has emerged indicating that both antibiotics and essential oils possess modes of action which are independent of their antimicrobial activity when facing an infection.

In addition, neutrophils express Fc receptors, which are responsible for phagocytosis and intracellular killing of opsonized microbial pathogens, and it has been reported that this response can be blocked by inhibitors of ROS and by inhibitors of the H_2O_2−myeloperoxidase−chloride system.[35] Both activities have been reported in many of these essential oils in preliminary studies of our group,[36] showing consistency of the relationship between ROS inhibition and phagocytosis reduction.

Activity on Human Complement System. Results of the hemolytic assay for human complement activity are shown in Table 2. Different degrees of inhibitory activity were evident on the classical pathway of the complement system, whereas all essential oils were found inactive in the alternative pathway experiment. No other results on essential oils activity on complement system have been found in the literature. Nevertheless, a similar pattern of activity has also been described for other extracts or substances of terpenoid nature.[37] A closer look at individual results of the classical pathway shows that eugenol and clove oil had similar moderate IC_{50} values (78.3 and 74.9 μg/mL, respectively). This, together with the fact that clove terpenes showed almost no activity, points to

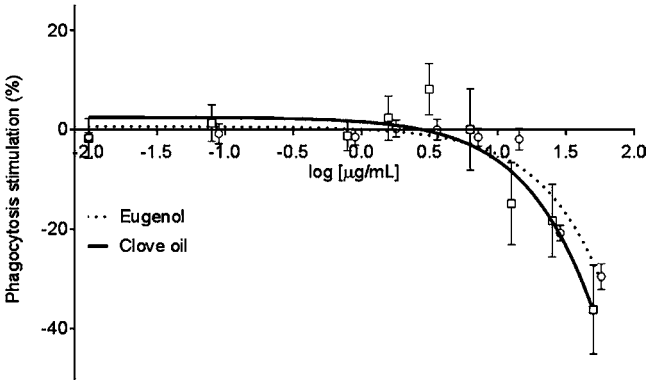

Figure 2. Activity of clove oil and eugenol on phagocytosis by human neutrophils (stimulation %, mean ± SD).

eugenol as the source of activity in clove oil (Figure 3). Other phenol-rich essential oils (red thyme, Spanish oregano, and

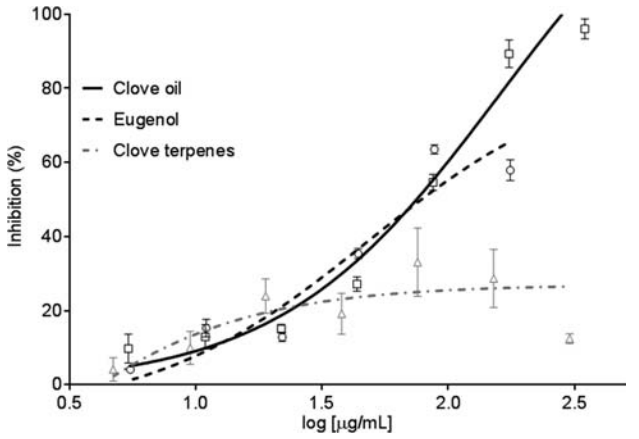

Figure 3. Activity of clove oil, clove terpenes, and eugenol on the classic pathway of the human complement system (inhibition %, mean ± SD).

tarragon) also displayed a similar mild inhibitory activity. It is interesting to highlight that carvacrol, the main constituent of the Spanish oregano oil, was more active that the essential oil, whereas thymol, the major component of red thyme oil, was less active than the essential oil. Maybe in red thyme essential oil other substances take part in its activity, whereas carvacrol remains as the main source of activity for Spanish oregano. All phenols tested, either monoterpenes (thymol and carvacrol) or phenylpropanoids (eugenol), had a similar behavior (Figure 4). In the essential oils tested from the *Melaleuca* genus, some activity was found, although it was moderate. This was the case

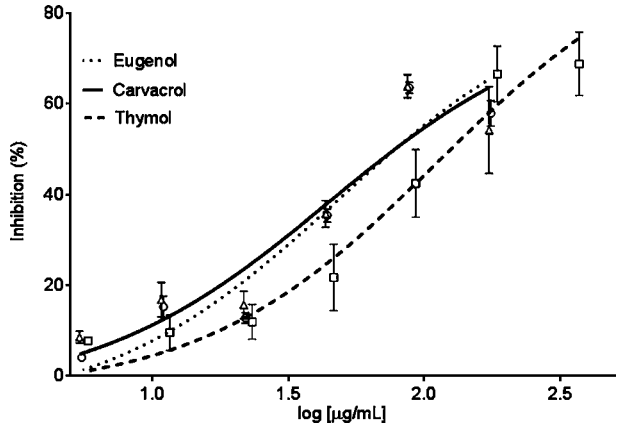

Figure 4. Activity of eugenol, carvacrol, and thymol on the classic pathway of the human complement system (inhibition %, mean ± SD).

of niaouli, tea tree, and cajuput oils. Tea tree oil is rich in terpinen-4-ol (44.5%), whereas in niaouli and cajuput oils 1,8-cineole is the major constituent (58.3 and 67.8%, respectively). Essential oils of bay laurel (IC_{50} = 155.4 μg/mL) and rosemary (showing a 27% inhibition at 154.7 μg/mL, $p < 0.01$) were also rich in 1,8-cineole (49.7 and 65.6%, respectively), which suggests a possible role of this compound in the anticomplementary activity. Other oxygenated monoterpene-rich oils and fractions showed moderate to weak activities, with IC_{50} values of 75.2 μg/mL for palmarosa oil (with 80.3% of geraniol), 126.1 μg/mL for the mixture of bornyl and isobornyl acetates, and 1540.4 μg/mL for coriander oil (with 74.0% of linalool). Results confirm that oxygen-containing compounds (either phenylpropanoids or monoterpenes) confer higher inhibitory activity of the classical pathway of the complement system than monoterpene hydrocarbons. Among oxygen-containing compounds, phenols, especially eugenol and carvacrol, showed the best profile.

Hemolytic effects of the essential oils tested were also examined. In vitro testing for hemolytic action has been used as one of the methods of triage for different toxic agents. Hemolysis tests are a simple tool to detect membrane toxicity and cytotoxicity. Most of the essential oils studied caused erythrocyte lysis at concentrations >200 μg/mL, showing thus a low toxicity toward membranes. The most noticeable action on erythrocyte membrane integrity was rendered by juniper oil and nutmeg terpenes, which caused erythrocyte membrane lysis at concentrations <100 μg/mL. Both of them are very rich in α-pinene and β-pinene. Those monoterpenes seem to increase erythrocyte lysis, a process that could be related to their capacity to affect cell membrane integrity with the sequential loss of control over chemio-osmotic processes and finally cell lyses and death.[38]

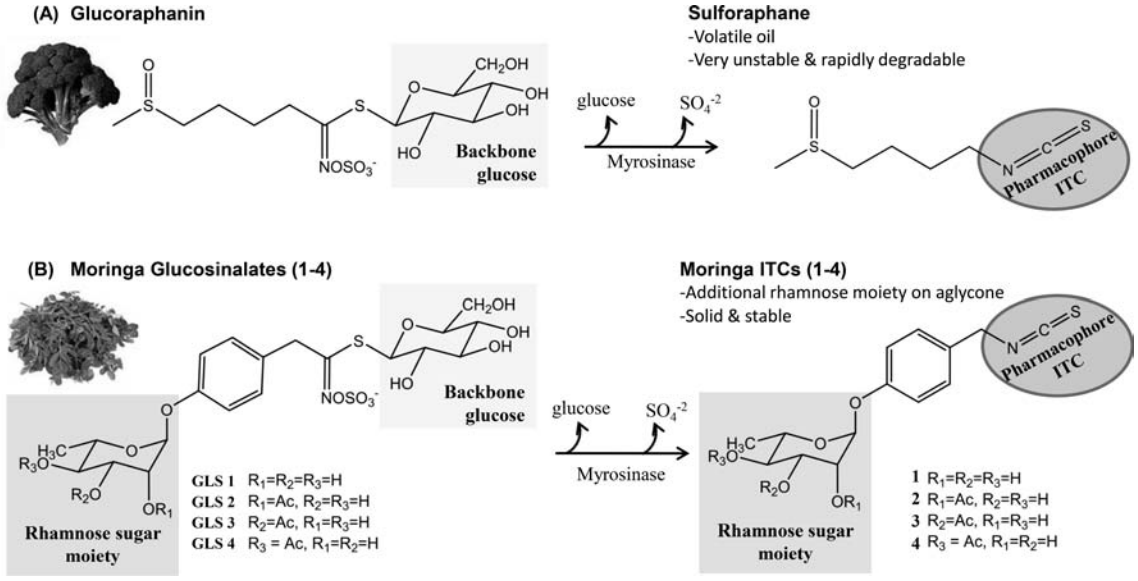

Figure 1. Enzymatic conversion of (A) glucorophanin from broccoli to sulforaphane (SF) and of (B) moringa glucosinolates (GLSs) to isothiocyanates (ITCs) **1**−**4**.

content from the leaves of *M. oleifera* has shown that GLS **1** (see Figure 1B for the structure) is present in significant concentrations (ranging between 33.9 and 59.4 mg/g dry weight of the tissue). However, the concentration of its monoacetyl isomers, especially GLSs **2** and **3**, are relatively less abundant (ranging between 1.2 and 5.0 mg/g dry weight of the tissue).[12] The occurrence of these compounds at relatively low levels makes isolation of them and their corresponding ITCs a purification challenge. Herein, we accomplished a large-scale fractionation of moringa leaf extract to yield ITC-rich fractions by fast partition counter current chromatography (FCPC) using a three-phase solvent system, which has been previously used to separate a mixture of plant compounds having a broad range of polarity in a one-step operation.[13] We applied this system followed by solid phase extraction (SPE) to further enrich the ITC content of the fractions, thus enabling the isolation of other, less abundant monoacetyl isomers. The methanolic extract of moringa was prepared from finely chopped and crushed fresh leaves to activate plant myrosinase for the efficient conversion of GLSs to corresponding ITCs.

The use of moringa leaves as traditional medicine dates back to ancient times. Growing scientific evidence has suggested the effectiveness of moringa in treating inflammation, hyperlipidemia, hyperglycemia, hypertension, bacterial and viral infections, ulcers, and cancer.[14−16] It is now well-known that many of these conditions are brought on and/or exacerbated by oxidative and electrophilic stress.[17] Thus, moringa's ability to prevent and treat such conditions may be due to the high level of antioxidant/bioactive compounds present in the leaves including vitamins, micronutrients, and polyphenols.[14,18] To date, moringa ITCs have not been well studied for their antioxidant activity. Therefore, this study was designed to evaluate and distinguish the role of moringa polyphenols and ITCs in both direct and indirect antioxidant capacities.

Generally, direct antioxidants are redox active, short-lived small molecules that directly scavenge reactive oxygen and/or nitrogen species.[17] On the other hand, indirect antioxidants induce a battery of phase II xenobiotic metabolizing enzymes (XMEs) through a shared Keap1/Nrf2/ARE pathway resulting in increased antioxidant capacity and long-lived protective effect compared to direct antioxidants.[17] Among phase II XMEs, NAD(P)H quinone oxidoreductase 1 [NQO1, EC 1.6.99.2] serves as a cytoprotective marker enzyme to evaluate indirect antioxidant potential of various phytochemicals including ITCs.[19,20] NQO1 catalyzes a two-electron reduction of highly reactive quinone molecules that are found in automobile exhaust, cigarette smoke, and many foods.[21] Numerous studies have shown associations between elevated NQO1 activity and protection against cancer and inflammatory diseases.[22,23]

Assaying NQO1 inducer potency has been used to isolate several chemoprotective agents from plant materials, leading to the synthesis of more effective ITCs and curcumin derivatives.[24] SF was first isolated from broccoli by monitoring NQO1 inducer potency.[25] In the current work, polyphenol-rich fractions, ITC-enriched fractions, compounds **1** and **4**, and SF were tested and compared for indirect antioxidant activity by measuring induction of NQO1 activity in murine hepatoma cells and direct antioxidant activity by measuring the oxygen radical absorbance capacity (ORAC). This study also demonstrates the effectiveness of FCPC and solid phase extraction (SPE) to concentrate polyphenols and ITCs from moringa leaves.

MATERIALS AND METHODS

Chemicals. Acetonitrile, 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), fluorescein sodium salt, Folin−Ciocalteu phenol reagent, gallic acid, *n*-hexane, methanol, methyl acetate, *β*-naphthoflavone (BNF), phosphate-buffered saline (PBS) 10× concentrate, L-sulforaphane (SF), and trolox [(±)-6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid, 97%] were purchased from Sigma-Aldrich (St. Louis, MO, USA). Fetal bovine serum and *α*-minimum essential medium (MEM) were purchased from Invitrogen (Carlsbad, CA, USA). All solvents were of analytical grade. Water used in the experiments was purified using a Millipore water purification system with a minimum resistivity of 18.2 MΩ·cm (Bedford, MA, USA).

Compounds **1** and **4** were previously purified in our laboratory from a methanolic extract of fresh moringa leaves by HPLC as described by Waterman et al.[8] The chemical purity of isolated ITCs was confirmed by LC-MS and ^{1}H NMR analyses.[8]

DOI: 10.1021/jf505014n
J. Agric. Food Chem. 2015, 63, 1505−1513

Plant Material and Preparation of Crude Extract. Fresh leaves from moringa (Indian PKM variety) were shipped overnight from Moringa Farms, Sherman Oaks, CA, USA. A voucher specimen (CW1) was prepared and deposited at the Chrysler Herbarium of Rutgers University (CHRB). The leaves were extracted on the day of arrival. Briefly, 200 g of fresh leaves was finely chopped and crushed by using a pestle and mortar to activate myrosinase enzymes and conversion of GLSs into corresponding ITCs by tissue damaging. The resulting material was extracted in methanol (3 × 300 mL, overnight) at room temperature by continuous shaking. Solvent was removed from extract under reduced pressure by rotary evaporation. The moringa methanol extract (ME) was frozen at −80 °C, lyophilized, and stored at −20 °C.

Selection and Preparation of the Solvent System. The following three-phase solvent system was selected according to the partition coefficient (K) of compounds **1** and **4**: *n*-hexane/methyl acetate/acetonitrile/water (4:4:3:4). K values were determined as follows: 1 mg of ME was dissolved in 500 μL of a pre-equilibrated two- or three-phase solvent system in a vial with vigorous shaking. After equilibration, equal amounts (100 μL) of upper and lower/middle (in the case of the three-phase solvent system) phases were analyzed by LC-MS using the conditions described under LC-MS Analysis and Quantification of ITCs. The K value is defined as the ratio between the peak area of each ITC in the upper phase (UP) and lower phase (LP), ($K_{UP/LP}$) for a two-phase solvent system or as the ratio between the peak area of each ITC in the middle phase (MP) and lower phase ($K_{MP/LP}$) for a three-phase solvent system.

The selected three-phase solvent system of FCPC was equilibrated in a separatory funnel and left for equilibration at room temperature overnight. The three phases were separated and degassed by sonication for 15 min shortly before use.

Fractionation of ME by FCPC. Counter current chromatography was performed by a bench-scale fast centrifugal partition chromatography sytem FCPC1000, v 1.0, from Kromaton (Annonay, France) with a rotor volume of 1000 mL and maximum pressure of 860 psi. For fractionation, the column was first filled with MP and LP in a ratio of (7:3) at a flow rate of 80 mL/min while rotating at 300 rpm. The system was then equilibrated with UP at a flow rate of 10 mL/min and 750 rpm. A 3 g sample of ME was suspended in 10 mL of each phase of the solvent system used for separation. ME was sonicated briefly and filtered through a 0.45 μm pore. As the UP was pumped at 10 mL/min at 750 rpm, the sample was injected through the Rheodyne valve. UV detection was performed at 227 nm, and 20 mL fractions were collected every 2 min with a CHF122 SC Advantec fraction collector (Dublin, CA, USA).

Enrichment of Fractions by SPE. FCPC fractions, particularly C, D, and E (50−100 mg), were dissolved in 1 mL of water containing 1% acetic acid and sonicated for 10−15 min. A 3 mL SPE column with C18 absorbents (J. T. Baker, Bakerbond) was equilibrated by 3 mL of methanol followed by 3 mL of water containing 1% acetic acid. The sample solution (1 mL) was loaded into the SPE column. The aliquots (1 mL × 3) of water (1% acetic acid) and methanol (1 mL × 3) were successively applied into the SPE tube, and two elutes were collected separately and evaporated to dryness. The methanol elute was used for further characterization of fractions in terms of ITC content, total polyphenol content (TPC), ORAC, and NQO1 activity assays.

LC-MS Analysis and Quantification of ITCs. LC-MS analysis was performed using the Dionex UltiMate 3000 RSLC ultrahigh-pressure liquid chromatography system, consisting of a workstation with Dionex Chromeleon v. 6.8 software package, solvent rack/degasser SRD-3400, pulseless chromatography pump HPG-3400RS, autosampler WPS-3000RS, column compartment TCC-3000RS, and photodiode array detector DAD-3000RS. After the photodiode array detector, the eluent flow was guided to a Varian 1200L (Varian Inc., Palo Alto, CA, USA) triple-quadrupole mass detector with electrospray ionization interface, operating in the negative ionization mode. The voltage was adjusted to −4.5 kV, heated capillary temperature was 280 °C, and sheath gas (zero grade compressed air) was used for the negative ionization mode. The mass detector was used in scanning mode from 65 to 1500 atomic mass units. Data from the the Varian 1200L mass detector were collected, compiled, and analyzed using Varian's MS Workstation, v. 6.9, SP2. Compounds were separated on a Phenomenex Luna C8 reversed phase column, size 150 × 2 mm, particle size = 3 μm, pore size = 100 Å. The mobile phase consisted of two components: solvent A (0.5% ACS grade acetic acid in double-distilled deionized water, pH 3−3.5), and solvent B (acetonitrile). The initial conditions of the gradient were 95% A and 5% B. The gradient progressed linearly to 5% A and 95% B over 30 min and then remained isocratic for the next 8 min. During the following 4 min, the ratio of solvents A and B was brought to initial conditions linearly. An 8 min equilibration interval was included between subsequent injections.

ITCs were characterized on the basis of their retention times, UV maxima, and MS fragmentation patterns. The MS data obtained for the ITCs (**1**−**4**) gave the expected m/z values and fragment ions that were characteristic for these compounds.[8] In the current study, the quantification of ITCs in the fractions were done by using standard curves generated for pure **1** and **4**, which were purified (>98%) previously as described by Waterman et al.[8] Briefly, 1 μL LC-MS injections of compound **1** at 20, 100, and 200 ng/μL generated a standard curve ($y = 123x - 0.098$, $R^2 = 1$), and injections of compound **4** at 10, 50, and 100 ng/μL generated a standard curve ($y = 104.32x - 0.098$, $R^2 > 0.99$). The concentrations of compounds **2** and **3** in the fractions and crude extract were estimated by using the standard curve of compound **4**. All injections were repeated at least three times for either standard curve generation or determination of ITC content in the fractions. Therefore, results are represented as means ± SD of three independent measurements.

Analyses of TPC and ORAC. TPC was quantified according to a modified Folin−Ciocalteu method[26] as previously described[27] and expressed as mean gallic acid equivalents (GAE) of at least three independent experiments. ORAC was determined by using fluorescein as the fluorescent probe and AAPH as a peroxyl radical generator in a procedure adapted from a previously published method.[28] ORAC results for fractions and ME were expressed as μM Trolox equiv (TE)/g and directly expressed as TE for **1**, **4**, and SF. All samples were assayed in triplicate. Results are presented as means ± SD.

NQO1 Induction Assay: Cell Culture and Treatment. Hepa1c1c7 mouse hepatoma cells (CRL-2026, American Type Culture Collection, Manassas, VA, USA) were plated in 24-well tissue culture plates (Greiner Bio One, Frickenhausen, Germany) and grown at 37 °C in a humidified incubator with 5% CO_2 to near confluence in α-MEM without ribonucleosides or deoxyribonucleosides (Invitrogen Corp., Carlsbad, CA, USA) supplemented with 100 IU/mL penicillin, 100 mg/mL streptomycin (Cellgro, Manassas, VA, USA), and 10% (v/v) fetal bovine serum. Confluent cells were washed two times with PBS (1×) and incubated in serum-free α-MEM overnight (18 h). Cells were treated in triplicate with BNF (0.05−5 μM), SF (5 μM), extract/fractions (ME, A−C, F, 1, 5, and 10 μg/mL; D, E, 1, 2.5, and 5 μg/mL), and compounds **1** (1, 5, and 10 μM) and **4** (1, 2.5, and 5 μM) in serum-free media for 48 h. The NQO1 activity in the cultured cells was assayed in duplicate at the end of the incubation by using an Abcam NQO1 activity assay kit (Abcam, Cambridge, MA, USA). Briefly, cells were washed with PBS (1×) twice and solubilized in 0.2 mL of extraction buffer supplied by the manufacturer. Cells were scraped and incubated on ice for 15 min. Then, lysates were centrifuged at 18000*g* for 20 min at 4 °C. Supernatant was assayed immediately or stored at −80 °C. The protein concentration in the supernatant was quantified by the Pierce BCA Protein Assay Kit (Thermo Scientific, Rockford, IL, USA). The NQO1 activity was measured at 440 nm for 5 min. The linear rate of increase in absorbance was examined over time. The NQO1 activity was normalized to total protein content of each sample to eliminate sample-to-sample variability. NQO1 fold induction was expressed as specific activity of treatment over those of control. Results are means ± SD of three independent experiments.

Cell Viability. Hepa1c1c7 cells were plated into 24-well plates at 1 × 10^5 cells/well and grown for 48 h (90% confluent), and then confluent cells were washed two times with PBS (1×) and incubated in serum-free α-MEM overnight (18 h). ME (1−25 μg/mL), fractions

DOI: 10.1021/jf505014n
J. Agric. Food Chem. 2015, 63, 1505−1513

(A, B, 10 and 25 μg/mL; C−F, 1−25 μg/mL), and compounds **1** and compound **4** (both 5 and 10 μM), dissolved in ethanol (0.25% v/v final concentrations), were added to cells together with vehicle control (ethanol alone) and incubated for an additional 48 h. The effect of treatments on cell viability was examined by using MTT (TCI, Portland, OR, USA).[29] MTT working solution (5 mg/mL in 1× PBS) was filtered through a 0.22 μm cellulose membrane (Corning, Corning, NY, USA) and added to treated cells during the last 3 h of treatment (48 h). Media were carefully aspirated; cells were dissolved in DMSO, and the absorbance was read at 570 nm. Results are means ± SD of three independent experiments.

Statistical Analysis. Data were analyzed by one-way ANOVA followed by a Dunnett or Wilcoxon test as indicated. Pearson's correlation coefficients for ORAC results with TPCs were calculated using means of triplicate measurements. For statistical analysis GraphPad Prism version 6.02 for Windows (GraphPad Software, Inc.) was used.

RESULTS AND DISCUSSION

Optimization of FCPC Solvent System. Various two-phase solvent systems for FCPC separations were tested and *K* values measured for compounds **1** and **4** (Table 1). Three two-phase solvent systems *n*-butanol/ethyl acetate/water, methanol/ethyl acetate/water, and *n*-hexane/ethyl acetate/methanol/water at different volume ratios could not provide acceptable partition coefficients, ideally 0.5−2.0 for efficient separation.[30] The three-phase solvent system composed of *n*-hexane/methyl acetate/acetonitrile/water (4:4:3:4) was selected for the current study as the best solvent system on the basis of the optimal partition coefficient of ITCs between the MP and LP. Accordingly, the ideal $K_{MP/LP}$ value obtained for **1** (1.61) together with a larger value for **4** (5.14) suggest that relatively less hydrophilic **4** should be eluted first by MP, followed by more hydrophilic **1** by LP. With this strategy, **1** and **4** were separated completely within a single FCPC run even though their structure differed only by the presence of one acetyl group.

Table 1. Partition Coefficients (*K*) of 1 and 4 in Various Solvent Systems

		partition coefficient[a] (*K*)	
solvent system	ratio	**1**	**4**
n-butanol/ethyl acetate/water	1:1.5:2.5	28.5	74.5
methanol/ethyl acetate/water	1:3:2	3.97	9.66
	1:2:2	3.97	8.24
n-hexane/ethyl acetate/methanol/water	4:6:4:6	0.01	0.03
	3:7:4:6	0.09	0.37
	3:7:3:7	0.02	0.10
	35:100:35:100	0.02	0.07

Separation by FCPC. The UV absorption of compounds separated by FCPC in ME is shown in Figure 2. The starting mobile UP was eluted for 100 min to obtain hydrophobic compounds and then switched to MP to elute moderately hydrophilic compounds for 100 min. Finally, the highly polar compounds were separated by eluting the column with LP for 150 min. LC-MS analyses revealed that fractions A, collected between 0 and 92 min (393 mg; 13.1%), and B, collected between 94 and 172 min (231 mg; 7.7%), were composed of nonpolar compounds such as fatty acids and chlorophylls. Fractions C, collected between 176 and 196 min (111 mg; 3.7%), D, collected between 198 and 204 min (123 mg; 4.1%), and E, collected between 206 and 224 min (108 mg; 3.6%), contained high levels of compounds **1**−**4** (Figure 3). The UV profile of fraction C showed compound **4** representing 94% of the total peak area (Figure 3A) and fraction E with compound **1** at 87% of total peak area (Figure 3C), demonstrating efficient separation of these two structurally similar compounds by FCPC. Fraction D contained all ITCs (**1**−**4**) together with niazicin A (see enlarged representation in Figure 3B). Fraction F (2.014 g, 67%), eluted between 226 and 360 min (Figure 2), contained the majority of polyphenolic compounds.

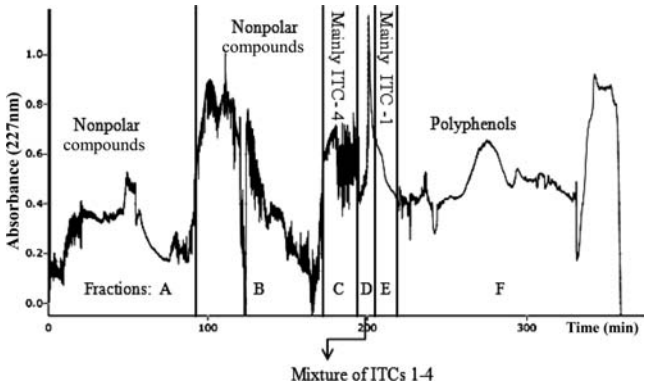

Figure 2. Fractionation chromatogram of moringa methanolic leaf extract (ME) by fast centrifugal partition chromatography (FCPC) using *n*-hexane/methyl acetate/acetonitrile/water (4:4:3:4) three-phase solvent system.

Enrichment by SPE. ITCs **1**−**4** were quantified in fractions C, D, and E before and after SPE by LC-MS analysis as previously described[6] and expressed as percent of fraction dry weight (DW). There was significant enrichment in the total concentration of ITCs (**1**−**4**), after SPE in all three fractions (Figure 4). The concentration of ITCs (**1**−**4**) was increased by 3.7-fold in fraction C-SPE, yielding concentrations of 1.62 ± 0.07% (**1**), 1.50 ± 0.01% (**2**), 1.66 ± 0.11% (**3**), and 5.4 ± 0.08% (**4**) of fraction DW. Fraction D-SPE was enriched by 2.1-fold yielding concentrations of 6.41 ± 0.01% (**1**), 4.00 ± 0.05% (**2**), 1.85 ± 0.05% (**3**), and 5.18 ± 0.06% (**4**) of fraction DW. The highest enrichment (15-fold) was observed in fraction E, initially containing 2.0% (±0.14) of **4** and increasing to 30% (±0.43) of fraction DW after SPE. Overall, fractions obtained by FCPC/SPE contained higher percentage values of **1**−**4** when compared to the crude extract, which contained 1.46% (±0.05) of **1**, 1.36% (±0.07) of **4**, and undetectable amounts of **2** and **3**. These results demonstrated an efficient method to concentrate ITCs for bioassay applications or for further purification by HPLC.

TPC and ORAC. Generally, phenolic compounds are direct antioxidants, which can effectively scavenge and/or chelate readily oxidizable reactive compounds. Moringa extracts and fractions containing phenolic acids (chlorogenic acid, ellagic acids) and flavonoids (mostly quercetin, kaempferol, and rutin) possess direct antioxidant activity in several in vitro assays including β-carotene bleaching, ferric reducing, DPPH/super-

oxide/hydroxyl radical scavenging, and lipid peroxidation.[18,31] However, there have not been any studies evaluating the role of moringa ITCs in direct antioxidant activity. Therefore, we evaluated the direct antioxidant capacity of moringa FCPC fractions containing different classes of compounds ranging from essential oils and chlorophylls to ITCs and polyphenols by using the in vitro ORAC assay. ORAC provides an improved analysis technique for direct antioxidant capacity by measuring the inhibition of the peroxyl radical (predominant free radical in biological system) damage over a time course and combining these factors into a single "area under curve" (AUC) quantity.[32] We also measured TPC of each fraction to establish the contribution of polyphenol components of moringa to direct antioxidant capacity (Figure 5A).

As seen in Figure 5A, the highest ORAC value was obtained for ME (12721 ± 310 μmol TE/g extract) with the highest TPC (18.1 ± 0.3 mg GAE/100 mg). The ORAC of ME was higher than reported values for coffee powder (10007 μmol TE/g), black tea leaves (1566−1629 μmol TE/g), grape seeds (11681−11889 μmol TE/g), and blueberry extracts (2441−2792 μmol TE/g), which have been noted for their high antioxidant values.[32,33] Although TPC of fraction F was 2.6 times less than TPC of ME, the ORAC of fraction F (12452 ± 488 TE/g) was not significantly different from the ORAC of the ME. The LC-MS analysis of fraction F showed much higher peak areas of rutin, chlorogenic acid, and quercetin-malonyl-glucoside compared to the ME, suggesting these polyphenols concentrated in fraction F play a significant role in the observed high direct antioxidant activity.

In SPE-enriched ITC fractions C, D, and E, the ORAC values were found to be moderate, almost 2−3 times less than that of fraction F. Statistical analyses performed for these fractions revealed that, although ORAC values were significantly correlated ($r = 0.99$, $p < 0.05$) with TPC, they did not correlate with total ITC content. These findings support the role of moringa polyphenols as direct antioxidants, however, leaving the role of ITCs uncertain. For further investigation, we determined the ORAC of compounds **1** and **4** in comparison to SF, which has no direct antioxidant activity.[34] Figure 5B reports the linear regression analyses of trolox, compounds **1** and **4** (ranging from 1.25 to 12.5 μM), and SF (12.5−62.5 μM) with respect to their net AUC value. SF was found to have the

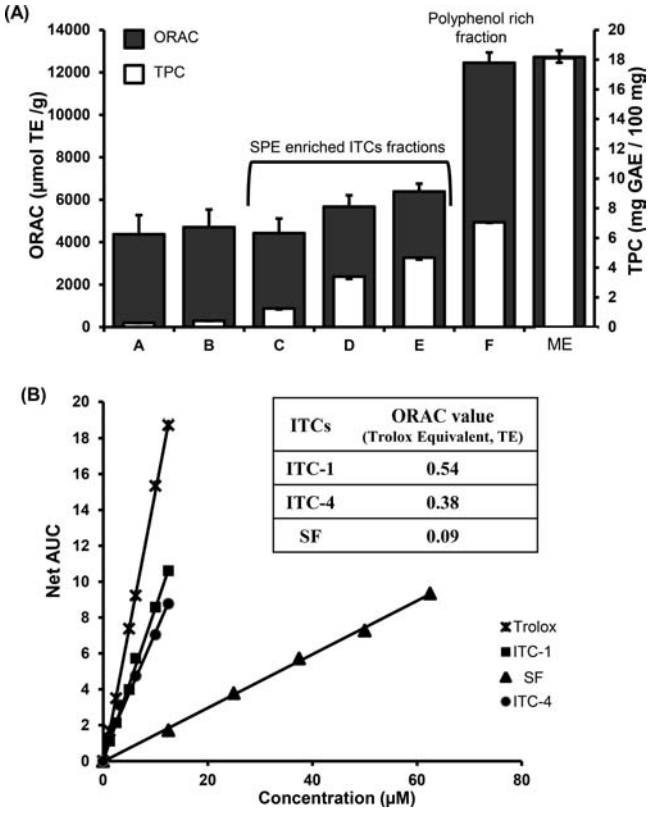

Figure 5. (A) Oxygen radical absorbance capacity (ORAC) and total polyphenol content (TPC) of fractions (A–F) and moringa methanol extract (ME). ORAC was determined as μmol Trolox equiv (TE)/g. TPC was determined as mg gallic acid equiv/100 mg extract or fractions. (B) Linear regression of ORAC value as a function of the concentration (μM) of Trolox ($y = 1.534x \pm 0.017$; $r = 0.999$), **1** ($y = 0.824x \pm 0.042$; $r = 0.989$), **4** ($y = 0.576x \pm 0.042$; $r = 0.989$), and SF ($y = 0.1494x \pm 0.0048$; $r = 0.996$). The table on the graph shows TE values of each ITC calculated by slope of compound/slope of trolox. The net AUCs were calculated by subtracting AUC of blank (75 mM potassium phosphate buffer at pH 7.4) from AUC of sample. Data represent the mean of three independent experiments.

lowest ORAC value (0.09 TE); however, both **1** (0.54 TE) and **4** (0.38 TE) had 6 and 4.2 times higher ($p < 0.0001$) ORAC compared to SF. This relatively high antioxidant capacity of compounds **1** and **4** most likely can be attributed to the presence of an aromatic side chain and increased stability of molecules due to the presence of a rhamnose sugar moiety (Figure 1B). On the basis of previous papers, ORAC values of **1** and **4** are considerably lower than those of other direct acting phenolic compounds such as quercetin (7.28 TE), rutin (6.01 TE), and chlorogenic acid (3.14 TE).[33] On the other hand, the similarity of our data to the ORAC of some physiologically active endogenous antioxidants such as glutathione (0.57 TE) and ascorbic acid (0.75 TE)[35] suggests that moringa ITCs may act as direct antioxidants.

Effects of ME, Fractions, and ITCs on NQO1 Catalytic Activity. Up-regulation of phase II XMEs by indirect antioxidants has been widely accepted as one of the preventive mechanisms of action against several pathological conditions. Among these enzymes, NQO1 has been accepted as a biomarker in the discovery of natural chemopreventive and anti-inflammatory agents due its widespread presence in all mammalians, high magnitude of response toward inducers, and ease of enzymatic detection.[36] The measurement of NQO1 activity in Hepa1c1c7 mouse hepatoma cells provides a reliable, specific, and reproducible method for determining inducer potency of pure[25,37,38] as well as complex bioactive (mixtures or plant extracts) compounds.[39,40] In the current work, cell viability was tested over a range of 1–25 μg/mL for fractions/ME and 5–10 μM for pure ITCs to determine doses that maintain cell viability of >95% (see Figure S1 in the Supporting Information), confirming that the observed induction was due to potency of inducers rather than an artifact of cytotoxicity in the NQO1 assay. Accordingly, ME, SPE fractions, and pure ITCs were all tested at at least three noncytotoxic doses (Figures 6A and 7). The ME (1, 5, and 10 μg/mL) significantly ($p < 0.001$) induced NQO1 activity up to 4.8-fold compared to untreated-control cells in the mouse Hepa1c1c7 cell line (Figure 6A). The three SPE-enriched ITC fractions, C (1–10 μg/mL), D, and E (both at 1–5 μg/mL), also significantly ($p < 0.001$) elevated NQO1 activity. Figure 6B represents induction level of fractions and ME at a fixed dose of 5 μg/mL (common noncytotoxic dose for all) together with total ITC yield. The highest level of induction in NQO1 activity was detected in fraction E containing the highest total ITC yield (30%, ITCs), followed by fractions D (17.4% ITCs) and C (11.5% ITCs). The correlation of ITC yields in the fractions with their NQO1 induction capacity confirms that the compounds with ITC pharmacophore (–N═C═S group) are highly effective in inducing indirect antioxidant activity. Fractions A and B, which do not contain ITCs, showed NQO1 activity at the same low level as the control, indicating the fatty acids and chlorophylls do not have any indirect antioxidant activity.

Similarly, fraction F did not induce NQO1 activity even at the relatively high dose (10 μg/mL; Figure 6A), indicating polyphenols present in this fraction (predominantly hydroxylated flavones, quercetin 3-*O*-rutinoside, quercetin 3-*O*-(6″-malonylglucoside), and 5-caffeoylquinic acid) do not possess indirect antioxidant capacity, confirming a recent study which showed that hydroxylated flavones are ineffective at inducing cytoprotective enzymes, despite having substantial direct antioxidant activity.[41] However, other classes of polyphenols, including methoxylated flavones, have been shown to significantly increase NQO1 and elicit cytoprotective enzyme activity.[20,38] Accordingly, we observed a clear dose-dependent induction pattern in cells treated with β-naphthoflavone (5,6-benzoflavone, BNF) (Figure 6B), a classical phenolic inducer of NQO1,[42] confirming the sensitivity of the cells to certain polyphenols under our experimental conditions.

As seen in Figure 7, in addition to the ME and FCPC fractions, compounds **1** (1–10 μM) and **4** (1–5 μM) were tested for their NQO1 inducer capacities in comparison to SF (5 μM). Previously, it was shown that SF is the most potent inducer of NQO1 activity, reaching a maximum induction of 3–5-fold between 2.5 and 8 μM concentrations.[25,37,43] In accordance with these studies, the current work showed 5 μM SF induced NQO1 activity 4.2-fold. At this concentration, compounds **1** and **4** induced NQO1 activity 4.3- and 3.9-fold, respectively, showing that SF and ITCs (**1**, **4**) from moringa are equipotent inducers of NQO1. For compound **1**, concentrations of 10 μM did not cause any greater induction than 5 μM did. Similarly, a dose response could not be observed from 1 to 5 μM for compound **4**, indicating that a clear dose-dependent response occurs under 1 μM dose range. To our knowledge, this is the first study demonstrating that moringa ITCs can significantly induce NQO1 activity at such low concentrations; therefore, it may be a practical dietary

alternative to SF from broccoli due to increased stability as previously shown.

In summary, the separation and concentration of distinct classes of compounds in moringa leaves, namely, phenolics and ITCs, were successfully achieved through FCPC fractionation followed by SPE. These enriched fractions allowed direct and indirect antioxidant analysis, distinguishing which phytochemicals are responsible for differential antioxidant mechanism. We determined that the polyphenol-rich fraction had high ORAC, indicating strong direct antioxidant activity, whereas ITC-enriched fractions, compounds **1** and **4**, effectively induced NQO1 activity, representing their potent indirect antioxidant activity.

The unique combination of direct (polyphenols) and indirect (ITCs) antioxidant compounds in moringa provides justification and support for the therapeutic uses of polyphenol- and ITC-enriched moringa products. One of the major findings of this study is that compounds **1** and **4** are as potent as SF in inducing NQO1 activity. This indirect antioxidant potency of moringa ITCs, combined with their unique chemical stability and anti-inflammatory activity, makes them attractive food-based therapeutic alternatives to unstable ITCs such as SF. Health-related applications will require the purification of ITCs (**1**–**4**) in significant quantities. The large-scale fractionation followed by SPE enrichment techniques reported here may provide an efficient strategy for ITC isolation.

Protean precast gels, and Precision Plus Protein Standards (recombinant proteins expressed by *E. coli* with molecular masses of 10, 15, 20, 25, 37, 50, 75, 100, 150, and 250 kDa) (all from Bio-Rad-Laboratories (Hercules, CA)) were employed for the separation of proteins by SDS-PAGE. Quick Start Bradford-1xDye reagent from Bio-Rad-Laboratories was employed for the estimation of proteins by Bradford assay. Hydrochloric acid, sodium dihydrogen phosphate, sodium hydroxide (all from Merck), sodium tetraborate, and Thermolysin enzyme (both from Sigma-Aldrich) were used for the digestion of proteins. Alcalase 2.4 L FG and Flavourzyme 1000 L were kindly donated by Novozymes Spain S.A. (Madrid, Spain). Sodium chloride (Merck), angiotensin converting enzyme (ACE), ethanol (EtOH), 2-[4-(2-hydroxyethyl)-1-piperazinyl]-ethanesulfonic acid (HEPES), hippuryl-histidyl-leucine (HHL), 1,10-phenanthroline, 2-mercaptoethanol, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), albumin from bovine serum, ammonium thiocyanate, hydrogen peroxide, ferrous sulfate, iron(II) sulfate, iron(II) chloride, iron(III)chloride, L-gluthathion (GSH), linolenic acid, methanol, *ortho*-phthalaldehyde, potassium ferricyanide, trichloroacetic acid, and potassium persulfate (all from Sigma-Aldrich) were used to carry out in vitro assays. Acetonitrile (ACN) HPLC gradient grade (Scharlab), trifluoroacetic acid (TFA), and acetic acid (both from Sigma-Aldrich) were employed in the preparation of mobile phases in HPLC and HPLC-Q-TOF experiments.

Protein Extraction. The extraction procedure was similar to the described by Esteve et al.[12] with some modifications. Cherry pulp was removed, and the stone was broken to extract cherry seeds. Seeds were milled, and fat was removed by extracting three times with hexane (25 mL per 0.5 g of seeds). Seeds moisture was determined keeping them at 103 ± 2 °C until constant weight. Defatted seeds were stored at −20 °C until use. The procedure used to extract proteins from cherry seeds consisted of mixing 30 mg of defatted seeds with 5 mL of 100 mM Tris-HCl buffer (pH 7.5) containing 1% SDS and 0.5% DTT. Extraction was carried out using high intensity focused ultrasounds (HIFU) for 5 min and an amplitude of 30% followed by centrifugation at 4000*g* for 20 min. Proteins from the supernatant were next precipitated with 10 mL of cold acetone at 4 °C for 1 h. After centrifugation at 4000*g* for 10 min, precipitated proteins were dried overnight at 37 °C. Pellets were weighed and then dissolved in the previous Tris-HCl buffer (without DTT) using HIFU for 5 min at 30% amplitude. The solution was filtrated through 0.45 μm and stored at 4 °C until use. The protein content in this solution was estimated by Bradford assay.[13]

Protein Separation. Proteins were separated by SDS-PAGE and RP-HPLC. SDS-PAGE separation was carried out in a Mini-Protean from Bio Rad. Samples were prepared by mixing 15 μL of the cherry seed protein isolate with 15 μL of Laemmli buffer containing 5% (v/v) β-mercaptoethanol and by heating for 5 min at 100 °C. Electrophoresis was carried out on commercial Ready Gel Precast Gels using Tris/glycine/SDS as running buffer and applying 80 V for 5 min and 200 V for 30 min. For the estimation of molecular weights, peptide standards (10, 15, 20, 25, 37, 50, 75, 100, 150, and 250 kDa) were used as a ladder. After separation, proteins were fixed with 50 mL of 10% (v/v) glacial acetic acid/40% (v/v) MeOH gently shaking for 30 min and stained with 50 mL of Bio-Safe Coomassie stain by slightly shaking for 1 h. Finally, the gel was washed with Milli-Q water for 2 h.

RP-HPLC separation of the cherry seed protein isolate was performed in a modular Agilent Technologies liquid chromatograph (Pittsburgh, PA). All samples were prepared twice and measured by duplicate. A Poros R2/10 Perfusion column (4.6 mm D × 50 mm) at a flow-rate of 2 mL/min and a temperature of 25 °C were used. The gradient was 30−40% B in 13 min, 40−60% B in 6 min, 60−80% B in 1 min, and 80−30% B in 2 min. Mobile phase A was water with 0.1% (v/v) of TFA, and mobile phase B consisted of ACN with 0.1% (v/v) TFA. Detection was carried out with a fluorescent detector at λ_{exc} = 280 and λ_{em} = 360 nm.

Protein Digestion and Fractionation. Digestion of extracted proteins was carried out using three different enzymes: Alcalase (borate buffer (pH 8.5), 0.10 AU enzyme/g protein), Thermolysin (phosphate buffer (pH 8.0), 0.4 g enzyme/g protein), and Flavourzyme (bicarbonate buffer (pH 6.0), 75 AU enzyme/g protein). In all cases, a protein concentration of 2.5 mg/mL, a digestion temperature of 50 °C, and a digestion time of 7 h were selected. Additionally, blank digestions without proteins prepared by mixing buffer and enzyme were carried out. Digestions were carried out by slight mixing (600 rpm) at a controlled temperature in a Thermomixer Compact (Eppendorf AG, Hamburg, Gernmany). Digestions were stopped by heating to 100 °C for, at least, 10 min, and then they were centrifuged (5 min at 7000 rpm).

Hydrolysates were fractionated by ultrafiltration using Vivaspin 500 PES molecular weight (Mw) cutoff filters (5 kDa) (Sartorius Stedim biotech, Goettingen, Germany) and Amicon Mw cutoff filters (3 kDa) (Millipore).

Degree of Hydrolysis (% DH). The degree of hydrolysis was determined by the OPA assay following the method of Wang et al.[14] with modifications. OPA mixture (5 mL) consisted of 2.5 mL of 100 mM sodium tetraborate, 1 mL of 5% (w/v) SDS, 100 μL of 40 mg/mL OPA dissolved in MeOH, 10 μL of β-mercaptoethanol, and 1.39 mL of water. The assay consisted of mixing 2.5 μL of sample with 100 μL of OPA mixture and measuring the absorbance at 340 nm (spectrophotometer Lambda 35, PerkinElmer, Waltham, MA) after 8 min at room temperature. The peptide content was calculated by interpolation in a calibration curve obtained using GSH (0−5 mg/mL). The degree of hydrolysis was calculated by the following equation:

$$\mathrm{DH} = \frac{\text{peptide content}}{\text{protein content}} \times 100 \quad (1)$$

where the protein content was determined by the Bradford assay.

Antioxidant Capacity. Four different in vitro antioxidant assays were carried out for the evaluation of the antioxidant capacity of hydrolysates from the cherry seed protein isolate.

ABTS Radical Scavenging Assay. The scavenging capacity against ABTS radicals was evaluated according to the method of Wiriyaphan et al.[15] with modifications. $ABTS^{\bullet+}$ stock solution was prepared by mixing a 7.4 mM ABTS solution with 2.6 mM potassium persulfate in 10 mM phosphate buffer (pH 7.4) for, at least, 16 h kept in the dark. $ABTS^{\bullet+}$ working solution was daily prepared by mixing the stock solution with 10 mM phosphate buffer (pH 7.4). The assay was carried out by mixing 1 μL of sample with 100 μL of $ABTS^{\bullet+}$ working solution for 6 min at room temperature. The absorbance corresponding to $ABTS^{\bullet+}$ was measured at 734 nm. $ABTS^{\bullet+}$ scavenging capacity was calculated using the following equation:

$$\text{ABTS radical scavenging capacity (\%)} = \left(\frac{\mathrm{Abs_{blank}} - \mathrm{Abs_{sample}}}{\mathrm{Abs_{blank}}}\right) \times 100 \quad (2)$$

where Abs_{sample} was the absorbance of 1 μL of sample with 100 μL of $ABTS^{\bullet+}$ working solution and Abs_{blank} was the absorbance of 1 μL of digestion buffer with 100 μL of $ABTS^{\bullet+}$ working solution. Trolox (1 mM) was employed as positive control.

Hydroxyl Radical Scavenging Assay. The capacity to scavenge hydroxyl radicals was evaluated by the method of Ajibola et al.[16] with modifications. Hydroxyl radicals were obtained by the oxidation of Fe(II) with hydrogen peroxide. Antioxidant compounds inhibit the oxidation of Fe(II) and the formation of hydroxyl radicals. The assay was monitored by measuring the absorbance corresponding to the colored complex resulted from the reaction between Fe(II) and 1,10-phenanthroline. The assay consisted of mixing 50 μL of 3 mM 1,10-phenanthroline in 0.1 M phosphate buffer (pH 7.4), 50 μL of 3 mM ferrous sulfate, 50 μL of sample, and 50 μL of 0.01% (v/v) hydrogen peroxide. The mixture was incubated for 1 h at 37 °C, and the absorbance of the Fe(II) complex was measured at 536 nm. The hydroxyl radical scavenging capacity was evaluated according to the following equation:

DOI: 10.1021/jf505037p
J. Agric. Food Chem. 2015, 63, 1514−1520

hydroxyl radical scavenging capacity (%)

$$= \left(\frac{\text{Abs}_{\text{sample}} - \text{Abs}_{\text{blank}}}{\text{Abs}_{\text{control}} - \text{Abs}_{\text{blank}}}\right) \times 100 \quad (3)$$

where $\text{Abs}_{\text{sample}}$ was the absorbance of the sample, $\text{Abs}_{\text{blank}}$ was the absorbance of the digestion buffer, and $\text{Abs}_{\text{control}}$ was the absorbance of the solution resulting when adding the digestion buffer instead of sample and water instead of hydrogen peroxide. GSH (1 mg/mL) was employed as positive control.

Ferric Ion Reducing Antioxidant Power (FRAP) Assay. This assay measures the capacity of the sample to reduce Fe(III) from ferricyanide, and it was evaluated according to the method proposed by Ajibola et al.[16] with modifications. The assay consisted of incubating 12.5 μL of sample with 12.5 μL of 0.2 M phosphate buffer (pH 6.6) and 25 μL of 1% potassium ferricyanide solution for 20 min at 50 °C in the Thermomixer. The reaction was stopped with 25 μL of 10% (w/v) trichloroacetic acid solution. This solution (50 μL) was mixed with 60 μL of water and 15 μL of 2.5% iron(III) chloride solution, and after 3 min, the absorption at 700 nm was measured. The reducing power was calculated according to the following equation:

$$\text{reducing power} = \frac{\text{Abs}_{\text{sample}}}{\text{peptide content}} \quad (4)$$

where $\text{Abs}_{\text{sample}}$ was the absorbance obtained for the hydrolyzate, and the peptide content was that calculated by the OPA assay. The positive control was GSH (0−1 mg/mL). The percentage of inhibition was calculated considering the reducing power corresponding to 1 mg/mL GSH as the maximum reduction.

Capacity To Inhibit Lipid Peroxidation. This assay was carried out by the method developed by Chen et al.[17] with modifications. The assay involved mixing 20 μL of sample, 20 μL of 0.13% (v/v) linoleic acid in EtOH, and 10 μL of water at 40 °C for 144 h (6 days) in the dark. The degree of oxidation was monitored by mixing 2.5 μL of that solution with 175 μL of 75% (v/v) EtOH, 2.5 μL of 30% (w/v) ammonium thiocyanate, and 2.5 μL of 20 mM Fe(II) chloride in 3.5% (v/v) HCl for 3 min at room temperature and measuring the absorbance of the resulting ferric thiocyanate at 500 nm. The capacity to inhibit lipid peroxidation of linoleic acid was calculated using the following equation:

lipid peroxidation inhibition capacity

$$= \left(1 - \frac{\text{Abs}_{\text{sample,144h}} - \text{Abs}_{\text{sample,0h}}}{\text{Abs}_{\text{blank,144h}} - \text{Abs}_{\text{blank,0h}}}\right) \times 100 \quad (5)$$

where $\text{Abs}_{\text{sample,144h}}$ and $\text{Abs}_{\text{blank,144h}}$ were the absorbances of the sample and digestion buffer for 144 h, respectively; and $\text{Abs}_{\text{sample,0h}}$ and $\text{Abs}_{\text{blank,0h}}$ were the initial absorbances of the sample and digestion buffer, respectively.

ACE Inhibition Capacity. ACE inhibition capacity was expressed as the peptide concentration needed for the 50% inhibition of ACE activity (IC_{50}). For that purpose, an assay developed by Geng et al.[18] based on the hydrolysis of the tripeptide HHL into hippuric acid (HA) by the action of ACE was employed. The assay measures the capacity of hydrolyzates to inhibit ACE activity by monitoring the signal corresponding to HA. To calculate the IC_{50} value, the whole peptide extract and dilutions up to 1:10 ratio were measured for every hydrolysate. All measurements were made by duplicate. In every case, 2.5 μL of sample was mixed with 10 μL of ACE (0.05 U/mL), 17.5 μL of 50 mM HEPES buffer (pH 8.3) with 300 mM NaCl, and 5 μL of HHL (1.25 mg/mL). For the controls, 2.5 μL of the corresponding digestion buffer was used. The mixture was kept at 37 °C (in the Thermomixer), and the reaction was stopped by the addition of 50 μL of cold ACN (−20 °C). Separation and detection of HA was performed by HPLC using a Chromolith Performance RP-18e column (100 mm × 4.6 mm ID) from Merck. Separation was carried out at 25 °C, and mobile phases consisted of water with 0.025% (v/v) TFA (mobile phase A) and ACN with 0.025% (v/v) TFA (mobile phase B). The injection volume was 10 μL. A linear gradient from 5% to 95% B in 10 min followed by 95% to 5% B in 2 min was used. Detection was made at 228 nm. Percentage of ACE inhibition was calculated using the following expression where A_{control} was the area under the peak of HA in the control sample and A_{sample} was the area under the peak of HA in the sample.

$$\%\ \text{ACE inhibition} = \frac{A_{\text{control}} - A_{\text{sample}}}{A_{\text{control}}} \quad (6)$$

For every hydrolysate, the % of ACE inhibition of the undiluted and diluted sample was plotted against the peptide concentration (determined by OPA assay), and the IC_{50} value was determined from the signal corresponding to an inhibition of 50% of ACE.

HPLC-Q-TOF-MS Identification of Bioactive Peptides. Identification of peptides was carried out by MS/MS detection using a quadrupole time-of-flight (Q-TOF) series 6530 coupled to a HPLC (model 1100) both from Agilent Technologies. An Ascentis Express peptide ES-C18 (100 mm × 2.1 mm, 2.7 μm particle size, 160 Å pore size) analytical column with a guard column Ascentis Express peptide ES-C18 (5 mm × 2.1 mm), both from Sigma-Aldrich, was employed for the separation of peptides. Elution gradient employed for the separation of peptides in fraction >5 kDa was: 3% B for 6 min, followed by 3−43% B in 20 min, 43−55% B in 2 min, 55−74% B in 9 min, 74−95% B in 2 min, 1 min at 95% B, and 95−3% B in 2 min. Separation of peptides in the fraction <3 kDa was carried out with an elution gradient at 3% B for 7 min, 3−60% B in 28 min, 60−95% B in 3 min, 95% B for 2 min, and 95−3% B in 2 min. The rest of the parameters were: separation temperature, 25 °C; injection volume, 15 μL; and flow rate, 0.3 mL/min. Mobile phases A and B consisted of water and ACN, both containing 0.3% (v/v) acetic acid. Electrospray ionization in the positive ion mode at a capillary voltage of 3500 V and a MS-range from m/z 200 to 2200 were employed. Other MS conditions were: dry gas flow, 12 L/min; dry gas temperature, 350 °C; nebulizer pressure, 50 psig; sheath gas flow, 12 L/min; and sheath gas temperature, 400 °C. The fragmentation energy was calculated taking into account 5 V per 100 Da molecular weight.

In all cases, two independent extracts were analyzed by duplicate. Peaks software (Bioinformatics Solutions Inc., Waterloo, ON, Canada) was employed for the treatment of MS/MS data and de novo peptide sequencing using an error tolerance of 50.0 ppm for the precursor and 0.5 kDa for the fragment. Peptide identification was accepted if peptides appeared in the two independent samples analyzed by duplicate and presented an average local confidence (ALC (%), expected percentage of correct amino acids in the peptide sequence) above 90%. Moreover, because the equipment is not able to distinguish between I and L amino acids due to their equal molecular masses, both amino acids must be considered.

Statistical Analysis. Statistical analysis was performed using Statgraphics Software Plus 5.1 (Statpoint Technologies, Inc., Warranton, VA).

RESULTS AND DISCUSSION

To obtain peptides from cherry seeds, it is necessary to extract first cherry seed proteins. Despite that there is no method previously developed for the extraction of cherry seeds proteins, the group experience on the extraction of proteins from other seeds like olive[12] and plum[19] was very useful. Using extraction conditions described in the Materials and Methods, the protein content, estimated by Bradford assay, was 39.2 ± 5.8 g protein/100 g in defatted and dried seeds. This content is similar to the observed previously for plum seeds.[19] Extracted proteins were next separated by SDS-PAGE (see Figure 1) observing numerous bands below 75 kDa. It was important to highlight the bands appearing around 10, 15, and 20 kDa. Additionally, the RP-HPLC separation of the extract using fluorescent detection at wavelengths corresponding to tryptophan and tyrosine amino acids also showed many signals that could correspond to proteins (results not shown). All of these results

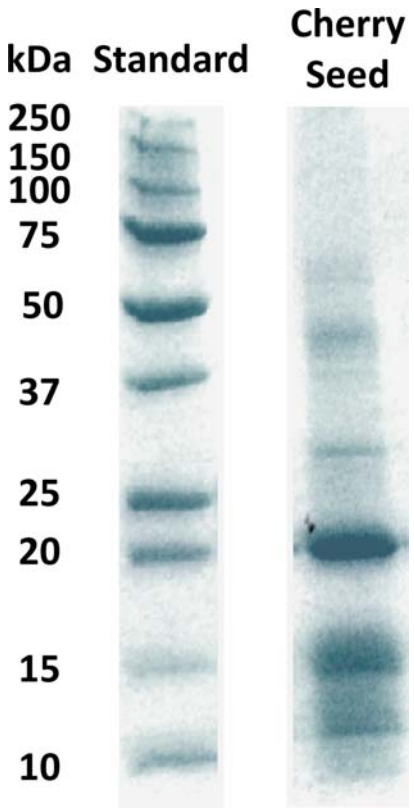

Figure 1. SDS-PAGE separation of proteins from the cherry seed protein isolate.

demonstrated that the procedure enabled the extraction of proteins from cherry seeds.

To obtain peptides from this cherry seed protein isolate, extracted proteins have to be digested with suitable enzymes.

Optimization of the Digestion of the Cherry Seed Protein Isolate. Taking into account bibliographic data and research group experience, Alcalase, Thermolysin, and Flavourzyme were the enzymes chosen for the hydrolysis of the cherry seed protein isolate. To obtain the highest digestion efficiency, different parameters were optimized with every enzyme: pH, protein concentration, enzyme:protein ratio, and digestion time. Digestion temperature was always 50 °C, corresponding to the highest enzymes activity. The optimization of the digestion was monitored by the determination of the degree of hydrolysis. Table 1 groups the conditions tested in every case.

There was not any significant variation ($P > 0.05$) in the hydrolysis degree when using Alcalase enzyme at pH's 8.0 and 8.5, while Flavourzyme showed a higher hydrolysis degree at pH 6.0 than at higher pH's. In the case of Thermolysin, a pH 8.0 was selected taking into account previous results from our research group.[19,20] Regarding the substrate concentration, as expected, the degree of hydrolysis decreases when increasing the substrate concentration, and a concentration of 2.5 mg/mL was selected for the three enzymes. Moreover, different enzyme:substrate ratios were tried. There was no significant variation ($P > 0.05$) in the hydrolysis degree when using Alcalase enzyme at different enzyme:substrate ratios, and the lowest value tried (0.10 AU/g proteins) was chosen. In the case of Flavourzyme, the enzyme:substrate ratio yielding the highest hydrolysis degree was 75 AU/g protein. Finally, the hydrolysis degree when using Thermolysin varied from 34% (at 0.03 g enzyme/g protein) to 49% (at 0.4 g enzyme/g protein), this being the enzyme:substrate ratio first chosen. Nevertheless, further investigations revealed that a high enzyme:substrate ratio resulted in enzyme autolysis, and, thus, a lower enzyme:substrate ratio (0.05 g enzyme/g protein) was finally selected. In all cases, hydrolysis degree increased rapidly in the first hours of digestions, and then it showed a slow increase up to 24 h. Nevertheless, black digestions performed at 24 h also showed the enzyme autolysis, and, to prevent it, a digestion time of 7 h was chosen for the three enzymes. Finally, Table 1 shows the hydrolysis degree obtained under optimal conditions for the three enzymes. In comparison with olive[20] and plum[19] seed proteins, these hydrolysis degrees were slightly lower. There was no significant difference among the hydrolysis degrees observed with the three enzymes ($P > 0.05$).

Evaluation of the In Vitro Antioxidant Capacity of Hydrolysates Obtained from Cherry Seed Protein Isolate. Antioxidant properties were evaluated in hydrolysates obtained using the three enzymes under optimal conditions. For that purpose, four different assays evaluating different antioxidant capabilities were applied: radical scavenging capacity, reduction capacity, and capacity to inhibit lipid peroxidation. Figure 2 shows the antioxidant capacity obtained

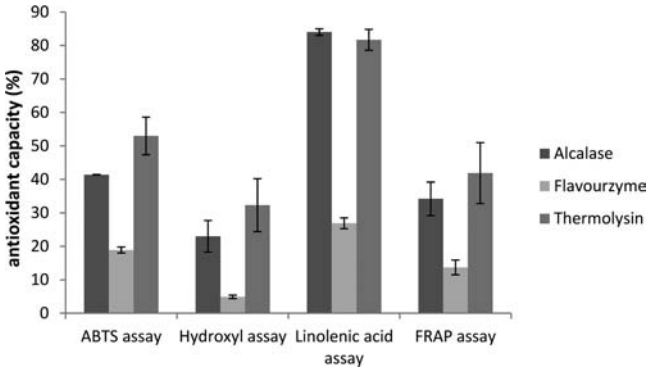

Figure 2. Antioxidant capacity of the cherry seed protein isolate digested with Alcalase, Flavourzyme, and Thermolysin and evaluated using different assays.

Table 1. Parameters Optimized in the Digestion of the Cherry Seed Protein Isolate with Alcalase, Flavourzyme, and Thermolysin Enzymes[a]

enzyme	pH	protein concentration (mg/mL)	enzyme:protein ratio	digestion time (h)	hydrolysis degree (%)[b]
Alcalase	8.0, **8.5**	**2.5**, 5.0, 7.5, 10	**0.10**, 0.15, 0.30, 0.50, 0.90 AU enzyme/g protein	0.5, 1, 1.5, 2, 3, 4, 7, 24	51 ± 2

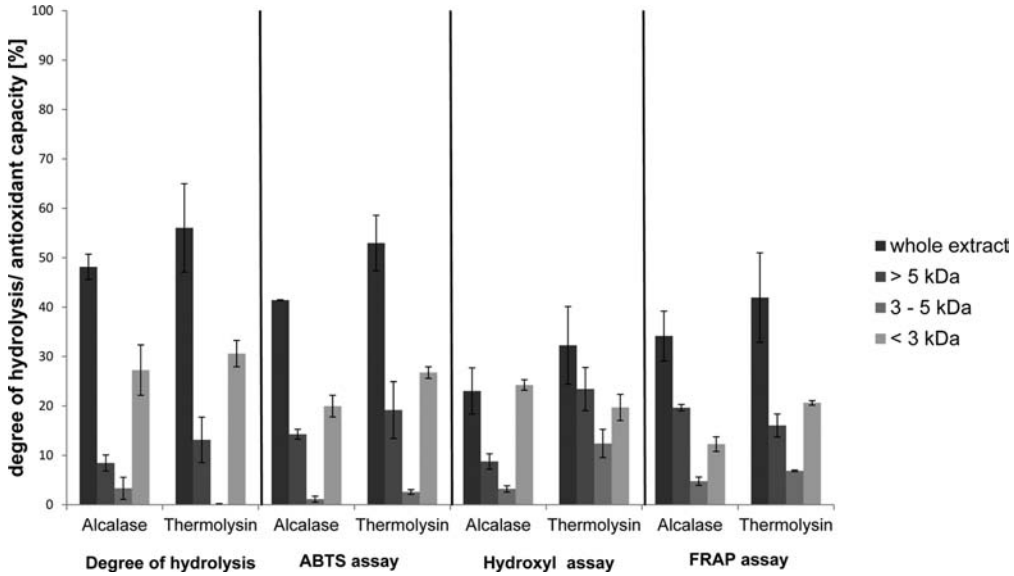

Figure 3. Comparison of hydrolysis degree and antioxidant capacity of fractions obtained from the cherry seed peptide extracts using Alcalase and Thermolysin with those corresponding to the whole extract.

by the two radical scavenging assays (ABTS and hydroxyl radical scavenging assays), by the assay measuring the reduction capacity of peptides (FRAP assay), and by the assay evaluating the capacity to inhibit lipid peroxidation. In all cases, Flavourzyme was the enzyme yielding the peptides with the lowest antioxidant capacity, while Alcalase and Thermolysin resulted in the peptides with the highest antioxidant capacities. These results were similar to those observed with peptides obtained from plum[19] and olive[20] seed proteins. Nevertheless, in comparison with olive and plum seeds, antioxidant capacity of cherry seed peptides was lower when using the ABTS and the hydroxyl radical assays. To obtain a fraction containing most antioxidant peptides, whole peptide extracts obtained with Alcalase and Thermolysin enzymes were fractionated according to their molecular weights within fractions above 5 kDa, from 5 to 3 kDa, and below 3 kDa. Figure 3 shows the antioxidant capacity of the whole peptide extracts and fractions. In all cases, the whole peptide extract showed a higher antioxidant capacity than the fractions, with the fraction from 3 to 5 kDa the one that always yielded the lowest antioxidant capacity, while fractions above 5 kDa and below 3 kDa showed higher values. These results were compared to the amount of peptides determined by OPA assay in the whole peptide extract and in every fraction. As expected, the fraction showing the highest peptide amount was the fraction below 3 kDa, while the fraction above 5 kDa presented a much lower peptide content. This situation was also observed in olive seed peptide fractions.[20] Taking into account these data, the fraction containing peptides with the highest antioxidant capacities seemed to be the fraction above 5 kDa for both Alcalase and Thermolysin enzymes. Therefore, these fractions were selected for the identification of peptides by MS.

Evaluation of the Antihypertensive Capacity of Hydrolysates Obtained from the Cherry Seed Protein Isolate. Antihypertensive capacity of whole peptide extracts was evaluated by measuring the capacity to inhibit ACE activity. Figure 4A shows no ACE inhibition in the case of the Flavourzyme peptide extract, while the Thermolysin peptide extract showed the lowest IC_{50} value (0.31 ± 0.07 mg/mL) and, thus, the highest inhibition capacity. Results obtained were

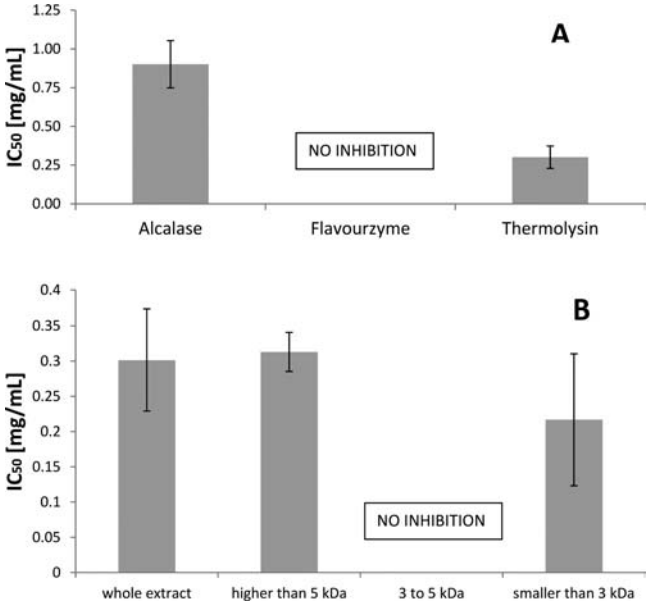

Figure 4. IC_{50} values (mg/mL) of the cherry seed protein isolate digested with Alcalase, Flavourzyme, and Thermolysin (A) under optimal conditions and of the peptide fractions obtained from the Thermolysin peptide extract (B).

again compared to those from plum[19] and olive[20] seed proteins. ACE inhibition activity of cherry seed peptides was similar to the observed in plum seed peptides but lower than that observed in olive seeds peptides. Thermolysin fractions were next obtained by ultrafiltration, and ACE inhibition capacity was evaluated in every fraction (see Figure 4B). The fraction below 3 kDa yielded the highest capacity to inhibit ACE activity, while the fraction from 3 to 5 kDa showed no ACE inhibition.

Peptide Identification in Most Bioactive Fractions by RP-HPLC-ESI-Q-TOF. Peptide identification was carried out in the fractions yielding the highest antioxidant capacity (fractions above 5 kDa obtained with Alcalase and Thermolysin enzymes)

DOI: 10.1021/jf505037p
J. Agric. Food Chem. 2015, 63, 1514−1520

and antihypertensive capacity (fraction below 3 kDa obtained with the Thermolysin enzyme).

Peptide Identification in the Fraction above 5 kDa from the Alcalase Peptide Extract. A total of 51 different peptides were identified in the two independent samples of cherry seed peptides injected by duplicate. Nevertheless, only six common peptides were observed in the four analyses. To increase the number of identified peptides, more concentrated peptide extracts were next analyzed (10-fold more concentrated). Using these concentrated samples, eight additional peptides were observed, although one peptide (TELAL), originally observed in the diluted sample, was not identified in the concentrated one. Ionization of this peptide could have been suppressed by other peptides in the concentrated sample. Identified peptides have been grouped in Table 2. Identified peptides showed molecular weights below 5 kDa in all cases (M_w < 1.3 kDa).

Table 2. Peptides Identified by RP-HPLC-Q-TOF in Fractions above 5 kDa from the Alcalase or Thermolysin Peptide Extracts (Fractions Showing the Highest Antioxidant Capacity) and in the Fraction below 3 kDa from the Thermolysin Digestion Extract (Fraction Showing the Highest Antihypertensive Capacity)

[a]Peptides only observed in the diluted sample.

These results could suggest a very low selectivity in the ultrafiltration process as it was observed previously.[21] No common peptide was observed with peptides identified in the olive seed[20] peptide extract, while one common peptide (NLPLL) was identified when comparing with peptides in plum seed[19] peptide extract.

Peptide Identification in the Fraction above 5 kDa from the Thermolysin Peptide Extract. In this case, 50 different peptides were identified in the two independent samples of cherry seed peptides injected by duplicate. Among them, 14 common peptides were observed. When more concentrated samples were analyzed, three new peptides were identified, but there were six peptides, observed in the diluted samples, that could not be detected in the concentrated ones probably due to ionization suppression. All identified peptides are listed in Table 2. Again, the low efficiency of the ultrafiltration procedure could be the reason for the low molecular weight of identified peptides. All peptides observed in the fractions above 5 kDa, showing antioxidant ability (see Table 2), presented common features. Indeed, all peptides showed a high percentage of hydrophobic (V, I, L) and aromatic amino acids (H, F, W, Y), common features within antioxidant peptides.[22]

Peptide Identification in the Fraction below 3 kDa from the Thermolysin Peptide Extract. A total of 21 different peptides were identified in the two independent samples of cherry seed peptides injected by duplicate, with just five being the number of common peptides. Some of these peptides presented proline (P) in its sequence that is a characteristic feature within antihypertensive peptides.[11] All of these peptides were previously observed in the fraction above 5 kDa, confirming the low selectivity of ultrafiltration filters. Many of these peptides were also observed in plum seed[19] peptide extract (LYSPH, LYTPH, LLAQA, LAGNPENE, LLNDE, LLMQ), but no common peptide was detected when comparing with olive seed peptides.[20]

In conclusion, it has been possible to extract proteins from a waste material derived from the processing of cherry. Protein content of cherry seeds was close to 39% of the dried and defatted seed. The digestion of extracted proteins with different enzymes enabled one to obtain peptides showing antioxidant and antihypertensive properties. Flavourzyme was the enzyme yielding the peptides with the lowest antihypertensive and antioxidant capacity, while Thermolysin was the enzyme showing the peptides with the highest antihypertensive capacity. Fractionation of peptides by ultrafiltration allowed one to obtain fractions with high antioxidant or antihypertensive capacities. HPLC-ESI-Q-TOF enabled one to identify the peptides in most active fractions, which are potentially responsible for the observed bioactivities. Identified peptides in antioxidant fractions showed less than 10 amino acids and a high number of hydrophobic and aromatic amino acids, which are characteristic features for antioxidant peptides. Some identified peptides in antihypertensive fraction contained proline, which is a characteristic amino acid within antihypertensive peptides. These results open a new pathway for the recovery of this waste material, its revalorization, and reuse.

cancer chemoprevention,[14−18] antivirus,[19] antiobesity,[20,21] and anti-inflammation.[15,22] Nevertheless, the investigation of this pleiotropic molecule on the neuronal system has only been limitedly cultivated,[23] and the underlying mechanism of the action has not been well elucidated.

As our continued efforts in discovering and developing novel redox-active small molecules as potential therapeutic agents,[24−30] we synthesized Xn and investigated its cytoprotection and the underlying mechanism in a neuronlike rat pheochromocytoma cell line, PC12. Xn was prepared from the readily available starting materials in seven steps with a total yield of 5.0%. As a polyphenolic compound, Xn moderately scavenges free radicals in vitro. Moreover, Xn efficiently activates the Nrf2−ARE signaling pathway at submicromolar concentrations in PC12 cells, leading to upregulation of a panel of phase II enzyme expression and remarkable protection of the cells from hydrogen peroxide (H_2O_2)- or 6-hydroxydopamine (6-OHDA)-induced neurotoxicity. We further clarified that the potential neuroprotection of Xn is dependent on both the α,β-unsaturated ketone moiety within Xn and the activation of transcription factor Nrf2. Our results demonstrate, for the first time, that Xn is a small-molecule activator of the Nrf2−ARE pathway in neuronal cells and suggest that Xn might be a potential candidate for the prevention of neurodegeneration. The structural determinant of such cytoprotection sheds light on designing and developing novel therapeutic agents.

MATERIALS AND METHODS

Materials. Dulbecco's modified Eagle's medium (DMEM), *N*-acetyl-Asp-Glu-Val-Asp-*p*-nitroanilide (Ac-DEVD-pNA), G418 disulfate salt, dimethyl sulfoxide (DMSO), yeast glutathione reductase (GR), Hoechst 33342, and 2′,7′-dichlorfluorescein diacetate (DCFH-DA) were obtained from Sigma-Aldrich (St. Louis, MO). NADPH was obtained from Roche (Mannheim, Germany). 2,2′-Azinobis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS), 2,6-dichlorophenol indophenol (DCPIP), 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH), *tert*-butylhydroquinone (tBHQ), and β-NADH were purchased from Sigma-Aldrich. Fetal bovine serum (FBS) was obtained from HyClone, Thermo Fisher Scientific (Waltham, MA). The recombinant rat TrxR1, which has a specific activity of 50% of that of the wild-type rat TrxR1 with the DTNB assay, was a gift from Prof. Arne Holmgren at Karolinska Institute, Sweden. *Escherichia coli* Trx was purchased from IMCO (Stockholm, Sweden, www.imcocorp.se). Anti-TrxR1 antibody was obtained from Santa Cruz Biotechnology (Santa Cruz, CA). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), penicillin, and streptomycin were obtained from Amresco (Solon, OH). Bovine serum albumin (BSA), phenylmethanesulfonyl fluoride (PMSF), sodium orthovanadate (Na_3VO_4), and antilamin and antiactin antibodies were obtained from Beyotime (Nantong, China). 5,5′-Dithiobis(2-nitrobenzoic acid) (DTNB) was obtained from J&K Scientific (Beijing, China). 6-Hydroxydopamine hydrobromide (6-OHDA), anti-TrxR1 antibody, anti-Trx1 antibody, and anti-Nrf2 antibody were from Santa Cruz Biotechnology. Anti-HO-1 antibody and anti-NQO1 antibody were obtained from Sangon Biotech (Shanghai, China). The shRNA plasmids targeting coding regions of the rat Nrf2 gene (shNrf2) and the control nontargeting shRNA (shNT) were purchased from GenePharma Co., Ltd. (Shanghai, China). GeneTran III transfection reagent was obtained from Biomiga (San Diego, CA). All other reagents were of analytical grade.

In Vitro Antioxidant Activity of Xn. *ABTS Free-Radical-Scavenging Activity.* The $ABTS^{\bullet+}$ scavenging capacity was determined according to the published method.[27] The $ABTS^{\bullet+}$ radical cation solution, which was prepared from oxidation of ABTS (7 mM) by potassium persulfate (2.5 mM) for 12−16 h in the dark at room temperature, was diluted to an absorbance of 0.700 ± 0.020 at 734 nm. The $ABTS^{\bullet+}$ solution (2 mL) and the antioxidant solution (100 μL) were mixed and incubated at room temperature. After 30 min, the absorbance at 734 nm was determined. The absorbance of the free radical solution without Xn was divided by that with 40 μM Xn to give the percentage of the remaining free radicals.

Assay of Thiobarbituric Acid Reactive Substances (TBARSs). The erythrocyte ghost, prepared following the published procedures,[27] was diluted to a final protein concentration of 0.96 mg/mL and incubated at 37 °C in 0.1 M PBS (pH 7.4). The lipid peroxidation was initiated by the addition of AAPH in the presence or absence of Xn (40 μM). The reaction mixture was gently shaken at 37 °C for 30 min. The reaction mixture was taken out, and a TCA−TBA−HCl stock solution (15% (w/v) trichloroacetic acid, 0.375% (w/v) TBA, 0.25 M HCl) was added, together with 0.02% (w/v) BHT. This amount of BHT completely prevents the formation of any nonspecific TBARS from the decomposition of AAPH during the subsequent boiling. The resulting mixture was heated in a boiling water bath for 15 min. After cooling, the precipitate was removed by centrifugation. TBARS in the supernatant was quantified at 532 nm using an extinction coefficient of $1.56 \times 10^5\ M^{-1}\ cm^{-1}$.[27]

Cell Cultures. The rat adrenal pheochromocytoma cell line PC12 was obtained from the Shanghai Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences. The cells were cultured in DMEM medium supplemented with 10% FBS, 2 mM glutamine, and 100 units/mL penicillin/streptomycin and maintained in a humidified atmosphere with 5% CO_2 at 37 °C. The generation of Nrf2-knockdown PC12 cells is described in the following section.

Cytotoxicity Assays. *MTT Assay.* To investigate the cytotoxicity of Xn on PC12 cells, the cells were seeded at a density of 1×10^4 cells/well in 96-well plates for 24 h followed by incubation with Xn or other agents for 24 h at 37 °C in a final volume of 100 μL. For the H_2O_2 or 6-OHDA injury model, PC12 cells (1×10^4 cells/well) were plated in a 96-well plate and allowed to adhere for 24 h. After the cells were further treated with the indicated concentrations of Xn or DMSO (control) for 24 h, the medium was removed and replaced with fresh medium containing 600 μM H_2O_2 for 12 h or 200 μM 6-OHDA for 24 h. At the end of the treatments, 10 μL of MTT (5 mg/mL) was added to each well followed by incubation for an additional 4 h at 37 °C. An extraction buffer (100 μL, 10% SDS, 5% isobutanol, 0.1% HCl) was added, and the cells were incubated overnight at 37 °C. The absorbance was measured at 570 nm using a microplate reader (Thermo Scientific Multiskan GO, Finland).

Lactate Dehydrogenase (LDH) Release Assay. PC12 cells were seeded in 12-well plates at a density of 2×10^5 cells/well. On the following day, the cells were exposed to various concentrations of Xn for 24 h, followed by addition of 600 μM H_2O_2 for an additional 12 h or 200 μM 6-OHDA for an additional 24 h. The leakage of LDH from cultured cells was quantified by measuring LDH activity in the culture medium. Briefly, 50 μL of the culture medium was mixed with 110 μL of 100 mM Tris−HCl buffer (pH 7.4), 20 μL of 2 mM NADH, and 20 μL of 20 mM pyruvate, and the change of absorbance at 340 nm due to the consumption of NADH was monitored every 20 s for 5 min. The content of LDH release was calculated by normalizing the LDH activity of samples to that measured in culture medium from the control cells.

Hoechst 33342 Staining. PC12 cells were plated in 12-well plates at a density of 2×10^5 cells/well. On the following day, the cells were incubated with the indicated concentrations of Xn for 24 h. After replacement with the fresh medium containing 600 μM H_2O_2 or 200 μM 6-OHDA, the cells were allowed to continue growing for 12 h (H_2O_2) or for 24 h (6-OHDA). After the treatments, Hoechst 33342 was subsequently added to a final concentration of 5 μg/mL to stain the nuclei. The cells were visualized and photographed with a Leica inverted fluorescent microscope.

Measurement of Caspase-3 Activity. PC12 cells were seeded in 60 mm dishes at a density of 2×10^6 cells/well for 24 h and then treated with different concentrations of Xn or DMSO for another 24 h. After replacement with the fresh medium containing 600 μM H_2O_2 or 200 μM 6-OHDA for 24 h, the cells were harvested, washed with PBS, and lysed with RIPA buffer (50 mM Tris−HC,l pH 7.5, 2 mM EDTA, 0.5% deoxycholate, 150 mM NaCl, 1% Triton X-100, 0.1% SDS, 1 mM

DOI: 10.1021/jf505075n
J. Agric. Food Chem. 2015, 63, 1521−1531

Na_3VO_4, and 1 mM PMSF) for 30 min on ice. The protein concentration was quantified using the Bradford procedure. A cell extract containing 15 μg of total proteins was incubated with the assay mixture (50 mM Hepes, 2 mM EDTA, 5% glycerol, 10 mM DTT, 0.1% CHAPS, 0.2 mM Ac-DEVD-pNA, pH 7.5) for 4 h at 37 °C in a final volume of 100 μL. The absorbance at 405 nm was measured using a microplate reader. The caspase-3 activity was expressed as the percentage of the control cells that grow with DMSO treatment.

Assessment of the Intracellular ROS. PC12 cells (2×10^5 cells/well) were seeded into 12-well plates and allowed to adhere for 24 h. Then the cells were treated with Xn or DMSO for another 24 h, followed by replacement with the fresh medium containing 600 μM H_2O_2 for 3 h or 200 μM 6-OHDA for 6 h. After removal of the culture medium, the ROS indicator DCFH-DA (10 μM) in fresh FBS-free medium was added to each well, and incubation was continued for 30 min at 37 °C in the dark. The cells were visualized and photographed under a fluorescent microscope. Intracellular ROS were quantified in PC12 cells using the green fluorescent probe DCFH-DA. Cells were seeded at 1×10^4 cells/well in black 96-well plates for 1 d. The cells were exposed to 600 μM H_2O_2 for 3 h or 200 μM 6-OHDA for 6 h after a 24 h pretreatment with or without Xn. After removal of the medium and staining of the cells with DCFH-DA (10 μM) for 30 min, the cells were washed with PBS and the fluorescence intensity at 525 nm excited at 488 nm in each well was read by an Infinite M200 (Tecan). The ROS levels are expressed as the percentage of treated cells compared to the control.

Real-Time Reverse Transcription PCR (RT-PCR). PC12 cells were seeded in 60 mm dishes at a density of 2×10^6 cells/well for 24 h, followed by treatment with 0.5 μM Xn for 0, 6, and 12 h. As a positive control, the cells were treated with tBHQ (20 μM) for 6 h. For the injury models, the cells were further exposed to 600 μM H_2O_2 for 6 h or 200 μM 6-OHDA for 12 h after the cells were pretreated with Xn for 6 h. Total RNA was isolated from cells using an RNAiso Plus (TaKaRa, Dalian, China) according to the manufacture's protocol and quantified through 260 nm/280 nm wavelength measurement. Reverse transcription was performed using a Primescript RT reagent kit according to the manufacture's protocol (TaKaRa). RT-PCR was performed on an Agilent Technologies Stratagene Mx3005P RT-PCR system using SYBR Premix Ex Taq II (Tli RNaseH Plus). PCR primers specific to each gene were as follows: glyceraldehyde-3-phosphate dehydrogenase (GAPDH), 5′-cagtgccagcctcgtctcat-3′ (forward, F) and 5′-aggggccatccacagtcttc-3′ (reverse, R); heme oxygenase 1 (HO-1), 5′-gccctggaagaggagatagag-3′ (F) and 5′-tagtgctgtgtggct-ggtgt-3′ (R); NAD(P)H:quinone oxidoreductase 1 (NQO1), 5′-tcaccactctactttgctccaa-3′ (F) and 5′-ttttctgctcctcttgaacctc-3′ (R); thioredoxin 1 (Trx1), 5′-ccttctttcattccctctgtgac-3′ (F) and 5′-cccaa-ccttttgacccttttttat-3′ (R); thioredoxin reductase 1 (TrxR1), 5′-actgc-tcaatccacaaacagc-3′ (F) and 5′-ccacggtctctaagccaatagt-3′ (R); catalytic subunit of glutamate−cysteine ligase (GCLC), 5′-caaggacaagaacac-accatct-3′ (F) and 5′-cagcactcaaagccataacaat-3′ (R); modifier subunit of glutamate−cysteine ligase (GCLM), 5′-ggcacaggtaaaacccaatagt-3′ (F) and 5′-ttcaatgtcagggatgctttct-3′ (R). The GAPDH was used as an internal control. Target gene expression was measured and was normalized to the GAPDH expression level.

Measurement of Total Glutathione. Quantification of the total glutathione was based on the enzymatic recycling method.[31] PC12 cells were seeded in 60 mm dishes at a density of 2×10^6 cells/well for 24 h and treated with different concentrations of Xn or vehicle for 24 h. For each sample, cells were collected and resuspended using ice-cold extraction buffer containing 0.1% Triton X-100 and 0.6% sulfosalicyclic acid in 0.1 M potassium phosphate buffer with 5 mM EDTA disodium salt, pH 7.5 (KPE buffer) . The cell suspension was sonicated in ice every 30 s for 2−3 min. After the cell suspension was centrifuged at 3000*g* for 4 min at 4 °C, the supernatant was immediately transferred to a new Eppendorf tube. A 120 μL solution containing 0.33 mg/mL DTNB and 1.66 units/mL glutathione reductase was added to each sample (20 μL). β-NADPH (60 μL, 0.66 mg/mL) was then added quickly, and the absorbance at 412 nm was measured every 15 s for 2 min. The same amounts of DMSO were added to the control experiments, and the activity is expressed as a percentage of the control.

Measurement of NQO1 Activity. The NQO1 activity was determined spectrophotometrically by monitoring the reduction of the electron acceptor 2,6-DCPIP at 600 nm.[27] In brief, PC12 cells were seeded in 60 mm dishes at a density of 2×10^6 cells/well for 24 h and treated with different concentrations of Xn or DMSO for another 24 h. The cells were harvested and lysed in RIPA buffer. The total protein concentration was quantified using the Bradford procedure. The enzymatic reaction was initiated by the addition of cell lysate (5 μg of total protein) to the reaction mixture (2 mM Tris−HCl, pH 7.4, 200 μM NADH, and 40 μM DCPIP), and the decrease in absorbance at 600 nm was measured every 15 s for 2 min at room temperature in the presence or absence of 20 μM dicoumarol, a known NQO1 inhibitor. The dicoumarol-inhibitable part of DCPIP's reduction was used to calculate the NQO1 activity. The same amounts of DMSO were added to the control experiments, and the activity is expressed as a percentage of the control.

Determination of Trx and TrxR Activity. After PC12 cells were treated with different concentrations of Xn for 24 h, the cells were harvested and washed twice with PBS. Total cellular proteins were extracted by RIPA buffer for 30 min on ice. The total protein content was quantified using the Bradford procedure. Trx and TrxR activity in cell lysates was measured by the end point insulin reduction assay.[32] Briefly, the cell extract containing 20 μg of total proteins was incubated in a final reaction volume of 50 μL containing 100 mM Tris−HCl (pH 7.6), 0.3 mM insulin, 660 μM NADPH, 3 mM EDTA, and 15 μM *E. coli* Trx (for assaying the activity of TrxR) or 250 nM recombinant rat TrxR1 (for assaying the activity of Trx) for 30 min at 37 °C. The reaction was terminated by adding 200 μL of 1 mM DTNB in 6 M guanidine hydrochloride, pH 8.0. A blank sample, containing everything except TrxR or Trx, was treated in the same manner. The absorbance at 412 nm was measured, and the blank value was subtracted from the corresponding absorbance value of the sample. The same amounts of DMSO were added to the control experiments, and the activity is expressed as a percentage of the control.

Western Blot Analysis. PC12 cells (4×10^6 cells/well) seeded in 100 mm dishes for 1 d and subsequently treated with Xn (0.5 μM) for 0, 2, 4, 6, 8 h were harvested, and different cell extracts were prepared according to the published procedure.[27] For the whole cell protein extraction, PC12 cells were washed with ice-cold PBS three times and then with RIPA buffer for 30 min on ice. Cell lysates were centrifuged at 12000*g* for 20 min at 4 °C, and the supernatant was collected for analysis or stored at −80 °C.

For the cytosolic and nuclear extracts, the cells were rinsed with ice-cold PBS, and the pellet was dissolved in 100 μL of buffer A (10 mM Hepes, pH 7.9, 10 mM KCl, 0.1 mM EDTA, 0.1 mM EGTA, 1 μM DTT, and 1 μM protease inhibitor cocktail freshly added to buffer A). After 15 min of incubation, 10 μL of Nonidet-P40 (10%) was added, and the lysate was vortexed for 15 s. Thereafter, the lysate was repeatedly centrifuged for 10 min (1000*g*, 4 °C) to separate the nuclei from the cytosolic fraction. The supernatant (cytosolic fraction) was stored on ice. The pellet was resuspended in 100 μL of buffer B (20 mM Hepes, pH 7.9, 0.4 M NaCl, 1 mM EDTA, 1 mM EGTA, 1 μM DTT, and 1 μM protease inhibitor cocktail freshly added to buffer B) and incubated on ice for 15 min with vortexing for 10−15 s every 2 min. After a final centrifugation step for 10 min (20000*g*, 4 °C), the supernatant (nuclear extract) and the cytosolic extract were used for analysis or stored at −80 °C. For Western blot analysis, equal amounts of protein in each lysate sample were separated by SDS−PAGE and electroblotted onto a PVDF membrane (Millipore, United States). After blocking with 2.5% nonfat milk at room temperature for 2 h, the membranes were incubated with primary antibodies at 4 °C overnight. The membranes were washed with TBST three times and then incubated with horseradish peroxidase-conjugated secondary antibodies at room temperature for 1 h. The signal was detected using an enhanced chemiluminescence (ECL) kit from GE Healthcare. The band intensity was quantified by Image Pro Plus 6.0

Generation of Nrf2-Knockdown PC12 Cells Using Short Hairpin RNAs. The short hairpin RNAs specifically targeting the rat

Nrf2 gene (shNrf2) and with a scrambled sequence (shNT) as the control were used for Nrf2-knockdown experiments.[27] The exponentially growing PC12 cells were transfected with different shRNAs using GeneTran III transfection reagent according to the manufacture's instructions. After 48 h of transfection, the cells were maintained in DMEM, 10% FBS, 2 mM glutamine, and 100 units/mL penicillin/streptomycin at 37 °C in a humidified atmosphere of 5% CO_2 and selected by supplementation with 0.5 mg/mL G418. Knockdown of the Nrf2 expression in the cells was analyzed by Western blotting.

Statistics. Data are presented as the mean ± SE. Statistical differences between two groups were assessed by Student's *t* test. Comparisons among multiple groups were performed using one-way analysis of variance (ANOVA), followed by a post hoc Scheffe test. $P < 0.05$ was used as the criterion for statistical significance.

RESULTS AND DISCUSSION

Chemical Synthesis. Xn and TH-Xn described in this study were prepared according to the published procedures.[30,33] The synthetic routes are illustrated in Scheme 1 and afforded a total yield of 5.0% in seven steps. Analysis of the chemical structure of Xn reveals it belongs to chalcones, the structure of which could be easily constructed by the base-catalyzed Claisen−Schmidt condensation of an aldehyde and ketone in a polar solvent such as ethanol or methanol. The key intermediate **4** was prepared from **3** via para-Claisen rearrangement. The skeleton of Xn was afforded by reaction of **5** with *p*-hydroxybenzaldehyde employing KOH as a catalyst in anhydrous methanol. Removal of the methoxymethyl protecting groups under acidic conditions furnishes the desired Xn. TH-Xn was prepared by the Pt/C-catalyzed hydrogenation of Xn. Xn and TH-Xn were fully characterized by ^1H and ^{13}C NMR and MS (Figures S2−S6 in the Supporting Information). The detailed chemical syntheses are described in the Supporting Information. The stability of Xn was determined in DMEM cell culture medium by scanning its absorbance spectra, and >90% of the compound remained after 6 h (Figure S1, Supporting Information).

Scavenging Free Radicals in Vitro. Xn is a polyphenol, and thus, we first investigated its antioxidant activity in vitro. ABTS radical cation is a stable radical with a characteristic absorbance at 734 nm. Neutralization of ABTS free radicals could be easily determined by following the decrease of optical density at 734 nm. As shown in Figure 1A, Xn displays moderate efficiency to scavenge ABTS free radicals. We also employed a model of free-radical-mediated lipid peroxidation to assay the antioxidant activity of Xn. Thermal decomposition of AAPH in aqueous solution under aerobic conditions constantly generates peroxyl radicals, which attack membrane unsaturated lipids to induce lipid peroxidation. Xn remarkably protects the erythrocyte ghost from AAPH-induced formation of TBARS (Figure 1B), a biomarker of lipid peroxidation. Taken together, Xn could directly scavenge free radicals in vitro.

Protecting PC12 Cells from H_2O_2- and 6-OHDA-Induced Damage. As Xn was reported to have cytotoxicity,[16,18] we first determined this effect in PC12 cells. Xn shows little cytotoxicity toward PC12 cells at submicromolar concentrations, and significant cytotoxicity was observed only at concentrations greater than 2 μM (Figure 2A). Thus, the concentrations of Xn used in the following protection experiments are no more than 1 μM. Next, we asked if Xn has cytoprotection at nontoxic concentrations in PC12 cells. Hydrogen peroxide, an endogenous cellular signaling molecule, has been extensively used as an inducer of oxidative stress in many cellular models. As shown in Figure 2B, PC12 cells treated with H_2O_2 only showed about 50% cell death compared with the control group. However, if the cells were pretreated with Xn (0.5 μM) for 24 h followed by H_2O_2 insult, the population of viable cells increased to about 75%. This protection was significant even at 0.1 μM Xn. 6-OHDA is a

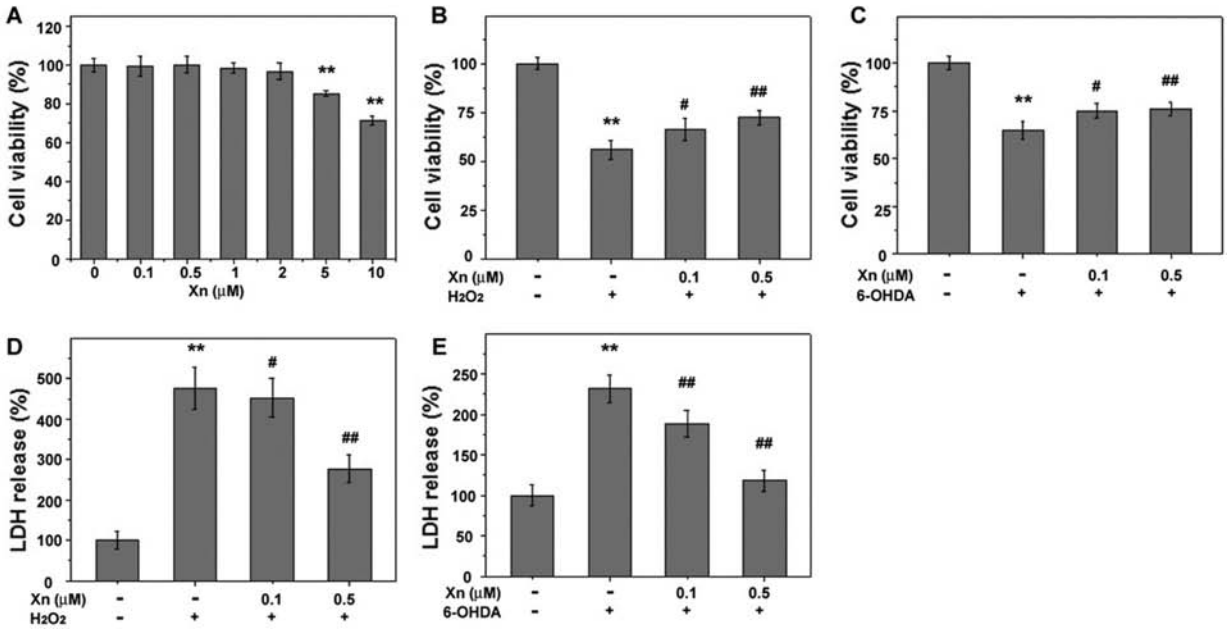

Figure 2. Protection of Xn against H_2O_2- or 6-OHDA-induced PC12 cell damage. (A) Cytotoxicity evaluation of Xn toward PC12 cells. The cells were treated with the indicated concentrations of Xn for 24 h, and the cytotoxicity of Xn was determined by the MTT assay. Protection against (B) H_2O_2-induced and (C) 6-OHDA-induced PC12 cell damage. PC12 cells (1×10^4 cells/well) were plated in a 96-well plate for 1 d and subsequently treated with Xn for another 24 h. After replacement with the fresh medium containing H_2O_2 and 6-OHDA and after incubation was continued for the indicated times, the cell viability was measured by MTT assay. The content of LDH in the medium after H_2O_2 (D) or 6-OHDA (E) treatment was determined as described in the Materials and Methods. All data represent the means ± SE of three independent experiments. Key: **, $P < 0.01$ vs the vehicle group; #, $P < 0.05$ vs the H_2O_2- or 6-OHDA-treated group; ##, $P < 0.01$ vs the H_2O_2- or 6-OHDA-treated group.

potent neurotoxin and is widely used to generate an experimental model of Parkinson's disease. 6-OHDA-mediated neurotoxicity is engendered, at least in part, by its ability to generate ROS.[34] As shown in Figure 2C, 6-OHDA treatment reduced cell viability to about 60% of that of the control. Similarly, addition of Xn, at either 0.1 or 0.5 μM, also markedly promoted cell viability to more than 75%. Lactate dehydrogenase (LDH) is a soluble cytosolic enzyme that is released into the culture medium following loss of membrane integrity resulting from cell damage. To confirm the cytoprotection of Xn, we further determined the content of LDH leakage after H_2O_2 or 6-OHDA insult. As shown in Figure 2D,E, H_2O_2 and 6-OHDA cause ~4.7-fold and ~2.4-fold increases of LDH release, respectively. Pretreatment of PC12 cells with Xn significantly reduces the leakage of LDH in a dose-dependent manner. Taken together, Xn at nontoxic concentration can significantly protect PC12 cells from H_2O_2- or 6-OHDA-induced cell damage.

Alleviating H_2O_2- and 6-OHDA-Induced PC12 Cell Apoptosis. Nuclear condensation and caspase-3 activation are hallmarks of cell apoptosis. The morphologic changes of the nuclei were revealed by Hoechst staining. As shown in Figure 3A,B, both H_2O_2 and 6-OHDA elicit apoptosis in PC12 cells evidenced by the appearance of apoptotic nuclei as highly fluorescent, condensed bodies (indicated by arrows), while no apparent apoptotic nuclei were observed in control cells. Pretreatment of PC12 cells with nontoxic concentrations of Xn remarkably lowers the population of apoptotic nuclei. Activation of caspase-3 is a biochemical character in all apoptotic cells. We thus further quantified the level of caspase-3 activation. Both H_2O_2 and 6-OHDA activate the cellular caspase-3, but with different potencies (Figure 3C,D). Again, Xn significantly alleviates the extent of caspase-3 activation in a concentration-dependent manner. Collectively, Xn alleviates H_2O_2- and 6-OHDA-induced apoptotic cell death in PC12 cells.

Preventing ROS Accumulation in PC12 Cells. DCFH-DA is a cell-permeable, nonfluorescent probe. After diffusing into cells, DCFH-DA is deacetylated by cellular esterases to nonfluorescent 2′,7′-dichlorodihydrofluorescin (DCFH), which is rapidly converted to highly fluorescent 2′,7′-dichlorofluorescein (DCF) upon reacting with ROS. Stimulation of the cells with H_2O_2 or 6-OHDA leads to intracellular burst of ROS, while the control cells display a negligible ROS level, as revealed by DCFH-DA staining (Figure 4A,B), and the quantifying results are shown in Figure 4C,D. Pretreatment of the cells with Xn remarkably reduces the ROS accumulation induced by either H_2O_2 or 6-OHDA. As oxidative stress, arising from the overproduction of ROS beyond the cellular capacity to remove them, has been implicated in a common pathway of neurotoxicity in a wide variety of acute and chronic neurologic disorders, the inhibition of ROS accumulation in neuronal cells might be the molecular basis of the neuroprotective action of Xn.

Inducing Phase II Gene Expression. Xn belongs to the chalcone family, which bears an α,β-unsaturated ketone structure. Due to the electron-deficient character of the double bond, this structure is renowned as a Michael acceptor moiety, which is a core structure of many reported small-molecule ARE inducers.[7] In analogy to known ARE activators, we thus hypothesized that Xn might activate the cellular ARE response. We measured the expression of Nrf2-driven antioxidant/detoxifying genes (HO-1, NQO1, Trx1, TrxR1, GCLC, and GCLM) at 0, 6, and 12 h after treatment with Xn (0.5 μM) in PC12 cells (Figure 5). Although the positive control tBHQ displays more potency, the induction of these genes by Xn is

DOI: 10.1021/jf505075n

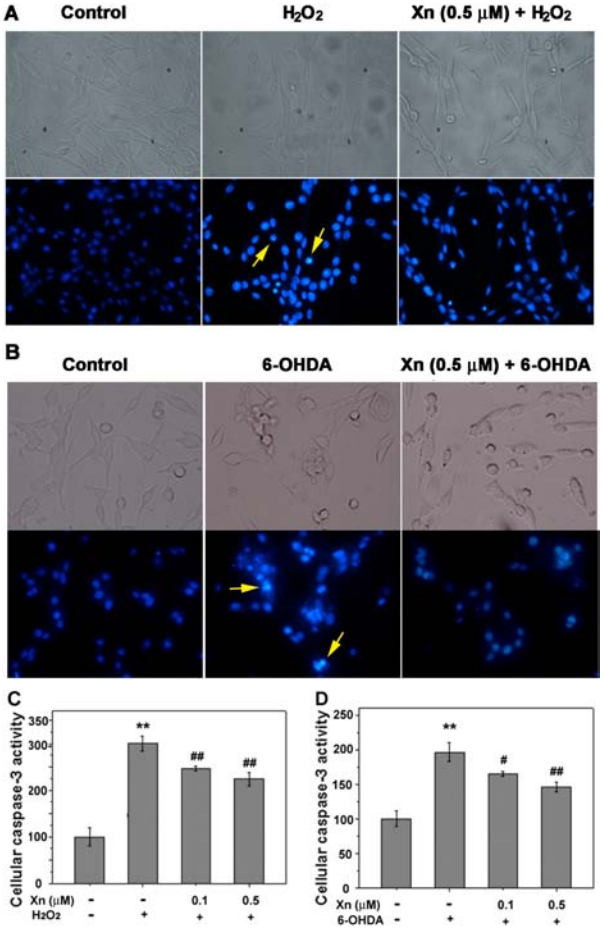

Figure 3. Inhibition of H_2O_2- or 6-OHDA-induced apoptosis in PC12 cells. PC12 cells were treated as described in the Materials and Methods, and the morphological changes of the nuclei were determined by Hoechst 33342 staining (A, B). Activation of the cellular caspase-3 (C, D) was determined by a colorimetric assay as described in the Materials and Methods. The data represent the means ± SE of three independent experiments. Key: **, $P < 0.01$ vs the vehicle group; #, $P < 0.05$ vs the H_2O_2- or 6-OHDA-treated group; ##, $P < 0.01$ vs the H_2O_2- or 6-OHDA-treated group.

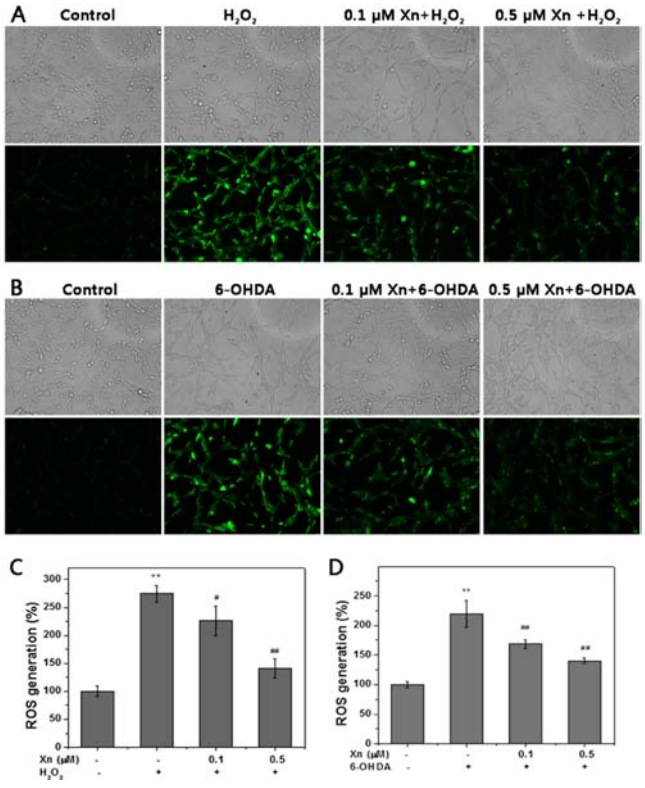

Figure 4. Prevention of ROS accumulation in PC12 cells by Xn. Pretreatment of the cells with Xn significantly alleviates ROS accumulation induced by H_2O_2 (A, C) or 6-OHDA (B, D) determined by DCFH-DA staining as described in the Materials and Methods. The fluorescence images (A, B) were acquired by inverted fluorescence microscopy. The ROS level was quantified in (C) and (D) by a fluorescence microplate reader, Infinite M200 (Tecan). Key: **, $P < 0.01$ vs the vehicle group; #, $P < 0.05$ vs the H_2O_2- or 6-OHDA-treated group; ##, $P < 0.01$ vs the H_2O_2- or 6-OHDA-treated group.

significant. The time-course studies showed the highest induction of the genes at 6 h after stimulation with Xn. The HO-1 and TrxR1 mRNAs were highly transcribed by ∼2.8- and 2.3-fold increases, respectively, after treatment with Xn for 6 h. The induction of other genes is moderate but sustainable, and this induction could last for 12 h. The phase II genes were also induced if the cells were pretreated with Xn followed by the oxidant insults. Our data suggest that Xn treatment can effectively promote the transcription of Nrf2-driven antioxidant/detoxifying genes.

Upregulating the Antioxidant Defense System in PC12 Cells. The induction of phase II enzymes is an important defense mechanism against exogenous stress. As a series of phase II genes have been upregulated at different levels, we then examined the corresponding gene products. Xn dose-dependently elevated HO-1, NQO1, TrxR1, and Trx1 protein expression (Figure 6). The glutamate cysteine ligase, composed of a GCLC and a GCLM subunit, is a rate-limiting enzyme for cellular GSH synthesis. As a consequence of the elevation of GCLC gene expression, the total GSH level in PC12 cells was increased by ∼1.6-fold (Figure 6C). By adopting the

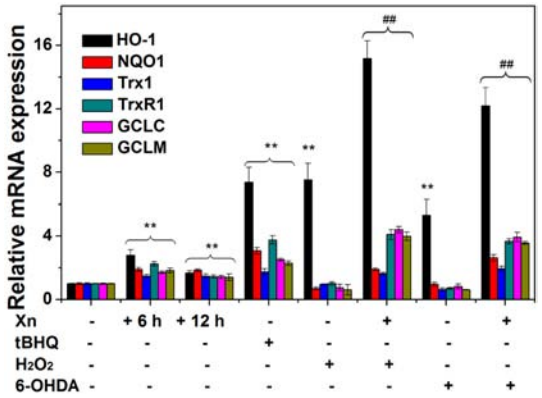

Figure 5. Induction of cytoprotective genes in PC12 cells by Xn. The cells were treated, and the mRNA levels of different genes were analyzed and normalized using GAPDH as an internal standard by qRT-PCR as described in the Materials and Methods. Pretreatment of the cells with Xn significantly elevates phase II gene expression under H_2O_2 or 6-OHDA conditions determined by qRT-PCR. PC12 cells were pretreated with Xn for 6 h or cotreated with H_2O_2 or 6-OHDA for another 6 or 12 h. tBHQ was used as a positive control. The data represent the means ± SE of three independent experiments. Key: *, $P < 0.05$ vs the control group (0 h); **, $P < 0.01$ vs the control group (0 h); #, $P < 0.05$ vs the H_2O_2- or 6-OHDA-treated group; ##, $P < 0.01$ vs the H_2O_2- or 6-OHDA-treated group.

convenient assays, we further determined the cellular activity of NQO1, TrxR1, and Trx1. In line with the upregulation of protein expression, all the enzymes' activities were significantly increased (Figure 6F,I,L). After Xn (0.5 μM) treatment, the NQO1 activity (Figure 6F), TrxR1 activity (Figure 6I), and Trx1 activity (Figure 6L) were increased by ∼1.7-, ∼1.2-, and ∼1.5-fold, respectively. Our data demonstrate that Xn at submicromolar concentration could efficiently boost various endogenous cytoprotective molecules.

Promoting Nrf2 Nuclear Localization. Induction of antioxidant gene expression via the Nrf2-dependent cytoprotective pathway requires translocation of Nrf2 from the cytosol to the nucleus. We therefore examined whether Xn could promote Nrf2 to accumulate in the nuclei. After isolation of the nuclei from the cells, the total Nrf2, the cytosolic Nrf2, and the nuclear Nrf2 were determined by immunoblots. Upon Xn treatment, immunoblotting results revealed that the total Nrf2 expression increased, peaking at 4 h, and decreased to the basal level at 8 h (Figure 7A). Notably, the cytosolic Nrf2 decreased gradually, coincident with its continuous accumulation in the nuclei (Figure 7B,C), indicating the translocation of Nrf2 from the cytosol to the nuclei. We also analyzed the change of nuclear Nrf2 under H_2O_2 or 6-OHDA treatment conditions. As shown in Figure 7D, H_2O_2 or 6-OHDA alone has a marginal effect on the Nrf2 nuclear accumulation. However, after pretreatment with Xn followed by the oxidant insult, the amount of Nrf2 in the nucleus remarkably increased. The presence of Nrf2 in the nuclei would facilitate its binding to ARE and thus subsequently initiates the transcription process to induce the phase II gene expression.

Requiring the α,β-Unsaturated Ketone Structure in Xn and Nrf2 for Cytoprotection. As aforementioned, we speculated that the α,β-unsaturated ketone moiety in Xn and the transcription factor Nrf2 are key determinants for the action of Xn in PC12 cells. We prepared TH-Xn, a molecule without the α,β-unsaturated ketone structure, and generated Nrf2-knockdown PC12 cells to validate the molecular mechanism underlying the cytoprotection of Xn. Hydrogenation of Xn to TH-Xn almost completely abolishes the protective effect (Figure 8A), indicating the importance of the α,β-unsaturated ketone structure in Xn. Next, we compared the protection of Xn in PC12 cells with different Nrf2 expressions. After confirmation of the knockdown efficiency of Nrf2 (Figure 8B), we evaluated the effect of Xn against oxidative insult toward different cells. As shown in Figure 8C,D, Xn displays a protective pattern in PC12 cells transfected with shNT similar to that observed in wild-type PC12 cells. However, this protection is drastically lost in PC12 cells transfected with

J. Agric. Food Chem. 2015, 63, 1521−1531

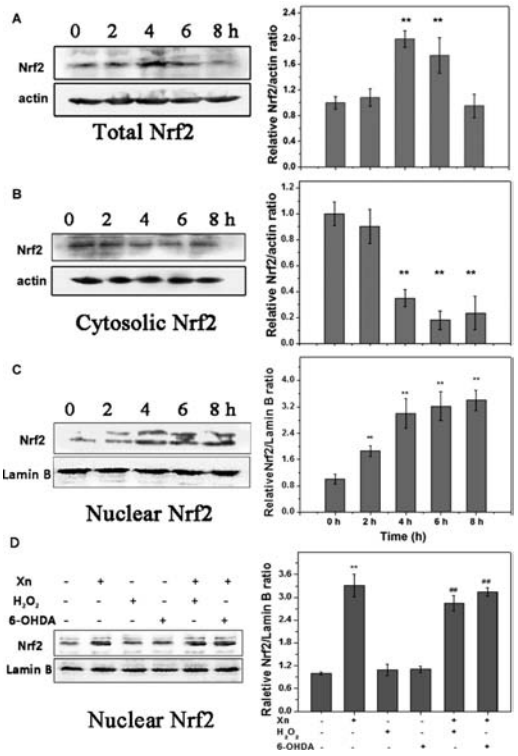

Figure 7. Promotion of Nrf2 nuclear accumulation by Xn. After the cells were treated with Xn (0.5 μM) for 0, 2, 4, 6, and 8 h, they were harvested, and different cell extracts were prepared as described in the Materials and Methods. The total Nrf2 (A), cytosolic Nrf2 (B), and nuclear Nrf2 (C) were analyzed by Western blotting. (D) Pretreatment of the cells with Xn promotes nuclear Nrf2 accumulation under H_2O_2 or 6-OHDA treatment conditions. PC12 cells were pretreated with Xn for 6 h and cotreated with H_2O_2 or 6-OHDA for another 6 or 12 h. Actin or lamin B was used as a loading control. Quantification of the blots is presented in the right panel. The data are expressed as the means ± SE of three experiments. Key: *, $P < 0.05$ vs the control group (0 h); **, $P < 0.01$ vs the control group (0 h). #, $P < 0.05$ vs the H_2O_2- or 6-OHDA-treated group; ##, $P < 0.01$ vs the H_2O_2- or 6-OHDA-treated group.

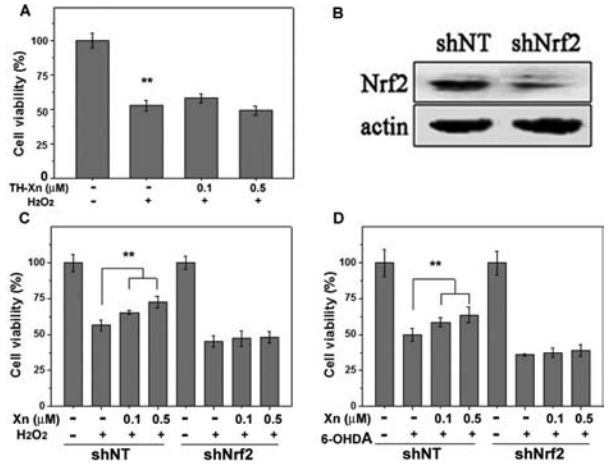

Figure 8. Involvement of Nrf2 in the cytoprotection of Xn in PC12 cells. (A) Protection of TH-Xn against H_2O_2-induced PC12 cell damage. (B) Evaluation of Nrf2-knockdown efficiency by different shRNAs. PC12 cells were transfected with shRNAs specifically targeting the rat Nrf2 gene (shNrf2s) or nontargeting shRNA (shNT), and the efficiency of silencing Nrf2 was evaluated by Western blots. (C, D) Impairment of cytoprotection of Xn in Nrf2-knockdown cells. Different PC12 cells were treated with Xn for 24 h followed by treatment with 600 μM H_2O_2 for 12 h or 200 μM 6-OHDA for 24 h. The cell viability was determined by MTT assay. The results are expressed as the means ± SE. Key: **, $P < 0.01$; *, $P < 0.05$.

shNrf2 (Figure 8C,D), demonstrating the definite involvement of Nrf2 in cytoprotection of Xn in PC12 cells.

Common targets and mechanisms of neurodegenerative diseases have been elegantly summarized in a recent paper.[35] Among various pathogenic hypotheses, increasing evidence has supported that oxidative stress is a causal, or at least an ancillary, factor in the progressive degeneration of a subset of neurons, which is the pathologic hallmark of adult-onset neurodegenerative diseases.[1,36] Surgical operation to replace the dying or dead neurons in these diseases has been demonstrated only with limited success.[37] Therefore, pharmacological management intended to assuage the oxidative stress is one promising strategy to protect loss of neurons, which is expected to eventually lead to retardation or blockage of the neurodegenerative progression. Tactics against oxidative stress include direct antioxidative action by supplying exogenous antioxidants and indirect defense by activating the pathway(s) involved in expression of endogenous cytoprotective molecules. In this regard, accumulating enthusiasm has been devoted to discovering and developing novel antioxidants or molecules that may prompt endogenous antioxidant defense as potential therapeutic agents for neurodegenerative disorders.[7]

Preceding studies have suggested that Xn could promote neuronal differentiation as well as neurite outgrowth[23] and prevent middle cerebral artery occlusion-induced cerebral ischemia in rats[38] to confer neuroprotective function. We revealed in this work for the first time that Xn displayed potent cytoprotection against H_2O_2- or 6-OHDA-mediated cell damage in PC12 cells via the induction of phase II antioxidant/detoxifying enzymes. Treatment of PC12 cells with Xn significantly upregulates a set of Nrf2-driven phase II genes as well as the corresponding gene products, including the antioxidant enzymes (HO-1, NQO1, Trx1, and TrxR1) and small peptide antioxidant GSH. Activation of Nrf2 by Xn in different types of cells, including microglial BV2 cells,[22] human hepatocytes,[39] and Hepa 1c1c7 cells,[40] and even in vivo,[41] has been reported. Besides, Xn has been demonstrated to possess diverse functions in a variety of cellular assays, such as anticancer[14−18] and anti-inflammation.[15,22] However, there has been no study on induction of Nrf2 in neuronal cells prior to this work, and most of the activity in these cellular assays requires higher concentrations of Xn (>1 μM). We demonstrated that Xn, as low as 0.1 μM, could significantly protect neuronal cells from oxidative insult. This concentration could be easily reached in vivo by daily intake of Xn-containing products, such as beers. The pharmacokinetics and metabolites of xanthohumol in rats have been evaluated by giving the rats intravenous injection or oral administration.[20,42] The highest plasma concentration of 2.97 mg/L (~8 μM) could be reached after intravenous injection at a dose of 1.86 mg/kg. Oral administration of Xn also leads to a significant amount of plasma circulation. One major challenge for most neuroprotective agents is their ability to pass through the blood−brain barrier (BBB). There are no available BBB penetration data for the flavonoid Xn. However, there is strong evidence showing that structurally different flavonoids are able to traverse the BBB.[43] The prenyl group further increases the

DOI: 10.1021/jf505075n
J. Agric. Food Chem. 2015, 63, 1521−1531

lipophilicity of Xn, which favors BBB penetration. It is much like Xn having the ability to pass through the BBB in vivo. Thus, our finding, i.e., the induction of endogenous cytoprotective enzymes by Xn to confer potential neuroprotection, is of physiological significance.

The Keap1−Nrf2−ARE regulatory pathway plays a central role in protecting cells against oxidative or electrophilic insult. Under unstressed conditions, Nrf2 is bound to the repressor protein Keap1, which anchors Nrf2 in the cytoplasm and targets it for ubiquitination and proteasome degradation. Upon exposure to stressors, the Nrf2−Keap1 complex dissociates and Nrf2 translocates to the nucleus. The mechanisms underlying the activation of the Keap1−Nrf2−ARE pathway are not well understood but may involve oxidation/alkylation of key thiol(s) in Keap1 and/or phosphorylation of Nrf2. Upon exposure to electrophiles or oxidants, the Cys-rich protein Keap1 is modified by forming covalent adduct or disulfide bond(s) within the protein, and it is this Cys-based modification of Keap1 that allows dissociation of Nrf2 from Keap1 and subsequent nuclear translocation of Nrf2. Analysis of the chemical structure of Xn reveals that the molecule contains one α,β-unsaturated ketone moiety, a thiol-reactive electrophilic center that may covalently modify the Cys thiols. Many natural or synthetic molecules bearing such a structure are known effective inducers of phase II genes.[6,44] Thus, alkylation of certain Cys residue(s) might be the molecular basis for the activation of the Keap1−Nrf2−ARE pathway by Xn, which was evidenced by the liquid chromatography−tandem mass spectrometry analysis[40] and our observation that removal of the electrophilic center from Xn blocks such protection (Figure 8A). Abrogating the protection of Xn by silencing Nrf2 expression in PC12 cells further supports the involvement of Nrf2 in the cellular action of Xn. Our findings suggest a novel neuroprotective mechanism of Xn shown schematically in Figure 9. The lipophilic character of Xn allows it to easily

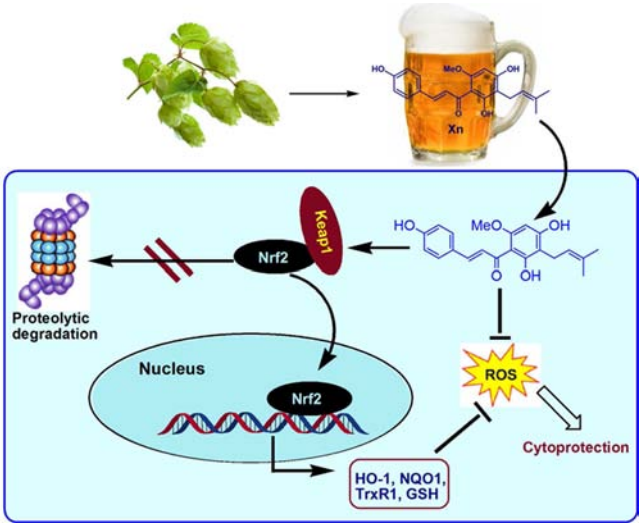

Figure 9. A neuroprotective mode of Xn in PC12 cells.

penetrate the cell membrane and accumulate within cells. As a polyphenol, Xn could directly neutralize ROS. Furthermore, the α,β-unsaturated ketone structure in Xn allows it to bind covalently to the Cys residue(s) in the cytosolic inhibitory protein Keap1, thus breaking the Keap1−Nrf2 complex to prevent proteasome degradation of Nrf2 and release Nrf2. Subsequently, Nrf2 is translocated into the nucleus, where it binds to ARE and initiates the transcription of a variety of cytoprotective genes to confer protection against oxidative stress.

In summary, we conclude that Xn is effective in preventing oxidative-stress-induced neuronal cell damage. Xn displays a moderate capacity to directly neutralize ROS in vitro. More importantly, this cytoprotection is mediated by the induction of endogenous antioxidant defense molecules, which relies on the α,β-unsaturated ketone structure in Xn and the transcription factor Nrf2 in PC12 cells as removal of such a chemical structure or knockdown of Nrf2 abolishes the protection. Our discovery discloses that Xn is a novel small-molecule activator of the Keap1−Nrf2 pathway and provides deep insights into understanding the molecular mechanism underlying the cytoprotection of Xn. This mechanism of action could lead to the design and development of novel small molecules as potential neuroprotective agents.

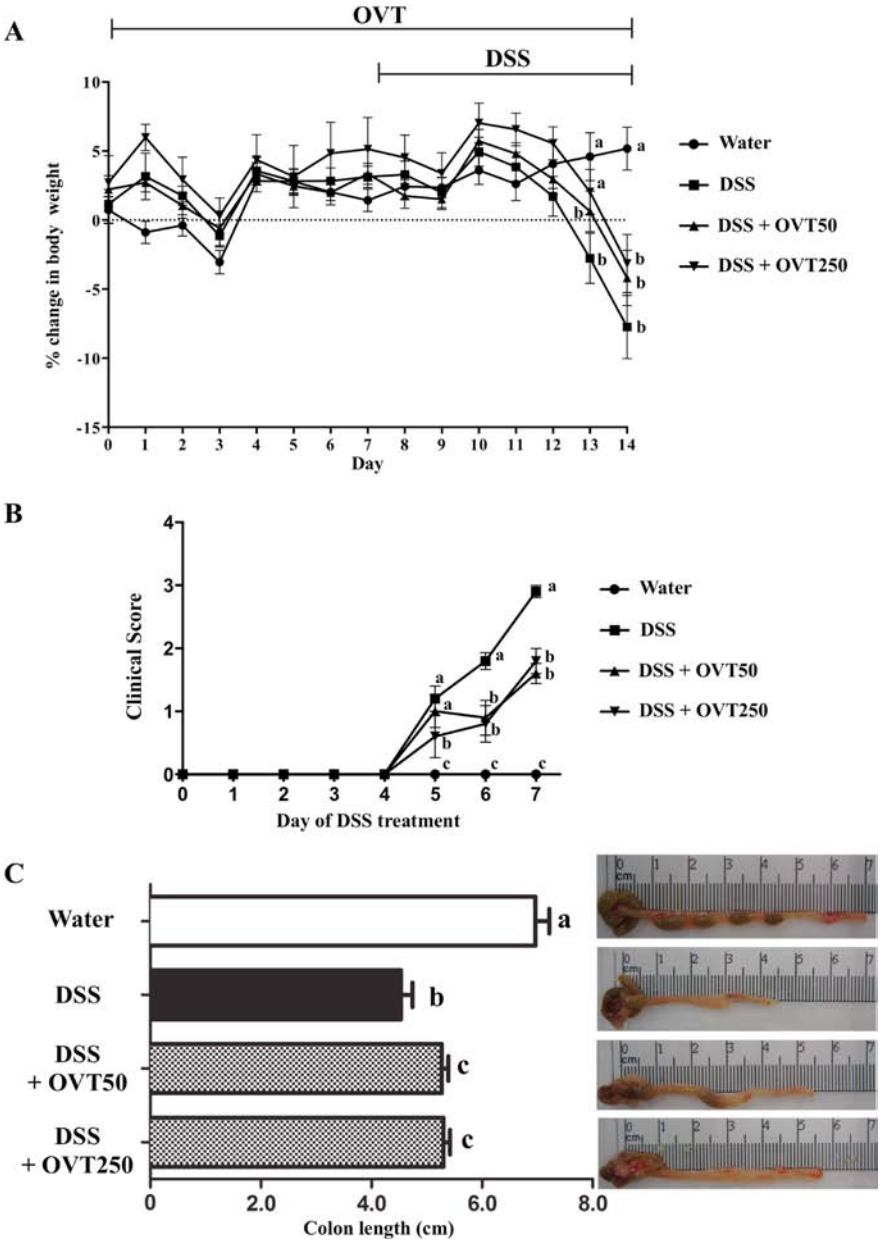

Figure 1. OVT ameliorates DSS-induced colitis. Mice were given 50 or 250 mg/kg BW OVT for 14 days. On day 7, colitis was induced with 5% DSS water. (A) Mice were weighed daily, and changes in body weight are reported as percent change relative to the initial weight. (B) Mice were scored daily for clinical signs of DSS-induced colitis. (C) After 14 days, the extracted colons were measured from the end of cecum to the anus. Data represent the mean ± SEM of n = 10/group. Unless indicated, no significance difference was observed between groups. Values without a common letter are significantly different at $P < 0.05$.

1.0 mL/min for 40 min. The purified OVT was dialyzed (MWCO 8000 tubing) against Milli-Q water and lyophilized. The purity was determined by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) and confirmed as >90% (data not shown).

Induction of Colitis and Sample Treatment. All animal experiments were approved by the University of Guelph Animal Care Committee and carried out in accordance with the Canadian Council of Animal Care Guide to the Care and Use of Experimental Animals (eAUP no. 1536). The experiments for induction of DSS-induced colitis in mice were performed as previously described.[11] Briefly, 40 female BALB/c mice (6−8 weeks; Charles River Laboratories, Montreal, QC, Canada) were randomly divided into four groups (n = 10/group) and housed with a 12 h light/dark cycle with access to standard food and water ad libitum. OVT (50 or 250 mg/kg BW/day) was given by oral gavage for 14 days. On the seventh day, 5% (w/v) DSS (MW 36−50 kDa; MP Biomedical, Solon, OH, USA) was added to drinking water to induce acute colitis for 7 days. The DSS solution was replaced every other day. The negative control group received water only. The positive group received water with DSS for 7 days. Body weights were measured on a daily basis. The daily weight changes were calculated by percent in relation to the initial weight measured. After 14 days, mice were humanely euthanized, and colons were collected and sectioned longitudinally. Colon samples were flash frozen and stored at −80 °C until further analysis.

Clinical Evaluation of Colitis. Mice were examined daily for stool consistency, presence of blood in stool, and general appearance. The clinical scoring was performed as described earlier by Maxwell et al.[20] and defined as follows: stool score, 0 = normal, 1 = moist/sticky stool, 2 = soft stool, 3 = diarrhea; stool blood score, 0 = no blood, 1 = evidence of blood in stool or around anus, 2 = severe bleeding; mouse

DOI: 10.1021/jf505248n
J. Agric. Food Chem. 2015, 63, 1532−1539

appearance, 0 = normal, 1 = ruffled fur or altered gait, 2 = lethargic or moribund.

Cytokine Concentration in Colon Samples. The colons were excised and homogenized in ice-cold phosphate-buffered saline (PBS) containing proteinase inhibitors (1 mM phenylmethanesulfonyl fluoride (PMSF), 0.1 mM ethylenediaminetetraacetic acid (EDTA), 10 μg/mL aprotinin, 10 μg/mL leupeptin, and 10 μg/mL pepstain A; Sigma-Aldrich) for 3 min using a homogenizer (Polytron PT 1200, Kinematica AG, Luzern, Switzerland). The supernatants were collected following centrifugation at 10000*g* for 10 min. The concentration of protein was determined by using a DC protein assay (Bio-Rad), according to the manufacturer's instruction. Tumor necrosis factor (TNF)-α and interleukin (IL)-6 cytokine concentration were determined by ELISA as described earlier.[11] IL-17A was measured using an IL-17A ELISA kit (eBioscience, San Diego, CA, USA), according to the manufacturer's protocol. The following antibodies and standard proteins for ELISA were obtained from BD Bioscience (San Jose, CA, USA): anti-mouse TNF-α, biotin anti-mouse TNF-α, recombinant mouse TNF-α, anti-mouse IL-6, biotin anti-mouse IL-6, recombinant mouse IL-6, and avidin–horseradish peroxidase (Av-HRP). Briefly, 96-well ELISA plates (Corning, Corning, NY, USA) were coated with anti-mouse TNF-α antibody (1:500, diluted in 0.2 M sodium phosphate buffer, pH 6.5) or anti-mouse IL-6 antibody (1:250, diluted in 0.1 M sodium phosphate buffer, pH 9.0) overnight at 4 °C. The plate was blocked with PBS containing 1% bovine serum albumin (BSA; Fisher Scientific, Ottawa, ON, Canada) for 1 h at 37 °C. Colon supernatant samples and diluted standards were added to the plate and incubated for 2 h at 37 °C. Biotin anti-mouse TNF-α (1:500, v/v) or anti-mouse IL-6 antibody (1:500, v/v) was further added and incubated for 1 h at 37 °C. Av-HRP (1:2000, v/v) was added for 0.5 h at 37 °C. The plate was washed three times with PBS-0.05% Tween 20 (PBS-T). Then, 100 μL of 3,3′,5,5′-tetramethylbenzidine (TMB; Sigma-Aldrich) was added to each well, and the reaction was stopped by adding 0.5 N H_2SO_4 (50 μL/well). The absorbance was measured at 450 nm by a plate reader (iMark model 550, Bio-Rad). The concentration of these cytokines was determined from the standard calibration curves and reported as picograms of cytokine relative to protein concentration in the supernatant.

RNA Isolation, cDNA Synthesis, and Real-Time PCR. Total RNA from the colon was extracted according to a previous study.[11] Briefly, the colon was homogenized in Trizol reagent (Life Technologies, Carlsbad, CA, USA) and total RNA was extracted by using an Aurum Total RNA Mini Kit (Bio-Rad) according to the manufacturer's instructions. The quantity and quality of RNA were determined by Nano Drop ND-1000 (Thermo Scientific, Waltham, MA, USA). The cDNA was synthesized using the qScript cDNA synthesis kit (Quanta BioSciences, Gaithersburg, MD, USA), according to the manufacturer's instructions. Real-time quantitative PCR was carried out using PerfeCTa SYBR Green Supermix (Quanta Biosciences) on a MyiQ single-color real-time PCR detection system (Bio-Rad) using the following conditions: denaturation for 15 s at 95 °C, annealing for 15 s at 58 °C, and extension for 30 s at 72 °C. The mouse primers used were as follows: β-actin, forward, 5′-GAAATC-GTGCGTGACATCAAAG-3′, reverse, 5′-TGTAGTTCATGGATG-CCACAG-3′; TNF-α, forward, 5′-CCCCAAAGGGATGAGAAGTT-3′, reverse, 5′-CACTTGGTGGTTTGCTACGA-3′; IL-6, forward, 5′-CCGGAGAGGAGACTTCACAG-3′, reverse, 5′-CAGAATTGC-CATTGCACAAC-3′; IL-1β, forward, 5′-GGATGAGGACATGAG-CACCT-3′, reverse, 5′-AGCTCATATGGGTCCGACAG-3′; interferon (IFN)-γ, forward, 5′-GCTCTTCCTCATGGCTGTTT-3′, reverse, 5′-GTCACCATCCTTTTGCCAGT-3′; monocyte chemoattractant protein (MCP)-1, forward, 5′-CCCAATGAGTAGGCTGGAGA-3′, reverse, 5′-TCTGGACCCATTCCTTCTTG-3′, IL-17A, forward, 5′-CCAGGGAGAGCTTCATCTGT-3′, reverse, 5′-AGGAAGTCC-TTGGCCTCAGT-3′; IL-10, forward, 5′-GCCTTATCGGAAATG-ATCCA-3′, reverse, 5′-AGGGGAGAAATCGATGACAG-3′. These primers were obtained from the University of Guelph Laboratory Services Molecular Biology Section (Guelph, ON, Canada). Relative gene expression was calculated according to the $2^{-\Delta\Delta Ct}$ method[21] using mouse β-actin as an endogenous control for normalization. Results were expressed as fold changes relative to the negative control samples.

Histological Analysis. A section of the distal colon was fixed in 10% (w/v) buffered formalin (Fisher Scientific). Paraffin-embedded sections were stained with hematoxylin and eosin (H&E) (Animal Health Laboratory, University of Guelph, Guelph, ON, Canada). The stained samples were examined using a Leica DMR microscope (Leica Microsystems, Wetzlar, Germany). Histological scoring of the colitic lesions was evaluated in a double-blinded fashion by a pathologist using the previously reported scoring system[11] with respect to the degree, extent, and depth of inflammation and the severity of damage of the glands and epitheliums. The total sum of histologic score ranged from 0 to 19.

Statistical Analysis. The results were expressed as the mean ± SEM. Statistical analyses were performed using GraphPad Prism version 5.0 (GraphPad, San Diego, CA, USA). Statistical differences between curves were analyzed using two-way analysis of variance (ANOVA) followed by Tukey's multiple-comparison test. Statistical differences between individual group were determined using one-way ANOVA followed by Tukey's multiple-comparison test. $P < 0.05$ was considered statistically significant.

RESULTS

Effects of OVT on the Development of DSS-Induced Colitis in Mice. To determine a possible dose-dependent effect of OVT, OVT was administered by oral gavage at two different doses: 50 and 250 mg/kg BW. The DSS treatment for 7 days exacerbated the progression of acute colitis characterized by weight loss, the presence of blood in stool, and diarrhea. As shown in Figure 1A, the ratio of changing body weight in the positive (DSS) group was significantly decreased in the last 2 days of DSS treatment (days 13 and 14 of the study, $P < 0.001$), compared with the negative control (water) group. The high-dose OVT (DSS + OVT250) group had significantly lower body weight loss than the DSS group on the sixth day of DSS treatment (day 13, $P = 0.048$ vs DSS) and tended to be lower on the seventh day (day 14, $P = 0.064$ vs DSS) (Figure 1A). In the low-dose OVT group (DSS + OVT50), the decrease in the ratio of weight change between days 12 and 13 tended to be lower than that in the DSS treatment (DSS, 1.7 ± 1.4 to −2.8 ± 1.8%; DSS + OVT50, 3.0 ± 1.1 to 0.6 ± 1.5%); however, no significant improvement of DSS-induced weight loss was observed (day 13, $P = 0.256$; day 14, $P = 0.221$ vs DSS) (Figure 1A). The average of initial weights did not differ among each group (water group, 17.3 ± 0.4 g; DSS group, 17.0 ± 0.3 g; DSS + OVT50 group, 17.1 ± 0.3 g; DSS + OVT250 group, 16.9 ± 0.3 g). The increase of clinical scores was also observed in the DSS group on the fifth day of DSS treatment ($P < 0.001$), compared with the control group. As shown in Figure 1B, low-dose OVT treatment significantly decreased the severity of DSS-induced clinical signs on the sixth and seventh days of DSS treatment (day 6, $P < 0.001$; day 7, $P < 0.001$ vs DSS) and high-dose treatment also reduced the signs on the fifth, sixth, and seventh days (day 5, $P = 0.003$; day 6, $P < 0.001$; day 7, $P < 0.001$ vs DSS). The consumption of water among groups showed no significant differences during the whole experiment, and no clinical signs were observed in mice before the start of DSS treatment (data not shown). The colon shortening induced by DSS has already been shown to be inversely linked with the severity of DSS-induced colitis in mice.[22] As shown in Figure 1C, the significant shortening of the colon length was confirmed in the DSS group (water, 7.0 ± 0.3 cm; DSS, 4.6 ± 0.2 cm; $P < 0.001$ vs water), whereas both doses of OVT treatment remarkably improved the colon length

DOI: 10.1021/jf505248n
J. Agric. Food Chem. 2015, 63, 1532−1539

(DSS + OVT50, 5.3 ± 0.1 cm, $P = 0.039$; DSS + OVT250, 5.3 ± 0.1 cm, $P = 0.030$ vs DSS).

Effects of OVT on the Expression of Inflammatory Cytokines in DSS-Treated Mice. The anti-inflammatory effects of OVT in the colon were investigated by measuring protein and mRNA expression of the inflammatory cytokines in the colon. As shown in Figure 2, DSS treatment remarkably

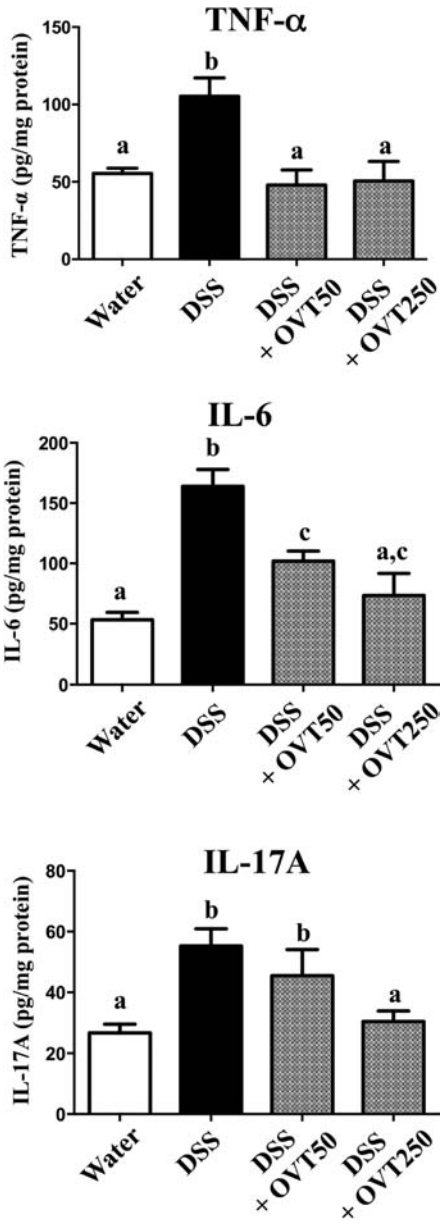

Figure 2. Effect of OVT on inflammatory cytokine protein expression in the colon of DSS-treated mice. Protein expression of TNF-α, IL-6, and IL-17A was determined by ELISA. Results were expressed as picograms of cytokine relative to protein concentration in the colon supernatant. Data represent the mean ± SEM of $n = 10$/group. Values without a common letter are significantly different at $P < 0.05$.

increased the protein expression of TNF-α, IL-6, and IL-17A, compared to the water group (TNF-α, water, 55.4 ± 3.4 pg/mg protein, DSS, 105.4 ± 11.8 pg/mg protein, $P = 0.014$; IL-6, water, 53.2 ± 6.2 pg/mg protein, DSS, 163.9 ± 14.0 pg/mg protein, $P < 0.001$; IL-17A, water, 26.7 ± 2.9 pg/mg protein, DSS, 55.3 ± 5.6 pg/mg protein, $P = 0.010$ vs water). Both doses of OVT significantly inhibited the DSS-induced expression of TNF-α and IL-6 (TNF-α, DSS + OVT50, 47.9 ± 9.8 pg/mg protein, $P = 0.005$; DSS + OVT250, 50.6 ± 12.6 pg/mg protein, $P = 0.007$; IL-6, DSS + OVT50, 102.0 ± 8.4 pg/mg protein, $P = 0.009$; DSS + OVT250, 73.5 ± 16.3 pg/mg protein, $P < 0.001$ vs DSS); high-dose OVT treatment also significantly decreased IL-17A expression (DSS + OVT50, 45.5 ± 8.6 pg/mg protein, $P = 0.561$; DSS + OVT250, 30.5 ± 3.4 pg/mg protein, $P = 0.024$ vs DSS). In addition, as shown in Figure 3, both doses of OVT significantly inhibited the mRNA expression of pro-inflammatory cytokines TNF-α ($P < 0.001$ vs DSS), IL-6 ($P < 0.05$ vs DSS), IL-1β ($P < 0.05$ vs DSS), IFN-γ ($P < 0.01$ vs DSS), MCP-1 ($P < 0.05$ vs DSS), and IL-17A ($P < 0.01$ vs DSS). However, the expression of IL-10, an anti-inflammatory cytokine, was not affected by OVT treatment, suggesting that the anti-inflammatory action of OVT is likely not associated with its ability to inhibit the expression of anti-inflammatory cytokines in the colon.

Effect of OVT on the Histological and Morphological Damage in DSS-Treated Mice. The treatment effects of OVT on histological and morphological damages in the colons were examined following the histological grading system as described before.[11] The observations were confirmed by estimation of biological parameters relevant to colonic inflammation. Colonic inflammation is characterized by severe lesions in the mucosa, alteration of epithelial structure, increase in neutrophil population and lymphocyte infiltration into the mucosal and submucosal areas, and loss of crypts. The colons from the negative control group displayed typical characteristic features of normal glands, abundant goblet cells in epithelium, no mucosal hyperplasia, and a small amount of infiltrated immune cells (Figure 4A). In contrast, the DSS-treated colons displayed severe epithelial damage with extensive loss of glands, depletion of the goblet cells, thickening of the mucosa, cellular infiltration into the submucosa and lamina propria, and destruction of the architecture (Figure 4B), resulting in a high histological score (Figure 4E). Both doses of OVT remarkably ($P < 0.05$) reduced the total histological score (Figure 4E) compared with the DSS group. As shown in Figure 4C,D, OVT-treated colons displayed a decrease in inflammatory cellular infiltration of cells with mild loss of epithelial cells and less expansion of the lesion area. These data suggested that OVT treatment improved the colonic inflammation based on histological analysis, which confirms beneficial preventative effects of OVT on colitis progression.

DISCUSSION

In the present study, we have made progress toward elucidating the mechanism of action of OVT in the amelioration of DSS-induced colitis in mice. Currently, most conventional medical treatments for IBD are mainly based on the use of anti-inflammatory drugs such as 5-aminosalicylates or biological agents such as anti-TNF-α antibody. However, the long-term use of these immunosuppressive agents is associated with strong side effects, including infectious complications that weaken the immune system, resulting in malignancies and severe heart failure.[4] Therefore, complementary and effective treatments for IBD are needed. Several dietary intervention trials have reported beneficial effects in maintaining remission or improving recovery of lesion in IBD patients.[23−28] Our previous in vivo and in vitro studies demonstrated that some egg proteins or peptides[5−9] could ameliorate the colonic inflammatory responses and the development of colitis. OVT

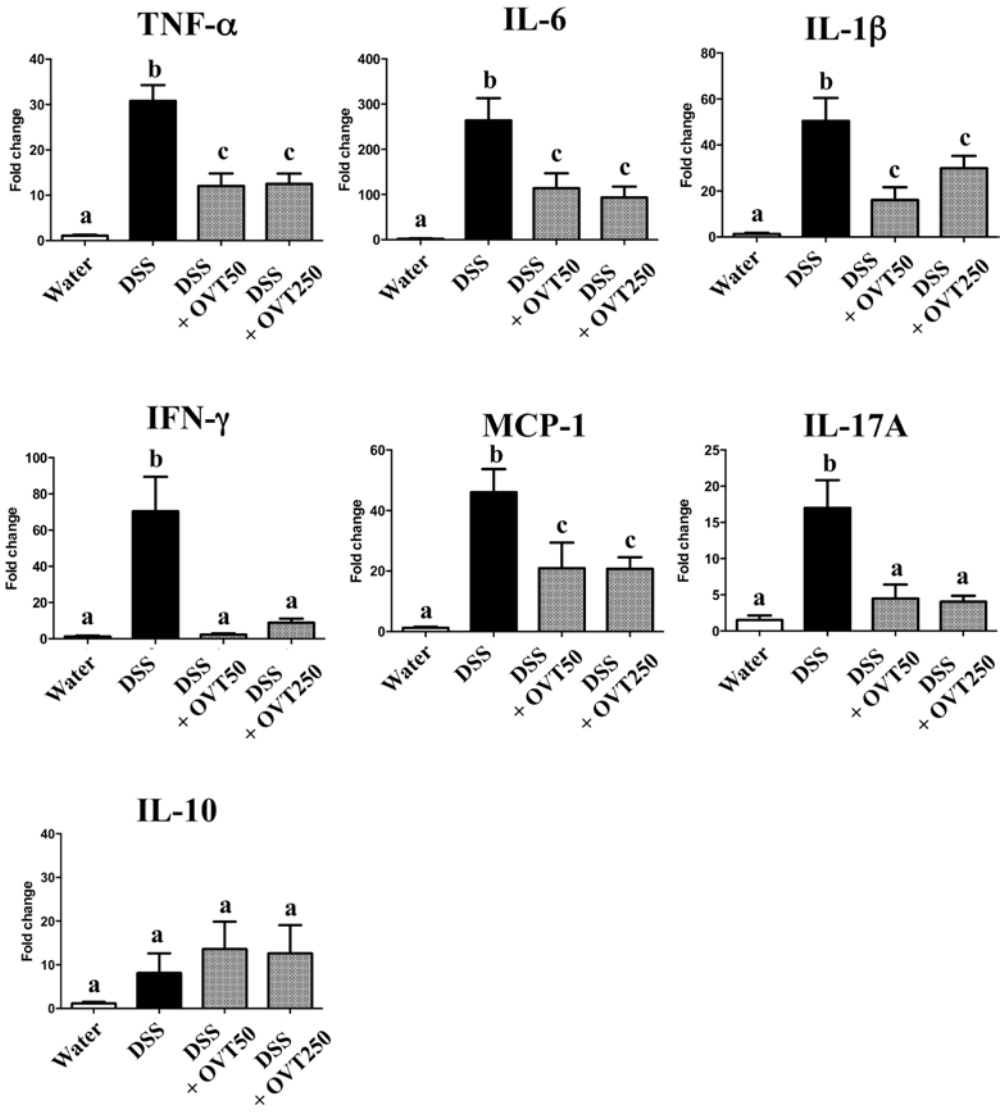

Figure 3. Effect of OVT on inflammatory cytokine gene expression in the colon of DSS-treated mice. Relative mRNA expressions of TNF-α, IL-6, IL-1β, IFN-γ, MCP-1, IL-17A, and IL-10 were measured by real-time PCR. Results were expressed as fold change relative to negative control mice. Data represent the mean ± SEM of n = 10/group. Values without a common letter are significantly different at $P < 0.05$.

has been shown earlier to possess antibacterial activity and antioxidant activity,[17] but the anti-inflammatory effect of OVT on IBD has not been performed yet. To the best of our knowledge, the present study is the first of its kind to demonstrate that OVT (50 or 250 mg/kg BW) successfully attenuated DSS-induced intestinal inflammation in mice. In macroscopic and clinical evaluation analyses, both doses of OVT significantly inhibited clinical signs and colon shortening in DSS-induced colitis mice. In addition, OVT significantly suppressed local expression of cytokines (TNF-α, IL-6, IL-1β, IFN-γ, MCP-1, and IL-17A) in the colon. These results suggested that OVT would block the pathological progress of UC by inhibiting cytokine production. Likewise, histological analysis revealed that OVT improved the function of colon impaired by DSS induction, suggesting OVT was able to attenuate clinical symptoms of colitis in the present study, even at low dose (50 mg/kg BW).

The present study demonstrated that OVT significantly decreased the clinical score and prevented the colon shortening induced by DSS treatment. In addition, the improvement of weight loss was shown in the high-dose group. Cytokines play a crucial role in developing the perpetuating inflammation in IBD. The recruitment of macrophages, neutrophils, and T cells are enhanced by cytokines, resulting in dysregulated immune response and chronic inflammation.[29] Increases in the expression of cytokines, such as TNF-α, IL-6, IL-1β, IFN-γ, and MCP-1, have been shown in both mouse models of DSS-induced colitis[30,31] and IBD patients.[32,33] TNF-α and IL-6 are key cytokines involved in the amplification of mucosal inflammation, including the activation of macrophages, neutrophils, and T cells, in IBD patients.[32] IL-1β is produced by activated macrophages partially through ROS generation[34] and plays a key role in the onset of IBD.[35] IFN-γ is involved in the perpetuation of intestinal inflammation, which increases the severity of IBD in the colon.[36] MCP-1 is involved in the infiltration of immune cells from the bloodstream into the mucosa and submucosa during chronic IBD.[37] Moreover, the involvement of IL-17A in the pathogenesis of IBD has recently been explored. IL-17A was known to be produced mainly in a subset of T lymphocytes named Th17. Jiang et al.[38] reported that the increase of Th17 cells and Th17-related cytokines was correlated with the elevation of disease activity in IBD patients.

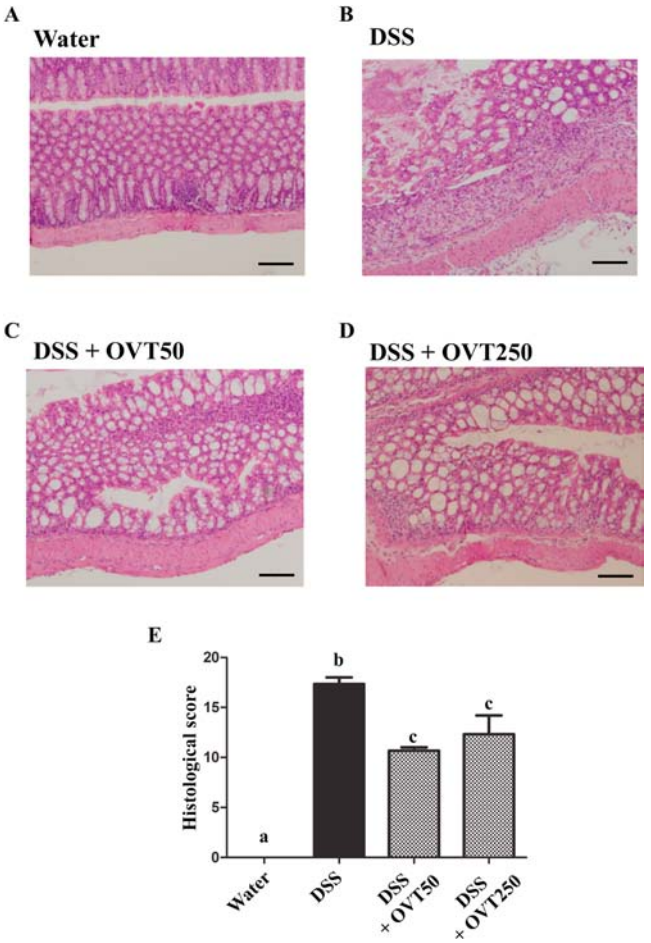

Figure 4. Effect of OVT on colon histology. (A–D) Representative H&E-stained colon sections are shown at 4× magnification. Black scale bar indicates 100 μm for all panels. (E) Colon sections were scored for DSS-induced colonic inflammation and tissue injury as previously described.[11] Data represent the mean ± SEM of $n = 3$. Values without a common letter are significantly different at $P < 0.05$.

Ito et al.[39] demonstrated that deficient IL-17A gene expression contributed to the prevention of the progression of colitis in DSS-treated mice through the inhibition of MCP-1 expression and neutrophil infiltration. IL-1β,[40] IL-6, and transforming growth factor-β (TGF-β)[41] were shown to be involved in the induction of Th17 differentiation, which in turn accelerated the secretion of IL-17A associated with neutrophil infiltration. Here, we have demonstrated that OVT treatment significantly reduced the expression of the cytokine proteins (TNF-α and IL-6) and mRNA (TNF-α, IL-6, IL-1β, IFN-γ, MCP-1, and IL-17A) in the colonic tissue. The significant decrease of IL-17A protein was not observed in low-dose OVT, but this low dose significantly inhibited the mRNA expression of IL-17A, IL-1β, IL-6, and MCP-1 that might be involved in Th17-related inflammatory pathways and improved the colitic histological score. These results are consistent with other recent studies which demonstrated that dipeptide Ala-Gln[42] or the immune milk[43] treatment could reduce the Th17-related inflammation responses and improve the histological damage in the colon of DSS-treated mice, suggesting OVT may be involved in the regulation of IL-17A-related inflammatory responses.

The OVT hydrolysates produced by acidic or enzymatic digestion have been indicated to possesses higher antioxidant activity than the native protein.[19] In addition, tripeptides Ile-Arg-Trp and Ile-Gln-Trp, derived from OVT, were found to attenuate TNF-α-induced inflammatory responses and oxidative stress in vascular endothelial cells.[44] The underlying molecular mechanisms of anti-inflammatory effect by OVT were not fully investigated, but these findings suggested the possibility of involvement in the prevention of IBD by OVT-derived peptides. Further experiments to examine the anti-inflammatory effects and underlying mechanisms of OVT and OVT hydrolysates are in progress.

In conclusion, we demonstrated for the first time the potent immune-modulating property of the egg white protein ovotransferrin. The administration of OVT prevented the progression of DSS-induced colitis in mice and had a preventative effect by inhibiting the epithelial dysfunction and modulating the cytokine profile. We suggest that OVT may be validated as a potential effective agent in the management of chronic intestinal inflammatory diseases.

IV colorectal adenocarcinoma, in which cancer cells have spread to nearby lymph nodes and other organs or tissues (common destinations: liver and lungs). The irinotecan-resistant (CPT-11-R) LoVo colon cancer cell line was originally constructed by challenging parental LoVo cells with increasing doses of CPT-11.[11]

CPT-11-R cells were previously shown to activate the EGFR/IKKα/β/NF-κB pathway, leading to increased basal autophagy.[11] NF-κB mediates chemoresistance and activates autophagy in cancer cells.[12−15] In addition, NF-κB is a molecular target in treatments of a variety of cancers, including colon cancer.[16]

TQ is a 164.2 g/mol phytochemical from *Nigella sativa* and displayed different pharmaceutical functions, such as analgesic, anticancer, and antioxidation in the heart.[17−19] TQ was shown to have anticancer effects against a variety of cancers, such as brain, breast, colon, liver, lung, and prostate cancers.[20−23] Moreover, TQ was shown to alter activity of different mitogen-activated protein kinases (MAPKs) in treating cancers.[24−26]

Certain cancer treatments, such as curcumin, genistein, and resveratrol, are able to activate autophagy, leading to caspase-independent cancer cell death.[27] Under stressful conditions, the mitochondrial outer membrane can become permeabilized, leading to abnormal mitochondrial membrane potential, namely, MOMP.[28] MOMP has been known to result in apoptosis. In addition, MOMP also causes mitophagy, a special type of autophagy that involves engulfment of permeabilized mitochondria into autophagosomes and subsequent degradation of the cargos and mitochondrial proteins. LAMP2 is a lysosomal protein that mediates fusion of lysosome and autophagosome,[29] and SQSTM1/p62 is a receptor for mitophagy.[30] These two serve as mitophagy markers. In addition, some phytochemicals, such as sulforaphane[31] and pentagalloylglucose (PGG),[32] were reported to induce caspase-independent, autophagic cell death (ACD) in cancer cells.

The purpose of this study was to investigate the mechanism through which TQ induces death of CPT-11-R LoVo colon cancer cells.

MATERIALS AND METHODS

Cell Culture. The LoVo colon cancer cell line was purchased from Bioresource Collection and Research Center (BCRC, Hsinchu, Taiwan). The CPT-11-R LoVo colon cancer cell line was constructed by stepwise challenges of CPT-11 (described previously).[11] CPT-11-R cells were cultured in Dulbecco's modified Eagle's medium (DMEM,Sigma-Aldrich, St. Louis, MO) with 10% cosmic calf serum (CCS, HyClone, Logan, UT) in humidified air with 5% CO_2 at 37 °C. The cell medium was changed 48 h after sub-cultivation. A total of 3.5 mL of Dulbecco's phosphate-buffered saline (PBS, GIBCO, Auckland, New Zealand) was used to wash each 10 cm culture plate or vessel. CPT-11-R cells were treated with bafilomycin-A1 (Baf-A1, lysosome inhibitor, Calbiochem, Billerica, MA), LY294002 (class I and III PI3K inhibitor, Promega, Madison, WI), 3-methyladenine (3-MA, class III PI3K inhibitor, Sigma, St. Louis, MO), SB230580 (p38 inhibitor, Promega, Madison, WI), SP600125 (JNK inhibitor, Sigma-Aldrich, St. Louis, MO), TQ (Sigma-Aldrich, St. Louis, MO), or *Z*-DEVD-fluoromethylketone (*Z*-DEVD-fmk, caspase 3 inhibitor, BioVision, Milpitas, CA) for later experiments.

Immunofluorescence Microscopy. CPT-11-R cells were grown in a 12 well plate (1×10^5 cells/well) containing DMEM (10% CCS). After 12 h, different doses of TQ (2, 4, 6, and 8 μM) were added to appropriate wells. After 24 h of administration of TQ, the plates were washed with 1× PBS (0.5 mL/well) 3 times. Then, 0.5 mL of fixation solution (4% paraformaldehyde in 1× PBS) was added to each well to fix the cells for 1 h at room temperature (RT). In the process of cell permeabilization, 0.5 mL of permeabilization solution (0.1% Triton X-100 in 0.1% sodium citrate) was added to cells in each well and the plate was rest on ice for 2 min without shaking. A 10% CCS was added to wells to prevent non-specific binding. Stock primary antibody solution was diluted 100× with 1× PBS, and the diluted solution was added to each well (500 μL/well). Then, the plate was sealed in a plastic wrap, shaken for 20 s at RT, and stored at 4 °C for at least 24 h. The diluted primary antibody solution was then recycled. Stock secondary antibody solution was diluted 100× with 1× PBS, and the diluted solution was added to each well (500 μL/well). Then, the plate was sealed in a tin foil, shaken for 20 s at RT, and stored at RT. The diluted secondary antibody solution was discarded. A total of 500 μL of 10000× diluted DAPI was added to each well. The plate was covered with a tin foil and rested for 30 min at RT. Then, each well was washed with 0.5 mL of 1× PBS 3 times at RT and added with 0.6 mL of 1× PBS. Finally, the cells were observed under a confocal microscope.

The following primary antibody was used in this assay for different experiments: anti-LC3 (Cell Signaling, Boston, MA). The following fluorescent secondary antibody was used in this assay for different experiments: Alexa Fluor488 goat anti-rabbit IgG (H+L), 2 mg/mL (green, Invitrogen, Carlsbad, CA).

JC-1 Staining Assay. CPT-11-R cells were grown in 12 well plates (1×10^5 cells/well) containing DMEM (10% CCS). After 12 h, different doses of TQ (2, 4, 6, and 8 μM) were added to appropriate wells. After 24 h of administration of TQ, 25 μL of 200× JC-1 stock solution (1 mg/mL, Sigma, St. Louis, MO) was mixed with 4 mL of deionized distilled water (DDW) and 1 mL of 5× JC-1 staining buffer (avoiding light, Sigma, St. Louis, MO) to make the JC-1 staining mixture. A total of 0.5 mL of JC-1 staining mixture per well was added. The plates were covered with tin foils and placed in humidified air with 5% CO_2 at 37 °C for 30 min. During incubation, 5× JC-1 staining buffer was mixed with DDW in a 1:4 ratio (washing buffer). Each well was washed with 0.5 mL of washing buffer 3 times after incubation. Finally, 3 mL of DMEM (10% CCS) was added to each well, and then cells were observed under a fluorescent microscope using Cy3 (red; excitation, 525 nm; emission, 590 nm) and FITC (green; excitation, 490 nm; emission, 530 nm).

TUNEL Assay. CPT-11-R cells were grown in a 12 well plate (1×10^5 cells/well) containing DMEM (10% CCS). After 12 hours, different doses of TQ (2, 4, 6, and 8 μM) were added to appropriate wells. After 24 h of administration of TQ, each well was washed with 1× PBS (1 mL/well) and incubated with fixation solution (1 mL/well, 4% paraformaldehyde in 1× PBS at pH 7.4) at RT for 1 h. Blocking buffer (3% H_2O_2 in 100% methanol) was added (1 mL/well), and the plate was rested for 10 min at RT. Permeabilization solution (0.1% Triton X-100 in 0.1% sodium citrate) was added (0.5 mL/well), and the 12 well plate was placed on ice for 2 min without shaking. A 10× diluted TUNEL reagent [Enzyme Solution and Label Solution (In Situ Cell Death Detection Kit), Roche, Indianapolis, IN] was added (200−250 μL/well), and the plate was placed in humidified air at 37 °C, avoiding light for 1 h for the reagent to react with cell nuclei. A 10000× diluted DAPI per well was added (200 μL/well), and the plate was covered with tin foil and rested for 25 min. Finally, the cells were observed under a fluorescent microscope.

Western Blotting. CPT-11-R LoVo colon cancer cells were grown in 10 cm culture dishes containing DMEM (10% CCS) at 80−90% confluency. After 12 h, different doses of TQ (2, 4, 6, and 8 μM) were added to appropriate plates. After 24 h of administration of TQ, cells from each plate were collected with cell lysis buffer [50 mM Tris base (pH 7.5), 0.5 M NaCl, 1 mM EDTA (pH 8.0), 1 mM β-mercaptoethanol, 1% NP40, 1% glycerol, and protease inhibitor] (100 μL/plate). Equal amounts of protein samples (40 μg) were separated by 12% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (75 V, 2.5 h) in running buffer (0.3% Tris base, 1.47% glycine, and 0.1% SDS) and then transferred to polyvinylidene difluoride (PVDF) membranes (100 V, 2 h) in transfer buffer (0.3% Tris base, 1.44% glycine, and 20% methanol), which were incubated in blocking buffer [5% milk in 1× TBS (0.13% Tris base, 0.9% NaCl, and 0.05% Tween-20)] for 1 h at RT. PVDF membranes were rocked in 1:1000 primary antibody solutions at least once overnight at 4 °C. Then, PVDF membranes were incubated in 1:1000 secondary antibody solutions for 1 h at RT. Finally, the results were detected with a LAS-3000 luminescent image analyzer (Fujifilm, Tokyo, Japan).

J. Agric. Food Chem. 2015, 63, 1540−1546

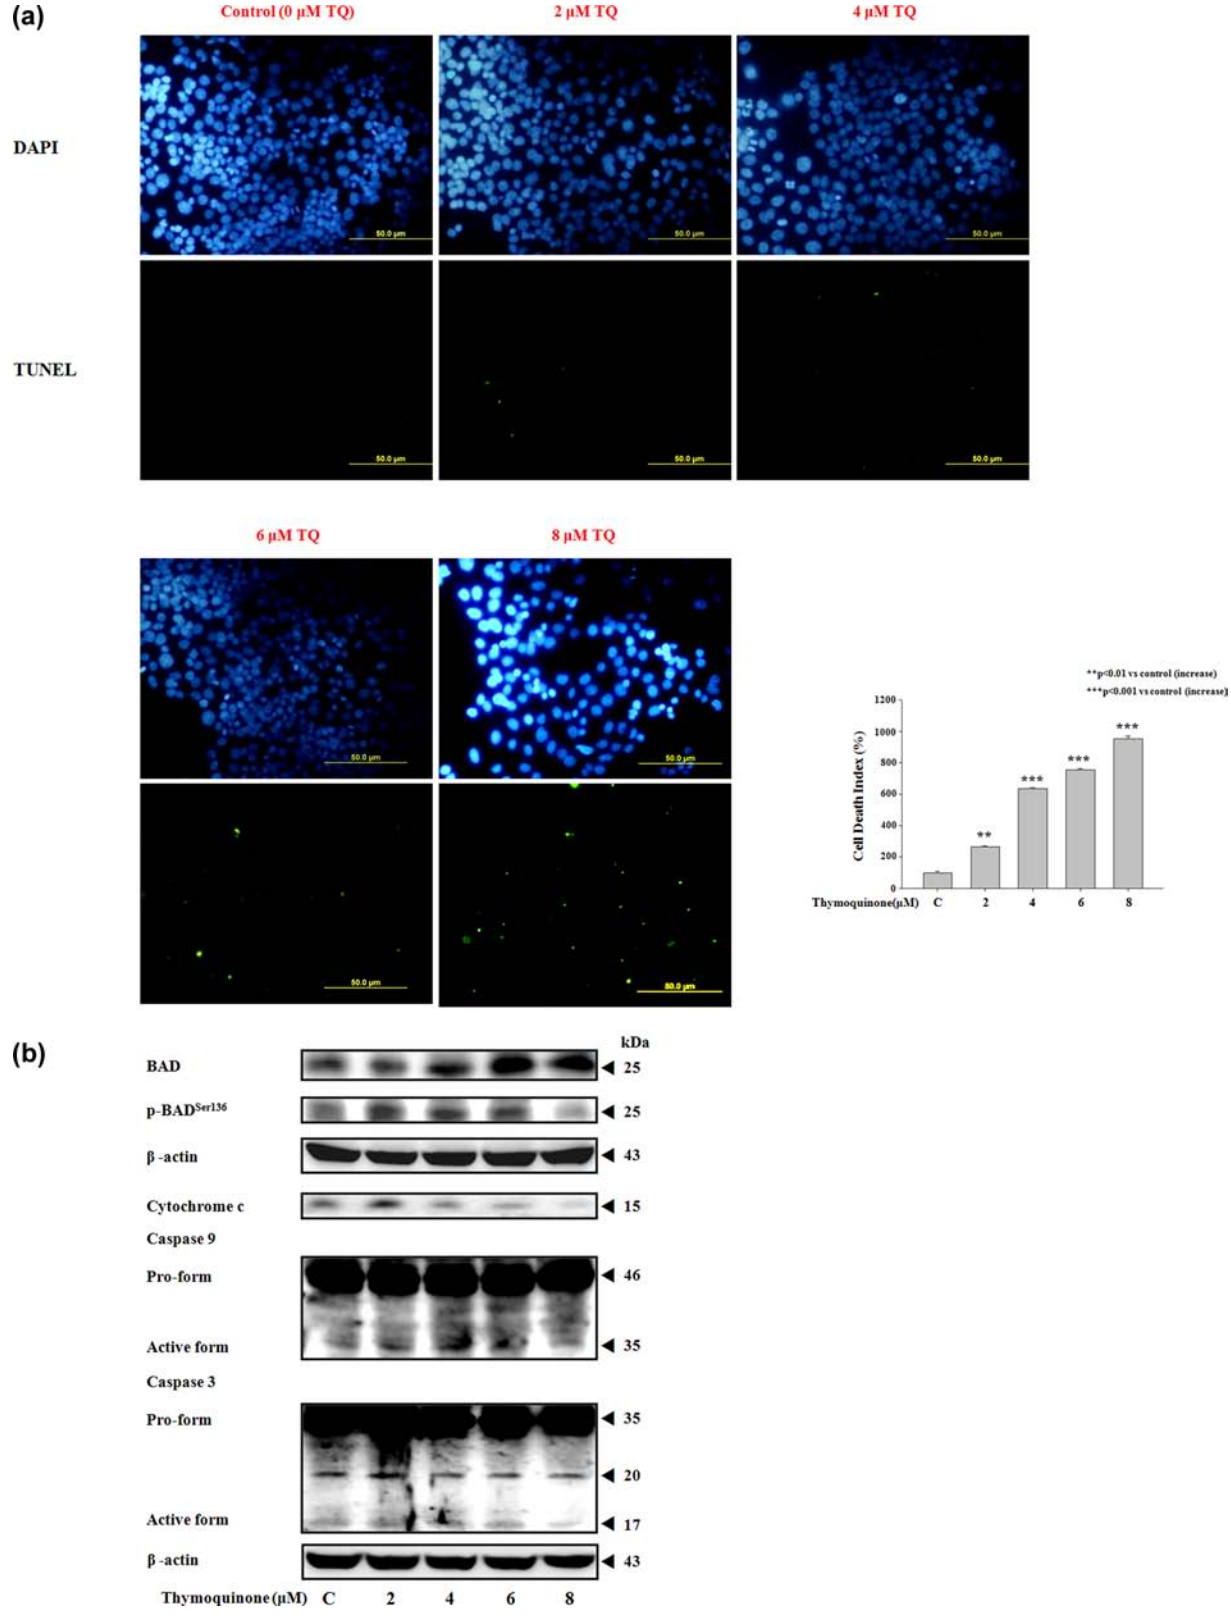

Figure 1. TQ resulted in increasing total cell death index but did not upregulate apoptosis at increasing doses. (a) After 12 h of seeding CPT-11-R LoVo colon cancer cells in 12 well culture plates, different doses of TQ were added. The TUNEL assay was conducted 24 h after administration of TQ. TQ elevated the percentage of TUNEL-positive cells/total cell death index of CPT-11-R cells. (b) After 12 h of seeding CPT-11-R cells in 10 cm culture plates, different doses of TQ were added. Western blotting was conducted 24 h after administration of TQ. TQ resulted in an initial activation of apoptosis, which decreased at increasing doses of the phytochemical.

Statistical Analysis. Each sample was analyzed on the basis of results that were repeated at least 3 times, and SigmaPlot 10.0 software and standard *t* test were used to analyze each numeric data. In all cases, differences at $p < 0.05$ were regarded as statistically significant; differences at $p < 0.01$ or $p < 0.001$ were considered to have higher statistical significance.

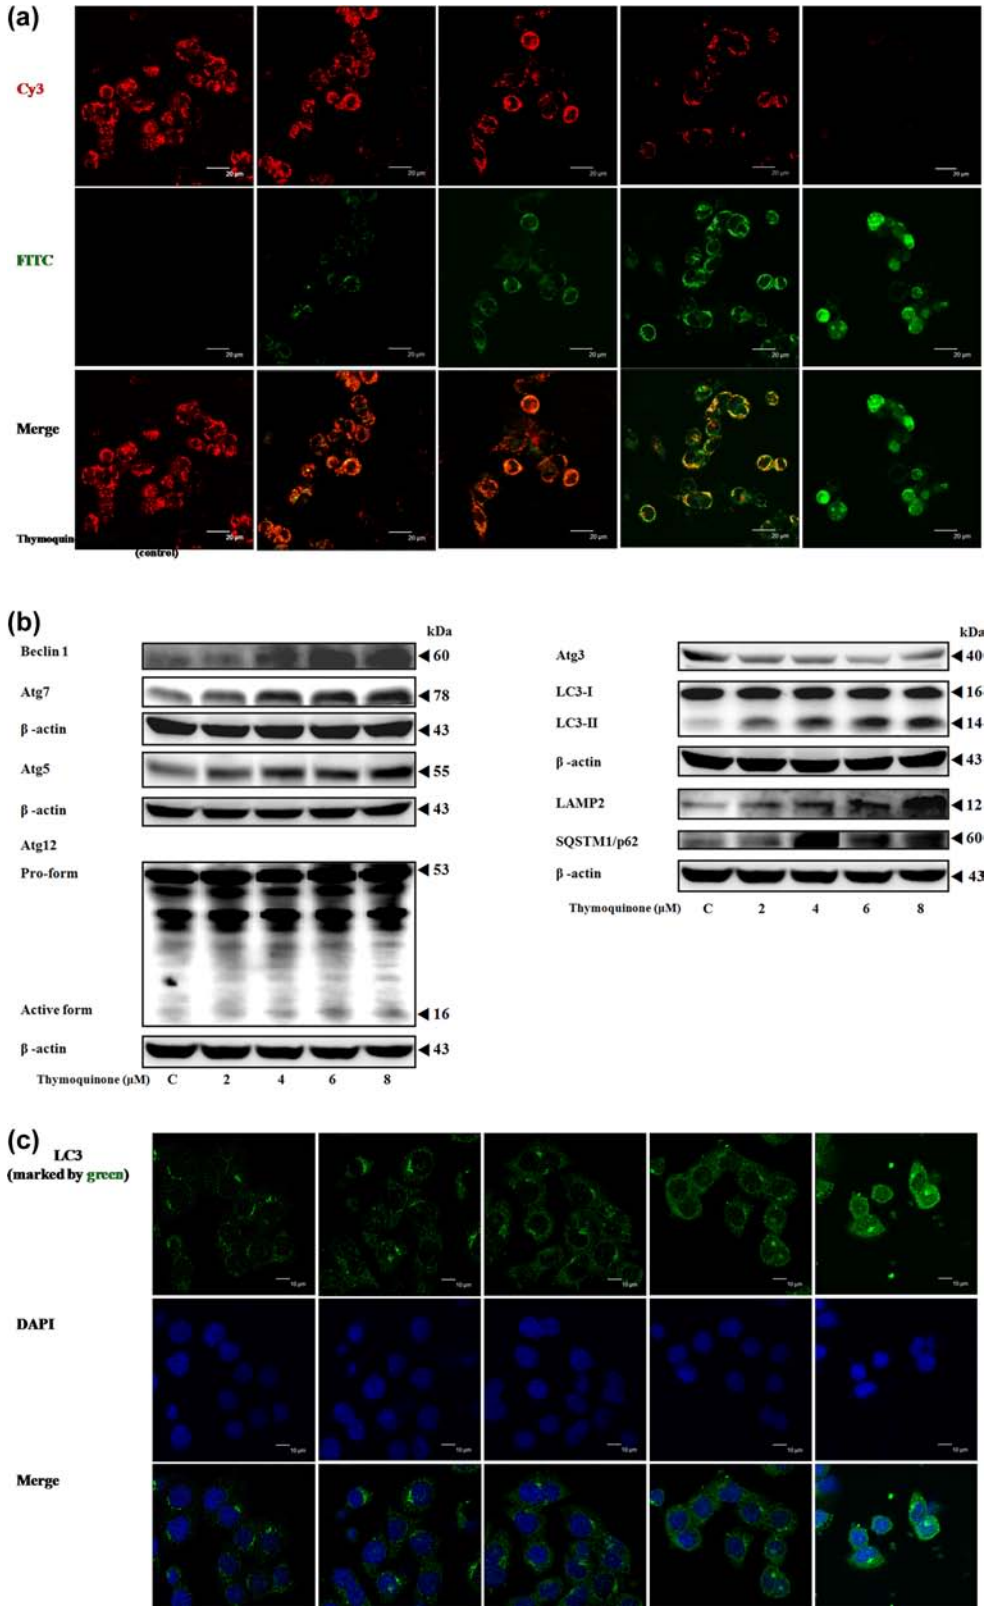

Figure 2. TQ induced ACD of CPT-11-R cells involving MOMP. (a) After 12 h of seeding CPT-11-R cells in 10 cm culture plates, different doses of TQ were added. JC-1 staining was conducted 24 h after administration of TQ. TQ increased the FITC (JC-1 monomer) signal and reduced the Cy3 (JC-1 aggregate) signal dose-dependently. (b) After 12 h of seeding CPT-11-R cells in 10 cm culture plates, different doses of TQ were added. Western blotting was conducted 24 h after administration of TQ. TQ caused increased Atg5, Atg7, Atg12, Beclin-1, LC3-II, LAMP2, and SQSTM1/p62 and reduced Atg3. (c) After 12 h of seeding CPT-11-R cells in 12 well culture plates, different doses of TQ were added. Immunofluorescence microscopy was conducted 24 h after administration of TQ. TQ increased cellular expression of LC3 in a dose-dependent manner.

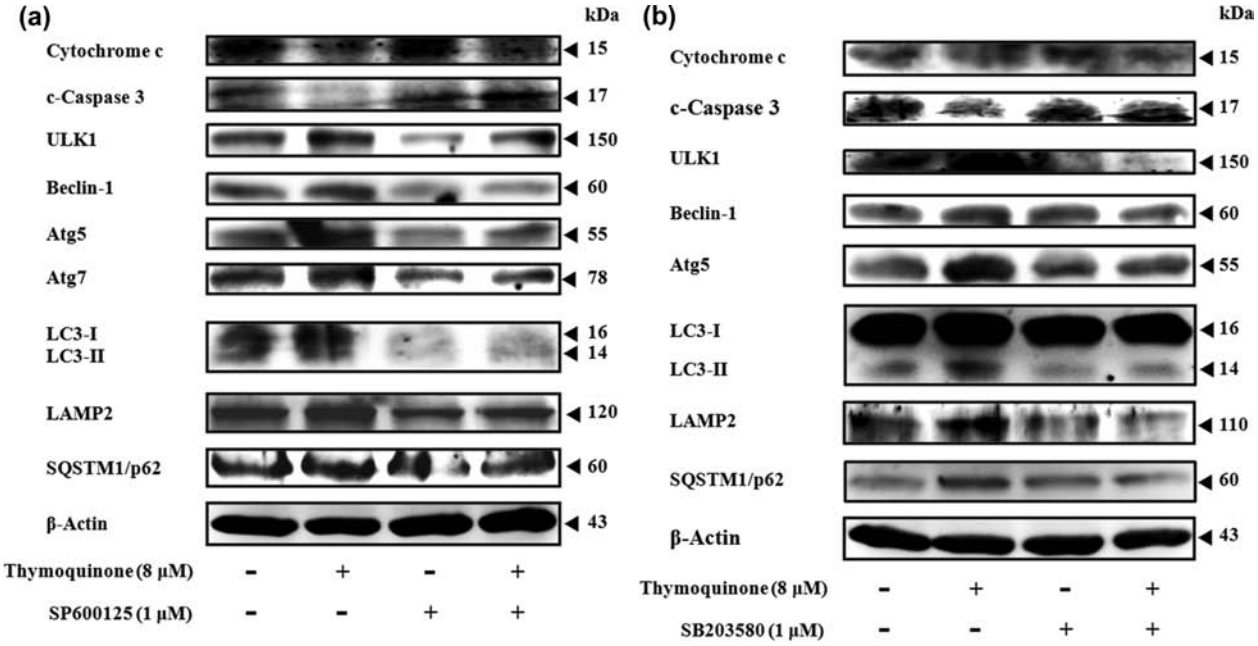

Figure 3. TQ induced ACD of CPT-11-R cells via activation of JNK and p38. (a) After 12 h of seeding CPT-11-R cells in 10 cm culture plates, 1 μM SP600125 was added first, followed by 8 μM TQ at 2 h later. Western blotting was conducted 24 h after administration of TQ. SP600125 reversed TQ-induced cell death. (b) After 12 h of seeding CPT-11-R cells in 10 cm culture plates, 1 μM SB203580 was added first, followed by 8 μM TQ at 2 h later. Western blotting was conducted 24 h after administration of TQ. SB203580 reversed TQ-induced ACD.

RESULTS

TQ Resulted in ACD in CPT-11-R Cells via Activation of JNK and p38 and MOMP. In a traditional view, cancer treatments are known to cause apoptosis in cancer cells. However, certain phytochemicals were shown to induce caspase-independent ACD in cancers. Therefore, the authors investigated which type of cell death (i.e., apoptosis or ACD) was caused by TQ in CPT-11-R cells.

First, TQ dose-dependently elevated the total cell death index (166.4, 534.54, 653.79, and 853.94% increase compared to the control) (Figure 1a). TQ increased unphosphorylated BAD and reduced phosphorylated BAD (Figure 1b). However, TQ only caused increased cytochrome *c*, caspase 9, and caspase 3 at 2 μM, which then decreased at increasing doses. The effect of TQ on mitochondrial membrane potential and autophagy in CPT-11-R cells was investigated. The JC-1 staining assay was conducted to access TQ-induced MOMP, and western blotting was conducted to investigate TQ-induced autophagy. TQ caused a dose-dependent increase in the FITC (JC-1 monomer) signal and a dose-dependent decrease in the Cy3 (JC-1 aggregate) signal (Figure 2a). Further, TQ upregulated protein levels of Atg5, Atg7, Atg12, Beclin-1, LAMP2, LC3-II, and SQSTM1/p62, while that of Atg3 was reduced (Figure 2b). TQ also dose-dependently increased cellular expression of LC3 (Figure 2c). Therefore, TQ induced ACD via MOMP.

Finally, TQ was found to activate JNK and p38, which are stress-activated protein kinases; it was assumed that JNK or p38 mediated TQ-induced ACD. The 8 μM TQ reduced cytochrome *c* and cleaved caspase 3 but increased Atg5, Atg7, Beclin-1, LAMP2, LC3, SQSTM1/p62, and ULK1 (Figure 3a). The 1 μM SP600125 restored protein levels of cytochrome *c* and cleaved caspase 3 while deducting those of Atg5, Atg7, Beclin-1, LAMP2, LC3, SQSTM1/p62, and ULK1, which were lower than the control. SP600125 also reversed TQ-induced ACD. SB203580 also had similar effects on TQ-induced ACD in CPT-11-R LoVo colon cancer cells (Figure 3b) and, therefore, reversed the effect of TQ. Therefore, JNK and p38 mediated TQ-induced ACD in CPT-11-R cells.

Relationship between TQ-Induced Apoptosis and ACD. In Figures 1 and 2, TQ resulted in increased total cell death, initial activation of apoptosis, increased autophagy activity, and increased expression of mitophagy markers (LAMP2 and SQSTM1/p62). TQ induced apoptosis and autophagy at 2 μM, and then at increasing doses, apoptosis was decreased, while autophagy was elevated. Therefore, the authors attempted to determine the relationship between and TQ-induced apoptosis and ACD.

TQ activated Atg7, Beclin-1, caspase 3, and LC3 at 2 μM (Figure 4). Co-treating with 50 μM 3-MA resulted in decreased Atg7, Beclin-1, and LC3 and increased caspase 3 activation. Baf-A1 caused increased accumulation of Atg7, Beclin-1, and LC3 but did not increase caspase 3 in the presence of 2 μM TQ. The 1 μM LY294002 resulted in reduced Beclin-1 and LC3 but did not reduce Atg7 or increase caspase 3 when co-administered with TQ. Finally, 2 μM *Z*-DEVD-fmk caused increased Atg7 and LC3, decreased caspase 3, but did not upregulate Beclin-1. Therefore, TQ activated apoptosis prior to initiation of ACD in CPT-11-R LoVo cells, and the key switching step must had occurred early in the formation of autophagosome.

DISCUSSION

Besides eliminating tumor cells, chemotherapeutic drugs cause side effects and result in chemoresistant tumors in patients.[3] Therefore, there is a need for alternative cancer treatments.[4] Phytochemicals serve as an alternative method to treat colon cancer and are by means of targeted therapy.[7,8] CPT-11-R LoVo colon cancer cells were generated by challenging parental cells with increasing doses of CPT-11 and activate the NF-κB pathway to promote basal autophagy.[11] TQ is a phytochemical that was applied to treat different cancers, including colon cancer.[20] In addition, TQ altered activity of MAPKs in treating cancers.[24−26]

DOI: 10.1021/jf5054063
J. Agric. Food Chem. 2015, 63, 1540−1546

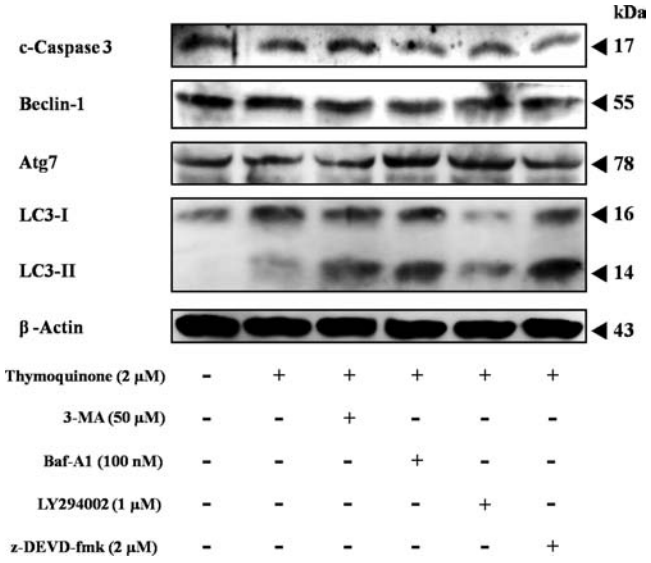

Figure 4. TQ induced apoptosis before inducing ACD in CPT-11-R LoVo cells. After 12 h of seeding CPT-11-R cells in 10 cm culture plates, 50 μM 3-MA, 100 nM Baf-A1, 1 μM LY294002, and 2 μM *Z*-DEVD-fmk were added to separate plates, followed by 2 μM TQ to appropriate plates at 2 h later. Western blotting was conducted 24 h after administration of TQ. Apoptosis was induced by TQ before ACD.

Traditionally, cancer treatments usually cause apoptosis of tumor cells. Therefore, the authors first investigated whether TQ caused apoptosis in CPT-11-R cells. TQ caused a dose-dependent increase in the cell death index. However, although apoptosis was initially activated TQ, it still decreased at increasing doses of the phytochemical. Therefore, the possibility of ACD was considered. First TQ resulted in a dose-dependent increase in MOMP, and then TQ elevated protein levels of Atg5, Atg7, Atg12, Beclin-1, LAMP2, LC3-II, and SQSTM1/p62, while that of Atg3 was reduced. Furthermore, TQ also increased LC3 intracellular expression dose-dependently. In addition, autophagy is a context-dependent process; its outcomes in terms of cellular response are different.[33] In CPT-11-R cells, NF-κB activation resulted in increased basal autophagy.[11] However, TQ was previously shown to inhibit NF-κB in CPT-11-R cells (unpublished result). In this study, it resulted in increased autophagy and decreased cell viability. Together these results showed that TQ induced ACD via MOMP (mitophagy). In a review by Tait et al., MOMP can result in caspase-dependent (apoptosis) or caspase-independent (autophagy) cell death.[28] In this study, TQ induced, in an initial activation of mitochondria-dependent cell death, a dose-dependent increase in autophagy and MOMP in CPT-11-R cells. Finally, TQ was found to induce ACD by activation of JNK and p38 in CPT-11-R LoVo colon cancer cells. Therefore, TQ resulted in autophagic cell death via MOMP and activation of JNK and p38.

Finally, because TQ initially resulted in activation of apoptosis and autophagy and the latter took over cell death at increasing doses, it was necessary to determine which TQ-induced apoptosis and autophagy occurred earlier than the other. TQ at 2 μM activated both apoptosis and autophagy (Figure 4); however, 3-MA co-administration pointed the direction of cell death toward apoptosis, and that of *Z*-DEVD-fmk pointed to ACD. In addition, TQ caused elevated MOMP and protein levels of mitophagy markers, LAMP2 and SQSTM1/p62. TQ also caused increased Atg7 and Atg12 while reducing Atg3. Therefore, it was concluded that apoptosis was induced by TQ before activating ACD and the key switching step occurred at initiation of autophagosome formation. Therefore, TQ initially activated both apoptosis and ACD; however, at increasing doses, intracellular damages must be increasingly more severe (such as a number of dysfunctional mitochondria), and therefore, the upregulated autophagic process functioned to clear damaged organelles and other intracellular components, resulting in caspase-independent ACD (Figure 5). In other studies, different phytochemicals induced ACD at increasing doses with or without an initial apoptosis, such as dihydrocapsaicin, PGG, resveratrol, SAHA, and sulforaphane.[31,32,34−36]

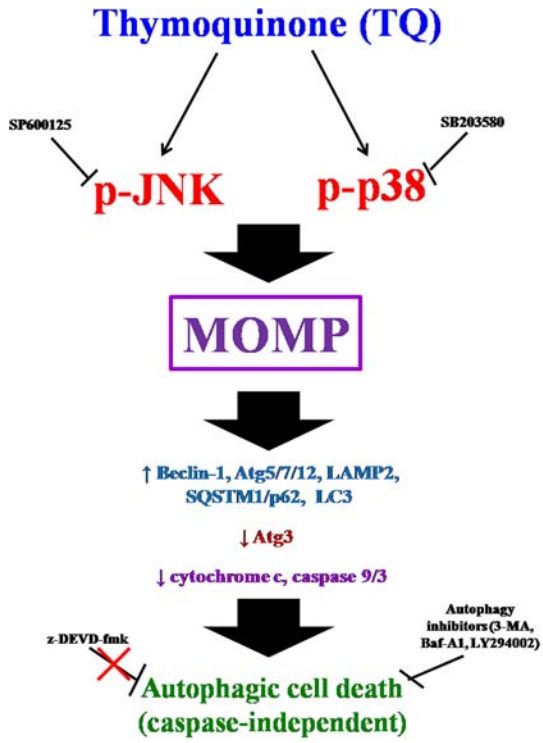

Figure 5. Schematic representation of TQ-induced caspase-independent, autophagic cell death via MOMP and activation of JNK and p38 in CPT-11-R LoVo colon cancer cells.

To summarize, TQ caused in autophagic cell death via MOMP and activation of JNK and p38 in CPT-11-R LoVo colon cancer cells. This activation of ACD occurred after induction of apoptosis by TQ. Furthermore, the key switching event occurred at early autophagosome formation. Therefore, TQ causes mitochondrial-dependent ACD via MOMP and JNK and p38 activation in CPT-11-R LoVo colon cancer cells.

wogonoside (>98.0%), galangin (>97.0%), gallocatechin-3-gallate (GCG) (>98.0%), epicatechin (EC) (>98.0%), epigallocatechin (EGC) (>98.0%), kaempferide (>97.0%), quercetin (>97.0%), catechin (C) (96.0%), quercitrin (>98.0%), isorhametin (>98.0%), myricitrin (>98.0%), formononetin 7-*O*-glucoside (>98.0%), genistin (>98.0%), daidzin (>96.0%), biochanin A (>98.0%), naringin (>95.0%), narirutin (>97.0%), hesperidin (>97.0%), liquiritigenin (>98.0%), and liquiritin (>98.0%) were obtained from Aladdin Chemistry Co. Ltd. (Shanghai, China). Methanol and acetonitrile (HPLC grade) were purchased from Baker (J.T. Baker). Penicillin, streptomycin, L-glutamine, and fetal bovine serum (FBS) were all purchased from Biochrom AG (Berlin, Germany). Dulbecco's modified Eagle's medium (DMEM) was obtained from Sigma (St Louis, MO). MiliQ water was used throughout the experiments. Other organic solvents and reagents were of analytical reagent grade.

Instrumentation and Chromatographic Conditions. The high performance liquid chromatography (HPLC) system consisted of a Waters 1525 Binary HPLC pump, a Waters 2487 Dual λ absorbance detector, and a Waters 717 autosampler. Separation was carried out on a YMC America C_{18} column (4.6 mm × 150 mm; 5 μm) (Pennsylvania). The polyphenols were classified into seven groups: flavones, multihydroxyflavonols, flavonols, flavanones, isoflavones, catechins, and stilbenoids (Table 1). The mobile phase consisted of 0.1% phosphoric acid (A) and acetonitrile (B) and was degassed prior to use (Table 2). The flow rate was 1.0 mL/min.

Stability of Polyphenols in Cell Culture Medium. Polyphenols were dissolved in methanol or DMSO to obtain a 10^{-2} mol/L standard stock solutions. DMEM was supplemented with 10% FBS, 50 U/mL penicillin, 100 mg/L streptomycin, and L-glutamine. The standard stock solutions of polyphenols were diluted to 1×10^{-3} mol/L with DMEM before testing. 50 μL of the diluted polyphenol solution was added to 4950 μL DMEM (prewarmed to 37 °C in a 5% CO_2 atmosphere 30 min prior to experiments); then, the mixtures were incubated at 37 °C in 5% CO_2. At 1, 10, 30, 60, 90, 120, and 180 min, a sample of 500 μL was withdrawn and immediately mixed with 1000 μL cold methanol (−20 °C) and kept at −20 °C for 30 min to precipitate the proteins. After centrifugation at 12 000 × *g* for 10 min at 4 °C, a 50 μL aliquot was injected to the HPLC system.

Stability of Polyphenols in Human Plasma. Human plasma from three volunteers was obtained from a local blood bank (Bayerisches Rotes Kreuz, München, Germany). The standard stock solutions of flavonols (myricetin, myricitrin, quercetin, and kaempferol) were diluted to 1×10^{-3} mol/L with MiliQ water before testing. A 50 μL portion of the diluted flavonol solution was added to 4950 μL of the pooled human plasma (prewarmed to 37 °C for 30 min prior to experiments); then, the mixtures were incubated at 37 °C. After 1, 10, 30, 60, 90, 120, and 180 min, a sample of 500 μL was withdrawn and immediately mixed with 1000 μL cold methanol (−20 °C) and kept at −20 °C for 30 min to precipitate the proteins. After centrifugation at 12 000 × *g* for 10 min at 4 °C, a 50 μL aliquot was injected to the HPLC system.

Determination of Protein Concentrations in DMEM and Human Plasma. The protein concentrations in DMEM and human plasma were determined using the BCA protein assay (Thermo Scientific).[22] For calibration curves BSA (125 μg/mL to 2000 μg/mL) was used as standard. DMEM and human plasma were diluted with PBS before testing.

Data Analysis. An early degradation time ($^{C}T_{10}$) and a half degradation time ($^{C}T_{50}$) have been defined to characterize the stability of a compound (initial concentration of C μM) in a specific biological or biochemical system. $^{C}T_{10}$ and $^{C}T_{50}$ represent the time that is required for 10% and 50%, respectively, degradation of an individual compound *in vitro*. The $^{C}T_{10}$ and $^{C}T_{50}$ of each compound were derived from time-response curves. The time−concentration curve was fitted using linear, polynomial, or exponential data regression. $^{C}T_{10}$ and $^{C}T_{50}$ values were defined as the time when the concentration of polyphenol decreased to 10% or 50% of the initial concentration.

Statistical Analysis. All experiments were repeated three times. All values were expressed as means ± standard deviations.

RESULTS

Stability of Polyphenols in Cell Culture Medium. After incubation with DMEM at 37 °C for 1, 10, 30, 60, 90, 120, and 180 min, the concentrations of polyphenols were determined to compile time−concentration response curves. The $^{10}T_{10}$ and $^{10}T_{50}$ values of polyphenols (initial concentration 10 μM) in DMEM at 37 °C varied considerably (Table 1). Some polyphenols, such as myricetin, C, EGCG, GCG, and EGC, were significantly degraded within 10 min of incubation ($^{10}T_{10}$ < 1 min, $^{10}T_{50}$ < 1 min). However, most polyphenols such as isoflavones flavanones and less-hydroxyflavonols were very stable even after 3 h incubation ($^{10}T_{10}$ > 180 min, $^{10}T_{50}$ > 180 min).

Flavonols. *Hydroxylation. 1. Hydroxylation on Ring B.* The hydroxylation at the ring B of flavonols significantly affected the stability (Figure 1). Myricetin (3′,4′,5′-OH) ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$ < 1 min; Table 1) was highly instable, degraded to 26% within 1 min, and completely disappeared within 10 min. Quercetin (3′,4′-OH) ($^{10}T_{10}$ = 4.66 min and $^{10}T_{50}$ = 17.96 min) decreased to 25% of the initial concentration within 30 min and almost disappeared after 120 min incubation. Kaempferol (4′-OH) ($^{10}T_{10}$ = 46.68 min and $^{10}T_{50}$ = 119.47 min) was more stable than myricetin and quercetin. Moreover, kaempferol was found to degrade linearly while quercetin degraded exponentially. Galangin without any hydroxyl groups on ring B appeared to be most stable over a 3 h time course ($^{10}T_{10}$ > 180 min and $^{10}T_{50}$ > 180 min). Likewise, 3,4′-dihydroxyflavone was more stable than 3-hydroxyflavone (Figure 3).

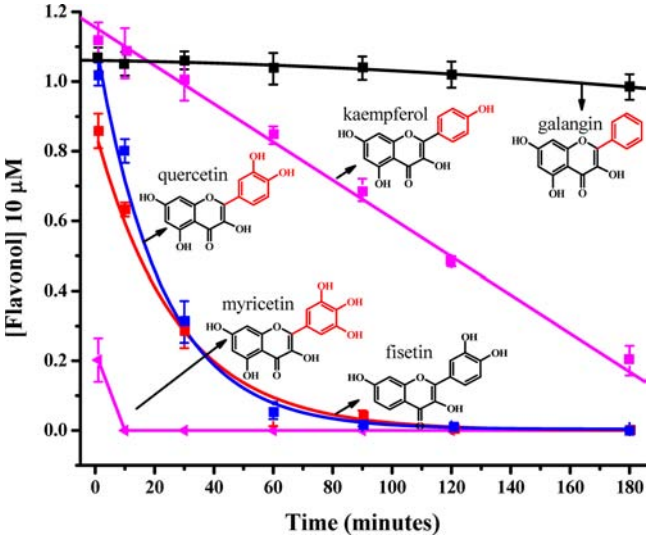

Figure 1. Stability of multihydroxyflavonols (initial concentration 10 μM) in DMEM incubated at 37 °C in 5% CO_2. These results are the mean of three independently performed experiments.

2. Hydroxylation on Ring A. Quercetin (3,5,7,3′,4′-OH) ($^{10}T_{10}$ = 4.66 min and $^{10}T_{50}$ = 17.96 min) exhibited slightly higher stability as compared to fisetin (3,7,3′,4′-OH) ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$ = 14.40 min; Figure 1).

Methoxylation. The methoxylation at ring B of multihydroxyflavonols apparently improved their stability (Figure 2). Isorhametin revealed a slightly higher stability than quercetin ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$ = 14.40 min versus $^{10}T_{10}$ < 1 min and $^{10}T_{50}$ = 14.40 min); the methoxylation at the C-4′ position of kaempferol ($^{10}T_{10}$ = 46.68 min and $^{10}T_{50}$ = 119.47 min) significantly enhanced its stability (kaempferide, $^{10}T_{10}$ = 150.02 min and $^{10}T_{50}$ > 180 min). However, the methoxylation of less hydroxylated flavonols such as 3-hydroxyflavonol slightly compromised their stability (Figure 3). 3,4′-Dihydroxyflavone and 4′-hydroxyflavone showed a slightly higher stability than 3-hydroxy-4′-methoxyflavone and 4′-methoxyflavone (Table 1).

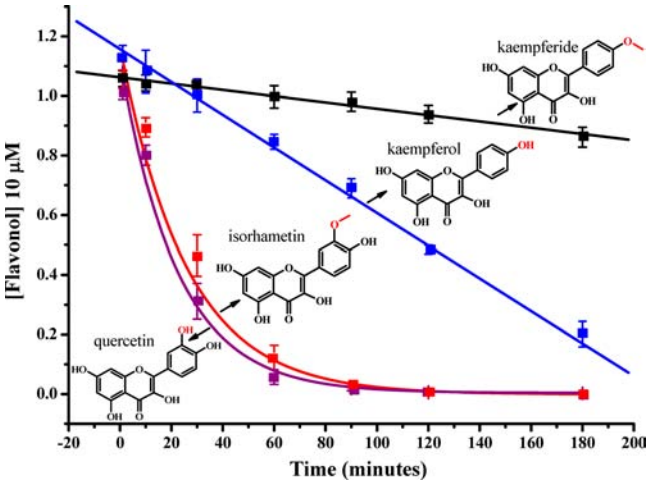

Figure 2. Methoxylation on ring B of multihydroxyflavonols (initial concentration 10 μM) improved the stability in DMEM incubated at 37 °C in 5% CO_2. These results are the mean of three independently performed experiments.

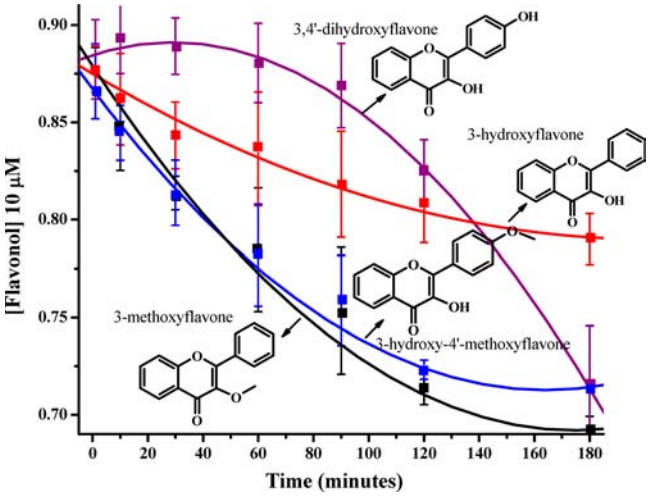

Figure 3. Methoxylation of flavonols (initial concentration 10 μM) slightly weakened the stability in DMEM incubated at 37 °C in 5% CO_2. These results are the mean of three independently performed experiments.

Glycosylation. In the present study, the glycosylation of flavonols significantly enhanced their stability. Compared with quercetin ($^{10}T_{10}$ = 4.66 min and $^{10}T_{50}$ = 17.96 min; Figure 4), quercitrin and rutin were more stable during 3 h of incubation in DMEM medium with T_{10} > 180 min and T_{50} > 180 min. After 3 h of incubation, quercetin almost completely disappeared, but quercitrin and rutin barely degraded (Figure 4). Myricitrin ($^{10}T_{10}$ = 20.66 min and $^{10}T_{50}$ = 63.95 min) also showed higher stability than myricetin ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$

DOI: 10.1021/jf505514d
J. Agric. Food Chem. 2015, 63, 1547−1557

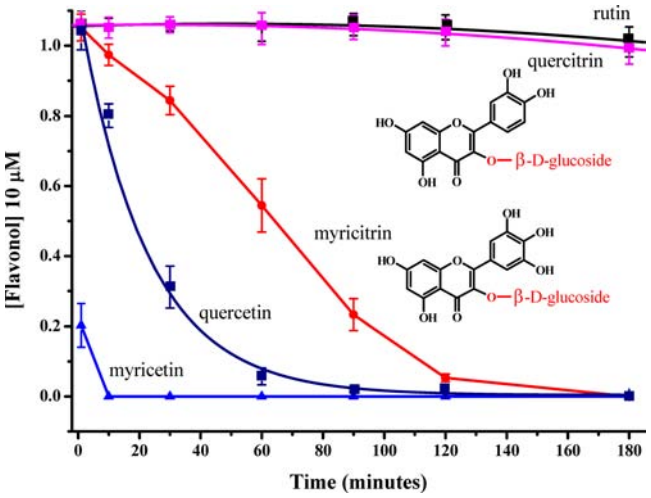

Figure 4. Glycosylation of flavonols (initial concentration 10 μM) improved the stability in DMEM incubated at 37 °C in 5% CO_2. These results are the mean of three independently performed experiments.

< 1 min). Even with the glycoside attached at the C-3 positon of myricitrin, it was still instable and entirely vanished after 3 h incubation. Apparently, the pyrogallol moiety in myricetin and myricitrin were the key structures influencing the stability.

Flavones. *Hydroxylation. 1. Hydroxylation in Ring B.* The hydroxylation at the ring B of flavones obviously influenced the stability (Figure 5). Chrysin (no hydroxyl group in the B-ring)

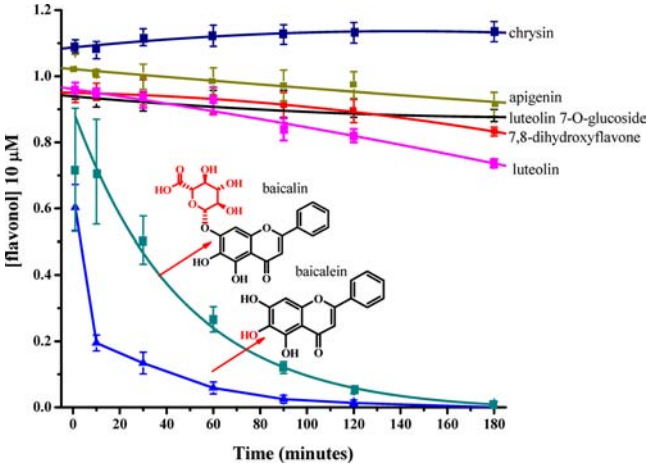

Figure 5. Stability of flavones (initial concentration 10 μM) in DMEM incubated at 37 °C in 5% CO_2. These results are the mean of three independently performed experiments.

and apigenin (4′-OH in ring B) were very stable during 3 h incubation in DMEM ($^{10}T_{10}$ > 180 min and $^{10}T_{50}$ > 180 min). Compared with chrysin and apigenin, luteolin (3′,4′-OH on ring B) showed a slightly lower stability (T_{10} = 56.35 min and T_{50} > 180 min). The general pattern of flavone stability was determined as chrysin > apigenin > luteolin. Apparently, the hydroxylation on ring B of flavones would slightly increase the stability.

2. Hydroxylation in Ring A. Baicalein (5,6,7-OH) ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$ = 3.04 min) showed significantly lower stability than chrysin (5,7-OH) ($^{10}T_{10}$ > 180 min and T_{50} > 180 min) and 7,8-dihydroxyflavone (7,8-OH) ($^{10}T_{10}$ = 104.1 min and $^{10}T_{50}$ > 180 min, Figure 5), which suggested that the hydroxylation in ring A of flavones decreased the stability of flavones. The influence of various substitutions in ring A on the stability of flavones was determined as resorcinol-type (chrysin) > catechol-type (7,8-dihydroxyflavone) > pyrogallol-type (baicalein).

3. Hydroxylation in Ring C (C-3 Position). Galangin (5,7-dihydroxyflavonol) and chrysin (5,7-dihydroxyflavone) without any hydroxyl groups at ring B were all very stable in DMEM ($^{10}T_{10}$ > 180 min and T_{50} > 180 min). Compared to flavonols with hydroxyl groups on ring B [kaempferol ($^{10}T_{10}$ = 46.68 min and $^{10}T_{50}$ =119.47 min), and quercetin ($^{10}T_{10}$ = 4.66 min and $^{10}T_{50}$ =17.96 min)], flavones [apigenin ($^{10}T_{10}$ > 180 min and $^{10}T_{50}$ > 180 min), and luteolin ($^{10}T_{10}$ = 56.35 and $^{10}T_{50}$ > 180)] were found to be more stable during 3 h incubation in DMEM (Table 1 and Figures 1 and 5). Obviously, a hydroxylation in the ring C (C-3 position) of flavones with hydroxyl groups on ring B reduced their stability.

Glycosylation. The sugar moieties are in C-7 or C-8 position of ring A (Table 1). Luteolin 7-*O*-glucoside obviously exhibited higher stability than luteolin. Baicalin ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$ = 27.31 min) also showed a higher stability than baicalein ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$= 3.04 min). Even a glycoside attached at the C-7 positon of baicalein was still instable and entirely decomposed after 3 h incubation in DMEM.

Isoflavones. All the isoflavones tested were very stable during 3 h incubation in DMEM ($^{10}T_{10}$ > 180 min and $^{10}T_{50}$ > 180 min), which might be due to their few hydroxyl groups in the rings A and B. The concentrations of isoflavones after 3 h incubated in DMEM (initial concentration 10 μM) (Table 1) were determined as biochanin A (10.81 ± 0.22 μM) > genistein (10.30 ± 0.26 μM) > daidzein (10.28 ± 0.16 μM) > puerarin (10.04 ± 0.13 μM) > formononetin (9.92 ± 0.14 μM) > genistin (9.67 ± 0.10 μM) > formononetin 7-*O*-glucoside (9.11 ± 0.13 μM) > daidzin (9.01 ± 0.02 μM).

Hydrogenation of the C_2=C_3 Double Bond. Naringenin, naringin, narirutin, hesperetin, hesperidin, liquiritigenin, and liquiritin were stable during 3 h incubation in DMEM ($^{10}T_{10}$ > 180 min and $^{10}T_{50}$ > 180 min; Table 1). In contrast, dihydromyricetin was degraded during the incubation period ($^{10}T_{10}$ < 1.0 min and $^{10}T_{50}$ = 1.91 min). Compared with the flavonoid apigenin, the flavanoid naringenin displayed a slightly higher stability ($^{10}T_{10}$ > 180 min and $^{10}T_{50}$ > 180 min). However, dihydromyricetin was very instable ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$ = 1.91 min) with more than 90% being decomposed within 10 min incubation. However, dihydromyricetin was more stable than myricetin ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$ < 1 min).

Catechins. Catechins are the major polyphenols in green tea leaves. The major catechins of green tea extract are C, EC, EGC, EGCG, EGC, and GCG. The order of stability of catechins was determined as ECG> EC > EGCG> GCG > EGC ≈ C (Figure 6 and Table 1). EGC and C were extremely instable and completely decomposed within 1 min. EGCG and GCG revealed significant instability within 10 min. The initial concentrations (10 μM) of catechins decreased within 10 min: ECG (9.8 ± 1.1 μM) > EC (9.6 ± 0.1 μM) > EGCG (2.1 ± 0.3 μM) > GCG (0.76 ± 0.8 μM) > EGC = C (0) (Figure 7). Apparently, the pyrogallol-type catechins showed lower stability than the catechol-type catechins. The galloylation of catechins obviously improved their stability. However, specific to various substitutions on ring B, the degree of influence was quite different. For the pyrogallol-type catechins, a galloylation

DOI: 10.1021/jf505514d

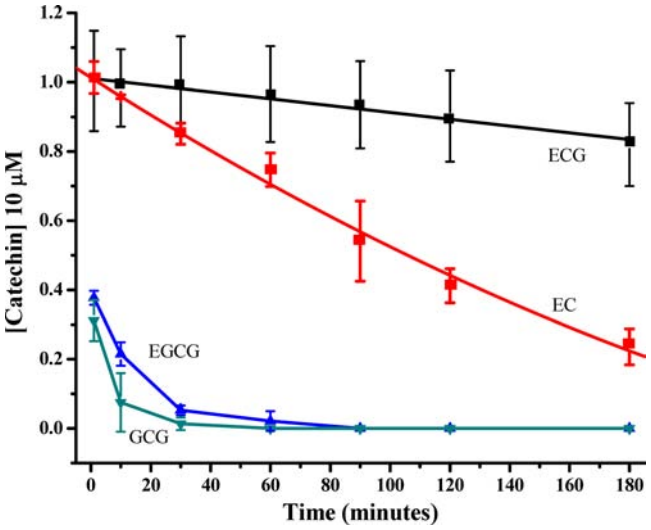

Figure 6. Stability of catechins (initial concentration 10 μM) in DMEM incubated at 37 °C in 5% CO_2. These results are the mean of three independently performed experiments.

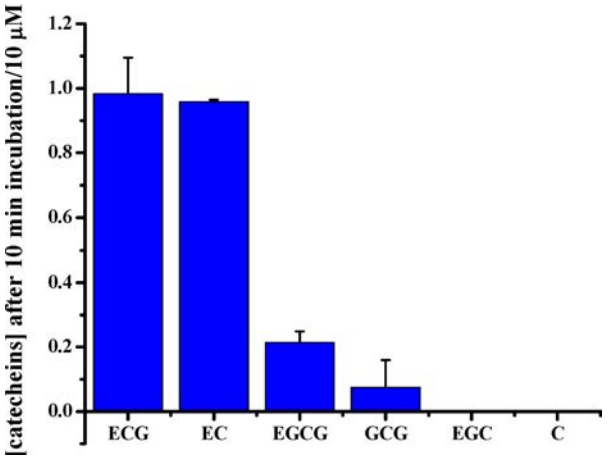

Figure 7. Concentration of catechins after 10 min incubated in DMEM. These results are the mean of three independently performed experiments.

significantly enhanced the stability. For catechol-type catechins, a galloylation only slightly increased the stability. Moreover, the catechins with 2,3-*cis* structure exhibited higher stability than the catechins with 2,3-*trans* structure.

Stilbenoids. A hydroxylation, glycosylation, and methylation of resveratrol significantly influenced the stability of its derivatives isorhapontigenin, oxyresveratrol, pinostilbene, pterostilbene, and piceid (Table 1, Figure 8). Compared with resveratrol (3,5,4′-OH) ($^{10}T_{10}$ = 165.92 min and $^{10}T_{50}$ > 180 min), piceatannol (3,5,4′,5′-OH) ($^{10}T_{10}$ = 5.68 min and $^{10}T_{50}$= 22.51 min) and oxyresveratrol (3,5,4′,6′−OH) ($^{10}T_{10}$ = 11.57 min and $^{10}T_{50}$= 59.12 min) with an additional hydroxyl group on ring B were instable during the 3 h incubation. The stability of resorcinol-type stilbenoids was higher than that of catechol-type stilbenoids. The 5′-methoxylation of piceatannol to isorhapontigenin (3,5,4′-OH,5′-OCH_3) ($^{10}T_{10}$ = 81.14 min and $^{10}T_{50}$ > 180 min) clearly improved the stability. The methoxylation on ring A of resveratrol to pinostilbene (3,4′-OH,5-OCH_3) ($^{10}T_{10}$ > 180 min and T_{50} > 180 min) and pterostilbene (4′-OH,3,5-OCH_3) ($^{10}T_{10}$ > 180 min and $^{10}T_{50}$ > 180 min) slightly enhanced the stability. Piceid (3, 4′-OH,5-O-glucoside) ($^{10}T_{10}$ > 180 min and $^{10}T_{50}$ > 180 min) was the most stable compound among stilbenoids tested: it was more stable than resveratrol (3,5,4′-OH). The concentrations of stilbenoids after 3 h incubated in DMEM (initial concentration 10 μM) (Figure 9) were determined as piceid (10.8 ± 0.6 μM) > pterostilbene (10.7 ± 0.9 μM) > pinostilbene (10.4 ± 0.04 μM) > resveratrol (8.7 ± 0.09 μM) > isorhapontigenin (7.9 ± 0.2 μM) > oxyresveratrol (1.8 ± 0.22 μM) > piceatannol (0). It was concluded that the glycosylation and methoxylation of OH moiety on stilbenoids would enhance the stability and the hydroxylation of stilbenoids decreases the stability.

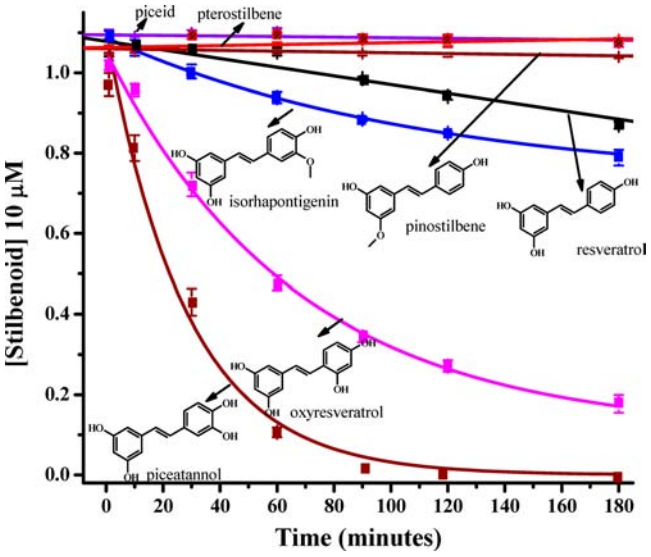

Figure 8. Stability of stilbenoids (initial concentration 10 μM) in DMEM incubated at 37 °C in 5% CO_2. These results are the mean of three independently performed experiments.

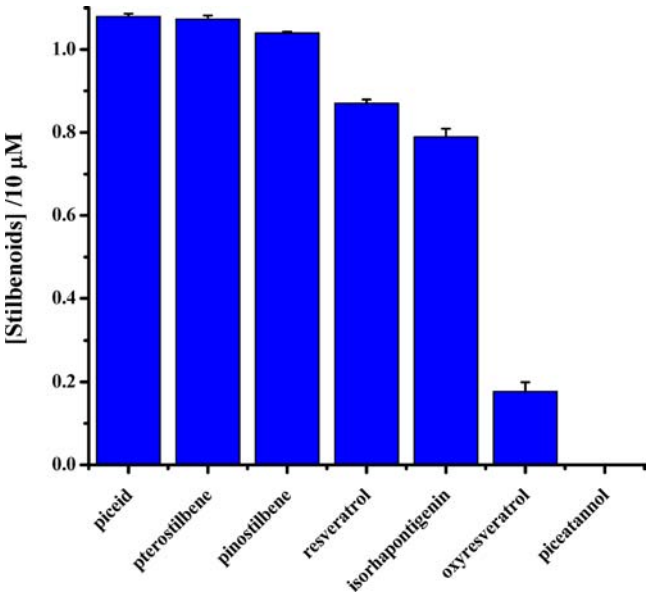

Figure 9. Concentration of stilbenoids after 3 h incubated in DMEM at 37 °C in 5% CO_2. These results are the mean of three independently performed experiments.

Correlation of the Stability with the Antioxidant Potential of the Compounds. The correlation between the stability and the antioxidant properties of polyphenols was

DOI: 10.1021/jf505514d
J. Agric. Food Chem. 2015, 63, 1547−1557

analyzed using published data of the antioxidant potential.[23] There was a weak linear relationship between the stability and antioxidant potential (Figure 10, $R^2(^{10}T_{10})$=0.5399, $R^2(^{10}T_{50})$=0.6336). For example, the TEAC values (ABTS) of flavonols were determined as quercetin > kaempferol > myricetin > galangin,[23] which is different from the following order of stability: galangin > kaempferol > quercetin > myricetin. Rutin ($TEAC_{ABTS}$ = 2.02 mM; $TEAC_{DPPH}$ = 2.33 mM) showed much higher antioxidant potential than baicalin ($TEAC_{ABTS}$ = 1.55 mM; $TEAC_{DPPH}$ = 1.79 mM).[23] However, rutin ($^{10}T_{10}$ > 180 min and $^{10}T_{50}$ > 180 min) was much more stable than baicalin under the cell culture conditions.

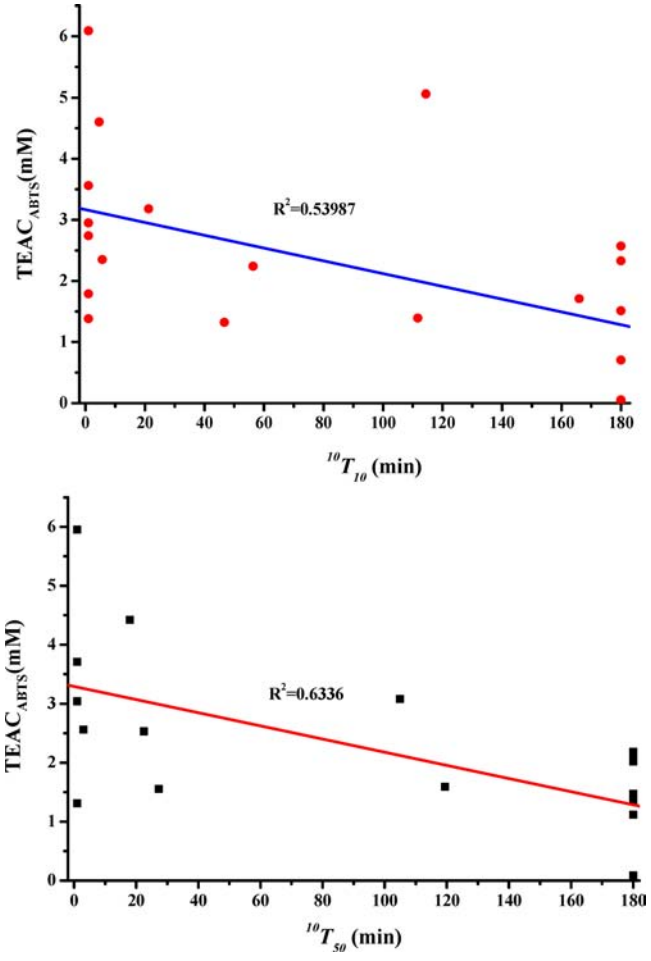

Figure 10. Correlation between the stability of polyphenols in DMEM and their antioxidant properties. The data of the antioxidant potential of polyphenols are expressed as TEAC values (mM) based on the ABTS assay and DPPH assay.[23]

Stability of Flavonols in Human Plasma. The stablility of flavonols such as myricetin, myricitrin, quercetin, and kaempferol, which were particularly instable under the cell culture conditions, was further investigated. It was found that myricetin was still highly instable in human plasma; however, myricetin revealed increased stability in human plasma as compared to DMEM. After incubation with DMEM at 37 °C for 10 min, there was no more myricetin detectable (Figure 1), but when incubated with human plasma at 37 °C for 180 min, myricetin was still present (Figure 11). The stability of myricitrin, quercetin, and kaempferol (initial concentration 10 μM) in human plasma at 37 °C was determined as $^{10}T_{50}$ > 180 min. The $^{10}T_{50}$ values of myricitrin, quercetin, and kaempferol (initial concentration 10 μM) in DMEM at 37 °C were determined as 119.47, 17.96, and 63.95 min (Table 1).

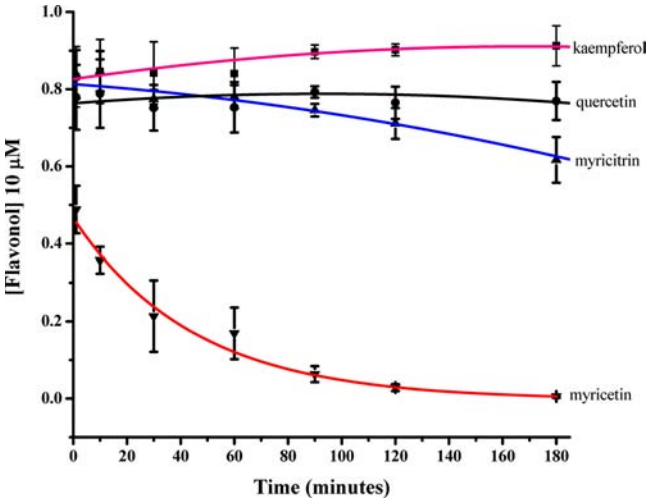

Figure 11. Stability of flavonols (initial concentration 10 μM) in human plasma incubated at 37 °C in 5% CO_2. These results are the mean of three independently performed experiments.

Protein Concentrations in DMEM and Human Plasma. The protein concentration in DMEM supplemented with 10% FBS was determined as 0.41 g/L; the total protein concentration in human plasma was 61.7 g/L.

DISCUSSION

Numerous researchers in biological and medicinal areas use cell cultures for their experiments, which provide information on cell proliferation and apoptosis, cell signaling, and regulation of gene expression and protein synthesis under controlled and reproducible conditions.[24] However, when working with polyphenols it must be taken into consideration that these compounds might not be stable under the cell culture conditions and that artifacts might arise.[24] The results of our study revealed that the factors influencing the stability of polyphenol in cell culture medium include the initial concentration of polyphenol, temperature, the presence and concentration of proteins, and the pH value. In contrast, the polyphenols' stability in organic solvents depends mainly on their initial concentration and the temperature. Thus, the stability of polyphenols in cell culture medium differs from that in organic solvents.

Several groups have investigated the stability of selected tea catchins under the cell culture conditions.[15,25] However, the structure−stability relationship of dietary polyphenols has not been systematically and comprehensively investigated for the main groups of polyphenols and their major representatives. The present study revealed a systematic influence of the chemical stucture of polyphenols on their stability under the cell culture conditions (Figure 12). We defined and used for the first time an early degradation ($^{C}T_{10}$) and a half degradation time ($^{C}T_{50}$) to characterize and compare the stability of the individual compounds. It was concluded that polyphenols with divergent structure significantly differed regarding their stability in cell culture medium. The stability of flavonoids was mainly correlated with structural motifs of the molecules, which also frequently affect their reactivity and bioactivity in a variety of physiological processes.[26] Important structural motifs were

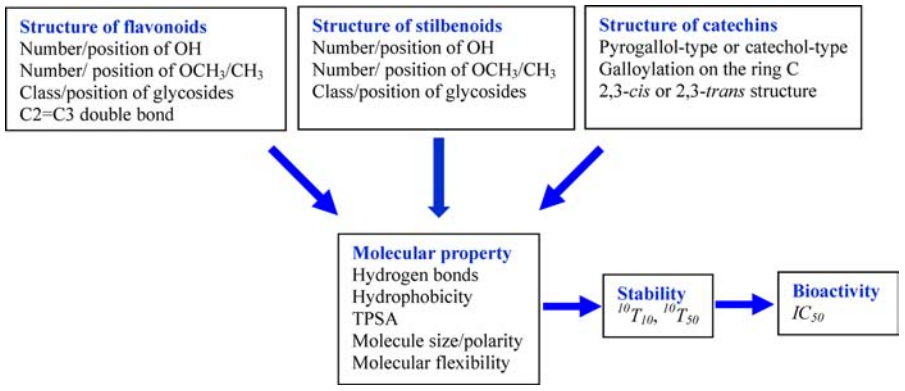

Figure 12. Structural and molecular properties of polyphenols that influence the stability of polyphenols.

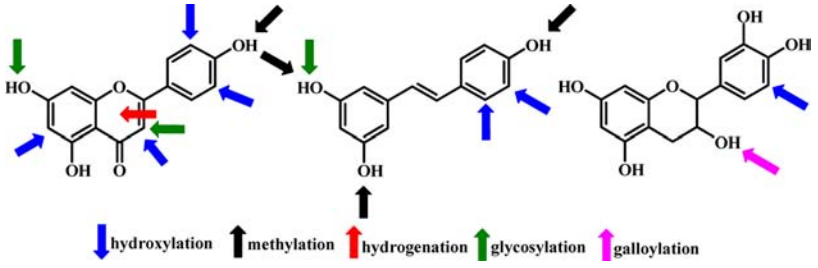

Figure 13. Potential sites of polyphenols affecting the stability are schematically illustrated. The up arrows represent increasing the stability; the down arrows represent decreasing the stability.

determined as follows (1) for flavonoids: (a) the number and position of the hydroxyl groups on the rings A, B, and C; (b) the methoxyl or methyl groups in the rings A and B; (c) the class and position of the glycosides; (d) the degree of saturation of the ring C (the presence or absence of a C_2=C_3 double bond). Motifs follow (2) for silbenoids: (a) the number and position of the hydroxyl and methoxyl moieties on the rings A and B; (b) the class and position of the glycosides. Motifs follow (3) for catechins: pyrogallol-type or catechol-type for ring B; (b) galloylation on the ring C; (c) 2,3-*cis* or 2,3-*trans* structure.

The structure−stability relationships of polyphenols determined under the cell culture conditions were summarized (Figure 13). Hydroxylation on flavonoids usually weakened the stability. The hydroxyl substitutions on the nucleus rings of flavonoids influencing the stability were determined as resorcinol-type > catechol-type > pyrogallol-type. Maini et al. investigated the UVA-light and aqueous stability of galangin, kaempferol, quercetin, and myricetin and analyzed the stability of these flavonols in DMEM at room temperature (25 °C).[27] They also observed a lower stability of these compounds under the cell culture conditions compared to in aqueous solution. As expected, the temperature is also an important factor affecting the stability. The lower stability of catechol-type and pyrogallol-type flavonols is likely due to more hydrogen-bond donating hydroxyl groups and the formation of an ortho-quinone on ring B, which favors the formation of a critical carbocation intermediate on ring C during the oxidative decomposition.[28,29] The hydroxyl group at C-5 position can form a hydrogen bond with the carbonyl group at C-5 position, which may enhance the stability. However, hydroxylation on ring A of flavonols is not the key factor influencing the stability.

Natural dietary flavonols are found mainly as 3- and 7-*O*-glycosides, and the plant flavones are mainly found as 4′- and 7-*O*-glycosides.[5,30,31] Even though the effect of glycosylation on the stability of flavonoids has been discussed previously,[32] there is limited information on the stability of flavonoid *O*-glycosides in DMEM. Herein, the influence of glycosylation of dietary flavonols and flavones on the stability in DMEM medium was investigated. *C* or *O*-Glycosylation of flavonoids obviously enhanced the stability. It was reported that *C*-glycosylated flavonoids are more stable in comparison with aglycones or *O*-glycosylated flavonoids.[33] However, we found that apigenin *C*- and *O*-glycosides were very stable during 3 h incubation in DMEM (T_{10} > 180 min and T_{50} > 180 min), which were similar to the aglycone. It has been reported that the glycosylation of flavonoids decreases antioxidant activity,[34] and this negative effect may result from the properties of sugar itself, rather than from the loss of a free hydroxyl group.[35] Plumb et al. have also reported that antioxidant capacities of flavonol glycosides present in tea decrease as the number of glycosidic moieties increased.[36] Moreover, the glycosylation is not the crucial factor deciding the stability of flavones and flavonols, which depends on the substitutions on the nucleus rings of flavonoids.

In the present study it was found that the hydrogenation of the C2=C3 double bond of flavonoids to corresponding flavanoids increased the stability. However, along with disparate substitutions on the nucleus rings, the degree of influence is not identical. Planarity of the C ring in flavonoids maybe important for the stability, as the molecules with saturated C2—C3 bonds (flavanones and certain others) permit more twisting of ring B with reference to ring C. A C2=C3 double bond increases the delocalization of π-electrons across those conjugated systems and the *p*-conjugation of the bond linking the rings B and C, which favors near-planarity of the two rings.[37]

Stilbenoids are phytoalexins become activated when plants are stressed and are important polyphenols with the C_6−C_2−C_6 structure.[38] The typical natural stilbenoids are resveratrol and its 3-glucoside, piceid.[39] We found that the glycosylation and methoxylation of stilbenoids enhanced the stability, and the

DOI: 10.1021/jf505514d
J. Agric. Food Chem. 2015, 63, 1547−1557

hydroxylation of stilbenoids decreased the stability. Long et al. found that pyrogallol-type compounds decompose in cell culture media to generate significant amounts of H_2O_2.[40] 3,4,5,4′-Tetrahydroxystilbene and 3,3′,4,4′,5,5′-trihydroxystilbene, but not resveratrol, generate measurable amounts of H_2O_2 when incubated in DMEM at a concentration of 50 μM.[41]

Some polyphenols displayed instability in cell culture medium. It has been reported that reactive oxygen species are formed under most cell culture conditions.[14] For example, EGCG has been shown to be instable and subject to oxidation and polymerization, resulting in the formation of reactive oxygen species.[14,15] It appears that also different cell culture media might have a different influence on the stability of polyphenols. In the present study, it was found that EGCG (initial concentration 10 μM) was very instable in DMEM without cells ($^{10}T_{10}$ < 1 min and $^{10}T_{50}$ < 1 min). It was reported that in McCoy's 5A culture media, the $^{25}T_{50}$ of EGCG (initial concentration 10 μM) was less than 30 min; surprisingly, the stability was prolonged to 130 min in the presence of HT-29 cells.[15] In contrast, it was reported that quercetin (initial concentration 25 μM) was very instable when incubated with DMEM in the presence of HT29 cells ($^{25}T_{50}$ = 30 min).[42] In the present study, the $^{10}T_{50}$ of quercetin (initial concentration 10 μM) was 17.96 min with DMEM in the absence of cells, which is not consistent with the notion that cells enhance the stability of quercetin. It needs further investigations to clarify the stability of polyphenols in the presence of cells. Generally, it seems possible that various cellular enzymes compromise the compounds' stability via degradation or metabolism. On the other side, adsorption of polyphenols to cellular proteins might enhance the stability of the compounds. Such a stabilizing effect has been described for polpyphenols attached to plasma proteins.[43,44]

Several factors, such as pH, proteins, antioxidant levels, and the presence of metal ions, might influence the stability of polyphenols, and pH is possibly the most critical determinant.[15,45] In DMEM, quercetin was shown to be very stable at pH of 6 and decomposed under pH of 7 and 8.[45] Other constituents in DMEM obviously also influenced its stability because quercetin was reported to be more stable in H_2O than in DMEM. However, most supplements for cell culture media, such as HEPES, glucose, sodium pyruvate, antibiotics, and FBS, had a neglible influence on the stability of quercetin.[45] Yet, it is not clear for how these factors influence other polyphenols.

Kosińska et al. investigated the stability of polyphenol extracts from cocoa, green tea, and strawberries in HBSS buffer.[46] They found that most of the polyphenols decomposed during 2 h of incubation. EGCG and EGC were very vulnerable in HBSS both at pH 6.5 and 7.4; their specific molecular structure was discussed to be responsible for this phenomenon.[46] The flavan-3-ols from cocoa were more stable at pH 6.5 than at pH 7.4. The major oxidative products of EGCG in McCoy's 5A culture media were theasinensin and its dimer.[15] However, the mechanism should be further elucidated. Autooxidation was observed for EGCG in air-saturated Tris buffer, which may generate $\bullet O_2^-$ and quinones to form H_2O_2.[47] It was reported that the stability of EGCG was significantly enhanced in the presence of SOD in the cell culture medium, which prolonged the T_{50} of EGCG to 24 h. The presence of 5% serum in the medium also prolonged the T_{50} of EGCG to 1 h.[47]

On the basis of many previous and recent findings,[48−52] it appears that favorable structures required for radical scavenging of polyphenols follow these requirements: (a) the *o*-dihydroxyl (3′,4′-diOH, i.e., catechol) structure in the B-ring, (b) the C_2−C_3 double bond (in conjugation with the 4-oxo group), (c) the presence of both 3-OH and 5-OH groups for the maximal radical scavenging capacity and the strongest radical absorption. (d) In the absence of *o*-dihydroxyl structure in the B ring, the hydroxyl substituents in a catechol structure on the A ring are able to compensate and become a larger determinant of flavonoid antiradical activity. These summarized structural features are partially similar to the partial structures that make the molecule more prone to instability under the cell culture conditions.

It was obvious to speculate that the polyphenols' degree of stability in cell culture medium merely reflected their antioxidant properties. However, in the present study it was found that there was no strong correlation between the antioxidant potential of polyphenols and their stability. Consequently, it can be assumed that oxidation processes are not the only factor governing the stability of polyphenols in biological systems. Other influences such as polyphenol−protein interactions or complex formation might play an important role, too. It has been reported that binding to human plasma proteins improved the polyphenols' stability and protected against oxidation.[43] Our results are consistent with that observation. We found that polyphenols revealed a higher stability in human plasma as compared to DMEM. The protein concentration determined in human plasma was 150-fold higher than in DMEM which suggested that the adsorption of polyphenols to plasma proteins contributed to their enhanced stability in this matrix. The degree of plasma protein binding has been shown to be highly variable among individual polyphenolic compounds,[44] and it needs to be investigated how strong the extent of protein binding correlates with the compounds' stability in plasma or cell culture medium.

At this point, it is not clear whether similar degraded or oxidized polyphenol products can be found in human plasma and cell culture medium. The compounds may exhibit different degradation or oxidation patterns, which might also help explaining the different results from cell experiments *in vitro* and animal/human experiments *in vivo*.[53] It also has to be considered that the degraded or metabolized polyphenol might exhibit a bioactivity which might be different from the parent compound.[21] In 2010, D'Archivio et al. criticized that a large number of *in vitro* studies tested polyphenols rather than their active metabolites.[54] So, we might be looking at the wrong compounds when investigating the mechanisms contributing to the health benefits of polyphenols. Recently, it was shown that metabolites of resveratrol (resveratrol 3-*O*-sulfate, resveratrol 3-*O*-glucuronide, and resveratrol 4′-*O*-glucuronide) inhibited human colon carcinoma and metastatic cell proliferation through an accumulation of cells in DNA replication phase and by inducing DNA damage.[55] Further investigations should clarify the precise mechanisms of degradation of polyphenols in cell culture medium and plasma and take the bioactivity of the resulting derivatives into consideration. In the case that an individual polyphenol displays pronounced instability in cell culture medium while exerting significant cellular effects, it should be considered that not the mother compound but a degradation product or metabolite is the actual bioactive principle.[56,57] Further isolation and identification of the final degraded products is necessary to explore the mechanism, as well as to investigate the bioactivity of the derivatives and metabolites of polyphenols. To summarize, it is essential to

DOI: 10.1021/jf505514d
J. Agric. Food Chem. 2015, 63, 1547−1557

account for polyphenol stability in cell culture experiments to avoid erroneous conclusions.

In conclusion, the influence of cell culture conditions on the stability and fate of polyphenols is rarely considered, which might result in misleading conclusions about the compound's bioactivity or the active principle. In the current investigation, the structure−stability relationship of polyphenols incubated with the cell culture medium DMEM was comprehensively investigated. Some polyphenols, especially aglycones with catechol or pyrogallol structures and pyrogallol-type glycosides, were evidently instable. The additional hydroxyl moieties attached to ring B of flavonols obviously weakened the compound's stability under the cell culture conditions. The glycosylation of a hydroxyl group of the pyrogallol moiety in flavones slightly enhanced the stability. It appears that the glycosylation of isoflavones decreased and the methoxylation of isoflavones increased their stability. The C2═C3 double bond in conjugation with a 4-oxo group is also considered as an important role for the stability. The hydrogenation of the C2═C3 double bond of flavanoids to corresponding flavonoids increased the stability. We suggest that the stability of polyphenols in a biological system is not solely governed by the oxidation processes, because the degradation tendency of these polyphenols was not highly correlated with their antioxidant potential. Polyphenols were considerably more stable in human plasma as compared to DMEM, which may be based on polyphenol−protein interactions enhancing the compounds' stability.[10] Our results might be used to further investigate the mechanism of degradation or metabolism of polyphenols in cell culture and human plasma, which might stimulate the search for the actual bioactive compounds derived from polyphenols.

Table 1. Enzyme-Mediated PS Synthesis in Various [Ch][AA] ILs

Entry	ILs	Side chain of amino acid	Viscosity (mPa·s)[19]	V_0 (μmol PS/min)	PS yield (%)[a]	Time (h)	PA content[b]
1	[Ch][Gly]		121	0.64	78.1	12	-
2	[Ch][Ala]		163	0.62	76.2	15	-
3	[Ch][Val]		372	0.58	70.9	36	-
4	[Ch][Ser]		402	0.57	73.3	36	-
5	[Ch][Thr]		454	0.56	71.6	36	-
6	[Ch][Leu]		476	0.56	60.4	36	-
7	[Ch][Ile]		480	0.56	57.5	36	-
8	[Ch][Pro]		500	0.45	50.1	42	-
9	[Ch][Phe]		520	0.50	45.2	42	-
10	[Ch][His]		980	0.49	46.7	48	-
11	[Ch][Asp]		2060	0.36	84.3	60	-
12	[Ch][Glu]		2308	0.36	86.5	60	-

[a]Maximum yield. [b]PA was not detected during the sample analysis by HPLC.

0.5% water (based on the total weight of the reaction system). Samples (50 μL) were taken from the reaction mixture at specified time intervals, centrifuged to obtain the upper layer, and analyzed by HPLC.

Analysis of the Samples.[20] The sample was analyzed by a Waters e2695 HPLC system (Waters, Milford, U.S.A.) with an evaporative light scattering detector (ELSD). External standards of PC, PS, and PA were used to prepare calibration solutions at five different concentrations. Two microliter sample and 1 mL hexane−isopropane (1/1, v/v) were precisely measured and mixed thoroughly. Ten microliters of the aforementioned mixture was injected. HPLC separation was on a Lichrospher 100 Diol column (5 μm, 250 mm × 4.6 mm, Merck). Mobile phase A was *n*-hexane/2-propanol/methanol (38:1:1, v/v). Mobile phase B was 2-propanol/methanol (2:3, v/v). Each mobile phase contained 1 mM ammonium acetate. The flow rate was 1.5 mL min^{-1}, and the gradient was as follows: 0−18.7% B from 0 to 20 min, 18.7−100% B from 20 to 20.2 min, 100% B from 20.2 to 25 min, 100−0% B from 25 to 25.1 min, and 0% B from 25.1 to 30 min. The column temperature and drift pipe temperature were controlled at 25 and 65 °C, respectively, and the nitrogen pressure was controlled at 40 psi. The retention times were 2.52, 2.95, and 23.83 min for PA, PS, and PC, respectively. PS yield was calculated from the HPLC data. The average error for this assay is less than 0.5%. All the reported data are averages of experiments performed at least in duplicate.

Operational Stability (Reusability) of PLD in [Ch][Glu]. The operational stabilities of PLD in [Ch][Glu] during batch reactions were evaluated. After each batch reaction, PLD was separated by filtration using Whatman #1 filter paper, washed with isopropyl alcohol three times, and then added into the fresh reaction mixtures for the next batch.

RESULTS AND DISCUSSION

In this work, 12 [Ch][AA] ILs, i.e., [Ch][Gly], [Ch][Ala], [Ch][Val], [Ch][Ser], [Ch][Thr], [Ch][Leu], [Ch][Ile], [Ch][Pro], [Ch][Phe], [Ch][His], [Ch][Asp], and [Ch][Glu], were successfully applied to enzymatic synthesis of PS. Table 1 shows that the prepared ILs had an obvious effect on the enzymatic reaction for PS synthesis. The reaction initial rate (V_0), PS yield, and the reaction time were measured to evaluate the enzymatic reaction.

As can be seen from Table 1, the initial reaction rates were remarkably influenced by the ILs employed. The minimum V_0 (0.36 μmol PS/min) was obtained in [Ch][Asp] and [Ch][Glu], while the maximum V_0 (0.64 μmol PS/min) was achieved when [Ch][Gly] was used as the reaction medium. It is clear that the V_0 values varied with the viscosity of the [Ch][AA] ILs used. Generally, the viscosity is one of the most important factors affecting the applications of the solvent for catalysis. It is well-known that an increase in solvent viscosity can augment the diffusion resistance of substrates, thus enhancing the mass transfer limitations and impairing the interactions between enzyme particles and substrates. Accordingly, the increase in the viscosity of the [Ch][AA] ILs resulted in the decrease of the V_0 value with the exception of [Ch][Pro].

Also, the V_0 values showed a clear dependence on the anion structures of the [Ch][AA] ILs. An increase in the number of carbon atoms in the side chain of amino acid generally resulted in a lower V_0 value (Table 1, entries 1, 2, 3, 6, and 7). Of the ILs tested, [Ch][Gly], with the anion being the simplest amino acid, displayed the highest V_0 value (0.64 μmol PS/min). In addition to the molecular size of the anion, the introduction of extra hydroxyl, phenyl ring, or carboxylic acid group

DOI: 10.1021/jf505296k
J. Agric. Food Chem. 2015, 63, 1558−1561

significantly decreased the V_0 value (Table 1, entries 4, 5, 8−12). In the [Ch][AA] ILs containing hydroxyl group in the side chain of amino acid ([Ch][Ser] and [Ch][Thr]), the V_0 values were slightly lower, while the ILs with aromatic group in the anions displayed relatively lower V_0 values (i.e., 0.45, 0.50, and 0.49 μmol PS/min for [Ch][Pro], [Ch][Phe], and [Ch][His], respectively). Unfortunately, the lowest V_0 values of 0.36 μmol PS/min were recorded for [Ch][Asp] and [Ch][Glu] in which the acidic amino acids served as the anions. A reason for the substantial correlation between V_0 values and the anion structures of the [Ch][AA] ILs may be that the efficiency of the enzyme action during PS synthesis was affected by the solvent used. Particularly, the intermolecular forces of the ILs such as van der Waals, hydrogen bond, and π-stacking interactions might contribute to this effect.

Moreover, the maximal PS yields of the PLD-mediated reaction and the time they consumed in all the [Ch][AA] ILs employed are presented in Table 1 columns 6 and 7, respectively. As can be observed, although the PS yield value in [Ch][Gly] was only 78.1%, the reaction time (12 h) it needed was the shortest. By contrast, the reaction in [Ch][Glu] proceeded slowest but constantly increased up to the highest PS yield value of 86.5% after 60 h. Obviously, the lowest PS yield (45.2%) was found in [Ch][Phe].

In Table 1, we found that the PS yield has no apparent dependence on the viscosity of the [Ch][AA] ILs used. Similarly, it was shown that the PS yields showed a close correlation to the anion structures of the [Ch][AA] ILs as well. When the side chain of amino acid was alkyl group, elongation of the side chain generally led to lower PS yield (Table 1, entries 1, 2, 3, 6, and 7). The [Ch][AA] ILs containing basic amino acids as the anions displayed relatively lower PS yields, i.e., 73% and 71% for [Ch][Ser] and [Ch][Thr], respectively. The introduction of an additional carboxylic acid group to the side chain of the amino acid substantially increased the PS yields (Table 1, entries 12 and 13). Higher PS yields of 84% and 86% were exhibited in [Ch][Asp] and [Ch][Glu], respectively. To be noted was that the introduction of a phenyl ring exerted drastic effect on the PS yields (Table 1, entries 8−10). The PS yields obtained in three [Ch][AA] ILs with aromatic group were much lower. In particular, the lowest PS yield (45%) was found in [Ch][Phe]. As we all know, the maximal PS yield value was attributable to the thermodynamic equilibrium of the enzymatic transphosphatidylation of PC with L-serine for PS synthesis. Consequently, as far as the dependence of PS yield on the [Ch][AA] ILs was concerned, a speculative explanation could be that the thermodynamic equilibrium of the enzyme-mediated reaction may be affected by the ILs used. Furthermore, the [Ch][AA] ILs effects on the thermodynamic equilibrium of the reaction may be due to their specific structures, especially the anions structures.

From a practical viewpoint, the reusability of the biocatalyst is one of essential factors for the cost-efficiency. If the biocatalyst can be reused, the economical sustainability is increased. Encouraged by the excellent experiment results above, the operational stability of PLD in [Ch][Glu] was investigated to further examine the potential of the enzyme as a catalyst for PS production. After each batch reaction, the enzyme was recovered by filtration, and the next batch was carried out with fresh substrates. Figure 1 presents the plot of the activity of the enzyme as a function of the number of reaction batches. Batch 0 corresponds to the activity of the fresh enzyme employed in the first reaction trial which was taken as 100%. It was worth noting that PLD displayed excellent operational stability, and 75% of its original activity was maintained after being used for 10 batches, highlighting the presumable cost-effectiveness of the enzyme.

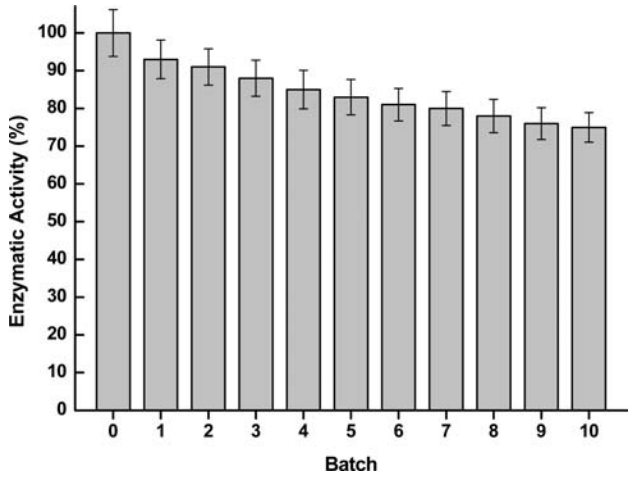

Figure 1. Operational stability of PLD in [Ch][Glu]. Reaction conditions: 3.0 mL of [Ch][Glu], 0.05 mmol PC, 0.15 mmol L-serine, 60 U PLD, 0.5% water (based on the total weight of the reaction system), 40 °C.

In general, the whole synthesis process for PS is highlighted by the application of eco-friendly solvents [Ch][AA] ILs as the reaction media. An efficient, cost-effective, and easy-to-use "green chemistry" method for the enzymatic PS preparation was provided. Additionally, the excellent results make the biobased ionic liquids promising candidates for use as environmentally friendly solvents in biocatalysis applications.
