Table 1. Different Methods of Detection Pyrethroids

methodology	detection limit	detection rate (%)	advantages	disadvantages
this method	9.17−60 nM L^{-1}	61.4−106.2	high sensitivity, simplicity, speed, convenience, efficiency	immaturity, boundedness
Huang et al.[15]	2.1−6.9 ng kg^{-1}	73.4−120.1	accuracy, high sensitivity	multistep, time-consuming, expensive instruments
Deme et al.[16]	0.01−1 μg kg^{-1}	62−110	accuracy, high sensitivity	multistep, complexity, time-consuming, expensive instruments,
Esteve-Turrillas et al.[17]	0.08−5.4 μg kg^{-1}	84−120	accuracy, high sensitivity	multistep, complexity, time-consuming, expensive instruments
Ma and Chen[34]	3.5 ng kg^{-1}	82.4−101.7	accuracy, high sensitivity	multistep, complexity, time-consuming, inaccuracy
Song et al.[37]	5−10 μM L^{-1}	97.8−103.5	convenience, efficiency, simplicity	time-consuming, boundedness, complexity, immaturity

pyrethroids from soil with microwave-aided extraction (MAE) methodology. Although such methods are quite accurate, they depend on multistep sample cleanup procedures and result in relatively expensive and time-consuming processes. Thus, the exploitation of novel functional materials for the simple, rapid, and highly sensitive detection of trace pyrethroid insecticides remains a challenge, especially in complicated sample matrices.

A promising way to achieve the tailored selective detection of analytes is to use molecularly imprinted polymers (MIPs). Because the MIPs can be easily prepared with low cost, in addition to their greater stability, the molecularly imprinted materials will attract more and more people.[18−24] In our research group, Pan and co-workers have synthesized molecularly imprinted polymers based on magnetic halloysite nanotube composites with selective recognition of 2,4,6-trichlorophenol.[25] Xu and co-workers synthesized thermally responsive magnetic molecularly imprinted polymers for selective removal of antibiotics from aqueous solution.[26] Obviously, compared with the traditional separation−enrichment method, MIPs with selective recognition ability can separate the target molecule conveniently and effectively, excluding the influence of any other structural analogues. Moreover, the method to prepare MIPs is simple. Also, MIPs, with good reproducibility, can be stored easily.[27−29] The excellent performance of molecularly imprinted polymers allows them to be widely used in many fields.[30−32] Shi et al.[33] concentrated pyrethroid selectivity from aquaculture water with molecularly imprinted solid phase extraction methodology and detected pyrethroid with GC. Ma and Chen[34] prepared a magnetic surface molecularly imprinted polymer based on carbon nanotube, which adsorbed LC selectively. However, as to the level of molecular imprinting technique, it is still a challenge for us to find a more convenient and effective way to detect pyrethroid pesticide residues in the environment.

The fluorescence detection method is efficient, simple, and sensitive. It has great potential in the field of analyzing samples quickly. Compared with HPLC, it has advantages in solvent consumption, sample pretreatment, and test time. We can design an experiment to adapt the molecular imprinting technology to fluorescence detection, to take advantage of the recognition and capture ability of MIPs to make target molecules be adsorbed on MIPs selectively, in order that they can be separated with interfering substances, and then the fluorescence analyzer can be used to detect fluorescence. For the reason that it contains fluorescent nanomaterials during the synthesizing process of molecularly imprinted polymerization, the fluorescence intensity will quench after the reaction of target molecules and MIPs.[35] Zhao et al. have synthesized composite quantum dots molecularly imprinted polymer (QDs@MIP) nanospheres for specific recognition and direct fluorescent quantification of pesticides in aqueous media.[36] Song et al.[37] prepared porous silica fluorescent nanospheres recognizing LC in aqueous media efficiently. We make the comparison of this method and other methods in Table 1. As shown in the table, the method of detection of LC has some advantages compared with the others. This method not only has the advantages of high sensitivity, simplicity, efficiency, speed, and convenience but also could deal with complex samples. The interference of coexisting substance in specimen material can be eliminated by this coupling technology, and the selectivity of molecular imprinting can be combined with the high sensitivity of fluorescence detection. As a result, we get a new detection and analysis method.

In this study, fluorescent molecularly imprinted polymers (SiO_2@FITC-APTS@MIPs) were proposed for the analysis of LC based on the LC-resulted fluorescence quenching of the fluorescent dye anchored on the MIP polymer, which was covalently coated on the surface of SiO_2 via a surface molecular imprinting process. We chose Chinese spirit as a practical sample, a kind of distilling liquor unique to China. Chinese spirit is a popular drink in China for its special aroma. The main raw material of Chinese spirit is grain. However, pyrethroid is a kind of broad-spectrum insecticide for these agricultural products. Therefore, not only can the Chinese spirit as a sample reveal the detection levels of SiO_2@FITC-APTS@MIPs in complex samples but also the SiO_2@FITC-APTS@MIPs can be a steppingstone to detect additional practical samples in the future. On the whole, through the experiment of the fluorescence detection of LC in Chinese spirits, we can see that the SiO_2@FITC-APTS@MIPs have a broad prospect in the food safety analysis field.

EXPERIMENTAL PROCEDURES

Materials. Tetraethyl orthosilicate (TEOS, AR), divinylbenzene (DVB, AR), and fluorescein 5(6)-isothiocyanate (FITC, AR) were all purchased from Aladdin Reagent Co., Ltd. (Shanghai, China). 3-Aminopropyltriethoxysilane (APTS, AR) was purchased from Energy Chemical (Shanghai, China). Acrylamide (AM, AR), acetonitrile, and ammonium hydroxide were all purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). 2,2′-Azobis(isobutyronitrile) (AIBN, AR) was obtained from Tianjin Guangfu Fine Chemical Research Institute (Tianjin, China). All of the pyrethroid pesticides, LC, β-cyfluthrin (BC), esfenvalerate (FE), and bifenthrin (BI), were obtained from Yingtianyi Standard Sample Co. (Beijing, China), and the corresponding chemical structures of the pyrethroids are displayed in Figure 5. Doubly distilled water was used for cleaning processes.

Instrument. Infrared spectra (4000−400 cm^{-1}) were recorded on a Nicolet NEXUS-470 FT-IR apparatus (USA). The morphologies of SiO_2@FITC-APTS@MIPs/SiO_2@FITC-APTS@NIPs were observed by a scanning electron microscope (SEM, JEOL, JSM-7001F) and a

transmission electron microscope (TEM, JEOL, JEM-2100). Fluorescence intensity was measured by using a Cary Eclipse fluorescence spectrophotometer (Varian, USA). UV−vis adsorption spectra were obtained with a UV−vis spectrophotometer (UV-2450, Shimadzu, Japan). Laser confocal microscopy images of SiO_2@FITC-APTS@MIPs samples were observed using a TCS SP5 II confocal microscope (Leica, Germany) with a 488 nm solid state laser light source. Transient fluorescence spectra were measured on a QuantaMaster 40 spectrofluorometer (Photon Technology International, USA). TGA of the samples was performed for powder samples (about 10 mg) using a Diamond TG/DTA instruments (PerkinElmer, USA) under a nitrogen atmosphere up to 1000 °C with a heating rate of 10 °C min^{-1}.

Preparation of SiO_2 and SiO_2@FITC-APTS. Silica has been widely used as substrate material due to its chemical stability and the property of easy modification.[38] First, SiO_2 beads were prepared according to the stöver process.[39,40] Typically, 2.0 mL of $NH_3{\cdot}H_2O$ was dissolved in 25 mL of ethanol and 25 mL of double-distilled water in a 100 mL round-bottom flask by sonication for 15 min. Then, 2.0 mL of TEOS was slowly added into the flask sequentially. The mixture was allowed to react for 24 h at room temperature under a continuous stirring of 1000 rpm. The resulting product was separated from the solvent by centrifuge and washed rotationally by ethanol and double-distilled water several times.

Typically, 40 mg of FITC was dissolved in 2.0 mL of APTS in a 10 mL test tube for 48 h in darkness at room temperature under continuous stirring of 800 rpm first. The reaction formula is shown in Figure S1 in the Supporting Information. After the reaction for 24 h, we obtained a FITC-APTS mixture.[41] Then SiO_2 beads was scattered in 100 mL of ethanol by sonication in a 250 mL brown round-bottom flask, and 5.0 mL of $NH_3{\cdot}H_2O$ and 30 mL of double-distilled water were added into the flask. Then the mixture was slowly added into the flask sequentially and allowed to react for 24 h in darkness at room temperature under continuous stirring of 1000 rpm. The resulting SiO_2@FITC-APTS was separated from the solvent by centrifuge and was repeatedly washed.

Synthesis of SiO_2@FITC-APTS@MIPs and SiO_2@FITC-APTS@NIPs. The synthesis of SiO_2@FITC-APTS@MIPs via a multistep precipitation polymerization procedure is illustrated in Figure 1. The first and second steps were narrated in the above. The third step was to prepare the preassemble solution. Typically, LC (0.50 g, 1.0 mmol) and AM (0.2840 g, 4.0 mmol) were dissolved with 20 mL of acetonitrile in a 50 mL beaker under the dark environment for 1.0 h. Then 200 mg of SiO_2@FITC-APTS beads was added into a 250 mL brown round-bottom flask and scattered in 70 mL of acetonitrile by sonication for 1.0 h. After this, the mixture (LC and AM) was poured into the flask, and 0.8 mL of DVB was added into the flask at the same time. The mixture was degassed in an ultrasonic bath for 10 min and sparged with oxygen-free nitrogen for 10 min. Then, the flask was submerged in a thermostatically controlled oil bath, which was in stirring condition, and the stirring rate was 1200 rpm. After the temperature was increased from room temperature to 60 °C within 30 min, free radical initiator AIBN (about 0.02 g) was added into the flask, and then the temperature was maintained at 60 °C for a further 24 h. After the reaction, the SiO_2@FITC-APTS@MIPs beads were collected from the reaction medium by centrifuge, and the product was rinsed several times with ethanol and double-distilled water. After that, the beads were eluted with 100 mL of acetic acid/methanol (10:90, v/v) to remove LC templates by Soxhlet extractor. Finally, after 5 days of elution, the product SiO_2@FITC-APTS@MIPs were obtained, which were dried under vacuum for 12 h at 40 °C. In principle, the methods of preparing SiO_2@FITC-APTS@NIP beads and SiO_2@FITC-APTS@MIPs were the same, the only difference being that the former lacked the LC template.

RESULTS AND DISCUSSION

Characterization of SiO_2@FITC-APTS@MIPs and SiO_2@FITC-APTS@NIPs. The products of SiO_2, SiO_2@FITC-APTS, and SiO_2@FITC-APTS@MIPs were investigated by FT-IR spectroscopy (Supporting Information, Figure S2). SiO_2 (Figure S2a) spheres displayed the characteristic signals of Si−O at 473 and 803 cm^{-1}, and they were attributed to symmetric stretching vibration and bending vibration, respectively. The strong and broad peak around 1103 cm^{-1} indicated Si−O−Si asymmetric stretching. These results suggested that the tetraethyl orthosilicate successfully condensed into silicon dioxide by hydrolysis. Compared with the infrared data of pure SiO_2, the SiO_2@FITC-APTS (Figure S2b) displayed the characteristic peak of amino groups at 1403 cm^{-1}.[42] The presence of bands around 2926 cm^{-1} suggested the aliphatic C−H stretching.[43] These facts showed the presence of amine ligands on the surface of SiO_2. As shown in Figure S2c, para-substituted benzene surface deformation vibration was about 832 cm^{-1}, meta-substituted benzene surface deformation vibration was about 712 cm^{-1}, and 794 and 900 cm^{-1} were the characteristic peaks of divinylbenzene. The characteristic peaks of the benzene ring frame vibration at about 1606 cm^{-1} and C═O stretching vibration of amide at 1683 cm^{-1} indicated that the MIPs layer had been successfully compounded on the surface of SiO_2@FITC-APTS.

To ascertain the synthesizing of materials further, UV−vis spectra of SiO_2@FITC-APTS@MIPs, SiO_2@FITC-APTS, FITC-APTS, APTS, FITC, and SiO_2 were measured as

DOI: 10.1021/jf5043823
J. Agric. Food Chem. 2015, 63, 2392−2399

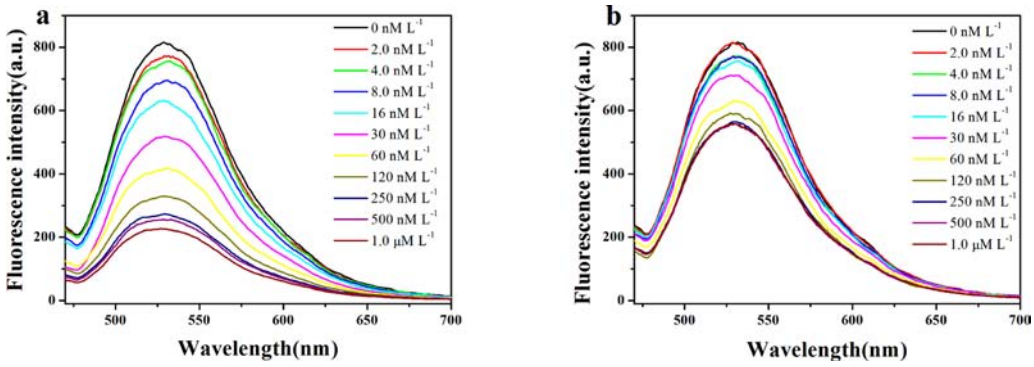

Figure 2. Response of SiO_2@FITC-APTS@MIPs (a) and SiO_2@FITC-APTS@NIPs (b) to LC in the concentration range from 0 to 1.0 μM L^{-1}.

shown in Figure S3 in the Supporting Information. The figure showed that pure SiO_2 (purple) and APTS (green) almost have no visible absorption peaks. The solution of FITC (yellow) displayed two visible absorption peaks at 455 and 485 nm, whereas the FITC−APTS conjugates (blue) showed only one visible absorbance at 502 nm, indicating that a strong interaction occurred between APTS and FITC molecules. In the meantime, the dispersive liquid of SiO_2@FITC-APTS (red) showed nearly a visible absorption peak at 505 nm. The solution of SiO_2@FITC-APTS@MIPs (black) showed a strong absorption peak at 505 nm. From the above phenomenon, we found that the FITC−APTS conjugates, directly and successfully, grafted on the surface of SiO_2 by the means of APTS condensation.

The SiO_2@FITC-APTS@MIPs (black) dispersive liquid displayed the visible absorption peak of dye FITC with the λ_{max} at 506 nm, whereas the pure SiO_2 showed scarcely any visible absorption as indicated in Figure S4 of the Supporting Information. The fluorescence spectra of SiO_2@FITC-APTS@MIPs (blue) dispersive liquid displayed a green fluorescence emission with λ_{max} at 531 nm (excited at 450 nm), which is identical to the emission spectra of the dye FITC.

The size and shape of SiO_2 and SiO_2@FITC-APTS@MIPs were examined by SEM and TEM techniques. The SEM and TEM images of SiO_2 beads are shown in Figure 5a,c. It can be observed that the diameter of pure SiO_2 was about 300 nm. It can be seen that the pure SiO_2 was dispersed fully before polymerization; that is to say, it had the good monodispersity. The size and shape of SiO_2@FITC-APTS@MIPs are shown in Figure 5b,d. After being coated with FITC−APTS and MIPs, the diameter of the SiO_2@FITC-APTS@MIPs increased to about 500 nm, and the grain size was increased about 100 nm. As shown in the inset of Figure 5d, it was clearly observed that the product of SiO_2@FITC-APTS@MIPs beads had an approximately spherical shape and good monodispersity. It is observed that the product of SiO_2@FITC-APTS@MIPs not only keeps the spherical morphology but also still has good monodispersity after polymerization. On the whole, it was confirmed that the SiO_2@FITC-APTS@MIPs beads with core−shell structure had been successfully prepared.

The fluorescent images of SiO_2@FITC-APTS and SiO_2@FITC-APTS@MIPs were observed by confocal laser scanning microscope. Excitation wavelength and emission wavelength were 488 and 525 nm, respectively. Apparently, SiO_2@FITC-APTS@MIPs had strong fluorescence emission. As can be seen from the diagram, the monodispersity of SiO_2@FITC-APTS (a) and SiO_2@FITC-APTS@MIPs (b) did not change greatly before or after aggregation. The molecularly imprinted polymer still had the better monodispersity, and there is no serious reunion, which contributes to detection of the target molecule.

Figure S7 of the Supporting Information shows the TGA of SiO_2@FITC-APTS@MIPs and SiO_2@FITC-APTS@NIPs. It can be observed that the weight losses of SiO_2@FITC-APTS@MIPs and SiO_2@FITC-APTS@NIPs before 900 °C were ∼71.52 and ∼71.91%, respectively. The slight weight difference may be attributed to crystal water. The whole thermogravimetric process could be divided roughly into three stages. First, the temperature was before 100 °C, due to the loss interior water of crystallization. Second, the temperature was started at 350−500 °C, and weight losses of SiO_2@FITC-APTS@MIPs and SiO_2@FITC-APTS@NIPs were about 56.40 and 57.12%, respectively. The second weight loss stage can be ascribed to the polymerization of organic matter decomposition. The third weight loss stage started at 500−920 °C, during which the weight losses of SiO_2@FITC-APTS@MIPs and SiO_2@FITC-APTS@NIPs were 15.12 and 14.79%, respectively. This might be the reason for thermal decomposition of the modification of FITC-APTS. We could draw the conclusions that, first, the curves of imprinting and nonimprinting are almost the same. Second, polymers were grafted onto the surface of SiO_2 particles successfully, and the amounts of loss and use were equal. Finally, better temperature resistance of obtained products proved that thermal decomposition at room temperature does not readily occur.

Fluorescence Detection of SiO_2@FITC-APTS@MIPs Beads. All luminescence experiments were carried out at room temperature. The fluorescence spectrophotometer was used to monitor the fluorescence intensity of different molecularly imprinted polymers with the excitation wavelength of 450 nm. The samples of SiO_2@FITC-APTS@MIPs beads (50 mg) were dispersed in 100 mL alcohol solutions, which were prepared for spectrum measurement. Afterward, we prepared LC solution of different concentration ranges (0−1.0 μM L^{-1}). Then 5.0 mL of the sample solutions was poured into various concentrations of the 5.0 mL LC solution. Before spectrum measurement, the mixture of samples solution was stirred thoroughly. The fluorescence quenching efficiency of the SiO_2@FITC-APTS@MIPs beads with LC was calculated by Stern−Volmer equation, and the linear relationship could be described by $(F_0/F - 1)$ versus the concentration (nM L^{-1}). The same procedure was performed for the SiO_2@FITC-APTS@NIPs.

From the data in Figure 2a, it can be seen that with the increase of concentration of LC, the fluorescence intensity became weaker and weaker, and the reduced degree of fluorescence intensity in SiO_2@FITC-APTS@MIPs was

DOI: 10.1021/jf5043823
J. Agric. Food Chem. 2015, 63, 2392−2399

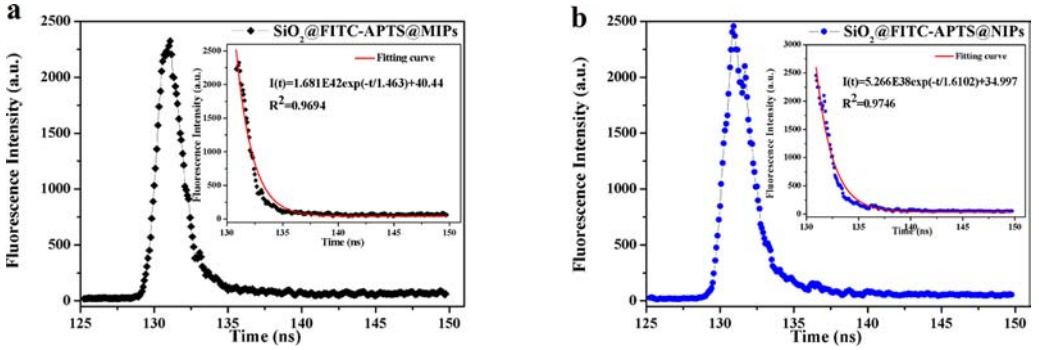

Figure 3. Transient fluorescence spectra of SiO_2@FITC-APTS@MIPs (a) and SiO_2@FITC-APTS@NIPs (b), for which the excitation wavelengths are 450 nm. Time-resolved fluorescence curves SiO_2@FITC-APTS@MIPs and SiO_2@FITC-APTS@NIPs are illustrated.

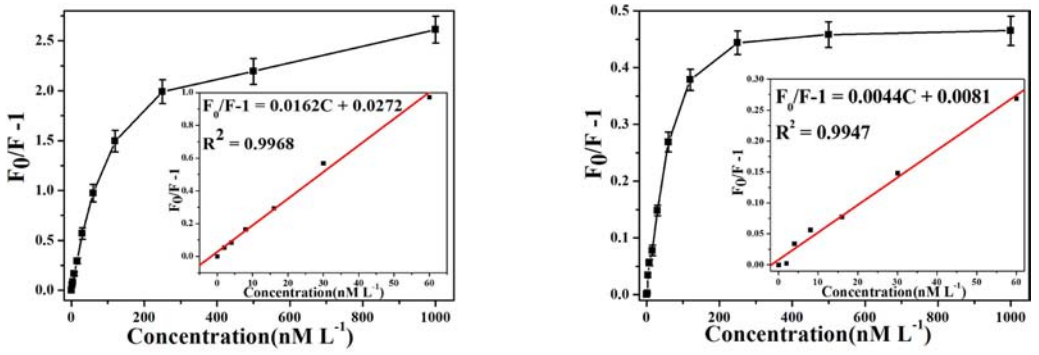

Figure 4. Fluorescence quenching efficiency changed according to LC concentration. (Insets) Linear equations of SiO_2@FITC-APTS@MIPs (a, left) and SiO_2@FITC-APTS@NIPs (b, right).

notably higher than that of the SiO_2@FITC-APTS@NIPs (Figure 2b). Therefore, we found that SiO_2@FITC-APTS@MIPs could detect the LC by fluorescence quenching. However, when the concentration of LC was between 250 and 1000 nM L^{-1}, the fluorescence intensity change was no longer apparent. As shown in Figure 2b, the fluorescence intensity changed, but it was of small amplitude along with the concentration of LC increasing. The fluorescence intensities of the SiO_2@FITC-APTS@MIPs and SiO_2@FITC-APTS@NIPs were important data to evaluate the selectivity and sensitivity of the materials obtained. It was illustrated that the spatial adsorption sites could be incorporated into the SiO_2@FITC-APTS@MIPs matrix, but a slightly in SiO_2@FITC-APTS@NIPs. In addition, it was also confirmed that the SiO_2@FITC-APTS@MIPs beads had been produced successfully.

The transient fluorescence spectra of SiO_2@FITC-APTS@MIPs and SiO_2@FITC-APTS@NIPs are displayed in Figure 3. The time-resolved fluorescence curves are illustrated in Figures. Decay in the fluorescence intensity (I) with time (t) was fitted by an exponential function

$$I(t) = A \exp(-t/\tau)$$

where τ is the lifetime and A is the amplitude.

As can be seen from Figure 3, the obvious fluorescence decay was found clearly illustrated. The two decay curves were fitted by exponential function. The nolinear equations of SiO_2@FITC-APTS@MIPs (Figure 3a) and NIPs (Figure 3b) were $I(t)$ = 1.681E42 exp($-t$/1.463) + 40.44 and $I(t)$ = 5.266E38 exp($-t$/1.6102) + 34.997, and the corresponding correlation coefficients (R^2) were R^2 = 0.9694 and R^2 = 0.9746, respectively. From the equations, we found that the lifetimes of SiO_2@FITC-APTS@MIPs and NIPs are τ = 1.463 ns and τ_0 = 1.610 ns, respectively.

Generally speaking, a collision would happen between fluorophor and quencher. This kind of collision may be a dynamic collision,[44] but it may also be an optical collision[45] for the dimolecule was in the excited state. To investigate the fluorescence quenching mechanism of SiO_2@FITC-APTS@MIPs with LC, the quenching efficiency of SiO_2@FITC-APTS@MIPs was evaluated by the Stern−Volmer equation, as follows:

$$F_0/F = 1 + K_{SV}C = 1 + K_q\tau_0 C \quad (1)$$

F_0 is the initial fluorescence intensity without analyte. F is the fluorescence intensity with the concentration of analyte. K_{SV} is the Stern−Volmer quenching constant in units of L mol^{-1}. C is the concentration of molecular targets. K_q is the rate constant of the bimolecular quenching process in units of L mol^{-1} s^{-1}. τ_0 is the lifetime without quenching agent.

We did reproducibility experiments three times and acquired Figure 4 by their average. As shown in Figure 3a, LC, the concentration range of which was 0−60 nM L^{-1}, could have a good linear relationship with fluorescence intensity. The linear equation of SiO_2@FITC-APTS@MIPs was $F_0/F - 1$ = 0.0162C + 0.0272, and the corresponding correlation coefficient was R^2 = 0.9968. The limit of detection is evaluated using LOD = $3\sigma/S$ and is found to be 9.17 nM L^{-1}, where σ is the standard deviation of the blank signal and S is the slope of the linear calibration plot. From Figure 4a, we could see that the concentration range of analyte was 0−60 nM L^{-1}. From Figure 4b, we could see the linear equation of fluorescence intensity and the concentration of LC (also from 0 to 60 nM L^{-1}) was $F_0/F - 1$ = 0.0044C + 0.0081, with R^2 = 0.9947.

DOI: 10.1021/jf5043823
J. Agric. Food Chem. 2015, 63, 2392−2399

When it surpassed the range of linear concentration, the slope of quenching became gentle. When the concentration was >250 nM L^{-1}, the quenching rate almost reached saturation.

The lifetimes are quite different whether the quenching agent exists or not. We found another kind of representation of the Stern−Volmer equation according to eq 1

$$\tau_0/\tau = 1 + K_{SV}C = 1 + K_q\tau_0 C \quad (2)$$

where τ is the lifetime with quenching agent.

According to eq 2, we found the relationship $K_{SV} = K_q\tau_0$. Now we know τ_0 = 1.6102 ns, which does not exist for quenching agent, and K_{SV} = 0.0044 L mol^{-1} via the above linear equation of SiO_2@FITC-APTS@NIPs. Therefore, $K_{q(NIPs)}$ = 3.792E6 L mol^{-1} s^{-1} was calculated by the equation. $K_{q(MIPs)}$ = 1.107E7 L mol^{-1} s^{-1} by the same method. K_q is the rate constant of the bimolecular quenching process, which represents bimolecular encountering frequency orders of magnitude. The rate constant (K_q) of maximum diffusion-controlled dynamic quenching, which is between the quenching agent and fluorescent molecule, is 2.0E10 L mol^{-1} s^{-1}.[46] The K_q in this study is always <2.0E10 L mol^{-1} s^{-1}, so the reason for fluorescence quenching is dynamic quenching. Due to many specific binding sites existing in the fluorescent molecularly imprinted polymer because $K_{q(MIPs)}$ (1.107E7 L mol^{-1} s^{-1}) > $K_{q(NIPs)}$ (3.792E6 L mol^{-1} s^{-1}), the fluorescent molecularly imprinted polymer is more likely to cause the fluorescence quenching phenomenon than fluorescent molecularly non-imprinted polymer. That is to say, the fluorescent molecularly imprinted polymer is more likely to occur with bimolecular dynamic collision, thereby producing dynamic quenching. We could draw the conclusion that the molecularly imprinted polymer not only had a high quenching rate but also a wide linear range. The obtained high quenching efficiency of the SiO_2@FITC-APTS@MIPs resulted from specific recognition sites for template molecule created during the course of imprinting.

Selectivity Determination. To measure the selectivity of the SiO_2@FITC-APTS@MIPs beads further, we made a comparison between the potential interference of several structurally related compounds (BC, FE, and BI) and LC. The SiO_2@FITC-APTS@MIPs beads were added to 10 mL of ethanol solutions containing 30 nM L^{-1} of BC, FE, and BI, respectively. The mixture was stirred for 1.0 h at the room temperature. The fluorescence intensity was detected by the fluorescence spectrophotometer, and $[(F_0/F) - 1]$ was calculated with the fluorescent data.

As shown in Figure S8a in the Supporting Information, the fluorescence quenching intensity of SiO_2@FITC-APTS@MIPs for LC was much lower than that of the structural analogues. It showed that only LC could adapt to the recognition sites in SiO_2@FITC-APTS@MIPs rather than other structural analogues, which could generate more fluorescence quenching efficiency. However, SiO_2@FITC-APTS@NIPs had a lower fluorescence quenching rate than the imprinting in Figure S8b. Other structural analogues were the same as LC, and their fluorescence quenching rates were all low. In conclusion, the fluorescence quenching of SiO_2@FITC-APTS@NIPs was invisible, because there were nonspecific recognition sites in SiO_2@FITC-APTS@NIPs.

As shown in Figure 5, the chemical structures of each structural analogue are displayed. We could see from Figure 5 that the fluorescence quenching efficiency of SiO_2@FITC-APTS@MIPs for LC was much higher than that of other

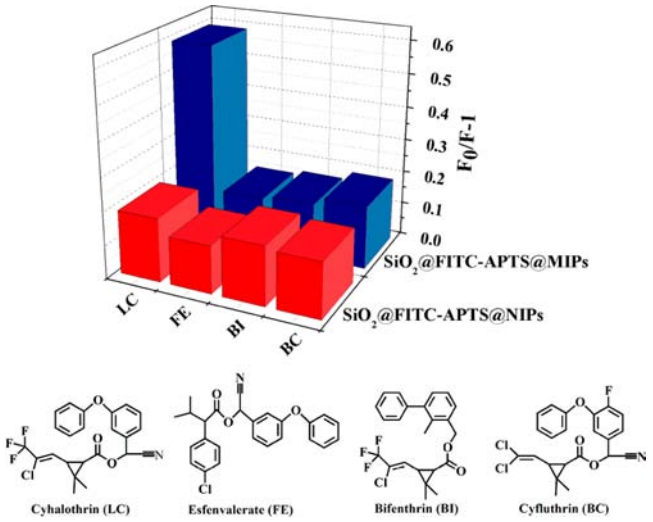

Figure 5. Quenching amount of SiO_2@FITC-APTS@MIPs and NIPs by different kinds of 30 nM L^{-1} pyrethroid pesticides and the chemical structures of each pyrethroid pesticide.

structural analogues. The results showed that SiO_2@FITC-APTS@MIPs had good selectivity for λ-cyhalothrin and none of the competitors being evaluated led to any significant fluorescence quenching rate. It can be proved that the SiO_2@FITC-APTS@MIPs beads provided high selectivity for LC, which was produced for the reason that there were specific recognition sites of LC in SiO_2@FITC-APTS@MIPs.

To further the investigation of how the competitive analogue affects the fluorescence quenching, BC, FE, and BI, these three competitive pesticides, were added into LC solution to form blend solutions, and the concentrations of λ-cyhalothrin and the competitive pesticides were all 30 nM L^{-1}. As can be seen from Figure 6, these three competitive pesticides could not obviously interfere with the fluorescence intensity of SiO_2@FITC-APTS@MIPs and NIPs. As can be seen from Figure 6a, the addition of structural analogues had almost no effect on the detection of LC. The last complex sample (LC, BC, BI, and FE) had too many structural analogues, so the SiO_2@FITC-APTS@MIPs could not detect the LC very well. The SiO_2@FITC-APTS@NIPs may be for the same reason in Figure 6b. From what had been discussed above, we could draw the conclusion that the SiO_2@FITC-APTS@MIPs provided high selectivity for LC, and it had good anti-interference for structural analogues. That is to say, the product of SiO_2@FITC-APTS@MIPs can identify the target molecule from the complex samples very well.

Application to Water Sample Analysis. To assess the applicability of SiO_2@FITC-APTS@MIPs beads in three water samples, we collected the distilled water and tap water from the laboratory, and we bought the Chinese spirits from a supermarket in China. We selected four concentrations to evaluate the applicability of SiO_2@FITC-APTS@MIPs beads and got the recovery by parallel measurement five times. The 5.0 mL water sample was added into 5.0 mL of LC solution (0−500 nM L^{-1}) and analyzed by the procedure mentioned above. Table 2 lists the corresponding results. The results showed that the SiO_2@FITC-APTS@MIPs had a good recovery in the linear concentration range, regardless of whether it was water sample or Chinese spirits. The recovery is smaller and smaller beyond the linear concentration range. The Chinese spirit sample is relatively complex, but it still has a

good recovery. This suggests that the SiO_2@FITC-APTS@MIPs could analyze LC in Chinese spirit samples. The results clearly establish that the SiO_2@FITC-APTS@MIPs can attain good recovery and can be effectively applied in the detection of LC in Chinese spirits.

To appraise the detection for SiO_2@FITC-APTS@MIPs beads with interferences further, we selected a better recovery of concentration (60 nM L^{-1}) to assess the applicability of SiO_2@FITC-APTS@MIPs. The Chinese spirit sample 5.0 mL was added into 5.0 mL of LC solution (60 nM L^{-1}) and analyzed according to the procedure mentioned above. The recovery of the Chinese spirit sample was obtained by carrying out parallel measurements five times. Table 3 lists the corresponding results. As shown, all recoveries were >100%. The existence of error is allowed. The concentration of the

[a]Average of five measurements.

fluorescent molecularly imprinted polymers in 60 nM L^{-1} is the maximum detectable concentration in the linear interval area. At the same time, the fluorescence quenching is the strongest. First, there are acids, aldehydes, ketones, aldehydes, aromatics, and other compounds in Chinese spirits. The feeble fluorescence quenching of the fluorescent molecularly imprinted polymers was caused by certain compounds in the Chinese spirits, thus resulting in the recovery becoming larger. Because the chemical structures of other competitive pyrethroids are similar to that of the target molecule, these other competitive pyrethroids also can produce certain fluorescence quenching of fluorescent molecularly imprinted polymer. However, it is not the main reason for the fluorescence quenching. Therefore, we found that the recovery would become larger with the increasing kinds of pyrethroid. On the whole, the results showed that the recovery has almost no change with single distracters. Although the recovery of the last test with three distractors is not as good as before, it still has relatively stable recovery. On the whole, the SiO_2@FITC-APTS@MIPs can attain satisfactory recovery in complex Chinese spirits.

To appraise the regeneration for SiO_2@FITC-APTS@MIPs beads, 60 nM L^{-1} LC solutions were first prepared. One hundred milligrams of SiO_2@FITC-APTS@MIPs beads was added into 100 mL of LC solution and incubated for 2.0 h before fluorescence measurement. After the test, the SiO_2@FITC-APTS@MIPs beads containing LC were washed with methanol−acetic acid solution, collected by centrifuge, and rinsed with ethanol. As shown in Figure S9 in the Supporting Information, the SiO_2@FITC-APTS@MIPs beads have certified that they can be reused five times without remarkable loss of signal intensity.

Conclusion. In summary, by combining a surface imprinting technique and fluorescent polymers, core−shell submicrometer SiO_2@FITC-APTS@MIPs on the surface of SiO_2 beads, which can be applied to the selective detection of LC, were synthesized. The unique aspects of SiO_2@FITC-APTS@MIPs, such as molecular recognition, fast separation, and fluorescence detection of target molecule were realized and discussed in detail. The adsorption of LC was detected by fluorescence spectrophotometer, and, using the Stern−Volmer equation, analyzed for fluorescence intensity. It is noteworthy that the SiO_2@FITC-APTS@MIPs not only have fluorescence property but also have quick detection, high fluorescence intensity, and good selective recognition for the target molecule. The experimental results showed the fluorescence quenching efficiency of SiO_2@FITC-APTS@MIPs for LC was

DOI: 10.1021/jf5043823
J. Agric. Food Chem. 2015, 63, 2392−2399

much higher than that of the structurally analogous composite and the SiO_2@FITC-APTS@NIPs, and it illustrated that the adsorption capacity and selectivity of the SiO_2@FITC-APTS@MIPs for the target molecule were good. From the SiO_2@FITC-APTS@MIPs detected LC in Chinese spirit samples, it can be seen that the SiO_2@FITC-APTS@MIPs not only has the advantage of high selectivity of molecular imprinting technique but also has the advantage of high sensitivity. On the whole, the present studies not only provide a new way to actualize selectively fluorescent detection of pyrethroid pesticides but also improve the potential application of molecularly imprinted polymers in the analysis field.

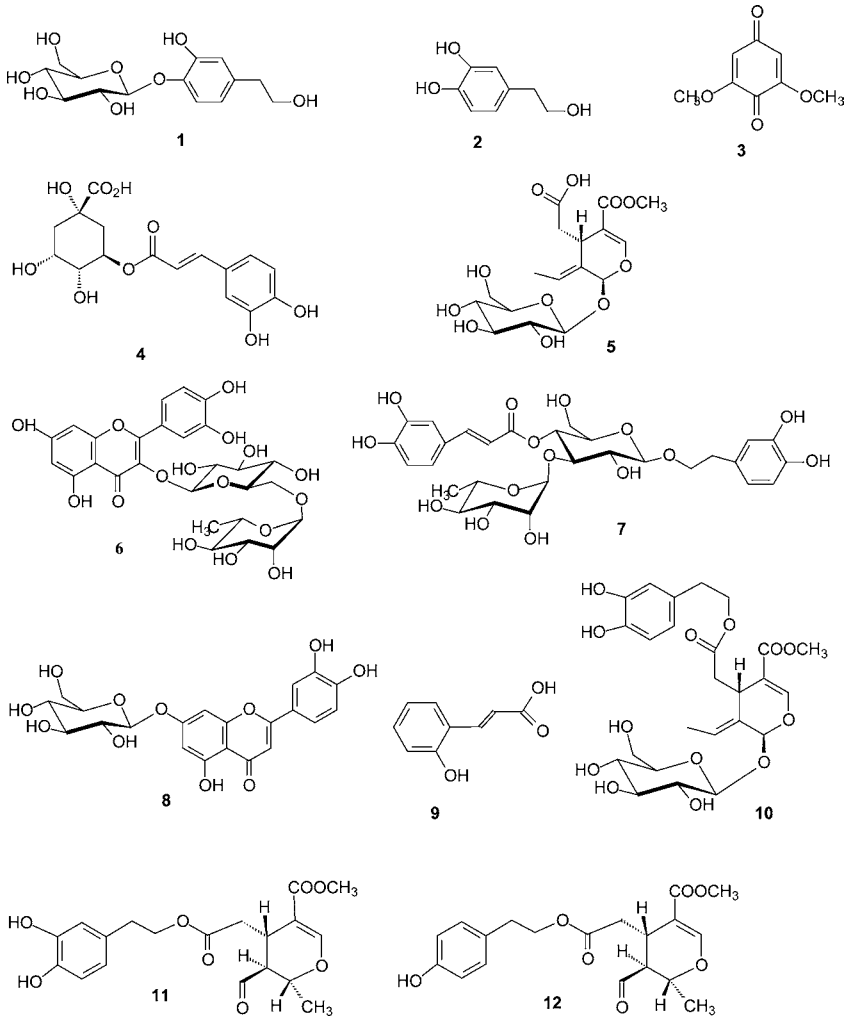

Figure 1. Structures of the studied compounds.

which contain very low amounts of oleuropein,[9] dry salt processing leads to a higher concentration of oleuropein,[5] highlighting the critical role of processing in the chemical composition of finished olives.[4] California-style black ripe olive processing methods involve harvesting olives before complete maturity (green). The raw olives are either directly treated with lye to remove bitterness or preserved in an acidic brine solution (0.2−0.4% calcium chloride, pH < 4.0) until they can be lye-treated and processed. A mild fermentation may occur during the initial brine storage. This style of processing results in olives with the lowest levels of oleuropein and bitterness.[10]

Herein, we describe a rapid ultrahigh-pressure liquid chromatography (UHPLC) triple-quadrupole tandem mass spectrometry (QqQ MS/MS) method using dynamic multiple reaction monitoring (dMRM) for the measurement of a range of key bitter and bioactive constituents in olives. The method was applied for the simultaneous quantitation of hydroxytyrosol-4-*O*-glucoside (**1**), hydroxytyrosol (**2**), 2,6-dimethoxy-*p*-benzoquinone (**3**), chlorogenic acid (**4**), oleoside-11-methyl ester (**5**), rutin (**6**), verbascoside (**7**), luteolin-7-*O*-glucoside (**8**), *o*-coumaric acid (**9**), oleuropein (**10**), oleuropein aglycone monoaldehydic form (**11**), and ligstroside aglycone monoaldehydic form (**12**) (Figure 1) in three different varieties of fresh and processed olives cured using either dry salt or California-style black ripe processing methods.

MATERIALS AND METHODS

Chemicals. High-performance liquid chromatography (HPLC)-grade formic acid, acetonitrile, hexane, and methanol were obtained from Fisher Scientific (Fair Lawn, NJ).

Samples. Dry salt-cured Throuba Thassos olives were purchased from a local market in Davis, CA, and the producer was contacted for processing conditions. The Throuba Thassos olives were treated with 40% dry salt for 2 months. After curing, the olives were washed with water and dried at ambient temperature for 2−3 days before packaging. Dry salt Mission olives were purchased directly from the grower/processor at the local farmers' market in Davis, CA. According to the producer, the olives were treated with dry salt (1:1, w/w) for 3 months. After curing, the olives were washed with water and sun-dried. California-style black ripe olives were prepared using fresh Manzanilla olives collected in early October 2011 in Davis, CA. The fresh samples were analyzed on the day that they were collected. California-style black ripe olives were produced using typical commercial processing.[11] Briefly, the olives were prepared by immersion in a 1−2% sodium hydroxide solution over 3 consecutive days until the lye penetrated the cuticle layers, 1−2 mm of the pulp, and the pit. During the intervals between lye treatments, the fruit was suspended in water, in which air is bubbled for 24 h. Oxygen is required for the black color formation, an oxidation reaction that results from the oxidation and polymerization of *o*-diphenols, mainly hydroxytyrosol and caffeic acid. A ferrous gluconate solution (0.1%, w/v) was added for 24 h to fix the developed black color. Olives were then rinsed with water to neutralize the solution. Olives were packed in a 3% sodium chloride solution and sterilized at 121 °C for 15 min.

[a]All compounds were monitored in negative mode with the exception of compound 3, which was monitored in positive mode.

Reference Compounds. Hydroxytyrosol, oleuropein, rutin, chlorogenic acid, and *o*-coumaric acid were purchased from Extrasynthese (Genay, France), and their purity as stated by the supplier was >98%. Hydroxytyrosol-4-*O*-glucoside, luteolin-7-*O*-glucoside, verbascoside, oleoside-11-methyl ester, 2,6-dimethoxy-*p*-benzoquinone, oleuropein, and ligstroside aglycones were isolated after chromatographic purification from olives. The identity and purity of the isolated compounds was established using nuclear magnetic resonance (NMR) spectroscopy and, in all cases, was >95%.

Extraction and Sample Preparation. A random sampling of 20−30 olives was separated into three sub-samples. Each sub-sample was homogenized individually. A 10 g (wet weight) sample of olive pulp was removed and extracted immediately with 25 mL of MeOH/H_2O (4:1, v/v) in an ultrasonic bath for 45 min at 25 °C. A 25 mL aliquot of hexane was added for oil removal, and the mixture was shaken for 30 s. The supernatant was separated with centrifugation at 4000 rpm for 3 min. The hexane phase was removed, and a 1 mL aliquot of the MeOH/H_2O phase was filtered through a 0.45 μm filter (EMD Millipore, Billerica, MA), diluted with H_2O (1:50), and injected into the liquid chromatography−mass spectrometry (LC−MS).

UHPLC−MS/MS Analysis. Analysis of the 12 phenolic and secoiridoid compounds was performed on a 1290 Infinity UHPLC interfaced to a 6460 QqQ MS/MS with electrospray ionization (ESI) via Jet Stream technology (Agilent Technologies, Santa Clara, CA). The UHPLC was equipped with a binary pump with an integrated vacuum degasser (G4220A), an autosampler (G4226A) with a thermostat (G1330B), and a thermostated column compartment (G1316C). The column used was a 150 × 2.1 mm inner diameter, 2.7 μm, Poroshell 120 EC-C18 (Agilent Technologies, Santa Clara, CA). The mobile phase consisted of 0.1% formic acid in water (A) and acetonitrile (B) with the following gradient program: 0−2.5 min, 10% B; 2.5−3.0 min, 10−25% B; 3.0−6.0 min, 25% B; 6.0−7.5 min, 25−40% B; 7.5−8.5 min, 40−95% B; and 8.5−9.5 min, 95% B. The flow rate was 0.4 mL/min, and the injection volume was 1.0 μL.

Negative and positive ESI modes were used. The drying gas temperatures and flow rate were 250 °C and 8 L/min, respectively. The sheath gas temperature and flow rate were 350 °C and 11 L/min, respectively, and the nebulizer gas pressure was 45 psi. The capillary voltage was 3.5 kV for positive and negative modes, and the nozzle voltage was 0 and 1.5 kV for positive and negative modes, respectively.

Dynamic MRM mode was used to analyze olive phenolic and secoiridoid compounds. A cycle time of 500 ms was used. Dwell times were automatically set using cycle time and peak overlap. Precursor ions and product ions were identified and optimized using MassHunter Optimizer (Agilent Technologies). A summary of the precursor ions and product ions used for quantitation is given in Table 1.

Calibration Curves. Standard stock solutions of 1.0 mg/mL were prepared in methanol. Stock solutions were diluted in MeOH/H_2O (4:1, v/v) to give a concentration ranging from 0.001 to 50 μg/mL. Stock solutions were used to identify the linear range for quantitation (LRQ), limit of detection (LOD; S/N > 3), and limit of quantitation (LOQ; S/N > 10) for each analyte. Olive samples were spiked to give concentrations of analytes at 0.002, 0.02, 0.2, 1, 2, and 5 mg/g of olive by diluting appropriate volumes of the stock standard solutions with MeOH/H_2O (4:1, v/v) and mixing with 10.0 g of olive flesh (cv. Manzanilla) after California-style black ripe processing. This olive matrix was selected because it presented the lowest concentrations of the analytes, making the construction of the calibration curves easier. The area of each analyte was measured in a blank matrix standard and then again after the addition of a known amount of standard analyte to the matrix. The difference in area measured for each analyte peak, before and after spiking, was directly correlated with the spiked amount to construct the calibration curve.

Method Validation. The method was checked for the linearity, precision [calculated as the relative standard deviation % (RSD %)], accuracy [evaluated as the relative percentage error % (Er %)], and sensitivity [defined by the limit of detection (LOD) and limit of quantitation (LOQ)].

RESULTS AND DISCUSSION

A UHPLC−QqQ MS/MS method using dynamic MRM was developed to quantitate a range of bitter and biologically active

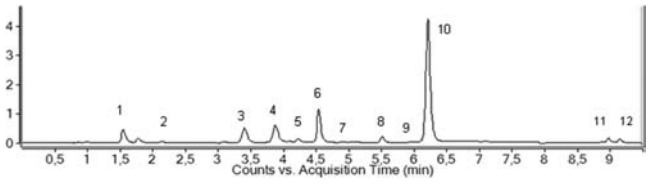

Figure 2. Total ion chromatogram of a mixture of the studied compounds. The numbers assigned to each peak correspond to each of the studied compounds.

phenolic and secoiridoid compounds in table olives. This method offers improved sensitivity, selectivity, and throughput (<10 min/run) in comparison to previously reported methods, as reviewed by Segura-Carretero et al.[12] The usefulness of the new method was demonstrated in the simultaneous quantitation of a broad range of phenolic and secoiridoid compounds in fresh and finished olive products generated by dry salt or California-style debittering methods. Rapid reliable methods for the quantitation of hydroxytyrosol, oleuropein, and their derivatives is of special interest because these compounds have been recently recognized by the European Union (EU) as agents protecting low-density lipoprotein (LDL) oxidation and, thus, offering cardiovascular protection.[13] Currently, this health claim is recognized only for olive oil. To date, several gas

chromatography/mass spectrometry (GC/MS), HPLC−ultraviolet (UV), or LC/MS methods are available for monitoring phenolic and secoiridoid compounds in olive products (e.g., olive oil, olive leaves, and olive fruits).[12] The GC/MS methods require derivatization and long analysis times (30−120 min).[14] The HPLC−UV methods have low sensitivity (e.g., LOQ = 1 μg/mL for hydroxytyrosol[5]) and are limited by long chromatographic separation times (20−100 min).[12] Additionally, in some cases, HPLC−UV methods are unable to resolve overlapped peaks,[15] making the simultaneous quantitation of numerous compounds difficult, especially in short separation times. Rapid LC/MS methods have been applied to unprocessed olives but are restricted to the quantitation of oleuropein and hydroxytyrosol.[16,17] A HPLC−Orbitrap MS/MS method for quantitation of nine compounds in fresh olives was recently reported.[18] The HPLC−Orbitrap and current UHPLC−QqQ methods present similar LODs and LOQs for oleuropein, hydroxytyrosol, oleuropein aglycone, and ligstroside aglycone, the only four common compounds studied using the two methods; however, the Orbitrap method presented a longer analysis time (31 min), and the quantitation range was restricted to higher concentrations (e.g., 1000−50 000 ng/mL compared to 100−12 500 ng/mL for oleuropein aglycone and 500−20 000 ng/mL versus 50−6250 ng/mL for hydroxytyr-

DOI: 10.1021/jf506367e
J. Agric. Food Chem. 2015, 63, 2400−2405

osol). Moreover, the HPLC−Orbitrap method relies on calibration curves that were constructed by dilution of standard compounds in a different solvent (acetonitrile) than the solvent used for the dilution of the real samples (methanol and water). Extraction or dilution of oleocanthal and oleacein using methanol can have a negative impact on their levels as recently reported[19,20] and has the potential to impact other compounds (e.g., oleuropein aglycone and ligstroside aglycone) because these two compounds easily isomerize[20] and require well-controlled conditions for accurate measurements.

Recovery from the olive matrix varied. At high concentrations of added standards (1−5 ppm), recoveries were 85−95%, whereas at low concentrations (0.1−0.5 ppm), recoveries were 50−60%. For this reason, it was necessary to use calibration curves constructed with the addition of known amounts to olive matrix, instead of calibration curves constructed with pure compounds in solution. The method was checked for linearity, precision, accuracy, LOD, and LOQ, and the results were satisfactory. These results show that the method can be efficiently used for the measurement of target analytes. Intraday precision (repeatability) was in all cases <10%.

Special care was taken during the extraction to reduce the risk of enzymatic degradation of sensitive compounds, such as oleuropein and other glucosides, and for this purpose, the olive pulp was extracted immediately after crushing. However, specific experiments examining the role of the sample preparation procedure on the formation of aglycones were not performed.

A total ion chromatogram with all studied compounds (Figure 2) and a representative MRM-extracted chromatogram of Mission olives (Figure 3) demonstrate clearly resolved peaks. Although this study focused on quantitation of 12 targeted compounds, we were able to tentatively identify isomers, such as hydroxytyrosol-1-*O*-glucoside (1.8 min) and luteolin-4-*O*-glucoside (5.95 min), as well as tyrosol glucoside (salidroside), tyrosol, caffeic acid, and methoxytyrosol (data not shown). Tyrosol does not ionize well in ESI mode and, therefore, can only be quantitated at high concentrations. Because the levels of tyrosol were below the level of quantitation, it was not included in this study.

The levels of the 12 secoiridoid and phenolic compounds measured in fresh and California-style black ripe processed Manzanilla olives are given in Table 2. The levels of oleuropein (9186 ± 530 μg/g), oleuropein aglycone monoaldehyde (2126 ± 190 μg/g), and hydroxytyrosol (894.5 ± 45.2 μg/g) were measured in fresh olives (wet weight). After California-style black ripe processing, only hydroxytyrosol, hydroxytyrosol-4-*O*-glucoside, and oleuropein could be detected in levels of 210.0 ± 18.8, 73.1 ± 5.5, and 36.7 ± 3.1 μg/g wet weight, respectively. All of the other compounds presented concentrations lower than 10 μg/g wet weight. Chlorogenic acid, rutin, verbascoside, *o*-coumaric acid, oleuropein aglycone, and ligstroside aglycone could not be detected. These data indicate that California-style black ripe olive processing methods lead to significant reductions in the levels of the secoridoid and phenolic compounds evaluated in this study. This finding is in accordance with previous reports on phenolic compound change during California-style processing;[5] however, herein, a larger range of compounds was evaluated and with higher sensitivity.

In contrast to California-style olives, the dry salt Mission and Throuba Thassos olives presented relatively higher amounts of almost all studied compounds. For example, in Mission and Throuba Thassos olives, the levels were of oleuropein (516.2 ± 44.3 and 1459.5 ± 100.1 μg/g of wet weight), oleoside methyl ester (1393.8 ± 60.1 and 4238.1 ± 333.4 μg/g of wet weight), hydroxytyrosol (633.8 ± 55.1 and 195.1 ± 7.8 μg/g of wet weight), and hydroxytyrosol glucosides (1890.4 ± 150.5 and 263.5 ± 19.1 μg/g of wet weight) (Table 2). These findings support dry salt debittering methods as being advantageous for the retention of polyphenolic and secoiridoid constituents in table olives,[3] and they are not restricted to a specific variety; two commercial samples of two cultivars of different geographic origins presented similar retention of the targeted compounds.

The information presented herein demonstrates wide variation in the composition of a range of key bioactive phenolics in olives that is dependent upon both the variety and processing method used to create the olive product, and these factor need to be considered when developing possible health claims for table olives and their products.

quantitative results.[26] Despite this, it presents a great difficulty in determining Na^+ due to the generation of Auger electrons, which decreases the fluorescence yield and limits its use in quantitative analysis of this element.[27] In addition to this effect, scattering effects of radiation such as Rayleigh, Compton, and Raman, also occur.[27−29] This situation requires specially designed tools for quantification, such as the fundamental parameters method (FP). The FP method is considered the state of the art in the correction of these effects and has the ability to apply theoretical corrections for the interelemental effect.[30−33] An example of FP use is the metal determination in rice samples[34] or in medicinal plants.[35]

Multivariate analysis, also known as chemometric tools, can also be employed, such as principal component analysis (PCA), which can reduce the size of the original data set. Furthermore, it is possible to recognize trends, outliers, and, most importantly, variables.[36−38] In the literature, examples are found of XRF and chemometric tools combination used to recognize similarities between samples, such as in honey bee.[39]

Calibration models can also be constructed by establishing a quantitative relationship between the information provided by the equipment and the properties of interest. Partial least squares (PLS) regression[40] performs predictions for sample values that have no previous classification,[41,42] being an important tool in analytical chemistry and also in industrial process control.[43] This strategy was employed to determine the energy value of flour and breakfast cereals;[44] to calibrate acidity, alcohol, and sucrose in *cachaça*;[45] to determine TiO_2 in toothpastes;[46] and for quality parameters of sugar cane,[47] always without reagent consumption and waste generation.

The goal of this study is to quantify the amounts of Na and K in samples of table salt (refined and marine) and low-sodium salt by EDXRF to compare three different quantification methodologies: the FP method, univariate calibration, and multivariate regression models by PLS.

MATERIALS AND METHODS

Samples. In the study, 21 samples of table salt were used. The samples were acquired in supermarkets and natural food stores in Campinas, SP, Brazil. The types, numbers of samples of each class, and the codes used for each brand are shown in Table 1.

Table 1. Types, Numbers of Samples, and Brands of Table Salt Used in the Study for the Na^+ and K^+ Determinations

salt type	no. of samples	brands
refined	8	RS1, RS2, RS3, RS4, RS5, RS6, RS7, RS8
low-sodium	7	LS1, LS2, LS3, LS4, LS5, LS6, LS7
marine	6	MS1, MS2, MS3, MS4, MS5, MS6

Samples of ca. 10 g were ground with a mortar and pestle, dried at 150 °C for 24 h, and stored in a desiccator prior to analysis. Specific cells were completely filled with salt (Chemplex 1300 cells with Chemplex 2.5 mm thick Mylar film) for EDXRF analysis in the spectrometer. The same treatment was used for the standards construction using analytical grade NaCl (Merck, Rio de Janeiro, Brazil) and KCl (Vetec, Rio de Janeiro, Brazil).

Fourteen standards with various concentrations of Na^+ and K^+ were prepared, in duplicate, by the mixing of NaCl and KCl. The standards were weighed on an analytical balance to five decimal places and comprise the ranges from 0 to 39 g/100 g of Na (0−100 g/100 g NaCl) and from 0 to 52 g/100 g for K (0−100 g/100 g KCl).

Irradiation Conditions. An EDXRF spectrometer (Shimadzu EDX700) with a rhodium target X-ray tube and a Si(Li) detector was used. The applied voltage for the X-ray tube was 50 kV; the detector dead time, 25%; collimator, 5 mm; and irradiation time, 500 s. The scanning range was from 0 to 20 keV with energy steps of 0.01 keV.

Experimental Data Processing. For peak areas and background signal calculations for Na and K analytical curves were used the programs WinSPEDAC 2.2 and WinQxas 1.30 (International Atomic Energy Agency).[48]

Fundamental parameters results were calculated by Shimadzu EDX700 software, version DXP-700E 1.00.

Matlab 7.0 (MathWorks) and PLSToolbox 4.0 (Eigenvector Research) were used to carry out PCA and PLS. The only preprocessing employed was data mean centering.

RESULTS AND DISCUSSION

Fundamental Parameters Determination. The FP method has the ability to resolve interferences caused by interelemental effects, especially in not very complex samples, such as table salt. However, this advantage is overcome by the nature of the elements Na, K, and Cl, which have atomic numbers of <22. The results for the NaCl and KCl standards concentration have deviations from the expected stoichiometric ratio (Table 2).

The results show that the FP quantification is not satisfactory, and other approaches are required to determine the salt composition, such as calibration by characteristic peak areas of the elements.

Determination by Peak Area Calculation. Figure 1a shows the overlapped EDXRF spectra of all standards, refined salt (RS), marine salt (MS), and low-sodium salt (LS) samples. The region from 0 to 4 keV, which contains the Na, K, and Cl characteristic Kα peaks, is shown in Figure 1b.

With the values of the calculated areas by WinQxas 1.30 program, a calibration curve was constructed for Na^+ (Figure 2a) through the directly proportional relationship between intensity (cps/μA) and standards concentration (g/100 g).

The low fluorescence intensity of Na leads to a low value of the slope (0.037). Nevertheless, there is a reasonable correlation between the obtained data, as shown by the regression coefficient value (r = 0.974).

The same treatment was performed for K, whose Kα peak areas (3.31 keV) were measured and plotted (Figure 2b). Again, data showed good correlation for the element (r = 0.992).

Finally, Na^+ and K^+ concentrations in refined, marine, and low-sodium salts samples were estimated. The calculated values

for the Na element in table and marine salt samples were close to theoretical value for pure NaCl, which was 39 g/100 g (Table 3).

Apparently, table salts have higher levels of Na^+ than marine salts, once the refining process removes other elements such as Ca or Mg. Moreover, the salts have various origins and undergo different industrial processes, resulting in changes in the concentrations.

With respect to K in the low-sodium salt, there is a great variation in the sample concentration: from 6 ± 2 to 22 ± 1 g/100 g (Table 3). This may occur due to a manufacturer option to add other elements or compounds to reduce the Na^+ content. In low-sodium salt samples, the Na^+ reduction ranged from 13 to 58%.

Chemometric Analysis. The univariate calibration difficulties, that is, the difficulties in spectral manipulation for net intensity peak determination, and high levels of Na^+ in low-sodium salt samples led us to the use of chemometric tools as an alternative method for salt quantification. The standards and samples spectral data have 2048 intensity values related to each energy channel, with energies between 0 and 20 keV and resolution of 0.01 keV. Spectral data were mean centered, and the models were built with the software Matlab 7.0 (MathWorks) and PLSToolbox 4.0 (Eigenvector Research). In the statistical multivariate analysis 21 samples for PCA models were employed: 8 of refined salt, 6 of marine salt, and 7 of low-sodium salt, thus assembling a (21 × 2048) matrix. For the PLS models, 14 NaCl + KCl standards were made in duplicate. From this set, 7 were used for Na external validation and the

other 7 for K validation. Finally, the 21 real samples were quantified in the PLS model performed with the spiked standards. Therefore, for multivariate analysis the spectral data are not manipulated but used as obtained after a simple preprocessing step.

PCA allowed the classification of the marine and table salts due to their Cl content and also due to some physical characteristics, such as moisture, particle size, and minor elements composition. For some samples the presence of an anti-humectant agent also allowed a differentiation. Detailed PCA discussion is presented in the Supporting Information.

Na^+ Quantification by PLS. After the qualitative results of PCA, the next step was to build a PLS calibration model for Na and K. Spectral data were mean-centered, and the choice of latent variables number (LV) was performed based on the root-mean-square error of cross-validation (RMSECV) and the amount of accumulated information for each LV.

Five LVs were chosen on the basis of the variables contribution presented in the loadings graphs, and correlation curves were constructed for Na^+ values (measured and predicted) for calibration and cross-validation (RMSECV 1.286, cumulative variance in X 99.65%, cumulative variance in Y 99.08%). The values of correlation coefficients for calibration (r_{cal} = 0.995) and cross-validation (r_{val} = 0.988) show a good model correlation ability (Figure 3).

Table S1 in the Supporting Information shows the average values and prediction errors associated with the internal

RS8	39 ± 3	42 ± 1								

calibration of the model, with most of the errors being below 10%. Only standard 12 shows an average error of 16%, probably because it displays the lowest content of Na^+, resulting in a difficult adjustment by the model. From an analysis of the errors, it is observed that in the range equivalent to samples—from pure NaCl (39% Na) by low-sodium salt samples (19% Na) concentration—they are acceptable (<10%).

Another tool for model evaluation is the use of an external validation step, as shown in Table 4. Again the model was suitable for Na^+ quantification in table salt samples, with errors exceeding a value of 5% in only one of the standards. This standard has a Na^+ concentration of 11 g/100 g, lower than all of the commercial samples.

The model was used to predict the Na values in 21 commercial samples (Table 5). In the refined salt samples (RS1−RS8), the levels found are placed between 31.1 ± 0.5 and 44.5 ± 0.5 g/100 g, with most samples having a higher content than pure NaCl, 39 g/100 g. This trend was observed only in 33% of marine salt (MS1−MS6) samples. These results emphasize the difficulty of determining light elements by XRF.

Finally, with regard to low-sodium salt, the PLS model indicated that Na^+ reduction, which should be at least 50%, was observed only for the LS5 sample (60%). The calibration capability (RMSEC) and prediction of cross-validation (RMSECV) were evaluated, being 0.811 and 1.286 g/100 g, respectively, whereas the *t* test concluded that systematic errors in the model are not significant, because t_{bias} calculated (0.069) was lower than t_{bias} tabulated (1.994).

K^+ Quantification by PLS. Similarly, a model for K was constructed, and calculated values of RMSECV and accumulated variance in *X* and *Y* led to the choice of four LVs (RMSECV 2.040, cumulative variance in *X* 99.78%, cumulative variance in *Y* 98.93%).

Table S2 in the Supporting Information presents the absolute prediction average errors for the internal validation (cross-validation), with larger errors for samples that have lower concentrations of element (standard 2, 3, and 4). In samples with concentration >23 g/100 g, the errors did not exceed 10%. This indicates the possibility to use the model for table salt samples with reduction of 50% of Na^+ by adding KCl.

Graphics of measured and predicted K^+ values were constructed for the calibration and cross-validation (Figure 4). The model has good correlation ability, as indicated by the correlation coefficients of calibration (r_{cal} = 0.995) and cross-validation (r_{val} = 0.993).

For external validation samples, errors are <10% for standards 10 and 11, with 25.8 and 31.5 g/100 g, respectively (Table 6).

Again, the model shows good calibration capability (RMSEC) and prediction of cross-validation (RMSECV), being 1.811 and 2.040 g/100 g, respectively. The *t* test concluded that systematic errors in the model are not significant, because t_{bias} calculated (0.180) was lower than t_{bias} tabulated (1.990).

Finally, the model for quantifying K^+ concentration was applied in seven commercial low-sodium salt samples with values from 7 ± 1 to 39.8 ± 0.7 g/100 g (Table 7).

Samples LS3 and LS4 (same brand but different batches) exhibit good agreement; on the other hand, this is not the case with LS1 and LS2 and LS5 and LS6 (from the same supplier). This discrepancy could be credited to the option of manufacturers to add other compounds rather than KCl or variations in the manufacturing process or raw materials. Taking into account these concentration variations in samples of the same suppliers and high deviation of the calibration, the method must be employed with reservations for determining K^+ in low-sodium salts.

Comparison of the Employed Methods. Table 8 shows a comparison of Na^+ levels in refined and marine salts, and in most cases some discrepancies between values occur. These differences may be positive or negative, with no apparent trend being detected. The same comparison was made for K^+.

For sea salt there is a reasonable correlation for Na, whereas for K in low-sodium salt the differences are more pronounced. The best results for Na in PLS can be attributed to a possible enhancement of the source scattering, because it is more susceptible to the effect for being a lighter element than K. A *t* test stated that there are no significant differences in the methods for Na quantification, because the calculated value (0.296) is lower than the tabulated value (2.086) for a confidence level of 95%.

The determination of Na^+ and K^+, due to their characteristics, are hard tasks to be achieved by XRF. The FP method, which considers all of the element signals present in the sample, is more subject to variations and deviations and sometimes is impracticable. The univariate method with peak area calibration is, in this specific case, a more interesting alternative, even though the several steps to manipulate the spectral data to obtain the net intensity area of the peaks demands longer analysis times. With respect to the time of the data preprocessing, chemometrics is faster than the univariate method because the spectra are used as obtained.

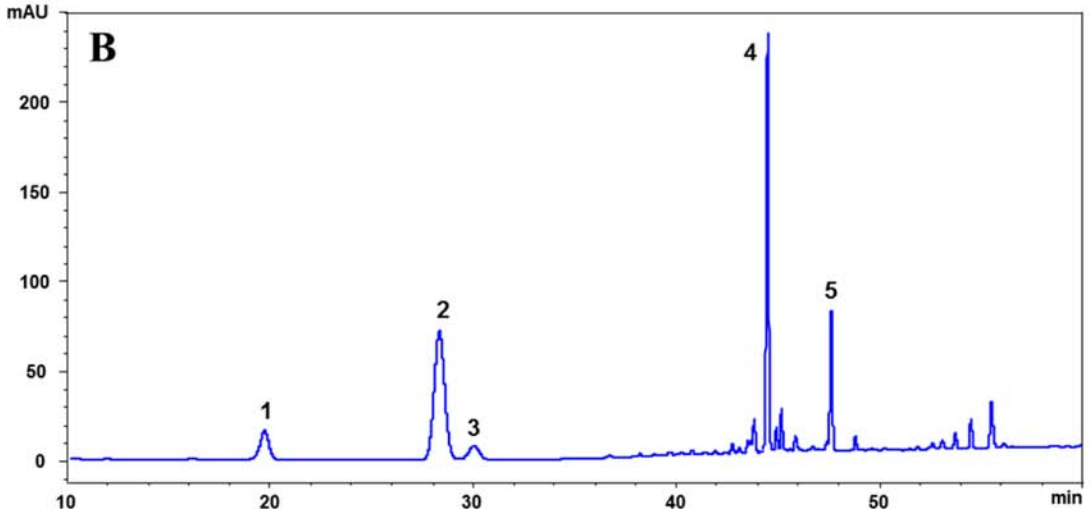

Figure 1. Chemical structures of notoginsenoside R1, ginsenoside Rg1, Re, Rb1 and Rd (A), and representative HPLC-UV chromatogram of PNS. HPLC was performed using an Agilent Zorbax Extend-C18 (250 × 4.6 mm i.d.,5 μm) and an Agilent Zorbax Extend-C18 guard columns (12.5 × 4.6 mm i.d.,5 μm) at 40 °C. The mobile phase consisted of water (a) and acetonitrile (b) using the following gradient program: 0−30 min, 18−19%b; 30−40 min, 19−31%b; 40−60 min, 31−70%b. Flow rate was kept at 1.5 mL/min, the detection wavelength was set at 203 nm, and the sample injection volume was 10 μL. Peaks: 1, notoginsenoside R1; 2−5, ginsenosides Rg1, Re, Rb1, and Rd, respectively. Glc, β-D-glucose; Rha, α-L-rhamnose; Xyl, β-D-xylose.

rated fatty acids,[12] have been shown to possess protective effects against ethanol-induced liver injury. Root of *Panax notoginseng* (Burk.) F. H. Chen, also called as Sanqi in Chinese, is a highly valued medicinal herbs that has been traditionally applied to clinic for preventive and therapeutic purposes, especially for cardiovascular diseases and hepatic diseases, either alone or in combination.[13] *P. notoginseng* is contained in several famous Chinese traditional formulas, such as "*Pian Zi Huang*", which is used for the treatment of virus hepatitis. *P. notoginseng* has also been widely used for a variety of medicinal cuisines for the diverse purposes, including soup, stew, and beverage. Dammarane-type triterpene saponins are generally considered to be the major bioactive constituents in *P. notoginseng*.[13,14] An increasing number of in vivo and in vitro studies have demonstrated that *P. notoginseng* and its saponins exerted extensively beneficial effects on several systems, including hematological,[15] immune,[16] cardiovascular,[17] central nervous,[18] and endocrine systems.[19] However, the effect of *P. notoginseng* saponins (PNS) on ethanol-induced liver injury has not been fully elucidated.

A mouse model of acute alcohol consumption could be used to investigate the early effects of alcohol-induced liver injury and is well-suited to mimicking acute alcohol administration, with blood ethanol concentrations, behavioral effects, and physiological changes comparable to those of binge drinking in humans.[20] In the present study, the protective effect of PNS on

DOI: 10.1021/jf502990n
J. Agric. Food Chem. 2015, 63, 2413−2422

acute ethanol-induced liver injury and its underlying molecular mechanisms were investigated in a mouse model of binge drinking.

MATERIALS AND METHODS

Chemicals. *Panax notoginseng* saponins (PNS) was purchased from International Laboratory Inc. (San Francisco, CA, U.S.A.) with the labeled purity of over 95%. Authentic saponins, including notoginsenoside R1, ginsenosides Rg1, Re, Rb1, and Rd, were purchased from National Institute for the Control of Pharmaceutical and Biological Products (Beijing, P.R. China) and their structures are shown in Figure 1A. Absolute ethanol (99.9%) was the product of Sigma-Aldrich (St Louis, MO, U.S.A.). The preparations were made fresh every time before the commencement of the experiment. HPLC-grade acetonitrile was purchased from Merck KGaA (Darmstadt, Germany), and deionized water was prepared by a Milli-Q purification system (Millipore, Bedford, MA, U.S.A.). All other chemicals were of analytical grade.

HPLC Analysis of PNS. To ensure the consistency of its efficacy, the commercial PNS was analyzed by high-performance liquid chromatography (HPLC) as previously developed chromatographic conditions.[17,21,22] Briefly, the analysis was achieved using an Aglient 1100 series HPLC apparatus (Palo Alto, CA, USA). An Zorbax Extend-C18 (250 × 4.6 mm i.d., 5 μm) and an Zorbax Extend-C18 guard columns (12.5 × 4.6 mm i.d., 5 μm) were used at a column temperature of 40 °C. The mobile phase consisted of water (A) and acetonitrile (B) using the following gradient program: 0−30 min, 18−19% B; 30−40 min, 19−31% B; 40−60 min, 31−70% B. Flow rate was kept at 1.5 mL/min, analyte was detected at 203 nm, and the sample injection volume was 10 μL.

Animals and Treatments. All the animal procedures were approved by Animal Ethics Committee, Institute of Chinese Medical Sciences, University of Macau (Approval No. AEC-13-002), and every effort was made to minimize animal suffering. Male C57BL/6 mice, weighting 25−30g, were purchased from Laboratory Animal Services Center, the Chinese University of Hong Kong (Hong Kong, China). Mice were maintained on individually ventilated cage (IVC) system in a temperature (22.5 ± 0.5 °C) and humidity (50 ± 5%) controlled rooms with a 12 h light/dark cycle and allowed free access to water and standard lab chow. After 2 weeks acclimation, all mice were randomly divided into four groups (i.e., control group, ethanol group, and two PNS treatment groups). A mouse model of binge drinking was used to induce acute ethanol-induced liver injury. Low-dose and high-dose group animals were orally administered PNS at doses of 100 and 300 mg/kg BW, respectively for 7 days prior to ethanol challenge, at the same time, mice in control and ethanol groups received an equal volume of water. On day 8, mice received three acute doses of 60% (v/v) ethanol (4.7 g/kg BW) in water every 12 h by oral gavage. Control mice were treated with an isocaloric maltose solution to eliminate the difference in energy between the control and ethanol groups. The used ethanol dose had shown to cause significant liver injury, as described in our previous study.[12] At 4 h after the last administration, mice were sacrificed and their blood samples, whole livers, and epididymal fats were immediately collected. The portion of tissues from the same lobe of liver in each mouse was embedded in OCT (frozen tissue matrix) for histological analysis. The remaining liver tissue and epididymal fat were stored at −80 °C until analyzed.

Measurement of Serum Aminotransferase Levels. Serum biochemical markers (e.g., alanine aminotransferase (ALT) and aspartate aminotransferase (AST)) are commonly used to indicate liver injury.[23] To examine the effect of PNS on acute ethanol-induced hepatotoxicity, serum levels of ALT and AST were determined by using commercial spectrophotometric kits (Nanjing Jiancheng Bioengineering Institute, Nanjing, China) according to the manufacturer's instructions.

Histological Assay. The embedded liver sample slices were processed by standard Oil Red O staining procedure. Briefly, liver cryostat sections (8 μm) were fixed with 4% phosphate-buffered paraformaldehyde (pH = 7.4), stained with Oil Red O (Sigma-Aldrich, St Louis, MO, U.S.A.) and counterstained with hematoxylin (Sigma-Aldrich). The stained sections were examined and recorded by an Olympus CX-31 light microscopy with CCD camera (Olympus Crop, Tokyo, Japan).

Measurement of Serum and Hepatic Triglyceride Contents. Triglyceride levels in serum and liver samples were quantitatively determined by a Triglyceride Quantification Kit (Beijing BHKT Clinical Reagent Co., Ltd., Beijing, China) following the manufacturer's protocol. For hepatic triglyceride assay, 50 mg of liver tissue was homogenized in 450 μL of chloroform/methanol solution (2:1, v/v). After extraction for 24 h at 4 °C, 500 μL 0.9% NaCl was added to each sample. Samples were then centrifuged at 2000 rpm for 15 min, and the organic phase (lower) was removed to a new tube and dried under nitrogen gas. The resulting residue was dissolved in 100 μL phosphate-buffered saline containing 1% Triton X-100 and the triglyceride contents were then determined by using a Triglyceride Quantification Kit. The value of hepatic triglyceride content was normalized to wet tissue weight and expressed as mg/g of liver. Serum triglyceride levels of mice were also examined by the identical kit.

Determination of Hepatic ROS, MDA, SOD, and GSH Levels. Liver tissue was homogenized in 19 volumes of cold radioimmunoprecipitation assay buffer (RIPA buffer, Beyotime Institute of Biotechnology, Nanjing, China) and the tissue homogenate (5%, w/v) was prepared. After centrifugation at 12500*g* for 20 min at 4 °C, the supernatant was collected for the measurement of hepatic superoxide dismutase (SOD) activity, and the levels of reactive oxygen species (ROS), malondialdehyde (MDA), and glutathione (GSH) using commercial Superoxide Dismutase Assay Kit, Reactive Oxygen Species Detection Assay Kit, Malondialdehyde Assay Kit, and Reduced Glutathione Assay Kit (Nanjing Jiancheng Institute, China), respectively, according to the manufacturer's instructions. The values were normalized to hepatic total protein.

Measurement of Hepatic Cytokines. Hepatic TNF-α and IL-6, were quantified using commercial TNF-α and IL-6 ELISA kits. Briefly, 50 mg of liver tissue was homogenized in 450 μL PBS containing 0.5% Triton X-100 and 1% phenylmethylsulfonyl fluoride (PMSF) protease inhibitor (Thermo Scientific), then centrifugated at 12 000*g* for 10 min.[24] The levels of TNF-α and IL-6 in the supernatant were respectively examined by using Mouse TNF-α and IL-6 ELISA MAX Standard kits (BioLegend Inc., San Diego, CA, U.S.A.). The values were normalized to total protein and expressed as pg/mg of protein.

Measurement of Adipose Tissue Lipolysis. Lipolysis of adipose tissue was measured as free fatty acid (FFA) released into the culture medium ex vivo. Briefly, fresh epididymal adipose tissue explants were washed in culture plates with prewarmed Dulbecco's PBS containing 100 U/mL penicillin and 100 mg/mL streptomycin. After removing possible blood vessels and connective tissues, approximate 30 mg of adipose tissue was transferred to 12-well plates, cut into small pieces, and cultured in 2 mL DMEM supplemented with L-glutamine (2 mM), penicillin (50 U/mL), streptomycin (50 mg/mL), and 2% fatty acid-free bovine serum albumin for 2 h. FFA released into the culture medium was measured by using a Fatty Acid Quantification Kit (Biovision, Milpitas, CA) according to its manufacturer's instruction. The FFA in serum was also determined using the same kit.

Western Blotting Analysis. Total proteins were extracted from liver and epididymal adipose tissue using RIPA buffer containing 1% phenylmethanesulfonylfluoride (Beyotime Institute of Biotechnology) and 1% phosphatase inhibitor cocktail. Protein concentrations were measured with Pierce BCA Protein Assay Kit (Thermo Fisher Scientific Inc., Rockford, IL, U.S.A.). Aliquots containing 60 μg protein samples were separated by electrophoresis on 8% or 10% SDS-PAGE gel and transferred onto a polyvinylidene fluoride (PVDF) membranes. After blocking with 5% nonfat dry milk in Tris-buffered saline with 0.1% Tween-20 (TBST) for 1h at room temperature, the membranes were immunoblotted with primary antibodies, including CYP2E1 (1:500; Abcam, Cambridge, U.K.), HSL (1:1000; Cell Signaling Technology, Danvers, MA), Phospho-HSL (1:1000; Cell Signaling Technology) and GAPDH (1:1500; Cell Signaling Technology) at 4 °C for overnight. HSL antibody can recognize both phosphorylated HSL and unphosphorylated HSL, and phospho-

DOI: 10.1021/jf502990n
J. Agric. Food Chem. 2015, 63, 2413−2422

HSL antibody specifically recognized the phosphorylated HSL. After three 10 min washings in TBST, the membranes were incubated with second antibody HRP-linked antimouse IgG (1:3000; Cell Signaling Technology) at room temperature for 1 h. The protein bands were visualized by using Amersham ECL Select Western Blotting Detection Reagent (GE Healthcare Bio-Sciences., Piscataway, NJ, U.S.A.) under in Bio-Rad ChemiDoc XRS System (Bio-Rad Laboratories, Inc., Hercules, CA, U.S.A.), and quantified by densitometry analysis using Quantity One software (Bio-Rad).

Real Time-PCR Analysis. Total RNA was extracted from liver using Trizol reagent (Life Technologies Corp., Grand Island, NY, U.S.A.) and cDNA was synthesized using a random primer and TaqMan Reverse Transcription Reagents Kit (Life Technologies). The sequences of CD36 (forward: 5′-ATGGGCTGTGAT CGGAACTG-3′; reverse: 5′-GTCTTCCCAATAAGCATGTCTCC-3′) and β-actin (forward: 5′-GGCTGTATTCCCCTCCATCG-3′; reverse: 5′-CCAGTTGGTAACAATGCCATGT-3′) were obtained from the Primer Bank (http://pga.mgh.harvard.edu/primerbank). Real Time-PCR reactions were performed by using SYBR Green PCR Master Mix in an Applied Biosystems 7500 Real-Time PCR System (Life Technologies) and normalized to β-actin content.

Statistical Analysis. Data was expressed as mean ± standard deviation (SD). Student's t-test was used for between-group comparison using GraphPad Prism 5.0 software. The levels of significance was considered at $P < 0.05$.

RESULTS

Saponin Composition of PNS. The commercial PNS from *P. notoginseng* contains a number of different dammarane triterpene saponins. In order to ensure quality consistency of the tested sample and experimental reproducibility, the chemical characteristics of PNS was profiled using the previously developed HPLC-UV method (Figure 1B).[17,21,22] Notoginsenoside R1, ginsenosides Rg1, Re, Rb1, and Rd were well identified by comparing the retention times of the peaks with those of the reference compounds eluted under the same chromatographic conditions, and their individual concentrations were determined to be 8.1%, 32.0%, 3.9%, 33.4%, and 7.4% of PNS, respectively.

Body Weight, Liver Weight, and Liver Index. The body weight, liver weight, and liver index (liver weight/body weight, %) were compared across four groups and were shown in Table 1. Three doses of ethanol administration and PNS treatment did not affect animal body weight and liver weight, when compared to control group. However, the liver index in ethanol group was remarkably increased by 9.0%, the most plausible explanation was that alcohol exposure caused the lipid accumulation in the liver. This increase was prevented by PNS treatments, especially by high-dose PNS (300 mg/kg BW) treatment. Low-dose PNS (100 mg/kg BW) showed a decreasing tendency compared to ethanol group, but there was no significant difference.

Table 1. Effects of PNS on Body Weight, Liver Weight and Liver Index (Liver Weight/Body Weight, %) in Ethanol-Treated Mice[a]

	control	ethanol	ethanol + PNS (100 mg/kg)	ethanol + PNS (300 mg/kg)
body weight (g)	28.2 ± 0.9	28.0 ± 2.3	26.9 ± 1.4	26.9 ± 3.0
liver weight (g)	1.12 ± 0.09	1.21 ± 0.08	1.16 ± 0.08	1.11 ± 0.14
liver index (%)	3.98 ± 0.38	4.34 ± 0.16[b]	4.29 ± 0.17	4.11 ± 0.19[c]

[a]Data are expressed as mean ± SD ($n = 6$). [b]$P < 0.01$, compared to the control group. [c]$P < 0.05$, compared to the ethanol group.

PNS Attenuated Acute Ethanol-Induced Hepatoxicity. ALT and AST are released from the cytoplasm of hepatocytes that have suffered structural damage. Their serum activities were most commonly used as reliable primary indicators for clinical monitoring of liver injury.[8] As shown in Figure 2, serum

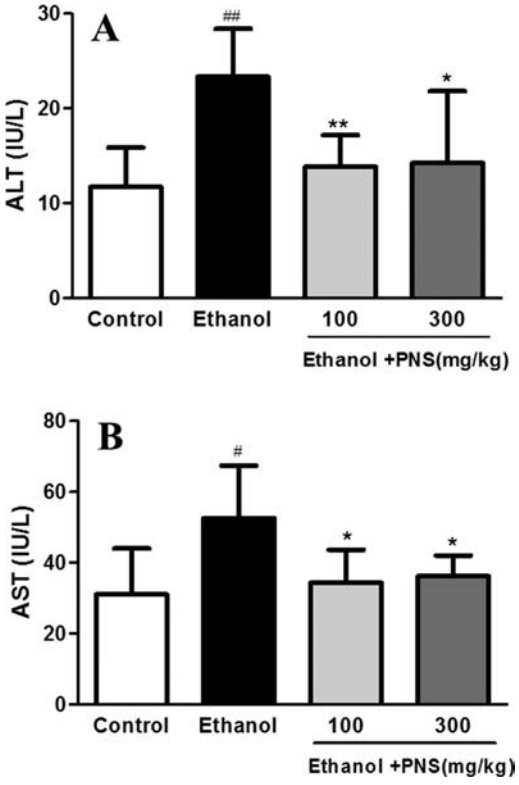

Figure 2. Effects of PNS on acute ethanol-induced changes in serum enzyme activities of (A) ALT and (B) AST. Value represents means ± SD ($n = 6$). IU/L, International Unit per liter; $^{\#}P < 0.05$ and $^{\#\#}P < 0.01$ compared to the control group; $^{*}P < 0.05$ and $^{**}P < 0.01$, compared to the ethanol group.

levels of ALT and AST in ethanol group were significantly increased by 100% (23.4 ± 5.0 vs 11.7 ± 4.1) and 69.1% (52.6 ± 14.9 vs 31.1 ± 12.9), respectively, over those in control group. However, it was also apparent that the pretreatment with PNS, either low-dose or high-dose, was effective in suppressing the acute ethanol-induced liver injury by decreasing the levels of serum ALT and AST activities. Nevertheless, this suppressive effect on ethanol-induced injury did not appear in dose dependent manner.

PNS Prevented Acute Ethanol-Induced Lipid Accumulation in Liver. To assess the effect of PNS on hepatic steatosis induced by acute ethanol intake, hepatic lipid accumulation was qualitatively examined by Oil Red O staining and quantitatively determined by a triglyceride quantification kit. After three doses of ethanol administration via oral gavage, mice from both the ethanol groups and ethanol + PNS groups exhibited obvious accumulation of neutral lipid droplets in their livers when compared to control group, as illustrated by Oil Red O staining (Figure 3A–D). The lipid droplets in the livers of PNS-treated groups were much smaller and fewer than those

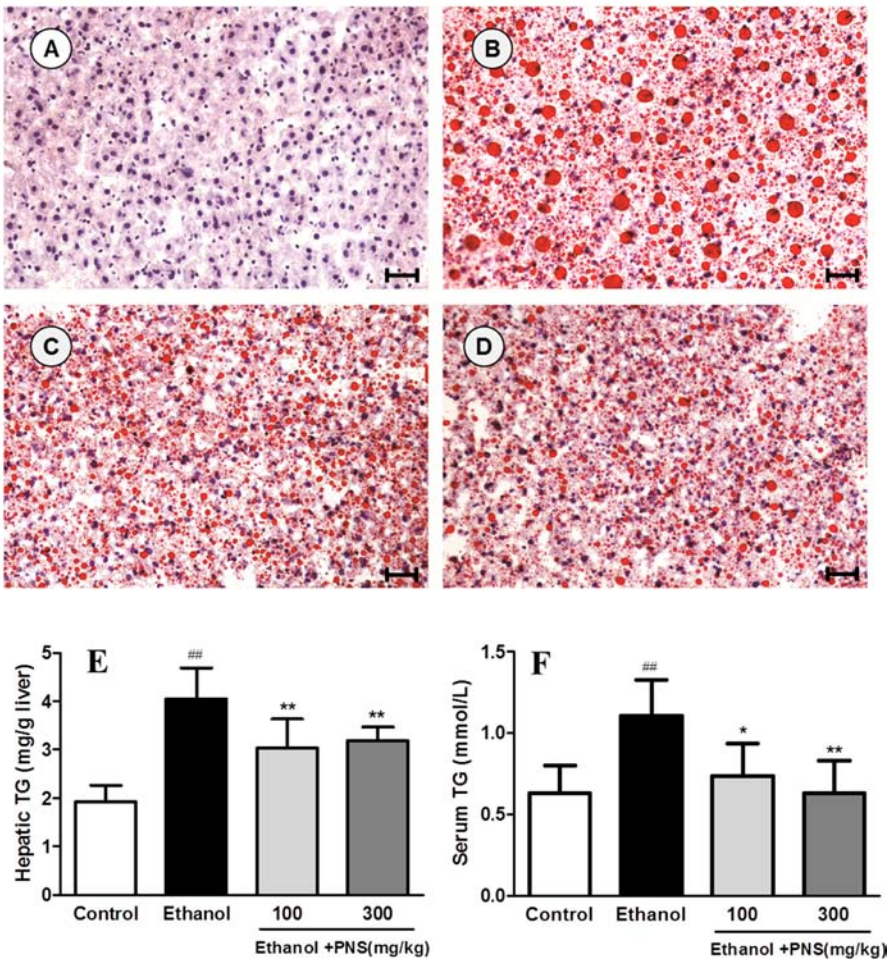

Figure 3. PNS suppressed acute ethanol-induced hepatic lipid accumulation. Representative Oil Red O-stained sections of the livers from (A) control, (B) ethanol group, (C) ethanol + PNS (100 mg/kg BW), and (D) ethanol + PNS (300 mg/kg BW) (400 × magnification; scale bars, 25 μm); (E) hepatic triglyceride levels; and (F) serum triglyceride levels. Value represents means ± SD (n = 6). $^{\#\#}P < 0.01$, compared to control group; $^{*}P < 0.05$, $^{**}P < 0.01$, compared to ethanol group.

in the ethanol group. Quantitative analysis confirmed the histological results by demonstrating that acute ethanol gavage dramatically increased the hepatic triglyceride content in mice, and this elevation was significantly diminished by pretreatment of PNS at dose of 100 mg/kg or 300 mg/kg (Figure 3E). In addition, serum triglyceride levels in PNS-treated mice were significantly lower when compared to that of ethanol group (Figure 3F). These data clearly indicated that PNS could effectively acute ethanol-induced liver injury, at least in part, through reversing hepatic lipid accumulation.

Effect of PNS on WAT Lipolysis and Hepatic Fatty Acid Uptake. To gain insight into the mechanisms underlying inhibitory effect of PNS on acute ethanol-induced hepatic steatosis, we examined the lipolysis capacity of white adipose tissue (WAT) and the expressions of the related gene involved in fatty acid transportation from adipose tissue to liver. Lipolysis capacity was determined by incubating freshly isolated epididymal WAT. As shown in Figure 4A, adipose explants from alcohol-fed mice showed a significant increase in FFA release during 2 h incubation, in comparison to control group. Pretreatment with PNS completely abolished the increased FFA release from epididymal WAT induced by ethanol intake. These results were consistent with the change in serum FFA level, PNS could prevent the serum FFA content elevated by acute ethanol consumption (Figure 4B). Hormone-sensitive lipase (HSL) is the rate-limiting enzyme for lipolysis of triglyceride in adipose tissue, and the activity of HSL is primarily regulated by phosphorylation−dephosphorylation reactions.[25] Therefore, the protein expression levels of total HSL and phosphorylated HSL (p-HSL) in epididymal WAT were examined by Western blotting analysis. As shown in Figure 4C and D, acute ethanol exposure obviously up-regulated the protein expressions of p-HSL and total HSL, as well as p-HSL/HSL ratio, which were suppressed by PNS. Our results suggested that pretreatment with PNS improved the acute ethanol-induced WAT dysfunction, which was associated with inhibiting the expressions of p-HSL and total HSL.

CD36 is a major fatty acid translocase for hepatic fatty acid uptake.[26] The transcriptional levels of CD36 in liver tissue were also examined by real-time PCR analysis. Acute ethanol feeding significantly increased the mRNA expression of CD36 in liver, which was normalized by PNS (Figure 4E). These data suggested that PNS might decrease the elevation of hepatic fatty acid uptake stimulated by ethanol feeding.

PNS Relieved Ethanol-Mediated Oxidative Stress. The term oxidative stress characterizes an imbalance between endogenous prooxidants (e.g., ROS) and antioxidants (e.g., SOD and GSH), ROS has a great potential to react with lipids,

ROS (unit/μg protein)	80.3 ± 4.2	87.0 ± 4.3[b]	76.3 ± 3.8[e]	79.2 ± 3.4[e]
MDA (nmol/mg protein)	1.39 ± 0.08	3.41 ± 0.74[c]	1.69 ± 0.11[e]	1.67 ± 0.25[e]
GSH (μmol/g protein)	18.4 ± 1.92	5.10 ± 1.12[c]	16.3 ± 4.10[e]	17.5 ± 1.46[e]
SOD (U/mg protein)	163 ± 13.2	147 ± 6.9[b]	170 ± 1.7[e]	182 ± 14.8[e]

[a]Data are expressed as mean ± SD (n = 6). [b]$P < 0.01$ and. [c]$P < 0.01$ compared to the control group. [d]$P < 0.05$ and. [e]$P < 0.01$, compared to the ethanol group.

leading to lipid peroxidation (LPO), which results in cell membrane damage. Malonyldialdehyde (MDA), an principal product of LPO, has been widely used as indicator of LPO and a marker for the status of oxidative damage.[27] To evaluate the effects of PNS on acute ethanol-mediated oxidative stress, the productions of ROS and MDA, and the GSH levels, as well as SOD activity in liver were measured and shown in Table 2. Three doses ethanol administration significantly increased hepatic ROS and MDA levels by 8.3% ($p < 0.05$) and 148% ($p < 0.01$), respectively, when compared to those in control mice. Pretreatment with PNS at doses of 100 mg/kg and 300 mg/kg significantly inhibited the elevation of hepatic ROS by 12.3% and 8.9%, and MDA by 50.6% and 50.4%, respectively. These results were consistent with the changes in serum levels of ALT and AST (Figure 2) that are primary indicators for liver injury. Conversely, three doses of ethanol intake resulted in the decreases of the antioxidant parameters, such as hepatic GSH content and SOD activity, both low-dose and high-dose of PNS remarkably ameliorated the depletion of GSH and SOD.

To understand the mechanism of the attenuation of ethanol-mediated oxidative stress by PNS, protein expression of CYP2E1, a major contributor to ROS production, was examined by immunoblot analysis. As shown in Figure 5, three doses of ethanol gavage remarkably increased the protein expression of CYP2E1 by 87.1% in comparison to control group. This elevation of CYP2E1 expression was inhibited significantly by PNS in a dose-dependent manner. Our results suggested that the protective effect of PNS on ethanol-

mediated oxidative stress was associated with down-regulation of CYP2E1 in liver.

PNS Reduced the Production of Hepatic Inflammatory Cytokines. To examine the effect of PNS treatment on acute ethanol-induced inflammatory cytokines, the hepatic levels of TNF-α and IL-6 were measured using commercial ELISA kits. As shown in Figure 6, the production of both TNF-α and IL-6 were significantly increased in the livers of ethanol group, compared to those in the control group. These increases were attenuated by PNS treatment at dose of either 100 mg/kg or 300 mg/kg.

DISCUSSION

Despite the economic burden of ALD and its serious effect on public health, there are few satisfactory therapeutic approaches to prevent or reverse the progression of ALD.[1] In recent years, much attention has been paid to bioactive components from herbal medicines for the prevention and treatment of ALD.[8] In the present study, the effect of PNS treatment on acute ethanol-induced liver injury was investigated using a binge drinking mouse model. Our results demonstrated that pretreatment of PNS markedly ameliorated liver injury induced by three doses of ethanol. This protective effect was associated with the reduced hepatic lipid accumulation and decreased ethanol-mediated oxidative stress.

Hepatic steatosis, characterized by excessive triglyceride accumulation in the cytoplasm of hepatocytes, is the earliest stage in the progression of ALD and most common response of liver to acute or chronic alcohol exposure. The excessive lipids dominate the cytoplasmic space of the hepatocytes, which greatly affect cellular function and make the hepatocytes susceptible to hepatotoxins, such as lipopolysaccharide (LPS),[28] and oxidative stress.[4] Thus, the suppression of hepatic lipid accumulation during alcohol consumption might block further liver injury. Our data demonstrated that PNS treatment significantly decreased acute ethanol-induced hepatic steatosis, as described by Oil Red O staining and quantification of hepatic triglycerides. An increasing number of studies have indicated that chronic alcohol exposure for weeks stimulates adipose tissue lipolysis and elevates hepatic fatty acid uptake capability, leading to the increased fatty acid influx to the liver, which also involved in pathogenesis of alcoholic steatosis.[4,5] However, the

DOI: 10.1021/jf502990n
J. Agric. Food Chem. 2015, 63, 2413−2422

role of this effect in hepatic steatosis induced by acute alcohol intake has not been addressed yet. Increasing hepatic de novo lipogenesis has been considered to be mainly responsible for hepatic lipid accumulation in acute ethanol consumption model. However, it appears that there is not enough time to express a series of lipogenic genes to biosynthesize the large amount of triglyceride from glucose in such short-term. Adipose tissue derived-fatty acids influx to the liver might be a more important and economical contributor to acute ethanol-induced hepatic steatosis. Our results demonstrated, for the first time, that our mouse model of alcohol binge drinking by gavaging three doses every 12 h, stimulated adipose tissue lipolysis and elevated hepatic fatty acid uptake, which could be prevented by PNS treatment. In order to further reveal the underlying molecular mechanisms, the expressions of the related genes in adipose and liver tissues were examined. HSL is a key rate-limiting enzyme responsible for hydrolyzing triacylglycerols, diacylglycerols, and monoacylglycerols to release the fatty acid in adipose tissue, and activated via phosphorylation by PKA, acyclic AMP-dependent kinase.[29] CD36 is a key transport protein involved in regulating the uptake of fatty acids across the plasma membrane in hepatocytes. Our data indicated that PNS could normalize the increased protein levels of total HSL and phosphorylated HSL and inhibited the augmented mRNA expression of hepatic CD36 induced by acute ethanol exposure, which mainly contributed to its inhibitory effect on adipose tissue lipolysis and hepatic fatty acid uptake, respectively. These effects of PNS might contribute to its protective effect against ethanol-induced hepatic injury.

The importance of oxidative stress in ethanol-induced liver injury and the pathogenesis of ALD is now well recognized.[6] Both acute and chronic alcohol exposure increases the production of ROS, including superoxide, hydroxyl radical and hydrogen peroxide, leading to oxidative stress in the liver. Ethanol-induced ROS production appears to be toxic to hepatocytes because it reacts with most cellular macromolecules by causing DNA damage, denaturing proteins, and increasing lipid peroxidation of cellular membrane.[30] In addition, ethanol-mediated oxidative stress also depleted endogenous antioxidative defenses, including enzymatic and nonenzymatic antioxidants.[31] SOD is an important endogenous antioxidant enzyme involved in ROS elimination and serves as the first line of defense against oxidative damage.[32] GSH, a nonenzymatic antioxidant, acts as a direct ROS scavenger and the substrate of GSH-related detoxifying and antioxidant enzymes.[33] Our results demonstrated that PNS not only could decrease the production of hepatic ROS induced by three doses of ethanol but also ameliorated the depletion of antioxidants, including SOD and GSH. ROS triggered oxidative stress usually showed an increase in MDA levels, an end-product of lipid peroxidation.[27] Generally, ROS has a great potential to react with lipids, particularly polyunsaturated fatty acids, which results in cell membrane damage. Thus, MDA has been widely used as indicator of lipid peroxidation and a marker for the status of oxidative stress. In our study, PNS prevented the elevation of hepatic MDA levels induced by acute ethanol intake, indicating the decrease lipid peroxidation in the liver. In order to further investigate the mechanisms underlying the antioxidative stress effect of PNS, the expression of CYP2E1 in liver was examined. CYP2E1 has been considered to be a major contributor to ethanol-induced oxidative stress and to ethanol induced liver injury. The expression and activity of CYP2E1 are elevated by alcohol intake, which catalyzes conversion of ethanol to acetaldehyde in the presence of iron, and causes ROS overproduction.[34] The results of present study indicated that pretreatment with PNS inhibited the ethanol-induced elevation of hepatic CYP2E1 expression, which contributed to its antioxidative stress effect.

Several inflammatory cytokines play a crucial role in the progression of ALD, especially from hepatic steatosis to steatohepatitis, which is featured by the presence of inflammatory infiltrate and hepatocyte damage.[35] It was well-known that oxidative stress also stimulates the release of these cytokines and amplify the inflammation response to cause further liver damage.[36] TNF-α and IL-6, mainly produced by sensitized Kupffer cells and the recruited monocytes, have been widely considered to be the most important cytokines in alcohol induced liver injury.[35] Besides inflammatory and cytotoxic effects, TNF-α also increases fatty acid de novo synthesis by stimulating the maturation of transcription factor sterol regulatory element binding protein-1c (SREBP-1c).[37] The results from this study showed that PNS reduced hepatic production of the inflammatory cytokines, TNF-α and IL-6, and also contributed to its protective effect on acute ethanol-induced liver injury.

In pharmacological evaluation of PNS, it is important to understand not only its chemical components but also which PNS-derived compounds circulate considerably in plasma after dosing. After oral administration of the aqueous extract of *P. notoginseng*, 20(*S*)-protopanaxadiol, 20(*S*)-protopanaxatriol, and their oxidized metabolites, as well as compound K represent major circulating forms of ginsenosides through the ginsenoside deglycosylation by the colonic microflora and sapogenin oxidation by enterohepatic cytochrome P450 enzymes in rats and human.[38,39] In this study, the protective effects of PNS against acute ethanol-induced liver injury might be attributed to these deglycosylated products of ginsenosides in bloodstream.

Taken together, the pretreatment with PNS effectively attenuated acute ethanol-induced liver injury. This protective effect might be associated with ameliorating hepatic steatosis and reducing ethanol-mediated oxidative stress. Our findings suggested that PNS had the potential to be developed to an effective preventable agent in acute ethanol-induced liver injury.

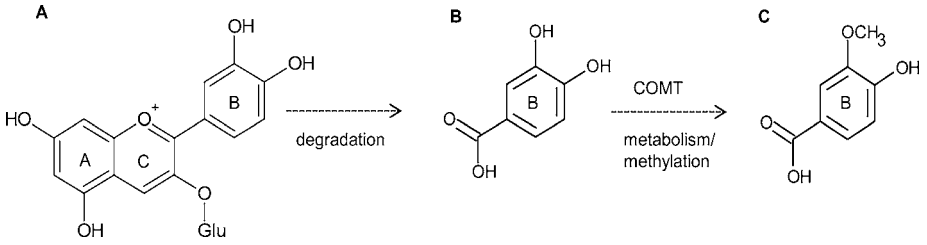

Figure 1. Chemical structures of the anthocyanin cyanidin-3-glucoside (A), its B-ring degradation product protocatechuic acid (B), and the mono-*O*-methylated metabolite of protocatechuic acid, vanillic acid (C). COMT, catechol *O*-methyltransferase.

solutions were prepared in dimethyl sulfoxide (DMSO) and stored at −80 °C. Fetal bovine serum (FBS, heat-inactivated) was purchased from Biosera (Ringmer, U.K.), and tumor necrosis factor-alpha (TNF-α), TRIzol reagent, and SuperScript II Reverse Transcriptase were obtained from Life Technologies (Paisley, U.K.).

Precision 2× real-time PCR MasterMix with SYBRGreen was obtained from PrimerDesign Ltd. (Southampton, U.K.). Custom primer sets for human NOX2, NOX4, $p22^{phox}$, $p47^{phox}$, and $p67^{phox}$ were supplied by PrimerDesign Ltd., and custom primers for human HO-1 (HMOX-1) by Life Technologies. Primer sequences are provided as Supporting Information (Table S1).

NuPAGE sample reducing agent and LDS sample buffer were purchased from Life Technologies, and Precision Plus Protein Dual Color standards were purchased from Bio-Rad Laboratories, Inc. (Hemel Hempstead, U.K.).

Cell Culture. Early passage, pooled HUVECs were purchased from TCS Cellworks (Buckingham, U.K.) and used between passages 2 and 4. Cells were routinely cultured in large vessel endothelial cell growth medium (TCS CellWorks) at 37 °C and 5% CO_2. HUVECs were subcultured using 0.025% trypsin and 0.01% ethylenediaminetetraacetic acid (EDTA) (TCS CellWorks).

Cryopreserved, second passage, single donor HCAECs were purchased from PromoCell GmbH (Heidelberg, Germany) and used between passages 3 and 6. Cells were routinely cultured in endothelial cell medium MV (PromoCell GmbH) at 37 °C and 5% CO_2. HCAECs were subcultured using 0.04% trypsin and 0.03% EDTA (PromoCell GmbH).

Cytotoxicity Assay. The maximal level of flavonoids and flavonoid metabolites reported in the systemic circulation is generally below 10 μM,[1] hence this concentration was the maximum in vitro concentration utilized in the present study. Cell viability following exposure to 10 μM of treatment compounds was determined using cell proliferation reagent WST-1 (Roche Applied Science, Burgess Hill, U.K.) in accordance with the manufacturer's protocol. The assay was conducted using fibronectin-coated microplates seeded with HUVECs at a density of ∼10,000 cells/well, and subsequently grown to confluence as determined by light microscopy. After incubation with treatment compounds for 24 h, 10 μL of WST-1 reagent was added to each well, and plates were incubated for a further 4 h. Absorbance was measured at 440−450 nm using a microplate reader [Fluostar/Polarstar Optima, BMG Labtech (Aylesbury, U.K.)].

Nitrite/Nitrate Assay and eNOS Enzyme-Linked Immunosorbent Assay (ELISA). Fibronectin-coated 24-well plates were seeded with HUVECs at a density of ∼30,000 cells/well, and cells were grown to confluence. Cells were then cultured in the absence or presence of treatment compounds (0.1, 1, or 10 μM) for 24 h; after which supernatants were removed and stored at −80 °C. Cells were washed once with warm phosphate-buffered saline (PBS) and then harvested in trypsin/EDTA and trypsin-blocking solution. Cell suspensions were stored at −80 °C until lysis. Nitric oxide production was assessed using a colorimetric microplate assay (Cayman Chemical Company Nitrate/Nitrite Colorimetric Assay Kit from Cambridge Bioscience, Cambridge, U.K.) according to the manufacturer's instructions. The average intra-assay coefficient of variation (CV) was 6.63% ± 1.10% (mean ± SD, n = 3), and the interassay CV was 2.38% (n = 3). Quantification of eNOS in HUVEC lysates was performed with the Quantikine Human eNOS Immunoassay (R&D Systems, Abingdon, U.K.) according to the manufacturer's instructions. The average intra-assay CV was 4.67% ± 1.86% (mean ± SD, n = 3), and the interassay CV was 6.10% (n = 3).

Stimulated Superoxide Production Assay. Superoxide production was assessed using a modified cytochrome *c* assay.[20,21] The modified assay utilized fibronectin-coated 24-well plates seeded with HUVECs at a density of ∼50,000 cells/well, and grown to confluence, after which cells were washed once with warm Medium 199 (supplemented with 2% FBS) and incubated for 16−18 h. Cells were then washed once with warm PBS and incubated for 6 h in supplemented phenol-red free Medium 199 (Invitrogen, Paisley, U.K.) with 0.1 μM angiotensin II, 30 μM ferricytochrome *c*, and 0.1, 1, or 10 μM of the treatment compounds or 5 μM VAS2870 (selective NOX inhibitor[22]), in the presence or absence of 65 units of superoxide dismutase (SOD). Aliquots of cell supernatants were subsequently transferred to a 96-well microplate for measurement of absorbance at 550 nm. Culture plates were frozen at −80 °C for protein extraction.

Direct Cytochrome *c* Reduction. Direct reduction of cytochrome *c* was assessed by coincubation of treatment compounds in cell-free extracts at concentrations of 2, 20, 200, and 2000 μM with 20 μM cytochrome *c* in PBS at 37 °C, as described previously for catechols and quinols.[23] The spontaneous reduction of cytochrome *c* was monitored kinetically at 550 nm over 2 h. Cytochrome *c* reduction was quantified using the millimolar extinction coefficient for reduced cytochrome *c* (29.5 mM cm^{-1}).

Superoxide Production. Cell-free superoxide production by xanthine/xanthine oxidase was measured using a previously described method.[21] Briefly, 200 μM of cytochrome *c*, 0.1 U/mL xanthine oxidase, and 200 μM xanthine was added to 1, 10, 100, and 1000 μM of the treatment compounds in 50 mM sodium phosphate buffer (pH 7.4). The reaction kinetics of cytochrome *c* was monitored at 550 nm at 25 °C over 15 min (to reaction plateau). Superoxide generated was determined by subtracting the rate of cytochrome *c* reduction (increase in absorbance at 550 nm) in the presence of SOD versus parallel incubations in the absence of SOD.

Stimulated NOX Isoform/Subunit Gene Expression Assay. Twenty-four well plates (SPL Life Sciences) coated with fibronectin were seeded with HUVECs at a density of ∼30,000 cells/well and the cells grown to confluence. Culture medium was then aspirated, and the cells were incubated for 16−18 h in M199 supplemented with 2% FBS. Thereafter, the cells were incubated for 4 h in supplemented M199 alone (basal), or medium with 0.1 μM angiotensin II in the presence or absence of 0.1, 1, or 10 μM vanillic acid. After incubation, the plates were either frozen at −80 °C or used for RNA extraction.

Stimulated $p47^{phox}$ Protein Expression Assay. Six-well plates (SPL Life Sciences) coated with fibronectin were seeded with HUVECs or HCAECs at a density of 100,000 cells/well, and cells were grown to confluence. Culture medium was then aspirated, and the cells were incubated for 16−18 h in M199 supplemented with 2% FBS (HUVECs only). Cells were subsequently incubated for 5 h in supplemented M199 alone (basal), or medium with 20 ng/mL TNF-α in the presence or absence of 0.1, 1, or 10 μM vanillic acid. After incubation, medium was aspirated from all wells, and the plates frozen at −80 °C until protein extraction.

Endothelial HO-1 Expression Assay. Expression of HO-1 mRNA/protein was assessed using fibronectin-coated 6-well plates (SPL Life Sciences) seeded with HUVECs or HCAECs at a density of

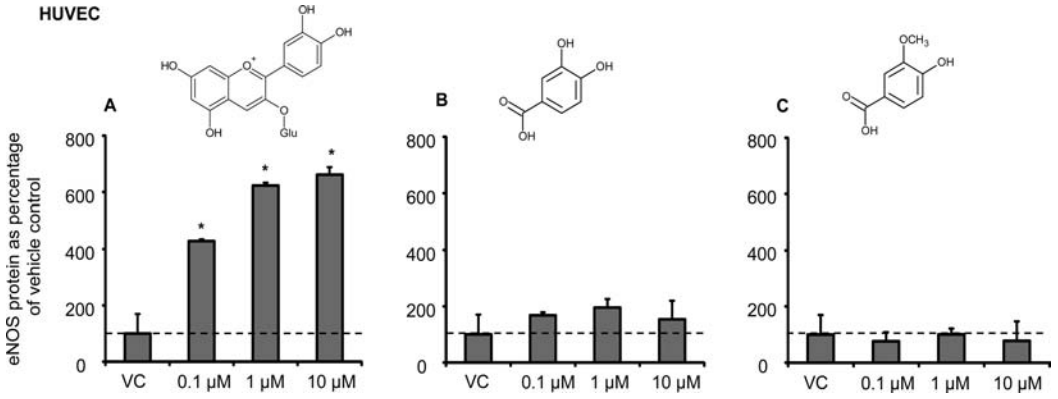

Figure 2. Modulation of endothelial eNOS expression (as quantified by ELISA of cell lysates) following 24 h incubation of HUVECs with vehicle control [0.05% DMSO in supplemented culture medium] (VC) or 0.1−10 μM cyanidin-3-glucoside (A), protocatechuic acid (B), and vanillic acid (C). Data are graphed as mean eNOS protein as percentage of vehicle control (designated as 100% and marked by dashed line); mean ± SD (n = 3). *Significant difference versus vehicle control (p < 0.05).

~100,000 cells/well, and grown to ~70% confluence. Culture medium was then aspirated, and the cells were incubated for 6 h in supplemented culture medium alone (basal), or medium with 10 ng/mL phorbol 12-myristate 13-acetate (PMA, positive control), vehicle control (0.005% DMSO; HUVECs only), or 0.1, 1, or 10 μM vanillic acid. After incubation, medium was aspirated from all wells and the plates either frozen at −80 °C or used for RNA or protein extraction.

Reverse Transcription−Quantitative Polymerase Chain Reaction. RNA was extracted from cells using TRIzol reagent, according to the manufacturer's instructions; and 1 μg of each sample was utilized in a reverse transcription reaction with SuperScript II. Analysis of gene expression was performed using the Applied Biosystems 7500 Real time PCR System (Life Technologies; 7500 software version 2.0) with SYBRGreen detection. Typically, 25 ng of cDNA was amplified with 300 nM of the appropriate primer set. Following enzyme activation at 95 °C for 10 min, 50 cycles of denaturation (15 s at 95 °C) and data collection (60 s at 60 °C) were performed. Relative changes in gene expression were quantified using the comparative C_t method.[24] Optimal stably expressed human reference genes for normalization of C_t data were identified using a geNormPLUS kit with primer sets for six genes (PPIA, PRDM4, UBE2D2, UBE4A, TWY1, VIPAS39) supplied by PrimerDesign Ltd.

Immunoblot Analysis of Endothelial NOX Isoform/Subunit and HO-1 Expression. Cells were harvested and lysed with 1% IGEPAL (octylphenoxy polyethoxyethanol, CA-630), 150 mM NaCl, 20 mM Tris, and 10% glycerol (pH 8.0), supplemented with protease inhibitors (Roche Complete Protease Inhibitor Cocktail). Plates were incubated with lysis buffer for 0.5 h at 4 °C, and recovered solutions were subjected to cell disruption by oscillation (50 Hz for 5 min with Qiagen TissueLyser LT). After centrifugation at 13,000 rpm (15 min at 4 °C) the protein content of the supernatants was assayed using the Pierce BCA Protein Assay Kit (Fisher Scientific U.K. Ltd., Loughborough, U.K.) according to the manufacturer's instructions.

For SDS−PAGE, cell lysates were reduced using 50 mM dithiothreitol. Briefly, 15−25 μg of protein was loaded onto a 4% polyacrylamide stacking gel, and separated across a 10% resolving gel (at 25 mA for 1 h) prior to semidry transfer to Immobilon-FL PVDF membrane (Millipore, Watford, U.K.) at 200 mA for 1.5 h. Membranes were blocked for 1 h at room temperature and incubated overnight (at 4 °C) with chicken polyclonal anti-glyceraldehyde-3-phosphate dehydrogenase (GAPDH, Millipore) or goat polyclonal anti-actin (Santa Cruz Biotechnology, Inc., California, USA); and either rabbit polyclonal anti-gp91phox (Millipore), rabbit polyclonal anti-NOX4 (Abcam, Cambridge, U.K.), rabbit polyclonal anti-$p47^{phox}$ (Santa Cruz Biotechnology, Inc., or Abcam), or rabbit polyclonal anti-HO-1 (Abcam). Membranes were then washed prior to incubation with either donkey anti-chicken IgG (IR dye 680 LT) or donkey anti-goat IgG (IR dye 680) and goat anti-rabbit IgG (IR dye 800 CW) (Li-Cor, Cambridge, U.K.) for 1 h at room temperature. Membranes were washed and subsequently imaged and quantified using an Odyssey Infrared Imaging System (Li-Cor; Application Software version 3.0.21).

Statistical Analysis. Analysis of variance (ANOVA) with LSD post hoc test was performed using SPSS software (IBM, New York, USA) version 18 for Windows. Significance was determined at the 5% level relative to basal or the assay control. Three biological replicates for each control or treatment were utilized for analysis unless otherwise noted. Means of biological replicates were represented graphically, with error bars denoting standard deviation from the mean. For each control or treatment in the stimulated superoxide production assay, mean absorbance ratio (550 nm/620 nm) in the presence of SOD (n = 3) was subtracted from individual absorbance ratio values in the absence of SOD (n = 3), to correct for cytochrome c reduction owing to generated superoxide. Mean SOD-corrected absorbance ratio for each treatment was then represented graphically as percentage of that for the angiotensin II control.

RESULTS

Endothelial Cytotoxicity. All treatments were screened for cytotoxicity at a concentration of 10 μM, representing the highest concentration used in subsequent bioactivity investigations. No significant effects (p > 0.05) on endothelial cell viability were observed following a 24 h incubation of HUVECs with 10 μM of any treatment compound (data not shown).

Endothelial NO Production. Cyanidin-3-glucoside and the phenolic derivatives protocatechuic acid and vanillic acid did not significantly alter endothelial NO production as measured by levels of NO decomposition products (nitrite and nitrate) in HUVEC supernatants (Supporting Information, Figure S1). Resveratrol (100 μM) and PMA (10 nM) were used as positive controls to confirm the sensitivity of the assay and elicited significant increases in total nitrite and nitrate (>270% above basal levels).

eNOS Expression in Cultured HUVECs. Significant upregulation of eNOS (p < 0.001) was observed following 24 h incubation of HUVECs with 0.1, 1, and 10 μM cyanidin-3-glucoside (~4−7-fold increase; Figure 2A). No significant alteration in eNOS levels was observed at any concentration of protocatechuic acid (Figure 2B) or vanillic acid (Figure 2C).

Stimulated Endothelial Superoxide Production. The generation of superoxide anion was confirmed using a previously reported NOX inhibitor VAS2870,[22] in the presence and absence of angiotensin II, where coincubation with

DOI: 10.1021/jf5041993
J. Agric. Food Chem. 2015, 63, 2423−2431

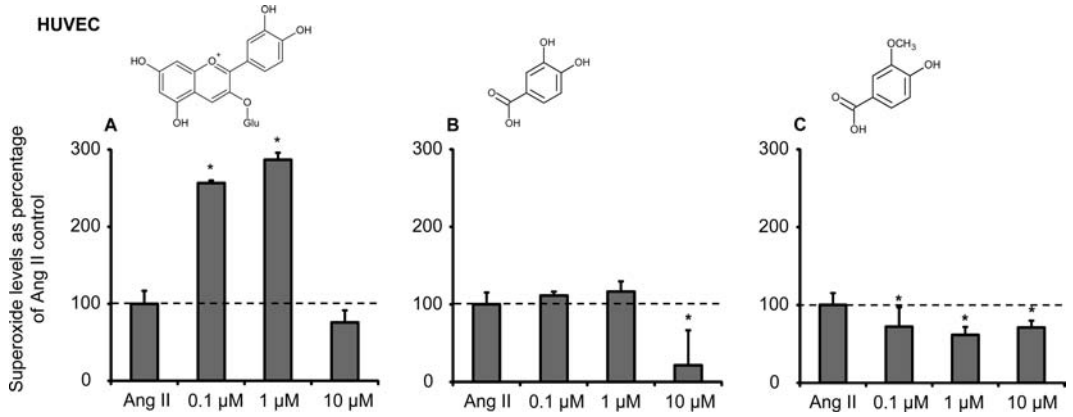

Figure 3. Modulation of angiotensin II (Ang II)-stimulated HUVEC superoxide production by 0.1−10 μM cyanidin-3-glucoside (A), protocatechuic acid (B), or vanillic acid (C). Superoxide production was quantified by reduction of extracellular ferricytochrome *c*. Data are graphed as SOD-corrected mean absorbance (OD) ratio (550 nm/620 nm) as percentage of Ang II control (designated as 100% and marked by dashed line); mean ± SD (n = 3). *Significant difference versus Ang II stimulated control (p < 0.05).

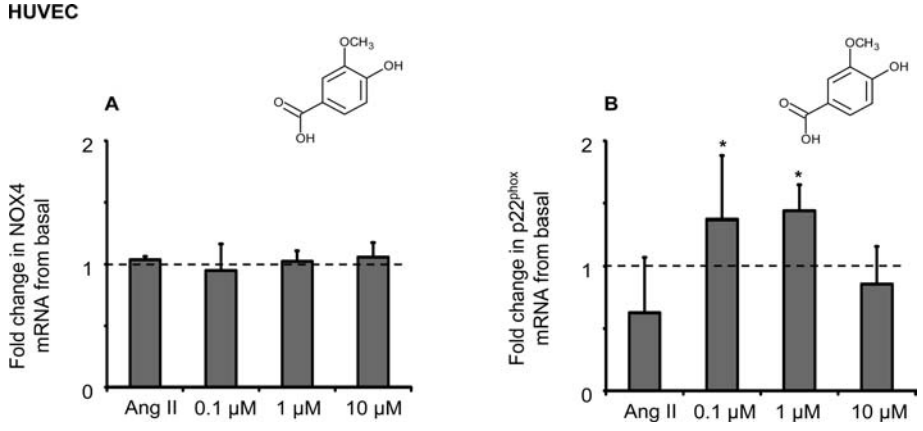

Figure 4. Modulation of HUVEC NOX4 (A) or $p22^{phox}$ (B) mRNA levels following 4 h incubation with 0.1 μM angiotensin II control (Ang II), or Ang II with 0.1 μM, 1 μM, or 10 μM vanillic acid, presented as fold change versus unstimulated cells (basal; designated as 1 and marked by dashed line). Relative quantification was performed by RT-qPCR using the comparative C_t method, incorporating the geometric mean of reference genes UBE4A and VIPAS39 as the normalization factor. Data are graphed as mean ± SD (n = 3). *Significant difference versus Ang II stimulated control (p < 0.05).

VAS2870 significantly reduced superoxide production (p < 0.01) (Supporting Information, Figure S2).

Significantly elevated superoxide levels were detected following incubation of cells with 0.1 μM and 1 μM cyanidin-3-glucoside (∼3-fold increase; Figure 3A), relative to the angiotensin II stimulated control. A significant decrease in superoxide (p < 0.001) was induced by protocatechuic acid, at 10 μM (∼5-fold decrease; Figure 3B), while vanillic acid elicited statistically significant reductions (p < 0.05) in superoxide at all concentrations examined (∼2-fold decrease at 1 μM; Figure 3C). A linear dose−response relationship was not evident for any treatment. Control experiments were conducted to exclude possible confounding through direct reduction of cytochrome *c*, or scavenging of NOX-derived superoxide radicals, by the treatments. There was no significant impact on cytochrome *c* reduction (≤0.02 nmol h^{-1}) or superoxide levels (75−106% of control) during incubations with treatment compounds at concentrations up to 10 μM in cell-free systems.

Stimulated Endothelial Gene Expression of NOX Isoforms and Subunits. Vanillic acid was examined for effects on stimulated endothelial gene expression of the NOX2 and NOX4 isoforms, and the associated subunits $p22^{phox}$, $p47^{phox}$, and $p67^{phox}$. Real time PCR melt curve data indicated non-specific amplification for NOX2, $p47^{phox}$, and $p67^{phox}$ primer sets (data not shown); therefore relative quantification of gene expression was performed for NOX4 and $p22^{phox}$ only. Coincubation of HUVECs with angiotensin II and vanillic acid (0.1, 1, and 10 μM) for 4 h elicited no significant differences in NOX4 mRNA compared to the angiotensin II control (p > 0.05; Figure 4A). A statistically significant (p < 0.05) upregulation of $p22^{phox}$ mRNA levels was observed with vanillic acid at 0.1 μM and 1 μM (Figure 4B).

Stimulated Endothelial Protein Expression of NOX Isoforms and Subunits. The modulation of NOX2 and NOX4 isoforms by vanillic acid was further characterized at the protein level. Following angiotensin II stimulation, weak immunoreactive bands corresponding to NOX2 were visualized by immunoblotting of endothelial lysates, such that quantification of bands by densitometry was not possible (data not shown). By contrast, angiotensin II-induced upregulation of NOX4 expression was observed, although this was not significantly modulated (p > 0.05) by coincubation of cells with angiotensin II and vanillic acid at any concentration examined (0.1−10 μM) (Figure 5).

DOI: 10.1021/jf5041993
J. Agric. Food Chem. 2015, 63, 2423−2431

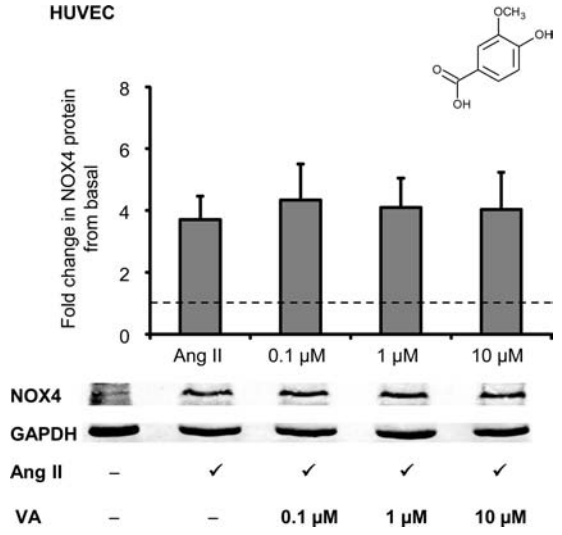

Figure 5. Expression of NOX4 protein in cell lysates from unstimulated HUVECs (basal) and following 6 h incubation with 0.1 μM angiotensin II (Ang II), or Ang II with 0.1 μM, 1 μM, or 10 μM vanillic acid (VA). Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was utilized as a loading control for immunoblotting of cell lysates. Graphs show fold increase in NOX4 expression relative to basal (designated as 1 and marked by dashed line), after quantification by densitometry and normalization to loading control (mean ± SD, n = 5).

The effect of vanillic acid on stimulated protein expression of the key NOX2 subunit p47^{phox} was also investigated as a possible mechanism of NOX inhibition. Following coincubation of HUVECs with 20 ng/mL TNF-α and increasing concentrations of vanillic acid (0.1, 1, or 10 μM) for 5 h, a trend toward decreased p47^{phox} expression was observed relative to TNF-α alone (Figure 6A), although these changes were not statistically significant (p = 0.06 at 1 μM and 10 μM vanillic acid). A confirmatory experiment was conducted using the HCAEC model, but here no effect was detected on TNF-α stimulated p47^{phox} expression (p > 0.05; Figure 6B).

Endothelial HO-1 Expression. Modulation of HO-1 expression by vanillic acid was examined as a putative indirect mechanism of NOX inhibition. Incubation of HUVECs with the protein kinase C activator PMA (at 10 ng/mL) for 6 h induced a significant increase in basal HO-1 mRNA levels (p < 0.001 versus vehicle control; Figure 7). Vanillic acid, at concentrations of 0.1, 1, and 10 μM, elicited a concentration-dependent elevation in endothelial HO-1 mRNA (~1.6-fold versus unstimulated cells with 10 μM vanillic acid), with a trend toward significance compared to vehicle control (p = 0.1) at 10 μM (Figure 7). Trends toward elevated expression of HO-1 protein in HUVECs were also observed following a 6 h incubation with PMA (~1.9-fold increase versus unstimulated

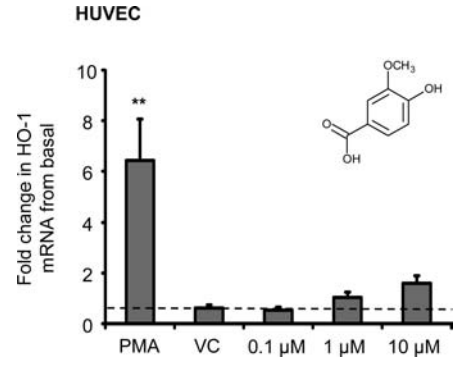

Figure 7. Modulation of HUVEC HO-1 mRNA levels following 6 h incubation with vehicle control (VC, 0.005% DMSO), 10 ng/mL phorbol 12-myristate 13-acetate (PMA), or 0.1 μM, 1 μM, or 10 μM vanillic acid, presented as fold change versus untreated (basal) cells (designated as 1 and marked by dashed line). Relative quantification was performed by RT-qPCR using the comparative C_t method, incorporating the geometric mean of human reference genes TYW1 and PPIA as the normalization factor. Data are graphed as mean ± SD (n = 3). *Significant difference versus vehicle control (*p < 0.01).

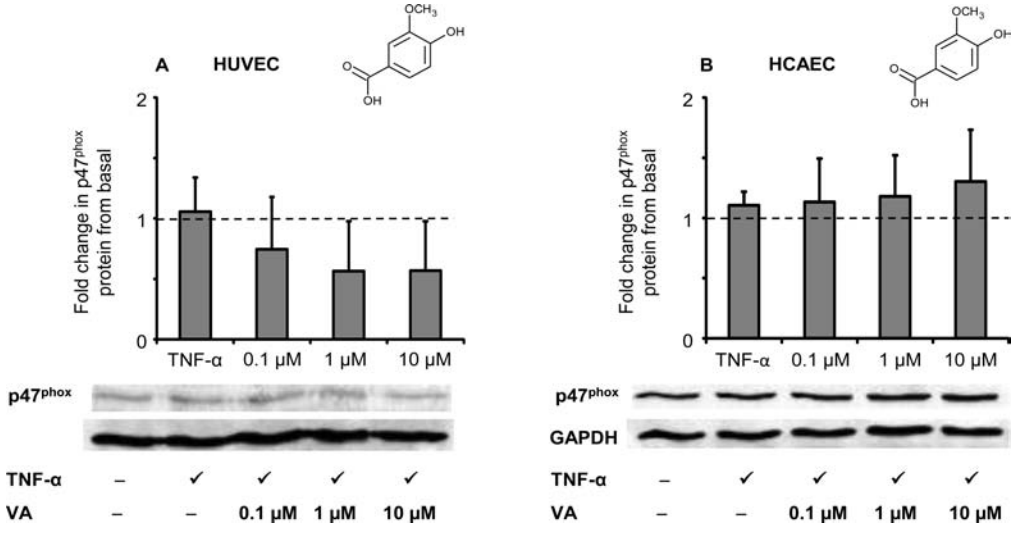

Figure 6. Expression of p47^{phox} protein in HUVEC (A) or HCAEC (B) lysates from unstimulated cells (basal) and following 5 h incubation with 20 ng/mL TNF-α, or TNF-α with 0.1 μM, 1 μM, or 10 μM vanillic acid. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was utilized as a loading control for immunoblotting of cell lysates. Graphs show fold increase in p47^{phox} expression relative to basal (designated as 1 and marked by dashed line), after quantification by densitometry and normalization to loading control. Data are graphed as mean ± SD (n = 5 for HUVECs and n = 4 for HCAECs).

DOI: 10.1021/jf5041993
J. Agric. Food Chem. 2015, 63, 2423−2431

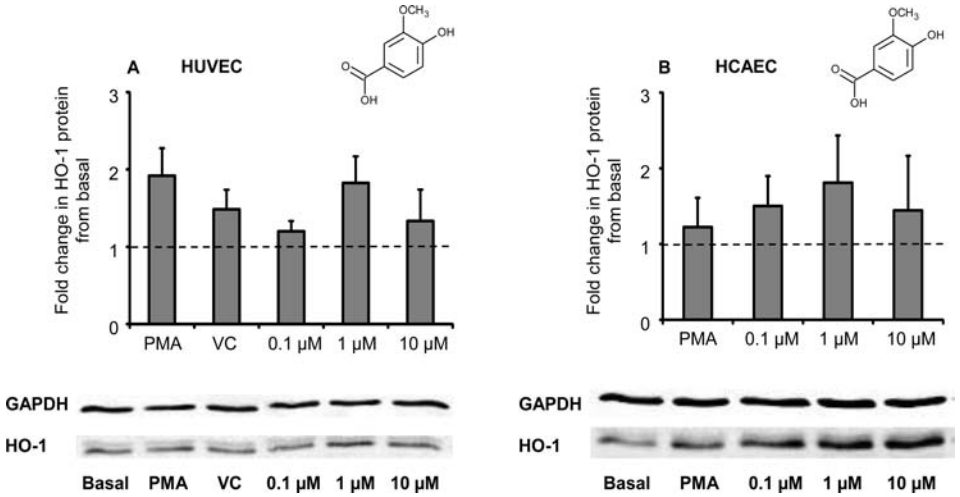

Figure 8. Expression of HO-1 protein in HUVEC (A) or HCAEC (B) lysates from untreated cells (basal) and following 6 h incubation with 10 ng/mL phorbol 12-myristate 13-acetate (PMA), vehicle control (VC, 0.005% DMSO; HUVECs only), or 0.1 μM, 1 μM, or 10 μM vanillic acid. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was utilized as a loading control for immunoblotting of cell lysates. Graphs show fold increase in HO-1 expression relative to basal (designated as 1 and marked by dashed line), after quantification by densitometry and normalization to loading control. Data are graphed as mean ± SD (n = 4).

cells) or vanillic acid (~1.8-fold increase at 1 μM vanillic acid) relative to the vehicle control (p = 0.07 and p = 0.1 respectively; Figure 8A). Since the vehicle control (0.005% DMSO) also appeared to upregulate HO-1 protein, vanillic acid was prepared directly in aqueous solution for use in the HCAEC model, to exclude any vehicle-related effects. Expression of HO-1 protein was slightly elevated following a 6 h incubation with PMA in the HCAEC model (~1.2-fold increase versus unstimulated cells; Figure 8B). An apparent upregulation of HO-1 protein was observed at all concentrations of vanillic acid tested (Figure 8B), with a trend toward significance at 1 μM (~1.8-fold increase; p = 0.07) relative to basal.

DISCUSSION

The low bioavailability of parent anthocyanins suggests that their bioactivity in vivo is mediated by phenolic metabolites, which have recently been reported as the main circulating species following anthocyanin consumption.[17−19] Here, we report that phenolic metabolites appear to modulate vascular endothelial cell function through alternative mechanisms to those previously described for parent anthocyanins. In the present study, the parent anthocyanin increased eNOS expression, whereas phenolic derivatives had no effect. However, these metabolites elicited reductions in superoxide production, which could subsequently decrease scavenging of NO. Recent studies by Czank et al. (2013) and de Ferrars et al. (2014) have confirmed a physiologically appropriate range for anthocyanin metabolites in humans of 0.1−10 μM,[17−19] and the present study assessed potential mechanisms of activity at these concentrations. Indeed, following consumption of 500 mg of ^{13}C-labeled cyanidin-3-glucoside, a serum C_{max} of 1.85 μM has been reported for vanillic acid, with 1 μM concentrations persisting for up to 24 h,[19] suggesting that phenolic derivatives of anthocyanins may be present in the systemic circulation at low micromolar levels for at least 18−24 h after ingestion of parent anthocyanins. Based on our findings, physiologically relevant levels of anthocyanin metabolites are likely to act indirectly to maintain vascular homeostasis, through induction of HO-1 and decreased endothelial superoxide generation, as opposed to directly stimulating eNOS activity and NO production.

Endothelium-derived NO is a key component of vascular homeostasis,[11] and prior in vitro studies have described both upregulation and activation of the eNOS enzyme by anthocyanins (including cyanidin-3-glucoside) in cultured endothelial cells at concentrations ranging from 0.001 μM up to 250 μM.[7,8,13] Interestingly, in the present study we observed differential bioactivity for cyanidin-3-glucoside relative to its phenolic acid derivatives. Specifically, no treatment compounds significantly modulated endothelial NO production, however, cyanidin-3-glucoside significantly upregulated eNOS protein levels, while the phenolic derivatives remained inactive (Figure 2).

NOX enzymes represent a major source of reactive oxygen species in the vasculature,[12,25] and anthocyanin metabolites could act as endothelial NOX inhibitors, based on previously reported structure−activity studies.[21] In the current study, differential bioactivity was again observed for cyanidin-3-glucoside relative to its phenolic acid derivatives. A significant elevation in superoxide levels was elicited by cyanidin-3-glucoside; and in contrast, both protocatechuic acid and vanillic acid significantly reduced superoxide levels (Figure 3). While previous reports have described superoxide scavenging[26] and direct cytochrome c reduction[27] elicited by flavonoids, such activity is reported at much higher concentrations (~40−100 μM) than those used in the current investigation (≤10 μM), and control experiments in cell-free incubations confirmed negligible superoxide scavenging or direct cytochrome c reduction by the treatments. High concentrations of phenolic compounds in culture medium have also been reported to result in the generation of hydrogen peroxide,[28] which could potentially interfere with assay methodologies; however, only minimal hydrogen peroxide formation has previously been reported for delphinidin (at 10 μM),[28] which is one of the most reactive anthocyanins.[29] Therefore, data from cell-free experiments in the current study indicate that the treatment compounds do not directly scavenge superoxide radicals, as negligible activity was observed, and the present findings likely

DOI: 10.1021/jf5041993
J. Agric. Food Chem. 2015, 63, 2423−2431

reflect reduced endothelial superoxide generation as opposed to radical scavenging.

The phenolic derivative vanillic acid (the methylated metabolite of protocatechuic acid) was subsequently selected to explore mechanisms potentially underlying the observed reductions in superoxide production. In the present study, vanillic acid at a concentration of 1 μM significantly reduced endothelial superoxide levels, which is comparable to the C_{max} value reported by Czank et al. (2013) for ^{13}C-labeled phase II conjugates of protocatechuic acid (2.35 μM) following ingestion of ^{13}C-labeled cyanidin-3-glucoside.[17] Steffen et al. (2008) have previously described NOX inhibitory activity of vanillic acid in disintegrated HUVECs (IC_{50} = 8.1 μM), with minimal direct superoxide scavenging activity in a cell-free system (IC_{50} > 100 μM),[21] which was confirmed by the absence of direct superoxide scavenging by vanillic acid in the present study.

NOX4 is reported to be the major vascular endothelial isoform,[30,31] producing mainly hydrogen peroxide;[32] and while NOX4-derived hydrogen peroxide would not act to limit NO bioavailability,[33] it might induce vasodilation through hyperpolarization independently of NO activity.[34] In contrast NOX2 generates superoxide[35] and may have a key role in regulating vascular function.[32,36] Both NOX2 and NOX4 associate with the integral membrane protein $p22^{phox}$,[37] but activation of NOX2 follows the recruitment of additional cytosolic proteins including $p47^{phox}$ ("organizer" subunit) and $p67^{phox}$ ("activator" subunit).[37,38] Modulation of the expression of NOX2 and NOX4 isoforms, and associated subunits ($p22^{phox}$, $p47^{phox}$, and $p67^{phox}$) by vanillic acid was therefore explored using RT-qPCR. Coincubation of angiotensin II with vanillic acid elicited no significant changes in levels of endothelial NOX4 mRNA relative to angiotensin II alone (Figure 4A). However, a significant upregulation of $p22^{phox}$ mRNA levels was observed with 0.1 and 1 μM vanillic acid (Figure 4B), while we were unable to assess transcriptional modulation of the superoxide-generating NOX2 isoform, or $p47^{phox}$ and $p67^{phox}$. Therefore, the effects of vanillic acid on the stimulated expression of NOX2 and $p47^{phox}$, and also NOX4, were explored at the protein level.

There was no significant modulation of stimulated NOX4 protein expression by vanillic acid (Figure 5), indicating that this particular metabolite does not affect endothelial NOX4 protein. NOX2 expression was more difficult to discern by immunoblotting of cell lysates, which may reflect low mRNA/protein expression in vascular cells, and/or poor antibody specificity, although upregulation of NOX2 in HUVECs following angiotensin II stimulation has been previously reported.[20] Interestingly, the observed elevation in $p22^{phox}$ mRNA induced by vanillic acid did not appear to be associated with increased NOX4 or NOX2 protein levels. Modulation of $p47^{phox}$ protein expression was examined as a possible mechanism of NOX2 inhibition, and here a trend was observed toward downregulation of $p47^{phox}$ protein following coincubation with TNF-α and vanillic acid (Figure 6A). Interestingly, in the HCAEC model, vanillic acid did not modulate stimulated $p47^{phox}$ expression (Figure 6B), and thus vanillic acid does not appear to significantly alter $p47^{phox}$ levels (under the present conditions) and therefore affect NOX2 activity by this mechanism. However, the anthocyanidin delphinidin has recently been reported to inhibit $p47^{phox}$ translocation and NOX activity in human dermal fibroblasts,[39] suggesting another potential mechanism by which anthocyanins and/or their degradation products could modulate NOX function.

Upregulation of HO-1 has been reported to inhibit NOX function;[14,15] and previous studies have described induction of HO-1 expression by anthocyanins and/or their metabolites in human endothelial cells.[13,40] For example, Nrf2 nuclear translocation and HO-1 expression in cultured HUVECs was elicited by serum samples obtained from healthy subjects following ingestion of 160 mg of purified anthocyanins, which may reflect activity of anthocyanin metabolites as opposed to parent compounds.[40] Moreover, delphinidin-3-glucoside has previously been reported to enhance survival of murine hepatocytes exposed to a cytotoxic concentration of epigallocatechin-3-gallate through upregulation of HO-1 mRNA levels.[41] Endothelial homeostasis is maintained through the action of vasodilators such as NO, however NO bioactivity is diminished by radicals such as $O_2^{\bullet-}$ which are produced through activation of NOX.[9,12] Anthocyanin metabolites could potentially indirectly maintain vascular homeostasis by inducing HO-1, with subsequent inhibition of NOX activity, thus reducing the scavenging of NO by NOX-derived superoxide.[14,15,40] Therefore, the potential indirect effect of vanillic acid on NOX activity was explored by assessing modulation of endothelial HO-1 expression. Following exposure of HUVECs to vanillic acid, elevated HO-1 mRNA levels were observed in what appeared to be a concentration-dependent response (Figure 7), with a trend toward significance relative to the vehicle control (at 10 μM vanillic acid). Likewise, vanillic acid increased HUVEC HO-1 protein expression (Figure 8A), and densitometric analysis indicated a trend toward significance at 1 μM. The vehicle control also appeared to moderately upregulate HO-1, reflecting previously reported studies in HUVECs with low concentrations of DMSO (0−0.8%).[42] As such, vanillic acid was prepared directly in aqueous solution for investigation in the HCAEC model, where a similar trend for upregulation of HO-1 protein was evident (at 1 μM; Figure 8B), suggesting an inverted U-shaped dose response.

A possible limitation of the current investigation was the use of HUVECs as an in vitro model. While HUVECs are widely used for research concerning general properties of endothelial cells,[43] an arterial endothelial cell type may be more appropriate for studies investigating the potential modulation of NOX activity in relation to endothelial dysfunction. Thus, as part of the current investigation confirmatory studies were conducted for potential modulation of $p47^{phox}$/HO-1 expression, using HCAECs as a more physiologically representative endothelial model. Furthermore, in the present study there was no effect of cyanidin-3-glucoside on endothelial NO production (Supporting Information, Figure S1), despite a previous report of activation of eNOS by cyanidin-3-glucoside at concentrations of ≤5 μM in HUVECs.[7] It is possible that assessing eNOS activity by investigating enzyme phosphorylation, as described previously for blackcurrant anthocyanins in a HUVEC model,[44] could have provided further information as to the effects of treatment compounds upon eNOS. NO production was clearly increased by PMA and resveratrol in control experiments, indicating adequate assay sensitivity for the detection of NO-derived nitrite/nitrate in aqueous solution. It is however possible that the assay was not sensitive enough to detect subtle changes in nitrite/nitrate. Interestingly, and with the possible exception of the upregulation of eNOS by cyanidin-3-glucoside, linear dose−response relationships were not observed for any treatment in the current investigation,

DOI: 10.1021/jf5041993
J. Agric. Food Chem. 2015, 63, 2423−2431

suggesting differential bioactivity of anthocyanins and their metabolites across dose ranges, as described previously for cyanidin-3-glucoside.[8] However, as only three concentrations of the treatment compounds were assessed in the current study, it is not possible to draw definitive conclusions regarding dose−response relationships, and a wider dosage range is required to confirm our observations.

Another limitation of the present study was the poor qPCR specificity observed for NOX2, $p47^{phox}$, and $p67^{phox}$, which precluded determination of relative changes in expression for these transcripts. Previously reported studies have suggested low or no endothelial expression of NOX2 mRNA,[30,45] and low expression of $p47^{phox}$ and $p67^{phox}$ mRNA in HUVECs.[30] Moreover, minimal changes were detected in NOX4 gene expression, and $p47^{phox}$ protein expression, following stimulation with angiotensin II or TNF-α respectively, although limited upregulation of $p47^{phox}$ was consistent in both HUVEC and HCAEC models.

In the present study, cyanidin-3-glucoside significantly upregulated endothelial expression of eNOS as previously reported for unmetabolized anthocyanins,[8,13] however the phenolic acid derivatives were not active. By contrast, both the degradation product protocatechuic acid and its phase II metabolite vanillic acid significantly reduced endothelial superoxide levels, whereas the parent anthocyanin did not. These data suggest a differential bioactivity of anthocyanins relative to their phenolic derivatives. Our findings therefore indicate that anthocyanins may directly stimulate eNOS, eliciting improved endothelial function; however, when anthocyanins are metabolized, this direct effect upon eNOS is lost. Nevertheless, their metabolites could maintain vascular homeostasis through indirectly preserving NO bioactivity, by mechanisms involving NOX or HO-1. It must be noted that Czank et al. (2013) identified 16 phenolic metabolites of cyanidin-3-glucoside in human serum,[17] which should all be investigated for potential vascular bioactivity in future studies. Indeed, preliminary data from ongoing studies in our laboratory suggest that protocatechuic acid, and protocatechuic acid in combination with vanillic acid, upregulate HO-1 protein expression in rat aortic smooth muscle cells in vitro (data not shown).

In conclusion, there was no direct effect of vanillic acid on endothelial protein expression of eNOS or NOX isoforms in the present investigation, whereas HO-1 protein was modestly increased, indicating different mechanisms of bioactivity for phenolic derivatives relative to parent anthocyanins. This also suggests a potential indirect activity of anthocyanin metabolites in maintaining vascular homeostasis in vivo.

$CD44^+$ or $CD133^+$,[17] and CSCs that have survived chemotherapeutic drug treatment can be obtained using their drug-resistance feature.[3,10] In addition, using the induction of epithelia to mesenchymal transition (EMT) in tumor cells, the specific tumor cell population that exhibits stemness after dedifferentiation can be obtained.[18]

Gupta et al.[19] showed that salinomycin selectively kills CSCs and effectively inhibits BCSC survival and mammosphere formation. These results showed that specific inhibition of mammosphere formation might be regarded as an effective measure for breast cancer treatment. Because therapeutic drugs, such as paclitaxel, doxorubicin, docetaxel, and cyclophosphamide, are already used to target breast cancer, development of an adjuvant therapy to target CSCs from natural products that are highly safe, do not have side effects, and can strengthen the effect of chemotherapeutic drugs should be a feasible strategy for breast cancer treatment.[12]

6-Gingerol (6-G) is the most abundant polyphenolic compound in ginger (*Zingiber officinalis*); after dehydration, 6-G becomes 6-shogaol (6-S), which has higher physiological activities. 6-S is the source of the pungent constituent of ginger; it can attenuate neuroinflammation and cognitive deficits[20] and induce colon cancer cell apoptosis through the induction of reactive oxygen species (ROS) production and activation of the caspase pathway.[21] Weng et al.[22] showed that 6-S and 6-G inhibit the invasive characteristics of liver cancer cells. Pterostilbene (PTE), which is extensively present in blueberries and grapes, is a dimethylated analogue of resveratrol and a natural antibacterial substance.[23] Simoni et al.[24] confirmed that PTE can effectively induce apoptosis in HL-60 leukemia cells and can inhibit the invasion and metastasis functions of HepG2 liver cancer cells through the inhibition of the expression of NF-κB and AP-1 transcriptional factors and MMP-9.[23] Nobiletin (5,6,7,8,3′,4′-hexamethoxyflavone, NOL) and 5-hydroxy-3,6,7,8,3′,4′-hexamethoxyflavone (5-HF) are both flavonoids in citrus fruits; previous studies have confirmed that they have antitumor potentials, such as the inhibition of tumor cell invasion and promotion of apoptosis.[25,26]

Modern chemotherapies are designed to prevent the local recurrences of primary tumors and the distant metastases of tumor cells. However, the effective doses of many chemotherapeutics cause severe side effects. There is considerable interest in the discovery and investigation of more potent anticancer stemness compounds to prevent and delay cancer recurrence. Important attributes of an ideal inhibitor would be easy obtainment, absorption, and excretion, little or none toxicity, and the absence of serious side effects. Naturally occurring polyphenols such as 6-G, 6-S, 5-HF, NOL, and PTE should, therefore, be ideal candidates for reducing cancer stemness. Although previous paper have described the antitumor activities of the above phytochemicals, no studies have been made of their selective cytotoxic effects on CSCs and their parental cancer cells. In the field of CSC studies, BCSCs were discovered early and could be identified using cell surface antigens. Therefore, there are detailed reports on the isolation and identification of CSCs that can be referenced. On the basis of these reports, this study aimed to investigate the effects of 6-S, 6-G, PTE, NOL, and 5-HF on BCSC proliferation and clarify the underlying molecular mechanisms.

MATERIALS AND METHODS

Chemicals. 6-G and 6-S were isolated and purified as previously described.[27] 5-HF and NOL were synthesized according to the previous method.[28] PTE was synthesized according to the method reported by Pettit et al.[29] Epidermal growth factor (EGF), basic fibroblast growth factor (bFGF), human leukemia inhibitory factor (hLIF), insulin-transferrin-sodium selenite supplement (ITSS), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), fish gelatin, anti-β-actin antibody, HEPES buffer, Tween-20, and sodium bicarbonate were purchased from Sigma Chemical Co. (St. Louis, MO, USA). The protein assay kit and Tris-base were obtained from Bio-Rad (Hercules, CA, USA). B27 supplement, Dulbecco's modified Eagle's medium/Ham's F-12 (DMEM/F12) medium, Roswell Park Memorial Institute (RPMI) 1640 medium, fetal bovine serum (FBS), trypsin-EDTA, propidium iodide (PI), and penicillin–streptomycin were purchased from Invitrogen (Carlsbad, CA, USA). The nuclear/cytosol fractionation kit was purchased from BioVision (Milpitas, CA, USA). Dimethyl sulfoxide (DMSO) was obtained from Merck Co. (Darmstadt, Germany). Anti-phospho-GSK3β (ser9), anti-notch, anti-STAT3, anti-phospho-STAT3, anti-survivin, and anti-Sonic-hedgehog antibodies were obtained from Millipore (Bedford, MA, USA). Anti-β-catenin, anti-phospho-β-catenin (Ser33/37/Thr41), anti-mTOR, anti-phospho-mTOR, anti-Akt, and anti-phospho-Akt (ser473) antibodies were purchased from Cell Signaling Technology (Beverly, MA, USA). Anti-cyclin D1, anti-c-Myc, and anti-GSK3 antibodies were obtained from Santa Cruz Biotechnology Inc. (Santa Cruz, CA, USA). Anti-CD44-PE and anti-CD24-FITC antibodies were obtained from Biolegend (San Diego, CA, USA), and the horseradish peroxidase-conjugated anti-mouse secondary antibody was obtained from Bethyl Laboratories Inc. (Montgomery, TX, USA).

Cell Line and Culture. The MCF-7 human breast adenocarcinoma cell line was obtained from the Bioresource Collection and Research Center (BCRC 60436; Food Industry Research and Development Institute) and was cultured in DMEM supplemented with 10% v/v FBS in a humidified atmosphere of 95% air and 5% CO_2. The medium was changed three times per week. The MCF-7 cells were estrogen receptor positive and characterized as having a low metastatic phenotype.

BCSC Isolation and Culture. MCF-7 cells were detached and resuspended in PBS containing 1% FBS and 1% penicillin/streptomycin (10^6 cells/100 μL). Combinations of fluorochrome-conjugated monoclonal antibodies against human CD44 (FITC) and CD24 (PE) or their respective isotype controls were added to the cell suspension at concentrations recommended by the manufacturer and incubated at 4 °C in the dark for 30 min. Cells were analyzed and sorted on an FACSAria Cell Sorter unit (Becton Dickinson, San Jose, CA, USA), using PI as a viable stain. BCSCs were gated on low side scatter, low-to-moderate forward scatter, and low PI. The $CD44^+/CD24^{-/low}$ phenotype was used to identify and isolate BCSCs, according to a previous study.[30] For data acquisition, at least 10000 events were analyzed. The purity and viability of isolated cells were routinely >98%, as determined by trypan blue dye exclusion. The sorted BCSCs were cultured in stem cell medium (SCM, DMEM/F12 medium containing B27 supplement, 10 ng/mL EGF, bFGF, and ITSS) without FBS.

Mammosphere Formation. Sorted cells were plated on ultralow attachment plates (Corning, Acton, MA, USA) at a density of 20000 viable cells per milliliter and a density of 1000 cells per milliliter for subsequent passages. Cells were grown in SCM as described above. Mammospheres were collected by gentle centrifugation (800 rpm) after 7–10 days and were dissociated enzymatically (10 min in 0.05% trypsin) and mechanically, using a fire-polished Pasteur pipet. The cells obtained from dissociation were passed through a 40 μm sieve and analyzed microscopically for single cellularity. Cells plated at low densities (1000 cells/mL) were grown in conditioned medium from high-density sorted cultures in suspension.

Soft Agar for Anchorage-Independent Growth Assay. BCSCs were harvested and seeded in six-well plates (5×10^4 cells/well) coated with 0.6% agarose. Anchorage-independent growth was assessed after incubation for 10–14 days in culture medium with or without the tested phytochemicals (0, 25, and 50 μM), which was replaced every 2 days. The plates were stained with 0.005% crystal

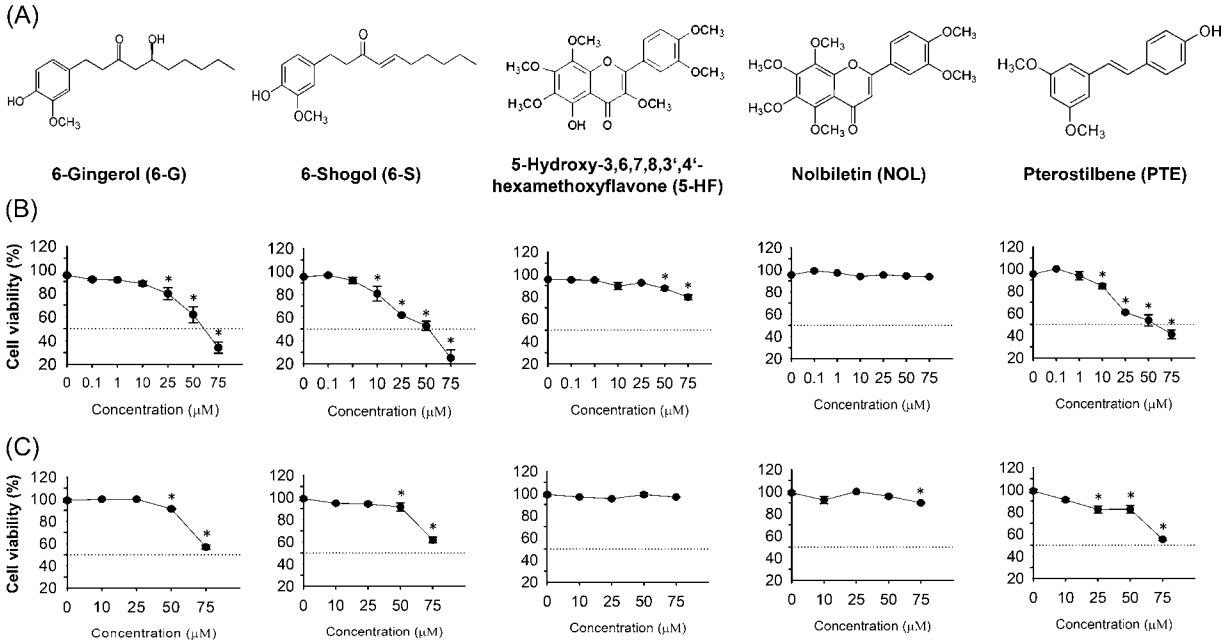

Figure 1. Selective cytotoxicity of 6-gingerol (6-G), 6-shogaol (6-S), 5-hydroxy-3,6,7,8,3′,4′-hexamethoxyflavone (5-HF), nobiletin (NOL), and pterostilbene (PTE) (A) against the $CD44^+/CD24^-$ cell population of MCF-7 cells (B) and MCF7 human breast cancer cells (C). MCF-7 cells or MCF7 $CD44^+/CD24^-$ cells were treated with 0−75 μM of the tested compounds for 72 h. The reported values are the mean ± SD (n = 3); ∗, p < 0.01, indicates significant differences compared with the control group.

violet, and the colonies were counted manually under a microscope and imaged.

Western Blotting. BCSCs were treated with 6-S or PTE for 4−24 h. After treatment, the cell lysates and nuclear fractions were prepared using a nuclear/cytosol fractionation kit. The protein concentrations of the cell lysate and nuclear fractions were estimated with the Bio-Rad DC protein assay using BSA as the standard. Total proteins (25−50 μg) were separated by SDS-PAGE using a 10% polyacrylamide gel and then transferred onto a nitrocellulose membrane. The membrane was blocked with 1% fish gelatin in PBS with 0.05% Tween 20 (pH 7.2) for 1 h. The membranes were then incubated with primary antibodies (1:1000) at 4 °C overnight, followed by incubation with a horseradish peroxide-linked secondary antibody (1:10000). The protein bands were visualized using the ChemiLucent ECL Detection System (Millipore) and the Biospectrum AC Imaging System (UVP, Upland, CA, USA). The expression levels of the proteins of interest were normalized to the expression of β-actin. The intensity of the chemiluminescence signal was quantified using the UVP VisionWorksLS Image Acquisition and Analysis software.

Statistical Analyses. Each experiment was performed in triplicate. The results are expressed as the mean ± SD. The statistical analyses were performed using SAS software, and the variances were assessed using ANOVAs. Significant differences (p < 0.05) between the means were identified by Duncan's multiple-range tests.

RESULTS

Cytotoxic Effects of the Selected Phytochemicals on BCSCs. This study selected five phytochemicals, 6-G, 6-S, 5-HF, NOL, and PTE (Figure 1A), to evaluate with regard to their cytotoxicity on MCF-7 BCSCs ($CD44^+/CD24^-$ subpopulations of MCF-7 cells) and MCF-7 breast cancer cells using the trypan blue assay. The results showed that, of the above five phytochemicals tested at doses of 0.1−75 μM, the IC_{50} values of 6-G, 6-S, and PTE on BCSCs were 50, 25, and 25 μM, respectively (Figure 1B), which was more significant than their effects on MCF-7 parental cells (Figure 1C). Of note, none of these compounds had a cytotoxic effect on primary cultured rat hepatocytes at a concentration of 25 μM for the same time frame (Supporting Information). These results indicated that 6-S and PTE had potent selective toxic effects on BCSCs. Subsequent experiments evaluated the effects of 6-S and PTE on BCSC characteristics.

6-S and PTE Induce Changes in Cell Morphology and Mammosphere-Forming Capacity of BCSCs. The images of cell morphology in Figure 2A show that after a 6 h treatment with 6-S or PTE, cell necrosis phenomena, such as membrane injury and bleb formation, were induced in BCSCs. Mammosphere formation is an important indicator of BCSC differentiation. After BCSCs were treated with 6-S or PTE for 72 h, robust mammosphere disruptions were induced (Figure 2B, left panel), and the number of mammospheres was effectively reduced (Figure 2B, right panel). In addition, this study further simulated a nutrient-deficient or -sufficient environment using SCM without FBS or RPMI 1640 medium containing 10% FBS, respectively, to investigate the effects of 6-S and PTE on mammospheres under different FBS concentrations. The results showed that large BCSC mammospheres were easily induced in a nutrient-deficient environment, whereas mammospheres were at a dormant status in a nutrient-sufficient environment. Under culture conditions without FBS, PTE more effectively reduced the volume of mammospheres than 6-S and promoted their disintegration; however, in an environment containing FBS, neither compound had any influence on mammospheres (Figure 2C).

Effects of 6-S or PTE Combined with Paclitaxel on the Differentiated BCSC Population. This study cultured BCSCs in RPMI medium containing 10% FBS to promote differentiation to observe the effects of the chemotherapeutic drug paclitaxel on the differentiated BCSC population when combined with either 6-S or PTE. Figure 3A shows that 10 nM paclitaxel had significant cytotoxic effects on the differentiated BCSC populations; however, this cytotoxicity was not increased when the dose was increased to 50 nM (Figure 3A, p > 0.05). It is worth noting that 6-S and PTE (Figure 3B) already doubled

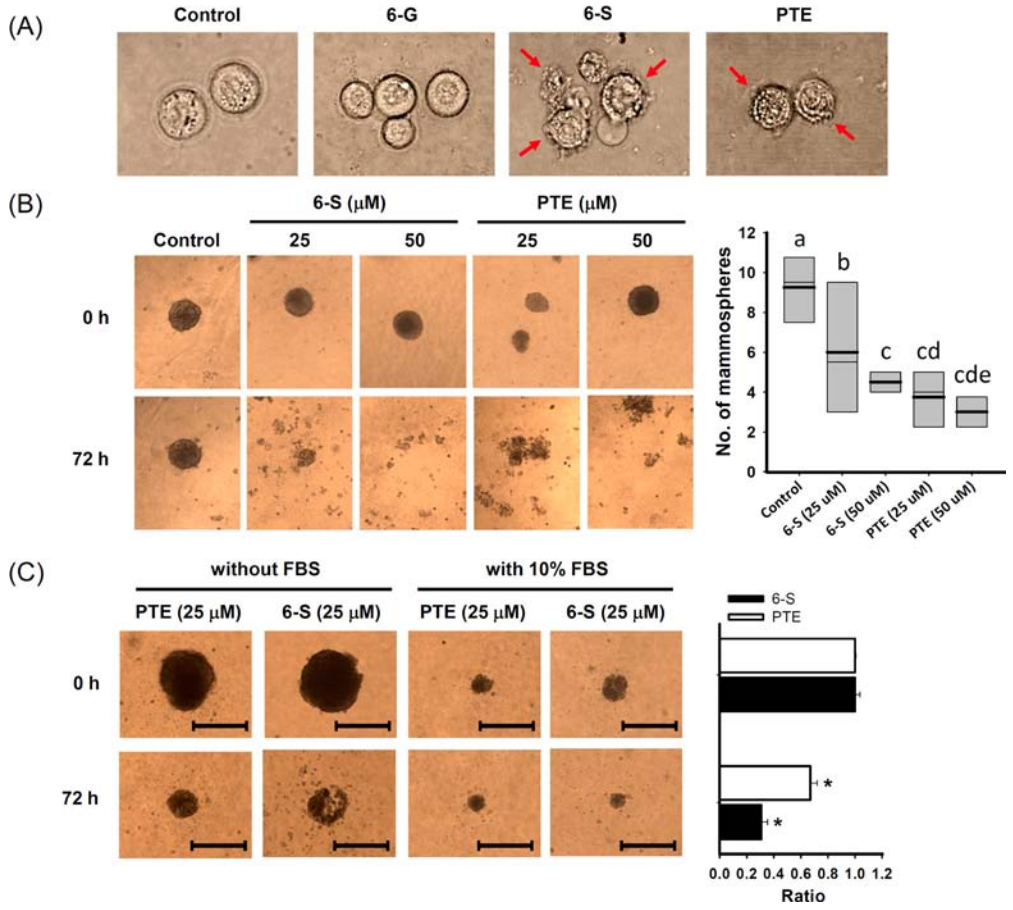

Figure 2. Effects of 6-G, 6-S, and PTE on BCSC morphology, mammosphere formation, and colony formation. (A) Images show the morphology of BCSCs treated with 100 μM of the tested compounds for 6 h (400×). The red arrows indicate blebs on the cell surface. (B) The left-side panels of the figure show mammosphere morphology changes for 0 and 72 h (40×). The right-side panels represent the number of mammospheres (line indicates the median). The cells were treated with 25 or 50 μM 6-S and PTE for 72 h (n = 4). The boxes represent the 25th to 75th percentiles, and horizontal lines within the box represent mean (bold) and median (thin) values, respectively. The bars with different letters are significantly different from each other in individual assays ($p < 0.05$). (C) Images show the morphology of mammospheres that were cultured in stem cell medium without FBS and in RPMI medium plus 10% FBS (40×). The cells were grown in 0.3% soft agar for 14 days and then treated with 25 μM 6-S and PTE for a further 72 h. The right-side panel represents the quantified size of the mammospheres in the left panel. The reported values are the mean ± SD (n = 3); *, $p < 0.05$, indicates significant differences from the control group. BCSCs, breast cancer stem cells.

the cytotoxicity of chemotherapeutic drugs on the differentiated BCSC populations at low doses (0.5 and 10 μM; Figure 3C); therefore, they may increase the antitumor effects of chemotherapeutic drugs.

Effects of 6-S and PTE on the Expression of CD44/CD24 Surface Markers on BCSCs. It is known that the degree of breast cancer cell malignancy is closely associated with the expression of $CD44^+/CD24^-$ on stem cells.[30] When the CD44 surface antigen is activated, breast cancer cell populations evolve into cell populations that have increased invasiveness. This study used flow cytometry to observe the effects of 6-S or PTE on stem cell surface antigen expression in BCSCs. The cell population in the $CD44^+/CD24^-$ quadrant was the BCSC population, whereas the cell population in the $CD44^-/CD24^-$ quadrant was the cell population that had lost stemness. Figure 4 shows that after culture of 6-S or PTE (25 μM) with BCSCs for 72 h, the number of BCSCs was inhibited, and the number of cells that did not have stemness was significantly increased ($p < 0.05$). The maintenance of BCSC stemness was inhibited through a decrease in CD44 expression.

Effects of 6-S and PTE on the Hedgehog Signaling Pathway in BCSCs. The hedgehog signal transduction pathway and β-catenin transcription activity can regulate the differentiation and self-renewal of CSCs.[31] Many studies have regarded the hedgehog pathway as an important indicator for the suppression of drug resistance in CSCs and tumor recurrence. This study cultured BCSCs in SCM with 6-S or PTE (5 and 25 μM) for 4, 8, and 24 h and analyzed the changes in the expression levels of hedgehog, phospho-Akt, Akt, phospho-GSK3β, and GSK3β. The results showed that 6-S (Figure 5A) and PTE (Figure 5B) effectively inhibited hedgehog protein expression and Akt and GSK3β phosphorylation ($p < 0.05$).

Effects of 6-S and PTE on β-Catenin Phosphorylation and Downstream Protein Expression in BCSCs. The Wnt/β-catenin signaling transduction pathway is very important for the maintenance of CSC stemness. Studies have indicated that β-catenin activation is an important target for regulation of CSC differentiation and inhibition of tumor recurrence. In this study, BCSCs were treated with 6-S or PTE (5 and 25 μM) for 4, 8, and 24 h to analyze the changes in the expression of phospho-β-catenin, β-catenin, cyclin D1, and c-Myc. The results showed that 6-S (Figure 6A) and PTE (Figure 6B), at a concentration of 25 μM, significantly induced β-catenin

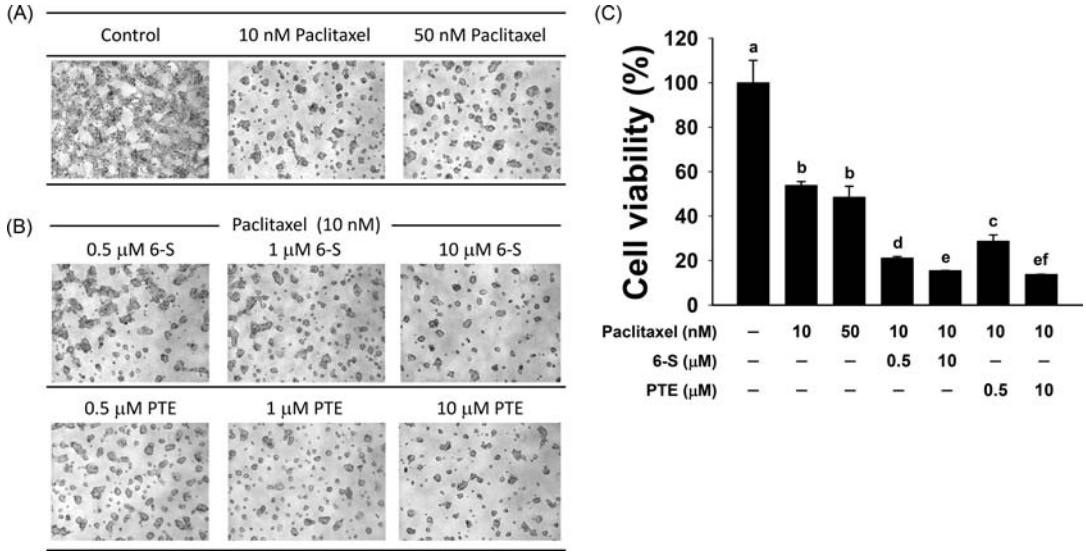

Figure 3. Effects of paclitaxel with or without 6-S and PTE on cell morphology and viability of differentiated BCSCs. BCSCs were first cultured in RPMI medium plus 10% FBS for 7 days to simulate differentiation. Cells were then treated with different concentrations of paclitaxel (A) and 10 nM paclitaxel plus 6-S or 10 nM paclitaxel plus PTE (B) for 72 h. (C) Quantified cell viability in groups A and B. The reported values are the mean ± SD (n = 3). Bars with different letters are significantly different from each other in individual assays (p < 0.05).

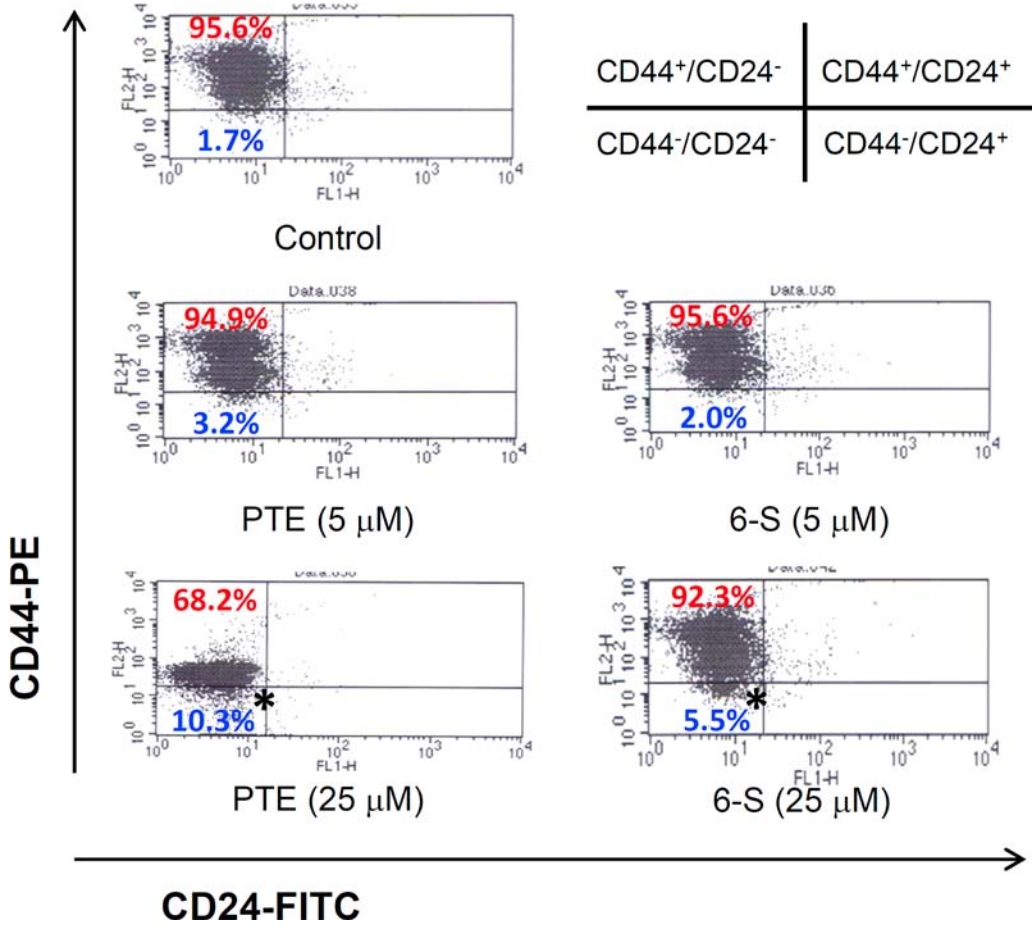

Figure 4. Effects of 6-S and PTE on the expression of the cell surface marker CD44/CD24 in BCSCs. The cells were treated with 0−25 μM 6-S and PTE for 72 h. FITC/PE double-stained cells were analyzed by flow cytometry. Cells that were $CD44^+/CD24^-$ represent the BCSC population. Cells with $CD44^-/CD24^-$ represent a loss of stemness. *, p < 0.05, indicates significant differences compared with the control group.

phosphorylation to increase its degradation and inhibit protein expression of cyclin D1 and c-Myc (p < 0.05). Therefore, 6-S and PTE both effectively increased the level of β-catenin phosphorylation and inhibited the expression of the downstream cyclin D1 and c-Myc proteins; the inhibitory effect of PTE was more significant.

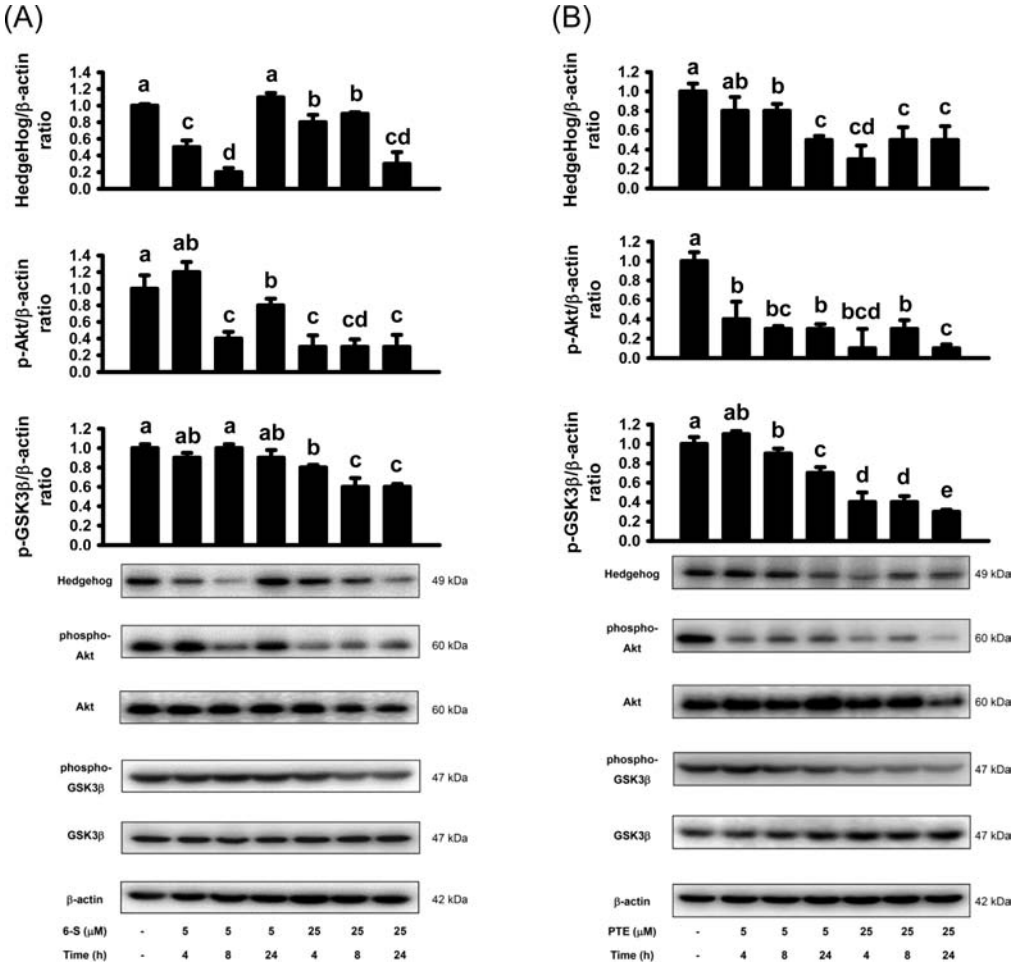

Figure 5. Effects of 6-S (A) and PTE (B) on protein expression of hedgehog signaling in BCSCs. Cells were treated with 25 μM of tested compounds for 4, 8, and 24 h, respectively. The relative density was compared with the control. All experiments were performed in duplicate and repeated at least three times. Quantitative data are expressed as the mean ± standard deviation. Bars with different letters are significantly different from each other in individual assays ($p < 0.05$).

DISCUSSION

General stem cells have the ability to differentiate into many different cells. However, abnormal stem cells will develop into abnormal cell populations. These abnormal stem cells are CSCs. Because CSCs can survive in a nutrient- and oxygen-deficient environment and have drug resistance, they are considered one reason that cancer cannot be completely cured.

Phytochemicals have been discovered to have antioxidant, anti-inflammatory, and antitumor activities. Because their side effects can be milder than those of chemotherapeutic drugs, they have been extensively applied and investigated in clinical cancer studies.[12] For example, citrus fruits are rich in NOL and 5-HF, which have been discovered in previous studies to have anti-invasion activity against cancer cells and can inhibit colon cancer proliferation and induce apoptosis.[32] The study by Weng et al.[22] showed that the active ingredients of ginger, 6-G and 6-S, and the component of berries, PTE, inhibit liver cancer cell metastasis. Our previous studies showed that 6-S and PTE inhibit invadopodia formation in breast cancer cells and inhibit invasive metastasis.[33] Therefore, these two phytochemicals, 6-S and PTE, might have excellent antitumor potential. This study selected the above phytochemicals to investigate their effects on the suppression of BCSC survival and mammosphere formation as well as the effects of complementary chemotherapeutic drugs on BCSCs. The antitumor activity and the molecular mechanism of 6-S and PTE were also clarified.

A review of the study by Gupta et al.[19] and many other papers showed that because BCSCs have the feature of self-renewal and might produce drug resistance, during the screening of compounds that can inhibit BCSC survival, the culture time should be estimated to at least the third generation. Therefore, 72 h was selected as the culture time in this study to investigate the effects of these compounds. The MCF-7 breast cancer cells and the human BCSCs isolated from MCF-7 cells using $CD44^{+}/CD24^{-/low}$ were treated with different concentrations (0−75 μM) of 5-HF, 6-G, 6-S, NOL, and PTE to evaluate their effects on cell survival. 6-S and PTE demonstrated the highest cytotoxicity levels against BCSCs. After BCSCs were treated with 25 μM 6-S or PTE for 72 h, the cell survival rate was reduced to <50%. However, treatment of MCF-7 breast cancer cells with these two chemicals at 25 μM (LD50) for 72 h showed that the cell survival rates were both maintained above 80%. Next, after BCSCs were treated with 6-G at 50 μM for 72 h, the cell survival rate was also reduced to 50%, whereas under the same concentration and time, the survival rate of treated MCF-7 cells was maintained at 90% (Figure 1B,C). Therefore, these three compounds might have the potential to specifically inhibit BCSCs. Further treatment of cells with these three compounds at a concentration of 25 or

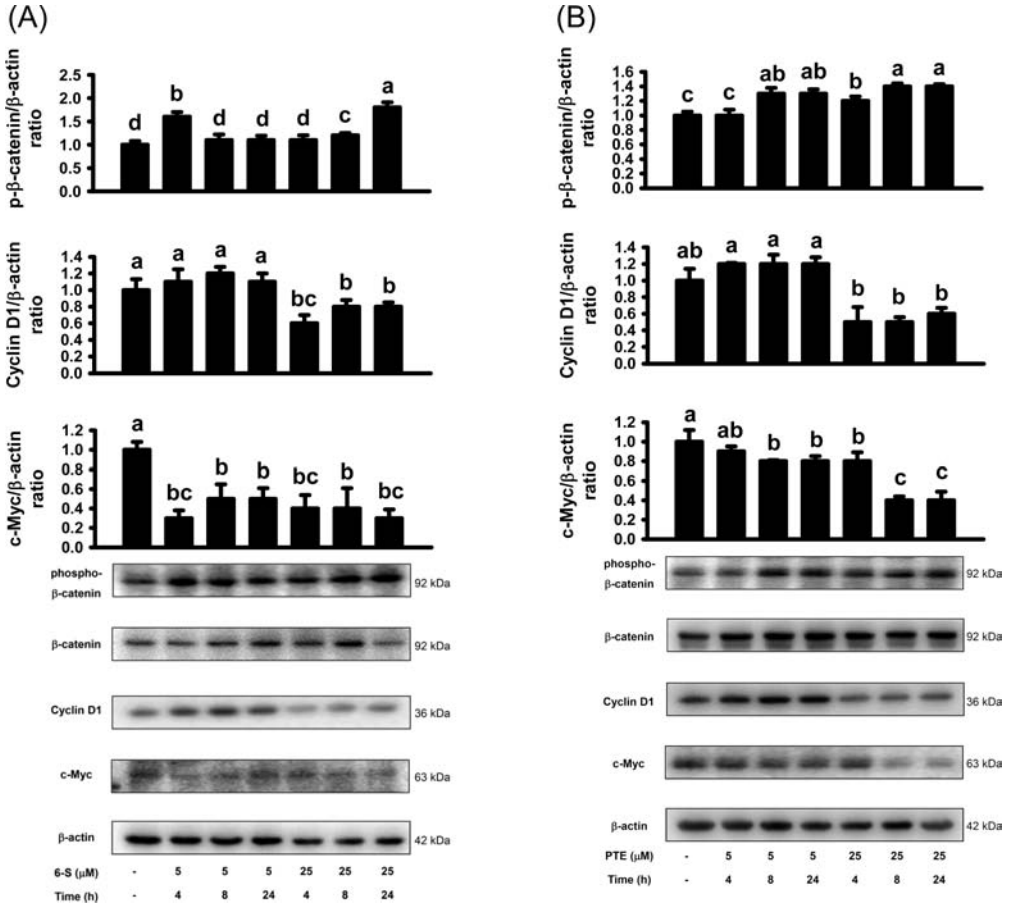

Figure 6. Effect of 6-S (A) and PTE (B) on protein expression of β-catenin, c-Myc, and cyclin D1 in BCSCs. The cells were treated with 25 μM of tested compounds for 4, 8, and 24 h, respectively. The relative density was compared with the control. All experiments were performed in duplicate and repeated at least three times. Quantitative data are expressed as the mean ± standard deviation. Bars with different letters are significantly different from each other in individual assays ($p < 0.05$).

100 μM showed that 6-S and PTE promoted bleb formation on the surface of BCSCs within 3−6 h, whereas 6-G did not cause bleb formation under the same conditions (Figure 2A). Therefore, it was speculated that 6-S and PTE had the most potential to inhibit BCSCs. Because their influences on the regulation of intracellular signaling proteins might start between 3 and 6 h, subsequent experiments selected 4, 8, and 24 h as controls.

CSCs have self-renewal and high differentiation potentials. Their growth does not require serum, their number in cell populations is small, and they are present as an unstable suspension. In in vitro cultured BCSCs, they aggregate into floating clumps to facilitate attached differentiation. These clumps are called spheroids and are specifically called mammospheres in breast cancer cells. Mammospheres form a functional mammary tree after long-term culture. Studies have shown that treatment of sulforaphane (5 μM) with BCSC-like cells isolated using ALDH for 7 days effectively reduced the size of mammospheres.[34] Kakarala et al.[35] treated mammospheres with curcumin or piperine and obtained similar results. The results of this study in Figure 2B,C confirmed that 6-S and PTE reduced the size and number of mammospheres.

There are already several drugs in clinical use with excellent treatment effects on breast cancer such as cyclophosphamide, paclitaxel, doxorubicin, and docetaxel; therefore, current treatment strategies that target CSCs might supplement chemodrugs to achieve the goal of eliminating breast cancer.[3,12] Therefore, the present study referenced the method of Lee et al.[36] to add serum into the BCSC culture to promote cell differentiation to simulate the condition of tumor recurrence and growth. Next, 6-S, PTE, and paclitaxel were cultured with this cell population for 72 h to observe whether these two compounds and paclitaxel had a synergistic effect on the suppression of tumor growth. The results in Figure 3 show that although paclitaxel (10 and 50 nM) had toxicity on the differentiated cell population of BCSCs, the effect was not dose dependent ($p > 0.05$). Of note, 6-S and PTE had auxiliary effects on paclitaxel to reduce the survival of that cell population. Studies have shown that the combination of curcumin (10 μM) and paclitaxel (10 μM) significantly reduced tumor size in nude mice, decreased MMP-9 expression in tumor, and promoted breast cancer cell apoptosis.[37] The study by Aggarwal et al.[38] also indicated that curcumin (50 μM), which is a polyphenolic compound similar to the samples used in this study, assists paclitaxel (10 μM) in reducing the survival rate of breast cancer MDA-MB435 cells by 80%.

The present study demonstrated that 6-S and PTE inhibit BCSCs from forming mammospheres and have synergistic effects with paclitaxel. To confirm the mechanism underlying the regulation of BCSC characteristics by these two compounds, further investigation was performed on whether the signaling pathway of BCSCs to maintain their self-renewal was affected by 6-S and PTE. CSCs are identified using different cell surface antigens; for example, BCSCs have been

J. Agric. Food Chem. 2015, 63, 2432−2441

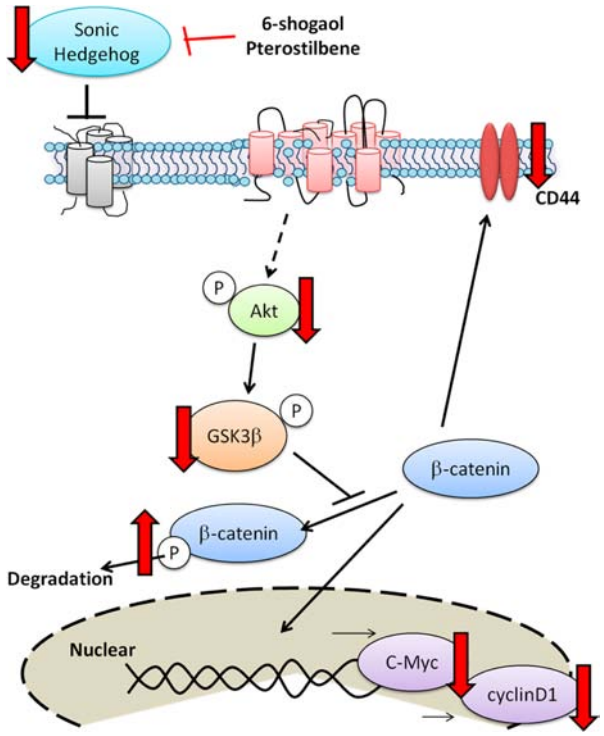

Figure 7. Schematic representation of the mechanisms of action by 6-S and PTE in the inhibition of BCSC stemness. 6-S and PTE mediate CD44 expression through the reduction of hedgehog and β-catenin in BCSCs. 6-S and PTE lead to reduced expression of hedgehog, inhibit the phosphorylation of Akt and GSK3β, and decrease the translocation of β-catenin, followed by the down-regulation of CD44, c-Myc, and cyclin D1 expression.

isolated using $CD44^{+}/CD24^{-/low}$ expression on the cell surface of MCF-7 cells.[5] The decrease of CD44 expression reduced the tumorigenicity of BCSCs in vivo; thus, it was speculated that CD44 expression is associated with the maintenance of stemness.[39] Therefore, this study cultured 6-S or PTE with BCSCs for 72 h to observe their influences on CD44 and CD24 cell surface antigens. Figure 4 shows that 6-S and PTE effectively decreased the expression of CD44. This result was similar to the results of So et al.,[40] who used a novel Gemini vitamin D analogue, BXL0124. Recent studies also showed that caffeic acid phenethyl ester, a derivative of the natural polyphenolic compound caffeic acid, reduces the percentage of CSCs in the MDA-MB231 cell line to inhibit CSC proliferation.[41] Studies have also shown that acetaminophen induces BCSC differentiation, decreases CD44 expression, and causes these cells to lose tumorigenicity in nude mice.[42]

It is known that hedgehog, Notch, PI3K/Akt, and Wnt/β-catenin are associated with self-renewal of cells and stem cell survival in normal organs or embryonic stem cells.[12] Studies have indicated that these signaling pathways might also participate in the maintenance of the stemness of $CD44^{+}/CD24^{-/low}$ BCSCs.[13] CSCs play very important roles in the recurrence and growth of many tumors, whereas Wnt/β-catenin is associated with CSC differentiation. In many antitumor (such as lung cancer and brain cancer) studies that have targeted CSCs, the inhibition of intracellular concentration and the transcription activity of β-catenin were used as a target.[10,43] Hope et al.[44] used a low dose of resveratrol to regulate β-catenin transcription activities and achieved the inhibition of the differentiation of many liver cancer cells to prevent the aggravation of liver cancer. Therefore, inhibition of the transcription activity of β-catenin might successfully inhibit CSCs to produce drug resistance and promote tumor recurrence.[45]

Studies showed that the EMT pathway can induce tumor cells to produce CSCs with stemness; therefore, if EMT activation could be inhibited through the TGF-β or Wnt signaling pathways, then CSC proliferation could be reduced. The EMT pathway is induced by the Twist and Snail proteins. Twist can inhibit the phosphorylation of the downstream β-catenin and Snail proteins through the promotion of phosphorylation of Akt (Ser 473) and GSK3β (Ser 9) to increase CD44 expression and achieve the goal of maintaining stemness. In addition, Twist can also inhibit E-cadherin activation and its ability to bind β-catenin, which further inhibits cell invasion and metastasis.[39] The regulation of Akt and GSK3β is also affected by the hedgehog signaling pathway. Sonic hedgehog interacts with its transmembrane receptor patched to release smoothed protein to further activate PI3K and Akt, thus promoting GSK3β phosphorylation and reducing its activity. When GSK3β activity decreased, β-catenin phosphorylation is reduced, and its degradation pathway is suppressed; at the same time, CG44 expression is increased. Excess β-catenin translocates into the nucleus to promote cell proliferation and differentiation and then interacts with the TCF/LEF complex to transcribe cyclin D1 and c-Myc. Furthermore, the levels of phosphorylated Akt, phosphorylated GSK3β, and β-catenin in mammospheres are all significantly higher than those in general attachment-type tumor cells.[46] Introduction of the Akt inhibitor perifosine (orally active alkylphosphocholine) into mammary stem cells or progenitor cells promotes β-catenin phosphorylation. Therefore, this study focused on whether 6-S and PTE had inhibitory effects on the signaling pathways that maintained the above CSC characteristics.

Results in this study showed that treatment of BCSCs with 6-S (5 μM) for 8 h significantly decreased hedgehog expression and Akt phosphorylation. 6-S at a concentration of 25 μM significantly decreased hedgehog expression and Akt phosphorylation after 4 h, and this effect was stably maintained for 24 h (Figure 5A). Figure 6A shows that treatment of BCSCs with 6-S (25 μM) for 8 h increased β-catenin phosphorylation and caused its degradation. Further observation of the expression of downstream cyclin D1 and c-Myc proteins also showed that 6-S at a concentration of 25 μM triggered down-regulation of cyclin D1 and c-Myc within 4 h. A previous study treated a polyphenolic compound, curcumin (50 μM), with MDA-MB435 breast cancer cells and showed that the expression of cyclin D1 and c-Myc proteins was inhibited.[38]

The results in Figure 5B show that PTE cultured with BCSCs significantly inhibited hedgehog expression and Akt phosphorylation. In addition, with regard to GSK3β activity, PTE reduced the levels of GSK3β phosphorylation. At 25 μM, PTE increased β-catenin phosphorylation and promoted its degradation (Figure 6B). Further observation of the downstream cyclin D1 and c-Myc protein expression showed that PTE also effectively reduced the expression of these two proteins. The study by Lepourcelet et al.[47] also observed that the two natural compounds isolated from fungi, PKF115-584 and CGF049090 (5 μM), significantly inhibited the intracellular concentrations of β-catenin and the expression of cyclin D1 and c-Myc proteins.

DOI: 10.1021/acs.jafc.5b00002
J. Agric. Food Chem. 2015, 63, 2432−2441

In summary, the increased phosphorylation of β-catenin by 6-S and PTE might be through the reduction of hedgehog protein expression and Akt and GSK3β phosphorylation, thus reducing the expression of downstream c-Myc and cyclin D1 proteins (Figure 7). Therefore, 6-S and PTE activated β-catenin degradation to reduce CD44 activity and affect the maintenance of stemness of CSCs to further induce the loss of tumorigenicity of these BCSCs.

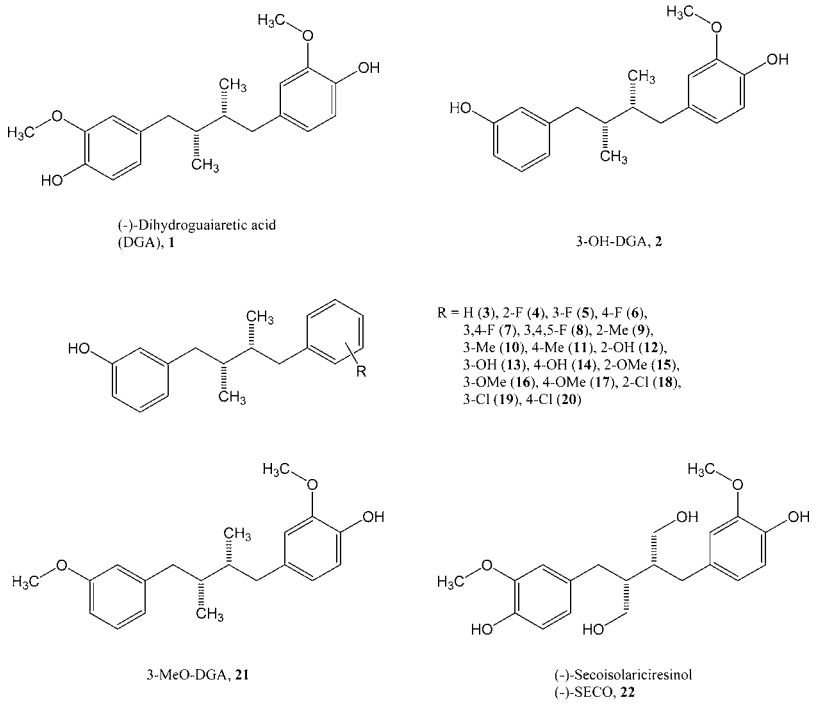

Figure 1. Structures of (−)-dihydroguaiaretic acid, **1**; its 3-OH derivatives, **2**−**20**; 3-OMe-DGA derivative **21**; and secoisolariciresinol **22**.

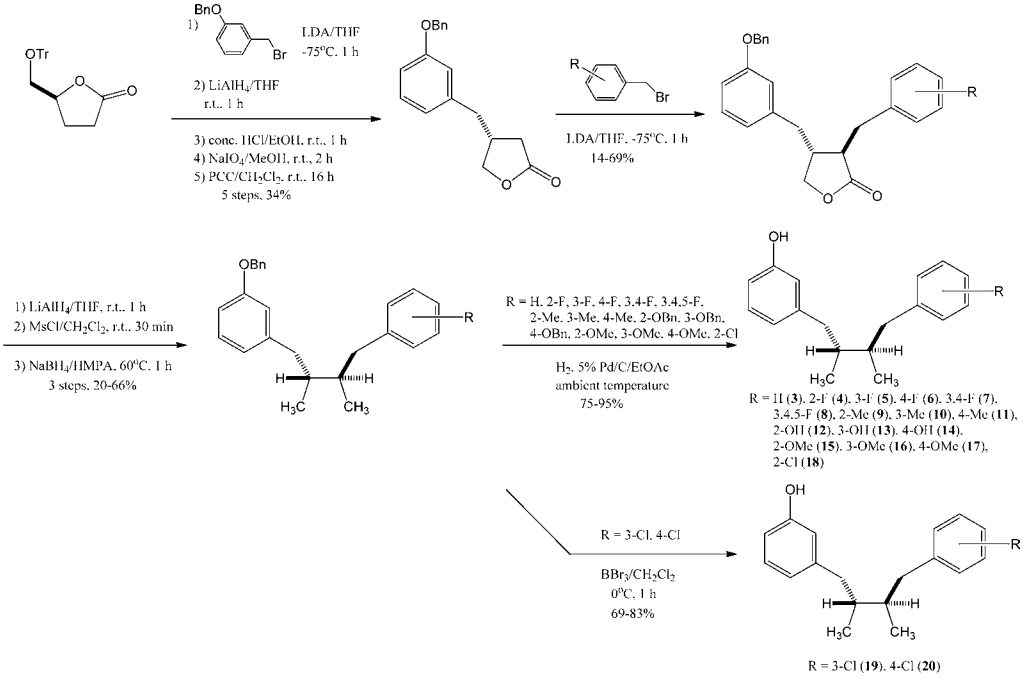

Figure 2. Synthetic scheme of compounds **3**−**20**.

lignans.[9] The synthetic scheme is shown in Figure 2, which was fundamentally the same as the earlier report.[7] Compounds **4**−**18** were obtained from (*R*)-3-(3-benzyloxybenzyl)-4-butanolide and the corresponding substituted benzyl bromide (preparation for hydroxybenzyl derivatives **12**−**14** needs a benzyloxybenzyl bromide to be deprotected in the final step) by employing the same method described for the synthesis of **3**. Compound **20** was synthesized using the preparation procedure of compound **19**. Compounds **21** and **22** were our stock samples.

Synthesis of Derivatives. *(8R,8′R)-Lignan-3-ol* ***3***. To a solution of lithium diisopropylamide (2.10 mmol) in tetrahydrofuran (THF, 10 mL) was added a solution of (*R*)-3-(3-benzyloxybenzyl)-4-butanolide (0.50 g, 1.77 mmol; see the preparation method in the Supporting Information) in THF (10 mL), and then the resulting solution was stirred at −70 °C for 30 min before addition of a solution of benzyl bromide (0.30 g, 1.75 mmol) in THF (5 mL). After the reaction solution was stirred at −70 °C for 1 h, saturated (sat.) aqueous (aq) NH_4Cl solution and ethyl acetate (EtOAc) were added. The organic solution was separated, washed with brine, dried (Na_2SO_4), and concentrated. The residue was applied to silica gel column chromatography (EtOAc/hexane = 1/3). To an ice-cooled suspension of $LiAlH_4$ (14 mg, 0.37 mmol) in THF (5 mL) was added a solution of the obtained compound in THF (5 mL). The resulting reaction mixture was stirred at room temperature for 30 min, and then sat. aq

DOI: 10.1021/jf504816a
J. Agric. Food Chem. 2015, 63, 2442−2448

$MgSO_4$ and K_2CO_3 were added. The mixture was stirred at room temperature for 30 min. After filtration of the mixture, the filtrate was concentrated. To an ice-cooled solution of the residue and Et_3N (0.54 mL, 3.87 mmol) in CH_2Cl_2 (5 mL) was added MsCl (0.30 mL, 3.88 mmol). After the reaction mixture was stirred at room temperature for 30 min, H_2O and CH_2Cl_2 were added. The organic solution was separated, dried (Na_2SO_4), and concentrated. A solution of the residue and $NaBH_4$ (90 mg, 2.38 mmol) in hexamethylphosphoric triamide (HMPA, 5 mL) was heated at 60 °C for 30 min before additions of sat. aq NH_4Cl solution and EtOAc. The organic solution was separated, washed with brine, dried (Na_2SO_4), and concentrated. A reaction mixture of the residue and 5% Pd/C (0.20 g) in EtOAc (10 mL) was stirred under H_2 gas at the ambient temperature for 2 h before filtration. The filtrate was concentrated, and then the residue was applied to silica gel column chromatography (EtOAc/hexane = 1/5) to give **3** (40 mg, 0.16 mmol, 9% in 5 steps) as a colorless oil, $[\alpha]^{20}_D$ = −29 (*c* 0.5, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.82 (3H, d, *J* = 6.4 Hz), 0.84 (3H, d, *J* = 6.4 Hz), 1.78−1.82 (2H, m), 2.38 (1H, dd, *J* = 13.3, 8.0 Hz), 2.43 (1H, dd, *J* = 12.5, 8.2 Hz), 2.60 (1H, dd, *J* = 12.5, 6.2 Hz), 2.64 (1H, dd, *J* = 13.3, 6.5 Hz), 4.77 (1H, s), 6.51 (1H, m), 6.62−6.67 (2H, m), 7.09−7.13 (2H, m), 7.13 (1H, d, *J* = 7.2 Hz), 7.17 (1H, m), 7.24−7.27 (2H, m). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.0, 37.8, 38.1, 41.2, 41.4, 112.5, 115.8, 121.6, 125.6, 128.1, 129.1, 129.2, 141.6, 143.6, 155.3. (8R,8′R)-3′-Chlorolignan-3-ol **19**. (8*R*,8′*R*)-3-Benzyloxy-3′-chlorolignane was obtained from (*R*)-3-(3-benzyloxybenzyl)-4-butanolide and 3-chlorobenzyl bromide by employing the same method described for the synthesis of **3**. To a solution of (8*R*,8′*R*)-3-benzyloxy-3′-chlorolignane (0.10 g, 0.35 mmol) in CH_2Cl_2 (5 mL) was added BBr_3 (0.049 mL, 0.52 mmol) at −10 °C, and then the reaction solution was stirred at −10 °C for 30 min before addition of sat. aq $NaHCO_3$ solution. The organic solution was separated, washed with brine, and dried (Na_2SO_4). Concentration followed by silica gel column chromatography (EtOAc/hexane = 1/4) gave the title compound (69 mg, 0.24 mmol, 32% in 5 steps) as a colorless oil, $[\alpha]^{20}_D$ = −32 (c 0.9, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.819 (3H, d, J = 6.6 Hz), 0.824 (3H, d, J = 6.6 Hz), 1.74−1.82 (2H, m), 2.37 (1H, dd, J = 13.6, 7.9 Hz), 2.39 (1H, dd, J = 13.6, 8.0 Hz), 2.59 (1H, dd, J = 13.6, 8.0 Hz), 2.60 (1H, dd, J = 13.6, 8.6 Hz), 4.85 (1H, s), 6.55 (1H, m), 6.65 (1H, dd, J = 7.6, 2.8 Hz), 6.66 (1H, d, J = 7.2 Hz), 6.96 (1H, m), 7.08 (1H, m), 7.10−7.19 (3H, m). ^{13}C NMR ($CDCl_3$) δ: 13.9, 14.0, 37.78, 37.82, 41.0, 41.1, 112.6, 115.8, 121.6, 125.8, 127.2, 129.0, 129.32, 129.34, 133.8, 143.4, 143.7, 155.3. EIMS m/z (%): 288 (M^+, 17), 125 (27), 108 (100). HRMS (EI) m/z: calcd for $C_{18}H_{21}OCl$, 288.1282; found, 288.1285.

Insects. Eggs of the common house mosquito *Culex pipiens* were purchased from Sumika Techno Service Co., Ltd. (Hyogo, Japan), and reared. Larvae were maintained at 25 °C under a photoperiod of 12 h of light and 12 h of darkness.

Evaluation of the Larvicidal Activity. The larvicidal activity of the test compounds was evaluated according to our earlier report.[7] Briefly, 20 larvae (10 larvae released in 1 mL of water × 2 tubes) were prepared for each concentration, and the lethal concentration for inducing death in 50% of mosquito larvae [LC_{50} (M)] 24 h after applying the compound was calculated by probit analysis.[10] The acute toxic symptom at the concentration of 2.5 × 10^{-4} M was also monitored within 2 h using the same procedure. The insecticidal assay was performed in triplicate. Dimethylsulfoxide (DMSO) at the concentration of 0.5% demonstrated no adverse effect on mosquitoes. Imidacloprid was employed as a positive control.

Evaluation of the Inhibitory Activity of the Chemicals on the O_2 Consumption of the Mitochondrial Fraction. The O_2 consumption inhibitory activity was measured for compound **6**, inducing the highest acute toxic symptom in the present study, as well as for the reference compounds **1** ((−)-DGA) and **2** (3-OH-DGA). To compare **1**, **2**, and **6**, the inhibitory activities of 3-methoxy-DGA derivatives (3-OMe-DGA) and (−)-secoisolariciresinol ((−)-SECO) (compounds **21** and **22** in Figure 1), whose LC_{50} values were 4.73 × 10^{-5} and >45 × 10^{-5} M (mortality is 0% at this concentration), respectively,[7] were also evaluated. In 10 mL of the ice cold buffer A (3 mM Tris-HCl buffer (pH 7.4) containing 0.25 M sucrose and 1 mM EDTA), 2.8 g of rat liver was homogenized, followed by centrifugation (500*g*, 10 min, 4 °C). The resultant pellet was suspended in buffer A, and the solution was centrifuged (8,000*g*, 10 min, 4 °C; two times) to get the mitochondrial fraction (resuspended in buffer A). After the protein concentration of the fraction was measured by the Bradford Reagent (Sigma) with bovine serum albumin as the standard, it was adjusted to 5 mg/mL using buffer A. The prepared mitochondrial fraction was kept at −80 °C before use.

In each well of a 96-well microplate (Nunc F96 MicroWell black polystyrene plate, Thermo Fisher Scientific K. K., Yokohama, Japan) were added 1 μL of DMSO solution containing each test sample, 50 μL of buffer B (3 mM Tris-HCl buffer (pH 7.4) containing 0.25 M sucrose, 1 mM EDTA, and 125 mM succinic acid disodium salt), 50 μL of buffer C (3 mM Tris-HCl buffer (pH 7.4) containing 0.25 M sucrose, 1 mM EDTA, and 8.25 mM ADP), 100 μL of MitoXpress probe solution (Luxcel Biosciences, Ltd., Cork, Ireland; 0.1 μM of the solution diluted by buffer A), and 50 μL of the mitochondrial fraction. The DMSO solutions without any samples and 160 μM NaCN were employed as the negative and positive controls, respectively. After addition of 100 μL of the mineral oil into each well, the fluorescence intensity was recorded by using the fluorescence microplate reader (SH-8000Lab, Corona electric Co., Ltd., Hitachinaka, Japan) in the time-dependent manner (time-resolved mode; 30 °C, 3.3 min intervals

DOI: 10.1021/jf504816a
J. Agric. Food Chem. 2015, 63, 2442−2448

for 99 min, excitation 380 nm, emission 650 nm, and 100 μs as the delay and gate times.). The final concentrations of the test samples other than SECO **22** were set to 4, 40, 120, and 200 μM. SECO was applied at the concentration of 3.98×10^{-3} M. The slope of the intensity over time for each curve was calculated, and the concentration, which induced the mean value of the slope values of the positive and negative controls, was defined as the EC_{50} value (M). The assay was performed in triplicate or more (n = 3–5).

RESULTS AND DISCUSSION

LC_{50} values of the synthesized lignan derivatives are shown in Table 1. Compared with the activity of (−)-DGA and SECO (LC_{50} values were ca. $3.5–4.5 \times 10^{-5}$ M), that of the unsubstituted compound **3** was somewhat low (7×10^{-5} M). The fluorinated compounds **4**–**8** showed a higher activity than the unsubstituted compound **3**. The 2-F derivative **4** showed the highest activity, 3.5-fold higher than that of compound **3**. Differing potency among the positions of the substituents was not observed (compounds **4**–**6**), and the potency of multiple substituted derivatives (compounds **7** and **8**) did not differ from that of the monofluorinated compounds. Among the methylated compounds **9**–**11**, 3-Me and 4-Me derivatives (compounds **10** and **11**) were 2- and 4-fold less potent, respectively, than 2-Me derivative (compound **9**), which was almost equipotent to the fluorinated compounds. The 4-OH derivative **14** showed higher potency than the other OH derivatives **12** and **13**, and the 3-OMe derivative **16** showed higher potency than that of the other positioned OMe derivatives **15** and **17**. The replacement of a fluorine atom of compounds **4**–**6** with a chlorine atom retained the high activity. The ratio of the highest activity (2-F **4**, 2.01×10^{-5} M) to the lowest (4-Me **11**, 12.1×10^{-5} M) was 6, demonstrating that the effect of the substituent at the 7′ phenyl moiety on activity was not as large when a compound had the 3-OH phenyl ring at the 7 position, regardless of the physicochemical properties of the substituents, such as electron-withdrawing/donating and hydrophilic/hydrophobic features.

Table 1. Larvicidal Activity against *Culex pipiens* of 3-OH DGA Derivatives 24 h after the Sample Application (LC_{50} (M), Mean ± SEM)[a]

		insecticidal activity			insecticidal activity
no.		LC_{50} ($\times 10^{-5}$ M)	no.		LC_{50} ($\times 10^{-5}$ M)

[a]Data are represented as mean and standard error of mean (n = 3). Not significantly different from each other when labeled with the same letters (one-way ANOVA, Tukey; $P < 0.05$; PRISM software 5.0). The LC_{50} value of imidacloprid (positive control) was $2.66 \pm 0.52 \times 10^{-7}$ M (n = 3).

For all of the synthesized compounds, their acute toxic symptom against the larvae of the mosquitoes was observed (Figure 3). The unsubstituted derivative **3** was equipotent to 3-OH DGA **2** (Figure 3A). Among the derivatives with an ortho-substituted phenyl group (Figure 3B), the 2-F derivative **4** induced complete death of the larvae within 1 h, whereas the 2-OH derivatives **18** induced a mortality of only 60% in 2 h [62 ± 12% (n = 3)]. The other ortho-substituted compounds (2-Me, 2-OMe, and 2-Cl) showed almost the same curves as one

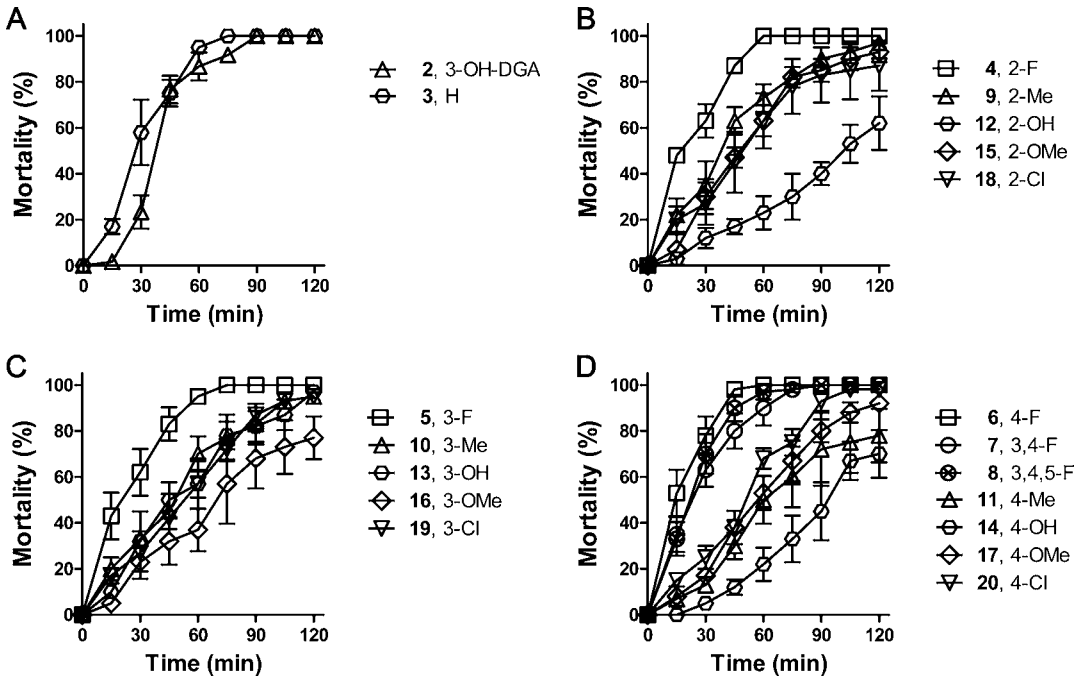

Figure 3. Time-dependent curves of the acute larvicidal activity against *Culex pipiens* of the test chemicals within 2 h. No adverse effect on mosquitoes was observed in the control within 2 h. (A) 3-OH-DGA **2** and the unsubstituted **3**, (B) ortho-substituted phenyl derivatives **4**, **9**, **12**, **15**, and **18**, (C) meta-substituted phenyl derivatives **5**, **10**, **13**, **16**, and **19**, and (D) para-substituted phenyl derivatives **6**, **11**, **14**, **17**, and **20** and multifluorinated derivatives **7** and **8**.

another. Among the meta-substituted compounds (Figure 3C), the 3-F derivative **5** killed all of the mosquitoes at 75 min, showing some delay compared with the 2-F derivative. The 3-OMe derivative **16** did not completely kill the mosquitoes even after 120 min [mortality, 77 ± 9% (n = 3)]. Among the para-substituted compounds (Figure 3D), 4-F derivative **6** killed almost all larvae within 45 min, showing the fastest larvicidal activity among all of the synthesized compounds. The 4-OH derivative **14** killed 70% of mosquitoes at 120 min [mortality, 70 ± 10% (n = 3)]. Compound **2**, inducing high mortality within 1 h (Figure 3A), has 3-OMe as well as 4-OH groups, although the compound having either the 3-OMe or 4-OH group took much more time to kill the mosquito larvae. The reason why compound **2** induced the acute toxic symptom remains unclear, but the multiple substituents may exert a synergistic effect. The multifluorine-substituted derivatives **7** and **8** killed most of the mosquitoes within 1 h; the same effectiveness was observed for the monofluorinated derivatives. Replacement of a fluorine atom of compounds **4**–**6** with a chlorine atom (compounds **18**–**20**) reduced the speed of killing of the mosquito larvae (for example, ca. 100% mortality induced by the 4-Cl derivative **20** was observed 90–105 min after application), suggesting that electron-withdrawing groups do not always induce rapid toxicity. Ultimately, the unsubstituted derivative **3** and fluorinated compounds **4**–**8** were found to exhibit higher toxicity than the others, suggesting that smaller substituents better promote acute toxicity. The 3-OMe derivative **16**, which did not kill mosquitoes perfectly within 2 h, showed higher insecticidal activity (Table 1), suggesting that acute toxicity is not the primary factor for inducing high insecticidal activity.

In search of clues to the mode of action of the active lignan derivatives, we investigated whether or not compounds **1**, **2**, **6** (selected for most acute toxicity), **21** (selected for exerting almost the same insecticidal activity as compounds **2** and **6**, but not acute toxicity), and **22** (selected for exerting neither insecticidal activity nor acute toxicity) were able to suppress the O_2 consumption of the mitochondrial fraction, associated with the respiratory system (Table 2). All of the insecticidal compounds tested in the O_2 consumption assay were found to show suppressive activity at almost the same concentration, whether they induced acute toxic symptom or not. (−)-SECO **22** did not suppress the O_2 consumption even at the 50-fold higher concentration. Although a good correlation between the insecticidal (LC_{50}) and O_2 consumption (IC_{50}) activities was not observed (data not shown), the insecticidal lignan derivatives suppressed the O_2 consumption of the mitochondrial fraction in vitro, suggesting that their insecticidal activity was associated, at least in part, with the inhibition of the respiratory system. Compounds **1** and **21**, which did not kill mosquito larvae within 2 h, may take more time to reach target sites in insects, probably owing to their hydrophobicity. As insecticides and acaricides, mitochondrial electron transport inhibitors, such as tebufenpyrad and Fenpyroximate (targeting complex I), have been developed,[11] and investigation of the novel structure of complex I inhibitors has been reported.[12] In the present study, it remains unclear how the synthesized lignan derivatives suppressed the O_2 consumption in the mitochondrial fraction; however, it has been reported that a partially demethylated DGA (2,3-dimethyl-1-(3,4-dihydroxyphenyl)-4-(4-hydroxy-3-methoxyphenyl)butane) showed inhibitory activity toward mitochondrial succinoxidase and the NADH-oxidase enzyme system,[13] suggesting that the present lignan derivatives also inhibit mitochondrial electron transport.

Table 2. Oxygen Consumption Inhibitory Activity of (−)-DGA Derivatives (IC_{50} (M), Mean ± SEM)

		oxygen consumption inhibitory activity[a]	insecticidal activity	acute toxicity
no.		IC_{50} ($\times 10^{-5}$ M)	LC_{50} at 24 h ($\times 10^{-5}$ M)	mortality at 45 min (%)
1	(−)-DGA	6.89 ± 2.69 (n = 4)	3.52 ± 0.56[b]	0
2	3-OH-DGA	6.78 ± 2.41 (n = 5)	4.57 ± 1.27[b]	83 ± 4.4
6	4-F	4.03 ± 0.83 (n = 3)	3.66 ± 1.08[c]	98 ± 1.7
21	3-OMe-DGA	5.08 ± 1.52 (n = 4)	4.73 ± 1.46[b]	0
22	(−)-SECO	>398 (n = 3)	>45[b]	0

[a]The IC_{50} value of NaCN (positive control) was 3.66 ± 0.02 × 10^{-6} M (n = 3). [b]Cited from ref 7. [c]Cited from Table 1.

In summary, we identified 3-OH-DGA derivatives, in particular, monofluorinated 3-OH-DGA derivatives, showing insecticidal activity as well as acute toxicity against the larvae of the mosquito, *C. pipiens*. Some of the compounds were found to inhibit the O_2 consumption of the mitochondrial fraction, suggesting that they inhibit the respiratory system. The insecticidal activity of these natural lignan-based compounds was lower than that of imidacloprid, one of the most famous commercial neuroactive insecticides (LC_{50} value of imidacloprid was 2.66 ± 0.52 × 10^{-7} M (n = 3)). But the simple structure of the compounds inducing acute larvicidal activity and structure–activity relationship elucidated in the present study should be available for further structural modification, leading to novel and useful vector-control agents.

are responsible for the immune stimulatory activity of YFWGE.[26,28] Furthermore, Tuscano et al.[29] showed that YFWGE contains proteins (polypeptides) with molecular weights of 5−100 kilodaltons (kd) that are active in inhibiting the proliferation of cancer cells. Thus, there is interest in developing wheat germ using biotechnology with lactic acid bacteria and yeast.

Although wheat germ fermentation has been widely studied, there is little information about the anticarcinogenic activity of wheat germ extract fermented with lactic acid bacteria. In 2013, lactic acid bacteria isolated from wheat germ were characterized and selected on the basis of technological performance to be used as starters for fermenting wheat germ, and an Italian researcher found that the fermented wheat germ extract could inhibit the growth of the colorectal cancer cell lines HT-29, HCT-8, and DLD-1.[30] However, only the benzoquinones of the fermentation extracts were analyzed, and thus further research is needed on other anticarcinogenic components.

In this study, we evaluate the anticarcinogenic activities of *Lactobacillus plantarum* dy-1 fermented wheat germ extracts (LFWGE), including the growth inhibition and induction of apoptosis via the Caspase-3 signaling pathway in the human colon cancer HT-29 cell line. In addition, some of the compounds in LFWGE were analyzed and identified.

MATERIALS AND METHODS

Materials and Chemicals. The fresh wheat germ was purchased from Shandong Yongle of China. The moisture, ash, and fat content were determined according to the Approved Methods of the American Association of Cereal Chemists.[31] The crude protein content (Kjeldahl method) was measured with a semiautomatic Kjeldahl apparatus (K355, Buchi, Switzerland) and a Metrohm 877 Titrino Plus Automatic Titrator (Switzerland). A conversion factor of 5.70 was used. The lactobacillus strain *Lactobacillus plantarum* dy-1 was previously isolated by authors. HT-29 colon cancer cells were provided by the Cell Bank at the Chinese Academy of Sciences in Shanghai. Foetal bovine serum and McCOY'S 5A medium were purchased from GIBCO. Trypsin-EDTA was purchased from Beyotime. Annexin V-FITC, propidium iodide (PI), Hoechst dye 33342, penicillin, chloramphenicol, 2,6-dimethoxybenzoquinone, gallic acid, Folin-Ciocalteu reagent, coomassie brilliant blue R250, and bovine serum albumin were purchased from Sigma-Aldrich, Inc. (Supelco, Bellefonte, PA). The MTT (3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide), sephadex G-50, and sephacryl S-200 were purchased from Shanghai Chuangsai Scientific Instrument Limited Co. (Shanghai, China). All of the other reagents and solvents were purchased from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China) and were of either analytical or chromatographic grade.

Preparation of the Extracts. *Lactobacillus plantarum* dy-1 was used as the starter culture in the direct vat set fermentation, which was previously isolated from pickles by authors. Its preservation number is CGMCC NO. 6016 in the Chinese Common Microbe Bacterial Preservation Administration Center database. *Lactobacillus plantarum* dy-1 was cultivated in MRS, treated with a protective agent (20% skim milk, 10% fucose, 14% monosodium glutamate, 6% sorbitol, and 6% vitamin C), and lyophilized to powder. The wheat germ was crushed and passed through a 100-mesh sieve. A 200 g portion of wheat germ powders, 1.4 L of distilled water, and 4 g of freeze-dried fungus powder containing *Lactobacillus plantarum* dy-1 (cell density 4×10^8 cfu/g) were shaken and incubated at 30 °C for 24 h in a microbiological incubator. After fermentation, the solution was centrifuged at 12 000 *g* for 15 min at 4 °C using a refrigerated centrifuge (Jouan, France), and then the supernatant was freeze-dried into a powder (LFWGE) using a vacuum freeze-dryer (Marin Christ, Germany). For the unfermented wheat germ, 200 g of powder was extracted with 1.4 L of distilled water at room temperature for 3 h in shaking tables. The supernatant was collected by centrifuging, and then freeze-dried into a powder (WGE) under the same conditions as the fermented wheat germ. This step was repeated six times for analysis. The freeze-dried samples were stored in sealed containers at −20 °C for further analysis. The extraction yield was calculated by the following equation: extraction yield (%) = [weight of freeze-dried powder/weight of WG (g)] × 100.

Extraction of Benzoquinones and HPLC Analysis. The benzoquinones were extracted and analyzed using the following procedure. About 0.5 g of WGE or LFWGE was dissolved into 50 mL of double-distilled water and subjected three times to extraction by shaking with 25 mL of chloroform ($CHCl_3$).[32] The $CHCl_3$ layers were pooled, washed three times with distilled water, and dried over anhydrous Na_2SO_4. The solvent was evaporated to dryness by rotary evaporation at 40 °C. The residue was redissolved in 5 mL of $CHCl_3$ and filtered through a 0.22 μm filter membrane. The filtrate was analyzed by a high performance liquid chromatography (HPLC) system consisting of an Äkta purifier HPLC equipped with shim-pack VP-ODS (250 mm × 4.6 mm, 5 μm) and an ultraviolet detector operating at 288 nm. The mobile phase was a water/methyl alcohol mixture (80:20, v/v), with the flow rate and sample injection volume fixed at 1 mL/min and 20 μL, respectively. The temperature was 25 °C. 2,6-Dimethoxybenzoquinone (Sigma) dissolved in 100% $CHCl_3$ was used as reference to assign retention times and generate the calibration curve

Determination of the Protein Content and SDS-PAGE Analysis of the Extracts. The protein content of the extracts was determined using the Kjeldahl method. A conversion factor of 5.70 was used.

The size and purity of the extracted protein were analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), which was performed as follows. The aqueous solutions of LFWGE and WGE were mixed with a quarter volume of sample buffer (10% SDS, 0.5% bromophenol blue, 0.25 M Tris-HCl, pH 6.8, 50% glycerin, and 5% β-mercaptoethanol) and heated in a water bath at 100 °C for 5 min. After centrifugation (6000 × *g* for 10 min), 10 μL of the supernatant was electrophoresed with 12% gel concentration and mini-cell apparatus (Bio-Rad) at 20 mA for 3 h and stained with Coomassie brilliant blue R-250 for 2 h followed by destaining using methanol/acetic acid/water at a ratio of 10:7.5:82.5. A GS-800 calibrated densitometer (Bio-Rad) was used to scan the gel.

Separation and Identification of Proteins in the LFWGE. The components of the LFWGE, which were concentrated by precipitation with solid ammonium sulfate to 80−90% saturation, were separated and purified. After being centrifuged (12 000 *g* for 15 min at 4 °C), the precipitate was redissolved in distilled water and dialyzed (molecular weight cut off: 8000−10000 Da) against distilled water at 4 °C for 48 h (renewal of distilled water every other 4−8 h), and finally freeze-dried. Then, the freeze-dried powder was dissolved in phosphate buffer (pH 7.2, 10 mmol/L), and the solution was passed through a sephadex G-50 column (1.6 cm × 50 cm) in series with a sephacryl S-200 (1.6 cm × 50 cm) column at 1 mL/min equilibrated and eluted with phosphate buffer (pH 7.2, 10 mmol/L). The eluent was monitored at 280 nm by UV absorbance, and fractioned peaks were collected, dialyzed against distilled water, and freeze-dried for the assay of anticarcinogenic activity. The anticarcinogenic fractions of the eluent were analyzed by liquid chromatography and tandem mass spectrometry (LC-MS/MS) analysis at the Institute of Biochemistry and Cell Biology, Shanghai Institutes for Biological Sciences (SIBS) of the Chinese Academy of Sciences (CAS).

RP-HPLC was performed using a surveyor LC system (Thermo Finnigan, San Jose, CA) on a C18 column (RP, 180 μm × 150 mm, BioBasic C18, 5 μm, Thermo Hypersil-Keystone). The pump flow rate was 2 μL/min. Mobile phase A was 0.1% formic acid in water, and mobile phase B was 0.1% formic acid in acetonitrile. The protein mixtures were eluted using a gradient of 5−65% B over 30 min. The mass spectral data were acquired on an LTQ linear ion trap mass spectrometer (Thermo Finnigan) equipped with an electrospray interface operated in positive ion mode. The temperature of the heated capillary was set at 200 °C. A voltage of 3.2 kV applied to the ESI needle resulted in a distinct signal. The mass spectrometer was set so that one full MS scan was followed by three MS/MS scans on the three most intense ions from the MS spectrum with the following Dynamic

Exclusion TM settings: repeat count, 2; repeat duration, 0.5 min; exclusion duration, 2.0 min.

Determination of the Total Phenols Content. The total phenol content in WGE and LFWGE was determined using the Folin-Ciocalteu method, slightly modified according to Heimler et al.[33] About 0.5 g of WGE or LFWGE was weighed in a 100 mL volumetric flask and dissolved in 40% ethanol aqueous solution. Then, 1 mL of the solution was added to 4 mL of deionized water and 1 mL of Folin-Ciocalteu reagent in glass test tubes. After the mixture was shaken, 10 mL of a 7% aqueous Na_2CO_3 solution was added, and the mixture was shaken once again. The final volume was adjusted to 20 mL with distilled water. After 90 min of reaction at 45 °C, the absorbance at 765 nm using a spectrophotometer (model UV-9600, Rayleigh, Beijing, China) with water as a blank was measured and used to calculate the phenol content, with gallic acid as a standard. The total phenol amount was expressed as gallic acid equivalent (GAE, mg gallic acid/g sample) through the calibration curve of gallic acid. The calibration curve ranged from 20 to 100 μg/mL (R^2 = 0.9924).

Determination and Extraction of the Total Sugar Content. The total polysaccharide content was determined by the phenol-sulfuric acid method with slight modifications.[34] First, 2 mL of the sample solution was vortex-mixed with 1 mL of 5% phenol in water before rapidly adding 5 mL of concentrated sulfuric acid. After 30 min of standing at room temperature, the absorbance of the sample solution was measured at 490 nm against the blank, which was prepared by substituting distilled water for the sample solution. Aqueous glucose solutions of different concentrations (5, 10, 20, 40, 80, and 160 μg/mL) were used for the standards. The results were expressed as grams of glucose per 100 g of extract.

Crude polysaccharides were extracted with hot water from the LFWGE. The extraction procedure was as follows. First, 25 g of LFWGE was dissolved in 150 mL of double-distilled water, heated at 100 °C for 10 min and then filtered. The clear solution was concentrated in a rotary evaporator under reduced pressure at 50 °C. Then, the concentrated solution was precipitated by the addition of absolute ethanol (4 times the volume of concentrated solution) at 4 °C, followed by centrifugation at 4800 × *g* (20 min) to yield the crude polysaccharides. Then, the deproteinization of the crude polysaccharides was performed using the Sevag method.[35] Finally, the polysaccharide samples were freeze-dried into a powder.

Determination of Lactic Acid Content. The lactic acid content in the LFWGE was determined by high performance liquid chromatography (HPLC). The samples were dissolved in distilled water (about 1.0 mg/mL) and filtered through a 0.45 μm PTFE membrane filter. The WGE or LFWGE was analyzed by a Shimadzu LC-20A HPLC system (Shimadzu Corp., Kyoto, Japan) equipped with a photodiode array (PDA). The operating conditions included a shim-pack VP-ODS C-18 (250 mm × 4.6 mm, 5 μm) column (Shimadzu Corp., Kyoto, Japan), a mobile phase of 3% methanol/0.01 mol/L K_2HPO_4 (pH 2.5), a volume injection of 20 μL, a flow rate of 0.8 mL/min, and detection at 210 nm at 25 °C. The standard curves for lactic acid (Sangon Biotech Co., Ltd., Shanghai, China) were used to quantify the acid.

Cell Lines and Cell Culture. The human colon cancer cell line HT-29 was used for experimentation and obtained from the Shanghai Institutes for Biological Sciences (SIBS) of the Chinese Academy of Sciences (CAS). The HT-29 cells were cultured as monolayers with up to 80% confluence in McCOY'S 5A supplemented with 10% heat-inactivated fetal calf serum and 1% penicillin/streptomycin at 37 °C and 5% CO_2 in humidified air. Cell counts were determined using a microcell counter CC-108 (Sysmex, Kobe, Japan), and cells in a logarithmic phase of growth were used for all of the studies described below.

Growth Inhibition Assay. Cell growth was determined by the MTT (3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide) assay.[5] The HT-29 cells were placed in 96-well plates 24 h before treatment. Following treatment with 125−4000 μg/mL of LFWGE (adjustment of pH to 7.0 with 0.1 M NaOH) and WGE (control), the proliferation activity of the cells was tested after 24, 48, and 72 h of incubation. Following treatment with 12.5−100 μg/mL of 2,6-dimethoxy benzoquinone (standard), 25−200 μg/mL of protein fraction, 250−4000 μg/mL of sugar, and 25−100 μg/mL of lactic acid (standard), respectively, the proliferation activity of the cells was measured after 24 h of incubation.

Absorbance was measured at 490 nm using a Multiskan Spectrum (Thermo Electron Corp., Asheville, NC). Cell viability was expressed as a percentage of the control culture value, which was considered to be 100% viable.

Cell Cycle Distribution Analysis. The HT-29 cells (0.4×10^6 per mL) were seeded in 6-well culture plates and incubated with increasing concentrations of LFWGE [0 (double-distilled water), 0.2, 0.4, 0.8 mg/mL] at 37 °C under cell culture conditions. After 48 h, the cells were harvested and suspended in 5 mL of cold PBS, centrifuged (500 g for 10 min), and resuspended and fixed in 3 mL of cold ethanol (70%) for overnight at 4 °C. After washing twice with cold PBS, RNase A and propidium iodide were added to a final concentration of 50 μg/mL each. The sample was then incubated at 4 °C for 30−60 min before measurement. The cells were analyzed on a flow cytometer (Beckman Coulter), and the cell cycle distribution was calculated with the ModFit LT software (Verity Software House, Topsham, ME).

Hoechst Dye 33342 Staining. The HT-29 cells (0.4×10^6 per mL) were seeded in 12-well culture plates and exposed to 1 mg/mL concentrations of LFWGE for 48 h. Hoechst 33342 was added directly to the cells to a final concentration of 5 μg/mL. After 15 min at room temperature in the dark, the cells were visualized with a Leica DMR XA fluorescence microscope (Leica Microsystems Wetzlar GmbH, Wetzlar, Germany) equipped with the appropriate filters for Hoechst 33342 to determine the nuclear morphological changes.

Assessment of Apoptosis by Flow Cytometry. Apoptosis was determined with an apoptosis kit (Sigma). The procedure was performed according to the manufacturer's instructions. Briefly, after treatment with different concentrations (0.25, 0.5, 1, 2, and 4 mg/L) of LFWGE for 24, 48, and 72 h, the HT-29 cells were harvested and collected by centrifugation. The cells were washed with ice-cold PBS and resuspended in the binding buffer at a concentration of 10^6 cells/mL. Then, 500 μL of cell suspension was mixed with 5 μL of annexin V-FITC and 10 μL of propidium iodide (PI) solution. The mixtures were incubated for 10 min at 4 °C and protected from exposure to light. The fluorescence of the cells was analyzed by flow cytometry. Approximately 2×10^4 cells were tested for each histogram by flow cytometry.

Quantitative PCR. Approximately 2×10^7 HT-29 cells were lysed in Trizol Reagent. Total RNA was prepared according to the manufacturer's instructions (Takara, Japan). To remove the genomic DNA, 5 μg of total RNA was treated with 5U RNase-free DNaseI for 30 min at 37 °C. After the DNase treatment, the RNA were incubated at 65 °C for 10 min. RNA integrity was assessed by an Agilent 2100 Bioanalyzer (Agilent Technologies, Palo Alto, CA). Quantitative PCR was used to generate RNA with two sharp ribosomal 18S and 28S bands. First-strand cDNA synthesis was carried out on 2 μg of the total RNA from each sample with the PrimeScript RT Master Mix (Takara, Japan) first-strand synthesis kit for RT-PCR according to the manufacturer's instructions. Experimental wells containing 25 μL of SYBR Green PCR Master Mix (Takara, Japan) were run using north tube plates. Quantitative PCR was conducted on the iCycler according to the SYBR Green method. Forward and reverse primers were designed using the tools available through the MIT Whitehead Institute web page. The primer sequences were as follows: caspase-3(F) AACCTCAGGGAAACATTCAG, caspase3(R) GGCTCAGAAGCACACAAAC; caspase8(F) GGATGCCTTGATGTTATTCC, caspase8(R) AGTTCCCTTTCCATCTCCTC; caspase9(F) TTCCCAGGTTTGTTTCCTG, caspase9(R) ACCCTAAGCAGGAGGGACTG; caspase7(F) GAAGAGGCTCCTGGTTTGTG, caspase7(R) TCATGGAAGTGTGGGTCATC; actin(F) AGCGAGCATCCCCCAAAGTT, and actin(R) GGGCACGAAGGCTCATCATT. Quantitative PCR amplification for all of the caspases included preincubation at 94 °C for 6 min, followed by 38 cycles at 95 °C for 5 s, 57 °C for 45 s, and 72 °C for 30 s. The relative expression of mRNA was calculated using the $2^{-\Delta\Delta Ct}$ method.[36]

Caspase-3 Activity. The caspase-3 activity was determined using a caspase-3 activity kit (Nanjing Jiancheng Bioengineering Research Institute, Nanjing, China). Cell lysates were prepared after their respective treatment with various designated procedures, and the assays were performed on 96-well microtiter plates by incubating 10 μL of cell lysate protein per sample in 80 μL reaction buffer (1% NP-40, 20 mM Tris-HCl (PH 7.5), 137 mM Nad, and 10% glycerol) containing 10 μL of caspase-3 substrate (Ac-DEVD-pNA) (acetyl-Asp-Glu-Val-Asp p-nitroanilide) (2 mM). The lysates were incubated at 37 °C for 4 h. The samples were measured with an ELISA reader at an absorbance of 405 nm by a spectrophotometer.

Statistical Analysis. All of the statistical analyses were accomplished by using SPSS Statistics software version 17.0 (SPSS, Chicago, IL). Analysis of variance (ANOVA) was used to test for differences between the means.

RESULTS AND DISCUSSION

Yield and Chemical Composition of the Extracts. The composition of raw wheat germ was as follows: moisture 12.48 ± 0.46%, crude protein (N × 5.70) 37.88 ± 0.24% of dry matter (d.m.); fat 11.91 ± 0.34% of d.m.; and ash 7.68 ± 0.09% of d.m. In this experiment, the yields of the aqueous extract of LFWGE and WGE were 22.19 ± 1.32% and 40.02 ± 1.82%, respectively.

Table 1 presents the composition of LFWGE and WGE. As shown, WGE contained 32.90 ± 0.57% of crude protein and 43.05 ± 1.23% of total sugar. After 24 h of incubation with *Lactobacillus plantarum* dy-1 (initial cell density 4 × 10^8 cfu/g) at 30 °C (the optimum fermentation condition according to some preliminary work for antitumor activity), the protein in LFWGE slightly increased to 34.36 ± 0.23% and the sugar decreased to 33.04 ± 1.03%. In addition, the total phenol content of WGE was 20.81 ± 0.11 mg/g (expressed as the gallic acid equivalent, mg gallic acid/g dried extract). The total phenol content of LFWGE was to 28.48 ± 0.16 mg/g. Lactic acid was not detectable in WGE, whereas 27.7 ± 1.2 mg/g of lactic acid was found in LFWGE.

Table 1. Main Composition (% Dry-Weight) of LFWGE and WGE[a]

composition	WGE	LFWGE
2, 6-dimethoxybenzoquinone (μg/g)	33.85 ± 2.85	181.10 ± 4.56
protein (%, w/w)	32.90 ± 0.57	34.36 ± 0.23
total phenols (mg gallic acid/g)	20.81 ± 0.11	28.48 ± 0.16
total sugar (%, w/w)	43.05 ± 1.23	33.04 ± 1.03
lactic acid (mg/g)	0	27.7 ± 1.2

[a]The results are expressed as the mean (±SD), n = 3.

Due to the difficulty of buying 2-methoxy benzoquinone in China, 2,6-dimethoxybenzoquinone was selected as the analysis target. The 2,6-dimethoxybenzoquinone content in WGE and LFWGE was then determined by $CHCl_3$ selective extraction and HPLC analysis. WGE contained 2, 6-dimethoxybenzoquinone at a concentration of 33.82 ± 2.85 μg/g. After fermentation, the concentration of 2, 6-dimethoxybenzoquinone in LFWGE increased to 181.10 ± 4.56 μg/g (Table 1). This result shows that the fermentation had a significant effect on the 2,6-dimethoxybenzoquinone content of the aqueous extract of wheat germ, which may be attributable to the release of benzoquinones present in wheat germ as glucosides, as found by Rizzello et al.[30] and Yoo et al.[37]

Inhibition of Cell Proliferation in LFWGE-Treated HT-29 Cells. To examine the effects of LFWGE and WGE on cell growth, their inhibitory capacity against HT-29 colon cancer cells was assessed using the MTT assay. Logarithmically growing HT-29 cells were seeded at a concentration of 3 × 10^4 cells per mL, and then HT-29 colon cancer cells were treated with different concentrations of LFWGE and WGE (0.125−4 mg/mL) for 24, 48, and 72 h. As shown in Figure 1, WGE hardly inhibited cell proliferation in the HT-29 cells. However, with increasing concentrations of LFWGE, an increasing inhibition of cell proliferation in HT-29 cells was observed, with different degrees of potency between incubation times. The IC_{50} value was defined as the concentration at which the cell proliferation was inhibited by 50% of the control cells. LFWGE inhibited the growth of HT-29 cells in a dose- and time-dependent manner with IC_{50} values of 1.288, 0.6397, and 0.5435 mg/mL, respectively. These results indicate that LFWGE displays anticarcinogenic activity in HT-29 colon cancer cells.

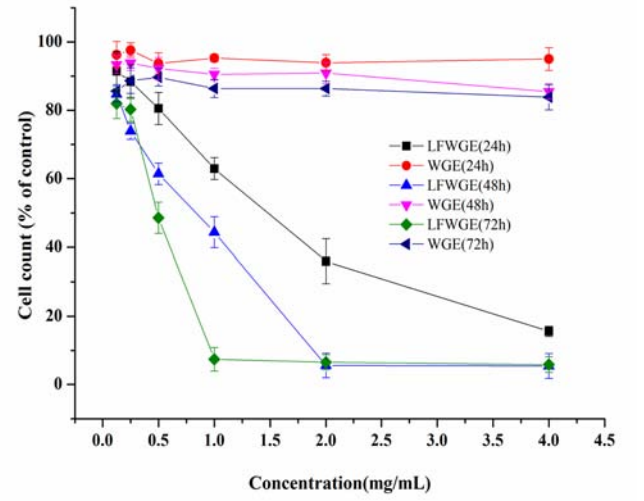

Figure 1. HT-29 cell proliferation in response to LFWGE and WGE treatment. Colon cell cultures were treated with increasing doses of LFWGE as indicated on the x axis. Cell proliferation was determined by formazan dye uptake and expressed as a percent of untreated control cell proliferation. Mean ± SD, n = 8.

Several studies have described the promising anticarcinogenic activity of a yeast (*Saccharomyces cerevisiae*) fermented wheat germ extract (Avemar), which is attributed to two quinones: 2,6-dimethoxybenzoquinone (2,6-DMBQ) and 2-methoxy benzoquinone (2-MBQ).[27,28] Yoo et al.[37] and Rizzello et al.[31] also demonstrated that both benzoquinones could be obtained from wheat germ using lactic acid bacteria fermentation. The HT-29 cells were treated with multiple levels of 2,6-DMBQ isolated from LFWGE to determine the dose-dependent response to this compound. The results obtained, shown in Table 2, show that the cell proliferation inhibition rate increased with the concentration. However, combined with the results of LFWGE treatment and 2,6-DMBQ content, we found that the proliferation of HT-29 cell was inhibited not only by benzoquinones. Therefore, further research on other functional components is still needed.

Some studies have also exploited the potential of specific low molecular proteins or polypeptides to reduce or inhibit the growth or proliferation of a cancer cell.[29] Proteins played a role in this study, and their effects on the cancer cells by isolated protein fractions from LFWGE were analyzed. Electrophoresis (SDS-PAGE) of WGE and LFWGE was performed to obtain

information on the molecular weight and distribution patterns of the protein components (Figure 2a,b). Protein bands were observed distinctly between 15 and 120 kDa in WGE, and between 15 and 40 kDa in LFWGE.

The extracted proteins were isolated and purified by sephadex G-50 and sephacryl S-200 gel filtration. To improve the separation efficiency, series columns were adopted. A typical elution profile is shown in Figure 3. The elution profile

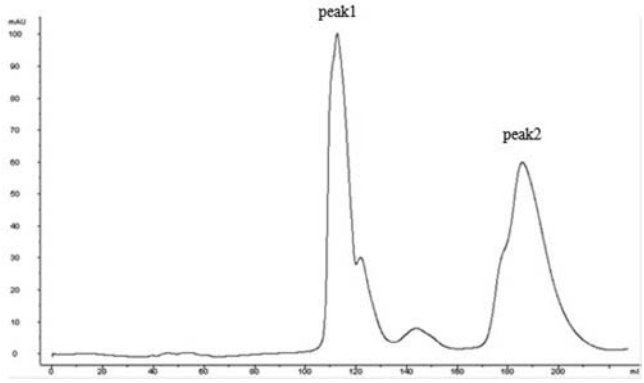

Figure 3. Chromatography of LFWGE on Sephadex G-50 column and sephacryl S-200 column. Eluent: phosphate buffer (pH 7.2, 10 mmol/L); flow rate, 1 mL/min.

was reproducible and revealed two main peaks (due to collection and detection difficulties, other smaller peaks were ignored). Among them, the peak1 fraction indicated the highest anticarcinogenic activity inhibiting the growth of HT-29 cells with 88.6% in 200 μg/mL (Table 2). An LC-MS/MS analysis was carried out for peak 1, and 21 proteins were observed and identified by searching against the NCBInr viridiplantae protein database. The active proteins were added to those listed in Table 3.

In addition, to determine which sugars in LFWGE might be at work, sugars were extracted and treated on HT-29 cells to

trace any activity. The result showed no anticarcinogenic activity (Table 2).

It is important to note that the pH was adjusted to 7.0 with 0.1 M of NaOH in vitro treated with LFWGE to eliminate the influence of low pH, which was attributed to the production of lactic acid during fermentation. The effect of lactic acid in the HT-29 cell lines was studied, but the result showed that it had no significant effect on the HT-29 cells (Table 2).

Cell Cycle Distribution after Treatment with LFWGE. To further confirm the proliferation inhibiting effect of LFWGE on HT-29 cells, the cell cycle distribution was analyzed by flow cytometry. Preliminary experiments have shown that while the cells die within 72 h, they do not change significantly for 24 h, so 48 h treatment was selected. The effect of LFWGE on the cell cycle distribution of HT-29 cells is shown in Figure 4. In the control cells, the cell cycle pattern remained constant over time. After 48 h of incubation with increasing doses of LFWGE, the percentage of cells in each phase was as follows: G_0/G_1 phase (DNA presynthetic phase), 61.2%, 70.2%, and 80.8%; S phase (DNA synthesis phase), 28.4%, 25%, and 14.8%; G_2/M phase (DNA postsynthetic and mitosis phases), 10.5%, 4.78%, and 4.34%, respectively. Overall, a broad peak appeared in the G_0/G_1 region with a significant decrease in the S cycle phase. Therefore, LFWGE halted the cell cycle transition of HT-29 cells in the G_0/G_1 phase of the cell cycle, resulting in the depletion of G_2/M phase cells. Studies have shown that Avemar also stops the cell cycle transition of HT-29 cells in the G_0/G_1 phase of the cell cycle and halts the cell cycle transition of HL-60 cells in the G_2/M phase of the cell cycle.[38]

Induction of Apoptosis by LFWGE. To evaluate the effect of LFWGE on the induction of apoptosis, the HT-29 cells were incubated with 0.25, 0.5, 1, 2, and 4 mg/mL of LFWGE for 24, 48, and 72 h, and then double stained with annexin V-FITC and PI, followed by quantitative flow cytometry analysis. The results confirmed that LFWGE induced the apoptosis of HT-29 cells, which was positively correlated with LFWGE dose

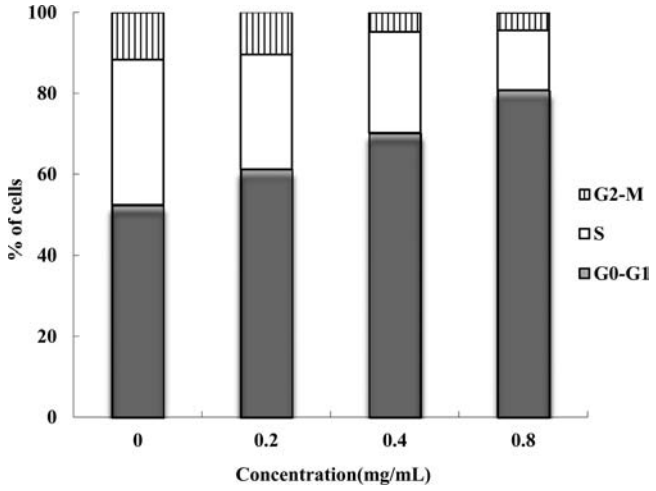

Figure 4. HT-29 cell cycle changes in response to LFWGE treatment (48 h). HT-29 cell cultures were treated with increasing doses of LFWGE as indicated on the right column, and cell cycle distribution was determined using flow cytometry after PI staining, and expressed as a percent of G_0/G_1, S, and G_2/M cycle phases. The DNA histograms show that LFWGE induced a dose-dependent decrease in the S cycle phase, whereas there was a significant expansion of the G_0/G_1 cycle phase consistent with an increase in the number of apoptotic HT-29 cell figures. Analysis by flow cytometry showed the distinct signals and cell frequencies associated with the arrested cell cycle status as described under the Results and Discussion section (n = 6).

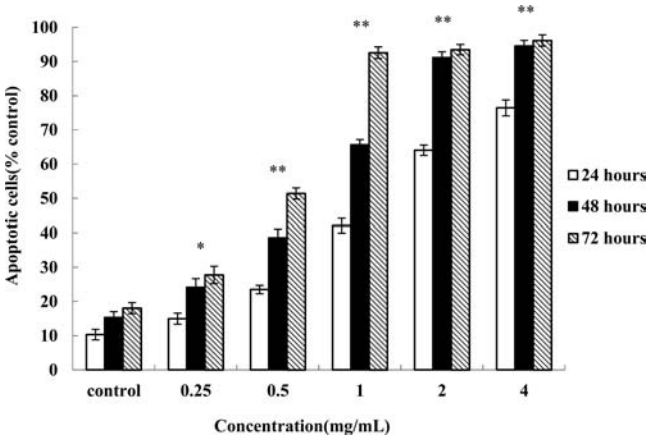

Figure 5. HT-29 cell apoptosis in response to LFWGE treatment. HT-29 cell cultures were treated with increasing doses of LFWGE as indicated on the *x* axis, and the number of apoptotic HT-29 cell was determined using flow cytometry after PI and annexin V staining. Mean ± SD $n = 3$, *, $p < 0.05$, **, $p < 0.01$.

and incubation time (Figure 5). The cells were double stained with annexin V-FITC and propidium iodide and analyzed by flow cytometry to examine the distribution of late and early apoptotic cells. The control cells demonstrated normal cell viability without significant cell apoptosis. In contrast, after treatment with 1 mg/mL of LFWGE, the portion of normal cells was only 2.6%, whereas the proportion of early apoptotic cells was 68.4% and that of late apoptotic cells was 28.9%. From these results, we found that LFWGE functions similarly to Avemar. It has been previously shown that Avemar treatment leads to an increase in apoptosis.[31,39] However, with regard to potency, the former is more effective than the latter.

Cell death in multicellular organisms exhibits two patterns: necrosis and apoptosis. Apoptosis is a process of programmed cell death characterized by various biochemical and morphological changes, including cell shrinkage, chromatin condensation, internucleosomal DNA fragmentation and the formation of "apoptotic bodies".[40] To further elucidate apoptotic cell death due to the exposure of HT-29 cells to LFWGE, the cells were stained with Hoechst dye 33342 and examined using a Leica DMR XA fluorescence microscope. As shown in Figure 6, the

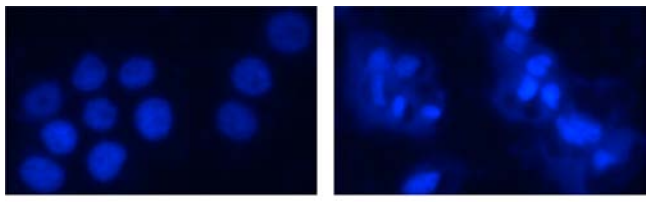

Figure 6. Effect of LFWGE treatment on the nuclear morphological changes of HT-29 cells: (a) control cells; (b) cells treated with 1 mg/mL LFWGE for 72 h. The medium was removed, and the cells were incubated with 5 μg/mL Hoechst for 15 min at room temperature in the dark. Stained solution was washed out, and cells were visualized under fluorescence microscopy (200×).

control cells exhibited intact and round-shaped nuclei characterized by a diffused chromatin structure (a). In contrast, exposure to 1 mg/mL of LFWGE for 72 h significantly altered the HT-29 cell morphology; that is, the nucleus exhibited condensed chromatin (b), which is characteristic of apoptotic cells. Moreover, combined with the cell cycle distribution, we found that the cell nuclei of early apoptotic cells were pycnoid or round-bead shaped, whereas those of late apoptotic cells appeared to have apoptotic bodies (Figure 7).

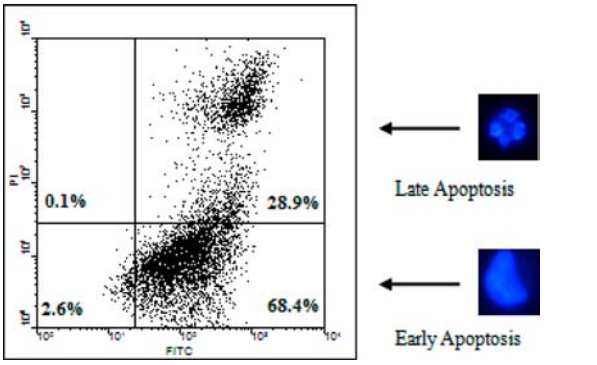

Figure 7. HT-29 cell early apoptosis and late apoptosis in response to LFWGE treatment using flow cytometry. HT-29 cell cultures were treated with 1 mg/mL LFWGE (72 h), and the formation of early apoptotic and late apoptotic HT-29 cell figures was determined using PI and Annexin V-FITC staining. The majority (68.4%, right bottom quadrant) of HT-29 cells exhibited early apoptosis as indicated by the limited nuclear fragmentation. Late apoptosis/necrosis was present in 28.9% (right upper quadrant) of HT-29 cells with advanced nuclear fragmentation and limited staining, while the frequency of normal cells dropped to 2.6% as observed in the left bottom quadrant of the flow cytometry screen ($n = 6$).

Role of Caspases in the Apoptotic Effect of LFWGE. Apoptosis is a well-controlled process involving a programmed set of cellular events partially mediated by caspases, which are the cysteine aspartate proteases involved in apoptosis that lead to the loss of cellular structure and function, phosphatidylserine exposure, and ultimately cell death.[41] Initiator caspases, such as caspases-2, -8, and -9, are closely linked to pro-apoptotic signals.[42] The effector caspases-3, -6, and -7 cleave cytoskeletal and nuclear proteins to induce apoptosis.[43,44] We therefore approached the question of caspases involvement in HT-29 cell processes by assaying the transcriptional regulation of caspases mRNA. The RNA purity was quantified by spectrophotometer with a OD260/280 ratio of 1.8 to 2.0 for all specimens. The RNA integrity was determined by 1% agarose gel electrophoresis, yielding two sharp ribosomal 18S and 28S bands. The expression of caspase-3, caspase-7, caspase-8, and caspase-9 was presented as $2^{-\Delta\Delta Ct}$. Caspase-3, caspase-7, caspase-8, and caspase-9 mRNA expression at 48 h after the addition of 0.4 and 0.8 mg/mL of LFWGE was detected by qPCR. Following the treatment of the HT-29 cells with increasing doses of LFWGE, the mRNA expression levels of caspase-3 ($F = 163.59$, $P = 0.000$), caspase-7 ($F = 504.491$, $P = 0.000$), caspase-8 ($F = 403.52$, $P = 0.000$) and caspase-9 ($F = 1465.930$, $P = 0.000$) significantly increased compared with the control group (Figure 8).

Caspase-3 is an executioner caspase activated by multiple pathways[45] that has been shown to increase with Avemar treatment.[32] The treatment of HT-29 cells with 0.4, 0.8, and 1.5 mg/mL of LFWGE for 48 h induced a dose-dependent activation of caspase-3. LFWGE induced a detectable increase in caspase-3 activity after 48 h of treatment, showing a 1.6-, 2.6-, and 4.08-fold increase, respectively (Figure 9). Therefore, growth inhibition and the induction of apoptosis in tumor

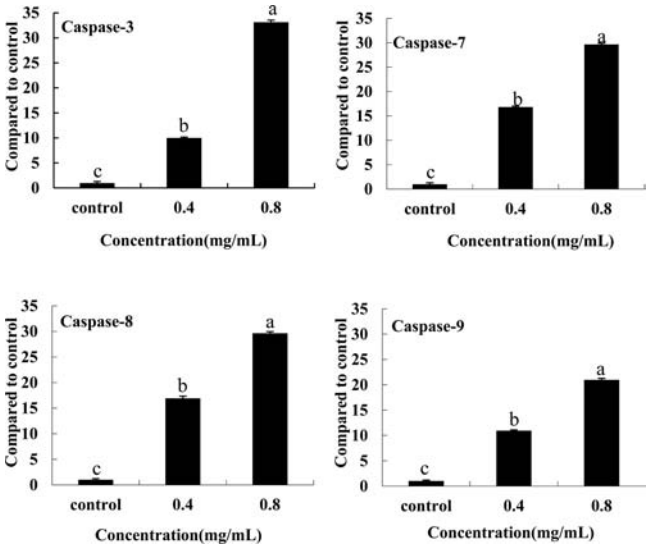

Figure 8. Caspase-3, caspase-8, caspase-9, and caspase-7 mRNA expression analysis following treatment of HT-29 cells with LFWGE (0.4 mg/mL, 0.8 mg/mL) for 48 h. The differences in expression after treatment with the various concentrations of LFWGE were calculated using the ANOVA method. $n = 6$.

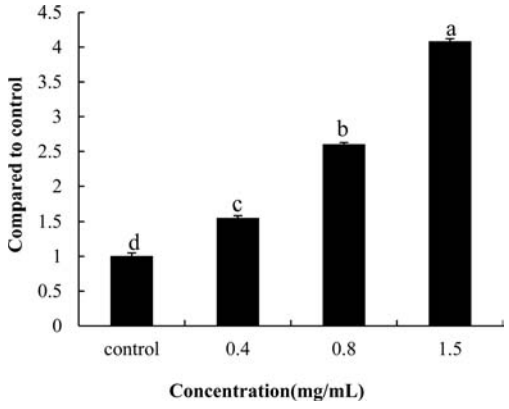

Figure 9. LFWGE activation of caspase-3 in HT-29 cells. HT-29 cells were treated in medium with 0.4, 0.8, and 1.5 mg/mL of LFWGE for 48 h, and then caspase-3 activity was estimated. Values are presented as the mean ± SD, and expressed as fold increase over the pre-treatment level (experimental/control). $n = 6$.

cells may be associated with the increased expression of caspases.

In conclusion, our findings confirm the value of LFWGE as a natural product with anticarcinogenic properties. LFWGE as a strong regulator is able to inhibit the growth of HT-29 cells and induce apoptosis in vitro. Further research is required to identify which components or which group of low molecular weight proteins are the most pronounced functional ingredients. In addition, the results indicate the possible involvement of a coordinated caspases response to induce apoptosis. On the basis of our data, LFWGE might warrant further investigation in the prevention or treatment of human colon cancer.

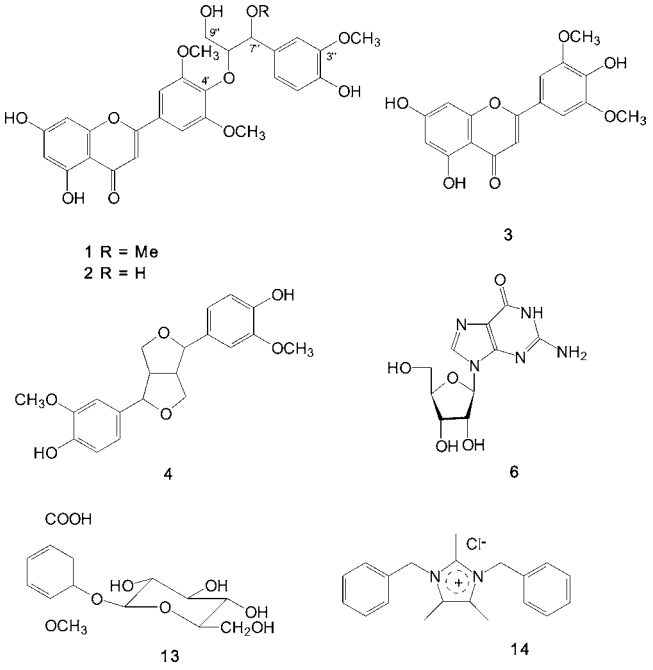

Figure 1. Structures of compounds **1**–**4**, **6**, **13**, and **14**.

acetonitrile and increased to 95% acetonitrile over 40 min and then increased to 100% acetonitrile over 5 min. At the end of the run, 100% of acetonitrile was allowed to flush the column for 5 min, and an additional 10 min of post run time was set to allow for equilibration of the column with the starting eluant. The UV detector was set at 280 nm wavelength, and the column temperature was ambient.

Plant Material. The roots of maca, *L. meyenii*, were collected from the Andean mountains of Peru. The species was identified using a HPLC method by comparison with an authentic sample. A voucher specimen (MA10205) was deposited in the Herbarium of Naturex, Inc.

Extraction and Isolation of *L. meyenii* Constituents. Two different extracts were prepared before isolation. The first extraction was carried out with 20 kg of maca root powder, which was extracted by H_2O three times (50 L × 3) at room temperature. The extract was concentrated (4.3 kg) and chromatographed on the column of CG 161 resin (Rohm and Haas, Philadelphia, PA, USA) (27 L, 26 cm × 180 cm), eluting with a H_2O/EtOH (1:0, 9:1, 3:1, 2:1, 1:1, 0:1) solvent system. A volume of 3 L was used in each step, and 1 L was collected as one fraction (named I fractions). The 90% H_2O/EtOH eluates (I 4–6, 78 g) were column chromatographed (CC) on an FPX 66 (Rohm and Haas, Inc.) (2.0 L, 12 cm × 50 cm) and eluted with H_2O/EtOH (1:0, 9:1, 3:1, 2:1, 1:3, 0:1) solvent system. Four liters of solvent was used in each step, and 1.0 L was collected as a fraction (named II fractions). A total of 24 fractions were collected and concentrated. These fractions were separately and repeatedly subjected to CC over MCI GEL CHP-20P (Mitsubishi Kasei Co.) and/or Sephadex LH-20

(Sigma Chemical Co., St. Louis, MO, USA) (100 mL, 2.5 cm × 40 cm) and eluted with a gradient H_2O/MeOH solvent system to yield **6** (33 mg from fractions II 5−6, t_R = 6.0 min in HPLC), **7** (35 mg from fractions II 5−6, t_R = 9.8 min), **8** (27 mg from fractions II 7−9, t_R = 10.3 min), **12** (25 mg from fractions II 10−12, t_R = 13.8 min), and **13** (5 mg from fractions II 5−6, t_R = 6.2 min). The 75% H_2O/EtOH fractions (I 7−9, 22g) from CG 161 resin were CC on FPX 66 using the same condition as described above and produced III serial fractions. These fractions were separately and repeatedly subjected to CC over MCI GEL CHP-20P and/or Sephadex LH-20 using gradient H_2O/MeOH to yield **9** (16 mg from fractions III 10−11, t_R = 12.0 min), **10** (156 mg from fractions III 8−9, t_R = 17.7 min), and **11** (162 mg from fractions III 12−14, t_R = 10.8 min). The second extraction was performed using 120 kg of maca roots. The air-dried root powder was extracted with H_2O twice (800 L × 2) at room temperature. After the H_2O extract was drained, the remaining roots were extracted with 95% EtOH three times (800 L × 3). The EtOH solutions were combined and concentrated under reduced pressure to yield ethanol extract (6.1 kg), which was suspended in H_2O and successively partitioned with hexane and EtOAc (10 L × 3). The EtOAc phase was concentrated (528 g) and CC on silica gel (2.5 kg, 12 cm × 50 cm), using a step gradient solvent system of hexane/acetone (10:1, 5:1, 2:1, 1:1, 0:1). In each step, 5 L of solvent was used and 1 L was collected as a fraction. Factions 12−18 were combined and concentrated (23 g) and were CC on polyamide resin (Sigma Chemical Co., St. Louis, MO, USA) (500 mL, 3.5 cm × 60 cm) using a H_2O/EtOH as solvent system (1:0, 10:1, 5:1, 3:1, 2:1, 1:1, 1:2, 0:1). A total of 1.5 L was used in each step, and 0.5 L was collected as one fraction (named IV fractions). These fractions were further CC over MCI GEL CHP-20P and/or Sephadex LH-20 and eluted with a gradient H_2O/MeOH system to yield **1** (21 mg from fractions IV 13−15, t_R = 28.0 min), **2** (17 mg from fractions IV 9−12, t_R = 25.1 min), **3** (2 mg from fractions IV 9−12, t_R = 28.5 min), **4** (3 mg from fractions IV 9−12, t_R = 13.9 min), and **5** (5 mg from fractions IV 16−19, t_R = 19.5 min).

NMR and ESI-MS of Flavonoids. *Tricin 4′-O-[threo- β-guaiacyl-(7″-O-methyl)-glyceryl] ether (**1**):* yellow amorphous powder; $C_{28}H_{28}O_{11}$; $[\alpha]_D^{25}$ −0.9° (*c* 1.00, MeOH); UV (MeOH) λ_{max} (log ε) 215, 272, 340 nm; IR (amorphous powder) ν_{max} 3316, 1595, 1419, 1182, 1025 cm^{-1}; ^1H and ^{13}C NMR data, see Table 1; HRESIMS *m*/*z* 541.1647 $[M + H]^+$ (calculated for $C_{28}H_{29}O_{11}$, 541.1639).

*Tricin 4′-O-(erythro-β-guaiacyl-glyceryl) ether (**2**):* yellow amorphous powder; $C_{27}H_{26}O_{11}$; $[\alpha]_D^{25}$ −0.9° (*c* 0.90, MeOH); UV (MeOH) λ_{max} (log ε) 205, 270, 338 nm; ^1H and ^{13}C NMR data, see Table 1; HRESIMS *m*/*z* 527.1553 $[M + H]^+$ (calculated for $C_{27}H_{27}O_{11}$, 527.1542).

*Tricin (**3**):* yellow amorphous powder; $C_{17}H_{14}O_7$; ^1H NMR (400 MHz, CD_3OD) δ 6.42 (1H, s, H-3), 6.18 (1H, d, *J* = 2.0 Hz, H-8), 5.98 (1H, d, *J* = 2.0 Hz, H-6), 7.18 (2H, s, H-2′ and 6′H), 3.91 (6H, s, 3′ and 5′-OCH_3); ^{13}C NMR (100 MHz, CD_3OD) δ 166.1 (C-2), 104.3 (C-3), 183.7 (C-4), 163.1 (C-5), 100.2 (C-6), 165.8 (C-7), 95.2 (C-8), 159.3 (C-9), 104.5 (C-10), 122.5 (C-1′), 105.0 (C-2′ and 6′), 149.5 (C-3′ and 5′), 141.0 (C-4′), 56.8 (C-3′ and 5′-OCH_3); HRESIMS *m*/*z* 331.0811 $[M + H]^+$ (calculated for $C_{17}H_{15}O_7$, 331.0818).

*Pinoresinol (**4**):* white amorphous powder; $C_{20}H_{22}O_6$; ^1H NMR (400 MHz, CD_3OD) δ 6.93 (2H, d, *J* = 1.2 Hz, H-2 $ 2′), 6.75 (2H, d, *J* = 8.0 Hz, H-5 and 5′), 6.80 (2H, dd, *J* = 8.0, 2.0 Hz, H-6 and 6′), 4.69 (2H, d, *J* = 4.4 Hz, H-7 and 7′), 3.12 (2H, dd, *J* = 6.4, 4.4 Hz, H-8 and 8′), 4.21 (2H, dd, *J* = 8.8, 6.8 Hz, H-9 and 9′), 3.81 (2H, dd, *J* = 8.8, 5.2 Hz, H-9 and 9′), 3.84 (6H, s, 3′ and 3″-OCH_3); ^{13}C NMR (100 MHz, CD_3OD) δ 133.7 (C-1 and 1′), 110.9 (C-2 and 2′), 149.1 (C-3 and 3′), 147.3 (C-4 and 4′), 116.0 (C-5 and 5′), 120.0 (C-6 and 6′), 87.5 (C-7 and 7′), 55.3 (C-8 and 8′), 72.6 (C-9 and 9′), 56.3 (C-3′ and 3″-OCH_3); HRESIMS *m*/*z* 359.1489 $[M + H]^+$ (calculated for $C_{20}H_{23}O_6$, 359.1495).

*4-Hydroxycinnamic acid (**5**):* white powder; $C_9H_8O_3$; ^1H NMR (400 MHz, CD_3OD) δ 7.40 (2H, d, *J* = 8.8 Hz, H-2 and 6), 6.76 (2H, d, *J* = 8.8 Hz, H-3 and 5), 7.56 (1H, d, *J* = 16.4 Hz, H-7), 6.24 (1H, d, *J* = 16.4 Hz, H-8); ^{13}C NMR (100 MHz, CD_3OD) δ 127.1 (C-1), 131.1 (C-2 and 6), 116.8 (C-3 and 5), 161.1 (C-4), 146.6 (C-7), 115.5 (C-8), 171.1 (C-9); ESI-MS (negative) *m*/*z* 163 $[M - H]^-$, $C_9H_7O_3$.

*Guanosine (**6**):* white powder; $C_{10}H_{13}N_5O_5$; ^1H NMR (400 MHz, DMSO-d_6) δ 7.93 (1H, s, H-8), 5.67 (H, d, *J* = 4.4 Hz, H-1′), 4.39 (1H, br s, H-2′), 4.07 (1H, br s, H-3′), 3.84 (1H, br s, H-4′), 3.69 (1H, d, *J* = 11.2 Hz, H-5′a), 3.51 (1H, d, *J* = 11.2 Hz, H-5′b); ^{13}C NMR (100 MHz, DMSO-d_6) δ 157.0 (C-1), 116.4 (C-2), 151.4 (C-3), 153.5 (C-5), 136.0 (C-8), 86.4 (C-1′), 73.6 (C-2′), 70.3 (C-3′), 85.2 (C-4′), 61.8 (C-5′); ESI-MS (positive) *m*/*z* 284 $[M + H]^+$, $C_{10}H_{14}N_5O_5$.

*Glucotropaeolin (**7**):* white powder; $C_{14}H_{18}NO_9S_2K$; ^1H NMR (400 MHz, CD_3OD) δ 7.38 (2H, d, *J* = 7.6 Hz, H-2 and 6), 7.32 (2H, dd, *J* = 7.6, 0.8 Hz, H-3 and 5), 7.22 (1H, t, *J* = 7.2 Hz, H-4), 4.45 (H, d, *J* = 9.2 Hz, H-7a), 4.22 (H, d, *J* = 9.2 Hz, H-7b), 4.63 (H, br s, H-1′), 4.03 (H, d, *J* = 16.0 Hz, H-6′a), 3.82 (H, d, *J* = 16.0 Hz, H-6′b), 3.57 (H, dd, *J* = 10.0, 2.4 Hz, H-4′), 3.07−3.23 (3H, m, H-2′, 3′, and 5′); ^{13}C NMR (100 MHz, CD_3OD) δ 137.4 (C-1), 129.3 (C-2 and 6), 129.9 (C-3 and 5), 128.2 (C-4), 39.6 (C-7), 160.7 (C-8), 82.8 (C-1′), 74.1 (C-2′), 79.3 (C-3′), 71.1 (C-4′), 82.2 (C-5′), 62.7 (C-6′); ESI-MS (negative) *m*/*z* 408 $[M - H]^-$, $C_{14}H_{17}NO_9S_2$.

*Desulfoglucotropaeolin (**8**):* white powder; $C_{14}H_{19}NO_6S$; ^1H NMR (400 MHz, CD_3OD) δ 7.30 (2H, overlapped, H-2 and 6), 7.27 (2H, overlapped, H-3 and 5), 7.20 (1H, overlapped, H-4); ^{13}C NMR (100 MHz, CD_3OD) δ 138.0 (C-1), 128.8 (C-2 and 6), 129.4 (C-3 and 5), 127.6 (C-4), 39.0 (C-7), 153.4 (C-8), 82.1 (C-1′), 74.0 (C-2′), 79.0 (C-3′), 70.8 (C-4′), 81.7 (C-5′), 62.3 (C-6′); ESI-MS (negative) *m*/*z* 328 $[M - H]^-$, $C_{14}H_{18}NO_6S$.

*3-Hydroxybenzylisothiocyanate (**9**):* white powder; C_8H_7NOS; ^1H NMR (400 MHz, CD_3OD) δ 6.72 (1H, s, H-2), 6.64 (1H, dd, *J* = 8.0, 2.8 Hz, H-4), 7.09 (1H, t, *J* = 8.0 Hz, H-5), 6.73 (H, dd, *J* = 8.0, 2.8 Hz, H-6), 3.40 (2H, s, H-7); ^{13}C NMR (100 MHz, CD_3OD) δ 138.2 (C-1), 117.0 (C-2), 158.6 (C-3), 114.8 (C-4), 130.5 (C-5), 121.3 (C-6), 43.4 (C-7), 177.1 (C-8); ESI-MS (negative) *m*/*z* 163 $[M - H]^-$, C_8H_6NOS.

*Malic acid benzoate (**10**):* white powder; $C_{11}H_{10}O_6$; ^1H NMR (400 MHz, CD_3OD) δ 7.97 (2H, d, *J* = 8.0 Hz, H-2 and 6), 7.56 (2H, t, *J* = 7.2 Hz, H-3 and 5), 7.41 (1H, m, H-4), 5.61 (1H, dd, *J* = 7.2, 4.8 Hz, H-2′), 3.01 (2H, t, *J* = 4.0 Hz, H-3′); ^{13}C NMR (100 MHz, CD_3OD) δ 130.2 (C-1), 130.6 (C-2 and 6), 134.7 (C-3 and 5), 129.5 (C-4), 167.1 (C-7), 173.1 (C-1′), 70.3 (C-2′), 36.9 (C-3′), 172.4 (C-4′); ESI-MS (negative) *m*/*z* 237 $[M - H]^-$, $C_{11}H_9O_6$.

*5-(Hydroxymethyl)furfural (**11**):* colorless oil; $C_6H_6O_3$; ^1H NMR (400 MHz, CD_3OD) δ 9.52 (1H, s, H-6), 7.38 (1H, d, *J* = 3.6 Hz, H-2), 6.57 (1H, d, *J* = 3.6 Hz, H-2), 4.60 (2H, s, H-5); ^{13}C NMR (100 MHz, CD_3OD) δ 153.8 (C-1), 124.9 (C-2), 110.9 (C-3), 163.1 (C-4), 57.6 (C-5); ESI-MS (negative) *m*/*z* 125 $[M - H]^-$, $C_6H_5O_3$.

*D-Phenylalanine (**12**):* white powder; $C_9H_{10}NO_2$; ^1H NMR (400 MHz, CD_3OD) δ 7.33 (5H, m, H-2, 3, 4, 5, and 6), 3.26 (H, dd, *J* = 15.2, 5.2 Hz, H-7a), 3.03 (H, dd, *J* = 15.2, 8.8 Hz, H-7b), 3.85 (1H, dd, *J* = 8.8, 5.2 Hz, H-8); ^{13}C NMR (100 MHz, CD_3OD) δ 135.6 (C-1), 130.0 (C-2 and 6), 130.4 (C-3 and 5), 128.7 (C-4), 37.2 (C-7), 55.5 (C-8), 171.8 (C-9); ESI-MS (negative) *m*/*z* 164 $[M - H]^-$, $C_9H_{10}NO_2$.

*Vanillic acid 4-O-β-D-glucoside (**13**):* white powder; $C_{14}H_{18}O_9$; ^1H NMR (400 MHz, CD_3OD) δ 7.56 (1H, s, H-2), 7.16 (1H, d, *J* = 8.0 Hz, H-5), 7.60 (1H, d, *J* = 8.0 Hz, H-6), 3.86 (3H, s, 3-OCH_3), 5.00 (H, d, *J* = 7.2 Hz, H-1′), 3.52 (1H, m, H-2′), 3.40 (1H, m, H-3′), 3.48 (1H, m, H-4′), 3.45 (1H, m, H-5′), 3.89 (1H, m, H-6′a), 3.67 (1H, dd, *J* = 12.0, 4.8 Hz, H-6′b); ^{13}C NMR (100 MHz, CD_3OD) δ 126.1 (C-1), 114.1 (C-2), 150.1 (C-3), 151.8 (C-4), 116.1 (C-5), 124.7 (C-6), 169.7 (C-7), 56.6 (3-OCH_3), 101.8 (C-1′), 74.6 (C-2′), 77.7 (C-3′), 71.1 (C-4′), 78.2 (C-5′), 62.3 (C-6′); ESI-MS (negative) *m*/*z* 329 $[M - H]^-$, $C_{14}H_{17}O_9$.

Cell Culture and Chemicals. The COLO 205 cell lines were isolated from human colon adenocarcinoma (ATCC CCL-222). Human promyelocytic leukemia (HL-60) cells were obtained from American Type Culture Collection (Rockville, MD, USA). The human HepG2 hepatocellular carcinoma cell lines (BCRC 60025) were obtained from the Food Industry Research and Development Institute (Hsinchu, Taiwan). COLO 205 and HL-60 cell lines were grown at 37 °C in 5% CO_2 atmosphere in RPMI. Hep G2 cells were grown in

DOI: 10.1021/acs.jafc.5b00219
J. Agric. Food Chem. 2015, 63, 2458−2463

Dulbecco's minimal essential medium (DMEM) supplemented with 10% heat-inactivated fetal calf serum (Gibco BRL, Grand Island, NY, USA), 100 units/mL of penicillin, and 100 μg/mL of streptomycin and kept at 37 °C in a humidified atmosphere of 5% CO_2 in air. Selected compounds were dissolved in dimethyl sulfoxide (DMSO). Propidium iodide was obtained from Sigma Chemical Co. (St. Louis, MO, USA).

Determination of Cell Viability. Cell viability was assayed by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay.[15] Briefly, human cancer cells were plated at a density of 1×10^5 cells/mL into 24-well plates. After overnight growth, cells were pretreated with various concentrations of test compounds for 24 h. The final concentration of dimethyl sulfoxide (DMSO) in the culture medium was <0.05%.[27,29] At the end of treatment, 30 μL of MTT was added, and the cells were incubated for a further 4 h. Cell viability was determined by scanning with an enzyme-linked immunosorbent assay reader with a 570 nm filter.

Nitrite Assay. The RAW 264.7 cells are treated with selected compounds and LPS or LPS alone. The supernatants are harvested, and the amount of nitrite, an indicator of NO synthesis, is measured by use of the Griess reaction. Briefly, supernatants (100 μL) are mixed with the same volume of Griess reagent (1% sulfanilamide in 5% phosphoric acid and 0.1% naphthylethylenediamine dihydrochloride in water) in duplicate on 96-well plates. After incubation at room temperature for 10 min, absorbance at 570 nm is measured with an ELISA reader (Thermo Labsystems Multiskan Ascent, Kaikki Oikeudet, Finland).

RESULTS AND DISCUSSION

The air-dried roots of *L. meyenii* were extracted with H_2O and subsequently with 95% EtOH to provide two extracts. The separation was conducted by using a combination of column chromatography on CG 161, FPX 66, silica gel, MCI GEL CHP-20P, and Sephadex LH-20, and a total of 13 compounds were isolated from the two extracts, including two flavonolignans, tricin 4′-*O*-[*threo*-β-guaiacyl-(7″-*O*-methyl)-glyceryl] ether (**1**)[36] and tricin 4′-*O*-(*erythro*-β-guaiacyl-glyceryl) ether (**2**),[35] and one flavonoid, tricin (**3**),[28] together with pinoresinol (**4**),[17] 4-hydroxycinnamic acid (**5**), guanosine (**6**), glucotropaeolin (**7**),[25,30] desulfoglucotropaeolin (**8**),[31] 3-hydroxybenzylisothiocyanate (**9**),[25,32] malic acid benzoate (**10**),[25] 5-(hydroxymethyl)furfural (**11**), D-phenylalanine (**12**), and vanillic acid 4-*O*-β-D-glucopyranoside (**13**).[33] Compounds **1**−**3**, **5**, **6**, **8**, **9**, **11**, and **13** were for the first time isolated from this plant. All of the structures were established by spectroscopic methods, including ^{1}H, ^{13}C NMR, DEPT, 2D correlation spectroscopy, MS, HRESIMS, and chemical properties. The known compounds were identified by NMR data compared with those reported in the literature. Compounds **7**, **8**, **11**, and **12** were identified by direct comparison with commercial standards.

Compound **1** was obtained as a yellow amorphous powder. Its molecular formula, $C_{28}H_{28}O_{11}$, was established on the basis of HRESIMS (*m*/*z* 541.1742 $[M + H]^+$, calcd for $C_{28}H_{29}O_{11}$, 541.1710). The IR spectrum showed the OH absorption (3316 cm^{-1}) and aromatic rings (1615, 1595 cm^{-1}). The UV spectrum of **1** exhibited maximum absorptions at 215, 272, and 340 nm, typical for a flavone derivative. The ^{13}C NMR spectrum revealed the presence of 28 carbon signals, including a conjugated ketonic carbon (δ 183.6), 20 aromatic or olefinic (δ 95.2−166.0), 4 methoxy (δ 56.3, 56.7, 56.7, and 56.8), 2 oxygenated methine (δ 86.6 and 83.7), and 1 oxygenated methylene carbon signals (δ 61.7). These signals correspond to a methoxy and one phenylpropanoid-substituted flavonoid of **1**. The ^{1}H NMR spectrum contained signals of a 3′,4′,5′-trihydroxy substituted B-ring at δ 7.06 (2H, s, H-2′, 6′), and it was confirmed by the observed long-range correlations of H-2′ (6′) with C-2 (δ 165.0), C-1′ (δ 127.4), C-3′ (5′) (δ 154.6), C-4′ (δ 140.2), and C-6′ (2′) (δ 104.7) in the gHMBC spectrum. The signal at δ 6.57 (1H, s, H-3) was assigned to H-3 on the basis of its long-range correlations with C-2, C-4 (δ 183.6), C-10 (δ 105.5), and C-1′ in the gHMBC spectrum, as well as NOE correlation of H-3 with H-2′ (6′) in the ROESY spectrum. Two broad singlets at δ 6.39 and 6.13 were assigned to be H-8 and H-6, respectively, in the 5,7-dihydroxy-substituted A-ring. The assignments were confirmed by the long-range correlations of H-8 with C-7 (δ 166.0), C-9 (δ 159.2), and C-10 and of H-6 with C-5 (δ 163.0), C-7, C-8 (δ 95.2), and C-10 in the gHMBC spectrum, respectively. The correlations of two *O*-methyl protons at δ 3.83 (6H, s, OCH_3) with C-3′ (5′) (δ 154.6) in the gHMBC spectrum, as well as the NOE correlations with H-2′ (6′) in the ROESY spectrum, indicated that two methoxy groups were substituted at C-3′ and 5′. Thus, the flavone moiety was identified as 5,7,4′-trihydroxy-3′,5′-dimethoxyflavone (tricin). Additional NMR data showed the existence of a guaiacylglycerol moiety by the presence of an ABX spin system in ^{1}H NMR at δ 6.75 (1H, br s, H-5″), 6.80 (1H, dd, *J* = 4.8, 1.6 Hz, H-6″), and 6.89 (1H, d, *J* = 1.6 Hz, H-2″) for the guaiacyl part and signals at δ 4.46 (1H, d, *J* = 6.0 Hz, H-7″), 4.43 (1H, m, H-8″), 3.92 (1H, dd, *J* = 12.0, 4.4 Hz, H-9″), and 3.73 (1H, dd, *J* = 12.0, 3.2 Hz, H-9″) for the glycerol part. The methoxy group in guaiacyl was confirmed by the observed correlation between the *O*-methyl protons at δ 3.81 (3H, s, OCH_3) and C-3″(δ 148.8) in the gHMBC and NOE correlation between the methoxy protons and H-2″ in the ROESY spectrum, respectively. The fourth methoxy group (δ 3.89) (3H, s, OCH_3) was located at C-7″, because a 9.5 ppm downfield shift for C-7″ (δ 83.7) in **1** was observed, when compared to compound **2**, where C-7″ (δ 74.2) was hydroxyl group substituted.[34,35] The linkage between the moieties of tricin and guaiacylglycerol was suggested through 4′-O-C-8″, as the signals of C-3′, 5′ (δ 154.6) of **1** showed a 5.1 ppm downfield shift compared with those of tricin (**3**) at C-3′, 5′ (δ 149.5). Very similar chemical shifts of C-8″ and C-9″ of **1** to those found in **2** and literature data[34] were in accord with the above suggestion. The coupling constant of $J_{H\text{-}7'',H\text{-}8''}$ for **1** was 6.0 Hz in methanol-d_6, corresponding to a *threo* form of chiral centers at C-7″ and C-8″ based on empirical observation.[35,36] Therefore, **1** was identified to be tricin 4′-*O*-[*threo*-β-guaiacyl-(7″-*O*-methyl)-glyceryl] ether, and **2** was idenfied to be tricin 4′-*O*-(erythro-β-guaiacyl-glyceryl) ether, two flavonolignan compounds from *L. meyenii*. The complete ^{1}H and ^{13}C NMR assignments are given in Table 1.

Compounds **1**−**3** and lepidiline B (**14**, previously isolated from *L. meyenii*)[26] were tested with regard to their effects on nitrite production in LPS-activated macrophages. As shown in Table 2, when RAW 264.7 cells were treated with test compounds at 40 μg/mL and LPS (100 ng/mL), the potency of inhibitory effect on nitrite production showed the sequence

1 > **14** > **3** > **2**, where **1** and **14** significantly inhibited NO production. The four compounds were also assayed for cytotoxicity in HL-60, Hep G2, and COLO 205 cell lines. Compounds **1**, **3**, and **14** showed moderate to weak effect against HL-60 cells with IC_{50} values of 40.4, 52.1, and 52.0 μM, respectively, whereas no cytotoxicity was observed for these compounds in Hep G2 and COLO 205 cell lines (Table 3).

Table 3. Effect of Different Compounds on the Growth of Various Human Cancer Cells[a]

	IC_{50} (μM) for cell line		
compound	HL-60	Hep G2	COLO 205
1	40.4 ± 1.9	>100	>100
2	>100	>100	>100
3	52.1 ± 3.7	>100	>100
14	52.0 ± 1.1	>100	>100
doxorubicin[b]	4.64 ± 0.05	4.82 ± 0.05	16.12 ± 1.49

[a]Cells were treated with various concentrations of selected compounds for 24 h. Cell viability then was determined by the MTT assay as described. Each experiment was independently performed three times and expressed as the mean ± SE. [b]Positive control compound.

Compound **14** was previously reported against the UMUC3, PACA2, MDA231, and FDIGROV cell lines with ED_{50} values of 6.47, 1.38, 1.66, and 5.26 μg/mL, respectively.[25] The three isolated flavonoids in the present investigation all consist of a tricin unit. Tricin, which exists as glycoside in rice bran and other grass species, has been considered as a potential cancer chemopreventive agent in humans.[37] Some other isolated compounds in the current study have also been reported to possess different biological activities.

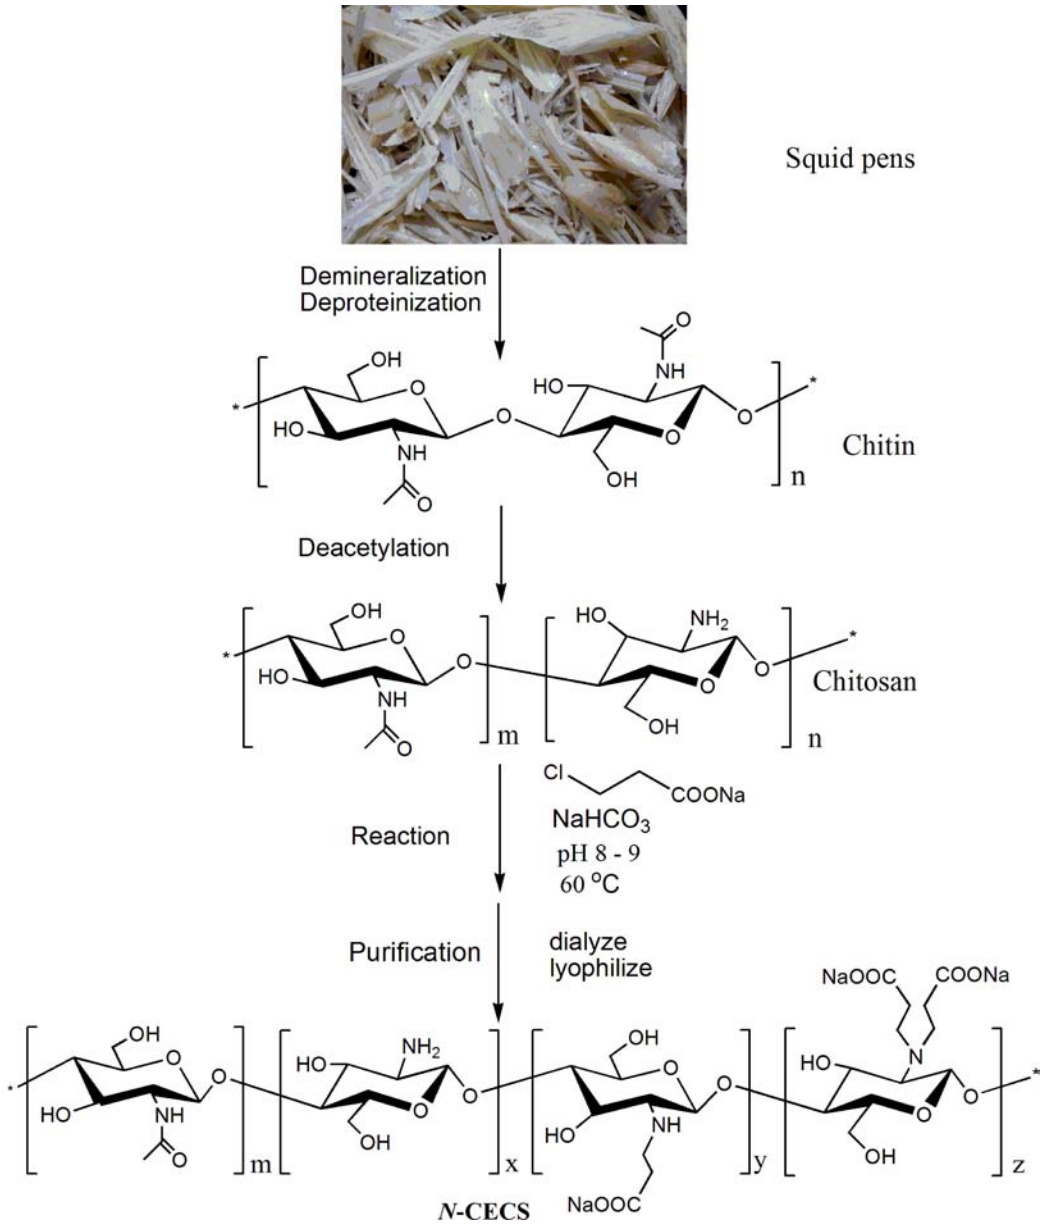

Figure 1. Preparation of water-soluble *N*-CECS.

can be synthesized via Michael-type 1,4-conjugate addition[24−26] or alkylation by halocarboxylic acids in neutral or mild alkaline conditions.[21,22]

Reactive oxygen species (ROS) have a wide variety of pathological effects, including in cancer, cardiovascular disease, diabetes, and atherosclerosis.[27] Antioxidants can reduce oxidative damage by scavenging ROS or preventing the generation of ROS. The use of synthetic antioxidants, such as butylated hydroxyanisole, *tert*-butylhydroquinone, and propyl gallate, is strictly regulated because of their potential health hazards. Recently, the antioxidant activity of chitosan and its derivatives have attracted the most attention in replacing synthetic species because of their nontoxic nature and natural abundance.[8,10,28,29] Furthermore, the extent to which carboxyethyl groups have been added to the polymer chain will directly affect the properties of CECS. However, to the best of our knowledge, there have been very few attempts to evaluate the relationship between the biochemical activities of *N*-CECS and their different degrees of carboxyethyl substitution.

In this paper, chitosan was prepared by alkaline N-deacetylation of squid pen *β*-chitin, and three *N*-(2-carboxyethyl)chitosans (*N*-CECS) with different degrees of substitution (DS) of carboxyethyls were synthesized to investigate the effect of substituting groups on the antioxidant activity and bile acid binding capacity. The antioxidant activity of *N*-CECS was investigated by scavenging 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) radicals ($ABTS^{\bullet+}$) and superoxide anion radicals ($^{\bullet}O_2^-$) and reducing power. In addition, the *in vitro* bile acid binding capacity of the derivatives was evaluated.

MATERIALS AND METHODS

Materials. Squid pens were provided by Hangzhou Baokai Biochemical Co., Ltd. (Hangzhou, China). 3-Chloropropionic acid, sodium bicarbonate, sodium acetate trihydrate, ferrous sulfate, bile acid (derived from taurocholate), furfual, nitro blue tetrazolium (NBT), phenazine methosulfate (PMS), ABTS, potassium ferricyanide [$K_3Fe(CN)_6$], reduced nicotinamide adenine dinucleotide (NADH), and

DOI: 10.1021/jf505581n
J. Agric. Food Chem. 2015, 63, 2464−2471

trichloroacetic acid were purchased from Aladdin Reagent Co., Ltd. (Shanghai, China). Sodium phosphate monobasic monohydrate, sodium phosphate dibasic anhydrous, and acetic acid were purchased from Sangon Biotech Co., Ltd. (Shanghai, China). All other chemicals were of analytical grade and used without further purification. All water used in the extraction and analysis was distilled and deionized.

Preparation of Chitosan from Squid Pens. The preparation of chitosan from squid pens was carried out using the method by Huang et al.[8] Chitosan with a degree of deacetylation of more than 90% was prepared from squid pens with a viscosity average molecular weight of 6.5×10^5 Da.

Preparation of *N*-CECS. *N*-CECS was synthesized as described by Skorik et al.[21]and Kogan et al.[22] According to Figure 1, chitosan (2 g) was dissolved in water (140 mL) containing 3-chloropropionic acid for 1 h. An amount of $NaHCO_3$ equivalent to the 3-chloropropionic was added to the dissolved chitosan in batches, which was stirred for an additional 30 min to remove the excess CO_2 (pH ~ 6.5). After stirring at 60 °C for 6 h, $NaHCO_3$ (6 g) was added, and after 1−2 h, the pH of the mixture was adjusted to be 8.5 by adding 10% NaOH. When the reaction was complete, the product was filtered and precipitated in ethanol and the precipitant was subsequently dissolved in water (20 mg/mL). The solution was acidified to pH 1−2 with concentrated HCl. The product was then dialyzed using a regenerated cellulose membrane (molecular weight cutoff of 3500) against distilled water for 2−3 days and lyophilized to obtain purified *N*-CECS. The sample was kept in a refrigerator for 4 °C.

Characterization of *N*-CECS Derivatives. Fourier transform infrared (FTIR) spectra of chitosan and *N*-CECS were obtained using a Bruker FTIR spectrometer (Vertex 70, Bruker Optik GmbH, Ettlingen, Germany). ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra of *N*-CECS were recorded on a Bruker AVANCE III 500 MHz using D_2O as the solvent operating at 25 °C. Determination of the DS was estimated by the integrals of $\delta(-CH_2COOH)$ in the amino group from the following equation:

$$\mathrm{DS} = \frac{y + 2z}{x + y + z} \tag{1}$$

where x corresponds to the mole fraction of no carboxyethylated glucosamine units, y is the mole fraction of mono-carboxyethylated glucosamine units, and z is the mole fraction of di-carboxyethylated glucosamine units.

The X-ray diffraction (XRD) spectra of the samples in powder form were performed by a X-ray scattering diffractometer (X'Pert PRO, PANalytical, Netherlands) with Cu Kα 185 radiation (λ = 1.5444) in the range of 5−40° (2θ) at a voltage of 40 kV and current of 40 mA. To minimize the influence of the uneven surface of samples on the diffraction angle, each *N*-CECS was pressed into a 0.8 mm thick pellet with 10 MPa of pressure.

The CHN elemental analysis of chitosan and *N*-CECS was performed on a Vario El cube CHNOS elemental analyzer (Elementar Analysensysteme GmbH, Hanau, Germany). The degree of deacetylation (DDA) value of chitosan samples was calculated from the following equation:[30]

$$\mathrm{DDA}\ (\%) = \frac{6.857 - C/N}{1.714} \tag{2}$$

DS was designated as the average number of carboxyethyl groups on each D-glucosamine. It was calculated as C (%)/N (%)

$$\mathrm{DS} = \frac{14}{36}\frac{[C/N(\mathrm{CECS}) - 5.14]}{\mathrm{DDA}\ (\%)} \tag{3}$$

where the C/N is a percentage ratio of these elements in the derivative and in the original chitosan. The constant 5.14 is the C/N value of chitosan at a deacetylation degree of 100%. There were two hydrogen atoms on each amino group, which could be substituted by the carboxyethyl groups. When the hydrogen atoms of $-NH_2$ on chitosan were fully substituted, the DS of *N*-CECS was 200%.

Estimation of *N*-CECS Water Solubility. The water solubility of *N*-CECS at various pH values was determined by a turbidity measurement.[31] An aqueous solution of *N*-CECS (2 mg/mL, pH 1.5) was prepared; NaOH solution (10 M) was added to adjust the pH. The transmittance of the solutions at different pH values was recorded on a METASH UV-5500PC spectrophotometer at 600 nm.

Bile Acid Binding Capacity Assay. The bile acid binding capacity of *N*-CECS was investigated *in vitro* using the method by Muzzarelli et al.[32] and Zhao et al.,[10] with minor modifications. An aliquot of the sample (1 mL, 10 mg/mL) was mixed with 0.4 mL of 5 mg/mL bile acid, and the mixtures were adjusted to a total volume of 5 mL with distilled water. The mixtures were incubated for 2 h at 37 °C and then filtered. The resulting samples (1 mL) were mixed with 1 mL of 1% (w/v) furfural and 13 mL of 45% (v/v) sulfuric acid. The samples were then incubated for 20 min at 70 °C, and the absorbance was measured at 605 nm.

ABTS Radical Scavenging Ability. The radical scavenging activity of *N*-CECS toward ABTS was measured on the basis of the method by Prouillac et al.[33] and Re et al.,[34] with some modifications. Briefly, the ABTS radical cation ($ABTS^{\bullet+}$) was generated by mixing an ABTS diammonium salt solution (7.4 mM in water) with the same volume of potassium persulfate aqueous solution (2.6 mM). The mixture was kept in the dark overnight until the reaction was complete. The working solution was prepared by diluting the ABTS stock solution in phosphate-buffered saline (PBS) solution (0.1 M, pH 7.4) to an absorbance of 0.7 at 734 nm. The free radical scavenging activity was assessed by mixing the $ABTS^{\bullet+}$ working solution (0.8 mL) with *N*-CECS solution (0.2 mL) and shaking for 30 s. After reaction for 20 min, the scavenging activity was calculated according to the following equation:

$$\text{scavenging effect}\ (\%) = \left(1 - \frac{A_{\mathrm{sample}}}{A_{\mathrm{control}}}\right) \times 100 \tag{4}$$

where A_{control} was the absorbance of the initial concentration of $ABTS^{\bullet+}$ (distilled water instead of sample) and A_{sample} was the absorbance of the remaining concentration of $ABTS^{\bullet+}$ in the presence of *N*-CECS. The EC_{50} value (mg/mL) is the effective concentration at which $ABTS^{\bullet+}$ radicals were scavenged by 50%.

Superoxide Radical Scavenging Ability. The superoxide scavenging ability of *N*-CECS was assessed by the method of Zhao et al.[10] and Yuan et al.[35] Each sample (2−10 mg/mL, 0.2 mL) were mixed separately with 0.2 mL of NADH (471.6 μM) and 0.2 mL of NBT (342.5 μM) in 0.05 M Tris−HCl buffer (pH 8.0). The reaction was initiated by adding 0.2 mL of PMS solution (163 μM) to the mixture and then incubated at 25 °C for 5 min, and the absorbance at 560 nm was measured against blank samples. In control, the sample was substituted with Tris−HCl buffer (0.05 M, pH 8.0). Decreased absorbance of the reaction mixture indicated increased superoxide anion scavenging activity.

Reducing Power Measurement. The reducing power of *N*-CECS samples was measured as described by Huang et al.[36] The reaction mixture contained different concentrations of *N*-CECS samples (0.2 mL), 0.2 M sodium phosphate buffer at pH 6.6 (0.2 mL), and 1% (w/v) potassium ferricyanide (0.2 mL). The mixtures were blended well and incubated for 20 min at 50 °C. Then, 10% (w/v) trichloroacetic acid (0.2 mL) was added to the mixtures and centrifuged at 4000 rpm for 10 min. The supernatant (0.5 mL) was mixed with distilled water (0.5 mL) and 0.1% (w/v) ferric chloride solution (0.1 mL). The absorbance values were determined at 700 nm. Increased absorbance of the reaction mixture indicated an increased reducing power.

Statistical Analysis. All of the analyses were performed at least in triplicate. Each experimental data point represents the mean from three independent experiments. The deviation from the mean at the 95% significance level was used for statistical analysis.

RESULTS AND DISCUSSION

Characterization of *N*-CECS. The preparation process and reaction conditions of *N*-CECS with different DS from squid pens are shown in Figure 1. Infrared spectroscopy has been

DOI: 10.1021/jf505581n
J. Agric. Food Chem. 2015, 63, 2464−2471

used to determine the structure of chitosan and *N*-CECS.[26,37] Figure 2 displays the FTIR spectrum of chitosan and *N*-CECS.

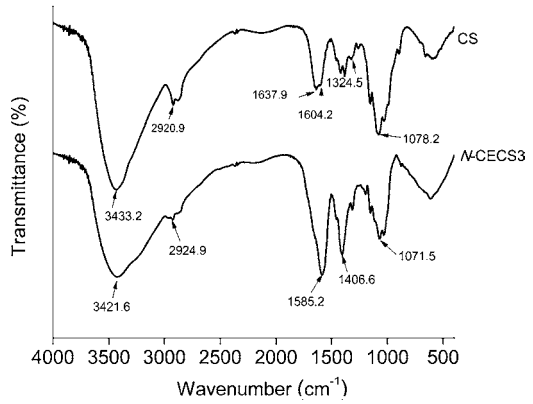

Figure 2. FTIR spectra of chitosan (CS) and *N*-CECS. The DS value of *N*-CECS was 1.41 by ^{1}H NMR.

Both characteristic peaks for chitosan at 3433 and 1078 cm^{-1} could be attributed to the O−H and C−O stretching vibrations, respectively. After carboxyethylation, two new bands at 1585 and 1407 cm^{-1} were observed. These were characteristic peaks of the stretching vibration of asymmetric and symmetric carboxyl groups, respectively.[10,38] Therefore, the FTIR data suggested that carboxyethyl groups were present in the derivative.

To compare the crystalline properties between the different samples, the XRD patterns of chitosan, *N*-CECS1, *N*-CECS2, and *N*-CECS3 are depicted in Figure 3. The peak registered

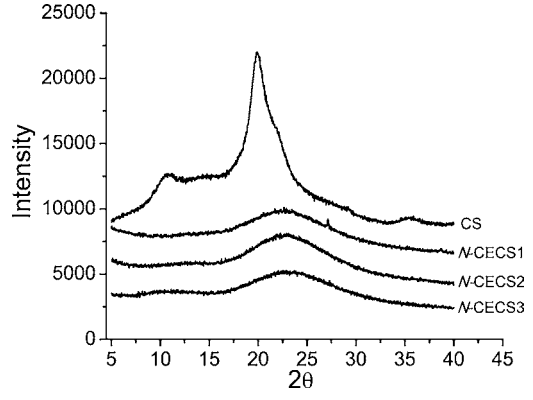

Figure 3. XRD patterns of chitosan (CS) and *N*-CECS with different DS. DS values of *N*-CECS1, *N*-CECS2, and *N*-CECS3 calculated by ^{1}H NMR were 0.88, 1.06, and 1.41, respectively.

near 19.90° highlights the relatively regular crystal lattice of chitosan. In comparison to unmodified chitosan, the X-ray patterns of *N*-CECS samples exhibit some changes to both their diffraction angles and peak intensity. The peak intensity registered near 19.90° decreased and shifted to a higher 2θ value (22.70°). The rigid crystalline structure of chitosan is mostly maintained by the intra- and intermolecular hydrogen bonds.[39]

The introduction of carboxyethyl groups disturbed the crystal domain of chitosan because of the high steric hindrance. Thus, the peaks of the crystal associated with chitosan were weakened and broadened. The change in these characteristic XRD peaks demonstrated that chitosan transited from a crystalline structure to an amorphous state through the carboxyethylation process.

The chemical structure of *N*-CECS was further characterized by ^{1}H and ^{13}C NMR spectroscopies. Figures 4 and 5 show typical ^{1}H and ^{13}C NMR spectra of the reaction product, respectively. Mono- and dicarboxyethylated amines are distinguishable on the spectrum because of the two different chemical shifts of $-CH_2COONa$ (2.56 and 2.80 ppm). The ^{13}C NMR spectrum of *N*-CECS showed as expected chemical shifts of carbonyl atoms of carboxyethyl (179.54 ppm), α-methylene of carboxyethyl of $GlcNR_2$ (33.51 ppm), and α-methylene of carboxyethyl of GlcNHR (36.39 ppm). The spectrum was comparable to literature reports.[21,22] The ^{1}H and ^{13}C NMR spectra further prove the substitution of the carboxyethyl group onto the amino groups of the chitosan backbone. Skorik et al.[22] reported that the chemoselectivity of chitosan carboxyalkylation arose from the mild alkaline reaction conditions. This makes it possible to differentiate the reactivity of $-OH$ and $-NH_2$ groups. Mild conditions (pH 8−9) facilitated alkylation of chitosan exclusively on the amino groups.

The high substitution found on the amino groups could hardly be achieved via Michael addition reaction.[24−26,40,41] Moreover, the structure of *N*-CECS was different from that of *N,O*-(2-carboxyethyl)chitosan (*N,O*-CECS); methylene of the carboxyethyl group substituted on C-6 also existed in the ^{1}H NMR spectrum of *N,O*-CECS in addition to the carboxyethylation of the amide group.[37] The DS values were calculated by ^{1}H NMR and elemental analysis (Table 1). The data showed that the DS values from ^{1}H NMR were similar to those from elemental analysis.

Water Solubility. Carboxyalkylation of chitosan can greatly improve its water solubility. Figure 6 illustrates the solubility of *N*-CECS with different DQ values at different pH values. The solubility of all *N*-CECS samples decreased with the increase of pH, and the corresponding pH of *N*-CECS1, *N*-CECS2, and *N*-CECS3 with minimum solubility is 5.6, 4.1, and 3.3, respectively. Further increasing the pH, however, led to a drastic increase in solubility and finally plateaued.

Figure 6 also showed good water solubility of all *N*-CECS above pH 6.5, but chitosan has poor solubility at pH > 6.5. The possible explanation for this phenomenon might be that the solubility of polyampholytes is the lowest at the isoelectric point (pI), all *N*-CECS samples with an amino group and a carboxyethyl group are polyampholytes, and pI of all *N*-CECS is different. When negative charge in the *N*-CECS structure increases upon introduction of carboxyethyl groups, the corresponding pI of *N*-CECS decreased. *N*-CECS had a more amorphous structure than chitosan, but the pI of *N*-CECS has a positive correlation with the pH of the minimum solubility.

***In Vitro* Bile Acid Binding Capacity.** The *in vitro* bile acid binding capacities of *N*-CECS are shown in Table 1. The binding capacity of *N*-CECS1, *N*-CECS2, and *N*-CECS3 against bile acid was 27.2, 36.9, and 0 mg/g (1.9-, 2.6-, and 0-fold higher than chitosan), respectively.

Previous reports have showed that the charge−charge interactions are the major force between the anionic bile acid and the bile acid sequestrants.[36,42] In comparison to native chitosan, the introduction of carboxyethyl groups severely disrupted the inner structure of *N*-CECS. The ability of *N*-CECS to form hydrogen bonds declined sharply; that is, the amino groups were activated, which increases the bile acid binding capacity. When a negative charge in the *N*-CECS structure increased above a certain level upon the introduction

[a]The molar ratio of 3-chloropropionic acid/D-glucosamine. [b]DS was calculated per D-glucosamine residue of chitosan by elemental analysis. [c]See Figure 1. [d]DS was calculated per D-glucosamine residue of chitosan by ^{1}H NMR spectrum, DS = $(y + 2z)/(x + y + z)$. [e]Bile acid (BA) binding capacity (mg/g).

of carboxyethyl groups, the significant decrease in the bile acid binding capacity could be caused by ionic repulsion because of its anionic characteristics. Moreover, the solubility improvement of *N*-CECS also enhances its biological activity, including bile acid binding capacity.[43] Thus, *N*-CECS with enhanced bile acid binding capacity may be used as an ingredient in the pharmaceutical industry to possibly reduce cholesterol and blood pressure.

Scavenging Effect on ABTS Radicals. The ABTS free radicals have been widely used for testing the preliminary radical scavenging capacity of plant extracts or antioxidants.[44] ABTS radical scavenging is an electron-transfer reaction; the addition of antioxidants to the preformed radical cation $ABTS^{\bullet+}$ reduces ABTS. This extent of the reaction and the kinetics depends upon the antioxidant activity, the concentration of the antioxidant, and the duration of the reaction.[33] The scavenging activities of *N*-CECS toward ABTS radicals with varying DS and concentrations are shown in Figure 7. Figure 7 showed that the scavenging ability of *N*-CECS toward ABTS radicals improved as a function of concentrations. The

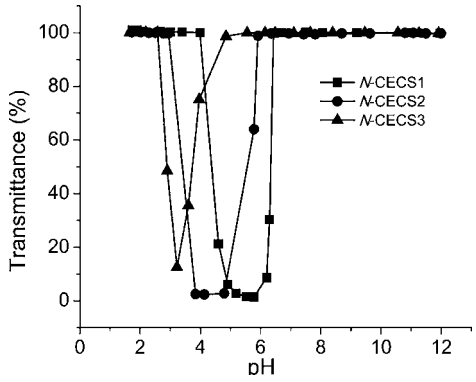

Figure 6. pH dependence of *N*-CECS water solubility with different DS. DS values of *N*-CECS1, *N*-CECS2, and *N*-CECS3 calculated by ^{1}H NMR were 0.88, 1.06, and 1.41, respectively.

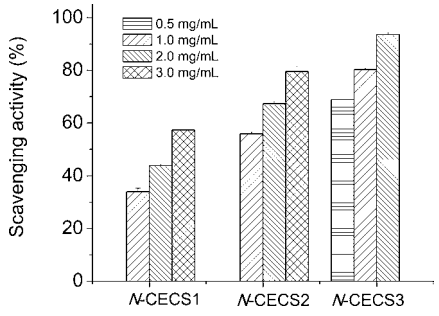

Figure 7. Scavenging effect of *N*-CECS with different DS toward ABTS radicals. DS values of *N*-CECS1, *N*-CECS2, and *N*-CECS3 calculated by ^{1}H NMR were 0.88, 1.06, and 1.41, respectively.

EC_{50} values of *N*-CECS1, *N*-CECS2, and *N*-CECS3 toward the ABTS radical were 1.83, 1.23, and 0.33 mg/mL, respectively. The data indicated that the addition of carboxyethyl groups to chitosan improved its scavenging activities against the ABTS radicals.

The hydroxyl group of chitosan and its derivatives plays an important role in scavenging the ABTS radicals.[17] The formation of inter- and intramolecular hydrogen bonds in chitosan inhibited the reaction of ABTS radicals with the active hydroxyl groups. In comparison to chitosan, the inner structure of *N*-CECS was severely disrupted by the introduction of hydrophilic *N*-carboxyethyl groups. The ability to form hydrogen bonds declined sharply; that is, more active hydroxyl groups in the *N*-CECS polymer chains were exposed. As the DS increased, the numbers of active hydroxyl groups in *N*-CECS increased. Thus, there were better scavenging abilities by *N*-CECS samples with a higher DS than *N*-CECS samples with a lower DS.

Cheng et al.[16] reported that the scavenging of ABTS radicals by hydroxypropyl chitosan (HPCS) with different DS (0.42−2.25) were below 40% at 10 mg/mL. Huang et al.[17] showed that the scavenging of ABTS radicals by *N*-(2-hydroxy)propyl-3-trimethylammonium chitosan chloride (HTCC) with different DS (0.77−1.06) was below 35% at 5 mg/mL. In comparison to HTCC and HPCS chitosans, *N*-CECS was more effective in ABTS radical scavenging activity.

Superoxide Radical Scavenging Activity. The superoxide anion formed in almost all aerobic cells is known to be very harmful to cellular components and is a precursor of more reactive oxidative species, such as single oxygen and hydroxyl radicals.[44,45] Figure 8 depicts the scavenging activities of *N*-CECS with varying DS and concentrations on superoxide radicals. The scavenging effect of all forms of *N*-CECS toward superoxide radical correlated well with their concentrations. The correlation between the carboxyethyl content (DS) of *N*-CECS and their superoxide radical scavenging activity was positive. At 10 mg/mL, the scavenging effect on superoxide radicals of *N*-CECS1, *N*-CECS2, and *N*-CECS3 was 42.08, 45.92, and 50.44%, respectively. The corresponding EC_{50} values (mg/mL) were 13.32, 11.52, and 9.75. In comparison to the previously reported EC_{50} value for chitosan (14.58 mg/mL),[10] *N*-CECS was more effective than chitosan at eliminating superoxide radicals.

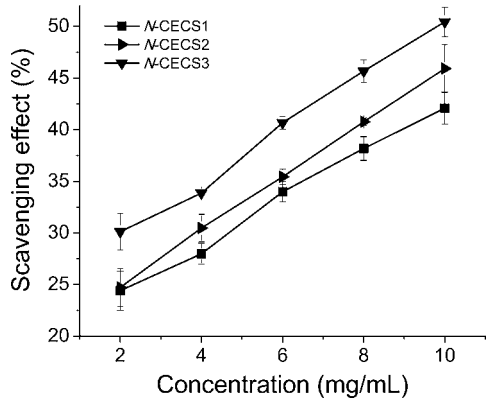

Figure 8. Scavenging effect of *N*-CECS with different DS toward superoxide radicals. DS values of *N*-CECS1, *N*-CECS2, and *N*-CECS3 calculated by ^{1}H NMR were 0.88, 1.06, and 1.41, respectively.

Chitosan has two hydroxyl groups and one amino group in its basic unit. Polysaccharides with scavenging effects toward superoxide anion all have one or more alcohol or phenolic hydroxyl groups. The formation of hydrogen bonds in chitosan inhibited the reaction of superoxide anion with the active hydroxyl groups in the polymer chains.[8,10] After etherification, more hydroxyl groups are activated, and this is helpful for enhancing the scavenging effect toward the superoxide radical. As an electron-donating group, the carboxyethyl group may enhance the electron cloud density of the active hydroxyl group in the *N*-CECS polymer chain. Thus, the electron-donating activity of *N*-CECS increased, and the scavenging effect on superoxide anion increased, when the DS increased from 0.88 to 1.41. We conclude that *N*-CECS may be an antioxidant based on its ability to scavenge ABTS and superoxide radicals.

Reducing Power. Figure 9 depicts the reducing power of *N*-CECS with different DS values using the potassium ferricyanide reduction method. As shown in Figure 9, the reducing power of *N*-CECS correlated well with increasing the concentration. However, the correlation between the carboxyethyl content (DS) of *N*-CECS and reducing power was not positive. At 6 mg/mL, the absorbance values of *N*-CECS1, *N*-CECS2, and *N*-CECS3 were 0.049, 0.064, and 0.032, respectively. Huang et al.[8] reported that, at 2 mg/mL, the reducing power of low-molecular-weight (LMW) chitosans was more than 0.50. In comparison to LMW chitosans, it seems that *N*-CECS has poor reducing power. Previous studies have shown direct correlation between the antioxidant activities and the reducing power of certain plant extracts.[37,46,47] The reducing properties are generally associated with the presence of reductones that break the free radical chain by donating a hydrogen atom.[44] The reducing power of *N*-CECS suggested

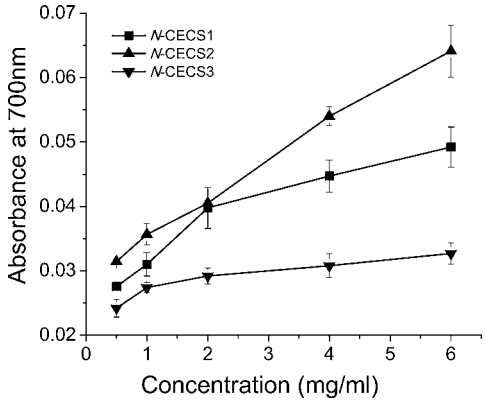

Figure 9. Reducing power of *N*-CECS with different DS. DS values of *N*-CECS1, *N*-CECS2, and *N*-CECS3 calculated by ^{1}H NMR were 0.88, 1.06, and 1.41, respectively.

that it was likely to contribute insignificantly toward the observed antioxidant effect.

applied on silica gel 60 (Merck, 230−400 mesh), Sephadex LH-20 (Amersham Pharmacia Biotech), and Li Chroprep RP-18 (Merck, 40−63 μm).

The EtOAc-soluble portion (65 g) was subjected to a silica gel column in gradient elution of mixed solvent compoed of *n*-hexane−EtOAc−MeOH and led to 25 fractions (E1−E25). Fraction E11 (640 mg) was separated via another silica gel column with hexane−ethyl acetate mixture as the eluent to obtain 15 subfractions (E11-1−E11-15). Fraction E10 (642 mg) was fractionated by a Sephadex LH-20 column (100% acetone) to give nine subfractions (E10-1−E10-9). Compound **1** (7 mg) was purified by LH-20 chromatography (100% acetone) from subfraction E11-10 (228 mg) together with eight portions (E11-10-1−E11-10-8). Compounds **2** (7 mg), **3** (4 mg), and **7** (2 mg) were, respectively, isolated form fractions E11-10-3, E10-5, and E10-7 by C-18 reverse-phase chromatography with MeOH−H_2O (7:3−1:0); besides, six subfractions (E10-7-1−E10-7-6) were obtained. Moreover, compounds **4** (2 mg) and **8** (1 mg) were isolated from subfraction E10-7-3 and subjected to silica gel column purification and by reverse-phase HPLC (MeOH/H_2O = 85:15). On the other hand, the nonpolar section, hexane layer, was separated in the same way as the EtOAc−solution part, and 10 fractions (H1−H10) were given. Fraction H8 was reapplied to a silica gel column using *n*-hexane−EtOAc mixtures in stepwise-increasing polarity to fractionate 14 segments (H8-1−H8-14). The subfraction H8-11 (3.5 g) was further purified through an Amberlite XAD-2 column (100% MeOH), a Toyopearl HW-40F column, and a RP-HPLC column (MeOH/H_2O = 85:15), resulting in compounds **5** (4 mg), **6** (2 mg), and **9** (9 mg).

*Litchtocotrienol A (**1**).* **1** was a colorless oil. CD (MeOH, c = 0.12, nm (ε)) 212 (−1.09), 225 (+14.33), 291 (−0.83). $[\alpha]^{25}_{D}$ −75 (c = 0.2, $CHCl_3$). In Vitro Cytotoxicity Assay. The cytotoxicity assays for these new isolated litchtocotrienols against HepG2 2.2.1.5 (human hepatocellular carcinoma cells) obtained from Prof. Pei-Jer Chen of National Taiwan University and AGS (ATCC CRL 1739; human gastric adenocarcinoma) were estimated by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) colorimetric method.[21,22] Briefly, 10% FBS dilution of cancer cells was loaded in 96-well plates and then incubated for 24 h to allow for attaching to the microtiter plate. Pure compounds in different concentrations (2−20 μg/mL) and positive control (doxorubicin and 5-fluorouracil) treated on cancer cells and then hatched at 37 °C in a 5% CO_2 incubator for 24 h. After incubation, the medium was removed from each well and added 100 μL of MTT (dissolved in PBS) at 37 °C for 1 h, and then MTT crystals were washed away by DMSO. Finally, each plate was measured by a plate reader at 570 nm, and the cytotoxic intensity of each compound was determined by the OD values.

RESULTS AND DISCUSSION

The structures of the isolated compounds were determined by extensive spectroscopic analysis, including nuclear magnetic resonance (NMR), high-resolution mass spectroscopy (HR-ESIMS), UV, IR, and circular dichroism (CD) techniques.

Compound **1**, Figure 1, was obtained as a colorless oil. The molecular formula, $C_{27}H_{42}O_4$ with 7 degrees of unsaturation, was deduced from the pseudo-molecular ion (m/z 453.2962, $[M + Na]^+$ calcd for 453.2975) in HRESIMS. The IR spectrum showed the absorptions of the hydroxyl group (3394 cm^{-1}) and aromatic ring (1609 cm^{-1}). The ^1H NMR spectrum (Table 1) exhibited six tertiary methyl signals at δ_H 1.16, 1.20, 1.26, 1.59, 1.60, and 2.13 and five methine resonances at δ_H 3.36 (br d, J = 10.2 Hz), 5.13 (br t, J = 6.6 Hz), 5.17 (br t, J = 6.6 Hz), 6.39 (d, J = 2.4 Hz), and 6.48 (d, J = 2.4 Hz). In the DEPT NMR spectra, 27 signals were categorized into six methyl carbons at δ_C 15.8, 15.9, 16.1, 23.2, 24.0, and 26.3, eight methylene carbons at δ_C 22.1, 22.4, 26.4, 29.6, 31.3, 36.7, 39.4, and 39.5, five methine carbons at δ_C 78.3, 112.6, 115.6, 124.5, and 125.0, and eight quaternary carbons at δ_C 73.0, 75.2, 121.2, 127.3, 134.9, 134.9, 145.9, and 147.7 (Table 2). Four sections (**I**−**IV**, Supporting Information) were established from key cross-peaks in the COSY spectrum (H-3/H-4, H-1′/H-2′/H-3′, H-5′/H-6′/H-7′, H-9′/H-10′/H-11′). In the HMBC spectrum, the correlations of H-5 with C-4a (δ_C 121.2), C-6 (δ_C 147.7), C-7 (δ_C 115.6), and C-8a (δ_C 145.9) and that of Me-18′ with C-8 (δ_C 127.3), C-7, and C-8a revealed that compound **1** possessed a *m*-cresol structure. In addition, the ^1H−^{13}C heteronuclear correlations of Me-17′ with the oxygenated quaternary carbon C-2 (δ_C 75.2), C-3 (δ_C 31.3), and C-1′ (δ_C 39.4) as well as that of H-4 with C-4a plus the segment **I** extend the *m*-cresol to a chromanol ring moiety. Likewise, fragments **II**−**IV** combined with the HMBC correlations of the methyl protons at Me-16′ with C-3′ (δ_C 124.5), C-4′ (δ_C 134.9), and C-5′ (δ_C 39.5), Me-15 with C-7′ (δ_C 125.0), C-8′ (δ_C 134.9), and C-9′ (δ_C 36.7), and two geminal methyls Me-13′ and Me-14′ both showed correlations with C-11′ (δ_C 78.3) and C-12′(δ_C 73.0), indicating a long linear geranyl portion connected with 2,3-pentanediol. Therefore, the planar structure of **1**, which pertained to the δ-tocotrienol skeleton, was assigned as litchtocotrienol A.[23−27]

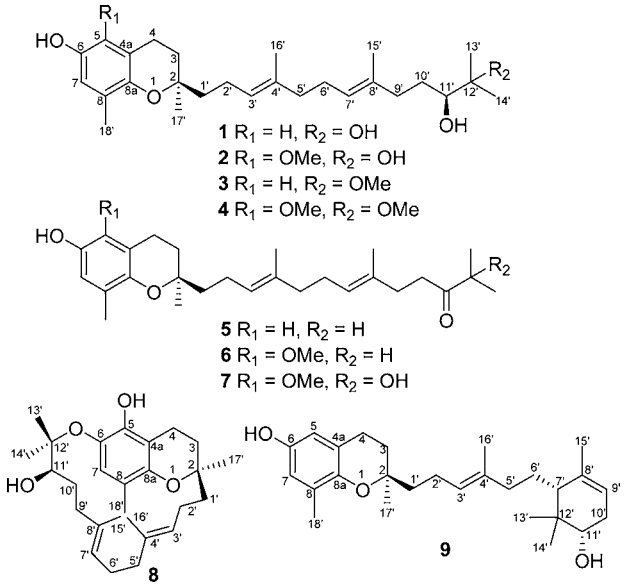

Figure 1. Structures of compounds **1**−**9** from the leaves of *L. chinensis*.

The configuration of **1** was determined mainly from NOESY correlations and the circular dichroism (CD) spectrum. The carbon resonances of two vinyl methyls Me-15′ (δ_C 15.9) and Me-16′ (δ_C 15.8) combined with the NOESY cross-peaks of H-1′/H-3′/H-5′ and H-2′/Me-16′/H-5′/H-7′ explained the *E* geometry for the $\Delta^{3'4'}$ and $\Delta^{7'8'}$ double bonds. Besides, the *R* configuration of C-11′ was assigned by comprehensive comparison of NMR data with that of (1*R*, 2*R*, 4*S*, 17*R*)-loba-8,10,13(15)-triene-17,18-diol.[28,29] Additionally, the absolute configuration of the chiral center at C-2 was suggested by CD observation. The negative Cotton effect at 291 ($\Delta\varepsilon$ −0.83)

DOI: 10.1021/jf5056387
J. Agric. Food Chem. 2015, 63, 2472−2478

nm in the CD spectrum indicated that **1** has the *R* configuration at C-2.[30,31]

Compound **2** possessed a pseudomolecular ion peak at *m/z* 483.3085 by HRESIMS, appropriate for a molecular formula of $C_{28}H_{44}O_5$. The same units of unsaturation and similar ^1H and ^{13}C NMR data (Tables 1 and 2) to **1** disclosed that these two structures pertain to the same litchtocotrienol-type framework, and thus, **2** is an analogue of **1**. The difference between **1** and **2** was an aromatic proton H-5 (δ_H 6.39) in **1** and a methoxyl group (δ_H 3.78) in **2**. The actual structure was confirmed by key HMBC correlations of H-4 (δ_H 2.75), H-7 (δ_H 6.62), and H_3-19′ (δ_H 3.78) with C-5 (δ_C 142.3). The similar NOESY correlations suggested the same configuration of the hydroxylated farnesyl tail in **2**. Moreover, the negative CD curve at 278 ($\Delta\varepsilon$ −0.49) nm assigned the *R* chirality of C-2.[30,31] Consequently, compound **2** was named litchtocotrienol B, a 5-methoxyl analogue of litchtocotrienol A.

Compound **3** was isolated as colorless oil, and the HRESIMS of **3** afforded a $[M + Na]^+$ ion at *m/z* 467.3128, implying the molecular formula $C_{28}H_{44}O_4$ and 7 indices of unsaturation. ^1H and ^{13}C NMR spectra of **3** were similar to those of **1**, and the formula difference indicated that **3** has a homologous structure. Moreover, the extra methyl protons at δ_H 3.22 and the same counts of each carbon multiplicities showing in the DEPT analyses indicated that **3** was a methylated derivative of **1**. The HMBC correlation of *O*-methyl (δ_H 3.22) with the quaternary carbon C-12′ (δc 76.8) pointed the evident position at the end of the side chain. Equally, the negative CD band allowed the *R* assignment at C-2. On the basis of the above data, the structure of **3** was elucidated as (*R*)-2-((*S*,3*E*,7*E*)-11-hydroxy-12-methoxy-4,8,12-trimethyltrideca-3,7-dien-1-yl)-2,8-dimethylchroman-6-ol, designated as litchtocotrienol C.

The molecular formula of **4** was calculated as $C_{29}H_{46}O_5$ with 7 degrees of unsaturation deducing from the HR-ESIMS. The similar UV, IR, and NMR spectra suggested that compound **4** possessed the same litchtocotrienol skeleton. Comprehensive analyses and comparisons of NMR data of compounds **2**−**4** showed that **4** differed from **2** by one aliphatic methoxy (δ_H 3.22, δ_C 49.0) and from **3** by one aromatic methoxy signal (δ_H 3.78, δ_C 60.6). In the HMBC spectrum, the methyl protons of OMe-5 (δ_H 3.78, 3H, s) were associated with C-5 (δ_C 142.2) while OMe-12′ corresponded with C-12′ (δ_C 76.8). These two essential HMBC correlations evidenced that compound **4** performed 12′-*O*-methylation of **2**, while it acted as a 5′-*O*-methylated mimic of **3** and thus was given the name litchtocotrienol D.

On the basis of the characteristics of IR and NMR data and HR-ESIMS information (*m/z* 435.2861, $[M + Na]^+$), compound **5** was identified as a δ-tocotrienol analogue with a molecular formula $C_{27}H_{40}O_3$ (8 degrees of unsaturation). The main structural difference from previous litchtocotrienols **1**−**4** was that compound **5** contained a ketone group according to the IR vibration at 1705 cm^{-1} and the downfield carbon signal at δ_C 214.8. After ^1H, ^{13}C, and DEPT NMR analyses, compound **5** was composed of two methyl groups instead of one methoxyl group. The COSY fragment of Me-13′/H-12′/Me-14′ along with the long rang $^1H-^{13}C$ associations of H-9′, H-10′, H-12′, Me-13′, and Me-14′ with C-11′ (δ_C 214.8) inferred an isopropyl group unit adjacent to a ketone group (C-11′). The configuration of **5** was determined from interpretation of NOESY and CD spectra. The *E* stereochemistry of two olefins at the side chain was assigned by the presence of the NOESY correlations of H-2′/Me-16′ and H-6′/Me-15′. The 2*R* configuration was determined by comparison of the CD spectrum with that of **1** and the literature.[31] Thus, compound **5** was identified as (6*E*,10*E*)-13-((*R*)-6-hydroxy-2,8-dimethylchroman-2-yl)-2,6,10-trimethyltrideca-6,10-dien-3-one, and the name litchtocotrienol E was given.

The HR-ESIMS spectrum of compound **6** exhibited a pseudo-molecular ion at *m/z* 465.2962 $[M + Na^+]$, consistent with a molecular formula of $C_{28}H_{42}O_4$ (8 degrees of unsaturation). The IR spectrum of **6** showed a similar absorbance to that of **5**, including functional groups of hydroxyl (3425 cm^{-1}) and ketone (1708 cm^{-1}), suggesting that **6** was an analogue of **5**. By comparing the NMR data, the methine H-5 on the benzene moiety in **5** was substituted by a methoxyl group (OMe-19′) in **6**, which was also confirmed by the HMBC correlation from OMe-19′ (δ_H 3.78) to C-5 (δ_C 142.3). The 2*R* configuration at the dihydropyran ring was corroborated by the CD measurement (278 nm, −1.19) and compared with that of **1**. Thus, the structure of litchtocotrienol F was unambiguously established.

Compound **7** possessed a molecular formula of $C_{28}H_{42}O_5$ with 8 units of unsaturation by deducing from the HR-ESIMS peak at *m/z* 481.2910 $[M + Na]^+$. The specific NMR peaks (six methyls and a *m*-cresol) revealed that **7** also possessed a chromanol ring moiety with a side chain containing three double bonds. Except the geranyl part, the quaternary carbon resonance at δ_C 214.1 and the IR absorption at 1699 cm^{-1} indicated that the third sp^2-hybridized carbon was a ketone functionality as compounds **5** and **6**. The protons of H-4, H-7, and Me-19′ corresponded with C-5 in the HMBC spectrum, suggesting a 5-methoxyl modification. Meanwhile, the HMBC correlations of both Me-13′ and Me-14′ with the oxygenated quaternary carbon C-12′ (δ_C 76.2) and that of H-9′, H-10′, Me-13′, and Me-14′ with carbonyl carbon C-11′ (δ_C 214.1) evidenced that the side chain ended in a 2-hydroxyl isobutanone. Finally, it gave the name litchtocotrienol G to compound **7**, a 12′-hydroxylated derivate of **2**.

Compound **8** was obtained as a colorless oil and had a molecular ion peak at *m/z* 451.2820 $[M + Na]^+$ (calcd for 451.2819) in HRESIMS, corresponding to the molecular formula $C_{27}H_{40}O_4$ and 8 degrees of unsaturation. The IR and ^1H and ^{13}C NMR spectra of **8** revealed that **8** should be a derivative of itchtocotrienol without ketone structure. Similarly, the gross structure of **8** was mainly established by the COSY correlations of H-3/H-4, H-1′/H-2′/H-3′, H-5′/H-6′/H-7′, and H-9′/H-10′/H-11′ connected by the HMBC correlations of the methyl protons at Me-16′ with C-3′ (δ_C 124.6), C-4′ (δ_C 137.1), and C-5′ (δ_C 38.4) and Me-15′ with C-7′ (δ_C 127.1), C-8′ (δ_C 133.9), and C-9′ (δ_C 34.1). Furthermore, the HMBC correlations of two terminal methyl protons (Me-13′and Me-14′) with C-11′ (δ_C 72.0) and C-12′ (δ_C 83.2) indicated the linear prenyl chain attached to a 2, 3-pentanediol group via C-11′. Thus far, seven degrees of unsaturation were applied; an extra ring was required for compound **8**. There are four possible ether arrangements for cycling through an oxygen bridge (C-5 or C-6 connected with C-11′ or C-12′) by considering of ^1H and ^{13}C NMR data. The absence of the proton−carbon correlations of H-11′ with C-5 or C-6 inferred that either the ring was formed via the linkage between C-5 and C-12′ or that between C-6 and C-12′. This problem was solved by the presence of the key NOESY correlation (Figure 2) of H-7/Me-14′ which only appeared in the ether linkage crossing C-6 and C-12′. Therefore, the planar structure of **8** was identified

DOI: 10.1021/jf5056387
J. Agric. Food Chem. 2015, 63, 2472−2478

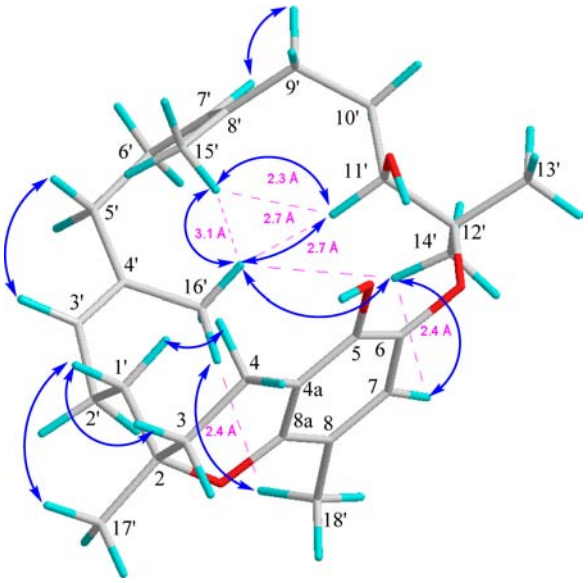

Figure 2. Selected NOESY correlations of **8**.

as the δ-tocotrienol skeleton and occupied an unusual oxacyclicnonadecane ring.

The configuration of **8** was determined mainly from the NOESY correlations and circular dichroism. The CD spectrum of **8** exhibited the negative Cotton effect at 282 ($\Delta\varepsilon$ −2.67) nm, indicating 2*R* chiral center.[23−27,31] Thus, it was assumed that Me-17′ of **8** favored the α orientation as those naturally occurring chromane derivatives and the prenyl chain was on the β face. The NOESY correlations of H-3′/H-5′and H-7′/H-9′ could assign the *E* geometry of the double bonds. Importantly, H-11′, Me-14′, Me-15′, and Me-18′ showed the dipolar couplings with Me-16′ (Figure 2), which had a quasi-equatorial orientation and was upfield shifted to δ_H 1.03 by anisotropic effects from the benzene ring, confirming the existence of this macrocyclic structure, and revealed the α orientation of H-11′. Thus, the whole structure of **8** was elucidated and named cyclolitchtocotrienol A.

Compound **9** had the molecular formula $C_{27}H_{40}O_3$ with 8 indices of unsaturation by measuring the HR-ESIMS. Analysis of ^{13}C NMR data showed 10 olefinic signals which revealed that compound **9** contained a tricyclic ring system. The ^1H NMR spectrum exhibited two characteristic methine signals at δ_H 6.39 (d, *J* = 2.8 Hz) and 6.48 (d, *J* = 2.8 Hz) coupled with the HMQC spectrum as well as the UV maximal absorption at 293 nm (log ε = 3.0), revealing the presence of a hydroquinone-type moiety.[32] The $^1H-^1H$ COSY spectrum of **9** showed four segments similar to that in **1** and with the aid of key correlations in the HMBC spectrum (H-4, H-5, and H-7/C-8a; Me-18′/C-7, C-8, and C-8a; Me-17′/C-1′, C-2, and C-3; H-4/C-2, C-4a, and C-5; Me-16′/C-3′, C-4′, and C-5′), illustrating the chromanol moiety attached with the first isoprene unit (C-1′∼C-5′) via C-2. However, the proton sequence III revealed H-5′/H-6′ connecting to an aliphatic proton H-7′ rather than to an olefinic one and H-10′/H-11′ corresponding to a sp^2 methine proton H-9′ not a sp^3 methylene, and the HMBC correlations of Me-15′/C-7′, C-8′, and C-9′ indicated that the last double bond was located at $\Delta^{8/9'}$ and suggested the presence of an additional ring at the prenyl portion. Incorporating with the long-range heteronuclear couplings of H-7′ with C-8′, C-9′, and C-11′ as well as of Me-13′ and Me-14′ with C-7′, C-11′ and C-12′ allowed the accomplishment of the rest of the structure containing the third ring, a trimethylcyclohexenol. Consequently, the planar structure of cyclolitchtocotrienol A was established as a new chromane meroditerpene.

The CD curve of **9** showing a negative Cotton effect at 267 nm proved the absolute 2*R* of **9**. The NOESY correlations of H-7′ and H-10′b/H-11′, H-11′/Me-13′ indicated that these protons were at the same β position. On the other hand, the NOESY cross-peak of H-10′a/Me-14′ showed the α orientation of H-10′a and Me-14′. Furthermore, the β orientation of both H-7′ and H-11′ was identified by the ^1H and ^{13}C NMR signal comparisons of **9** and camelliol C, which also contained a trimethylcyclohexenol portion.[33] On the basis of above interpretation, the configuration of **9** was unambiguously established as 2*R*, 7′*R**, and 11′*S**.

Human hepatocellular carcinoma (HepG2 2.2.15) and human gastric epithelial (AGS) cells were chosen to test the in vitro cytotoxicity of the isolated compounds. The results (Table 3) showed that compounds **1**−**8** exhibited minor cytotoxic activities against HepG2 2.2.15 and AGS cells line.

Table 3. Cytotoxicity of 1−8 on Tumor Cell Lines, IC_{50} (μM)

compound	HepG2	AGS	compound	HepG2	AGS
1	11.11	10.91	**6**	12.30	49.24
2	14.18	32.02	**7**	34.13	43.24
3	22.66	24.20	**8**	16.52	NT[a]
4	NT[a]	26.76	5-fluorouracil[b]	62.9	
5	10.71	27.36	doxorubicin[b]		11.0

[a]Not tested. [b]Used as positive control.

As for the bioassay of anti-HepG2 2.2.15 cells, litchtocotrienol C (C-12′ methylated form of **1**) was 2 times less potent than that of **1**, but litchtocotrienol B (5-methoxylated form of **1**) possessed slightly weaker anti-HepG2 activity than **1**. A similar situation was observed between compounds **5** with **7** and between **5** with **6**. The above findings suggested that the functional groups at position C-12′ rather than at the chromanol ring moiety were important for the cytotoxicity against HepG2 cells of δ-tocotrienol-type compounds. As for the bioassay of anti-AGS cells, litchtocotrienols B and C were about 3 and 2 times less potent than that of **1**, respectively. In addition, compounds **6** and **7** (5-methoxylated form of **5**) were both 2 times less potent than that of **5**. These results suggested that the functional groups at position C-5 of δ-tocotrienol-type compounds were important for anti-AGS cell activities.

whole broth of A. camphorata are not well-defined in high-fat diet (HFD)-induced diabetic mice.

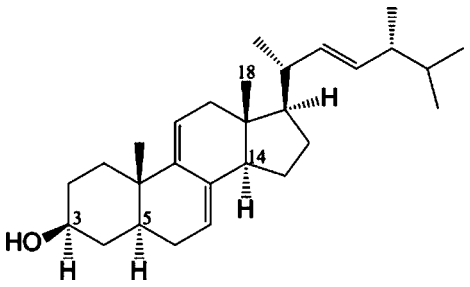

Figure 1. Structure of ergostatrien-3β-ol (EK100).

Glucose transporter 4 (GLUT4) is a key regulator of whole-body glucose homeostasis.[8] Both insulin and exercise induce a translocation of glucose transporter GLUT4 from intracellular storage compartments toward the plasma membrane in adipocytes and skeletal muscle cells, allowing the cell to take up glucose.[8,9] Impairment of GLUT4 expressions, GLUT4 translocation, and/or insulin signaling may affect insulin-stimulated glucose uptake, which would result in insulin resistance and hyperglycemia.[10] Thus, therapeutic strategies based on enhancing GLUT4 expressions may facilitate drug discovery.

AMP-activated protein kinase (AMPK) is a key regulator of glucose and lipid metabolism. Because glucose and lipid metabolism is dysregulated in type 2 diabetes mellitius,[11] AMPK modulators have been proposed to be promising therapies. Metformin is also known to activate AMPK and stimulate human skeletal muscle, promote GLUT4 membrane translocation, and stimulate insulin-independent glucose uptake.[12]

Thiazolidinediones (TZDs) such as rosiglitazone are antidiabetic peroxisome proliferator-activated receptor (PPAR) γ agonists. PPARγ activator like TZDs decrease blood glucose levels.[13] Rosiglitazone does not stimulate insulin secretion. Rosiglitazone was approved for glycemic control in people with type 2 diabetes. Rosiglitazone directly targets insulin resistance and increases peripheral glucose uptake, thus improving glycemic control. The modes of action of rosiglitazone mainly contributed to the insulin-sensitizing effect and GLUT4 levels.[14]

Fenofibrate is an activator of PPARα[15] and has been used for the management of hypertriglyceridemia for many years.[16] PPARα is a key regulator of genes associated with lipid metabolism, which results in a decrease in circulating triglycerides and fatty acids via modulation of many target genes involved in lipogenesis, fatty acid oxidation, and energy expenditure.[17]

The model of C57BL/6J mouse that was fed a high fat-diet (HFD) is a robust and efficient model for early type 2 diabetes.[18] The C57BL/6J mouse is susceptible not only to HFD-induced marked increases in adipose tissue mass but also to pronounced insulin resistance, hyperlipidemia, hyperinsulinemia, hypertriglycemia, and hypercholesterolemia.[19] Metformin is a widely used antidiabetic agent in the treatment of type 2 diabetes mellitius.[11] Metformin activates AMPK in both hepatocyte and skeletal muscle.[11,20] Nevertheless, metformin causes few adverse effects, including lactic acidosis, and this drug is regarded as a potential treatment for type 1 and type 2 diabetes. TZDs not only activate AMPK through a signal pathway that is different from metformin but also further activate AMPK.[21] This influence in plasma adipocytokine concentration is associated with a decrease in accumulation in the liver and improvement in insulin resistance.[21] Thus, Rosi was chosen as a positive control for comparison with the antidiabetic effects of EK100. Phosphorylation of Thr 172 of α subunits is essential for AMPK activity.[22] Therefore, HFD-fed mouse models are chosen to address the effect and mode of action of EK100 on AMPK activity and GLUT4 content, and to compare with Rosi and Feno. As a possible molecular mechanism of EK100, the target gene expressions involved in antidiabetes and antihyperlipidemia in peripheral tissues were also investigated.

MATERIALS AND METHODS

Chemicals. A hemoglobin A_{1c} kit was obtained from BioSystems S.A. (Barcelona, Costa Brava, Spain). GLUT4, structural proteins GAPDH and β-actin were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA); phospho-AMPK was obtained from Abcam Inc. (Cambridge, MA, USA); phospho-Akt, total AMPK, and total Akt were from Cell Signaling Technology, Inc. (Danver MA, USA); the BCA protein assay kit was from Thermo Scientific (Rockford, IL, USA); and the ECL reagent kit was from GE Healthcare BioSciences (Buckinghamshire, UK). Secondary antibody antirabbit was from Jackson ImmunoResearch Laboratories, Inc. (West Grove, PA, USA).

Fungus Material. The freeze-dried powder of *A. camphorata* submerged whole broth was provided by the Biotechnology Center of Grape King Inc., Chung-Li City, Taiwan.

Isolation and Determination of the Active Compound. The freeze-dried powder of *A. camphorata* of the submerged whole broth (1.6 kg) was extracted three times with methanol (16 L) at room temperature (1 day each). The methanol extract was evaporated *in vacuo* to obtain a brown residue, which was suspended in H_2O (1 L) and then partitioned (three times) with 1 L of ethyl acetate. The EtOAc fraction (95 g) was chromatographed on silica gel and eluted with mixtures of hexane and EtOAc to increase polarity and further purified with high performance liquid chromatography (HPLC). EK100 (5.4 g) was eluted with 10% EtOAc in hexane, and recrystallization with EtOH.[23]

Experimental Animals. The experiments were conducted under the guidelines of the Institutional Animal Care and Use Committee of Central Taiwan University of Science and Technology. As previously described,[24−26] four-week-old male C57BL/6J mice (n = 63) was purchased from the National Laboratory Animal Breeding and Research Center, Ministry of Science and Technology. After 1-week of acclimatization, mice were designed to initiate the study, and the study lasted for 12 weeks. First, mice were divided randomly into two groups (the control (CON) group (n = 9), which received a low-fat diet (Diet 12450B, Research Diets, Inc., New Brunswick, NJ, USA), and the high-fat diet (HFD)-fed group (n = 54), which was fed a 45% high-fat diet (Diet 12451, Research Diets, Inc.)). After 8 weeks of diet induction, HFD-treated mice were further randomly subdivided into six groups (n = 9 per group), receiving EK100 (10, 20, 40 mg/kg/day body wt) or fenofibrate (Feno; purchased from Sigma Chemical Co, St Louis, and administrated at a dose of 250 mg/kg/day body wt) or rosiglitazone (Rosi; 1% methylcellulose 10 mg/kg body weight, obtained from GlaxoSmithKline Product No: BRL49653 C) or vehicle by oral gavages one time per day for another 4 weeks and still on high-fat diet. The CON group and high-fat control (HF) group were given with vehicle only. The low-fat diet consisted of fat 10%, whereas the high-fat diet (HFD) consisted of fat 45% (of total energy, % kcal). The compositions of the experimental diets are shown as described.[24] At the end of the study, food was deprived from the animals (from 10 p.m. to 10 a.m.). On the next day, the mice were sacrificed, and blood and tissue were collected for analysis. Livers, skeletal muscles, and white adipose tissues (WATs) (including epididymal, mesenteric and retroperitoneal WAT) were excised and weighed, and then

immediately stored in a freezer at −80 °C. Heparin (30 units/mL) (Sigma) was added to blood samples. Plasma samples were collected by centrifugation at 1600*g* for 15 min at 4 °C within 30 min, and plasma was obtained for insulin and leptin level analysis.

Body Weight, Body Weight Gain, and Food Intake Analysis. Throughout the study, body weight and food intake were daily recorded at the same time. Body weight gain is defined as the difference between 1 day and the next day. The pellet food was weighed and placed in a cage food container. After 24 h, the remaining food was weighed and the crumbs were collected as much as possible. Based on the difference between 1 day and the next day, the daily food intake was calculated.

Blood Glucose and Glycated Hemoglobin (HbA1c) Levels and Biochemical Analysis. Blood samples (0.8 mL) were collected from the retro-orbital sinuses of fasting mice, and glucose level was measured by the glucose oxidase method (model 1500; Sidekick Glucose Analyzer; YSI Inc., Yellow Springs, OH, USA). Percent HbA_{1c} was detected with a Hemoglobin A_{1c} kit (BioSystems S.A., Barcelona, Spain). Plasma triglycerides (TG), total cholesterol (TC), free fatty acids (FFA), high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C) were determined using commercial assay kits (Triglycerides-E test, Cholesterol-E test, and FFA-C test, Wako Pure Chemical, Osaka, Japan; HDL-C-test and LDL-C-test, Roche Diagnostics GmbH, Indianapolis, USA) according to their instructions. A mouse insulin ELISA kit (Sibayagi, Gunma, Japan) and mouse leptin ELISA kit (Morinaga, Yokohama, Japan) were used to measure blood insulin and leptin levels, respectively.

Histopathological Examination. A portion of the collected epididymal WAT and liver tissue was fixed with formalin (200 g/kg) neutral buffered solution and embedded in paraffin. Sections (8 μm) were cut and stained with hematoxylin and eosin. A microscope (Leica, DM2500) and Leica Digital camera (DFC-425-C) were used for microscopic examination and images taken, respectively.

Hepatic Lipids Measurements. Hepatic lipids were extracted as previously described.[25] Liver sample (0.375 g) was homogenized with 1 mL of distilled water for 5 min for the hepatic lipid extraction and analyzed using a triglycerides kit as used for serum lipids.

Relative Quantization of mRNA Indicating Gene Expression Analysis. The experiment was performed as in a previously described protocol.[24−27] Total RNA from the liver tissue was isolated with a Trizol reagent (Molecular Research Center, Inc., Cincinnati, OH, USA) according to the manufacturer's directions. Total RNA (1 μg) was reverse transcribed to cDNA with 5 μL of Moloney murine leukemia virus reverse transcriptase (Epicenter, Madison, WI, USA) as a previously described protocol.[24−27] The polymerase chain reaction (PCR) was performed in a final 25 μL containing 1 U Blend Taq-Plus (TOYOBO, Japan), 1 μL of the RT first-strand cDNA product, 10 μM of each forward (F) and reverse (R) primer, 75 mM Tris-HCl (pH 8.3) containing 1 mg/L Tween 20, 2.5 mM dNTP, and 2 mM $MgCl_2$. The primers are shown in Table 1. The products were run on 2% agarose gels and stained with ethidium bromide. The relative density of the band was evaluated using AlphaDigiDoc 1201 software (Alpha Innotech Co., San Leandro, CA, USA). All of the measured PCR products were normalized to the amount of cDNA of GAPDH in each sample.

Western Blotting Analysis. Protein extractions and immunoblots for the determination of GLUT4, phospho-AMPK (Thr172), and phospho-Akt (Ser 473) proteins were carried out on frozen skeletal muscle and liver tissue from mice, which follows a previous paper.[25−27] Additionally, GLUT4 was carried out on frozen skeletal muscle from mice, and the total membrane fractions were collected with buffer and centrifuged as a previously described.[28−30] The protein contents of GLUT4, phospho-AMPK, phospho-Akt, total AMPK, and total Akt were detected by blotting. Western blotting had been determined as described elsewhere.[25−28] Subsequently, antibodys were detected using horseradish peroxidase linked to a goat anti-IgG rabbit secondary

antibody and visualized using an ECL system. The density blotting was analyzed using Alpha Easy FC software (Alpha Innotech Corp., Randburg, South Africa). Structural proteins GAPDH and β-actin were obtained by stripping the nitrocellulose membrane proteins of liver and skeletal muscle, respectively.

Statistical Analysis. All results were presented as mean and standard error. Whenever possible, data were subjected to analysis of variance, followed by Dunnett's multiple range tests, using SPSS software (SPSS Inc., Chicago, IL, USA). P < 0.05 was considered to be statistically significant.

RESULTS

Body Weight, Food Intake, and Tissue Weight. All group mice begin with similar mean body weights (18.9 ± 0.2 g). Mice on HFD for 12 weeks displayed significantly greater increases in body weight and body weight gain compared to CON littermates (Figure 2A and Table 2). Administration of K3 and Feno displayed resistance to bodyweight gain. HF mice consume high-fat diets much less than CON littermates (Figure 2B). All the EK100-, Feno- and Rosi-treated mice and HF mice consume high-fat diets similarly. Feeding a HFD displayed a

J. Agric. Food Chem. 2015, 63, 2479−2489

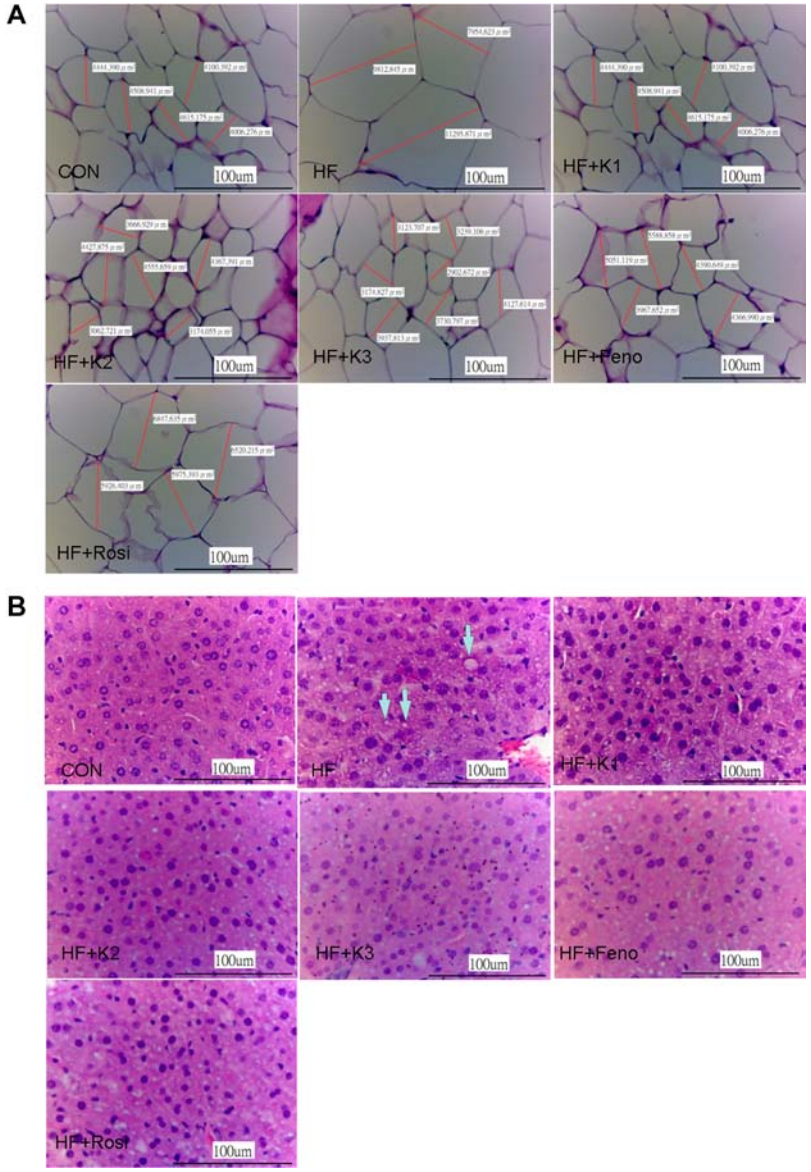

Figure 3. Effects of ergostatrien-3β-ol (EK100) on (A) epididymal WAT and (B) liver tissue morphology in the low-fat (CON), high-fat (HF), HF + K1, HF + K2, HF + K3, or HF + Feno, or HF + Rosi groups. Pictures of hematoxylin and eosin-stained sections of (A) epididymal adipocytes (Magnification: 10 (ocular) × 20 (object lens)) from mice fed with EK100. The appearance of adipocyte is polyhedral and displayed the string-like cytosol surrounded by a vacuole (H&E stain); and (B) liver tissue (Magnification: 10 (ocular) × 20 (object lens)) from mice fed with EK100. The high-fat diet induced the hepatic ballooning degeneration in the HF group as compared with the CON group. The ballooning degeneration is a form of liver parenchymal cell death, and the nucleolus was squeezed into the other side of the named balloon (as the arrow indicates). Each presented image is typical and representative of nine mice. Ergostatrien-3β-ol (EK100): K1:10, K2:20, K3:40 mg/kg body wt; Feno: fenofibrate (250 mg/kg body wt); Rosi: rosiglitazone (10 mg/kg body wt).

marked increase in weights of absolute adipose tissues (epididymal, visceral fat, mesenteric and retroperitoneal WAT) (Table 2 and Figure 2C). The K1-, K2-, K3-, Feno-, and Rosi-treated mice displayed a decrease in weights of retroperitoneal WAT and visceral fat. The K1-, K2-, K3-, and Rosi-treated mice reduced weights of epididymal WAT. The K3- and Rosi-treated mice display less mesenteric WAT weights. The brown adipose tissue (BAT) mass was decreased in K2-, K3- and Feno-treated mice. The K2- and K3-treated mice showed an increase in skeletal muscle mass. Feno-treated mice showed a marked increase in liver weight (Table 2).

Blood Glucose and HbA1c Levels. After 8 weeks on HFD, HF mice displayed the hyperglycemia evidence compared with the CON mice ($P < 0.001$). Administration of K1, K2, K3, Feno, and Rosi significantly reduced blood glucose levels ($P < 0.001$, $P < 0.001$, $P < 0.001$, $P < 0.001$, $P < 0.001$, respectively) (Figure 2D). The percent of hemoglobin was evaluated nonenzymatically (percent HbA1c) as an integrated measure of long-term blood glucose regulation. Blood levels of HbA1c were significantly greater in the HF group than in the CON group. Treatment with K1, K2, K3, Feno, and Rosi decreased HbA1c levels in blood (Table 2).

Blood Lipid and Hepatic Lipid. HFD caused increases in blood total cholesterol (TC), triglyceride (TG), and free fatty acid (FFA) (Figure 2E and F and Table 2). The K1-, K2-, K3-, and Rosi-treated mice lowered TC levels ($P < 0.05$, $P < 0.01$, $P < 0.001$, $P < 0.05$, respectively). The K1-, K2-, K3-, Feno-, and Rosi-treated mice decreased TG level. The K1-, K2-, K3-,

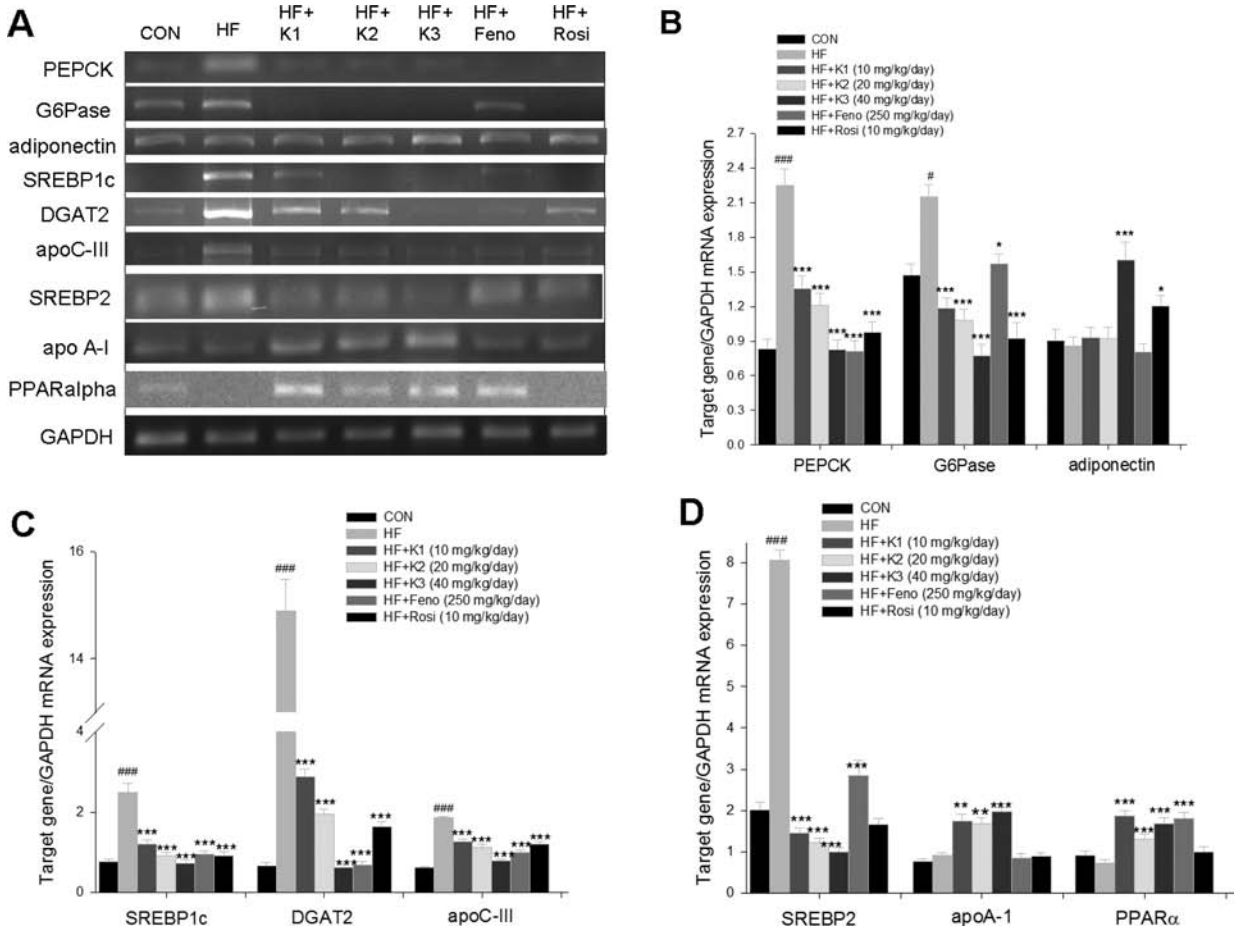

Figure 4. Semiquantitative RT-PCR analysis on PEPCK, G6 Pase, adiponectin, SREBP1c, DGAT2, apo C-III, SREBP2, apo A-I, and PPARα mRNA expression in liver tissue of the mice receiving ergostatrien-3β-ol (EK100) by oral gavage for 4 weeks. All values are means ± SE (n = 9). $^{\#}$ $P < 0.05$ and $^{\#\#\#}$ $P < 0.001$ compared with the control (CON) group; * $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$ compared with the high-fat plus vehicle (HF) group. Ergostatrien-3β-ol (EK100): K1:10, K2:20, K3:40 mg/kg body wt; Feno: fenofibrate (250 mg/kg body wt); Rosi: rosiglitazone (10 mg/kg body wt). Total RNA (1 μg) isolated from tissue was reverse transcripted by MMLV-RT, 10 μL of RT products were used as templates for PCR. Signals were quantitated by image analysis; each value was normalized by GAPDH.

Feno-, and Rosi-treated mice showed decreased FFA concentrations. The K1-, K2-, K3-, and Feno-treated mice increased high-density lipoprotein cholesterol (HDL-C) levels (Table 2). The K3- and Rosi-treated mice displayed a decrease in low-density lipoprotein cholesterol (LDL-C) level. HFD caused increases in the total lipids of liver and concentrations of triacylglycerol, while treatment with K1, K2, K3, Rosi, and Feno displayed marked decreases in these phenomena (Table 2).

Blood Leptin and Insulin Levels. Blood leptin and insulin levels were greater in the HF group than in the CON group (Figure 2G and H). The K1-, K2-, K3-, Feno-, and Rosi-treated mice displayed a decrease in blood leptin and insulin levels.

Histopathology Examination. Feeding a HFD induced hypertrophy of adipocytes (the average areas of adipocytes in the HF group and CON group are 9604.2 ± 281.3 and 3797.5 ± 412.9 μm^2, respectively), whereas mice treated with K1 (4204.0 ± 131.5 μm^2), K2 (3535.7 ± 340.2 μm^2), K3 (3458.9 ± 30.7 μm^2), and Feno (4175.4 ± 322.9 μm^2) showed significantly lower hypertrophy. The average area of the Rosi-treated mice is 5598.6 ± 162.7 μm^2 (Figure 3A). Feeding a HFD induced ballooning degeneration of hepatocyte. Administration of K1, K2, K3, Feno, and Rosi decreased the ballooning degeneration (Figure 3B).

Targeted Gene mRNA Expressions in Liver Tissue. The HFD induced higher expression levels of phosphoenol pyruvate carboxykinase (PEPCK), glucose-6-phosphatase (G6 Pase), sterol regulatory element binding protein 1c (SREBP1c), acyl-coenzyme A: diacylglycerol acyltransferase 2 (DGAT2), apolipoprotein C-III (apo C-III), and SREBP2 in the HF group than in the CON group. Administration of K1, K2, K3, Feno, and Rosi showed a decreased mRNA level of PEPCK, G6 Pase, SREBP1c, DGAT2, apo C-III, and SREBP2. K3- and Rosi-treated mice increased the mRNA level of adiponectin. The K1-, K2-, and K3-treated mice show increased mRNA levels of apolipoprotein A-I (apo A-I). Administration of K1, K2, K3, and Feno increased the mRNA level of PPARα (Figure 4).

Western Blotting of GLUT4, phospho-Akt (Ser 473)/ total Akt, and Phospho- AMPK (Thr172) Proteins. The levels of GLUT4 and phospho-Akt/total Akt were lower in HF mice than in CON mice. K1-, K2-, K3-, Feno-, and Rosi-treated mice show increased muscular GLUT4 protein contents ($P < 0.01$, $P < 0.01$, $P < 0.001$, $P < 0.05$, $P < 0.001$, respectively). Administration of K1, K2, K3, and Rosi displayed higher levels of phospho-Akt/total Akt than in HF mice. The mice on HFD showed decreased phospho-AMPK in liver tissue and skeletal muscle. The protein contents of phospho-AMPK were

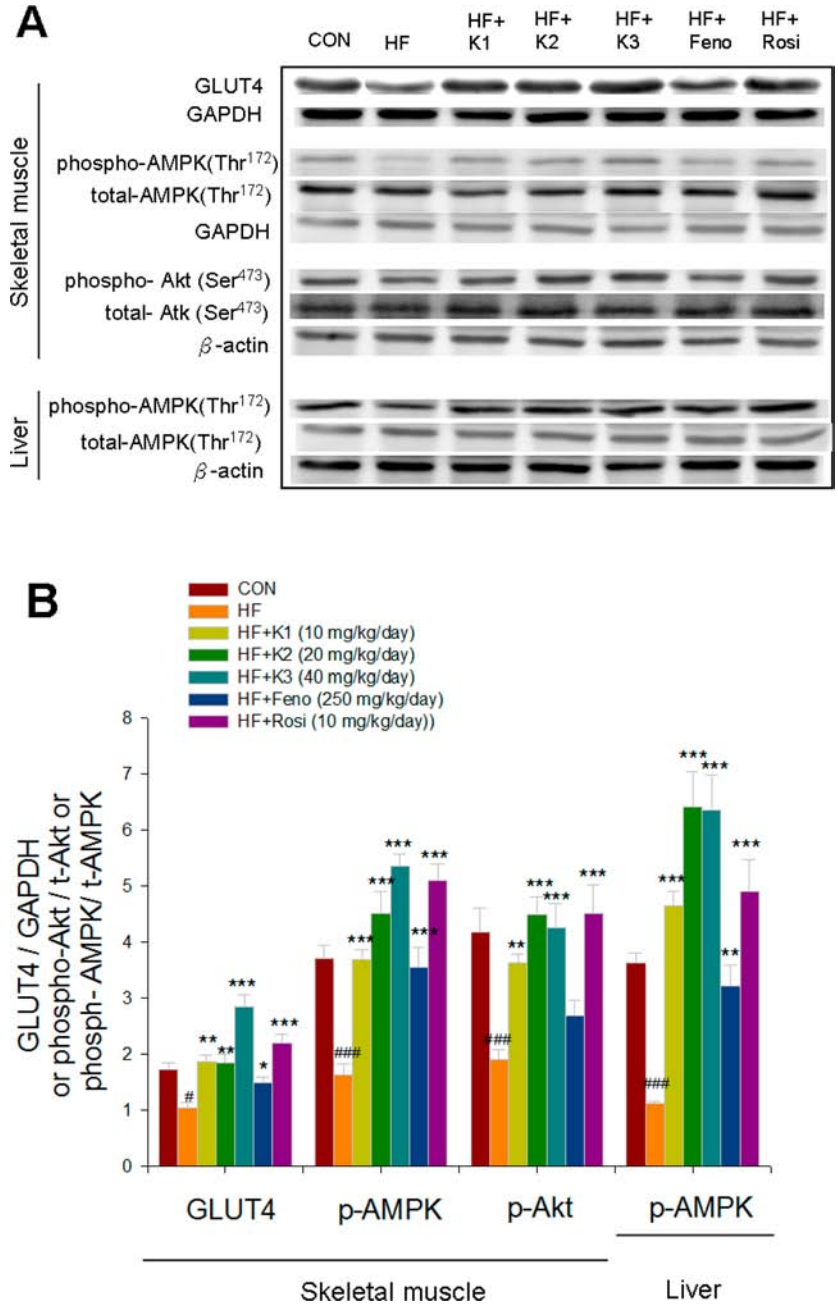

Figure 5. Protein contents of GLUT4, phospho-AMPK (Thr172)/total AMPK, and phospho-Akt/total Akt in skeletal muscle and phospho-AMPK (Thr172)/total AMPK in liver tissue of the mice receiving ergostatrien-3β-ol (EK100) by oral gavage for 4 weeks. Protein was separated by 12% SDS-PAGE detected by Western blot. All values are means ± SE (n = 9). $^{\#}$ $P < 0.05$ and $^{\#\#\#}$ $P < 0.001$ compared with the control (CON) group; * $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$ compared with the high-fat plus vehicle (HF) group. Ergostatrien-3β-ol: K1:10, K2:20, K3:40 mg/kg body wt; Feno: fenofibrate (250 mg/kg body wt); Rosi: rosiglitazone (10 mg/kg body wt).

significantly increased in the K1-, K2-, K3-, Feno-, and Rosi-treated groups in liver tissue ($P < 0.001$, $P < 0.001$, $P < 0.001$, $P < 0.01$, $P < 0.001$, respectively) and in skeletal muscle ($P < 0.001$, $P < 0.001$, $P < 0.001$, $P < 0.001$, $P < 0.001$, respectively) (Figure 5).

DISCUSSION

The present study demonstrated that EK100-treated mice displayed effectively lower blood glucose and circulating triglyceride levels. In this study, high-fat feeding induces hyperglycemia and hyperinsulinemia. EK100 treatment significantly decreased blood glucose levels and makes mice resistant to HFD-induced hyperinsulinemia, suggesting EK100 displayed increased insulin sensitivity or efficiency. In the present study, Rosi and Feno caused reduced blood glucose level, consistent with earlier observations.[13,29] Moreover, the level of blood glycosylated HbA1c, which is a maker of long-term control of blood glucose, is also significantly decreased. On the other hand, HFD caused an increase in circulating triglyceride and total cholesterol levels, which were consistent with earlier studies,[19] while they were significantly lowered in EK100-treated mice. These data reinforce that EK100 is effective to improve insulin resistance and dyslipidemia in a mouse model of Type 2 diabetes and dyslipidemia. The

J. Agric. Food Chem. 2015, 63, 2479−2489

physiological relevance of these findings is supported by the increased skeletal muscular GLUT4 contents and activation of AMPK in both skeletal muscle and liver tissue.

To ascertain whether EK100 regulates glucose utilization, we evaluated the membrane protein contents of GLUT4 in skeletal muscle because glucose uptake is primarily mediated by skeletal muscle. Levels of GLUT4 movement to the plasma membrane were assessed, as it is an essential step for insulin-responsive glucose in skeletal muscle that becomes defective in insulin resistance.[8] All EK100-treated mice display an enhancement of muscular GLUT4 protein; moreover, EK100 (K3) and Rosi treatment displayed approximately 2.7-fold and 2.1-fold enhancement, respectively, implying that EK100 treated mice are indeed hypersensitive to insulin and exhibit antidiabetic activity. Rosi has been shown to act as an insulin sensitizer.

The apparent insulin sensitivity of EK100-treated mice prompted our interest in EK100 regulation of GLUT4 and Akt. There are two principal mechanisms involved in promoting tranlocation of GLUT4 to the plasma membrane, including insulin signaling through the phosphatidylinositol 3′ kinase (PI3-kinase)/Akt pathway and the AMPK pathway.[8] Previous findings showed that a mutation in the gene encoding Akt2/PK Bβ resulted in severe insulin resistance,[30] establishing Akt2/PK Bβ as a key protein in the maintenance of euglycemia. To explore the mechanism of enhanced GLUT4 proteins by EK100, we measured phosphorylation of Akt levels in skeletal muscle. We observed that EK100 manifested elevated phosphorylation of Akt levels in skeletal muscle, implying that the enhanced GLUT4 proteins by EK100 appear to be in part mediated by the insulin signaling pathway through increased phosphorylation of Akt.

The phosphorylation of the AMPK pathway is another major regulator of GLUT4 translocation during exercise or in response to some antidiabetic agents such as AICAR and metformin.[8] In this study, we found that EK100-treated mice manifest elevated phosphorylation of AMPK levels in both skeletal muscle and liver tissue. Metformin is used for the treatment of type 2 diabetes due to increased skeletal muscular glucose uptake and reduced hepatic glucose production.[11,20] The present results demonstrated that EK100-treated mice were protected from HFD-induced hyperglycemia by AMPK activities and GLUT4 proteins. Whether skeletal muscular activation of AMPK by EK100 is responsible for overall GLUT4 regulation, the potential mechanisms require further investigation of the phosphorylation of AS160.

PEPCK and G6 Pase are key rate-limiting enzymes of gluconeogenesis.[31] The liver of diabetic rats showed a significant increase in the activities of G6 Pase.[31] Over-expression of PEPCK enzyme in mice results in symptoms of type 2 diabetes. The published research further showed that activation of AMPK in turn inhibited the expression of the hepatic gluconeogenic genes PEPCK and G6 Pase.[32] Activation of AMPK has been implicated in metformin action in hepatocytes.[11] Metformin decreases hyperglycemia primarily by suppressing glucose production by the liver (hepatic gluconeogenesis).[20] EK100-treated mice elicited decreased expressions of PEPCK and G6 Pase. Thus, the antidiabetic effect of EK100 is possibly partly due to down-regulation of PEPCK and G6 Pase. Collectively, this study demonstrated that EK100 caused glucose lowering by AMPK activation in both liver tissue and skeletal muscle, besides its ability to increase glucose uptake in skeletal muscle, possibly by down-regulations of PEPCK to inhibit hepatic glucose production.

Our second goal was to determine the molecular mechanism of EK100-mediated hypolipidemic effects. Fenofibrate, a PPARα agonist, has been recommended to reduce circulating triglycerides.[17] In this study, Feno displayed a decrease of the circulating TG level by 47.9%, while Rosi decreased the circulating TG level less. EK100 showed a moderate reduction in levels of TG. PPARα agonist is known to down-regulate numerous genes involved in lipid synthesis. PPARα ligands (such as fibrates) reduce the expression of apo C-III gene,[33] thus resulting in a hypotriglyceridemic effect. PPARα has been shown to regulate lipid metabolism and fatty acid oxidation. SREBP-1c plays a key role in the activation of lipogenic enzyme expression, fatty acid synthesis and triglyceride accumulation,[34] and it plays the role of PPARα in SREBP- mediated regulation of lipogenic genes.[35] In this study, EK100-treated mice displayed an increase in expressions of PPARα but a reduction in SREBP1c and DGAT2 mRNA. DGAT2 is known to catalyze the final step in the synthesis of triglycerides.[36] Therefore, the down-regulation of DGAT2 seems to be responsible for the hepatic triglyceride output, thus resulting in a decrease in blood TG. These findings further confirmed that EK100 displayed hypolipidemic activity partly via regulation of genes associated with fatty acid oxidation and lipogenesis.

K3-treated mice showed reduced body weight, which primarily reflects decreased fat accumulation with reduced weight of epididymal adipose tissue (EWAT) as well as decreased weight of visceral fat. Although their body weight was lower, K3-treated mice show increased skeletal muscle mass. These findings were consistent with an earlier report,[37] which revealed that increased Akt signaling resulted in muscle hypertrophy, increased insulin sensitivity, and resistance to HFD-induced weight gain. Akt activation is a common feature of the diverse model of increased insulin sensitivity. Both reduced obesity and increased Akt signaling may elicit the improved insulin sensitivity of the K3-treated mice.

Histology investigation has revealed that EK100 treatment lowered the area of adipocytes. Because circulating TG level is fluctuating and liver is the major organ responsible for metabolizing fat, presumably EK100 reflected the movement of fat from adipose tissue to liver by increasing hepatic lipid metabolism, which led to reduced adipocyte size and nearly invisible liver lipid droplets.

It was observed that EK100 decreased blood TC and TG levels while it increased HDL-C concentrations. Moreover, only K3-treated mice displayed a decrease in LDL-C levels. PPARα agonists are known to reduce LDL-C and increase HDL-C. In this study, Feno-treated mice reduced adiposity[17] and displayed no changes in total cholesterol (TC) and LDL-C levels, but increased HDL-C concentrations, consistent with an earlier study.[38] The difference between EK100 and Feno is that EK100-treated mice show significantly decreased TC levels whereas Feno-treated mice display unchanged levels in this manifest hypercholesterolemia animal model.

An additional mechanism that plays a role in the hypolipidemic effect was also examined. In this study, EK100-treated mice displayed reduced blood TC levels and decreased SREBP2 expression, since SREBP2 plays a major role in the regulation of cholesterol synthesis,[39] implying that the potential mechanism of EK100 was involved in SREPB2 on the inhibitory action of cholesterol synthesis. PPARα ligands are used widely to lower serum TG and to increase HDL-C in patients with obesity and dyslipidemia.[40] In this study, EK100 enhanced both HDL-C levels and apo A-I expression. HDL-C

DOI: 10.1021/acs.jafc.5b00073
J. Agric. Food Chem. 2015, 63, 2479−2489

is positively associated with a decreased risk of coronary heart disease (CHD). Since apo A-I has been reported to be synthesized by liver cells[41] and the major apolipoproteins of HDL-C are apo A-I and apo A-II,[42] the observed increase in HDL-C level by EK100 was presumably mediated by enhanced hepatic apo A-I production. These data are important because they suggest that EK100 treatment resulted in elevated HDL-C concentration, a known physiological consequence that may be useful in cardiovascular events.

In conclusion, EK100 exhibited not only lowered blood glucose levels accompanied by decreased HbA1c and ameliorated insulin resistance but also diminished blood TC and TG levels. EK100 exerted significantly increased GLUT4 protein in skeletal muscle, which enhanced glucose uptake; moreover, EK100 increased phosphorylation of AMPK in liver and reduced PEPCK and G6 Pase expressions, which decreased hepatic glucose production, leading to exertion of an antihyperglycemic effect. On the other hand, EK100 enhanced hepatic expressions of PPARα (fatty acid oxidation) and reduced SREBP1c (lipogenesis), thus resulting in lowering circulating TG levels. Moreover, EK100 reduced hepatic expressions of SREBP2 while it enhanced apo A-I and thus contributed to a decrease in blood TC and a rise in the plasma HDL-C level. Our results reinforce that EK100 will have therapeutic potential in treating type 2 diabetes associated with hyperlipidemia.

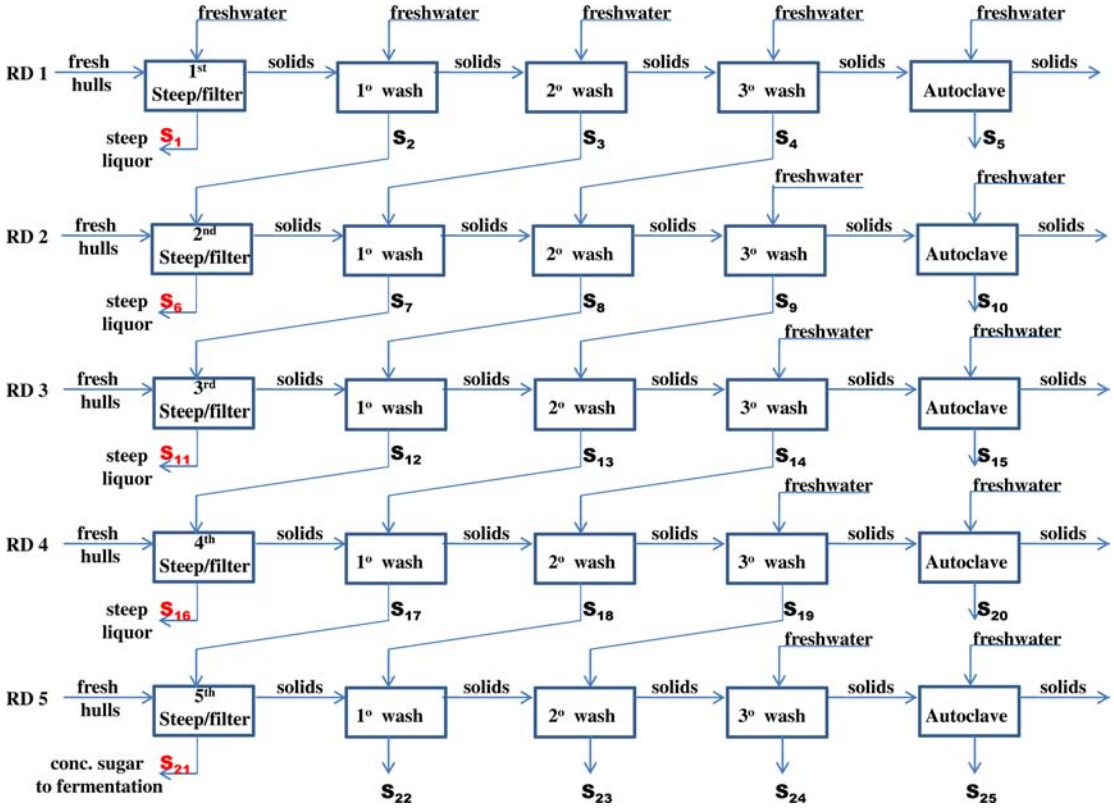

Figure 1. Laboratory extraction scheme utilized to mimic countercurrent extraction.

Quantitative Sugar Extraction. Sugar quantification was achieved by modification of the method of Sequeira and Lew[2] by using three successive blender extractions (Ninja NJ600 Professional Blender) each time using fresh, hot tap water (50 °C) and 1 min of blending time at 5% solids. Liquid/solids separation was accomplished using Whatman no. 4 filter paper in a pressurized air filter (OFI Testing Equipment, model 140-31) operated just above atmospheric pressure to force as much liquor out of the hulls as possible yet not create channeling. The final extraction via autoclave (L30 cycle) ensured that all sugars were quantified and on average released about 5% of additional free sugars.

The sugars and sugar alcohols were then analyzed by HPLC (Agilent 1200 series) equipped with a binary pump, an HPX-87P (Bio-Rad) column, and an RI detector. Mobile phase was water, flow rate was 0.5 mL/min, the column compartment was heated to 85 °C to enhance separation, and the RI detector was operated at its maximum of 55 °C. External calibration was used to quantify the free sugars and sugar alcohols (glucose, sucrose, fructose, xylose, inositol, and sorbitol). Each analysis was performed in triplicate.

Analysis of Filter Cake. The spent almond hulls (insoluble material after extraction) were dried and subjected in triplicate to standard analysis for quantification of the cell wall carbohydrate polymer composition by Wiley milling to pass a 40-mesh screen followed by dissolution of the polymeric materials in 3% H_2SO_4.[16] The insoluble residue after acid hydrolysis was measured gravimetrically and fired in the muffle furnace at 550 °C for 6 h to quantify acid-insoluble ash and organic matter. A 1 mL aliquot of the liquid fraction was neutralized with $CaCO_3$ and centrifuged to remove insoluble salts, and the resulting neutral solution was analyzed by HPLC. The system and operating conditions were identical to those described above for free fermentable sugars, but the external calibration standard set consisted of cell wall sugar residues (glucose, xylose, galactose, arabinose, mannose).

Optimizing Solids Content, Water Recovery, and Pectinase Application Experiments. Solids content was varied from 5 to 20% with incubation for either 1 h or overnight time periods. The almond hulls were diluted with 50 °C tap water to the specified solids content in the blender and milled for 1 min to reduce particle size and initiate swelling. After transfer to an Erlenmeyer flask, the hulls suspension was incubated according to the desired time period at 50 °C in an orbital incubator shaker (Amerex Instruments, Inc., model SK-747R) at 150 rpm. At the end of the incubation period, filtration was performed using the pressure filter, and the resulting filtrate was weighed for water recovery and sampled for analysis of sugar content by HPLC.

For the pectinase application experiments two approaches were taken. First, the almond hulls were milled at 20% solids content for 1 min followed by the addition of pectinase from *Aspergillus aculeatus* (Pectinex, Sigma-Aldrich). The pectinase content was varied from 0 to 0.75% (w/v), the mixture was incubated with orbital shaking (150 rpm) for 1 h, and then the filtration/analysis as described above was performed to obtain the experimental results. Second, the identical procedure of milling was performed, and then the pectinase (0.5% w/v) was added and the incubation time varied from 0 to 60 min. Again, experimental workup was identical to previous analyses.

Countercurrent Extraction. Figure 1 depicts the concept of countercurrent extraction in which the solvent (water) and the solid matrix (almond hulls) contact each other in opposite flow directions. In this case, a 1 h steep followed by filtration and then three rapid extraction (wash) stages recovered the bulk of the free sugars. Fresh water was introduced in the final extraction (third wash stage), and the third filtrate from the final stage was cascaded forward to serve as wash water for the prior (second) wash stage. The wash water cascaded forward becomes progressively higher in sugar concentration as the solid phase is washed free of sugars as it moves through the extraction process. The filtrate from the first wash stage is the dilution water for the steep process, and the isolated steep liquor is the concentrated sugar product.

The countercurrent experiment consisted of five rounds of extraction as described in the previous paragraph. Specifically, the fresh hulls (40 g, db) were diluted to 20% solids with 50 °C tap water, milled for 1 min in a blender, and transferred to an Erlenmeyer flask along with 0.5% (w/v) pectinase, and then the flask was placed in an

DOI: 10.1021/jf5048332
J. Agric. Food Chem. 2015, 63, 2490−2498

incubator at 50 °C for 1 h. After the steep process, the solids were filtered over the pressure filter apparatus. The filtrate (S_1, Figure 1), termed the steep liquor, was saved as sugar concentrate. For the first round of processing only, the hulls were resuspended in 200 mL of hot tap water, blended for 1 min, and refiltered in the same apparatus. This process was repeated a total of three times, and the filtrates produced were saved to serve as wash water (labeled S_2, S_3, and S_4, respectively) in the following round of extractions. In this way a feed-forward recycle loop was created between previous and subsequent rounds of extraction.

For each of the subsequent four rounds of extraction, the procedure was identical to that described above except that the dilution water for the steep and the first two washing stages was the filtrates produced in the preceding round of extraction (in this case S_2, S_3, and S_4 for the steep, first and second wash stages for round 2, respectively). In all cases the third (final stage) wash water was hot tap water. A final L30 autoclave cycle followed by a final filtration quantified the total sugar in the almond hull sample and accounted for variability in the feedstock. The filter cake after the final filtration was weighed and dried to complete the mass and water balances. Both internal and external mass balances were performed to estimate equilibrium sugar concentrations and also to calculate recovery efficiencies. Sugar concentrations were quantified by HPLC as described above.

Large Batch. To obtain a large volume of sugar concentrate for fermentation studies, 1 kg of almond hulls was suspended at 10% solids content and milled in a Waring blender for 1 min, transferred to a Fernbach flask, along with 0.5% (w/v) pectinase, and incubated for 1 h at 50 °C. In the case of large scale sugar concentrate production, the hulls were hand squeezed using grade 60 cheesecloth (Fisher) for solids retention. The filtrate was recovered and weighed, whereas the solids were weighed, analyzed for TS, and discarded. The filtrate was used to wet the next round of almond hulls with the charge of hulls determined to be 10% solids on a filtrate basis. This procedure of concentrating was used until sufficient sugar concentration was achieved.

Ethanol Fermentation. Fermentation was performed using an overnight seed culture of *Saccharomyces cerevisiae* D5A (ATCC 200062) with 0.0125 g of dry yeast added to 50 mL of seed media. Sterilized culture media (autoclaved for 20 min at 121 °C) consisted of glucose (150 g/L), yeast extract (7.5 g/L), ammonium sulfate (22.5 g/L), dipotassium phosphate (15 g/L), and magnesium sulfate heptahydrate (3 g/L).[17] The pH of this seed media was adjusted to 4.5, with temperature maintained at 30 °C under gentle mixing (200 rpm) using a shaker incubator. Growth of this seed culture was completed after glucose concentration fell below 2 g/L. Inocula from the seed culture were rinsed twice by centrifuging at 4500 rpm for 10 min, decanting the supernatant, resuspending cells in the same volume of distilled water, and repeating this process. Resuspended cells ($^1/_{10}$th dilution) were used to inoculate the concentrated sugar solutions supplemented with 1% yeast extract and 2% peptone and sterilized for 20 min at 121 °C. The fermentations were incubated for 24 h at 30 °C with glucose and ethanol concentrations monitored by HPLC.

Distillation. The ethanol was recovered by simple distillation to leave behind a thin stillage stock solution for high-rate anaerobic digestion. Specifically, a 2 L distilling flask in an electric heating mantle was filled half full (1 L volume) with broth containing ~7.5% (v/v) ethanol. Under low heat, the broth was heated so as to cause the ethanol to evaporate and rise into the fractional condensing column providing high-efficiency separation of the ethanol. The vapor phase azeotrope was cooled via a water jacket and recovered in a flask containing activated carbon and molecular sieves to remove volatiles and residual water. The solution retained in the distilling flask was saved as the thin stillage and used for biogas production.

Anaerobic Digestion of the Thin Stillage. A 1 L upflow attached-growth anaerobic reactor was utilized to determine the biomethane potential (BMP) and the anaerobic biodegradability of the thin stillage. The reactor was packed with biological filter media (Eheim Substrat Pro biological filter media, Eheim, Germany) and had a working volume of 720 mL. The system also contained a separatory funnel modified to serve as an in-line clarifier external to the reactor to collect sloughed biomass and also to allow for removal and wasting of accumulated solids and filtrate. In all, the total system volume was 1.07 L. Flow rate (20 mL/min) was controlled via a peristaltic pump with an overall system turnover of slightly less than 55 min. Flow to the reactor was in the upflow direction to an internal overflow weir for a total contact time of 36 min per reactor pass. The weir overflow fed by gravity to the separatory funnel, and the clarifier overflowed to the pump inlet to complete the flow loop. The reactor was jacketed for temperature control, which was maintained at 37 °C via a circulating water bath. Gas flow was collected in a calibrated 9 L gas accumulator filled with 10 N KOH to strip CO_2 from the biogas so that only CH_4 was stored. CH_4 produced was measured by volume displacement of a free floating inner cylinder within the accumulator and measurement of the height the cylinder was raised.

The reactor was populated by settling 250 mL of an anaerobic culture from a nursery reactor and inoculating the biological filter media with the supernatant. The culture was established on the attached growth medium with a glucose solution to increase population prior to the introduction of the thin stillage. The reactor was then acclimated to the thin stillage for an additional month before BMP was estimated by feeding weekly over a 7 week period. Known volumes of concentrated thin stillage were diluted with RO H_2O to create a stock feed. The feed was then sampled to obtain a diluted soluble chemical oxygen demand COD (SCOD) content and fed to the reactor. SCOD was performed with a Chemetrics COD kit using their midrange tubes and heated with a HACH meter (model CR2200). COD was measured using a UV−vis spectrophotometer (Molecular Devices M2) and calibrated using 1000 and 10000 ppm of COD standards (A-7301 and A-7310, respectively, from Chemetrics).

RESULTS AND DISCUSSION

Physical Properties of Fresh Almond Hulls and Measurement of Soluble Sugars. Nonpareil almond hulls were used for all of the following experiments and determined to be 80% total solids (TS). Nonpareil hulls were reported previously to be of low contaminant content;[5] however, for this study, the hulls were hand sorted to ensure 100% hull content in all samples. The ash content was 3.5% (Table 1).

It is known that almond hulls contain free fermentable sugars (sucrose, glucose, fructose) and nonfermentable sugars and

Table 1. Compositional Analysis of the Almond Hulls Used in This Study Compared to Literature Values[a]

	dry hulls	soluble	insoluble	lit. values[ref]
fermentable sugars	37.3 (1.1)	37.3		21.2[3]−24.5[2]
sucrose	5.2 (0.6)	5.2		5.3[2]−10.6[3]

J. Agric. Food Chem. 2015, 63, 2490−2498

sugar alcohols (xylose, inositol, sorbitol).[2,3,14] The four-step procedure used here achieved total sugar levels >30% higher than reported in the previous literature (reported in Table 1 for comparison). Literature values for sucrose contents range from 5.3 to 10.6%,[2,3] comparable to or higher than the current results (5.2%, Table 1). Inositol values are similar to the reported values (~2%), whereas the sorbitol levels measured here are slightly higher (5.9 vs 2.7−4.6%). The quantitative difference between techniques is expressed in this analysis as marked increases in the contents of glucose and fructose, 16.3 and 15.9%, respectively. Reported literature values range from 5.8 to 10.4% for glucose and from 4.8 to 8.8% for fructose.[2,3] Enhancement of the glucose and fructose contents could in part be a result of the decomposition of sucrose (a dimer of glucose and fructose) into its monomeric components but does not completely account for the difference. The difference may also be attributed to variety or breeding, changes in agricultural approaches, location, environmental conditions, sensitivity of analysis, higher degree of quantitation, or other factors. In total for the almond hulls analyzed here, fermentable sugar (FS) content is 37% and total sugar plus sugar alcohol content is 46%. Total extractable sugar plus sugar alcohol contents reported by the previous studies range from 25.6 to 31.5%[2,3,18] (Table 1).

The free fermentable sugars comprise 75% of the soluble components of the almond hulls with the remainder being soluble ash (3.4%) and unknown compounds (21.3%), comprised in part by the following categories: tannins, polyphenols, fats, proteins, pectins, gums, and other polysaccharides (Table 1).[4]

Characterization of the Insoluble Fraction (Spent Almond Hulls). The structural carbohydrate composition was determined by acid hydrolysis of the spent almond hulls (residual almond cake) after hot water extraction. Analysis of the residue assuming no losses during extraction indicates that the dry raw hulls contain 6.6% cellulose, 6.0% hemicellulose, and 12.3% lignin (acid-insoluble fraction). The cellulose and hemicellulose contents are slightly lower than previous results from dairy forage analysis (12.8 and 9.0%, respectively, on average), and the lignin content is slightly higher in this analysis (12.3%) versus an average of 10% reported previously.[4,19−22]

In total, 68% of the spent almond hulls is readily identifiable based upon cell wall analysis and ash content and, overall, 74.7% of the total almond hull content is identified by the procedures utilized here (Table 1).

Practical Solids Content and Water Recovery. Commercial ethanol production requires a high sugar concentration for fermentation, because high sugar levels result in sufficient alcohol content to make distillation economical.[23] The hulls were first subjected to a steeping process at 1 h and overnight time periods to determine maximum practical solids content and maximum achievable sugar recovery. The extent to which the fermentable sugars may be recovered is a function of the free water availability due to the absorptive capacity of the hulls and the equilibrium sugar concentration. Almond hulls are highly hydrophilic and can absorb and retain 10−15 times their weight in water. The initial steeping step involves wetting of the hulls and, as a result a substantial proportion of the solvent (and solute), remains with the solid phase, thus reducing extraction efficiency. Figure 2 shows the results at various solids content for the 1 h and overnight periods. As can be seen, low solids (5%) and overnight extraction result in 74% recovery of the free sugars but at very low concentration (17.6 g/L FS or 22.4 g/L TS). In all other cases, overnight sugar recovery was equal to or lower than that for the 1 h steep duration due to lower water recovery resulting from complete saturation of the almond hulls. Additionally, sugar concentrations were equivalent over the two time frames, suggesting a 1 h steep was sufficient to achieve equilibration of the free and absorbed solutes. At 20% solids content and a 1 h steep, sugar concentration (65 g/L FS) was sufficiently high to use this as a basis for a multistage extraction process.

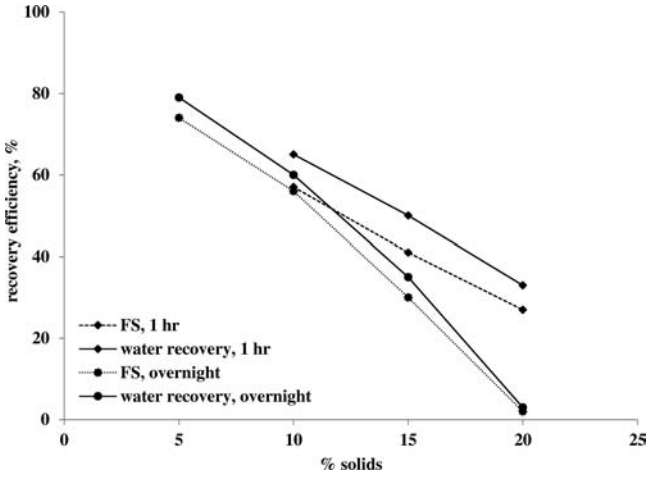

Figure 2. Effect of solids content and extraction duration on free fermentable sugar and free water recovery.

Pectinase Application. It has been reported previously that almond hulls contain pectin[4,24] or pectin-like hydrocolloids. Many fruit-processing operations include the use of pectinase to control the viscosity, improve liquids/solids separation, and clarify juice products.[25] Pectin is located in the primary cell wall and middle lamella and provides firmness or compression rigidity to the fruit.[26] Almond hulls have a tremendous propensity to absorb and hold water, in part due to the pectin molecules, making free sugar extraction and disposal of the residuals more difficult. As a result, pectinase applications were explored to improve sugar extraction and water recovery. The enzyme cocktail used in this study contains methyl esterases and polygalacturonases as well as small amounts of hemicellulases and cellulases, all of which can contribute to the breakdown of the cell wall to facilitate fermentable sugar extraction.

Almond hulls were steeped at 20% solids loading at 50 °C for 1 h with pectinase enzymes at application rates ranging from 0 to 0.75% (w/v). After a 1 h steep with no enzyme, the entire volume of water was absorbed by the control (i.e., no steep liquor available). Steep liquor recovery improves to 26% of applied with 0.25% pectinase application and then increases only slightly (34%) at the higher enzyme dosages. It is likely that the enzyme application removes the rigid, hydrophilic pectin material, decreasing the absorptivity of the hull, making more free water available, and facilitating equilibration of the free and absorbed solutes. Figure 3a illustrates how the maximum sugar extraction levels are directly tied to water recovery. Higher sugar recovery rates require additional extraction stages. Figure 3a also shows that the sugar yield after steep liquor recovery and first extraction (wash) improves 36% over the control with just 0.10% enzyme application and improves to 76% at 0.75% application. In total, at sufficient

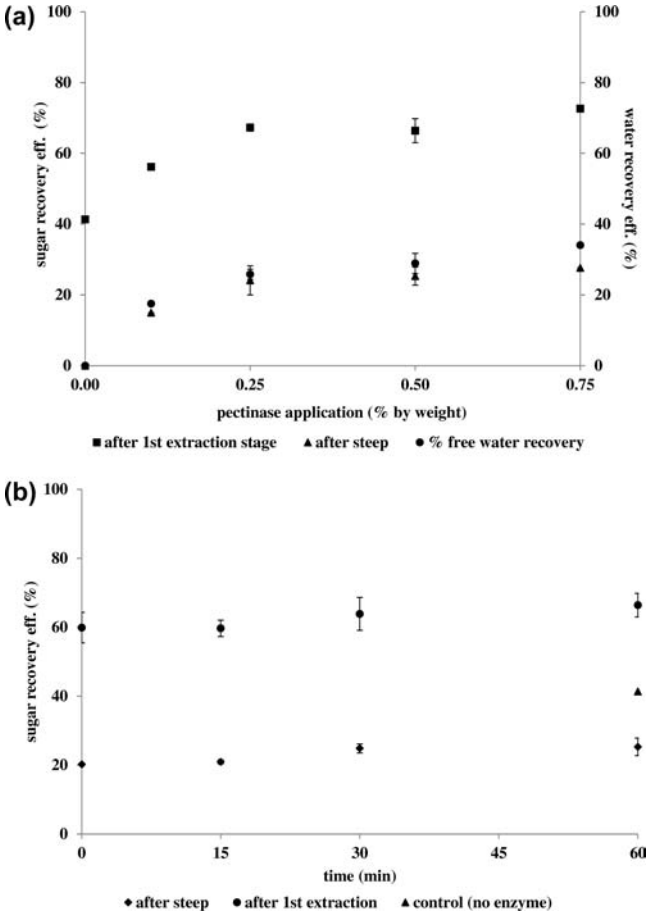

Figure 3. (a) Effect of pectinase application on the efficiency of sugar recovery through steep and first wash stage. Steeping was performed at 50 °C for 60 min. (b) Improvement in sugar recovery with pectinase treatments (0.5% w/v) over time.

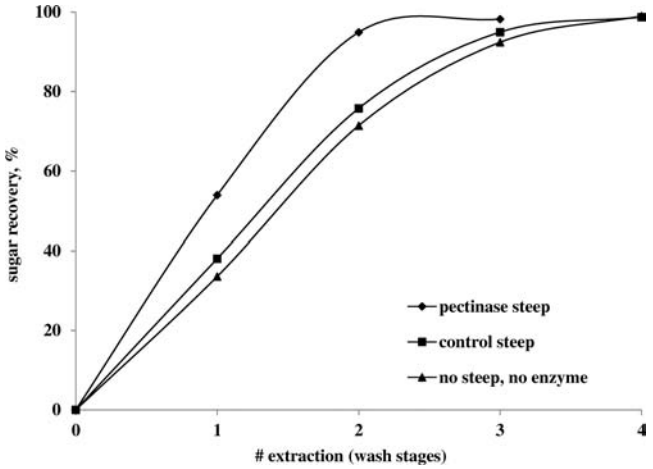

Figure 4. Free sugar extraction with and without pectinase enzyme application and steeping. When applied, enzyme application was 0.5% (w/v) and steep time was 60 min at 50 °C.

enzyme application rates, sugar recovery after steeping and first-stage washing is ~70%.

To examine the benefits of steep time, enzyme application was maintained at 0.5% (w/v) and steep time varied. Figure 3b shows sugar yields in the steep liquor increase only slightly (from 20 to 25%) over steep time varying from 0 to 60 min. The data indicate that equilibration occurs rather quickly, at least during the initial contact of the almond hulls with the solvent as milling in the blender reduces particle size. The apparent benefit of the pectinase is that it reduces the swelling capacity of the hulls and maintains a free volume during the wetting process so that recovery of free sugars can occur after saturation of the hulls is achieved. In comparison to the control (60 min with no enzyme), sugar recovery after steep liquor recovery and first-stage extraction increases 60%, and this is due to the reduction in the water-retaining capacity of the hulls. Over the time curve the enhancement of sugar recovery is less because equilibration between free and absorbed solute is quickly achieved. As a result, it may be acceptable to shorten steep time and reduce overall processing time.

Figure 4 shows the effects of steeping and pectinase additions versus the control (no enzyme, no equilibration time). The control solubilizes the readily available soluble sugars, but contact time is not sufficient for diffusion of water into hulls. As such, a fair volume of water is recovered through filtration but with fairly low sugar concentration (46 g/L FS). Steeping with no enzyme produces a more concentrated product (88 g/L FS), but very little free water is available after a single stage and the total sugar recovery is similar to the control. Only slightly more sugar is recovered by steeping without pectinase application (38% recovery vs 34%) than for no equilibration time. The two curves mirror each other in slope as the hulls become saturated and sugar extraction is equivalent because structurally the hulls remain similar. After three extraction stages, 96 and 93% of sugar was recovered, respectively, for steeping without enzyme and no steep options. An additional stage recovers 99% of the sugar in both of these cases.

The pectinase steeped hulls release significant volumes of free water and fermentable sugars, resulting in a high sugar concentration in the steep liquor (74 g/L FS). Hence, much more sugar is recovered in the first stage of extraction. Figure 4 also shows that enzyme application under ideal conditions (fresh wash water) results in complete sugar recovery in three filtration steps and that 96% recovery is already achieved after only two filtrations. Enhanced sugar recovery is important in commercial processing to reduce the number of stages required for recovery of product and also to maximize the product concentration. As a result, the application of pectinase is beneficial to accelerate sugar recovery, produce higher volumes of free water at high solids processing conditions, and produce higher fermentable sugar concentrations.

Countercurrent Extraction of Free Fermentable Sugars. On the basis of the above results a series of experiments were devised to mimic countercurrent extraction of soluble sugars, analogous to a diffuser, which is used in the food-processing industry for extraction of sugars. The counter flowing water is fresh at its inlet point and progressively increases in sugar concentration as it contacts sugar-rich hulls (Figure 1). The process involves (1) diffusion of the lower strength solvent (water) into the substrate, (2) dissolution and equilibration of soluble components, and (3) forced displacement of the free water and solubles by low-pressure filtration (extraction).

Five rounds of extraction were performed to reproduce the concentration of sugars analogous to the countercurrent extraction process. Round 1 utilized fresh water as the wash water and produced a steep liquor, S_1 (84 g/L total sugar and sugar alcohol concentration) and a battery of filtrates (S_2, S_3,

DOI: 10.1021/jf5048332
J. Agric. Food Chem. 2015, 63, 2490−2498

S_4) to serve as wash water in the subsequent rounds. S_2 served as the dilution water for the fresh almond hulls in round 2, carrying along with it a total sugar concentration of 39 g/L total sugars (30 g/L FS). By mass balance, the equilibrium sugar content in the round 2 steep liquor (S_6) was calculated as the sugar input divided by the total of the free and absorbed water and should be 115 g/L total sugars. By measurement of the filtrate (S_6, Figure 1), the actual concentration was 117 g/L (91 g/L FS), indicating that the steep process was adequate for equilibration. The first wash stage consists of suspension of the almond hull cake in the second filtrate from round 1 extraction (S_3, Figure 1) for the duration of milling (1 min) followed by filtration. Interestingly, the observed sugar concentration in S_7 (56 g/L total sugar, 44 g/L FS) was predicted by the equilibrium sugar calculation, indicating that the contact time during milling in the blender was sufficient for equilibration. Observed values were consistently in sync with predicted values (± 10%) throughout, especially with the more concentrated filtrates. Dilute filtrates had a larger percent difference but were close in value for g/L total sugar. Throughout the entirety of the study, the free fermentable sugar content was 0.78 g per g of total sugar extracted, which demonstrates that no preferential extraction of one type of sugar or sugar alcohol is occurring.

Figure 5 shows the average efficiency of sugar recovery by each individual extraction stage and the cumulative average

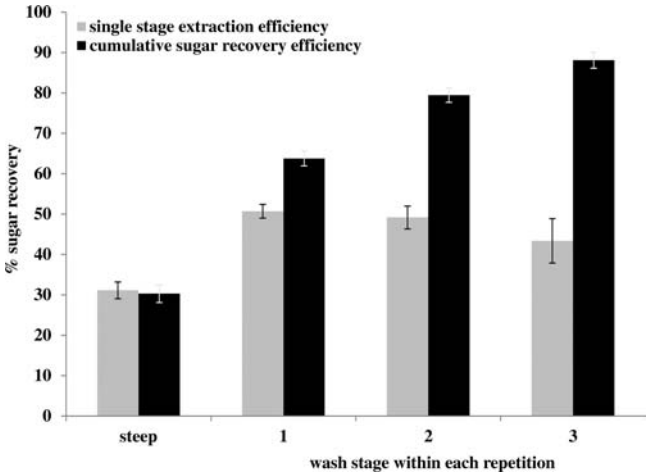

Figure 5. Sugar recovery efficiency for individual extraction stages within countercurrent extraction repetitions (gray bars); average cumulative sugar recovery within repetition (black bars).

across the three wash stages. Efficiency is lowest during the steep stage as the hulls are saturating, and the free water recovery yields are lower. On average, 70% of the steep water is retained within the hulls. Because the yield of extractable sugar is dependent upon free water recovery, it follows that sugar recovery is only ~30% on average (see Figure 2a). After steeping, the hulls are saturated and the process equilibrates, whereby extraction stage efficiencies vary from 51 to 49 to 43% in the first to third stages, respectively. The efficiency is defined as the total sugar in the filtrate divided by the total sugar in the solid matrix and the wash solution. The first and second stage sugar recoveries are closely related to water recovery yields; however, the third stage strays somewhat from this relationship. Specifically, the average water recovery from the third wash stage was 60%; however, the average sugar recovery yield was only 43%. At this point, the average particle size is small after four 1 min milling treatments and a 1 h enzyme steep. The deviation from the water recovery relationship may indicate that displacement is incomplete, the residual sugar is difficult to completely extract, or the final autoclave cycle causes some minor depolymerization of hemicelluloses.

Figure 5 also depicts cumulative extraction efficiency defined as the total cumulative sugar recovery combined over the steep and three extraction stages divided by the total sugar input with the solid hulls and recycled wash water. On average, the cumulative recovery was 88% and varied between 83 and 93% over the five repetitions. The data show that although the extraction efficiencies per repetition do not decrease with increasing sugar concentrations (i.e., rounds 4 and 5), larger amounts of sugar are not extracted through three wash stages as the feedback wash loop contains larger amounts of sugar than are actually input with the hulls. Including the recycled sugars in the efficiency calculation, repetitions 4 and 5 are 83 and 88% efficient, respectively. However, using the calculation of losses divided by input with the fresh hulls would return values of 78 and 69%. The lingering sugar with the residue after three extraction stages and high sugar concentrations throughout indicates that a fourth extraction stage may be useful to achieve better sugar recovery.

Five consecutive countercurrent extractions were performed to concentrate the soluble sugars in the product; however, equilibrium was not quite reached by this point. After a single round of extraction, the concentrated sugar product contained 65 g/L FS (84 g/L total sugars), and after round 5, the product contained 131 g/L FS (169 g/L total sugars) (Figure 6). The

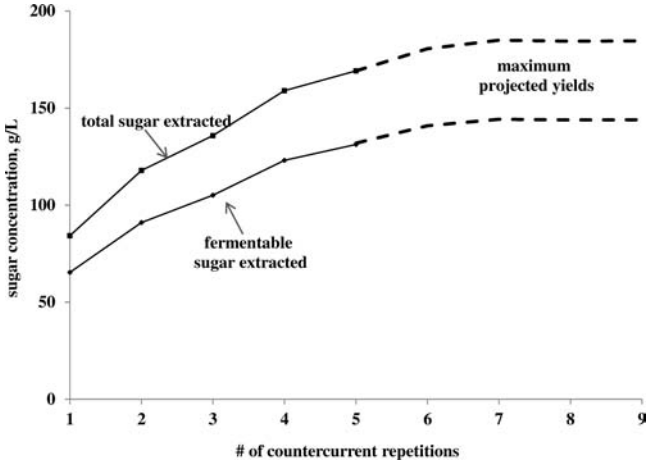

Figure 6. Total sugars and free fermentable sugars extracted per countercurrent repetition. Solid line represents laboratory data; dashed lines represent theoretical yields based upon modeling using measured extraction efficiencies.

results demonstrate that countercurrent extraction is efficient for producing a high free fermentable sugar concentration for fermentation to alcohol. In practice, the sugar concentration would increase until equilibrium is achieved through the system, and this would be the operational target. On the basis of the extraction efficiencies, the point of equilibrium was estimated as depicted by the dashed line extensions in Figure 6. Calculations indicate that two additional rounds of extraction would bring the concentrated product close to an equilibrium point of 184 g/L TS (144 g/L FS), which would mark the highest concentration that can be achieved through countercurrent extraction.

Filter cake residues were collected and analyzed for moisture content and percent of original almond hull remaining. The average solids content of the spent almond hull cake was 9.2%, and overall the average recovery of solids was 28.5% of the original almond hull input, about 10% lower than the quantification assay. Discrepancies could be related to pectinase application or additional handling.

Fermentation of Soluble Sugars to Alcohol. The countercurrent extraction experiment demonstrates that the sugar concentration in the steep liquor and wash filtrates can be progressively enhanced providing data for estimation of the maximum producible sugar concentrations. The countercurrent experiment, however, utilized small product volumes, with insufficient quantity to carry out a significant, reproducible fermentation experiment. Accordingly, a large extraction starting with 1 kg of almond hulls was undertaken to ultimately produce a large volume of high sugar product for fermentation experiments. Sugar content was monitored until the total sugar content was 178 g/L (140 g/L fermentable sugars). Figure 7 shows the average results of fermentation of the sugar solution after a 24 h conversion period. The yields were an average of 86% of the theoretical ethanol (using four replicate experiments) and an average of 7.4% (v/v) ethanol concentration in the resulting beer. Furthermore, mass balance on the fermentable sugars shows a nearly complete utilization of both glucose and fructose and an average of 87% utilization of the sucrose in solution. Inhibitors such as furfural, HMF, and acetic acid were tracked but were not present in any appreciable concentration.

Anaerobic Fermentation of Thin Stillage to Methane. The beer was subjected to overhead distillation to separate and purify the ethanol but also to create a thin stillage for further analysis. The thin stillage was analyzed for SCOD content and stored in the refrigerator for further use. A total of 60−70% of the almond hull was solubilized during the extraction process, whereas the fermentable sugars utilizable by the yeast comprise only slightly more than half of this content. As a result, the beer has an amber color and a very high SCOD content (233,250

DOI: 10.1021/jf5048332
J. Agric. Food Chem. 2015, 63, 2490−2498

mg/L), thus making it a very good candidate for biogas production.

A 1 L mesophilic upflow attached growth anaerobic reactor (AGR) packed with biological filter media and equipped with an internal overflow weir was commissioned to analyze the biodegradability and biomethane potential (BMP) of the thin stillage. To measure BMP, the reactor was batch fed with a 1 week retention time to allow for complete decomposition of the feed substrate, although decomposition typically took <72 h. The organic loading rate (0.67 g/L day) was intentionally held low for the BMP analysis over a 1 week hydraulic retention time (HRT).

The reactor was acclimated over 1 month to allow for a stable culture with constant pH. The reactor was then operated over a 7 week period on the thin stillage, and the average biomethane yield was 297 mL CH_4/g SCOD destroyed, with an average SCOD feed destruction of 90% (Table 2). Background SCOD levels remained stable throughout operation, declining to levels comparable to the initial SCOD concentration prior to feeding. indicating nearly complete destruction. Volatile fatty acids were tracked but did not accumulate, and the inositol and sorbitol in the feed were completely degraded. The alkalinity remained high (~2500 mg $CaCO_3$ eq/L) in conjunction with a pH that averaged 7.1−7.3. Effluent SCOD levels were 1.2−1.5 g/L SCOD. Overall, it appears that the thin stillage is very amenable to biogas production.

Bioenergy Potential of Soluble Components of Almond Hulls. On the basis of the Nonpareil almond hulls used here, it can be estimated that the theoretical ethanol potential on a dry ton basis is 64 gal (242 L). On the basis of sugar recovery and fermentation efficiencies, the realistic ethanol potential is 49 gal (185 L)/t hulls (db). This result is higher than previously reported (39 gal, 148 L)[18] but is in alignment with the higher fermentable sugar contents that were detected in this study. In addition, this study estimated the biomethane potential per gram of SCOD destroyed. Estimating the biomethane potential on a per tonne basis was done on the basis of the amount of hulls used for preparing the bulk solution for fermentation, which is roughly estimated at 75 m^3 CH_4/t of fresh hulls (db). In total, 1 t of hulls can provide a minimum of 6700 MJ of locally produced bioenergy with the breakout being 58% of the energy arising from ethanol and 42% from biogas.

In conclusion, almond hulls are a major California agricultural residue and contain very high levels of free fermentable sugars and other carbohydrates that can be made available for a number of uses, including locally produced transportation fuels such as bioethanol and biogas. Via an optimization analysis, the maximum practical solids concentration (20%) that could be utilized for effective sugar extraction with both acceptable water recovery yields and sugar concentrations was determined. Sugar extraction is directly related to the ability to recover free water because the equilibrium relationship between the free and absorbed water limits the recovery potential of the soluble sugar in any one extraction stage. Small additions (~0.5% w/v) of pectinase can reduce the absorptive capacity of the hulls and improve the subsequent additional free water recovery thereby aiding sugar recovery, especially in the initial extraction stages.

High solids (20%) countercurrent extraction was utilized to extract and accumulate the free fermentable sugars for further use. The initial free fermentable sugar concentrate increased from 65 g/L fermentable sugars after one round of extraction to 131 g/L after five rounds of extraction as a result of the applied countercurrent approach. Extraction efficiency was high, 88% overall; however, the number of extraction stages within each round of extraction would ideally be extended one or two wash stages as the sugars concentrate in the recycle loop.

The beer produced from fermentation of the concentrated steep liquor had an average ethanol content of 7.4% (v/v), well within a range that is acceptable for economic distillation. Fermentation efficiencies were high (86%), and the fermentation was complete in <24 h. The thin stillage after distillation was rich in SCOD (233 g/L) and was fed to an attached growth reactor for the measurement of biomethane potential. The biomethane potential was determined to be 297 mL/g SCOD destroyed, the efficiency in SCOD destruction was 90%, and the effluent SCOD concentrations were low (1.2 g/L SCOD). Overall, it was estimated that almond hulls are capable of delivering a minimum of 185 L EtOH/t of fresh hulls (db) and approximately 75 m^3 CH_4/t of fresh hulls (db).

enzymatic treatments to remove cross-links, and new cross-links being formed. An overview of tanning chemistry has been presented.[6] Some aspects of chemical treatments of skins and their effect on structure have been observed previously with liming of skins (increasing the pH with calcium hydroxide) showing a decrease in the D-spacing of collagen.[7] Dehydration of parchment has been shown to result in a decrease in collagen D-spacing from 64.5 to 60.0 nm.[8] Pickling and retanning agents have been shown to swell collagen fibers at low pH.[9] At low ionic strength and nonisoelectric pH, charge-dependent interactions (screening and selective ion adsorption) are prevalent in maintaining the collagen architecture,[10] which is also reflected in the greater thermal stability of collagen at low pH[11] and in the elastic response of collagen.[12]

In this work, we use SAXS to investigate the changes that take place in the microstructure of leather through the different stages of processing from skin to leather. The structural basis of these changes at the level of the collagen fibrils is not fully understood and forms the basis of this investigation.

EXPERIMENTAL PROCEDURES

Ovine pelts were obtained from 5-month-old, early-season New Zealand Romney cross lambs. Samples were removed from the same skin during several stages of processing at or near the "official sampling position" (OSP).[13] These stages were termed fresh green, salted, pickled, pretanned, wet blue, retanned, dry crust, and dry crust staked. Cross sections were cut parallel to the backbone and as close together as possible. The samples, except for dry crust and dry crust staked, all had high moisture contents because these were taken during processing.

Conventional beamhouse and tanning processes were used to generate the leather. A pelt was depilated using a caustic treatment, and then the residual keratinaceous material was removed. The pelt was washed, pretanned, and degreased using 4% (w chemical/w limed leather for all percent chemical additions unless otherwise stated) Tetrapol LTN (Shamrock Group) and 2% Zoldine ZE (The Dow Co.). Sodium formate was added followed by sodium bicarbonate, which was gradually added to increase the pH to 7.5−8. The pickled pelt was then chrome tanned.

The resulting "wet blue" pelt was first neutralized, then washed, and retanned using 2% w/w synthetic retanning agent (Tanicor PW, Clariant, Germany) and 3% w/w vegetable tanning material (mimosa, Tanac, Brazil). Fat liquor was added at a concentration of 6% by weight of wet leather and the leather processed at 50 °C for 45 min. Finally, the leather was fixed by the addition of 0.5% w/w formic acid and processed for 30 min followed by draining and washing.

Tear strengths of the leathers were tested using standard methods.[14,15] Samples (strips 1 × 50 mm) were tested on an Instron 4467. "Dry" samples were conditioned at 23 °C and 50% relative humidity for 24 h before testing following the standard method.[16] "Wet" samples were in contact with free liquid up to the point at which they were tested.

Diffraction patterns were recorded on the Australian Synchrotron SAXS/WAXS beamline, utilizing a high-intensity undulator source. Energy resolution of 10^{-4} was obtained from a cryo-cooled Si (111) double-crystal monochromator, and the beam size (fwhm focused at the sample) was 250 × 80 μm, with a total photon flux of about 2 × 10^{12} ph s^{-1}. All diffraction patterns were recorded with an X-ray energy of 11 keV using a Pilatus 1 M detector with an active area of 170 × 170 mm and a sample-to-detector distance of 3371 mm. Exposure time for diffraction patterns was 1 s, and data processing was carried out using SAXS15ID software.[17] The partially processed leather samples were sandwiched between kapton tape to prevent drying and mounted for X-ray analysis.

A custom-built stretching apparatus was built for in situ SAXS measurements as described elsewhere.[18] Strips of leather, 1 × 30 mm, cut from the OSP, were mounted horizontally without tension and without slack, with a measured separation between the jaws, typically of 15 mm. SAXS patterns were taken through the full thickness of the sample and the force and extension information recorded. The sample was stretched by 1 mm and was maintained at this extension for 1 min before patterns were recorded. This process was repeated with the sample stretched a further 1 mm each time until the sample failed.

Orientation index (OI) is defined as (90° − OA)/90°, where OA is the azimuthal angle range that contains 50% of the microfibrils centered at 180°. OI is used to give a measure of the spread of microfibril orientation (an OI of 1 indicates the microfibrils are completely parallel to each other; an OI of 0 indicates the microfibrils are completely randomly oriented). The OI is calculated from the spread in azimuthal angle of the most intense D-spacing peak (at around 0.059−0.060 $Å^{-1}$).[19]

The D-spacing was determined from Bragg's law by taking the center of a Gaussian curve fitted to the sixth-order diffraction peak of an integrated intensity plot for each spectrum.

RESULTS

Orientation Index Changes. The OI of the corium region is higher than that of the grain region throughout all of the processing stages (Figure 1). Whereas there is considerable variation in the OI during processing, the OI of the final staked dry crust leather is fairly similar to that of the fresh green skin so that overall there is not a large change in OI.

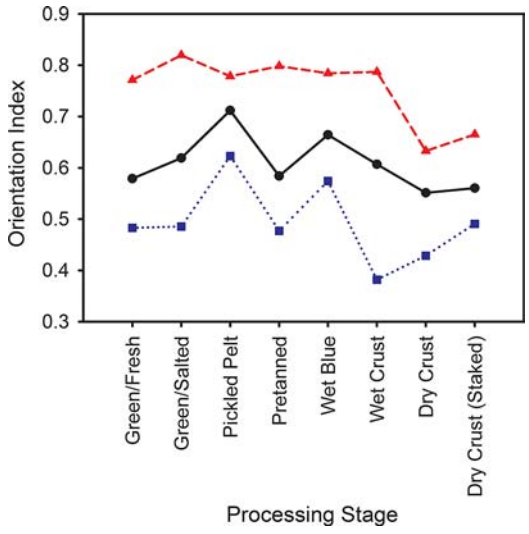

Figure 1. Variation in orientation index for all stages of processing: (red triangles) corium; (blue squares) grain; (black circles) average.

Orientation Index and Thickness. The thickness of the skin or leather varies by a factor of >2 during processing. With this variation of thickness there is a change in OI (Figure 2). The stages appear to be in two groups with the dry samples (salted, pretanned, dry crust, and dry crust staked) in one group of lower OI, which decreases with increasing thickness, and the wet samples (pickled, wet blue, retanned, and fresh green) in another group of higher OI that decreases with increasing thickness.

D-Spacing with Processing and pH. Significant changes are observed in the D-spacing of the collagen fibrils with the application of each process step (Figure 3). Both the corium and the grain regions of the leather have similar D-spacings and are similarly affected by the processing. The most significant change in D-spacing occurs with pretanning, when there is a contraction of the D-spacing of 1.4−1.5 nm (2%). The pH of the solutions in which each process takes place does not appear

to correlate with the D-spacing (Figure 4). For fresh green and salted skins the pH was measured by a surface probe rather

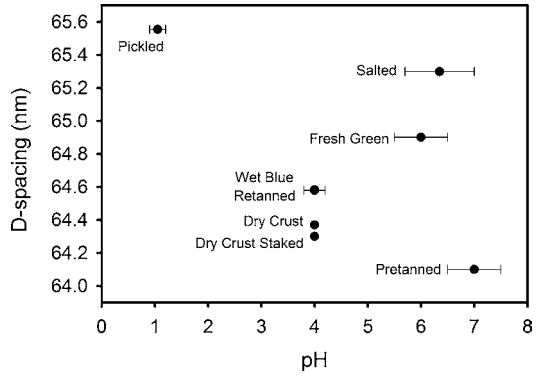

Figure 4. Variation of D-spacing with pH (wet blue and retanned points are coincident).

than the process liquor as used in the later stages. Although there is not a correlation of D-spacing with pH, it appears that there is a relationship between D-spacing and the moisture content. The three dry samples have a lower D-spacing than the wet samples.

Orientation Index and pH. The OI appears to be correlated with pH (Figure 5) (linear regression: $r^2 = 0.335$, $t = -1.74$, $P = 0.133$). However, as discussed later in the paper, we believe this correlation is not a causal relationship.

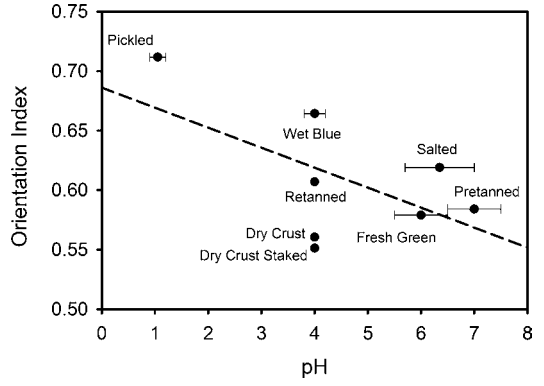

Figure 5. Correlation of OI with pH.

D-Spacing and Orientation Index. A correlation is observed between OI and D-spacing (Figure 6). The

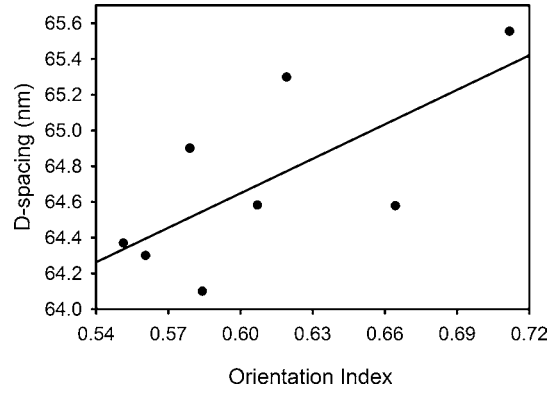

Figure 6. D-spacing versus OI for samples of different stages of processing when held without tension.

correlation is statistically significant (linear regression: $r^2 = 0.485$, $t = 2.4$, $P = 0.055$). However, as is discussed later in the paper, we believe this correlation is not a causal relationship.

Stress–Strain. Stress–strain curves were measured in situ at the synchrotron during SAXS data collection (Figure 7). The samples were not of a uniform width, so an absolute comparison of the modulus of elasticity from these curves is not possible. However, it is possible in a very general way to compare the shapes of the curves. Most of the samples show a toe region, with an initial lower elastic modulus, followed by a linear region.

Orientation Index and D-Spacing with Mechanical Stretching. There is an increase in D-spacing as the skin or leather samples are stretched (Figure 8). This increase in D-spacing is a measure of the stress being transferred to the individual fibrils, causing their length to increase. An increase in OI on stretching is also found (Figure 9) as the collagen fibrils realign in the direction of the applied force (values for the D-spacing and OI changes are found in the Supporting Information). At every stage of the leather processing, a strain applied to the samples results in an increase in OI.

DISCUSSION

We have measured the changes to the structure and arrangement of collagen fibrils in skin during several stages of the chemical processing to form leather. These build a picture of what happens in the process of transforming skin to leather.

Model of Orientation Index Change with Thickness. At the different stages of the processing of skin to leather, the thickness of the skin varies, at times becoming thicker and at other times thinner. The variation in thickness amounted to a factor of 2.25. If the collagen fibrils are not lying flat, then as the thickness of the leather increases, the angle of these fibrils to the plane of leather will increase (Figure 10). This will cause a change in OI. We have therefore developed a model for the change in OI with thickness changes. This enables us to determine how much of the OI change is due just to the change in thickness and how much is due to other factors.

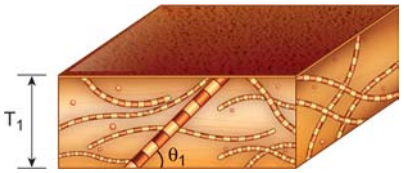

Figure 10. Illustration of the change in collagen fibril angle θ_1 to the plane of leather as the thickness T_1 of the leather changes.

The range of fiber angles in a sample is given by the OI, which is derived from the orientation angle, OA.[1] OA is defined as the subtended angle that contains half the fibrils; that is, it satisfies eq 1.

$$0.5 = \frac{\int_{\theta=-\mathrm{OA}/2}^{\theta=\mathrm{OA}/2} \theta N \, \mathrm{d}\theta}{\int_{\theta=-90^\circ}^{\theta=90^\circ} \theta N \, \mathrm{d}\theta} \quad (1)$$

N is the number of fibrils, and θ is the fiber angle (relative to the plane of the leather). In practice, this is determined from the SAXS diffraction pattern by the integrated intensity versus azimuthal angle for one of the D-spacing diffraction peaks, eq 2:

$$0.5 = \frac{\int_{\phi=-\mathrm{OA}/2}^{\phi=\mathrm{OA}/2} \phi I \, \mathrm{d}\phi}{\int_{\phi=-90^\circ}^{\phi=90^\circ} \phi I \, \mathrm{d}\phi} \quad (2)$$

I is the diffraction intensity of a selected D-spacing diffraction peak above a fitted background, and φ is the azimuthal angle of the diffracted X-rays.

OI is derived from OA by eq 3.

$$\mathrm{OI} = \frac{1 - \mathrm{OA}}{\mathrm{OA}} \quad (3)$$

Therefore, for perfect alignment in the reference direction, which is normally the plane of a piece of leather or skin, OI = 1; for no alignment or completely isotropic fibrils, OI = 0; and for perfect alignment at right angles to the reference direction, OI = −1.

If a sample of leather containing a fiber expands in thickness uniformly, and the fiber is at an angle θ_1 from the base (Figure 10), then the new angle of the fiber, θ_2, depends on the change in thickness by eq 4.

$$\frac{T_2}{T_1} = \frac{\tan \theta_2}{\tan \theta_1} \quad (4)$$

T_1 is the original thickness, and T_2 is the new thickness.

Rearranging eq 4 for θ_2 gives the new angle of the fiber after the leather has increased in thickness:

DOI: 10.1021/jf506357j
J. Agric. Food Chem. 2015, 63, 2499−2505

$$\theta_2 = \tan^{-1}\left(\frac{T_2}{T_1}\tan\theta_1\right) \quad (5)$$

It is then possible to calculate a transformed OA after stretching. The OA defines the subtended angle of 50% of the fibers. Therefore, fibers that have an initial angle from the reference angle of greater than half the OA will, after transformation, still have an angle greater than the transformed OA; fibers that have an initial angle lower than half the OA will, after transformation, still have an angle lower than half the transformed OA. In other words, the 50% inside the OA will remain inside the OA, the 50% outside the OA will remain outside the OA. Therefore, it is only necessary to calculate the transformation by eq 5 of the angle that is the OA to calculate the new OA that represents the new fiber distribution.

As an illustration of the extent of this change, for thickness changes similar to those observed here, some values are listed in Table 1. Note that expanding the thickness sufficiently results in an alignment of fibers vertically (negative OI).

Table 1. Calculated Change in Orientation Index of Collagen Fibrils for Different Thicknesses of Material

	new OI when		
starting OI	T_2/T_1 = 1.5	T_2/T_1 = 2.0	T_2/T_1 = 2.5
0.00	−0.25	−0.41	−0.52
0.10	−0.16	−0.33	−0.44
0.20	−0.05	−0.23	−0.36
0.30	0.05	−0.13	−0.26
0.40	0.17	−0.01	−0.15
0.50	0.29	0.12	−0.02
0.60	0.42	0.27	0.13
0.70	0.56	0.43	0.31
0.80	0.70	0.61	0.52
0.9	0.85	0.80	0.75
1	1.00	1.00	1.00

We did also consider how the OI might be affected by the area change to the leather, with wet stages generally of larger area than dry stages. This expansion of area would influence the OI in the opposite sense to the thickness change. However, the area change of the skin is small, <5%, and can be neglected compared with the >100% change in the thickness.

With the thickness taken into account, the OI now reflects any underlying structural changes that take place during the chemical and mechanical processing of skin to leather. The OI has therefore been recalculated for each sample using the thinnest sample, the salted skin, as the reference, and the adjusted results are presented in the following analysis.

Orientation Index and Water. Once the effect of thickness on the OI is removed, it can be seen that the samples fall into two groups (Figure 11). There are the fresh green, pickled, wet blue, and retanned materials. These all have a high OI (corrected for thickness relative to salted) of around 0.8. These samples are all wet. The pretanned, dry crust, and dry crust staked all have a corrected OI of around 0.67. These samples are all dry. The salted skin also has a low OI, of 0.62, and it is also a dry sample. Therefore, the factor that separates the high OI from the low OI materials is the wetness of the samples. When these collagen materials are dried, the OI decreases. Although it might be tempting to ascribe this to a crimping of the collagen fibrils as the materials dry, which would result in a lower OI, crimping in not observed in skin (unlike in tendon or pericardium,[20] for example). Therefore, by removing the thickness effect, we have been able to identify that there is a fundamental change between wet and dry stages, but we have not determined the mechanism of this change. It is suggested that a possible mechanism could be the space filling that results from hydration creates a hindrance to the movement of fibrils and leads to a higher OI at higher moisture contents. At lower moisture contents there is more space available for fibers to bend and adjust themselves into positions resulting in lower OI.

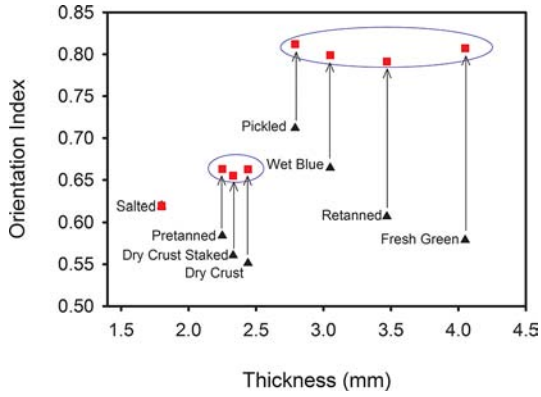

Figure 11. Fibril orientation index versus thickness: (black triangles) measured OI; (red squares) calculated OI adjusted for thickness changes (relative to salted).

D-Spacing and Orientation Index. Once the OI is corrected for thickness effects, there is no longer a statistically significant correlation between D-spacing and OI (Supporting Information, Figure S1) (linear regression: $r^2 = 0.109$, $t = 0.855$, $P = 0.426$). It is known that the result of straining leather is a straightening or alignment of the fibrils (an increase in OI) and that D-spacing measures the stress applied to individual fibrils.[18] A correlation between OI and D-spacing during different stages of processing would have suggested that these were both due to changes in internal strain in leather: when strain is released, D-spacing decreases and OI decreases. However, this was not observed here.

D-Spacing and Water. It was found that the D-spacing is lower in the dry samples by 0.38 nm; wet samples, which include fresh green, pickled, wet blue, and retanned, have an average D-spacing of 64.90 (σ = 0.46) nm, whereas dry samples, which include salted, pretanned, dry crust, and dry crust staked, have an average D-spacing of 64.52 (σ = 0.53) nm. It has previously been shown by X-ray diffraction and by atomic force microscopy that the D-spacing is moisture dependent with a reduction in D-spacing on drying.[8,21−24] This is believed to be due to the collapse of the gap and overlap regions and the partial shearing of unit cell contents within the gap region upon loss of water.[21]

D-Spacing and pH. It is perhaps a little surprising that D-spacing is not affected by pH. The D-period is affected both by the length of the tropocollagen units and by the way these tropocollagen units are assembled into the collagen fibril. The length of these structures is partially determined by the length of the hydrogen bonds between collagen molecules within the tropocollagens and by hydrophobic interactions between tropocollagen units. pH can affect hydrogen bonding, which, in collagen and other proteins, relies on a polar interaction between specific functional groups on amino acids.[10,11]

DOI: 10.1021/jf506357j
J. Agric. Food Chem. 2015, 63, 2499−2505

Mechanisms for fibril elongation by chemical treatments have previously been discussed,[20,25] and it appears that pH does not have an impact here.

Orientation Index and pH. Once the OI is corrected for thickness, it is apparent that there is no correlation between OI and pH (Supporting Information, Figure S2) (linear regression: r^2−0.0215, t = 0.488, P = 0.22). These instead fall into two groups: low OI for dry samples and high OI for wet samples, irrespective of the pH conditions.

Response to Strain. We found that when strain was applied to the samples, both the OI and D-spacing increased. It has previously been shown that upon stretching of leather, collagen fibrils first realign and then lengthen (an increase in the OI followed by an increase in the D-spacing)[18] and that collagen fibrils are very resilient with a high Poisson's ratio.[26] In pretanned, dry crust, and dry crust staked samples, the OI increased first after the first few increments in strain, and then the D-spacing increased with the further strain. These samples form a cluster at an OI of approximately 0.67 following thickness correction. The D-spacing of the wet samples (fresh green, pickled, wet blue, and retanned) increased with the first application of strain. These wet samples form a cluster with an OI of about 0.80. It is possible for the dry group to undergo more realignment with strain than the wet group because the dry samples have a lower OI initially and therefore more scope for change. Therefore, in the wet samples, because less realignment is possible, the strain was taken on by the individual collagen fibrils sooner, as shown by the immediate increase in D-spacing.

Cross-Linking. In the process of treating skin to produce leather, naturally present cross-links are removed and new cross-links are formed. The natural glycosaminoglycan cross-links are removed in the liming and bating stages so that the processed skin, known as pickled, should have fewer cross-links. New cross-links are added at the pretanned and wet blue stages. Although there have been studies on the effects of cross-linking on fibril alignment, there have been mixed conclusions drawn about the influence of cross-linking. It has been suggested that cross-links may stabilize a network structure (with fewer aligned fibrils)[27,28] and that removal of cross-links may destabilize the network structure, leading to fibrils becoming more aligned.[28] However, such behavior is not observed here during processing, where some of the cross-linking would be expected to be removed by the end of the pickled stage, and then cross-links are added by the completion of the wet blue stage.

We have found that although processing results in changes in OI, this is not a fundamental redistribution of fibrils but is rather a decrease in OI that occurs as the thickness increases and also (independently of thickness) as the water content increases. This understanding may be useful for relating structural changes that occur during different stages of processing to the development of the final physical characteristics of leather. For example, if fibril orientation is critical to strength in certain leathers, the structural relationship that should exist between the fresh skin and the final leather is now known, and it is possible to seek to maintain this characteristic during processing or modify it appropriately.

into reasons for possible physical and viscosity changes observed in *t,t* CLA-rich eggs.

Previous egg enrichment studies either report the modified fatty acid composition relative to control eggs, or determine changes in egg quality. Correlations between egg quality alterations and fatty acid composition are rarely reported. The aim of this experiment was to investigate the effects of *t,t* CLA enrichment on egg quality during a typical shelf life of 30 days refrigerated storage. In addition, correlations between CLA-egg yolk fatty acid composition and any resulting quality or viscosity changes were also explored. The objectives were to determine the effect of *t,t* CLA-rich soy oil in feed on egg yolk viscosity and yolk quality during refrigerated storage. Yolk quality parameters that were investigated included yolk weight, yolk index, moisture content, pH, and vitelline membrane strength.

EXPERIMENTAL SECTION

Materials. All solvents used for sample preparation were analytical grade. The fatty acid methyl ester (FAME) internal standard and long chain polyunsaturated FAME standards used were purchased from Supelco (Bellefonte, PA).

Methods. *CLA–Rich Soy Oil Production.* A 18% CLA-rich soybean oil used in the feeding trial was produced by linoleic acid photoisomerization using a pilot scale unit and method of Jain and Proctor.[13] The refined, bleached and deodorized (RBD) soybean oil was provided by Riceland Foods (Stuttgart, AR).

Feeding and Egg Production. Feed Preparation. CLA oil produced by photoisomerization (18% CLA) was combined with RBD soybean oil to produce treatment oils containing 15%, 10%, 5%, 2.5% and 0% CLA. The fatty acid composition for the soybean oil and CLA oil are provided in Table 1. The feed used for the study was a pelleted commercial corn and soybean meal-based finisher diet provided by Cobb-Vantress (Siloam Springs, AR). Feed was formulated without meat or animal byproducts to meet or exceed minimum NRC (1994) standards for all ingredients. Treatment diets were produced by adding 10% (wt.) soy oil or CLA oil to the standard commercial feed and combined using a Hobart stand mixer.

Table 1. Fatty Acid Composition of Refined, Bleached, and Deodorized (RBD) Soy Oil before Photoisomerization, and Resulting CLA-Rich Soy Oil after 12 h Photoisomerization

Fatty acid	RBD Soy oil (g FA/100 g oil)	CLARSO (g FA/100 g oil)
Palmitic acid C16:0	12.2 ± 0.05	12.2 ± 0.02
Palmitoleic acid C16:1	0.09 ± 0.001	0.09 ± 0.001

trans, *trans* CLA	ND	13.1 ± 0.02
Total CLA	ND	18.15 ± 0.03

[1]Not detected.

Diet Administration. Animal procedures were approved by the University of Arkansas Institutional Animal Care and Use Committee (Protocol # 13033). One hundred single-comb white leghorn chicks were reared under standard commercial conditions. At 25 weeks, 60 hens were randomly chosen and assigned to single bird cages in blocks of 5 birds each, separated by 2 empty cages. All hens received the same standard commercial finisher diet until the feeding trial began at 33 weeks. Each soybean oil diet (15%, 10%, 5%, 2.5% and 0% CLA) was randomly assigned to 2 blocks of 5 birds each, resulting in 10 birds receiving each treatment diet. The remaining two hen blocks continued to receive standard commercial feed without additional soybean oil and served as a standard control group.

Egg Collection. After 12 days of treatment feed administration, eggs were collected daily, counted, and labeled with cage number and date for 20 days. Eggs were stored in a walk in cooler at 4 °C. Eggs used for analysis were refrigerated for either 0, 5, 10, 20, or 30 days prior to analysis.

Fatty Acid Analysis. Yolk Lipid Extractions. Total yolk lipids were extracted from quadruplicate eggs from each treatment and storage duration [$N = 120$] using a rapid hexane/isopropanol method.[17] A 0.5 g yolk sample was collected in a 7 mL glass vial and dissolved in 5 mL hexane/isopropanol (1:1, v/v), vortexed for 5 min, and allowed to settle. The liquid containing the lipid extract was decanted into a 50 mL plastic centrifuge tube and used for subsequent FAME preparation.

Fatty Acid Analysis as FAMEs. Fatty acid methyl esters (FAMEs) were prepared from all extractions using a rapid, micro FAMEs preparation method modified for the volume of lipid extract solution.[18] Decanted extraction samples in 50 mL centrifuge tubes were combined with 0.5 mL of a prepared 1% (wt.) heptadecanoic acid (C17:0) methyl ester solution in hexane. Then 1 mL of toluene and 4 mL of 0.5 M sodium methoxide in methanol were added to each tube. The centrifuge tubes were placed in a h 50 °C water bath for 10 min with constant agitation and then removed and cooled at ambient temperature for 2 min. Glacial acetic acid, 0.2 mL, was added to each tube to inhibit sodium hydroxide formation. Five mL of distilled water was added, followed by 2 mL of hexane. The tubes were vortexed for 2 min and then the immiscible layers were allowed to separate. The upper layer was pipetted out and dried over anhydrous sodium sulfate for 15–20 s.

Duplicate fatty acid profiles were obtained for each lipid extraction by GC with a SP 2560 fused silica capillary column (100 m × 0.25 mm i.d. × 2 μm film thickness; Supelco Inc. Bellefonte, PA), and a flame ionization detector (FID model 3800, Varian, Walnut Creek, CA). Samples of 3.0 μL were injected by autosampler. The FID settings were as follows: oven temp = 250 °C; sensitivity = 12, He gas = 30 mL/min, H2 = 31 mL/min, air = 296 mL/min, and over program time = 111 min. Total fatty acid composition, CLA concentration and CLA isomer concentration were calculated by the following equation:

$$[\%\text{fatty acid}] = ([\text{HME}] \times \text{sample peak area} \times \text{relative response factor})/\text{HME peak area}$$

The position of double bonds in CLA-rich soybean oil produced by photoisomerization[13] were previously determined by silver ion HPLC.[14] Fatty acid percent concentration were converted to mmoles of fatty acid/100 g yolk based on the molar mass of each fatty acid and lipid extract as constituting 32% of total yolk weight.

Statistical Analysis. Data were analyzed by ANOVA in response to dietary CLA concentration. Tukey's test was used to compare treatment means, which were deemed significant a $p \leq 0.05$. P-values comparing individual treatments were determined using orthogonal contrast analysis.

Viscosity Analysis. Triplicate yolks from all six treatment groups (standard control, soy control, 15%, 10%, 5%, and 2.5% CLA) were analyzed in duplicate as either freshly laid yolks (0 day), or after 20 or 30 day refrigerated storage [$N = 54$]. In addition, triplicate control, soy control, and CLA-rich eggs containing the highest dietary CLA concentration were analyzed in duplicate after 5 and 10 days of refrigerated storage [$N = 18$]. An AR-2000 Rheometer was used for viscosity analysis.[19] Each yolk sample was vortexed for 20 s and 2 aliquots of yolk were dispensed from a 1 mL auto pipet on the lower rheometer plate. A 40 mm diameter sand-blasted geometry was applied to the sample surface at a constant shear rate of 100 s^{-1}. The initial plate temperature was stabilized at 4 °C for 2 min and then heated at a constant rate of 10 °C/min until a final temperature of 60 °C was reached. Sheer stress (Pa) measurements were recorded 100x

[a]Soybean oils had 0% (soy control), 2.5%, 5%, 10% or 15% CLA concentrations. Concentrations are expressed as mmol of fatty acid per 100 g yolk. Connecting letters within the same row indicate significant differences in fatty acid concentration.

per minute. Viscosity was calculated as shear stress divided by the constant sheer rate.

Statistical Analysis. Yolk viscosity data has been determined to fit the Power Law in the temperature range of 4°- 60 °C, and can be adequately modeled by a nonlinear exponential 3-parameter model that describes the asymptote, viscosity at initial temperature, and decay rate (eq 1).[20] Parameter estimates were compared by analysis of means at an alpha level of 0.05 in response to storage duration and CLA concentration.

$$\text{Viscosity} = A + B \times e^{(C \times \text{Temp})} \quad \text{(eq 1)}$$

where A = asymptote, B = scale, and C = decay rate.

Correlations between viscosity at 4 °C and fatty acid compositions were determined for 0, 20, and 30 day eggs. Correlation values 0.30 and above indicate a weak linear relationship, values 0.50 and above indicate a moderate linear relationship, and values above 0.70 indicate a strong linear relationship. If the value is negative the paired items are inversely correlated.

Egg Quality Analysis. Egg Yolk Physical Properties. Duplicate eggs from duplicate treatment blocks were analyzed fresh (0 day), or after 20 or 30 days of refrigerated storage. Whole egg weights were measured and recorded, followed by yolk weights, which were weighed after being gently rolled on a Kim-wipe to remove any adhering albumen and chalazae. Yolk index (YI), defined as the ratio of yolk height to diameter, was measured using a caliper and recorded.

Vitelline Membrane Strength (VMS). The force required to puncture through the yolk vitelline membrane was determined using TA-XT2i Texture analyzer equipped with a 5 kg load cell and a 1 mm probe.[27] The probe was calibrated at 18 mm above the platform. The test speed was set at 3.2 mm/s and distance target mode was 13 mm. The peak force (g) was recorded as VMS for quadruplicate eggs from each treatment group on each refrigerated storage duration.

Yolk pH and Moisture Content. Yolk pH was measured in triplicate on day 0, 20, and 30 d eggs. Yolk moisture content was determined gravimetrically in duplicate eggs during the 30 d refrigerated. Yolks were dried in an oven at 100 °C for 20 h.[21]

Statistical Analysis. Data were analyzed according to a split-plot design, with dietary CLA concentration as the whole plot and duration of egg storage as the subplots, to determine main effects of dietary CLA and duration of storage, and their interactions. Tukey's test was used to compare treatment and main effect means, as appropriate. When dietary CLA by refrigeration duration interactions were observed, comparisons among treatments were made. Otherwise, comparisons were made among main means.

RESULTS AND DISCUSSION

Fatty Acid Analysis. Total yolk CLA, CLA isomers and PUFA concentrations are presented in Table 2. Egg yolk total CLA increased linearly as dietary CLA levels increased (mmol CLA/g yolk = 0.05 + 0.18 g CLA/kg feed, R^2 = 0.8). *trans, trans* CLA was the most abundant isomer in all CLA-rich yolks, and increased linearly in response to total CLA in the diet (mmol *t,t* CLA/g yolk = 0.02 + 0.1 g CLA/kg feed, R^2 = 0.77). Yolks with the lowest CLA concentration had 42% of CLA in *t,t* form, while yolks with the greatest CLA levels had 53% in *t,t* form. The *c*-9, *t*-11 CLA concentration was similar in all CLA yolks, but its proportion of total CLA decreased from 28% to only 5% in response to higher CLA levels in the diet. The proportion of *t*-10, *c*-12 to total CLA was similar in all CLA yolks at about 15%, and its concentration increased linearly with CLA in the diet (mmol *t*-10,*c*-12 CLA/g yolk = −0.02 + 0.04 g CLA/kg feed, R^2 = 0.80). All other CLA isomers maintained similar proportions of total CLA, and increased linearly in response to dietary concentration. However, previous studies reported that the *cis*-9, *trans*-11 CLA isomer was preferentially incorporated in CLA yolks, whereas the *t*-10, *c*-12 incorporation was less efficient.[2] In contrast, when *t,t* CLA-rich soybean oil was used in the feed, *t,t* CLA was preferentially incorporated, followed by *t*-10, *c*-12.

Linoleic and linolenic acid concentrations were similar in all eggs produced from soy oil-rich diets, and were significantly greater than the standard control yolks ($p < 0.001$). While standard control egg yolks had the greatest arachidonic acid (AA) concentration at 0.17 mmol/100 g yolk, AA levels in the other treatment yolks had such a large variation that no significant differences could be determined relative to control yolks. Eicosapentaneoic acid (EPA) concentration was greatest in yolks from the soy control diet, but its concentration decreased significantly with increasing CLA concentration ($p < 0.001$). However, yolks containing 0.5 mmol of CLA per 100 g yolk contained a similar amount of EPA when compared with standard control eggs. Docosahexaneoic acid (DHA) concentration was also greatest in soy control yolks and decreased with increasing CLA concentration ($p \leq 0.003$). However, DHA levels in egg yolks with the greatest CLA concentration were similar to DHA levels in standard control egg yolks ($p = 0.60$).

[a]Yolks were stored at 4 °C prior to analysis. Variable estimates were compared by analysis of means at 0.05 alpha-level for each storage duration. Connecting letters within the same row indicate significant differences from the model mean.

Previous studies have reported significantly lower long chain PUFA levels in CLA-rich eggs and have deemed this effect undesirable.[1,2,8] Ahn et al. reported a decrease in AA concentration from 3.7% to 2.7% of total FA when hens were fed 2.5% CLA, while Chamruspollert et al. reported a more dramatic drop in AA levels from 3.9% to 2.6% of total FA from hens fed 2.5% CLA.[1,8] However, this consequence of CLA enrichment seemed to be lessened using the *t,t* CLA-rich soybean oil, as standard control yolks contained 1.7% AA of total FA while CLA-rich yolks produced from 1.5% CLA in the diet lowered AA concentration to 1.4% of total FA (0.13 mmol CLA/100 g yolk). Likewise, Szymczyk and Pisulewski reported a DHA decrease from 1.4% to 0.2% of total FA with 2% CLA present in the diet.[2] However, DHA levels in CLA-rich yolks and control yolks were not significantly different in this study. The reduction of these fatty acids and subsequent increase in stearic acid has been attributed to stearoyl-coenzyme A desaturase inhibition in the liver.[22,23] This lesser decrease in DHA may be preferable, when compared with eggs produced from feeding *cis,trans* mixtures.

J. Agric. Food Chem. 2015, 63, 2506−2513

Table 3 presents yolk saturated and monounsaturated fatty acid levels. Egg yolk total saturated fatty acid (SFA) content significantly increased as yolk total CLA concentration increased ($p < 0.001$), while soy control egg yolks had significantly lower saturated fat levels in comparison to standard control yolks ($p = 0.02$). Previous CLA feeding trials using *cis,trans* isomer mixtures observed a 34% increase in SFA levels with only 0.5% CLA in the diet.[7] However, CLA-rich soybean oil raised SFA levels by only 28% with 1.5% CLA in the diet, relative to soy control yolks.

Table 3 also shows that egg yolk monounsaturated fatty acid (MUFA) concentration decreased significantly in yolks produced from all soy oil diets. The MUFA decrease became more substantial as yolk CLA concentration increased. Previous studies reported a 32% drop in MUFA concentrations.[7] This study determined only 25% decrease in MUFA concentration in yolks containing the greatest CLA concentrations, relative to the control yolks. The overall trends in fatty acid composition modifications are similar to previous reports with a significant increase in saturated fatty acids and subsequent decrease in monounsaturated fatty acids.[1,2,4,5] However, *t,t* CLA-rich soybean oil reduced these changes relative to previous studies.

Viscosity analysis. *Fresh Egg Yolks.* Table 4 shows the initial viscosity, asymptote (lowest part of curve), and average decay rate. Supplemental Figure 1 shows the differences in viscosity among yolks on days 0, 20, and 30. On day 0 yolks containing 2.7 mmol of CLA had significantly greater initial viscosity than all other yolk types ($p < 0.05$). However, initial yolk viscosity was not consecutively lowered with respect to decreasing yolk CLA concentration. For example, egg yolks containing 0.9 mmol CLA displayed a significantly lower initial viscosity compared to all other yolks. Analysis of means revealed that fresh egg yolks from soybean oil-enriched diets displayed viscosities that leveled off at similar values (asymptote) while standard control yolk leveled off at a significantly lower viscosity. The viscosity decay rates were faster in response to increasing yolk CLA concentration, while control and soy control yolks displayed similar decay rates.

Correlations between initial viscosity and fatty acid composition in day 0 yolks revealed that viscosity was moderately correlated with total SFA ($R = 0.43$) and CLA concentration ($R = 0.54$), and moderately inversely correlated with EPA concentration ($R = -0.57$). The fatty acid composition shows that EPA concentrations in 0.9 and 2.0 mmol CLA yolks are similar, and that they drop significantly in 2.7 mmol CLA yolks. It is not completely apparent why 0.9 mmol CLA yolks displayed such a low initial viscosity compared to all other yolks, but it may be due to a synergistic effect of EPA and CLA levels, along with a SFA level that is not significantly different from control yolks.

Egg Yolks Refrigerated for 5 days. After 5 days of refrigeration CLA yolks have a significantly greater initial viscosity of 3 Pa·s than control yolks with an initial viscosity of 1.9 Pa·s, while soy control yolks had a significantly lower initial viscosity at 1.6 Pa·s than control yolks. The viscosity decay rate was significantly faster in CLA yolks, followed by soy control, and control yolks. Control yolk viscosity had a greater asymptote than CLA or soy control yolks, which had similar asymptotes.

Egg Yolks Refrigerated for 10 days. CLA yolks continued to have significantly greater initial viscosities in comparison to both the control and soy control yolks. However, both CLA and soy control yolks stored for 10 days had initial viscosities that were actually greater than their 5 day old counterparts. Although asymptote estimates provided by modeling indicate that CLA yolk levels off at a greater viscosity than control yolks, the statistical significance was not apparent from analysis of means. Viscosity decay rates were similar between control yolks, while CLA yolk viscosity decreased significantly more quickly in response to increasing temperature.

Egg Yolks Refrigerated for 20 days. Decreases in yolk initial viscosity seem to correspond to decreasing CLA concentration, but 0.9 mmol CLA yolks exhibited lower initial viscosity than 0.5 mmol CLA yolks. Control yolks, soy control yolks, and 0.9 mmol CLA yolks leveled off at similar viscosities, while all other CLA yolks displayed significantly greater asymptote values. Decay rates were similar among all yolk types. Correlations on viscosity and fatty acid profile from day 20 yolks revealed that viscosity was strongly correlated with CLA concentration ($R = 0.81$), total SFA ($R = 0.74$), and palmitic acid concentration ($R = 0.72$), and had a strong inverse correlation with oleic acid concentration ($R = -0.72$). In addition, initial viscosity was moderately inversely correlated with EPA concentration ($R = -0.69$). It seems that as storage duration increases, CLA and saturated fat concentration were correlated with increasing yolk viscosity, while oleic and EPA concentration were negatively correlated with viscosity.

Egg Yolks Refrigerated for 30 days. Yolks containing 2.0 and 2.7 mmol CLA exhibited nearly identical viscosity trends and have significantly greater initial viscosities than all other yolk types. Control, soy control, and 0.9 mmol CLA yolks have similar initial viscosities, while 0.5 mmol yolks exhibit significantly lower initial viscosity than all other yolk types. All viscosities level off at similar levels regardless of CLA concentration. Multivariate analysis revealed only slight correlations between viscosity and fatty acid composition, namely, myristic acid ($R = 0.46$), palmitic acid ($R = 0.35$), CLA ($R = 0.36$), and a slight inverse correlation with DHA ($R = -0.38$).

In both control and soy control yolks, viscosity is similar during the first 10 days of refrigerated storage, and then a significant decrease is observed after 20 days refrigeration. Alternatively, the CLA-rich yolks have a significantly greater overall viscosity, and a marked decrease in viscosity is only apparent after 30 days of refrigeration. It may be that changes in viscosity after 30 days storage were more influenced by changes in other yolk quality parameters, such as moisture content and pH, rather than fatty acid composition.

CLA yolks containing the greatest CLA enrichment were considerably more viscous at low temperatures and retained their thickness for a longer storage duration. This effect may be advantageous in the preparation of mayonnaises and salad dressing recipes, where commercial products' microbial safety is more likely controlled by the acidity of the product, rather than a heat treatment. However, this increased viscosity was not solely a function of increased CLA concentration, but rather the distinct fatty acid composition changes that were a result of CLA enrichment. It was anticipated that the greater viscosities in CLA-rich yolks would be most highly correlated with saturated fatty acid content because a previous study identified significantly increased concentrations of saturated triacylglycerol species.[16] However, a relationship between SFA and viscosity was only apparent after the yolks had been refrigerated for 20 days. It seems that yolk viscosity was a collective effect of the fatty acid composition, not just one specific type of fatty acid.

[a]Connecting letters within the same column identify values with no significant difference at the 0.05 α-level.

Yolks with most CLA enrichment had the greatest viscosity. The viscosity changes during refrigeration at 4 °C indicate that CLA eggs that have been stored up to 20 days may provide improved food texture, mouth feel characteristics compared to fresh control eggs. This would enhance the viscosity of mayonnaises and salad dressings, custard desserts, and sauces, which is the most desirable sensory attribute by consumers.[24]

Egg Quality Analysis. *Egg Yolk Physical Properties.* Table 5 shows whole egg weights of day 0 eggs, and eggs refrigerated for 20 and 30 days. Day 0 eggs showed the greatest variability in whole egg weight, so no statistical differences could be determined. However, during refrigeration all egg weight variability decreased. Inclusion of control soy oil and CLA soy oil in the diet significantly reduced whole egg weights, relative to hens fed the unmodified control diet (p = 0.009), despite the additional metabolizable energy added with soy oil supplementation. Eggs containing the most CLA (2.7 mmol/100 g yolk) had significantly lower whole egg weights after 20 and 30 days storage. However, all other CLA-rich egg weights were not significantly different from the soy control eggs (p = 0.65). Storage time did not have a significant effect overall on whole egg weights (p = 0.98). However, eggs produced from control soy oil or CLA-soy oil diets seemed to lose weight during storage while control yolks' total weight increased during storage. As an egg ages, it loses moisture and CO_2 through the shell pores, and both loses are dependent on storage temperature and relative humidity. While the decrease in total egg weight may be due to non-CLA soy fatty acids, CLA seemed to enhance this weight loss effect and may have some influence on how the egg is transpiring during storage. Other studies have reported conflicting results on total egg weight. Suksombat et al. (2006) reported significant egg weight decreases with CLA, while another study determined no difference among CLA and control yolk weights.[5,8]

Table 5 shows the yolk weights of control and CLA-rich eggs as analyzed at 0, 20, and 30 days of storage. Egg yolks containing 2.0 mmol of CLA were significantly smaller than soy control yolks (p = 0.006). However, all other CLA yolk weights were not significantly different from both control yolks. After 20 and 30 days of storage no significant differences could be determined among yolk types. CLA-rich soy oil prevented yolk weight reduction that has been previously reported from *cis, trans* CLA supplementation.[5]

There were no differences in yolk index (YI) at day 0 across in treatments, so YI was unaffected by CLA-rich soy oil supplementation (p = 0.60, Table 5). After 20 days there were no differences in yolk indices (p = 0.73). After 30 days of storage YI the only significant difference was that the 2.0 mmol CLA yolk YI were smaller than the controls. CLA-rich yolks have been previously reported to affect YI in comparison with control yolks.[6] However, this study determined that changes in YI were more dependent on storage time than CLA content. In contrast, previous findings reported the effect of CLA but did not account for normal storage time and temperatures. For example Kim et al. stored eggs at −50 °C, which may have altered YI, as yolks irreversibly gel during freezing.[6] Schafer et al. observed very tall CLA yolks and larger YI than control yolks but did not indicate egg storage time, which would produce very different results from those reported in our study.[29]

DOI: 10.1021/jf504759w
J. Agric. Food Chem. 2015, 63, 2506−2513

Vitelline Membrane Strength. At day 0 VMS was greatest in control, soy control, and yolks containing 0.5 mmol of CLA ($p < 0.001$, Table 5). After 20 days eggs with the highest CLA had the strongest VMS, while control yolks has the weakest VMS. After 30 days of refrigeration yolks containing 0.5 and 0.9 mmol CLA had the strongest VMS, followed by 2.0 mmol CLA, standard control, and 2.7 mmol CLA yolks, while soy control yolks were still significantly weaker.

CLA incorporation maintained VMS up to 20 days, while diets containing unmodified soy oil resulted in weaker membranes after 5 days (data not shown). Vitelline membrane strength has been reported in omega-3 eggs, but not in previous CLA feeding trials. CLA-rich yolks with 2.7 mmol CLA did have significantly lower membrane strengths at day 0 and were maintained through day 20. After 30 days 2.7 mmol CLA yolks were significantly stronger than soy control eggs. Yolks containing 0.5 and 0.9 mmol CLA had the greatest VMS after 30 days of refrigeration. An omega-3 egg study determined that these designer eggs had significant decreases in vitelline membrane strength, resulting in shorter shelf life.[25] The fact that CLA yolks VMS increased during storage may be beneficial for shelf life and storage.

Yolk pH and Moisture Content. Yolk pH was similar in all day 0 egg yolks at 6.2 (Table 5). After 20 days of refrigerated storage, both types of control yolks, and the two lower CLA yolk concentrations had not changed significantly, while the 2.0 and 2.7 mmol CLA yolks had pH values above 6.3. After 30 days in refrigeration, control yolks and yolks containing 0.5 mmol CLA had pH at 6.08 and 6.05, respectively, while the yolks containing greater levels of CLA had pH all above 7.15. These changes in pH were similar to previous yolk CLA enrichment reports.[7]

Table 5 shows changes in yolk moisture content during 30 days of refrigeration. Yolk moisture content was similar among day 0 eggs regardless of CLA concentration at 47−48%, and increased significantly in response to refrigerated storage ($p < 0.001$). This increase was significantly greater as yolk CLA concentration increased ($p = 0.008$). Yolks containing the three greatest CLA concentrations had moisture contents of 53% after 30 days of refrigeration, while both control and soy control yolks and 0.5 mmol CLA yolks had moisture contents slightly lower than 49%.

Both pH and moisture content increased with increased yolk CLA concentrations, which has been speculated to be due to increased permeability through the vitelline membrane.[7] However, other CLA egg studies have reported some pink discoloration in the albumen after refrigeration, and have also attributed the effect to membrane permeability.[26] This effect was not observed from *trans, trans* CLA eggs up to 30 days. Further investigations on the vitelline membrane physiochemical and structural properties may provide further insight into the aging and shelf life of both CLA and standard eggs.

This study reported increase in saturated fatty acid in CLA eggs, relative to conventional eggs but not to the same degree as described in previous studies.[1,2,5] Viscosity and VMS have not been previously reported in CLA eggs. Both determinations were greater than those of the control yolks, and these qualities were preserved longer throughout storage. These enhanced qualities may benefit egg shelf life and provide advantages in prepared egg based dressings and sauces. The study did not find changes in CLA yolk weights or yolk indices, relative to controls. In contrast, other studies report CLA eggs had smaller yolk weights and larger yolk indices relative to conventional eggs, but storage conditions were either unspecified or different from those in this study. Egg yolk viscosity and VMS in CLA eggs is worthy of further study, as they may affect egg quality and have food processing applications.

tion is available on Pickering emulsions stabilized by the particles of biological origin, such as cellulose nanocrystals,[17] chitin nanocrystals,[18] phytosterol,[19] modified starch,[20] and zein colloid particles.[16,21] Those works focused mainly on the fabrication and physical performances of the emulsions; little is known about their oxidant stability.

Zein, a prolamin, is the major storage protein in corn or maize. It contains sharply defined hydrophobic and hydrophilic domains at its surface and is capable of self-assembly to form a wide variety of mesostructures.[22] Zein particles have been studied for delivery and encapsulation,[23] but their use as Pickering emulsifiers are still limited. Theoretically, the Pickering emulsifiers should remain insoluble in both phases and remain intact over the lifetime of the emulsions.[12,16] Therefore, zein particles with partial wettability possesses promising potential in the manufacture of food-grade Pickering emulsions. de Folter et al. reported that zein particles (approximately 80 nm) were able to stabilize oil-in-water emulsions, but emulsion stability should be improved because free oil appeared after 3 days of storage.[21] Zein has a high proportion of apolar amino acid (>50%); as a result, the surface of zein particles seems quite hydrophobic. They tend to aggregate in the aqueous circumstance and are hard to arrange at the oil−water interface, leading to unstable Pickering emulsions. Some pertinent strategy should be utilized to tune the surface wettability of zein particles so as to form stable Pickering emulsions, for example, the interaction between proteins and polysaccharides.

Curcumin, a hydrophobic polyphenol with yellow color, is a major constituent extracted from the dried root of turmeric, the rhizome of the herb *Curcuma longa*.[24] It is an effective and potent antioxidant.[25] In addition, curcumin is a fluorophore, and its fluorescence can be monitored by excitation by an argon laser at 488 nm.[26] Curcumin was encapsulated in silica nanoparticle stabilized Pickering emulsion to study its fat during storage and simulated digestion.[27] In this paper, we demonstrate the fabrication of stable, soap-free, and edible Pickering emulsions based on fully natural renewable resources using protein/polysaccharide complex particles. This work attempted to protect lipid droplets of emulsions from peroxidation via manipulating the emulsions' interfacial framework using the Pickering mechanism and interface cargo of antioxidant. For this purpose, dual-function particles acting as Pickering emulsifier and interfacial transport vehicles of curcumin (a model antioxidant) were fabricated via a simple co-assembly approach. We propose a novel strategy to target accumulation of antioxidants at the interface via dual-function particles and compare the oxidative stability of encapsulated corn oil via either shell or core antioxidant. Pickering emulsions were characterized by confocal laser scanning microscopy (CLSM), particle size distribution, zeta potential, and physical stability measurements. The oxidative status of the samples was assessed by monitoring the formation of primary and secondary products during thermally accelerated oxidation storage. In addition, a schematic illustration of the formation pathway of zein/CH complex particle (ZCP)-stabilized antioxidant emulsions was proposed to correlate the oxidative stability of Pickering emulsions with their interfacial architecture.

MATERIALS AND METHODS

Materials. Zein (product Z 3625) and chitosan were purchased from Sigma Chemical Co. (St. Louis, MO, USA). According to the manufacturer, the molecular weight of the chitosan was approximately 500 kDa and the degree of deacetylation was 90%. Fluorescent dyes including Nile Red, Nile Blue A, and fluoresceine 5(6)-isothiocyanate mixed isomers (FITCs) were obtained from Sigma-Aldrich, Inc. (St. Louis, MO, USA). Chitosan was labeled by FITCs to check its distribution in emulsions. In short, the FITC solution (in ethanol) was added to chitosan solution, and FITC-labeled chitosan was precipitated using 0.2 mol L^{-1} NaOH and obtained via centrifugation (4000*g* 15 min) after 1 h of incubation at 40 °C. The unreacted FITC was removed before freeze-drying by dialysis against deionized water under darkness until no free FITCs were detected. 1,1,3,3-Tetramethoxypropane, thiobarbituric acid, and trichloroacetic acid were purchased from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China). Corn oil was purchased from a local supermarket (Guangzhou, China). All other chemicals used were of analytical grade.

Solution Preparation. Zein stock solutions was produced by dissolving 10.0 g of zein powder in 100 mL of aqueous ethanol binary solvent (70 v/v %). Curcumin-loaded zein solutions were prepared by adding curcumin to the preceding zein solutions at curcumin-to-zein ratios of 1:100, 1:50, and 1:20, respectively. Chitosan (CH) solutions were produced by dispersing 0.5 g of chitosan powder into 100 mL of 1% acetic acid under magnetic stirring overnight to facilitate chitosan hydration.

Particle Synthesis. Dual-function ZCP (or ZCP-cur) was fabricated via a so-called antisolvent procedure. All operations were at room temperature. Curcumin-loaded zein solutions were trickled into CH solutions within 2 min under shearing at 5000 rpm using an Ultraturax T10 homogenizer. After another 10 min of shearing, the remaining ethanol in the particle dispersions was removed by an RV 10 digital rotary evaporator (IkA-Works Inc., Staufen, Germany). Finally, the zein and CH concentrations in the dispersion were 7 and 0.35%, respectively. The plain ZCP was produced according to the same procedure without curcumin addition. Particle size, shape, and ζ-potential of fresh ZCP and ZCP-cur dispersions were characterized prior to the emulsion preparation.

Preparation of Pickering Emulsion. The preceding ZCP and ZCP-cur were utilized to prepare Pickering emulsions, ZCP-stabilized emulsions (ZCPEs), and ZCP-cur stabilized emulsions (ZCP-curEs). All emulsions were prepared using an oil−water ratio of 50:50. In brief, 5 mL of corn oil was added to 5 mL of the particles suspensions in a glass vial, and the resultant mixtures were sheared using an Ultraturax T10 homogenizer (IkA-Works Inc.) at 6000 rpm for 5 min at room temperature to yield the Pickering emulsions. For ZCPE-cur, curcumin was incorporated in corn oil at curcumin-to-zein ratios of 1:100, 1:50, and 1:20, respectively, prior to the emulsion preparation.

Zeta-Potential Measurements. Zeta potentials of the complex particle dispersions and Pickering emulsions were determined by a Zetasizer Nano (Malvern Instruments Ltd., Worcestershire, UK) at room temperature. Each value represents the average of at least three independent trials.

Contact Angle Measurements. Three-phase contact angle (θ) measurements were measured using an OCA 20 AMP (Dataphysics Instruments GmbH, Germany) equipped with a high-speed video camera. Colloid particle dispersions were freeze-dried to yield particle powders that were compressed to produce tablets of 13 mm in diameter and 2 mm in thickness. The tablets were then immersed in corn oil bath, and 2 μL of Milli-Q water was deposited gently on the tablets using a high-precision injector. The drop image was photographed using the high-speed video camera at a rate of 10 pictures per second, and the LaPlace−Young equation was utilized to fit the profile data of the droplet to calculate the θ. Measurements were averaged over at least 10 droplets.

Morphology Observation. Topographic structures of ZCP were analyzed by a Zeiss Merlin Field emission scanning electron microscope (Zeiss, Oberkochen, German). The freeze-dried ZCP powers were utilized to investigate their morphological attributes, and they were loosely glued onto a conductive adhesive mounted on a stainless steel stage. Subsequently, they were coated with a thin (<20 nm) conductive gold and platinum layer using a sputter coater (Hummer XP, Anatech, Union City, CA, USA). Representative SEM images were reported.

J. Agric. Food Chem. 2015, 63, 2514−2524

Particle Size Distribution of Pickering Emulsion. Droplet size distributions of the Pickering emulsion were measured immediately after the emulsification and after 2 and 7 weeks of storage at room temperature, using a Mastersizer 2000 (Malvern Instruments Ltd.). The samples were diluted in deionized water at 2000 rpm until an obscuration rate of 10% was obtained. The Mie theory was applied by considering the following optical properties for corn oil droplets: a refractive index of 1.330 and absorption of 0.001. Volume mean diameter ($D_{4,3}$) and surface mean diameter ($D_{3,2}$) parameters were calculated from particle size profiles of the Pickering emulsions according to eqs 1 and 2, respectively.

$$D_{4,3} = \frac{\sum n_i d_i^4}{\sum n_i d_i^3} \quad (1)$$

$$D_{3,2} = \frac{\sum n_i d_i^3}{\sum n_i d_i^2} \quad (2)$$

n_i is the number of droplets of a determined size range, and d_i is the droplet diameter.

Stability Test. *Long-Term Storage Stability.* Pickering emulsions were sealed in glass test tubes for 7 weeks at room temperature. Droplet size and size distributions as well as visual appearance of the emulsions were monitored periodically.

Centrifugation Stability. Emulsion stability was checked by centrifugation for 30 min at 5500 *g*, and the thickness of the creaming layer was measured with a digital caliper.[17]

Creaming Stability. The creaming stability of the emulsions was analyzed via creaming index (CI).[28] Emulsion samples were poured into glass tubes (2.8 cm in diameter 7.5 cm in height), and the tubes were sealed to prevent moisture evaporation. The samples were monitored for 7 weeks. The CI values were calculated according to eq 3

$$\mathrm{CI}\ (\%) = H_s/H_e \quad (3)$$

where H_s is the serum layer height and H_e is the total emulsion height.

Confocal Laser Scanning Microscopy. CLSM experiments were performed according to the procedure of Ma et al.,[29] using a Leica TCS SP5 CSLM (Leica Microsystems Inc., Heidelberg, Germany). Various specimens of the Pickering emulsions were dyed with a mixed fluorescent dye solution consisting of 1 mg mL^{-1} Nile Red and 1 mg mL^{-1} Nile Blue A (in isopropyl alcohol). The dyed emulsions were put on concave slides, and then the concave slides were covered with coverslips. Finally, glycerol was coated around the coverslips to seal the samples. The fluorescent dyes were excited by either an argon laser at 488 nm for Nile Red or a helium neon (He−Ne) laser at 633 nm for Nile Blue A. In addition, curcumin fluorescence was monitored by exciting by an argon laser at 488 nm,[26] reflecting its distribution within the Pickering emulsions. FITC-labeled chitosan was utilized to synthesize ZCPs and yield Pickering emulsion, and FITC fluorescence was visualized using an argon laser at 488 nm to explore the role of chitosan in the formation of ZCP-stabilized Pickering emulsions.

Lipid Oxidation Measurements. The fresh emulsions (10 mL) were immediately placed in a sealed screw-cap glass tube and kept in an oven for 22 days at 40 °C to accelerate oxidation of corn oil. An aliquot of 0.5 mL of emulsions was periodically taken out to determine the primary and secondary oxidant products.

Primary Lipid Oxidation Products. Lipid hydroperoxide, as the marker of primary products of lipid oxidation, was measured according to the procedure described by Tong et al.[30] An aliquot of 200 mg of the Pickering emulsions was mixed with 1.5 mL of isooctane/2-propanol (3:1, v/v) by vortexing (10 s, three times), and the organic phase was isolated by centrifugation (2000*g*, 5 min). An aliquot of 0.2 mL the resultant supernatant was admixed to 2.8 mL of methanol/1-butanol (2:1, v/v) solution, followed by 15 μL of 3.94 M ammonium thiocyanate and 15 μL of ferrous iron solution. Ferrous iron solution was prepared by mixing $BaCl_2$ and $FeSO_4$ to final concentrations of 0.132 and 0.144 mol L^{-1}, respectively. After 20 min of incubation, the absorbance of the solutions was read at 510 nm using an UV−visible spectrophotometer (UV-2300, TianMei Techcomp Limited., Shanghai, China). Hydroperoxide concentrations were calculated from the standard curve of hydrogen peroxide.

Secondary Lipid Oxidation Products. The secondary oxidation products were monitored via the thiobarbituric acid reactive substances (TBARS) protocol.[30] This approach was developed to quantify malondialdehyde (MDA), one of two marked biproducts of lipid peroxidation. In brief, an aliquot (0.2 mL) of the Pickering emulsions after accelerated storage for 22 days was admixed with 1.8 mL of deionized water and 4.0 mL of thiobarbituric acid (TBA) solution, which was prepared by dissolving 15 g of trichloroacetic acid (15% w/v) and 0.375 g of TBA (0.375%) in 100 mL of 0.25 mol L^{-1} HCl. The resulting mixtures were heated for 15 min in a boiling water bath and then cooled to room temperature using tap water. Finally, the mixture was centrifuged at 2000*g* for 15 min. The MDA−TBA adducts formed from the reaction of the MDA in the emulsion samples with the TBA reagent were detected colorimetrically, and the absorbance was read at 532 nm. The MDA concentrations were calculated from a standard curve made from 1,1,3,3-tetraethoxypropane.

Hexanal Measurements. An aliquot (8 mL) of fresh emulsions was put into 10 mL headspace vials, and the vials were sealed with silicone rubber Teflon caps using a crimper. After thermally accelerated storage (40 °C, 22 days) in a dark oven, the headspace hexanal of the Pickering emulsion specimens was determined using a Trace DSQ II GC-MS (Thermo-Fisher Scientific, Waltham, MA, USA) according to the procedures of Panya et al.[31] and Wan et al.[32] In brief, solid phase microextraction (PME) trials were performed as follows. A 75 μm stable flex PME fiber (carboxen/polydimethylsiloxane, Supelco, Bellefonte, PA, USA) was inserted in the sample headspace through a vial septum, and the PME process was continued for 10 min at 55 °C. The PME fiber was desorbed in the GC detector at a split ratio of 1:10 (250 °C, 3 min). GC analysis of the headspace hexanal was carried out using a TR-5MS capillary column (30 m × 25 mm × 0.25 μm). The temperatures of the injector, flame ionization detector, and oven were 250, 250, and 60 °C, respectively. Test time was set at 15 min. Triplicate tests were performed for each emulsion sample.

Statistics. Statistical analyses were performed using an analysis of variance (ANOVA) procedure of the SPSS 13.0 statistic analysis program, and the differences between means of the trials were detected by a least significant difference (LSD) test ($P < 0.05$).

RESULTS AND DISCUSSION

Wetting Properties. The wettability of the particles at the interface plays a crucial role in the formation of stable Pickering emulsions. The partial wettability attributes can facilitate efficient packing of particles at the oil−water interface to form steric hindrance against droplet coalescence. Contact angle measurement (CAM) was a potent technique for evaluating the wetting properties of a surface. The wetting properties of ZCP were investigated by measuring three-phase contact angles (θ) of ZCP films that were immersed in corn oil. Figure 1 shows typical images of water droplets deposited to zein films immersed in corn oil. The θ of zein particles without chitosan was 112.73 ± 1.29°. This result may be associated with the nature of zein possessing >50% hydrophobic amino acid. The decrease in the θ of the ZCP indicates a successful surface coating of zein particles with chitosan (Figure 1). The association between chitosan and zein particles at acidic pH via weak electrostatic interaction between the positively charged amino of chitosan and the nonprotonated carboxyl groups of zein at acidic pH (~3.5) caused an increase in the free amino and hydroxyl group at the surface of zein particles, thereby lessening their hydrophobic characteristics. The θ data (about 82°) clearly demonstrated that the ZCP at CH-to-zein ratios of 1:20 and 1:10 are potentially suitable materials as Pickering emulsifier to yield oil-in-water Pickering emulsions. In contrast, the θ values of the ZCP at the CH-to-zein ratio of 1:50 did not situate between chitosan-free zein particles and

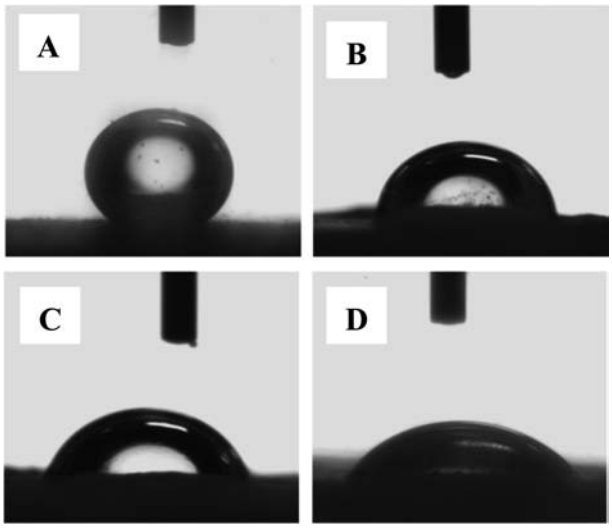

Figure 1. Typical three-phase contact angles (θ) of ZCP films as a function of CH-to-zein ratios: (A) plain zein; (B) 1:10; (C) 1:20; (D) 1:50.

ZCP with the CH-to-zein ratios of 1:10 and 1:20. The underlying mechanism for this phenomenon was unknown, but it was repeatable. Furthermore, in other experiments, we utilized *n*-tetradecane to replace corn oil and found a similar phenomenon. In this work, the ZCPs produced at a CH-to-zein ratio of 1:20 were utilized to fabricate Pickering emulsions.

Particle Size Characterization of ZCP and ZCP-cur. Figure 2B shows typical droplet size distribution of ZCP and ZCP-cur. The ZCP showed a nearly monomodal droplet size distribution, and the position of the maxima appeared at 1−2 μm, which was consistent with morphological observation by the SEM (Figure 2C). Curcumin loading changed the size distributions of the particles from a nearly narrow monomodal (ZCP) to bimodal (ZCP-cur) patterns, and two overlay peaks at 0.9 and 8−10 μm were observed in the size distribution profiles (Figure 2B). This phenomenon indicated that curcumin loading affected the self-assembly process of amphiphilic zein. Concomitantly, the $D_{3,2}$ and $D_{4,3}$ were calculated to reflect quantitatively the changes in the size of ZCP due to the curcumin additions. Curcumin loadings did not cause marked alterations in the $D_{3,2}$ and $D_{4,3}$ of the ZCP (Table 1). In theory, the desorption energy of particles can easily reach several thousands of k_BT (T, absolute temperature; k_B, Boltzmann constant) even for nanoscale particles at the oil−water interface.[33] This suggests that once the solid particles are absorbed at the interface, they are anchored irreversibly. Furthermore, the larger the particles, the more the detachment energy.[13] Therefore, micrometer-sized ZCPs possess a promising potential to form stable Pickering emulsions with food-grade status once they are absorbed at the oil−water interface.

Table 1. Mean Particle Size and Zeta Potentials of Zein/CH Particles Loaded with Various Curcumin Concentrations[a]

particle type	cur/zein ratio	$D_{3,2}$ (μm)	$D_{4,3}$ (μm)	zeta potential (mV)
ZCP[b]	0	1.58 ± 0.51	6.03 ± 0.38	64.0 ± 1.6
ZCP-cur[c]	1:100	1.73 ± 0.33	6.14 ± 1.92	64.9 ± 1.9
ZCP-cur[c]	1:50	1.81 ± 0.11	5.15 ± 0.35	61.7 ± 0.5
ZCP-cur[c]	1:20	2.07 ± 0.35	5.64 ± 0.58	57.3 ± 1.9

[a]Values are expressed as the means and standard deviations of three measurements. [b]ZCP, zein/CH complex particles. [c]ZCP, zein/CH complex particles with various curcumin loadings.

Zeta potentials of ZCPs with or without curcumin ranged from 57.3 ± 1.9 to 63 ± 1.6 mV (Table 1), implying the presence of strong electrostatic repulsion among lipid droplets stabilized by zein/CH microspheres. The correlation between effective Pickering stabilization and particle flocculating conditions was well-established experimentally,[34] and it was also confirmed theoretically.[35] ZCPs flocculated after 12 h of storage at room conditions to form a deposit layer at the bottom of the glass tube (Figure 2A), supporting the formation of stable Pickering emulsions.

Physical Performance of Pickering Emulsions. Emulsion type (either o/w or w/o) was deduced by observing what happened when a drop of emulsions was added to either oil or water. ZCP-stabilized Pickering emulsion rapidly dispersed when it was added to water, confirming that it is an o/w emulsion.

Visual Appearance. Figure 3 shows the visual appearance of the Pickering emulsions stabilized by ZCP and ZCP-cur. Visual inspection revealed the fresh emulsions remained homogeneous without noticeable sign of creaming or phase separation. ZCP-stabilized Pickering emulsions were milky white, whereas the emulsion color changed from milky white to yellow upon incorporation of curcumin, irrespective of curcumin locations and/or concentrations (ZCP-curE and/or ZCPE-cur) (Figure 3). A lipid droplet-enriched cream layer gradually appeared as a

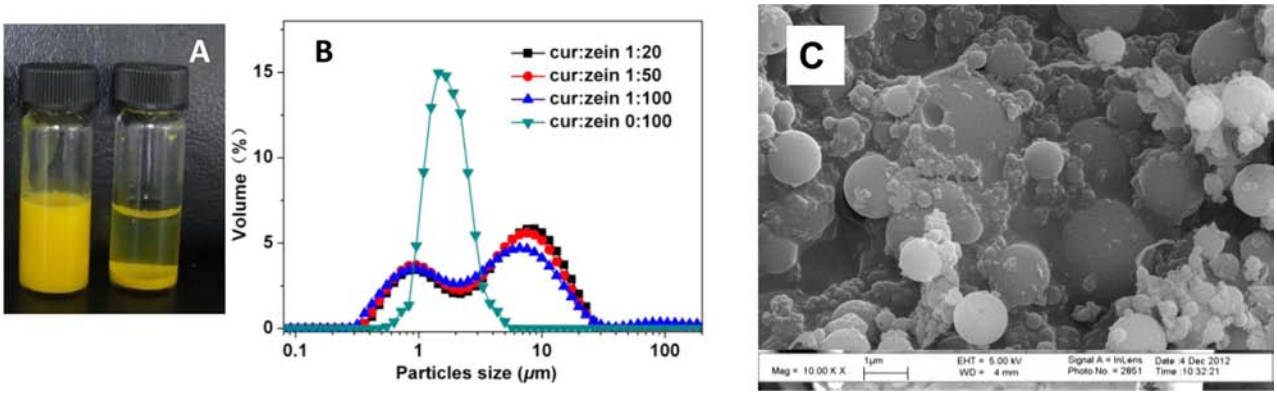

Figure 2. Visual appearance (A), particle size distributions (B), and topography (C) of the ZCP. (A) Fresh ZCP dispersion (left) and after 12 h of storage (right).

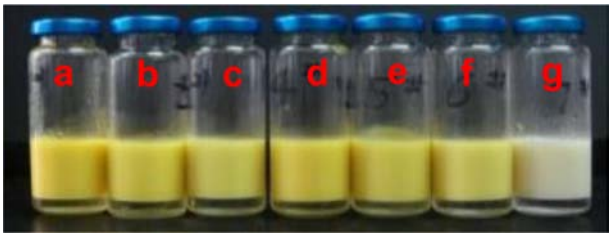

Figure 3. Visual appearance of Pickering emulsions stabilized by ZCP or ZCP-cur: (a–c) ZCP-curE at curcumin-to-zein ratios of 1:100, 1:50, and 1:20, respectively; (d–f) ZCPE-cur at curcumin-to-zein ratios of 1:100, 1:50, and 1:20, respectively; (g) ZCPE.

result of gravitational separation of the emulsion samples during the storage.[36] After 5 h of storage, the interface was positioned at a height of 3–4 mm for ZCPE, ZCPE-cur, and ZCP-curE. After 2 weeks, the height slightly increased to 15 mm, corresponding to about 30% of the height of raw emulsions, and the height of the interface reached a plateau for all emulsions. Interestingly, the creaming of the encapsulated droplets did not lead to irreversible flocculation and completely disappeared after gentle shaking. In contrast, de Folter et al. fabricated zein nanoparticles (about 80 nm)-stabilized Pickering emulsion and reported the height slightly increased to 45% after 2 weeks of storage and free oil occurred after 3 days of storage.[21] Therefore, ZCP-stabilized Pickering emulsions were more stable than the plain zein particle-stabilized emulsion.

Long-Term Stability of Emulsions. Long-term stability is a prerequisite property for emulsions used in various fields. Selected droplet size distributions of the emulsions are shown in Figure 4, and detailed surface mean diameters ($D_{3,2}$) of Pickering emulsions a function of storage times are listed in Table 2. ZCPE showed a multimodal droplet size distribution, and the maxima appeared at 10–20 μm (Figure 4). A minor peak at about 1 μm may pertain to the remaining ZCP in the continuous phase, and a peak at ~1000 μm can be attributed to the presence of multiple emulsion phenomena in ZCP-stabilized emulsions, confirmed by CLSM technique (Figure 6A,C). The peak at ~1000 μm disappeared after 2 weeks of storage at room temperature, whereas the others remained nearly unaffected after storage for 2 weeks and longer for various emulsions. Concomitantly, the mean particle size was used to quantitatively characterize the size of Pickering emulsion over the storage for 7 weeks, reflecting that all preparations were micrometer-sized. The $D_{3,2}$ of ZCPE was 14.87 ± 1.45 μm. ZCPE-cur and ZCP-curE had similar particle sizes (Table 2). The $D_{3,2}$ values of these emulsions were stable for 7 weeks (Table 2), reflecting that no coalescence occurs during the storages.

Centrifugation Stability. Centrifugation accelerates the creaming process of emulsions, forcing the droplets to concentrate. The excess water is then excluded from the emulsion, leading to close packing conditions. The creaming index after the centrifugation was used to reflect their physical stabilities. After centrifugation at 4000*g*, the CI was about 44% for tested emulsions, which was higher than that after 1 week of storage (23.8–25%) and 7 weeks of storage (28.5–30.0%) (Table 3), reflecting that excess water was excluded from the emulsion in the course of centrifugation. In addition, the deposit was detected at the bottom of the centrifugal tube, reflecting the ZCP in the Pickering emulsions was excess (Figure 5). However, the tested emulsions were not "broken up", indicating that the emulsions resisted the stress induced by the centrifugation.

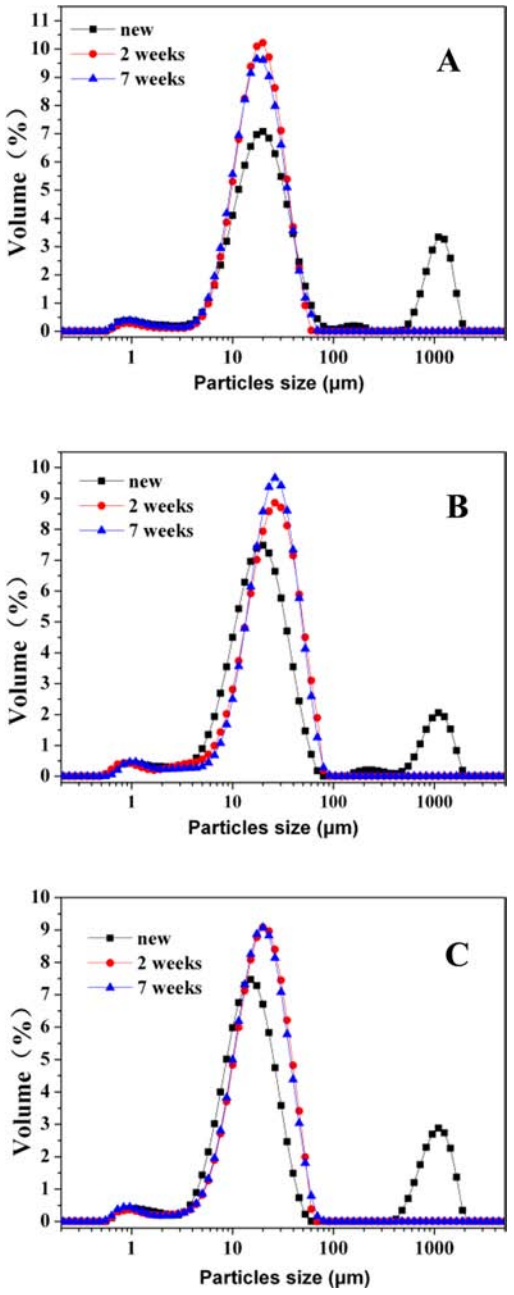

Figure 4. Typical particle size distribution of the emulsions stabilized by ZCP or ZCP-cur at selected storage times: (A) ZCP-stabilized emulsions (ZCPE); (B) emulsions stabilized by ZCP-cur (ZCP-curE) at a curcumin-to-zein ratio of 1:50; (C) ZCP-stabilized emulsions via loading curcumin (ZCPE-cur) at a curcumin-to-zein ratio of 1:50.

Microstructure. The morphological structure of emulsions, including interfacial characteristics (composition, thickness, and integrality) and the distribution of antioxidant within the emulsions, determined to some degree their physical performance and oxidant stability. It can be evaluated by the CLSM technique by the linkage of fluorescence labeling and electronic microscopy. Figure 6A shows overlay fluorescence micrographs of ZCP-stabilized emulsions. Micrographs were taken of the same area during selective excitation with either Nile Red (oil, green) or Nile Blue A (zein, red). Green fluorescence from Nile Red lay in the spherical droplets, and there were obvious red

circles around spherical droplets (Figure 6A), further confirming that an o/w emulsion was formed when the ZCP was utilized as Pickering emulsifier (θ = 82°, Figure 1). This result is consistent with previous findings that particles with θ < 90° yield an o/w emulsion.[37] Droplet sizes of the emulsions ranged between 5 and 50 μm, evidenced by the results determined by Mastesizer 2000 (Figure 4). In general, full coverage by solid particles is not necessary to produce stable Pickering emulsions.[11,38] Figure 6A2 shows the blowup of a single lipid droplet of Pickering emulsion, displaying the intact and thick ZCP shells coating the surface of spherical droplets. This kind of interface framework contributed to the aforementioned stabilization phenomena of the Pickering emulsions and gave them a promising potential against lipid oxidation via physical barrier of particle-based interfacial membrane.

Curcumin fluorescence was excited by an argon laser at 488 to distinguish its distribution within the emulsions. In this work, the dual-function particles (ZCP-cur) were produced via a co-assembly approach, and the utilization of ZCP-cur as particulate emulsifier resulted in a targeted accumulation of curcumin at the oil−water interfaces, evidenced by the presence of obvious blue circles around emulsion droplets (black) (Figure 6B). In contrast, curcumin was distributed uniformly within the interior of dispersed droplets when it was admixed to corn oil prior to the emulsification (Figure 6C). The distribution of curcumin within the Pickering emulsions played a key role in the oxidant stability of the emulsions.

Primary and Secondary Oxidative Products of Pickering Emulsions. Corn oil is labile to oxidation because its fatty acids consist of >56% linoleic acid and about 30% oleic acid.[39] The oxidative stability of corn oil-in-water Pickering emulsions was evaluated by monitoring the formation of the complementary markers during thermally accelerated storage.

Lipid Hydroperoxides (LP). LP concentration was determined to reflect the initial lipid oxidation rate of the emulsions. Figure 7A displays the LP concentrations of ZCP-stabilized Pickering emulsions (ZCPEs) as a function of incubation time. They increased gradually from 0.95 ± 0.30 mmol/kg of oil (fresh) to 18.57 ± 0.24 and 49.05 ± 0.63 mmol/kg of oil after 9 and 22 days of storage at 40 °C, respectively. Comparatively, ZCP was more effective in inhibiting lipid oxidation of the emulsions than protein-type emulsifiers or protein/polysaccharide complex, for example, soy protein, whey protein, and soy protein isolate (SPI)/pectin.[32,40] LP concentrations in the WPI- and SPI-stabilized emulsions increased to 113.2 and 205.5 mmol/kg of oil, respectively, after 185 h (7−8 days) of storage at 37 °C.[40] Wan et al. fabricated complex interfaces of SPI and stevioside (STE) micelles and reported the hydroperoxides of the emulsions were about 120 mmol/kg oil after 21 days of storage at 37 °C.[32] The phenomena may be attributed to the interfacial characteristics of ZCPEs in which network fabrics of zein/CH complex particles at the surface of spherical droplets were confirmed via CLSM technique (Figure 7A). Similarly, the peroxide value (PV) of Pickering emulsion stabilized by microcrystalline cellulose (MCC) or modified starch (MS)

DOI: 10.1021/jf505227a
J. Agric. Food Chem. 2015, 63, 2514−2524

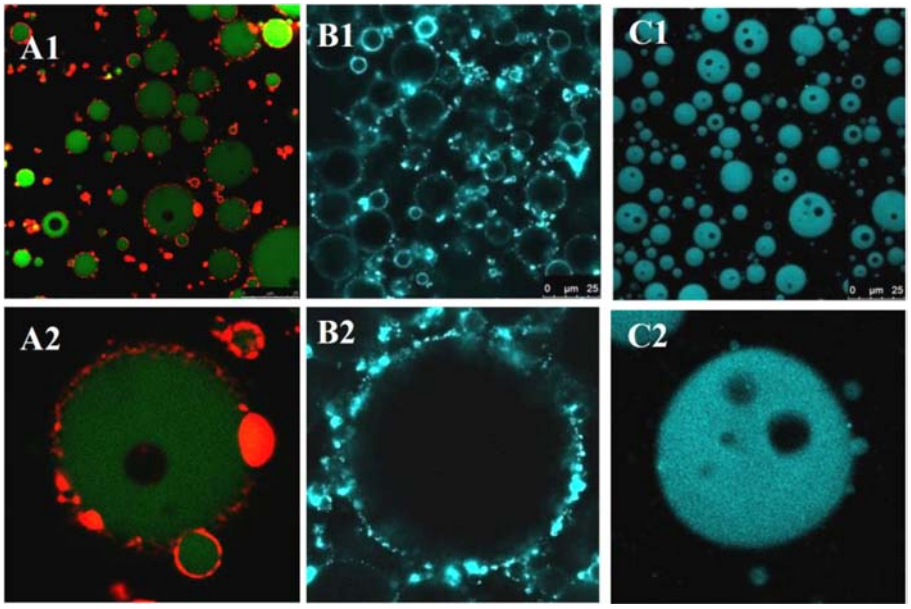

Figure 6. CLSM images of Pickering emulsions: (A1, A2) ZCP-stabilized emulsions (ZCPE) (corn oil was stained with Nile Red, and zein was stained by Nile Blue A; the fluorescent dyes were excited at 488 nm for Nile Red (green) and at 633 nm for Nile Blue A (red)); (B1, B2) emulsions stabilized by ZCP-cur (ZCP-curE) at a curcumin-to-zein ratio of 1:50 (curcumin fluorescence was monitored by excitation by an argon laser at 488 nm (blue)); (C1, C2) ZCP-stabilized emulsions via loading curcumin (ZCPE-cur) at a curcumin-to-zein ratio of 1:50 (curcumin fluorescence was monitored by excitation at 488 nm (blue)).

increased to 8−20 mM after 7 days of incubation at 40 °C, in a particle concentration- and type-dependent manner.[41,42] Therefore, particle-stabilized emulsions can restrict the formation of primary oxidant products, and ZCP is a suitable particulate emulsifier to form stable Pickering emulsions with depressed initial oxidant rate.

The oxidative stability of the emulsions depended on the curcumin locations. Curcumin was found to be an effective and potent antioxidant in different in vitro assays.[25] The antioxidant activity of curcumin incorporated into the droplet's shell of the ZCPE was compared with that of it admixed into the oil phase prior to the emulsification. Dual-function particles serving as a particulate emulsifier and interfacial cargo of curcumin were fabricated via a simple co-assembly approach, and the targeted accumulation of curcumin at the interface was achieved using the dual-function particles (ZCP-cur) (Figure 7A). As a consequence, antioxidant interfacial shells around spherical droplets were formed, endowing the emulsions with improved oxidative stability. The LP decreased by approximately 50% from 49.05 (ZCPE) to 20.14−24.14 (ZCP-curE) mmol/kg oil after 22 days of storage at 40 °C depending on the curcumin loadings within the ZCP (Figure 7A). In contrast, the LP of Pickering emulsions decreased slightly from 49.05 (ZCPE) to 25.46−40.89 (ZCPE-cur) by directly admixing curcumin in corn oil before the emulsification (Figure 7A). Therefore, fabrication of antioxidant interface via dual-function ZCP is a promising approach to enhance further the oxidant stability of ZCPE.

Secondary Oxidant Products. Measuring the secondary products of lipid peroxidation is one of the most widely accepted assays for the oxidative stability of emulsions.[43] MDA, a marker of secondary oxidative products, was monitored by TBARS assay. Figure 7B displays MDA content of the ZCPEs after 22 days of storage at 40 °C. The MDA value of the emulsion was 53.99 ± 6.04 μmol/kg oil. Comparatively, ZCPs were more effective in inhibiting lipid oxidation of the emulsions than biopolymers, for example, protein-type or protein/polysaccharide complex emulsifiers. The MDA of SPI-stabilized emulsions was about 20 mmol/kg oil under accelerated storage at 50 °C for 10 days.[7] Lomova et al. fabricated the emulsions stabilized by complex interface of BSA and biocompatible polyelectrolytes and reported the MDA of the emulsion ranged from 40 to 100 mmol/kg oil during storage for 0−15 days at 37 °C.[1] The MDA of ZCPE were lower than those of the preceding emulsions by 2−3 orders of magnitude. The irreversible adsorption of ZCP at the interface resulted in submicrometer interfacial barriers, restricting the interactions between LP at the interface and pro-oxidants (e.g., Fe^{2+}) in the continuous phase via steric hindrance. In addition, strongly positive ZCP shells around dispersed droplets did have an advantage over negatively charged emulsions regarding the oxidative stability.

To further clarify the influence of antioxidant locations on the oxidative stability of the Pickering emulsions, the MDAs of the emulsions with shell curcumin or core curcumin were analyzed and compared. CLSM trials confirmed the targeted accumulation of curcumin at the oil−water interfaces via the cargo of the ZCP (Figure 7B), producing antioxidant interface shells around spherical droplets. The interfacial frameworks markedly enhanced oxidative stability of the emulsions. The MDA decreased by approximately 50% from 53.99 (ZCPE) to 24.57−33.34 μmol/kg oil (ZCP-curE) after 22 days of storage at 40 °C in a loading-dependent manner (Figure 7B). In contrast, the MDA decreased slightly from 53.99 (ZCPE) to 32.37−37.83 μmol/kg oil (ZCPE-cur) after 22 days of incubation at 40 °C when curcumin was directly incorporated within the dispersed droplets (Figure 7B). Hence, the formation of the antioxidant shell around dispersed droplet surfaces appears to be an advantageous strategy to protect emulsified oil against oxidation rather than admixing antioxidants into oil core.

J. Agric. Food Chem. 2015, 63, 2514−2524

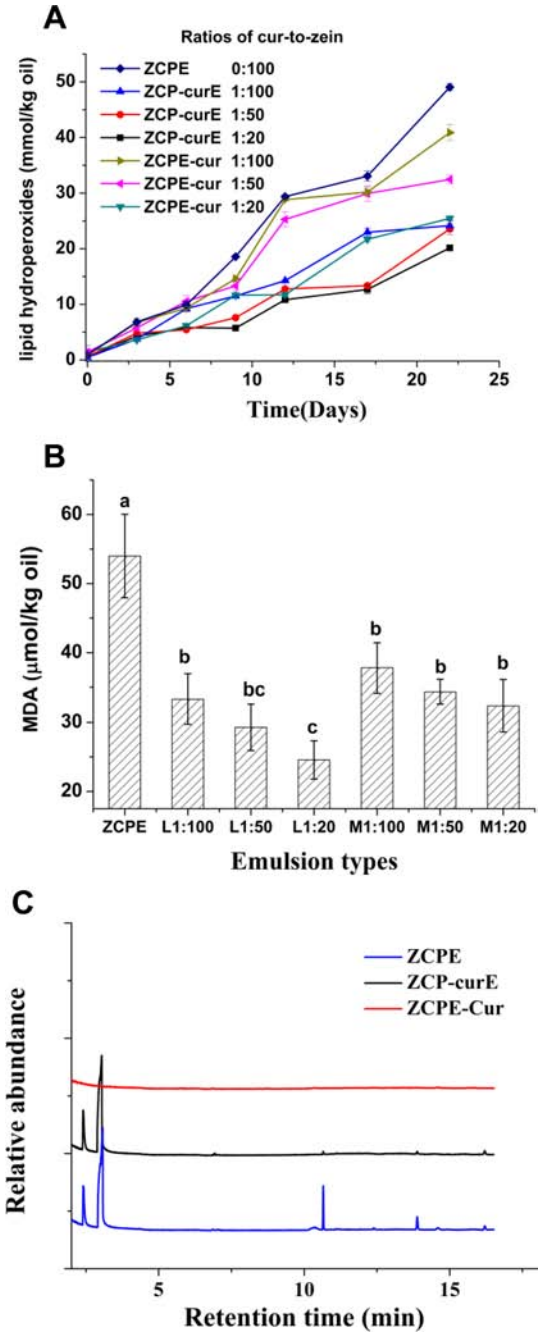

Figure 7. Primary and secondary oxidant products of Pickering emulsions under accelerated storages at 40 °C: (A) LP content; (B) MDA content (L1:100, L1:50, and L1:20 represent ZCP-curE at three curcumin/zein ratios; M1:100, M1:50, and M1:20 represent ZCPE-cur at three curcumin/zein ratios; different characters (a–c) on the columns represent significant difference); (C) hexanal content.

Headspace Hexanal. There was a complex mixture for secondary lipid oxidation products, and hexanal, a volatile compound, is another marker of secondary oxidation products. The hexanal level of Pickering emulsions was analyzed by headspace gas chromatography (Figure 7C). In our laboratory, hexanal content in SPI and SPI–resveratrol emulsions was analyzed using headspace gas chromatography, confirming the presence of an identified hexanal peak at approximately 7 min for the emulsions after 21 days of storage.[32] The situation changes drastically when ZCPs were utilized as the particulate emulsifier, where no hexanal was detected in headspace gas chromatography of the Pickering emulsions using the preceding protocol for SPI and SPI–resveratrol emulsions (Figure 7C). Furthermore, the smell of rancidity did not appear as well. These results were consistent with the TBARS assay (Figure 7B) where the MDA values of ZCP emulsions were markedly lower than those of the emulsions stabilized by SPI or complex polyelectrolytes.[1,7] Thus, headspace hexanal analysis provided further evidence that ZCP effectively improved the oxidative stability of emulsions. As expected, there was no detectable headspace hexanal peak in headspace gas chromatography of ZCPE-cur and ZCP-curE after 22 day storage at 40 °C (Figure 7C).

Schematic Illustration. The interfacial architecture is a determined factor for the oxidant stability of the emulsions. Fabrication of Pickering emulsions is a promising strategy to improve the oxidative stability of the emulsions via the formation of dense particle-based interfacial layers, providing a physical barrier against the pro-oxidants. The MDA value of ZCPE was lower than that of the emulsions stabilized by the biopolymers by 2–3 orders of magnitude.[1,7] Concomitantly, no detectable hexanal peak in headspace gas chromatography appeared for the ZCPE after 22 days of storage at 40 °C. Curcumin is an effective and potent antioxidant; the introduction of curcumin further enhanced the oxidative stability of the emulsions, depending on curcumin loadings and locations (Figure 7). Especially, the targeted migration of curcumin at the oil–water interfaces was put into practice when ZCP was utilized as the interface delivery of curcumin, further slowing the lipid oxidation in the emulsions (Figure 7).

Herein, a schematic diagram for the formation pathway of ZCP-stabilized antioxidant Pickering emulsions is proposed to correlate the oxidative stability and physical performance of the Pickering emulsions with their interface frameworks, so as to elucidate the possible mechanism for excellent physical and oxidative stability for ZCP-stabilized Pickering emulsions (Figure 8). Chitosan, a pH responsive polymer, is not a conventionally good emulsifier. It is able to in situ self-assemble at pH >6.0 to form nanoparticles or micrometer-sized floccular precipitates, and these aggregates can adsorb at the oil–water interface to yield Pickering emulsions.[44] Demulsification happened when the pH of the emulsions was adjusted to 6.0 or lower, indicating chitosan has low surface activity at acidic pH.[44] In this work, ZCP-stabilized Pickering emulsions were fabricated at pH 3.5, at which chitosan possesses low surface activity. To shed light on the role of chitosan in emulsion formation and performance, we performed additional experiments using FITC-labeled chitosan to produce ZCP. Unexpectedly, the CLSM photograph indicated that chitosan formed a network on the surface of dispersed droplets in the Pickering emulsions at acidic pH. It has been proposed that the steric particle-based barrier in Pickering emulsions is not a simple bilayer or monolayer, but a network of particles, adsorbed at the oil–water interface.[11,45] This phenomenon was also observed in our Pickering emulsions in which ZCPs assemble through the bridging flocculation of chitosan to form dense particle-based networks at the oil–water interface (Figures 5 and 9). The zeta potentials were 64.0 ± 1.6 and 62.4 ± 2.4 for ZCP and ZCPEs, respectively (Tables 1 and 2). The cations' screening effect also contributed to depressed oxidative degradation of emulsified lipid in the Pickering emulsions. This kind of interface framework endowed the emulsions with predominant oxidative stability.

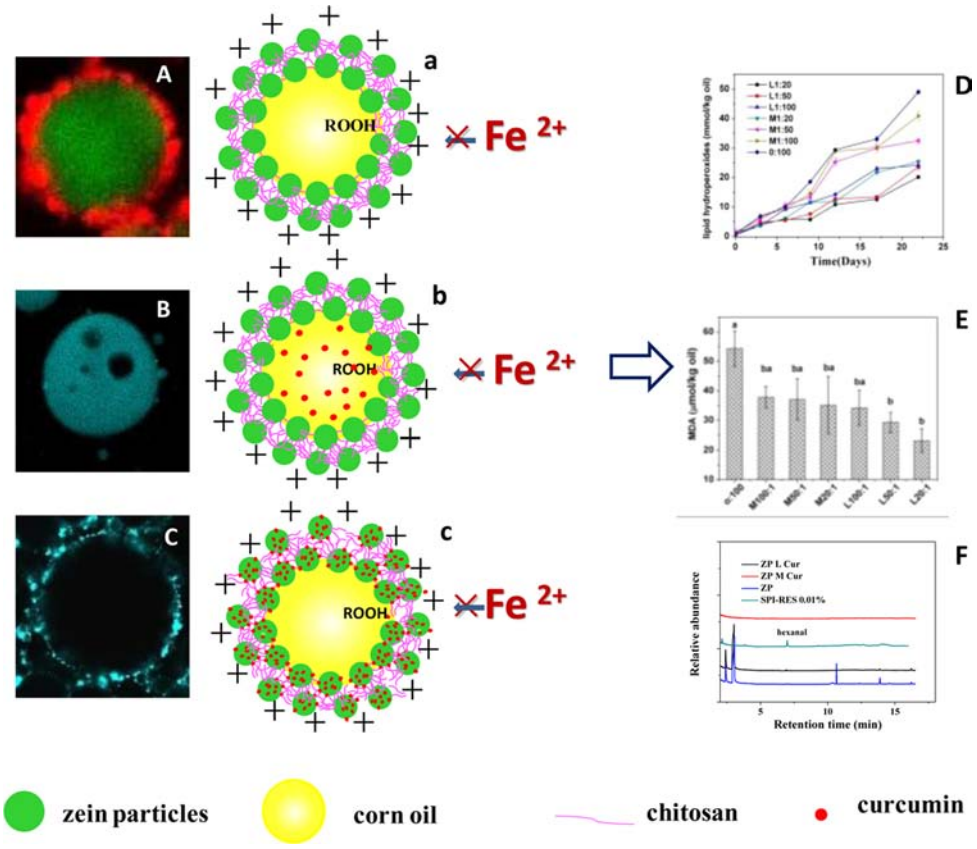

Figure 8. Schematic diagram for the formation pathway of ZCP-stabilized antioxidant Pickering emulsions proposed to relate oxidative stability and physical performance of the emulsions with their interface frameworks. Fe^{2+} was utilized as a representative pro-oxidant.

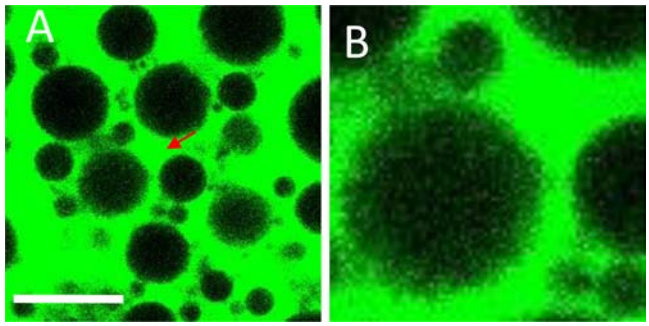

Figure 9. CLSM images of Pickering emulsions stabilized by zein/FITC-labeled chitosan particles. FITC fluorescence was visualized using an argon laser at 488 nm (green) to explore the distribution of chitosan within the emulsions. Panel B is an amplified image of panel A at the arrow.

To further enhance the oxidative stability of the emulsions, curcumin was introduced into the emulsions via shell antioxidant and core antioxidant approaches (Figures 7 and 8B,C). In the case of the shell antioxidant approach, curcumin-loaded ZCPs (ZCP-cur) were used to form antioxidant shells around the dispersed droplets. In addition to static hindrance and electrostatic effect of interfacial shells formed by the ZCPs, the targeted accumulation of curcumin, a natural antioxidant within the interface layer, may give them antioxidant capacity via chelating metallic ion (e.g., Fe^{2+}) activity and scavenging free highly reactive radicals such as alkoxyl and peroxyl radicals. Therefore, the oxidative stability of Pickering emulsion was further improved in a dose-dependent manner (Figure 7). In the case of core antioxidant, curcumin was added to the oil phase prior to the emulsification. Curcumin was distributed uniformly with the interior of dispersed oil droplets (Figure 6C). Both LP and MDA concentrations decreased slightly when compared with those of the ZCPE (Figure 7A,B). The incorporation of curcumin in the dispersed oil phase retards the lipid peroxidation via mainly chain-breaking mechanism of curcumin targeting radicals formed inside the oil core during the course of lipid autoxidization. As expected, the formation of the antioxidant interface appears to be a promising strategy to protect emulsified oil against oxidation rather than admixing antioxidants into the oil core.

Conclusion. Novel edible Pickering emulsions stabilized by zein/chitosan complex particles were fabricated to enhance oxidative stability of the emulsions. ZCPs were more effective in inhibiting lipid oxidation of the emulsions than the biopolymers, and the MDA values of ZCPE were lower than that of the biopolymer-stabilized emulsions by 2−3 orders of magnitude. The introduction of curcumin in Pickering emulsions further improved the oxidative stability of the emulsions in a curcumin location-dependent manner. Especially, the formation of antioxidant interface via interfacial cargo of curcumin markedly enhanced the oxidative stability of the emulsions. Interestingly, no detectable hexanal peak appeared in the headspace gas chromatography of the Pickering emulsions. The CLSM photograph confirmed the formation of dense ZCP-based networks at the oil−water interface, a typical Pickering-type steric barrier. The novel interfacial architecture of Pickering emulsions stabilized by dual-function ZCP-cur gave them excellent physical performance and

oxidative stability. Some other factors (e.g., bulk viscosity, free ZCCP) are also important to the physical and oxidative stability of Pickering emulsions; their roles are worth addressing in future works. A schematic illustration of the formation pathway of ZCP-stabilized antioxidant emulsions was proposed to correlate the oxidative stability of the Pickering emulsions with their interfacial architectures. This study opens a promising pathway for producing antioxidant emulsions via the combination of Pickering stabilization mechanism and interfacial cargo of antioxidant.

Ethanol, Glycerol, Acetic Acid, and Lactic Acid. These compounds were quantified by using a HPLC-RI (PerkinElmer, Flexar) system equipped with Aminex column (HPX-87H, 300 mm × 7.8 mm; Bio-Rad) under isocratic conditions (40 °C) at a flow of 0.5 mL min^{-1} of 2.5 mM H_2SO_4.

Fermentable Sugars. Fermentable sugars were analyzed by high-performance anion exchange chromatography (HPAEC) (Dionex ICS-3000) with pulse amperometric detection (PAD) using a CarboPac PA-1 (4 mm × 250 mm) analytical column and a CarboPac PA-1 (4 mm × 50 mm) guard column at 30 °C (Dionex Corp, Sunnyvale, CA, USA). The system was equilibrated with 100 mM NaOH. After injection of a 100 μL filtered (0.45 μm), diluted sample, 100 mM NaOH was run through the column (5 min). Separation was achieved with a gradient (1 mL min^{-1}) of 100−300 mM NaOH in 3 min and then 300−250 mM NaOH + 75 mM sodium acetate in 15 min, and a final washing step with 100 mM NaOH + 300 mM sodium acetate and 300 mM NaOH. The flow rate was 1 mL min^{-1}. The results were confirmed by MSQ detection (HPAEC-MS) using a CarboPac PA200 (3 mm × 250 mm) with a CarboPac PA200 guard (3 mm × 50 mm) column (Dionex) with a configuration as described by Bruggink et al.[4] and a gradient as described by Mikkelson et al.[5]

Hop-Derived Bitter Compounds. For quantitation of 96 hop-derived bitter compounds, beer samples were degassed by ultrasonification and filtered (0.45 μm), and an aliquot (5 μL) was analyzed by HPLC-MS/MS_{MRM} as reported recently.[6,7]

Yeast-Derived Flavor Compounds. These compounds in bottle A56 and reference beers were determined by GC analysis as described[8] and those in bottle C49 by headspace-GC-MS. 1-Butanol was used as internal standard. Samples (4 mL) of C49 were filtered (0.45 μm) and incubated at 60 °C for 30 min, and then 1 mL was injected (splitless; 260 °C; flow = 14.9 mL min^{-1}) into a gas chromatograph (Agilent 6890 series; Palo Alto, CA, USA) combined with an MS detector (Agilent 5973 Network MSD, USA) and an SPME autosampler (Combipal, Varian Inc., USA). Analytes were separated on a BPX5 capillary column (60 m × 0.25 mm with phase thickness = 1.0 μm; SGE Analytical Science Pty Ltd., Australia). The carrier gas was helium (1.7 mL min^{-1}). The temperature program was 50 °C for 3 min, 10 °C min^{-1} to 100 °C, 5 °C min^{-1} to 140 °C, 15 °C min^{-1} to 260 °C, and then isothermal elution for 1 min. MSD was operated in electron impact mode at 70 eV, in the full scan mode (m/z 40−550). The ion source temperature was 230 °C, and the interface was 280 °C. Compounds were identified by comparison with authentic standards and the mass spectra in Palisade Complete 600 K Mass Spectral Library (Palisade Mass Spectrometry, USA) and were quantified using standard curves.

Total Vicinal Diketones (VDKs). VDKs were measured according to Analytica-EBC method 9.10.[3]

Carbonyl Compounds. Carbonyl compounds were analyzed as oximes by using GC-ECD as described by Ojala et al.[9] To 5 mL beer samples were added 500 μL of 0.4% (w/v) PFBOA (*O*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine hydrochloride) solution and 100 μL of internal standard (benzaldehyde; 0.1% v/v). Samples were then incubated at room temperature for 2 h. Reaction was stopped by adding 100 μL of 9 M H_2SO_4, and oximes were extracted into 2 mL of hexane. Samples (2 μL, split injection 12.5:1) were analyzed using GC-ECD (Agilent 6890 Series). Analytes were separated in constant flow mode with helium as carrier gas (1.2 mL min^{-1}) on a DP-5 capillary column (30 m × 0.32 mm) with a phase thickness of 0.50 μm (Agilent). The injector was kept at 260 °C, and the ECD was kept at 300 °C. The temperature program was 100 °C for 2 min, 8 °C min^{-1} to 250 °C, and a 5 min hold. Compounds were identified with authentic standards and quantified with standard calibration curves.

Short-Chain Fatty Acids. Short-chain fatty acids were extracted with diethyl ether from 4 mL of acidified beer samples as described by Schooley et al.[10] Internal standard was heptanoic acid (C7). Diethyl ether extracts (2 μL, splitless injection) were analyzed by GC-FID (Agilent 6890 series). Analytes were separated on a DP-FFAP capillary column (30 m × 0.32 mm; phase thickness = 0.25 μm; Agilent). The carrier gas was helium (2.7 mL min^{-1}). The injector and FID were at 250 °C. The temperature program was 50 °C for 3 min, 25 °C min^{-1} to 100 °C, 10 °C min^{-1} to 240 °C, and a 10 min hold. Compounds were quantified using authentic standards.

Bound and Free Phenolic Acids (PAs). Beer samples (250 μL) were mixed with 2 M NaOH (1.1 mL, for hydrolysis of bound PAs) or water (1.1 mL, for free PAs). After 16 h in the dark, samples were acidified with 5 M HCl and extracted with ethyl acetate (3 × 2 mL). The extracts were dried under nitrogen and residues dissolved in 0.5 mL of methanol, filtered, and used to quantify free and total PAs by ultraperformance liquid chromatography (UPLC). Portions (200 μL) of the methanol samples were dried and dissolved in 30 μL of dichloromethane (DCM) and derivatized with MSTFA (*N*-methyl-*N*-trimethylsilyltrifluoroacetamide, Pierce, Rockford, IL, USA; 25 μL, 80 °C for 20 min) for GC-MS analysis of minor PAs.

Volatile Phenols. Beer samples (0.5 mL) were vortexed, spiked with heptadecanoic acid (10 μg), and extracted with DCM (2 × 4 mL). The separated DCM extracts were dried under nitrogen and redissolved in 100 μL of DCM. Half (50 μL) of each extract was trimethylsilylated with MSTFA (25 μL, 80 °C for 20 min). Underivatized and derivatized samples were both analyzed by GC-MS.

Phenolic compounds were analyzed using UPLC and GC-MS. A Waters Acquity UPLC was equipped with a Waters Acquity BEH C18 column (1.7 μm, 2.1 × 100 mm) combined with a VanGuard pre-column (2.1 × 5 mm 1.7 μm). The solvent was 5% formic acid and acetonitrile. Flow was 0.43 mL min^{-1}. The proportion of acetonitrile was increased linearly from 5 to 90% in 9 min and returned to 5% in 2 min. The diode array detector was used at 190−600 nm. Ferulic, sinapic, and *p*-coumaric acids were quantified at 320 nm by using standard curves of authentic compounds (0.1−100 μg mL^{-1}). For GC-MS analyses, an Agilent 7890A GC was equipped with a 5975C mass selective detector and Rtx-5MS silica capillary column (15 m, 0.25 mm i.d., phase thickness of 0.25 μm (Restek, Bellefonte, PA, USA)). The oven temperature was increased from 70 °C (1 min) at 10 °C min^{-1} to 270 °C (4 min). The split ratio was 25:1, and the samples were injected by a Gerstel Maestro MPS 2 sampling system (Gerstel GmbH & Co.KG, Mühlheim an der Ruhr, Germany). Data were collected in the full scan mode (m/z 40−600). Compounds were identified by retention times and library comparison (NIST '08, Scientific Instrument Services, Inc., Ringoes, NJ, USA).

Protein Content. Proteins were precipitated from beers (400−500 μL) with acetone (1600 μL) at −20 °C. Precipitates from centrifugation (720*g*, 5 min) were dissolved in 25 μL of rehydration buffer (2 M thiourea, 7 M urea, 0.5% Triton-X-100, 0.5% Pharmalyte 3−10) and assayed by 2-D Quant Kit (GE Healthcare UK Limited, Buckinghamshire, UK) with bovine serum albumin as standard.

Amino Acids. Total and free amino acids were analyzed with Mass TRAK Amino Acid Analysis Application Solution (Waters, Milford, MA, USA). Samples for total amino acids were hydrolyzed in 6 N HCl at 110 °C for 20 h and then dried under nitrogen, dissolved in 200 μL of water, redried, and dissolved in 200 μL of 0.1 N HCl. Hydrolyzed and untreated samples (10 μL) were mixed with internal standard (10 μL of 250 μM norvaline) and derivatized (AccQ·Fluor reagent kit; Waters). AccQ·Fluor reagent (20 μL) and boric acid buffer (70 μL) were added, and the mixture was vortexed for 60 s. UPLC-MS analysis involved an Acquity UPLC system (Waters) with a diode array detector. Chromatography involved an Acquity Mass TRAK (2.1 × 150 mm, 1.7 μm) column (Waters) at 43 °C. The injection volume was 2.0 μL. Separation was achieved by gradient elution with 10% (v/v) Amino Acid Analysis Concentrate A in water and Amino Acid Analysis Eluent B at 0.4 mL min^{-1}, monitoring the effluent at 260 nm.

RESULTS

Bottles. Bottles A56 (Figure 1) and C49 were similar brown glass bottles, 245 mm high including the 80 mm neck. The diameters increased from 85 mm at the base to 90 mm at the shoulder. The necks were about 37 mm in diameter. The bases had conical depressions about 40 mm deep (as in traditional wine bottles). Bottle A56 showed no signs of sand abrasion or glass corrosion (Risto Aalto, Riikka Alvik, Markku Annila, Ulla Klemelä, and Kaisa Koivisto, personal communication). It

Figure 1. Bottle A56.

appeared to have been mouth blown while revolving in a cylindrical mold, which shaped the wall (marks from the mold were visible on the wall). The bottle's mouth was apparently formed by wrapping strips of hot glass round the cut neck. No labels remained on either bottle. Both bottles were closed with rather coarse-grained corks that protruded several millimeters out of the necks.

Bubbles of gas, presumably CO_2, formed during sampling, producing a light foam. Both beers were bright golden yellow, with little haze. Both beers smelt of autolyzed yeast, dimethyl sulfide, Bakelite, burnt rubber, over-ripe cheese, and goat, with phenolic and sulfury notes. As the samples warmed to room temperature, the smell of hydrogen sulfide disappeared and that of butyric acid (particularly strong in C49) strengthened.

Physicochemical Analyses. Compared to modern beers, the shipwreck beers contained similar levels of potassium but 15−60-fold more sodium (Table 1), presumably derived from seawater. This may have diluted the beers up to 30%. Ethanol contents were low (2.8−3.2% ABV) compared to typical modern lagers and ales. The mass ratios of glycerol/ethanol were 4.5% for both shipwreck beers, which is typical for a yeast fermentation product. Both beers were acidic, with pH about 1 unit below modern values. The color strengths were in the range of modern ales and lagers (and much lower than those of porters or stouts). Bitterness was lower in A56 (9.9 IBU, corresponding to a modern light lager) and higher in C49 (16 IBU). Sulfur dioxide was not detected in A56 (not tested in C49): original sulfur dioxide would probably be oxidized over the 170 years under water. FAN was low (61 mg L^{-1}) for A56 but normal (114 mg L^{-1}) for C49. Protein levels (5−7 mg L^{-1}) were very low in both beers.

Table 1. Physicochemical Properties of Shipwreck Beers

property	unit	beer A56	beer C49	modern beers[a]
ethanol	ABV[b] (% v/v)	2.8	3.2	3−6
glycerol	g L^{-1}	1.0	1.1	1−2
pH		3.18	3.39	3.9−4.5
color	EBC[c] units	8.9	10.5	2−27
bitterness	IBU[d]	9.9	16	6−30
apparent extract	°Plato	1.32	3.10	1−5
real extract	°Plato	2.24	3.98	3−6
SO_2 (sulfite)	mg L^{-1}	<0.4	NA[f]	0−10
FAN[e]	mg L^{-1}	61	114	40−250
protein	mg L^{-1}	5−7	5−7	200−500
glucose	g L^{-1}	1.35	9.8	0
fructose	g L^{-1}	<0.04	<0.04	0
sucrose	g L^{-1}	<0.04	<0.04	0
maltose	g L^{-1}	0.14	1.2	0.0−2.5
maltotriose	g L^{-1}	0.073	0.11	0.0−3.0
Na^+ (sodium)	mg L^{-1}	1200	890	20−60
K^+ (potassium)	mg L^{-1}	440	510	500

[a]Results for shipwreck beers A56 and C49 are compared with typical values for modern ales and lagers. Concentrations are for the beer "as is", i.e., values have not been normalized to a standard ethanol concentration. [b]ABV, alcohol by volume. [c]EBC, European Brewing Convention. [d]IBU, International Bitterness Unit. [e]FAN, free amino nitrogen. [f]NA, not analyzed.

Fermentable Sugars. A small amount of maltose was present in A56 and much more in C49, which contained more maltose than is typical in modern beers (Table 1). Both shipwreck beers contained less maltrotriose than maltose, whereas modern beers contain more maltotriose than maltose.[11] Both beers, especially C49, contained unexpectedly large amounts of glucose (glucose is usually consumed completely early in fermentation). Fructose and sucrose were not detected in either shipwreck beer. Like glucose, these sugars are consumed in early fermentation (their presence would suggest deliberate sweetening).

Apparent extracts (1.32 °Plato for A56 and 3.10 °Plato for C49) were at the low end of the range for modern ales and lagers (Table 1). Real extracts, calculated from the apparent extracts and ethanol concentrations, were 2.24 °Plato (A56) and 3.98 °Plato (C49). Total carbohydrate levels were not measured, but the difference between real extracts and residual sugars and salts suggests that starch was still present at about 17 g L^{-1} (A56) and 25 (C49) g L^{-1}.

Hop Components. The shipwreck beers contained small amounts of some iso-α-acids, which are considered the key bitter compounds in beer (Table 2). Among these iso-α-acids, *cis*-isohumulone and *cis*-isocohumulone were found in both beers, whereas additional isomers were detectable in C49 only. Besides the iso-α-acids, some of their degradation products such as tri- and tetracyclic degradation products, allo-iso-α-acids, scorpiohumols, and the tricyclohumolactols were detected (Table 2). These compounds are formed upon beer aging by an acid-catalyzed degradation of iso-α-acids.[12−14] In addition, hulupone and hulupinic acid were found as degradation products of hop β-acids. Only small amounts of xanthohumol, isoxanthohumol, and 6- and 8-prenylnaringenin were detected, although their presence was unequivocally confirmed. Hydroperoxides of allo-iso-α-acids, tricyclic degradation products of β-acids, and hydroperoxides and hydroxides of tricyclolupones are known hop derivatives,[12−14] but were not detected in either shipwreck beer. Their absence is, however, not unexpected as they are susceptible to chemical degradation from autoxidation and acid-catalyzed reactions. A series of oxidation products of α-, iso-α-, and β-acids such as humulinons, allohumulonhydroxides, and humulinic acids was detected in C49 but not in A56. Most other hop-derived compounds present in A56 were detected in C49 at higher concentrations. The higher concentration of most hop components in C49 than in A56 agrees with the more pronounced bitterness of C49 (Table 1).

Yeast-Derived Flavor Compounds. Yeasts produce compounds that contribute to the flavor of fermented beverages. Some of these compounds were analyzed in the

shipwreck beers and six reference beers. Results were normalized to a standard ethanol concentration of 35 g L^{-1}. The (normalized) concentrations of most compounds in the shipwreck beers were within or close to the range found in the reference beers (Figure 2). However, there were exceptions. Acetaldehyde, with a Tb (taste threshold in beer) of 25 mg L^{-1} (unless stated otherwise, taste thresholds in beer and flavor descriptions are from Meilgaard[15]) and a green leaf flavor, was

J. Agric. Food Chem. 2015, 63, 2525−2536

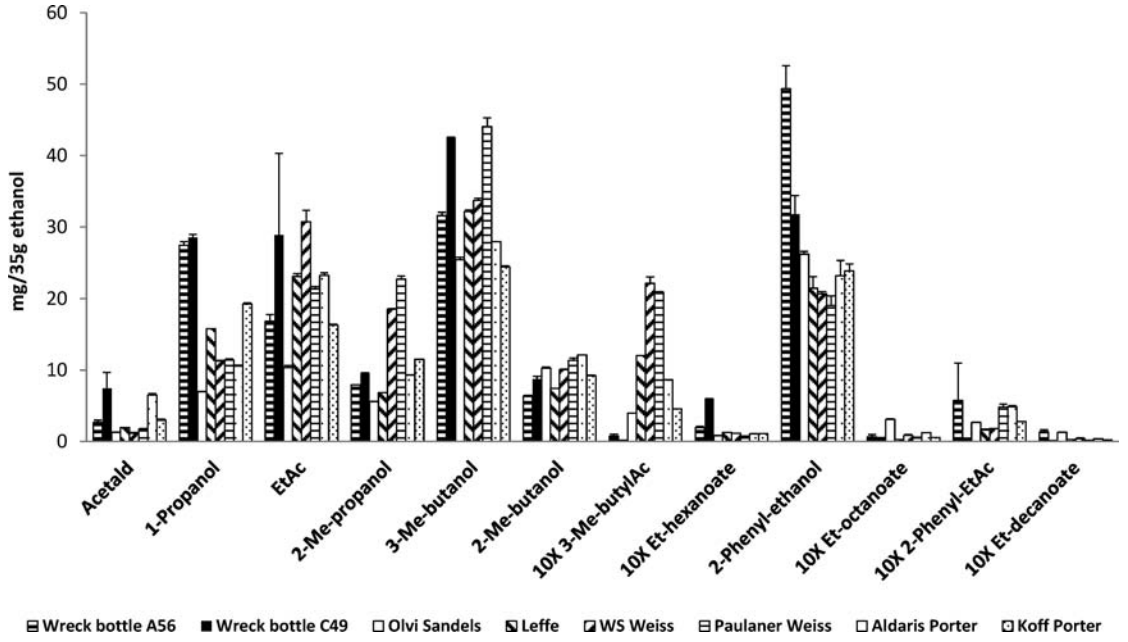

Figure 2. Yeast-derived flavor compounds in shipwreck and six modern reference beers. Concentrations are normalized to an ethanol concentration of 35 g L^{-1}. Actual ethanol concentrations (g L^{-1}) were as follows: A56, 22.2; C49, 25.6; Olvi Sandels, 37.4; Leffe Brune, 49.7; Weihenstephan Hefe Weissbier, 45.0; Paulaner Hefe Weissbier, 43.8; Aldaris Porter, 54.3; and Koff Porter, 59.2. Abbreviations are acetald, acetaldehyde; EtAc, ethyl acetate; 2-Me-propanol, 2-methylpropanol; 3-Me-butanol, 3-methylbutanol; 2-Me-butanol, 2-methylbutanol; 3-Me-butylAc, 3-methylbutyl acetate; Et-hexanoate, ethyl hexanoate; Et-octanoate, ethyl octanoate; 2-Phenyl-EtAc, 2-phenylethyl acetate; Et-decanoate, ethyl decanoate. Where indicated (10 X), the concentrations of some compounds have been multiplied by 10. Results are averages of duplicate or triplicate analyses, and error bars show the SDs.

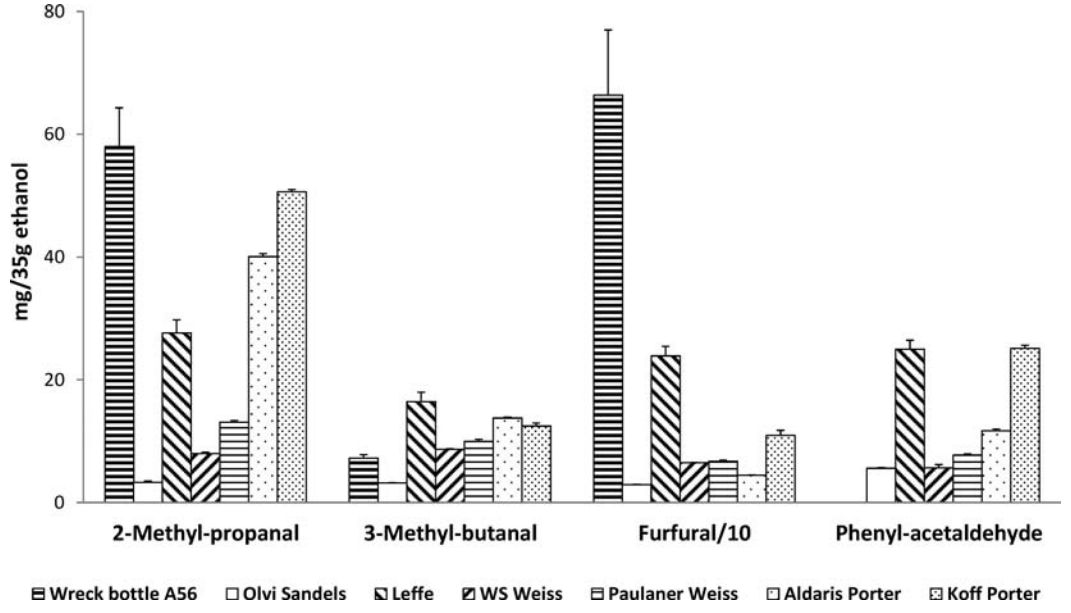

Figure 3. Carbonyl concentrations in shipwreck beer A56 and six reference beers. Concentrations are normalized to an ethanol concentration of 35 g L^{-1} (see Figure 2). Furfural/10 indicates the furfural concentration divided by 10. Results are averages of two or (wreck bottle A56) three determinations, and error bars show the SDs.

relatively high in C49 as was 1-propanol (Tb = 800 mg L^{-1}; alcohol) in both shipwreck beers. 3-Methylbutyl acetate (Tb = 1.6 mg L^{-1}; banana) was markedly low in both shipwreck beers. Ethyl hexanoate (Tb = 0.23 mg L^{-1}; apple) was high in both shipwreck beers, especially C49. Ethyl decanoate (Tb = 0.9 mg L^{-1}; sweet apple) was high in A56 (and also in the beer Olvi Sandels). 2-Phenylethanol (Tb = 125 mg L^{-1}; rose) was high in A56 and slightly high in C49. 2-Phenylethyl acetate (Tb = 3.8 mg L^{-1}; rose) was possibly high in A56, but low in C49.

Carbonyl Compounds. Two vicinal diketones, which are also yeast-derived and can cause a buttery or butterscotch-like flavor considered unacceptable in lagers but appreciated in some ales, were measured in A56 and the reference beers. Normalized concentrations of diacetyl (Tb = 150 μg L^{-1}) were 36 μg L^{-1} for A56 compared to 15 μg L^{-1} for Olvi Sandels and

[a]Concentrations (mg L^{-1}) are averages of two analyses and normalized to an ethanol concentration of 35 g L^{-1}. Values in parentheses denote the percentage of free, unbound compound with respect to the total concentration for that particular compound.

34−64 μg L^{-1} for the other reference beers. Pentanedione (Tb = 900 μg L^{-1}) was low in A56 (7 μg L^{-1}) and was below the average concentration (14 μg L^{-1}) found in the reference beers. The levels of four other carbonyl compounds in shipwreck beer A56 and the reference beers are compared in Figure 3 (not measured in C49). All of the beers contained between 3.2 μg L^{-1} (Olvi Sandels) and 16.5 (Leffe Brune) μg L^{-1} 3-methylbutanal (Tb = 600 μg L^{-1}; unripe banana). There was greater variation for the other carbonyls. For 2-methylpropanal (Tb = 1000 μg L^{-1}; banana, melon) reference beers contained between 3.3 μg L^{-1} (Olvi Sandels) and 51 (Koff Porter) μg L^{-1}, whereas the shipwreck beer contained 58 μg L^{-1}. Phenylacetaldehyde (Tb = 1600 μg L^{-1}; hyacinth) could not be detected in the shipwreck beer and was between 5.7 μg L^{-1} (Weihenstephan Weissbier) and 25 (Koff Porter) μg L^{-1} in the reference beers. Furfural (Tb = 150 mg L^{-1}) ranged between 29 μg L^{-1} (Olvi Sandels) and 240 (Koff Porter) μg L^{-1} in the references and was much higher (664 μg L^{-1}), but still below threshold, in the shipwreck beer.

Organic Acids. Several fatty acids were measured in shipwreck beer A56 and three reference beers (Figure 4). The (normalized) concentration of lactic acid (Tb = 400 mg L^{-1}; acid) was extremely high (11.7 g L^{-1}) in A56 (and 10.5 g L^{-1} in C49; not shown in Figure 4) compared to the reference beers (100−200 mg L^{-1}). Acetic acid (Tb = 175 mg L^{-1}; vinegar) levels were also relatively high: 70−180 mg L^{-1} in the

reference beers compared with 493 mg L^{-1} in A56 and 542 mg L^{-1} in C49 (not shown in Figure 4). The other measured organic acids were present at much lower concentrations in the reference beers (0.2−16 mg L^{-1}). A56 contained higher levels of most of these acids, including about 20-fold more butyric acid (Tb = 2.2 mg L^{-1}; buttery, sweaty) and 15-fold more propionic acid (Tb = 150 mg L^{-1}; vinegar).

Phenolics. Several phenolic compounds were measured in the shipwreck beers and three reference beers (Table 3). Among these five beers, the wheat beer, Paulaner Weiss, was exceptional. It contained at least 5-fold more 4-vinylguaiacol and 2-fold more 4-vinylsyringol than any other beer and exhibited the highest concentrations of sinapic acid and 4-hydroxyphenylethanol and the lowest concentrations of *p*-coumaric, caffeic, and 4-hydroxyphenylacetic acids. The proportions of free compared to total hydroxycinnamic acids were much smaller (0% ferulic, 5% sinapic, and 15% *p*-coumaric) for Paulaner Weiss than for all other beers (7−17% ferulic, 9−22% sinapic, and 61−78% *p*-coumaric). The shipwreck beers more closely resembled the other references, Olvi Sandels (a lager) and Koff Porter. Total concentrations of phenolic acids in the shipwreck beers were within ±60% of those in the Olvi Sandels and/or Koff Porter references, except that vanillic and 4-hydroxyphenylacetic acids were 2−3-fold higher in the shipwreck beers. A56 contained more 4-vinylguaiacol than the Olvi Sandels and Koff Porter references, but much less than Paulaner Weiss. 4-Ethylguaiacol was below the limit of quantification in all beers.

Amino Acids. After acid hydrolysis, the main (total) amino acids in shipwreck beers were glutamate/glutamic acid, proline, and glycine (Table 4). The amino acid composition of the shipwreck beers was similar to that of modern commercial beers,[16] except that shipwreck beers had relatively more proline and alanine and less asparagine/aspartic acid. Proline was the main free amino acid in both shipwreck beers. The amino acid profiles of the two beers were similar, but C49 had a higher proportion of free glycine and a smaller proportion of free threonine and proline than A56. Differences of the same magnitude are found between different modern beers.[17]

Table 4. Amino Acid Profiles with (Total Amino Acids) and without (Free Amino Acids) Acid Hydrolysis

	total amino acids (%)		free amino acids (%)	
	A56	C49	A56	C49
alanine	9.6	9.6	12.2	12.9
arginine	1.9	1.8	3.2	3.0
aspartic acid + asparagine	5.1	4.9	5.8	5.0
cysteine	0.4	0.3	0.0	0.0
glutamic acid + glutamine	22.0	23.1	7.4	6.7

DISCUSSION

The overall shape and detailed features of bottles A56 and C49 indicate a high-quality technology that was not yet used in Finland in 1840, but had been used to manufacture beer bottles for two or three decades in central and northern Europe (personal communication; Risto Aalto, Riikka Alvik, Markku Annila, Ulla Klemelä, and Kaisa Koivisto). The presence of hop components (extensively degraded), maltose, and maltotriose identifies the bottles' contents as beers. The higher concentrations of hop components in beer C49 than in A56 cannot be explained by different degrees of chemical degradation or dilution by seawater and indicates that the bottles contained two different beers. Both shipwreck beers contained too little protein (Table 1) to permit protein identification by 2D gel electrophoresis. Most of the original protein was probably hydrolyzed (e.g., by proteolytic activity of lactic acid bacteria) and partially consumed by microorganisms during aging (both beers contained large numbers of dead bacteria and yeast). Peptides that may have been liberated by hydrolysis and still present in the beer would not have been detected in the protein assay employed as the acetone precipitation step is much less efficient for peptides than for proteins. The amino acid profiles of both beers were broadly similar to those of modern commercial beers (Table 4) and clearly different from, for example, that of apple cider.[18] Features such as the relatively high free proline content are consistent with the raw material being cereal grain but do not distinguish between barley and wheat, which have very similar amino acid profiles.[16] Furthermore, the amino acid profiles of the shipwreck beers have been disturbed by the activity of microbial contaminants.

The presence of hop-derived bitter compounds confirms the use of hops for bittering the beers. Kettle-boiling induces the transformation of α-acids to iso-α-acids and that of β-acids to hulupones.[6] The lack of α- and β-acids and the presence of iso-α-acids and hulupones therefore indicate that hops were added to the worts before kettle-boiling. The amounts of *cis*-iso-α-acids were higher than those of the corresponding *trans*-iso-α-acids, which is in line with the higher stability of *cis*-iso-α-acids and literature findings that *trans*-iso-α-acids are readily transformed into tri- and tetracyclocohumols, scorpiohumols, and tricyclolactohumols by proton catalysis during aging of beer.[7] Compared to modern beers, rather high amounts of these four compounds were detected; for example, 7.76 and 4.24 μmol L^{-1} of tri- and tetracyclocohumol were found in C49 compared to 1.00 and 0.46 μmol L^{-1} in a fresh Pilsner-type beer.[7] The high levels of these aging products can be explained by the low pH and long "reaction time" in the shipwreck. Interestingly, the unexpectedly large amounts of β-acid degradation products hulupones and hulupinic acid are consistent with old hop varieties containing higher levels of β-acids than modern varieties, which have been bred to maximize the α-acid content.

The lack of hydroxides and hydroperoxides of iso-α- and β-acids in beer A56 indicates that the degradation of the hop components was primarily driven by proton-catalyzed reactions rather than by autoxidation involving oxygen. In contrast, beer C49 contained oxidation products of α-, iso-α-, and β-acids such as hydroxides of allo-iso-α-acids, hulupones, and humulinic acids, clearly indicating autoxidation of hop

DOI: 10.1021/jf5052943
J. Agric. Food Chem. 2015, 63, 2525−2536

components during aging. These differences may be due partly to ingress of air after bottling of C49 but also suggest that the two beers originated from different batches of hops.

Both shipwreck beers contained much more sodium than is usual in beers. Presumably either Na^+ ions diffused into the beers through the cork or seawater entered the bottles. Assuming average concentrations during the last 170 years of 3000 mg Na L^{-1} and 100 mg K L^{-1} in the sea around the wreck at 50 m depth (Baltic salinity varies with time, location, and depth[19]), the beers may have been diluted with seawater by up to about 30%. Concentrations of other analytes may be too low by up to 30% from this cause alone. This may account for the low levels of ethanol in the beers. Concentrations in Figures 2−4 and Table 3 are normalized to 35 g ethanol L^{-1}, which corrects for simple dilution and provides a more meaningful comparison with the reference beers.

The predominant organoleptic properties of both shipwreck beers were unpleasant (acidic, salty, burnt, sulfury, etc.). These negative qualities masked any fruitiness, maltiness, or hopiness. The levels of several organic acids were unusually high in the shipwreck beers (Figure 4), which presumably caused their low pH (Table 1) and vinegary, goaty, and soured milk flavors. Optical and electron microscopy revealed numerous bacteria in both beers and four species of (non-spore-forming) lactic acid bacteria were recovered by cultivation (R, Juvonen, M. Raulio, A. Wilhelmson, and E. Storgårds, E; manuscript in preparation). The organic acids found in the beers can be produced by bacterial activity (e.g., lactic acid bacteria can produce several volatile fatty acids as well as larger amounts of lactic and acetic acids[20−22]). In the 1840s, "microbiological hygiene" was a matter of trial and error with empirical experience but no scientific basis. Flavors now known to be caused by bacteria may have been intended (as for Belgian Geuze beers) or production faults. In either case, the bacterial activity continued after the shipwreck and eventually produced unacceptably large amounts of organic acids. The presence of live, non-spore-forming bacteria means that vegetative cells have been metabolizing continuously, albeit slowly, for about 170 years.

Compared to modern beers,[11] beer A56 contained less maltose and both beers contained much less maltotriose and relatively high concentrations of glucose (Table 1). A plausible explanation is that after the initial (yeast-driven) fermentation, contaminating microbes excreted enzymes (e.g., amyloglucosidase) able to degrade residual carbohydrates to glucose. This glucose supply probably supported the growth and fermentative activity of lactic acid bacteria and other microbes. As conditions deteriorated (e.g., acidity increasing), the production of glucose exceeded the fermentative capacity of the remaining viable microbes, and glucose began to accumulate. This hypothesis would explain the high glucose and low maltotriose in the shipwreck beers, but does not immediately explain the relatively high maltose in beer C49.

Despite the unpleasant organoleptic features probably resulting from bacterial spoilage, chemical analyses revealed profiles of yeast-derived flavor compounds broadly similar to those of modern beers (Figure 2). There were some notable peculiarities. Both beers contained very little 3-methylbutyl acetate, but rather high levels of 2-phenylethanol and 1-propanol; A56 contained a high level of 2-phenylethyl acetate, but C49 contained very little; A56 (but not C49) contained a high level of ethyl decanoate and C49 especially contained a high level of ethyl hexanoate. A problem is to determine how much these results reflect the original character of the two beers rather than chemical changes during 170 years at about 4 °C. To our knowledge, there are no studies of the chemical stability of beer over such a long time. Vanderhaegen et al.[23] studied the stability of top-fermented beer for 6 months at 0, 20, or 40 °C. Rates of change were very temperature-sensitive. Many compounds that changed markedly in 6 months at 20 or 40 °C were stable at 0 °C. The amounts of ethyl acetate and 3-methylbutyl acetate decreased by 25 and 60%, respectively, at 40 °C, but did not change at 0 °C. Thus, possibly both shipwreck beers originally contained only little 3-methylbutyl acetate, an important flavor component (banana) of modern beers. More probably, its concentration has decreased during the long aging. Lambic beers contain little 3-methylbutyl acetate, and this is thought to result from the activity of an esterase produced by *Dekkera* (*Brettanomyces*) yeasts during the lambic fermentation.[24] Considering the lack of ethylphenol compounds in the beers, it may be more likely that an esterase derived from lysed *Saccharomyces* cells contributed to the loss of 3-methylbutyl acetate.[25]

Vanderhaegen et al.[23] found that ethyl hexanoate, octanoate, and decanoate in beer decreased rapidly during storage at 20 or 40 °C, and ethyl octanoate and decanoate decreased by 10 and 25% during 6 months at 0 °C. Malfliet et al.[26] observed similar lowering of flavor compound concentrations in a range of modern beers stored at 30 °C for 60 days or at 22 °C for 9 months. Thus, the original levels of ethyl hexanoate in both shipwreck beers and of ethyl decanoate in beer A56 were probably at least as high as shown in Figure 2 and would have contributed fruity (apple) flavors to the fresh beers. Ethyl hexanoate was above its taste threshold[15] of 0.2 mg L^{-1} in both beers. However, if an appropriate esterase was present, these esters could, instead, have been formed in the bottles from ethanol and hexanoic and decanoic acids produced by spoilage micro-organisms, so that the levels in Figure 2 may overestimate those of the fresh beers.

The level of 1-propanol may have been increased by metabolic interactions of lactic acid bacteria. *Lactobacillus buchneri* can convert lactate into 1,2-propanediol, which *Lactobacillus diolivorans* can further convert into 1-propanol and propionic acid.[21,2728]

We did not find long-term stability studies for phenylethanol. Malfliet et al.[26] noted that the phenylethyl acetate concentration was lowered by 10−20% during aging, possibly explaining the relatively low level of this compound compared to the phenylethanol in beer C49. The phenylethanol concentration in A56 shipwreck beer (Figure 2) was nearly twice that of modern beers but still below the taste threshold[15] of 125 mg L^{-1}. Phenylethyl acetate in beer A56 (0.68 mg L^{-1}), although higher than in the reference beers (Figure 2), was below its taste threshold[15] (3.8 mg L^{-1}). It is known that compounds present in concentrations below their taste threshold concentrations can still contribute to the general flavor of beers because of synergistic effects,[15] so that in typical modern beers phenylethanol and phenylethyl acetate contribute to the general floral flavor, rather than imparting a specific rose flavor. Yet, the higher concentrations of these compounds in one or both shipwreck beers may have introduced clearer rose notes. At least sake strains of *S. cerevisiae* can evolve to produce high levels of phenylethanol.[29,30,46] Unusually high levels of phenylalanine in the wort can also result in higher phenylethanol levels.[31−33] Moreover, increased uptake of phenylalanine occurs at higher temperatures[34] and may contribute to higher concentrations of phenylethanol in wines

DOI: 10.1021/jf5052943
J. Agric. Food Chem. 2015, 63, 2525−2536

fermented at higher temperatures.[35] Fermentation temperatures were poorly controlled in the 1840s and may have been relatively high during the summer. However, high phenylethanol concentrations might also have been caused by non-*Saccharomyces* yeasts in the brewing process. In the 1840s, pure yeast cultures were an unknown concept. Top fermentation was still the principal method. Fermentations were performed in open, wooden vessels that provided good attachment surfaces for microbes and were difficult to clean. Fermentations were open to airborne contamination and were pitched with the entire microbiota collected from a previous fermentation by skimming. This could have included several yeasts that today are classified as brewery contaminants, including *Dekkera* spp., *Kluyveromyces marxianus* and *Hanseniaspora* spp. that can produce high levels of phenylethanol.[33,36−41]

The level of total diacetyl (i.e., free diacetyl plus its α-acetolactic acid precursor) in beer A56 was within the typical range for beer, whereas the total pentanedione concentration was low (these two vicinal diketones were not analyzed in beer C49). In contrast to that, Vanderhaegen et al.[23] found large increases in diacetyl (3-fold at 0 °C; 50-fold at 40 °C) and pentanedione (30% at 0 °C and 8-fold at 40 °C) during storage of top-fermented beer for 6 months. Apparently this did not happen during aging of beer A56. Rather, this beer may have initially contained low levels of α-acetolactate and the 2,3-pentanedione precursor α-acetohydroxybutyrate, but a high fermentation temperature and low pH due to bacterial activity in the open fermentation vessels could have favored rapid oxidative decarboxylation of the α-acetohydroxy acids and prompted yeast-catalyzed reduction of the resulting vicinal diketones to the corresponding, flavor-neutral alcohols.

Shipwreck beer A56 contained slightly more 2-methylpropanal than the two reference porters but much more than the lager (Olvi Sandels) (Figure 3). 2-Methylpropanal increases during aging, and levels in the A56 beer are similar to those in pale lagers aged for 6 months at 22 °C[26] The level of 3-methylbutanal in A56 was about twice that in Olvi Sandels, but less than that found in modern wheat beers and porters. Levels of 3-methylbutanal can increase 6-fold (reaching 21−43 μg L^{-1}) during storage of top-fermented beers and lagers, especially in the presence of oxygen.[23,26] The relatively low value for 3-methylbutanal in beer A56 suggests that this bottle did not contain much oxygen or that the reactions leading to its formation were very slow at deep Baltic sea temperatures (approximately 4 °C). This assumption is clearly supported by the fact that, in contrast to beer C49, no hop-derived oxidation products of the α-, iso-α-, or β-acids were detected in beer A56.

Furfural is formed during aging of beers.[23] However, its level was less than that (2500 μg L^{-1}) reached during aging of a modern ale for 6 months at 40 °C[23] and much less than the reported taste threshold in beer[15] (150,000 μg L^{-1}). Yet, A56 contained much more furfural (660 μg L^{-1}) than any of the reference beers and very much more than a modern lager (29 μg L^{-1} for the Olvi Sandels). It might also have been formed thermally during mashing. Presumably the mash and wort were heated over an open fire, requiring very effective stirring to prevent burning of local patches of mash against the inner wall of the pot. Whether the resulting burnt flavor (not necessarily from furfural itself) was perceived as positive or negative is unclear.

We have no information about the stability of phenolic compounds in beer at about 4 °C. Still, the concentrations of phenolic compounds remaining in the shipwreck beers were similar to those found in a bottom-fermented lager (Olvi Sandels) and top-fermented porter (Koff Porter) but differed from those in a modern wheat beer (Paulaner Weiss). Paulaner Weiss contained 5−20-fold more 4-vinylguaiacol (clove flavor) than the shipwreck beers and much smaller proportions of the free forms of ferulic, sinapic, and *p*-coumaric acids (Table 3). 4-Vinylguaiacol is formed by decarboxylation of (free) ferulic acid catalyzed by phenylacrylic decarboxylase (Pad1). Pad1 is absent from bottom-fermenting (lager) strains of brewer's yeast[42] but present in some top-fermenting strains (including all tested strains used for production of wheat beers[42]) and in *Brettanomyces* (*Dekkera*) yeasts[44] and some lactic acid bacteria.[45] Table 3 results suggest that all of the free ferulic acid in Paulaner Weiss has been decarboxylated to 4-vinylguaiacol, but that, in contrast, most of the microorganisms responsible for the fermentation of the shipwreck beers did not produce active Pad1. The small amounts of 4-vinylguaiacol found in the shipwreck beers and the other two reference beers may derive from thermal degradation of ferulic acid during wort boiling.[43] The very small amounts of 4-ethylguaiacol in both shipwreck beers (Table 3) suggest that *Dekkera* spp. did not contribute significantly to their fermentation, because these yeasts produce large amounts of ethylphenols.[43] Levels of total and free ferulic acid are in agreement with those reported by Vanbeneden et al.[43] for 58 beers of many types (bound, 11.4 ± 2.6 mg L^{-1}; free, 1.3 ± 0.8 mg L^{-1}), except that the concentration of free ferulic acid in Paulaner Weiss was lower than in many wheat beers (0.81 ± 0.44; $n = 9$).

In summary, these two about 170-year-old bottles contained two different beers, one (C49) more strongly hopped than the other (A56) with the low α-acid yielding hop varieties common in the 19th century. Both beers exhibited typical profiles of yeast-derived flavor compounds and of phenolics. Present knowledge of the long-term chemical and microbiological stability of these compounds is not adequate to assess how closely the observed profiles indicate the original flavor of the beers. The flavors of these compounds were hidden by very high levels of organic acids, probably produced by bacterial spoilage. The composition of the microbial mixture used to produce these beers is unclear, but it probably did not include many strains producing the Pad1 enzyme responsible for the volatile phenols characteristic of wheat beers. Pad1 activity is common in wild yeast, and its absence suggests that the yeasts employed were domesticated rather than wild.[47]

Table 1. The feeding experiment was approved by the Iowa State University Institutional Animal Care and Use Committee (IACUC).

Table 1. Concentrations of Annatto and α-Tocopherol in Supplemented Diets

diet	annatto[a] (ppm)	α-tocopherol[b] (TC, ppm)
control	0	0
T3 100	100	0
T3 500	500	0
T3 2000	2000	0
TC 200	2000	200
TC 600	2000	600
TC 1000	2000	1000

[a]Annatto tocotrienols: total tocotrienols, 74.5% (δ-tocotrienol 89.2%, γ-tocotrienol 10.8%, and other tocotrienols/tocopherols <1%). [b]α-Tocopherol: 96.6%

The base diet met the NRC nutrient recommendations.[17] The hens were randomly assigned to a treatment and were kept in an environment similar to that of most modern industry laying facilities. The average temperature was 25 °C and the average relative humidity was 40%. The lighting was on for 16 h and off the remaining 8 h of the day. Three hens were placed in each cage (experimental unit, EU) with 30 cages (10 stacks with 3 tiers per stack) total. Only 28 cages were needed to house the 84 laying hens; two cages were not used due to air velocity difference and failure of eggs to roll to the front, causing breakage. There were seven treatments diets (Table 1) with four replicates (4 EUs) for each treatment, thus 12 hens per treatment diet. Upon arrival to the new environment, the hens were given a week of acclimation. No mortalities occurred during this study.

Feed Mixing. A horizontal mixer (Precision horizontal batch mixer; H.C. Davis Sons Mfg Co., Inc., Bonner Springs, KS) combined the base diet for 30 min. To mix the supplements into the base diet, the appropriate amount of annatto and/or α-tocopherol was weighed and then was mixed into a small amount of the base diet to ensure it was well incorporated. This mixture was then added to more feed and mixed well with a Hobart mixer (model H-600; Hobart, Troy, OH). This portion was then incorporated into the entire diet portion with the same horizontal mixer that was used to mix the base diet. Feed was stored at refrigeration temperatures (4 °C) away from light and taken to the experimental site daily, where hens were fed and watered ad libitum throughout the entire study. Daily measurements taken precisely every 24 h were feed disappearance and egg production. Hen body weight was taken weekly as an indicator if the hens were eating properly.

Egg Sampling and Storage. The eggs were collected daily for the first 2 weeks and weekly for the remaining 5 weeks. Eggs were taken from 2 days and pooled (i.e., day 1 and day 2 eggs are referred to day 2 eggs in this study). The sampling days were 2 (1−2 days), 4 (3−4 days), 6 (5−6 days), 8 (7−8 days), 10 (9−10 days), 12 (11−12 days), 14 (13−14 days), 21 (20−21 days), 28 (27−28 days), 35 (34−35 days), 42 (41−42 days), and 49 (48−49 days). For sample preparation, the egg yolks were carefully separated from the albumen and rolled on a paper towel to ensure only yolk was taken. The yolks from one cage over 2 days were homogenized manually, and a sample was taken and stored at −4 °C until further analyses were carried out. The frozen egg yolks were then freeze-dried (Virtis Genesis 25LE) for at least 72 h to remove the moisture by sublimation to preserve the lipids.

Physical and Sensory Properties of Eggs and Egg Yolks. The quality of the eggs collected was measured at every sampling time by using a high-accuracy digital egg tester DET6000 (Nabel, Japan). The measurements taken included whole egg weight (grams), eggshell strength (newtons), egg yolk color (yolk color fan, YCF), Haugh unit (calculated from albumen height), and eggshell thickness (millimeters). The YCF taken objectively by this instrument is based on tristimulus values standardized by the 1931 CIE colormetric according to the instrument manual.

Trained Sensory Panel Evaluation on Egg Yolk. To determine whether and how different the treatment eggs (days 35 and 36) were from the control, nine panelists were trained in four training sessions to evaluate the egg yolk for yolk color (less to more yellow), moistness (low to high), smoothness (lumpy to smooth), chalkiness or mouth drying (none to intense), savory egg yolk flavor (none to intense), bitterness (none to intense), and off-flavor (none to intense) on a 15 cm line scale. To calibrate the panelists to these attributes, anchors were used and included egg yolks from the extreme diets (control, T3 2000, and TC 1000) for each scale, YCF for yolk color, and quinine solution for bitterness. For sample preparation, eggs were hard-boiled and consistently cooled by refrigeration, followed by cutting in half and serving to the panelists, cut side down, on a plate labeled with a random 3-digit code in a random order to minimize bias. The four replicates were evaluated on four separate days with panelists' scores averaged on each day.

For all remaining analyses, the egg yolk was carefully separated from the albumen and analysis was conducted on only the egg yolk. Viscosity was measured on the raw separated egg yolks collected from day 47 by use of a Haake RS 150 rheometer (ThermoOrion, Karlsruhe, Germany). This measurement was taken as explained in Walker et al.[2]

Chemical Properties of Egg Yolks. *Total Egg Yolk Moisture.* Total moisture was measured by drying 2 g of yolk in an aluminum dish for 4−5 h at 105 °C as stated in AOAC Standard Method 922.06. This measurement was done on day 28 yolks after they were homogenized.

Egg Yolk Lipid Extraction. Freeze-dried egg yolk samples were ground with a mortar and pestle to reduce particle size, and the yolk was a fine powder. About 0.5 g of the ground freeze-dried yolk powder was accurately weighed into a glass vial and mixed with 5.0 mL of chloroform/methanol (2:1 v/v), similar to the procedure of Folch et al.[18] The vials were capped and manually shaken for 30 s to ensure full dispersion of the solid in the solvent. The vials were placed in a shaker at ambient temperature overnight and then centrifuged to obtain a clear layer. Approximately 2 mL of the supernatant was filtered through a 0.45 μm filter [polytetrafluoroethylene, PTFE] with a glass syringe. The filtrate (1.0 mL) was taken precisely and placed in a preweighed glass vial, and the solvent was evaporated with a nitrogen evaporator to prevent lipid oxidation. To ensure all of the residual solvent was removed, the samples were placed in a vacuum oven at ambient temperature overnight. The vials were weighed to calculate total oil extracted. The oil was then dissolved in HPLC-grade hexanes and stored in an explosion-proof −20 °C freezer until further analyses were carried out, including HPLC quantification of tocopherols and tocotrienols.

Egg Yolk Phospholipid Composition. ^{31}P NMR was used to determine the phospholipid profile for day 21 egg yolk samples. After the egg yolk oil was extracted, a small sample (80−120 mg) of oil was taken and prepared as explained by Yao and Jung.[19] These samples were analyzed for phospholipid content and class composition in the egg yolk oil.

Egg Yolk Fatty Acid Composition. A small sample of egg yolk oil from day 49 was converted to fatty acid methyl esters (FAME) by mixing the lipid with 1 mL of 1 M sodium methoxide at ambient temperature for 5 h. The reaction was stopped by adding 3 mL of deionized (DI) water. Hexanes (2 mL) were added to extract the FAME to the top layer. The FAME samples were then analyzed by gas chromatography (GC; Hewlett-Packard 5890 series II) with a FID detector and a capillary column from Supelco (Bellefonte, PA; SP-2340, 60 m long × 0.25 mm internal diameter ×0.2 μm film thickness). Parameters used for GC quantification were injector and detector temperature of 250 °C and oven temperature-programmed to start at 100 °C and rise 4 °C/min to finish at 240 °C. The flow of gases was set as in Walker et al.[2] A standard solution of FAME (Nu-Check Prep Inc. GC reference standard 566) was used to identify fatty acid peaks in the egg yolk lipid samples.

Vitamin E Content in Egg Yolk. Egg oil was dissolved in an appropriate volume of HPLC-grade hexanes to obtain vitamin E isomers in the quantifiable region. HPLC was run as explained in Walker et al.[2] Concentrations of tocopherols and tocotrienols were determined by normal-phase HPLC with a Luna 3 μm NH_2 100 Å, 150 mm × 3.0 mm column (Phenomenex, Torrance, CA) and fluorescence detection. The separation was achieved isocratically with a mobile phase of 98% hexanes and 2% 2-propanol.

Vitamin E Transfer Efficiency to Egg Yolk. Transfer efficiency was calculated on the basis of the maximum concentration reached for each treatment (all of these occurred at approximately day 10). For this calculation, the amount of supplement that theoretically could have been completely or 100% transferred (i.e., the amount of supplement provided from feed daily) was calculated from supplement composition (Table 1), daily feed consumption, laying rate, and egg yolk weight. The ratio of the value quantified to the theoretical value calculated on the basis of complete transfer is the transfer efficiency, expressed as a percentage.

Egg Yolk Cholesterol Quantification. To quantify total cholesterol in the egg yolks, a Wako Cholesterol E (Mountain View, CA) kit was used. The procedure was carried out as instructed, with 2 mg of freeze-dried egg yolk (weighed with an analytical balance) mixed with the color reagent provided by the kit. This mixture was shaken and allowed to react for 15 min at 37 °C, ensuring that all of the yolk was uniformly dispersed in solution for blue pigment formation. The samples were centrifuged to settle the egg yolk particle, and the liquid was carefully pipetted into a cuvette. The cuvette was read on a spectrophotometer (Beckman Coulter DU 720 UV/vis spectrophotometer) at 600 nm, with DI water as a blank. A standard curve was constructed each time samples were measured, by use of the standard cholesterol provided in the kit, to quantify the cholesterol in the egg yolks.

Statistical Analysis. Statistical analysis was done with JMP Pro (version 10, SAS Institute Inc., Cary, NC). One-way analysis of variance (ANOVA) was used for mean comparisons, and all-pairwise comparisons were done by use of Tukey's honest significant difference (HSD) at $p = 0.01$ (sensory and fatty acid data) or $p = 0.05$ (all other data).

RESULTS AND DISCUSSION

Hen Production Performance. The daily feed disappearance, weekly laying rate (100 × eggs produced/hens in cage), and weekly averaged hen body weight are shown in Table 2. No significant differences were found among treatments in the laying rate or hen body weight. The laying rate was over 90% for all diets, similar to that reported in literature.[2,13,20] All hens on treatment diets consumed significantly more feed than those

DOI: 10.1021/jf505536u
J. Agric. Food Chem. 2015, 63, 2537−2544

on the control diet, with no differences among treatments, indicating that the annatto additive caused the hens to consume more feed even at the lowest concentration.

Annatto has a potent red-orange color from bixin and norbixin carotenoids present and is traditionally used in many industries for coloring various products. But due to the low lighting in the environment, broad-spectrum sight of the laying hens,[21] and low concentration of supplement in the feed with very subtle visual change in color of feed, the cause for the higher feed disappearance is not believed to be associated with the color of the additive. The pure annatto supplement used was tasted by the researchers, and it had a bitter and fruity taste. Its addition to the feed may have made the feed more palatable to the laying hens, causing an increase in the average amount of feed consumed. Chickens have been shown to be sensitive to salty or bitter substances.[22] Not knowing how the laying hens perceive the annatto supplement, it is difficult to know exactly what caused this increase. The hens consuming more feed but not producing more eggs would lead to higher production costs. The egg is considered to be the gold standard for protein;[23] thus increasing the cost of production is not desirable for the industry or egg consumers. A potential application of this supplementation may be for broiler chickens for more rapid muscle growth. Kudo et al.[24] found that broiler chickens had the highest number of taste buds over layer type and Rhode Island Red type. The higher feed consumption likely can lead to faster rate of growth and meat production.

Physical and Sensory Properties of Eggs and Egg Yolks. No significant differences were found in whole egg weight, egg yolk weight, egg shell strength, yolk color, Haugh unit (HU), or egg shell thickness averaged over time (Table 3). It was expected that there would be minimal changes in the physical and quality properties due to the supplements. All HUs on average were greater than 72, indicating that the eggs produced in this feeding study were AA eggs by USDA grading standards,[25] and the HUs were similar to those found in literature.[2,26] Significant differences were found in yolk viscosity, with many of the treatment diets (T3 500, T3 2000, TC 200, and TC 600) being significantly lower than the control.

Kirunda et al.[27] also reported inconsistent and lower measurements for viscosity of yolk from diets with vitamin E supplementation. Environmental or storage conditions may cause changes in viscosity, that is, increasing storage time decreases viscosity,[28] but all eggs were exposed to the same environmental and storage conditions. In the study of Walker et al.,[2] the only significant difference in yolks from hens supplemented with palm toco concentrate and astaxanthin was the emulsification capacity, with a significant decrease upon increased level of supplementation. It is uncertain why a decrease in emulsification capacity was seen in the egg yolks, but it was thought to be due to changes in egg yolk protein and lipid interactions. A similar change could have occurred in this study due to feed supplementation. Egg yolk is a complex system with a large amount of water, lipoproteins, and free proteins. Understanding the changes in viscosity will require further compositional and microstructural studies of the yolk, which are beyond the scope of this work. Nonetheless, such changes in viscosity may impact the egg yolk functionality and its applications.

Trained Sensory Panel Evaluation on Egg Yolk. A trained sensory panel was carried out to determine what changes were perceived by a trained sensory panel. No significant differences were perceived in moistness, smoothness, chalkiness/mouth drying, bitterness, or off-flavor (Table 3). It is interesting to note that a general trend is seen that as the moistness increased, the viscosity decreased, although not significantly. Although the annatto supplement had bitter, astringent, and fruity flavors, these flavors of the pure annatto extract were not transferred to the eggs based on the trained sensory panelist's evaluation. Panelists did perceive the yolks of the TC 200 and TC 600 diets to be significantly more yellow than those of the control. The egg yolk color measured instrumentally (Table 3) did not show any significant differences in the color of the raw egg, indicating that cooking of the eggs may have enhanced the difference in yellow color of the yolk. The scale set by panelists was a narrow range in yellow color with the extremes not being unacceptable to a consumer, indicating although a change in yolk color in some of the supplemented diets was perceived, it was not seen as a negative quality. Some consumers prefer a more intense yellow or paler yellow egg yolk. Preferences in egg yolk color also vary with geographical and cultural differences, with many consumers associating a certain color of egg yolk with level of quality and safety of the eggs.[29,30] Other studies had shown an increase in the yellow color of egg yolks with annatto supplementation,[20,29] but the levels of supplementation in this study were much lower, thus showing much less of an effect on yolk color. The savory yolk flavor was perceived to be lowest in the TC 1000 diet, but the level of change is not expected to be unacceptable to consumers.

Chemical Properties of Egg Yolks. *Total Egg Yolk Moisture.* There was no significant difference among the treatment diets for moisture content (48.30−48.84%). Moisture content of an egg yolk can vary with breeds of chicken, but 48−49% moisture is consistent with the dry solids content of 52−53% reported by Varadarajulu and Cunningham.[31] Generally, 50% moisture content is accepted for an egg yolk,[32] and the values found in this study were comparable to this.

Because significant differences were found in viscosity, it was expected that there would be differences in moisture content. Many of the treatments had lower viscosity values than the control, indicating a thinner yolk, which would be attributed to higher moisture; but this was not observed.

Egg Yolk Lipid Content. There was no significant difference among the treatment diets for egg yolk lipid content (63.43−64.34% dry basis, db). The total lipid found in the egg yolks was slightly higher than that found in literature of 62.5% dry basis.[32] It was assumed that the modification of the Folch[16] lipid extraction procedure of not using a water wash step would leave extractable proteins in the lipid extract, thus causing the increase. However, when the traditional Folch wash was carried out for the same egg yolk samples, the results were similar to those measured with the modified method.

Egg Yolk Phospholipid Composition. ^{31}P NMR was performed to determine the weight percent of phospholipids for egg yolks from day 21. Peaks in the NMR spectrum were identified by methodology from Yao and Jung.[19] No significant differences were found among treatment diets in any of the phospholipids. The major phospholipids detected were phosphatidylcholine (74.74−75.54%) and phosphatidylethanolamine (19.00−20.25%), which are expected in egg yolk. The total phospholipid in the yolk lipid (21.11−24.94%) was comparable with that reported in literature.[2,32] Other minor phospholipids in the egg yolk samples were phosphatidylinositol (0.82−1.48%), lysophosphatidylcholine (1.22−1.44%),

J. Agric. Food Chem. 2015, 63, 2537−2544

sphingomyelin (1.90−2.47%), and lysophosphatidylethanolamine (0.59−0.80%). Phospholipids have many applications in the food industry[33] and are important biological molecules in maintaining a healthy body.[34]

Egg Yolk Fatty Acid Composition. The fatty acids detected in day 49 yolk samples were 16:0 (24.37−26.26%), 16:1 (2.04−2.57%), 18:0 (9.29−10.05%), 18:1 (39.53−40.92%), 18:2 (15.91−17.05%), 20:4 (1.88−2.19%), and 22:6 (0.48−0.60). There were no significant differences in any of the fatty acids reported across the treatment diets, and the percentages found are similar to those reported in literature.[2,32,35]

Vitamin E Content in Egg Yolk. After 10 days of feeding the supplement diets, a steady state of nutrient transfer of vitamin E to the egg yolk was reached, as shown in Figure 1, the same as reported by Walker et al.[2] The forms of vitamin E reported in the figure include α-tocopherol, γ-T3, and δ-T3 because these are the major forms of vitamin E in the supplements added to the feed. It is evident from the kinetics of transfer shown in Figure 1 that α-tocopherol was transferred at a much higher rate than either γ- or δ-T3, even when supplemented in similar amounts.

To understand how the additives were transferred to the yolk, measurements after steady state (day 10 and after) were averaged and compared, as shown in Table 4. Diets without α-tocopherol supplementation (control, T3 100, T3 500, and T3 2000) were not significantly different, with similar amounts of α-tocopherol as reported by the USDA Nutrient Database.[36] There is α-tocopherol in the base diet, and the amount found and transfer efficiencies are the same across these treatments. As expected, the amount of α-tocopherol in the egg yolks significantly increased as the amount of α-tocopherol added to the feed increased. At steady state, γ-T3 was the highest in T3 2000, showing that α-tocopherol did decrease the amount of γ-T3 transferred, but this was not significant until the use of highest level of α-tocopherol (TC 1000). This outcome indicates that when α-tocopherol is present at a high concentration, it lowers the amount of γ-T3 transferred to the egg yolk from the feed.

δ-T3 was significantly higher in diets supplemented with 2000 ppm of annatto, with none of the diets supplemented with α-tocopherol being significantly different from T3 2000. Therefore, α-tocopherol did not impact the transfer of δ-T3 as it did for γ-T3, and this is believed to be due to the differences and similarities of structure between the various forms of vitamin E. γ-T3 is more structurally similar to α-tocopherol (three methyl groups) with two methyl groups on the ring structure, but δ-T3 has only one methyl group on the phenolic ring.[3] α-Tocopherol is reported to interfere with absorption of T3s with a dose−response relationship,[37] and this is believed to be due to how the various forms of vitamin E are inherently transported and distributed.

When the supplement diets without α-tocopherol were compared, T3 500 and T3 2000 diets were significantly higher in γ- and δ-T3 than the control, and they were different from each other. Thus, it is possible to increase γ- and δ-T3 in the egg yolks with increasing annatto supplementation, although this was not proportional to its concentration in the feed and the quantity transferred is not very high.

Vitamin E Transfer Efficiency to Egg Yolks. α-Tocopherol was transferred much more efficiently (21.19−49.17%) to the egg yolk than either γ-T3 (0.50−0.96%) or δ-T3 (0.74−0.93%), as reported in Table 5. Significant decreases in the transfer efficiency of α-tocopherol were observed when it was supplemented at higher concentration. Decreases in γ-T3 transfer efficiencies were observed after supplementation passed

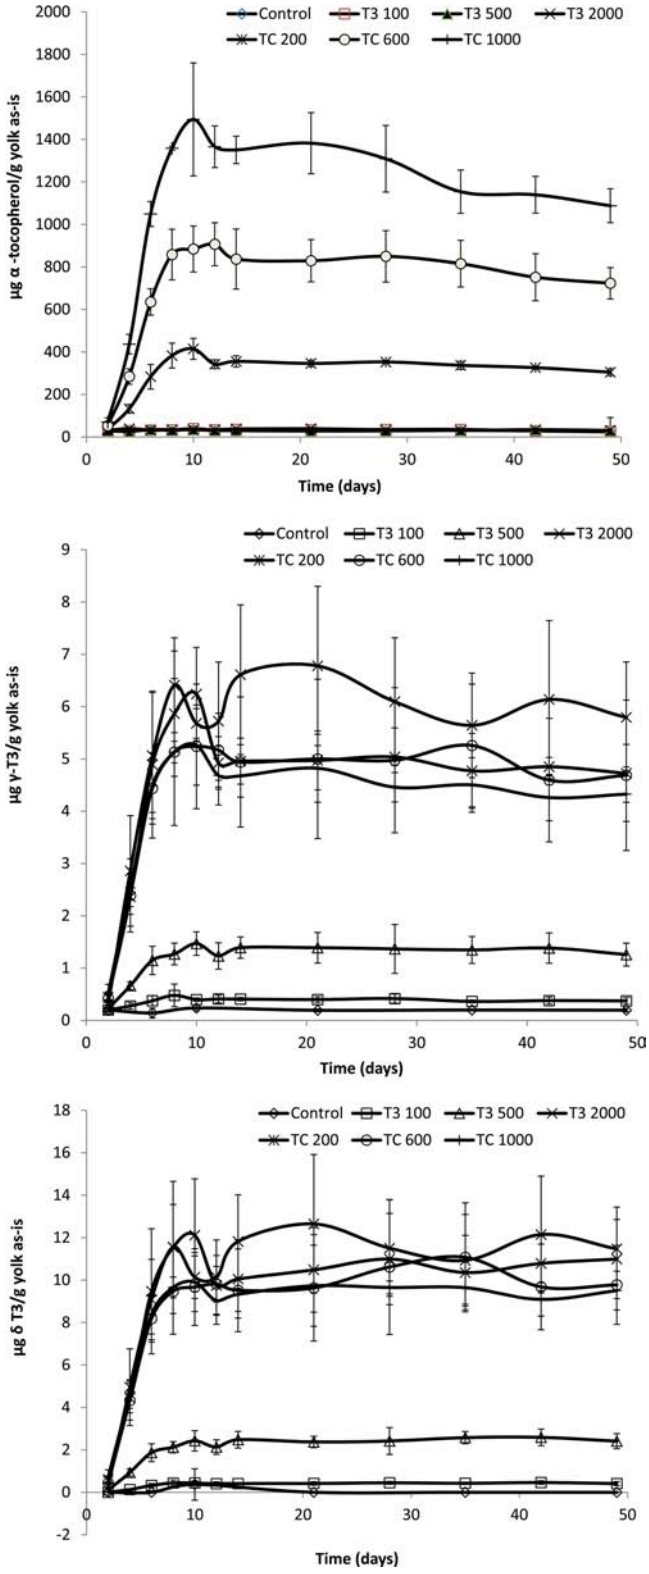

Figure 1. Kinetics of (top) α-tocopherol, (middle) γ-T3, and (bottom) δ-T3 accumulation in egg yolk over 7-week feeding period, showing means and standard deviation bars (n = 4). Diets are detailed in Table 1. T3 = ppm of annatto; TC = ppm of α-tocopherol with constant 2000 ppm of annatto.

significance[c]	*	*	NS

[a]Values are means at maximum value ± standard deviations for $n = 4$. Different uppercase letters (comparing all treatments), and Greek letters (comparing T3 2000, TC 200, TC 600, and TC 1000) in the same column indicate significant differences at the 95% confidence level. [b]Diets are detailed in Table 1. Tocotrienols (T3) = ppm of annatto; α-tocopherol (TC) = ppm of α-tocopherol with constant 2000 ppm of annatto. [c]NS, not significant at 5%.

100 ppm, but the efficiency was not impacted by added α-tocopherol.

The transfer efficiency for α-tocopherol was much higher than that reported by Walker et al.[2] (9.9%) and very similar to that reported by Walde et al.[13] (39.59−44.78%). Efficiency decreased as more α-tocopherol was added. This decrease indicates that there was a leveling off, possibly due to saturation of the α-tocopherol transfer protein (αTTP) in the liver that is an important step in the uptake of vitamin E, especially α-tocopherol.

Tocotrienols had been shown to have poor absorption and transfer to egg yolks in the literature previously;[2,13] thus low transfer efficiencies were not unexpected. The transfer efficiency of γ-T3 was higher than those reported by both Walker et al.[2] (<about 0.1%) and Walde et al.[13] (0.37−0.40%). δ-T3 was transferred at a level higher than that reported by Walker et al. and Walde et al. (about 0%).

α-Tocopherol was more efficiently transferred to the yolk and this was expected due to the presence of an αTTP in the liver, which preferentially binds α-tocopherol, making it more bioavailable.[4] When the highest T3 diet, T3 2000, is compared with the TC diets, no significant differences are found, indicating that adding more α-tocopherol did not impact the transfer efficiency of γ-T3. This can also be seen in δ-T3, with no significant differences among the treatment diets. This trend was expected because α-tocopherol dominated the αTTP, causing the T3s to be mostly excreted. Overall, it was observed that annatto T3s were not well absorbed, with high concentration detected in the manure (manuscript under review), showing a need for a better carrier system or matrix to transport T3s into the body.

Egg Yolk Cholesterol Quantification. The amount of cholesterol in day 2, 21, and 49 yolks was determined spectrophotometrically, and the results are shown in Table 6.

Table 6. Cholesterol Content of Day 2, 21, and 49 Egg Yolks from Diets with Different Levels of Annatto Tocotrienol and α-Tocopherol Supplementation[a]

	cholesterol (mg/g of yolk as-is)		
diet[b]	day 2	day 21	day 49
control	14.62 ± 1.64	14.61 ± 1.22	14.87 ± 0.49
T3 100	14.71 ± 1.74	15.80 ± 2.93	15.21 ± 1.71
T3 500	14.09 ± 1.32	14.60 ± 1.13	14.37 ± 1.03
T3 2000	15.18 ± 1.41	14.37 ± 1.03	14.46 ± 0.25
TC 200	13.68 ± 0.96	13.20 ± 1.50	13.49 ± 0.92
TC 600	14.90 ± 0.68	15.52 ± 1.43	13.52 ± 0.45
TC 1000	14.71 ± 1.43	13.24 ± 1.21	13.94 ± 1.42
significance[c]	NS	NS	NS

[a]Values are means ± standard deviations for $n = 4$. [b]Diets are detailed in Table 1. Tocotrienols (T3) = ppm of annatto; α-tocopherol (TC) = ppm of α-tocopherol with constant 2000 ppm of annatto. [c]NS, not significant at 5%.

This method was a modification that used a cholesterol quantification kit designed for biological samples, especially blood serum. To validate this method, various tests were performed to ensure it was accurate and appropriate. With the freeze-dried egg yolk being a mass of solid particles, the concern was length of time for the reaction to reach completion. A time-lapse study was done to ensure that all cholesterol present in the egg yolk powder reacted fully. It was observed that at 15 min (3 times longer than required by kit), the ratio of absorbance to mass of freeze-dried egg yolk reached a constant, and it did not change significantly after 15 min.

When an average of the egg yolk weights (14.61 g/yolk) is used, the range of cholesterol in the yolks was 192−231 mg/yolk. This amount is in general consistent with values reported in the literature.[39−41] Kazmierska et al.[41] discussed how different techniques for quantifying cholesterol gave slightly different results. For this reason, AOCS saponification and then GC method (Ca 6b-53) was done on selected treatments

DOI: 10.1021/jf505536u
J. Agric. Food Chem. 2015, 63, 2537−2544

(control and T3 2000) to compare the amount of cholesterol quantified. No significant differences were detected among treatments. However, it was noted that the kit used in this study resulted in 18.37−20.63% higher values than the AOCS saponification and GC method, possibly due to complete quantification of all cholesterol forms. The kit method in this study allowed for detection of both free cholesterol and cholesterol ester, with the enzyme cholesterol ester hydrolase freeing cholesterol esters to allow for total quantification.

It is well-known that cholesterol ester takes longer to free the cholesterol during saponification compared to the hydrolysis of other lipid ester bonds.[42] It is not well understood how the amount of cholesterol changes (i.e., hydrolysis of ester or degradation of the free sterol) under conditions of heat and high pH during saponification. Busch and King[43] reported that cholesterol was heat-labile at 45 °C in the presence of 1 M KOH, which are conditions typically milder than that used in various cholesterol quantification procedures. Egg yolks were reported to have 10−15% of the cholesterol present as esters.[44] If the ester hydrolysis was incomplete or there was free cholesterol degradation during the saponification, the standard AOCS method would lead to an underestimation of the total cholesterol content.

In reporting the amount of cholesterol in an egg, it is important to specify the weight size class of the egg (peewee, small, medium, large, extra-large, or jumbo).[25] The average egg weight found in this study was 59.69 ± 0.37 g (with shell). According to the USDA Nutrient Database,[36] a large egg is 50 g and an extra-large egg is 56 g at a minimum without shell, so it is most appropriate to use the USDA grading manual[25] (weights with shells included) to categorize the eggs with shell in this study. According to these standards, the eggs in this study are large eggs. USDA reports the yolk of a large egg to be 17 g, much larger than the average in this study (14.61 g). Our yolk weight is very accurate because any attached egg albumen outside the yolk was removed with paper towels. It is evident that, based on weight for the large egg class and its yolk size as determined in this study, the amount of cholesterol reported by the USDA nutrient database, 184 mg/large yolk or 12.6 mg cholesterol/g of yolk as-is, is lower than that found in this study, 14.4 mg cholesterol/g of yolk as-is average across all treatments and days. The reasons for this difference are discussed above.

No significant cholesterol reductions over the feeding study were seen across treatment diets. Walde et al.[13] found a 4% or 6% reduction in diets supplemented with barley or palm T3s, respectively, but this trend was not seen in our study. A key difference in our study and the study by Walde et al.[13] is the form and amount of T3s present in the sources. Barley had mixed tocopherols and T3s, with α-T3 being the dominant form. Palm also contained mixed tocopherols, with γ-T3 being the dominant molecule. Even though egg from this study can contain up to a similar level of total T3 (~100 μg/egg) as that of Walde et al., we did not observe cholesterol reduction. Harder et al.[15] also observed lower cholesterol content in eggs with higher levels of supplemented annatto in the feed, particularly above 1.5% supplementation. However, there was no information on the T3 content in the annatto. Nonetheless, McGonigle et al.[16] observed no significant difference in the cholesterol content in eggs when feed was supplemented with annatto, similar to the observation in this study.

T3s have been shown to lower cholesterol levels in many studies.[5−12] Yu et al.[12] showed that supplementation with 50−2000 ppm of δ- and γ-T3 in young female chickens caused decreases in total serum cholesterol (32%), LDL levels (66%), and triacylglycerols (TAGs), with minimal changes to HDL cholesterol. In our study, blood samples were taken from the hens at day 49 of our feeding trial (37 weeks old), and they also showed no significant changes in lipid chemistry (total cholesterol, HDL, and TAGs; data reported in Hansen et al., manuscript under review). We do not know the cause of the different outcomes, but we thought that the use of young female birds versus adult laying hens may play a role in these differences.

In summary, annatto and α-tocopherol supplements did not significantly impact most of the hen performance indicators and quality parameters of the resulting egg yolks. Significant differences were found in daily feed disappearance, egg yolk viscosity, sensory yolk color, and savory yolk flavor and in the amount and transfer efficiency of various forms of vitamin E in the egg yolks. On the basis of both data over time and transfer efficiencies at the maximum value for α-tocopherol, γ-T3, and δ-T3, it is evident that α-tocopherol is much better transferred to hen egg yolks and does play some role in how the other forms of vitamin E are absorbed. This study confirms that the T3s cannot be substantially transferred in hen's body and yolk, even when there is no significant amount of α-tocopherol present to compete with the binding protein. This study illustrates that by changing what is in laying-hen feed, it is possible to change the nutrients in an egg, but only when the physiology of the animals allows. Novel approaches have to be designed to overcome the physiology barrier in order to make the hens more efficiently transfer the T3s to the egg. With a better delivery system, it may be possible to observe a cholesterol reduction effect of T3s in egg.

QDs. A conventional bulk polymerization was adopted to construct the MIP layer on the QDs for production of sesamol recognition sites in the prepared optosensing imprinted polymers. The MIPs and QDs acted as the recognition and response elements, respectively, and a spectrofluorometer was used as the signal output element in the process of experiment. The advantages of this experiment are easy preparation, portability, and simple and rapid operation.

MATERIALS AND METHODS

Materials and Reagents. Sesamol, piperonal (PN), *tert*-butylhydroquinone (TBHQ), and *tert*-butylhydroxyanisole (BHA) were obtained from Acros Organics (Morris Plains, NJ, USA). Other chemicals used for the MIP synthesis were the functional monomer methacrylic acid (MAA) and the cross-linker ethylene glycol dimethacrylate (EGDMA), which were purchased from Sigma-Aldrich (Shanghai, China), and 2,2-azobis(isobutyronitrile) (AIBN, 99%), which was purchased from Tianjin Kermel Chemical Reagents Co., Ltd. (Tianjin, China). CdSe/ZnS QDs were purchased from Jiayuan (Wuhan, China). Anhydrous ethanol and chloroform were of analytical reagent grade from Tianjin No. 1 Chemical Reagent Factory (Tianjin, China). Refined sesame oil was obtained from a local factory.

Characterization. Fluorescence measurements were performed on an F-2500 spectrofluorometer (Hitachi, Japan) equipped with a quartz cell (1 cm × 1 cm). It was carried out with the excitation wavelength of 280 nm with a recording emission range of 500−650 nm, and the slit widths of the excitation and emission were both 2.5 nm. UV−vis spectra (200−800 nm) were recorded on the Cary 50-Bio UV spectrometer (Victoria, Australia). Scanning electron microscopy (SEM, SU1510, Hitachi, Japan) was employed to observe the surface morphology and microstructure of synthetic material. Transmission electron microscope (TEM) images were obtained on a 2010 FEF microscope (JEOL, Tokyo, Japan). Samples for TEM were obtained by drying droplets of the sample in absolute alcohol on a 300-mesh Cu grid coated with a lacey carbon film.

Preparation of the Optosensing Chip. One-step polymerization was used to fabricate the optosensing material of MIP-coated CdSe/ZnS QDs. Under dark conditions, sesamol template molecule (1.0 mmol) and CdSe/ZnS QDs (0.05 mmol) were, respectively, dissolved in chloroform (5.0 mL). The functional monomer MAA (8.0 mmol) was added, and the solution was stirred for 30 min. Then cross-linker EGDMA (25 mmol) and free radical initiator AIBN (45 mg) were added. After the mixture had been stirred for another 30 min, it was sealed and thermally initiated in a water bath at 60 °C for 20 h. After the polymerization, the polymers were ground to powder using a mortar and then sieved through a 200-mesh sieve. The template molecule of sesamol was removed by Soxhlet extraction with 200 mL of methanol until sesamol was no longer detected and then put in a vacuum dryer at 40 °C for 10 h. The optosensing materials of MIP-coated CdSe/ZnS QDs were obtained. The nonmolecularly imprinted polymers (NIPs) were prepared using the same procedure but without addition of sesamol. The optosensing material of MIP- or NIP-coated (0.5 mg) CdSe/ZnS QDs was transferred to a chitosan solution (0.5%, 5 mL) and ultrasonicated for a few minutes to yield a 0.1 mg/mL suspension that was dropped (10 μL) onto the surface of a commercial 9 MHz AT-cut quartz crystal with polished Au electrodes to prepare the optosensing chip.

Selectivity Experiments of Sesamol by the Optosensing Chip. Selectivity experiments were carried out using PN as a sesamol structural analogue and TBHQ and BHA as structural and functional analogues for sesamol in sesame oil. The prepared optosensing chip was put into the quartz cell containing anhydrous ethanol solution (3 mL) and then dropped into the different concentrations of analyte for spectrofluorometer analysis.

Analysis of Sesame Oil Samples. The sesame oil samples (0.1 g) were spiked with sesamol at three different levels: 5, 10, and 20 μg g^{-1}, respectively. The oil/sesamol mixture was left to stand for 12 h, and then it was dissolved in anhydrous ethanol (10 mL). Three milliliters was removed and put into a quartz cell before the optosensing chip was added for spectrofluorometer analysis.

Statistical Analysis. The results were expressed in terms of standard deviation for three independent determinations. Student's t test was applied to calculate the significant difference between values.

RESULTS AND DISCUSSION

Fabrication of an Optosensing Chip for Sesamol. We propose a one-step synthetic strategy for the optosensing imprinted materials of MIP-coated CdSe/ZnS QDs and then drop it on the surface of a commercial 9 MHz AT-cut quartz crystal to prepare an optosensing chip. The general scheme for the synthesis process is illustrated in Figure 1. Typically, CdSe/ZnS QDs are wrapped in MIPs by cross-linking the functional monomers (MAA) and cross-linker (EGDMA). Subsequently, the carboxyl groups of MAA reacted with the phenolic hydroxyl groups of the template molecules (sesamol) via hydrogen bonding. The sesamol molecules were extracted from the prepolymer using 200 mL of methanol to decompose the hydrogen bond, yielding distinct sesamol binding sites. Prior to the removal of the sesamol, the fluorescence intensity of the MIP-coated QDs was about 64.3% of that from NIP-coated QDs, but after removal of the sesamol, the fluorescence intensity of the MIP-coated QDs increased to 98.3% of that from NIP-coated QDs (Figure 2). These results indicated the facile and effective removal of the sesamol from the starting material. Finally, the optosensing material was put into a chitosan solution to form a uniform suspension after it was dropped on the surface of a chip. To verify the effects of the chitosan solution on the recognition

site of MIPs, the same amounts of MIPs were added to absorb the same concentration of sesamol in the presence or absence of chitosan. The role of chitosan was to locate for the prepared materials on the surface of the sensing chip. The fluorescence intensities of the two samples were nearly the same, as shown in Figure S1 (Supporting Information), which indicated that the chitosan solution did not affect the adsorption properties of MIPs.

Characterization of QDs and Optosensing Imprinted Material. The TEM image of the initial CdSe/ZnS QDs (Supporting Information, Figure S2a) indicates a uniform size and distribution. The SEM image of the MIP-coated CdSe/ZnS QDs (Supporting Information, Figure S2b) reveals a spherical morphology with a larger particle size than that of the initial CdSe/ZnS QDs. This indicated that the MIPs layer coated the surface of the CdSe/ZnS QDs.

Reacting Mechanism of the Optosensing Chip for Sesamol. The fluorescence intensity of the optosensing chip decreased significantly in the presence of sesamol and recovered after the sesamol was extracted. A charge transfer from QDs to sesamol is responsible for the fluorescence quenching of the CdSe/ZnS QDs. Such a charge-transfer mechanism has also been suggested by Tu et al.[24] The UV absorption band of sesamol is close to the band gap of the CdSe/ZnS QDs as revealed by the absorption spectra (Figure 3), the charges of the conductive

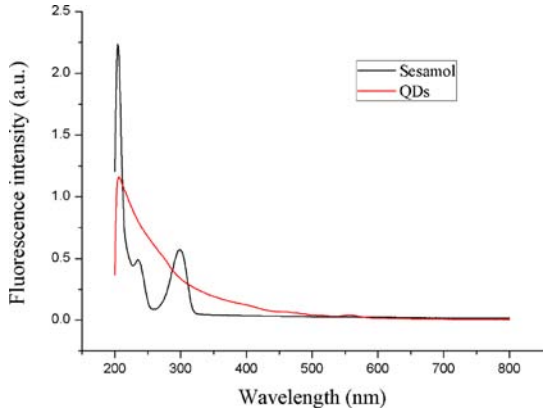

Figure 3. UV−vis spectra of sesamol solution and the optosensing material.

bands of the CdSe/ZnS QDs can transfer to the lowest unoccupied molecular orbital of the UV band of sesamol molecules. There is no spectral overlap between the absorption spectrum of the sesamol species and the emission spectrum of the QDs.

Analytical Figures of the Optosensing Chip for the Fluorescence Detection of Sesamol. The fluorescence quenching in this system followed the Stern−Volmer equation as shown in Figure 4

$$F_0/F = 1 + K_{SV}[C] \quad (1)$$

where F_0 and F are the fluorescence intensity of QDs in the absence and presence of sesamol, respectively, K_{SV} is the Stern−Volmer constant, and [C] is the quencher concentration. This equation was used to quantify the different quenching constants in this research, and the ratio of K_{SV} of the MIPs and NIPs ($K_{SV,MIPs}/K_{SV,NIPs}$) was defined as the imprinting factor to evaluate the selectivity of the optosensing chip.

To further evaluate the analytical performance of the optosensing chip, the detection limit and linear range were investigated. The optosensing chip exhibits linear fluorescent quenching for sesamol in the concentration range from 2.4×10^{-6} to 1.2×10^{-3} mol L^{-1} with a correlation coefficient of 0.9976 and $F_0/F = 0.0014Q + 1.5594$ (where Q is the concentration of sesamol in μmol L^{-1}). The detection limit, which was calculated as the concentration of sesamol that quenched 3 times the standard deviation of the blank signal and then divided by the slope of the standard curve, was 7.2×10^{-8} mol L^{-1}. Finally, the relative standard deviation for five repeated measurements of 4.8×10^{-4} mol L^{-1} sesamol was 2.2%.

Specificity of the Optosensing Chip. The performance of the optosensing chip was further demonstrated by competitive binding experiment. PN as a structural analogue for sesamol and TBHQ and BHA as structural and functional analogues in sesame oil were involved to evaluate the specificity of the optosensing chip. As shown in Figure 5a, the changes in fluorescence intensity of MIP-coated QDs for sesamol were much greater than those for PN, TBHQ, and BHA, owing to the high selectivity and specificity of MIPs. The result demonstrated that the recognition of MIP-coated QDs is based on the interactions of the size, shape, and functionality of the template. Therefore, sesamol was strongly bound to the particles and caused a significant change of fluorescence intensity. When sesamol was not existent, the adsorption capacity of the optosensing chip for the analogues was obvious. This demonstrated that the optosensing chip could be applied to the analysis of similar structure, when sesamol did not exist in the real sample. Furthermore, the changes in fluorescence intensity for the MIP-coated QDs were much higher than those for the NIP-coated QDs. This indicated that the imprinted cavities allowed the sesamol to access the receptor sites by the removal of the template, during the preparation process.

The competitive binding experiment was performed by fixing the concentration of sesamol and increasing the concentration of PN. As shown in Figure 5b, the changes in fluorescence intensity were not obvious by the increase of the ratio of $C_{PN}/C_{Sesamol}$. Although the same hydrogen bond formed between PN and MAA, because of a structure similar to that of sesamol, the adsorption capacity for PN was much lower than that for sesamol.

Reproducibility of the Optosensing Chip. The advantage of the optosensing chip is good reproducibility, and it can be used repeatedly. The reproducibility of the optosensing chip was investigated by measuring the fluorescence intensity response in a seamol at a concentration of 4.8×10^{-4} mol L^{-1}. After each measurement, the chip was washed with methanol/acetic acid (9:1, v/v) to remove the analyte molecules. The relative standard deviation (RSD) for the five repeated analyses was 2.2%, indicating a good reproducibility.

Application of the Optosensing Chip to the Detection of Sesamol in Sesame Oil Samples. The developed fluorescence method based on the optosensing chip of MIP-coated CdSe/ZnS QDs was applied to determine sesamol in sesame oil samples. For this purpose, sesame oil samples from a local factory were determined to be free of sesamol by the HPLC method. Because of the complex oil samples, the available interferences affecting the application performance of the optosensing chip were unpredictable. A recovery study was carried out on the samples spiked with 5, 10, and 20 μg g^{-1} sesamol to evaluate the accuracy for sesamol determination in real samples by the developed fluorescence method (Table 1).

Table 1. Spiked Recovery Results for the Determination of Sesamol in Sesame Oil Samples (RSD%, n = 3)

spike level (μg g^{-1})	theor level (μg g^{-1})	determined[a] (mean ± SD; n = 3, μg g^{-1})	recovery (%)
5	1.5	1.48 ± 0.17	98.7
10	3	3.07 ± 0.09	102.3
20	6	5.69 ± 0.32	94.8

[a]Determined results are not significantly different with spike levels ($t < t_{0.05}$). Values given are the means of three samples ± standard deviation.

The recoveries ranging from 94.8 to 102.3% showed the ability of our optosensing chip to provide accurate measures of sesamol concentrations in real sesame oil samples. The imprinting factor, which is calculated as the ratio of $K_{SV,MIPs}$ to $K_{SV,NIPs}$, was 3.9 for sesamol, indicating an efficient imprinting.

The practicality of the developed optosensing chip method was validated by a comparison with the totally independent technique of HPLC, with a UV detector. Sesamol was detected by absorbance at 294 nm. The results of spike−recovery test by HPLC-UV are shown in Table S1 (Supporting Information). Student's t test was applied to calculate the significant difference between the developed method and HPLC-UV. The result of statistical analysis was 1.9 (less than $t_{0.05}$), which indicated that the difference of the two methods was not significant. This was consistent with the developed fluorescence method of optosensing chip based on MIP-coated CdSe/ZnS QDs.

Conclusions. In summary, a novel method for the detection of sesamol based on an optosensing chip is developed in this

DOI: 10.1021/jf505790c
J. Agric. Food Chem. 2015, 63, 2545−2549

study. It was successfully applied to analyze sesamol in real sesame oil samples, without prior separation or derivatization processes and without large-scale instrumentation, using only a simple spectrofluorometer. Although the optosensing analytical method is still in its infancy, the simple preparation, high selectivity, low cost, and simple sample pretreatment processes make this technique attractive.

Myofibrils were isolated according to the method of Park et al.[13] Thawed and minced muscle was homogenized by blending for 30 s in an ultraturrax with 4 volumes (w/v) of a cold isolation buffer (10 mM sodium phosphate buffer, 0.1 M NaCl, 2 mM $MgCl_2$, and 1 mM ethylene glycol tetraacetic acid (EGTA), pH 7.0). The muscle homogenate was centrifuged at 2000*g* for 15 min, and the supernatant was discarded. The myofibril pellet was washed two more times with 4 volumes of the same isolation buffer using the same blending and centrifugation conditions as indicated above. The myofibril pellet was then washed three more times with 4 volumes of 0.1 M NaCl under the same conditions as above except that, in the last wash, the myofibril suspension was filtered through a strainer to remove connective tissue, and its pH was adjusted to 6.0 with 0.1 N HCl prior to centrifugation. The isolated myofibrillar proteins were stored in a tightly capped bottle, kept on ice, and used within 24 h. The protein concentration of the myofibril pellet was measured by the biuret method[15] using bovine serum albumin (BSA) as standard.

The myofibrillar proteins were oxidized under meat-processing conditions according to the method of Estévez et al.[16] Briefly, the isolated myofibrillar proteins were suspended in 15 mM piperazine-*N*,*N*-bis(2-ethanesulfonic acid) (PIPES) buffer (pH 6.0) containing 0.6 M NaCl (total volume = 30 mL; 20 mg protein/mL). The suspensions were oxidized with 0.01 mM $FeCl_3$, 0.1 mM ascorbic acid, and 1 mM H_2O_2 (final concentration). Three doses of $NaNO_2$ (0, 100, or 1000 mg $NaNO_2$/kg protein) were added, and the samples were incubated at 37 °C for 7 days with constant stirring. After 30 min (without incubation at 37 °C) and 4 and 7 days, suspensions were divided in aliquots of 1.2 mL and stored at −80 °C until analysis. Myofibrillar proteins suspended in PIPES buffer without oxidants or $NaNO_2$ were used as nonoxidized control.

Raw Porcine Patties. Lean porcine longissimus muscles were purchased from a local slaughterhouse at 2 days post mortem. Three treatments were considered: 0, 18, or 180 mg of $NaNO_2$ per kilogram patty. In the basic formulation, the ingredients were as follows: 500 g of meat, 35 g of distilled water, 8.5 g of sodium chloride, and 0, 0.01, or 0.1 g of $NaNO_2$. The muscles were trimmed of visible fat and connective tissue and subsequently diced into approximately 5 g pieces. The meat was ground in a grinder (Omega T-12) equipped with a 10 mm plate. NaCl and $NaNO_2$ were dissolved in the distilled water and immediately added to the meat. After mixing of the batter by hand, the mixture was ground once more with a 3.5 mm plate. Nine patties of 40 g were prepared per treatment. Three patties were immediately vacuum-packed and stored at −80 °C until analysis (day 0). The six remaining patties were wrapped in an oxygen-permeable film and subjected to illuminated chilled display (4 °C, 1000 lx). After 4 and 7 days of display, three patties were vacuum-packed and stored at −80 °C until analysis. The entire patty manufacturing and display process was performed in duplicate.

Chemical Analyses. *Proximate Composition.* Dry matter, crude protein, and crude fat contents were analyzed on two unexposed patties per treatment according to ISO 1442-1973, ISO 937-1978, and ISO 1444-1973 methods, respectively. Results were expressed as grams per 100 g of fresh matter. The pH was measured using a glass pH-electrode.

Thiol Concentration. The thiol concentration was determined in the isolated myofibrillar proteins and patties after derivatization by Ellman's reagent, 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), adopted from Jongberg et al.[5] An aliquot of 1.2 mL myofibrillar protein suspension was defrosted and centrifuged for 20 min at 2000*g*. The supernatant was carefully discarded, and 1.0 mL of 0.1 M tris(hydroxymethyl)aminomethane (TRIS) buffer (pH 8.0) was added to the pellet, vortexed, and centrifuged at 2000*g* for 20 min. After the supernatant had been discarded, 1.0 mL of TRIS buffer was added to the pellet, and everything was transferred to a test tube. The microtube was rinsed twice with 1 mL of TRIS buffer, which was also transferred to the test tube. Three milliliters of 10% sodium dodecyl sulfate (SDS) in 0.1 M TRIS buffer (pH 8.0) was added, and the proteins were dissolved by 1 h of incubation in a water bath heated to 80 °C. After cooling, samples were centrifuged at 1400*g* for 10 min, and the thiol concentration of the supernatant was analyzed. For the raw patties, 2 g was homogenized with 50 mL of 5% SDS buffer. The proteins were dissolved by 1 h of incubation in a water bath heated to 80 °C. After cooling, samples were filtered, and the filtrate was used for further analysis. For both the myofibrillar proteins and the patties, 2 mL of 0.1 M TRIS buffer (pH 8.0) and 0.5 mL of 10 mM DTNB dissolved in 0.10 M TRIS buffer (pH 8.0) were added to 0.5 mL of sample. For each sample a blank was included containing 0.5 mL of sample and 2.5 mL of 0.10 M TRIS buffer (pH 8.0). A solution containing 0.5 mL of 5% SDS in TRIS buffer (pH 8.0), 0.5 mL of 10 mM DTNB, and 2.0 mL of 0.1 M TRIS buffer (pH 8.0) was used as reagent blank. All mixtures were protected against light and allowed to react for exactly 30 min. The absorbance was measured spectrophotometrically at 412 nm, and the thiol concentration was calculated using the formula of Lambert−Beer (ε_{412} = 14000 M^{-1} cm^{-1}) and expressed in nanomoles of thiol per milligram of protein. The blank samples were used to determine the protein content. Protein content was analyzed spectrophotometrically at 280 nm using a BSA standard curve.

Protein Carbonyl Content. The protein carbonyl content of the isolated myofibrillar proteins and patties was determined by derivatization with 2,4-dinitrophenylhydrazine (DNPH) as described by Levine et al.[17] with some modifications. An aliquot of 1.2 mL of myofibrillar protein suspension was defrosted and centrifuged for 20 min at 2000*g*. The pellet was then resuspended in 1 mL of phosphate buffer (20 mM, pH 6.5), and four aliquots of 0.2 mL were taken. For the raw patties, 3 g of meat with 30 mL of phosphate buffer (20 mM, pH 6.5 containing 0.6 M NaCl) was homogenized and four aliquots of 0.2 mL were taken. All aliquots were treated with 1 mL of ice-cold trichloroacetic acid (TCA, 10%) to precipitate the proteins. The samples were left for 15 min in an ice bath, and after centrifugation at 2000*g* for 30 min, the supernatant was discarded. Another milliliter of ice-cold TCA (10%) was added, and the above-mentioned procedure was repeated. For both the myofibrillar protein isolates and the patty pellets, two aliquots were treated with 0.5 mL of 10 mM DNPH dissolved in 2.0 M HCl, and two aliquots were treated with 0.5 mL of 2.0 M HCl (blank). The samples were placed on a vortex (350 rpm) for 1 h covered from light to derivatize. Subsequently, 0.5 mL of ice-cold 20% TCA was added, vortexed, and placed on ice for 15 min before centrifugation at 2000*g* for 20 min, after which the supernatant was discarded. Excess DNPH was removed by three washings with 1.0 mL of ethanol/ethyl acetate (1:1 v/v), vortexing, and centrifuging at 2000*g* for 20 min. After every wash, the supernatant was discarded. Following the final wash, excess solvent was removed by leaving the samples for 15 min under the hood. The pellets were dissolved in 1.0 mL of 6.0 M guanidine hydrochloride in 20 mM phosphate buffer (pH 6.5) and placed on a vortex (350 rpm) for 30 min covered from light. The final solution was centrifuged at 9500*g* for 10 min to remove insoluble material. The carbonyl concentration (nmol/mg protein) was calculated from the absorbance at 280 and 370 nm of the samples using the equation[17]

$$\frac{C_{\text{hydrazone}}}{C_{\text{protein}}} = \frac{A_{370}}{\varepsilon_{\text{hydrazone},370} \times (A_{280} - A_{370} \times 0.43)} \times 10^6$$

where $\varepsilon_{\text{hydrazone},370}$ is 22000 M^{-1} cm^{-1} and the carbonyl concentrations obtained from the blanks were subtracted from the contribution obtained from the corresponding treated sample.

Protein Solubility. Changes in solubility of the myofibrillar protein suspension were measured according to the method of Liu et al.[18] with minor modifications. Protein solubility was defined as the protein concentration in the supernatant, after centrifugation at 5000*g* (for 15 min), divided by the protein concentration of the original myofibril suspension. The protein concentration was determined according to the biuret method[15] using BSA as standard and expressed as milligrams of soluble protein per 100 mg of protein. For the patties, 3 g of meat was homogenized with 30 mL of NaCl (0.015 M). The concentration of the obtained protein solution was determined using the biuret method after centrifugation at 2000*g* for 10 min. Results were expressed as milligrams of solubilized protein per gram of meat.

3-Nitrotyrosine. The 3-nitrotyrosine content was quantified spectrophotometrically after alkalinization in both the myofibrillar protein isolates and patties according to the method of Fontana et al.[19] with some modifications. Aliquots of 1.2 mL of myofibrillar protein isolates were defrosted, and two aliquots of 0.5 mL were taken. After centrifugation at 2000*g* for 30 min, the supernatant was carefully discarded. For the raw patties, 3 g of meat with 30 mL of phosphate buffer (20 mM, pH 6.5 containing 0.6 M NaCl) was homogenized, and two aliquots of 0.2 mL were treated with 1 mL of ice-cold TCA (10%). The samples were left for 15 min in an ice bath, and after centrifugation at 2000*g* for 30 min, the supernatant was discarded. Another milliliter of ice-cold TCA (10%) was added, and the above-mentioned procedure was repeated. To both the myofibrillar protein and patty pellets was added 1 mL of guanidine−HCl (6 M). After 1 h on a vortex, 0.6 mL was transferred into a microtube, an equal amount of bicarbonate buffer (0.2 M, pH 10.5) was added, and the samples were centrifuged at 9500*g* for 10 min. The 3-nitrotyrosine content was quantified spectrophotometrically at 430 nm, using 3-nitro-L-tyrosine as standard. The total protein content was quantified at 280 nm using BSA as standard. Results were expressed as nanomoles of 3-nitrotyrosine per milligram of protein.

Lipid Oxidation. Malondialdehyde, a secondary lipid oxidation product, was determined in the patties following a thiobarbituric acid reactive substances (TBARS) method using extraction with perchloric acid.[3] Malondialdehyde forms a colored complex with thiobarbituric acid, which was determined spectrophotometrically at 532 nm. Five grams of minced patty was dispensed in a plastic tube and homogenized with 30 mL of perchloric acid (0.6 M) and 1 mL of butylhydroxytoluene (1.5% (w/v) in ethanol). The homogenate was filtered, and 5 mL aliquots were mixed with 1 mL of thiobarbituric acid (6 mM) in test tubes. The test tubes were placed in a boiling water bath for 35 min. After cooling, the absorbance was measured at 532 nm. The standard curve was prepared using 1,1,3,3-tetramethoxypropane, and results were expressed as milligrams of malonaldehyde per kilogram of patty.

Statistical Analysis. Statistical analysis was performed using SPSS version 22. Two-way analysis of variance (ANOVA) was used to evaluate the main effects "display time" and "$NaNO_2$" and their interaction term. Differences between treatments were tested using Tukey's post hoc test operating at a 5% level of significance.

RESULTS

Proximate Composition of the Patties. Across treatments, the mean pH, dry matter, and fat and protein contents of the patties were respectively 5.40 ± 0.03, 25.5 ± 0.4 g/100 g patty, 1.35 ± 0.23 g/100 g patty, and 19.9 ± 0.6 g/100 g patty. No treatment effects were observed ($p > 0.05$).

Protein Carbonyl Content. Seven days of induced in vitro oxidation resulted in an approximately 10-fold higher content of carbonyl compounds in the isolated myofibrillar proteins when compared to the nonoxidized myofibrillar proteins (Figure 1A). The addition of sodium nitrite affected the formation of carbonyl compounds after 30 min of induced oxidation as significantly higher carbonyl concentrations were found in the samples treated with 1000 mg/kg $NaNO_2$ compared to the treatment without $NaNO_2$. However, this effect was not observed after 4 and 7 days of induced oxidation (Figure 1A). For the patties, on average significantly lower carbonyl concentrations were found across days of display in patties treated with 180 mg/kg sodium nitrite compared to 0 and 18 mg/kg (Table 1); however, within each day of display no significant differences were observed (Figure 1B). The carbonyl concentrations of the patties did not change significantly during the whole period of illuminated chilled display (Table 1).

Protein Thiol Groups. From the moment the oxidants were added to the isolated myofibrillar proteins, the thiol concentrations decreased 4-fold compared to the nonoxidized myofibrillar proteins (Figure 2A). During the following 7 days no further decrease of thiol groups was observed, and the addition of sodium nitrite did not affect the thiol content (Table 1). Across treatments, the thiol content of the patties decreased significantly during illuminated chilled display (Table 1). The addition of 180 mg $NaNO_2$/kg resulted at days 4 and 7 of illuminated display in significantly lower thiol concentrations compared to the other two treatments (Figure 2B).

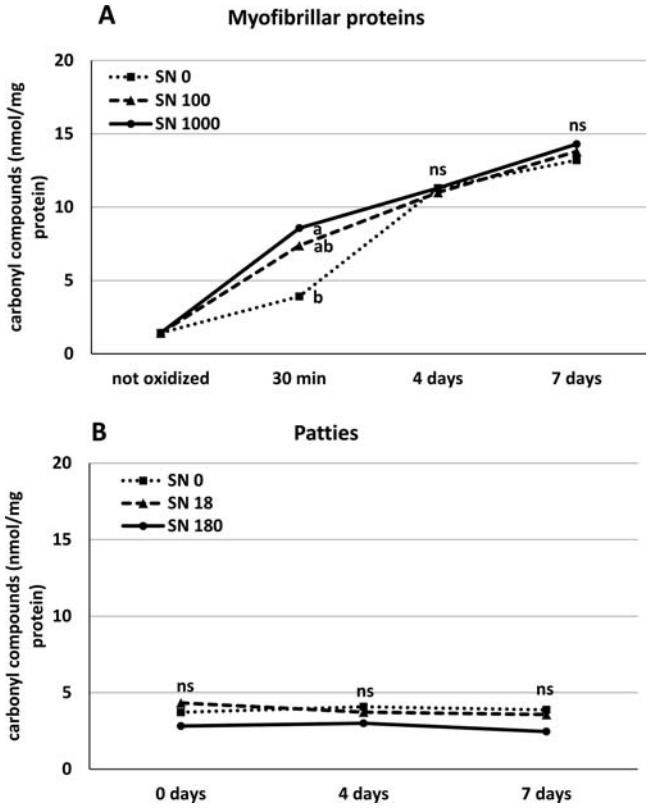

Figure 1. Effect of nitrite dose (SN, mg/kg) on protein carbonyl compounds (nmol/mg protein) in (A) myofibrillar protein isolates during Fenton reagent-induced oxidation ($n = 3$) and in (B) raw patties during illuminated chilled display ($n = 6$). ns, not significant; a, b, values within a display day with different letters are significantly different ($p < 0.05$).

Protein Solubility. The protein solubility of the isolated myofibrillar proteins after 30 min of induced oxidation was 2-fold higher compared to the nonoxidized myofibrillar proteins, probably because of the added NaCl (Figure 3A). The protein solubility decreased significantly in the myofibrillar protein isolates during in vitro oxidation and in the patties during illuminated chilled display (Table 1). No effect of nitrite on protein solubility was found for either the isolated myofibrillar proteins or the patties (Figure 3 and Table 1).

3-Nitrotyrosine. The 3-nitrotyrosine content of the isolated myofibrillar proteins remained constant during the experiment, except for 2-fold lower 3-nitrotyrosine concentrations in samples treated with 100 and 1000 mg $NaNO_2$/kg after 30 min of induced oxidation (Figure 4A). The 3-nitrotyrosine content of the patties was not affected by the added sodium nitrite content (Figure 4B) or by the display period (Table 1).

Lipid Oxidation. A significant increase of TBARS values was observed during illuminated chilled display for the

untreated samples, whereas no increase was found in any nitrite-treated samples (Figure 5).

DISCUSSION

This study investigated the effect of sodium nitrite on protein oxidation and nitration in two different meat model systems. In the myofibrillar protein isolates, 100 and 1000 mg $NaNO_2$/kg protein was used, which corresponds approximately to the addition of 20 and 200 mg of $NaNO_2$ to 1 kg of lean meat (assuming a dry matter content of 20%).

$NaNO_2$ has antioxidant activity against lipid oxidation, which is mostly explained by its ability to break the radical chain processes after its conversion to nitric oxide and by chelating iron, a known oxidation promoter.[20] As the mechanism behind the oxidation of proteins is believed to proceed via a free radical chain reaction similar to that of lipid oxidation,[1] it can be hypothesized that $NaNO_2$ will act as an antioxidant against protein oxidation. On the other hand, $NaNO_2$ could also act as pro-oxidant because, after its reduction to nitric oxide, peroxynitrite can be formed by reacting with a superoxide anion. Peroxynitrite can induce lipid oxidation in food systems and [21] protein oxidation in vivo[22] and can cause discoloration of muscle foods by oxidizing oxymyoglobin.[23] Although nitrite showed the expected antioxidant effect against lipid oxidation in the patties, no clear pro- or antioxidant effect against protein oxidation was found in the present study. According to Rubbo et al.,[24] the pro-oxidant versus antioxidant outcome of nitric oxide critically depends on the relative concentrations of

individual reactive species such as superoxide anions, hydrogen peroxides, and hydroxyl radicals.

These reactive species are abundantly present in in vitro oxidation systems, which could explain the pro-oxidative effect of sodium nitrite on the formation of carbonyl compounds in the isolated myofibrillar proteins, 0.5 h after the addition of the oxidants. Similar to the present results, Villaverde et al.[25] observed a fast pro-oxidant effect of nitrite on protein carbonylation immediately after the addition of nitrite to a meat batter. As discussed by these authors, nitrite is an efficient pro-oxidant as it is able to initiate oxidative reactions by abstracting an electron from a sensitive molecule[20] and to form reactive nitrogen species that could initiate oxidative reactions in meat systems.[26] In addition, the sodium nitrite and pro-oxidants were added simultaneously in the present study, which could have affected the reaction pathways of nitrite. Furthermore, the intensity of the induced oxidation could have masked the pro-oxidant effect of nitrite in isolated myofibrillar proteins at later time points. Villaverde et al.[12] reported a negligible effect of sodium nitrite on the α-aminoadepic semialdehyde content of isolated myofibrillar proteins after 4 days of induced oxidation in a similar in vitro system, which is in accordance with the present results. In the patties, sodium nitrite may first react with other meat components before oxidation during illuminated chilled display occurs, possibly explaining why a different effect of nitrite was found in the isolated myofibrillar proteins compared to the patties. For example, nitrite can react with myoglobin, resulting in nitrosylmyoglobin,[27] which appears to be active as an antioxidant both through dissociation of nitric oxide and through direct reaction with activated oxygen species.[20] In addition, nitric oxide can react with the free radical intermediates of lipid oxidation, and these compounds can function both as nitric oxide donors and as antioxidants.[28] The oxidation of thiol groups leads to a series of complex reactions resulting in the formation of various oxidized products such as sulfenic acid, sulfinic acid, and disulfide cross-links.[1] In addition, Sullivan and Sebranek[27] found decreasing thiol groups with increasing ingoing sodium nitrite and attributed this to the formation of S-nitrosothiol groups. A lower thiol content was therefore expected in the sodium nitrite-treated samples, which was observed in the patties with 180 mg/kg sodium nitrite, but not in the myofibrillar isolates. It is likely that the intensity of the induced oxidation, which resulted in an overall large loss of thiol groups, masked this effect. The values obtained for protein solubility, progress of protein carbonyl formation, and loss in thiol groups in induced in vitro oxidation of the isolated myofibrillar proteins compare well with the observations of respectively Liu et al.,[18] Estévez and Heinonen,[14] and Liu and Xiong.[29] The effects are greater compared to those usually found in real meat products, as the concentrations of oxidants applied in a model system are designed to stimulate oxidation.

It is not clear whether the addition of sodium nitrite affected the 3-nitrotyrosine content post mortem, and additional investigations are necessary to explore the occurrence of 3-nitrotyrosine in muscle foods and its potential influence on the quality. An increase in 3-nitrotyrosine content in the sodium nitrite-treated samples was hypothesized, but conversely a decrease was seen in the myofibrillar protein isolates after 30 min of induced oxidation. This was rather unexpected, especially because after 4 days of induced oxidation the 3-nitrotyrosine content reached its basal value again. It can be speculated that the simultaneous increase in carbonyl compounds plays a role; however, this has to be further investigated. The present findings suggest that 3-nitrotyrosine is not a good marker for protein oxidation in cured meat products, but on the contrary, Villaverde et al.[12] did find higher amounts of 3-nitrotyrosine in myofibrillar protein isolates treated with sodium nitrite. In that study, similar oxidation conditions were applied as in the present study, but with considerably higher concentrations of nitrite. Also, ascorbic acid

DOI: 10.1021/jf505775u
J. Agric. Food Chem. 2015, 63, 2550−2556

was added to the isolates in our study. Villaverde et al.[12] reported that ascorbate can inhibit the nitrosation of myofibrillar proteins dose-dependently. Furthermore, the quantification of 3-nitrotyrosine was performed at a higher pH than in the study of Villaverde et al.[12] (10.5 versus 3.5). According to Yang et al.[30] tyrosine and nitrotyrosine both exhibit an absorption peak at 280 nm, and nitrotyrosine has an additional peak at 430 nm in basic solutions (pH ≥9.5) and at 357 nm in acidic solutions (pH ≤3.5). In the present study, the analysis was carried out at basic conditions to reduce the risks of artifacts, as the nitration of tyrosine under acidic conditions in the presence of only trace quantities of nitrite has been reported.[31]

One item to be further explored is the variation between animals and between muscles of the basal 3-nitrotyrosine content. It is therefore interesting to quantify the 3-nitrotyrosine content as nanomoles of 3-nitrotyrosine per milligram of meat protein instead of reporting band intensities from Western blots. The occurrence of 3-nitrotyrosine in muscle proteins is a result of oxidative stress in vivo,[22] so basal levels of 3-nitrotyrosine in the porcine patties as well as in the myofibrillar protein isolates were expected. Stagsted et al.[11] found significantly higher basal concentrations of 3-nitrotyrosine in meat of chickens fed a low antioxidant diet compared to chickens fed a low antioxidant diet in combination with corn. As 3-nitrotyrosine may affect the structure and function of proteins,[32] it was hypothesized that 3-nitrotyrosine could be a marker for protein oxidation in cured meat products, affecting the quality of muscle foods. From the present results, however, it can be concluded that nitrite curing has no effect on the 3-nitrotyrosine content during chilled display.

In conclusion, sodium nitrite did not reveal clear pro- or antioxidant effects against protein oxidation in different meat models. 3-Nitrotyrosine was present in untreated meat proteins, but whether other compounds and process conditions influence its occurrence post mortem and whether this is a suitable marker for protein oxidation in processed meat remain to be elucidated.

promising natural compounds are well-known plant constituents, such as resveratrol from grapes,[14] curcumin from turmeric,[15] hydroxytyrosol from olive,[16] as well as ubiquitous lignin-related phenylpropanoids.[17,18] Interestingly, the latter group acts as natural surface-functionalizing materials, impregnating the plant cell wall and conferring antimicrobial activity upon it in case of pathogen attack.[19] Using natural phenolic compounds as a basis for active food-contact surfaces is still in its infancy. Rhim and Ng[20] proposed to use nanocomposite technology to produce environmentally friendly antimicrobial food packaging and food-contact surfaces by blending nanolignin with biodegradable polymers. This approach proved feasible in the textile industry when fabrics with antimicrobial activity were produced by adding lignin nanoparticles to the fiber.[21] To the best of our knowledge, no screening of various phenolic compounds for their potential as functionalizing ingredients for antimicrobial surfaces has been performed until now.

Curcumin (1,7-bis(4-hydroxy-3-methoxyphenyl)-1,6-heptadiene-3,5-dione), a natural phenylpropanoid dimer, is one of the promising candidates for the role of a natural food-grade surface-functionalizing phenolic compound. It is an active principle of turmeric *Curcuma longa* L. used as a traditional spice and folk medicine in South and South-East Asia and Middle East. Curcumin exhibits various biological activities including antiproliferative, antioxidant, and wound healing effects[22] and has a self-affirmed "Generally Recognized as Safe" (GRAS) status.[23] Curcumin possesses antibacterial properties against a number of Gram-positive and Gram-negative bacteria.[15,24] However, poor water solubility limits the application of curcumin as antimicrobial agent in its native form. Reduction of the particle size down to the nanorange markedly improved water dispersibility and antimicrobial efficacy of curcumin.[25] Nanoparticles of curcumin (nanocurcumin) having a size distribution in the range of 2−40 nm prepared by a wet-milling technique were more effective than regular curcumin against *S. aureus*, *B. subtilis*, *E. coli*, *P. aeruginosa*, *Penicillium notatum*, and *Aspergillus niger*. Transmission electron microscopy revealed permeation of nanocurcumin particles inside the Gram-positive bacteria followed by cell wall disintegration and eventually cell death. In spite of the unique combination of antimicrobial potency, food origin, and health benefits, no attempts have been taken until now to use curcumin for developing antimicrobial food-contacting surfaces. However, curcumin impregnation conferred antimicrobial activity to wool fabric.[26]

Polydiacetylene (PDA) vesicles are a novel carrier system for hydrophobic materials poorly soluble in water, such as anticancer drug paclitaxel based on plant component taxol.[27] Incorporation of a polymerizable diacetylene into the lipid bilayer greatly improves the stability of the vesicles compared with the conventional liposomes. Furthermore, the PDA vesicles can be covalently bound to the surface of solid substrates such as glass.[28] Dogra et al.[29] studied the interaction of glucose-tagged PDA vesicles (either giant or nanoscale-sized) with *E. coli* as a model of molecular recognition mechanisms. However, to the best of our knowledge, this system has not been used so far for delivery of antimicrobial activity and for construction of antimicrobial active surfaces.

The ultimate goal of this research was developing novel antimicrobial food-contact materials based on phenylpropanoids or related natural compounds. In order to reach this goal, the work comprised the following steps: (a) selecting the most promising antimicrobial compound; (b) building PDA nanovesicles functionalized with the selected compound; (c) binding the vesicles to a glass surface; (d) testing the antimicrobial activity of the vesicles, both suspended and immobilized, toward Gram-positive and Gram-negative bacteria, as well as toward yeast.

MATERIALS AND METHODS

Chemicals. The phenolic compounds and methyl-*β*-cyclodextrin (MBCD, MW 1331) were supplied by Sigma-Aldrich Israel (Rehovot, Israel). If not specified differently, other solvents and chemicals were from Fisher Scientific, Fair Lawn, NJ. 1-(3-(Dimethylamino)propyl)-3-ethylcarbodiimide hydrochloride and 10,12-pentacosadiynoic acid were from GFS Chemicals, Columbus OH, and 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) was from Avanti Polar Lipids, Alabaster, AL. Nutrient media were purchased from BD Difco Laboratories, Detroit, MI, except for the nutrient yeast dextrose broth (NYDB) that was prepared using nutrient broth (Difco), yeast extract (Pronadisa Conda, Madrid, Spain), and D-(+)-glucose (Merck, Darmstadt, Germany) in amounts of 0.8, 0.5, and 1.0 g per 1 L water, respectively.

Screening Antimicrobial Activity of MBCD-Encapsulated Phenolic Compounds. *Microencapsulation of Phenolic Compounds.* The following phenolic compounds were tested in this study: *p*-coumaric acid, caffeic acid, ferulic acid, sinapic acid, coniferaldehyde, sinapaldehyde, coniferyl alcohol, sinapyl alcohol, hydroxytyrosol, resveratrol, and curcumin (Figure 1). Equal volumes of a 20 mM

J. Agric. Food Chem. 2015, 63, 2557−2565

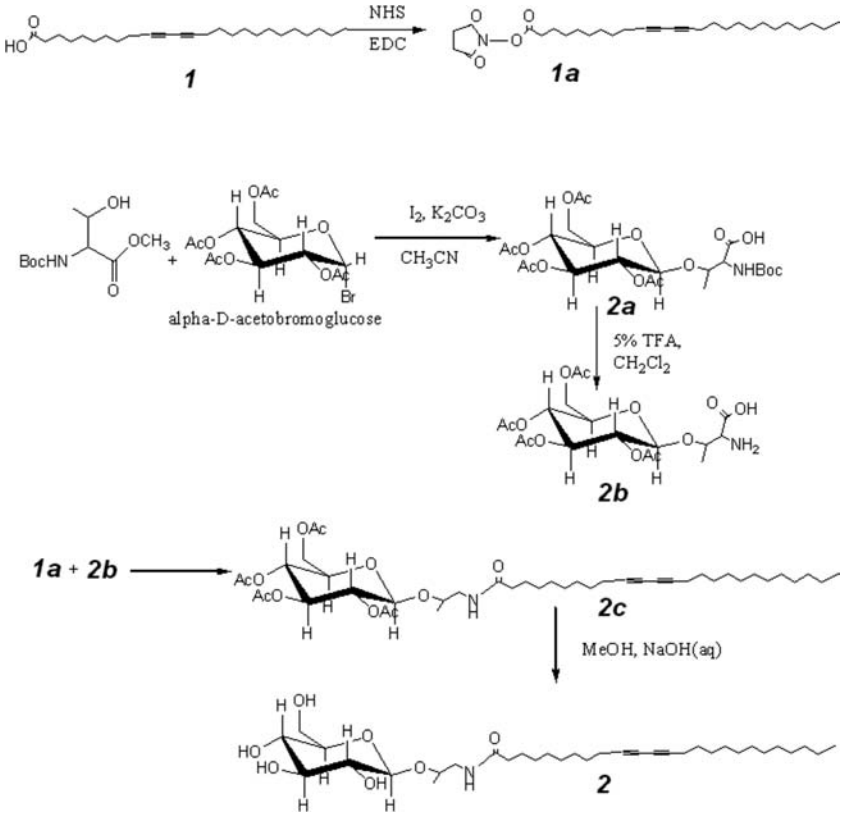

Figure 2. Synthesis of diacetylene monomers. Monomers: ***1***, 10,12-pentacosadiynoic acid, ***1a***, NHS-tagged diacetylene monomer, ***2***, glucose-tagged diacetylene monomer.

ethanolic solution of a phenolic compound tested and a 20 mM aqueous solution of MBCD were mixed and stirred for 2 h on a magnetic stirrer at room temperature. Ethanol was removed from the mixture by evaporation under vacuum to half-volume (Rotavapor R-124, Buchi, Flawil, Switzerland). The nonencapsulated residue of the phenolic compound was removed by filtration through a sterile 0.45 μ Millex filter with Durapore membrane (Millipore, Cork, Ireland). The obtained filter-sterilized aqueous dispersion of the phenolic−MBCD complex (Ph−MBCD) was kept in a refrigerator until use. The concentration of the phenolic compound in the Ph−MBCD was determined by diluting the aqueous dispersion with ethanol in a ratio of 1:9 and measuring its absorbance with an Ultrospec 2100 pro spectrophotometer (Amersham Biosciences, Piscataway NJ) at a characteristic wavelength in comparison with the calibration curve of the compound in 90% ethanol. In particular, wavelengths of 262 and 425 nm were used for curcumin quantification.

Assay of the Antimicrobial Activity of MBCD-Encapsulated Phenolic Compounds. Cells of *E. coli* (ATCC 25922) were grown overnight in LB broth (Lennox) liquid medium, separated from the medium by centrifugation, washed with sterile water, and resuspended in a fresh double-strength LB medium to reach an optical density of 0.2 at a wavelength of 600 nm. The bacterial suspensions were further diluted 1:1 with aqueous Ph−MBCD dispersions and sterile water to obtain various concentrations of phenolics but the same initial *E. coli* dilution. The bacterial suspensions were aseptically pipetted into the wells of a 96-well microplate, 0.2 mL per plate, and incubated for 20 h at 27 °C in an EnSpire multilabel plate reader (PerkinElmer, Waltham MA, USA) with hourly 10 s shaking. The experiments were run in triplicate and in addition to treatments (viable *E. coli* + Ph−MBCD) included blanks (nutrient medium without *E. coli* + Ph−MBCD), positive controls (viable *E. coli* + nutrient medium and MBCD without phenolics), and negative controls (*E. coli* killed by boiling + Ph−MBCD). The bacterial growth was registered by hourly measurement of turbidity as optical density at 600 nm and evaluated as added area under the growth curve (AAUC) during the whole cultivation period (20 h). Growth inhibition was calculated as AAUC reduction (%) in the presence of a given phenolic concentration compared with a positive control without phenolics. The half-maximal inhibitory concentration (IC_{50}) was determined as a concentration required for 50% growth inhibition and minimum inhibitory concentration (MIC) as the lowest concentration resulting in complete growth prevention. A similar technique was used for evaluating the effect of curcumin−MBCD complex on yeast *Saccharomyces cerevisiae* growth, except for using the NYDB instead of the LB medium.

Synthesis of Diacetylene Monomers. The synthesis procedures are schematically presented in Figure 2.

Synthesis of N-Hydroxysuccinimide (NHS)-Tagged Diacetylene Monomer. NHS (0.348 g, 3.0 mmol) was added to a solution of 10,12-pentacosadiynoic acid ***1*** (1.00 g, 2.7 mmol) in 20 mL of anhydrous dichloromethane (DCM), followed by adding 1-(3-(dimethylamino)propyl)-3-ethylcarbodiimide hydrochloride (0.570 g, 3.1 mmol) to the same solution. The solution was stirred at room temperature for 2 h followed by rotary evaporation of the solvent. The residue was extracted with diethyl ether and washed with water three times. The organic layer was dried with magnesium sulfate for 0.5 h and then filtered. The solvent was removed by rotary evaporation to give a white solid powder of NHS-tagged diacetylene monomer ***1a*** (1.18g, 93%).

Synthesis of Glucose-Tagged Diacetylene Monomer. Synthesis of ***2a.*** N-Boc-L-threonine (2.65 g, 12.0 mmol), acetobromoglucose (2.46 g, 6.0 mmol), and potassium carbonate (1.24 g, 9.0 mmol) were dissolved in 40 mL of dry acetonitrile under argon atmosphere with stirring for 10 min. Iodine (2.28 g, 9.0 mmol) was then added against a flow of argon. The glassware was then sealed and stirred at room temperature with the exclusion of light for 6 h. A saturated sodium thiosulfate aqueous solution was added to the above stirring solution, until the deep red color had disappeared, leaving a slightly yellow solution. The insoluble residual potassium carbonate was removed by filtration. The filtrate was concentrated to 1/4 of its original volume under reduced pressure on a rotary evaporator. DCM (40 mL) was

DOI: 10.1021/jf505442w
J. Agric. Food Chem. 2015, 63, 2557−2565

added to the mixture, and the solution was extracted with sodium bicarbonate aqueous solution (5% w/v, 50 mL) one time, followed by brine (50 mL) two times; the organic layer was dried over magnesium sulfate. The crude products were purified by flash chromatography using a glass column packed with silica gel and a gradient solvent system hexane/ethyl acetate 10:1 to 1:4. The major fraction was collected and evaporated in vacuum to a white solid ***2a***; yield 1.75 g, 53%.

*Synthesis of **2b**.* The product ***2a*** (1.5 g, 2.73 mmol) was dissolved in 20 mL of anhydrous DCM under argon. Trifluoroacetic acid (1.0 mL, 13.01 mmol) was then added dropwise to it, and the solution was stirred at room temperature for 3 h. The process was monitored by TLC until no starting materials were detected. The solvent was evaporated under reduced pressure to give a viscous liquid ***2b***.

*Synthesis of **2c**.* Triethylamine (1.49 mL, 10.6 mmol) and a solution of ***2b*** (0.867 g, 1.93 mmol) in 10 mL of anhydrous DCM were added to a solution of ***1a*** (1.0 g, 2.12 mmol) in 20 mL of anhydrous DCM. After stirring over 36 h, the solvent was removed by rotary evaporation. The residue was redissolved in 20 mL of DCM, and then it was washed with the following solutions: 1 M HCl aqueous solution (twice), saturated sodium bicarbonate solution (twice), and saturated sodium chloride solution (once). The organic layer was dried with magnesium sulfate, filtered, and evaporated to give crude semisolid. The crude products were purified by flash chromatography (silica gel, chloroform/methanol 20:1). Compound ***2c*** was obtained as a white powder (1.102 g, 75%).

*Synthesis of **2**.* Compound ***2c*** (1.0 g, 1.31 mmol) was dissolved in 50 mL of methanol containing 0.05 N sodium methanolate and was stirred at room temperature overnight. Ion exchange resin was added to the solution until the pH $\leq$ 6 was reached. The solution was filtered, and the solvent was removed by rotary evaporation to get a white solid. The crude products were purified by flash chromatography (silica gel, chloroform/methanol 2:1). Compound ***2*** (glucose-tagged diacetylene monomer) was obtained as a white powder (0.389 g, 50%).

Preparation and Characteristic of Curcumin-Functionalized PDA Nanovesicles. Curcumin was used for preparing functionalized nanovesicles due to its superior antimicrobial potency shown in preliminary screening tests.

Self-Assembly of Curcumin-Functionalized Nanovesicles. A mixture containing 10,12-pentacosadiynoic acid, glucose-tagged and NHS-tagged diacetylene monomers, and DMPC in a ratio of 4:4:2:1 was dissolved in chloroform in a round-bottom flask, and the solvent was then evaporated completely to yield a thin film of monomers. The film was hydrated with a saturated aqueous solution of curcumin and sonicated at 76 °C for 15 min using a probe sonicator (Vibra-cell Model CV 33, Sonics & Materials, Inc., Newton, CN, USA). Sonication resulted in vesicle formation and inclusion of curcumin in the hydrophobic bilayer of the vesicles. The dispersion was then passed through a 0.8 μm nylon filter (Whatman, Inc., Piscataway, NJ, USA) to remove the lipid aggregates and cooled at 4 °C overnight to promote self-assembly of the monomers. The obtained filtrate was optically clear. Free curcumin was removed by dialysis using a Spectra/Por Biotech Cellulose Ester membrane, MWCO 100 000 (Fisher Scientific International, Inc., Hampton, NH, USA) preliminarily soaked in deionized water for 15 min. The final dispersion was collected in a vial covered with aluminum foil. Curcumin concentration in the vesicle dispersion was determined spectrophotometrically after its dilution in ratio (1:9) with ethanol using the extinction coefficient of 59 500 M^{-1} cm^{-1} in 90% ethanol at 425 nm. Typically, the curcumin concentration in the dispersion varied within the range 0.1−0.5 mM.

Binding Curcumin-Functionalized Nanovesicles to Glass Surface. The nanovesicles, with or without curcumin, were bound to the surface of silanized glass slides through amidization between the amine groups of the aminosilane and the NHS head groups of PDA-NHS. Glass slides, 25 × 25 mm, were cleaned by sonication in acetone for 10 min, dried under argon for 5 min, and treated with freshly prepared Piranha solution (70% H_2SO_4, 30% H_2O_2) for 30 min. The cleaned slides were rinsed with copious amounts of distilled water and dried under vacuum. Silanization was performed at room temperature by immersing the glass slides in 4% aminosilane solution, 1% acetic acid, and 95% ethanol under continuous stirring for 4 h at room temperature. The silanized glass slides were then cleaned with ethanol for about 10 min, baked at 110 °C overnight, and brought back to room temperature. Slides were dipped in curcumin nanovesicle dispersion for 1 h and then kept in vacuum desiccator overnight.

Spectroscopic Measurements and Atomic Force Microscopy. UV−vis absorption spectra of all of the samples were recorded at room temperature using a PerkinElmer Lambda 25 (spectral slit width 1 nm) UV/vis spectrometer using a cuvette of 1 cm path length. Fluorescence emission spectra of all of the samples were recorded at room temperature using a PerkinElmer Lambda 55 (spectral slit width 1 nm) luminescence spectrometer (PerkinElmer, Waltham MA, USA). The samples were excited at 350 nm, and emission was recorded in 360−650 nm range.

The topology of nanovesicles on glass surfaces was investigated by atomic force microscopy (AFM) using a TopoMetrix TMX 1010 Explorer instrument (TopoMetrix/Veeco Instruments, Santa Clara CA) in tapping mode using antimony-doped silicon tip. The largest scanning area was 80 × 80 μm, and the highest z resolution of the instrument was 0.2 nm. The samples were prepared by applying nanovesicle dispersion on a mica or glass surface, followed by overnight drying under vacuum.

The transmission electron microscopy (TEM) images of liposomes were obtained after staining the liposomes with 2% phosphotungstic acid using a Hitachi S-7100 TEM instrument (Hitachi HTA, Inc., Schaumburg, IL, USA) operating at an accelerating voltage of 100 kV. The liposome samples were deposited onto Formvar-coated copper grids (Ted Pella, Inc., Redding CA, USA) for obtaining TEM images.

Visualization of Nanovesicle Contact with E. coli Cells. In order to visualize the contact of nanovesicles with *E. coli* cells, the vesicles were tagged with Sulforhodamine 101 (SR-101) having red emission and *E. coli* was stained with 4′,6-diamidino-2-phenylindole (DAPI) having blue emission as described in the previous publication.[29] A DAPI filter (excitation and emission band widths 349 ± 25 and 459 ± 25 nm, respectively) and a 41004 Texas Red filter (exciting and emitting band widths 527−567 and 605−682 nm, respectively) were used for capturing blue and red emission.

Testing the Antimicrobial Activity of Curcumin-Functionalized Nanovesicles. The cultures of *E. coli* W 1485 and *Bacillus cereus* ATCC 14579 were grown on tryptic soy broth (TSB) medium at 37 °C for 12 h and harvested by centrifugation (Beckman J2-M1, Schaumburg, IL, USA) for 10 min at 5500*g* and 4 °C. The pellet was suspended in 50 mL of phosphate buffer saline (PBS) at pH 7.0. Serial dilutions were made and plated onto tryptic soy agar (TSA) plates for colony-forming units (CFU) enumeration.

The antibacterial activity of suspended and glass-bound curcumin-functionalized nanovesicles (CFN) was studied by the shake flask assay method in comparison with vesicles containing no curcumin (control). Two milliliters of the vesicle dispersion was added into the sterile conical flask containing 23 mL of PBS. For studying the antimicrobial activity of CFN-coated glass slides they were placed in a sterile conical flask containing 50 mL of PBS at pH 7.0. Glass slides coated with nanovesicles without curcumin served as control. A 1 mL amount of test culture suspension was pipetted into the flask, which brought the initial cell density of the cell suspension to approximately 10^5 CFU mL^{-1}. Flasks were incubated in a gyratory water bath shaker (New Brunswick Scientific, Edison, NJ) at 36 °C for 48 h. Viable bacteria in the flasks at different time intervals were counted by plating aliquots of serial dilutions onto TSA media and incubating for 18−24 h at 35 °C.

A similar approach was used for evaluating the effect of curcumin-containing nanovesicles on the survival of yeast *S. cerevisiae* in nongrowing medium (PBS at pH 7.4), except for using NYDB for initial growing of the *S. cerevisiae* culture and potato dextrose agar amended with 100 ppm chloramphenicol for plating. The incubation duration was extended to 120 h.

Statistics. Bacterial counts (CFU mL^{-1}) were obtained from three replicates, and resulting means were converted to $\log_{10}$ CFU mL^{-1}.

DOI: 10.1021/jf505442w
J. Agric. Food Chem. 2015, 63, 2557−2565

Resulting $\log_{10}$ CFU mL^{-1} reduction values were compared by analysis of variance (ANOVA) and Tukey's HSD (honestly significant difference) tests using SAS 9.2 software (SAS Institute Inc., Cary, NC).

RESULTS

Active Principle Selection: Curcumin as a Promising Antimicrobial Compound. The phenolic compounds tested varied greatly in their inhibitory activity toward *E. coli*. Just a few compounds having 4-hydroxy-3-methoxy substituents demonstrated a complete inhibition of *E. coli* growth at concentrations tested: curcumin, coniferaldehyde, and ferulic acid (Table 1). Within the series with the same substituents the activity declined in the order aldehyde > acid ≫ alcohol. Curcumin showed by far the highest inhibitory effect among the compounds tested. An example of the curcumin effect on *E. coli* proliferation is presented in Figure 3. At 0.2 mM curcumin reduced the growth rate of *E. coli* approximately by one-half, while 0.4 mM curcumin resulted in full arrest of bacterial proliferation, so that the growth curve overlapped with that of the dead culture. The growth of the yeast *S. cerevisiae* was also inhibited by the MBCD-encapsulated curcumin with an IC_{50} value of 0.67 mM (data not shown). No growth inhibition was shown by MBCD at 5 mM, the highest concentration tested. Curcumin was chosen as the promising active principle for further research.

Table 1. Inhibitory Activity of MBCD-Encapsulated Phenolic Compounds toward *E. coli*

compound	group	substitution	IC_{50} (mM)	MIC (mM)
p-coumaric acid	phenylpropanoid acid	4-hydroxy	9.2	n.d.[a]
caffeic acid	phenylpropanoid acid	3,4-dihydroxy	8.3	>13
ferulic acid	phenylpropanoid acid	4-hydroxy-3-methoxy	4.4	6.4
sinapic acid	phenylpropanoid acid	4-hydroxy-3,5-dimethoxy	7.9	n.d.
coniferaldehyde	phenylpropanoid aldehyde	4-hydroxy-3-methoxy	3.0	6.8
sinapaldehyde	phenylpropanoid aldehyde	4-hydroxy-3,5-dimethoxy	5.6	n.d.
coniferyl alcohol	phenylpropanoid alcohol	4-hydroxy-3-methoxy	13.6	n.d.
sinapyl alcohol	phenylpropanoid alcohol	4-hydroxy-3,5-dimethoxy	16.0	n.d.
hydroxytyrosol	phenylethanoid alcohol	3,4-dihydroxy	10.5	n.d.
resveratrol	stilbenoid	3,5,4′-trihydroxy	6.1	n.d.
curcumin	phenylpropanoid dimer	4-hydroxy-3-methoxy	0.17	0.4

[a]MIC was evaluated only when complete inhibition was reached; n.d., not determined.

Characteristics of Curcumin-Functionalized Nanovesicles. Curcumin-functionalized nanovesicles (CFN) were prepared as described in Materials and Methods. The particle dimensions were in a range of 50−400 nm (Figure 4). The polymerized PDA nanovesicles containing no curcumin were characterized by absorption peaks at 590 and 640 nm, while the ethanolic curcumin solution had maximal absorption at 428 nm (Figure 5A and 5B, respectively). Both PDA and curcumin characteristic maxima were presented in the absorption spectrum of CFN (Figure 5C).

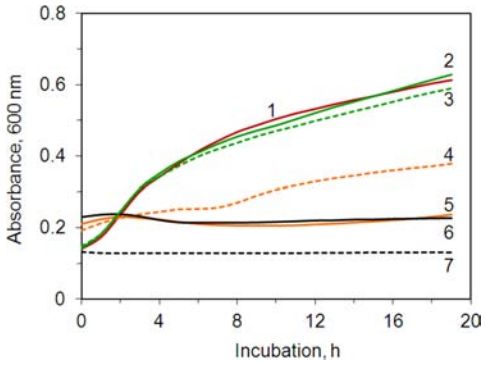

Figure 3. Effects of curcumin and MBCD concentrations on *E. coli* growth. Curves designation: (1) no additives (control); (2) 5 mM MBCD; (3) 2.5 mM MBCD; (4) 0.2 mM curcumin + 2.5 mM MBCD; (5) 0.4 mM curcumin + 5 mM MBCD; (6) 0.4 mM curcumin + 5 mM MBCD (thermally inactivated culture); (7) no additives (thermally inactivated culture). Curves 1−5 correspond to viable *E. coli* culture.

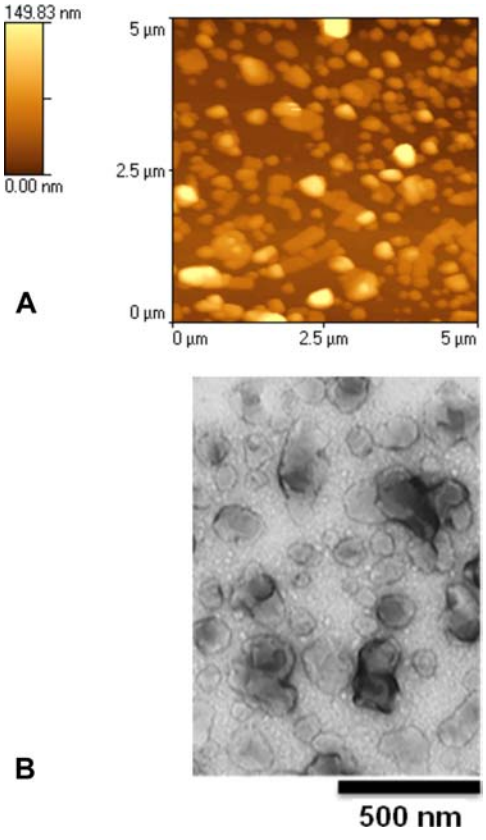

Figure 4. AFM (A) and TEM (B) images of the PDA nanovesicles.

Indication of curcumin location within the nanovesicles could be obtained from comparing the fluorescence emission spectrum of CFN with the emission spectra of curcumin in solvents of different polarities. Figure 6 represents the emission spectra of curcumin dissolved in hexane, toluene, chloroform, tetrahydrofuran, ethanol, and water whose dielectric constant values at 20 °C were 1.89, 2.38, 4.81, 7.52, 25.30, and 80.10, respectively.[30] In agreement with the literature,[31] polar solvents tended to shift the curcumin emission maxima toward higher wavelength. The comparison indicated that at least part of the CFN-associated curcumin was located in relatively nonpolar medium having a dielectric constant between 4.8 and 7.5, rather

DOI: 10.1021/jf505442w
J. Agric. Food Chem. 2015, 63, 2557−2565

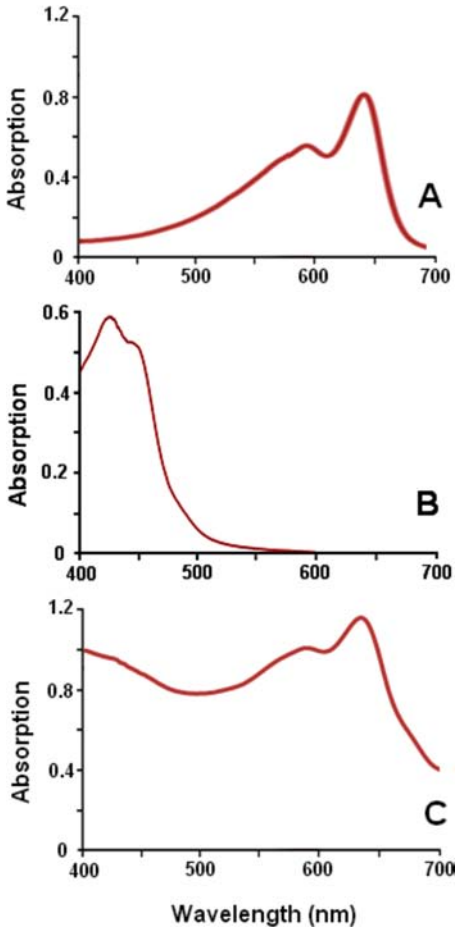

Figure 5. Absorption spectra of PDA vesicles without curcumin (A), ethanolic solution of curcumin (B), and curcumin-functionalized PDA vesicles (C).

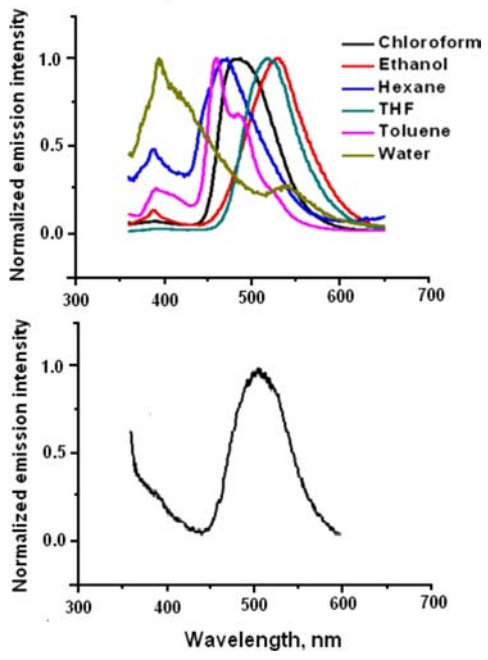

Figure 6. Emission spectra of curcumin in solvents of different polarity (top) and of the CFN-enclosed curcumin (bottom).

than in aqueous environment. The presented dielectric constant range was comparable with that of polymerized PDA.[32] It can be suggested that due to its hydrophobicity curcumin molecules tend to concentrate in the lipophilic bilayer of the nanovesicle.

Interaction of Free and Surface-Bound CFN with Bacteria. When brought in contact with *E. coli*, the nanovesicles tended to bind to the bacterial surface as shown in Figure 7, presenting a fluorescent micrograph of SR-101-tagged nanovesicles (red) and DAPI-stained *E. coli* nucleoid (blue). As shown previously, this binding was due to the presence of covalently bound receptor (glucose) in the bilayer of the nanovesicles.[29]

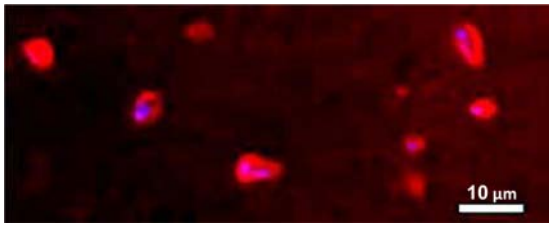

Figure 7. Fluorescence micrograph of SR-101-tagged nanovesicles (red emission) bound to the surface of *E. coli* stained with DAPI (blue emission in the nucleoid region).

The CFN demonstrated bactericidal activity toward both Gram-negative (*E. coli*) and vegetative cells of Gram-positive (*B. cereus*) bacteria, reducing their counts in phosphate-buffered saline (PBS) at pH 7.0 from 5 log to an undetectable level within 8 h (Figure 8). Only limited activity (not more than 1 log reduction) was observed against yeast (data not shown).

The attachment of CFN to glass slides rendered antibacterial activity to their surface. Incubation of *E. coli* with CFN-bound glass resulted in a reduction in its viable counts by 2.5 log CFU mL^{-1} (Figure 9A). With *B. cereus*, fast viability decline was observed within 4 h of incubation with the coated glass (Figure 9B). The reduction was 1.3 log CFU mL^{-1} without curcumin and 2.5 log CFU mL^{-1} in the presence of curcumin. No significant changes in viable counts of *B. cereus* occurred during further incubation. In parallel, the formation of spores was observed in *B. cereus* cultures, both in the presence of curcumin and in the control.

DISCUSSION

Within the series of phenylpropanoids with the same substitution pattern, the activity decreased in the order aldehyde > acid ≫ alcohol. Curcumin, with two carbonyl groups and "double coniferaldehyde" structure, also apparently obeyed this trend. Similar tendencies in the activity of phenylpropanoids against several microorganisms were demonstrated by Barber et al.,[17] except for curcumin behavior that was not analyzed by those authors. Prevalence of curcumin over monomeric phenylpropanoids (e.g., ferulic acid) in anticancer and antiviral activity was demonstrated by Huang et al.[33] and Bourne et al.,[34] respectively. It was reported that the antibacterial effect of curcumin may be related, in particular, to inhibition of assembly and polymerization of the citoskeletal protein FtsZ playing a role in prokaryote cell division.[24,35] Kaur et al.[35] located the binding site of curcumin to the FtsZ molecule and stressed the potential of curcumin for the development of novel antimicrobials.

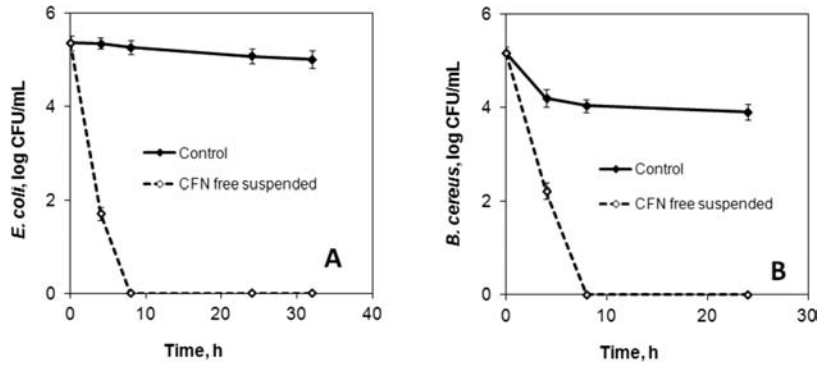

Figure 8. Viable counts of *E. coli* (A) and *B. cereus* (B) in PBS. Dashed lines: free-suspended CFN (0.25 mM curcumin). Solid lines: particles without curcumin (control).

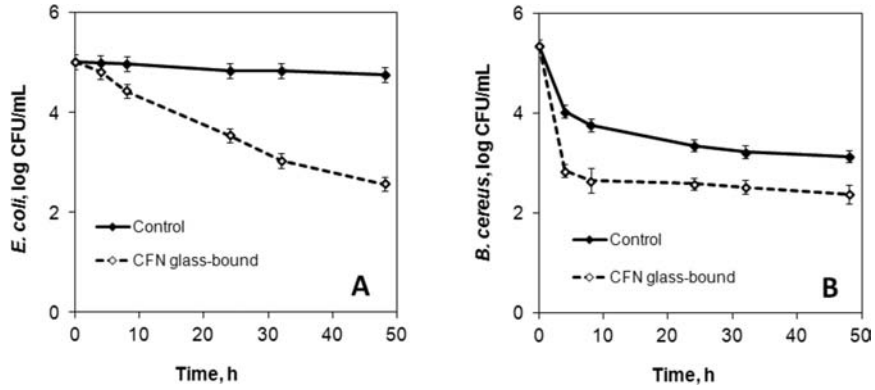

Figure 9. Viable counts of *E. coli* (A) and *B. cereus* (B) in PBS. Dashed lines: CFN-coated glass slides (approximately 1 μg curcumin per cm^2). Solid lines: glass slides coated with nanoparticles without curcumin (control).

Our suggestion about localization of curcumin within the membrane bilayer region rather than in more polar environments of the vesicle's cavity or interface region is in agreement with the report of Kunwar et al.[36] concerning phospholipid liposomes. Similarly, Sun et al.[37] investigated the interaction of curcumin with bilayer lipid membranes of giant unilamellar vesicles and came to the conclusion that curcumin initially binds to the interface and then is eventually inserted into the nonpolar hydrocarbon region.

Interaction of CFN-enclosed curcumin with bacterial membranes deserves further investigation in order to understand the mode of its antimicrobial action. Several possible mechanisms were proposed for liposome–bacterial cell interaction.[38] The two most relevant alternatives are (a) a fusigenic mechanism based on the merger of liposome bilayer with the cellular membrane releasing the vesicle content inside the cell[38] and (b) the "collision" mechanism, including intermembrane transfer of lipophilic materials without disruption of membranes.[39] Considering the strongly lipophilic character of curcumin and its bilayer localization, we suggest that the collision mechanism prevails in the mode of action of CFN. Since this mechanism is not associated with membrane disruption, it may allow longer functional durability of the CFN-coated surfaces.

To the best of our knowledge, this is the first report of curcumin-functionalized active antimicrobial surfaces. Obviously, physical contact of these surfaces with microbial cells was necessary for realization of their bactericidal potential. Inclusion of glucose in the interface layer of the vesicles facilitated their binding with bacteria based on ligand–receptor interaction.[29] On the other hand, the shake flask assay might not ensure optimal contact of bacteria suspended in the whole PBS volume with the CFN-coated glass. These contact limitations might result in certain reduction of efficacy of glass-bound vs free-suspended CFN toward *E. coli*. Sporulation of *B. cereus* caused by contact with nanovesicle-coated glass (with or without addition of curcumin) might affect the results obtained with this species. An optimal standardized procedure for testing the antimicrobial activity of active surfaces has yet to be developed. At any rate, the trials have shown a significant count reduction of both Gram-negative and Gram-positive bacteria caused by the contact with CFN-coated glass as compared with glass coated with nanovesicles without curcumin. On the other hand, further optimization of the nanovesicle efficacy is needed.

In summary, this study has demonstrated the advantages of curcumin as a potent natural antibacterial compound far exceeding other phenolic compounds tested. This activity was retained after inclusion of curcumin in liposome-type PDA nanovesicles and further covalent binding of the vesicles to glass surface. Thus, for the first time active antimicrobial surfaces functionalized by the natural food-grade compound curcumin were prepared. The activity of the curcumin-functionalized surfaces was demonstrated toward both Gram-negative (*E. coli*) and Gram-positive (*B. cereus*) bacteria. After efficacy optimization, this approach can be implemented, without imposing a health risk, for controlling microbial growth and preventing cross-contamination and biofilm formation on food-contacting surfaces (equipment, utensils, packaging) used in the food industry and home cooking.

for which the European Commission has issued "indicative" levels for the presence of acrylamide.[18]

The European food industry has devised many strategies for reducing acrylamide formation by modifying food processing. These have been compiled in a "*Toolbox*" produced by Food Drink Europe.[19] Analysis of manufacturers' data on acrylamide levels in potato chips in Europe showed a clear, statistically significant downward trend for mean levels of acrylamide from 763 (±91.1) μg/kg (parts per billion) in 2002 to 358 (±2.5) μg/kg in 2011, a decrease of 53% (±13.5), which was taken as evidence of the effectiveness of the "*Toolbox*".[20] However, the effect of seasonality arising from the influence of potato storage on acrylamide levels was evident in the study, and this was consistent with the results of a study that had analyzed samples of commercial potatoes in the United Kingdom from harvest through 9 months of storage,[21] showing the difficulty of processing a variable raw material to give a consistently low acrylamide level in the product. In the United States, the Food and Drug Administration has developed an "action plan" with a number of goals, including identifying means to reduce exposure. A North American perspective on the issue and the response to it has been given by Bethke and Bussan.[22]

Reducing the acrylamide-forming potential of potatoes and making it more consistent would be a great help to the food industry. In the United States, The J. R. Simplot Co. has recently begun to market a low-acrylamide biotech potato variety that has reduced activity of an asparagine synthetase gene (*ASN1*), two genes encoding enzymes of starch breakdown, phosphorylase L (*PhL*), and starch-associated R1 (*R1*), as well as a gene (*PPO5*) encoding polyphenol oxidase, an enzyme involved in bruising.[23,24] There is currently no possibility of such an approach being taken in Europe, but plant and agronomic science still have an important part to play, for example, through the identification and production of crop genotypes that stay consistently low in acrylamide-forming potential through a range of environments and conditions, including storage, and the development of best crop management practice.[25]

Conditions and length of storage are clearly aspects of potato management that can be optimized to keep acrylamide-forming potential as low as possible, and nutrition is another, with nitrogen availability, for example, increasing the acrylamide-forming potential of most varieties but decreasing it in some, whereas sulfur application reduces glucose concentrations and mitigates the effect of high nitrogen application in some varieties.[26] In this study, the impact of a third aspect of potato management, irrigation, was assessed, and the related issue of the effect of severe drought stress was investigated. The results showed water availability to have profound effects on the free amino acid and sugar concentrations and acrylamide-forming potential of potatoes. Lack of irrigation in the field and severe drought stress imposed in a glasshouse both brought about significant but different changes in composition, and different genotypes were affected in dissimilar fashion by the same treatment, indicating that there is no single, unifying potato tuber drought stress response.

MATERIALS AND METHODS

Chemicals. Ethanol (95% v/v, analytical grade) (Thermo Fisher Scientific UK Ltd., Loughborough, UK), HCl (Corning Life Science; supplied by Sigma-Adrich Company Ltd., Poole, UK), and acrylamide-$^{13}C_3$ (Sigma-Adrich Co. Ltd., Poole, UK) were used. KOH for IC chromatography (Thermo Fisher Scientific UK Ltd.), amino acid standards (Phenomenex, Torrence, CA, USA), isotopically labeled amino acids (Cambridge Isotope Laboratories, Inc., Andover, MA, USA), and helium (high purity) (BOC Industrial Gases, Sheffield, UK) were also acquired.

Commercial Potato Samples. Tubers from five varieties of potatoes (*S. tuberosum*) grown commercially in the United Kingdom in 2011 were provided by Higgins Group (Doncaster, UK). They came from adjacent irrigated and not-irrigated fields in Herefordshire and Shropshire in western England and from Norfolk in eastern England, water being supplied to the irrigated plants when required in the judgment of the farm manager. The potatoes were planted in April and harvested between late September and early November 2011. Nitrogen, phosphate, and potassium fertilizer was applied at levels recommended in the *Fertiliser Manual* (RB209),[27] which takes into account soil type and intrinsic soil nutrient levels. In all cases, irrigated and not-irrigated plots received the same fertilizer treatment. After harvest, the potatoes were kept in a commercial potato store at 8.5–9.5 °C, in line with normal UK practice, until analysis in January 2012. The varieties were Hermes, Markies, and Ramos, considered to be drought-tolerant, and Lady Claire and Saturna, which are drought-sensitive. Replication was derived from randomly sampling five tubers from each plot.

Glasshouse Experiment. A split-plot experiment in two blocks was set up in four deep troughs (2 m long × 0.625 m wide × 0.55 m deep), consisting of a two-variety (Saturna and Markies) by two-treatment (watered and drought-stressed) factorial. Two containers formed a block, one for watered and one for drought-stressed main-plot treatment. Each main plot was further divided into six split-plots, with three tubers of each of the two varieties being planted on February 16, 2012, one tuber per split-plot. All split-plots were sealed compartments in the container to maintain watered and drought-stressed conditions and prevent leakage between compartments. Day temperature was maintained at 18 °C and night temperature at 16 °C; supplementary lighting was used to provide the plants with a 16 h day. The troughs were filled with compost (Rothamsted mixture, requiring no additional fertilizer) on top of a 2.5 cm layer of J. Arthur Bower's Hydroleca (lightweight clay aggregate beads; William Sinclair Horticulture Ltd., Lincoln, UK) to allow efficient drainage.

Water was supplied automatically through a drip-feed for 3 min per day from the day of planting. On April 25 (68 days after planting) the plants began to flower, a developmental change that coincides closely with tuber initiation. At this point, watering to the drought treatment plants was reduced to 1 min per day and again on May 18 (91 days after planting) to 1 min per week. On June 7 (111 days after planting) the supply to the watered plants was increased to 6 min per day, and on September 6 (202 days after planting) watering to all plants was ceased to encourage senescence. Leaf water potential at mid-day was measured in a pressure chamber (PMS Instrument Co., Corvallis, OR, USA) to ensure that the plants for which water was withheld were drought-stressed. The plants were harvested on September 27, 2012 (223 days after planting).

Free Amino Acid and Sugar Concentrations. Free amino acids and sugars were measured as described previously.[21] Flour was prepared from individual freeze-dried tubers, and free amino acids were derivatized and then analyzed by gas chromatography–mass spectrometry (GC-MS) using an Agilent 5975 system (Agilent, Santa Clara, CA, USA). Note that arginine cannot be measured using this system, whereas cysteine concentrations were too low to measure accurately. Sugar concentrations were measured using a Dionex ion chromatography system with a 250 × 4 mm Carbopac PA1 column (Dionex Corp., Sunnyvale, CA, USA), operated using Chromeleon software, also as described previously.[21]

Acrylamide Formation. Acrylamide was measured in cooked potato flour after heating to 160 °C for 20 min. The analysis was performed by liquid chromatography–tandem mass spectrometry (LC-MS/MS) using an Agilent 1200 high-performance liquid chromatography (HPLC) system with a 6410 triple-quadrupole mass spectrometer with electrospray ion source in positive ion mode, as previously described.[21]

DOI: 10.1021/jf506031w
J. Agric. Food Chem. 2015, 63, 2566–2575

Statistical Analyses. The method of Residual Maximum Likelihood (REML) as implemented in *GenStat* (16th ed., VSN International Ltd., Hemel Hempstead, UK) was used to fit a linear mixed model to the data on the $\log_e$ scale, this transformation ensuring constant variance across the variety by treatment combinations. The analysis tested (F tests) the main effects and interactions between factors. For the field experiment, these factors were variety nested in type (drought-tolerant and -sensitive) and irrigation/nonirrigation, whereas random effects of location had to be accounted for. In the glasshouse experiment, the factors were variety and treatment (drought-stressed or watered), with blocks, main-plots, and split-plots being the random effects. Significant ($p < 0.05$, F test) terms for inspection were disseminated by considering differences between means of biological interest in terms of the standard error of the difference (SED) values on the relevant degrees of freedom (df). The least significant difference (LSD) was therefore used to judge significance at the 5% level.

For further inspection of the data, Pearson's correlation coefficients (r) were calculated between all pairs of responses, for the full data set and also for data pertaining to the separate treatments (irrigated and not-irrigated; watered or drought-stressed). These correlations were tested for significance using F tests.

RESULTS AND DISCUSSION

Effect of Irrigation on Tuber Composition in Five Potato Varieties Grown on Commercial Farms in the United Kingdom in 2011. Potato varieties Ramos, Lady Claire, Saturna, Hermes, and Markies were grown in three regions of the United Kingdom, namely, Herefordshire and Shropshire in western England and Norfolk in eastern England, under irrigated and not-irrigated conditions. The meteorological data for the United Kingdom in 2011 are available from the UK Meteorological Office: http://www.metoffice.gov.uk/climate/uk/2011/. Notable features of that year for England were a very warm and dry spring (the mean temperature for April was 3.5 °C above average), giving way to a rather cool summer with rainfall close to the average, although regionally variable. Eastern England, including Norfolk, where the Markies samples came from, was very dry in the spring, but the dry spell broke in June.

Data were obtained from tuber samples on free amino acids (excluding arginine, which cannot be measured by the method used, and cysteine, which was present at concentrations lower than would be required to allow reliable measurement) and the sugars glucose, fructose, and sucrose. Total amino acid content was calculated along with the ratio of free asparagine to total free amino acid concentration, a parameter that was identified as potentially related to acrylamide formation in a study that modeled the kinetics of acrylamide formation in French fry production.[28] Total sugar content was also calculated along with the sum of glucose and fructose as reducing sugars (potatoes contain very little maltose, and this was not measured). Data on acrylamide formation in heated flour were also obtained for analysis. The complete data set is given in Supporting Information Tables S1–S3.

The data were subjected to REML analysis following a $\log_e$ transformation to ensure constant variance across the variety by treatment (irrigated versus not irrigated) combinations. The results are shown in Table 1. There was a significant interaction ($p < 0.05$, F test) between treatment and variety nested in type for proline, tryptophan, glucose, total reducing sugars, and acrylamide. There was also a significant ($p < 0.05$, F test) interaction of type with treatment for free glutamine and the ratio of free asparagine to total free amino acids, indicating that the drought-tolerant and -sensitive varieties responded differently to irrigation with respect to these parameters. There were significant ($p < 0.05$, F test) varietal differences, nested in type, for free alanine, glycine, leucine, threonine, serine, γ-aminobutyric acid (GABA), asparagine, aspartic acid, glutamic acid, phenylalanine, glutamine, lysine, tyrosine, total free amino acids, the ratio of free asparagine to total free amino acids, and fructose. There was also a main effect ($p = 0.001$, F test) of treatment for fructose and a main effect of type ($p < 0.001$, F test) for free valine, isoleucine, and methionine. The relevant means, standard error of the difference between means (SED) (df), and least significant difference (LSD) (5%) values for comparisons are given in Table 2.

Table 2a shows the relevant means for the different varieties nested in type. Saturna had significantly different ($p < 0.05$, LSD) and lower concentrations of free alanine, glycine, threonine, serine, GABA, glutamine, lysine, and total free amino acids than the other varieties. The drought-tolerant varieties generally had greater concentrations of most free

[a]The grand mean (n = 50) and corresponding standard error (SE) are given for sucrose and total sugars, these having no effects at all. Back-transformed means (mmol per kg for amino acids and mg per kg for sugars) are given in parentheses. [b]Comparing means having 10 replicates. [c]Comparing means having 10 replicates with means having 15 replicates. [d]Comparing means having 15 replicates. [e]Drought-sensitive varieties.

amino acids than the drought-sensitive varieties and were more consistent as a group, although Hermes had significantly different ($p < 0.05$, LSD) and lower free glycine, aspartic acid, and total free amino acids and greater leucine and tyrosine than Markies and Ramos. Markies had the highest concentration of free asparagine, significantly different ($p < 0.05$, LSD) from Lady Claire, Saturna, and Hermes but not from Ramos. However, Saturna had the greatest ratio of free asparagine to total free amino acids, significantly different ($p < 0.05$, LSD) from the other varieties. Markies and Ramos had the greatest fructose, significantly different ($p < 0.05$, LSD) from the other three varieties.

The two types (drought-tolerant and -sensitive) differed significantly ($p < 0.05$, F test) as a whole, regardless of within-type (varietal) influence, only in that the tolerant varieties showed greater concentrations of valine, isoleucine, and methionine (Table 2b), but there was an interaction between type and treatment (Table 2c): free glutamine was significantly different ($p < 0.05$, LSD) and lower in the not-irrigated samples than the irrigated for the drought-sensitive varieties but higher for the drought-tolerant varieties, whereas the ratio of free asparagine to total free amino acids was significantly different ($p < 0.05$, LSD) and higher in the not-irrigated samples than the irrigated samples for the drought-sensitive varieties but slightly lower for the drought-tolerant varieties.

There were more effects from the interaction between treatment and variety nested in type (Table 2d), indicating that the varieties responded differently to irrigation. There was a higher concentration of proline in the not-irrigated conditions for all varieties but significantly so ($p < 0.05$, LSD) for Lady Claire and Ramos, the latter having a tremendous increase of 13.9-fold from 7.02 mmol/kg with irrigation to 104.58 mmol/kg without irrigation. An increase in proline concentration in response to drought and other treatments that cause osmotic stress has been observed in many plant species and has led to the hypothesis that it is not just a symptom of stress but part of the stress response, decreasing cell osmotic potential and thereby increasing turgor while decreasing plant water potential. This hypothesis has been reviewed in detail (and with some skepticism) by Lawlor.[29] The results of the present study would support an increase in free proline concentration being part of the response to drought stress, except that the varietal type was not well-associated with the quantity of increased proline, because Lady Claire is known to be drought-sensitive, whereas Ramos is drought-tolerant. The tryptophan concentration also suggested a differential response to irrigation for the varieties: the concentration was significantly different ($p < 0.05$, LSD) and higher for Saturna in the not-irrigated than in the irrigated sample, but significantly different ($p < 0.05$, LSD) and lower for Lady Claire.

Drought stress has also been shown to bring about an interconversion of simple sugars and complex carbohydrates, such as starch and fructan, in some plant species, and, as with proline, an increase in the concentration of simple sugars has been proposed to act as an osmotic protectant.[2,5] However, in this study, the glucose concentration was significantly different ($p < 0.05$, LSD) and lower in the not-irrigated samples for Lady Claire, Saturna, and Ramos and also substantially lower for Hermes, although slightly increased for Markies. Similar results were seen for total reducing sugars, albeit with Markies now showing a decrease.

There was no significant effect of the treatment, either on its own or interacting with type or variety nested in type, on the concentration of the other acrylamide precursor, free asparagine ($p = 0.088$, F test), but the indication was for an increase in all five varieties, with 124.84 mmol/kg in the not-irrigated samples and 107.66 mmol/kg in the irrigated samples, a 1.16-fold difference.

Acrylamide formation was lower for all varieties without irrigation and significantly so ($p < 0.05$, LSD) for Saturna (by 0.262 mg/kg on average) and Ramos (by 1.118 mg/kg on average). Previous studies have shown the relationship between precursor concentration and acrylamide formation in potato to be complex,[30] but glucose concentration has been a major factor in determining the acrylamide-forming potential in most of the data sets that have been obtained.[21,26,28,30−32] The correlation ($r = 0.625$, $p < 0.001$) between glucose concentration and acrylamide formation in this data set is shown in Figure 1A, and the lower glucose concentration in the not-irrigated samples was almost certainly responsible for the reduced acrylamide formation observed (Table 2d). There were also positive although not strong correlations with sucrose ($r = 0.304$, $p = 0.034$), total reducing sugars ($r = 0.492$, $p < 0.001$), and total sugar ($r = 0.458$, $p = 0.001$).

Free asparagine concentration has also been shown to contribute positively to the variance in acrylamide formation in some data sets,[21,30,33,34] but the correlation here was weak and negative ($r = -0.328$, $p = 0.022$). There was, however, a striking nonlinear relationship ($r = -0.589$, $p < 0.001$) of decreased acrylamide with increased proline (Figure 1B), with the very high proline concentrations brought about by nonirrigation, particularly in Ramos (Table 2d), being associated with reduced acrylamide formation. Proline has been shown to inhibit acrylamide formation in model systems[35] but is usually present in potatoes at much lower concentrations than asparagine, so the data presented here are the first to suggest that this could occur in a food matrix.

Effect of Drought Stress on Tuber Composition in Two Potato Varieties Grown in a Glasshouse. To apply a more controlled and severe drought stress, an experiment was conducted in a glasshouse. Two varieties, Markies, which is drought-tolerant, and Saturna, which is drought-sensitive, were selected for the study. For the plants to be able to develop a full-size root system and form tubers without physical

DOI: 10.1021/jf506031w
J. Agric. Food Chem. 2015, 63, 2566−2575

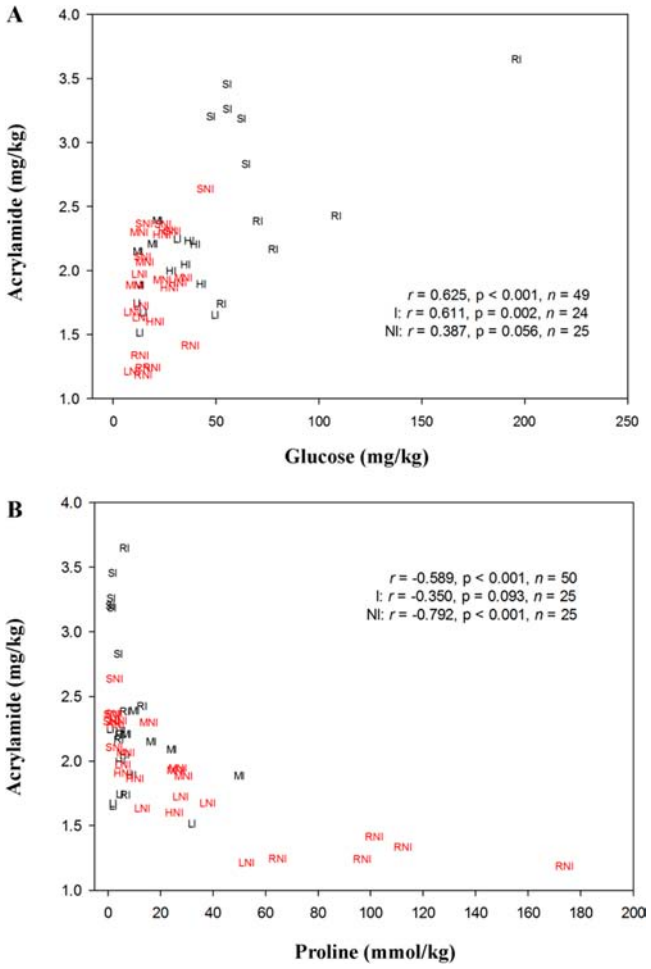

Figure 1. Graphs showing the correlation between glucose (A) and proline (B) concentrations and acrylamide formation in potato flour heated to 160 °C for 20 min. The flour was prepared from five varieties of potatoes grown, with and without irrigation, on commercial farms in the United Kingdom in 2011. The varieties were Hermes (H), Lady Claire (L), Markies (M), Ramos (R), and Saturna (S). Points on the graphs from irrigated potatoes are denoted I in black, whereas those for not-irrigated potatoes are denoted NI in red. The Pearson correlation coefficients (r), corresponding p values (F test), and number of pairs of observations (n) are given on the graphs.

restriction, the plants were grown in deep troughs filled with compost over a 2.5 cm layer of beads to allow drainage. A randomized, split-plot design was used, and drought stress was applied by reducing watering to half of the plants (drought) and maintaining it for the others (watered) (see Materials and Methods for details).

Watering of the drought plants was reduced after 68 days, at which point the plants were beginning to tuberize, and tubers were harvested after 7 months, when the plants were beginning to senesce. In previous glasshouse experiments on potato, the life cycle from planting to harvest has been 12 weeks,[34] the difference being that the plants were grown in pots containing vermiculite so that feeding with minerals could be controlled. In the present study, growing the plants in sufficient depth of compost to allow full root development resulted in a life cycle duration much more similar to that in the field in the United Kingdom.

Leaf water potential (LWP) at mid-day was monitored to ensure that the plants for which water was being withheld were drought-stressed. At the beginning of the treatment, LWP ranged from 4 to 6 MPa for Saturna and from 6 to 7.5 MPa for Markies. After 3 weeks of the treatment, the range of LWP for watered Saturna was 4.5−5.5 MPa and for watered Markies, 3.5−5.5 MPa, whereas the range in drought-stressed Saturna had risen to 8.5−10.5 MPa and for Markies, 10−11 MPa. These levels were maintained until the plants began to senesce.

Data were obtained on concentrations of free amino acids (once again without arginine and cysteine) and sugars (glucose, fructose, and sucrose). Total free amino acid content was calculated along with the ratio of free asparagine to total free amino acid content. Total sugar content was also calculated along with the sum of glucose and fructose as reducing sugars. Data on acrylamide formation in heated flour were also obtained for analysis. The full data set is given in Supporting Information Tables S4−S6.

REML was applied to the data on the $\log_e$ scale, this transformation ensuring constant variance across the variety by treatment combinations. The results are given in Table 3.

Table 4. continued

[a]The grand mean (n = 24) and corresponding standard error (SE) are given for amino acids and sugars with no effects of variety or stress. Back-transformed means (mmol per kg for amino acids and mg per kg for sugars) are given in parentheses. [b]Back-transformed means (mmol per kg) are given in parentheses. [c]The first SED and LSD of each pair in the table are for comparison of the varieties in either drought or control condition; the second SED and LSD of each pair are for all other comparisons. Back-transformed means (mmol per kg) are given in parentheses. [d]There was no significant (p < 0.05, F test) effect of stress for acrylamide or sugars (Table 3), but the full means table is included here for inspection. Back-transformed means (mg per kg for sugars and μg per kg for acrylamide) are given in parentheses.

There was an interaction (p < 0.05, F test) between stress and variety for free valine, leucine, histidine, and tyrosine. There was a main effect (p < 0.05, F test) of stress only for α-aminobutyric acid (AABA) and asparagine. There was a main effect (p < 0.05, F test) of variety only for free alanine, glycine, isoleucine, proline, phenylalanine, glutamine, lysine, tryptophan, the ratio of free asparagine to total free amino acids, glucose, and reducing sugars. There was no significant (p < 0.05, F test) effect of either stress or variety for acrylamide.

The relevant means and SED (df) and LSD (5%) values for metabolites showing a main effect of variety only are given in Table 4a. Markies had significantly different (p < 0.05, F test) and greater concentrations of free alanine, glycine, proline, and glutamine, as well as glucose and reducing sugars, than Saturna. Meanwhile, Saturna had significantly different (p < 0.05, F test) and greater concentrations of free isoleucine, phenylalanine, lysine, and tryptophan and a greater ratio of free asparagine to total free amino acids than Markies.

Two free amino acids, asparagine and AABA, showed a significant effect (p < 0.05, F test) of the treatment alone (in other words, the two varieties responded in similar fashion) (Table 4b). AABA concentration was somewhat greater in the potatoes from drought-stressed than watered plants, but free asparagine was almost doubled, from 132.03 to 242.26 mmol/kg. Four other free amino acids, valine, leucine, histidine, and tyrosine, showed an effect of the stress interacting with variety (in other words, the varieties responded differently) (Table 4c). For free valine, Saturna showed a substantial increase under the stress, whereas Markies had a considerable decrease, so that the difference between the varieties was significant (p < 0.05, LSD) under stress. A similar effect was seen for leucine and tyrosine. For histidine there was an increase under the stress for both varieties, but more so for Markies (4.4-fold), giving a significant (p < 0.05, LSD) difference between the varieties under the stress condition.

Proline concentration increased in both varieties in response to drought but, in contrast to the field-grown potatoes, the response was not statistically significant (p = 0.238, F test, for the main effect of stress and p = 0.159, F test, for the variety by stress interaction). There was also no overall significant effect of the treatment on sugar concentrations or acrylamide formation, but Table 4d gives the means for information. Markies showed considerably less acrylamide in the drought than in the watered condition (consistent with the result of the field study), whereas Saturna showed slightly more. For Saturna, the increase in acrylamide formation could be explained by increases in glucose and fructose. However, in Markies glucose was substantially higher in the drought samples than in the watered samples (Table 4d), and, given that free asparagine concentration was also almost doubled in the drought-stressed samples compared with the watered (Table 4b), the reduction in acrylamide formation is surprising. Fructose concentration did decrease in drought-stressed Markies, and fructose has been shown to be more reactive than glucose in kinetic modeling of acrylamide formation in French fries.[28] Nevertheless, the fact that both total reducing sugar and free asparagine concentration rose in Markies in response to drought stress but acrylamide formation declined does suggest that other factors were involved, and this requires further study.

Another notable aspect of the study was that lack of irrigation to commercial, field-grown potatoes, destined for the food chain, resulted in statistically significant changes in composition, even in the temperate United Kingdom in a year with not-unusual levels of rainfall. This is an example of the potential impact of environmental and management factors on crop composition, nutritional value, and processing properties.[2] Furthermore, the changes caused by lack of irrigation in the field were different in some respects from those brought about by more extreme drought stress imposed in the glasshouse. The most striking contrast between the effects of the moderate and more extreme stress was in the change in free asparagine concentration, which did not differ with statistical significance in the irrigated versus not-irrigated field samples but which showed a big increase in response to drought stress in the glasshouse.

The accumulation of free asparagine has been observed in diverse plant species in response to a range of abiotic stresses,[36] and, of course, this has potential implications for food safety.[2] Free proline, an increase in the concentration of which is also associated with abiotic stress, did not increase significantly in response to drought in the glasshouse experiment, but did in the field. Proline has been shown to increase in concentration in the leaves of drought-stressed potato plants,[37,38] with more accumulating in drought-sensitive than -tolerant genotypes. However, drought tolerance has also been suggested to be dependent on root growth rather than responses in the leaves.[39] The subject is reviewed comprehensively by Monneveux et al.,[40] but, as is generally the case with effects of stresses such as drought on plants, physiological studies have focused on the vegetative parts of the plant and the ability of the plant to survive the stress, not on the composition of the tubers. Unfortunately, the field data on Ramos, which showed a massive change in proline concentration in tubers in response to lack of irrigation, was not available in time to have included this variety in the glasshouse experiment. The increase in proline concentration in Ramos in the field was far greater than in the other varieties, showing that different genotypes of potato are affected in dissimilar fashion by the same abiotic stress. Consequently, the study did not identify a unifying potato tuber drought stress response.

The differing responses of the potatoes to lack of irrigation in the field and severe drought stress imposed in a glasshouse support the growing realization among plant physiologists that mild and extreme stresses may provoke very different responses in plants. This was discussed by Hancock et al.[41] in the context of temperature stress responses in potato, drawing on hypotheses put forward by Skirycz et al.[42] and Cramer et

DOI: 10.1021/jf506031w

al.[43] The results of the present study are consistent with this new paradigm.

Implications for Commercial Potato Production. Although the field and glasshouse experiments produced different responses and raised new questions about the relationship between precursor concentration and acrylamide formation, the effect of irrigation in the field on acrylamide formation during processing was clear: irrigation led to an increase in acrylamide formation. It must be borne in mind that the study concerned samples from one harvest year. Nevertheless, it would be sensible for potato farmers to irrigate only if necessary to maintain the health and yield of the crop.

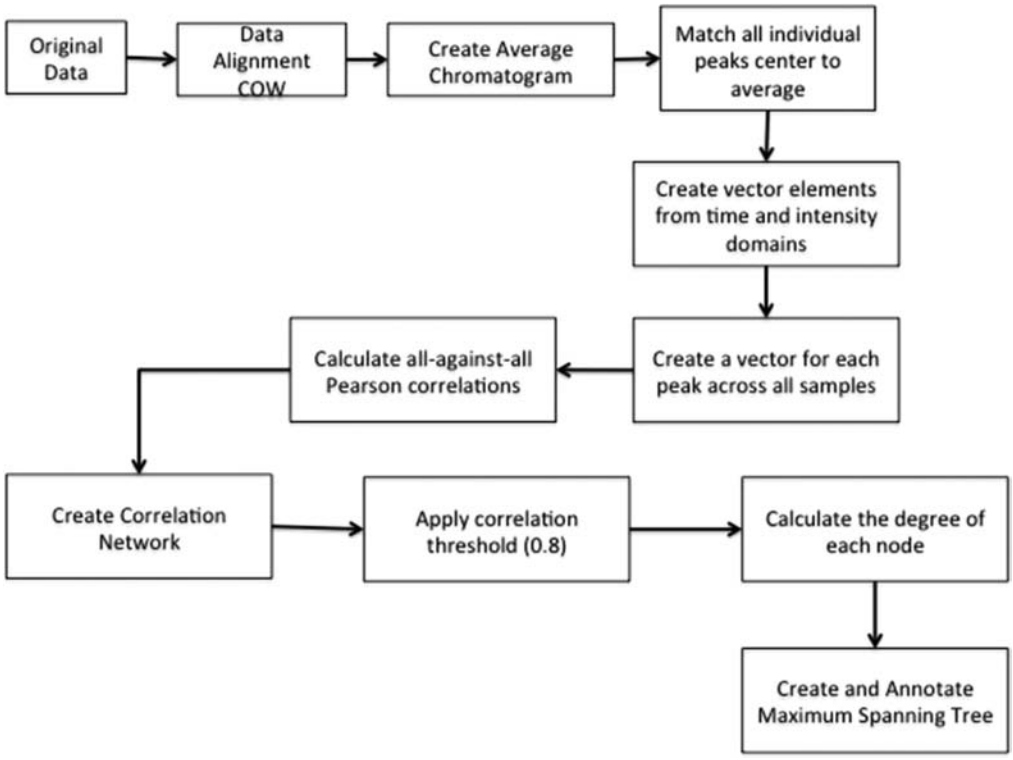

Figure 1. Flowchart for kinetic network reconstruction.

constructed from the peaks found in the total ion current (TIC). Some nodes of the network were subsequently identified and quantified in forced-aged wines (wines stored on different conditions of oxygen and temperature) to determine their kinetic parameters

MATERIALS AND METHODS

Reagents. Chemicals and standards were obtained from Sigma-Aldrich, USA (high-purity grade, >99.0%). Dichloromethane and anhydrous sodium sulfate were obtained from Merck, Darmstadt, Germany.

Wine Material. Thirty-four samples of Port wine with ages between 1 and 129 years were used. All wines were matured in oak barrels and were made following the standard traditional winemaking procedures for Port wine. For the isothermal protocol, 16 L of Port wine made on the year of the experiment (without any oak contact) with pH 3.4, a dissolved-oxygen concentration of 2.5 mg/L, a free-SO_2 level of 17 mg/L, a reducing-sugars level of 105 g/L, and 20.5% alcohol were used in order to determine kinetic parameters.

Isothermal Protocol. Kinetics for each compound detected in Port wine were followed using an isothermal storage method in order to determine the effects of oxygen and temperature. Isothermal storage was carried out at different temperatures (20, 30, 35, and 40 °C) and a series of sequential oxygen saturations inside a hermetically sealed vessel (0 to 10 saturations). Oxygen treatments included 0 (F1), 3 (F2), 5 (F3), and 10 (F4) saturations. Each combination of oxygen/temperature conditions was carried out in glass vessels containing 500 mL of wine. Oxygen saturation was achieved by stirring the sample for roughly 1 h, until an oxygen concentration of about 8−9 mg/L was reached. The F1 group was never supplemented with O_2. F2 was saturated on days 14, 35, and 56. F3 was saturated in the beginning of the experiment and at days 14, 28, 42, and 56. F4 was saturated with O_2 on days 0, 14, 21, 28, 35, 42, 49, 56, and 63.

This forced-aging protocol was carried out in duplicate. For logistical reasons, not all samples were analyzed by GC-MS, but rather the replicate was used as a crosscheck procedure.

Measurements of Dissolved Oxygen. Oxygen concentrations were measured using a Fibox 3 LCD fiber optic oxygen transmitter, a polymer optical fiber, and planar oxygen-sensitive spots (5 mm sensor spots PSt3) from PreSens Precision Sensing GmbH (Germany). The sensor was positioned in the center of the vessel (500 mL) where it remained in contact with the wine at all times.

Chemical Analysis. The extraction procedure was based on the one described by Silva Ferreira et al.[5] Briefly, 50 mL samples of Port were spiked with 50 μL of 3-octanol in a hydro alcoholic solution (1:1, v/v) at 427 mg/L as the internal standard and 5 g of anhydrous sodium sulfate. The wine was extracted twice with 5 mL of dicloromethane. The two organic phases obtained were blended and dried over anhydrous sodium sulfate. Two milliliters of this organic extract was concentrated to 0.4 mL under a nitrogen stream.

GC-MS Analysis. Extracts were analyzed using a Varian 450 gas chromatograph, equipped with a mass detector using Varian 240-MS and Saturn GC-MS workstation software, version 5.51. The injector port was heated to 220 °C. The split vent was opened after 30 s. The carrier gas was helium C-60 (Gasin, Portugal) at a 1 mL/min constant flow. The oven temperature was set at 40 °C for 1 min, then increased at 2 °C/min to 220 °C, and held for 30 min. All mass spectra were acquired in the electron-impact (EI) mode. The ion-trap temperatures were 230, 45, and 170 °C. The mass range was m/z 33−350, with a scan rate of 6 scans/s. The emission current was 50 μA, and the electron multiplier was set in relative mode to autotune procedure. The maximum ionization time was 25000 μs, with an ionization storage level of m/z 35. The injection volume was 1 μL, and the analysis was carried out in full-scan mode. Compound identification was achieved from comparisons of mass spectra obtained from the sample with those from pure standards injected under the same conditions, via comparisons of the Kovats indices and the mass spectra present in NIST 05 MS Library Database.

Statistical Analysis. Statistical analysis and the developed methodology involving the experimental data were carried out with R 2.12.1 for Mac, using the following packages: (i) classical multivariate analysis library (mva), (ii) main library of Venables and Ripley's (MASS), (iii) Harrell miscellaneous (Hmisc), and (iv) R-base packages (R-Project, 2012).

J. Agric. Food Chem. 2015, 63, 2576−2581

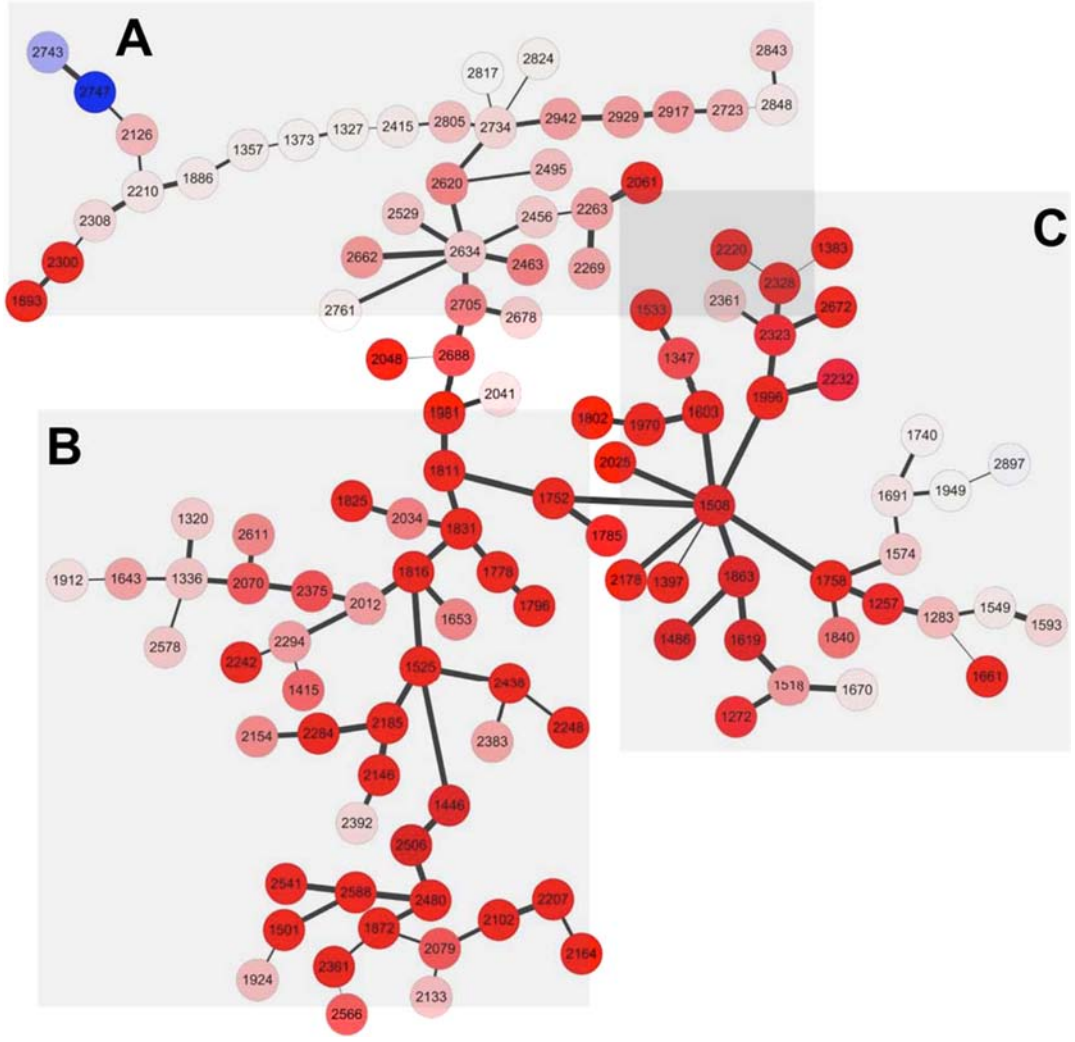

Figure 2. GC-MS putative kinetic network.

Data Preprocessing. The ASCII file of chromatographic data obtained from each sample was extracted, and a matrix was created containing all of the chromatograms. The intensities were normalized by dividing each value by the intensity of the internal standard (3-octanol). All of the m/z channels were normalized to total intensity to yield a total ion current (TIC) chromatogram for each sample. The resulting data set was then imported into The UnscramblerX 10.1 (Camo, Sweden), where the first stage of the alignment of chromatograms was carried out using Correlation Optimized Warping (COW).[6] The saturated peaks were then removed and the baseline corrected. The resulting matrix (GC-MS-TIC matrix) was then used for multivariate data analysis as described in the statistical analysis section.

KINETIC NETWORK RECONSTRUCTION

To reconstruct the underlying kinetic network, the fingerprint needed to be further compressed to a single value for each putative molecule detected by GC-MS. Thus, each chromatographic peak needed to be replaced with a single value for the intensity and retention time at the apex of each peak; therefore, a more refined alignment procedure was required. This was achieved as illustrated in Figure 1. Briefly, an "average" chromatogram was created by taking the mean of the values at each elution point in the GC-MS-TIC matrix. The wavelet method of Du et al.,[7] which was originally developed for peak-calling in peptide mass-spec data, was adapted for finding peak centers in chromatographic data, and a Mexican-hat wavelet was used to determine the location of all of the peaks in the average and sample chromatograms. A custom-built Perl program was integrated with the R-based wavelet method to achieve this. The distances between the locations of all of the peaks in each sample chromatogram and the locations of the peaks in the average chromatogram were calculated. It was observed that there was a correlation between peak height and the amount of peak-center shift that occurred across chromatograms; thus, we devised a two-step process for aligning sample peaks to those of the average chromatogram. If the (internal-standard-normalized) height of the average peak was greater than 2 and the distance to the nearest sample peak was less than 0.3 min, then the intensity value of the sample peak was assigned as the sample value at the average peak location. However, if the (internal-standard-normalized) height of the average peak was less than 2 and the distance to the nearest sample peak was less than 0.15 min, then the intensity value of the sample peak was assigned as the sample value at the average peak retention time. This algorithm was implemented in Perl.

As a result of this process, a new matrix was created that contained the retention time of all peaks in the average chromatogram and the intensity values of all of the peak centers from each sample aligned to these average retention times. Thus, a vector was created for each peak (presumably representing a compound) across all samples. A total correlation comparison

was done calculating the Pearson correlation among each and every peak vector. As such, one is able to track the increase or decrease of compounds (peaks) during the aging process and determine the correlative relationships among them. We applied a Pearson-correlation threshold of 0.8 and represented the remaining relationships as a mathematical graph in order to form a correlation network with the nodes representing peaks and the edges weighted with the Pearson correlations among the peak vectors. To reconstruct the most likely kinetic network underlying the set of chemical reactions involved in the aging process, a maximum-spanning tree was created by transforming the edge weights into inverse correlations (by taking the difference between the number 1 and the absolute correlation values) and the subsequent use of a minimum-spanning tree (mst) algorithm[8] on the this inverse correlation network. A minimum-spanning tree represents the shortest possible path through a graph and, as such, selects for the smallest inverse correlation (i.e., highest correlation) pairs among all nodes in the network. The resulting networks were visualized in Cytoscape.[9]

Kinetic Parameters. Nonlinear regression for model fitting was carried out on all data, using a one-step methodology,[10] by maximizing the likelihood function for all temperatures and using

bootstrap sampling to estimate the prediction residuals sum of squares (PRESS) criterion.[11,12] The lack-of-fit test was carried out to determine the adequacy of the regression model, and the studentized effect was studied at a 5% confidence level.

The general rate law for compound formation is

$$r = \frac{\mathrm{d}[\mathrm{compound}]}{\mathrm{d}t} = k_{\mathrm{obs}} * [\mathrm{compound}]$$

Therefore, the kinetic rate may follow the Arrhenius behavior with temperature.

$$k_{\mathrm{app}} = k_{\mathrm{ref}} \exp\left[-\frac{E_{\mathrm{a}}}{R}\left(\frac{1}{T} - \frac{1}{T_{\mathrm{ref}}}\right)\right]$$

where k_{ref} (day^{-1}) is the kinetic rate at the reference temperature T_{ref} (Kelvin), E_{a} represents the Arrhenius activation energy (J mol^{-1}), and R is the universal gas constant (Joule mole^{-1} Kelvin^{-1}).

Statistical analysis and the developed methodology involving the experimental data were carried out with R 2.12.1 for MAC using R-base packages (R-Project).

All the calculated kinetic models have p values below 0.05.

RESULTS AND DISCUSSION

Figure 2 shows the maximum-spanning tree derived from the correlation network among all peaks. Each node represents the center of a peak (Kovats index), and each edge represents the best correlation among the peaks. Fold changes between 1- and 129-year-old wines were calculated for each peak and the nodes colored accordingly, with shades of red representing increasing concentration and shades of blue representing decreasing concentration. The thickness of each edge has been scaled to represent the level of correlation (thicker lines mean higher correlation values). It was possible to observe three main branches indicated as A, B, and C.

It was observed that branch A (Figure 3) included compounds such as hexanoic (1886), octanoic (2110), and decanoic (2308) acids that cluster together. The ANOVA on perturbed wines shows that acids are not dependent on temperature or oxygen. In fact, because acid concentration during wine aging is regulated by the esterification/hydrolysis between the acid and the corresponding ester, acids may be formed as a result of hydrolysis, be lost through chemical esterification, or remain at a near-constant equilibrium concentration depending on their initial, post-fermentation levels.[13] When the system is in balance, there is a constant correlation between the concentrations of the substances present, governed by the mass action law.

Branch B (Figure 4) contains two compounds that are demonstrated to be highly sensitive to temperature as a result of their high activation energy (HMF (2506) and furfural (1446)), which suggests that the other compounds in the branch may also be sensitive to temperature. A summary of the ANOVA results is present on each figure as well as the time of expression of each compound identified. All the compounds identified tend to increase during aging, and ANOVA shows that significant differences were established across the temperature conditions, meaning that the compounds identified were all dependent on temperature. It is possible to observe three sub-branches apparently related to activation energy. The sub-branches of vanillin (2541), γ-ethoxycarbonyl-γ-butyrolactone (2207), diethyl tartrate (2361), and triethyl citrate (2480) have an E_{a} between 16 and 36 kJ/mol. The organic acid esters, diethyl tartrate (2361) and triethyl citrate (2480), tend to increase as a result of the high concentration of the respective acids (tartaric and citric acids), by the reaction between the acid and the ethanol (esterification reaction). According to Ribéreau-Gayon and Peynoud,[14] polyprotic acids such as tartaric, citric, and malic

DOI: 10.1021/jf5055084
J. Agric. Food Chem. 2015, 63, 2576−2581

acid esterified more rapidly than the monoprotic acids acetic, propanoic, and butanoic acid, and temperature accelerates the reaction. γ-Ethoxycarbonyl-γ-butyrolactone (2207) is a lactone that probably results from glutamic acid or related compounds and is dependent on wine aging, contributing a cherry aroma to wine.[15] The formation of the lactone is an esterification reaction. Vanillin (2541) is a phenolic aldehyde related with barrel aging. Its sensitivity to temperature in wines that were not subject to wood contact is still unknown. Diethyl glutarate (2392) and ethyl-2-furoate (1525) are located in a second sub-branch. These two compounds have activation energies of 74 and 56 kJ/mol, respectively, which are higher than those present in the posterior sub-branch. Ethyl-2-furoate (1525) is also dependent on temperature, and its formation is related to the Maillard reaction. In summary, this branch contains compounds related to temperature, and it would appear that there is an association between network location and activation energy.

Branch C (Figure 5) contains compounds related to oxidation, such as benzaldehyde (1508) (formed by the oxidation of benzyl alcohol), dioxanes (1486 and 1863), and dioxolanes (1619) (formed by the reaction of ethanal and glycerol). One region of this branch (C.1., Figure 5) seems to indicate a correlation between sotolon (2232) and 3-hydroxy-2-methyl-4H-pyran-4-one (1996, maltol). These two compounds have somewhat similar chemical structures (i.e., a furanone and a pyranone, respectively), and both have a very sweet aroma, normally classified in the same group of aromas with flavors of burnt sugar, caramel, and maple. However, the sensorial impact of each compound occurs at different orders of magnitude, parts per billion for sotolon and parts per million for maltol.

Sotolon is dependent on temperature and oxygen, which suggests that maltol is dependent on the same parameters; in fact, the ANOVA indicates that the compound is sensitive to both parameters and has a very high activation energy when compared to sotolon. This suggests that maltol is much more sensitive to temperature than sotolon. Yaylayan et al. observed that maltol formation is related to 1-deoxyosone, an important intermediary of the Maillard reaction.[16] However, there are no studies on the impact of oxidation on its formation.

Other compounds present in sub-branch C.1. (Figure 5) appear to be connected to sotolon and maltol. These compounds are probably dependent on oxygen and temperature, and their identification could be useful in the unraveling of the connection between the Maillard mechanism and oxidation.

These observations would seem to validate the assumptions made that compounds grouped on the same branch of the network have the same time of expression and consequently the same kinetic order. It was also observed that compounds grouped together are sensitive to the same technological parameter.

We believe that this network-driven approach to the study of large kinetic systems is proving to be a useful tool for identifying putative compounds of interest and for mechanistic hypothesis generation that can subsequently be tested experimentally. We would recommend that this type of chemiomics approach become a standard workflow for the future investigation of complex chemical systems.

Correction to In Vitro Bioaccessibility of Carotenoids, Flavonoids, and Vitamin C from Differently Processed Oranges and Orange Juices [*Citrus sinensis* (L.) Osbeck]

Julian K. Aschoff, Sabrina Kaufmann, Onur Kalkan, Sybille Neidhart, Reinhold Carle, and Ralf M. Schweiggert*

J. Agric. Food Chem. **2015**, *63* (2), 578−587. DOI: 10.1021/jf505297t

In our paper, the dietary fiber contents of the test foods are shown in Table 3 to demonstrate their reduction upon dejuicing of fresh oranges. The values were shown in "g/100 g of dry weight (DW)", although the footnote stated "g/100 g of fresh weight (FW)". Consequently, on page 583, we erroneously compared the dietary fiber content of orange (DW) to that of tomato (FW). We calculated the dietary fiber level of oranges per g/100 FW (**2.2 g/100 g FW**), which should be used for this comparison instead.

This correction does not affect the validity of our discussion.

expressed as haloxyfop"),[7] and residue enforcement methods (e.g., the German official multiresidue method)[8] do not address enantiomer composition. Moreover, the fate of individual stereoisomers in soil is not well understood. Although the rapid enantiomerization of several FOPs, for example, fluazifop, diclofop, and fenoxaprop, in soil was previously described,[3,9−11] a deeper insight into the mechanism and actual conversion rates are still missing.

In this paper, we describe an enantioselective analytical method used to isolate milligram quantities of single enantiomers of haloxyfop (both acid and methyl ester) based on HPLC as well as a method for the enantioselctive analysis of these compounds in soil extracts based on GC-MS. The latter was also used to analyze the compounds in plant extracts as reported in our companion paper.[12] Our results confirm the rapid hydrolysis of haloxyfop-methyl (Ha-me) to haloxyfop (Ha-acid) in soil. We then examine the rapid and preferential interconversion and further degradation of Ha-acid in soil as determined by incubating the racemic compound and the pure *R*- and *S*-enantiomers. Three different soils are used to determine if soil properties have any influence on the enantioselectivity of transformation. Control experiments in sterile soil are performed to determine whether the conversion is biologically mediated. A hypothesis on the mechanism of conversion in soil is postulated on the basis of H−D exchange experiments and mass spectrometric analysis. Mathematic modeling is applied to derive kinetic parameters for *R*/*S* interconversion and degradation in soil.

MATERIALS AND METHODS

Reference Materials. Racemic haloxyfop-methyl and haloxyfop-P-methyl (*rac*-Ha-me and *R*-Ha-me; 99.2 and 99.1%, respectively) were obtained from Dow AgroSciences, Hitchin, UK, and *rac*-haloxyfop (*rac*-Ha-acid, 99.8%) was from Riedel de Haen, Seelze, Germany. Pure *R*- and *S*-enantiomers of Ha-me and Ha-acid were isolated from the racemates by enantioselective HPLC (see below). *rac*-Fluazifop (*rac*-Fl-acid, 94.5%, from Dr. Ehrenstorfer, Augsburg, Germany) and *rac*-fluazifop-methyl (*rac*-Fl-me), prepared by methylation of *rac*-Fl-acid using diazomethane (see below), were used as internal standards. For CAS names of the various compounds used, see Supporting Information Table S2.

Semipreparative Isolation of *R*- and *S*-Enantiomers of Ha-me and Ha-acid. Pure *R*- and *S*-enantiomers of Ha-me were prepared from the racemic compound in milligram quantities by enantioselective HPLC according to a method published by CIPAC.[13] The enantiomers were separated on a silica gel column coated with cellulose tricinnamate (Chiralcel OK, 25 cm × 4 mm, 10 μm particle size; Daicel Chemical Industries, Osaka, Japan) at ambient temperature using heptane/isopropanol/methanol (85:5:10) as eluent at a flow rate of 1 mL/min and UV detection at 280 nm. *R*- and *S*-enantiomers of Ha-me eluted baseline separated after 6.7 and 8.8 min, respectively, with peak widths of 1.0 and 1.5 min (chromatogram, see Supporting Information Figure S5).

Pure enantiomers of Ha-acid were prepared using the same column and heptane/isopropanol/acetic acid (95:5:0.1) as eluent at a flow rate of 1 mL/min and UV detection at 280 nm. *R*- and *S*-Ha-acid eluted baseline separated after 13.5 and 20.4 min, respectively (peak widths of 4 and 6 min; chromatogram see Supporting Information Figure S6). A total of 10 injections of *rac*-Ha-me and *rac*-Ha-acid (0.5 mg in 100 μL), respectively, were made, and fractions were collected at the exit of the UV detector while the UV trace was observed. The pooled fractions contained approximately 2 mg of each enantiomer with >99% enantiomeric purity as determined by enantioselective GC-MS after methylation with diazomethane when appropriate (see below). Isolated enantiomers were stored in mobile phase until used for incubation experiments. Aliquots were then evaporated to dryness and redissolved in spiking solution (water or water/methanol, see below).

Incubation of Ha-me and Ha-acid in Soil. Soil samples were collected at sampling locations in close proximity to those of the Swiss soil monitoring network (NABO, www.bafu.admin.ch/boden). The soils were selected to cover a wide range of properties, in particular pH and organic carbon (Table 1). Standard equipment was used for sampling soil from the top 10 cm. The soils were kept in the dark at ≈4 °C for no more than 6 months prior to use.

Portions of 2 mm sieved, field-moist soil (100 g) were spread on glass dishes, and the test substance was applied using a small spray bottle (1−2 mL of an aqueous solution containing 100 μg per enantiomer of Ha-acid). For experiments with Ha-me (only with soil Neualp), the spike solution contained 30% methanol as cosolvent to increase the solubility (note the solubility of Ha-me in water is 9.1 mg/L[7]). The resulting spike levels were 1 μg enantiomer/g moist soil and thus high enough to allow for reliable quantification down to 1% of the initial concentration. This spike level is somewhat higher than the concentrations expected from typical application rates in the field of up to 160 g/ha (0.21 μg/g assuming uniform incorporation in the top 5 cm soil layer and a bulk density of 1.5 g/cm^3) but is not expected to affect soil microorganisms. Separate experiments were carried out with racemic compounds and with pure *R*- and *S*-enantiomers. The soils were then thoroughly mixed, transferred to Erlenmeyer flasks, closed with air-permeable cellulose plugs, and incubated at 20 °C in the dark for up to 4 days. The moisture of the soils (24−174 g water/100 g dry soil, corresponding to 37−60% of the maximum water-holding capacity) was regularly checked by weighing and kept constant by the addition of distilled water. At appropriate time intervals, aliquots of 10 g of soil were removed for extraction and analysis.

Sterile Control Experiments. Abiotic transformation of Ha-acid was studied using a γ-irradiated soil (soil Dübendorf, Table 1) as sterile control. Portions of 200 g of soil in closed screw-cap glass jars were exposed for a few hours to γ-irradiation (dosimeter controlled total dose of 30 kGy) from a commercial ^{60}Co source (Leoni Studer-Hard, Däniken, Switzerland). The glass jars were kept tightly closed after irradiation until the start of the incubation experiments to ensure sterile conditions. Spiking was done in the same way as for the nonsterile soils except that the soil was kept in the glass jars during spiking. Nevertheless, sterile conditions were broken upon spiking. As the incubation experiments lasted for only a few days, this was not expected to allow for restoration of any substantial biological activity in the soil.

H−D Exchange Experiments. Three 100 g portions of 2 mm sieved, field-moist soil (Neualp, Table 1) were spread on glass dishes

DOI: 10.1021/jf505241t
J. Agric. Food Chem. 2015, 63, 2583−2590

and allowed to dry to approximately 50% of their initial water content. The evaporated water was replaced by dropwise addition of deuterium oxide (Fluka, Buchs, Switzerland) to achieve an approximate 1:1 ratio of H_2O/D_2O. As D_2O can be toxic to soil microorganisms, a larger proportion was avoided. The soils were then spiked in the same way as the other soils (separate experiments with *rac*-Ha-acid and with pure *R*- and *S*-enantiomers). Soil moisture was maintained by the addition of a 1:1 mixture of distilled water and deuterium oxide.

Extraction and Derivatization. Soil samples from experiments with Ha-acid (10 g) were collected from the incubation vessels in 20 mL glass scintillation vials. Immediately after weighing, 10 mL of methanol and 100 μL of a methanolic solution of *rac*-Fl-acid (0.1 μg/μL) were added and the vials closed and vigorously shaken by hand for approximately 1 min and then stored at −20 °C until further processed (typically within 1 day). The vials were centrifuged at a relative centrifugal force (RCF) of 720 for 5 min (rotor with a radius of 16 cm, 2000 rpm), and the clear supernatants were removed into 30 mL glass vials, diluted with 10 mL of distilled water, and acidified to pH ≈1 by the addition of 4 drops of 5 M sulfuric acid. The extracts were then partitioned twice with 5 mL of dichloromethane, and the combined organic extracts were allowed to evaporate to dryness overnight in a fume hood. The extracts were then redissolved in a few drops of methanol and methylated by the addition of approximately 300 μL of an ethereal diazomethane solution until the yellow color of the diazomethane persisted (see ref 14 and cautionary note therein). The reaction mixtures were allowed to stand for 15 min and then carefully evaporated to dryness in a stream of air, and the dry residues were dissolved in 5 mL of hexane. An aliquot of 1 μL was used for GC-MS analysis. Absolute recoveries over the extraction and derivatization procedure, determined in soil Neualp, were 71% for both Fl-acid and Ha-acid, respectively (spike level, 1 μg/g moist soil). This indicates that both compounds show very similar behavior and that Fl-acid is thus an appropriate internal standard for Ha-acid. The method precision, expressed as relative standard deviation of multiple extractions, on average was 3.2% (range, from 0.3 to 5.9%).

In exploratory experiments with Ha-me, the same extraction procedure was used. In contrast to the experiments with Ha-acid, prior to the extraction the soil samples were fortified with 10 μg of *rac*-Fl-acid in 100 μL of methanol and 10 μg of *rac*-Fl-me in 100 μL of ethyl acetate as internal standards. The samples were derivatized with diazoethane (for a description of the preparation, see ref 12) rather than diazomethane, to allow for the simultaneous determination of parent Ha-me as well as Ha-acid formed during incubation. An aliquot of 1 μL was used for GC-MS analysis. Absolute recoveries over the extraction and derivatization procedure were 68 and 71% for Fl-me and Ha-me, respectively (spike level, 1 μg/g moist soil).

Several control experiments were conducted to ensure that no artifacts were produced during extraction and derivatization. Selected samples were spiked only with Fl-acid and then derivatized with diazomethane or diazoethane to confirm that no (<1%) ethyl ester was formed upon methylation and vice versa. Samples spiked only with Fl-me were derivatized with diazoethane to confirm that no transesterification occurred (<1% Fl-et present in ethylated soil extract dissolved in ethyl acetate). Finally, soils freshly spiked with single isomers of Ha-me and Ha-acid were processed to confirm that no hydrolysis and no enantiomerization occurred during sample preparation.

Enantioselective GC-MS Analysis. A Quattro Micro GC-MS/MS system (Waters Corp., Milford, MA, USA) connected to a HP6890N gas chromatograph (Agilent Technologies, Santa Clara, CA, USA) fitted with a PAL autosampler (CTC Analytics, Zwingen, Switzerland) was used in the electron ionization (EI, 70 eV, 180 °C) mode. Full-scan EI mass spectra (m/z 35−435, 0.5 s/scan, nominal mass resolution) were recorded for analyte detection and identification. Analysis of the methyl and ethyl esters was carried out in the selected ion monitoring mode for optimum sensitivity (cycle time = 0.5 s) using the m/z values listed in Table 2.

A custom-made 20 m GC column coated with OV 1701 containing 15% (w/w) permethyl-β-cyclodextrin with a film thickness of 0.1 μm (BGB Analytics, Boeckten, Switzerland) was used for separation. The

Table 2. GC-MS Masses Used for Determination of Target Compounds, Retention Times of the Enantiomers, and Chromatographic Resolution Achieved with the Permethyl-β-Cyclodextrin Column

target compound	m/z (all M^+)	retention times (min)	resolution
fluazifop-methyl (Fl-me)	341.1	38.5/38.7	1.4
fluazifop-ethyl (Fl-et)	355.1	39.9/40.1	1.3
haloxyfop-methyl (Ha-me)	375.1	41.3/41.5	1.3
haloxyfop-D_1-methyl	376.1	41.3/41.5	1.3
haloxyfop-ethyl (Ha-et)	389.1	42.7/42.9	1.2

GC conditions were as follows: split/splitless injection (240 °C, 48 s splitless time); temperature program, 50 °C for 2 min, increase to 120 °C at a rate of 25 °C/min and to 220 °C (upper temperature limit for this type of columns) at 2 °C/min. Helium was used as carrier gas at a flow rate of 2 mL/min. The column showed excellent stability, low bleed, and good and constant, nearly baseline, resolution of Ha-me, Ha-et, Fl-me, and Fl-et enantiomers (Table 2).

Kinetic Evaluation of Experimental Data. All kinetic analyses of experiments were performed using the modeling software Aquasim, version 2.1b.[15] Degradation and isomerization were implemented as first-order processes based on the conceptual model given in Figure 2,

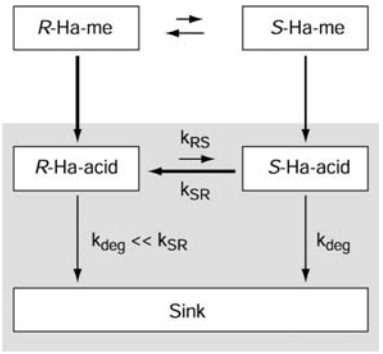

Figure 2. Reaction scheme and definitions of reaction rate constants used in the model calculations. The shaded area highlights the portion that was covered by model calculations.

and the corresponding rate constants were determined by fitting the modeled curves to measured data. The rate equations used for curve fitting were

$$d[S]/dt = k_{RS} \times [R] - (k_{SR} + k_{deg}) \times [S]$$

$$d[R]/dt = k_{SR} \times [S] - (k_{RS} + k_{deg}) \times [R]$$

Initial enantiomer concentrations were not fixed, but were fitted as additional parameters, with the following exceptions: the initial concentration of *S*-Ha-acid in the experiment with enantiopure *R*-Ha-acid was set to zero (and vice versa), and equal initial concentrations of *R*- and *S*-Ha-acid were assumed in the experiments with *rac*-Ha-acid.

Fitting was done in several steps. First, all rate constants, including separate degradation rate constants for each enantiomer, were fitted individually for each experiment. This approach did not yield satisfying solutions for the degradation rate constants because isomerization (particularly $S \rightarrow R$) is substantially faster than degradation. It is thus not possible to determine whether the *S*- or the *R*-enantiomer is more rapidly degraded because a small change in the isomerization rate constants would compensate for that difference. Therefore, a more robust fitting approach was used assuming that both enantiomers are degraded with an equal rate constant, k_{deg}. Isomerization rate constants k_{RS} and k_{SR}, respectively, were fitted for each soil simultaneously with data from the experiments with *rac*-Ha-acid and the pure *R*- and *S*-

DOI: 10.1021/jf505241t
J. Agric. Food Chem. 2015, 63, 2583−2590

enantiomers, using the enantiomer fractions[16] ([R]/([R] + [S]) and [S]/([R] + [S]), respectively) rather than individual concentrations as fit targets. The fitted values for k_{RS} and k_{SR} were then fixed, and k_{deg} values were determined for each individual experiment by fitting of the total concentrations (sum of *R*- and *S*-enantiomers).

RESULTS AND DISCUSSION

Analytical Considerations. For the sensitive and accurate enantioselective determination of Ha-me and Ha-acid in soil, chiral GC with mass spectrometric detection was used. Ha-acid and Fl-acid (internal standard) were converted to the respective methyl esters using diazomethane. In the initial experiments with Ha-me, selected samples were derivatized with diazo*ethane* to allow for simultaneous detection of Ha-acid (as ethyl ester) and Ha-me. Experiments with sterile soil showed that the extraction and derivatization procedures did not change the enantiomer ratios of Ha-acid.

Several chiral GC columns were evaluated for resolution of haloxyfop and fluazifop enantiomers. Whereas a dimethyl-*tert*-butyldimethylsilyl-*β*-cyclodextrin column had shown excellent enantiomer resolution of various phenoxypropionic acid herbicides,[17] this selector was found to provide insufficient chromatographic resolution of haloxyfop and fluazifop enantiomers. Eventually, a column coated with OV 1701 containing 15% (w/w) permethyl-*β*-cyclodextrin provided best resolution and allowed elution of the target analytes below 200 °C and, thus, well below the temperature limit of the column of 220 °C (Figure 3).

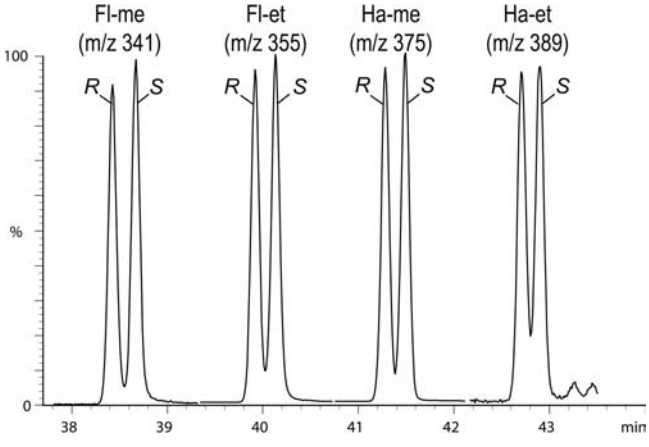

Figure 3. EI SIM chromatograms of racemic reference compounds of the methyl and ethyl esters of fluazifop (internal standard) and haloxyfop, analyzed on the enantioselective permethyl-*β*-cyclodextrin column.

The same enantiomer elution order (*R* prior to *S*) was observed for Ha-me, Ha-et, and Fl-me on this chiral selector. It is interesting to note that the same elution order was observed for ibuprofen, when considering its reverted absolute configuration at the *α*-carbon atom (*S* prior to *R*).[18] This indicates a common principle toward chiral recognition of the propionic acid moiety by this cyclodextrin derivative.

Whereas the enantiomer composition of Ha-acid was expected to change during incubation, the racemic fluazifop, serving as an internal standard, theoretically should always show enantiomer ratios of 1:1. The actual ratios for *rac*-Fl-acid (analyzed as methyl and ethyl esters) on a new GC column were indeed very close to 1:1, but with aging of the column, they were shifted toward a small excess in the later eluted *S*-enantiomer (Figure 3), which is commonly observed in enantioselective GC. In this particular case, the shift of apparent peak area ratios was small (approximately 0.9:1.1), and it was not due to peak tailing. Using the observed apparent ratio of the internal standard it was possible to apply a correction factor to the experimental data and thus to obtain accurate enantiomer ratios for haloxyfop.

Exploratory Soil Incubations of Ha-me. In initial experiments, *rac*-Ha-me or its pure enantiomers were incubated for 0, 2, and 4 h in soil Neualp (Table 1). In Figure 4 we show

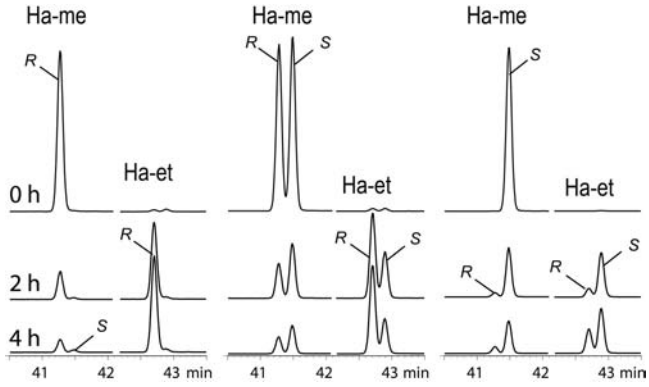

Figure 4. EI SIM chromatograms (*m*/*z* 375 + 389) of extracts of soil Neualp spiked with *R*- (left), *rac*- (middle), and *S*-Ha-me (right) immediately after spiking (top) and 2 h (middle) and 4 h later (bottom). Signals are normalized to the peaks for Fl-me used as internal standard. Note the rapid disappearance of Ha-me and the concurrent formation of Ha-acid (analyzed as ethyl ester).

chromatograms from these incubations. In all three experiments, Ha-me rapidly disappeared with half-lives of <2 h, and approximately 75% of the applied Ha-me was transformed to Ha-acid. The chromatograms from the incubation with *rac*-Ha-me indicate that degradation is enantioselective with faster dissipation of the *R*-enantiomer (residual composition, $R < S$). Degradation of the enantiopure compounds was associated with formation of small amounts of the antipode, indicating that enantiomerization occurred, although at a much slower rate compared to degradation.

This initial set of experiments confirmed that rapid degradation of Ha-me was leading to Ha-acid, consistent with previous studies.[7,19] Indeed, the 0 h ("quasi-zero") samples already showed the presence of some small amounts of free acid (analyzed as ethyl esters, Figure 4), whereas standards of Ha-me contained no detectable amounts of free acid. Apparently, the short time (a few minutes) required for preparation (spiking, mixing of soil, sampling) was sufficient to form free acid by hydrolysis of the methyl ester. In the 2 h sample, then, the presence of acid was significant, thus clearly indicating rapid hydrolysis of the methyl ester to the free acid. In a review,[20] the properties of microbial carboxy esterases were described and enantioselective cleavage of, for example, substituted phenoxypropionic acids was reported. Apparently, these esterases are widespread in soil microbiology, which could explain the fast ester cleavage of Ha-me.

Closer inspection of the signals for Ha-acid (analyzed as its ethyl ester) in Figure 4, from incubation of *rac*- and particularly from *S*-Ha-me, indicates that the proportion of *R*-Ha-acid formed is larger than would be expected from the stereochemical composition of the precursor. Furthermore, the proportion of the *R*-enantiomer increases from the 2 h to the

DOI: 10.1021/jf505241t
J. Agric. Food Chem. 2015, 63, 2583−2590

4 h sample. This indicates that Ha-acid enantiomers formed in soil are rapidly interconverted, with preference for the *R*-enantiomer. This interconversion appears to be faster than the actual degradation of Ha-acid, as its impact on the enantiomer composition is clearly observed. As Ha-acid is the active metabolite of Ha-me and is present in soil much longer than Ha-me, its enantiomer composition determines the residual herbicidal activity. Therefore, we investigated the degradation and enantiomerization of Ha-acid in soil in more detail.

Incubation of *rac*-, *R*-, and *S*-Ha-acid in Three Different Soils. Separate incubation experiments were conducted with racemic and enantiopure Ha-acid to investigate possible enantioselective degradation as well as conversion of one enantiomer to the other. From the experiment with Ha-me it was expected that changes in enantiomeric composition are fast. Therefore, short initial sampling intervals of 4 h were chosen, except for soil Dübendorf (Table 1), for which 1 day intervals were used.

In all three soils, the enantiomer composition of spiked Ha-acid changed rapidly as indicated by the chromatograms shown in Figure 5. In fact, the enantiomer ratio after 8 h of incubation was almost independent of the initial enantiomer composition. The change in composition was faster than the overall dissipation of Ha-acid in soil. It involved the formation of *R*-from *S*-Ha-acid and, to a lesser degree, also the reverse reaction. The enantiomer composition eventually approached a steady state, where the concentration of the *R*-enantiomer was about 10 times that of the *S*-enantiomer. The composition in the three soils, expressed as enantiomer fraction (here defined as concentration of *S*-enantiomer divided by total concentration), is shown in Figure 6. From the curves it is suggested that the final enantiomer composition is independent of the initial composition and very similar in all three soils, whereas the rate at which this composition was achieved differed slightly (curve fitting, see below).

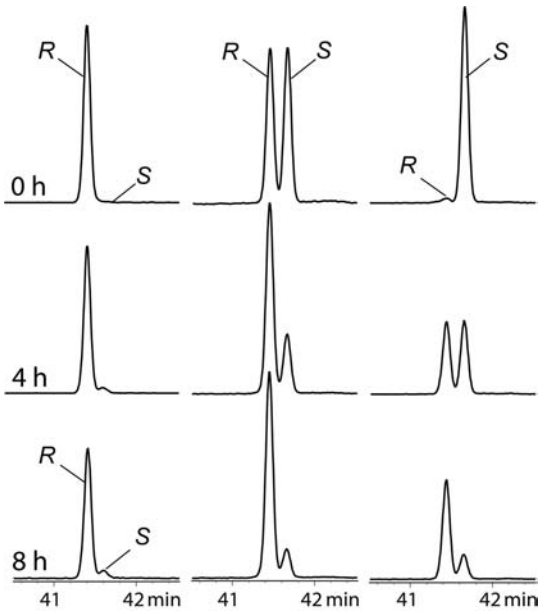

Figure 5. EI SIM chromatograms (m/z 375) of extracts of soil Neualp spiked with *R*- (left), *rac*- (middle), and *S*-Ha-acid (right) immediately after spiking (top) and 4 h (middle) and 8 h later (bottom), analyzed after methylation. Signals are normalized to the peaks for fluazifop used as internal standard. Note the rapid disappearance of *S*-Ha-acid and the concurrent formation of the *R*-enantiomer.

In the sterile soil, no degradation and no change in enantiomer composition were observed over the first 4 days of incubation, indicating that degradation as well as enantiomerization in soil are microbially mediated processes. After prolonged incubation, some conversion was observed, probably due to regrowth of microorganisms as sterile conditions were broken with spiking and sampling.

Kinetic Modeling of Degradation and Enantiomerization of Ha-acid in Soils. The experimental data in the three nonsterile soils were fitted using the conceptual model shown in Figure 2. In total, three rate constants were fitted to describe the conversion of *R*- to *S*-Ha-acid and vice versa, as well as overall degradation. The actual degradation of Ha-acid was found to be much slower than enantiomerization. Consequently, the degradation rate constants could not be fitted individually for each enantiomer and were thus assumed to be equal for *R*- and *S*-Ha-acid. This does not necessarily mean that the enantiomers were degraded equally quickly, but rather that any differences in degradation rates would be compensated by the rapid enantiomerization.

As an example, the fitting of degradation and enantiomerization of Ha-acid in soil Neualp is shown in Figure 7, where the fitted curves describe the observed behavior (formation and dissipation of enantiomers as well as overall degradation) correctly. The kinetic parameters thus derived for this and the two other soils are shown in Table 3. Overall, degradation was faster in soil Neualp (half-lives = ln $2/k_{deg}$, 2.3−4.0 days) than in the other two soils (6.0−9.3 days). Degradation in the experiments with *rac*-Ha-acid was consistently slower than in experiments with the pure enantiomers. This may be due to the fact that *rac*-Ha-acid was spiked with a slightly lower water volume, and the soil was thus a little less moist (Table 1).

The rate constants for conversion of *R*- to *S*-Ha-acid (k_{RS}) were only somewhat higher than the degradation rate constants in the same soils, whereas the rate constants for the reverse reaction were substantially (≈20 times) higher.

Due to rapid enantiomerization, a steady-state enantiomeric composition was achieved within 1−2 days of incubation (Figure 6). From the enantiomerization rate constans (k_{RS} and k_{SR}) equilibrium constants (K_{enant}) for the enantiomerization of Ha-acid can be calculated as

$$K_{enant} = k_{RS}/k_{SR}$$

The value of K_{enant} corresponds to the enantiomer ratio S/R at steady state. As shown in Table 3, the values for K_{enant} ranged from 0.061 to 0.082 and were thus very similar in all three soils.

This is in contrast to the situation when a chiral compound is degraded enantioselectively, but with no apparent enantiomerization, such as with the chiral fungicide metalaxyl.[21] In that case, the enantiomer ratio (ER) changes with incubation time according to the equation

$$\ln(ER) = \ln(ER_0) - \Delta k \times t$$

where Δk is the difference of the degradation rate constants of the two enantiomers and ER_0 is the enantiomer ratio at time zero. This equation indicates that the enantiomer ratio will not reach a steady state at any given time.

In a recent paper on diclofop-methyl,[10] a herbicide that is structurally closely related to Ha-me, the authors used the above equation to evaluate their experimental data. However, they did not take into consideration the rapid enantiomeriza-

tion of diclofop acid. To test the applicability of our approach for evaluation of Ha-acid to other, similar cases, we used the data for diclofop acid from ref 10 and applied the same conceptual model as for Ha-acid to derive the kinetic parameters. The resulting plots and kinetic parameters are shown in the Supporting Information (Figures S1−S4; Table S1). Indeed, acceptable fits for diclofop acid were obtained in this way from those previously published data.

Comparison of Haloxyfop Behavior in Soil with That of Other Phenoxy Acids. Isomerization of chiral pesticides in the environment was described for numerous compounds from different chemical families.[22] Rapid conversion of enantiomers with clear preference for the *R*-enantiomer was also observed for other FOPs, for example, for fluazifop,[9] diclofop,[3,10] and fenoxaprop.[3] It is also consistent with field experiments with Ha-me, where it was shown that the efficacy of the substance against weeds depended strongly on the enantiomeric

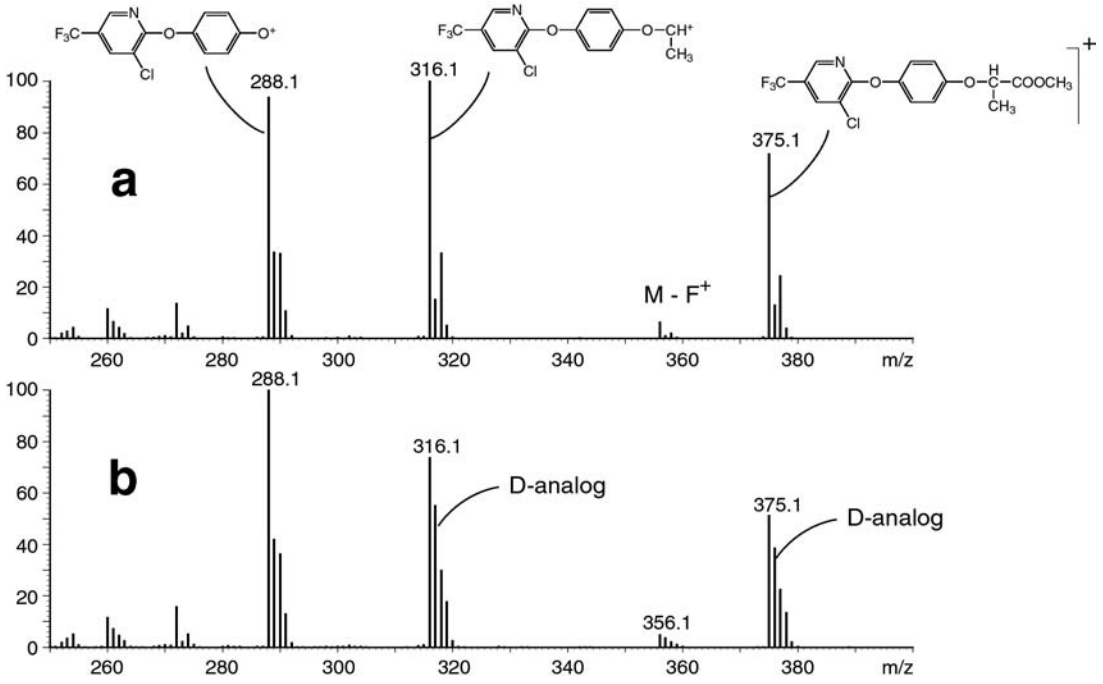

Figure 8. Partial mass spectra of (a) Ha-me (reference compound) and of (b) Ha-acid after 4 h of incubation in soil in the presence of D_2O and subsequent methylation. Note the incorporation of a single deuterium into Ha-acid as indicated by the changed isotope profiles of the molecular and the major ions at m/z 375 and 316, respectively (panel b).

composition when applied postemergent (thus applied to the leaves), whereas it was practically independent of the enantiomeric composition when applied pre-emergent (and is thus taken up from soil).[11] In the latter study, residues extracted from soil 7 days after application of Ha-me consisted mainly of *R*-Ha-acid.

Conversion of enantiomers was also observed for phenoxypropionic acid herbicides such as mecoprop and dichlorprop.[17,23] However, in contrast to our results with Ha-acid, degradation appeared to be faster than enantiomerization.[17] The enantioselectivity of degradation/enantiomerization of mecoprop and dichlorprop varied over a wide range and apparently changed with soil pH values (see ref 24 and references therein), whereas no pH dependence with respect to the preferential formation of the *R*-enantiomer was observed with Ha-acid in the three soils studied here.

Mechanistic Considerations from H−D Exchange Experiments. Full-scan MS clearly indicated the incorporation of deuterium when Ha-acid was incubated in soil where water was partially replaced with D_2O (H/D ratio of about 1:1). The EI mass spectra of Ha-me (Figure 8), Ha-et, and Fl-me are very similar in that all three show intense molecular ions and agree in their major fragmentation pathways. Ha-me (M^+ = 375) and Ha-et (M^+ = 389) yield the same major fragment ions at m/z 316 (loss of $COOCH_3$ and $COOC_2H_5$, respectively) and m/z 288 (loss of $CHCH_3COOCH_3$ and $CHCH_3COOC_2H_5$, respectively). No significant differences were observed in the spectra of the enantiomers.

As shown in Figure 8, the mass spectrum of Ha-acid after incubation in D_2O-containing soil and analyzed as methyl ester clearly shows changed isotopic patterns of M^+ (note increased signal of m/z 376) and for the main fragment ion at m/z 316 (increased signal of m/z 317) due to the incorporation of a single D into the molecule. The exact location of D was deduced from the fact that the isotopic pattern of fragment ion m/z 288 (loss of the complete propionic acid side chain) was still the same as with the native compound. This locates the D label at one of two carbons (C-2 or C-3) of the propionic acid moiety, most likely at C-2 (the methin-H), in the same sense as was observed with the propionic acid herbicide mecoprop.[23] The amount of D incorporation, estimated from the signal intensities at m/z 375 and 376 and when corrected for ^{13}C contributions, was about 35%.

The H−D exchange presumably follows a scheme such as outlined in Figure 9 via a planar transitional enolate structure

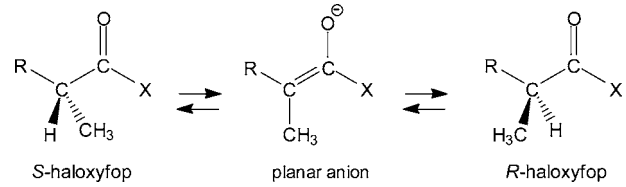

Figure 9. Proposed mechanism for the conversion of the enantiomers of Ha-me and Ha-acid in soil. "X" depicts a methoxy, a hydroxy, or a possible intermediate coenzyme A ester, analogous to that proposed for aryl propionic acid isomerization in mammalian metabolism.[6]

(back/front addition of H/D). However, the exchanged proton located next to the carboxylic acid moiety is only weakly acidic. Consequently, this reaction requires enzymatic activity such as in biologically active soils. For APAs it was shown that epimerization proceeds via formation of a coenzyme A thioester.[6] The enzyme that catalyzes epimerization of the coenzyme A esters of APAs in rats (2-arylpropionyl-coenzyme A epimerase) was isolated from rat liver[25] and was subsequently shown to be closely related, if not identical, to the 2-methylacyl-coenzyme A racemases present in peroxisomes and mitochondria,[26] which are involved in the metabolism of branched-chain fatty acids.[27] Although the epimerase is not enantioselective,

DOI: 10.1021/jf505241t
J. Agric. Food Chem. 2015, 63, 2583−2590

the net formation of an excess of one enantiomer results from enantioselective formation of the coenzyme A thioester.[6]

It is interesting to note that in the WHO JMPR evaluation of haloxyfop[28] the reviewer concluded that in mammals Ha-me undergoes rapid ester cleavage in vivo, followed by an equally rapid and almost complete conversion of *S*- to *R*-Ha-acid. There seems to be a striking similarity in the findings from the studies in rodents, dogs, and monkeys with our finding of the rapid transformations of Ha-me and Ha-acid in biologically active soils. This may indicate that the same biochemical processes are involved in soil as in mammalian conversion of haloxyfop enantiomers, and these may even be very closely related to those involved in the conversion of APA enantiomers.

In contrast to these similarities in behavior of Ha-acid enantiomers in mammalian and soil metabolism, no conversion of Ha-acid enantiomers and no enantioselectivity in degradation of Ha-me or Ha-acid were found in plants.[12] Consequently, the residues in plants most likely reflect the stereoisomer composition of the compound that was applied (uptake by leaves) or that was formed in soil (root uptake).

enantiomer composition was not changed. Unfortunately, later sampling was not performed. "Chiral stability" of the enantiomers of diclofop and quizalofop was also observed in studies with freshwater algae.[22,23] A further study was conducted with cole.[24] After foliar treatment, diclofop-methyl and diclofop-acid were both degraded enantioselectively with a preference for the *S*-enantiomers. However, since no experiments were performed with pure enantiomers, no conclusion could be made on possible interconversion.

No experimental data are currently available on the behavior of the enantiomers of haloxyfop-methyl in plants (chemical structure, see Figure 1). In the European registration process, it

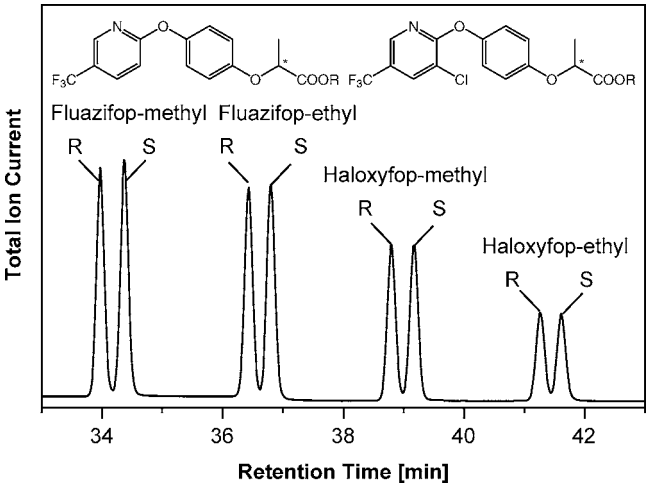

Figure 1. Reconstructed ion chromatogram of eight mass traces showing the elution of the enantiomers of haloxyfop-methyl (concentrations, 1.7 mg/g plant dry weight), haloxyfop-acid (analyzed as ethyl-ester, 1.0 mg/g), and the corresponding internal standards (fluazifop) in an ethylated extract from blackgrass, sampled 24 h after treatment with *rac*-haloxyfop-methyl. Nonenantioselective metabolism was observed for both methyl-ester and acid.

was concluded that "due to the lack of isomeric specificity of the [...] analytical methods, any possible stereochemical inversion in either direction in food of plant and animal origin could not be detected".[25] The selective herbicide is used for the postemergent control of annual and perennial grasses in sugar beet, fodder beet, oilseed rape, potatoes, vegetables, sunflowers, soya beans, vines, strawberries, and other dicotyledonous crops.[26,27] Haloxyfop-methyl is absorbed by leaves and roots and is metabolized to haloxyfop-acid and conjugates with glucose and other sugars.[27]

The present study aims at filling this data gap with regard to metabolism in plants. Our enantiomer-specific, gas chromatographic method allowed us to investigate the enantioselectivity of degradation of haloxyfop-methyl and haloxyfop-acid in plants. Possible interconversion of enantiomers was studied by using pure *R*-haloxyfop-methyl. For our experiments, we selected blackgrass as a typical weed that is controlled with haloxyfop-methyl and garden cress as a dicotyledonous plant that is not sensitive to the herbicide and, from an experimental point of view, was easy to cultivate. The herbicide was applied to the aerial parts of the plants in a way that excluded root uptake so that processes in leaves and shoots could be studied.

MATERIALS AND METHODS

Chemicals and Reagents. Racemic haloxyfop-methyl (purity, 97.5%; CAS name, see Supporting Information, Table S2 in ref 15), racemic haloxyfop-acid (99.5%), and racemic fluazifop-acid (94.5%) were from Ehrenstorfer, Augsburg, Germany. Haloxyfop-P-methyl (99.3%), racemic fluazifop-methyl (97.4%), N-nitroso-N-ethylurea (containing 2% acetic acid as stabilizer), and the nonionic detergent Tween 60 were from Sigma-Aldrich, Steinheim, Germany. A blank formulation (EF-1400) was obtained from Dow AgroSciences, Norfolk, UK. CIPAC standard water D with a hardness of 342 ppm and a pH of 6.9 was prepared as described in ref 28. The mineral fertilizer Kristalon Red Acid was from Yara, Oslo, Norway. LP0013 Agar Technical (No. 3) was purchased from Oxoid, Basingstoke, UK.

Plants. Seeds of blackgrass, *Alopecurus myosuroides* (LS-Number Fors000021), were from Appels Wilde Samen, Darmstadt, Germany, and garden cress, *Lepidium sativum* (UFA 50280), was from Fenaco, Winterthur, Switzerland. The plants were grown on agar, which was either poured on sterile polystyrene Petri dishes (diameter, 9 cm) or filled into 40 mL clear glass vials (diameter, 2.8 cm, Figure 2). Agar-

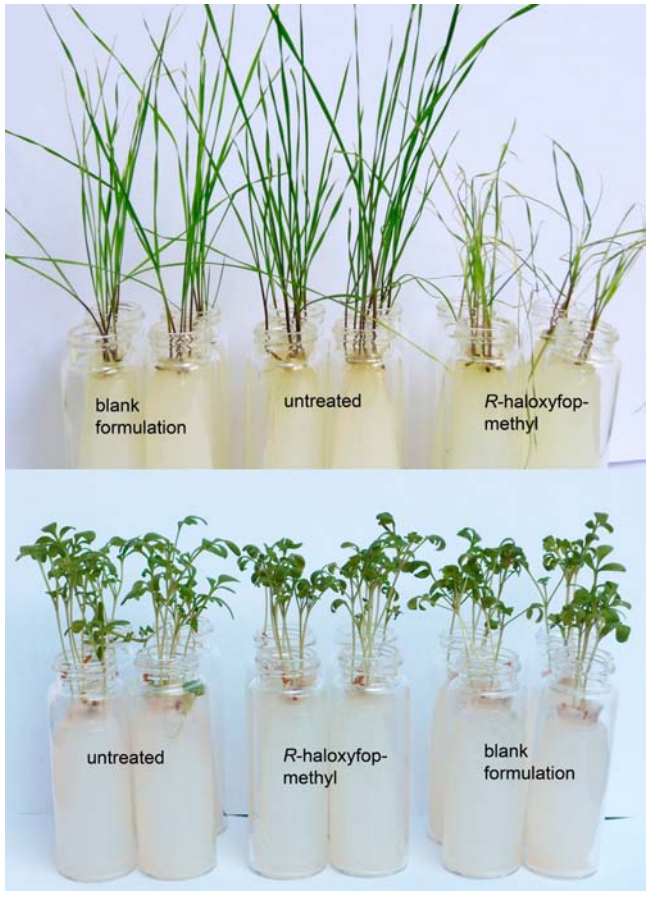

Figure 2. Blackgrass (top) and garden cress (bottom) 96 h after treatment with formulated *R*-haloxyfop-methyl, a blank formulation, and grown without treatment. The herbicide has selective activity on true grasses (*Poaceae*).

medium for Petri dishes was prepared with tap water at a concentration of 12 g/L, the medium for vials with a nutrient solution (0.1% Kristalon Red Acid, pH ≈ 7) at a concentration of 15 g/L. Agar was autoclaved at 121 °C for 15 min.

The germination rate of blackgrass after 1 week was about 30−40%. Therefore, seeds were first sown on agar plates, and germinated seedlings were then transplanted into agar vials. In a clean air bench, 25 seeds were spread on each plate and covered with a polystyrene lid. To suppress growth of fungi in the agar, blackgrass seeds were first

DOI: 10.1021/jf505242f
J. Agric. Food Chem. 2015, 63, 2591−2596

disinfected. For that, seeds were placed into a tea strainer and dipped in aqueous acetic acid (7%, with addition of ∼1 g/L of the surfactant Tween 60) for 15 min. Thereafter, the seeds were thoroughly rinsed in tap water for 2 h. After sowing, the agar plates were kept in a greenhouse chamber at 80% relative humidity and a temperature of ∼25 °C (day) or ∼18 °C (night). The seedlings were exposed to natural sunlight (November−January at 47° N, attenuated by the windows of the greenhouse) and, as necessary, artificial light (high pressure sodium lamps, type Master SON-T PIA Plus 400 W, Philips) to give a total irradiance of ∼250 W/m^2 (photoperiod, 14 h per day). After about 7 days, five seedlings were transplanted into a 40 mL glass vial filled with nutrient agar (planting depth of seeds, ∼5 mm; the roots of the seedlings were completely pushed into the agar). These vials were kept in the greenhouse for another 10 days. After this time, the grass seedlings typically had developed three leaves with a length of ∼10−15 cm.

Garden cress was directly sown into the glass vials since germination was nearly 100%. Five seeds were placed ∼3 mm deep into the nutrient agar. After 7 days in the greenhouse, the cress seedlings had two leaves (cotyledons) and shoot lengths of ∼4−7 cm.

Herbicide Application on Blackgrass. Haloxyfop-methyl has a low water solubility of 9 mg/L at 25 °C.[27] To improve its solubility in the application solution and its uptake by weeds, commercial herbicides (e.g., Gallant) additionally contain adjuvants, aromatic solvents, and emulsifiers. For our experiments, we dissolved ∼50 mg of racemic haloxyfop-methyl (or ∼25 mg *R*-haloxyfop-methyl) in ∼400 mg blank formulation, an emulsifiable concentrate with the code EF-1400 (composition confidential). This solution was then mixed with 30 mL of CIPAC standard water D. The resulting, milky emulsion thus contained 1.6 g/L *rac*-haloxyfop-methyl or 0.8 g/L *R*-haloxyfop-methyl. Assuming that 200 L are sprayed per hectare, these concentrations correspond to application rates of 320 g/ha *rac*-haloxyfop-methyl or 160 g/ha *R*-haloxyfop-methyl, the latter being the currently approved, maximum application rate in Switzerland. For a preliminary experiment, an application solution was prepared with haloxyfop-methyl, composed of $[R]$:$[S]$ = 2:1, at a concentration of 1.5 g/L (note that, based on the label, the test substance should have been racemic). To investigate possible herbicidal effects of the adjuvants, the blank formulation was also diluted with CIPAC water as described above but without the addition of haloxyfop-methyl.

The application method was designed to ensure that the herbicide is only taken up through leaves (and not by roots via agar) and that it is distributed as evenly as possible on the leaves. For that, the grass leaves were inserted overhead into an empty test tube (160 mm × 16 mm), which was then filled with application solution. Within less than 5 s, the leaves were pulled out of the test tube, and the application solution was allowed to drip off the leaves, still overhead (we assume that the tips of the leaves received somewhat higher amounts of active substance and formulation). After 2 min, the treated plants were placed into a climate chamber at 21−22 °C and 65% relative humidity and illuminated by two types of lamps simulating natural sunlight (three tubular low-pressure mercury-vapor fluorescent lamps, type TL40*W*/05, Philips, emitting radiation between 300 and 460 nm; and three tubular fluorescent lamps, type F40*W*/125-RS, Sylvania, emitting radiation between 400 and 650 nm). Grass leaf samples were collected immediately after application and 2, 5, 24, 32, 48, 72, and 96 h later. At each sampling time, five leaves were harvested and extracted as described later. Extractions and analyses were performed in triplicate at all time-points.

Herbicide Application on Garden Cress. For garden cress, a more diluted application solution was prepared (reason, see Results and Discussion section): ∼6 mg of racemic haloxyfop-methyl (or ∼3 mg of *R*-haloxyfop-methyl) was dissolved in ∼50 mg of EF-1400 and mixed with 30 mL of CIPAC standard water D (resulting concentrations, 0.2 g/L *rac*-haloxyfop-methyl or 0.1 g/L *R*-haloxyfop-methyl). The cress leaves were directly dipped into the application solution, pulled out within less than 5 s, and allowed to drip off overhead for 2 min. Then, the plants were placed into the climate chamber (conditions as described for blackgrass). Leaf samples were taken immediately after application and 2, 5, 24, 32, 48, 72, and 96 h later (in triplicate). All leaves of a particular vial were used for extraction.

Extraction. The harvested plant material was cut into pieces of ∼2 cm and extracted with 10 mL of methanol containing 10 μg of racemic fluazifop-methyl and fluazifop-acid as internal standards (chemical structures, see Figure 1). Extraction was facilitated by sonication for at least 5 min or until visually all chlorophyll was extracted and the leaves were bleached. An aliquot of the extract was then removed for spectrophotometric analysis of chlorophyll a at wavelengths of 665, 652, and 750 nm, as described in ref 29. With tweezers, the bleached leaves were removed from the extract and dried in an oven at 60 °C for 1 h to determine their dry weight (3−6 mg per five blackgrass leaves, 6−18 mg per five cress plants, depending on their age).

Ethylation of Haloxyfop-Acid, Cleanup. To analyze haloxyfop-acid and fluazifop-acid by GC−MS, it was necessary to derivatize. Ethylation was considered appropriate as it allowed, in contrast to methylation, distinction of haloxyfop-methyl and -acid, analyzed as ethyl ester. Prior to derivatization, the methanolic extract was reduced to a volume of ∼100 μL on a heating plate (80 °C) with a gentle flow of N_2. The concentrated extract was acidified with 2−3 drops of 0.5% trifluoroacetic acid in methanol. Haloxyfop-acid and fluazifop-acid were then derivatized by addition of ∼750 μL of diazoethane in methyl *tert*-butyl ether (MTBE).

Diazoethane was prepared as follows. In a 50 mL glass bottle, 1.5 g of N-nitroso-N-ethylurea was dissolved in 30 mL of MTBE and placed on ice. To this solution, 6 mL of 40% aqueous potassium hydroxide was added, and the bottle was loosely covered so that gas formed during reaction could escape. After gas formation had ceased (∼1 h), the orange colored organic layer containing the diazoethane was transferred to a 50 mL glass bottle containing a few potassium hydroxide pellets and stored in the freezer (−20 °C) until use (usually within 1 week). Note that diazoethane is toxic by inhalation and by contact with skin or eyes, and thus, all handling was strictly done in a fume hood. Likewise, the compound is explosive, and contact with sharp glassware must be avoided. Prior to disposal of any waste, excess diazoethane was reacted with dilute acetic acid in methanol.

No methyl ester was formed from ethylation of the acid in methanol/MTBE. After derivatization and evaporation of the solvents, the residues were dissolved in ∼100 μL of ethyl acetate. For cleanup, the derivatized extract was passed through a silica mini-column (5 mm i.d. Pasteur pipet filled with ∼60 mm of silica gel 60, Merck, Darmstadt, Germany, dried at 140 °C for 24 h, deactivated with 5% water, and topped with 10 mm of anhydrous sodium sulfate). The analytes were eluted with 10 mL of ethyl acetate. The eluate was carefully concentrated with a gentle flow of N_2 and mild heating to a final volume of 1 mL and quantitatively transferred into a 2 mL autosampler glass vial.

Enantioselective GC−MS Analysis. The enantiomers of haloxyfop-methyl, haloxyfop-ethyl, and the corresponding internal standards (fluazifop-methyl and fluazifop-ethyl) were separated on a chiral GC column coated with permethyl-β-cyclodextrin (15%) in OV1701 (BGB 171, 20 m, 0.25 mm i.d., 0.15 μm film, BGB, Boeckten, Switzerland). GC conditions were as follows: 1 μL split/splitless injection (240 °C, initial 48 s splitless); temperature program, 70 °C, 2 min isothermal, 25 °C/min to 150 °C, 1 °C/min to 200 °C, isothermal hold at 220 °C; constant flow, 2 mL/min helium. The GC was coupled to a Voyager single quadrupole MS (Finnigan, Manchester, UK) operated in electron impact ionization (70 eV, 180 °C) and selected-ion-monitoring mode. Haloxyfop-methyl, haloxyfop-ethyl, fluazifop-methyl, and fluazifop-ethyl were quantified using the ions m/z 375 (316 and 288 for confirmatory purposes), 389 (316, 288), 341 (282, 254), and 355 (282, 254), respectively. The enantiomer resolution of the four analytes was ∼1.3, 1.2, 1.4, and 1.3, respectively (defined as $R = 2\,(t_{r2} - t_{r1})/(w_1 + w_2)$, where t_{ri} is the retention time of enantiomer i, and w_i is the width at the base of peak i). A representative chromatogram of a plant extract is shown in Figure 1. The elution order of the enantiomers was *R* prior to *S* for all compounds as determined with pure reference substances. Quantification was based on peak area ratios relative to the internal standards

and in reference to suitable standard solutions of the racemic compounds. For more details on the analytical method, see ref 15.

RESULTS AND DISCUSSION

Rapid Ester Cleavage of Haloxyfop-Methyl to Haloxyfop-Acid in Blackgrass. After application on blackgrass, *rac*-haloxyfop-methyl was rapidly metabolized to haloxyfop-acid, the herbicidally active compound (Figure 3a). Within 24 and

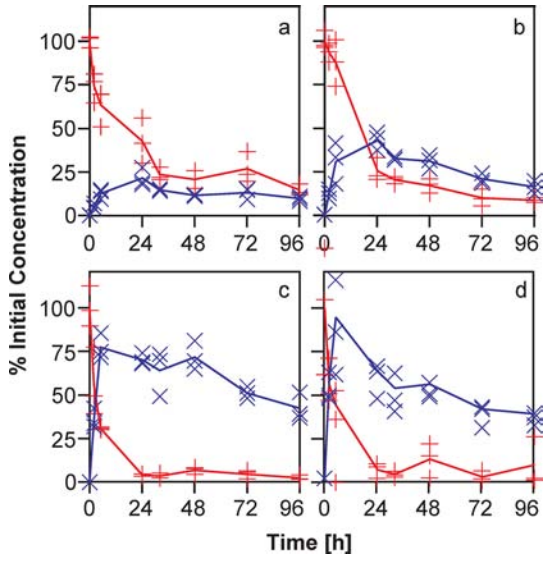

Figure 3. Metabolism of haloxyfop-methyl and haloxyfop-acid in blackgrass (a,b) and garden cress (c,d) after treatment with *rac*-haloxyfop-methyl (a,c) or *R*-haloxyfop-methyl (b,d). Symbols depict individual concentration data for haloxyfop-methyl (+) and haloxyfop-acid (×); the lines connect mean concentrations of three replicates. Residues are based on plant dry weight and those of the metabolite in parent equivalents. The enantiomer composition remained constant throughout the experiments.

32 h, concentrations of haloxyfop-methyl decreased by more than 50% and 75%, respectively (residues based on plant dry weight). Residues of haloxyfop-acid reached a maximum of ∼22% (parent equivalents) 24 h after treatment, which suggested that the acid was further metabolized (or that other primary metabolites were formed besides). Moreover, plant growth also resulted in somewhat lower concentrations (dilution effect, less than a factor of two).

After 32 h, metabolism of parent and metabolite slowed down considerably (Figure 3a). At the same time, the treated grass showed first withering symptoms (see Figure 2 for grass treated with *R*-haloxyfop-methyl). Within about 1 week, the leaves turned completely brown. Concurrently, the chlorophyll a content decreased from ∼20 mg/g (dry weight) before treatment to less than 3 mg/g 96 h after treatment (data not shown). In the control experiment, where blackgrass was treated with blank formulation, without the active compound, no striking herbicidal injuries were observed. Only the leaf tips slightly turned brown, whereas untreated grass showed no symptoms at all (Figure 2).

Nonenantioselective Metabolism of Haloxyfop-Methyl and Haloxyfop-Acid in Blackgrass. The enantiomer composition of haloxyfop-methyl in blackgrass did not change within the 96-h duration of the experiment (Figure 1). The enantiomer fraction (defined as EF = $[R]/([R] + [S])$, where $[R]$ and $[S]$ are the concentrations of *R*- and *S*-haloxyfop-methyl, respectively) varied between 0.48 and 0.51, which indicated that metabolism was nonenantioselective. The enantiomer composition of the acid metabolite also remained constant within 96 h, which suggested that not only the formation, but also the further transformation was non-enantioselective (Figure 1). EF values ranged from 0.47−0.54. Enantiomer fractions showed clearly less variation than the concentrations of the individual enantiomers since it was not possible to apply the test substance in a way to ensure that all plants received exactly the same amount of herbicide (see Materials and Methods section), whereas the enantiomer composition in the application solution was, of course, reproducible.

"Chiral Stability" of Haloxyfop-Methyl and Haloxyfop-Acid in Blackgrass. After application of *rac*-haloxyfop-methyl on blackgrass, residues thus remained racemic. However, the observed, constant enantiomer fractions of 0.5 may, in principle, also be the result of a fast racemization in the leaves. To investigate a possible interconversion of enantiomers, further blackgrass plants were treated with pure *R*-haloxyfop-methyl. These experiments confirmed that no *S*-haloxyfop-methyl and no *S*-haloxyfop-acid were formed from the corresponding *R*-enantiomers. The plant extracts only contained traces of the *S*-enantiomers that were already present in the reference material (∼1%). The opposite process, conversion of the *S*- into the *R*-enantiomers, could also be excluded since metabolism was nonenantioselective in experiments with the racemic herbicide. Therefore, additional experiments with pure *S*-haloxyfop-methyl were not performed as they were not considered necessary.

Appearance and degree of necrosis symptoms and reduction of the chlorophyll a content were similar after treatment with *R*-haloxyfop-methyl as in the experiments with *rac*-haloxyfop-methyl (Figure 2). Note that the same amount of the *R*-enantiomer was applied (*R*-haloxyfop is the herbicidally active form).

Concentration-Dependent Formation of Haloxyfop-Acid. The rate of degradation/dissipation of *R*-haloxyfop-methyl was similar to that of *rac*-haloxyfop-methyl (Figure 3a,b). However, in the experiments with pure *R*-haloxyfop-methyl, concentrations of *R*-haloxyfop-acid reached a maximum of ∼43% (parent equivalents), which is twice as high as in the corresponding experiments with the racemic compound (∼22%). In a further experiment, where blackgrass was treated with haloxyfop-methyl, composed of $[R]:[S]$ = 2:1, the maximum concentration of the acid was just between the above values, ∼32% (data not shown). A simple explanation for these differences in relative formation cannot be given as it is obviously not due to preferential conversion of enantiomers nor due to obvious differences in senescence. Formation of the acid may, however, depend on the concentration of applied haloxyfop-methyl. Indeed, when considering further data from experiments with garden cress (see below), which were conducted with clearly lower herbicide concentrations, a good correlation was found between maximum formation of haloxyfop-acid and initial concentration of haloxyfop-methyl in the leaves (Figure 4). Nonetheless, the underlying biochemical explanation for this observation remains unclear.

Phytotoxic Injuries on Garden Cress Caused by the Blank Formulation. Haloxyfop has selective activity on true grasses (*Poaceae*) but no activity on other monocotyledonous and dicotyledonous plants.[12] Garden cress was selected as representative dicotyledonous plant since it has a high

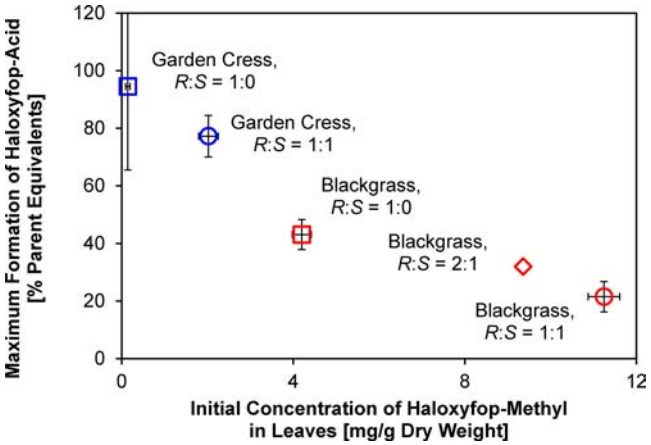

Figure 4. Maximum formation of haloxyfop-acid in experiments with blackgrass and garden cress treated with haloxyfop-methyl at different concentrations and enantiomer composition in the application solution; thus, different initial concentration in the leaves. Error bars indicate the standard deviation of three replicate experiments. The maximum formation of haloxyfop-acid is given in parent equivalents in relation to the mean initial concentration in the leaves. Note that these values are not corrected for plant growth.

germination rate and can easily be cultivated. In preliminary experiments, garden cress was treated with the same solution/emulsion of formulated haloxyfop-methyl as used for blackgrass. However, the plants showed severe withering symptoms already after 24 h. The control experiment, in which plants were treated with blank formulation only, indicated that the observed phytotoxicity was caused by the formulation rather than by haloxyfop. The amount of water used to dilute the formulated herbicide was chosen as it would be done in agricultural practice, but we assume that with the treatment procedure (dipping of leaves in the application solution to avoid uptake by roots), considerably higher amounts of active substance and adjuvants were finally applied to the leaves than with a spray application under normal field conditions. Therefore, a more diluted application solution (8×) was prepared for the definitive experiments with garden cress. Phytotoxic injuries were now clearly reduced, and only the most tender leaves showed minor symptoms. After 96 h, treated (formulation with and without haloxyfop-methyl) and untreated cress plants looked quite similar (Figure 2).

Nonenantioselective Metabolism of Haloxyfop-Methyl and Haloxyfop-Acid in Garden Cress. In garden cress, metabolism of haloxyfop-methyl was faster than in blackgrass, with a half-life of ∼3 h (Figure 3c,d for treatment with *rac*- and *R*-haloxyfop-methyl). However, the residues of the methyl-ester did not decline further between 24 and 96 h after treatment. Apparently, this small residue fraction (<10%) is not available for metabolism, for example, it may be associated with lipophilic waxes in the cuticle of the leaves.

Maximum formation of the acid metabolite was observed already 5 h after treatment (Figure 3c,d). Up to ∼95% (average of three replicates) was formed from *R*-haloxyfop-methyl and ∼77% from the racemic compound. The correlation shown in Figure 4 suggests that maximum formation depends on the initial concentration of haloxyfop-methyl in the leaves (see Discussion section above). In experiments with garden cress, variability of the measured concentrations in the three replicates was quite high, in particular at early sampling times (Figure 3c,d). In bent leaves (Figure 2), small droplets of application solution adhered instead of a homogeneous, thin film, and consequently, application to cress leaves was less reproducible than with blackgrass. After 5 h, the concentration of the acid slowly decreased (Figure 3c,d) not only due to further metabolism, but also of course due to plant growth.

In experiments with *rac*-haloxyfop-methyl applied on garden cress, the enantiomer fractions ranged from 0.44−0.57 for the parent compound and from 0.47−0.52 for the acid metabolite. The EF values thus slightly deviated from 0.50, in particular, at low residue levels of haloxyfop-methyl but without a clear temporal trend. Again, in experiments with *R*-haloxyfop-methyl, no formation of *S*-haloxyfop-methyl and *S*-haloxyfop-acid was observed, which suggests that metabolism of parent and metabolite was not or only slightly enantioselective and that no conversion of enantiomers occurred.

Remarkable Contrast Between Chiral Stability in Plants and Rapid Interconversion of Enantiomers of Haloxyfop-Acid in Soil. Our experiments with blackgrass and garden cress showed that the enantiomer composition of haloxyfop-methyl and its major metabolite haloxyfop-acid was not changed in plants either by enantioselective metabolism or by interconversion of enantiomers. Blackgrass is susceptible to the herbicide, whereas the dicotyledonous garden cress is not susceptible. These findings with regard to chiral stability can thus probably be generalized to most mono- and dicotyledonous plants. Consequently, it may be expected that residues in crops have the same enantiomer composition as in the applied product provided that the compound is applied postemergent and primarily taken up through leaves. In rotational and succeeding crops, uptake of haloxyfop-acid from soil occurs via roots, and potential residues should then predominantly contain the *R*-enantiomer. However, because of the relatively fast degradation of the acid in soils (typical half-lives under field conditions, 5−27 days[25]), measurable residues would only be expected when the succeeding crop is planted shortly after application of the herbicide, for example, after failure of the preceding crop.

Chiral stability in plants strongly contrasts the observed, rapid conversion of *S*- to *R*-haloxyfop-acid in soils[12,15] and mammals.[25] In soils, this transformation is biologically mediated (probably via deprotonation at the methine carbon[7,15]), whereas in plants, apparently, no such enzymes are present or accept haloxyfop-acid as substrate. It was speculated that in plants, enzyme-mediated interconversion of enantiomers of chiral pesticides is less common than in soil,[7] but at the same time, it was also stated that more plant metabolism studies would be needed to support such a conclusion.

The present study shows that the use of the herbicidally active, pure *R*-haloxyfop-methyl rather than the racemic compound is advantageous from an environmental perspective. It allows 50% lower application rates at similar field performance, results in lower residues in crops and environment, and may lead to fewer side effects on nontarget organisms.

excessively large amount of highly soluble nitrogen compounds. As SRF/CRF release their nutrients slowly and gradually during all vegetation seasons, they need to be applied only once, greatly reducing both time and energy consumption. A better and more efficient use of nutrients can lead both to a reduction of waste material produced by the fertilizer industry and to a reduction in natural gas consumption.

One of the drawbacks of CRFs, particularly polymer-coated CRFs, is that after nutrient consumption, a considerable amount of nonfunctional polymer remains in the soil, amounting to approximately 50 kg/ha per year.[4] It should be kept in mind in that context that the average consumption of nutrients (NPK) in the European Union is approximately 100 kg/ha per year. One possible solution that has not yet been implemented on a large scale is to produce CRF using biodegradable materials,[13] either natural materials or biosynthetic materials manufactured from renewable raw materials. Among the various biodegradable materials used for this purpose, starch and its derivatives seem to be the most extensively investigated,[14,15] although cellulose and its derivatives,[16−18] chitosan,[19,20] and polylactic acid[21] have also recently been examined for this application as described in the literature.

All of the products with prolonged nutrient release, available on the market, including commercially successful ones such as Osmocote, Multicote, Meister, Nutricote, Basacote, or Polyon, are manufactured with the use of polymers that are not biodegradable. The objective of this research was to obtain materials with controlled-release properties by coating granules of a mineral fertilizer with a layer of biodegradable aliphatic copolymer of poly(butylene succinate) and a butylene ester of dilinoleic acid (PBS/DLA) using an immersion method, to characterize the prepared materials, and to evaluate the nutrient release kinetics. As far as we know this kind of copolyester (PBS/DLA) has not been used in the preparation of controlled-release fertilizer; however, copolyesters of succinic acid with starch[22] and maleic anhydride[23] have been evaluated as biodegradable matrix materials for the controlled release of bacterial fertilizers.

MATERIALS AND METHODS

Materials. The source of active, mineral, macronutrient components (nitrogen, phosphorus, potassium) for this experiment was the commercial, granulated, multicomponent fertilizer NPK(S) 6−20−30−(7). This fertilizer contains at least 92% of particles within the range of 2−5 mm. Its bulk density is approximately 0.9−1.0 kg/dm^3. For the experiment, the granule fraction with a diameter of 3−4 mm was selected.

The fertilizer was commercially produced according to the Dorr-Oliver method.[24] The mixture of phosphoric and sulfuric acid was neutralized in the saturator with ammonia to obtain monoammonium phosphate and ammonium sulfate slurry, which was then granulated in the blunger with potassium chloride and small amounts of magnesium carbonate as a filler. Fertilizer granules were dried, crushed, sieved, and conditioned to obtain the final product. The contents of the three main components of the fertilizer, namely, nitrogen (5.9 wt % N-NH_4^+), phosphorus (19.8 wt % total P_2O_5, 18.2 wt % water-soluble P_2O_5), and potassium (29.5 wt % K_2O), were determined by potentiometry with an Orion 9512 ion selective electrode (Thermo Fisher Scientific, Beverly, MA, USA), spectrophotometry with a Spekol 11 instrument (Carl Zeiss, Oberkochen, Germany) and emission flame photometry with a BWB-1 instrument (BWB Technologies, Newbury, UK), respectively. These measured contents of the mineral components are consistent with the data declared by the fertilizer producer.

The aliphatic copolymer of PBS and a butylene ester of DLA (PBS/DLA) was used as a coating material. The aliphatic copolyester was synthesized through direct melt polycondensation in the presence of 1,4-butanediol.[25] This copolyester is a multiblock thermoplastic elastomer composed of soft sequences containing flexible chains of butylene ester of DLA and PBS as hard segments. The obtained copolymer contains 60 wt % PBS and 40 wt % DLA. This material was shown to be biodegradable in biodegradation tests carried out on thin polymer films (60 × 60 × 0.5 mm) under controlled conditions at 50 °C for 3 months in a mixture of sand and compost, according to the previously reported procedure.[26] The weight losses of the PBS/DLA copolyester were approximately 5 wt % after 1 month, 8 wt % after 2 months, and 10 wt % within 3 months of incubation;[25] however, there are reports on complete biodegradation of PBS and PBS blends with various organic materials.[22,23,27]

Despite the fact that the use of PBS/DLA in the preparation of controlled-release fertilizers may bring many benefits, especially in the context of environment protection, it should be kept in mind that PBS is not a cost-effective material. The price of commercially available PBS is approximately 5.4−5.6 euro/kg, and it is comparable with other synthetic biodegradable polyesters[28] but slightly higher than the price of biobased, biodegradable polymers from natural resources and several times higher than the price of conventional, not biodegradable synthetic polymers. The high price of PBS, being the main obstacle of its possible acceptance as a fertilizer component, can be lowered by the preparation of PBS blends with various organic materials from natural resources, for example, with dilinoleic acid.

Preparation. The granules of the multicomponent fertilizer in the 3−4 mm fraction were weighed and coated with a layer of biodegradable copolyester of PBS/DLA by the immersion method. For this purpose, appropriate amounts of solid polymer were dissolved, gradually and with the use of a magnetic stirrer, in appropriate amounts of chloroform (preferably 10 ± 0.1 g of PBS/DLA and 90 ± 0.1 g of chloroform) to obtain a 10 wt % solution. Fertilizer granules were placed separately as a monolayer on the stainless steel wire cloth (opening size = 1.6 mm × 1.6 mm) and dipped into the solution, with a contact time of 2−3 s, at a constant temperature of 25 °C, and then dried at 60 °C to evaporate the solvent residue. Repeating this dipping/drying procedure controlled and determined the amount of polymer layer coating the granules. After preparation, the coated fertilizer granules were weighed again. This method was used to prepare materials with various polymer to fertilizer (P/F) mass ratios.

Methods. The morphology of the polymer-coated granules and the thickness of the coating layers were examined using an SU8020 scanning electron microscope with cold field emission and a resolving power of 1.3 nm (Hitachi High-Technologies Corp., Tokyo, Japan) coupled with an energy dispersive NSS 312 X-ray analyzer (Thermo Fisher Scientific, Madison, WI). Granules of the prepared fertilizer materials were mechanically polished to achieve a flat cross section and then placed on double-sided adhesive tape kept on an aluminum stub. Granules were sprayed with a thin conductive film of chromium in a Q150T ES turbo-pumped sputter coater (Quorum Technologies, Laughton, UK). Coated fertilizers were observed at an accelerating voltage of 138 eV. Cross sections through the granules of the prepared fertilizer materials were recorded at a magnification of 20×. The thickness of the polymer layers was measured at a magnification of 100×. EDX mapping was also performed.

XRD experiments were performed on an X'Pert PRO powder diffractometer (PANalytical, Almelo, The Netherlands) with a proportional detector, computer-aided data acquisition, and a copper lamp as an X-ray radiation source. The XRD patterns were recorded over the 2θ range from 10 to 60°.

The mechanical strength of the prepared material granules was measured using a commercial table-top Zwick/Roell Z2.5 strength-testing machine (Zwick GmbH, Ulm, Germany) with the TestExpert II ver. 2.2 software. The granules were individually compressed in the radial direction between two rigid plates with a maximum testing force F_{max} of 2.5 kN at a constant crosshead test speed of 10 mm/s. The load at which the granule fractured was recorded as the crushing

DOI: 10.1021/acs.jafc.5b00518
J. Agric. Food Chem. 2015, 63, 2597−2605

strength. For each sample, a total of 25 parallel measurements were carried out. Crushing strength was normalized to the granule diameter and compared with the mechanical properties of a commercial fertilizer.

Nutrient release from the prepared fertilizer materials was measured over time in water. A sample of the prepared material (preferably five granules, weighed with the accuracy of 0.0001 g) was placed in a plastic cap beaker with 50 ± 0.5 mL of distilled water. The sample was incubated at a constant temperature of 25 ± 0.5 °C. After 1 h of incubation, the solution was decanted and the beaker was again filled with 50 ± 0.5 mL of distilled water. This procedure was repeated after 3, 6, and 24 h and after 3, 5, 7, 14, 21, and 28 days. Spectrophotometric and potentiometric methods were used to determine the amounts of released phosphates and ammonium, respectively.

The overall release of water-soluble mineral components of the fertilizer was also monitored and analyzed with the use of a CPC 505 pH/conductivity meter with temperature compensation (Elmetron, Zabrze, Poland). Polymer-coated granules with a given polymer to fertilizer ratio (P/F) were placed into distilled water at ambient temperature, and the conductivity was measured automatically every hour for 6 days (144 h). At the end of the experiment, the granules were mechanically crushed to determine the final conductivity value.

Data analysis software system STATISTICA version 10.0 was used to evaluate descriptive statistics, that is, standard deviation and standard error. To describe experimental data related to nutrient release experiments with model lines, OriginPro 8 software was used.

RESULTS AND DISCUSSION

Morphology and Structure. Granules of the NPK fertilizer are initially of regular, spherical shape and uniform light gray to dark gray color. No permanent caking of the fertilizer granules is observed: they are hard, although when subjected to adequate crushing force, they can be easily crumbled into small pieces that can then be milled into a powder. XRD measurements (Figure 1) demonstrate that the

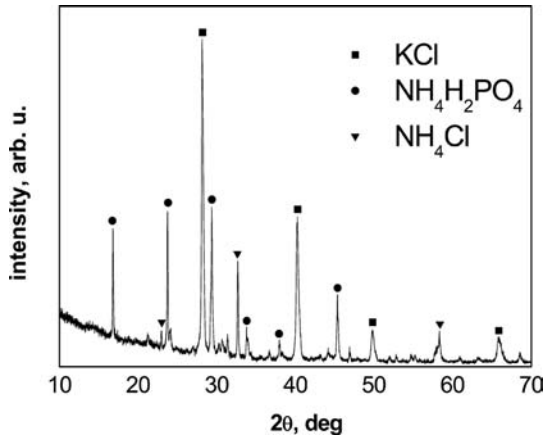

Figure 1. XRD image of the commercial, multicomponent fertilizer NPK(S) 6−20−30−(7).

NPK fertilizer includes nitrogen, phosphorus, and potassium mainly in the form of dihydrogen ammonium phosphate, ammonium chloride, and potassium chloride. Nonetheless, as the multicomponent NPK fertilizer is an example of a complex fertilizer, some small amounts of additional compounds resulting from reactions between initial substrates may also be observed and identified.

Fertilizer granules were coated with PBS/DLA copolyester by the immersion method to create over 40 samples of materials with different polymer to fertilizer mass ratios and with various layer thicknesses. The mass ratio of polymer to fertilizer P/F was determined on the basis of the mass balance of the process. Fertilizer materials have been obtained with mass ratios P/F ranging from 0.18 to 0.26. The fertilizer granules are completely covered with the polymer. The prepared materials consist of a fertilizer core surrounded by an inert polymer layer. The surface of the prepared materials is uniform, dense, and compact. There are no visible cracks or fractures on the material surfaces. The degree of coverage of granules with the polymer, that is, the polymer to fertilizer mass ratio, increased with the number of immersion cycles and the contact time.

Cross-sectional SEM images of the NPK fertilizer granules covered with PBS/DLA at two different polymer to fertilizer mass ratio extremes of 0.18 and 0.26 are presented in Figure 2.

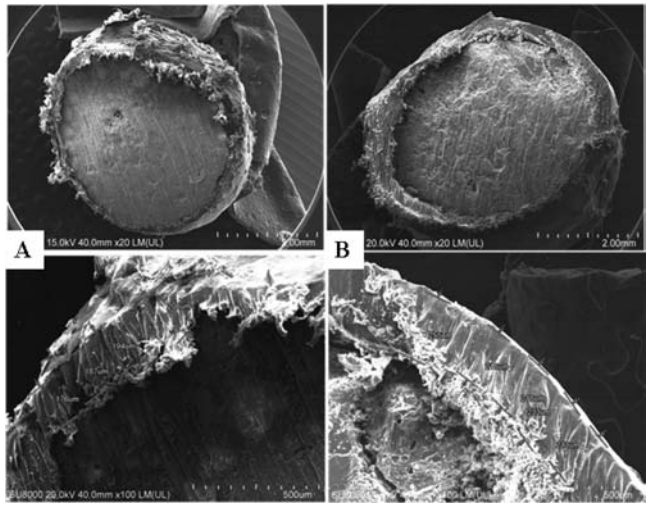

Figure 2. SEM images of the fertilizer granules coated with PBS/DLA with extreme polymer to fertilizer mass ratios: (A) P/F = 0.18; (B) P/F = 0.26.

As the thickness of the layer varies around the granule, 20 measurements were made to ensure accurate evaluation, with 5 measurements for every quarter of the granule cross section. On the basis of the performed measurements, the mean value of the polymer coating thickness was determined to be 190.4 μm (with a standard deviation of 9.21 and a standard error of 2.06) in the case of the material with P/F = 0.18 (Figure 2A) and 231.2 μm (with a standard deviation of 8.81 and a standard error of 1.97) in the case of the material with the mass ratio P/F = 0.26 (Figure 2B).

The distribution of elements in the prepared materials was characterized using a scanning electron microscope coupled with the energy dispersive X-ray analyzer. The EDX mapping of the cross section of the material with P/F = 0.18 is presented in Figure 3. The EDX analysis demonstrates that only carbon and oxygen are present in the polymer coating layer. This observation is consistent with the chemical composition of the polymer used in the experiment. The structure of the formed layer is rather homogeneous, with carbon and oxygen atoms spread quite uniformly throughout the layer. The EDX analysis demonstrates that the components of the polymer coating do not penetrate into the granule core, which appears to be quite heterogeneous. The EDX mapping exhibits areas with higher concentrations of potassium (red dots) and chlorine (bright pink dots). The increased incidence of these

DOI: 10.1021/acs.jafc.5b00518
J. Agric. Food Chem. 2015, 63, 2597−2605

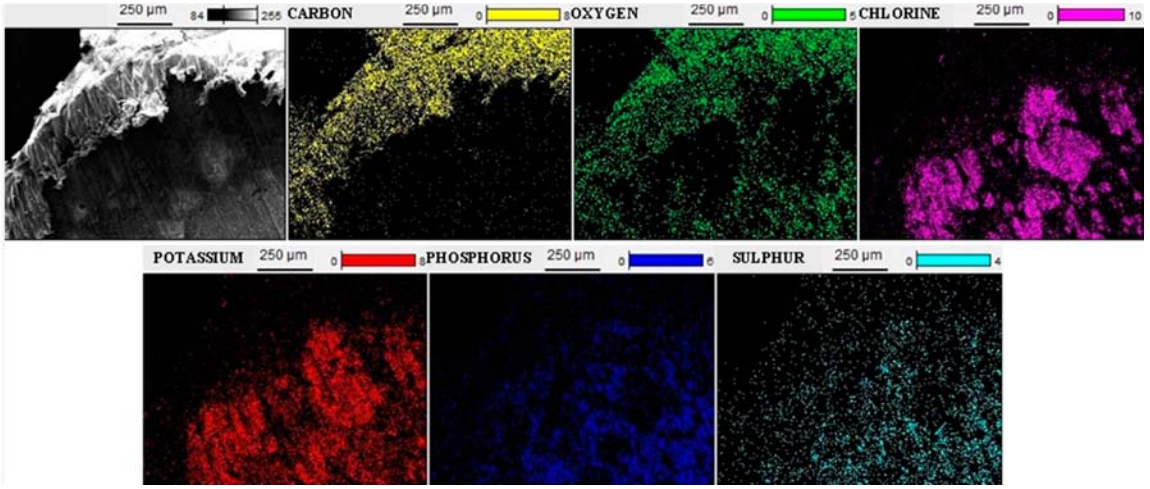

Figure 3. EDX mapping of the elements for the material with polymer to fertilizer mass ratio P/F = 0.18. Elements correspond to the color code indicated at the top of each panel.

elements results from the presence of larger particles of potassium chloride in those places. It is expected that the concentrations of oxygen (green dots) and phosphorus (dark blue dots), as the components of ammonium phosphate salts, are significantly lower in these areas. The EDX mapping also indicates that small amounts of sulfur (light blue dots) are spread evenly throughout the granule. Setting aside the location and arrangement of the elements in the granule core, the EDX analysis demonstrates that fertilizer components from the granule core do not pass into the polymer layer. To confirm that observation, a granule covered with a polymer layer was cut in half and the mineral components of the fertilizer were rinsed off with water. A meticulous and thorough inspection of the polymer layer revealed no differences in appearance between the inside and outside surfaces of the layer.

To investigate whether any interactions occur between the fertilizer components and the polymer material used to cover the granules, XRD analysis was also performed. The XRD spectra of the prepared materials (not presented here) were compared with the spectrum of the initial NPK fertilizer. These spectra are highly similar, with no differences observed in the position and intensity of the peaks between the spectra of the prepared materials and the initial NPK fertilizer. All recorded peaks can be assigned only to the fertilizer components. On the basis of the fact that no new peaks are present in the spectra of the prepared materials, no new phases are formed during the coating process. Therefore, the interactions between the fertilizer components of the granule and the polymer layer components are physical but not chemical in nature.

Mechanical Properties. Crushing strength was measured for samples of prepared materials with the lowest and highest polymer to fertilizer mass ratios of 0.18 and 0.26, respectively, and for the initial NPK fertilizer. For each sample, 25 parallel measurements were performed, and the mean value of the crushing strength was then calculated. The dependence of the crushing strength on deformation for the polymer-coated materials and for the initial NPK fertilizer are presented in Figure 4.

Fertilizers can be considered typical materials with a brittle failure mode. Fertilizer granules are porous, containing various mineral compounds with many flaws, dislocations, and crystal edges.[29,30] Any discontinuity in the fertilizer granule bulk should be treated as a defect and the reason for the stress

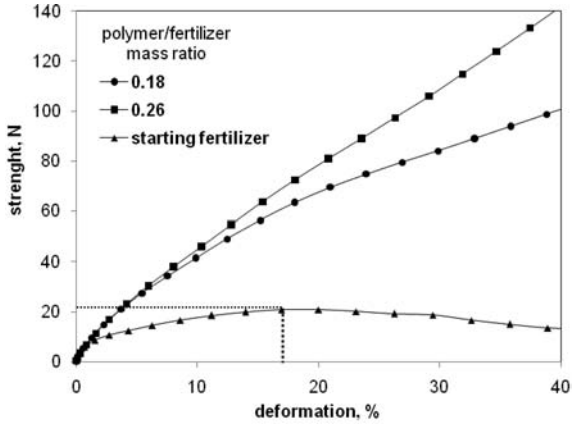

Figure 4. Crushing strength as a function of deformation for materials with different polymer to fertilizer mass ratios and for the uncoated, starting NPK fertilizer.

concentration. The mechanical damage to the fertilizer granule results from brittle failure due to an abrupt disastrous increase of a decisive defect under tensile stress induced in the material bulk. In the case of the initial NPK fertilizer, fracture or, rather, cracking of the granule occurred at the crushing strength of 21 N, with the mean deformation of 17% (Figure 4). The obtained crushing strength (21 N) corresponds to a pressure of 2.1 kg/granule and is comparable with the literature data for various granulated fertilizer compounds: urea, 1.5−3.5 kg/granule; triple superphosphate (TSP), 1.5−3 kg/granule; monoammonium phosphate (MAP), 2−3 kg/granule; or ammonium sulfate, 1.5−2.5 kg/granule.[31] Compared with the starting NPK fertilizer, polymer-coated granules exhibited significantly higher resistance toward the crushing force (Figure 4). For both prepared and examined materials, the crushing force continuously increased with deformation up to 50%, and no fracture or cracking of the samples was observed. The crushing force reached the value of almost 170 N in the case of the material with the polymer to fertilizer mass ratio of 0.26, and 120 N for the material with the polymer to fertilizer mass ratio of 0.18. On the basis of the experiments and dependencies presented here, it is not possible to determine the maximum crushing strength for the prepared polymer-coated materials because of their ductile properties. Instead of a brittle failure,

DOI: 10.1021/acs.jafc.5b00518
J. Agric. Food Chem. 2015, 63, 2597−2605

only a plastic deformation of these samples can be observed, evidently within the deformation region from 0 to 50%.

Nutrient Release. All prepared polymer-coated materials were tested in water-release experiments. This kind of approach (nutrient release in water) is fully acceptable: several papers using that approach have been published recently.[16,18,32−35] Nutrient release in water and nutrient release in soil are quite different aspects of the topic. Undoubtedly, field experiments are necessary in the further and final assessment of the product, but these experiments will be addressed in another paper. Besides, as it was clearly indicated in the relevant references,[16,36] nutrient release in soil can be easily predicted from release experiments performed in water, although the nutrient release rate depends on the medium used, with the fastest release rate observed in water, followed by water-saturated sand and, finally, sand.[36]

Figure 5 presents the results of the investigation of phosphate release from the prepared polymer-coated materials

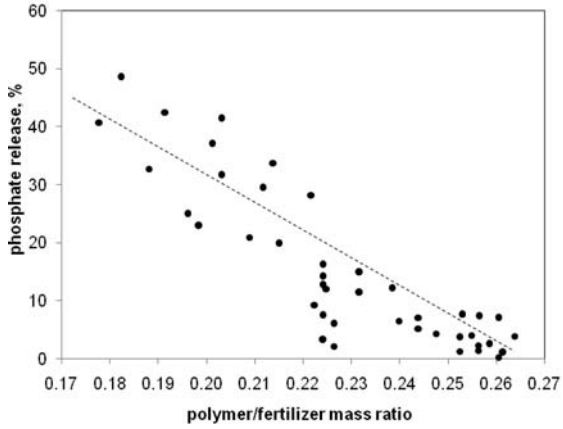

Figure 5. Release of phosphates versus the polymer to fertilizer mass ratio P/F after 24 h.

over 24 h. The data presented here show that for the group of materials with polymer to fertilizer mass ratios in the range from approximately 0.23 to 0.26, <15% of phosphates is released within 24 h. Additionally, long-term release experiments have demonstrated that the release of phosphate from this group of materials is <75% within 28 days. On the other hand, for the group of materials with polymer to fertilizer mass ratios of <0.23, >15% of phosphates are released within 24 h. Solely on the basis of these phosphate release results, the materials prepared here with polymer to fertilizer mass ratios ranging from approximately 0.23 to 0.26 meet the first and second criteria of controlled-release fertilizers, whereas those with mass ratios of <0.23 do not.

A series of papers[36−39] reported that the release rate of phosphates is lower than those of K, N-NH_4^+, and N-NO_3^-. There is no consensus as to the margin of that discrepancy. In some experiments, the release rate of phosphates was 45−70% slower than that of nitrates,[36] but only a 10% difference was observed in another study.[38] The presence of strong interactions among nutrients in the fertilizer granule and differences in nutrient solubility could lead to this observed difference in release rate.[36] Generally, the phosphate release rate can be treated as a "bottleneck" for overall nutrient release. The kinetics of chemical processes are known to be controlled by their slowest steps. The release of phosphates from controlled-release fertilizers is the slowest step; therefore, their release rate determines the overall nutrient release from that type of material. To define controlled-release fertilizers, however, rather than knowing which fertilizer component is released most slowly, it is important to know which is released most quickly or to determine the overall nutrient release rate.

Additional experiments have been conducted to more accurately assess the release properties of the materials prepared here. The release of ammonium and phosphate ions for the sample of prepared material with the highest mass ratio of polymer to fertilizer (P/F = 0.26) is compared in Figure 6A.

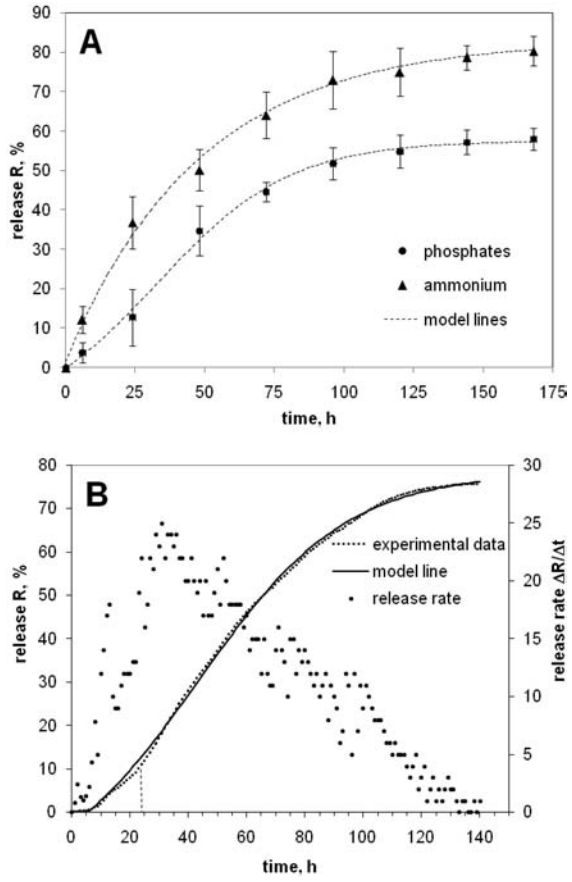

Figure 6. Comparison between the release of ammonium and phosphate ions (A) and the nutrient release measured by conductivity (B) for the sample of prepared material with the highest polymer to fertilizer mass ratio (P/F = 0.26).

Throughout the whole experiment, the release of phosphates is slower than the release of ammonium ions. However, the most significant difference in release is observed during the first 24 h. After that time, the cumulative release for phosphate and ammonium ions is 13 and 37%, respectively, whereas after 7 days it is 58 and 80%. The average difference between the release of phosphate and ammonium ions is 19%.

Figure 6B presents the results of nutrient release measured by conductivity for the sample of prepared material with the highest mass ratio of polymer to fertilizer (P/F = 0.26). The release of the mineral components of the fertilizer, R (%), was calculated according to the following equation, where σ_t represents the measured conductivity at time t and σ_F represents the final conductivity value:

DOI: 10.1021/acs.jafc.5b00518
J. Agric. Food Chem. 2015, 63, 2597−2605

$$R = \frac{\sigma_t \times 100}{\sigma_F} \quad (1)$$

Several studies have shown[36,40,41] that nutrient release from polymer-coated CRF can be described in three stages: lag period, linear stage, and decay period. In the experiment presented here (Figure 6B), the lag period is quite long. Placing the tangent line onto the experimental curve at the inflection point (31st hour) enables a rough estimate of the lag time, which is between 5 and 14 h. The linear stage of the release profile cannot be identified because the release rate constantly increases until the maximum release rate is reached at the 31st hour of the process. From that point, the release rate slowly decays, almost reaching zero after 140 h. Two further observations are worth mentioning. First, between hours 8 and 14, the release rate substantially increases, which might be related to the earlier differences in the release rates of fertilizer components. Second, after 24 h, the release of all water-soluble fertilizer components is approximately 11%, significantly below the limit of the first requirement of slow/controlled-release fertilizers.

On the basis of the experimental results presented here, the following conceptual model of nutrient release from the prepared fertilizer material can be proposed. At the very beginning of the process, after immersion of the polymer-coated fertilizer in water, water starts to diffuse through the polymer layer to penetrate the inner part of the granule. The fertilizer material is mainly composed of readily water-soluble compounds with similar water solubilities (KCl, 342 g/dm^3; NH_4Cl, 370 g/dm^3; $NH_4H_2PO_4$, 370 g/dm^3). The fertilizer components begin to dissolve in water. On the basis of the initial fertilizer composition and XRD measurement results (Figure 1), it is obvious that the same amounts of ammonium and phosphate ions result from the dissolution of dihydrogen ammonium phosphate. However, an additional amount of ammonium ions is present within the granule due to ammonium chloride dissolution. Therefore, it seems reasonable to conclude that the concentration of ammonium ions in the water-penetrated fertilizer granule is greater than the concentration of phosphate ions. Moreover, the concentration of phosphate ions is lower because slight amounts of phosphorus (approximately 8%) are bound up in the form of water-insoluble compounds. Differences in these ion concentrations may be one of the factors affecting nutrient release from polymer-coated fertilizer. Water-dissolved components of the fertilizer diffuse through the polymer layer outside the granule. As the driving force for diffusion depends on the component concentration gradient, the release of ammonium ions surpasses the release of phosphate ions. In discussing the release of ions (nutrients) from polymer-coated fertilizer, two other parameters should be considered, diffusion coefficients in water and ionic radii of nonhydrated and hydrated ions (Supporting Information, Table SI-A).[42−46] As the ionic potential $|Z_i|/r_i$ increases, where $|Z_i|$ is the absolute value of the charge of ion i and r_i is the crystal ionic radius of ion i, the ionic diffusion in water decreases. The reason for that dependence is that the hydration layer of the water molecules around the ion becomes thicker, thus hindering movement of the ion. The diffusion of phosphate ions in water is around 3 times less than the diffusion of ammonium ions in water, thus contributing to the slower release of phosphate ions from the polymer-coated granule.

Summarizing the previous considerations, both the observed discrepancy between the release of phosphate and ammonium ions (Figure 6A) and the substantial increase in the release rate between hours 8 and 14 of the process (Figure 6B) can be explained by the influence of nutrient concentration and diffusion properties of those nutrients in water. However, on the basis of the available experimental data, it is not possible to assess the mutual interaction of these factors in this phenomenon.

The release of phosphates and nutrients in general from the prepared polymer-coated materials depends on the polymer to fertilizer mass ratio (Figure 5). The phosphate release decreases as the mass ratio of polymer to fertilizer increases and as the layer thickness increases. The diffusion mechanism of the release can be noted as a reason for that correlation.[36] As the layer thickness increases, the value of the diffusion coefficient, D, decreases and the release process becomes increasingly hindered. The value of diffusion coefficient D through the polymer layer can be calculated according to the equation

$$D = \frac{h^2}{6 \times t_{lag}} \quad (2)$$

Taking the value of the polymer layer thickness (h = 231 μm) (Figure 2) and the value of the lag period (t_{lag} = 5−14 h) (Figure 6B) for the material with the highest polymer to fertilizer mass ratio (P/F = 0.26), the estimated value of diffusion coefficient D may be in the range of (0.176−0.494) × 10^{-8} cm^2/s. The diffusion coefficient through the polymer layer, D, is around 4 orders of magnitude smaller than the diffusion coefficient in water, D^0, presented earlier. The obtained D value refers to the diffusion of all water-soluble components of the fertilizer. We cannot provide detailed values for particular ions based on this experimental data, but this will be addressed in future research.

Note that all release experiments presented here were conducted in water. As mentioned earlier, nutrient release from polymer-coated controlled-release fertilizers is mainly controlled by diffusion. When materials with biodegradable polymer coatings are investigated in those conditions (water release experiments), the diffusion through the polymer layer has a critical impact on the release pattern. If the release experiments from materials coated with these biodegradable polymers were performed in soil, then some other factors and parameters would be important, especially microorganism-induced biodegradation of the polymer layer. Whereas microorganism-related biodegradation of the polymer layer and its influence on nutrient release are not addressed in the current work, that issue should be the topic of future research.

Figure 7 presents the results of 28 day release experiments for the polymer-coated materials with polymer to fertilizer mass ratios of 0.18, 0.20, 0.24, and 0.26 and the NPK fertilizer. During these experiments, the amounts of released phosphates were determined as a function of time at a constant temperature of 25 °C. The release of phosphates from the NPK fertilizer was very fast, with all phosphates released within 55−60 min. On the basis of the results presented here, all coated materials exhibit slower release of phosphates in comparison with the starting fertilizer.

Nutrient uptake by plants exhibits a sigmoidal relationship with the point in the plant's vegetation cycle.[3,4,46,47] Therefore, all experimental data presented related to nutrient release from the prepared polymer-coated materials were described and

DOI: 10.1021/acs.jafc.5b00518
J. Agric. Food Chem. 2015, 63, 2597−2605

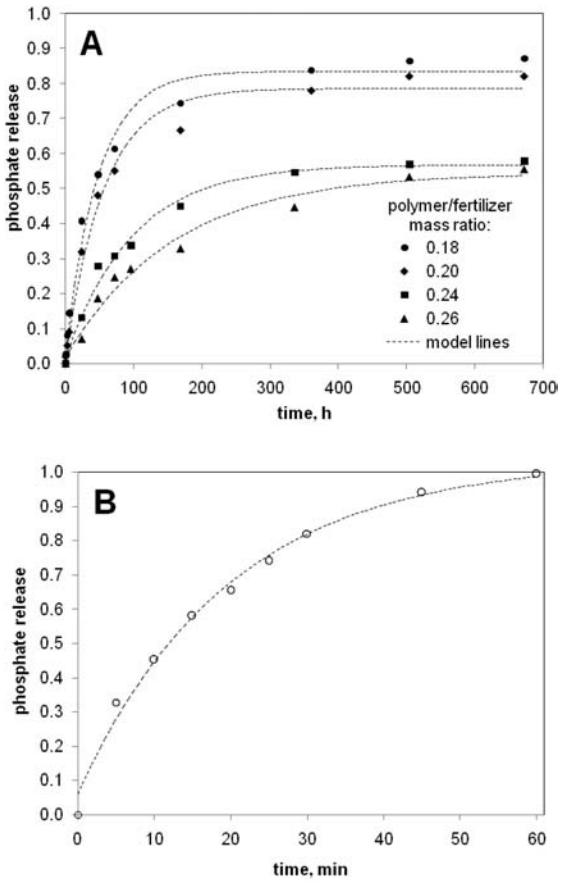

Figure 7. Release of phosphates within 28 days from (A) polymer-coated materials with polymer to fertilizer mass ratios of 0.18, 0.20, 0.24, and 0.26 amd (B) uncoated NPK fertilizer.

interpreted with a kinetic model. To interpret the kinetic data, a sigmoidal model equation was applied:

$$R = \frac{M_t}{M_\infty} = \frac{a - b}{1 + \exp\left(\frac{t - d}{c}\right)} + b \quad (3)$$

M_t/M_∞ is the fraction of nutrients released at time t and a, b, c, and d are the parameters of the sigmoidal equation.

The experimental data of nutrient release from the prepared polymer-coated materials and the predicted values calculated using the sigmoidal equation are compared in Figures 6 and 7. The sigmoidal model satisfactorily fits the experimental data, with the best result obtained for the experiment performed using the conductivity method (Figure 6B). On the basis of the applied sigmoidal model, the constants and correlation coefficients of the equations were determined and are given in Supporting Information Table SI-B.

The sigmoidal equation produces model lines that fit the experimental data very well as expressed by correlation coefficients. Keeping in mind the fact that the nutrient uptake by plants follows a sigmoidal curve and that the sigmoidal model has already been applied to describe controlled release,[48−50] the sigmoidal equation used in the present work satisfactorily predicts the release of phosphates from the prepared polymer-coated materials.

In conclusion, the new, innovative, biodegradable copolymer of poly(butylene succinate) and the butylene ester of saturated dilinoleic acid was successfully applied in the preparation of fertilizer materials with controlled and prolonged nutrient release. Multicomponent fertilizer granules can be coated with a polymer layer using the immersion method, which creates an incentive to use the process on a larger scale, for example, by spraying in a drum granulator or in the Wurster bed.

The obtained polymer-coated materials differ from each other in the layer thickness and the polymer to fertilizer mass ratio. The mass ratio of polymer to fertilizer ranged from 0.18 to 0.26, and the layer thickness ranged from 190 to 230 μm. The interactions between the fertilizer components of the granule and the polymer layer components were found to be physical rather than chemical in nature. The mechanical properties of the fertilizer granules coated with the copolyester layer are significantly better than those of the NPK fertilizer.

Release experiments have shown that polymer-coated materials with polymer to fertilizer mass ratios of 0.23−0.26 meet the requirements of controlled-release fertilizers. The overall nutrient release was <15% within 24 h and approximately 75% after 28 days, although the ammonium ion release during the first 24 h of the experiment was significantly higher than the release of phosphate ions. The concentrations of the mineral components inside the water-penetrated fertilizer granules and the diffusion properties of the nutrients in water have been indicated as the reasons for that discrepancy. Nutrient release from the polymer-coated materials decreased with the increasing layer thickness. The diffusion mechanism of release has been noted as a reason for that correlation. The diffusion coefficient through the polymer layer was estimated as $D = (0.176−0.494) \times 10^{-8}$ cm^2/s. The experimental kinetic data of nutrient release from the prepared polymer-coated materials have been accurately described using a sigmoidal model equation.

synthesized by a facile method with modifications. Synthesized CuNPs have been tested against mung bean plants and, as a comparison, a commercially available bulk counterpart, copper sulfate (CS) salt, is used under controlled laboratory condition. At 0.05 mg/L concentration, CS promotes plant growth and development as per earlier literature. It also elevates the function of photosynthetic machineries; the rate of carbon and nitrogen assimilation as Cu is known to be a cofactor in these metabolic processes.[10] CS treatment at or above 0.5 mg/L resulted in severe tissue injuries, causing reduction in growth, even death, of the plants.[11] Cu toxicity is a threat worldwide because of its tendency to produce harmful Cu chelates during interaction with soil colloids and nutrients, which are detrimental to the surrounding microflora.[12] In this study, we demonstrate a single-step designed encapsulation of CuNP within a biocompatible polymer to reduce its toxic response. Sustained release of nutrient interacts with biological sites, which controls the toxic response. Biochemical experiments have been carried out on isolated chloroplast (Chl) of mung bean plant treated with CuNPs, which demonstrates that CuNPs are more effective than CS to some extent. In a tandem process the effects of both nano and bulk counterpart of Cu in carbon and nitrogen assimilation have been checked. Interestingly, CuNP shows greater efficacy in contrast to CS. A series of biophysical techniques are used to confirm the bioavailability and uptake within the system. Oxidative stress markers, both antioxidative and non-antioxidative enzyme levels, show that CuNP does not inhibit any toxic response to the treated plant system. CuNP, both in physiological and biochemical aspects, worked significantly better than CS, which caused cellular toxicity because of dysfunctional metabolic pathways. The whole study is assisted by a probable mechanistic interpretation to outline its beneficial response. In light of these aforementioned analyses we envision CuNPs future prospect in crop management with reduced toxic response in contrast to its bulk counterpart. To the best of our knowledge this is the first effort to use biocompatible polymer-encapsulated CuNPs for augmentation of photosynthesis, elevated carbon and nitrogen assimilation, and improved morphological and physiological outputs within a plant system.

MATERIALS AND METHODS

CuNP Synthesis. Half a gram of copper sulfate was allowed to dissolve in 2 mL of water; to it was added 20 mL of PEG-200. The resultant mixture was sonicated in a sonication bath (100 Hz) for about 5 min to obtain a homogeneous dispersion. To the resultant dispersion was added dropwise an aqueous solution of sodium borohydride (0.1 M), and the reaction mixture was subjected to a microwave heating (450 W) until a characteristic reddish color was developed. Then the mixture was centrifuged and washed with ethanol three times to remove impurities and placed in a hot-air oven at 80 °C to obtain polymer-encapsulated CuNP.

Plant Material and Growth Conditions. Mung bean seeds (*Vigna radiata* var. Sonali) were purchased from Berhampur Pulse and Oil Research Centre. Seeds (20 seeds/replicate; 3 replicates in total) were washed in deionized double-distilled water and surface sterilized with 5% sodium hypochloride solution for about 20 min. Then the seeds were washed thoroughly with deionized double-distilled water and imbibed with the treatment solutions (control; CuNP 0.05, 0.1, 0.5, and 1 mg/L; CS 0.05, 0.1, 0.5, and 1 mg/L) in the dark for 4−6 h prior to the germination. Detailed growth conditions of plants are described in the Supporting Information (SI).

Morphological Parameters. Root and shoot lengths and fresh and dry weights of CuNP- and CS-treated plants were measured. Dry weight was recorded by drying the plants at 80 °C for 24 h.

Estimation of Photosynthetic Pigment Content. Control and treated leaves were centrifuged twice with 80% alkaline acetone at 6000*g* for 20 min, and chlorophyll content was estimated with the supernatant spectrophotometrically[13] in terms of micrograms of chlorophyll per gram of fresh tissue. Carotenoid was estimated according to the method of Davies with little modification,[14] and the data were expressed in terms of optical density (OD) per gram of fresh weight.

Isolation of Chloroplast. Mung bean leaves were homogenized in isolation buffer (330 mM mannitol, 30 mM HEPES, 2 mM EDTA, 3 mM MgCl, and 0.1% w/v BSA, pH 7.8).[15] The homogenate was filtered and centrifuged. Supernatant was further centrifuged at 1000*g* for 5 min at 4 °C.

Estimation of Fluorescence and Irradiance of Chloroplast by Photoluminescence (PL) Spectra. Chloroplast suspension contained 100 μM potassium phosphate buffer (pH 7.8), 2 μM NaCN, and 1.25 mM sucrose. The fluorescence spectra of the control and treated chloroplasts were recorded at 273 K under a 440 nm excitation wavelength. Photosynthesis versus irradiance (PI) of treated and untreated chloroplasts was calculated accordingly.[16]

Photoreduction Activities. The electron transport through the whole chain of photosynthesis was measured polarographically with an Oxygraph oxygen electrode (Hansatech Instruments, UK).[17] Oxygen evolution was assayed in a medium containing chloroplasts equivalent to 378 μg/mL of chlorophyll. Hill activity was measured according to the method of Vishniac.[18] Ferricyanide and nicotinamide adenine dinucleotide phosphate (NADP) reduction were determined by spectrophotometric methods.[19] Light-induced adenosine triphosphate (ATP) content of chloroplasts was measured by comparing the ATP level in the dark and after 1 min of illumination.[20]

Carbon Assimilation Assay. Chloroplast NADP-glyceraldehydes-3-phosphate dehydrogenase (GPDHase) activity was determined following the method of Taylor et al.[21] The enzyme was activated by a solution containing 0.2 M tricine (pH 8.4) and 20 mM ATP added to 0.1 mL of the solution containing the extracted enzymes. After 5 min, reaction medium (62.5 mM tricine (pH 8.4), 16 mM $MgCl_2$, 7.8 mM ATP, and 0.2 mM NADPH) was added to it. Fifty millimolar glycerate 3-P was then added to initiate the reaction and the oxidation of NADPH monitored at 340 nm. Fructose-1,6-bisphosphatase (FBPase) was activated by preincubation of enzyme extract with reaction medium (0.14 M tricine (pH 7.9), 14 mM $MgCl_2$, and 7 mM DTT). Sixty millimolar fructose-1,6-bisphosphate was added after 10 min and terminated after 15 min by the addition of 0.5 mL of 10% (w/v) TCA. This solution was cleared by centrifugation for 10 min at 12000*g* to determine the enzymatic activity. Ribulose-5-phosphate kinase (RBPase) activity was analyzed by 0.1 M tricine (pH 7.6) and 15 mM DTT for 1 h. After that, reaction medium (66 mM tricine (pH 7.6), 13 mM $MgC1_2$, 1.3 mM P-pyruvic acid, 1.3 mM ATP, 0.33 mM NADH, and 2 units each of phosphoriboisomerase, pyruvate kinase, and lactic dehydrogenase) was added. The reaction was initiated by 30 mM ribose-5-P and the oxidation of NADH monitored at 340 nm.

Nitrogen Metabolism. *Preparation of Leaf and Root Enzyme Extract.* Control and treated plants were homogenized at a ratio of 1:10 (w/v) in 50 mM phosphate buffer (pH 7.5) containing 2 mM EDTA, 1.5% (w/v) soluble casein, 2 mM DDT, and 1% (w/v) insoluble PVPP at cold temperature and centrifuged at 3000*g* for 5 min. Supernatant was again centrifuged at 30000*g* for 20 min. The extract was then used for enzymatic assays.

Determination of NO_3^-. Enzyme extract was added to a 10% salicyclic acid solution dissolved in 12 N sulfuric acid (w/v). NO_3^- content was measured as described by Cataldo et al.[22] The results were expressed as micromoles per gram of fresh weight.

Determination of Nitrate Reduction (NR) Activity. Enzyme extract was mixed in the reaction mixture containing 100 mM phosphate buffer (pH 7.5), 100 mM KNO_3, 10 mM cysteine, and 2 mM NADH. After 30 min of incubation at 30 °C, 1 M zinc acetate was added. The nitrite formed was determined at 540 nm, and NR activity was expressed as micromoles of NO_3^- formed per gram of fresh weight per hour.

Determination of Nitrite Reduction (NiR) Activity. To the reaction mixture (50 mM phosphate buffer (pH 7.5), 20 mM KNO_2, 5 mM methyl viologen (MV), 300 mM $NaHCO_3$) was added enzyme extract at

DOI: 10.1021/jf504614w
J. Agric. Food Chem. 2015, 63, 2606−2617

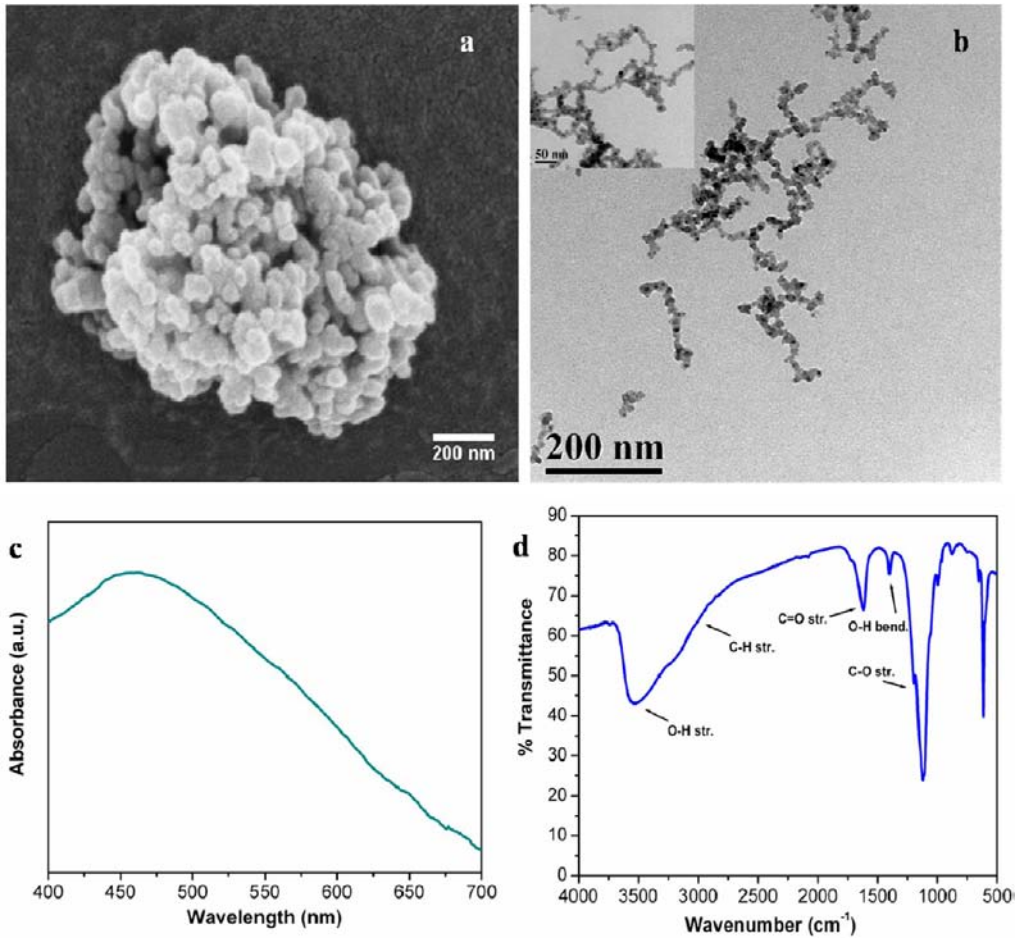

Figure 1. (a) FESEM image, (b) TEM image, (c) UV−vis spectra, and (d) FTIR spectra of CuNP.

30 °C. After 30 min, NiR activity was determined by the disappearance of NO_2^- from the reaction medium and expressed as micromoles of NO_2^- formed per gram of fresh weight per hour.

Determination of Glutamine Synthetase (GS) Activity. Enzyme extract was added in the reaction mixture containing 100 mM phosphate buffer (pH 7.5), 4 mM EDTA, 1 M sodium glutamate, 450 mM $MgSO_4 \cdot 7H_2O$, 300 mM hydroxylamine, and 100 mM ATP. The formation of glutamylhydroxamate was measured at 540 nm after complexing with acidified ferric chloride. GS activity was expressed as formed glutamylhydroxamate in grans of fresh weight per hour.

Determination of NADH-Glutamate Synthase (GOGAT) Activity. The reaction mixture contained 50 mM phosphate buffer (pH 7.5) with 0.1% (v/v) mercaptoethanol, 1 mM EDTA, 18.75 mM 2-oxoglutarate, 15 mM aminoxyacetate, 1.5 mM NADH, 75 mM L-glutamine, and enzyme extract. The decrease in absorbance was recorded for 5 min at 28 °C. The activity was expressed as micromoles of NAD per gram of fresh weight per hour.

Uptake of CuNP by Fluorescence Microscopy Study. CuNPs were amine functionalized and conjugated with fluorescein-B-isothiocyanate (FITC) for uptake study. Ultrathin cross sections of treated plant samples were fixed in 2% glutaraldehyde followed by washing in graded ethanol and observed under confocal microscope.[5]

Electron Micrographic Study. Transmission electron microscopy (TEM) and field emission scanning electron microscope (FESEM) of treated and untreated chloroplasts were performed for analyzing the interaction between chloroplast and CuNPs in photosynthesis. Chloroplasts were fixed with glutaraldehyde, stained with osmium tetraoxide, and washed in graded ethanol for observation under an electron microscope.

Cu Release Study by Inductively Coupled Plasma Optical Emission Spectroscopy (ICPOES). Cu release from CuNPs was monitored by using ICPOES at pH 7, that is, the pH of the plant growth medium. One hundred milliliters of CuNP dispersion of the aforementioned concentrations in Milli-Q water was allowed to stir for 24 h. The resultant dispersion was centrifuged and subjected to digestion in the presence of ultrapure nitric acid followed by estimation against a standard.[5]

Enzyme Assays Related to Oxidative Stress. Control and treated plants were ground in Tris-HCl buffer (pH 7.5) containing EDTA and polyvinylpyrrolidone followed by centrifugation at 0 °C. The supernatant was used for enzymatic assays. Superoxide dismutase (SOD) activity was estimated following a standard procedure.[23] Peroxidase (POD) activity was assayed according to the method of Chance et al.[24] The total peroxide content of plant tissue was estimated according to the method of Thurman et al.[25] Glutathione reductase (GR) was assayed according to the procedure of Wang.[26] Catalase (CAT) activity was assayed according to the method of Beers et al.[27] Activity of polyphenol oxidase (PPO) was assayed following standard methods.[28] Estimation of proline was done according to the method of Bates et al.[29] Phenol content was estimated according to the method of Malik et al.[30]

Estimation of Total Amino Acid (AA), Lipid, Protein, and Carbohydrate Contents. AA content in plant samples was estimated according to the ninhydrin method. Protein contents were estimated according to the method of Lowry et al. Lipid content was estimated according to the Bligh method. Total carbohydrate content was estimated following Loewus.

RESULTS AND DISCUSSION

Physicochemical Characterization of CuNP. Herein we demonstrated a designed synthesis of CuNPs encapsulated within a polymeric matrix followed by evaluation of its photosynthetic efficacy, carbon and nitrogen assimilation, and

Chlorophyll a, F = 76.5579, P < 0.000001; chlorophyll b, F = 464.8072, P < 0.0000001. (c) CuNP and CS on carotenoid content of 15-day-treated mung bean plants. Data represent the mean ± SE (n, no. of samples = 3). Carotene, F = 37.9368, P < 0.00001; xanthophyll, F = 75.1419, P < 0.00001. Within each type of treatment, mean pigment content (±SE, n = 3) followed by the same upper case letter is not significantly different for a particular dose; within each dose mean pigment content followed by the same lower case letter is not significantly different (Tukey–Kramer HSD test).

biosafety study in plant systems. In correlation bulk counterpart CS was also considered for a brief comparison. FESEM was used to evaluate the morphology of CuNPs, which justified spherical particles sheathed within a polymeric matrix (Figure 1a). TEM image showed that small spherical particles of almost 20 nm were formed during the synthesis (Figure 1b). In situ encapsulation of

DOI: 10.1021/jf504614w
J. Agric. Food Chem. 2015, 63, 2606−2617

CuNP within PEG-200 resulting in a chain-like unique morphology. This unique Cu nanochain array was composed of spherical CuNPs encapsulated within PEG-200 to yield a uniform dispersion, which was visible in the high-resolution image (Figure 1b, inset). It was well documented that the CuNP nanochain array was originally reddish; during synthesis a drastic blue to reddish coloration signified the formation of CuNP. A subsequent UV−vis absorbance at around 450−480 nm was noted, which also justified the formation of CuNPs (Figure 1c) and corroborated previous experimental findings. Polymeric encapsulation within PEG-200 resulted in suppression in crystallinity within CuNP in X-ray diffraction (XRD) pattern (SI, Figure S1). This amorphous nature of encapsulating agent was also consistent with the literature. Energy dispersive X-ray (EDX) analysis also justified that Cu is present as the main constituent. Additional peaks of impurities were avoided, which confirmed that CuNPs were obtained in their pure form (SI, Figure S2). The surface topology and height profile were obtained by atomic force microscopy (AFM). AFM image (SI, Figure S3) verified that the average height of the PEG-200 encapsulated CuNPs was 6−8 nm. Surface functionality of CuNPs was confirmed from Fourier transformed infrared (FTIR) spectra (Figure 1d). CuNPs were hydrophilic with the existence of surface hydroxyl and carbonyl/carboxyl groups. Spectral pattern confirmed C—H stretching, O—H bending, C═O stretching, and C—O stretching, which arose due to surface PEG-200 during encapsulation of CuNPs. A sustained release of 0.0136 ppm from predesigned 0.05 mg/L CuNP nanochain arrays after 24 h was noted by ICPOES under mimicking environment sealed inside a dialysis bag (SI, Figure S4). Sustained release of Cu from polymer-encapsulated nanochain array resulted in lower availability of Cu to the in vitro system in contrast to its bulk counterpart CS. As a result, toxicity symptoms were reduced to some extent in this smart designed nanochain array. Meanwhile, the hydrophilic character produced aqueous stability for the in vitro experiment. Altogether this paper claims well characterized, stable, polymer-encapsulated designed CuNPs to be useful for in vitro and in vivo plant experiments.

CuNPs at a Recommended Dose Promoted the Growth of 15-Day-Treated Mung Bean Plants. Cu is a known essential micronutrient in both algae and higher plants.[31] The bulk counterpart of CuNP, that is, CS, has now been extensively applied in the field to abate Cu-induced nutritional disorder. However, at or above certain concentration limits, it imparts toxicity to the plants, resulting in a decrease in plant yield; external toxic symptoms are the consequence of periodically or permanently changed cellular metabolism. Both CuNP and CS at different physiological doses were tested on mung bean plants, and several growth parameters were checked thereafter. In all cases, CuNPs worked better than CS in terms of root and shoot lengths and fresh and dry weights as noted in Table 1. Figure 2a shows the digital images of 15-day-treated plants in contrast to the control ones. Both CuNPs and CS had positive effects on plants at doses of 0.5 and 0.1 mg/L with respect to control, but beyond that dose, a plant's growth was affected by CS treatment. Plants are very sensitive to Cu toxicity, displaying metabolic disturbances and growth inhibition with Cu contents slightly higher than the normal levels in tissues. CuNP-treated plants were found to be healthy at all doses without any chlorotic or necrotic symptoms. Therefore, no significant abnormalities or stress response was noted in CuNP-treated sets; in fact, CuNPs exhibited growth promotion of the plants.

Increased Chlorophyll and Carotenoid Contents in CuNP-Treated Plants Even at a Dose of 1 mg/L. It is well established that in both Cu-deficient and -excess plants, a change in chlorophyll (Chl) content alters chloroplast structure and thylakoid membrane composition in leaves of spinach, rice, wheat, and bean in experimental growth conditions.[1] Cu interferes with the biosynthesis of the photosynthetic machinery modifying the pigment and protein compositions of photosynthetic membranes. This is attributed to the reduction of Chl content and subsequent substitution of the central Mg ion of Chl by Cu in vivo, leading to the inhibition of photosynthesis.[32] In our experiment in both Cu-deficient and CS-treated plants (at higher doses), similar results were observed. In the case of CuNP-treated plants, Chl-*a* content was increased specifically in all treatments, indicating CuNPs might have a momentous effect in photosynthesis, as chl-*a* is key player in the light-dependent photosynthetic pathway (Figure 2b). Carotenoid, the other important factor, which protects the photosynthetic machinery from any abiotic stress, was simultaneously checked. In CuNP-treated plants, both xanthophyll and carotene were found to be increased significantly with respect to its CS and the control (Figure 2c). Therefore, photosynthetic machinery was prevented from unnecessary external stress during CuNP treatment.

CuNP at 0.05 mg/L Enhanced the Activity of Light Reaction in Photosynthesis. In natural photosynthesis, incident light electronically excites a membrane-bound protein−pigment complex, called photosystem (PS). The photogenerated electrons are rapidly delivered to reaction centers (both PSI and PSII) with the help of antenna pigments along the electron transport chain (ETC) through a series of oxidizing agents for regenerating NADPH cofactors. These cofactors drive redox enzymatic reactions to synthesize organic compounds in the Calvin cycle.

At the initial stage of light-dependent reaction, some associated pigments, called antenna pigments, along with some light-harvesting proteins capture solar energy and transfer it to the reaction center. When the energy stored in chlorophylls in the excited state is rapidly dissipated by excitation transfer, the excited state is said to be quenched.[33] This quenching is believed to originate directly from the light-harvesting pigment bed and is influenced more by CuNP treatment than its bulk counterpart. Therefore, more intense energy transfer to the reaction center in the form of non-photosynthetic fluorescence was noted in CuNP treatment in contrast to CS treatment (SI, Figure S5). If the excited state of chlorophyll is not rapidly quenched by excitation transfer, it can react with molecular oxygen to form singlet oxygen. The extremely reactive singlet oxygen can damage many cellular components and hamper the photoefficiency of PSII. Photosynthesis irradiance (PI) response was evaluated (SI, Figure S6) to understand the relationship between CuNP and pigment efficiency in terms of energy capture and subsequent transfer of exciton. Enhancement in response curve after CuNP treatment with respect to control supported that CuNP did not encourage photochemical damage on PSII; the subsequent quenching (SI, Figure S6) was due to non-photosynthetic change during energy transfer. This initial stimulation after CuNP treatment provided a strong basis to trace out next sets of photochemical assays to address photosynthetic efficiency.

From the reaction center, the excited PSII transfers an electron to pheophytin. On the oxidizing site of PSII, it is rereduced by oxidation of water, generating molecular oxygen, which is a byproduct of photosynthesis. Pheophytin transfers electrons to a series of electron acceptors to cytochrome b_6f complex. A Cu−

protein component, called plastocyanin, then transfers electrons from the cytochrome complex to PSI. Thereafter, a series of electron acceptors transfers electrons to produce NADPH, which is an essential component to be used in a later stage, that is, dark reaction of photosynthesis. Therefore, photosynthetic efficacy was measured in light of a series of biochemical reactions in the presence of different electron acceptors.

Cu, being a metalloprotein component of plastocyanin, induces structural changes in photosynthetic membrane leading to the inhibition of electron flux. As a result, at any alteration of doses, it inhibits sites of photosynthesis starting from the Hill reaction, that is, the processes of oxygen evolution, photosynthetic ET, and photophosphorylation to dark reaction. Excess Cu indirectly disturbs iron incorporation into Q_A–Fe sites in Chl, causing inhibition of PSII acceptor sites.[34] In our experiments, at higher doses of CS treated Chl showed impaired photosynthesis in all aspects of light reactions starting from the Hill reaction, whole chain ET, and PSI and PSII activity to photophosphorylation. CuNP at all doses was found to enhance light reaction, reducing the harmful effect of Cu deficiency and/or toxicity. Polarographic study for efficiency of whole chain electron transport (Figure 3a) and subsequent oxygen evolution (Figure 3b) in light reaction corroborated the previous results. The effect was maximum at the dose of 0.05 mg/L compared to CS counterpart in the Hill reaction (Figure 3c), ferricyanide reduction assay (PSII activity) (Figure 3d), and ferricyanide–NADP reduction (PSI activity) (Figure 3e).

Photophosphorylation is the process of converting energy from a light-excited electron into the pyrophosphate bond of an adenosine diphosphate (ADP) molecule. During water splitting the liberated proton is bypassed to the ATPase complex by a proton gradient to form ATP from ADP, which is an important

material for dark reactions. In CuNP-treated Chl, ATP content was found to be greater than its bulk counterpart CS. No apparent toxicity was observed even at the highest dose of CuNP as noted in CS-treated Chl (Figure 3f).

In brief, when light falls on the green cells CuNP encouraged the energy packets present in the pigment bed to transfer the electron readily to the reaction center without hampering the pigment machinery, that is, PSII or PSI. CuNP positively enhanced the efficiency of chloroplast in light-mediated entire electron transfer process (30.29% more than control Chl when measured polarographically). It stimulated the PSII activity (20.5% more activity was observed with respect to control), resulting in greater oxygen evolution. CuNP also promoted the PSI activity probably because of its interaction between Cu–protein components, plastocyanin. As a result, photophosphorylation activity was also improved after CuNP treatment. CuNP thus modulated the entire light reaction positively with effective influence on electron transport chain along with phosphorylation activity as seen in Scheme 1.

CuNP Enhanced the Activity of Light-Regulating Enzymes in Dark Reaction of Photosynthesis. In light-independent reaction, CO_2 and water are enzymatically combined with a 5-C molecule to generate two molecules of a 3-C intermediate, which is reduced to carbohydrate by enzymatic reactions driven by ATP and NADPH generated photochemically. CuNP was found to facilitate the light–dark modulation providing an on–off switch for three key enzymes in the Calvin cycle, namely, fructose-1,6-bisphosphate phosphatase (FBPase), ribulose-5-phosphate kinase (RBPase), and NADP-glyceraldehyde-3-phosphate dehydrogenase (GPDHase). When CuNP-treated Chl was subjected to evaluation of GPDHase (Figure 4a), RBPase (Figure 4b), and FBPase activity (Figure 4c), it was noted that CuNP exhibited greater efficacy in contrast to its bulk counterpart CS. Interestingly, 0.05 mg/L was found to be most effective among all of the dosages, although CuNP had a strong influence on FBPase activity among these three enzymes. This result indicated that CuNP might play a pivotal role in the dark reaction of photosynthesis.

CuNP in Nitrogen Metabolism. Plant growth and photosynthetic ability can be improved by enhancing the nitrogen supply within the system, and therefore it is essential to evaluate the interactive effect of CuNP on nitrogen metabolism in the plant. The first step of this process is the reduction of nitrate in cytosol, and the reaction is catalyzed by nitrate reductase (NR), in which nitrate ion is converted to nitrite ion. Because nitrite is a highly reactive, potentially toxic ion, plant cells immediately transport the nitrite generated by NR from cytosol into chloroplastic leaves and plastids in roots.[35] Here, with the help of nitrite reductase (NiR), nitrite is transferred to ammonium ion. To avoid ammonium toxicity, plants rapidly convert

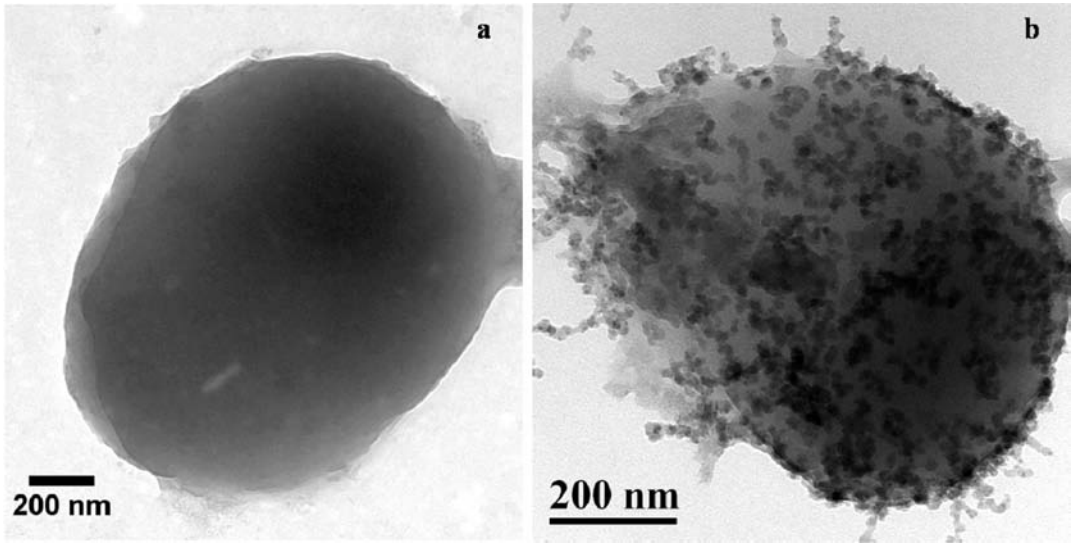

Figure 6. TEM images of (a) control and (b) CuNP-treated chloroplasts.

ammonium ion into amino acids (AAs) with the help of glutamine synthase (GS) and glutamate synthase (GOGAT). GS combines ammonium with glutamate to form glutamine, whereas GOGAT assimilates glutamine translocated from roots to leaves. Once assimilated into glutamate and glutamine, nitrogen is incorporated to AA via transamination reactions. Therefore, the activities of all four enzymes are imperative in nitrogen assimilation and can be stimulated by essential heavy metals.[36] In this paper, CuNP at modulated dose was found to be pertinent for use as an integral component in nitrogen fertilizer as it enhanced the activity of NR (Figure 5a), NiR (Figure 5b), GS (Figure 5c), and GOGAT (Figure 5d). Free nitrate ion concentration was much less in the system compared to the control (SI, Figure S7), ruling out the possibility of nitrate

toxicity leading to cellular injuries within the system. CuNP treatment at all doses worked better than the bulk counterpart at their respective concentrations. Therefore, it justified that CuNP might have a significant and implicit role in both photosynthesis and nitrogen metabolism as it offset all ominous effects of Cu toxicity caused in the agricultural sector.

Bioavailability and Uptake of CuNP. Due to strong binding of Cu by organic matter and other soil colloids, its mobility is severely restricted and the fraction of total Cu available for plant uptake is usually very low. Therefore, uptake and distribution of the CuNP within the plant system was important to execute the response. Compared to the bulk counterpart, availability of CuNP into the rhizosphere is expected to be very high because of its size, high surface by volume ratio, and unique physicochemical properties.[37] Bioavailability of CuNP within the plant sample was verified by confocal microscopy. To demonstrate its bioavailability, CuNP was conjugated with FITC following our previous study.[5] FITC-conjugated CuNP-treated mung bean plants were then observed under confocal microscopy. Leaf and root sections (SI, Figure S8a,b) demonstrated bright green color under confocal microscopy at 488 nm excitation wavelength, although the leaf section appeared to be brighter under confocal microscopy. A direct biomass distribution of CuNP-treated mung bean sample was observed by ICPOES as shown in the SI (Table S1). Distribution of Cu was greater in leaf than in root, which corroborated the confocal results as well.

We assessed the morphology of treated and control Chl by electron microscopy experiments. Treated samples retained similar spherical morphology under scanning electron microscopy (SEM). No significant alterations in morphology were observed in the post-treated samples (SI, Figure S9a). EDX analysis associated with SEM verified the presence of CuNP within the Chl (SI, Figure S9b). Finally, the TEM image demonstrated the presence of small-sized CuNPs over the surface of Chl without altering its uniform spherical morphology (Figure 6).

Consequently, excess Cu causes reduction of Chl content, connected with partial destruction of grana and considerable modification of lipid–protein composition in thylakoid membranes depending upon the duration of Cu action. As a consequence, we checked the morphology of root and leaf sections under a light microscope; no abnormalities in tissue anatomy were found, which corroborated the previous results. In root tissues, epi- and endodermis pericycle and vascular bundles were also normal in position and shape (SI, Figure S10). In leaves, spongy and palisade parenchyma were normal in position and shape with respect to control; even no sunken stomata were observed (SI, Figure S11). Therefore, we conclude CuNP is readily taken up by the root from rhizosphere and is subsequently transported to leaves via shoot. CuNPs did not impart any structural changes in the root or leaf tissue, not even to the Chl, signifying its compatibility with the plant system.

Mechanistic Interpretation or Mode of Action of CuNP. Under physiological processes in plants, Cu exists as the Cu^{2+}/Cu^{1+} system.[38] Cu acts as a structural element in regulatory proteins and participates in photosynthetic ETC, mitochondrial respiration, oxidative stress response, cell wall metabolism, and hormone signaling. In its absence, plants develop specific deficiency symptoms, which affect mostly the early devel-

DOI: 10.1021/jf504614w
J. Agric. Food Chem. 2015, 63, 2606–2617

opmental stages of plant and reproductive organs. Besides the redox properties, those make Cu an essential element also contributing to inherent toxicity. Redox cycling between Cu^{2+} and Cu^{1+} can trigger the production of highly toxic hydroxyl radicals with subsequent damage in nucleic acid, proteins, and other biomolecules. On the other hand, Cu has a strong affinity with thiols and can displace metals in proteins.[39] At the same time Cu is also prone to surface oxidation upon exposure to ambient condition. Therefore, we strategically encapsulated CuNP within a biocompatible polymer. Biocompatible polymer PEG-200 was already approved by the U.S. FDA for biomedical applications. This encapsulation prevented unnecessary leaching of Cu from the constituents and at the same time prevented oxidation of Cu under the conditions. Therefore, the recycling of Cu^{2+}/Cu^{1+} was controlled and a moderate amount of Cu would be released from the polymer matrix, ensuring no or little cellular damage within the system. Cu from CuNP was already noted by ICPOES as shown in Table 1 (SI). Meanwhile, Cu, being an inherent functional component of enzymatic reactions including the ETC pathway, nitrogen assimilation, CuNP was found to be enhanced and/or to modulate the significant biochemical pathways in the photosynthesis and nitrogen metabolism; a small but significant amount of released Cu from nanochain arrays was sufficient to execute the response.

Biosafety of CuNP in the Plant System. As CuNP enhanced the nitrogen assimilation and protected the cellular machinery from photochemical damages, it was obvious that the basic components of biomolecules such as protein, AA, reducing sugar, and total lipid content would be increased. The amount of reducing sugar was increased in all treated sets, although maximum efficacy was observed at 0.05 mg/L. Increase in sugar content, evidence of enhancement in photosynthesis, is shown in the SI (Figure S12a). Free AA content was elevated in CuNP-treated plants with respect to control and their respective bulk counterparts (SI, Figure S12b). This was possibly because of the modulatory effect of CuNP on nitrogen assimilation. CuNP directly or indirectly influenced many physiological processes, which were interconnected to photochemical reactions in nitrogen metabolism. Thereafter, protein (SI, Figure S12c) and total lipid content (SI, Figure S12d) were also increased in CuNP-treated plants compared to its control and bulk counterpart.

CuNP in Oxidative Stress. In plants, reactive oxygen species (ROS) are continuously produced as byproducts in various metabolic pathways localized in different cellular compartments. Under physiological steady-state conditions, these molecules are scavenged by different antioxidative defense components that are often confined to particular compartments.[40] Catalase (CAT) is involved in scavenging hydrogen peroxide during photorespiration and β-oxidation of fatty acids. In both leaves and roots CAT activity was unaltered after CuNP treatment with respect to control; however, at higher doses of CS, it was decreased at an alarming rate (Figure 7a). This result justified that even after CuNP treatment stress response was minimum. Peroxidase (POD) participates in developmental processes, ethylene biosynthesis, and defense. POD levels were almost unchanged between control and CuNP-treated sets, whereas CS showed drastic changes with respect to control (Figure 7b). Therefore, CuNP-treated plant tissues (both root and leaf) were not significantly altered, maintaining normal homeostasis into the metabolic system; ROS-mediated damage was insignificant. Superoxide dismutase (SOD) represents a group of multimeric metalloenzymes catalyzing the disproportion of superoxide free radical, generated by univalent reduction of molecular oxygen to hydrogen peroxide in different cellular compartments. No significant deviations of enzymatic activities with respect to control were observed at CuNP-treated plants at recommended doses as observed in Figure 7c. GR is a member of the flavoenzymes family, which catalyzes the NADPH-dependent reduction of glutathione disulfide to glutathione. In CuNP-treated sets GR levels showed minor alterations with respect to control, whereas CS showed drastic changes (Figure 7d). In both roots and leaves after CuNP treatment GR activities were increased with respect to control, but not in a dose-dependent manner because of the high affinity of Cu to bind with the −SH group of the protein moiety. Non-antioxidative protein components such as phenol (SI, Figure S13a), total peroxide (SI, Figure S13b), proline (SI, Figure S13c), and polyphenol oxidase (SI, Figure S13d) (PPO) were also determined as plants have general strategies to induce the activities of these non-antioxidative proteins to overcome the oxidative stress due to imposition of abiotic stress. Except proline, no abnormal activities were observed in CuNP-treated root and leaf tissues. Proline is a known stress marker, which counterbalances the detrimental effect of stress to maintain the equilibrium of the cellular machineries. Therefore, the elevated activities of proline in CuNP-treated sets helped to surpass the possible harmful effect of plants as enforced by the nanoparticle action. This ensured the protective baseline for the plant from any abiotic stress that had been impaired at high concentration of CS to the system. Direct exposure or release of Cu^{2+} from CS could result from oxidative stress and damage within cellular network, but deliberate embedding within a polymeric matrix resulted in controlled release of Cu from CuNP to yield the beneficial response as a micronutrient for crop management.

In a nutshell, biochemical and physiological implications as well as efficacy of newly synthesized polymer-encapsulated CuNP on plant systems had been established in comparison to its bulk counterpart CS. This not only promised to improve crop productivity by modulating photochemical pathway but also decimated the nutritional disorder by catalyzing the nitrogen assimilatory pathway and carbon assimilation. It reduced the toxicity issues developed by the commercially available salt CS, as it was biosafe at the physiological dosages used in these experiments. Ready uptake within the plant system verified its bioavailability; at the same time, strategic encapsulation within the biocompatible polymer matrix reduced the toxic response and ensured stability to some extent. At recommended dosages its efficacy in photosynthesis and biocompatibility were ensured in contrast to its bulk counterpart CS; cellular machineries were protected as well. Moreover, polymer-encapsulated CuNP might serve as a boon in the agricultural arena, being a suitable alternative of copper micronutrient, and hence it could be included in fertilizers amalgamated with other necessary macro- and micronutrients. We believe systematic modification in nanoparticle synthesis can lead to greater such beneficial response in the near future for crop management. Detailed toxicological profiling and thorough testing are also required prior to its commercialization, but it is an initial step that can provide a baseline for future research for sustainable development in agri-economics.

four to six months. Finally, in Phase III, fruit growth is mostly arrested, and the fruit undergoes a nonclimacteric ripening process.[13] Therefore, the final sizes of citrus fruit are determined by both the cell number and the cell size, which are determined by the processes of cell division and cell expansion, respectively. Any perturbations to the two processes may cause alterations in final fruit size.[14]

Numerous studies have demonstrated that rootstocks exert a significant influence on fruit quality under diverse cultivation conditions. To gain insight into the potential mechanisms by which rootstocks influence fruit size, we investigated the effects of two citrus rootstocks on the fruit growth of 'Shatangju' mandarin. The rootstock genotypes chosen were Trifoliate orange (*Poncirus trifoliata* (L.) Raf.) and Canton lemon (*Citrus limonia* Osbeck), which are known to confer low and high scion vigor, respectively, in China.[15] We also conducted a hormone analysis and an expression-profiling study of the fruit from the two graft combinations.

MATERIALS AND METHODS

Plant Materials. This study was conducted at a commercial orchard in Yangchun, Guangdong Province, China (latitude 22°06′ N; longitude 111°42′ E; altitude 12.5 m). This area has a subtropical monsoon climate with a mean annual precipitation of 2380 mm, a mean annual temperature of 22.3 °C, and an annual mean of 1748.2 h of sunshine. The soil was classified as a red soil, with a pH of 5. The evaluated rootstocks were Trifoliate orange and Canton lemon, two rootstocks that are widely employed in China citrus production. Virus-free budwood of the 'Shatangju' mandarin was budded onto these rootstocks in January 2003, and the grafted plants were planted in spring 2004 at a spacing of 2.5 m × 3.0 m. The terms 'Shatangju'/Trifoliate orange and 'Shatangju'/Canton lemon are used to refer specifically to the 'Shatangju' mandarin grafted on either the Trifoliate orange rootstock or the Canton lemon rootstock, respectively. The experimental design was a randomized complete block with five replicates, and the experimental unit was a single tree per plot. Disease and pest control measures were performed according to an integrated pest management method.

Fruit quality was assessed from 2009 to 2012. Each year, 10 fruits were collected from each citrus tree in late December. For fruit quality analysis, the fruits were collected from the four quadrants of each plant, and the fruit fresh weight and fruit diameter were measured. The TSS content, which is expressed in °Brix, was assessed using a digital refractometer. The titratable acidity (TA) was determined by titration with 0.31 N NaOH. For the evaluations of tree growth in 2011 and 2012, the trunk diameter at 10 cm above the grafting line, the canopy volume, and the yield were measured. The canopy volume was calculated using the equation for one-half of a prolate spheroid.

For fruit growth analysis, five fruit samples per tree were collected in accordance with the following schedule: October 16, 2012; November 15, 2012; December 5, 2012; December 25, 2012; and January 13, 2013. The collected fruits were transported to the laboratory on dry ice and immediately separated into the peel and flesh components, frozen in liquid nitrogen, and stored at −80 °C until further analysis.

Cell-Size Measurements. Samples of 'Shatangju' mandarin fruits produced on the two rootstocks were collected on the designated sampling dates, and healthy peel sections along the equatorial region were removed and fixed in an FAA (formaldehyde, acetic acid, and ethanol) fixative. The fixed peel samples were dehydrated with ethanol and then embedded in paraffin according to the method previously described by Cajuste et al.[16] The embedded tissues were sliced into 8 μm sections and stained with a 0.5% hematoxylin staining solution. For each fruit, three to five sections of peel were analyzed. The cell diameter, as an indicator of cell size, was measured in the flavedo layer, which comprises the exocarp for a citrus fruit, excluding the outer epidermal layer and the oil-gland region. The mean cell size was calculated for each section.

Phytohormone Determinations. Fruit tissues were powdered in liquid nitrogen, extracted with 80% (v/v) methanol, containing 1 mM butylated hydroxy−toluene (BHT), for 4 h at 4 °C in the darkness, and then, centrifuged for 15 min at 6000 rpm before the supernatants were collected. The residue was extracted a second time as above, the supernatants were combined, and the volume was recorded. The supernatants were purified on a C18 Sep-Pak cartridge (Waters, Milford, MA, USA), evaporated to dryness in vacuum, and redissolved in a phosphate-buffered saline solution (pH 7.5). The contents of endogenous indole-3-acetic acid (IAA), zeatin riboside (ZR), gibberellins (GAs), and abscisic acid (ABA) were quantified by an enzyme-linked immunosorbent assay (ELISA) according to previously described procedures.[17,18] The ELISA kit was purchased from China Agricultural University. The absorbance of each well was measured at 490 nm using a Microplate Reader (Infinite M200, Tecan, Austria). Two replicates were performed for each measurement.

RNA Extraction and cDNA Synthesis. Total RNA was extracted from the frozen peel and pulp tissues of 'Shatangju' mandarin with TRIzol reagent according to the manufacturer's protocol (TaKaRa, Otsu, Japan), and was then treated with DNase I (TaKaRa). UV absorption spectrophotometry and gel electrophoresis were employed to assess RNA quality and quantity. Subsequently, single-stranded cDNA was synthesized from the extracted total RNA using oligo(dT) primers and M-MLV reverse transcriptase (TaKaRa) following the manufacturer's instructions.

Sequence Retrieval, Primer Design, and Quantitative Real-Time PCR Analysis. Gene sequences were retrieved from the NCBI (http://www.ncbi.nlm.nih.gov/) and orange genome bank (http://citrus.hzau.edu.cn/orange/index.php) by performing keyword searches as well as homology searches. All of the gene-specific primers for real-time polymerase chain reaction (PCR) were designed using the Primer

DOI: 10.1021/jf505843n
J. Agric. Food Chem. 2015, 63, 2618−2627

5 and BatchPrimer3 programs. The actin gene was used as a reference gene to normalize the expression of other genes. The primer sequences are listed in Table 1. Standard curves were created by analyzing a dilution series of mixed cDNA (spanning five orders of magnitude) to calculate the gene-specific PCR efficiency and the regression coefficient for each gene.

Quantitative real-time PCR was performed in 384-well plates in a LightCycler 480 instrument (Roche, Basel, Switzerland) using the LightCycler 480 SYBR Green I Master kit. Each reaction mixture contained 5 μL of SYBR Green I Master, 3.2 μL of PCR-grade water, 1 μL of cDNA, and 0.4 μL of each of the 10 μM forward and the 10 μM reverse gene-specific primers for a final volume of 10 μL. Quantitative real-time PCR analysis was performed using the manufacturer's recommended cycling parameters. The final relative expression levels of the target genes were calculated by the formula $2^{-\Delta\Delta CT}$.[19] Gene expression values represent the means of three biological replicates for each treatment.

Statistical Analysis. Data were subjected to a *t* test using the SPSS 18.0 software (SPSS Inc., Chicago, IL, USA), and the figures were created using OriginPro 8.5 (OriginLab Corporation, Northampton, MA, USA).

RESULTS AND DISCUSSION

Fruit Growth and Development. The choice of rootstock had a significant effect on tree vigor. The 'Shatangju' mandarin trees grafted on Canton lemon produced a greater canopy volume in both years and a larger trunk diameter (Table 2), which showed more vigorous growth compared with the trees that were grafted onto Trifoliate orange. The 'Shatangju' mandarin trees produced similar fruit yields on the two rootstocks (Table 2). Fruit quality was determined for each commercial harvest from 2009 to 2012 (fifth to seventh year after planting) (Table 3). Trees grafted on Canton lemon produced larger fruit in terms of fruit weight and fruit transverse diameter, which were 25% and 9% greater, respectively, than the corresponding values for the 'Shatangju'/Trifoliate orange fruits.

Table 2. Tree Size and Yield of 'Shatangju' Mandarin on Canton Lemon and Trifoliate Orange Rootstocks, Average of the Years 2011 and 2012[a]

rootstock	trunk diameter 10 cm above grafting line (cm)	canopy volume (m^3)	yield (kg)
Canton lemon	32.6 ± 1.6*	11.1 ± 0.4*	39.71 ± 4.1
Trifoliate orange	24.6 ± 0.4	9.05 ± 0.3	45.58 ± 4.2

[a]Data are means ± standard error of two years. Within a column, * indicates a significant difference on the basis of the independent-sample *t* test at $P < 0.05$.

Furthermore, the growth of 'Shatangju' mandarin fruit was significantly influenced by rootstocks (Figure 1). After a period during which the fruit weight steadily increased until December 5, the rate of increase becomes very slow, broadly resembling a flat line (constant weight) on 'Shatangju'/Trifoliate orange, resulting in a final fruit weight and size of only 68.3 g and 54.9 mm, respectively (Figure 1A, B). In contrast, the weight and size of fruits of 'Shatangju'/Canton lemon continued to increase linearly to approximately 86 g and 61 mm, respectively, which were approximately 26% and 11% heavier and larger than the corresponding 'Shatangju'/Trifoliate orange values (Figure 1A, B). No difference in fruit size was observed between the trees on both rootstocks before December, which is consistent with our previous investigation of the 2011 growing season (data not shown).

A classic example of the effect of rootstock on fruit size is provided by a comparison of sour orange and Rough lemon rootstocks. Fruits from trees grafted on Rough lemon were larger, compared to fruits from trees grafted on sour orange.[20] Other studies have also reported that fruits from trees grafted on vigorous rootstocks, such as Rangpur lime, 'Volkamer' lemon, and 'Orlando' tangelo, are generally larger than those produced by trees on dwarfing rootstocks, for example, Trifoliate orange.[2,5,8] Furthermore, 'Shatangju'/Trifoliate orange trees produced fruits with higher TSS contents and TA values. No significant effects of rootstock on other fruit quality characteristics such as seed number and peel thickness were observed (Table 3).

Studies have demonstrated that fruit size is correlated with the number of seeds per fruit[21] and the crop load.[22] Our results revealed that the seed numbers (Table 3) and the fruit yields (Table 2) did not differ significantly between the rootstocks, indicating that the effect of the citrus rootstock on the fruit size may be independent of any effect on the seed number or the fruit yield in this study.

Meanwhile, the mean size of the flavedo cells was determined in cross sections of the equatorial regions of the epicarp (Figure 1C). Differences in the fruit size can be attributed to differences in cell size, cell number, or the amount of intercellular space.[14] During the ripening period, the normal progression of cell expansion was arrested in the flavedo cells in the 'Shatangju'/Trifoliate orange, while the cell size of the 'Shatangju'/Canton lemon continued to increase linearly, which induced a 11.6% greater final cell diameter than 'Shatangju'/Trifoliate orange at the time of harvest (Figure 1C). In short, the results suggest that an enhancement of cell size, caused by increased cell enlargement, contributed greatly to the increase in the fruit size in 'Shatangju'/Canton lemon compared with 'Shatangju'/Trifoliate orange.

Hormone Levels. An increase in the IAA levels was observed in both the peel and the pulp of 'Shatangju'/Canton lemon after December 5, whereas the IAA levels in fruits of 'Shatangju'/Trifoliate orange remained stable, resulting in

Table 3. Mean Values of Fruit Quality Variables for 'Shatangju' Mandarin Grafted on Either Canton Lemon or Trifoliate Orange Rootstocks, for the Period from 2009−2012[a]

rootstock	fruit weight (g)	fruit transverse diameter (mm)	fruit vertical diameter (mm)	peel thickness (mm)	edible portion (%)	TSS (°Brix)	seed no. per fruit	TA (%)
Canton lemon	71.94 ± 3.0*	54.47 ± 1.2*	44.19 ± 0.9	2.31 ± 0.15	68.46 ± 1.6	10.67 ± 0.5*	14.37 ± 2.0	0.29 ± 0.02*
Trifoliate orange	57.55 ± 3.1	49.99 ± 1.5	41.81 ± 0.9	2.13 ± 0.12	70.84 ± 1.7	12.50 ± 0.3	12.71 ± 1.6	0.36 ± 0.02

significantly higher IAA concentrations in 'Shatangju'/Canton lemon during the ripening stage (Figure 2). The importance of auxins for fruit growth and maturation has been well established for a wide array of climacteric and nonclimacteric fruits. A number of studies have demonstrated that the IAA concentrations are typically high during the beginning of the cell expansion stage and then decline to low levels at the onset of ripening.[23,24] By drawing on literature, it is clear that auxins are responsible for the increase in cell enlargement in fruit tissues.[25−27] Applications of synthetic auxins after physiological drop have been demonstrated to increase late-stage citrus fruit growth and the final fruit size by affecting cell enlargement, rather than cell division, during juice vesicle development.[28,29]

Meanwhile, auxins may also play a relevant role in the control of fruit ripening.[30] Applications of exogenous auxin delayed fruit ripening.[31] For example, a preveraison auxin treatment delayed grape berry ripening, as measured by TSS, anthocyanins, and the onset of berry size increase, but increased the final fruit size.[32] Thus, we concluded that the higher IAA levels in fruits of 'Shatangju'/Canton lemon likely promoted cell enlargement, resulting in relatively larger fruit size during the later stages of fruit growth. Moreover, numerous studies have also described the effects of synthetic auxins on a range of citrus cultivars during the preharvest stage. Modise et al.[33] suggested that the preharvest application of synthetic auxin inhibits the natural fall of orange fruit and increases the weight of the fruits that are retained, but contrasting results were described by Almeida et al.,[34] who reported no significant effect of synthetic auxin on the fruit size.

GAs have been known for a long time for their role in fruit set and development and promote both cell division and expansion.[30] During the later stage of fruit development, the GA concentrations remained at a very low level after a decline in both tissues of 'Shatangju' mandarin fruit, and there was no difference in GA levels between the rootstocks (Figure 2). Meanwhile, the ZR concentrations in the fruit of 'Shatangju' mandarin decreased with ripening and were not significantly affected by the choice of rootstock except December 5 in the peel (Figure 2).

The ABA concentrations gradually increased in the peel during fruit development and ripening, and the ABA concentration was significantly greater in 'Shatangju'/Trifoliate orange after December 5 (Figure 2). In the pulp, the ABA concentration time series followed a flattened curve, and the ABA concentration of the peel from the 'Shatangju'/Trifoliate orange was greater compared with the peel from the 'Shatangju'/Canton lemon. The ABA level is usually very low in the unripe fruit but increases as a fruit ripens.[35,36] It was found that dwarfing rootstocks could induce higher ABA levels in the grafted trees.[37] So, the higher ABA level in the fruit of 'Shatangju'/Trifoliate orange may be attributed to a rootstock dwarfing effect induced by Trifoliate orange. ABA plays a positive role in fruit ripening, particularly for nonclimacteric fruit,[38] but exerts an inhibiting effect on plant growth.[39] Several studies have indicated that ABA, which serves as an antagonist to the other growth promoting hormones,[40,41] had a negative impact on cell division by blocking or slowing the cell cycle progression[42,43] and inhibited IAA-induced cell enlargement.[44,45] The higher ABA levels in 'Shatangju'/Trifoliate orange may inhibit the fruit growth and cell expansion through suppressing the synthesis of growth promoting hormones, such as GA and auxin.

Expression Levels of Auxin-Related Genes in the Fruit. Auxin is generally produced in the young developing regions of plants such as the shoot apex, emerging leaves, developing lateral roots, primary root tips, and developing seeds.[46] During the cell expansion stage of the fruit, auxin is transported from the seeds, which are an important site of auxin biosynthesis, to the fruit pedicel and the parent plant.[47] As fruits mature and the seeds become dormant, auxin biosynthesis and export from the seeds are inhibited, and the concentrations in the fruit decrease.[30,48] In this study, the final IAA concentrations in the seeds did not differ between the rootstocks (data not shown). Regarding the fruit, the explanation for the increased IAA levels in the fruits of 'Shatangju'/Canton lemon during the later stages of fruit growth is considered.

Auxin transport or distribution is known to passively occur through the bulk flow in the mature phloem and actively

through carrier-mediated cell-to-cell movement.[46,49] The PIN and AUX/LAX proteins have been suggested to function as the auxin efflux and influx carriers, respectively.[49] The results presented in Figure 3A demonstrate that the expression of *AUX1* and *LAX2* genes were upregulated and exhibited significantly higher levels in the peel of 'Shatangju'/Canton lemon at the later stage. The accumulation of AUX1 transcript was also markedly higher in the pulp of 'Shatangju'/Canton lemon (Figure 3B). In contrast, the majority of the PIN family genes was scarcely expressed in the 'Shatangju' mandarin except *PIN1* and *PIN-LIKES 2*, which showed considerably irregular expression patterns in the fruit, suggesting that, in fruit, the auxin influx may be promoted and may be greater than the auxin efflux at this stage. Previous studies have reported that AUX1 can regulate auxin transport between (and within) IAA source and sink tissues and facilitate auxin uptake in sink tissues.[50,51] *LAX3*, another homologous gene, has been suggested to maintain the auxin sink-strength in sink tissues.[52] Hence, we conclude that the higher IAA levels in fruits of 'Shatangju'/Canton lemon may be attributed to an increased IAA import from locations in the parent tree such as the leaves or roots.

To strengthen our understanding of the role of IAA in fruit development and ripening, the relative expression levels of ARFs were assessed by qPCR analyses (Figure 4). ARFs bind to auxin response elements (AuxREs) in the promoters of auxin-regulated genes and mediate auxin signaling by activating or repressing the transcription of these genes.[53] ARFs appear to act at the core of the auxin signal transduction pathway. When the auxin concentrations are low, ARFs dimerize with the Aux/IAA protein, resulting in the repression of auxin response genes. In contrast, higher auxin concentrations cause degradation of the Aux/IAA protein through the 26S proteasome and the release of ARF transcription factors to modulate the expression of early auxin response genes.[54] Recent studies have reported that ARFs are involved in the regulation of various aspects of fruit development.[48,55]

In this study, *ARF2* expression gradually decreased in fruits of 'Shatangju'/Canton lemon, whereas the pattern differed and the level of accumulation was significantly higher in 'Shatangju'/Trifoliate orange during the ripening period (Figure 4). A

similar behavior was also observed for *ARF1*, which has been suggested to share redundant functions with *ARF2* in *Arabidopsis*.[56] In *Arabidopsis*, *arf2* mutants exhibit pleiotropic effects, including elongated hypocotyls and larger organ sizes because of the increases in cell division and cell expansion.[57] However, the role of the ARF2 protein in auxin signaling remains largely unknown. Several studies have reported that *arf2* mutations do not affect auxin signaling nor the endogenous free auxin content,[56,58] suggesting that *ARF2* does not participate in the auxin response pathway. ARF2 is thought to act as a transcriptional repressor and to have strong binding activity to synthetic auxin response elements.[59] ARF2 may mask the effect of AuxREs and prevent the binding of other ARFs, especially ARF transcriptional activators.[56,60]

Furthermore, in this study, the accumulation of *ARF6* transcripts increased with increasing ripening in the peel and pulp, and the transcript level was markedly higher in 'Shatangju'/Canton lemon during the later stages of fruit development (Figure 4), suggesting that *ARF6* may be involved in the regulation of 'Shatangju' mandarin fruit size. *ARF6* is believed to function as a transcriptional activator in *Arabidopsis*[59] and is a cleavage target of the microRNA miR167.[61] Devoghalaere et al.[48] reported that *ARF6* was upregulated in the later stage of apple fruit development, which is consistent with our study. The genetic marker developed from *ARF6* was also mapped to the fruit size QTL, although this marker is not the strongest in that region.[48] These results indicate that ARF genes are involved in the control of fruit size and that citrus rootstocks may modulate auxin signaling by affecting the ARF gene transcription levels in fruit, resulting in changes in fruit size.

Expansin Gene Expression Levels in Fruit. Expansins are cell-wall-loosening proteins that induce the hydrolysis of matrix polymers, enabling the extension of plant cell walls.[62] We evaluated the changes in expansin gene expression levels in 'Shatangju' mandarin grafted on two rootstocks because expansins have been suggested to play key roles in cell expansion and fruit softening during fruit growth and ripening.[63]

The accumulation patterns for EXP1 transcripts were similar for the peel and pulp of 'Shatangju' mandarin fruit (Figure 5). *EXP1* expression gradually increased before December 5 and

then steadily decreased; at this time, the level of *EXP1* expression was greater in the fruit of 'Shatangju'/Canton lemon than in 'Shatangju'/Trifoliate orange in both tissues. The *EXP10* gene in the pulp was upregulated during the ripening period, and the expression levels were also higher in 'Shatangju'/Canton lemon at the later stage. The observed increase in *EXP1* expression levels was in accordance with the results of Rose et al.,[64] who reported that *EXP1* is specifically expressed in ripening tomato fruit, suggesting that expansins may contribute to cell wall disassembly and fruit softening. In addition, transgenic experiments have demonstrated increased cell elongation and organ dimensions in plants overexpressing *EXPA1*[65] or *EXP10*.[66] The *EXP3* expression patterns were irregular in the pulp, but the expression level in the peel was greater in 'Shatangju'/Canton lemon than in 'Shatangju'/Trifoliate orange (Figure 5). Hence, the larger fruit size of 'Shatangju'/Canton lemon is likely related to the higher activity of expansins, which function endogenously, because the activity

of cell-wall-loosening agents contribute to cell expansion. The reason for the change in expansin activity of citrus fruit on various rootstocks is obscure. However, the activity of expansins may be regulated by either auxin,[67] ethylene, or the cell wall pH.[68]

In conclusion, our results have demonstrated that citrus rootstocks exert a significant effect on fruit size through the regulation of cell size. The difference in fruit size was closely related to the increase in the IAA levels in the fruit of 'Shatangju'/Canton lemon, which may result from the enhanced IAA import from parent trees. Multiple ARF genes, such as the transcriptional repressors *ARF1* and *ARF2* and the transcriptional activator *ARF6*, were significantly affected by the choice of rootstock and may be involved in the control of the fruit size. Although the IAA level in the 'Shatangju' mandarin fruit is closely related to the fruit size control induced by rootstocks, further studies are needed to confirm this relationship on other scions that are grafted onto different rootstocks and to survey whether the application of synthetic auxins strengthens or weakens the rootstock effect on fruit growth regulation.

In addition, the ABA concentrations in the fruit of 'Shatangju'/Trifoliate orange were greater than those in 'Shatangju'/Canton lemon at the later stage of fruit development. The higher ABA levels in 'Shatangju'/Trifoliate orange may inhibit the fruit growth and cell expansion through suppression of the synthesis of growth promoting hormones. Moreover, our present results indicate that the larger fruit of 'Shatangju'/Canton lemon may be attributed to the enhanced cell expansion, which is achieved through increased cell wall loosening because of higher expansin gene transcript levels and through the concomitant higher water uptake associated with the more extensive rooting system of this vigorous rootstock. The results of this study imply that multiple pathways may influence citrus rootstocks regarding fruit growth, and an understanding of these mechanisms may optimize the production of high quality citrus fruits.

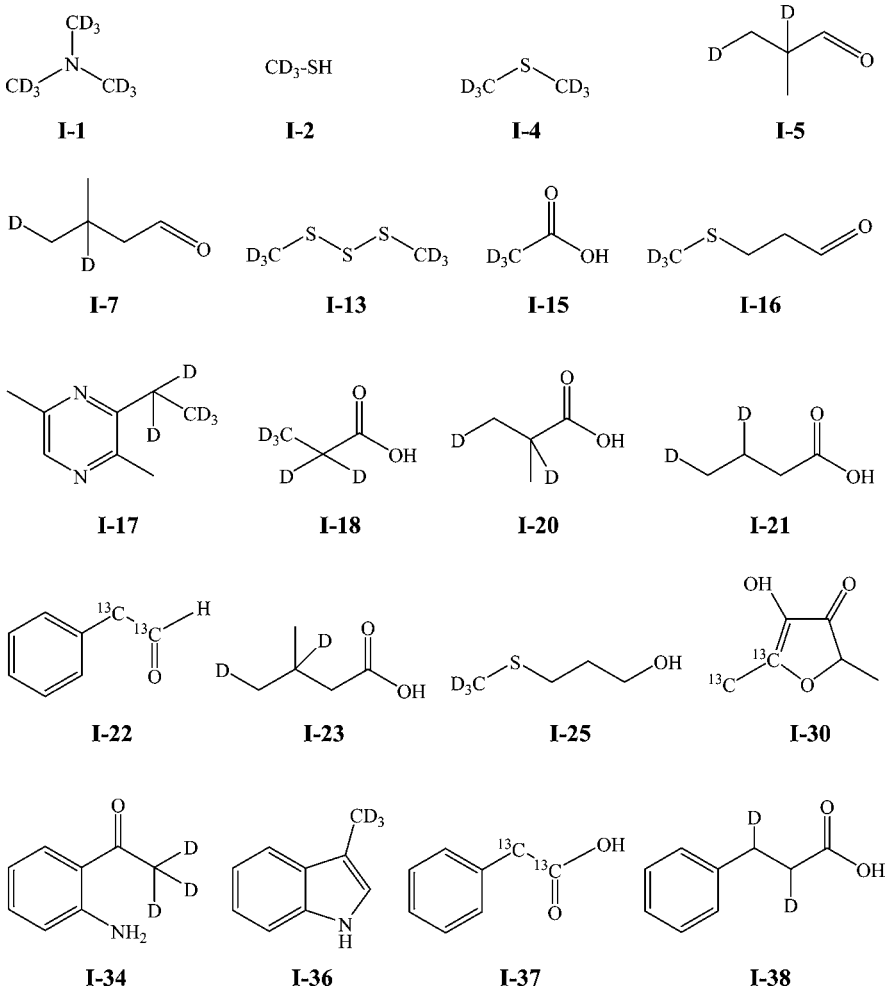

Figure 1. Structures for labeled standards used in stable isotope dilution assays.

concentration of each odorant as well as the matrix composition the product. This approach can be used to verify the results of instrumental analyses and reveal which odorants make the greatest contribution to the overall aroma of the product.

The aim of this study was to identify the key aroma components of premium commercial Thai fish sauce by application of the complementary GC−O techniques, aroma extract dilution analysis (AEDA), static headspace dilution analysis (SHDA), and by calculation of OAVs for predominant odorants based on accurate concentrations determined by SIDA. In addition, the impact of selected predominant odorants on the overall aroma of fish sauce was elucidated by aroma recombination and omission studies.

MATERIALS AND METHODS

Fish Sauce Samples. Two leading brands of commercial premium fish sauce (nam pla) were obtained from a local market (Bangkok, Thailand). They are referred to as fish sauce A (Rayong Fish Sauce Industry Co., Ltd., Rayong, Thailand) and fish sauce B (Marine Resources and Development Co., Ltd., Chantaburi, Thailand). Fish sauce A contained 23.99% (w/w) NaCl and 2.58% (w/w) total nitrogen, while NaCl and total nitrogen contents for fish sauce B were 24.85% (w/w) and 2.18% (w/w), respectively.

Reference Standard Compounds. The following chemicals (listed in Tables 2−7) were obtained from commercial sources given in parentheses: nos. **1**−**8**, **13**, **16**−**25**, **27**, **29**, **30**, and **33**−**38** (Sigma-Aldrich, St. Louis, MO); **15** (Fisher Scientific, Pittsburgh, PA); **28** (Firmenich, Princeton, NJ); **10** (Bedoukian Research Inc., Danbury, CT); **31** and **32** (TCI America, Portland, OR); **11** (Lancaster, Windham, NH). 2-Acetyl-1-pyrroline (no. **12**) was synthesized using the procedure described by Fuganti et al.,[9] and (*Z*)-1,5-octadien-3-one (no. **14**) was synthesized according to Lin et al.[10] Odorless deionized−distilled water was prepared by boiling glass-distilled water in an open flask until its volume was reduced by one-fourth of the original volume.

Isotopically Labeled Compounds. Structures for labeled standards used for quantification by stable isotope dilutions assays are provided in Figure 1. The following labeled compounds were obtained from commercial sources: [$^2H_9$]-trimethylamine (**I-1**), [$^2H_2$]-3-methylbutanal (**I-7**), [$^2H_3$]-acetic acid (**I-15**) (CDN, Pointe-Claire, Quebec, Canada); [$^2H_6$]-dimethyl sulfide (**I-4**) (Sigma-Aldrich); [$^2H_5$]-propanoic acid (**I-18**) (Cambridge Isotope Laboratories, Inc., Tewksbury MA); and [$^{13}C_2$]-2-phenylacetic acid (**I-37**) (Isotec, Miamisburg, OH).

The following labeled compounds were synthesized using previously published methods: [$^2H_3$]-methanethiol (**I-2**),[11] [$^2H_6$]-dimethyltrisulfide (**I-13**),[12] [$^2H_3$]-3-(methylthio)propanal (**I-16**),[12] [$^2H_5$]-3,6-dimethyl-2-ethylpyrazine (**I-17**),[13] [$^2H_2$]-butanoic acid (**I-21**),[14] [$^{13}C_2$]-phenylacetaldehyde (**I-22**),[15] [$^2H_2$]-3-methylbutanoic acid (**I-23**),[14] [$^{13}C_2$]-4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (**I-30**),[16] [$^2H_3$]-*o*-aminoacetophenone (**I-34**),[17] and [$^2H_3$]-skatole (**I-36**).[18]

Synthesis. [2,3-$^2H_2$]-2-Methylpropanal (**I-5**) and [2,3-$^2H_2$]-2-methylpropanoic acid were synthesized from the corresponding labeled alcohol. The uniformly deuterium labeled alcohol was synthesized following a published procedure described for the synthesis of 5,6-[$^2H_2$]-hexan-1-ol[19] with some modifications.

DOI: 10.1021/jf5061248
J. Agric. Food Chem. 2015, 63, 2628−2638

[2,3-$^2H_2$]-2-Methylpropan-1-ol. Chlorotri(triphenylphosphine)-rhodium(I) (Wilkinson's catalyst; Sigma-Aldrich) (15 wt % of the alkenol; 0.45 g) and 2-methyl-2-propen-1-ol (Sigma-Aldrich; 2.5 g, 34.7 mmol) were placed in a pressure reactor equipped with stir bar and rubber septum. The reactor was sealed, then flushed for 5 min with deuterium gas (UHP grade 99.995%; isotopic enrichment 99.7%; Matheson Tri-Gas, Parsippany, NJ) using a needle placed below the surface of the solution. Reaction was carried out at 40 psi until the reaction was complete. The spent catalyst was removed by centrifugation. The target compound was purified by vacuum distillation.

Yield: 1.83 g (99% purity). MS-EI, *m/z* (%): 76 (11) (M+), 58 (5), 57 (7), 46 (5), 45 (100), 44 (64), 43 (59), 42 (42), 41 (13), 40 (13), 39 (8).

[2,3-$^2H_2$]-2-Methylpropanal (I-5). [2,3-$^2H_2$]-2-Methylpropan-1-ol (0.38 g; 5.0 mmol) in 2 mL of dichloromethane was added to a 10 mL suspension of pyridinium chlorochromate (Sigma-Aldrich) (1.2 g; 5.5 mmol) in dichloromethane. The mixture was stirred for 1.5 h at room temperature, and 20 mL of diethyl ether was added. The supernatant was decanted, and the residue was extracted with diethyl ether (3 × 5 mL) until the black gum became granular in consistency. The combined organic phase was filtered through a 10 g bed of Florisil (Sigma-Aldrich). The target compound (**I-5**) was purified by vacuum distillation prior to removal of solvent.

Yield: 0.18 g (92.2% purity). MS-EI, *m/z* (%): 75 (8) (M + 1), 74 (54) (M+), 73 (21), 58 (6), 59 (7), 45 (100), 44 (67), 43 (60), 42 (65), 40 (45), 39 (21).

[2,3-$^2H_2$]-2-Methylpropanoic Acid (I-20). [2,3-$^2H_2$]-2-Methylpropan-1-ol (1.0 g; 13 mmol) was added to a vigorously stirred solution of potassium permanganate (2.5 g, 16 mmol) dissolved in 50 mL of aqueous 0.15 M NaOH in a 200 mL flask. After 2 h, the mixture was acidified with 1 M HCl and then extracted with diethyl ether (3 × 20 mL). The ether layer was extracted with aqueous 0.5 M NaOH (3 × 20 mL). The NaOH extract was acidified with aqueous 4 M HCl and then extracted with ether (3 × 20 mL). The ether layer was washed with aqueous saturated NaCl (2 × 20 mL) and dried over anhydrous Na_2SO_4 (5 g). The target compound (**I-20**) was obtained after removal of the solvent.

Yield: 0.2552 g (98% purity). MS-EI *m/z* (%): 90 (8) (M+), 75 (15), 74 (19), 46 (6), 45 (100), 44 (11), 43 (29), 42 (20), 41 (6), 40 (9).

[2,3-$^2H_2$]-3-Phenylpropanoic Acid (I-38). The deuterated acid was synthesized from cinnamic acid using a modification of the procedure described above for synthesis of [2,3-$^2H_2$]-2-methylpropan-1-ol. Chlorotri(triphenylphosphine)rhodium(I) (Wilkinson's catalyst) (15 wt % of the alkenoic acid; 0.15 g) plus (*E*)-cinnamic acid (Eastman Kodak Co., Rochester, NY; 1.0 g; 34.7 mmol) and 5.0 mL of methanol-*d* (Sigma-Aldrich) were placed in a pressure reactor equipped with stir bar and rubber septum. The reactor was sealed then flushed for 5 min with deuterium gas (UHP grade 99.995%; isotopic enrichment 99.7%; Matheson Tri-Gas) using a needle placed below the surface of the solution. Reaction was carried out at 40 psi until the reaction was complete. The spent catalyst was removed by centrifugation and the solvent evaporated to yield the target compound (**I-38**).

Yield: 0.92 g (95% purity). MS-EI, *m/z* (%): 152 (42) (M+), 107 (15), 106 (43), 105 (22), 93 (9), 92 (100), 91 (16), 80 (5), 79 (10), 78 (13), 77 (6), 66 (8), 52 (6), 51 (10).

Sample Preparation. *Direct Solvent Extraction (DSE).* Fish sauce (20 g) plus 100 mL of odorless-distilled water was mixed well with 25 μL of an internal standard stock solution (1.15 μg/μL of 2-ethyl butyric acid in methanol as acidic fraction internal standard, 1.32 μg/μL of 2-methyl-3-heptanone, and 1.13 μg/μL of 2,4,6-trimethylpyridine in methanol as neutral/basic fraction internal standard). The pH was adjusted to ∼2.0 using 2 M HCl and extracted three times with diethyl ether (100 mL total volume). After the third extraction, the pH of sample was raised to ∼9.0 using 2 M NaOH and extracted three times with diethyl ether (100 mL total volume). The pooled solvent extract (200 mL) was concentrated to 50 mL using a Vigreux column in a 43 °C water bath.

Solvent-Assisted Flavor Evaporation (SAFE). Extracts prepared by DSE were subjected to SAFE to remove any nonvolatile materials, as previously described.[20] The SAFE extract was concentrated to 30 mL using a Vigreux column in a 43 °C water bath and separated into acidic (AF) and neutral/basic (NBF) fractions. The aroma extract (30 mL) was extracted with aqueous 0.1 M NaOH (3 × 20 mL), and the upper layer (diethyl ether) containing the neutral/basic volatiles fraction (NBF) was collected. The aqueous layers were pooled, acidified to pH ∼2.0 with 4 M HCl, saturated with NaCl, and then extracted with diethyl ether (3 × 20 mL). The upper layer containing the acidic volatiles (AF) was collected. The two fractions were washed twice with 15 mL of saturated NaCl solution to 10 mL using a Vigreux column and then dried over 2 g of anhydrous Na_2SO_4. Final volumes of extracts were concentrated using a gentle stream of nitrogen gas to 900 μL for AF and 100 μL for NBF. Extracts were stored in 2 mL glass vials at −70 °C until analysis.

Aroma Extract Dilution Analysis (AEDA). AF and NBF extracts were diluted by volume (1 part aroma extract to 2 parts solvent) in diethyl ether. Each dilution was analyzed by gas chromatography−olfactometry (GC−O) using a 6890 GC (Agilent Technologies, Inc., Palo Alto, CA) equipped with a flame ionization detector (FID) and olfactory detection port (DATU Technology Transfer, Geneva, NY). The sample (2 μL) was injected using direct cool-on-column mode (+3 °C temperature tracking). Separations were performed on polar (Rtx-Wax, 15 m × 0.32 mm i.d.; 0.5 μm film; Restek, Bellefonate, PA) and nonpolar (Rtx-5 SLIMS, 15 m × 0.32 mm i.d.; 0.5 μm film; Restek) columns. The GC oven temperature was programmed from 40 to 225 °C at a rate of 10 °C/min, with initial and final holding times of 5 and 20 min, respectively. Helium was used as the carrier gas at a constant flow rate of 2.2 mL/min. Column effluent was split 1:1 between the FID and the sniffing port using deactivated fused silica tubing (each 1 m × 0.25 mm i.d.; Restek). The FID and sniffing port were maintained at a temperature of 250 °C. GC−O was conducted by two experienced panelists. The flavor dilution factor (FD factor) for a compound was the highest dilution at which it was detected by GC−O. Other details of the procedure have been previously described.[21]

Static Headspace Dilution Analysis (SHDA). GC−O was conducted using a 6890 GC (Agilent Technologies, Inc.) equipped with an FID and olfactory detector port (ODP2; Gerstel, Inc., Germany). Fish sauce sample (5 g) was placed in a 250 mL round-bottom flask and sealed with a PTFE-lined septum. The flask was equilibrated at 40 °C for 30 min with agitation provided by a magnetic stir bar. Each headspace volume (25, 5, 1, 0.2, or 0.04 mL) was injected via a heated (50 °C) gastight syringe into a cooled injection system (CIS-4, Gerstel, Inc.) operating in the solvent vent mode [−120 °C (0.10 min hold) ramped at 12 °C/s to 260 °C (10 min hold); 50 mL/min initial vent flow (0.10 min hold), 1.10 min splitless time, 50 mL/min final split flow]. Separations were performed on Rtx-Wax (15 m × 0.53 mm i.d.; 1 μm film; Restek) and Rtx-5 columns (15 m × 0.53 mm i.d.; 1 μm film; Restek). The GC oven temperature was programmed from 35 to 225 °C at a rate of 6 °C/min, with initial and final holding times of 5 and 10 min, respectively. The FID and ODP2 temperatures were maintained at 250 °C. Column effluent was split 1:1 between the FID and ODP2 using deactivated fused silica tubing as described earlier. Other details of the procedure have been previously described.[21]

Gas Chromatography−Mass Spectrometry (GC−MS). The GC−MS analyses were performed using a 6890 GC/5973 mass selective detector (MSD; Agilent Technologies, Inc.) system. Each aroma extract (1 μL) was injected into a cooled injection system (CIS-4, Gerstel, Inc.) operating in the cold splitless-mode [−50 °C initial temperature (0.10 min hold); ramp rate 12 °C/s; 260 °C final temperature (10 min hold); 1.10 min valve-delay, the 50 mL/min vent flow]. Separations were performed on Stabilwax (30 m × 0.25 mm i.d.; 0.25 μm film; Restek) and Sac-5 columns (30 m × 0.25 mm i.d.; 0.25 μm film; Supleco, Bellefonte, PA). Helium was used as carrier gas at a constant rate of 1.0 mL/min. The GC oven temperature was programmed from 35 to 225 °C at a rate of 4 °C/min with initial and final holding times of 5 and 20 min, respectively. MSD conditions were: capillary direct interface temperature, 280 °C; ionization energy,

70 eV; mass range, 35−350 amu; electron multiplier voltage (Autotune +200 V); scan rate, 5.2 scans/s.

Headspace-Solid Phase Microextraction (H-SPME). For identification of highly volatile odorants, fish sauce sample (1 g) was placed in a 22 mL headspace vial and spiked with 5 μL of internal standards (1.15 μg/μL of 2-ethyl butyric acid, 1.32 μg/μL of 2-methyl-3-heptanone, and 1.13 μg/μL of 2,4,6-trimethylpyridine in methanol). The sample was sealed immediately with a PTFE-lined septum and preincubated at 40 °C for 10 min with agitation (500 rpm, 60 s on, 10 s off) using a MPS2 autosampler (Gerstel, Inc.). Then, a SPME fiber (50/30 μm DVB/carboxen/polydimethylsiloxane fiber; Supelco) was exposed to the vial headspace for 20 min. Then fiber was desorbed by splitless injection (injector temperature 260 °C; splitless time 4 min; vent flow 50 mL/min) into GC−MS system with the same settings as described above. The GC oven temperature was programmed from 35 to 225 °C at a rate of 6 °C/min with an initial and final holding time of 5 and 20 min, respectively.

Compound Identification. Compounds were tentatively identified by GC−O by comparing their retention indices (RIs) and odor properties with those of authentic reference compounds. Compounds were positively identified by comparing their RIs, odor properties, and mass spectra with authentic reference compounds. A homologous series of *n*-alkanes was used for determination of RIs according to the method of van den Dool and Kratz.[22]

Compound Quantification. For quantification of methanethiol (no. **2**), the concentration of the synthesized [$^2H_3$]-methanethiol was first determined by analysis using a 6890 GC−flame photometric detector (GC−FPD) system (Agilent Technologies, Inc.). Headspace volume of methanethiol (50−300 μL) or [$^2H_3$]-methanethiol (5 mL) were drawn by a gastight syringe and injected into 5 mL of methanol in 22 mL sealed headspace vials. Each methanolic sample (1 μL) was injected using hot split mode into an Rtx-Wax column (15 m × 0.53 mm i.d.; 1 um film; Restek). The concentration of [$^2H_3$]-methanethiol (13.7 μg/mL) in the stock solution was determined by comparing its peak area with a standard curve generated from known concentrations of methanethiol (seven levels, from 7.4 to 48.9 μg/mL). For analysis, fish sauce sample was spiked with an appropriate headspace volume of [$^2H_3$]-methanethiol and quantified by H-SPME as described above.

Other compounds in low abundance were quantified by H-SPME and DSE-SAFE as described above, respectively. Highly abundant compounds were analyzed by DSE as described above, except that a 5 g sample was first mixed with isotopically labeled compounds. Then sample was diluted and mixed well with 25 mL of odorless-distilled water. The sample was extracted three times with diethyl ether (60 mL total volume). The pooled solvent extract (60 mL) was evaporated to 10 mL using a Vigreux column in a 43 °C water bath, dried over 2 g of anhydrous Na_2SO_4, and further concentrated to 200 μL under nitrogen gas stream.

The selected ions and response factors of the target (unlabeled) and labeled compounds were determined by H-SPME-GC−MS and GC−MS as described above (Table 2). Response factor for each compound was determined by measuring five levels of defined mixtures of the respective labeled and unlabeled compounds. Concentration for each compound in fish sauce was calculated using the response factor and area of the selected ion and expressed as micrograms per kilogram (ppb). Odor-activity values (OAVs) were calculated by dividing the concentrations by the respective odor thresholds in water, obtained from literature.

Sensory Analysis. *Comparison of Fish Sauce and the Complete Fish Sauce Aroma Model.* Aroma profiling was done by descriptive sensory analysis as previously described.[21] One gram of fish sauce was dissolved in the matrix (10 mL of 0.1 M phosphate buffer, pH 5.6, 25% NaCl) and presented to panelists in 125 mL Nalgene PTFE wash bottles (Fisher, Pittsburgh, PA, USA) with siphon tubes removed from the caps. Bottles were covered with aluminum foil to prevent any visual bias and labeled with random three-digit codes. The 11-member panel (five males, six females, 20−48 years old) were asked to identify and define descriptive terms of fish sauce sample and to determine appropriate aroma references. Odor notes representing fish sauce samples were selected and included cheesy, potatoey, brothy/meaty, fishy/briny, malty, and sulfur (Table 1). Intensity of each reference material was rated on 15 cm universal scales, with intensity ratings of 0 and 15 corresponding to none and very intense, respectively (Table 1). Intensity ratings for the standards were used as calibration references for rating the intensities of the fish sauce samples and the aroma reconstitution models. The complete recombination models, consisting of 21 odorants, were prepared by mixing 1 mL of each stock solution (Table 3) in 10 mL of the aforementioned matrix based on the determined concentrations (Table 3). The panelists were asked to evaluate the intensities of each odor attribute in the fish sauce samples and models. Samples were evaluated in duplicate. Differences among samples were evaluated by analysis of variance with means separation using SPSS version 11 software (SPSS Inc., Chicago, IL).

Table 1. Attributes, References, and Rating for Sensory Descriptive Analysis of Fish Sauce

attribute	reference[a]	rating[b]
cheesy	0.1 g of parmesan cheese	9
potatoey	10 g of mashed potato	8
brothy/meaty	10 mL of a 1% yeast extract aqueous solution	5
fishy/briny	10 mL of a 100 ppb trimethylamine aqueous solution	8
malty	0.1 g of dark chocolate	8
sulfur	2 g of boiled Brussels sprouts	12

[a]Samples were presented in 125 mL PTFE bottles. [b]Aroma intensity was rated on a 15 cm universal scale, with intensity ratings of 0 and 15 corresponding to none and very, respectively.

Omission Experiments. Omission models were prepared in the same matrix described for the recombination models, except that various groups of compounds, namely acids, aldehydes, sulfur compounds, and low OVA compounds, were omitted from each model (Table 3). Sensory comparison of the omission models to the recombination (complete) models was performed using the R-index by ranking method.[23] Panelists were asked to rank the omission models on how different they were from the complete model, from most similar to least similar (n = 19; 5 males, 14 females). The degree of difference of each model compared against complete model was calculated using John Brown computations.[24]

RESULTS AND DISCUSSION

Identification of Odor-Active Compounds. Odor-active compounds from two brands of premium Thai fish sauce (A and B) were isolated by DSE/SAFE. To avoid interferences during GC−O, the aroma extracts were first separated into acidic (AF) and neutral/basic (NBF) fractions. The 29 compounds with $\log_3$FD factor of ≥1 were detected by AEDA, consisting of 11 acidic compounds (Table 4) and 18 neutral/basic compounds (Table 5). The AEDA results for the two fish sauce samples were similar. Compounds in AF with high $\log_3$FD values included acetic acid (vinegar), butanoic acid (cheesy), 3-methyl butanoic acid (cheesy, sweaty), 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (burnt sugar), 4-hydroxy-2-ethyl-5-methyl-3(2*H*)-furanone (burnt sugar), and 2-phenylacetic acid (rosy, plastic). These were regarded as the predominant acidic odorants based on their high $\log_3$FD factor (≥6). Likewise, predominant odorants in the NBF ($\log_3$FD factor ≥3) were 3-methylbutanal (malty, dark chocolate), 3-(methylthio)propanal (cooked potato), phenylacetaldehyde (rosy, plastic), and *o*-aminoacetophenone (musky, grape, stale).

In a previous study, 2-methylpropanal, 2-methylbutanal, 2-pentanone, 2-ethylpyridine, dimethyl trisulfide, 3-(methylthio)-propanal, and 3-methylbutanoic acid were reported with high FD factors and were regarded as principal contributors to the aroma of Thai fish sauce.[5] The results of the present study

confirm the importance of most of the above compounds, except for 2-pentanone and 2-ethylpyridine. Furthermore, 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone, 4-hydroxy-2(or 5)-ethyl-5(or 2)-methyl-3(2*H*)-furanone, and 3-hydroxy-4,5-dimethyl-2(5*H*) furanone were identified for the first time as odor-active compounds in fish sauce.

4-Hydroxy-2,5-dimethyl-3(2*H*)-furanone has been found in many foods, including pineapple,[25] strawberry,[26] beef broth,[27]

roasted almond,[28] and soy sauce.[29] It is a degradation product of an Amadori compound via 2,3-enolization, elongation by the Strecker aldehydes, and reduction of the resulting acetylformoin-type intermediates.[16] Its presence in fish sauce might be desirable because of its pleasant caramel/burnt sugar-like, sweet and fruity aroma note.

4-Hydroxy-2(or 5)-ethyl-5(or 2)-methyl-3(2*H*)-furanone and 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone were tentatively identified and are likely to be the important compounds due to their low odor threshold values of 1.15 and 0.001 (*μ*g/L), respectively.[30] However, these two compounds were present in only trace levels and were not detected by GC−MS. Sasaki et al.[31] reported that 4-hydroxy-2(or 5)-ethyl-5(or 2)-methyl-3(2*H*)-furanone can be produced by yeast fermentation via the pentose-phosphate cycle. In addition, this compound was also formed through the Maillard reaction of pentose.[16] 3-Hydroxy-4,5-dimethyl-2(5*H*)-furanone is well-known as providing a spicy/curry aroma note and has been found in many food products.[30] This compound is reported for the first time as highly odor-active compound in fish sauce on the basis of its odor-activity in air (GC−O). Its presence in fish sauce might be desirable because of its seasoning (curry)-like aroma. It has been reported as a degradation product of threonine.[32] In addition, Kobayashi[33] reported that in sake and wine 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone may be formed via aldol condensation of acetaldehyde and R-ketobutyric acid followed by lactonization.

Thirteen odorants were detected by SHDA of highly volatile compounds including two unknown compounds (Table 6). The highest FD factors (≥25) were found in methanethiol

[h]Not available.

factors reported on the Rtx-Wax column are for the coeluted compounds.

Methanethiol, acetaldehyde, and dimethyl sulfide were not detected by AEDA. Because of their high volatility, these compounds might be coeluted with solvent and/or lost during the extraction and concentration procedures. Therefore, the aroma contribution of very volatile compounds were estimated by directly analyzing the headspace above fish sauce with decreased volumes. In addition, 2-methyl-(3-methyldithio)-furan was not detected by AEDA but tentatively identified by SHDA. This sulfur-containing furan contributed a thiamin/meaty aroma note and might play an important role in the overall aroma of fish sauce due to its very low odor threshold in water of 0.004 μg/L.[30] This compound has been considered as an odor-active compound in a beef-like flavor produced by extrusion of enzyme-hydrolyzed vegetable protein (E-HVP)[34] and yeast extract.[35] 2-Methyl-(3-methyldithio)furan can be formed via the reaction of 2-methyl-3-furanthiol with methanethiol or by Maillard reaction of ribose and cysteine.[36] This is the first report of 2-methyl-(3-methyldithio)furan as one of the potent odorants in the headspace of fish sauce. Alcohols and esters were also found in fish sauce samples, but they showed very low FD factors (data not shown). Thus, these compounds were not considered as important odor-active compounds and were, therefore, not quantified.

Quantitative Analysis of Selected Odorants. There were 21 odorants selected for quantification (Figure 2). The concentrations and odor-activity values (OAVs) of these odorants are presented in Table 7. The major volatile constituents of the premium Thai fish sauces were volatile short-chain fatty acids, namely acetic acid followed by butanoic acid, propanoic acid, and 3-methylbutanoic acid. Five volatile acids were previously reported in Malaysian fish sauce with acetic acid being the most abundant, followed by 3-methylbutanoic acid, 2-methylpropanoic acid, butanoic acid, and benzoic acid.[37] In addition, pentanoic acid, hexanoic acid, 2-methylheaxanoic acid, heptanoic acid, and octanoic acid have also been reported in fish sauce[7,37] However, these were not considered as odor-active compounds in this study. Other moderately abundant compounds in both fish sauces were 3-methylbutanal, 3-(methylthio)propanal, 2-methylpropanoic acid, 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone, 2-phenylacetic acid, and 3-phenylpropanoic acid. On the other hand, trimethylamine, 3,6-dimethyl-2-ethylpyrazine, *o*-aminoacetophenone, and skatole were present at low concentrations (<10 μg/kg). Despite their low levels, these compounds might have a significant impact on fish sauce aroma because of their low odor detection threshold values.

Although AEDA is a useful technique for screening odor-active compounds, it does not provide information about the contribution of individual compounds to the overall aroma. Because compounds are extracted from the sample matrix with a solvent and volatilized during GC−O, these odorants are detected based on odor activity in air without considering interactions with the food matrix. For this reason, the use of OAVs may provide a better assessment of the odor activities of compounds as long as the quantitative data and the odor detection thresholds are accurate.

In this study, OAVs were calculated using odor detection thresholds determined in water, which was appropriate because fish sauce is mainly an aqueous product. Due to its low threshold, 3-methylbutanal had the highest OAV in both

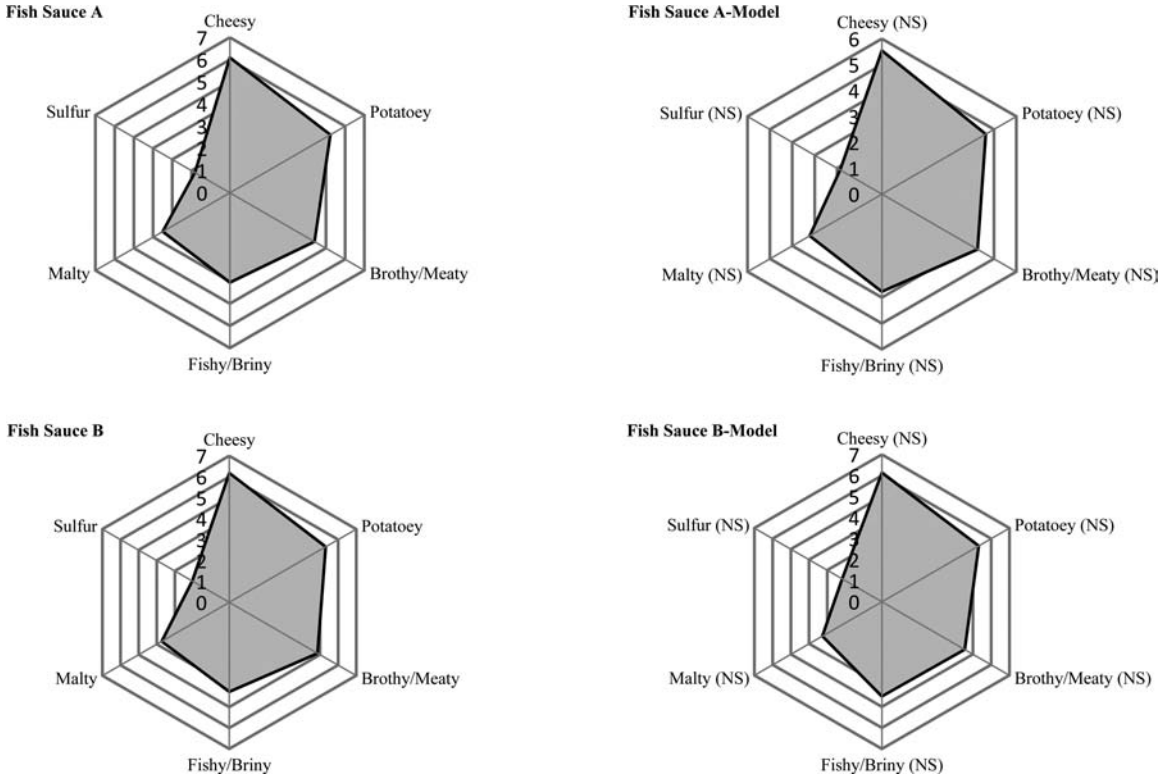

Figure 3. Sensory descriptive aroma profile comparison of fish sauces and recombination models. NS, not significantly different between fish sauce and the complete fish sauce model ($p > 0.05$).

samples despite its low abundance. In addition, high OAVs (>500) for methanethiol, 2-methylpropanal, dimethyl trisulfide, 3-(methylthio)propanal, and butanoic acid indicate the importance of these compounds in the overall aroma of premium Thai fish sauce. Certain volatile compounds, namely 3-methylbutanol, 2-methylbutanal, 3-methylbutanal, dimethyl disulfide, 3-(methylthio)propanal, 3-methylbutanoic acid, and benzaldehyde, have been previously reported to contribute to the characteristic aroma of Malaysian fish sauce.[37] Giri et al.[5] reported that butanoic acid had the highest OAV in premium Thai fish sauce, followed by 2-methylbutanoic acid, dimethyl trisulfide, 3-(methylthio)propanal, acetic acid, and trimethylamine. Shimoda et al.[38] reported that volatility of trimethylamine increased with pH. In this study, trimethylamine, due to its low OAVs, was of only minor importance to the overall aroma of both fish sauces.

Valine and leucine are precursors for 2-methylpropanal and 3-methylbutanal, respectively, which are formed via an amino acid catabolism pathway.[39] In addition, aldehydes can be formed by either enzymatic routes, including transamination and decarboxylation pathways, or by nonenzymatic reactions, such as the Strecker degradation.[40] Methionine is a precursor for 3-(methylthio)propanal, methanethiol, dimethyl sulfide, dimethyl disulfide, and dimethyl trisulfide.[41] Butanoic acid is likely to form by atmospheric oxidation of fish lipids,[29] and it also can be derived from amino acids via bacterial activity.[42] Halophilic bacteria can change the aroma profile of fish sauce. For example, *Tetragenococcus halophilus* has been shown to reduce dimethyl disulfide content in fish sauce.[43] Whereas, *Virgibacillus* sp. SK37 appeared to increase the content of 2-methylpropanal, 2-methylbutanal, 3-methylbutanal, acetic acid, and 2-methylpropanoic acid.[44]

The remaining odorants in Table 7 with OAVs > 100 may also be important aroma contributors. These include dimethyl sulfide, 2-methylbutanal, acetic acid, propanoic acid, 2-methylpropanoic acid, and 3-methylbutanoic acid. Because of their low OVAs (<1), 3,6-dimethyl-2-ethylpyradzine and skatole may contribute only slightly to the overall aromas of the two fish sauces.

Sensory Attributes of Fish Sauce and Aroma Model. Dougan and Haward[45] reported that three distinctive notes contributed to the odor of fish sauce were ammoniacal, cheesy, and meaty notes. In addition, burnt, fishy, sweaty, fecal, rancid, and nutty notes were found as distinctive notes for Thai fish sauce.[5,6] In this study, cheesy, malty, potatoey, brothy/meaty, fishy/briny, malty, and sulfur were the main aroma attributes detected in both fish sauces (Figure 3). Volatile short-chain fatty acids such as acetic acid, butanoic acid, 2-methlylpropanoic acid, 2/3-methylbutanoic, pentanoic acid, and heptanoic acid have been proposed to be responsible for the cheesy note of fish sauce.[5−7] Fukami et al.[6] found that four odor-active compounds contributing to the distinctive odor of Thai fish sauce were 2-methylpropanal, 2-methylbutanal, 2-ethylpyridine, and dimethyl trisulfide. 2-Ethylpyridine and dimethyl trisulfide contributed to fishy note. 2-Methylpropanal together with 2-methylbutanal and 2-ethylpyridine have been reported to contribute to meaty odor, whereas 2-methylpropanal, 2-methylbutanal, and 3-methylbutanal have been described as nutty odor in fish sauce.[5]

Intensities for all aroma attributes of both fish sauce samples were comparable to those of the respective reconstitution models (Figure 3, $p > 0.05$). These results demonstrate that the selection of odor-active compounds based on AEDA/SHDA were appropriate, and the results of quantitative experiments were highly accurate. Therefore, the reconstitution models were

DOI: 10.1021/jf5061248
J. Agric. Food Chem. 2015, 63, 2628−2638

considered to provide an accurate representation of the overall aroma of Thai premium fish sauce.

Omission Studies. Formulations for reconstitution and omission model mixtures are described in Table 7. Models in which either acids, aldehydes, or sulfur-containing compounds were omitted differed (α = 0.05) from the respective complete models (Table 8). The omission of sulfur-containing caused the most noticeable difference. This in agreement with the high OAVs determined for methanethiol, dimethyl trisulfide, and 3-(methylthio)propanal. Similarly, the omission of aldehydes and acids also caused significant differences. This is not surprising because these groups contained odorants with high OAVs, e.g., 3-methylbutanal in the aldehyde group and butanoic acid in the acids group. As expected, the models in which compounds with low OAV compounds were omitted did not differ from the complete models. This finding confirms that low OAV compounds, including trimethylamine, 3,6-dimethyl-2-ethylpyrazine, 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone, *o*-aminoacetophenone, and skatole, had little influence on the overall aroma of fish sauce.

Table 8. R-Index Ranking Test Comparison of Complete Recombination Aroma Models Against Respective Omission Models

	R-index (significance)[a]	
comparison of complete model against	fish sauce A	fish sauce B
model with acids omitted	73.68*	78.95*
model with aldehydes omitted	73.68*	73.68*
model with sulfur compounds omitted	89.47*	84.21*
model with low OAV compounds omitted	63.16	63.16

[a]Degree of difference of each model against complete model (n = 19). *Significant difference from complete model at α = 0.05 (critical value, expressed in percentage; R-index 50% for two-tailed test, α = 0.05 and n = 19 is 20.97).

need for any derivatization step. For this purpose, a suitable background electrolyte (BGE) is added, CE separation being performed at pH > 12, where the hydroxyl groups of carbohydrates are ionized.[24−27,29,30]

In this work, an indirect capillary zone electrophoresis (CZE) method for the determination of sugars in several fruit juices and nectars was developed. The separation of carbohydrates was optimized in terms of an anionic chromophore (2,6-pyridine dicarboxylic acid, PDC) content in the BGE and in other CZE parameters. The carbohydrate and sodium cyclamate (Cyc, sweetener found in some nectars) content present in different fruit juices and nectars was obtained. Using sugar concentration ratios as predictors, a linear discriminant analysis (LDA) model to classify juices according to the type of fruit was constructed. Also, data treatment by multiple linear regression (MLR) was used to detect and quantify blends of pineapple and orange juices with grape juice.

MATERIALS AND METHODS

Chemicals and Samples. The following analytical grade reagents were used: sodium hydroxide (NaOH), D-fructose 1,6-biphosphate trisodium salt (internal standard, IS), 2,6-pyridine dicarboxylic acid (PDC), and cetyltrimethylammonium bromide (CTAB) (Sigma-Aldrich, St. Louis, MO). Deionized water (Barnstead deionizer, Sybron, Boston, MA) was also used. The analytical standards were sodium cyclamate (Cyc), glucose (Glu), fructose (Fru), sucrose (Suc), and sorbitol (Sor) (Sigma-Aldrich). Individual stock solutions of Cyc (0.3 g L^{-1}) and sugars (10 g L^{-1}) were prepared in water. The fruit juices and nectars employed in this study and their commercial brands are shown in Table 1.

To evaluate the possibility of detecting blends of fruit juices, binary mixtures containing different percentages of pineapple−grape and orange−grape juices were prepared. To improve the robustness of the MLR models, the mixtures were prepared using all the available fruit juices, which were randomly selected and mixed. For instance, for the pineapple−grape mixture, a total of 28 mixtures, four for each different percentage, which comprised between 0 and 100% pineapple, were performed. One more set of 28 mixtures containing the same percentages of orange juice was also prepared for the orange−grape mixture. Thus, a total of 56 mixtures were obtained.

Instrumentation and Procedures. An HP[3D] CE system (Agilent, Waldbronn, Germany) provided with a diode array spectrophotometric detector and uncoated fused-silica capillaries (Polymicro Technologies, Phoenix, AZ) of 48.5 cm length (40 cm effective length) × 50 μm id (375 μm od) was used. New capillaries were successively flushed with 1 and 0.1 M NaOH and water at 60 °C for 10 min each. Between runs, the capillary was flushed with the BGE for 4 min. The CZE optimal parameters employed in this study are summarized in Table 2. Data acquisition was performed with ChemStation Software (Rev.A.10.01, Agilent). Statistical data treatment was performed using SPSS (v. 15.0, Statistical Package for the Social Sciences, Chicago, IL).

Table 2. CZE Optimal Parameters Employed in This Study

sample injection	50 mbar × 6 s
separation voltage	25 kV
temperature	15 °C
BGE composition	10 mM PDC + 0.5 mM CTAB at pH 12.1

Sample Preparation. Fruit juice and nectar samples, previously refrigerated at 5 °C, were centrifuged at 10000 rpm for 10 min. The supernatant was properly diluted with water, and for quantification purposes, the IS at 250 mg L^{-1} was also added. All samples were injected three times.

RESULTS AND DISCUSSION

Optimization of Separation Conditions. In order to optimize sugar and Cyc separation, a test mixture containing the standards and the IS described in the Chemicals and Samples section was used. The initial BGE composition and separation conditions were adapted from the literature.[31] Thus, a BGE containing 20 mM PDC and 0.5 mM CTAB at pH 12.1 (at −25 kV and 20 °C) was initially tested in this study. Under these conditions (see Figure 1A), the Fru/Glu peak pair (peaks labeled as 2 and 3) was not baseline resolved, and a significant disturbance between Suc and Sor (peaks labeled as 4 and 5) was evidenced. Moreover, a relatively high signal-to-noise ratio was also observed. Thus, in order to improve sensitivity, peak efficiency, and resolution, the effect of PDC concentration in the BGE was first investigated. With a constant concentration of 0.5 mM CTAB in the BGE, the PDC concentration was varied between 5 and 20 mM (see Figure 1). Analysis time decreased when the PDC content was reduced due to an increase in EOF; however, when a 5 mM PDC (Figure 1D) was used, sensitivity was lower than that obtained with 10 mM (Figure 1C). Thus, this concentration was chosen as the best compromise between sensitivity, resolution, and analysis time.

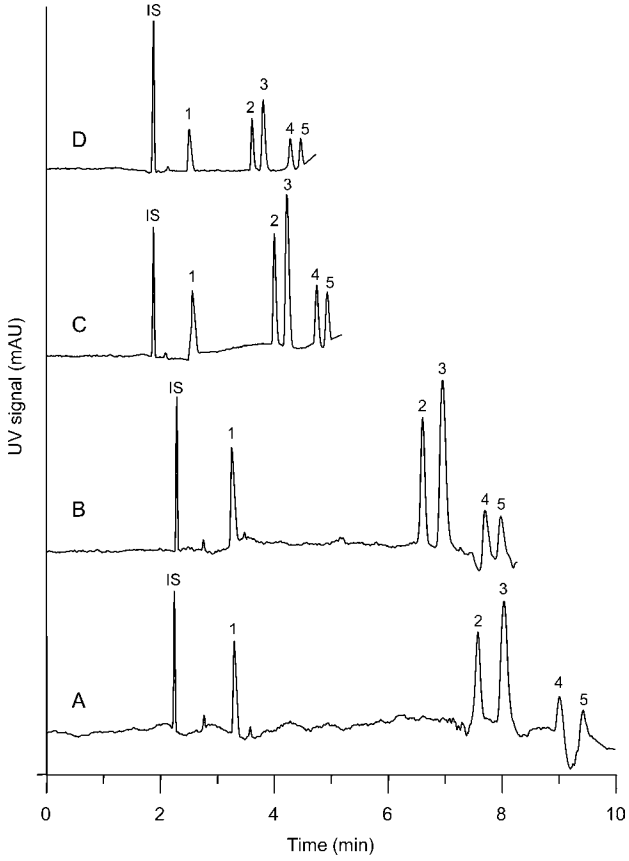

Figure 1. Influence of PDC content on the separation of analyte standards using a 20 mM (A), 15 mM (B), 10 mM (C), and 5 mM (D) PDC content in a BGE composed of 0.5 mM CTAB at pH 12.1. CZE conditions: Hydrodynamic injection, 50 mbar for 6 s; separation voltage, −25 kV at 20 °C; indirect detection, 575 nm (214 nm as reference). Peak identification: IS; 1, Cyc; 2, Fru; 3, Glu; 4, Suc; 5, Sor.

Next, the effect of temperature was studied. For this purpose, temperature was varied between 10 and 25 °C (see Figure S1 of Supporting Information). As it can be observed, analysis time

Sor	1.33	0.27	2.45	1.42	0.0022	0.995	0.0023	0.996	18.1	59.7

[a] RSD relative standard deviation; t_m: migration time; r^2: regression coefficient; SA, standard addition; LOD: limit of detection; LOQ: limit of quantification. [b]Obtained from the slope of calibration curve constructed using peak area ratios (analyte area/IS area) vs analyte concentration (μg mL^{-1}).

decreased with increasing temperature due to a decrease in the buffer viscosity; however, a progressive loss in the resolution of the Suc/Sor peak pair (peaks labeled as 4 and 5) was also evidenced. Thus, a temperature of 15 °C was selected as the best compromise between analysis time and peak resolution.

After selection of the optimal temperature, the applied voltage for analyte separation was next optimized. For this purpose, different applied voltages, ranging from −15 to −30 kV, were applied. The separation voltage directly regulates migration time, also affecting peak resolution. When the applied voltage was lower than −25 kV, peak resolution decreased, while at a voltage of −30 kV, where resolution increased, a loss in peak efficiency (peak broadening) was evidenced (data not shown). Thus, as a compromise between peak resolution and efficiency, a voltage of −25 kV was selected for further studies.

On the other hand, hydrodynamic injection was selected since more reproducible results were obtained compared with electrokinetic injection. Injection time was varied between 2 and 10 s. Sensitivity increased when injection time was increased. However, more than 6 s resulted in no separation of Suc and Sor peaks. Consequently, an injection time of 6 s was selected as the optimum value.

Thus, the optimal separation conditions were BGE containing 10 mM PDC and 0.5 mM CTAB at pH 12.1, separation at −25 kV and 15 °C, injection of 50 mbar × 6 s (see Table 2). Under these conditions, the analyte standards were separated and quantified in less than 6 min with good resolutions (see Figure S1B, Supporting Information).

Performance Characteristics of the CZE Method. In order to significantly reduce the imprecision related to injection and ensure better reproducibility, the use of an IS in quantitative analysis is generally preferred.[32] Precision was determined by studying the intra- and interday repeatabilities of migration times and peak areas (analyte area/IS area) obtained by injecting the same 200 μg mL^{-1} solution for all analytes 6 times per day during 3 days (see Table 3). In all cases, the relative standard deviation (RSD) values were lower than 1.42% and 2.45% for migration times and peak areas, respectively.

External calibration curves of peak areas were constructed using the IS by injecting six standard solutions between 100 and 10000 μg mL^{-1} for Glu, Fru, Suc, and Sor, and between 50 and 500 μg mL^{-1} for Cyc. Straight lines with r^2 > 0.992 were obtained. The limits of detection (LOD) and limits of quantification (LOQ) were estimated for signal-to-noise ratios of 3 and 10, respectively. As observed in Table 3, LODs and LOQs ranged from 11.6 to 18.1 μg mL^{-1} and from 38.3 to 59.7 μg mL^{-1}, respectively. These values were comparable to those obtained by the CE methods with indirect photometric detection.[25,33−35]

Peak identification was performed by comparing migration times with those of the standards, and when necessary also by spiking the samples with the standards. Additionally, standard addition calibration curves were obtained by adding to the extracts at least four solutions with increasing concentrations up to 200 and 5000 μg mL^{-1} for Cyc and sugars, respectively. The curves were linear with r^2 > 0.992, and in all cases, the slope of calibration curve did not differ significantly from that obtained with the external calibration method. From these results, it can be concluded that no matrix effect was observed in the determination of these analytes in the fruit juices and nectars analyzed. Thus, external calibration curves were employed for analyte quantification in all analyzed samples.

Quantification of Sugars and Cyc in Fruit Juices and Nectars. Under the optimized conditions, all the fruit juices and nectars included in Table 1 were subjected to CZE analysis. Figure 2 shows representative CZE electropherograms of an apple (A), grape (B), and orange juices (C) and orange nectar (D). A summary of the contents found (expressed as minimum and maximum values in g L^{-1}) for the analyzed fruit juices and nectars is presented in Table 4. Some variability in the sugar levels can be observed among the analyzed samples, which was in accordance with previous studies.[7,36] Factors such as variety, climate and origin, maturity, and processing practices and storage, among others, can affect the sugar composition of juices. Apart from the sugar contents, the Fru/Glu ratio was also given in fruit juices. This ratio is a useful index for the evaluation of the product quality and authenticity in fruit juices.[2,14]

The Fru content in apple juices is typically two to three times higher than the Glu content.[5,14] Thus, the Glu levels should vary between 15 and 35 g L^{-1}, giving Glu/Fru ratios within the range of 0.3−0.5.[14] All apple juices analyzed (A1−A8) followed the reference guidelines of the Association of the Industry of Juices and Nectars (AIJN).[14] Sor was also used as an indicator of fruit juice authenticity, since its concentration differs over a large range between different fruits. For instance, high Sor levels are found in pears (10−25 g L^{-1}) and in apples (2.5−7 g L^{-1}), while no Sor or only low traces are found in grape and citrus fruits.[37] Thus, the appearance of Sor in samples not obtained from pear or apple could be a good marker of juice adulteration. On the other hand, grape juice did not contain any Suc, and the concentration range for Fru and Glu should be 60−110 g L^{-1}.[14] In our case, all fruit grape juices investigated (G1−G8) fell within this range. The Glu/Fru ratio in orange and mandarin juices is always less than 1, following all orange (O1−O8) and mandarin (M1−M8) juices the AIJN recom-

DOI: 10.1021/acs.jafc.5b00122
J. Agric. Food Chem. 2015, 63, 2639−2646

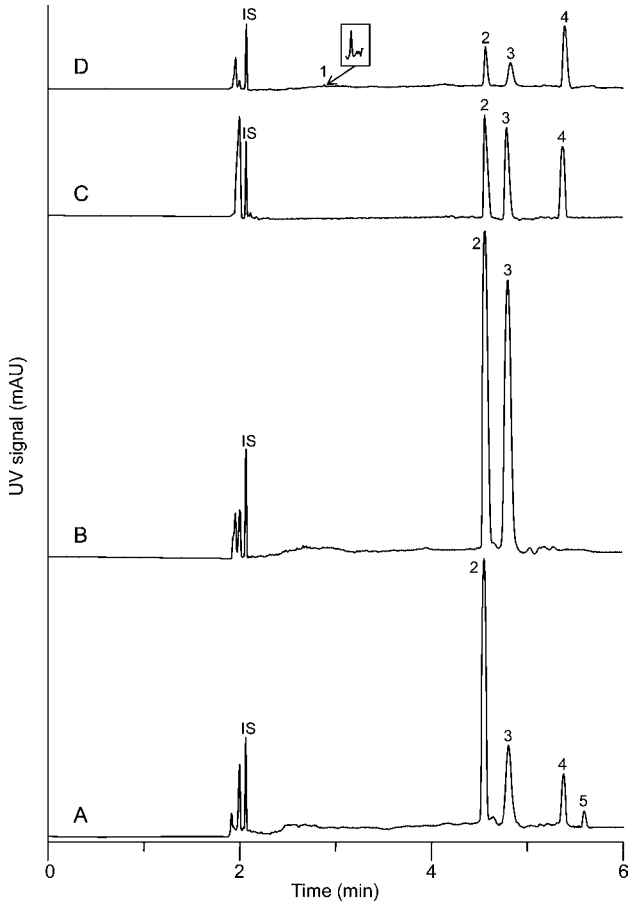

Figure 2. Representative electropherograms of apple juice (A), grape juice (B), orange juice (C), and orange nectar (D). CZE conditions: BGE composed of 10 mM PDC and 0.5 mM CTAB at pH 12.1; hydrodynamic injection, 50 mbar for 6 s; separation voltage, −25 kV at 15 °C. Other conditions as in Figure 1.

mendations. The levels of Fru and Glu in pineapple juice should be ranged between 15 and 40 g L^{-1}, whereas the concentration of Suc was within 25−80 g L^{-1}. A Fru/Glu ratio between 0.8 and 1.25 is commonly used as a good index of authenticity.[14] The pineapple juice samples (P1−P8) were in accordance with the AIJN criteria.

The determination of sugar composition in nectars was also performed (see Table 4). The contents of Fru and Glu were lower than those obtained with the orange and pineapple juices, which could be attributed to the addition of water to "fruit concentrate". According to the directive 2012/12/EU,[38] fruit nectars are a fermentable but unfermented product obtained by adding water and sugars or honey or both to the fruit juices, fruit juices from concentrate, concentrated fruit juices, or fruit purée or to a mixture of those products. The addition of sugars or honey is permitted up to 20% of the total weight of the finished product. Moreover, in most cases, the Suc content was higher than that found in authentic fruit juices (for samples ON3, ON4, PN1, PN2, and PN3), whereas in a few cases, low contents of Suc were found (samples ON1 and ON2). The presence of these large contents of Suc suggested that this sugar has been added in these samples.

Additionally, artificial sweeteners are allowed in nectars sold for dietetic purposes. The EU permitted cyclamates (Cyc) (E952, cyclamic acid, and its sodium and calcium salts) as sweeteners for a variety of food products, with a maximum acceptable level in fruit nectars of 250 mg L^{-1},[38] whereas for Codex GSFA the level is established at 400 mg kg^{-1}.[39] From the six orange nectars analyzed, only two samples (ON1 and ON5) contained Cyc (being consistent with that declared in their labels), but one sample (ON1) exceeded slightly the maximum levels allowed.

At the sight of the differences observed in sugar concentrations, the possibility of using these contents to distinguish fruit juices was considered. For this purpose, a graph of Fru/Glu versus Suc/total sugars was first tried. As shown in Figure 3, this plot was not able to discriminate between citrus

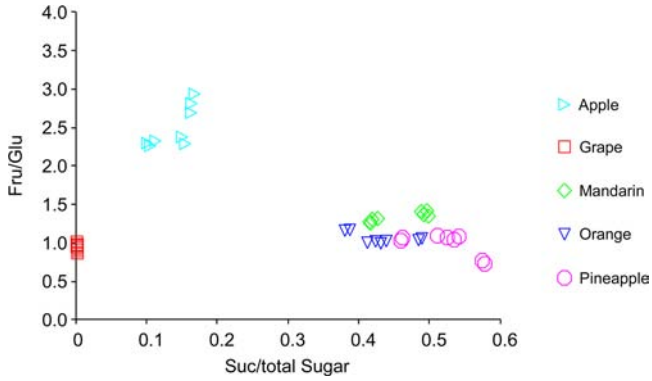

Figure 3. Graph of Fru/Glu versus Suc/total sugars of the studied fruit juices.

(orange and mandarin) and pineapple juices. Thus, in order to discriminate between juices obtained from different fruits, the construction of an LDA model was next considered.

Classification of Juices Obtained from Different Fruits by LDA: Evaluation of the Possibility of Detecting Juice Blends. LDA, a supervised classification technique, is widely recognized as an excellent tool to obtain vectors showing the maximal resolution between a set of previously defined categories. In LDA, vectors minimizing Wilks' lambda, λ_w, are

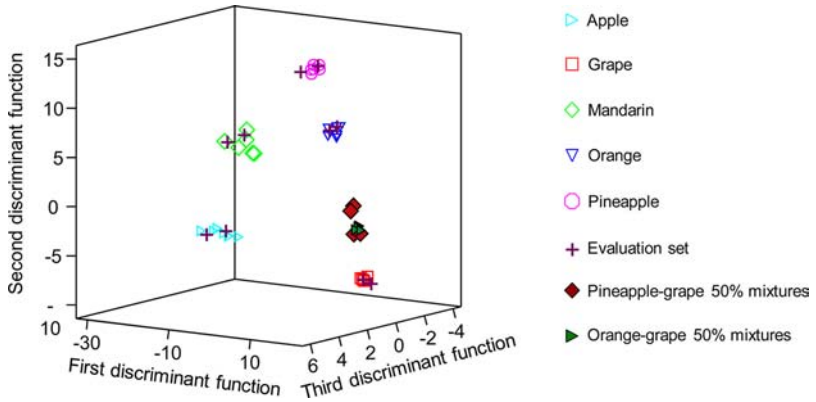

Figure 4. Score plot on an oblique plane of the three-dimensional space defined by the three first discriminant functions of the LDA model constructed to discriminate between juices obtained from different fruits. Evaluation set samples and fruit juice blends at a 50% level of each juice are labeled as indicated in figure legend.

obtained.[40] This parameter is calculated as the sum of squares of the distances between points belonging to the same category divided by the total sum of squares. Values of λ_w approaching zero are obtained with well-resolved categories, whereas overlapped categories make λ_w approach one. Up to $N - 1$ discriminant vectors are constructed by LDA, with N being the lowest value for either the number of predictors or the number of categories. The selection of the predictors to be included in the LDA models was performed using the SPSS stepwise algorithm. According to this algorithm, a predictor is selected when the reduction of λ_w produced after its inclusion in the model exceeds F_{in}, the entrance threshold of a test of comparison of variances or F test. However, the entrance of a new predictor modifies the significance of those predictors that are already present in the model. For this reason, after the inclusion of a new predictor, a rejection threshold, F_{out}, is used to decide whether one of the other predictors should be removed from the model. The process terminates when there are no predictors entering or being eliminated from the model. The default probability values of F_{in} and F_{out} of 0.05 and 0.10, respectively, were adopted.

Thus, for LDA, a data matrix was constructed using the concentration values of Table 4, divided by pairs, as original variables, in order to minimize the differences arising from the sugar concentrations found in the fruit juices considered in this study. This matrix contained 40 objects, which corresponded to all the fruit juices of Table 1, and six predictors, which were obtained by dividing each analyte concentration (Fru, Glu, Suc, and Sor) by the concentration of each one of the other analytes, taking into account that any pair of concentrations should be considered only once. A response column, containing the categories corresponding to the five fruit types, was added to this matrix. This matrix was divided in two groups of objects to constitute the training and evaluation sets. The training set was composed by 30 objects (6 juices × 5 fruit types), while the evaluation set was constituted by the remaining samples (10 objects).

When the LDA model was constructed, an excellent resolution between all the category pairs was achieved (Figure 4, $\lambda_w < 0.01$). The variables selected by the SPSS stepwise algorithm and the corresponding standardized coefficients of the model, showing the predictors with large discriminant capabilities, are given in Table 5. According to this table, the main concentration ratios selected by the algorithm to construct the LDA model corresponded to Suc/Fru and Suc/Glu. With this model and leave-one-out validation, all the objects of the training set were correctly classified. On the other hand, the prediction capability of the model was evaluated using the evaluation set. In this case, all the objects (represented with a cross symbol in Figure 4) were correctly assigned within a 95% probability level.

Table 5. Predictors Selected and Corresponding Standardized Coefficients of the LDA Model Constructed To Discriminate between Juices Obtained from Different Fruits

predictors[a]	f_1	f_2	f_3	f_4
Glu/Fru	3.17	−0.29	0.34	0.82
Suc/Fru	−4.61	1.34	−2.28	−0.89
Sor/Fru	−1.10	−0.39	−0.37	0.53
Suc/Glu	4.74	−0.34	2.68	1.28
Sor/Suc	2.44	−0.01	0.68	1.03

[a]Sugar concentration ratios.

The possibility of detecting fruit juice blends by LDA was also evaluated. For this purpose, different fruit juice mixtures (pineapple−grape and orange−grape), with a 50% content of each juice, were used to check whether the model is able to assign them to a category or whether, in contrast, the model is not able to assign them, which will demonstrate that those samples are juice blends. As it can be observed in Figure 4, pineapple−grape and orange−grape mixtures overlapped. However, in any case, any sample was assigned to any given category. Thus, it is demonstrated that the model is able to discriminate pure fruit juices from mixtures of them.

MLR Model Construction To Predict Blends of Fruit Juices. Finally, to evaluate the possibility of detecting different percentages of fruit juices in binary mixtures, two MLR models for pineapple−grape and orange−grape were constructed. To select the predictors used in the construction of MLR models, the SPSS stepwise algorithm with the default probability values of F_{in} and F_{out} of 0.05 and 0.10, respectively, was adopted. For MLR studies, calibration and external validation sets were constructed, one for each pair of fruit juices. The calibration matrices contained 21 objects (3 mixtures × 7 percentage levels), while the seven remaining mixtures were used as external validation set. These matrices contained also the six predictors and a response column with the pineapple or orange percentage. A plot showing the predicted versus the nominal fruit juice percentages for the two types of binary mixtures is shown in Figure 5. The predictors selected and their

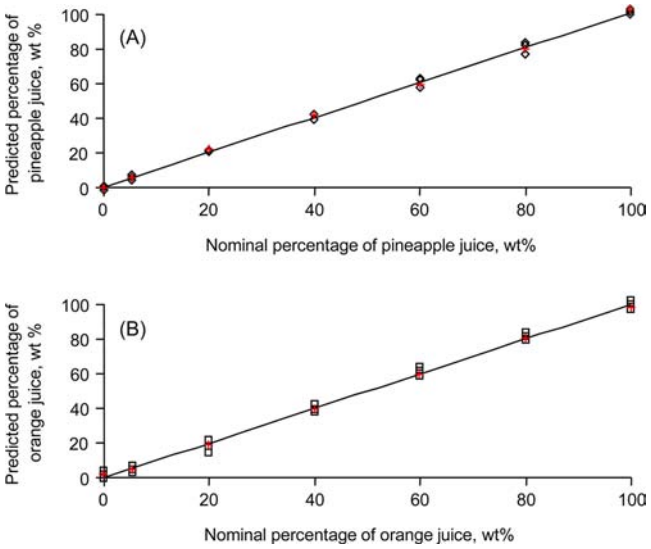

Figure 5. Predicted (MLR) versus nominal fruit juice percentages for (A) pineapple−grape and (B) orange−grape binary mixtures. External validation set samples are labeled with a cross symbol. The straight line is $y = x$.

corresponding nonstandardized model coefficients are given in Table 6. The regression coefficients and the average prediction errors (calculated as the sum of the absolute differences between expected and predicted fruit juice percentages divided by the number of predictions) are also provided. For both models using leave-one-out validation, the average prediction errors were lower than 4.0%. On the other hand, when the models were applied to the validation sets, an excellent prediction capability was observed (Figure 5, red cross symbols), the average validation errors being below 5.2%. The LODs (calculated as three times the standard deviation at 5% grape juice) are also given in Table 6. In both blend juices, these values were below 4.7%, which may be considered as a reasonable limit to discern between intentional addition and possible contamination because the same processing equipment was used for different juices. However, better LODs were found in the literature[1] using a metabolomics approach (with UPLC-QToF MS), which represented a high cost methodology (need for specialized ultrahigh pressure and MS systems). Finally, the commercially available mixtures of fruit juices were used to check whether the model was able to correctly predict the percentages stated in product labels. In all cases, the percentages found were consistent with the values indicated in the label, which clearly proved the usefulness of the MLR models constructed.

Table 6. Predictors Selected and Their Corresponding Nonstandarized Model Coefficients (coef.), Linear Regression Coefficients (R^2) and Average Prediction Errors (avg pred. error) Obtained for the MLR Models Constructed To Predict Binary Mixtures of Fruit Juices

binary mixture	predictor	coef.	R^2	avg pred. error (%)	LOD (%)
pineapple−grape	constant	278.42	0.990	3.8	4.7
	Suc/Fru	−490.50			
	Suc/Glu	413.09			
	Glu/Fru	−179.11			
orange−grape	constant	−285.15	0.997	3.2	3.7
	Glu/Fru	360.60			
	Suc/Fru	−938.29			
	Suc/Glu	875.33			

In summary, a fast, simple and reliable CZE method with indirect UV detection to determine sugars commonly present in several fruit juices and nectars has been established. The combination of CZE analysis with different chemometric tools (LDA and MLR) provides a simple way to classify juices from different fruits as well as to quantify different juice blends. Therefore, the present methodology provides an effective tool for quality control purposes in the juice industry and regulatory agencies.

[a]Eluate used in next round of SELEX. [b]Fraction used in negative or counter selection. [c]Eluate used for cloning.

Conjugation of BCM-7, BCM-5, BCM-9A1, and BCM-9A2 Peptides to Magnetic Beads. BCM-7, BCM-5, BCM-9A1, and BCM-9A2 peptides (Technoconcept) were conjugated to tosyl activated Dynabeads M-280 (Invitrogen) as per manufacturer protocol. A 100 mM borate buffer was prepared by adding 6.18 g of boric acid in 800 mL of water. The pH was adjusted to 7.8 by 1 N NaOH; the final volume of the solution was made to be 1000 mL by the addition of water. A sample of 2×10^8 beads were washed four times with 100 mM borate buffer (pH 7.8). To the washed beads were added 100 μL of peptide (1 mg/mL in water); 50 μL of 100 mM borate buffer, pH 7.8; and 100 μL of 3.0 M ammonium sulfate (prepared in borate buffer, pH 7.8). The contents were incubated for 20 h at 37 °C. The unconjugated peptides were removed by washing the beads with borate buffer. The remaining sites on the beads were blocked by immersing beads in 0.5% bovine serum albumin (BSA) prepared in phosphate buffer saline (PBS), pH 7.4, for 1 h at 37 °C. After the blocking solution was removed, peptide conjugated beads were suspended in 0.1% BSA-PBS, pH 7.4, stored at 4 °C, and used within 15 days.

Amplification of ssDNA Library. A 500 ng sample of 72 nt long ssDNA (MW = 22 067 Da) library[19] (Integrative DNA technology, IDT) was amplified in 5 parallel reactions by PCR. This will essentially have $(500 \times 10^{-9})(6.023 \times 10^{23})/22\,067 = 1.36 \times 10^{13}$ molecules. Total randomness possible from 36 variable nucleotides in the 72 nt. long library will be $4^{36} = 4.7 \times 10^{21}$. However, the maximum randomness from a 500 ng library will be limited to 10^{13}. Each reaction mixture was composed of 50 mM $(NH_4)_2SO_4$, 100 mM Tris-HCl, 2.0 mM $MgCl_2$, 0.2 mM dNTPs, 100 ng of ssDNA library, 1.0 μM each of forward primer (5′-ATCCGTCACACCTGCTCT-3′) and phosphorylated reverse primer (5′-P-ATACGGGAGCCAACACCA-3′), and 1.5 U Taq DNA polymerase in a volume of 50 μL. The amplification conditions used are as follows: an initial heat activation step at 95 °C for 5 min and 30 cycles of 95 °C for 1 min, 55 °C for 1 min, 72 °C for 1 min, and an extension step of 2 min at 72 °C. Amplification of the library was confirmed by resolving PCR product on 3% agarose gel electrophoresis.

Conversion of dsDNA into ssDNA. Amplified PCR product without further purification was digested by λ exonuclease[20] (Fermentas) and digestion reaction was monitored on 3% agarose gel electrophoresis. After 100 min of digestion, the reaction was stopped by inactivating λ exonuclease, which was achieved by heating at 85 °C for 10 min. The product was purified by Qiax II gel extraction kit (Qiagen). The preparation (pure DNA) was stored at −20 °C until further use. On the day of SELEX, the contents were thawed and diluted with 100 μL of binding buffer (20 mM Tris HCl, 100 mM NaCl, 2.0 mM $MgCl_2$, 5.0 mM KCl, 1.0 mM $CaCl_2$, and 0.02% Tween 20, pH 7.6). The undigested reverse strands were further separated by snap cooling, which was achieved by heating of purified product at 90 °C for 15 min and immediately placing on ice for 5 min.[21]

SELEX. An amplified ssDNA library (10 μg) was incubated with BCM-7 conjugated beads (2×10^8) in 100 μL of binding buffer for 1 h at 28 °C with intermittent tapping of tubes to prevent settling of magnetic beads. Then, the beads were washed with 100 μL of binding buffer to remove unbound ssDNA, while bound ssDNA was eluted with elution buffer (20 mM Tris HCl, 10.0 mM EDTA, 3.5 M Urea, and 0.02% Tween 20, pH 8.0) at 80 °C for 10 min. Ten rounds of SELEX were performed to enrich target-specific oligonucleotides (aptamers). To enhance the specificity of the selected oligonucleotides, negative selector and counter selectors (BCM-5, BCM-9A1, and BCM-9A2 coated magnetic beads) were used. In negative selection, tosyl activated magnetic beads were blocked by 0.5% BSA (prepared in PBS) for 1 h at 37 °C. In each round of SELEX, ssDNA eluted from the last elution was amplified. Amplification conditions used are as follows: an initial heat activation step at 95 °C for 3 min and 17 cycles of 95 °C for 14 s, 55 °C for 23 s, 72 °C for 17 s, and an extension step of 2 min at 72 °C. The concentration of PCR product was determined by nanophotometer and was digested by addition of 10U λ exonuclease for every 2.0 μg of amplified product. The digested PCR product was purified by using Qiax II gel extraction kit, snap cooled, and used for the next round of SELEX. The conditions in various rounds of SELEX are provided in Table 1.

Enrichment of BCM-7 specific aptamer after each round of SELEX was evaluated by amplification of 1.0 μL of aliquot taken from each round of washings and elutions. The PCR reaction conditions used were the same as those mentioned above. The PCR product was confirmed by resolving on 3% agarose gel electrophoresis. The amount of DNA was calculated by gel analysis software (SynGene, Synoptis). The aptamers obtained after the last round of SELEX were amplified by using forward primer (5′-ATCCGTCACACCTGCTCT-3′) and reverse primer (5′-ATACGGGAGCCAACACCA-3′). The PCR product was inserted into pGEM T cloning vector (Promega). The recombinant vector was cloned into *Escherichia coli* (DH5α). A total of 41 clones were selected for sequencing (SciGenom).

Determination of Dissociation Constant. Prior to use, BCM-7 conjugated magnetic beads were washed and suspended in binding buffer. A 100 μL sample of 5−325 nM, 5(6)-carboxyfluorescein labeled aptamer (IDT) (prepared in binding buffer) was mixed with 50 μL of BCM-7 conjugated beads (1×10^8) for 1 h at 28 °C. Unbound aptamers were collected by five quick successive washing with binding buffer of 100 μL each. Bound aptamers were eluted with five successive treatments of beads with elution buffer of 100 μL each at 80 °C for 10 min.[22] The unbound and bound aptamers were separately pooled. Labeled aptamers were measured at 494 nm excitation and 520 nm emission wavelengths (Varian, Cary Eclipse Fluorescence Spectrophotometer). The dissociation constant (K_d) was calculated by nonlinear regression analysis using Graph Pad Prism 5 software.

Binding Selectivity of BCM-7 Apatmers. Selected aptamers were tested for their ability to bind with BCM-7/BCM-9A1/BCM-

DOI: 10.1021/acs.jafc.5b00007
J. Agric. Food Chem. 2015, 63, 2647−2653

9A2 by following the protocol as described by Niazi et al.[23] In brief, 500 ng of 5(6)-carboxyfluorescein labeled aptamer (dissolved in 100 μL of binding buffer) was mixed with 50 μL of peptide-coated beads (1×10^8) and incubated for 1 h at 28 °C. The unbound and bound aptamers were collected as mentioned above, and the fluorescence was measured.

Secondary Structure Prediction of Aptamers. Secondary structures of the aptamers were obtained by online program Mfold (http://mfold.rit.albany.edu/?q=mfold/DNA-Folding-Form) at 100 mM NaCl, 2.0 mM $MgCl_2$, and 28 °C to determine the possible interacting regions of the aptamers.

Gold Nanoparticles-Aptasensor. Gold nanoparticles (GNPs) were prepared by reduction of gold(III) chloride trihydrate (Sigma) by sodium citrate (Sigma).[24] The concentration of gold nanoparticles was calculated from the molar extinction coefficient value of 2.43×10^8 M^{-1} cm^{-1} at 520 nm[25] for 23 nm GNPs. A 20 μL sample of 100 μM aptamers was mixed with 10.0 mL of 5.0 nM GNPs suspended in water, and the mixture was incubated for 1 h[26,27] at 25 °C. Aptamer-coated GNPs were pelleted by centrifugation (8000 rpm, 20 min). The supernatant was discarded. The pelleted GNPs were resuspended in water. A 25 μL sample of varied concentration of BCM-7 from 1 to 30 μg/mL (prepared in water) were mixed with 200 μL of 5.0 nM aptamer-coated GNPs. After 1 h of incubation, 25 μL of 350 mM NaCl was added, and the contents were gently but quickly mixed. The color change of GNPs was recorded within 3 min.

Enzyme-Linked Aptamer-Sorbent Assay. Aptamers were evaluated for their potential use for the estimation of BCM-7 content using an enzyme-linked aptamer-sorbent assay. A 12 μL sample of 10 μM of each of five biotinylated aptamers (seq1, seq7, seq10, seqU4, and seqU5) (IDT), were mixed and further diluted by adding 1140 μL of 5X SSCT buffer (75 mM sodium citrate, 750 mM sodium chloride, and 0.05% Tween 20), pH 7.0. A 100 μL portion of the aptamer-mix was added to each well in a 96-well streptavidin coated plate (Nunc). After 1 h of incubation at room temperature, wells were washed three times with 2X SSCT (30 mM sodium citrate, 300 mM sodium chloride, and 0.05% Tween 20), pH 7.0 to remove unbound biotinylated aptamers. Then, wells were blocked by treating overnight with 1.5% BSA at 4 °C. Wells were washed three times with 1X phosphate saline buffer (PBS) at pH 7.4 to remove excess BSA. Then, 100 μL of BCM-7 at variable concentration (10−1000 ng/mL, prepared in water) were added, and the plate was incubated for 90 min at 25 °C. The wells were washed three times with 1X PBS at pH 7.4. Then, wells were treated with 1/2000 times diluted 100 μL of BCM-7-peroxidase conjugate (Merck) for 90 min at 25 °C. After incubation with conjugate, the plate was washed five times with 1X PBS, pH 7.4, to remove unbound BCM-7-peroxidase conjugate followed by addition of 100 μL of 3,3′,5,5′-tetramethylbenzidine (TMB) (Sigma). The plate was further incubated for 15 min at 37 °C, and then the reaction was stopped by adding 100 μL of 2 N HCl. The absorbance was recorded at 450 nm. in ELISA plate reader (BioTek).

Cross reactivity of individual BCM-7 specific aptamers (seq1, seq10, seq7, seqU5, seq3, seq4, seq6, seqU2, and seqU4) with BCM-5, BCM-9A1, and BCM-9A2 peptides was determined in a manner similar to that described above using 500 nM biotinylated BCM-7 aptamers and 500 ng/mL concentration of BCM-7/BCM-5/BCM-9A1/BCM-9A2 peptide.

BCM-7 aptamers (seqU4) were also evaluated for their possible use in development of ELASA method applicable to blood, urine, and β-casein digest. For this purpose, plasma (rat), urine (human), and β-casein digest (bovine) were spiked with BCM-7 peptide (3.2−200 μg/mL). A 15 mL sample of urine was treated with 50 μL (187 U) of urease at room temperature for 1 h to remove urea from urine; β-casein from bovine (sigma) was digested according to Jinsmaa and Yoshikawa protocol.[12] The 50 μL of urine or plasma or β-casein digest, 50 μL binding buffer, and 100 μL, 1/4000 times diluted BCM-7-peroxidase (diluted in binding buffer) were added simultaneously to each well. The 96-well plate was incubated for 90 min at room temperature and then subjected to peroxidase assay as described above.

RESULTS

Selection of Aptamers. An in vitro selection of ssDNA that binds to BCM-7 conjugated to tosyl activated magnetic beads by the SELEX process was conducted. DNA aptamers specific to BCM-7 were selected from a pool of 10^{13} random DNA library. A total of ten SELEX rounds including negative and counter selections made gradual enrichment of oligonucleotides. The percentage of ssDNA binding to BCM-7 from DNA pool was significantly increased with increasing the SELEX rounds. Before the fifth round of selection, the negative selection was performed by using magnetic beads. BCM-5, BCM-9A1, and BCM-9A2 counter selector peptides were used after SELEX round number 5, 6, and 7 respectively. The negative and counter selections were used to improve the specificity of aptamers for BCM-7. Sequences of inserts from 41 independent clones revealed a total of 15 different aptamers. Out of 15 aptamers, seq10, seq1, seqU1, seqU3, seqU4, seq7, and seq4 were present in 10, 6, 5, 4, 3, 3, and 2 of the independent clones, respectively (Table 2), indicating enrichment of aptamers. Thirteen aptamers were 72 nt long, and the remaining two aptamers (seq6 and seq9) were 71 nt long. Seq9 and seq10 aptamers have one base difference as seq9 lacked guanosine base at the 43rd position. Loss of one nucleotide in 71 nt long aptamer can happen during PCR amplification.

Dissociation Constant and Binding Selectivity Study of BCM-7 Specific Aptamers. The dissociation constant values of BCM-7 aptamers were in the range of 7.69−156.66 nM. Seq6 showed the lowest dissociation constant value (7.69 nM), while seq8 showed the highest value (156.66 nM) (Table 2).

Binding selectivity of nine aptamers, viz., seq1, seq10, seq7, seqU5, seq3, seq4, seq6, seqU2, and seqU4, toward BCM-7, BCM-9A1, and BCM-9A2 peptides was evaluated. In general, the binding of fluorescent labeled aptamers to BCM-7 was generally higher in comparison to BCM-9A1 or BCM-9A2 (Figure 1). Aptamers seq10, seqU5, seq4, seq6, seqU2, and seqU4 bind to a similar extent to BCM-9A1 and BCM-9A2. However, seq7 and seq3 aptamers cross-reacted preferably to BCM-9A1. Also, seq10, seq7, seqU5, and seqU4 aptamers exhibited lower cross-reaction with BCM-9A1 and BCM-9A2 (Figure 1).

Predicted Secondary Structure of BCM-7 Aptamers. Secondary structure of the selected aptamers was predicted by online program Mfold. Five structural motifs common in at least two aptamers were obtained by Mfold software (Figure 2 and Supporting Information). The selected aptamers were classified into six groups based on presence or absence of motifs (Table 3). Nine aptamers showed one common motif with at least one aptamer. The remaining six aptamers had no common motifs and hence were grouped in group 6. These motifs are present in the form of loops which are predominantly created by G-C linkage. For several aptamers, more than one Mfold structure were predicted. There are four aptamers in group 1, three aptamers in group 2, and two aptamers each in groups 3, 4, and 5. The remaining six aptamers which lacked conserved motif structure were grouped in group 6.

Recognition of BCM-7 by Aptamer-Coated Gold Nanoparticles. Selected aptamers from Mfold groups (seqU4, seq1, seqU5, seq10, seqU2, and seq7) were evaluated for their recognition at different concentrations of BCM-7 ranging from 1 to 30 μg/mL. The visible color change (pink to purple) in GNP was noted at 10−30 μg/mL concentration of

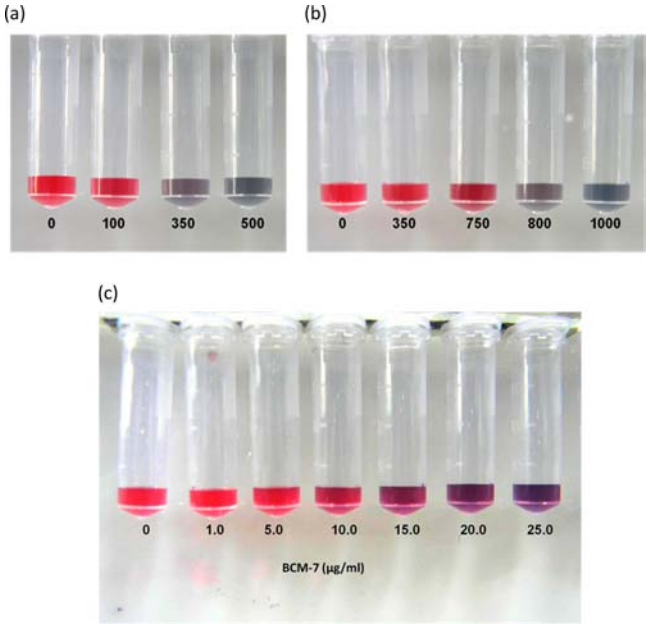

Figure 3. Color change in gold nanoparticles (GNPs): (a) NaCl addition at indicated concentrations (mM) to GNPs, (b) NaCl addition at indicated concentrations in mM to GNPs conjugated to aptamer (seqU4), and (c) color change in GNPs conjugated with aptamer (seqU4) on incubation with different concentrations (μg/mL) of BCM-7 and 350 mM NaCl.

aptamers (seq1, seq7, seq10, seqU4, and seqU5) was allowed to bind to the plate using biotin−avidin interaction. BCM-7 and BCM-7 peroxidase conjugate competed for limited amount of aptamer. There was an inverse relationship between peroxidase activity and BCM-7 concentration. The IC_{50} value was 250 ng/mL for BCM-7 (Figure 4a).

Cross recognition of selected nine aptamers to BCM-5, BCM-9A1, and BCM-9A2 peptides was also checked. In a 96-well plate format, BCM-7-peroxidase competed with BCM-5, BCM-7, BCM-9A1, or BCM-9A2. The extent of binding of these peptides is reflected in the extent of the drop in absorbance. For example, seqU5 aptamer has failed to recognize all the peptides including BCM-7. Seq7 has cross reacted with BCM-5, BCM-9A1, and BCM-9A2. Seq3, seq4, seq6, and seqU4 have shown lower cross-recognition among the nine aptamers tested (Figure 4b).

The ELASA method was used to evaluate whether aptamers could recognize spiked BCM-7 in biological fluids. Urine contains urea which may interfere in recognition of BCM-7 by aptamer; therefore, the urine sample was treated with urease before its use in ELASA. BCM-7-peroxidase competed with spiked BCM-7 present in urine, plasma, and β-casein digest samples as indicated by lowered absorbance with increasing concentration of BCM-7 (Figure 5). Results also suggest that some component of urine and plasma interferes in the assay (see absorbance value in corresponding control and blank samples) (Figure 5).

DISCUSSION

BCM-7 has been linked with certain noncommunicable diseases such as type I diabetes, coronary heart disease, schizophrenia, and autism; suitable ligands which can recognize BCM-7 are required for method development. This paper describes in vitro selection of aptamers that bind to BCM-7 with high affinity. Out of 15 aptamers, five aptamers are generated with forward primer while ten aptamers start with reverse primer. This

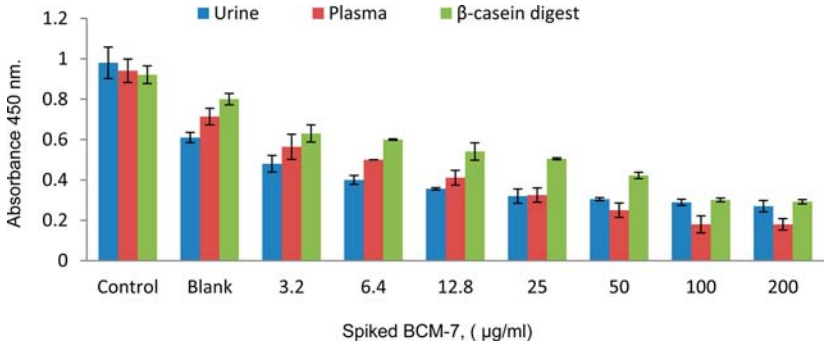

Figure 5. ELASA for BCM-7 in urine, plasma, and β-casein digest. "Control" and "blank" represent peroxidase activity in the absence of BCM-7 in binding buffer, urine, plasma, or β-casein digest, respectively.

clearly indicates that λ exonuclease was not able to fully digest the dsDNA. Available protocol for digestion of dsDNA by λ exonuclease requires prior purification of PCR product. However, there is a loss in yield that occurs during purification. In the present work, PCR product was digested with λ exonuclease without prior purification. This results in incomplete digestion. In fact, 13% dsDNA (GelQuant software) was found in DNA-digest by λ exonuclease, based on the intensity of dsDNA and ssDNA bands after their separation on agarose gel electrophoresis. Thus, the remaining dsDNA was converted to ssDNA by snap cool method.

The mean K_d values of forward strand aptamer (mean K_d = 42.0 nM) and reverse strand aptamers (mean K_d = 50.2 nM) suggest that both groups of aptamers have similar binding affinity for the target. The K_d values of repeat-aptamers were also compared with those of nonrepeat aptamers, and it was found that the mean K_d values of repeat-aptamers (mean K_d = 42.0 nM) were similar to that of nonrepeat aptamers (mean K_d = 49.5 nM).

Nine aptamers (seq1, seq10, seq7, seqU5, seq3, seq4, seq6, seqU2, and seqU4) were used for comparing their specificity in two different experimental designs (Figures 1 and 4b). The results suggest that the extent of cross reaction of aptamers with BCM-9A1 and BCM-9A2 was not similar and was dependent on the experimental format used. In one format, aptamer was labeled with 6-carboxyfluorescein, while in the other format, aptamers were labeled with biotin. Thus, it appears that modification of the aptamer with a label might result in structural changes which effect recognition of BCM-7 and cross reaction with BCM-9A1 and BCM-9A2. Also, it is to be noted that in the ELASA method aptamers are in an immobilized form, whereas in other experimental deigns using magnetic beads (binding selectivity), aptamers remain in the free form.

Gold nanoparticles (GNPs), a colorimetric-based method, was used to establish proof of principle of recognition of BCM-7 by aptamers. The aptamer-coated gold nanoparticles exhibited stability toward NaCl higher than that of naked GNPs. The enhanced stability is an indication of coating of aptamer on GNP surface because this results in enhanced negative charge on GNPs. Because of high affinity of aptamer for BCM-7, the later is removed from GNPs surface. Such GNPs lack enhanced stability and aggregate at lower NaCl concentration.

BCM-7-peroxidase competed with BCM-7 in spiked biological fluids in ELASA, suggesting that aptamers can work in the 96-well format. However, it appears that some component of urine and plasma interferes in the assay. Even the ELISA base method for assaying BCM-7 from urine requires prior extraction for determination of BCM-7 concentration.[15]

addition method is also not yet present in the literature. It works when the calibration graph was formed after the equivalent point because of dynamic quenching with excess iron(III) ions.

MATERIALS AND METHODS

Instrumentation. A PerkinElmer UV−vis dpectrophotometer and a PTI spectrofluorometer (QM 2006 model) were used to measure absorbance and fluorescence intensity, respectively. The excitation wavelength was 375 nm, and fluorescence emission spectra were recorded in the range of 400−650 nm with a slit width of 1.0 nm. A Jenway 3040 ion analyzer was used to measure the pH of the solutions.

Reagents. In all analytical measurements, pipets and vessels kept in dilute nitric acid at least overnight and subsequently washed three times with distilled water were used. Analytical grade chemicals and solvents were purchased from Merck (Darmstadt, Germany) and Fluka (Buch, Swetzerland). Stock solutions (1000 mg/L) of metal cations were prepared by dissolving an appropriate amount of nitrate salts in deionized water. Working standard solutions were obtained by appropriate dilution of these stock standard solutions. The buffer solutions (AVS Titrinorm, Merck Certipur) were purchased from Merck. Sandy soil standard (CRM-SA-C) was supplied from High-Purity Standards, Inc., and Mixed Polish Herbs standard (INCT-MPH-2) from Institute of Nuclear Chemistry and Technology. 2-(4-Fluorophenyl)-3-hydroxy-2,3-dihydroquinoline-4(1*H*)-one (Figure S1, Supporting Information) was prepared according to the literature. The synthetic procedure is described in the Supporting Information. A 2.6×10^{-3} mol/L solution of this compound was prepared by dissolving the appropriate amount of this ligand in 100 mL of methanol and was kept in a refrigerator at 4 °C for 1 week.

Samples. All food samples were purchased from local supermarkets and iron tablets from pharmacies in Trabzon, Turkey. The streamwater sample was collected from Değirmendere in Trabzon and was filtered through a 0.45 mm cellulose nitrate membrane. The vegetable samples were washed thoroughly with tap water and deionized water. Then, the samples were dried at 105 °C for 24 h and ground. Digestion of the dried samples (0.5 g) was carried out using 6.0 mL of HNO_3 and 2.0 mL of H_2O_2, and digestion of standard reference materials (0.5 g) was carried out using 1.5 mL of HNO_3, 4.5 mL of HCl, 1.0 mL of HF, and 2.0 mL of H_2O_2 in a closed microwave digestion system. After the microwave digestion process, the solutions were filtered through a 0.45 mm cellulose nitrate membrane and evaporated. Then, the volume was completed to 25 mL with deionized water. To digest the dried iron tablets, one iron tablet was dissolved in 60 mL of deionized water using an ultrasonic bath. Then, the temperature was set to 200 °C on the hot plate, and 3 mL of HNO_3 was added gradually. The solutions were filtered through a 0.45 mm cellulose nitrate membrane, and the final volume was completed to 25 mL with deionized water.

Optimum Conditions. Some parameters of the proposed method, such as solvent and concentration of ligand, solution pH, complexation time, and constant iron(III) concentration, were optimized. DMF, acetonitrile, THF, ethanol, and methanol were tested as a ligand solvent. Among these solvents, methanol was preferred because it is cheap and has high fluorescence intensity. A series of buffer solutions (pH from 2 to 10) was used to optimize solution pH. pH 7 was suitable for the study because of the high fluorescence intensity of the solution at this pH. Only 4 min was enough for complexation. Various constant iron(III) concentrations (0.2−3.0 mg/L) were tested to obtain accurate results with modified standard addition method. The optimum constant iron(III) concentration was 1.0 mg/L.

Proposed Method. The proposed method is based on fluorescence quenching of an azaflavanon-3-ol compound, which has been recently reported in the literature, with the iron(III) ion. A modified standard addition method was used to determine the iron content of food samples. Just like a standard addition method, it has not been reported in the literature according to our knowledge. One more tube (first tube) was used in this method. A certain amount of analyte and ligand was added to all tubes and the first tube. A certain amount of sample was added to all tubes, except for the first tube. The fluorescence intensities of the first tube containing the blank solution and the second tube and the slope of the calibration graph were used to calculate iron(III) concentration. The iron(III) complex has a lower fluorescence intensity compared to the free azaflavanon-3-ol ligand. After the iron(III) complex is formed, excess iron(III) ion (quencher) causes dynamic quenching of the complex, which is regular for increasing iron(III) concentration between 2.4 and 21.6 mg/L, and it is used to determine the iron content of the sample.

The modified standard addition method was used to determine the iron concentration in all samples. A constant amount of iron(III) (1 mg/L), 2 mL of ligand (1.3×10^{-5} M), and an aliquot sample solution were added to all tubes. Only the sample was not added to the first tube. Therefore, a blank solution without the sample in the first tube was prepared. Increasing amounts of iron were added to the third and next tubes. The pH of all solutions was set to 7 with citric acid buffer before the final volume was completed to 4 mL. Fluorescence intensity was measured at 503 nm for all solutions. The iron(III) concentration was calculated from eq 1

$$C_x = (F_0 - F_1)/m \quad (1)$$

where C_x is the iron concentration of the sample in the tubes, F_0 and F_1 are the fluorescence intensities of the first and second tubes, respectively, and m is the slope of the standard addition graph. According to this type of standard addition procedure, the difference between F_0 and F_1 is related to the iron concentration of the sample in the tubes. Figure S2 (Supporting Information) shows the standard addition graph for the determination of iron (2.5 mg/L) in spinach.

RESULTS AND DISCUSSION

When the ligand is excited at 375 nm, it gives a maximum emission band at 503 nm. Excitation and emission spectra of the ligand are given in Figure S3 (Supporting Information). Figure S4 (Supporting Information) shows the effects of Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Al^{3+}, Sn^{2+}, Pb^{2+}, Cr^{3+}, Mn^{2+}, Fe^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Ag^+, Zn^{2+}, Cd^{2+}, and Hg^{2+} ions (1.3×10^{-4} M) on the fluorescence spectra of the ligand (1.3×10^{-5} M). As can be seen from Figure S4, there are moderate changes in the fluorescence intensity of the ligand for many ions, except for Fe^{2+} and Fe^{3+} ions. Al^{3+} causes a small shift in fluorescence spectra to short wavelength. However, spectrofluorometric titrations showed that there is no regular change for fluorescence intensity with increasing aluminum concentrations. In contrast, increasing Fe^{2+} and Fe^{3+} concentrations cause quenching on the fluorescence intensity of the ligand at 503 nm. Because the samples were digested in acidic media, iron(II) was oxidized to iron(III), and the method was based on quenching of the iron(III) ion.

Effect of pH. The effect of pH on the fluorescence intensity of the solution containing equivalent ligand and iron(III) (1.3×10^{-5} M) is shown in Figure S5 (Supporting Information). Citric acid−sodium hydroxide−hydrochloric acid, acetic acid−ammonium acetate, citric acid−sodium hydroxide, HEPES, and boric acid−sodium hydroxide−hydrochloric acid buffers were tested to set the pH of the solutions. As seen from Figure S5, the fluorescence intensity was satisfactorily high and nearly the same between pH 6 and 8. Iron determination was carried out with a variety of buffer solutions. The lowest relative error percent for the standard iron(III) solution was obtained for the citric acid buffer solution (pH 7). Therefore, this buffer solution was used for iron determination.

Effect of Reagent Concentration. To determine optimum reagent concentration, spectrofluorometric titrations were performed by using solutions of the ligand in the range from 5.0×10^{-5} to 2.6×10^{-6} M. The values of fluorescence intensity at 503 nm were plotted against the iron(III) concentration.

DOI: 10.1021/jf505336d
J. Agric. Food Chem. 2015, 63, 2654−2659

When 1.3×10^{-5} M ligand concentration was used, the highest R^2 value (0.9949) was obtained. Therefore, further studies were carried out at this concentration.

Effect of Constant Iron Concentration. The constant iron(III) concentration used in the modified standard addition method was optimized by changing from 0.2 to 3.0 mg/L. Measurements were carried out in Sandy Soil C and iron tablet 1 for 2.5 mg/L iron(III) concentration, and the results are shown in Table S1 (Supporting Information). As seen from Table S1, the low relative errors were 1.5 and 1.1% for 1 mg/L in the case of Sandy Soil C and iron tablet 1, respectively. Between constant iron concentrations of 1.3 and 2.0 mg/L, the RE% values were below 2.5. However, the lower concentration (1 mg/L) was preferred as the constant iron concentration.

Time before Measurement. The emission spectrum of the mixture containing an equivalent amount of iron(III) and the ligand (1.3×10^{-5} M) was obtained in the range of 1−15 min. It was seen that the fluorescence intensity did not change after 1 min (Figure S6, Supporting Information). There was very little change in the fluorescence intensity from 1.0 until 15 min, which means that a few minutes before the measurements was enough.

Composition and Stability of the Complex. The Job method was used to investigate the nature of the complex in methanol/water (1:1). The concentration of ligand and iron(III) was 2.6×10^{-6} M, and total solution volume was 4 mL. As seen from Figure S7 (Supporting Information), the plot of fluorescence intensity versus the ligand volume showed a break point at 2 mL, indicating that complex composition was 1:1. The conditional formation constant (log K ± standard deviation), calculated according to a known method[31] using the spectrofluorometric titration data ($N = 3$), was found to be 3.40 ± 0.09.

Effect of Foreign Ions. The potential interference due to common coexisting ions encountered in a natural sample was tested by adding these ions to the solution containing the equivalent ligand and iron(III) (1.3×10^{-5} M). The fluorescence intensity of the solution was compared with that of the solution containing only the ligand and iron(III). The tolerance limit was recognized at ±5% difference in the analytical signals. Ions Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Al^{3+}, Cr^{3+}, Sn^{2+}, Pb^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, Cd^{2+}, Hg^{2+}, Ag^+, Cu^{2+}, Mn^{2+},OH^-, $C_2O_4^{2-}$, CO_3^{2-}, SO_4^{2-}, $S_2O_7^{2-}$, $Cr_2O_7^{2-}$, CrO_4^{2}, HCO_3^-, HSO_4^-, $H_2PO_4^-$, CN^-, SCN^-, HSO_4^-, F^-, Cl^-, Br^-, I^-, and CH_3COO^- were examined. As seen from Table S2 (Supporting Information), the effect of the tested foreign ions is negligible.

Quenching Mechanism. The Stern−Volmer relationship[32] (eq 2) expresses the efficiency of quenching of a fluorophore by a quencher.

$$F_0/F = 1 + K_{SV}[Q] \quad (2)$$

F_0 and F are the fluorescence intensities in the absence and presence of the quencher, respectively. K_{SV} is the Stern−Volmer quenching constant, and [Q] is the concentration of the quencher. If a system obeys the Stern−Volmer equation, a plot of F_0/F versus [Q] will give a straight line with a slope of K_{SV} and a y-axis intercept of 1. However, a positive deviation may be observed in the Stern−Volmer graph above a certain quencher concentration. In this case, both dynamic and static quenchings are efficient in the system.[33]

Figure S8 (Supporting Information) shows the Stern−Volmer plot of the iron(III)−ligand system. As seen from Figure S8, the F_0/F term linearly increased with increasing iron(III) concentration until 4×10^{-4} M, after which a positive deviation was observed. This result shows that both static and dynamic quenching exist in the system. As known, static quenching requires a ground state complex and is distinguished from dynamic quenching with temperature effect.[23] Dynamic quenching is a kind of collisional quenching, and quenching efficiency increases with increasing temperature. The inset of Figure S8 shows the temperature effect on fluorescence efficiency (F_0/F). As seen from the Figure S8 inset, the quenching efficiency does not increase with increasing temperature. Conversely, the lower fluorescence efficiency is observed when the temperature increases from 298 to 333 K. Therefore, it may be concluded from the consideration of Figure S8 that static quenching, proving a formation of complex between ligand and iron(III) ion, is effective in the fluorescence quenching.

Analytical Performance. An external calibration line based on fluorescence quenching of the 1.3×10^{-5} M ligand showed linearity within the concentration range of 1.4−21.6 mg/L. However, accuracy was not good in iron determination in samples using the external calibration graph. Because of this, a modified standard addition method was used in iron determination. The analytical performance data for the developed method under the optimized conditions are presented in Table S3 (Supporting Information).

The data given in Table S3 indicate that a linear relationship was found between the fluorescence intensity at 503 nm and the concentration of the iron(III) in the range of 2.4−21.6 mg/L. The correlation coefficient was 0.9949, indicating good linearity.

Table 1. Determination of Iron in Two Reference Materials ($N = 3$)

sample	found value	RSD%	certified value
Sandy Soil C	13.9	1.96	13.9
Mixed Polish Herbs	0.45	1.38	0.46

Table 5. Analytical and Operational Parameters of the Proposed Method and Previously Reported Methods Based on Spectrofluorometry and Atomic Spectrometry

reagent, method	sample	sample preparation	procedures before measurement	pH	linear range (mg/L)	LOD (mg/L)	ref
2-(4-fluorophenyl)-3-hydroxy-2,3-dihydroquinoline-4(1*H*)-one, SF	rocket, dill, mint, spinach, purslane, red lentils, dry beans, and iron medicinal tablets	microwave-assisted digestion for food samples for about 20 min, wet digestion for iron medicinal tablets	modified standard addition method, waiting only 1−2 min before the measurement	7	2.40−2.60	0.81	PM
5-(8-hydroxy-2-quinolinylmethyl)-2,8-dithia-5-aza-2,6-pyridinophane, SF	rice, spinach, different water samples	left at 500 °C for 2 h, dissolving in nitric acid, dilution with an acetate buffer	preparation of a film, waiting >20 min to soak in buffer solution, and 5 min for fluorescence stability	5.5	33.6−0.006	0.0028	29
2-(2-hydroxyphenyl)-4(3*H*)-quinazolinone, SF	multivitamin tablets	dissolvied in aqua regia, heated to dryness, dilution to 10 mL with NaOAc−HOAc	preparation of an optode membrane and dried for 24 h before being used	2.5−4.5	0.04−7.80	0.005	26
2-pyridinecarbaldehyde−phenylenedihydrazone, SF	milk powder and jasmine tea	incineration for 270 and 60 min at 500 °C, for milk powder and jasmine tea, respectively	waiting 30 min for fluorescence stability	4.6	0.03−0.56	0.02	27
4-hydroxyquinoline, SF	bovine liver	acidic digestion	masking with KF, waiting 20 min for fluorescence stability		0.28−0.56	0.168	28
5-hydroxy-4-ethyl-5,6-dipyridin-2-yl-4,5-dihydro-2*H*-[1,2,4]-triazine-3-thione, FAAS	macaroni, wheat, flour, and some water samples	for food samples, dissolving concentrated HNO_3 and evaporation to dryness, oxidation with H_2O_2	SPE with the impregnated Amberlite XAD-16 resin, waiting for saturation for 2 h with the ligand solution, PF: 25	5.0		0.00459	11
zirconium(IV) hydroxide, FAAS	natural waters, coffee, fish, tobacco, black and green tea	digestion in microwave system for 26 min	coprecipitation with zirconium(IV), centrifugation for 15 min, dissolving the precipitate with 1 mL of concentrated HNO_3, PF: 25	8.0	0.25−5.0	0.00153	13
dimethyl (*E*)-2-[(*Z*)-1-acetyl)-2-hydroxy-1-propenyl]-2-butenedioate, FAAS	river water, rainwater, drinking water, and powdered milk	powdered milk charring at 300 °C for an hour, turned into ash overnight until becoming a grayish white color	extraction with modified octadecyl silica membrane disk using a vacuum, stripping iron(III) from the disk with EDTA solution, PF: 166	2.5	0.0400−1.0	0.0028	10
ammonium pyrolidine−dithiocarbamate−Chromosorb 102, $Ce(OH)_4$, FAAS or GFAAS	baking soda and baking powder samples	dissolving in a mixture of concentrated HNO_3 and distilled water before neutralization with NH_3	SPE with APDC-Chromosorb 102 and coprecipitation with $Ce(OH)_4$, PE: NA	6.00, 10.5	N.A	0.26, 0.12	12
8-oxyquinoline, FAAS	natural and mineral waters	complexation with 8-oxyquinoline solution	extraction of the complex to chloroform for 2 min	5.0	0.1−4.0	0.1	9

J. Agric. Food Chem. 2015, 63, 2654−2659
DOI: 10.1021/jf505336d

The LOD ($3 \times S_d/m$) and LOQ ($9 \times S_d/m$) were determined using the standard deviation of 11 measurements of the blank response (S_d) and the slope of the calibration line (m) according to IUPAC recommendations.

Accuracy. The accuracy of the proposed method was verified by analyzing two standard reference materials (CRM-SA-C Sandy Soil C and Mixed Polish Herbs INCT-MPH-2). A good agreement was found between obtained values and certified values (Table 1). Statistical analysis of the results using Student's t test shows no significant difference between obtained values and certified values. The calculated Student's t value (3.48) was less than the theoretical value (4.30) at a confidence level of 95%.

The food samples and two iron tablets were analyzed according to a modified standard addition method. Analysis of the same food samples was carried out by using a standard ICP-OES method, whereas standard NMKL 161 method was used to analyze iron tablets. The results are given in Tables 2 and 3. Statistical analysis of the results using Student's t test showed no significant difference between the results.

The accuracy was also tested by using a standard addition technique. The modified standard addition method was applied to a streamwater sample (Değirmendere, Trabzon) spiked at three iron(III) concentration levels, and recoveries between 98.9 and 99.6% were obtained (Table 4). The results showed that the proposed method can be applied for the determination of iron in foods, iron tablets, and water samples.

Comparison with Other Methods. A comparison of the analytical and operational parameters of the spectrofluorometric and atomic methods that are already present in the literature and the proposed method for the determination of Fe(III) is given in Table 5. Compared to previous methods, the proposed method is relatively time-saving and simpler.[10−13,26−29] Lower detection limits could be obtained by some atomic methods.[10,11,13] However, as seen from Table 5, time-consuming solid phase extraction and coprecipitation methods have been applied to separation and preconcentration of iron(III) ion in these studies. The preconcentration factors (PF) are given for these atomic methods in Table 5. Detection limits of some spectrofluorometric methods are also lower than the proposed method. However, sample preparation and treatment of these methods are more time-consuming than those of the proposed method (Table 5).

Advantages of the Proposed Method. The proposed method can be applied to various food samples and iron medicinal tablets. Sample digestion carried out in 20 min in a closed microwave system is not time-consuming compared with many methods in the literature (Table 5). There is no need either for the separation of iron(III) ion from sample solution or sample treatment stage before the measurement. A modified standard addition method handles probable matrix effects. A time of 1−2 min was sufficient before measurement to obtain a stable fluorescence response. Thus, this property of the proposed method is one of its advantages when compared to others (Table 5). The recovery studies showed that the proposed method can also be applied to water samples having proper iron(III) concentrations. Moreover, the used reagent is a kind of flavonoid compound. Flavonoids are known as useful compounds for the human body. In this context, it can be thought that the reagent is environmentally friendly. Spectrofluorometric methods are much cheaper compared with atomic methods. Consequently, these advantages make the proposed method time-saving, simple, and economic compared to several other methods in the literature.

Action.[13] This protocol was integrated with a simulation of the final intestinal degradation step using porcine jejunal brush border membrane (BBM) vesicles.

MATERIALS AND METHODS

Chemicals. Enzymes used for in vitro human digestion were purchased from Sigma (St Louis, MO, USA) in line with those indicated by the Infogest protocol.[13] Urea, DTT, 2-(N-morpholino)ethanesulfonic acid (MES), Tris-HCl, *p*-toluene-sulfonyl-L-arginine methyl ester (TAME), sodium phosphate, ammonium bicarbonate, acetic acid, sulfosalicylic acid, trichloroacetic acid (TCA) and modified Lowry assay kit were from Sigma-Aldrich as well. Egg lecithin was from Lipid Products (Redhill UK). HPLC-grade solvents were from Merck (Whitehouse Station, NJ, USA). Electrophoresis reagents were all from Invitrogen (Carlsbad, CA, USA).

Pasta Cooking. A sample of a commercial brand of pasta (spaghetti type, 100% durum wheat semolina) was processed according to Hoebler et al.[14] Pasta (100 g) was cooked in 1.0 L of water (tap water) containing 3.5 g of NaCl for 10 min.

Whole Protein Extraction. An aliquot of raw pasta and cooked (undigested) pasta was ground, and whole protein was extracted twice in 1 mL of 7 M urea, 80 mmol/L Tris-HCl, pH 7.5, under magnetic stirring overnight at 4 °C. The sample was centrifuged at 10 000 g for 20 min. The surnatant was collected and desalted with Econo-Pac 10 DG columns (Biorad, Milan, Italy), eluting with 25 mmol/L ammonium bicarbonate. A modified Lowry method assay determined a protein concentration of 6.42 and 3.76 mg/mL for raw pasta and cooked pasta, respectively. Finally, samples were lyophilized and stored at −20 °C.

In Vitro Human Digestion. After cooking, the pasta was immediately subjected to in vitro simulated human digestion using the static model system as developed in the framework of the Infogest COST Action.[13] Simulated salivary fluid (SSF), simulated gastric fluid (SGF), and simulated intestinal fluid (SIF) were prepared according to the harmonized conditions.[13]

Oral Phase. Mastication was simulated by using a common manual mincer. A 5 g quantity of cooked pasta was mixed with 5 mL of SSF and minced for 2 min. SSF included 1500 U mL^{-1} of human salivary amylase.

Gastric Phase. The oral digesta was mixed with SGF (50:50 v/v); to this mixture was added gastric liposome (egg lecithin prepared in a vesicular form) up to a 0.17 mmol/L final concentration, 2000 U/mL of SGF porcine pepsin, and 80U/mL of SGF fungal lipase. The pH of the digesta was adjusted to 3, and the incubation was carried out for 2 h in a shaking incubator at 37 °C and 170 rpm. Samples were collected at different times (0, 30, 60, 90, and 120 min); the reaction was stopped by raising the pH to 7.0. Proteolysis was monitored by SDS-PAGE analysis.

Duodenal Phase. Gastric digesta (50:50 v/v) was added to the SIF containing 10 mmol/L bile salts (5 mmol/L sodium taurocholate, 5 mmol/L sodium glycodeoxycholate, and 1.8 mmol/L egg lecithin final concentration) and pancreatin. The amount of pancreatin added was calculated on the basis of the measured activity of trypsin, up to 100 U of trypsin/mL final volume. Trypsin activity was determined by TAME assay.[15] Each sample was incubated for 2 h in a shaking incubator at 37 °C. Aliquots were collected at different times (0, 5, 15, 30, 60, 90, and 120 min). The reaction was stopped by raising the pH to 10, and digestion was monitored by SDS-PAGE analysis.

Intestinal Brush Border Membrane Digestion. BBM enzymes (650 mU/mg) were obtained from pig jejunum according to the method described by Shirazi-Beechey et al.[16] Triplicate aliquots of each sample after duodenal digestion were diluted 2-fold with 0.1 mol/L sodium phosphate buffer, pH-adjusted to 7.2, and incubated for up to 4 h after BBM supplementation; the reaction was stopped by heating for 5 min in a boiling-water bath. Each sample (aliquots of 1 mL) was then chromatographed using an Econo-Pac 10 DG size-exclusion-chromatography (SEC) prepacked column (Bio-Rad Laboratories, Hercules, CA, USA) by eluting with 25 mmol/L Tris−HCl, pH 7.0, to separate the protein from the low MW peptide fraction. Effluents were collected in fractions of 1 mL and monitored by UV absorbance at 280 nm (Ultrospec 2100 pro, Amersham Biosciences). The peptide fractions (M_r < 6 kDa) were pooled and further desalted using Sep-Pak C18 prepacked cartridges (Waters, Milford, MA, USA), washed with aqueous 0.1% TFA (v/v), and eluted with 70% ACN (v/v)/0.1% TFA (v/v).

Analysis of Protein Recovered from the Pasta Cooking Water. After the pasta was cooked as described above, 250 mL of the cooking water was recovered and dialyzed overnight with a dialysis membrane (molecular weight cutoff = 3 kDa) against 0.1 M acetic acid. The sample was then lyophilized and resuspended in 1 mL of 50 mmol/L Tris-HCl, pH 7.5. The sample was further freed from low MW compounds by filtration through Econo-Pac 10 DG columns (Biorad) and eluted with 25 mmol/L ammonium bicarbonate, pH 8.5.

In Vitro Digestion of Salt Soluble Proteins. Salt-soluble proteins (albumin/globulin) were extracted from raw and cooked undigested pasta, according to the procedure described by Mamone et al.[17] Proteins were then digested by simulating gastric, pancreatic, and BBM in vitro digestion.[18] To confirm the stability of selected wheat albumins/globulins, in this case we used a simplified model of gastrointestinal digestion that minimized the presence of interfering compounds.[17]

SDS-PAGE Analysis. SDS-PAGE was performed on 15% or 4−20%-gradient gels run for 35 min at 200 V in MES buffer. Aliquots (1 mL) of oral−gastric and oral−gastric−duodenal (OGD) digesta were centrifuged at 4000 g for 20 min. The supernatant (75 μL) was with diluted 25 μL of NuPAGE LDS (Invitrogen) sample buffer (4×) containing DTT at a final concentration of 5 mmol/L. The pellet was resuspended in 100 μL NuPAGE LDS sample buffer (1×) containing 5 mmol/L DTT. Samples were heated for 10 min at 70 °C, and 20 μL of each gastric or duodenal fraction, respectively, was loaded into adjacent wells in the gel. Whole proteins (15 μg) extracted from raw and cooked undigested pasta were also run.

The gels were fixed with 50 mL of sulfosalicylic acid/TCA in a 10.5:36 ratio in 300 mL of water for 30 min, washed twice with water, and stained using colloidal Coomassie G250.

The protein bands of interest were excised from the gels with a scalpel, placed in Eppendorf tubes, washed twice with 50 μL of Milli-Q-purified water, and destained with 50 mmol/L ammonium bicarbonate in 50% (v/v) aqueous acetonitrile. The destained gel pieces were dehydrated by submersion in acetonitrile, dried under vacuum, and incubated on ice in 20 μL of 50 mmol/L ammonium bicarbonate containing 12 ng/μL trypsin. Gel pieces were allowed to rehydrate for 45 min. Afterward, the excess of trypsin solution was removed, and the protein bands were incubated overnight at 37°C. The tryptic digests were extracted in 40 μL of 50% acetonitrile/2.5% formic

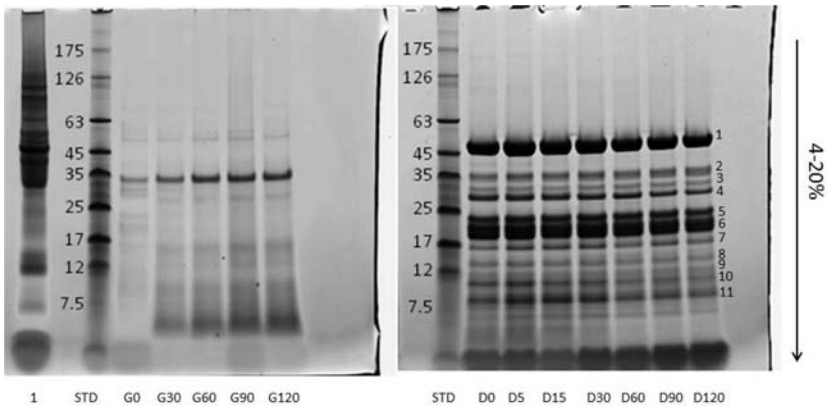

Figure 1. SDS PAGE (4−20%) analysis of gastric (left panel) and pancreatic (right panel) digestion of cooked pasta. MW markers (STD) are indicated on the left-hand side of each gel. Whole proteins from raw pasta were also run (1). The numbers on bottom denote the incubation times in minutes for gastric (G) and duodenal (D) digestion. Bands from D120 were cut and digested with trypsin for proteomic analysis.

acid and concentrated to a tenth of the original volume in a vacuum centrifuge before mass spectrometry analysis.

Western Blot Analysis. The proteins separated by SDS-PAGE (15%) were electroblotted onto nitrocellulose membranes (Transblot nitrocellulose, Bio-Rad) at 120 V for 60 min. The membrane was blocked for 1 h at room temperature using 5% nonfat milk in TBS-T (Tris saline buffer plus 0.05% Tween-20) for 1 h. The membranes were then incubated overnight at 4 °C with pooled sera (n = 8) of celiac subjects (age range = 5−36 years, average age = 24 years) or from healthy individuals (n = 4) as the negative controls, diluted 1/500 in TBS-T. Sera were pooled in order to average the individual variability of the immune response. After washing with TBS-T, monoclonal peroxidase-conjugated antihuman IgA antibody (Sigma) diluted in blocking solution (1/10 000) was applied to the membrane for 2 h at RT. The membrane was extensively rinsed with TBS-T (3 × 10 min) and finally with TBS (1 × 10 min) before development. The immunoreactive bands were detected using a chemiluminescence reagent (ECL Plus, GE Healthcare) and X-ray film (Kodak, Chalons/Saône, France).

Mass Spectrometry Analysis. Nanoflow LC-ESI MS/MS analysis was carried out using an Ultimate 3000 HPLC (Dionex, Sunnydale, CA, USA) instrument coupled to a Q-STAR mass spectrometer (Applied BioSystems, Framingham, USA). The eluents were (A) 5% ACN in 0.1% FA and (B) 80% ACN in 0.08% FA. The peptides were loaded into a C_{18} loading cartridge (LC Packings, USA) and separated with a C_{18} PepMap100 column (15 cm length, 75 μm ID and 300 Å [LC Packings]) using a 5−40% linear gradient of eluent B over 60 min at a constant flow rate of 300 nL/min. LC-MS/MS experiments were performed in the information-dependent acquisition (IDA) mode. The precursor ions were selected using the following MS to MS/MS switch criteria: ion m/z > 400, charge states = 2 to 4, intensity exceeding 15 counts, and ion tolerance of 50.0 mmu; former target ions were excluded for 30 s. CID was used to fragment the multiple-charged ions, and nitrogen was used as the collision gas. The raw spectra files were used to generate text files in Mascot generic file format (.mgf), which were submitted to the Mascot ver. 2.3 (http://www.matrixscience.com) and Batch-tag (Protein Prospector, University of California San Francisco, USA) search engines.

Tryptic peptides from SDS-PAGE bands were identified by Mascot (version 2.3) search engine using the following criteria: databases, NCBI and Uniprot; taxonomy, other green plants; type of search, MS/MS ion search; enzyme, trypsin; fixed modifications, carbamidomethyl; variable modifications, methionine oxidation and pyro-Glu formation through N-terminal loss of ammonia at Gln; mass values, monoisotopic; parent tolerance, 0.08 Da; MS/MS tolerance, 0.15 Da; number of maximum missed cleavages, 1.

Peptides released from OGD and BBM hydrolysis were identified using the Batch-Tag web tool Protein Prospector (http://prospector.ucsf.edu), taxonomically restricting the search to *Triticum*. The same search criteria used above were utilized. The resulting peptide identifications were validated by manual inspection of the MS/MS spectra. The peptide entries were considered identified when the measured molecular weight corresponded to the expected value and a sequence of at least three consecutive b or y ions occurred in the spectrum. For each of the protein/peptide fractions, nanoflow LC−MS/MS analyses were run in triplicate, and only matches occurring in all three analyses were included in the entry list.

RESULTS

Pasta proteins were digested using an in vitro static OGD digestion model that mimics human physiological conditions.[13] The digestion steps were carried out under simulated physiological conditions, including digestive enzymes and their activity as well as pH, lipid, and salt concentrations. Digestion times were selected according to the average transit time of chyme in the respective compartments. A more exhaustive justification of the conditions used is given in Minekus et al.[13] Our model also included an additional step with porcine intestinal BBM hydrolases that simulates peptide degradation at the level of the jejunum.[16] Assessment of the peptide stability relative to treatment with BBM peptidases has already demonstrated in vivo persistence, intended as in vitro−in vivo correspondence, because it supported the discovery of some of the most important determinants of CD.[5,19]

SDS-PAGE Analysis. The kinetics of simulated gastric digestion was assessed by SDS-PAGE (Figure 1). The protein patterns arising from digestion of pasta at 0−120 min were compared to the intact proteins extracted from raw undigested pasta. The pattern of the uncooked sample showed the typical protein components of *Triticum* wheat flour, which can be grouped into HMW-GS (65−90 kDa), ω-gliadins (44−55 kDa), LMW-GS (30−40 kDa), and α/β- and γ-gliadins (30−45 kDa).[20] Bands of albumins/globulins were also detected,

including β-amylase(s) (60 kDa) and alpha-amylase/trypsin inhibitor (ATI) (14−16 kDa).[21]

In cooked pasta at the beginning of gastric digestion, wheat proteins were not detected except for a faint band, most likely because the proteins remained insoluble in the saline buffer or were still embedded in the starchy matrix of pasta (Figure 1, left panel). The main band at 35 kDa was identified as porcine pepsin by LC−MS/MS of tryptic-derived peptides (not shown). Because of its high concentration in SGF, pepsin masked the pasta proteinaceous material with similar molecular weight and interfered with data evaluation. The increased accumulation of low MW polypeptides (7−17 kDa) indicated the progressive degradation of proteins during digestion from 30 to 120 min. These polypeptides were made soluble by the proteolytic action of pepsin on the insoluble parent proteins.

After a 2 h incubation, the simulated gastric digests were subjected to simulated duodenal digestion, and aliquots were sampled over the 0−120 min time course for SDS-PAGE analysis (Figure 1, right panel). The progressive appearance of newly formed LMW polypeptides was the result of extensive hydrolysis by pancreatic enzymes. However, the complex protein pattern generated by the action of porcine pancreatin, used at such a high proteases-to-substrate ratio, could bias the clear detection of the products of digestion.[22]

Identification of Proteins Resistant to OGD Digestion. A proteomic approach was employed for the analysis of the polypeptides that survived the OGD digestion model. The numbered bands of the D120 lane were excised from the gel and selected for proteomic analysis (Figure 1, right panel). Except for the broad band at ∼5 kDa that escaped identification, the protein components were characterized by LC−MS/MS analysis. The list of significant protein hits from the Mascot search is shown in Table 1. No gluten polypeptides were detected, whereas the main bands were from pancreatic enzymes. The occurrence of multiple bands for a single enzyme is most likely due to autolysis or mutual digestion among pancreatin hydrolases. The large relative amount of pancreatin enzymes also complicated the identification of proteins that survived digestion.[22]

Non specific-lipid transfer protein (nsLTP), one of the metabolic proteins (albumins and globulins), was the only wheat-derived gene product identified. Neither any protein belonging to the albumin/globulin fraction nor gluten (gliadin and glutenin) was identified. These results indicated that with the exception of nsLTP the pasta proteins were digested relatively rapidly into small peptides that escaped detection by SDS-PAGE electrophoresis.

Analysis of IgA-Reactive Proteins in OGD Digesta. The immunoreactivity of the OGD digesta against the IgA antibodies in a sera pool of CD patients was assayed (Figure 2). The OGD digesta effluents (both collected at 2 h) were centrifuged, and the resulting soluble and insoluble fractions were run on SDS-PAGE for immunoblotting analysis. The total protein extracted from the cooked pasta before digestion was used as the positive control. The sera pool of healthy subjects did not bind to any band (not shown), confirming the specificity of the immunoreaction. As shown in Figure 2, the major IgA-reactive undigested proteins were detected between 30 and 97 kDa. The soluble gastric digesta (lane 3) showed a main immune-reactive band with an M_r of 45 kDa. Conversely, the distribution of IgA-binding proteins in the insoluble gastric sample (lane 2) was comparable with that of the total protein patterns (lane 1), indicating that the majority of the immunoreactive pasta proteins, in all likelihood composed of the gliadin fraction, were not solubilized and were pelleted by centrifugation. This might be a result of a chemically reversible heat-induced protein aggregation that occurs during pasta processing. Such aggregation can decrease protein solubility in the acidic gastric environment, as previously demonstrated.[23] However, after simulated OGD hydrolysis, only a few faint bands were still detected in both the insoluble (lane 4) and soluble (lane 5) fractions, indicating that the majority of IgA-binding proteins were degraded by pancreatic proteases.

Identification of Pasta-Derived Peptides. To identify the most stable polypeptide sequences and to narrow the list of epitopes that are potentially involved in eliciting immune reactions, it is necessary to consider the action of intestinal BBM enzymes located on the polarized apical surface of the duodenal and jejunal enterocytes. The use of BBM enzymes is a fundamental step in assessing intestinal stability because the BBM enzyme mixture contains a series of endo- and exopeptidases with a range of different cleavage specificities that have significant effects in gradually shortening the surviving OGD peptides into di-, tri-, and oligopeptides as well as free amino acids. The OGD digesta were incubated with BBM enzymes purified from pig intestinal jejunum and then fractionated by SEC, allowing the separation of the large pasta polypeptides from the >6 kDa fraction (here referred to as the "peptide" fraction). The peptide fraction was analyzed via LC−MS/MS followed by software-assisted database searching. A comprehensive list of the 61 peptides surviving the digestion of pasta is reported in Table S1 (Supporting Information). The highest number of peptides arose from the γ-gliadin and LMW-glutenin proteins, which presented several motifs associated with the induction of CD. For instance, QGQGIIQPQQPA, QQPQQPFPQ, and PQQSFPQQQ fragments are generally classified among the main gliadin toxic motifs, commonly indicated as γ-II (or glia-γ30),[24−26] γ-VIIa,[25] and γ-I,[25] respectively.

The peptide α-gli 31−55 (LGQQQPFPPQQPYPQPQPFP-SQQPY), together with its shortened form, namely, α-gli 31−51, were also released in the digesta. This gliadin domain harbors the toxic motifs 31−43 and 44−55.[27] The potential stability of α-gli 31−55 under GI degradation has been already demonstrated in our previous studies.[18,28] The α-gli 56−68 peptide, largely used as a model peptide in CD investigations, was degraded into shorter fragments (i.e., QPFQPQLP and QPFQPQL), with lower immunogenicity compared to their parent peptide.[29,30] A few fragments arising from HMW By8 and Bx7 glutenin were also found, whereas β-amylase peptides were the only nongluten peptides identified. Most likely because of their prompt full digestion, no other peptides deriving from the soluble-protein fraction (albumins and globulins) occurred in detectable amounts. Nevertheless, the possibility that the overabundant amount of gluten-derived peptides suppressed the detection of low-abundance fragments of metabolic proteins can not be ruled out.

A more comprehensive characterization of the peptide fractions was severely challenged by a series of concomitant factors, including the extreme heterogeneity of the parent proteins, the possible heat-induced modifications of proteins, the nontryptic nature of the peptides, and the unpredictable cleavage specificity of protein hydrolysis resulting from the action of a pool of proteases and peptidases. Indeed, the faint MS/MS production of b- and y-series fragments and the abnormally intense internal-fragment ions, combined with the lack of amino acid constraints at the N- and C-terminal position, decreased the identification rate. Thus, although more than 200 peptides with M_r values between 400 and 6000 were detected in the LC−MS/MS chromatogram, two-thirds of these peptides remained unidentified due to low database scores.

Identification of Protein Lost in the Cooking Water. Because nsLTP was the only protein identified in the digested sample, we assumed that salt-soluble proteins might have leached into the water during the cooking process. To track the fate of expected and well-established potential allergens,[31] the proteins released into the cooking water were extracted and analyzed by SDS-PAGE (Figure 3). The protein profile was

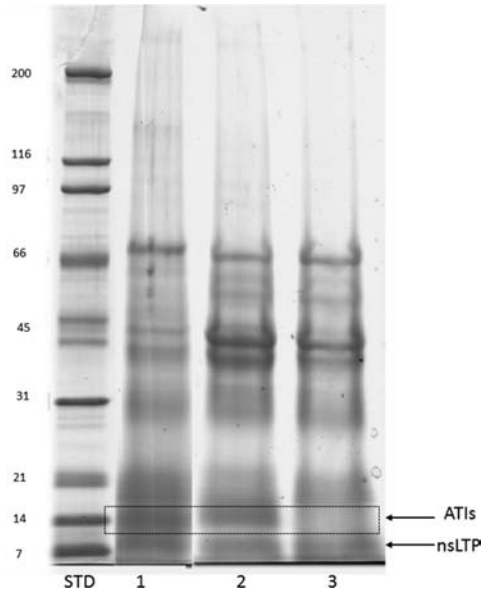

Figure 3. SDS-PAGE (15%) analysis of cooking-water protein (lane 1) and salt-soluble proteins extracted from raw (lane 2) and cooked (lane 3) pasta. MW markers (STD) are on the left. Arrows indicate the region of ATIs and nsLTP. ATIs were identified as ATIs -CM3 (gil 100834), -CM16 (P16851) and -CM2 (gil123956). nsLTP was identified as P16851.

compared to the salt-soluble fractions isolated from the raw and cooked (undigested) pasta. The identity of each polypeptide was assessed by proteomic analysis (not shown). Minor changes were observed among the individual fractions, indicating that only a part of the salt-soluble proteins were dispersed in the water during cooking. The bands at 9 kDa, corresponding to wheat nsLTP, were detected in all samples. A noticeable difference was due to the bands with an estimated M_r of 14 kDa, which were missing in the cooked pasta pattern (lane 3). These proteins, identified as ATI-CM3 (gil100834), -CM16 (P16851), and -CM2 (gil123956) and detected in the raw pasta sample (lane 2), were entirely retrieved in the cooking water (lane 1). This finding may explain why ATIs were not detected in the digesta as either whole proteins or peptides, despite their high abundance in flour and their relative stability to withstand hydrolysis, which is functionally ascribable to their role as protease inhibitors.

To confirm the digestion stability of ATIs, a simulated gastrointestinal digestion was performed specifically on the albumin/globulin fractions extracted from the raw and cooked pasta. In this case, the proteins were digested using a simplified model on a purified fraction[18] to minimize interference from both the matrix and high amount of pancreatin enzymes. SDS-PAGE analysis (Figure 4) showed the complete degradation of the albumins/globulins from raw pasta, with the exception of nsLTP and ATIs that both exhibited high resistance to proteases (lane 3). In contrast, in digested cooked pasta, nsLTP was the only salt-soluble protein still detectable (lane 4), whereas ATIs were no longer detected (lane 4). This experiment confirmed that ATIs, though resistant to digestion,

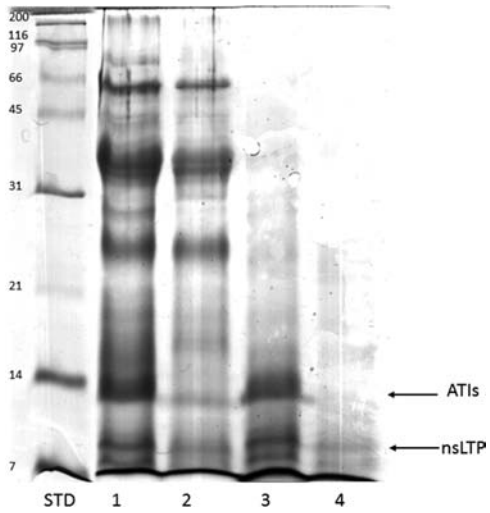

Figure 4. SDS-PAGE (15%) analysis of salt-soluble proteins before and after simulated GI digestion. Lanes 1 and 3, albumin/globulin proteins extracted from raw pasta before and after digestion, respectively. Lanes 2 and 4, albumin/globulin proteins extracted from cooked pasta before and after digestion, respectively. Arrows indicate the region of ATIs and nsLTP proteins. ATIs were identified as ATI-CM3 (gi|100834), -CM16 (P16851), and -CM2 (gi|123956). nsLTP was identified as P16851.

are lost in the cooking water so that nsLTP was the only salt-soluble protein found in the digested pasta (Figure 1).

DISCUSSION

The identification of the (poly)peptides surviving the in vitro model has important biochemical, immunochemical, and potentially allergenic implications. Previous attempts in this sense did not take into account the effect of the matrix in a real-food system,[18,28,32] which is expected to dramatically influence the accessibility of proteins to proteases as well as their susceptibility to hydrolysis, thereby contributing to the determination of the bioaccessibility, and hence the bioavailability, of wheat peptides. Alternatively, simplified digestion models that did not adequately mirror the physiological process of protein hydrolysis have been carried out on several wheat-based systems and may result in a poor in vitro−in vivo correspondence.[12]

In the present study, by accurately mimicking the human physiological conditions, we determined the effect of simulated digestion on proteins from pasta prepared according to ordinary home-cooking conditions. Although proteins are not affected by oral-phase hydrolysis, chewing and the action of human α-amylase are important to shear and break down the starch gel, so making the protein-cleavage sites accessible to proteolysis. However, a consistent pellet, containing particles of undigested pasta, was still evident after gastric digestion. SDS-PAGE and Western blot analysis showed that the majority of wheat proteins were not solubilized in the acidic environment of gastric juice and were resistant to pepsin action. This behavior is related to the heat-induced modifications of the wheat proteins.[7] As demonstrated in previous studies, thermal modifications occurring during industrial dehydration (i.e., up to 110 °C) and domestic cooking processes induce the aggregation of wheat proteins by disulfide bond formation and hydrophobic interactions, which combine with the intrinsically low water solubility of the gluten proteins.[23,33] In support of these data, HPLC analysis was carried out on the ethanol-extracted gliadins before and after cooking the pasta, as shown in Figure S1 (Supporting Information). Ethanol buffer extracts only monomeric gliadins that do not contain covalent cross-links.[3] Before cooking, the gliadin profile was somewhat similar to that of the gliadins extracted from flour, whereas the chromatogram dramatically changed after cooking. In particular, the peaks of ω-gliadins, which do not contain cysteine residues, were practically unaffected by cooking, whereas those relevant to α/β- and γ-gliadins significantly decreased after cooking, suggesting that these proteins underwent massive thermally induced aggregation (Figure S1).

Following the action of duodenal enzymes, the digesta became liquid, though highly viscous, as a result of the partial hydrolysis of starch by pancreatic α-amylase. After 2 h of simulated duodenal digestion, the wheat gluten proteins were almost completely degraded. Western blot analysis showed that few soluble and insoluble IgA-reactive bands resisted OGD digestion. These polypeptides were not identified by proteomic analysis, also as a consequence of the thermally induced protein modifications (i.e cross-linking, Maillard reaction, and deamidation).

The OGD digestion process releases immunologically active peptides that are able to reach the intestinal lumen and trigger immune responses in susceptible individuals. However, before crossing the gut epithelium, the peptides are further hydrolyzed by endo-/exopeptidases of BBM enterocytes, which typically degrade peptides to single amino acids or short di- or tripeptides. Because of their high percentage of proline residues, many gliadin and glutenin peptides are resistant to BBM digestion. The α-gliadin-derived 33-mer peptide, which is considered the most immunogenic and highly BBM-digestion-resistant peptide, was not detected because it is not expressed by *T. durum*, being characteristic of the D genome of *T. aestivum* (soft wheat).[19] However, several peptides containing epitopes that can trigger immune responses in CD patients were identified in the samples resulting from complete digestion. For instance, peptide 31−55, harboring toxic sequences 31−43 and 44−55, was found to be stable to digestion.[18,28] However, the repertoire of the pasta-derived OGD/BBM-digestion-resistant peptides still remains partial, as only approximately one-third of the peptides were clearly identified.

The incomplete identification can be primarily attributed to (i) the formation of high molecular mass peptides not easily detectable with the MS-based approaches, (ii) the incompleteness of wheat protein database annotation, (iii) intrinsic technical challenges, as explained in the Results section, and (iv) the very dynamic range of the components, which limits the identification of low-abundance peptides and is also due to ion-suppression effects. It has to be emphasized that in this research we used a representative commercial brand of pasta. The high genetic polymorphism of wheat cultivars might be a further source of heterogeneity and gluten-derived peptides could diverge to some extent if pasta samples produced with different wheat accession are analyzed.[34]

nsLTP was the only protein virtually unaffected by OGD digestion. This protein can elicit IgE-mediated sensitization in predisposed allergic individuals.[31] Previous reports demonstrated that nsLTP, along with other albumin/globulin proteins, is highly resistant to proteolysis especially those proteins functionally acting as proteases/inhibitors, such as ATIs.[35,36] These latter proteins were not found in cooked pasta because

DOI: 10.1021/jf505461x
J. Agric. Food Chem. 2015, 63, 2660−2667

they were almost completely dispersed in the cooking water. ATIs are known to be the major allergen responsible for baker's asthma.[6] In vitro studies demonstrated that ATIs could also play a major role in triggering the innate immune response in CD. More recently, it has been suggested that ATIs may fuel inflammation and immune reactions in other intestinal and nonintestinal immune disorders, in particular nonceliac gluten sensitivity.[37] This would indicate that pasta, as it is normally prepared, has a lower allergenic potency than raw flour and (probably) bakery products, and should be less toxic for gluten-related disorder patients who show symptoms after eating pasta. This finding is also in line with the results by De Gregorio et al.[7] who observed that the processing of wheat flour decreases the allergenic potency of the major salt-soluble wheat proteins (IgE-binding capacity) in the resulting food products.

In conclusion, we demonstrated that the proteins from cooked pasta are completely hydrolyzed during in vitro digestion, releasing gliadin and glutenin peptides that contain amino acid sequences harmful to CD patients. Among the wheat IgE allergens, nsLTP is highly resistant to both cooking and hydrolysis, whereas important allergen proteins such as ATIs are lost during pasta cooking.

The application of the harmonized static digestion model that mimics in vivo physiology provided new insights for establishing the evolution of wheat proteins during pasta processing, cooking, and digestion in humans. Thus, we also provide insights into the possible immunological implications and the possible effects of gluten resistant epitopes on human health.

Aspergillus niger, 300 AGU/g) were from Novozymes, Bagsvaerd, Denmark. The complex carbohydrase mixture Driselase (from Basidiomycetes), coniferaldehyde, sinapaldehyde, *p*-coumaric acid, borohydride exchange resin (2.5−5.0 mmol BH_4^-/g resin), acetyl bromide, diisobutylaluminum hydride, and the deuterated solvents were from Sigma-Aldrich, St. Louis, MO. Acetic anhydride, NaOH, NH_4Cl, Na_2HPO_4, NaH_2PO_4, and ethyl acetate were from Roth, Karlsruhe, Germany. Pyridine, glacial acetic acid, $MgSO_4$, HCl, methanol, dichloromethane, petroleum ether, *n*-hexane, 1,4-dioxane, ethanol, and acetone were obtained from VWR, Radnor, PA.

General. NMR analyses were performed on a Bruker (Rheinstetten, Germany) 250 MHz spectrometer using acetone-d_6 as solvent. NMR data of synthesized monolignols and their precursors were compared to those described in the lignin model database.[12] Solid-phase extraction (SPE) columns (Discovery, LC-SI, 500 mg/3 mL) were purchased from Supelco, Bellefonte, PA and Phenomenex, Torrance, CA (STRATA-X, polymeric reversed phase, 200 mg/3 mL). Filter papers were obtained from Macherey & Nagel, Düren, Germany (4−12 μm), and Roth, Karlsruhe, Germany (12−15 μm). GC analyses were carried out on a Shimadzu (Kyoto, Japan) GC-MS system (GC-2010plus, GC-MS-QP2010Ultra) using a 30 m × 0.25 mm, 0.25 μm Rtx-5MS column (Restek, Bellefonte, PA) and on a GC-FID system (GC-2010Plus) using a 30 m × 0.32 mm, 0.25 μm HP-5 column (Agilent, Santa Clara, CA).

Synthesis of Coniferyl and Sinapyl Alcohol. Coniferyl and sinapyl alcohols were synthesized from coniferaldehyde and sinapaldehyde as previously described.[13] In brief, coniferaldehyde/sinapaldehyde (205 mg/200 mg) were reduced in methanol (MeOH) (8 mL) by using a borohydride exchange resin (BER; 920 mg/770 mg), which was washed twice with 6 mL of MeOH before use. The reaction mixture was stirred at room temperature for 1 h/3 h. The resin was filtered off through glass wool, and the filtrate was evaporated. Cleanup was carried out using silica gel SPE columns: The columns were conditioned with 5 mL of ethyl acetate, the reaction mixture was applied in 5 mL of ethyl acetate, and the columns were eluted with 25 mL of ethyl acetate. Crystallization from dichloromethane/petroleum ether yielded pale yellow needles (57−67%) of coniferyl alcohol. Dichloromethane was added to the dried sinapyl alcohol, and the solution was kept in a freezer for several days. Since no crystallization was achieved, sinapyl alcohol was obtained as a yellow oil (67−95%).

Synthesis of *p*-Coumaryl Alcohol. *p*-Coumaryl alcohol was synthesized from *p*-coumaric acid in two steps as previously described.[14] Ethyl *p*-coumarate was prepared by stirring 1 g of *p*-coumaric acid and 5 mL of acetyl chloride in 50 mL of ethanol at room temperature for 17 h. After evaporation of the solvents, the procedure was repeated. The product was crystallized from ethyl acetate/petroleum ether. Ethyl *p*-coumarate was reduced using diisobutylaluminum hydride (DIBAL-H). Ethyl *p*-coumarate (640 mg) in 30 mL of toluene was ice cooled under nitrogen, and 12 mL of DIBAL-H was slowly added. The reaction mixture was stirred for 1 h, and the reaction was quenched by adding 5 mL of ethanol. The solvent was partially removed under reduced pressure, and 50 mL of water was added. The aqueous layer was extracted four times by using ethyl acetate. Pale yellow crystals of *p*-coumaryl alcohol (85−94%) were obtained by crystallization from dichloromethane/petroleum ether.

Synthesis of Diacetylated *p*-Coumaryl, Coniferyl, And Sinapyl Alcohols. Diacetylation of the three *p*-hydroxycinnamyl alcohols was carried out as described in the protocol of the DFRC method.[9] *p*-Hydroxycinnamyl alcohols (*p*-coumaryl alcohol, 162 mg; coniferyl alcohol, 189 mg; sinapyl alcohol, 216 mg), acetic anhydride (3.3 mL), and pyridine (3.2 mL) were stirred for 40 min at room temperature. The solvents were evaporated, and coevaporation was carried out using ethanol. The diacetylated compounds were obtained as yellow oils. For the synthesis of deuterium-labeled (hexadeuterated) *p*-hydroxycinnamyl alcohols acetic anhydride-d_6 was used. ^{1}H NMR (*p*-coumaryl diacetate-d_6), δ [ppm]: δ 7.50 (d, 2H, J = 8.6 Hz, H2/H6), 7.10 (d, 2H, J = 8.7 Hz, H3/H5), 6.71 (d, 1H, J = 16.0 Hz, Hα), 6.35 (dt, 1H, J = 16.0, 6.2 Hz, Hβ), 4.69 (dd, 2H, J = 6.2, 1.4 Hz, Hγ). ^{1}H NMR (coniferyl alcohol diacetate-d_6), δ [ppm]: δ 7.23 (s, 1H, H2), 7.02 (m, 2H, H5/H6), 6.69 (dt, 1H, J = 15.9, 1.3 Hz, Hα), 6.37 (dt, 1H, J = 15.9, 6.2 Hz, Hβ), 4.69 (dd, 2H, J = 6.2, 1.4 Hz, Hγ), 3.85 (s, 3H, OCH_3). ^{1}H NMR (sinapyl alcohol diacetate-d_6), δ [ppm]: δ 6.85 (s, 2H, H2/H6), 6.67 (dt, 1H, J = 15.9, 1.2 Hz, Hα), 6.39 (dt, 1H, J = 15.9, 6.2 Hz, Hβ), 4.69 (dd, 2H, J = 6.2, 1.3 Hz, Hγ), 3.81 (s, 6H, OCH_3).

Plant Material. All fruits and vegetables (pear (*Pyrus communis* L.), carrot (*Daucus carota* L. subsp. *sativus*), asparagus (*Asparagus officinalis* L.), and small radish (*Raphanus sativus* L. var. *sativus*), also known as European radish) were obtained from a local grocery store. Asparagus was peeled whereas pear, carrot, and European radish were used unpeeled; however, the cores of the pears were removed.

Preparation of Insoluble Fibers. All fruits and vegetables were freeze dried and milled to a particle size of <0.5 mm. Dried material (20 g) was suspended in 0.08 M sodium phosphate buffer pH 6.2 (200 mL), and 1.5 mL of α-amylase was added. The suspension was placed in a water bath (92 °C) for 20 min and shaken every 5 min. The samples were cooled to room temperature, and the pH was adjusted to 7.5 with 0.275 M NaOH. After adding 600 μL of protease, the samples were incubated for 30 min at 60 °C with continuous agitation. The samples were cooled down; the pH was adjusted to 4.5 with 0.375 M HCl and, after adding 700 μL of amyloglucosidase, incubated in a water bath for 30 min at 60 °C. The suspensions were filtered through filter paper (12−15 μm), and the residues were washed three times with hot water (60 °C), ethanol, and acetone and finally air dried under the fume hood. To remove small amounts of remaining lignin-like low molecular weight material, the insoluble fibers were further extracted with ethanol (8 h), ethyl acetate (8 h), and *n*-hexane (8 h) using a Soxhlet apparatus. Finally, the insoluble fibers were dried at 40 °C in a vacuum oven.

Enzyme Digestion. Insoluble fibers (1 g) were suspended in 100 mL of water and incubated with 60 mg of Driselase at 37 °C for 48 h. After inactivation of the enzymes (5 min, 100 °C), the samples were centrifuged for 10 min at 2500 rpm and washed twice with water, ethanol, and acetone. The residues were dried in a vacuum oven at 40 °C.

DFRC Method. The DFRC method was performed as described by Bunzel et al.[11] with minor modifications. About 10−25 mg (pear, 24 mg; radish, 11 mg; carrot and asparagus, 15 mg) of enzyme-digested insoluble dietary fiber were mixed with 7.5 mL of acetyl bromide reagent (acetyl bromide/glacial acetic acid, 20/80, v/v), and the mixture was stirred at 50 °C for 3 h. The solvent was removed by rotary evaporation, and 7.5 mL of acidic reduction solvent (dioxane/glacial acetic acid/water, 5/4/1, v/v/v) and about 50 mg of zinc dust were added. The mixture was stirred at room temperature for 40 min. This mixture, 10 mL of dichloromethane, and 10 mL of saturated NH_4Cl were transferred into a separatory funnel, and the internal standards (deuterium-labeled *p*-hydroxycinnamyl alcohol diacetates) were added. The amounts of added standard compounds depend on the dilution after sample cleanup (final internal standard concentration, 30 μM). The organic layer was separated, and extraction of the aqueous phase with 10 mL of dichloromethane was repeated twice. The combined organic layers were washed twice with 10 mL of saturated NH_4Cl and dried over $MgSO_4$. The mixture was filtered through filter paper (4−12 μm), and the solvent was evaporated.

For the acetylation step, 1.5 mL of dichloromethane, 200 μL of pyridine, and 200 μL of acetic anhydride were added to the residue. The mixture was stirred overnight, and the solvents were removed under reduced pressure (coevaporation with ethanol, 3×).

Sample Cleanup. The residue, which was obtained from the DFRC method, was dissolved in 1 mL of MeOH (ultrasonic bath). The mixture was centrifuged (3 min at 13 000 rpm), and the supernatant was removed and evaporated. The residue after evaporation was dissolved in 1 mL of MeOH/H_2O (40/60, v/v). Sample cleanup was carried out using polymeric reversed phase SPE tubes (conditioning with 3 mL of each MeOH and H_2O, application of the sample, washing with 3 mL of each H_2O and MeOH/H_2O (20/80, v/v), elution with 9 mL of MeOH), and the solvent was removed under reduced pressure.

[a]Only relative intensities ≥ 3% are shown. The *m/z* values chosen for selected-ion monitoring mode are underlined. [b]Molecular ion. [c]Fragment resulting from ketene loss from the molecular ion. [d]Fragment resulting from McLafferty rearrangement after ketene loss. [e]Benzylic cation fragment.

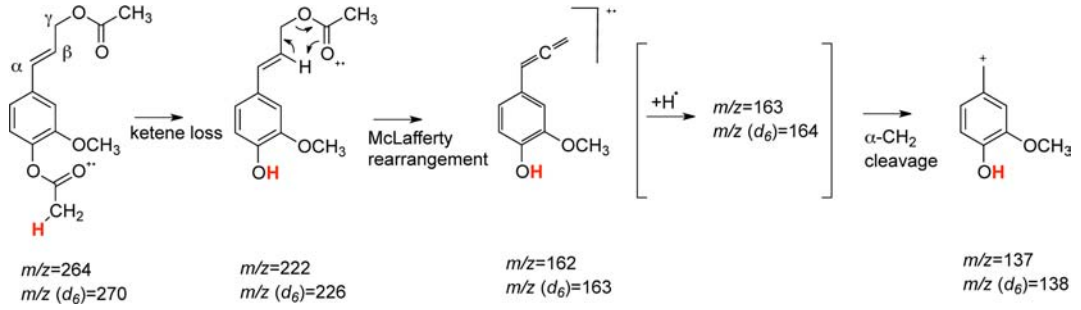

Figure 1. Characteristic fragmentations (EI-MS) of diacetylated coniferyl alcohol. *m/z* values of the products from the nondeuterated and the hexadeuterated (identified by the -d_6 descriptor in the figure) compounds resulting from ketene loss, McLafferty rearrangement, and α-CH_2 cleavage are indicated. Fragmentation reactions of diacetylated *p*-coumaryl and sinapyl alcohols are analogous.

GC-MS and GC-FID Analysis. DFRC monomers were separated and quantitated by GC-MS (EI) using He (1 mL/min) as carrier gas. GC conditions were as follows: initial column temperature 160 °C, ramped at 10 °C/min to 230 °C, ramped at 5 °C/min to 240 °C, ramped at 20 °C/min to 260 °C, ramped at 10 °C/min to 300 °C and held for 10 min; injector temperature 250 °C; split ratio 1/30. MS conditions were as follows: ion source temperature 220 °C, interface temperature 275 °C. Quantification was carried out in the selected-ion monitoring (SIM) mode using ions with the following *m/z*: *m/z* = 192/196 for *p*-coumaryl alcohol diacetate/*p*-coumaryl alcohol diacetate-d_6; *m/z* = 222/226 for coniferyl alcohol diacetate/coniferyl alcohol diacetate-d_6; *m/z* = 252/256 for sinapyl alcohol diacetate/sinapyl alcohol diacetate-d_6. Mass spectrometric detection was carried out only near the retention times of the compounds to avoid unnecessary contamination of the MS system.

GC-FID was used for analyzing low-lignin samples using the original DFRC protocol.[9] GC-FID conditions were as follows: He (1 mL/min) as carrier gas, injector temperature 220 °C, split ratio 1/10, detector temperature 310 °C. GC conditions: initial column temperature 160 °C, ramped at 5 °C/min to 210 °C, ramped at 2 °C/min to 280 °C, ramped at 10 °C/min to 310 °C, and held for 10 min.

Method Validation. Calibration curves were obtained from standard solutions (5−95 μM of the diacetylated hydroxycinnamyl alcohols) in MeOH. The deuterium-labeled internal standard compounds were added to the standard solutions (final concentration of the deuterium-labeled compounds, 30 μM). All solutions were measured in triplicate. The following validation parameters were tested: homogeneity of variances, detection limit (here signal-to-noise ratio of 5:1−10:1; see also Results and Discussion), quantification limit (here lowest calibration point used; see also Results and Discussion), linearity (residual plots, correlation coefficient). The recovery was estimated by comparing the peak area of ions from the hexadeuterated internal standard compounds obtained during sample application to the average peak area obtained from direct injection of the hexadeuterated internal standard compounds (concentration 30 μM) in the GC-SIM-MS sytem.

RESULTS AND DISCUSSION

GC-MS Fragmentation of Standard Compounds. GC-FID is routinely used to determine the ratios of diacetylated DFRC products. However, due to high levels of coeluting matrix compounds, peak identification and integration is often problematic, especially for low-lignin samples. GC-MS analysis in the SIM mode offers both higher selectivity and higher sensitivity. Ideally GC-SIM-MS is combined with using stable-isotope-labeled standard compounds. Here, by acetylation of the *p*-hydroxycinnamyl alcohols using perdeuterated acetic anhydride, six deuterium labels were incorporated into each of the three *p*-hydroxycinnamyl alcohol diacetates. A prerequisite for using the deuterium-labeled diacetates as internal standards is the occurrence of at least one main fragment that is different from the nonlabeled diacetates and thus can be used for quantification. Table 1 summarizes the EI-MS fragmentation patterns (70 eV) of the synthesized compounds. Generally, phenolic acetates lose ketene, which has also been described for lignin dimers.[15] During the loss of ketene one proton of the phenolic acetyl group remains with the parental molecule (Figure 1, using the example of diacetylated coniferyl alcohol). This explains the difference of four mass units between the ketene loss fragment of the nonlabeled (e.g., *m/z* = 222 for diacetylated coniferyl alcohol) and the corresponding hexadeuterated compounds (e.g., *m/z* = 226 for the deuterated

DOI: 10.1021/jf506221p
J. Agric. Food Chem. 2015, 63, 2668−2673

diacetylated coniferyl alcohol). The loss of m/z = 60 can be explained by a McLafferty rearrangement leading to cleavage of γ-acetates. Also, cleavage of α-CH_2 structures, leading to their corresponding benzylic cations, can be observed. In general, the fragments are comparable to those described in the literature,[10] but the intensities are different from literature data.

For coniferyl alcohol diacetate/coniferyl alcohol diacetate-d_6 (GDiAc/GDiAc-d_6) and sinapyl alcohol diacetate/sinapyl alcohol diacetate-d_6 (SDiAc/SDiAc-d_6) the base peak was chosen for GC-SIM-MS quantification. This was not possible for *p*-coumaryl alcohol diacetate (HDiAc) because the base peak of *p*-coumaryl alcohol diacetate-d_6 (HDiAc-d_6) occurs in the spectrum of the nondeuterated compound and vice versa. Thus, m/z = 192 and 196 were chosen to quantitate HDiAc and HDiAc-d_6, respectively. Figure 2 shows the GC-SIM-MS chromatogram of the synthesized standard compounds and their corresponding labeled compounds.

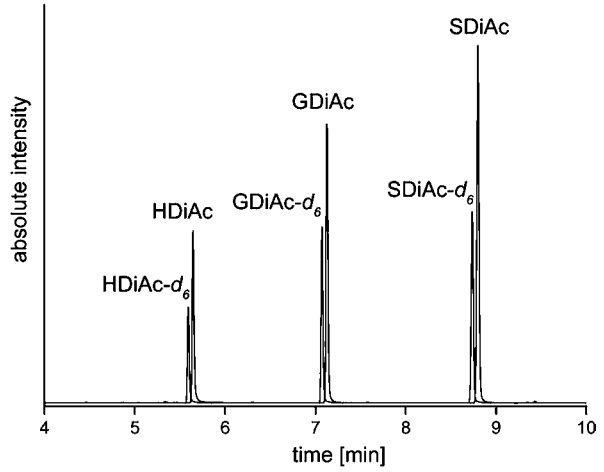

Figure 2. GC-MS chromatogram of the analysis of a standard mixture containing diacetylated *p*-coumaryl (HDiAc), coniferyl (GDiAc), and sinapyl (SDiAc) alcohols and their corresponding labeled compounds (d_6). Detection was carried out in selected-ion monitoring mode with m/z = 192/196 for HDiAc/HDiAc-d_6, m/z = 222/226 for GDiAc/GDiAc-d_6, and m/z = 252/256 for SDiAc/SDiAc-d_6.

Method Validation. The calibration curves of the three standard compounds were repeatedly analyzed in a range of 5−95 μM. Standard deviations of repeated injections were partially ≥20% depending on the concentration and/or day, suggesting less stable fragmentation. By using the corresponding deuterium-labeled compounds as internal standards to calculate the calibration curves, the standard deviations were more acceptable (0.1−2.0%). Thus, regression lines were obtained by plotting the area of analyte/area of internal standard [30 μM, see below] on the *y*-axis vs analyte concentration on the *x*-axis. The fact that less reproducible fragmentation can be corrected for by using the deuterated compounds as internal standards demonstrates the importance of internal standards that are structurally similar to the diacetylated DFRC products. For all calibration points an internal standard concentration of 30 μM was used, roughly representing the middle of the concentration range tested. The use of a fixed internal standard concentration implies a disadvantage that is, however, minor compared to the advantages of the method: The ready-to-analyze sample solutions need to contain the defined concentration of internal standards (30 μM). If absolutely no information about the lignin amount/composition of the sample is known or assessable, a preceding analysis of the sample material has to be performed. This additional performance is necessary to determine if and which final dilution is necessary to get the sample solution into the calibrated concentration range. Then, the concentration of the internal standard compounds added during sample preparation has to be adapted to this dilution.

Visual evaluation of the standard curves of the three acetylated monomers revealed that higher order polynomial regression may fit the data better than a linear regression. Therefore, a polynomial regression (second order) was used and confirmed by the correlation coefficient and residual analysis. Because homogeneity of variances at the highest and lowest concentration was not given, a weighted regression (with reduced chi^2, weighting factor 1/standard deviation^2) was used. The standard deviation of each calibration point was between 0.1% and 2.0% applying the parameters used. The most important validation parameters are shown in Table 2.

Table 2. Validation Parameters for the Calibration of *p*-Coumaryl Alcohol Diacetate (HDiAc), Coniferyl Alcohol Diacetate (GDiAc), and Sinapyl Alcohol Diacetate (SDiAc)[a]

	calibration equation (polynomial model)	correlation coefficient	LOD[b] [μM]	LOQ [μM]	recovery[c] (%)
HDiAc	$y = 0.00654 + 0.04094x + (8.59968 \times 10^{-5})x^2$	1.0000	0.007	5	99−142
GDiAc	$y = 0.00225 + 0.03314x + (1.2895 \times 10^{-4})x^2$	1.0000	0.001	5	68−185
SDiAc	$y = -0.00984 + 0.03872x + (1.553252 \times 10^{-4})x^2$	0.9997	0.05	5	77−179

[a]The corresponding deuterium-labeled compounds (final concentration: 30 μM) were used to correct for less stable fragmentation. The tested range was 5−95 μM for all three compounds. LOD, limit of detection; LOQ, limit of quantification. [b]Rough estimate due to less stable fragmentation (see text). [c]Estimated from the recovered area of the internal standard compounds added during sample preparation (see text).

Due to the less stable fragmentation of the analytes, the limits of detection and quantification (LOD, LOQ) determined via the signal-to-noise ratio are rather rough estimates than definite values. Also, due to the less stable fragmentation it was not possible to define exact concentrations with signal-to-noise ratios of 3:1 (LOD) or 9:1 (LOQ). Therefore, the LOD was defined by injecting standard solutions with decreasing concentrations in triplicate until a signal-to-noise ratio of about 5:1−10:1 was found in all three replicates. The limit of quantification was set as the lowest calibration point due to the mentioned problems in determining this validation parameter.

To test day-to-day reproducibility, the standard solutions were reinjected after 8 days and regression lines were compared. The calibration equations were similar, suggesting that the method was robust if performed as described. Also, the standard solutions were freshly prepared and analyzed. In this case, the regression lines vary in an acceptable way due to minor variations during solution preparation. These data suggest that a complete calibration with each sample set is not necessary. Instead, it is recommended to double check the regression lines by three calibration points before analysis of each sample set.

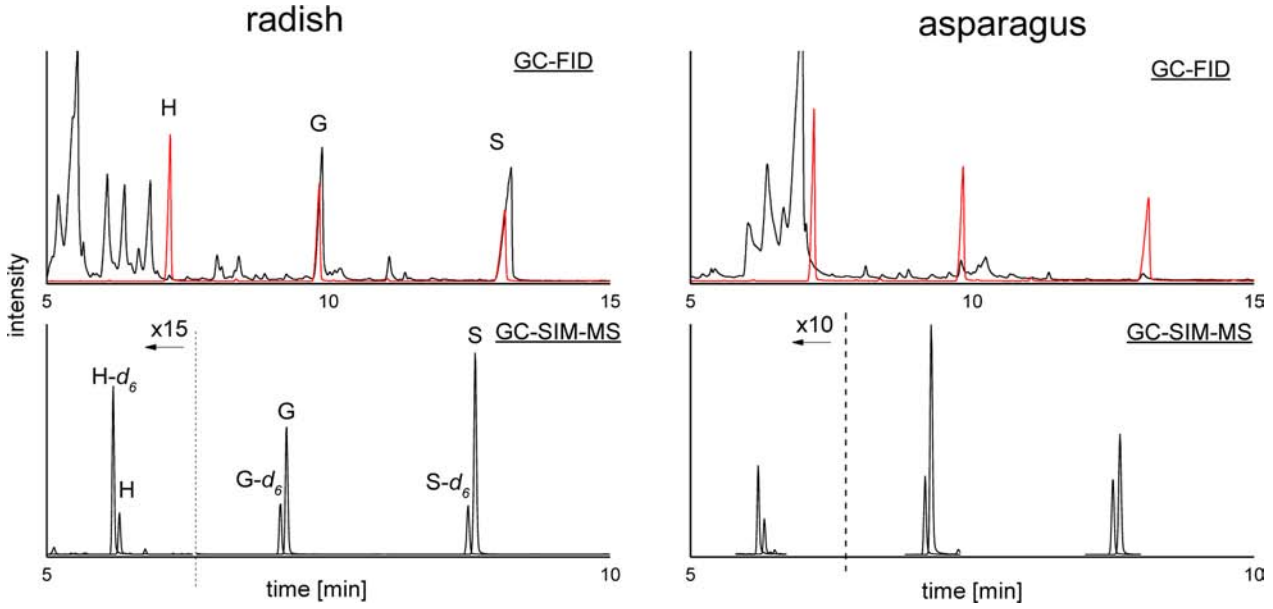

Figure 3. Comparison of chromatograms from derivatization followed by reductive cleavage (DFRC) products from radish (left) and asparagus (right). GC-FID chromatograms were obtained without modified sample cleanup. Colored lines represent the overlaid chromatograms of the standard compounds. GC-SIM-(selected-ion monitoring)-MS chromatograms were obtained by using the modified method. Peaks representing *p*-coumaryl alcohol diacetate and deuterated *p*-coumaryl alcohol diacetate are enlarged 15- (radish) and 10-fold (asparagus). HDiAc, *p*-hydroxyphenyl unit; G, guaiacyl unit; S, syringyl unit; d_6, hexadeuterated internal standard compounds.

Recoveries were estimated by using the analyzed areas of the internal standard compounds added before extraction of the liberated monomers during application of the method to low-lignin[11] samples (pear, radish, carrot, and asparagus, see below). Recovery rates were calculated by comparing these areas to the average areas of the deuterated internal standards obtained from direct injection of the internal standard solution (30 μM). It has to be kept in mind that the recovery rates determined here are only rough estimates due to one-point calibration without correcting this data point for fragmentation instabilities. The recovery rates were between 99% and 142% for HDiAc-d_6, 68−185% for GDiAc-d_6, and 77−179% for SDiAc-d_6. As described above, the standard deviations of repeated analyses of a single calibration point without adjustment for fragmentation instabilities using an internal standard are often ≥20% and can be up to 40%. However, despite large variations of the recovery rates due to noncorrected fragmentation instabilities, the average values demonstrate that major quantities of the liberated DFRC products are indeed analyzed after sample preparation and cleanup (see below). Furthermore, the MS fragmentation and detection does not seem to be suppressed significantly by matrix effects. In addition, the calculation of the actual monomer amount is not as important as the determination of the monolignol ratios. Because the DFRC method only cleaves β-O-4 linkages, the calculated ratios represent the monomers that are involved in these units. Because the β-O-4 linkages usually represent > 50% and up to 80% of the linkages in the lignin polymer the obtained ratios reflect well the composition of the lignin polymer. This has also been demonstrated by comparison of the G/S ratios of lignins from plant-based foods determined by the DFRC method with the G/S ratios of isolated lignins analyzed by 2D-NMR.[16]

Sample Cleanup. Sample cleanup is adapted to low-lignin samples to reduce the high matrix-derived content that can contaminate the GC-MS system. The original protocol describes a dissolution of the sample in dichloromethane after the acetylation step and before GC-MS analysis.[9] Dichloromethane dissolves the entire residue, i.e., DFRC products and (acetylated) matrix-derived components. Because the acetylated DFRC products are soluble in MeOH this solvent was chosen instead of dichloromethane to dissolve the DFRC residue after acetylation. Using MeOH leaves, conveniently, a large amount of matrix-derived components undissolved. Additionally, an SPE step was established for further cleanup. A polymeric reversed phase, which provides strong retention of aromatic compounds due to $\pi-\pi$ bonding interactions next to hydrogen bonding, was chosen as the stationary phase. The loading solution was MeOH/water (40/60, v/v), which was tested to completely dissolve the standard compounds. SPE conditions were tested by using a mixture of all standard compounds. The solution was loaded onto the column, which was washed and eluted in several steps using different volumes of H_2O and MeOH mixtures in different ratios. All eluates were collected separately and analyzed for DFRC products.

The results showed that loading in MeOH/H_2O (40/60, v/v) and washing with H_2O and MeOH/H_2O (20/80, v/v) result in a loss of about 1% of the standard compounds. Also, the recovery rates of the internal standard compounds (68−185% depending on the determined monomer) as determined during application of the sample cleanup on different plant-based food samples reveal applicability of the chosen conditions for complex, high-matrix samples.

Application. The developed method was applied to fibers from four plant-based food samples: pear, radish, carrot, and asparagus. The enzymatic digestion of the extracted fibers by using an enzyme mixture capable of digesting cell wall polysaccharides is recommended because it reduces the sample matrix load, which contaminates the MS system. Figure 3 shows the chromatograms of radish and asparagus DFRC products measured by GC-FID (original DFRC protocol[9]) or GC-SIM-MS (modified sample cleanup). The GC-FID

chromatogram reveals the existence of a large amount of matrix from low-lignified samples, complicating the identification and/or quantification of the acetylated DFRC products. Using the newly developed GC-SIM-MS method these problems are minimized.

The results from the application of the DFRC method to food samples are summarized in Table 3. To characterize the lignin composition H:G:S proportions and G/S ratios were calculated. The insoluble dietary fiber lignin of carrots shows a high G/S ratio (ca. 38) and can be classified as a G-rich lignin. In contrast, lignins from pear, radish, and asparagus are characterized by balanced G/S ratios. These values are generally comparable to literature data.[11] Smaller differences can be explained by different maturation stages of the used samples and methodological differences. Furthermore, by using the GC-SIM-MS method, H units were detected in quantifiable amounts in all samples analyzed. In comparison to G and S units, the amounts were low, with the exception of carrot lignin with an H/S ratio of 0.87. Bunzel et al.[11] could detect quantifiable amounts of H units from lignins of radish only. Although differences in the plant materials are possible, the detection of minor amounts of H units in this study is most likely due to the increased selectivity and sensitivity of the newly developed stable-isotope dilution GC-MS approach.

Table 3. Monolignol Composition of Fibers from Pear, Radish, Carrot, and Asparagus Determined by the Derivatization Followed by Reductive Cleavage (DFRC) Method with Modified Sample Cleanup and GC-Selected-Ion Monitoring (SIM)-MS Analysis[a]

	H:G:S [mol %]	ratio G/S	ratio G/S from literature[11]
pear	0.18:53.28:46.54	1.15 (±0.03)	0.6 (±0.04)
radish	1.29:44.75:53.96	0.80 (±0.14)	1.5 (±0.18)
carrot	2.32:94.97:2.71	35.24 (±2.45)	38.8 (±6.11)
asparagus	0.85:67.04:32.11	2.10 (±0.17)	3.3 (±0.28)

[a]Ratios of H (*p*-hydroxyphenyl unit), G (guaiacyl unit), and S (syringyl unit) were determined as percentages on a molar basis. G/S ratios are calculated on molar basis too. Each sample was measured in duplicate. Uncertainties of measurement are indicated in brackets as range/2. For quantification, the hexadeuterated internal standards were used at a concentration of 30 μM.

example, the following (peak area) percentages have been reported: sabinene (42−63%), α-phellandrene (37−63%), linalool (30−68%), and β-pinene (35−78%).[9−12] On the other hand, at least four terpenes have been reported with consistently predominate (+)-enantiomers, viz., α-pinene (60−90%), terpinen-4-ol (65−70%), α-terpineol (70−78%), and limonene (58−62%).[9−13] No clear standard has been developed primarily due to the limited number of investigations and samples. The measurement of chiral ratios of TTO components is demanding and often requires the use of multidimensional GC or NMR with lanthanide shift reagents. These techniques are labor intensive and require extensive operator expertise.

Chemometrics has increasingly found applications in quality control of natural products. It can be used to extract chemically relevant information out of large quantities of chemical data to provide a better way to represent and display the information as well as a better understanding of the chemical system. Two chemometric approaches are usually applied: the targeted approach selectively analyzes a subset of compounds, while the nontargeted approach provides a holistic analysis of the entire chemical data set. Chemometrics has been used extensively[14−18] for the analysis of infrared and mass spectra of essential oils. However, this data analysis tool has not been used to validate TTOs or commercial products based on GC/MS data with conventional or chiral columns.

The inherent complexity and variability within plants and essential oils pose challenges in the identification and quantification of specific chemical compounds as quality control parameters. The need exists for the development of chemical analysis techniques and data analysis tools that can profile the whole chemical system including those components present at very low concentration levels. As part of an ongoing research program on authentication, safety, and quality control of phytochemicals, the present investigation was carried out employing the aforementioned conventional and chiral GC/MS systems combined with chemometric analyses to assess the quality of tea tree oils and commercial products. The study involved a large number (n = 104) of samples divided into two categories, viz., known provenance essential oils and commercial products of unknown provenance. Thus, an independent norm from the chiral analysis for a given set of samples could be established for comparison purposes. The objectives of the current investigation were to employ the three previously discussed techniques in the investigation of an extensive set of TTOs and commercial products. This holistic approach will be used to identify TTO and commercial samples that do not represent the common terpinen-4-ol type of tea tree oil.

MATERIALS AND METHODS

Sample Information. Fifty-seven known provenance tea tree oil samples (A1−14, A17−40, A48−64, A84, and A90) were obtained by steam distillation of *Melaleuca alternifolia*. Oils A15 and 16 were obtained from the steam distillation of *M. linariifolia* and *M. dissitiflora*, respectively. Forty-three commercial samples that claimed to be tea tree oil samples (A41−44, A46, A47, A65−83, A85−89, A92, and A100−110) were purchased from various foreign sources. The provenance of these samples was unknown. Sample A45 was sold as synthetic tea tree oil, and A99 was sold as synthetic terpinen-4-ol. All TTOs and commercial products were collected by the Australian Tea Tree Industry Association (ATTIA, Casino NSW, Australia). Specimens of all samples are deposited at the botanical repository of the National Center for Natural Products Research (NCNPR), University of Mississippi.

Reagents and Standards. GC-grade n-hexane and the reference standards α-thujene (**1**), α-pinene (**2**), β-pinene (**4**), myrcene (**5**), α-phellandrene (**6**), α-terpinene (**7**), p-cymene (**8**), limonene (**10**), γ-terpinene (**11**), terpinolene (**12**), and terpinen-4-ol (**13**) (listed in Table 1 and Figure S1, Supporting Information) were purchased from Sigma-Aldrich. A mixture of a series of n-alkanes (C_9H_{20} to $C_{22}H_{46}$) was used for the determination of the retention indices, and the alkane standards were purchased from PolyScience Corp. The analytical standard n-tridecane ($C_{13}H_{28}$) was selected as the internal standard and obtained from PolyScience Corp. The enantiomeric compounds of α-pinene, limonene, terpinen-4-ol, and α-terpineol were purchased from Sigma-Aldrich.

Table 1. Twenty Most Abundant Compounds in the Tea Tree Oil Sample (A-22) by Conventional GC/MS Analysis

no.	compound	retention index	literature value[17] (methyl silicone column)	% peak area (ISO)
1	α-thujene	925	931	
2	α-pinene	931	939	1−6
3	sabinene	965	972	trace−3.5
4	β-pinene	969	978	
5	myrcene	983	986	
6	α-phellandrene	996	1002	
7	α-terpinene	1009	1016	5−13
8	p-cymene	1011	1016	0.5−8
9	1,8-cineole	1019	1025	trace−15
10	limonene	1021	1025	0.5−1.5
11	γ-terpinene	1052	1056	10−28
12	terpinolene	1083	1081	1.5−5
13	terpinen-4-ol	1172	1175	30−48
14	α-terpineol	1182	1185	1.5−8
15	aromadendrene	1452	1475	trace−3
16	*allo*-aromadendrene	1471		
17	ledene	1503	1484	trace−3
18	δ-cadinene	1526	1524	trace−3
19	globulol	1568		trace−1
20	viridiflorol	1577	1588	trace−1

Sample Preparation. Five microliter samples were diluted in 1 mL of n-hexane. The selected internal standard ($C_{13}H_{28}$) was added to each sample solution at a constant concentration.

Chromatography Instruments and Conditions. *Conventional GC/MS Analyses.* Gas chromatographic analysis was performed on an Agilent 7890 GC instrument equipped with an Agilent 5975C mass-specific detector and an Agilent 7693 autosampler. An Agilent J&W HP-1 fused silica capillary column (60 m × 0.25 mm i.d.) coated with a 0.25 μm film of cross-linked 100% dimethyl-polysiloxane was used with helium as the carrier gas at a constant pressure of 24 psi. In a typical analysis, the oven was held for 2 min at 50 °C and then programmed at 2.0 °C/min to 180 °C. The post run was set at 250 °C for 5 min to clean up the column. The injector temperature was 250 °C. The split ratio was set to 25:1. Duplicate injections were made for each sample.

For the scan measurements, the spectra were recorded at 70 eV from m/z 35 to 450. Compound identification involved comparison of the spectra with the databases (Wiley and NIST) using a probability-based matching algorithm. Further identification was based on the relative retention indices compared with the literature and the reference standards purchased from commercial sources.

Chiral GC/MS Analyses. The same instrument setting used for the conventional GC/MS analysis was applied for the chiral GC/MS analysis. The chiral GC/MS column was an Agilent J&W HP-Chiral-20β (30 m × 0.25 mm, i.d.) coated with a 0.25 μm film of 20% β-cyclodextrin in (35%-phenyl)-methylpolysiloxane. Helium was used as a carrier gas. The flow rate was 1 mL/min for the first 27 min and then programmed at 0.2−3 mL/min for the rest of the experiment. In a typical chiral analysis, the oven was held for 10 min at 50 °C and programmed at 3.0 °C/min to 100 °C, 2.0 °C/min to 140 °C, and then 4.0 °C/min to 180 °C in the last step. The injector temperature was 250 °C. The split ratio

J. Agric. Food Chem. 2015, 63, 2674−2682

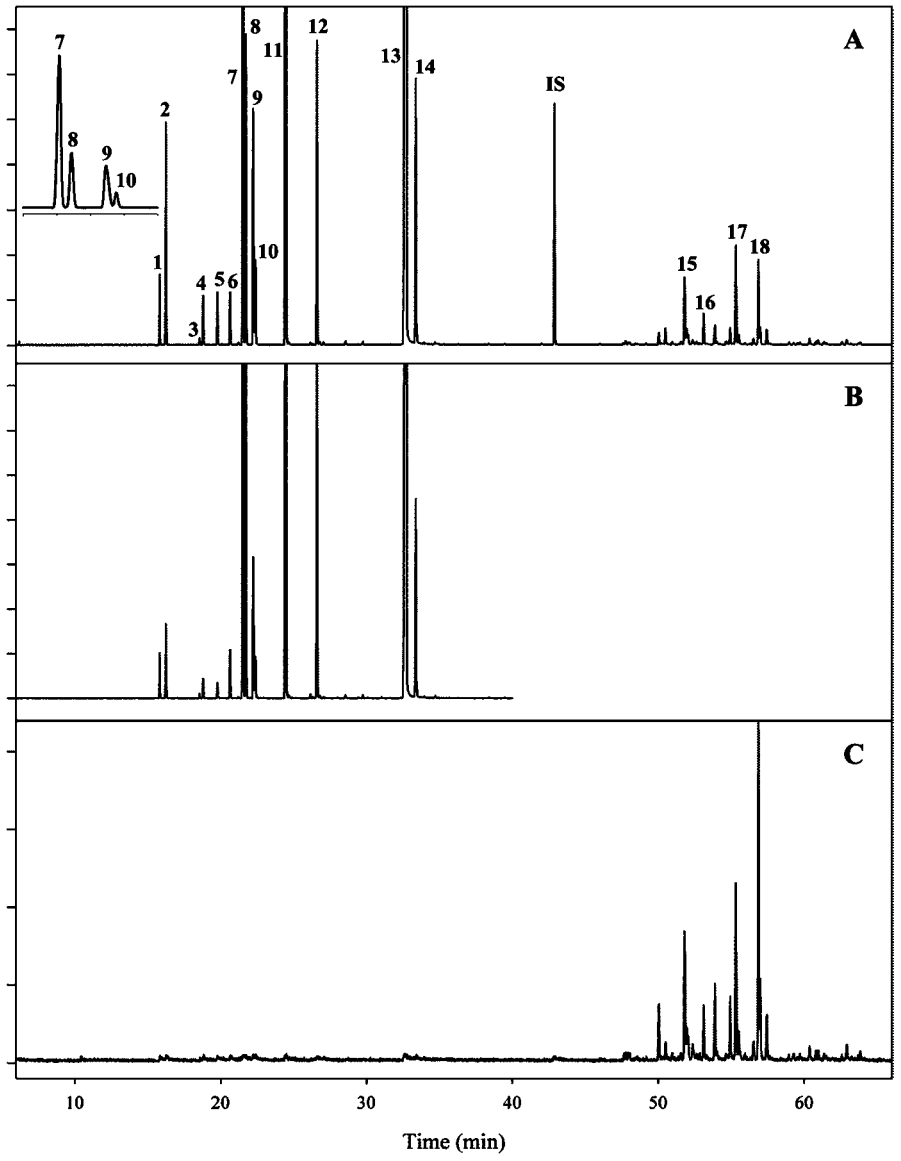

Figure 1. GC/MS chromatograms of sample A-22. (A) Total ion chromatogram (m/z 35−450). (B) Extracted ion chromatogram (m/z 136) for monoterpenes. (C) Extracted ion chromatogram (m/z 204) for sesquiterpenes.

was set to 40:1. Duplicate injections were made for each sample. The mass spectra were recorded at 70 eV from m/z 40 to 550.

Chemometric Analysis. The GC/MS data were acquired by Agilent MSD Productivity ChemStation software (E.02.02). Extraction of the GC/MS data was performed using the NIST Automated Mass Spectral Deconvolution and Identification Software (AMDIS). Ions were extracted as entities characterized by retention time (t_R), peak intensity, and mass to charge ratio (m/z). The ELU file format required for the chemometric analysis was created by AMDIS for each sample and then exported into the Mass Profiler Professional software (MPP, version B.12.05, Agilent Technologies).

A holistic nontargeted approach was used for the preprocessing of GC/MS data using the full spectra which allows for unbiased analysis. The initial stage involved baseline correction, data smoothing, and peak alignment. Various minimum abundance settings and compound quality score filter parameters were examined; 5000 counts and a score of 20 were finally selected for the entities extraction in the entire experiment time window for the minimum absolute abundance and minimum quality score, respectively. Alignment of retention time with a tolerance retention time window of 0.15 min and similarity of spectral pattern was carried out across the entire sample set. The internal standard selected for GC/MS analysis was applied for normalization of the peak intensity to account for the differences in the abundances of each compound. A list of 634 entities obtained from the MPP software was exported to SIMCA (version 12) for chemometric analysis. Principal component analysis (PCA) was performed for a quick overview of the data. A sample class predictive model (PCA-class) based on the TTO samples that met the ISO standards was constructed. The class predictive model was cross-validated and then applied to evaluate the remainder of the samples in the TTO data set.

RESULTS AND DISCUSSION

Typical chromatograms of a TTO sample obtained from GC/MS with a conventional stationary phase (HP-1) and a chiral stationary phase (HP-Chiral-20B) are shown in Figures 1 and 2, respectively. The assignment of the 20 components and their corresponding retention indices in the conventional chromatogram as well as the concentration limits regulated by ISO standards are listed in Table 1. Table S1, Supporting Information, gives the (peak area percentage) analysis results for the 20 compounds listed in Table 1 with the conventional GC stationary phase. Table S2, Supporting Information, gives the results from chiral analyses.

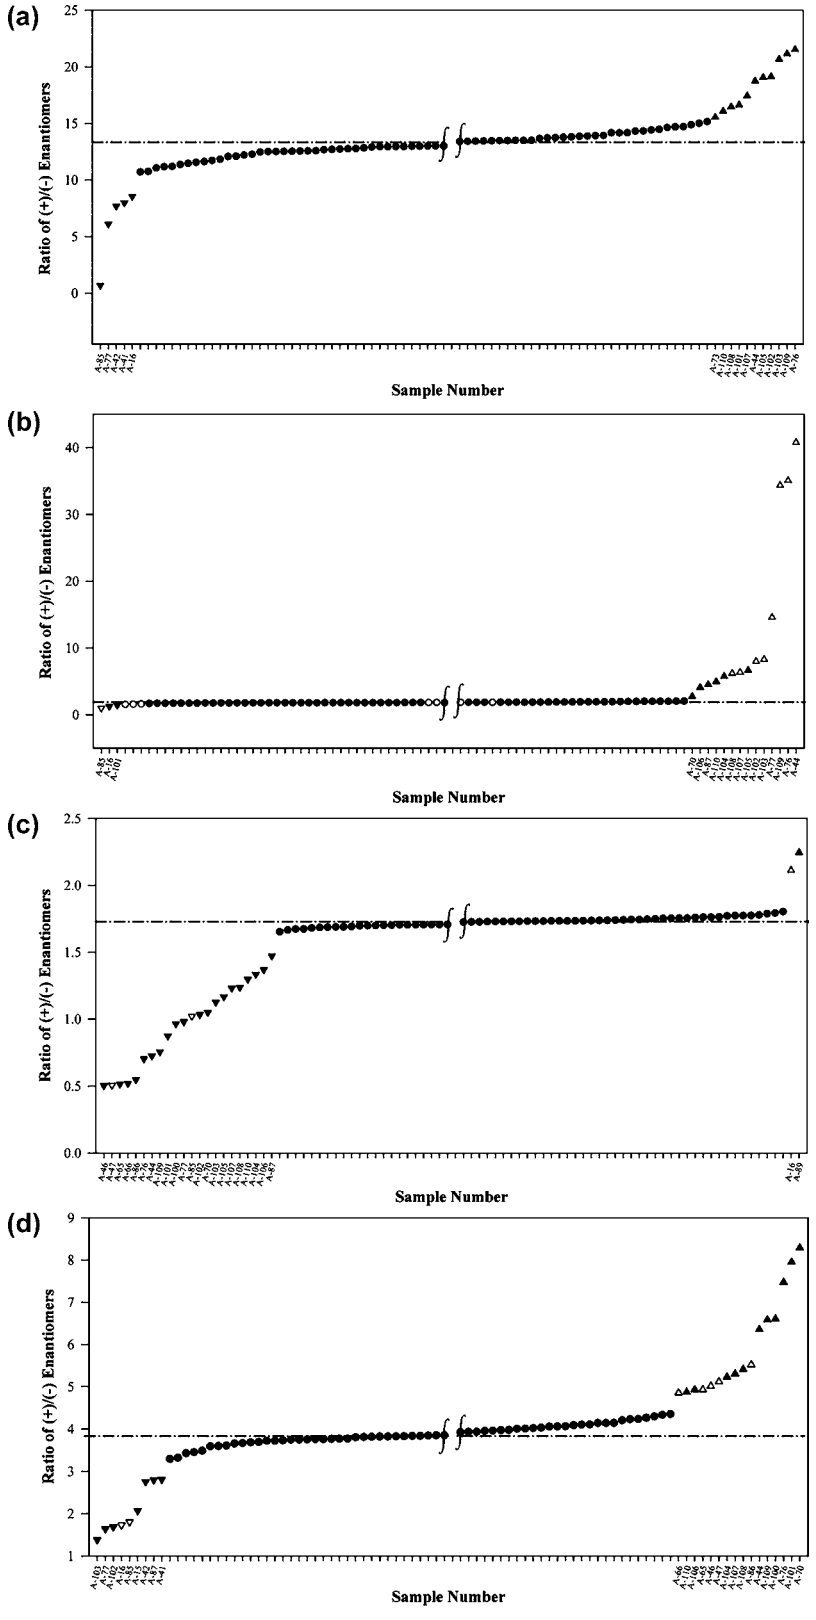

Figure 4. (A) Chiral analysis results for α-pinene. Gap in the data represents the omission of 15 points with the average enantiomeric ratio. Samples that displayed an enantiomeric ratio greater/less than the average of TTOs ± three times the standard deviation (SD) are shown as ▲/▼ in the figure. (B) Chiral analysis results for limonene. Data points shown with open symbols represent samples that did not meet ISO standards. (C) Chiral analysis results for terpinen-4-ol. (D) Chiral analysis results for α-terpineol.

Conventional GC/MS Analyses: Comparison with ISO Standards. *Known Provenance Tea Tree Oil Samples.* Figure 3 shows the concentration ranges of the eight major ISO-specified terpenes and related alcohols and ethers along with the ranges of concentration specified by ISO 4730-2004. The measured concentration ranges for the same components in the

DOI: 10.1021/acs.jafc.5b00147
J. Agric. Food Chem. 2015, 63, 2674−2682

ATTIA TTO samples are also shown in the figure. The compounds that were outside the ISO standards are marked in gray in Table S1, Supporting Information. Fourteen of 57 TTO samples did not meet at least one of the ISO standards, even though all of the oils were ISO compliant when distilled as evidenced by certificates of analysis obtained by ATTIA immediately after distillation. The primary problems were excess *p*-cymene and diminished α- and γ-terpinene as well as terpinolene concentrations. Auto-oxidation was probably responsible for most of the observed deviations.[19] Aside from the four probe solutes involved in the generation of *p*-cymene, all of the TTOs were within ISO standards for the other 10 solutes.

The analytical results for the five sesquiterpenes specified in the ISO standards are included in the tables; however, their concentrations were always less than 3%. Their low concentrations and relatively high variability and uncertainty limited their use as verification probes.

Commercial Samples. In Table S1, Supporting Information, the TTO and commercial samples that did not meet the ISO standards are marked in gray. Samples A45 and A99 were labeled as synthetic TTO and synthetic terpinen-4-ol, respectively. These synthetic samples both contained about 95% terpinen-4-ol along with low concentrations of α- and γ-terpinene and *p*-cymene. Twenty-three other commercial samples did not meet ISO standards. The major problems were an excess of limonene (16 samples), α-terpineol (7 samples), or *p*-cymene (11 samples). A lower number of samples was deficient in α-terpinene (7 samples), γ-terpinene (4 samples), and terpinen-4-ol (3 samples).

On the basis of solely the ISO standards, 49% of the commercial TTO samples were not qualified to be sold as "tea tree oils" on the commercial market. This raises the question whether or not the ISO standards alone are sufficient to positively identify oils and commercial products that actually contain Australian "terpinen-4-ol type" tree oil. The most common secondary test for TTO quality evaluation involves the analysis of chiral components.

Chiral GC/MS Analyses. A complete chiral analysis was carried out for the entire data set for four terpenes with predominately (+)-enantiomer for which standards were available, viz., α-pinene, limonene, terpinen-4-ol, and α-terpineol. The results for all of the chiral solutes are given in Table S2, Supporting Information.

Resolution of limonene enantiomers from *p*-cymene has proven to be a difficult problem in many investigations of the chiral components of TTOs.[10,12,13] *p*-Cymene has been reported to coelute with (+)-limonene[10,12] or (−)-limonene.[13] Two-dimensional GC has been used to overcome this problem.[11,12] In the current study, *p*-cymene (**8**) was found to elute between (−)- and (+)-limonene (**10**) as shown in Figure 2. The mass spectrum for limonene shows a base peak at *m*/*z* 68 (isoprenyl), while the spectrum for *p*-cymene is barren in this mass region. Thus, selected ion monitoring at *m*/*z* 68 was used to differentiate limonene from *p*-cymene (*m*/*z* 134) as shown in the inset (C) of Figure 2.

Known Provenance Tea Tree Oil Samples. The enantiomeric ratios +/− for all of the known provenance essential oil samples were calculated and used as the norm for evaluation of the commercial samples. The tea tree oil samples showed consistent enantiomeric ratios. The averages and standard deviations were 13.0 (±0.8), 1.83 (±0.08), 1.72 (±0.03), and 3.86 (±0.03) for α-pinene, limonene, terpinen-4-ol, and α-terpineol, respectively. The chiral ratios of α-pinene, limonene, terpinen-4-ol, and α-terpineol for all of tea tree oils and commercial products are shown in Figure 4A−D. The lines in the plots are the averages for the enantiomeric ratios of just the known provenance oil samples. Incomplete resolution of enantiomers skewed the results toward the later eluting enantiomer, i.e., the (+)-enantiomer for all compounds except α-terpineol. The effect was especially obvious for the components at the highest concentration and lowest resolution, viz., the alcohols. Better resolution could be obtained with dilute samples or higher split ratio but with an unacceptable loss of sensitivity.

The analyses of a large number of samples allowed the establishment of a characteristic +/− chiral ratio, i.e., the average of the TTO data, without regard to previously published data. Outliers could be identified by their "distance" from the average. Thus, the absolute value of the chiral ratio was less important than the deviation of a sample from the norm of the TTO data set.

Commercial Samples. Except for the synthetic samples, all of the ATTIA samples met the ISO standards (1−6%) for α-pinene. Figure 4A shows the chiral results and outliers for α-pinene. The data are given as the ratio (+/−)-enantiomers rather than percentages because it was easier to identify outliers with ratios rather than percentages. Mosandl[11] reported ratios of 6−10, Southwell reported a ratio of 9.3,[6] and Leach[13] reported a ratio of 9. The average value for α-pinene in Table S2, Supporting Information, was 13.0. Outliers were identified as samples that displayed an enantiomeric ratio greater than the average plus three times the standard deviation (SD). These points are shown as ▲ in the figure. The same criterion was used to determine outliers below the average minus three times the SD (▼). The chiral results did not show a clear plateau. This compound is ubiquitous in many natural products, and the concentration range was low, so this probe solute is not satisfactory for quality control of TTO products.

The chiral results for limonene are illustrated in Figure 4B. The ratio of (+/−)-isomers in TTO has been reported as 1.4−1.6 by Mosandl[11] and 1.7 by Shellie.[12] In the present study, the average value for the limonene data was 1.83 for the 57 TTO samples, all of which met the ISO standards (0.5−1.5%). Four commercial samples, viz., A44, A76, A77, and A109, contained almost exclusively (+)-limonene. Samples A16, A85, and 101 contained a racemic mixture of limonene enantiomers. Ten other samples contained primarily the (+)-isomer but in concentrations higher than the average of all samples. Of the 17 samples that were outliers for the limonene chirality, 9 were also outliers for the ISO standards. The samples that did not meet ISO standards are shown as open data points in the figures.

Terpinen-4-ol or 4-terpineol is a major, characteristic component of TTO (30−48%) and the basis for the so-called terpinen-4-ol type of TTO. Previous literature reports the chiral ratios for terpinen-4-ol in TTO range from 2.17,[2] 1.96,[9] 2.13−2.57,[10] 1.78−2.23,[11] 2.22,[12] and 1.88.[13] The average of the data for terpinen-4-ol in Table S2, Supporting Information, was 1.72. The results are shown in Figure 4C. Only two samples (A16 and A89) displayed an excess of the (+)-enantiomer. However, 22 samples had measured ratios significantly less than the average of the full data set. Because of the broad range of concentration (30−48%) for terpinen-4-ol specified in the ISO document, only three samples (A16, A47, and A85), other than the two synthetic samples, did not meet the ISO standards for terpinen-4-ol.

The two synthetic samples (A45 and A99) both gave measured +/− ratios of ∼0.3 compared to the average of 1.72 for the natural essential oil samples. Thus, a low enantiomeric ratio for

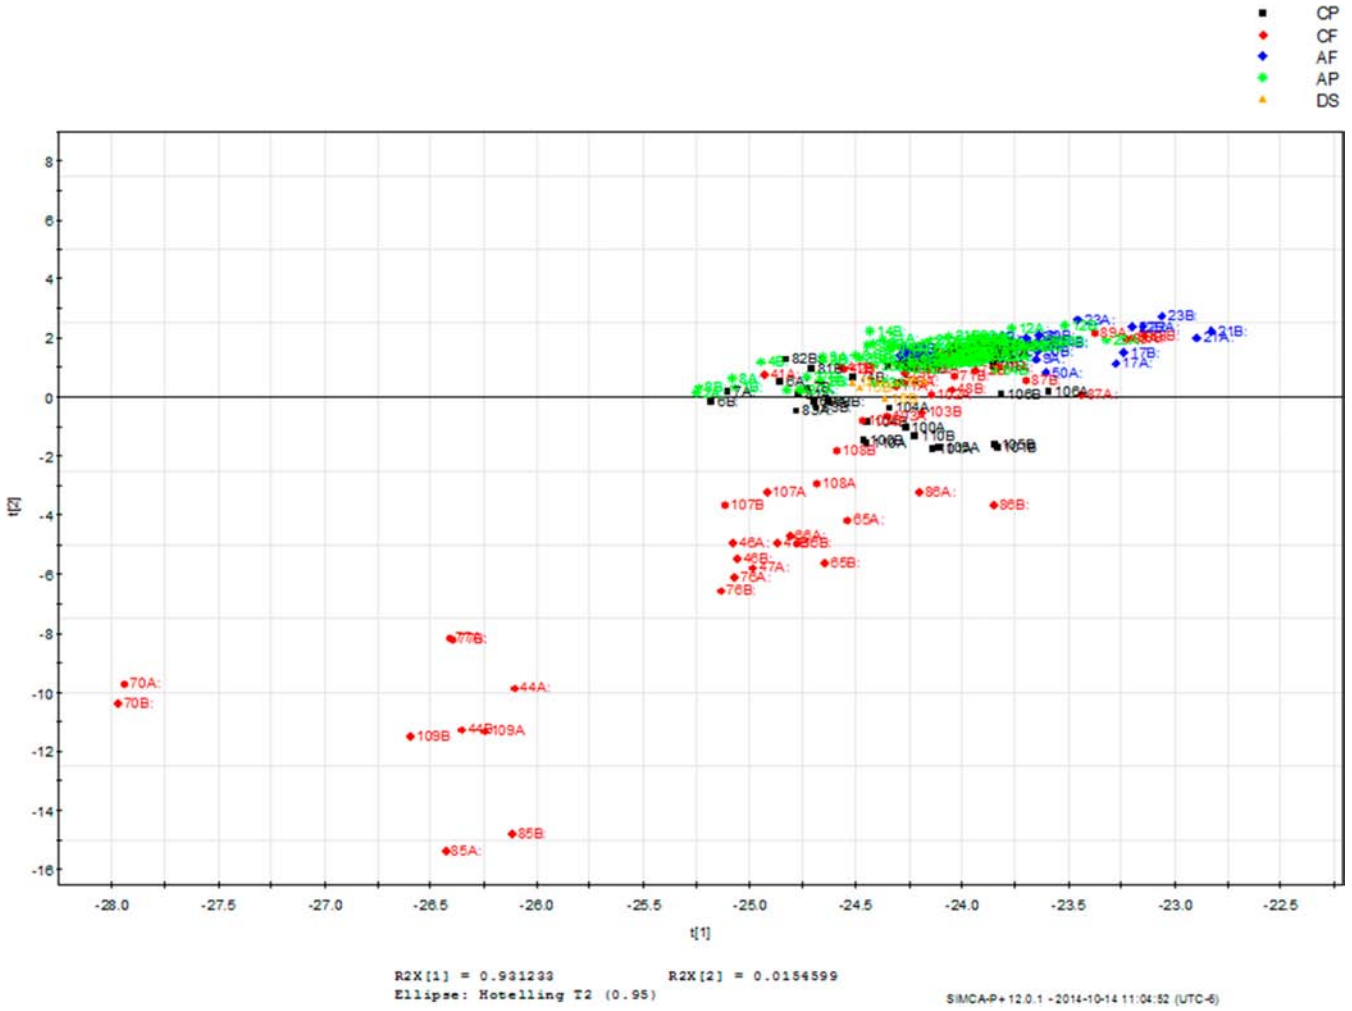

Figure 5. PCA score plot of the TTOs and commercial products. CP: Commercial samples met ISO standards. CF: Commercial samples failed to meet ISO standards. AF: TTOs failed to meet ISO standards. AP: TTOs met ISO standards. DS: Different species (A15 and A16).

this component may be a clear indication of substitution or adulteration in commercial products.

The results for the chiral analysis for α-terpineol are shown in Figure 4D. The previously measured chiral ratios for α-terpineol in TTOs were 2.92,[2] 3.31,[9] 2.85−3.35,[10] 2.65,[12] and 2.94.[13] The average for all of the TTO samples in Table S2, Supporting Information, was 3.86. Sixteen samples had excessively high +/− ratios, while nine displayed excessively low ratios. With this probe solute, there were seven samples (shown in Figure 4D as open data points) that did not meet the ISO composition standards and were outliers from the average value in the chiral analyses. Thus, this solute may provide a method for the detection of unacceptable commercial products that would not be detected with the ISO standards alone.

Chiral analysis can be used to identify commercial samples that are unacceptable in chiral distribution but satisfactory in chemical composition (chemotype). However, chiral GC is difficult. Baseline resolution between enantiomers is hard to achieve and even more difficult to maintain especially with complex samples such as natural products. Thus, chiral analysis alone is possibly not the optimum method for evaluating or validating commercial TTO products.

Chemometric Analyses. Chiral analysis is based only on limited probe solutes such as α-pinene, limonene, terpinen-4-ol, and α-terpineol. GC/MS analysis is a more holistic approach utilizing information concerning all of the components in a TTO or commercial sample. However, three-dimensional GC/MS data sets are difficult to interpret because of their sheer size. For example, in the present study with 104 samples, ca. 50 components with a mass range of 500 amu, the data set contained over 2 million points. Chemometric pattern recognition techniques, such as principal component analysis, are valuable tools for reducing the complexity of such data sets.

The GC/MS results normalized to the internal standard, $C_{13}H_{28}$, were subjected to PCA, in which all observations and variables are present. The scores plot for the entire data set is shown in Figure 5. The summary of the fit of the model is displayed with R^2X (cum) [R^2X shows the percentage of variance in the data that is explained by a particular component, R^2X(cum) sums up the R^2X as they accumulate with an increase in the number of components] and Q^2 (cum) [indicates the predictive ability of the model]. In total the PCA describes 93.1% of the variation (R^2X) in the data with a Q^2 of 93.0% for the first component indicating good prediction properties of the model. The first two components explain 96.0% of the variables. The R^2 and Q^2 plot for the PCA is given in Figure S2, Supporting Information. In this case, PCA provides an overview of the data and identifies the trends, groups, and strong outliers.

Class prediction analysis has proven to be a valuable technique in characterization and authentication of traditional medicinal

DOI: 10.1021/acs.jafc.5b00147
J. Agric. Food Chem. 2015, 63, 2674−2682

plants. The class prediction model allows assigning new samples into previously determined groups in an unbiased fashion. This workflow would be very useful for the QC of natural products and dietary supplements because the batch samples can be automatically acquired, processed, and class predicted. In the current investigation, all known provenance TTOs that met the ISO standards cluster in a single group (green) in the PCA score plot (Figure 5). The chiral ratios of α-pinene, limonene, terpinen-4-ol, and α-terpineol for the tea tree oil samples in this group were also within the ranges of norms. Thus, this group of samples was used to construct a class predictive model (PCA-class). The PCA-class model was cross-validated and used to evaluate all commercial samples and the TTO samples that did not meet the ISO standards. The R^2 and Q^2 values for the PCA class model (Figure S3, Supporting Information) were 95.5% and 95.4%, respectively. The results given in Table S3, Supporting Information, provide a confidence measure to the prediction, PModXPS+. This value shows the probability of the predicted observations belonging to the model. Observations with a probability of belonging less than 5% (PModXPS+ < 0.05) are considered to be outliers of the class predictive model and dissimilar to the observations used to build the model. In particular, there were several commercial products that met the ISO specifications but displayed unusual enantiomeric ratios (A100, A101, A104−106, and A110); those commercial products were also identified as outliers by the class prediction model. Additionally, there were TTOs and commercial products (A9, A17, A21−23, A48, A-50, and A-79) that met the chiral specifications but did not meet the ISO standards; they were also outliers identified by the PCA class prediction model. The results from the class prediction model and the outliers identified by different methods are summarized in Table S3, Supporting Information.

In conclusion, both chiral and conventional GC/MS analysis can be used to identify abnormal commercial tea tree oil products. Four chiral components, viz., α-pinene, limonene, terpinen-4-ol, and α-terpineol, were utilized for chiral analysis of the TTO samples. These compounds are major components of terpinen-4-ol type oils. Chiral analysis based on these four probes could be used to identify unsatisfactory, adulterated, substituted, or otherwise unusual commercial TTO products.

Analysis of three-dimensional GC/MS data along with chemometrics can also be used to isolate outliers in commercial samples. In this investigation, the outliers identified by chiral analysis coincided with the outliers identified by the class predictive model for all of the TTO components.

NMR Analysis. NMR spectra were measured with a JNM-A400 spectrometer (JEOL, Japan). The NMR spectra (^{1}H, ^{13}C, DEPT, COSY, CHSHF, HMBC) of isolated inositols were measured with D_2O and 3-(trimethylsilyl)propionic acid sodium salt as an internal standard.

Extraction and Separation of Inositols from Plants. Ten grams of each plant was homogenized in 100 mL of 80% EtOH for 1 min with a Polytron (Kinematica AG, Switzerland) at room temperature. After filtration of the mixture with a filter paper under suction, the residue was re-extracted twice with 100 mL of 80% EtOH. Filtrates were combined and concentrated to dryness with a rotary evaporator under vacuo. The dried filtrate was dissolved in 20 mL of water and extracted three times with 10 mL of *n*-pentane to remove chlorophyll. The water solution was concentrated to remove *n*-pentane and made up to 50 mL with water. One milliliter of the solution was passed through an ODS cartridge (⌀ 1 × 1 cm, BondElut C18, Varian) equilibrated with water after washing thoroughly with MeOH. The pass-through fraction was charged to a Dowex 1 × 4 column ($^-$OH type, ⌀ 0.6 × 3.5 cm) connected to an ODS cartridge. The cartridge was washed with 3 mL of water. The eluate was successively passed through the Dowex small column. After removal of the ODS cartridge, the Dowex column was further washed with 4 mL of water. Eluates (total 8 mL) were combined and made up to 10 mL with water. Twenty-five microliters of the solution containing inositols was analyzed by HPAE-PAD. Extraction and separation of inositols from each plant and HPAE-PAD analysis were carried out twice and the contents of inositols averaged.

Isolation and Identification of Inositols. Several inositols were isolated from the remaining solutions of the above crude extracts and used in the preparation of samples for the HPAE-PAD analyses. The extract solutions were charged to a Wakosil ODS (C18, Tokyo, Japan) column (⌀ 2 × 10 cm) and washed with water. The pass-through fractions were concentrated and further separated with a Dowex 1 × 4 column ($^-$OH type, ⌀2 × 10 cm). Water elutes were fractionated into 5 g each and eluates of each fraction detected by spotting on a TLC plate, spraying 40% sulfuric acid to spots, and heating the plates at 105 °C. Fractions containing inositols were concentrated and lyophilized. Chemical structures of isolates were identified by comparison with NMR spectra of authentic samples or the literature.[11−21]

Determination of Hydroxyl Radical Scavenging Activity. The hydroxyl radical scavenging activities of inositols were determined by adding them to a generating/detecting system and observing their competition with the detector.[9] Hydroxyl radicals were generated from ascorbate and detected by their ability to hydroxylate salicylic acid.[9,10,22] The reaction mixture contained 150 mM K-Pi buffer (pH 7.4), 0.26 mM ascorbic acid, 0.15 mM Fe(III)−EDTA, 0.6 mM H_2O_2, 2 mM sodium salicylate, and 20 mM inositol or other compound in a total volume of 2 mL. After incubation for 60 min at 25 °C, hydroxylated salicylate was extracted and spectrophotometrically determined by the following methods. To the reaction mixture were added 0.5 mL of 2.0 M HCl saturated NaCl and 2 mL of diethyl ether, and then the solution was mixed with a Vortex mixer for 30 s. After removal of the upper ether layer, hydroxylated salicylate was re-extracted with 2 mL of diethyl ether. The combined ether layer was evaporated to dryness at 50 °C with N_2 gas. To the residues dissolved in 0.25 mL of deionized water were added 0.125 mL of 10% (w/v) trichloroacetic acid dissolved in 0.5 M HCl, 0.25 mL of 10% (w/v) sodium tungstate, and 0.25 mL of 0.5% (w/v) sodium nitrite. After standing for 5 min, 0.5 mL of 0.5 M KOH and 1.375 mL of deionized water was added to the solution, and absorbances were measured at 510 nm. Assays for each compound were carried out four times, and the inhibitory activities on salicylate hydroxylation by hydroxyl radicals were averaged.

RESULTS AND DISCUSSION

Separation and Determination of Inositols by HPAE-PAD. Chair conformations of *myo*-inositol, *chiro*-inositol, and *scyllo*-inositol including ononitol, sequoyitol, and pinitol are indicated in Figure 1. Inositols contain six hydrogen atoms. In the *scyllo*-inositol (c), the bonds of hydrogen atoms are all axial, whereas those of the hydrogen atoms at the 2-position in *myo*-inositol (a) and at the 1- and 6-positions in *chiro*-inositol (b) are equatorial. Ononitol and pinitol are methylated compounds consisting of *myo*-inositol at the OH of the 4-position and *chiro*-inositol at the OH of the 3-position. The five compounds having similar structures were well separated by HPAE-PAD with a Dionex CarboPac MA1 column (Figure 2). 5-*O*-Methyl-*myo*-inositol (sequoyitol) and *β*-D-methyl-glucose (d), however, had the same retention times as ononitol and *scyllo*-inositols,

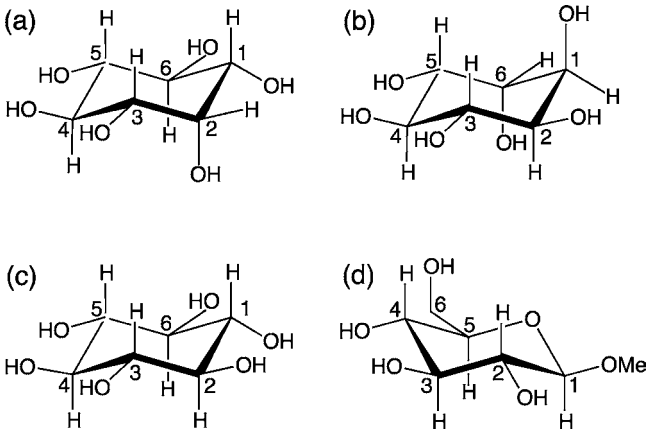

Figure 1. Structures of *myo*-inositol (a), *chiro*-inositol (b), *scyllo*-inositol (c), and *β*-D-methyl-glucose (d). O-methylated compounds at the 4-and 5-positions in (a) and at the 3-position in (b) are ononitol, sequoyitol, and pinitol, respectively.

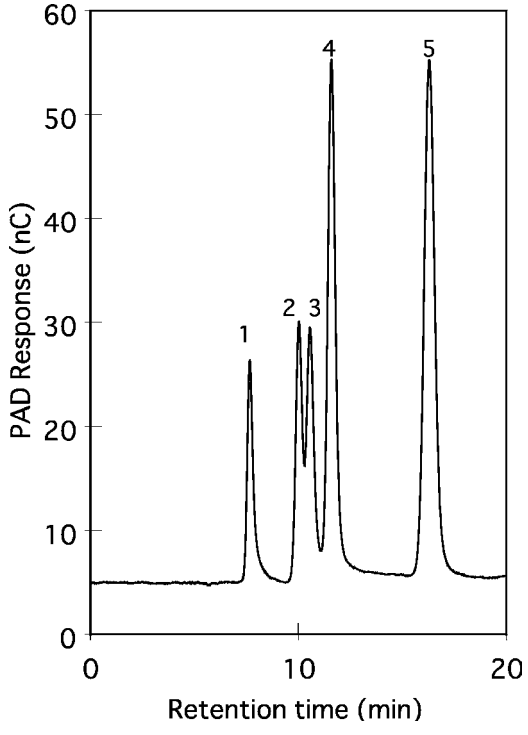

Figure 2. Separation of inositols by HPAE-PAD. Peaks: 1, ononitol or sequoyitol (retention time, 7.7 min); 2, pinitol (10.0 min); 3, *myo*-inositol (10.6 min); 4, *scyllo*-inositol or *β*-D-methyl-glucose (11.6 min); 5, *chiro*-inositol (16.3 min). Additionally, retention time of glucose was 37.4 min. See the details of the separation conditions under Materials and Methods.

[a]Underlined values were identified by NMR analyses. –, undetected. [b]In clover, β-D-methyl-glucose was detected instead of *scyllo*-inositol. [c]In gingko, sequoyitol (5-*O*-methyl-*myo*-inositol) was detected instead of ononitol.

respectively (Figure 2), under our HPLC conditions. By PAD, we were able to determine the sugars and cyclitols in the amounts of 10 pmol, without modifications.[7]

Identification of Inositols by NMR. In Table 1, the compounds with the values underlined were all identified by ^{1}H and ^{13}C NMR analyses after the isolations, which were completed by using Wakosil ODS and Dowex 1 × 4 columns as indicated under Materials and Methods. The yields of most isolates in Table 1 were >40%. The ^{1}H NMR spectra in Figure 3 are distinguishable from each other for identifications. The H-2 position in *myo*-inositol, the H-1 and H-6 positions in *chiro*-inositol, and those in their methylated compounds were equatorial (Figure 1). Signals of these protons were detected at approximately 4.0 ppm (Figure 3A–E). Proton signals of methoxyl groups were observed at 3.6 ppm in methylated compounds (Figure 3B,C,E). Methylations of the hydroxyl groups in *myo*-inositol and *chiro*-inositol changed the chemical shifts of the axial protons, especially H-4 of B, H-5 of C, and H-3 of E showed low frequencies. By comparing the signal patterns of the ^{1}H NMR spectra in pinitol, ononitol, and sequoyitol, we were able to identify each of them easily. Furthermore, the spectrum of β-D-methyl-glucose is similar to that of the methylated inositols, but the existences of anomeric proton of H-1 (about 4.4 ppm) and 2 protons of H-6 are remarkably different from the inositols (Figure 3E). On the other hand, the signals of protons and carbon atoms were each observed as one signal (3.35 and 76.4 ppm, respectively) in authentic *scyllo*-inositol, the structure of which is symmetric (Figure 1).

^{1}H NMR and ^{13}C NMR Spectral Data. The spectra of *myo*-inositol, D-*chiro*-inositol, D-pinitol, and β-D-methyl-glucose were in agreement with those of the authentic samples and data in the literature.[11−21] The NMR spectral data of methylated inositols were assigned as follows:

Ononitol: ^{1}H NMR (400 MHz, D_2O) δ 4.05 (1H, t, J = 2.8 Hz, H-2), 3.67 (1H, t, J = 5.6 Hz, H-6), 3.63 (1H, t, J = 5.6 Hz, H-3), 3.60 (3H, s, 4-OMe), 3.49 (1H, dd, J = 10.0, 2.8 Hz, H-1), 3.39 (1H, t, J = 9.2 Hz, H-4), 3.36 (1H, t, J = 9.2 Hz, H-5); ^{13}C NMR (100 MHz, D_2O) δ 85.3 (C-4), 76.5 (C-5), 75.3 (C-6), 75.1 (C-2), 73.8 (C-1), 73.4 (C-3), 62.6 (OMe).[12,15]

Sequoyitol: ^{1}H NMR (400 MHz, D_2O) δ 4.05 (1H, t, J = 2.8 Hz, H-2), 3.71 (2H, t, J = 10.0 Hz, H-4, H-6), 3.60 (3H, s, 5-OMe), 3.55 (2H, dd, J = 10.0, 2.8 Hz, H-1, H-3), 3.07 (1H, t, J = 9.6 Hz, H-5); ^{13}C NMR (100 MHz, D_2O) δ 87.0 (C-5), 74.8 (C-2), 74.5 (C-4, C-6), 73.9 (C-1, C-3), 62.4 (OMe).[14]

D-Pinitol: ^{1}H NMR (400 MHz, D_2O) δ 4.01 (2H, m, H-1, H-6), 3.82 (1H, dd, J = 10.0, 2.0 Hz, H-5), 3.77 (1H, dd, J = 10.0, 2.0 Hz, H-2), 3.66 (1H, t, J = 10.0 Hz, H-4), 3.60 (3H, s, 3-OMe), 3.35 (1H, t, J = 10.0 Hz, H-3); ^{13}C NMR (100 MHz, D_2O) δ 85.6 (C-3), 74.9 (C-4), 74.5 (C-1 or C-6), 74.3 (C-6 or C-1), 73.4 (C-2), 72.6 (C-5), 62.5 (OMe).[13]

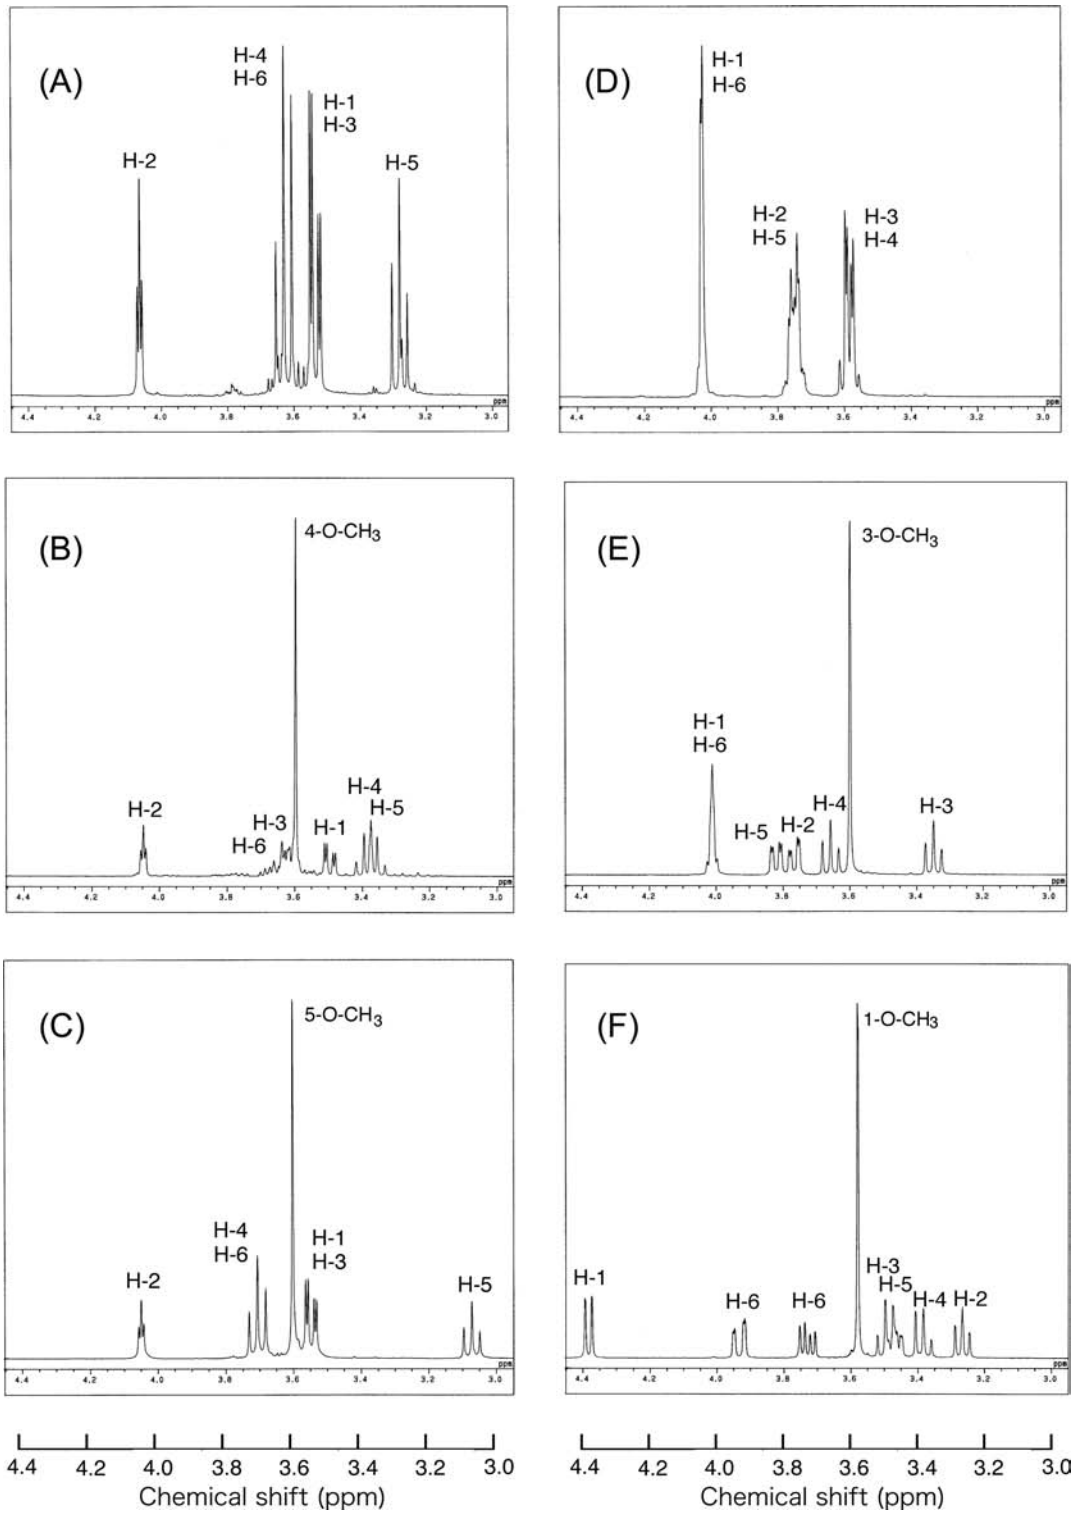

Figure 3. ^{1}H NMR spectra of several isolates: (A) *myo*-inositol from young leaf of dandelion; (B) ononitol from stem and leaf of sticky mouse-ear; (C) sequoyitol from young leaf of ginkgo; (D) *chiro*-inositol from young leaf of Japanese mallotus; (E) pinitol from stem and leaf of chickweed; (F) *β*-D-methyl-glucose from stem of white clover. As compared with these spectra, only one signal was observed at 3.35 ppm in the spectrum of authentic *scyllo*-inositol.

Content of Inositols in the Familiar Plants. The content of inositols in 45 kinds of edible plants from 23 families was investigated. Table 1 shows that 12 familiar plants contain large amounts of *myo*-inositol, *chiro*-inositol, and their methylated compounds. Soybean, white, red and bush clovers, locust tree, wisteria, and kudzu, which are all Fabaceae plants, contained pinitol of 200−600 mg/100 g fresh weight. Similar amounts of pinitol were found in sticky mouse-ear, chickweed, and ginkgo, whereas dandelion and Japanese mallotus contained large amounts of nonmethylated type *chiro*-inositol. Kim et al.[6] reported that total *chiro*-inositol contents in 100 g dry weight of carob pod, *Bougainvillea*, soy whey, and soybean oligosacchar-

DOI: 10.1021/jf5041367
J. Agric. Food Chem. 2015, 63, 2683−2688

ides were 4.0, 2.0, 2.0, and 1.74 g, respectively. A comparison with moisture contents showed 100 g dry weights of pinitol for young leaves of soybean, stems of white clover, stems of red clover, young leaves of locust tree, sticky mouse-ear, and chickweed were 1.54, 5.29, 3.93, 2.46, 1.92, and 2.71 g, respectively. On the other hand, peaks of ononitol were detected in Fabaceae plants and sticky mouse-ear, especially in the young leaves of locust trees. In ginkgo a peak of ononitol was detected, but this compound was identified as sequoyitol by NMR analysis after isolation. Similarly, in the peaks of *scyllo*-inositol detected in white and red clovers by HPAE-PAD, *β*-D-methyl-glucose was detected. In plants the accumulation of pinitol is commonly thought to be beneficial for stress adaptation and stabilization of membranes against osmotic alternations.[13] Furthermore, the plants used in this study were collected in the spring, suggesting that plants accumulate large amounts of inositols as cryoprotectants to protect themselves against the winter cold.[8] Furthermore, Adams et al. reported an apparent correlation in the postharvest longevity of flowers and content of inositols, particularly D-pinitol.[7] Pinitol content of flower petals from carnation was 7.2 mg/g FW.[7] It is presumed that pinitol is biosynthesized from *myo*-inositol via ononitol or sequoyitol.[15,23,24] In dandelion and Japanese mallotus (Table 1), it is suggested that some *myo*-inositol remains without methylation and that ononitol has already been epimerized and demethylated to be *chiro*-inositol, whereas pinitol in ginkgo, which belongs to gymnosperm, seems to be synthesized via sequoyitol.[15,23,24] In the plants not shown in Table 1, 4.9 mg/100 g FW of ononitol, 19.0 mg/100 g FW of pinitol, and 3.4 mg/100 g FW of *myo*-inositol in ice plant (*Mesembryanthemum crystallinum*) and 40.8 mg/100 g FW of pinitol and 27.9 mg/100 g FW of *myo*-inositol in *Artemisia indica* were detected. Furthermore, 160−210 mg/100 g FW of *myo*-inositol was detected in the leaves of *Cercidiphyllum japonicum*, *Lonicera japonica*, *Morus alba*, and *Diospyros kaki*. Furthermore, dandelion and Japanese mallotus (Table 1) contained 191.3 (or 141.3) mg/100 g FW and 156.4 mg/100 g FW of *chiro*-inositol, respectively. These high contents are compared to the other plants in Table 1. The sprouts of mung bean are reported to contain 5.79 mg/g DW or less of *chiro*-inositol,[25] which is not more than half the content of dandelion or almost the same as Japanese mallotus.

Hydroxyl Radical Scavenging Activity of Inositols. Table 2 shows the inhibitory effects of *myo*-inositol, *scyllo*-inositol, *chiro*-inositol, their methylated inositols, and several other compounds on salicylate hydroxylation by hydroxyl radicals. Inhibition with *myo*-inositol and *scyllo*-inositol was approximately 55%. Inhibition by *chiro*-inositol, mannitol, sorbitol, and glucose was about 65%. Furthermore, inhibitory activities of pinitol, ononitol, sequoyitol, and *β*-D-methyl-glucose were about 75%, which are higher than those of their native compounds by 10−20%. These results indicate that the methylated compounds have high activities for hydroxyl radical scavenging. On the other hand, substantial amounts ranging from 2.5 to 6.5 mM of *myo*-inositol, *chiro*-inositol, and *scyllo*-inositol were detected in mouse blood plasma after oral administration of 1 g/kg BW of three inositols.[26] This suggests that inositols can function as strong hydroxyl radical scavengers in the human body.

Applications in Our Daily Lives. This study showed that plants containing large amounts of inositols are commonly grown as well-known plants (Table 1). Boiled young soybeans are very often eaten in Japan, so people can ingest pinitol in their daily lives. However, the young leaves of soybean can be easily used for fried foods and soups. Young vines of kudzu are grown in spring to summer. Other Fabaceae plants such as clovers and locust trees are found everywhere and can be easily used. Furthermore, dandelion, sticky mouse-ear, and chickweed are weeds that are useful for human health. Leaves of ginkgo tree, dandelion, and kaki are already used as herbal teas in Japan. Other than eating plants, extracts from plants with boiled water are useful for cooking. Kim et al.[6] isolated pinitol from soy whey and carob pod and indicated that oral administration of soy pinitol and carob pinitol (10 mg/kg) decreased blood glucose by 15% at 2−6 h in streptozotocin-induced diabetic rats. This study demonstrated that pinitol can be beneficial in controlling blood glucose in an animal model of diabetes mellitus. On the other hand, considerable amounts of *myo*-inositol, *chiro*-inositol, and their methylated compounds, which are effective hydroxyl radical scavengers (Table 2), may be incorporated into the blood.[26] These results indicate that inositols play very important roles for protecting humans from stresses. Although we did not examine the physiological functions of inositols from the plants in this study, isolates from our plants likely have the same functions as those from soy whey and carob pod. Ingesting these plants is expected to provide good effects for human health. The familiar edible plants in this study may be more easily available and economical sources of inositols.

Table 2. Inhibitory Effect of Various Compounds on Salicylate Hydroxylation by Hydroxyl Radicals

compound	inhibition[a] (%)
myo-inositol	54.5 ± 3.8
scyllo-inositol	56.2 ± 1.5
chiro-inositol	66.0 ± 1.0
pinitol (3-*O*-methyl-*chiro*-inositol)	75.6 ± 1.3
ononitol (4-*O*-methyl-*myo*-inositol)	74.9 ± 1.7
sequoyitol (5-*O*-methyl-*myo*-inositol)	76.4 ± 1.2
mannitol	65.8 ± 2.0
sorbitol	66.9 ± 1.3
glucose	64.3 ± 2.4
β-D-methyl-glucose	75.7 ± 1.2
proline	22.3 ± 3.3
glycinebetaine	0.5 ± 3.4

[a]Inhibition (%) is expressed as $(1 - P/C) \times 100$, where P is A_{510} in the salicylate hydroxylation reaction with inositols or other compounds and C is A_{510} in the control reaction without those compounds; values are means ± SD.

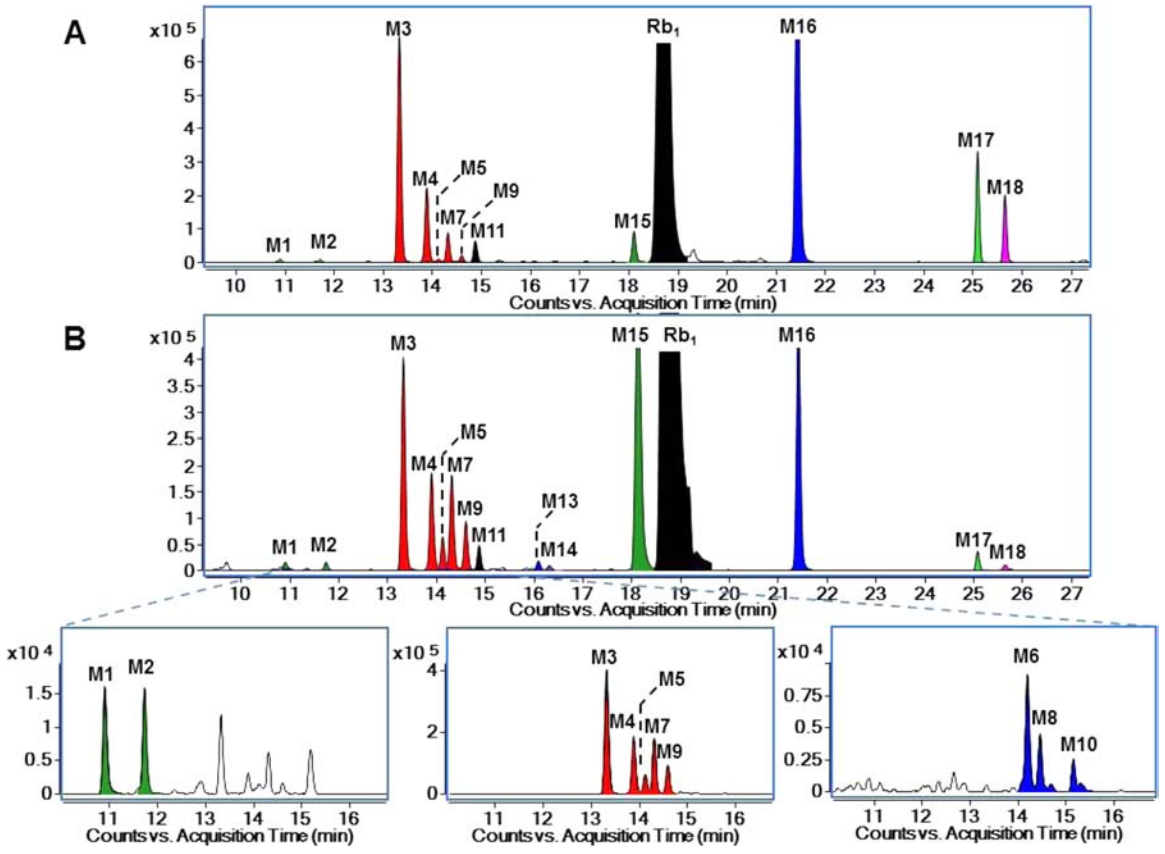

Figure 1. Extracted compound chromatograms (ECC) of metabolites in rat plasma and urine after iv injection of Rb_1 at a dosage of 20 mg/kg: (A) metabolites in plasma sample collected at 5 min after iv injection; (B) metabolites in urine samples collected during 3−6 h after iv dose of Rb_1.

pharmacological effects of the primary ginsenosides as well as their relevant metabolites. However, metabolism of the intact ginsenosides following intravenous administration remains unknown. Consequently, a huge gap between the considerable systemic effects of primary ginsenosides and metabolites reaching circulation system still exist.

In addition to the well-known deglycosylation and dehydration pathways, ginsenosides have been increasingly reported to undergo oxidation.[19−25] Oxygenated metabolites of both intact and deglycosylated ginsenosides have been observed as circulating metabolites.[19,20,22,26,27] Recently, structures of oxygenated metabolites formed in liver microsomes of secondary ginsenosides, that is, Rh_2,[25] PPD,[28] Rh_1, and Rg_2,[29] have been elucidated. However, primary ginsenosides appeared to be metabolized via pathways distinct from that of secondary ginsenosides as they were not metabolized in microsomes. Structures of resulting oxygenated metabolites of primary ginsenosides were still not fully characterized due to technique difficulties, that is, a limitation in determining the exact oxygenated site solely by mass spectrometry, and difficulties in obtaining metabolites in adequate amounts for NMR measurements.

As aforementioned, we herein carried out an extensive in vivo metabolite profiling of ginsenoside Rb_1, the representative PPD-type primary ginsenoside in ginseng, American ginseng, and notoginseng, with a focus on the characterization of its oxygenated metabolites in rat plasma and urine.

MATERIALS AND METHODS

Chemicals and Materials. Ginsenoside Rd and 20(*S*)-Rg_3 (purity ≥ 98%) were purchased from Chengdu Scholar Biotech Co., Ltd. (Chengdu, China). Ginsenoside Rb_1 and F_2 (purity ≥ 98%) were purchased from Chengdu MUST Bio-Technology Co., Ltd. (Chengdu, China). Rose Bengal, triphenylphosphine, Shi Epoxidation Diketal Catalyst (ketone), OXONE, EDTA-Na, and sodium bicarbonate were purchased from Sigma-Aldrich (St. Louis, MO, USA). Liver microsomes, NADPH Regenerating System Solution A (containing 31 mM $NADP^+$, 66 mM glucose-6-phosphate, and 66 mM $MgCl_2$) and Solution B (containing 40 U/mL glucose-6-phosphate dehydrogenase in 5 mM sodium citrate) were purchased from BD Biosciences (San Jose, CA, USA). Saline was purchased from Baxter (Deerfield, IL, USA). HPLC grade methanol (MeOH) and acetonitrile (ACN) were purchased from Anaqua Chemicals Supply Inc., Ltd. (Houston, TX, USA), and distilled water was purified by Milli-Q system (Millipore, Billerica, MA, USA). All other chemicals were of analytical reagent grade.

Animals. Male SD rats (n = 2 for each route of administration) weighing 200−220 g were purchased from the Laboratory Animal Services Center, Chinese University of Hong Kong. All animals were acclimated for more than 1 week under a 12 h light/12 h dark cycle at a room temperature of 22 ± 1 °C. Animal care and treatment procedures were in accordance with the Institutional Guidelines and Animal Ordinance (Department of Health, Hong Kong Special Administrative Region) and approved by the Committee on the Use of Human and Animal Subjects in Teaching and Research of the Hong Kong Baptist University. The rats were fasted overnight but with access to water before the experiment.

UHPLC/TOF MS Analysis of Metabolites. Metabolites in the biological samples of both in vivo and in vitro metabolism experiments were analyzed by using an Agilent 1290 Infinity ultrahigh-performance liquid chromatography (UHPLC) system coupled to an Agilent 6230 accurate-mass time-of-flight (TOF) mass spectrometer (MS) (Agilent, Santa Clara, CA, USA). MS/MS experiments were carried out on an Agilent 1290 Infinity UHPLC system coupled with an Agilent 6550 quadrupole-time-of-flight (Q-TOF) MS.

The chromatography was performed on a Waters Acquity BEH C_{18} column (2.1 × 100 mm, 1.7 μm). The mobile phase consisted of 0.1%

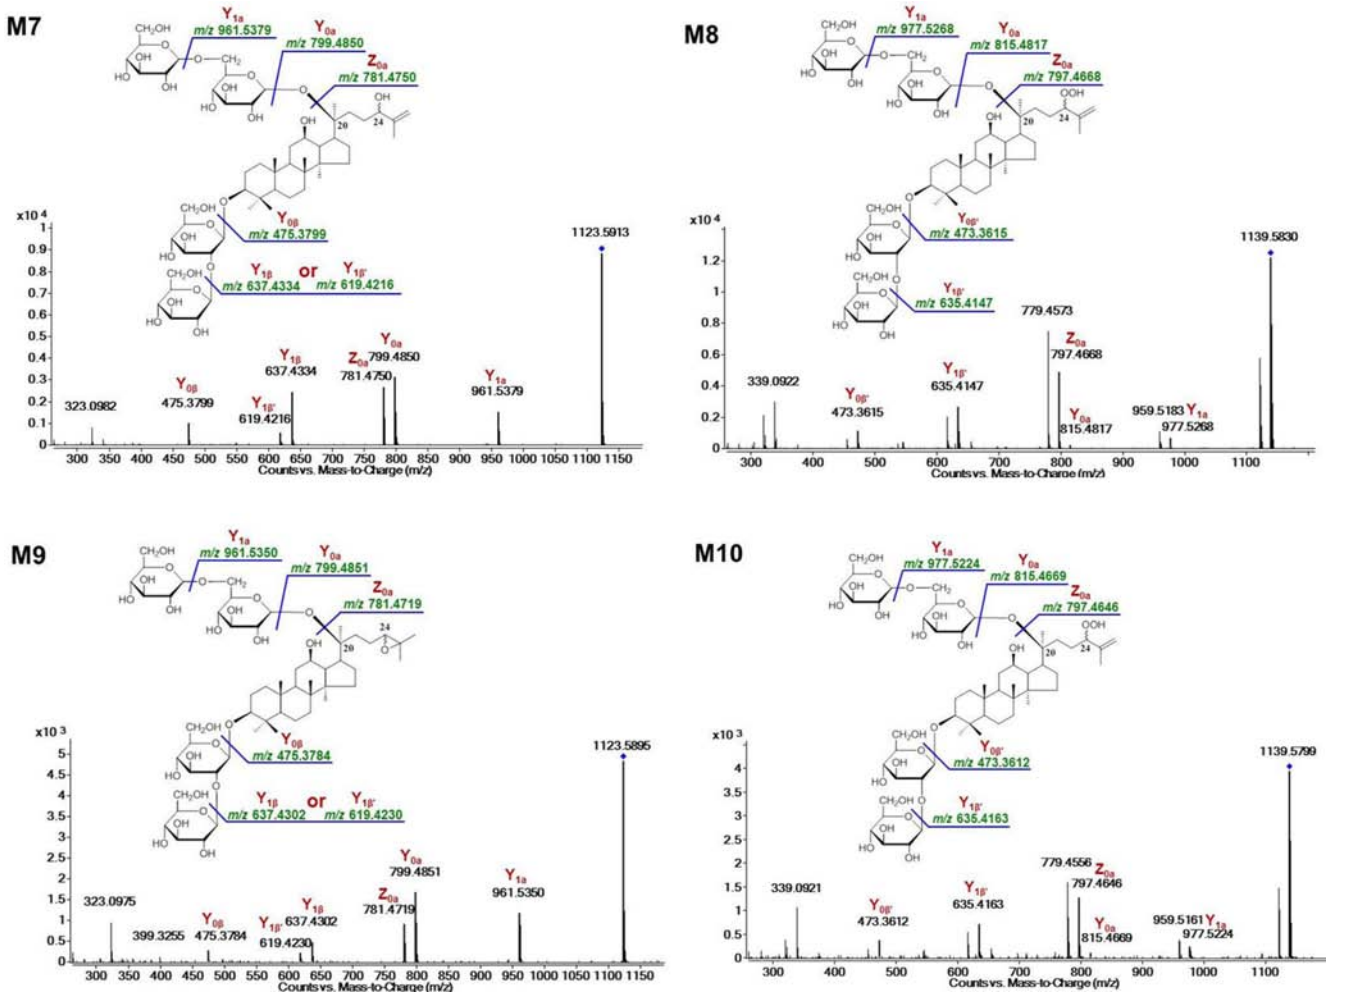

Figure 2. High-resolution MS/MS of urinary **M1**−**M10** obtained on Q-TOF MS.

formic acid in Milli-Q water (A) and ACN containing 0.1% formic acid (B). The optimized UPLC elution condition as follows was employed: from 10 to 40% B at 0−23 min, from 40 to 85% B at 23−27 min, from 85 to 100% B at 27−29 min, and finally maintained at 100% B for 3 min at a flow rate of 0.35 mL/min. The injection volume was 5 μL.

The ESI-MS was performed in the negative mode, and the source parameters were as follows: dry gas (N_2) temperature and flow rate were 325 °C and 11 L/min, respectively; sheath gas (N_2) temperature and flow rate were 350 °C and 11 L/min, respectively; nebulizer, 40 psi; fragmentor voltage, 175 V; skimmer voltage, 65 V. The acquisition mass range was m/z 100−1700, and the MS scan rate was 2 spectra/s. A reference solution was nebulized for continuous calibration in the negative mode using the reference masses of m/z 112.9856 and 966.0007. The targeted MS/MS collision energy (CE) was set at three different values from 20 to 60 eV. All MS and MS/MS data were processed using Agilent MassHunter Qualitative Analysis B.06.00 software.

In Vivo Metabolism of Ginsenoside Rb_1 Following Intravenous Injection and Oral Administration in Rat. Ginsenoside Rb_1 was first dissolved in saline (8 mg/mL), and then a single intravenous (iv) dose of Rb_1 solution (20 mg/kg) was given through the caudal vein. The blood (0.2 mL) was withdrawn via medial canthus of the eye at 0, 5, 15, and 30 min and 1, 2, 3, 4, 5, 6, 7, 24, and 48 h postadministration. One hundred microliters of plasma was collected by centrifuging the blood at 4000 rpm for 5 min, and then 200 μL of ACN was added for protein precipitation and ginsenoside extraction. After centrifugation at 14000 rpm for 5 min, the supernatant was transferred into a new tube and dried by speed vacuum. The residue was reconstituted with 100 μL of 50% MeOH. Each sample was centrifuged at 14000 rpm for 5 min before UPLC/TOF MS analysis. For oral administration, Rb_1 was dissolved in water (2.5 mg/mL) and given at a dose of 50 mg/kg. The blood (0.2 mL) was withdrawn via medial canthus of the eye at 0, 0.5, 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 8.5, 9, 9.5, 10, 24, 27, and 34 h postadministration. Urine samples were collected at time intervals of 0−3, 3−7, 7−10, 10−24, and 24−34 h. For analysis, 1 mL of urine was extracted with 0.5 mL of water-saturated *n*-BuOH three times. The *n*-BuOH layers were then combined and dried by speed vacuum. The resulting residue was reconstituted in 100 μL of 50% MeOH and filtered through a 0.2 μm filter.

Chemical Synthesis of Oxygenated Metabolites. Photosensitized oxygenation was carried out to synthesize the oxygenated products following our protocol described previously.[23] Briefly, a solution of ginsenoside Rb_1 (150 mg) and Rose Bengal (150 mg) in 120 mL of MeOH was stirred and irradiated with a 400 W lamp under an oxygen atmosphere at room temperature for 6 h to synthesize crude dioxygenated Rb_1 (Rb_1 + 2O). Triphenylphosphine (35 mg) was further added to the reaction solution and was stirred at room temperature for 2 h for the production of crude mono-oxygenated Rb_1 (Rb_1 + O). Both solutions were evaporated to a small volume under reduced pressure and then directly subjected to a reverse phase preparative column, respectively (isocatic elution with 35% ACN at the flow rate of 2.5 mL/min) to give individual mono-oxygenated Rb_1 (Rb_1 + O (I), Rb_1 + O (II), and Rb_1 + O (III)) and individual dioxygenated Rb_1 (Rb_1 + 2O (I), Rb_1 + 2O (II), and Rb_1 + 2O (III)).

Epoxidation was performed following the procedures described in the literature with minor modifications in our laboratory.[23] Briefly, a solution of ginsenoside Rb_1 (100 mg) in ACN (10 mL) was mixed with an aqueous EDTA-Na solution (0.4 μM, 10 mL). The mixed

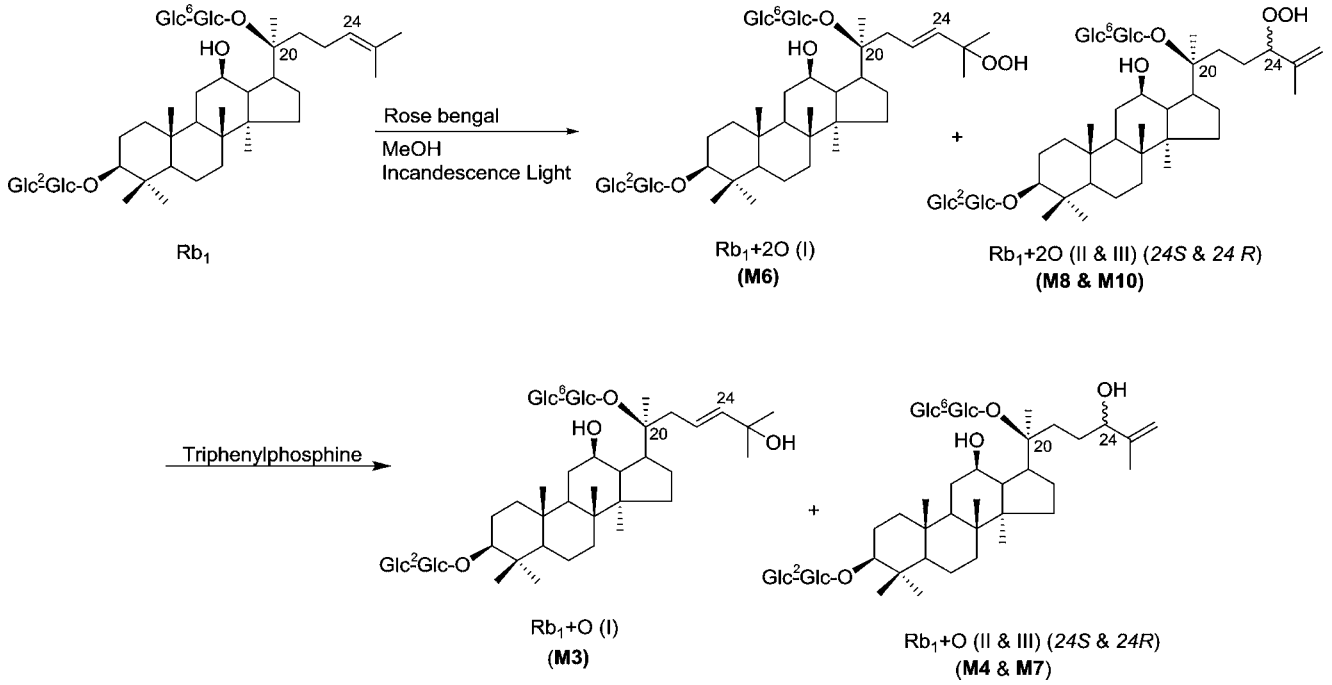
Scheme 1. Chemical Synthesis of Mono- and Dioxygenated Derivatives of Ginsenoside Rb_1



solution was cooled to 0 °C, and then an epoxidation dibetal catalyst solution (ketone, 15 mM in ACN) and a mixture of sodium bicarbonate (67.5 mM) and OXONE (45 mM) were added. The homogeneous solution was stirred for 2 h. Because the epoxide was quite unstable and easily changed to diol (Rb_1 + O + H_2O) as a byproduct, a mixture of Rb_1 epoxides (Rb_1-Epo) and diols (Rb_1 + O + H_2O) appeared in the reaction solution. The reaction solution was reduced in volume by speed vacuum under low temperature and then was directly subjected to a reverse phase preparative column (gradient elution with 10−35% ACN at the flow rate of 2.5 mL/min) to afford individual Rb_1 epoxides (Rb_1-Epo (I) and Rb_1-Epo (II)) and individual Rb_1 diols (Rb_1 + O + H_2O (I) and Rb_1 + O + H_2O (II)).

Chemical structures of the synthesized metabolites were characterized on the basis of the elucidation of NMR data. ^1H and ^{13}C NMR data were measured on a Bruker Ascend 600 NMR spectrometer (600 MHz for ^1H NMR and 150 MHz for ^{13}C NMR).

In Vitro Metabolism of Ginsenoside Rb_1. Metabolism of ginsenoside Rb_1 in liver microsomes and S9 fraction was carried out initially by dissolving Rb_1 in potassium phosphate buffer (pH 7.4), followed by the addition of NADPH Regenerating System Solutions A and B. After prewarming at 37 °C for 5 min, liver microsomes or S9 fraction was added and incubated at 37 °C for 2 h. The reaction was quenched by adding 2-fold ACN for protein precipitation and ginsenoside extraction. After centrifugation at 14000 rpm for 5 min, the supernatant was collected for analysis.

Ginsenoside Rb_1 was spiked in fresh blood, red blood cells, and plasma, respectively. After incubation at 37 °C for 2 h, 100 μL of H_2O was added in the red blood cell sample and incubated at 37 °C for 5 min, whereas plasma was collected from whole blood by centrifugation at 4000 rpm for 5 min. Two-fold ACN was added in the cell lysed sample or plasma for protein precipitation and ginsenoside extraction. After centrifugation at 14000 rpm for 5 min, the supernatant was collected for analysis.

RESULTS

Characterization of Oxygenated Metabolites of Ginsenoside Rb_1 in Rat Urine and Plasma after Intravenous Administration. It has been suggested that oxygenated metabolites of ginsenosides were majorly derived from tissue oxidation.[27] Therefore, oxygenated metabolites of Rb_1 in plasma and urine following iv administration were examined first. All possible metabolites were screened and compared with the profiles of the blank plasma and urine samples collected before administration. As a result, the metabolite profile in plasma samples was found to be generally consistent with that of urine samples (Figure 1A, B), but metabolites in urine samples appeared to be more abundant and diverse (Figure 1B) and therefore were characterized first.

As shown in Figure 1, in total 18 metabolites (**M1**−**M18**) appeared in urine after dosing, among which three groups of peaks corresponding to oxygenated metabolites could be clearly observed at retention times smaller than that of Rb_1 (chromatograms of blank samples are given in the Supporting Information). The first group of the peaks (**M1** and **M2**) (t_R of 10.5−12.5 min) gave $[M - H]^-$ ion peaks at m/z exactly 34 Da more than that of Rb_1, indicating introduction of an O and an H_2O into the molecule of Rb_1, which was confirmed by the molecular formula derived from accurate mass. The MS/MS spectra of **M1** and **M2** showed fragment ions corresponding to the sequential loss of glucose moieties (Figure 2; Table 1). The product ion derived from the loss of all sugar moieties was observed at m/z 493.3872, which was 34 Da greater than corresponding product ion of Rb_1 at m/z 459.3839, indicating that the additional O and H_2O were located on the aglycone moiety. The second group of metabolites (t_R of 13.0−15.0 min) (**M3**, **M4**, **M5**, **M7**, and **M9**) gave $[M - H]^-$ ions that can be assigned as Rb_1 + O on the basis of the accurate mass and isotope abundance, showing that these five metabolites were mono-oxygenated derivatives of Rb_1. Targeted MS/MS experiments of these metabolites gave fragment ions derived from sequential cleavage of glycosidic bonds (Figure 2; Table 1), indicating the introduction of an O atom into the aglycone moiety of these metabolites. The last group of peaks (t_R of 14.0−15.5 min) (**M6**, **M8**, and **M10**) was assigned as dioxygenated metabolites of Rb_1 on the basis of accurate mass and isotope cluster information. MS/MS experiment revealed that the dioxygenation occurred at the aglycone

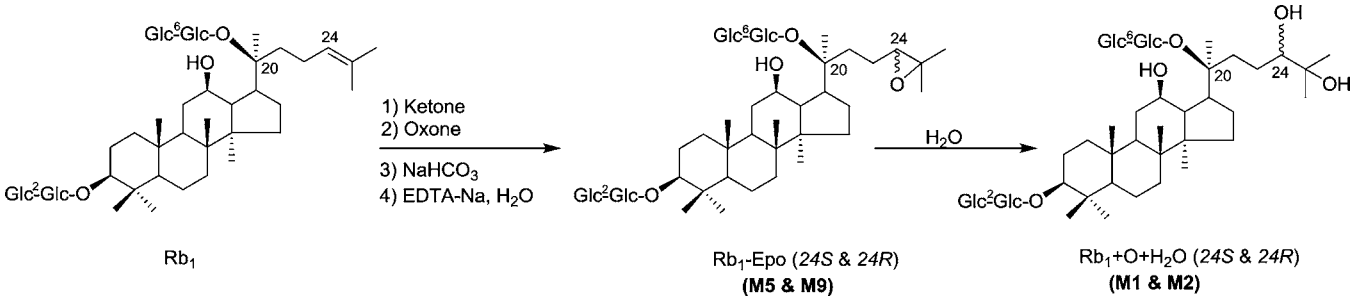
J. Agric. Food Chem. 2015, 63, 2689−2700

Scheme 2. Chemical Synthesis of Rb_1 Epoxides and Corresponding Diols



moiety (Figure 2; Table 1). In all of the high-resolution MS/MS spectra of **M1**−**M10** obtained on Q-TOF MS, the sequential fragment resulting from the loss of sugar could be clearly observed (Figure 2).

Although all above oxygenations were suggested to occur on the aglycone part by MS/MS experiments, further structural information related to the exact oxygenation site cannot be obtained solely on the basis of MS/MS experiment. Therefore, possible oxygenated metabolites were chemically synthesized for further characterization. Taking into consideration the chemical characteristic of Rb_1, as well as the possible oxygenation pathway that may lead to the incorporation of an oxygen atom into the molecule, we speculated that Rb_1 may undergo initial oxygenation via either epoxidation or hydroxylation along with displacement of the double bond of the side chain. Therefore, we synthesized epoxides of Rb_1 and photosensitized Rb_1 by using Rb_1 as starting material (Schemes 1 and 2). Chemical structures of these synthesized metabolites were characterized on the basis of spectroscopic data (Supporting Information). They were used as authentic standards for the identification of the above-mentioned oxygenated metabolites (Figure 3).

The synthesized compounds were then employed as standards for the identification of the oxygenated metabolites, which was implemented by comparing retention time, high-resolution MS, and MS/MS pattern of the metabolites with those of synthesized standards. Consequently, **M1** and **M2** were identified as a pair of enantiomers (24α- and 24β-forms) of 3-*O*-[β-D-glucopyranosyl (1→2)-β-D-glucopyranosyl]-20-*O*-[β-D-glucopyranosyl (1→6)-β-D-glucopyranosyl] 3β,12β,20-(*S*),24,25-pentahydroxy-dammarane (quinquenoside L16).[30] The three major mono-oxygenated metabolites (**M3**, **M4**, and **M7**) were identified as 24- and 25-hydroxyl derivatives of Rb_1, that is, 3-*O*-[β-D-glucopyranosyl (1→2)-β-D-glucopyranosyl]-20-*O*-[β-D-glucopyranosyl (1→6)-β-D-glucopyranosyl] 3β,12β,20(*S*),25-tetrahydroxy-dammar-23-ene (notoginsenoside A) (**M3**),[31] 3-*O*-[β-D-glucopyranosyl (1→2)-β-D-glucopyranosyl]-20-*O*-[β-D-glucopyranosyl (1→6)-β-D-glucopyranosyl] 3β,12β,20(*S*)-trihydroxy-24ξ-hydroxydammar-25-ene (ginsenoside V) (**M4** and **M7**),[32] whereas the two minor mono-oxygenated metabolites (**M5** and **M9**) were characterized to be epoxyginsenoside Rb_1 (24α- and 24β-forms).[33,34] The three dioxygenated metabolites (**M6**, **M8**, and **M10**) were identified as 24- and 25-hydroperoxides of Rb_1, that is, 3-*O*-[β-D-glucopyranosyl (1→2)-β-D-glucopyranosyl]-20-*O*-[β-D-glucopyranosyl (1→6)-β-D-glucopyranosyl] 3β,12β,20(*S*)-trihydroxy-25-hydroperoxydammar-23-ene (notoginsenoside K) (**M6**)[35] and 3-*O*-[β-D-glucopyranosyl (1→2)-β-D-glucopyranosyl]-20-*O*-[β-D-glucopyranosyl (1→6)-β-D-glucopyranosyl] 3β,12β,20(*S*)-trihydroxy-24ξ-hydroperoxydammar-25-ene (notoginsenoside C)

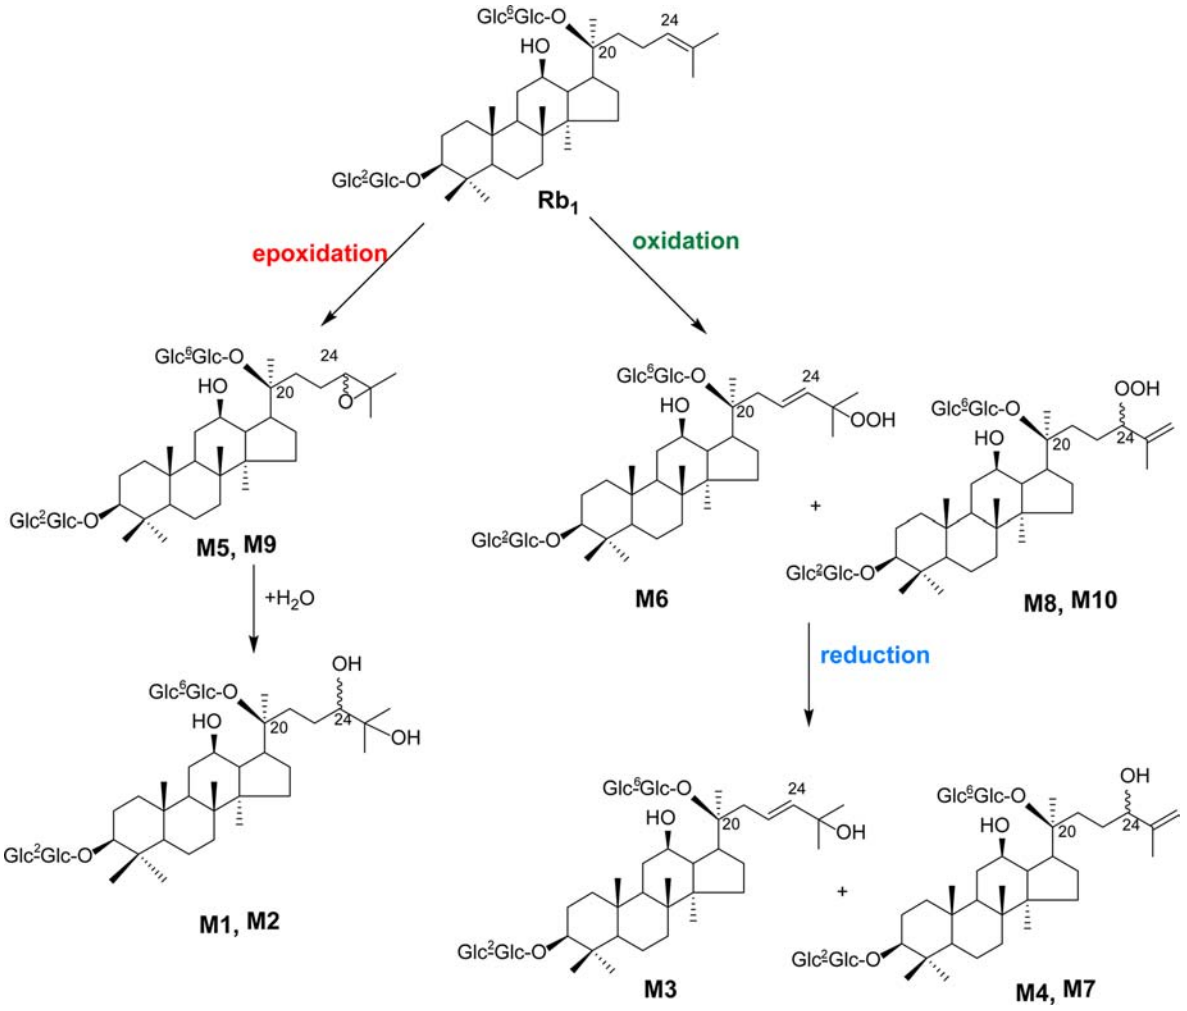

Figure 4. Proposed oxygenation metabolism pathway of ginsenoside Rb_1 in vivo.

(**M8** and **M10**).[31] A metabolism pathway of the major oxygenated metabolites is proposed in Figure 4.

In addition to the major oxygenated metabolites, another eight metabolites (**M11**–**M18**) were observed in rat urine after iv administration of Rb_1 (Figure 1; Table 1). On the basis of the molecular formula derived from accurate mass, **M11** was assigned as dehydrogenation product of mono-oxygenated Rb_1 (Rb_1 + O − 2H). **M12** and **M14** were tentatively identified as mono-oxygenated Rd (Rd + O). **M13** was assigned as Rk_1/Rg_5 + 2O − 2H. **M15** was identified to be the dehydrogenated derivative of Rb_1 (Rb_1 − 2H), whereas **M16**, **M17**, and **M18** were characterized as Rd, F_2, and 20(*S*)-Rg_3 respectively, all of which were deglycosylated products of Rb_1. Characterization of **M16**–**M18** was further confirmed by comparison with authentic ginsenosides, suggesting that deglycosylation is another metabolic pathway of primary ginsenosides in the circulating system (Table 1).

In plasma samples, metabolites **M1** and **M2**, as well as five mono-oxygenated metabolites (**M3**, **M4**, **M5**, **M7**, and **M9**), can be clearly observed. Dehydrogenated metabolites (**M15**) and deglycosylated metabolites (**M16**, **M17**, and **M18**) also appeared in the bloodstream. However, three dioxygenated metabolites (**M6**, **M8**, and **M10**) together with oxygenated metabolites of secondary ginsenoside, that is, **M12** and **M14** (Rd + O) and **M13** (Rk_1/Rg_5 + 2O − 2H), were absent in plasma samples. Because these urinary metabolites possessed increased polarity relative to their parent ginsenosides, their absence in plasma might be due to fast elimination through kidney clearance. By contrast, the relative levels of the deglycosylated metabolites (**M16**–**M18**) in plasma were obviously higher than those in urine, implying that these metabolites were excreted into urine very slowly and thereby accumulated in the bloodstream.

Metabolite Profile in Rat Urine and Plasma after Oral Administration of Rb_1. After oral administration of Rb_1, metabolites in rat plasma and urine were characterized by using a similar approach as that for the iv dose. Metabolites in both plasma and urine after oral administration were significantly less than that observed for iv administration. In plasma, nine metabolites in total were detected (Figure 5A), including three mono-oxygenated metabolites (**M3**, **M4**, and **M7**), two dehydrogenated metabolites (**M11** and **M15**), and two deglycosylated metabolites (**M16** and **M18**), as well as oxygenated Rg_3 (**M19**). Mono-oxygenated Rb_1, **M3**, **M4**, and **M7** were found to be the major metabolites of Rb_1 appearing in the circulating system. The existence of these metabolites in blank plasma and urine samples was examined, and the results suggested that these metabolites were derived from the metabolism of ginsenosides rather than interferences pre-existing in plasma or urine (Supporting Information).

To survey the systemic availability of these metabolites, rat plasma samples collected at different time points were

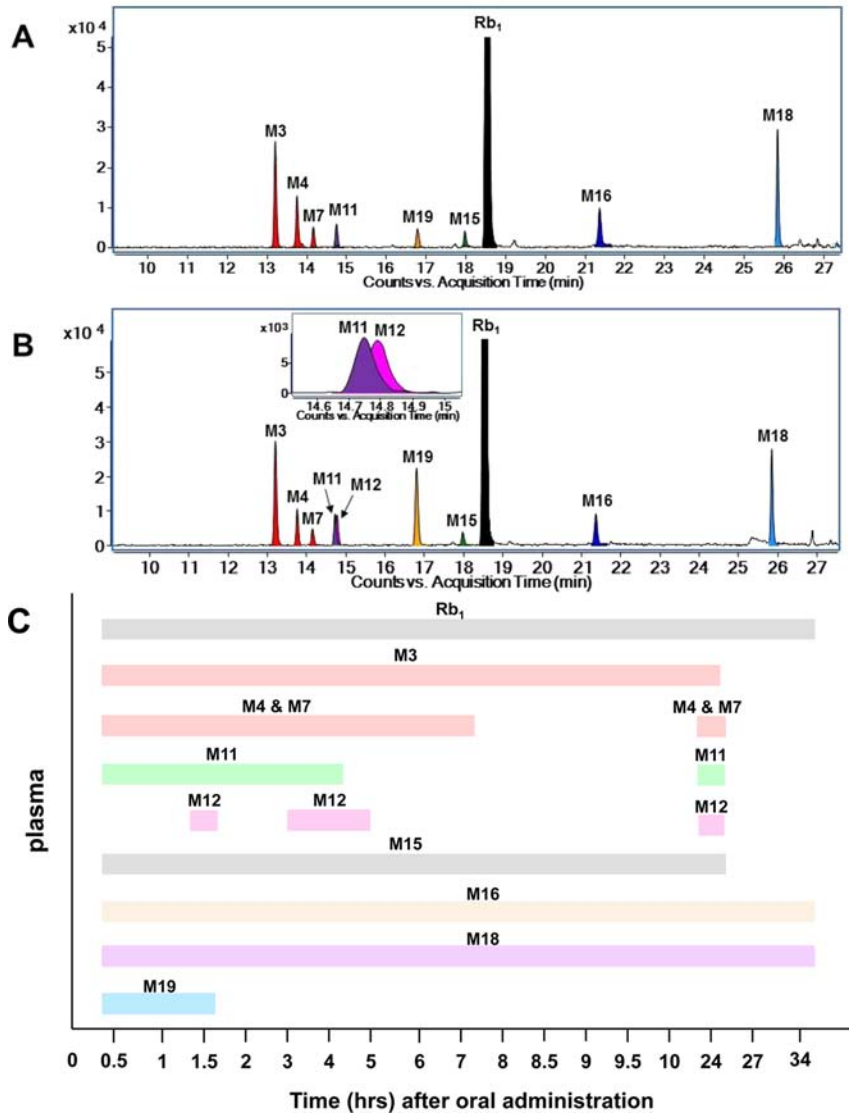

Figure 5. Ginsenoside Rb_1 and its metabolites identified in plasma following oral administration: (A, B) extracted compound chromatograms (ECC) of metabolites identified in plasma collected at 0.5 and 1.5 h after oral dose of Rb_1; (C) appearance of metabolites in rat plasma at different time intervals after oral dose of Rb_1.

examined for all identified metabolites. As shown in Figure 5C, Rb_1, **M3**, **M15**, **M16**, and **M18** were found to be continuously present in the bloodstream for >24 h. However, **M4**, **M7**, **M11**, and **M12** appeared in the plasma at intervals of 0−8 h and after 24 h, whereas the oral administration-specific metabolite **M19** was measured within only 1.5 h after administration. The time duration for the occurrence of the metabolites provided clues for their metabolism site. For instance, the metabolites detected at the early stage, for example, oxygenated Rd (**M12**), might result from oxidation of deglycosylated metabolites that derived from gastric acid decomposition. By contrast, the oxygenated Rd observed at the late stage might result from tissue oxidation of intestinal-decomposed Rb_1.

The plasma metabolites were also excreted into urine (Figure 6A). Twelve metabolites were detected in urine, among which **M1**, **M2**, and **M9** were not found in plasma. The appearance duration of these metabolites in urine showed certain differences. Seven abundant metabolites, **M3**, **M4**, **M7**, **M11**, **M12**, **M15**, **M16**, and **M18**, were detected in urine samples for a long duration (up to 24 h). Less abundant metabolites, **M1**, **M2**, and **M9**, were mainly measured in urine samples within 7 h after oral administration, whereas **M19** appeared in urine only within 3 h after oral dose.

In Vitro Metabolism of Rb_1 in Liver Microsomes, S9 Fraction, and Rat Blood. To get information about the metabolism site of the oxygenated metabolites, in vitro metabolism of Rb_1 in liver microsomes and blood was investigated. Hepatic metabolism is the leading drug disposition pathway because liver is the major site of drug metabolism in which a complex array of phase I, phase II, and phase III transporter systems function in the systemic clearance of xenobiotics. Several studies have revealed the involvement of P450-mediated metabolism in the elimination of secondary ginsenosides and proposed oxygenation as the major metabolic pathway.[19,20,22,36] Therefore, biotransformation of Rb_1 in liver microsomes and S9 fraction was examined. However, neither oxygenated products nor other metabolites were observed during the incubation duration of 2 h. The results were consistent with that observed for the primary PPT-type ginsenosides.[29] Similarly, no metabolites of Rb_1 were detected

when it was incubated in fresh blood, red blood cells, and plasma for 2 h, showing that Rb_1 was quite stable in blood. These results suggested that oxygenated metabolites of Rb_1 might result from tissue oxidation as previously suggested.[27]

DISCUSSION

Primary ginsenosides such as Rb_1 and Rg_1, although poorly absorbed after oral administration, were still demonstrated to be relatively abundant ginsenosides reaching the circulation system after oral administration of notoginseng extract, in comparison with secondary ginsenosides such as Rg_3 and Rg_2.[27] In multiple-dose treatment, the primary ginsenosides were found to further accumulate substantially in the systemic circulation, resulting in a considerably higher plasma level.[26] Metabolism of the primary ginsenosides after entering the bloodstream represented one of the essential issues for further evaluation of these intact ginsenosides. Tissue oxygenation has been suggested to be the major metabolism pathway of primary ginsenosides apart from deglycosylation and dehydration in the gastrointestinal tract.[20,24] The resulting mono-oxygenated metabolites were further estimated to account for about 10−15% elimination of intravenously administered Rb_1 in a single iv dose.[27] These results collectively directed the necessity for the characterization of the chemical structures of oxygenated metabolites.

To overcome the technique limitations for structural characterization of metabolites, that is, accumulating adequate amount of metabolites for NMR measurements, we utilized a chemical synthesis approach to obtain chemical standards and unambiguously identified five mono-oxygenated metabolites, three dioxygenated metabolites, and two diol metabolites of Rb_1 in plasma and urine for the first time.

By using such a chemical synthesis approach, we confirmed the generation of two 24,25-epoxides (**M5** and **M9**) of primary ginsenoside as circulating metabolites in plasma and urine. Oxidation of the olefin bond to form epoxide is a well-known oxidation reaction catalyzed by CYP and therefore was proposed to be an important oxidation pathway of ginsenosides in several previous studies.[25,28,29] However, as epoxides are quite reactive due to ring strain, their rearranged products, 20,24-epoxides, are usually observed as the final oxygenated metabolites. Alternatively, the reactive epoxides were captured with nucleophile trapping agents such as GSH to confirm the formation of these bioactive metabolites, whereas the epoxides themselves were normally undetectable. Our study represents the first report of the direct detection of 24,25-epoxides of Rb_1 (**M5** and **M9**) as in vivo metabolites. Accordingly, the diols of Rb_1 (**M1** and **M2**) were identified unambiguously as the in vivo metabolites of Rb_1 for the first time.

Notably, after oral administration, mono-oxygenated metabolites (**M3**, **M4**, and **M7**) represented major metabolites of Rb_1 reaching the circulation system and appearing in the bloodstream once Rb_1 was absorbed. These oxygenated metabolites presented in plasma continuously for 8−24 h after orally taken. Two diol metabolites (**M1** and **M2**) also appeared in urine samples as abundant metabolites. As the sequential metabolites of epoxides (**M5** and **M9**), the appearance of **M1** and **M2** in urine suggested the formation of 24,25-epoxides of Rb_1 in the circulation system. These results concomitantly indicated notable exposure of oxygenated metabolites of Rb_1 after oral administration.

The oxygenated metabolism of ginsenosides with additional hydroxyl or epoxy groups in the side chain may lead to changes in the bioactivity. It has been reported that notoginsenoside H,

DOI: 10.1021/acs.jafc.5b00710
J. Agric. Food Chem. 2015, 63, 2689−2700

a saponin having a side chain the same as that of metabolite **M3**, exhibited immunological adjuvant activity by profoundly increasing the level of IgG in mice sensitized with ovalbumin. Rb_1 epoxide is a patented apoptosis inhibitor and regeneration promoter,[33] implicating its potential bioactivity. On the basis of the mass of the evidence, the mono-oxygenated metabolites of ginsenosides might contribute to the observed pharmacological activity and therapeutic effect of ginsenosides and ginseng product, which needs to be further explored.

Collectively, the structures of 10 oxygenated metabolites in rat urine and plasma after iv administration of Rb_1 were unambiguously characterized. These metabolites were further proved to be major metabolites of ginsenoside Rb_1 appearing in the bloodstream after oral administration. As the major circulating metabolites of ginsenoside Rb_1 after both intravenous injection and oral administration, these metabolites have great potential to be responsible for the observed pharmacological activity and therapeutic effect of ginsenosides. Therefore, exact characterization of the chemical structures of these circulating oxygenated metabolites would shed light on the clarification of possible toxic or pharmacologically active metabolites, thus providing valuable information for explaining the multiple pharmacological activities of ginseng products. The results were also informative for the design of the next generation of drugs to circumvent the undesired metabolic fate of ginsenosides. Moreover, clarification of metabolites reaching the circulation system will lay the foundation for the assessment of pharmacokinetics of ginsenosides and its metabolites. Corresponding results will in turn provide important clues pertaining to various aspects of the disposition of ginsenosides, including first-pass metabolism, elimination half-life, and overall bioavailability.

However, only the influence of germination with water in the dark on the isoflavone contents of chickpeas has been studied. Therefore, in this study, we carried out a quantitative analysis of isoflavone contents and composition in chickpeas and chickpea sprouts by growing them in different conditions, including in light, under ethanol stress, and under salt stress. Employing this analysis, we determined the optimal germination time to maximize isoflavone contents for the purpose of maximizing the nutraceutical benefits of chickpea sprout isoflavone consumption.

MATERIALS AND METHODS

Materials. Chickpeas, 88-1, were provided by the Institute of Food Crops, Xinjiang Academy of Agricultural Sciences in China.

Reagent. Authentic standards of biochanin A and formononetin were purchased from Sigma-Aldrich (Shanghai, China). Acetonitrile, acetic acid, and methanol used were all high-performance liquid chromatography (HPLC)-grade and purchased from Fisher Chemicals (Shanghai, China). NaCl, $NaSO_4$, NaClO, and ethanol were all analytical-grade and purchased from the Beijing Chemical Industry Group (Beijing, China).

Germination of Chickpeas. Chickpea treatments were performed in sterilized sprouting cartridges, which accommodated 300 g of dry chickpeas. The chickpeas were subjected to four different treatments: germination in the dark (GD), germination in the light (GL), germination under ethanol stress (GE), or germination under salt stress (GS) in the dark. The treatment methods and experimental stages are presented in Table 1. In all of the treatments, chickpeas were sequentially subjected to soaking (20 h) and germination stages (12 days). The chickpeas were first surface-sterilized by immersing them in a 1% (w/v) NaClO solution (5 L/kg of chickpeas) for 1 h at room temperature and then rinsed 4 times with distilled pall water (3 L/kg of chickpeas). Then, the sterilized chickpeas were soaked for 20 h at 25 °C in sterilized distilled water in the absence of light, except for the salinity stress chickpeas (GS), which were soaked in a saline solution (1:1 NaCl/$NaSO_4$) of different concentrations (0.01, 0.02, 0.03, and 0.04 mol/L) for 20 h. Subsequently, the soaked chickpeas were put in sterilized plastic cartridges and germinated at 25 °C and 95% relative humidity (RH) in a sprouting machine that was sterilized according to the instructions of the manufacturer in advance. Then, for the experiments with light (GL), a light incubator was placed on top of the machine and used to simulate natural sunlight. The light was applied during the all of the germination stages. In the experiments with ethanol treatments (GE), chickpea sprouts were soaked in solutions of 1, 3, and 5% (v/v) ethanol for 12 h at room temperature for elicitation. All of the experiments were performed in triplicate. Chickpea sprouts in each group were collected on days 2, 4, 6, 8, 10, and 12 and immediately stored at −20 °C.

Table 1. Summary of Different Chickpea Treatments[a]

	stage		
treatment	soaking	germination	ethanol soaking
untreated	–	–	–
GD	√	√ (dark)	–
GL	√	√ (light)	–
GE	√	√ (dark)	√ (1, 3, and 5%)
GS	√ (salt soaking)	√ (dark)	–

[a]GD, germination in the dark; GL, germination in the light. GE, germination under ethanol stress; GS, germination under salt stress; –, treatment mentioned was not performed; and √, treatment mentioned was performed.

Extraction of Isoflavones. Extractions were carried out according to the method previously described, with slight modifications.[19] All samples were dried at 50 °C and milled with a laboratory mill using a 60 mesh screen sieve. A total of 1 g of the ground samples was

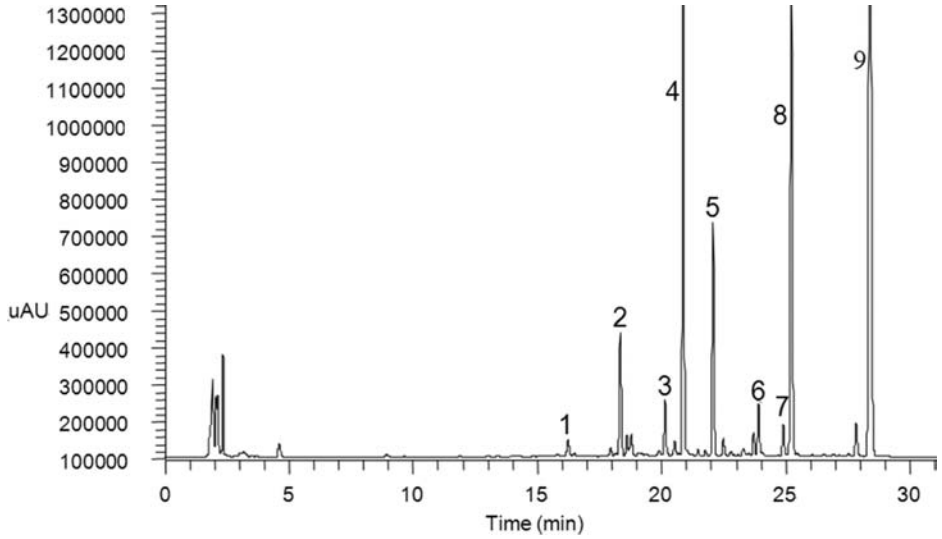

Figure 1. UHPLC−UV profile of 70% aqueous EtOH extracts of germinated chickpeas in the light, with HPLC chromatograms shown at 280 nm. Peaks: 1, glycitein glucoside acetylated; 2, ononin; 3, daidzein; 4, biochanin A glucoside; 5, biochanin A glucoside malonylated; 6, genistein; 7, pseudobaptigenin; 8, formononetin; and 9, biochanin A.

extracted twice and put into 10 mL of 70% ethanol solutions for 3 h at 70 °C. After extraction, the mixture was centrifuged at 3000*g* for 10 min to separate the supernatant. The supernatants were combined and stored at 4 °C for later analysis.

Analysis of Isoflavones. The identification of isoflavones was performed on the basis of ultraviolet (UV) and mass spectrometry (MS) spectra according to Simons et al.[16] and Aisyah et al.[17] The samples were analyzed by ultrahigh-pressure liquid chromatography (UHPLC)−MS. The UHPLC system (San Jose, CA) was equipped with two Shimadzu pumps, a Shimadzu autosampler, and a photodiode array (PDA) detector. Each sample (1 μL) was injected onto a Waters Acquity UPLC BEH shield RP18 column (2.1 × 150 mm, 1.7 mm particle size) with a Waters Acquity UPLC shield RP18 Vanguard pre-column (2.1 × 5 mm, 1.7 mm particle size, Waters, Milford, MA). Water acidified with 0.1% (v/v) acetic acid, eluent A, and acetonitrile (ACN) acidified with 0.1% (v/v) acetic acid, eluent B, were used as solvents at a flow rate of 300 μL/min. The temperature of the column oven was controlled to be 35 °C, and the PDA detector was set to measure a range of 200−400 nm. The elution profile was as follows: 0−5 min, isocratic on 15% (v/v) B; 5−15 min, linear gradient from 15 to 30% (v/v) B; 15−25 min, linear gradient from 30 to 60% (v/v) B; 25−45 min, linear gradient from 60 to 80% (v/v) B; 45−50 min, linear gradient from 80 to 95% (v/v) B; 50−55 min, linear gradient from 95 to 15% (v/v) B; and 55−58 min, isocratic on 15% (v/v) B. A mass spectrometric analysis was performed on a Thermo Scientific LTQ-XL (San Jose, CA) equipped with an electrospray ionization (ESI)−MS probe coupled with reversed-phase (RP)-UHPLC. Nitrogen was used as a sheath and auxiliary gas. Data were obtained in the m/z range of 150−1500. Data-dependent MS^n analysis was performed with a normalized collision energy of 35%. To this end, the system was tuned with biochanin A in both the positive ionization (PI) and negative ionization (NI) modes. For both modes, the ion transfer tube (ITT) temperature was 350 °C and the source voltage was 4.8 kV. Quantification was performed on the basis of the absorption at 280 nm using Xcalibur (version 2.1.0, Thermo Scientific).

For many compounds, no commercial standards were available. The concentrations of individual isoflavonoids were evaluated using the calibration curve of biochanin A (mg/g; 10−0.0001 mg/mL; R^2 = 0.9999).

Statistical Analysis. All values were expressed as the mean ± standard deviation ($\bar{X}$ ± SD). Data were analyzed by one-way analysis of variance (ANOVA), followed by post-hoc Dunnett's t test, using the SAS software. Differences of $p < 0.05$ were considered significant.

RESULTS AND DISCUSSION

Isoflavone Contents in Germinated Chickpea Seeds under Water in the Dark. The variation of isoflavone contents in chickpea seeds and sprouts during germination are shown in Table 2. The contents of formononetin and biochanin A were 0.10 ± 0.01 and 0.18 ± 0.02 mg/10 g, respectively, in the untreated chickpea seeds. During germination, the contents of formononetin and biochanin A increased; the maximum amount was obtained on day 10 (1.42 ± 0.06 and 2.10 ± 0.08 mg/g, respectively). These results suggest that formononetin and biochanin A are principal isoflavones in both chickpea seeds and sprouts and are consistent with results reported by Ma et al.[20] Except for genistein, all of the other isoflavones that we tested increased with treatment and reached their peak content on day 10 ($p < 0.05$). However, genistein showed an opposite tendency and was undetectable after 4 days. Because genistein is formed by the hydrolysis of glycosides through β-glucosidase, the decrease of genistein observed in this study may have resulted from the inhibition of the activity of β-glycosidase during germination.[21] Moreover, the total isoflavone content showed a similar pattern to formononetin and biochanin A from seeds (0.59 ± 0.06 mg/10 g) to 10 day sprouts (6.82 ± 0.33 mg/g). This increase in isoflavone contents may be induced by the metabolic pathways of naringeninchalcone and isoliquiritigenin, the precursors of isoflavonoids commonly found in legumes.[22] However, a slight decrease in the isoflavone contents was observed between days 10 and 12. Terrence et al.[23] reported that the primary soybean leaf tissues underwent a programmed shift from isoflavonoid to flavonoid metabolism 3 days after germination. The decrease observed in this study may be due to a conversion of isoflavonoids to other isoflavones. In addition, the chickpea sprouts contained ononin, pseudobaptigenin, and glycitein glucoside acetylated, which were undetected in the chickpea seeds. Our results showed that the isoflavone composition changed during germination. It has been reported that sprouts grown in the dark have a lower overall nutritional value than sprouts grown under light, because of the lack of photosynthesis in dark conditions.[14] Thus, the following section

J. Agric. Food Chem. 2015, 63, 2701−2707

investigates the changes of isoflavones in chickpea sprouts germinated in the light.

Isoflavone Contents in Germinated Chickpea Seeds under Water in the Light. We used HPLC−MS to quantify the individual isoflavones of these chickpea sprouts (Figure 1). The isoflavone contents of the chickpea sprouts germinated in the light are listed in Table 3. Exposing the chickpea seedlings to light boosted the accumulation of all of the isoflavones in our experiments, except genistein, which was undetectable after 2 days. The chickpea sprouts germinated on day 8 and had the highest formononetin and biochanin A contents (1.54 ± 0.04 and 2.34 ± 0.04 mg/g, respectively), which were 154 and 130 times higher, respectively, than their contents in untreated chickpea seeds and 1.2 times higher than their contents in the GD group. The same trend was also observed in other isoflavones compared to the GD group, except genistein. These results were consistent with a study by Phommalth et al.,[24] who reported that soybean seeds germinated with light treatments could produce over 1.53 times more isoflavones than when grown under dark conditions. Moreover, the total isoflavone content in chickpea sprouts dramatically increased, from 2.40 ± 0.11 to 4.86 ± 0.14 mg/g during days 2 and 4, and the maximum amount (8.14 ± 0.21 mg/g) of total isoflavones was obtained on day 8. Isoflavones were synthesized in the malonate and phenylpropanoid pathways using three malonyl-CoAs and one coumaroyl-CoA, which are produced during photosynthesis.[14] Light has been thought to increase the amount of malonyl-CoA and coumaroyl-CoA by promoting photosynthesis, thus, in turn, enhance the precursor for isoflavone production commonly found in legumes.[21] Light may influence the phenylalanine ammonia-lyase (PAL), which is reported to be an initial enzyme for synthesizing the isoflavone and result in the biosynthesis of isoflavone compounds[25] apart from the efficiency of photosynthesis.

Isoflavone Content in Germinated Chickpea Seeds in the Ethanol Treatment. The changes of isoflavone contents during germination using ethanol are presented in Table 4. The isoflavone contents of chickpea sprouts significantly increased ($p < 0.05$) compared to the untreated chickpea seeds. The maximum amount of formononetin and biochanin A (1.53 ± 0.05 and 2.21 ± 0.04 mg/g, respectively) in the chickpea sprouts was observed in 3% ethanol-treated chickpea sprouts on day 10. Moreover, the highest total isoflavone content (7.01 ± 0.18 mg/g) was also obtained in the 3% ethanol-treated group. However, in comparison to the GD group, only a slight increase (not significant) in isoflavone contents and slight changes in the composition of isoflavones were observed. Moreover, there was no significant difference among 1% ethanol, 5% ethanol, and GD groups.

Stimulation of the defense response of plants has a large potential to alter the metabolites of the plant, especially when germinated seeds are abruptly exposed to external stresses.[26] In this study, ethanol was used as an external stress to stimulate the defense response of the chickpeas, thus increasing the isoflavone contents. Moreover, ethanol has been reported to induce alcohol dehydrogenase (ADH) activity and could stimulate alcohol fermentation via the action of ADH under aerobic conditions,[27] which, in turn, could induce the conversion of other compounds to other isoflavones.

Isoflavone Contents in Germinated Chickpea Seeds after Salinity Stress Treatment. The isoflavone contents of the chickpea sprouts germinated in saline solutions at the concentrations of 0.01, 0.02, 0.03, and 0.04 mol/L are summarized

here. In comparison to chickpea sprouts that germinated in 0.01, 0.02, and 0.04 mol/L saline solutions, the isoflavone contents in 0.03 mol/L saline solution were higher, as shown in Table 5. The formononetin content of samples germinated in 0.03 mol/L saline solutions increased to 0.75 ± 0.02 mg/g, and the biochanin A content increased to 0.90 ± 0.02 mg/g on day 2, which was significantly higher ($p < 0.05$) than in untreated chickpea seeds. Genistein was undetected in all of the stages of germination, and ononin, pseudobaptigenin, and glycitein glucoside acetylated were only detected in chickpea sprouts. Moreover, the 0.03 mol/L salt stress significantly enhanced the total isoflavone content, and it reached a peak value (6.93 ± 0.02 mg/g) on day 10.

Salinity can induce osmotic and ionic imbalances inside plant cells, thus affecting plant growth and metabolism.[28] However, our results showed that a low-concentration salt stress could increase the total isoflavone content in chickpea sprouts. Similar results on soybeans have been reported by Abdul et al.,[18] who stated that a low concentration of salt stress exposure on a plant could promote photosynthesis, thus enhancing the accumulation of metabolites in the plant.

In conclusion, in this study, we demonstrated that different stimuli had positive effects on the isoflavone content and composition of chickpea sprouts, and the maximum amount of total isoflavones was obtained on day 10, except for in the GL group, in which the maximum amount was obtained on day 8. On the basis of our results, we suggest that the application of light is the most effective method for producing functional foods with high isoflavone contents, which might help to improve the nutritional quality and health benefits of chickpea sprouts.

kDa permeate of the heat-treated 10% DH hydrolysate (86.6% protein via Kjeldahl, containing 9.2% ash), the 30 kDa retentate of the control 5% DH hydrolysate (87.5% protein via Kjeldahl, containing 8.7% ash), and their respective whole unfractionated hydrolysates (87.1 and 86.4% protein, respectively).

For fortification of hydrolysate fractions, Fe^{2+} (139 mg of $FeSO_4 \cdot 7H_2O$) was added to 100 mL of 20 g protein L^{-1} solutions (initial concentration) of hydrolysate fractions adjusted to pH 5 with 1 N HCl.

Total Iron Concentration, Ferrous Chelation Determination, and Solid Phase Extraction. Total iron was determined as previously described by O'Loughlin et al.[17] modified from the method of Voillier et al.[21] Briefly, test samples were dissolved in 0.5 M HCl and stored overnight. Test samples (200 μL, 1 g L^{-1}) were diluted with 1.5 mL of dH_2O, and 300 μL of 1.4 M hydroxylamine hydrochloride was subsequently added, whereupon the mixture was vortexed and allowed to stand for 30 min. Ferrozine reagent (200 μL), 0.01 M in 0.1 M ammonium acetate, was added along with 300 μL of 5 M ammonium acetate and the mixture allowed to stand for 3 min. The absorbance was read at 562 nm against a standard curve of $FeSO_4$.

The ferrous chelating capability of the WPI and whole and fractionated hydrolysates was determined using a modification of the method of Decker and Welch[22] as previously described by O'Loughlin et al.[17] Briefly, test samples (1 mL of 1 g L^{-1}) were mixed with 1.35 mL of dH_2O and 50 μL of 2 mM $FeCl_2$. After vortexing, the reaction was initiated with 100 μL of ferrozine, vortexed again, and allowed to stand for 10 min. Samples were read at 562 nm, and EDTA-Na_2 was used as a positive control for the assay. A standard curve for EDTA chelation of iron was prepared for 0.5−100 μM EDTA, giving the following linear relationship:

$$y(A_{562}) = -0.0105x + 1.1476 \ (R^2 = 0.997) \quad (1)$$

The concentration of selected hydrolysates needed to chelate 50% of the ferrous iron (CC_{50}) was determined by assaying and plotting various concentrations of hydrolysates against percentage chelation. Utilizing concentrations of the samples ranging from 0.5 to 10 g L^{-1}, it was possible to determine the concentration of selected samples needed to chelate 50% of the ferrous iron (CC_{50}) under the assay conditions with 2 mM $FeCl_2$.

Solid phase extraction (SPE) was carried out on Phenomenex Strata X cartridges (Phenomenex, Cheshire, UK) using the method of Nongonierma et al.[23] Cartridges were conditioned with methanol followed by washing with Milli-Q water. Samples (5 g protein L^{-1}) were loaded onto the cartridge, where flow-through was extracted under vacuum (≤−381 mmHg). Washes (four times) with Milli-Q water were pooled for analysis. Subsequently, 80% (v/v) acetonitrile (MeCN) was utilized (three times) to elute the bound fraction from the cartridge. Fractions were evaporated on a Büchi Rotavapor R-210 (Büchi Labortechnik AG, Switzerland) and freeze-dried on a Labconco 12 L FreeZone 12 plus freeze drier (Labconco, Kansas City, MO, USA) prior to analysis.

Total and Free Amino Acid Analysis of Hydrolysate Fractions and Iron Solubility of Dispersions. Total and free amino acid analysis was performed as previously described by O'Loughlin et al.[19] A JEOL JLC-500/V Amino Tac amino acid analyzer fitted with a JEOL Na^+ high-performance cation-exchange column (JEOL (UK) Ltd., Herts, UK) was utilized, and deproteination was accomplished with 10% (v v^{-1}) trichloroacetic acid (TCA) followed by centrifugation at 20000*g* for 20 min. The extracted supernatant was analyzed for amino acids through visible adsorption photometry after separation using ion exchange. Ninhydrin derivatization with norvaline was used as an internal standard. For total amino acid analysis samples were heated in 6 M HCl for 23 h under reflux at 105 °C before application to the JLC-500/V analyzer.

For total iron solubility, test samples (10 g L^{-1}) were centrifuged (Eppendorf 5810 R, Eppendorf GmbH, Hamburg, Germany) at 3000*g* for 20 min, whereupon the supernatant was extracted and diluted 1:9 using 0.5 N HCl and stored overnight. Total iron was determined using the previously mentioned methodology.

Attenuated Total Reflectance−Fourier Transform Infrared (ATR-FTIR) Spectroscopy of WPI, Hydrolysates, and Iron-Fortified Dispersions. Secondary structural changes were determined using ATR-FTIR spectroscopy. This was performed utilizing a Bruker Tensor 27 FTIR spectrometer (Bruker Optik GmbH, Ettlingen, Germany) with a thermally controlled BioATR Cell II. Sample solution (25 μL, 10 g L^{-1}) was placed onto the ZnSe crystal, and a total of 180 scans were performed for each sample at a resolution of 4 cm^{-1}. Interferograms were Fourier transformed and analyzed with Bruker OPUS 5.5 software, where both water vapor and CO_2 compensations were performed and data were vector normalized.

Simulated Gastrointestinal Digestion (SGID) of Ferrous-Chelating Fractions. A static two-stage SGID process was performed on the iron-chelating fractions using a modification of the methodology of Walsh et al.[24] The simulated gastric fluid contained pepsin (EC 3.4.23.1, calculated activity of 837 UHb mg^{-1} protein) dispersed in 150 mM NaCl at a concentration of 4 g L^{-1} (final pH 5.5). The simulated pancreatic juice (SPJ) was prepared according to the following protocol: 4.5 g of Corolase PP, 62.5 g of $NaHCO_3$, and 30 g of bile salts per liter of dH_2O modified from the method of Le et al.[25]

Iron-fortified samples (100 mL, 20 g protein L^{-1}) were preincubated at 37 °C for 30 min under stirring (at 140 rpm). The pH of the solution was reduced to 3.5 at 37 °C with 1 N HCl, whereupon a 10 mL solution of simulated gastric fluid was added to give a final E:S of 1:100. The solution was then reduced to a final pH of 2 at 37 °C. Aliquots, 1 mL, were extracted at 1, 10, 30, 60, and 90 min after reaction. After 90 min, the pH was adjusted to pH 7.5 using 0.6 M Na_2HPO_4. SPJ (1:10 v/v of sample) was subsequently added to the solution, which was incubated at 37 °C for 150 min. Enzyme activity was terminated by heating at 80 °C for 20 min.

Chromatographic Characterization of Control and Heated-Treated WPI Solutions. Reversed-phase (C18) HPLC was performed as previously described by O'Loughlin et al.[19] Briefly, a Phenomenex Jupiter C18 column was used (Phenomenex, Cheshire, UK) under gradient elution conditions: solvent B, from 0 to 100% in 30 min, 100% for 5 min, from 100 to 0% in 5 min, and 0% for 5 min at a flow rate of 1 mL min^{-1}, where solvent B was 80% MeCN and 0.1% TFA (v v^{-1}). Solvent A was 0.1% TFA (v v^{-1}).

Size-exclusion chromatography (SEC) described by O'Loughlin et al.[19] utilized a TSK Gel G2000SW, 7.8 mm × 600 mm, column (TosoHaas Bioscience GmbH, Stuttgart, Germany) using an isocratic gradient of 30% (v v^{-1}) MeCN and 0.1% (v v^{-1}) trifluoroacetic acid (TFA) at a flow rate of 0.5 mL min^{-1} over 60 min.

Both C18 and SEC were performed on a Waters 2695 separation module and a Waters 2487 dual-wavelength absorbance detector running on Waters Empower software (Milford, MA, USA).

Statistical Analysis. Statistical analysis was through the use of Minitab 15 software (Minitab Inc., State College, PA, USA). When necessary, data are presented as the mean ± SD for $n = 2$ determinations. The statistical difference of means was determined through the use of a one-way ANOVA followed by a Tukey test.

RESULTS AND DISCUSSION

Amino Acid Content and Ferrous-Chelating Capability of Whey Protein Isolate Hydrolysate Fractions. In a previous investigation by the authors, the ferrous-chelating capabilities of WPI hydrolysates were correlated with their respective average molecular weights (M_w).[17] A total of 22 pilot-scale fractions produced during the study were the subject of further analysis of their iron-chelating characteristics. O'Loughlin et al. showed that a 30 kDa retentate from a 5% DH hydrolysate of unheated control WPI (WPI-C-5DH-30R) possessed a CC_{50} value of 4.500 ± 0.009 g protein L^{-1}.[17] Correspondingly, a 1 kDa permeate of a 10% DH hydrolysate of the prior heat-treated (80 °C, 10 min) WPI (WPI-HT-10DH-1P) possessed a CC_{50} value of 0.846 ± 0.031 g protein L^{-1}. The chelating capability of hydrolysate fractions was shown to increase with a reduction in the average M_w of the fraction.[17]

DOI: 10.1021/jf505817a
J. Agric. Food Chem. 2015, 63, 2708−2714

The WPI-C-5DH-30R fraction possessed 57.5 ± 1.3% of material >30 kDa with the WPI-HT-10DH-1P fraction possessing 80.2 ± 1.1% of material <1 kDa. This altered size distribution of the fractions possessing the greatest and least ferrous-chelating capabilities is shown in Supplementary Figure 1 in the Supporting Information.

During an examination of total and free amino acid concentration of WPI, WPI-C-5DH-30R, and WPI-HT-10DH-1P fractions, there was a significantly ($P < 0.05$) large increase in the total concentration of certain aromatic and basic amino acids in the 1 kDa permeate, especially significantly higher ($P < 0.05$) concentrations of total lysine (Lys), phenylalanine (Phe), and tyrosine (Tyr) and also polar threonine (Thr) compared to the 30 kDa retentate, which possessed higher levels of asparagine/aspartate, glycine (Gly), and leucine (Leu) (Table 1). From Table 1, the concentrations

[a]The same letter across a row indicates no significant difference ($P < 0.05$). [b]30 kDa retentate of hydrolyzed to 5% DH control WPI. [c]1 kDa permeate of hydrolyzed to 10% DH heat-treated (80 °C for 10 min) WPI.

of Asn/Asp, Gly, and Leu in the 30 kDa retentate are similar to those in the control WPI, and therefore they are not considered responsible for the lower chelating capability. There was also a significantly higher histidine (His) concentration in the 1 kDa permeate sample (22.9 ± 0.9 g kg^{-1}) than in the 30 kDa retentate sample (12.4 ± 1.4 g kg^{-1}, Table 1). His is known to play a role in regulating essential trace elements such as iron, and a previous study has demonstrated experimentally that high blood serum levels of iron in humans can be caused by a diet low in His.[26] His is also essential for the binding of ferric (Fe^{3+}) iron to lactoferrin,[27] where the iron-binding active site consists of two tyrosines, a histidine and an aspartate residue.[28] The aromatic amino acids, Phe and Tyr, have been shown previously to provide a negative surface for electrostatic cation interaction, with a buildup of negative charges being present over the face of the benzene ring.[29] This could also be a possible mechanism for interaction with iron cations in the hydrolysate fractions. Whereas previous studies have highlighted Cys playing a central role in facilitating iron chelation,[30] our results demonstrated a greater concentration of Cys residues in the high M_w 30 kDa retentate sample (11.7 ± 1.2 g kg^{-1}), which had a reduced chelating capability, compared to the WPI control and 1 kDa permeate of the 10% DH hydrolysate of heat-treated WPI (1.9 ± 1.3 and 3.6 ± 1.1 g kg^{-1}, respectively; Table 1). Free amino acid analysis of the respective samples was also carried out and demonstrated higher, by up to a factor of 48, concentrations of free arginine (Arg), His, Lys, Phe, and Tyr in the 1 kDa permeate sample (Supplementary Table 1).

Further fractionation of the relatively strong chelating 1 kDa permeate (WPI-HT-10DH-1P) using SPE resulted in a flow-through (relatively more hydrophilic) fraction (Figure 1A) and

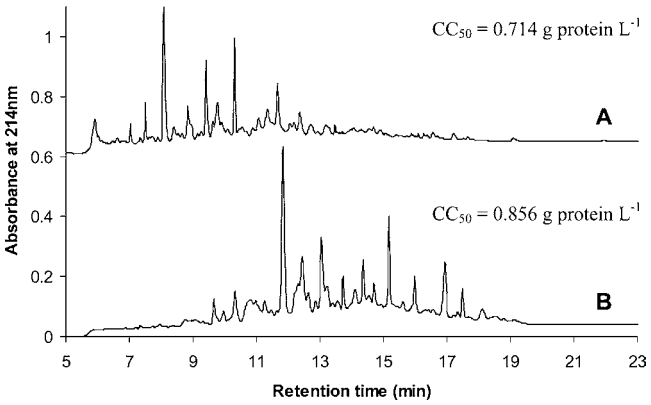

Figure 1. C18 RP-HPLC chromatograms of whey protein isolate (WPI) hydrolysate fraction WPI heat-treated 10% DH−1 kDa permeate subjected to solid-phase extraction (SPE): (A) SPE cartridge flow-through; (B) 80% (v/v) acetonitrile eluate. CC_{50} describes the concentration required to chelate 50% of the Fe^{2+} from 2 mM $FeCl_2$ under assay conditions.

a bound fraction eluted from the matrix using 80% (v/v) MeCN (Figure 1B). Ferrous-chelating capability was higher in the more hydrophilic (CC_{50} = 0.714 g protein L^{-1}) than in the hydrophobic fraction (CC_{50} = 0.856 g protein L^{-1}; Figure 1B). A significantly ($P < 0.05$) higher percentage of hydrophobic amino acids, for example, Ala, Leu, Phe, and Tyr, was present in the bound eluate than in the flow-through fraction containing higher total concentrations of Arg, His, and Lys (Supplementary Table 2). The elevated levels of free His in the fraction may act as monodentate ligands complexing iron through N-containing imidazole side groups. Whereas the concentration through UF/SPE of certain amino acids, for example, His, is concomitant with increased ferrous chelation, the authors postulate that there could also be peptide complexes present that participate in chelation capability in this study.

Through utilization of various concentrations of a known Fe-chelator, EDTA,[31] it was possible to deduce the equivalent concentration of EDTA needed to give the same level of chelation for the 30 kDa retentate and 1 kDa permeate samples. A 1 g L^{-1} solution of the unhydrolyzed unheated WPI, which possessed a ferrous-chelating ability of 9.13 ± 0.21%,[17] was equivalent to 9.22 ± 0.24 μM EDTA as derived from the standard curve. The 1 kDa permeate of the heat-treated 10%

DOI: 10.1021/jf505817a
J. Agric. Food Chem. 2015, 63, 2708−2714

DH WPI hydrolysate possessed a ferrous-chelating capability equivalent to 84.40 ± 1.01 μM EDTA at 1 g L^{-1}. SPE of the 1 kDa permeate sample resulted in a hydrophilic fraction that was equivalent to 93.24 ± 0.87 μM EDTA in ferrous-chelating capability and a hydrophobic fraction with a respective chelating capability of 80.94 ± 0.87 μM EDTA, both at 1 g L^{-1}. The use of EDTA further demonstrates the increased chelation in the lower M_w and hydrophilic fractions and relates this to a known iron chelator. These fractions can offer qualified advantages similar to iron−amino acid chelates, such as ferrous bis-glycinate, which are better tolerated compared to traditional iron supplements and have received approval by EFSA.[32,33]

Fourier Transformed Infrared Spectroscopy of Whey Protein Isolate, Hydrolysates, and Ferrous-Chelating Fractions. FTIR spectroscopy of the 1 kDa permeate solution prior to, and after, iron fortification demonstrated altered structural characteristics (Figure 2). From Figure 2, the FTIR

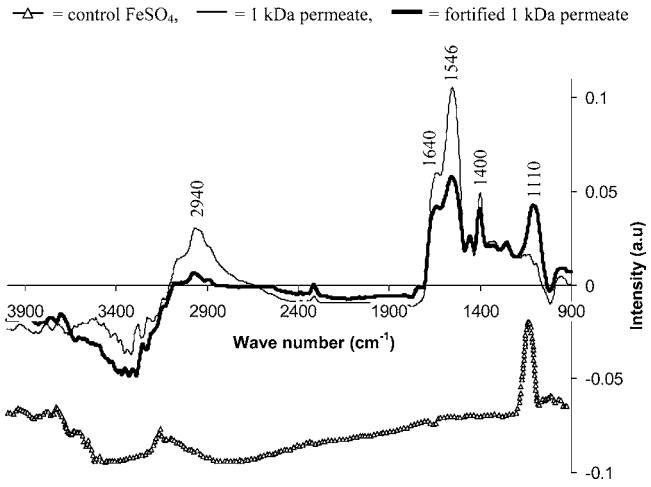

Figure 2. Fourier transformed infrared interferograms of control $FeSO_4$ solution and whey protein isolate hydrolysate fractions of control 1 kDa permeate and iron-fortified 1 kDa permeate.

interferogram of the 1 kDa permeate solution prior to iron fortification exhibits prominent peak intensities at 1640, 1546, and 1400 cm^{-1}. An $FeSO_4$ solution (1.39 g L^{-1} w/v), on the other hand, had a prominent peak intensity at wavenumber 1110 cm^{-1}, which was also identifiable following iron fortification of the 1 kDa permeate along with extensive reductions in peak intensities in the amide I and amide II regions at 1640 and 1546 cm^{-1}, respectively (Figure 2). A corresponding decrease in intensity in the 3100−2700 cm^{-1} region (intensity maximum = 2940 cm^{-1}) of the spectrum of the fortified 1 kDa concurs with a previously reported C−H stretching vibration (ν) of aliphatic CH_2 at 2850−2950 cm^{-1} and C−H ν of aromatic residues at 3050−3080 cm^{-1}.[34,35] An intensification/weakening of vibrations (Figure 2) demonstrates a causative molecular interaction between the ferrous sulfate and the hydrolysate fraction, although whether this is related to Fe−peptide complexing or individual amino acid−Fe interactions is interpretive. The authors postulate that both could be occurring simultaneously. Chaud et al. showed a similar intensity pattern with a ferric−casein hydrolysate complex, attributing chelation to C−O−Fe binding.[12] However, in our case, the concentration of the naturally occurring phenol, Tyr (which could undergo C−O−H substitution), was reduced in the SPE fraction (Supplementary Table 2). Nevertheless, the reduction in aliphatic CH_2 stretching intensity and reduced intensity around amide I (primarily ν C═O) and amide II (N−H deformation) points to, at the very least, altered bond energies.

Iron Solubility and Simulated Gastrointestinal Digestion of Iron-Fortified Whey Protein Isolate Hydrolysate Fractions. The bioavailability of $FeSO_4$ is negatively affected by large changes in intestinal pH; for example, a sudden drop to pH ∼2 under gastric conditions is later corrected to near-neutral pH during subsequent duodenal digestion and absorption.[36−38] This has led to the use of ferric pyrophosphate or NaFe(III)EDTA as more stable replacement additives, the latter having an iron content of 12.5−13.5%.[39] The promising chelating properties of the hydrolysate fractions prompted further investigation of their capacity to solubilize $FeSO_4$ at levels equivalent to higher levels of iron fortification recommended in the diet of pregnant women.[40] Experimentally, this was pursued by examining the solubility of control solutions of $FeSO_4{\cdot}7H_2O$ in Milli-Q water (1.39 g L^{-1} w/v) and fortified (at equivalent level) hydrolysate fractions (10 g L^{-1} w/v) as a function of pH (Figure 3). Dispersion of 1.39 g of

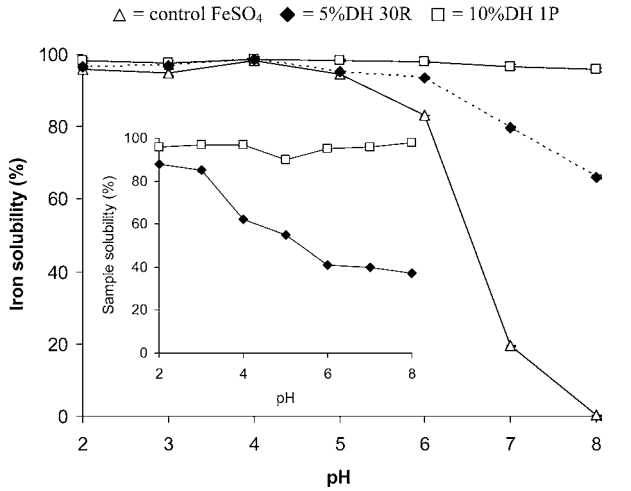

Figure 3. Iron solubility determinations, pH 2−8, for 28 mg of Fe (as $FeSO_4{\cdot}7H_2O$) in control Milli-Q water solutions (100 mL) and hydrolysate dispersions (100 mL, 10 g L^{-1}). WPI control, 5% DH−30 kDa retentate; WPI heat-treated, 10% DH−1 kDa permeate. (Inset) Inherent sample solubility (10 g L^{-1}) over pH 2−8.

$FeSO_4$ L^{-1} in 10 g L^{-1} hydrolysate fractions increased the iron solubility by varying degrees, with those possessing the previously determined lowest and highest CC_{50} values being presented in Figure 3. From Figure 3, the total iron solubility was >95% for all samples (control and fortified hydrolysate fractions) at pH 2−5. Thereafter, total iron solubility declined rapidly in the case of the control (aqueous dispersion), whereas that of the fortified 30 kDa retentate was reduced to 79.6 ± 1.2% at pH 7 and to 66.1 ± 1.0% at pH 8. Only a small (relatively) decrease was observed (to 95.8 ± 1.5% at pH 8) in the iron solubility with the 1 kDa hydrolysate permeate derived from the heat-treated WPI (Figure 3). This fraction was capable of sustaining the highest iron solubility of all fortified samples.

WPI and hydrolysate samples were also analyzed for their inherent solubility over the pH range of 2−8 with the solubility curves for the 30 kDa retentate of the control 5% DH and the 1 kDa permeate of the 10% DH hydrolysate of heat-treated WPI shown in Figure 3 (inset). Generally, the solubility of the 1 kDa

DOI: 10.1021/jf505817a
J. Agric. Food Chem. 2015, 63, 2708−2714

permeate remained high (dropping to 90.2% at pH 5). Conversely, the solubility of the 30 kDa retentate sample was generally poor, dropping to 37.3% at pH 8 from a solubility maximum of 88.2% at pH 2 (Figure 3, inset).

Oral ingestion of fortified hydrolysates may result in exposure to a range of gastrointestinal, luminal, and serum proteinases and peptidases, which may affect iron solubility/bioaccessibility. Initial SGID demonstrated the selective proteolytic digestion of whey proteins (Supplementary Figure 2), with the peptic resistance of β-lg in agreement with previous work.[41,42] Iron-fortified (139 mg of $FeSO_4 \cdot 7H_2O$) samples (20 g L^{-1} protein) were subjected to SGID to ascertain iron solubility during and subsequent to digestion. Figure 4

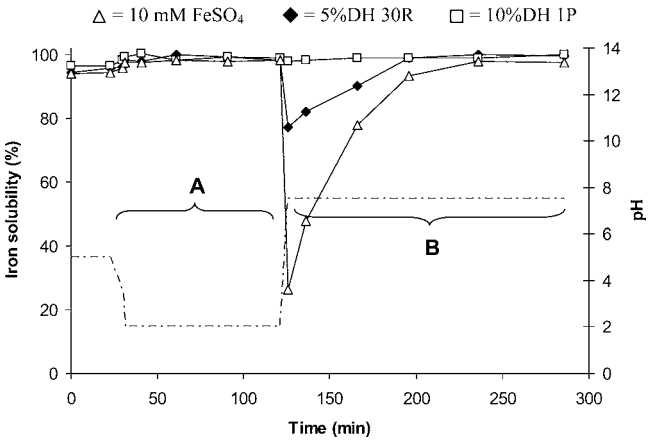

Figure 4. Iron solubility during simulated gastrointestinal digestion of 10 mM $FeSO_4$ control and fortified (2.78 g $FeSO_4$ L^{-1}) whey protein isolate (WPI) hydrolysate dispersions (20 g L^{-1} (initial)): (A) gastric phase; (B) duodenal phase. WPI control, 5% DH−30 kDa retentate; WPI heat-treated, 10% DH−1 kDa permeate.

demonstrates the iron solubility of the 1 kDa permeate and the 30 kDa retentate samples over the course of gastric (marked A in Figure 4) and duodenal (marked B in Figure 4) digestion. From Figure 4, iron solubility remains generally high (≥94.3%) through fortification at pH 5 and subsequent gastric digestion at pH 2 in both samples. However, adjustment of the pH to 7.5 with dibasic sodium phosphate reduced the iron solubility of the 30 kDa retentate sample to 77.1%, although the solubility recovered to approximately 99% after 75 min of simulated duodenal digestion (Figure 4). The authors postulated that this was the result of both the higher ferrous chelating capacity of the 1 kDa sample (CC_{50} = 0.83 ± 0.03 g protein L^{-1}) and also possible chelating capabilities of the constituents of the simulated intestinal fluid. From this, the chelating capacity (expressed as a CC_{50}) of the bile extract was determined to be 1.24 ± 0.10 g L^{-1}, which concurs with the known strong ferrous-chelating capability of porcine bile extract.[43] The iron solubility under SGID of all samples is demonstrated in Supplementary Figure 3.

The SGID of the fortified 1 kDa permeate (Figure 5) reveals relatively minor breakdown following termination of digestion (D, $t_{+286\ min}$) when compared to the undigested sample at time zero (A, t_0). This is corroborated by the statistically insignificant ($P < 0.05$) differences in iron solubility of the samples determined at different reaction time points for gastric (B) and duodenal digestion (C and D, Figure 5). This is in contrast to the 30 kDa retentate sample, where the total iron solubility (TIS) decreased to 77.0 ± 1.2% at pH 7.5 and increased upon

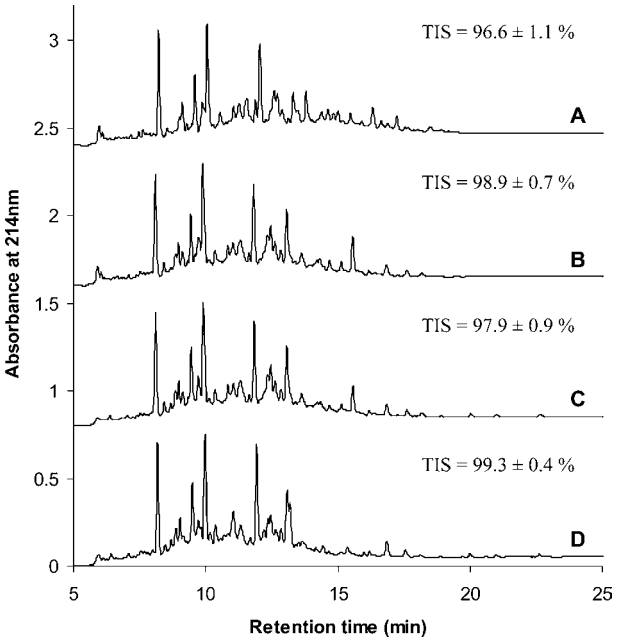

Figure 5. C18 RP-HPLC chromatograms of simulated gastrointestinal digests of the whey protein isolate (WPI) hydrolysate ferrous-chelating fraction, WPI heat-treated, 10% DH−1 kDa permeate: (A) undigested sample at t_0; (B) gastric digest at $t_{+90\ min}$; (C) intestinal digest at $t_{+95\ min}$; (D) intestinal digest at $t_{+286\ min}$. TIS, total iron solubility.

complete simulated digestion, serving to again highlight the relatively poor chelating characteristics of the 30 kDa retentate fraction (Figure 6). Tracking the course of SGID using C18 RP-HPLC (Figure 6) highlighted a reduction in the more hydrophobic material present toward the right of the

chromatogram (A, t_0) and a general leftward shift in the chromatograms as digestion occurs with the increasing formation of peptide material in the 30 kDa retentate sample (Figure 6B–D). The high M_w more hydrophobic material present in the 30 kDa retentate sample (marked "w" in Figure 6) is reduced relatively quickly to more hydrophilic, smaller M_w material, upon gastric digestion with pepsin. This is in agreement with previous work on peptic digestion of aggregated/high M_w whey proteins.[44]

This study utilized enzymatic hydrolysis in conjunction with a prior heat treatment to facilitate the production, and subsequent fractionation, of a ferrous-chelating hydrolysate fraction from WPI. The 1 kDa permeate fraction possessed a ferrous-chelating capability equivalent to 84.4 μM EDTA and had a high content of certain aromatic and basic amino acid residues. ATR-FTIR spectroscopy demonstrated that there was a molecular level interaction between the 1 kDa permeate and the ferrous sulfate. Fractionation of the 1 kDa permeate via solid phase extraction yielded a hydrophilic fraction with increased chelation capability, with this fraction having a relatively high content of hydrophilic amino acids, namely, Arg, His, and Lys. The ferrous-chelating 1 kDa permeate fraction was utilized to stabilize iron during SGID, maintaining iron solubility ≥98% throughout digestion. This is exemplified by the 72% increase in the determined solubility of total iron at pH 7.5 subsequent to peptic digestion compared to a $FeSO_4 \cdot 7H_2O$ control solution. It is postulated, therefore, that the 1 kDa hydrolysate fraction is a potential candidate ingredient for formulation into products to enhance iron bioaccessibility. Further investigation into the mechanism of iron chelation by the 1 kDa permeate hydrolysate fraction is warranted.

such as lipid peroxidation. Lutein is dominant in oats, barley, spelt, and durum wheat whereas zeaxanthin is the main component in corn.[23] Carotenoids content, composition, and distribution in cereal grains have been well studied.[20,22,25−28] However, there is limited information on antioxidant potential of carotenoid from cereal grain fractions. Therefore, we hypothesize that carotenoids in aleurone, germ, and endosperm fractions of barley, corn, and wheat can prevent chronic diseases by acting as antioxidants through an oxidative balance mechanism. The main objective of this study was to investigate the antioxidant potential of carotenoid extracts of hand-separated aleurone, germ, and endosperm fractions of barley, corn, and wheat.

MATERIALS AND METHODS

Chemicals and Materials. HPLC grade acetonitrile, hexane, methylbutyl ether (MtBE) 1-butanol, and methanol were acquired from Fisher Scientific (Whitby, ON, Canada). Carotenoid standards, lutein (98.2%), and zeaxanthin (95.8%), were acquired from Chromadex Inc. (Santa Ana, CA), 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS; ≥98%), 2,2′azobis (2-amidinopropane)-dihydrochloride (AAPH), 2,2,-diphenyl-1-picrylhydrazyl (DPPH) (95%), and butylated hydroxytoluene (BHT) were acquired from Sigma-Aldrich (St. Louis, MO). The fluorescent dye, 5-(and-6)-chloromethyl-2′,7′-dichlorofluorescin diacetate (CM-H_2DCFDA), was acquired from Invitrogen (Eugene, OR). Fluorescein and trolox (6-hydroxy-2,5,7,8-tramethylchroman-2-carboxylic acid) were acquired from Fisher Acros Organics (Morris Plains, NJ). Dimethyl sulfoxide (DMSO), 3-(4,5-dimethylthiazolyl-2)-2,5-diphenyltetrazolium bromide (MTT), fetal bovine serum (FBS), hybrid-care medium, Caco-2, HT-29, and FHs 74 were acquired from American Type Culture Collection (ATCC) (Manassas, VA). The cell culture medium, Dulbecco's modified Eagle's medium (DMEM), was acquired from Sigma-Aldrich (St. Louis, MO), as were Dulbecco's phosphate buffer solution (PBS), L-glutamine (≥99%), sodium pyruvate (≥99%), epidermal growth factor (EGF), and transferrin human (hTF; ≥98%). Penicillin/streptomycin was acquired from Gibco BRL (Burlington, ON, Canada). Trypsin 0.05% was acquired from Thermo Scientific (Logan, UT). RNeasy mini kit was obtained from Qiagen (Mississauga, ON, Canada). RT^2 First Strand kit and RT^2 Profiler array (PAHS-065Y) were obtained from SABioscience (Mississauga, ON, Canada). The 25 cm^2 polystyrene flask or Transwell and 96-well flat bottom polystyrene microplate were purchased from Corning Incorporated (Ithaca, NY).

Samples. Three cereal grains, barley (regular), corn (flint), and wheat (MSUD8006), as described by Ndolo and Beta[28] were used.

Sample Preparation. The grains were hand dissected to separate the aleurone, germ, and endosperm according to the procedure described by Stewart, Nield, and Lott[29] with further modifications. The grains were brush at the ends, and germs were removed by a sharp scalpel. The degermed grains were soaked in 0.1% (v/v) sodium hypochlorite (NaClO) for 15−20 min to sterilize the surfaces and rinsed using sterile deionized water. The seeds were then placed in 10 cm Petri dishes lined with 2 ashless filters, moistened with 10 mL of sterile deionized water. The Petri dishes were wrapped in aluminum foil and kept at 20 °C for 48 h. The aleurone and endosperm were separated using a scalpel and stored at −20 °C. Samples were freeze-dried thereafter and ground using a multiuse blade grinder, model PCC 770 (Loblaws Inc. MO, Canada) to pass through a 0.5 mm sieve. The ground samples were stored at −20 °C before extraction and analysis.

Extraction of Carotenoids. The extraction method of Cha et al.[30] was further modified for this assay. One-gram samples (aleurone, germ, and endosperm) were extracted in a 100 mL ethanol solution (95%) containing 0.1% (w/v) butylated hydroxytoluene (BHT) at room temperature in the dark. After 3 h of extraction under continuous shaking, the mixtures were filtered through a Whatman no. 1 filter paper. Still at room temperature and in the dark, 120 μL of 100% potassium hydroxide (KOH) was added to 5 mL of the contents for saponification. After saponification for 1 h, 3 mL of hexane was added to partition carotenoids. The mixture was shaken for 1 min and then diluted with 3 mL of water. The mixture was allowed to stand in an amber separatory funnel to clearly separate the two phases. The upper layer containing carotenoids was collected, and the residue was repeatedly extracted until it contained no trace of carotenoids. The carotenoid extracts were concentrated using rotary evaporation.

Preparation of Test Solutions. For biochemical model, the concentrated carotenoid extracts were redissolved in 5 mL methanol/saturated butanol to prepare test solutions. For the in vitro model, stock solutions of carotenoid extracts were prepared by reconstituting concentrated carotenoid extracts in 10% DMSO with PBS. The final concentration of DMSO was less than 1%. The original carotenoid stock solutions were 200 mg/mL which were further diluted to working solutions of 100, 20, 5, 0.5 mg/mL with PBS.

Biochemical Models. *Determination of Total Carotenoid Content (TCC).* The extracted carotenoids were reconstituted with water-saturated butanol and transferred to semimicro quartz cuvette and absorbance measured at 450 nm using Ultrospec 1100 pro, UV/visible spectrophotometer (Biomicron Ltd. Cambridge CB4 QFJ, England). All analysis were conducted in triplicates and expressed as μg xanthophylls equivalent/g sample

$$C = \frac{(5 \times A)}{S \times W\left[\frac{\mu g}{g}\right]} \quad (1)$$

where C = xanthophyll content, μg/g; A = absorbance reading; S = regression coefficient (the number that expresses the relationship which is created based on concentration of xanthophyll working standard solutions in μg/mL and the absorbance); 5 = dilution factor (the factor based on the total extracted volume of 5 mL); and W = sample weight, g.[25]

HPLC Analysis of Carotenoids. Carotenoids were quantified by HPLC, using external calibration of standard mix (lutein and zeaxanthin). Freshly extracted samples were filtered through 0.45 μm nylon disc filter into brown HPLC vial. The quantification of carotenoids was done according to methods from Ndolo and Beta[28] and Abdel-Aal et al.[25] with some modifications. The quantification of carotenoids was performed by an HPLC (Waters 2695) equipment with a photoiodide array detector (PDA) (Waters 996) and autosampler (Waters 717 plus) (Waters, Milford, MA). YMC carotenoid S-3, 3 μm packing, 4.6 × 100 mm column (Waters, Milford, MA) was used. The column was operated at 35 °C, and 20 μL of sample was injected by autosampler and eluted with gradient system consisting of (A) methanol/methyl *tert*-butyl ether/milli-Q water (81:15:4 v/v/v) and (B) methyl *tert*-butyl ether/methanol (90:10 v/v). The flow rate was set at 1 mL/min. The gradient was programmed as follows: 0−9 min, 100−75% A; 10−12 min, 0% A; 12−13 min, 0−100% A; and 13−20 min, 100% A. The separation of carotenoids was detected and measured at 450 nm. Carotenoids in samples were identified based on retention times of standards. Six concentrations in the range of 0.05−5.0 μg/mL per 20 μL were prepared for lutein and zeaxanthin to generate regression equations for quantification.

Estimation of Antioxidant Activity of Carotenoids. *Determination of DPPH Radical Scavenging Activity.* The DPPH method of Brand-William et al.[31] as modified by Li et al.[32] was further modified for this assay. Sixty μM DPPH radical solution was freshly prepared from a stock solution of 300 μM. Extracts (100 μL) were reacted with 3.9 mL of the DPPH radical solution for 30 min. The absorbance at 515 nm was measured against a blank of pure methanol using Ultraspec 1100 pro, UV/visible spectrophotometer (Biomicron Ltd. Cambridge CB4 QFJ, England). The analysis was conducted in quadruplicates. Concentrations ranging from 100 to 800 μmol were used for the trolox standard curve. Antioxidant activity was calculated as a % DPPH radical scavenging activity as

DOI: 10.1021/jf5058606
J. Agric. Food Chem. 2015, 63, 2715−2724

$$\text{DPPH radical scavenging activity}(\%) = \left(1 - \left[\frac{A_{\text{sample}} - A_{\text{Control}}}{A_{\text{control}} - A_{\text{blank}}}\right]\right) \times 100 \quad (2)$$

where $A_{control}$ is the absorbance of DPPH radical in methanol at 0 min and A_{sample} is the absorbance of DPPH radical for the sample extract or standard at 30 min. A calibration curve of % DPPH decolorization obtained from different concentration of trolox was used to quantify the antioxidant capacity of the extracts. Antioxidant capacity was expressed using Trolox equivalents (TE) per gram of dry samples.

Determination of ABTS Radical Scavenging Activity. The ABTS method of Pellegrini et al.[33] was further modified for this assay. Samples of 7 mM of ABTS reagent and 2.45 mM of potassium persulfate solution were mixed and allowed to stand in the dark at room temperature for 16 h before use. Prior to assay, the solution was diluted in methanol to give absorbance at 734 nm of 0.7 ± 0.02. Extracts (100 μL) were reacted with 3.9 mL of the ABTS radical solution for 30 min. The absorbance at 734 nm was measured against a blank of pure methanol using Ultraspec 1100 pro, UV/visible spectrophotometer (Biomicron Ltd. Cambridge CB4 QFJ, England). The analysis was conducted in quadruplicates. Concentrations ranging from 100 to 800 μmol were used for the trolox standard curve. Antioxidant activity was calculated as a % ABTS radical scavenging

$$\text{ABTS radical scavenging activity}(\%) = \left(1 - \left[\frac{A_{\text{sample}} - A_{\text{control}}}{A_{\text{control}} - A_{\text{blank}}}\right]\right) \times 100 \quad (3)$$

where $A_{control}$ is the absorbance of ABTS radical in methanol at 0 min and A_{sample} is the absorbance of ABTS radical for the sample extract or standard at 30 min. A calibration curve of % ABTS decolorization obtained from different concentration of trolox was used to quantify the antioxidant capacity of the fractions extracts. Antioxidant capacity was expressed using Trolox equivalents (TE) per gram of dry samples.

Determination of Oxygen Radical Absorbance Capacity. The determination of oxygen radical absorbance capacity ($ORAC_{FL}$), first developed by Cao et al.,[34] was conducted according to Huang et al.[35] and Li et al.[36] A FLx800 microplate fluorescence reader (Bio-Tek Instruments, Inc., Winooski, VT) was used with fluorescence filters for an excitation wavelength of 485/20 nm and an emission wavelength of 528/20 nm. The plate reader was controlled by KC4 3.0 software (version 29). The instrument was monitored by KC4 3.0 software, version 29. Dilutions of barley, corn, and wheat extracts and trolox standard were done manually. A volume of 300 μL each of buffer solution (blank) and diluted sample solution and trolox standard was transferred to a 96-well flat bottom polystyrene microplate according to their allocated wells. Trolox standards 12.5, 25, 50, and 100 μM were used. The remainder of the procedure was conducted according to Li et al.[36] Antioxidant capacity was calculated based on the method by Huang et al.[37] Regression equation between trolox concentration and the net area under the fluorescence decay curve was constructed. The analysis was conducted in quadruplicates. The formula to obtain the area under curve (AUC) was

$$\text{AUC} = 0.5 + \frac{f_1}{f_0} + \ldots\frac{f_i}{f_0} + \ldots\frac{f_{49}}{f_0} + \ldots 0.5\frac{f_{50}}{f_0} \quad (4)$$

where f_0 = initial fluorescence reading at 0 min and f_i = fluorescence reading at time i min. Relative ORAC value was calculated according to the formula:

$$\text{relative ORAC Value} = \frac{\text{AUC}_{\text{sample}} - \text{AUC}_{\text{blank}}}{\text{AUC}_{\text{Trolox}} - \text{AUC}_{\text{blank}}}\left(\frac{\text{molarity of trolox}}{\text{molarity of sample}}\right) \quad (5)$$

In Vitro Models. *Cell Culture Assay.* Three in vitro models were used in this study: Caco-2, HT-29, and FHs 74 Int. Caco-2 is structurally and functionally similar to human intestinal epithelium, which is the first to come in contact with food. They are regarded as a simple in vitro model for the study of drug transportation and absorption in human intestinal mucosa.[37] HT-29, a cell line with epithelial morphology, is used to study drug transportation, absorption, and secretion by intestinal cells.[38] It was used to verify the data from the Caco-2 cell line. FHs 74 Int is primary human fetal intestine cell culture which does not form confluent, polarized monolayers in culture yet is otherwise genotypically similar to neonatal enterocytes. It has been reported to show mature epithelial-like characteristics.[39]

All 3 cell lines were grown in 25 cm^2 polystyrene flask or Transwell culture chamber. The Caco-2 and HT-29 were maintained in DMEM with D-glucose content supplemented with 10% FBS, penicillin (100 kU/L), streptomycin (100g/L), 200 mM L-glutamine, 100 mM sodium pyruvate, and hTF. FHs 74 Int cells were cultured using Hybri-Care medium with 10% FBS, penicillin (10 kU/L), streptomycin (100g/L), and EGF (40 μg/L). Cells were subcultured after reaching confluence using trypsin (0.05%). Cells were maintained at 37 °C in a 5% CO_2 humidified incubator for optimal growth.

Cytotoxicity Assay. Aleurone, germ, and endosperm fractions of barley, corn, and wheat were tested for their cytotoxicity using the MTT colorimetric assay according to the protocol provided by the manufacturer with some modifications. Caco-2, HT-29, and FHs 74 Int cell suspensions (100 μL) were seeded in a 96 well plate and maintained until confluent (a concentration of 1×10^5/mL) for 72 h. Following cell confluence, media from all wells were aspirated. Then 100 μL of 20, 5, and 0.5 mg/mL sample extract and 100 μL of PBS for control wells were added. Blank well contained PBS only. Cells were treated and left in the incubator for 4 h. MTT reagent (10 μL) was added to all wells including the control wells and left in the incubator for 3 h. After 3 h, dots of purple precipitates were visible under microscope and all 110 μL of treatment solution was then aspirated, and 100 μL of detergent reagent was added to all plates including the control. The plates were swirled gently. The plates were covered with aluminum foil and left in the dark for 15 min at room temperature. After 15 min, plate covers were removed and absorbance measured at 560 nm using Opsys MR 96-well reader (Dynex Technologies, Chantilly, VA). Cytotoxicity level (%) was then calculated by comparing absorbance of samples to that of control. Analysis was done in quadruplicates.

Cytoprotective Activity against AAPH-Induced Oxidation. The cytoprotection of extracts of cereal grain fractions against AAPH-induced oxidation were determined by MTT assay according to Gliwa et al.[40] with some modifications. Caco-2, HT-29, and FHs 74 Int cells suspensions (100 μL) were seeded in 96-well plates and maintained until confluent (a concentration of 1×10^5/mL) for 72 h. Following cell confluence, media from all wells were aspirated, and then 100 μL of 20, 5, and 0.5 mg/mL sample extract was added to appropriate sample wells and 100 μL of PBS was added to control wells. Blank wells contained PBS only. After 2 h of incubation, 10 μL of 3 mM AAPH was added to sample and AAPH positive control wells. Cells were incubated for another 4 h. After that, MTT reagent was added to all except the blank wells, and the plates were incubated for 3 h until the intracellular punctate purple precipitate was visible under the microscope. Detergent reagent was then added to all except the blank wells. The plates were swirled gently. The plates were covered with aluminum foil and left in the dark for 15 min at room temperature. After 15 min, plate covers were removed and the plate was measured for absorbance at 560 nm using Opsys MR 96-well reader (Dynex Technologies, Chantilly, VA). Cytotoxicity level (%) was then calculated by comparing absorbance to that of control.

Intracellular Oxidative Stress. Determination of intracellular oxidative stress was based on the oxidation of CM-H_2DCFDA to yield an intracellular-trapped fluorescent compound. Aleurone, germ, and endosperm fractions of barley, corn, and wheat were then tested for their effect on cellular oxidative status according to Wolfe and Liu[41] with some modifications. Caco-2, HT-29, and FHs 74 Int cell suspensions (100 μL) were seeded in a 96-well plate and maintained until confluent (a concentration of 1×10^5/mL) for 72 h. The media from all wells were aspirated, and 100 μL of 20, 5, and 0.5 mg/mL

DOI: 10.1021/jf5058606
J. Agric. Food Chem. 2015, 63, 2715−2724

sample extract and 100 μL of PBS for control wells were added. The blank well contained PBS only. The cells were treated and left for 1 h. At 30 min of incubation, 100 μL of 10 μM CM-H_2DCFDA solution was added to all wells. The final concentration of CM-H_2DCFDA was then 5 μM. After 1 h of incubation, all 200 μL of treatment solutions was removed and 100 μL of 500 μM AAPH dissolved in PBS was added to all wells except negative control (100 μL of PBS was added instead). The plates were then read immediately by Fluoroskan Ascent FL 96-well plate reader (ThermoLabsystems, Franklin, MA). Temperature was set at 37 °C, emission wavelength at 527 nm, and excitation wavelength at 485 nm, and measurements were taken every 30 min for 2 h. The analysis was done in quadruplicates. The CAA value was calculated by integrating area under the curve (AUC) for each sample and standard using final assay values and their linear regression formula below:

$$\mathrm{AUC} = 1 + \frac{\mathrm{RFU}_1}{\mathrm{RFU}_0} + \frac{\mathrm{RFU}_2}{\mathrm{RFU}_0} + \frac{\mathrm{RFU}_3}{\mathrm{RFU}_0} + \ldots + \frac{\mathrm{RFU}_{120}}{\mathrm{RFU}_0} \quad (6)$$

RFU_0 = relative fluorescence value of time zero

RFU_x = relative fluorescence value of time point

The AUC values were used to determine CAA values according to the formula

$$\text{CAA value} = 100 - \left(\frac{\mathrm{AUC}_{\text{Antioxidant}}}{\mathrm{AUC}_{\text{Control}}}\right) \times 100 \quad (7)$$

Microarray Analysis. RNA of HT-29 cells were isolated using RNeasy mini kit and on-column DNase treatment to eliminate genomic DNA contamination according to manufacturer's instructions. An equal amounts of RNA (500 ng) was reverse transcribed to cDNA using a RT^2 First strand kit according to the manufacturer's instructions. Samples were diluted in quantitative polymerase chain reaction (qPCR) master mix (RT^2 SYBR Green; SABioscience Corp.) according to the supplier's directions and pipetted into 96-well PCR array plates. Real-time PCR for the human oxidative stress and antioxidant defense PCR array (PAHS-065Y) consisting of 84 antioxidant enzymes with 3 RT controls and 3 positive PCR controls, a genomic contamination control, and 5 constitutively expressed housekeeping genes was performed according to the manufacturer's instructions using ABI 7500 standard Real-time PCR system (Applied Biosystems). Three independent replicates of each treatment with or without aleurone, germ, and endosperm fractions of corn were performed and data analyzed using software from the SABioscience Web site.[42]

Statistical Analysis. Data obtained in both the biochemical model and in vitro model assay were analyzed as complete randomized design (CRD)-factorial plus control using the one-way analysis of variance (ANOVA) with GLIMMIX Procedure of SAS, release 9.3 (SAS 2014; SAS Institute). Data obtained from microarray analyses were analyzed using a two-tailed t test assuming equal variance. Sample means were compared using Tukey–Kramer multiple comparison procedure, and data was considered significantly different when $P < 0.05$. All results are presented as mean ± standard error.

RESULTS AND DISCUSSION

Biochemical Models. *Total Carotenoid Content in Aleurone, Endosperm, and Germ of Barley, Corn, and Wheat.* Figure 1 shows total carotenoid content (TCC) expressed as xanthophyll equivalent (mg/kg) in cereal grain fractions. TCC differed significantly among fractions from different cereal grains ($P < 0.001$). TCC was highest in germ fraction of the cereal grains (57.3–60.3 mg/kg) and lower in aleurone and endosperm of barley (28.6 and 28.9 mg/kg, respectively). Corn germ had the highest concentration of carotenoid compared to the other samples ($P < 0.001$). The higher content of TCC in germ could be attributed to the presence of yellow carotenoid pigments. Our results are consistent with studies by Panfili et al.[23] and Ndolo and

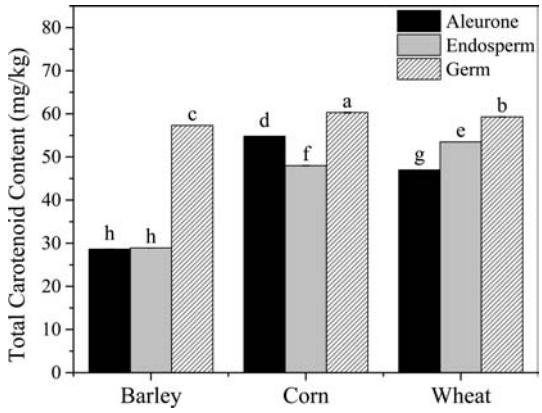

Figure 1. Total carotenoid content (mg/kg) in aleurone, endosperm, and germ fractions of barley, corn, and wheat. Data presented are mean ± standard error ($n = 3$). Different letters indicate significant differences ($p < 0.05$, Tukey–Kramer's multiple range test) among fractions for each cereal.

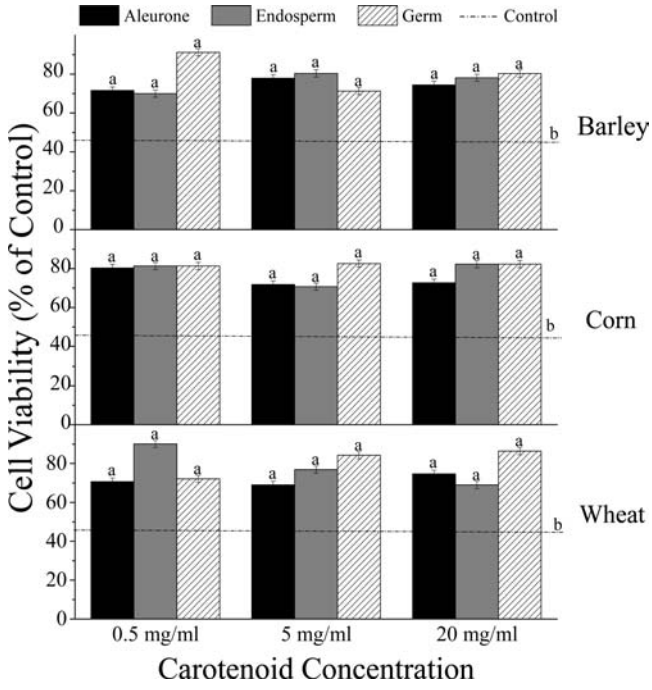

Figure 4. Cytoprotective activity of aleurone, germ, and endosperm fractions of barley, corn, and wheat at different concentrations, 0.5, 5, and 20 mg/mL (mean ± standard error, $n = 4$), in confluent HT-29 cell line against AAPH-induced oxidation. Different letters indicate significant differences ($p < 0.05$, Tukey–Kramer's multiple range test) among fractions for each cereal.

Carotenoids Analysis in Aleurone, Endosperm, and Germ of Barley, Corn, and Wheat. The short method was chosen assuming BHT-ethanol extracted mainly polar carotenoids unlike nonpolar ones, which are found in minimal amount in cereal grains. Carotenoid identification was accomplished by comparing the retention times (t_R) in the sample and those of external standards and the UV–visible absorption spectra from literature. Two peaks were identified for lutein and zeaxanthin, the primary carotenoids found in cereal grains and products.[23,43] Quantitative data were calculated from the linear calibration curves. Lutein levels varied significantly ($P < 0.01$) in all cereal grain fractions. It ranged from nd-1328 μg/kg in barley to 72–431 μg/kg in wheat and 72–1369 μg/kg in corn fractions ($P < 0.01$) (Table 1). The endosperm fraction of corn had higher lutein content (1369 μg/kg) followed by germ fraction of barley (1328 μg/kg) and with no detection in the endosperm of barley. Zeaxanthin levels also varied significantly ($P < 0.01$) in all cereal grain fractions. It ranged from nd-15139 μg/kg in barley to 358–13671 μg/kg in corn and 7–215 μg/kg in wheat. The germ fraction of barley had higher zeaxanthin content (15139 μg/kg) followed by endosperm fraction of corn (13671 μg/kg) and with no detection in the endosperm of barley. Corn fractions had higher levels of zeaxanthin than barley and wheat, and even higher than whole meal as previously shown by Ndolo and Beta.[23] Zeaxanthin has been reported to be concentrated in the germ fraction of wheat[23] and corn endosperm.[44] In the present study, zeaxanthin was also reported as the dominant carotenoid in the aleurone layer in wheat consistent with results reported by Ndolo and Beta.[28] In this study, lutein and zeaxanthin were unevenly distributed in grain fractions and were not detected in the endosperm of barley. Differences in lutein and zeaxanthin levels would be

[a]List of differentially expressed genes. Fold change represents the average of DNA expression level in HT-29 cells treated with aleurone, germ, and endosperm fractions of corn. n = 3 in each condition. endo = endosperm; aleu = aleurone.

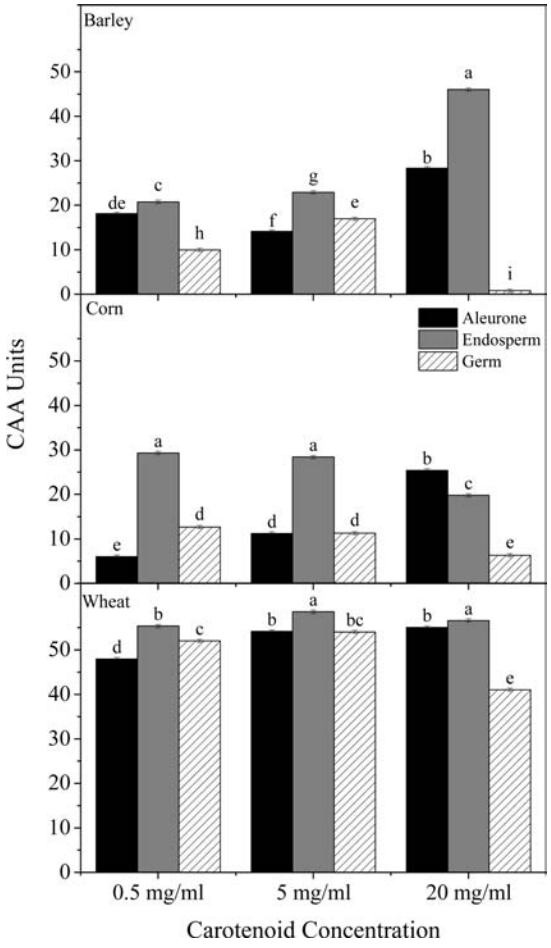

Figure 5. CAA values of aleurone, germ, and endosperm fractions of barley, corn, and wheat at different concentrations, 0.5, 5, and 20 mg/mL (mean ± standard error, n = 8), using Caco-2 cell line. Different letters indicate significant differences (p < 0.05, Tukey-Kramer's multiple range test) among fractions for each cereal.

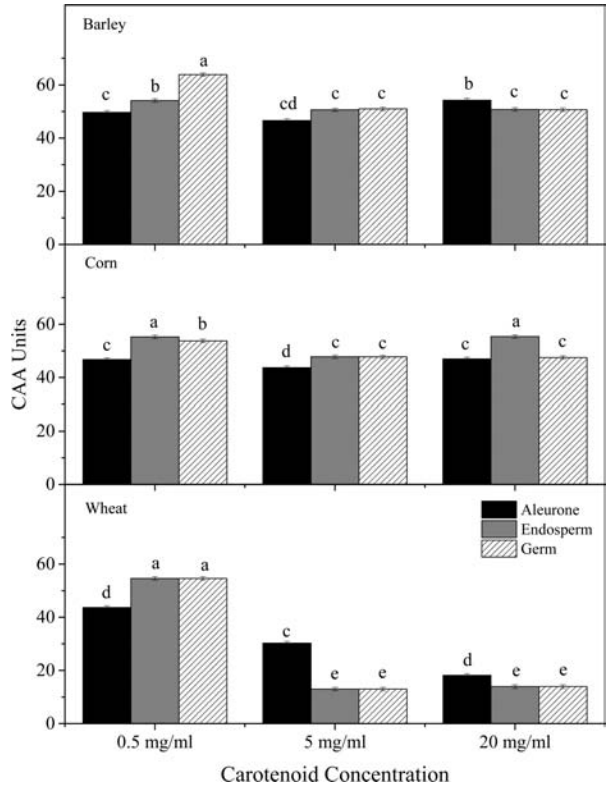

Figure 6. CAA values of aleurone, germ, and endosperm fractions of barley, corn, and wheat at different concentrations, 0.5, 5, and 20 mg/mL (mean ± standard error, n = 8), using FHs 74 Int cell line. Different letters indicate significant differences (p < 0.05, Tukey–Kramer's multiple range test) among fractions for each cereal.

attributable to genetic differences and growing location which affect chemical composition of the cereal grains.[23,44]

DPPH Antioxidant Activity. DPPH scavenging activity is based on discoloration as a result of reduction of DPPH free radical by antioxidant.[31] Our results (Table 2) suggest the better ability to quench DPPH free radicals by the aleurone of corn and barley than of wheat, germ of barley than that of corn and wheat, endosperm of corn than that of barley and wheat (P < 0.01). The antioxidant activity of the fractions ranged from 4.3 to 76.8 for barley, 37.1 to 71.0 for corn, and 25.1 to 50.1 μM trolox equivalent for wheat (Table 2). Barley germ had higher DPPH free radical quenching activity with barley endosperm having the lowest activity (P < 0.01). The low DPPH scavenging activity in the endosperm of barley may be attributed to the low TCC and absence of lutein and zeaxanthin. According to a study by Mortensen and Skibsted[45] on role of carotenoid structure in radical scavenging reaction, zeaxanthin is more reactive than lutein although their order of reactivity shows only slight differences. DPPH scavenging activity in germ fractions ranged from 37.1 μM for wheat to 76.8 μM for barley in aleurone fractions and 44.4 μM for wheat and 71.0 μM for corn.

ABTS+ Antioxidant Activity. ABST+ scavenging activity is based on ABTS+ radical losing its blue-green color when reduced to ABTS at 734 nm.[33] The ABTS scavenging activity ranged from 32.0 to 67.7 for barley, 43.5 to 53.3 for corn, and 41.6 to 43.9 μM trolox equivalent for wheat fractions (Table 2).

DOI: 10.1021/jf5058606
J. Agric. Food Chem. 2015, 63, 2715−2724

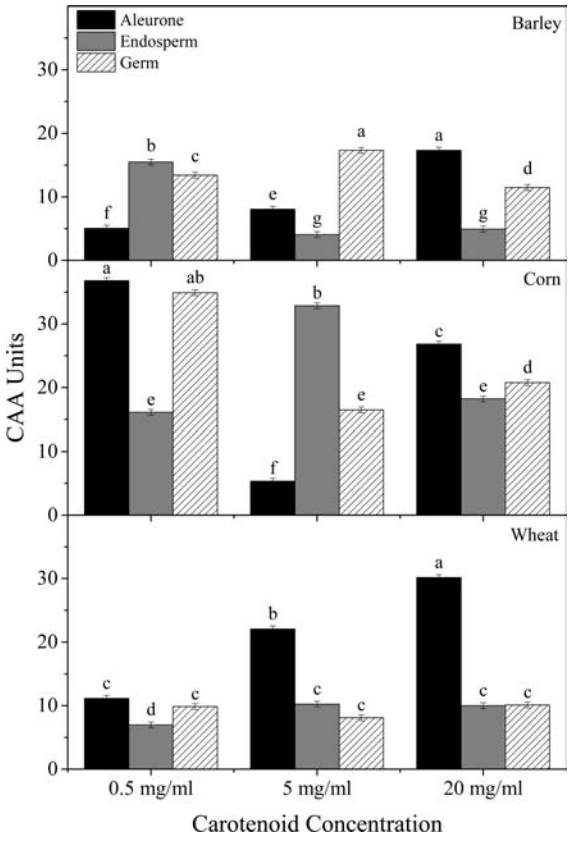

Figure 7. CAA values of aleurone, germ, and endosperm fractions of barley, corn, and wheat at different concentrations, 0.5, 5, and 20 mg/mL (mean ± standard error, n = 8), using HT-29. Different letters indicate significant differences (p < 0.05, Tukey–Kramer's multiple range test) among fractions for each cereal.

Our results suggest that germ of barley had the higher antioxidant activity compared to that of corn and wheat (P < 0.01). Furthermore, the results suggest the better ability to scavenge ABTS free radicals by the aleurone of barley and corn than of wheat, and endosperm of corn than that of wheat and barley. Germ fractions had scavenging activity ranging 43.1 μM for wheat to 67.6 μM for barley; aleurone fractions 41.6 μM for wheat and 51.7 μM for barley; endosperm fractions 32.0 μM for barley and for 53.3 corn (Table 2).

ORAC Values. ORAC assay is based on the principle that antioxidants will prevent peroxyl radicals generated by AAPH from decaying the fluorescence intensity of fluorescein.[34] The ability of a compound to delay the loss of fluorescence intensity over time is a measure of antioxidant capacity. Our results show that ORAC values ranged from 18.3 to 37.3 μmol trolox equivalent (TE)/gram (g) of matter (Table 2). ORAC values were generally low in endosperm (18.3–33.8 μmol TE/g of dry matter) compared to germ and aleurone fractions. Among aleurone fractions, barley had lowest ORAC values. In contrast, ORAC values of germ fractions were highest ranging from 29.3 for wheat and 37.3 μmol TE/g of dry matter for corn. ORAC values were also higher in aleurone fractions, 24.7 for wheat and 30.5 μmol TE/g of dry matter for corn likely due to variation in zeaxanthin levels (Table 1).

In Vitro Models. *Cytotoxicity Assay.* The MTT colorimetric assay evaluated the cytotoxicity of aleurone, germ, and endosperm fractions of barley, corn, and wheat. The cytotoxicity assay was performed to confirm that the sample treatments had minimal negative effect on the viability of the cell line. Compared to the untreated control, extracts were not cytotoxic to Caco-2 (84–115%) (Figure 2; Table 3). Analysis of variance of cytotoxicity data from factorial plus control showed no significant differences between the interactions but showed significant effects between fractions (P < 0.02) which did not pose any toxicity (Figure 2; Table 3). An extract is considered toxic if it is lethal to 50% of the organisms exposed to it in a toxic test. Therefore, our results indicate that different fractions, concentrations, and sources had no negative effect on cell viability. Similar trends were observed with FHs 74 Int and HT-29 cell lines (data not shown). There was no nutrient impact described by the cytotoxicity assay; however, the cytoprotective and intracellular oxidative stress assays further explored antioxidant activity of the sample treatment with different concentrations (0.5, 5, and 20 mg/mL). In order to determine the optimal concentration of AAPH to induce cellular oxidative stress in Caco-2, HT-29, and FHs 74 Int, we constructed dose dependent curves. AAPH concentrations of 0, 1, 3, 5, 10, 15, 20, 25 mM prepared in PBS were incubated with confluent cells in 96-well plates for 4 h. Cell death by AAPH-induced oxidation was determined by MTT assay and expressed as cell viability (%). An escalating concentration of AAPH from 0 to 25 mM resulted in an increasing cell loss in all the cell lines. After 4 h of treatment with AAPH, up to 45–55% loss of cell viability was observed (Figure 3). Different LD_{50} (the concentration of a substance that is lethal to 50% of the organisms exposed to it in a toxic test) obtained from concentration–response curves of the three cell lines indicated Caco-2 cells (LD_{50} = 42.9) are more sensitive than FHs 74 Int (LD_{50} = 37.3) and HT-29 cells (LD_{50} = 22.8) in the presence of AAPH. On basis of the results, 3 mM of AAPH was chosen to stimulate sufficient levels of oxidation in the subsequent study.

Cytoprotective Activity of Aleurone, Endosperm, and Germ Extracts of Barley, Corn and Wheat against AAPH-Induced Cytotoxicity. Based on the cytotoxicity results, 0.5, 5, and 20 mg/mL of aleurone, endosperm, and germ fractions extracts were applied against 3 mM AAPH-induced oxidative damage in Caco-2, HT-29, and FHs 74 Int cells. Analysis of variance of AAPH-induced cytotoxicity data was not significant for the main factors but showed significant effects for all the interactions (P < 0.0001; Figure 4, Table 4). This therefore, indicated different sources, fractions, and concentrations attenuate free radical toxicity differently. The cell viability increased from 45.5% (cell treated with 3 mM of AAPH only) to a maximum of 95.1% (cell pretreated with 0.5, 5, and 20 mg/mL of aleurone, germ, and endosperm extracts followed by 3 mM of AAPH) (Figure 4; Table 4). Similarly, 0.5, 5, and 20 mg/mL of extracts suppressed the AAPH-initiated oxidation damage in Caco-2 and FHs 74 Int cells (data not shown). Elisia and Kitts[46] have previously indicated that AAPH-initiated loss of cell viability in Caco-2 cells is partially attributed to the inductive effect of AAPH on cell apoptosis. AAPH under thermal decomposition produces peroxyl radicals in cultured cell, and this will increase lipid peroxidation, damage cell membrane integrity, and eventually induce cell apoptosis.[47] In this study, all concentrations of cereal grain fractions displayed effective protection in Caco-2, HT-29, and FHs 74 Int cells against AAPH-induced cell loss. Thus, carotenoid extracts from cereal grain fractions may function as free radical cleaner to reduce cellular ROS level and prevent the formation of apoptosis cells caused by AAPH oxidation.

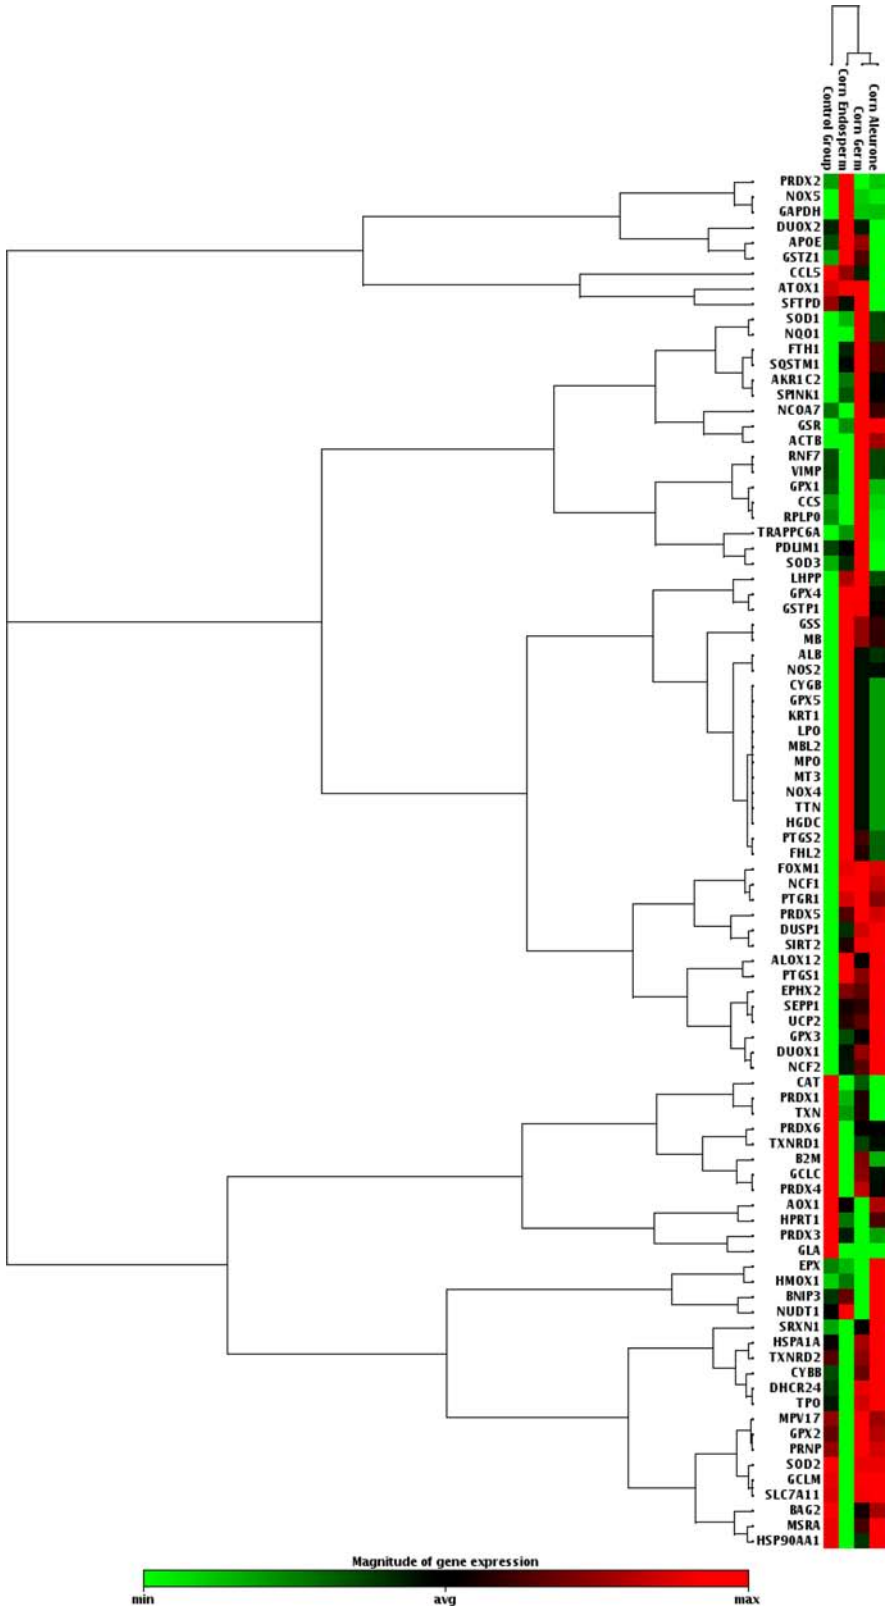

Figure 8. Clustergram or heatmap analysis: The clustergram or heatmap represents expression levels of 84 genes in four conditions (control, endosperm, germ, and aleurone of corn) relative to an average of five housekeeping genes. Each horizontal line in the heatmap represents a single gene, and the columns represent groups. Samples clustered according to the condition. Red represents high expression, while green represents low expression.

Intracellular Oxidative Stress. CM-H_2DCFDA is a fluorogenic dye for measuring hydroxyl, peroxyl, and other ROS activity within the cell. After diffusion into the cell, CM-H_2DCFDA is deacetylated by cellular easterases to a non-fluorescent compound which is later oxidized by ROS into 2′,7′-dichlorofluorescin (DCF). DCF is a highly fluorescent

DOI: 10.1021/jf5058606
J. Agric. Food Chem. 2015, 63, 2715−2724

compound that can be detected by fluorescence spectroscopy with maximum excitation and emission spectra of 495 and 529 nm, respectively. The reaction of sample-treated cell lines against APPH-induced free radical oxidation is shown in Figures 5−7. AAPH induced the oxidation of the dye CM-H_2DCFDA to DCF. The fluorescence intensity of DCF was measured to represent the rate of oxidation. Positive (+) controls showed the fluorescence intensity of the AAPH oxidation over time, while negative (−) controls were cells to which AAPH was not added. They were used to illustrate conditions devoid of any oxidation inducer. Cell lines treated with cereal fractions carotenoid extracts showed the inhibition of oxidation as their fluorescence intensities were higher than the negative control but less than the positive control over time. CAA units were then calculated (eqs 6 and 7) based on the fluorescence intensity of the fraction extracts and AAPH-treated cells. In Caco-2 cell line, CAA ranged from 5.0 to 55.0 CAA units (Figure 5). Wheat fraction always showed the highest antioxidant activity whereas barley fractions showed the lowest CAA units. In FHs 74 Int cell line, CAA ranged from 15.0 to 63.0 CAA units (Figure 6). Barley germ at 0.5 mg/mL showed higher CAA units than wheat which had the lowest. Corn endosperm had highest antioxidant activity while wheat had lowest CAA units. Barley and wheat aleurone fractions at 20 mg/mL showed highest and lowest CAA units, respectively. Using HT-29 cell line, CAA ranged from 5.0 to 37.5 CAA units (Figure 7). Corn fraction always showed the highest antioxidant activity whereas barley fractions showed the lowest CAA units. On the basis of current study, all tested doses inhibited ROS as shown by increase in CAA units ($P < 0.05$).

Aleurone, Endosperm, and Germ Fractions of Corn and Antioxidant Gene Regulation in HT-29 Intestinal Cells. Based on the TCC, lutein and zeaxanthin levels, cytoprotective activity, and CAA results, HT-29 were treated with 20 mg/mL of aleurone, endosperm, and germ fractions of corn to assess abundance of oxidative stress-related genes. Extracted RNA was determined spectrophotometrically at 260/280 nm with NanoDrop ND-1000 (NanoDrop Technologies, Inc.) to be $A_{260/280} = 1.91$. Of the 84 antioxidant pathway genes included in this oxidative stress and antioxidants defense array, the expression of 28 genes was altered by corn aleurone, endosperm, and germ treatments ($P < 0.05$) (Figure 8). However, we only observed twofold upregulation of myoglobin (MB), neutrophil cytosolic factor 1 (NCF1) and NADPH oxidase, EF-hand calcium binding domain 5 (NOX5) and twofold down regulation of chemokine (C−C motif) ligand 5 (CCL5), BCL2-associated athanogene 2 (BAG), and solute carrier family 7 (anionic amino acid transporter light chain, xc- system), member 11 (SLC7A11) in different fractions (Table 4). However, *P*-values did not indicate statistical significance for NOX5 and CCL5 in all fractions, NCF1 in endosperm and SCL7A11 in aleurone and germ. The microarray antioxidant enzymes are enzymes that catalyze the reduction of hydroperoxides and other organic hydroperoxides. The upregulation of 28 genes therefore represents a cell-protective mechanism by which intestinal cells manage oxidative stress elicited by exposure to aleurone, germ, and endosperm fractions.

Generally, lutein and zeaxanthin and TCC were unevenly distributed across the grain fraction. For all cereal grain fractions, the germ had significantly ($P < 0.001$) higher levels of TCC than aleurone and endosperm (corn > wheat > barley). In barley and wheat, lutein and zeaxanthin were concentrated in the germ unlike in corn where they are concentrated in endosperm. DPPH and ABTS showed radical scavenging; ORAC activity showed antioxidant activity. All cereal grain fractions displayed effective protection in Caco-2, HT-29, and FHs 74 Int cells against AAPH-induced cell loss and inhibited ROS as shown by increase in CAA units. Thus, carotenoid extracts from cereal grain fractions may function as free radical cleaner to reduce cellular ROS level and prevent the formation of apoptosis cells caused by AAPH oxidation. On the basis of the current studies, we conclude that carotenoids of aleurone, germ, and endosperm from barley, corn, and wheat improved antioxidant activity and thus have the potential to mitigate oxidative stress. We also showed that antioxidant activity of cereal grain fractions might be through endogenous scavenging and gene expression mechanisms. These findings indicate that corn endosperm, aleurone, and germ of corn, barley, and wheat might be useful functional ingredients in curbing oxidative stress, hence preventing human pathogenesis.

MATERIALS AND METHODS

The net absorption of betaine and choline was studied in three experiments. In the first experiment, pigs were fed a low-fiber Western style diet (WSD)[32] or WSD with added purified betaine, and in the following two experiments, the net absorption of betaine and choline was studied in pigs fed various types of high-fiber breads. The pigs were fed either breads based on whole-grain wheat or wheat aleurone, which they had been adapted to for 4 days,[33] referred to as chronic uptake of betaine, or rye breads with whole rye kernels or milled rye[34] as a single meal, which will be termed acute uptake of betaine.

Animal Model. The pigs for the studies were obtained from the swineherd at Aarhus University, Foulum, Department of Animal Science. The porto-arterial catheterized pig model was used to study the net absorption of betaine and choline. The pigs were surgically fitted with permanent catheters in the portal vein and in the mesenteric artery; in the first experiment, a catheter was furthermore placed in the hepatic vein. An ultrasonic flow probe (Transonic, 20PAU probe, 18/20 mm; Transonic System, Inc., Ithaca, NY, USA) was placed around the portal vein to enable measurement of portal blood flow. The surgical procedure was described in detail by Jørgensen et al.[35] The pigs were allowed to recover from surgery for 5−9 days before entering the experimental period.

The pigs were kept individually in pens with visual and physical contact with neighboring pigs through railings. No bedding was provided, but an elevated plastic grid covering half of the pen allowed the pigs to rest and stay dry. The pigs had ad libitum access to water.

The animal experiments were conducted in compliance with procedures approved by the Danish Animal Experiments Inspectorate, Ministry of Food, Agriculture and Fisheries, Danish Veterinary and Food Administration, in accordance with the Danish Ministry of Justice, Law 1306 of November 23, 2007, concerning experiments with animals and care of experimental animals.

Experimental Design. *Experiment 1: Absorption of Betaine in Pigs Fed a Low-Fiber Diet with or without Betaine Supplementation.* Four female pigs (Duroc × Danish landrace × Yorkshire) with an initial body weight of 59.9 (SEM 2.2) kg surgically fitted with permanent catheters in the mesenteric artery, portal vein, and hepatic vein were included in the experiment. The pigs were fed WSD based on white wheat flour and formulated to be high in saturated fat, protein, and refined carbohydrates and low in dietary fiber (Supporting Information Table S1) for a week prior to blood sampling. After the first sampling, the pigs were fed WSD for an additional 4 days followed by 3 days when they were fed WSD supplemented with betaine (50 mg kg^{-1} body weight) (Betafin S1, Danisco Animal Nutrition, Dupont), and the second blood sampling was conducted after the morning feeding on the fourth day. The chemical composition of the WSD diet is given in Supporting Information Table S1.[32]

Experiment 2: Absorption of Betaine and Choline from Whole-Grain Wheat or Wheat Aleurone, Chronic Intake. Six female pigs (Danish landrace × Yorkshire) with an initial body weight of 56.5 (SEM 1.8) kg surgically fitted with permanent catheters in the mesenteric artery and the portal vein were included in the experiment. The pigs were fed two experimental diets in a cross-over design. Each experimental period lasted 1 week. During dayd 1−3 the pigs were fed a wash-out diet based on white wheat flour (WFL), and on days 4−7 the pigs were fed one of two experimental breads based on either whole-grain wheat (WGW) or wheat aleurone-rich flour (WAF) (Supporting Information, Table S2). On the sampling day the pigs were fed the experimental bread in the morning, and in the evening they were switched to WFL. The ingredients for the experimental breads and their chemical composition are shown in Supporting Information Table S2.[33]

Experiment 3: Absorption of Betaine and Choline from Rye Bread with or without Whole Rye Kernels, Acute Intake. Six female pigs (Duroc × Danish landrace × Yorkshire) with an initial body weight of 60.2 (SEM 3.1) kg surgically fitted with permanent catheters in the mesenteric artery and the portal vein were included in the experiment. The pigs were fed a semisynthetic low-fiber wash-out diet based on wheat flour, whey protein, canola oil, and a vitamin−mineral mixture containing synthetic amino acids (Supporting Information, Table S3), and on experimental days they were fed one of two breads as a single meal prior to collection of blood. The breads were a rye bread with intact kernels (RK) and a dark ground rye bread (GR). The breads are commercially available, produced by Lantmännen Schulstad A/S (Hammerholmen, Hvidovre, Denmark) and sold as Levebrød Multikernerugbrød (multiseed rye bread) (RK) and Mørkt rugbrød (dark rye bread) (GR). The breads were portioned to provide 200 g of available carbohydrate. The chemical composition of the semisynthetic diet and the breads is given in Supporting Information Table S3.[34]

Sample Collection. On sampling days, portal blood flow was measured for 2 min immediately prior to blood sampling. Blood samples were subsequently collected simultaneously from both/all three catheters. The first blood sample was collected 30 or 15 min prior to feeding ($t = 0$) and following samples were collected at 30, 60, 90, 120, and 240 min after feeding. In experiment 2, additional blood samples were collected at 15 and 45 min after feeding. Blood samples were collected in heparinized vacutainers (Greiner Bio-One, Kremsmünster, Austria). Blood was centrifuged (2000*g* for 12 min at 4 °C), and plasma was immediately frozen at −80 °C until analysis.

Solvents and Reagents. HPLC grade acetonitrile and methanol were purchased from VWR − Bie & Berntsen A/S (Herlev, Denmark). Formic acid, betaine, and choline as well as D_9-betaine and D_{11}-choline were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Processing of Plasma and Feed Samples. Choline and betaine in plasma were determined using a modification of the method described by Bruce and co-workers.[36] Plasma was thawed, and aliquots (50 μL) were taken and placed into 2 mL centrifuge tubes. To the aliquots was added 150 μL of internal standard solution (10 μM D_9-betaine and D_9-choline in methanol). After vortexing, the samples were placed at 4 °C for 20 min and centrifuged at 13200*g* for 10 min at 4 °C. The supernatant was pipetted into 200 μL vials for analysis.

Feed (50 mg) was extracted with 5 mL of extraction solution (7.5 μM D_9-betaine and D_9-choline in methanol/water (75:25 v/v)). The mixture was stirred for 5 min and subsequently centrifuged (3000 rpm, 4 °C, 10 min). The supernatant was pipetted into 200 μL vials for analysis.

Analysis of Betaine and Choline by HPLC-ESI-QTOF-MS. Plasma and feed samples were analyzed using a Dionex Ultimate 300 HPLC system (Thermo Scientific Dionex, Sunnyvale, CA, USA) coupled to a MicroTOF-Q quadropole time-of-flight mass spectrometer (Bruker Daltonics, Bremen, Germany). Chromatographic separation was performed on an Ascentis Express HILIC column (2.1 mm × 10 cm, 2.7 μm) (Supelco Analytical, Bellefonte, PA, USA) together with a Ascentis Express HILIC guard column (0.5 cm × 2.1 mm, 2.7 μm) (Supelco Analytical). The column was maintained at 30 °C. Mobile phase A consisted of 5 mM ammonium acetate (adjusted to pH 4 with formic acid), whereas mobile phase B consisted of acetonitrile and 0.025% formic acid. The system equilibrated at 10% A for 5 min before the sample (5 μL) was injected, and the gradient started after 1 min. The gradient increased linearly to 60% A within 5 min and increased linearly from 60 to 90% A within 6 min. The gradient returned to 10% A in 30 s. The total analysis time was 16.5 min, and the flow rate was 100 μL/min.

MS data were acquired in positive electrospray (ESI) mode in a scan range from m/z 50 to 1000 at a sampling rate of 2 Hz. ESI parameters were as follows: capillary, 4.5 kV; nebulizer pressure, 1.8 bar; dry gas flow, 8 L min^{-1}; dry gas temperature, 200 °C. Lithium formate solution (5 mM) was used for automatic calibration and injected at the beginning of each chromatographic run. Blank runs and additional quality control (QC) samples were interspersed between the samples under investigation.

Data were processed using Compass DataAnalysis (version 4.0, Bruker Daltonik GmbH) and Compass QuantAnalysis (version 2.2). The accurate masses of betaine and choline (m/z 118.0860 and 104.1070, respectively) and the internal standards D_9-betaine and D_9-choline (m/z 127.1420 and 113.1630, respectively) were used. Standard curves were prepared from choline and betaine standards with internal standards (7.5 μM D_9-betaine and D_9-choline). The concentrations ranged from 0.39 to 100 μM and from 3.9 to 1000 μM for choline and betaine, respectively, and standard curves were

DOI: 10.1021/jf506024v
J. Agric. Food Chem. 2015, 63, 2725−2733

constructed by linear regression analyses. The regression equations, linear ranges, and correlation coefficients of betaine and choline are summarized in Supporting Information Table S4.

Calculations. The net absorptions (net portal flux) of betaine and choline were calculated using the portal−arterial concentration differences ($c_p - c_a$) and the portal flow measurements using Fick's principle.[30] This was done using the equation

$$q = (c_p - c_a) \times F(dt)$$

where q is the amount of absorbed betaine or choline during the time dt and F is the flow in the portal vein. The concentration of metabolites in the portal vein and mesenteric artery is given by c_p and c_a, respectively. During the postprandial period between t_0 and t_n the quantity absorbed, Q, was calculated as

$$Q = \sum_{t_n}^{t_0} q$$

The enrichment across the gastrointestinal tract was calculated as

$$GI_{enrich} = \frac{c_p - c_a}{c_a} \times 100\%$$

where c_a and c_p denote the concentration of metabolites in the mesenteric artery and the portal vein, respectively.

The net hepatic flux (NHF) of betaine and choline from 0 to 4 h after the first daily meal was determined as

$$NHF = \left(c_h \times \frac{F}{0.85}\right) - (c_p \times F) - \left(c_a \times \left(\frac{F}{0.85} - F\right)\right)$$

where F is the flow in the portal vein, and the total blood flow to the liver was assumed to be 85% from the portal vein and 15% from the hepatic arteries based on the results of Kristensen and co-workers;[31] c_h, c_p, and c_a denote the concentration of metabolites in the hepatic vein, portal vein, and mesenteric artery, respectively.

Furthermore, the hepatic extractions, H_{ex}, of betaine and choline from 0 to 4 h after the first daily meal were determined as

$$H_{ex} = \frac{-NHF}{(c_p \times F) + \left(c_a \times \left(\frac{F}{0.85} - F\right)\right)} \times 100\%$$

Statistics. The effect of the experimental diets within each experiments was analyzed as repeated measurements using the MIXED procedure of Statistical Analysis Software (SAS Institute Inc., Cary, NC, USA) as described by Littell et al.[37] using the model

$$Y_{ijkl} = \mu + \alpha_i + \beta_j + \alpha\beta_{ij} + \gamma_k + \upsilon_l + \tau_{ikl} + \varepsilon_{ijkl}$$

where Y_{ijkl} is the dependent variable, μ is the overall mean, α_i is the effect of diet, β_j is time after feeding, and $\alpha\beta_{ij}$ is the interaction between diet and time. γ_k is the experimental week, and υ_l is the random effect of pig; τ_{ikl} is the random component related to the lth pig fed the ith diet in the kth week, and ε_{ijkl} is the residual error component. The pig and pig × week × diet were included as random components to account for repeated measurements (within pigs and within pigs with sampling days, respectively). Results are presented as least-squares means with their SE. To obtain normality, data on betaine concentrations in the first experiment and in the acute experiment and the net absorption of betaine in the first experiment were logarithm transformed before the statistical analysis. Because confidence intervals on the original scale are not symmetric around the parameter estimates, the 95% confidence intervals rather than SE are presented for those responses. Levels of significance were reported as being significant when $p \leq 0.05$ and as a tendency when $0.05 < p \leq 0.10$.

The relationship between fasting plasma betaine and the betaine concentration in the feed was described by a mechanistic growth model

$$Y = \alpha(1 - \beta\ e^{-cT})$$

where y is the dependent variable (plasma betaine concentration), α the asymptotic value, c the growth rate, β the scale, and T the betaine concentration in the feed. The statistical analysis of the relationship between betaine concentration in the feed and plasma betaine concentration was carried out using JMP, version 11.1.1 (SAS Institute Inc.).

RESULTS

Concentrations of Betaine and Choline in the Experimental Diets. The concentrations of betaine and choline in diets are presented in Table 1. In the diets used in experiment 1 a very low betaine concentration was found in WSD (0.19 mg/g fresh weight). When this diet was supplemented with betaine to provide the pigs with 50 mg betaine/kg body weight, it resulted in a betaine concentration in the diet of 7.59 mg/g fresh weight. In experiment 2, the content of betaine was more than twice as high in WAF (1.75 mg/g fresh weight) as in WGW (0.74 mg/g fresh weight), whereas the betaine concentrations were comparable in the rye breads with or without whole kernels used in experiment 3 (1.53−1.58 mg/g fresh weight). The choline concentration in the experimental diets was less variable (0.05−0.20 mg/g fresh weight), with the lowest concentrations found in the low-fiber diets.

Table 1. Betaine and Choline Concentration in the Experimental Diets and the Intake of Betaine and Choline during the Meal Prior to Sampling

		dietary concentration (mg/g fresh wt)		dietary intake (mg)	
expt	diet[a]	betaine	choline	betaine	choline
1	WSD	0.19 ± 0.01	0.048 ± 0.003	96	24
	WSD + betaine	7.59 ± 0.89	0.046 ± 0.005	3780	23
2	WGW	0.74 ± 0.08	0.150 ± 0.001	760	74
	WAF	1.75 ± 0.27	0.209 ± 0.056	1673	199
3	wash-out	0.30 ± 0.03	0.062 ± 0.003	–[b]	–[b]
	RK	1.53 ± 0.17	0.150 ± 0.021	923	90
	GR	1.58 ± 0.26	0.191 ± 0.031	1013	123

[a]WSD, Western style diet; WGW, whole-grain wheat; WAF, wheat aleurone-rich flour; RK, rye bread with intact kernels; GR, dark ground rye bread. [b]The absorption of betaine and choline was not measured after intake of the wash-out diet.

Net Absorption and Net Hepatic Flux of Betaine and Choline in Pigs Fed a Diet Low in Betaine without and with Added Betaine. The mean betaine concentration was highly elevated in arterial, portal, and hepatic blood of the pigs fed WSD with added betaine compared to WSD without betaine (Table 2). This is also clearly seen in the plasma concentrations during 0−4 h after the first meal of the day (Figure 1a). In pigs fed WSD supplemented with betaine, betaine in the portal vein increased rapidly during the first 30 min post feeding and remained high until 120 min post feeding. Betaine in arterial and hepatic blood was maximal 60 min after feeding and declined thereafter. Betaine concentration was similar at the three sampling sites 180 min post feeding. The net absorption of betaine was 6.21 mmol/h when the pigs were fed WSD supplemented with betaine. This was significantly higher than the net absorption from the WSD diet. The net hepatic flux of betaine was negative (−12.3 mmol/h), indicating that betaine was metabolized in the liver. This

[a]WSD, Western style diet; WSD + betaine, Western style diet supplemented with betaine. [b]Values are back-transformed least-squares means (lower and upper limits of the 95% confidence interval).

corresponded to a hepatic extraction of 10% of the betaine entering the liver when WSD was supplemented with betaine, whereas only 2% was extracted when a diet low in betaine (WSD) was fed. The mean choline concentration did not differ in arterial, portal, or hepatic blood of pigs fed WSD or WSD supplemented with betaine (Table 2), but the concentration was higher in the portal vein than in the mesenteric artery and hepatic vein (Figure 1b), and the portal concentration peaked 30 min after feeding. The net absorption of choline did not differ between diets. The net hepatic flux of choline was 1 mmol/h, and around 50% of the choline was extracted in the liver irrespective of diet.

Effects of High-Fiber Breads on Plasma Concentrations of Betaine and Choline. Mean betaine concentration was significantly affected by diet and time in both arterial and portal blood when WGW and WAF were fed (Table 3), whereas feeding two types of rye bread once introduced no difference in the mean arterial and portal betaine concentrations. In Figure 2, the betaine concentrations during the first 0−4 h after the first daily meal are shown. When WAF and WGW were fed, a clear difference between the experimental diets is observed (Figure 2a). Pigs fed the WAF diet had higher betaine concentration in both arterial and portal blood during the experimental period than pigs fed WGW. For pigs fed the WAF diet the betaine concentration increased 2 h after feeding, whereas the concentration remained constant in pigs fed WGW. Feeding rye bread without (GR) or with whole kernels (RK) did not result in differences in the betaine concentration in arterial and portal blood during 0−4 h after the first meal of the day (Figure 2b). The betaine concentration increased from 30 to 120 min after ingestion of the first meal of the day, whereafter it reached a plateau.

The mean concentrations of choline in arterial and portal blood did not differ in pigs fed WAF or WGW (Table 3) as also reflected in the plasma choline concentrations during 0−4 h after the first daily meal (Figure 3a). However, the difference between the portal and arterial concentrations was considerable. When consuming rye bread without (GR) or with whole kernels (RK), pigs achieved minor but significant differences in plasma choline concentrations in both arterial and portal blood (Figure 3b).

Absorption across the Gastrointestinal Tract of Betaine and Choline in Pigs Fed High-Fiber Breads. Diet did not influence the net absorption of betaine (Table 4). The net absorption was low and quite variable, and there was no clear effect of the type of experiment, chronic versus acute. The net absorption of choline was not affected by diet, and no difference was observed between the two types of experiment. Although the net absorptions of betaine and choline on a molar basis were similar, the enrichment of betaine across the gastrointestinal tract was very low compared to the enrichment of choline.

Fasting Plasma Betaine in Relation to the Betaine Content in the Feed. The relationship between the fasting plasma betaine in the mesenteric artery and the betaine content in the feed can be explained by a mechanistic growth model

Plasma betaine concentrations (μmol/L) in the portal vein (●) and the mesenteric artery (○) in pigs fed (a) a diet with wheat aleurone flour (WAF) or a diet with whole-grain wheat (WGW) and (b) rye bread with ground rye (GR) or whole rye kernels (RK). The p values for each sampling point are shown in Table 3.

(Figure 4). The model has a growth rate of 0.77 μmol betaine/L plasma/g betaine/kg feed, and the asymptote of the model is 577 μmol/L (R^2 = 0.97).

DISCUSSION

The highest betaine concentration was found in the WAF diet followed by the two rye diets (RK and GR) and the WGW diet, with the lowest levels in the WSD and wash-out diet. These differences reflected the differences in betaine concentration

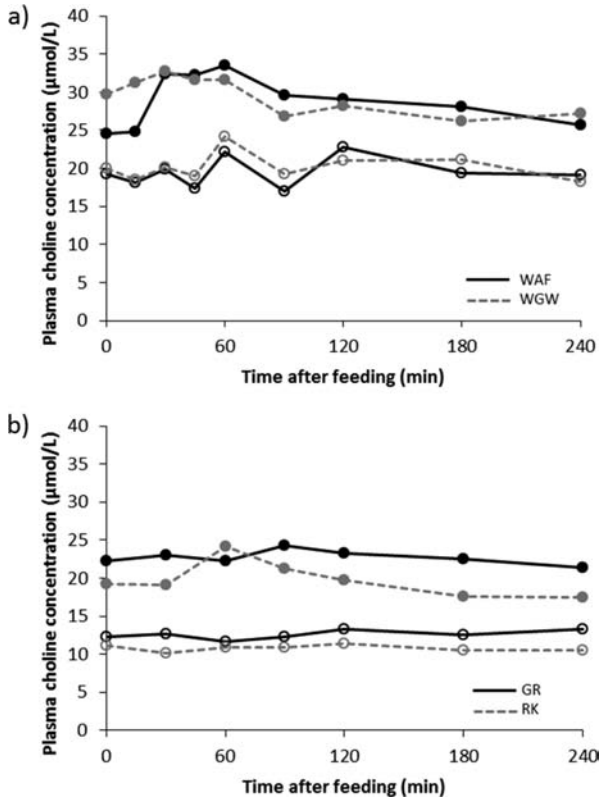

Figure 3. Plasma choline concentrations (μmol/L) in the portal vein (●) and the mesenteric artery (○) in pigs fed (a) a diet with wheat aleurone flour (WAF) or a diet with whole-grain wheat (WGW) and (b) rye bread with ground rye (GR) or whole rye kernels (RK). The p values for each sampling point are shown in Table 3.

between the different tissues of the wheat grain; the betaine concentration is highest in the aleurone tissue and lowest in the endosperm[17] and between cereals with a higher concentration of betaine in rye than in wheat.[15] The two types of rye bread had similar betaine contents, which was not surprising as the main difference between the two bread types was milling or not of the rye kernels.

The choline content of the experimental diets was low and varied less than the betaine content, which reflects that items in high-fiber diets do not belong to groups of ingredients with high choline content, being eggs, red meat, poultry, and milk,[38] and that the choline content of cereal grains is less variable.[15]

The major finding of our study was the distinct difference in absorption patterns when betaine was added as a supplement to a refined Western style diet as compared to when provided from cereals naturally rich in betaine. Thus, when pigs were fed WSD supplemented with betaine (50 mg kg^{-1} body weight), a sharp increase in portal betaine concentration was observed 30 min postprandial. This is in accordance with results obtained in humans following a single oral dose of betaine, where the plasma betaine concentration peaked 60 min after intake.[39] The time difference between the present study and the human study is most likely due to the fact that the blood samples in the present study were taken from the portal vein, where betaine appears immediately after absorption, whereas the samples in the human study were taken in a peripheral vein. In the present study the plasma betaine profile obtained from the mesenteric artery may be compared to peripheral blood samples and the betaine concentration was maximal in the artery 60 min

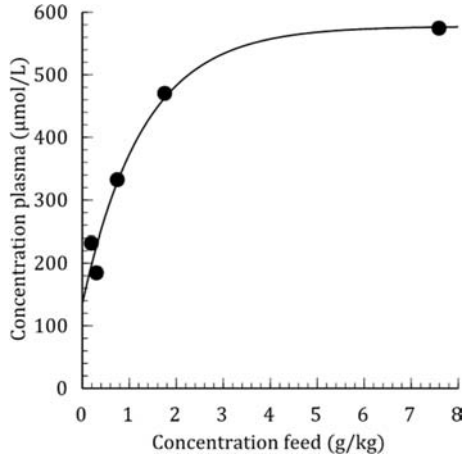

Figure 4. Relationship between fasting plasma betaine in the mesenteric artery (μmol/L) and the betaine content of the feed (μmol/g). Estimated relationship: fasting plasma betain = $577 \times (1 - 0.77 \times e^{(-0.77 \times \text{betain in feed})})$, $R^2 = 0.97$.

postprandial. The plasma betaine observed in pigs fed WSD supplemented with betaine was comparable to what has been observed in humans given the same dose,[39] indicating that pigs and humans have the same capacity to digest and absorb betaine.

DOI: 10.1021/jf506024v
J. Agric. Food Chem. 2015, 63, 2725−2733

In contrast to the rapid absorption of betaine provided as a supplement, betaine embedded in dietary fiber sources is more slowly available as it has to be liberated from the matrix prior to absorption. The postprandial absorption profile in the portal vein was significantly affected by time in all three experiments. The concentration of betaine in the portal vein increased from 60 to 90 min after feeding and peaked 120 min postprandial for pigs fed WAF, GR, and RK. For the WGW and the WSD diets the betaine remained constant after feeding, although at different levels due to the different betaine contents of the diets. The postprandial profiles for diets high in betaine are comparable to those obtained in humans, where it was observed that the betaine concentration increased 120 min after a whole-grain meal and 60 min after a refined-grain meal.[19] The lack of interaction between diet and time in portal vein samples when high-fiber breads were eaten indicated that the accessibility of betaine did not differ between the diets within each experiment. Betaine is a water-soluble compound. It is not known to be bound to any matrix,[14] but it is encapsulated in the aleurone cells. The aleurone cell wall has a rigid structure, which does not allow endogenous enzymes (proteases, carbohydrases) to pass, whereas water-soluble molecules of relatively low molecular weight may pass. Therefore, the cell wall structure of the aleurone cells is responsible for the delayed absorption of betaine in the cereal diets compared to the added betaine. The present study further shows that grinding of rye kernels does not increase the bioavailability of betaine, supporting that the aleurone cell wall is the major hindrance to betaine absorption. Ultrafine grinding or bioprocessing of wheat and rye bran has been shown to increase the antioxidant activity and bioaccessibility of phenolic compounds, presumably due to breakdown of the aleurone layer,[40−42] but whether this increases the bioavailability of betaine as well remains to be investigated.

The plasma betaine concentrations observed in the present experiment after consumption of dietary betaine are generally higher than those observed in humans.[7,19,22,39] The habitual diet of pigs contains a high amount of cereals compared to that of humans, and hence pigs are expected to have a high daily intake of betaine. This has been suggested to lead to the higher plasma concentration of betaine in pigs when compared to humans.[43]

The fasting plasma concentration of betaine reflected the concentration of betaine in the experimental diets in the chronic experiments and in the wash-out diet in the acute experiment. A previous study in pigs showed that when the diet was changed from a low-fiber diet to a high-fiber diet, the fasting betaine level in plasma increased gradually during 3 days,[21] and thus the fasting plasma concentrations observed in this study may be considered to have reached a steady state. In humans it was observed that the fasting betaine concentration was increased 2 days after changing to a high-betaine diet.[7] A chicken study showed that the presence of betaine in the diet increased the Na^+-coupled component of betaine transport and led to a higher capacity of betaine uptake,[44] and hence a higher betaine uptake may be expected when the animals were adapted to the diets. In the present study no clear difference in the absorption profiles was observed when the high-fiber breads were fed in a chronic or an acute experiment, but the betaine concentration after feeding WAF in a chronic experiment was twice as high as when rye bread was fed in an acute experiment, even though the betaine concentrations of the diets were similar, indicating that adaptation to the diet increased the absorption capacity. The observed relationship between fasting plasma betaine concentration and betaine content in the feed indicates that chronic exposure increases the basic circulating level of betaine. However, there is an upper limit on the fasting plasma betaine concentration, probably reflecting a balance between absorption, conversion to other metabolites, and excretion to urine.

Although we found postprandial differences in portal and arterial concentrations and fasting betaine concentrations that were correlated to the dietary levels of betaine, similar betaine concentrations in the portal vein and the mesenteric artery were seen for all but the diet supplemented with betaine. This indicates slow release of betaine from the fiber matrix, giving rise to a low net absorption of betaine from the diets. When betaine was added to the diet, a higher concentration of betaine was observed in the portal vein than in the mesenteric artery during 30−120 min after feeding; however, the net absorption of betaine was still low. The negative net hepatic metabolism shows that betaine was either accumulated or metabolized in the liver. The only known metabolism of betaine is by the zinc metalloenzyme betaine-homocysteine methyltransferase, which is located in the liver and kidneys.[45] This enzyme transfers a methyl group from betaine to homocysteine to produce dimethylglycine and methionine, respectively.[1] In the present study we did not measure the concentration of dimethylglycine in plasma, and consequently we are not able to confirm whether betaine was accumulated or metabolized in the liver. Studies in rats and chicken have shown that when high-betaine diets are fed, betaine is accumulated in the liver,[25,46] and in rats the betaine concentration in liver showed both a plasma-related and a plasma-independent component.[47]

Plasma choline showed a consistent difference between the concentration in the portal vein and the mesenteric artery, disclosing the absorption of choline from the gastrointestinal tract. Measurements of hepatic vein concentrations showed that choline is metabolized in the liver. The major fate of choline is the phosphorylation to phosphocholine, but in the liver it may be oxidized to betaine as well.[48] In the present study, betaine was shown to be metabolized or stored in the liver. This means that if choline was oxidized to betaine, this additional betaine was either immediately stored or metabolized in the liver. The concentration of choline in the hepatic vein was consistently slightly lower than the concentration in the mesenteric artery, indicating that free choline was released from the tissues to the circulation. Different postprandial profiles of choline were observed. When WSD or WSD + betaine was fed, a clear choline peak 30 min after feeding was seen. In contrast, the choline concentration in the portal vein remained constant after feeding with the high-fiber breads. The difference presumably resides in the fat source used in the diets. WSD contained lard, which contains a high amount of choline, whereas the choline content of soybean oil and rapeseed oil used in the studies with bread is low.[38]

In conclusion, using the porto-arterial catheterized pig model the present study showed that free betaine is rapidly absorbed to the portal vein, whereas the absorption of betaine from cereal sources is slower, reflecting a delayed liberation of betaine from the matrix prior to absorption. There was, however, no difference in the rate of absorption from the different cereal sources ,which indicates that the encapsulation of betaine in the aleurone cell layer delays the absorption of betaine from cereal sources. To increase the bioavailability of betaine, the use of ultrafine grinding or bioprocessing (e.g., a

DOI: 10.1021/jf506024v
J. Agric. Food Chem. 2015, 63, 2725−2733

combination of hydrolytic enzymes and yeast fermentation) of bran or aleurone fractions could be considered. Due to a rapid metabolism of betaine, the portal-arterial difference in betaine concentration is very low. The results of the current study indicate that it is preferable to provide betaine as part of a whole-grain diet rather than a concentrate as this ensures slow release of betaine with impact on the circulating levels of betaine and with modest diurnal fluctuation.

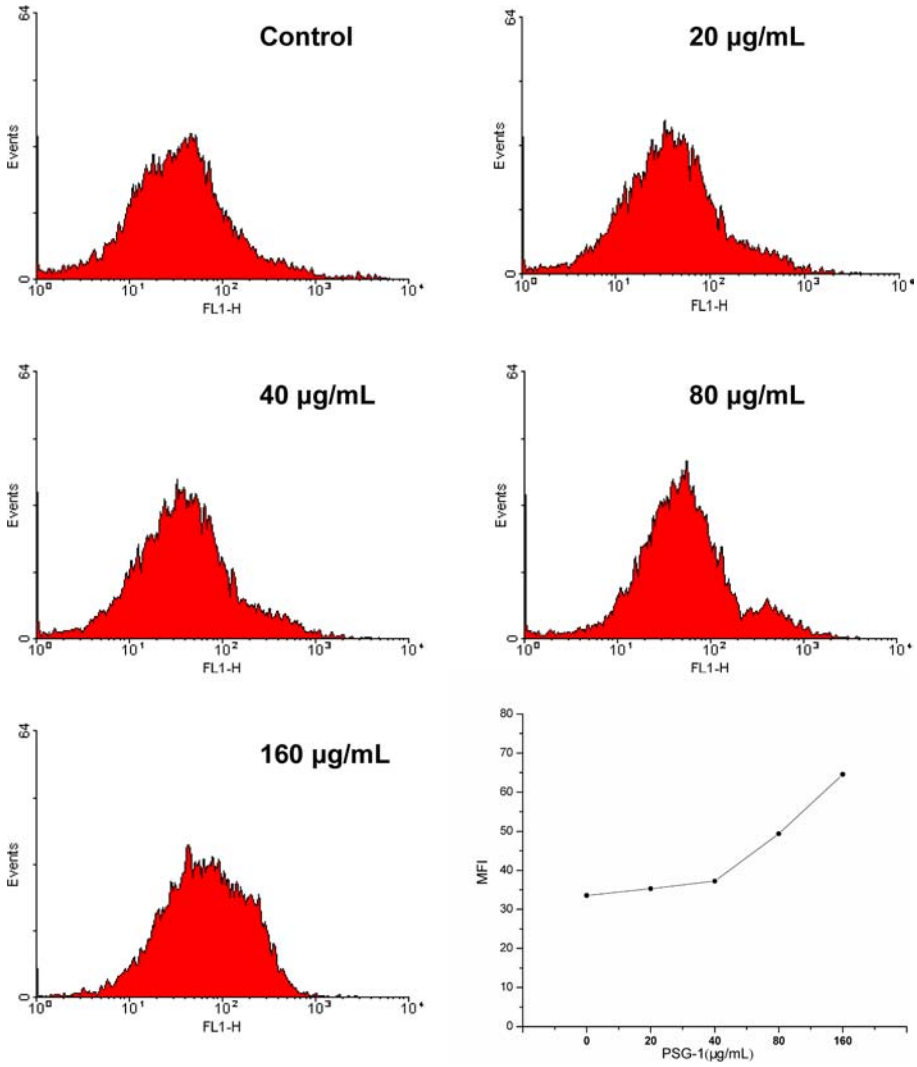

Figure 1. Effect of PSG-1 on the intracellular Ca^{2+} concentration in spleen lymphocytes. Spleen lymphocytes were seeded at a density of 1×10^6 cells/well in the 24 well plate and incubated with PSG-1 (20, 40, 80, and 160 μg/mL) for 48 h. The cells were washed twice with PBS and incubated with the Fluo-3/AM at 37 °C for 60 min. Flow cytometry was performed to measure the fluorescent signal.

Cell culture products were obtained from Life Technologies (Paisley, U.K.).

Preparation of Spleen Lymphocytes. Female BALB/c mice (8 weeks old, 18−20 g) were purchased from Shanghai Slac Laboratory Animal Center, Chinese Academy of Sciences (Shanghai, China). The extirpated spleens were minced into small pieces with scissors in a germ-free condition and then suspended in RPMI 1640 medium. Single-cell suspension was prepared by filtering the suspension through a sterile sieve mesh. The cells were treated with lysis buffer (0.15 M NH_4Cl, 0.01 M $KHCO_3$, and 0.1 mM Na_2EDTA at pH 7.4) to remove red blood cells, followed by washing twice with cold phosphate-buffered saline (PBS). Then, the cells were adjusted to the concentration of 5×10^6 cells/mL in RPMI 1640 medium supplemented with 10% fetal calf serum and incubated for 3 h in Petri dishes. The suspended cells were collected.

Cytokine Measurement by ELISA. Spleen lymphocytes were seeded at a density of 5×10^5 cells/well in the 96 well plate and cultured with various concentrations of PSG-1 for 48 h. The supernatants were harvested, and a level of IL-2 was determined by an ELISA kit according to the instructions of the manufacturer.

Measurement of Intracellular Ca^{2+}. $[Ca^{2+}]_i$ was measured in spleen lymphocyte using a Fluo-3/AM fluorescent probe. Briefly, spleen lymphocytes were seeded at a density of 1×10^6 cells/well in the 24 well plate and stimulated with various concentrations of PSG-1 for 48 h. The cells were collected and washed twice with PBS, followed by incubation with the fluorescent probe Fluo-3/AM at 37 °C for 60 min. After washing twice with PBS, the $[Ca^{2+}]_i$ level, seen as the fluorescent signal, was measured by flow cytometry.

Measurement of CaN Activity. Spleen lymphocytes were seeded at a density of 1×10^6 cells/well in the 24 well plate and stimulated with various concentrations of PSG-1 for 48 h. CaN activity was measured using a CaN activity assay kit according to the instructions of the manufacturer. Briefly, the cells were treated by lysis buffer (reagent B) provided in the kit. The RII phosphopetide was used as the substrate for CaN. The detection of free inorganic phosphate released from RII by CaN was based on the ferrous sulfate method. The optical density at 660 nm was determined for each sample using a microplate reader (Bio-Rad, Hercules, CA). The specific CaN activity was expressed as the fold induction over untreated cells.

Transient Transfection and Luciferase Reporter Assay. Spleen lymphocytes were transiently transfected with pGL4.30-[luc2P/NFAT-RE/Hygro] using FuGENE HD transfection reagent according to the instructions of the manufacturer. Transfected cells were subcultured and seeded at 2×10^5 cells/well in the 24 well plate. The cells were incubated with various concentrations of PSG-1 for 48 h. After incubation, the cells were washed with PBS and extracted in lysis buffer. Luciferase activity was measured using the luciferase assay system according to the instructions of the manufacturer. The specific transactivation was expressed as the fold induction over untreated cells.

Assay of PKC Activity. Spleen lymphocytes were seeded at a density of 2×10^6 cells/well in the 6 well plate and stimulated with various concentrations of PSG-1 for 48 h. Then, the cells were collected and washed twice with PBS. The PKC activity was measured using the PepTag assay for non-radioactive detection of PKC kit according to the instructions of the manufacturer. Briefly, the cells were resuspended and homogenized in 0.5 mL of cold PKC extraction buffer and then centrifuged at 14000*g* for 5 min, and the supernatants were purified on a 1 mL column of DEAE cellulose. The resultant fractions were eluted by PKC extraction buffer and incubated with PKC reaction mixture, followed by agarose gel separation. The bands were quantization by spectrophotometry.

Statistical Analysis. Values are expressed as means ± standard error of the mean (SEM). One-way analysis of variance followed by the Student−Newman−Keuls test was used to determine the statistical significance between various groups. A value of $p < 0.05$ was considered to be statistically significant.

RESULTS

Effect of PSG-1 on the Ca^{2+} Concentration in Spleen Lymphocytes. To examine the effect of PSG-1 on the Ca^{2+} concentration in spleen lymphocytes, flow cytometry was performed to detect the intracellular Ca^{2+} concentration after treatment with various concentrations of PSG-1 (20, 40, 80, and 160 μg/mL). As shown in Figure 1, PSG-1 administration elevated the Ca^{2+} concentration in a dose-dependent manner.

Effect of PSG-1 on CaN Activity in Spleen Lymphocytes. The colorimetric method was used to measure the CaN activity in spleen lymphocytes. It was found that PSG-1 (20, 40, 80, and 160 μg/mL) dose-dependently enhanced CaN activity in spleen lymphocytes (Figure 2).

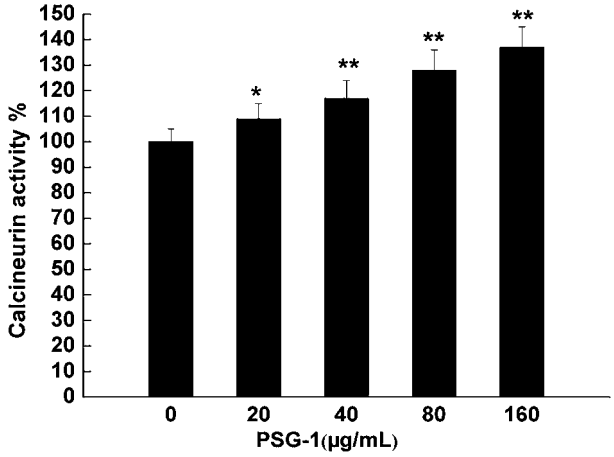

Figure 2. Effect of PSG-1 on CaN activity in spleen lymphocytes. Spleen lymphocytes (2×10^6 cells/well) were seeded in the 6 well plate and cultured with various concentrations of PSG-1 for 48 h. The cells were harvested, and CaN activity was determined by the CaN activity assay kit according to the instructions of the manufacturer. The data are expressed as the mean ± SEM for three separate experiments. (*) $p < 0.05$ and (**) $p < 0.01$ versus the control group.

Effect of PSG-1 on NFAT Transactivation Activity in Spleen Lymphocytes. NFAT is known as an important transcription factor. In the present study, a transient transfection and luciferase reporter assay was used to determine the effect of PSG-1 on NFAT transactivation activity in spleen lymphocytes. As shown in Figure 3, PSG-1 treatment (20, 40, 80, and 160 μg/mL) robustly increased luciferase activity in a dose-dependent manner, which suggested that PSG-1 could enhance NFAT transactivation activity in spleen lymphocytes.

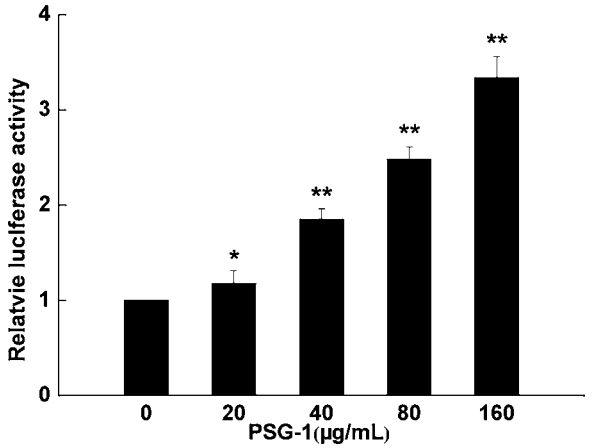

Figure 3. Effect of PSG-1 on NFAT transactivation activity in spleen lymphocytes. Spleen lymphocytes were transiently transfected with pGL4.30[luc2P/NFAT-RE/Hygro] and seeded at 2×10^5 cells/well in the 24 well plate. The cells were stimulated with various concentrations of PSG-1 for 48 h. After incubation, the cells were washed and extracted in lysis buffer. Then, luciferase activity was measured using the luciferase assay system according to the instructions of the manufacturer. The data are expressed as the mean ± SEM for three separate experiments. (*) $p < 0.05$ and (**) $p < 0.01$ versus the control group.

Effect of CaN Inhibitors on NFAT Transactivation Activity Induced by PSG-1 in Spleen Lymphocytes. To determine the role of CaN in PSG-1-mediated activation of NFAT, we used the specific pharmacological antagonists cyclosporin A (CsA) and FK506, which inhibit the activation of CaN. Working concentrations of the inhibitors did not affect the viability of cells (data not shown). Transfected spleen lymphocytes were pre-incubated with various concentrations of CaN inhibitors, CsA (0.25, 0.5, and 1 μM) and FK506 (0.25, 0.5, and 1 μM) for 30 min and then treated with PSG-1 (160 μg/mL) for an additional 48 h. As shown in Figure 4A, luciferase activity was gradually reduced by pretreatment with increasing concentrations of CsA. Similarly, there was a dose-dependent decrease of luciferase activity by the pretreatment of FK506, and PSG-1-induced luciferase activity returned to the basal level when pretreated with 1 μM FK506.

Effect of CaN Inhibitors on IL-2 Production Induced by PSG-1 in Spleen Lymphocytes. To examine the potential role of CaN in the regulation of IL-2 production in PSG-1-stimulated spleen lymphocytes, the cells were pretreated by CsA (0.25, 0.5, and 1 μM) and FK506 (0.25, 0.5, and 1 μM) for 30 min, followed by PSG-1 treatment (160 μg/mL) for 48 h, and then, the IL-2 level was measured by ELISA. As shown in Figure 4B, CsA and FK506 dose-dependently inhibited the PSG-1-induced IL-2 production in spleen lymphocytes.

Effect of PSG-1 on PKC Activity in Spleen Lymphocytes. Furthermore, the effect of PSG-1 on PKC activity was measured. PKC activity was dramatically increased by PSG-1 (20, 40, 80, and 160 μg/mL) in spleen lymphocytes, as compared to the control group (Figure 5).

Effect of the PKC Inhibitor on NFAT Transactivation Activity Induced by PSG-1 in Spleen Lymphocytes. To investigate the role of PKC on NFAT activation induced by PSG-1 in spleen lymphocytes, PKC inhibitor calphostin C (25, 50, and 100 nM) was used to treat the transfected spleen

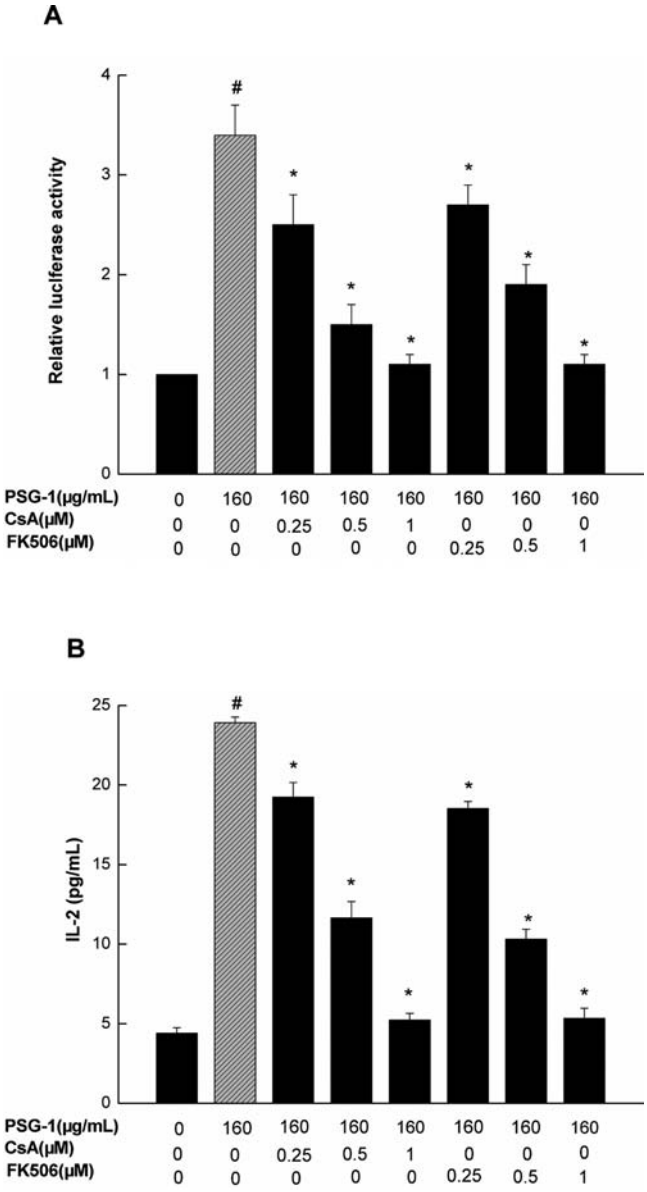

Figure 4. Effect of CaN inhibitors CsA and FK506 on NFAT transactivation activity and IL-2 production induced by PSG-1 in spleen lymphocytes. (A) Transfected spleen lymphocytes were pre-incubated with CsA (0.25, 0.5, and 1 μM) and FK506 (0.25, 0.5, and 1 μM) for 30 min and treated with PSG-1 (160 μg/mL) for an additional 48 h. Then, luciferase activity was measured. (B) Cells were pre-incubated with various concentrations of inhibitors for 30 min, followed by PSG-1 stimulation (160 μg/mL) for an additional 48 h. After incubation, released IL-2 in the supernatant was measured by ELISA. The data are expressed as the mean ± SEM for three separate experiments. (#) $p < 0.05$ versus the control group, and (*) $p < 0.05$ versus the PSG-1 alone group.

lymphocytes for 30 min before PSG-1 treatment (160 μg/mL) for 48 h and then NFAT transactivation activity was measured. As shown in Figure 6A, in comparison to the PSG-1 group, luciferase activities in all three calphostin C groups (25, 50, and 100 nM) were obviously decreased.

Effect of the PKC Inhibitor on IL-2 Production Induced by PSG-1 in Spleen Lymphocytes. The effect of PKC on PSG-1-induced IL-2 production was studied. Prior to the addition of PSG-1 (160 μg/mL), spleen lymphocytes were treated with different concentrations of PKC inhibitor (25, 50, and 100 nM). ELISA was used to measure the IL-2 secretion in the supernatant. As shown in Figure 6B, the production of PSG-1-induced IL-2 was significantly decreased by all inhibitor treatments in a dose-dependent manner ($p < 0.05$). These results demonstrated that the PKC-related signaling pathway was involved in PSG-1-induced IL-2 secretion in spleen lymphocytes.

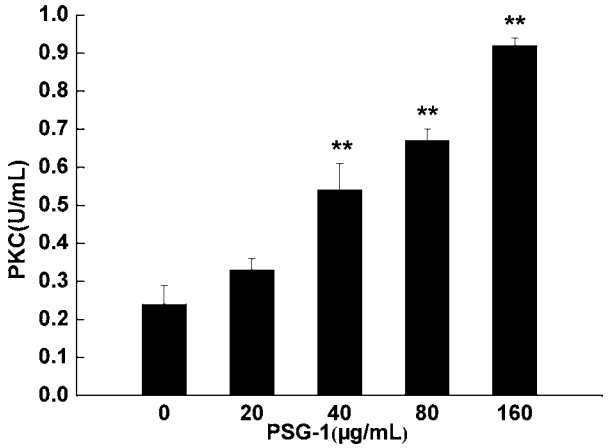

Figure 5. Effect of PSG-1 on PKC activity in spleen lymphocytes. Spleen lymphocytes were seeded at a density of 2×10^6 cells/well in the 6 well plate and stimulated with various concentrations of PSG-1 for 48 h. The cells were collected for measuring PKC activity using the PepTag assay for non-radioactive detection of PKC kit according to the instructions of the manufacturer. The data are expressed as the mean ± SEM for three separate experiments. (*) $p < 0.05$ and (**) $p < 0.01$ versus the control group.

DISCUSSION

Cytokines are intercellular signaling proteins that exert profound effects on the control of homeostasis in the whole organism; thus, monitoring the level of cytokine production is a widely used method to evaluate augmentation activity on immune response. IL-2 is an important cytokine in the cellular and humoral responses. It plays a vital role in regulating functions of all subsets of T cells as well as NK cells, LAK cells, B cells, etc.[28] Our previous study found that PSG-1 significantly increased IL-2 production in spleen lymphocytes, indicating that PSG-1 could activate spleen lymphocytes. To further elucidate the underlying molecular mechanism, we focused on characterizing the signaling pathways involved in the spleen lymphocyte activation by PSG-1.

Ca^{2+} is known as the most widely used intracellular messenger, which encodes a range of cellular information through regulation of Ca^{2+} signals.[2] In response to diverse stimuli, elevation in the concentration of Ca^{2+} in the cytosol triggers many types of events, which play essential roles in lymphocyte activation and maturation.[29] In the present study, flow cytometry analysis using a Fura-3/AM fluorescence probe showed that PSG-1 dramatically increased the intracellular Ca^{2+} level in spleen lymphocytes. CaN is well-known as an unique Ca^{2+}-dependent serine/threonine protein phosphatase, which was originally identified as a calmodulin-binding protein in the brain.[30] It has been reported that CaN activity induced by the increased intracellular Ca^{2+} level played a critical role in diverse biological processes, including lymphocyte function.[31] In our study, we found that CaN activity was noticeably enhanced by PSG-1 treatment, indicating that PSG-1 may activate spleen lymphocytes via the Ca^{2+}/CaN pathway.

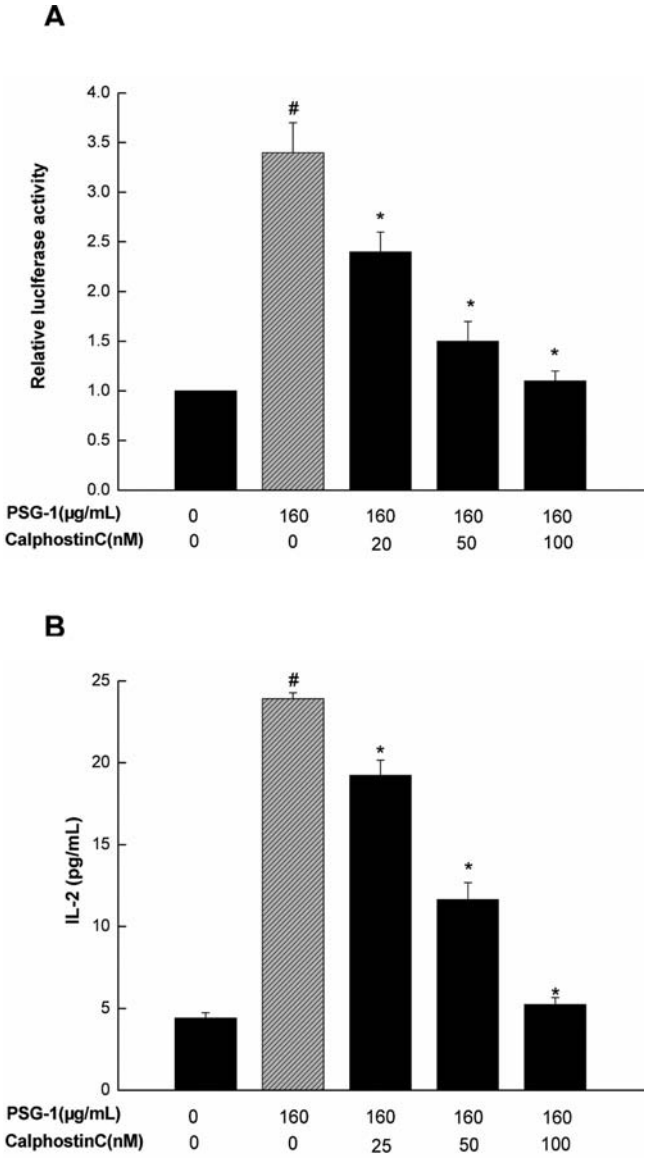

Figure 6. Effect of PKC inhibitor calphostin C on NFAT transactivation activity and IL-2 production induced by PSG-1 in spleen lymphocytes. (A) Calphostin C (25, 50, and 100 nM) was used to treat the transfected spleen lymphocytes for 30 min before PSG-1 treatment (160 μg/mL) for 48 h, and then luciferase activity was measured. (B) Cells were pre-incubated with calphostin C (25, 50, and 100 nM) for 30 min and then stimulated by PSG-1 (160 μg/mL) for 48 h. The supernatant was collected for measuring IL-2 production by ELISA. The data are expressed as the mean ± SEM for three separate experiments. (#) $p < 0.05$ versus the control group, and (*) $p < 0.05$ versus the PSG-1 alone group.

NFAT, a family of four transcription factors first described in lymphocytes, has been found to express in almost all vertebrate cell types.[32] To assess the effect of PSG-1 on NFAT activity in spleen lymphocytes, we performed transient transfection and detected the luciferase activity by the luciferase reporter assay. The data showed that PSG-1 was capable of elevating NFAT activity in a dose-dependent manner. Diverse transcription factors have been reported to be regulated by CaN in many cell types. Among these, NFAT is of special interest and best studied. In resting cells, NFAT resides in the cytoplasm in a phosphorylated form. Upon dephosphorylation by CaN, it subsequently translocates to the nucleus.[33] In this study, we used a pharmacological assay using specific CaN inhibitors (CsA and FK506) to investigate whether NFAT activation by PSG-1 was triggered by CaN. PSG-1-induced NFAT activity was found to be abrogated by the treatment of CsA and FK506. These results suggested that the Ca^{2+}/CaN signaling pathway may act upstream of NFAT activation in PSG-1-stimulated spleen lymphocytes.

It is well-documented that NFAT plays an essential role in immune response via mediating transcription of a number of cytokines. After translocation from the cytoplasm to the nucleus, NFAT subsequently binds to the promoter of cytokines and then stimulates gene expression.[6] To determine the role of the Ca^{2+}/CaN/NFAT pathway in the regulation of PSG-1-induced IL-2 production in spleen lymphocytes, we tested the effect of CaN inhibitors, CsA and FK506, on IL-2 secretion and found that IL-2 production was inhibited by CsA and FK506 in a dose-dependent manner. These results demonstrated that the Ca^{2+}/CaN/NFAT pathway was involved in PSG-1-induced IL-2 secretion in spleen lymphocytes. Taken together, the above results illustrated that PSG-1 may induce spleen lymphocyte activation at least in part via the Ca^{2+}/CaN/NFAT/IL-2 signaling pathway.

PKC, a calcium-dependent kinase, exists in many different cell types.[7] PKC-regulated signaling pathways play significant roles in a wide variety of aspects of immune responses, including development, differentiation, activation, and survival of lymphocytes.[8] Our results showed that PSG-1 significantly enhanced PKC activity in spleen lymphocytes, indicating the involvement of PKC in PSG-1-mediated spleen lymphocyte activation. More and more evidence indicate that PKC signaling also involves the regulation of NFAT activation. In fact, DNA binding by NFAT is quite weak; therefore, it needs a partner for tight association with DNA. Thus, Ca^{2+}/CaN signaling becomes dependent upon coincident PKC signaling for activation of NFAT-dependent transcription.[34,35] To study the putative role of PKC in PSG-1-induced NFAT activation, we tested the effect of the PKC inhibitor on NFAT activity and found that inhibition of PKC by calphostin C diminished PSG-1-induced NFAT activity in a dose-dependent manner, suggesting that the induction of NFAT activity by PSG-1 was dependent upon PKC in spleen lymphocytes. Furthermore, we examined whether PKC was involved in the regulation of IL-2 production induced by PSG-1. Pharmacological dissection using specific PKC inhibitor calphostin C significantly decreased the PSG-1-induced IL-2 production, indicating that PKC was involved in IL-2 production stimulated by PSG-1. On the basis of these results, we concluded that the PKC/NFAT/IL-2 signaling pathway may play an important role in the lymphocyte activation by PSG-1.

In summary, the present study established a signaling pathway, Ca^{2+}/CaN/NFAT/IL-2, by which PSG-1 exerted its effects on the activation of spleen lymphocytes. Moreover, we further demonstrated that the PKC/NFAT/IL-2 signaling pathway cooperatively regulated PSG-1-induced spleen lymphocyte activation. However, because spleen lymphocytes consist of several subgroups, how PSG-1 affects a specific subgroup, such as T cell and B cell, is necessary to be clarified in further studies.

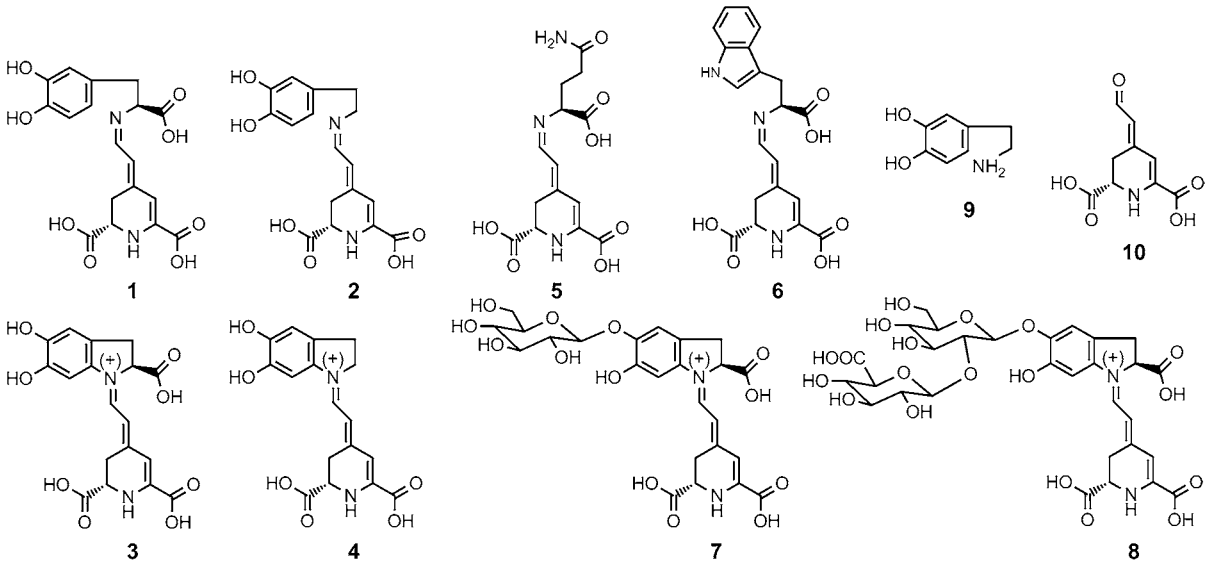

Figure 1. Structures for the dihydroxylated betalains dopaxanthin (1), miraxanthin V (2), betanidin (3), and decarboxy-betanidin (4). Structures for additional pigments obtained in this study are also shown, corresponding to the betaxanthins vulgaxanthin I (5) and tryptophan-betaxanthin (6) and the betacyanins betanin (7) and amaranthin (8). Precursor molecules dopamine (9) and betalamic acid (10) are also shown.

in the sources of betaxanthins and betacyanins may lead to different shades to be used in the coloration of foods and beverages. In this sense, some betalain-containing plants of the Amaranthaceae are consumed cooked or fresh[17,18] and used in traditional medicine to alleviate the symptoms of inflammation.[19,20]

Dihydroxylated betalains have the potential to become bioactive constituents in foods and can be combined to generate tailor-made colors which can be encapsulated to obtain products with a shelf life of months.[21] This study was designed to develop cell cultures of *Celosia argentea* as a model plant of the Amaranthaceae family and to explore the potential of liquid culture in the production of dihydroxylated betalains. The appearance of structurally related molecules is quantitated and discussed in terms of the biosynthetic pathway of betalains.

MATERIALS AND METHODS

Chemicals. Chemicals and reagents were purchased from Sigma (St. Louis, MO). Solvents were from Merck Chemicals Ltd. (Dorset, England). HPLC-grade acetonitrile and methanol were purchased from Labscan Ltd. (Dublin, Ireland). Distilled water was purified using a Milli-Q system (Millipore, Bedford, MA).

Plant Material. *C. argentea* var. *plumosa* plants with violet inflorescences were obtained from Viveros la Generala (Murcia, Spain) and grown at the greenhouse facilities at the University of Murcia (Murcia, Southeastern Spain). Seeds were surface sterilized in commercial liquid detergent 1% for 15 min, followed by 70% ethanol for 30 s, and by 1.8% sodium hypoclorite solution containing 0.2% Tween-20 for 30 min. Seeds were then washed three times with sterile water under aseptic conditions. Sterile seeds were transferred to sterilized tubes (25 × 150 mm) containing 15 mL of semisolid Murashige and Skoog medium (MS).[22] Seedlings were grown up to 2 cm (20 days), and then hypocotyls were removed as explants source. Hypocotyls were transferred to individual tubes ($n = 6$), with 10 mL of MS medium supplemented with different plant growth regulators (PGRs). Environmental conditions consisted of a photoperiod of 16 h under fluorescent light at an irradiance of 50 μmol/m^2/s and temperatures of 23 (day) and 18 °C (night)

Callus Induction. The culture medium used was MS supplemented with 30 g/L sucrose and 2 g/L of the solidifying agent phytagel. To assess response to callus explant induction media were enriched with different concentrations and combinations of PGRs: 6-benzylaminopurine (BAP) (0.0, 4.44, 6.66, 8.88 μM) with 2,4-dichlorophenoxyacetic acid (2,4-D) (0.0, 6.79, 9.05 μM) (Table 1). All

Table 1. Effect of Plant Growth Regulators (PGRs) on Callus Induction from Hypocotyls Explants Obtained from *C. argentea* var. *plumosa* after 30 Days of Culture[a]

PGRs (μM)		
BAP	2,4-D	callus-forming explants (%)
0.00	0.00	0.00[a]
0.00	6.79	0.00[a]
0.00	9.05	0.00[a]
4.44	0.00	0.00[a]
4.44	6.79	0.00[a]
4.44	9.05	33.33[a,b]
6.66	0.00	66.66[b]
6.66	6.79	100.00[b]
6.66	9.05	33.33[a,b]
8.88	0.00	33.33[a,b]
8.88	6.79	100.00[b]
8.88	9.05	100.00[b]

[a]Each value was derived from three independent tubes containing three different explants. Those values sharing the same letter correspond to nonsignificant differences according to the Tukey test ($p < 0.05$).

culture media were adjusted to pH 5.8 with 1 N NaOH and HCl and sterilized by autoclaving at 121 °C for 18 min. The cultures were incubated under a photoperiod of 16 h under fluorescent light at an irradiance of 50 μmol/m^2/s and temperatures of 23 (day) and 18 °C (night). The response of the explants for callus formation at each induction treatment was expressed as the percentage of the number of forming callus hypocotyls explants on the total evaluated, which was recorded at day 30 of culture. Propagation of callus cell lines was done under the same conditions in a MS medium supplemented with 6.66 μM BAP and 6.79 μM 2,4-D. It was selected for proliferation by subcultures on fresh medium with induction every 20 days for 9 subculture cycles. Subculturing and selection gave rise to two callus cell lines with different colors: yellow and red.

Establishment of Cell Suspension Culture and Growth Kinetics. *C. argentea* cell suspension culture was initiated from 3-

DOI: 10.1021/acs.jafc.5b00065
J. Agric. Food Chem. 2015, 63, 2741−2749

week-old red friable callus by transferring 2.5 g to 100 mL Erlenmeyer flasks containing 30 mL of callus induction medium (without phytagel) supplemented with 10 mM ascorbic acid in order to avoid dopamine oxidation and incubated under the same conditions on an orbital shaker at 110 rpm. After subculturing every 15 days during 3 months, the cells were sieved through 200 μm nylon cloth filters in order to obtain a homogeneous and fine cell suspension culture. Then, the culture was maintained during 6 months by subculturing every 15 days using a cell inoculum size of 10% (v/v) in 500 mL Erlenmeyer flasks containing 100 mL of cultured medium. To determine the growth kinetics, 2.5 g of fresh cells harvested after 8 days was inoculated into 100 mL Erlenmeyer flasks containing 30 mL of liquid MS medium supplemented with 3% sucrose (w/v), 10 mM ascorbic acid, BAP 6.66 μM, and 2,4-D 6.79 μM. Aliquots were removed every 3−10 days over a 30 day period from culture flasks and used to determine cell growth, cell morphology, cell viability, and dopamine and betalains content. All experiments were performed in triplicate (n = 3), and the results were expressed as mean values and standard deviations (SD).

Cell Viability. Cell viability was determined by the Evan's blue staining test.[23] A 2 mL amount of samples from each flask was incubated into 0.25% Evan's blue stain for 5 min, and then at least 700 cells were counted. This was repeated twice for each measurement (n = 6).

Preparation of Extracts. Callus samples and cell suspensions of 1, 8, 15, and 30 days of culture were homogenized manually in 10 mM phosphate buffer pH 6.0 containing 10 mM ascorbic acid. The resulting homogenate and samples of the liquid medium of the suspension culture were centrifuged at 14 000g for 15 min. The supernatant of each sample was used for analysis of betalains and dopamine (n = 3) by HPLC. The whole process was carried out at 4 °C. The humidity percentage and dry weight of the cells was obtained with a Kern MLS electronic moisture analyzer (Balingen, Germany).

Standard Betalains. Betanin was obtained from roots of *Beta vulgaris*, dopaxanthin was extracted and purified from yellow flowers of *L. productus*, betanidin was obtained from violet flowers of the same plant, and amaranthin was extracted from *Amaranthus spinosus*.[2,24] Other pigments were obtained by a combined procedure for the release of betalamic acid from purified betanin and condensation with the amine dopamine and the amino acids (*S*)-glutamine and (*S*)-tryptophan, following a previously described method.[25] Betalamic acid was obtained through basic hydrolysis of betanin.[26] All compounds were characterized spectrophotometrically, chromatographically, and by electrospray ionization mass spectrometry (ESI-MS).

Anionic Exchange Chromatography. Anionic exchange chromatography was performed in an Äkta purifier apparatus (Amersham Biosciences, Uppsala, Sweden) using a 25 × 7 mm, 1 mL Q-Sepharose Fast Flow column (cross-linked agarose with quaternary ammonium as exchanger group, 90 μm particle size). Solvents used were sodium phosphate 10 mM, pH 6.0 (solvent A), and 10 mM sodium phosphate, pH 6.0, with 2 M NaCl (solvent B). After sample injection, the elution process was as follows: 0% B from beginning to 3 mL, and then a linear gradient was developed from 0% B to 35% B in 20 mL. In all cases, the flow rate was 1 mL/min, 1 mL fractions were collected, and injection volume was 1 mL. Elutions were followed by UV−vis detection at 280, 480, and 536 nm.

Solid-Phase Extraction. One milliliter C-18 cartridges (Waters, Milford, MA) were conditioned with 5 mL of ethanol followed by 10 mL of purified water. Aqueous solutions of extracted pigments and semisynthetic betalains were injected and bound to the minicolumn. Salts and buffers were washed off by rinsing the column with purified water. Betalains were eluted with ethanol, and the resulting fraction was evaporated to dryness under reduced pressure at room temperature. The residue was redissolved in water for further use or stored at −80 °C.

HPLC-DAD Analysis. A Shimadzu LC-20AD apparatus (Kyoto, Japan) equipped with a SPD-M20A photodiode array detector (PDA) was used for analytical HPLC separations. Reversed phase chromatography was performed with a 250 mm × 4.6 mm i.d., 5 μm, Kromasil 100 C-18 column (Teknokroma, Barcelona, Spain) for identification of betalains.[27] Solvent A was water with 0.05% trifluoroacetic acid (TFA), and solvent B was composed of acetonitrile with 0.05% TFA. A linear gradient was performed for 42 min from 0% B to 65% B. The flow rate was 1 mL/min, operated at 30 °C. Elutions were followed at λ = 270 (dopamine), 405 (betalamic acid), 480 (betaxanthins), and 536 nm (betacyanins). Injection volume was 40 μL. Dopamine and betalains presented the same elution times as the corresponding standards in coelution experiments and superimposable spectra.

Elecrospray Ionization Mass Spectrometry. A VL 1100 apparatus with LC/MSD Trap (Agilent Technologies, Palo Alto, CA) was used for HPLC-ESI-MS analyses. Elution conditions were as described above using the same column (250 mm × 4.6 mm i.d., 5 μm, Kromasil 100 C-18) decreasing the flow rate to 0.8 mL/min. Vaporizer temperature was 350 °C, and voltage was maintained at 3.5 kV. The sheath gas was nitrogen, operated at a pressure of 45 psi. Samples were ionized in positive mode. Ion monitoring mode was full scan in the range m/z 50−1000. The electron multiplier voltage for detection was 1350 V.

UV−Vis Spectroscopy. A V-630 spectrometer (Jasco Corporation, Tokyo, Japan) attached to a Tectron thermostatic bath (JP Selecta, Barcelona, Spain) was used for UV−vis spectroscopy. For quantitation of betalains, pigment concentration was evaluated using molar extinction coefficients of ε = 46 000 (dopaxanthin), 27 000 (betalamic acid), 44 000 (tryptophan-betaxanthin), 46 000 (dopaxanthin), 48 000 (glutamine-betaxanthin and dopamine-betaxanthin), 65 000 (betanin and amaranthin), and 54 000 $M^{-1}\cdot cm^{-1}$ (betanidin).[28−30] All measurements were performed in water at 25 °C.

Microscopy. Brightfield and fluorescence microscopy were performed in a Leica DMRB microscope (Leica Microsystems, Wetzlar, Germany) with incident light beam. In the case of fluorescence imaging, the filtercube I3 (Leica Microsystems) was used limiting excitation to the range λ = 450−490 nm.

Statistical Analysis. Data analysis was carried out by using ANOVA variance parametric analysis and Tuckey range test ($P < 0.05$) using SPSS software, version 8.0 (SPSS, Chicago, IL). In each case, errors associated with the results provided were calculated on the basis of the residual standard deviation.

RESULTS AND DISCUSSION

Establishment of Callus Lines of *C. argentea* var. *plumosa*. All seeds from *C. argentea* var. *plumosa* were geminated on day 10 after sowing, with no sign of microbial contamination. Seedlings were maintained under aseptic conditions for 20 days and then used for callus induction experiments (Figure 2A). Hypocotyls were considered as primary explant sources due to the presence of meristem tissue and the reported endogenous levels of auxins and cytokines.[31,32] Table 1 summarizes the results for callus induction as affected by the presence and concentration of different plant growth regulators. It can be seen that the sole presence of 2,4-dichlorophenoxyacetic acid (2,4-D) was not enough to induce the formation of calli. Such inhibition of the cell growth could be due to the overexpression of genes ARR7 and ARR15 promoted by the auxin as previously reported.[33] The presence of 6-benzylaminopurine (BAP) at a concentration 4.44 μM also yielded negative results if no other regulator was present, in accordance to previous reports with *Celosia cristata*.[34] Treatments with BAP at concentrations 6.66 and 8.88 μM and the combination of 6.66 μM BAP with 9.05 μM 2,4-D generated calli with pale brown color with yields of 33% or 66%. Experiments with the highest concentrations of BAP and 2,4-D showed 100% induction capacity of white-green calli in 30-day cultures.

The medium suplemented with 6.66 μM BAP and 6.79 μM 2,4-D showed the highest cell growth, and the cell mass

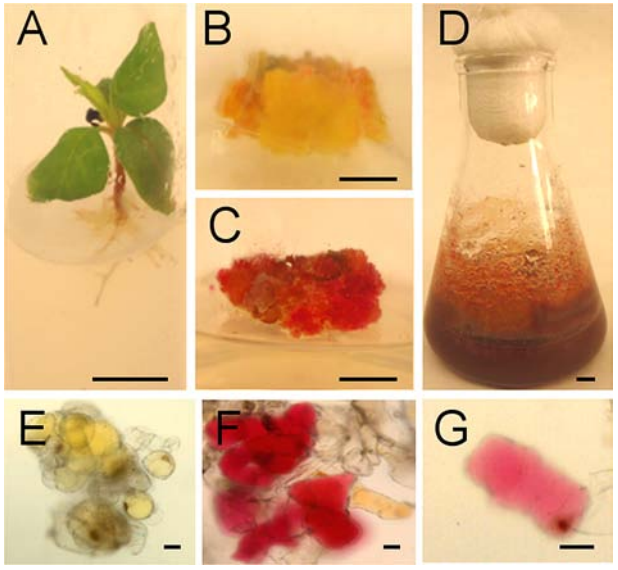

Figure 2. Establishment of in vitro cell lines derived from *C. argentea* var. *plumosa*. (A) Twenty days old seedling used as explants source. (B and C) Macroscopic images showing phenotypic characteristics for yellow and red callus lines, respectively. (D) Suspension culture 15 days after inoculation. (E, F, and G) Brightfield microscopic images of cells present in yellow callus, red callus, and suspension culture, respectively.

presented yellow and red color after 14 days of culture, spreading to the full explants at day 30. The presence of yellow and red colors suggested the presence of betalains. These data are in relation to the observations on the halophytic plant *Suaeda salsa*,[35] on *C. cristata*,[34,36] and on *B. vulgaris* cultures.[37] Due to the presence of red and yellow hues and the culture characteristics, the medium supplemented with 6.66 μM BAP and 6.79 μM 2,4-D was considered for further experimentation. Callus propagation was performed in fresh medium every 20 days for 11 cycles (total cultivation time 7.5 months). As a result of this process two stable and differentially colored lines of *C. argentea* were established: yellow and red (Figure 2B and 2C). Both cell lines obtained were observed under microscopy. The yellow line showed a round shape and yellow pigmentation compatible with the presence of betaxanthins (Figure 2E). The red cell line presented a morphology with round and elongated cells with a major presence of the former (Figure 2F). This phenomenon might be in relation with the cohesive properties of the cell wall reported to occur during plant cell division.[38] Red pigmentation was observed within the line cells compatible with the presence of betacyanins.

Pigment Identification in Yellow and Red Cell Lines. The yellow and red *C. argentea* cell lines obtained were analyzed in terms of the presence of the bioactive pigments betalains. Samples from both lines were extracted and analyzed by HPLC with PDA and ESI-MS/MS detection (Table 2). The yellow line exhibited the major presence of the betaxanthins vulgaxanthin I (**5**), derived from L-glutamine (1.78 mg/g dry weight) and miraxanthin V (**2**), derived from dopamine (1.64 mg/g dry weight) (Table 2). Other betaxanthins detected were those derived from L-dihydroxyphenylalanine (L-DOPA), named dopaxanthin (**1**), and L-tryptophan (**6**). In addition to the yellow pigments, the betacyanins amaranthin (**8**) and betanin (**7**) and the dihydroxylated betanidin (**3**) and decarboxy-betanidin (**4**) were also identified.

J. Agric. Food Chem. 2015, 63, 2741−2749

In the red line, coloration was also due to betalains and the content of betacyanins was higher. In this case the major pigment detected was the violet amaranthin (**8**) (4.92 mg/g dry weight), accompanied by decarboxy-betanidin (**4**) (1.32 mg/g dry weight), betanin (**7**) (0.80 mg/g dry weight), and betanidin (**3**) (0.74 mg/g dry weight). Betaxanthins were also present (Table 2) with dopamine-derived betaxanthin (**2**) being the major yellow pigment (3.04 mg/g dry weight). The joint presence of betacyanins (violet) and betaxanthins (yellow) yields the red color described for the cell mass. Inflorescences of the starting plant material and the hypocotyls used to establish the cell lines were violet. These two samples were also analyzed as a control, and only the presence of amaranthin (**8**) and its isomer iso-amaranthin were found (Table 2). The number of betalains present in the cell cultures indicates that the presence of 6.79 μM 2,4-D and 6.66 μM BAP promotes the biosynthesis of an increased number of betalains compared to the starting plant material. This could be due to the effect of 2,4-D and BAP in the concentrations mentioned on the expression of the key enzymes of the biosynthetic pathway of betalains: 4,5-DOPA-extradiol dioxygenase (DODA), tyrosinase, and cytochrome P450. In this sense, the levels of DODA mRNA and the accumulation of betalains have been previously correlated with the concentration of the growth regulators in in vitro cultures of *S. salsa*.[35]

The presence of betaxanthins in the cells of the yellow *C. argentea* line together with the described fluorescence of these pigments under physiological conditions[39] makes the cells fluorescent in the visible range of the electromagnetic spectrum. Figure 3 shows the pictures derived from the betaxanthins

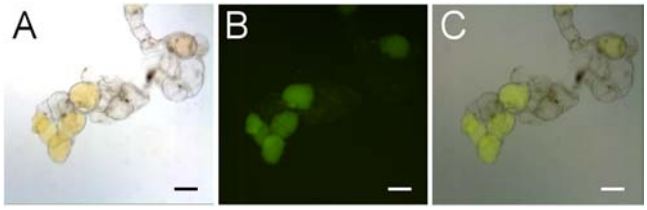

Figure 3. *C. argentea* microscopic images of cells present in the yellow line callus. (A) Brightfield technique. (B) Fluorescence. Only yellow portions of the brightfield image, containing betaxanthins, present light emission in the fluorescence image. (C) Combination of the previous two images.

autofluorescence obtained under a filter system able to irradiate the sample with blue light and to record the emitted light in the green range of the visible spectrum. As can be seen, only the yellow portions of the brightfield image, containing the yellow pigments, present light emission in the fluorescence image. Fluorescence of betaxanthins has previously been used to visualize petal cells[39] and to detect the presence of *Plasmodium falciparum* (malaria) in erythrocytes.[40] However, this is the first time that betalains fluorescence was demonstrated to be of utility in the visualization of plant single cells grown in vitro.

All pigments were identified by comparison with real standards in terms of HPLC retention times, PDA spectra, and electrospray ionization mass spectrometry (ESI-MS) analyses. The mass values determined for the parent ions of all compounds were as expected for the corresponding protonated molecular ions $[M + H]^+$ of the betalains, thus confirming the proposed structures (Table 2). For pigments containing a quaternary ammonium substructure, the mass obtained corresponds to the charged form, as drawn in Figure 1. In all cases a daughter ion corresponding to m/z $[M + H]^+ - 44$ was detected, accounting for loss of a carboxylic group. For betanin (**7**) (R_t 10.25 min), the main daughter ion was m/z 389, corresponding to the mass determined for betanidin (**3**), obtained through cleavage of the glucose unit at the level of the *O*-glucosidic bond (m/z $[M + H]^+ - 162$). Amaranthin (**8**) (R_t 9.48 min) yielded a molecular ion of m/z 727 that was fragmented into m/z 551, corresponding to loss of a glucuronic acid moiety m/z $[M + H]^+ - 176$ (betanin), and into m/z 389, corresponding to an additional loss of glucose m/z $[M + H]^+ - 176-162$ (betanidin). Betanidin (**3**) itself was also present in the extracts derived from both cell lines (R_t 11.76 min). Thus, all the intermediates of the biochemical route of carboxylated betacyanins from betanidin to amaranthin were present. This suggests the transformation of betanidin (**3**) into betanin (**7**) by glucosylation[16] and betanin into amaranthin (**8**) by addition of a glucuronic acid residue. The presence of the intermediates points to the biosynthesis of amaranthin in the callus through this route instead of via cyclo-DOPA glucosylation and glucuronylation and further condensation with betanidin.[41] These intermediates were not present in the starting plant material inflorescences or hypocotyls, where only the final product of the route amaranthin was detected.

The possible presence in the cell cultures of the structural unit of all betalains, betalamic acid (**10**), and the precursor molecule for miraxanthin V, dopamine (**9**), was also investigated. Betalamic acid could be detected in the yellow *C. argentea* cell line at 0.29 mg/g dry weight (Table 2), while in the red line a higher content was detected with 0.46 mg/g dry weight. The presence of betalamic acid (**10**) complements the presence of intermediates of the biosynthetic pathway of betalains. It is an elusive molecule derived from cyclization of the 4,5-seco-DOPA molecule obtained by intramolecular cleavage of the amino acid L-DOPA by the enzyme 4,5-DOPA-extradiol-dioxygenase.[2] Free betalamic acid has previously been found as a natural constituent in fruits of *Opuntia ficus-indica*.[42] Dopamine (**9**) was also detected in the cell lines at significant quantities. Identification was corroborated by comparison with commercial standard (R_t 8.60 min) and ESI-MS. A predominant daughter ion of m/z 137 resulting from loss of the amine group was found in the standard and culture-derived compound. This metabolite was not detected in the plant inflorescences or hypocotyls, but its presence accounts for 17.70 mg/g dry weight in the yellow cell line and 19.63 mg/g dry weight in the red line. In addition to its role as the building block of betalains, betalamic acid itself is a natural pigment with strong antioxidant activity.[26] Dopamine acts as a neurotransmitter, and its deficit has been reported in mental illness such as depression.[5]

The presence of the dihydroxylated betacyanins betanidin (**3**) and decarboxy-betanidin (**4**) and the DOPA and dopamine-derived betaxanthins (**1**, **2**) in the obtained cell cultures is of particular relevance due to their strong antioxidant and free radical scavenging activities.[3,4,43] Furthermore, the tryptophan-derived betaxanthin (**6**) present in both cell lines has recently been identified among all traditional Chinese medicine phytochemicals in a massive in silico screening as a bioactive compound interacting with the age-related enzymes sirtuins.[44] Tryptophan-derived betaxanthin is a lead compound with possible application in drug development for diseases associated with aging.

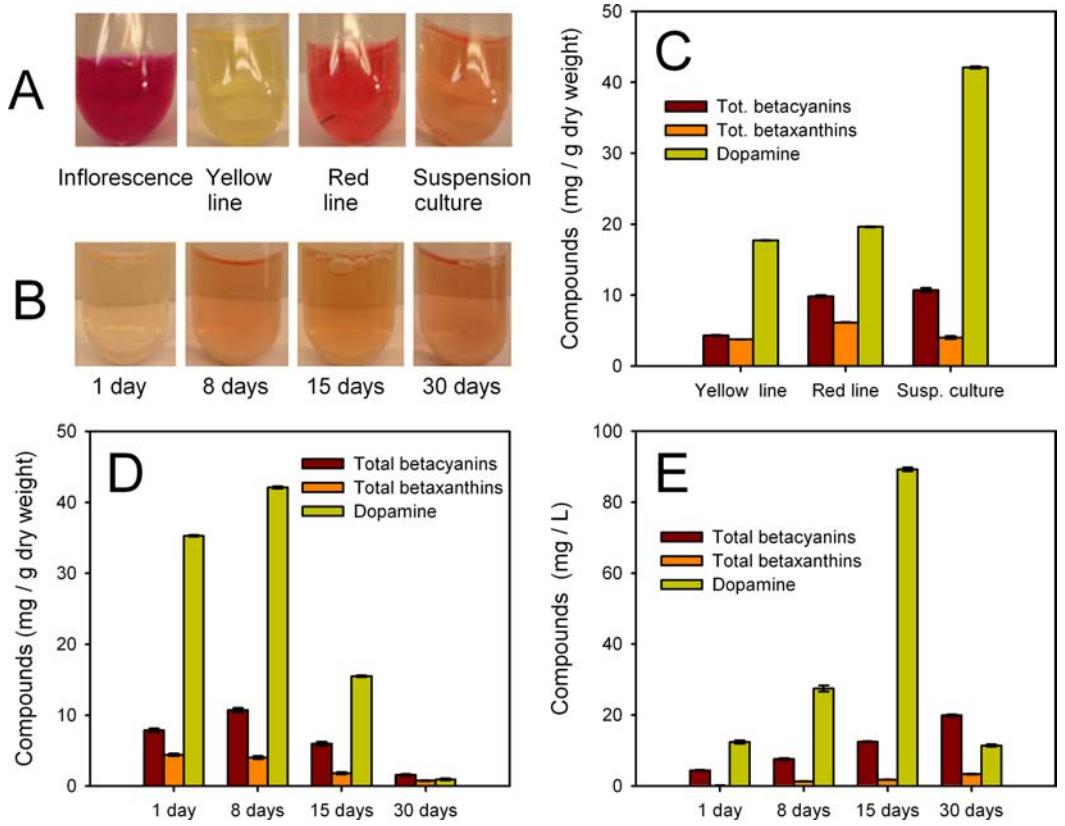

Figure 4. Production of betalains and dopamine by cell lines derived from *C. argentea* var. *plumosa*. (A) Picture showing the pigmentation of cell extracts obtained from plant inflorescences, yellow callus line, red callus line, and suspension culture 8 days after inoculation. (B) Color evolution of the liquid culture medium photographed 1, 8, 15, and 30 days after inoculation. (C) Total pigment content and dopamine presence in extracts obtained from solid and suspension cultures. (D) Time evolution for the production of betalains and dopamine in the cells of the suspension culture at the indicated times after inoculation. (E) Time evolution for the presence of betalains and dopamine in the liquid medium at the indicated times after inoculation.

Suspension Cultures of *C. argentea*. The analyses performed in the cell lines derived from *C. argentea* show that the red line produces higher levels of dopamine, betacyanins, and betaxanthins than the yellow homologue (Figure 4C). Thus, the red cell line was chosen to attempt a suspension culture of *C. argentea* that could be used to produce the identified phytochemicals. The liquid culture was successfully established in MS liquid medium supplemented with 30 g/L sucrose, 6.66 μM BAP, 6.79 μM 2,4-D, and 10 mM ascorbic acid. Figure 2D shows the established culture. The cell growth curve (Figure 5) indicates that a lag phase was present for 4 days, in which biomass reached 3.18 g dry weight/L. After this time, cells entered exponential growth phase. Growth was prolonged up to day 15, and in that time the accumulated biomass was 10.96 g dry weight/L. During this phase, the doubling time of the culture was 6.1 days with a calculated growth rate (μ) of 0.113/day.

During the whole culture time the pH of the suspension was monitored (results not shown) with no significant variation being recorded and a mean pH value of 4.9. This is a convenient pH value to promote the stability of the pigments betalains with special emphasis of those containing the dihydroxylated moiety.[21] The cell shape found in suspension was elongated, showing predominantly red coloration (96%) (Figure 2G). In addition to the red-colored cells, yellow cells were detected in a much lesser extent (4%). This points to the joint presence of betaxanthins and betacyanins in the majority of cells, as detected in the red callus used to start the liquid culture. Cells tended to form aggregates, probably in relation to the cohesive properties of the cell wall and the hydrodynamic stress experienced in suspension culture.[38] Cell viability was also monitored during the process and maintained at 74% during the 30 days of culture period. Viability is well above the limit of 50% considered as positive in plant cell culture,[45] thus confirming the success of the *C. argentea* suspension culture.

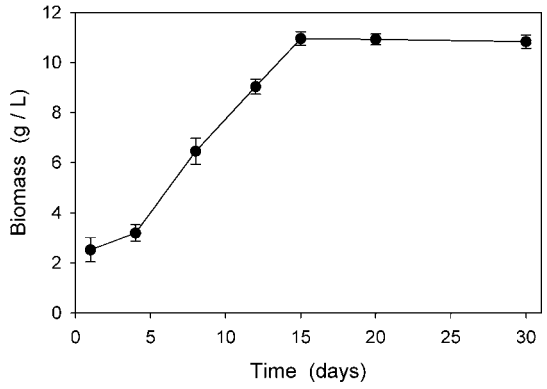

Figure 5. Growth curve for the suspension culture of *C. argentea* obtained in MS liquid medium supplemented with 30 g/L sucrose, 6.66 μM BAP, 6.79 μM 2,4-D, and 10 mM ascorbic acid.

Production of Betalains and Dopamine in Liquid Culture. The presence of betalains and dopamine in *C. argentea* liquid culture was analyzed by HPLC-PDA and ESI-

[a]nd: Not detected.

MS. Pigments were identified and quantitated both in cells and in liquid medium at different culture times. Cell extracts and media analyses were performed at days 1, 8, 15, and 30 as shown in Tables 2 and 3. Cells exhibited maximum accumulation of total betalains at day 8, corresponding to the exponential growth phase (Figure 4D). Up to 10 pigments were identified corresponding to those present in the calli with a higher content of miraxanthin V (**2**) (1.84 mg/g dry weight), vulgaxanthin I (**5**) (2.01 mg/g dry weight), and betanidin (**3**) (6.27 mg/g dry weight).

This pigment content explains the cell suspension coloration and suggests the possible secretion of pigments into the culture medium. Table 3 shows the results for the analyses of the medium at different culture times. The presence of betalains was detected during all of the process, increasing with incubation time (Figure 4B and 4E). Pigments identified in the culture medium were betalamic acid (**10**), vulgaxanthin I (**5**), miraxanthin V (**2**), amaranthin (**8**), and betanidin (**3**). The total quantity of betalains detected at the end of culture (day 30) was 23.27 mg/L, mainly accounting for the presence of the dihydroxylated betacyanin betanidin (**3**) (13.40 mg/L). Betanidin, which is the betalain with the strongest antioxidant and free radical scavenging activities and also involved in the anti-inflammatory potential of betalain-containing extracts,[46,47] is here the betalain produced in a higher extent.

Cells grown in liquid culture presented a significant increase in the content of dopamine (**9**) in comparison to the levels detected in the cells grown in solid media. After 8 days in liquid culture the levels of dopamine in the cells were 42.08 mg/g dry weight, which is more than double the levels found in the cells grown in solid media (19.62 mg/g dry weight for the red line) (Figure 4C). Plant cells in suspension suffer hydrodynamic forces due to continuous shaking which generates a stress probably involved in the increase of the secondary metabolism.[48,49] Dopamine was also detected to a lesser extent in the culture medium. Figure 4E shows the time evolution of dopamine content. In this case the maximum concentration was achieved after 15 days of culture with a content of 89 mg/L. Although the presence of dopamine in *C. argentea* was known for intact plants,[12] this is the first report on the production of the metabolite in cell culture. In vitro production of dopamine through a plant cell culture was previously only attempted for another plant belonging to the Caryophyllales, *Portulaca oleracea* but using *Agrobacterium rhizogenes* transformation. This achieved a maximum production of dopamine of 0.90 mg/g dry weight after 28 days of culture and chemical elicitation.[50] This value is far from the 42.08 mg/g dry weight obtained here in only 8 days with untransformed cells of *C. argentea*, thus significantly increasing the yield and reducing the culture time.

Cell cultures of *C. argentea* produce four dihydroxylated betalains with the highest antioxidant and free radical scavenging activities, the carboxylated dopaxanthin (**1**) and betanidin (**3**) and the decarboxylated homologues miraxanthin V (**2**) and decarboxy-betanidin (**4**). In addition, they produce tryptophan-betaxanthin (**6**), which has been identified among the bioactive compounds of the traditional Chinese medicine database for their interaction with the age-related enzymes sirtuins. The joint presence of these bioactive betalains together with the production of dopamine (**9**) shows the ability of cell cultures of *C. argentea* to become stable sources of valuable phytochemicals of potential application in the food, pharmaceutical, and cosmetic fields.

However, the wax composition has been recently correlated also with the antioxidant and anti-inflammatory proprieties.[20,32] The main triterpenoids detected in apple cuticular wax are ursolic, oleanolic, and betulinic acids. Ursolic acid is a ubiquitous triterpenoid in the plant kingdom that was long considered to be biologically inactive, whereas in recent years it has attracted considerable interest because of its pharmacological effects such as the inhibition proliferation of HepG2 human hepatoma cells, MCF-7 human breast cancer cells, and Caco-2 human colon cancer cells.[32]

Only recently, breeding for phytochemicals in horticultural crops has been identified as an important goal in the development of new cultivated lines. The plant's genotype is considered of primal importance in the determination of its phytochemical profile, often surpassing the impact of cultural practices such as irrigation or fertilization. Horticultural crops such as strawberry, apple, tomato, potato, cabbage, broccoli, lettuce, onion, cranberry, and raspberry are currently the subject of breeding programs in which the phytochemical content was considered a key component.[33] The effect of domestication and particularly of breeding on apple bioactive compounds content is still unresolved and is a matter of debate. The inconsistency of recent results[20,22,34] has not yet elucidated the effective impact of breeding activities on the total phytochemical content in apple fruit. We suggest that this open question deserves further investigation since the breeding of the future cultivars should have the roots in a solid knowledge of metabolic phylogenesis, taking into account the composition and relationships among the apples of the past (wild species, old cultivars) and of the present (elite cultivars).

In the present study, a broad apple germplasm collection, composed by both wild and domesticated species, was analyzed to assess the amount of main bioactive compounds of apple fruit, namely, phenolics, triterpenes, and ascorbic acid. The availability of this repertoire of information allowed the study of the largest catalogue of apple bioactive compounds to date presented to the scientific community. It allowed one to discover that apple is a significant dietary source of resveratrols (*trans*- and *cis*-piceid). Moreover, the effect of domestication on the actual concentration of these compounds and their potential role in breeding programs are discussed.

MATERIALS AND METHODS

Plant Material and Fruit Sampling. Metabolic profiling was performed on an apple fruit collection represented by 247 accessions, composed by both wild *Malus* species (97) and *Malus* × *domestica* cultivars (150) (Supporting Information, Table 1). Plant materials were planted in triplicate for each accession and grown at the experimental orchard of the Fondazione Edmund Mach in the Northern part of Italy (Province of Trento). Each plant was maintained following standard agronomical management for pruning, thinning, and pest disease control.

A minimum of five homogeneous apples, harvested at optimal ripening stage as defined by the Extension Service of the Fondazione Edmund Mach, and by fruit color comparison, were collected from each accession and maintained at room temperature (~20 °C) overnight before sampling. The entire collection was assessed for bioactive compound profiling in the first year, while in the second year, only a subset, composed by 23 commercially important accessions, was assessed in order to validate the procedure.

The core of three fruits per sample was removed with an apple corer. Three slices (cortex + skin) of each fruit, taken from opposite sides, were cut in small pieces, ground under liquid nitrogen, and stored in falcon tubes at −80 °C until the analysis.

Phenolic Compound Analysis. Extraction and analysis of phenols were performed according to the UPLC-MS/MS method published by Vrhovsek et al.[26] An aliquot of 2 g of powdered tissues was extracted in sealed glass vials using 4 mL of water/methanol/chloroform solution (20:40:40). After vortexing for 1 min, the samples were mixed using an orbital shaker for 15 min at room temperature and further centrifuged at 1000*g* (4 °C) for 10 min, after which the upper phases, made up of aqueous methanol extract, were collected. Extraction was repeated by adding another 2.4 mL of water/methanol (1:2) to the pellet and chloroform fractions. After the final centrifugation, the upper phases from the two extractions were combined and brought to the volume of 10 mL and filtered with a 0.2 μm PTFE filter prior to liquid chromatography−mass spectrometry analysis. Ultraperformance liquid chromatography was performed employing a Waters Acquity UPLC system (Milford, MA, USA) coupled to a Waters Xevo TQMS (Milford, MA, USA) working in ESI ionization mode. Separation of the phenolic compounds was achieved on a Waters Acquity HSS T3 column 1.8 μm, 100 mm × 2.1 mm (Milford, MA, USA), kept at 40 °C, with two solvents: A (water containing 0.1% formic acid) and B (acetonitrile containing 0.1% formic acid). The flow was 0.4 mL/min, and the gradient profile was 0 min, 5% B; from 0 to 3 min, linear gradient to 20% B; from 3 to 4.3 min, isocratic 20% B; from 4.3 to 9 min, linear gradient to 45% B; from 9 to 11 min, linear gradient to 100% B; from 11 to 13 min, wash at 100% B; and from 13.01 to 15 min, back to the initial conditions of 5% B. From both standard solutions and samples, kept at 6 °C, a volume of 2 μL was injected, after which the needle was rinsed with 600 μL of weak wash solution (water/methanol, 90:10) and 200 μL of strong wash solution (methanol/water, 90:10). Detection was performed by multiple reaction monitoring (MRM) with a Waters Xevo TQMS (Milford, MA, USA) triple quadrupole (QqQ) equipped with an electrospray (ESI) source. Capillary voltage was 3.5 kV in positive mode and −2.5 kV in negative mode; the source was kept at 150 °C; desolvation temperature was 500 °C; cone gas flow, 50 L/h; and desolvation gas flow, 800 L/h. Unit resolution was applied to each quadrupole. Each phenolic compound was analyzed under the optimized MRM conditions (precursor and product ions, quantifier and qualifiers, collision energies, and cone voltages) described by Vrhovsek et al.[26] Data were processed by Waters MassLynx 4.1 and TargetLynx software.

Triterpenoids Analysis. The extraction was performed according to Andre et al.[20] Five milliliters of ethyl acetate and 5 mL of hexane were added to an aliquot of 500 mg of powdered tissues, shaken for 1 h, and centrifuged at 2000*g* for 10 min. The dried extract was dissolved in 1 mL of ethanol and filtrated. Quantification and separation of triterpenoids was carried out with a Waters HPLC system Alliance 2695 Separations Module equipped with a mass spectrometer Micromass ZQ and Waters Empower Pro software. The separation was performed on Phenomenex Luna C18 column, 250 × 2 mm, 5 μm and with a mobile phase consisting of 1% formic acid in water (solvent A) and methanol (solvent B). The column was heated at 35 °C with a flow of 0.3 mL/min under the following conditions: linear gradient from 50 to 85% of B in 5 min, to 90% B in 25 min. The column was washed with 100% B for 5 min and equilibrated with the initial conditions for another 5 min. The injection volume was 20 μL. The conditions of the mass spectrometer were capillary voltage 3000 V, cone voltage 25 V, extractor voltage 10 V, source temperature 125 °C, desolvation temperature 500 °C, cone gas flow (N2) 30 l/h, and desolvation gas flow (N2) 1000 L/h. The scan speed was 0.1 s in SIM mode with detection in negative mode at m/z 455.50. The retention time for the betulinic acid was 21.5 min, 22.7 min for oleanolic acid, and 23.2 min for ursolic acid.

Organic Acids Analysis. An aliquot of 5 g of the edible part of the frozen fruit was homogenized in 50 mL of a solution of metaphosphoric acid (0.6%) in water containing sodium *meta*-bisulfite (1 g/L). Analysis of organic acids was performed as described in Vrhovsek et al.[35] The separation was carried out on a Waters 2690 HPLC system equipped with Waters 2996 DAD (Waters, Milford, MA), and Empower Software (Waters, Milford, MA.) on a reversed-phase column Discovery, RP C18 (Supelco, 250 × 4 mm, 5 μm). [a]μg/g FW.

solvent used was 0.07% phosphoric acid in water. The isocratic separation was carried out at 30 °C in 10 min. After each run, the column was washed for 5 min with 15% acetonitrile in 0.07% phosphoric acid in water and afterward equilibrated for 7 min prior to each analysis. The flow rate was 0.6 mL/min, the injection volume was 20 μL, and the UV−vis signal was set at 243 nm for ascorbic acid and 210 nm for malic acid.

Statistical Analysis. Multivariate statistical analysis was performed on log transformed data using R 3.0.2 internal statistical functions and the external packages "PCA", "gplots", "ape", and "diversitree". Visualization of significant metabolite correlations ($p < 0.01$; $R > 0.50$) was conducted by the generation of a Correlation Analysis Network with Cytoscape.

RESULTS AND DISCUSSION

Total Bioactive Compounds of Apple Species. Total content of bioactive compounds, mainly phenolics, triterpenoids, and ascorbic acid, significantly differed among wild *Malus* species as well as a *M.* × *domestica* cultivars (Table 1).

The overall content of phenols in *M.* × *domestica* ranged between 225 μg/g FW (cv Laimburg Gelber Edelaefer) and 3307 μg/g FW (cv Permein dorato) with the elite market cultivars (Supporting Information, Table 2) in the range between 435 μg/g FW (cv Scilate) and 2450 μg/g FW (cv Renetta Canada). More variation was found between the wild *Malus* species, ranging between 353 μg/g FW (*M.* × *Dawsoniana*) and 6513 μg/g FW (*M. angustifolia*). Distribution of each phenolic compounds in the groups of genotypes assessed in this research is reported in Table 1. In detail, wild *Malus* species were characterized by a higher average content of all phenolic compounds than *M.* × *domestica*, for which the differences between old and elite cultivars were negligible. Remarkably, the dihydrochalcone (phloridzin) content assessed in wild *Malus* species (average of 262 μg/g FW with a maximum of 1081 μg/g FW) was significantly higher when compared with the levels recorded on the *M.* × *domestica* species (average of 52 μg/g FW with a maximum of 310 μg/g FW).

The total content of triterpenoids in *M.* × *domestica* accessions ranged between 6 μg/g FW (cv Spitzlederer) and 1121 μg/g FW (cv Napoleone), with the market elite cultivars between 233 μg/g FW (cv Renetta Canada) and 785 μg/g FW (cv Mutsu). Comparable variation was also found between the wild *Malus* species that ranged between 58 μg/g FW (*M.* × *Hartwigii*) and 1384 μg/g FW (*M. sylvestris*) (Supporting Information, Table 1). Likewise, average content of each triterpenoids (namely, ursolic, oleanolic, and betulinic acids) did not relevantly diverge between *M.* × *domestica* and wild *Malus* accessions. The most abundant triterpenoid, as already reported by Andre et al.[20] and Frighetto et al.,[31] was ursolic acid followed by its isomeric compound oleanolic and betulinic acid (average values, respectively, around 400, 60, and 10 μg/g FW).

Differences in organic acids content between *M.* × *domestica* and wild *Malus* accessions were more noticeable when compared to the other investigated metabolites. In fact, most of the wild *Malus* species had a relevant higher average content of both ascorbic and malic acid (140 and 16319 μg/g FW, respectively). Contrarily, no remarkable differences were discovered between old and elite *M.* × *domestica* cultivars

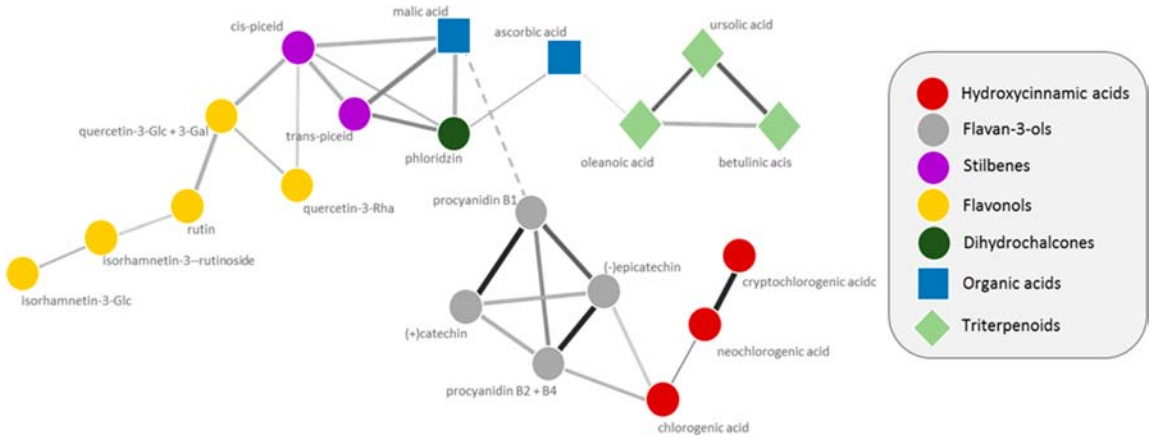

Figure 1. Correlation Analysis Networks (CAN) for the entire bioactive metabolite data set. The network is obtained by determining the significant Pearson correlations ($p < 0.01$) among the metabolites. The color coding of the edges (gradient from light gray to blank) denotes the level of correlation (from 0.5 to 1). Positive and negative correlations are shown, respectively, by solid and dash lines.

(average value of ascorbic and malic acid around 80 μg/g FW and 7000 μg/g FW, respectively).

Correlation network analysis of the investigated metabolites (Figure 1) was mainly assessed to check the accuracy of the used data set rather than to gain knowledge about the metabolic pathways of apple secondary metabolites. The network was created from a significant Pearson correlation data set ($P < 0.01$, Pearson correlation threshold = $\pm$ 0.5), computed among the metabolites detected in all 247 apple accessions present in the collection. The correlation network depicted the robustness and correctness of the data set used in this investigation (*M.* × *domestica* and wild *Malus* species accessions analyzed in two seasons) since compounds belonging to the same chemical family were closely grouped together in accordance with their metabolic pathways.

Phenolic Compounds. Phenolic compound variability assessed within the apple germplasm by principal component analysis (PCA) confirmed the results previously described in Table 1 (Figure 2a). Old and elite *M.* × *domestica* populations

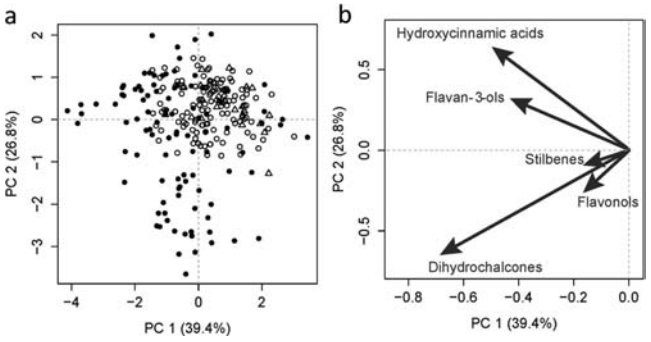

Figure 2. PCA plot (a) and loading projection (b) of the phenolic compounds assessed in the *Malus* germplasm: (●) wild *Malus*, (O) *M.* × *domestica* OLD cvs, and (Δ) *M.* × *domestica* ELITE cvs.

were not noticeably discriminated based on their phenolic content and profile, while a broad collection of wild *Malus* species species (those located in the left and bottom space of Figure 2, panel a) was markedly distinguished mostly according to the second principal component variation (PC2, 26.8%). Most of this variation was due to a generally higher concentration of dihydrochalcones, stilbenes, and flavonols as depicted in the PCA loading plot (Figure 2b). Nevertheless, also the variation of the first principal component (PC1, 39.4%) disclosed a reduced but significant cluster of wild *Malus* accessions characterized by a higher content of hydroxycinnamic acids and flavan-3-ols.

The hydroxycinnamic acid (neochlorogenic acid, cryptochlorogenic acid, and chlorogenic acid) average content assessed on wild *Malus* species was 30% higher than that on *M.* × *domestica* cultivars (Figure 3a and Supporting Information, Figures 1 and 2). Only 16 over the 150 *M.* × *domestica* cultivars showed a content higher than the 75th percentile assessed in wild *Malus* species; among them, Rosa di Caldaro represented the only cultivar with still a marketable value. Among all *Malus* species accessions, *M. brevipes*, *M. angustifolia*, *M.* × *bracteata*, *M. ioensis*, and *M. orthocarpa* were the species with the highest content of hydroxycinnamic acids. Since several unappreciated quality traits, mainly fruit bitterness and astringency[36] and flesh browning after cutting,[37] are commonly related the hydroxycinnamic acids level, the lower content assessed into the "elite" *M.* × *domestica* cultivars (Supporting Information, Figure 1) may be accredited to breeding strategies aimed to reduce these unpleasant features.

Stilbenes, represented by *trans*- and *cis*-piceid, are the phenolic compound class with the lowest concentration detected in *Malus* species fruit. Before the present study, it was only reported in "Golden Delicious" apple,[26] while previously it was considered a "foreign" phytoalexin only reported in transgenic apple transformed with the stilbene synthase gene from grapevine.[38,39] *trans*-Piceid and *cis*-piceid were identified and also quantified for the first time in apple thanks to the very high sensitivity of MS/MS mass spectrometers coupled to a UHPLC separation system. Their identification was furthermore unequivocally confirmed by UHPLC interfaced with two high resolution mass spectrometers (Synapt-QTOF and Orbitrap) by three independent parameters: accurate mass, fragmentation patterns, and retention time (Supporting Information, Figures 3 and 4). Despite their relatively low concentrations, the presence of resveratrol glucosides in apple should lead to not negligible contribution to the dietary intake of resveratrol. From the analysis of the Spanish branch of the EPIC cohort ($n = 40.574$), we know that approximately 32% of the population did not consume resveratrol, while for the remaining group, the most

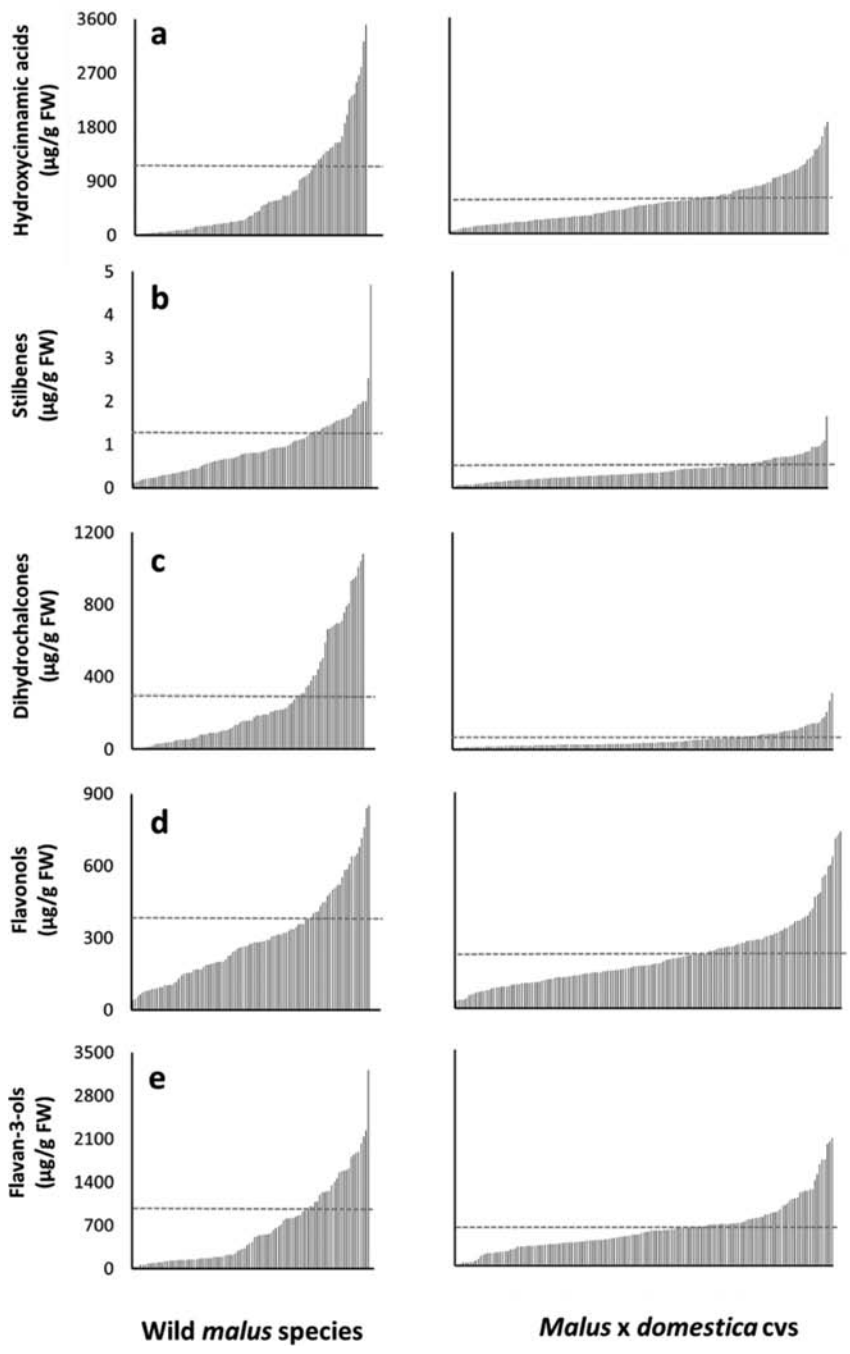

Figure 3. Bar chart plots of phenolic compound content (hydroxycinnamic acids, stilbenes, dihydrochalcones, flavonols, and flavan-3-ols) assessed in the *Malus* germplasm (left column plots, 97 wild *Malus* accessions; right column plots, 150 *M.* × *domestica* cvs). The 75th percentile levels are represented by the dashed line. Distribution density plots of each compound class are reported in Supporting Information, Figure 2.

important sources of resveratrols (piceid + free resveratrols) are wines (98.4%) and grape and grape juices (1.6%), whereas peanuts, pistachios, and berries contributed to less than 0.01%.[40] The average daily intake of resveratrol in the EPIC population was estimated at 137 and 686 μg/day for women and men, respectively. The mean apple consumption per person in the EPIC-Spain study was approximately 90g/day, with 90% of the population being consumers.[40−42] With a mean total content in cultivated apples of 0.4 μg/g FW (Table 1), this would provide 36 μg per day. From the combination of the above data, it appears that apple is the second highest dietary source of resveratrol after wines. The estimated dietary intake of resveratrols is slightly higher, and the percentage of population not exposed to resveratrols is lower than previously reported, after accounting for the presence of resveratrols in apple.

Resveratrol average content in wild *Malus* species was 130% higher than that in *M.* × *domestica*, for which no relevant differences were found between old and elite cultivars (Figure 3b and Supporting Information, Figure 1). Red Field, Geflammter Kardinal, and Renetta Canada had the highest piceide content among the *M.* × *domestica* cultivars while, among the wild *Malus* species, the highest content was detected in *M. sikkimensis* and *M. baccata*.

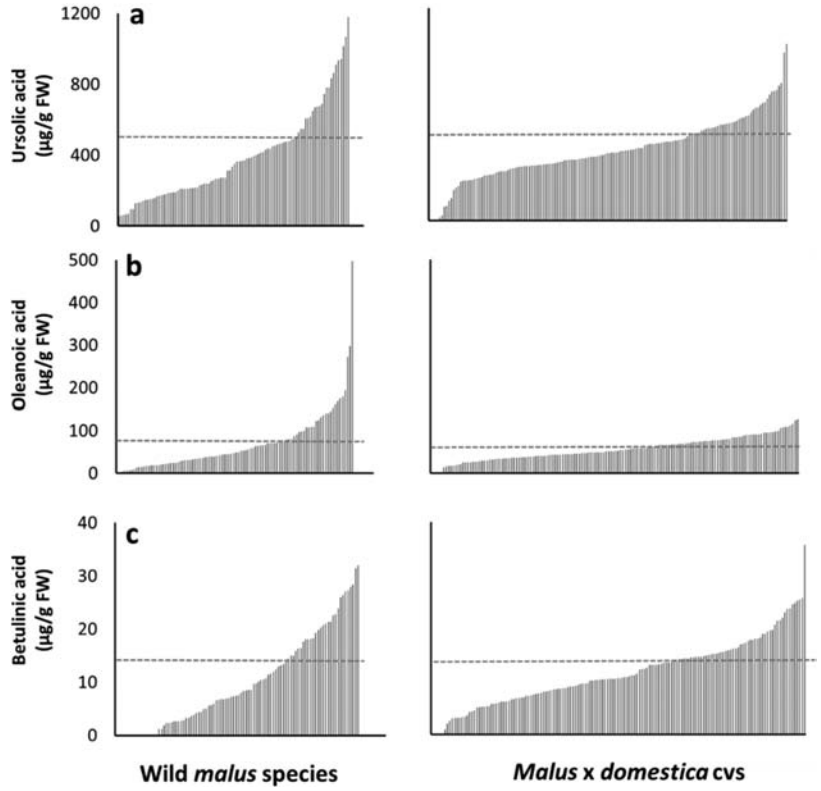

Figure 4. Bar chart plots of triterpenoid compound content (ursolic acids, oleanolic acid, and betulinic acid) assessed in the *Malus* germplasm (left column plots, 97 wild *Malus* accessions; right column plots, 150 *M.* × *domestica* cvs). The 75th percentile levels are represented by the dashed line. Distribution density plots of each compound class are reported in Supporting Information, Figure 2.

The main dihydrochalcone detected in *Malus* species is phlorizin.[20,22,27,35] Phlorizin content evaluated in this experiment significantly varied between *M.* × *domestica* and wild *Malus* accessions (Figure 3c and Supporting Information, Figure 1 and 2). A large number of wild *Malus* species, 25 in total, presented a phloridzine content higher than the maximum level discovered in *M.* × *domestica* cultivars. As a consequence, on the contrary from the other detected secondary metabolites, the distribution of wild *Malus* species based on phloridzin level turned out to be wider and not normally distributed (Supporting Information, Figures 2). Among the *Malus* species *M. ioensis*, *M. angustifolia*, *M. halliana*, *M. yunnanensis*, and *M. honanensis* showed the highest values. No significant differences were found between the old and the elite *M.* × *domestica* cultivars; remarkably, none of them reached the 75th percentile level (332 µg/g FW) recorded on the wild *Malus* species. In accordance with Ehrenkranz et al.,[27] all Renetta accessions (i.e., Renetta grigia, Renetta Canada, and Renetta Canada bianca) were characterized by a high phloridzin content (Supporting Information, Table 2); among the elite cultivars Renetta Canada was, indeed, the one with the highest content (144 µg/g FW).

As depicted by the PCA analysis (Figure 2a,b), fruits of *M.* × *domestica* differed from the ones of wild *Malus* species also due to the generally lower content of flavonols (quercetin-3-rhamnoside, isorhamnetin-3-glucoside, rutin, isorhamnetin-3-rutinoside, quercetin-3-glucoside, and quercetin-3- galactopyranoside; Figure 3d and Supporting Information, Figure 1). However, this separation based on flavonols content was not so distinctive as the discrimination based on hydroxycinnamic acid, stilbene, and dihydrochalcone levels (Figure 3a,b,c). Average value of flavonol content of *M.* × *domestica* cultivars was around 216 µg/g FW, without any relevant differences between elite and old cultivars, while for the wild *Malus* species, it was around 300 µg/g FW. Among the *M.* × *domestica* cultivars, Falchs Guldering, Roter Eiser, and Modì showed the highest flavonol content, whereas the highest among the wild *Malus* species was assessed on *M. halliana*, *M. kansuensis*, *M.* × *hartvigii*, and *M.* × *transitoria*.

Any relevant difference on flavan-3-ol average content (catechin, epicatechin, procyanidin B1, procyanidin B2, and procyanidin B4) was not detected between fruits of *M.* × *domestica* and wild *Malus* (Figure 3e and Supporting Information, Figures 1 and 2). *M. mandshurica*, *M. orientalis*, *M. angustifolia*, and *M. sieversii* were the wild *Malus* acessions with the highest content of flavan-3-ols, while Renetta Baumann, Blancje di Cattino, Lampone, and Aranciata di Cox were the predominant ones among *M.* × *domestica*.

Ordinarily, phenolic content of apple fruit is a relatively unstable trait among seasons due to the high influence of growing and climatic conditions.[24,43] However, repetition of analysis in the second year on a selected minor array of cultivars (23 cultivars, see Supporting Information, Table 1) revealed a reasonable stable total phenolic content with a correlation (R^2) of 0.78 between the two seasons (Supporting Information, Figure 5).

Triterpenoid Compounds. Despite a broad variation in triterpenoid content among wild *Malus* species as well as among *M.* x *domestic*a cultivars (Figure 4 and Supporting Information, Figures 1 and 2) any relevant differences based on triterpenoids (ursolic, oleanolic, and betulinic acids) average content were not discovered (Table 1). Only a minor pool of

J. Agric. Food Chem. 2015, 63, 2750−2759

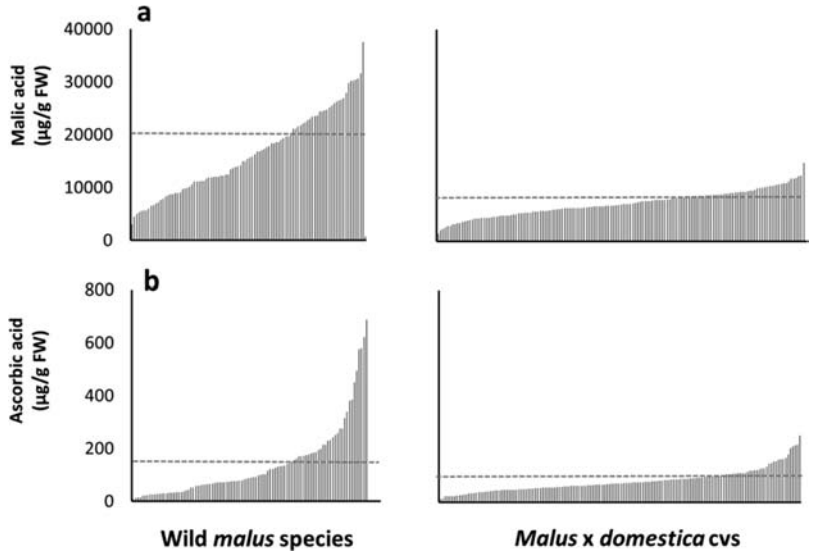

Figure 5. Bar chart plots of organic acid content (malic acid and ascorbic acid) assessed in the *Malus* germplasm (left column plots, 97 wild *Malus* accessions; right column plots, 150 *M.* × *domestica* cvs). The 75th percentile levels are represented by the dashed line. Distribution density plots of each compound class are reported in Supporting Information, Figure 2.

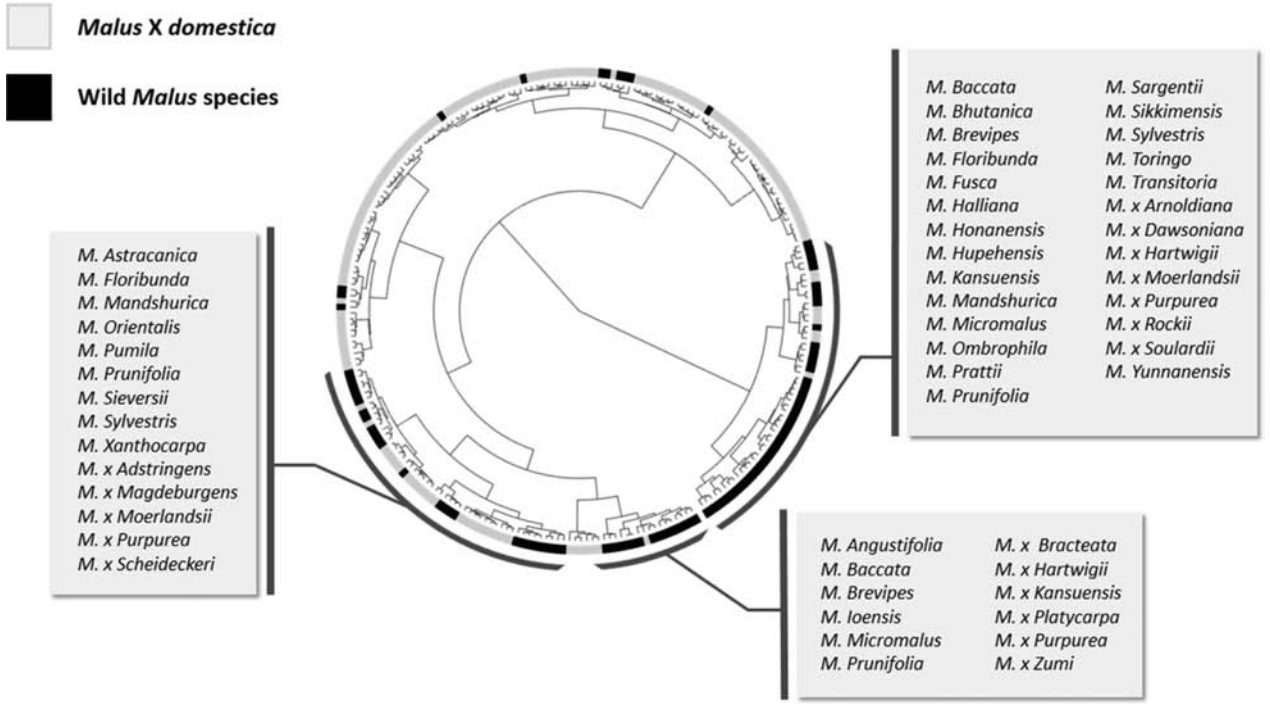

Figure 6. Polar dendrogram based on the cluster analysis performed in the apple germplasm (black, 97 wild *Malus* accessions; light gray, 150 *M.* × *domestica* cvs). Cluster analysis was performed using Ward's method on log transformed data of bioactive compounds content. A high resolution vector form chart is reported in Supporting Information, Figure 6.

wild *Malus* species (*M. ioensis*, *M.* × *soulardii*, and *M. orientalis*) was characterized by a relatively higher content of oleanolic acid (from 4 to 7 times higher fold value with respect to the average content). These irrelevant dissimilarities between *M.* × *domestica* and wild *Malus* accessions may indicate a low pressure of apple domestication and breeding on the expression of this metabolic trait. Up to now, indeed, the content of triterpenoids was not a chief quality trait for apple breeding programs, even though recent studies depicted a possible remarkable role of triterpenoids as functional metabolites for human health.[20,30,32,44] In addition, variation in triterpenoids content, mainly of the fruit skin, ensued to have a possible role in enhancing fruit storability and in inducing resistance to abiotic and biotic stress.[45,46]

Repetition of analysis in the second year on a selected small range of cultivar (n = 23) revealed a correlation (R^2) of 0.50 (Supporting Information, Figure 5). The lower correlation for triterpenoids, in comparison with the other metabolites investigated in this study, may reflect their skin location, which is more exposed to the environment compared to the flesh.

J. Agric. Food Chem. 2015, 63, 2750−2759

Organic Acids. Malic acid is known to be the most abundant organic acid in apple (Table 1 and Supporting Information, Figures 1 and 2). Differences in malic acid content between *M.* × *domestica* and wild *Malus* species were evident. In fact, most of the wild *Malus* accessions and several old apple cultivars (i.e., Gelber Edelapfel, Tiroler Spitzlederer, or Osnabrücker Renette) were characterized by a significant higher content of malic acid (Figure 5a and Supporting Information, Figures 1 and 2). Considering the fruit acidity level, one of the main quality traits for apple fruit breeding and selection,[47,48] these results confirmed the loss of acidity throughout apple domestication.

Similar results were found also for the ascorbic acid content (Figure 5b, and Supporting Information, Figures 1 and 2). Wild *Malus* species showed a 2-fold higher average value of ascorbic acid than *M.* × *domestica* cultivars. Only 5 over the 150 *M.* × *domestica* cultivars analyzed (cvs Schöner von Nordhausen, Calvilla bianca d'inverno, Renetta Ananas, Gelber Edelapfel, and Zuccalmaglio) had an ascorbic acid content higher than the 75th percentile (176 μg/g FW) assessed in wild *Malus* species. Repetition of analysis in the second year on a selected small range of cultivar (n = 23) revealed a stable total content of ascorbic acid (Supporting Information, Figure 5) with a correlation (R^2) between the two seasons of 0.77. Healthy benefits of apple consumption were generally associated with the high phenolic content rather than the ascorbic acid content since ascorbic content of apples was considered inferior than other commonly consumed fruit and vegetables such as strawberries, oranges, tomato, spinach, or kiwifruit.[34,49−51] Bearing in mind the high average daily intake of apple fruit, these results depicted how inappropriate this generalization is since several *M. domestica* cultivars and in particular a group of wild *Malus* species showed an ascorbic acid content comparable to or even greater than that of other ascorbic acid rich fruits.

Metabolic Phylogenetic Organization of the Genus *Malus*. In the geographical area of apple domestication (Central Asia), more than 40 different species have been characterized.[52] According to the genetic information available to date, the most closely related species to *M.* × *domestica* are represented by *M. asiatica*, *M. baccata*, *M. micromalus*, *M. orientalis*, *M. prunifolia*, *M. siversii*, and *M. sylvestris*. This set of species was included in the final list of 247 accessions considered for this investigation and clustered in a polar dendrogram based on their metabolic content (Figure 6). The grouping performed employing the Ward's algorithm reveals four clades, showing a clear distinction between the several wild *Malus* species (clustered toward the outer edges of the dendrogram) and the *M.* × *domestica* varieties (for the most located in the central portion of the cluster), besides some specific cases. Within the group of the *M.* × *domestica* varieties, three particular *Malus* species were retrieved: *M. sieversii*, *M. pumila*, and *M. floribunda*. It is worth noting that the specific organization of the *Malus* species based on the accumulation of secondary metabolites showed a high consistency with the phylogenetic organization known for apple. *M. sieversii*, which is closely located to the domesticated varieties, was recognized as the closest ancestor to *M.* × *domestica*, especially for fruit quality traits.[53] Genetic analysis carried out during the effort of the "Golden Delicious" genome sequencing confirmed that *M.* × *domestica* derived by *M. sieversii* species.[54] This work also reported that due to the "instant domestication" process occurring in apples, *M. sieversii* and *M.* × *domestica* could be actually considered as a single species, named *M. pumila*. This finding additionally validates the reliability of the metabolic assessment performed here that positioned *M. pumila* within the *M.* × *domestica* group and close to the *M. sieversii* accessions.

Another wild species located within the group of *M.* × *domestica* interesting to note is represented by *M. floribumnda*. This is the most used genetic resource to introgress the *Vf* gene, conferring the natural resistance to scab, the most severe fungal disease in apple.[55,56] This species was in fact largely used in breeding programs, enabling the release of the resistant cultivars available nowadays on the market. One of these varieties, "Ligol", was also included in the set investigated here. The fact that "Ligol" was closely clustered to a *M. floribunda* accession additionally confirms that secondary metabolites play a fundamental role in the control of pathogen attack, favorable for the creation of disease resistant varieties.

In this work, we employed a comprehensive characterization of the several nutraceutical compounds presented in apple fruit, phenols, triterpenoids, and ascorbic acid, by screening a broad collection of wild and domesticated *Malus* species. Results confirmed that the selection pressure of domestication and breeding did not uniformly affect all the phytochemicals contained in apple. For instance, organic acids (malic and ascorbic acids) and some phenolics (stilbenes, hydroxycinnamic acids, and dihydrochalcones) were significantly influenced by selection, while some other relevant flavonoids (flavonols and flavan-3-ols) and triterpenoids (ursolic, oleanolic, and betulinic acids) were not. In our opinion, these results may allow, in the near future, to assist in the selection of *Malus* accessions with specific nutraceutical traits suitable to establish innovative breeding strategies or to patent new functional foods and beverages fundamental to the human diet.

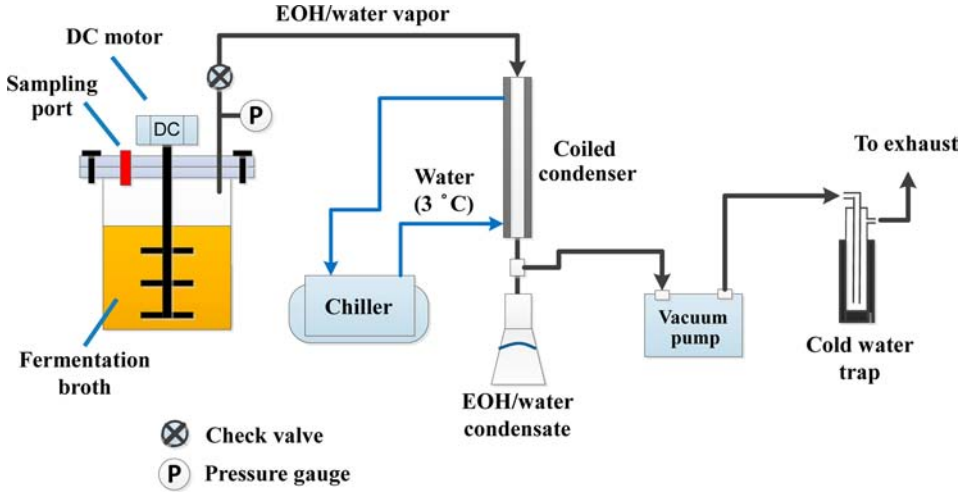

Figure 1. Experimental setup for the food waste fermentation with the vacuum stripping system. The arrows in the figure show flow direction. The vacuum fermentation system consisted of a 3 L water-jacked fermenter, a vacuum pump, a condensation system with a chiller and a coiled condenser, and a cold water trap. During the vacuum application, ethanol and water vapors evaporated from the fermentation broth and condensed in the condensation system. The escaped (uncondensed) ethanol and water vapors were collected in the cold-water trap.

following condensation system with cooling or chilling water. In the vacuum fermentation system, a low ethanol concentration can be maintained in the fermenter during fermentation, thereby eliminating or minimizing yeast ethanol inhibition.[23,27]

The objective of this study was to produce ethanol from food waste at high solids content with vacuum recovery technology. Fermentation of food waste at high solids content results in a very viscous mash and a high glucose concentration (which also inhibits yeast). To overcome this problem, granular starch hydrolyzing enzyme (GSHE) was used to directly digest raw starch in food waste at low temperatures (<48 °C) during simultaneous saccharification and fermentation. GSHE decreases the viscosity of the fermentation broth and reduces the yeast glucose inhibition by gradually breaking down starch to glucose during fermentation.[23,28]

MATERIALS AND METHODS

Design and Characterization of the Vacuum Recovery Process. The vacuum fermentation system was modified on the basis of the system reported by Shihadeh et al.[23] (Figure 1). It consisted of a 3 L jacketed fermenter (Biostat MD, Sartorius BBI Systems, Edgewood, NY), which was sealed and modified for accommodating thermocouples and venting and sampling ports. Slurry (fermentation mixture) was agitated by paddle-type blades driven by an alternating current (AC)/direct current (DC) motor drive (KD P/N 3402-008, Hurst, Princeton, NJ). The vacuum recovery system was connected to the fermenter venting port through a check valve (Figure 1). The evaporated ethanol and water vapor was condensed by passing through a coiled condenser (5977-19, Ace Glass, Vineland, NJ), which was circulated with chilled water at 3 °C from a refrigerated water bath (PolyScience 9106, Cole-Parmer, Vernon Hills, IL). The condensate was collected in a 250 mL conical flask. Vacuum was generated with a dry vacuum pump at 6.7 kPa (28 in Hg gauge) (DryFast model 2044, Welch, Niles, IL). Vacuum pressure was monitored at the fermentation vessel with a pressure gauge (45W1000, Ashcroft, Straford, CT). Vacuum outlet was connected to a cold-water trap (LG-11025, Wilmad Lab Glass, Buena, NJ) chilled with iced water, to collect the escaping ethanol vapors.

To evaluate the vacuum process for ethanol recovery from a dilute solution, the vacuum recovery experiment was conducted at 32 °C using a model ethanol solution in the fermenter. The initial ethanol concentrations in the model solution were 40, 80, and 160 g/L, respectively. Vacuum pressure at 6.7 kPa (28 in Hg gauge) was applied to the ethanol model solution for 1 h, during which the model solution boiled and the vapors were condensed in a 250 mL conical flask. At the completion of each vacuum application, the remaining solution in the fermenter, the condensate in the conical flask, and the solution in the cold water trap were collected and analyzed for volumes and ethanol concentrations.

Experimental Materials and Reagents. The food waste was obtained from a local retail store in Urbana, IL, and mainly contained mashed potatoes, sweet corn, and white bread and was used as a model food waste. The moisture content of the food waste was 64.0%. The composition of the food waste (dry matter basis) was 63.5% starch, 4.3% glucose, 13.9% protein, 4.1% oil, 5.2% neutral detergent fiber, and 3.4% ash. The procedures of the composition measurements are provided in Analytical Procedures and Calculations. The high starch content in the food waste sample was very similar to the sample reported in the previous study.[29] Received food waste was pulverized and mixed using a fruit/vegetable mixer for 3 min, analyzed for moisture content, and stored at 4 °C for the following experiments. For the fermentation slurry preparation, 10 N sulfuric acid (Ricca Chemical, Arlington, TX), solid urea (Fisher Scientific, Waltham, MA), and active dry yeast (Ethanol Red, Fermentis, Lesaffre Yeast, Milwaukee, WI) were used. Enzymes used in the fermentation processes were GHSE (Stargen 002) and protease (GC 212) obtained from Dupont Industrial Biosciences (Palo Alto, CA). Stargen 002 contained *Aspergillus kawachi* α-amylase expressed in *Trichoderma reesei* and a glucoamylase from *Trichoderma reesei* that work synergistically to hydrolyze granular starch substrate to glucose, and it had an activity of ≥570 GSHU/g (where GSHU = granular starch hydrolyzing units). Protease enzyme, GC 212, was obtained by fermentation of a selected strain of *Aspergillus niger* and was able to hydrolyze peptide bonds along a protein chain. It had an activity of 2000 SAPU/g (where SAPU = spectrophotometer acid protease units).

Conventional Fermentation in a Batch Reactor. Fermentation slurry at 35% solid contents (w/w) was prepared by mixing 500 g of dry weight of mixed food waste with a calculated amount of deionized water. The fermentation slurry was then adjusted to pH 4.0 using 10 N sulfuric acid. Experiments were performed in a 3 L fermenter. The slurry was added with 3 mL of GSHE enzyme (Stargen 002), 0.2 mL of protease enzyme (GC 212), 2 mL of urea solution (50%, w/v), and 2 mL of prepared yeast culture. Yeast culture was prepared by dispersing 5 g of active dry yeast and 25 g of deionized water and agitated at 90 rpm at 32 °C for 20 min in an incubator shaker (C24 incubator shaker, New Brunswick, NJ). Fermentation was conducted for 72 h at 32 °C with continuous agitation at 30 rpm. The enzymatic

DOI: 10.1021/jf5054029
J. Agric. Food Chem. 2015, 63, 2760−2766

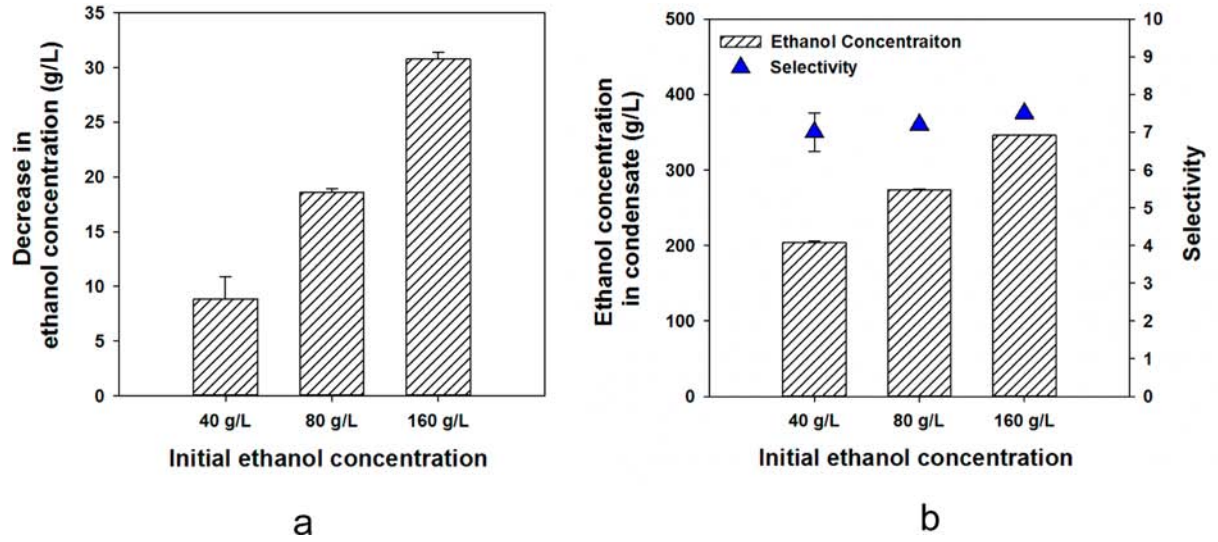

Figure 2. (a) Decrease in ethanol concentrations in the fermenter and (b) ethanol concentrations in the condensate and the vacuum selectivity after 1 h, with vacuum application of the model solution at different initial concentrations.

hydrolysis gradually reduced the slurry viscosity, thus causing an increase in revolutions per minute (rpm) of the agitator higher than 30. Therefore, the agitation rate was checked and manually reset to 30 rpm after each sampling. Fermentation was monitored by taking 1 mL of slurry sample at 4, 8, 12, 24, 36, 48, and 72 h and measuring sugars, ethanol, glycerol, and acid concentrations using high-performance liquid chromatography (HPLC) with at least two determinations. Fermentation was conducted in triplicates.

Vacuum Fermentation. The slurry used for the vacuum fermentation was the same as that used for the conventional fermentation experiments. The developed vacuum recovery system was used (Figure 1). The fermentation was allowed to proceed for 24 h, during which the ethanol concentration approached around 100 g/L and was followed by ethanol recovery by the vacuum stripping (6.7 ± 0.2 kPa), during which broth in the bioreactor boiled at the fermentation temperature, generating ethanol and water vapors. Ethanol and water vapors were then condensed in the coiled condenser at 3 °C and collected in the conical flask. The outlet from the vacuum pump was connected to the cold-water trap, to collect the uncondensed ethanol vapors. Foaming, caused by CO_2 bubbling during the initial vacuum application, was controlled by increasing the agitation rate to 60 rpm and gradually increasing vacuum to the set point. At the completion of each vacuum application, vacuum was stopped and filtered air (filter = 0.2 μm) was introduced gradually to the system until pressure equilibrated to atmosphere. Samples were taken before and after each vacuum application to monitor the immediate effect of vacuum stripping on the ethanol concentration in the fermentation broth. Also, the condensate in the conical flask and the solution in the cold-water trap were collected and analyzed for volumes and ethanol concentrations, to calculate the ethanol yield at each time period. Fermentation was conducted in triplicates.

Analytical Procedures and Calculations. The moisture content of the food waste was determined by drying samples in a forced-draft oven at 135 °C for 2 h.[30] The glucose and starch concentrations in the food waste was measured by the modified dilute acid method.[31] The crude protein, oil, and ash concentrations in the food waste were determined according the AOCS Official and Tentative Methods Ba 4e-93, Am 5-04, and Ba 5a-49, respectively. The neutral detergent fiber concentration in the food waste was determined using the ANKOM$^{200/220}$ fiber analyzer (ANKOM Technology, Macedon, NY).[32] Fermentation samples were analyzed with HPLC (column, Aminex HPX-87H organic acid, Bio-Rad, Hercules, CA; system, Breeze, Waters Corporation, Milford, MA) for glucose, ethanol, glycerol, and acetic acid concentrations. Broth samples were centrifuged for 3 min at 11000*g* (model 5425, Eppendorf, Westbury, NY). Supernatants were filtered through a 0.2 μm filter into a 0.2 mL HPLC vial insert. Ethanol productivity or ethanol production rate was calculated as the produced ethanol (g/L in broth) divided by the fermentation time period. The ethanol yield was defined as total grams of ethanol produced per kilograms of dry food waste.[11,12,33] Ethanol conversion efficiency was calculated by the ratio of actual ethanol yield over theoretical ethanol yield, which was based on the starch and sugar contents in the food waste.[34] Because both ethanol and water in the fermentation broth evaporated during the vacuum application, ethanol selectivity was calculated to measure the preferential removal of ethanol over other components (water in this case). The ethanol selectivity was calculated as

$$\alpha = \frac{y/(1-y)}{x/(1-x)}$$

where x and y are weight fractions of ethanol in fermentation broth and condensate, respectively.

RESULTS AND DISCUSSION

Characterization of Vacuum Technology for Ethanol Recovery. To study the ethanol recovery characteristics under the vacuum application, ethanol recovery experiments were conducted using model ethanol solution at different initial ethanol concentrations (40, 80, and 160 g/L), which covered the possible ethanol concentration range in the food waste fermentation. After 1 h of vacuum application, the ethanol concentration in the model solution decreased by 9−31 g/L, depending upon the initial ethanol concentrations in the model solution. As the initial ethanol concentration in the fermenter increased from 40 to 160 g/L, a greater decrease in the ethanol concentration was observed after the vacuum stripping (Figure 2a). This trend agrees well with the previous studies,[35] which used vacuum technology to remove butanol during fermentation. For a successful application of vacuum stripping to ethanol recovery, the ethanol removal rate should be greater than the ethanol production rate by fermentation, to avoid the ethanol accumulation in the fermentation broth. The ethanol removal rates (9−31 g L^{-1} h^{-1}) in this study were higher than the ethanol production rates (<5 g L^{-1} h^{-1}), as shown in Figure 4. Therefore, the developed vacuum recovery system could be applied to maintain ethanol concentrations in broth at low levels and reduce yeast ethanol inhibition.

J. Agric. Food Chem. 2015, 63, 2760−2766

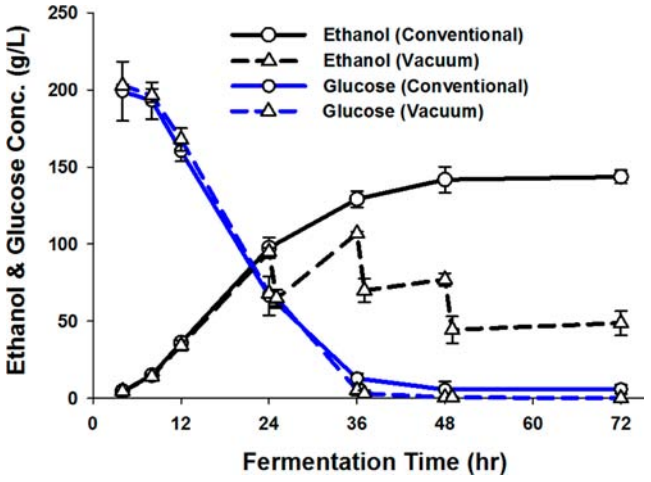

Figure 3. Ethanol and glucose concentrations during SLSF in both conventional and vacuum fermentations.

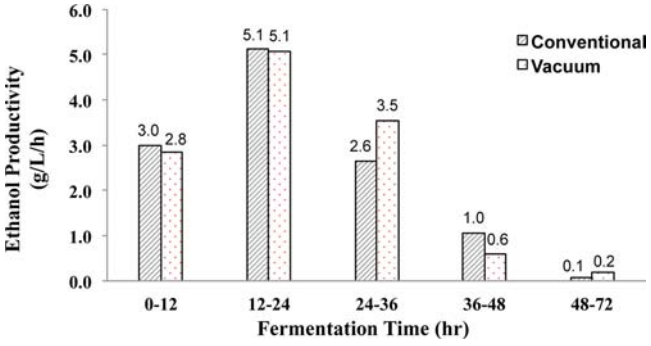

Figure 4. Ethanol productivity in the conventional and vacuum fermentation.

The ethanol concentration in the condensate was found to be much higher than that in the model solution in the fermenter (Figure 2b). The ethanol concentrations in the condensates were 204, 274, and 346 g/L, when the initial ethanol concentrations in the fermenter were 40, 80, and 160 g/L, respectively. This indicates that the vacuum recovery system not only removes ethanol from the fermentation broth but also concentrates it. Selectivity is a variable commonly used to evaluate the ability of a product recovery technology to separate a target product (ethanol in this case) from a mixture. Figure 2b shows that the initial ethanol concentrations in the model solution did not have large effects on the ethanol selectivity. The selectivity was found to be close to 7 for the model solution with all three ethanol concentrations.

Conventional Ethanol Fermentation. The conventional fermentation without vacuum application was conducted in a batch mode. Figure 3 shows the ethanol and glucose concentrations during 72 h of fermentation. The glucose concentration was 199 g/L at 4 h and decreased rapidly during the fermentation process. The ethanol concentration increased to 144 g/L at the end of the fermentation. The residual glucose concentration was 5.7 g/L at 72 h (Table 1), indicating an incomplete fermentation in the batch fermenter. The major reason for fermentation cessation before the exhaustion of glucose was probably due to the high ethanol concentration, which can inhibit yeast.[23,26] Nevertheless, the final ethanol concentration of the batch fermentation was higher than that from the previous studies (Table 2), where the final ethanol concentrations in the broth were between 9 and 82 g/L. The high ethanol concentrations obtained in this study were mainly attributed to the high solids content slurry used for the fermentation and the high starch concentration in the food waste. Higher ethanol concentrations in the fermentation broth can decrease the distillation energy costs, thereby reducing the related capital and operation costs for the conversion of food waste to ethanol.

Table 1. Comparison of Ethanol Fermentation of Food Waste with and without Vacuum Stripping

	residual glucose (g/L)	ethanol yield (g/kg of food waste)	conversion efficiency (%)
conventional fermentation	5.7 ± 2.0	326.5 ± 5.4	85.4 ± 1.4
vacuum fermentation	0.0 ± 0.0	357.5 ± 13.0	93.6 ± 3.4

Table 2. Production of Ethanol from Food Wastes from Different Sources

source of food waste	solid content for fermentation	final ethanol concentration (g/L)	reference
cafeteria	12.1% (w/w)	29.1	15
cafeteria	16.3−19.0% (w/v)	45.0	22
cafeteria	12.9% (w/w)	8.9−55.7	39
dinning room	<20.5% (w/w)	75.9−81.5	29
household	35 and 45% (w/v)	34.9 and 42.8	11
retail store	35% (w/w)	144	this study

Ethanol Fermentation with Vacuum Stripping. To assess the performance of simultaneous ethanol fermentation and recovery by vacuum stripping, the vacuum recovery system for the food waste fermentation was applied. During the 72 h fermentation, vacuum stripping was applied for 1 h at 24, 36, and 48 h, respectively. Figure 3 shows the ethanol and glucose concentrations during fermentation. In the first 24 h, the ethanol concentration increased rapidly to 95 g/L because of sufficient glucose in the fermentation broth. After 1 h of vacuum application, the ethanol concentration decreased to 64 g/L, because of the evaporation of ethanol under the vacuum condition. The ethanol concentration in the fermentation broth decreased by 31, 37, and 33 g/L, when vacuum stripping was applied for 1 h at 24, 36, and 48 h, respectively. Overall, the vacuum stripping successfully removed ethanol and controlled ethanol concentrations below 100 g/L in the fermentation broth, thus reducing yeast ethanol inhibition.

The glucose concentration was 203 g/L in the fermentation broth at 4 h and decreased rapidly to a negligible amount at 36 h (Figure 5). At the end of fermentation (72 h), there was no residual glucose left (Table 1), indicating a complete fermentation in this study. This was mainly due to the reduced ethanol inhibition by controlling the ethanol concentrations at low levels in the broth with the vacuum application. To note, even at 0 g/L glucose concentration, the ethanol concentration was shown to increase slightly between 48 and 72 h. This may be due to glucose being slowly released during the simultaneous liquefaction, saccharification, and fermentation (SLSF) with GSHE enzyme, and yeast used glucose faster than it was released by hydrolysis of the food waste. This phenomenon was also reported in the previous studies when corn or wheat straw was used as the substrate for the simultaneous saccharification and fermentation to produce ethanol or butanol.[23,28,36]

J. Agric. Food Chem. 2015, 63, 2760−2766

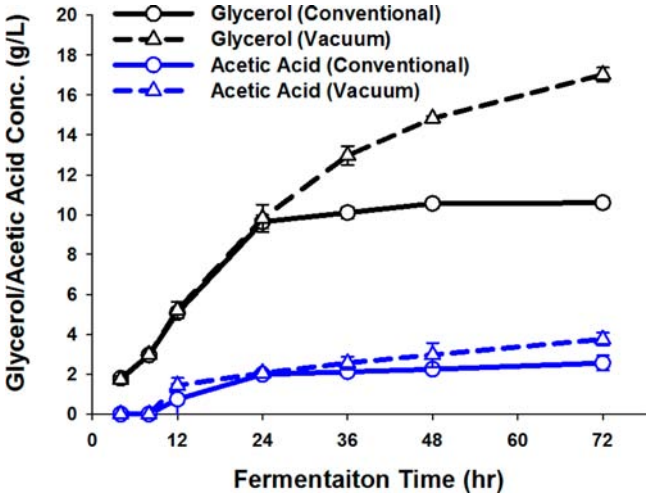

Figure 5. Byproduct (glycerol and acetic acid) concentrations during 72 h of fermentation of the food waste.

Comparison between Ethanol Fermentation with and without Vacuum Stripping. The residual glucose concentration, ethanol yield, and conversion efficiency for both the conventional and vacuum fermentations are presented in Table 1. The ethanol yield for the conventional fermentation was found to be 327 g/kg of food waste (dry matter), while the ethanol yield for the vacuum fermentation was 9% higher at 358 g/kg of food waste. This finding was in agreement with the residual glucose concentrations and the conversion efficiency in Table 1. As discussed above, the residual glucose was zero in the vacuum fermentation but was 5.7 g/L in the conventional fermentation because of yeast ethanol inhibition, which lowered the ethanol yield. The ethanol conversion efficiency for the vacuum fermentation was 93.6%, higher than that for the conventional fermentation efficiency at 85.4%, showing the advantages of applying the vacuum recovery system to the fermentation process. Considering that some sugar was used for yeast growth and that there were other metabolites produced (glycerol, succinic and acetic acids, etc.),[37] the ethanol conversion by vacuum application at 93.6% was quite satisfactory. Overall, the vacuum fermentation showed some advantages over the conventional fermentation for food waste, in terms of the ethanol yield and conversion efficiency.

For the vacuum recovery system, the fermentation design is more complex compared to the conventional fermentation. The energy consumption for vacuum pumps and chilling required for condensation of evaporated ethanol may be high. However, the increase in the ethanol yield and productivity could potentially offset the increased cost of energy for vacuum pumps and chilling. For example, a 9% increase in the ethanol yield in a 50 million gallon capacity ethanol plant (typical size in the U.S.) means an additional 4.5 million gallons of ethanol, which can generate multimillion dollars for the plant. A detailed techno-economic evaluation of vacuum recovery fermentation is warranted to determine its economic viability.

Ethanol productivity for both the conventional and vacuum fermentations at different time periods are shown in Figure 4. The ethanol productivities at 0−12 and 12−24 h time periods were very close between the conventional and vacuum fermentation, because the vacuum stripping was not applied until 24 h. During the time period from 24 to 36 h, the ethanol productivity for the vacuum fermentation (3.5 g L^{-1} h^{-1}) was higher than that for the conventional fermentation (2.6 g L^{-1} h^{-1}), which again was because of the relieved ethanol inhibition by applying the vacuum stripping. During the time period from 36 to 48 h, the ethanol productivity for the vacuum fermentation was 0.6 g L^{-1} h^{-1}, while the ethanol productivity for the conventional fermentation was higher at 1.0 g L^{-1} h^{-1}. This was probably due to the higher amount of glucose left in the conventional fermentation during this time period (Figures 2 and 3). Matsakas et al.[11] summarized various studies on food waste fermentations and showed that the ethanol productivities were between 0.49 and 4.11 g L^{-1} h^{-1}, which was very close to the values showed in Figure 4 in this study.

Glycerol is a byproduct of yeast metabolism, and its production amount was less than ethanol and carbon dioxide during yeast ethanol fermentation. A higher amount of glycerol production usually indicates increased yeast stress.[37] In this study, the glycerol concentrations in the fermentation broth were higher during the vacuum fermentation (17 g/L) than the conventional fermentation (10 g/L) (Figure 5). It was because the removal of ethanol and water from the fermentation broth by vacuum stripping concentrated the glycerol in fermentation broth. A higher glycerol concentration could inhibit yeast metabolism; however, a review of the literature shows that the glycerol inhibition is not significant until it reached 100 g/L.[38] Therefore, the accumulated glycerol by the vacuum recovery system was not a factor in our study. Again, because of the concentration effect, the organic acid (acetic acid) concentrations were higher during the vacuum fermentation than the conventional fermentation (Figure 5). It is noteworthy that no glycerol or acetic acid was found in the condensate.

In conclusion, food waste at high solids content (35%, w/w) was used to produce ethanol with and without the vacuum recovery technology. After 72 h of fermentation, the ethanol concentration in the fermentation broth was 144 g/L for the conventional fermentation. The residual glucose concentration at 72 h was 5.7 g/L, indicating an incomplete fermentation. The conventional fermentation produced 327 g of ethanol from each kilogram of food waste. The vacuum fermentation process integrated with product recovery successfully controlled the ethanol concentration in the fermentation broth below 100 g/L, thereby reducing yeast ethanol inhibition. The vacuum fermentation allowed for complete utilization of glucose in the fermentation broth and produced 358 g of ethanol from each kilogram of food waste. The ethanol conversion efficiency for the vacuum fermentation was 93.6%, higher than that for the conventional fermentation at 85.4%.

anticancer activities in triggering apoptosis, activating PKC-delta/caspase-3 proteins, and down-regulating the proto-oncogenes in MCF-7 and HeLa cancer cell lines.[27] It is particularly meaningful that PEs could be an important starting material for the synthesis of a promising anti-AIDS drug, prostratin.[28,29]

Similar to the discovery in a recently published paper,[14] our previous published paper disclosed that the total content level of PEs (equivalent to TPA) using the internal standard method at 280 nm is 20 times over that using the external standard method,[15] because the λ_{max} of UV absorbance of TPA is at 242 nm.[14,15] Hence, the purity of PEs is generally regarded as 100% (equivalent to TPA), which is actually below 5%.[16] In this regard, it is very necessary to acquire high-purity PEs to revaluate their toxicity and bioactivity.

At present, continuous liquid−liquid extraction, silica gel column chromatography, and semipreparative HPLC are the conventional strategies for separation and purification of PEs from *J. curcas* seeds.[13−15,17,26] Considering the rapid growth in the jatropha biodiesel industry, the appropriate utilization of PEs (as a byproduct of *J. curcas* seeds) could contribute to enhancing the economic viability and sustainability of the *J. curcas* production chain. It is necessary to establish an effective and rapid method for separating the PEs with a high recovery rate. In this work, PEs were successfully isolated and purified from *J. curcas* seeds by high-speed countercurrent chromatography (HSCCC). In addition, a combined HSCCC and semipreparative HPLC method was established to purify JC1. Furthermore, UPLC−PDA and UPLC−MS were also developed and established to analyze characteristics of the isolated JC1 and the PE-rich crude extracts.

MATERIALS AND METHODS

Materials. Methanol and acetonitrile (HPLC grade) were purchased from Swell Scientific Instruments Co., Ltd. (Chengdu, China). Formic acid (HPLC grade) was purchased from the Chengdu Kelong Reagent Co., Ltd. (Chengdu, China). Water (HPLC grade) was prepared using an ultrapure water system (UPA, Chongqing, China). All of the other reagents used in the present study were of analytical grade. TPA (99%, CAS Registry No. 16561-29-8) was obtained from Sigma-Aldrich (Shanghai, China). *J. curcas* seeds were collected from Xichang (Sichuan, China) in 2013 and were identified by Prof. Tang Lin (Sichuan University).

PE-Rich Crude Extract Preparations. A fine powder of dried *J. curcas* seeds (3.10 kg) was extracted by ethyl acetate (20 L) at room temperature two times (each for 24 h). All the filtrates were combined and concentrated under reduced pressure by a rotary evaporator at 45 °C to gain an oily substance (985.2 g), and 200 g of the oily substance was dissolved with methanol (1000 mL). Subsequently, the mixed solution was frozen at 4 °C for 24 h to produce an upper clarification layer of methanol (PE-rich solution) and a precipitate (168.3 g). The upper methanol layer was concentrated under reduced pressure by rotary evaporation at 55 °C to obtain PE-rich crude extract (23.8 g).

HSCCC Separation Apparatus. A TBE-300C HSCCC (Shanghai Tauto Biotech Co., Ltd., Shanghai, China) is coupled with a set of three multilayer coils and a 20 mL sample loop. The solvents were delivered by a TBP 5002 pump (Shanghai Tauto Biotech Co., Ltd., Shanghai, China). A DC-0506 constant-temperature circulating implement (Shanghai Sunny Hengping Scientific Instrument Co., Ltd., Shanghai, China) was used to control the separation temperature. The UV absorbance of eluent was monitored by a UV-2000 detector (Shanghai Sanotac Scientific Instrument Co., Ltd., Shanghai, China) at the wavelength of 280 nm. The data were collected by an Easy Chrom 1000 workstation (Beijing Qingbohua Ltd., Beijing, China). The temperature of the separation column was maintained at 25 °C. A FB-36/7 air compressor pump was used to force out the stationary phase.

Measurement of Partition Coefficient. Similar to previous studies,[30−34] the optimal two-phase solvent systems are evaluated with partition coefficient (K) and separation factor (α) by HPLC methods. K is defined as A_{upper}/A_{lower} of each analyte, in which, A_{upper} and A_{lower} are the HPLC peak areas of objective compounds in the upper and lower phases, respectively. α is defined as the proportion between the partition coefficients of the two components ($\alpha = K_1/K_2$, $K_1 > K_2$). The HPLC analysis was performed on an Agilent 1200 series system with a C18 column (4.6 × 250 mm, 5.0 μm) at 30 °C. The mobile phase was acetonitrile−water (80:20, v/v) at the flow rate of 0.8 mL/min. The detection wavelength was set at 280 nm. Briefly, a series of two-phase solvent systems (*n*-hexane−ethyl acetate−methanol−water = 1:1:1:1, 3:1:3:1, 2:2:3:1, 3:3:3:1, and 1.5:1.5:1.2:0.5, v/v) was screened as follows: approximately 0.1 mL of primary crude extract sample was placed in a 10 mL test tube, to which was added 2 mL of each phase of the equilibrated two-phase solvent system; the tube was rigorously shaken for 1 min and left to stand at room temperature until equilibrium was obtained. Then, 20 μL of the upper and lower phases was analyzed by HPLC at 280 nm, respectively.

Preparation of Two-Phase Solvent System and Sample Solution. The two-phase solvent system was prepared by adding each solvent to a separatory funnel. After shaking and thoroughly equilibrating at room temperature, the upper phase and lower phase were then separated and degassed ultrasonically for 30 min. The upper phase was used as the stationary phase while the lower phase as the mobile phase. The sample solution for HSCCC separation was prepared by dissolving 2 g of PE-rich crude extract in 20 mL of the lower phase.

HSCCC Separation Procedure. The multilayer coil column was first entirely filled with the stationary phase at a flow rate of 30.0 mL/min. The apparatus was rotated at 800 rpm and then the mobile phase was pumped into the column at a flow rate of 10 mL/min in the head-to-tail elution mode. The mobile phase eluting at the tail outlet indicated that hydrodynamic equilibrium had been reached. Subsequently, 20 mL of sample solution was injected into the column. The peak fractions were collected manually according to the elution profile and evaporated under reduced pressure.

Analysis and Characterization of HSCCC Fractions. PE-rich crude extract sample and each peak fraction obtained from HSCCC were analyzed by HPLC−UV using peak area calculation. The HPLC analyses were performed on an Agilent 1200 series system (Agilent Technologies) equipped with a quaternary pump, a vacuum degasser, an autoinjector, and an ultraviolet detector. The HPLC separation was performed on a C18 column (Ultimate, 4.6 × 250 mm, 4.7 μm, Welch Materials, Inc.) at 30 °C. The ultraviolet detector was set at 280 nm according to the λ_{max} of UV absorbance of PEs. All of the samples were eluted at 0.80 mL/min using an isocratic elution of acetonitrile and water containing 0.2% formic acid (80/20, v/v). Agilent Chemstation version B.04.01 was used for the system control and data acquisition.

Purification and Identification of JC1. A continuous repeated semipreparative HPLC method was applied to further purify the JC1. The separation of JC1 was performed on a reversed-phase C8 semipreparative column (Welchrom-C8, 10 × 250 mm, 5 μm) with an isocratic elution of acetonitrile−water (80:20, v/v) at a flow rate of 2.5 mL/min. The monitoring of the wavelength was set at 280 nm. The purity of JC1 was identified by HPLC. MS spectra of JC1 was measured in the positive mode ($[M + Na]^+$) using a microTOF-QII mass spectrometer (Bruker Daltonics).

UPLC−PDA and UPLC−MS Analysis of Isolated JC1 and PE-Rich Crude Extract. UPLC−PDA analyses were performed on an ACQUITY UPLC H-class system (Waters) equipped with a QSM quaternary solvent manager, an FTN autosampler manager, and an eLambda photodiode array detector. The chromatographic separation was performed on an Acquity UPLC BEH C18 column (1.7 μm, 2.1 × 150 mm, Waters) at 40 °C. All of the samples were eluted at 0.40 mL/min using an isocratic elution of solvent A and B (80/20, v/v), in which solvent A was composed of acetonitrile−water (90/10, v/v) containing 0.1% formic acid and 0.05% ammonium formate and solvent B was water containing 0.1% formic acid and 0.05% ammonium formate. The sample injection volume was 2 μL. The

detection range of the ultraviolet detector was set from 200 to 400 nm. Monitoring of the wavelength was set at 280 nm according to the λ_{max} of the UV absorbance of PEs. Empower software version 3.0 was used for the system control and data acquisition.

UPLC−MS analyses were performed on an ACQUITY UPLC I-Class-Xevo TQD System (Waters) interfaced with a Waters Quattro Premier XE triple quadrupole mass spectrometer equipped with electrospray ionization operated in the positive ionization mode. The chromatographic separation condition of the UPLC−MS analyses was the same as for the UPLC−PDA analyses. The source-dependent parameters maintained for the analytes were as follows: cone gas flow, 50 L/h; desolvation gas flow, 500 L/h; capillary voltage, 3.0 kV, source temperature, 120 °C; desolvation temperature, 500 °C. The optimum values for compound-dependent parameters of cone voltage and collision energy were set at 30 V and 10 eV. Detection of the ions was performed in the multiple-reaction monitoring (MRM) mode, by monitoring the transition pairs (precursor to product ion) of m/z for PEs. Mass Lynx software version 4.1 was used to control all parameters of UPLC and MS.

RESULTS AND DISCUSSION

Selection of the Two-Phase Solvent System. Five main peaks (regarded as JC1−JC5 according to their retention times, which appeared orderly in chromatograms) determined by HPLC were used to select the appropriate two-phase solvent system. The results of the partition coefficients (K) and separation factors (α) of these compounds in various two-solvent systems are listed in Table 1. According to the published papers,[30−34] the appropriate two-phase solvent system requires the following considerations: (1) the equilibrating time should be considerably short enough (<30 s); (2) K should be in a suitable range, usually between 0.2 and 5; and (3) α should be greater than 1.5. After repeated attempts, the two-phase solvent system composed of *n*-hexane−ethyl acetate−methanol−water (1.5:1.5:1.2:0.5, v/v) was considered as optimal for its appropriate K and α values.

Isolation of PEs Fractions by HSCCC. The retention of the stationary phase was 56.7%. Fraction peaks A and B were separated in 30 min with a total mobile elution volume of 300 mL (Figure 2A). Isolated fraction peaks A and B were analyzed by HPLC (Figure 2C.c2,c3). In the HSCCC separation, the expected result is five fractions (Figure 2C.c4). It should be noted that the main PE, JC1, can be isolated fast, and the purity increased from 48.5% to 85.0% (Figure 2C.c3,c4). Compared with the literature,[12−15] the conventional isolation methods of PEs, including liquid−liquid extraction and silica gel column chromatography, are time-consuming, require a large amounts of organic solvents, and typically require numerous steps, resulting in lower recovery and higher cost. In this work, the separation of PEs by HSCCC shows an excellent sample recovery, low cost, and high efficiency.

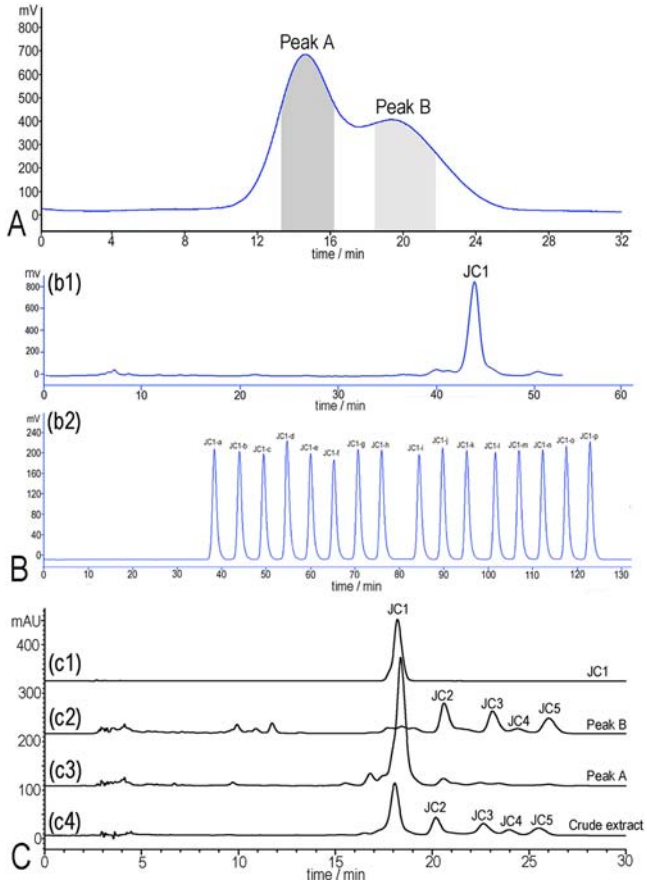

Figure 2. (A) Preparative HSCCC chromatogram of PE-rich crude extract from *J. curcas* seeds. (B) Primary semipreparative HPLC−UV chromatogram of fraction peak A isolated by HSCCC (b1), continuous semipreparative HPLC−UV chromatogram of JC1 using repeating sample injection at an interval of 5 min [the letters a−p (end-label of JC1) represent the continuous repeating sample injection order (b2)]; (C) HPLC−UV chromatograms of JC1 (c1), peak B fraction isolated by HSCCC (c2), peak A fraction isolated by HSCCC (c3), and PEs-rich crude extract (c4).

Purification and Identification of JC1. The semipreparative HPLC chromatogram of peak A is shown in Figure 2B.b1. Subsequently, JC1 was further purified by using continuous semipreparative HPLC through repeating sample injection at an interval of 5 min (Figure 2B.b2). The purity of JC1 measured by HPLC was 99.8% (Figure 2C.c1). The HR−MS spectrum of JC1 is shown in Figure 3C, and the molecular ion peak is 733.3695 m/z ($[M + Na]^+$). According to the papers published over 20 years, JC1 has the highest levels of all the PEs in *J. curcas* seeds.[12−15,17,26] Therefore, it is obvious that the isolated compound in this work is JC1.

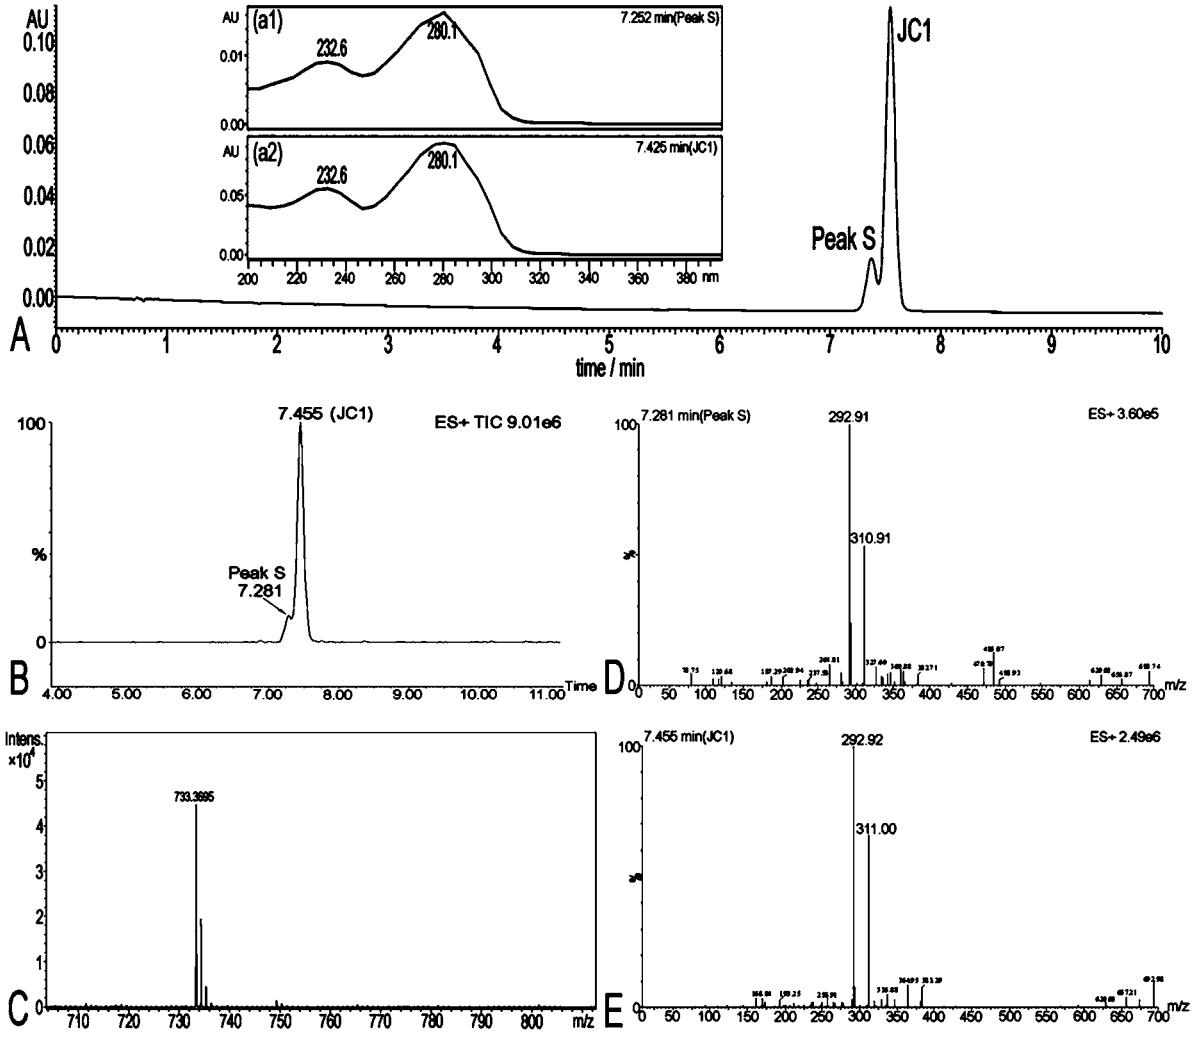

Figure 3. (A) UPLC−UV chromatogram of JC1 and peak S at 280 nm and the UV absorbance spectrogram of peak S (a1) and JC1 (a2). (B) TIC chromatogram of the JC1 and peak S. (C) MS spectrum of the JC1 and peak S. (D) Product ion MS spectrum of peak S. (E) Product ion MS spectrum of JC1.

UPLC−PDA and UPLC−MS Analysis of Isolated JC1 and PE-Rich Crude Extract. It was regrettable that the purity of JC1 was only 87.8% (Figure 3A) by UPLC using the peak area calculation method. It was easily to observe that there is a peak, labeled S, with a UV absorption spectrogram highly similar to that of JC1 (Figure 3A.a1,a2). As we known, the purity of JC1 was usually measured by conventional HPLC using the peak area calculation method in previously published papers.[13−15] The result of UPLC indicated that Peak S (Figure 3A) is difficult to separate from JC1 using conventional HPLC (Figure 2C.c1). Subsequently, UPLC−MS was established and successfully used to identify the characteristics of Peak S. Figure 3B showed the TIC chromatogram of JC1. In the positive ion mass spectra, peak S showed the same quasi-molecular ion peak ($[M + H - H_2O]^+$) at about 693.00 m/z and several similar sequence-specific fragment ions (at about 365.00, 311.00 and 292.90 m/z) as JC1 (Figure 3D,E). The molecular mass of the mother nucleus (12-deoxy-16-hydroxyphorbol, Figure 1) in JC1 is 364.4327, so the fragment ion at about 365.00 m/z was the mother nucleus ion peak ($[M]^+$); moreover, 311.00 and 292.90 m/z were the fragment ions $[M - 3H_2O]^+$ and $[M - 4H_2O]^+$ of the mother nucleus, respectively. Thus, it was easily deduced that peak S is the isomer of JC1.

Furthermore, the sample of JC1 showed only one peak with HPLC but contained another peak (peak S) by UPLC; this cast doubt on the five to seven PE peaks presented by *J. curcas* with the conventional HPLC method.[14−17,35] Thus, it was imperative to establish a high-resolution method to confirm this doubt. In this work, an UPLC−PDA method was developed and applied to analyze the PE-rich crude extract. In our recently published paper, when using a high-resolution C18 column (2.7 μm) instead of the conventional C18 column (4.5 μm), the HPLC−UV chromatogram at 280 nm of PE-rich crude extract showed more than nine peaks, five of which were main ones.[15] The content levels of PEs in *J. curcas* seeds or their related products are always calculated by the total amount equivalent to TPA using an internal standard method.[11,16,35] In this study, TPA was selected as an internal standard to establish the UPLC−PDA method for the PE-rich crude extract. The UPLC−UV chromatograms at 240, 280, and 304 nm of the PE-rich crude extract and TPA are shown in parts A, B, and C of Figure 4, respectively. It was interesting that more than 17 peaks were separated out at 280 nm (Figure 4B). However, similar to previous reports,[14−17] about five to seven peaks were exhibited in the HPLC−UV chromatogram at 280 nm (Figure 2C.c4). It is certified that the λ_{max} of PEs is always at about 280

DOI: 10.1021/jf505655b
J. Agric. Food Chem. 2015, 63, 2767−2772

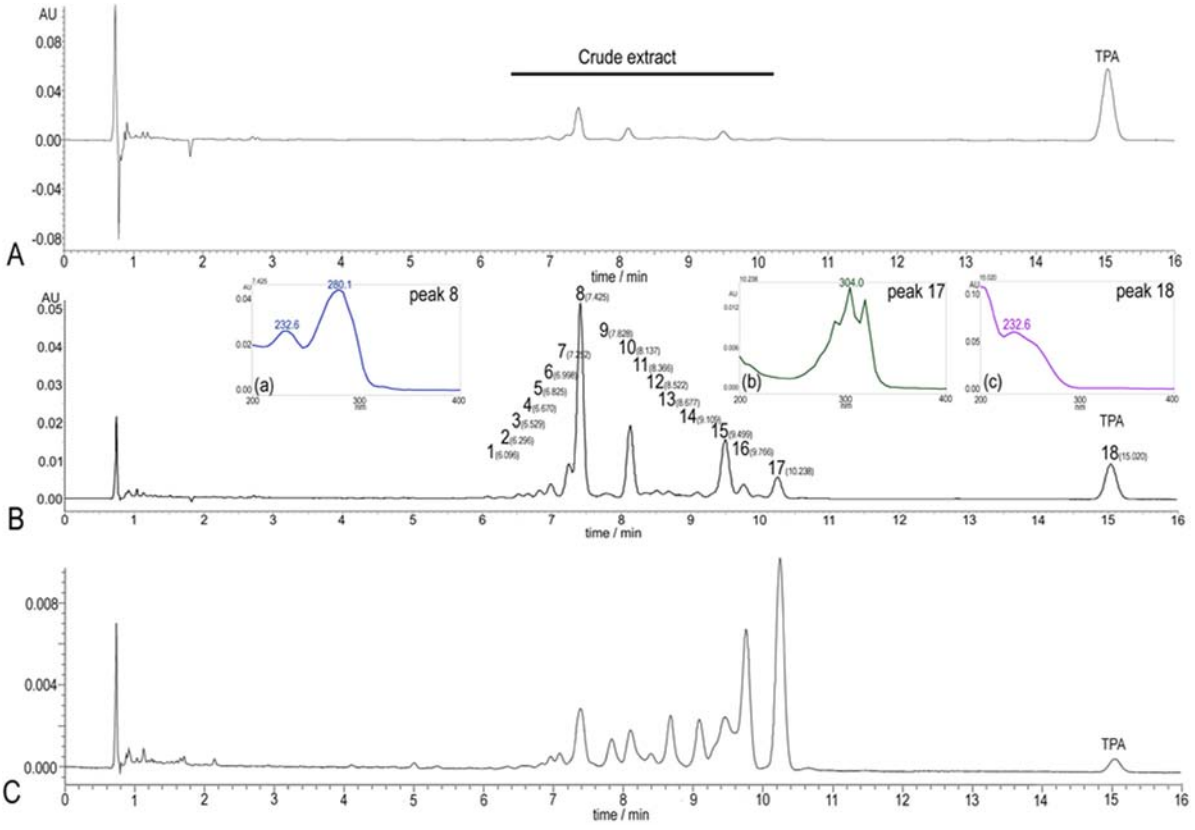

Figure 4. (A) UPLC−UV chromatograms of PE-rich extract and TPA at 240 nm. (B) UPLC−UV chromatograms of PE-rich extract and TPA at 280 nm, UV absorbance spectrogram of peak 8 (a), UV absorbance spectrogram of peak 17 (b), and UV absorbance spectrogram of peak 18 (c). (C) UPLC−UV chromatograms of PE-rich extract and TPA at 304 nm. (TPA is phorbol 12-myristate-13-acetate. "Crude extract" represents the main peaks detected from the PE-rich crude extracts, and 1−18 represent the order in which the peaks were detected during UPLC.)

nm, and the λ_{max} of TPA is at about 242 nm.[14,15] Obviously, the results of the UV absorption spectrogram also demonstrated the λ_{max} of more than 12 peaks was at about 280 nm, including peaks 1−8, 10−12, and 15, all of which were similar to peak 8 (JC1, Figure 4B.a), at the same time, their secondary λ_{max} was at about 232 nm similar to that of TPA (Figure 4B.c). It was easily deduced that there could exist more than 12 homologous compounds of PEs. However, four peaks (λ_{max} at about 304 nm), peaks 13, 14, 16, and 17 (Figure 4B.b), were significantly different from the peak of JC1. It is questionable whether these four peaks (λ_{max} at about 304 nm) are homologues of PEs.

UPLC−MS was used to further certify whether those four peaks are homologues of PEs. The TIC chromatogram of PE-rich crude extract is shown in the Supporting Material (Figure S1). In the positive-ion mass spectra, more than 15 compounds showed the same quasi-molecular ion peaks at about 693.00 ($[M + H - H_2O]^+$) in corresponding mass spectra (Supporting Information, Figure S1) and several similar sequence-specific fragment ions (at about 365.00, 311.00 and 292.90), all of which were similar to those of JC1 (Figure 3E). This indicates that these 15 compounds all contained the same mother nucleus. Therefore, these results indicate that the more than 15 compounds found by UPLC−MS are all homologues of PEs.

In this work, a rapid and efficient HSCCC method was developed and successfully applied to separate the PEs from *J. curcas* seeds. In addition, the combination of HSCCC and semipreparative HPLC was developed and successfully applied to purify the JC1. Meanwhile, the PE-rich crude extract from *J. curcas* was also analyzed by UPLC−PDA and UPLC−MS, and the results indicated there may be more than 15 analogues of PEs in *J. curcas* seeds. This work will enhance the economic viability and sustainability of the *J. curcas* production chain.

J. Agric. Food Chem. 2015, 63, 2767−2772

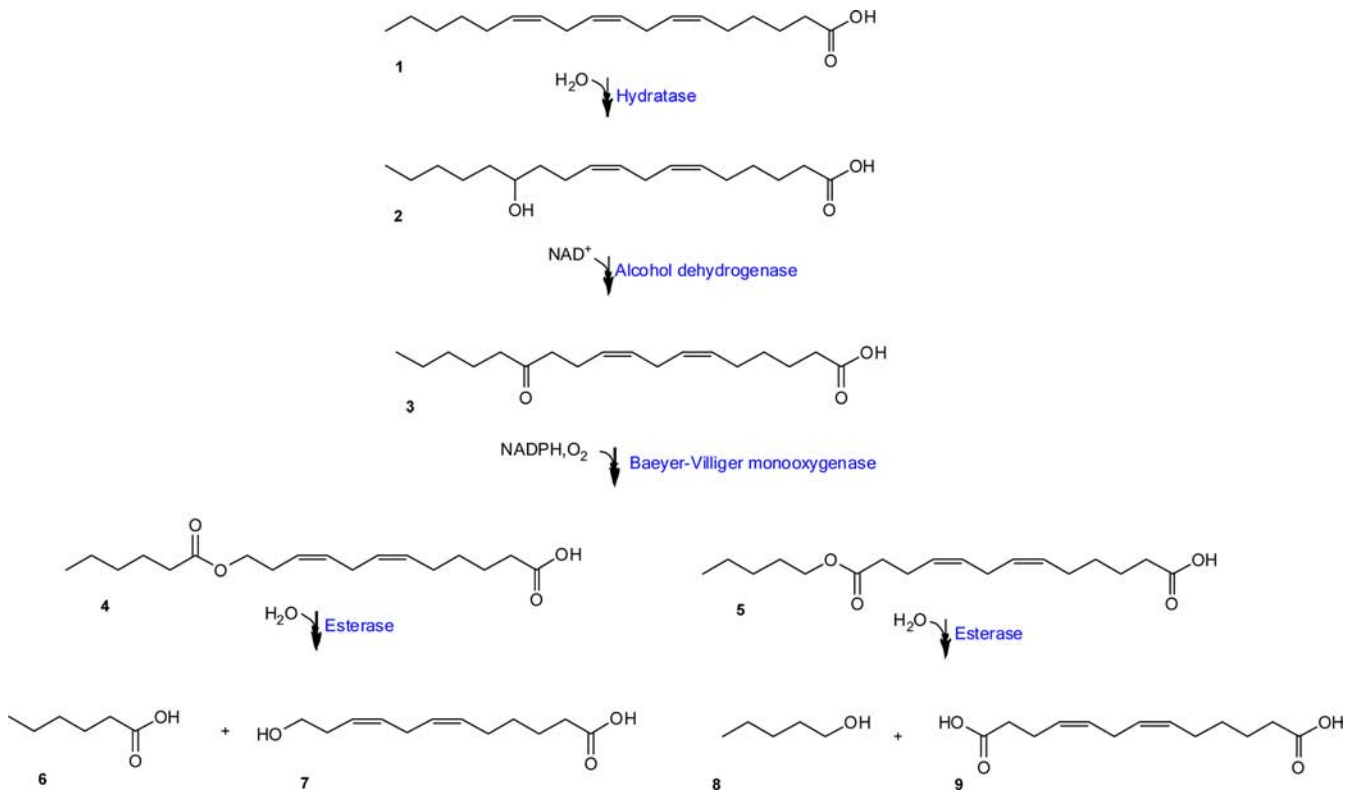

Figure 1. Designed biotransformation pathway 1. γ-Linolenic acid (**1**) was converted into *n*-hexanoic acid (**6**) and (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**) or *n*-pentanol (**8**) and (4*Z*,7*Z*)-trideca-4,7-dienedioic acid (**9**) by the multistep enzyme reactions.

hydratase gene was induced by adding 0.1 mM isopropyl-β-D-thiogalactopyranoside (IPTG) at an optical density (OD_{600}) of 0.5. Afterward, the culture was further incubated at 16 °C for 16 h. The recombinant *E. coli* BL21(DE3), used for hydration of γ-linolenic acid and biotransformation of hydroxy fatty acids, was cultivated in a Riesenberg medium, which was supplemented with 10 g L^{-1} glucose and the appropriate antibiotics for plasmid maintenance (Supporting Information Table S1). The Riesenberg medium consisted of 4 g L^{-1} $(NH_4)_2HPO_4$, 13.5 g L^{-1} KH_2PO_4, 1.7 g L^{-1} citric acid, 1.4 g L^{-1} $MgSO_4$, and 10 mL L^{-1} trace metal solution (10 g L^{-1} $FeSO_4$, 2.25 g L^{-1} $ZnSO_4$, 1.0 g L^{-1} $CuSO_4$, 0.5 g L^{-1} $MnSO_4$, 0.23 g L^{-1} $Na_2B_4O_7$, 2.0 g L^{-1} $CaCl_2$, and 0.1 g L^{-1} $(NH_4)_6Mo_7O_{24}$). *Stenotrophomonas nitritireducens* (Table S1) used for the hydration of the C9 double bond in γ-linolenic acid was cultivated in a nutrient medium as described previously.[23]

Reagents. γ-Linolenic acid (**1**), palmitic acid, *n*-hexanoic acid (**6**), *n*-pentanol (**8**), and ethyl acetate were obtained from Sigma-Aldrich. (6*Z*,9*Z*)-13-Hydroxyoctadeca-6,9-dienoic acid (**2**) and (6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid (**10**) were prepared via hydration of γ-linolenic acid with a linoleate C12 double-bond hydratase or a linoleate C9 double-bond hydratase in our laboratory (see Purification of Hydroxy Fatty Acids below for details). (6*Z*,9*Z*)-12-Hydroxydodeca-6,9-dienoic acid (**7**), (*Z*)-9-hydroxynon-6-enoic acid (**15**), (*Z*)-dec-4-enedioic acid (**17**), and (4*Z*,7*Z*)-trideca-4,7-dienedioic acid (**9**) were synthesized from (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**) or (6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid (**10**) via the recombinant *E. coli*-based biocatalysis in our laboratory (see Purification of Unsaturated Carboxylic Acids below for details).

Purification of a Linoleate C12 Double-Bond Hydratase. The linoleate C12 double bond-hydratase of *L. acidophilus* was purified as previously reported.[22] In brief, after cultivation of recombinant *E. coli* ER2566 harboring the linoleate C12 double-bond hydratase gene of *L. acidophilus*, the cell mass was harvested, washed, and resuspended into 50 mM phosphate buffer (pH 8.0) containing 300 mM NaCl, 10 mM imidazole, and 0.1 mM phenylmethanesulfonyl fluoride as a protease inhibitor. The resuspended cells were disrupted, and the supernatant was applied to a His-Trap HP chromatography column (GE Healthcare) equilibrated with 50 mM phosphate buffer (pH 8.0) containing 300 mM NaCl. The active fractions were collected and dialyzed against 50 mM citrate−phosphate buffer (pH 7.0).

Hydration of γ-Linolenic Acid. The enzymatic transformation of γ-linolenic acid into (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid was performed in 50 mM citrate−phosphate buffer (pH 7.0) containing 10 mM substrate and 2% (v/v) ethanol. In a 15 mL polypropylene tube with a screw cap, 3 mL of reaction mixture was incubated at 35 °C for 6 h with agitation at 200 rpm. The purified hydratases were applied to 3 mg mL^{-1}. One unit (U) of the hydratase activity is defined as 1 μmol of (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid produced per minute at 35 °C.

The whole-cell transformation of γ-linolenic acid into (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid was performed in 50 mM Tris-HCl buffer (pH 7.0) containing 38 mM substrate and 0.05% (v/v) Tween 80. In a 15 mL polypropylene tube with a screw cap, 3 mL of reaction mixture was incubated at 35 °C for 24 h with agitation at 200 rpm. The recombinant *E. coli* BL21(DE3) expressing the linoleate C12 double-bond hydratase of *L. acidophilus* NBRC 13951 was added to 14.4 g L^{-1}.

The hydration of γ-linolenic acid into (6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid with *S. nitritireducens* was carried out in 10 mL of 50 mM citrate−phosphate buffer (pH 7.0). γ-Linolenic acid was added to a reaction medium containing 20 g dry cells L^{-1} and 0.05% (v/v) Tween 80. The reaction mixture was incubated at 30 °C and sparged with a gas mixture consisting of 95% N_2 and 5% CO_2 at 0.02 vvm to maintain anaerobic conditions.[23]

Biotransformation of Hydroxy Fatty Acids. The biotransformation of the hydroxy fatty acids with recombinant *E. coli* cells was carried out on the basis of our earlier work.[21] Briefly, the recombinant cells were cultivated in the Riesenberg medium at 30 °C, and the expression of the target genes was induced with 0.1 mM IPTG and/or 2.0 g L^{-1} rhamnose at an OD_{600} of 0.5. Thereafter, the cultivation temperature was reduced to 20 °C to facilitate the soluble expression of the target genes (Supporting Information Figure S4). When the added

DOI: 10.1021/jf5058843
J. Agric. Food Chem. 2015, 63, 2773−2781

glucose was consumed, the recombinant cells were harvested by centrifugation at 3500*g* for 15 min at 4 °C and used as biocatalysts. The biotransformation was initiated by adding 2 mM of a hydroxy fatty acid to 50 mM Tris-HCl buffer (pH 8.0) containing 0.5 g L^{-1} Tween 80 and 7.2 g dry cells L^{-1} of the recombinant *E. coli* BL21(DE3) that expressed the ADH from *Micrococcus luteus*, the esterase from *P. fluorescens* SIK WI, and the BVMO from either *Pseudomonas putida* KT2440 or *Pseudomonas fluorescens* DSM 50106. The biotransformations were conducted in a shaking incubator (35 °C and 200 rpm).

Product Analysis by GC-MS. The concentrations of the remaining fatty acids and accumulating carboxylic acids in the medium (i.e., γ-linolenic acid (**1**), (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**), (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**), (*Z*)-9-hydroxynon-6-enoic acid (**15**), (4*Z*,7*Z*)-trideca-4,7-dienedioic acid (**9**), and (*Z*)-dec-4-enedioic acid (**17**)) were determined as described previously.[21] The reaction medium was mixed with an equal volume of ethyl acetate containing 2 or 5 g L^{-1} palmitic acid as an internal standard. The organic phase was harvested after vigorous vortexing and then derivatized with *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA). The trimethylsilyl (TMS) derivatives were analyzed using a Thermo Ultra Trace GC system connected to an ion trap mass detector (Thermo ITQ1100 GC-ion Trap MS; Thermo Scientific). The derivatives were separated on a nonpolar capillary column (30 m length, 0.25 μm film thickness, HP-5MS; Agilent, Santa Clara, CA, USA). A linear temperature gradient was programmed as follows: 90 °C, 15 °C min^{-1} to 200 °C; 200 °C, 5 °C min^{-1} to 250 °C; 90 °C, 15 °C min^{-1} to 200 °C; and 200 °C, 5 °C min^{-1} to 280 °C. The injection port temperature was 230 °C. Mass spectra were obtained by electron impact ionization at 70 eV. Scan spectra were obtained within the range of m/z 100−600. Selected ion monitoring (SIM) was used for the detection and fragmentation analysis of the reaction products.

Product Analysis by GC. The obtained hydroxy fatty acids were derivatized by using a 3:1 mixture of pyridine and MSTFA. TMS-derivatized hydroxy fatty acids were analyzed by GC (Agilent 6890N) equipped with a flame ionization detector and an SPB-1 capillary column (15 m × 0.32 mm inside diameter, 0.25 μm thickness; Supelco) using palmitic acid as an internal standard.[23] The column temperature increased from 150 to 210 °C at an initial rate of 4 °C min^{-1} and then at rate of 30 °C min^{-1} until 280 °C, and this temperature was maintained at 280 °C for 5 min. The injector and detector temperatures were held at 260 and 250 °C, respectively.

Identification of the Biotransformation Products. The biotransformation products were identified by GC-MS or NMR analyses. (*Z*)-9-Hydroxynon-6-enoic acid (**15**), (4*Z*,7*Z*)-trideca-4,7-dienedioic acid (**9**), and (*Z*)-dec-4-enedioic acid (**17**) were identified by GC-MS analysis and comparison to pure reference compounds (Figures 4 and 7). (6*Z*,9*Z*)-13-Hydroxyoctadeca-6,9-dienoic acid (**2**) and (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**) were identified by GC-MS and NMR analyses (see Figure S3 in the Supporting Information for identification of (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid and Figure S5 for identification of (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid). Identification of compounds **2**, **7**, **9**, **15**, and **17** was further confirmed by the GC-MS analysis of their hydrogenated products, which were obtained by catalytic hydrogenation (Figures 4, 7, and S1B).

Purification of the Biotransformation Products. *Purification of Hydroxy Fatty Acids.* The hydroxy fatty acids (i.e., (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**) and (6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid (**10**)) were isolated from the reaction medium by solvent extraction and column chromatography as described previously.[23] In brief, the biotransformation products were isolated by the extraction using two volumes of ethyl acetate two times. After the organic layer was separated from the aqueous phase, the organic extracts were dried with Na_2SO_4 and concentrated by the evaporation in vacuo. The concentrate was purified by the silicic acid column chromatography with methanol gradient (0−5%, v/v) in CH_3Cl (50 mL). Any impurities and the remaining substrate were washed off with CH_3Cl and 1% methanol in CH_3Cl. In the case of (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid, the concentrate was purified with a semipreparative HPLC system (Agilent) equipped with a Nucleosil C-18 semiprep column as described in a previous study[24] (see Figure S2 in the Supporting Information for purification of (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid).

Table 1. Products Accessible through the Multistep Biocatalysis

starting material	final product	product yield[a] (%)
γ-linolenic acid (**1**)	(6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**)	92 ± 2 (60%, 96%)[b]
	(6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid (**10**)	97 ± 4
(6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**)	(6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**)	81 ± 4 (43%, 71%)[b]
	(4*Z*,7*Z*)-trideca-4,7-dienedioic acid (**9**)	34 ± 6[c]
(6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid (**10**)	(*Z*)-9-hydroxynon-6-enoic acid (**15**)	72 ± 7
	(*Z*)-dec-4-enedioic acid (**17**)	73 ± 4

[a]The product yield was calculated on the basis of the substrate depletion and the product concentration, which were determined by GC-MS. All experiments were carried out in triplicate. [b]The numbers in parentheses indicate the isolated yield and purity, respectively. The isolated yields were calculated on the basis of the amount of the products isolated and the amount of the substrates added into the reaction medium. [c]The product yields were low compared to those of the other products because (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**) was coproduced during biotransformation (Figure 3B).

Purification of Unsaturated Carboxylic Acids. The medium-chain, unsaturated carboxylic acids (e.g., 12-hydroxydodeca-6,9-dienoic acid, 9-hydroxynona-6-enoic acid, and 1,10-deca-6-enedioic acid) were isolated from the whole-cell reaction medium as described previously.[21,25] In brief, the biotransformation products were extracted with ethyl acetate three times. The extract was dried over $MgSO_4$ and concentrated via evaporation in vacuo. The impurities (e.g., *n*-alkanoic acids coproduced during biotransformations and long-chain fatty acids originating from the starting materials) were removed by washing with hexane (see Figure S6 in the Supporting Information for purification of (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid). (6*Z*,9*Z*)-12-Hydroxydodeca-6,9-dienoic acid was also purified by HPLC (Figure S5).

RESULTS

The fatty acid double-bond hydratases and BVMOs were the key enzymes in our designed biotransformation pathways because the structures of the final products were determined by the regioselectivity of both enzymes (Figures 1 and 5). Thereby, the first step was to select the appropriate enzymes in terms of substrate scope and regioselectivity for the production of the target compounds.

Screening of a γ-Linolenic Acid C12 Double-Bond Hydratase. Recently, a linoleate C12 double-bond hydratase of *L. acidophilus* NBRC 13951 was cloned and characterized.[22] Thereby, the enzyme was first examined for hydration of the C12 double bond in γ-linolenic acid. The enzyme was produced in *E. coli* ER2566 and subjected to purification via His-Trap affinity chromatography. Afterward, the purified enzyme was added to 50 mM citrate−phosphate buffer (pH 7.0) containing 10 mM γ-linolenic acid. A single product was accumulated in the reaction mixture (Figure 2A and Supporting Information Figure S1A). The product (**2**) was purified to a purity of >96% via solvent extraction and column chromatography (Figure S2). The mass spectrum contained peaks at m/z 173 and 369 due to the α-cleavages at both sides of the hydroxy-TMS function at

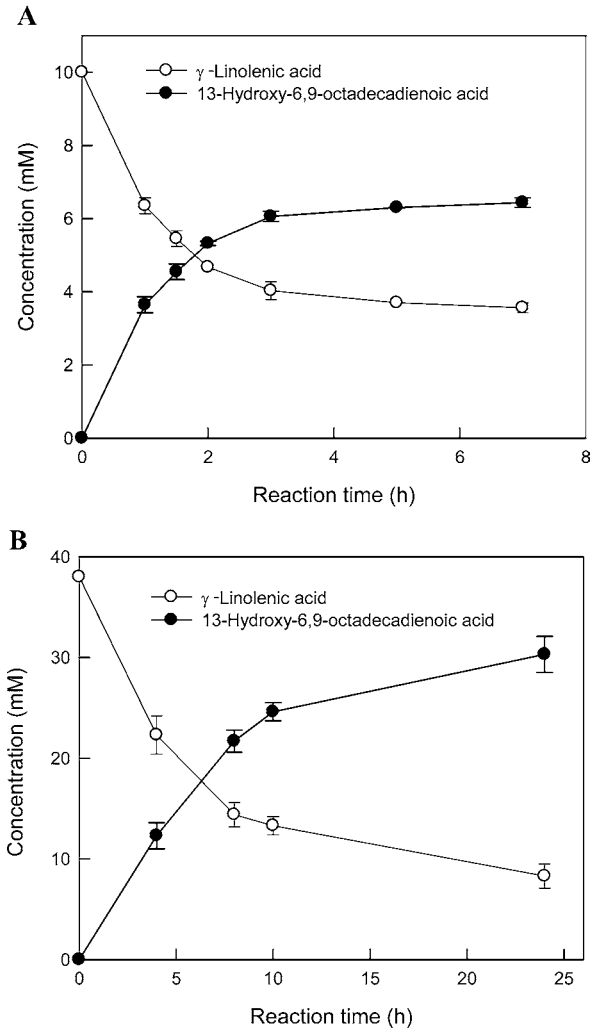

Figure 2. Biotransformation of γ-linolenic acid. γ-Linolenic acid (**1**) was converted into (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**) by (A) the isolated linoleate C12 double-bond hydratase of *L. acidiphilus* NBRC 13951 or (B) the recombinant *E. coli* BL21(DE3) expressing the linoleate C12 double-bond hydratase of *L. acidiphilus* NBRC 13951. The experiments were carried out in triplicate, and the error bars indicate the standard deviation.

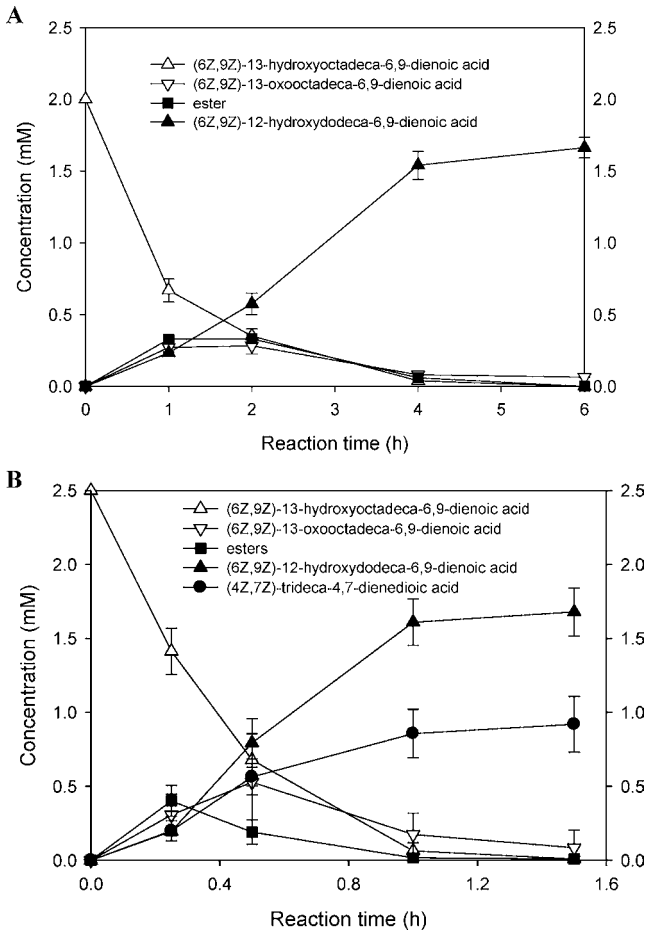

Figure 3. Biotransformation of (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid. (6*Z*,9*Z*)-13-Hydroxyoctadeca-6,9-dienoic acid (**2**) was converted into (A) (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**) or (B) (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid and (4*Z*,7*Z*)-trideca-4,7-dienedioic acid (**9**). The first biotransformation was conducted with the recombinant *E. coli* BL21(DE3) pACYC-ADH, pET-BmoF1, pCOLA-PFE1 expressing the ADH from *M. luteus*, the BVMO from *P. fluorescens* DSM 50106, and the esterase from *P. fluorescens* SIK WI. The second biotransformation was conducted with the recombinant *E. coli* BL21(DE3) pACYC-ADH-BVMO, pCOLA-PFE1, expressing the ADH from *M. luteus*, the BVMO from *Ps. putida* KT2440, and the esterase from *P. fluorescens* SIK WI. The experiments were carried out in triplicate, and the error bars indicate the standard deviation.

C13, whereas the mass spectrum of the hydrogenation product showed peaks at m/z 173 and 373 (Figure S1B). The resonance signals at 3.63 ppm (m, 1H) and four olefinic protons at 5.38 (m, 4H, H-6, H-7, H-9, and H-10) in ^{1}H NMR indicated the existence of a hydroxyl group and a double bond (Figure S3). The observed signal at 71.8 ppm (C-13) of ^{13}C NMR also supported the existence of one hydroxyl group (Figure S3). On the basis of these data, the product was identified as (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**). The concentration of (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid in the reaction medium increased to 6 mM. The hydration rate was increased to 21 U g protein^{-1} at t < 1 h. The isolated yield of the compound was ∼60% with a purity of 96% (Table 1). This result indicated that the linoleate C12 double-bond hydratase also exhibited very high regioselectivity with γ-linolenic acid.

Whole-Cell Production of (6*Z*,9*Z*)-13-Hydroxyoctadeca-6,9-dienoic Acid. The microbial production of (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**) from γ-linolenic acid was also investigated. After batch cultivation of recombinant *E. coli* BL21(DE3) expressing the linoleate C12 double-bond hydratase of *L. acidophilus* NBRC 13951, cell harvest via centrifugation, and resuspension into 50 mM Tris-HCl buffer (pH 7.0), γ-linolenic acid was added to a concentration of 38 mM in the reaction medium. γ-Linolenic acid was converted into the target product at a rate of 2.9 μmol g dry cells^{-1} min^{-1} (i.e., 2.9 U g dry cells^{-1}) at t < 10 h, thus resulting in a final product concentration of ∼30 mM (8.9 g L^{-1}) in the reaction medium (Figure 2B). The bioconversion yield, which was calculated on the basis of the substrate depletion and the product concentration determined by GC-MS, reached >95%. The byproduct formation was hardly observed (Supporting Information Figure S1B). These results indicated that the whole-cell biotransformation system was quite efficient in terms of reaction selectivity and rate.

Biotransformation of (6*Z*,9*Z*)-13-Hydroxyoctadeca-6,9-dienoic Acid (2). Hydroxy fatty acids are used as starting materials for the production of diverse secondary metabolites and signaling molecules in living organisms.[12,13] Thus, we

The bottom panel shows the mass spectrum of the hydrogenated product of (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid, which is identical to that of the authentic compound 12-hydroxydodecanoic acid. (B) GC-MS of the biotransformation products, which were produced with the recombinant *E. coli* BL21(DE3) pACYC-ADH-BVMO, pCOLA-PFE1. The bottom panel shows the mass spectrum of the hydrogenated product of (4*Z*,7*Z*)-trideca-4,7-dienedioic acid, which is identical to that of the authentic compound tridecane-1,13-dioic acid.

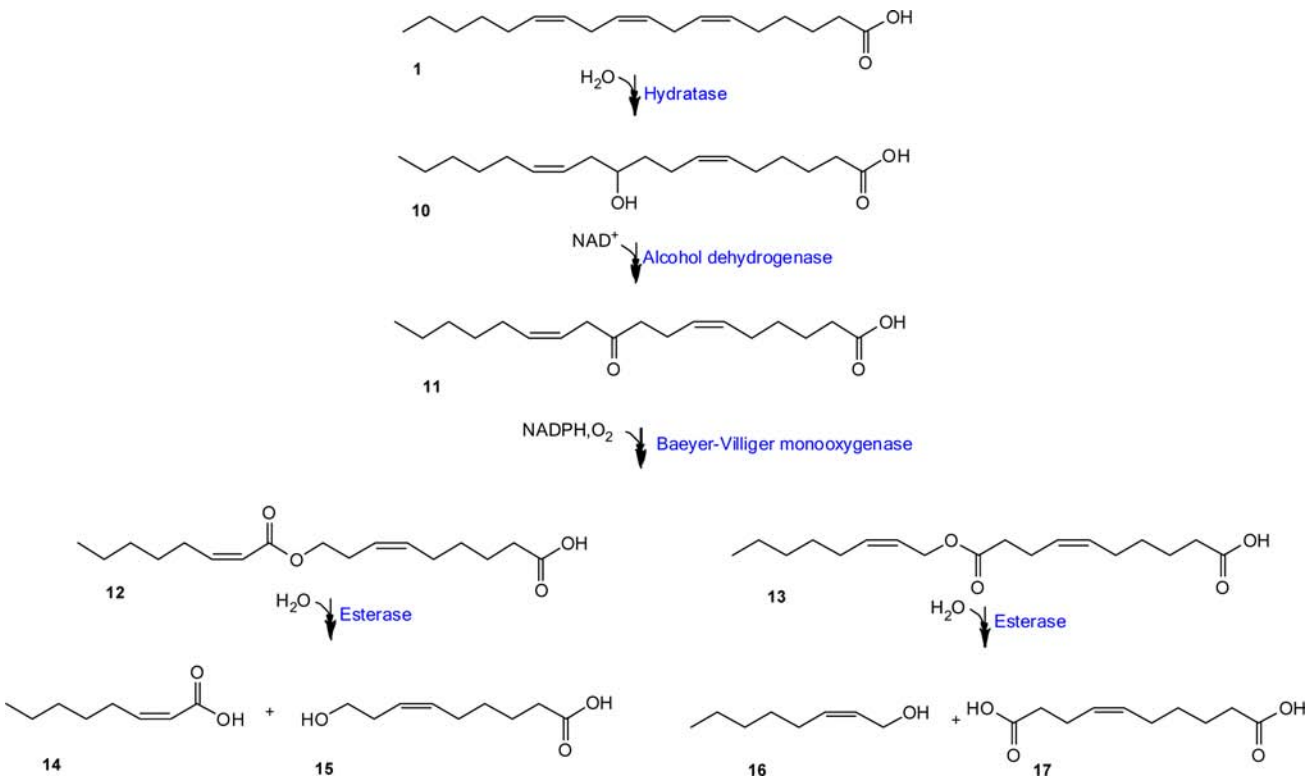

Figure 5. Designed biotransformation pathway 2. γ-Linolenic acid (**1**) is converted into 2-nonenoic acid (**14**) and (*Z*)-9-hydroxynon-6-enoic acid (**15**) or 2-octenol (**16**) and (*Z*)-dec-4-enedioic acid (**17**) by the multistep enzyme reactions.

investigated the biotransformation of (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**) into C12 oxylipins (e.g., (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**)). The substrate (**2**) was prepared after the whole-cell reaction of γ-linolenic acid,

DOI: 10.1021/jf5058843
J. Agric. Food Chem. 2015, 63, 2773−2781

isolation via ethyl acetate extraction, and concentration via evaporation in vacuo. The BVMO enzymes, which determine the chemical structure of the final products due to their regioselectivity, were first examined. The BVMOs that are active with long-chain aliphatic ketones[26−29] were chosen as candidates. When the recombinant *E. coli* BL21(DE3) pACYC-ADH, pET-BmoF1, pCOLA-PFE1 expressing an alcohol dehydrogenase (ADH) from *Micrococcus luteus* NCTC2665, a BVMO from *Pseudomonas fluorescens* DSM 50106,[30] and an esterase from *P. fluorescens* SIK WI was added to the reaction medium containing (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**), the compound was selectively converted into (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**) and *n*-hexanoic acid (**6**) via (6*Z*,9*Z*)-13-oxooctadeca-6,9-dienoic acid (**3**) and the ester (**4**) (Figures 3A and 4A). (6*Z*,9*Z*)-12-Hydroxydodeca-6,9-dienoic acid (**7**) was identified via GC-MS and NMR analyses after purification (Figures 4A and S5). Notably, the target product (**7**) was produced with a final concentration of 1.6 mM from 2.0 mM of the substrate (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid.

On the other hand, the addition of the recombinant *E. coli* BL21(DE3) pACYC-ADH-BVMO, pCOLA-PFE1 expressing an ADH from *M. luteus* NCTC2665, a BVMO from *Pseudomonas putida* KT2440,[27] and an esterase from *P. fluorescens* SIK WI resulted in a production of not only (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**) and *n*-hexanoic acid (**6**) but also (4*Z*,7*Z*)-trideca-4,7-dienedioic acid (**9**) and *n*-pentanol (**8**) (Figures 3B and 4B). (4*Z*,7*Z*)-Trideca-4,7-dienedioic acid was identified on the basis of the GC-MS analysis data of the pure compound 1,12-dodec-9-enedioic acid,[31] which has the same functional group in the fatty acid skeleton. It was assumed that the ester compound (**5**) was produced via the formation of the abnormal ester, which was driven by migration of the less-substituted carbon center during BVMO catalysis.[32,33]

Biotransformation of (6*Z*,12*Z*)-10-Hydroxyoctadeca-6,12-dienoic Acid (10). The biotransformation of (6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid (**10**) (Figure 5), which had been produced from γ-linolenic acid by using the hydratase of *S. nitritireducens*[23] (Supporting Information Figure S7), was also carried out using the setup identical to the biotransformation of (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**). (*Z*)-9-Hydroxynon-6-enoic acid (**15**) and 2-nonenoic acid (**14**) were produced as the major products by recombinant *E. coli* BL21(DE3) pACYC-ADH-BVMO, pCOLA-PFE1 (Figures 6A and 7A). 9-Hydroxynona-6-enoic acid was identified on the basis of the GC-MS analysis data of the pure compound 12-hydroxyundec-9-enoic acid,[15] which has the same functional group in the fatty acid skeleton. Notably, the BVMO of *P. putida* KT2440 showed quite high selectivity with oxygenation of (6*Z*,12*Z*)-10-oxooctadeca-6,12-dienoic acid (**11**), but it showed low selectivity with (6*Z*,9*Z*)-13-oxooctadeca-6,9-dienoic acid (**3**) (Figure 3B).

The biotransformation of (6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid (**10**) with recombinant *E. coli* BL21(DE3) pACYC-ADH, pET-BmoF1, pCOLA-PFE1 expressing the BVMO from *P. fluorescens* DSM50106 instead of the BVMO from *P. putida* KT2440 resulted in the production of (*Z*)-dec-4-enedioic acid (**17**) and 2-octenol as the major products (Figures 6B and 7B). These results indicated that a variety of plant oxylipins could be produced via combined biocatalysis using fatty acid double-bond hydratases and BVMOs.

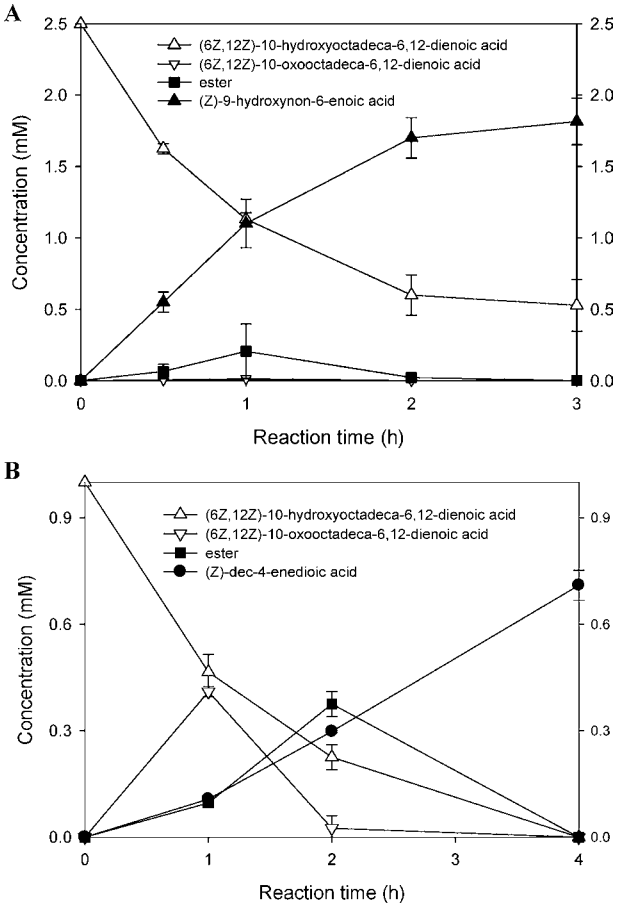

Figure 6. Biotransformation of (6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid. (6*Z*,12*Z*)-10-Hydroxyoctadeca-6,12-dienoic acid (**10**) was converted by (A) the recombinant *E. coli* BL21(DE3) pACYC-ADH-BVMO, pCOLA-PFE1, and (B) the recombinant *E. coli* BL21(DE3) pACYC-ADH, pET-BmoF1, pCOLA-PFE1. The experiments were carried out in triplicate, and the error bars indicate standard deviation.

DISCUSSION

A family of oxygenated unsaturated carboxylic acids (e.g., oxylipins) that play important roles in plant signaling and defense are usually produced via a serial reaction of lipoxygenases and hydroperoxide lyases belonging to CYP74 family.[15] For instance, 12-hydroxydodec-9-enoic acid, 12-oxododec-9-enoic acid, and 1,12-dodec-9-enedioic acid, which were reported to stimulate growth of the roots of plant seedlings, were synthesized from α-linolenic acid by 13-lipoxygenases, hydroperoxide lyases, and alcohol dehydrogenases. 9-Hydroxynonanoic acid and 1,9-nonanedioic acid, which are involved in defense against infection, were produced from α-linolenic acid by 9-lipoxygenases, hydroperoxide lyases, and alcohol dehydrogenases.[15]

Because the oxygenated carboxylic acids have a great potential not only as agrochemicals but also as building blocks and/or additives for the production of plastics (e.g., polyamides and polyesters), resins, hot melt adhesives, powder coatings, corrosion inhibitors, lubricants, plasticizers, greases, and perfumes,[14,18,34,35] their biosyntheses have been extensively investigated. For instance, 9-oxononanoic acid was produced from linoleic acid via an enzymatic two-step reaction catalyzed by the 9*S*-lipoxygenase of *Solanum tuberosum* and the 9/13-hydroperoxide lyase of *Cucumis melo*.[19] Another example was the biotransformation of α-linoleic acid into 3(*Z*)-hexenal

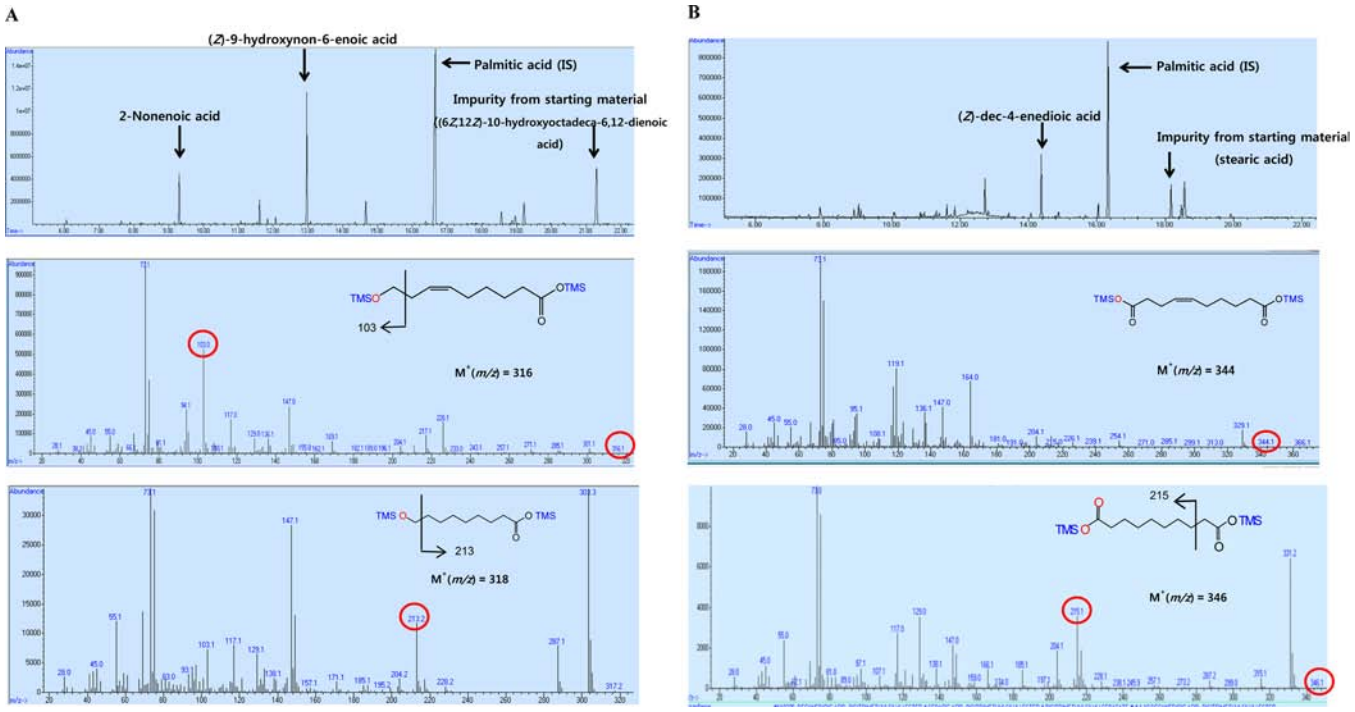

Figure 7. GC-MS analysis of (6*Z*,12*Z*)-10-hydroxyoctadeca-6,12-dienoic acid biotransformation products. (A) GC-MS of the biotransformation products, which were produced with the recombinant *E. coli* BL21(DE3) pACYC-ADH-BVMO, pCOLA-PFE1. The bottom panel shows the mass spectrum of the hydrogenated product of (*Z*)-9-hydroxynon-6-enoic acid, which is identical to that of the authentic compound 9-hydroxynonanoic acid. (B) GC-MS of the biotransformation products, which were produced with the recombinant *E. coli* BL21(DE3) pACYC-ADH, pET-BmoF1, pCOLA-PFE1. The bottom panel shows the mass spectrum of the hydrogenated product of (*Z*)-dec-4-enedioic acid, which is identical to that of the authentic compound decane-1,10-dioic acid.

and 12-oxododec-9-enoic acid by a recombinant *S. cerevisiae* expressing a soybean lipoxygenase and watermelon hydroperoxide lyase.[20] However, the productivity of the biocatalysts appeared to be limited due to the low expression level of the plant enzymes in the microbial cells.

This study herein demonstrated that a variety of the industrially relevant fatty acids and carboxylic acids (i.e., (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**), (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**), (*Z*)-9-hydroxynon-6-enoic acid (**15**), (4*Z*,7*Z*)-trideca-4,7-dienedioic acid (**9**), and (*Z*)-dec-4-enedioic acid (**17**)) could be produced from renewable fatty acids (i.e., γ-linolenic acid) by using artificial multistep enzyme reaction pathways (Figures 1 and 5). The synthetic pathways were composed of enzymes originating solely from bacteria, which could be overexpressed easily in functional forms in bacterial cells.

Some of the key enzymes in the biotransformations reported herein are the BVMOs. The regiospecificity of the enzymes was crucial for providing access to the desired reaction products (Figures 1 and 5). The BVMOs (EC 1.4.13.22) catalyzed the insertion of oxygen into the carbon skeletons adjacent to the carbonyl groups.[36−38] The regiochemistry of the reaction was governed by predictable conformational, steric, and electronic effects as the rearrangement process of the tetrahedral peroxo Criegee intermediate proceeded with strict retention of configuration. Common representative substrates were simple cyclic ketones (e.g., cyclobutanone, cyclopentanone, cyclohexanone, and cycloheptanone), chiral cyclic ketones (e.g., 2-methylcyclopentanone and bicyclo[3.2.0]hept-2-en-6-one), and aliphatic ketones (e.g., 2-octanone).[38] Most BVMOs discovered so far showed catalytic activity for the oxygenation of simple cyclic ketones and chiral cyclic ketones, and only a small number of BVMOs including the BVMO from *P. fluorescens* DSM 50106,[30] *P. putida* KT2440,[27,39] *R. jostii* RHA1,[40] *P. veronii* MEK700,[26] *P. cepacia*,[28] and *Mycobacterium tuberculosis*[29] were found to be active with aliphatic ketones.

The present study herein demonstrated that product profiles of the novel biosynthetic pathways (Figures 1 and 5) were dependent on the catalytic activity, but they were especially dependent on the regioselectivity of the BVMOs (Figures 3 and 6). The BVMO originating from *P. fluorescens* DSM 50106 catalyzed the normal ester formation with (6*Z*,9*Z*)-13-oxooctadeca-6,9-dienoic acid (**3**), which was driven by migration of the more-substituted carbon center during BVMO catalysis (Figure 3A). However, the BVMO from *P. putida* KT2440 showed a quite high activity toward the abnormal ester formation[32,33] in the case of (6*Z*,9*Z*)-13-oxooctadeca-6,9-dienoic acid (**3**) (Figure 3B). Notably, the BVMO from *P. fluorescens* DSM 50106 catalyzed the abnormal ester formation of (6*Z*,12*Z*)-10-oxooctadeca-6,12-dienoic acid (**11**), thus resulting in the production of 1,10-dec-6-enedioic acid (Figure 6B). Unfortunately, the BVMOs from *P. fluorescens* DSM 50106 and *P. putida* KT2440 were too unstable to allow for the proper investigation of their kinetic properties and their 3-D structures. As a result, a detailed investigation of their regioselectivity is currently severely hampered.

In summary, we demonstrated that a variety of plant oxylipins (i.e., (6*Z*,9*Z*)-13-hydroxyoctadeca-6,9-dienoic acid (**2**), (6*Z*,9*Z*)-12-hydroxydodeca-6,9-dienoic acid (**7**), (*Z*)-9-hydroxynon-6-enoic acid (**15**), (4*Z*,7*Z*)-trideca-4,7-dienedioic acid (**9**), and (*Z*)-dec-4-enedioic acid (**17**)) could be produced from a renewable fatty acid (i.e., γ-linolenic acid) via the regioselective BVMO-based whole-cell biocatalysis. This study will contribute to the preparation of industrially relevant unsaturated carboxylic acids.

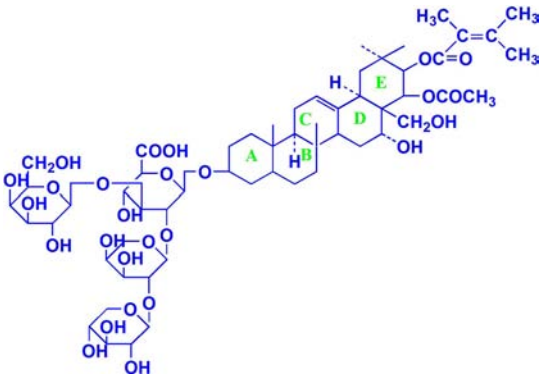

Figure 1. Chemical structural formula of tea saponin.

retardant systems. Using TS in intumescent flame retardant coatings could provide a new idea for the research and development of green flame retardant coatings as well as open up new avenues for its utilization. On the other hand, there could be a potential application and economic prospect of TS-IFRCs because TS has the advantages of being rich, renewable, biodegradable, and environmentally friendly. The coatings were formulated based on TS, APP, and PER. The flame retardant properties of TS-IFRCs were evaluated by limited oxygen index (LOI), smoke density (SDR), and ignition temperature (IT), and the combustion characteristics of TS-IFRCs were tested by cone calorimetry (CONE). Thermal analysis and scanning electron microscopy observations were also conducted.

MATERIALS AND METHODS

Materials. Ammonium polyphosphate (APP, $n > 1000$, industrial) was provided by Zhejiang Longyou Gede Chemical Corp. Alkyd varnish (commercial product), with a medium oil length and solid content of 48.26%, was produced by Hunan Xiangjiang Coating Group. Pentaerythritol (PER, AR) was provided by Kermel Tianjin Chemical Reagent Development Center. Tea saponin (TS, industrial) is a kind of saponin mixture extracted from *C. oleifera* cake, and the content of TS is approximately 60%. Melamine (MEL, CP) was produced by Sinopharm Chemical Reagent Co., Ltd. Three-layer plywood and wood board (Chinese fir) were used as substrates for painting.

Preparation of TS-IFRCs. The TS-IFRCs were prepared by compounding intumescent flame retardants containing APP, PER, and TS (with weight ratios of 15:4:1, 15:7:3, and 15:7:1, respectively) with alkyd varnish; the weight ratio of intumescent flame retardants and alkyd varnish was 3:2. Dispersing agents and other additives were also introduced to improve the overall properties of the coatings. Figure 2 shows the preparation process of TS-IFRCs. In addition, the traditional intumescent flame retardant coatings containing melamine (MEL-IFRC) were selected as a comparison. To make the comparison representative, many screening experiments were also conducted on the basis of previously studied works[26,27] to determine the weight ratio among APP:PER:MEL of MEL-IFRC to be 12:7:1.5 or 24:14:3. In this case, the comparison showed good flame retardancy.

Residue and Expansion Rate Measurement. Residue and expansion rate of the TS-IFRCs with various contents of TS were measured to determine the best formulation of the TS-IFRCs. Liquid flame retardant coatings were poured into the mold and cured at 23 ± 2 °C for 15 days in a ventilated environment. The samples for the test were prepared by cutting cured coatings into pieces of the size of 30 mm × 10 mm × 3 mm (about 1.5 g, accurate to 0.1 mg). Then the samples were placed in an SX-12-10 type box resistance furnace at a constant temperature of 400 °C for 10 min to measure the residue (g carbon/g sample) and expansion rate (mL/g). The residue and expansion rate of coatings were calculated according to the following formulas, respectively.

$$\text{residue} = \frac{\text{wt of carbon residue after heating } (G_2)}{\text{wt of sample } (G_1)}$$

$$\text{expansion rate} = \frac{\text{vol changes before and after heating } (\Delta V)}{\text{wt of sample } (G_1)}$$

Flame Retardancy and Smoke Suppression Tests. The effect of TS on flame retardancy and smoke suppression in the TS-IFRCs was evaluated by means of limiting oxygen index (LOI), ignition temperature (IT), and smoke density measurement (SD). The test samples were prepared in the same way of painting the liquid TS-IFRCs on three-layer plywood twice; the coated plates were dried at 23 ± 2 °C for 15 days in a ventilated environment. The coated weight was about 500 g/m^2, and total thickness of dry film was 1 mm. The LOI tests of the coated plates (140 mm × 6.5 mm × 3 mm) were performed by a JF-3 type oxygen index apparatus (ISO 4589 standard). A JCY-1 material smoke density tester was employed to measure smoke density (coated plates, 30 mm × 30 mm × 3 mm). The ignition temperature was tested on a DW-02 ignition temperature tester (curing coating after crushing and sieving, D = 0.5−1.0 mm).

Analysis of Cone Calorimetry. The combustion behavior of the coated plates (wood boards, 100 mm × 100 mm × 10 mm, coated 500 g/m^2) was investigated by cone calorimetry according to the ISO 5660-1 standard. The test samples were prepared in a similar way as above with regard to painting the liquid TS-IFRCs on wood boards twice; the coated plates were dried at 23 ± 2 °C for 15 days in a ventilated environment. The coated weight was about 500 g/m^2, and total thickness of dry film was 1 mm. The test coated plates were heated after being wrapped in aluminum foil with the upper surface exposed. The measurements were conducted for three replicates per sample under an irradiative heat flow of 50 kW/m^2 horizontally, following the procedure described by Alongi.[9,28] Parameters such as total heat release (THR, kW/m^2), heat release rate (HRR, kW/m^2), effective heat of combustion (EHC, kJ/kg), mass loss rate (MLR, g/s), and total smoke release (TSR, m^2/m^2) were measured. For comparisons, the plates were coated with alkyd varnish and MEL-

J. Agric. Food Chem. 2015, 63, 2782−2788

IFRC with the weight ratio among APP, PER, and MEL of 24:14:3, respectively.

Simultaneous Thermal Analysis of TS-IFRCs. The thermal stability of TS-IFRCs was evaluated by thermogravimetric analyses (TG) and differential scanning calorimetry (DSC) analyses using a NETZSCH STA 449 F3 Jupiter simultaneous thermal analyzer according to the ISO 11357 standard. The measurements were performed for three replicates per sample by placing the samples in open alumina pans (ca. 8.0 ± 0.5 mg) under nitrogen purge (20 cm^3/min) over the whole range of temperature from 40 to 800 °C at a heating rate of 10 °C/min. TG, DTG, and DSC analyses were obtained by using Origin Software 8.0.

Scanning Electron Microscopy (SEM) Observations. SEM observations of the char layer of TS-IFRC sample after being heated at 400 °C for 10 min were performed by a FEI Quanta 450 scanning electron microscope operated at 15 kV and 200× and 1000× levels of magnification.

RESULTS AND DISCUSSION

Thermal Analysis of TS-IFRCs. As seen from the TG-DTG curves in Figure 3a, the thermal degradation process of TS-IFRCs can be broadly divided into three stages. The temperature ranging from 177 to 276 °C is the minor weight loss stage for the total weight loss of 10.4%, which may be caused by the initial thermal decomposition reaction of TS-IFRCs, including the deamination of APP and dehydration of TS to generate noncombustible gas NH_3 and H_2O.[6] In the second stage ranging from 276 to 392 °C, the serious weight loss stage was monitored with a weight loss of 31.6%. At this stage APP, TS, PER, and alkyd resin pyrolyzed severely, and a large amount of gas was generated to form a rich intumescent char layer with catalysis by APP, hindering the decomposition of the TS-IFRCs. The temperature of the third thermal degradation stage was from 392 to 600 °C, and the weight loss was 13.3%. On the other hand, the thermal degradation curves of TS-IFRCs were basically consistent with the curves of MEL-IFRC, whereas the weight loss rate was lower than that of MEL-IFRC; the residue weight of TS-IFRCs during the degradation process was obviously higher than that of MEL-IFRC, and the final weight residual was 39.0%, much higher than the 31.1% of MEL-IFRC and 11.1% of alkyd resin, which indicated that TS combined with other components had a good influence on thermostability. The thermal degradation was weakened, and the carbon residue and thermal stability of the flame retardant coatings were improved effectively.

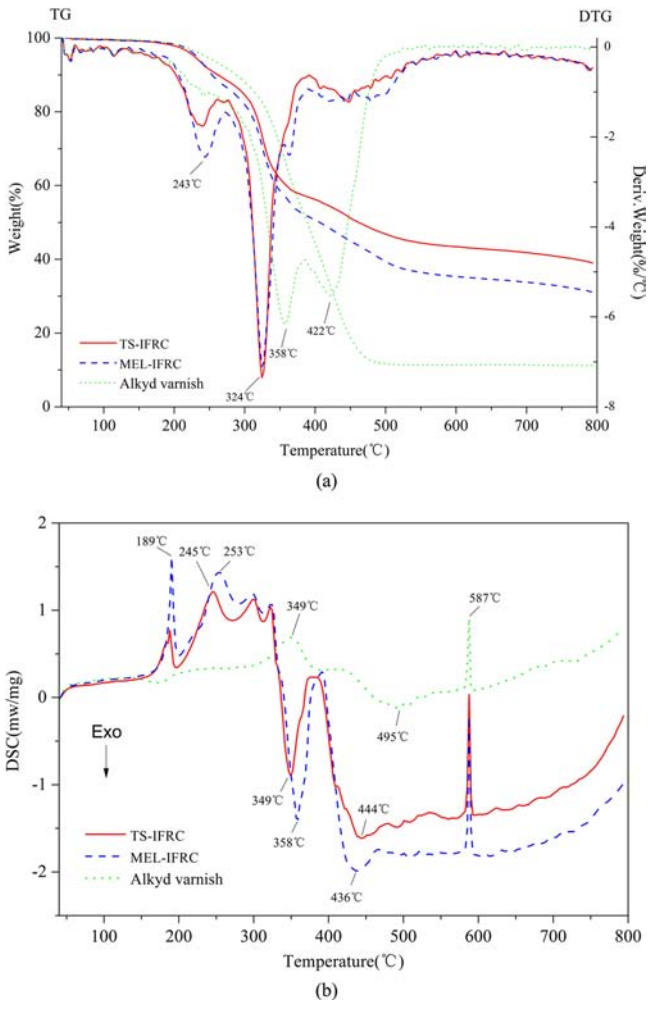

Figure 3. TG-DTG (a) and DSC (b) curves of TS-IFRCs.

DSC curves in Figure 3b revealed that there are mainly two endothermic regions and two exothermic regions during the whole degradation process. At the first endothermic region of the temperature ranging from 160 to 200 °C, there was a sharp endothermic peak at 189 °C, which can be interpreted as the amount of heat needed to be concentrated for the preliminary decomposition of volatile substance released from TS-IFRCs. The temperature ranging from 200 to 320 °C was the second endothermic region, in which there were three small continuous endothermic peaks at temperatures of 245, 300, and 323 °C, respectively. At this region, the TS-IFRCs system continued to absorb heat to concentrate energy for the decomposition of TS-IFRCs and charring, which corresponded to early in the second stage of thermal degradation. Although with the temperature increasing, the flame retardant coating system was decomposed, a lot of heat was released to form the first exothermic region from 330 to 380 °C with a sharp exothermic peak at 349 °C. The second exothermic region was around the temperature of 444 °C, with a wide exothermic peak, owing to the continuous heat released from the decomposition of flame retardant intumescent char layer with the temperature increasing, which corresponds with the third stage of thermal degradation. On the other hand, at the high temperature of 587 °C, it is evident that there was also a sharp endothermic peak, which may be interpreted as a phase change occurring for a sublimation of residue char within a large amount of heat. Compared with the heat release process of the MEL-IFRC, the endothermic peak at 253 °C and the exothermic peak at 358 °C of TS-IFRCs were shifted to the low-temperature area, which was beneficial to the formation of intumescent char layer at low temperature. Furthermore, during the thermal decomposition process, the levels of heat absorption and heat release of TS-IFRCs were larger than those of alkyd resin, but were significantly smaller than those of MEL-IFRC. It was demonstrated that TS-IFRCs had less dependence on heat demand or contribution from outside, which was conducive to slowing the rate of the pyrolysis process and was crucial to the flame retardancy of TS-IFRCs.

From the above, the degradation mechanism can be simply interpreted as APP and PER having nearly no weight loss before 200 °C, whereas TS decomposed with a small weight loss of about 10% at the range from 80 to 190 °C, which mainly eliminated a lot of water vapor to retard oxygen gas and heat. Therefore, we consider this stage as a gas phase flame retardant mechanism before 200 °C. With the decomposition of TS-

DOI: 10.1021/jf505898d
J. Agric. Food Chem. 2015, 63, 2782−2788

IFRCs, APP began to decompose at about 300 °C, eliminating ammonia and water, and interacted with PER to form the char structure, whereas TS involved a key weight loss ranging from 200 to 500 °C, eliminating water and carbon dioxide, which could blow the char formed by APP, PER, and itself to form a uniform and compact intumescent charring layer, which is effective for good thermal and oxygen blockage. We consider this stage as a condensed phase flame retardant mechanism.

Effects of TS on Residue and Expansion Rate of TS-IFRCs. The effects of TS on the performance of TS-IFRCs were studied by fixing the weight ratio of APP and PER in flame retardant systems of TS-IFRCs. The effects of the content of TS on residue and expansion properties of TS-IFRCs are shown in Table 1.

Table 1. Effects of Tea Saponin on Performance of TS-IFRCs

sample[a]	flame retardant coating formulation m(APP):m(PER):m(TS)	residue at 400 °C (g/g)	expansion rate (mL/g)
A_1	alkyd varnish + 40% IFR (12:7:1)	0.477	12
A_2	alkyd varnish + 40% IFR (12:7:3)	0.511	10
A_3	alkyd varnish + 40% IFR (12:7:6)	0.353	9
A_4	alkyd varnish + 40% IFR (12:7:9)	0.332	4
A_5	alkyd varnish + 40% IFR (12:7:12)	0.348	6
B_1	alkyd varnish + 40% IFR (24:14:3)	0.359	8
B_2	alkyd varnish	0.906	3

[a]B_1 refers to melamine comparison, with the flame retardant formula APP:PER:MEL = 24:14:3; B_2 refers to alkyd varnish comparison.

It was shown that TS as blowing agent and carbon source with a different weight ratio in intumescent flame retardant systems can obviously affect the residue and expansion rate of coatings. For A_1 and A_2 with weight ratios of 12:7:1 and 12:7:3 in the TS-IFRC system, the char residues were 0.477 and 0.511 g/g, respectively, higher than the 0.359 g/g of B_2, which contains MEL as blowing agent. The expansion rates of A_1 and A_2 (12 and 10 mL/g, respectively) were also significantly superior to those of alkyd varnishes and MEL-IFRC (B_2 and B_1). The well-developed intumescent char layer could decrease the destruction of gas flow and heat flow and isolate the oxygen, which was effective in retarding the tendency of the fire. However, with the weight ratio of TS increased, the residue and expansion rate of TS-IFRCs decreased. This could possibly be explained by the fact that TS was rich in carbon and hydroxyl groups; as a result, it could promote the formation of char layer during heating and release H_2O, CO_2, and other nonflammable gas to protect the intumescent char layer. However, when the content of TS was too high, as observed in the test, the gas released in the process of thermal decomposition was too much and resulted in the burst of the expanding bubble in char layer, so the quality of the fire retardant char layer was reduced, and, as a result, the effects of flame retardancy and heat insulation were reduced.

Flame Retardant Performance Analysis of TS-IFRCs. As seen from Table 2, when a certain amount of TS was contained in the coatings, the limited oxygen index and ignition temperature were substantially improved: the LOI increased from 24.2 to 43.8%, and the ignition temperature increased from 245 to 310 °C. Compared with the MEL-IFRC plate with a LOI of 38.6%, TS-IFRC plates had some obvious advantages, and the ignition temperature was also slightly higher. It was found that the smoke densities of TS-IFRC plates of different

Table 2. Flame Retardant Performance Indices of TS-IFRCs

sample[a]	LOI (%)	IT (°C)	SDR (g/m^3)
A_1*	43.8 ± 0.06	305 ± 2.9	60.47 ± 2.42
A_2*	38.8 ± 0.12	310 ± 2.9	26.61 ± 1.81
B_1*	38.6 ± 0.06	305 ± 2.9	53.21 ± 2.49
B_2*	38.0 ± 0.12		42.25 ± 2.19
B_3*	24.2 ± 0.12	245 ± 2.9	9.61 ± 0.38

[a]A_1* and A_2* refer to TS-IFRC plates, with the flame retardant formula APP:PER:TS = 15:4:1, 15:7:3, respectively; B_1* refers to MEL-IFRC plate as a comparison, with the flame retardant formula APP:PER:MEL = 24:14:3; B_2* refers to flame retardant coating plate without TS, with the flame retardant formula APP:PER:TS = 12:7:0; B_3* refers to alkyd varnish coating plate as a comparison.

proportions are quite different. When the weight ratio of APP, PER, and TS was 15:7:3 in the TS-IFRCs system, the smoke density with only 26.61 g/m^3 was far lower than those of MEL-IFRC plate and flame retardant coating plate without TS, which greatly reduced the potential danger of the combustion of flame retardant coating plates, whereas when the weight ratio of APP, PER, and TS was 15:4:1, the smoke density was 60.47 g/m^3.

In addition, as seen from SEM micrographs of the outer surface of char layer of TS -IFRC plates at 200× and 1000× magnification, respectively, in Figure 4, at high temperature the

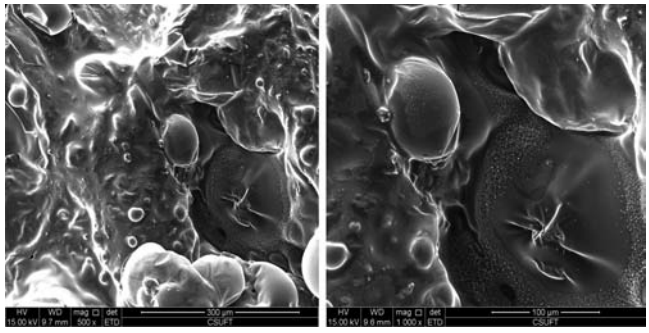

Figure 4. SEM micrographs of intumescent char layer of TS-IFRCs.

surface of flame retardant coating plates formed a well-developed intumescent char layer with a lot of expanding bubbles, and the structure of the intumescent char layer was dense and uniform, which was conductive to decreasing the thermal conductivity coefficient between the intumescent char layer and the substrate; the intumescent char layer effectively prevents oxygen flow and heat flux from eroding into the matrix. It could be explained that TS, being rich in carbon source, can cooperate with PER to play a key role in strengthening the quality of the char layer and preventing the intumescent char layer from being damaged by air flow and heat to decrease the efficiency of flame retardant coatings.

Combustion Performance Analysis of TS-IFRCs. At present, the cone calorimeter test is considered to be an effective way to simulate actual fire burning behavior due to its good correlation with large-scale combustion experiments, which can accurately measure the mass loss rate, heat release rate, smoke production rate, content of toxic gases, and other parameters of materials in the event of burning. Therefore, it was not surprising that the cone calorimeter was increasingly found to be a characterization tool in the research and development of flame retardant materials internationally.[29−32]

Heat release rate (HRR) is an important parameter indicating the spread trends of a fire and the degree of fire

DOI: 10.1021/jf505898d
J. Agric. Food Chem. 2015, 63, 2782−2788

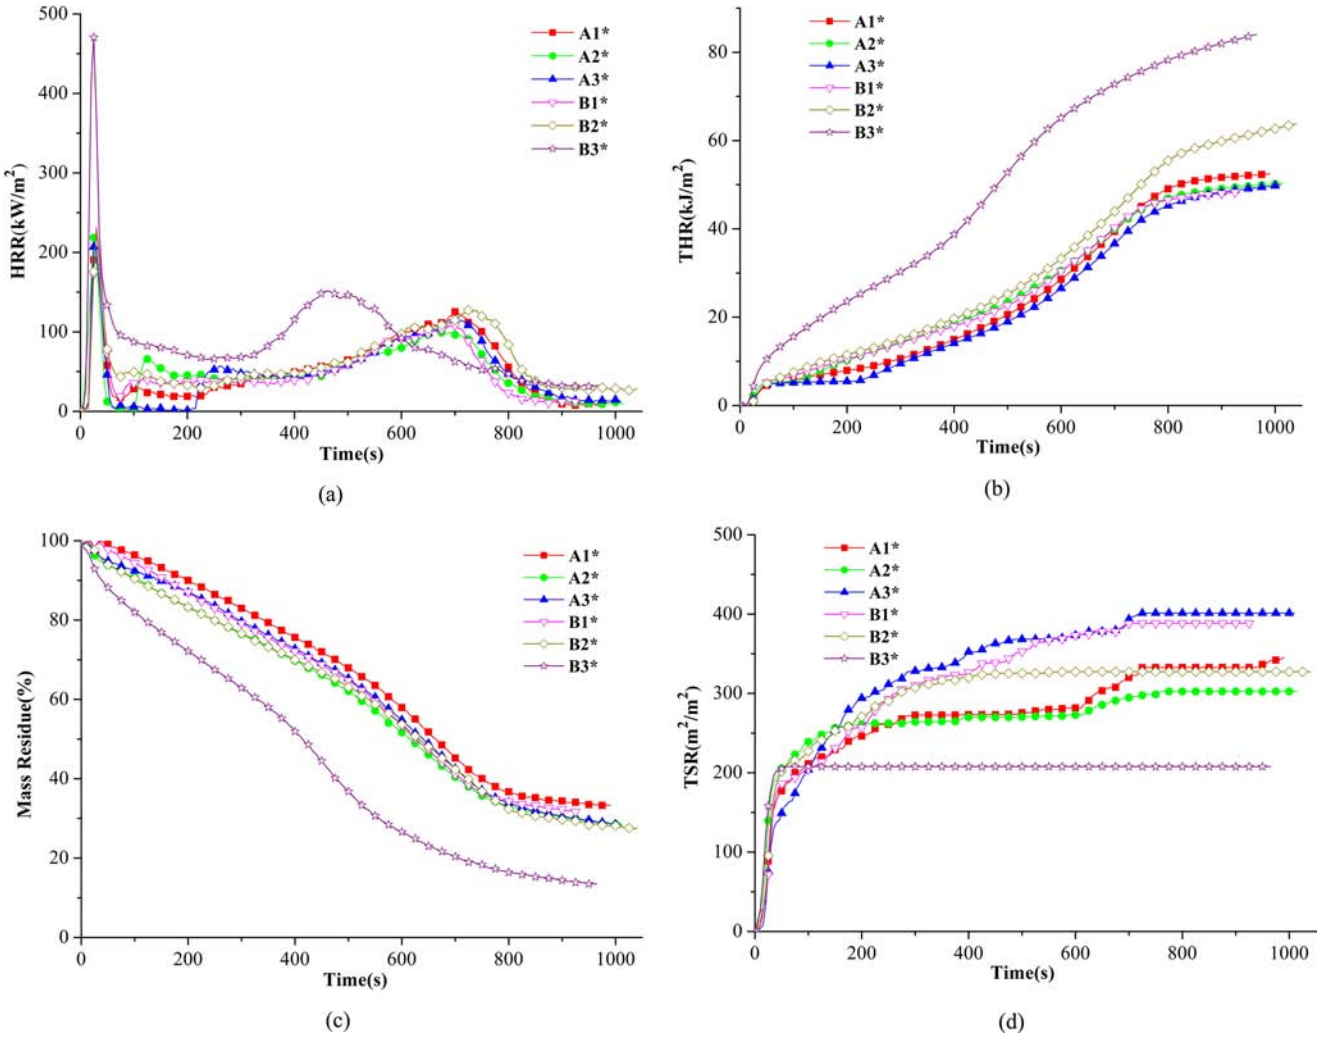

Figure 5. Cone calorimetery test curves of TS-IFRC plates: (a) heat release rate curves; (b) total heat release curves; (c) mass residual curves; (d) total smoke release curves.

hazard. The greater the value of HRR is, the greater the degree of fire risk.[33] The peak heat release rate (pk-HRR), the maximum value of HRR, determines the scale of the fire greatly.[28] The heat release rate curves of different formulations of TS-IFRC plates under the thermal radiation power of 50 kW/m^2 are shown in Figure 5a.

Table 3 and Figure 5a show that the pk-HRR of TS-IFRC plates (190.62 kW/m^2) was significantly lower than that of flame retardant coating plate without TS (227.52 kW/m^2) and MEL-IFRC plate (231.57 kW/m^2). At the same time, the m-HRR of TS-IFRC plates was lower by 25.16 and 6.5% than those of flame retardant coating plate without TS and MEL-IFRC plate, respectively. It was also illustrated that there were two pk-HRR in the combustion process of the flame retardant coating plates. The first pk-HRR came almost at the time of about 25−30 s; subsequently, the HRR of TS-IFRC reduced significantly at a certain degree. Particularly after the first pk-HRR, the A_2* and A_3* plates coated with TS-IFRCs smoldered for 55 and 165 s, respectively, the HRR of which almost decreased to 0, which successfully limited the growth of the fire. Specifically, the HRR of TS-IFRC plates was always obviously lower than those of MEL-IFRC plate and flame retardant coating plate without TS in the entire combustion process, which indicated that the addition of TS can inhibit the HRR of TS-IFRC plates, slow the process of the combustion, and effectively reduce the risk of fire.

From Table 3 and Figure 5b, it is shown that the THR values of TS-IFRC plates were much lower than those of MEL-IFRC plate and the flame retardant coating plate without TS in the entire combustion process. In addition, the THR values of A_3* were reduced by 68.42 and 27.88%, respectively, compared with the alkyd varnish and flame retardant coating plate without TS, which is a key factor to control the scale and spread of the fire.[31]

The mean effective heats of combustion (m-EHC) of the TS-IFRC plates shown in Table 3 were much superior to those of MEL-IFRC plate and flame retardant coating plate without TS. Especially, the values of A_3* being 9.95 KJ/kg decreased by 33.78%, compared with that of the flame retardant coating plate without TS. It could be explained that the addition of the blowing agent (TS) played an extremely important role in making the formation of the intumescent protective char layer rapid, which successfully slowed the accumulation of the heat in the system.

The mass loss of TS-IFRC plates is shown in Table 3 and Figure 5c. The mean mass loss rates (m-MLR) of A_1* and A_3* were slightly higher than those of MEL-IFRC plate and flame retardant coating plate without TS, but the m-MLR of the A_2*

[a]A_1*, A_2*, and A_3* refer to TS-IFRC plates, with the flame retardant formulas APP:PER:TS = 15:4:1, 15:7:3, 15:7:1, respectively; B_1* refers to MEL-IFRC plate as a comparison, with the flame retardant formula APP:PER:MEL = 24:14:3; B_2* refers to flame retardant coating plate without TS as a comparison, with the flame retardant formula APP:PER:TS = 12:7:0; B_3* refers to alkyd varnish coating plate as a comparison. Cone calorimeter test was carried out at a thermal radiation power of 50 kw/m^2.

was much lower than those of any other coatings, only 0.0405 g/s. Figure 5d shows that the mass residue of TS-IFRC plates was relatively higher than that of other coatings throughout the combustion process. At the time of 600 s the mass residue of A_1* was 57.91%, higher than the 53.37% of MEL-IFRC plate and 53.59% of flame retardant coating plate without TS, and much higher than the 26.59% of alkyd varnish coating plate. In addition, after the combustion, the mass residue of A_1* was still the highest at 33.41%, and the mass residues of the other TS-IFRC plates (A_2* and A_3*) were also quite high at 28.17 and 28.61%, respectively.

Furthermore, the properties of smoke release of TS-IFRC plates were studied by analyzing total smoke release (TSR), specific extinction area (SEA), CO yields (COY), and CO_2 yields (CO_2Y) collected by a cone calorimeter. The values of TSR, mean-SEA, mean-COY, and mean-CO_2Y are shown in Table 3, and the total smoke release curve is described in Figure 5d. From Table 3 and Figure 5d, it was concluded that there was a big difference among the TSR values of TS-IFRC plates with different flame retardant formulations; for example, the TSR values of A_1* and A_2* were always lower than the values of MEL-IFRC plate and flame retardant coating plate without TS in the early stage of combustion, but the TSR value of A_3* was the highest. As far as the mean-SEA was concerned, the SEA values of all TS-IFRC plates were decreased significantly, compared with those of flame retardant coating plate without TS and alkyd varnish coating plate, which indicated that TS was conducive to a small SEA value and a low smoke production of TS-IFRC plates during the combustion. In addition, the values of mean-COY and mean-CO_2Y showed that the decrease of CO yields of TS-IFRC plates was not apparent; only the COY value of A_1* was much less than those of the other flame retardant coating plates. The COY values of A_2* and A_3* were similar to that of MEL-IFRC plate, but were much higher than those of flame retardant coating plate without TS and alkyd varnish coating plate. At the same time, the CO_2Y values of TS-IFRC plates were approximate to each other among the flame retardant coating plates, but much lower than that of alkyd varnish coating plate, which can be explained by the incomplete combustion of TS-IFRCs, releasing more CO and less CO_2.

In this study, it was confirmed that the natural product tea saponin (TS) used in a dual role of blowing agent and carbon source in TS-IFRCs can play an important role in improving the flame retardancy, smoke release, and thermostability of TS-IFRCs. When the weight ratio of APP, PER, and TS is 15:4−7:1−3 for a certain addition in TS-IFRCs, the TS-IFRCs exhibited a pretty good flame retardancy, which effectively inhibited the heat release of TS-IFRC plates and reduced heat release rate, effective heat, and smoke release. Absolutely on the basis of this work, the mechanism of action of tea saponin in flame retardant coatings will be the focus of future study.

bypass this inefficient metabolic step and might result in the enrichment of eggs with amounts of EPA and DHA that today are only achievable by direct supplementation of hens' diet with these VLC n-3 PUFAs. Moreover, because egg FA profiles typically reflect the hens' dietary FA pattern,[12,18] SDA-enriched eggs would theoretically supply additional EPA and DHA via subsequent bioconversion following consumption by humans. In the present study, we fed hens a diet containing high-SDA soybean oil (SBO), which has been engineered through expression of both the Δ6 and Δ15 desaturase enzymes in the soybean plant,[19] and compared it to diets containing conventional SBO (CON), flaxseed oil (FLAX), or fish oil (FISH).

MATERIALS AND METHODS

Animals, Diets, and Management. One-hundred, day-old Hy-Line W-36 chicks, vaccinated against Marek's Disease, were obtained from the Hy-Line hatchery in Elizabethtown, PA. Feeding and lighting programs were conducted in general accordance with breeder recommendations.[20] At 18 wk of age, 80 hens were transferred from floor pens in the pullet rearing facility to individual 30 cm (w) × 43 cm (d) × 36 cm (h) cages with sloping wire floors in the layer facility and were provided 16 h of light daily. A standard corn−soybean meal−based layer mash (MW-121, Wenger Feeds, Rheems, PA) calculated to contain 18.5% crude protein, 2880 kcal metabolizable energy, 4.31% available calcium, and 0.51% available phosphorus, was fed until 33 wk of age, at which time the supplemental dietary fat content of the mash was increased to 5% (animal−vegetable fat blend) in order to acclimate the hens to a higher dietary fat level that was maintained in the experimental diets. At 38 wk of age (d 0 of the study), the 40 best performing hens were selected based on 5-d pre-experimental egg weight and egg production, and 32 birds were allocated (n = 8) to one of four dietary treatments (see below). At that time, the 8 additional hens, with similar average egg production rates and egg weights as the 32 utilized in the feeding trial, were euthanized by electric stunning and exsanguination. Their livers and abdominal fat pads were excised, weighed, and snap-frozen in liquid nitrogen until subsequent analysis for FA content and expression of key genes affecting lipid metabolism (d 0 baseline data).

Diets, differing only in supplemental oil sources, were formulated to meet or exceed the nutritional requirements of W-36 hens[20] and were fed for a period of 28 d. The oil sources were as follows: (1) conventional SBO (CON; Monsanto Company, St. Louis, MO); (2) SDA-enriched SBO from soybean plants engineered to produce oil with significant quantities of SDA (SDA; Monsanto Company, St. Louis, MO); (3) flaxseed oil (FLAX; cold pressed; Jedwards International, Inc., Quincy, MA); (4) fish oil (FISH; refined, deodorized, purified, and molecularly distilled; Jedwards International, Inc., Quincy, MA) (Table 1). Feed and water were provided for ad libitum consumption. Hen body weight was recorded on d 0 and d 28, and individual hen feed intakes and egg weights were recorded daily.

Two of the hens, one from the CON treatment and one from the FLAX treatment, were removed from the study due to a cessation of feed intake and/or egg production on d 19 and d 14, respectively. The former hen had a large mite infestation while the latter hen was subsequently diagnosed with severe chronic active ulcerative stomatitis (inflammation of the mucous membrane of the mouth) with periostial new bone formation of the mandible, which likely caused pain in the beak and mouth. Thus, since the data from these hens were not used in the study, there were 7 hens each in the CON and FLAX diets, and 8 hens each in the SDA and FISH diets.

At the end of the study (d 28), the remaining 30 hens were euthanized by electric stunning and exsanguination. Their livers and abdominal fat pads were excised, weighed, and snap-frozen in liquid nitrogen and stored at −80 °C until subsequent analysis for FA content and expression of key genes affecting lipid metabolism. All animal protocols were approved by the Institutional Animal Care and Use Committee of The Pennsylvania State University (IACUC #37025).

[a]Diets contained 5% supplemental conventional soybean oil (CON), stearidonic acid-enriched soybean oil (SDA), flaxseed oil (FLAX), or fish oil (FISH). [b]Santoquin 4Q-T (Novus International, Inc., St. Charles, MO), a fat-soluble liquid antioxidant feed additive, was added directly to each oil and stirred prior to mixing the oil with the basal. The final content of Santoquin 4Q-T in each diet was calculated to be 62.5 ppm or 0.00625%, and is noted as Tr = trace. [c]The proprietary basal mixture consisted primarily of ground corn, soybean meal, ground wheat, distillers grains with solubles, and wheat middlings, with supplemental vitamins, minerals, essential oils, prebiotic substances, and enzymes. The diet was formulated to meet or exceed the nutrient requirements of the Hy-Line W-36 hen.[20] [d]Mean of two analyses per sample. [e]ND = not detected.

Diet, Egg, and Tissue Analyses. One egg per hen was collected on d 0, d 14, and d 28 of treatment for the determination of component weights and percentages.[21] Diets and lyophilized egg yolks were analyzed for crude protein, crude fat, and total cholesterol contents by the Agricultural Experiment Station Chemical Laboratories at the University of Missouri—Columbia using AOAC International official methods 990.03, 920.39, and 941.09, respectively.[22] Diets, egg yolk, liver, and adipose tissue (abdominal fat pad) samples were acid methylated according to Garcés and Mancha[23] (80 °C for 2 h in reagent containing heptane, methanol, toluene, 2,2-dimethoxypropane, and sulfuric acid at 48.5:32:14:4:1.5, v:v) and yolk FA methyl esters were cholesterol-depleted using an SPE column, as described by Tyburczy et al.[24] Individual FAs were separated and quantified by gas−liquid chromatography using an Agilent 6890A gas chromatograph (Agilent Technologies, Palo Alto, CA) equipped with a fused-silica capillary column (SP2560; 100 m × 25 mm i.d. with 0.2-μm film thickness; Supelco, Inc., Bellefonte, PA) and a flame ionization detector.[25] The oven program was 70 °C for 4 min, 8 °C/min ramp to 110 °C, 5 °C/min ramp to 170 °C for 10 min, and 4 °C/min ramp to 215 °C for 23 min. Inlet and detector temperatures were 250 °C with a 50:1 or 100:1 split ratio. Hydrogen carrier gas flow rate was 1 mL/min. FA concentration and methylation efficiencies were determined using dual external standards (13:0 free FA and 19:0

[a]Diets contained 5% supplemental conventional soybean oil (CON), stearidonic acid-enriched soybean oil (SDA), flaxseed oil (FLAX), or fish oil (FISH). [b]SFA = saturated fatty acids; MUFA = monounsaturated fatty acids; PUFA = polyunsaturated fatty acids; vLC n-3 = polyunsaturated n-3 fatty acids greater than 18 carbons. [c]ND = not detected.

methyl ester; Nu-Chek Prep, Inc., Elysian, MN). Peaks were identified based on purified standards (GLC780 and GLC461; Nu-Chek Prep), and 20:4 n-3 was identified using a purified stock (Caymen Chemical Company, Ann Arbor, MI). An equal weight standard (GLC461; Nu-Chek Prep) was used for calculation of recovery factors.

Gene Expression Analysis. Total RNA was extracted from liver tissue by chloroform−phenol extraction followed by column purification with on-column Dnase treatment (Total RNA II Kit with optional Dnase, Omega Bio-Tek, Norcross, GA). The concentration and quality of RNA was determined using an Experion System (Bio-Rad Laboratories, Hercules, CA). cDNA was synthesized from total RNA using random primers (High Capacity cDNA synthesis kit, Life Sciences Advanced Technologies, Inc., St. Petersburg, FL). Expression of long chain FA desaturases (SCD1, FADS1, and FADS2), FA elongases (ELOVL2 and ELOVL5), a lipogenic enzyme (FASN), a cholesterol synthesis enzyme (HMGCR), FA oxidation enzymes (CPT1a and ACOX1), lipogenic transcription factors (SREBP1 and MLX), and two housekeeping genes (BACT and B2M) was determined in quadruplicate by relative quantification SYBR Green Real-Time PCR (PerfeCTa SYBR Green Supermix with ROX, Quanta BioSciences, Gaithersburg, MD) using an 7900 Fast Real-Time PCR System (Applied Biosystems, Grand Island, NY). Gene specific primers (intron spanning when possible) were designed using Primer-BLAST (NCBI; see Supporting Information) and validated for linearity and efficiency. Gene expression was quantified relative to a standard curve of serially diluted cDNA in each plate. The geometric mean of the housekeeping genes[26] was used as a covariant in the statistical analysis and data is reported relative to the control (set to 100).

Statistical Analyses. Data with multiple observations per hen (e.g., feed intake, egg production, body weight, and egg composition) were analyzed as a repeated measures design using Proc Mixed (SAS Institute, Cary, NC). The model included the random effect of bird nested in treatment and the fixed effect of treatment, day, and the interaction of treatment × day. Treatment effects were similar between d 14 and d 28; therefore, only d 28 data are presented. A Protected LSD was used within d 28 when the treatment × day interaction was significant. Data with a single observation per hen were analyzed with a model that included the fixed effect of treatment and means were separated by a Protected LSD when treatment was significant ($P \leq 0.05$). Data was log transformed when necessary and back transformed data are reported. Data points outside of ±3 Studentized residuals were considered outliers and removed from the analysis. This rarely occurred for more than 1 value per variable.

RESULTS

Experimental Diets and Animal Performance. The analyzed fat contents of the four experimental diets agreed well with calculated contents (7.3% fat), on both a crude fat and a sum of FA basis (Tables 1 and 2). The FA profile of the CON diet was representative of the incorporated commercial SBO (6.9% 18:3 n-3 and 7.0% total n-3 FA; Table 2). The high SDA SBO contained 37.4% n-3 FA (13.1% 18:3 n-3 and 24.3% 18:4 n-3) and 6.4% 18:3 n-6 primarily at the expense of 18:1 c9 and linoleic acid (LA; 18:2 n-6; Table 2). The flaxseed oil contained 50.9% 18:3 n-3 and the fish oil contained 30.5% total VLC n-3

[a]Values are d 28 least-squares means of 7 hens each for the CON and FLAX diets, and of 8 hens each for the SDA and FISH diets. Average d 28 yolk weights of eggs from hens fed the CON, SDA, FLAX, or FISH diets were 15.38, 14.94, 15.11, and 15.18 g, respectively ($P = 0.74$). [b]VLC n-3 = polyunsaturated n-3 fatty acids greater than 18 carbons. [c]Values within a row with different letters are significantly different ($P < 0.05$). [d]ND = not detected

(including 17.2% EPA and 10.9% DHA; Table 2). All diets were sufficiently palatable, and daily intake did not differ between treatment groups, averaging 96.6 g/d (see Supporting Information). Since daily intakes did not differ, the relative differences in FA intakes were therefore similar to the differences in the composition of the experimental oils.

Overall, there was no significant effect of dietary oils on hen performance. When averaged across diets, hens gained 11.3 g of body weight (BW) in 28 d, had a hen-d egg production rate of 90.5%, produced eggs weighing 60.7 g, and consumed 1.77 g feed/g egg mass (see Supporting Information). In addition, there were no significant effects of diet on egg component (yolk, albumen, shell) weights, egg component relative percentages, or yolk cholesterol, crude fat, or crude protein contents, regardless of how they were expressed (mg/g yolk, mg/yolk, or % of yolk dry matter; see Supporting Information).

Yolk Fatty Acid Composition. For egg yolks and tissues, the d 0 FA compositions did not differ from those of the CON diet at 28 d (data not shown). In addition, since the d 14 and d 28 data were not different within a dietary group, only the d 28 data are reported.

Yolk contents of EPA, docosapentaenoic acid (DPA, 22:5 n-3), DHA, and total VLC n-3 PUFAs were greater ($P < 0.001$) in eggs from hens fed FISH compared to the other three diets, while yolk ALA contents were highest ($P < 0.001$) in hens fed FLAX diet (Table 3). In terms of absolute content of VLC n-3 PUFAs, yolks from hens fed the CON, SDA, and FLAX diets contained only 17% (51 mg/305 mg), 41% (125 mg/305 mg), or 30% (91 mg/305 mg), respectively, of the amount in yolks from FISH-fed hens (Table 3).

As compared to the CON and FLAX diets, feeding hens SDA increased ($P < 0.001$) yolk contents of SDA, eicosatetraenoic acid (ETA, C20:4 n-3), EPA, DPA, and DHA, as well as total VLC n-3 PUFAs, on both an absolute and a relative (% of FAs) basis (exception: EPA contents on a mg/yolk basis; SDA value was 67% greater than FLAX value, but NS). Additionally, although the FLAX diet contained more ALA (21.7 g/kg) than the total amount of ALA + SDA in the SDA diet (6.3 g/kg and 8.6 g/kg, respectively; Table 2), the latter were more efficiently desaturated and elongated to VLC n-3 PUFAs than was ALA alone from flaxseed oil. In this regard, laying hens incorporated 0.132 mg, 0.041 mg, or 0.075 mg (estimated; see below) of VLC n-3 PUFAs daily into egg yolk for each milligram of ingested ALA from SBO (CON), ALA from flaxseed oil (FLAX), or SDA, respectively (Table 4). Since the SDA oil also contained ALA, a mathematical calculation was used to estimate the contribution of ALA to egg yolk vLC n-3 PUFA content. Specifically, a conversion value of 0.120 mg VLC n-3 PUFAs/mg ALA ingested was used to estimate the amount of VLC n-3 PUFAs in egg yolks of SDA-fed hens that were derived from ALA. This figure was generated by proportioning the daily ALA intake of the SDA hens (557 mg), as compared to the CON (355 mg) and FLAX hens (2138 mg), to the CON and FLAX ALA conversion values. The estimated amount of yolk VLC n-3 PUFAs derived from ingested ALA were then subtracted from the total VLC n-3 PUFAs in the egg yolks of SDA-fed hens, the difference was divided by the daily SDA intake, and the value was multiplied by hen-day production to generate the daily SDA conversion value (0.075).

	20% ground flaxseed	ALA	0.006
	30% ground flaxseed	ALA	0.003
Cherian and Sim (1991)[28]	control	ALA	0.304
	8% ground flaxseed	ALA	0.054
	16% ground flaxseed	ALA	0.044
Aymond and Van Elswyk (1995)[29]	control	ALA	0.121
	5% whole flaxseed	ALA	0.058
	5% ground flaxseed	ALA	0.052
	15% whole flaxseed	ALA	0.018
	15% ground flaxseed	ALA	0.021

[a]Diets in the present study contained 5% supplemental conventional soybean oil (CON), flaxseed oil (FLAX), or stearidonic acid-enriched soybean oil (SDA). Intakes of VLC n-3 PUFAs for all three treatment groups of the present study were ∼10 mg/hen/d; linoleic acid (18:2 n-6) intakes averaged ∼3400, 2200, and 2400 mg/hen/d for the CON, FLAX, and SDA groups, respectively. [b]Values are means (±SD). In vivo conversion for the present study was estimated as ([mg yolk ETA+EPA+DPA+DHA in eggs laid on d 28] × 28-d hen-d egg production)/(mg ALA intake per d or mg SDA intake per d). In vivo conversion for the three other studies was calculated in a similar manner. A conversion value of 0.120 mg VLC n-3 PUFAs/mg ALA ingested (see text for derivation of this figure) was used to estimate the amount of VLC n-3 PUFAs in egg yolks of SDA-fed hens that were derived from ALA. This amount was subtracted from the total amount of VLC n-3 PUFAs in the yolks of SDA-fed hens in order to determine the amount derived from SDA. ETA = eicosatetraenoic acid; EPA = eicosapentaenoic acid; DPA = docosapentaenoic acid, DHA = docosahexaenoic acid. [c]Caston and Leeson (1990) did not report flaxseed ALA content; it was assumed to be similar to the flaxseed fed by Cherian and Sim (1991). For Caston and Leeson (1991) and Aymond and Van Elswyk (1995), a daily intake of 350 mg of ALA for the control diet was assumed since feed intake data were not reported and diets were corn-based, as in the present study. A daily feed intake of 100 g/hen/d for Cherian and Sim (1991) was assumed since feed intakes were not reported.

The increase in n-3 FAs in all treatments was predominantly offset by a decrease in LA, and small differences in other FAs were observed depending on the specific profile of each oil (e.g., increased 14:0 and decreased 18:1 c9 in FISH). Additionally, feeding FLAX increased yolk 16:1 and 18:1 c9 contents, which may have been reflective of elevated hepatic stearoyl-CoA desaturase activity. Lastly, expression of the Δ6 desaturase in the high SDA soybeans promotes the enhanced synthesis of γ-linoleic acid (GLA; 18:3 n-6) from LA. As a result, GLA levels in the SDA oil were approximately 20-fold higher as compared to the other three oils (Table 2), and hens fed the SDA diet had the highest egg GLA contents (16 mg/yolk vs 5 mg, 3 mg, or 3 mg for the CON, FLAX, and FISH diets, respectively; Table 3). Egg yolks from SDA-fed hens were similarly enriched with 20:3 n-6, the elongation product of GLA (Table 3).

Liver and Adipose Tissue Weights. Liver and abdominal fat pad absolute and relative weights were unaffected by dietary treatment. Averaged across the four dietary treatments, hen BW, liver weight, abdominal fat pad weight, liver weight as % of BW, and abdominal fat pad as a % of BW were 1,636 g, 29.0 g, 82.6 g, 1.77%, and 5.01%, respectively (see Supporting Information).

Liver Fatty Acid Composition. As compared to egg yolk FA profiles (% of FAs; Table 3), liver lipids were relatively richer in stearic acid (18:0), arachidonic acid (20:4 n-6), and DHA, and contained less oleic acid (18:1-c9) and ALA (Table 5). Moreover, relative to the amount of total n-3 FAs, liver lipid (Table 5) was richer in VLC n-3 PUFAs both on an absolute and relative basis, as compared to egg yolk (Table 3) for each treatment group. This was a reflection of the liver's metabolic capacity to desaturate and elongate dietary ALA and SDA and the preference for VLC n-3 FAs in hepatic phospholipid membranes. Additionally, liver tissue fatty acid composition and profile were similar between d 0 (baseline) and the CON treatment at the end of the experiment (d 28; data not shown). As compared to livers from CON hens, livers of birds fed SDA or FLAX contained more than twice the amount of total n-3 FAs (P < 0.001; Table 5). However, livers from SDA-fed hens contained proportionately more VLC n-3 PUFAS, which was a reflection of the more efficient conversion of SDA + ALA vs ALA alone to DTA, EPA, DPA, and DHA (Table 4).

Adipose Tissue Fatty Acid Composition. As compared to yolk FA profiles (% of FAs; Table 3), adipose tissue (abdominal fat pad) had similar contents of 18:1 c9 and ALA, proportionately greater contents of LA and SDA, and lesser amounts of palmitic acid (16:0), 18:0, 20:4 n-6, EPA, DPA, DHA, total n-3 FAs, and VLC n-3 PUFAs (Table 6). Dietary SDA greatly elevated adipose SDA content (1443 mg/100 g tissue; 1.79% of FAs), while EPA, DPA, and DHA were only detected in adipose from hens fed the FISH diet (Table 6). ETA was detected only in adipose tissue from hens fed the SDA and FISH diets, which provided further evidence that dietary SDA was more efficiently converted to VLC n-3 PUFAs than was ALA. As compared to liver (on a mg/100 g fresh tissue basis), adipose contained approximately 12-fold more total FAs and higher total n-3 FAs, but had much lower contents of VLC n-3 PUFAs (Tables 5 and 6). This was most likely a reflection of the relative differences in the contribution of membrane phospholipid and neutral lipids to the total FA content of the two tissues[30] and the low activity of elongase and Δ5 and Δ6 desaturase enzymes in adipose tissue.[31]

[a]Values are d 28 least-squares means of 7 hens each for the CON and FLAX diets, and of 8 hens each for the SDA and FISH diets. Average liver weights for hens fed the CON, SDA, FLAX, and FISH diets were 30.4, 27.9, 28.1, and 29.5 g, respectively ($P = 0.48$). [b]VLC n-3 = polyunsaturated n-3 fatty acids greater than 18 carbons. [c]Values within a row with different letters are significantly different ($P < 0.05$). [d]ND = not detected

Hepatic Gene Expression. Expression of SREBP1 was 36% lower in livers of hens fed FISH compared to the CON diet (see Supporting Information). Expression of other genes assayed, including long-chain FA desaturases (SCD1, FADS1, and FADS2), FA elongases (ELOVL2 and ELOVL5), a lipogenic enzyme (FASN), a cholesterol synthesis enzyme (HMGCR), FA oxidation enzymes (CPT1a and ACOX1), and lipogenic transcription factors (SREBP1 and MLX), were not changed by treatment (see Supporting Information). It is noteworthy that HMGCR gene expression was also 43% lower in FISH-fed birds as compared to CON hens, but the difference was not significant ($P = 0.19$).

DISCUSSION

Although the laying hen converted approximately 2-fold more ingested SDA vs ingested ALA from FLAX into egg yolk VLC n-3 PUFAs (Table 4), the absolute amounts of ETA + EPA + DPA + DHA were much less than that in yolks from hens fed the FISH diet (Table 3). We therefore must reject our hypothesis that bypassing the first FADS2 reaction, by feeding laying hens SDA, would enrich eggs with EPA and DHA at levels comparable to those attained by direct dietary supplementation of these VLC n-3 PUFAs. In addition, the current work suggests that, in the chicken, other control points besides the initial Δ6-desaturase (FADS2) reaction (ALA → SDA) exist in the biosynthesis of DHA from ALA, such as steps catalyzed by elongases[17,32] or, depending upon the dietary abundance of ALA, possibly the second Δ6-desaturase reaction[17] (24:5 n-3 → 24:6 n-3; the latter undergoes β-oxidation to yield DHA). It is also conceivable that either the in vivo conversion rate of ALA (or SDA) to DHA, and/or the capacity of the n-3 PUFA biosynthetic pathway, is simply not great enough in the laying hen to allow for the deposition of EPA and DHA into egg yolk at levels equal to those attained by direct dietary supplementation.

The dietary ratio of LA:ALA is another factor that can affect the conversion of ALA to VLC n-3 PUFAs.[33,34] However, LA intakes were similar for the SDA and FLAX groups, averaging approximately 2400 mg/hen/d and 2200 mg/hen/d, respectively, while CON birds ingested approximately 1000 mg/d more LA than the SDA hens but had a greater rate of conversion of ALA (vs SDA) to VLC n-3 PUFAs (0.132 and 0.075, respectively; Table 4).

The in vivo conversion rates of SDA and ALA to VLC n-3 PUFAs observed in the present study were similar to those calculated for hens fed control and flaxseed diets in three previous reports (Table 4).[27−29] In those studies, as the amount of dietary ALA from flaxseed increased, the calculated rate of in vivo conversion to egg yolk VLC n-3 PUFAs decreased. This suggested that high dietary levels of ALA attenuated its hepatic elongation and desaturation and/or enhanced its oxidation or transport to peripheral tissues. Although in the present study it was impossible to know the exact conversion rate of ALA to VLC n-3 PUFAs in the SDA-fed hens, we assumed that it

[a]Values are d 28 least-squares means of 7 hens each for the CON and FLAX diets, and of 8 hens each for the SDA and FISH diets. Average abdominal fat pad weights for hens fed the CON, SDA, FLAX, and FISH diets were 82.5 g, 77.8 g. 87.3 g, and 82.6 g, respectively ($P = 0.84$). [b]VLC n-3 = n-3 polyunsaturated fatty acids greater than 18 carbons. [c]Values within a row with different letters are significantly different ($P < 0.05$). [d]ND = not detected

decreased linearly with ALA intake and that there was no inhibition of ALA conversion by SDA. Future work will need to be conducted to assess the latter assumption.

With an average VLC n-3 PUFA content of 305 mg (Table 3), it should be noted that consumption of one egg from the FISH-fed hens would exceed the *2010 Dietary Guidelines for Americans* recommended average daily intake of 250 mg of EPA and DHA,[7] while two eggs from SDA-fed hens would have to be eaten to meet this level. However, because of their cholesterol content, consumption of two eggs per day would not be recommended for "hyper-responders", who exhibit significant increases in circulating low density lipoprotein cholesterol in response to increases in dietary cholesterol, or for persons with elevated plasma low density lipoprotein cholesterol levels, diabetes, and/or cardiovascular disease.[35] Thus, a plant-based dietary supplement capable of enriching eggs with VLC n-3 PUFA levels similar to that attained by feeding hens FISH remains elusive. Feeding fish oil or algae oil remains the most efficient method for maximizing the deposition of VLC n-3 PUFAs in egg yolk[10] or broiler meat,[36] although product oxidative stability or organoleptic properties may not be ideal.

The general lack of effect of dietary SDA on the expression of hepatic lipolytic and lipogenic genes (see Supporting Information) was somewhat surprising, but agreed with a recent report in swine.[37] Another unexpected and novel finding of the present work was that SDA appeared to be more readily incorporated into adipose tissue than into egg yolk. Abdominal fat pads from SDA-fed hens contained 1443 mg SDA and no VLC n-3 PUFAs per 100 g fresh tissue (Table 6). In contrast, only 71 mg (or 9%) of the calculated 761 mg of SDA consumed daily was deposited into egg yolk, either intact (14 mg SDA; Table 3) or in the form of VLC n-3 PUFAs (57 mg). The latter figure was calculated from the estimated in vivo conversion rate of 0.075 mg VLC n-3 PUFAs incorporated into egg yolk per mg SDA intake per d (see Table 4) × 761 mg SDA consumed/hen/d. Thus, most of the consumed SDA, which was assumed to be readily absorbed from the intestine, was likely oxidized and/or transported from the liver to somatic tissues such as adipose. Additionally, of the 125 mg total VLC n-3 PUFAs per yolk of eggs from hens fed the SDA diet (Table 3), by difference 68 mg were presumably derived from the bioconversion of ALA, which agrees well with the calculated amount (67 mg; 0.120 estimated conversion value ×557 mg intake per d). In contrast, FISH-fed hens deposited 305 mg (Table 3), or approximately 33%, of 933 mg of VLC n-3 PUFAs consumed daily directly into egg yolk (933 mg calculated from data in Table 2 and Supporting Information). A small amount of the 305 mg of yolk VLC n-3 PUFAs most likely was derived from the 167 mg of ALA and 88 mg of SDA consumed daily by the hens (calculated from data in Table 2 and Supporting Information).

Another possible reason for the higher SDA content of adipose tissue compared to egg yolk is that deposition into the former was cumulative over 28 d, while a growing ovarian follicle (future egg yolk) accumulates most of its lipids (and

DOI: 10.1021/jf505185u
J. Agric. Food Chem. 2015, 63, 2789−2797

protein) during the final 4−6 d prior to ovulation.[38] Moreover, since the abdominal fat pad represents only a portion of the total body adipose tissue, the absolute amount of SDA deposited ex ovo would be even greater. This raised a question as to how SDA was transported to the abdominal fat pad, since current dogma would predict that most of the absorbed dietary SDA would be esterified into liver triglycerides, packaged into "yolk-targeted" very low density lipoprotein particles,[39] secreted into the bloodstream, and taken up by growing oocytes (future egg yolks) via receptor-mediated endocytosis,[40] thereby preferentially enriching egg yolk. One possibility is that, within the liver, SDA distributes into various intracellular lipid pools and is metabolized differently than other 18-carbon PUFAs, such as GLA, as has been reported in rat hepatocytes.[41] Our findings therefore suggest that, in the chicken, an alternate major pathway for SDA secretion and transport may exist, either via secretion from the liver into the bloodstream as an albumin-bound nonesterified fatty acid or possibly as a component of another recently reported subclass of VLDL particles containing apolipoprotein-VLDL-IV (Apo-IV), which are excluded from oocytic uptake and deliver their lipids to somatic cells.[42] These possibilities await further investigation.

fermentation by applying cell wall profiling methods that were optimized for grape berries.[24] Both ripe and overripe grapes were used in order to investigate the impact of cell wall degradation resulting from ripening on these processes. We have applied comprehensive microarray polymer profiling (CoMPP) to monitor the cell wall polysaccharides and proteins directly by virtue of the presence of epitopes. To our knowledge, this is the first study that uses CoMPP to investigate the effect of maceration enzymes on the cell walls of grape berry skin during wine fermentation. CoMPP analysis is a semiquantitative high-throughput profiling technique and consists of the sequential extraction of the pectin (CDTA extract) and hemicellulose (NaOH extract) fractions from cell wall material.[25] These fractions are then printed onto nitrocellulose membranes and probed with monoclonal antibodies (mAbs) as well as carbohydrate-binding modules (CBMs). The data obtained provides an indication of the relative abundance of specific cell wall polysaccharides in a sample. The CoMPP data is supported by monosaccharide compositional analysis (GC-MS) and reflectance spectroscopy (FT-MIR) data. Multivariate data analysis tools were used to identify the components that characterized the differences in cell walls sourced from the different treatments. The combination of methods employed are complementary and produced valuable information on the variation in both the surface polymers as well as the profile of polymer building blocks present at different ripeness levels, winemaking stages, or after different enzyme treatments.

MATERIALS AND METHODS

Vinification of Wine. *Vitis vinifera* cv Pinotage grapes were sourced from vineyards in the Boland region of South Africa during the 2012 and 2013 vintages. Fermentations were done in triplicate in 2012 and quadruplicate in 2013 in polypropylene buckets with 5 kg of destemmed and crushed grapes per bucket (weighed, destemmed, and crushed individually; one bucket is one biological repeat). After the grapes were crushed, sodium metabisulfite was added (30 ppm of SO_2), and the total acid was adjusted to 6.5 g/L. The yeast strain, *Saccharomyces cerevisiae* VIN13 (Anchor Yeast, Johannesburg, South Africa), was rehydrated and inoculated according to the manufacturer's recommendations, and yeast nutrition was supplemented with Fermaid K (Lallemand, Bellville, South Africa). Where applicable, Rapidase Ex Color, -CB, and -Expression (DSM Food Specialties, Heerlen, The Netherlands) were added to the crushed grapes at a dosage of 0.03 g/L. The manufacturer of these enzymes declares that all the mixes have primarily pectinolytic activity but that RapidaseCB has been formulated with enhanced polygalacturonase activity, Rapidase Ex Color has additional hemicellulases for optimum grape skin extraction during maceration, and Rapidase Expression formulations contain arabinases and rhamnogalacturonases (product data sheets, http:\\www.dsm-foodspecialities.com). Fermentations were conducted at 25 °C, and the grape skin caps were punched down twice daily. At the end of alcoholic fermentation, the wines were pressed and transferred to 4.5 L glass bottles fitted with fermentation caps. The pomace was stored at 4 °C until analysis (up to 1 week). Freeze-dried *Oenococcus oeni* Lalvin VP41 (Lallemand, South Africa), supplemented with OPTI-MALO-PLUS (Lallemand), was inoculated in the wine to induce malolactic fermentation (MLF), and the fermentations were incubated at 20 °C. At the end of MLF, the wine was racked off the lees, sulfited (80 ppm of SO_2), stabilized at 4 °C, and then filtered and bottled.

General Oenological Parameters. Three 50 mL samples of the juice were randomly selected from the buckets after the grapes were crushed and analyzed for sugar and acid concentration using Fourier transform infrared (FT-IR) spectroscopy with a WineScan FT120 Basic (FOSS Analytical, Hillerød, Denmark). The same instrument was used to analyze the pH, volatile acidity, total acid, glucose + fructose, and ethanol levels of two 50 mL wine samples from each biological repeat at the end of MLF. The FT-IR scans were done in duplicate per sample (two technical repeats). Wine samples for color analysis were collected three months after the wines had been bottled. The pH of all samples was adjusted to 3.5, and the color characteristics were determined according to Iland et al.[26] using a Specord 50 UV/vis spectrophotometer (Analytik Jena, Jena, Germany). The analysis was done in triplicate.

Pinotage Skin Cell Wall Preparation. For the fresh grape skin samples, the grapes were selected from different harvest crates, from different bunches, and from the top, middle, and bottom of a bunch to mimic the variability that is found in a commercial harvest batch. The berries were frozen and stored at −20 °C before the skins were obtained by manually peeling the grapes with a scalpel and flash-freezing the skins in liquid nitrogen. A group of 21 samples (each 10 g wet weight) was collected in 2012 and kept at −80 °C before freeze-drying (likewise 12 samples in 2013). The fermented grape skin samples (with and without enzyme treatment) were collected at the end of alcoholic fermentation after pressing (at least two samples per biological repeat) and stored at 4 °C before excess pulp was removed from the skins with a scalpel and the skins were freeze-dried. Samples (each 10 g wet weight) were milled and homogenized with a Retsch MM400 mixer mill (Retsch, Haan, Germany) at a frequency of 30 Hz for 30 s, and the resulting powder was used for the isolation of the cell walls using the method described by Ortega-Regules et al.[27] with the following changes. The first acetone step after the buffered phenol extraction was omitted. Furthermore, after the third acetone wash, the alcohol-insoluble residue (AIR) was air-dried, then mixed with a volume of Milli-Q water roughly equal to the pellet size of the AIR, frozen at −80 °C, and then freeze-dried.

Mid-Infrared Spectroscopy. AIR samples isolated from fresh and fermented Pinotage skins (with and without the addition of maceration enzymes) were analyzed by infrared spectroscopy. The samples were placed in direct contact with the diamond window and the spectra between 4000 and 600 cm^{-1} were acquired using a NEXUS 670 (Thermo Scientific, MA, USA) fitted with a Golden Gate Diamond ATR (attenuated total reflectance). A Geon-KBr beam splitter and DTGS/Csl detector were used and each sample was scanned 128 times. The FT-MIR spectra data were filtered with a MSC (multiplicative scatter correction) filter to compensate for light scattering and differences in the effective path length. The spectra for the fingerprint region (1400−800 cm^{-1}, where every polysaccharide has its own unique pattern) as well as wavelengths from 1400 up to 1800 cm^{-1} that conveys information about functional groups[28,29] were compared between treatments. The spectra shown in the Results section represent the average absorbance from at least five AIR samples per treatment. Technical repeats were done once every 10th scan to control for technical reproducibility.

Monosaccharide Analysis of Cell Wall Samples. The monosaccharide composition of the AIR isolated from the grape skins was analyzed according to the method described in ref 30 and used on grape cell walls in ref 24, including a few modifications. Approximately 5 mg of AIR was hydrolyzed to monosaccharides using 2 M TFA and incubated for 2 h at 110 °C.[30] This was followed by derivatization to methoxy sugars at 80 °C for 16 h. After silylation with HMDS/TMCS/pyridine (3:1:9, Sylon HTP kit, Sigma-Aldrich, MO, USA), the derivatives were separated and analyzed in a gas chromatograph instrument (Agilent 6890 N, Agilent Technologies, CA, USA) coupled to an Agilent 5975 MS mass spectrometer detector, using a polar (95% dimethylpolysiloxane) ZB-Semivolatiles Guardian GC column (30 m, 0.25 mm ID, 0.25 μm film thickness). The oven temperature was maintained at 70 °C for 2 min, ramped up at a rate of 1 °C/min to 76 °C, then increased at 8 °C/min to 300 °C, and then held for 5 min. The monosaccharide composition was expressed as the mole percentage contribution of each monosaccharide in relation to the nine monosaccharides present. Error bars in the histograms or the standard deviation in the tables represent the mean of at least three biological samples.

J. Agric. Food Chem. 2015, 63, 2798−2810

Comprehensive Microarray Polymer Profiling (CoMPP) Analysis of Cell Wall Fractions. The pectin- and hemicellulose-rich fractions of the cell wall samples were sequentially extracted from 10 mg AIR samples using the solvents CDTA (diamino-cyclo-hexane-tetra-acetic acid) and NaOH, respectively, according to a procedure described elsewhere.[24] Arrays printed with the different fractions were probed individually with 26 different mAbs and CBMs as previously described.[25] A mean spot signal was calculated, whereafter it was normalized to the highest signal in the data set (set as 100), and a cutoff value of five was used.

Multivariate and Univariate Statistics. Univariate statistical analyses were done (ANOVA, with $P = 0.05$) under the guidance of the Centre for Statistical Consultation at Stellenbosch University (Prof. Martin Kidd) using Statistica 10 (StatSoft Southern Africa - Analytics, Sandton, South Africa). Multivariate analysis by means of principle component analysis (PCA)[31] and orthogonal projections to latent structures (OPLS) were performed using SIMCA 13 software package (Umetrics AB, Umeå, Sweden).

RESULTS AND DISCUSSION

In this study, we used Pinotage grapes at different ripeness levels as reflected in the glucose + fructose (2012: 227 g/L and 2013: 265 g/L) and total acid (2012: 5.37 g/L and 2013: 4.85 g/L) concentrations of the juice samples (Table S1). According to traditional ripeness criteria discussed in the Supporting Information (section S 1.1), the grapes at 22.7 °B were considered to be at optimum ripeness, whereas those at 26.5 °B are deemed overripe.[32,33] Each year, we compared the cell wall composition of fresh (unfermented) skins with skins that went through an alcoholic fermentation. Additionally, we investigated the cell walls from fermentations supplemented with commercial maceration enzymes and compared them to their no-enzyme-added counterparts to determine the changes caused by enzymatic hydrolysis. To evaluate the influence of ripeness levels, we compared the results from the samples over the two years with each other.

Effect of Ripeness Level in the Fresh Grape Skin Cell Walls. The mole percentage (mol %) ratio of the nine main monosaccharides found in grape skin cell walls of Pinotage is shown in Figure 1 and confirms the abundance (ca. 35 mol %) of galacturonic acid (GalA) as previously shown for grape skin.[14] The profile obtained (ca. 20 mol % Ara, arabinose, 15 mol % Xyl, xylose, and Gal, galactose, and lower than 10 mol % for the other sugars) compared well with other red wine cultivars such as Cabernet Sauvignon, Merlot, and Shiraz.[27,34] However, direct comparisons of monosaccharides levels should be avoided because of the different methods that were used to determine the uronic acids (TMS methyl glycosides or alditol acetates)[30] because this influences the relative molar ratios obtained.

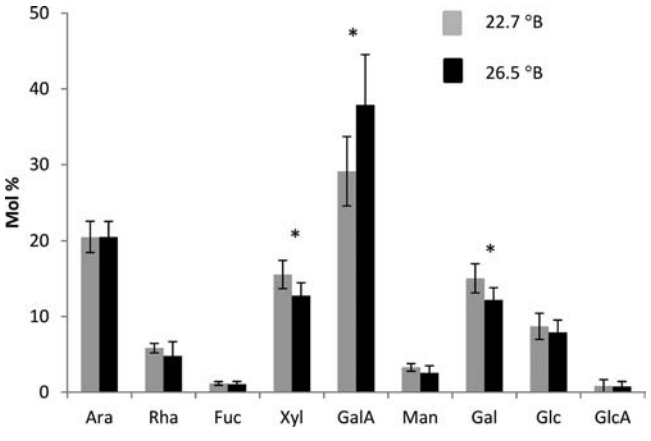

Figure 1. Monosaccharide composition of cell walls from ripe (22.7 °B, 2012) and overripe (26.5 °B, 2013) fresh Pinotage grape skin.The bars represent the average of at least 10 biological repeats. The stars indicate a statistically significant difference for a specific monosaccharide (t test, 95% confidence level) between the two ripeness levels. Ara, arabinose; Rha, rhamnose; Fuc, fucose; Xyl, xylose; GalA, galacturonic acid; Man, mannose; Gal, galactose; Glc, glucose; and GlcA, glucuronic acid.

The abundance of homogalacturonan (HG) in the skin cell walls was confirmed with the CoMPP analysis, as indicated by the signal values in the heat map (Figure 2, CDTA fraction, fresh samples). The cell walls also contained high levels of xyloglucan (mAbs LM15 and LM25) and cellulose (mAb CBM3a), with the latter dissolving along with the hemicellulose fraction (Figure 2, NaOH fraction, fresh samples) which might be a reflection of the known association between the cellulose and hemicellulose network in plant cell walls.[35] Both the pectin and the hemicellulose fraction showed the presence of arabinogalactan proteins (AGPs) and extensins. α-1,5-L-Arabinan and β-1,4-D-galactan, probably linked to rhamnogalaturonan I (RG-I), were found in the hemicellulosic fraction. This corresponded with work done by Zykwinska et al.[36] on alkali extracts from potato and sugar beet cell walls where they observed strong interaction between arabinan or galactan side chains and the cellulose microfibrils surface and were also observe in grape tissue.[24]

Comparing ripe (22.7 °B) with overripe (26.5 °B) Pinotage skin cell walls (Figure 1), the overripe samples had significantly less (95% confidence level) Gal (2.9 mol % decrease) and Xyl (2.8 mol % decrease) but more GalA (8.8 mol % increase). The lower percentage contribution of Gal in the overripe grapes corresponds with what other authors[17,24,34] described as typical changes during fruit and grape berry ripening and is believed to be related to arabinogalactan degradation as fruit softens. The lower mole percentage of Xyl and Gal in the overripe grapes is corroborated by the CoMPP analysis (Figures 2 and 3A,B, fresh samples and PCA plot of NaOH fraction, respectively) where a decrease in xyloglucan (mAbs LM15 and LM25) and β-1,4-D-(galacto)(gluco)mannan (mAb LM21) was observed in the skin cell walls of the riper grapes. This was accompanied by a decrease in cellulose (mAb CBM3a). Similar results were seen by Yakushiji et al.,[37] and Vicens et al.[17] reported a decrease in Xyl with a concurrent decrease in xyloglucan during ripening, confirming that not only pectin polysaccharides depolymerize with fruit ripening, but also hemicelluloses.

There is no consensus yet on the fate of GalA in the grape skin during ripening. According to the data from Ortega-Regules et al.,[34] the uronic acid concentration reaches a peak before grape maturity and then declines (Monastrel and Cabernet Sauvignon grapes), but this was not confirmed for all the cultivars that were tested (Syrah increased and Merlot decreased with ripening). The higher levels of GalA found in our overripe grape skins might be due to mesocarp material that peeled off along with the skin. The higher GalA levels were confirmed with the CoMPP data (Figures 2 and 4A,B, PCA plot and CDTA extract, respectively) where the overripe skins were more abundant in HG epitopes (mAbs LM18, LM19, JIM7, and JIM5) than the ripe skins. Additionally, the overripe skins showed more arabinogalactan proteins (AGPs, mAbs JIM8 and JIM13), which corresponded well with the observed accumulation of structural cell wall proteins during fruit

J. Agric. Food Chem. 2015, 63, 2798−2810

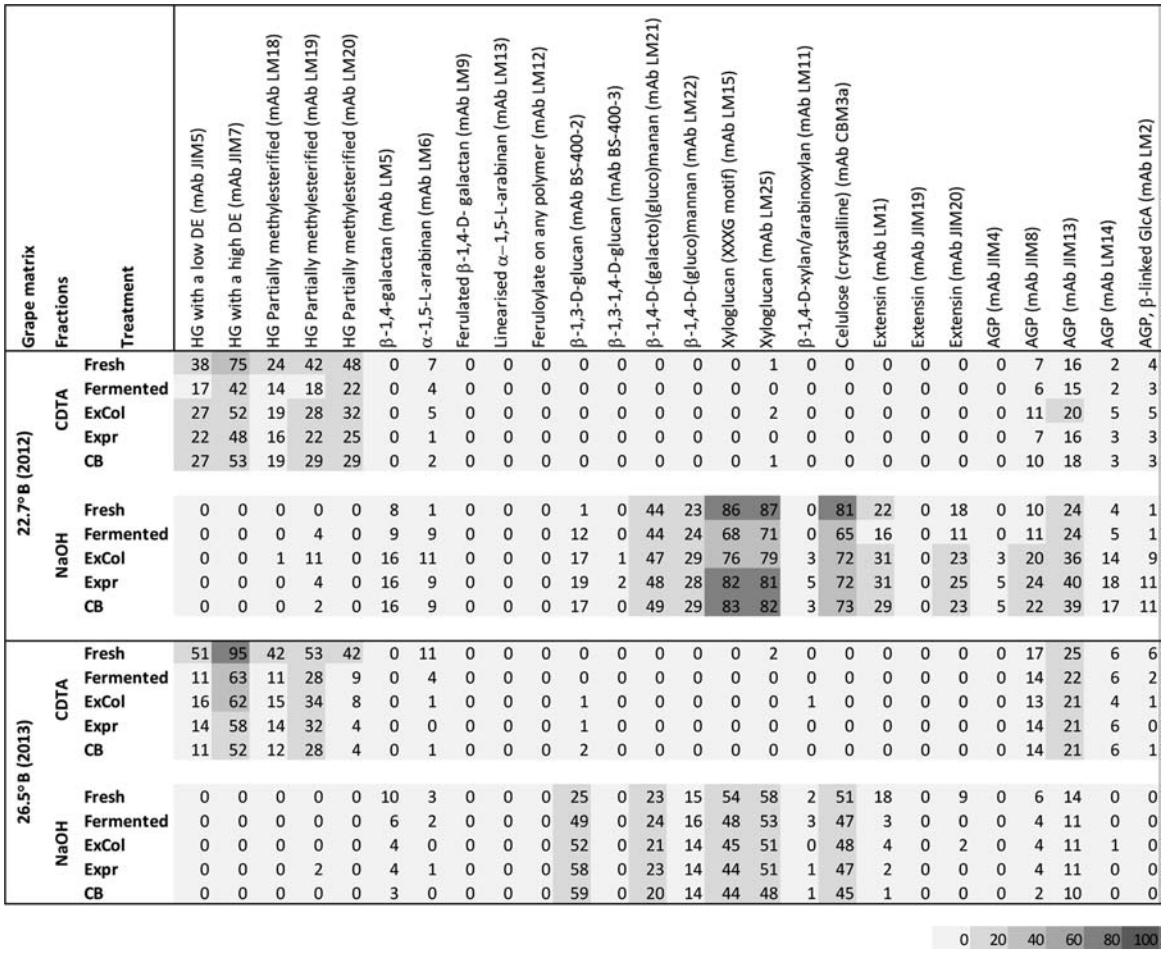

Figure 2. Heat map (CoMPP results) showing the relative abundance of the cell wall polysaccharides found in the pectin (CDTA) and hemicellulose (NaOH) fractions extracted from the cell walls of fresh and fermented (with and without maceration enzyme treatment) grape skins. Fresh = extracts from fresh skin cell walls. Fermented = extracts prepared from the cell walls of skins sampled at the end of alcoholic fermentation (without enzyme addition). ExCol, Expr, and CB = the same as Fermented but with the addition of Rapidase ExColor, Expression, and -CB enzymes, respectively. Values are the average of at least 3 biological repeats.

ripening.[17,38] The overripe samples were more abundant in *β*-1,3-D-glucan (callose, NaOH fraction, Figure 3B, PC2 = 11%), which is typically formed in response to pathogen-induced stress or wounding.[39] The overripe and softer grapes were probably more vulnerable to wounding during the harvest and the peeling of the skins. The separation of the 22.7 °B samples from the 26.5 °B samples is not dominated by the abundance of mAb BS400-2 (callose) as suggested by Figure 3 because the overall pattern of a PCA where we excluded this antibody (results not shown) were unchanged from the PCA in Figure 3.

The PCA plots of the CoMPP data for fresh cell walls sampled from grapes at the two different ripeness levels (Figures 3A and 4A) showed significant heterogeneity between the samples within a harvest. This is indicated in the NaOH fraction (Figure 3) by the different subgroups formed by the 26.5 °B samples (circled) as well as by a strong spread of the 22.7 °B samples along the second component axis, (arrow). Closer examination of the CDTA fraction revealed that certain samples from both ripeness levels clustered together (Figure 4, indicated in a block) because they have an abundance of HG, AGPs, and extensins. These samples thus contained a higher percentage of riper skins than the other samples from their respective ripeness-level groups and demonstrated the heterogeneity found in the grapes harvested for a standard commercial wine fermentation.

Effect of the Maceration Enzymes on the Fermented Grape Skin Cell Walls. During the maceration step of red wine fermentation, the ethanol formed penetrates the berry cell walls and permeabilizes the plasma and the vacuolar membranes of the cells and serves as an extraction solvent for a range of molecules, including high-molecular-weight tannins.[6] Furthermore, pectin solubilization also occurs during fermentation because organic acids such as malate, citrate, and phytic acids present in grape must act as chelating agents, removing the calcium ions that form bridges between HG polymers.[22] Thus, even with no addition of maceration enzymes, cell wall modifications probably occur as a consequence of the fermentation process alone.

The most marked impact of the fermentation process (Figure 5) was an increase in mannose (Man, 2.9 mol % in 2012 and 5.3 mol % in 2013) and glucose (Glc, 8.2 mol % in 2012 and 6.8 mol % in 2013) and a slight decrease in Ara (3.8 mol % in 2012 and 2.7 mol % in 2013). The increase in Glc and Man is probably due to a reduction in pectin polymers, leading to a relative increase in polymers such as cellulose, mannan, and xyloglucan. Although not statistically significant, GalA values showed a decreasing trend (2.8 mol % in 2012 and 5.6 mol % in

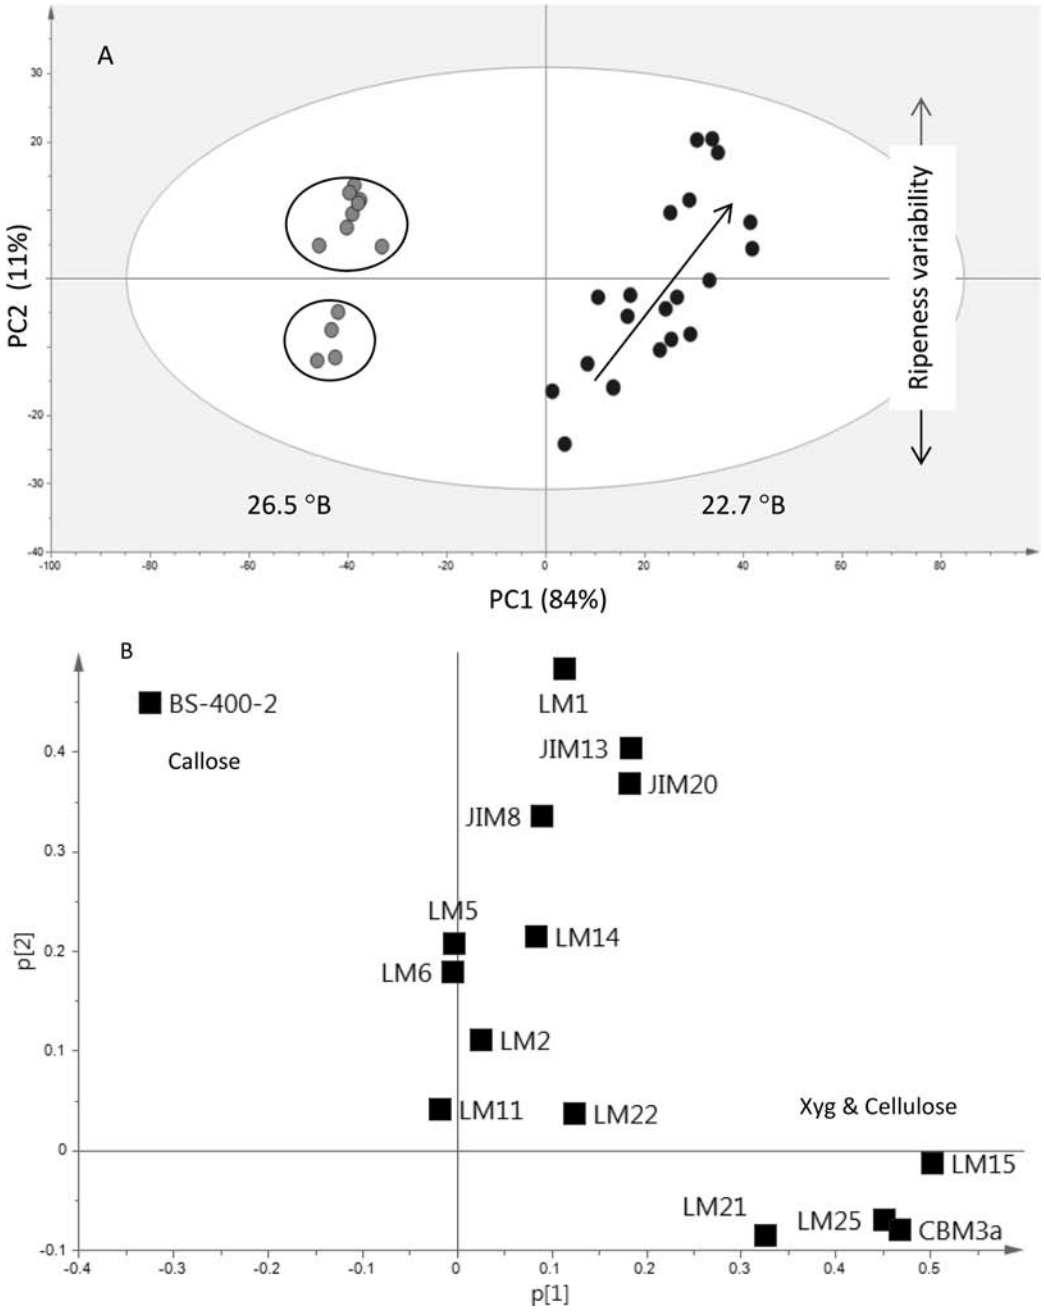

Figure 3. CoMPP results showing a PCA score plot (A) and loading plot (B) of the hemicellulose fraction (NaOH) of cell walls from fresh skins for ripe (22.7 °B, 2012, solid black circles) and overripe (26.5 °B, 2013, solid gray circles) grapes. Subgroups are circled, and the variance in the ripe (22.7 °B) skin data is highlighted with an arrow. Xyg = xyloglucan.

2013; *t* test, 90% significance) as a result of the fermentation. This decrease was also clearly visible in the CoMPP data (Figure S1 A,B). This PCA plot shows the fermented (without enzyme) samples on the left separate from the fresh, unfermented samples on the right. The separation or variance was due to the abundance of HG polymers (labeled by mAbs JIM5, JIM7, LM18, LM19, and LM20) in the fresh samples. A similar analysis with the FT-MIR spectra (Figure 6) also indicated that the fresh skin cell walls had more pectin (high absorbance at 1095 and 1157−1147 cm^{-1}).

Another explanation for the elevated Man concentration (Figure 5) of the fermented samples may be the presence of the wine yeast. A total of 40% of the wine yeast cell wall (dry weight) consists of mannoproteins, and 98% of the sugar in this cell wall component is Man.[40] Yeast cell wall debris that sticks to grape skin fragments could possibly end up in the cell wall extracts and thus inflate the Man values. Similarly, yeast cell wall debris that contains β-1,3-D-glucan[41] might also have contributed to the elevation in Glc concentration seen but a more likely source could be callose (β-1,3-D-glucan) formation in the fermented grape skins. The formation of callose in grape berries that are crushed and punched down during the red wine production process is plausible, and CoMPP analysis confirmed the presence of β-1,3-D-glucan (mAb BS-400-2, specific to callose). It is not known whether this mAb will also label β-1,3-D-glucan in yeast cell walls; however in other results by our group (unpublished), we regularly see a signal for mAb BS-400-2 in grape tissue that did not undergo fermentation.

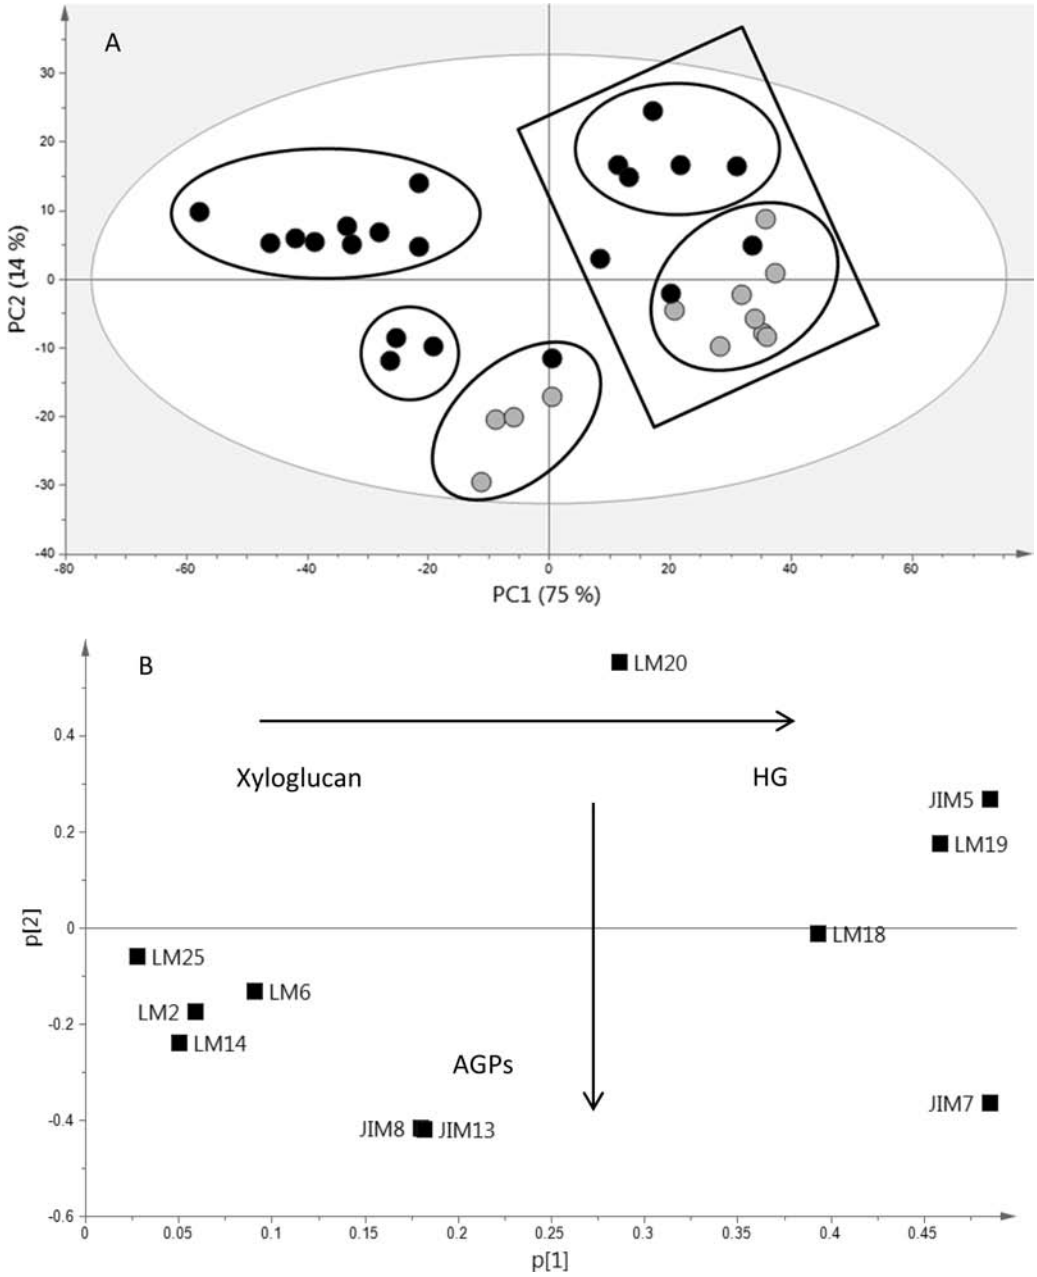

Figure 4. CoMPP results showing a PCA score plot (A) and loading plot (B) of the pectin fraction (CDTA) of cell walls from fresh Pinotage skins at different ripeness levels (22.7 °B, 2012, solid black circles, and 26.5 °B, 2013, solid gray circles). Subgroups are encircled and indicate that the separation of the groups is driven by an abundance in AGPs and HG.

Finally, the decrease in Ara because of the fermentation process may be attributed to the release of AGPs and type II arabinogalactans into the fermenting must. These molecules constitute ca. 40% of the total polysaccharides found in red wine[42,43] and Guadalupe and Ayestarán[44] showed that the Ara concentration increased to more than 150 mg/L at the end of alcoholic fermentation. However, the FT-MIR data (Figure 6) showed that the fermented skin cell walls had more protein (high absorbance at 1650 and 1550 cm^{-1}) than the fresh skins. This seems to be in contrast to the decrease in Ara and the assumed loss of AGPs, but it needs to be considered that the monosaccharide analysis measured the total amount of Ara in the samples, whereas the FT-MIR spectra only evaluated the surface or cell wall proteins exposed after depectination. In general, therefore, we see that the fermentation process caused similar compositional changes in the skin cell walls of grapes, irrespective of the ripeness level of the skins. However, the ripeness might have an influence on the magnitude of the changes observed. This can be seen in Figure 6 at wavelengths 1550 and 1650 cm^{-1}, where the gray dotted line that represents the fermented samples at 26.5 °B showed the largest deviation from the fresh samples.

Color analysis on the wine prepared in this study showed no significant improvement in the color density of the wines produced from enzyme-treated fermentations (Supporting Information, section S 1.2 and Table S1). To supplement this indirect evaluation of the impact of enzymes, we asked whether this implies that the maceration enzymes did not alter the cell walls of the skins. This led to the final investigation of this study where we aimed to determine how typical commercial

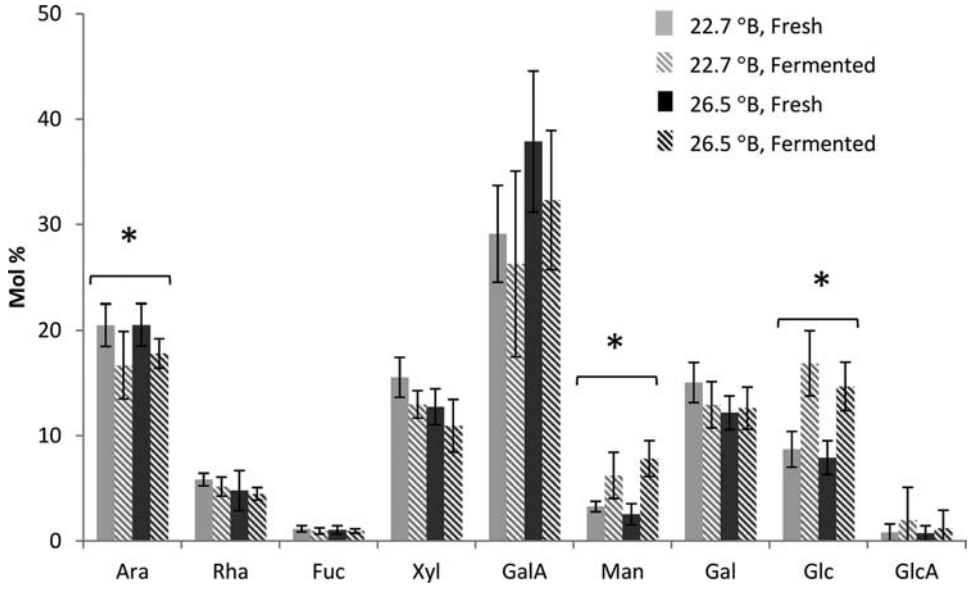

Figure 5. Mole percentage (mol %) changes in the monosaccharide composition of the cell walls extracted from fresh and fermented Pinotage skins in 2012 and 2013. Significant changes (indicated by stars) brought about by the fermentation process include an increase in Man and Glc and a slight decrease in Ara (95% confidence level, ANOVA). The bars represent the average of at least three biological repeats.

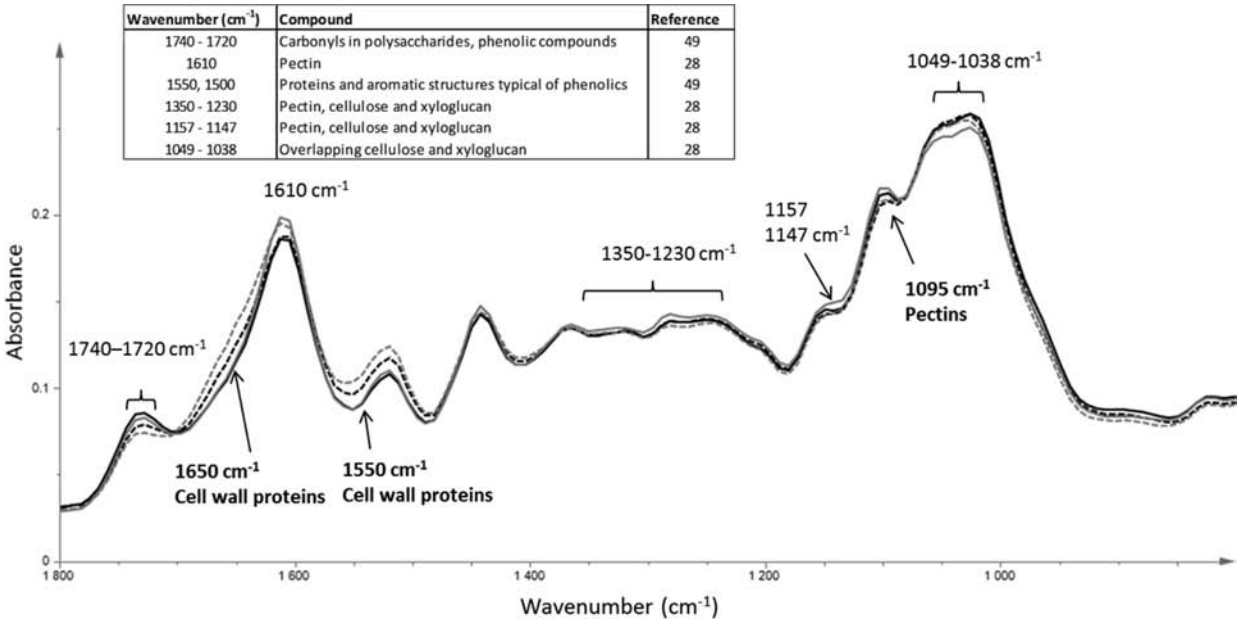

Figure 6. FT-MIR spectra of the fresh versus fermented (without enzymes) cell walls at two ripeness levels. Solid black and dashed black lines, fresh and fermented 22.7 °B 2012, respectively, and solid gray and dashed gray lines, fresh and fermented 26.5 °B 2013, respectively. The areas and peaks that represent typical chemical groups found in plant cell walls are shown on the spectra and in the table. The greatest variations are at wavelengths 1650 and 1550 cm^{-1} where the cell walls isolated from the fresh skins have a lower absorbance than the fermented samples, indicating that they have less cell wall proteins. Another interesting area is the peak at 1095 cm^{-1} that shows that the cell walls isolated from fresh skins have more pectin than the fermented samples. The spectra represent the average absorbance from at least five AIR samples per treatment.

maceration enzymes change the cell walls of grape skins during fermentation. We therefore compared the samples from the enzyme-free fermentations with samples from the enzyme-assisted fermentations. The most dominant changes (Figure 7, 95% confidence level, ANOVA) to the monosaccharide composition of the cell walls brought about by the enzymes were: (1) an increase in Man (avg. of 3.7 mol % in 2012 and 4.8 mol % in 2013) and Glc (no significant increase in 2012 and avg. of 4.7 mol % in 2013) and (2) a decrease in Ara (avg. of 2.3 mol % in 2012 and 2.9 mol % in 2013), Rha (avg. of 0.9 mol % in 2012 and 1.1 mol % in 2013), and GalA (no significant increase in 2012 and an avg. of 9.6 mol % in 2013) composition. As previously discussed, the relative increase of the cellulose, mannan, and xyloglucan monosaccharides (Man and Glc) is a consequence of the degradation of pectin polymers (HG and RG), but this time it was due to the hydrolysis and depectination of the cell wall polysaccharides by the maceration enzymes (enzyme-treated values were compared to control fermentation values). Similarly, the decrease in Ara and Rha is an indication of RG-I, arabinan, and AGP

DOI: 10.1021/jf505200m

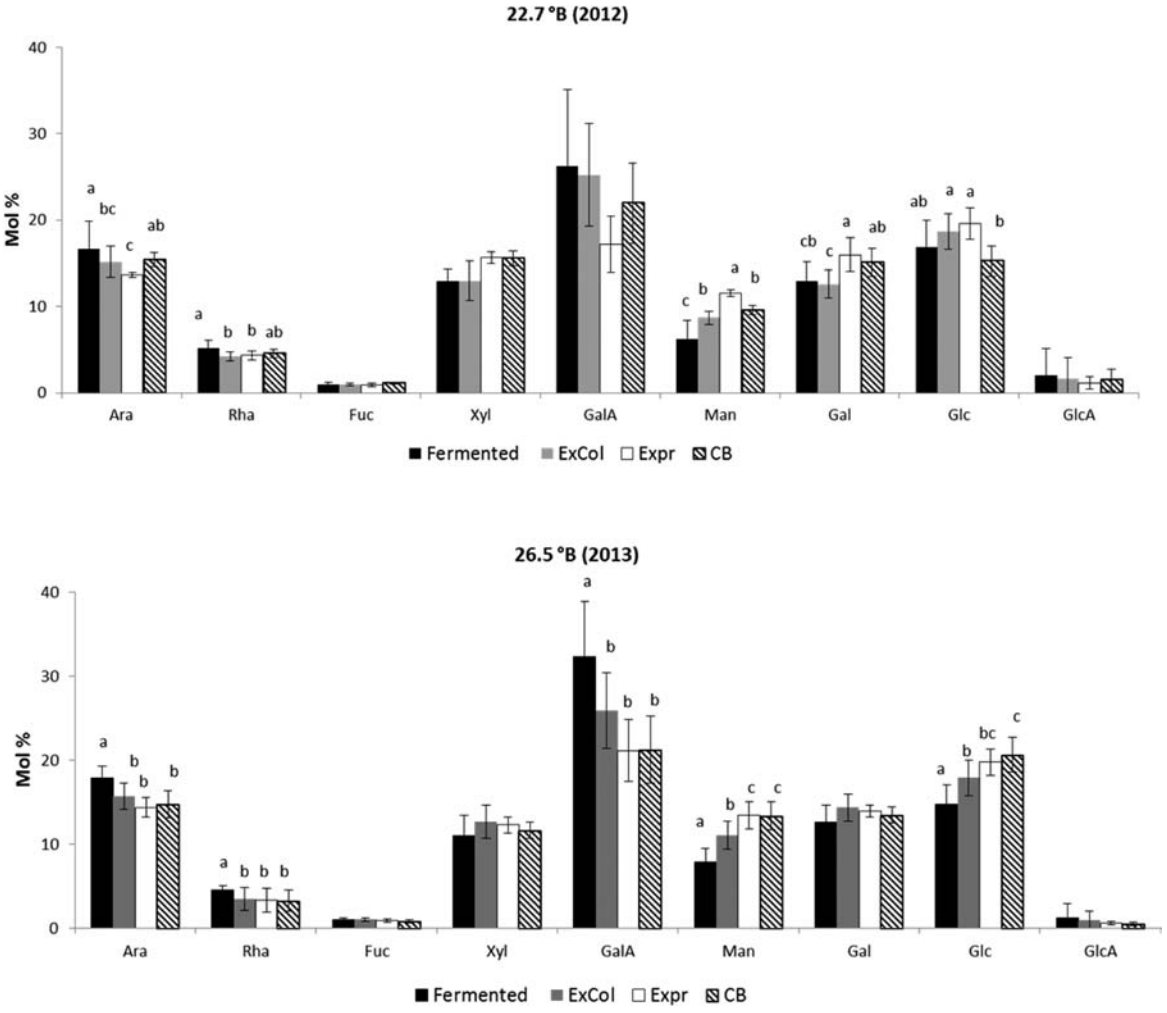

Figure 7. Mole percentage (mol %) changes in the monosaccharide composition of the cell walls from Pinotage skins from fermented (no enzyme addition) and maceration enzyme-treated fermentations at 22.7 and 26.5 °B. Different letters indicate a significant difference between the different treatments for a specific sugar (95% confidence level, ANOVA). "Fermented" stands for cell wall samples from fermentation without enzyme addition. "ExCol", "Expr", and "CB" represent cell wall samples from fermentation with the addition of Rapidase Ex Color, Rapidase Expression, and Rapidase CB, respectively. The values represent the average of three biological repeats.

degradation. We thus see the same type of monosaccharide changes occurring in enzyme-free and enzyme-assisted fermentation, but the enzymes increased the magnitude of the changes. Maceration enzymes might also introduce additional changes to the cell wall such as the proportional decrease in Rha (Figure 7) because a similar decrease was not observed under enzyme-free conditions (Figure 5).

On the polymer level (CoMPP data), one would expect to see that maceration enzyme action lead to a consequential decrease in pectin polymers, reflecting the decrease in GalA and Rha values. We did in fact note a loss of pectin in the FT-MIR spectra (Figure S2) for the enzyme-treated samples. One would expect depectination to be the most prominent change because pectinases are the major enzyme activity present in the maceration enzyme preparations that were used. However, the CoMPP heat map (Figure 2) showed an increase in HG labeling (CDTA fraction, all HG mAbs) of the enzyme-treated skins of 2012 (22.7 °B) compared to that of the control fermentation skins. Considering that the polymers that were identified in the different fractions of the CoMPP analysis were those polymers extracted and dissolved in CDTA and NaOH, respectively, we can speculate that the increase in HG was the result of enzyme hydrolysis that unravelled the cell wall structure. This process allowed more of the HG that is interspersed with the hemicellulose−cellulose scaffold to move out and dissolve in CDTA, leading to higher labeling signals. In the overripe grape skins (26.5 °B) however, the values only increased for mAbs JIM5 and LM19 and only for ExCol treated samples. In general, for the overripe grape skins there was only an initial marked decrease in HG and α-1,5-L-arabinan as a result of the depectination that took place during the standard red wine fermentation (no added enzymes).

In the hemicellulose fraction of the ripe grapes 2012 (Figure 2), there was an increase in the dissolved β-1,4-D-galactan, mannans (slight), xyloglucans (mAbs LM15 and LM25), cellulose (mAb CBM3a), extensins (mAb JIM20), and AGPs (mAbs JIM4, JIM8, JIM13, LM14, and LM2), which can all be ascribed to the hydrolysis actions of the enzymes that enhanced the solubilization of these polymers in the NaOH extract. As with the CDTA fraction, these effects were not repeated in the NaOH fraction of the overripe grapes. This may indicate that the high degree of cell wall degradation that took place because of the natural grape-ripening processes in the overripe grapes led to a nearly complete removal of all easily accessible cell wall

DOI: 10.1021/jf505200m
J. Agric. Food Chem. 2015, 63, 2798−2810

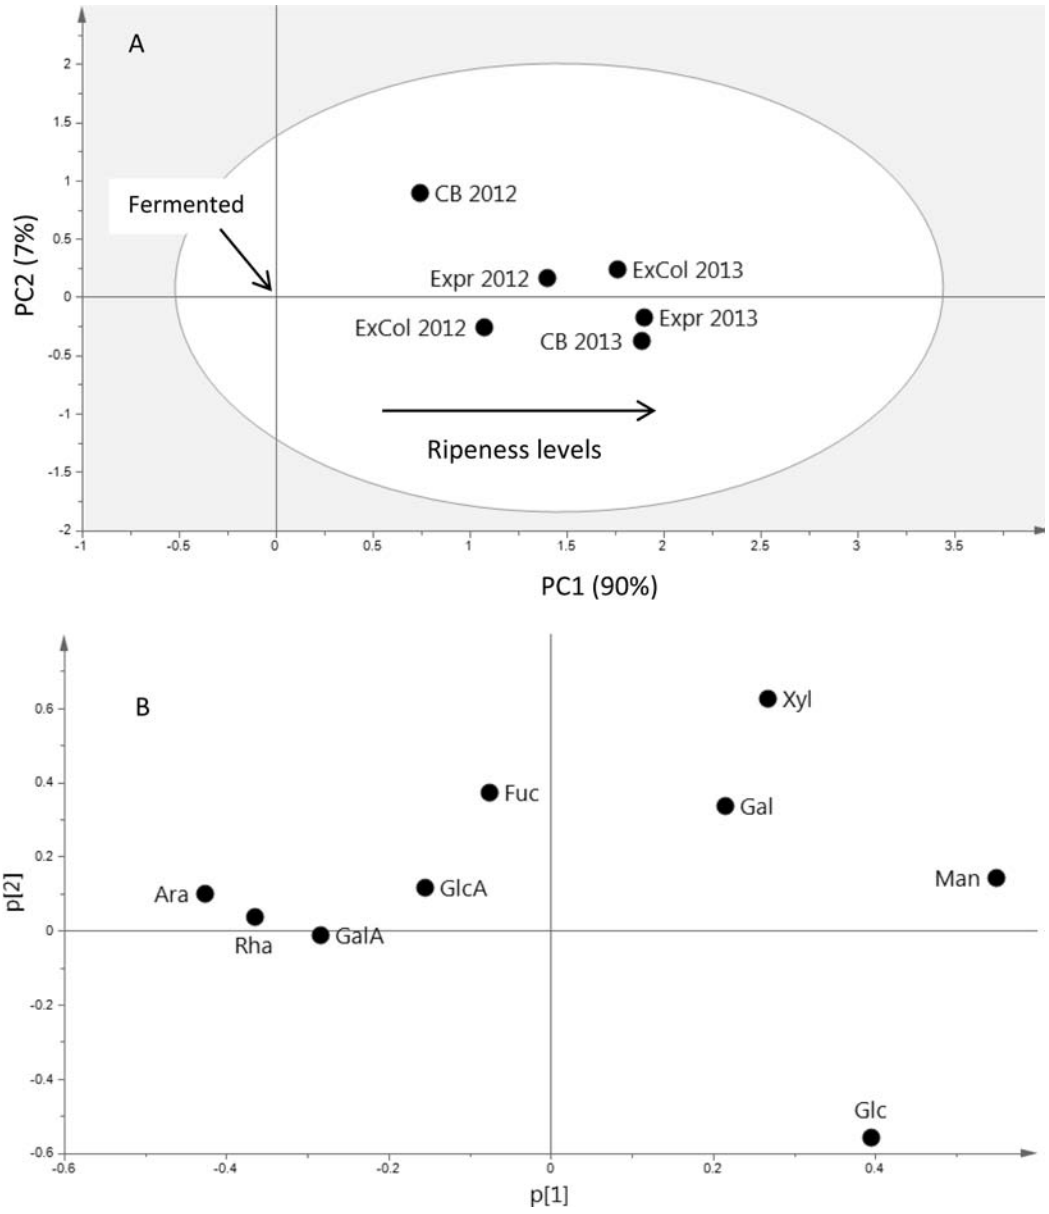

Figure 8. Score (A) and loading (B) plots of a correlation matrix analysis on the monosaccharide composition of enzyme-treated grape skin cell walls compared to samples from the control fermentation (no enzyme addition is represented by the intersection of the axis) at two different ripeness levels.

polymers during fermentation, even in the control fermentation. No significant additional change caused by hydrolysis by the maceration enzymes could be detected in the overripe cell walls. Thus, the maceration enzyme actions quantitatively (monosaccharide data) have a similar effect to that of the natural grape-tissue-ripening enzymes (depectination), but their mode of action might be different. The former seem to contribute to an increase in cell wall porosity, which is not seen with the latter. This might indicate that the plant ripening enzymes act in a block-wise fashion (as seen with plant pectin methyl esterases (pPME),[45,46] whereas the fungal enzymes from commercial maceration preparations act more randomly (as seen with some fungal PMEs).[47] However, the differences observed might just be a factor of the degree of degradation that has taken place. As hydrolysis time increase (as grapes ripen or have a longer incubation with maceration enzymes), the degradation might progress in alternating stages of depolymerization and diffusion of the resulting oligomers into the surrounding matrix (fermenting must) and pore formation.

Orthogonal projections to latent structures (OPLS) models[48] were used to focus more specifically on the difference between each enzyme treatment effect versus its control. The resulting six OPLS models (three treatments/vintage) can be summarized by its correlation loadings. These correlation values of the models were portrayed in principle component analysis (PCA) plots (Figures 8 and 9 for monosaccharides and CoMPP data, respectively). Figure 8 showed that in terms of monosaccharide composition all the enzymes had a similar effect on the cell wall (all are in the same direction, a distance away from the control samples represented by the intersection of the axis). However, the 2013 enzyme-treated samples were further removed along the first component axis (PC1 = 90%) than were the 2012 samples, indicating a greater impact on monosaccharide composition. This impact is partly due to the hydrolysis by

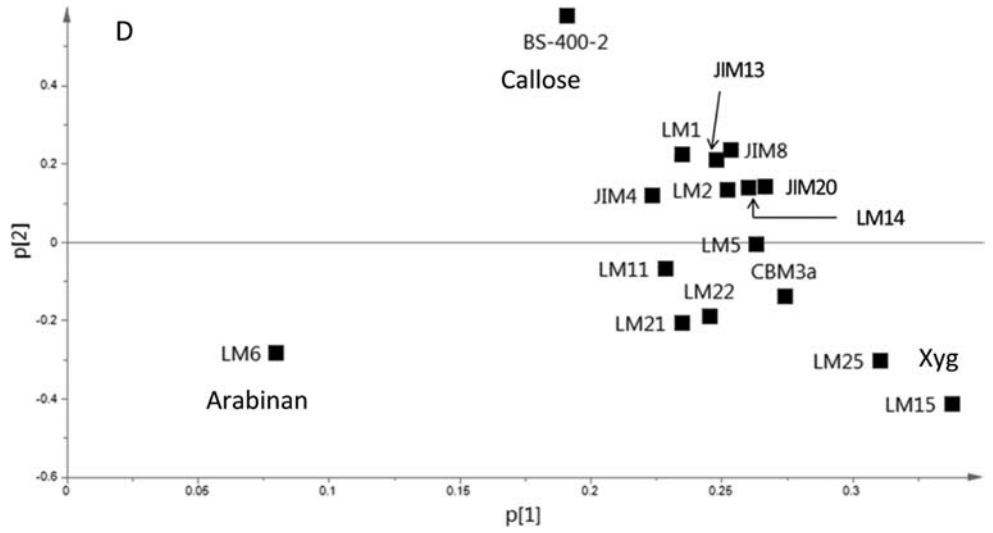

Figure 9. Score (A) and loading (B) plots of a correlation matrix analysis on the CDTA fraction (CoMPP data) of enzyme-treated grape-skin cell walls compared to samples from the control fermentation (no enzyme addition). Score (C) and loading (D) plots of a correlation matrix analysis on the NaOH fraction (CoMPP data) of enzyme-treated grape-skin cell walls compared to samples from the control fermentation (no enzyme addition). The codes for the epitopes are described in Figure 2. Xyg = xyloglucan.

the commercial maceration enzymes, but it is also the result of endogenous cell wall enzymes. The loading plot confirms that the enzyme-treated cell walls have higher proportions of Man and Glc and lower percentages of Ara, Rha, and GalA than the control group. The cell walls treated with Rapidase CB during 2012 are the main contributors to the variance along the second component of the model, and this variance is driven by a relative abundance of Xyl in the samples. According to the manufacturer, Rapidase CB has primarily pectinase activity with enhanced polygalacturonases; thus, this unique behavior could not be connected to a specific enzyme activity present in Rapidase CB.

On a polymer level (CoMPP data), the correlation values obtained from OPLS models on individual enzyme treatments versus the enzyme-free fermentation are shown in the PCA plots of Figure 9. In the analysis of the CDTA fraction (Figure 9A,B), ExCol 2012 and CB 2012 were positively correlated with an abundance in HG (mAbs JIM7 and LM20) in the first component (PC1 = 68%), likewise xyloglucan (mAb LM25), α-1,5-L-arabinan (mAb LM6), and AGPs (mAbs JIM13, LM14, and LM2) in the second component (PC2 = 26%). Expr 2012 had a positive correlation with HG labeled by mAbs LM18, LM19, and JIM5. In 2013, Expr and ExCol showed a positive correlation with an abundance in HG (mAbs LM19, LM18, and JIM5; also seen in the heat map, Figure 2), but CB 2013 did not show the same effect. In the NaOH fraction (Figure 9C,D), all the enzyme treatments in 2012 correlated positively (PC1 = 82%) with the abundance in β-1,4-galactan (mAb LM5), mannan (mAbs LM21 and LM22), xyloglucan, cellulose, and AGP. The opposite was true for all the enzymes in 2013. Thus, the enzyme action in ExCol 2012, CB 2012, Expr 2013, and ExCol 2013 enhanced extraction of HG in the CDTA fraction, although the effect was much stronger in 2012. In the hemicellulose fraction, all the enzymes treatments in 2012 enhanced the extraction of hemicelluloses, cellulose, and AGPs, whereas none of the enzyme treatments in 2013 caused any changes.

Taken together, we saw that all enzyme treatments group together in the same direction for grapes from a specific year, which indicated that they affected the cell walls in a similar fashion. The ripeness level of grapes had a significant effect on the cell walls of the grape tissue as a result of the action of the endogenous enzymes. The maceration enzymes appear to have similar activity profiles to these enzymes, which makes it difficult to distinguishing between the action of the ripening enzymes and the maceration enzymes. However, this could also be due to the limitations of the CoMPP technique.

In conclusion, this study shows that depectination and consequential exposure of the hemicellulose−cellulose framework and proteins of the cell walls in the skin occurs as a consequence of the fermentation (no enzymes) process. With the addition of maceration enzymes, further depectination takes place and, depending on the ripeness level of the grapes, it was possible to infer an unravelling of the cell wall. We were unable to distinguish between the different maceration enzyme preparations in terms of their specific effects on the cell walls. Future work could use samples from the same vineyard at different harvest dates (levels of ripeness) and different concentrations of maceration enzymes to refine the observations made here. Together with the wine color analysis, it is necessary to look at the concentration of polyphenols retained in the grape skin tissue after fermentation and maceration enzyme treatment.

■ ASSOCIATED CONTENT

Supporting Information

A detailed discussion on the ripeness levels of the grapes, the FT-IR analysis of the wine, the results obtained with the wine color analysis, a PCA plot that shows the patterns in the data when comparing fresh and fermented samples, and the FT-MIR spectra for the enzyme-treated cell walls. This material is available free of charge via the Internet at http://pubs.acs.org.

Author Contributions

A.J.J.Z. collected the data, interpreted the results, and drafted the manuscript. J.P.M. and M.A.V. designed the study and helped with data interpretation and preparation of the final document. J.U.F. and W.G.T.W. did the CoMPP analysis. J.T. advised on multivariate data analysis.

Funding

Funding for this study was provided by the Wine Industry Network of Expertise and Technology (Winetech), the Technology and Human Resources for Industry Programme (THRIP), the Institute for Wine Biotechnology (IWBT), Stellenbosch University, and the National Research Foundation (NRF).
